In a different way, the number of HUVECs adhered to the various surfaces were also estimated by monitoring fluorescence emission of cells incubated with resazurine. The cell dehydrogenase enzyme converts resazurine into resorufine, the concentration of which was monitored by measuring the intensity of fluorescence for each surface and comparing with a blank. First, the culture medium and the cells in suspension were aspirateded from the wells, and the surfaces were rinsed with PBS. A solution of 1/10 of resazurine 250μg/mL and 9/10 of culture medium M199 supplemented with heparin and FBS was prepared and maintained at 37 °C. Aliquots of 100 μL were added to each wells, and the surfaces were stored in the incubator. Fluorescence measurements were made on a Bio-Tek FL600 luminescence spectrometer with settings of excitation and emission wavelengths at 485 nm and 590 nm, respectively. All experiments were performed in triplicate.

HUVEC Fixation and Staining. After the 2 h of adhesion or the 72 h of spreading and migration, the culture medium was aspired from the wells and HUVECs were fixed for 30 min at room temperature with 3.7% formaldehyde in PBS. The formaldehyde solution was then removed from the wells, and cells were washed three times with PBS. Cell permeability was increased with a solution of PBS with 3% BSA and 0.1% saponine for 1 h 30 min at room temperature. This solution was removed, and cells were stained using 1:3000 DAPI and 1:400 Rhodamine−Phalloidin in PBS and maintained in the 37 °C incubator for 1 h. Cells were then washed six times with PBS and 0.05% Tween 20 before the surfaces were fixed between blade and lamella to be observed under the microscope.

Microscopy and Image Analysis. Microscopic pictures of every HUVECs seeded surfaces were taken using a Nikon E800 confocal microscope equipped with a Hamamatsu Orca ER digital camera (Nikon Canada, Mississauga ON). Pictures taken in microscopy were analyzed using Adobe Photoshop histogram and color selection pixels count functions. Image color selection allowed to distinguish between background and cellular bodies. A ratio between the number of pixels corresponding to cellular bodies and the total number of pixels provided a percentage of cellular coverage of the surface. The total number of pixels was of course similar for all images (all microscope images compared in this study being the same size).

RESULTS AND DISCUSSION

The various peptides were grafted on the surface through simple chemical reactions. First, an ammonia plasma treatment allowed the introduction of about 13% of nitrogen-containing species, one-third of which were amino groups according to vapor-phase chemical derivatization using 5-bromosalicylaldehyde (*26,* 28). S-SMCC was then allowed to react with the highly reactive amino groups to provide maleimido groups on the polymer surface. According to previous results (*28*), this reaction is complete. The maleimide functionalities were useful to covalently conjugate peptides through terminal end thio-containing cysteine residues. A schematic example of these chemical reactions and the XPS spectra monitored after each step of the conjugation procedure are shown in Figure 1.

As can be seen in Figure 1, the peptide graftings on the SMCC-conjugated surfaces did not bring important changes from a XPS point of view. Therefore, to ascertain the covalent conjugation of these peptides on the PTFE surface, a CRGDY peptide was iodinated using the simple chemical reaction between the tyrosine residue and Iodobeads (Figure 2). Iodine has a high XPS sensitivity index, and therefore its detection on the PTFE surface confirmed the covalent binding of the peptides on the polymer surface (Figure 3) through the reaction between the thiolic group of the terminal cysteine and the maleimido group previously introduced on the polymer surface.

All peptide-grafted surfaces, both in solution and homogeneously printed (meaning that the peptide solution was printed everywhere on the PTFE surface), were analyzed by XPS. Similar results were obtained for each grafting procedure (Table 1), indicating that the printing technique did not alter the capacity of the peptides to react with the maleimide functionalities previously grafted on the PTFE surface.

The two most common ink jet dispensing technologies are thermal and piezoelectric. Both modes have been tested in the literature, and the thermal dispensing technology appears to be more reliable for printing biological solutions (*32*). This technology is based on the expulsion of picoliter-sized droplets from the capillary nozzles of the printhead which is assembled directly on the cartridge and consists of a nozzle plate with multiple capillaries or ink-ejection orifices surrounded by resistive heater elements. When a current pulse is received by an individual heater element, the rapid transfer of heat to a small portion of the sample solution located in a capillary causes its vaporization, creating a vapor bubble. The vapor bubble creates a volume displacement that leads to the expulsion of a droplet. Therefore, it was important that the conductivity of the original ink and our peptide solutions be identical (0.08 μS/cm or a resistance of 12 Mohm-cm). The local temperature applied to a small sample volume by the heater elements can reach 200 °C. Concerns about the integrity of the peptides have been addressed, and no degradation has been observed, as relative surface concentrations obtained through XPS analyses were similar for printed peptides as compared to conventional in-solution grafted peptides. This result is in agreement with various studies who have addressed this question concerning other biomolecules such as DNA, enzymes, and proteins (*31, 33*). Furthermore, we did not observed clogging problems caused by heat-aggregation of peptides in the printhead. Therefore, the commercial tricolor cartridge can be successfully washed and refilled with peptide solutions for

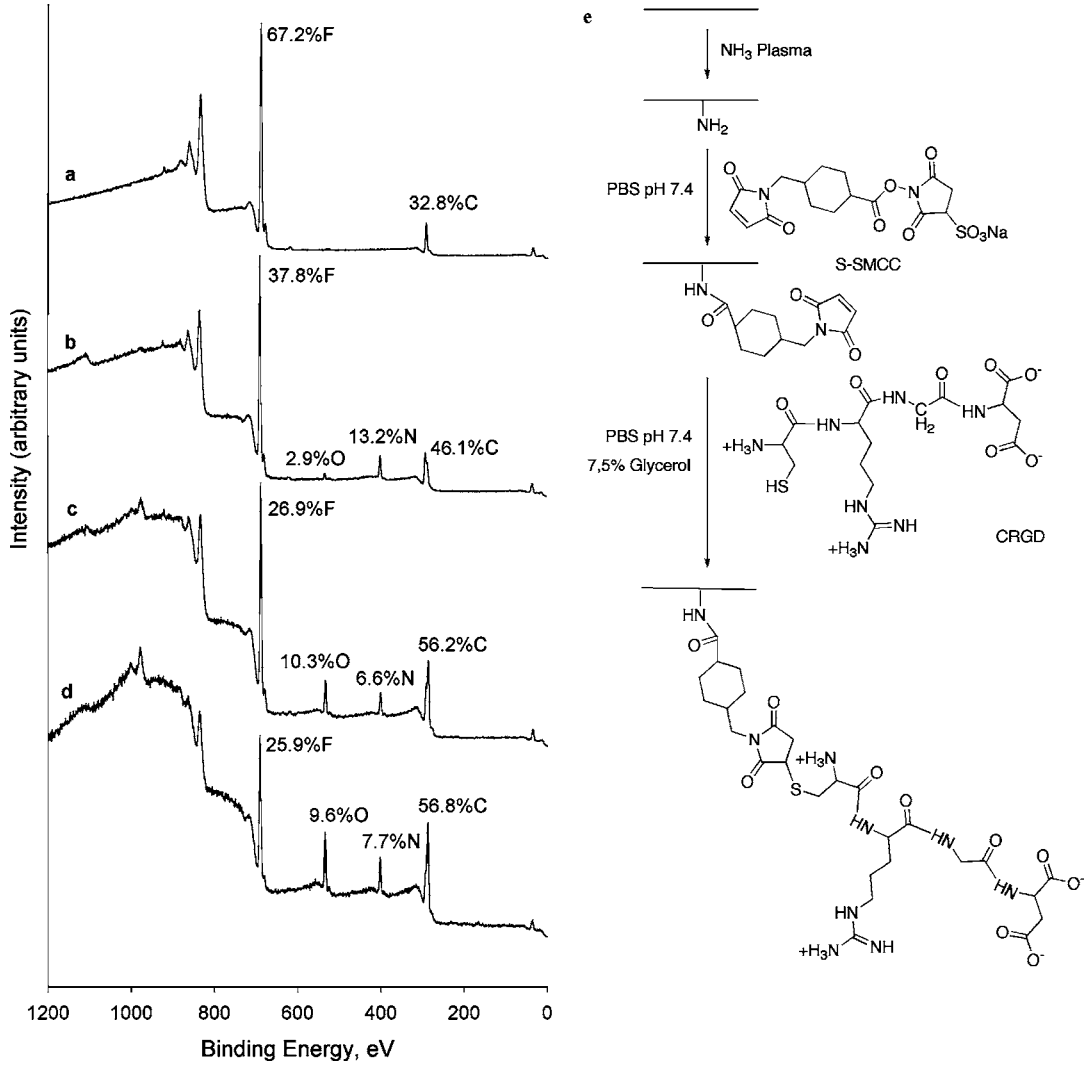

Figure 1. XPS spectra monitoring each reaction step of the CRGD grafting procedure: a**.** Virgin PTFE. b**.** Ammonia plasma-treated PTFE. c**.** SMCC-grafted PTFE. d**.** CRGD conjugated to plasma-treated SMCC-grafted PTFE. e**.** Synthetic scheme of CRGD peptide grafting on a PTFE film.

precise microdeposition of the surfaces. This procedure did not compromise the performance of the printer nor did it damage the printhead or alter the integrity of the various peptides. The use of the tricolor cartridge instead of the black one allowed the deposition of arrays containing up to three different peptides at the time.

The quantity of peptides deposited in each printed spot was calculated by weighing the cartridge before and after printing a large known number of spots (*33*). In the present study, it was found that each 300 μm wide spot printed on the polymer contained 0.18 nL of the peptide solutions (0.18 nL/spots of 90 000 μm^2 or 2.0 fL/μm^2). Roda et al. (*33*), using a HP DeskJet 600 and printing horseradish peroxidase (HRP) on cellulose paper, found that 17 nL/spots of 1 mm in diameter (21.6 fL/μm^2) were deposited on the surface of their substrate. This large difference is mainly attributed to the properties of the surface to be printed on. Cellulose paper is absorbent, and the authors used the highest quality printer settings to deposit the HRP, whereas PTFE is impermeable and printing with the highest quality printer mode deposited a volume of solution too large to maintain independent spots and retain the micropatterned design. Okamoto and al. (*31*) have printed DNA on glass surfaces using Bubble Jet printers from Canon (BJC-600 and BJC-700J). The resolution of their printer was 360 $\times$ 720 dpi, and they printed 24 pL of their solution per droplet (9.6 fL/μm^2) onto a glass surface. Again, the quantity of solution deposited is higher than the quantity we deposited on PTFE, and this can probably be explained by the more hydrophilic property of the glass substrate compared to ammonia plasma-treated PTFE.

To determine whether it was easier to print pure color in RGB color-space mode or in CMYK mode, we printed individual colors on premium picture paper and observed the prints with an optical microscope. The pure-color prints were obtained in the RGB color-scale mode with codes 0, 255, 255 for pure cyan, 255, 0, 255 for pure magenta, and 255, 255, 0 for pure yellow. Droplets on clean PTFE film presented a diameter of 10 μm or a surface area of 80 μm^2 (Figure 4a). Unsurprisingly, because plasma-treated PTFE is hydrophilic and still maintains its nonabsorbance property, droplets of this size could not be obtained on this surface. With this printer, the smallest micropatterned spots obtained were squares of 300 μm of width since smaller independent droplets combined together (Figure 4b).

To evaluate the peptides' capacity to promote adhesion, PTFE surfaces conjugated in solution with each individual peptide and with combination of CRGD/CWQPPRARI and CGRGDS/CWQPPRARI were seeded with HUVECs. After 2 h of HUVECs adhesion, the surfaces

were rinsed with sterile PBS, and cells were harvested using trypsin-EDTA and counted (Figure 5). From these results, some important trends need to be pointed out. First, there is a significant difference in the capacity of the peptide-grafted surfaces to favor adhesion compared to the control surfaces. Surfaces grafted with peptides were more attractive to cells than control surfaces. Another important point to notice is that, although CRGE peptide is stated in the literature (*34*) as a negative control of CRGD, in the sense that it does not support adhesion of cells, in this part of the study the short adhesion period of 2 h was insufficient at demonstrating a difference between these two peptides. Probably for the same reason, CGRGDS, which is known to better enhance adhesion of cells on surfaces (*35*), did not stand out from CRGD. Finally, the peptide CWQPPRARI, which was shown (*24, 25*) to favor adhesion, spreading and migration of endothelial cells, did favor adhesion of HUVECs to PTFE in a comparable way to CRGD. Similar trends were noticed while the cells attached to the surfaces were counted after incubating the cells with resazurine (Figure 6); that is to say that no individual peptide appeared more adhesive than one other, but peptide-grafted surface were more favorable to adhesion of HUVECs than control surfaces. Therefore, the initial HUVEC adhesion does not depend on the chemical structure of the peptides nor does it depend on the combination of peptides covalently bonded to the PTFE surface.

Adhesion, spreading, and migration of HUVECs on surfaces either grafted with individual peptides in solution, peptide mixtures in solution, or combination of peptides micropatterned was also examined in microscopy (Table 2). These images confirmed the results presented in Figures 5 and 6, as they also demonstrated that the initial cellular adhesion did not depend on the

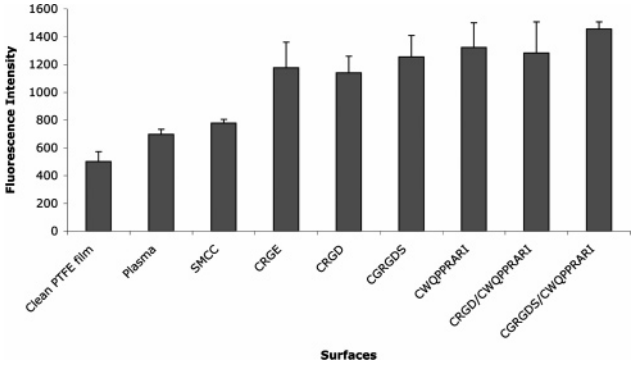

Figure 6. The number of HUVECs adhered to the different surfaces was estimated by monitoring fluorescence emission of cells incubated with resazurine after 2 h of adhesion on various PTFE surfaces.

chemical structure of the peptides conjugated to the surface. In addition, they also revealed that similar cellular adhesion was observed for combination of peptides either coconjugated in solution or micropatterned on the PTFE surface, in accordance with our previous statement that the printing technique did not alter neither the peptides integrity nor their capacity to promote adhesion of cells. Typical examples of these images are presented in Table 2. From these images, qualitative conclusions can be drawn. First, clean PTFE film does not support adhesion of endothelial cells, although some cells were observed on the surface. These cells were very small in size, and the actin cytoskeleton was disrupting. This cytoskeletal disruption alone presets apoptosis (*36*), and therefore no cells were observed on the virgin PTFE surface after 72 h. Microscopic images of CRGE- and CRGD-grafted surfaces in adhesion tests were very similar with small round cells, indicating poor adhesion and spreading, and other larger spreading cells. Besides these early adhesion results, there was a major difference between these two types of modified surfaces after 72 h. Cells on the CRGE-conjugated surfaces were deprived of any attachment signal, and most of them did not survive over a three-day period of time. Hence, almost no cells were observed on the CRGE surfaces in the spreading and migration tests, and the ones that were present looked abnormal with fragmented nuclei and distorted cytoskeletons. On the contrary, cells on the CRGD surfaces were larger, some were still round-shaped, but many were spreading and their nuclei were intact. These observations are in accordance with what we know from the literature; cellular functions are regulated both by the adhesion of cells to the surface via the integrin receptors (*1*) and by their subsequent spreading (*37, 38*). Whitesides and colleagues have also demonstrated that reduction of cell spreading is associated with a decrease in cell survival, as the more retracted and round the cells, the greater the apoptotic rate (*39*). PTFE surfaces conjugated with CGRGDS did not exhibit many more adhered cells than CRGD surfaces after 2 h of adhesion, but the cells on the CGRGDS surfaces were wider and their cytoskeleton was more developed. Again in the 72-h spreading and migration tests, there were not more cells on the CGRGDS surfaces compared to the CRGD surface, but cell spreading was obvious. Some cells on the CWQPPRARI surface, after 2

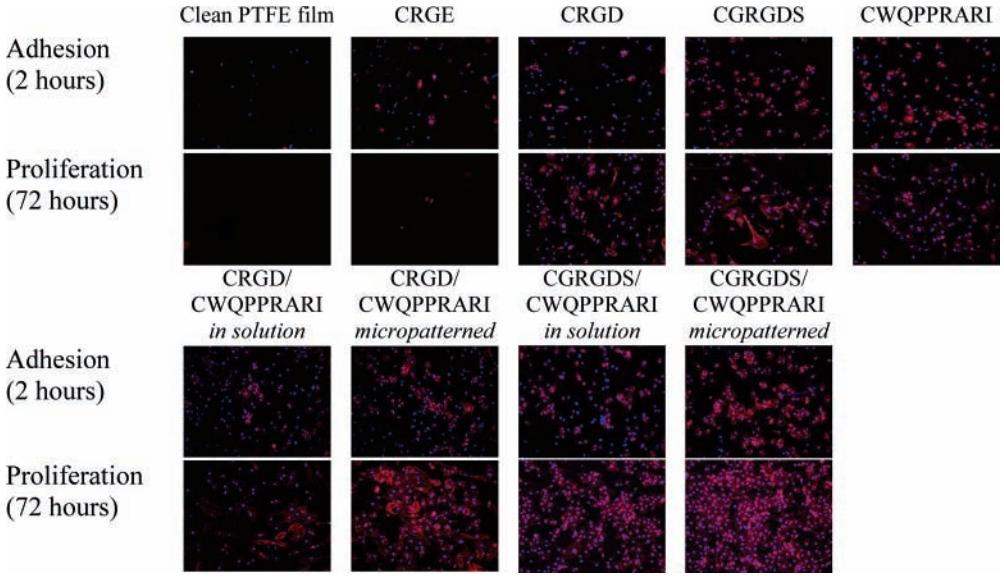
Table 2: Typical Microscopic Images (100×) of the Various Surfaces without Distinction between the Grafting Technique for Individual Peptides and with Distinction between the Grafting Procedure Performed Either in Solution or via the Microprinting Technique for the Surfaces Conjugated with a Combination of Peptides[a]



[a] Cells were fixed and colored with DAPI and Rhodamine−Phalloidin after 2 h in the adhesion experiments and after 72 h in the proliferation experiments.

h of adhesion, were round-shaped and did not present much of a cytoskeleton, but in general they seemed well-adhered to the surface and undergoing spreading. After 72 h of spreading and migration on these surfaces, the cells were fully spread and some appeared to be in motion with projections in similar directions. This is in agreement with results in the literature presenting this amino acid sequence as an adhesion signal (*40*) and spreading and migration signal (*24, 25*).

Microscopic images captured for the surfaces conjugated with a combination of peptides, either CRGD or CGRGDS and CWQPPRARI, did not present noteworthy differences between the substrates conjugated with the peptides in solution or via the micropatterning technique after 2 h of adhesion. On the other hand, there was a significant difference between the two combinations of peptides. The simultaneous conjugation of adhesion signal CRGD and spreading and migration signal CWQPPRARI did seem to define a more adhesive surface than CWQPPRARI peptide alone but not to a great extent. Concurrently, the conjugation of CGRGDS and CWQPPRARI did definitely define a more adhesive surface than individual peptides alone. Quantitatively, there were not a greater number of cells adhered to the surface, but from the glimpse of an eye, it was obvious that the cells were larger and spreading out.

After 72 h of spreading and migration, there was a major difference between the peptide-combined surfaces grafted in solution and via the printing technique. On the CRGD/CWQPPRARI surfaces, cells were spreading and the cytoskeleton was effusive. There were more cells on the micropatterned surface than on the surface with the combination of peptides conjugated in solution. Moreover, there seems to be a certain directional organization in the spreading of these cells, indicating that cells might be communicating with one another. Surfaces conjugated with both CGRGDS and CWQPPRARI fully supported endothelial cell attachment and spreading. The microscopic images captured for these surfaces indicated that this combination of adhesion and proliferation signal was the key combination in this study to promote endothelialization of PTFE surfaces, the ultimate goal being to develop ePTFE vascular grafts able to promote and support an endothelial cell layer at the luminal face. CGRGDS and CWQPPRARI peptides grafted in solution did enhance attachment and spreading of HUVECs to a great extent. Nevertheless, the micropatterning printing technique seems to be advantageous in promoting endothelialization since the surfaces were nearly fully covered with cells. These results are in agreement with Whitesides and colleagues who have demonstrated the influence of micropatterned surfaces on the control of cell shape, position, and function (*41*).

To draw some quantitative conclusions from these microscopic images, they were processed through Adobe Photoshop histogram function. Values corresponding to the percentage of cell coverage of the surfaces were calculated from ratios between the number of pixels corresponding to cell bodies and the total number of pixels. Results for the adhesion and the spreading and migration experiments are presented in Figures 7 and 8.

Unsurprisingly, from these results it can be concluded that virgin PTFE is not suitable at promoting and supporting adhesion of endothelial cells over a period of 72 h. Thus, even though some cells were present on this surface after 2 h of adhesion, none were capable of surviving over a 3-day period of time. In the same way, CRGE did not support adhesion, spreading, and migration of HUVECs over the same period of time. The ability of CRGD surfaces to promote adhesion of endothelial cells and the inability of CRGE to do so is in agreement with previous studies in the literature (*42*−*44*). Again, there was only a slight difference between CRGD and CGRGDS in their capacity of promoting and supporting adhesion of HUVECs. Although CWQPPRARI alone did no better than RGD-type peptides at promoting adhesion, spreading, and migration of HUVECs, the combination of CRGD/CWQPPRARI and most appreciably the combination of CGRGDS/CWQPPRARI did enhance adhesion, spreading, and migration of endothelial cells significantly.

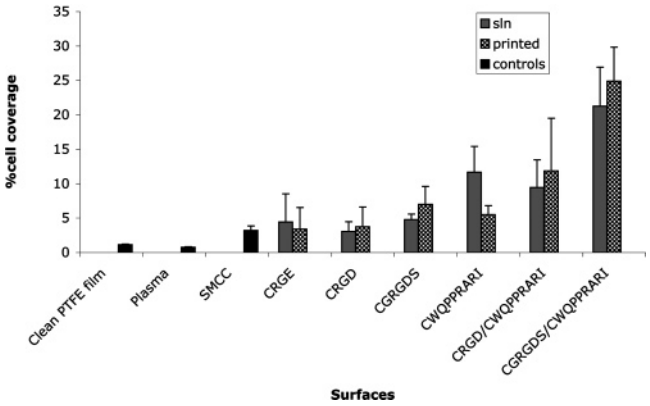


Figure 7. Percentage of cellular coverage of PTFE surfaces after 2 h of adhesion calculated from a ratio between the number of pixels corresponding to cellular bodies/total number of pixels for microscopic pictures. PTFE surfaces were grafted with various peptides and combinations of peptides, either in solution or printed in micropatterns of 300 μm.

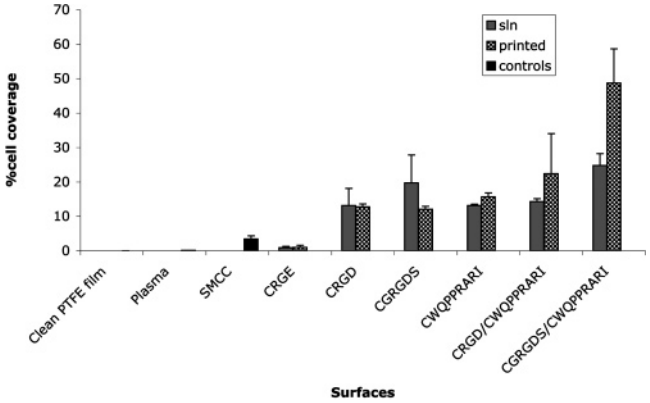

Figure 8. Percentage of cellular coverage of PTFE surfaces after 72 h of spreading and migration calculated from a ratio between the number of pixels corresponding to cellular bodies/total number of pixels for microscopic pictures. PTFE surfaces were grafted with various peptides and combinations of peptides, either in solution or printed in micropatterns of 300 μm.

Therefore, it appeared that a combination of both adhesion and, spreading, and migration peptides is better than individual peptide at promoting and supporting endothelialization of PTFE films. Although CGRGDS was not markedly better than CRGD at enhancing HUVECs adhesion, in the presence of CWQPPRARI, CGRGDS was more effective than CRGD for endothelialization of PTFE. In addition, our data clearly demonstrated that micropatterning CWQPPRARI and CGRGDS side by side on the polymer surface rather than coconjugating them led to an improvement of the HUVEC migration and spreading after 72 h.

CONCLUSIONS

In this study, PTFE surfaces were covalently conjugated with various peptides containing RGD and WQPPRARI sequences which were selected for their adhesive, spreading, and migration properties toward endothelial cells. Our data indicate that the initial cell adhesion does not depend on the chemical structure and combination of the peptides covalently bonded to the PTFE surface either through conventional in-solution conjugation or through the micropatterning printing technique. Despite these initial adhesion results, our data clearly indicate that spreading and migration of endothelial cells are enhanced while coconjugating RGD-type peptide and WQPPRARI peptides. Outstanding results for adhesion, spreading, and migration of endothelial cells on the modified PTFE surface were obtained with the combination of GRGDS and WQPPRARI. This behavior was further improved by micropatterning these peptides on specific areas of the polymer surface.

ACKNOWLEDGMENT

Special thanks to Dr. Pascale Chevallier for XPS analyses, Richard Janvier for technical assistance with HUVEC culture, Dr. Stephane Turgeon for multidisciplinary technical assistance, and Louis Gagné for undergraduate work. We would also like to extend our gratitude to Dr. Madeleine Carreau for providing the microscope facilities and Dr. René C.-Gaudreault for advice and providing the HUVECs. We kindly acknowledge Gilles Brassard from ARC/PreciJet for excellent advice concerning printers and cartridges, as well as providing some cartridges. Finally, special thanks to Nicolas Dubé for computer engineering support and numerous advice. We acknowledge grants from the National Science and Engineering Research Council (NSERC) of Canada and the Fonds pour la Recherche en Santé du Québec (FRSQ) (G.L). V. Gauvreau acknowledges a graduate scholarship from NSERC.

Affinity Enhancement Bivalent Morpholinos for Pretargeting: Surface Plasmon Resonance Studies of Molecular Dimensions

Jiang He,* Xinrong Liu, Surong Zhang, Guozheng Liu, and Donald J. Hnatowich

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, Massachusetts 01655. Received March 4, 2005; Revised Manuscript Received July 18, 2005

Bivalent effectors have been reported to provide superior pretargeting by affinity enhancement. We recently reported that one bivalent MORF (phosphorodiamidate morpholino, a DNA analogue oligomer) exhibited affinity enhancement (ratio of bivalent to monovalent equilibrium constants for binding) to immobilized complementary DNA (cDNA) by surface plasmon resonance (SPR). Because bivalent effectors using oligomers are easily synthesized with molecular spacing between binding sites, an important determinant of binding, adjustable simply by selecting linkers of different dimensions and/or lengthening or shortening the oligomer chain length, they may have advantages over existing bivalent effectors. We synthesized four bivalent MORFs with different dimensions between binding sites and measured binding affinities and affinity enhancement by SPR. An 18 mer (MORF18) was made bivalent by dimerizing both with disuccinimidyl suberate (DSS) and disuccinimidyl glutarate (DSG) linkers. By again using DSS but adding seven nonbinding adenine bases and by eliminating six binding bases, a total of four bivalent effectors, DSS-MORF12, DSG-MORF18, DSS-MORF18, and DSS-MORF25, were prepared with two different hybridization affinities (i.e. MORF12 and MORF18/25) and three different spacings (i.e. 20, 25, and 100 Å) between binding sites. The biotinylated cDNA was immobilized on a sensor chip at 500 and 100 RU coating densities providing an average cDNA separation of 25 and 80 Å. As expected, bimolecular binding dominated monomolecular binding in all cases, especially at lower MORF effector concentrations and at higher coating densities. All bivalent MORFs showed equilibrium constants superior to their monovalent form and therefore affinity enhancement. DSS-MORF25 showed the highest equilibrium constant for bimolecular binding presumably because of its larger separation between binding sites. Nevertheless, DSS-MORF12 showed the largest affinity enhancement of almost 3 orders of magnitude presumably because the shorter chain lowered the equilibrium constant for monomolecular binding. We have shown that bivalent effectors may be easily synthesized using MORF. The results provide further evidence that the use of bivalent effectors can greatly improve MORF pretargeting and, finally, that bivalent MORFs with reduced equilibrium constants may actually exhibit higher affinity enhancement.

INTRODUCTION

Pretargeting has been intensively studied for tumor imaging and therapy (*1*–*4*). Two pretargeting methods have entered clinical trials using either bispecific antibodies with specificity for both tumor antigens and a radiolabeled effector or several avidin/streptavidin–biotin recognition systems (*5*–*8*). The success claimed for the former approach has been attributed in large part to affinity enhancement resulting from the bridging of two antibodies on the tumor surface by the radiolabeled bivalent effector (i.e. "affinity enhancement system" or AES). The bivalent effectors used successfully include Ac-Lys(In-DTPA)-Tyr-Lys(In-DTPA)-Lys(TscG-Cys-)-NH_2 (*7*, *9*), Janus bivalent hapten (*10*), pGlu-Leu-Tyr-Glu-Asn-Lys(DTPA)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu and DTPA-Gly-Glu-Leu-Tyr-Glu-Asn-Lys(Ac)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu (DTPA-Gly-NT) (*11*), and Ac-Phe-Lys(-DTPA)-Tyr-Lys(DTPA)-NH_2 (*12*) and have been variously radiolabeled with ^{99m}Tc, ^{188}Re, ^{125}I, ^{131}I, ^{111}In, and most recently ^{68}Ga for radioimmunodetection and radiotherapy in tumor animal models (*7*, *13*–*16*). One observation from these investigations has been the importance of molecular spacing between binding sites. It may be estimated that about 25 Å between the binding sites has been successfully used previously (*12*). Furthermore, a recent publication has shown that a bivalent receptor binding agent showed a 200-fold increase in affinity as the spacer between binding sites varied from 4 to 20 carbon atoms (i.e. 5–25 Å) (*17*). This laboratory has previously reported encouraging results in tumored mice with pretargeting but using DNA and its analogues (collectively: oligomers) in which an antitumor antibody conjugated with an oligomer, currently a phosphorodiamidate morpholino (MORF), serves as the first injection while the radiolabel is administered later on the complementary oligomer, currently a complementary MORF (i.e. cMORF), as effector (*18*–*21*).

One advantage of using oligomers for pretargeting is the ease with which bivalent effectors for affinity enhancement pretargeting may be constructed and the ease with which the molecular dimension separating the binding sites may be shortened or elongated. In a previous paper (*22*), we reported initial observations of affinity enhancement. We now describe further evaluations by surface plasmon resonance (SPR) of the influence of spacing, effector concentration, coating density, and oligomer chain length on affinity enhancement. Bivalent MORFs were synthesized with molecular dimension varied either by attaching linkers of different dimension or by elongating or shortening the oligomer chain.

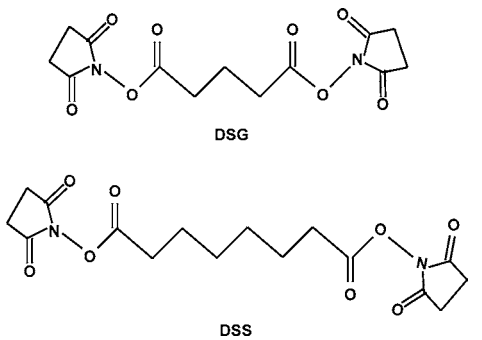

Figure 1. Molecular structures of DSS and DSG.

Specifically, an 18 mer amino-derivitized MORF (i.e. MORF18) was made bivalent by dimerizing both with disuccinimidyl suberate (DSS) and disuccinimidyl glutarate (DSG) linkers. Again using DSS as linker, the bivalent MORF was further elongated by adding seven bases (all adenines and therefore not participating in hybridization). Thus DSG-MORF18, DSS-MORF18, and DSS-MORF25 were prepared with 20, 25, and 100 Å between binding sites. Investigations of these three bivalent MORFs suggested that further improvements might result from reducing the number of hybridizing bases by subtracting six bases. Therefore, by again using DSS as linker, DSS-MORF12 was synthesized with 25 Å between binding sites but with a lower binding affinity by virtue of fewer bases. SPR was used to measure the affinity (i.e. equilibrium constant) for bivalent and monovalent binding of each of the four MORFs and affinity enhancement defined as the ratio of equilibrium constants of the bivalent over the corresponding monovalent MORF. To measure these properties, a biotinylated cDNA was immobilized on a sensor chip at two densities and the hybridization properties of bivalent and monovalent MORFs were measured.

MATERIALS AND METHODS

All MORFs and cMORFs [collectively: (c)MORF] were purchased prepurified with amine modification on the 3′ equivalent end (Gene-Tools, Corvallis, OR) and were used as received. The MORF linker of this investigation was $C(O)OCH_2C_6H_4CH_2NH_2$ except in the case of MORF25 in which only the $C(O)CH_2CH_2NH_2$ linker was supplied by the manufacturer. Because of the longer dimensions of the bivalent MORF25s, the 7−8 Å difference in linker dimensions is immaterial. Biotinylated (c)DNA having the same sequences as the (c)MORF were purchased from Qiagen Inc. (Valencia, CA) and were also used as received. Biotinylated (c)DNAs were obtained with a flexible tetra(ethylene glycol) (TEG) linker of about 26 Å in length. Disuccinimidyl suberate (DSS) and disuccinimidyl glutarate (DSG) were purchased from Pierce (Rockford, IL) while anhydrous dimethylformamide (DMF), *N*-methyl-2-pyrrodinone (NMP), and diisopropylethylamine (DIEA) were from Sigma-Aldrich (St Louis, MO). All other chemicals were reagent grade and were used without purification. The DSS-MORF18 used in this investigation is identical to the bivalent MORF used previously by this laboratory (*22*).

Synthesis of Bivalent MORF. The structures of DSS and DSG linkers are shown in Figure 1. When the bivalent MORF is prepared by the attachment of one MORF to each end of the linker, the DSG linker adds about 20 Å to the overall length of the bivalent MORF while the DSS linker adds about 25 Å. The preparation of bivalent MORFs was as previously described (*22*). Typically, about 1.5 mg (0.25 μmol) of amine-derivitized MORF was dissolved in 1.0 mL of 1-methyl-2-pyrrolidinone (NMP). A 0.125 μmol amount of DSS or DSG in NMP solution at 2 mg/mL was added, followed by 0.66 μmol of *N*,*N*-diisopropylethylamine (DIEA). This mixture was incubated at room temperature for 2 d. The bivalent MORF was purified by Q Sepharose ion exchange (IE) HPLC. The collected fractions of bivalent MORFs were passed through a PD-10 column in 50 mM phosphate buffer. The molecular weight of the product was confirmed by MALDI-TOF before storage at freezer temperatures for future use. The spacings between the two binding regions are about 20, 25, and 100 Å for DSG-MORF18, DSS-MORF18, and DSS-MOR25, respectively.

The average distance between binding sites of the immobilized cDNA on the sensor chip may be estimated using the manufacturer's value of 10000 pg streptavidin/mm^2 on the SA chip (i.e. 1.66×10^{-13} mol streptavidin/mm^2). Since the sensorgram response is directly related to the concentration bound, it may be estimated that saturating the streptavidin coating with cDNA would provide a response of about 4000 RU (response units). From this a density of about 99×10^{-12} mm^2/DNA and 19.8×10^{-12} mm^2/DNA can be estimated for a coating density of 100 RU and 500 RU. Therefore, the distance between the attachment of two neighboring cDNAs would be 80 Å and 25 Å for 100 RU and 500 RU, respectively. However, since the nonbinding regions of each immobilized cDNA is estimated to be about 26 Å and the immobilized cDNAs are capable of free rotation about their tether, with the exception of the shortest bivalent (DSG-MORF18) at the lowest cDNA density, all bivalent MORFs of this investigations were capable of bridging cDNAs at both densities.

Chromatography. Ion exchange chromatography was used to purify the bivalent from unreacted monovalent MORFs as previously described (*22*), taking advantage of the fact that tyrosine bases will be negatively charged at pH 12. Ion exchange (IE) HPLC was performed using a HiTrap Q HP column (Amersham Biosciences, Uppsala, Sweden) with 0.01 N NaOH (solvent A) and 0.01 N NaOH in 2 N NaCl (solvent B) at a flow rate of 1.0 mL/min, going from 100% A to 70% A over 30 min. Before each analysis, the column was stabilized with 0.01 N NaOH and after each analysis the column was cleaned with solvent B. For small scale preparative purification, samples were loaded on the column by several injections in running solvent A but without exceeding the column's maximum binding capability. The bivalent MORF was collected in fractions during the gradient elution.

Surface Plasmon Resonance Measurements. SPR was performed on a BIAcore 2000 (BIAcore, Piscataway, NJ) instrument operating at room temperature as previously described (*22*). As before, (c)DNAs rather than (c)-MORFs were immobilized because of earlier difficulties in immobilizing biotinylated (c)MORFs. Biotinylated (c)-DNA at 20 nM was added in 5−10 μL aliquots to a new streptavidin−dextran-coated sensor chip (SA) at a flow rate of 20 μL/min only until a response of about 100 (±10) or 500 (±30) RU was reached. The absence of mass transfer effects was confirmed by running separately one concentration of free MORF at three different flow rates (10, 30, and 75 μL/min) and demonstrating identical response and curve shape for all three sensorgrams. When the identical measurement was performed on a sensor chip to which cDNA was added to a response of 750 RU, evidence of mass transfer effects was observed and accordingly this chip was not used in subsequent studies. Figure 2. Normalized sensorgrams showing similar association kinetics but strikingly different dissociation kinetics for DSS-MORF25 (trace 1), DSS-MORF18 (trace 2), DSG-MORF18 (trace 3), DSS-MORF12 (trace 4), MORF18 (trace 5), MORF25 (trace 6), and MORF12 (trace 7). Obtained at 10 nM concentration and at 100 RU coating density.

Table 1. Properties of Bivalent MORFs (base sequences of native MORFs, MW calculated, MW found)

bivalent MORF	MORF sequence	MW expected (found ± SD), Da
DSG-MORF18	TCTTCTACTTCACAACTA	12424 (12397± 27)
DSS-MORF18	TCTTCTACTTCACAACTA	12466 (12474± 8)
DSS-MORF25	TCTTCTACTTCACAACTA-AAAAAAA	17034 (16998± 36)
DSS-MORF12	TCTTCTACTTCA	8508 (8498± 10)

were prepared at six concentrations of MORF from 0.0 to 40 nM in the same running buffer (10 mM HEPES, 150 mM NaCl, 3.4 mM Na_2EDTA, 0.005% P20, pH 7.4) and injected separately onto the active (cDNA) or control (DNA) surface at a flow rate of 30 μL/min to minimize the mass transfer effect. The chip surface was regenerated by injection of 100 mM HCl. To correct for nonspecific binding and refractive index changes, the control responses were subtracted from those obtained from the active surface. A minor baseline drift resulting from a slow dissociation of the complex on the active and control surfaces was eliminated by also subtracting sensorgrams obtained following the injection of running buffer (*23*).

In the first series of experiments, samples of monovalent MORFs (MORF18 and MORF25) and bivalent MORFs (DSS-MORF18, DSG-MORF18, DSS-MORF25) were run at six concentrations on both the 100 and 500 RU chips and with a dissociation time of only 25 min. In the second series of experiments, all six concentrations were again run but with dissociation time of 1 h to obtain more accurate values for the dissociation rate constants. In the third series of experiments, the monovalent MORF12 and bivalent DSS-MORF12 were run at the six concentrations on both 100RU and 500RU chips for 25 min. In every case, the measurement was repeated four times and, as mentioned above, each sample was run on both the cDNA and DNA chips at the same surface density so that results with the latter could be used to correct for bulk refractive index changes (*23*).

Sensorgram Kinetic Analysis. Sensorgram curves were evaluated using numerical integration algorithms (BIAevaluation 3.0, BIAcore, Piscataway, NJ). The algorithm may be programmed for simple monomolecular 1:1 Langmuir interactions of a monovalent effector (A) or for a bivalent effector (AA) binding monomolecularly (i.e. A+L→AL where A is the effector, in this case MORF, and L is immobilized ligand, in this case cDNA) or binding bimolecularly (i.e. AA+L→AAL and AAL+L→LAAL). In addition, the algorithm may be programmed to analyze globally (i.e. all effector concentrations considered together to provide one value for each of the two rate constants, association and dissociation) or locally (i.e. each effector concentration considered separately to provide one value for each of the two rate constants for each effector concentration). An added complication in the case of bivalent effector binding is the possibility that the binding may be both monomolecular and bimolecular and thus cannot be accurately modeled. To emphasis this fact, the rate constants in this report for bivalent MORFs are referred to as "apparent". While different model and fitting methods were used by us previously, in this study, the simple monomolecular 1:1 Langmuir interaction model was used to compare the four bivalent MORFs with their corresponding monovalent form. It should be noted that in each comparison, the concentrations were adjusted to the same molarity of effector and therefore the MORF molarity of the bivalent effector was twice that of the monovalent effector. Finally, the program provides for each analysis a Chi2 (χ^2) value that is a statistical measure of how closely the model fits the experimental data. In general, χ^2 values lower than about 10 signify a good fit.

RESULTS

Synthesis of Bivalent MORF. The amine derivatized MORFs were dimerized with DSS or DSG for 2 days in the presence of NMP and DIEA followed by purification by ion exchange chromatography. Changing from alkaline solution to phosphate buffer or water was performed on a PD-10 column. The correct structure of all four bivalent MORFs was confirmed by MALDI-TOF MS as shown in Table 1.

Surface Plasmon Resonance Measurements. The SPR measurements were performed at both cDNA surface densities of 100 and 500 RUs and at six concentrations of the monovalent and bivalent MORFs in the concentration range from 0 to 40 nM. Figure 2 presents

Table 2. Kinetics Rate Constants and Equilibrium Constants for Monovalent MORF12, MORF18, and MORF25 and the Apparent Kinetic Rate Constants and Equilibrium Constants for the Corresponding Bivalent MORFs Obtained at Both CDNA Surface Densities[a]

[a] Analysis by global fitting using the 1:1 Langmuir interaction model. k_a: association rate constant; k_d: dissociation rate constant; K_{equ}: equilibrium constant; X^2: index for goodness of fit. Standard deviations in parentheses.

normalized sensograms of the four bivalent and the three monovalent MORFs at 10 nM concentration and at 100 RU cDNA coating density. The sensorgram of all seven MORFs have been overlayed to illustrate the striking differences in dissociation rate. Among the bivalent MORFs, the order of increased stability to dissociation is DSSMORF25 > DSSMORF18 > DSGMORF18 > DSSMORF12. Among the monovalent MORFs, this order is MORF25 ~ MORF18 ≫ MORF12 (there should be no significant difference between MORF25 and MORF18 since they have the same binding region in this study). Furthermore the bivalent MORF12 exhibited stability comparable to that of the larger monovalent MORF25. Finally, except for this similarity, all bivalent MORFs showed increased stability over all monovalent MORFs. The kinetic rate constants and equilibrium constants for monovalent MORF12, MORF18, and MORF25 and the apparent kinetic rate constants and equilibrium constants for the corresponding bivalent DSG-MORF18, DSS-MORF18, DSS-MORF25, and DSS-MORF12 obtained at both cDNA surface densities are presented in Table 2. Analysis was by global fitting using the simpler 1:1 Langmuir interaction algorithm. Included in the table are the ratios of affinity constants for bivalent over corresponding monovalent binding at both cDNA densities. As shown, the equilibrium constants for the three monovalent MORFs binding are little changed between cDNA densities. Figure 3 presented sensorgrams obtained at 5 nM for the bivalent and monovalent MORF12s only. At both surface densities, the bivalent MORF12 shows a profoundly higher association and lower dissociation phase and therefore a significantly improved equilibrium constant due to bimolecular binding.

Considering first only DSG-MORF18, DSS-MORF18, and DSS-MORF25, although these three bivalent MORFs possess the same binding region, they show statistically significantly ($p < 0.04$) different affinity enhancement presumably as a result of the different molecular dimension. As shown in the table, at low cDNA coating density of 100 RU, both DSS-linked MORFs show affinity enhancements of about 20-fold compared to about 2 for the shorter DSG-MORF18. This result could be predicted on the basis of molecular dimensions. At the lowest 100 RU coating density, the separation between attached cDNAs is estimated to be about 80 Å. The maximum radius of each cDNA when fully extended is about 26 Å, leaving a gap of about 28 Å. Because of its longer 25 Å length, bivalent MORFs attached with the DSS linker are capable of bridging this gap. By contrast, bivalent MORFs attached via the 20 Å DSG linker are too short and therefore are capable only of monovalent binding with the result that affinity enhancement is prevented. However, at high coating density, all three sets of bivalent MORFs showed superior K_{equ} with the highest improvement of 40−50-fold for DSS-MORF18 and DSS-MORF25. These results are reasonable since high coating densities should favor bivalent binding of the bivalent MORFs. Only in the case of low coating density and the bivalent MORF with the shortest linker, DSG-MORF18, was the enhancement minimal over the monovalent MORF.

Furthermore, the bivalent MORF12 showed much higher association rate constants along with lower dissociation rate constant both at 100 RU or 500 RU cDNA coating density compared with monovalent MORF12 to provide equilibrium constants 500 to1000-fold higher (i.e. 500 to1000 higher affinity enhancement) at both cDNA densities. The striking affinity enhancement due to bimolecular binding in the case of bivalent MORF is clearly seen in Figure 3 by comparison of sensorgrams with the monovalent MORF12 at both coating densities. Sensorgrams of DSS-MORF12 show greater response in association phase at each concentration (data not presented). Furthermore, the dissociation of monovalent MORF12 is essentially completed by about 1500 s while at this time DSS-MORF12 is still about 55% and 87% intact at 100 RU and 500 RU, respectively.

DISCUSSION

Earlier this laboratory reported that binding of one bivalent MORF to immobilized cDNA was bimolecular under the conditions of that study and, presumably as a result, exhibited a faster association rate and a slower dissociation rate and therefore a higher affinity constant and affinity enhancement. Since the probability of monomolecular binding (AAL) compared to bimolecular binding (LAAL) will depend on the molecular dimensions of the bivalent effector (in this case MORF) and the concentration (spacing) and flexibility of the ligand molecules (in this case cDNA) on the immobilized surface (*24*), in this present investigation, SPR was used to compare the behavior of four bivalent MORFs differing in the spacing between binding sites with their corresponding monovalent form during hybridization to immobilized cDNA at two densities

In general, low cDNA densities and higher MORF effector concentrations will favor monomolecular binding,

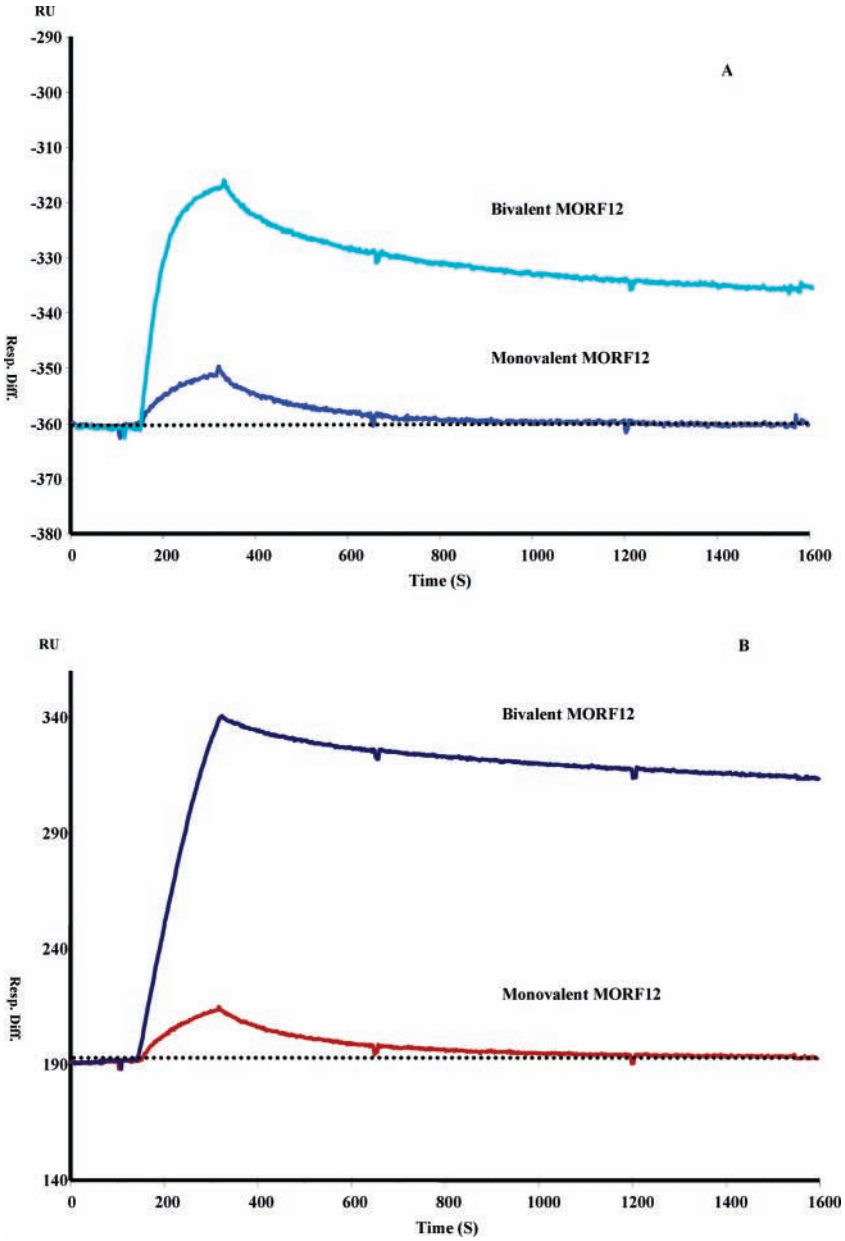

Figure 3. Sensorgrams obtained at 5 nM for the bivalent and monovalent MORF12 at 100RU (panel A) and 500RU (panel B) surface densities showing the significantly improved association and dissociation constant of the bivalent MORF12 due to bimolecular binding. The MORF concentrations of the bivalent MORF are twice the effector concentrations.

in the first instance because of the greater spacing between cDNAs (thus making more difficult bridging by the effector) and in the latter instance because the cDNAs are more likely to be saturated with MORF bound monomolecularly (since bimolecular binding is a two-step process initially requiring monomolecular binding). Therefore, six concentrations not exceeding 40 nM (to avoid monomolecular binding saturation) of all effectors and two coating densities of 100 RU and 500 RU were used in this investigation. As shown in Table 2, presumably because of its shorter spacing between binding sites, the bivalent DSG-MORF18 showed affinity enhancement at the 500 RU cDNA density but not at the lower 100 RU density. By contrast, the bivalent MORFs DSS-MORF18 and DSS-MORF25 with their longer spacing between binding sites showed comparably higher affinity enhancement compared to their corresponding monovalent MORF18 and MORF25 respectively at both densities.

It is important to point out that in the sensorgram analysis, quantitative evaluation was made difficult by the high cDNA densities required to achieve bimolecular binding. These high densities can result in mass transport effects and, furthermore, can complicate the analysis by permitting rebinding during dissociation. In this investigation it was possible to prevent mass transport complications by adjusting the flow rate to be in a range where the response was shown to be flow-rate-independent. However, it was not possible to eliminate rebinding effects especially in case of effectors with very high intrinsic affinities. Thus rebinding contributed partially to the resulting kinetic analysis. This was the case for monovalent MORF18, monovalent MORF25, and all bivalents due to their high affinity. Rebinding effects may be suspected when the dissociation rates are slower at lower effector concentrations compared to higher concentrations. Normally all concentrations should give the same affinity constants. At very low concentration as used in this investigation, the cDNA is not saturated at the high coating density and thus rebinding is possible. Under these conditions, the dissociation rates are slower

at low effector concentrations compared to higher concentrations. That the dissociation rate of monovalent 12 mer MORF at all six concentrations was identical even at the highest 500 RU density (data not presented) may imply little rebinding in the case of this effector. This result is presumably due to an intrinsic low affinity resulting from the shorter chain length. Therefore the "rebinding" (lower dissociation rate at lower concentration) for the bivalent 12 mer MORF (DSS-MORF12) must be due to the enhanced affinity from bimolecular binding. However, while rebinding will complicate accurate analysis of SPR results, it may favorably contribute to a longer retention of the effector in tumor.

The importance of selecting the proper molecular dimensions in oligomer effectors intended for affinity enhancement pretargeting rests in the promise of greatly improved target/nontarget ratios. A higher equilibrium constant for bimolecular binding over monomolecular binding (i.e. affinity enhancement) would favor dissociation and minimal binding in blood and other nontarget tissues because of the lower cMORF densities in these sites at the time of effector administration. One result of this investigation is the observation that higher affinity of binding (i.e. higher equilibrium constants) of effector does not necessarily translate into higher affinity enhancement. Since affinity enhancement is the ratio of equilibrium constants for bimolecular over monomolecular binding, a high equilibrium constant for monomolecular binding may reduce the ratio to insignificance. This is apparently the case for DSS-MORF18 and DSS-MORF25, both of which show higher equilibrium constants than DSS-MORF12 yet both show lower affinity enhancements.

CONCLUSION

As shown herein, the distance between binding sites in MORF effectors may be adjusted simply by changing the linker length and/or by elongating or shortening the base chain. These results also show that bimolecular binding was occurring in the case of the bivalent MORF by the higher equilibrium constants for the bivalent MORF compared to their corresponding monovalent form. Furthermore, these results also provide further evidence that bivalency may be superior to monovalency in MORF pretargeting applications in the affinity enhancement observed in all cases of bivalent MORF and cDNA densities. However, since affinity enhancement is the ratio of equilibrium constants for bimolecular over monomolecular binding, that the bivalent MORF derivatized from shorter chain effector (i.e., DSS-MORF12) showed the greatest affinity enhancement suggests that higher equilibrium constant and higher affinity enhancement may not be synonymous.

A Dielectric-Sensitive Fluorescent DNA Probe for Monitoring Polarities on the Interior of a DNA-Binding Protein

Akimitsu Okamoto,*,† Kazuki Tainaka,† and Isao Saito*,‡

Department of Synthetic Chemistry and Biological Chemistry, Faculty of Engineering, Kyoto University, Kyoto 615-8510, Japan, and NEWCAT Institute, School of Engineering, Nihon University, and SORST, Japan Science and Technology Agency, Tamura, Koriyama 963-8642, Japan. Received March 15, 2005; Revised Manuscript Received July 8, 2005

We report a novel fluorescent nucleobase, ^{DNC}U, for the mapping of the local dielectric properties around DNA. Fluorescence spectra of the nucleoside d^{DNC}U showed a significant shift depending on the solvent polarity. This property was used to determine the dielectric constants of the interior of DNA-binding proteins, such as DNA polymerases. We were able to demonstrate that the DNA-binding region of the Klenow fragment is a lower polarity site, as shown by the blue shift of the fluorescence peak originating from ^{DNC}U.

INTRODUCTION

Local variations in the structure and dynamics of biomolecules play important roles in mediating the interaction events between biomolecules, such as DNA-protein recognition. In particular, monitoring of the local dielectric property change in DNA is very important because the structures of DNA−protein complexes and their interactions are influenced by their local dielectric effects (*1*−*3*). For such a purpose, a fluorescent probe, which is incorporated site specifically into the DNA sequence of interest and is sensitive to the change of its local microenvironment, is highly desirable. The well-known fluorophore 6-(dimethylamino)-2-acylnaphthalene (DAN) and its derivatives are among the most promising candidates for such a dielectric-sensitive fluorescent probe, because they show a sensitive solvatofluorochromic behavior (*4*−*8*). In addition, DAN is free from the contribution of ionic interactions because it has no permanent charge. Recently, an alanine derivative of DAN, Aladan, was developed and incorporated site-selectively into buried and exposed sites using a nonsense suppression method (*9*). It was sensitive to the polarity of its surroundings. Thus, such DAN derivatives would also be useful as dielectric-sensitive fluorescence probes for examining the change in the polarity of the microenvironments of DNA surroundings and the DNA−protein interaction site. In particular, when the fluorophore is tethered to a nucleobase in oligodeoxynucleotide (ODN) probes via a rigid linker, the change in the dielectric properties at a specific site on the target sequences would be easily monitored.

Herein, we report a mapping of the dielectric nature of the microenvironment around DNA using a novel DAN family, 6-(dimethylamino)-2-naphthalenecarboxamide (DNC)-tethered 2′-deoxyuridine (^{DNC}U), which can be easily prepared via a short synthetic process. This fluorescent nucleoside offers high sensitivity toward the solvent polarity. A series of fluorescence spectra for ^{DNC}U-containing ODN showed a large shift, indicating a significant change in the dielectric constants of the microenvironment around ^{DNC}U. We also monitored the local dielectric properties of the DNA-binding region of DNA polymerase using the fluorescence change of ^{DNC}U-containing ODN.

EXPERIMENTAL PROCEDURES

General. ^{1}H NMR and ^{13}C NMR spectra were measured with Varian Mercury 400 spectrometer. Coupling constants (J value) are reported in hertz. The chemical shifts are shown in ppm downfield from tetramethylsilane, using residual chloroform (δ = 7.24 in ^{1}H NMR, δ = 77.0 in ^{13}C NMR), dimethyl sulfoxide (δ = 2.48 in ^{1}H NMR, δ = 39.5 in ^{13}C NMR), and methanol (δ = 3.30 in ^{1}H NMR) as an internal standard. Fast-atom bombardment (FAB) masses were recorded on a JEOL JMS HX-110A spectrometer.

The reagents for DNA synthesis were purchased from Glen Research. Masses of oligodeoxynucleotides were determined with a matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF MS) (Perseptive Voyager Elite, acceleration voltage 21 kV, negative mode) with 2′,3′,4′-trihydroxyacetophenone as a matrix, using T_8 ([M − H]$^-$ 2370.61) and T_{17} ([M − H]$^-$ 5108.37) as internal standards for oligodeoxynucleotides. The Klenow fragment was purchased from Takara. Calf intestinal alkaline phosphatase (Promega), *Crotalus adamanteus* venom phosphodiesterase I (USB), and *Penicillium citrinum* nuclease P1 (Roche) were used for the enzymatic digestion of ODNs. All aqueous solutions utilized purified water (Millipore, Milli-Q sp UF). Reversed-phase high-performance liquid chromatography (HPLC) was performed on CHEMCOBOND 5-ODS−H columns (10 × 150 mm, 4.6 × 150 mm) with a Gilson Chromatograph, Model 305, using a UV detector, Model 118, at 254 nm.

6-Dimethyl-2-naphthoylpropargylamide (2). To a solution of 6-amino-2-naphthoic acid (**1**) (500 mg, 2.67 mmol) in methanol (20 mL) was added cyanoborohydride

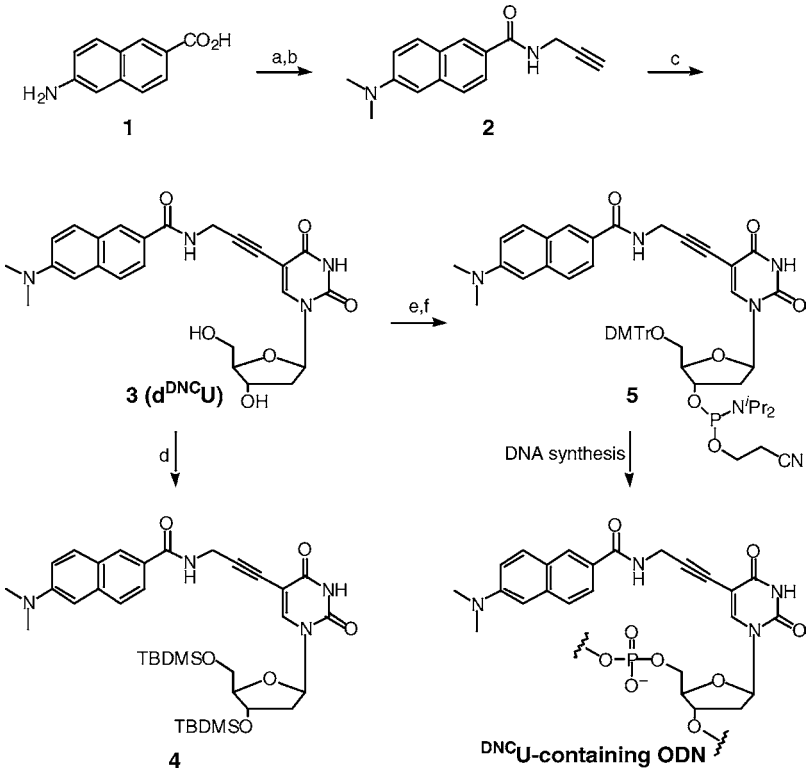
Scheme 1. Synthesis of ^{DNC}U-containing ODN[a]



[a] (a) Formaldehyde, sodium cyanoborohydride, methanol, room temperature, 2 h, 99%; (b) propargylamine, PyBOP, DMF, room temperature, 1 h, 84%; (c) 5-iodo-2′-deoxyuridine, CuI, $Pd(PPh_3)_4$, triethylamine, DMF, room temperature, 6 h, 94%; (d) *tert*-butyldimethylsilyl chloride, imidazole, DMF, room temperature, 5 h, 54%; (e) 4,4′-dimethoxytrityl chloride, pyridine, room temperature, 6 h, 61%; (f) 2-cyanoethyl tetraisopropylphosphorodiamidite, tetrazole, acetonitrile, room temperature, 2 h, quant.

(600 mg, 9.55 mmol) and formaldehyde (37% in water, 4 mL). The mixture was stirred at room temperature for 2 h, and the solvent was dried in vacuo. The crude product was dissolved in water (100 mL) and washed with ethyl acetate (100 mL). Concentrated HCl was added to adjust the pH of the solution (pH 1.0), and the suspension was extracted with ethyl acetate to yield a pale-yellow solid (570 mg, 99%): ^{1}H NMR (CD_3OD, 400 MHz) δ = 8.39 (s, 1H), 7.85 (dd, 1H, J = 8.4, 1.6 Hz), 7.79 (d, 1H, J = 9.2 Hz), 7.64 (d, 1H, J = 8.4 Hz), 7.13 (dd, 1H, J = 9.2, 2.8 Hz), 6.95 (d, 1H, J = 2.8 Hz), 3.08 (s, 6H); MS (EI$^+$) *m/z* (%) 215 [M$^+$]; HRMS (FAB) calcd for $C_{13}H_{13}O_2N$ [M$^+$] 215.0946, found 215.0946.

To a solution of the product (570 mg, 2.65 mmol) in dry DMF (20 mL) was added PyBOP (1.39 g, 2.67 mmol). The mixture was stirred at room temperature, and propargylamine (746 μL, 10.68 mmol) was added to the solution. The reaction mixture was stirred for 1 h, concentrated in vacuo, and diluted with ethyl acetate (40 mL). This solution was washed with aqueous $NaHCO_3$ (20 mL) and brine (20 mL), dried over Na_2SO_4, filtered, and evaporated. The crude product was purified by silica gel column chromatography (ethyl acetate:hexane = 1:2) to yield **2** (559 mg, 84%) as a pale-yellow solid: ^{1}H NMR ($CDCl_3$, 400 MHz) δ = 8.18 (d, 1H, J = 1.6 Hz), 7.76−7.73 (m, 2H), 7.61 (d, 1H, J = 8.4 Hz), 7.13 (dd, 1H, J = 8.8, 2.4 Hz), 6.85 (d, 1H, J = 2.4 Hz), 4.27 (dd, 2H, J = 5.2, 2.4 Hz), 3.06 (s, 6H), 2.26 (t, 1H, J = 2.4 Hz); ^{13}C NMR (DMSO-d_6, 100 MHz) δ = 166.4, 149.7, 136.4, 130.0, 127.7, 126.8, 125.9, 125.0, 124.5, 116.8, 105.1, 81.8, 72.9, 40.2, 28.7; MS (FAB, NBA/$CHCl_3$) *m/z* (%) 252 [M$^+$]; HRMS (FAB) calcd for $C_{16}H_{16}N_2O$ [M$^+$] 252.1266, found 252.1263.

5-[3-(6-Dimethylaminonaphthalenecarboxamido)-propynyl]-2′-deoxyuridine (3, d^{DNC}U). To a solution of **2** (907 mg, 3.6 mmol), 2′-deoxy-5-iodouridine (850 mg, 2.4 mmol), and triethylamine (270 μL) in 1 mL of anhydrous DMF were added tetrakis(triphenylphosphine)palladium(0) (555 mg, 0.48 mmol) and copper(I) iodide (183 mg, 0.96 mmol) under nitrogen. The mixture was stirred at room temperature for 6 h. The resulting mixture was concentrated in vacuo and diluted with ethyl acetate (30 mL). This solution was washed with 5% EDTA solution (30 mL) and 5% sodium bisulfite solution (30 mL), dried over Na_2SO_4, filtered, and evaporated. The crude product was purified by silica gel column chromatography (chloroform:methanol = 20:1) to yield **3** (1.08 mg, 94%) as a pale-yellow solid: ^{1}H NMR (DMSO-d_6, 400 MHz) δ = 11.61 (s, 1H), 8.93 (t, 1H, J = 5.5 Hz), 8.28 (d, 1H, J = 1.6 Hz), 8.15 (s, 1H), 7.80−7.77 (m, 2H), 7.66 (d, 1H, J = 8.8 Hz), 7.25 (dd, 1H, J = 9.2, 2.6 Hz), 6.93 (d, 1H, J = 2.6 Hz), 6.09 (t, 1H, J = 6.7 Hz), 5.21 (d, 1H, J = 4.2 Hz), 5.07 (t, 1H, J = 5.0 Hz), 4.30 (d, 2H, J = 5.5 Hz), 4.22−4.18 (m, 1H), 3.77 (dd, 1H, J = 6.5, 3.4 Hz), 3.61−3.51 (m, 2H), 3.02 (s, 6H), 2.11−2.08 (m, 2H); ^{13}C NMR (DMSO-d_6, 100 MHz) δ = 166.3, 161.9, 149.8, 149.7, 143.8, 136.4, 130.0, 127.8, 126.7, 125.9, 125.0, 124.5, 116.8, 105.1, 98.5, 90.3, 87.8, 84.9, 74.3, 70.5, 61.2, 40.3, 29.5; MS (FAB, NBA/DMSO) *m/z* (%) 479 [(M + H)$^+$]; HRMS (FAB) calcd for $C_{25}H_{26}N_4O_6$ [M$^+$] 478.1850, found 478.1852.

3′,5′-Bis-*O*-(*tert*-butyldimethylsilyl)-5-[3-(6-dimethylaminonaphthalenecarboxamido)propynyl]-2′-deoxyuridine (4). To a solution of **3** (74 mg, 0.16 mmol) in dry DMF (1 mL) was added *tert*-butyldimethylchlorosilane (70 mg, 0.46 mmol) and imidazole (32 g, 0.46 mmol). The mixture was stirred at room temperature for 5 h. The mixture was concentrated in vacuo and diluted with chloroform (30 mL). This solution was washed with aqueous $NaHCO_3$ (30 mL) and brine (30 mL), dried over

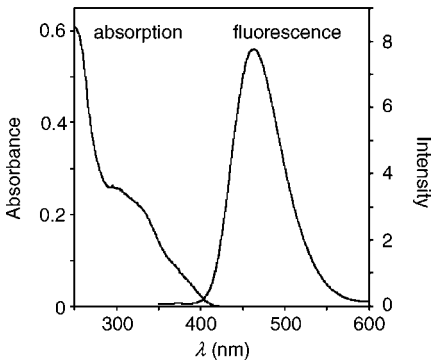


Figure 1. Absorption and fluorescence spectra of 2.5 μM d^{DNC}U in 50 mM sodium phosphate and 0.1 M sodium chloride (pH = 7.0). λ_{exc} = 332 nm, λ_{fl} = 463 nm.

Na_2SO_4, filtered, and evaporated. The crude product was purified by silica gel column chromatography (chloroform:methanol = 50:1) to yield **4** (58.7 mg, 54%) as a pale-yellow solid: ^{1}H NMR ($CDCl_3$, 400 MHz) δ = 8.83 (s, 1H), 8.20 (s, 1H), 8.04 (s, 1H), 7.79−7.74 (m, 2H), 7.65 (d, 1H, J = 8.6 Hz), 7.21 (d, 1H, J = 8.2 Hz), 6.87 (s, 1H), 6.66 (s, 1H), 6.28 (dd, 1H, J = 7.3, 6.0 Hz), 4.47 (d, 2H, J = 4.9 Hz), 4.39 (dt, 1H, J = 5.7, 2.6 Hz), 3.97 (dd, 1H, J = 4.6, 2.2 Hz), 3.89 (dd, 1H, J = 11.5, 2.6 Hz), 3.75 (dd, 1H, J = 11.5, 2.2 Hz), 3.08 (s, 6H), 2.31 (ddd, 1H, J = 13.2, 5.9, 2.7 Hz), 2.02 (ddd, 1H, J = 13.2, 7.3, 5.9 Hz); ^{13}C NMR ($CDCl_3$, 100 MHz) δ = 167.1, 161.6, 149.0, 143.2, 136.7, 130.1, 129.1, 127.8, 127.6, 126.4, 124.1, 116.6, 113.2, 99.4, 89.9, 88.4, 85.9, 74.8, 72.3, 62.9, 42.1, 30.6, 26.0, 25.7, 18.4, 18.0, −4.7, −4.9, −5.4, −5.6; MS (FAB, NBA) *m/z* (%) 706 [M$^+$]; HRMS (FAB) calcd for $C_{37}H_{54}N_4O_6Si_2$ [M$^+$] 706.3582, found 706.3597.

5-[3-(6-Dimethylaminonaphthalenecarboxamido)-propynyl]-5′-*O*-(4,4′-dimet hoxytrityl)-2′-deoxyuridine 3′-*O*-cyanoethyl-*N*,*N*′-diisopropylphosphoramidite (5). To a solution of **3** (1.08 g, 2.51 mmol) in dry pyridine (20 mL) was added 4,4′-dimethoxytrithyl chloride (1.27 g, 3.76 mmol). The mixture was stirred at room temperature for 6 h. The mixture was concentrated in vacuo and diluted with ethyl acetate (200 mL). This solution was washed with aqueous $NaHCO_3$ (150 mL) and brine (150 mL), dried over Na_2SO_4, filtered, and evaporated. The crude product was purified by silica gel column chromatography (chloroform:methanol = 100:1 containing 5% triethylamine) to yield a pale-yellow solid (1.20 g, 61%): ^{1}H NMR (DMSO-d_6, 400 MHz) δ = 11.65 (s, 1H), 8.82 (t, 1H, J = 5.3 Hz), 8.27 (d, 1H, J = 1.3 Hz), 7.89 (s, 1H), 7.79−7.76 (m, 2H), 7.66 (d, 1H, J = 8.8 Hz), 7.39−7.37 (m, 2H), 7.30−7.16 (m, 7H), 6.94 (d, 1H, J = 2.4 Hz), 6.88 (dd, 4H, J = 9.1, 2.7 Hz), 6.09 (t, 1H, J = 6.7 Hz), 5.30 (d, 1H, J = 4.6 Hz), 4.26−4.22 (m, 2H), 4.16 (d, 2H, J = 5.3 Hz), 3.91−3.88 (m, 1H), 3.70 (d, 6H, J = 2.2 Hz), 3.26−3.22 (m, 1H), 3.07−3.04 (m, 1H), 3.02 (s, 6H), 2.26 (dt, 1H, J = 13.7, 6.8 Hz), 2.15 (ddd, 1H, J = 13.5, 6.3, 3.6 Hz); ^{13}C NMR (DMSO-d_6, 100 MHz) δ = 166.2, 161.8, 158.3, 158.2, 149.7, 149.5, 145.0, 143.4, 136.4, 135.9, 135.4, 130.0, 129.9, 129.8, 128.1, 127.8, 127.7, 125.8, 124.9, 124.5, 116.8, 113.44, 113.40, 105.1, 98.6, 90.2, 86.0, 85.2, 70.7, 64.0, 55.2, 40.2, 29.4; MS (FAB, NBA/$CHCl_3$) *m/z* (%) 780 [(M + H)$^+$]; HRMS (FAB) calcd for $C_{46}H_{44}N_4O_8$ [(M + H)$^+$] 780.3159, found 780.3163.

To a solution of the product (45 mg, 0.058 mmol) in dry acetonitrile (2 mL) was added 2-cyanoethyl tetraisopropyldiphosphoramidite (19 μL, 0.058 mmol) and tetrazole (4.9 mg, 0.070 mmol). The mixture was stirred at room temperature for 2 h. The solvent was evaporated, and the residue was directly used in an automated DNA synthesizer without further purification.

Oligodeoxynucleotide (ODN) Synthesis and Characterization. ODNs were synthesized by a conventional phosphoramidite method by using an Applied Biosystems 392 DNA/RNA synthesizer. ODNs were purified by reverse-phase HPLC on a 5-ODS−H column (10 × 150 mm, elution with 0.1 M triethylamine acetate (TEAA), pH 7.0, linear gradient over 50 min from 0 to 50% acetonitrile at a flow rate 3.0 mL/min). ODNs containing modified nucleotides were fully digested with calf intestine alkaline phosphatase (50 U/mL), snake venom phosphodiesterase (0.15 U/mL), and P1 nuclease (50 U/mL) at 37 °C for 3 h. Digested solutions were analyzed by HPLC on a CHEMCOBOND 5-ODS−H column (4.6 × 150 mm), elution with a solvent mixture of 0.1 M triethylamine acetate (TEAA), pH 7.0, flow rate 1.0 mL/min). Concentration of each ODN was determined by comparing peak areas with standard solution containing dA, dC, dG, and dT at a concentration of 0.1 mM. 5′-d(TTGCTCATCTTGTT^{DNC}UTGCCGACGCTACATT-GCCAAGG)-3′: MALDI-TOF [(M − H)$^-$] calcd 10930.13, found 10930.36.

UV Absorption Measurements. Absorption spectra were obtained using an Ultraspec 3000pro UV−vis spectrophotometer (Amarsham Pharmacia Biotech) at room temperature using a 1-cm path length cell.

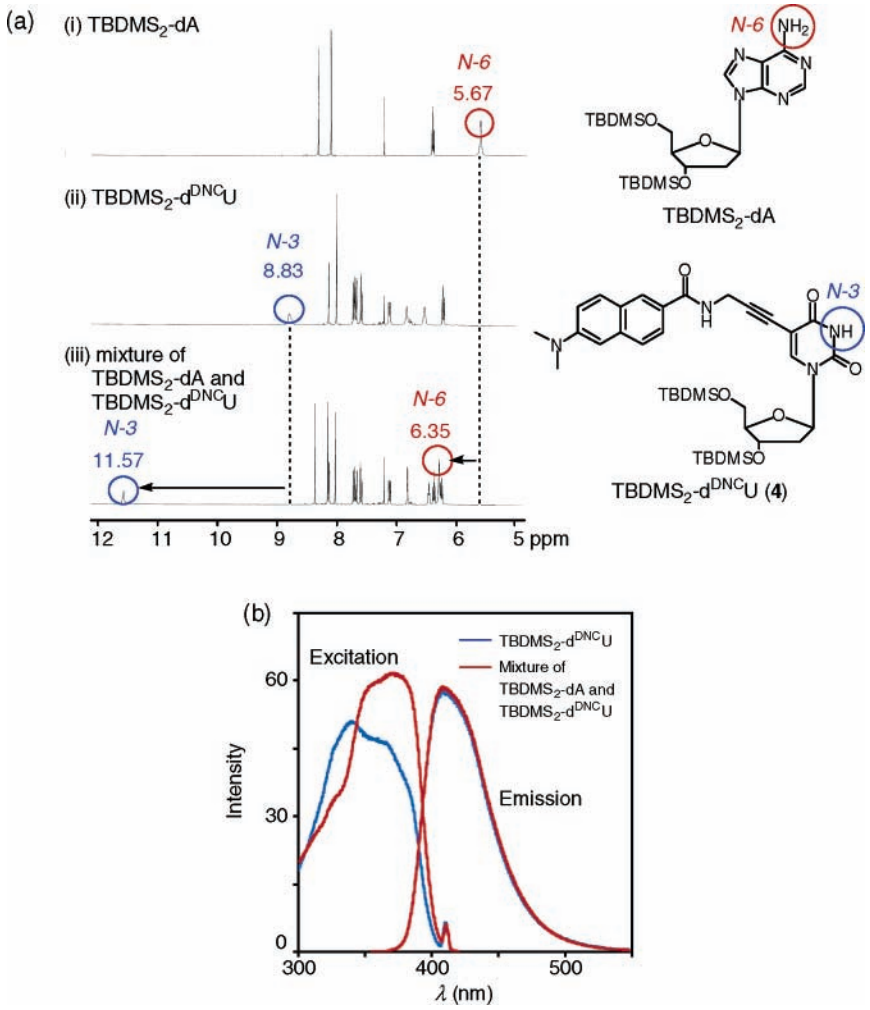

Figure 3. Effect of hydrogen bonds between a ^{DNC}U−A base pair on fluorescence wavelength. (a) ^{1}H NMR spectra of (i) 0.1 M TBDMS$_2$-dA, (ii) 0.1 M TBDMS$_2$-d^{DNC}U, and (iii) 1:1 mixture of 0.1 M TBDMS$_2$-dA and 0.1 M TBDMS$_2$-d^{DNC}U in $CDCl_3$ at 25 °C. (b) Fluorescence excitation and emission spectra of 1 mM TBDMS$_2$-d^{DNC}U in the presence and absence of 1 mM TBDMS$_2$-dA in $CDCl_3$ at 25 °C. $\lambda_{exc} = 350$ nm, $\lambda_{fl} = 414$ nm.

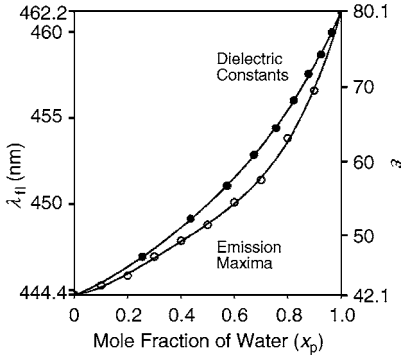

Figure 4. Variation of the fluorescence emission maxima (λ_{fl}, open circles) and dielectric constants (ϵ, filled circles) for water−glycol binary mixtures at 20 °C. For the dielectric constants in the figure, the data described in ref 13 are used.

Fluorescence Experiments. Fluorescence spectra were obtained using a Shimadzu RF-5300PC spectrofluorophotometer at 25 °C using 1-cm path length cell. The excitation bandwidth was 1.5 nm. The emission bandwidth was 1.5 nm.

The fluorescence quantum yields (Φ_F) were determined using 9,10-diphenylanthracene as a reference with a known Φ_F of 0.95 in ethanol. The area of the emission spectrum was integrated using the software available in the instrument, and the quantum yield is calculated according to the following equation

$$\Phi_{F(S)}/\Phi_{F(R)} = [A_{(S)}/A_{(R)}] \times [(\mathrm{Abs})_{(R)}/(\mathrm{Abs})_{(S)}] \times [n_{(S)}^2/n_{(R)}^2] \quad (1)$$

Here, $\Phi_{F(S)}$ and $\Phi_{F(R)}$ are the fluorescence quantum yield of the sample and the reference, respectively. $A_{(S)}$ and $A_{(R)}$ are the area under the fluorescence spectra of the sample and the reference, respectively, $(\mathrm{Abs})_{(S)}$ and $(\mathrm{Abs})_{(R)}$ are the respective optical densities of the sample and the reference solution at the wavelength of excitation, and $n_{(S)}$ and $n_{(R)}$ are the values of refractive index for the respective solvents used for the sample (1.333) and the reference (1.383).

RESULTS AND DISCUSSION

Synthesis of the novel deoxyuridine-based fluorophore, d^{DNC}U (**3**), is outlined in Scheme 1. Commercially available 6-amino-2-naphthoic acid (**1**) was methylated through the reduction of the imine and then condensed with propargylamine to yield **2**. Sonogashira coupling of **2** with 5-iodo-2′-deoxyuridine afforded the fluorescence-labeled nucleoside **3**.

The DNC fluorophore in ^{DNC}U possesses an amide group, unlike conventional DAN fluorophores. The amide group facilitated the incorporation of the fluorophore to a substrate (i.e., uracil base), but it may show a different

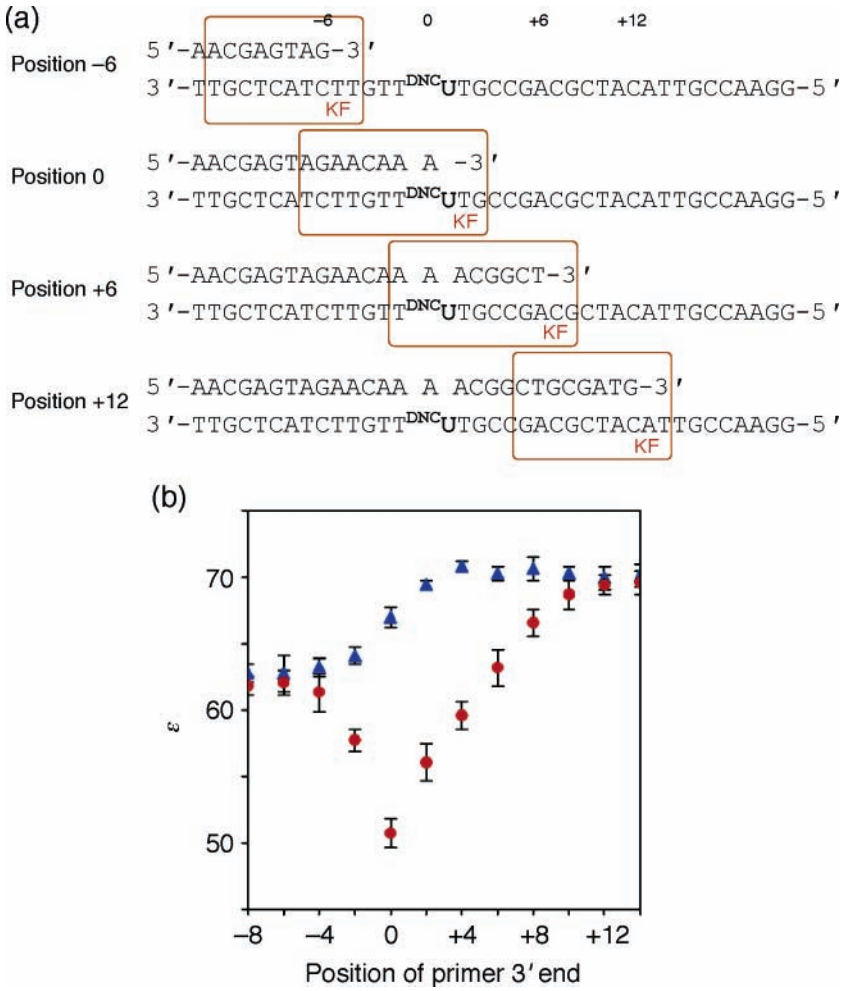

Figure 5. Monitoring the dielectric environments near ^{DNC}U in ODN duplexes containing primers of different length. (a) The examples of primer−template duplexes used in this study. The numbering system used for duplexes defines the position of ^{DNC}U as 0. The region of duplex binding with the KF is depicted by orange frames. (b) Variation of the dielectric constants around ^{DNC}U in the primer−template duplex for different primer length. According to Figure 4, each of the dielectric constants was calculated from the emission wavelength obtained by measurement of the fluorescence emission spectra of 2.5 μM of primer−template duplexes in the presence of KF (1.0 equiv) in 100 mM Tris−HCl (pH 7.5), 70 mM magnesium chloride, and 1 mM dithiothreitol on 326-nm excitation. The change of the dielectric constants observed for primer−template duplexes is depicted with blue triangles, and the data for duplexes bound by KF are plotted with red circles.

dielectric sensitivity from DAN fluorophores. Therefore, we initially measured absorption and fluorescence spectra of a nucleoside d^{DNC}U. The UV absorption of d^{DNC}U had a shoulder from 290 to 410 nm in sodium phosphate buffer (pH 7.0), and the fluorescence was observed at 463 nm on excitation at 332 nm ($\Phi_F = 0.019$) (Figure 1). The fluorescence of d^{DNC}U was dependent on the solvent, e.g., $\lambda_{fl} = 444$ nm, $\Phi_F = 0.140$ in glycol, and $\lambda_{fl} = 415$ nm, $\Phi_F = 0.208$, in ethyl acetate (Figure 2a). The fluorescence emission maxima of d^{DNC}U observed in different solvents were plotted against the dielectric constant for each solvent (*10*) (Figure 2b). A series of fluorescence spectra showed significant shifts of the fluorescence emission with solvent polarity, and the fluorescence emission maxima were shifted from 403 nm (toluene) to 463 nm (water). The shift by solvent polarity can be explained in terms of the dipole interaction theory of Lippert and Mataga (*11*, *12*). An inset in Figure 2b shows a plot of the Stokes shifts ($\Delta\nu$) against the orientational polarizability (Δf) of the solvent. Solvents that can form hydrogen bonds as a proton donor produce larger $\Delta\nu$ than do aprotic solvents. In particular, the $\Delta\nu$ of water clearly deviated from a straight line in the plot. Large solvatofluorochromic shifts of d^{DNC}U in protic solvents were attributed to specific solute−solvent interactions, such as hydrogen bonding.

This solvatofluorochromic shift is due to DNC chromophore−solvent interactions. Hydrogen bonding to the uracil region of d^{DNC}U may also alter the fluorescence properties of d^{DNC}U. To investigate the effect of uracil−solvent interaction on the fluorescence shift, we prepared a chloroform-soluble nucleoside **4**, which was synthesized by protection of the hydroxy groups of **3** with *tert*-butyldimethylsilyl (TBDMS) groups (Scheme 1). The fluorescence spectra of **4** did not show a significant shift on the addition of *O*,*O*′-bis(TBDMS)-protected dA in deuterated chloroform, although the change of the chemical shift of the N3 imino proton of **4** by hydrogen bonding with adenine was observed in ^{1}H NMR spectra (Figure 3). Therefore, the solvatofluorochromic shift of d^{DNC}U fluorescence was predominantly due to the DNC chromophore−solvent interaction not to the hydrogen bonding at the uracil base of ^{DNC}U.

We next examined the change in the fluorescence emission of ^{DNC}U in binary mixtures of water (dielectric constant, $\epsilon = 80.1$) and glycol ($\epsilon = 42.1$) to correlate the fluorescence emission with dielectric constants (Figure 4). The emission wavelength increases monotonically

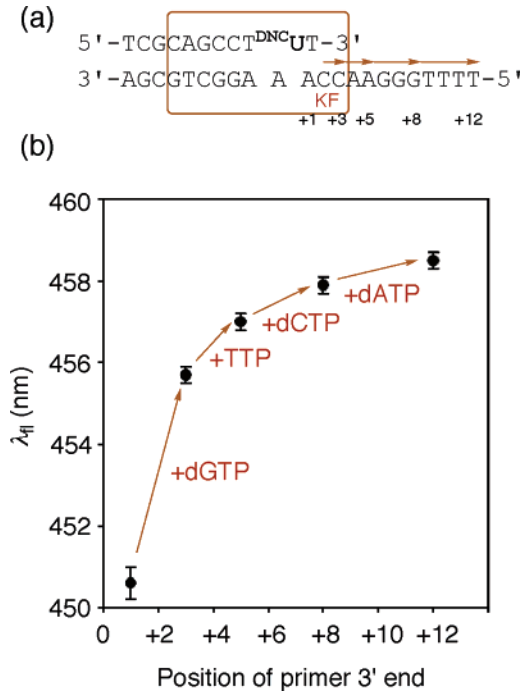

Figure 6. (a) Sequence of a ^{DNC}U-labeled primer−template duplex used for a primer extension assay. (b) Variation of the fluorescence emission maxima (λ_{fl}) of a duplex-KF complex on the addition of dNTP. A sample solution contained 2.5 μM of primer−template duplexes and KF (1.0 equiv) in 100 mM Tris−HCl (pH 7.5), 70 mM magnesium chloride, and 1 mM dithiothreitol. The emission wavelength was obtained by measuring fluorescence emission spectra of the sample where each dNTP (250 μM) was successively added (λ_{exc} = 326 nm).

with increasing water/glycol ratio. The curvature of the fluorescence emission maxima of d^{DNC}U in binary mixtures roughly corresponded to that for the dielectric constants (*13*), although a small gap caused by a preferential solvation process was observed (*14*, *15*). These data facilitate the direct conversion of the given fluorescence emission wavelength to dielectric constants.

Having established the variation of fluorescence wavelength of d^{DNC}U with solvent dielectric constant, we next examined the incorporation of ^{DNC}U into ODNs and measured their fluorescence spectra. Nucleoside **3** was converted to cyanoethyl phosphoramidite **5** for the DNA synthesizer (Scheme 1). After ODN synthesis, deprotection was conducted with aqueous ammonia at 55 °C for 16 h to give ^{DNC}U-containing ODN. By use of a ^{DNC}U-containing 37-mer ODN (template ODN) prepared according to the above procedure (MALDI-TOF [(M − H)$^-$] calcd 10930.13, found 10930.36), we examined the hybridization with short ODNs with different nucleotide lengths (primer ODNs) (Figure 5a). By variation of the length of the hybridized primer ODNs, the local dielectric constants of single-stranded sites, duplex regions, and single strand−duplex junction sites were examined. The numbering system used for duplexes defines the position of ^{DNC}U as 0. The fluorescence maxima observed for each duplex were converted to the local dielectric constants according to Figure 4, and the result is shown in Figure 5b (blue triangles). When ^{DNC}U was located at a single-strand site (the 3′ end of the primer ODN was at positions −8 to −4), the wavelength of the emission maximum was 452 nm on excitation at 326 nm, and the dielectric constant of the ^{DNC}U site corresponded to 63. On the other hand, when ^{DNC}U was located in a duplex region (the 3′ end of the primer ODN was at positions +4 to +14), the maximum of the fluorescence emission was observed at 456 nm. The dielectric constant of the duplex was estimated to be 70. At the single strand−duplex junction, the emission maximum of ^{DNC}U gradually shifted from 452 to 456 nm as the primer ODN was extended. The fluorescence shift induced by site-specific incorporation of ^{DNC}U reflects the difference in dielectric constants between the outside of the duplex major groove and the inside of a folded single strand. In the duplex, the DNC fluorophore attached to the uracil C-5 position via a rigid propargyl linker extruded to the outside of the major groove, a water-accessible site, due to base pairing with an adenine base, whereas ^{DNC}U in the coiled single strand would be shielded from the aqueous phase. ^{DNC}U incorporated into DNA effectively acted as a dielectric-sensitive probe.

We monitored the dielectric nature of the binding site of DNA-binding proteins using the fluorescence of ^{DNC}U-containing ODN. We investigated the dielectric constants of the DNA-binding site in the Klenow fragment (KF) of DNA polymerase I from *Escherichia coli*, which contains the polymerase and 3′−5′ proofreading exonuclease activities and has long been used as a good model system for studying the molecular mechanism of template-directed DNA synthesis (*16*−*19*). The change in the emission maxima of the 1:1 complexes formed by KF and ^{DNC}U-containing duplex was monitored. The local dielectric constants, which were calculated from the emission wavelength of the ^{DNC}U-containing template ODN hybridized with primer ODNs of different length, were plotted as shown in Figure 5b (red circles). When the 3′ end of the primer was at position −6, the dielectric constant of the KF−duplex complex was almost the same as that observed for the KF-free sample. Also, for the duplexes where the end of the primer exceeded position +10, the dielectric constant was nearly equal to that for the polymerase-free sample. On the other hand, when the 3′ end of the primer was located between positions −2 and +6, the emission maximum showed a characteristic blue shift on binding to KF, suggesting that the dielectric constants of the microenvironments around ^{DNC}U drastically decreased. The decrease in the dielectric constants observed for the complex of ^{DNC}U-containing ODN and KF was in good agreement with the fact that about 8 base pairs of the duplex region upstream of the primer end were covered with KF, as demonstrated by DNA footprinting experiments (*16*, *20*). In particular, when the 3′ end of the primer was at position 0, a minimum dielectric constant was observed (λ_{fl} = 448 nm, ϵ = 51). In this case, ^{DNC}U was located in the vicinity of the incorporation site of triphosphate in KF. The duplex in the incorporation site of triphosphates is known to be tightly captured by the side chains of the palm and thumb subdomains (*21*, *22*). We were able to confirm easily the lower hydrophilicity of the microenvironment around the incorporation site of triphosphates in KF.

We next examined a primer extension assay in the presence of dNTPs using KF. The ^{DNC}U-labeled primer−template duplex used for this assay is shown in Figure 6a. In this assay, dGTP was initially added to a sample containing the duplex and KF, and then TTP, dCTP, and dATP were added successively. The fluorescence observed after the addition of each dNTP gradually shifted to longer wavelength (Figure 6b). This result shows that the location of a ^{DNC}U base on the primer shifted from less polar enzyme interior to more polar exterior, in tandem with KF migration through the DNA polymerization process. We were able to monitor the change of microenvironmental polarities of the enzyme from inside

to outside using a ^{DNC}U-containing probe. These results suggest that the ^{DNC}U-containing probe can be used to investigate polarities on the inside of DNA-binding protein.

In conclusion, we prepared a novel fluorescent nucleoside ^{DNC}U via a few synthetic steps. This nucleoside offers high fluorescence sensitivity to the solvent polarity and was able to directly sense local dielectric properties by the fluorescence change. A series of fluorescence spectra showed a remarkable shift depending on the polarity of the microenvironment around ^{DNC}U. In addition, the change of fluorescence emission of ^{DNC}U by the close contact with KF enabled us to determine dielectric constants of each DNA-binding site of KF. Therefore, ^{DNC}U-containing ODN serves as an effective dielectric-sensitive fluorescence probe for monitoring the change of local dielectric properties on the interior of a DNA-protein complex.

Targeted Delivery of Plasmid DNA into the Nucleus of Cells via Nuclear Localization Signal Peptide Conjugated to DNA Intercalating Bis- and Trisacridines

Takehiko Shiraishi, Ramin Hamzavi,† and Peter E. Nielsen*

Department of Medical Biochemistry and Genetics, The Panum Institute, University of Copenhagen, Blegdamsvej 3c, 2200 Copenhagen N, Denmark. Received March 23, 2005; Revised Manuscript Received July 15, 2005

Efficient nuclear targeting via nonviral delivery of DNA is still an unmet challenge in gene therapy. We have synthesized a novel 9-aminoacridine amino acid monomer that conveniently allows multiple acridines to be incorporated into peptide conjugates. In particular we have prepared bis- and trisacridine conjugates of nuclear localization signal peptide (NLS) ($(Acr)_2$−NLS and $(Acr)_3$−NLS) and studied these as functional transporters for the nuclear delivery of DNA. We show that these conjugates can enhance transfection efficacy as well as nuclear localization of plasmid DNA by more than 50-fold when combined with polyethylenimine at an N:P ratio of 2−3. These conjugates have high reversible affinity for double stranded DNA by intercalation and the technique provides a simple means of associating NLS with DNA of any sequence and at any ratio.

INTRODUCTION

Low efficiency of gene transfer is a major barrier for the development of nonviral gene therapy. Compared with adenovirus vectors (*1*), which provide nearly 100% transduction of endothelial cells *in* vivo and in vitro, the efficiency of nonviral gene transfer methods are far inferior (*2*−*4*). Transfection of DNA by nonviral systems is limited by cellular uptake, endosomal escape, as well as translocation of the DNA from the cytoplasm into the nucleus. Especially, transfer of plasmid DNA to the nucleus remains a critically limiting step (*5*, *6*). It has been shown that expression of a gene from plasmid DNA injected directly into the nucleus is much higher than from plasmid injected into the cytoplasm (*7*), for which less than 1% is typically internalized in the nucleus. In contrast, the efficiency of adenovirus transduction is attributed to the efficiency of receptor recognition, endosome escape, and nuclear pore recognition. However, adding replication-deficient adenovirus to lipid−DNA complexes during transfection provides an only modest increase in transfection efficiency (*8*). These results indicate that even with endosome escape facilitated by adenovirus, translocation of cytoplasmic plasmid DNAs to the nucleus remains a significant limiting step in nonviral gene transfer.

Molecules, larger than 30−60 kDa, require active transport system via nuclear localization signals to be transported into the nucleus from the cytoplasm (*9*). To achieve an effective nuclear translocation of target molecules, the SV40 basic nuclear localization signal (NLS) peptide has been used extensively as a carrier for large proteins (*9*), as well as for DNA (*3*). Recently, Sebestyen et al. (*10*) demonstrated a significant increase of nuclear uptake of plasmid DNA upon covalent conjugation to the NLS peptide. However, as a consequence of this modification, the DNA significantly lost biological activity. Branden et al. (*3*) exploited a peptide nucleic acid (PNA) for noncovalent conjugation of NLS to plasmid DNA via sequence-specific binding of PNA to the DNA, thereby improving the nuclear translocation of DNA without decreasing gene expression activity. However, their method requires introduction and/or selection of a PNA-binding sequence that does not interfere with the proliferation and transcriptional activities of the vector. In addition, specific PNA/NLS conjugates must be synthesized for each target DNA. Therefore, more simple methods for noncovalent conjugation of DNA to a NLS peptide could be advantageous.

We decided to take advantage of the high affinity of bis- and tris-intercalating compounds (*11*) in order to achieve strong reversible binding of nuclear localization signal peptide (NLS) to dsDNA. We now report the synthesis of a novel 9-aminoacridine amino acid monomer that allows multiple acridines to be incorporated into peptide conjugates. In particular we have prepared bis- and trisacridine conjugates of NLS ($(Acr)_2$−NLS and $(Acr)_3$−NLS) and studied these as functional transporters for the nuclear delivery of DNA.

EXPERIMENTAL PROCEDURES

Synthesis of 9-Aminoacridine NLS Conjugate (Acr−NLS). The sequences and nomenclature of the Acr−NLS conjugates and NLS are listed in Figure 1. Peptide conjugate and PNA syntheses were carried out by standard solid support methodology as reported elsewhere (*12*). The peptides were high-performance liquid chromatography purified and characterized by matrix-assisted laser desorption-ionization time-of-flight (MALDI-TOF) mass spectrometry (Figure 1B). Purified peptides were lyophilized and stored at 4 °C until use.

Synthesis of Acr^{aeg} Monomer (Scheme 1). Reagents and solvents were obtained from commercial sources and used without further purification unless indicated. NMR spectra were recorded in DMSO-*d6* on a 500-MHz Bruker

spectrometer and fast-atom bombardment (FAB) mass spectra on a JEOL HX 110/110 mass spectrometer.

N-(Acridine-9-yl)-6-aminohexanoic acid (**I**) was prepared essentially as described (13): 9-chloroacridine (2.1 g, 10 mmol), 6-aminohexanoic acid (1.1 g, 8.4 mmol), and phenol (9.4 g, 0.1 mol) were mixed and stirred at 85 °C overnight. The reaction mixture was cooled to room temperature, and ethyl acetate (200 mL) was added and extracted with saturated aqueous $NaHCO_3$. The organic phase was dried over $MgSO_4$ and evaporated to dryness. The title compound (2.2 g, 85%) was obtained as a yellow powder. Mp: 160−162 °C; MS (FAB) *m/z* 309 (M + H); ^{1}H NMR (DMSO-*d6*): δ 8.6−7.4 (m, 8H, acridine aromatics), 4.03 (t, 2H, J = 7.0 Hz), 2.22 (t, 2H, J = 7.0 Hz), 1.90 (m, 2H), 1.55 (m, 2H), 1.40 (m, 2H); ^{13}C NMR (DMSO-*d6*): δ 174.22, 156.36, 134.03, 129.07, 125.67, 122.75, 118.76, 115.02, 112.25, 48.37, 33.36, 28.54, 25.58, 23.91; HRMS $(M + H)^+$, calcd (found) for $C_{19}H_{20}N_2O_2$: 309.1603 (309.1610).

Methyl-N-(2-bocaminoethyl)-N-[N-(acridine-9-yl)-6-aminohexanoyl]]glycinate (**II**). Compound **I** (3.1 g, 10 mmol), DhbtOH (1.8 g, 11 mmol), and DCC (3.1 g, 15 mmol) were dissolved in DMF (50 mL) and stirred for 30 min under nitrogen. A solution of *N*-(2-bocaminoethyl)glycine methyl ester (14) (2.1 g, 9 mmol) in DMF (10 mL) was added, and the reaction mixture was stirred overnight. Volatiles were removed under vacuum, and the residue was dissolved in ethyl acetate. Insoluble DCU was filtered off, and the filtrate was extracted with saturated aqueous $NaHCO_3$. The organic phase was dried over $MgSO_4$ and evaporated to dryness under vacuum. The residue was purified on a silica gel column eluting with ethyl acetate/methanol (7:1 v/v) to provide **2** (3.3 g, 63.5%) as yellow crystals. Mp: 65−67 °C; MS (FAB) *m/z* 523 (M + H); ^{1}H NMR (DMSO-*d6*) (major rotamer): δ 8.3−7.2 (m, 8H, acridine aromatics), 6.85 (t, 1H, J = 7.0 Hz), 3.95 (s, 2H), 3.80 (t, 2H, J = 7.0 Hz), 3.60 (s, 3H), 3.4−3.2 (m, 3H), 3.1−3.0 (m, 3H), 2.25 (t, 2H, J = 7 Hz), 1.8−1.7 (m, 2H), 1.5 (m, 2H), 1.3 (S, 9H); ^{13}C NMR (DMSO-*d6*): δ 205.08, 204,91, 202.77, 202.47, 187.96, 184.18, 162.51, 162.37,

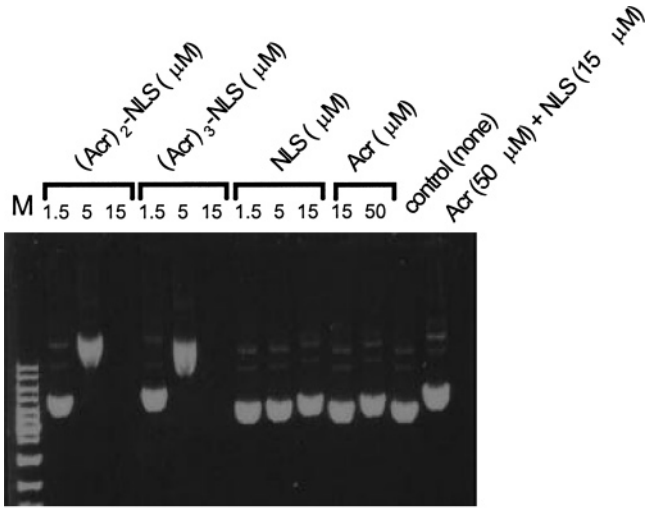

Figure 2. Gel-shift assay of Acr−NLSs binding to plasmid DNA. Plasmid pRL-CMV (2 μg) was incubated with test compounds for 30 min at room temperature. After incubation, the samples were analyzed by electrophoresis in 0.75% agarose gel using ethidium bromide staining for DNA detection. Lane M is a GeneRuler DNA Ladder Mix (MBI Fermentas).

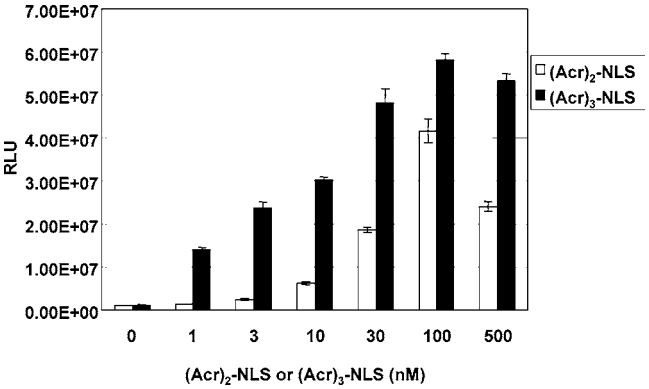

Figure 3. Effect of $(Acr)_2$−NLS or $(Acr)_3$−NLS concentrations on the transfection of JAR cells. A luciferase DNA vector (1 μg/mL of pGL3-control vector, Promega) in complex with polyethylenimine (PEI) (at the N:P ratio 3) was complexed with $(Acr)_2$−NLS or $(Acr)_3$−NLS at the different concentrations. The cells were transfected with the complex of DNA/$(Acr)_3$−NLS/PEI or DNA/$(Acr)_2$−NLS/PEI for 24 h and subsequently assayed for luciferase activity. Luciferase values are mean ± SD of at least three experiments and are presented as RLUs (relative light units) after normalization for protein concentrations.

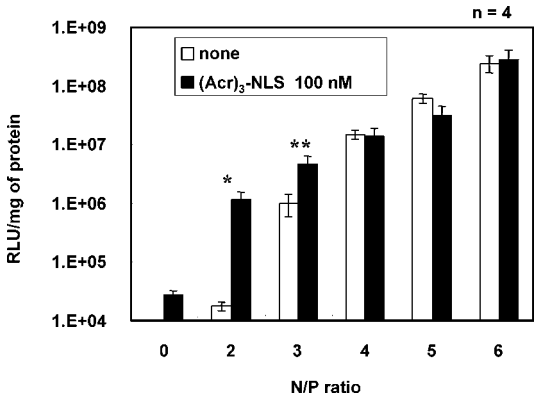

Figure 4. Effect of N:P ratio on the transfection of JAR cells by the luciferase vector DNA. pGL3-control vector (1 μg/mL, Promega) in complex with $(Acr)_3$−NLS and PEI at the different N:P ratios was used. The cells were transfected with the DNA/$(Acr)_3$−NLS/PEI or DNA/PEI complex for 24 h and subsequently assayed for luciferase activity. Luciferase values are mean ± standard deviation (SD) of at least four experiments and have been normalized for protein concentrations. An asterisk indicates significant difference between DNA/PEI and Acr−NLS/DNA/PEI ($P < 0.01$). Two asterisks indicate a significant difference between DNA/PEI and Acr−NLS/DNA/ PEI ($P < 0.05$).

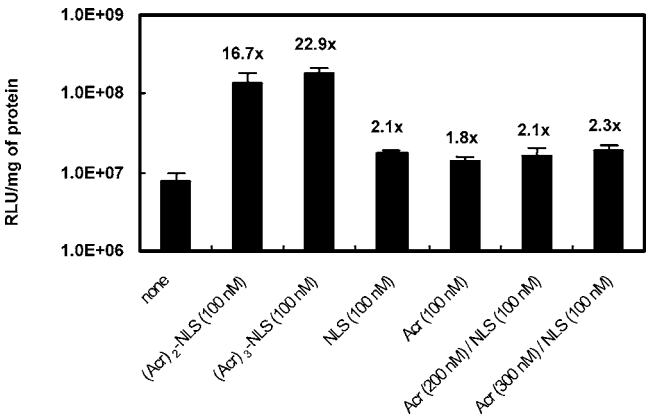

Figure 5. Transfection of JAR cells by complexes of luciferase vector DNA. pGL3 control vector (1 μg/mL, Promega) and test compounds at the indicated concentrations in complex with PEI (N:P ratios = 3) was used. The cells were transfected with the complex for 24 h and subsequently assayed for luciferase activity. Luciferase values are mean ± SD of at least three experiments and have been normalized for protein concentrations. The numbers on each bar indicate the fold of activation compare to the value from the control (DNA/PEI, no test compounds).

*N-(2-Bocaminoethyl)-N-[N-(acridine-9-yl)-6-aminohexanoyl]]glycine (***III***).* Compound **II** (2.6 g, 5 mmol) was dissolved in tetrahydrofuran (10 mL). NaOH (20 mL, 2M) was added, and the reaction mixture was stirred for 15 min. The pH adjusted to 4 by addition of HCl (2 M). The precipitate was filtered off and washed with water. The title compound (2.1 g, 84%) was obtained as a yellow powder. MS (FAB) *m/z* 509 (M + H); ^{1}H NMR (DMSO-*d6*) (major rotamer): δ 8.6−7.4 (m, 8H), 6.85 (br. s, 1H), 4.1−3.9 (m, 4H), 3.4−3.3 (m, 2H), 3.1−3.0 (m, 2H), 2.32 (t, 2H, $J = 7$ Hz), 2.0−1.8 (m, 2H), 1.6−1.5 (m, 2H), 1.4 (m, 2H), 1.3 (S, 9H); ^{13}C NMR (DMSO-*d6*): δ 210.19, 205.05, 204.10, 187.94, 185.00, 162.97, 157.43, 153.96, 149.88, 139.32, 129.50, 110.01, 109.72, 98.04, 92.83, 82.35, 70.37, 65.49, 64.38, 64.20, 62.95, 60.70, 60.46, 59.75, 57.46, 56.59, 54.08; HRMS $(M + H)^+$, calcd (found) for $C_{28}H_{37}N_4O_5$: 509.2764 (509.2763).

Cell Culture. JAR cells were used for transfections and were cultivated in RPMI-1640 (Sigma) supplemented with 10% fetal bovine serum, 1% Glutamax (Gibco), 100 IU/mL penicillin, and 100 μg/mL streptomycin. All cultures were incubated at 37 °C in humidified air with 5% CO_2.

Gel Mobility Shift Assay of Acr−NLSs for the DNA Binding. The plasmid DNA (100 μg/mL of pRL-CMV, Promega) was incubated at room temperature for 30 min with Acr−NLSs or other test compounds at the desired concentrations. Then the complexes were analyzed on a 0.75% agarose gel (*15*) with 1 × TBE buffer. After separation, gels were stained by ethidiumbromide (EtBr) and subjected to image analysis.

Formation and Transfection of Acr−NLS/DNA/PEI Complex. Cells were reseeded and incubated for

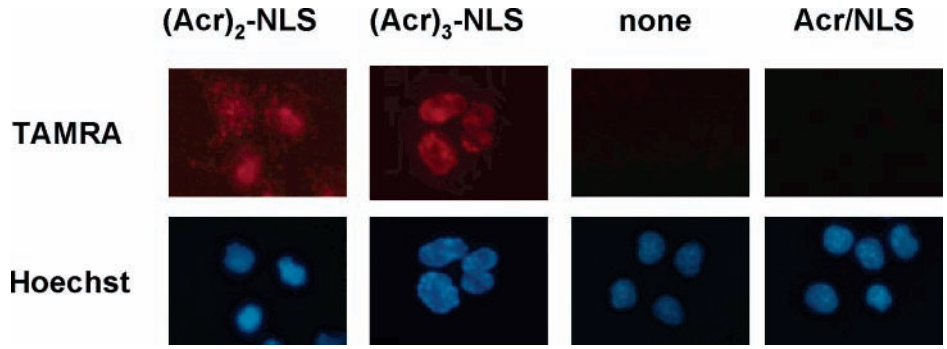

Figure 6. Increase of nuclear localization of the transfected DNA by $(Acr)_2$−NLS and $(Acr)_3$−NLS. JAR cells were transfected with the complex of TAMRA−PNA-labeled DNA (1 μg/mL, see Materials and Methods for detail) and auxiliary compounds in combination with PEI (N:P ratio at 3). After 24 h incubation, the cells were incubated with 2 μg/mL Hoechst33342 for 10 min at 37 °C and subjected to fluorescence microscopy analysis without fixation. TAMRA and Hoechst indicate the fluorescence images from TAMRA and Hoechst3342, respectively. $(Acr)_2$−NLS, 100 nM; $(Acr)_3$−NLS, 100 nM; Acr/NLS, Acr (300 nM)/NLS (100 nM).

16−24 h at 37 °C in 5% CO_2 to give 40−60% cell confluency at the time of transfection. For transfection of the plasmid DNA, cells were seeded in 24-well plates (Nunc) or 4-well chamber slides (Nunc), respectively. Before transfections, cell culture medium were replaced with 0.2 mL of OPTI-MEM (Gibco) supplemented with 1% FBS. To prepare the complexes of Acr−NLS, DNA, and polyethylenimine (PEI), 250 ng of DNA was incubated for 30 min at room temperature with Acr−NLS or other compounds in 25 μL of 150 mM NaCl. Then this solution was mixed with 25 μL of PEI solution in 150 mM NaCl. After 15 min of incubation at room temperature, 50 μL of Acr−NLS/DNA/PEI solution was added to the cells in the 0.2 mL of OPTI-MEM (1% FBS).

Luciferase Assay. Twenty-four hours after transfection, cells were subjected to the luciferase assay (Promega kit) according to the manufacturers instruction. Luciferase activities were normalized by protein concentrations and are presented as relative light unit (RLU). Protein concentrations were determined by BCA protein assay kit (Pierce) according to the manufacturers instruction.

Fluorescence Microscopic Analysis. For the nuclear localization studies of DNA, plasmid DNA (pRL-CMV, Promega) labeled with a TAMRA−bis-PNA conjugate was used (*16*, *17*). (The sequence of bis-PNA is TAMRA-(eg1)2-$T_{lys}TT_{lys}CT_{lys}$CTT-(eg1)3-TTJTJTTT-NH2, where TAMRA is 5(6)-carboxy-tetramethylrhodamine, J is pseudo-isocytosine (*16*) (placed in the Hoogsteen strand), T_{lys} is a lysine backbone PNA T-monomer (*18*), and eg1 is an 8-amino-3,6-dioxaoctanoic acid linker). For the labeling, 100 μg/mL of plasmid DNA was incubated with the 4 μM bis-PNA in water overnight at 37 °C. The complex of the DNA/bis-PNA was purified prior to transfection by using a PCR Cleaning Kit (BIO-RAD). Complexation and transfection of the complex (DNA/Acr−NLS/PEI) was performed as described above. Twenty-four hours after transfection, cells were incubated with 2 μg/mL of Hoechst33342 for 10 min at 37 °C, rinsed twice with phosphate-buffered saline, and subjected to fluorescence microscopic analysis using a LEITZ WETZLAR fluorescent microscope (DIALUX 22EB(Germany)) at 400× magnification.

RESULTS AND DISCUSSION

Bis- and tris-intercalating agents bind to double-stranded DNA with extremely high affinity ($K_d < 10^{-9}$ M), with slow off-rate kinetics, and without pronounced sequence selectivity (*11*, *15*). We therefore decided to investigate whether such ligands might be exploited to strongly and reversibly attach multiple copies of nuclear localization peptide (NLS) to plasmid DNA in order to facilitate nuclear delivery in gene-therapy approaches. To this end we designed a Boc-protected 9-aminoacridine amino acid monomer based on the peptide nucleic acid aminoethylglycine backbone (*18*) (Scheme 1). This monomer (eventually in combination with *N*-(acridine-9-yl)-6-aminohexanoic acid) allowed us to construct NLS oligoacridine conjugates by conventional continuous solid-phase peptide synthesis (Figure 1).

Gel Shift Assay for DNA Binding of the 9-Aminoacridine−NLS Conjugates (Acr−NLS). To study the association of Acr−NLS with plasmid DNA, an agarose gel-shift assay was carried out (*15*). Plasmid DNA (pRL-CMV) was mixed with increasing amounts of $(Acr)_2$−NLS or $(Acr)_3$−NLS and analyzed by electrophoresis in a 0.75% agarose gel. As shown in Figure 2, both $(Acr)_2$−NLS and $(Acr)_3$−NLS retarded the migration of the plasmid DNA at a concentration of 5 μM, while at 15 μM of $(Acr)_2$−NLS or $(Acr)_3$−NLS the DNA was retained in the wells. In contrast, NLS peptide or Acr monomer (Acr) (or a combination of the two) did not retard the DNA migration even at the highest concentrations tested (15 μM and 50 μM respectively). Therefore, as expected, only the bis- and trisacridine derivatives have sufficient DNA affinity to remain bound to the DNA during electrophoresis and cause band shifts (*15*).

Enhancement of Plasmid DNA Transfection Efficiency and Nuclear Localization of the Plasmid DNA by Acr−NLSs. For the transfection study with the luciferase-coding plasmid DNA, the polycationic transfection reagent PEI was used in complex with Acr−NLS/DNA. PEI is required for neutralization and condensation of the DNA to obtain spontaneous cellular uptake. We first determined the dose effect of the Acr−NLS conjugates (Figure 3). These results revealed first of all that the trisacridine conjugate is more potent than the bisacridine conjugate and second that both reagents show optimal effects around 100 nM at the conditions used. To establish the maximal DNA transfection efficiency by the Acr−NLS conjugates, the N:P ratio between nitrogen residues (of PEI) and phosphate residues (of DNA) was optimized. Luciferase plasmid DNA or the plasmid DNA/Acr−NLS complex was mixed with different concentration of PEI (at N:P ratio of 0, 2, 3, 4, 5, and 6) and used for transfection. Without PEI addition, DNA and $(Acr)_3$−NLS/DNA complex did not accomplish significant transfection (Figure 4), whereas using a combined $(Acr)_3$−NLS/DNA/PEI complex resulted in higher transfection efficiency compared to the control DNA/PEI complex alone (no Acr−

NLS addition) at an N:P ratio of 2 and 3. However, the effect of the $(Acr)_3$−PNA disappeared at N:P ratio 4, 5, and 6. $(Acr)_2$−NLS gave results similar to those of $(Acr)_3$−NLS at the N/P ratio 2 and 3 (data not shown).

Control experiments (Figure 5) showed that neither NLS or acridine alone or in combination yielded transfection efficiencies comparable to those obtained with either of the conjugates. Similar results were obtained from the experiments with GFP plasmid and also with HeLa cells (data not shown). These results suggest that this method can be used for double stranded DNA regardless of sequence.

Finally, the effects of Acr−NLS on the localization of the fluorescence-labeled DNA were investigated. JAR cells were transfected with rhodamine-labeled plasmid DNA with or without addition of 100 nM of Acr−NLSs in combination with PEI at the N:P ratio of 3. The accumulation of fluorescence in the nucleus was observed in the cells transfected by DNA/$(Acr)_2$−NLS/PEI and DNA/$(Acr)_3$−NLS/PEI complexes, whereas no accumulation of fluorescence was seen in the nucleus of the cells treated with Acr/NLS/DNA/PEI complexes (Figure 6). In addition, neither Acr nor NLS peptide itself induced a significant accumulation of fluorescent DNA in the nucleus (data not shown). Thus the observed increase of the DNA nuclear localization would explain the increment of transfection efficiency of luciferase plasmid DNA by Acr−NLSs.

CONCLUSIONS

The present results demonstrate that bis- and trisacridine NLS conjugates, due to their high affinty for double-stranded DNA, can be used as auxiliary agents for promoting nuclear localization of cellularly transfected DNA vectors, thereby enhancing their expression. We also observe that in our experiments the enhancing effect is limited to a narrow N:P ratio of transfection agent to DNA. However, it may well be possible to optimize the effect using other transfection reagents and by further optimization of the NLS conjugates. Finally, we note that the new acridine monomer may have a multitude of applications in constructing other peptides and ligands that bind strongly to dsDNA by intercalation.

Received March 23, 2005; Revised Manuscript Received July 20, 2005

Because breast cancer cells often express either Her2/neu or carcinoembryonic antigen (CEA) or both, these tumor markers are good targets for radioimmunotherapy using Y-90-labeled antibodies. We performed studies on nude mice bearing xenografts from MCF7, a cell line that has low Her2 and CEA expression, to more accurately reflect the more usual situation in breast cancer. Although uptake of In-111 anti-CEA into tumors was lower than that for In-111-labeled anti-Her2, radioimmunotherapy (RIT) with Y-90 anti-CEA was equivalent to that of Y-90 anti-Her2. When either Y-90 antibody was combined with a split-dose treatment with Taxol, the antitumor effect was greater than with either agent alone. When Y-90 anti-CEA was combined with a single dose of Taxol, the results were equivalent to the split-dose regimen. RIT plus cold Herceptin had no additional effects on tumor size reduction over RIT alone. When animals were first treated with Y-90 anti-Her2 and imaged 1−2 weeks later with In-111 anti-CEA or anti-Her2, tumor uptake was higher for anti-CEA and improved over tumor uptake with no prior RIT. These results suggest that a split dose of RIT with anti-Her2 antibody followed by anti-CEA antibody would be more effective than a single dose of either. This prediction was partially confirmed in a controlled study comparing single- vs split-dose anti-Her2 RIT followed by either anti-Her2 or anti-CEA RIT. These studies suggest that combined RIT and Taxol therapy are suitable in breast cancers expressing either low amounts of Her2 or CEA, thus expanding the number of eligible patients for combined therapies. They further suggest that split-dose RIT using different combinations of Y-90-labeled antibodies is effective in antitumor therapy.

INTRODUCTION

Despite the use of combination chemotherapy, metastatic breast cancer is invariably a fatal disease (*1*). The advent of monoclonal antibodies as therapeutic approaches has made it possible to directly target cell surface receptors that are required for tumor cell growth. One of the most studied antibodies in this approach is Herceptin (trastuzumab) that targets Her2, a member of the EGFR family (*2*, *3*). Unfortunately, anti-Her2 therapy is limited to tumors that overexpress Her2, limiting this therapy to a small subset (15−20%) of breast cancer patients (*4*). A further problem is that Herceptin as a single agent is cytostatic (*5*) and must be used in combination with chemotherapeutic agents to achieve maximum therapeutic benefit (*6*). Among the combination therapies, it has been used with doxorubicin/cyclophosphamide (AC), Taxol (*7*), and more recently, docetaxel plus platinum salts (*8*). Although response rates of up to 79% have been reported (*8*), the median time to progression of 9.9−15.5 months suggests that further improvement is warranted. In addition, prolonged use of Herceptin with some drugs, especially doxorubicin, have led to cardiac toxicity in as many as 27% of treated patients (*9*).

In view of these problems, we have been exploring the use of Y-90 radioimmunotherapy (RIT) as an alternative to cold antibody therapy. Y-90 is a high-energy beta emitter with a half-life of 2.7 days and a maximum path length of 11 mm in tissue. Antibodies conjugated to chelates such as DTPA (*10*) and DOTA (*11*) readily bind Y-90 just prior to injection, thus making this approach attractive in the clinic. A major advantage of RIT is that the once the antibody is targeted to the tumor, it exerts a direct cytotoxic effect. Disadvantages of this approach are the logistical production of radiolabeled antibodies with associated waste disposal and the time required for effective targeting to the tumor because while the radiolabeled antibody is in circulation there is accumulated bone marrow toxicity (*12*, *13*). While many researchers have tried to decrease blood circulation time by engineering small-sized antibody fragments, the net effect is usually faster renal excretion reducing tumor uptake accordingly (*14*). As a result most RIT approaches have relied on whole antibodies engineered as chimeric (*15*−*17*) or humanized (*18*−*21*) versions to maximize tumor uptake while reducing immunogenicity.

The excellent targeting properties of radiolabeled anti-Her2 antibodies has long been appreciated and shown to be effective in reducing tumor size in animal models (*11*, *22*). However, these studies, like therapy with cold Herceptin, have been focused on tumors that overexpress

Her2. Similarly, we have focused our efforts on the use of radiolabeled anti-carcinoembryonic antigen (anti-CEA) antibodies on tumors that overexpress CEA (*23*). In clinical trials in which Y-90 anti-CEA Mab cT8.66 was administered as a single agent to patients with colorectal cancer, only modest effects on tumors were seen, while in CEA-positive breast cancer patients the effects were more impressive (*16*, *24*). The conclusion from these studies is that combination therapies of RIT plus chemotherapy will be required to produce more lasting results. CEA is an attractive cell surface target in that it is expressed in about 50% of breast cancers (*25*) and is a reliable marker for breast cancer recurrence (*26*−*28*). Since most breast cancers express Her2 at some level, the combined expression of Her2 and CEA in breast cancers is about 50%. In this study, we now ask the question, can RIT, especially RIT combined with chemotherapy, be effective against breast tumors that have low to moderate amounts of target antigens such as Her2 and CEA? To answer this question in a preclinical setting, we have grown dual Her2 and CEA positive MCF7 cells as xenografts in nude mice and treated the animals with either Y-90-labeled Herceptin or cT84.66 in the presence or absence of Taxol. This cell line has low amounts of cell surface Her2 (*29*) that fall below the amount required for successful cold Herceptin therapy and has moderate to low amounts of cell surface CEA (*30*). The results suggest that in combination with Taxol, the amount of RIT to produce sustained tumor reductions can be reduced 50% or more over that required producing equivalent results as a single agent. Quite surprising, while In-111-labeled cT84.66 tumor targeting was low (tumor-to-blood ratio of 1.0), RIT with Y-90-labeled cT84.66 was as effective as Y-90-labeled Herceptin in this animal model. The results are encouraging in that the use of RIT with these antibodies may be effective even in tumors with low amounts of cell surface antigen, thus opening up this therapy to a larger group of patients compared to the current scenario with cold Herceptin. A second intriguing result from this study was that animals treated with Y-90 Herceptin exhibited an increased uptake of In-111 cT84.66 compared to In-111 Herceptin, suggesting that sequential RIT first with Y-90 Herceptin and then with Y-90 cT84.66 may be possible in tumors that express both Her2 and CEA. This approach would be especially attractive in treating tumors that downregulate a target antigen after initial therapy.

MATERIALS AND METHODS

Materials. MCF-7 cells were obtained from ATCC and maintained in sterile growth media consisted of Eagle's Minimal Essential media 1× (EMEM) (Cellgro, Herndon, VA) supplemented with 10% heat-inactivated fetal bovine serum (FBS) (Omega Scientific, Tarzana, CA), and 1% L-glutamine, 10 mM sodium pyruvate, 0.1 mM nonessential AA. Media was sterile filtered through a 0.2 μm vacuum filter. Herceptin was obtained from the City of Hope Pharmacy and dialyzed vs PBS prior to conjugation. 1B4M chelate was a generous gift from Dr. Martin Brechbiel (NCI) and was conjugated to Herceptin according to established methods (*10*). DOTA-conjugated chimeric anti-CEA antibody cT84.66 has been previously described by us (*31*, *32*). The number of chelates per antibody which were determined using In-111 isotope dilution in $InCl_3$ essentially according to Lewis et al. (*32*) was 3 and 2.4 for 1B4M-Herceptin and DOTA-cT84.66, respectively. Chelate conjugated antibodies were radiolabled with In-111 (Amersham, 1−2 mCi per 0.1 mg of protein) as previously described (*32*).

MCF-7 Xenograft Model. Female, athymic nu/nu mice (Charles River), 10−12 weeks old, were exposed to 200 RADS external beam Co-60 irradiation 3 days prior to MCF-7 implantation and given sulfatrim antibiotic water for two weeks. Two days prior to MCF-7 implantation mice were administered 0.8 mg of Delestrogen IM injection in the thigh. MCF-7 cells (5×10^6) in EMEM and Matrigel were implanted into each mouse subcutaneous in the flank. Tumors were established within 10−14 days postinjection. Before therapy studies began, tumor-bearing animals were separated into treatment groups based on tumor size (100−200 mg), so all groups average tumor volumes were similar at the onset of the therapy studies. Tumor volumes were estimated twice weekly using the formula length × width^2/2. Relative tumor volume was calculated as the ratio of the current measurement to the initial value. Weights of the animals, measured in grams, were recorded once a week; no animal had more than a 2% weight loss during the course of the experiment.

Radioimaging and Biodistribution Studies. Athymic mice bearing MCF-7 xenografts were injected with 200 μL (2.8 μg of 0.9 μCi/μg) of In-111-labeled 1B4M-Herceptin via tail vein. Five mice per time point were sacrificed at 0, 2, 24, 48, 72, and 96 h postinjection and biodistributions performed (blood, liver, spleen, kidneys, lungs, tumor, and carcass). Alternatively, mice were tail injected with 200 μL (3.2 μg of 1.25 μCi/μg) of In-111-DOTA-cT84.66. Results were calculated as percent injected dose per gram (%ID/g) vs time. For radioimaging, mice were injected with 15 μCi In-111-1B4M-Herceptin (6 μg) and imaged using a BIOSPACE γ imager instrument with settings of 154−188 keV and 220−270 keV.

RIT and Combined Therapy Studies. *RIT and Cold Herceptin*. Four Y-90-DOTA cT84.66 RIT treatment groups (eight Athymic mice per group bearing MCF-7 xenografts) were as follows: 50 μCi RIT, 100 μCi RIT, 50 μCi RIT with cold Herceptin, and 100 μCi RIT with cold Herceptin. A fifth group of mice received only cold Herceptin, which was used as a non-RIT control. The three groups that received the cold Herceptin were administered two IP injection doses (200 μg each), 9 days apart. The sixth group of mice received a single IP injection of sterile saline (no treatment control). The six groups of mice were monitored daily for 5 weeks.

RIT and Single Dose Taxol. Four Y-90-DOTA-cT84.66 RIT treatment groups (eight athymic mice per group bearing MCF-7 xenografts) were as follows: 20 μCi RIT, 40 μCi RIT, 20 μCi RIT with Taxol, and 40 μCi RIT with Taxol. The fifth group received Taxol only. The three groups that received Taxol were administered a single bolus IP of 600 μg Taxol admininistered 24 h post RIT. The sixth group received a single IP injection of sterile saline (no treatment control). The six groups of mice were monitored daily for 5 weeks.

RIT and Two Doses of Taxol. Four Y-90-DOTA-cT84.66 RIT treatment groups (eight athymic mice per group bearing MCF-7 xenografts) were as follows: 40 μCi RIT, 80 μCi RIT, 40 μCi RIT with Taxol, or 80 μCi RIT with Taxol. The fifth group received Taxol only. The three groups that received Taxol were administered two IP injections of 300 μg Taxol 48 and 72 h after RIT. The sixth group received a single IP injection of sterile saline (no treatment control). The six groups of mice were monitored daily for 5 weeks. An identical study was performed with Y-90-1B4M-Herceptin.

RIT Followed by In-111 Antibody Biodistribution. Eight treatment groups (8 athymic nude mice bearing MCF-7 xenografts per group) were as follows: four

groups received 60 μCi Y-90-1B4M-Herceptin, two of which received 200 μL either In-111-labeled cT84.66 (1.7 μg of 2.4 μCi/μg) or Herceptin (1.7 μg of 2.4 μCi/μg) 7 days after initial therapy and two groups of which received either In-111-labeled DOTA-cT84.66 (2.5 μg of 2.4 μCi/μg) or In-111 1B4M-Herceptin (2 μg of 2.35 μCi/μg) 14 days after initial therapy. The other four groups were as follows: no RIT, two groups on day 7 received either In-111-labeled DOTA-cT84.66 or In-111-labeled 1B4M-Herceptin. The final two groups received either In-111-labeled DOTA-cT84.66 or 1B4M-Herceptin on day 14. The In-111-labeled anibody was injected via tail vein, and animals were sacrificed 72 h postinjection and biodistributions were performed (blood, liver, spleen, kidneys, lungs, tumor, and carcass).

RIT Followed by Second-Dose RIT. Six treatment groups (10 athymic nude mice bearing MCF-7 xenografts per group) were as follows: three groups received 60 μCi (8 μg) of Y-90-1B4M-Herceptin of which one group received no second therapy, one received a second therapy with 40 μCi (5.6 μg) of Y-90-1B4M-Herceptin and the final group received a second therapy with 40 μCi (6 μg) of Y-90-DOTA-cT84.66 administered 14 days after the first RIT. Two other groups received no initial RIT but on day 14 received either 40 μCi (5.6 μg) of Y-90-1B4M-Herceptin or 40 μCi (6 μg) of Y-90-DOTA-cT84.66. The final group received only saline via tail vein and served as the no-treatment therapy control. All RIT was administered via tail vein in 200 μL total volume injected.

Data Analysis. For biodistribution studies, the results were reported as %ID/g of tissue vs time. Comparisons were made by t-test and p values were calculated. For RIT or combined RIT and Taxol studies, average relative tumor volumes vs time were reported and the curves were analyzed by ANOVA (two-factor without replication).

[a] Five animals per each time point were analyzed for the indicated tissues. Results are reported as %ID/g with the standard deviation given below.

RESULTS

Biodistributions of In-111-Labeled Anti-CEA and Anti-Her2 Antibodies in MCF-7 Xenografts. CEA and Her2 are expressed in breast cancer in variable amounts (*2*, *25*). The overall positivity for CEA is about 50%, but the expression level is usually much less than in colon cancer. Her2 is overexpressed in 15−20% of breast cancers but is moderately expressed in higher numbers, perhaps up to 30−40% (*33*). However, Herceptin therapy is only appropriate in the tumors that overexpress Her2. We were therefore interested in testing the possibility of using RIT or combined RIT and Taxol therapy to treat tumors that had low to moderate amounts of either antigen. For these reasons, we chose MCF-7 cells which express both Her2 and CEA in low to moderate amounts. To determine the potential for RIT, we first compared the uptake of In-111-labeled anti-CEA (cT84.66) and anti-Her2 (Herceptin) in nude mice bearing MCF-7 xenografts. As shown in Table 1 tumor uptake reached a maximum in 48−72 h with values of 11.6 (±2.3) and 25.0 (±5.6) %ID/g for anti-CEA and anti-Her2, respectively. The tumor-to-blood ratios at maximum uptake were 1.0 and 2.0 for anti-CEA and anti-Her2, respectively. The low tumor-to-blood ratio for the anti-CEA study was especially worrisome, since bone marrow toxicity is the major side effect in high dose RIT. In general, tumor-to-blood ratios of at least 2:1 are preferred to minimize this toxicity. Thus, from the results of the biodistribution data, we predicted that anti-Her2 would be the superior antibody for RIT in this tumor model. Nonetheless, we proceeded to compare both antibodies in RIT since the tumor model provided a unique opportunity to see if the biodistribution results would correctly predict the RIT results.

RIT and Taxol Therapy with Y-90-Labeled Anti-CEA and Anti-Her2 Antibodies in MCF-7 Xenografts. Since previous studies have shown that only high-dose RIT with or without autologous blood or marrow transplant (BMT) gave superior responses for single agent therapy (*34*), we considered from the outset to perform combined RIT plus chemotherapy in the tumor model system. Taxol was chosen as the agent of choice because of its prevalent use in breast cancer therapy especially when used with Herceptin cold antibody therapy. On the basis of the results of DeNardo and co-workers in which RIT with various taxol combinations were explored (*35*), we chose to administer single-dose RIT followed by two doses of taxol IP (300 μg). Since previous experience established that 100−120 μCi/mouse of Y-90-cT84.66 therapy was sufficient to cause >50% tumor growth inhibition (*11*), we explored the use of lower-dose RIT (40 and 80 μCi) so that the effect of Taxol (if any) would not be obscured by the RIT. As shown in Figure 1A, the relative tumor volume of the control animals increased by 2−2.5-fold over 35 days, while Taxol-only treated animals showed a brief period of tumor growth inhibition but ultimately reached the same size as control animals. Animals treated with 40 μCi of Y-90-cT84.66 exhibited a similar reduction in tumor growth compared to Taxol alone (p = 0.29), but by the end of 35 days tumor regrowth was apparent. When the RIT dose was increased to 80 μCi/animal a substantial tumor growth inhibition was seen, even at the end of 35 days (p =

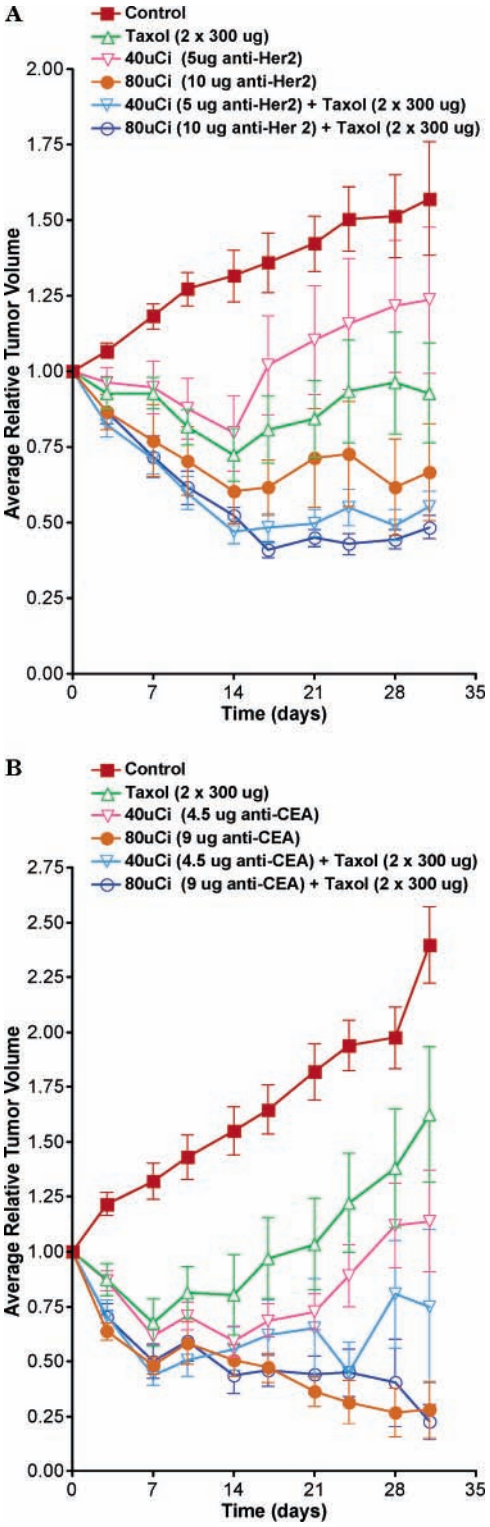

Figure 1. Radioimmunotherapy of established MCF-7 tumors in nude mice with Y-90-labeled anti-Her2 or anti-CEA antibodies in combination with a split dose dose of Taxol. Groups of eight mice were injected IV with either (A) Y-90-labeled anti-Her2 antibody or (B) Y-90-labeled anti-CEA antibody. Taxol (300 μg) was administered IP 48 and 72 h post RIT. The tumor volume for each mouse at the time indicated was normalized to the tumor volume at the start of treatment (average relative tumor volume) and was plotted versus days after the start of treatment.

0.0006). The addition of Taxol to the 40 μCi RIT and 80 μCi RIT further improved the tumor effect ($p = 0.003$ for both). Essentially similar results were obtained for

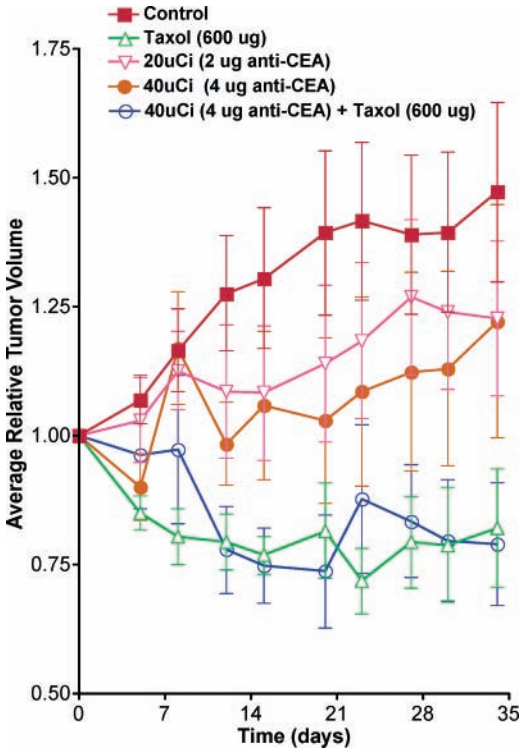

Figure 2. Radioimmunotherapy of established MCF-7 tumors in nude mice with Y-90-labeled anti-CEA antibody in combination with a single dose of Taxol. Groups of eight mice were injected IV with Y-90-labeled anti-CEA antibody. Taxol (600 μg) was administered IP 48 h post RIT. The tumor volume for each mouse at the time indicated was normalized to the tumor volume at the start of treatment (average relative tumor volume) and was plotted versus days after the start of treatment.

Y-90-labeled anti-Her2 RIT at two dose levels with or without Taxol (Figure 1B).

At first inspection, the results surprised us because based on the biodistribution results shown in Table 1 we expected superior results with anti-Her2 RIT vs anti-CEA RIT. Since the tumor cell line and animal model are identical, we tentatively conclude that there is an inherent advantage to anti-CEA RIT over anti-Her2 RIT. We therefore decided to explore this phenomenon more thoroughly by performing other RIT studies with Y-90 anti-CEA, one using RIT plus a single dose of Taxol and another using RIT plus cold Herceptin.

RIT with Y-90-Labeled Anti-CEA and Taxol or Cold Herceptin in MCF-7 Xenografts. Since DeNardo and co-workers (*35*) had shown that a single dose of 600 μg of Taxol IP 24 h after RIT was equivalent to a split dose of 300 μg of Taxol at 48 and 72 h post RIT, we chose the single-dose regimen to repeat the study and chose the 40 μCi dose of RIT with Taxol to determine if the single dose was equivalent to the split-dose regimen. The results shown in Figure 2 demonstrate a more prolonged tumor suppression with the single dose of Taxol compared to the split-dose regimen (compare Figure 1 to Figure 2, taxol only, $p = 0.01$) while the 40 μCi RIT only demonstrated tumor reduction followed by regrowth, similar to the results shown in Figure 1. Single-dose Taxol plus 40 μCi of RIT resulted in prolonged tumor suppression, greater than that observed for either Taxol or RIT alone ($p = 0.00007$ and 0.0003, respectively). In this case, the results were essentially equivalent to the higher-dose RIT combined therapy results shown in Figure 1 ($p = 0.56$). Thus, it is likely either single or split doses of Taxol plus single-dose RIT are promising therapies for CEA-positive breast cancers.

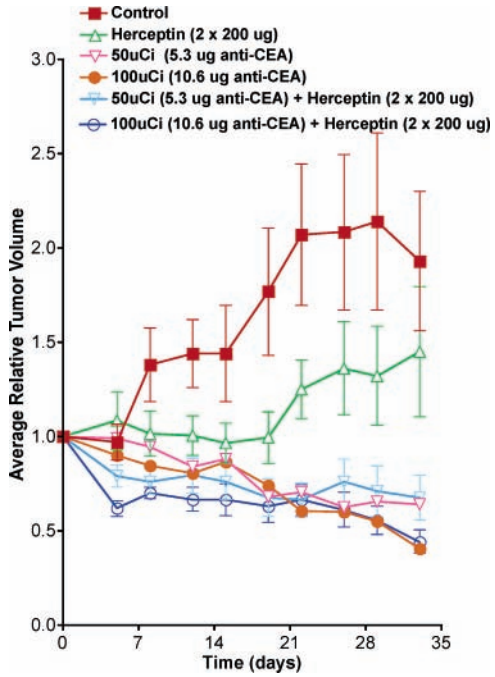

Figure 3. Radioimmunotherapy of established MCF-7 tumors in nude mice with Y-90-labeled anti-CEA antibody in combination with a split dose of cold anti-Her2 antibody. Groups of eight mice were injected IV with Y-90-labeled anti-CEA antibody. Anti-Her2 antibody (200 μg) was administered IP at day 0 and day 9 post RIT. The tumor volume for each mouse at the time indicated was normalized to the tumor volume at the start of treatment (average relative tumor volume) and was plotted versus days after the start of treatment.

It has been previously shown that cold Herceptin has a minimal effect on tumors with a low expression level of Her2 (*36*). Since the expression level of Her2 is low and the gene is not amplified in MCF-7 cells (*29*), we expected that treatment of the animals with cold Herceptin would have no effect on tumor growth. Nonetheless, it is evident that many patients with low levels of Her2 expression are still treated with Herceptin, and we felt it prudent to determine if RIT plus cold Herceptin had an additive tumor effect. Therefore, MCF-7 xenograft-bearing animals were treated with Herceptin alone (200 μg IP at days 0 and 9), RIT alone (50 or 100 μCi), and Herceptin plus RIT (Figure 3). Tumor growths curves for untreated, day 0−33, or Herceptin-treated, day 19−50, animals after initial tumor suppression were essential identical ($p = 0.28$), while either 50 or 100 μCi of RIT with Y-90 anti-CEA produced substantial tumor growth inhibition ($p = 0.000004$ for both) with a good separation between the two doses of RIT. The addition of cold Herceptin had no additive effect on either dose of RIT ($p = 0.57$, $p = 0.14$, respectively).

Effect of Y-90 Anti-Her2 RIT on Anti-CEA and Anti-Her2 Uptake. The above results suggest that either anti-Her2 or anti-CEA RIT would have antitumor effects even in tumors expressing low levels of one or the other antigen. However, we were also interested in the possibility of treating tumors expressing both antigens by sequential RIT first with one then the other Y-90-labeled antibody. The rationale for this approach is that single agent RIT against a tumor antigen may cause selective outgrowth of tumors that downregulate the antigen even further, thus rendering the complete ablation of the tumor unfeasible even with subsequent doses. If the tumor were treated first with one RIT agent and then a second, one would predict that the sequential dual therapy would be more efficacious than repeated administration of the single agent. As a first step in testing this approach, we treated MCF-7 xenograft-bearing animals with Y-90 anti-Her2 (60 μCi) for 7 or 14 days at which point the tumor growth reduction had reached its maximal effect and then administered In-111-labeled anti-Her2 or anti-CEA to determine if either or both antibodies have altered tumor uptake. Because the number of animals required to perform this experiment, we limited the biodistribution data to 72 h after administration of the In-111-labeled antibody in which the maximum tumor uptake is know to occur (see Table 1). We also performed whole animal imaging at various times to verify that tumor uptake of In-111 antibody was uniform over the time course of RIT. The results shown in Table 2 demonstrate that the tumor and blood values are statistically similar for In-111 anti-Her2 with or without Y-90 anti-Her2 RIT ($p = 0.06$); however, for In-111 anti-CEA, there is a substantial increase in tumor uptake after Y-90 anti-Her2 therapy ($p = 0.0005$). The results are even more striking because the In-111 anti-Her2 results serve as a control for the In-111 anti-CEA results.

Whole body images of the mice after 7 days of RIT and 74 h after administration of In-111 anti-CEA revealed about a 2-fold increase in tumor uptake, comparing animals imaged with In-111 anti-Her2 or those receiving

[a] Five animals were analyzed for the indicated tissues at the 72 h time point. Results are reported as %ID/g with the standard deviation given below.

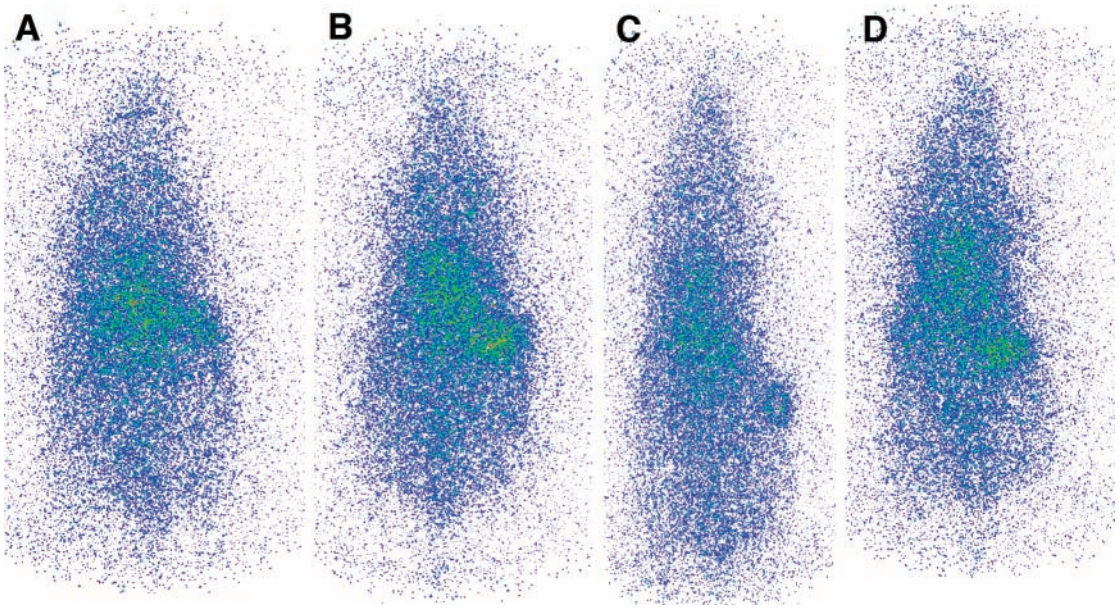

Figure 4. Radioimmunoimaging of established MCF-7 tumors in nude mice with In-111-labeled anti-Her2 or anti-CEA antibody, pretreated with Y-90-labeled anti-Her2 antibody. Groups of eight mice were treated IV with 60 μCi (6 μg) of Y-90-labeled anti-Her2 antibody followed by either 15 μCi (6 μg) of In-111-labeled anti-Her2 or 15 μCi (12 μg) of In-111-labeled anti-CEA antibody 7 days after the start of RIT. Images were acquired 74 h after injection of In-111-labeled antibodies. The central organ is liver and SC tumors are on located on the right side. A and C: In-111-labeled anti-Her2 antibody. B and D: In-111-labeled anti-CEA. A and B: images taken 10 days after start of RIT. C and D: images taken 10 days after injection of saline (no treatment controls).

no therapy (Figure 4). Similar results were obtained for animals treated for 14 days and then imaged with either In-111-labeled antibody. These images agree with the results of the animal biodistributions and demonstrate that prior RIT did not affect the time course of In-111 antibody uptake in tumor or normal tissues.

Split-Dose RIT with Y-90-Labeled Anti-Her2 Followed by Y-90-Labeled Anti-CEA or Anti-Her2 Antibodies. Since In-111-labeled anti-CEA uptake increased after Y-90-labeled anti-Her2 RIT, we proceeded to test the effect of split-dose RIT, first with anti-Her2 and second with anti-Her2 or anti-CEA RIT. The first dose of RIT was administered at 60 μCi as suggested by the optimal anti-CEA uptake seen in Figure 4. The second dose of RIT was reduced to 40 μCi and administered 7 days after the first dose to minimize bone marrow toxicity. As seen in Figure 5, the single dose of Y-90-labeled anti-Her2 RIT resulted in significant tumor reduction compared to controls, but the tumors continued to grow at a reduced rate. In animals that received no first dose of RIT but received the "second" dose of either Y-90-labeled antibody, tumor growth followed the controls until the "second" dose was administered at which point tumor growth was retarded but remained above 1.25 in relative tumor volume units. In animals that received the first dose of RIT followed by the second dose of either Y-90-labeled antibody, tumor volume showed a substantial reduction below 1.00 relative tumor volume units out to 60 days. It also appears that second RIT treatment with Y-90-labeled anti-CEA is more effective than that with Y-90-labeled anti-Her2 antibody. The curves are significantly different when analyzed by ANOVA ($p < 0.05$) but not significantly different when analyzed by the t-test ($p = 0.05$). Thus, we conclude that a split dose of RIT with either antibody is effective and that the increased uptake of In-111-labeled anti-CEA observed in Figure 4 (Table 2) may predict a more effective split-dose RIT for anti-Her2/anti-CEA vs anti-Her2/anti-Her2. To confirm this prediction additional experiments would be necessary with different doses of RIT for each antibody. We believe that experiments of this nature are beyond the useful limits of this animal model.

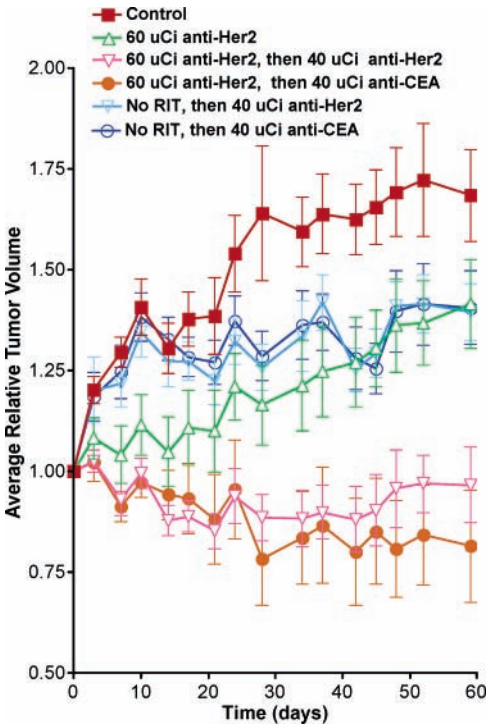

Figure 5. Radioimmunotherapy of established MCF-7 tumors in nude mice with Y-90-labeled anti-Her2 antibody followed by either Y-90-labeled anti-Her2 or anti-CEA antibody. Groups of 10 mice were injected IV with 60 μCi (8 μg) of Y-90-labeled anti-Her2 antibody followed by either 40 μCi (5.6 μg) of Y-90-labeled anti-Her2 or 40 μCi (6 μg) of Y-90-labeled anti-CEA 14 days later. The tumor volume for each mouse at the time indicated was normalized to the tumor volume at the start of treatment (average relative tumor volume) and was plotted versus days after the start of treatment.

DISCUSSION

Since it is unlikely that single agent therapies will be effective against metastatic breast cancer, new approaches to combined therapies need to be explored. In this regard, the combination of RIT and chemotherapy is relatively untried, and as previously mentioned, may allow the treatment of a greater number of patients than is possible for cold antibody/chemotherapy combinations. Our initial hypothesis that RIT would be more effective than cold antibody even against a tumor with relatively low to moderate amounts of target antigen was verified in the case of Her2 expression on MCF-7 cells. Surprisingly, in the case of CEA expression, which is also low on MCF-7 cells and led to disappointing tumor targeting as judged by a tumor-to-blood ratio of 1.0, RIT was equally effective for anti-CEA as for anti-HER2. Furthermore, we were able to reduce the amount of RIT required to produce an effective reduction in tumor size by the addition of Taxol as a chemotherapeutic agent. In our study, we were guided by the previous work of DeNardo and co-workers [35] who showed that the optimal combination of Taxol with RIT was either a single IP dose 24 h post RIT or a split IP dose at 48 and 72 h post RIT. Since in their study administration of Taxol prior to RIT was equivalent to single agent therapy, we tested only the single or split-dose regimen. Likewise, since the blood levels of Taxol were previously studied by DeNardo and co-workers (*35*) and shown to be within the effective range for 3−4 days, we did not measure blood levels. Our results closely mimic those obtained by DeNardo and co-workers (*35*) who performed their studies in a different tumor model (HBT 3477) with a different Y-90-labeled antibody (ChL6). Thus, it appears that the increased efficacy of RIT plus Taxol can be generalized, especially in the case of breast tumors. In our study, we had roughly equivalent results between the single or split-dose Taxol plus RIT regimens, suggesting that the largest antitumor effect occurred within the first few days of treatment, with tumor reductions of greater than 50% lasting up to 35 days. Since tumor growth was not monitored beyond 35 days, it is possible that some of the tumors would eventually regrow, requiring a second round of treatment. However, in one of the groups (80 μCi 90Y-cT84.66 ± Taxol), no detectable tumors were seen in 6/15 animals out to 35 days.

Although it is generally recognized that only tumors that overexpress Her2 respond to cold Herceptin therapy, we felt compelled to determine if cold Herceptin therapy plus RIT was effective in this animal model. In this study, a split IP dose of cold Herceptin (200 μg) was administered at day 0 and day 9 after RIT. This regimen was adopted from our previous study in which we administered either 50 or 200 μg of cold 4D5, the parent monoclonal antibody for Herceptin, to nude mice bearing MCF-7/Her2 xenografts [11]. In that study, there was a 50% reduction in tumor growth at the end of 28 days. However, in our current study no long-term antitumor effect was observed for cold Herceptin only, as expected for a low Her2 expressing tumor (compared to the Her2 transfected MCF-7 cells used in the previous study). Furthermore, cold Herceptin therapy did not increase the antitumor effect of RIT, demonstrating the complete lack of an antitumor effect for Herceptin even in the presence of other cytotoxic agents. The findings of this study as a control for the next study (Herceptin RIT followed by antibody uptake at later times) are relevant in that even high-dose Herceptin has no antitumor tumor effect on MCF-7 xenografts. Thus, the antitumor effect is due to RIT alone.

When animals bearing MCF-7 xenografts were treated with Y-90 anti-Her2 and followed by In-111 anti-Her2 or anti-CEA 7−14 days later, a substantial increase in anti-CEA but not anti-Her2 uptake was observed compared to untreated controls. These results suggest that sequential treatment of tumors positive for both Her2 and CEA is feasible and may have an advantage over repeated RIT with the same agent. The mechanism for the increase in anti-CEA uptake was not studied. Possibilities include that anti-Her2 RIT induced expression of CEA or that prior therapy made CEA produced by the tumor more accessible. In consideration, of the latter possibility, antibody uptake is limited by tumor perfusion, which is known to be inhibited by high local intratumoral pressure (*37*−*39*). It is likely that some of this barrier is disrupted by tumor and vascular necrosis caused by RIT. Furthermore, in the untreated tumors (no RIT), tumor size has increased by 20% (Table 2), while tumor size has been reduced by 15% in the RIT-treated animals. Since uptake is measured as %ID/g, and we have observed that smaller tumors have an apparent advantage in uptake over larger tumors (*23*, *40*), the increase in uptake is not surprising. However, the same effect is not observed for anti-Her2 uptake. Again, the mechanism was not studied. Thus, in this case the above arguments are unlikely to apply. In fact, one possibility is that antigen expression actually decreased in treated animals and was offset by the expected increase in uptake for a smaller tumor size. While further studies are warranted to unravel the underlying mechanisms, we conclude that sequential RIT therapy using different antibodies, especially combined with Taxoids such as paclitaxel and docetaxel are worth exploring.

Synthesis and Biological Evaluation of Diethylenetriamine Pentaacetic acid−Polyethylene Glycol−Folate: A New Folate-Derived, ^{99m}Tc-Based Radiopharmaceutical

Min Liu,[†] Wen Xu,[†] Ling-jie Xu,[†] Gao-ren Zhong,[†] Shao-liang Chen,[‡] and Wei-yue Lu*[,†]

Fudan-Pharmco Targeting Drug Research Center, Department of Pharmaceutics, School of Pharmacy, University of Fudan, Shanghai, 200032, China, and Department of Nuclear Medicine, Zhongshan Hospital, Shanghai, China. Received April 21, 2005; Revised Manuscript Received August 2, 2005

^{99m}Technetium-labeled diethylenetriamine pentaacetic acid−polyethylene glycol−folate (DTPA−PEG−folate) was synthesized and tested as a radiopharmaceutical agent, which targeted the lymphatic system with metastatic tumor. Folic acid was reacted with $H_2N-PEG-NH_2$ to yield $H_2N-PEG-$folate. After purification by anion-exchange chromatography, the product was reacted with cyclic DTPA. By removal of unreacted DTPA by size-exclusion chromatography, DTPA−PEG−Folate was obtained. Fluorescein-5-isothiocyanate (FITC)-labeled DTPA−PEG−folate and DTPA−PEG−OCH_3 were prepared via a dicyclohexylcarbodiimide-mediated coupling. In vitro competitive binding test showed that the uptake of [^{125}I] folic acid was inhibited by DTPA−PEG−folate and the 50% inhibitory concentration was 4.37 pmol/L ($R^2 = 0.9922$). The relative affinity of DTPA−PEG−FITC was 0.18 for human folate receptor comparing with folic acid. In cultured tumor cells, uptake of fluorescence-labeled DTPA−PEG−folate was found to increase significantly in folate-deficient medium compared with that of untargeted DTPA−PEG−OCH_3 and FITC−ethylenediamine. The competition with free folic acid blocked the cell uptake of DTPA−PEG−folate. These results confirmed the DTPA−PEG−folate entered into KB cells through the folate receptor endocytosis pathway in vitro. The radiolabeled yield of [^{99m}Tc] DTPA−PEG−folate was in excess of 98%, and specific activities of 7.4 kBq (0.2μCi/μg) were achieved. After subcutaneous injection, [^{99m}Tc] DTPA−PEG−folate exhibited an initial increase and successive decline of accumulation in popliteal nodes in normal Wistar rats. Expect for the kidney, uptake by other tissues was rather low. In a normal rabbit imagine study, the lymphatic vessels were readily visualized by single-photon-emmission computed tomography following subcutaneous injection of [^{99m}Tc] DTPA−PEG−folate. In conclusion, the [^{99m}Tc] DTPA−PEG−folate conjugate may have a potential as a lymphatic tumor-targeted radiopharmaceutical.

INTRODUCTION

The lymphatic system comprises a network of lymphatic vessels and lymph nodes throughout the body. It often serves as a primary route for dissemination of many solid tumors, including carcinomas of colon, lung, breast, renal, cervix, and prostate (*1*−*4*). Furthermore, lymph nodes could provide ideal tumor-cell "incubators" with long residence time. Assessment of lymph node status could determine the stage of numerous malignancies. Therefore, it would be great interest to develop reliable techniques for evaluating the lymph nodes stage in cancer patients.

The direct lymphography (such as lymphoangiogram) and other modern indirect techniques (such as compounded tomography and magnetic resonance) are commonly used for detecting nodal metastases. However, these methods could only detect the lymph node's abnormality by nodal enlargement, but that does not always imply malignant involvement at the initial stage (many nodes have been infiltrated or replaced by tumor without change in size) (*5*). Since Sherman first reported lymph node accumulation of interstitially injected radioactive colloidal gold in 1953, many studies have exploited radiolabeled colloidal particles (liposomes, emulsions, or micelles) and macromolecules (dextran, polylysine, human serum albumin, monoclonal antibody and their fragments, polyethylene glycol, and other synthetic polymers) for better detection of lymph nodes (*5*−*14*). Among these radiological agents, only monoclonal antibodies could actively bind and target to tumor cells in the lymph nodes and detect occult metastases of tumor (*10*, *11*). On the contrary, labeling with monoclonal antibodies has been rather disappointed because of its concomitant clearance by lymph node macrophages as well as the lack of a uniform expression of surface antigen specific for a designed monoclonal antibody.

Folate receptor is a glycosyl-phosphatidylinositol-linked membrane glycoprotein with an apparent molecular weight of ~38−40 kDa. It preferentially expresses with enhanced binding affinity for folic acid in many types of tumors, including ovarian, lung, colorectal, renal, breast cell cancers, and non-Hodgkin's lymphomas (*15*). Radioactive tracers and drug carriers utilizing folate conjugates for tumor targeting have been studied (*15*−*21*). Additionally, folate receptor was associated with parameters of biological aggressiveness in cancers. With high histological grade, advanced stage, and serious histology in ovarian neoplasmas, folate receptor was overexpressed to a higher degree. A multiple comparison

analysis showed that folate receptor expression of stage IV and omental metastases was significantly higher that that in stage I (*22*). Moreover, it had been reported that folate–fluorescein could be easily distinguished the tumor loci of submillimeter size, which spread through the vascular system, from adjacent normal tissues (*23*). Thus, folic acid owned a potential value as a targeting ligand for metastatic tumor through lymphatic system. To our knowledge, few were reported in the literatures concerning folate conjugates for lymphatic targeting.

As a first step toward the design of a radiological agent for imaging the tumor metastatic lymph node, we adopted a macromolecular receptor-binding radiotracer, [^{99m}Tc] diethylenetriamine pentaacetic acid–polyethylene glycol–folate (DTPA–PEG–folate). The only study where PEG was adopted for targeting lymphatic system after subcutaneous injection was reported by Desser et al. (*9*). In their work, PEG conjugate provided excellent popliteal nodal enhancement. However, further study on delivering H_2N–PEG–folate conjugates to tumor metastatic lymph nodes via receptor-mediated pathways has not yet been reported. In this paper, we described the synthesis of DTPA–PEG–folate conjugates, which displayed good targeting activities for tumor cells via the folate receptor in vitro, as well as lymphatic system in the normal animal.

EXPERIMENTAL PROCEDURES

Materials. H_2N–PEG–NH_2 (MW 2000) and H_2N–PEG–OCH_3 (MW 2000) were prepared as described previously (*24*). Cyclic DTPA dianhydride, folic acid, *N*,*N*′-dicyclohexylcarbodiimide, and ethylenediamine (EDA) were purchased from Sigma (St. Louise, Mo, USA). Fluorescein-5-isothiocyanate (FITC) was obtained from Molecular Probes, Co. (Eugene, Oregon, USA). [^{125}I] folic acid came from Naval radioimmunity center (Beijing, China, the radioactivity was 7.69 TBq/mmol). Other chemicals reagents used in the study were certified analytical reagent grade (Shanghai Chemical Reagent Company, Shanghai, China). Solvents for high-performance liqui chromatography (HPLC) were HPLC grade accordingly. KB cell, a human oral epidermoid carcinoma cell line that overexpresses folate receptor, was provided by Shanghai Institutes for Biological Sciences (Chinese Academic of Sciences).

Synthesis of H_2N–PEG–Folate. Two grams (1 mmol) of H_2N–PEG–NH_2 was dissolved in 15 mL of dry dimethyl sulfoxide containing an equimolar folic acid. Dicyclohexylcarbodiimide (0.2 g) and 40μL of pyridine were added. The mixture was stirred overnight in the dark at 25 °C. Deionized water (30 mL) was added, ss and the insoluble byproduct, dicyclohexylurea, was removed by centrifugation. The supernate was dialyzed against deionized water to remove dimethyl sulfoxide in the reaction mixture and lyophilized. A yellow powder (0.35 g) was obtained. The H_2N–PEG–folate was separated from folate–PEG–folate and unreacted folic acid and H_2N–PEG–NH_2 by using a DEAE–sepharose anion-exchange column (26 mm × 10 cm, Biosciences, Uppsala, Sweden) on a ÄKTA explorer 100 system (Amersham Biosciences, Uppsala, Sweden) consisting of Pump P-900, Pump P-950, Monitor UV-900, and Frac-900 at room temperature. The column was loaded with 10 mg of H_2N–PEG–folate crude sample per mL bed volume. The column was then washed with a gradient (eluent A, 100 mM ammonium acetate buffer, pH 10.0; eluent B, water; gradient, 90% B for 3 column volumes, 90–75% B at 3 column volumes, keeping 75% B and 50% B at 1 column volume, respectively, in the end washing the column with 0.5 M NaCl, at a flow rate of 5 mL/min). The result was seen in Figure 1. Fractions were collected, desalted, and lyophilized.

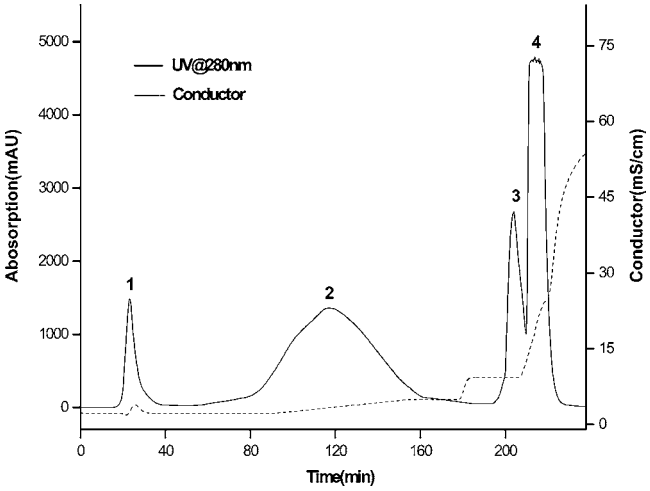

Figure 1. Purified H_2N–PEG–folate on a DEAE–Sepharose anion-exchange column by gradient elution. Peak 1, uncharged impurities including H_2N–PEG–NH_2 and some small molecules; peak 2, H_2N–PEG–folate; peak 3, folate–PEG–folate; peak 4, folic acid.

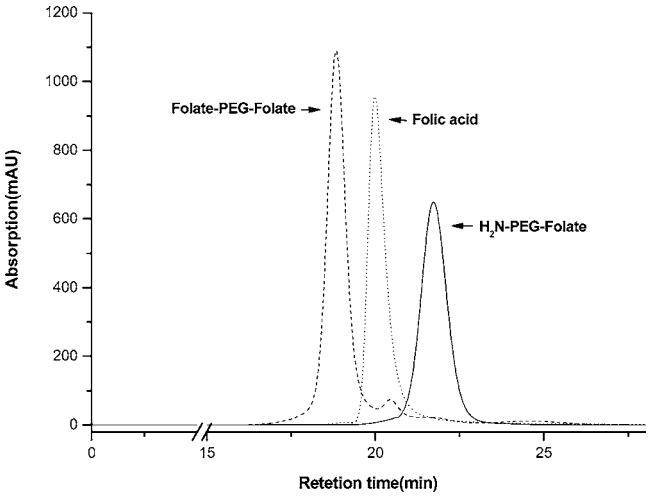

Figure 2. Analysis for H_2N–PEG–folate and impurities on a TSK GEL G4000PW$_{XL}$ column 4.6 mm × 30 cm. Elution, 5 mM NaCl; flow rate, 0.5 mL/min; temperature, 25 °C; detection, UV@280 nm).

Analytical chromatography was performed on an Agilent 1100 series quaternary HPLC system (Palo Alto, California, USA) equipped with a vacuum degasser, an autosampler, a thermostetted column, and a UV and refractive index detector. The chemical purity of H_2N–PEG–folate was examined by analytical HPLC on a 300 × 7.8 mm inside diameter TSK-GEL G4000PW$_{XL}$ (10 μm particle size, 300 Å pore size, Tosoh Corporation, Minato-ku, Tokyo, Japan) with a TSK-GUARDCOLUMN at 25 °C [H_2N–PEG–folate, t_R = 21.76 min; folic acid, t_R = 19.97 min; folate–PEG–folate, t_R = 18.89 min; H_2N–PEG–NH_2, t_R = 31.84 min; eluent, 5 mM NaCl]. The results were shown in Figure 2. ^{1}H NMR (500 MHz, D_2O) δ (ppm) for H_2N–PEG–folate: 8.67 (s, C7–H, 1H), 7.66 (d, 2′,6′-H, 2H), 6.63 (d, 3′,5′-H, 2H), 4.34 (minor and major αCH_2 of Glu, 1H), and ~2.0–2.4 (m, β, γ-CH_2 of GLu, 4H) for folate; ~3.1–4.0 (m, $-OCH_2CH_2$) for PEG.

Synthesis of DTPA–PEG–Folate. DTPA–PEG–folate was obtained by reacting 200 mg H_2N–PEG–folate

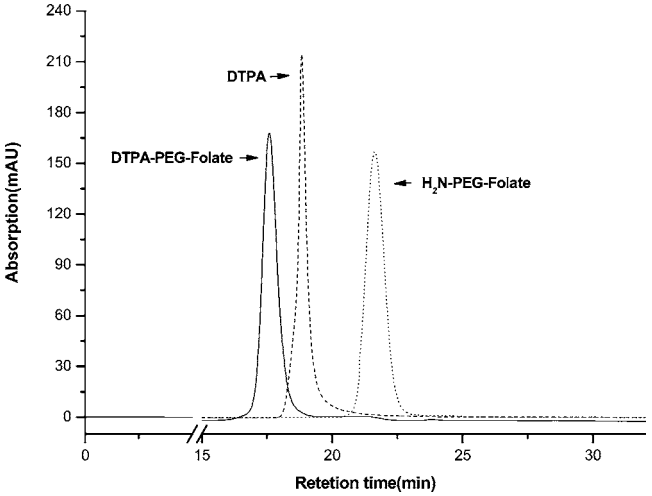

Figure 3. Analysis for DTPA−PEG−folate and impurities on a TSK GEL G4000PW_{XL} column 4.6 mm × 30 cm. Elution, 5 mM NaCl; flow rate, 0.5 mL/min; temperature, 25 °C; detection, UV@280 nm for both DTPA−PEG−folate and H_2N−PEG−folate, UV@200 nm for DTPA).

with 1.25 times molar quantity of DTPA dianhydride in 10 mL of dimethyl sulfoxide at 25 °C. When analytical HPLC showed the absence of the H_2N−PEG−folate, 10 mL of deionized water was added to the mixture. The mixture was dialyzed against deionized water to remove dimethyl sulfoxide in the reaction solution and lyophilized. The DTPA−PEG−folate was separated using the ÄKTA explorer 100 system equipped with a Sephadex G-15 column to remove unreacted DTPA. The eluent was 50 mM acetate buffer (pH 3.2) containing 50% alcohol with 1 mL/min flow rate. The sample was collected, desalted, and lyophilized. Analytical HPLC on the TSK GEL G4000PWXL column revealed a single peak with a retention time of 17.59 min (eluent, 5 mM NaCl). The starting material DTPA and H_2N−PEG−folate was individually eluted at 18.84 min and 21.76 min. Figure 3 revealed the results. ^{1}H NMR (500 MHz, D_2O) δ (ppm) for DTPA−PEG−folate: 3.29 (t, C5, C7−2H) and 3.42 (t, C4, C8−2H) for DTPA; 8.67 (s, C7−H, 1H), 7.66 (d, 2′,6′-H, 2H), 6.63 (d, 3′,5′-H, 2H), 4.34 (minor and major αCH_2 of Glu, 1H), and ∼2.0−2.4 (m, β,γ-CH_2 of GLu, 4H) for folate; ∼3.6−3.8 (bs, $-OCH_2CH_2$) for PEG.

Similarly, we used the above method to obtain the conjugate of DTPA−PEG−OCH_3. ^{1}H NMR (500 MHz, D_2O) δ (ppm): 3.29 (t, C5, C7−2H) and 3.42 (t, C4, C8−2H) for DTPA; ∼3.6−3.8 (bs, $-OCH_2CH_2$) for PEG.

Synthesis and Purification of the FITC−EDA. FITC (62 mg, 0.16 mmol) dispersed in 0.2 mL of *N*,*N*′-dimethylformamide was reacted with 50 molar equiv of EDA at 25 °C for 30 min. The resulting EDA−FITC was mixed with the same volume of deionized water and separated from unreacted FITC and EDA by HPLC on SymmetryPrep C-18 reversed column (300 mm × 19 mm, Waters Co.) using a stepped gradient (eluent A, 10 mM CH_3COONH_4; eluent B, 15% acetonitrile in 10 mM CH_3COONH_4; gradient, 2 column volume for eluent A, and then 2 column volume for eluent B at a flow rate 10 mL/min). The eluent time for EDA, EDA−FITC, and FITC were 8.2, 30, and 39 min, respectively.

Analytical chromatography was performed on an SHIMADZA HPLC equipped with a liquid chromatography, a vacuum degasser, an autosampler, and a fluorescence detector (Japan). The chemical purity and identity of EDA−FITC was examined by analytical HPLC on a Diamonsil C-18 reversed-phase column (200 mm × 4.6 mm, Dikma Technologies) [EDA−FITC, T_R = 8.5 min; FITC, T_R = 13.2 min; the eluent, 15% acetonitrile in 10 mM CH_3COONH_4 at a flow rate of 0.8 mL/min; Fluorescence detection, E_x = 490 nm, E_m = 518 nm]. High-resolution mass spectroscopy (MS) (Agilent, California, USA): EDA−FITC, $C_{23}H_{19}O_5N_3S$ $[M + H]^+$ 450.5, found 450.0.

Fluorescent Labeling of PEG Derivatives. DTPA−PEG−folate (5.6 mg, 2 mmol) and dicyclohexylcarbodiimide (1.5 mg, 7.3 mmol) were dissolved in 0.25 mL of dimethyl sulfoxide containing 10 μL of pyridine. The reaction mixture was stirred for 1 h before FITC−EDA (0.9 mg, 2 mmol) was added. The free FITC−EDA was monitored of by analytical HPLC on a TSK GEL G4000PWXL column (300 mm × 7.8 mm,) [FITC-labeled DTPA−PEG−folate, T_R = 26.1 min; FITC−EDA, T_R = 35.9 min; the eluent, 20% acetonitrile in 100 mM NaCl at a flow rate of 0.5 mL/min; fluorescence detection, E_x = 490 nm, E_m = 518 nm]. As soon as the free FITC−EDA disappeared, the same amount of deionized water was added to the reaction mixture and the unsolved material was filtered. Other small molecules were removed by G-15 sephadex column. The chemical purity assay of FITC-labeled DTPA−PEG−folate was conducted as described above.

As a nontargeted agent, FITC-labeled DTPA−PEG−OCH_3 was prepared similarly.

In Vitro Competitive Binding Assay. All biological experiments were carried out with KB cell line, enriched with folate receptors. The competitive binding-assay was conducted as described previously (*18*, *25*, *26*) with slight modification. Briefly, 24 h prior to experiment, KB cell were cultured in folate-deficient RPMI medium (RPMI-1640, Gibcol Co., USA) supplemented with 10%v/v heat-inactivated fetal calf serum (Gibcol Co., USA), and temperature was maintained at 37 °C in an atmosphere containing 5% carbon dioxide/95% air humidified atmosphere. A total of 5 × 10^5 KB cells in 0.5 mL of serum-supplemented folate-deficient RPMI medium was added to the plastic test tube containing 0.1 mL [^{125}I] folic acid. Nonradiolabeled folic acid, DTPA−PEG−OCH_3, and DTPA−PEG−folate with different concentrations were added to the cell suspension, respectively. After incubation for 1 h at 4 °C, the KB cells were centrifuged to remove the unbinding [^{125}I] folic acid and washed 3 times with phosphated-buffered saline and placed in a γ counter (SN-682 Radioimmunity γ-Counter, Shanghai Institutes for Nuclear Sciences, China) to determine the amount of cell-associated [^{125}I] folic acid. The total binding and nonspecific binding were determined at the same time. All data were recounted depending on [^{125}I] decay, and the result was shown in Figure 4.

Fluorescent Microscopy Studies. KB cells were transferred to 33-mm culture dishes at 2 × 10^5 cells per dish 24 h prior to the assay adopting folate-deficient RPMI-1640 medium supplemented with 10%v/v heat-inactivated fetal calf serum. The cells were incubated for 24 h at 37 °C with 0.5 μM solution of FITC-labeled DTPA−PEG−folate, DTPA−PEG−OCH_3, and FITC−EDA diluted in folate-deficient culture medium, respectively. In free folate competition studies, 1 mM folic acid was added to incubation medium. After washing three times with PBS, the cell-associated fluorescence was determined by FITC fluorescence on an Olympus Image-Pro Plus fluorescence microscope (Japan).

Radiolabeling of DTPA−PEG−Folate. To label DTPA−PEG−folate with ^{99m}Tc as described previously (*13*, *18*), first a solution of DTPA−PEG−folate (10 mg/mL) in 10 mmol/L phosphate buffer (pH 7.2, 0.9%NaCl)

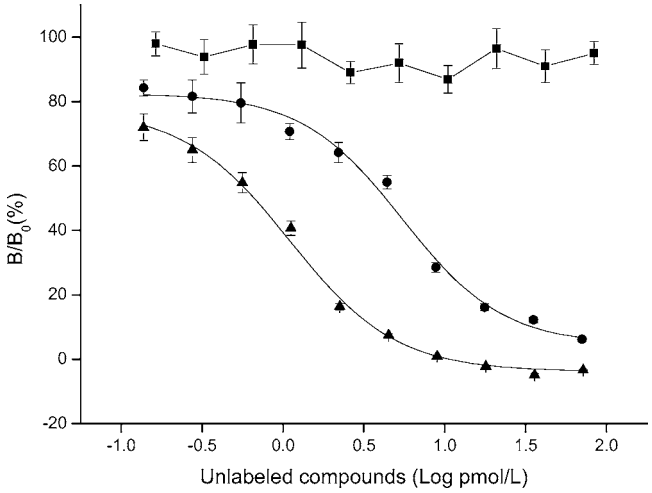

Figure 4. Competition study of binding to cellular folate receptor with free folic acid (--▲--), DTPA−PEG−OCH_3 (--■--), and DTPA−PEG−folate (--●--). Radiolabeled folic acid was added to KB cell monolayers, which were incubated at 4 °C for 1 h with or without the competitions at the concentrations shown ($n = 3$).

was mixed with 0.02 mL solution of tin chloride (10 mg $SnCl_2-2H_2O$ in 1 mL of 1 mol/L HCl followed by 8.8 mL of distilled water). Second, the mixture was incubated with freshly eluted 0.1 mL (approximately 74 MBq) of sodium pertechnetate ($NaTcO_4$). The reaction was allowed to stand for 15 min at room temperature. The purity of radiolabeled compound was analyzed by paper chromatography (*27*−*29*) and by electrophoresis (*30*). The paper chromatography was used for distinguishing [^{99m}Tc] DTPA−PEG−folate from unbounded $Na^{99m}TcO_4$, and the electrophoresis was performed for determining the [^{99m}Tc] colloid.

Biodistribution and Imaging of [^{99m}Tc]DTPA−PEG−Folate. The biodistribution of Wistar rats was obtained following subcutaneous injection of [^{99m}Tc] DTPA−PEG−folate. During the test, Wistar rats (three weeks old) were fed on normal folate-rich diet. [^{99m}Tc] DTPA−PEG−folate (0.1 mL, 10 mg/ml) was injected into foodpad of Wistar rats. Three rats were studied at each time point. At different times after injection, the animals were euthanized and popliteal lymph nodes and other tissues were excised and assayed for radioactivity. The biodistribution of the tracer in each animal was calculated as a percentage of injected dose per gram of tissue wet weight (%ID/g), using reference counts from an accurately diluted sample of the original injection.

In addition, [^{99m}Tc] DTPA−PEG−folate (0.1 mL, 10 mg/mL) was injected into the web space between the second and third in both hind feed of the rabbits. Then the continuous imaging was performed in whole body and the radioactivity change of [^{99m}Tc] DTPA−PEG−folate was measured by single-photon-emmission computed tomography (SPECT) at 5, 15, and 120 min, respectively. The experiment results were given in Figure 7.

RESULTS

Synthesis. The general strategy of the synthesis is shown in Figure 8. $H_2N-PEG-$folate was synthesized as previously described (*14*). The conjugation of folic acid to the unprotected primary amine of PEG was a complicated process. Because of no selectivity of two end functional groups of $H_2N-PEG-NH_2$, the byproduct folate−PEG−folate was synthesized as soon as the yield ratio of $H_2N-PEG-$folate was over 25% (determined by HPLC). Additionally, unreacted folic acid and $H_2N-PEG-NH_2$ interfered with the purity of $H_2N-PEG-$folate. Because of the ionic difference of these molecules, we decided to adopt ion-exchange chromatography for separation. Figure 1 showed the optimized gradient purification of crude $H_2N-PEG-$folate performed on a DEAE−Sepharose anion-exchange column. As expected, the uncharged $H_2N-PEG-NH_2$ was eluted first, followed by $H_2N-PEG-$folate, folate−PEG−folate, and folic acid successively. The purity was confirmed by analytical HPLC (Figure 2). The liquid exclusion−adsorption chromatography (LEAC), which we reported previously (*17*), was an important method for a qualifying HPLC analysis of PEG derivatives. On the basis of LEAC, $H_2N-PEG-$folate could be efficiently identified from other impurities. Since $H_2N-PEG-NH_2$ could not be detected by UV spectroscope, we had adopted refractive index detection (data not shown).

The DTPA−PEG−folate conjugate was obtained by reaction of DTPA dianhydride with the purified H_2N-

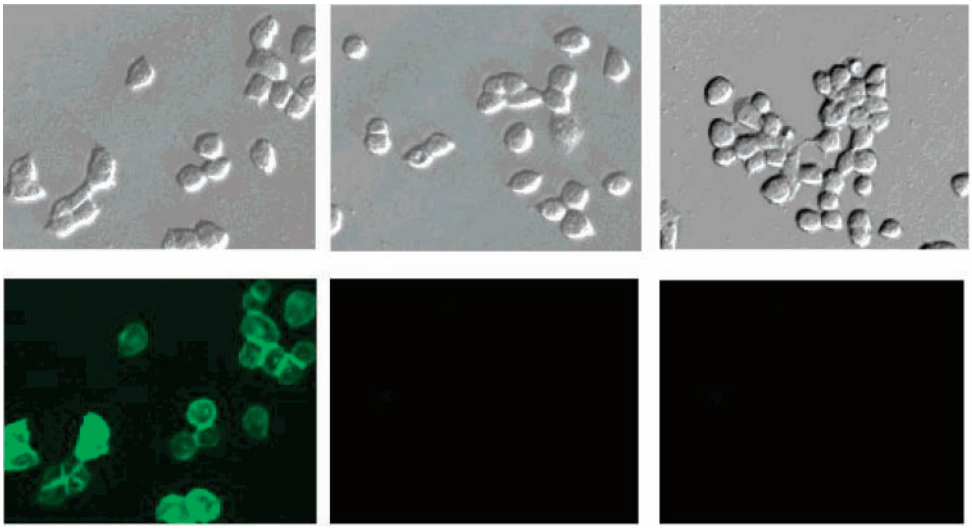

Figure 5. Cellular accumulation of fluorescein-labeled PEG conjugates in KB cells. Cells were incubated with 0.5 μM substrates for 24 h at 37 °C and photographed in both the phase-contrast and fluorescence mode on microscope as described in methods. Left, KB cells treated with FITC-labeled DTPA−PEG−folate; middle, cells treated with DTPA−PEG−OCH_3; right, cells treated with FITC-labeled DTPA−PEG−folate containing 1 mM of free folic acid. Upper panels, micrographs taken in the phase-contrast mode; lower panels, the same field viewed in the fluorescence mode.

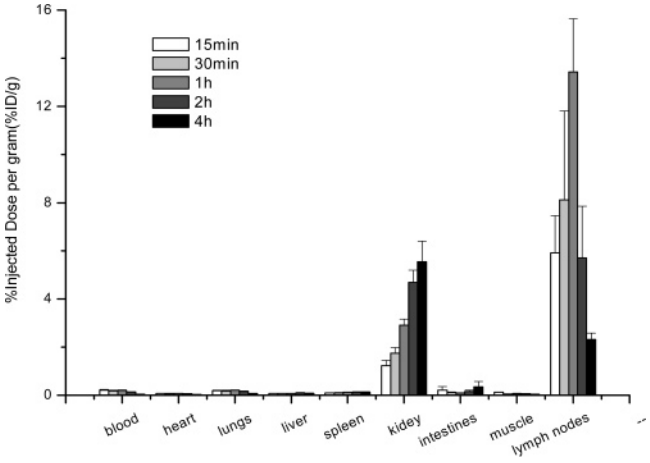

Figure 6. Percent injected dose vs time of lymphotrophic imaging agent [^{99m}Tc] DTPA−PEG−Folate using the Wistar rats. Data were acquired following subcutaneous administration of the radiotracers ($n = 3$; DTPA−PEG−folate dose = 1 mg per rat).

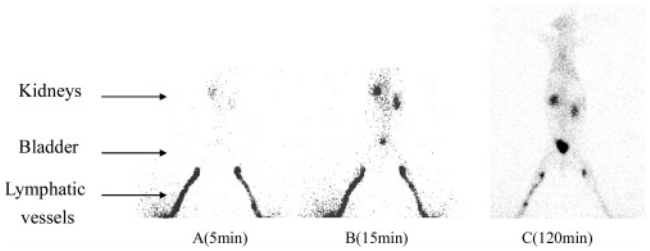

Figure 7. SPECT imagines of rabbits injected subcutaneously in the hind feet with [^{99m}Tc] DTPA−PEG−folate. ($n = 2$; DTPA−PEG−folate dose = 1 mg/per rabbit).

PEG−folate. Because of higher reactive activity of cyclic DTPA, the synthesis was completed within 10 min. To control the process more easily, the amount of DTPA was a little more than that of H_2N−PEG−folate. The major side product DTPA−bis-PEG−folate did not emerge when the H_2N−PEG−folate had run out. Therefore, the excess of unreacted DTPA became the only impurity in the reaction mixture and was easily removed by size-exclusion chromatography. Figure 3 showed the purity of DTPA−PEG−folate.

EDA was conjugated to FITC to serve as a linker between the fluorescein and DTPA−PEG−Folate. The mass spectroscope analysis showed the FITC-EDA $[M + H]^+$ parent ion peak at $m/e = 450.5$ (calculated 450.0), indicating the desired 1/1conjugation ratio. The chemical purity was confirmed by analytical HPLC. FITC-labeled PEG conjugates were synthesized in order to evaluate, by fluorescence-sensitive techniques, whether the conjugated folate altered the PEG compounds accumulation in KB cells. FITC-labeled DTPA−PEG−folate and DTPA−PEG−OCH_3 were prepared via a dicyclohexylcarbodiimide-mediated coupling. The chemical purity was also confirmed by analytical HPLC. In fact, the FITC labeling in the DTPA−PEG compounds was randomly placed. It is possible that the FITC−EDA moiety reacted with not the carboxylates of DTPA but also the lone remaining carboxylate group of folic acid.

Competition Binding Study in Vitro. To determine whether DTPA−PEG−folate could compete as the folate receptor against [^{125}I] folic acid, the in vitro binding tests on KB cell line were carried out. As shown in Figure 4, with the increasing concentration of the unlabeled folic acid and DTPA−PEG−folate, the uptake of [^{125}I] folic acid by KB cell gradually decreased. As a control group,

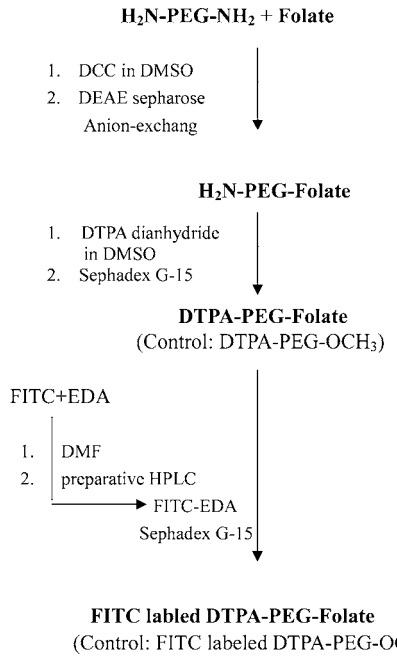

Figure 8. Synthesis of DTPA−PEG−folate and FITC-labeled PEG conjugates.

unlabeled DTPA−PEG−OCH_3 had no effect on the uptake of [^{125}I] folic acid. Therefore, DTPA−PEG−folate, as well as folic acid, could combine with folate-receptor enriched on KB cell membrane. The data were analyzed adopting Graphpad Prim 4.0 software. Compared with free folic acid, DTPA−PEG−folate had higher IC_{50} values (folic acid, $IC_{50} = 0.7726$ pmon/L; DTPA−PEG−folate, $IC_{50} = 4.37$ pmol/L ($R^2 = 0.9922$).

The relative affinity was adopted to evaluate a ligand's ability of folate derivatives to directly compete with folic acid for binding to cell surface receptors. Simply, the relative affinity was defined as the inverse molar ratio of compound required to displace 50% of [^{125}I] folic acid bound to folate receptor on KB cells, and the relative affinity of folic acid for the folate receptor was set to 1. Therefore, we calculated that DTPA−PEG−folate had an affinity of 0.18 relative to that of folic acid for human folate receptors. Thus, DTPA−PEG modification of folate lowered the vitamin's intrinsic affinity for folate receptors. The possible reason may be the interference by PEG lineal molecule.

Cell Uptake Studies of Fluorescence-Labeled PEG Derivatives. All biological experiments were carried out with the KB cell line, enriched with folate receptors. The cell uptake of FITC-labeled compounds was evaluated by the fluorescent microscopy. The results clearly indicated that the uptake of DTPA−PEG−folate increased significantly in folate-deficient medium compared with the uptake of untargeted DTPA−PEG−OCH_3 and FITC−EDA. The competition with free folic acid blocked the cell uptake of DTPA−PEG−folate (shown in Figure 5). These results confirmed the DTPA−PEG−folate entered into KB cells through the folate receptor endocytosis pathway.

Radiolabeling. The paper chromatography demonstrated an absence of unbounded $Na^{99m}TcO_4$ that would be detected by the radioactivity profile at the front (data not shown). [^{99m}Tc] Colloid was detected in the product by electrophoresis, which would be existed by radioactivity profile at the end (data not shown). The radiolabeled yield was in excess of 98%. The specific activity was 7.4 kBq (0.2μCi/μg).

Biodistribution. Figure 6 showed the %ID/g for the popliteal nodes and other tissues at 15 min, 30 min, 1 h, 2 h, and 4 h postadministration of [^{99m}Tc] DTPA−PEG−folate. In this test, a fast accumulation and clearance was obtained throughout popliteal nodes. The amount of radioactivity in the lymph nodes was 5.913 ± 1.549 %ID/g at 15 min postinjection, increased to the maximum (13.432 ± 2.207 %ID/g) at 1 h postinjection and then decreased to 2.314 ± 0.278 %ID/g at 4 h. In addition, this radiotracer kept a high accumulation in the kidney during the whole test.

Figure 7 showed continuous images obtained 2 h after subcutaneous injection of [^{99m}Tc] DTPA−PEG−folate at web space between second and third toes in both hind feet of rabbits. The lymphatic vessels were prominent as early as 5 min after injection. The lymph images continued to develop at 15 min as well as the early development of a body pool. Kidneys and bladders began to be prominent at this time. At the end of 2 h, node images faded.

DISCUSSION

The lymphatic route is known to be one of the primary pathways for tumor metastasis. Tumor cells that have detached from the tissue or have invaded a lymphatic vessel became trapped in the meshwork of a lymph node. Some metastatic cancers appear to spread via lymphatics, particularly those of epithelial origin including breast, colon, lung, ovary, and prostate (*1*−*4*). The previous studies have shown that the folate receptor is overexpressed in many types of tumors derived from epithelial cancers (*15*). Furthermore, high dedifferentiated metastatic cancers express considerably more folate receptor than their localized, low-grade counterparts (*22*). Therefore, with respect to folic acid with high affinity for folate receptors ($K_d = 10^{-9}$−10^{-10} M) (*31*, *32*), the vitamin was worthy of attention as a targeting ligand for metastatic tumor thought lymphatic system. To our knowledge, most studies about tumor located the lymphatic system focused on monoclonal antibodies, which could actively bind and target to tumor cells in the lymph nodes (*10*, *11*). Compared with monoclonal antibody, folic acid has lower imunogenicity and relatively simpler chemistry. Thus, folate conjugate was made for targeting lymphatic tumor in this study. Otherwise, the widely used macromolecules targeting the lymphatic system include dextran, polylysine, human serum albumin, monoclonal antibodies, and other synthetic polymers. Our choice of PEG as a molecular backbone was based on the following reason: PEG is hydrophilic and structurally flexible, potentially evading the recognization and phagocytosis by macrophage cells in the lymphatic system. This enables folate-modified PEG to selectively bind with a metastatic tumor-cell leading to receptor-mediated endocytosis. As a first step, in this paper, we prepared the folate conjugates, determined the folate receptors mediated endocytosis in vitro, and lymphatic targeting in normal animals. Our following study was the demonstration of the tumor model with lymphatic metastases to better verify folate conjugate targeting.

Our results from competition binding study and cell uptake studies in vitro demonstrated the receptor-mediated endocytosis properties of the folate conjugate with a PEG backbone. The biodistribution and imaging measurement in a normal animal revealed a lymph targeting effect of DTPA−PEG−folate. These properties are highly desirable for a targeted radiopharmaceutical for imaging neoplastic cells overpressing folate receptors in lymphatic system.

In the biological test, the DTPA−PEG−folate showed a high uptake in the kidneys in normal rabbits, consistent with the known presence of folate receptors in the proximal tubules of the kidneys (*33*−*36*). In fact, the amount of the radiopharmaceutical in the kidneys was affected by two factors: first, the kidneys behaving as a clearance organ; second, as a tissue capable of receptor-specific trace accumulation. We once determinated the biodistribution of [^{99m}] DTPA−PEG−folate in the athymic mice. Dates showed that the kidneys' uptake of the agent was 3.872 ± 0.294, 5.844 ± 0.442, and 0.130 ± 0.009 %ID/g (n = 4) at 1 h, 4 h, and 24 h, respectively, at a dose of 1 mg per rat. The agent was absolutely cleared by the kidney at 24 h. At present, the folate receptor positive tumor model in the lymphatic system is being set up. The suitable time point would be identified for not only adequate clearance of the DTPA−PEG−folate in the kidneys but keeping folate receptor mediated bound in tumor.

According to previous studies (*14*), compounds with MW > 16 000 Da are mainly absorbed by the lymphatic vessels, hardly gaining access to blood capillaries. In our paper, the molecular weight of DTPA−PEG−folate is about 2 800 Da. We considered whether the micelles appear during subcutaneous administration of DTPA−PEG−folate. To test the hypothesis, we tried to determine the hydrodynamic diameter of DTPA−PEG−folate by dynamic light scattering (Zeta Potential/Particle Sizer NICOMP 380ZLS (PSS·NICOMP, USA). The conjugate was assayed for 20 min at a concentration of 10 mg/mL in phosphate buffer (pH 7.2, 0.9% NaCl). However, there were no nanoparticles to be detected. Additionally, we investigated the biodistribution of DTPA−PEG−folate at different concentrations (from 0.1 to 10 mg/mL) after subcutaneous injection; the data still revealed the popliteal node targeting. In addition, DTPA−PEG−OCH_3 also showed lymph nodes targeting after subcutaneous injection (13.243 ± 2.345 and 23.730 ± 5.473 %ID/g at 1 and 4 h, respectively, in athymic mice after subcutaneous injection at dose of 1 mg per rat). Therefore, we supposed the possible reasons resulting in the phenomenon, which might be due to its linear structure and negatively charged free carboxyl groups in the DTPA−PEG−folate conjugate. It was reported that negatively charged particles showed a faster lymph delivery than cationic charged or neutral ones (*14*). Certainly, this hypothesis still needs further verification.

Matrix Metalloprotease Triggered Delivery of Cancer Chemotherapeutics from Hydrogel Matrixes

Jovita R. Tauro[†] and Richard A. Gemeinhart*[,†,‡]

Departments of Biopharmaceutical Sciences and Bioengineering, The University of Illinois, Chicago, Illinois 60612-7231. Received April 28, 2005; Revised Manuscript Received July 19, 2005

Glioblastoma multiforme (GBM) is a highly advanced and invasive brain tumor due to which current treatments cannot completely treat GBM or prevent recurrence. Therefore, adjunctive treatments are required. As part of the invasive and angiogenic nature of GBM, it has been well established that matrix metalloprotease-2 (MMP-2) and MMP-9 are overactive. To better treat GBM using chemotherapy, we have designed a hydrogel-based delivery system that can control the release of drugs based on the activity of MMPs. A model chemotherapeutic agent, cisplatin (CDDP), complexed to an MMP substrate (peptide-linker) was incorporated into poly(ethylene glycol) diacrylate hydrogel wafers having different poly(ethylene glycol) chain lengths ($M_n \approx 574$ and 4000). Hydrogel wafers were studied for physical characteristics and drug release in the presence and absence of MMPs. There was a substantial increase in CDDP release for the poly(ethylene glycol) 4000 hydrogel indicating that this chain length provides a mesh size that is sufficient to permit MMP activity within the hydrogel. CDDP bioactivity increased when the cell media was spiked with MMPs (0% cell survival) in case of the longer chain length as compared to in the absence of MMPs (approximately 50% cell survival). The results suggest that this system can be used for selective, local delivery of drugs where higher amounts of the drug are released in response to metastasis, angiogenesis, and invasion-promoting proteases. This strategy may prove to be a novel and effective method to overcome inadequacies in current controlled drug release systems.

INTRODUCTION

Brain tumors are especially difficult to treat due to the lack of chemotherapeutic agent blood-brain barrier (BBB) transport. Of all brain tumors, the most advanced stage of astrocytic brain tumor, glioblastoma multiforme (GBM) or World Health Organization Grade IV glioma, is highly proliferative and shows wide areas of necrosis surrounded by invasive tumor tissue and extensive neovascularization (*1*, *2*). The mean survival time for patients with GBM is one year due to the highly invasive nature of the disease (*1*) leading to recurrence even after treatment (*3*). Currently available chemotherapeutic agents, including cisplatin (CDDP), can only slightly prolong the mean survival time of patients (*4*). Therefore, better treatment strategies are necessary to effectively treat GBM and other forms of brain tumor. In an attempt to better treat brain tumors, local delivery of chemotherapeutics has been utilized (*5*). These local drug delivery systems release drugs at a constant rate that is dictated by hydrolysis of a polymeric carrier; drug delivery is not correlated with any biologic response. Over the last several decades, it has been recognized that the current paradigm of arbitrary and nonspecific delivery of chemotherapeutics can be improved by targeting the activation or release of the chemotherapeutic at a desired site via specific active mechanisms (*6*, *7*). With this in mind, systems that utilize tumor biology have been proposed and utilized to improve the outcome for brain tumor and other cancer patients (*8*).

Several aspects of tumor biology can be exploited to utilize tumor biology for delivery of chemotherapeutics, including tissue invasion, angiogenesis, and metastasis, all of which require the degradation of extracellular matrix (ECM) proteins. Many proteases are implicated in ECM degradation and matrix metalloproteases (MMPs) have been shown to actively participate in degradation of ECM and activation of invasion promoting growth factors (*9*). MMPs play an important and beneficial role in tissue remodeling, wound healing, and angiogenesis along with negative roles in tumor invasion and neovascularization (*10*, *11*). Unequivocal data confirms that the levels of MMP-2 and MMP-9 are observed to increase in correlation with tumor progression in human gliomas (*12*, *13*). Initial attempts to exploit MMPs as a chemotherapeutic target using synthetic MMP inhibitors (MMPis) prevented glioma invasion by inhibiting MMP activity. MMPis reduced glioma growth and invasion in vitro and in animal models (*14*, *15*) but have achieved disappointing results in Phase I, II, and III clinical trials for many reasons (*16*). Despite these disappointing clinical results with MMPis, MMPs may still be an excellent target for chemotherapeutic delivery if an alternate approach is taken: a prodruglike approach.

To achieve a prodruglike approach, an understanding of MMPs proteolytic character is needed. Each MMP has different specificities for the constituents of the ECM; however, MMP-2 and MMP-9 show a great amount of overlap in their substrate specificities. Substrates common to both gelatinases include gelatins, collagens IV and V, elastin, and aggrecans (*17*). By use of these overlapping specificities, it is possible to design peptide sub-

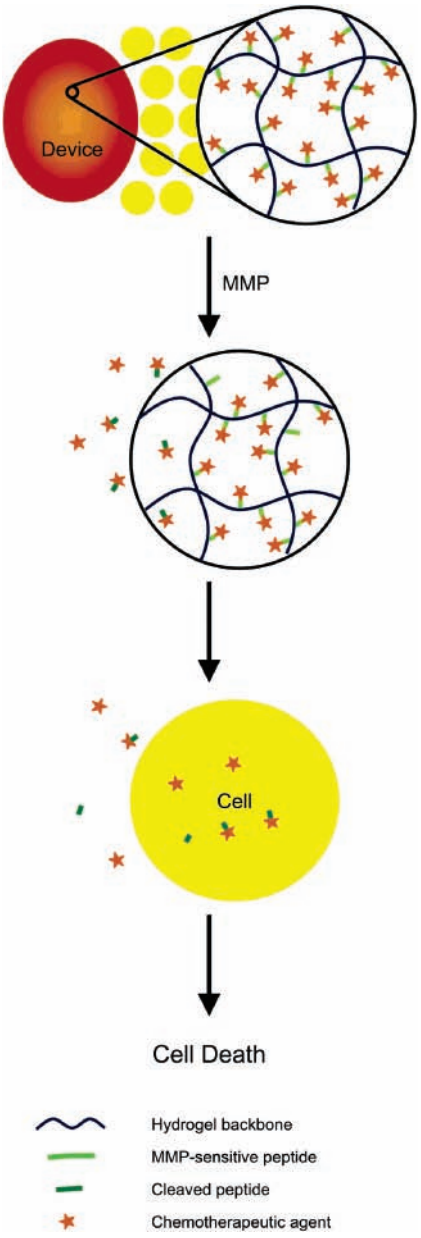

Figure 1. Schematic representation of the drug activation mechanism proposed. In this, CDDP (orange star) is complexed to peptides (light-green lines) pendant on the backbone of a hydrogel matrix (blue lines) of a hydrogel device (red circle) placed near tumor cells (yellow circles). As matrix metalloproteases diffuse through the matrix, the peptides are cleaved releasing CDDP−peptide (dark-green lines) complexes. These complexes may dissociate or enter cells as a complex. CDDP is then able to have the therapeutic effect only when released from the hydrogel matrix. Once released by MMP cleavage (or nonspecific means), the chemotherapeutic agent can enter a cell and have the therapeutic effect (cell death).

strates for releasing drug when MMPs are active similar to a traditional prodrug. In this hydrogel-based prodrug system, peptide substrates act as MMP degradable spacers binding the chemotherapeutic agent to a hydrogel matrix; therefore, the prodrug is retained at the site of implantation by the hydrogel matrix. Our rationale for this design was to use a peptide−drug complex that will release an active form of the drug from the matrix when the peptide is cleaved by MMPs (Figure 1).

Hydrogels were chosen as matrixes due to the inherent biocompatibility of the cross-linked polymeric network (*18*). Hydrogel biocompatibility can be attributed to their hydrophilicity and ability to imbibe large amounts of biological fluids (*19*, *20*). Also, hydrogels closely resemble natural living ECM (*21*) creating a perfect environment for a matrix to mimic MMPs natural activity. In addition, poly(ethylene glycol) diacrylate (PEGDA) hydrogels of different PEG chain lengths are known to allow protein diffusion through the matrix if appropriate mesh size is attained (*22*). Hydrogels of this type have even been produced to allow degradation via MMPs thereby releasing PEG chains and natural products and allowing for aid in regeneration (*23*).

The described study utilizes a PEGDA-based hydrogel to locally target one of the major characteristics of GBM and utilizes this characteristic to selectively deliver a model chemotherapeutic agent, CDDP. Physical properties and in vitro activity of the system have been studied to confirm that MMPs can be used to activate a chemotherapeutic agent from a synthetic hydrogel matrix. With the application of this technology, the problems of recurrence and invasion are expected to be mitigated as the drug will be activated as a tumor attempts to metastasize or recur locally. Localized delivery minimizes systemic toxicity and targets activation of the drug to the site of malignancy. The ability of a delivery system to release the drug when activated by MMPs may help in the development of a successful strategy for treatment of GBM and should be explored further in relation to GBM and other solid tumors.

EXPERIMENTAL PROCEDURES

The MMP-sensitive peptide substrate, CGLDD, and the expected cleaved fragment, LDD (*24*), were synthesized by the University of Illinois at Chicago Research Resources Center with the N-terminal amine blocked by acylation. Peptide structures were confirmed by liquid chromatography mass spectrometry. MMP-2 and MMP-9 were purchased from Calbiochem and activated as suggested by the manufactured using 4-(hydroxymercury)-benzoic acid (Acros Organics, NJ). Short-chain PEGDA ($M_n = 700$, PEG(574)DA) macromer was purchased from Sigma Aldrich Chemical company (Milwaukee, WI). Long-chain PEGDA ($M_n = 4126$, PEG(4000)DA) macromer was purchased from Polysciences, Inc. (Warrington, PA). All remaining chemicals were purchased from Fisher Scientific (Fairlawn, NJ) and used without further purification unless specified.

Preparation and Characterization of Hydrogels. MMP-sensitive peptide substrate (2 mM) was dissolved in water and mixed with PEG(574)DA (100 mM) or PEG-(4000)DA (15.9 mM) and stirred overnight. Michael addition of the acrylate group to the sulfhydryl group on cysteine (*25*) was confirmed using Ellman's reagent (Pierce, Milwaukee, WI), thereby quantifying reduction in free sulfhydryl groups (*26*). PEGDA−peptide solutions (or peptide-free PEGDA at the concentrations listed above) were polymerized without further purification between glass slides to form sheets of hydrogels using ammonium persulfate (20 mM) and N,N,N,N-tetramethylethylenediamine (51.6 mM) as the initiator pair. Hydrogels were cut into 6 mm diameter wafers using a biopsy punch, washed repeatedly in deionized water to remove unpolymerized monomers, and finally allowed to dry in a vacuum oven. CDDP was aquated at pH 7.4 using silver nitrate (*27*) and reacted overnight with hydrogels. Hydrogels containing the peptide were washed to remove excess CDDP. CDDP was entrapped in hydrogels without peptide by using the same procedure as described without washing. CDDP entrapment and complexation in hydrogels was determined by spectropho-

tometeric *o*-phenylenediamine (OPDA) assay (*28*). The mesh size (ξ) of hydrogels was determined to compare with MMP penetration (*29*).

Cell Culture and MMP Activity. A malignant glioma cell line (U-87 MG, ATTC #HTB-14) was grown and maintained in Eagles minimum essential media with 10% fetal bovine serum, 1% penicillin/streptomycin, sodium pyruvate (110 mg/L), L-glutamine (292 mg/L), and nonessential amino acids. Cells were cultured at 37 °C in 5% CO_2. To confirm MMP expression and activity in U-87 MG cells, cells were subcultured under standard conditions for 24 h, then supplemented media was replaced with serum-free media and cultured for an additional 24 or 48 h. The serum-free media was removed and analyzed for presence for MMPs by gelatin zymography (*30*). Cell-treated media (10 μL) was loaded on Ready Gel zymography gels (Bio-Rad Laboratories, Hercules, Ca) and electrophoresed at 100 V. The gels were then washed, incubated, stained, and analyzed for presence of MMPs.

CDDP Release. CDDP release from the hydrogels was determined at 37 °C in a buffer containing Tris−HCl (50 mM), NaCl (0.2 M), $CaCl_2 \cdot 2H_2O$ (10 mM), Brij-35 (0.05%), and $ZnSO_4 \cdot 7H_2O$ (50 μM) in the presence and absence of MMPs (at a final concentration of 10 nM). Released CDDP was determined using the spectrophotometeric OPDA assay (*28*). CDDP release profiles were compared to CDDP release profiles for hydrogels with entrapped CDDP; no peptide was present in the hydrogel for entrapped CDDP studies, which act as a diffusional release control.

Peptide Toxicity and CDDP Activity. To determine the activity of released CDDP, the cleaved peptide fragment LDD was complexed with CDDP using the same procedure as described earlier for hydrogels. Cytotoxicity of the MMP cleaved fragment, LDD, and LDD−CDDP complex was determined by incubating U-87 MG cells with varying concentrations of these peptides in supplemented serum free media for 24 h.

To determine the activity of the hydrogel−CDDP complex devices, hydrogels were incubated with cells in supplemented serum-free media for 24 h. For specific samples, MMP (10 nM) was added to media to supplement the MMPs expressed by U-87 MG cells (*31*) and thus accentuate the MMP effect on CDDP release. Activity of the hydrogel−CDDP complex devices was also studied in the absence of added MMPs. Cell viability with respect to the untreated control was calculated using a modified MTT assay (Cell Titer 96 Aqueous One Solution Cell Proliferation Assay; Promega; Madison, WI) (*32*).

RESULTS

Preparation of Hydrogels. Peptide−PEGDA conjugation was nearly complete after overnight incubation at room temperature as determined by quantitative analysis of free sulfhydryl groups. There was 74.1 ± 3.2% efficiency for conjugation with the PEG(574)DA and 76.1 ± 1% efficiency for conjugation with the PEG(4000)-DA, and the reaction did not proceed further following extended incubation under these conditions. Since this reaction mixture was not further purified prior to polymerization, further incorporation of the peptide is expected by further Michael reaction or chain-transfer reactions with the peptide (*33*). In similar studies with fluorescent-labeled peptide, no peptide was released from the hydrogel without addition of MMPs (data not shown).

PEGDA and PEGDA−peptide hydrogels reached the critical gelation point within 5 min of initiation, but the reaction was continued at 37 °C for a minimum of 1 h to increase the extent of polymerization. PEG(574)DA hydrogels had a mesh size (21±4 nm) that was smaller than PEG(4000)DA hydrogels (79±7 nm). This was expected since PEG(4000)DA hydrogels have significantly longer PEG chains; this increased mesh size allows for substantially higher water content. This larger mesh size was expected to allow MMP-2 and MMP-9 to more freely diffuse in the PEG(4000)DA hydrogel than the PEG(574)-DA hydrogel.

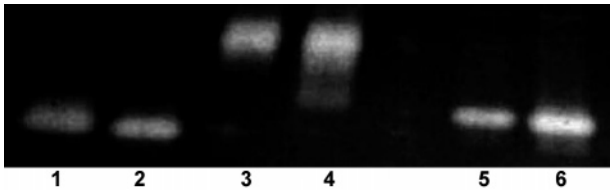

Figure 2. Detection of MMPs by gelatin zymography. Lane 1, Pro-MMP-2; Lane 2, active MMP-2; Lane 3, Pro-MMP-9; Lane 4, active MMP-9; Lane 5, 24 h U-87 MG expression; Lane 6, 48 h U-87 MG expression.

As expected, entrapped CDDP content was found to be much higher than complexed CDDP content since washing removed CDDP that was not complexed to the hydrogel. PEG(574)DA entrapped 22.1 ± 0.9 μg (0.317 μg/mm^3), and 8.6 ± 0.1 μg (0.122 μg/mm^3) was retained as CDDP−hydrogel complexes. Also, the CDDP content was found to be higher in the PEG(4000)DA hydrogels than in the PEG(574)DA hydrogels. PEG(4000)DA hydrogels entrapped 55.7 ± 6.1 μg (0.43 μg/mm^3) while 20.5 ± 1.4 μg (0.157 μg/mm^3) was retained as peptide−CDDP complexes.

MMP Activity. U-87 MG cells express MMP-2 when cultured in media for 24 and 48 h (Figure 2). Pro-MMP-2 increased as cells are incubated for extended periods. Active MMP-2 was detected at 48 h. MMP-9 was not expressed at detectable levels in the cells for up to 48 h. However, this cell line may be used as an in vitro model since the expression and functions of MMP-2 and MMP-9 are known to be heterogeneous in clinical GBM presentation (*9*, *12*) and MMP-2 and MMP-9 have overlapping substrate specificities.

CDDP Release. CDDP was complexed with the carboxyl groups of aspartic acids in the substrate peptide (Figure 3) (*27*). We have previously shown that CDDP complexation delays the release of CDDP from hydrogel particles (*34*). This was confirmed for peptide complexation in this study. CDDP entrapped in PEGDA hydrogels with no carboxylic content was released nearly instantaneously in a burst profile (Figure 4). Peptide complexed CDDP exhibited a slowed release over time even without MMPs present indicating that the complexation was taking place but was not sufficient for complete retention of the drug. However, with the addition of MMPs, there was a marked increase in the amount of CDDP released from the PEG(4000)DA hydrogels but not the PEG(574)DA hydrogels. This suggests that the peptide CGLDD was cleaved from the PEG-(4000)DA hydrogels in a manner dependent upon MMPs if the MMPs are able to enter the hydrogel matrix.

Peptide Toxicity and CDDP Activity. As anticipated, the expected cleaved fragment, LDD, showed no toxicity when incubated with U-87 MG cells. However, the complex, LDD−CDDP, had activity (EC_{50} = 234.7 μM) approximately an order of magnitude below CDDP (EC_{50} = 41.5 μM) (Figure 5). Complexed CDDP retained activity with some loss due to complexation. PEGDA hydrogels and PEGDA−peptide hydrogels without CDDP

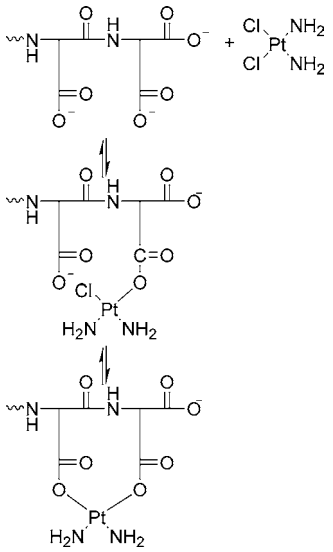

Figure 3. Generalized complexation chemistry of CDDP with carboxylic acid groups, which was utilized in this study. Platinum can interact with aspartic acid side groups as shown or with the carboxyl-terminal group in the peptide. The complexation is dynamic, so both interactions are expected.

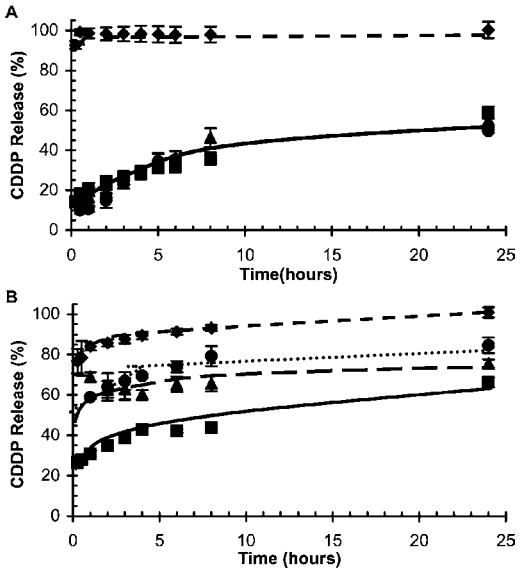

Figure 4. (a). CDDP release from PEG(574)DA hydrogels where (◆) CDDP was entrapped with no complexation, (■) CDDP was complexed to the hydrogel, (●) CDDP was complexed to the hydrogel with MMP-9 added to the release media (10 nM), and (▲) CDDP was complexed to the hydrogel with MMP-2 added to the release media (10 nM). (b) CDDP release from PEG(4000)DA hydrogels where (◆) CDDP was entrapped with no complexation, (■) CDDP was complexed to the hydrogel, (●) CDDP was complexed to the hydrogel with MMP-9 added to the release media (10 nM), and (▲) CDDP was complexed to the hydrogel with MMP-2 added to the release media (10 nM).

were not cytotoxic in the presence or absence of MMP-2 or MMP-9 (Figure 6). CDDP entrapped in PEGDA hydrogels exhibited similar activity to the amount of CDDP that was loaded into the hydrogel. Upon complexation, PEGDA−peptide−CDDP hydrogels exhibited activity at a level well below the amount of CDDP loaded. Activity of CDDP released from PEG(574)DA peptide−CDDP complex hydrogels was not influenced by MMP addition. CDDP released from PEG(4000)DA peptide−CDDP complex hydrogels showed higher activity than CDDP released from PEG(574)DA hydrogels with and without the addition of MMPs. Also, with the addition

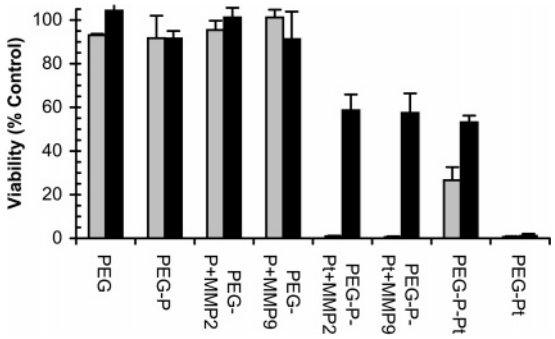

Figure 6. Activity of CDDP released from (dark bars) PEG(574)DA and (light bars) PEG(4000)DA hydrogels. Hydrogels without CDDP or peptides (PEG), hydrogels with peptide incorporated but with CDDP in the absence (PEG-P), and presence of MMP-2 (PEG-P + MMP2) or MMP-9 (PEG-P + MMP9), hydrogels with entrapped CDDP but without peptide for complexation (PEG-Pt), and hydrogels with peptide−CDDP complex in the absence (PEG-P−Pt) and presence of MMP-2 (PEG-P−Pt + MMP2) or MMP-9 (PEG-P−Pt + MMP9).

of MMP-2 or MMP-9 to PEG(4000)DA peptide−CDDP complex hydrogels, higher CDDP activity was observed than in the absence of MMPs. This was not seen with the PEG(574)DA hydrogels. The increase in CDDP activity supports and reinforces the data obtained by CDDP release suggesting that more CDDP was released in the presence of MMPs.

DISCUSSION

PEGDA hydrogels have been widely accepted in many biomedical applications over the last several years (*35*). Hydrogels prepared using PEG(574)DA and PEG(4000)-DA have adequate physical characteristics for implantation and manipulation prior to placement. The current formulations are biodegradable, but the time course for biodegradation is quite slow. This would cause accumulation of PEGDA hydrogel at the site of implantation. To overcome this problem, PEGDA hydrogels could be made to biodegrade at a faster rate by several modifications (*36*). PEGDA hydrogels can be made biodegradable by incorporating a biodegradable cross linker or by utilizing biodegradable copolymers (*37*−*40*). The extent and rate or degradation would be controlled by the specific degradation mechanism used. Future generations of this type of system should integrate such biodegradable nature. However, it was necessary to confirm the possibility of drug activation prior to adding a potentially confounding variable such as biodegradation. Once proteolytic release of anticancer agents is understood, appropriate degradation mechanisms can be incorporated into the system that allow full control of release while limiting accumulation of the hydrogel at the site of implantation. It should be noted, however, that PEGDA

hydrogels are well tolerated in the body even when left for significant periods.

PEGDA hydrogels are hydrophilic, biocompatible, nontoxic, and exhibit variable mesh size depending upon PEG macromer length. Large PEG chain lengths allow proteins to diffuse throughout the matrix while smaller PEG chain lengths can be used to control the accessibility of the matrix to specific proteins (*22*). This work has shown that adequate PEGDA chain length can be attained to allow diffusion of MMPs throughout the matrix, thus releasing a chemotherapeutic agent from the matrix via MMP cleavage of peptide substrates. Hydrogels containing peptide−CDDP complex provided a level of control for the release of CDDP to the tumor cells. We did not show complete control over delivery of CDDP; the CDDP−peptide complex allows nonspecific release of approximately 50% of bound CDDP in the first day regardless of chain length. Increasing CDDP binding efficiency with a hydrogel by increasing the carboxylic acid content has been shown to slow the nonspecific CDDP release from hydrogel particles (*34*). Alternate platinum chemistries are also possible if platinum-based drugs are desired to be delivered. Our group has successfully bound platinum to amine groups of hydrogel and showed limited release over a week or longer (*41*). Utilization of covalent coupling of alternate drugs could also alleviate the problem of nonspecific release (*8*). Alternate chemistries should allow a more specific release of chemotherapeutics from the device. A perfectly designed system would allow release of the chemotherapeutic agent in a MMP dose-dependent manner. Most importantly, when no MMP is present, no chemotherapeutic should be released. As the concentration of MMP increases, the amount of chemotherapeutic should increase. This would ensure minimal toxicity due to the chemotherapeutic and maximum release with protease activity. Despite the setback of nonspecific release, we were able to confirm that MMP-specific release of CDDP is possible from a hydrogel matrix.

When glioma cells attempt to grow and invade the surrounding tissue or even in culture, MMPs are expressed (Figure 2). This led to increased CDDP release when MMPs were present (Figure 4). The fact that PEG(574)DA hydrogels do not allow increased release of CDDP upon MMP addition while PEG(4000)DA hydrogels do allow accelerated release of CDDP confirms our hypothesis that adequate mesh size can be obtained. Thus, this system will deliver a higher dose of the drug selectively to the most invasive portion of the tumor. This was also confirmed by examining the activity of the devices (Figure 6). Cells are not influenced by any hydrogels that do not possess CDDP, and when no CDDP complexation exists, cells are not able to survive. Upon peptide−CDDP complexation within PEG(574)DA hydrogels, intermediate CDDP activity was observed after 24 h with no increase upon MMP addition. When peptide−CDDP is complexed within PEG(4000)DA hydrogels, CDDP was substantially more active. Without MMPs, fewer cells survive when treated with PEG(4000)DA hydrogels than when treated with equivalent PEG(574)DA hydrogels. This is due to MMP diffusion into the PEG(4000)DA hydrogels and subsequent increased release of CDDP. CDDP activity was increased by addition of MMPs as expected for a Michaelis−Menten-type kinetics ($V_{max} = k_{cat} \cdot [E]_{tot}$). Further studies are needed to better characterize the exact kinetics of release under these circumstances, and we hope to report these results in the future. The end result is not in question, increased CDDP was released when MMPs are added to the system. This type of delivery should greatly increase the efficacy of drug delivery systems.

Local delivery and controlled activation of the drug reduces unnecessary exposure to other organs. Since the drug was released in high doses at the tumor site it may have better efficacy. Problems with currently utilized routes of chemotherapeutic agent delivery, such as inability to cross the BBB and systemic toxicity, would be averted. Since the conjugation of the peptide within PEGDA has a high yield, loading of the drug can be maximized by increasing the concentration of the peptide. The peptide used for the study is a substrate for MMP-2 and MMP-9 with efforts underway to design substrates specific for these and other enzymes. Having an array of substrates would allow for tailoring a device to a specific patient or for a particular tumor type. Not only is peptide choice important for specificity and kinetic control of cleavage but activity of the released drug is also influenced by peptide modification.

Minimization of loss of activity of the drug due to complexation has to be considered in designing peptides; our current example indicated a reduction in activity from CDDP (Figure 5). By selective control over peptides, more active CDDP (or other drug) analogue can be released from the hydrogel matrix. Our data showed that peptide substrates for MMP-2 and MMP-9 can be cleaved by these enzymes within hydrogels thus releasing an active form of CDDP.

Other groups have shown activity of drugs when covalently attached to MMP substrates (*42*) or released from MMP-sensitive micelles (*31*). We have focused on localized delivery due to questions that exists concerning the heterogeneity of tumor vascular permeability in different tumor types and proteases present within the blood. In our system, the activity of the complexed drug toward the glioma cell line was retained (although slightly attenuated) after cleavage. We have not overlooked the fact that transport of materials away from the device may hinder the area of effectiveness, but we also believe that polymer therapeutics that rely on vascular permeability have potential liabilities that can be addressed using local device placement. We hope to report in vivo results with this system soon. From these studies, hydrogel-based matrixes may prove to be excellent carriers for chemotherapeutics when local delivery is desired particularly when a prodruglike approach is used.

CONCLUSION

Current treatments have not improved the poor prognosis of GBM to a significant degree. It is necessary to develop drug delivery systems that reduce the problems of toxicity, recurrence, and invasion in this disease. By utilization of the biology of GBM, we have proposed a novel method of utilizing the overactivity of MMP-2 and MMP-9 in GBM to activate a prodrug from a hydrogel matrix. When CDDP is entrapped within PEGDA hydrogels, CDDP is released within a short period (greater than 95% within an hour). CDDP can be retained in PEGDA hydrogels by complexation with aspartate-containing peptides (approximately 50% release in 24 h). When MMPs are present, CDDP is released at an accelerated rate when adequate mesh size of the hydrogel matrix is present. PEG(4000)DA hydrogels have sufficient mesh size for MMP diffusion but not PEG(574)DA hydrogels. Thus, PEG(4000)DA hydrogels containing drug−peptide prodrugs have shown great promise for locally controlling the release of chemotherapeutics. Active drug was cleaved from the hydrogel in the pres-

ence of MMPs and the cleaved drug retained activity toward glioma cells. This system warrants future research with MMP substrates and drugs and should be further explored.

ACKNOWLEDGMENT

The authors thank Dr. Hayat Onyuksel for use of equipment, Bob Lee for peptide production, Avni Shah for technical assistance, Xiaoliang Yan for helpful discussion, and Ernest J. Gemeinhart for technical assistance, helpful discussion, and review of this manuscript. This study was supported in part by the National Eye Institute (R03 EY014357) and the American Brain Tumor Association, Kathy Murphy Translational Research Grant. This investigation was conducted in a facility constructed with support from Research Facilities Improvement Program Grant Number C06 RR15482 from the National Center for Research Resources, NIH.

Synthesis of Biodegradable Cross-Linked Poly(*β*-amino ester) for Gene Delivery and Its Modification, Inducing Enhanced Transfection Efficiency and Stepwise Degradation

Tae-il Kim,[†] Hyo Jung Seo,[†] Joon Sig Choi,[‡] Jae Keun Yoon,[†] Jung-un Baek,[†] Kwan Kim,[†] and Jong-Sang Park[†,*]

School of Chemistry & Molecular Engineering, Seoul National University, San 56-1, Shillim-dong, Kwanak-gu, Seoul 151-742, Korea and Department of Biochemistry, Chungnam National University, 220 Gung-dong, Yuseong-gu, Daejeon 305-764, Korea. Received December 15, 2004

Biodegradable cross-linked poly(*β*-amino ester) (CLPAE) was synthesized by Michael addition of pentaerythritol triacrylate and *N*,*N*-dimethylethylenediamine and modified with aminohexanoic acid and lysine to CLPAE-Ahx and CLPAE-Lys, respectively, for a gene delivery system. They could self-assemble with plasmid DNA, forming nanosized polyplexes, and CLPAE-Ahx polyplex released plasmid DNA slowly during a week through stepwise degradation. The polymers showed minimal cytotoxicity on 293 cells due to their biodegradability and biocompatibility. Transfection efficiencies of CLPAE-Ahx and CLPAE-Lys were comparable to that of PEI in 293 cells and C2C12 cells. Additionally, high transfection of CLPAE-Ahx on primary rat aorta vascular smooth muscle cells (SMC) and primary mouse embryonic fibroblast cells (MEF) shows a potential for a gene delivery system on primary cells, restenosis treatment of human SMC, and MEF cell function research. In conclusion, CLPAE-Ahx could be used as a nontoxic and highly efficient gene delivery system.

INTRODUCTION

During the past decade, intensive research and development in multidisciplinary fields have been directed toward developing safer and more efficient methods for transferring therapeutic genes into cells and for eventual use in human gene therapy (*1*).

Several successful clinical trials reported so far involved viral vector systems (retroviruses, adenoviruses) that provide efficient transduction and high levels of gene expression. However, their severe immunogenicity and toxicity are still major obstacles for viral vector-mediated gene therapy (*2*). For these reasons, as alternative tools to such risky viral vectors, nonviral vectors have been introduced and studied for their potential to provide safer, more desirable methods for gene delivery and clinical gene therapy (*3*−*6*).

Studies have been performed to improve gene delivery efficiency of polymeric gene carriers and to reduce their cytotoxicity in many labs. Among them, the introduction of biodegradability such as ester, phosphoester, or disulfide bonds to the polymeric carriers was proved to be very successful for lowering cytotoxicity (*7*−*10*). However, the results from these approaches were dependent on specific conditions, so structure−activity relationships could not be obtained easily. Recently, Langer et al. constructed structurally manifold polymer libraries by using combinatorial reactions of amine derivatives and diacrylate monomers and screened them by high-throughput cell-based screening assay (*11*−*13*). Through this strategy, they discovered a few candidates showing very high gene delivery efficiency.

In general, linear cationic polyester polymers are reported to be degraded very fast in aqueous solution and to release DNA from polyplexes within a few hours (*14*). This means that the application of linear polyester polymers could be limited in the long term because of its fast degradation rate. So, we designed a novel cross-linked poly(*β*-amino ester) polymer (CLPAE) to control its degradation rate and deliver DNA for a longer period.

In this report, we present the synthesis, characterization of CLPAE, and further modification of the polymer for application to gene delivery. Also, self-assembly of polymers with plasmid DNA, in vitro DNA release, and cell-based experiments investigating cytotoxicity and transfection efficiency are performed and presented.

EXPERIMENTAL PROCEDURES

Materials. Poly(ethylenimine) (25 kDa), pentaerythritol triacrylate, *N*,*N*-dimethylethylenediamine (95%), *N*,*N*-diisopropylethylamine (DIPEA), piperidine, and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich (St. Louis, MO). *N*-Hydroxybenzotriazole (HOBt) and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) were purchased from Anaspec, Inc. (San Jose, CA). Fmoc-6-aminohexanoic acid (Fmoc-*ϵ*-Ahx-OH) and Fmoc-Lys(Fmoc)-OH were purchased from Novabiochem (Laufelfingen, Switzerland). pGL3-control vector, Luciferase 1000 Assay System, and Reporter Lysis Buffer were purchased from Promega (Madison, WI). The luciferase expression plasmid (pCN-Luci) was a kind gift from Hyung-suk Jang in Samsung Medical Center (Seoul, Korea). pCN-Luci was constructed by subcloning cDNA of *Photinus pyralis* luciferase with a 21-amino acid nuclear localization signal from SV40 large T antigen to pCN (*15*). PicoGreen was purchased from Molecular Probes (Eugene, OR). Fetal bovine serum (FBS), Minimal Essential Medium (MEM), and Dulbecco's modified Eagle's medium (DMEM) were purchased from GIBCO (Gaithersburg, MD). Micro BCA protein assay kit was purchased from Pierce (Rockford, IL). All other chemicals were purchased and used without any further purification.

Polymer Synthesis. *N*,*N*-Dimethylethylenediamine (0.481 mL, 4.16 mmol) and pentaerythritol triacrylate (0.526 mL, 2.08 mmol) were dissolved in methylene chloride (3 mL), respectively. Then, diamine solution was added to triacrylate solution dropwise, keeping it at 50 °C. After 2 days when a yellow precipitate was found in the reaction mixture, it was cooled to room temperature and evaporated under vacuum. The remnant was precipitated into diethyl ether two times to remove residual amine, leaving a light yellow solid, CLPAE.

Also, CLPAE was further modified to acquire the enhanced properties of gene delivery by the introduction of aminohexanoic acid (Ahx) or lysine (Lys) residues. These conjugation reactions were conducted by coupling the carboxylic group of the acid to the hydroxyl group of the triacrylate with HOBt/HBTU. Fmoc-protected Ahx and Lys were used to prevent side reactions.

(1) Aminohexanoic Acid-Conjugated CLPAE (CLPAE-Ahx). First, 100 mg of CLPAE was mixed in DMF with a large excess of Fmoc-ϵ-Ahx-OH (248 mg, 0.702 mmol), HOBt (94.8 mg, 0.702 mmol), and HBTU (266 mg, 0.702 mmol). At this time, a large excess of coupling reagents was used to complete the conjugation because we did not know the exact amount of hydroxyl groups in CLPAE. Then, DIPEA (245 μL, 1.40 mmol) was added to the reaction mixture. The reaction was allowed to proceed at room temperature for 2 days to complete the reaction. After the coupling reaction was completed, the product was precipitated with an excess of diethyl ether three times to remove the excess of coupling reagents and DMF. Dried under a vacuum, the product was dissolved in DMF and mixed with an equal volume of piperidine (30% in DMF) at room temperature for 20 min to remove the Fmoc group of aminohexanoic acid. The reaction mixture was precipitated again with diethyl ether to remove the piperidine and reaction remnants and dried under vacuum, leaving a sticky yellow solid, CLPAE-Ahx. Each coupling reaction and Fmoc-deprotection reaction was confirmed by ^{1}H NMR.

(2) Lysine-Conjugated CLPAE (CLPAE-Lys). CLPAE (100 mg) was mixed in DMF. Then an equimolar amount of Fmoc-Lys-(Fmoc)-OH (415 mg, 0.702 mmol), HOBt, HBTU, and DIPEA in accordance with the above procedure was dissolved in DMF and added to the CLPAE solution. Afterward, following the coupling reaction, the Fmoc-deprotection and diethyl ether precipitation steps were carried out in the same way as in the above-mentioned CLPAE-Ahx synthesis.

^{1}H NMR Spectroscopy. ^{1}H NMR spectra of the polymers were obtained using a Bruker DPX-300 NMR spectrometer (300 MHz). For analysis, the polymer samples were dissolved in D_2O or MeOD containing 0.05% 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid sodium salt as an internal reference (0 ppm). A known molar quantitiy of benzoic acid was added to sample solutions as a NMR standard to quantify the degree of modification with Ahx and Lys for further experiments.

Molecular Weight Analysis. The average molecular weight of polymers was determined by multiangle laser light scattering (MALLS) in combination with size exclusion chromatography (SEC). The SEC system included a P680 HPLC pump from Dionex Corp. (Sunnyvale, CA). Polymer samples were detected by a three-angle laser light scattering detector (miniDAWN Tristar, 30 mW GaAs laser, 690 nm, K5 cell) and an interferometric refractometer (Optilab DSP, P10 cell) from Wyatt Technologies (Santa Barbara, CA). The MALLS system was operated by Astra software version 4.90. DMF (HPLC grade, Mallinckrodt) was used as an eluent after being filtered through a 0.22 μm filter and degassed before use. A Styragel HR 3 column from Waters (Milford, MA) was used. All sample solutions were filtered through a 0.45 μm filter again. The solution was delivered to a flow cell inlet at a constant flow rate of 0.5 mL/min.

Quantitative Analysis of Primary Amine Numbers of CLPAE-Ahx and CLPAE-Lys. A series of ethanol amine solutions of various concentrations was mixed with 50 mM borate buffer to 800 μL of the total volume to construct the standard calibration curve. Fluorescamine solution (1 mg/mL in DMF) (200 μL) was mixed with the amine solution. After 12 min incubation, 1.5 mL of stop solution (DMF/water, 50% v/v) was added to quench the reaction. Fluorescence measurements were carried out with a FP-750 spectrofluorometer (Jasco) at room temperature. Excitation and emission wavelengths were 360 and 465 nm. In the case of polymer samples, fluorescence was measured in the same way. A standard curve prepared in this way was used to analyze the amount of primary amines/μg polymer quantitatively.

Gel Retardation Assays. Polymer/plasmid complexes (polyplexes) at various weight ratios ranging from 0.5 to 7 were prepared in HEPES-buffered saline (HBS, 20 mM HEPES, 150 mM NaCl, pH 7.4). After 30 min incubation at room temperature for complex formation, the samples were electrophoresed on a 0.7% (w/v) agarose gel and then stained in a 1% (w/v) ethidium bromide solution. After 40 min staining, the gel was analyzed on a UV illuminator to show the location of the DNA.

Polymer/DNA Self-Assembly Analysis by PicoGreen Assay. PicoGreen assay was carried out to analyze the self-assembly of polymer/plasmid DNA quantitatively as reported recently (*16*). Briefly, PicoGreen reagent (200X) was diluted to 200-fold in TE buffer before the experiment. The diluted PicoGreen stock solution (200 μL) was mixed with the same volume of blank solution or polyplex solution (1 μg DNA, 1X HBS) prepared at various weight ratios ranging from 0 to 10. After 2 min incubation, each solution was added to 1.6 mL of TE buffer in a test tube. Fluorescence was measured with a FP-750 spectrofluorometer (Jasco) at room temperature. Excitation and emission wavelength were set at 480 and 520 nm, respectively.

Polyplex Size Measurements. The hydrodynamic diameters of the polymer/plasmid DNA complexes were determined by light scattering. Polyplex solutions (500 μL) containing 10 μg of DNA were prepared at various weight ratios ranging from 0.5 to 40. After 30 min incubation, polyplex solutions were diluted to a final volume of 2 mL prior to measurements. Polyplex sizes were measured using a Zetasizer 3000HS (Malvern Instruments, UK). The laser used is a nominal 5 mW HeNe laser having a 633 nm wavelength. Scattered light was detected at a 90° angle. The refractive index (1.33) and the viscosity (0.89) of ultrapure water were used at 25 °C for measurements. Zetasizer 3000 (Advanced) Size mode v1.61 software was used for data acquisition. Data analysis was performed in automatic mode. Measured sizes were presented as the average values of 10 runs.

Atomic Force Microscopy (AFM). The particle shapes and sizes of the polymer/plasmid DNA complexes were analyzed using atomic force microscopy (Nanoscope IIIa system, Digital Instruments, Inc., Santa Barbara. CA). The samples were prepared by mixing 0.1 μg of plasmid DNA with aqueous polymer solution at various weight ratios to obtain a final DNA concentration of 10 ng/μL. After 30 min incubation, 1 μL aliquots of the complex solutions were placed on freshly cleaved mica surface and allowed to stick for 1−2 min. Excess solution was removed by careful absorption onto filter paper, and the mica surface was further dried at room temperature for 24 h. The image mode was set to tapping mode, and the scanning speed was 1−5 Hz.

Zeta-Potential Measurements. One hundred microliter quantities of polyplex solutions containing 2 μg of DNA were prepared at various weight ratios ranging from 0.5 to 10. After 30 min incubation, 25 μL quantities of polyplex solutions were diluted to 10 mL of the final volume prior to measurements. Zeta-potential measurements were carried out using a Zetasizer 3000HS (Malvern Instruments, UK) at 25 °C. Zetasizer 3000 (Advanced) Zeta mode v1.61 software was used for data acquisition. The sampling time was set to automatic. Potential values were presented as the average value of 5 runs.

In Vitro DNA Release Measurements. In vitro DNA release from polyplex according to the degradation of polymer in aqueous solution was analyzed by PicoGreen assay. Each procedure was identical to that in the experiments described above except that the weight ratio of polyplex used was 20 where polymers formed stable complexes with plasmid DNA. The polyplexes formed in HBS (pH 7.4) were incubated at 37 °C and collected for assay at various times ranging from the first to the 10th day. Results were expressed in % fluorescence relative to control plasmid DNA.

Cell Lines. HepG2 human hepatocellular carcinoma cells were maintained in MEM, and 293 human kidney transformed

cells and C2C12 mouse myoblast cells were maintained in DMEM medium with 10% fetal bovine serum (FBS) at 37 °C in 5% CO_2. The primary rat aorta vascular smooth muscle cells (SMC) were a kind gift from Hyung-suk Jang in Samsung Medical Center (Seoul, Korea) and maintained in DMEM/F12 medium with 10% fetal bovine serum (FBS) at 37 °C in 5% CO_2. The primary mouse embryonic fibroblast cells (MEF) were a kind gift from Prof. Han-Woong Lee in Sungkyunkwan University, School of Medicine. MEFs were prepared from 13.5 day postcoitus mouse (FVB/NJ strain) embryos and maintained in DMEM medium with 10% fetal bovine serum (FBS) at 37 °C in 5% CO_2. All media contained 1% antibiotic agent.

Cytotoxicity Assay. The cytotoxicity of the polymers was measured by MTT assay. 293 cells were seeded in a 96-well tissue culture plate at 10^4 cells per well in 90 μL of DMEM medium containing 10% FBS. Cells achieving 70−80% confluence after 24 h were exposed to 10 μL of the polymer solutions having various concentrations for 24 h. Then, 25 μL of stock solution of MTT (2 mg/mL in DPBS) were added to each well. After 4 h of incubation at 37 °C, each medium was removed and 150 μL of DMSO was added to each well to dissolve the formazan crystal formed by proliferating cells. Absorbance was measured at 570 nm using a microplate reader (Molecular Devices Co., Menlo Park, CA) and recorded as a percentage relative to untreated control cells.

In Vitro Transfection. HepG2 and 293 cells were seeded at a density of 1.5×10^5 cells/well in a 24-well plate in medium containing 10% FBS and grown to reach 70−80% confluence prior to transfection. C2C12 (7×10^4 cells/well) cells, SMC (4×10^4 cells/well) cells, and MEF (6×10^4 cells/well) cells were seeded in the same way. Before transfection, the cells were rinsed with DPBS, and serum-free or serum-containing medium was added to each well. The cells were treated with polyplex solutions containing 2 μg of plasmid DNA at different weight ratios for 4 h at 37 °C. All the cells were tested with the control pGL3 plasmid except MEF cells for which pCN-Luci plasmid was used. In the presence of serum, the cells were incubated for 24 h after transfection. After exchange of medium, cells were further incubated for 2 days after transfection. Then the growth medium was removed, and the cells were rinsed with DPBS and shaken for 30 min at room temperature in 120 μL of Reporter Lysis Buffer. Luciferase activity was measured by a luminescence assay, and a protein assay was performed using a Micro BCA Protein Assay Reagent Kit. Ten microliters of the lysate was dispensed into a luminometer tube, and luciferase activity was integrated over 10 s with a 2 s measurement delay in a Lumat LB 9507 luminometer (Berthold, Germany) with an automatic injection of 50 μL of Luciferase Assay Reagent. The final results were reported in terms of RLU/mg cellular protein.

RESULTS AND DISCUSSION

Synthesis of CLPAE, CLPAE-Ahx, and CLPAE-Lys. It was reported by Ferruti et al. in 1970 (*17*) that linear poly(amido amine) was synthesized by simple Michael addition of bifunctional amines and bisacrylamides. Poly(amido amine)s of both linear and dendritic structure have been investigated and applied in various fields including gene delivery (*18*−*20*).

Recently, Langer et al. reported a series of achievements in relation to synthesis of poly(amino ester) polymers, their identification, and application to gene transfer by a high-throughput cell-based screening assay (*11*−*13*). They possessed several advantages for gene transfer such as a simple and inexpensive polymerization step and low cytotoxicity due to the biodegradability of the polymer. However, considerable screening is required to find nontoxic efficient gene delivery carriers among the library of randomly synthesized candidate polymers. Moreover, it is well-known that linear polyester polymers tend to be degraded within several hours in aqueous solution (*7*, *14*). The instability and fast degradation of polyplexes formed from these linear polymers limit their potential for long-term application including in vivo gene delivery.

So, we designed cross-linked poly(amino ester) polymers to improve stability and to reduce the fast degradation rate of the polymer. It was reported that cross-linked ester polymer was degraded more slowly under physiological conditions than linear polymer and possessed the endosome buffering effect due to its three-dimensional structure and internal tertiary amines, yielding high transfection efficiency (TE) in mammalian cells (*21*). To synthesize cross-linked polymers, triacrylate was used as a trivalent linker. Pentaerythritol triacrylate was chosen because it has the shortest carbon backbone length among analogous acrylate monomers for high charge density, which is known to generally lead to high TE in cells. Moreover, it has a hydroxyl group, which would enhance water solubility of the polymer and enable further modification of the polymer with other functional groups after polymerization. In the case of the amine monomer, we used *N*,*N*-dimethylethylenediamine that has only one primary amine which could react with acrylates, thus avoiding the formation of excessively complex polymer networks insoluble in aqueous solution.

Scheme 1 shows the synthesis of CLPAE and its modification procedures to prepare CLPAE-Ahx and CLPAE-Lys. CLPAE was synthesized from the nucleophilic Michael addition of *N*,*N*-dimethylethylenediamine with pentaerythritol triacrylate in MC at 50 °C for 2 days. Attempts to synthesize CLPAE under other solvent conditions (DMF, THF etc.) resulted in polymers that could not condense DNA efficiently and showed a very low TE in 293 cells through preliminary experiments (data not shown) So, MC was selected as the optimal solvent for the preparation of CLPAE.

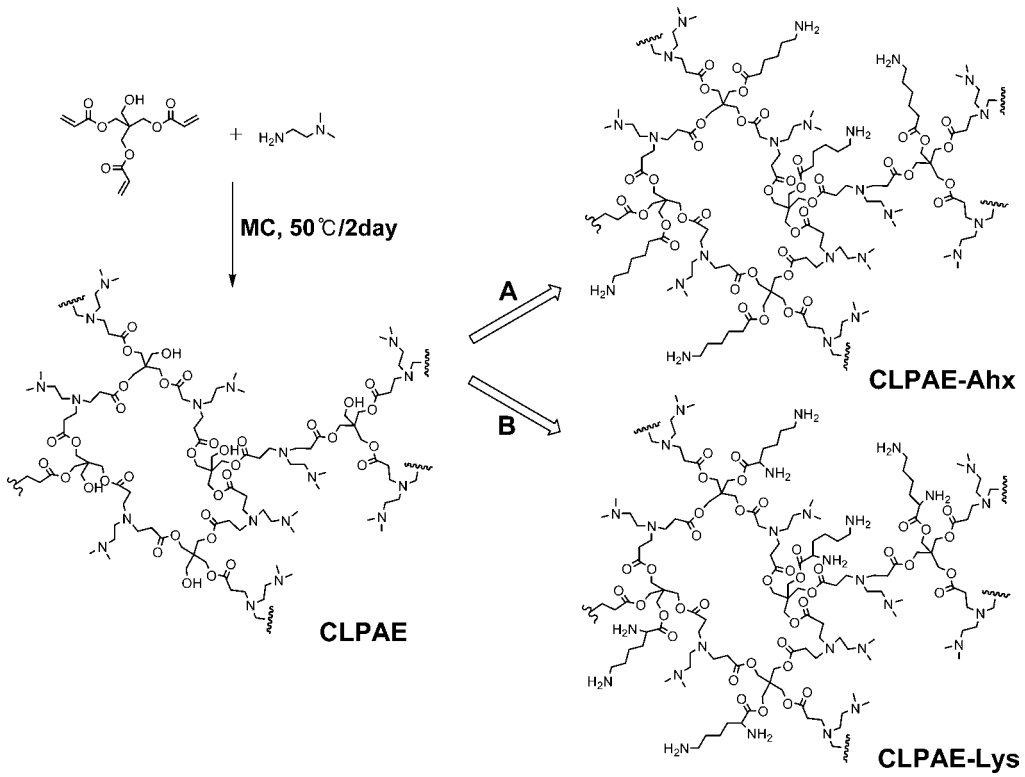
In the case of linear poly(amino ester) polymers, the molar reaction ratio between amine and diacrylate must be equal for a complete stoichiometric reaction yielding the highest molecular weight of the polymer. However, for cross-linked polymers, investigation of the optimal mole ratio was required because triacrylate has three functional groups and diamine has two. CLPAE was synthesized at 1, 2, and 3 mole ratios (amine/acrylate). To determine the optimal ratio, they were analyzed by ^{1}H NMR. From the ^{1}H NMR spectra, we found that CLPAE showed residual unreacted acrylate groups at a mole ratio of 1, and the peaks of acrylate groups had vanished completely at a mole ratio of 2 (data not shown). Therefore, the reaction mole ratio was set to 2 throughout the experiments.

After 2 days of polymerization, a weak yellow precipitate was observed in the reaction mixture. The product was precipitated in an excess volume of diethyl ether two times, leaving a yellow solid. CLPAE was soluble in water and methanol but not in DMF.

Then, CLPAE was further modified by conjugating with aminohexanoic acid (Ahx) and lysine (Lys). Ahx and Lys residues were introduced in order to enhance the DNA-condensing ability of the polymers. The conjugation reaction was performed by coupling the hydroxyl groups of the triacrylate backbone in CLPAE with carboxylic acid using HOBt and HBTU as coupling agents. Because it was complicated work to quantify the amount of hydroxyl groups in CLPAE, we used excessive molar quantities of Fmoc-protected acids and coupling agents for complete conjugation. Also, the reaction time was prolonged to 2 days for the same reason.

After 2 days of coupling in DMF at room temperature, DMF-insoluble CLPAE was dissolved in the reaction mixture in DMF, suggesting that Fmoc-Ahx or Fmoc-Lys was coupled to CLPAE, increasing its solubility in DMF. The reaction solution was evaporated and then precipi-

Scheme 1. The Synthetic Scheme of CLPAE, CLPAE-Ahx, and CLPAE-Lys



tated in diethyl ether three times to remove the excess of residual coupling agents and starting materials (Ahx or Lys). Then, Fmoc groups of aminohexanoic acid or lysine were removed by 15% piperidine solution at room temperature for 20 min to expose primary amines.

Characterization of CLPAE, CLPAE-Ahx, and CLPAE-Lys. The molecular weights (MWs) of the polymers were determined by multiangle laser light scattering (MALLS) combined with size exclusion chromatography. This method is known to be able to determine the absolute MWs of polymers without the need for reference standard polymers (*22*). Molecular weights were calculated by Astra software version 4.90. The eluent solvent was DMF.

The molecular weights of the polymers were as follows. CLPAE-Ahx: $M_n = 2.54 \times 10^4$ g/mol, $M_w = 3.40 \times 10^4$ g/mol (PDI = 1.34), dn/dc = 0.0498; CLPAE-Lys: $M_n = 2.18 \times 10^4$ g/mol, $M_w = 3.28 \times 10^4$ g/mol (PDI = 1.50), dn/dc = 0.0548. The MW of CLPAE could not be obtained by MALLS because it was not soluble in DMF. The increased MW of CLPAE-Ahx is thought to be due to the number of the coupled Ahx being greater than for Lys, a view that corresponds with the following ^{1}H NMR spectra and primary amine quantification results.

We obtained ^{1}H NMR spectra of CLPAE-Ahx and CLPAE-Lys to examine the average degree of modification of aminohexanoic acid or lysine, and the molecular weight of only CLPAE based on the NMR results. A known molar quantity of benzoic acid was added as an internal standard because its proton peaks do not overlap with those of CLPAE and it does not react with CLPAE. We could obtain the number of conjugated aminohexanoic acid or lysine molecules per polymer by calculating the ratio between the number of moles of benzoic acid protons and the NMR peak intensities.

Table 1 shows the average degree of Ahx or Lys modification and the molecular weights of the polymers. We found that an average of 77 molecules of Ahx were conjugated to CLPAE-Ahx and 66 molecules of Lys to CLPAE-Lys. The molecular weight of only CLPAE can be inversely calculated because the value after subtraction of the total MW of conjugated Ahx or Lys from the MW of modified CLPAEs equals the MW of unmodified CLPAE. The molecular weight of only CLPAE was determined to be 2.52×10^4 g/mol and 2.43×10^4 g/mol based on calculations from CLPAE-Ahx and CLPAE-Lys, respectively. The lower degree of modification of Lys compared to Ahx is thought to be due to steric hindrance of di-Fmoc-lysine and this result agrees well with primary amine quantification assay as follows.

Table 1. Molecular Weights of the Polymers and the Degree of Modification with Ahx or Lys[a]

	M_n from MALLS (g/mol)	M_w from MALLS (g/mol)	degree of modification from NMR	M_w of CLPAE from calculation (g/mol)
CLPAE-Ahx	2.54×10^4	3.40×10^4	77	2.52×10^4
CLPAE-Lys	2.18×10^4	3.28×10^4	66	2.43×10^4

[a] Molecular weights of CLPAE-Ahx and CLPAE-Lys were obtained from MALLS.

Quantification of primary amine amount by fluorescamine assay showed that CLPAE-Ahx had 2.0 nmol primary amines/μg of polymer and CLPAE-Lys had 1.5 nmol/μg. Only CLPAE showed a negligible value, confirming that CLPAE itself had no effect on amine quantification.

Formation of Polymer/DNA Polyplexes. The self-assemblies of each polymer and plasmid DNA were observed by using agarose gel electrophoresis and PicoGreen assay, respectively. Figure 1 shows the gel retardation results of each polymer with plasmid DNA. CLPAE was found not to retard plasmid DNA until the weight ratio reached 3. In contrast to CLPAE, the polyplexes of CLPAE-Ahx and CLPAE-Lys with DNA showed complete retardation even at a weight ratio of 1.

These results were compared with PicoGreen exclusion

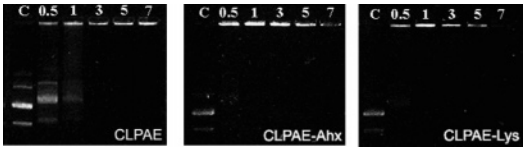


Figure 1. Gel retardation assay. C: DNA only. Numbers represent the weight ratio of the polyplexes.

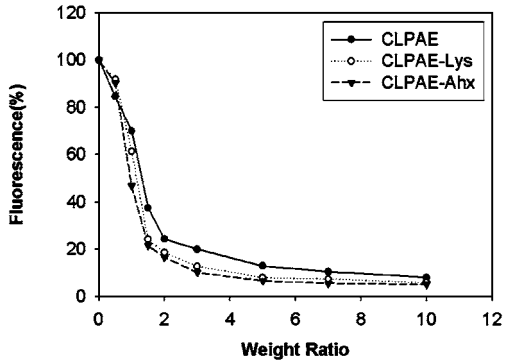

Figure 2. DNA complexation assay using PicoGreen reagent. Excitation and emission wavelength were set at 480 and 520 nm, respectively.

assay results (Figure 2). PicoGreen reagent is a DNA intercalating dye like ethidium bromide (*23*). So, the fluorescence of PicoGreen reagent is inhibited when the DNA is condensed into particles by self-assembly with cationic polymers. CLPAE/DNA polyplex showed an 85% relative fluorescence at a weight ratio of 0.5, which decreased sharply to 8% at a weight ratio of 10. CLPAE-Ahx and CLPAE-Lys were observed to show a greater DNA condensing ability than CLPAE. CLPAE-Ahx polyplex showed a 90% fluorescence value at a weight ratio of 0.5 and this decreased abruptly to 5% at a weight ratio of 10. Although the fluorescence of CLPAE-Lys polyplex was slightly higher than that of CLPAE-Ahx for all the weight ratios examined, the profile was similar to that of CLPAE-Ahx polyplex. These results correspond with gel retardation results and mean that a series of newly synthesized polymers could condense plasmid DNA efficiently with differences of a degree. Polymers condensed DNA compactly in order of CLPAE-Ahx > CLPAE-Lys > CLPAE. This may be due to the differences in the amount of primary amine or amine density, according to amine quantification results. However, at a weight ratio of 1 each polymer showed no less than 47, 61, 70% fluorescence in order of CLPAE-Ahx, CLPAE-Lys, CLPAE, respectively. This is thought to be due to the high sensitivity of the PicoGreen reagent.

Average Size Measurements of Polyplexes. The polyplex sizes and their distributions were determined by a Zetasizer. Each polyplex was prepared at various weight ratios ranging from 0.5 to 40 at room temperature. As shown in Figure 3, the polymers were found to have a similar tendency for average sizes of polyplexes to be about 120−180 nm over a weight ratio of 2, which were thought to be appropriate sizes for gene transfer. Abrupt size increments of polyplexes due to hydrophobic interaction between polyplexes arising from charge neutralization were observed at a low weight ratio. Interestingly, although CLPAE and CLPAE-Lys polyplexes showed maximum sizes (370, 352 nm respectively) at a weight ratio of 1, CLPAE-Ahx was observed to have a maximum size (334 nm) at a lower weight ratio of 0.7, not 1. This means CLPAE-Ahx possessed a higher amine density and was able to condense DNA more compactly than the other

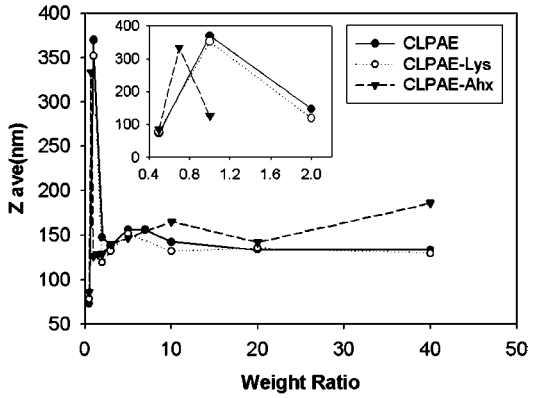

Figure 3. Average size measurements of polyplexes by Zetasizer. The inside box shows values at subdivided weight ratios ranging from 0.5 to 2.0.

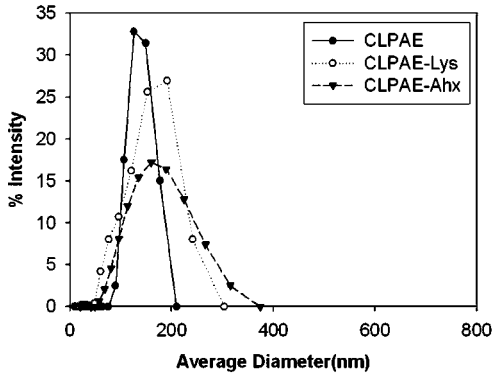

Figure 4. Average size distributions of the polyplexes at weight ratio of 20.

polymers synthesized, agreeing well with the amine quantification results.

Figure 4 shows the size distribution of each polyplex at a weight ratio of 20. CLPAE polyplexes were found to have a 97% population for a size range from 106 to 177 nm. Aggregates larger than 1 μm were not observed in any complexes. However, CLPAE-Lys and CLPAE-Ahx polyplexes were observed to have broader size distributions. It is considered that the irregularly modified polymer structure could lead to the formation of less homogeneous complexes with plasmid DNA. DLS results show that the polymers could form nanosized complexes with plasmid DNA having narrow size distributions.

Morphology of Polyplexes. The morphologies of polyplexes of the polymers were observed by AFM. Figure 5 shows AFM images of CLPAE polyplexes at various weight ratios ranging from 1 to 20. At a weight ratio of 1, CLPAE could not condense DNA completely (Figure 5A). Aggregates of 388−424 nm diameter and partially condensed DNA of irregular form were found. However, as the weight ratio of polymer increased to 10, they disappeared and compact sphere polyplexes of 125−190 nm size were observed (Figure 5B). Like CLPAE, CLPAE-Lys and CLPAE-Ahx showed compact spherical polyplex particles of about 80−200 nm size at a weight ratio of 20 (Figure 5C, 5D). These results agreed well with DLS data. The height of each polyplex was also determined to be 7−15 nm. As the weight ratio of polymer increased, the heights of polyplexes decreased. In general, a convolution of the imaging-tip's shape with the object's actual shape is known to affect the width of the object, while in such convolutions the height of the object is affected only by the compressibility of the object (*24*). So, it was

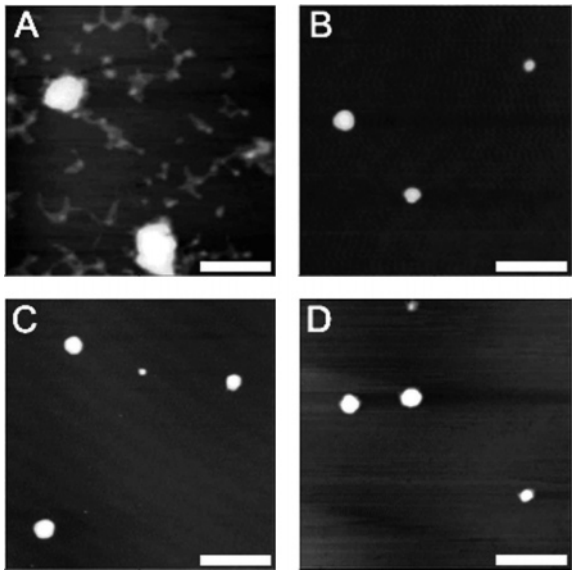

Figure 5. AFM images of the polyplexes. CLPAE: (A) weight ratio of 1, (B) 10, CLPAE-Lys: (C) 20, CLPAE-Ahx: (D) 20. The scale bars represent 1 μm.

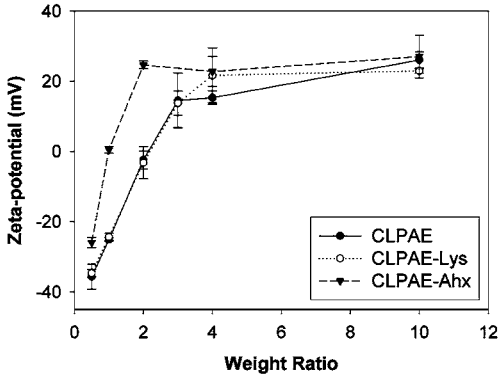

Figure 6. Zeta-potential measurements. Potential values are presented as the average value of 5 runs at 25 °C.

revealed that the polyplexes formed smaller and more compact particles as the weight ratio of polymer to DNA increased.

Zeta-Potential Measurements. Zeta-potentials of each polyplex were determined at various weight ratios. As shown in Figure 6, CLPAE and CLPAE-Lys polyplexes were found to have similar zeta-potential values at all weight ratios examined. They did not show positive values until the weight ratio was increased up to 2. However, the zeta-potential value of CLPAE-Ahx polyplex rose to almost the zero point even at a weight ratio of 1, and it showed a value of 24.6 ± 1.1 mV at 2. Because negative zeta-potential values of polyplexes were induced by phosphate anions of DNA of complex surfaces at low weight ratios where cationic polymers could not condense DNA completely, positive values of complexes mean the formation of stably compact complexes. Positively charged polyplexes are known to bind cellular membranes well, inducing endocytosis of the polyplexes (*25*). This result agreed well with our expectation and previous reports that a large number of CLPAE-Ahx-conjugated primary amines would lead to polyplex formation earlier than for tertiary amines of CLPAE.

In Vitro DNA Release Study. Linear types of biodegradable ester backbone polymers (PHPE, PAGA, etc.) were found to be decomposed in pH 7.4 solution within a few hours (*7*, *14*). This means biodegradable linear

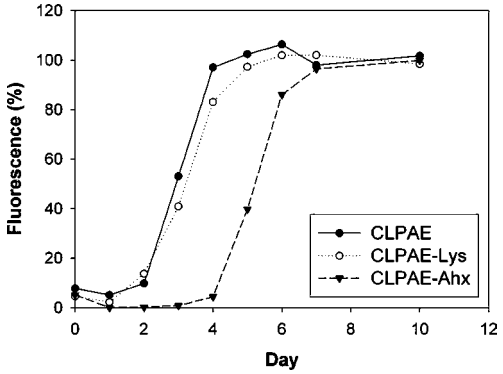

Figure 7. In vitro release profile of DNA from polyplexes by Picogreen reagent assay. Results are expressed in % fluorescence relative to control plasmid DNA.

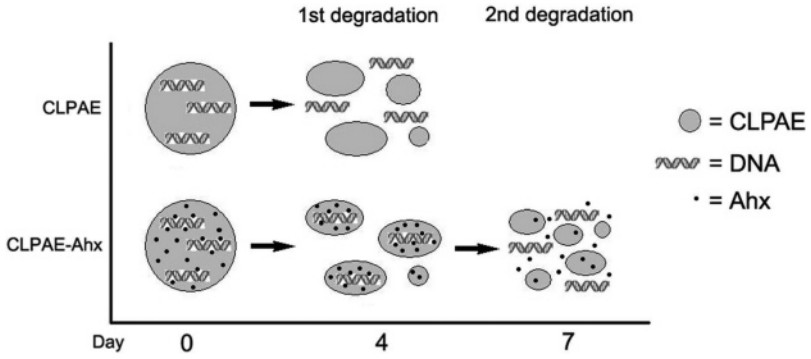
polymeric gene carriers would not be suitable for in vivo gene delivery for long-term applications. On the other hand, a cross-linked polyester polymer (n-PAE, etc.) showed a slower degradation rate and a prolonged DNA release profile in vitro, due to its structural property that one bond break could not cause a whole split of a polymer molecule directly (*21*). So, we designed a cross-linked poly(amino ester) polymer for gene delivery and examined the DNA release from polyplexes to confirm its merit.

In vitro DNA release was observed by PicoGreen assay, measuring the fluorescence quenching of DNA from polyplexes (Figure 7). We could not observe any significant increase in the fluorescence values of all polyplexes during the first 2 days. After 2 days, CLPAE and CLPAE-Lys/plasmid complexes showed gradual increases in DNA release values (53% and 41%, respectively, on day 3). CLPAE polyplex released almost 100% of the DNA by day 4, while, on the other hand DNA release reached 97% on day 5 in the case of CLPAE-Lys polyplex. However, CLPAE-Ahx polyplex was found to show a negligible value for DNA release until even day 4. On day 5, DNA release of CLPAE-Ahx polyplex increased to only 40% and reached 100% by day 7.

We confirm that these new cross-linked polymers are degraded more slowly than linear-type ester polymers and could release DNA outward polyplex in a more retained pattern, so, for long-term in vivo application, this type of polymer would have therapeutic merits. It may be due to the primary amines of the polymer binding with plasmid DNA more effectively that CLPAE-Ahx polyplex showed the most retained release profile among them.

Moreover, this result shows that DNA release due to the degradation of the polymers possibly would follow a stepwise mechanism (Scheme 2). During the time from day 2 to day 4 when the amount of DNA release rose to 100%, CLPAE backbone and tertiary amine moieties might be degraded and so CLPAE could not condense DNA anymore (first degradation step). Also, CLPAE-Ahx polyplex is thought to be under the same 'first degradation step' during this time. However, CLPAE-Ahx could condense plasmid DNA due to the primary amines of aminohexanoic acids after degradation, in contrast to CLPAE. Then, aminohexanoic acids of the polymer would be gradually degraded and cleaved from the polymer, inducing plasmid DNA release from day 4 to day 7 (second degradation step). We think that this stepwise degradation mechanism might result from the differences in the susceptibility to hydrolysis between the ester bonds of the CLPAE backbone and the ester linkages of

Scheme 2. The Degradation Mechanism of CLPAE and CLPAE-Ahx Polyplexes with Plasmid DNA



aminohexanoic acid to CLPAE. In the case of CLPAE-Lys, this effect was slight due to the polymer having fewer primary amines. Because primary amines of these 'self-destroying polymers' are thought to bind to DNA phosphates, not to attack ester bonds after forming polyplexes, the degradation rate of CLPAE-Ahx polyplex would be slower than that of CLPAE polyplex (*7*).

Cytotoxicity. Nontoxicity is one of the most important features for gene delivery carriers. In general, cytotoxicity is known to arise from the accumulation of nondegraded and nondischarged polymers in cells. So, many trials have been performed to reduce the toxicity of the gene carrier until now, which included the introduction of biodegradability to the polymer through such functionalities as ester, phosphoester, or disulfide bonds. Lim et al. reported that cationic polymers composed of ester backbone were barely toxic to mammalian cells (*8*, *21*).

We investigated the cytotoxicity of CLPAE, CLPAE-Ahx, and CLPAE-Lys by using MTT assay in 293 cells (Figure 8). The viability of 293 cells decreased abruptly according to an increase in the concentration of PEI, which shows the well-known cytotoxicity of PEI. CLPAE, CLPAE-Ahx and CLPAE-Lys provided favorable results. They showed about 80% cell viability even at a high concentration (50 μg/mL polymer concentration). This low toxicity may be due to the nontoxic building blocks and degradation products of polymers arising from a backbone of ester bonds. CLPAE-Ahx was found to show the lowest cell viability across the whole concentration range. It is thought that large numbers of primary amines of CLPAE-Ahx damage cells.

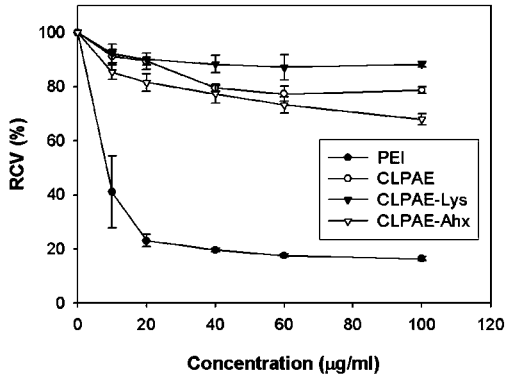


Figure 8. Cytotoxicity in 293 cells by MTT assay. Each data point represents the mean ± standard deviation ($n = 5$).

Transfection Efficiency (TE). The transfection abilities of CLPAEs were evaluated on three kinds of cell lines (293 human kidney transformed cells, C2C12 mouse myoblast cells, HepG2 human hepatocellular carcinoma cells), primary rat aorta vascular smooth muscle cells, and primary mouse embryonic fibroblast cells. PEI was used as the control for the standard gene carrier (*26*). As shown in Figure 9A, CLPAE showed very low TE but CLPAE-Ahx and CLPAE-Lys showed considerably enhanced TE compared with CLPAE on 293 cells. At the optimized weight ratio, TE of CLPAE-Ahx increased to 22 and 306 times over that of CLPAE in the absence and presence of serum, respectively. CLPAE-Lys also showed

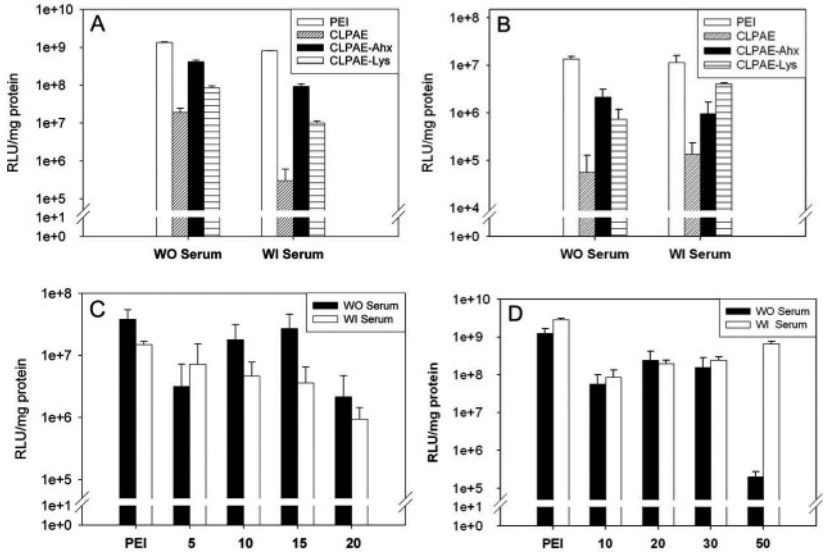

Figure 9. Transfection efficiencies of the polymers on 293 cells (A), C2C12 cells (B). (C and D) Transfection efficiency of CLPAE-Ahx on SMC and MEF cells, respectively. Numbers represent weight ratios.

enhanced TE (4−33 times that of CLPAE) although not by as much as for CLPAE-Ahx. We found similar enhancement effects on TE of CLPAE-Ahx and CLPAE-Lys as for CLPAE against C2C12 cells (Figure 9B). Fibroblast cells such as C2C12 are known to be hardly transfected, so the TE of PEI on C2C12 decreased to about 1% of TE on 293 cells. The TE of CLPAE-Ahx was enhanced 38 times more than that of CLPAE in the absence of serum. Although, interestingly, CLPAE-Lys showed an increase in its TE 30 times greater than CLPAE in the presence of serum, the existence of serum was found to reduce the TE of the polymers generally because cationic gene carriers possessing many positive charges are known to interact with negatively charged serum proteins (*27*, *28*).

The transfection efficiency of CLPAE was found to be much enhanced after coupling with aminohexanoic acid and lysine. Although CLPAE formed nanosized polyplexes having physicochemical properties very similar to those of CLPAE-Ahx and CLPAE-Lys with the exception of their having a slightly lower condensing ability, the TE of CLPAE was very low in the cell lines tested. This result suggests that a self-assembling ability with DNA to the compact nanoparticles simply could not lead to high transfection efficiency on cells. Therefore, primary amine residues such as aminohexanoic acid or lysine residue of CLPAE-Ahx and CLPAE-Lys are thought to certainly participate in the cellular uptake of polyplexes because CLPAE does not have primary amines but rather tertiary amines.

To examine applications on primary cells of CLPAE-Ahx showing generally the highest TE, transfection was carried out on the primary rat aorta vascular smooth muscle cells (SMC) and primary mouse embryonic fibroblast (MEF) cells. The accelerated proliferation of SMCs was reported to be a characteristic feature of atherosclerosis, or renarrowing of the artery (restenosis) after insertion of a stent within the artery wall for coronary artery disease (*29*, *30*). The mechanism of those two syndromes was partially understood but thought to be induced by the manifestation of genetic products such as platelet-derived growth factor (PDGF) (*31*). So, it could probably be a powerful tool for treating these diseases with gene therapy to deliver therapeutic genes with CLPAE-Ahx to vascular smooth muscle cells.

MEF cells are usually used as feeder cells to establish pluripotent embryonic stem (ES) cells. It is important to analyze the real functions of MEF cells and the secreted factors to influence ES cells within the culture system for establishment of a feeder-free culture environment (*32*). To study these through in vitro and ex vivo research, efficient delivery of various functional genes to MEF cells with CLPAE-Ahx could provide a useful tool.

As shown in Figure 9C and 9D, CLPAE-Ahx showed TE comparable to that of PEI on primary SMCs and MEF cells. It is due to higher expression level of pCN-Luci vector than pGL3 vector that TEs of polymers on MEF cells are much enhanced in contrast to those on SMCs. MEF cells showed sensitivity to cytotoxicity of PEI, so the TE of PEI was lower in the absence of serum than in the presence of serum contrary to transfection on other cells. Therefore, CLPAE-Ahx could be used for coronary artery diseases by in vivo gene delivery systems or research of primary MEF cell functions due to its high TE comparable to that of PEI on SMC and MEF cells and its low toxicity would ensure safe gene delivery.

CONCLUSION

We designed and synthesized a cross-linked poly(β-amino ester) for gene delivery to control its degradation rate and conjugated it with aminohexanoic acid or lysine to improve its transfection efficiency on mammalian cells. These CLPAE, CLPAE-Ahx, and CLPAE-Lys polymers showed great ability to form nanosized spherical polyplexes with DNA having narrow size distributions. Fulfilling our expectations, polyplexes of CLPAE-Ahx could release DNA even for a week through stepwise degradation. The polymers had low cytotoxicity in 293 cells. CLPAE-Ahx and CLPAE-Lys showed greatly enhanced transfection efficiencies in comparison to CLPAE on various cell lines, and the TE of CLPAE-Ahx is comparable to that of PEI on primary SMCs and MEF cells. It is evident that we could control the in vitro release rate of DNA by using cross-linked ester polymers, and the TE of polymeric gene carrier could be enhanced by conjugation with aminohexanoic acid or lysine. Therefore, CLPAE-Ahx has much potential as a nontoxic and efficient gene carrier.

Received January 19, 2005; Revised Manuscript Received July 1, 2005

In this paper we investigated the use of regioselectively addressable functionalized templates (RAFTs) as new scaffolds for the design of anticancer vaccine candidates. We report the synthesis of well-defined multiepitopic RAFT scaffolds and their immunological evaluation. These conjugates exhibit clustered Tn analogue as tumor-associated carbohydrate antigen (TACA, B-cell epitope) and the $CD4^+$ helper T-cell peptide from the type 1 poliovirus. The saccharidic and peptidic epitopes were both synthesized separately and combined regioselectively to the RAFT core using a sequential oxime bond formation strategy. B- and T-antigenicity and immunogenicity of the vaccine candidates were investigated in vitro and in vivo. These studies clearly demonstrate that the saccharidic part of the conjugates is recognized by Tn-specific monoclonal antibodies. Moreover, the antibodies elicited by immunization of mice with our vaccine candidates recognize the native form of Tn epitope expressed on human tumor cells. Together with oxime ligation technique, these results suggest that the RAFT scaffold provides a promising and suitable tool for engineering potent synthetic anticancer vaccine.

INTRODUCTION

Tumor-associated carbohydrate antigens (TACAs) such as Tn, TF, and sTn are overexpressed in clusters at the malignant cell surface in breast, prostate, lung, and pancreatic cancers (*1*−*5*). While these carbohydrate-based cancer antigens represent attractive targets for epithelial cancer immunotherapy (*6*−*10*), their weak immunogenicity remains critical for the design of efficient synthetic anticancer vaccines. A first generation of vaccines in which the TACAs are conjugated to an immunogenic carrier protein such as KLH (*6*, *11*−*17*), BSA, or OSA (*16*, *18*, *19*) has been developed few years ago. Particularly, a mucin-derived glycopeptide−KLH conjugate containing three Tn antigens designed by S. Danishefsky has been used in clinical trials as putative synthetic vaccine against prostate cancer (*16*). This approach has proved to induce an immune response specifically directed against the targeted tumors. However, in most cases the low level of the desired antibodies, due to the low molecular ratio of the TACA over the carrier protein, the resulting irrelevant response against the carrier, and the undefined composition of the molecule, represent major limitations for their use in cancer therapy.

An alternative class of fully synthetic vaccines based on peptide or lipopeptide cores (*20*−*23*) has been designed to circumvent some of these drawbacks. Especially, branched templates of accurate chemical definition such as dendrimeric lysine scaffolds, namely multiple antigen peptide (MAP) (*24*−*29*) or multiple antigen glycopeptide (MAG) (*25*, *30*), have been used as a nonimmunogenic carrier in which the B-cell antigens are radiated from the core to immunogenic T-cell helper peptides. This alternative has emerged considerable interests by presenting a high density of clustered antigens at the surface of a small peptidic scaffold as found for Tn antigen on tumors and eliciting also a strong specific antibody response (*31*, *32*). Indeed, MAG molecule exhibiting four copies of a $CD4^+$ T-cell epitope together with the tri-Tn glycotope presented high immunogenicity in mice (*32*) and in nonhuman primates (*33*) and afforded good protection in prophylactic and therapeutic vaccinations against the development of Tn-expressing tumor cells in mice. The humoral response was dominated by IgG antibodies supporting the notion that a T-cell dependent response was induced.

Following a similar approach, we investigated in this study the use of regioselectively addressable functionalized templates (RAFTs) (*34*), as new scaffolds for the design of anticancer vaccines. RAFTs are topological templates which are commonly composed of a backbone-cyclized decapeptide containing two proline-glycine as β-turns inducers (*35*) that stabilize their conformation in solution. They have found useful applications in the past as protein mimics (*36*−*39*) and more recently as vectors for neo-vasculature targeting in tumor therapy (*40*) or as cell surface mimics for multivalent presentation of carbohydrates (*41*, *42*). These cyclic templates should also provide a suitable tool for the multimeric presentation of B- and T-epitopes. Indeed they offer the advantages via lysinyl side chains of displaying two independent functional faces, one dedicated to the attachment of the TACA moieties in a multivalent manner and the

other to the T-cell peptide epitopes. We thus synthesized new multiepitopic neoglycoconjugates combining clustered Tn antigen analogue as TACA and T-cell epitope from the type 1 poliovirus as a $CD4^+$ T-cell epitope (Figure 1).

B- and T-antigenicity of our vaccine candidates RAFT-(4GalNAc,1PV)[1] **15a** and RAFT(4GalNAc,2PV) **15b** were finally investigated in vitro by ELISA and T-cell stimulation assays. Their immunogenicity was also studied in vivo by immunization of mice. Synthetic and biological results are reported in details in this paper.

EXPERIMENTAL PROCEDURES

Syntheses. Protected amino acids and Rink amide MBHA resin were purchased from France Biochem S.A. or Advanced ChemTech Europe. All chemical reagents and solvents were purchased from Sigma Aldrich, Fluka, Acros, or Carlo-Erba and were used without further purification. Analytical TLCs were performed on 0.2 mm silica 60 coated aluminum foils with F-254 indicator (Merck). Preparative column chromatographies were done using silica gel (Merck 60, 200−63 μm). Melting points were measured on an Electrothermal Series IA9100 apparatus. ^{1}H and ^{13}C NMR spectra were recorded on Bruker AC300 spectrometers and chemical shift (δ) are reported in parts per million (ppm). Spectra were referenced to the residual proton solvent peaks. The cyclic templates **12a**,**b** (*34*, *40*) and biotin sulfone (*43*) were prepared as previously described. Reverse phase HPLC analyses were performed on Waters equipment using C_{18} columns. The analytical (Nucleosil 120 Å 3 μm C_{18} particles, 30 × 4.6 mm^2) was operated at 1.3 mL/min and the preparative column (Delta-Pak 300 Å 15 μm C_{18} particles, 200 × 25 mm^2) at 22 mL/min with UV monitoring at 214 and 250 nm using a linear A−B gradient (buffer A: 0.09% TFA in water; buffer B: 0.09% TFA in 90% acetonitrile). Mass spectra were obtained by electron spray ionization (ES-MS) on a VG Platform II or by chemical ionization (CI-MS) on a Thermofinnigan Polaris Q in the positive mode.

[1] To facilitate the reading of this manuscript, we used a simplified nomenclature for the RAFT conjugates. For instance, RAFT(4GalNAc,1PV) **15a** denotes the RAFT presenting four GalNAc moieties on the upper face and one PV fragment on the other face.

3,4,6-Tri-*O*-acetyl-2-azido-2-deoxy-D-galactopyranosyl Fluoride (4). The glycosylfluoride **4** was prepared from **3** after azidonitration of the commercial 3,4,6-tri-*O*-acetyl galactal **1** (*44*) then denitration reaction (*45*) using the following procedure. Under inert gas, the compound **3** (4.36 g, 13.2 mmol) was dissolved in dry THF (116 mL) and the solution was cooled at −30 °C. Diethylaminosulfur trifluoride (2.08 mL, 15.8 mmol) was then added, and the solution was stirred at room temperature during 30 min. After addition of methanol (10 mL) at −30 °C, the solution was concentrated and taken up with dichloromethane. The organic layer was washed successively with saturated solution of $NaHCO_3$ then water, dried over sodium sulfate, and evaporated to get the compound **4** (4.30 g, 97%) as a colorless oil; ^{1}H NMR (300 MHz, $CDCl_3$) δ 5.71 (dd, $J_{1\alpha,2\alpha}$ = 2.6 Hz, $J_{1\alpha,F}$ = 52.2 Hz, H-1$_\alpha$), 5.48 (dd, $J_{4\alpha,5\alpha}$ = 1.2 Hz, $J_{3\alpha,4\alpha}$ = 3.2 Hz, H-4$_\alpha$), 5.36−5.34 (m, H-3$_\alpha$), 5.32 (td, $J_{4\beta,5\beta}$ = 1.1 Hz, $J_{3\beta,4\beta}$ = 3.3 Hz, H-4$_\beta$), 5.09 (dd, $J_{1\beta,2\beta}$ = 7.5 Hz, $J_{1\beta,F}$ = 51.8 Hz, H-1$_\beta$), 4.83 (ddd, $J_{3\beta,F}$ = 0.8 Hz, $J_{3\beta,4\beta}$ = 3.3 Hz, $J_{2\beta,3\beta}$ = 10.9 Hz, H-3$_\beta$), 4.36 (td, $J_{4\alpha,5\alpha}$ = 1.2 Hz, $J_{5\alpha,6\alpha}$ = 6.4 Hz, H-5$_\alpha$), 4.17−4.06 (m, H-6$_{\alpha,\beta}$), 3.96 (bt, $J_{5\beta,6\beta}$ = 6.3 Hz, H-5$_\beta$), 3.78 (ddd, $J_{1\beta,2\beta}$ = 7.5 Hz, $J_{2\beta,3\beta}$ = 10.9 Hz, $J_{2\beta,F}$ = 12.7 Hz, H-2$_\beta$), 3.78−3.68 (m, H-2$_\alpha$), 2.13−2.01 (6s, 6OCOCH$_3$); ^{13}C NMR (75 MHz, $CDCl_3$) δ 170.7 (C=O), 170.3 (C=O), 170.2 (C=O), 170.0 (C=O), 169.6 (C=O), 108.3 (d, $J_{C-1\beta,F}$ = 217 Hz, C-1$_\beta$), 106.2 (d, $J_{C-1\alpha,F}$ = 224 Hz, C-1$_\alpha$), 71.6 (C-5$_\beta$), 71.0 (d, $J_{C-3\beta,F}$ = 11 Hz, C-3$_\beta$), 69.5 (C-5$_\alpha$), 68.5 (C-3$_\alpha$), 67.2 (C-4$_\alpha$), 66.3 (C-4$_\beta$), 61.8 (C-6$_\alpha$), 61.5 (C-6$_\beta$), 61.2 (d, $J_{C-2\beta,F}$ = 22 Hz, C-2$_\beta$), 57.8 (d, $J_{C-2\alpha,F}$ = 24 Hz, C-2$_\alpha$), 21.0 (OCOCH$_3$), 20.9 (OCOCH$_3$), 20.8 (OCOCH$_3$). This product was used without further purification.

***O*-(3,4,6-Tri-*O*-acetyl-2-azido-2-deoxy-D-galactopyranosyl)-*N*-oxyphthalimide (5).** To a stirring solution in dichloromethane (200 mL) containing compound **4** (4.30 g, 13.0 mmol), *N*-hydroxyphthalimide (2.12 g, 13.0 mmol), and triethylamine (1.81 mL, 13.0 mmol) was added $BF_3{\cdot}Et_2O$ (3.52 mL, 65.0 mmol). The reaction was stirred at room temperature until completion (reaction monitored by thin-layer chromatography). After addition of dichloromethane (200 mL), the organic layer was washed several times with 10% aqueous sodium hydrogenocarbonate, dried under sodium sulfate, and evaporated. The alpha and beta anomers were finally separated by silica gel chromatography (dichloromethane/ethyl

acetate, 9/1) to give pure compound **5** (2.35 g, 38%) after crystallization from diethyl ether/pentane; mp 105−107 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.85−7.75 (m, 4 H, $H_{ar.}$), 5.57 (bd, 2 H, $J_{1,2} = J_{3,4} = 3.4$ Hz, H-1, H-4), 5.47 (dd, 1 H, $J_{1,2} = 3.4$ Hz, $J_{2,3} = 11.3$ Hz, H-3), 5.17 (bt, 1 H, $J_{5,6a} = 6.4$ Hz, H-5), 4.23 (dd, 1 H, $J_{5,6a} = 6.4$ Hz, $J_{6a,6b} = 11.3$ Hz, H-6a), 3.97−3.92 (m, 2 H, H-2, H-6b), 2.14, 2.06, 2.02 (3s, 9 H, $3OCOCH_3$); ^{13}C NMR (75 MHz, $CDCl_3$) δ 170.8 ($C{=}O_{Ac}$), 170.3 ($C{=}O_{Ac}$), 169.9 ($C{=}O_{Ac}$), 163.3 ($C{=}O_{Pht}$), 135.2 ($CH_{ar.}$), 129.1 ($C_{ar.}$), 124.2 ($CH_{ar.}$), 103.5 (C-1),69.2 (C-5), 68.2 (C-4), 67.7 (C-3), 61.6 (C-6), 57.0 (C-2), 21.1 ($OCOCH_3$); MS-ES (positive mode): calcd for $C_{20}H_{19}N_4O_{10}$-Na: 498.09 $[M + Na]^+$, found: 497.96. The corresponding beta anomer (3.09 g; 50%) was also obtained; mp 78−80 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ = 7.92−7.78 (m, 4 H, $H_{ar.}$), 5.37 (dd, 1 H, $J_{4,5} = 1.1$ Hz, $J_{3,4} = 3.3$ Hz, H-4), 5.03 (d, 1 H, $J_{1,2} = 8.4$ Hz, H-1), 4.89 (dd, 1 H, $J_{3,4} = 3.3$ Hz, $J_{2,3} = 10.7$ Hz, H-3), 4.20−4.13 (m, 2 H, H-6), 4.00 (dd, 1 H, $J_{1,2} = 8.4$ Hz, $J_{2,3} = 10.7$ Hz, H-2), 3.91 (td, 1 H, $J_{4,5} = 1.1$ Hz, $J_{5,6} = 6.9$ Hz, H-5), 2.18, 2.09, 1.97 (3s, 9 H, $3OCOCH_3$); ^{13}C NMR (75 MHz, $CDCl_3$) δ = 170.6 ($C{=}O_{Ac}$), 170.4 ($C{=}O_{Ac}$), 170.0 ($C{=}O_{Ac}$), 163.0 ($C{=}O_{Pht}$), 135.2 ($CH_{ar.}$), 129.1 ($C_{ar.}$), 124.3 ($CH_{ar.}$), 106.2 (C-1), 71.8 (C-5), 71.4 (C-3), 66.1 (C-4), 61.1 (C-6), 59.5 (C-2), 21.0 ($OCOCH_3$), 20.9 ($OCOCH_3$), 20.9 ($OCOCH_3$).

***O*-(2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranosyl)-*N*-oxyphthalimide (6).** To compound **5** (1.68 g, 3.5 mmol) dissolved in a solution of methanol/acetic anhydride (9/1, 40 mL) was added Pd/C 10% (0.38 g, 0.3 mmol). The mixture was stirred at room temperature under an atmosphere of hydrogen for 1 h. The catalyst was then removed by filtration under Celite and washed with methanol. After evaporation of the solvent under reduced pressure, the residue was finally purified by silica gel chromatography (dichloromethane/ethyl acetate, 4/1 then pure ethyl acetate) to afford *N*-acetylated derivative **6** (0.92 g, 53%) as a white powder after precipitation from dichloromethane/diethyl ether; mp 148−150 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.86−7.77 (m, 4 H, $H_{ar.}$), 6.07 (d, 1 H, $J_{2,NH} = 9.6$ Hz, NH), 5.54 (d, 1 H, $J_{3,4} = 3.0$ Hz, H-4), 5.38 (d, 1 H, $J_{1,2} = 3.4$ Hz, H-1), 5.34 (dd, 1 H, $J_{3,4} = 3.0$ Hz, $J_{2,3} = 11.3$ Hz, H-3), 5.08 (bt, 1 H, $J_{5,6} = 6.4$ Hz, H-5), 4.80 (ddd, 1 H, $J_{1,2} = 3.4$ Hz, $J_{2,NH} = 9.6$ Hz, $J_{2,3} = 11.3$ Hz, H-2), 4.30 (dd, 1 H, $J_{5,6} = 6.4$ Hz, $J_{6a,6b} = 11.3$ Hz, H-6a), 4.00 (dd, 1 H, $J_{5,6} = 6.4$ Hz, $J_{6a,6b} = 11.3$ Hz, H-6b), 2.18, 2.12, 2.09, 2.04 (4s, 12 H, $3OCOCH_3$, $NHCOCH_3$); ^{13}C NMR (75 MHz, $CDCl_3$) δ 171.2 (C=O), 135.2 ($CH_{ar.}$), 129.1 ($C_{ar.}$), 124.2 ($CH_{ar.}$), 105.4 (C-1), 71.5, 69.5, 67.7, 61.9 (C-3, C-4, C-5, C-6), 47.7 (C-2), 21.1 ($OCOCH_3$).

***O*-α-D-Galactopyranosyloxyamine (7).** The compound **6** (0.86 g, 1.7 mmol) was dissolved in a solution of ethanol/methylhydrazine (1/1, 10 mL) and stirred at room-temperature overnight. After evaporation of the mixture, the residue was purified by flash silica gel chromatography (dichloromethane/ethanol, 7/3 then pure ethanol) to obtain the pure aminooxylated product **7** (0.37 g, 90%) as a white powder; ^{1}H NMR (300 MHz, D_2O) δ 4.99 (d, 1 H, $J_{1,2} = 4.1$ Hz, H-1), 4.24 (dd, 1 H, $J_{1,2} = 4.1$ Hz, $J_{2,3} = 11.3$ Hz, H-2), 4.03−3.99 (m, 2 H, H-4, H-5), 3.89−3.76 (m, 3 H, H-3, H-6), 2.08 (s, 3 H, $HNCOCH_3$); ^{13}C NMR (75 MHz, D_2O) δ 175.0 ($HNCOCH_3$), 101.0 (C-1), 71.4, 68.8 (C-4, C-5), 68.0 (C-3), 61.5 (C-6), 49.6 (C-2), 22.3 ($HNCOCH_3$); MS-CI (positive mode): calcd for $C_8H_{17}N_2O_6$ 237.10 $[M + H]^+$, found: 237.1.

OHCOC-KLFAVWKITYKDT-NH_2 (11). The protected peptide sequence, precursor of peptide **10**, H-S(*t*Bu)K-(Boc)LFAVW(Boc)K(Boc)IT(*t*Bu)Y(*t*Bu)K(Boc)D(*t*Bu)T-(*t*Bu)-NH_2, was built up by Fmoc/*t*Bu strategy from 200 mg of Rink amide MBHA resin (substituted at ca. 0.61 mmol/g). Coupling steps were performed using 2 equiv of Nα-Fmoc-protected amino acid activated in situ with 2 equiv of PyBOP and 4 equiv of DIPEA in DMF (5 mL) for 40 min. Removal steps of Nα-Fmoc protecting groups were achieved by treatment with a piperidine/DMF solution (1/4, 5 mL) three times during 10 min. Finally, the peptide was recovered upon acid cleavage by a solution of TFA/TIS/H_2O/*p*-cresol 89/1/5/5 (5 mL x 30 min, three times). The cleavage solutions were concentrated under vacuum and the peptide H-SKLFAVWKITYKDT-NH_2 **10** was obtained as TFA salt (114 mg, 41%) after precipitation from ether and RP-HPLC purification (0 to 50% B in 30 min); $t_R = 8.3$ min (5 to 100% B in 15 min, 214 and 250 nm); ES-MS calcd for $C_{82}H_{127}N_{19}O_{20}$ (1699.0): *m/z* 850.3 $(M + 2H)^{2+}$, 567.3 $(M + 3H)^{3+}$. The serine oxidation of the peptide **10** (40 mg, 17.6 μmol) was carried out in a phosphate buffer 0.01 M pH 7.3 (2×10^{-3} M solution) using 1.5 equiv of $NaIO_4$ (5.6 mg) for 40 min. The solution was purified by RP-HPLC (5 to 100% B in 30 min) to afford the aldehyde **11** (31 mg, 83%) as a white salt; $t_R = 8.6$ min (5 to 100% B in 15 min, 214 and 250 nm); ES-MS calcd for $C_{81}H_{122}N_{18}O_{20}$ (1667.9): *m/z* 834.6 $(M + 2H)^{2+}$, 556.8 $(M + 3H)^{3+}$.

RAFT(4Ser,1$COCH_2ONH_2$)[1] (13a). Removal of Boc moieties from RAFT(4Boc,1Alloc) **12a** (360 mg, 0.240 mmol) was carried out in a solution containing 50% TFA in DCM (15 mL) for 1h at room temperature. The crude was concentrated, triturated and washed with diethyl ether to yield RAFT(4NH_2,1Alloc) as a white TFA salt (305 mg, 82%). This compound (295 mg, 0.19 mmol) was dissolved in 20 mL of DMF, BocSer(*t*Bu)OH (198 mg, 0.76 mmol), and PyBOP (394 mg, 0.76 mmol) were added and the pH was adjusted to 8−9 by adding DIPEA (198 μL, 1.14 mmol). The solution was stirred 2 h at room temperature, the solvent was removed, and diethyl ether was added to precipitate the RAFT(4BocSer(*t*Bu),1Alloc)-used without further purification (275 mg, 70%); $t_R = 14.8$ min (5 to 100% B in 15 min, 214 nm); ES-MS calcd for $C_{99}H_{173}N_{19}O_{28}$ (2077.6): *m/z* 1039.7 $(M + 2H)^{2+}$, 693.3 $(M + 3H)^{3+}$. Alloc group was removed from the crude (0.13 mmol) dissolved in 20 mL of dry DCM/THF (10/1) under argon by adding $PhSiH_3$ (583 μL, 3.25 mmol) and then $Pd(PPh_3)_4$ (55 mg, 0.03 mmol) for 1 h. The solution was filtrated on C_{18} silica gel, the filtrate was evaporated and precipitated in ether to get after purification (5 to 100% B in 30 min) the RAFT(4BocSer(*t*Bu),1NH_2) (231 mg, 84%); $t_R = 13.4$ min (5 to 100% B in 15 min, 214 nm); ES-MS calcd for $C_{95}H_{169}N_{19}O_{26}$ (1993.5): *m/z* 1993.9 $(M + H)^+$, 997.5 $(M + 2H)^{2+}$. To a solution of RAFT(4BocSer-(*t*Bu),1NH_2) (60 mg, 28 μmol) in 10 mL of DMF, $BocNHOCH_2CO_2Su$ (10 mg, 34 μmol) was added and DIPEA (12 μL, 68 μmol) to adjust the pH at 8−9. The reaction was stirred for 45 min at room temperature and then concentrated under reduce pressure. The crude RAFT(4BocSer(*t*Bu),1$COCH_2ONHBoc$) was obtained (49 mg, 81%) as a white powder after precipitation and washing with diethyl ether; $t_R = 14.6$ min (5 to 100% B in 15 min, 214 nm). Removal of Boc and *t*Bu moieties were achieved by treatment with 10 mL of a solution of TFA/TIS/H_2O 95/2.5/2.5 for 2 h. Evaporation of solvent and precipitation in diethyl ether afforded the template RAFT(4Ser,1$COCH_2ONH_2$) **13a** (40 mg, 87%); $t_R = 5.6$ min (5 to 100% B in 15 min, 214 nm); ES-MS calcd for $C_{61}H_{108}N_{20}O_{20}$ (1441.6): *m/z* 721.3 $(M + 2H)^{2+}$, 481.2 $(M + 3H)^{3+}$, 361.2 $(M + 4H)^{4+}$.

RAFT(4Ser,2$COCH_2ONH_2$) (13b). The same procedure applied from **12b** (100 mg, 0.06 mmol) allowed to get the intermediate RAFT(4BocSer(*t*Bu),2NH_2) (60 mg,

0.03 mmol) in 43% overall yield. t_R = 12.5 min (5 to 100% B in 15 min, 214 nm). The RAFT(4BocSer(*t*Bu),2NH_2) gave, after coupling of Boc$NHOCH_2CO_2Su$ and Boc and *t*Bu removals, the peptide **13b** (40 mg, 0.018 mmol) in 68% yield. t_R = 5.5 min (5 to 100% B in 15 min, 214 nm); ES-MS calcd for $C_{66}H_{118}N_{22}O_{22}$ (1571.8): *m/z* 786.4 $(M + 2H)^{2+}$, 524.7 $(M + 3H)^{3+}$, 393.2 $(M + 4H)^{4+}$.

RAFT(4Ser,1PV) (14a). RAFT(4Ser,1$COCH_2ONH_2$) **13a** (16 mg, 7.9 μmol) and PV aldehyde **11** (16.8 mg, 7.9 μmol) were ligated in 5 mL of sodium acetate buffer 0.1 M pH 4. After 24 h under stirring the mixture was purified by RP-HPLC (5 to 40% B in 30 min) and the RAFT(4Ser,1PV) **14a** was obtained as a white powder (25 mg, 78%); t_R = 10.9 min (5 to 60% B in 15 min); ES-MS calcd for $C_{142}H_{228}N_{38}O_{39}$ (3091.6): *m/z* 1546.5 $(M + 2H)^{2+}$, 1031.3 $(M + 3H)^{3+}$, 773.8 $(M + 4H)^{4+}$, 619.3 $(M + 5H)^{5+}$.

RAFT(4Ser,2PV) (14b). The same procedure was applied from RAFT(4Ser,2$COCH_2ONH_2$) **13b** (12 mg, 5.3 μmol) and an excess of PV aldehyde **11** (34 mg, 16 μmol). The excess of **11** was trapped by adding benzyloxyamine and the mixture was purified by RP-HPLC (0 to 50% B in 40 min) to yield **14b** (24 mg, 72%); t_R = 14.4 min (0 to 50% B in 15 min, 214 and 250 nm). ES-MS calcd for $C_{228}H_{358}N_{58}O_{60}$ (4871.7): *m/z* 1624.4 $(M + 3H)^{3+}$, 1218.8 $(M + 4H)^{4+}$, 975.3 $(M + 5H)^{5+}$, 812.9 $(M + 6H)^{6+}$, 696.9 $(M + 7H)^{7+}$, 609.9 $(M + 8H)^{8+}$, 542.3 $(M + 9H)^{8+}$.

RAFT(4GalNAc,1PV) (15a). The RAFT(4Ser,1PV) **14a** (10.5 mg, 3.4 μmol) was oxidized using a polymer supported periodate (2.5 μmol/mg, 19.75 μmol) in phosphate buffer (0.01 M, pH 7.3) for 5 h. The mixture was filtered to remove the polymer-resin and purified to yield RAFT(4COCHO,1PV) (8.7 mg, 86%) (5 to 40% B in 30 min). t_R = 11.4 min (5 to 60% B in 15 min, 214 and 250 nm). RAFT(4COCHO,1PV) (8.7 mg, 2.9 μmol) and αGalNAc-ONH_2 sugar **7** (6.4 mg, 27 μmol) were stirred in sodium acetate buffer (0.1 M, pH 4) for 36 h and the solution was purified by RP-HPLC (15 to 45% B in 45 min) to afford the RAFT(4GalNAc,1PV) **15a** (7.4 mg, 66%); t_R = 11.3 min (15 to 45% B in 15 min, 214 and 250 nm); ES-MS calcd for $C_{170}H_{264}N_{42}O_{59}$ (3840.2): *m/z* 1920.6 $(M + 2H)^{2+}$, 1280.7 $(M + 3H)^{3+}$, 970.3 $(M + K+3H)^{4+}$, 776.5 $(M + K + 4H)^{5+}$.

RAFT(4GalNAc,2PV) (15b). The RAFT(4Ser,2PV) **14b** (15 mg, 2.4 μmol) was oxidized using the same procedure to afford after purification (5 to 100% B in 30 min) RAFT(4COCHO,2PV) (11.8 mg, 87%); t_R = 9.1 min (5 to 100% B, 15 min, 214 and 250 nm). RAFT(4COCHO,2PV) (10 mg, 1.76 μmol) and 8 equiv of αGalNAc-ONH_2 **7** (3.3 mg, 14 μmol) were stirred in 1 mL of sodium acetate buffer (0.1 M, pH 4) for 40 days. The mixture was purified by RP-HPLC (15 to 45% B in 30 min) and **15b** (7.2 mg, 63%) was obtained as a white lyophilisat; t_R = 13.7 min (15 to 45% B in 15 min, 214 and 250 nm); ES-MS calcd for $C_{256}H_{394}N_{62}O_{80}$ (5620.4): *m/z* 1405.4 $(M + 4H)^{4+}$, 1124.7 $(M + 5H)^{5+}$, 937.5 $(M + 6H)^{6+}$.

RAFT(4Ser,1Biotin) (16). The biotin sulfone (10.6 mg, 38 μmol) was coupled on the template RAFT-(4BocSer(*t*Bu),1NH_2) (40 mg, 19 μmol) using PyBOP as activating agent (20 mg, 38 μmol), and DIPEA (20 μL, 114 μmol) in 6 mL of DMF. After 3 h under stirring, the solvent was concentrated and the crude product precipitated from diethyl ether. It was triturated and washed several times in ether to afford the intermediate RAFT-(4BocSer(*t*Bu),1Biotin) (30 mg, 70%) after purification (5 to 100% B in 30 min); t_R = 13.3 min (5 to 100% B in 15 min, 214 nm); ES-MS calcd for $C_{105}H_{183}N_{21}O_{30}S$ (2251.8): *m/z* 1126.9 $(M + 2H)^{2+}$, 751.3 $(M + 3H)^{3+}$. Removal of Boc and *t*Bu protecting groups were achieved by treatment with 10 mL of TFA for 2 h. Evaporation of solvent and precipitation with diethyl ether allowed to get the RAFT(4Ser,1Biotin) **16** (24 mg, 86%) after purification (5 to 40% B in 40 min); t_R = 6.1 min (5 to 100% B in 15 min, 214 nm); ES-MS calcd for $C_{69}H_{119}N_{21}O_{22}S$ (1626.9): *m/z* 814.0 $(M + 2H)^{2+}$, 543.2 $(M + 3H)^{3+}$.

RAFT(4Glc,1Biotin) (17) and RAFT(4GalNAc,1-Biotin) (18). The serine oxidation of **16** (20 mg, 9.6 μmol) was carried out in 1 h using 4.8 equiv of $NaIO_4$ (10 mg) in 5 mL of water. The solution was directly purified by RP-HPLC (0 to 50% B in 30 min) to afford the RAFT-(4COCHO,1Biotin) (12 mg, 83%); t_R = 8.9 min (0 to 50% B in 15 min, 214 nm). To a solution containing the intermediate RAFT(4COCHO,1Biotin) (6 mg, 4 μmol) in 2 mL of sodium acetate buffer (0.1 mM, pH 4) was added the βGlc-ONH_2 derivative **9** (6.3 mg, 32 μmol) or the αGalNAc-ONH_2 **7** (7.5 mg, 32 μmol). The reactions followed by RP-HPLC were placed under stirring at room temperature for 24 h. Conjugates RAFT(4Glc,1Biotin) **17** (5.3 mg, 66%) and RAFT(4GalNAc,1Biotin) **18** (6.3 mg, 60%) were isolated after RP-HPLC purification (0 to 50% B in 30 min) as white powders; **17**: t_R = 9.2 min (0 to 50% B in 15 min, 214 and 250 nm); ES-MS calcd for $C_{89}H_{143}N_{21}O_{42}S$ (2211.3): *m/z* 1106.5 $(M + 2H)^{2+}$; **18**: t_R = 9.1 min (0 to 50% B in 15 min, 214 and 250 nm); ES-MS calcd for $C_{97}H_{155}N_{25}O_{42}S$ (2375.5): *m/z* 1188.8 $(M + 2H)^{2+}$, 792.4 $(M + 3H)^{3+}$.

ELISA and Flow Cytometry. The antigenicity of the RAFT(4GalNAc,1Biotin) **18** was assessed by ELISA using two monoclonal antibodies specific for the Tn antigen, the 83D4 (IgM; kindly given by Dr. E. Osinaga, Facultad de Medicina, Montevideo, Uruguay) and the 6E11 (IgG3; produced in our lab (unpublished data)). RAFT-(4Ser,1Biotin) **16** and RAFT(4Glc,1Biotin) **18** were used as control for specificity. The immunogenicity of the RAFT compounds was assessed in BALB/c mice (CER Janvier, Le Genest St Ile, France). For this purpose, mice were ip immunized with the different RAFTs containing one and two PV sequences **15a**,**b** and **14a**,**b** in alum. Various times after immunization sera were collected and tested for IgG antibodies by ELISA using RAFT-(4GalNAc,1Biotin) **18** or RAFT(4Ser,1Biotin) **16**. Serial dilutions of sera were performed and bound antibodies were revealed using goat anti-mouse IgG peroxidase conjugate (Sigma, St. Louis, MO) and *O*-phenyldiamine/H_2O_2 substrate. Plates were read photometrically at 492 nm in an ELISA auto-reader (Dynatech, Marnes la Coquette, France). The negative control consisted of naive mouse sera diluted 100-fold. ELISA antibody titers were determined by linear regression analysis, plotting dilution versus absorbance at 492 nm. The titers were calculated to be the Log_{10} highest dilution which gave twice the absorbance of normal mouse sera diluted 1/100. Titers are given as the arithmetic mean ± SD of the Log_{10} titers. Sera were also tested at 1/50 dilution by flow cytometry for recognition of Tn-expressing human Jurkat tumor cell line. Cells were first incubated for 30 min with serial dilutions of sera at 4 °C in PBS containing 5% fetal calf serum and 0.05% sodium azide. Then, cells were incubated for 30 min with an anti-mouse IgG conjugated to phycoerythrin (Caltag, Burlingame, CA). Cells were analyzed using a FACScan flow cytometer (Becton Dickinson, Mountain View, CA), and data analysis was performed with CellQuest software (Becton Dickinson). The data are shown as histograms corresponding to the fluorescence of cells incubated with the secondary reagent alone or together with sera.

T-Cell Assays. The recognition by specific T-cells of the poliovirus T-cell epitope contained in the RAFT-

(4Ser,1PV) **13a** and the RAFT(4GalNAc,1PV) **15a** was analyzed using a specific T-cell hybridoma and bone marrow-derived dendritic cells as antigen-presenting cells. T-cell hybridomas (10^5) were cultured with dendritic cells (10^5) in the presence of the RAFT at several concentrations for 24 h in RPMI 1640 supplemented with 10% FCS, antibiotics, L-glutamine, and mercaptoethanol. Interleukin 2 production by hybridoma T-cells was assessed by the measure of the proliferative response of the interleukin 2-dependent CTLL cell line using [^{3}H]-thymidine.

RESULTS AND DISCUSSION

Design of the Vaccine Candidates. Taking advantages of the synthetic versatility of the RAFT platform, we designed our vaccine candidates **15a** and **15b** so that to mimic through one domain of the template the clustering of the mucin-associated Tn antigen (Figure 1) which characterizes the surface of epithelial tumors (*4*, *5*). We assembled regioselectively on the other domain a peptide fragment from poliovirus in order to stimulate $CD4^+$ T-cells and activate the production of specific antibodies for the TACA by B-cells (Figure 1). We chose the peptide fragment KLFAVWKITYKDT from the type I-poliovirus protein since it previously proved to provide efficient T-cell help for the induction of antibody responses in BALB/c mice (*31*).

One critical aspect of our approach focuses on controlling the molecular assembly processes which are essential to warrant the structure of the target molecule. While many chemical methodologies including solution and solid-phase synthesis protocols have been reported so far, the assembly of carbohydrate-based bioconjugates remains fastidious due to numerous manipulations of orthogonal protecting groups (*46*−*49*). As an attractive synthetic alternative, we and other have demonstrated recently that chemoselective ligation via oxime or polyoxime bond formation offers a convenient strategy for the convergent assembly of bioconjugates (*40*−*42*, *50*−*59*). Indeed, this ligation technique is highly efficient, compatible with a wide range of chemical functions and allows the ligation between unprotected fragments in minimal chemical transformations without any coupling reagent. Moreover, the oxime linkage has been shown to be stable under physiological conditions (*51*, *60*), and its use for ligation of peptide epitopes in vaccines has been found advantageous (*61*−*63*).

Such oxime-based strategy requires the synthesis of the RAFT molecule, bearing serine residues as masked glyoxylyl aldehyde functions on the upper domain and protected aminooxy groups on the other domain, and of the B/T-epitopes displaying the suitable complementary functions. For this purpose, we prepared the aminooxylated αGalNAc moiety **7** as a carbohydrate analogue of the native Tn form (αGalNAcSer/Thr) in mucin glycoproteins (*1*−*3*). Since it was previously attested that other carbohydrate-based Tn analogues present similar antigenicity as the native antigen (*21*, *64*−*66*), we expected that this modification should not affect the immunological properties of our constructions. Especially, a vaccine bearing an *O*-aliphatic aglycone instead of natural amino acid carrier has proved to be more antigenic than the natural Tn-based conjugate (*67*). In the case of the PV fragment moiety, this one was functionalized by an *N*-terminal aldehyde spacer prior to its grafting to the RAFT template.

Synthesis of the Aminooxylated Tn Analogue 7 and Glucose 9. The Tn analogue (αGalNAc-ONH_2) **7** containing an aminoxy group at its anomeric position has been synthesized according to the previously published procedure (Scheme 1A) (*68*). Starting from the commercial triacetylated galactal **1**, the azidonitration reaction described by R. U. Lemieux and R. M. Ratcliffe (*44*) followed by the anomeric denitration of compound **2** with sodium nitrite in aqueous dioxane at 80 °C (*45*) gave **3**. Treatment of **3** with DAST in THF (*69*) provided glycosyl fluoride **4** which was glycosylated in CH_2Cl_2 with *N*-hydroxyphthalimide as precursor of the aminooxy function using $BF_3{\cdot}Et_2O$ as a promoter in the presence of triethylamine. The alpha and beta anomers were easily separated by silica gel chromatography to obtain **5** in 50% yield (38% for the beta anomer). The azido group was then converted into the NHAc function by a catalytic hydrogenation in CH_3OH/Ac_2O to get **6**. After complete acetate deprotection and aminooxy formation with methylhydrazine, we obtained the alpha aminooxylated Tn antigen **7** in 90% yield. The aminooxylated β-glucose **9** was obtained following the phase-transfer catalysis pro-

cedure described by R. Roy from the activated derivative **8** (Scheme 1B) (*70*).

Synthesis of the T-Cell PV Epitope Aldehyde 11. The minimal $CD4^+$ T-cell epitope sequence from the poliovirus type 1, KLFAVWKITYKDT, corresponds to the 103−115 amino acid sequence that is immunogenic in BALB/c mice. We have introduced a serine residue at the N-terminal position to access to the aldehyde function after oxidation. The targeted sequence H-SKLFAVWKI-TYKDT-NH_2 **7** was built up by standard Fmoc/*t*Bu strategy from the Rink amide MBHA resin using PyBOP as coupling reagent and diisopropylethylamine (DIPEA) as base. We obtained the fully unprotected peptide **10** in 41% overall yield after removal from the resin and reverse phase HPLC purification (Scheme 2). An adapted oxidation procedure was used for the sodium periodate oxidation of the serine residue due to the presence of tryptophane. We carried out the reaction in phosphate buffer at pH 7.3, and the peptide aldehyde **11** was obtained in 83% yield.

Synthesis of the RAFT Scaffolds 13a,b. The chemoselective oxime-based strategy requires the appropriate RAFT cores **13a** or **13b** to combine the PV aldehyde **11** and the aminooxy sugars **7** and **9**. These key intermediates **13a**,**b** present two distinct domains, one bearing aminooxy acetyl sites to ligate the PV sequence and the other bearing four serine residues allowing the combination with the sugar moieties after an oxidation step. They have been prepared (Scheme 3) from the corresponding cyclic scaffolds **12a** and **12b** (*34*, *40*) presenting Alloc and Boc orthogonal protecting groups at the lysinyl side chains. The removal of Boc groups from the four lysine residues was first achieved in acidic conditions (50% of TFA in CH_2Cl_2) and followed by the coupling of protected serine BocSer(*t*Bu)OH residues using standard coupling conditions. The aminooxyacetyl moieties were incorporated on the other face as *N*-Boc-*O*-(carboxymethyl)hydroxylamine succinimide ester (*71*)

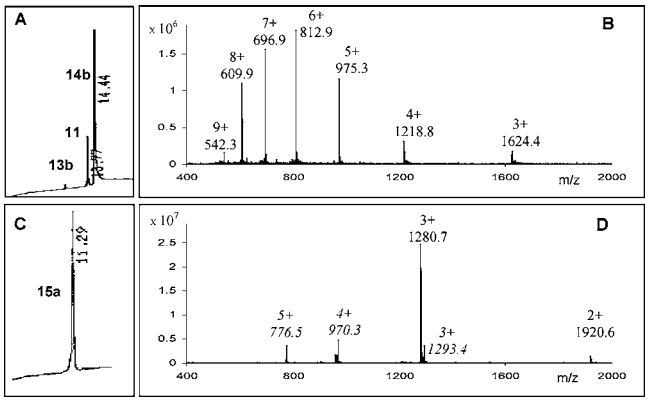

Figure 2. (A) HPLC profile (Nucleosil 100 Å 5 μm C_{18} particles, 250 × 4.6 mm; solvent B: 0.09% TFA in 90% acetonitrile and solvent A: 0.09% TFA; 1.3 mL/min; linear gradient 100:0 A:B to 50:50 in 15 min; detection $\lambda = 214$ and 250 nm) of the reaction mixture **14b** after 20 h (the RAFT core **13b** is completely consumed after 24 h); (B) ES-MS (positive mode) of **14b** after purification; (C) HPLC profile (linear gradient 85:15 A:B to 55:45 A:B in 15 min; detection $\lambda = 214$ and 250 nm) of the reaction mixture **15a** after 36 h; (D) ES-MS (positive mode) of **15a** after purification: numbers in italics correspond to the potassium adducts.

after the removal of the Alloc groups using $Pd(PPh_3)_4$/$PhSiH_3$ procedure (*72*). Further removal of the Boc and *t*Bu from the serine and aminooxyacetyl residues gave the appropriate templates **13a** and **13b** in 72% and 68% yields, respectively.

Regio/chemoselective Assembly of the Vaccine Candidates 15a and 15b. We prepared vaccine candidates bearing four copies of the Tn analogues and one or two copies of the T-cell epitope sequence to determine whether we could further increase the immunogenicity of our vaccines. The ligation of the T-cell peptide fragment **11** and αGalNAc-ONH_2 **7** were carried out by consecutive oxime bond formation (Scheme 3). PV alde-

Scheme 4. Synthesis of Biotinylated Compounds 16−18[a]

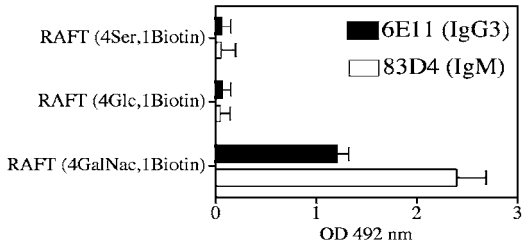

Figure 3. Antigenicity of the RAFT bearing the Tn antigen analogue. 6E11 (IgG3) and 83D4 (IgM) monoclonal antibodies specific for the tumor-associated Tn carbohydrate antigen were tested by ELISA for the recognition of RAFT(4GalNAc,1Biotin) **18**, RAFT(4Glc,1Biotin) **17** or RAFT(4Ser,1Biotin) **16** directly coated on microtiter plates. Error bars refer to the standard error to the mean of triplicate measures.

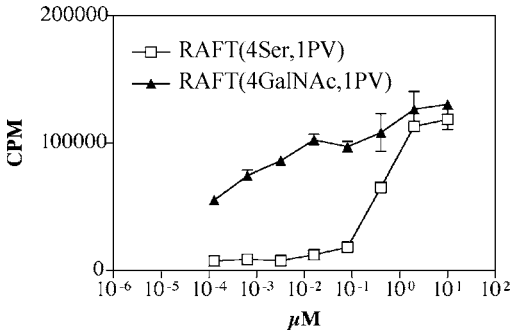

Figure 4. Activation of a PV-specific T-cell hybridoma by the PV-containing RAFTs **14a** and **15a** in the presence of antigen-presenting cells. T-cell hybridoma were cultured with dendritic cells in the presence of the indicated RAFTs at different doses. Interleukin-2 secretion following T-cell hybridoma stimulation was assessed by the proliferation of the interleukin 2-dependent CTLL cell line using [^{3}H]-thymidine. Error bars refer to the standard error to the mean titer of 5 individual sera.

hyde **11** was first assembled to the cores **13a** and **13b** in sodium acetate buffer following the typical chemoselective ligation procedure we previously described (*40*−*42*). The progress of the reactions was monitored by RP-HPLC, and no significant difference of reactivity was noticed between the templates **13a** and **13b**. The completeness of the coupling reaction required up to 24 h to give cleanly mono- and bivalent compounds **14a** and **14b** which have been fully characterized by ES-MS (Figure 2A,B). These conjugates **14a**,**b** bearing serine residues have been used as reference compounds in immunological assays. After liberation of the four aldehyde functions by sodium periodate oxidation of serine moieties, the aminooxylated Tn antigen **7** was incorporated through the same chemoselective coupling conditions. As we expected, the crude reaction mixtures were clean confirming the high efficiency of the chemoselective ligation method (Figure 2C,D). The conjugates **15a**,**b** were finally isolated in almost 65% yield after semipreparative HPLC purification.

Synthesis of Biotinylated Glycoconjugates. Several compounds presenting a biotin moiety instead of the PV fragment on the lower face of the core have also been synthesized for the ELISA tests. The conjugates **16**, **17**, and **18** (Scheme 4) bearing serine, β-Glc, or α-GalNAc residues, respectively, have been used as reference compounds to assess the specificity of the immune response. They were prepared from the intermediate displaying four protected serine residues and one unprotected lysine site for biotin attachment. While preliminary experiments have shown that biotins are partially oxidized during the oxidative cleavage of serines, we decided to incorporate biotin sulfone (*43*) to get well-defined conjugates. The biotin was directly coupled using amide linkage to get **16** after removal of Boc and *t*Bu protecting groups of serine. Oxidation of **16** and further ligation of aminooxy sugars α-GalNAc-ONH_2 **7** and β-Glc-ONH_2 **9** afforded the glycoconjugates **18** and **17** in 60 and 66% yield, respectively.

B-Cell Antigenicity. We first investigated by ELISA the ability of the GalNAc moiety incorporated into the RAFT platform to be recognized by monoclonal antibodies (mAbs) specific for the Tn antigen. The two anti-Tn mAbs, an IgG3 (6E11) and an IgM (83D4), were both able to interact with the RAFT(4GalNAc,1Biotin) **18**, but not with the RAFT(4Ser,1Biotin) **16** or the RAFT(4Glc,1Biotin) **17** (Figure 3). This clearly demonstrates that the recognition is directed specifically toward the carbohydrate moiety of compound **18**.

These results also give an accurate view of the display of TACA at the RAFT surface for antibody recognition. The recognition of RAFT(4GalNAc,1Biotin) by these antibodies indicates that the multimeric presentation in the RAFT system is able to mimic the carbohydrate part of the repeated glycosylated serine/threonine unit found on natural tumor-associated mucins. Therefore, our unnatural Tn analogues represent suitable models for humoral stimulation as other reported analogues (*64*−*67*).

T-Cell Antigenicity. To elicit an IgG humoral response, an efficient presentation of the T-cell epitope by MHC II molecules on the antigen-presenting cells (APC) surface is required for T-cell stimulation. Therefore, we analyzed in vitro by a T-cell stimulation assay the recognition of the PV epitope when incorporated into the

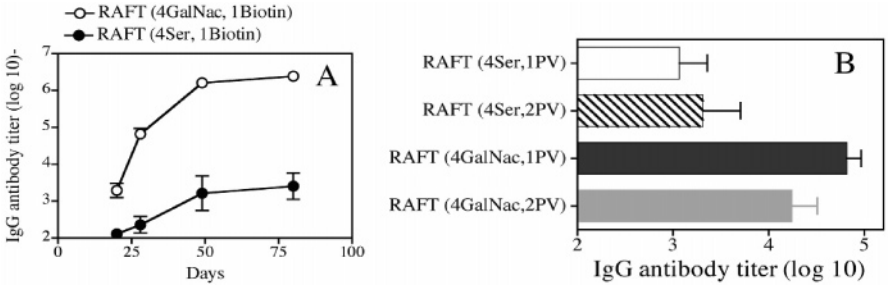

Figure 5. Immunogenicity of the RAFT displaying the Tn analogue. (A) BALB/c mice ($n = 5$) were immunized on days 0, 21 and 42 with 10 μg of RAFT(4GalNAc,1PV) **15a** in alum. Mice were then bled at various times after immunization. Sera from these mice were analyzed by ELISA for antibody titers against RAFT(4GalNAc,1Biotin) **18** or RAFT(4Ser,1Biotin) **16** as indicated. (B) Mice were immunized on days 0 and 21 with 10 μg of RAFT(4GalNAc,1PV) **15a**, RAFT(4GalNAc,2PV) **15b**, RAFT(4Ser,1PV) **14a** or RAFT-(4Ser,2PV) **14b**. Sera collected at day 28 were analyzed for antibody titers against RAFT(4GalNAc,1Biotin) **18**. Results are expressed as mean of log10 IgG antibody titers.

RAFT core. Dendritic cells were incubated with the RAFT(4GalNAc,1PV) **15a** or the RAFT(4Ser,1PV) **14a** in the presence of a PV-specific T-cell hybridoma. Secreted interleukin-2 (IL-2) was determined in a radioactive proliferation assay by measuring the incorporation of [^{3}H]-thymidine by the IL-2 dependent CTLL cell line (Figure 4). IL-2 secretion by activated T-cell hybridoma following the recognition of peptide-MHC II complexes on the dendritic cell surface by T-cell receptors (TCR) correlates with the incorporation of [^{3}H]-thymidine by CTLL cells.

As shown in Figure 4, both the unglycosylated **14a** and the glycosylated **15a** conjugates stimulate the PV-specific T-cell hybridoma. This indicates that despite being ligated in an unnatural way the T-cell determinant is efficiently presented by APC to CD4$^+$ T-cells. The response (IL-2 production) induced by the RAFT **15a** was dramatically enhanced at significantly lower doses compared to the response obtained with the unglycosylated RAFT **14a**. Indeed, T-cell stimulation was obtained with about 10 000-fold less RAFT **15a** dose compared to the RAFT **14a**, suggesting that the presence of the Tn antigen increases the presentation of the PV peptide by MHC class II molecules. This result further confirms previous observations on the enhanced T-cell stimulation induced by peptides bearing the Tn antigen (*31*, *64*). Although the mechanism underlying this phenomenon is unclear, it may strongly benefit to the glycosylated RAFT **15a** for stimulating immune responses.

Immunogenicity. We next evaluated the immunogenicity of our RAFT constructs exhibiting one or two copies of PV peptide in BALB/c mice. The RAFT(4GalNAc,1PV) **15a** was first used to immunize mice and to elicit Tn-specific IgG antibodies. Indeed, sera from immunized mice and tested by enzyme-linked immunosorbent assay against biotinylated conjugates were able to strongly recognize the RAFT(4GalNAc,1Biotin) **18** (Figure 5A).

Only 0.1−1% of the antibodies raised by the RAFT-(4GalNAc,1PV) **15a** recognized the RAFT devoid of the GalNAc moiety (i.e. RAFT(4Ser,1Biotin) **16**) demonstrating a limited reactivity against the RAFT platform. These results confirm the ability of the cyclic template as nonimmunogenic carrier for vaccine constructs which is in good agreement with a previous study (*39*).

To determine whether we could further increase the immunogenicity of our conjugates, the antibody response induced by the RAFT(4GalNAc,2PV) **15b** carrying two copies of the T-helper PV peptide was also investigated. However, the incorporation of a second copy of the T-cell epitope did not result in an increase of immunogenicity since we observed a similar antibody response when compared with **15a** (Figure 5B). In addition, the immune

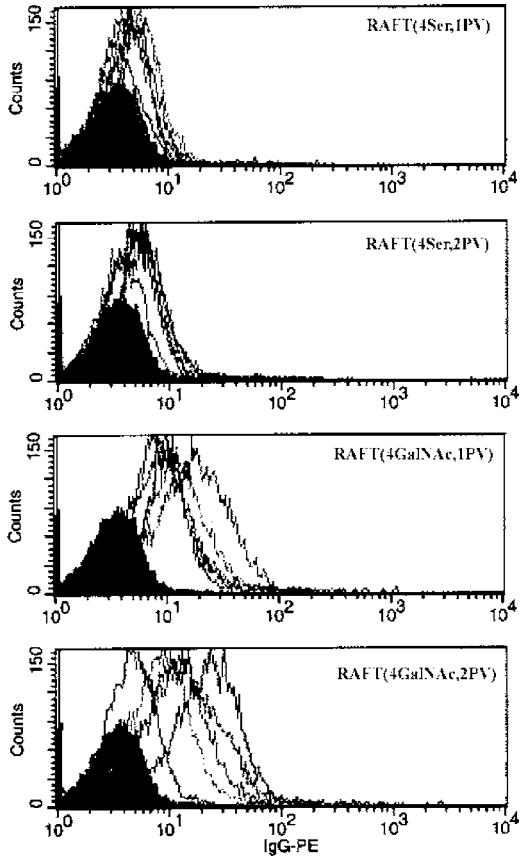

Figure 6. Antibodies induced following immunization with **15a** or **15b** recognize the native form of Tn on human Jurkat cells. Sera obtained from mice (n=5) immunized with RAFT-(4GalNAc,1PV) **15a**, RAFT(4GalNAc,2PV) **15b**, RAFT(4Ser,1PV) **14a** or RAFT(4Ser,2PV) **14b** were analyzed by flow cytometry for the recognition of native Tn on Jurkat cells. FACS data are shown as histograms corresponding to the mean fluorescence intensity of Jurkat cells stained with sera or in the absence of serum and revealed PE-conjugated anti-mouse IgG antibodies. For each group, staining obtained with five individual mouse sera (empty histogram) is shown as compared to the fluorescence obtained with PE-conjugated anti-mouse IgG antibodies in the absence of serum (plain histogram).

response induced by our RAFT-based vaccine candidates results probably from the convenient presentation of multiple copies of the B-cell epitope on the RAFT surface. Indeed, a previous study using dimeric or trimeric molecules based onto a lysine core bearing both T-cell and B-cell determinants has shown that the presentation of the determinants to T-cells may be different for linear compared to branched immunogens bearing the same determinants (*27*). Particularly, the number of the B-cell

epitopes into a branched construct could facilitate its uptake by specific B-cells in vivo and the subsequent presentation to helper T-cells.

RAFT(4GalNAc,1PV) 15a Induces Abs That Recognize Tumor Cells. To clearly determine whether the antibodies elicited by the RAFT are able to recognize the native form of Tn, we tested by flow cytometry their binding to the human Jurkat tumor cell line expressing the Tn antigen. As shown in Figure 6, sera from mice immunized with RAFT(4GalNAc,1PV) **15a** or RAFT-(4GalNAc,2PV) **15b** were able to recognize the Jurkat cells, whereas control RAFT(4Ser,1PV) **14a** and RAFT-(4Ser,2PV) **14b** devoid of TACA did not.

These results show the ability of the RAFT constructs bearing Tn- and PV-epitopes to elicit an immune response specifically directed against the native form of Tn displayed by cancer cells.

CONCLUSION

In conclusion, we investigated here the use of the RAFT platforms for the preparation of potential anticancer vaccine candidates. On the basis of previous studies, we designed RAFT molecules displaying clustered Tn antigen analogue to mimic the epithelial tumor surface and immunogenic $CD4^+$ T-cell epitope. The synthesis of such well-defined multiepitopic glycoconjugates is based on a sequential oxime bond ligation between the carrier and the B/T-cell epitopes. The immunological evaluation of our RAFT glycoconjugates clearly demonstrate a promising potential of such scaffold as a nonimmunogenic build-in vaccine carrier. Indeed, the antibodies elicited by immunization of mice with our molecules recognize the native form of Tn epitope expressed on human tumor cells, suggesting that the RAFT display Tn antigen analogues in a convenient clustered manner. Altogether, this preliminary study opens interesting perspectives to employ the RAFT scaffold in engineering potent immunogenic conjugates as vaccine candidates. Indeed, the modularity and versatility of the molecular assembly as well as the efficiency of oxime-based strategy might be further exploited to improve the immune response by combining TACAs with other immunogenic peptides and/or immunoadjuvants and to develop multicomponent therapeutic vaccines.

Preparation of Efficient Gene Carriers Using a Polyamidoamine Dendron-Bearing Lipid: Improvement of Serum Resistance

Toshinari Takahashi,[†] Atsushi Harada,[†] Nobuhiko Emi,[‡] and Kenji Kono*,[†]

Department of Applied Chemistry, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 599-8531, Japan, and Department of Hematology, Nagoya University Graduate School of Medicine, Nagoya, Aichi 466−8550, Aichi, Japan. Received January 20, 2005; Revised Manuscript Received July 4, 2005

In a previous study, we developed a novel cationic lipid consisting of polyamidoamine dendron of third generation and two dodecyl chains, designated as DL-G3, which in combination with a fusogenic lipid dioleoylphosphatidylethanolamine (DOPE) achieves efficient transfection of CV1 cells by synergetic action of the proton sponge effect and membrane fusion. This study examines the effect of serum on the transfection activity of the DL-G3−DOPE−plasmid DNA lipoplexes. The transfection activity of a lipoplex with a composition optimized in the absence of serum decreased markedly in the presence of serum. However, the lipoplexes that induce efficient transfection in the presence of serum were obtainable by controlling the charge ratio of the primary amine of the DL-G3 to the phosphate group (N/P ratio) and DOPE content. The complex, which exhibited the highest transfection activity in the presence of serum, has a lower N/P ratio and higher DOPE content than that optimized in the absence of serum. Whereas disintegration of these complexes was induced by addition of heparin, which is a polysaccharide with negatively charged groups, the complex that retained transfection activity in the presence of serum required more negative charges of heparin for complex disintegration. That result implies its higher stability against negatively charged serum proteins. Comparison of the serum-resistant complex with some commercially available transfection reagents, such as Lipofectamine and SuperFect, indicates that the DL-G3 complex achieved more efficient transfection of these cells in the presence of serum.

INTRODUCTION

Development of nonviral systems that introduce therapeutic genes efficiently into a target cell has been highly desired for the establishment of gene therapy. Synthetic systems based on lipids or polymers with positive charges have been studied actively for this purpose, but their activity still requires improvement. These systems can form complexes with plasmid DNA, which are termed lipoplexes (lipid-based complexes) and polyplexes (polymer-based complexes) through electrostatic interactions (*1*, *2*). These complexes can interact strongly with cells through electrostatic interactions. They are taken up by the cells through the endocytic pathway. Avoidance of plasmid DNA degradation in the lysosome and its transfer into cytosol are considered to be a key process for efficient transfection. Cationic lipid-based systems are considered to promote this process by fusing with and destabilizing the endosomal membrane with the help of fusogenic lipids such as dioleoylphosphatidylethanolamine (DOPE). Some synthetic cationic polymers such as poly(ethylenimine) (*3*, *4*) and polyamidoamine dendrimers (*5*) also induce efficient transfection of cells by enhancing the transfer of plasmid DNA into cytosol through the so-called proton sponge effect (*6*).

In a previous study (*7*), we developed a novel type of cationic lipids that consist of two dodecyl groups and a polyamidoamine dendron as a headgroup because these dendron-bearing lipids can form lipoplexes with DOPE and plasmid DNA, which achieve efficient transfection of cells by the synergetic action of membrane fusion and the proton sponge effect. In fact, in combination with DOPE, the lipid with the third generation dendron, DL-G3 (Figure 1), achieved more efficient transfection of CV1 cells, a green monkey kidney cell line, than widely used nonviral vectors.

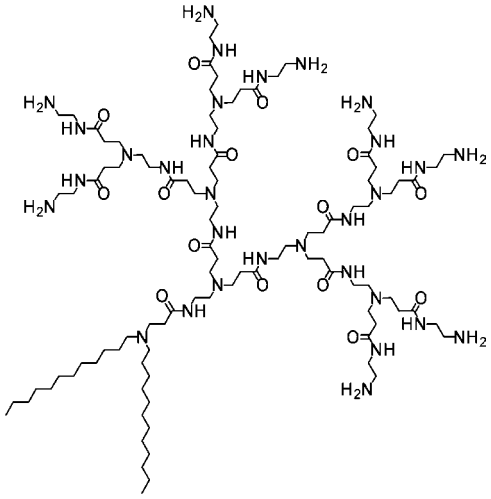

Figure 1. Structure of DL-G3.

A major problem for the cationic lipid/polymer-based gene carriers is their sensitivity to serum proteins: their transfection activity is lowered dramatically in the presence of serum proteins (*8*−*14*). Their complexes with plasmid DNA interact with serum components and cause

their disintegration, resulting in plasmid DNA release and its degradation (*12*−*15*). Therefore, optimal transfection with these systems must be performed in the absence of serum. Such a serum-sensitive property of the cationic lipid/polymer-based gene carriers apparently restricts their in vivo application and reduces their usefulness as a vector for gene therapy.

To overcome the inhibitory effect of serum on transfection mediated by these gene carriers, many efforts have been made by various approaches. Among them are enhancement of cellular uptake of the complexes through endocytosis by increasing positive charges of the complexes (*12*, *16*) or by attaching target cell specific ligands to the complexes (*17*, *18*), and promotion of transfer of endocytosed genes into cytosol by conjugation of membrane disruptive molecules with the complexes (*17*, *19*, *20*, *21*).

In a previous study, we examined transfection activity of the lipoplexes containing dendron-bearing lipids in the absence of serum. However, considering the strong ability of these dendron-bearing lipid-based lipoplexes to enhance transfer of the gene into cytosol and controllability of their charge density by changing their composition, it is expected that these lipoplexes could achieve efficient transfection in the presence of serum proteins. Therefore, this study is particularly intended to produce lipoplexes that can achieve efficient transfection using DL-G3 and DOPE. Their lipoplex with an optimized composition was found to possess a much higher activity than some commercially available transfection reagents, such as Lipofectamine and SuperFect. We describe the importance of both the ratio of the primary amines of the DL-G3 to the phosphate groups of plasmid DNA and the content of DOPE of lipoplexes for the production of lipoplexes with serum resistance.

EXPERIMENTAL PROCEDURES

General Methods. DOPE was kindly donated by Nippon Oil and Fats Co. (Tokyo, Japan). Fetal calf serum (FCS) was obtained from JRH Biosciences (Tokyo, Japan). Dulbecco's modified Eagle's medium (DMEM) was from Nissui Pharmaceutical (Tokyo, Japan). Tris(hydroxymethyl)aminomethane (Tris) was obtained from Kishida Chemical (Osaka, Japan). Heparin sodium salt was purchased from Sigma (St. Louis, MO). Agarose was purchased from nacalai tesque (Kyoto, Japan). Ethidium bromide was purchased from Wako Pure Chemical Industries (Osaka, Japan). Lipofectamine and SuperFect were purchased from Invitrogen (Carlsbad, CA) and Qiagen (Hilden, Germany), respectively. DL-G3 was synthesized by the procedure previously described (*7*).

Preparation of Lipoplexes. To a dry thin membrane of a mixture of the DL-G3 and a given amount of DOPE was added phosphate-buffered saline (PBS), and the mixture was sonicated for 2 min using a bath-type sonicator to afford a lipid suspension. Plasmid DNA p10, which contains a firefly luciferase coding sequence derived from pGL3-basic (Promega, Madison, WI) between Rous sarcoma virus LTR and polyadenylation signal, (1 μg), was dissolved in 20 mM Tris-HCl buffer (pH 7.4, 50 μL), was mixed with the lipid suspension (50 μL), and incubated for 30 min at room temperature to afford a lipoplex with a given ratio of primary amino group of DL-G3 to DNA phosphate (N/P ratios).

Transfection. Transfection of CV1 cells was done according to the following procedures unless otherwise noted in the text. The cells were seeded in 0.5 mL of DMEM supplemented with 10% FCS in 24-well culture plates at 5.0×10^4 cells per well the day before transfection. The cells were washed with PBS containing 0.36 mM $CaCl_2$ and 0.42 mM $MgCl_2$ [PBS(+)] and then covered with DMEM supplemented with a given amount of FCS (1 mL). The lipoplex-containing plasmid DNA (1 μg) was added gently to the cells and incubated at 37 °C for 4 h. Then, the cells were rinsed with PBS(+), covered with DMEM containing 10% FCS, and incubated at 37 °C. After 40 h, the cells were lysed by adding 50 μL of Luc-PGC-50 detergent (Toyo Ink, Tokyo, Japan). A 20 μL aliquot from each dish was used for one luciferase assay using a kit (Toyo Ink) and a Lumat LB9507 luminometer (Berthold, Bad Wildbad, Germany). The protein content of the lysate was measured by Coomassie Protein Assay Reagent (Pierce, IL) using bovine serum albumin as the standard. Transfection by Lipofectamine and SuperFect was performed according to their protocols recommended by the manufacturers. Transfection of HepG2 cells was performed according to the above procedure except that the cells were seeded 2 days before the transfection.

Interaction of the Lipoplexes with Heparin. The DL-G3−DOPE lipoplexes with varying N/P ratios and DOPE contents were prepared by mixing plasmid DNA (1 μg) dissolved in 20 mM Tris-HCl buffer (2.5 μl) and lipid suspension (2.5 μL). After 30 min-incubation at room temperature, the DL-G3−DOPE lipoplexes were added to a given amount (0−2 μg) of heparin dissolved in PBS (5 μL) and incubated for 30 min at room temperature. The samples (10 μL) were electrophoresed on 0.6 wt % agarose gel in 40 mM Tris, 20 mM sodium acetate, and 2 mM EDTA buffer (pH 8.0) containing 1 μg/mL ethidium bromide at 100 V for 30 min. The ethidium bromide-stained bands were visualized using a LAS-1000UVmini (FUJIFILM, Japan) and analyzed with Science Lab 2003 Multi Gauge software (FUJIFILM, Japan).

RESULTS AND DISCUSSION

Effects of Lipoplex Composition on Transfection Activity in the Presence of Serum. Our previous study developed cationic lipids that comprise two dodecyl groups and polyamidoamine dendron of varying generations because we expected that these lipids can form lipoplexes, which achieve an efficient transfection of cells through the synergy of membrane fusion and the proton sponge effect, with DOPE (*7*). When mixed with DOPE, one dendron-bearing lipid, DL-G3, induced transfection of CV1 cells more efficiently than a widely used lipoplex consisting of DC-chol and DOPE in a medium without serum.

We have already established the composition of a lipoplex composed of DL-G3, DOPE, and plasmid DNA with high transfection activity. Specifically, we described lipoplexes with an N/P ratio of 5 and DL-G3/DOPE ratio of 1/5 (*7*). Thereby, we first examined the effect of serum concentration on transfection activity of DL-G3−DOPE lipoplexes with that composition. Figure 2 depicts luciferase activity of CV 1 cells treated with the lipoplex in a medium with varying serum contents. As Figure 2 shows, the presence of even 10% of serum abolished the transfection activity of the DL-G3−DOPE lipoplex. Many studies have revealed that the transfection activity of lipoplexes is reduced dramatically in the presence of serum by interaction between lipoplexes and serum proteins (*12*−*15*). This result indicates that the DL-G3−DOPE lipoplex with this composition is as highly serum-sensitive as other types of cationic lipid-based vectors.

As mentioned previously, the optimum composition of the DL-G3−DOPE lipoplex was established under condi-

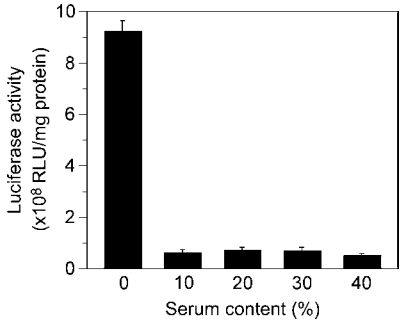

Figure 2. Effect of serum on transfection of CV1 cells mediated by the DL-G3−DOPE lipoplex with N/P ratio of 5 and DOPE/DL-G3 ratio of 5. The cells (5×10^4) were treated with the lipoplexes containing 1 μg of DNA in the medium with varying contents of FCS. Each bar represents the mean ± SD ($n = 3$).

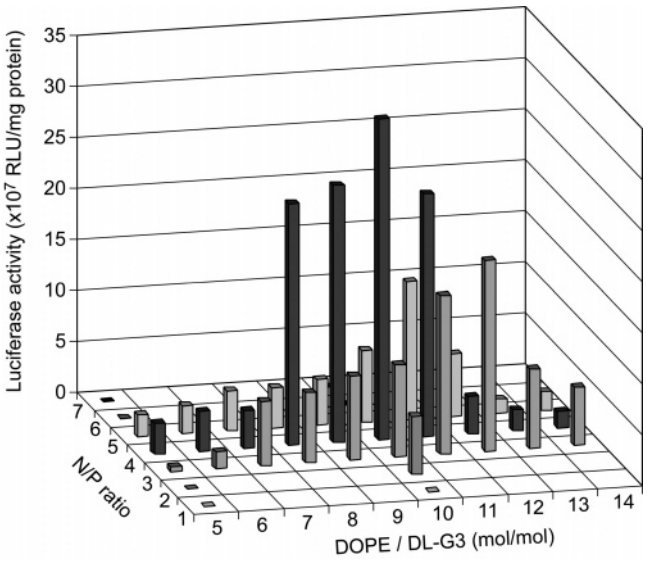

Figure 3. Influences of N/P and DOPE/DL-G3 ratios of lipoplexes on their transfection activity. The cells (5×10^4) were treated with the lipoplexes containing 1μg DNA in the presence of 9.1% FCS. Each bar represents the mean ($n = 4$).

tions without serum. Therefore, the optimum composition of the lipoplex for transfection in the presence of serum might differ from the composition optimized in the absence of serum. For that reason, we next attempted the optimization of the composition of the DL-G3−DOPE lipoplex in the presence of serum (Figure 3).

Inclusion of DOPE in the lipoplex is important because this lipid provides fusion ability to the lipoplex (*22*, *23*). We prepared dispersions of mixtures of DL-G3 and DOPE with varying molar ratios and incubated them with plasmid DNA to obtain lipoplexes with varying DOPE contents at varying N/P ratios. Expression of luciferase in the CV 1 cells treated with these lipoplexes is shown in Figure 3. As that figure shows, the cellular expression of luciferase is dependent on the lipoplex's DOPE content. For example, when the lipoplexes with an N/P ratio of 4 were used, the cellular luciferase activity increased 10-fold as the DOPE content of the lipoplex increased from 5 to 10. However, higher DOPE content of the lipoplexes eliminated their activity. Because DOPE is an electronically neutral lipid, the charge density of the lipoplexes decreases with increasing DOPE content, thereby reducing their affinity to the cellular surface. A similar tendency was shown by lipoplexes with N/P ratios of 3 and 5, but their maximum activities were apparent at DOPE/DL-G3 ratios of 12 and 11 for lipoplexes with the N/P ratios of 3 and 5, respectively. These results indicate that inclusion of DOPE is crucial to obtain potent lipoplexes for use in the presence of serum.

On the other hand, the N/P ratio is another important factor which affects lipoplex activity. As Figure 3 shows, transfection activity of the DL-G3−DOPE lipoplexes changed remarkably depending on the N/P ratio. For lipoplexes with the DOPE/DL-G3 ratio of 10, the activity increases concomitant with an increasing N/P ratio and becomes greatest at the ratio of 4. The transfection activity of the DL-G3−DOPE lipoplexes was affected markedly by both the DOPE/DL-G3 and N/P ratios. However, Figure 3 illustrates that a lipoplex with a DOPE/DL-G3 ratio of 10 and the N/P ratio of 4 exhibited the highest activity in the presence of serum.

As mentioned previously, the lipoplex optimized in the absence of serum has an N/P ratio of 5 and a DOPE/DL-G3 ratio of 5. Compared with this, the lipoplex optimized in the presence of serum has a slightly lower N/P ratio and a two-times-higher DOPE/DL-G3 ratio. Both the lower N/P ratio and the higher DOPE content mean that the lipoplex obtained in this study has a lower charge density than the lipoplex optimized in the absence of serum. The electrostatic force is likely to play an important role in interaction of the lipoplex with serum proteins. Therefore, the lower charge density of the lipoplex may contribute to its weaker interaction with serum proteins and prevent the loss of transfection activity induced by interaction with serum proteins. Indeed, the interaction of the lipoplex with the cellular membrane is based on their electrostatic interaction. For that reason, the low charge density of the lipoplex may also cause a weak interaction with the cell that could result in a lower transfection activity. However, the higher DOPE content of the lipoplex might increase fusion ability of the lipoplex, which could compensate the reduced affinity. As a result, the lipoplex obtained in this study exhibited the high transfection activity.

Figure 4 illustrates the influence of serum concentration on transfection activity of the DL-G3−DOPE lipoplexes optimized in the presence of serum and absence of serum. When serum was absent, both lipoplexes exhibited similar and high transfection activities (Figure 4A), though the activity of the lipoplex optimized in the presence of serum was somewhat higher than that of the lipoplex optimized in the absence of serum. This may be due to the difference of the procedures for optimization of these lipoplexes (*7*). When the serum was present, both lipoplexes reduced the transfection activity. However, the extent of reduction of that activity differed between these lipoplexes. As Figure 4B shows, the lipoplex optimized in the absence of serum retained only 7% of the original activity when 10−40% of serum was contained in the medium of transfection. In contrast, the lipoplex prepared in this study exhibited 20−30% of the original activity under the same conditions. Consequently, we infer that the DL-G3−DOPE lipoplex with the low N/P ratio and the high DOPE content are more resistant to serum.

Interaction of Lipoplexes with Heparin. As mentioned above, the serum-resistance of DL-G3−DOPE lipoplexes was affected significantly by the N/P ratio and the DOPE content. Transfection activity of the lipoplex with the N/P ratio of 5 and the DOPE/DL-G3 ratio of 5 was diminished strongly by serum, whereas the lipoplex with a slightly lower N/P ratio and a higher DOPE content can retain its activity in the presence of serum.

Inactivation of the DL-G3−DOPE lipoplex in the presence of serum is considered to be induced mainly by electrostatic interaction between the lipoplexes with negatively charged serum proteins. In fact, disintegration

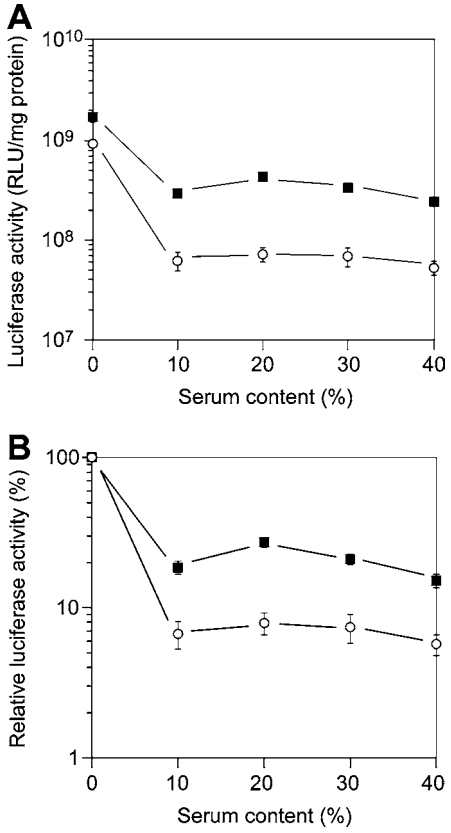

Figure 4. Serum-induced reduction of transfection activity for DL-G3−DOPE lipoplex with N/P ratio of 5 and DOPE/DL-G3 ratio of 5 (○) and DL-G3−DOPE lipoplex with N/P ratio of 4 and DOPE/DL-G3 ratio of 10 (■). Cellular luciferase activity (A) and percentage of cellular luciferase activity in the absence of serum (B) were shown as a function of serum content of the transfection medium. The cells (5×10^4) were treated with DL-G3−DOPE lipoplexes containing 1μg DNA. Each point represents the mean ± SD ($n = 3$).

of lipoplexes associated with the release of plasmid DNA has often been observed in the presence of serum because the plasmid DNA bound to the cationic lipid molecules is replaced by the negatively charged serum proteins (*12*−*15*).

Some polyanions, such as heparin and dextran sulfate, are also known to dissociate DNA from lipoplexes (*24*, *25*). They have been used to estimate the stability of the lipoplexes. Therefore, we examined the effect of addition of heparin on dissociation of plasmid DNA from the DL-G3−DOPE lipoplexes to evaluate their stability using agarose gel retardation assay (Figure 5). In this experiment, lipoplexes with varying N/P ratios and DOPE/DL-G3 ratios were incubated with varying amounts of heparin for 30 min, then electrophoresed on an agarose gel. As Figs. 5A−C show, a band corresponding to free plasmid DNA appeared as the amount of heparin added to the lipoplexes was increased, indicating that these lipoplexes were disintegrated by interaction with heparin.

Liberation of plasmid DNA was caused mainly by their electrostatic interaction. Therefore, we investigated the correlation between the amount of released plasmid DNA and the charge balance of the mixture of the lipoplex and heparin. Heparin is known to be a highly sulfated glycosaminoglycan consisting of (1 → 4)-*O*-(α-L-idopyranosyluronic acid 2-sulfate)−(1→ 4)-(2-deoxyl-2-sulfamino-α-D-glucopyranosyl 6-sulfate) as a major repeating unit (*26*, *27*). Thus, we calculated the amount of negative charge of heparin by assuming the structure of heparin as repeats of this disaccharide unit. Figure 5D depicts

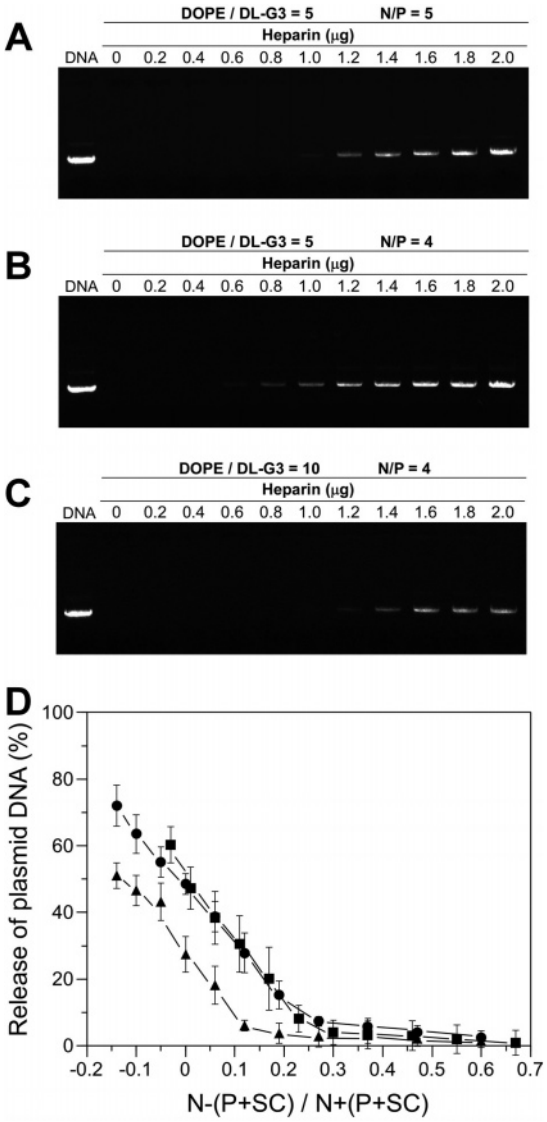

Figure 5. Agarose gel electrophoresis of DL-G3−DOPE lipoplexes with N/P ratio of 5 and DOPE/DL-G3 ratio of 5 (A), with N/P ratio of 4 and DOPE/DL-G3 ratio of 5 (B) and with N/P ratio of 4 and DOPE/DL-G3 ratio of 10 (C) in the presence of varying amounts of heparin. (D) Percent release of plasmid DNA from DL-G3−DOPE lipoplexes with varying compositions as a function of difference between negative and positive charges of lipoplexes normalized by their total charge: ■, lipoplex with N/P ratio of 5 and DOPE/DL-G3 ratio of 5; ●, lipoplex with N/P ratio of 4 and DOPE/DL-G3 ratio of 5; ▲, lipoplex with N/P ratio of 4 and DOPE/DL-G3 ratio of 10. Each point represents the mean ± SD ($n = 3$). N, P, and SC represent amounts of charge of the primary amine of the DL-G3, phosphate group of DNA, and total of sulfonate and carboxyl groups of heparin, respectively.

the percentage of released plasmid DNA as a function of the difference between positive and negative charges of the lipoplex−heparin mixture normalized by its total amount of charge. Figure 5D shows the curve for a lipoplex with an N/P ratio of 5 and with a DOPE/DL-G3 ratio of 5 (■). It also depicts the curve for a lipoplex with an N/P ratio of 4 and a DOPE/DL-G3 ratio of 5 (●). They are approximately identical. This result indicates that the liberation of plasmid DNA from these lipoplexes is controlled simply by their charge balance when the DOPE content of the lipoplexes was the same. However, comparison between the lipoplex with the N/P ratio of 4 and the DOPE/DL-G3 ratio of 5 and the lipoplex with the same N/P ratio and with the DOPE/DL-G3 ratio of

10 (▲) indicates that the latter requires more negative charge than the former for liberation of plasmid DNA, suggesting that inclusion of DOPE contributes to lipoplex stability. Probably, DOPE molecules inserted in the complex could stabilize the electrostatic binding between DNA and the DL-G3 by hydrophobic interaction and cover the DNA efficiently, isolating it from the outer environment and suppressing interaction with negatively charged molecules. Therefore, it is likely that the high content of DOPE in the lipoplex with the N/P ratio of 4 and the DOPE/DL-G3 ratio of 10 can enhance stability of the lipoplex and provide a high serum-resistant property to the lipoplex.

In addition, particle size of the complexes can be another factor that affects interaction of the lipoplexes with serum protein and their serum-sensitivity. Thus, we measured size of the lipoplexes by DLS. The sizes of serum-resistant and serum-sensitive lipoplexes were shown to be 767 ± 183 nm and 616 ± 193 nm, respectively. The slightly smaller size of the latter may enhance its serum sensitivity to some extent, because it would interact more actively with serum proteins due to their larger surface area.

To know whether the optimized DL-G3-based lipoplex can be used for another type of cells, we further examined transfection of HepG2 cells, which are frequently used for the evaluation of transfection activity for various types of gene vectors. We found that the cells after treatment with this lipoplex in the absence and in the presence of serum exhibited the luciferase activity of 3.2 ± 0.4 × 10^8 RLU/mg protein and 2.2 ± 0.4 × 10^8 RLU/mg protein ($n = 6$), respectively. Since CV1 cells treated with this lipoplex in the absence and in the presence of serum showed luciferase activity of about 20 × 10^8 RLU/mg protein and about 3.5 × 10^8 RLU/mg protein, respectively (Figure 4A), this lipoplex seems to be somewhat less effective for HepG2 than CV1 cells. However, the cellular luciferase activity induced by the treatment in the presence of serum was 70% of the luciferase activity induced by the treatment in the absence of serum. This result indicates that this optimized lipoplex could be useful for the transfection of various types of cells in the presence of serum.

Comparison with Various Vectors. To estimate the potential of the DL-G3−DOPE lipoplex as a gene vector, we compared its transfection activity with those of Lipofectamine and SuperFect: both are widely used and commercially available vectors. CV1 cells were treated with the DL-G3−DOPE lipoplexes, the Lipofectamine-plasmid DNA complex, and the SuperFect-plasmid DNA complex in the absence of serum or in the presence of 10% FCS. Figure 6 represents the expression of luciferase in the cells treated with these lipoplexes or complexes. In the absence of serum, DL-G3−DOPE lipoplex induced roughly a two-times-higher level and a six-times-higher level of luciferase expression than Lipofectamine complex and SuperFect complex, respectively. As expected, a decrease in transfection efficiency was shown for all vectors in the presence of serum. Especially, the influence of serum was significant for the Lipofectamine complex. In this case, luciferase expression was reduced to 1/180th of that in the absence of serum. A remarkable decrease in transfection efficiency induced by serum was again evident in transfection with the SuperFect complex, in which the cellular luciferase expression was reduced to 1/50th of that in the absence of serum. A 1/6th-fold reduction was apparent in the case of the DL-G3−DOPE lipoplex-mediated transfection in the presence of serum. However, this lipoplex displayed a reduction with much less extent of magnitude than other complexes. As a result, this lipoplex achieved 48−64-times higher expression of the introduced gene in CV1 cells than these widely used vectors under experimental conditions, suggesting its usefulness as a vector for use in the presence of serum.

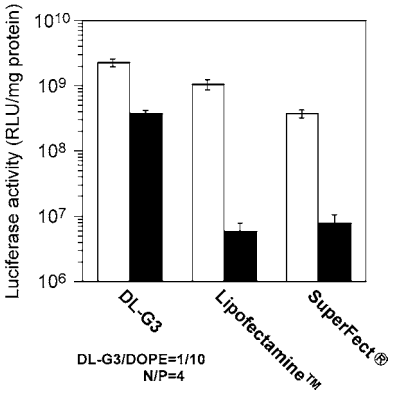

Figure 6. Comparison of transfection activity of DL-G3−DOPE lipoplex with Lipofectamine and SuperFect reagents. The cells (5×10^4) were treated with vectors containing 1μg DNA in the absence (open bars) and presence of 10% FCS (closed bars). The DL-G3−DOPE lipoplex with N/P ratio of 4 and DOPE/DL-G3 ratio of 10 was used. Each bar represents the mean ± SD ($n = 3$).

CONCLUSION

This work was intended to prepare an efficient vector that can achieve gene transfection of cells in the presence of serum using polyamidoamine dendron-bearing lipid DL-G3 and fusogenic lipid DOPE, by the synergetic action of membrane fusion and the proton sponge effect. Results show that transfection activity of the DL-G3−DOPE lipoplexes was highly dependent on their composition, such as the N/P and DOPE/DL-G3 ratios. However, by adjusting the N/P and DOPE/DL-G3 ratios to 4 and 10, respectively, we obtained a lipoplex that exhibited high transfection activity in the presence and absence of serum. Although the obtained lipoplex showed some extent of reduction of transfection activity in the presence of serum, the lipoplex retained much higher activity than some widely used and commercially available transfection reagents. These results strongly suggest that the DL-G3−DOPE lipoplex is a promising nonviral vector for gene therapy.

Synthesis and Photodynamic Activity of Novel Asymmetrically Substituted Fluorinated Phthalocyanines

Wesley M. Sharman and Johan E. van Lier*

Department of Nuclear Medicine and Radiobiology, Faculty of Medicine, Université de Sherbrooke, Sherbrooke, Québec, Canada J1H 5N4. Received January 31, 2005; Revised Manuscript Received June 9, 2005

A series of asymmetrically substituted dodecafluorinated phthalocyanines has been synthesized via the Kobayashi ring expansion reaction of the corresponding dodecafluorinated boron subphthalocyanine with differently substituted 1,3-diiminoisoindolines. The mild reaction conditions employed during this ring expansion reaction gave rise exclusively to 3:1 asymmetrically substituted dodecafluorinated phthalocyanines. Metal insertion into the metal-free phthalocyanines was accomplished by heating at 40 °C in *N*,*N*-dimethylformamide in the presence of zinc bromide. The resulting zinc dodecafluorophthalocyanines were formulated as Cremophor EL oil−water emulsions and evaluated as photosensitizers in vitro against EMT-6 mouse mammary tumor cells. As compared to the previously studied zinc hexadecafluorophthalocyanine, these new asymmetrical zinc dodecafluorophthalocyanines exhibited improved photodynamic activity.

INTRODUCTION

Tetrapyrrolic macrocycles such as porphyrins represent one of the most important and more interesting ligand systems, not only due to their ubiquitous presence in nature but also because of their unique physical, chemical, biological, and spectral properties. Phthalocyanines (Pc)[1] are azoporphyrin derivatives and have been extensively studied to examine structure−activity relationships and to improve upon some of the unique characteristics of the tetrapyrrolic chromophore (*2*−*4*). Since their serendipitous discovery and identification (*2*, *3*), phthalocyanines have been used extensively as dyes and pigments in the paint, printing, textile, and paper industries due to their intense blue-green color, high dyeing power, photostability, insolubility in most solvents, and chemical inertness (*4*). In addition, phthalocyanines have found industrial applicability as photoconducting agents in photocopying devices and as catalysts for important industry reactions (*1*, *5*). In fact, cobalt phthalocyanine derivatives are used in the Merox process for the oxidation of sulfur compounds in gasoline fractions (*6*). More recently, phthalocyanines have found high-technology applications in electrophotography (*7*), ink jet printing (*8*), and data storage (*9*, *10*). Even with these important industrial and high-technology applications, the potential of phthalocyanines remains relatively untapped. Due to their unique chemical and physical properties, the importance of phthalocyanines is rapidly growing in a number of other fields. These fields include chemical sensors (*11*), electrochromism (*12*), molecular metals (*13*), liquid crystals (*14*), Langmuir−Blodgett films (*15*), functional polymers (*16*), semiconductors (*17*), nonlinear optical (NLO) applications (*18*), and photosensitizers for photodynamic therapy (PDT) (*19*, *20*).

Diverse applications such as those proposed for Pcs require compounds with distinct and well-defined physical, chemical, and electronic properties. These necessitate synthetic approaches for the preparation of single isomers or well-defined isomeric mixtures of substituted Pcs and for the preparation of Pcs bearing novel substituents. In addition, for a number of these applications, the physical and chemical properties of Pcs are enhanced when the Pcs are asymmetrically substituted. For instance, whereas symmetrically substituted Pcs exhibit large optical nonlinearities and third-order harmonic generation due to their extensively delocalized 18-π electron system, second-order nonlinear optical effects are present in only noncentrosymmetric molecules and are enhanced by electron-donating, electron-withdrawing push−pull systems (*18*). In light of this, the synthesis of unsymmetrically substituted Pcs bearing both electron-donating and electron-withdrawing functional groups has been investigated (*21*, *22*). In addition to the potential utility in NLO applications, it has been established that asymmetrically substituted phthalocyanines often exhibit increased potential as photosensitizers for photodynamic therapy (*23*, *24*).

A number of different strategies have been investigated to prepare asymmetrically substituted noncentrosymmetric Pcs. The most commonly used synthetic approach is the statistical mixed condensation of differently substituted phthalocyanine precursors (*25*). Although the yield of the desired substitution pattern has been enhanced by carefully selecting the substituents on the phthalocyanine precursors, the molecular proportions of the individual precursors, and the reaction conditions used, the statistical mixed condensation method involving

two differently substituted phthalocyanine precursors does lead to a mixture of six differently substituted phthalocyanine products that must be separated, usually by chromatography. If the two Pc precursors used differ significantly in their solubility in a given solvent, separation of the differently substituted Pcs may be relatively simple due to the different solubilities of the resulting Pcs. However, in most cases, this separation has proven to be troublesome.

Another method investigated is a polymer-support route in which one of the phthalocyanine precursors is covalently attached to a polymer support prior to the synthesis of the Pc (*26*). Following the synthesis of the macrocycle, the polymer-bound Pc is obtained by filtration and the bond to the polymer is cleaved to yield pure 3:1 unsymmetrically substituted Pc. Although this method has been used successfully to prepare pure unsymmetrically substituted Pcs, it is limited by the number of functional groups that can be covalently bonded to the polymer support. Furthermore, yields are less than satisfactory due to the low bonding capacity of the polymer support.

The Kobayashi ring expansion reaction of boron subphthalocyanines provides an efficient method for preparing 3:1 unsymmetrically substituted Pcs (*27*). Boron subPc are the lower homologues of phthalocyanines, consisting of a tripyrrolic macrocycle (*28*). The loss of an isoindoline unit causes a hypsochromic shift in the Q-band of the electronic spectra to around 560−580 nm, lending a reddish purple color to solutions of these subPcs. Whereas Pcs are extremely stable molecules exhibiting a high degree of planarity in their central aromatic core, subPcs have a cone-shaped structure, with the boron coordinated in a tetrahedral geometry with a single axial ligand. Their extensively delocalized 14-π electron system and their cone-shaped structure have led to investigations in the utility of subPcs in NLO applications (*29*). In light of this, a number of substituted subPcs have been prepared (*29*−*34*). In addition, attempts have been made to alter the properties of subPcs by varying the axial ligand coordinated to the boron (*32*, *35*, *36*). It has been demonstrated that the less stable subPcs readily react with 1,3-diiminoisoindolines in a ring enlargement reaction to yield 3:1 unsymmetrically substituted Pcs (*27*, *37*). First disclosed by Kobayashi in 1990, this ring enlargement reaction unfortunately may lead to a mixture of differently substituted Pcs, and it has been proposed that the ring enlargement reaction of subPcs is a nonselective multistep reaction which depends greatly on the nature of the substituents on the subPcs, the reactivity of the 1,3-diiminoisodoline, the solvent, and the reaction conditions used (*21*, *38*, *39*). Although this greatly limits the general synthetic utility of this reaction, this reaction protocol has been shown to be useful in a number of examples, giving the desired 3:1 unsymmetrically substituted Pc in good yields and as a pure single phthalocyanine product (*27*, *37*, *40*−*43*).

To further investigations carried out by our group using zinc hexadecafluorophthalocyanine and zinc dodecafluorophthalo-4-sulfophthalocyanine, the Kobayashi ring expansion reaction of boron dodecafluorosubphthalocyanine (**2**) has been examined. We have found that subPc **2** readily reacts with 1,3-diiminoisoindolines under extremely mild conditions to give the corresponding 3:1 unsymmetrically substituted phthalocyanine in good yields and without contamination with phthalocyanines with differing substitution patterns. Furthermore, we have found that the starting boron subPc **2** can be prepared under much milder conditions than those described in the literature (*34*). The photodynamic activity, in terms of both singlet oxygen generation and in vitro photocytotoxicity, of some of the resulting unsymmetrically substituted dodecafluorinated Pcs has been determined and has indicated that asymmetry, even in lipophilic photosensitizers, improves the photodynamic efficacy of these compounds.

EXPERINEMTAL PROCEDURES

All solvents were of HPLC grade and were used without further purification unless otherwise stated. Tetrafluorophthalonitrile, 3-nitrophthalonitrile, and 4-*tert*-butylphthalonitrile were purchased from TCI America (Portland, OR). 1-Dodecyne, 1,2-dicyanobenzene, 1,2,4,5-tetracyanobenzene, 4-nitrophthalonitrile, 1,3-diiminoisoindoline, dichlorobis(triphenyl-phosphine)palladium(II), 10% palladium on carbon, 1 M boron tribromide in dichloromethane, and zinc bromide were purchased from Aldrich (Oakville, ON, Canada). 4-Iodophthalonitrile (*44*), 3-iodophthalonitrile (*45*), 4,5-diiodophthalonitrile (*46*), 5-*tert*-butyl-1,3-diiminoisoindoline, 5-nitro-1,3-diiminoisoindoline, 5-iodo-1,3-diiminoisoindoline, 4-iodo-1,3-diiminoisoindoline, 5,6-diiodo-1,3-diiminoisoindoline, 5,6-dicyano-1,3-diiminoisoindoline, 2,3-dihydro-1,3-diimino-1*H*-benz[*f*]isoindole (*47*−*50*), $ZnPcF_{16}$ (*51*), $ZnPcF_{12}S_1$ (*52*), and $AlPcS_4$ (*53*, *54*) were prepared by using modified literature procedures. UV−vis spectra were recorded with a Hitachi U-2000 spectrophotometer. ^1H and ^{19}F NMR spectra were obtained on a Brucker AC-300 spectrometer. FAB-MS were obtained on an LG Autospec Q mass spectrometer.

4,5-(1-Dodecynl)phthalonitrile. 4,5-Diiodophthalonitrile (2.61 g; 6.87×10^{-3} mol) was dissolved in 50 mL of triethylamine and 5 mL of DMF. To this was added 300 mg of dichlorobis(triphenylphosphine)palladium(II). The reaction mixture was stirred at 100 °C under an inert atmosphere and 6.4 mL of 1-dodecyne (2.99×10^{-2} mol; 4.35 equiv). The reaction was monitored by thin-layer chromatography (TLC) (10% diethyl ether in hexanes). After 2 h, the reaction was cooled and filtered, and the filtrate was evaporated to dryness under reduced pressure. The resulting solid was purified by column chromatography on silica using 10% diethyl ether in hexanes as eluant. The desired product was obtained in a yield of 2.66 g (84.7%): $C_{32}H_{44}N_2$, MS (EI), *m/e* 456 (M^+), 385 [$M^+ - CH_3(CH_2)_4$], 371 [$M^+ - CH_3(CH_2)_5$]; HR MS (EI), *m/z* calcd for $C_{32}H_{44}N_2$, 456.3504, found, 456.3522.

4,5-(Dodecyl)phthalonitrile. 4,5-(1-Dodecynl)phthalonitrile (2.5 g; 5.47×10^{-3} mol) was dissolved in 200 mL of tetrahydrofuran (THF). To this solution was added 500 mg of 10% palladium on carbon. The suspension was stirred at room temperature, and hydrogen gas was bubbled through the reaction mixture. The reaction was monitored by TLC (10% diethyl ether in hexanes). After 6 h, the reaction mixture was filtered to remove the catalyst, and the filtrate was evaporated to dryness under reduced pressure. The resulting solid was purified by column chromatography on silica using 10% diethyl ether in hexanes as eluant. The desired product was obtained in a yield of 2.42 g (95.2%): $C_{32}H_{52}N_2$ MS (EI), *m/e* 464 (M^+), 449 ($M^+ - CH_3$), 435 ($M^+ - 2CH_3$), 421 ($M^+ - CH_3$, CH_3CH_2); HR MS (EI), *m/z* calcd for $C_{32}H_{52}N_2$, 464.4130, found, 464.4122.

5,6-Didodecyl-1,3-diiminoisoindoline (3g). Sodium metal (68.5 mg; 2.98×10^{-3} mol) was dissolved in 30 mL of methanol. Ammonia gas was bubbled through the reaction mixture for 5 min prior to the addition of 4,5-(dodecyl)phthalonitrile (919 mg; 1.98×10^{-3} mol). The

mixture was stirred at 60 °C with periodic bubbling of ammonia. The reaction was monitored by TLC (20% methanol in toluene). After 10 h, the mixture was cooled to 0 °C, saturated with ammonia gas, sealed, and stirred at 4 °C overnight. The reaction mixture was then warmed to room temperature, and the solvent was removed under reduced pressure. The resulting solid was washed with concentrated NH_4Cl, water, and ice-cold methanol and dried. The desired product was obtained in a yield of 938 mg (98.5%): $C_{32}H_{55}N_3$ MS (EI), *m/e* 482 ($M^+ + H$); HR MS (EI), *m/z* calcd for $C_{32}H_{55}N_3$, 481.4396, found, 481.4401.

Dodecafluorosubphthalocyanato Boron(III) Bromide (SubPcF$_{12}$) (2). Tetrafluorophthalonitrile (**1**) (518 mg; 2.59×10^{-3} mol) was dissolved in a minimum amount of chlorobenzene (1.8 mL). The resulting solution was stirred at room temperature, and 1.8 mL of 1 M BBr_3 in dichloromethane (1.80×10^{-3} mol of BBr_3; 0.7 equiv) was added. After 5 min, the reaction mixture was heated to 60 °C and after 1 h cooled to room temperature. The solvent was removed by rotary evaporation at reduced pressure, and the resulting solid was dissolved in 30% THF in hexanes. This solution was filtered and purified by column chromatography over neutral alumina using 30% THF in hexanes as eluant. The desired product was obtained in a yield of 402 mg (67.4%): $C_{24}N_6BBrF_{12}$ MS (FAB), *m/e* 692 ($M^+ + H$), 612 ($M^+ - Br$); ^{19}F NMR (dichloromethane) δ −59.76, −59.81, −70.18, −70.23 [$\delta = 0$ for trifluoroacetic acid (TFA)]; UV−vis, λ (dichloromethane) (log ϵ) 577 nm (4.93), 532 nm (2.01).

Synthesis of Dodecafluorinated Phthalocyanines. *1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluorophthalocyaninate (H$_2$PcF$_{12}$) (**4a**).* To a stirred solution of (dodecafluorosubphthalocyanato)boron(III) bromide (**2**) (400 mg; 5.78×10^{-4} mol) in 4 mL of DMSO was added a solution of 1,3-diiminoisoindoline (**3a**) (451 mg; 3.11×10^{-3} mol; 5.4 equiv) in 6 mL of DMSO at room temperature. The reaction mixture instantly lost its intense purple color and gradually became blue. After 2−4 h, the reaction mixture was added to a large excess of methanol (50 mL). The suspension was left at 4 °C overnight, and then the green solid was collected by centrifuging. The desired product was obtained in a yield of 244 mg (59.5%): MS (FAB), *m/e* 731 ($M^+ + H$); HR MS (FAB), *m/z* calcd for $C_{32}H_6N_8F_{12}$, 730.0524, found, 730.0572; UV−vis, λ (DMF) 671, 601 nm.

The following dodecafluorinated phthalocyanine derivatives were prepared using the same synthetic procedure described above. Note that for 5,6-didodecyl-1,3-diiminoisoindoline (**3g**), the reaction was accomplished using a 1:1 solvent mixture of DMSO and chlorobenzene.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23-tert-butylphthalocyaninate (**4b**).* Yield, 40.5%; MS (FAB), *m/e* 786 ($M^+ + H$); UV−vis, λ (DMF) 673, 606 nm.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23-nitrophthalocyaninate (**4c**).* Yield, 20.7%; MS (FAB), *m/e* 776 ($M^+ + H$); UV−vis, λ (DMF) 684, 667, 635 nm.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23-iodophthalocyaninate (**4d**).* Yield, 25.9%; MS (FAB), *m/e* 857 ($M^+ + H$); UV−vis, λ (DMF) 671, 607 nm.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-22-iodophthalocyaninate (**4e**).* Yield, 18.7%; MS (FAB), *m/e* 857 ($M^+ + H$); UV−vis, λ (DMF) 680, 612 nm.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23,24-diiodophthalocyaninate (**4f**).* Yield, 30.3%; MS (FAB), *m/e* 983 ($M^+ + H$); UV−vis, λ (DMF) 669, 612 nm.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23,24-didodecylphthalocyaninate (**4g**).* Yield, 11.7%; MS (FAB), *m/e* 1067 ($M^+ + H$); UV−vis, λ (DMF) 676, 613 nm.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23,24-dicyanophthalocyaninate (**4h**).* Yield, 28.8%; MS (FAB), *m/e* 780 (M^+); UV−vis, λ (DMF) 689, 661, 636 nm.

*(1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro)tribenzo[b,g,l]naphthalo[2,3-q]-porphyrazine (**4i**).* Yield, 51.8%; MS (FAB), *m/e* 780 (M^+); UV−vis, λ (DMF) 700, 675, 620, 604 nm.

Synthesis of Dodecafluorinated Zinc Phthalocyanines. *1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluorophthalocyaninato Zinc (**5a**).* 1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluorophthalocyaninate (**4a**) (100 mg; 1.37×10^{-4} mol) was suspended in 5 mL of DMF. To this was added zinc bromide (72 mg; 3.20×10^{-4}; 2.3 equiv). The reaction mixture was heated to 40 °C for 2 h and was then cooled to room temperature. The solvent was removed by rotary evaporation under reduced pressure, and the resulting solid was washed twice with 1.2 M hydrochloric acid (25 mL each) and twice with 95% ethanol (25 mL each). The solid was dried and then dissolved in tetrahydrofuran and purified by column chromatography on silica gel (40% THF in hexanes). The desired product was obtained in a yield of 105 mg (96%): MS (FAB), *m/e* 793 ($M^+ + H$); HR MS (FAB), *m/z* calcd for $C_{32}H_4N_8F_{12}Zn$, 791.9659, found, 791.9648; UV−vis, λ (THF) (log ϵ) 674 (5.13), 604 (4.38), 356 nm (4.57).

The following dodecafluorinated zinc phthalocyanine derivatives were prepared using the same synthetic procedure described above.

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23-tert-butylphthalocyaninato Zinc [ZnPcF$_{12}$(tert-butyl)] (**5b**).* Yield, 98%; MS (FAB), *m/e* 849 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 663 (5.16), 629 (4.91), 355 nm (4.89).

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23-nitrophthalocyaninato Zinc [ZnPcF$_{12}$(NO$_2$)] (**5c**).* Yield, 91%; $C_{32}H_3N_9O_2F_{12}Zn$ MS (FAB), *m/e* 838 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 678 (4.92), 667 (4.88), 620 (4.55), 601 (4.53), 340 nm (4.89).

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23-iodophthalocyaninato Zinc [ZnPcF$_{12}$(4-I)] (**5d**).* Yield, 95%; $C_{32}H_3N_8F_{12}IZn$ MS (FAB), *m/e* 919 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 671 (5.10), 640 (4.66), 608 (4.48) 357 nm (4.66).

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-22-iodophthalocyaninato Zinc [ZnPcF$_{12}$(3-I)] (**5e**).* Yield, 92%; $C_{32}H_3N_8F_{12}IZn$ MS (FAB), *m/e* 919 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 680 (5.19), 612 (4.54), 344 nm (4.66).

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23,24-diiodophthalocyaninato Zinc [ZnPcF$_{12}$(I$_2$)] (**5f**).* Yield, 97%; $C_{32}H_2N_8F_{12}I_2Zn$ MS (FAB), *m/e* 1045 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 676 (5.21), 643 (4.69), 355 nm (4.91).

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23,24-didodecylphthalocyaninato zinc (ZnPcF$_{12}$(C$_{12}$)$_2$) (**5g**).* Yield, 88%; $C_{56}H_{52}N_8F_{12}Zn$ MS (FAB), *m/e* 1129 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 683 (4.90), 664 (4.86), 359 nm (4.61).

*1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro-23,24-dicyanophthalocyaninato Zinc [ZnPcF$_{12}$(CN)$_2$] (**5h**).* Yield, 90%; $C_{34}H_2N_{10}F_{12}Zn$ MS (FAB), *m/e* 843 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 675 (5.11), 620 (4.75), 359 nm (4.88).

*(1,2,3,4,8,9,10,11,15,16,17,18-Dodecafluoro)tribenzo[b,g,l]naphthalo[2,3-q]-porphyrazine Zinc (ZnPcF$_{12}$nap) (**5i**).* Yield, 98%; $C_{36}H_6N_8F_{12}Zn$ MS (FAB), *m/e* 843 ($M^+ + H$); UV−vis, λ (THF) (log ϵ) 710 (4.96), 679 (4.92), 352 (4.55), 337 nm (4.39).

Drug Formulation. To impart water solubility, phthalocyanines **5a**−**5i** were formulated as Cremophor EL emulsions as previously published (*55*). Briefly, the Pcs were dissolved in THF, and 1 mL of Cremophor EL and 0.3 mL of 1,2-propanediol were added to the solutions. The solutions were then sonicated for 30 min,

followed by removal of the THF solvent by rotary evaporation under reduced pressure. Phosphate-buffered saline (PBS) (8.7 mL) was added to the viscous liquid, and the mixture was sonicated for 30 min. The resulting emulsion was filtered (0.45 μm, Millipore). Concentrations were determined by serial dilution of the stock preparation with THF.

l-Tryptophan Photooxidation (*56*). A solution of 5 μM Pc and 5 mM L-tryptophan in PBS (1 mL total volume) was irradiated using a high-intensity xenon light source (model IL 302) equipped with a CermaxR xenon short-arc 300 W lamp (model LX300F) (ILC Technology, Sunnydayle, CA). A liquid guide fiber-optic (model 77556, Oriel Corp., Stratford, CT) was used to deliver the light. Two filters, an LS-700 and an LL-600 (Corion, Holliston, MA), were used to allow transmission of light in the 600−700 nm range. [Note that the LS-700 filter was removed when (1,2,3,4,8,9,10,11,15,16,17,18-dodecafluoro)tribenzo[*b*,*g*,*l*]naphthalo[2,3-*q*]porphyrazine zinc was used.] The fluence rate was 150 mW cm^{-2}. After 2 and 4 min of irradiation, 80 μL samples were removed from the photooxidation reaction and were analyzed by HPLC to quantify the characteristic hydroperoxide products of singlet oxygen tryptophan peroxidation (3a-hydroperoxy-1,2,3,3a,8,8a-hexahydropyrrolo[2,3-*b*]indole-2-carboxylic acid; HPPI isomers) (t_R = 5.8 and 8.6 min, t_R for tryptophan = 15.7 min). The relative HPPI yield was measured from the HPPI chromatogram peak areas using a Shimadzu HPLC system (Kyoto, Japan) composed of an LC-600 pump, an SP-6AV UV−visible detector, a DGV-4A degasser, an LPM-600 low-pressure mixing system, a rheodyne injector, and the EZChrom chromatography data acquisition and analysis system. During this analysis, a C18 Radial Pak cartridge (10 × 0.8 cm) filled with 4 μm Nova Pak C18 reversed phase packing was eluted at 1.5 mL min^{-1} with 0.1% TFA in water and a linear gradient over 25 min from 1 to 30% methanol (0.1% TFA). The wavelength of a UV−vis detector was set at 280 nm. The relative HPPI yield was evaluated by comparing the peak areas corresponding to the HPPI isomers to the total tryptophan peak area and then arbitrarily comparing this ratio to the ratio obtained using $AlPcS_4$ in PBS.

In Vitro Photocytotoxicity. A suspension of ~1.5 × 10^4 EMT-6 cells per well in 100 μL of Waymouth 15% FBS was incubated overnight at 37 °C with 5% CO_2 in 96-well microtitration plates (Falcon). The FBS solution was supplemented with 1% L-glutamine and 1% penicillin−streptomycin. The first column (eight wells) served as a blank control (no cells), wheres the second and third columns (16 wells) served as a control (no phthalocyanine added, 100% cell survival). The cells were rinsed twice with PBS, and then 50 μL of Pcs **5a**, **5b**, and **5g** was added at concentrations of 1 and 5 μM in Waymouth 1% FBS. The plates were incubated at 37 °C with 5% CO_2 for 1 or 24 h. Before irradiation, the cells were rinsed twice with PBS and then refed with 100 μL of Waymouth 15% FBS. Irradiation consisted of illuminating the microtitration plates with red light (660−700 nm) at graded fluences of 0−54 J cm^{-2} at a fluence rate of 100 mW cm^{-2}. The light source consisted of two 500 W tungsten/halogen lamps (GTE Sylvania, Drummondville, PQ, Canada) fitted with a circulating refrigerated filter containing aqueous rhodamine B (Sigma, ON, Canada) (OD_{580} = 1.25). Cell survival was then assessed by means of the colorimetric MTT assay (*23*).

A MTT (Aldrich Canada Ltd., Oakville, ON, Canada) stock solution of 5 mg mL^{-1} was prepared and kept at 4 °C in the dark. Upon a 5-fold dilution in Waymouth 15% FBS, 50 μL of the MTT solution was added to all of the wells of the microtitration plate, and the cells were incubated for 4 h at 37 °C with 5% CO_2. Acidic sodium dodecyl sulfate (SDS) solution (10% SDS in 0.01 N HCl) (100 μL) was then added to each well, and the cells were incubated for 24 h at 37 °C with 5% CO_2. Following this incubation, the microtitration plates were agitated at room temperature for 10 s, and the absorbance at 595 nm was read on a microplate reader (Bio-Rad, ON, Canada). The percent cell survival was determined as follows. The average absorbance of the blank cells containing only MTT solution was subtracted from the average absorbance obtained from the wells of identical treatment as well as subtracted from the average absorbance measured from the control wells containing untreated cells (which represent 100% cell viability). The percent cell survival was calculated by dividing the absorbance of the treated cells by the absorbance of the nontreated cells and multiplying by 100. Eight replicates were run, and experiments were repeated three times.

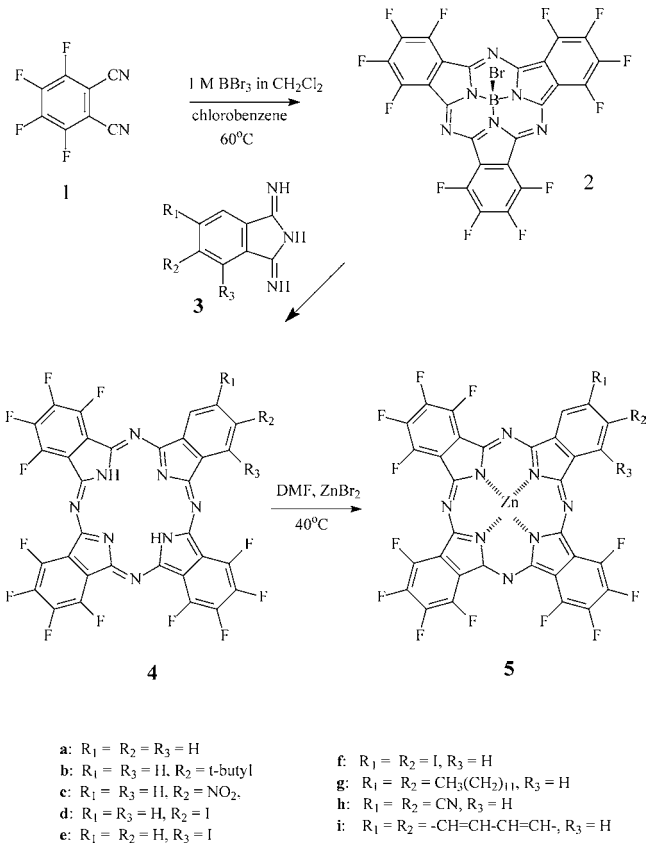

Figure 1. Synthesis of dodecafluorinated phthalocyanines **4a**−**i** via the Kobayashi ring expansion reaction of dodecafluorosubphthalocyanato boron(III) bromide (**2**).

RESULTS

Synthesis of Boron Dodecafluorinated Subphthalocyanine (2). The tetrafluorophthalonitrile readily reacts with the stronger Lewis acid boron tribromide in chlorobenzene at temperatures of 40−60 °C, with the reaction mixture rapidly adopting the characteristic intense purple color of the corresponding subPc (Figure 1). In fact, the reaction proceeded relatively smoothly in dichloromethane at room temperature, although yields of the desired tripyrrolic macrocycle were significantly lower and reaction times were longer. The use of chlorobenzene instead of the higher boiling 1-chloronaphthalene greatly eased the purification of the dodecafluoro-

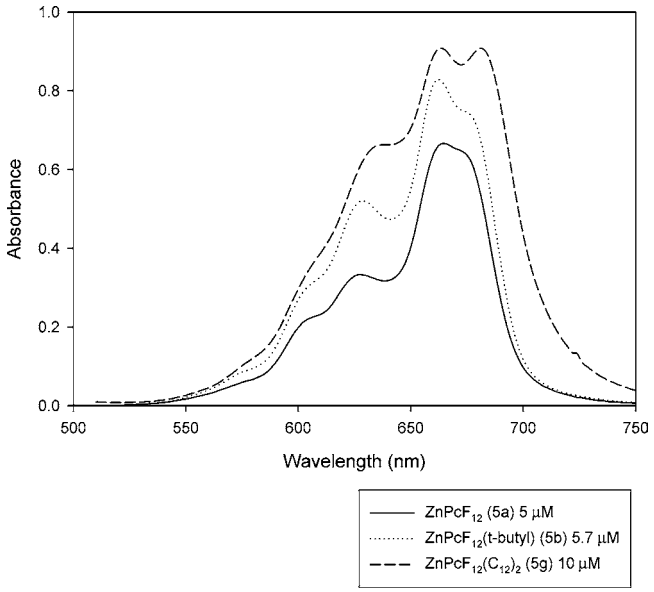

Figure 2. UV−vis spectra of **5a**, **5b**, and **5g** in THF.

subphthalocyanine **2**. The latter product was purified by column chromatography on neutral alumina in the dark (70% yield).

At lower reaction temperatures (0 °C) in either dichloromethane or chlorobenzene a transient blue intermediate, which absorbed around 660 nn, was obtained instead of the desired intensely purple subPc **2**.

Kobayashi Ring Expansion Reaction of the Boron Dodecafluorinated Subphthalocyanine (2). SubPc 2 readily reacted with various 1,3-diiminoisoindolines (**3a**−**3i**) in DMSO to give the corresponding 3:1 unsymmetrically substituted dodecafluorinated phthalocyanines (**4a**−**4i**) (Figure 1). The reaction proceeded exceptionally rapidly, being complete after 1 h, with an immediate loss of the intense purple color of the subPc solution. In the case of 5,6-didodecyl-1,3-diiminoisoindoline (**3g**), the 1,3-diiminoisoindoline was only marginally soluble in DMSO, necessitating the use of a 1:1 mixture of DMSO and chlorobenzene as reaction solvent. The metal-free Pcs **4a**−**4i** prepared by this reaction were typically insoluble in the reaction solvent and precipitated from solution in yields ranging from 10 to 60%. In cases where the Pc product was slightly soluble in the reaction solvent, the product could readily be isolated by adding the reaction mixture to a large excess of methanol. The resulting green precipitate could be isolated by centrifugation or filtration. Mass spectra of all final Pc products exhibited intense peaks corresponding to the molecular ion (M^+) or $M^+ + 1$. The metal-free dodecafluorinated phthalocyanines **4a**−**4i** were practically insoluble in most common organic solvents but slightly soluble in DMF. Electronic absorption spectra in DMF displayed characteristic Q-band absorptions around 670−680 nm with a weaker satellite in the range of 600−620 nm (Figure 2). The extended conjugation of (1,2,3,4,8,9,10,11,15,16,17,-18-dodecafluoro)tribenzo[*b*,*g*,*l*]naphthalo[2,3-*q*]porphyrazine (**4i**) shifted the absorption to a longer wavelength (700, 675 nm) as would be expected. Metal ion insertion was accomplished in nearly quantitative yield by suspending the metal-free dodecafluorinated Pcs **4a**−**i** in DMF at 40−60 °C in the presence of the metal ion (Figure 1). Other reaction solvents such as NMP failed to give the corresponding ZnPc and led to important macrocycle degradation. Attempts were undertaken to prepare the corresponding dodecafluorinated ZnPc directly by adding zinc ions to the Kobayashi ring expansion reaction. However, although the reaction appeared to give the desired 3:1 unsymmetrically substituted Pc, yields were greatly decreased. In addition, the ZnPcs exhibited higher solubility in the reaction solvent, leading to significant difficulties in isolating and purifying the final phthalocyanine product.

Table 1. Relative Hydroperoxide Yields as a Result of L-Tryptophan Photooxidation

photosensitizer[a]	λ_{max} (nm)	relative peroxide yield
$AlPcS_4$ (in PBS)[b]	680	1
$AlPcS_4$	678	1.15
$ZnPcF_{16}$	678	1.40
$ZnPcF_{12}S$	674	1.82
$ZnPcF_{12}$ (**5a**)	674	1.38
$ZnPcF_{12}$(*tert*-butyl) (**5b**)	663	1.49
$ZnPcF_{12}(NO_2)$ (**5c**)	678, 667	2.30
$ZnPcF_{12}$(4-I) (**5d**)	671	2.43
$ZnPcF_{12}$(3-I) (**5e**)	680	2.31
$ZnPcF_{12}(I_2)$ (**5f**)	676	2.00
$ZnPcF_{12}(C_{12})_2$ (**5g**)	683, 664	1.17
$ZnPcF_{12}(CN)_2$ (**5h**)	675	1.64
$ZnPcF_{12}$nap (**5i**)	710, 679	1.85

[a] Formulated as 0.5% Cremophor EL emulsions unless otherwise noted. [b] The singlet oxygen yield for $AlPcS_4$ in phosphate buffer (1% Triton X) has been reported to be 0.43 (*72*).

Tryptophan Photooxidation. The asymmetrically substituted dodecafluorinated ZnPcs **5a**−**5i** formulated as Cremophor/PBS emulsions were exposed to red light in the presence of L-tryptophan. The relative yield of HPPI isomers was then determined by HPLC and compared to that of $AlPcS_4$ in PBS, the yield of which was arbitrarily set at 1 (Table 1). The CRM emulsions of **5a**−**5i** exhibited improved yields of the HPPI isomers as compared to $AlPcS_4$ in PBS. Formulation of $AlPcS_4$ in CRM also led to slightly improve L-tryptophan photooxidation, most likely as a result of decreased aggregation of the chromophore. The most significant photooxidation of L-tryptophan was obtained using the iodinated Pc derivatives, with relative HPPI yields of 2.43, 2.31, and 2.00 obtained for Pcs **5d**, **5e**, and **5f**, respectively. The nitro-substituted derivative **5c** also provided L-tryptophan photooxidation that was >2 times higher than that observed for $AlPcS_4$ in PBS. On the other hand, the dodecafluorinated ZnPc substituted with two long alkyl chains (**5g**) gave HPPI yields comparable to $AlPcS_4$ in 1% CRM.

In Vitro Photodynamic Activity. Using a constant dye concentration of 1 or 5 μM, the photocytotoxicity of dodecafluorinated zinc phthalocyanines **5a**, **5b**, and **5g** on EMT-6 murine mammary tumor cells was measured after illumination for various amounts of time at a fluence rate of 100 mW/cm^2 as calculated over the range of the Q-band of phthalocyanines (660−700 nm). The light doses required to induce 50 and 90% cell death (LD_{50} and LD_{90}) were extrapolated from the resulting cell survival curves. No significant dark toxicity was observed for any of the photosensitizers examined at either concentration. Figure 3 shows histograms reporting the LD_{50} and LD_{90} after 1 and 24 h of incubation with photosensitizers **5a**, **5b**, and **5g** and for hexadecafluorinated ZnPc ($ZnPcF_{16}$), a photosensitizer that has already been extensively studied (*55*, *57*−*59*). The asymmetrically substituted photosensitizers **5a**, **5b**, and **5g** were more phototoxic than the symmetrically substituted $ZnPcF_{16}$ at both dye concentrations. The improved photocytotoxicity was more pronounced for the photosensitizers substituted with a *tert*-butyl group (**5b**) and was even more prominent for the dodecafluorinated phthalocyanine

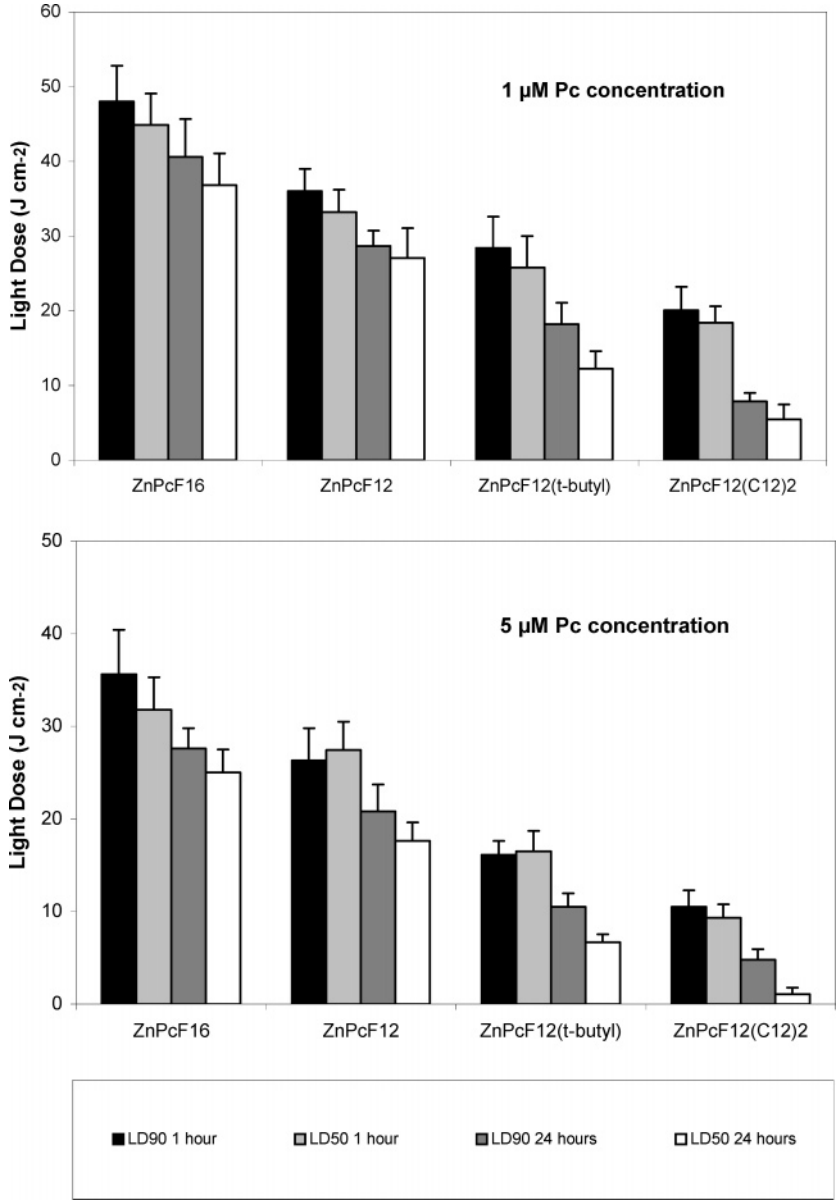

Figure 3. Photocytotoxicity of asymmetrically substituted fluorinated phthalocyanines: phototoxic activity of a 1 μM (top) or 5 μM (bottom) solution of zinc dodecafluorinated phthalocyanines **5a**, **5b**, and **5g** toward EMT-6 murine mammary tumor cells.

substituted with two dodecyl groups (**5g**). The difference in photocytotoxicity between these two photosensitizers and $ZnPcF_{16}$ is appreciably more important after incubation for 24 h.

DISCUSSION

Dodecafluorosubphthalocyanato boron(III) bromide (**2**) was successfully synthesized by the cyclotrimerization reaction of tetrafluorophthalonitrile with BBr_3 in chlorobenzene at 40−60 °C. Yields as high as 70% were obtained, which compare to 26% yield previously reported for the reaction of boron trichloride and tetrafluorophthalonitrile in benzene or 1-chloronaphthalene at elevated temperatures (*34*). It has been established that the reactivity of trisubstituted boron compounds toward the cyclotrimerization reaction is $B(alkyl)_3 < BPh_3 < BF_3 < BCl_3 < BBr_3$, an order that is closely related to the Lewis acidity of the boron compounds (*29*). In addition, the presence of four strongly electron-withdrawing fluorine atoms on the tetrafluorophthalonitrile starting material will activate the nitrile groups toward the cyclotrimerization reaction. A combination of the increased reactivity of the boron source and the activation of the nitrile groups of tetrafluorophthalonitrile toward the cyclotrimerization reaction results in the possibility of the reaction being carried out under milder reaction conditions, thus ensuring a higher yield of the desired boron dodecafluoro subPc. No exchange of fluorine for bromine was observed. This is despite the strong Lewis acidity of the boron tribromide and the known reactivity of tetrafluorophthalonitrile toward exchange reactions (*60*).

The resulting dodecafluorinated tripyrrolic macrocycle was purified by flash column chromatography on neutral alumina in the dark. It has been reported that subPcs bearing bromine axial ligands are fairly unstable with respect to axial ligand exchange and that purification of bromosubPcs via column chromatography resulted in an appreciable amount of replacement of the bromine axial ligand by OH (*29*). To overcome this, it has been suggested that these labile subPcs can be purified by precipitation or Soxhlet extraction with an appropriate solvent (*33*). However, in the current study, it was observed that addition of the chlorobenzene reaction mixture to excess hexanes led to degradation of the

macrocycle. This is despite reports that subPcs are stable in apolar solvents (*61*). On the other hand, it has been reported that dodecafluorosubphthalocyanato boron(III) chloride undergoes thermal decomposition in hexanes (*62*). Soxhlet extraction with dry dichloromethane of the solid obtained either by precipitation from excess hexanes or by evaporation of the dichlorobenzene from the reaction mixture also led to degradation of the subPc, significantly decreasing the yield of the desired product. Purification by flash column chromatography using 30% THF in hexanes or using dichloromethane proved to be the most efficient method of purifying dodecafluorosubphthalocyanato boron(III) bromide (**2**).

When attempts were made to prepare **2** at 0 °C, a labile blue product was obtained. Interestingly, we observed similar labile blue products when the cyclotrimerization of other phthalonitriles substituted with electron-withdrawing groups (such as 4-nitrophthalonitrile, 4-iodophthalonitrile, and 4,5-dicyanophthalonitrile) was carried out at 0 °C (results not presented). Although the identity of this labile species has not been fully elucidated, identification of this species may help determine the mechanism of the cyclotrimerization reaction, which in turn may help investigators in improving the synthesis and the utility of subPcs. The literature describes that dodecafluorosubphthalocyanato boron(III) chloride undergoes thermal decomposition in hexanes to yield a light blue product, the structure of which was not determined (*62*). We attempted to prepare Pc by reacting the transient blue complex with various 1,3-diiminoisoindolines. However, no green/blue product corresponding to phthalocyanines was obtained.

There are a number of possible identities for this transient blue species. It is well-known that boron trihalides readily form charge-transfer complexes with nitrile functional groups (*63*), and one would expect that some type of charge-transfer complex with the dinitrile functionality of phthalonitriles would form at some point during the synthesis of subPcs. However, it was observed that this transient blue intermediate transformed into the desired $subPcF_{12}$ upon heating of the reaction mixture. Furthermore, treatment of $subPcF_{12}$ with $NaBH_4$ resulted in a loss of the characteristic Q-band at 577 nm and the formation of a broad absorption around 660 nm, whereas treatment of the blue intermediate with DDQ led to a broad transient absorption centered near 580 nm. Because the bromide **2** absorbs at 577 nm and the transient blue species exhibits a broad absorption centered approximately at 660 nm, these results imply that the transient blue species requires oxidation in order to form the subPc. A bathochromic shift of the absorption from the subPc to the incompletely oxidized blue intermediate would not be unexpected. A loss of conjugation in tetrapyrrolic macrocycles is known to lead to red shifts in the λ_{max}. For instance, although the completely conjugated protoporphyrin IX absorbs at 630 nm, the incompletely conjugated verteporfin absorbs at 690 nm (*64*). It has been reported that the singlet excited state of dodecafluorosubphthalocyanato boron(III) chloride is a strong oxidant (*62*) with a one-electron reduction potential estimated to be approximately 1.7 V, suggesting that the relationship between the subPc and the blue species may pass via a photoexcited state of the subPc.

In the current study, the Kobayashi ring expansion reaction of the subPc **2** with various 1,3-diiminoisoindolines (**3a**−**3i**) selectively yielded the desired 3:1 asymmetrically substituted dodecafluorinated Pcs (**4a**−**4i**). Yields for the dodecafluorinated Pcs ranged from 18% to as high as 60%, although lower yields were obtained using 4-iodo-1,3-diiminoisoindoline (**3e**), probably a result of steric effects. Lower yields of Pc were also obtained using 5,6-didodecyl-1,3-diiminoisoindoline (**3g**). Both the steric effect and solubility of **3g** may have played a part in the lower yields obtained for 2,3,4,8,9,10,11,15,16,17,-18-dodecafluoro-23,24-didodecylphthalocyaninate (**4g**). Whereas the other 1,3-diiminoisoindoline derivatives employed could be solubilized in DMSO upon sonication, **3g** required the use of a 1:1 mixture of DMSO and chlorobenzene to obtain a solution. Conversely, when 5-*tert*-butyl-1,3-diiminoisoindoline was used instead of its unsubstituted derivative, the reaction did proceed to give some tetra-*tert*-butylphthalocyanine in pure DMSO, although yields were low (*37*).

Due to the known tendency of tetrafluorophthalonitrile to undergo an exchange reaction with DMF (*60*), attempts to insert metal ions such as Zn^{2+} into the metal-free dodecafluorinated phthalocyanines using solvents such as NMP were undertaken. Unfortunately, these metal ion insertion reactions were sluggish and gave unacceptable yields. To avoid any possible reaction between DMF and the perfluorinated macrocycle, reaction temperatures between 30 and 50 °C were employed and led to the corresponding zinc dodecafluorinated phthalocyanines in nearly quantitative yields.

Singlet oxygen is believed to be the most important reactive species generated during PDT and is capable of inducing important characteristic oxidative damage to a number of biologically important molecules including amino acids (*65*). L-Tryptophan photooxidation was used to evaluate the photodynamic potential of the asymmetrically substituted zinc dodecafluorinated phthalocyanines by comparing the relative HPPI yields obtained using these Pcs to the yield obtained using $AlPcS_4$ in PBS (which was arbitrarily set as 1) (*56*). In light of the heavy atom effect, it is not unexpected that these dodecafluorinated photosensitizers exhibit improved HPPI yields as compared to $AlPcS_4$, with the iodinated derivatives giving the highest singlet oxygen yields. The heavy atom effect dictates that the exchange of hydrogen atoms with heavier atoms (such as fluorine atoms) on a chromophore increases intersystem crossing from the singlet to the triplet state by increasing spin−orbital coupling, thus allowing otherwise forbidden changes in the spin state ($S_1 \rightarrow T_1$) (*66*). Accordingly, the exchange of hydrogen atoms for fluorine atoms of the periphery of phthalocyanine photosensitizers improves the photodynamic potential of the photosensitizer by improving triplet state yields.

Interestingly, for a series of zinc tetrahalogenated Pcs ($ZnPcX_4$, where X is Cl, Br, or I), it was observed that increases in triplet state formation and decreases in triplet-state lifetimes increased in the order Cl < Br < I, as would be expected in terms of spin−orbital coupling theory (*67*). However, the production of singlet oxygen was only slightly increased by the nature of the halogen atom. Although these results were not fully explained, it was noted that the tendency of these macrocycles to aggregate was in the order Br > I > Cl > H. As such, the improved photodynamic potential that results from the heavy atom effect may be somewhat counteracted by the tendency of Pcs to aggregate in solution. It has been shown that amphiphilic unsymmetrically substituted phthalocyanines bearing long alkyl chains exhibit decreased HPPI yields in the L-tryptophan photooxidation assay (*24*), even as CRM emulsion, due to important aggregation of the macrocycle, with the long alkyl chains increasing the lipophilicity of the Pcs. Whereas the zinc dodecafluorinated phthalocyanines are all lipophilic pho-

tosensitizers, it is believed that the longer alkyl chains promote aggregation of the phthalocyanine **5g**, even in CRM emulsions, resulting in decreased HPPI yields under these experimental conditions.

Most lipophilic Pcs, including unsubstituted ZnPc and AlOHPc, are highly insoluble in most common solvents. Thus, despite important photodynamic activity, the utility of such lipophilic Pcs is rather limited. Fluorine is very similar in atomic radius to hydrogen and can mimic hydrogen in biological environments. In addition, exchange of hydrogen atoms for fluorine atoms increases lipid solubility and thus may lead to enhanced interactions with biological membranes. A number of water-soluble amphiphilic fluorinated zinc phthalocyanines have also been synthesized and shown to have enhanced properties for photodynamic therapy (*68*, *69*). Additionally, a novel three-dimensional zinc perfluorinated phthalocyanine comprising 64 fluorine atoms has been synthesized from a novel nonplanar perfluorinated phthalonitrile and has been shown to have improved PDT efficiency as compared to $ZnPcF_{16}$ (*70*).

Preliminary in vitro PDT against EMT-6 tumor cells indicates that asymmetrically substituted dodecafluorinated phthalocyanines **5a**, **5b**, and **5g** are more photodynamically active than the symmetrically substituted $ZnPcF_{16}$ in CRM emulsions after incubations of 1 or 24 h (see Figure 3). Intriguingly, despite lower HPPI yields in the L-tryptophan photooxidation assay, **5g** was the most photodynamically active Pc examined. Whereas it was proposed that the lack of an appreciable activity of $ZnPcF_{16}$ and $ZnPcCl_{16}$ against M6 melanoma cells was due to aggregation of the PS even in the complicated environment of cells (*71*), the current study indicates that aggregation becomes less important in such biological systems, possibly due to interaction of proteins and lipoproteins with the planar Pc reducing the extent of aggregation.

CONCLUSION

DodecafluorosubPc boron(III) bromide (**2**) was prepared under milder conditions and shown to react readily with numerous 1,3-diiminoisoindolines in DMSO (Kobayashi ring expansion reaction), leading to the selective preparation of 3:1 unsymmetrically substituted dodecafluorinated phthalocyanines. Upon chelation to Zn^{2+} the resulting asymmetrically substituted dodecafluorinated ZnPcs were shown to be effective photosensitizers for the production of singlet oxygen. Preliminary in vitro photodynamic therapy against EMT-6 murine mammary tumor cells indicates that these compounds have potential as photosensitizers for PDT.

Tat Peptide as an Efficient Molecule To Translocate Gold Nanoparticles into the Cell Nucleus

Jesus M. de la Fuente*,§ and Catherine C. Berry

Centre for Cell Engineering, Institute of Biomedical and Life Science, Joseph Black Building, University of Glasgow, Glasgow G12 8QQ, U.K Received February 9, 2005; Revised Manuscript Received June 10, 2005

The labeling of targeting molecules with nanoparticles has revolutionized the visualization of cellular or tissue components by electron microscopy. A particularly desirable target is the nucleus, because the genetic information is there. To date, utilizing nanoparticles for nuclear targeting has not proved very successful due to the impermeable nature of the plasma and nuclear membranes; thus nanoparticle design and synthesis is a critical factor. We report in this article the synthesis of water-soluble gold nanoparticles functionalized with a Tat protein-derived peptide sequence by a straightforward and economical methodology. The particles were subsequently tested in vitro with a human fibroblast cell line by optical and transmission electron microscopy to determine the biocompatibility of these nanoparticles and whether the functionalization with the translocation peptide allowed particles to transfer across the cell membrane and locate in the nucleus.

INTRODUCTION

During the last 20 years, there has been a great deal of interest in the self-assembly fabrication of hybrid materials from inorganic nanoparticles and biomolecules (*1*). Nanoparticles are similar in size range to many common biomolecules and thus appear to be natural companions in hybrid systems. At present, it is straightforward to control and modify the properties of nanostructures to better suit their integration with biological systems, for example, controlling their size and modifying their surface layer for enhanced aqueous solubility, biocompatibility, or biorecognition (*2*, *3*).

This proposal of merging biological and nonbiological application systems at the nanoscale level has been used for research in cell and molecular biology for biosensing, bioimaging, masking of immunogenic moieties to targeted drug delivery, and interaction studies (*4*−*6*). For example, gold nanoparticles were initially used in biological applications in 1971, when Faulk and Taylor devised the immunogold staining procedure. More recently, the labeling of targeting molecules with nanoparticles has revolutionized the visualization of cellular or tissue components by electron microscopy (*7*). In fact, metal, semiconductor, polymer, and magnetic particles have been previously used to target cells (*8*−*14*). Most of these studies exclusively concerned particle entry into the cell cytoplasm. However, the nucleus is a particularly desirable target, because the genetic information of the cell and transcription machinery resides there. The diagnoses of disease phenotype, the identification of potential drug candidates, and the treatment of disease by novel methods such as antisense therapy could be enhanced greatly by the efficient transport of materials to living cell nuclei (*15*). However, one of the impediments in the use of nanoparticles for this purpose is their particularly low translocation efficiency into the cell nucleus.

Our research group is developing biocompatible fluorescence quantum dots and gold nanoparticles functionalized with different peptides to specifically label different receptors on the cell. Recently, we have reported the synthesis of CdS nanoparticles functionalized with a Tat protein-derived peptide sequence (*16*). This peptide sequence has previously been used as an efficient way of internalizing a number of marker proteins in cells (*17*, *18*).

In this study, gold nanoparticles protected with the non-amino-acid tiopronin and functionalized with a Tat protein-derived peptide were synthesized using a straightforward method. These nanoparticles are biocompatible and have been able to cross the cell and the nuclear membranes and accumulate in the cell nucleus.

EXPERIMENTAL PROCEDURES

Chemicals. Hydrogen tetrachloroaureate(III) trihydrate (99.9+%), (*N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride, and 2-[*N*-morpholino]ethanesulfonic acid (99.5%) were purchase from Sigma-Aldrich, *N*-(2-mercaptopropionyl)glycine (>98%) and *N*-hydroxysuccinimide (>97%) from Fluka, $NaBH_4$ (98%) from Lancaster, and Tat protein-derived peptide sequence (GRKKRRQRRR) from Southampton Polypeptides Ltd. House distilled water was further purified using a Milli-Q reagent grade water system (Millipore). Buffers were prepared according to standard laboratory procedure. Other chemicals were reagent grade and used as received.

General Procedures. ^{1}H NMR[1] spectra were acquired on Bruker DRX-400 spectrometers, and chemical shifts are given in ppm (δ) relative to the residual signal

of the solvent used. UV spectra were carried out with a UV/vis Shimadzu UV-3101PC spectrometer in Milli-Q water. Infrared spectra of solid samples pressed into a KBr plate were recorded from 4000 to 750 cm^{-1} with a JASCO FT/IR 410 model spectrometer.

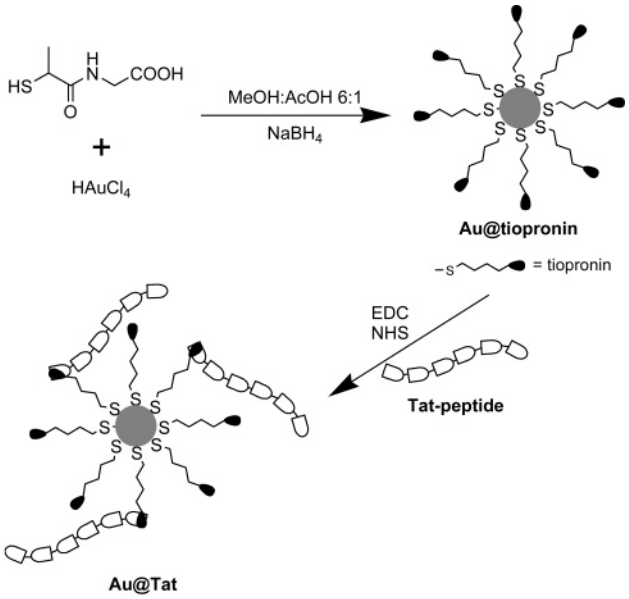
For TEM examinations, a single drop (10 μL) of the aqueous solution (0.1 mg mL^{-1}) of the gold nanoparticles was placed onto a copper grid coated with a carbon film. The grid was left to dry in air for several hours at room temperature. TEM analysis was carried out in a JEM-1200EX electron microscope working at 80 kV. Particle size distribution of the Au clusters was evaluated from several micrographs using an automatic image analyzer. The number of particles selected for consideration was around 400, which resulted in a stable size-distribution statistic.

Au@tiopronin. Hydrogen tetrachloroaureate(III) trihydrate (0.15 g, 0.4 mmol, 1 equiv) and *N*-(2-mercaptopropionyl)glycine (tiopronin; 0.19 g, 1.2 mmol, 3 equiv) were codissolved in 20 mL of 6:1 methanol/acetic acid, giving a ruby red solution. $NaBH_4$ (0.30 g, 8.0 mmol, 20 equiv) in 7.5 mL of H_2O was added with rapid stirring. The black suspension that was formed was stirred for an additional 30 min after cooling, and the solvent was then removed under vacuum at 40 °C. The crude **Au@tiopronin** was completely insoluble in methanol but quite soluble in water. It was purified by dialysis, in which the pH of 130 mg of crude product dissolved in 20 mL of water was adjusted to 1 by dropwise addition of concentrated HCl. This solution was loaded into 15 cm segments of seamless cellulose ester dialysis membrane (Sigma, MWCO = 10.000), placed in 4 L beakers of water, and stirred slowly, recharging with fresh water approximately every 10 h over the course of 72 h. The dark blue **Au@tiopronin** solutions were collected from the dialysis tubes and were lyophilized. The product materials were found to be spectroscopically clean (NMR, absence of signals due to unreacted thiol or disulfide byproducts). Yield: 96 mg. Average diameter: 2.8 nm. ^{1}H NMR (400 MHz, D_2O): δ = 4.40−3.75 (m), 3.70 (bs), 2.20−1.30 (m). UV/vis (H_2O): υ = 450, 560 nm (surface plasmon band). FT-IR (KBr): υ = 3436, 2920, 2855, 1624, 1385, 1297, 1260, 1019, 804 cm^{-1}.

Au@Tat. (*N*-(3-Dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC; 2 mg, 0.01 mmol) and *N*-hydroxysuccinimide (NHS; 3 mg, 0.025 mmol) were added to 4 mL of **Au@tiopronin** (2 mg) in 2-[*N*-morpholino]ethanesulfonic acid (MES) (50 mM, pH 6.5). The reaction proceeded for 30 min. After that, Tat peptide (112 μg, 0.000 08 mmol) was added, and the mixture was stirred for 24 h more. This solution was loaded into 6 cm segments of seamless cellulose ester dialysis membrane (Sigma, MWCO = 10.000), placed in 4 L beakers of water, and stirred slowly, recharging with fresh water approximately every 10 h over the course of 24 h. The dark blue **Au@Tat** solutions were collected from the dialysis tubes and were lyophilized. Yield: 1 mg. ^{1}H NMR (400 MHz, D_2O): δ = 4.65−4.80 (m), 4.25−3.75 (m), 3.66 (bs), 3.30−3.60 (m), 2.00−1.30 (m). UV/vis (H_2O): υ = 450, 560 nm (surface plasmon band). FT-IR (KBr): υ = 3419, 2917, 2842, 2357, 2330, 1647, 1635, 1452, 1418, 1385, 1310, 1283, 1111, 1024, 901, 799, 772 cm^{-1}.

Biocompatibility Assay. HTERT-BJ1 cells (10 000 cells) were cultivated in a 96 well plate at 37 °C in 5% CO_2. After 24 h, the medium was replaced with fresh medium containing the gold nanoparticles in varying concentrations. After cultivation again for 24 h, 20 μL of MTT dye solution (5 mg/mL in PBS) was added to each well. After 3 h of incubation at 37 °C and 5% CO_2, the medium was removed, the cells were washed with PBS, and formazan crystals were dissolved in 100 μL of DMSO. The absorbance of each well was read on a microplate reader (Dynatech MR7000 instruments) at 550 nm. The spectrophotometer was calibrated to zero absorbance using culture medium without cells. The relative cell viability (%) related to control wells containing cell culture medium without gold nanoparticles was calculated by $[A]_{test}/[A]_{control} \times 100$.

Scheme 1. Preparation of Au@Tat Nanoparticles



Cell Culture. Infinity telomerase-immortalized primary human fibroblasts (hTERT-BJ1, Clontech Laboratories, Inc., Palo Alto, CA) were seeded onto glass coverslips (13 mm diameter) at a density of 1×10^4 cells per disk in 1 mL of complete medium. The medium used was 71% Dulbecco's Modified Eagles Medium (DMEM) (Sigma, U.K.), 17.5% Medium 199, 9% fetal calf serum (FCS), 1.6% 200 mM L-glutamine, and 0.9% 100 mM sodium pyruvate. The cells were incubated at 37 °C with a 5% CO_2 atmosphere for 24 h. At this time point, the cells were incubated in complete medium supplemented with 0.05 mg mL^{-1} (≈1 μM) gold nanoparticles for 1 h more.

TEM. On removal of excess nanoparticles, cell samples were fixed in 1.5% gluteraldehyde (Sigma, Dorset, U.K.) in 0.1 M sodium cacodylate buffer (Agar, Essex, U.K.). Samples were subsequently post-fixed and stained with 1% osmium tetraoxide in buffer and were dehydrated through a series of alcohol concentrations (30%, 40%, 50%, 60%, 70%, 90%, 96%, 100%), prior to being resin-embedded. Sections were further enhanced with lead nitrate and viewed under a Zeiss 902 electron microscope at 80 kV.

RESULTS

Au@tiopronin nanoparticles were prepared using the procedure of Murray et al. (*19*). The reaction was executed in a methanolic/acetic acid mixture. Codissolution of $HAuCl_4$ and tiopronin gave a stable ruby-red solution. The addition of $NaBH_4$ reductant provided a dark brown solution (Scheme 1). The suspension was shaken for about 30 min, and then the solvent was removed. The nanoparticles were purified by dialysis and characterized by ^{1}H NMR, FT-IR, UV/vis and TEM. Figure 1 shows the TEM image and core size distribution histogram for **Au@tiopronin**. A mean diameter of 2.8 nm was found for the gold core of the nanoparticles. The

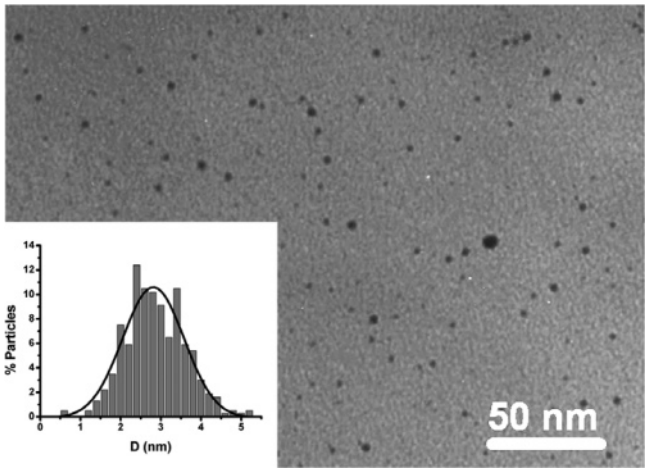


Figure 1. Transmission electron micrographs and core size-distribution histograms (inset) of **Au@tiopronin** nanoparticles.

UV/vis absorption spectrum showed a nondetectable surface plasmon band (SP band) (data not shown) as consequence of the small size of the clusters. ^{1}H NMR and FT-IR spectra confirmed the presence of tiopronin in the nanoparticles and the absence of other impurities.

The functionalization of **Au@tiopronin** with the Tat protein-derived sequence (GRKKRRQRRR) was carried out using the reactivity of the free carboxyl group of the tiopronin (Scheme 1). The reaction utilizes the water-soluble carbodiimide EDC to catalyze reactions between the nanoparticle acid groups and any of the amine groups of the peptide (*20*). We included NHS in the reaction mixture to improve the efficiency of the carbodiimide-mediated amide-forming reaction by producing hydrolysis-resistant active ester reaction intermediates (*21*). The resultant nanoparticles were analyzed by UV/vis, FT-IR, ^{1}H NMR, and TEM; nonagglutination was observed after Tat peptide coupling.

Biocompatibility studies of the **Au@tiopronin** and **Au@Tat** nanoparticles were undertaken by evaluating the cell viability of hTERT-BJ1 human fibroblasts by the MTT assay (*22*) (Figure 2). The metabolic activity and proliferation of fibroblasts was thus measured after 24 h culture and revealed no appreciable cytotoxic effects to cells at concentration as high as 5 μM, and the values reached 80% compared to untreated controls at concentrations higher than 10 μM.

TEM images taken after 1 h incubation with the particles (Figure 3) show that **Au@tiopronin** and **Au@Tat** were both taken up into the cell body. While **Au@Tat** particles were mainly located in the nucleus, only a few **Au@tiopronin** particles appeared to be taken into the cell through membrane invaginations and accumulate in the mitochondrial surroundings. **Au@tiopronin** nanoparticles were not detected in the nucleus in any case.

DISCUSSION

Based on our previous experience of sulfide-protected glyconanoparticles (*3*, *23*), we now report the simple synthesis of water-soluble and stable gold nanoparticles functionalized with a Tat protein-derived peptide sequence as a vehicle for ferrying nanoparticles into the cell nucleus.

The **Au@tiopronin** particles have been previously used in material science studies due their small size and their water-solubility, although their use in cell biology has not been extensively explored. These nanoparticles

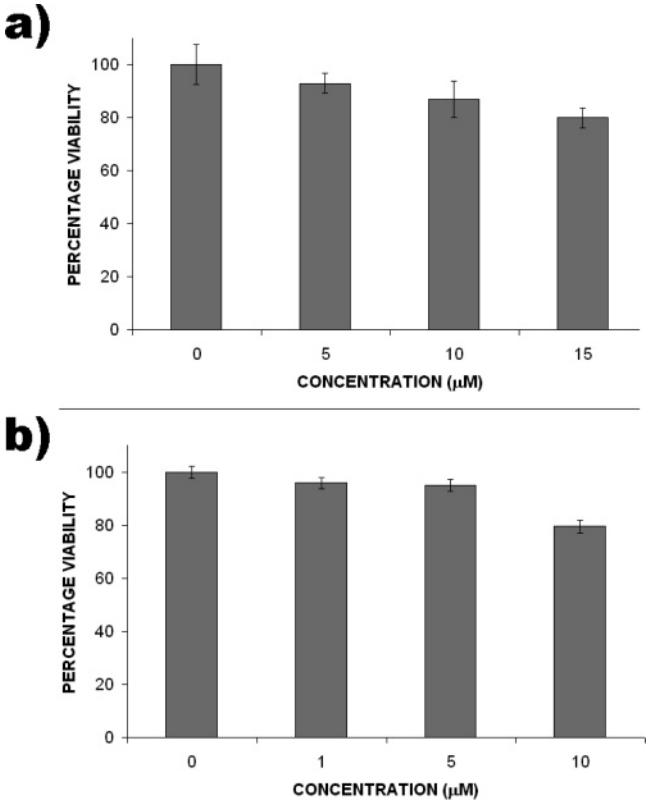

Figure 2. Cytotoxicity profiles of **Au@tiopronin** (a) and **Au@Tat** (b) nanoparticles when incubated with human fibroblasts as determined by MTT assay. Percentage of viability of fibroblasts was expressed relative to control cells ($n = 5$). Results are represented as mean ± standard deviations.

are useful tools for immunolabeling or as drug carriers due the absence of agglutination in physiological conditions and their easy functionalization. As previously stated, the free carboxyl group of the tiopronin is available for covalent coupling to various biomolecules by cross-linking to reactive amino groups. In this study, a peptide sequence derived from the HIV-1 Tat peptide has been coupled to the nanoparticle surface with a view to transfer gold nanoparticles into the cell nucleus.

The biocompatibility of **Au@tiopronin** and **Au@Tat** particles was studied using the MTT assay (*22*). This assay relies on the mitochondrial activity of fibroblasts and represents a parameter for their metabolic activity. Furthermore, it is a simple nonradiactive colorimetric assay allowing simple measurements of cell cytotoxicity, proliferation, or viability. Briefly, MTT is a yellow, water-soluble tetrazolium salt that metabolically active cells are able to convert into a water-insoluble dark-blue formazan by reductive cleavage of the tetrazolium ring. Formazan crystals can be dissolved in dimethylsulfoxide and quantified. Only 20% cytotoxicity was detected in both types of nanoparticles at concentrations up to 10 μM. Below this concentration, cellular metabolic activity did not change much in comparison with control cells (Figure 2). This low cytotoxicity allows us to use concentrations of these nanoparticles up to 10 μM for our cell nuclear labeling purposes.

The absence of impurities in the nanoparticles has been confirmed by ^{1}H NMR and FT-IR. Tat specific signals were not found in ^{1}H NMR due the low Tat/tiopronin ratio (≈1:50) (*19*) and the typical broadening of the ^{1}H NMR signals for this type of gold nanoparticles (*3*). The TEM images (Figure 1) and the almost nondetectable

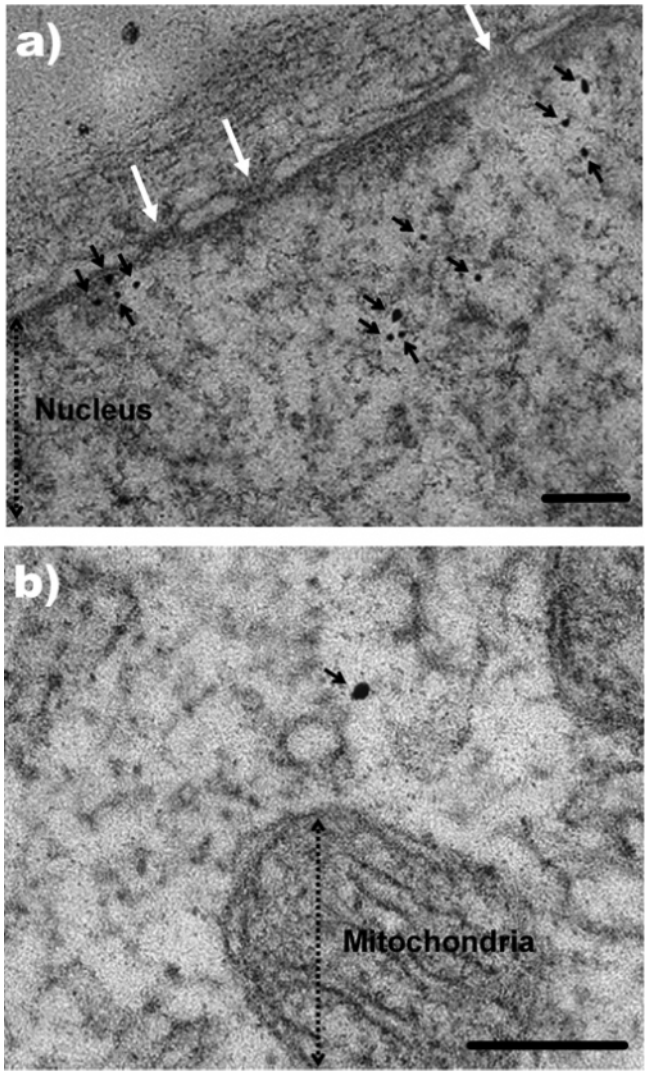

Figure 3. Transmission electron micrographs of human fibroblasts incubated with **Au@Tat** (a) and **Au@tiopronin** (b) nanoparticles. The black dots indicated with arrows are nanoparticles, and white arrows show nuclear membrane pores. (scale bars = 50 nm).

surface plasmon band confirm the small size of the clusters and the absence of aggregates.

In the present study, **Au@Tat** nanoparticles were explored to achieve nuclear targeting of human fibroblasts cells. Targeted nuclear delivery is a challenging task, because the **Au@Tat** nanoparticles must enter the cell, escape endosomal/lysosomal pathways, possess a nuclear localization sequence, and be small enough (<30 nm) to cross the nuclear membrane via nuclear pores. TEM studies have been developed to study cell and nuclear uptake.

It should be noted that the synthetic methodology reported here does not allow us to control the amino group of the Tat peptide that reacts with the nanoparticle. However, the different cell responses to **Au@Tat** in comparison with **Au@tiopronin** particles confirm the correct coupling of the Tat peptide sequence and its activity after the coupling.

The nucleus was clearly visible via TEM, and despite dense background nuclear staining, only **Au@Tat** particles were observed in the nucleus (Figure 3a). Nuclear membrane pores, the only known route of direct nucleocytoplasmic exchange of matter, were evident at the 30 nm size range and are thought to be the method of particle entry into the nucleus. **Au@tiopronin** particles were only detected in the cytoplasm in vacuoles or surrounding the mitochondria (Figure 3b), thus demonstrating the specificity of **Au@Tat** particles to be translocated and accumulate in the cell nucleus.

In conclusion, we have prepared and designed stable and water-soluble gold nanoparticles functionalized with a Tat protein-derived peptide sequence with an adequate size range to pass through nucleus pores. This functionalization has allowed the nanoparticles to penetrate the cell membrane and target the nucleus. This research has many potential applications in cell imaging, but also extends to wider biomedical applications, such as gene therapy and drug delivery.

ACKNOWLEDGMENT

This work was supported by EC, MEC, and University of Glasgow. J.M.F. thanks the MEC for a postdoctoral fellowship. We thank Mr. Jim Gallagher for help with TEM and Dr L. Cronin, Prof. A. S. G. Curtis, and Dr. M. Riehle for fruitful discussions.

New folate-conjugated superparamagnetic maghemite nanoparticles have been synthesized for the intracellular hyperthermia treatment of solid tumors. These ultradispersed nanosystems have been characterized for their physicochemical properties and tumor cell targeting ability, facilitated by surface modification with folic acid. Preliminary experiments of nanoparticles heating under the influence of an alternating magnetic field at 108 kHz have been also performed. The nanoparticle size, surface charge, and colloidal stability have been assessed in various conditions of ionic strength and pH. The ability of these folate "decorated" maghemite nanoparticles to recognize the folate receptor has been investigated both by surface plasmon resonance and in folate receptor expressing cell lines, using radiolabeled folic acid in competitive binding experiments. The specificity of nanoparticle cellular uptake has been further investigated by transmission electron microscopy after incubation of these nanoparticles in the presence of three cell lines with differing folate receptor expression levels. Qualitative and quantitative determinations of both folate nanoparticles and nontargeted control nanoparticles demonstrated a specific cell internalization of the folate superparamagnetic nanoparticles.

INTRODUCTION

In recent years, colloidal carriers have elicited many hopes for their potential as vectors for therapeutics and diagnostics in cancer therapy (*1*, *2*). As reviewed recently, metal-based colloids have many interesting applications in the biomedical field, too (*3*, *4*). For example, iron oxide nanoparticles, prospected in diagnostic clinical practice as magnetic resonance imaging enhancers in the mid 80s and currently in clinical phase IV, are nowadays among the most successful application of nanotechnologies in medicine (*5*, *6*). Nevertheless, some decades ago, such particles were already suggested as a tool to manage hyperthermia in solid tumors by heating them with alternating magnetic fields (*7*). Hyperthermia treatment of tumor and metastasis has, indeed, been demonstrated to be effective, either alone, the neoplastic cells being more thermosensitive than the normal ones, or in association with classical chemo- or radiotherapies (*8*−*10*). Despite some preliminary interesting results in preclinical tumor animal models (*11*), hyperthermia using superparamagnetic iron oxide particles has, however, been overlooked for almost a decade. Thanks to a new wave of interest for this technique, since the early 90s, a lot of progress has been made, especially in the field of superparamagnetic materials, so that finally the time seems to be ripe for the start of clinical studies (*12*, *13*). The hyperthermia is obtained by applying an alternating magnetic field of suitable frequency that produces heat dissipation through the oscillation of the internal magnetic moment of the superparamagnetic particles (*14*). Among the developments that have been considered for nanoparticle-mediated hyperthermia, we have focused our attention on the opportunity to achieve an intracellular hyperthermia treatment (*15*). The interest lies in the specific delivery of heat to target cells causing selective damage to their cytoplasm structures. Recently, a very similar approach, in which laser-absorbing gold nanoparticles were used, has been successfully applied to obtain specific targeting and killing of cancer cells (*16*). In the present study, we describe a new type of dextran-coated maghemite superparamagnetic nanoparticles targeted toward solid tumors through folate, covalently bound to the nanoparticle surface using a poly(ethylene)-

glycol (PEG) spacer. Folic acid (FA) has been chosen as the targeting moiety, since it has been observed that many solid tumors, such as ovarian and breast cancers, overexpress the specific receptor for this vitamin. In this paper, these FA-conjugated superparamagnetic nanoparticles have been characterized for their physicochemical properties, their heating capacity, and their efficacy in targeting cancer cells overexpressing the folate receptor.

MATERIALS AND METHODS

All chemicals and reagents, except where indicated, were provided by SIGMA-Aldrich (St.Quentin Fallavier, France). Cell culture media and reagents were obtained from Invitrogen-Lifetechnologies (Cergy Pontoise, France).

Superparamagnetic Nanoparticles Preparation. *Dextran-Coated Maghemite Nanocrystals Production.* Dextran-coated superparamagnetic maghemite (γ-Fe_2O_3) nanocrystals have been produced through a procedure already described (*14*, *15*). Briefly, the cores were produced by the coprecipitation of Fe(III) and Fe(II) ions in alkaline conditions, oxidation, and peptization to obtain a maghemite (γ-Fe_2O_3) cationic ferrofluid as previously reported (*16*). Subsequently, the surface modification of crystals was carried out by adding an amino silane coupling agent, γ-(aminopropyl)triethoxysilane, in methanol/water medium (1:1), followed by thermal treatment at 100−110 °C in glycerol for 2 h under vacuum. The flocculated particles were then washed with acetone and water and peptized with nitric acid until pH = 3. Such a ferrofluid was stable in a pH range of 1 to 8. The magnetic nanoparticles were sterically stabilized by activated dextran (70 kD). The activation was performed by partial oxidization of dextran vicinal diols into aldehyde groups with sodium metaperiodate. The oxidized dextran was allowed to react with the amino groups of maghemite in order to be anchored through covalent imine bonds (Shiff's bases). The colloidal suspension was washed by tangential ultrafiltration against 3 L of ultrapure water with a poly(ethersulfone) membrane (cutoff 100 000 g/mol) and stored at room temperature. Such dextran-coated maghemite nanoparticles may be described as a new covalent platform useful for MRI contrast enhancement as well as hyperthermia mediators. They were called VUSPIO for versatile ultrasmall superparamagnetic iron oxide (*14*, *15*).

Folate Conjugation. N-Hydroxysuccinimide ester of FA (NHS-folate) was prepared according to a method previously described (*17*). Briefly, 5 g of FA, dissolved in 100 mL of dry dimethyl sulfoxide containing 2.5 mL of triethylamine, was reacted with 2.6 g of *N*-hydroxysuccinimide in the presence of 4.7 g of dicyclohexylcarbodiimide overnight at room temperature. After removing the byproduct (dicyclohexylurea) by filtration, the yellow solid NHS-folate was then extracted by precipitation in diethyl ether, washed several times with anhydrous ether, and dried under vacuum. Amino−PEG−folate was prepared as follows: 1.351 g of NHS-folate was dissolved in 50 mL of DMSO and slowly added to 250 mL of carbonate/bicarbonate buffer (1 M, pH 11 adjusted with HCl 37%) containing 5 g of diaminotelechelic−PEG (Jeffamine ED-2003 from Huntsman, Salt Lake City). Two hours later, the solution was dialyzed against 5 L of water (MwCo 1000 g/mol). The dialysis procedure was repeated every 24 h for a total of 5 times. Amino−PEG−folate was characterized by ^{1}H NMR (300 MHz, DMSO-d_6): δ 8.61 (s, 7-H of FA, 1H), 7.65 (d, 13,15-H of FA, 2H), 6.64 (d, 12,16-H of FA, 2H), 4.25−4.15 (m, 19-H of FA, 1H), 3.75−3.45 (m, CH_2CH_2 of PEG, ∼170H), 1.07−0.87 (m, propylene CH_3 Jeffamine ED-2003, ∼15H). UV analysis allowed the determination of the folate content in the final product: 26.3 mg of amino−PEG−FA were dissolved in 2 mL of 10 mM phosphate buffer, 0.15 M NaCl, pH 7.5, diluted 50 times in phosphate buffer and analyzed by UV. The folate content was estimated on the basis of the FA extinction coefficient $\epsilon_M = 6197\ M^{-1}\cdot cm^{-1}$ at 363 nm and found equal to the average value of 1.02 folate group per amino−PEG−FA macromolecule.

Maghemite nanoparticles coated with activated dextran were then reacted with 75 mol % of monoamino−PEG and 25% of amino−PEG−FA in a 0.1 M borate buffer pH 9 in the presence of sodium borohydride 0.206 M. The pH was maintained at pH 9 by adding dropplets of NaOH 0.1 M. When the pH value was stabilized, the solution was left to react for 4 h at room temperature. In such conditions, the generated Schiff's bases were stabilized by reductive amination (VUSPIO−PEG−FA). The excess of unreacted materials and borate salts were removed through tangential ultrafiltration. The control nanoparticles were prepared according to the same procedure with 100% of monoamino−PEG (VUSPIO−PEG).

Physicochemical Characterization of Nanoparticles. *Nanoparticles Size and Surface Charge.* The mean particle size was determined by dynamic light scattering (DLS, N4Plus, Beckman-Coulter, USA). Hydrodynamic diameter measurements were performed at 20 °C and 90° angle, after dilution of the sample to 150 μg/mL iron oxide concentration either in NaCl solutions of increasing concentrations (up to 1 M), or in 0.01 M phosphate buffers at various pH (ranging from 4 to 10). Each sample was analyzed six times for a total period of analysis of 20 min. The surface charge of the nanoparticles was investigated through ζ potential measurements (Zetasizer 4, Malvern Instruments, UK) after dilution of the samples in 0.01 M phosphate buffers at pH between 4 and 10. Smoluchowsky approximation was applied in the calculation of ζ potential.

Nanoparticle Density. The density of the nanoparticles in suspension was measured at 20 °C using a high-precision digital densitometer (Analyzer Beer 2, Anton Paar, Austria). The densitometer was standardized using air (0.001238 g/cm^3) and water (0.998314 g/cm^3) at the same temperature. The nanoparticle density was calculated, as previously described (*21*), by successive approximation from the nanoparticles concentration and the density values obtained for the suspension and for the suspending medium (MilliQ water adjusted at pH 7.4 with NaOH), assuming that no interaction occurred between the nanoparticles and the suspending fluid.

Nanoparticle Structure and Morphology. The morphology of the nanoparticles was investigated by transmission electron microscopy (TEM, EM208 Philips, The Netherlands, operating at 80 keV) and high-resolution TEM (JEOL 2010, JEOL, Japan, operating at 200 keV) observations. Colloid suspensions were deposited on UV-ionized copper grids coated with Formvar film (200 mesh). After 5 min, the excess suspension was removed and the samples were observed. Electron diffraction experiments on samples prepared in the same way, but with nickel grids, have been performed in order to confirm the presence of the iron oxide crystals in the nanoparticles (CM 12, Philips, Netherlands).

Nanoparticle Heating. Magnetic heating of aqueous suspensions of nanoparticles (in the concentration range 2.5−3 $g_{maghemite}$/L) were performed under an alternating field of H_{max} = 88 mT and ν = 108 kHz, produced by a

Celes inductor C97104. Temperature was monitored by alcohol thermometer to avoid any inductive or capacitive heating of the temperature probe. The specific absorption rate was calculated using the simplified relation

$$SAR = \frac{C_{\text{water}}}{x_{\text{Fe}}} \frac{\Delta T}{\Delta t}$$

where C_{water} is the specific heat capacity of water, x_{Fe} is the mass fraction of iron, and $\Delta T/\Delta t$ is the slope of the temperature vs time dependence.

Targeting Properties of the Folate-Conjugated Nanoparticles. *Surface Plasmon Resonance Measurements.* Surface plasmon resonance was used to investigate the efficacy of the interaction between the FA binding protein (FBP) and the folate-functionalized nanoparticles. Measurements were carried out using a BIAcore 3000 (Pharmacia Biosensor AB, Sweden). Cows milk FBP was immobilized onto the surface of a carboximethyldextran-coated gold film (Sensor chip CM-5, BIAcore, Sweden) by amine coupling performed according to the general procedure recommended by the BIAcore supplier (*22*). Briefly, the flow channel of BIAcore was equilibrated with Hepes buffered saline (HBS = 10 mM Hepes pH 7.4, 150 mM NaCl, 3 mM EDTA, 0.005% surfactant P20), and then the following samples were successively injected into the system: (a) *N*-hydroxysuccinimmide solution + *N*′-(3-dimethyl-amino-propyl)-*N*-ethylcarbodiimide solution (1/1, v/v) to activate the carboxylated-dextran surface; (b) 1 mg/mL of FBP in 100 mM phosphate buffer pH 7.0, 4 mM mercaptoethanol, 10% v/v glycerol, and (c) 1 M ethanolamine pH 8.5, to quench residual *N*-hydroxysuccinimidyl esters on the sensor chip. FBP immobilization was then carried out afterward using a flow rate of 5 μL/min. Nanoparticle suspensions in HBS (1.07 mg/mL of Fe) were injected into the BIAcore flow channel at a flow rate of 5 μL/min and allowed to interact with the immobilized receptor for 10 min. The specific interaction with the protein shifted the wavelength at which the surface plasmon resonance occurred. This shift was registered as response units (RU). In a subsequent experiment of binding, a competitive inhibition was performed, nanoparticles being injected under the above operative conditions in the presence of 4 mM free FA.

In Vitro Cell Culture Experiments. *Cell Culture.* The cells cultivated for in vitro experiments were human epithelial mouth carcinoma, KB 3-1 (gift of Dr. S. Chevillard, Fontenay-aux-Roses, France), human breast adenocarcinoma, MCF7 (ATCC, USA), and human cervix adenocarcinoma, HeLa cell line (gift of Prof. C. Malvy, Institut Gustave Roussy, Paris, France). All cell lines were grown in folate-free Dulbecco Modified Eagle's Medium (FFDMEM) with 10% fetal calf serum, 100 units/mL penicillin and 100 μg/mL streptomycin, 4 mM L-glutamine at 37 °C in a 5% CO_2/95% air humidified atmosphere. The concentration of FA was 5−6 nM in folate-free medium containing serum, therefore close to the natural physiologic conditions (5−30 nM) (*23*, *24*). Cells were grown in the above-mentioned conditions at least 1 week prior the experiments to reach the maximal expression level of the folate receptor (FR) for KB and HeLa cells as described in a previous study (*25*). MCF7 cells, which do not express the FR, were used as control.

Cytotoxicity. Nanoparticle cytotoxicity was assessed by the 3-(4,5-dimethylthiazol)-2-diphenyltertrazolium bromide (MTT) test (*26*). Cells were seeded in 96-well tissue culture plates at a density of 5×10^4 cells/well. After 24 h, the culture medium was replaced with 200 μL of FFDMEM containing increasing concentrations of nanoparticles. After 3 h incubation, 20 μL of a solution of MTT (5 mg/mL in NaCl 0.9%) was added to each well and a further 3 h incubation at 37 °C was allowed. At the end of this time the supernatant was carefully removed from each well, without taking off the blue formazan crystals produced by viable cells. Then to completely dissolve the crystals, 200 μL of solvent (1:1, dimethylformamide/sodium dodecylsulfate 20% aqueous solution) were added to each well followed by 3 h incubation at 37 °C. Colorimetric measurements were performed at 570 nm with a scanning multiwell spectrometer (Multiskan MS, Labsystems, Finland). Absorbance values for untreated wells were taken as control reference (100% survival).

Inhibition of the Uptake of Radiolabeled FA into Cells by Nanoparticles. The interaction of nanoparticles with cells expressing the folate receptors was assessed through the measurement of the inhibition of the free tritium-labeled FA uptake ([^{3}H]-FA), as has been shown previously (*27*). Briefly, KB 3-1 cells were allowed to grow in folate-free medium for 1 week. Thereafter, 5×10^5 cells were seeded in 6-well plates. Wells containing medium but without cells were used as control for the unspecific adsorption of the radiolabeled FA on plastic surfaces. Twenty-four hours later, after careful washing with phosphate-buffered saline (PBS), cells were incubated for 30 min at 37 °C with 1 mL of FFDMEM containing 0.1 μM radiolabeled FA and increasing amounts of FA-functionalized iron oxide particles. Afterward, the plates were rinsed twice with PBS, pH 7.4 at 4 °C. Cells were then treated overnight at ambient temperature with 1 mL of 0.1% v/v Triton ×100, and the amount of radioactivity present in the cell lysate was determined by liquid scintillation counting (LS6000 TA, Beckman-Coulter, USA). The results were expressed as percentage of cell-associated radioactivity, the amount found in the absence of nanoparticles being taken as the 100% uptake value. Experiments were repeated in the same conditions but using control nanoparticles (VUSPIO−PEG). All experiments were replicated at least three times.

Folate-Targeted Nanoparticles Cell Uptake Experiments. The cell uptake of γ-Fe_2O_3 nanoparticles was investigated using TEM. Samples were prepared by the following procedure (*28*): cells grown for 1 week in FFDMEM were incubated for 3 h with nanoparticles (150 μg/mL of γ-Fe_2O_3 in FFDMEM). Then, after repeated washing with PBS, pH 7.4, cells were fixed with 2.5% glutaraldehyde in 0.1 M cacodylate buffer (5 mM $CaCl_2$, 5 mM $MgCl_2$, 0.1 M sucrose, pH 7.2) for 1 h at 4 °C. Samples were postfixed in 1% osmium tetroxide in the same buffer for 1 h at room temperature and washed. Cells were scraped and concentrated in 2.5% agar in 0.05 M cacodylate buffer. The specimens were then treated with 2% uranyl acetate solution for 1 h. The material was subsequently dehydrated by means of ethanol/water solutions, with increasing ethanol content and embedded in a epoxy resin (Epikote 812, Fluka, Switzerland). The samples were cut at 70 nm (ultrathin sections) with an ultramicrotome (Ultracut UCT, Leica, Austria). Ultrathin sections of the preparation were stained with 5% uranyl acetate and Reynolds reagent (0.2% lead citrate) and observed on a transmission electron microscope at 80 kV (EM 208, Philips, Netherlands)

Ultrathin sections (70 nm) of the preparation were obtained and rapidly double stained with 5% uranyl acetate, followed by Reynolds reagent (0.2% lead citrate). The presence of iron oxide nanocrystals within the cells

has been confirmed by energy-dispersive X-ray (EDX) spectroscopy and by dark-field observations in TEM (CM12, Philips, The Netherlands, equipped with an EDAX−EDX analyzer). Qualitative and quantitative determination of nanoparticle uptake were obtained by visual localization and counting of the nanoparticles on 10 cell sections for each sample. For each of the three different cell lines a specific uptake index (SUI) was determined and calculated as the ratio between the number of folate-targeted nanoparticles taken up by the cells and the number of nontargeted particles taken up in the same conditions (i.e., nonspecific uptake).

To approximately evaluate the iron oxide concentration achievable within lysosomes, where targeted cells appear to be gathered, an image analysis has been performed using the software ImageJ 1.32j (Wayne Rasband, National Institute of Health, USA). The area of the entire lysosome presented in Figure 9 and the number of particles enclosed have been evaluated. The minimum and maximum values used for detecting particles were 10 and 100 pixels. With the knowledge that the slice observed is 70 nm thick and making the limiting approximation that we see only iron oxide nanocrystals of 5 nm diameter and of known density (4.87 g/cm^3 as calculated for maghemite crystals), we can calculate the iron oxide concentration.

RESULTS

Nanoparticle Size and Surface Charge. As shown in Figure 1, iron oxide nanoparticles, functionalized with PEG or with PEG−FA had a mean diameter between 60 and 80 nm and polydispersity indexes lower than 0.3. pH and ionic strength did not influence significantly either the mean size or the polydispersity index of the nanoparticles. ζ potential measurements showed slight negative values for dextran-coated iron oxide nanoparticles before pegylation (Figure 2). When these nanoparticles were functionalized with PEG, their ζ potential was not affected by the pH of the dispersing medium. On the contrary, when coated with folate-derivatized PEG, the nanoparticle charge got increasingly negative with rising pH which is probably due to the progressive deprotonation of the FA carboxylic groups.

Nanoparticle Morphology and Density. As observed by TEM, iron oxide nanoparticles were roughly round shaped with narrow size distribution (Figure 3). Furthermore, it was possible to identify more electron-dense structures nonhomogeneously distributed in their bodies. Their crystalline nature was showed by high-resolution microscopy, while their electron diffraction pattern identified them as maghemite (γ-Fe_2O_3) nanocrystals (Figure 4). The overall particle diameter was between 10 and 20 nm, while the embedded nanocrystals were between 5 and 10 nm. The observed "grapelike" organization of the particles in TEM micrographs is a consequence of the removal of the dispersing phase during sample preparation and is not representative of the real state of nanoparticles in suspension. The difference in the mean sizes obtained by PCS measurements, and electron microscopy has already been observed with other materials (*29*), possibly due to the hydrophilic polymer coating of the particles which increases significantly the hydrodynamic diameter, especially with very

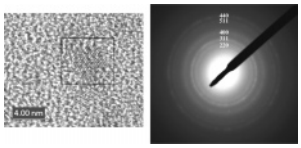

Figure 4. High-resolution TEM image of dextran-coated iron oxide nanoparticle (left). Electron diffraction pattern obtained with the particles, which matches with the one expected for γ-Fe_2O_3 crystals (right).

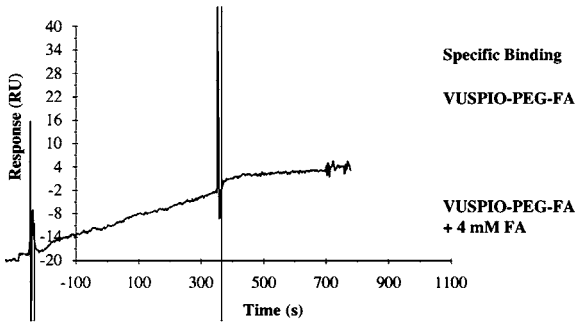

Figure 5. Surface plasmon resonance sensorgram of iron oxide nanoparticles functionalized with PEG−FA (VUSPIO−PEG−FA) and of the same nanoparticles in the presence of 4 mM free FA (VUSPIO−PEG−FA + 4 mM FA). Subtraction of the sensogram in the presence of folate from that in absence of folate gives the specific binding of the nanoparticles to FBP.

small colloids. However, a slight aggregation of nanoparticles in suspension could not be excluded.

The nanoparticle density was found to be 2.76 g/cm^3 due to the presence of high-density nanocrystals (4.87 g/cm^3, as calculated for maghemite crystals). Thus, the number of nanocrystals embedded in individual nanoparticles could be calculated, from the concentration and the density for both of them. The values obtained for different sized nanoparticles varied from 1 to 8 crystals for nanoparticles with diameters between 10 and 20 nm, which is comparable with the TEM observations.

Nanoparticle Heating. Experiments performed on pegylated and folate-conjugated nanoparticles dispersed in water led to quite similar results, with a heating ramp of 7 ± 1 °C per 20 min period. The specific absorption rate, defined as the heating power of the magnetic material per gram, was calculated: SAR = 13 ± 3 W/g_{Fe}. These results are coherent with the ones obtained for the maghemite nanocrystals alone (SAR = 13.8 W/g_{Fe}).

Nanoparticle Cytotoxicity. Both pegylated and folate-linked nanoparticles were tested for their cytotoxicity on three cell lines (HeLa, KB, MCF7) at various concentrations up to 200 μg/mL of Fe_2O_3 (see Supporting Information). After 3 h of incubation only slight cytotoxicity was observed, survival rates being higher than 75% even at the higher nanoparticles concentrations (*30*). Furthermore, no significant difference was shown between the cytotoxicities of the targeted and nontargeted particles (unpaired two-tailed t-test, $p > 0.20$).

Folate Targeting Efficiency. The interaction of the folate-conjugated nanoparticles with the FBP was observed by surface plasmon resonance. In Figure 5, it can be observed that, at the time of sample injection, the addition of a solution having a different refractive index compared to the eluent induced a spike in the signal (RU). The subsequent and progressive increase of the response signal for the folate-conjugated nanoparticles was a sign of the progressive binding of these nanoparticles to the protein linked onto the chip surface. During the washing procedure following the interaction

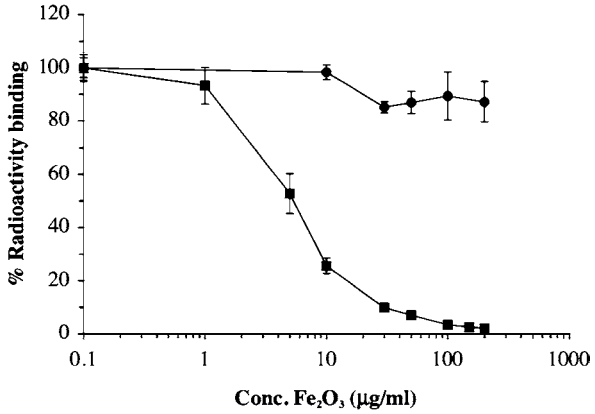

Figure 6. Commpetitive inhibition of the uptake of tritium labeled FA in the presence of increasing concentrations of iron oxide nanoparticles functionalized with PEG−FA (■, VUSPIO−PEG−FA) or PEG alone (●, VUSPIO−PEG). $n = 3 \pm$ SD.

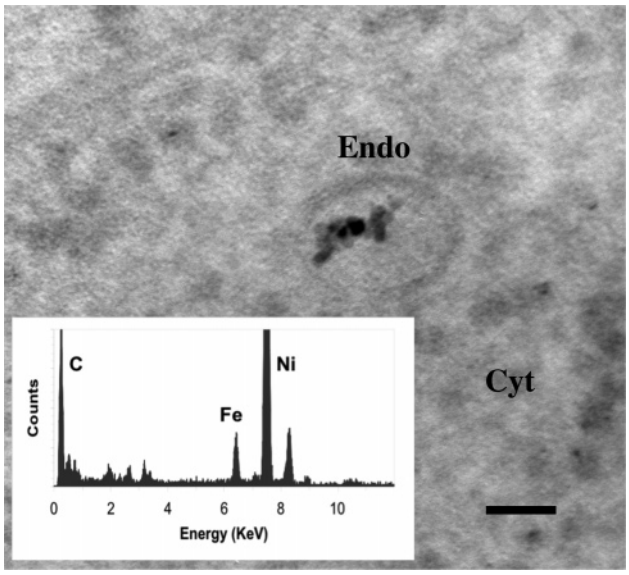

Figure 7. TEM image of an of an agglomerate of few nanoparticles in an endosome in KB cells. The EDX analysis of the object is reported superimposed. (C = carbon; Fe = iron; Ni = nickel; Cyt = cytoplasm; E = endosome; bar = 50 nm).

phase, only a very slight decrease in the signal could be observed, demonstrating a strong specific interaction between the nanoparticles and the FBP. When the experiment was carried out in the presence of free FA (4 mM), no positive signal could be recorded, indicating that the interaction between the folate-functionalized nanoparticles and the chip surface was competitively inhibited by FA free in solution. In control experiments performed with dextran-coated iron oxide nanoparticles functionalized with PEG, no signal was elicited.

To ascertain whether specific interactions between folate-functionalized maghemite nanoparticles and the folate receptor also occurred in vitro, in cell culture conditions, further experiments with tritium-labeled FA were carried out with the KB cell line, which expresses the folate receptor at a dramatically high level (Figure 6). When incubated with radiolabeled FA alone, KB cells avidly captured the radioactive compound. Conversely, FA uptake progressively decreased along with the addition of increasing amounts of folate-targeted nanoparticles (VUSPIO−PEG−FA). It is noteworthy that, for the higher nanoparticle concentrations, almost no cell-associated radioactivity could be detected. Finally, if control nanoparticles (VUSPIO−PEG) were incubated in

Table 1. Uptake of Iron Oxide Nanoparticles by Cells

	nanoparticles taken up per cell[a]		
cell line	VUSPIO−PEG	VUSPIO−PEG-FA	t-test probability
HeLa	15.4 ± 6.9	46.3 ± 18.6	<0.05
KB 3-1	45.2 ± 8.5	307.5 ± 69.7	<0.01
MCF7	58.4 ± 38.3	65.7 ± 60.0	>0.2

[a] Data are presented as mean ± SD (n = 10).

the same conditions, almost no inhibition of the radioactivity cell uptake was observed.

Cell Uptake of Nanoparticles. The uptake of nanoparticles by the different cell lines was investigated by TEM. The presence of iron particles in the intracellular compartment could clearly be identified by EDX spectroscopy, as shown in Figure 7. Maghemite nanocrystals were also recognized by dark-field TEM observations. In these experiments the orientation of the sample was set in order to collect electrons predominantly diffracted by maghemite nanocrystals. Images of KB cell lysosomes containing several nanocrystals are shown in Figure 8.

As predicted from the cytotoxicity experiments, TEM observations showed that cellular structures were well preserved with no visible abnormalities, following incubation with the nanoparticles. In the case of HeLa and KB cells, folate-conjugated nanoparticles were found intracellularly, mainly in endosomes and, especially, in several large multivesicular structures, identified as late endolysosomes, also called residual bodies (see Figure 8). In MCF7 cells, which do not express the folate receptor, we found some nanoparticles near the cell plasmatic membranes and a small number of them were found in lysosomal structures too. Incubation of the three cell lines with control iron oxide nanoparticles without FA bound onto their surface (VUSPIO−PEG) was performed under the same conditions to evaluate the nonspecific cell uptake. The mean number of particles found per cell was calculated for targeted and nontargeted superparamagnetic nanoparticles for each cell line. These results along with a statistical evaluation of their differences (unpaired two-tailed t-test) are presented in Table 1. The targeting efficacy of the folate nanoparticles has been expressed using the SUI, calculated as the ratio between the number of folate-targeted nanoparticles taken up by the cells and the number of nontargeted particles taken up in the same conditions (i.e., unspecific uptake) (Figure 9). In the case of the folate receptor expressing KB and HeLa cells, nanoparticle uptake was greater for targeted nanoparticles (VUSPIO−PEG−FA); the SUI value was approximately 7 (for KB cells) and 3 (for HeLa cells). Conversely, MCF7 cell uptake level of targeted and control particles was quite similar, the SUI being nearly equal to 1. Folate-targeted nanoparticles appeared to be gathered into numerous lysosomes. To determine if the quantity of nanocrystals taken up by cells would be

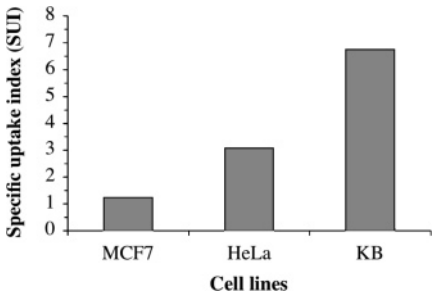

Figure 9. Specific uptake index for the three cell lines. The index is calculated as the ratio between the number of folate-targeted particles (VUSPIO−PEG−FA) internalized by cells and the number of control particles (VUSPIO−PEG) captured by cells in the same conditions.

sufficient for an efficient and rapid heating, we evaluated their concentration in those cellular structures. We calculated that the concentration of iron oxide attained in the endolysosome presented in Figure 8 was in the order of 3 mg/mL.

DISCUSSION

The design of superparamagnetic iron oxide nanoparticles interacting with tumors has received increasing interest in the past few years, as indicated by the number of papers recently published on this subject (*31*−*33*). In particular, the challenge has been to obtain nanoparticles stable in physiological conditions, able to selectively target tumor cells. We produced here iron oxide nanocrystals coated with dextran and successively modified at their surface with PEG and FA. Despite the relatively low surface charge of these nanoparticles, a good colloidal stability has been obtained at both acid and alkaline pH, as well as in the presence of high salt concentrations. This suggests that stabilization of maghemite nanoparticles was primarily dependent on steric repulsion due to their coating with hydrophilic polymers. Thus, dextran and PEG covalently bound to the particle surface are efficient in avoiding their aggregation in the tested conditions, which opens the way for their use in still more complex biological media. These characteristics of stability and steric repulsion should allow these small particles to circulate for a prolonged time in the blood compartment, avoiding the scavenging of the macrophages of the reticulo-endothelial system (*34*, *35*) and allowing the diffusion toward the tumor site, by virtue of the known enhanced permeability and retention effect (*36*, *37*). Furthermore, their superparamagnetic properties were shown not to be modified by the surface functionalization, and particles were able to increase the temperature of an aqueous suspension at a constant rate under an appropriate oscillating magnetic field. With regard to the targeting efficacy, the set of experiments performed in

this study, with plasmon resonance, cell culture competitive assays, and cell nanoparticle capture have clearly demonstrated the capacity of these folate functionalized nanoparticles to specifically target cancer cells with membrane expression of the FA receptor. In fact, as shown in Table 1, the MCF7 cells, deprived of FA receptors, did not uptake more folate-functionalized nanoparticles than the control nanoparticles (no significant difference between the two uptake). In the same conditions, in HeLa and KB cells the folate nanoparticles were taken up in much greater number than the control nanoparticles (significant difference, $p < 0.05$ and $p < 0.01$ respectively). The receptor-mediated endocytotic process ended in the accumulation of the nanoparticles in one of the common metabolic degradation pathways of foreign materials taken up by cells. In fact, the accumulation of folate-targeted molecular conjugates in lysosomes has already been observed with antifolate drugs and folate-targeted carriers such as polyplexes and cyclodextrines (*27*, *38*, *39*). Interestingly, the increase of nanoparticle uptake appeared to be proportional to the folate receptor expression level in HeLa and KB cells. Indeed, as reported before, the folate receptor was 3−4 times more expressed in KB cells compared to HeLa cells (*25*). In addition, the iron concentration attained in cellular structure as lysosomes (3 g/L) appeared to be well suited to obtain a local intracellular heating. Temperature increase to values above 43 °C for a sufficient period of time should be able to cause selective damage and death of cells containing high amounts of iron oxide nanoparticles (*9*).

CONCLUSIONS

In a scientific panorama in which folate-mediated solid tumor targeting seems to become one of the major breakthrough in tumor diagnosis and treatment, the new targeted maghemite nanoparticles presented here are very promising nanosystems for performing a targeted intracellular hyperthermic treatment of tumors overexpressing the folate receptor. Our current research efforts consist in building a hyperthermia apparatus equipped with a large solenoid in which magnetic alternating current field will be homogeneous at the Petri dish scale. Then, in vitro heating experiments will be envisaged and their therapeutic effect will be evaluated.

ACKNOWLEDGMENT

The excellent assistance of Mme. Odile Kaitasov in electron microscopy experiments and of M. Richard Harvey in text reviewing are gratefully acknowledged. Authors would like to thank the Association pour la Recherche sur le Cancer for the financial support to the work of F.S.

Received March 3, 2005; Revised Manuscript Received June 16, 2005

A new solid-phase synthetic methodology was developed that enables libraries of peptide-based Tc(I)/Re(I) radiopharmaceuticals to be prepared using a conventional automated peptide synthesizer. Through the use of a tridentate ligand derived from N-α-Fmoc-L-lysine, which we refer to as a single amino acid chelate (SAAC), a series of 12 novel bioconjugates [R-NH(CO)ZLF(SAAC)G, R = ethyl, isopropyl, *n*-propyl, *tert*-butyl, *n*-butyl, benzyl; Z = Met, Nle] that are designed to target the formyl peptide receptor (FPR) were prepared. Construction of the library was carried out in a multiwell format on an Advanced ChemTech 348 peptide synthesizer where multi-milligram quantities of each peptide were isolated in high purity without HPLC purification. After characterization, the library components were screened for their affinity for the FPR receptor using flow cytometry where the K_d values were found to be in the low micromolar range (0.5−3.0 μM). Compound **5j** was subsequently labeled with ^{99m}Tc(I) and the product isolated in high radiochemical yield using a simple Sep-Pak purification procedure. The retention time of the labeled compound matched that of the fully characterized Re-analogue which was prepared through the use of the same solid-phase synthesis methodology that was used to construct the library. The work reported here is a rare example of a method by which libraries of peptide-ligand conjugates and their rhenium complexes can be prepared.

INTRODUCTION

Short peptide sequences are one of the most effective vectors for targeting radionuclides to specific receptor systems (*1*). As a result, there are a number of peptide-based imaging agents that are currently used clinically or that are undergoing clinical trials (*2*). The archetypal example is ^{111}In-labeled Octreotide, which is a somatostatin analogue used to image neuroendocrine tumors (*3*).

One of the attractive features of peptides is that they can be easily modified to optimize receptor binding affinity, pharmacokinetics, and clearance rates and pathways. The sequence of the amino acids, the addition of prosthetic groups, and, in the case of metalloradionuclides, the nature of the chelating group can all be changed to obtain the desired biodistribution profile. Because of this flexibility, the opportunity presents itself to prepare libraries of peptide-ligand conjugates in parallel or in combination as a means of rapidly identifying the ideal choice of factors. Despite recent reports on the development of new solid-phase synthetic procedures (*4*−*7*), the majority of radiopharmaceuticals continue to be prepared using linear discovery strategies which are significantly less efficient than contemporary drug discovery methodologies.

Recently we described a novel solid-phase synthetic strategy for incorporating a Tc(I)/Re(I) binding ligand, which we refer to as a single amino acid chelate (SAAC) (**1a**, Figure 1), into peptides (*8*, *9*). The SAAC, which is derived from lysine, can be introduced into a peptide as if it were a natural amino acid making the chelate a convenient and versatile synthon for preparing peptide-targeted radiopharmaceuticals. The current objective was to develop the means to use the SAAC system to prepare libraries of chelate-derived peptides as a new strategy for discovering novel radiopharmaceuticals.

As a model system, we selected the fMLF peptide which has been used to direct ^{99m}Tc to sites of infection and inflammation by targeting the formal peptide receptor (FPR) on leukocytes (*10*−*24*). Unfortunately, fMLF is an agonist which causes unwanted side effects (neutropenia) even when the apparent specific activity of the tracer is very high (*23*). One approach to overcoming this issue is to develop an analogue of fMLF which behaves as an antagonist rather than an agonist (*16*).

By changing the nature of the formyl group in fMLF to substituted ureas, a series of antagonists for the FPR that have reasonably high binding affinities were discovered (*25*). A ^{99m}Tc-labeled SAAC analogue of the urea-derived peptides could therefore be used to image sites of infection and inflammation without causing neutro-

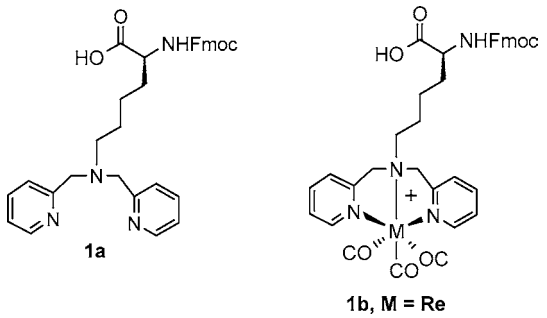

Figure 1. A Single Amino Acid Chelate (SAAC) and its complex with the $[Re(CO)_3]^+$ core.

penia. To obtain a viable agent, the peptide-SAAC derivative must maintain reasonable affinity for the FPR while also possessing the appropriate distribution kinetics and clearance mechanism (*16*, *23*). As a means of identifying compounds that meet these criteria, a parallel array of RNHC(O)ZLF(SAAC)G derivatives were prepared in which factors that can change receptor binding affinity and/or the distribution/mode of clearance (i.e. the substituents off the urea (R) and the nature of the first amino acid (Z)) were varied.

EXPERIMENTAL PROCEDURES

Materials. Unless otherwise stated, all reagents and solvents were ACS grade or higher and used without further purification from commercial suppliers. Polystyrene-based *N*-α-9-fluorenylmethoxycarbonyl (Fmoc)-glycine loaded SASRIN resin (0.69 mmol g^{-1}, 1% divinylbenzene, 200−400 mesh) was obtained from Bachem Inc. Fmoc-protected amino acids were purchased from Nova-Biochem Inc., Bachem Inc., and Advanced ChemTech Inc. Fluorescein-labeled fNLFNTK was purchased from Molecular Probes Inc. (product # F-1314). The isocyanates were purchased shortly before use from Sigma-Aldrich Co.

Instrumentation. All peptides were prepared on an Advanced ChemTech 348 Ω Peptide Synthesizer using a 40-well reaction block. Peptides were analyzed by positive ion electrospray mass spectrometry on a Micromass Quattro Ultima instrument. Samples were dissolved in 50/50 CH_3CN/H_2O prior to analysis. FTIR spectra were acquired on a Bio-Rad FTS-40 FTIR spectrometer. NMR experiments were performed using a Bruker AV 600 NMR spectrometer. In terms of signals, s refers to a singlet, d refers to doublet, dd refers to doublet of doublets, and m refers to multiplet.

Analytical HPLC was performed using a Varian Pro Star model 330 PDA detector and model 230 solvent delivery system and a C-18 Microsorb column (4.6 × 250 mm, 300 Å/5 μm). For the peptides and the analysis of the Re complex, the elution protocol was a linear gradient of 100% water containing 0.1% TFA to 100% acetonitrile containing 0.1% TFA over 20 min. The flow rate was 1.0 mL min^{-1}, and all runs were monitored at $\lambda = 254$ and 214 nm. For the reactions involving ^{99m}Tc, HPLC experiments were performed on a Varian Prostar Model 230 HPLC (high performance liquid chromatography) instrument coupled to a Bio-Rad IN/US γ-detector using a Nucleosil (L x ID = 250 × 4.6 mm), analytical column (300 Å/5 μm, RP-C18). The mobile phase consisted of Solvent A = triethylammonium phosphate buffer (pH = 2−2.5), Solvent B = CH_3OH. Gradient: 0−3 min, 100% A; 3−6 min, 100% A to 75% A; 6−9 min, 75% A to 67% A; 9−20 min, 67% A to 0% A; 20−22 min, 0% A; 22−25 min, 0% A to 100% A; 25−30 min, 100% A.

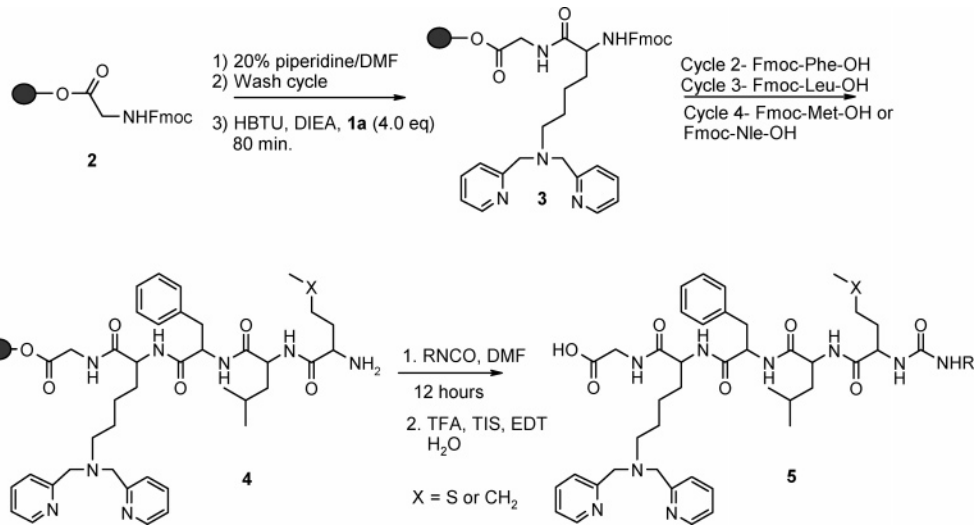
Solid-Phase Peptide Synthesis. Fmoc-glycine-loaded SASRIN resin (150 mg, 0.69 mmol/g) was added to 12 wells of the reaction block, suspended in DMF (2 mL/well), and shaken at 900 rpm for 1 min. The wells were subsequently filtered, suspended in THF (2 mL/well), shaken at 900 rpm for 1 min, and drained for 90 s. The THF wash was repeated two more times. The DMF wash was then repeated a final two times to complete the general wash cycle. This procedure was used between every deprotection and coupling step. Fmoc deprotection was brought about through the addition of 25% v/v piperidine−DMF solution to the active vessels (2 mL/well) and shaking for 5 min at 900 rpm. Following filtration, the process was repeated, shaking for 10 min. The deprotected resin-bound amino acid was washed using the general wash procedure and subsequently coupled to the next Fmoc-protected amino acid using a standard HBTU coupling technique. Coupling reactions initially involved adding DMF (200 μL) to the active vessels followed by the addition of a 4-fold excess of the protected amino acid as a 0.5 M solution in DMF. Four equivalents of HBTU as a 0.5 M solution in DMF was then added followed by a 8-fold excess of DIPEA as 2.0 M solution in DMF. The reaction block was subsequently shaken for 80 min at 900 rpm. Following filtration, the resin was washed using the general washing procedure prior to the start of the next cycle.

Once the final amino acid had been added and the Fmoc group removed, a pause was introduced into the peptide program so that 10 equiv of the isocyanates in DMF (0.5 M solution) could be added. The reaction block was then shaken at 900 rpm under nitrogen for 12 h. The reaction vessels were emptied and the resins washed using the general wash cycle. Peptides were cleaved from the resin support using a TFA cocktail containing EDT (2%), water (2%), and TIS (2%). The cleavage cocktail, cooled to 0 °C, was added to the resin and the mixture allowed to warm to room temperature over 60 min. The suspension was filtered into cold diethyl ether and the resulting heterogeneous solution centrifuged at 3000 rpm and −5 °C for 10 min. The resulting pellet was washed with cold diethyl ether (3 × 25 mL), dissolved in distilled−deionized water, and lyophilized, yielding a white solid for all compounds.

Preparation of $[^{99m}Tc(CO)_3(OH_2)_3]^+$. A 10 mL penicillin vial containing $K_2[BH_3{\cdot}CO_2]$, (8.5 mg, 63 μmol), $Na_2B_4O_7{\cdot}10H_2O$ (2.9 mg, 8.0 μmol), Na/K-tartrate (15.0 mg, 53 μmol), and Na_2CO_3 (4.0 mg, 38 μmol) was fitted with a rubber septum and the vial flushed with N_2(g) for 15 min. ^{99m}Tc-generator eluate (370 MBq, 10 mCi) in 500 μL of saline was added by a syringe, and the solution was heated to 95 °C for 30 min. After cooling on an ice-bath, the alkaline solution was neutralized by the addition of 28 μL of HCl (12 M HCl in 100 μL of H_2O). Quality control was performed by gradient HPLC (yields ≥ 95%).

Radiolabeling 5j. An aliquot (250 μL) of **5j** (0.5 mg, 0.58 μmol) dissolved in 200 μL of 100 mM phosphate buffer (pH = 7.2) and 300 μL of CH_3CN was added to the solution containing $[^{99m}Tc(CO)_3(OH_2)_3]^+$ by syringe and the mixture heated to 70 °C for 45 min. The reaction mixture was cooled in an ice bath and the product isolated using a Sep-Pak (Waters, C_{18}). The Sep-Pak was conditioned prior to use with absolute ethanol (10 mL), acetonitrile (10 mL), 1:1 acetonitrile/10 mM HCl (10 mL), and 10 mM HCl (10 mL). After loading the reaction solution onto the conditioned Sep-Pak, the column was washed with 10 mM HCl (7 × 1 mL), 1:4 acetonitrile/10 mM HCl (2 × 1 mL), 1:1 acetonitrile/10 mM HCl (2 × 1 mL), 4:1 acetonitrile/10 mM HCl (2 × 1 mL), and finally

Scheme 1



acetonitrile (5 × 1 mL). Compound **6b** eluted in fractions 12−17 (radiochemical yield = 90%, radiochemical purity ≥ 98%).

Ligand Challenge Experiments. Cysteine (0.13 μmol in 5 mL of ddH_2O) and histidine (0.13 μmol in 5 mL of ddH_2O) were added to two separate vials each containing 11.1 MBq to 18.5 MBq (300−500 μCi) of purified **6b** in 250 μL of 100 mM phosphate buffer. Both vials were incubated at 37 °C for 24 h. Aliquots were taken periodically and analyzed by HPLC.

Leukocyte Preparation. Whole human blood (10−15 mL) was collected in vacutainer tubes (Becton Dickinson) containing sodium heparin. The red blood cells were lysed using a modified ammonium chloride method (1 part whole blood to 23 parts 0.145 M ammonium chloride solution containing 1.5 mM potassium bicarbonate and 0.1 mM EDTA). Tubes were incubated at room temperature for 15 min and then centrifuged in a Beckman Coulter Allegra 6R centrifuge at 900 rpm (400 g) for 7 min at 5 °C. The supernatant was removed and the pellet of leukocytes subsequently resuspended in HBSS containing 0.1% BSA, 10 mM HEPES, and 1.5 mM $CaCl_2$ (HBSS+). The cells were spun for 7 min at 400 g at 5 °C, the supernatant was removed, and the pellet was resuspended in HBSS+. Cell counts were performed using a hemacytometer and a Beckman Coulter Z2 Coulter Particle Count and Size Analyzer. Cell concentrations were adjusted to 2×10^6 mL^{-1}.

Flow Cytometry. Samples were run on a Beckman Coulter EPICS XL, equipped with an argon laser (488 nm excitation wavelength). Fluorescence was measured using a 525 ± 15 nm band-pass filter. The flow cytometer was calibrated with fluorescein isothiocyanate (FITC) labeled beads (Quantum 26 Beads, Bangs Laboratories, Inc, Fishers, IN) prior to sample analysis. The fluorescence intensity of the standard was provided by the manufacturer in units of Molecules of Equivalent Soluble Fluorochrome (MESF) and ranged from 5300 to 468 800. A linear fit of MESF versus mean channel number of the beads was used to convert all subsequent mean channel values to MESF values.

Equilibrium Binding Assay. The equilibrium-binding assay was used to determine the number of formyl peptide receptors (FPRs) on the surface of the neutrophils and the dissociation constant (K_d) of the fluorescein-labeled fNLFNTK (Molecular Probes) (1.0 nM) by preparing a saturated binding curve of peptide concentrations verses fluorescence intensity. Peptide stock solutions were made by dissolving the peptide derivatives in DMSO and then diluting with HBSS+ to the desired concentrations, ensuring the concentration of DMSO was less than 0.1%. Cells at 1×10^6 mL^{-1} were equilibrated with 0.25, 0.50. 1.0, 3.0, 5.0, 10.0, and 20.0 nM solutions of the peptide derivatives (U) in duplicate. The samples were incubated for 2 h at 0 °C in the dark and then run on the flow cytometer. Neutrophils were gated on the basis of forward and side scatter parameters using Expo 32 ADC software (Beckman Coulter). All samples were repeated in the presence of 30 μM fMLF to account for nonspecific binding. The number of receptor−ligand complexes per cell (B) was determined using the following equation, where Q is a normalization factor used by Waller et al. (*28*) and F is the total fluorescence per cell:

$$\mathrm{B(in\ ligand\ bound\ per\ cell)} = F\left(\frac{\mathrm{MESF}}{\mathrm{cell}}\right) \times Q$$

The level of nonspecific binding did not vary significantly with the concentration of labeled peptide; thus, an average value of nonspecific binding was subtracted from the total fluorescence per cell, F, when determining the number of receptor−ligand complexes. The total number of N-formyl peptide receptors, R_{tot}, and the equilibrium dissociation constant, K_d, were evaluated by minimizing the squared residual of the equilibrium solution using a one-site binding model (see the following equation). The values of R_{tot} and K_d for each donor were solved simultaneously.

$$[\mathrm{LR}] = \frac{R_{\mathrm{tot}}[\mathrm{L}]}{[\mathrm{L}] + K_d}$$

RESULTS

Peptide Synthesis. Solid-phase synthesis (Scheme 1) was carried out on an advanced Advanced ChemTech 348 Ω synthesizer using all L-amino acids. For each peptide, the synthesis began by coupling Fmoc protected SAAC to SASRIN resin bound glycine using a standard HBTU coupling protocol. After deprotection with 20% piperidine in DMF, the phenylalanine and leucine residues were added. Following removal of the Fmoc group on leucine, Fmoc-methionine or Fmoc-norleucine were added and subsequently deprotected.

Conversion of **4** to the corresponding ureas (see Table 4) was carried out by adding different isocyanates to the

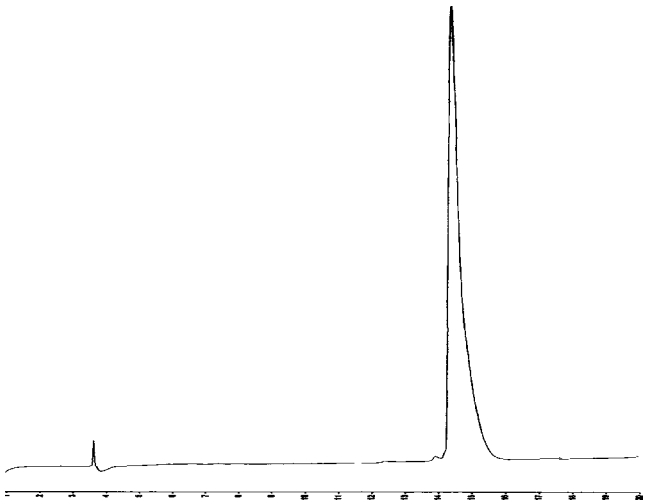


Figure 2. HPLC chromatogram (UV-detection, $\lambda = 254$ nm) of **5j**.

reaction wells. The duration of the reaction needed to achieve complete conversion to the urea (12 h) was determined in advance of preparing the library by carrying out a model reaction using the least reactive isocyanate (*tert*-butyl isocyanate). During these experiments, samples of resin were periodically extracted from the reaction well and exposed to ninhydrin (*26*) until complete conversion to the urea was indicated.

Peptides were cleaved from the support under argon or nitrogen using a cocktail consisting of 94% TFA, 2% EDT, 2% TIS, and 2% water (*27*). It was important to exclude moisture and oxygen during the cleavage reaction to avoid oxidation of the methionine containing peptides. Following precipitation using cold diethyl ether and centrifugation, the peptide conjugates were dissolved in water, lyophilized, and analyzed for purity. The HPLC chromatograms of the peptides, including the *tert*-butyl derivative **5j** (Figure 2), showed that the products had been prepared in very high purity in all cases and that no further purification was needed. The Re complex of **5j** was prepared using an identical solid-phase synthetic procedure except that compound **1b** was substituted for **1a**.

Characterization. Peptides were analyzed by electrospray mass spectrometry, and in each case the observed molecular ions were consistent with the mass of the desired compounds (Table 1). IR analysis confirmed the presence of the urea group, in which the C=O stretch appeared between 1535 cm^{-1} and 1553 cm^{-1} (Table 1). In the case of the Re complex of **5j**, the metal CO stretches appeared at 1916 cm^{-1} and 2031 cm^{-1}.

The *tert*-butyl urea **5j** was further characterized using ^{1}H and ^{13}C NMR spectroscopy (Tables 2 and 3). The ^{1}H NMR of **5j** (Figure 3) shows a number of multiplets in the aromatic region which were assigned to the pyridine rings of the SAAC and the aromatic group of phenylalanine. The alpha protons of the amino acids appear between 4 and 5 ppm, which along with the side chain residues, were readily assigned using standard two-dimensional experiments (COSY, HSQC, and HMBC). A

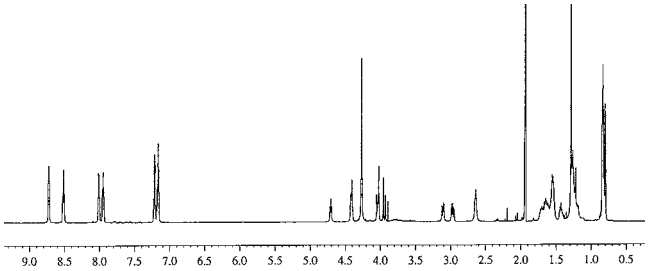

Figure 3. ^{1}H NMR of **5j** (600 MHz, 1:1 CD_3CN/TFA-*d*).

Table 4. Peptides and Binding Affinities (K_d)

compd	peptide	K_d (μM)
5a	ethyl-NH(CO)-Met-Leu-Phe-SAAC-Gly	2.9 ± 0.8

5m	fMLF	0.032 ± 0.003

singlet corresponding to the tBu group appeared at 1.29 ppm in the ^{1}H NMR while the signal arising from the alpha proton of norleucine was present at 4.04 ppm, which showed a correlation to the urea carbonyl carbon (177.6 ppm) in the HMBC spectrum. The resonances remaining in the carbonyl region of the ^{13}C NMR spectrum were consistent with the number of amide/acid groups in the peptide backbone. The carbonyl groups were assigned using a TOCSY experiment, which in turn confirmed the proposed connectivity of the peptide.

In Vitro Screening Studies using Flow Cytometry. Peptides were screened on a flow cytometer using a competitive binding assay where the concentration of the competitor was allowed to vary while maintaining the concentration of the fluorescent peptide (*28*−*30*). Competitive binding data was obtained on the same day using the same human donor as for the equilibrium binding data, to minimize variability in the number of receptors. Cells (10^6 mL^{-1}) were incubated with 1.0 nM fluorescein-labeled fNLFNTK and 0, 1, 15, 100, 300, 700, 1000, and 1400 nM competitor in duplicate for 3 h at 0 °C in the dark. The equilibrium dissociation constant for the competing unlabeled ligand, K_d, was determined following literature procedures by fitting the specific ligand bound data to the same one-site binding model. The peptide, fMLF was used as a reference standard. Its K_d value was in good agreement with the value reported in the literature (*21*, *28*). The K_d values for a reference standard (fMLF) and library constituents are given in Table 4.

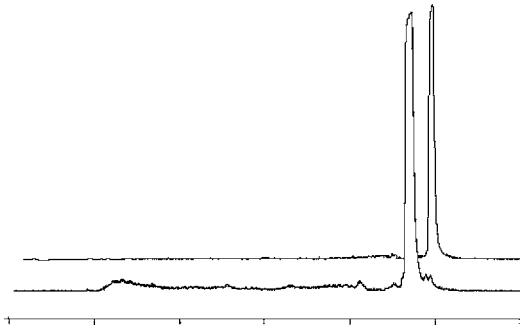

Figure 4. γ-Radiochromatograms of $[^{99m}Tc(CO)_3(OH_2)_3]^+$ and **5j** after 45 min at 70 °C (bottom) and purified **6b** (top).

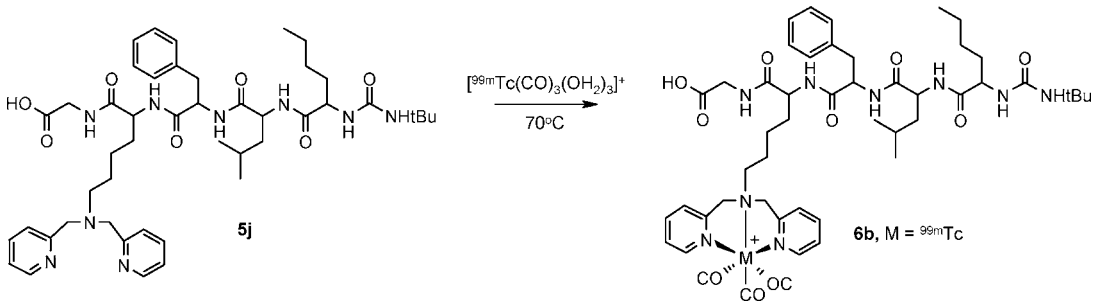
Radiochemistry. The peptide **5j** (250 μg) was combined with 307 MBq (8.3 mCi) of $[^{99m}Tc(CO)_3(OH_2)]^+$ in a mixture of PBS buffer and acetonitrile (Scheme 2). After heating the reaction to 70°C for 45 min, the desired product, **6b**, was isolated, free from any unlabeled peptide, using a simple Sep-Pak purification method. The radiochemical yield of the isolated product was 90% with a radiochemical purity of greater than 98%. The γ-HPLC trace of the crude reaction mixture and the purified product are shown in Figure 4.

Compound **6b** was subsequently incubated with a large excess of cysteine and histidine as a preliminary means of evaluating the complexes tendency to undergo transchelation in the presence of a large excess of competing donors. After 24 h, the labeled peptide showed no signs of degradation which is consistent with the low spin d^6 electronic configuration of the octahedral metal complex.

DISCUSSION

The single amino acid chelate (SAAC) is a lysine derivative where the Fmoc protected form can be readily incorporated into a growing peptide using conventional peptide synthesis protocols. The chelate, which is soluble in water (when completely deprotected) and organic solvents (when protected), was prepared in very high yield on the multigram scale using a one-pot procedure involving relatively inexpensive starting materials. In the work reported here, a convenient solid-phase synthesis strategy was developed for preparing a small 12-member library of N-terminal urea derivatives of MLF(SAAC)G and NleLF(SAAC)G peptides where the nature of the urea substituent was varied. The peptides **5a**−**l** were prepared using a standard coupling/deblocking procedure in very high purities without having to employ preparative HPLC. The fact that the products were produced in such high purity contrasts the synthesis of the *N*-formyl analogue where it was necessary to purify fMLF(SAAC)G by HPLC because the methionine group rapidly epimerized during synthesis to give two diastereomers. With the approach reported here, there was no evidence of epimerization in the HPLC or the NMR data.

Scheme 2



The reported methodology was capable of producing sufficient quantities of each peptide to allow for both detailed characterization of the desired products and in vitro screening studies (vide infra). The electrospray mass spectrometry data agreed in all cases with the calculated spectra, and, as mentioned previously, HPLC confirmed the purity of each sample. Additional characterization of the library constituents can be obtained through ^{1}H and ^{13}C NMR experiments. The spectra, including the data presented for compound **5j**, were consistent with the proposed structures of the peptides.

In terms of binding to the FPR receptor, all compounds had K_d values in the low micromolar range which is in agreement with the data reported by Higgins et al. (*25*). These results indicate that the addition of the SAAC group does not have a detrimental influence on the behavior of the peptide in terms of binding to the FPR receptor. This observation in turn is consistent with the data reported by Cavicchioni et al. which suggests that C-terminal variants of fMLF type peptides do not significantly influence the peptides receptor binding affinity (*31*). The structure of the urea appeared to have a small affect on the K_d values where bulky groups (tBu, ^{i}Pr) generally reduced the K_d values whereas the peptides containing linear alkyl substituents, particularly the ^{n}Bu groups, showed somewhat higher affinity. In addition to considering K_d values, it is important to note that changing the nature of the urea and first amino acid will have a significant impact on the distribution and mode of clearance of the agents. Consequently, the ^{99m}Tc complexes of the library components will be screened in vivo in the appropriate animal model and the derivative showing the optimal distribution profile evaluated further.

We have previously established that the single amino acid chelates form stable complexes with Re(I). To demonstrate that the SAAC-peptide derivatives can also be labeled efficiently with ^{99m}Tc, compound **5j** was reacted with $[^{99m}Tc(CO)_3(OH_2)]^+$, which was prepared using a formulation that is employed in commercially available carbonyl labeling kits. The labeled peptide, **6b**, was isolated in excellent yield using a small amount of ligand (250 μg). To verify the nature of the ^{99m}Tc complex, the corresponding Re complex **6a** was prepared via the same solid-phase synthetic procedure used to prepare **5j** except that compound **1b** was employed in place of **1a**. The HPLC retention time of a sample of compound **6a**, which had been previously characterized by LCMS, matched that for **6b**.

The ability to verify the nature of a ^{99m}Tc complex using a well characterized Re standard is an attractive feature of the SAAC system. With a number of traditional ligand systems (*32*−*36*) it is often difficult to prepare the corresponding Re or ^{99}Tc complexes (let alone to use them for solid-phase synthesis) which in turn complicates the process of identifying compounds produced at the tracer level. With the SAAC system, the Re complexes can be prepared after hits from the library are identified or they can be synthesized in concert with the free ligands without having to significantly modify the original solid-phase synthetic methodology.

CONCLUSIONS

The reported methodology demonstrates the ease with which a library of peptide-ligand derivatives can be developed using the SAAC system. Increasing the size and structural diversity of the library is readily achievable by not only varying the end terminal groups and the nature of the natural amino acids, but also the position of the SAAC. Furthermore, because the ligand is based on a natural amino acid, either enantiomer of the SAAC can be readily incorporated at any position in a peptide. As such, the SAAC chelating system can be used to prepare libraries of a wide range of peptide-based radiopharmaceuticals using a conventional automated peptide synthesizer. In the case reported here, the library constituents show similar K_d values and will therefore be screened in vivo to determine the impact of the various substitutions on biodistribution profiles.

ACKNOWLEDGMENT

We would like to acknowledge the Ontario Research and Development Challenge Fund (ORDCF) and The National Sciences and Engineering Research Council (NSERC) of Canada for funding and for providing a Scholarship for K.A.S.

Quaternary Ammonium Polysaccharides for Gene Delivery

Ira Yudovin-Farber,[†] Chava Yanay,[‡] Tony Azzam,[†] Michal Linial,[‡] and Abraham J. Domb*[,†,§]

Department of Medicinal Chemistry and Natural Products, School of Pharmacy, Faculty of Medicine, The Hebrew University of Jerusalem, P.O.B. 12065 Jerusalem 91120, Israel, Department of Biological Chemistry−Life Science, The Hebrew University of Jerusalem, Jerusalem 91905, Israel, and Alex Grass Center for Drug Design and Synthesis, The Hebrew University of Jerusalem. Received March 8, 2005; Revised Manuscript Received July 27, 2005

Cationic polysaccharides were synthesized by conjugation of various monoquaternary (MQ) ammonium oligoamines to oxidized dextran by reductive amination and tested for gene transfection. Polycations of dextran grafted with MQ ammonium oligoamines of two to four amino groups were investigated for their ability to cause pCMV-GFP encoding for green fluorescence protein and β-Gal encoding for β-galactosidase protein transfection on EPC and HEK-293 cell lines. These polycations were expected to strongly complex DNA due to increased surface cationic charge of the carrier, which may result in a higher transfection yield. However, the transfection yields were much lower compared to the parent vector, dextran-spermine conjugate, which was highly effective both in vitro and in vivo.

INTRODUCTION

The basic concept of gene therapy is that disease can be treated by transfer of genetic material into specific cells of a patient to supplement defective genes responsible for disease development (*1*). The main problem of gene therapy is gene delivery to gain high expression with maximal safety to the patient. A number of techniques have been developed for DNA delivery: direct introduction of transgene using cell electroporation, microinjection of DNA, and incorporation of the gene by viruses (*2*) and synthetic vectors (*3*). Viral vectors including retroviruses, adenoviruses, and adeno-associated viruses impress by their high efficiency in introducing their genetic material into host cells (*4*), although immunogenicity, inflammatory effects, and safety concerns restrict their usefulness. The advantages of nonviral vectors are that they do not integrate into chromosome, can introduce DNA into nondividing cells, do not possess infective risk, and are significantly less expensive and easy to handle than viral vectors (*5*). The major disadvantage of nonviral systems is their low transfection efficiency. The nonviral delivery vectors should overcome intracellular barriers, such as endosomes and nuclear membranes (*6*).

Polycations are a leading class of nonviral gene delivery systems due to their versatility in molecular weight, polymer type, polymer-DNA ratio, molecular architecture, and the ability to introduce target-specific moieties. Polycations and negatively charged nucleic acids can spontaneously form nanocomplexes by electrostatic interaction.

Polycation reduces the electrostatic repulsion between DNA and the cell membrane by neutralizing the DNA negative charge and also protects it from enzymatic digestion by nucleases in serum and extracellular fluids. Cationic materials that are commonly used in gene delivery include poly(L-lysine) (*7*), cationic liposomes (*8*), polyethyleneimine (*9*), dendrimers (*9*), poly(L-histidine) (*10*), polyvinylpyridine, and cationic polysaccharides (*11*, *12*). Polycations that are used as gene delivery systems are polyamines that contain primary, secondary, or tertiary amines (*11*). Under physiological conditions, polyamines become cationic and condense DNA into compact structures.

In our previous publications, we reported on a new type of biodegradable polycation based on grafted oligoamine residues on natural polysaccharides (*13*). From a large number of oligoamine conjugates, the dextran−spermine conjugate was found to be the most active in transfecting a wide range of cell lines and plasmids in vitro and in vivo (*14*). This high transfection of dextran−spermine may be attributed to the spermine residues and architecture of the polysaccharide, which apparently play a significant role in cell transfection (*14*, *15*).

The effectiveness of the carrier is related to the ability of the polycation to condense DNA that is dependent on the structure of the polymer, the distance of cationic charge from the backbone, charge spacing along the polymer backbone, order of charged amine, and molecular weight. One way to achieve improved uptake into cells is by increasing the surface charge of complexes (*16*). This modification is expected to result in higher affinity to negatively charged cell membrane constituents and therefore to a higher rate of uptake. The charge of the carrier can also influence the size of the polymer−DNA complex (polyplex) that plays a significant role in the endosomal uptake (*17*), the cytoplasmatic transport and the migration through the nucleoporecomplexes which mediate the bidirectional transport between cytoplasm and nucleus.

This report focuses on the synthesis of various oligoamines bearing a quaternary ammonium group conjugated to dextrans (Scheme 2) and investigates their transfection capacity in vitro. Monoquaternary (MQ) ammonium oligoamine−dextran conjugates were prepared and tested for their gene transfection efficiency on EPC and HEK-293 cell lines. These agents showed

moderate toxicity when tested on human embryonal kidney HEK-293 cells.

MATERIALS AND METHODS

Materials. Dextran of an average molecular weight of 40 kDa, 1,4-butane diamine and 1,2-ethylenediamine, potassium periodate (KIO_4), sodium borohydride ($NaBH_4$), di-*tert*-butyl dicarbonate, and diisopropylethylamine (DIEA) were obtained from Sigma-Aldrich Israel, Rehovot. Spermine and ethyl trifluoroacetate were obtained from Fluka Chemie (Buchs, Switzerland). All solvents and reagents were of analytical grade and were used as received. Tetrahydrofuran (THF) was dried by distillation over sodium/benzophenone.

A sage-metering pump model-365 (Orion, NJ) was used for slow and reproducible addition of reactants. Average molecular weights of polycations were estimated by a GPC-Spectra Physics instrument (Darmstadt, Germany) consisting of a pump, column (Shodex KB-803), and refractive index (RI) detector using pullulan standards (PSS, Mainz, Germany) with molecular weights between 5 800 and 212 000. Eluents used were 0.05 M $NaNO_3$ for the uncharged polymers and 5% (w/v) NaH_2PO_4 in 3% (v/v) acetonitrile (pH 4) for the cationic conjugates (*18*). The degree of conjugation was estimated by elemental microanalysis of nitrogen (%N) using a Perkin-Elmer 2400/II CHN analyzer. ^1H NMR spectra (D_2O, $CDCl_3$ or DMSO-d_6) were obtained on a Varian 300-MHz spec-

trometer in 5-mm outside diameter tubes. D_2O/$CDCl_3$/DMSO-d_6 containing tetramethylsilane served as solvent and shift reference. Fourier transform (FT) IR spectra were recorded on a Perkin-Elmer, 2000 FTIR. Purified plasmid (pCMV-GFP and pCMV-β-Gal) were from Qiagen kit, Germany. Fetal calf serum (FCS), 4 mM glutamine, penicillin, streptomycin, and amphotericin B were from Beit Haemek, Israel. Alamarblue reagent was from Biosorce, Israel. Cell transfection with pCMV-GFP was analyzed by fluorescence microscope instrument using model Axiovert 35, Zeiss, Jena, Germany.

Methods. *Synthesis of tri-tert-Butyl Carbonyl Spermine (tri-BOC Spermine).* Spermine was selectively protected on one of the primary amino functional groups by reaction with ethyl trifluoroacetate. Spermine (21.96 mmol, 4.4 g) was dissolved in 250 mL of absolute methanol, and the solution was cooled to −78 °C, then an equimolar (21.96 mmol, 3.1 g) amount of ethyl trifluoroacetate was added during 1 h at −78 °C under nitrogen atmosphere. Stirring was continued for 1 h at 0 °C to complete the reaction. The remaining three amino functional groups were BOC protected with di-*tert*-butyl dicarbonate (4.0 equiv, 87.84 mmol, 19.1 g) that was added, and the mixture was stirred at 0 °C for 1 h under nitrogen atmosphere and then overnight at room temperature. The trifluoroacetamide protecting group was then cleaved by adding 30 mL of 25% ammonia solution (pH of the mixtrure was 11), and stirring was continued for 16 h at room temperature under nitrogen atmosphere. The resulting tri-BOC spermine was purified from di-BOC spermine by chromatography over silica gel (dichloromethane (DCM):MeOH:NH_4OH 70:10:1 to 50:10:1 v/v/v). Average yield: 50%.

^{1}H NMR (DMSO, ppm): 1.4 (s, 27H, BOC hydrogens), 1.6 (m, 4H, NH(BOC)$(CH_2)_3$N(BOC)CH_2*CH_2*CH_2N-(BOC)$(CH_2)_3NH_2$), 1.72 (m, 4H, NH(BOC)CH_2*CH_2*CH_2N-(BOC)$(CH_2)_4$ N(BOC)CH_2*CH_2*CH_2NH_2), 2.6 (m, 2H, NH-(BOC)$(CH_2)_3$N(BOC)$(CH_2)_4$N(BOC)CH_2CH_2*CH_2NH_2), 3.1 (m, 10H, NH(BOC)*CH_2*CH_2*CH_2*N(BOC) *$CH_2CH_2CH_2$*-*CH_2*N(BOC)*$CH_2CH_2CH_2NH_2$*).

Synthesis of MQ Ammonium Spermine (MQ−Spermine). Tri-BOC spermine (2.0 mmol, 1.0 g) was dissolved in 25 mL of anhydrous THF. The solution was cooled to 0 °C, then diisopropylethylamine (5.0 equiv, 10.0 mmol, 1.75 mL) and dimethyl sulfate (4.0 equiv, 8.0 mmol, 0.75 mL) dissolved in minimum amount of THF were added to the flask. The mixture was stirred for 24 h at room temperature under nitrogen atmosphere. Diisopropylethylammonium salt was discarded by filtration. The filtrate was evaporated under reduced pressure. The crude was dissolved in a mixture of trifluoroacetic acid (TFA) and DCM (TFA:DCM 10:90 v/v) for 2 h at room temperature to deprotect three amino functional groups. DCM and TFA were evaporated under reduced pressure, and the residue was redissolved in double deionized water (DDW) and purified from sulfate by Dowex-1 anion-exchange resin (chloride form). The fractions were picked and freeze dried. Average yield: 90%.

^{1}H NMR (D_2O, ppm, tetrahydrochloride form): 1.62 (m, 4H, $H_3N(CH_2)_3NH_2CH_2$*CH_2*$CH_2CH_2NH_2(CH_2)_3$N-$(CH_3)_3$), 1.9 (m, 2H, H_3NCH_2*$CH_2CH_2NH_2(CH_2)_4$ NH_2-$(CH_2)_3N(CH_3)_3$), 2.08 (m, 2H, $H_3N(CH_2)_3NH_2(CH_2)_4$- NH_2-CH_2*$CH_2CH_2N(CH_3)_3$), 3.0 (m, 12H, $H_3NCH_2CH_2$*CH_2*-NH_2*$CH_2CH_2CH_2$*CH_2NH_2-*CH_2CH_2*$CH_2N(CH_3)_3$), 3.28 (m, 9H, $H_3N(CH_2)_3NH_2(CH_2)_4NH_2CH_2CH_2CH_2N$*$(CH_3)_3$*). Elemental Analysis: %N = 13.36, %Cl = 34.

Synthesis of Dextran−MQ−Spermine Conjugate. Oxidized polysaccharide (1.0 g, 6.25 mmol of aldehyde groups) (*19*) was dissolved in 100 mL of DDW, and the solution was slowly added over several hours to a solution containing 6.25 mmol MQ−spermine dissolved in 50 mL of borate buffer (0.1 M, pH 11). The mixture was stirred at room temperature for 24 h. $NaBH_4$ (1.0 g, 4.0 equimolar) was added to reduce the formed imine bonds and stirring was continued for 48 h at room temperature. The reduction was repeated with an additional portion of $NaBH_4$ (1 g), and stirring was continued for additional 24 h. The resulting solution was poured into a dialysis membrane (3 500 cutoff, Membrane Filtration Products, Inc., San Antonio, TX) and dialyzed against DDW at 4 °C for 3 days. The dialysate was lyophilized to dryness. Average yield: 50% (w/w).

^{1}H NMR (D_2O, ppm): 1.45 (m, 4H, MQ−spermine hydrogens), 1.63 (m, 4H, MQ−spermine hydrogens), 2.64 (m, 10H, MQ−spermine hydrogens), 3.0 (m, 9H, methyl hydrogens of MQ−spermine), 3.0 (m, 2H, MQ−spermine hydrogens), 3.30−4.45 (m, glucose hydrogens), and 5.01 (m, 1H, anomeric hydrogen).

Synthesis of BOC-1,2-ethylenediamine. Solution of di-*tert*-butyl dicarbonate (2.45 g, 0.011 mol) in dioxane (30 mL) was added over a period of 3 h to a solution of 1,2-ethylenediamine (5.25 g, 0.087 mol) in 30 mL of dioxane. The mixture was allowed to stir for 24 h at room temperature, and the solvent was removed under reduced pressure. The residue was dissolved in 50 mL of DDW, and the insoluble bis-substituted product was collected by filtration. The white filtrate that contained monoprotected 1,2-ethylenediamine was extracted with DCM (3 × 50 mL), dried over anhydrous $MgSO_4$, filtered, and evaporated to dryness. The crude yellow oil was further dried under vacuum over solid NaOH pellets. Average yield: 90%.

^{1}H NMR ($CDCl_3$, ppm): 1.4 (s, 9H, COOC*$(CH_3)_3$*), 2.8 (t, 2H, -*CH_2*−NH_2), 3.15 (m, 2H, BOC−NH-*CH_2*-) and 5.02 (br, 1H, *NH*-BOC).

Synthesis of MQ Ammonium 1,2-Ethylenediamine (MQ−1,2-Ethylenediamine). BOC-1,2-ethylenediamine (1.0 g, 6.25 mmol) was dissolved in 5 mL of anhydrous dimethylformamide (DMF), then 3.7 mL of anhydrous tributylamine (TBA) was added to the flask. The mixture was cooled to 0 °C, and 3.3 g of methyl iodide (3.5 equimolar) was added. Stirring was continued overnight at room temperature under nitrogen atmosphere. Solvent and excess TBA were removed under reduced pressure and the resulting product was incubated for 2 h in 5 mL of TFA:DCM (10:90 v/v) at room temperature to deprotect the amino groups. The product was precipitated in 100 mL of diethyl ether, and the yellow precipitate was further dried under vacuum over solid NaOH pellets. The yellow precipitate was dissolved in DDW (5 mL) and purified from iodide by Dowex-1 anion-exchange resin (chloride form). The fractions were picked and freeze dried. Average yield: 80%.

^{1}H NMR (DMSO, ppm, dichloride form): 3.140 (s, 9H, −N(*CH_3*)$_3$), 3.282 (t, 2H, −*CH_2*−NH_3), 3.481 (t, 2H, −*CH_2*−$N(CH_3)_3$), and 7.942 (br, 3H, −CH_2*NH_3*).

Synthesis of Dextran−MQ−1,2-Ethylenediamine Conjugate. Oxidized dextran (100.0 mg, 0.625 mmol) was dissolved in 10 mL of DDW, and the solution was slowly added over several hours to a solution containing 0.625 mmol of MQ ammonium−1,2-ethylenediamine (1.0 equimolar) dissolved in 5 mL of borate buffer (0.1 M, pH 11). The mixture was stirred at room temperature for 24 h. $NaBH_4$ powder (100.0 mg, 4 equimolar) was added to reduce the imine bonds to amines, and the mixture was further stirred for 48 h under the same conditions. The reduction was repeated with an additional portion of $NaBH_4$ (100.0 mg), and stirring was continued for ad-

ditional 24 h under the same conditions. Then, the reaction mixture was dialyzed (3500 cutoff, Membrane Filtration Products, Inc., San Antonio, TX) against DDW at 4 °C for 3 days. The dialysate was lyophilized to dryness. Average yield: 35% w/w.

^{1}H NMR (D_2O, ppm): 2.9 (m, 2H, methylene hydrogens), 3.3 (s, 9H, methyl hydrogens), 3.3 (m, 2H, methylene hydrogens), 3.3−4.45 (m, glucose hydrogens) and 5.01 (m, 1H, anomeric hydrogen).

Synthesis of BOC−1,4-Butane Diamine. Solution of di-*tert*-butyl dicarbonate (2.45 g, 0.011 mol) in dioxane (30 mL) was added over a period of 3 h to a solution of 1,4-butane diamine (7.67 g, 0.087 mol) in 30 mL of dioxane. The mixture was stirred for 24 h at room temperature, and the solvent was evaporated. The residue was dissolved in 50 mL of DDW, and the insoluble bis-substituted product was collected by filtration. Contained monoprotected 1,4-butane diamine filtrate was extracted with DCM (3 × 50 mL), dried over anhydrous $MgSO_4$, filtered, and evaporated to dryness. The crude was dried under vacuum over solid NaOH pellets. Average yield: 90%.

^{1}H NMR ($CDCl_3$, ppm): 1.4 (m, 9H, COOC*(CH_3)$_3$*), 1.45 (m, 4H, BOC−NH−CH_2−*(CH_2)$_2$*−CH_2−NH_2), 2.6 (t, 2H, −*CH_2*−NH_2), 3.07 (m, 2H, BOC−NH−*CH_2*−), and 4.8 (br, 1H, *NH*-BOC).

Synthesis of MQ Ammonium−1,4-Butane Diamine (MQ−1,4-Butane Diamine). BOC−1,4-butane diamine (1.0 g, 5.31 mmol) was dissolved in 5 mL of anhydrous dimethylformamide (DMF), then 3.2 mL of anhydrous tributylamine (TBA) was added to the flask. The mixture was cooled to 0 °C, and 2.8 g of methyl iodide (3.5 equimolar) was added. Solution was stirred overnight at room temperature under nitrogen atmosphere. Solvent and excess TBA were removed under reduced pressure, and the resulting product was incubated for 2 h in 5 mL of TFA:DCM (10:90 v/v) at room temperature. The product was precipitated in 100 mL of diethyl ether, and the precipitate was further dried under vacuum over solid NaOH pellets. Average yield: 80%.

^{1}H NMR (D_2O, ppm, dichloride form): 1.8 (m, 2H, −*CH_2*−CH_2−NH_3), 1.9 (m, 2H, −*CH_2*−CH_2−$N(CH_3)_3$), 3.09 (m, 2H, −*CH_2*−NH_3), 3.15 (s, 9H, −$N(CH_3)_3$), and 3.4 (t, 2H, −*CH_2*−$N(CH_3)_3$).

Synthesis of Dextran−MQ−1,4-Butane Diamine Conjugate. Oxidized dextran (100.0 mg, 0.625 mmol) was dissolved in 10 mL of DDW, and the solution was slowly added over several hours to a solution containing 0.625 mmol of MQ ammonium 1,4-butane diamine (1.0 equimolar) dissolved in 5 mL of borate buffer (0.1 M, pH 11). The mixture was stirred at room temperature for 24 h. $NaBH_4$ (100.0 mg, 4 equimolar) was added to reduce the imine bonds to amines, and the mixture was further stirred for 48 h under the same conditions. The reduction was repeated with an additional portion of $NaBH_4$ (100.0 mg), and stirring was continued for additional 24 h under the same conditions. Then, the reaction mixture was dialyzed (3500 cutoff, Membrane Filtration Products, Inc., San Antonio, TX) against DDW at 4 °C for 3 days. The dialysate was lyophilized to dryness. Average yield: 35% w/w.

^{1}H NMR (D_2O, ppm): 1.41 (m, 2H, −*CH_2*−CH_2−NH−glucose unit), 1.7 (m, 2H, −*CH_2*−CH_2−$N(CH_3)_3$), 2.5 (m, 2H, −*CH_2*−NH−glucose unit), 3.25 (m, 2H, −*CH_2*−$N(CH_3)_3$), 3.3 (m, 9H, −N*(CH_3)$_3$*), 3.3−4.45 (m, glucose hydrogens), and 5.01 (m, 1H, anomeric hydrogen).

Preparation of Plasmid DNAs. Plasmid DNAs used in the transfection experiments were pCMV-GFP encoding for green fluorescence protein and pCMV-β-Gal encoding β-Galactosidase. Plasmid DNAs were separately amplified in a XL-blue *Escherichia coli* and isolated using Qiagen Maxi kit-25 (Qiagen kit, Germany). Briefly, the grown bacteria were harvested and lysed in a 1% aqueous solution of sodium dodecyl sulfate (SDS) and 0.1% RNase A solution in NaOH (pH 8.0). The lysate was neutralized by the addition of 3 M potassium acetate (pH 5.5). After separation of the insoluble portion by centrifuging at 14 000 *g* for 30 min, the lysate was applied to an anion-exchange resin (Qiagentip, Germany), followed by high salt washing (buffer containing 1 M NaCl) to remove traces of RNAs and denatured proteins. The plasmid DNA was eluted with an elution buffer containing 1.25 M NaCl at pH 8.5, desalted, and precipitated by 2-propanol. The precipitated plasmid DNA was centrifuged at 14 000 rpm for 10 min at 4 °C, and washed twice with 70% ethanol−water. After centrifugation (14 000 rpm, 2 min, 4 °C), the resulting plasmid DNA was air dried and dissolved in a small volume of 10 mM Tris−Cl pH 7.5. The purity of plasmid DNA was checked routinely, and the absorbance ratio of 260 nm to 280 nm ranged from 1.8 to 2.0.

In vitro Transfection. In vitro transfection procedure was based on the previous publications (*20*). Human embryonal kidney (HEK-293) cells were used in the transfection experiments. Purified plasmid per well of transfected cells (0.5 μg) was mixed with the polycation at various weight-mixing ratios ranging from 3 to 9 w/w (polycation/ DNA). The polycation/DNA complex mixtures were diluted to a final volume of 200 μL with Dulbecco's modified Eagle's Medium (DMEM) and allowed to stand at room temperature for 40 min. Twenty-four-well plates coated with polyethyleneimine were seeded 24 h before transfection at 7 × 10^4 cells per well. Cultures were washed with preheated (37 °C) phosphate-buffered saline (PBS), and the solution of the complexes was added to the wells and cultured at 37 °C in 95% air/5% CO_2. Four hours after transfection, cell medium was replaced with DMEM containing 10% fetal calf serum (FCS), 4 mM glutamine, penicillin, streptomycin, and amphotericin B. Cells were further cultured for 48−72 h. At this time, transfection efficiency and toxicity were assayed.

For determination of the transfection efficiency, cultures were washed gently with warm PBS and then subjected to lysis and colorimetric β-galactosidase quantitative determination, measuring the amount of 2-nitrophenol formed in situ from cleavage of 2-nitrophenyl-B-D-galactopyranoside (ONPG) by β-galactosidase. Briefly: 300 μL of the reaction solution consisting of 1 mM $MgCl_2$, 45 mM β-mercaptoEtOH, 73 mM Na_2HPO_4, 16 mM NaH_2PO_4, 0.1% SDS, and 0.88 mg/mL ONPG were applied onto each well, and the cells were then incubated at 37 °C for 30 min until a yellow color developed. Reaction was stopped with 500 μL of 1 M solution Na_2CO_3. The amount of 2-nitrophenol formed was determined by measuring optical density at 420 nm.

Cells transfected with pCMV-GFP were analyzed for gene expression using fluorescence microscope instrument.

For the assessment of the number of vital cells in each well, Alamarblue method was used, in which the reduction of Alamarblue from the oxidized indigo blue, non-fluorescing state to the reduced fluorescent pink state is indicative of the proportion of living cells in each well. Alamarblue reagent was diluted to 5% in growing media and applied to the culture for 4 h, after which the OD at 570 nm was measured.

Percent toxicity was calculated as 100 − OD_{570}SAMPLE/OD_{570}CTRL × 100, where the control group was not

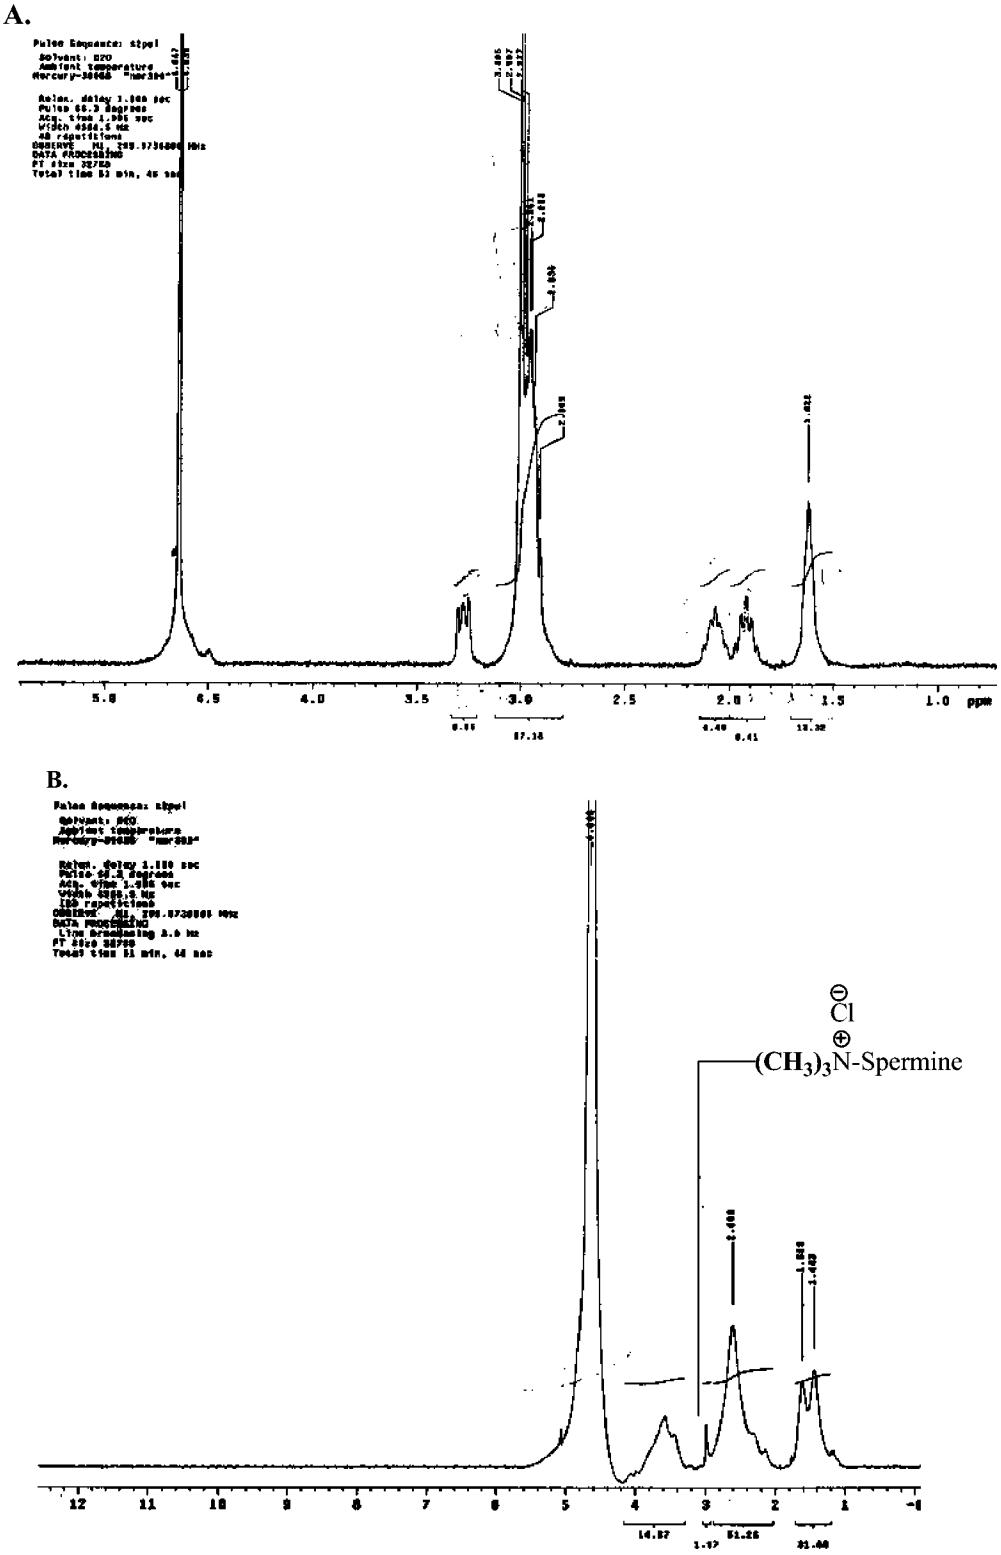

Figure 1. (A) ^{1}H NMR spectrum of the MQ−spermine. (B) ^{1}H NMR spectrum of the compound #C.

subjected to any treatment but underwent the identical culturing and washing procedure.

RESULTS AND DISCUSSION

Chemistry. In the present study, we have prepared quaternorized conjugates and investigated their transfection efficiency and cytotoxicity. Oligoamine derivatives having a quaternary ammonium salt in one end and a primary amine group in the other end were synthesized as illustrated in Scheme 1. Tri-BOC spermine derivative was prepared in several steps using TFA and BOC orthogonal protecting groups. Ethyl trifluoroacetate was added at −78 °C to obtain the predominantly monotrifluoroacetamide derivative, followed by reaction with excess of di-*tert*-butyl dicarbonate to obtain the fully mixed protected derivative. The trifluoroacetamide protecting groups were removed by concentrated ammonia, yielding the tri-BOC spermine derivative. The tri-BOC spermine was then treated with dimethyl sulfate or methyl iodide to obtain the tri-BOC monoquaternary

Table 1. Structures of Oligoamines Used in the Preparation of Dextran−Oligoamine Polycations

Oligoamine used for conjugation	Oligoamine structure	^{1}H-NMR (ppm)
Spermine		(D_2O):1.645 (m), 1.804 (m) and 2.185 (m)
MQ-spermine		(D_2O):1.62 (m), 1.9 (m), 2.08 (m), 3 (m) and 3.28 (m)
MQ-1,2- ethylene diamine		(DMSO):3.1 (s), 3.28 (t) and 3.48 (m)
MQ-1,4-butane diamine		(D_2O):1.8 (m), 1.9 (m), 3.09 (m), 3.15 (s) and 3.4 (t)

Table 2. Chemical Characterization of Dextran−Oligoamine Conjuagates[a]

[a] Oligoamine was reacted with oxidized dextran (~50% dialdehyde) at a 1:1 aldehyde/oligoamine mole ratio. [b] Found nitrogen content (elemental analysis). [c] Amount of primary amine (mmol/g) in conjugates determined by the TNBS method. [d] Average molecular weight (Mn) and polydispersity (P = Mw/Mn) were determined by GPC. The remarkable difference in molecular weight of the #A and #B and #D and #E conjugates is explained by the use of dextran of 40 and 10 kDa as starting material. [e] β-Galactosidase quantitative determination (OD). Trasfection yield of the polycations, prepared at 3:1 weight ratio (polymer/DNA), were compared to calcium phosphate used as a positive reference (OD = 1.307).

ammonium spermine derivative as a sulfate or iodide salt. Deprotection of BOC groups was achieved by treating with trifluoroacetic acid to obtain the MQ−spermine derivative. Figure 1A shows the ^{1}H NMR spectrum obtained from this derivative. The remaining MQ ammonium alkane diamine derivatives were similarly prepared.

Oxidized dextrans having similar molecular weight and aldehyde content were reacted under the same conditions with MQ ammonium tetramine and diamine (Table 1) followed by treating with sodium borohydride to obtain the amine conjugate (Scheme 2). MQ−oligoamine derivatives were chemically characterized (Table 2). The degree of substitution with MQ−oligoamine moieties was estimated by microanalysis (%N), primary amine content (TNBS) (*13*), and ^{1}H NMR spectroscopy. Negligible primary amino group content was obtained for conjugates that were fully grafted with MQ ammonium oligoamines. This was expected by the fact that these oligoamine derivatives are being all grafted and terminated with quaternary ammonium functionalities.

Transfection Results. Transfection experiments of grafted oxidized dextran with MQ−spermine, MQ ammonium−1,4-butane diamine, and MQ ammonium−1,2-ethylenediamine were performed using EPC cell line in serum-free medium (SFM). Plasmid used for these studies was pCMV-luciferase encoding for luciferase protein. Luciferase was quantitatively assayed using commercial enzyme-linked immunosorbent assay kits according to standart protocols. Dextran−spermine based polycations were found to be highly effective in transfecting cells in vitro (*21*) and in vivo (*14*, *22*), therefore dextran−spermine was used as a positive reference.

Since spermine is clearly the active moiety in the transfection (*21*), it was plausible that increasing the charge level of the carrier by MQ−spermine conjugation onto dextran (Scheme 2, product #d) would result in enhanced transfection efficiency. However, in comparison with leading derivative dextran−spermine, all quaternary ammonium derivatives resulted in negligible transfection in all tests (Table 2). Possible explanation for this behavior is probably a result of the high cationic nature of the quaternary ammonium moieties, which form a too strong complex with DNA. In other words, quaternary ammonium groups seem to form too strong and stable complexes with DNA to be released, which led to a dramatic decrease in the transfection efficiencies. These results strengthen Margreet hypothesis about quaternary ammonium groups that form complexes efficiently with DNA, reflecting a stronger bond than with primary amino groups (*23*). We hypothesize that an additional explanation for the reduced transfection yield is the difference in the branching of the polymer. It was shown that dextran−spermine is a branched polymer with some

spermine residues serve as branching agents (*13*, *23*). The degree of branching can be determined according to the following equation

$$\%\text{branching} = [(\text{spermine (total)} - \text{spermine (graft)})/\text{spermine (total)}] \times 100$$

where spermine (total) is determined by %N (microanalysis) and spermine (graft) can be determined by primary amine content (TNBS). In our case, 11% branching spermine moieties were obtained in the compound #F. On the other hand, use of the MQ−spermine reduces the degree of branching and thus a less branched polycation is obtained which affects the transfection yield. More studies will be needed to confirm this hypothesis. The structures of dextran−spermine and dextran−MQ−spermine are given in Scheme 2 (products #c and #d, respectively).

Grafting of the oligoamines mixtures to oxidized dextran was the further step of our study. Dextran conjugates of mixtures of intact spermine and MQ−spermine were prepared by reacting oxidized dextran starting from different molecular weights with mixtures of spermine: MQ−spermine at 95:5 to 80:20 mole ratios followed by reduction with $NaBH_4$ (Scheme 2, product #e). Chemical characteristic of these compounds and ^1H NMR spectrum of one of them is given in Table 2 (compounds #A−E) and Figure 1B, respectively. The purpose of this step was to evaluate transfection efficiencies of these polymers as a function of MQ ammonium spermine percentages to the total grafted oligoamine.

The transfection with these derivatives was performed in SFM applying HEK-293 cells. Plasmids used for these studies were pCMV-GFP encoding for green fluorescence protein as a marker gene and β-Gal encoding for β-galactosidase protein. Stock solutions of DNA and polycations were mixed at various weight ratios, diluted with DMEM, and left at room temperature. After 40 min, complex solutions were added separately to each cell well. After 4 h, SFM was replaced with a fresh medium. Incubation was continued for 48−72 h to complete transfection. Transfection yield was defined by colorimetric β-galactosidase quantitative determination, measuring the amount of 2-nitrophenol formed in situ from cleavage of 2-nitrophenyl-B-D-galactopyranoside by β-galactosidase. In the case of GFP protein, the transfection yield was quantified by visual counting of fluorescent cells in a certain field using a fluorescent microscope (data not shown). Calcium phosphate precipitating technique and dextran−spermine were used as positive reference. MQ ammonium conjugates were prepared and tested for their transfectivity. Each single polymer was tested over a range of polymer/DNA ratios from 3 to 9. Figure 2 demonstrates a series of transfection results, applying HEK-293 cells and β-Gal transfection systems. These conjugates showed low transfection yield even at 5% MQ−spermine content at both low and high molecular weight conjugates (compounds #A and #D). Further increase of weight ratio (polymer/DNA) resulted only in a slight improvement of the transfection yield (Figure 2). These results indicate that conjugation of MQ−spermine and probably other quaternary ammonium derivatives have negative effect on the transfection yield and that spermine remains the most effective as oligoamine graft.

Evaluation of the Cytotoxicity. One of the requirements of the polymeric vectors for use in gene therapy is the absence of cytotoxicity. Cytotoxicity evaluation of the tested conjugates was performed by the Alamarblue method (*24*). Polycation solutions and plasmid DNA were mixed at 3:1, 6:1, and 9:1 weight ratios (polymer/DNA). Toxicity of the polyplexes was presented by the number of vital cells in each well. Several conjugates showed a dose−response correlation between the polymer concentration and cell-growth inhibition (compounds #F and #A). Majority of the compounds demonstrated moderate effect on the cell viability or no toxicity at all at 3:1 weight ratio (dextran−spermine/DNA). However, an additional increase in the weight ratio resulted in a raise of cytotoxic properties of the majority of the samples (Figure 3).

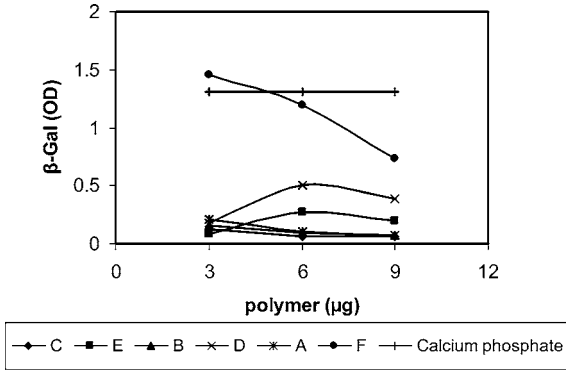

Figure 2. Transfection efficiencies of β-Gal system in HEK-293 cells applying on mixed MQ−spermine/spermine grafted derivatives as vectors (Table 2). Calcium phosphate and dextran−spermine were used as positive reference.

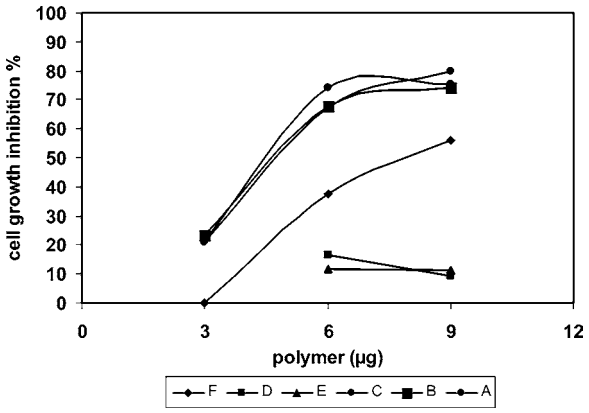

Figure 3. Average cytotoxicity of the tested compounds. Cytotoxicity test was performed using Alamarblue method (*24*) on HEK-293 cells applying dextran−spermine and mixed MQ−spermine/spermine derivatives (see Table 2).

CONCLUSION

On the basis of the assumption that quaternorization may enhance the DNA-condensing ability of the cationic polysaccharides, various polycations were prepared by reductive amination between MQ ammonium oligoamines and oxidized dextran. The cationic polysaccharides demonstrated low transfection efficiency in EPC and HEK-293 cells. Mixed grafted MQ−spermine/spermine caused loss of transfection yield. This study proves again that the dextran−spermine conjugate, a biodegradable cationic polysaccharide, remains to be a promising gene carrier. Further attempts to improve its performance by quaternorization of the spermine residue resulted in the loss of activity and increased toxicity.

Cationic membrane disruptive peptides such as melittin would appear to have attributes necessary for DNA delivery: DNA binding via electrostatic interactions and membrane lysis to enable cytoplasmic delivery. However, the relatively small overall charge of membrane disruptive peptides results in weak interactions with DNA. As a model of cationic membrane disruptive peptides, amphiphilic polyvinyl ethers were synthesized. The number of positively charged groups incorporated into these polymers is substantially greater than membrane-active peptides, which enables these polymers to form stable complexes with DNA. By varying the length of the hydrophobic groups incorporated into the polymer from one to four carbons, the dependence of membrane activity on side chain length was established. The ability of these polymers to transfect DNA in tissue culture was tested, and it was found that transfection efficiency is dependent upon the membrane disruptive activity of the polymer. Comparison of melittin and synthetic polymers suggests that transfection and toxicity appear to be dependent upon their affinity for DNA. This demonstration of relationships among membrane lysis, transfection, DNA binding, and polymer side-chain composition establishes a new class of transfection reagents and may guide in the design of polymers and formulations that will enable efficient in vivo transfection.

INTRODUCTION

To protect DNA from nucleases and facilitate gene delivery, DNA is complexed with a cationic agent, either a cationic lipid, lipoplexes, or a cationic polymer, polyplexes (*1*). Either "plex" enters the cell via endocytosis and is contained in intracellular vesicles that mature into degradative lysosomes. To escape to the cytoplasm and ultimately gain entry to the nucleus, some form of endosomolytic activity must be incorporated into the delivery system. We report in this communication the creation of polymers that simultaneously possess DNA complexation and membrane-disruptive properties. Use of these polymers greatly simplifies formulation of polyplexes and improves biologically relevant delivery of DNA to cells.

Membrane-disruptive polycations in polyplexes is a relatively uncommon strategy to promote endosomolysis. All membrane-lytic peptides and polymers are amphipathic in character, i.e., they contain both hydrophilic and hydrophobic functional groups. The most studied membrane-disruptive polymers are negatively charged peptides that form amphiphilic helices capable of membrane insertion. Formation of the helices is pH-dependent and occurs in the acidic environment of the mature endosome or lysosome. Examples of these types of peptides are those derived from viral coat proteins, such as the influenza hemagglutinin-like peptide GALA (*2*, *3*). Synthetic polymers polyethyl and polypropyl acrylic acids also have pH-dependent membrane disruptive (*4*, *5*) and transfection (*6*) activities.

In addition to membrane-active anionic peptides, there are also membrane disruptive cationic peptides, such as melittin (GIGAILKVLATGLPTLISWIKNKRKQ) and the lysine analogue of GALA (*7*) (KALA: WEAKLAKALAKALAKHLAKALAKALKACEA) that have been studied for their ability to transfect DNA. However, the interaction between DNA and small polycations such as melittin and KALA (both with +5 net charge) are relatively weak compared to larger polycations, resulting in the formation of particles that dissociate in the presence of physiological salt (*8*, *9*). Therefore, it is not surprising that recent studies using cationic membrane-disruptive peptides as transfection reagents covalently attach the peptides to larger polycations such as poly-L-lysine and polyethyleneimine (*10*–*12*).

To combine DNA binding ability and membrane disruptive activity into the same polymer, we synthesized polycations that mimic the amphipathic nature of membrane-active peptides, but with charge sufficient for the formation of stable DNA complexes. Since the hydrophobic/hydrophilic ratio required to attain membrane lysis has, in contrast to polyanions (*4*, *5*), not been considered for polycations, we systematically varied the size of the hydrophobic groups.

EXPERIMENTAL SECTION

Materials. 2-Vinyloxyethylphthalimide was synthesized according to literature procedure from phthalimide and 2-chloroethyl vinyl ether (*13*). 2-Chloroethyl vinyl ether, phthalimide, ethyl vinyl ether, propyl vinyl ether, butyl vinyl ether, and boron trifluoride diethyl etherate ($BF_3{\cdot}OEt_2$) were purchased from Aldrich. Methyl vinyl ether was purchased from Matheson. Melittin was synthesized by an Applied Biosystems 433A peptide synthesizer using standard peptide synthesis methods.

Synthesis of Polyvinyl Ethers. 2-Vinyloxyethylphthalimide (1 g, 4.6 mmol) and methyl vinyl ether (0.267 g, 4.6 mmol), ethyl vinyl ether (0.332 g, 4.6 mmol), propyl vinyl ether (0.396 g, 4.6 mmol), or butyl vinyl ether

(0.460 g, 4.6 mmol) were dissolved in 25 mL of anhydrous dichloromethane. These solutions were then brought to −78 °C, $BF_3{\cdot}OEt_2$ (0.065 g, 0.46 mmol) was added, and the reaction was allowed to proceed for 3 h at −78 °C. The polymerization was then stopped by the addition of 50/50 mixture of ammonium hydroxide in methanol. The solvents were then removed by rotary evaporation. The polymer was then dissolved in 30 mL of 1,4-dioxane/methanol (2/1). To this solution was added hydrazine (0.147 g, 46 mmol), and the mixture was heated to reflux for 3 h. The solvents were then removed by rotary evaporation, and the resulting solid was then brought up in 20 mL of 0.5M HCl and refluxed for 15 min, diluted with 20 mL distilled water, and refluxed for additional 1 h. This solution was then neutralized with NaOH, cooled to room temperature, transferred to 3500 molecular weight cutoff cellulose tubing, and dialyzed for 24 h (2 × 20L) against distilled water and lyophilized.

Separation of Polymers by Size Exclusion Chromatography. Lyophilized polymer was dissolved in water. A 5 mL aliquot was placed onto a 2.5 × 20 cm column packed with Sephacryl S-200. The column was eluted with 25 mM $(NH_4)_2CO_3$ 5% ethanol, pH 9. Ten microliter fractions were collected after the dead volume (25 mL). Fractions were then assayed by trinitrobenzenesulfonic acid for amine content. The eluted polymer was pooled into four equal fractions and lyophilized. Fractions were submitted for carbon, nitrogen, and hydrogen elemental analysis at Galbraith Laboratories (Knoxville, TN). Due the hydroscopic nature of the polymers, only the carbon and nitrogen data were used to determine monomer incorporation ratios. The fourth fractions showed the most consistent incorporation ratios and were therefore used in subsequent assays.

DNA Labeling. Covalent labeling of plasmid DNA with fluorophores was performed using tetramethylrhodamine (TMR) LabelIT reagent (Mirus Corp., Madison, WI) as previously described (*14*). LabelIT reagents are nitrogen mustard alkylating reagents that react primarily with guanine bases (*15*). Briefly, plasmid DNA and a solution of LabelIT reagent in methyl sulfoxide (100 mg/mL) were mixed in 1 mL of 10 mM HEPES, pH 7.5, at a LabelIT/DNA ratio of 5:1 (w/w). The reaction mixture was incubated for 1 h at 37 °C. Labeled DNA was then precipitated three times in 70% ethanol with 0.2 MNaCl.

DNA Condensation Assay. The collapse of TMR-labeled DNA was assessed using a quantitative assay based on condensation-induced quenching of a fluorophore covalently attached to DNA (*14*). Briefly, TMR-DNA (10 μg) was mixed with various quantities of polyvinyl ethers or melittin in 0.5 mL of 10 mM HEPES, pH 7.5. Rhodamine fluorescence of the samples was measured using a Varian spectrofluorometer (excitation wavelength (λ_{ex}) of 546 nm; emission wavelength (λ_{em}) of 576 nm) at room temperature. A graph of fluorescence as a function of added polymer was composed of two regions: a condensation phase where each addition of polymer resulted in a linear decrease in fluorescence, and the condensed phase where the labeled DNA was fully condensed. The concentration of polymer required for condensation was calculated by fitting of the steepest portion of the condensation phase and condensed phase to linear equations and determining the intercept of the two lines. A summary of data is presented in Table 2. Titration curves are presented as supplementary data.

Determination of Polymer Size. The molecular weights of the polymers were then determined by GPC using Eprogen Inc. CATSEC100, CATSEC300, and CATSEC1000 columns in series. The running buffer was 200 mM NaCl and 10% MeOH. Polyvinylpyridine standards (1.5, 6.5 12, 21, 47, 65, 78, 115, 287, and 1,260 kD) were used as the calibration curve. To detect the polyvinyl ethers, they were labeled with Cy3 with Cy3-*N*-hydroxysuccinimide (Amersham), which was detected at 555 nm.

The log of the molecular weight of the polyvinylpyridine standards were linear with respect to retention time, and from this relationship we were able to estimate the molecular at any retention time. From this relationship, we calculated the molecular weight M_w of the polymers according to the equation $M_w = \sum_t A_t M_t / \sum_t M_t$ where A_t is the absorbance measured at time t and M_t is the molecular weight based upon standards that elutes at that time.

Table 1. Composition and Size of Amphipathic Polyvinyl Ethers

polymer	formula from EA	mw per charge by EA[a]	mw per charge by DNA (ratio of two charge density determinations)
methyl	C_5N	147	154 (1.0)
ethyl	C_7N	165	147 (0.9)
propyl	C_6N	153	153 (1.0)
butyl	C_7N	164	166 (0.8)
mellitin		680	891 (0.8)

[a] Molecular weight of polyvinyl ethers per charge is calculated as amine free base. Melittin's molecular weight is calculated using a trifluoroacetate counterion.

Table 2. Characterization of Amphipathic Polyvinyl Ethers

polymer	molecular weight of polymer[a] (charge)	[NaCl]* (M)[b]
methyl	8500 (57)	0.6
ethyl	2500 (15)	0.4
propyl	4200 (27)	0.5
butyl	5000 (30)	0.5
melittin	3275 (5)	0.1

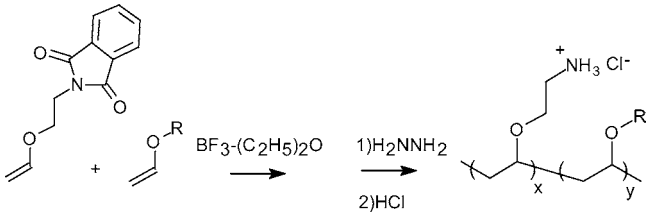
[a] Molecular weight based on free bases, number of charges per polymer in parentheses. [b] [NaCl]*,the concentration of NaCl required to displace polycation from plasmid DNA.

Polycation-pDNA Stability Assay. To determine the relative strength of the interactions between the peptides and polycations, the concentration of salt required to displace a polycation from TMR-labeled DNA was determined. TMR-DNA (10 μg) was condensed at N:P ratio of 2:1, as determined by condensation assays, in 10 mM HEPES, pH 7.5. To this solution were added increasing concentrations of NaCl from a 5 M stock. The fluorescence of the samples was then measured (λ_{ex}= 546 nm λ_{em}= 576 nm). A graph of fluorescence as a function of [NaCl] was a composed of two regions: a lag phase where increasing salt resulted in little or no increase in fluorescence and a decondensation phase where each addition of salt resulted in a linear increase in fluorescence. The concentration of NaCl required for decondensation was calculated by fitting of the lag phase and decondensed phase to a linear equation and determining the intercept of the two lines.

Particle Sizing. To a solution of 5 mM HEPES pH 7.5, 150 mM NaCl, and 10 μg/mL plasmid pCIluc was added polyvinyl ether to 20 μg/mL or polyethyleneimine to 10 μg/mL. After 30 min, the size of the particles was measured by light scattering at 532 nm using a Brookhaven Instruments Corporation, ZetaPlus Particle Sizer, I90.

Liposome Lysis. Egg phosphatidylcholine (10 mg) was hydrated with 1 mL of buffer containing 100 mM carboxyfluorescein (CF) and 10 mM HEPES pH 7.5.

Scheme 1. Synthesis of Amphipathic Polyvinyl Ethers



Liposomes were then extruded through 100-nm pore polycarbonate filters (Nucleopore, Pleasanton, CA). Unentrapped CF was removed by size exclusion chromatography using Sepharose 4B-200 eluting with 10 mM HEPES, pH 8, 0.1 M NaCl. A 200 μL aliquot of the CF-loaded liposomes was added to 1.8 mL of isotonic buffer. Fluorescence ($\lambda_{ex} = 488$, $\lambda_{em} = 540$) was measured 30 min after addition of 0.25 μg of polymers or melittin to vesicle suspensions. At the end of each experiment, vesicles were disrupted by the addition of 40 μL of a 1% Triton X-100 solution to determine maximal lysis.

Transfection. Hepa-1clc7 cells (mouse hepatoma) were cultured in 1 mL of Dubelco's modified Eagle Media containing 10% fetal bovine serum. Amphipathic polyvinyl ethers, melittin, or PEI was added to plasmid DNA at a 2:1 wt:wt ratio, which corresponds to approximately a 4:1 N:P ratio (10 μg/mL, pCIluc; prepared according to published procedure (*16*)) in 0.5 mL of 150 mM NaCl and 5 mM HEPES, pH 7.5. Formulated DNA (1 μg) was added to the cells, and 48 h later the confluency of the cells was estimated. All samples, except melittin, had levels of confluency comparable to cells grown in the absence of polymer. The cells were harvested and assayed for luciferase expression as previously reported (*17*). The amount of transfection is average transfection for two separate wells of cells.

Cell Toxicity Assay. After 48 h of incubation with DNA−polycation complexes according to transfection protocol, 500 μg of MTT in PBS solution (5 mg/mL) was added to the culture for 1 h. The media were then aspirated, and the cells were washed with 1 mL of PBS. The cells were then dissolved by addition of 1 mL of 10% SDS in 10 mM HCl. After rocking the samples overnight at room temperature, 300 μL of solution was transferred into 96-well plates and the absorbance of the solution at 410 nm was measured using a Molecular Devices SpectraMax Plus (Sunnyvale, CA). Absorbances were normalized to cells grown in the absence of transfection complexes. Each experiment was average of six experiments.

RESULTS AND DISCUSSION

Amphiphilic polyvinyl ethers were synthesized from amino and hydrophobic vinyl ether monomers. Amino groups were incorporated into polyvinyl ethers using an amine-protected phthalimido vinyl ether (*13*). Alkyl groups were incorporated using methyl, ethyl, propyl, or butyl alkyl vinyl ethers (R = CH_3, CH_2CH_3, $CH_2CH_2CH_3$, or CH_2 CH_2CH_3 in Scheme 1). After removal of the phthalimido groups, the polymers were dialyzed to remove salts, monomers, and oligomers. The polymers were further purified using size exclusion chromatography to remove unreacted monomers and oligomers.

The incorporation of monomers into the polymers was measured by elemental analysis, which determines the ratio of carbon to nitrogen and thereby the ratio of amine to alkyl groups in the polymer (Table 1). By elemental analysis and DNA condensation (vide infra), we determined that the smaller size exclusion fractions had amine to alkyl group incorporation ratios that were more consistent with each other in the series and with the feed ratios. For this reason, only comparisons between these fractions are presented in this report.

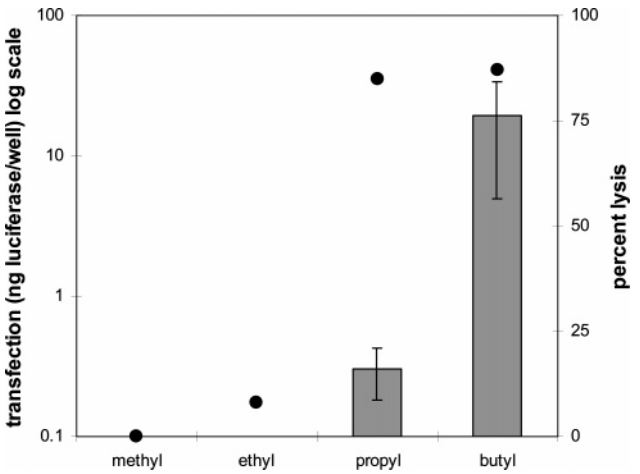


Figure 1. Transfection and lysis as function of side chain composition. Transfection ability (bars, see Table 3) and liposome lysis activity of polymers as a function of polymer side chain length.

In addition to measuring amine incorporation ratios by elemental analysis, the charge density, and consequently the amine content, of the polymer was measured by determining the amount of polymer required to condense fluorophore-labeled DNA (Table 1) (*14*). As one would expect, the DNA condensing ability of a polycation correlates with the number of positively charged functional groups. For comparison, the charge density of the amphipathic peptide melittin was also measured. Note that, in low salt, melittin's charge density as measured by its ability to condense DNA does correlate with its charge.

The molecular weights, and thereby the number of amines, of the polymers were measured using size exclusion columns. The smallest polymer, the ethyl vinyl ether-derived polymer, had an average charge of +15, which is well above melittin and KALA. More importantly for transfection is that these polymers bind DNA in the presence of physiological concentrations of salt, which roughly corresponds to 150 mM NaCl. To establish the relative stabilities of the complexes between the polycations and DNA, we determined the amount of salt required to induce release of DNA from the complex ([NaCl]* in Table 2). Using fluorophore-labeled DNA condensed at a 2:1 amine-to-phosphate ratio, we measured the amount of NaCl to induce DNA release. For the oligocation melittin, the DNA complex completely dissociates below physiological salt concentrations, ca. 70 mM NaCl. In contrast, the amphiphilic polyvinyl ethers are displaced at much higher concentrations of salt (>400 mM).

The membrane-lytic abilities of the amphipathic polyvinyl ethers were measured by analyzing their ability to lyse carboxyfluorescein-loaded liposomes. Similar to data obtained by others studying membrane-lytic polyanions (*4*, *5*), the abilities of the polyvinyl ethers to lyse liposomes are indeed dependent on the size of the hydrophobic chain. The polymer containing butyl groups is the most lytic followed by the propyl and ethyl in order of lytic ability (Figure 1, circles). The butyl-containing polymer possesses lytic activity comparable to melittin (80% lysis with 0.25 μg of melittin). The methyl-derived polymer was completely inactive for lysis.

Table 3. Transfection and Toxicity of Amphipathic Polycations in Hepa Cells

polycation	ng luciferase per well	% MTT[a]
methyl vinyl ether	0.068 ± 0.029	94 ± 11
ethyl vinyl ether	0.054 ± 0.028	100 ± 3
propyl vinyl ether	0.30 ± 0.12	90 ± 4
butyl vinyl ether	19 ± 14	94 ± 9
polyethyleneimine	1.1 ± 0.4	105 ± 5
melittin	0.015 ± 0.003	67 ± 12

[a] Percent of metabolized MTT relative to cells grown in absence of DNA complexes.

The ability of the amphiphilic polyvinyl ethers to transfect DNA was tested at various (N/P) ratios using a mouse hepatoma cell line. Optimal transfections are observed for the polyvinyl ethers at a 4/1 N/P ratio (Figure 1: bars and Table 3: column 1). Branched PEI, a standard polyplex-based transfection reagent, and melittin were also tested in the assay at a 8:1 and 4:1 N:P ratios, respectively. The ability of the polyvinyl ethers to transfect DNA positively correlated with their membrane lytic activity; the highest levels of transfection were obtained with the polymers containing butyl groups, whereas transfection levels obtained using polymers containing shorter alkyl side chains were progressively lower. These data suggest that transfection activity of the polymers is derived at least in part from membrane activity. Similar results were obtained using the HEK (human epithelial kidney) 293 cell line (see Supporting Information).

The sizes of the complexes are important for transfection. Complexes were formulated at physiologically relevant ionic strength (150 mM NaCl), which results in particles that are roughly 900 ± 200 nm in size. Formulation at low salt conditions does result in smaller particles (ca 100 nm); however, these particles are roughly 100 times less effective transfection reagents. This dependence upon size is seen for other transfection reagents (*18*, *19*). The reason for the dependence of transfection upon complex size is a matter of debate; however, the dependence appears to be common to all transfection reagents and is an impediment that needs to be removed for most in vivo delivery applications.

One would expect membrane active polymers to have inherent cell toxicity. Cell confluencies, a qualitative measure of cell viability based upon cell coverage on the well surface as judged by microscopy, indicated little or no toxicity at the levels used for transfection. We do observe decreased levels of cell confluency if higher concentrations of butyl-containing polymer were used. To get a more quantitative measure of cell viability, we assayed cell metabolism using methylthiazolyldiphenyltetrazolium bromide (MTT). MTT is reduced by mitochondrial dehydrogenases of metabolically active cells into a water insoluble blue formazan, which may be quantified by absorbance spectroscopy. Testing the transfection complexes we found that there appears to be slight, although only the propyl-containing polymer is statistically significant, toxicity (Table 3). In general, more toxicity was observed for 293 cells (see Supporting Information), which, as expected, correlates with membrane lytic activity.

The polycation PEI is, to date, the most effective and studied polyplex-based transfection reagent. However, under the conditions reported in Table 3, the butyl-based polyvinyl ether is 10-fold more effective at DNA delivery. Transfection levels comparable to the butyl polyvinyl ether can be achieved with PEI at higher N:P ratios and if the transfection is performed in serum free conditions. These requirements are achievable in vitro but put severe limitations on the use of PEI in vivo.

As might be predicted given its weak interaction with DNA, melittin performed extremely poorly as a transfection reagent. Poor transfection efficiency was observed for melittin at all N:P ratios with greater toxicity at increased levels of melittin. DNA−melittin complexes dissociate under physiological conditions (Table 3), which we believe is the cause of poor transfection and toxicity. In contrast, the relatively strong interaction between the butyl-containing polyvinyl ether and DNA attenuates its membrane lytic activity and, presumably, its cell toxicity. The butyl-containing polymer with DNA has slight toxicity (Table 3), but polymer alone without DNA causes observable toxicity (75 ± 5% MTT metabolized relative to untreated cells). The inhibition of polymer membrane activity by DNA is also demonstrated in the observation that toxicity is observed for the butyl-containing polymer at higher N:P ratios. For amphiphilic polycation-based transfections, membrane lytic activity may be masked until endocytosis forces the membrane surface to come in close contact with the polymer. Contact with the membrane causes displacement of the polymer from DNA, membrane lysis, and, ultimately, transfection. A similar displacement of cation and DNA is hypothesized to occur in cationic lipid-based transfections (*20*). The transfection activity of the butyl-containing polyvinyl ether may then be a result of a fine balance between DNA and membrane binding, which implies that modifications of either interaction would greatly affect transfection efficiency. We believe this is the first study to demonstrate a correlation among transfection activity, membrane lytic ability, and polymer side-chain composition for polycations, which creates a new class of transfection reagents and will aid in the design of polymers and formulations that will enable efficient in vivo transfection.

ACKNOWLEDGMENT

The authors thank Sean Monahan for synthesis of melittin, Stephanie Bertin for tissue culture work, and So Wong and Vladimir Budker for helpful discussions.

Department of Molecular and Cellular Biochemistry, Department of Chemistry, and Kentucky Center for Structural Biology, University of Kentucky, Lexington, Kentucky 40536-0084. Received March 8, 2005; Revised Manuscript Received June 20, 2005

Farnesylation of proteins is catalyzed by protein farnesyl transferase (FTase) and is obligatory for the function of the oncoprotein Ras and a variety of other physiologically important proteins. The rapid and selective detection of cellular protein farnesylation status is crucial to understanding both the function of farnesylated proteins and FTase inhibitors. The unnatural FPP analogue 8-anilinogeranyl diphosphate (AGPP, **3b**) is an effective alternative substrate for mammalian FTase. Using antibodies specific for the anilinogeranyl moiety, we show that the alcohol precursor (AGOH, **5b**) of AGPP is incorporated into cellular proteins in an FTase dependent manner competitive with endogenous pools of FPP. Continuous treatment of HEK-293 cells with 100 μM AGOH for up to 3 days is neither cytotoxic or cytostatic. Antibodies to detect the unnatural anilinogeranyl group were raised against bovine serum albumin (BSA) and keyhole limpet hemocyanin (KLH) bioconjugates of the activated hapten *N*-hydroxyphthalimido-succinyl-(*S*-anilinogeranyl)-L-cysteine methyl ester **9a**. Polyclonal antisera containing anti-anilinogeranyl antibodies were generated by immunization of rabbits and a monoclonal anti-anilinogeranyl antibody was raised in mice. ELISA and western blotting of anilinogeranyl modified proteins were used to show the selectivity and measure the titer of the antibodies. The unnatural FPP analogue and corresponding antibodies provide a simple and rapid method for monitoring FTase activity in cells and detection of cellular proteins modified by AGOH **5a**.

INTRODUCTION

A wide variety of proteins, including Ras, require posttranslational prenylation for their proper membrane localization and activity (*1*–*5*). Protein farnesyl transferase (FTase) catalyzes the transfer of a farnesyl group from farnesyl diphosphate (FPP, **1b** Figure 1) to proteins with a cysteine residue located in a C-terminal Ca_1a_2X motif where C is the modified cysteine, a_1 and a_2 are often an aliphatic residue, and X is Ser, Met, Ala, or Gln (*6*–*8*). Specifically, prenylation is obligatory for the oncogenic effects of mutant Ras (*9*). Mutated forms of Ras genes are among the most common genetic abnormality in human cancer, occurring in 10 to 30% of all neoplasms (*10*–*13*). These observations have lead to the development of a number of FTase inhibitors (FTIs) which block Ras farnesylation and appropriate subcellular localization and activity, in addition to inhibiting growth of Ras transformed cells. Various FTIs are currently in phase I, II, and III clinical trials as antineoplastic agents (*14*–*16*). Farnesylation is the first and obligatory step in an ordered series of posttranslational modifications which mediate membrane localization and possibly protein–protein interactions for a variety of proteins involved in cellular regulatory events (*17*–*19*). After farnesylation, the a_1a_2X peptide is cleaved by the endopeptidase RCE1 (*20*) followed by methylation of the carboxyl of the now terminal farnesylated cysteine residue by the protein-S-isoprenylcysteine O-methyltransferase (*21*). Similar posttranslational modifications occur on the relatively small set of farnesylated cellular proteins, not all of which have

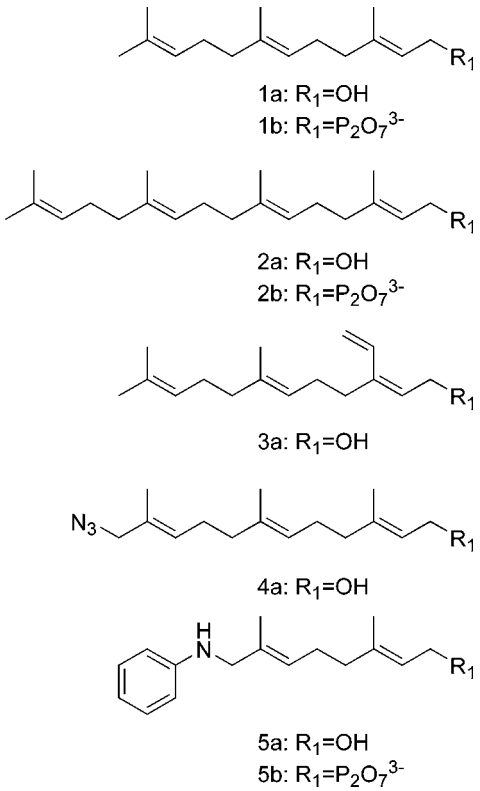

Figure 1. Analogues of FPP.

been identified or characterized. Interestingly, various lines of evidence suggest that one or more of these other proteins, other than Ras, are the actual functional target of FTIs (*22*−*25*). Therefore, the rapid and selective detection of cellular protein farnesylation status and easy isolation of farnesylated proteins is crucial to understanding both the function of farnesylated proteins and of FTase inhibitors.

Monitoring the prenylation state of proteins in cells is a challenging undertaking. Initially, prenylation of proteins was discovered by metabolic labeling with [^{3}H]mevalonolactone (*26*). In these experiments, some of the tritium label was incorporated into both farnesylated and geranylgeranylated proteins. Subsequently, a salvage pathway was discovered where radiolabeled farnesol **1a** (FOH) and geranylgeraniol **2a** (GGOH), precursors of FPP **1b** and GGPP **2b**, were selectively incorporated into their respective farrnesylated or geranylgeranylated proteins (*27*). A significant drawback of these approaches is the inherently low sensitivity of autoraidographic detection of the weak tritium β-emission. In fact, it can take up to four weeks to visualize proteins extracted from cells labeled with tritiated mevalonate or farnesol by autoradiography (*28*). Also, the incorporation of tritiated prenyl groups does not provide a convenient method for isolation of these modified proteins.

The facile detection, isolation and purification of farnesylated proteins based solely on their posttranslational modification status is essential to understanding the mechanism of cellular growth inhibition by FTIs. Antibodies are useful both in the routine detection and immunoprecipitation of proteins with other posttranslational modifications, such as phosphorylation (*29*). However, reports of previous attempts to produce antibodies to detect farnesylated proteins have had mixed results. Two of these reports described nonspecific antibodies that could not differentiate between proteins modified by farnesylation, geranylgeranylation, or other lipids (*30*, *31*). The other report from Baron et al. does describe the production of anti-farnesyl antibodies specific for farnesylation, but the analysis for specificity was limited (*32*). These antibodies are apparently not available commercially, and all of the commercially available sources for anti-farnesyl antibodies cross-react with geranylgeranylated proteins.

An attractive alternative to targeting the natural farnesyl moiety is to detect proteins modified with unnatural farnesyl analogues. Several unnatural analogues of FPP appear to be utilized by cells and incorporated into the proteins by FTase, including the unnatural FPP analogue 3-vinyl-farnesol **3a**, a prodrug of the FTase transferable 3-vinyl-farnesyl diphosphate (3vFPP) **3b**, and 8-azido-farnesol **4** (*28*). A tagging-via-substrate (TAS) approach to the detection and isolation of farnesylated proteins involving the incorporation of **4** into cellular proteins has been developed by Kho et al. (*33*). Modified proteins were isolated from cell lysates using a biotinylated phosphine capture reagent and subsequently identified by mass spectrometry. However, the sensitivity is relatively low, and the technique does not lend itself to the routine detection of modified proteins. A more convenient method to simplify the detection of such proteins would be to use antibodies specific for the unnatural modification.

A variety of FPP analogues that may be useful in implementing this strategy have been prepared by our group and others (*34*−*37*). Anilinogeranyl diphosphate (AGPP) **5b** is transferred by FTase to protein substrates with kinetics similar to that of FPP and does not resemble any known natural protein modification (*38*, *39*). Antibodies against an anilinogeranyl (AG) epitope may circumvent the problems associated with tritium labeling, and the preparation of anti-farnesyl antibodies and provide a facile way to detect and isolate prenylated proteins.

We report the preparation of anti-anilinogeranyl antibodies (polyAG-Ab) raised against hapten **9a** that detect proteins modified with an anilinogeranyl moiety derived from AGPP **5b**. Activated ester hapten **9a** was synthesized and coupled to immunogenic carrier proteins and used to raise antibodies directed to the anilinogeranyl modification. The primary antibodies were able to bind proteins with an intact analogue modified C-terminal Ca_1a_2X motif. We demonstrate that anilinogeraniol **5a**, a prodrug form of AGPP **5b**, is incorporated into cellular proteins in an FTase dependent manner, and that endogenous protein labeling was competitive with endogenous FPP **1b**. Combining the unnatural FPP analogue AGPP with anti-anilinogeranyl antibodies provides a useful reagent system to monitor the prenylation status and effects of FTIs in cells.

EXPERIMENTAL PROCEDURES

General. All reactions were conducted under dry argon and stirred magnetically, except as noted. Reaction temperatures refer to the external bath temperatures. Analytical TLC was performed on precoated (0.25 mm) silica gel 60F-245 (Merck) plates and developed with given solvent conditions. Visualization was achieved by UV irradiation, iodine, or by subjecting the plates to a 15% sulfuric acid, 1% ceric ammonium sulfate, 2% molybdic anhydride solution followed by heating. Flash chromatography was performed on Merck silica gel 60 (230−400 mesh ASTM). All chromatography solvents were purchased from VWR (EM Science-Omnisolv high purity) and used as received. All reagents were purchased from Aldrich or Alfa Aesar. NMR Spectra were obtained in $CDCl_3$ (unless otherwise noted) at 200 or 400 MHz. Chemical shifts for the following deuterated solvents are reported in ppm downfield using the indicated reference peaks: $CDCl_3$ ($CDCl_3$ internal peak 7.27 ppm for ^{1}H, 77.4 ppm for ^{13}C). ESI-MS was performed at the University of Kentucky Mass Spectra Facility.

Anilinogeranyl Cysteine Methyl Ester. 2-Amino-3-(3,7-dimethyl-8-phenylamino-octa-2,6-dienylsulfanyl)-propionic Acid Methyl Ester (7a). Chloride **6a** was prepared from the corresponding alcohol (734 mg, 3.0 mmol) in 10 mL of acetonitrile as previously described (*38*). A solution of L-cysteine methyl ester hydrochloride (1.13 g, 6.50 mmol) in 20 mL of 7 M NH_3/MeOH was added to the cooled solution (−20 °C) of chloride **6a**. The reaction initially formed a white precipitate which quickly disappeared. After 3 h, the reaction mixture was allowed to warm to room temperature over 1 h. The reaction mixture was partitioned between ether and water and extracted with ether (3×). The combined organic extracts were then dried over $MgSO_4$, and solvent was evaporated. Purification by flash chromatography (1:2:8) i-PrOH:EtOAc:hexane yielded 625 mg (60%) of a yellow oil. R_f = 0.32 in 1:2:5 i-PrOH:EtOAc:hexane ^{1}H NMR ($CDCl_3$, 200 MHz) 7.10 (t, 2H, J = 8.0 Hz), 6.63 (t, 1H, J = 7.2 Hz), 6.55 (d, 2H, J = 8.0 Hz) 5.39 (t, 1H, J = 8.0 Hz), 5.23 (t, 1H, J = 8 Hz), 3.75 (s, 3H), 3.59 (m, 3H), 3.13 (m, 2H), 2.86−2.95 (2d, 1H), 2.65−2.76 (2d, 1H), 2.06−2.19 (m, 4H), 1.63 (s, 3H), 1.62 (s, 3H) ^{13}C NMR ($CDCl_3$, 50 MHz) 174.58, 148.77, 139.42, 132.96, 129.38, 125.75, 120.53, 117.39, 113.08, 54.51, 52.49, 51.96, 39.50, 36.61, 30.14, 26.30, 16.33, 14.98; MS: (ESI, +) ($M - H^+$) 363

Farnesyl Cysteine Methyl Ester. 2-Amino-3-(3,7,-11-trimethyl-dodeca-2,6,10-trienylsulfanyl)-propionic Acid Methyl Ester (7b). Into a 100 mL round-bottomed flask at 0 °C was added L-cysteine methyl ester (1.38 g, 10.2 mmol) in 60 mL of 7 M NH_3/MeOH. Neat farnesyl bromide (**6b**) (1.00 g 3.52 mmol) was then added, and the solution was stirred at 0 °C for 4 h. The reaction mixture was partitioned between ether and water and extracted 3× with ether, and extracts were combined, dried over $MgSO_4$, filtered, and evaporated. Purification by flash chromatography (1% MeOH:$CHCl_3$) yielded 881 mg (74%) of a clear oil. $R_f = 0.22$ in 5% MeOH in $CHCl_3$. ^{1}H NMR ($CDCl_3$, 400 MHz): 5.24 (t, 1H, $J = 8$ Hz), 5.10 (m, 2H), 3.75 (s, 3H), 3.64 (q, 1H), 3.10−3.25 (m, 2H), 2.86−2.91 (2d, 1H), 2.65−2.71 (2d, 1H), 2.04−2.10 (m, 6H), 2.04(m, 6H) 2.0 (t, 2H), 1.69 (s, 3H), 1.68 (s. 3H), 1.60 (s, 6H); ^{13}C NMR ($CDCl_3$, 50 MHz) 174.93, 139.91, 135.71, 131.62, 124.69, 124.11, 120.35, 54.64, 52.35, 39.93, 36.77, 30.15, 26.98, 26.67, 25.86, 17.86, 16.33, 16.21 MS: (ESI, +) ($M - H^+$) 340.

General Conditions for Succinylation (8a,b). Cysteine methyl ester **7b** (881 mg, 2.6 mmol) was diluted in 20 mL of 1:1 THF:CH_2Cl_2 in a 100 mL round-bottomed flask. Succinic anhydride (280 mg, 2.8 mmol) was then added and the mixture stirred for 4 h, followed by evaporation of solvent. The residue was diluted in ether, washed sequentially with water and brine, and then dried over sodium sulfate and concentrated in vacuo.

Anilinogeranyl Cysteine Succinate. *N*-[2-(3,7-Dimethyl-8-phenylamino-octa-2,6-dienylsulfanyl)-1-methoxycarbonyl-ethyl]-succinamic Acid (8a). Cysteine methyl ester **7a** (302 mg, 0.83 mmol) provided 250 mg (65%) of succinate **8a** as a white solid. Purification by flash chromatography (1:4:5: 0.1 i-PrOH:EtOAc: hexane:acetic acid) $R_f = 0.32$ (1:4:5 i-PrOH:EtOAc: hexane.) ^{1}H NMR ($CDCl_3$, 400 MHz) 7.12 (t, 2H, $J = 8.0$ Hz), 6.65 (t, 2H, $J = 8.0$ Hz), 6.58 (t, 2H), 5.34 (t, 1H, $J = 8.0$ Hz) 5.14 (t, 1H, $J = 8.0$ Hz), 4.75 (m, 1H), 3.72 (s, 3H), 3.60 (s, 2H), 3.11 (m, 2H), 2.79−2.93 (m, 2H), 2.65 (t, 2H, $J = 8.0$ Hz), 2.52 (t, 2H, $J = 8$ Hz), 2.11 (t, 2H, $J = 8$ Hz) 2.02 (t, 2H, $J = 8$ Hz), 1.63 (s, 3H), 1.62 (s, 3H); ^{13}C NMR ($CDCl_3$, 50 MHz) 176.95, 171.84, 171.55, 148.48, 139.80, 132.79, 129.34, 125.86, 120.06, 117.68, 113.36, 52.91, 52.13, 39.42, 33.55, 30.69, 30.19, 29.53, 28.92, 26.22, 16.25, 14.96 MS: (ESI, +) ($M - H^+$) 463.

Farnesyl Cysteine Succinate. *N*-[1-Methoxycarbonyl-2-(3,7,11-trimethyl-dodeca-2,6,10-trienylsulfanyl)-ethyl]-succinamic Acid (8b). Cysteine methyl ester **7b** (881 mg, 2.6 mmol) provided 937 mg (82%) of succinate **8b** as a white solid. Puification by flash chromatography (1:2:7 i-PrOH:EtOAc:hexane) ^{1}H NMR ($CDCl_3$, 400 MHz) 10.55 (bs, 1H), 6.72 (d, 1H, $J = 8$ Hz), 5.17 (t, 1H, $J = 8$ Hz), 5.07 (m, 2H), 4.75−4.80 (q, 1H), 3.73−3.73 (s, 3H), 3.13 (m, 2H), 2.90−2.94 (m, 1H), 2.80−2.85 (m, 1H), 2.69 (t, 2H), 2.57 (t, 2H), 1.92−2.08 (m, 8H), 1.65 (s, 3H), 1.64 (s, 3H), 1.57 (s, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) 177.40, 171.90, 171.64, 140.17, 135.44, 131.38, 124.44, 124.38, n123.85, 123.78, 119.60, 119.55, 52.80, 52.75, 52.01, 51.97, 39.79, 39.72, 33.28, 31.67, 30.55, 29.96, 29.39, 26.80, 26.51, 25.79, 22.74, 17.78, 16.19, 16.10; MS: (ESI, +) ($M - H^+$) 438.

General Conditions for Activated Ester Formation (9a,b). Succinamic acid **8c** (59.6 mg, 0.126 mmol) was dissolved in 10 mL of dry acetonitrile in a 100 mL round-bottomed flask. Carbonyldiimidazole (26.4 mg 0.163 mmol) was then added, and the mixture was allowed to stir for 5 min. *N*-Hydroxypthalimide (26.4 mg, 0.163 mmol) was added, and the solution was stirred for 1.5 h. The solvent was then evaporated.

Anilinogeranyl Cysteine Succinyl Phthalimide. *N*-[2-(3,7-Dimethyl-8-phenylamino-octa-2,6-diensulfanyl)-1-methoxycarbonyl-ethyl]-succinamic Acid 1,3-Dioxo-1,2-;dihydro-isoindol-2-yl Ester (9a). Succinate **8a** (30 mg, 0.07 mmol) provided 25 mg (63%) of phthalimide **9a** as a yellow/brown oil. Purified by column chromatography ($CHCl_3$). $R_f = 0.28$ (1:1) hexane:EtOAc ^{1}H NMR ($CDCl_3$, 400 MHz): 7.88 (q, 2H), 7.78 (q, 2H), 7.16 (t, 2H), 6.68 (t, 1H), 6.60 (d, 2H), 6.37 (d, 1H), 5.37 (t, 1H), 5.17 (t, 1H), 4.83 (m, 1H), 3.76 (s, 3H), 3.63 (s, 2H), 3.15 (m, 2H), 3.06 (t, 2H), 2.92 (m, 2H), 2.71 (t, 2H), 2.03−2.18 (m, 4H), 1.67 (s, 3H), 1.65 (s, 3H); ^{13}C NMR ($CDCl_3$, 50 MHz): 171.43, 169.94, 169.12, 161.93, 148.70, 139.79, 134.06, 132.89, 129.34, 125.72, 124.19, 120.08, 117.38, 113.07, 52.86, 52.10, 51.97, 39.43, 33.64, 30.63, 30.21, 26.78, 26.25, 16.26, 14.94 MS: (ESI, +) ($M - H^+$) 608.

Farnesyl Cysteine Succinyl Phthalimide. *N*-[1-Methoxycarbonyl-2-(3,7,11-trimethyl-dodeca-2,6,10-trienylsulfanyl)-ethyl]-succinamic Acid 1,3-Dioxo-1,2-dihydro-isoindol-2-yl Ester (9b). Succinate **9b** (60 mg, 0.14 mmol) provided 80 mg (58%) of phthalimide **10b** as a brown oil. Purified by column chromatography ($CHCl_3$). $R_f = 0.3$ (1:1) hexane:EtOAc. ^{1}H NMR ($CDCl_3$, 400 MHz) 7.88 (q, 2H), 7.79 (q, 2H), 6.38 (d, 1H), 5.20(t, 1H), 5.09 (t, 2H), 4.82 (m, 1H), 3.76 (s, 3H), 3.74 (s, 2H), 3.11−3.22 (m, 2H), 3.07 (t, 2H), 2.86−3.00 (m, 2H), 2.74 (t, 2H), 1.95−2.10 (m, 8H), 1.68 (s, 3H), 1.66 (s, 3H), 1.60 (s, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) 171.44, 169.90, 169.93, 161.91, 140.29, 135.57, 134.96, 131.53, 129.06, 124.50, 124.19, 123.90, 119.64, 52.85, 52.00, 39.88, 39.81, 33.54, 30.62, 30.14, 29.03, 28.23, 26.90, 26.75, 26.59, 25.90, 17.89, 16.31, 16.21.

General Conditions for Benzylamine Coupling (10a,b). Phthaimide **9b** (47.2 mg, 0.08 mmol) was dissolved in 1 mL of acetonitrile and 5 mL of 5% $NaHCO_3$ buffer pH = 9 in a 25 mL round-bottom flask. Benzylamine (17.3 mg, 0.16 mmol) was then added, and the reaction was allowed to stir for 1.5 h at room temperature. Water (10 mL) was added, the aqueous phase was extracted with ether (3×) and dried over $MgSO_4$, and the organic solvent was evaporated.

Anilinogeranyl Benzylamine. 2-(3-Benzylcarbamoyl-propionylamino)-3-(3,7-dimethyl-8-phenylamino-octa-2,6-dienylsulfanyl)-propionic Acid Methyl Ester (10a). Phthalimide **9a** (133 mg, 0.22 mmol) provided 59 mg (48%) of amide **10a** as a white solid. Purification by column chromatography (3:7) hexane:EtOAc. ^{1}H NMR ($CDCl_3$, 400 MHz) 7.21−7.31 (m, 5H), 7.12 (t, 2H), 6.55−6.66 (m, 4H), 6.23 (bt, 1H), 5.34 (t, 1H), 5.14 (t, 1H), 4.71 (q, 1H), 4.38 (d, 2H, $J = 6$ Hz), 3.70 (s, 3H), 3.59 (bs, 2H), 3.10 (m, 2H), 2.76−2.91 (m, 2H), 2.50−2.61 (m, 4H), 1.99−2.13 (m, 4H), 1.63 (s, 3H), 1.62 (s, 3H) ^{13}C NMR ($CDCl_3$, 50 MHz): 172.23, 171.94, 171.46, 148.63, 139.77, 138.41, 132.84, 129.42, 129.34, 129.19, 128.94, 128.87, 128.08, 127.93, 127.73, 125.74, 120.08, 117.411, 113.10, 52.82, 52.09, 51.963, 43.85, 39.45, 33.50, 31.71, 31.66, 30.12, 26.25, 16.28, 14.95 MS: (ESI, +) ($M - H^+$) 552.

Farnesyl Benzylamine. 2-(3-Benzylcarbamoyl-propionylamino)-3-(3,7,11-trimethyl-dodeca-2,6,10-trienylsulfanyl)propionic Acid Methyl Ester (10b). Phthalimide **10b** (47 mg, 0.08 mmol) provided 42 mg (67%) of amide **11b** as a white solid. Purification by column chromatography (4:6) hexane:EtOAc. ^{1}H NMR ($CDCl_3$, 400 MHz) 7.25−7.34 (m, 5H), 6.623 (d, 1H), 6.28 (t, 1H), 5.20 (t, 1H), 5.09 (t, 2H), 4.75 (q, 1H), 4.44 (d, 2H), 3.75 (s, 3H), 3.09−3.22 (m, 2H), 2.81−2.96 (m, 2H), 2.55−2.67 (m, 4H), 1.96−2.13 (m, 8H), 1.68 (s, 3H), 1.67 (s, 3H), 1.60 (s, 6H); ^{13}C NMR ($CDCl_3$, 50 MHz): 172.21,

171.94, 171.47, 140.29, 138.44, 135.60, 131.54, 128.87, 127.94, 127.64, 124.53, 123.93, 119.72, 52.79, 52.07, 43.89, 39.92, 39.84, 33.47, 31.77, 31.73, 30.12, 26.95, 26.66, 25.91, 17.90, 16.36, 16.23; MS: (ESI, +) ($M - H^+$) 529.

General Conditions for Protein Coupling (11a,b and 12a,b). Phthalimido esters (**9a**,**b**) were dissolved in 6 mL of 1:5 acetonitrile and 5% $NaHCO_3$ in a 100 mL pear-shaped flask. BSA (**12**) (0.1 mL of 10 mg/mL solution in phosphate buffered saline (PBS) pH 7.2) or KLH protein (**11**) (3 mL of 10 mg/mL solution in PBS pH 7.2) was added and stirred vigorously for 2 h or until analysis by TLC in 1:1 hexane:EtOAc showed no residual activated phthalimide ester spot. The solution was dialyzed overnight in 20% DMSO, PBS pH 7.5 then PBS (3 × 1L, 6 h each).

Antibody Generation. Hapten protein conjugates **11a** and **11b** were used to immunize rabbits subcutaneously by emulsifying 1.5 mg of each conjugate with Freund's complete adjuvant. This was followed by six secondary boosters of the same dose with incomplete Freund adjuvant at intervals of 14 days. The rabbits were bled 10 days after each boost. Blood was allowed to coagulate overnight in 50 mL centrifuge tubes, and sera was collected and stored at 0 °C.

ELISA Screening. ELISA plates (96-well polystyrene) were coated with 100 μL per well of BSA conjugates or BSA (1 μg/mL) in PBS (pH = 7.6) and incubated for 1 h at 37 °C. The plates were then washed thoroughly with 10% Tween in PBS buffer (PT) (pH = 7.4). One hundred fifty microliters of serum diluted 1:100 in PT buffer containing casein (PCT) was added and diluted 1:3 down the plate, then incubated 1 h at 37 °C. The plates were washed with PT buffer, and 100 μL of secondary antibody (1:10 000) was added to each well. The plates were incubated 1 h at 37 °C and again washed. One hundred microliters of *p*-nitrophenyl phosphate was added to each well (2 pills in 10 mL of Tris buffer pH = 9.5). After 20 min, color began to develop and absorbance was read at 405 nm.

FTase Protein Substrate Modification. Two micrograms of recombinant bacterially expressed RDJ2 (*40*) was incubated with 20 μM AGPP **5b** or FPP **1b** and 5 μg of FTase in 50 μL of Tris-HCl buffer (pH = 7.4) The reactions were incubated for 30 min at 37 °C and then boiled with SDS, and PAGE was performed using the protein concentrations indicated on the blots.

Cell Culture and Transient Transfection of GST-Tagged Q61LH-Ras. HEK-293 cells were routinely subcultured twice weekly at a split ratio of 1:4 in DMEM containing 5% FBS to maintain exponential growth. Cells used for experiments were of passage number 0−20. HEK cells were seeded 24 h prior to transfection at 60−70% confluency onto poly-L-lysine-coated plates. Monolayers of HEK cells were transiently transfected with 2 μg of pEBG-H-Ras-Q61L or pEBG alone (*41*) in a 35 mm dish using the calcium phosphate precipitation method as previously described (*42*) The cells were harvested at 48 h, washed with 2 × 10 mL of PBS, lysed by sonication, and frozen at −70 °C.

AGOH Labeling and FTI Inhibition of Label in HEK-293 Cells. Plates were coated with poly-L-lysine and seeded with HEK cells in Dulbecco's modified Eagle's medium with 5% fetal bovine serum. Cells were incubated in medium containing 30 μM lovostatin and 10 μM GGOH for 24 h. The media were poured off then replenished with media without lovostatin and GGOH and were treated with 3 μM FTI-277 (calbiochem), 20 μM GGTI-2147 (calbiochem), or no inhibitor and incubated at 37 °C for 1 h. DMSO as a vehicle, or 100 μM AGOH **5a** was then added and incubated at 37 °C for 2 h. Medium was then removed, and cells were extracted into 300 μL of PBS-containing protease inhibitor cocktail set 1 (Calbiochem). The samples were sonicated and centrifuged for 5 min. The supernatant was removed and used for western blotting.

AGOH Incorporation into Unblocked Cells. Plates were coated with poly-L-lysine and seeded with HEK cells in Dulbecco's modified Eagle's medium with 5% fetal bovine serum. The cells were then treated with DMSO as a vehicle, or 30 μM AGOH **5a** was then added and incubated at 37 °C for the indicated time points. Medium was then removed, and cells were extracted into 300 μL of PBS-containing protease inhibitor cocktail set 1 (Calbiochem). The samples were sonicated and centrifuged for 5 min. The supernatant was removed and used for western blotting.

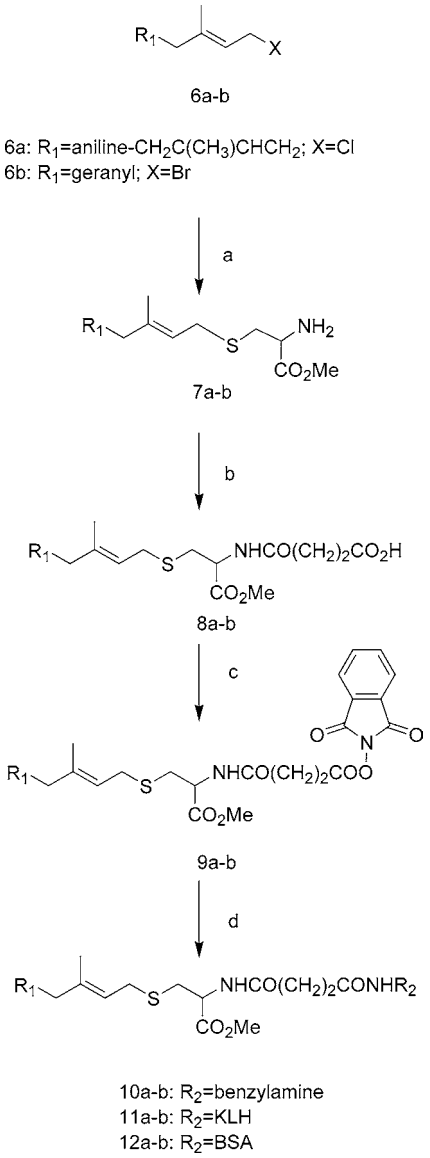
Western Blot Analysis. Cells were harvested by scraping into 300 μL of phosphate-buffered saline containing protease inhibitor cocktail set 1 (Calbiochem), followed by sonication on ice. Protein concentration was determined using a Bradford reagent kit (Pierce). The proteins from the FTase reaction mixtures or cell lysates were then separated using 12% SDS-polyacrylamide gels followed by transfer to nitrocellulose membranes. The membranes were incubated in blocking buffer PCT (see ELISA) for 1 h at room temperature, after which the following sequential steps were used: incubation with polyAG-Ab 1:1000 to 1:10 000 in PCT for 1 h; 3 × 15 min washes with vigorous shaking in PT buffer (see ELISA); incubation at room-temperature 1 h with goat anti-rabbit horseradish peroxidase-conjugated secondary antibody (Zymed) at a dilution of 1:20 000 in PCT buffer; four 15 min washes with PT buffer. The membranes were then subjected to enhanced chemiluminescence detection by incubation in 20 mL of detection buffer (Pierce Super Signal) for 1 min.

RESULTS

Synthesis of Analogue-Modified Antigen. The preparation of the prenyl analogue carrier protein conjugates **11a**,**b** and **12a**,**b** is outlined in Scheme 1. The haptens were designed to mimic the C-terminal peptide of a fully processed prenylated protein that had undergone both endoproteolysis and C-terminal methylation. Thioether **7a** was obtained in 60−74% yield by addition of a solution of L-cysteine methyl ester HCl in NH_3/MeOH to the previously described chloride **6a** (*39*) The farnesyl thioether **6b** was prepared by addition of farnesyl bromide **6b** to L-cysteine methyl ester HCl in NH_3/MeOH. Condensation of amines **7a**,**b** with succinic anhydride in THF:CH_2Cl_2 afforded succinates **8a**,**b** in 57%-85% yield after chromatography (*43*) Activated esters **9a**,**b** were prepared from carboxylates **8a**,**b** in 58%-85% yield by reaction with CDI followed by condensation with *N*-OH phthalimide (*44*) The *N*-hysdroxysuccimidyl (NHS) ester of a similar farnesyl hapten is reported to undergo an undesired intramolecular cyclization to an unreactive succinimide (*30*). In contrast to the NHS ester, phthalimdies **9a**,**b** were stable and showed no evidence of intramolecular cyclization. The suitability of phthalimdies **9a**,**b** to form conjugates with carrier protein was modeled under conditions typical for coupling activated esters to lysine residues. Condensation of benzylamine with phthalimdies **9a**,**b** in 1:5 acetonitrile:5% $NaHCO_3$ gave model amides **10a**,**b** in 51%-76% yield.

With activated haptens in hand, we proceeded to generate anilinogeranyl and farnesyl immunoconjugates.

Scheme 1. Synthesis of Analogue-Modified Haptens[a]



[a] Reagents: (a) Cysteine methyl ester HCl, NH_3/MeOH, 0 °C. (b) Succinic anhydride, THF/CH_2Cl_2. (c) *N*-Hydroxyphthalimide, CDI, MeCN. (d) R^2, $NaHCO_3$(aq)/MeCN.

Phthalimides **9a**,**b** were reacted with carrier proteins KLH and BSA to provide hapten conjugated proteins **11a**,**b** (AG-KLH and F-KLH) and **12a**,**b** (AG-BSA and F-BSA). BSA has approximately 32 reactive lysine residues and the extent of covalent modification of immunoconjugates **12a**,**b** was quantified by measuring the remaining free amino groups relative to unmodified BSA. BSA, and each of the BSA conjugates **12a**,**b** was reacted with trinitrobenzene sulfonate, and the ratio of free amines in unmodified BSA to modified BSA was determined by UV absorbance at 335 nm (*45*). We found that 50% of the lysine residues in immunoconjugates **12a**,**b** were modified by the activated esters **9a**,**b**. As KLH is a heterogeneous protein, similar assays to quantify the coupling efficiency were not performed. By analogy with the BSA results, we assumed a similar coupling efficiency for the KLH bioconjugates.

Generation of Anti-anilinogeranyl Antibodies. Polyclonal antibodies to the anilinogeranyl modification were prepared by immunizing rabbits with AG-KLH (**11a**). In our hands, F-KLH (**11b)** elicited no immunogenic response. This is in agreement with previous reports in which attempts to prepare anti-farnesyl antibodies have resulted in weakly binding reagents that recognize both farnesyl and geranylgeranyl isoprenoid lipids (*30*−*32*). Due to the poor immune response to the F-KLH protein (**11b**), we abandoned attempts to prepare an anti-farnesyl antibody. Polyclonal immune sera collected from the rabbits were screened using an enzyme linked immunosorbent assay (ELISA). No ELISA response was detected to unmodified BSA or AG-BSA (**12a)** in preimmune sera. Gratifyingly, sera antibodies raised against AG-KLH **11a** (polyAG-Ab) were able to bind to AG-BSA (**12a)** (Figure 2).

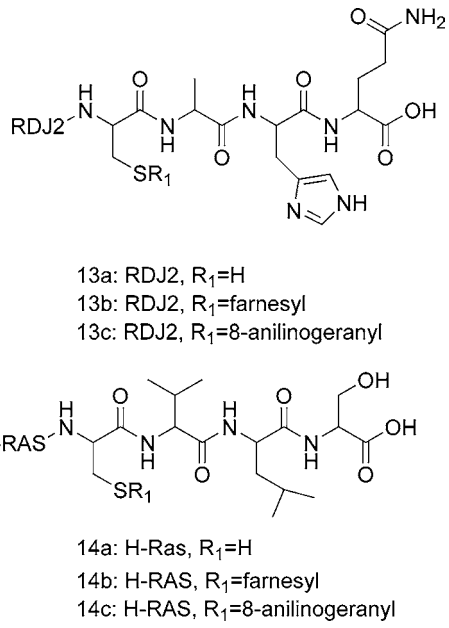


Figure 2. Ca_1a_2X modification.

Specificity and Analysis of Anti-anilinogeranyl Antibodies. The antibodies generated in this study were directed to proteins modified with cysteine methyl ester analogues of FPP. However, the actual antigen that is presented to the immune system is unknown, as the ester may be hydrolyzed by enzymes in the whole animal. Additionally, it is possible that in vivo incorporation of unnatural analogues into proteins will alter the normal Ca_1a_2X endoproteolysis and C-terminal methylation steps. The utility of the polyclonal anilinogeranyl antibodies might well be limited if they only recognized the cysteine methyl ester form of modified proteins. Therefore, it was essential to test the ability of these antibodies to recognize proteins modified by FTase with the anilinogeranyl moiety without subsequent endoproteolysis and C-terminal methylation. Bacterially expressed DNAJ-like RDJ2 (*40*) and Q61L oncogenic H-Ras proteins contain the unfarnesylated and unprocessed CAHQ and CVLS Ca_1a_2X motifs, respectively. FTase catalyzed in vitro modification of these proteins with FPP **1b** and AGPP **5b** provided lipid thioether linked proteins with intact Ca_1a_2X motifs **13a**−**c** and **14a**−**c** (Figure 2). These reaction mixtures were then analyzed by western blot with polyAG-Ab sera. Figure 3 shows that the polyAG-Ab was able to bind to AG-BSA **12a** derivatized by the methyl ester hapten as well as the AG-RDJ2 **13c** but showed no reactivity to the unmodified RDJ2 **13a**. Identical results were found when AG-Ras **14c** was examined (data not shown). Additionally, the antibodies were also unreactive toward farnesylated F-RDJ2 (**13b**) and F-Ras (**14b**) (data not shown).

FTase Dependent Anilinogeraniol Incorporation into Cellular Proteins. Farnesol **1a**, geranylgeraniol

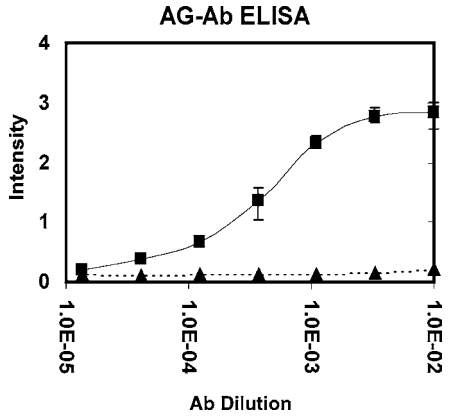

Figure 3. polyAG-Ab ELISA response to AG-BSA **11a** (squares), and unmodified BSA (triangles) (0.1 μg/well).

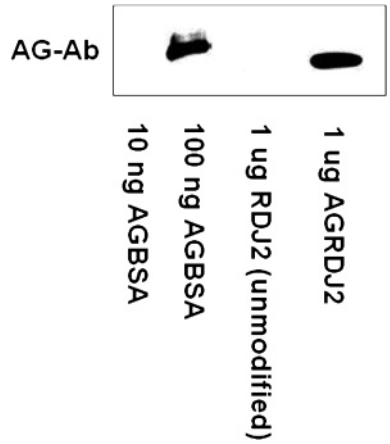

Figure 4. Western Blot analysis of anilinogeranyl modified RDJ2 and BSA proteins. RDJ2 proteins were modified in vitro with AGPP **5b** (AGRDJ2; lane 4). Standard chemically modified BSA proteins (AG-BSA **11a**; lanes 1 and 2) and unmodified RDJ2 proteins (AGPP lane 3 analyzed as negative control.)

2a, and a number of farnesol analogues become incorporated into cellular proteins when added to the culture media of growing cells (*27*, *28*, *46*, *47*). These compounds are thought to traverse the plasma membrane and act as a substrate for sequential kinase reactions to give FPP **1b**, GGPP **2b**, or the diphosphate analogue which can then be utilized by FTase or GGTaseI to appropriately modify cellular proteins (*46*, *48*). The kinases involved in the phosphorylation reactions have been characterized in plants but not in mammalian cells. In vitro, both FPP **1b** and AGPP **5b** are transferable by FTase to a CVLS substrate with similar k_{cat} and K_m values (*49*). Therefore, we speculated that anilinogeraniol might also cross the plasma membrane of cells, be converted to the diphosphate **5b**, and become incorporated into proteins by FTase. However, it was also possible that anilinogeraniol **5a** might be toxic to mammalian cells. Accordingly, the acute cytoxicity of anilinogeraniol **5a** was examined by incubating human embryonic kidney (HEK-293) cells with up to 100 μM anilinogeraniol **5a** for 3 days. Somewhat surprisingly, we found that cells treated with anilinogeraniol showed no morphological changes and no decrease in cell growth relative to controls at any of the concentrations tested (data not shown).

The polyAG-Ab's were used to probe extracts of HEK-293 cells incubated in the presence of AGOH **5a** to determine if the anilinogeranyl group was incorporated into cellular proteins. These cells were initially blocked with lovostatin an upstream inhibitor of endogenous FPP and GGPP formation and treated with GGOH for the geranylgeranylation of proteins critical to cell survival (*50*). Figure 5a shows that there are numerous anilinogeranyl modified proteins in cells treated with AGOH **5a**, while no proteins were detected in the absence of the unnatural FPP analogue. To determine whether the protein modification was FTase dependent, cells were incubated in the presence of AGOH **5a** and either the farnesyl transferase inhibitor FTI-277 (*51*) or the geranylgeranyl transferase I inhibitor GGTI-2147 (*52*). Lane 3 of Figure 4 shows that no anilinogeranyl modified proteins were detected in the presence of the FTI. However, in the presence of the geranylgeranyl transferase I inhibitor, the pattern of proteins modified with anilinogeranyl moiety was very similar to that without any inhibitor present. Interestingly, some additional, lower molecular weight polyAG-Ab reactive bands appear when GGTaseI is inhibited. FTase-catalyzed transfer of the anilinogeranyl lipid to protein is the most consistent explanation for these observations. These results also suggest that FTase may be able to utilize AGPP to modify some normally geranylgeranylated proteins when GGTaseI is inhibited. This is not unreasonable, as the normally farnesylated K-Ras4B becomes geranylgeranylated in the presence FTIs (*53*, *54*).

The AGOH analogue must undergo diphosphorylation to be incorporated into cellular proteins. This diphosphorylation may not be on a time-scale that allows competitive modification of proteins in the presence of FPP. Cells were incubated without a lovastatin blockade on endogenous FPP formation with 30 μM AGOH and sampled every few hours. Figure 5b shows that anilinogeranyl incorporation into proteins begins within 2 h of incubation with AGOH and is therefore competitive with the endogenous pools of FPP. Importantly, these experiments demonstrate that intracellular concentrations of AGPP **5b** can be achieved that are high enough to compete with the endogenous pool of FPP **1b** for FTase dependent transfer to proteins.

Figure 4 shows that a number of proteins with molecular weights ranging from 30 to 70 kDa are modified with the anilinogeranyl moiety. However, protein bands for Ras and other normally farnesylated small molecular weight GTPases in the 19−27 kDa range are conspicuously absent. Previous reports have shown that the majority of small molecular weight GTPases are normally geranylgeranylated and that the farnesylated small molecular weight GTPases are present in relatively low abundance (*27*). Consequently, the farnesylated small molecular weight GTPases are difficult to detect, and only faint bands corresponding to these molecules are found when tritium labeled farnesol **1a** is incubated with glioma cells (C6) or green monkey kidney cells (CV-1) (*46*). Determination of Ras prenylation status is an important assay in the evaluation of FTI efficacy and is most often carried out by metabolic labeling with ^{3}H-mevalonate (*25*). We probed extracts of cells overexpressing a GST-Ras fusion protein grown in the presence of AGOH with the polyAG-Ab to overcome the low natural levels of endogenous Ras. HEK-293 cells were transiently transfected with a vector expressing glutathione S-transferase (GST) tagged wild-type H-Ras. The cells were then incubated with AGOH **5a**, lysed, analyzed by SDS−PAGE, and probed with primary antibodies to the GST-tag and to the polyAG-Ab modification. Figure 6 shows a representative blot in which anilinogeranyl group is incorporated into the GST-tagged Ras protein and other higher molecular weight proteins. These results suggest that anilinogeranyl modified Ras is present in cells not

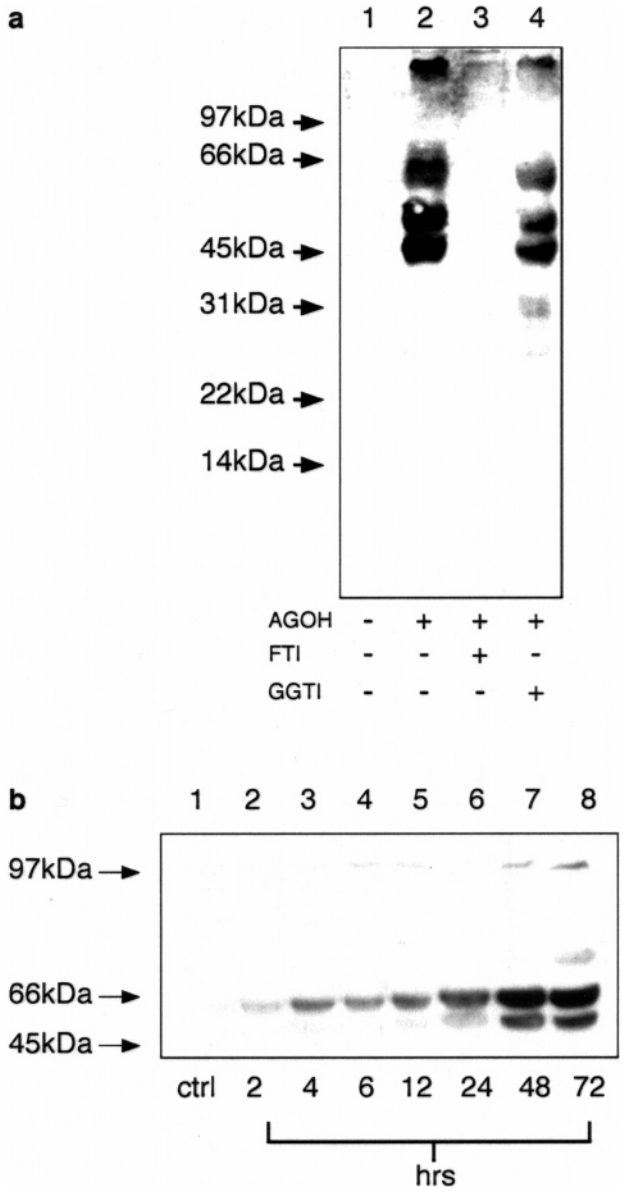

Figure 5. (a) Incorporation and detection of anilinogeranyl modified endogenous proteins. HEK-293 cells were incubated with 30 μM lovostatin and 10 μM GGOH for 1 day, and then media was poured off and the cells were incubated with or without 100 μM AGOH **3a** (lanes 1 and 2), in the presence and absence of an FTI or a GGTI (lanes 2−4). The cells were then analyzed by western blot with the AG-Ab sera. (b) Cells with no lovostatin blockade were incubated with 30 μM AGOH for the given time points then were harvested and lysed. Fifty micrograms of total protein was loaded onto an SDS−PAGE gel, transferred to nitrocellulose, and immunodetected using the polyAG-Ab.

overexpressing GST-Ras at concentrations below the level of detection possible with this antibody.

DISCUSSION

This report outlines a general strategy for detecting prenylated proteins using antibodies directed toward unnatural analogues of FPP **1b** bearing unique epitopes that can be transferred to proteins by FTase. We have found that the farnesol **1a** analogue AGOH **5a** can be utilized by a cell to modify proteins in an FTase dependent manner and is not particularly toxic. The structure of the anilinogeranyl moiety is also dissimilar to any other known cellular components or protein modifications making it an excellent epitope for selective antibody recognition. In this report we show that the AGPP prodrug anilinogeraniol is incorporated into cellular protein in the presence of the endogenous FPP pool. Previous reports of FPP analogue incorporation into cellular proteins have required lovastatin to block endogenous FPP formation in order to detect modified proteins. These reagents may be useful for the analysis of FTase-mediated protein modification and cellular events further downstream. The lack of acute cellular toxicity of AGOH **5a** may allow for long-term analysis of proteins modified by FTase by immunohistochemical methods. These antibodies could be especially useful for screening the activity and protein targeting of farnesyl transferase inhibitors helping to identify the targets of these reagents to better understand the role of farnesylated proteins in cancer biology.

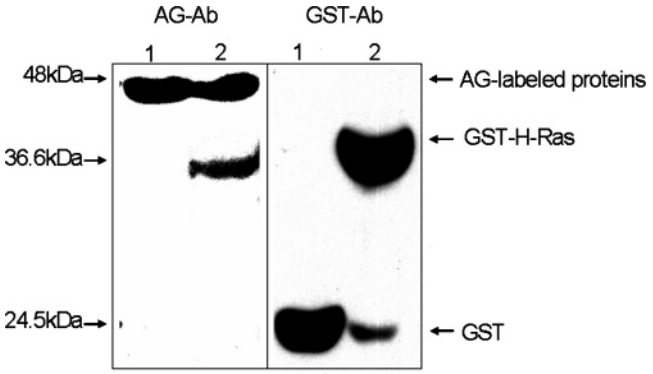

Figure 6. Incorporation into cells overexpresssing Ras. HEK-293 cells overexpressing GST-labeled Ras were incubated in medium containing 30 μM lovostatin and 10 μM GGOH overnight and then were treated with 100 μM AGOH **3a** in medium without the lovostatin blockade. The cells were lysed, run on an SDS−PAGE gel, and analyzed by western blot. Blots were probed with an anti-GST antibody (GST-Ab) or AG-Ab sera (AG-Ab). Lane 1 contains control cells without Ras overexpression, and lane 2 contains cells overexpressing GST-Ras. All cells were labeled with AGOH.

ACKNOWLEDGMENT

This work was supported in part by the Kentucky Lung Cancer Research Program (to H.P.S. and D.A.A.) and the National Institutes of Health (GM66152-01 to H.P.S.), and the NMR instruments used in this work were obtained with support from NSF CRIF Grant No. CHE-9974810. We thank Dr. Sidney W. Whiteheart, Todd Schraw, and Garland Crawford for help with rabbit immunization and bleeding. We thank Gamma One Laboratories, Inc., for monoclonal antibody preparations. We thank Dr. Carol Fierke, Heather Hartman, Katherine Hicks, and Jennifer Pickett for the gift of mammalian protein farnesyl transferase.

Supporting Information Available: ^{1}H and ^{13}C NMR and MS spectra of all new small molecules synthesized. This material is available free of charge via the Internet at http://pubs.acs.org/BC

Sulfhydryl-Selective, Covalent Labeling of Biomolecules with Transition Metallocarbonyl Complexes. Synthesis of (η^5-C_5H_5)M(CO)$_3$(η^1-*N*-Maleimidato) (M = Mo, W), X-ray Structure, and Reactivity Studies

Bogna Rudolf,[†] Marcin Palusiak,[‡] Janusz Zakrzewski,*[,†] Michèle Salmain,*[,§] and Gérard Jaouen[§]

Department of Organic Chemistry, University of Lodz, 90-136 Lodz, Narutowicza 68, Poland, Department of Crystallography, University of Lodz, 90−236 Lodz, Pomorska 149/153, Poland, and Ecole Nationale Supérieure de Chimie de Paris, Laboratoire de Chimie et Biochimie des Complexes Moléculaires (UMR CNRS 7576), 11 rue Pierre et Marie Curie 75231 Paris Cedex 05, France. Received March 11, 2005;
Revised Manuscript Received July 25, 2005

The photochemical reaction of (η^5-C_5H_5)Mo(CO)$_3$I with maleimide in the presence of diisopropylamine yielded complex (η^5-C_5H_5)Mo(CO)$_3$(η^1-*N*-maleimidato) **4** in 52% yield. The single-crystal X-ray structure of this complex was determined and shows unusual interactions between oxygen atoms of the maleimidato ligand and carbon atoms of the *cis*-C≡O ligands. The tungsten analogue of **4**, (η^5-C_5H_5)W(CO)$_3$(η^1-*N*-maleimidato) **5**, was synthesized in 37% yield by the reaction of (η^5-C_5H_5)W(CO)$_3$I with the thallium(I) salt of maleimide. Complexes **4** and **5** reacted with cysteine ethyl ester and glutathione to afford products of the addition of the sulfhydryl group to the ethylenic bond of the maleimidato ligand. The reaction of **4** and **5** with glutathione proceeded faster than the reaction of the analogous complex (η^5-C_5H_5)Fe(CO)$_2$(η^1-*N*-maleimidato) (**3**). However, all these complexes react with glutathione more slowly than *N*-ethylmaleimide. Complexes **4** and **5** were used for labeling of bovine serum albumin (BSA), enriched in thiol groups by reaction with Traut's reagent. Reaction of thiolated BSA containing 7.4 SH groups with **4** and **5** gave bioconjugates bearing 6.9 and 6.4 metallocarbonyl moieties, respectively. Under the same conditions, reaction with **3** afforded a BSA conjugate containing 7.6 metallocarbonyl moieties. Labeling was presumed to be site-specific, as the number of metallocarbonyl entities matched very well with the initial number of SH groups measured for the thiolated BSA sample. IR spectra of BSA labeled with **4** and **5** show intense $\nu_{(C\equiv O)}$ bands (2042 and 1948 cm^{-1} in the latter case), enabling sensitive detection of the bioconjugates in biological samples. Complexes **4** and **5** (especially the latter) should be of interest as heavy atom phasing reagents for protein X-ray crystallography.

INTRODUCTION

Side-chain selective, covalent labeling of biomolecules such as proteins with transition organometallic complexes endows the resulting bioconjugates with unusual redox properties (*1*), IR absorption (*2*) or luminescence features (*3*) enabling their sensitive detection in biological samples. In the particular case where the transition metal belongs to the second or third row, thus exhibiting high electron density, such a labeling may also be helpful in overcoming "the phase problem", one of the bottlenecks of X-ray protein crystallography (*4*).

The thiol group of free cysteine residues side-chain is the most reactive protein function because of its high nucleophilicity and as such an interesting target to introduce transition organometallic complexes into proteins. Maleimido compounds are often used to selectively alkylate thiols (*5*) but are seldom encountered in the transition organometallic series. For instance, a tetrairidium cluster carrying a single maleimido group was synthesized (*6*) and used to introduce heavy atoms into ribososomal particles for X-ray crystallographic studies (*7*). A related tetrairidium cluster was used for cryoelectron microscopy studies of the hepatitis B virus capsid (*8*). The ferrocenyl maleimides **1a** and **1b** were prepared and successfully used to attach a redox active ferrocenyl entity to genetically engineered cytochrome P_{450cam} (*9*) and β-lactamase (*10*). The cationic rhenium(I) polypyridine tricarbonyl maleimide complex **2** was used to attach strongly luminescent groups to several polypeptides and oligonucleotides (*2c*).

A few years ago we described the synthesis of the iron(II) dicarbonyl maleimide complex **3** (*11*). This compound was initially designed to introduce IR-detectable (η^5-C_5H_5)Fe(CO)$_2$ (Fp) moieties into thiol-containing biomolecules, such as the protein bovine serum albumin (BSA) (*12*) and the tripeptide glutathione (*13*) More recently, we were also able to label PAMAM generation 4 dendrimer by alkylation of its terminal free amino groups by complex **3** (*14*). The Fp moiety, as all the metallocarbonyl complexes, gives rise to very strong IR absorption bands, $\nu_{C\equiv O}$, appearing in the 1850−2100 cm^{-1} spectral

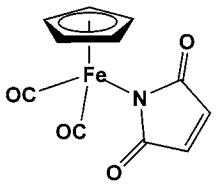
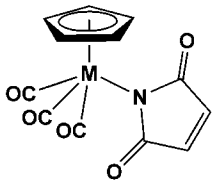
2



3



4 M = Mo
5 M = W

Herein we describe the synthesis of the molybdenum(II) and tungsten(II) cyclopentadienyl tricarbonyl complexes **4** and **5**, respectively, both containing the η^1-*N*-maleimidato ligand, along with reactivity studies toward cysteine ethyl ester, the cysteine-containing tripeptide glutathione, and a model protein, thiolated BSA. These two new metallocarbonyl maleimides are of interest as protein labeling reagents since they combine two features: an easy and sensitive IR detection of the organometallic probe with a possibility of application in protein X-ray crystallography (especially complex **5**).

EXPERIMENTAL SECTION

All syntheses were carried out under argon. Solvents were dried by using standard procedures. Compounds (η^5-C_5H_5)M(CO)$_3$I (M = Mo, W) were prepared by reaction of [(η^5-C_5H_5) M(CO)$_3$]$_2$ with iodine (*15*). Compound **3** was prepared according to an earlier published procedure (*11*). All other reagents are commercially available and were used as received. Chromatographic separations were carried out on silica gel 60 (Merck, 230−400 mesh ASTM). Phosphate-buffered saline (PBS) pH 7.4 was prepared by dissolving 8 g NaCl, 0.2 g KCl, 1.42 g $Na_2HPO_4 \cdot 2H_2O$, and 0.34 g KH_2PO_4 in 1 L of double-distilled grade water. Borate buffer pH 8.0 was prepared by dissolving 0.87 g B(OH)$_3$ and 0.57 g $Na_2B_4O_7 \cdot 10\ H_2O$ in 0.1 L of double-distilled grade water. ^{1}H NMR spectra were recorded on a Varian Gemini 200 BB (200 MHz) and a Bruker DRX 500 (500 MHz) spectrometers and were referenced to internal TMS. Reverse-phase HPLC analysis of glutathione conjugates was performed on a System Gold (Beckman Coulter) equipped with a 4.6 × 250 mm, 5 μm Si-C8 column (Kromasil, Eka Nobel). Compounds were eluted by applying 5 min after the injection a linear gradient from 10 to 100% of MeCN-0.1% TFA in water − 0.1% TFA in 20 min.

(η^5-C_5H_5)Mo(CO)$_3$ (η^1-*N*-Maleimidato) (4). A stirred, water-ice cooled, and argon-saturated solution of (η^5-C_5H_5)Mo(CO)$_3$I (244 mg, 0.67 mmol) and maleimide (58 mg, 0.6 mmol) in toluene (20 mL) containing diisopropylamine (1 mL) was illuminated with visible light (4 × 100 W tungsten lamps) for 2 h. The initial dark red color of the solution turned orange-yellow upon illumination. The grayish solid formed was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The residue was dissolved in chloroform and purified by column chromatography. A deep red band containing a small amount of the starting molybdenum complex was eluted with chloroform, followed by an orange band of **4** eluted with chloroform−methanol 3:1. The product was crystallized from chloroform−heptane. X-ray grade crystals were obtained from layered dichloromethane−hexane. Yield 106 mg (52%). ^{1}H NMR (δ, ppm): 6.70 (s, 2H, olefinic H's), 5.53 (s, 5H, Cp). IR (cm^{-1}): 2054, 1977 (C≡O), 1659 (CO imide). Anal. ($C_{12}H_7MoNO_5$) C, H, N.

(η^5-C_5H_5)W(CO)$_3$ (η^1-*N*-Maleimidato) (5). The thallium(I) salt of maleimide was prepared by treatment of a solution of maleimide (152 mg, 1.56 mmol) in ethanol (3.5 mL) with thallium(I) ethoxide (120 μL, 1.56 mmol). After 20 min stirring, the yellow solid formed was filtered off, washed with ethanol, and dried under vacuum. Then it was dissolved in DMF (6 mL), (η^5-C_5H_5)W(CO)$_3$I (162 mg, 0.35 mmol) was added, and the resulting solution was heated, with stirring, to 50 °C for 2 h. The solid formed was filtered off and the filtrate evaporated to dryness. The residue was dissolved in chloroform, washed five times with water, and dried (Na_2SO_4). Evaporation to dryness and flash chromatography recovered a small amount of (η^5-C_5H_5)W(CO)$_3$I (red band eluted with dichloromethane), followed by **5** (orange band eluted with dichloromethane−methanol 3:1). An analytical sample of **5** was prepared by recrystallization from dichloromethane−hexane. Yield 55 mg (37%). ^{1}H NMR (δ, ppm): 6.72 (s, 2H, olefinic H's), 5.64 (s, 5H, Cp). IR (cm^{-1}): 2046, 1957 (C≡O), 1664 (CO imide). Anal. ($C_{12}H_7NO_5W$) C, H, N.

Reaction of 4 and 5 with L-Cysteine Ethyl Ester. A solution of L-cysteine ethyl ester hydrochloride (28 mg, 0.15 mmol) and **4** or **5** (0.13 mmol) in methanol (5 mL) containing triethylamine (0.3 mL) was stirred at. r.t. for 2 h and evaporated to dryness. The residue, dissolved in chloroform, was chromatographed on SiO_2. First, small amounts of unreacted **4** or **5** were eluted with chloroform and then the products **6** or **7** were eluted with chloroform−methanol (95:5).

6: (orange oil). Yield 55 mg (87%). ^{1}H NMR (δ, ppm): 5.52 (s, 5H), 4.20 (q, J = 7.2 Hz, 2H), 3.80 (m, 2H), 2.8−3.4 (m, 3H), 2.47 (dd, J = 18.1 Hz, 3.8 Hz, 1H), 1.81 (bs, 2H) 1.288 and 1.284 (two triplets, J = 7.2 Hz, 3H). IR: (cm^{-1}) 2054, 1977, 1728, 1649. Anal. ($C_{17}H_{18}\ MoN_2O_7S$) C, H, N.

7: (orange oil). Yield 68 mg (91%). ^{1}H NMR (δ, ppm): 5.63 (s, 5H), 4.20 (q, J = 7.2 Hz, 2H), 3.65 (m, 2H), 2.8−3.4 (m, 3H), 2.49 (dd, J = 18.0 Hz, 3.8 Hz, 1H), 1.81 (bs, 2H) 1.29 (t, J = 7.2 Hz, 3H). IR: (cm^{-1}) 2046, 1959, 1732, 1655. Anal. ($C_{17}H_{18}\ N_2O_7SW$) C, H, N.

Kinetics Studies. Solutions (1 mL) containing compounds **4** or **5** (1×10^{-4} M) and glutathione (1×10^{-4} M) were prepared in PBS, and the reactions were monitored at 285 nm at room temperature. Second-order rate constants k and half-lives were calculated from the equation $(A_\infty - A_0)/(A_\infty - A) = kct + 1$ where A_0 is the absorbance at t = 0, A_∞ is the final absorbance, and c the initial concentration of reagents (i.e. 1×10^{-4} M).

Thiolation of BSA with Traut's Reagent. A mixture of BSA (5×10^{-5} M) and Traut's reagent (1×10^{-3} M) in borate buffer containing 10 mM EDTA was incubated for 1 h at 26 °C (sample volume = 3 mL). The solution was applied to a prepacked 10 mL gel desalting column

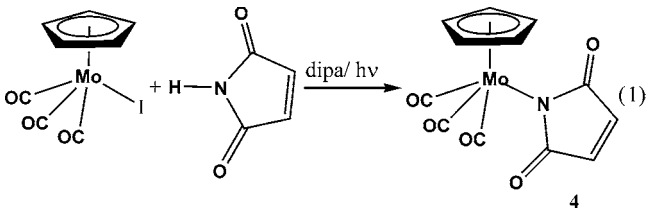
(Pierce Chemicals), and species were eluted with PBS containing 1 mM EDTA. The fractions containing the protein were pooled and the concentration of sulfhydryl groups was immediately determined by the Ellman's assay (*16*) whereas the BSA concentration was determined by optical density measurement at 280 nm taking an extinction coefficient ϵ of 43 600 M^{-1} cm^{-1} (*17*).

Labeling of Thiolated BSA with 3, 4, or 5. Mixtures of freshly prepared thiolated BSA (2.1×10^{-5} M) and **3**, **4**, or **5** (2.86×10^{-4} M) were incubated in PBS containing 1 mM EDTA for 24 h at 26 °C (sample volume = 1 mL). Solutions were applied to a 5 mL prepacked gel desalting column (Pierce Chemicals) and species eluted with PBS. Fifteen 0.5 mL fractions were collected, and those containing the protein were pooled and submitted to UV-visible analysis. The concentration of molybdenum and tungsten tricarbonyl succinimidato moieties was calculated from the optical density of the corresponding sample at 438 nm, taking ϵ equal to 460 M^{-1}·cm^{-1} for Mo or 710 M^{-1}·cm^{-1} for W. The concentration of iron dicarbonyl succinimidato moieties was calculated from the optical density of the corresponding sample at 365 nm, taking ϵ equal to 600 M^{-1}·cm^{-1}. The concentration of BSA was calculated from the optical density of the solutions at 280 nm after subtraction of the contribution of the metallocarbonyl succinimidato entities at this wavelength (ϵ(Mo-succinimidato) = 2960 M^{-1}·cm^{-1}; ϵ(W-succinimidato) = 3500 M^{-1}·cm^{-1}; ϵ(Fe-succinimidato) = 2400 M^{-1}·cm^{-1}).

RESULTS AND DISCUSSION

Synthesis of 4 and 5. The iron complex **3** had been prepared by the photochemical reaction of (η^5-C_5H_5) Fe($CO)_2$I with maleimide in the presence of diisopropylamine (dipa) (*11*). Considering the close analogy in the photochemical behavior of (η^5-C_5H_5) Fe($CO)_2$I and (η^5-C_5H_5)M($CO)_3$I (M = Mo, W) (*18*), we thought at first that it would be possible to apply the same approach for the synthesis of **4** and **5**.

We found unexpectedly that only (η^5-C_5H_5)Mo($CO)_3$I underwent photochemical substitution of iodide by the anion of maleimide upon illumination with visible light with maleimide and dipa in benzene (eq 1). Product **4** was isolated in 52% yield and characterized by spectroscopic methods, elemental analysis, and X-ray diffraction (vide infra).

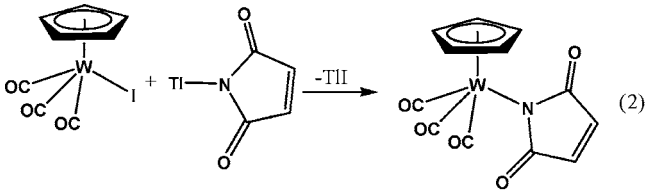


(1)

4

Attempts to prepare **5** in the same way starting from (η^5-C_5H_5)W($CO)_3$I failed. This complex proved completely inert when irradiated with visible light in benzene containing maleimide and dipa. A significantly lower photochemical reactivity of (η^5-C_5H_5)W($CO)_3$I in comparison to its molybdenum analogue had been previously reported and attributed to shorter lifetimes of the chemically reactive excited states, due to enhanced spin−orbit coupling facilitating physical deactivation pathways (*18c*).

We thus prepared **5** by reaction of (η^5-C_5H_5)W($CO)_3$I with the thallium salt of maleimide (eq 2). (A similar method was used earlier to prepare the $Mn(CO)_5$ complex of the succinimide anion (*19*)).



(2)

5

The thallium(I) salt of maleimide was prepared by reaction of maleimide with thallium(I) ethoxide in anhydrous ethanol. The product precipitating from the reaction mixture (assumed to be the expected thallium salt) was filtered off, dried, and used immediately in the reaction with (η^5-C_5H_5)W($CO)_3$I. The reaction proceeded smoothly in DMF at 50 °C and was accompanied by precipitation of TlI. Complex **5** was isolated in 37% yield and characterized by spectral methods and elemental analysis.

The IR and ^{1}H NMR spectral data of complexes **3**−**5** are collected in Table 1. Similarly as in **3**, the η^1-*N*-maleimidato ligand in **4** and **5** displays its $\nu_{(C=O)}$ imide band shifted toward lower wavenumbers in comparison to that of maleimide (1713 cm^{-1}). The NMR signals of the olefinic protons in **3**−**5** were slightly shifted upfield relative to the signal of the olefinic protons in maleimide (6.74 ppm). The above data are consistent with a significant increase of the electron density at the η^1-*N*-maleimidato ligand in **3**−**5** in comparison to maleimide, due to a high polarity of the metal−nitrogen bond and a d_π-p_π repulsion. Therefore, a reduced reactivity of **3**−**5** toward thiols can be expected, which was confirmed earlier for **3**. Hopefully, this complex still proved sufficiently reactive to enable the labeling of BSA (*12*). Complexes **4** and **5** are also characterized by the presence of two $\nu_{(C\equiv O)}$ bands in agreement with the local C_{3v} symmetry of the metallocarbonyl units.

Solid-State Structure of 4. The structure of **4** in the solid state, as determined by X-ray diffraction, is shown in Figure 1. Crystal and refinement data are collected in Table 2, and selected bond distances and angles in Table 3. Compound **4** crystallizes in the monoclinic $P2_1/c$ space group with one molecule in the asymmetric unit cell. The molybdenum atom is five-coordinated, with the *Cg* of the cyclopentadienyl ring at the apex and three carbonyls and the nitrogen atom of the η^1-N-coordinated maleimidato ligand in the basal positions of the square pyramid (a "four-legged piano stool structure"). Such a structure is typical for $CpM(CO)_3X$ molecules, where X denotes a 2e anionic ligand (*20*). The distance between the molybdenum atom and a *Cg* of the cyclopentadienyl ring is 2.001(2) Å. The Mo−C bond for the *trans*-C≡O ligand (1.991(3) Å) is substantially shorter than those for for the *cis*-C≡O ligands (2.029(3) Å and 2.028(3) Å). This means that the *trans*-C≡O ligand is stronger back-bonded than its cis-counterparts, presumably because of σ-donor and π-donor properties of the imidato ligand (*19*). An interesting feature observed in the crystal structure of **4** are short contacts between oxygen atoms of the maleimidato ligand and carbon atoms of the *cis*-C≡O ligands (the distances O(14)···C(20) and O(11)···C(40) are

2.673(4)Å and 2.796(4)Å, respectively). These interactions, which may have electrostatic nature, bring about tilting of C(20) and C(40) toward O(14) and O (11), respectively, and change angles O20−C20−Mo and O40−C40−Mo (172.7(3)° and 173.3(2)°, respectively, to compare with the angle O30−C30−Mo that equals 178.3(3)°). Similar interactions between organic carbonyl groups are frequently observed in X-ray structures (*21*). Since these interactions are intramolecular, they may exist not only in the crystal state, but also in solution, and may influence the reactivity of the maleimidato ligand.

Reaction of 4 and 5 with L-Cysteine Ethyl Ester and Glutathione. Having complexes **4** and **5** in hand, we first checked their reactivity toward the thiol group of L-cysteine ethyl ester. We found that this compound (generated in situ by reaction of L-cysteine ethyl ester hydrochloride with triethylamine) was readily S-alkylated by either **4** or **5** in methanol to afford the η^1-*N*-succinimidato complexes **6** and **7** in high yields (Scheme 1).

[a] Selected bond lengths (Å) and angles (deg).

The addition of the sulfhydryl group of L-cysteine ethyl ester to the C=C bond of the maleimidato ligand was confirmed by the lack of the characteristic $\nu_{(S-H)}$ absorption in the IR spectra of **6** and **7** (this absorption appears at 2474 cm^{-1} in the IR spectrum of L-cysteine ethyl ester). The complexity of the ^{1}H NMR spectra of **6** and **7** suggests the formation of two diastereomers as a result of the creation of the stereogenic center at the succinimide ring.

To compare the reactivity of **4** and **5** with that of **3**, the rate of reaction of these complexes with the cysteine-containing tripeptide glutathione was monitored from the change of absorbance at 285 nm in the UV−vis spectra accompanying the addition of glutathione to the maleimide C=C bond. Formation of the S-alkylation adducts was also monitored by reverse phase HPLC. In all cases, the reaction rate followed a second-order kinetics. Measured rate constants and reaction half-lives are gathered in Table 4.

As seen from Table 4, the addition of glutathione to **4** and **5** is faster than its addition to **3**. This difference may arise from a weaker d_π-p_π repulsion between the formally anionic maleimidato ligand and the d^4 metal (Mo(II) or W(II)) in **4** and **5** than the d^6 Fe(II) center in **3**. This repulsion is expected to increase the electron density at the C=C bond, making it less reactive toward nucleophilic attack. Similarly, a decrease of d_π-p_π repulsion is expected on going from Mo to W (the latter participates more in the back-bonding toward CO ligands), which may explain the slightly larger reaction rate of **5** in comparison with **4**. The aforementioned trends in back-bonding toward maleimidato ligand are reflected in the IR spectra of **3**−**5** (Table 1). The $\nu_{(C=O)}$ of imide carbonyls increases in the order **3** < **4** < **5**. Consequently, the extent of the back-bonding to the maleimidato ligand should follow the order **3** > **4** > **5**. Note finally that the rate of S-alkylation of glutathione with **4** or **5** was still slower than that of *N*-ethylmaleimide.

Both glutathione conjugates, analyzed by reverse phase HPLC under conditions reported in Experimental Sec-

tion, were eluted in the form of two very close peaks at retention time of 15.7 min, in agreement with the formation of two diastereoisomers. The almost equal intensity of both peaks suggests that addition of glutathione to **4** or **5** is not stereoselective.

Reactivity of 4 and 5 toward Thiolated BSA. Having demonstrated the reactivity of **4** and **5** toward the sulfhydryl group in two cysteine derivatives, we became interested in their reactivity toward a protein containing this group. Bovine serum albumin (BSA) is a well-characterized, low cost protein, which is widely used in labeling experiments. Unfortunately, BSA contains only one free cysteine (cysteine 34), and in the commercially available BSA samples, this residue is partially blocked by conjugation with other sulfhydryl compounds such as glutathione (*17*). Therefore, spectroscopic evidence of BSA labeling with **4** or **5** could be difficult to determine because of the expected very low small number of organometallic units bound to the protein. To overcome this problem, we decided to introduce onto BSA additional sulfhydryl groups before reaction with **4** or **5**. This was achieved by treatment of BSA with Traut's reagent, which enables conversion of some of the protein free amino groups (BSA possesses 60 such groups) into sulfhydryl groups (*5*) (Scheme 2).

Under the conditions described in Experimental section, we obtained a thiolated BSA sample containing an average of 7.4 SH groups per protein (including the existing free cysteine residue). This modified protein was then incubated with a 2-fold molar excess of **4** or **5** over the starting concentration of SH groups at pH 7.4 and 26 °C for 24 h. For comparison, an experiment using **3** in place of **4** or **5** was also run under the same conditions. These reaction conditions had been previously shown to enable selective labeling of BSA's thiol (*12*). The metalloconjugates were purified by gel filtration chromatography. The numbers n of metallocarbonyl entities introduced to thiolated BSA, as determined from UV-visible measurements, are reported in Table 5.

Table 5. Labeling of Thiolated BSA (containing 7.4 SH groups) with 3–5 (1.8 molar equiv per SH group) at pH 7.4 and 26 °C for 24 h

labeling complex	n (yield)
4	6.9 (93%)
5	6.4 (86%)
3	7.6 (103%)

It appears from Table 5 that complexes **4** and **5** (as well as complex **3**) were very efficient labeling agents of the protein thiols, with labeling yields all above 85%. The

reaction also appeared to be site-specific in the chosen conditions of reaction, as the number of metallocarbonyl entities matched very well with the initial number of SH groups measured for the thiolated BSA sample. The UV-visible and IR spectra of the metalloconjugates depicted in Figures 2−4 confirmed the covalent binding of both metallocarbonyl complexes to BSA.

CONCLUSION

We have synthesized metallocarbonyl complexes of Mo and W containing the (η^1-*N*-maleimidato) ligand, (η^5-C_5H_5)M(CO)$_3$(η^1-*N*-maleimidato). These complexes react with sulfhydryl groups of cysteine in cysteine ethyl ester and glutathione as well as with sulfhydryl groups introduced to BSA in reaction with Traut's reagent to afford the corresponding S-alkylated IR-detectable bioconjugates. The potential advantage of the synthesized complexes is the presence of heavy metal atoms, which may be helpful for solving proteins structure by X-ray crystallography.

Received May 4, 2005; Revised Manuscript Received June 16, 2005

Covalent attachment of poly(ethylene glycol) (PEG) molecules to drugs, proteins, and liposomes is a proven technology for improving their bioavailability, safety, and efficacy. Qualitative and quantitative analysis of PEG-derivatized molecules is important for both drug development and clinical applications. We previously reported the development of a monoclonal IgM antibody (AGP3) to PEG. We now describe a new IgG_1 monoclonal antibody (E11) to PEG and show that it can be used in combination with AGP3 to detect and quantify PEG-derivatized molecules. Both antibodies bound the repeating subunits of the PEG backbone and could detect free PEG and PEG-modified proteins by ELISA, immunoblotting, and flow cytometry. Detection sensitivity increased with the length and the number of PEG chains on pegylated molecules. Both antibodies also efficiently accelerated the clearance of a PEG-modified enzyme in vivo. A sandwich ELISA in which E11/AGP3 were employed as the capture/detection antibodies was developed to detect PEG-modified proteins at concentrations as low as 1.2 ng/mL. In addition, the ELISA could also quantify, in the presence of 10% fetal bovine serum, free methoxy-$PEG_{20,000}$, $PEG_{2,000}$-quantum dots, and $PEG_{2,000}$-liposomes at concentrations as low as 20 ng/mL (1.0 nM), 1.4 ng/mL (3.1 pM), and 2.4 ng/mL (3.13 nM phospholipids), respectively. Finally, we show that the sandwich ELISA could accurately measured the in vivo half-life of a PEG-modified enzyme. These antibodies should be generally applicable to the qualitative and quantitative analysis of all PEG-derivatized molecules.

INTRODUCTION

PEG[1] is a water-soluble, nontoxic, nonantigenic, biocompatible polymer that has been approved by the Food and Drug Administration (FDA) for human intravenous, oral, and dermal applications (*1*). Attachment of PEG chains to proteins can reduce their immunogenicity (*2*, *3*), minimize proteolytic cleavage (*4*, *5*), and increase their serum half-life (*6*, *7*). PEG-interferon α (*8*, *9*), PEG-filgrastim (*10*, *11*), and PEG-visomant (*12*) have been approved for clinical use by the FDA. PEG-modified liposomes are being developed for controlled-release and selective-delivery of drugs (*13*) and genes (*14*). PEG has also been attached to small molecules such as camptothecin (CPT) to produce greater tumor accumulation as compared to unmodified CPT (*15*). PEG-derivatization of superparamagnetic iron oxide (*16*) and quantum dots (*17*, *18*) can improve their biocompatibility and reduce receptor-mediated uptake by the reticuloendothelial system. It is anticipated that PEG will be increasingly employed to improve the properties of therapeutic agents as more proteins, macromolecular drugs, and imaging agents enter clinical trials.

Clinical development of PEG-modified molecules requires measurement of pharmacokinetic parameters in animals and patients. Ideally, the concentration of intact PEG-modified molecules should be measured in vivo. Until recently, however, simple and sensitive methods to measure intact PEG−protein conjugates were unavailable. We helped alleviate this problem by developing a monoclonal IgM antibody (AGP3) with specificity for PEG (*19*). AGP3 can be employed to measure PEG-modified protein by ELISA (*20*). We now report the development of a new monoclonal IgG antibody (E11) that specifically binds to PEG. We compare AGP3 and E11 for the detection of free PEG and PEG-modified proteins in immunoblots, ELISA, and flow cytometry. Because the specificity of two-step targeting strategies depends on the efficient clearance of the first-step targeting agent from the circulation (*21*), we also investigated the effectiveness of AGP3 and E11 for the in vivo clearance of PEG−enzyme conjugates. Finally, a sandwich ELISA using E11

as the capture antibody and AGP3 as the detection antibody was examined for the quantitation of free methoxy PEG, PEG−enzymes, PEG−quantum dots, and PEG−liposomes.

EXPERIMENTAL PROCEDURES

Reagents. Recombinant *E. coli*-derived β-glucuronidase (βG) was produced as described (*6*). Methoxy-PEG_{750}-NH_2 (750 Da) was obtained from Fluka Chemie (Buchs, Switzerland). PEG_{3400}-disuccinimidyl succinamide (3400 Da) and methoxy-PEG succinimidyl propionate (2000, 5000, and 20 000 Da) were purchased from Nektar Therapeutics (Birmingham, AL). Methoxy-PEG_{5000}-NH_2 (5000 Da), NH_2-PEG_{3400}-NH_2 (3400 kDa), methoxy-PEG_{2000}-OH (2000 Da), NH_2-PEG_{1500}-NH_2 (1500 Da), dansyl choride, dansylcadaverine, fluorescamine, and *p*-nitrophenyl-β-D-glucuronide were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). Amino-PEG_{2000}-qdot nanoparticles (10∼20 nm, 440 kDa) were purchased from Quantum Dot Corporation (Hayward, CA). $PEG_{2,000}$-liposomes were composed of hydrogenated soy phosphatidylcholine, cholesterol, and poly(ethylene glycol)-distearoylphosphatidylethanolamine with a mean size of 107 nm (polydispersity = 0.097) as described (*22*). Sephacryl S-200 HR gel was from Amersham Pharmacia Biotech Asia Pacific Ltd. (Taiwan). Specific pathogen-free BALB/c mice were obtained from the National Laboratory Animal Center, Taipei, Taiwan.

Antibodies and Cells. 1E8 (IgG_1 mAb against βG) and AGP3 (IgM mAb against PEG) have been described (*19*). Horseradish peroxidase (HRP)-conjugated goat anti-mouse IgM μ-chain antibody and HRP-conjugated goat anti-mouse IgG Fc were from Jackson ImmunoResearch Laboratories (Westgrove, PA). B16/DNS melanoma cells that stably express a functional anti-dansyl single-chain antibody (DNS scFv) on their surface have been described (*23*). To generate mAb E11 (IgG_1 mAb against PEG), female BALB/c mice were first iv injected with 200 μg of RH1−βG−PEG, a conjugate formed between a murine antibody and PEG-derivatized βG (*19*). The mice were ip injected with 100 μg RH1−βG−PEG one week later and then sc injected at weekly intervals with 50 μg of βG−PEG in complete Freund's adjuvant, 30 μg of βG−PEG in incomplete adjuvant, 30 μg of BSA−PEG in incomplete adjuvant, and 10 μg of BSA−PEG in incomplete adjuvant. Three days before fusion with FO myeloma cells, the mice were ip injected with 30 μg of BSA−PEG in PBS. Subsequent steps were the same as employed to generate AGP3 (*19*).

Synthesis of DNS−PEG Derivatives. NH_2-PEG_{1500}-NH_2 and NH_2-PEG_{3400}-NH_2 were reacted with dansyl chloride at a molar ratio of 5:1 in dichloromethane containing 0.1% triethylamine at room temperature for 1 h. The reaction mixture was separated on silica gel with dichloromethane-methanol (8:2 vol:vol) to produce DNS−PEG_{1500}-NH_2 and DNS−PEG_{3400}-NH_2. The presence of the dansyl group was verified by UV detection whereas primary amine groups were detected by reaction with nihydrin/2% solution (Sigma). PEG_{3400}-disuccinimidyl succinamide was reacted with dansylcadaverine at a molar ratio of 2:1 in dry dichloromethane containing 0.1% triethylamine at room temperature for 1 h. The resulting DNS−PEG_{3400}-succinimidyl succinamide (DNS−PEG_{3400}−SSA) was detected under UV illumination, eluted from silica gel with dichloromethane-methanol (9:1 vol:vol) and then immediately reacted with βG.

PEG Modification of βG. βG was passed through a Sephadex G-25 column equilibrated with 0.1 M $NaHCO_3$, pH 8.0, and then concentrated by ultrafiltration to 2 mg/mL. DNS−PEG_{3400}−SSA (4 mg per mg βG) was added for 2 h at room temperature. One-tenth volume of a saturated solution of glycine (pH 8.0) was added to stop the reaction. Unreacted PEG was removed by gel filtration on a Sephacryl S-200 HR column. Protein concentrations were determined by the bicinchoninic acid assay (Pierce, Rockford, IL) with bovine serum albumin used as the reference protein. The number of PEG molecules introduced in βG was estimated by measuring amine groups before and after PEG modification with fluorescamine (*23*). An average of 3.5 DNS_{3400}−PEG chains was attached to each 70-kDa subunit of the βG tetramer to form a 3.5DNS−PEG_{3400}−βG conjugate. Methoxypoly(ethylene glycol) succinimidyl propionate with MW of 20,000, 5000, and 2000 Da was reacted with βG (20 mg per mg βG) as previously described (*20*). An average of 5.1, 7.1, and 11.4 PEG chains were introduced per subunit of the βG tetramer to form 5.1$PEG_{20,000}$−βG, 7.1PEG_{5000}−βG, 11.4PEG_{2000}−βG with retention of 70%, 50%, and 43% of original βG enzymatic activity, respectively.

Immunoblotting of Free PEG and PEG−βG. Samples of βG (5 μg), 3.5DNS−PEG_{3400}−βG (5 μg), NH_2-PEG_{1500}-NH_2 (30 μg), and CH_3-PEG_{2000}-OH (30 μg) were electrophoresed in an 8% sodium-dodecyl sulfate polyacrylamide gel under reducing conditions before overnight transfer to nitrocellulose paper by capillary transfer in blotting buffer (50 mM NaCl, 2 mM EDTA, 0.5 mM 2-mercaptoethanol, 10 mM Tris-HCl, pH 7.5). Blots were blocked for 2 h with 5% skim milk and incubated for 1 h at 37 °C with 1 μg/mL 1E8, AGP3 or E11 in PBS containing 0.05% BSA. The blots were washed 3 times with PBS-T (0.05% Tween 20 in PBS) and twice with PBS before incubation with goat anti-mouse Ig-HRP for 40 min at 37°C. The blots were then washed three times with PBS-T and twice with PBS before specific bands were visualized by ECL detection according to the manufacturer's instructions (Pierce, Rockford, IL).

Antibody ELISA. Maxisorp 96-well microplates (Nalge Nunc International, Roskilde, Denmark) were coated with 10 μg/well CH_3-PEG_{750}-NH_2, NH_2-PEG_{1500}-NH_2, NH_2-PEG_{3400}-NH_2, or 3.5DNS−PEG_{3400}−βG in 0.1 M $NaHCO_3$, pH 8.0, for 3 h at 37 °C and then blocked with 2% skim milk. Graded concentrations of AGP3 and E11 were added to the plates at 37 °C for 1 h. The plates were washed three times with PBS-T and two times with PBS and then stained with HRP-labeled goat anti-mouse IgM μ chain (2 μg/mL) or HRP-labeled goat anti-mouse IgG Fc (2 μg/mL) for 1 h at 37 °C, respectively. The plates were washed and bound peroxidase activity was measured by adding 100 μL/well ABTS solution (0.4 mg/mL 2,2′-azino-di(3-ethylbenzthiazoline-6-sulfonic acid), 0.003% H_2O_2, 100 mM phosphate-citrate, pH 4.0) for 30 min at room temperature. Absorbance (405 nm) of wells was measured in a microplate reader (Molecular Device, Menlo Park, CA). Binding of CH_3-PEG_{750}-NH_2, NH_2-PEG_{1500}-NH_2, NH_2-PEG_{3400}-NH_2, and 3.5DNS−PEG_{3400}−βG to the microtiter plates was determined by assaying for the presence of amine groups with fluorescamine (*24*).

Flow Cytometer Analysis. B16/DNS cells (5×10^5) were incubated with 200 μL of DNS−PEG_{1500}-NH_2 (10 μg/mL), DNS−PEG_{3400}-NH_2 (10 μg/mL), 3.5DNS−PEG_{3400}−βG (10 μg/mL), or PBS at 4 °C for 1 h. The cells were washed twice with cold PBS and sequentially stained with AGP3 (5 μg/mL) and FITC-labeled goat anti-mouse IgM μ chain (5 μg/mL) or E11 (5 μg/mL) and FITC-labeled goat anti-mouse IgG Fc (5 μg/mL). The surface immun-

ofluorescence of 10 000 viable cells was measured with a flow cytometry (Beckman-Coulter, Miami, FL).

Clearance of PEG−*β*G Conjugates. Groups of 3 BALB/c mice were iv injected with100 μg of 5.1PEG$_{20,000}$−βG, 7.1PEG$_{5000}$−βG, or 11.4PEG$_{2000}$−βG at time zero. Blood samples (30 μL) were taken at 0.5, 3.5, and 9 h before iv injection of PBS, 150 μg of E11, or 180 μg of AGP3 at 9 h. Additional blood samples were taken at subsequent times (11, 14, and 28 h), and the serum concentration of βG−PEG was measured by a βG enzyme microassay as described (*19*). Sample concentrations were calculated by comparison of absorbance values with a standard curve constructed from known concentrations of 5.1PEG$_{20000}$−βG, 7.1PEG$_{5000}$−βG, and 11.4PEG$_{2000}$−βG. For meaningful comparison of clearance results, the measured concentrations of PEG−βG conjugates in mice injected with clearing antibodies were normalized to the mean concentration of PEG−βG conjugates in control (uncleared) mice just before clearance as previously described (*19*).

Sandwich ELISA. Maxisorp 96-well microplates were coated with 50 μL/well of E11 (20 μg/mL) or AGP3 (20 μg/mL) in 0.1 M $NaHCO_3$, pH 8.0, for 3 h at 37 °C. The plates were blocked with 2% skim milk in PBS overnight and then washed twice with PBS before graded concentrations of 3.5DNS−PEG$_{3400}$−βG, methoxy-PEG$_{20000}$ succinimidyl propionate (inactivated with 0.1 M Tris, pH 8.0), and PEG$_{2000}$-quantum dots or PEG$_{2000}$-liposomes in PBS containing 10% FBS were added for 1 h at 37 °C. The plates were washed three times with PBS-T and twice with PBS and were then sequentially stained with 50 μL/well AGP3 (20 μg/mL) and HRP-labeled goat anti-mouse IgM μ chain (5 μg/mL) or E11 (20 μg/mL) and HRP-labeled goat anti-mouse IgG Fc (5 μg/mL). The plates were washed and 100 μL/well ABTS substrate was added for 30 min at room temperature. The absorbance (405 nm) of the wells was measured in a microplate reader.

Determination of 3.5DNS−PEG$_{3400}$−*β*G Pharmacokinetics. BALB/c mice were iv injected with 150 μg of 3.5DNS−PEG$_{3400}$−βG and serum was isolated from blood samples (30 μL) that were periodically removed from the tail vein of the mice (0.17, 1.5, 4, 7, 11, 24, and 48 h). The concentration of 3.5DNS−PEG$_{3400}$−βG was measured by the new sandwich ELISA and by a βG enzyme microassay (*19*). βG concentrations were calculated by comparison of absorbance values with a standard curve constructed from known concentrations of 3.5DNS−PEG$_{3400}$−βG.

Data Analysis. Statistical significance of differences between mean values was estimated with Excel (Microsoft, Redmond, WA) using the independent *t*-test for unequal variances.

RESULTS

Detection of Free PEG and PEG-Modified Molecules. The specificity of the anti-PEG antibodies AGP3 and E11 was first examined in immunoblots. Figure 1a shows that the anti-βG antibody 1E8 detected βG and 3.5DNS−PEG$_{3400}$−βG, but not free NH_2-PEG$_{1500}$-NH_2 or CH_3-PEG$_{2000}$-OH. AGP3 and E11, in contrast, did not bind βG but detected 3.5DNS−PEG$_{3400}$−βG as well as free NH_2-PEG$_{1500}$-NH_2 and CH_3-PEG$_{2000}$-OH (Figures 1b and 1c). The ability of AGP3 and E11 to bind both NH_2-PEG$_{1500}$-NH_2 and CH_3-PEG$_{2000}$-OH demonstrates that these antibodies bind to the repeating OCH_2CH_2 backbone of PEG rather than to terminal CH_3, NH_2, or OH groups.

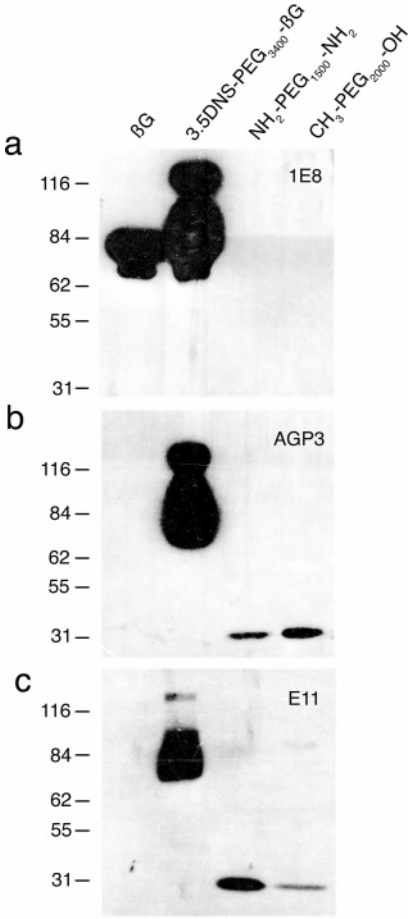

Figure 1. Immunoblot of free PEG and a PEG-modified enzyme. Samples were electrophoresed on a 8% reduced SDS polyacrylamide gel, transferred to nitrocellulose paper, and probed with mAb 1E8 (a), AGP3 (b) or E11 (c) as described in Experimental Procedures. Lane 1, βG; lane 2, 3.5DNS−PEG$_{3400}$−βG; lane 3, NH_2-PEG$_{1500}$-NH_2; lane 4, CH_3-PEG$_{2000}$-OH. kDa, molecular mass in thousands.

The binding of AGP3 and E11 to different lengths of free PEG (MW 750, 1500, 3400, and 5000 Da) was examined by first coating NH_2-PEG in the wells of microtiter plates and then performing ELISA. Coating of NH_2-PEG in the wells was verified by detecting the presence of the amine groups of NH_2-PEG with fluorescamine. Figure 2a shows that NH_2-PEG and 3.5DNS−PEG$_{3400}$−βG were successfully coated in the wells as demonstrated by increased fluorescence as compared with uncoated wells. Measurement of AGP3 (Figure 2b) and E11 (Figure 2c) binding to NH_2-PEG revealed that both antibodies bound NH_2-PEG$_{1500}$-NH_2, NH_2-PEG$_{3400}$-NH_2, and CH_3-PEG$_{5000}$-NH_2 but not CH_3-PEG$_{750}$-NH_2. Furthermore, the assay sensitivity was proportional to the length of the PEG chains, especially for E11. These results suggest that the binding epitope of both antibodies consists of at least 16 OCH_2CH_2 subunits (the number of subunits in PEG$_{750}$).

Adsorption of PEG chains to the plastic surface of microtiter plates could affect antibody binding. We therefore employed flow cytometry to measure AGP3 and E11 binding to PEG attached to the surface of mammalian cells. This was accomplished by introducing a dansyl moiety to the terminus of PEG to create DNS−PEG$_{1500}$-NH_2, DNS−PEG$_{3400}$-NH_2, and 3.5DNS−PEG$_{3400}$−βG. These conjugates were allowed to specifically bind to DNS scFv present on the surface B16/DNS cells. The cells were then sequentially stained with AGP3 and

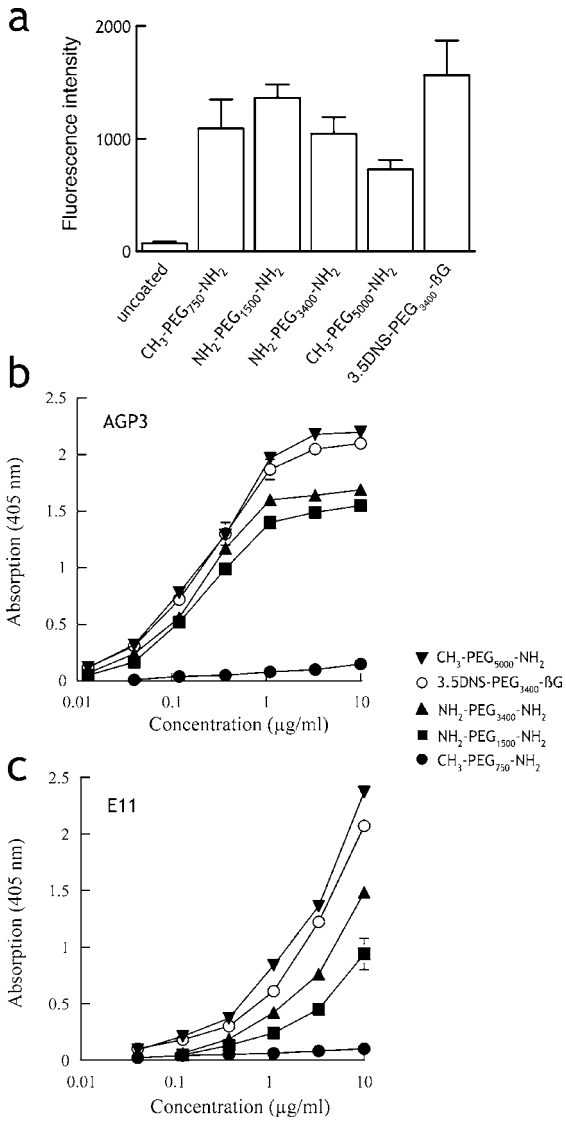

Figure 2. Qualitative analysis of PEG-derivatized molecules. (a) Coating of PEG and PEG-modified βG in microplates was confirmed by measuring the fluorescence intensity ($n = 3$) after reaction of amine groups with fluorescamine. Bars, SD. The binding of AGP3 (b) and E11 (c) to PEG and PEG-modified βG coated in microplates was detected by ELISA as described in the Experimental Procedures. The mean absorbance values (405 nm) of triplicate determinations are shown. Bars, SD.

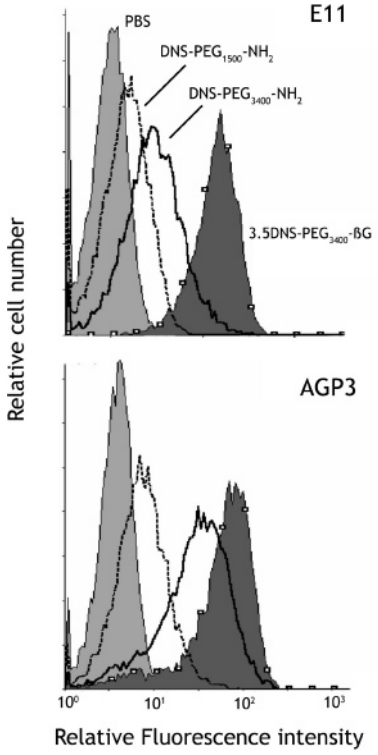

Figure 3. Flow cytometry analysis of PEG-derivatized molecules. B16/DNS cells were treated with PBS, DNS−PEG_{1500}-NH_2, DNS−PEG_{3400}-NH_2 or 3.5DNS−PEG_{3400}−βG at 4 °C for 1 h. The cells were washed and sequentially stained with E11 and FITC-labeled goat anti-mouse IgG Fc (upper panel) or AGP3 and FITC-labeled goat anti-mouse IgM μ chain (lower panel). The surface immunofluorescence of 10,000 viable cells was measured with a FACScaliber flow cytometer.

FITC-labeled goat anti-mouse IgM μ chain or E11 and FITC-labeled goat anti-mouse IgG Fc. Figure 3 shows that AGP3 and E11 could detect DNS−PEG_{1500}-NH_2, DNS−PEG_{3400}-NH_2, and 3.5DNS−PEG_{3400}−βG on B16/DNS cells. Consistent with the ELISA results, longer PEG chains resulted in increased sensitivity of the assay.

In Vivo Clearance of PEG−βG. To investigate the ability of AGP3 and E11 to clear PEG-modified proteins from the circulation, BALB/c mice were iv injected with 100 μg of 11.4PEG_{2000}−βG, 7.1PEG_{5000}−βG, or 5.1PEG_{20000}−βG, followed 9 h later by iv injection of AGP3 or E11 (2 nmoles of antigen-binding sites). Figure 4 shows that both AGP3 and E11 accelerated the clearance of PEG−βG conjugates from the circulation. E11 cleared significantly more PEG−βG conjugate than did AGP3. E11 was particularly effective at clearing βG modified with long-chained PEG; the serum concentration of 5.1$PEG_{20,000}$−βG was reduced by 200-fold in 2 h and 580-fold within 19 h after E11 administration as compared to control mice. These results suggest that AGP3 and E11 may be useful for accelerating the clearance of PEG-modified proteins in vivo.

Quantitative Sandwich ELISA. A sandwich ELISA was developed in which E11/AGP3 or AGP3/E11 was used for the capture/detection antibodies to measure free PEG and PEG-modified substances. Figure 5a shows that the assay sensitivity was about 4-fold greater when using E11 for capture and AGP3 for detection of 3.5DNS−PEG_{3400}−βG as compared with the opposite format. This assay could detect 3.5DNS−PEG_{3400}−βG at concentrations as low as 1.2 ng/mL (14.5 pM). In addition, the sandwich ELISA assay could also detect free methoxy-PEG_{20000}, PEG_{2000}-quantum dots, and PEG_{2000}-liposomes at concentrations as low as 20 ng/mL (1.0 nM), 1.4 ng/mL (3.1 pM) and 2.4 ng/mL (3.13 nM phospholipids), respectively (Figure 5b). The presence of 10% bovine serum in the samples did not affect assay sensitivity. To determine whether the sandwich ELISA assay could detect PEG-modified proteins in vivo, BALB/c mice were iv injected with 150 μg of 3.5DNS−PEG_{3400}−βG, and serum samples were periodically assayed for the concentration of the conjugate by the new sandwich ELISA or by measuring βG enzyme activity. Figure 5c shows that the measurement of 3.5DNS−PEG_{3400}−βG concentration by the sandwich ELISA and βG enzyme microassay gave similar results with estimated terminal half-lives of 6.3 and 5.5 h, respectively.

DISCUSSION

An increasing number of PEG conjugates are in late stage clinical trials or already approved for human use by the FDA including PEG-Intron for hepatitis C (*25*, *26*), PEG-Neupogen for neutropenia associated with cancer

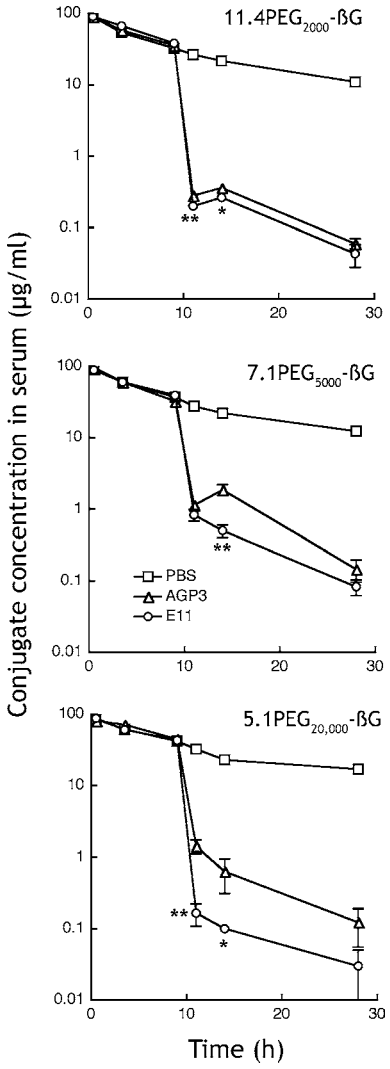

Figure 4. In vivo clearance of PEG−βG conjugates. Groups of 3 BALB/c mice were iv injected with 100 μm 11.4PEG$_{2000}$−βG (upper panel), 7.1PEG$_{5000}$−βG (middle panel) or 5.1PEG$_{20,000}$−βG (lower panel) at time zero. The mice received an iv injection of PBS (□), AGP3 (△) or E11 (○) at 9 h. The concentrations of the βG−PEG conjugates in serum at the indicated times were determined by assaying βG enzymatic activity. Bars, SD. Significant differences between βG−PEG concentrations after E11 and AGP3 treatment are indicated: *, $p \leq 0.05$; **, $p \leq 0.005$.

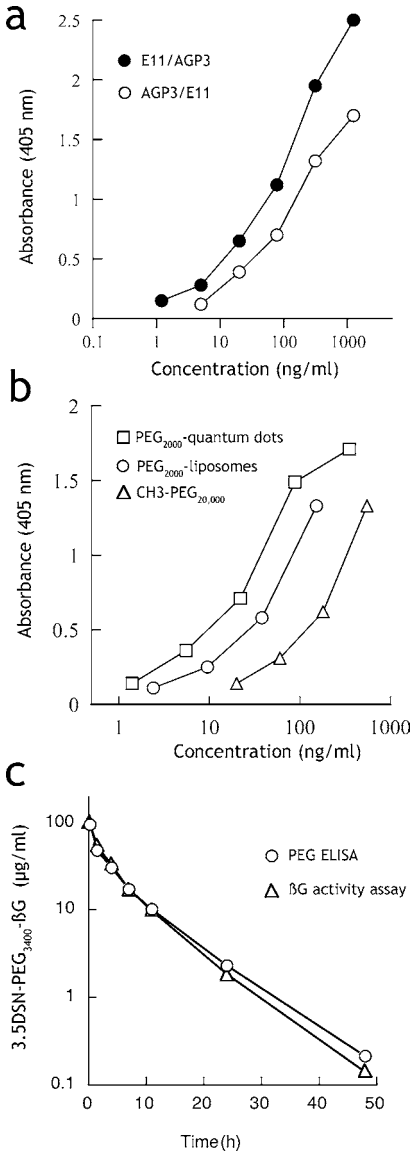

Figure 5. Quantitative analysis of PEG-derivatized molecules by ELISA. (a) Graded concentrations of 3.5DNS−PEG$_{3400}$−βG were assayed with a sandwich ELISA in which E11/AGP3 (●) or AGP3/E11 (○) were used for the capture/detection antibodies, respectively. The mean absorbance values of triplicate determinations are shown. Bars, SE. (b) A sandwich ELISA with E11 and AGP3 employed as the capture and detection antibodies, respectively, was used to measured the concentrations of PEG$_{2000}$-quantum dots (□), PEG$_{2000}$-liposomes (○) or free methoxy-PEG$_{20,000}$ (△) in PBS containing 10% serum. (c) Groups of three mice were iv injected with 3.5DNS−PEG$_{3400}$−βG at time zero. The concentration of 3.5DNS−PEG$_{3400}$−βG is serum was measured by the E11/AGP3 sandwich ELISA (O) or by the βG enzyme microassay (△). Bars, SD.

chemotherapy (*27*), PEG-Visomant for acromegaly (*28*), and PEG-coated liposomal doxorubicin (Caelyx) for cancer therapy (*29*). The ability to effectively control these diseases and minimize the injection frequency can result in better compliance and improved patient quality of life. For noninvasive imaging, PEG−quantum dots and PEG−superparamagnetic iron oxide have been extensively used in cell and animal biology for cell trafficking studies (*30*, *31*), tumor targeting (*18*, *32*), and diagnostics (*33*, *34*). Qualitative and quantitative analysis of poly(ethylene glycol)-derivatized molecules is important to determine their pharmacodynamic and pharmacokinetic parameters in animals and patients. In this report, we found that AGP3 and E11 recognize the repeating (OCH_2CH_2) subunits of the PEG backbone and could effectively clear PEG−βG from the circulation of mice. Furthermore, we developed a sandwich ELISA for the sensitive quantitation of PEG-modified molecules.

PEG can be linked to biological molecules by terminal group derivatization (*35*). First generation, low molecular weight PEG chains were found to poorly cover the surface of macromolecules and often drastically decreased the biological or pharmacological potency of proteins (*36*−*38*). To solve these problems, high molecular weight PEG can be used to maximize protection with better preservation of the bioactivity of pegylated molecules, allowing improved and prolonged performance (*39*). We found that AGP3 and E11 bind to the PEG backbone so that antibody binding did not depend on the identity of the pegylated molecule. These antibodies could therefore detect pegylated proteins, liposomes, and nanoparticles. The detection sensitivity increased with the length of the PEG chains on pegylated molecules. These results indicate that multiple AGP3 and E11 antibodies can bind to a single PEG chain, allowing amplification of the signal

as PEG chain length increases. These antibodies are therefore particularly suitable for the qualitative and quantitative analysis of high molecular weight PEG-modified molecules.

Given the well-known ability of PEG to decrease the immunogenicity of proteins (*2*, *3*), it is interesting that we have successfully generated two monoclonal antibodies against PEG. Antibodies can theoretically be generated against any molecule if it is first attached to a carrier protein to allow activation of cognate T helper cells. Indeed, antibodies have been generated against polymers such as dextran (*40*) and double-stranded synthetic polyribonucleotide complexes (*41*). PEG-modified proteins have been known to induce anti-PEG antibodies in rabbits (*42*) and repeated injections of rabbits with liposomes containing a PEG derivative of phosphatidyl ethanolamine induced anti-PEG antibodies (*43*). It should be appreciated, however, that we generated a reasonable anti-PEG antibody response in mice only after repeated immunizations with PEG−protein conjugates, indicating the difficulty in inducing a robust immune response against this polymer.

We have previously shown that AGP3 can accelerate the clearance of PEG_{5000}-modified proteins and improve the tumor/blood ratios of antibody−βG−PEG_{5000} conjugates for glucuronide prodrug therapy of cancer (*21*). In the present study, we found that both AGP3 and E11 reduced the serum concentration of $7.1PEG_{5000}$−βG as well as $11.4PEG_{2000}$−βG and $5.1PEG_{20,000}$−βG from the blood. Thus, effective clearance could be achieved for conjugates containing different lengths of PEG chains. AGP3 induced rapid uptake of radiolabeled antibody−βG−PEG conjugates in the liver of mice (*21*). Although in the present study we did not follow the distribution of the conjugates in tissues after clearance with E11, the liver is a likely route of elimination. These results indicate that AGP3 and E11 can be used to clear PEG-modified conjugates from the circulation and control the serum half-life to regulate the bioactivity of PEG-modified molecules in vivo.

Measurement of PEG-modified molecules by ELISA and flow cytometry revealed that AGP3 allowed greater assay sensitivity as compared to E11 (Figures 2 and 3). This is likely due to the higher avidity of AGP3 (10 antigen-binding sites versus 2 for E11) as well as the presence of 5 μ chain domains in AGP3, providing more binding sites for secondary detection antibodies. Increased binding of secondary detection antibodies may also explain why the combination of E11/AGP3 was more sensitive than AGP3/E11 as the capture/detection antibodies in the sandwich ELISA.

The newly developed sandwich ELISA can measure the concentrations of PEG-modified proteins, liposomes, quantum dots, and free PEG. The assay sensitivity ranged from the low nM to low pM level, several orders of magnitude more sensitive than previous methods (*24*, *44*). Assay sensitivity can likely be further increased by employing more sensitive colorimetric or fluorometric substrates (*45*, *46*). The sandwich ELISA did not require prior separation of conjugates from complex mixtures and allowed the detection of PEG−βG in serum samples. These characteristics should simplify measurement of PEG-modified molecules in serum samples for pharmacological and pharmacokinetic studies in vivo.

In summary, AGP3 and E11 bind to the repeating ethylene oxide subunits of PEG and therefore can detect PEG independently of the identity of the pegylated compound or chemistry of the linker. The sensitivity of detection depends on the length of the PEG chains; longer PEG chains result in increased sensitivity. These two antibodies should be generally applicable to quantify a wide-range of PEG-derivatized molecules. The newly developed sandwich ELISA may also be useful to measure PEG-modified molecules in patients for preclinical and clinical studies.

ACKNOWLEDGMENT

We thank the Biomedical Engineering Center, Industrial Technology Research Institute, Hsin Chu, Taiwan for providing $PEG_{2,000}$-liposomes. This work was supported by Academia Sinica, the National Research Program for Genomic Medicine (NRPGM), National Science Council, Taipei, Taiwan (NSC92-3112-B-037-002), and the National Health Research Institutes (NHRI-EX94-9420BI).

Monomolecular Multimodal Fluorescence-Radioisotope Imaging Agents

Zongren Zhang, Kexian Liang, Sharon Bloch, Mikhail Berezin, and Samuel Achilefu*

Department of Radiology, Washington University, St. Louis, Missouri 63110. Received May 5, 2005; Revised Manuscript Received August 8, 2005

Diagnosis of diseases by different imaging methods can provide complementary information about the functional status of diseased tissues or organs. To overcome the current difficulties in coregistering images from different imaging modalities with a high degree of accuracy, we prepared near-infrared (NIR) monomolecular multimodal imaging agents (MOMIAs) consisting of a heptamethine carbocyanine and ^{111}In−DOTA chelate that served as antennae for optical and scintigraphic imaging, respectively. Their spectral properties clearly show that coordination of indium to MOMIA increased the fluorescence intensity of the compounds. The MOMIAs are exceptionally stable in biological media and serum up to 24 h at 37 °C. Biodistribution of the compounds in mice obtained by fluorescence photon and γ-counts demonstrated a similar distribution trend of the molecular probe in different tissues, suggesting that the detected fluorescence and γ-emissions emanated from the same source (MOMIA). At 24 h postinjection, the MOMIAs were excreted by the renal and hepatobiliary systems and the blood level of a representative MOMIA was very low, thereby reducing background noise caused by circulating molecular probes. These findings demonstrate the feasibility of preparing single molecules with the capacity to emit discernible and diagnostic fluorescent and γ-radiations for optical and nuclear imaging of living organisms.

INTRODUCTION

Coregistration of tissue with different imaging modalities can furnish unique and complementary information that improves the accuracy of disease diagnosis and enhances patient management (*1*, *2*). For example, coregistration of tumors with magnetic resonance imaging (MRI) and positron emission tomography provides anatomical and functional information, which can be used to visualize metastatic foci and localize its exact position (*3*). These possibilities have led to the development of multimodal imaging instruments for clinical and preclinical applications.

Optical imaging is an emerging method that can benefit from a multimodal imaging strategy. The method is highly sensitive, with the capability of detecting minute amounts of light emitting materials in heterogeneous mediums (*4*, *5*). In addition, optical imaging also uses low energy radiation in the visible and infrared regions of the electromagnetic spectrum of light to assess biological processes in tissues. The distribution of chromophores within a few micrometers from the light source and detector systems can be localized with high resolution, thereby permitting the differentiation of normal from pathologic tissues (*6*−*8*). However, the ability to detect diagnostic chromophores and the image resolution obtained by optical methods degrade rapidly as the distance between source−detector pair and the target tissue volume progressively increases beyond several centimeters. This poor resolution is caused by the intrinsic absorption and scattering of light by tissue. Therefore, for noninvasive deep tissue imaging, optical methods would benefit from a multimodal strategy that can complement this weakness. Additionally, a multimodal approach that combines optical with one of the established imaging methods could accelerate its acceptance in clinical settings.

Recently, Ntziachristos et al. (*9*) coregistered indocyanine green (ICG)-enhanced optical images of breast cancer patients with DTPA−Gd-enhanced MRI. The results demonstrate that diffuse optical tomography can adequately localize and quantify exogenous optical contrast agents in breast cancers. Typical of most current multimodal imaging procedures, the investigators administered two different contrast agents to patients: a paramagnetic gadolinium DTPA chelate for MRI and ICG for optical imaging. Expectedly, the pharmacokinetics of both probes were very different and the potential toxic effects of each component can be additive. Understandably, a major problem with developing a single molecular entity that can produce detectable signals for each imaging method derives from differences in the sensitivities of each modality. For example, the design of a monomolecular Gd-based MRI−optical monomolecular multimodal imaging agent (MOMIA) must incorporate multiple Gd chelates per dye moiety to compensate for the relatively low sensitivity of the MRI method. Some common strategies employed to compensate for the large differences in local tissue sensitivities of different imaging systems require the use of large biomolecules, polymeric materials, liposomes, micelles, or nanoparticles (*10*−*13*). However, the inherent problems with large molecules, including low diffusion rate into diseased tissue, rapid uptake by the liver, and the potential to elicit adverse immune reactions, limit their utility as contrast agents for in vivo imaging studies (*14*). Recent approaches include the use of smaller molecular constructs to obtain multimodal agents for MRI and optical imaging studies (*15*).

The sensitivities of fluorescence and radionuclear

methods are comparable, which enable the incorporation of antennae for both methods into a relatively small molecular mass (<6 kDa) single molecule in a 1:1 signaling ratio. This optical−radionuclear molecular construct would allow the use of a short-lived radioisotope component of the MOMIA to localize diseases in deep tissue without the depth limitation of optical methods. After mapping the region of interest, longitudinal monitoring of the diseased tissue can be conducted by optical methods outside radioactivity restricted areas. Optical imaging in the near-infrared (NIR) region minimizes light attenuation by endogenous chromophores and facilitates deep tissue imaging. Accordingly, we report the synthesis of NIR light emitting dye−DOTA conjugates linked by alkyl or peptidyl units. We further assessed their spectral properties and biodistribution in mice. The fluorescence and γ-counts of the MOMIAs in different tissues were similar and demonstrate the feasibility of developing these molecular constructs for multimodal imaging by tandem optical and radionuclear methods.

MATERIALS AND METHODS

General. All solvents and chemicals were reagent grade and used without further purification. *N,N*-Diisopropylcarbodiimide (DIC) and glutaconaldehyde dianilide monohydrochloride were purchased from Lancaster Synthesis (Windham, NH). Dichloromethane (DCM), *N*,*N*-dimethylformamide (DMF), MeOH, and MeCN were from purchased from Fisher Scientific (Pittsburgh, PA). Fluorenylmethyl amino acids (Fmoc) and trifluoroacetic acid (TFA) were purchased from, respectively, AnaSpec Inc. (San Jose, CA) and Advanced ChemTech (Louisville, KY). Other commercial chemicals were purchased from Sigma-Aldrich (St. Louis, MO). Mass spectral analyses were performed on a Waters ZQ 4000 positive electrospray at a cone voltage of 67 V. All of the compounds including the intermediates and final products were fully identified by mass spectrometry/electrospray ionization high-performance liquid chromatography (MS/ESI HPLC) analyses performed on a Vydac C-18 polymeric reverse phase column (218TP, 5 μm, 300 Å, 4.6 mm × 250 mm) at a flow rate of 1.0 mL/min. Semipreparative HPLC was performed on a Vydac C-18 polymeric reverse phase column (218TP, 10 μm, 300 Å, 22 mm × 250 mm) at 9.5 mL/min. HPLC solvents consist of water containing 0.1% TFA (solvent A) and MeCN containing 0.1% TFA (solvent B). The elution protocol for analytical HPLC started with 90% A for 1 min, followed by a linear gradient to 30% A over 20 min, held at 30% A for 5 min, continued to 10% A for 5 min, and finally returned to 90% A over 2 min. The elution profiles of MOMIAs were monitored by UV absorbance at 254 and 214 nm. Absorbance spectra were measured on a Beckman Coulter DU 640 UV−visible spectrophotometer. Fluorescence spectra were recorded on a Fluorolog-3 spectrofluorometer (Horiba Jobin Yvon, Inc., Edison, NJ). Stock solutions (1.0 mM) of the dye and its conjugates were prepared by dissolving each sample in DMSO. UV−vis and fluorescence measurements were carried out by sequentially adding 0.5−2.0 μL aliquots of the stock solutions via a micropipet into 3 mL of 20% aqueous DMSO solution or other solvents in a quartz cuvette. The mixtures were stirred briefly for equilibration prior to data acquisition.

Synthesis of Cypate (1). Ac_2O (226 μL, 2.4 mmol) in DCM (1 mL) was added slowly to a stirred solution of glutaconic aldehyde dianilide hydrochloride (0.6 g, 2 mmol) and diisopropyl ethylamine (DIEA, 700 μL, 4 mmol) in DCM (4 mL). The solution was added to a warm (50 °C), stirred MeCN (10 mL) solution of NaOAc (0.8 g, 9.5 mmol) and 1-hydroxycarbonylethyl-2,3,3-trimethylbenzoindoleninium bromide (2.0 g, 5.5 mmol), which was prepared as described previously (*16*). The mixture was stirred for 30 min at 50 °C to give noticeable precipitates. Additional precipitates were obtained by adding ether to the reaction mixture. The solid was filtered and washed sequentially with ether, MeCN, ether, and water (1% TFA) to give 1.06 g (85%) of **1** as a red glistening solid. MS/ESI: 625 [M^+].

Synthesis of Tri-*t*-butyl DOTA (2). Benzyl bromoacetate (4.0 g, 17 mmol) in MeCN (80 mL) was added dropwise (3.5 h) to an ice-cooled mixture of K_2CO_3 (6.5 g, 47 mmol) and 1,4,7,10-tetraazacyclododecane tetrahydrochloride (5.0 g, 15.7 mmol) in MeCN (50 mL). The mixture was stirred for 30 min at 0 °C. K_2CO_3 (3.5 g, 25 mmol) was added as a solid, followed by dropwise (1 h) addition of *tert*-butyl bromoacetate (12.3 g, 62.8 mmol) in MeCN (80 mL). The resulting mixture was stirred at 0 °C overnight, and the solid was filtered. After the solid was further washed with MeCN/MeOH, the collected filtrates were combined and acidified with TFA to pH 5. The precipitate obtained after acidification was filtered and concentrated on a rotary evaporator. The solid residue was washed with ether and dried to give 9.3 g of a white powder. HPLC and MS studies indicated that powder consisted of 60% benzyl tri-*tert*-butyl DOTA and 40% tetra-*tert*-butyl DOTA. Because the tetra-*tert*-butyl byproduct is not reactive, the product mixture can be used in subsequent reactions without prior purification. MS/ESI: 663 [$M + H^+$], 701 [$M + K^+$].

Hydrogen was bubbled through a mixture of the solid (3 g) and Pd/C (10 wt %, 300 mg) in THF (180 mL)/MeOH (180 mL) at atmospheric pressure for 15 h. The Pd/C catalyst was removed by filtration, and the solvent was removed on a rotary evaporator to give crude solid product. The solid was further purified by recrystallization in acetone/*t*-BuOMe/hexanes system to give **2** (1.8 g) as a white solid. MS/ESI: 573 [$M + H^+$].

Synthesis of Tri-*t*-butyl DOTA−Hexanediamine−Cypate (4a). A mixture of tri-*tert*-butyl DOTA (349.2 μmol, 200 mg), 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU, 134 mg, 358 μmol), and *N*-hydroxybenzotriazole (HOBt, 50 mg, 326 μmol) in DMF/DCM (50:50 vol %, 7 mL) was shaken for 5 min. DIEA (92 μL, 523.8 μmol) was then added, and the mixture was shaken again for 10 min. 1,6-Hexanediamine (419.04 μmol, 49 mg) was added as a solid, and the mixture was shaken for 2 h before cypate (327 mg, 523.8 μmol), activated similarly, was added. The resulting mixture was shaken for 4 h. It was neutralized with dilute HCl (0.1 M). DCM was removed on a rotary evaporator, and the concentrated solution was treated with ether to precipitate the product, which was further washed sequentially with water, ether, and ethyl acetate. Pure product was isolated by semipreparative HPLC to give 40 mg of **4a**. MS/ESI: 1277 [M^+].

Synthesis of DOTA−Hexanediamine−Cypate (4). Tri-*tert*-butyl DOTA−hexanediamine−cypate (**4a**, 10.5 mg, 8.2 μmol) in TFA (2 mL) was stirred for 2 h at room temperature. TFA was removed, and the resulting green solid was washed with ether and separated by semipreparative HPLC to give 1.3 mg (1.17 μmol, 15% yield) of **4** as a green solid. MS/ESI: 1109 [M^+].

Synthesis of α−DOTA−Lys(ϵ-Cypate)−OH (5). Fmoc−Lys(Dde)−OH (655 mg, 1.23 mmol) in DCM (5 mL) and DMF (0.2 mL) was cooled by ice bath, and DIC (615 μmol, 96 μL) was added. The mixture was stirred at 0 °C for 20 min. DCM was removed on a rotary evaporator, and the residue was dissolved in DMF (5 mL).

The solution was transferred to a mixture of 4-(dimethylamino)pyridine (2.5 mg, 20.5 μmol) and Wang resin (100−200 mesh, 0.82 mmol/g, 250 mg, 205 μmol) preswelled in DMF. The mixture was shaken for 3 h, followed by filtration and sequential washing with DMF−MeOH−DMF−DCM−DMF. Fmoc was removed with 20% piperidine in DMSO and tri-*tert*-butyl DOTA (352 mg, 615 μmol), activated with HOBt (94 mg, 615 μmol)/HBTU (233 mg, 615 μmol)/DIEA (1.23 mmol. 214 μL), was conjugated to the α-amino group of lysine for 20 h. The Dde group was removed with 2% hydrazine in DMF and cypate (307 mg, 492 μmol) in DMF (2 mL)/DCM (2 mL), preactivated with HBTU (187 mg, 492 μmol) and HOBt (75 mg, 492 μmol), and DIEA (656 μmol, 114 μL) was added to the resin. The mixture was shaken for 5 h, filtered, and washed sequentially with DMF−DCM−DMF−DCM−DMF solvent system. The crude product was cleaved from the resin by shaking in TFA (5 mL) for 3 h. The product was purified by semipreparative HPLC to give 40 mg of the compound as a green solid. MS/ESI: 1139 $[M^+]$.

Synthesis of DOTA−Gly−Ser−Gly−Lys(ε-Cypate)−Ahx[1]−NH_2 (6). The peptides were prepared with ACT APEX 396 peptide synthesizer by standard Fmoc protocol (*17*), as described previously (*18*, *19*). Briefly, starting with a Rink amide resin, the Fmoc−Ahx−OH (75 μmol) was activated with a mixture of the coupling reagents HOBt (75 μmol) and HBTU (75 μmol) in the presence of DIEA (150 μmol). Deprotection of the Fmoc protecting group was accomplished with 20% piperidine in DMF. The tri-*tert*-butyl DOTA (75 μmol) was automatically coupled to the N-terminal amino group. The orthogonal protecting lysine group 2-(4,4-dimethyl-2.6-dioxycyclohexylidene)ethyl (Dde) was selectively removed with 2% hydrazine in DMF before adding the NIR probe, cypate. Simultaneous removal of side chain protecting groups and cleavage of the product from solid support were accomplished with a cleavage mixture of 95% TFA and 5% water. After lyophilization, the crude product was obtained as a green powder and purified by semipreparative HPLC to give **6** (6.5 mg, 18% yield). MS/ESI: 1453 $[MH]^+$, 727 $[M + 2H]^{2+}$.

Synthesis of Nonradioactive ^{115}In−MOMIAs (7 and 8). The labeling of compound **6** to give **8** is typical of the procedure used to successfully label MOMIAs with indium. Two drops of absolute ethanol were added to 2.3 mg (1.5 μmol) of compound **6** to form slurry. To this slurry was added 1 mL of a NaOAc−sodium ascorbate buffer (50 mM of NaOAc and 25 mM of sodium ascorbate). A solution of $InCl_3$ in 0.1 M HCl (1 mL, 1.1 mg, 4.74 μmol) was added to the reaction mixture to obtain a solution of pH 4.9. The solution was heated at 80 °C for 1 h, and the mixture was allowed to cool to room temperature. The solution retained its green color, and the product was purified by semipreparative HPLC using MeCN/H_2O gradient elution protocol (see General section above) to give 1.2 mg (0.77 μmol, 49% yield) of **6**. MS/ESI: 1564 $[M]^+$.

Similarly, compound **7** was prepared by adding $InCl_3$ (18.5 mg, 16 μmol) to a MeCN/water solution of **4** (15 mg, 13 μmol). The mixture was purified by semipreparative HPLC to obtain 2 mg (13%) of **7**. MS/ESI: 1221 $[M]^+$.

Radiolabeling of MOMIAs with ^{111}In (9). $^{111}InCl_3$ was purchased from Mallinckrodt, Inc. Compound **6** was radiolabeled by incubating 5.0 μg of it with 50 μCi of ^{111}In in a 25 mM NaOAc and 12.5 mM sodium ascorbate buffer. The pH was adjusted to 4.9 with 0.1 M HCl to give a total volume of 55 μL. The mixture was heated at 80 °C for 30 min. An equal volume of PBS containing 5% EtOH was added, and the solution was allowed to cool to room temperature. Visual inspection shows that it retained its green coloration after 24 h. Radio-TLC showed that the labeling was successful. An aliquot was placed in a tube and imaged with a Kodak Multistation Imager.

Stability of ^{115}In−DOTA−Gly−Ser−Gly−Lys(ε-Cypate)−Ahx−NH_2 (8). The stability of the representative compound was conducted using HPLC (Waters, Co.) by monitoring the signal intensity at 700 nm from a dual UV-vis absorbance detector. The 700 nm wavelength was chosen to avoid otherwise strong overlapping of signals between the serum and the compound **8** at lower wavelengths. HPLC analyses were conducted using Vydac C-18 polymeric reverse phase column (218TP, 5 μm, 300 Å, 4.6 mm × 100 mm) with water/MeCN−0.1% TFA mobile phase with a gradient from 10 to 95% MeCN in water in 14 min.

Approximately 0.2 mg of the lyophilized complex was dissolved first in 20 μL of DMSO and diluted with 80 μL of water. The solution was split into two vials: 60 μL was added into 940 μL of human serum in a 2 mL vial, and 30 μL was diluted with 470 μL of water (MQ). The vial with serum was capped and placed in an incubator at 37 °C. Aliquots of 60 μL were analyzed without dilution at different time points. The vial without serum was used as a reference standard. In addition, a standard serum solution was prepared by mixing 12 μL of DMSO, 48 μL of water (MQ), and 940 μL of human serum.

Biodistribution of MOMIAs by Fluorescence Method. All in vivo studies were performed in compliance with the Washington University Animal Study Committee's requirements for the care and use of laboratory animals in research. Nude mice were anesthetized with xylazine/ketamine cocktail via intraperitoneal injection. The samples were dissolved in 20% aqueous DMSO, and animals were injected via the lateral tail vein with doses of 0.3 μmol/kg body weight in a volume of 100 μL for each mouse. We used a noninvasive in vivo continuous wave fluorescence imaging apparatus to visualize the distribution and preferential tissue uptake of the MOMIAs.

Light from two laser diodes of nominal wavelength 780 nm and nominal power of 50 mW was launched into a fiber optic bundle. We used two laser diodes to produce as much uniform illumination of the whole animal or organ parts as possible. A defocusing lens in position after the bundle expanded the beam such that the whole mouse was illuminated. A Photometrics CCD camera (16 bit, 1024 × 1024 pixels, back illuminated, thermoelectric Peltier cooled with forced air) was used to capture the emitted photons. An interference filter (830 nm) was mounted in front of the CCD camera input lens such that only emitted fluorescent light from the contrast agent was imaged. Real-time acquisition, display, and data processing software (WinView/32) were used to obtain the optical imaging data.

At 24 h postinjection of the probe, the mice were euthanized and some organ parts were excised and rinsed with water. The tissues were placed under the CCD camera and the fluorescence emission from each organ was measured after excitation with the 780 nm laser sources. Tissue parts, instead of whole organs, were used to minimize problems associated with depth-dependent nonlinear fluorescence emission. A statistical program in the WinView package was used to estimate the mean fluorescence intensity per organ part.

[1] 6-Amino hexanoic acid.

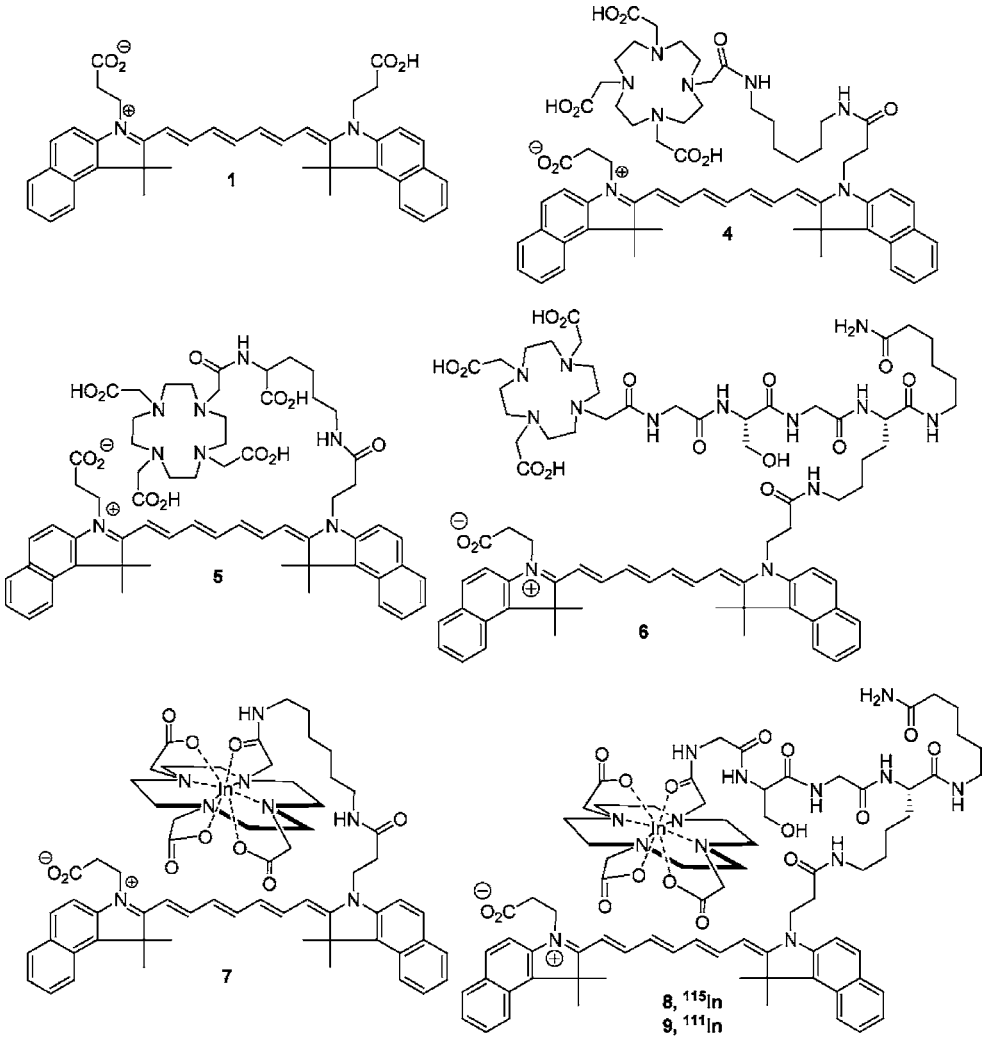

Figure 1. Structures of cypate, DOTA−cypate, and In−DOTA−cypate derivatives.

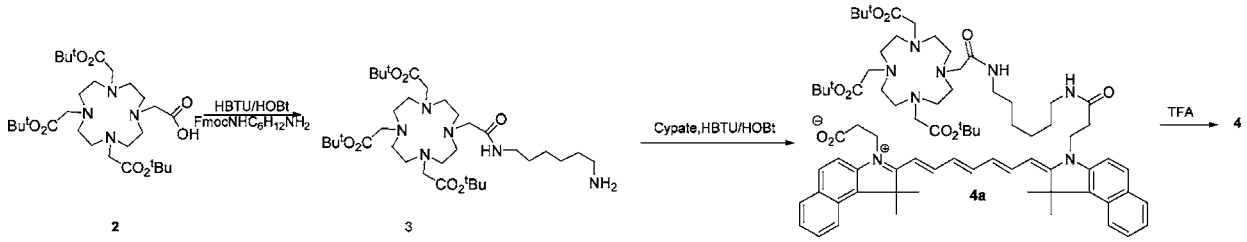
Scheme 1. Synthesis of DOTA−Ahx−Cypate MOMIA by Solution Method



Biodistribution of MOMIAs by γ-Counts Method. The mice were anesthetized as described above and injected with 10 μCi (100 μL) of ^{111}In labeled **9** via the lateral tail vein. Mice were imaged 1, 4, and 24 h postinjection with a Kodak Multistation Imager. At 24 h postinjection, we sacrificed the animals and weighed the organ parts and the activity/g organ was determined with a Packard Cobra II γ-counter.

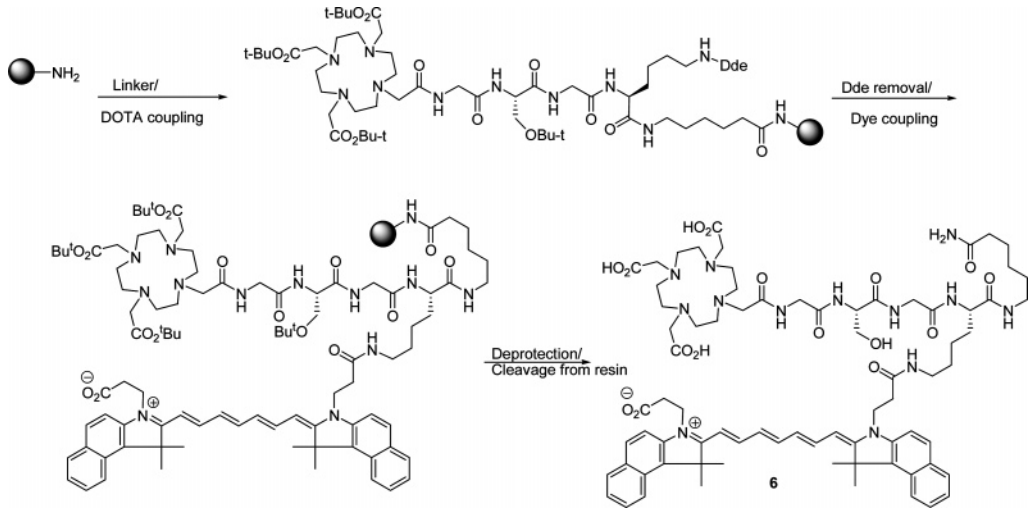
RESULTS AND DISCUSSION

The primary focus of this study was to develop novel optical−radionuclear MOMIAs that could provide complementary diagnostic information, minimize patient's exposure to ionizing radiation, simplify image reconstruction for optical diffusion tomography, and provide a means to monitor continuously the status of pathologic conditions by optical methods after the decay of a short-lived radioactive component. The use of NIR fluorescent dye for the optical signal allows for deep tissue imaging because absorption of light by tissue in this region is low, thereby allowing NIR light to penetrate several centimeters (*20*, *21*). We used ^{115}In isotope for nonradionuclear related studies to avoid contaminating routine laboratory instruments with radioactivity.

Synthesis. The MOMIAs (Figure 1) were synthesized by either solid phase or solution methods, based on the target compounds prepared.

Synthesis of MOMIAs by Solution Method. The procedure for the synthesis of **4** is summarized in Scheme 1. Both DOTA and cypate possess multiple carboxylic acid groups, and linkage of the two components via amide bonds with a diamino group would result in an intractable mixture of products. To improve reaction selectivity, we first reacted an orthogonally protected tri-*tert*-butyl DOTA (**2**) with a mono-Fmoc−1,6-hexyldiamine, followed by purification of the crude product on a silica gel column.

Scheme 2. Solid Phase Approach to the Synthesis of MOMIAs



It turned out that the Fmoc derivative was unstable during column purification, and compound **3** was isolated as the major product. This protocol, therefore, results in the direct synthesis of monoamino derivative of tri-*tert*-butyl DOTA. Through a careful control of the reaction conditions, compound **3** reacted with only one of the two carboxylic acid groups of cypate to afford **4a**. Subsequent treatment of **4a** with TFA gave the desired compound **4** in good yield. However, the intermediate Fmoc-protected DOTA−amine was unstable under ambient conditions and its purification was tedious. Consequently, we evaluated the preparation of MOMIAs by solid phase method (*17*, *18*).

Synthesis of MOMIAs by Solid Phase Method. Syntheses of MOMIAs **5** and **6** were conducted on solid support as summarized in Scheme 2 for the synthesis of **6**. The use of orthogonally protected amino acid strategy enabled us to selectively couple DOTA and cypate without interference from each other. Cleavage of the product from resin using TFA and subsequent workup afforded the desired compounds.

Labeling MOMIAs with Indium. The stability of the metal complexes of MOMIAs is a critical criterion for the use of DOTA−cypate conjugates for multimodal imaging. For this reason, we labeled the MOMIAs with both radioactive (^{111}In) and nonradioactive (^{115}In) isotopes. The radiolabeled analogues were used to evaluate the stability of the chelates in buffers and to perform the in vivo imaging studies. We used the nonradioactive chelate to monitor the HPLC stability of MOMIAs in serum by fluorescence assay and the effects of the metal complex on the fluorescence intensity relative to the unlabeled MOMIAs. The compounds were stable under HPLC purification conditions. Interestingly, the chelated and nonchelated MOMIAs had similar retention times when they were coinjected in the column. This suggests that the chelation of MOMIAs with indium has little effect on the hydrophilicity of the compounds. Mass spectral analysis of the purified MOMIA showed that the metal chelation was successful.

Spectral Properties of MOMIAs. An important consideration in designing MOMIAs is to ensure that the fluorescence emission of the compounds is not quenched after metal chelation. Consequently, we compared the spectral properties of the labeled and nonlabeled MOMIAs. The spectra of **6** and its In−DOTA complex **8** are typical of the indium-labeled MOMIAs. Both compounds are soluble in water, making it possible to prepare metal

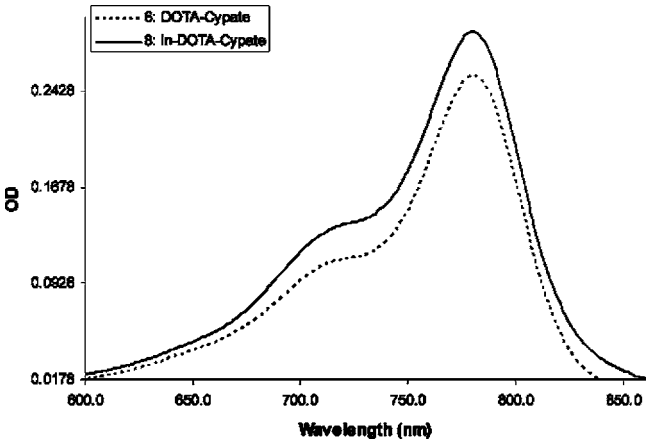


Figure 2. Absorption spectral properties of compounds **6** and **8** in water. The optical density and molar absorptivity of In chelate **8** are higher than those of the nonchelate analogue **6** at 1.8 μM.

complexes and study their spectral properties in aqueous medium. Equimolar concentrations (1.8 μM) of pure (>99% HPLC/MS purity) chelated and nonchelated compounds were prepared in deionized water. The absorption spectra of the compounds are shown in Figure 2. Interestingly, coordination of the metal increased the absorbance of **8** as compared with the nonchelated **6**. This spectral observation was confirmed by analysis of the molar absorptivity of both compounds, which showed a 16% increase in the molar absorptivity of **8** (ϵ 1.67 $\times$ 10^5 M^{-1} cm^{-1}) relative to the nonchelated **6** (ϵ 1.43 $\times$ 10^5 M^{-1} cm^{-1}).

Similarly, we evaluated the fluorescence emission of the compounds at an equimolar concentration of 1.8 μM at 760 and 780 nm excitation wavelengths. The full emission spectra at 760 nm excitation are shown in Figure 3, and the changes in their relative fluorescence intensity at 805 nm emission wavelength are shown in Table 1. This observation is consistent with the established effects of metals on the fluorescence properties of dyes (*22*, *23*). Particularly, this study suggests that radioisotopes of trivalent metals such as indium could play a dual role of providing γ-emissions for radionuclear imaging and augmenting the fluorescent intensity of molecular probes that would increase the sensitivity of detecting their distribution in tissues. Another interesting implication of the observed increase in fluorescence intensity after chelation of indium is that the changes

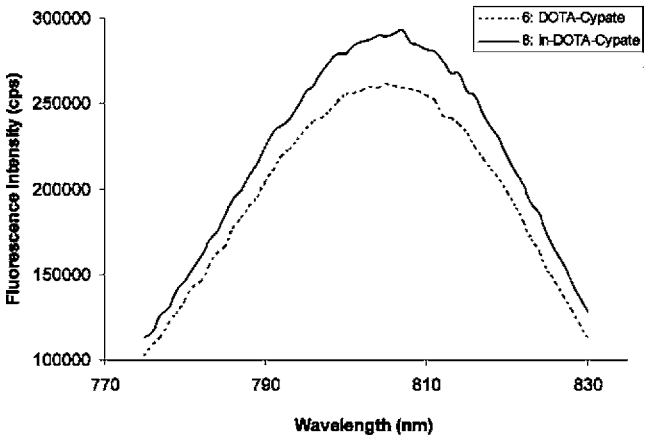

Figure 3. Fluorescence spectra of **6** (DOTA−cypate) and **8** (In−DOTA−cypate complex) in water at 760 nm excitation.

Table 1. Fluorescence Intensities of 6 and 8 at 760 and 780 nm Excitation Monitored at 805 nm Emission

excitation wavelength (nm)	fluorescence intensity of **6** at 805 nm/10^5 (cps)[a]	fluorescence intensity of **8** at 805 nm/10^5 (cps)	increase in fluorescence intensity (%)

780	2.29	2.42	6

[a] cps, photon counts per second.

are wavelength-dependent (Table 1). Conceptually, such wavelength dependency could be used for ratiometric imaging at two or more different wavelengths to increase the specificity of optical imaging methods.

Stability in Biological Media. The stability study of **8** was conducted by monitoring the signals from a dual UV absorbance detector at 254 and 700 nm on an HPLC system. At 254 nm, the signals from serum and **8** (retention time 8.4 min) strongly overlapped with prevailing signals from serum proteins. At 700 nm, the overlap was much weaker and the absorbance from **8** was dominant. Figure 4a,b shows the HPLC spectra of **8** and serum, which were also used as reference standards. Degradation was typically manifested by a gradual increase of one or more peaks as a function of time.

The indium complex showed remarkable hydrolytic stability in human serum. Taken within the first 2.5 h, the chromatograms were practically indistinguishable (Figure 5). Even after 48 h, no significant variations were observed in indium complex signal intensity (Figure 6), although some changes are noticeable between 1 and 6 min of the retention time.

Radio-TLC analyses (for radioactive indium MOMIA) showed that the compounds are stable in buffers up to 4 h postpreparation of the materials. The biodistribution studies did not show uptake of the MOMIAs in bone tissues, which is a useful index of chelate stability in vivo. Therefore, the MOMIAs are stable in serum and biological buffers.

The ability to monitor stability profile of the probes at 700 nm is advantageous because only the NIR probes absorb significantly in this spectral region, thereby eliminating the need to isolate the compounds before analysis. The data are reproducible with high precision because specific volumes from the same sample can be injected and the sample absorbance at the onset of the experiment acts as reference throughout the study.

Biodistribution of MOMIAs in Mice. *Optical Method.* Injection of MOMIAs into the lateral veins of mice and monitoring the distribution of the probe as a function of time showed that at 24 h postinjection, the molecular

probe was retained primarily in the liver and kidneys (Figure 7). The relative fluorescence intensity was obtained as the average intensity in the organs of interest. Expectedly, the more hydrophobic **4** was retained in many normal tissues as compared with **6**, which cleared from all organs at 24 h postinjection, except the liver and kidneys. For practical purposes, rapid clearance of molecular probes from nontarget tissues is highly desirable during imaging studies to minimize background signals from these probes. As a result, detection of high fluorescence in nonexcretory organs would provide important diagnostic information within a short period postinjection of the probe. This result suggests that compound **6** is suitable for designing target specific molecular probes for multimodal imaging.

[a] Fluorescence intensity was initially normalized relative to blood.

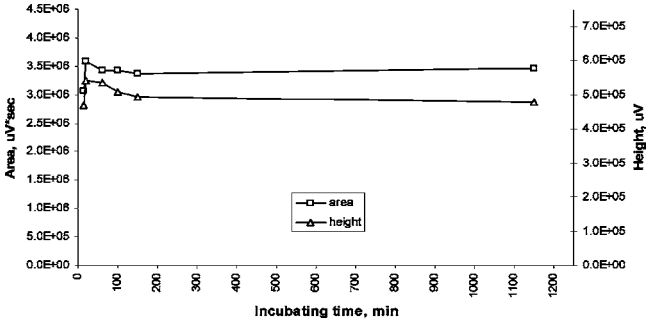

Figure 6. Quantitative results obtained by integration of area and height measurements at 8.3 min retention time shows the stability of indium complex **8**. The trace was obtained from a single test sample.

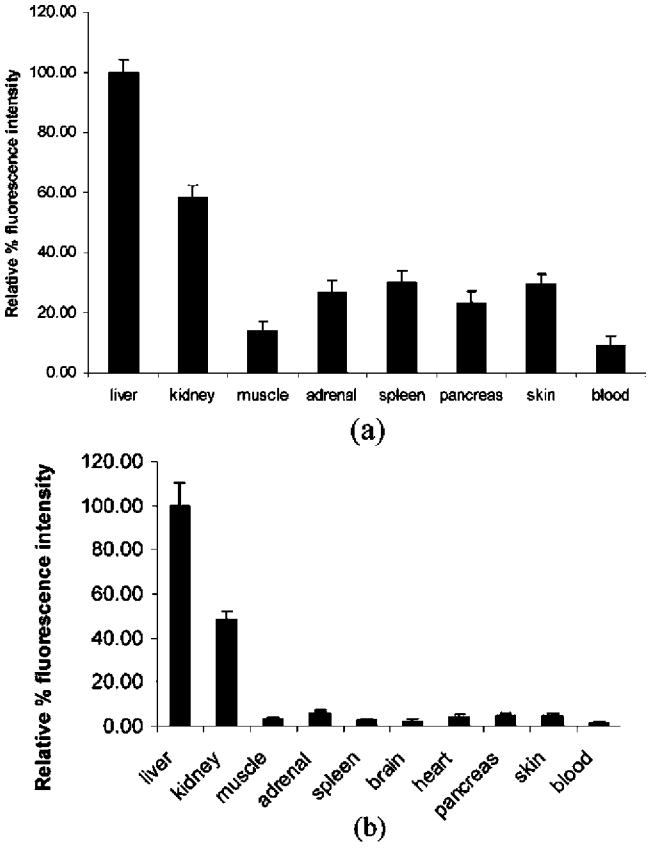

Figure 7. Distribution of (a) **4** and (b) **6** in nude mice at 24 h postinjection. Fluorescence intensity normalized to blood.

The ratio of the fluorescence intensity at 24 h relative to blood is shown in Table 2, indicating that most of the probe cleared from the body via urine (injected dose is 0.3 μmol/kg body weight of mouse; collected urine samples fluoresced). Interestingly, the fluorescence intensity of compound **6** in the brain was nearly twice relative to blood. Although this intensity is low as compared with the liver, it raises the possibility of optimizing compound **6** for brain imaging. Designing compounds that can cross the blood−brain barrier remains a challenge for imaging the brain with nonradionuclide imaging agents because

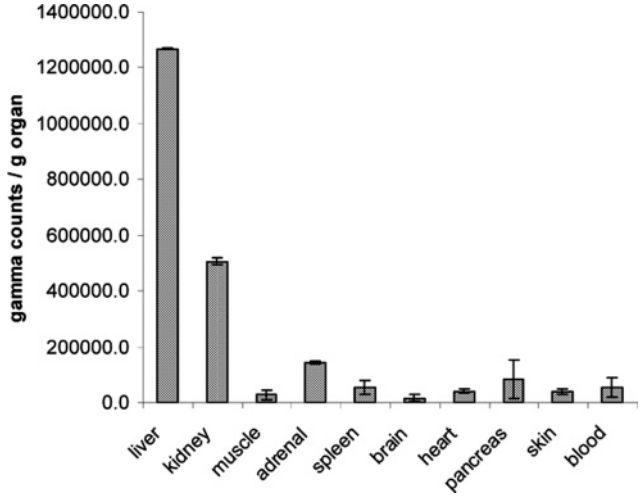

Figure 8. Biodistribution of **9** obtained by γ-counting method at 24 h postinjection.

Table 3. Distribution of 9 in Mice at 24 h Postinjection

of the typical low molecular weight and nonionic molecule requirements. However, a closer look at the structure of **6** shows that the molecule can adopt a neutral configuration where all of the four carboxylic acid groups are neutralized by the tertiary amino groups. Subsequent transport across the blood−brain barrier could be mediated by phosphorylation of the serine hydroxyl group. Further studies will be needed to explore this possibility.

Radionuclear Method. γ-Emitters are routinely used for radionuclear imaging by planar or 3D SPECT techniques (*24*, *25*). Our interest in γ-scintigraphy is due to its simplicity and high sensitivity. Unlike MR and CT imaging methods that require local tissue concentration of 10^{-4} (gadolinium or manganese) and 10^{-2} M (iodine or barium) of contrast agents for diagnostic imaging, γ-scintigraphy detects about 10^{-10} M of radiopharmaceuticals (^{111}In or ^{99m}Tc) in tissues (*1*, *10*). This sensitivity is improved in SPECT, which also has a higher anatomical resolution. The detection sensitivity of optical methods falls with the range of γ-scintigraphy, depending on the optical technique employed.

The radioactive indium was prepared as described in the Materials and Methods section. We injected 10 μCi of the ^{111}In−MOMIA (**9**) and conducted the scintigraphy on a Kodak multistation imager at 1, 4, and 24 h postinjection. At 24 h postinjection, we sacrificed the animals and weighed the organ parts and the activity was determined with a γ-counter. Figure 8 shows the biodistribution of the γ-counts normalized per gram organ, and Table 3 depicts the ratios of the γ-counts normalized to 1 g of blood. The biodistribution trend observed is similar to that obtained by the fluorescence intensity method, as summarized in Figure 9. The reason for the observed slight differences in the signal intensities

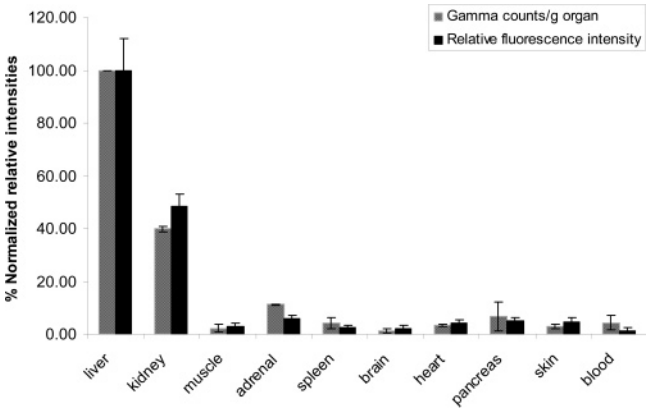

Figure 9. Comparative distribution of **8** and **9** obtained by γ- and fluorescence emission methods, respectively, at 24 postinjection of the molecular probes.

by both methods in some organs such as the kigneys and adrenal glands is probably due to interanimal biological variations.

CONCLUSION

We successfully prepared MOMIAs in good yields and successfully labeled them with radioactive and nonradioactive indium. As shown above, indium chelates of MOMIAs either retained or increased their fluorescence emission relative to the nonchelated MOMIAs. We also showed that the chelated and nonchelated MOMIAs are exceptionally stable in serum up to 48 h postincubation at 37 °C. The biodistribution studies by optical and radionuclear methods showed similar trends, indicating that both fluorescence and γ-emissions emanated from the same source. These findings demonstrate the feasibility of using MOMIA strategy to image tissues by combined optical and nuclear methods.

Protamine as an Efficient Membrane-Translocating Peptide

Fred Reynolds, Ralph Weissleder, and Lee Josephson*

Center for Molecular Imaging Research, Massachusetts General Hospital/Harvard Medical School, Boston, Massachusetts 02129. Received May 19, 2005; Revised Manuscript Received August 11, 2005

Protamine, a mixture of positively charged proteins from salmon roe used in diverse pharmaceutical applications, was reacted with the *N*-hydroxysuccinimide ester of tetramethylrhodamine to yield tetramethylrhodamine-labeled protamines (Pro(Rh)) containing one mole of fluorochrome per mole of protein. The internalization of tetramethylrhodamine-labeled protamine (Pro(Rh)) and the fluorescein-labeled tat peptide (Tat(Fl)) showed a similar dependence on time and concentration. Pro(Rh) and Tat(Fl) showed strong nuclear localizations, evident with both live cells and fixed cells costained with DAPI, a nuclear stain. The loss of fluorescence when cells were loaded with Pro(Rh) or Tat(Fl) was similar, further supporting a strong similarity between these two materials. Finally, when Pro(Ph) was covalently attached to the amino-CLIO nanoparticle, the cellular uptake of the nanoparticle was greatly enhanced. All experiments were performed with HeLa and CaCo-2 cells with similar results. These observations imply that protamine, a protein in regular clinical use, might be used for the design of novel membrane translocating/nuclear localizing pharmaceuticals whose development was initiated with other membrane-translocating peptides. In addition, the fluorescent protamines developed here might be used to further our understanding of this important pharmaceutical.

INTRODUCTION

Protamine, a mixture of proteins extracted from salmon roe, is in regular clinical use as an excipient in insulin formulations (*1*, *2*) and to reverse the anticoagulant properties of heparin (*3*). The biological role of protamine is to bind DNA and to provide a highly compact configuration of chromatin in the nucleus of the sperm (*4*, *5*). Protamine is arginine rich, a feature it shares with some viral proteins which utilize arginine rich sequences of amino acids to provide membrane-translocating and/or nuclear-localizing activities (*6*), see Table 1. We noted that protamine was not only arginine rich, but in common with viral translocation sequences had short sequences consisting of seven or more arginine residues (6). In addition, protamine has a single reactive amine at the N-terminus and a single carboxyl group at the C-terminus, a situation that might facilitate site-specific modification and the design of protamine-based probes.

We therefore investigated the membrane-translocating activity of protamine to add to the understanding of this important pharmaceutical and because protamine might be superior to other membrane-translocating peptides for drug delivery applications due to its ease of modification, low cost, availability, sterility, and GMP manufacture. Synthetic polyarginyl peptides have been exploited to provide improved forms of cyclosporine (*7*), improved radiotherapeutic agents (*8*), and improved methods of intracellular delivery of DNA and enzymes (*9*−*11*). Using fluorescent protamines, we show that protamine has a membrane-translocating activity comparable to that of the HIV[1] tat peptide and therefore might be an ideal carrier for drug delivery applications. Studies following the intracellular disposition of fluorescent protamines in vivo may prove helpful in understanding the fate of this widely used pharmaceutical after injection.

MATERIALS AND METHODS

The *N*-hydroxysuccinimide esters of 5-carboxytetramethylrhodamine and 5-carboxyfluorescein were from Molecular Probes (Eugene, OR). Protamine sulfate was from American Pharmaceutical Partners (Schaumburg, IL). Carbodiimide (1-ethyl-3(3′dimethylaminopropyl)carbodiimide) was from Novabicohem (LaJolla, CA). The Tat(Fl) peptide, see Table 1, was synthesized on an Advanced Chemtech Apex 396 peptide synthesizer (Advanced Chemtech, Louisville, KY) as described (*12*), except that an *N*-hydroxysuccinimide ester of fluorescein rather than fluorescein isothiocyanate was used. Tat(Fl)-CLIO was prepared as described (*13*).

To synthesize fluorescent protamines, 0.5 mg of the *N*-hydroxysuccinimide ester of either tetramethylrhodamine or fluorescein in 100 μL of DMSO was added to 5 mg of protamine (in 500 μL of 0.85 M NaCl as supplied) and 100 μL of PBS, and allowed to react overnight at 4°C. Peptides were purified using a reverse phase C18 column with acetonitrile/water gradients, and products were characterized by MALDI-MS. The molecular weights (M + 1) of the fluorescent protamines we synthesized were within 1 Da of the expected values (Table 1). Fluorescein-labeled protamine is denoted Pro(Fl), and tetramethylrhodamine-labeled protamine is denoted Pro(Rh).

To synthesize protamine-derivatized nanoparticles, amino-CLIO (*14*) was first reacted with Cy5.5 to yield CLIO(Cy5.5) as described (*15*). Unreacted Cy5.5 was removed by Sephadex G-25 gel filtration and Cy5.5 concentration determined spectrophotometrically (absorption at 675 nm, extinction coefficient of 250 000 L/mol-cm). Since there are 200−240 amines per 8000 Fe with the CLIO nanoparticle (*16*, *17*), and 8.0 were

[a] Protamine is a mixture of four peptides, protamines 1, 2, 3, and 4. Also shown are the arginyl rich sequences of peptides derived from viral genes that show a strong nuclear localizing activity (*6*). Numbers in parentheses are the numbers of arginines and total amino acids.

consumed by reaction with Cy5.5, the remaining amines were available to react with the C-terminal carboxyl group of Pro(Rh). The CLIO(Cy5.5) nanoparticle (1 mg Fe, 5.73 mg Fe/mL) was added to 200 μL of Pro(Ph) (2.65 mM). Eight milligrams of 1-ethyl-3(3′dimethyl-aminopropyl)carbodiimide in 1 mL of MES buffer (0.1 M, pH 4.9) were added, the mixture allowed to sit overnight, and unreacted Pro(Rh) was removed by gel filtration on Sephadex G50. There were 28 Pro(Rh) attached per 8000 Fe atoms determined from tetramethylrhodamine absorption (565 nm, extinction coefficient of 91 000 L/mol-cm). The nanoparticle is denoted Pro(Rh)-CLIO(Cy5.5).

CaCo-2 and HeLa cells were from ATCC (Manassas, VA) and grown according to ATCC specifications, except for the addition of penicillin/streptomycin. Cell culture reagents were from CellGrow (Herndon, VA).

Cell uptake of peptides or nanoparticles was determined using 24-well plates (250 μL media/well). Cells were incubated with peptide or nanoparticle for the indicated times and concentrations. Cells were washed three times with PBS and lysed (0.1% Triton X-100 μL in PBS), and fluorescence was determined on a plate reader (Molecular Devices, Sunnyvale, CA) (Figure 3). Cells were trypsinized for FACS measurements (FACS Caliber, Becton Dickinson, San Jose, CA) (Figure 1C). Cell counts were made with a Beckman Coulter Z1 cell counter (San Jose, CA). Amounts of cell associated peptide were determined by use of standards of fluorescent peptides.

To obtain the time course of fluorescence loss (Figure 4), cells were allowed to internalize peptide, washed, and incubated with media for varying times. Cell-associated fluorescence was determined after trypsinization and FACS. To demonstrate the uptake of nanoparticles (Figure 5), cells were trypsinized and cell-associated fluorescence determined by FACS. A portion of cells was spun down and lysed, and the iron uptake was obtained by calibration with fluorescent standards of each nanoparticle.

For microscopy, cells were grown on glass slides (Fisher Scientific, Pittsburgh, PA), exposed to 5 μM peptide for 4 h, and washed three times with PBS. Unfixed cells (Figure 1) were examined using a Nikon Eclipse TE2000-S epifluorescence microscope with long focal length optics (Torrance, CA). Cells were also fixed with 70% ethanol at 4 C for 90 min, washed with PBS, mounted using Vector Shield with DAPI (Vector Laboratories, Burlingame, CA), and examined by epifluorescence (Figure 2). Fluorescence microscopy used a Nikon Eclipse 80i epifluorescence microscope (Torrance, CA).

RESULTS

Protamine is a mixture of four proteins listed in the order of their peak height determined by mass spectrometry in Table 1. The mass of protamine 1 is that of the protamine denoted AI, gene accession number P02327 (NCBI-protein database). The mass of protamine 2 is that of the protamine denoted AII, gene accession number B02669 (NCBI-protein database). The composition of protamine 3 and protamine 4 is not known. Also shown are the arginyl rich sequences derived from viral genes that show a strong nuclear localizing activity (*6*) and membrane-translocating sequence of the tat peptide (*18*). Numbers in parentheses are the number of arginines and total number of amino acids for the peptide. Both protamine and viral-translocating sequences share an overall arginine rich character that consists of seven or more arginines.

Fluorescent protamines were synthesized by reacting the *N*-hydroxysuccinimidyl esters of 5-carboxytetramethylrhodamine and 5-carboxyfluorescein with protamine, to produce proteins containing a single fluoro-

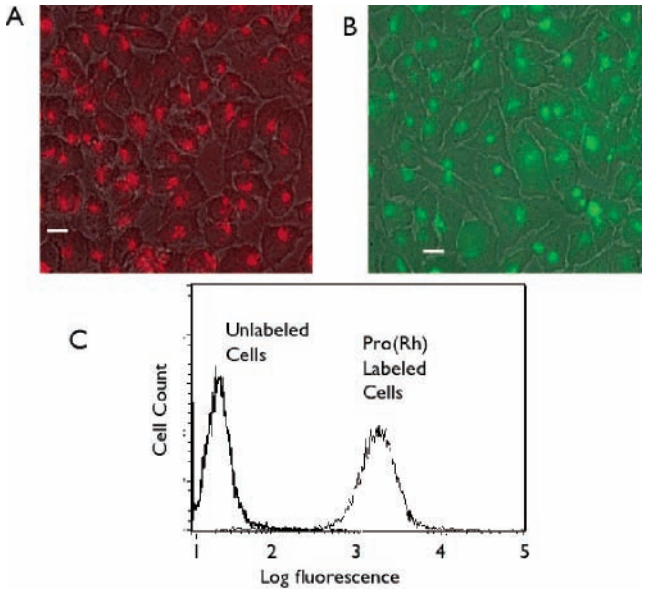

Figure 1. Internalization of rhodamine-labeled protamine and fluorescein-labeled tat peptide. HeLa cells were incubated (2 μM, 4 h) with either Pro(Rh) (A) or Tat(Fl) (B). Phase contrast images on unfixed cells were taken, and images from rhodamine channel (A) or fluorescein channel (B) were superimposed. Scale marker is 10 μm. (C) HeLa cells labeled with Pro(Ph) as above were trypsinized and analyzed by FACS.

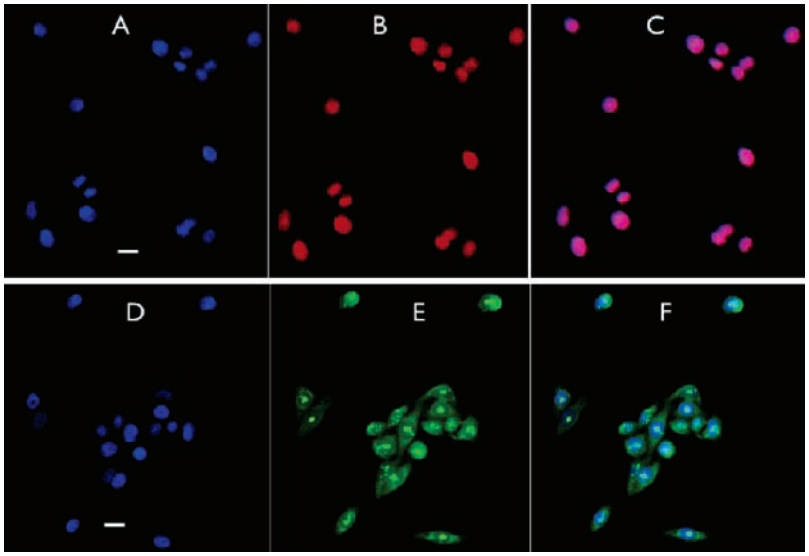

Figure 2. Nuclear localization of protamine or tat peptide. Cells were incubated with Pro(Rh) (A, B, C) or Tat(Fl) (D, E, F) at 2 μM fluorochrome for 4 h. Cells were washed, fixed, and stained with DAPI, a nuclear stain. (A and D) Cell nuclei shown by the DAPI (ultraviolet) channel. (B) Pro(Rh) visualized in rhodamine channel. (C) Overlay of parts A and B. (E) Tat(Fl) visualized in the fluorescein channel. (F) Overlay of parts D and E. Scale marker is 10 μm.

chrome as shown in Table 1. The site of attachment is presumed to be N-terminal proline residue, since none of the other amino acids have a reactive primary amine. The amines of the guanidinium group of arginine are not chemically reactive (*19*). After reaction with 5-carboxytetramethylrhodamine, the four protamines exhibited an increase in molecular weight consistent with the addition of a residue weight of tetramethylrhodamine ($C_{25}H_{20}O_4$, 412.45 Da). Similarly, after reaction with 5-carboxyfluorescein, four proteins were identified with an increase in molecular weight consistent with the addition of a residue of 5-carboxyfluorescein ($C_{21}H_{10}O_6$, 358.3 Da). The molecular weights obtained by reaction of protamine 1 with tetramethylrhodamine or fluorescein are given in Table 1. Protamine labeled with tetramethylrhodamine is denoted Pro(Rh), fluorescein-labeled protamine is denoted Pro(Fl), and fluorescein-labeled tat peptide is denoted Tat(Fl).

The uptake of Pro(Rh) and Tat(Fl) by HeLa cells is shown in Figure 1A and B, respectively after 4 h of incubation with each peptide and after cells were washed with PBS (three times) to remove any loosely adsorbed peptide. Phase contrast images and fluorescence micrographs in the rhodamine channel were obtained for cells exposed to Pro(Rh) and the images superimposed as shown in part A. Under these conditions, an intense fluorescence was seen in the center of the cell, which appeared to represent a nuclear accumulation as is discussed further below. Fluorescence was not associated with the cell membrane or in a punctate pattern in the cytoplasm typical of endosomal accumulation. A similar pattern was seen when HeLa cells were incubated with the Tat(Fl) peptide and the fluorescence from the fluorescein channel superimposed on phase contrast images (B). Pro(Rh)-treated HeLa cells were then trypsinized and the distribution of fluorescence obtained by FACS, as shown in Figure 1C. Pro(Rh) uniformly labeled cells in a manner to that seen with Tat(Fl) labeling; see for example Figure 2 of ref 15. All experiments in this report were performed on HeLa cells and CaCo-2 cells, with similar results, an example of which is shown in Figure 3.

To confirm that fluorescence was nuclear, the nuclei of cells incubated with Pro(Rh) or Tat(Fl) were stained with the nuclear stain DAPI. Figures 2A and 2D show the well-defined nuclei visualized as the fluorescence from DAPI nuclear stain. Figure 2B shows the tetramethylrhodamine fluorescence from cells incubated with Pro(Ph), which, based on the overlay, appeared to be nuclear (Figure 2C). Figure 2D shows the result obtained when cells were incubated with Tat(Fl) (fluorescein channel), which, based on the overlay with the DAPI stain, again appeared to be nuclear (Figure 2E). Thus, Rh(Pro) was internalized by cells and showed a nuclear accumulation in a manner similar to Tat(Fl).

We next examined the time course of internalization of the fluorescent protamines (Pro(Rh) and Pro(Fl)) and compared it with tat peptide (Tat(Fl)) as a function of time (Figure 3A) and concentration (Figure 3B). The internalization of Pro(Rh) was complete within 1 h and did not show saturation behavior with respect to concentration.

Previous studies with arginine rich peptides have shown internalization within 1 h and either a linear dependence of uptake on peptide concentration or some evidence of saturation at high peptide concentrations (*6*, *20*, *21*). The internalization of protamine was strongly dependent on the attached fluorochrome, with the uptake of Pro(Rh) being far greater than Pro(Fl), which may reflect an interaction between the negative charge on fluorescein and the positive charges on protamine. Data comparing the uptake of Pro(Ph) with HeLa cells and CaCo-2 cells is shown as example of the data we obtained showing the similar behavior of all proteins and peptides with these two cell types in all experiments. Data shown in Figure 3 is the cell-associated fluorescence measured after lysis and determination of fluorescence with a microtiter plate reader and standards, a procedure which permits expression of results in moles per cell. Trypsinization and FACS yielded similar relationships about the time course and amounts of uptake for the three peptides examined (data not shown). Thus, the kinetics of uptake and relative amounts of cell-associated Tat(Fl) and Pro(Ph) were similar when fluorescence was determined by lysis of adherent cells or with trypsinization and FACS (data not shown).

We next examined the loss of cell-associated fluorescence after HeLa cells were loaded with fluorescent

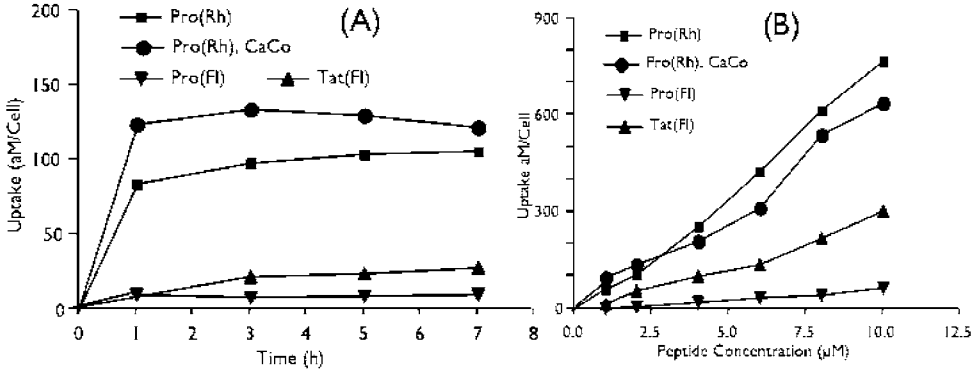

Figure 3. Uptake of protamine and tat peptide by HeLa cells. (A) Uptake of rhodamine protamine (Pro(Rh)) or fluorescein protamine (Pro(Fl)) and tat peptide (Tat(Fl)) as a function of time at 2 μM fluorochrome. (B) Uptake of Pro(Rh), Pro(Fl)), and Tat(Fl) as a function of peptide concentration at 4 h. Experiments were with HeLa cells except where indicated. Total cell-associated fluorescence was obtained after lysis.

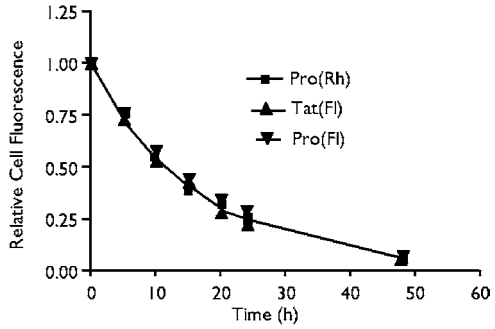

Figure 4. Loss of fluorescence after loading with protamine and tat peptide. HeLa cells were loaded with fluorescent protamines or tat peptide (2 μM, 4 h), washed, and incubated in peptide and protein free media for the indicated time. Cells were trypsinized, and fluorescence was determined by FACS.

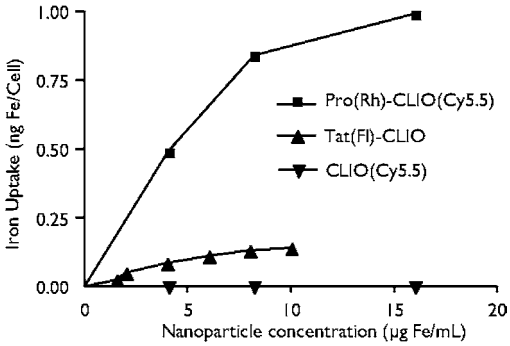

Figure 5. Uptake of protamine nanoparticles by HeLa Cells. Pro(Rh) was conjugated to the amino-CLIO nanoparticle to obtain Pro(Rh)CLIO(Cy5.5). Incubation was for 4 h. Cells were trypsinized, and fluorescence was determined by FACS.

protamines or Tat(Fl) as shown in Figure 4. The loss of fluorescence for Pro(Rh) was fit to single-exponential decay model and yielded half-lives of 12.2 h (Pro(Rh), 10.8 h (Tat(Fl)), and 13.0 h (Pro(Fl). All fits had values of r^2 greater than 0.99. Thus, the loss of cell-associated fluorescence was similar regardless of whether cells were loaded with either fluorescent protamine or the tat peptide.

A feature of the tat peptide is that when it is conjugated to enzymes, nanoparticles, or liposomes, it induces internalization and/or nuclear localization of these macromolecular or supramolecular materials (*22*−*24*). To examine whether protamine could act similarly, we attached Pro(Rh) to an amino-CLIO nanoparticle labeled with Cy5.5, by using a carbodiimide to react the C-terminal carboxyl group (Table 1) with the primary amine of the nanoparticle. The resulting nanoparticles are denoted Pro(Rh)-CLIO(Cy5.5) and CLIO(Cy5.5). As shown in Figure 5, polymer-coated nanoparticles such as CLIO(Cy5.5) are not significantly internalized by nonphagocytic cells such as HeLa cells. Conjugation of the Tat(Fl) peptide greatly increases nanoparticle internalization, an effect noted earlier (*13*, *22*). The attachment of protamine yielded a nanoparticle, Pro(Rh)-CLIO-(Cy5.5), that was internalized at 4−5 times higher levels than that of the nanoparticle with the tat peptide attached, Tat(Fl)-CLIO. Although the cellular uptake of CLIO(Cy5.5) was too low to quantitate in these fluorescence-based experiments, experiments with radiolabeled nanoparticles have demonstrated that the attachment of the tat peptide induces a 100-fold increase in nanoparticle internalization (*22*). Protamine, like tat peptide, can be conjugated to nanoparticles, and the resulting peptide−nanoparticle conjugate is readily internalized by cells.

DISCUSSION

Our goal was to demonstrate that protamine is an efficient membrane-translocating peptide, a previously unrecognized activity of this protein, by comparing its behavior with that of the tat peptide, a peptide with a well-recognized membrane-translocating activity. When HeLa cells where incubated with either peptide for 4 h, a time chosen to allow intracellular processing of peptides to proceed, both Pro(Rh) and Tat(Fl) showed a clear nuclear localization in living, unfixed cells (Figure 1). Nuclear localization with both peptides was also seen with fixed cells (Figure 2). Both peptides reached a nearly constant level of internalization by the initial time point of 1 h (Figure 3); the rapid kinetics of tat peptide internalization at shorter time points been described in detail elsewhere *(20*, *26)*. The similar disposition of Pro-(Ph) and Tat(Fl) by microscopy and their similar rates of efflux (Figure 4) indicate that both peptides are processed in a similar fashion by HeLa cells. Finally, when Pro(Rh) was attached to the magnetic nanoparticles, the cellular uptake of the nanoparticle was enhanced more than that obtained by conjugation of the tat peptide (Figure 5). The ability of the tat peptide to enhance the internalization of enzymes, liposomes, and other materials when conjugated to them is a characteristic of this peptide (*23*−*25*). Though in early studies the nuclear localization of tat peptide was not dependent on fixation (*18*), more recent studies have reported the tat peptide in cytoplasmic endocytic vesicles after membrane translocation and attributed the earlier nuclear localiza-

tion to the use of fixation procedures (*26*, *27*). In our hands, protamine and tat peptide gave similar images of nuclear localization with fixed and unfixed cells. Regardless of the final resolution of the intracellular fate of internalized tat peptide, the tat peptide is widely accepted as having a membrane-translocating activity (*28*−*31*). Since our data indicate that protamine and tat peptide behaved similarly, we therefore conclude that protamine, like other high arginine-containing peptides, is a membrane-translocating peptide.

Our results indicate that protamine has a membrane-translocating activity and nuclear localizing activity in vitro and suggest that protamine could have these activities in vivo, including after its intramuscular administration in insulin formulations. The development of fluorescent protamines may lead to an improved understanding of a material long used in pharmaceutical applications.

Our results also suggest the possible use of protamine for the design of new membrane-translocating peptide-based diagnostic or therapeutic pharmaceuticals, including some whose development has been initiated with other membrane-translocating peptides. The use of protamine in this fashion would have several advantages. First, the cost of the natural product protamine is currently substantially less than synthetic peptides. Protamine is available as a sterile solution (10 mg/mL, 5 mL) at less than $50/ampule compared to a price of at least $500 for 50 mg of 10 amino acid peptide made by solid-phase synthesis. This decreased cost could stimulate research or the clinical development of protamine-based conjugates. Second, protamine has a long history of use establishing its biological effects and general safety in humans. Finally protamine has only one reactive amine, the N-terminal proline, and, one carboxyl group, the C-terminus, facilitating the single point attachment of fluorochromes or drugs to protein. Our observations suggest that a protamine, a protein in regular parenteral use, might be a convenient raw material for use in the design of novel membrane-translocating/nuclear-localizing pharmaceuticals.

Antigen-Decorated Shell Cross-Linked Nanoparticles: Synthesis, Characterization, and Antibody Interactions

Maisie J. Joralemon,[†] Norah L. Smith,[‡] David Holowka,[‡] Barbara Baird,[‡] and Karen L. Wooley[†,*]

Center for Materials Innovation and Department of Chemistry, Washington University in Saint Louis, One Brookings Drive, Saint Louis, Missouri 63130-4899, and Department of Chemistry and Chemical Biology, Cornell University, Ithaca, New York 14853-1301. Received May 26, 2005

Antigen-decorated shell cross-linked knedel-like nanoparticles (SCKs) were synthesized and studied as multivalent nanoscale surfaces from which antibody-binding units were presented in a manner that was designed to approach virus particle surfaces. The SCK nanostructures were fabricated with control over the number of antigenic groups, from mixed micellization of amphiphilic diblock copolymer building blocks that contained either an antigen (2,4-dinitrophenyl) or an ethylpropionate group at the hydrophilic α-chain terminus. Amphiphilic diblock copolymers were synthesized by atom transfer radical polymerization of *tert*-butyl acrylate and methyl acrylate sequentially from either a 2,4-dinitrophenyl-functionalized initiator or ethyl 2-bromopropionate, followed by selective removal of the *tert*-butyl groups to afford 2,4-dinitrophenyl-poly(acrylic acid)$_{60}$-*b*-poly(methyl acrylate)$_{60}$ (DNP-PAA$_{60}$-*b*-PMA$_{60}$) and poly(acrylic acid)$_{70}$-*b*-poly(methyl acrylate) (PAA$_{70}$-*b*-PMA$_{70}$). Micelles were assembled via addition of water to THF solutions of the polymers in 0:1, 1:1, and 1:0 molar ratios of DNP-PAA$_{60}$-*b*-PMA$_{60}$ to PAA$_{70}$-*b*-PMA$_{70}$, followed by dialysis against water. The acrylic acid groups of the micelle coronas were partially cross-linked (nominally 50%) with 2,2′-(ethylenedioxy)bis-(ethylamine), in the presence of 1-(3′-dimethylaminopropyl)-3-ethylcarbodiimide methiodide. Following extensive dialysis against water, the 0%, 50%, and 100% dinitrophenylated shell cross-linked nanoparticles (DNP-SCKs) were characterized with dynamic light scattering (DLS), transmission electron microscopy (TEM), atomic force microscopy (AFM), differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), infrared and UV−vis spectroscopies, and analytical ultracentrifugation (AU). The surface accessibility and bioavailability of the DNP units upon the DNP-SCKs were investigated by performing quenching titrations of fluorescein-labeled IgE antibody in solution and degranulation of IgE sensitized RBL-2H3 cells. The DNP antigens proved to be surface-available and able to form multivalent bonds with IgE antibodies, causing degranulation.

INTRODUCTION

Since Edward Jenner's successful protection of humans from small pox was achieved by vaccination with cowpox in 1796, many resources have been devoted to devising formulations that train the human body to defend itself against attacks from diseases (*1*). These heroic efforts have grown into the diverse field of immunology, encompassing not only attacks from pathogens, but also allergic responses and autoimmune diseases. Traditionally, synthetic vaccines employ weakened strains of a pathogen to protect humans from disease and often consist of an antigen and a carrier or adjuvant. In some cases, the carrier acts as an adjuvant and has a marked role in the performance of the vaccine, lending improved properties that the antigen alone is unable to achieve. Examples of improved characteristics provided by the carrier include immunostimulation (*2*, *3*), enhanced solubility and circulation (*4*), and the display of multiple copies of the haptenic groups that identify the antigen (*5*).

Nanoparticle platforms that have been employed as antigenic carriers include liposomes and virosomes (*6*−*8*), immune stimulating complexes (ISCOMs) (*9*), chitosan (*10*−*12*), inorganic (*13*−*16*), polymer micelles (*17*, *18*), dendrimers (*19*−*21*), and other types of nanoparticles (*22*−*24*). These nanosized scaffolds hold the ability to impart the advantages of traditional antigen carriers, as well as unique characteristics such as the presentation of targeting ligands (*25*−*30*) and the sequestration and release of guest molecules (i.e. imaging agents and therapeutics) (*31*−*37*). SCKs (*38*−*40*) have demonstrated the ability to display multiple copies of biologically active ligands (*41*−*48*) and sequester guests (*49*−*54*) and could potentially improve the solubility and circulation of small guest molecules in vivo. The employment of SCKs as antigen carriers was, therefore, self-evident and as a fundamental investigation, a well-known antigenic group, 2,4-dinitrophenyl (DNP), was displayed multivalently from shell cross-linked nanoparticles.

This type of multivalent antigen presentation is important for participation in triggering an immune response (*55*−*57*). For example, the allergic response requires cross-linking of IgE that are bound to a receptor on a cell surface (*1*). Specifically upon cross-linking by multivalently displayed DNP, anti-DNP IgE antibodies bound to the high affinity receptor, FcεRI, on the surface of RBL-2H3 mast cells trigger release of histamine and other immune effectors, thus eliciting an immune response (*58*). The 2,4-dinitrophenylated shell cross-linked nanoparticles were designed to display the hapten both multivalently and at a sufficient surface density, based on the fundamental work of Baird et al. (*59*), to cross-

link the IgE antibodies bound to RBLs. In their study it was discovered that a third generation dendrimer was able to elicit an allergic immune response, while earlier generations were not. The density of the antigenic termini on SCKs were, therefore, varied to allow for comparisons of the multivalent binding interactions as a function of surface density for antigen presentation.

EXPERIMENTAL SECTION

Materials. Polymerizations were performed on a double manifold (0.1 mmHg vacuum, 99.99% N_2), with glassware and syringes that were dried in an oven (100 °C) for at least 1 h, and with syringes that were washed with N_2 (3 ×), prior to use. Tetrahydrofuran (99%), methyl acrylate (99%), and *tert*-butyl acrylate (99%) were received from Sigma-Aldrich Company (St. Louis, MO) and distilled from sodium/benzophenone and calcium hydride, respectively, under N_2 prior to use. Sodium bicarbonate (certified ACS) and magnesium sulfate (certified anhydrous) were obtained and used directly from Fisher Scientific (Pittsburgh, PA). All other materials were used as received from Sigma-Aldrich Company. Flash column chromatography was performed using 32−63 D 60 Å silica gel from ICN SiliTech (ICN Biomedicals GmbH, Eschwege, Germany). Spectra/Por membranes (Spectrum Medical Industries, Inc., Laguna Hills, CA) used for dialysis were obtained from Fisher Scientific (Pittsburgh, PA).

Anti-DNP IgE antibodies were purified (*60*) and labeled with FITC as described previously (*61*). RBL-2H3 cells were maintained as described previously (*60*, *62*) and used 3 to 5 days after passage. Dinitrophenylated bovine serum albumin (DNP-BSA) with an average of 16 DNP groups per protein was prepared as previously reported (*63*). All cell media and tissue culture additives were obtained from Gibco (Grand Island, NY).

Instrumentation. Infrared spectra were obtained on a Perkin-Elmer Spectrum BX FT-IR system using diffuse reflectance sampling accessories. ^{1}H NMR (300 MHz) and ^{13}C NMR (75 MHz) spectra were recorded in solution on a Varian Mercury 300 spectrometer with the solvent signal as reference. Glass-transition temperatures (T_g) were measured on a Mettler Toledo (Columbus, OH) DSC822^e differential scanning calorimeter. Data were acquired and analyzed with Thermal Analysis PC software (version 7.01; Mettler Toledo). Heating rates were 10 °C/min, and the T_g was taken as the midpoint of the inflection tangent, upon the third heating scan. Thermogravimetric analysis was performed on a Mettler Toledo SDTA851 TGA module with Thermal Analysis PC software (version 7.01; Mettler Toledo). Heating rates were 10 °C/min, and the onset temperature for weight loss was the point at which two tangential lines in the TGA curves intersected.

Gel permeation chromatography injections were made on a Waters Chromatography, Inc. (Milford, MA) 1515 isocratic HPLC pump, equipped with a Waters Chromatography, Inc. inline degasser AF, Breeze (version 3.30, Waters Chromatography, Inc.) software, a Model 2414 differential refractometer (Waters Inc.), a Precision Detectors, Inc. (Bellingham, MA) Model PD2020 dual-angle (15° and 90°) light scattering detector, and four PLgel polystyrene-*co*-divinylbenzene gel columns supplied by Polymer Laboratories, Inc. (Amherst, MA) connected in the following series: 5 μm Guard (50 × 7.5 mm), 5 μm Mixed-C (300 × 7.5 mm), 5 μm 10^4 Å (300 × 7.5 mm), and 5 μm 500 Å (300 × 7.5 mm). Data collection was performed with Precision Detectors, Inc. Precision Acquire 32 Acquisition Program. Data analysis was performed with Precision Detectors, Inc. Discovery 32 (version 1.027.000) software. Interdetector delay volume and the light scattering detector calibration constant were determined from a nearly monodisperse polystyrene calibrant (Pressure Chemical Co., $M_n = 90\,000$ g/mol, $M_w/M_n < 1.04$). The dn/dc values of the analyzed polymers were then determined from the differential refractometer response.

Hydrodynamic diameters (D_n) and size distributions for the SCKs in aqueous solutions were determined by dynamic light scattering (DLS). The DLS instrumentation consisted of a Brookhaven Instruments Limited (Worcestershire, U.K.) system, including a model BI-200SM goniometer, a model BI-9000AT digital correlator, a model EMI-9865 photomultiplier, and a model 95-2 Ar ion laser (Lexel, Corp.; Farmindale, NY) operated at 514.5 nm. Measurements were made at 20 ± 1 °C. Prior to analysis, solutions were centrifuged in a model 5414 microfuge (Brinkman Instruments, Inc.; Westbury, NY) for 4 min to remove dust particles. Scattered light was collected at a fixed angle of 90 °C. The digital correlator was operated with 522 ratio spaced channels and initial delay of 0.1 μs, a final delay of 5.0 μs, and a duration of 15 min. A photomulitplier aperture of 200 μm was used, and the incident laser intensity was adjusted to obtain a photon counting of 200 kcps. Only measurements in which the measured and calculated baselines of the intensity autocorrelation function agreed to within 0.1% were used to calculate particle size. Particle size distributions were performed with the ISDA software package (Brookhaven Instruments Company), which employed single-exponential fitting, cumulants analysis, and non-negatively constrained least-squares particle size distribution analysis routines. Transmission electron microscopy samples were diluted in water (9:1) and further diluted with a 1% phosphotungstic acid (PTA) stain (1:1). Carbon grids were prepared by a plasma treatment to increase the surface hydrophilicity. Micrographs were collected at 100 000× magnification and calibrated using a 41 nm polyacrylamide bead from NIST. Averages of particle diameters were generated from the analysis of a minimum of 150 particles from at least three different micrographs.

The height measurements and distributions for the SCKs were determined by tapping-mode AFM under ambient conditions in air. The AFM instrumentation consisted of a Nanoscope III BioScope system (Digital Instruments, Veeco Metrology Group; Santa Barbara, CA) and standard silicon tips (type, OTESPA-70; L, 160 μm; normal spring constant, 50 N/m; resonance frequency, 246−282 kHz). The sample solutions were drop (2 μL) deposited onto freshly cleaved mica and allowed to dry freely in air.

Analytical ultracentrifugation experiments were conducted on a Beckman Instruments, Inc. (Fullerton, CA) model Optima XL-I analytical ultracentrifuge fitted with a model An60-Ti four-hole rotor, and Epon charcoal-filled, six-channel centerpiece sample cells with matched sapphire windows. All data were recorded using the instrument's Rayleigh interferometric (refractive index) detection optics at 20 °C and 5000, 4000, and 3000 rpm, respectively, with a centrifugation time of 3−5 days to reach sedimentation equilibrium. The solution volume was 110 μL, and the optical path length was 12 mm. A Mettler-Parr model DMA 602 high-precision digital density meter was employed to determine the density at 20.0 °C for all solutions. All densities were an average of five runs, with measurements of 100 periods per run. The

weight-average degree of aggregation, N_{agg}, was computed as previously reported (*47*).

Synthesis of *N*-(2,4-Dinitrophenyl)ethanolamine (1). The previously described synthesis was followed (*64*). Into a 50 mL two-neck round-bottom flask fitted with a stopper and an inlet stopper was charged 1-iodo-2,4-dinitrobenzene (3.94 g, 13.4 mmol) and DMSO (15 mL). Upon stirring for 5 min at RT, all of the starting material had dissolved and ethanolamine (2.40 mL, 40.2 mmol) was added, followed by potassium hydroxide pellets (3.36 g, 60.3 mmol). The reaction was allowed to stir at RT for 2 h and was monitored by TLC (10% MeOH in CH_2Cl_2, $R_{f(product)} = 0.49$). The reaction mixture was poured over ice, and the bright yellow solid was isolated by vacuum filtration and recrystallized in ethanol. Isolated yield 1.58 g (52%). IR: 3571−3000, 3354, 3000−2750, 1616, 1580, 1330, 1301, 920 cm^{-1}. ^1H NMR (CD_2Cl_2): δ 1.96 (t, J = 5 Hz, 1H, $NHCH_2CH_2OH$), 3.58 (overlapping dt, J = 5 Hz, 2H, $NHCH_2CH_2OH$), 3.97 (overlapping dt, J = 5 Hz, 2H, $NHCH_2CH_2OH$), 7.00 (d, J = 10 Hz, 1H, ortho to $NHCH_2CH_2OH$), 8.26 (dd, J = 10 and 2 Hz, 1H, meta to $NHCH_2CH_2OH$), 8.80 (br s, 1H, $NHCH_2CH_2OH$), 9.09 (d, J = 2 Hz, 1H, meta to $NHCH_2CH_2OH$ and ortho to each NO_2) ppm. ^{13}C NMR (CD_2Cl_2): δ 45.9, 61.0, 114.9, 124.7, 130.8, 149.3 ppm. HRMS (ESI): calcd for ($C_8H_9N_3O_5$+H): 227.0542, found 227.0540 ± 1.0 ppm (MH^+).

Synthesis of 2-Bromopropionic Acid 2-(2,4-Dinitrophenylamino)ethyl Ester (2). A 50 mL two-neck round-bottom flask that was fitted with a N_2 inlet was flame-dried under vacuum and allowed to cool to RT under a flow of N_2. A solution of **1** (0.50 g, 2.2 mmol) in THF (6 mL) was added to the reaction flask via syringe, followed by addition of triethylamine (0.30 mL, 2.2 mmol) via syringe. The reaction mixture was allowed to stir under N_2 at 0 °C for 30 min. Prior to use, the 2-bromopropionyl bromide reagent bottle was allowed to stand in an ice bath for 30 min. 2-Bromopriopionyl bromide (0.50 mL, 4.8 mmol) was added to the reaction via syringe, and the reaction mixture was allowed to stir under N_2 at 0 °C for 2 h. The reaction progress was monitored by TLC (CH_2Cl_2, $R_{f(product)} = 0.86$). The reaction mixture was dissolved in CH_2Cl_2 and extracted three times with a saturated aq. solution of $NaHCO_3$, followed by three extractions with H_2O. The organic layer was dried with $MgSO_4$ and filtered, and the filtrate was concentrated by rotary evaporation to yield a yellow oil. The oil was dissolved in CH_2Cl_2 and eluted on a silica gel column with CH_2Cl_2 and then further purified by recrystallization in ether. Isolated yield 0.68 g (86%). IR: 3350, 3100−2700, 1818, 1740, 1617, 1589, 1440, 744, 557 cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.84 (overlapping doublets, J = 6 Hz, 3H, CH_3CHBr), 3.78 (overlapping dt, J = 6 Hz, 2H, $NHCH_2CH_2$), 4.41 (m, J = 7 Hz, 2H, $NHCH_2CH_2$), 4.50 (m, J = 6 Hz, 1H, CH_3CHBr), 7.02 (d, J = 9 Hz, 1H, ortho to $NHCH_2CH_2O$), 8.33 (d of d, J = 9 Hz, 2 Hz, 1H, meta to $NHCH_2CH_2O$), 8.75 (br t, J = 6 Hz, 1H, $NHCH_2CH_2O$), 9.17 (d, J = 2 Hz, 1H, meta to $NHCH_2CH_2O$ and ortho to each NO_2) ppm. ^{13}C NMR ($CDCl_3$): δ 21.6, 39.4, 42.1, 63.2, 114.0, 124.5, 130.7, 148.3, 170.4 ppm. HRMS (FAB): calcd for ($C_{11}H_{12}N_3O_6Br$+Li): 368.0069, found 368.0057 ± 3.4 ppm (MH^+).

Synthesis of 2,4-Dinitrophenylateded Poly(*tert*-butyl acrylate)$_{60}$ (3). A 100 mL two-neck round-bottom flask that was fitted with a gas inlet adapter and a stopcock was flame-dried under vacuum and allowed to cool to ambient temperature under N_2. The flask was charged with CuBr (0.368 g, 2.48 mmol), and a septum was placed over the stem of the stopcock. Under positive pressure of N_2, a solution of **2** (0.447 g, 1.24 mmol) dissolved in *tert*-butyl acrylate (36.3 mL, 0.25 mol) was added via syringe, followed by addition of pentamethyldiethylenetriamine (PMDETA) (0.52 mL, 2.5 mmol), via syringe. Following three freeze−pump−thaw degassing cycles, the reaction was allowed to stir for 3.5 h at 50 °C. After quenching of the polymerization by submerging the flask in liquid nitrogen, the mixture was allowed to warm to ambient temperature. The reaction mixture was diluted with tetrahydrofuran and filtered through an alumina plug. The filtrate was precipitated three times from tetrahydrofuran into a 70% methanol, deionized water solution: Isolated yield 18.69 g (88%). M_n = 8400 g/mol, M_w/M_n = 1.5 from SEC. DSC: $T_{g(DNP-PtBA)}$ = 45 °C, TGA: 210−242 °C = 43% mass loss, 242−294 °C = 10% mass loss, 294−500 °C = 33% mass loss, 500 °C = 14% mass remaining. IR: 3429, 3100−2600, 1734, 1717, 1617, 1474, 1253, 1166, 845 cm^{-1}. ^1H NMR($CDCl_3$): δ 1.42, (s, $C(CH_3)_3$), 1.70−2.00 (br, m, C*H* polymer backbone), 2.21 (br s, CH_2 polymer backbone), 3.73 (br m, $NHCH_2CH_2$), 4.36 (br m, $NHCH_2CH_2$), 7.02 (br m, 1H, ortho to $NHCH_2CH_2O$), 8.31 (br m, 1H, meta to $NHCH_2CH_2O$), 8.75 (br s, 1H, $NHCH_2CH_2O$), 9.14 (s, 1H, meta to $NHCH_2CH_2O$ and ortho to each NO_2) ppm. ^{13}C NMR ($CDCl_3$): δ 28.2, 37.5, 42.5, 80.5, 174.4 ppm. Elem. Anal. Theoretical C 64.27% H 9.17% N 0.52%, Br 0.99 Found C 64.49% H 9.17% N 0.36% Br 1.10%.

Synthesis of 2,4-Dinitrophenylateded Poly(*tert*-butyl acrylate)$_{60}$-*b*-poly(methyl acrylate)$_{60}$ (4). A 50 mL two-neck round-bottom flask that was fitted with a gas inlet adapter and a stopcock was flame-dried under vacuum and allowed to cool to ambient temperature under N_2. A septum was placed over the stem of the stopcock and under a positive pressure of N_2, and CuBr (0.0502 g, 0.350 mmol) was added followed by a solution of **3** (2.87 g, 0.34 mmol) dissolved in methyl acrylate (5.0 mL, 55 mmol). After three freeze−pump−thaw degassing cycles, PMDETA (0.07 mL, 0.3 mmol) was added via syringe under a positive pressure of N_2. Following a freeze−pump−thaw degassing cycle, the reaction mixture was allowed to stir for 4 h at 50 °C. After quenching the polymerization, by submersion of the flask in liquid nitrogen, and allowing the mixture to warm to ambient temperature, the reaction mixture was diluted with tetrahydrofuran and filtered through an alumina plug. The filtrate was precipitated three times from tetrahydrofuran into a 70% methanol, deionized water solution: Isolated yield 3.13 g (64%). M_n = 14280 g/mol, M_w/M_n = 1.1 from SEC. DSC: $T_{g(DNP-PtBA)}$ = 40 °C, $T_{g(PMA)}$ = 18 °C, TGA: 225−245 °C = 35% mass loss, 245−300 °C = 10% mass loss, 300−350 °C = 10% mass loss, 350−500 °C = 35% mass loss, 500 °C = 10% mass remaining. IR: 3434, 3100−2800, 1737, 1717, 1617, 1589, 1477, 1262, 1169, 845 cm^{-1}. ^1H NMR($CDCl_3$): δ 1.44 (br s, $C(CH_3)_3$), 1.20 − 2.00 (br m, CH_2 polymer backbone), 2.10−2.41 (br m, C*H* polymer backbone), 3.67 (br s, $COOCH_3$), 4.38 (br m, 3H, $CH_2COOCHCH_3$), 7.04 (br m, ortho to $NH_2CH_2CH_2$), 8.32 (br m, meta to $NH_2CH_2CH_2$), 8.75 (br m, $NHCH_2CH_2$), 9.16 (br m, meta to $NH_2CH_2CH_2$ and ortho to each NO_2) ppm. ^{13}C NMR ($CDCl_3$): δ 28.2, 35.4, 41.5, 51.9, 80.5, 174.4, 175.1 ppm. Elem. Anal. Theoretical C 60.95% H 8.33%, N 0.32%, Found C 63.01% H 9.06%, N 0.31%.

Synthesis of 2,4-Dinitrophenylateded Poly(acrylic acid)$_{60}$-*b*-poly(methyl acrylate)$_{60}$ (5). A 250 mL round-bottom flask, fitted with a gas inlet, was charged with **6** (2.00 g, 0.14 mmol) and a solution of trifluoroacetic acid (6.00 mL, 77.9 mmol) in dichloromethane (20.0 mL). The reaction was allowed to stir at ambient temperature overnight. The solvent was removed under vacuum, and

the resulting solid was taken up in tetrahydrofuran. The solution was transferred to a dialysis bag (MWCO 6−8 kDa), and the solution was dialyzed against a continuous flow of deionized water for 24 h. The final amphiphilic diblock copolymer was isolated by lyophilization: Isolated yield 1.46 g, (89%). DSC: $T_{g(DNP-PAA)}$ = 86 °C, $T_{g(PMA)}$ = 14 °C, TGA: 30−90 °C = 4% mass loss, 170−270 °C = 24% mass loss, 270−500 °C = 34% mass loss, 500 °C = 38% mass remaining. IR: 3670−3069, 3069−2729, 1730, 1712, 1694, 1557, 1446, 1210, 802 cm^{-1}. ^1H NMR (D_2O): δ 1.20−1.90 (br m, CH_2 polymer backbone), 2.10−2.40 (br s, CH polymer backbone), 3.70 (s, COOCH_3), 7.29 (br m, ortho to $NH_2CH_2CH_2$), 8.35 (br m d, meta *to* NH_2CH_2-CH_2), 9.11 (br s, meta to $NH_2CH_2CH_2$ and ortho to each NO_2) ppm. ^{13}C NMR (DMSO-d_6): δ 39.0, 40.1, 51.6, 174.5, 175.9 ppm.

Synthesis of Poly(*tert*-butyl acrylate)$_{70}$ (6). A 100 mL two-neck round-bottom flask that was fitted with a gas inlet adapter and a stopcock was flame-dried under vacuum and allowed to cool to ambient temperature under N_2. The flask was charged with CuBr (0.57 g, 3.97 mmol). A septum was placed over the stem of the stopcock, and under positive pressure of N_2, *tert*-butyl acrylate (22.0 mL, 150 mmol) was added via syringe, followed by addition of PMDETA (0.83 mL, 3.97 mmol), via syringe. After three freeze−pump−thaw degassing cycles, ethyl 2-bromopropionate (0.19 mL, 1.50 mmol) was added via syringe under a positive pressure of N_2. Following a freeze−pump−thaw degassing cycle, the reaction was allowed to stir for 1.5 h at 50 °C. The polymerization was quenched by submerging the flask in liquid nitrogen, and the mixture was allowed to warm to ambient temperature. The reaction mixture was diluted with tetrahydrofuran and filtered through an alumina plug. The filtrate was precipitated three times from tetrahydrofuran into a 70% methanol, deionized water solution: Isolated yield 13.0 g, (92%). M_n = 9420 g/mol, M_w/M_n = 1.1 from SEC. DSC: $T_{g(PtBA)}$ = 41 °C, TGA: 197−230 °C = 44% mass loss, 230−500 °C = 46% mass loss, 500 °C = 10% mass remaining. IR: 3100−2800, 1722, 1365, 1142, 844 cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.15 (t, J = 5 Hz, 3H, CH_2CH_3 end group), 1.21 (d, J = 5 Hz, 3H, CH_3CH end group), 1.43, (br s, C(CH_3)$_3$), 1.20−1.70 (br m, CH polymer backbone), 2.0−2.4, (br m, CH_2 polymer backbone), 4.11 (q, J = 5 Hz, 2H, CH_2CH_3 end group) ppm. ^{13}C NMR ($CDCl_3$): δ 28.2, 37.6, 42.5, 80.5, 174.4 ppm. Elem. Anal. Theoretical C 64.96% H 9.35%, Br 0.87%, Found C 65.17% H 9.43%.

Synthesis of Poly(*tert*-butyl acrylate)$_{70}$-*b*-poly(methyl acrylate)$_{70}$ (7). A 100 mL two-neck round-bottom flask that was fitted with a gas inlet adapter and a stopcock was flame-dried under vacuum and allowed to cool to ambient temperature under N_2. The flask was charged with CuBr (0.29 g, 2.0 mmol). A septum was placed over the stem of the stopcock, and under positive pressure of N_2, **1** (9.51 g, 1.01 mmol) dissolved in methyl acrylate (9.1 mL, 0.1 mol) was added via syringe. After three freeze−pump−thaw degassing cycles, PMDETA (0.42 mL, 2.0 mmol) was added via syringe under a positive pressure of N_2. Following a freeze−pump−thaw degassing cycle, the reaction was allowed to stir for 2 h at 50 °C. The polymerization was quenched by submerging the flask in liquid nitrogen, and the mixture was allowed to warm to ambient temperature. The reaction mixture was diluted with tetrahydrofuran and filtered through an alumina plug. The filtrate was precipitated three times from tetrahydrofuran into a 70% methanol, deionized water solution: Isolated yield 13.0 g, (72%). M_n = 16820 g/mol, M_w/M_n = 1.1 from SEC. DSC: $T_{g(PtBA)}$ = 39 °C, $T_{g(PMA)}$ = 19 °C, TGA: 236−250 °C = 25% mass loss, 250−374 °C = 16% mass loss, 374−500 °C = 50% mass loss, 500 °C = 9% mass remaining. IR: 3670−3300, 3100−2800, 1748, 1714, 1454, 1372, 849 cm^{-1}. ^1H NMR-($CDCl_3$): δ 1.42 (br s, C(CH_3)$_3$), 1.20−1.90 (br m, CH_2 polymer backbone), 2.10−2.40 (br m, CH polymer backbone), 3.65 (br s, COOCH_3), 4.11 (q, J = 5 Hz, 2H, CH_2-CH_3 end group) ppm. ^{13}C NMR($CDCl_3$): δ 28.2, 35.2, 41.5, 51.9, 80.6, 174.4, 175.1 ppm. Elem. Anal. Theoretical C 61.30% H 8.43%, Found C 61.36% H 8.32%.

Synthesis of Poly(acrylic acid)$_{70}$-*b*-poly(methyl acrylate)$_{70}$ (8). A 250 mL round-bottom flask, fitted with a gas inlet adapter, was charged with **2** (10.1 g, 0.56 mmol) and a solution of trifluoroacetic acid (30.0 mL, 0.39 mol) in dichloromethane (100.0 mL). The reaction was allowed to stir at ambient temperature for 9 h. The solvent was removed under vacuum, and the resulting solid was taken up in tetrahydrofuran. The solution was transferred to a dialysis bag (MWCO 6−8 kDa), and the solution was dialyzed against a continuous flow of deionized water for 24 h. The final amphiphilic diblock copolymer was isolated by lyophilization: Isolated yield 4.8 g, (77%). DSC: $T_{g(PAA)}$ = 116 °C, $T_{g(PMA)}$ = 14 °C, TGA: 253−329 °C = 20% mass loss, 329−500 °C = 70% mass loss, 500 °C = 10% mass remaining. IR: 3670−2276, 1748, 1717, 1453, 1267, 1174, 828 cm^{-1}. ^1H NMR (DMSO-d_6): δ 1.16 (t, J = 5 Hz, 3H, CH_2CH_3 end group), 1.20−1.90 (br m, CH_2 polymer backbone), 2.10−2.40 (br s, CH polymer backbone), 3.60 (br s, COOCH_3), 4.03 (q, J = 5 Hz, 2H, CH_2CH_3 end group) ppm. ^{13}C NMR (DMSO-d_6): δ 34.6, 40.9, 51.6, 174.5, 175.9, 176.0 ppm. Elem. Anal. Theoretical C 52.82% H 6.35%, Found C 53.02% H 6.44%.

Assembly of 0% DNP Micelle (9). Nanopure water (1.00 L, 18 MΩ-cm) was added dropwise via a syringe pump at a rate of 15.0 mL/h to a THF solution of **8** (1.2 g in 1.0 L). The solution was dialyzed (MWCO 6−8 kDa) against Nanopure water for 3 days. DLS: D_{av} = 12 ± 1 nm. ζ = −39 ± 1 mV.

Assembly of 50% DNP Micelle (10). Nanopure water (500 mL, 18 MΩ-cm) was added dropwise via a syringe pump at a rate of 15.0 mL/h to a THF solution of **8** (250 mL, 1.00 mg/mL) and **5** (250 mL, 1.00 mg/mL). The solution was dialyzed (MWCO 6−8 kDa) against Nanopure water for 3 days. DLS: NA, no correlation function due to the low concentration of the sample. ζ = −52 ± 1 mV.

Assembly of 100% DNP Micelle (11). Nanopure water (500 mL, 18 MΩ-cm) was added dropwise via a syringe pump at a rate of 15.0 mL/h to a THF solution of **5** (500 mL, 1.00 mg/L). The solution was dialyzed (MWCO 6−8 kDa) against Nanopure water for 3 days. DLS: D_{av} = 41 ± 10 nm. ζ = −35 ± 1 mV.

Synthesis of 0% DNP SCK (12). A solution of 2,2′-(ethylenedioxy)bis(ethylamine) in Nanopure water (1.82 mL, 1.23 mmol, 100 mg/mL) was added dropwise to the micelle solution (3.10 L, 4.92 mmol acrylic acid). The mixture was allowed to stir at RT for 1 h, and a solution of 1-(3′-dimethylaminopropyl)-3-ethylcarbodiimide methiodide in Nanopure water (7.31 mL, 2.46 mmol, 100 mg/mL) was then added dropwise to the reaction flask. The reaction was allowed to stir at RT for 12 h and was then dialyzed against Nanopure water (MWCO 12−14 kDa) for 4 days. DSC: T_g = 8 °C, TGA: 190−335 °C = 15% mass loss, 335−500 °C = 64% mass loss, 500 °C = 21% mass remaining. IR: 3685−3000, 3000−2670, 1737, 1651, 1639, 1440, 1265, 1166, 827 cm^{-1}. DLS: D_{av} = 24 ± 3 nm, AFM: H_{av} = 1.2 ± 0.3 nm, D_{av} = 47 ± 12 nm, TEM: D_{av} = 13 ± 2 nm. ζ = −25 ± 1 mV.

Synthesis of 50% DNP SCK (13). A solution of 2,2′-(ethylenedioxy)bis(ethylamine) in Nanopure water (1.15 mL, 0.78 mmol, 100 mg/mL) was added dropwise to the micelle solution (1.72 L, 3.11 mmol acrylic acid). The mixture was allowed to stir at RT for 1 h, and a solution of 1-(3′-dimethylaminopropyl)-3-ethylcarbodiimide methiodide in Nanopure water (4.64 mL, 1.56 mmol, 100 mg/mL) was then added dropwise to the reaction flask. The reaction was allowed to stir at RT for 12 h and was then dialyzed against Nanopure water (MWCO 12−14 kDa) for 4 days. DSC: T_g = 14 °C, TGA: 40−185 °C = 4% mass loss, 185−350 °C = 18% mass loss, 350−500 °C = 60% mass loss, 500 °C = 18% mass remaining. IR: 3685−3100, 3100−2660, 1734, 1631, 1639, 1445, 1260, 1164, 825 cm^{-1}. DLS: $D_{av} = 23 \pm 3$ nm, AFM: $H_{av} = 1.1 \pm 0.2$ nm, $D_{av} = 96 \pm 21$ nm, TEM: $D_{av} = 24 \pm 3$ nm. $\zeta = -31 \pm 1$ mV.

Synthesis of 100% DNP SCK (14). A solution of 2,2′-(ethylenedioxy)bis(ethylamine) in Nanopure water (1.10 mL, 0.75 mmol, 100 mg/mL) was added dropwise to the micelle solution (1.56 L, 3.01 mmol acrylic acid). The mixture was allowed to stir at RT for 1 h, and a solution of 1-(3′-dimethylaminopropyl)-3-ethylcarbodiimide methiodide in Nanopure water (4.50 mL, 1.51 mmol, 100 mg/mL) was then added dropwise to the reaction flask. The reaction was allowed to stir at RT for 12 h and was then dialyzed against Nanopure water (MWCO 12−14 kDa) for 4 days. DSC: T_g = 11 °C, TGA: 45−75 °C = 4% mass loss, 200−335 °C = 13% mass loss, 335−500 °C = 59%, 500 °C = 24% mass remaining. IR: 3600−3100, 3100−2665, 1735, 1661, 1647, 1450, 1265, 1167, 821 cm^{-1}. DLS: $D_{av} = 22 \pm 5$ nm, AFM: $H_{av} = 1.1 \pm 0.2$ nm, $D_{av} = 77 \pm 16$ nm, TEM: $D_{av} = 12 \pm 2$ nm. $\zeta = -27 \pm 1$ mV.

Titration of FITC-IgE Quenching by SCK Particles. Experiments were performed as previously reported (*59*, *61*). Briefly, aliquots of the SCKs in Nanopure water were added to a thermostatically controlled (37 °C), continuously stirred, acrylic cuvette containing a solution of fluorescein−isothiocyanate (FITC)-modified anti-DNP IgE (2 μg/mL) in buffered saline solution (BSS: 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 5.6 mM glucose, 20 mM HEPES, pH 7.4) containing gelatin (1 mg/mL). Fluorescence was monitored with a SLM 8000C spectrofluorometer(λ_{ex} = 490 nm, λ_{em} = 520 nm) over time, allowing the signal to reach equilibrium before the addition of another aliquot. Aliquots were added until the maximal quenching occurred, and the signal did not change significantly; this value was taken as saturation of the IgE. The fraction of bound IgE sites was calculated as:

$$\text{fraction of bound sites} = (I_o - I)/(I_o - I_f) \qquad (1)$$

where I_o is the average intensity of the IgE solution before the addition of aliquots, I_f is the average intensity of solution after maximal quenching, and I is the average of the last six data points of each addition, representing the intensity after addition of each aliquot of particles.

Degranulation Assays. Experiments were performed as previously reported (*65*, *66*). Briefly, a 96-well plate containing RBL-2H3 cells (10^6 cells/well) that had been sensitized with anti-DNP IgE at a 2−5 molar excess overnight (*62*) were stimulated with solutions of SCKs in Nanopure water (10^3−10^8 SCKs/cell), DNP-BSA (0.1 μg/mL), or TX-100 (0.1%) and allowed to incubate at 37 °C for 1 h. The release of β-hexosaminidase was monitored as previously described (*65*), using a fluorescence microplate reader (Tecan, Inc.). The percent degranulation was calculated based on the amount of β-hexosaminidase released upon treatment with 0.1% Triton-X 100 and corrected for spontaneous release in unstimulated cells. Experiments were performed in triplicate for each condition.

RESULTS AND DISCUSSION

Antigen-decorated SCKs were constructed from a combination of nonfunctionalized and chain-end functionalized amphiphilic diblock copolymers, which were assembled into micelles and cross-linked throughout the shell. The block lengths were intentionally maintained as relatively short segments in order to form small micelles, and amounts of DNP attached to the SCKs were controlled by the stoichiometric ratio of chain-end functionalized and nonfunctionalized polymers. The nanoparticles were designed to be flexible, shape-adaptable structures (*40*, *67*) having sizes of tens of nanometers in diameter to mimic the typical dimensions of virus particles. These allowed an appropriate density of surface-available antigens to bind multiple cell surface receptors per particle, since according to the immunon hypothesis, a minimum of 10 receptors must be clustered to induce a response (*56*). The physicochemical properties of the nanoparticles were fully characterized by IR and UV−vis spectroscopies, DLS, AFM, TEM, AU sedimentation equilibrium, DSC, TGA, and zeta potential measurements. The surface availability of the 2,4-dinitrophenylated chain-ends was evaluated by monitoring quenching caused upon binding of fluorescently labeled anti-DNP IgE antibodies with the SCKs and by measuring the degranulation caused by the binding of SCKs with anti-DNP IgE sensitized RBL cells.

To grow the chain-end functionalized amphiphilic diblock copolymer, from which the nanoparticles were constructed, a 2,4-dinitrophenylated atom transfer radical polymerization (ATRP) initiator was synthesized in two steps, shown in Scheme 1. Ethanolamine was added to the commercially available 1-iodo-2,4-dinitrobenzene starting material in the presence of KOH as previously reported (*64*), to afford the 2,4-dinitrophenylated alcohol **1**. The antigen-functionalized alkyl bromide initiator was then synthesized upon addition of 2-bromopropionyl bromide to **1** at 0 °C in the presence of triethylamine (TEA). Poly(*tert*-butyl acrylate)$_{60}$, **3**, was grown from the antigen-functionalized initiator under ATRP conditions. A poly(methyl acrlayte)$_{60}$ segment was then synthesized from the antigen-functionalized macroinitiator **3**, again under ATRP conditions, to yield 2,4-dinitrophenyl-poly(*tert*-butyl acrylate)$_{60}$-*b*-poly(methyl acrylate)$_{60}$ **4**. This diblock copolymer was transformed into an amphiphilic diblock copolymer through cleavage of the *tert*-butyl groups with a 30% solution of trifluoroacetic acid (TFA) in dichloromethane. Following dialysis of the reaction mixture into water, the amphiphilic diblock copolymer, 1,2-dinitrophenyl-poly(acrylic acid)$_{60}$-*b*-poly(methyl acrylate)$_{60}$ **5**, was formed, where the poly(acrylic acid) block was hydrophilic and the poly(methyl acrylate) block was hydrophobic. This amphiphilic character allowed assembly of the polymer chains into multimolecular micellar structures.

Selective cleavage of the tertiary ester side chain groups and retainment of the primary ester-linked antigenic chain-end group upon TFA treatment was confirmed via ^{1}H NMR spectroscopy. As shown in Figure 1, resonances characteristic of the 2,4-DNP aromatic region (protons a, b, and c) were observed from 7.2 to 9.2 ppm. Unfortunately, since the antigen is a chain-end moiety, the intensities of these proton signals were very weak

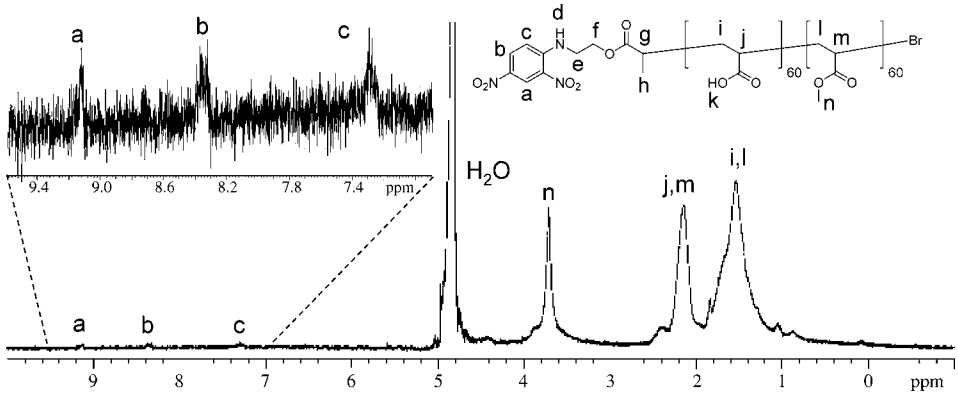

Figure 1. ^{1}H NMR (300 MHz, D_2O) spectrum of DNP-PAA_{60}-*b*-PMA_{60}, revealing resonances unique to the antigenic chain-end.

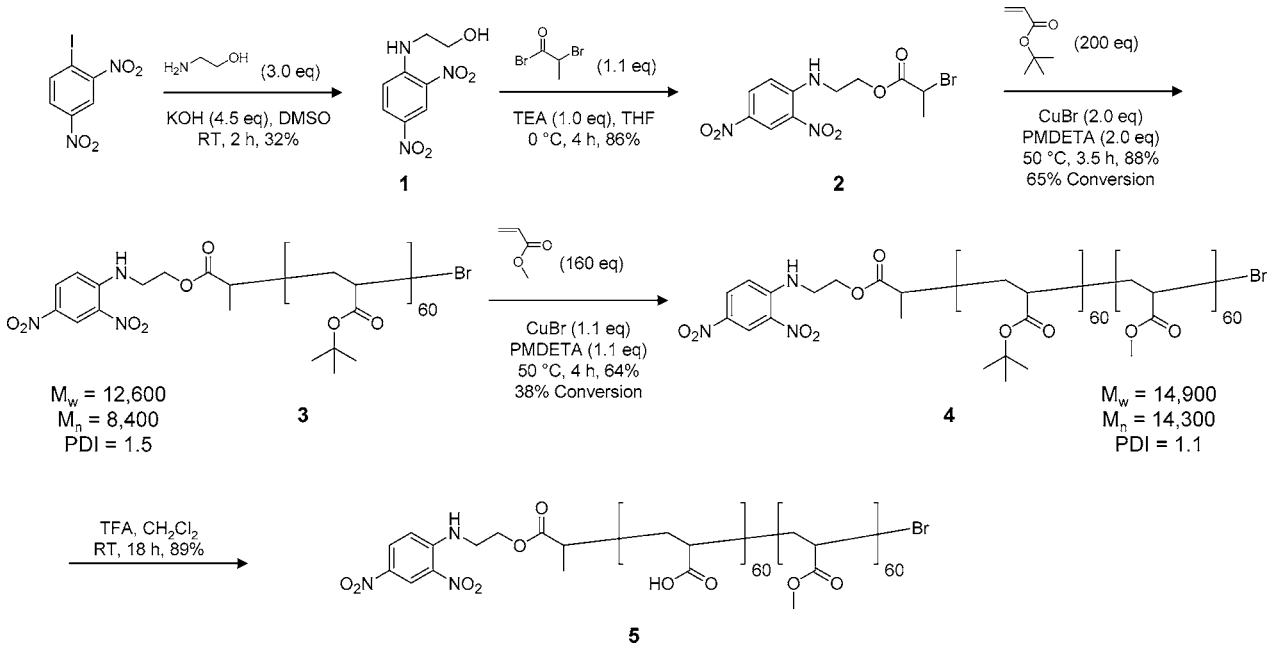
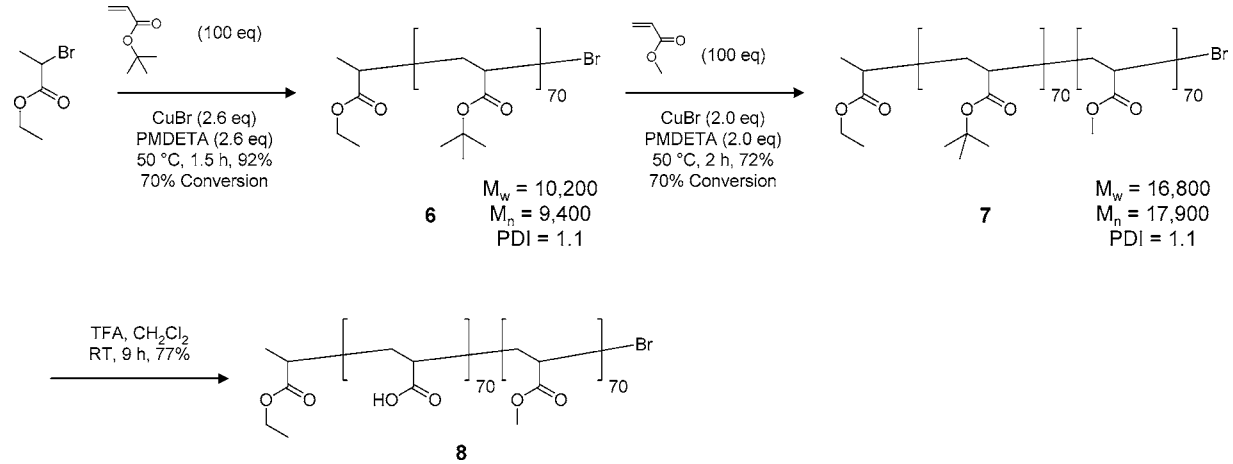
Scheme 1. Synthesis of 2,4-Dinitrophenylated Amphiphilic Diblock Copolymer, 5, via ATRP



Scheme 2. Synthesis of the Nonfunctionalized Amphiphilic Diblock Copolymer, 8, via ATRP



compared to the resonances of the polymer chain repeat unit protons; thus, integration of the unique 2,4-DNP signals was not quantitatively valid.

A nonfunctionalized amphiphilic diblock copolymer, similar in block length and composition, was synthesized in the same fashion as was performed for **5**, but with initiation from 2-ethyl bromopropionate, an alkyl bromide initiator for ATRP, as illustrated in Scheme 2. Again, under ATRP conditions, poly(*tert*-butyl acrylate) was grown to serve as a macroinitiator for the polymerization of methyl acrylate, which yielded poly(*tert*-butyl acrylate)$_{70}$-*b*-poly(methyl acrylate)$_{70}$. The *tert*-butyl groups were cleaved in the presence of TFA, to afford the amphiphilic diblock copolymer **8**. Each block was an average of 70 repeat units, giving the nonfunctionalized polymer both similar length and composition as the 2,4-

dinitrophenyl-terminated polymer. The similarities in both block length and composition were desired in order to promote the assembly of uniform micelles from a mixture of polymers **8** and **5**.

Micelles of nominally 0%, 50%, and 100% 2,4-dinitrophenyl-terminated polymer chains were assembled from the nonfunctionalized polymer **8**, a 1:1 stoichiometric mixture of the nonfunctionalized polymer **8** and the functionalized polymer **5**, and the functionalized polymer **5**, respectively. Each type of micelle was formed in the same general fashion involving slow addition of water (15 mL/h) to a solution of the polymer, or mixture of polymers, in tetrahydrofuran (THF). The micelle assemblies were then trapped by exchange of the THF with water via dialysis and further stabilized upon cross-linking of a portion of acrylic acid groups throughout the shell. Nominally, the nanoparticles were cross-linked to 50% upon addition of a bifunctional amine, 2,2′-(ethylenedioxy)bis(ethylamine), and a water soluble carbodiimide activator, 1-(3′-dimethylaminopropyl)-3-ethylcarbodiimide methiodide, as shown in Scheme 3, to yield 0%, 50%, and 100% 2,4-dinitrophenylated SCKs, **12**, **13**, and **14**, respectively.

The nanoparticles were characterized extensively by DLS, AFM, TEM, and AU sedimentation equilibrium, which allowed determination of the size and apparent molecular weight of the SCKs (Table 1). As expected from designing nonfunctionalized and functionalized amphiphilic diblock copolymers of similar length and composition, each type of nanoparticle exhibited similar diameters and heights, by DLS, and AFM techniques. However, TEM and AU sedimentation equilibrium experiments revealed differences between the 50% DNP-SCK and the other nanoparticles, which appeared to be of greater heterogeneity, possibly resulting from the mixed micellization conducted for this sample. Dynamic light scattering measurements of the nanoparticles in aqueous solution produced similar hydrodynamic diameters, ca. 23 nm (Table 1). Each type of SCK exhibited a low height value as measured by AFM, which is in agreement with their expected flexible, shape-adaptable character imparted by the poly(methyl acrylate) core material. The poly(methyl acrylate) chain segments exhibited T_g values below room temperature, and thus were fluidlike at room temperature and allowed the nanoparticles to flatten under the AFM tip on the mica substrate that was utilized for the AFM measurements (*40*, *67*). The flattening of the SCKs on the mica substrate

is further supported by the large diameters measured by AFM, although these diameters are qualitative, due to the inherent error caused by the width of the AFM tip.

The TEM measurements produced similar diameters (Table 1) for the 0% and 100% DNP nanoparticles of about 13 nm, whereas the 50% DNP-SCK had a larger diameter of 24 nm. This difference is especially interesting because the 50% DNP nanoparticle was the only particle derived from a mixed micelle system, and because both AFM and DLS measurements produced similar results for the 50% DNP-SCK in comparison to the 0% and 100% DNP-SCKs. Analytical ultracentrifugation sedimentation equilibrium measurements provided more insight into this intriguing difference.

AU sedimentation equilibrium measurements of three different concentrations of SCKs in both phosphate buffer and deuterated phosphate buffer, at three different speeds, along with acoustical density measurements of each solution, were employed to calculate the apparent molecular weight (M_{app}) of each type of nanoparticle (*47*). The M_{app} values and molecular weights of the amphiphilic diblock copolymers were then utilized (along with the molar fraction of each diblock for the 50% DNP-SCK) to calculate the number of chains per particle, or aggregation number (N_{agg}). From these measurements and calculations, it was determined that the 50% DNP-SCK was formed from a larger number of chains per particle (120 ± 20 chains/SCK) than were the 0% and 100% DNP-SCKs (10 ± 2 chains/SCK and 38 ± 11 chains/SCK), thus supporting the TEM finding that the 50% DNP nanoparticle was larger than the 0% and 100% DNP nanoparticles. Even though when measured in solution (DLS) and on a mica surface (AFM) each of the particles was of similar size, TEM and AU sedimentation equilibrium measurements were able to detect the difference between the 50% DNP SCK and the 0% and 100% DNP SCKs. The nanoparticles are of similar size, shape, and composition and thus differ mainly in the amount of chain-ends that are labeled with DNP. An increased propensity for aggregation, promoted by the heterogeneous surface composition, could provide an alternative explanation for the apparent differences with the 50% DNP SCK, relative to the homogeneous 0% and 100% DNP SCKs.

The surface availability of the DNP chain-ends on SCKs was evaluated by their capacity to quench fluorescent IgE in solution. Quenching titrations were achieved by making serial additions of SCK solutions to FITC modified IgE in solution. As antibodies bound to the DNP hapten attached to the nanoparticles, the fluorescence from the fluorecein derivatives near the binding pockets of the antibody was quenched; thus, the degree of fluorescence quenching can be related to the fraction of sites bound. Because the FITC modified IgE has fluorecein molecules both at the binding pocket and away from it, even when all the binding sites are occupied, there is still residual fluorescence. For this reason, the saturation point of the IgE is taken to be the point where addition of more antigen causes no additional quenching (Figure 2).

Interestingly, the 50% DNP-SCKs quenched approximately 25% more fluorescence at saturation than the 100% DNP-SCKs (data not shown), indicating that the 50% DNP particles may interact differently with the IgE in solution. As the SCKs are malleable, perhaps the spacing of DNP groups on the 50% particles is such that the particle can quench FITC fluorescence farther away from the site to which it is bound. The 100% DNP-SCK had a larger initial slope, indicating a higher apparent affinity (*58*). The 0% DNP SCKs caused limited quenching, consistent with little to no nonspecific binding interactions. It is evident from the titrations that the DNP antigens were presented from the SCKs as surface-available ligands that promoted the expected specific interactions with anti-DNP IgE in solution.

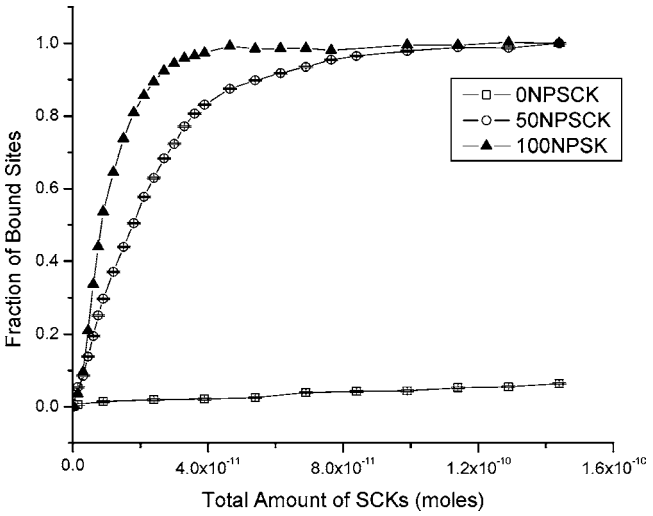

Figure 2. Fluorescence quenching of FITC−IgE by titration with 0%, 50%, and 100% DNP-SCKs. Data were normalized such that when $I = I_f$, the fraction of bound sites equaled 1.

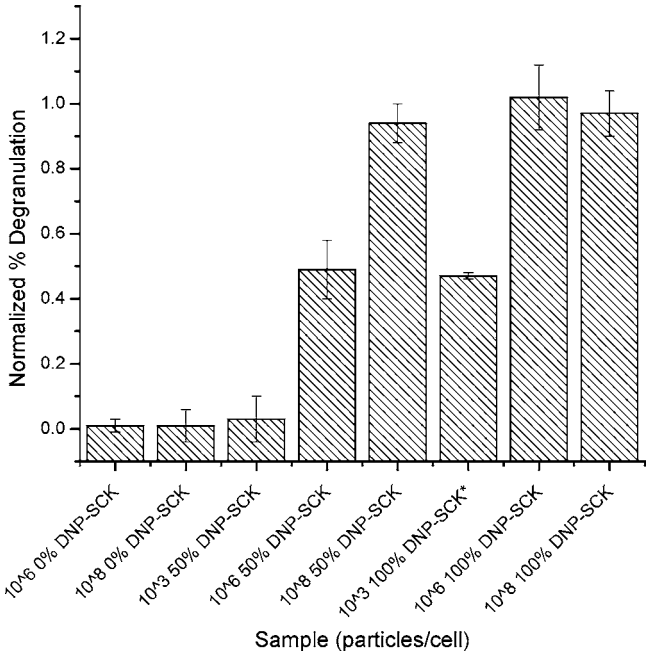

Figure 3. Percent degranulation observed from IgE sensitized cells. Degranulation Values were normalized to β-hexosaminidase release caused by DNP-BSA, which was 50% of maximal release by cells.

The capacity of the nanoparticle-bound antigen to be recognized by antibodies bound to cells, as well as their functional capacity to elicit an immune response, were evaluated through degranulation assays.

As expected from the bioavailiblity study with IgE in solution, the DNP groups on the SCK surface were able to bind IgE-FcϵRI on the surface of RBL-2H3 cells. At a concentration of 10^8 particles/cell the 50% and 100% DNP-SCKs stimulated degranulation comparable to standard DNP-BSA antigen (Figure 3). The 0% DNP-SCKs caused little to no degranulation at all concentrations examined. At lower concentrations, the 100% DNP-BSA SCKs stimulated maximal degranulation, relative to the

50% DNP-SCKs, yet modest degranulation was observed at the lower concentrations, 10^6 and 10^3 particles/cell, respectively. This may be a reflection of their higher apparent affinity for IgE or their capacity to cause more cross-linking of receptor complexes on the surface of the cell. One of the initial events in IgE-FcϵRI mediated signaling is the phosphorylation of specific motifs on the cytoplasmic domains of the receptor (*58*, *59*). Therefore, the tyrosine phosphorylation upon stimulation was examined by western blotting (*59*). Both the 50% and 100% DNP-SCKs were capable of causing an amount of stimulated tyrosine phosphorylation roughly similar to DNP-BSA, whereas the non-DNP-decorated SCKs were not. Taken together with the degranulation response, these results show that the DNP groups are both available for binding and, when presented polyvalently, are capable of causing a specific immune response.

CONCLUSIONS

Antigen-decorated SCKs with varying amounts of haptenic groups (0%, 50%, and 100% DNP) were constructed from self-assembled block copolymer micelles, followed by cross-linking throughout the shell, to achieve stabilization. The nanoparticles were characterized extensively and shown to be of similar size and composition to one another. However, the 50% DNP-SCK was of larger size and size distribution, as observed by TEM and AU sedimentation equilibrium experiments. These differences were attributed to the mixed micelle methodology employed for the assembly of the 50% DNP micelle, which resulted in two different polymers incorporated into the nanoparticle, giving a heterogeneous surface composition as well.

The DNP chain-ends were shown to be surface available while attached to the nanoparticles, by both fluorescence quenching titrations and degranulation assays. The 100% DNP-SCK displayed the highest apparent affinity for binding with anti-DNP IgE antibodies in solution. The 0% DNP-SCK demonstrated very little nonspecific interaction with the anti-DNP IgE in both the florescent quenching titrations and degranulation assays. Both the 50% and 100% DNP nanoparticles cross-linked the IgE antibodies bound to RBL cells and stimulated degranulation. The percentage of degranulation varied with nanoparticle dosage, as well as the amount DNP chain-ends in the nanoparticle. Both the 50% and 100% DNP-SCKs caused degranulation to similar degrees as the hapten bound to a traditional carrier (DNP-BSA positive control), thus behaving as effectors of an immune response, similar to the third generation dendrimer reported by Baird et al., rather than an inhibitor of the immune response.

The nanoparticle provides a good substrate from which antigens are displayed since the antigen is surface-available and multiple copies of the antigen are displayed from each SCK, allowing participation in multivalent binding events. These promising results indicate that shell cross-linked nanoparticles hold the potential to serve as multifunctional platforms for surface presentation of antigens, which in combination with efforts to define the structure and composition of the interior cavity of these nanoscale objects (*51*, *68*) is leading to their development as synthetic viruslike particles and eventually to their application as synthetic vaccines.

Competitive Binding Assay Using Fluorescence Resonance Energy Transfer for the Identification of Calmodulin Antagonists

Bethel Sharma,[†] Sapna K. Deo,[‡] Leonidas G. Bachas,[‡] and Sylvia Daunert*[,†,‡]

Department of Pharmaceutical Sciences, University of Kentucky, Lexington, Kentucky 40536-0082, and Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506-0055. Received June 6, 2005; Revised Manuscript Received August 12, 2005

The ubiquitous calcium regulating protein calmodulin (CaM) has been utilized as a model drug target in the design of a competitive binding fluorescence resonance energy transfer assay for pharmacological screening. The protein was labeled by covalently attaching the thiol-reactive fluorophore, *N*-[2-(1-maleimidyl)ethyl]-7-(diethylamino)coumarin-3-carboxamide (MDCC) to an engineered C-terminal cysteine residue. Binding of the environmentally sensitive hydrophobic probe 2,6-anilinonaphthalene sulfonate (2,6-ANS) to CaM could be monitored by an increase in the fluorescence emission intensity of the 2,6-ANS. Evidence of fluorescence resonance energy transfer (FRET) from 2,6-ANS (acting as a donor) to MDCC (the acceptor in this system) was also observed; fluorescence emission representative of MDCC could be seen after samples were excited at a wavelength specific for 2,6-ANS. The FRET signal was monitored as a function of the concentration of calmodulin antagonists in solution. Calibration curves for both a selection of small molecules and a series of peptides based upon known CaM-binding domains were obtained using this system. The assay demonstrated dose-dependent antagonism by analytes known to hinder the biological activity of CaM. These data indicate that the presence of molecules known to bind CaM interfere with the ability of FRET to occur, thus leading to a concentration-dependent decrease of the ratio of acceptor:donor fluorescence emission. This assay can serve as a general model for the development of other protein binding assays intended to screen for molecules with preferred binding activity.

INTRODUCTION

Fluorescence-based technologies are of great importance in pharmacological screening assays as they are amenable to miniaturization, and provide high sensitivity and signal-to-noise ratio. Fluorescence resonance energy transfer (FRET) is a valuable tool for characterizing proximity relationships within and between biomolecules (*1*−*11*). Many FRET assays make use of variants of the green fluorescent protein (GFP), in both in vitro and in vivo applications. In particular, fusion proteins between a target protein and two spectrally overlapping GFP's have been used in these types of assays (*12*). One limitation of GFP-based FRET assays is that fusion of one (or two) GFP molecules to a protein could affect the folding of the hybrid protein. Additionally, the bulkiness of GFP could place constraints on any associated ligand-induced conformational changes, thus hindering the use of this fluorescent protein as a signal generator for bioanalysis. Consequently, development of FRET labeling strategies that minimize interference in the target protein's normal folding and binding activities is advantageous. To that end, this manuscript describes the use of a FRET donor−acceptor pair that requires only a single residue modification that is distant from the binding site of the target protein for site-specific covalent attachment of the acceptor.

The efficiency of energy transfer in FRET is inversely related to the distance between the donor and acceptor fluorophores. Proximity (less than 100 Å) is important in achieving nonradiative transfer between the two fluorophores, even if there is a significant overlap of the donor emission and acceptor excitation wavelengths. Thus, FRET assays are useful as a type of "molecular gauge" of proximity relationships. This allows for great sensitivity in the detection of structural transitions or alterations (*13*).

As the human proteome becomes elucidated, new therapeutic targets are progressively identified. To evaluate libraries of drug candidates against these targets, initial screening assays for potency, selectivity, and activity are necessary. Accordingly, new screening assays that are fast, simple, with no complex separation steps, inexpensive, and easily amenable to miniaturization are critical tools in the drug discovery process. In that regard, we have used calmodulin (CaM) as a model drug target to demonstrate the feasibility of a newly designed method for rapid assessment of binding affinities of drug candidates in a homogeneous format. CaM is a small calcium-modulated protein found in all eukaryotes that binds to and activates its numerous target proteins (*14*−*18*).

Herein, we report the development of a screening assay to evaluate protein-binding activity employing FRET between a fluorescent molecule in the assay solution and CaM site-specifically labeled with *N*-[2-(1-maleimidyl)-ethyl]-7-(diethylamino)coumarin-3-carboxamide (MDCC). This assay is used to assess binding of a selection of antagonists including both drug molecules and peptides representative of CaM-binding domains, in the presence of the hydrophobic fluorescent probe, 2,6-anilinonaphthalene sulfonate (2,6-ANS). Upon binding of 2,6-ANS to CaM, energy transfer occurs between 2,6-ANS, which binds to CaM but can be displaced by the analyte, and

the covalently attached MDCC at the C-terminus of the protein. When there is drug or peptide present in the sample, the binding event displaces the noncovalently bound 2,6-ANS in a competitive manner. This consequently increases the distance between the two fluorophores, leading to a decrease in the observed emission signal from the FRET acceptor, MDCC. A change in the concentration of analyte present in the sample thereby alters the ratio of FRET acceptor to FRET donor fluorescence emission. We have constructed calibration curves to evaluate the response of a series of drugs and peptides with known affinity for calmodulin as well as selected control compounds.

MATERIALS AND METHODS

Reagents. All test compounds, buffers, salts, the myosin light chain kinase inhibitor peptide, and CaM-dependent protein kinase II-delta fragment peptide were purchased from Sigma (St. Louis, MO). All other CaM binding peptides were obtained from Calbiochem (San Diego, CA). Dithiothreitol (DTT) was acquired from Gold Biotech (St. Louis, MO). Isopropyl-β-D-thiogalactopyranoside (IPTG) and ampicillin were obtained from U.S. Biochemical (Cleveland, OH). Synthetic oligonucleotides used as primer sequences for PCR were prepared by Operon (Alameda, CA). Taq DNA polymerase, the protein expression kit, and any necessary restriction enzymes were purchased from New England Biolabs (Beverly, MA). The fluorescent probes MDCC and 2,6-ANS were obtained from Molecular Probes (Eugene, OR). The Bio-Rad protein assay reagent was purchased from Bio-Rad Laboratories (Hercules, CA).

Apparatus. Starter cell cultures were grown in an orbital shaker from Forma Scientific (Marietta, OH). Fermentation of bacterial cultures was performed using a bioreactor from New Brunswick Scientific (New Brunswick, NJ). Optical density of cell cultures was measured on a Spectronic 21-D spectrophotometer from Milton Roy (Rochester, NY). Protein samples were concentrated using a Christ lyophilizer (Osterode, Germany). Protein purity was verified by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS−PAGE) on a PhastSystem from Pharmacia Biotech (Uppsala, Sweden). Fluorescence studies were carried out on either a Fluorolog-2 spectrofluorometer from Spex-JY Horiba (Edison, NJ) or a Cary Eclipse spectrofluorometer equipped with a multiwell plate reader from Varian (Palo Alto, CA).

Protein Expression, Purification, and Labeling. *Cloning.* The New England Biolabs IMPACT-TWIN system was used to create a C-terminal fusion between a cleavable intein (solely for affinity purification on a chitin bead column) and a mutant CaM-containing a C-terminal cysteine residue. To generate the C-terminal cysteine CaM, a single round of PCR was performed with *Taq* DNA polymerase using the plasmid pVUC-1 (*19*) as a template. To add *Nde*I and *Sap*I sites at the 5′- and 3′-termini, respectively, and include an insertion of a single cysteine at the C-terminus, the forward primer (CaMNdeI-F) 5′-GGTGGTGGTGGTGGCATATGATGGCTGATCAGCTGACT-3′ and the reverse primer (CaMSapI-R) 5′-GGTGGTGGTGGTTGCTCTTCCGCAACATGATCCT-CCTCCGGACTTAGCCATCATAACCTG-3′ were designed. Gene amplification was carried out for 30 cycles using a Perkin-Elmer Gene Amp thermal cycler (Norwalk, CT). The PCR denaturation was at 94 °C for 0.5 min, the annealing at 55 °C for 1 min, and the elongation at 72 °C for 1 min. The *Sap*I and *Nde*I restriction sites were used to insert the PCR-amplified synthetic calmodulin gene into the pTWIN1 vector. The plasmid containing the inserted gene was transformed into *E. coli* strain ER2566. Transformants were grown on selective media, and positive transformants were sequenced to verify the presence of the plasmid pTWIN1−CaM, containing the C-terminal cysteine CaM gene.

Expression and Purification. The IMPACT-TWIN system was also used to express and purify the recombinant calmodulin. *E. coli* ER2566 cells harboring the pTWIN1−CaM plasmid were grown at 37 °C in Luria Bertani medium containing 100 μg/mL ampicillin for approximately 16 h, until the OD_{600} reached 0.6. Protein expression was induced with a final concentration of 1 mM IPTG for 4 h followed by centrifugation for 20 min at 3800*g* to harvest the cells. The pellet was resuspended in a pH 7.0 buffer containing 20 mM Tris-HCl, 500 mM NaCl, and 1 mM EGTA.

Following sonication to lyse the cells, and centrifugation to clarify the crude cell extract, the supernatant was loaded onto a 5-mL column of chitin beads equilibrated in the same 20 mM Tris-HCl buffer in order to selectively purify the CaM−chitin binding domain fusion protein from the cellular milieu. Two washes were performed to remove any remaining unbound protein. The first was with the same buffer used to resuspend the cells, and a second wash used the same buffer, but with the NaCl concentration increased to 1 M. Then, three column volumes of 20 mM Tris-HCl, pH 8.5, containing 500 mM NaCl and 40 mM DTT were passed through the column, the column flow was stopped, and the column was stored at 4 °C for 16 h while the on-column cleavage reaction occurred. The next day, three more column volumes of the DTT-containing buffer were used to elute the bound protein, releasing the CaM from the bound chitin-binding domain at the intein cleavage site. The mutant CaM was isolated at greater than 90% purity based on SDS−PAGE. Protein concentrations were measured using the Bio-Rad protein reagent, a modified Bradford assay reagent. Further purification occurred after the labeling reaction.

Labeling. The protein was labeled by covalently attaching the thiol-reactive fluorophore, MDCC to the engineered C-terminal cysteine residue on CaM. The concentration of the unlabeled protein fraction varied from batch to batch, but the molar ratio of fluorophore to protein in the reaction mixture was always approximately 10:1. The labeling reaction and subsequent separation of labeled protein from unbound fluorophore using size-exclusion chromatography was performed as in ref 29. The extent of MDCC labeling was assessed using the following equation:

$$\frac{\text{moles dye}}{\text{moles protein}} = \frac{A_x}{\epsilon \times b} \times \frac{\text{MW}_{\text{protein}}}{\text{mg}_{\text{protein}}/\text{mL}}$$

where A_x is the absorbance at 420 nm (MDCC maximum), ϵ is the extinction coefficient for MDCC = 50 200 cm^{-1} M^{-1}, and b is the path length in cm. Labeling efficiencies were typically around 70%.

Fluorescence Studies of Interaction between Calmodulin and 2,6-ANS. *Energy Transfer Studies*. 2,6-ANS binding to unlabeled CaM could be monitored by the increase in fluorescence emission intensity of the 2,6-ANS when samples were excited at 360 nm and emission was measured at 420 nm. To observe energy transfer from 2,6-ANS to a 0.5 μM concentration of MDCC-labeled CaM, the donor excitation wavelength used was 360 nm, and the acceptor emission was measured at 460 nm using

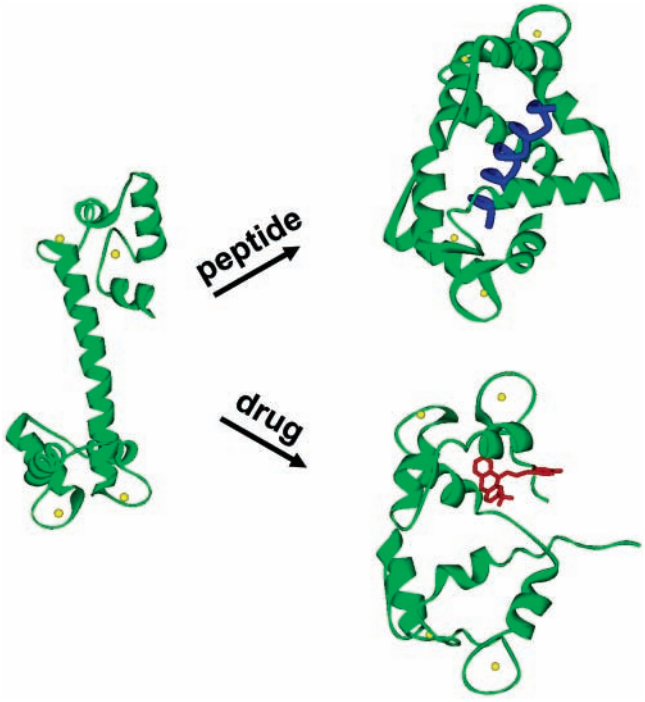

Figure 1. Crystal structure of Ca^{2+}−CaM (1EXR) bound to the myosin light chain kinase CaM-binding domain peptide, shown in blue (1CDL), and to the antipsychotic drug trifluoperazine, shown in red (1CTR). Calcium ions are shown in yellow. Protein databank (PDB) (*46*) files are indicated in parentheses.

a conventional benchtop fluorometer and poly(methyl methacrylate) cuvettes. Both studies were performed in a buffer containing 20 mM Tris-HCl, pH 8.0, with calcium-saturated CaM−MDCC.

Competitive Binding Experiments. CaM−MDCC was diluted to a final concentration of 0.5 μM in an assay volume of either 1.5 mL or 250 μL depending upon the assay platform used (conventional fluorometer or microtiter plate reader, respectively). The CaM solution was prepared in 20 mM Tris-HCl, pH 7.5, containing 100 mM KCl, 10 mM $CaCl_2$, and 0.5 μM 2,6-ANS. Each test sample was diluted to the final concentration with either buffer alone or varying concentrations of drug prepared in the buffer solution. The fluorescence was measured directly after a brief mixing step. Samples were excited at the donor excitation wavelength of 360 nm (2,6-ANS), and donor and acceptor emissions were measured at 410 nm (2,6-ANS) and 460 nm (MDCC). The ratio of acceptor to donor fluorescence was plotted versus analyte concentration to construct calibration curves.

RESULTS AND DISCUSSION

The crystal structures of three different conformations of calmodulin (Ca^{2+}−CaM, Ca^{2+}-peptide−CaM, and Ca^{2+}-TFP−CaM) are displayed in Figure 1. On the right, trifluoperazine (TFP) is shown bound to the C-terminal domain of the globular protein. While it is commonly acknowledged that the CaM−trifluoperazine complex has a 1:1 stoichiometry, evidence has been offered (including crystallographic data) that CaM can bind up to four molecules of trifluoperazine (TFP) in solution and form a compact globular structure (*20*−*23*). Assays have been developed to measure interactions of CaM with drugs and biomolecules previously. Calmodulin has been employed since the early 1990s as a calcium sensor (*24*, *25*). These biosensing systems utilized CaM labeled with fluorescent probes, either randomly or site selectively. In addition, other systems have been employed in ex vivo or in vivo Ca^{2+} detection utilizing the fusion of CaM to two flanking GFPs (*5*, *15*, *16*, *26*−*28*). Also, two different systems for the detection of phenothiazine-type drugs for high-throughput screening applications using calmodulin have been presented (*29*, *30*). Moreover, in another study a doubly labeled, agarose immobilized, CaM−maltose binding protein fusion protein was constructed for use in a FRET assay for single molecule detection of a CaM-binding peptide (*31*).

It is well established that solvent-exposed hydrophobic surfaces are formed upon Ca^{2+} binding to CaM (*14*−*16*). Anilinonaphthalene sulfonates (ANS) can serve as fluorescent probes of hydrophobicity as their quantum yield and emission maxima are dependent upon their environment. In water, ANS is virtually nonfluorescent, but in nonpolar environments it emits a bright blue fluorescence with a quantum yield ~0.70 (*32*). ANS has been used previously to measure the surface hydrophobic character of proteins and membranes, particularly during the folding/unfolding of proteins (*33*−*36*).

LaPorte et al. demonstrated through differential binding in the presence and absence of calcium that there are 2.1 ANS binding sites in CaM (*37*). Tsurata and Sano later argued that under LaPorte's experimental conditions, CaM could not be saturated with calcium, and that there were likely two to four ANS binding sites with binding constants ranging from 2.91 to 3.86 $\times$ 10^{-4} M^{-1} (*38*). Some investigators propose that the mode of ANS binding occurs through ion-pair formation between the sulfonate moiety and cationic groups on the protein (*39*−*41*). In fact, it has been suggested that ANS may be a conformational tightening agent, and that ANS fluorescence may not be entirely due to interactions with hydrophobic sites on the protein, but instead to less interaction with water (*40*). Taking into consideration the discussion over the true character of ANS binding, we have developed a system that operates at a constant ANS concentration to overcome any possible discrepancies due to the number of ANS molecules bound at any given time to CaM. We have also set the ANS concentration at a level below that at which the inner filter effect causes the ANS fluorescence to decrease.

In the presence of ANS and MDCC-labeled CaM, fluorescence was observed at the wavelength corresponding to the emission maximum of MDCC, with no direct excitation of the latter. This provided evidence that FRET could be monitored using our system. We achieved this by selectively exciting the ANS molecules, which exhibit weak fluorescence in aqueous solution and become noticeably fluorescent when CaM is present. We hypothesized that if ANS binds to CaM in its C-terminal hydrophobic region, it will be in close enough proximity to the C-terminal MDCC on the protein for fluorescence resonance energy transfer to occur, provided that the two molecules have sufficient spectral overlap. In fact, these two molecules were chosen because the emission of ANS and the excitation of MDCC are both close to 420 nm. Figure 2 depicts the principle of the FRET application described herein. On the right, a molecule of 2,6-ANS is shown near the hydrophobic binding pocket of the C-terminal domain of CaM, a potential binding site for ANS. In this instance, the bound MDCC at the C-terminus is in close enough proximity to the molecule of bound 2,6-ANS for energy transfer to occur. In the presence of phenothiazine-type compounds or CaM-binding peptides, a competitive binding interaction is introduced as the analyte (TFP in this case) replaces 2,6-ANS in the hydrophobic pocket of CaM. By removing the

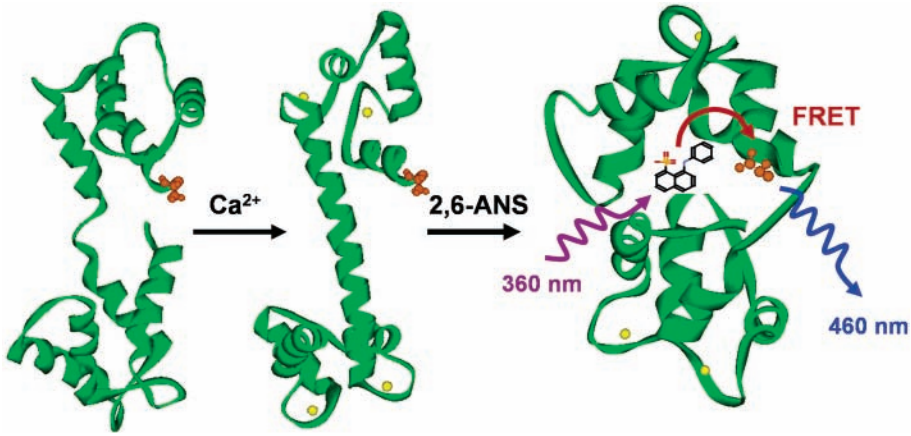

Figure 2. Proposed scenario demonstrating the predicted energy transfer from the bound 2,6-ANS to the C-terminal attached MDCC. It is hypothesized that energy transfer is inhibited when the protein binds to drugs or model peptide molecules. The C-terminal residue, where MDCC is attached, is highlighted in orange and 2,6-ANS is black.

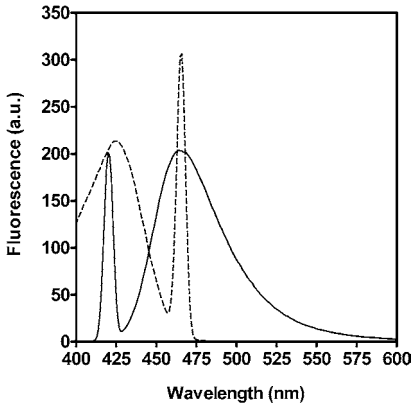

Figure 3. Excitation (- - -) and emission (—) spectra of 1 μM CaM−MDCC. The emission wavelength for the excitation trace was 460 nm. The excitation wavelength was set at 420 nm for the emission spectrum.

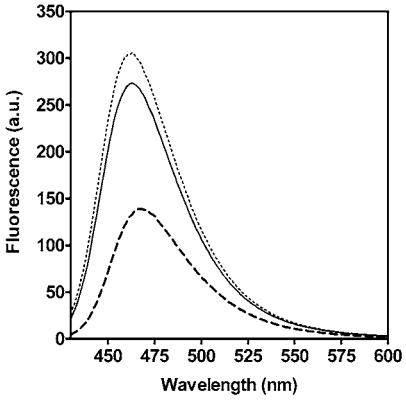

Figure 4. Effect of changing calcium concentrations on 1 μM CaM−MDCC fluorescence. 10 mM Ca^{2+} (- - -), 1 mM Ca^{2+} (—), and 1 mM EDTA (− − −) are shown. Excitation was at 420 nm.

bound 2,6-ANS from CaM, FRET is limited as the 2,6-ANS is too far away for any significant radiationless energy transfer to the bound MDCC molecule to occur.

The excitation and emission spectra of 1 μM CaM−MDCC in the presence of saturating calcium are shown in Figure 3. The effect of changing calcium concentrations on CaM−MDCC fluorescence was also assessed. In the presence of the metal complexing agent EDTA, the fluorescence of CaM−MDCC was lower than when Ca^{2+} was present (Figure 4). A concentration of 10 mM Ca^{2+} was

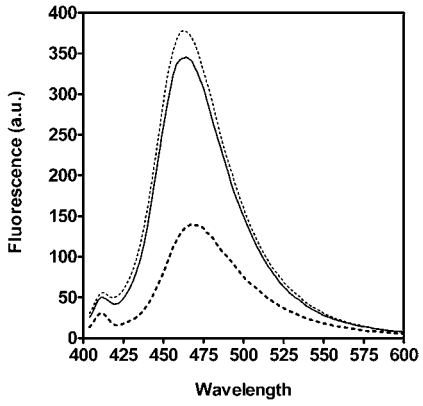

Figure 5. Effect of calcium concentration on energy transfer from 1 μM 2,6-ANS to 1 μM CaM−MDCC. 10 mM Ca^{2+} (- - -), 1 mM Ca^{2+} (—), and 1 mM EDTA (− − −) are shown. Excitation was at 360 nm.

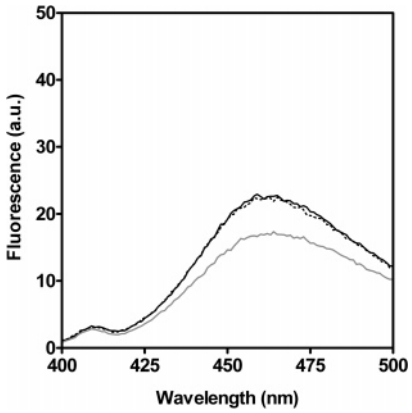

Figure 6. Effect of changing calcium concentrations on 0.25 μM CaM−MDCC with 1 μM 2,6-ANS. 10 mM Ca^{2+} (- - -), 1 mM Ca^{2+} (—), and 1 mM EDTA (—) are shown. The excitation was at 360 nm.

required to obtain maximum fluorescence emission at 460 nm. Thus, all assay buffers contained 10 mM calcium.

We also considered the effect of calcium on the efficiency of the FRET interaction. The calcium dependence of FRET between the two chromophores using 1 μM 2,6-ANS and 1 μM CaM−MDCC was studied, and the results are shown in Figure 5. The emission intensity at 460 nm was slightly higher when 10 mM calcium was present. Notice also that the ANS emission peak is shifted to 410 nm. The FRET ratios were thus calculated using 460/410 nm for the subsequent calibrations.

Table 1. Description of Peptides Used in This Study

synthetic peptide	amino acids	sequence	mw	description
CaM inhibitory peptide	17	Ac-RRKWQKTGHAVRAIGRL-NH_2	2074.5	based upon CaM binding domain of MLCK
CaM inhibitory peptide (control)	17	Ac-RRKEQKTGHAVRAIGRE-NH_2	2034.3	control for CaM inhibitory peptide
CaM binding domain	20	LKKFNARRKLKGAILTTMLA	2274.3	CaM kinase II residues 290−309
CaM kinase II inhibitor	29	MHRQETVDCLKKFNARRKLKGAILTTMLA	3374.1	CaM kinase II residues 281−309
myosin light chain kinase inhibitor	11	KRRWKKNFIAV-NH_2	1445	chicken smMLCK CaM binding domain
CaM dependent PK II-δ fragment(residues 345−358)	14	KSDGGVKKRKSSS	1450.6	substrate for brain Ca^{2+}/CaM-dependent PK IV

CaM−MDCC could be detected at concentrations above 10 nM (shown in Supporting Information). We selected 0.25 μM as the final concentration for the assay to minimize the amount of protein used that could give a signal at least 100-fold higher than the blank when using the Varian Cary Eclipse microtiter plate reader. The appropriate concentration of 2,6-ANS to use in the assay was determined by monitoring the change in ANS fluorescence in the presence of the previously selected 0.25 μM CaM−MDCC concentration. The fluorescence of ANS quickly diminishes as the concentration of the molecule in solution increases due to the inner filter effect. Therefore, an assay concentration of 1 μM was determined to be appropriate for our system. We then combined all of these conditions and measured the emission in smaller volume (250 μL) microtiter plate samples with 0.25 μM CaM−MDCC and 1 μM 2,6-ANS and evaluated the effect of calcium on the energy transfer under the final assay conditions. A calcium concentration of 1 mM resulted in a higher emission signal than when EDTA was present. Figure 6 demonstrates that in this case, changes in calcium concentration from 1 mM to 10 mM did not visibly alter the acceptor (MDCC) fluorescence emission at 460 nm.

Using the previously described conditions, energy transfer from 2,6-ANS to MDCC was observed and the ratio of acceptor to donor fluorescence intensity was related to the amount of drug or peptide present in each sample. Calibration curves for a series of peptides and drug compounds were obtained using this system. Table 1 and Figure 7 show the structures of all of the compounds that were tested using this assay, including negative controls that were used for selectivity testing (aspirin, propranolol, serotonin, and warfarin). The data indicate that the presence of known CaM antagonists interferes with the FRET activity, thus leading to a concentration-dependent decrease in the resultant fluorescence emission ratio. The observed changes could be a combination of dual effects, including the proposed displacement of 2,6-ANS, but also alteration of the local environment of the MDCC molecule upon drug or peptide binding. The graph in Figure 8 shows dose−response curves for changing concentrations of several peptides in the presence of CaM−MDCC and 2,6-ANS. Similar

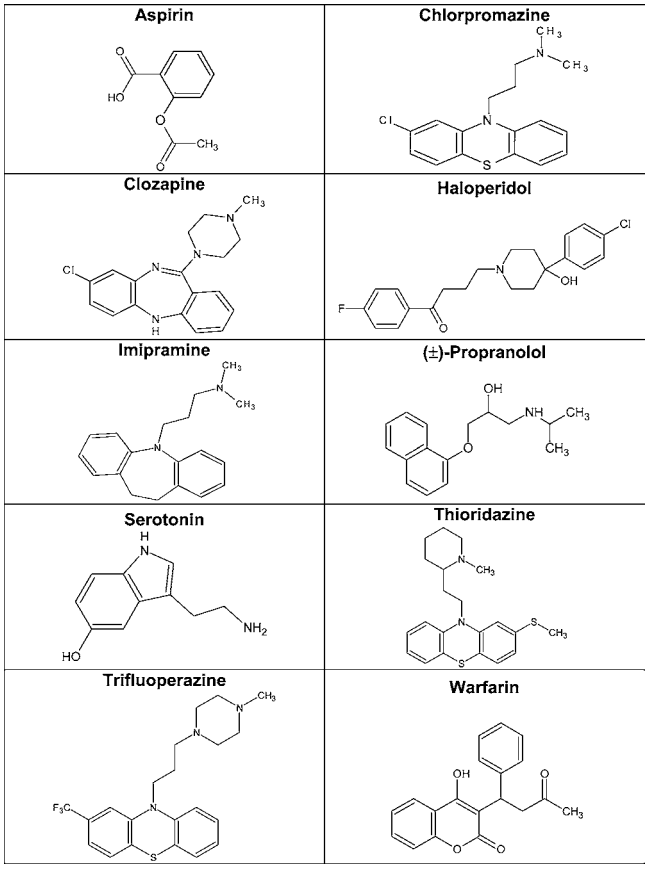

Figure 7. Structures of test compounds. Compounds listed are known CaM antagonists and are classified as phenothiazine (chlorpromazine, thioridazine, and trifluoperazine), dibenzazepine (clozapine, haloperidol), or tricyclic antidepressant (imipramine) drugs. The other compounds listed are controls.

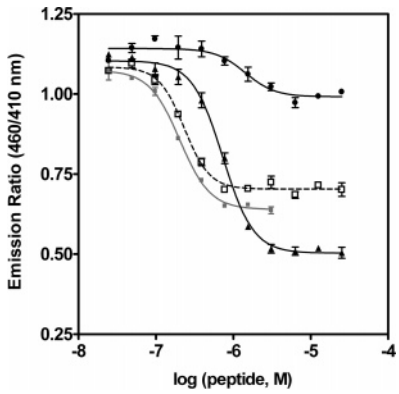

Figure 8. Calibration plots for MLCK inhibitor peptide (●), CaM inhibitory peptide (▲), CaM binding domain peptide (△), and CaM kinase II inhibitor peptide (■), are all described in Table 1.

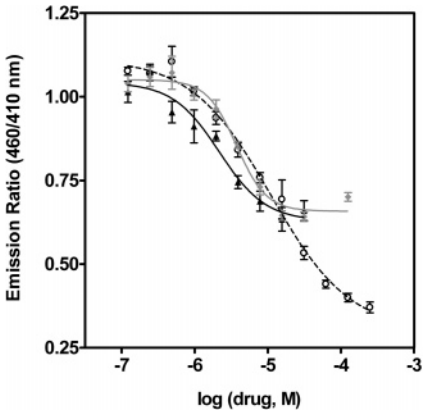

Figure 9. Calibration plots for the phenothiazine drugs chlorpromazine (◆), thioridazine (▲), and clozapine (○).

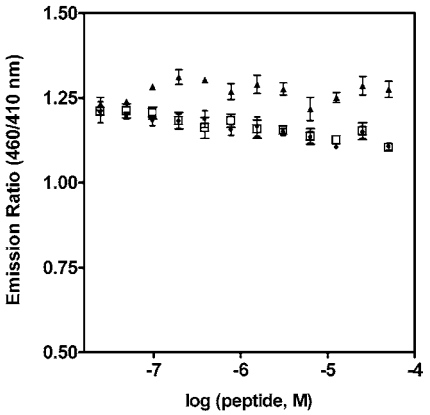

Figure 10. Calibration plots for CaM inhibitory peptide (control) (▲), and CaM dependent PK II-δ fragment (□) demonstrate results similar to when no peptide is present (●).

Table 2. Calculated IC_{50} Values Based upon Curve Fitting of Sigmoidal Dose−Response Curves Such as Those in Figures 8 and 9

peptide	IC_{50} (μM)	% FRET inhibition
CaM inhibitory peptide	0.731	100
CaM kinase II inhibitor	0.204	57
CaM binding domain	0.232	45
MLCK inhibitor	1.424	12

drug	IC_{50} (μM)	known K_i (μM)[a]
imipramine	12.5	14
thioridazine	2.16	-
clozapine	8.83	-
chlorpromazine	4.31	1.5
trifluoperazine	1.14	1.1
haloperidol	14.8	-

[a] Data from Reynolds and Claxton (1982).

results with a few representative drug compounds can be seen in Figure 9. Results from all peptides and drugs tested that affected the FRET have been compiled and presented in Table 2. The IC_{50} values represent the effective concentration corresponding to 50% of the maximum acceptor:donor FRET ratio.

It should be noted that no significant change in the FRET emission ratio was observed in the presence of compounds not known to affect the physiological behavior of CaM, such as aspirin and propranolol, which were used as negative controls (data not shown). Reynolds and Claxton have determined apparent K_i values for CaM with trifluoperazine, chlorpromazine, and imipramine, which are also listed in Table 2 (*42*). Their experiments measured the inhibition of CaM-activated guinea-pig heart phosphodiesterase by these compounds. IC_{50} values relate to the affinity of the interaction between ligands and receptors and have been shown by theoretical modeling to correlate with the K_D values (*43*). The present study and that of Reynolds and Claxton are in agreement with respect to the order of affinity of calmodulin for certain drugs, namely, trifluoperazine > chlorpromazine > imipramine.

The results from the peptides are indicative of their relative potencies. The CaM inhibitory peptide differs from the CaM inhibitory peptide (control) by only two residues selected to disrupt the interaction with calmodulin (*44*, *45*). The control peptide showed no change in the FRET emission ratio at any concentration tested, and similar results were obtained with the Ca^{2+}/CaM dependent protein kinase II-δ fragment as seen in Figure 10. The latter is actually a substrate for Ca^{2+}/CaM dependent protein kinase IV and was not expected to bind to CaM. For the peptides in Figure 8, we ranked the percent inhibition of FRET relative to the FRET inhibition obtained with the CaM inhibitory peptide (Table 2). The Ca^{2+}/CaM kinase II inhibitor peptide and CaM binding domain peptide, both derived from the CaM Kinase II CaM binding site, were found to be moderate FRET inhibitors, but had lower IC_{50} values than the CaM inhibitory peptide. A possible explanation for this difference in percent inhibition may relate to displacement of more than one molecule of 2,6-ANS per CaM. The myosin light chain kinase inhibitor peptide is a truncated version of the chicken smooth muscle myosin light chain kinase CaM binding domain. Thus, it was not surprising that is was the poorest inhibitor of FRET in our assay.

CONCLUSION

In summary, we have demonstrated the use of a competitive binding assay using FRET for the detection of drug and peptide antagonists of CaM. ANS has been shown to bind to hydrophobic binding sites and monitor binding events in a variety of proteins (*34*, *35*}. ANS has also been used as a monitor of conformation and an indicator of protein folding (*36*, *37*). Therefore, it is reasonable to conclude that ANS could be employed for applications in monitoring ligand-induced conformational changes in a wide range of binding proteins. Although ANS and the antagonists presumably bind at the same site in CaM, this is not a requirement for the type of FRET assay described herein. The only criterion is that the binding of a ligand to a protein binding site alters the binding constant of ANS to the protein. The two sites where ANS and the ligand bind need not be identical, and allosteric interaction would be sufficient. Thus, this FRET assay could be a model for other protein binding assays intended for use in pharmacological screening to detect compounds with desired properties. The assay has been proven to be rapid, simple, and economical, as it requires single rather than dual labeling for FRET. These are characteristics key to designing assays for drug candidate selection. The assay protocol developed also renders itself to automation, as it does not require complex separation steps. Finally, the sensitivity for both drug molecules and peptides has been demonstrated and compared among structurally related and unrelated compounds.

ACKNOWLEDGMENT

This work was funded by the National Aeronautics and Space Administration and the National Science Foundation. B.S. gratefully recognizes support from an Integrated Graduate Education and Research Traineeship predoctoral fellowship.

Received June 20, 2005; Revised Manuscript Received July 20, 2005

Optical imaging has attracted a great attention for studying molecular recognitions because minute fluorescent tracers can be detected in homogeneous and heterogeneous media with existing laboratory instruments. In our preliminary study, a clinically relevant photosensitizer (HPPH, a chlorophyll-a analog) was linked with a cyanine dye (with required photophysical characteristics but limited tumor selectivity), and the resulting conjugate was found to be an efficient tumor imaging (fluorescence imaging) and photosensitizing agent. Compared to HPPH, the presence of the cyanine dye moiety in the conjugate produced a significantly higher uptake in tumor than skin. At a therapeutic/imaging dose, the conjugate did not show any significant skin phototoxicity, a major drawback associated with most of the porphyrin-based photosensitizers. These results suggest that tumor-avid porphyrin-based compounds can be used as "vehicles" to deliver the desired fluorescent agent(s) to tumor. The development of tumor imaging or improved photodynamic therapy agent(s) by itself represents an important step, but a dual function agent (fluorescence imaging and photodynamic therapy) provides the potential for tumor detection and targeted photodynamic therapy, combining two modalities into a single cost-effective "see and treat" approach.

INTRODUCTION

As photosensitizing agents, porphyrin-based compounds have played a central role in photodynamic therapy (PDT), the sensitization of tumor tissue to destruction by light (*1*−*3*). Photofrin, which was developed in the Roswell Park Cancer Institute (RPCI), is being used worldwide for the treatment of a wide variety of solid tumors. In the US, Photofrin PDT is approved for the treatment of obstructive esophageal cancer, early- and late-state lung cancer, and high-grade dysplasia associated with Barretts esophagus (*4*). The demonstrated clinical usefulness of PDT has spawned the development of a large number of new photosensitizers, and numerous tetrapyrrole-based compounds have been synthesized in various laboratories (*5*, *6*). Since the introduction of first PDT drug Photofrin, there have been continuous efforts in various laboratories to improve photosensitizer's tumor selectivity and specificity (*7*). Tumor cells in general have nonspecific affinity for porphyrins, the mechanism of porphyrin retention in tumors is not well understood, although the balance between hydrophilicity and hydrophobicity is recognized as an important factor. Some attempts have been made to direct photosensitizers to a known cellular target by creating a photosensitizer conjugates, where the other molecule is a ligand specific to the target (*8*, *9*). Some other examples of such photosensitizers are: conjugates with cell-membrane cholesterol (*10*) antibody (*11*−*13*), chemotherapeutic agents (*14*), etc. Certain proteins and microspheres were also made to improve the pharmacology of the compounds (*15*, *16*). These strategies seldom work well because the pharmacological properties of both compounds are drastically altered.

At RPCI, we have identified highly promising photosensitizing agents among a series of alkyl ether analogues of pyropheophorbide-a, (665 nm) (*17*, *18*), purpurinimides (705 nm) (*19*−*22*), and bacteriopurpurinimides (796 nm) (*23*−*25*) on the basis of quantitative structure−activity relationship (SAR) and/or SAR studies. One of the compounds in a pyropheophorbide-a series [3-devinyl-3-(1-hexyloxy)ethyl analogue (HPPH)] is currently in Phase I/II clinical trials at RPCI for the treatment of esophageal, lung, and cutaneous tumors (*26*−*27*).

Porphyrins and related compounds have also been investigated for use in optical diagnostic technologies based on their fluorescent properties, e.g., fluorescence being exploited as a possible technique for guidance of surgical intervention (*28*). In such surgical-assist applications, the ability to provide real-time information about surgical margins would be highly useful. Unfortunately, despite the attractiveness of the porphyrin-based compounds as photosensitizers for PDT, most of these compounds do not possess the excitation and emission spectra favorable for fluorescent contrast agents for imaging deep tissues. First, to maximize penetration depth into tissues, excitation between 750 and 800 nm

is preferred and the Stokes shift must be large to enable discrimination of the small fluorescent component from the overwhelming large component of excitation light. An insufficient Stokes shift of 10−15 nm complicates the process of rejecting multiply scattered light, as the efficiency of the filters cannot be guaranteed. For these reasons, the usefulness of PDT agents for contrast is largely limited to superficial epithelial linings of accessible tissues.

In recent years, a number of optical imaging approaches have been reported (*29*). These techniques rely on fluorescence, reflectance, absorption, or bioluminescence as the source of contrast, while imaging systems can be based on diffuse optical tomography, surface-weighted imaging, phase-array detection, confocal imaging, multiphoton imaging, or microscopic imaging with intravital microscopy. However, with the exception of near-infrared (NIR) fluorescence imaging (*30*) and superficial confocal and two-photon imaging, these techniques currently are limited to experimental imaging to small animals. Unlike fluorescence microscopy of cells or thin-tissue samples, in vivo imaging is preferably performed in the NIR region (700−900 nm) because of more efficient tissue penetration of photons and minimal auto fluorescence in this region (*31*). Recently, this technology has been extended to in vivo imaging of biological targets and disease. It has been shown that frequency−domain photon migration (FDPM) with an image-intensified charge-coupled device (CCD) can be used for the detection of diseased tissues in vivo using fluorescent contrast agents (*32*). A number of different NIR fluorochromes such as cyanine dyes have been described with variable stabilities, quantum efficiencies, and ease of synthesis (*33*, *34*). Despite their excellent photophysical properties, except a few folic acid (*35*) or certain peptide-linked (*36*) cyanine dyes, most of them (e.g., indocyanine green) are not tumor specific and are eliminated rapidly from the organism. By realization of the importance of porphyrin-based compounds in tumor avidity and photosensitizing efficacy and the advantages of cyanine dyes for tumor imaging due to their inherent characteristic of NIR absorbance and emission, we were interested in designing "bifunctional agents" consisting of these two chromophores, which could produce the desired photophysical properties suitable for both tumor detection by optical imaging as well as therapy (PDT). Such image-guided PDT would represent a new paradigm for tumor treatment. To provide a proof of principle concept, we have prepared and preliminarily evaluated a conjugate comprised of the photosensitizer HPPH and cyanine dye IR820.

EXPERIMENTAL PROCEDURES

For ^{1}H NMR data, chemical shifts are expressed in ppm with reference to trimethylsilane (0.00 ppm). Column chromatographic separations were performed over silica gel 60 (70−230 mesh) or neutral alumina (Grade III (6% water), ∼150 mesh). Preparative thin-layer chromatography (TLC) was performed on silica 20 × 20 cm^2 TLC plates. The cyanine dye 1 was purchased from Aldrich Chemicals.

Cyanine Dye 3. Compound **1** (60 mg) and 4-aminothiophenol (60 mg) were dissolved in dry DMF and stirred overnight. DMF was removed by high vacuum, the residue was purified by chromatography using MeOH/CH_2Cl_2 (1:3) as the eluting solvent system, and **3** was obtained in ∼80% yield. NMR [MeOH (d4)], δ (ppm) 9.0 (d, 2H, H−a), 8.2 (d, 2H, H−b), 8.0 (t, 4H, H−c), 7.62 (d, 4H, H−d), 7.48 (2d overlapped to be triplet, 2H, H−e), 7.12 (d, 2H, H−f), 6.70 (d, 2H, H−g), 6.35 (d, 2H, H−h), 4.30 (t, 4H, H−i), 2.95 (t, 4H, H−j), 2.80 (m, 4H, H−k), 2.00 (m, 10H, 4H for H−l, 6H for m, n, o), 1.90 (s, 12H, H−p), 1.30 (s, H−q). MS for **3**: calcd $C_{52}H_{56}N_3NaO_6S_3$, 937; found, 937. High resolution (HR) MS for **3**: calcd $C_{52}H56N_3NaO_6S_3$, 937.3229; found, MH^+, $C_{52}H_{57}N_3NaO_6S_3$, 938.3320.

HPPH−Cyanine Dye Conjugate 5. HPPH **4** (100 mg) and DCC (110 mg) were dissolved in 1 mL of dry DMF and stirred for 10 min, and the solution of **3** (145 mg) in DMF (2 mL) and 10 mg DMAP were added. Twenty-four hours later, the reaction mixture was worked up. The residue was purified by chromatography using MeOH/CH_2Cl_2 (1:3) as the eluting solvent system, and **5** was obtained in ∼65% yield. UV−vis in H_2O: 848 nm (ϵ = 97547), 664 nm (ϵ = 53800), 413 nm (ϵ = 101456). UV−vis in MeOH: 833 nm (ϵ = 207455), 660 nm (ϵ = 53856), 408 nm (ϵ = 95222). NMR ($CHCl_3$) δ (ppm) for compound **5**: 9.47 (s, 1H, meso-H in HPPH part), 8.46 (s, 1H, meso-H in HPPH part), 8.35 (br-s, 3H, 1H for meso-H in HPPH part, 2H for H−a), 7.50 (m, 5H, 1H for H−b, 4H for H−c), 7.30 (m, 3H, 1H for H−b, 2H for H−e), 7.20 (s, 2H, H−f), 7.05 (s, 4H, H−d), 6.85 (s, 2H, H−g), 6.61 (s, 2H, H−h), 5.70 (br, 3H, 1H for H-3^1, 1H for H-17, 1H for H-18), 4.54 (br-doublet, 1H, H-13^2), 4.22 (br, 2H, H−i), 3.66 (br, 2H, H−i), 3.20 (br, 9H, 5H for HPPH part: 3H for 7-CH_3, 2H for 3^1-OC*H*$_2$(CH$_2$)$_4$CH$_3$, 4H for H−j), 3.03 (m, 4H, H−k), 2.90 (s, 1H, −CON*H*), 2.72 (br, 7H, 2H for 8-C*H*$_2$CH$_3$, 2H for 17-CH_2CH_2CO-, 3H for 2-CH_3), 2.55 (br, 5H, 2H for 17-CH_2CH_2CO-, 3H for 12-CH_3), 1.88 (br, 3H, 3-$CHCH_3$), 1.72−0.72 (many multiples, 36 protons, 22 H for dye part: 12H for H−p, 4H for H−l, 6H for H−m, n, o; 14 H for HPPH part, 3H for 18-CH_3, 3 H for 8-CH_2C*H*$_3$, 8H for 3^1-OCH$_2$(C*H*$_2$)$_4$CH$_3$), 0.62 (m, 3H, 3^1-OCH$_2$(CH$_2$)$_4$C*H*$_3$. MS for **5**: calcd $C_{91}H_{102}N_7NaO_9S_3$, 1555.6; found, 1555.7. HRMS for **5**: calcd $C_{91}H_{102}N_7NaO_9S_3$, 1555.6798; found MH^+ $C_{91}H_{103}N_7NaO_9S_3$, 1555.6920.

Formulation of the Conjugates. HPPH and the corresponding cyanine dye conjugate were insoluble in water. Therefore, these compounds were formulated in 1% Tween-80/5% dextrose solution. The concentration of the final formulation was determined by following the Beer−Lambert's law. The stability and purity of the conjugates in formulation was ascertained by high-performance liquid chromatography analysis.

Photophysical Characterization. Photophysical properties of the synthesized conjugates were examined in different solvents (water, methanol, chloroform, etc., depending on solubility). Methods of electronic absorption and steady-state and time-resolved luminescence spectroscopy were used (*37*). Steady-state measurements were performed using a Shimadzu UV-3101PC spectrophotometer (absorption spectra) and Fluorolog-3 spectrofluorometer (Jobin Yvon) (fluorescence spectra). A SPEX 270M spectrometer (Jobin Yvon) equipped with an InGaAs photodetector (Electrooptical Systems Inc., USA) was used for acquisition of singlet oxygen emission spectra and dye emission in the NIR spectral range. A diode-pumped solid-state laser (Verdi, Coherent) at 532 nm was the excitation source in this case.

For the measurement of fluorescence decays, a Becker & Hickl Photon counting module (SPC-830), equipped with a fast PMT (Hamamatsu H7422) having a system response of about a 300-ps full width at half maximum, was used. A Ti:Sapphire laser (Tsunami from Spectra Physics) tunable in the range of 740−880 nm (∼100-fs pulses at 82 MHz) using BBO crystal and the obtained

light were used to excite the sample solution in a cuvette. A PHD-400-X high-speed photodiode module was used to provide a synchronization signal from the Ti:Sapphire laser.

Cell Line. For HPPH and the corresponding cyanine dye conjugate, RIF (radiation induced fibrosarcoma) cells were cultured in αMEM medium. Semiconfluent culture was used for in vitro studies of photosensitivity (survival studies) and drug localization as well as propagation of tumors in vivo by following the methodology routinely used in our laboratory.

Intracellular Localization of Conjugates. To determine subcellular localization, HPPH and the conjugate were co-incubated with organelle-specific fluorescent probes. RIF cells were seeded at 2×10^5 on poly-L-lysine-coated cover slips in six-well plates and cultured for 24 h to allow attachment and spreading. HPPH or conjugates at appropriate concentrations (typically 0.5−2 μM) were added to cells in culture medium, and the cells incubated for 3 or 24 h at 37 °C, 5% CO_2 in the dark. To determine subcellular localization, cells were co-incubated with fluorescent probes (Molecular Probes, Invitrogen Carlsbad, CA) known to target mitochondria (Rhodamine 123, 1 μM or Mitotracker Green, 200 nM) or lysosomes (yellow-green Fluospheres 0.1 μm diameter, 1:10 000 dilution). Mitotracker Green and Fluospheres were added 24 h prior to microscopy, the latter with gently rocking and the R-123 was added during the final 30 min of incubation. The cells were then rinsed briefly with phosphate-buffered saline (PBS) and examined immediately by fluorescence microscopy (Zeiss Axiovert 35, Carl Zeiss, Inc., Germany) with a 200-W mercury arc lamp light source.

Fluorescence was imaged with a CCD camera and intensifier as previously described (*38*) and processed with Metamorphose 4.5 (Universal Imaging Corp., Downington, PA). Images of photosensitizers and co-localizing dyes in the same field were taken in rapid succession. Photosensitizers were detected using a combination of 530−580-nm excitation and 600-nm dichroic/615-nm long-pass emission filters. R-123, Mitotracker Green, and Fluospheres were detected using 445−490-nm excitation and 510-dichroic/520−560-nm long pass/emission filters.

In vitro Photosensitizing Efficacy. RIF tumor cells (*18*) were cultured in αMEM (Invitrogen, Carlsbad, CA) supplemented with 10% fetal calf serum (Herndon,VA) in 100% humidity with 5% CO_2. Cells were harvested and used for in vitro assays in the log phase of growth. In a typical experiment, cells will be seeded in replicates at 5×10^4 cells/well in 96-well plates. Cells were incubated overnight before adding the desired conjugate at variable concentrations (0.125, to 4.0 μM). After 3 or 24 h incubation with the drug in the dark, cells were exposed to laser light at the longest wavelength absorption peak of the conjugate to deliver doses of 0.5−4 J/cm^2. After light treatment, fresh medium was added and the cells were incubated for 48 h. Phototoxicity for each photosensitizer was assessed after 48 h by comparing growth of treated cells to control cells (no drug, no light) as measured by formazan production using the 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenylyetrazolium bromide (MTT) assay (*39*). Ten microliters of MTT (Sigma, St. Louis, MO) at 4 mg mL^{-1} in PBS was added, and the cells were incubated for 4 h. The medium was removed and the formazan crystals were dissolved in dimethyl sulfoxide (DMSO, FisherBiotech, Fair Lawn, NJ) at 100 μL per well. Formazan absorbance was read on a 96-well plate reader (Titertek Multiskan Plus MK II Miles Inc.) at 560 nm.

Tumor Uptake by in vivo Reflectance Spectroscopy. Tumor-bearing mice were anesthetized using ketamine/xylazine (2.2 mg/20 g mouse). The optical density as a function of wavelength was recorded before the intravenous (iv) injection of the conjugate (*40*). The monochromator was set to the expected longest wavelength of the experimental drug's in vitro absorption spectrum. The drugs were then administered by tail vein injection, and the light signal was recorded. The second spectrum was altered by the presence of drug in the tumor. This in vivo drug absorption spectrum was best displayed by taking the ratio of the post-injection spectrum to the pre-injection spectrum. This ratio offered the same advantages as a double beam absorption spectrophotometer. Data obtained before drug administration represented the reference spectrum. The ratio of these two spectra was not influenced by the wavelength dependence of the instrument. As a safeguard against day-to-day or hour-to-hour drift in the total light output of the lamp, both spectra (before and after administration) were normalized by dividing the signal strength at a wavelength where the drug absorption is negligible. To determine the uptake/clearance of tumor vs skin, another probe was used to record the in vivo absorption spectrum of the compound present in skin.

In vivo Antitumor Effect. Photosensitizers were injected intravenously (tail vein) in approximately 0.2-mL volumes. Mice bearing transplantable tumors were restrained without anesthesia in Plexiglas holders designed to expose only the tumor and a 2−4-mm angular margin of skin to light. For mice bearing spontaneous tumors at unpredictable sites, light exposure was flexibly adjusted to accommodate exposure of these sites. The tumors were exposed with a laser light source at appropriate absorption wavelength (Spectra Physics coherent argon-pumping tunable dye lasers, ranging from 630 to 800 nm, and ILX Light wave laser diode controller containing diodes of desired wavelength). The drug and light dosimetry followed the experimental design outlined previously (*18*). A typical experiment was as follows: Day 0: implant tumor. Staging day: select mice with tumor measuring 4.5−5.5 mm (longest axis), prepare photosensitizers, record body weight, and inject test photosensitizer (iv). Treatment day (chosen based on prior tumor uptake data determined by in vivo reflectance spectroscopy): expose tumors to light, measure tumor dimensions (orthogonal diameters) by caliper every other day for tumor growth/regrowth assays. The tumor volume, V, is calculated with the formula $V = (lw^2/2)$, where l is the longest axis of the tumor and w is the axis perpendicular to l. Observe treatment field, i.e., record observations of edema, erythema, and escar formation. Record time to regrowth of tumors to 400 mm^3 (those mice in which there was no tumor regrowth for 90 days, accounted as cured mice). Mice were sacrificed for ethical consideration when tumors reach that volume (400 mm^3).

Normal Tissue Responses. Foot response was judged using a 0−3 scale. 0 = no apparent difference from normal, 0.1 = very slight edema, 0.3 = slight edema, 0.5 = moderate edema, 0.75 = large edema and/or slight erythema, 1.0 = large edema and/or erythema with exudate, 1.2 = moderate erythema, with slight scaly or crusty appearance, 1.5 = definite erythema with definite scaly or crusty appearance, 1.65 = slight damage and or slight fusion of toes, *2.0 = most toes fused but general shape unchanged, 2.5 = foot shapeless with no toes, 3.0 = only stub of foot remaining (*41*).

Assessment of Vascular Perfusion. Fluorescein was used as a marker for vascular perfusion or changes

thereof (*42*). At various time points after PDT exposures of normal skin, each mouse was given intravenous injection of 0.2 mg of fluorescein dye (10 mg of sodium fluorescein per milliliter of HBSS; Baker Chemical, Phillipsberg, NJ). Immediately thereafter, the animal's back was illuminated with UV light (Black-Ray longwave lamp, Ultra-Violet products, Inc., San Gabriel, CA), and the fluorescein distribution between the treatment area and surrounding skin was visualized and recorded. To quantify the vascular photosensitivity, the PDT light doses were adjusted by increments of 5−25 J cm^{-2} (λ_{ex}, 490 nm; λ_{em}, 520 nm) from a base dose where no dye exclusion was observed until a minimum light dose to give complete exclusion of fluorescein from the treatment area, i.e., occlusion of the skin vasculature was established (*43*).

High-Resolution Tumor Imaging. Frozen tumor tissue was embedded in an ethanol−glycerol−water mixture (freezing point: −30 °C) and mounted in a redox machine: a 3D, high-resolution cryofluorometer scan system for 3D surface fluorometric scanning (*28*). The frozen tumor sample was ground flat for imaging before it was further ground down to obtain images usually every 100 μm. A bifurcated optical fiber bundle (7 quartz fibers, 70 μm core diameter for each, 1 fiber for emission in center, 6 fibers for excitation around the emission fiber) stepped across the tissue surface at a fixed distance from the tissue surface (70 μm). The filters for each substance's fluorescence excitation and emission were chosen based on the absorption and emission spectra of each fluorophores. By use of a mercury arc lamp as the excitation light source, the fluorescent signals of conjugate **5** (filters: ex, 405DF40; em, 670DF20), cyanine dye (filters: ex, 780; em, 856) were imaged for each depth of the tumor. The scanning was performed at 128 × 128 steps that covered 1.024 × 1.024 cm^2 area (80 μm per step). The fluorescence signals were recorded digitally on a PC and reconstructed later with MATLAB.

Whole-Body Imaging and Biodistribution Assays. Animal studies were performed in accordance with the Guide for the Use of Laboratory Animals. A noninvasive in vivo continuous wave fluorescence imaging apparatus was used to assess the localization and distribution of the conjugates, as described previously (*44*, *45*). Briefly, light from two laser diodes of nominal wavelength 780 or 808 nm and nominal power of 50 mW was launched into fiber optic bundles. The nominal 50 mW of incident power was reduced to about 20 mW at the output of the fiber optic bundle. A defocusing lens in position after the bundle was used to expand the beam such that nearly the whole mouse was illuminated. Digital images were recorded with a Photometrics CoolSNAP HQ CCD camera (12 bit, 1024 × 1024 pixels, back illuminated, thermoelectric Peltier cooled with forced air) equipped with an 830−870-nm interference filter. Images were acquired and processed using WinView software from Princeton Instruments. Data analysis consists of subtracting (pixel by pixel) the pre-injection or background image from the post-injection images and displaying the false color results. Integration of the relative fluorescence intensities of tumor vs surrounding tissues indicated qualitatively the extent of selective uptake of the molecular probe. Typically, the probes were administered via the lateral tail vein at dosages of 0.3 and 3.5 μmol/kg body weight of the mouse (depending on optimal therapeutic dose). Images were taken at 24, 48, and 72 h post-injection of the probe. The tumor-bearing mice (3 mice/group) were anesthetized with ketamine/xylazine via intraperitonial injection, and the conjugate was administered intravenously at a therapeutic dose. At the best imaging time (24 or 48 h), the animal was euthanized and selected organs were removed, washed, and placed on a dark background for fluorescence imaging. Tissue parts, instead of whole organs, were used to determine the relative fluorescence intensity in each organ to minimize problems associated with depth-dependent nonlinear fluorescence emission. A statistical program in the WinView package was used to estimate the mean fluorescence intensity per organ part.

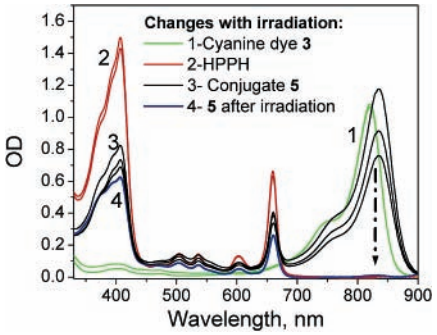

Figure 1. The absorption spectra of compounds **3**−**5** in dichloromethane. In conjugate **5**, irradiation of the HPPH absorption at 660 nm caused a significant decrease in the absorption of the cyanine dye at 831 nm (broad peak) and finally its complete photodestruction with a simultaneous increase in the intensity of HPPH absorption.

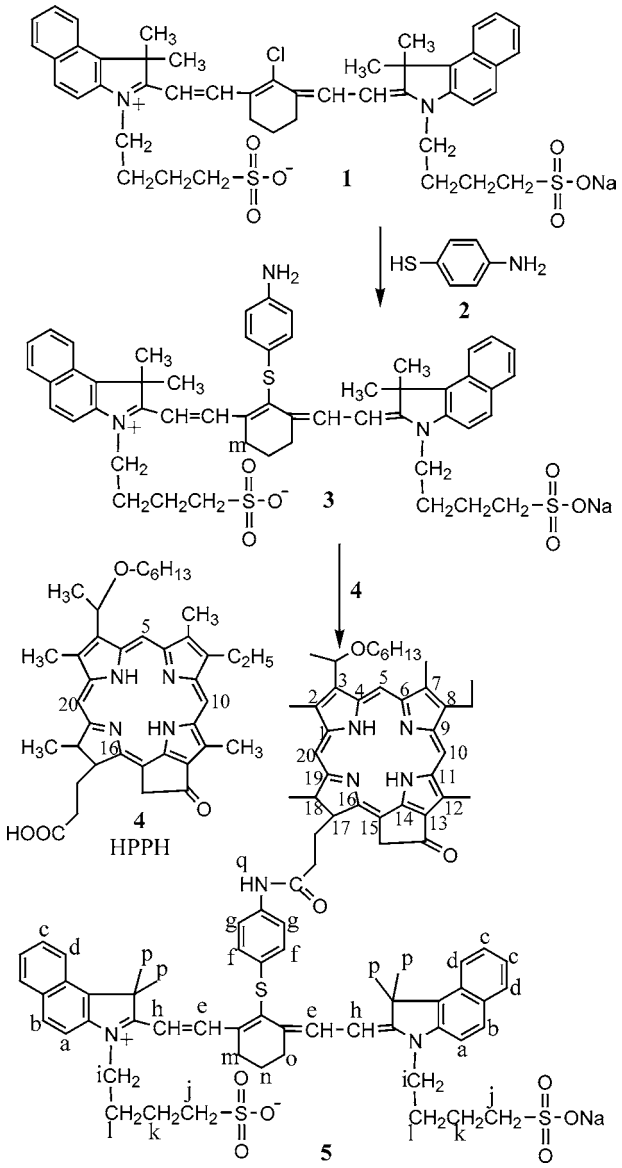
RESULTS AND DISCUSSION

Chemistry. As proof-of-principle of our approach to develop compounds with both imaging and therapeutic capabilities, we synthesized a conjugate **5** consisting of a highly effective photosensitizer, HPPH, and a cyanine dye exhibiting long wavelength absorption at 660 and 836 nm, respectively, with a strong emission at 865 m. In our preliminary study, the conjugate, designated as our lead compound, was evaluated for its photophysical characteristics, intracellular localization, in vivo tumor vs skin uptake, in vitro/in vivo photosensitizing efficacy, whole body imaging, biodistribution characteristics, and in vivo mechanistic and skin phototoxicity. These studies support the validity of our approach. The results are summarized as follows.

Synthesis of HPPH−Cyanine Dye Conjugate. The cyanine dye, namely, 2-[2-[2-chloro-3-[{1,3-dihydro-1,1-dimethyl-3-(4-sulfobutyl)-2H-benzo-(e)-indol-2-ylidene]-ethyl-indene]-1-cyclohexen-1-yl}ethenyl]-1,1-dimethyl-3-(4-sulfobutyl)-1H-benzo[e] indolium hydroxide, inner salt, sodium salt] **1** was first reacted with 4-aminophenylthiol and the corresponding 2-(4-aminophenylthioether) analogue **3** was isolated in 80% yield. Reaction of **3** with HPPH **4** (HPPH was prepared from chlorophyll-a by following the methodology developed in our laboratory) in the presence of DCC, and the desired HPPH−cyanine dye conjugate **5** was isolated in good yield (65%) (Scheme 1). UV, NMR, and mass spectrometry analyses confirmed the structure of the desired conjugate. The photophysical characteristic of the conjugate was first investigated before comparing its in vitro and in vivo photosensitizing efficacies and tumor-imaging capability with cyanine dye **3** and HPPH **4**.

Photophysical Studies. The electronic absorption spectrum of the conjugate **5** contains the characteristic absorption bands for two chromophores, i.e., HPPH **4** and the modified cyanine dye **3** (see Figure 1). The absorption characteristics of the HPPH moiety in the conjugate **5** remains practically unchanged in respect to the free HPPH.

Scheme 1. Synthesis of Conjugate 5



Compared to the free cyanine dye, in conjugate **5**, the absorption band for the cyanine dye moiety was found to be red shifted by 15 nm (820−835 in methanol), which is apparently associated with a change in environmental polarity caused by the presence of the HPPH moiety. Because of the similarity of the absorption spectra of HPPH and cyanine dye in conjugate **5** with respect to individual chromophores (without formation of any new absorption bands), it appears that the HPPH and cyanine dye π-electron systems in conjugate **5** absorb light practically independently. At the same absorption at the wavelength of excitation, the fluorescence intensity from the HPPH moiety in **5** was found to be significantly lower than observed for free HPPH. The electronic excitation energy transfer most probably occurs in **5** from the HPPH (donor) to the cyanine dye (acceptor). In methanol solution, irradiation of conjugate **5** at 532 nm (i.e., activation of HPPH) caused photolysis of cyanine dye moiety, and significant changes were observed in both absorption and fluorescence spectra. With increasing time of irradiation, absorption and fluorescence from the cyanine dye moiety at 835 and 875 nm, respectively, decreased, with a simultaneous increase in the intensity of fluorescence/absorption of the HPPH moiety. This is certainly due to the destruction of the π-electron system of the acceptor with subsequent discontinuation of a channel for the electronic excitation energy transfer. Comparison of the absorbance intensity ratios between nonirradiated vs irradiated −HPPH conjugate **5** (Figure 1) shows that the absorbance intensity of HPPH was increased by approximately 3-fold as a result of irradiation at 665 nm.

It was observed that, during irradiation (at 660 nm), the destruction of the cyanine dye moiety in conjugate **5** takes place continuously with a simultaneous increase in $^1O_2$ production (not shown). What is interesting to note is that the noticeable destruction of the cyanine dye moiety was observed only by excitation of the HPPH moiety and that the compound was found to be quite stable on exciting at the wavelengths that correspond to the cyanine dye moiety. Therefore, conjugate **5** shows an interesting characteristic for a suitable "bifunctional agent" that could be used for tumor imaging and therapy. Further detailed in vitro and in vivo photophysical investigations including the electrochemical studies with conjugate **5** are currently in progress and will be published elsewhere.

In vitro Photosensitizing Efficacy. The in vitro efficacy of the conjugate was determined in RIF cells, and the conjugate **5** was evaluated by performing two sets of experiments. After incubating the cells in the dark at 37 °C with 5 at various drug concentrations for 24 h, the medium was replaced with drug-free complete medium and cells were exposed to light either at 665 or 810 nm and the in vitro photosensitizing efficacy was determined by MTT assay (*39*).

In the first set of experiments, the photosensitizing activity of conjugate **5** was compared with HPPH. The cells were exposed to 665-nm laser light. As can be seen from Figure 2A, compared to HPPH the conjugate **5** was found to be equally effective. Interestingly, in a second set of experiments, on exposing cells to 810-nm diode light there was not any significant cell kill for either the cyanine dye **3** or conjugate **5** (Figure 2B). These results further confirm that the cyanine dye part of the moiety in conjugate **5** does not produce any significant singlet oxygen, which is a key cytotoxic agent for the destruction of tumor cells by PDT.

Comparative Intracellular Localization. Mitochondria have been identified as the most sensitive intracellular targets for PDT (*43*, *44*), and HPPH has been found to localize to the mitochondria (*46*). We therefore determined whether the conjugation of HPPH to cyanine dye affected the subcellular distribution of the photosensitizer. The localization of HPPH **4** and the corresponding cyanine dye conjugate **5** was investigated by co-incubating photosensitized RIF cells with Mitotracker Green (Molecular Probes, Eugene, OR) or Fluospheres (0.1 μm diameter latex heads labeled withfluorescein isothiocyanate 1/10 000 dilution by Molecular Probes, Eugene, OR), which target mitochondria and lysosomes, respectively. Fluorescence was imaged with a CCD camera and intensifier, and the images of photosensitizers and Mitotracker Green or Fluosphere localization were taken in rapid succession by following the literature procedure (*44*, *45*). From the results summarized in Figure 3, the imaging data clearly indicate that the HPPH and the conjugate localize in the same subcellular region as the mitochondrial marker, suggesting their affinity to mitochondria. The results obtained by using Fluospheres as a counterstain did not show any lysosomal colocalization (data not shown).

In vivo Photosensitizing Activity. The in vivo photosensitizing efficacy was determined in C3H mice transplanted with RIF tumors. Once the tumors reached

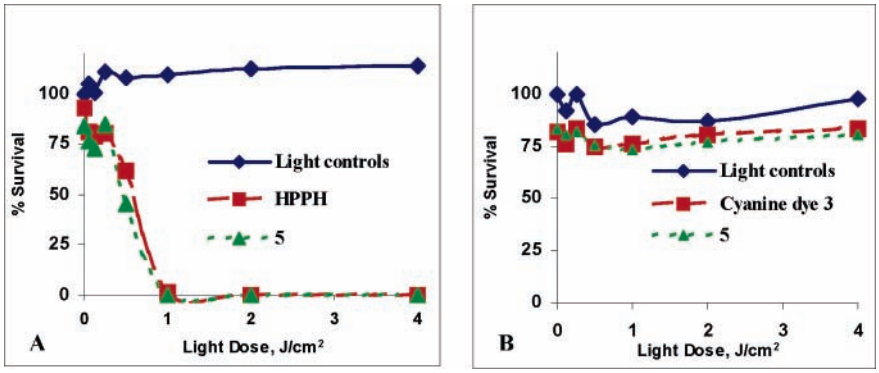


Figure 2. Comparative in vitro photosensitizing efficacy of the cyanine dye **3**, HPPH, and the corresponding cyanine dye conjugate **5** at equimolar concentration (0.6 μM) in RIF tumor cells: (A) the cells incunated with HPPH and the conjugate **5** were exposed to light at 665 nm and (B) the cyanine dye **3** and the conjugate **5** were exposed to light at 810 nm at variable light doses.

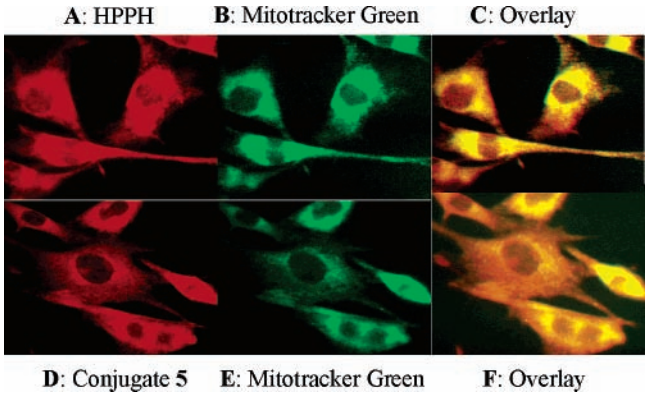

Figure 3. Comparative localization (false images) of HPPH **4** and conjugate **5** with Mitotracker Green (mitochondrial probe) in RIF cells after incubating for 24 h (for details, see the text).

4−5 mm^3, they were exposed to light (135 J/cm^2) at 24 h after injection of the conjugate at variable drug doses. The tumor growth (to reach >400 mm^3) was monitored daily for 30−90 days. As can be seen from Figure 4, clear dose−response relationships were observed, with a dose of 3.5 μmol/kg of the conjugate being highly effective in controlling the tumor regrowth (8/10 mice were tumor free at day 90). This therapeutic dose was subsequently chosen for tumor imaging.

High-Resolution Tumor Image. We have assessed the three-dimensional distribution of conjugate **5** in frozen sections of the RIF tumor, by means of fluorescence spectrophotometric imaging of successive slices through the frozen tissue block (*47*). Figure 5 illustrates a diffuse, heterogeneous distribution of **5** with maximal levels at the growing edge of the tumor, particularly indicated in the 300- and 900-μm sections, with little in the necrotic center. The histogram (D) for the distribution of conjugate **5** is broad Sand bimodal, ranging from 50 to >250 intensity values representing the low accumulation in the center compared to the viable periphery. The median tissue fluorescence in the absence of **5** was ~30 (C and F). The localized distribution of cyanine dye **3** is indicated in the same range. The dye is localized mainly in the tumor, both in the necrotic portion of the tumor and in the actively growing edge (see the 600-μm slice 3).

In vivo Imaging. Results of whole body fluorescence imaging (*48*) in the RIF tumor-bearing mouse, with excitation of the fluorescent cyanine dye moiety of conjugate **5** 24 h after administration, are shown in Figure 5. It was exciting to note that even at a dose of 0.3 μmol/kg, which was later found to be 8−10-fold less than the therapeutic dose, the conjugate showed significant tumor-imaging capability. Once the optimum therapeutic dose of 3.5 μmol/kg was determined, further imaging experiments were carried out to determine the time course of the tumor and the organ distribution of conjugate **5** in intact mice (Figure 5G) and in the isolated organs (Figure 6).

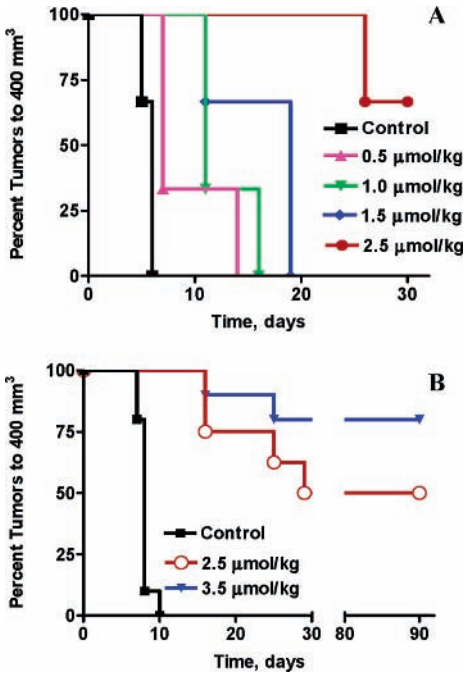

Figure 4. In vivo photosensitizing efficacy of conjugate **5** in C3H mice (10 mice/group) bearing RIF tumors and variable concentrations. The tumors were exposed to a laser light (665 nm, 135 J/cm^2) at 24 h after injection. (A) Drug concentrations = 0.5−2.5 μmol/kg. (B): Drug concentrations = 2.5 and 3.5 μmol/kg.

The organ distribution shown in Figure 6 confirms the whole mouse images. To quantitate the relative fluorescence intensity in each organ, we determined the mean fluorescent counts per organ, represented in a histogram format in Figure 6 (24, 48, and 72 h after injection). At 24 h, the probe is distributed in several organs, which confounds localization of the tumor by fluorescence imaging. However, 48 and 72 h after injection, the probe content in tumor is very high relative to the blood and to the different organs. The data demonstrate the high selectivity of the conjugate and clearly indicate the feasibility of identifying a tumor by optical imaging using a bifunctional cyanine photosensitizer probe.

Determination of Tumor/Skin Uptake Ratios and Skin Photosensitization. Persistence of photosensitizer

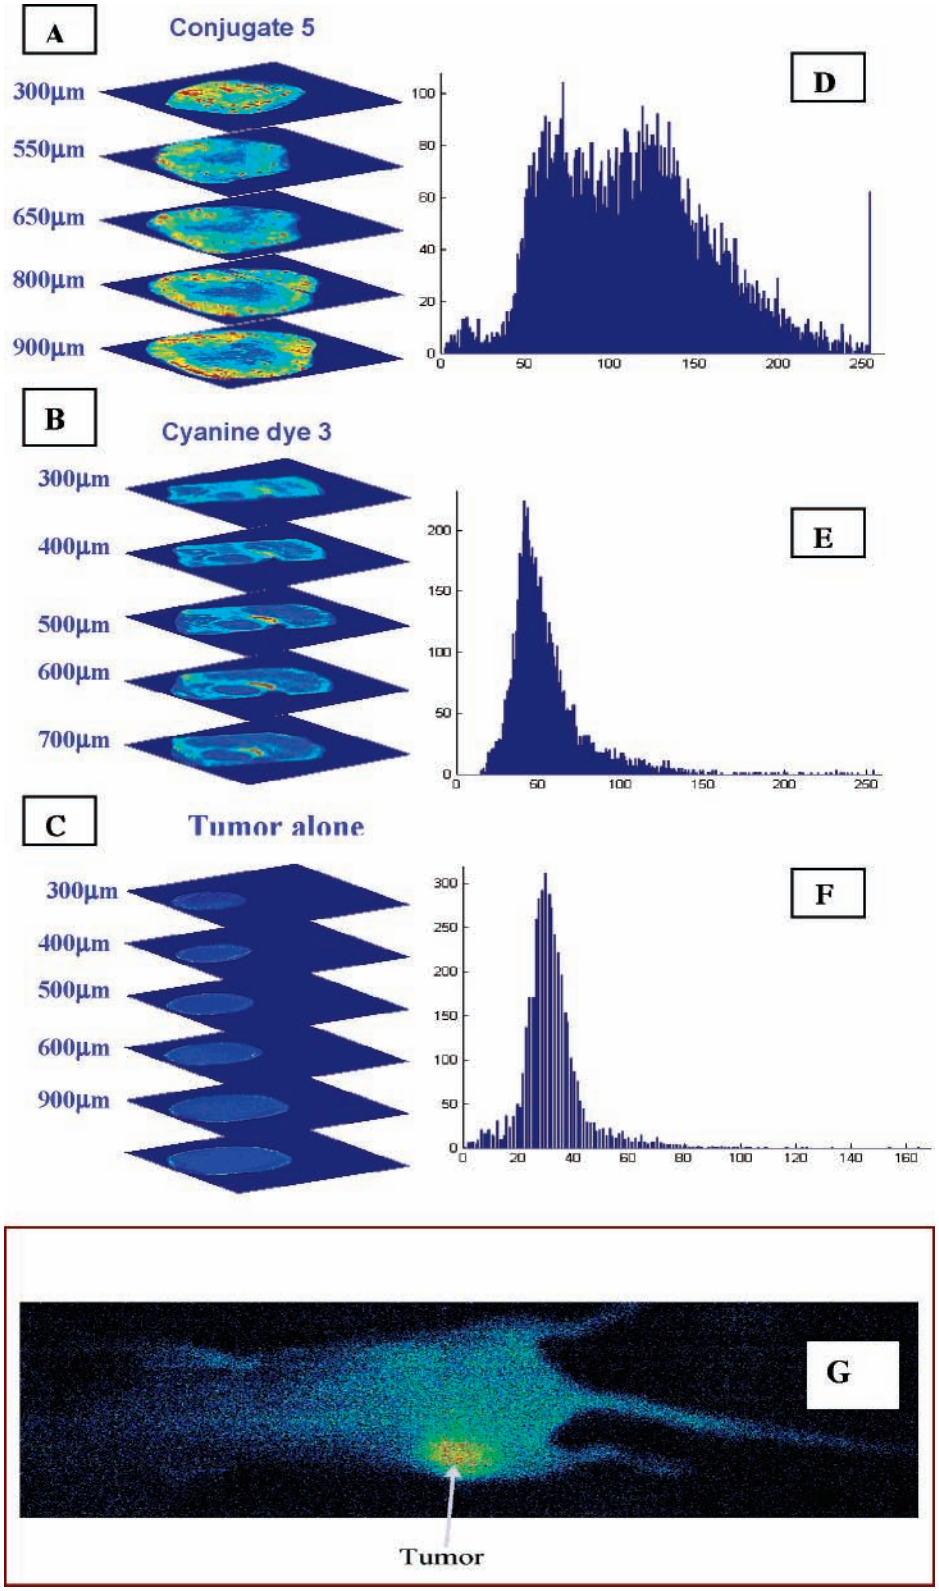

Figure 5. High-resolution tumor images at 24 h after injection: (A) conjugate **5** (3.5 μmole/kg), (B) cyanine dye **3** (3.5 μmole/kg), and (C) control (tumor alone). D, E, and F are their respective histograms (λ_{ex}, 780 nm; λ_{em}, 865 nm). (G) Localization of the conjugate **5** in a live mouse 24 h after injection (drug dose = 0.3 μmol/kg).

in the skin and resultant prolonged cutaneous photosensitivityhave been a major drawback for clinical PDT with porphyrin-based compounds (*49*). A high tumor:skin ratio of photosensitizer uptake therefore is critical for both tumor imaging and treatment.

The uptake of conjugate **5** (in tumor and skin) was determined by in vivo reflectance spectroscopy. In brief, conjugate **5** (3.5 μmol/kg) was injected into a C3H mouse bearing RIF tumors, and the in vivo absorption spectra of the conjugate present in tumor and skin were recorded at various time intervals by following the methodology routinely used in our laboratory. As can be seen from Figure 7A, the conjugate **5** produced a significantly higher uptake in tumor than skin at 24 h after injection.

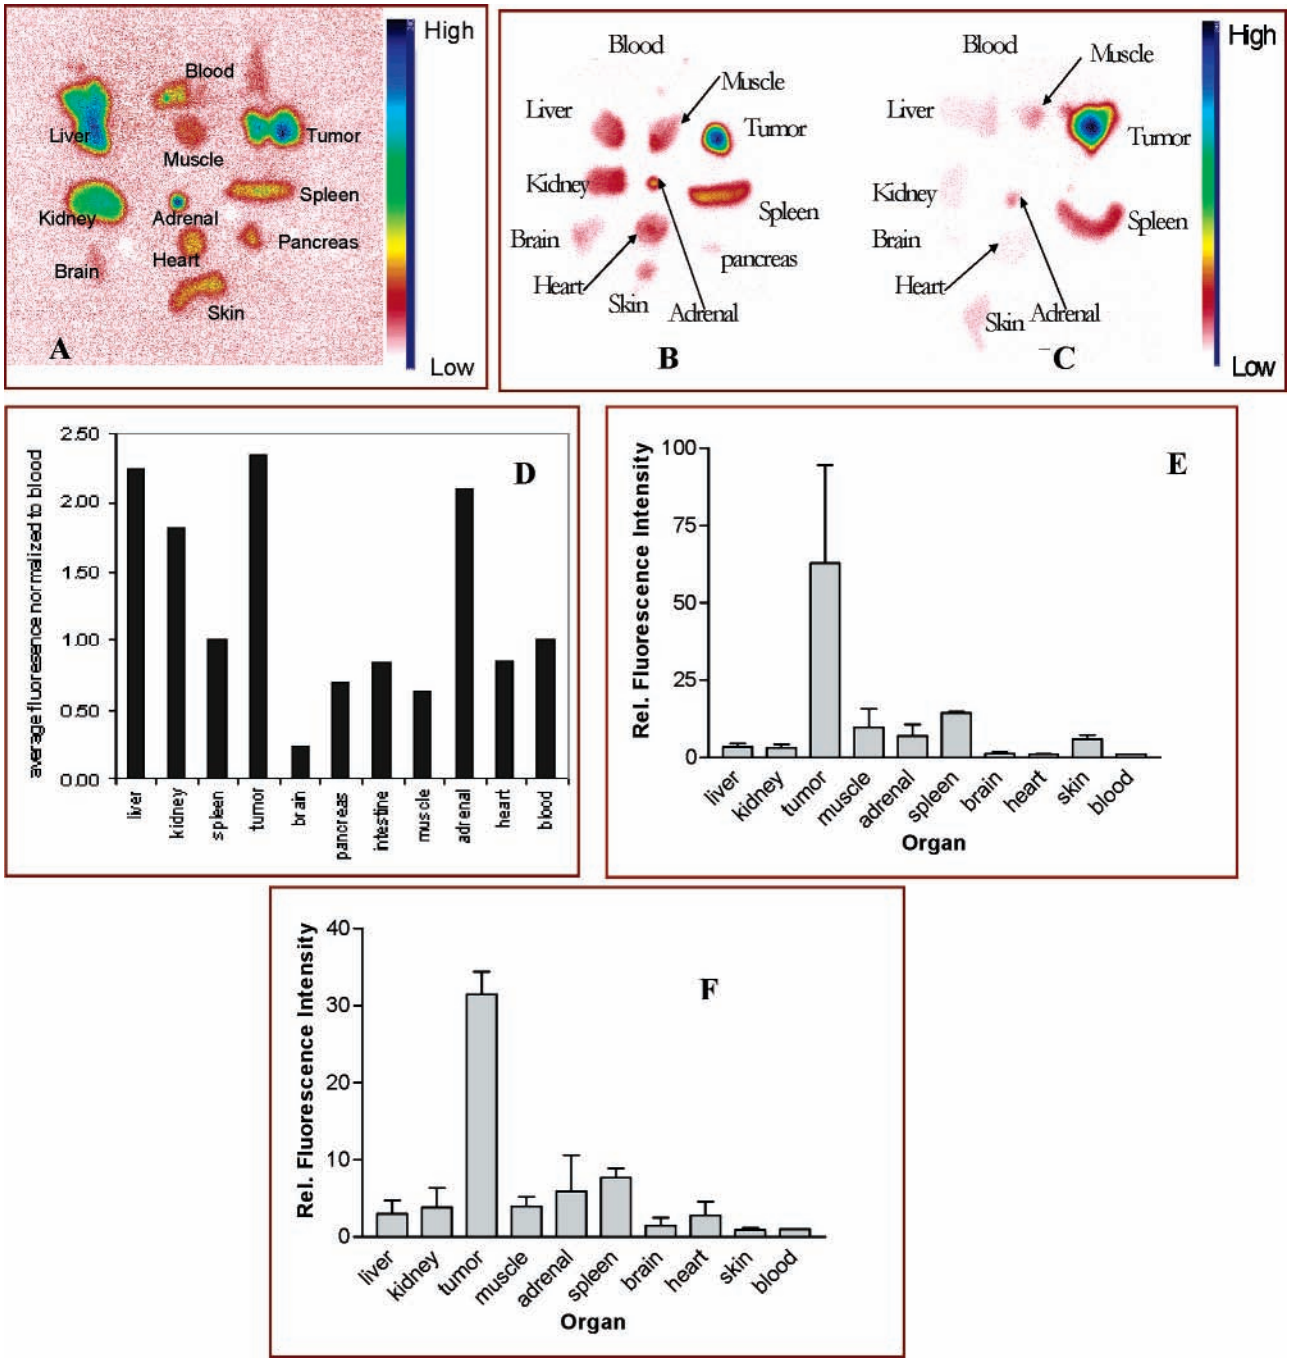

Figure 6. A, B, C: Images of the distribution of **5** in various organ parts at 24, 48, and 72 h after injection, respectively (drug dose = 3.5 μmol/kg). D, E, F: Relative fluorescence of conjugate **5** in selected organs at 24, 48, and 72 h after injection (2 mice/group). All intensities are relative to blood.

In a tumor, a substantial increase in drug uptake was observed from 24 to 48 h without a concomitant change in skin uptake. After 48 h, the drug concentration in tumor and skin began to decline, reaching negligible levels in the skin by 72 h while still maintaining relatively high tumor levels (Figure 7A). In contrast, as shown in Figure 7B, the cyanine dye **3** did not show any tumor selectivity and it cleared rapidly from tumor and skin, suggesting a remarkable difference in pharamacokinetic characteristics of the two compounds.

To validate the finding of low skin drug levels, general skin phototoxicity was assessed. The HPPH−cyanine dye conjugate **5** at a dose of 3.5 μmol/kg (therapeutic dose) was compared with HPPH and Photofrin at approximately equi-effective therapeutic doses. In each experiment, the mice (3 mice/group) were restrained without anesthesia in holders designed to allow the exposure of one hind foot. The foot was exposed to solar-simulated light for 30 min, either 24, 48, 72, and 96 h after injection. Foot response was judged using a 0−3 scale. As can be seen from Figure 7C, conjugate **5** had a minimal, transient response (score 0.1 24 h after injection) with no photosensitizing activity 48 h after injection, whereas HPPH at a 7.4-fold lower dose had greater skin phototoxicity 72 h after administration (Figure 7D). In contrast, Photofrin caused very significant phototoxicity, with scores of 1.5 (24 h), 1.5 (48 h), 1.4 (72 h), and 1.25 (96 h) (data not shown). These functional data confirm the imaging and absorption findings.

Effects on the Vasculature. In PDT-mediated therapy, it has been shown that vascular destruction in the tumor and immediate tumor-surrounding tissue can

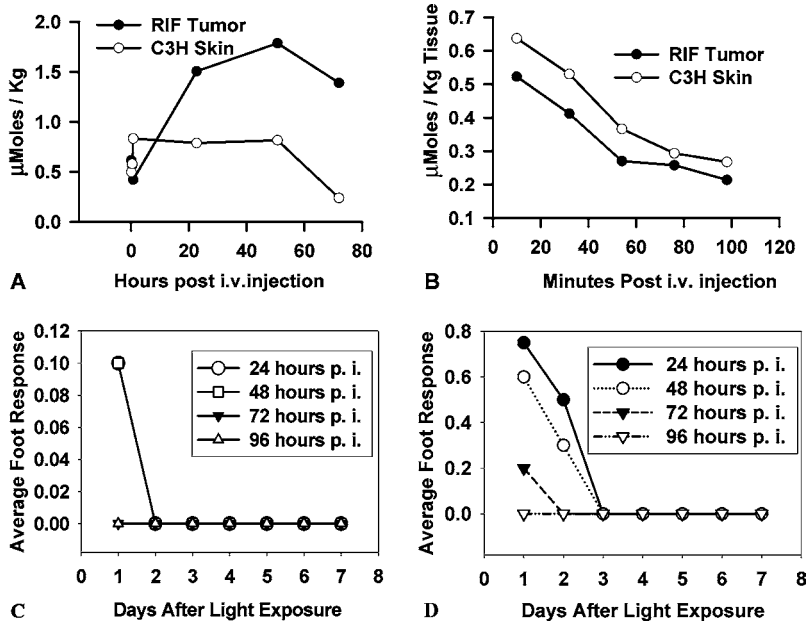

Figure 7. A and B: Tumor vs skin uptake of conjugate **5** and cyanine dye **3**, respectively, in C3H mice bearing RIF tumors at variable time points. C and D: Foot response in Swiss mice as a function of time after light and time interval between injection and light: (C) effect of conjugate **5** vs (D) HPPH on foot response at respective therapeutic doses (**5**, 3.5μmole/kg; HPPH, 0.47 μmol/kg) at various time intervals (for details see the text).

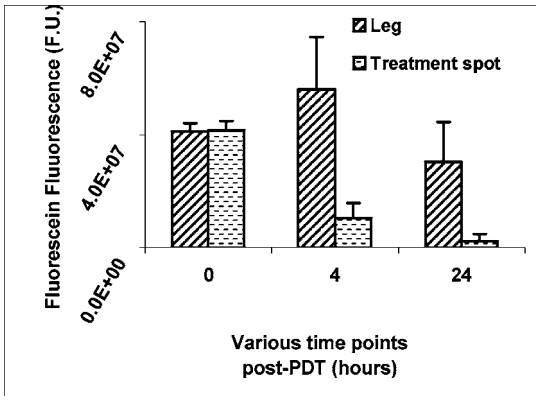

Figure 8. Vascular shutdown results obtained by fluorescein exclusion assay at 4 and 24 h after PDT.

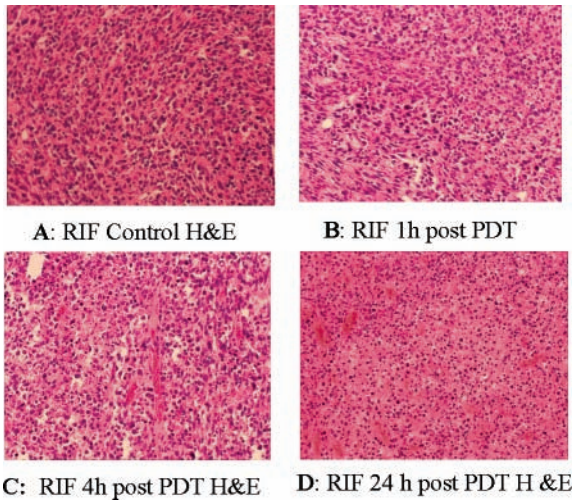

Figure 9. Histological analyses of conjugate **5** (after PDT). The dilated vessels at 4 h and necrosis at 24 h are evident.

contribute significantly to tumor control (*50*, *51*). Therefore, we determined the effects of the conjugate on the cutaneous vasculature. Conjugate **5** was injected intravenously, and 24 h later the mice in groups of three were treated with laser light at 665 nm for a total light dose of 135 J/cm^2 at a fluence rate of 75 mW/cm^2 (1 cm^2 diameter spot). The mice were evaluated for PDT-induced changes in vascular perfusion at various time points after PDT (0, 4, and 24 h) by injecting 0.20 cm^3 fluorescein (ex, 490 nm; em, 520 nm) intravenously as a perfusion marker. An in vivo fluorescence probe was then utilized to quantitate fluorescein fluorescence in the treatment site as compared to a nonlight treatment site. Each column represents the mean from three mice at each time point in comparison to the nontreated site.

As can be seen by Figure 8, immediately after PDT there is no difference in fluorescein fluorescence when comparing the drug/light treatment site to an unirradiated site of the leg.

However, at 4 and 24 h after PDT, there is a significant difference, with minimal to nearly no fluorescein fluorescence in the treated site, indicating that fluorescein was unable to penetrate due to vascular destruction. Histologic analysis confirmed this conclusion showing dilated and obstructed vessels, progressing toward hemorrhagic necrosis (Figure 9).

CONCLUSION

Our results indicate that (a) tumor-avid porphyrin-based compounds can be used as vehicles to deliver the optical imaging agent to tumor, (b) the inherent characteristics of two chromophores complement each other and their individual characteristics can be used for tumor detection and therapy, and (c) the presence of the cyanine dye appears to further improve the pharmacokinetics of the molecule, resulting in even faster clearance from the skin and elimination of prolonged skin phototoxicity, a major drawback associated with most porphyrin-based photosensitizers.

Our approach provides a unique opportunity for developing more tumor-specific, bifunctional agents for tumor detection and therapy by targeting those receptors known for high expression in tumors. Currently, the syntheses and biological studies of such target-specific

bifunctional agents containing more tumor-avid photosensitizers than HPPH and exhibit long-wavelength absorptions in the range of 700−800 nm are in progress.

Monofunctional Near-Infrared Fluorochromes for Imaging Applications

Scott A. Hilderbrand, Kimberley A. Kelly, Ralph Weissleder, and Ching-Hsuan Tung*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Room 5406, 149 13th Street, Charlestown, Massachusetts 02129. Received June 21, 2005;
Revised Manuscript Received August 9, 2005

In this report, the development of a new class of monocarboxylate functionalized cyanine derivatives using improved synthetic procedures is detailed. The employed synthetic strategy relies on efficient nucleophilic attack of alkyl-thiols on cyanine dyes bearing chloro-substituted polymethinic linkers. Monocarboxylate derivatized fluorochromes (CyTE dyes) can be prepared in one step in greater than 90% yield without the need for additional purification. Several of the fluorochromes synthesized by this route show no tendency to aggregate in aqueous solution and have excitation and emission maxima greater than 800 nm. The potential utility of the CyTE fluorochromes was demonstrated through direct labeling of phage displaying a vascular cellular adhesion molecule-1 (VCAM-1) targeting peptide. Endothelial cell internalization of the VCAM-1 targeted phage was monitored via near-infrared fluorescence microscopy.

INTRODUCTION

In recent years, there has been significant interest in the development of monofunctional, water-soluble near-infrared fluorochromes for use in a myriad of imaging applications. The development of new bright, water-soluble near-infrared (NIR) fluorochromes that are synthesized readily and are suitable for bioconjugation is necessary for the preparation of improved NIR probes for in vivo imaging. Fluorochromes with absorption and emission maxima between 650 and 900 nm are ideally suited for imaging in tissue due to the minimal absorption coefficients from hemoglobin, water, and lipids over this range (*1*). A variety of carboxylic acid derivatized cyanine dyes emitting in the NIR have been prepared (*2*−*11*). Many commonly used monofunctional dyes are asymmetric with a single carboxylic acid group attached to one of the indoleninium or benzindoleninium moieties (*3*, *4*, *6*, *9*). The condensation reactions to prepare these fluorochromes proceed in a stepwise fashion resulting in formation of the undesired symmetric dye as a byproduct with overall yields typically less than 10%. Although these dyes are components of a variety of receptor targeted (*9*, *12*−*15*) and fluorogenic (*16*−*18*) probes for optical imaging in vivo, the difficulty in preparation of large quantities of the purified fluorochromes may limit their widespread utility.

New high-yield routes for the synthesis of NIR fluorochromes suitable for imaging applications are needed. One strategy that provides access in 90% or greater yields to fluorochromes that can be conjugated is via nucleophilic attack on chloro-substituted cyanine dyes (*19*). A variety of water-soluble dyes containing aryl-ether, aryl-thioether, and alkyl-ether linkages have been prepared using this route (*2*, *7*, *10*, *11*, *20*). However, none of these dyes are optimal for imaging applications. Although they are water-soluble, cyanine fluorochromes containing an additional aryl group, such as an aryl-ether-modified cyanine dye, show an increased tendency to aggregate in aqueous solution (*2*), and the aryl-ether linkage in some of these fluorochromes is susceptible to cleavage (*21*). Several aryl-ether-, aryl-thioether-, and alkyl-ether-functionalized fluorochromes have been reported but there are only a few reports of their alkyl-thioether congeners (*22*, *23*). In this report, we detail general procedures for the synthesis of a variety of alkyl-thioether-containing cyanine fluorochrome derivatives (CyTE dyes). Some of these fluorochromes may be prepared in one step with excellent yields starting from commercially available dyes, show no tendency to aggregate in aqueous solution, and display absorption and emission maxima above 800 nm. To assess the utility of the CyTE fluorochromes, phage displaying the vascular cellular adhesion molecule-1 (VCAM-1) targeting peptide (VHSPNKK) (*24*) on the pIII coat protein of the phage were labeled with fluorochrome and imaged in live cells. Cell uptake experiments with the fluorochrome-labeled phage demonstrate the potential of the synthetically accessible CyTE dyes for use in NIR fluorescence imaging.

MATERIALS AND METHODS

General Considerations. All chemicals were purchased from Aldrich (Milwaukee, WI) or TCI America (Portland, OR) except PEG_7 thiol propionic acid, which was purchased from Polypure AS (Oslo, Norway), and were used as received. The dyes IR-783, IR-806, and IR-820 were purchased from Aldrich. All solvents including anhydrous dimethylformamide (DMF) and anhydrous dimethyl sulfoxide (DMSO) were obtained from Aldrich. High-performance liquid chromatography (HPLC) was performed on a Hitachi D-7000 instrument equipped with a L-7455 diode array detector. Nuclear magnetic resonance (NMR) data were collected on a Bruker DPX-400 spectrometer at ambient temperature and referenced to tetramethylsilane (TMS) or 2,2-dimethyl-2-silapentane-5-sulfonate sodium salt (DSS) internal standards. Absorption spectra were obtained on a Varian Cary 50-Bio UV/visible spectrophotometer (Palo Alto, CA). All extinc-

tion coefficient measurements in phosphate-buffered saline (PBS), pH 7.4, 10 mM phosphate, 2.7 mM potassium chloride, and 137 mM NaCl were performed in triplicate. For determination of the extinction coefficients, fresh stock solutions of HPLC-purified dye were prepared for each trial by dissolution of 2−3 mg portions of the dye, weighed on a Mettler AT201 analytical balance with an error of ±0.01 mg, in PBS using a 10 mL volumetric flask. The typical standard deviation for the extinction coefficient measurements is less than 5%. Fluorescence data were collected on a Horiba Jobin Yvon Fluorolog-3 spectrofluorometer (Edison, NJ) and were corrected for the detector sensitivity. Quantum yield measurements, performed in triplicate following published procedures (*25*), were collected using samples with absorbance values under 0.10 OD in PBS using indocyanine green (ICG) in DMSO ($\Phi_F = 0.106$) (*26*) as a standard. All samples used for the quantum yield determinations were excited at 775 nm. High-resolution electrospray ionization (ESI) mass spectra were collected on a Bruker Daltonics APEXII 3 T Fourier transform mass spectrometer in the Department of Chemistry Instrumentation Facility (DCIF) at the Massachusetts Institute of Technology.

CyTE-777 (1). To a solution of IR-783 (225 mg, 0.30 mmol) in 4 mL of anhydrous DMF was added 3-mercaptopropionic acid (30.5 μL, 0.35 mmol) and triethylamine (TEA) (49 μL, 0.35 mmol). The green solution was allowed to stir in the dark. After 15 h, the reaction was complete as monitored by HPLC. Crude **1**, which has sufficient purity for routine work, was isolated in 93% yield as a green solid by precipitation with *tert*-butyl methyl ether (TBME) and was washed with TBME (3 × 10 mL). Compound **1** was further purified by reverse-phase C-18 chromatography (Waters Sep-Pak C18 cartridge) with a mixture of 25% CH_3CN, 75% H_2O, and 0.1% TFA followed by 30% CH_3CN, 70% H_2O, and 0.1% TFA to yield pure **1** (204 mg, 83%). ^{1}H NMR (400 MHz, CD_3OD): δ 8.89 (d, 2H, J = 14.2 Hz), 7.49 (d, 2H, J = 7.4 Hz), 7.41 (t, 2H, J = 7.6 Hz), 7.34 (d, 2H, J = 7.8 Hz), 7.25 (t, 2H, J = 7.5 Hz), 6.32 (d, 2H, J = 14.3 Hz), 4.19 (t, 4H, J = 6.7 Hz), 3.06 (t, 2H, J = 7.0 Hz), 2.90−2.87 (m, 4H), 2.70 (t, 4H, J = 5.9 Hz), 2.56 (t, 2H, J = 6.9 Hz) 2.00−1.92 (m, 10H), 1.76 (s, 12H). λ_{max} (PBS, pH 7.4): 777 nm (ϵ = 130 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4): 0.02. HRMS-ESI $[M]^+$ *m/z* calcd for $C_{41}H_{53}N_2O_8S_3$ 797.2959, found 797.2976.

Intermediate (2). 1-(4-Sulfonatobutyl)-2,3,3-trimethylindoleninium-5-sulfonate (5) (1.25 g, 3.0 mmol), *N*-[(3-(anilinomethylene)-2-chloro-1-cyclohexen-1-yl)methylene]-aniline monohydrochloride (540 mg, 1.5 mmol), and potassium acetate (295 mg, 3.0 mmol) were dissolved in 20 mL of a 2:1:1 solution of MeOH, acetic anhydride, and pyridine. The solution was sealed in a thick-walled glass pressure reactor and heated at 140 °C for 25 min giving a dark blue solution containing a dark blue precipitate. After the mixture cooled to room temperature, the blue solid was isolated by filtration. Purification of the crude material by reverse-phase C-18 chromatography (Waters Sep-Pak C18 cartridge) with a mixture of 15% CH_3CN, 85% H_2O, and 0.1% TFA yields pure **2** (450 mg, 30%) as a green solid. ^{1}H NMR (400 MHz, D_2O): δ 8.16 (d, 2H, J = 13.8 Hz), 7.85 (s, 2H), 7.74 (d, 2H, J = 8.3 Hz), 7.27 (d, 2H, J = 8.4 Hz), 6.13 (d, 2H, J = 13.9 Hz), 4.10 (broad singlet, 4H), 2.96 (t, 4H, J = 6.6 Hz), 2.41 (broad singlet, 4H), 1.89−1.79 (m, 10H), 1.63 (s, 12H). λ_{max} (PBS, pH 7.4): 781 nm (ϵ = 248 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4): 0.02. HRMS-ESI $[M - 2H]^-$ *m/z* calcd for $C_{38}H_{46}ClN_2O_{12}S_4$ 885.1628, found 885.1567; $[M - 3H]^{2-}$ *m/z* calcd for $C_{38}H_{45}ClN_2O_{12}S_4$ 442.0777, found 442.0760.

CyTE-783 (3). To a solution of **2** (100 mg, 0.10 mmol) in 5 mL of anhydrous DMSO was added 3-mercaptopropionic acid (17.5 μL, 0.20 mmol) and TEA (28 μL, 0.20 mmol). The reaction was completed in 15 h as determined by HPLC. The crude product was precipitated by addition of 25 mL of toluene. This blue-green solid was collected by centrifugation and was washed with toluene (2 × 25 mL) followed by diethyl ether (2 × 25 mL) to give crude **3** (92 mg, 86%), which is sufficiently pure for routine work. The product was further purified by reverse-phase C-18 chromatography (Waters Sep-Pak C18 cartridge) with a mixture of 10% CH_3CN, 90% H_2O, and 0.1% TFA followed by 15% CH_3CN, 85% H_2O, and 0.1% TFA to yield pure **3** (76 mg, 71%) as a green solid. ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.70 (d, 2H, J = 14.1 Hz), 7.75 (d, 2H, J = 1.5 Hz), 7.63 (dd, 2H, J = 8.2 Hz, J = 1.5 Hz), 7.37 (d, 2H, J = 8.3 Hz), 6.36 (d, 2H, J = 14.2 Hz), 4.17 (broad singlet, 4H), 2.98 (t, 2H, J = 6.9 Hz), 2.67 (t, 4H, J = 5.7 Hz), 2.49−2.44 (m, 6H), 1.84−1.63 (m, 22H). λ_{max} (PBS, pH 7.4): 783 nm (ϵ = 174 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4): 0.02. HRMS-ESI $[M]^+$ *m/z* calcd for $C_{41}H_{53}N_2O_{14}S_5$ 957.2095, found 957.2125.

CyTE-822 (4). To a solution of IR-820 (255 mg, 0.30 mmol) in 4 mL of anhydrous DMF was added 3-mercaptopropionic acid (30.5 5 μL, 0.35 mmol) and TEA (30.5 μL, 0.35 mmol). The green solution was allowed to stir in the dark. After 15 h, the reaction was complete as monitored by HPLC. Crude **4** (246 mg, 89%) was isolated by precipitation from the reaction by addition of 10 mL of TBME and was washed with TBME (3 × 10 mL). Reverse-phase C-18 column chromatography (Waters Sep-Pak C18 cartridge) of the crude material eluting with 35% CH_3CN, 65% H_2O, and 0.1% TFA afforded **4** (143 mg, 52%) as a green solid. ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.83 (d, 2H, J = 14.0 Hz), 8.30 (d, 2H, J = 8.4 Hz), 8.09−8.02 (m, 4H), 7.80 (d, 2H, J = 8.9 Hz), 7.65 (t, 2H, J = 7.4 Hz), 7.51 (t, 2H, J = 7.4 Hz), 6.40 (d, 2H, J = 13.7 Hz), 4.33 (br s, 4H), 3.06 (t, 2H, J = 6.6 Hz), 2.72 (br s, 4H), 2.65−2.55 (m, 6H), 1.97 (s, 12H), 1.89−1.78 (m, 10H). λ_{max} (PBS/20% DMSO, pH 7.4): 822 nm (ϵ = 128 000 M^{-1} cm^{-1}). HRMS-ESI $[M]^+$ *m/z* calcd for $C_{49}H_{57}N_2O_8S_3$ 897.3272, found 897.3259.

CyTE-823 PEG (5). To a solution of IR-820 (255 mg, 0.30 mmol) in 4 mL of anhydrous DMF was added PEG_7 thiol propionic acid (183 mg, 0.40 mmol) and TEA (56 μL, 0.40 mmol). The green solution was allowed to stir in the dark for 15 h. A green solid was isolated by precipitation with 10 mL of TBME and was washed with 35 mL of TBME. The crude material was purified by reverse-phase C-18 chromatography (Waters Sep-Pak C18 cartridge) with a mixture of 25% CH_3CN, 75% H_2O, and 0.1% TFA, followed by 30% CH_3CN, 70% H_2O, and 0.1% TFA, and finally 35% CH_3CN, 65% H_2O, and 0.1% TFA to yield pure **5** (212 mg, 56%) as a green solid. ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.89 (d, 2H, J = 14.1 Hz), 8.30 (d, 2H, J = 8.6 Hz), 8.10−8.02 (m, 4H), 7.81 (d, 2H, J = 9.0 Hz), 7.65 (t, 2H, J = 7.3 Hz), 7.51 (t, 2H, J = 7.6 Hz), 6.41 (d, 2H, J = 14.3 Hz), 4.34 (br s, 4H), 3.64 (t, 2H, J = 6.4 Hz), 3.58 (t, 2H, J = 6.4 Hz), 3.53−3.41 (m, 28H), 3.04 (t, 2H, J = 6.5 Hz), 2.72 (br s, 4H), 2.64 (t, 4H, J = 7.3 Hz), 2.43 (t, 2H, J = 6.3 Hz), 1.99 (s, 12H), 1.88−1.78 (m, 10H). λ_{max} (PBS/20% DMSO, pH 7.4): 823 nm (ϵ = 116 000 M^{-1} cm^{-1}). HRMS-ESI $[M]^+$ *m/z* calcd for $C_{65}H_{89}N_2O_{16}S_3$ 1249.5369, found 1249.5345.

CyTE-807 (6). To a solution of IR-806 (221 mg, 0.30 mmol) in 4 mL of anhydrous DMF was added 3-mercaptopropionic acid (30.5 μL, 0.35 mmol) and TEA (49 μL, 0.35 mmol). After being stirred for 15 h, the reaction was complete as monitored by HPLC. Crude **6** (223 mg, 93%)

was isolated by precipitation from the reaction by addition of 10 mL TBME and was washed with TBME (3 × 10 mL). The crude material, which is sufficiently pure for routine work, was further purified by reverse-phase C-18 chromatography (Waters Sep-Pak C18 cartridge) with a mixture of 25% CH_3CN, 75% H_2O, and 0.1% TFA, followed by 30% CH_3CN, 70% H_2O, and 0.1% TFA to yield pure **6** (194 mg, 80%) as a green solid. ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.03 (d, 2H, J = 14.0 Hz), 7.60 (d, 2H, J = 7.3 Hz), 7.46−7.39 (m, 4 H), 7.25 (d, 2H, J = 7.4 Hz), 6.21 (d, 2H, J = 14.1 Hz), 4.18 (t, 4H, J = 6.7 Hz), 3.10 (t, 2H, J = 6.7 Hz), 2.94 (s, 4H), 2.60−2.52 (m, 6H), 1.83−1.73 (m, 8H), 1.66 (s, 12H). λ_{max} (PBS, pH 7.4): 807 nm (ϵ = 120 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4): 0.02. HRMS-ESI $[M]^+$ *m/z* calcd for $C_{40}H_{51}N_2O_8S_3$ 783.2802, found 783.2821.

CyTE-777 Succinimide Ester (7). To a solution of **1** (100 mg, 0.122 mmol) in 6 mL of anhydrous DMF was added *N*-hydroxysuccinimide (NHS) (1.40 g, 12.2 mmol), *N*,*N*′-diisopropylcarbodiimide (DIC) (1.91 mL, 12.2 mmol), and *N*-methylmorpholine (268 μL, 2.44 mmol). The resulting suspension was stirred at room temperature for 45 min. HPLC analysis of the crude reaction indicated over 90% conversion to the succinimide ester. The reaction was filtered to remove excess solid NHS and 20 mL of Et_2O was added to give a green oil. The ether layer was decanted, and the green oil was redissolved in 1 mL of DMF. This solution was precipitated by addition of 20 mL of Et_2O to yield a dark green paste. After this step was repeated one additional time, a free flowing green solid was isolated. The crude solid was subjected to preparative HPLC chromatography using a gradient of 22.5% CH_3CN to 90% CH_3CN in H_2O with 0.1% TFA to yield analytically pure **7** (47 mg, 42%). ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.67 (d, 2H, J = 14.0 Hz), 7.59 (d, 2H, J = 7.3 Hz), 7.47−7.39 (m, 4H), 7.26 (t, 2H, J = 7.3 Hz), 6.37 (d, 2H, J = 14.2 Hz), 4.20 (t, 4H, J = 6.7 Hz), 3.12 (t, 2H, J = 7.1 Hz), 3.01 (t, 2H, J = 6.3 Hz), 2.79 (s, 4H), 2.68 (br , 4H), 2.53 (t, partially overlapping the solvent peak, 4H, J = 7.3 Hz), 1.82−1.71 (m, 10H), 1.68 (s, 12H). HRMS-ESI $[M]^+$ *m/z* calcd for $C_{45}H_{56}N_3O_{10}S_3$ 894.3122, found 894.3155.

Phage Preparation and Labeling. Phage containing the VCAM-1 targeting sequence VHSPNKK (VHS-peptide) were isolated and amplified in *Escherichia coli*, and their titer was determined as described previously (*24*). Following isolation and titer determination, the phage were labeled directly with the activated ester of **CyTE-777** using a modified literature procedure (*27*). **CyTE-777** succinimidyl ester (5 μL at 5 μg/μL in DMSO) was added to 1 × 10^{12} plaque forming units (pfu) of VHS-peptide-displaying phage (VHS−phage) in 50 μL of Dulbecco's phosphate-buffered saline (DPBS) supplemented with 1 mM Ca^{2+} and 10 mM Mg^{2+}. The volume was increased to 100 μL with 0.1 M $NaHCO_3$ buffer, pH 8.3, and allowed to incubate for 1 h in the dark at room temperature while shaking. After incubation, the phage was precipitated by addition of 20 μL of a PEG 8000/2.5 M NaCl solution (40% w/v) and allowed to stand on ice for 1 h. The fluorochrome-labeled phage was pelleted by centrifugation at 10 000 rpm for 15 min, and the supernatant was discarded. The light green pellet was resuspended in 400 μL of the supplemented DPBS and subjected to an additional round of PEG precipitation to minimize residual free fluorochrome and to remove bacterial protein contaminants. The degree of labeling was determined by using the extinction coefficient of **CyTE-777** in PBS.

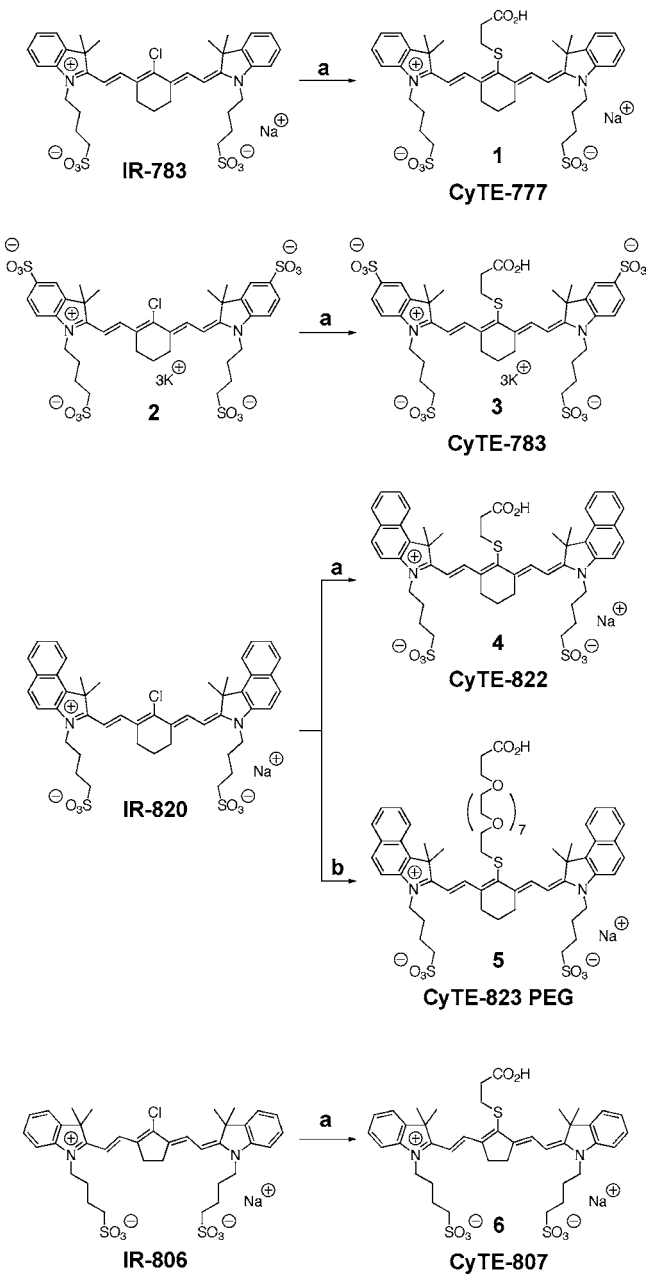
NIR Fluorescence Cellular Imaging. Murine cardiac endothelial cells (MCECs) constitutively expressing VCAM-1 were isolated and prepared as described previously (*28*, *29*). The cells were incubated with 1 × 10^{12} pfu of the **CyTE-777**-labeled VHS−phage in 400 μL of supplemented DPBS for 1 h at 37 °C, 5% CO_2. Following incubation, the cells were washed twice with DPBS/0.01% Tween 20, fixed with 2% paraformaldehyde supplemented with 10 mM Mg^{2+} and 1 mM Ca^{2+}, and then mounted to preserve fluorescence using VectaShield (Vector Laboratories, Burlingame, CA) containing the nuclear stain 4′,6-diamidino-2-phenylindole (DAPI). The cells were imaged on a Nikon Eclipse 80i fluorescence microscope with a 40× objective equipped with a Photometrics Cascade 512B CCD camera using excitation and emission filters from Chroma Technology. The nuclear stain DAPI was imaged using a 365 ± 5 nm band-pass filter for excitation and a 400 ± 5 nm cutoff filter for emission. The NIR fluorochrome **CyTE-777** was imaged using a 775 ± 25 nm band-pass filter for excitation and a 845 ± 28 nm band-pass filter for emission. Images with **CyTE-777** were acquired using a 2 s exposure time.

RESULTS AND DISCUSSION

Synthesis. In an effort to develop improved methods for the synthesis of cyanine NIR fluorochromes suitable for bioconjugation, new paths to generate symmetric monocarboxylic acid derivatives were explored. The ability to prepare a symmetric monofunctional dye streamlines the synthetic methodology by removing the need for the stepwise synthesis used to prepare asymmetric cyanine fluorochromes. One route to these symmetric fluorochromes, first reported in 1992, relies on the reaction of nucleophiles with cyanine dyes containing an activated chloro-substituent on the polymethinic linker (*19*). With this approach, it is possible to prepare a variety of symmetric cyanine dyes with several different nucleophiles. However, when ethylthiolate, prepared by deprotonation of mercaptoethane with sodium hydride, was used as the nucleophile, only the dehalogenated cyanine dye was obtained. We have developed a modified procedure using anhydrous DMF and triethylamine as a base that allows for the facile synthesis of symmetric alkylthioether derivatives. Conversion of the commercially available dye IR-783, which contains two alkyl sulfonate moieties, under these conditions with a slight excess of 3-mercaptopropionic acid gives the symmetric carboxylic acid functionalized **CyTE-777** in nearly quantitative yield (Scheme 1). The crude product from this reaction is sufficiently pure for subsequent transformation to the activated succinimide ester or for direct activation and use in solid-phase synthesis (unpublished results). Pure **CyTE-777** may be obtained by reverse-phase C-18 column chromatography in 83% yield.

To evaluate the effects of the degree of sulfonation on the properties of the fluorochromes, the tetrasulfonate analogue of **CyTE-777** was prepared. The synthesis of this derivative, **CyTE-783**, begins with the preparation of the tetrasulfonate intermediate **2**. This chloro-containing intermediate was prepared by the condensation of 2 equiv of 1-(4-sulfonatobutyl)-2,3,3-trimethylindoleninium-5-sulfonate with *N*-[(3-(anilinomethylene)-2-chloro-1-cyclohexen-1-yl)methylene]aniline monohydrochloride in the presence of methanol, TEA, and acetic anhydride. The methanol improves the solubility of the highly polar indoleninium precursor in the reaction mixture, thus enabling a shorter reaction time. The reaction was performed with heating to 140 °C for 25 min in a sealed pressure reactor. After the reaction mix cooled, column

Scheme 1



chromatography of the dark blue solid obtained from the reaction gives pure **2** in moderate yield. Due to the high degree of sulfonation on **2**, it is only moderately soluble in DMF; thus for the nucleophilic displacement with 3-mercaptopropionic acid, anhydrous DMSO was used as the solvent. As with the synthesis of **CyTE-777**, the reaction to generate **CyTE-783** (Scheme 1) is complete in less than 15 h as indicated by complete consumption of the starting chloro-functionalized dye. The purity of **CyTE-783** from the crude reaction is adequate for further work, and it can be purified rigorously by reverse-phase C-18 chromatography in 71% yield.

In an effort to prepare fluorochromes with absorption and emission greater than 800 nm, commercially available IR-820 was investigated as a precursor. The conditions used for generation of **CyTE-822** are similar to those used for **CyTE-777** (Scheme 1) and give a dark green solid in 52% yield after purification. In an effort

Table 1. Optical Properties of the CyTE Dyes in PBS, pH 7.4

	$\lambda_{max,abs}$ (nm)	$\lambda_{max,em}$ (nm)	ϵ (M^{-1} cm^{-1})
CyTE-777	777	812	130 000
CyTE-783	783	814	174 000
CyTE-822[a]	822	845	128 000
CyTE-823 PEG[a]	823	847	116 000
CyTE-807	807	839	120 000

[a] In PBS, pH 7.4, with 20% DMSO.

to devise derivatives that are less likely to aggregate in aqueous solution than **CyTE-822**, which is structurally similar to indocyanine green, a dye known to aggregate in aqueous media, functionalization of IR-820 with monodisperse PEG_7 thiol propionic acid was probed. Nucleophilic attack of the polyethylene glcyol (PEG) thiol on the chloro-substituted polymethinic linker of IR-820 gives **CyTE-823 PEG** (Scheme 1). Despite incorporation of the large PEG acid, purification of the fluorochrome is straightforward giving high-purity product in 56% yield. A final long wavelength fluorochrome, **CyTE-807**, was prepared through use of IR-806 in 80% yield following purification (Scheme 1). With this dye, the cyclic six-membered ring containing linker present in the previous CyTE fluorochrome derivatives is replaced by a more constrained five-membered ring. The removal of one methylene carbon from the cyclic ring results in significantly altered optical properties in comparison to the related **CyTE-777**.

Optical Properties. All of the alkyl-thioether-functionalized fluorochromes display long wavelength absorption and emission bands. The optical properties of these dyes are summarized in Table 1. **CyTE-777** and **CyTE-783** have absorption and emission bands that match closely those of ICG in water, which has an absorption maximum of 780 nm. Therefore these two dyes are well suited for imaging using currently available filter sets optimized for ICG. The absorption and emission spectra of **CyTE-777** are shown in Figure 1a. With **CyTE-777**, there is no indication for aggregation in PBS, which

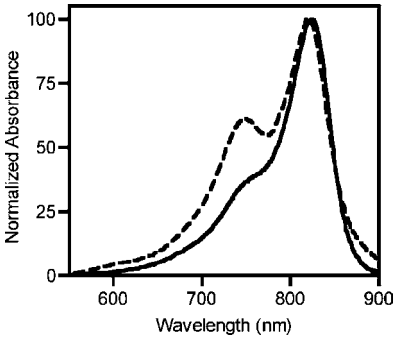

Figure 2. Absorption spectra of 1 μM solutions of **CyTE-823 PEG** in PBS (dashed line) showing the dimer at 750 nm, while in PBS with 20% DMSO (solid line), only the monomer is observed.

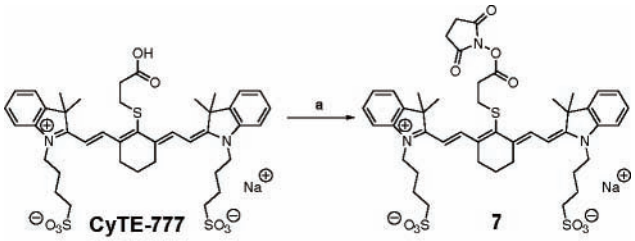
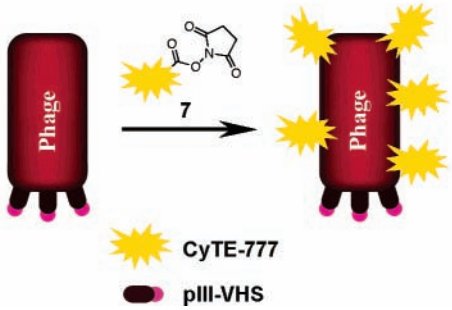
would manifest itself as a second absorption band approximately 70 nm to shorter wavelength (*30*). The short wavelength shoulder visible in the absorption spectrum of **CyTE-777** is a common feature of virtually all cyanine-based fluorochromes and is observed in less polar solvents such as DMSO and MeOH where there is no tendency for aggregation. The formation of dimers and other aggregates is undesirable because they frequently result in intermolecular quenching of fluorescence emission (*30*). The only significant difference in the optical properties between the disulfonate **CyTE-777** and the tetrasulfonate **CyTE-783** is their extinction coefficients, where a 25% increase is observed in PBS with the tetrasulfonate **CyTE-783**. In contrast to the increased extinction coefficient of **CyTE-783** when compared to **CyTE-777**, there are only minor differences in the absorption and emission maxima and quantum yields of the two dyes.

The long wavelength dye **CyTE-822** with benzindoleninium end groups is structurally similar to ICG; however, the alkyl-thioether moiety in the polymethinic linker results in a significant bathochromic shift of the absorption and emission maxima in comparison to ICG. As with ICG, **CyTE-822** shows a tendency to aggregate in aqueous solution. This aggregation is evident even at concentrations as low as 1 μM in PBS. The free monomer is only obtained in PBS with 20% DMSO. Aggregation of this derivative limits its potential utility for use as a fluorescent label for imaging applications.

To reduce the tendency for aggregation in aqueous solution, **CyTE-822** was modified with a hydrophilic poly(ethylene glycol) chain. This modified dye, **CyTE-823 PEG**, retains the long wavelength excitation and emission properties of **CyTE-822**; however, as with **CyTE-822**, it shows a tendency to aggregate in PBS (Figure 2). This indicates that the short PEG_7 chain is not sufficiently long to increase the solvent−dye affinity, which would result in diminished dye−dye aggregate formation.

Scheme 2





As an alternative for the preparation of a monocarboxylic acid derivatized fluorochrome with long wavelength absorption and emission, IR-806 was investigated as a building block. The alkyl-thioether containing **CyTE-807** has an absorption maximum of 807 nm in PBS and an emission maximum of 839 nm (Figure 1b). It also behaves like **CyTE-777** in PBS with no observable dye−dye aggregation. When compared to the structurally related **CyTE-777**, the absorption and emission bands shift 30 and 27 nm to longer wavelength, respectively. In addition to the wavelength shifts induced by the steric strain imposed by the cyclopentyl-containing polymethinic linker of **CyTE-807**, a slight decrease in the extinction coefficient from 130 000 M^{-1} cm^{-1} for **CyTE-777** to 120 000 M^{-1} cm^{-1} is observed. **CyTE-807** as well as other potential dyes containing a cyclopentyl-based polymethinic linker hold promise for use in imaging applications. Coupled with the proper filter sets, it may be possible to add an 800+ nm NIR fluorescence imaging channel to the currently used shorter wavelength channels.

Phage Labeling. To demonstrate the general applicability of the CyTE fluorochromes, **CyTE-777** was activated for use in phage labeling. Activation was

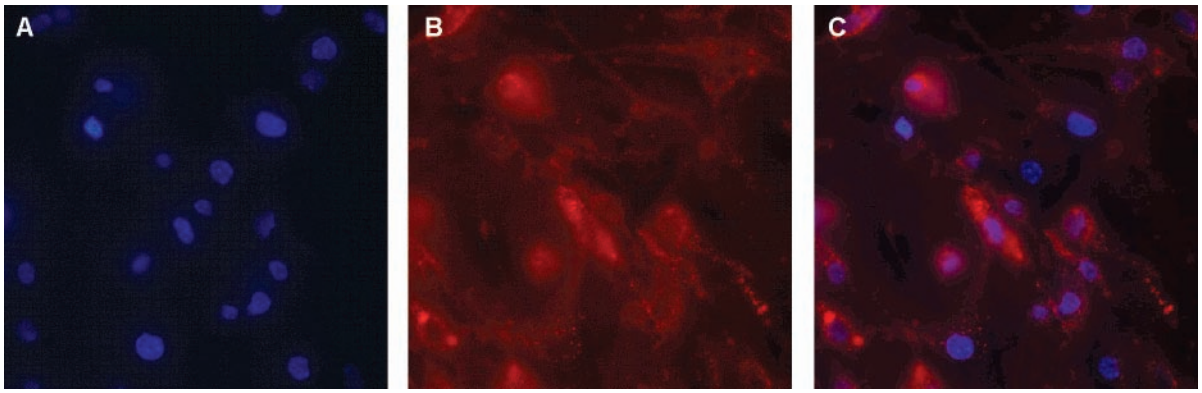


Figure 3. Fluorescence microscopy of MCECs incubated with **CyTE-777**-labeled VHS−phage for 1 h: (A) nuclear staining with DAPI; (B) staining of the **CyTE-777** conjugated phage; (C) the merged image indicating internalization of the labeled phage.

accomplished by treatment of **CyTE-777** with NHS in the presence of DIC and *N*-methylmorpholine (Scheme 2). Greater than 90% conversion to the activated ester was observed by HPLC. To label the VHS−phage, a modified literature procedure (*27*) was used where 1×10^{12} pfu of phage were treated with 25 μg of the activated fluorochrome for 1 h under slightly basic conditions (Scheme 2). By monitoring the fluorochrome absorbance, we determined the degree of labeling to be 1700 dye molecules per phage. The efficient labeling will facilitate imaging applications by enabling delivery of a large quantity of fluorochrome to the phage target. Conjugation of the dye to the phage was supported by observation of a shift in the absorption band of the conjugated **CyTE-777** from 777 to 798 nm in DPBS buffer. Bathochromic shifts in the absorption maxima of cyanine dyes are observed frequently in conjunction with a decrease in polarity of the fluorochrome local environment, such as provided by conjugation to the phage. In a similar system, the absorption maximum of ICG was reported to shift from 780 nm in water to 800 nm when bound to albumin (*30*).

Fluorescence Microscopy. To assess the performance of the fluorochrome-labeled VHS−phage for imaging, the probe was incubated with MCECs expressing VCAM-1. Following incubation for 1 h, the cells were monitored by fluorescence microscopy to visualize the distribution of the VCAM-1-specific phage. Dual channel fluorescence microscopy of stained nuclei and phage particles clearly shows phage internalization (Figure 3). The strong fluorescence signal observed is the result of multiple factors. Due to the high degree of fluorochrome labeling, the phage is capable of delivering a large fluorochrome payload, resulting in increased signal. In addition, binding and recognition of the phage by the surface receptors (VCAM-1) is a highly selective event. The VHS−phage have a high affinity for VCAM-1 since the peptides are present in 4−5 copies on the phage pIII coat proteins (*31*) resulting in multivalency, which increases the affinity through avidity effects (*32*). Finally, the VHS−phage is internalized by VCAM-1-expressing endothelial cells resulting in increased signal-to-noise ratios by biological amplification.

The alkyl-thioether-derivatized NIR fluorochromes hold promise for use in a wide variety of imaging applications. They are easily prepared from commercially available starting materials and require no additional purification prior to bioconjugation. One derivative, **CyTE-807**, displays absorption and emission maxima greater than 800 nm and does not aggregate in aqueous solution. By conjugation of **CyTE-777** to VHS−phage, imaging of VCAM-1-mediated internalization of the phage is possible. The fluorochrome-labeled phage constructs demonstrate a new potential imaging strategy that allows for highly selective, efficient delivery of large fluorochrome payloads.

Site-specific conjugation of small molecules and enzymes to monoclonal antibodies has broad utility in the formation of conjugates for therapeutic, diagnostic, or structural applications. Precise control over the location of conjugation would yield highly homogeneous materials that could have improved biological properties. We describe for the first time chemical reduction and oxidation methods that lead to preferential cleavage of particular monoclonal antibody interchain disulfides using the anti-CD30 IgG1 monoclonal antibody cAC10. Alkylation of the resulting cAC10 cysteine thiols with the potent antimitotic agent monomethyl auristatin E (MMAE) enabled the assignment of drug conjugation location by purification with hydrophobic interaction chromatography followed by analysis using reversed-phase HPLC and capillary electrophoresis. These analytical methods demonstrated that treating cAC10 with reducing agents such as DTT caused preferential reduction of heavy-light chain disulfides, while reoxidation of fully reduced cAC10 interchain disulfides caused preferential reformation of heavy-light chain disulfides. Following MMAE conjugation, the resulting conjugates had isomeric homogeneity as high as 60–90%, allowing for control of the distribution of molecular species. The resulting conjugates are highly active both in vitro and in vivo and are well tolerated at efficacious doses.

Monoclonal antibodies (mAbs) have been used extensively as carriers of fluorophores, radionuclides, cytotoxic agents, and enzymes, yielding conjugates that find utility in therapeutic (*1*–*3*) and imaging applications (*4*, *5*), ELISA-based assays (*6*), and for the investigation of protein structure and dynamics (*7*). The methods employed for making mAb-based conjugates can be classified in two general categories: those that involve the random modification of mAb amino acid residues, and those that are highly regioselective. Examples of random modification procedures include the acylation of lysine ϵ-amino groups (*8*), alkylation of tyrosines (*9*), and amidation of carboxylates (*10*). The biological and functional properties of these conjugates are often acceptable; however, random modification of mAbs may impair antigen binding and leads to conjugate heterogeneity.

In the past several years, a number of selective methods have been described to introduce molecules of interest onto mAbs. The ability to control the location and stoichiometry of conjugation can significantly improve the properties of mAb conjugates in some applications. The greatest selectivities are obtained using recombinant technologies for the production of fusion proteins (*11*–*14*). Selective modification has also been reported for such chemically based methods as reductive amination of oxidized mAb carbohydrates (*15*), photoaffinity labeling of unconventional mAb binding sites (*16*), and reduction–alkylation of antibody interchain disulfides (*17*, *18*).

We have previously described the preparation of mAb–drug conjugates for use as antitumor agents (*17*, *19*). The potent antimitotic agent monomethyl auristatin E (MMAE)[1] was conjugated to the chimeric anti-CD30 mAb cAC10, an IgG1 mAb with four interchain disulfides (Figure 1). Conjugates were formed through full reduction of all interchain disulfides, followed by alkylation with the drug–linker complex. The resulting mAb–drug conjugates were homogeneous in composition, with about eight drugs/mAb. Since mAb interchain disulfides are distant from the antigen binding site and are generally not required to maintain mAb integrity (*20*), this site-specific conjugation strategy yielded conjugates that were potent and selective for CD30-positive hematologic malignancies (*17*, *19*).

We recently demonstrated that drug-load stoichiometry significantly influenced conjugate pharmacokinetics, and that conjugates with fewer drugs/mAb had larger therapeutic windows (*21*). Specifically, conjugates with four drugs/mAb were highly active and significantly less toxic than their counterparts with eight drugs/mAb. However, such partially loaded conjugates are not homogeneous, and the number of drugs on each mAb vary from 0 to 8, with several isomers at each drug substitution level. To minimize the heterogeneity of these partially loaded conjugates with four drugs/mAb, we explored various reduction–alkylation strategies and evaluated the distribution of species formed. We recognized that the

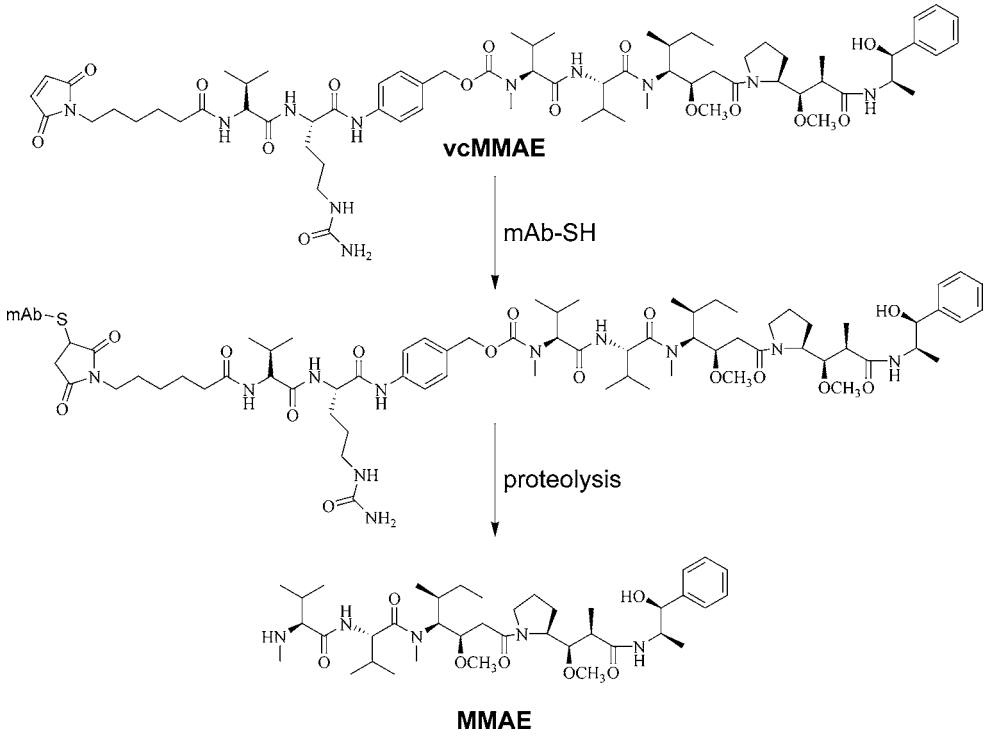

Figure 1. Conjugation strategy. The drug-linker vcMMAE reacts with a mAb cysteine to form the ADC. The potent antimitotic agent MMAE is released from the ADC following proteolysis. As many as eight molecules of vcMMAE can react with each mAb following reduction of the four interchain disulfides present in cAC10.

absolute drug loading and the isomeric distribution could play a role in efficacy and toxicity. However, the literature does not describe how to chemically control the isomeric distribution of drug loading, nor does it illustrate how to determine which of the various mAb thiols are drug substituted. To address these issues, analytical technologies were established to determine the sites of drug substitution, and conjugation methods were developed that allowed for isomeric homogeneities as high as 60−90%. The in vitro and in vivo properties of these conjugates are also described.

MATERIALS AND METHODS

Materials. cAC10, vcMMAE, and cAC10 with eight MMAE/mAb (E8) were prepared as previously described (*17*, *22*). DTT, DTPA, and 4,4′-dithiodipyridine were obtained from Sigma-Aldrich (St. Louis, MO). EDTA and sodium chloride were obtained from Cambrex (Rockland, ME). Sodium borate, sodium phosphate, and citric acid were obtained from Mallinckrodt (Phillipsburg, NJ). DTNB was obtained from Pierce (Rockford, IL). TCEP and aminoethanethiol were obtained from Acros (Morris Plains, NJ). Cysteine was obtained from Alfa Aesar (Ward Hill, MA).

Preparation of ADCs. cAC10-vcMMAE with an average of four MMAE/mAb, referred to as E4 mixture, was prepared as follows. Methods A and D were used to make cAC10-vcMMAE with 2 MMAE/mAb, referred to as E2 mixture, with the indicated substitutions.

Method A: Limited DTT Reduction. cAC10 was treated with 3.25 molar equiv of DTT (2.25 molar equiv for E2 mixture) in 0.025 M sodium borate pH 8, 0.025 M NaCl, 1 mM DTPA for 2 h at 37 °C. The excess DTT was purified away from the partially reduced cAC10 in the following manner. The mixture was first diluted 5-fold with water and applied to a hydroxyapatite column (Macroprep ceramic type I 40 μm, BioRad, Hercules, CA) at a flow rate of 10 mL/min. The column size was 1 mL per 10 mg of cAC10. The column was previously equilibrated with five column volumes of 0.5 M sodium phosphate pH 7, 10 mM NaCl and five column volumes of 10 mM sodium phosphate pH 7, 10 mM NaCl. Following application, the column was washed with five column volumes of 10 mM sodium phosphate pH 7, 10 mM NaCl and then eluted with 100 mM sodium phosphate pH 7, 10 mM NaCl. DTPA was added to 1 mM following elution. The protein concentration was quantified using an absorbance value of 1.58 at 280 nm for a 1.0 mg/mL solution, and the molar concentration was determined using a molecular weight of 148 449 g/mol. The concentration of mAb−cysteine thiols produced was determined by titrating with DTNB, typically resulting in 4.0 to 4.5 thiols/mAb when 3.25 molar equiv of DTT were used.

Partially reduced cAC10 was alkylated with 1.1 molar equiv of vcMMAE/mAb-cysteine thiol. The alkylation reaction was performed at 0 °C for 30 min. Cysteine (1 mM final) was used to quench any unreacted, excess vcMMAE. cAC10-vcMMAE was purified by hydroxyapatite chromatography as described above. Following elution, the buffer was changed to phosphate buffered saline (Invitrogen, Carlsbad, CA) using Amicon (Millipore, Bedford, MA) Ultrafree 30K cutoff spin concentration devices. The protein concentration was quantified using an absorbance value of 1.62 at 280 nm for a 1.0 mg/mL solution.

Method B: Limited TCEP Reduction. cAC10 was treated with 2.75 molar equiv of TCEP in 0.025 M sodium borate pH 8, 0.025 M NaCl, 1 mM DTPA for 2 h at 37 °C. Without purification, the mixture was then cooled to 0 °C and partially reduced cAC10 alkylated with vcMMAE as described above. cAC10-vcMMAE was purified using PD-10 columns (Amersham Biosciences, Piscataway, NJ) equilibrated with phosphate buffered saline.

Method C: Reduction of cAC10 with Aminoethanethiol. cAC10 was reduced with aminoethanethiol as previously

described for gamma globulin (*23*). The reduced mAb was alkylated with vcMMAE as described above.

Method D: DTNB Reoxidation of Fully Reduced cAC10. cAC10 was treated with a large excess (10 mM) of DTT in 0.025 M sodium borate pH 8, 0.025 M NaCl, 1 mM DTPA for 1 h at 37 °C and purified by hydroxyapatite chromatography as described above. The fully reduced cAC10 was cooled to 0 °C and then treated with 2.0 equiv of DTNB (3.0 for E2 mixture) or 4,4′-dipyridyldithiol (from 10 mM stock solutions) with rapid mixing. This mixture was incubated at 0 °C for 20 min. Without further purification, partially reoxidized cAC10 was alkylated with vcMMAE as previously described and the resulting conjugate was purified by hydroxyapatite chromatography as described above.

cAC10 Reduction Time Course. cAC10 was reduced with 3.0 equiv of DTT in 50 mM sodium phosphate pH 7.5 and 5 mM EDTA at 37 °C. At various times, samples were removed, quenched with an equal volume of ice-cold 200 mM sodium citrate pH 5, and purified using PD-10 columns equilibrated with phosphate buffered saline containing 5 mM EDTA. Reduced cAC10 was treated with vcMMAE as previously described and purified using PD-10 columns equilibrated with phosphate buffered saline.

Purification of E2, E4, and E6 by HIC. cAC10-vcMMAE was purified by HIC as previously described to yield ADCs with exactly two, four, or six MMAE/mAb (referred to as E2, E4, and E6, respectively) (*21*). Briefly, NaCl was added to cAC10-vcMMAE to give a final concentration of 2.0 M and this mixture applied to a phenyl HIC column. E2, E4, and E6 were eluted using step gradients of decreasing NaCl concentration. These purified fractions were analyzed by HIC−HPLC to determine drug loading purity as previously described (*21*, *24*). HIC peaks corresponding to E2, E4, or E6 were identified as previously described: cAC10 and vcMMAE have distinct absorbance maxima ($\lambda_{max} = 280$ and 248 nm, respectively) and overlaying the UV spectra of these peaks yields A248/280 ratios that increase with drug loading (*21*, 24). The HIC−HPLC method was also used to isolate small amounts of E2, E4, and E6.

Characterization of ADCs. The drug loading was estimated using the molar extinction coefficients at 248 and 280 nm of the mAb (9.413×10^4 and 2.3415×10^5 M^{-1} cm^{-1}, respectively) and drug (1.5×10^3 and 1.59×10^4 M^{-1} cm^{-1}, respectively) as previously described (*21*, *24*). Size-exclusion HPLC and C_{12} reversed-phase HPLC were used as previously described (*17*) to determine the amount of aggregate and free vcMMAE, respectively, present in the ADCs.

Analysis of ADCs by Capillary Electrophoresis. The ADCs were analyzed under denaturing but nonreducing conditions using an Agilent Bioanalyzer (Palo Alto, CA). A protein 200 chip was used under denaturing but nonreducing conditions as described by the manufacturer. Briefly, 4 μL of 1 mg/mL cAC10-vcMMAE was mixed with 2 μL of nonreducing loading buffer and heated to 100 °C for 5 min. Water (84 μL) was added and 6 μL of this mixture was loaded into each well of the chip. The molecular weights of peaks were determined using the molecular weight ladder provided and run concurrently, allowing assignment of L, H, HL, HH, HHL, and LHHL. Unconjugated cAC10 confirmed the assignment of LHHL, while E8 confirmed the assignment of L and H.

Analysis of ADCs by Reversed-Phase HPLC. ADCs were analyzed under denaturing and reducing conditions using a 2.1 × 150 mm, 8 μ, 1000 Å PLRP-S column (Polymer Laboratories, Amherst, MA). The flow rate was 1 mL/min, and the column temperature was 80 °C. Solvent A was 0.05% trifluoroacetic acid in water and solvent B was 0.04% trifluoroacetic acid in acetonitrile. The method consisted of the following: Isocratic 25% B for 3 min, a 25-min linear gradient to 50% B, a 2-min linear gradient to 95% B, a 1-min linear gradient to 25% B, and isocratic 25% B for 2 min. Injections were 10−20 μL of 1 mg/mL cAC10-vcMMAE previously reduced with 20 mM DTT at 37 °C for 15 min to cleave the remaining interchain disulfides. The number of moles and mole fraction of each chain was determined using the following molar extinction coefficients: 30 160 M^{-1} cm^{-1} (L0); 31 660 M^{-1} cm^{-1} (L1); 86 915 M^{-1} cm^{-1} (H0); 88 415 M^{-1} cm^{-1} (H1); 89 915 M^{-1} cm^{-1} (H2); 91 415 M^{-1} cm^{-1} (H3). Peak assignments were made with unconjugated cAC10 (L0 and H0) and E8 (L1 and H3). H1 and H2 were assigned by their elution time (eluting between H0 and H3) and UV spectra (the A248/280 ratio increases with drug loading).

Determination of Isomeric Distribution. The isomeric distribution for E2 and E6 was determined using solely reversed-phase HPLC data from the mole fractions determined above. For E2 isomer A, the mole fraction of L0 and H1 are equal, while for E2 isomer B, the mole fraction of L0, L1, H0, and H1 are equal. With the sum of the mole percent of L0, L1, H0, and H1 set to 100%, the percent isomer B can be determined as follows:

$$\%\,B = 2(\%\ \mathrm{L1}) + 2(\%\ \mathrm{H0}) \qquad (1)$$

where %L1 = mole fraction of L1 and %H0 = mole fraction H0. The percent of isomer A is assumed to be 100 − %B.

Similarly, for E6 isomer A, the mole fraction of L1 and H2 are equal, while for E6 isomer B, the mole fractions of L0, L1, H2, and H3 are equal. With the sum of the mole percent of L0, L1, H2, and H3 set to 100%, the percent isomer B can be determined as follows:

$$\%\,B = 2(\%\ \mathrm{L0}) + 2(\%\ \mathrm{H3}) \qquad (2)$$

where%L0 = mole fraction of L0 and %H3 = mole fraction H3. The percent of isomer A is assumed to be 100 − %B.

Due to more possible isomers, the percentages of the E4 isomers cannot be obtained solely from the reversed-phase HPLC data because no isomer gives a unique light and heavy chain pattern. The amount of E4 isomer A was first determined from capillary electrophoresis data using the HHL, HH, and HL peak areas as follows:

$$\%\,A = \frac{\dfrac{\mathrm{HHL}}{124720.8}}{\dfrac{\mathrm{HHL}}{124720.8} + \dfrac{\mathrm{HH}}{100992.6} + \dfrac{\mathrm{HL}}{2 \times 74224.5}} \qquad (3)$$

With the sum of the mole percent of L0, L1, H1, and H2 set to 100%, reversed-phase HPLC data was then used to solve for the remaining contribution of E4 isomers B and C using the following formulas:

$$\%\,B = \%\ \mathrm{H1} + \%\ \mathrm{L1} - 0.5(\%\,A) \qquad (4)$$

$$\%\,C = \%\ \mathrm{H2} + \%\ \mathrm{L0} - 0.5(\%\,A) \qquad (5)$$

where %H1 = mole fraction of H1, %L1 = mole fraction L1, %H2 = mole fraction H2, and %L0 = mole fraction L0.

Simulations. The simulated partial reduction of cAC10 was carried out using a series of coupled ordinary

differential equations (*25*) with an integration algorithm (fourth order Runge−Kutta) implemented as a VBA function in Excel (Microsoft Corp., Redmond, WA). The rate constants for reduction of heavy-light and heavy-heavy disulfides were equal. The simulation assumes 2 equivalent heavy-light and 2 equivalent heavy-heavy disulfides per mAb, with the relative rate constants for the reduction of the first and second of these equivalent disulfides being 2:1 due to the 2:1 stoichiometry (for example, when the first heavy-light disulfide is reduced, there are two heavy-light disulfides present, whereas when the second heavy-light disulfide is reduced, there is only one heavy-light disulfide present). The simulation used a concentration of reductant sufficient to reduce an average of two disulfides per mAb. Figures S1 and S2 show the mechanism and the differential equations used in the simulation.

Binding Studies. ADCs were labeled with 36 molar equiv of europium N1-isothiocyanate (Perkin-Elmer Biosciences, Wellesley MA) overnight at 4 °C in 50 mM Na_2CO_3, pH 9.0. Small molecular weight agents were removed by gel filtration on PD-10 columns equilibrated with Tris buffered saline (TBS, 50 mM Tris HCl, pH 8.0, 150 mM NaCl) followed by dialysis overnight in TBS at 4 °C. Conjugate concentration was determined by UV absorbance. Analysis of the europium content (by release into DELFIA enhancement solution, Perkin-Elmer) indicated that there were 5−7 europium labels/mAb. Karpas 299 ALCL cells (100 μL/well at 1×10^6/mL in TBS + 0.5% FBS, 10 μM EDTA) were incubated with increasing dilutions of labeled ADC or parental cAC10 for 1 h at 4 °C on a plate rocker. Following incubation, the cells were washed three times in TBS, resuspended in 200 μL of enhancement solution, transferred to DELFIA yellow sided plates, and incubated on an orbital shaker for 5 min at room temperature. Fluorescence was monitored using a Fusion HTS microplate reader (Perkin-Elmer) using the time-resolved fluorescence mode using an excitation wavelength of 335 nm and emission wavelength set at 620 nm. The time delay between excitation and emission was 400 μs. After reading, data were reduced and binding analyzed using the one-site binding model in GraphPad Prism version 4.01 for Windows (GraphPad Software, San Diego CA). Binding curves experiments were performed a minimum of three times to ensure accuracy.

Cytotoxicity Assays. The experiments were performed as previously described (*17*). Briefly, Karpas 299 cells were treated with ADCs for 92 h before adding resazurin and incubating an additional 4 h. Dye reduction was measured using a fluorescent plate reader.

In Vivo Studies. In vivo efficacy of ADCs in xenograft models of human $CD30^+$ tumors in SCID mice and the maximum tolerated dose of ADCs in BALB/c mice were performed as previously described (21). Briefly, subcutaneous Karpas-299 tumors were grown in C.B.-17 SCID mice, with the test articles administered when tumors reached approximately 100 mm^3 (length $\times$ width^2)/2. Animals (7−10/group) were injected iv with the ADCs at the doses indicated. Animals were considered cured if they were tumor free 101 days post tumor implant. Groups were compared for statistical significance by pair wise treatment of Kaplan−Meier analysis using GraphPad Prism version 4.01. To evaluate the MTD, BALB/c mice (parent strain of the C.B.-17 SCID) were administered with ADCs. Animal weights were measured and clinical observations were recorded over a 14 day period. The MTD was assigned as the highest single dose administered to an animal that did not result in weight loss ≥20% or lead to any signs of distress.

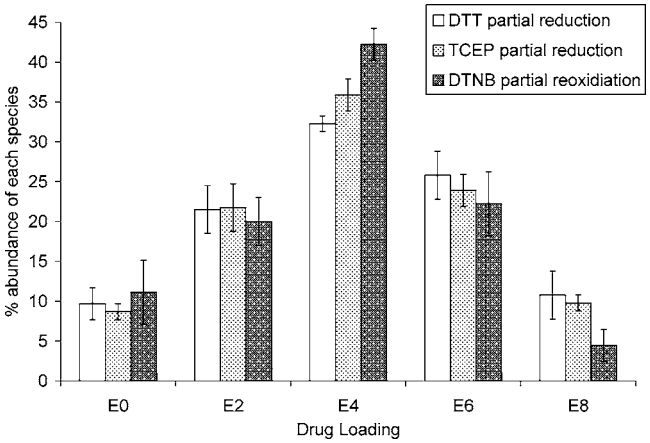

Figure 2. Composition of E4 mixture as a function of conjugation methodology. HIC−HPLC chromatograms were integrated to determine the abundance of E0, E2, E4, E6, and E8 in the mixtures. Values are ± standard deviation for four (DTT partial reduction), three (TCEP partial reduction), or six (DTNB partial reoxidation) separate experiments. The contributions from odd-loaded species, typically less than 10%, are not shown. The sum of E0, E2, E4, E6, and E8 was normalized to 100%.

RESULTS

Reduction Methods. Two general strategies were used to prepare ADCs with an average of four MMAE/mAb (referred to as E4 mixture). The first involved limited reduction of the interchain disulfides of the chimeric mAb cAC10, an IgG1, followed by alkylation with maleimidocaproyl-val-cit-PABA-MMAE (vcMMAE). This two-step process led to the formation of cAC10-vcMMAE. About 3.25 and 2.75 molar equiv of the strong reducing agents DTT and TCEP, respectively, were sufficient to cleave two interchain disulfide bonds, yielding an average of four cAC10 cysteines/mAb. Partial reduction of cAC10 could also be accomplished using the weaker reducing agent aminoethanethiol, which at pH 5 requires about 500 molar equiv to yield 4 cAC10 cysteines/mAb. Unlike the thiol-based reducing agents, phosphines such as TCEP react poorly with maleimides, and the excess reducing agent does not have to be removed before adding vcMMAE.

A second general strategy for controlled drug substitution involves fully reducing cAC10 with DTT and then partially reoxidizing the resulting thiol groups with DTNB. This reoxidation process is very efficient, requiring 2.0 equiv of DTNB to reoxidize eight mAb cysteines back to four. Treatment of this reoxidized mAb with a thiol such as cysteine does not liberate any bound thionitrobenzoic (TNB) acid, suggesting that the reoxidized cysteines are in the form of mAb disulfides rather than mixed TNB−cysteine disulfides. The remaining mAb cysteines can then be conjugated to vcMMAE.

Quantification of Drug Loading Levels. Figure 2 shows the normalized percentages of the even drug-loaded species prepared by DTT partial reduction, TCEP partial reduction, and partial DTNB reoxidation as determined by HIC−HPLC. The DTNB partial reoxidation method yields a slightly higher percentage of E4 (42%) than the partial reduction methods (32% for DTT and 36% for TCEP). This comes at the expense of mainly E6 and E8, which total about 37% for DTT partial reduction and 34% for TCEP partial reduction, while only 27% for DTNB partial reoxidation.

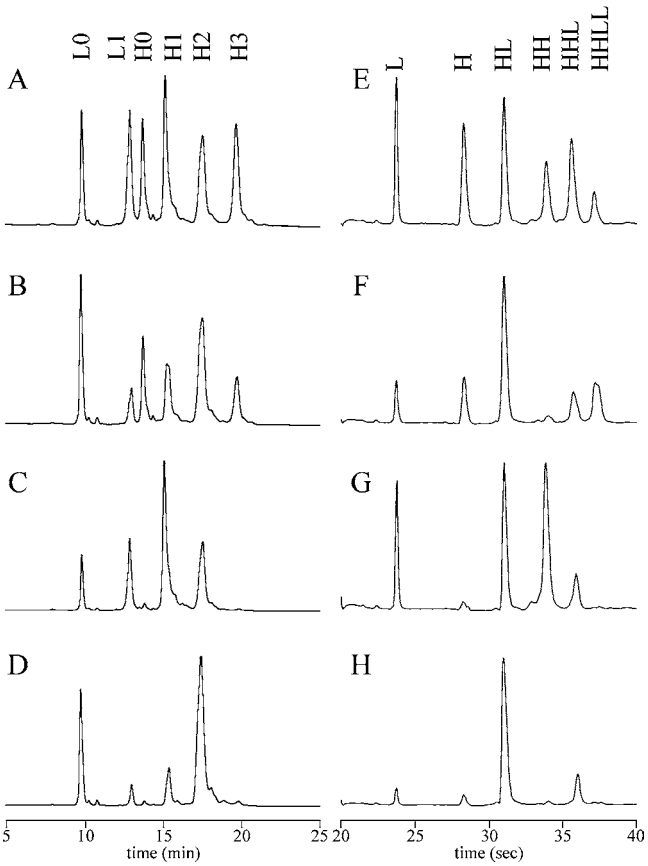

Figure 3. Analytical characterization of ADCs. (A−D) Reversed-phase HPLC and (E−H) capillary electrophoresis were used to analyze (A, E) E4 mixture made by partial DTT reduction followed by MMAE conjugation; (B, F) E4 mixture made by DTNB partial reoxidation followed by MMAE conjugation; (C, G) E4 made by partial DTT reduction followed by MMAE conjugation and purified by preparative HIC; and (D, H) E4 made by partial DTNB reoxidation followed by MMAE conjugation and purified by preparative HIC. HPLC injections were 20 μL of 1 mg/mL cAC10-vcMMAE treated with 20 mM DTT for 15 min at 37 °C. Separations were performed at 80 °C. Capillary electrophoresis was performed under nonreducing conditions.

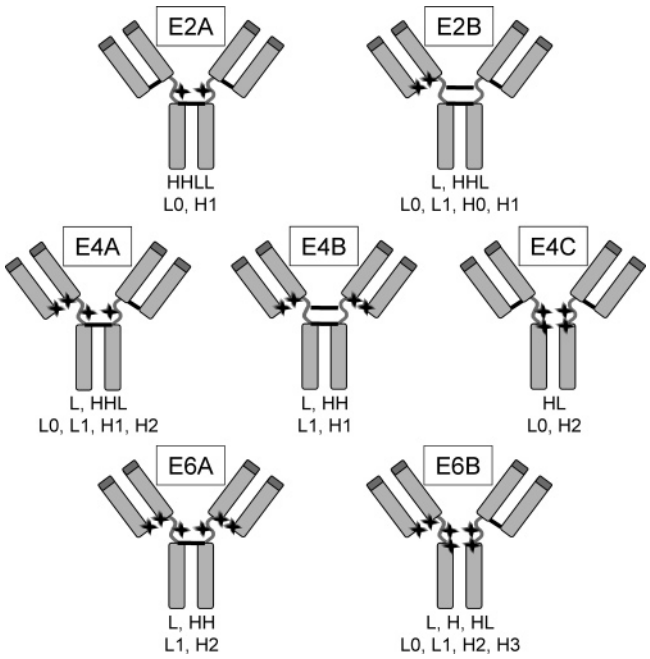

Figure 4. Potential isomers for E2, E4, and E6. Isomers with one heavy-heavy disulfide (2A, 4A, and 6A) can be further subdivided into isomers with either the first or the second disulfide intact, but because the analytical methods described herein cannot distinguish these subgroups, only one isomer is shown. Below the isomer are the chain compositions under denaturing conditions (first line, nonreducing; second line, reducing). For denaturing and nonreducing conditions, the possible species formed are L, H, HL, HH, HHL, and LHHL, where the remaining interchain disulfides link the indicated chains. For denaturing and reducing, the possible species formed are L0, L1, H0, H1, H2, and H3, in which the numbers indicate how many drug molecules are attached to the light or heavy chain. The locations of MMAE conjugation are indicated by stars. Unconjugated cAC10 (E0) and fully conjugated cAC10 (E8) are not shown.

Isomeric Populations. To determine the isomeric population of each of the drug loaded species, cAC10-vcMMAE prepared with various methods was first separated by preparative HIC, yielding E2, E4, and E6. The purities of these materials, with respect to their drug loading levels, was at least 95% as determined by analytical HIC−HPLC (*21*). The HIC-purified materials were then subjected a combination of reducing and nonreducing methods to assign the distribution of the drugs on the mAb. Reducing and denaturing reversed-phase HPLC was used to separate and quantify various light and heavy chain species. In this method, pretreatment of the ADC with an excess of DTT breaks the remaining interchain disulfides and allows separation of light chain with 0 or 1 drugs (L0 and L1) from heavy chain with 0, 1, 2, or 3 drugs (H0, H1, H2, and H3) (Figure 3, A−D). A second form of analysis involved nonreducing and denaturing capillary electrophoresis, allowing for the separation of 6 potential mAb species: L, H, HL, HH, HHL, and LHHL (Figure 3, E−H). Figure 4 shows the possible isomers of E2, E4, and E6 and the expected distribution of mAb fragments under denaturing conditions in both reducing and nonreducing environments. The isomeric populations of E2 and E6 were readily determined by reversed-phase HPLC since each isomer yields a unique fragment pattern. For example, isomer E2B yields L1 and H0 under denaturing and reducing conditions, while E2A yields L0 and H1. Under denaturing and nonreducing conditions, isomer E2A yields LHHL, while E2B yields L and HHL. For E4, the three potential isomers do not yield unique fragment patterns on reversed-phase HPLC or capillary electrophoresis alone, requiring that the combined results must be used to assign the isomeric population.

Figure 5 shows the percent composition for each of these isomers. Both partial reduction methods gave similar isomer populations. However, for E2, DTT partial reduction and DTNB partial reoxidation gave contrasting isomeric populations: the former method yielded 92% E2B, while the latter method yielded 77% E2A. Similarly, E4B is the predominant isomer for DTT partial reduction (59%), while E4C is the predominant isomer for DTNB partial reoxidation (75%). The chemistry used to prepare the reduced antibody plays a significant role in the location of the drugs in the resulting conjugate. Interestingly, both methods yield E6B as the predominant E6 isomer in very high yields (96−98%). There are also smaller differences in the distribution of isomers observed from the DTT and TCEP partial reduction methods, the largest of which can be seen in isomers E4B and E4C. DTT partial reduction yields about 2:1 E4B to E4C, while TCEP partial reduction yields about 1:1.

Simulated Partial Reduction. The observed drug loading levels and isomeric populations are significantly different for the partial reduction and partial reoxidation methods, which may indicate that there is some degree

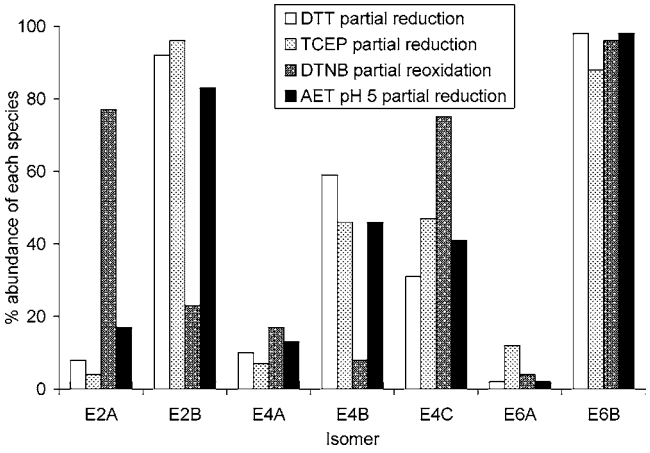

Figure 5. Composition of isomeric population of purified E2, E4, and E6. The percent of the E2 and E6 isomers were determined from reversed-phase HPLC data using eqs 1 and 2, respectively. The percent of E4A was determined from capillary electrophoresis data using eq 3 and then the percent of E4B and E4C were determined from reversed-phase HPLC data using eqs 4 and 5. For each drug loading level, the sum of the isomers is equal to 100%.

of selectivity in reducing and oxidizing mAb heavy-light and heavy-heavy disulfides. A simulation of cAC10 partial reduction was performed in which disulfides were allowed to be randomly reduced under conditions where the rate constants for the reduction of heavy-light and heavy-heavy disulfides were equal. Figure 6a shows the simulated drug loading levels for E0, E2, E4, E6, and E8 and the percent difference between these simulated values and the HIC−HPLC data for DTT and TCEP partial reduction. The percent difference varies systematically, in that the experimentally determined amounts of E0 and E8 were significantly larger than the simulated values, while the amounts of E2, E4, and E6 were slightly less than the simulated values. Figure 6b shows the simulated isomer populations and the percent difference between the simulation and the values determined from reversed-phase HPLC and capillary electrophoresis. The experimentally determined isomer abundances were as much as 250% more and up to nearly 100% less than the simulated values. No experimentally determined isomer abundance was within 75% of the simulated values. These results strongly suggest that the reduction is not a random process, and the rate constants for reduction of individual cAC10 disulfides are widely different.

DTT Reduction Time Course. Because of the long reduction time necessary to form partially reduced cAC10 with DTT, the isomeric population could change during the reduction reaction and using the end point of the reaction would not be representative of the overall reduction process. To address this, the isomeric compositions of the product ADCs were determined at various time intervals after the addition of the reducing agent. Reduction times of 10 to 120 min yielded drug loadings of 1.3 to 3.9 drugs/mAb. Table 1 shows that the isomeric composition does not change over the course of the reduction reaction. Thus, the reduction process is under kinetic rather than thermodynamic control, and using the end point of the reaction is appropriate.

Binding to CD30 Positive Cells. cAC10-vcMMAE conjugates were tested for their abilities to bind to CD30 positive Karpas 299 Anaplastic Large Cell Lymphoma cells. Table 2 shows that unmodified cAC10 and ADCs with two drugs/mAb bound with similar affinities, 2.0 to 3.6 nM. ADCs with four and eight drugs/mAb bound slightly weaker, 6.5 to 7.8 nM. The chemistry used to

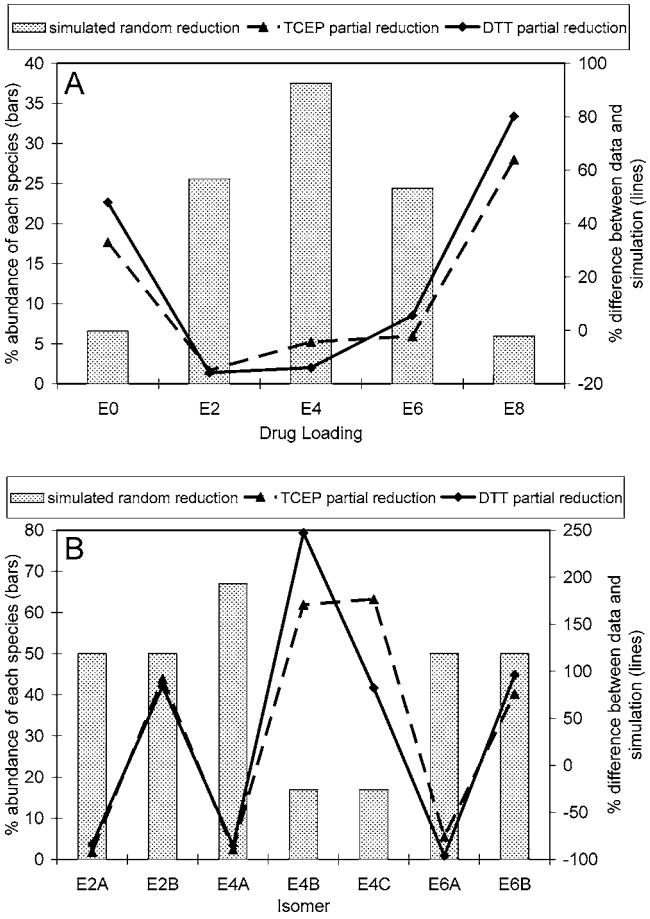

Figure 6. Simulation of random reduction reaction. cAC10 reduction was simulated with equal rate constants for reduction of heavy-heavy and heavy-light disulfides. (A) The simulated drug loading abundance is shown with bars for the reduction of an average of two disulfides to yield an average of four antibody cysteines. The percent differences between the experimentally determined drug loading abundance from HIC−HPLC data for DTT and TCEP partial reduction shown in Figure 2 and the simulated values are shown in lines. (B) The simulated isomer distribution is shown in bars. The percent differences between the experimentally determined isomer abundances shown in Figure 5 and the simulated values are shown in lines. In both panels, a positive number indicates that the experimental data is greater than the simulated value, while a negative number indicates that the experimental data is lower than the simulated value.

prepare the ADCs did not significantly influence the ability of the ADCs to bind to the cells.

In Vitro Cytotoxicity. Mixtures with an average of two and four drugs/mAb as well as HIC purified E2 and E4 were investigated for their in vitro activities on Karpas 299 cells. Table 2 shows the ADCs with two and four drugs/mAb have IC_{50} values from 11.4 to 13.8 ng/mL and 3.4 to 5.0 ng/mL, respectively. E8 gave the lowest value of 2.7 ng/mL and unconjugated cAC10 showed no effect. Thus, cytotoxic activity increases with increased drug substitution, but is not dependent on ADC isomeric composition.

In Vivo Toxicity and Therapeutic Efficacy. MTD values in immunocompetent BALB/c mice were determined by iv ADC injections. As previously described, the MTD of E8 was 50 mg/kg (*21*). Significantly more of the ADCs could be administered with lower drug loading. The best tolerated ADC was E2 made by DTT partial reduction, which was devoid of toxicity at 250 mg/kg, the highest dose tested. The MTD of E4 prepared by the DTNB partial reoxidation method was 120 mg/kg, which

E4 mixture DTT	N/D	3.4 ± 1.2
E4 DTT	7.76 ± 3.93	4.8 ± 0.7
E4 mixture DTNB	N/D	5.0 ± 0.0
E4 DTNB	7.69 ± 4.42	4.3 ± 0.9
E8	6.53 ± 3.09	2.7 ± 0.2

[a] Binding to Karpas 299, determined from four to seven independent measurement ± standard deviation. N/D, not determined. [b] In vitro cytotoxicity, in ng cAC10/mL, determined from three independent measurements ± standard deviation. N/D, not determined. cAC10 alone displays poor activity against Karpas 299.

was slightly less toxic than the corresponding E4 ADC prepared by DTT partial reduction (MTD of 100 mg/kg). Consistent with in vitro cytotoxicity, the number of drugs/mAb had a much more pronounced influence on toxicity than the placement of the drug on the mAb.

Therapeutic efficacy experiments were performed in SCID mice with subcutaneous Karpas 299 tumors. Single doses of the ADCs were given 11 (E4) or 14 (E2) days after tumor implant, when the tumors had reached approximately 100 mm^3. Figure 7a shows that for E2 made by DTT partial reduction and DTNB partial reoxidation methods, 1.0 mg/kg of ADC both gave delays in tumor growth. Although E2 made by DTT partial reduction gave five cures out of seven while E2 made by DTNB partial reoxidation provided one cure out of seven, Kaplan−Meier analysis for survival showed that there was not a statistical difference between these two chemistries ($P = 0.08$). However, since the P value is trending toward significance ($0.05 < P < 0.1$), further studies are required with larger group sizes to determine if these chemistries yield differences in efficacy. The E4 ADCs which were made by DTT partial reduction, TCEP partial reduction, and DTNB partial reoxidation gave delays in tumor growth at both 0.5 and 1.0 mg/kg (Figure 7b). Nearly identical cure rates were obtained at 1 mg/kg for all three production methods (eight to ten cures out of ten), suggesting that the production methods yielded ADCs with similar efficacies ($P = 0.15$ for E4 made by TCEP partial reduction compared to E4 made by either DTT partial reduction or DTNB partial reoxidation).

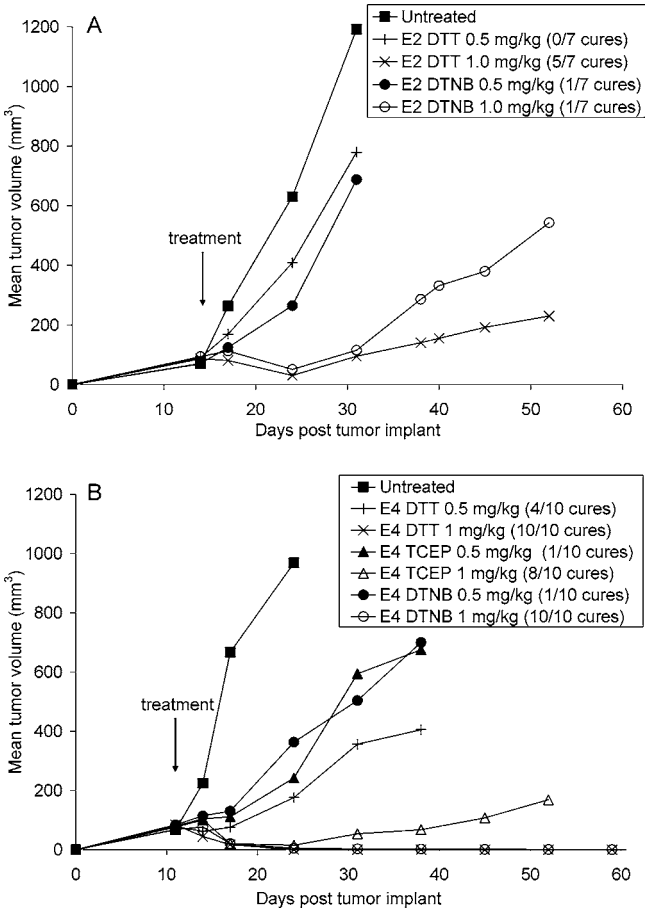

Figure 7. Single dose efficacy of E2 and E4. SCID mice with Karpas 299 tumors were treated with single doses of (A) E2 made by DTT partial reduction and DTNB partial reoxidation and (B) E4 made by DTT partial reduction, TCEP partial reduction, and DTNB partial reoxidation. Animals were considered cured if they were tumor free 101 days post tumor implant.

DISCUSSION

We have demonstrated for the first time that IgG1 interchain disulfide bonds can be distinguished by chemical reduction and oxidization methods. This was made possible using the drug MMAE to fix the disulfide bonding pattern by alkylating free cysteines, allowing separation of the drug loading levels by HIC, and facilitating the analysis of the isomeric populations.

As shown in Figure 3, the production method significantly affects the location of the drugs, suggesting that the mAb disulfides can be selectively reduced. Partial DTT reduction yields predominantly isomer E2B, which results from reduction of one of the heavy-light chain disulfides. Conjugates consisting of E4 were comprised mainly of isomer E4B, which results from the reduction of both heavy-light chain disulfides. The main E6 species detected was isomer E6B, which results from reduction of both heavy-heavy chain disulfides and one heavy-light chain disulfide, while isomers with one heavy-heavy chain disulfide reduced were in the extreme minority. On the other hand, partial DTNB reoxidation yields almost the opposite result for E2 and E4 isomers, with predominantly isomers E2A and E4C, where one heavy-heavy chain disulfide is intact, and the same result for E6. We have observed qualitatively similar preferences of the isomer populations from partial reduction and partial reoxidiation of the humanized anti-Her2 IgG1 Herceptin (data not shown).

Previous investigations of mAb disulfide biochemistry did not demonstrate whether there was selective reduction of particular mAb interchain disulfides, in part because of the inability to fractionate the reduction reaction into subpopulations together with the low resolution of the analytical techniques employed. SDS−PAGE was used extensively (*26*−*28*), but this technique could not resolve and quantify the nine possible isomers present in a mAb reduction reaction. Figure 3 shows that the E4 mixtures prepared by partial DTT reduction and partial DTNB reoxidation are difficult to distinguish, while HIC-purified E4 prepared by these chemistries are readily distinguished. In the past, analytical ultracentrifugation was also used to characterize mAb interchain disulfide reduction using aminoethanethiol under acidic conditions, and these data were used to suggest that exclusively heavy-heavy disulfides can be cleaved under these conditions (*29*−*31*). These data are even lower resolution than SDS−PAGE and cannot provide molecular characterization of the generated species. Our data are in contrast to this report, since partial reduction of cAC10 by aminoethanethiol at pH 5 results in a mixture of E4B and E4C present in nearly a 1:1 ratio (Figure 5), rather than only E4C, which would result from exclusive heavy-heavy disulfide reduction. The analytical technologies used in the previous reports (*29*−*31*) were evidently not sensitive enough to support the conclusions drawn.

The isomeric populations that result from partial DTT reduction demonstrate that IgG1 heavy-heavy disulfide bond cleavage is a cooperative process. Very little of any of the isomers with one heavy-heavy disulfide bond intact are observed, even at very early time points during the reduction (Table 1). The E2 isomer formed in greater than 90% abundance (E2B) has one heavy-light disulfide bond cleaved, while the predominant E4 isomer (E4B) has both of the heavy-light chain disulfides cleaved.

The simulated partial reduction with equal rate constants for heavy-light and heavy-heavy disulfide reduction confirm that the reduction of cAC10 is not a random process. The drug loading distribution and isomer distribution are significantly different between the simulation and experimental data, suggesting that a more complex model with unequal rate constants is much more appropriate in describing the cAC10 reduction process. We are currently performing additional simulations with other models to determine the rate constants that describe cAC10 reduction. These simulations will enable us to determine the relative rate constants of reduction of the heavy-light versus heavy-heavy disulfides, as well as the rate constants of reduction of the first versus the second heavy-light and heavy-heavy disulfides. Simulations may also be able to explain the small observed differences between DTT and TCEP partial reduction, with these two reducing agents potentially having different absolute reducing strengths as well as differences in their rate constants for reduction of individual disulfides.

Inspection of X-ray crystal structures (PDB structures include 1HZH and 1IGT) (*20*, *32*, *33*) show the region around these heavy-heavy disulfides to be highly flexible, and electron density is often absent. These disulfide bonds may be responsible for any local structure, and release of one may open up this region, allowing the second to be more exposed to solvent and reducing agents. The cleavage of these disulfides is not expected to cause large changes in the overall protein structure (*20*).

The partial DTNB reoxidation process preferentially re-forms the heavy-light chain disulfides, as was seen previously for air reoxidation (*26*). The E6 isomer formed in greater than 90% abundance (E6B) has one heavy-light disulfide, and the predominant E4 isomer (E4C) has both heavy-light disulfides. Unlike DTT reduction, reformation of the heavy-heavy disulfides does not appear to be cooperative, in that the predominant E2 isomer has just one heavy-heavy disulfide. Reformation of heavy-heavy disulfides appears to be merely kinetically slower than the heavy-light disulfides. If cleavage of the heavy-heavy disulfides releases the local structure and the previously paired cysteines can move away from each other, the kinetics of heavy-heavy disulfide bond formation will be slow. The heavy-light disulfide is probably not responsible for local structure or relative positioning of the heavy and light chains, and the unpaired cysteines will remain in close proximity and proper orientation for disulfide bond formation.

The chemistries described herein enable the generation of highly site-specific conjugates. For cAC10-vcMMAE, the effect of the location of the drugs on biological activity is modest, with the only significant difference being the MTD values of E4 made by DTNB partial reoxidation being higher than E4 made by DTT partial reduction. It is likely that other biologically interesting molecules such as fluorophores and fluorescence resonance energy transfer reagents may benefit from site-specific conjugation, and this is an area that we are currently investigating. The ability to control the molecular composition in ADCs by chemical means complements recombinant strategies, and allows for the generation of well-defined ADCs with potent biological activities.

Granulocyte macrophage colony-stimulating factor (GM-CSF) stimulates proliferation of hematopoietic cells of the macrophage and granulocyte lineages and is used clinically to treat neutropenia and other myeloid disorders. Because of its short circulating half-life, GM-CSF is administered to patients by daily injection. We describe here the engineering of highly potent, long-acting human GM-CSF proteins through site-specific modification of GM-CSF cysteine analogues with a cysteine-reactive poly(ethylene glycol) (PEG) reagent. Thirteen cysteine analogues of GM-CSF were constructed, primarily in nonhelical regions of the protein believed to lie away from the major receptor binding sites. The GM-CSF cysteine analogues were properly processed but insoluble following secretion into the *Escherichia coli* periplasm. The proteins were refolded and purified by column chromatography. Ten of the cysteine analogues could be modified with a 5-kDa maleimide PEG, and seven of the mono-PEGylated proteins were purified by ion-exchange column chromatography. Biological activities of the 13 cysteine analogues and 7 PEGylated cysteine analogues were comparable to that of wild-type GM-CSF in an in vitro cell proliferation assay using human TF-1 cells. One cysteine analogue was modified with larger 10-, 20-, and 40-kDa PEGs, with only minimal loss of in vitro bioactivity. Pharmacokinetic experiments in rats demonstrated that the PEGylated proteins had up to 47-fold longer circulating half-lives than wild-type GM-CSF. These data demonstrate the utility of site-specific PEGylation for creating highly potent, long-acting GM-CSF analogues and provide further evidence that the nonhelical regions of human GM-CSF examined are largely nonessential for biological activity of the protein.

INTRODUCTION

Granulocyte macrophage colony-stimulating factor (GM-CSF) stimulates the proliferation, differentiation, and functional activation of hematopoietic cells of the macrophage and granulocyte lineages. Recombinant human GM-CSF is used clinically to treat a variety of hematopoietic disorders, including reducing the severity of chemotherapy-induced neutropenia, accelerating hematopoietic recovery following bone marrow transplantation, and mobilizing blood progenitor cells for transplantation (*1*, *2*). Recombinant GM-CSF also has shown promise as a treatment for Crohn's disease and as an adjuvant therapy for melanoma (*3*, *4*). A limitation of current GM-CSF products is the fact that GM-CSF has a short circulating half-life (*1*, *2*) and must be administered to patients by daily injection for optimal effectiveness. Development of longer-acting forms of GM-CSF that require less frequent injections would be of significant benefit to patients and healthcare providers.

One method that has been used to prolong the circulating half-lives of protein therapeutics is to modify the protein with poly(ethylene glycol) (PEG) (*5*−*8*). Attachment of PEG to a protein increases the protein's effective size, thus reducing its clearance rate by the kidney and prolonging its circulating half-life. The most commonly used PEG reagents attach to primary and secondary amines on proteins, generally at lysine residues and/or at the N-terminal amino acid. This approach is not optimal for human GM-CSF because the protein contains six lysine residues in addition to the N-terminal amino acid. Five of these lysine residues are located in regions of the protein implicated in receptor binding (*9*, *10*). Site-directed mutagenesis studies showed that Lys72, Lys74, and Lys85 in Helix C and amino acids adjacent to these residues, Gly75 and Gln86, are required for optimal binding of GM-CSF to its receptor (*9*, *10*). The large number and critical locations of these lysine residues makes GM-CSF a poor target for modification with amine-reactive PEG reagents. Indeed, covalent modification of GM-CSF with an amine-reactive PEG reagent resulted in a heterogeneous mixture of mono- and multi-PEGylated GM-CSF variants that could not be separated from each other or from unmodified GM-CSF by conventional column chromatographic procedures (*11*). Additionally, partial loss of bioactivity was observed for the PEGylated GM-CSF mixture, but the effect was difficult to quantitate due to heterogeneity of the sample and inability to separate PEGylated protein from non PEGylated protein (*11*).

An alternative and potentially more selective method for PEGylating proteins covalently attaches PEG to cysteine residues using cysteine-reactive PEGs. At near-neutral pH, these PEG reagents selectively attach to the thiol groups of "free" cysteine residues, i.e., cysteine residues not involved in disulfide bonds. Most proteins, including GM-CSF, do not contain surface-exposed, free cysteine residues. By use of in vitro mutagenesis, it is

possible to introduce a non-native, free cysteine residue into a protein. The non-native cysteine residue can serve as the site for targeted modification of the protein with a cysteine-reactive PEG reagent, thus preserving biological activity of the modified protein (*12*). In this report, we describe the application of this technology to the rational design of highly potent, long acting human GM-CSF analogues.

EXPERIMENTAL PROCEDURES

Cloning of GM-CSF and Construction of GM-CSF Cysteine Analogues. A cDNA encoding human GM-CSF was cloned by the reverse transcriptase−polymerase chain reaction (PCR) method (*13*), using total RNA isolated from the human bladder carcinoma cell line 5637 (obtained from the American Type Culture Collection, Rockville, MD). The leader sequence of the *E. coli* heat-stable enterotoxin (STII) gene (*14*), preceded by an *Nde* I restriction site, was fused to the amino-terminal coding sequence of mature GM-CSF using PCR. At the same time, several changes in the GM-CSF gene were made to optimize the protein for expression in *E. coli*. A TAA stop codon, followed by an *Eco* RI restriction site, was added following the carboxy-terminal residue, E127, codons for prolines at positions 2, 6, 8, 12, 117, and 124 were all changed to CCG, and the codon for leucine at position 114 was changed to CTG. The STII-GM-CSF gene was cloned as a *Nde* I−*Eco* RI fragment into pUC18 (Sigma-Aldrich, Inc., St. Louis, MO), to create pBBT268, and its DNA sequence confirmed. The *Nde* I−*Eco* RI fragment of pBBT268 was subcloned subsequently into plasmid pBBT257, creating pBBT271. Plasmid pBBT257 was derived from the expression vector pCYB1 (New England BioLabs, Beverly, MA) by deleting the ampicillin-resistant gene of pCYB1 and replacing it with the gene for tetracycline resistance derived from plasmid pBR322 (*15*). In both pBBT257 and pCYB1, expression of the cloned gene is under the control of the *tac* promoter. Thirteen mutant GM-CSF genes were constructed by site-directed PCR-based mutagenesis (*16*, *17*) using pBBT268 as the DNA template. PCR products were digested with appropriate restriction endonucleases and cloned into pBBT268 vector DNA. Correct DNA sequences of all mutants were confirmed.

Expression and Purification of Wild-Type GM-CSF and GM-CSF Cysteine Analogues. Plasmids encoding wild-type GM-CSF and GM-CSF cysteine analogues were transformed into *E. coli* strain W3110. An overnight culture of each strain was inoculated at an optical density at 600 nm of ~0.05 in 400 mL of Luria Broth media containing 10 μg/mL tetracycline. When the culture reached an optical density of ~0.6, isopropyl-β-D-thiogalactopyranoside (IPTG) was added to a final concentration of 0.5 mM, and the induced culture was incubated overnight for about 16 h. The cells were pelleted by centrifugation and stored at −80 °C. The cell pellet was thawed and treated with 5 mL of bacterial protein extraction reagent (B-PER, Pierce Chemical Company, Rockford, IL) according to the manufacturer's protocols. Insoluble material was recovered by centrifugation and resuspended in B-PER. This mixture was treated with lysozyme (200 μg/mL) for 10 min to further disrupt the cell walls, and $MgCl_2$ (10 mM final concentration) and protease-free DNAse (2 μg/mL) were added. Insoluble GM-CSF was collected by centrifugation, resuspended in water, and recentrifuged. The insoluble pellet was dissolved in 10 mL of 8 M urea, 25 mM cysteine, and 20 mM Tris Base, stirred for 30 min at room temperature, and diluted into 100 mL of 20 mM Tris, 40 μM copper sulfate, 15% glycerol, pH 8.0. The refold mixture was held at 4 °C for 2 days, centrifuged, and loaded onto a 5-mL Q-Sepharose HiTrap column (Amersham Biosciences Corporation, Piscataway, NJ) equilibrated in 20 mM Tris, pH 8.0 (Buffer A). The bound proteins were eluted with a linear salt gradient from 0 to 35% Buffer B (1 M NaCl, 20 mM Tris, pH 8). Column fractions were analyzed by nonreducing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and fractions containing primarily GM-CSF were pooled. The Q-Sepharose pool was diluted with an equal volume of 30% ammonium sulfate and loaded onto a 1-mL Phenyl HP HiTrap column (Amersham Biosciences Corporation) previously equilibrated with 15% ammonium sulfate in 20 mM sodium phosphate, pH 7.5. GM-CSF was recovered from the column by elution with a reverse salt gradient (15% ammonium sulfate to 0% ammonium sulfate in 20 mM sodium phosphate, pH 7.5). Column fractions were analyzed by nonreducing SDS-PAGE and fractions containing GM-CSF, and no detectable contaminants were pooled.

PEGylation of GM-CSF Cysteine Analogues. Aliquots of 200−300 μg of the purified GM-CSF cysteine analogues were incubated with a 15-fold molar excess of Tris[2-carboxyethylphosphine]hydrochloride (TCEP, Pierce Chemical Company) and a 20-fold molar excess of a linear 5 kDa-maleimide-PEG (Nektar, Inc., Huntsville, AL). After 1.5 h at room temperature, the PEGylation mixture was diluted 20× with ice cold 20 mM Tris, pH 8.0, and loaded onto a 1-mL Q-Sepharose HiTrap column (Amersham Biosciences Corporation) equilibrated in 20 mM Tris, pH 8.0. Bound proteins were eluted as described above. Column fractions were analyzed by nonreducing SDS-PAGE, and fractions containing predominantly the mono-PEGylated GM-CSF cysteine analogue were pooled and stored at −80 °C. This procedure was scaled up to prepare the A3C analogue modified with linear 10- and 20-kDa maleimide PEGs and a branched 40-kDa maleimide PEG (Nektar, Inc.).

Biochemical Methods. N-Terminal protein sequencing was performed by Macromolecular Resources (Colorado State University, Fort Collins, CO) using an Edman degradation procedure. Protein samples were analyzed by SDS-PAGE on precast Tris−glycine polyacrylamide gels (Invitrogen Corporation, Carlsbad, CA) and stained with Coomassie Blue. 2-Mercaptoethanol was added to a final concentration of 1−5% (V/V) in sample buffer to reduce the proteins. Protein concentrations were determined using a Bradford protein assay kit (Bio-Rad Laboratories, Richmond, CA) using bovine serum albumin as the protein standard. Endotoxin levels of the proteins were measured using a chromogenic Limulus Amebocyte Lysate kit (QCL-1000, BioWhittaker, Walkersville, MD). Western blots were performed using standard methods. The primary antibody was polyclonal goat antihuman GM-CSF antisera (R&D Systems, Inc., Minneapolis, MN), and the secondary antibody was alkaline phosphatase-conjugated rabbit antigoat immunoglobulin antisera (Pierce Chemical Company). Western blots were developed using a NBT/BCIP staining kit (Promega Corporation, Madison, WI).

In Vitro Bioactivity Assays. The human TF-1 cell line was obtained from the American Type Culture Collection. The cells were maintained in RPMI 1640 media supplemented with 10% FBS, 50 units/mL penicillin, 50 μg/mL streptomycin, and 2 ng/mL recombinant human GM-CSF (*E. coli* derived; R&D Systems). For bioassays, the TF-1 cells were washed and resuspended at a concentration of 1×10^5/ml in RPMI 1640 media

containing 10% FBS, 50 units/mL penicillin, and 50 μg/mL streptomycin (assay media). Fifty microliters (5×10^3 cells) of the cell suspension was aliquotted per test well of a flat-bottom 96-well tissue culture plate. Serial dilutions of the protein samples to be tested were prepared in assay media. Serial dilutions of a commercial recombinant human GM-CSF standard (*E. coli* expressed; R&D Systems) were analyzed in parallel. Fifty microliters of the diluted protein samples were added to the test wells and the plates incubated at 37 °C in a humidified 5% CO_2 tissue culture incubator. Protein samples were assayed in triplicate wells. After 3 days, 20 μL of CellTiter 96 AQueous One Solution (Promega Corporation) was added to each well and the plates incubated at 37 °C in the tissue culture incubator for 1−4 h. Absorbance of the wells was read at 490 nm using a microplate reader.

Pharmacokinetic Experiments. Animal experiments were performed with the approval of BolderPATH's Institutional Animal Care and Use Committee. Groups of three male Sprague Dawley rats (Harlan Sprague Dawley, Inc., Indianapolis, IN), weighing 340−370 g each, received a single intravenous injection (lateral tail vein) of Leukine (sargramostim, a recombinant yeast-derived human GM-CSF containing a R23L amino acid substitution, Schering AG), wild-type *E. coli* expressed GM-CSF prepared by us, or the GM-CSF A3C cysteine analogue modified with 10-, 20-, or 40-kDa maleimide PEG, each at a dose of 100 μg protein/kg. At selected time points, blood samples (0.4 mL) were drawn from the rats into EDTA anticoagulant tubes. The blood samples were centrifuged and the plasma samples stored at −80 °C. Blood samples were drawn at 0.25, 1, 2, 4, 10, 24, 48, 72, 96, and 120 h after injection. A predose sample was drawn 1 day prior to injection of the test compounds. Plasma levels of the test proteins were quantitated using human GM-CSF enzyme-linked immunosorbent assay (ELISA) kits (R & D Systems, Inc.). Serial dilutions of plasma samples from one animal in each test group were analyzed in the in vitro bioassay to identify dilutions that fell within the linear range of the ELISA (7.8 to 500 pg/mL). Duplicate samples of appropriate dilutions of plasma samples from all rats were then analyzed in the ELISA. A subcutaneous pharmacokinetic experiment was performed in the same manner except that the protein samples were injected subcutaneously into the lateral sides of the rats. Blood samples were drawn at 0.16, 0.5, 1, 2, 4, 10, 24, 48, 72, 96, and 120 h after injection. Pharmacokinetic parameters were analyzed using the WinNonlin software package (Pharsight, Inc., MountainView, CA).

RESULTS

Expression of GM-CSF in *E. coli* Using the STII Signal Sequence. Human GM-CSF was engineered to be secreted to the *E. coli* periplasm by fusing the mature coding region of GM-CSF to the *E. coli* enterotoxin STII signal sequence. The protein was cloned under control of the *tac* promoter and expression of the protein induced by addition of IPTG to the cultures. SDS-PAGE analysis of the overnight induced cultures showed expression of a new 14-kDa protein, which is consistent with the mass of mature GM-CSF. These data suggested that the STII leader peptide had been removed, which was confirmed by the N-terminal sequencing studies presented below. Although GM-CSF appeared to be properly processed and secreted, the recombinant protein was largely insoluble. The insoluble protein was refolded using the procedure described in Experimental Procedures and purified from the refold mixture by Q-Sepharose and Phenyl-Sepharose column chromatography. N-Terminal sequencing of purified GM-CSF yielded the sequence APARSPS, which matches the first seven amino acids of mature human GM-CSF (*18*, *19*), and indicates that the N-terminus is correctly processed. Purified GM-CSF comigrated with an *E. coli* expressed human GM-CSF standard under reducing and nonreducing conditions (Figure 1). Western blots were used for this analysis because the commercial GM-CSF standard is formulated with a protein carrier. Both recombinant GM-CSF proteins exhibited a mobility shift to a higher apparent molecular weight under reducing conditions, presumably due to reduction of the two native intramolecular disulfide bonds, C54−C96 and C88−C121 (*20*). Bioactivities of the proteins were compared in an in vitro cell proliferation assay using human TF-1 cells. Our purified GM-CSF and the GM-CSF standard stimulated proliferation of human TF-1 cells to the same extent and had similar mean EC_{50} values of 105 and 97 pg/mL, respectively (Table 1).

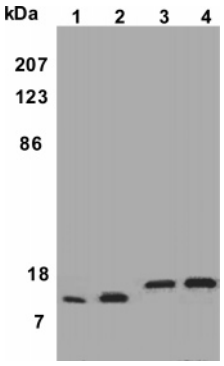

Figure 1. SDS-PAGE analysis of purified wild-type GM-CSF. Western blot of a wild-type GM-CSF standard (lanes 1 and 3; R & D Systems, Inc.) and our purified wild-type GM-CSF (lanes 2 and 4) following nonreducing (lanes 1 and 2) and reducing (lanes 3 and 4) SDS-PAGE. Positions of molecular weight standards are shown to the left.

Expression and In Vitro Bioactivities of GM-CSF Cysteine Analogues. Human GM-CSF has a compact globular structure, comprising four α-helices joined by loops (*10*, *20*, *21*). The four α-helices are termed A−D beginning from the N-terminus of the protein. The loop regions are referred to by the helices they join, e.g., the A−B loop joins helices A and B. We constructed 13 GM-CSF cysteine analogues, primarily in the nonhelical

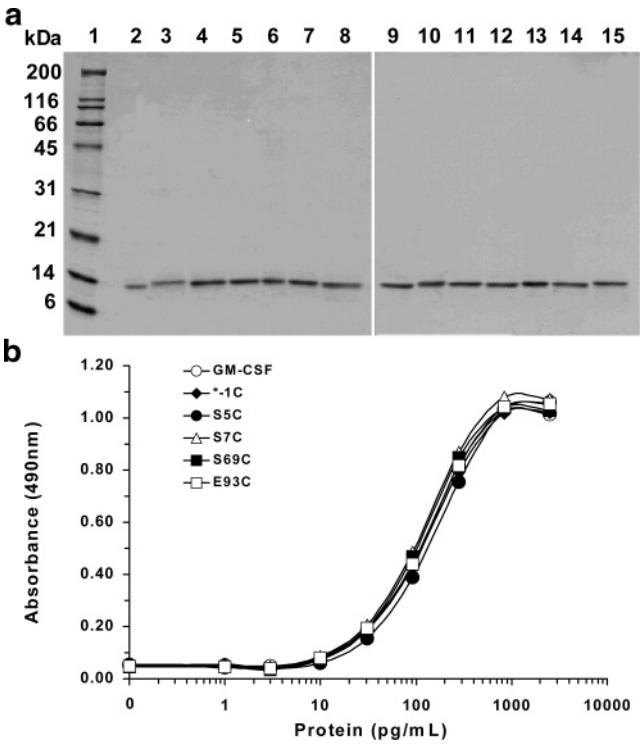

Figure 2. SDS-PAGE analysis and in vitro bioactivities of purified wild-type GM-CSF and GM-CSF cysteine analogues. Panel A shows nonreducing SDS-PAGE analysis of column pools of the purified GM-CSF cysteine analogues. Lane 1, molecular weight standards; Lane 2, wild-type GM-CSF; Lane 3, *−1C; Lane 4, A1C; Lane 5, A3C; Lane 6, S5C, Lane 7, S7C; Lane 8, N27C; Lane 9, S69C; Lane 10, E93C; Lane 11, T94C; Lane 12, T102C; Lane 13, V125C; Lane 14, Q126C; Lane 15, *128C. Proteins were stained with Coomassie Blue. Panel B shows dose−response curves for our wild-type GM-CSF and representative GM-CSF cysteine analogues for stimulating proliferation of TF-1 cells. Data are means of triplicate wells ± standard deviations (SD) from representative experiments. SDs were generally less than 5% of the means.

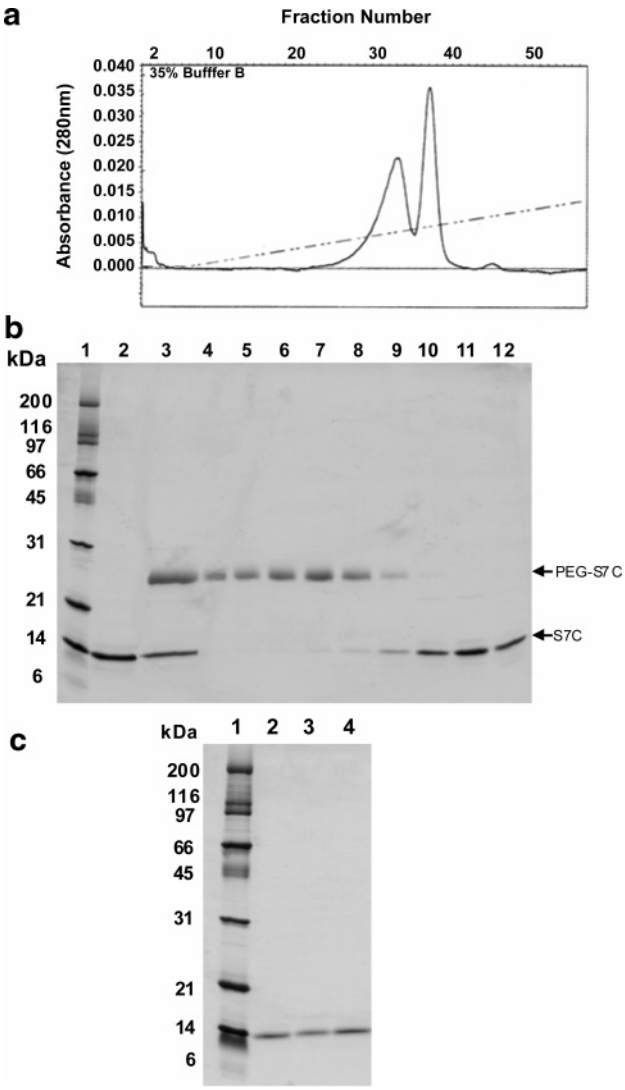

Figure 3. Purification of the PEGylated GM-CSF S7C protein and inability of wild-type GM-CSF to react with maleimide-PEG. Panel A shows Q-Sepharose column chromatography of the S7C PEGylation reaction products. Panel B shows nonreducing SDS-PAGE analysis of the Q-sepharose column fractions. Lane 1, molecular weight standards; Lane 2, S7C; Lane 3, S7C PEGylation reaction products; Lanes 4−12 represent Q-Sepharose column fractions 30−38. Fractions 30−34 (Lanes 4−8) contain predominantly PEGylated S7C. Fractions 36−38 (Lanes 10−12) contain unreacted S7C. Panel C is nonreducing SDS-PAGE analysis of wild-type GM-CSF PEGylation reaction products. Lane 1, molecular weight standards; Lane 2, wild-type GM-CSF; Lane 3, GM-CSF + 5-kDa maleimide−PEG; Lane 4, GM-CSF + 5-kDa maleimide−PEG + TCEP.

regions of the protein, which lie away from the identified receptor binding domains. Five cysteine analogues were constructed in the amino terminal region preceding helix A [*−1C (the addition of a cysteine residue preceding the natural amino terminus), A1C, A3C, S5C, and S7C]; one cysteine analogue was constructed in the B−C loop [S69C]; three cysteine analogues were constructed in the C−D loop [E93C, T94C, and T102C]; and three cysteine analogues were constructed in the carboxy-terminal region following helix D [V125C, Q126C, and *128C (the addition of a cysteine residue to the natural carboxy-terminus)]. We also constructed one cysteine analogue at an N-linked glycosylation site (N27C), which is the last amino acid in helix A. The GM-CSF cysteine analogues were expressed in *E. coli* using the STII signal sequence. Expression studies indicated that the cysteine analogues appeared to be correctly processed but largely insoluble. The cysteine analogues were refolded and purified using the protocols described for wild-type GM-CSF. Recoveries of the purified GM-CSF cysteine analogues ranged from 0.4 to 2.2 mg/400 mL of culture compared to 2.6 mg/400 mL of culture for wild-type GM-CSF. The cysteine analogues were recovered predominantly as monomers that comigrated with wild-type GM-CSF under reducing and nonreducing SDS-PAGE conditions. Nonreducing SDS-PAGE analysis of the 13 purified cysteine analogues is shown in Figure 2A. Mean EC_{50} values of the 13 cysteine analogues ranged from 80 to 134 pg/mL in the TF-1 cell proliferation assay and were similar to the EC_{50} of wild-type GM-CSF (Table 1). Dose−response curves for representative cysteine analogues are shown in Figure 2B.

Preparation and In Vitro Characterization of PEGylated GM-CSF Cysteine Analogues. The 13 purified GM-CSF cysteine analogues were reacted with a 5-kDa maleimide PEG under partial reducing conditions, as described in Experimental Procedures. These conditions yielded significant amounts of mono-PEGylated protein for 10 of the cysteine analogues. No di- or tri-PEGylated proteins were detected for any of the cysteine analogues. PEGylated GM-CSF cysteine analogues were purified from non-PEGylated protein by Q-Sepharose column chromatography (Figure 3A). Figure 3B, lane 3, shows nonreducing SDS-PAGE analysis of the PEGylation reaction for a representative cysteine ana-

Table 2. PEGylation Efficiencies and In Vitro Bioactivities of PEGylated GM-CSF Cysteine Analogues

GM-CSF analog	PEG size	PEGylation efficiency (%)[a]	EC_{50} (pg/mL)[b]
*−1C	5 kDa	45, 55	96 ± 5
A1C	5 kDa	55	115 ± 4
A3C	5 kDa	62	106 ± 3
A3C	10 kDa	70	78 ± 3
A3C	20 kDa	75	113 ± 5
A3C	40 kDa	70, 70	300 ± 50
S5C	5 kDa	76	80 ± 11
S7C	5 kDa	50, 70, 89	123 ± 15
S69C	5 kDa	71	88 ± 6
E93C	5 kDa	62	86 ± 5

[a] Percent PEGylated protein estimated by anion-exchange column chromatography of PEGylation reactions. Numbers represent results from individual PEGylation reactions. [b] Mean ± SD of at least 4 assays for each protein in the TF-1 cell proliferation assay.

logue, S7C. The only visible PEGylated species is the PEG-S7C monomer, which migrates with an apparent molecular mass of 26 kDa. Fractionation of the S7C PEGylation reaction mixture by Q-Sepharose column chromatography yielded two major peaks. SDS-PAGE analysis of the column fractions indicated that the early eluting peak was mono-PEGylated S7C, and the later eluting peak was unmodified S7C protein (Figure 3B). Fractions enriched for the mono-PEGylated S7C protein were pooled. The other GM-CSF cysteine analogues were PEGylated and purified by the same protocol. PEGylation efficiencies for the cysteine analogues were estimated from the peak areas of the Q-Sepharose column chromatograms and ranged from 11 (T102C) to 89% (S7C), with most analogues being in the 40−70% range (Table 2). No PEGylated products were observed for the three cysteine analogues near the C-terminus of the protein, V125C, Q126C, or *128C using these conditions. Wild-type GM-CSF did not PEGylate under the conditions used to PEGylate the cysteine analogues (Figure 3C), which strongly suggests that the site of PEGylation in the cysteine analogues is the newly introduced cysteine residue and not one of the four native cysteine residues.

Nonreducing SDS-PAGE analysis of the 10 purified PEGylated cysteine analogues is shown in Figure 4A. The PEGylated proteins displayed similar apparent molecular masses (26 kDa) by nonreducing SDS-PAGE, except for the PEG-E93C and PEG-T94C analogues, which displayed slightly smaller apparent molecular masses. The reason for this difference is unknown, although it may be significant that these analogues are adjacent residues in the C−D loop. Sufficient quantities of seven cysteine analogues (*−1C, A1C, A3C, S5C, S7C, S69C, and E93C) modified with a 5-kDa PEG were purified for accurate protein concentration and bioactivity measurements. Mean EC_{50} values for the PEG−GM−CSF cysteine analogues ranged from 80 to 123 pg/mL in the TF-1 cell proliferation assay and were similar to the EC_{50} of wild-type GM-CSF (Table 2). Dose−response curves for representative PEGylated GM-CSF cysteine analogues are shown in Figure 4.

The A3C protein was PEGylated with larger 10- and 20-kDa maleimide PEGs and a 40-kDa branched maleimide PEG and the PEGylated proteins purified by Q-Sepharose column chromatography as described above. SDS-PAGE analysis of the purified PEG-A3C proteins is shown in Figure 5A. Bioactivity experiments yielded mean EC_{50} values of 78, 113, and 300 pg/mL for the 10-, 20-, and 40-kDa PEG−A3C proteins in the TF-1 cell proliferation assay (Figure 5B and Table 2).

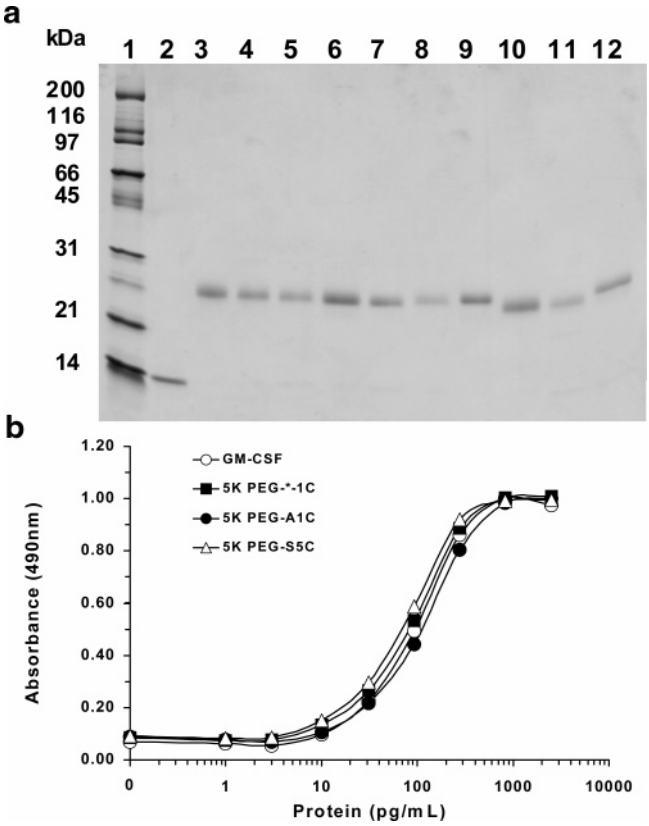

Figure 4. SDS-PAGE analysis and in vitro bioactivities of purified 5-kDa maleimide PEG−GM-CSF cysteine analogues. Panel A shows nonreducing SDS-PAGE analysis of column pools of purified PEG−GM-CSF cysteine analogues. Lane 1, molecular weight standards; Lane 2, wild-type GM-CSF; Lane 3, 5-kDa PEG−*-1C; Lane 4, 5-kDa PEG−A1C; Lane 5, 5-kDa PEG−A3C; Lane 6, 5 -kDa PEG−S5C; Lane 7, 5-kDa PEG−S7C; Lane 8, 5-kDa PEG−N27C; Lane 9, 5-kDa PEG−S69C; Lane 10, 5-kDa PEG−E93C; Lane 11, 5-kDa PEG−T94C; Lane 12, 5-kDa PEG−T102C. Proteins were stained with Coomassie Blue. Panel B shows dose−response curves for 5-kDA PEG−GM-CSF cysteine analogues and our wild-type GM-CSF for stimulating proliferation of TF-1 cells. Data are means of triplicate wells ± SD from representative experiments. SDs were generally less than 5% of the means.

Pharmacokinetic Experiments With PEGylated A3C Proteins. Circulating half-lives of the A3C protein modified with 10- and 20-kDa PEGs were determined by ELISA following intravenous administration to rats (Figure 6A). A commercial yeast-derived GM-CSF analogue (Leukine) and our *E. coli* derived wild-type GM-CSF were analyzed in parallel. Blood levels of the proteins were measured from 0.25 to 120 h after injection. Both Leukine and wild-type GM-CSF cleared rapidly from the rats and were undetectable 24 h after injection. Terminal half-lives for Leukine and wild-type GM-CSF were 0.9 and 1 h, respectively. In contrast, the PEGylated A3C proteins possessed significantly longer circulating half-lives. Both the initial distribution phase and the terminal half-life phase were longer for the PEGylated A3C proteins than for the wild-type GM-CSF proteins. Terminal half-lives for 10- and 20-kDa PEG−A3C proteins were 19 and 22 h, respectively. In a separate experiment, the terminal half-life of the 40-kDa PEG−A3C was determined to be 37 h following intravenous administration to rats (data not shown).

Half-lives of Leukine and the 10-, 20-, and 40-kDa PEG−A3C proteins also were determined following subcutaneous administration to rats. Blood levels of the proteins were measured from 0.16 to 120 h after injection

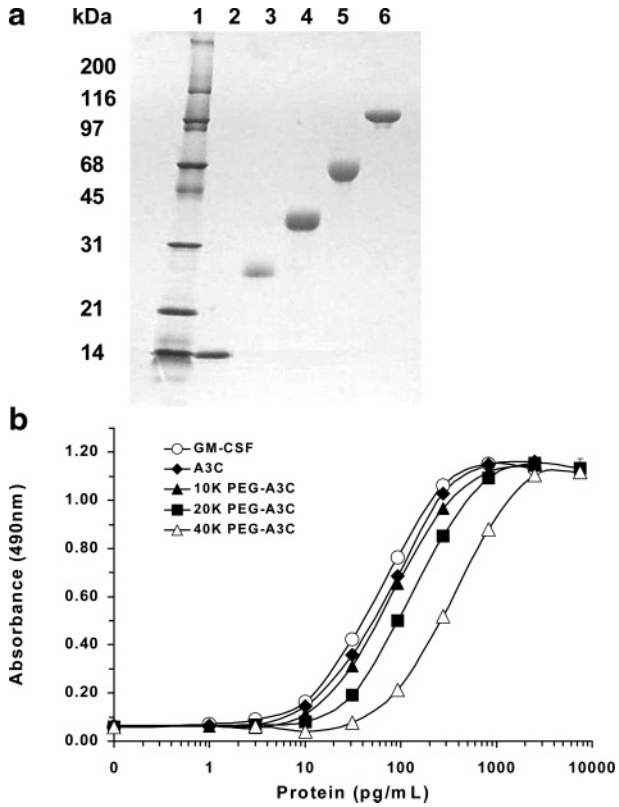

Figure 5. SDS-PAGE analysis and in vitro bioactivities of the GM-CSF A3C protein modified with different-sized PEGs. Panel A shows nonreducing SDS-PAGE analysis of the purified proteins. Lane 1, molecular weight standards; Lane 2, wild-type GM-CSF; Lanes 3−6 are column pools of the A3C protein modified with 5-, 10-, 20-, and 40-kDa maleimide−PEGs, respectively. Panel B shows dose−response curves for the 10-, 20-, and 40-kDa PEG−A3C proteins for stimulating proliferation of TF-1 cells. SDs were generally less than 5% of the means.

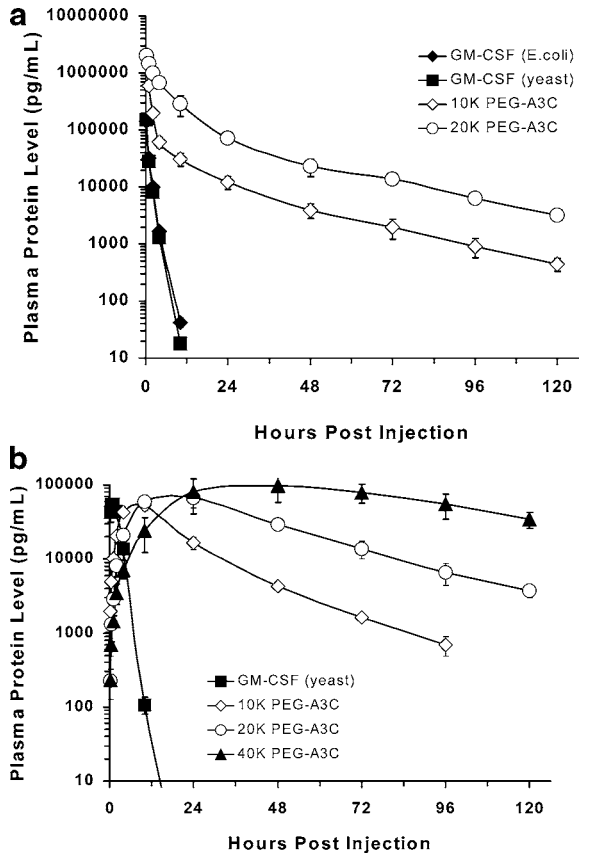

Figure 6. Circulating plasma levels of Leukine, *E. coli* derived wild-type GM-CSF and the GM-CSF−A3C protein modified with different-sized PEGs following (A) intravenous or (B) subcutaneous administration in rats. Data are means ± SD for three rats per group and were measured using human GM-CSF ELISAs. SDs were generally less than 25% of the means. The 120-h time point samples for the 10-kDa PEG−A3C protein in the subcutaneous study shown in (B) were lost and could not be analyzed.

and are shown in Figure 6B. Leukine reached maximum blood levels between 30 and 60 min after injection and decreased by greater than 10 000-fold to undetectable levels by 24 h after injection. The terminal half-life was 1 h. In contrast, blood levels of the 10-, 20-, and 40-kDa PEG−A3C proteins reached maximum levels at 10, 24, and 48 h after injection, respectively, indicating that the PEGylated proteins are absorbed more slowly than Leukine from the injection site. Terminal half-lives for the proteins were 14 h (10-kDa PEG−A3C), 23 h (20-kDa PEG−A3C), and 47 h (40-kDa PEG−A3C).

DISCUSSION

We found that wild-type human GM-CSF and human GM-CSF cysteine analogues can be secreted efficiently into the *E. coli* periplasm using the *E. coli* STII signal sequence. Although the STII signal sequence is correctly processed, the secreted proteins are insoluble and must be refolded into a biologically active form. Refolded GM-CSF comigrates with intracellular expressed *E. coli* GM-CSF and has a comparable specific activity in an in vitro cell proliferation assay using human TF-1 cells. Similar results were obtained using the bacterial ompA signal sequence to secrete human GM-CSF into the *E. coli* periplasm (*22*, *23*).

To identify sites in GM-CSF where a cysteine residue can be introduced and PEGylated without significantly affecting biological activity of the protein, we constructed a series of cysteine analogues in regions of the protein believed to lie away from the major receptor binding sites, which have been localized to helices A, C, and D (*9*, *10*, *24*−*27*). The 13 GM-CSF cysteine analogues analyzed possessed in vitro biological activities comparable to wild-type GM-CSF. The large number of highly active GM-CSF cysteine analogues identified was somewhat unexpected but probably biased by our choice of mutation sites. These data provide support for the notion that the regions of GM-CSF chosen for mutagenesis (the region preceding helix A, the B−C loop, the C−D loop, the region following helix D, and the N27 glycosylation site at the C-terminal end of helix A) are largely nonessential for proper in vitro biological activity of GM-CSF. The nonessential nature of these regions was explored further by attaching a large polymer, PEG, to the proteins at the cysteine residues introduced into these regions. All of the cysteine analogues, except those analogues located near the C-terminus of the protein, reacted with a maleimide PEG using our standard reaction conditions, yielding monoPEGylated proteins. Seven of the mono-PEGylated proteins were purified and their in vitro biological activities found to be similar to that of wild-type GM-CSF. These data strongly suggest that the amino acids analyzed (*−1, A1, A3, S5, S7, S69, and E93) and the regions in which they are located (the region preceding helix A, the B−C loop, and the C−D loop) are largely nonessential for *in vitro* biological activity of GM-CSF. Most of the in vitro bioactivity measurements for the GM-CSF cysteine analogues and PEGylated GM-CSF cysteine analogues were obtained from single preparations of the proteins. It remains to be determined

whether the minor differences observed in in vitro bioactivities of the proteins are due to intrinsic differences in bioactivities of the proteins or to other variables associated with purification, PEGylation, and quantitation of the proteins.

The three cysteine analogues introduced near the C-terminus of the protein, V125C, Q126C, or *128C, did not PEGylate using our standard PEGylation conditions. On the basis of the published structure of GM-CSF (*20*, *21*), these residues appear to be surface exposed and should be accessible to react with the PEG reagents. The C-terminal region of GM-CSF contains a short loop held together by a disulfide bond between residues C88 and C121 (*20*). It is possible that this disulfide loop, or another feature of this region, alters the local structure of the C-terminal region in a way that makes these residues unreactive with the PEG reagent. Other reaction conditions or use of other types of cysteine-reactive PEG reagents may permit modification of these residues. Studies with human growth hormone revealed that only selected surface-exposed lysine residues are modified by amine-reactive PEG reagents (*28*). These data, and those described here, indicate that surface accessibility is only one factor determining whether a particular amino acid residue will react with a PEG reagent.

With the A3C analogue, we explored the effect of different-sized PEGs on in vitro biological activity and circulating half-life of the protein. We found that modification of the A3C protein with linear 5-, 10-, and 20-kDa PEG reagents did not substantially affect in vitro biological activity of the protein, as measured by EC_{50} values in the TF-1 cell proliferation assay. Only when the protein was modified with a large, 40-kDa branched maleimide PEG did we detect an obvious decrease in in vitro bioactivity, but even this decrease was moderate (3-fold). Although this result is based upon a single preparation of the 40-kDA PEG−A3C protein, it is consistent with results by us (*29* and unpublished results) and others (*8*) showing greater loss of in in vitro bioactivity when proteins are modified with 40-kDa branched PEGs than with smaller, linear PEGs. Pharmacokinetic experiments demonstrated that the PEGylated GM-CSF (A3C) proteins have up to 47-fold longer circulating half-lives than unmodified GM-CSF proteins in rats. Circulating half-lives of the proteins correlated with the size of the PEG molecule, similar to what has been reported for other PEGylated proteins (*6*). Human GM-CSF is inactive in rodents due to a failure to bind rodent GM-CSF receptors (*19*). Since receptor-mediated endocytosis is one mechanism for promoting in vivo clearance of hematopoietic factors (*30*), the pharmacokinetic parameters obtained for the PEG-A3C protein in rats probably reflect primarily clearance of the protein by kidney filtration. The failure of human GM-CSF to function in rodents precluded us from measuring biological activities of the PEG-A3C proteins in these experiments. In studies to be reported elsewhere, we find that a site-specific PEGylated mouse GM-CSF homologue of human GM-CSF (A3C) is much more potent than mouse GM-CSF at stimulating granulopoiesis in rats (Lee, Rosendahl, Hughes, Cox, and Doherty, manuscript in preparation). Other researchers reported that a PEGylated murine GM-CSF protein was more effective than unPEGylated murine GM-CSF at expanding and stimulating differentiation of dendritic cells in mice (*31*, *32*).

The PEG−GM-CSF cysteine analogues described here have significantly different structural and biological properties than previously described nonspecific, amine-PEGylated GM-CSF proteins (*11*, *33*). Amine-PEGylated GM-CSF comprises a heterogeneous mixture of different molecular weight PEG−GM-CSF species modified at multiple amine groups and containing different numbers of PEG molecules. The various amine-PEGylated GM-CSF species could not be purified from each other or from nonPEGylated GM-CSF by conventional chromatography procedures, which prevented specific activity measurements of the various isoforms from being determined. An amine-PEGylated murine GM-CSF protein in which PEG is preferentially attached to the N-terminus of the protein has been described (*31*, *32*), but in vitro bioactivity and physical properties of the protein have not been reported. By contrast, each of the PEG−GM-CSF cysteine analogues described here is homogeneously modified at a single unique residue and can be readily purified from nonPEGylated GM-CSF by ion-exchange chromatography and possesses a specific activity in in vitro bioassays similar to wild-type GM-CSF. The high potency and long circulating half-lives of these site-specific PEGylated GM-CSF analogues warrant further investigation of their potential utility as human therapeutics.

ACKNOWLEDGMENT

Glycomimetics as Decorating Motifs for Oligonucleotides: Solid-Phase Synthesis, Stability, and Hybridization Properties of Carbopeptoid–Oligonucleotide Conjugates

Jennifer D'Onofrio, Marcella de Champdoré, Lorenzo De Napoli, Daniela Montesarchio,* and Giovanni Di Fabio

Dipartimento di Chimica Organica e Biochimica, Università degli Studi di Napoli "Federico II", Complesso Universitario di Monte S. Angelo, via Cynthia, 4, I-80126 Napoli, Italy. Received June 6, 2005

The online solid-phase synthesis of oligonucleotides conjugated at the 3′ end with [1–6]-linked oligosaccharide mimics having the O-glycosidic linkages replaced by amide bonds is here described. The assembly of the carbohydrate domain has been carried out by exploiting classical solid phase peptide synthetic protocols, starting from solid supports functionalized with 1-azido sugars, in association with suitably protected 1-azido uronic acids of glucose and lactose, chosen as model addition monomers. After the insertion of a flexible linker, elongation of the oligodeoxyribonucleotide (ODN) chain was performed by standard automated phosphoramidite protocols. 3′-Glycoconjugated 18-mers exhibited an increased enzymatic stability with respect to the same unmodified ODN sequence. UV thermal denaturation experiments showed that the presence of the oligosaccharide tail at the 3′ end of the oligonucleotides did not negatively interfere with their duplex formation abilities.

INTRODUCTION

The development of efficient therapeutic agents based on oligonucleotide molecules has been largely hampered by their reduced bioavailability, mainly due to the characteristic polyanionic nature. Poor intracellular delivery, limited access to the specific target, and low resistance to nucleases are the major obstacles to the in vivo efficacy of synthetic, nonmodified oligodeoxyribonucleotides (ODNs) and therefore to their use as gene expression regulators in antisense (*1*), antigene (*2*), or aptamer (*3*) strategies. The low biostability in cells has emerged as the most relevant limit to in vivo applications of synthetic ODNs containing only 3′–5′ phosphodiester linkages. Many research efforts have been devoted, in the past decade, to overcome these drawbacks (*4*–*7*). Oligonucleotide analogues having the 3′ end masked with protecting residues generally show a consistently increased in vivo half life, not being recognized by 3′ exonucleases, by far the most abundant nucleases in cells. Therefore 3′ conjugation with suitable appendages, imparting specific, desirable physicochemical properties, is usually considered as a necessary prerequisite for ODNs to exert their functions within the cell. In addition to conferring enhanced enzymatic resistance, an ideal conjugating molecule should be designed to improve the cellular uptake and avoid endosomal accumulation of ODNs. In this frame, oligosaccharides offer several advantages. First of all, their fundamental role in cell-to-cell communication is largely accepted, as well as their recognition properties by specific surface membrane receptors (lectins) (*8*–*11*). Second, it is possible to largely modulate their properties, by a priori determining composition, length, and stereochemistry of these biopolymers. An enormous progress has been recently made in oligosaccharide synthesis, so that efficient protocols, even in the solid phase, are available to synthesize tailored oligosaccharidic structures, by sequentially adding the chosen scaffolds under strict regio- and stereocontrol (*12*–*15*). Still, further optimization of the existing chemistry is needed before the construction of any saccharidic skeleton reaches the same reliability and efficiency currently achieved in the solid-phase synthesis of peptides and oligonucleotides, so that a complete automation of the synthetic process can be accomplished. The picture is more complicated if the target molecules are oligosaccharide–oligonucleotide hybrids (*16*). In fact, in addition to the intrinsic difficulties in generating the desired *O*-glycosidic linkages in the carbohydrate domain, the still unsolved, nontrivial problems related to the compatibility between the two chemistries do not allow a general and simple online synthesis. For example, in an online synthetic protocol involving first the assembly of the oligonucleotide chain, the successive glycosidation procedure for the direct insertion of saccharide monomers at the 5′-OH end of the ODN can cause non-negligible depurination, thus leading to failure sequences (*17*).

Because of the flourishing interest in glycobiology, glycomimetics have emerged as a field in rapid evolution (*18*, *19*). In fact, by selecting suitable mimics, a wide number of more stable and easy-to-handle oligosaccharidic surrogates can be efficiently prepared. In principle, many synthetic problems can thus be escaped while still maintaining the carbohydrate scaffolds, putatively responsible for the biological activity, in the required presentation of the crucial stereocenters.

In our ongoing studies on the solid-phase synthesis of modified and/or conjugated oligonucleotides, we recently reported a straightforward protocol for the preparation of ODNs conjugated with oligosaccharide mimics having phosphodiester bonds as the interglycosidic linkages (*20*, *21*). Particularly, glucose–phosphate or sucrose–phosphate moieties, chosen as model compounds, have been inserted at both ends of oligonucleotides. This strategy is based on the usage of ad hoc functionalized solid

supports and appropriate phosphoramidite derivatives of the mono- or disaccharide compound, which can be incorporated in the growing chain at the last step of automated oligonucleotide syntheses. Thus it is possible to exploit efficient and high fidelity reactions, based on standard phosphoramidite chemistry, to generate chemically and enzymatically stable phosphodiester linkages tethering one or more saccharide residues at both ends of the oligonucleotide backbone.

With the aim of exploring different types of glycomimetics, fully compatible with the oligonucleotide chemistry and, more in general, with solid-phase synthetic methods, we here describe the online solid-phase assembly of oligonucleotide hybrids conjugated at the 3′ end with oligosaccharide mimics in which the *O*-glycosidic linkages are replaced by amide bonds (Figure 1). These glycomimetics, for which Nicolaou and co-workers introduced the term "carbopeptoids" (*22*), can be assembled by exploiting easy and high-yielding coupling procedures, well optimized in solution (*23*−*25*), and solid-phase peptide synthesis (*26*−*28*). Oligomers based on such structural motifs can adopt well-defined secondary structures, stabilized by intramolecular hydrogen bonds in solution (*29*), and therefore result attractive foldamers, of interest for their potential selective recognition properties.

MATERIALS AND METHODS

All reagents were of the highest commercially available quality and were used as received. 1,3-Propanedithiol was distilled prior use. Tentagel-NH_2 resin (0.29 meq/g) was purchased from NovaBiochem. The solid support functionalizations were carried out in a short glass column (5 cm length, 1 cm i.d.) equipped with a sintered glass filter, a stopcock, and a cap. The oligonucleotides were assembled on an Expedite PerSeptive Biosystems DNA synthesizer, using commercially available 3′-*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite 2′-deoxyribonucleosides as building blocks.

The following abbreviations were used throughout the text: acetic anhydride (Ac_2O); dichloroacetic acid (DCA); dichloromethane (DCM); diisopropylcarbodiimide (DIC); diisopropylethylamine (DIPEA); *N*,*N*-dimethylaminopyridine (DMAP); *N*,*N*-dimethylformamide (DMF); 4,4′-dimethoxytriphenylmethyl (DMT); *O*-(7-azabenzotriazol-1-yl)-N,N,N′,N′-tetramethyluronium hexafluorophosphate (HATU); 1-hydroxybenzotriazole (HOBt); oligodeoxyribonucleotide (ODN); *p*-toluensulfonic acid (PTSA); pyridine (Py); triethylamine (TEA); trifluoroacetic acid (TFA); triethylammonium bicarbonate (TEAB); *tert*-butyldimethylsilyl (TBDMS); trimethylsilyl azide ($TMSN_3$).

High-performance liquid chromatography (HPLC) analyses and purifications were performed on a Beckman System Gold instrument equipped with a UV detector module 166 and a Shimadzu Chromatopac C-R6A integrator. By HPLC analysis on a Partisphere Whatman RP18 analytical column (125 × 4.0 mm, 5 μm), eluted with a linear gradient from 0 to 100% in 60 min of CH_3CN in TEAB buffer (0.1 M, pH 7.0), flow = 0.8 mL/min, the isolated oligomers **I**−**III** resulted to be more than 98% pure. NMR spectra were recorded on Bruker WM-400, Varian Gemini 300, Varian Gemini 200, and Varian Inova 500 spectrometers. All chemical shifts are expressed in ppm with respect to the residual solvent signal. Peak assignments have been carried out on the basis of H−H correlation spectroscopy and HSQC experiments. For the electrospray ionization spectroscopy mass spectrometry (ESI MS) analyses, a Waters Micromass ZQ instrument, equipped with an electrospray source, was used in the positive and/or negative mode. Matrix-assisted laser desorption ionization time-of-flight (MALDI TOF) mass spectrometric analyses were performed on a PerSeptive Biosystems Voyager-De Pro MALDI mass spectrometer in the linear mode using a picolinic/3-hydroxypicolinic acids mixture as the matrix. UV measurements and thermal denaturation experiments (detection at λ = 260 nm) were carried out on a Jasco V-530 UV spectrophotometer equipped with a Jasco ETC-505T temperature controller unit.

Synthesis of Glucose-Based Building Blocks 5 and 8. α-*1-Azido-4,6-benzyliden-*D*-glucopyranose (***2***).* α-Bromo-2,3,4,6-tetra-O-acetyl-D-glucose (1.0 g, 2.40 mmol), dissolved in 7 mL of anhydrous DMF, was treated with 470 mg (7.23 mmol) of sodium azide at 50 °C for 2 h. After 2 h, the reaction mixture was concentrated under reduced pressure and purified by silica gel chromatography (eluent system: acetone in CH_2Cl_2 from 0 to 3%), affording 857 mg of β-1-azido-2,3,4,6-tetra-O-acetyl-D-glucose (2.30 mmol, 95%).

The obtained compound (857 mg, 2.30 mmol) was then treated with 2 mL of NH_3/MeOH 7 N at 50 °C for 18 h. The mixture was concentrated under reduced pressure and then redissolved in 7 mL of anhydrous DMF and treated with 20 mg (0.11 mmol) of PTSA and 689 μL (4.60 mmol) of α,α-dimethoxytoluene at 50 °C for 6 h. The reaction mixture was then concentrated under reduced pressure and purified by silica gel chromatography (eluent system: acetone in CH_2Cl_2 from 5 to 10%), thus affording 685 mg (1.81 mmol, 80%) of **2** as a pure compound.

^{1}H NMR (500 MHz, CD_3OD): δ 7.50−7.33 (5H, complex signals, aromatic protons); 5.57 (1H, s, PhC*H*); 4.64 (1H, d, J = 9.0 Hz, H-1); 4.30 (1H, m, H-6_a); 3.79 (1H, t, J = 10.5 and 10.0 Hz, H-6_b); 3.67 (1H, t, J = 8.5 and 9.5 Hz, H-3); 3.55 (1H, m, H-5); 3.49 (1H, t, J = 9.0 and 9.5 Hz, H-4); 3.31 (1H, t, J = 9.0 and 9.5 Hz, H-2).

^{13}C NMR (125 MHz, CD_3OD): δ 139.49, 130.45, 129.53, and 128.00 (aromatic carbons); 103.41 (Ph*C*H); 92.96 (C-1β); 82.33 (C-4); 76.03 (C-2); 75.17 (C-3); 70.17 (C-5); 69.89 (C-6).

ESI-MS calculated for $C_{13}H_{15}N_3O_5$: 293.27. Found (positive ions): 316.40 ($M + Na^+$); 332.51 ($M + K^+$).

*β-1-Azido-2,3-di-O-acetyl-D-glucopyranose (***3***).* Compound **2** (685 mg, 1.81 mmol) was treated with 2 mL of Ac_2O in 3 mL of anhydrous pyridine at room temperature (rt). After 1 h, the reaction mixture was taken to dryness and the crude was treated with 5 mL of the system TFA/H_2O/DCM (1:0.5:10, v/v/v) at 0 °C for 3 h. The reaction was quenched by addition of a few drops of pyridine, concentrated under reduced pressure, and purified by silica gel chromatography (eluent system: CH_3OH in $CHCl_3$ from 1 to 5%), affording 477 mg (1.65 mmol, 90%) of **3** as a pure compound.

^{1}H NMR (500 MHz, CD_3OD): δ 5.09 (1H, t, J = 9.5 and 9.0 Hz, H-3); 4.81 (1H, d, J = 8.5 Hz, H-1); 4.75 (1H, t, J = 9.5 and 9.0 Hz, H-2); 3.92−3.72 (2H, m, H_2-6); 3.61 (1H, t, J = 9.5 and 9.5 Hz, H-4); 3.53 (1H, m, H-5); 2.04 and 2.03 (3H each, s's, 2 × COCH_3).

^{13}C NMR (125 MHz, CD_3OD): δ 172.54 and 171.68 (2 *C*O); 89.46 (C-1β); 80.50 (C-5); 77.22 (C-3); 73.19 (C-2); 69.51 (C-4); 62.48 (C-6); 21.28 and 21.05 (CO*C*H$_3$).

ESI-MS calculated for $C_{10}H_{15}N_3O_7$: 289.24. Found (positive ions): 312.16 (M + Na^+); 328.16 (M + K^+).

*β-1-Azido-2,3-di-O-acetyl-6-O−(4,4′-dimethoxytriphenylmethyl)-D-glucopyranose (***4***).* Compound **3** (477 mg, 1.65 mmol), dissolved in 4 mL of anhydrous pyridine, was treated with 670 mg (1.98 mmol) of DMTCl and 10 mg (0.08 mmol) of DMAP at 25 °C for 18 h. The reaction was quenched by addition of methanol. The resulting mixture was concentrated under reduced pressure and purified by silica gel chromatography (eluent system: ethyl acetate in benzene/Py 1:0.05, v/v, from 5 to 15%), which furnished 827 mg (1.40 mmol, 85%) of **4** as a pure compound.

^{1}H NMR (500 MHz, $CDCl_3$): δ 7.45−6.84 (13H, complex signals, aromatic protons); 5.06 (1H, t, J = 9.0 and 10.0 Hz, H-3); 4.91 (1H, t, J = 9.0 and 9.5 Hz, H-2); 4.60 (1H, d, J = 8.5 Hz, H-1); 3.84 (1H, t, J = 10.0 and 9.0 Hz, H-4); 3.82 (6H, s, OCH_3); 3.56 (1H, m, H-5); 3.45 (2H, m, H_2-6); 2.09 and 2.08 (3H each, s's, 2 × COCH_3).

^{13}C NMR (125 MHz, $CDCl_3$): δ 170.83 and 169.44 (2 *C*O); 158.50, 144.19, 135.29, 129.90, 129.86, 127.87, 126.86, and 113.17 (aromatic carbons); 87.47 (C-1β); 86.68 (quaternary carbon of DMT group); 76.22 (C-5); 74.98 (C-3); 70.75 (C-2); 70.17 (C-4); 63.21 (C-6); 55.08 (O*C*H$_3$); 20.66 and 20.51 (CO*C*H$_3$).

ESI-MS calculated for $C_{31}H_{33}N_3O_7$: 591.61. Found (positive ions): 614.15 (M + Na^+); 630.31 (M + K^+).

*β-1-Azido-2,3-di-O-acetyl-6-O−(4,4′-dimethoxytriphenylmethyl)-D-glucopyranose-4-O-succinic acid (***5***).* Compound **4** (827 mg, 1.40 mmol), dissolved in 4 mL of anhydrous pyridine, was treated with 630 mg (6.30 mmol) of succinic anhydride and 10 mg (0.074 mmol) of DMAP at 25 °C for 18 h. The reaction was quenched by addition of water and concentrated under reduced pressure. The residue was then taken up in 100 mL of $CHCl_3$, washed twice with water, and purified by silica gel chromatography (eluent system: CH_3OH in $CHCl_3$/Py 1:0.05, v/v, from 2 to 10%) affording 870 mg of **5** as a pure compound (1.26 mmol, 90%).

^{1}H NMR (500 MHz, $CDCl_3$): δ 7.45−6.82 (13H, complex signals, aromatic protons); 5.30 (1H, t, J = 10.0 and 10.0 Hz, H-4); 5.19 (1H, t, J = 10.0 and 10.0 Hz, H-3); 5.01 (1H, t, J = 9.0 and 9.0 Hz, H-2); 4.65 (1H, d, J = 8.5 Hz, H-1); 3.77 (6H, s, OCH_3); 3.69 (1H, m, H-5); 3.33−3.09 (2H, m, H_2-6); 2.49−2.38 (4H, m, CH_2 succinic group); 2.07 and 1.97 (3H each, s's, 2 × COCH_3).

^{13}C NMR (125 MHz, $CDCl_3$): δ 170.27 and 170.23 (2 *C*O); 158.39, 144.34, 135.64, 129.25, 128.21, 127.75, 126.72, and 113.03 (aromatic carbons); 87.36 (C-1β); 86.02 (quaternary carbon of DMT group); 75.51 (C-5); 72.57 (C-3); 70.94 (C-2); 68.18 (C-4); 61.42 (C-6); 55.05 (O*C*H$_3$); 28.69 and 28.61 (*C*H$_2$ succinic group); 20.44 and 20.38 (CO*C*H$_3$).

ESI-MS calculated for $C_{35}H_{37}N_3O_{12}$: 691.68. Found (negative ions): 690.38 (M − H)$^-$.

*β-1-Azido-2,3,4-tri-O-acetyl-6-O-tert-butyldimethylsilyl-D-glucopyranose (***7***).* 1-Azido-β-D-glucopyranose (390 mg, 1.9 mmol), dissolved in 5 mL of anhydrous DMF, was treated with 422 mg (2.8 mmol) of TBDMSCl and 258 mg (3.8 mmol) of imidazole at rt for 18 h. The reaction was quenched by addition of water at 0 °C, and the resulting mixture concentrated under reduced pressure. The residue was taken up in 100 mL of $CHCl_3$ and washed twice with 5% $NaHCO_3$ and then with water. The crude was purified by silica gel chromatography (eluent system: 5% CH_3OH in $CHCl_3$), affording 488 mg (1.6 mmol, 85%) of a pure compound. This was directly treated with 2 mL of Ac_2O in 3 mL of anhydrous pyridine at rt for 3 h. The reaction was quenched by addition of a few drops of CH_3OH and the mixture concentrated under reduced pressure. The residue afforded 690 mg (1.60 mmol) of **7** as a pure compound.

^{1}H NMR (400 MHz, $CDCl_3$): δ 5.17 (1H, t, J = 9.6 and 9.6 Hz, H-3); 5.06 (1H, t, J = 9.6 and 9.6 Hz, H-4); 4.89 (1H, t, J = 9.2 and 9.2 Hz, H-2); 4.55 (1H, d, J = 8.8 Hz, H-1); 3.76−3.66 (2H, m, H-6); 3.60 (1H, m, H-5); 2.03, 1.99 and 1.97 (3H each, s's, 3 × COCH_3); 0.86 {9H, s, [(CH_3)$_3$C]Si}; 0.04 and 0.028 [3H each, s's, Si(CH_3)$_2$].

^{13}C NMR (100 MHz, $CDCl_3$): δ 170.07, 169.07, and 169.00 (3 *C*O); 87.55 (C-1β); 76.78 (C-5); 72.87 (C-3); 70.71 (C-2); 68.20 (C-4); 61.93 (C-6); 25.63 {[(*C*H$_3$)$_3$C]Si}; 20.42 (CO*C*H$_3$); 18.17 [(CH$_3$)$_3$*C*]; −5.54 [Si(*C*H$_3$)$_2$].

ESI-MS calculated for $C_{18}H_{31}N_3O_8Si$: 445.54. Found (positive ions): 468.15 (M + Na^+); 484.25 (M + K^+).

*β-1-Azido-2,3,4-tri-O-acetyl-β-D-glucuronic acid (***8***).* Compound **7** (690 mg, 1.60 mmol) was treated with 3 mL of Jones reagent (5 g CrO_3/15 mL H_2O/5 mL H_2SO_4) at −15 °C for 15 min and then slowly taken to rt and left for additional 3 h under stirring. The reaction was quenched by addition of ethanol, neutralized by addition of 5% $NaHCO_3$ solution, and then washed once with $CHCl_3$. The aqueous phase was brought to pH = 2 with 3 M HCl and washed twice with $CHCl_3$. The organic layers were collected and concentrated under reduced pressure to give 497 mg (1.44 mmol, 90%) of **8** as a pure compound.

^{1}H NMR (300 MHz, $CDCl_3$): δ 5.30−5.25 (2H, overlapped signals, H-3 and H-4); 4.97 (1H, t, J = 8.6 and 9.4 Hz, H-2); 4.75 (1H, d, J = 8.8 Hz, H-1); 4.17 (1H, m, H-5); 2.08, 2.05, and 2.03 (3H each, s's, 3 × COCH_3).

^{13}C NMR (75 MHz, $CDCl_3$): δ 170.25, 169.74, 169.34, and 169.12 (3 *C*O and *C*OOH); 87.63 (C-1β); 73.25 (C-5); 71.76 (C-2); 70.16 (C-3); 68.63 (C-4); 20.29 (CO*C*H$_3$).

ESI-MS calculated for $C_{12}H_{15}N_3O_9$: 345.26. Found (negative ions): 344.18 (M − H)$^-$.

Synthesis of Lactose-Based Building Blocks 13 and 16. *β-1-Azido-lactose heptaacetate (***10***).* Lactose octaacetate (1.0 g, 1.47 mmol) was treated with 85 μL (0.73 mmol) of $SnCl_4$ and 483 μL (3.67 mmol) of trimethylsilyl azide in 20 mL of anhydrous CH_2Cl_2 and 1 mL of molecular sieves of 4 Å under nitrogen atmosphere for 18 h at rt. The reaction mixture was washed with 1 M $KHSO_4$ and then with water; the organic layers were collected and dried over anhydrous $MgSO_4$, affording 879 mg (1.32 mmol, 90%) of **10** as a pure compound.

^{1}H NMR (500 MHz, $CDCl_3$): δ 5.33 (1H, m, H-4 Gal); 5.19 (1H, t, J = 9.0 and 9.0 Hz, H-3 Glc); 5.08 (1H, t, J = 8.5 and 9.5 Hz, H-2 Gal); 4.94 (1H, dd, J = 3.5 and 10.5 Hz, H-3 Gal); 4.84 (1H, t, J = 9.5 and 9.5 Hz, H-2 Glc); 4.61 (1H, d, J = 9.0 Hz, H-1 Glc); 4.47 (1H, d, J =

7.5 Hz, H-1 Gal); 4.12−4.04 (4H, overlapped signals, H_2-6 Glc and H_2-6 Gal); 3.86 (1H, t, J = 7.0 and 7.0 Hz, H-5 Gal); 3.80 (1H, t, J = 9.5 and 9.5 Hz, H-4 Glc); 3.69 (1H, m, H-5 Glc); 2.08, 2.05, 2.04, 1.98, 1.97, 1.95, and 1.87 (3 H each, s's, 7 x $COCH_3$).

^{13}C NMR (125 MHz, $CDCl_3$): δ 170.13, 169.94, 169.86, 169.45, 169.31, and 168.89 (*C*O); 100.93 (C-1β Gal); 87.53 (C-1β Glc); 75.61 (C-4 Glc); 74.63 (C-5 Glc); 72.36 (C-3 Glc); 70.82 (C-5 Gal); 70.75 (C-3 Gal); 70.58 (C-2 Glc); 68.89 (C-2 Gal); 66.43 (C-4 Gal); 61.56 (C-6 Gal); 60.62 (C-6 Glc); 20.62, 20.55, 20.44, and 20.32 (CO*C*H_3).

ESI-MS calculated for $C_{26}H_{35}N_3O_{17}$: 661.57. Found (positive ions): 684.17 ($M + Na^+$); 700.14 ($M + K^+$).

*4,6-Benzyliden-2,3-di-O-acetyl-β-D-Galp(1→4)-1-azido-2,3,6-tri-O-acetyl-β-D-Glcp (***11***).* Compound **10** (879 mg, 1.32 mmol) was treated with 6 mL of NH_3/CH_3OH for 18 h at 50 °C. The mixture was concentrated under reduced pressure, redissolved in 7 mL of DMF, and then treated with 12 mg (0.06 mmol) of PTSA and 237 μL (1.58 mmol) of α,α-dimethoxytoluene at 50 °C for 6 h. The reaction mixture was diluted with AcOEt and washed twice with water. The organic phase was then taken to dryness and acetylated by treatment with 3:2 Py/acetic anhydride for 3 h at rt. The reaction mixture was concentrated under reduced pressure and purified by silica gel chromatography (eluent system: acetone in CH_2Cl_2 from 1 to 10%), affording 612 mg (0.92 mmol, 70%) of **11** as a pure compound.

^{1}H NMR (500 MHz, $CDCl_3$): δ 7.44−7.37 (5H, complex system, aromatic protons); 5.46 (1H, s, PhC*H*); 5.25−5.20 (2H, overlapped signals, H-2 Gal and H-3 Glc); 4.90−4.87 (2H, overlapped signals, H-3 Gal and H-2 Glc); 4.61 (1H, d, J = 9.0 Hz, H-1 Glc); 4.53 (1H, d, J = 12.0 Hz, H-6$_a$ Glc); 4.48 (1H, d, J = 8.5 Hz, H-1 Gal); 4.33 (1H, d, J = 3.5 Hz, H-4 Gal); 4.29 (1H, d, J = 11.0 Hz, H-6$_a$ Gal); 4.13 (1H, dd, J = 5.0 and 12.5 Hz, H-6$_b$ Glc); 4.05 (1H, d, J = 13.0 Hz, H-6$_b$ Gal); 3.81 (1H, t, J = 9.5 and 9.5 Hz, H-4 Glc); 3.71 (1H, m, H-5 Glc); 3.46 (1H, bs, H-5 Gal); 2.12, 2.10, 2.06, 2.05, and 2.03 (3H each, s's, 5 × $COCH_3$).

^{13}C NMR (125 MHz, $CDCl_3$): δ 170.59, 170.14, 169.42, 168.77, and 160.85 (*C*O); 137.26, 129.12, 128.14, and 126.34 (aromatic carbons); 101.23 (Ph*C*H); 100.94 (C-1β Gal); 87.74 (C-1β Glc); 75.33 (C-4 Glc and C-5 Glc); 74.93 (C-4 Gal); 72.97 (C-3 Glc); 71.91 (C-2 Glc); 70.74 (C-3 Gal); 68.83 (C-2 Gal); 68.30 (C-6 Glc); 66.41 (C-5 Gal); 61.60 (C-6 Gal); 20.69 and 20.47 (CO*C*H_3).

ESI-MS calculated for $C_{29}H_{35}N_3O_{15}$: 665.60. Found (positive ions): 688.28 ($M + Na^+$); 704.21 ($M + K^+$).

*2,3-Di-O-acetyl-β-D-Galp(1→4)-1-azido-2,3,6-tri-O-acetyl-β-D-Glcp (***12***).* Compound **11** (612 mg, 0.92 mmol) was treated with 5 mL of the system TFA/H_2O/DCM (1:0.5:10, v/v/v) at 0 °C for 3 h. The reaction was quenched by addition of pyridine, concentrated under reduced pressure, and purified by silica gel chromatography (eluent system: CH_3OH in $CHCl_3$ from 1 to 10%), affording 479 mg (0.83 mmol, 90%) of **12** as a pure compound.

^{1}H NMR (500 MHz, CD_3OD): δ 5.21 (1H, t, J = 9.5 and 9.5 Hz, H-3 Glc); 5.14 (1H, m, H-2 Gal); 4.87−4.81 (3H, overlapped signals, H-3 Gal, H-2 Glc, and H-1 Glc); 4.56 (1H, d, J = 7.5 Hz, H-1 Gal); 4.54−4.18 (2H, AB part of an ABX system, H_2-6 Glc); 4.06 (1H, d, J = 2.5 Hz, H-4 Gal); 3.92 (1H, t, J = 9.0 and 9.0 Hz, H-4 Glc); 3.86 (1H, m, H-5 Glc); 3.74 (2H, m, H_2-6 Gal); 3.62 (1H, t, J = 6.5 and 6.5 Hz, H-5 Gal); 2.12, 2.09, 2.08, 2.07, and 2.04 (3H each, s's, 5 × CO*C*H_3).

^{13}C NMR (125 MHz, CD_3OD): δ 172.83 and 171.81 (*C*O); 102.98 (C-1β Gal); 89.15 (C-1β Glc); 77.56 (C-4 Glc); 76.97 (C-5 Gal); 76.68 (C-5 Glc); 75.96 (C-3 Gal); 74.72 (C-3 Glc); 72.92 (C-2 Glc); 71.69 (C-2 Gal); 68.01 (C-4 Gal); 63.99 (C-6 Glc); 62.17 (C-6 Gal); 21.60, 21.29, 21.16, and 20.99 (CO*C*H_3).

ESI-MS calculated for $C_{22}H_{31}N_3O_{15}$: 577.49. Found (positive ions): 600.15 ($M + Na^+$); 616.31 ($M + K^+$).

*2,3-Di-O-acetyl-6-O−(4,4′-dimethoxytriphenylmethyl)-4-O-succinyl-β-D-Galp(1→4)-1-azido-2,3,6-tri-O-acetyl-β-D-Glcp (***13***).* Compound **12** (479 mg, 0.83 mmol), dissolved in 4 mL of anhydrous pyridine, was treated with 337 mg (0.99 mmol) of DMTCl and 5 mg (0.04 mmol) of DMAP at 25 °C for 18 h. The reaction was quenched by addition of methanol and the resulting mixture concentrated under reduced pressure. Purification by silica gel chromatography (eluent system: $CHCl_3$/Py 1:0.05, v/v) afforded 624 mg (0.71 mmol, 85%) of a pure compound, which was then dissolved in 4 mL of anhydrous Py and treated with 319 mg (3.19 mmol) of succinic anhydride and 5 mg (0.035 mmol) of DMAP at 25 °C for 18 h. The reaction was quenched by addition of water and concentrated under reduced pressure. The residue, taken up in 100 mL of $CHCl_3$, was washed twice with water, concentrated under reduced pressure, and purified by silica gel chromatography (eluent system: CH_3OH in $CHCl_3$/Py 1:0.05, v/v, from 2% to 10%), affording 617 mg of **13** as a pure compound (0.6 mmol, 89%).

^{1}H NMR (500 MHz, C_6D_6): δ 7.69−6.74 (13H, complex signals, aromatic protons); 6.17 (1H, d, J = 3.5 Hz, H-4 Gal); 5.62 (1H, m, H-2 Gal); 5.41 (1H, dd, J = 3.0 and 10.5 Hz, H-3 Gal); 5.33 (1H, t, J = 9.0 and 9.5 Hz, H-3 Glc); 5.12 (1H, t, J = 9.5 and 9.0 Hz, H-2 Glc); 4.50 (1H, d, J = 10.5 Hz, H-6$_a$ Glc); 4.40 (1H, d, J = 8.0 Hz, H-1 Gal); 4.14 (1H, partially overlapped signals, H-6$_b$ Glc); 4.12 (1H, d, J = 8.5 Hz, H-1 Glc); 3.78 (1H, m, H-6$_a$ Gal); 3.69 (1H, m, H-5 Gal); 3.48 (1H, m, H-6$_b$ Gal); 3.44 (4H, overlapped signals, OC*H*$_3$ DMT group and H-4 Glc); 3.27 (1H, m, H-5 Glc); 2.64−2.21 (4H, m, C*H*$_2$ succinic group); 2.06, 1.98, 1.91, 1.81, and 1.78 (3H each, s's, 5 × CO*CH*$_3$).

^{13}C NMR (125 MHz, C_6D_6): δ 174.23 (*C*OOH); 171.66, 170.13, 170.05, and 169.10 (*C*O); 159.35, 149.46, 144.70, 135.91, 130.72, 130.62, 130.41, 113.65, 128.75, 127.34, and 123.69 (aromatic carbons); 101.71 (C-1β Gal); 87.66 (C-1β Glc); 87.09 (quaternary carbon of DMT group); 76.57 (C-4 Glc); 75.02 (C-5 Glc); 73.11 (C-3 Glc); 72.44 (C-5 Gal); 71.80 (C-3 Gal); 71.18 (C-2 Glc); 70.01 (C-2 Gal); 67.46 (C-4 Gal); 62.40 (C-6 Glc); 60.93 (C-6 Gal); 54.80 (O*C*H$_3$ DMT group); 29.24 and 29.20 (C*H*$_2$ succinic group); 20.85, 20.47, 20.36, 20.20, and 20.10 (CO*C*H_3).

ESI-MS calculated for $C_{47}H_{53}N_3O_{20}$: 979.93. Found (negative ions): 978.50 $(M - H)^-$.

*2,3,4-Tri-O-acetyl-6-O-tert-butyldimethylsilyl-β-D-Galp-(1→4)-1-azido-2,3,6-tri-O-acetyl-β-D-Glcp (***15***).* Compound **12** (381 mg, 0.66 mmol), dissolved in 5 mL of DMF, was treated with 149 mg (0.99 mmol) of TBDMSCl and 90 mg (1.32 mmol) of imidazole at rt for 18 h. The reaction mixture was quenched by addition of water at 0 °C and concentrated under reduced pressure. The crude was taken up in 100 mL of $CHCl_3$ and washed twice with 5% $NaHCO_3$ and then with water. Purification by silica gel chromatography (eluent system: 2% CH_3OH in $CHCl_3$) afforded 366 mg (0.53 mmol, 80%) of a pure compound, which was directly acetylated by treatment with 3:2 Py/acetic anhydride at rt for 3 h. The reaction mixture was then diluted with $CHCl_3$ and washed twice with water; the organic layer was concentrated under reduced pressure, affording 388 mg (0.53 mmol) of **15** as a pure compound.

^{1}H NMR (500 MHz, $CDCl_3$): δ 5.41 (1H, d, J = 3.0 Hz, H-4 Gal); 5.17 (1H, t, J = 9.5 and 9.0 Hz, H-3 Glc); 5.05 (1H, m, H-2 Gal); 4.95 (1H, dd, J = 3.5 and 10.0 Hz, H-3 Glc); 4.82 (1H, t, J = 9.5 and 9.0 Hz, H-2 Glc); 4.59 (1H,

d, J = 8.5 Hz, H-1 Glc); 4.49 (1H, d, J = 12.0 Hz, H-6_a Glc); 4.43 (1H, d, J = 8.0 Hz, H-1 Gal); 4.07 (1H, dd, J = 4.5 and 12.0 Hz, H-6_b Glc); 3.80 (1H, t, J = 10.0 and 9.0 Hz, H-4 Glc); 3.69−3.61 (3H, overlapped signals, H-5 Glc, H-6_a Gal and H-5 Gal), 3.52 (1H, t, J = 7.5 and 8.0 Hz, H-6_b Gal); 2.10, 2.09, 20.4, 2.01, 2.00, and 1.93 (3H each, s's, 6 × COCH_3); 0.83 {9H, s, [(CH_3)$_3$C]Si}; −0.004 and −0.02 [3H each, s's, (CH_3)Si].

^{13}C NMR (125 MHz, $CDCl_3$): δ 170.08, 169.86, 169.66, 169.30, and 168.97 (*C*O); 100.82 (C-1β Gal); 87.50 (C-1β Glc); 75.21 (C-4 Glc); 74.57 and 73.41 (C-5 Glc and C-5 Gal); 72.42 (C-3 Glc); 71.06 (C-3 Gal); 70.79 (C-2 Glc); 69.26 (C-2 Gal); 66.35 (C-4 Gal); 61.53 (C-6 Glc); 59.88 (C-6 Gal); 25.47 {[(*C*H$_3$)$_3$C]Si}; 20.59, 20.45, 20.40, and 20.34 (CO*C*H$_3$); 17.88 (quaternary carbon of TBDMS group); −5.86 and −5.91 [(*C*H$_3$)$_2$Si].

ESI-MS calculated for $C_{30}H_{47}N_3O_{16}Si$: 733.79. Found (positive ions): 756.36 (M + Na^+); 772.32 (M + K^+).

*β-1-Azido-2,2′,3,3′,4′,6-hexa-O-acetyl-lacturonic Acid (***16***).* Compound **15** (388 mg, 0.53 mmol) was treated with 3 mL of Jones reagent (5 g CrO_3/15 mL H_2O/5 mL H_2SO_4) at −15 °C for 15 min, then slowly taken to rt and left for an additional 3 h under stirring. The reaction was quenched by addition of ethanol, neutralized by addition of 5% $NaHCO_3$ solution, and then washed once with $CHCl_3$. The aqueous phase was brought to pH = 2 with 3 M HCl and washed twice with $CHCl_3$. The organic layers were collected and concentrated under reduced pressure to give 298 mg (0.47 mmol, 90%) of **16** as a pure compound.

^{1}H NMR (500 MHz, $CDCl_3$): δ 5.68 (1H, d, J = 1.5 Hz, H-4 Gal); 5.26 (1H, t, J = 9.5 and 9.0 Hz, H-3 Glc); 5.12−5.05 (2H, overlapped signals, H-2 Gal and H-3 Gal); 4.84 (1H, t, J = 8.5 and 10.0 Hz, H-2 Glc); 4.68 (1H, d, J = 9.0 and 9.0 Hz, H-1 Glc); 4.58 (1H, d, J = 8.0 Hz, H-1 Gal); 4.50−4.47 (2H, overlapped signals, H-6_a Glc and H-5 Gal); 4.16 (1H, m, H-6_b Glc); 3.85−3.73 (2H, overlapped signals, H-4 Glc and H-5 Glc); 2.12, 2.11, 2.09, 2.08, 2.07, and 2.06 (3H each, s's, 6 × COCH_3).

^{13}C NMR (50 MHz, $CDCl_3$): δ 172.72, 172.39, 171.92, 171.48, 171.30, and 171.12 (*C*O and *C*OOH); 101.89 (C-1β Gal); 88.67 (C-1β Glc); 77.21 (C-5 Glc); 76.04 (C-5 Gal); 74.48 (C-2 Glc and C-3 Gal); 72.73 and 72.55 (C-2 Gal and C-3 Glc); 70.77 and 70.66 (C-4 Gal and C-4 Glc); 20.64, 20.57, and 20.48 (CO*C*H$_3$).

ESI-MS calculated for $C_{24}H_{31}N_3O_{17}$: 633.51. Found (negative ions): 632.18 (M − H)$^-$.

6-(4,4′-Dimethoxytriphenylmethoxy)hexanoic Acid Linker. Ethyl 6-hydroxyhexanoate (500 μL, 3.0 mmol), dissolved in 4 mL of anhydrous pyridine, was treated with 1.0 g (3.0 mmol) of DMTCl and 190 mg (1.5 mmol) of DMAP for 4 h at rt. The reaction mixture was quenched by addition of CH_3OH and concentrated under reduced pressure. The crude was taken up in 100 mL of $CHCl_3$ and washed twice with water. The obtained residue was dissolved in 4 mL of ethanol and treated with 25 mL of NaOH 6 M for 6 h at rt. The reaction mixture was diluted with $CHCl_3$ and washed twice with water. Purification by silica gel chromatography (eluent system: acetone in CH_2Cl_2/Py 1:0.05, v/v) afforded 1.0 g (2.25 mmol, 75%) of the desired 6-(4,4′-dimethoxytriphenylmethoxy)hexanoic acid as a pure compound.

^{1}H NMR (200 MHz, $CDCl_3$): δ 7.42−6.88 (13H, complex signals, aromatic protons); 3.86 (3H, s, OCH_3); 3.12 (2H, t, J = 4.4 and 4.2 Hz, CH_2 ϵ); 2.42 (2H, t, J = 4.8 and 5.2 Hz, CH_2 α); 1.69 (4H, overlapped signals, CH_2 β and CH_2 δ); 1.50 (2H, m, CH_2 γ).

^{13}C NMR (50 MHz, $CDCl_3$): δ 179.79 (*C*OOH); 158.20, 145.28, 136.55, 129.92, 128.07, 127.67, 126.54, and 112.89 (aromatic carbons); 85.59 (quaternary carbon of DMT group); 63.02 (*C*H$_2$ ϵ); 55.12 (OCH_3); 34.01 (*C*H$_2$ α); 29.68 (*C*H$_2$ β); 25.79 (*C*H$_2$ γ); 24.55 (*C*H$_2$ δ).

ESI-MS calculated for $C_{27}H_{30}O_5$: 434.52. Found (negative ions): 433.18 (M − H)$^-$.

Solid Support Functionalization: Synthesis of 18, 20, and 22. In a typical experiment, 300 mg of Tentagel−NH_2 (0.29 meq/g, 0.09 mmol) were reacted with 0.90 mmol of **5** or **13**, 130 μL (0.90 mmol) of DIC, 117 mg (0.90 mmol) of HOBt, and 150 μL (0.90 mmol) of DIEA in 500 μL of anhydrous DMF at rt for 12 h. After exhaustive washings with DCM, CH_3OH, and Et_2O, the support was dried under reduced pressure. DMT tests performed on dried and weighed samples of resulting supports **6** or **14** allowed to determine the incorporation yields of derivative **5** or **13**, respectively, onto the Tentagel resin, which resulted to be in the range 0.20−0.23 meq/g. DMT protecting group was removed by 1% DCA in DCM treatment, followed by a standard treatment with acetic anhydride in pyridine (2:3, v/v) to block the liberated 6-OH moiety. The resulting support (50 mg, 0.0095 mmol) was then treated with 24 μL (0.24 mmol) of 1,3-propanedithiol and 33 μL (0.24 mmol) of triethylamine in 300 μL of DMF under nitrogen atmosphere for 2 h at rt. After 2 h, the support was washed several times with anhydrous DMF and coupled with carboxylic acid **8** or **16** (0.095 mmol), 16 μL (0.095 mmol) of DIEA, 37 mg (0.095 mmol) of HATU, and 35 mg (0.095 mmol) of HOBt in 300 μL of DMF for 1.5 h at rt. The successive step required the treatment of the obtained supports (**17**, **19**, and **21**) with 24 μL (0.24 mmol) of 1,3-propanedithiol and 33 μL (0.24 mmol) of triethylamine in 300 μL of DMF under nitrogen atmosphere for 2 h at rt. After 2 h, the support was washed several times with anhydrous DMF and coupled with the 6-(4,4′-dimethoxytriphenylmethoxy)-hexanoic acid linker (0.095 mmol), 16 μL (0.095 mmol) of DIEA, 37 mg (0.095 mmol) of HATU, and 35 mg (0.095 mmol) of HOBt in 300 μL of DMF for 1.5 h at rt. DMT tests performed on dried and weighed samples of resulting supports **18**, **20**, and **22** allowed the determination of the support functionalization, which was always in the range 0.12−0.14 meq/g.

Synthesis of 3′-Glycoconjugates I, II, and III. ODN chain assembly was carried out on 50 mg (6.5 μmol) of supports **18**, **20**, or **22** on an automated DNA synthesizer following a standard phosphoramidite protocol with final DMT removal (*30*). The sequence d($^{5'}$GCGTGCCTCC-TCACTGGC$^{3'}$) was assembled, observing in all cases coupling yields always greater than 98%, as evaluated by DMT test. The oligomers were detached from the support and deprotected by an overnight concentrated aq ammonia treatment at 55 °C. The supernatant was filtered and the support washed with H_2O. The combined filtrates and washings were concentrated under reduced pressure, redissolved in H_2O, and analyzed and purified by HPLC on a Nucleogel SAX column (Macherey-Nagel, 1000−8/46); buffer A, 20 mM KH_2PO_4 aq solution, pH 7.0, containing 20% (v/v) CH_3CN; buffer B, 1 M KCl, 20 mM KH_2PO_4 aq solution, pH 7.0, containing 20% (v/v) CH_3CN; a linear gradient from 0 to 100% B in 30 min, flow rate 0.8 mL/min, was used. The isolated oligomers, having the following retention times: **I** = 21.37 min, **II** = 20.90 min, and **III** = 17.13 min, respectively, were collected and successively desalted by gel filtration on a Sephadex G25 column eluted with H_2O. HPLC profile of crude **III** is showed in Figure 2. By HPLC analysis on a Nucleosil 100−5 C18 analytical column (4.6 × 250 mm, 7 μm), the isolated oligomers resulted to be more than 98% pure (see Materials and Methods for conditions).

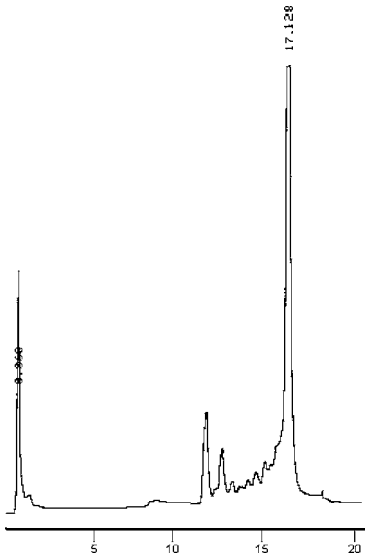

Figure 2. HPLC profile of crude oligonucleotide 3′-glycoconjugate **III** (conditions: Nucleogel SAX column; linear gradient from 0 to 100% B in 30 min; buffer A, 20 mM KH_2PO_4 aq solution, pH 7.0, containing 20% (v/v) CH_3CN; buffer B, 1 M KCl, 20 mM KH_2PO_4 aq. solution, pH 7.0, containing 20% (v/v) CH_3CN; flow rate 0.8 mL/min).

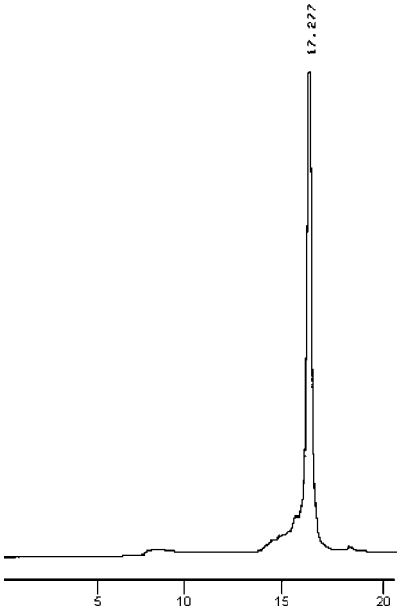

Figure 3. HPLC profile of purified oligonucleotide 3′-glycoconjugate **III** (conditions as reported in Figure 2) taken 20 days at pH 5.0.

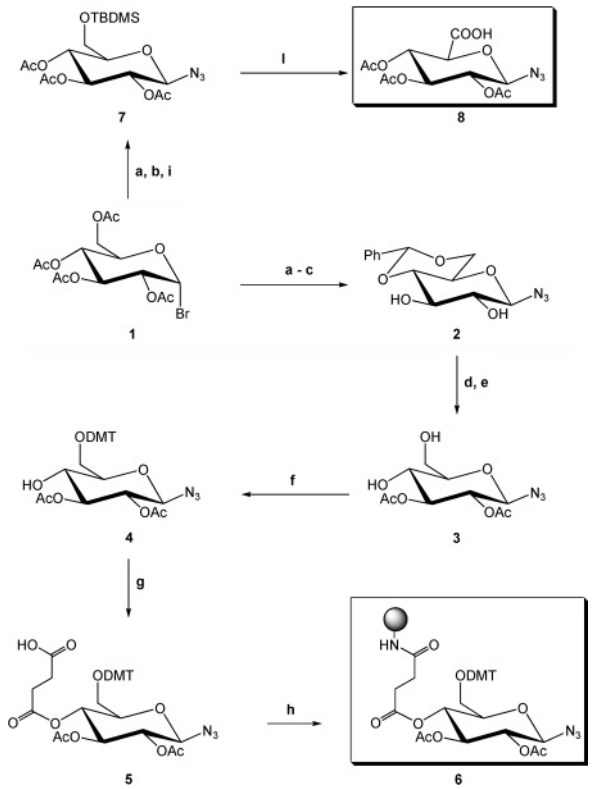
Compound **I** MALDI TOF-MS: calculated mass for $C_{190}H_{251}N_{64}O_{123}P_{18}$, 5954.06; found, *m/z* 5952.57 $(M - H)^-$.

Compound **II** MALDI TOF-MS: calculated mass for $C_{196}H_{261}N_{64}O_{128}P_{18}$, 6116.11; found, *m/z* 6113.62 $(M - H)^-$.

Compound **III** MALDI TOF-MS: calculated mass for $C_{202}H_{271}N_{64}O_{133}P_{18}$, 6278.17; found, *m/z* 6276.56 $(M - H)^-$.

Enzymatic Experiments. Glycoconjugate **III** (5.0 optical density units,OD) was incubated at 37 °C with 1.0 mL of bovine fetal serum. Small aliquots of the mixture were taken at defined time intervals, kept at 85 °C for 5 min, equilibrated at rt, and analyzed by HPLC on an analytical anion exchange column. A parallel experiment, carried out on 5.0 OD of unmodified ODN sequence d($^{5'}$GCGTGCCTCCTCACTGGC$^{3'}$), showed that the peak corresponding to the intact ODN was not apparent after 2 h, with the natural oligonucleotide completely digested to a complex mixture of 3′- and 5′-mononucleotides within 3 h. On the contrary, the peak corresponding to intact glycoconjugate **III** was not detected only after 6 h (Figure 3).

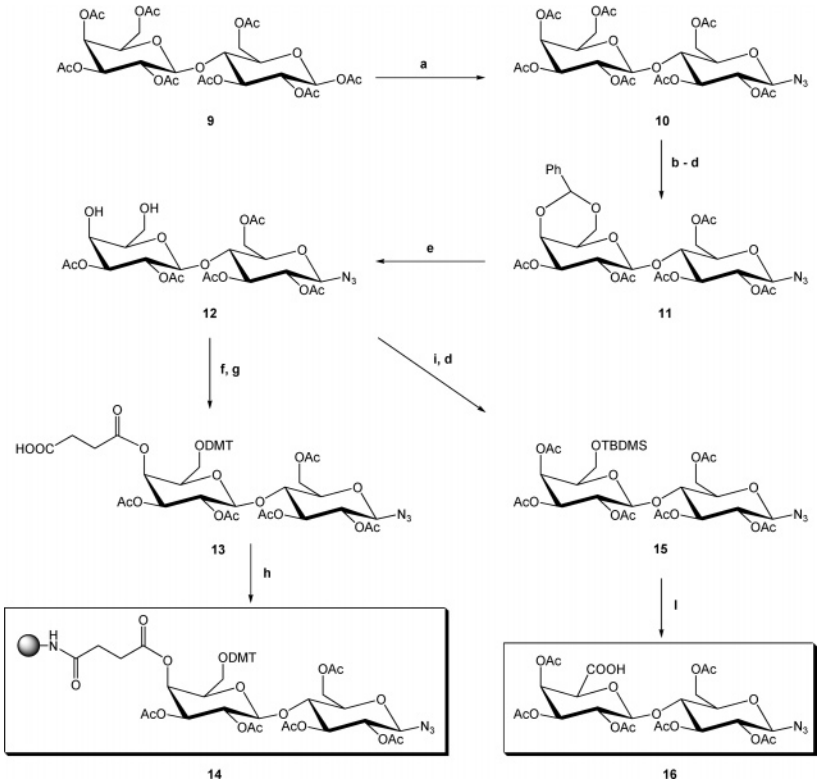
Scheme 1. Synthesis of 6 and 8



(a) NaN_3, DMF, 50 °C, 2 h, 95%; (b) 7M NH_3/CH_3OH, 50 °C, overnight, quant.; (c) PTSA, α,α-dimethoxytoluene 50 °C, 6 h, 80%; (d) Ac_2O/pyridine (2:3, v/v), rt, 30 min., quant.; (e) TFA/H_2O/DCM (1:0.5:10, v/v), 0 °C, 3 h, 90%; (f) DMTCl, DMAP, pyridine, rt, overnight, 85%; (g) succinic anhydride, DMAP, pyridine, rt, overnight, 90%; (h) Tentagel NH_2, DIPEA, DIC, HOBt, pyridine, rt, 48 h, 74%; (i) TBDMSCl, imidazole, DMF, rt, overnight, 85%; (l) Jones reagent, acetone, −15 °C to rt, 3 h, 90%.

Thermal Denaturation Experiments. The concentration of the synthesized ODNs was determined spectrophotometrically at $\lambda = 260$ nm and at 85 °C, using the molar extinction coefficient calculated for the unstacked oligonucleotide using the following extinction coefficients: 15400 (A); 11700 (G); 7300 (C); 8800 (T) cm^{-1} M^{-1} (*31*). In all cases, the contribution of the saccharidic residues to the absorbance at $\lambda = 260$ nm was considered negligible. A 100 mM NaCl, 10 mM NaH_2PO_4, aq solution at pH = 7.0 was used for the melting experiments. Melting curves were recorded using a concentration of approximately 1 μM for each strand in 1 mL of the tested solution in Teflon stoppered quartz cuvettes of 1 cm optical path length. The resulting solutions were then allowed to heat at 80 °C for 15 min, then slowly cooled and kept at 5 °C for 30 min. After thermal equilibration at 10 °C, UV absorption at $\lambda = 260$ nm was monitored as a function of the temperature, increased at a rate of 0.5 °C/min, typically in the range 20−80 °C. The melting temperatures, determined as the maxima of the first derivative of absorbance vs temperature plots, are the average values of three independent melting experiments. For all the studied cases, both the modified duplexes and the unmodified one, within the experimental error evaluated as ±0.5 °C, exhibited a melting temperature value of 60 °C.

Scheme 2. Synthesis of 14 and 16



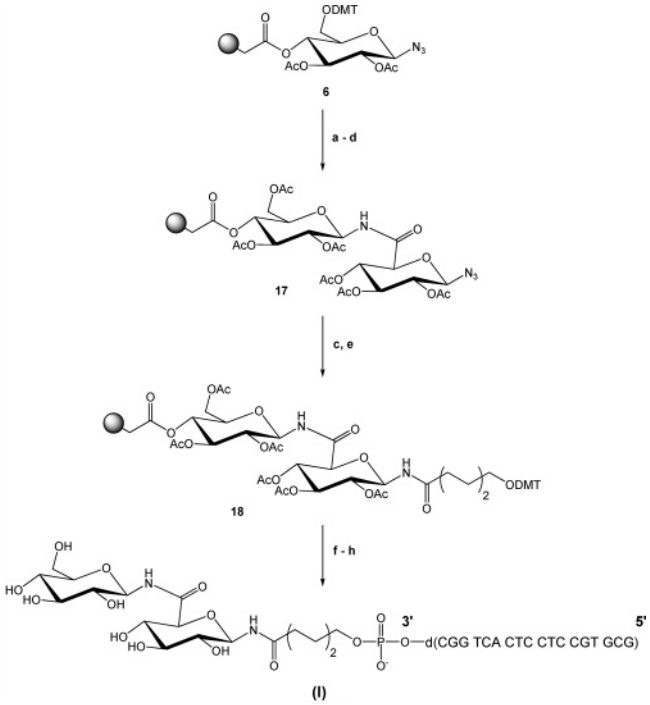
(a) $SnCl_4$, $TMSN_3$, DCM, molecular sieves, rt, 18 h, 90%; (b) 7M NH_3/CH_3OH, 50 °C, overnight, quant.; (c) PTSA, α,α-dimethoxytoluene, 50 °C, 5 h, 70%; (d) Ac_2O/pyridine (2:3, v/v), rt, 3 h, quant.; (e) TFA/H_2O/DCM (1:0.5:10, v/v), 0 °C, 3 h, 90%; (f) DMTCl, DMAP, pyridine, rt, overnight, 85%; (g) succinic anhydride, DMAP, pyridine, rt, overnight, 90%; (h) Tentagel NH_2, DIPEA, DIC, HOBt, pyridine, rt, 48 h, 70%; (i) TBDMSCl, imidazole, DMF, rt, overnight, 80%; (l) Jones reagent, acetone, −15 °C, 15 min, then rt, 3 h, 90%.

RESULTS AND DISCUSSION

In the here reported oligonucleotide hybrids, the saccharidic portion is composed of glucose- or lactose-based building blocks, chosen as model addition monomers, β-1,6-linked through amide bonds generated between the 1-amino function of the first sugar residue and the 6-COOH group of a suitably protected uronic acid derivative. The functionalization of the solid supports with the first sugar moiety and the synthesis of the building blocks are reported in Schemes 1 and 2, for glucose- and lactose-based molecules, respectively. In all cases, due to the intrinsic chemical instability of aminal functions, the building blocks are generated in the form of 1-azido derivatives. The azido group (*32*), as a masked form of a primary amine, offers several advantages: (i) it can be easily introduced; (ii) proved to be completely stable to the required chemical manipulations; and (iii) can be rapidly and in very high yields reduced to a primary amine in the solid phase immediately prior to the coupling with the selected uronic acid.

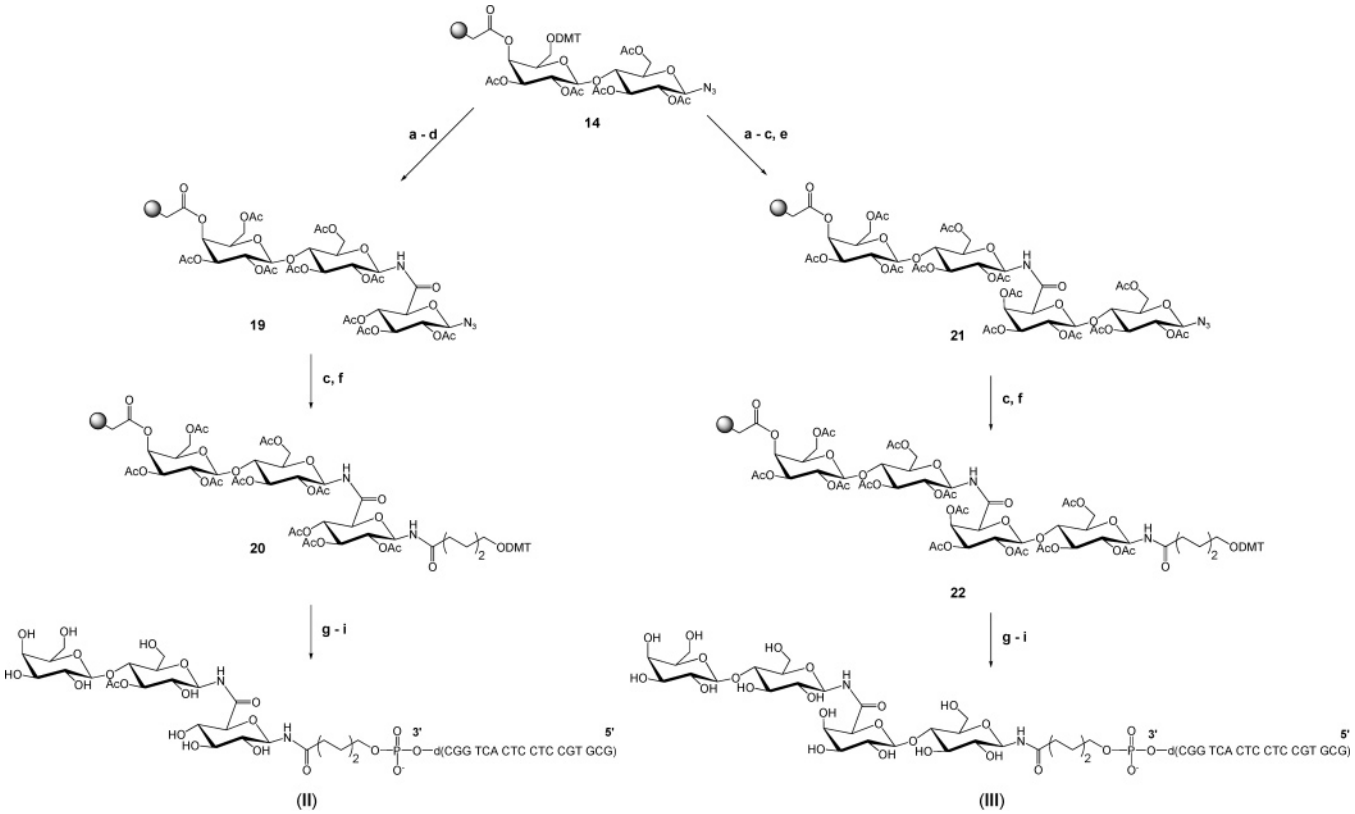
In the case of glucose derivatives, as described in Scheme 1, the β-azido group was classically inserted with an efficiency of 95% by reacting commercially available α-bromo-2,3,4,6-tetra-O-acetyl-D-glucose **1** with NaN_3 in DMF. After a methanolic ammonia treatment, β-1-azido-D-glucose, without isolation, was reacted with α,α-dimethoxytoluene in the presence of *p*-toluensulfonic acid to produce 4,6-protected derivative **2** in 80% yields. Treatment with acetic anhydride in pyridine, followed by benzylidene removal, gave compound **3** in 90% yields (for the two steps), which was then converted into derivative **4**, protected at the primary 6-OH position with the 4,4′-dimethoxytrityl group, in 85% yields. The successive reaction with succinic anhydride yielded intermediate **5** in 90% yields, which was then incorporated in the Tentagel amino solid support in the presence of DIC as

Scheme 3. Synthesis of Conjugate I



(a) 1% DCA in DCM, rt, 10 min; (b) Ac_2O/pyridine (1:1, v/v), rt, 30 min; (c) 1,3-propanedithiol, TEA, molecular sieves, DMF, rt, 2 h; (d) coupling with **8**, HATU, HOBt, DIPEA, DMF, rt, 1.5 h; (e) coupling with DMTO$(CH_2)_5$COOH, HATU, HOBt, DIPEA, DMF, rt, 1.5 h; (f) automated ODN chain assembly; (g) final DMT removal; (h) aq. NH_3, 50 °C, 6 h.

Scheme 4. Synthesis of Conjugates II and III



(a) 1% DCA in DCM, rt, 10 min; (b) Ac_2O/pyridine (1:1, v/v), rt, 30 min; (c) 1,3-propanedithiol, TEA, molecular sieves, DMF, rt, 2 h; (d) coupling with **8**, HATU, HOBt, DIPEA, DMF, rt, 1.5 h; (e) coupling with **16**, HATU, HOBt, DIPEA, DMF, rt, 1.5 h; (f) coupling with DMTO$(CH_2)_5$COOH, HATU, HOBt, DIPEA, DMF, rt, 1.5 h; (g) automated ODN chain assembly; (h) final DMT removal; (i) aq NH_3, 50 °C, 6 h.

the carboxyl activator, leading to **6**. Typically, functionalizations with the first glucose residue were in the range 0.20−0.23 meq/g, as evaluated by quantitative DMT test on weighed samples of dry resin **6**, corresponding to an average 74% incorporation yield.

The synthesis of building block **8** was achieved starting from **1**, which was first subjected, in a one-pot reaction, to NaN_3 treatment, then to deacetylation, followed by TBDMSCl addition (81% overall yields for the three steps). The obtained derivative was successively acetylated, leading to **7** in almost quantitative yields, which was then converted, by treatment with the Jones reagent, into **8** (90% yields for the two steps). Addition of sulfuric acid in pyridine caused both the TBDMS removal and the oxidation of the liberated hydroxyl group to carboxylic acid. Building block **8** had already been reported by Toth et al. (*27*), obtained from glucuronic acid in a two-step process with 73% overall yields. This synthon was exploited in the solid-phase synthesis, through standard Fmoc chemistry, of new glycosylated enkephalin analogues, containing one or two glucuronic acid residues connected at the C-terminus of the pentapeptide skeleton through amide bonds. In our strategy, compound **8** was obtained through five easy conversions, requiring only two chromatographic purifications, starting from **1** in 73% overall yield. This route, though longer, was preferred over the already published procedure, not involving the use of the aggressive and highly hygroscopic reagent tin (IV) chloride and therefore resulting in a more reproducible reaction system. **8** could be also directly obtained by oxidation of 1-azido-2,3,4-tri-O-acetyl-6-O-(4,4′-dimethoxytriphenylmethyl)-β-D-glucopyranose, but this procedure always gave an unclean reaction mixture.

To demonstrate that the here described procedure is not restricted only to monosaccharides but in principle can be easily extended to any preformed oligosaccharide, a similar protocol was developed for the synthesis of support **14**, functionalized with a β-1-azido lactose residue and the related lacturonic acid derivative **16**, to be used as the addition building block. Peracetylated lactose **9**, selected as the starting material, was first reacted with tin(IV) chloride and $TMSN_3$ in DCM, thus giving the corresponding β-1-azido derivative **10** in 90% yields. Deacetylation, followed by insertion of the benzylidene protecting group on the 4,6-OH functions of the galactose residue and then acetic anhydride treatment afforded **11** (70% yields for the three steps). TFA treatment to remove the benzylidene group yielded compound **12** with 90% yields, which was successively dimethoxytritylated on the primary hydroxyl (85% yields) and then succinylated at the free 4-OH function in 90% yields. Derivative **13** was then reacted with the Tentagel amino solid support in the presence of DIC as the condensing reagent, to afford functionalized support **14** with a typical loading of 0.20 meq/g (by DMT test).

1-Azido uronic acid **16** was synthesized from **12** in three steps, involving only one-column chromatography, and 72% overall yields. Reaction with TBDMSCl and imidazole in DMF gave a mixture of two regioisomers silylated, respectively, on the 6 and 4 positions, in 80% yields. This mixture was reacted as such with acetic anhydride in pyridine; under these conditions, the spontaneous migration of the TBDMS group from the 4- to the 6-OH position was observed, being **15** the sole obtained derivative. This compound was then treated with the Jones reagent, which afforded target compound

16 in 90% yield. In all the studied reactions, the azido group was found to be completely stable.

With the two functionalized solid supports **6** and **14** and the protected 1-azido uronic acids **8** and **16** as building blocks, the assembly of the glycomimetic domain was carried out in the solid phase, essentially following a previously reported protocol (*27*). The elongation cycle of the saccharidic portion required the following steps, based on simple and standard chemistry: (i) reduction of the 1-azido function by addition of 1,3-propanedithiol and Et_3N in DMF (*33*); (ii) coupling with the uronic acid building block **8** or **16** (10 equiv) in the presence of HATU (10 equiv), HOBt (10 equiv), and DIPEA (15 equiv) in DMF; (iii) capping by standard acetic anhydride treatment in pyridine (Schemes 3 and 4). Successively, a flexible 6-hydroxyhexanoic acid linker, protected at the hydroxy function as DMT−ether, was introduced in the solid support by exploiting the same coupling procedure described above. By quantitative DMT test on dried samples of supports **18**, **20**, and **22**, the loading of the linker was in the range 0.12−0.14 meq/g, thus indicating 65% overall yields for the whole synthetic cycle starting from **6** or **14**, with an average yield for each coupling cycle (reduction of the azide followed by amide bond formation) estimated to be not inferior to 80%. Assembly of the ODN chain could then be achieved starting from functionalized solid supports **18**, **20**, and **22** on an automated DNA synthesizer by exploiting standard phosphoramidite chemistry. Three 18-mers of sequence d(5′GCGTGCCTC-CTCACTGGC3′), differing in their saccharidic domains, were synthesized (**I**, **II**, and **III**). In all cases, DMT tests monitoring the efficiency of the ODN assembly indicated, for each coupling cycle, yields not inferior to 98%.

This ODN sequence was selected as a relevant target in antisense experiments, being complementary to a tract of mRNA of protein kinase A type 1 (PKA1), subunit RIα, which is overexpressed in the majority of human cancers. As potential therapeutic agents against neoplasia, several modifications of this sequence are currently under clinical trial (*34*, *35*).

Once completed the ODN chain assembly, detachment from the solid support and deprotection of the 3′-conjugated oligomers were achieved by treatment with concentrated aq ammonia. Purification of the detached material was carried out by HPLC on an anionic exchange Nucleogel column; HPLC profile of crude **III** is showed in Figure 2. The collected peaks were then desalted by gel filtration chromatography on a Sephadex G25 column eluted with H_2O. The isolated products were checked for purity by HPLC on an analytical RP18 column, showing all of them to be more than 98% pure. The synthesized ODNs **I**−**III** were characterized by mass analysis; in particular, MALDI-TOF MS spectra of each ODN conjugate showed a single peak in agreement with the expected molecular weight.

In a typical experiment, starting from 50 mg of support **6** or **14**, ca. 3 mg for each purified glycoconjugate **I**−**III** could be obtained, as evaluated by UV quantitation.

Samples of the functionalized supports **17**, **19**, and **21** were treated with aq ammonia and, in all cases, ^{1}H NMR analysis of the crude detached materials showed the coupling constants of the anomeric protons exclusively in the range 7.7−8.8 Hz, consistent with a β configuration, which indicates that the reducing thiol treatment on the 1-azido function, generally accepted as following a radicalic mechanism, does not affect the stereochemistry of the anomeric position.

The effect of the 3′-glycoconjugation on the chemical stability of the ODN was studied by incubating samples

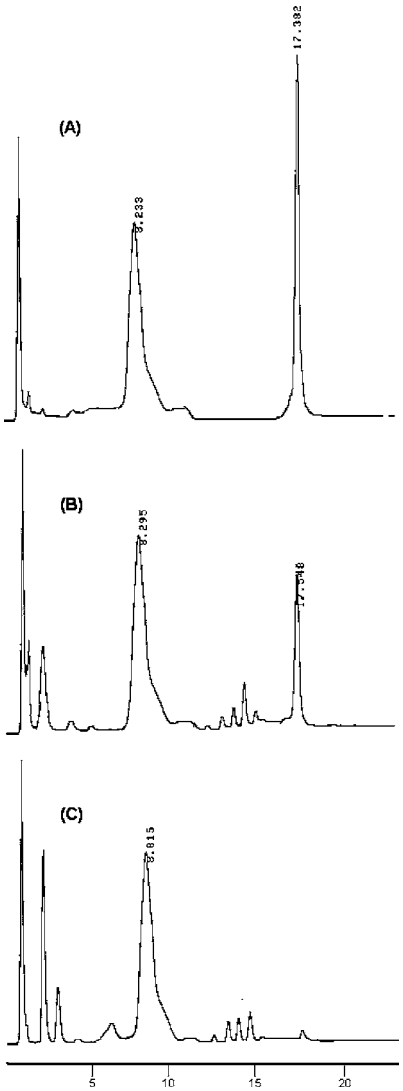


Figure 4. HPLC profiles of purified oligonucleotide 3′-glycoconjugate **III** (conditions as reported in Figure 2) treated with bovine fetal serum: panel A, aliquot of the mixture taken after 15 min; panel B, aliquot of the mixture taken after 3 h; panel C, aliquot of the mixture taken after 6 h.

of 1.0 OD of purified hybrids **I**−**III** at 37 °C with 1.0 mL of a phosphate buffer [20 mM KH_2PO_4 aq solution, containing 20% (v/v) CH_3CN] at pH values ranging from 5.0 to 9.0. In all cases, no degradation was observed even after 20 d, as judged by HPLC analysis of the treated oligomers on an analytical anionic exchange column (Figure 3). The stability of the synthesized glycoconjugates was investigated also in biological media: 3′-glycoconjugate **III** (1 OD) was incubated at 37 °C with 1 mL of bovine fetal serum and the mixture analyzed by HPLC. Total disappearance of the peak corresponding to the intact glycoconjugate was observed after 6 h (Figure 4), while the unconjugated 18-mer d(5′GCGTG-CCTCCTCACTGGC3′), treated in the same conditions for comparison, was completely degraded to a complex mixture of 3′- and 5′-mononucleotides in 3 h.

To investigate the binding affinities of the synthesized glycoconjugates with complementary DNA sequences, the UV thermal denaturation analysis of the duplex structures was carried out. Duplex formation was achieved by hybridizing oligomers **I**−**III** with equimolar amounts of the unmodified complementary 22-mer d(5′TTGCCAG-TGAGGAGGCACGCAT3′), dissolved in a 100 mM NaCl, 10 mM NaH_2PO_4, aq solution at pH = 7.0 at a final

concentration of approximately 1 μM per each strand. The melting curves of the duplexes under investigation registered at $\lambda = 260$ nm were in all cases superimposable to the one obtained in the same buffer conditions for the natural one ($T_m = 60$ °C), indicating that the recognition properties of oligonucleotide sequences were not modified upon 3′-conjugation with the here described glycomimetics.

CONCLUSIONS

We have synthesized, exploiting an online solid-phase procedure, new oligonucleotide hybrids, conjugated at the 3′-end of the chain with saccharide mimics having the O-glycosidic linkages replaced with stable 1,6-amide bonds. The key intermediate in our synthetic protocol is a suitably protected 1-azido uronic acid derivative of glucose or lactose (**8** or **16**, respectively), chosen as building blocks, in connection with the usage of Tentagel solid supports ad hoc functionalized with the first 1-azido sugar residue (**6** or **14**). To elongate the saccharidic domain, the azido function is in situ reduced to a primary amine just before the coupling step, performed on the solid support following a typical solid phase peptide synthetic protocol. After insertion of the flexible linker 6-hydroxyhexanoic acid, the oligonucleotide chain assembly was carried out by standard phosphoramidite chemistry. By exploitation of a completely automated synthetic process, three oligosaccharide−oligonucleotide hybrids were prepared and characterized by MALDI-TOF spectrometry. The presence of the saccharidic domain at the 3′-end of antisense 18-mer sequences significantly enhanced the stability of the oligonucleotides in bovine fetal serum, not negatively interfering with their ability to form stable duplexes with complementary DNA strands, as evaluated by UV thermal denaturation studies.

ACKNOWLEDGMENT

We thank MIUR (PRIN) and Regione Campania (Legge 5) for grants in support of this investigation and Centro di Metodologie Chimico-Fisiche (CIMCF), Università di Napoli "Federico II", for the NMR and MS facilities. The valuable contribution of Dr. Antonia De Capua in the initial part of the work is gratefully acknowledged.

TECHNICAL NOTES

Free Nonimmobilized Ligands as a Tool for Purification of Proteins

Guy Patchornik[†,*] and Amnon Albeck[§]

Affisink Biotechnology Ltd., 11 Hamaccabee St. Kiryat-Ono 55572, Israel, and The Julius Spokojny Bioorganic Chemistry Laboratory, Department of Chemistry, Bar-Ilan University, Ramat-Gan 52900, Israel.
Received March 28, 2005; Revised Manuscript Received July 11, 2005

Purification of proteins on a large scale is a complex multistep process, and alternative economic strategies are required. This study presents a novel approach (Affinity Sinking, AS) for purification of native proteins utilizing nonimmobilized modified ligands. The nonimmobilized state of the ligand circumvents the need for immobilizing ligands to polymeric supports. Therefore, purification from large volumes can be accomplished without the use of industrial-scale affinity columns. The mechanism of product capture is formation and precipitation of a specific [target-protein/modified-ligand] complex by using a soluble interconnecting entity that generates an insoluble [target-protein/modified-ligand/interconnecting entity] sediment containing the target protein. Rabbit IgG and two glycoproteins were purified accordingly, utilizing free avidin (as the interconnecting entity) and either desthiobiotinylated-protein A (DB-ProA) or desthiobiotinylated-concanavalin A (DB-ConA) as the modified ligand. The recovery yields for the IgG and the two glycoproteins were 80−86% and 70−75%, respectively. Target proteins are eluted from the generated pellet nearly without disrupting the [modified-ligand/interconnecting entity] macro-complex, thus enabling a practical procedure of recovering target proteins. Leaching of the DB-ProA ligand under eluting conditions (pH 3) was found to be lower than 1%. The two modified ligands, DB-ProA and DB-ConA, were regenerated without any chromatographic procedure in 80% and 85%-89% yield, respectively. The advantage of excluding the polymeric component from the purification process and obtaining highly purified proteins has been demonstrated, and it implies that other contaminants (e.g. endotoxins, prions, host DNA) could be excluded as well, thereby reducing the number of purification steps in a typical downstream process.

INTRODUCTION

There is a continuing search for alternative purification strategies capable of capturing minute amounts of target proteins from complex cell culture supernatants, plant extracts, or milk of transgenic animals containing excessive amounts of impurities (e.g. immunogenes, pyrogens, DNA, and perhaps endotoxins) (*1*, *2*). The scope of purification techniques is limited by the inherent tendency of proteins to denature in the presence of organic solvents, high temperature, or extreme pH. Therefore, low concentration of the target proteins, their fragility, and the need to cope with large amounts of complex media may have led to the fact that the least well engineered part in bioproduction processes are the purification steps (*3*), typically resulting in 50−80% of the total production cost (*4*, *5*). The largest purification factor within the multistep purification process is achieved by affinity chromatography (AC),[1] exploiting the high specific binding interaction between a ligand immobilized to a polymeric support and a protein of interest (Figure 1, A) (*6*, *7*). AC, perhaps the most widely used affinity technique at large-scale (*8*), has been used successfully in a number of biotech downstream processes, namely in the area of mammalian cell culture products (*9*).

Like any purification approach, AC suffers from several limitations at industrial scale. These include (a) careful control over column loading which generally results in formation of large volumes of dilute eluent, requiring concentration before further processing; (b) high operation and maintenance costs due to the high pressure involved and the special requirement for affinity media; (c) column fouling which prevents the use of AC during early product isolation when process streams are too crude; (d) capacity and flow rate limitations with an upper limit of 2−10 kg/day productivity for each production line; (e) limited adsorbent lifetime due to the growth of microorganisms that frequently either lead to breakdown of the column matrix or contaminate the product with unknown bacteria and their byproducts, or may even result in possible digestion of the product by the bacterial extracellular proteases; (f) implementation of harsh sanitizing protocols raise the concern of ligand degradation that may contaminate the product and decrease the capacity of the column. Therefore, a wide array of alternative affinity purification approaches has

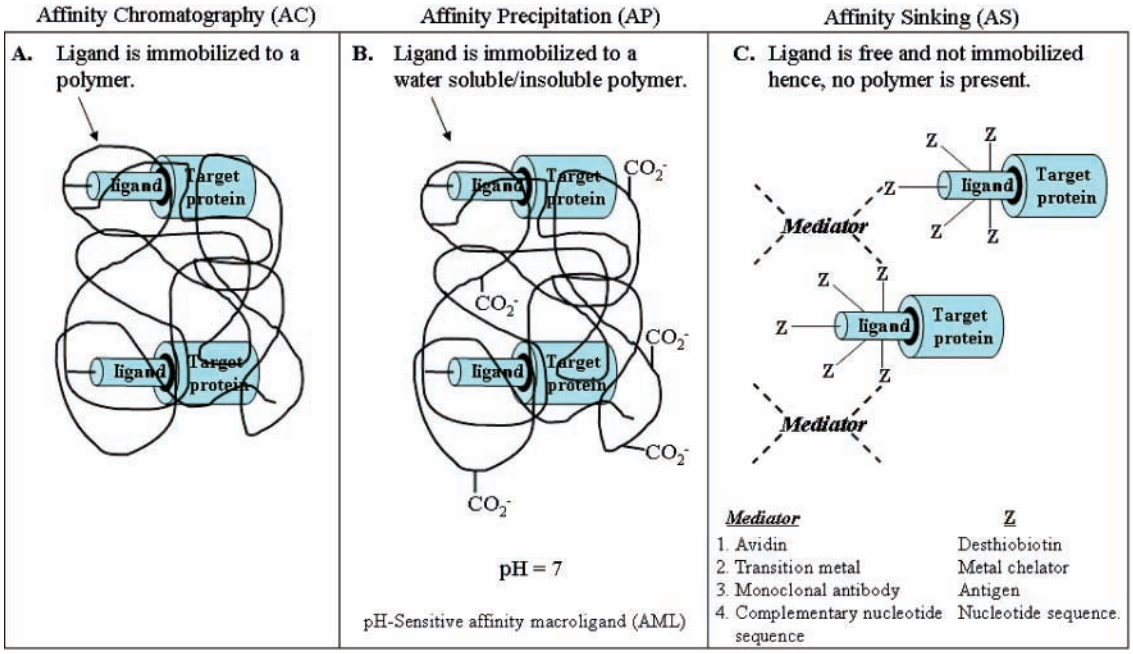

Figure 1. Comparison of the basic chemical architecture of AC, AP and AS. A. Ligands in AC are immobilized to insoluble polymeric matrixes. B. Ligands in AP are immobilized to water soluble polymers which would change reversibly to water insoluble upon a physiochemical change such as low pH. C. Ligands in AS are not immobilized but modified with a complexing entity enabling their precipitation upon addition of an appropriate mediator. Thus, no polymeric entity is present within the precipitation process and ligands are free in the medium.

been developed with the objective of meeting the unique difficulties addressed by large-scale purification (*10*−*15*).

Affinity precipitation (AP) (secondary effect), first introduced by Schneider et al. (*16*), has been postulated to become the purification technique with the highest large-scale potential (*4*, *17*−*19*). In AP, a water soluble polymer is conjugated with a specific ligand, generating an affinity macroligand (AML) (Figure 1, B). The AML forms a complex with the target molecule, which precipitates upon a critical physiochemical change in pH, temperature, or ionic strength. The target protein could then either be eluted directly from the [AML−target protein] complex or from the dissolved state of the complex under conditions which decrease the binding affinity between the AML and the target protein. The AML itself (without the target protein) is then precipitated again, leaving the target protein in the supernatant (*20*). The unique combination of specificity and precipitation features being utilized in all AP approaches has not yet led to an established downstream processing technique due to several difficulties: (a) steric hindrances induced by high molecular weight AML, limiting the access of the target molecule; (b) resolubilization of precipitated polymers was slow; (c) nonspecific adsorption and entrapment of impurities during precipitation was almost unavoidable, requiring up to three successive precipitation-resolubilization steps (*1*, *19*, *21*−*23*).

This state of affairs prompted us to develop the present specific precipitation approach, affinity sinking (AS), lacking any polymeric component and with ligands that are free in solution. Specific precipitation is obtained within two successive steps: first, the nonimmobilized modified ligand and the target protein are incubated to allow specific binding. This generates a [modified ligand−target protein] soluble complex. The latter complex is specifically precipitated by addition of an appropriate interconnecting entity (the mediator) such as free avidin that presumably forms macro networks with lower solubility properties (Figure 1, C). The approach was performed with two distinct ligands: (a) Protein A: a 42 kDa factor produced by *Staphylococcus aureus*, which specifically binds the constant region of a wide range of antibodies from various classes and therefore is extensively utilized for purification of immunoglobulins (*24*). (b) Concanavalin A: a lectin that exhibits distinct sugar specificities toward α-D-mannopyranosides, α-D-glucopyranosides, or α-*N*-acetyl-D-glucosaminides (*25*) and specifically binds glycoproteins. Both ligands were modified with desthiobiotin *N*-hydroxysuccinimidyl ester (desthiobiotin-NHS) and used for purification of rabbit IgG, porcine thyroglobulin, and glucose oxidase.

EXPERIMENTAL PROCEDURES

Materials. For SDS−PAGE, Precision plus protein standards and Gel Filtration Chromatography Standards were from Bio-Rad. All other reagents were of analytical grade. Tris (ultrapure) was from Bio-Lab, Jerusalem. Avidin, biotin, methyl α-D-glucopyranoside, concanavalin A Type IV, and EDTA were from Sigma. Porcine thyroglobulin and glucose oxidase were from GALAB Technologies GmbH, Germany. Desthiobiotin *N*-hydroxysuccinimidyl ester was from Berry & Associates, Dexter, MI. Recombinant protein A was from BioVision, Inc. (Palo Alto, CA). Rabbit IgG was from Sigma, Glucose oxidase kit was from Megazyme, Ireland.

Protein Analysis. Protein content was estimated by the method of Bradford (*26*), using bovine serum albumin as a standard.

Electrophoresis and Densitometry. Samples were loaded onto a 10% bis-Tris SDS-poly-acrylamide gel (1 mm thickness) according to Laemmli (*27*) and developed for 1 h at constant 120 V. All gels were stained with Coomassie Brilliant Blue R250, and the intensity of bands was measured by densitometry using the Scion Image program. These measurements were used for quantification of the recovery yields of the target proteins and their purity.

Preparation of Desthiobiotinylated Protein A (DB-ProA) and Desthiobiotinylated Concanavalin A (DB-ConA). Recombinant protein A or concanavalin A (ConA) were modified with desthiobiotin *N*-hydroxysuccinimidyl ester according to Bayer et al. (*28*), with a molar ratio of 4.4:1 between the desthiobiotin reagent and ConA, while protein A was modified accordingly with a molar ratio of 20:1.

Precipitation and Elution of Rabbit IgG. Precipitation was carried out at 4 °C in a medium containing: 50 mM sodium phosphate at pH 8, 0.23 mg/mL of DB-Pro A, 0.6 mg/mL rabbit IgG, and cell lysate in a total volume of 50 μL. A freshly prepared avidin solution (1.5 mg/mL final concentration) was added, and a precipitate was formed. This was followed by a short spin at 14000 rpm and removal of the supernatant. The pellet was resuspended once with 200 μL of 50 mM sodium phosphate buffer pH 8 and the supernatant discarded. To elute rabbit IgG, the pellet was further resuspended with 0.1 M sodium citrate pH 3, 0.9 M urea at 4°C for 10 min in a total volume of 50 μL with gentle agitation. After an additional spin, the supernatant was neutralized with 1 N NaOH and applied to the gel.

Regeneration of DB-ProA. Recovery of DB-Pro A was achieved by incubating the pellets in 0.1 M sodium citrate pH 3 and 5 mM of biotin at 4 °C for 10 min. A spin at 14000 rpm was performed and the supernatant was neutralized with 1 N NaOH and applied to the gel.

Precipitation of Porcine Thyroglobulin and Glucose Oxidase. Precipitations were carried out at 4 °C in a medium containing 20 mM Tris buffer pH 7.2, 3.3 mg/mL of DB-Con A, 2.2 mg/mL porcine thyroglobulin or 1.4 mg/mL glucose oxidase, and a mixture of native proteins (Biorad Gel Filtration Chromatography Standards), in a total volume of 30 μL. A freshly prepared avidin solution (3.3 mg/mL, final concentration) was then added, and a precipitate was formed. A short spin at 14 000 rpm allowed removal of the supernatant which contained the vast majority of the impurities, while the pellet was further washed by resuspending it once in 200 μL of 20 mM Tris buffer pH 7.2, and the supernatant discarded.

Elution of Porcine Thyroglobulin and Glucose Oxidase from the Pellets. Washed pellets were incubated at 4 °C for 2−5 min in a medium containing 0.1 M $NaHCO_3$ pH 7.8, 0.2 M methyl α-D-glucopyranoside (*29*), and 5 mM EDTA in a total volume of 30 μL with gentle agitation. After a short sedimentation at 14000 rpm, the supernatant of the pellet was applied to the gel.

Regeneration of DB-Con A. Recovery of DB-ConA was identical to that described above for DB-ProA.

Catalytic Activity of Glucose Oxidase. The catalytic activity of the purified glucose oxidase was studied with the glucose oxidase assay kit.

Generation of *E. coli* Lysate. BL21 bacteria harboring a pACYCDuet vector (Novagen) were grown in 4.5 L of LB medium for 2 h at 37 °C. Protein expression was induced by the addition of 0.05 mM IPTG, and the bacteria continued to grow for an additional 4 h at 15 °C. The bacteria were lysed by freeze thawing in lysis buffer (Tris 50 mM pH 8, 0.1 M NaCl, 20 mM imidazole, protease inhibitor cocktail, lysozyme, and Dnase) followed by sonication. The bacterial lysate was then centrifuged by ultracentrifugation at 40000 rpm, and the supernatant was applied to a Ni column at 4 °C. (The lysate is the flow-through from this Ni capture).

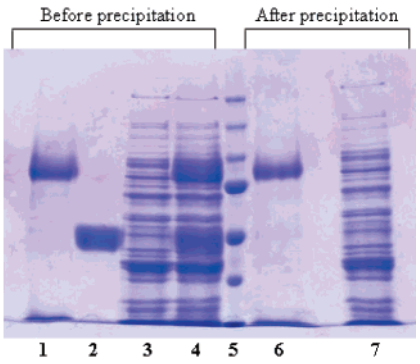

Figure 2. Purification of rabbit IgG from cell lysate, utilizing desthiobiotinylated protein A (DB-ProA) and free avidin. Lane 1 rabbit IgG; lane 2 DB-ProA; lane 3 bacterial cell lysate; lane 4 mixture of rabbit IgG, DB-ProA, and cell lysate; lane 5 Biorad prestained protein markers; lane 6 recovered IgG; lane 7 content of supernatant after specific precipitation of the IgG from the cell lysate.

RESULTS

Specific Precipitation and Elution of Target Proteins. *Rabbit IgG.* To demonstrate the selectively of the approach, rabbit IgG was purified from bacterial cell lysate. Thus, a medium containing whole cell lysate, DB-ProA, and rabbit IgG was prepared (Figure 2, lane 4). Upon addition of avidin, a precipitate was generated and the resulting pellet was washed once with 200 μL of fresh buffer. The washed pellet was further incubated under eluting conditions (0.1 M sodium citrate at pH 3, 4 °C, for 15 min), and the supernatant of the resuspended pellet was applied to the gel after being neutralized to pH 7. The recovery yield of the IgG was 85% (Figure 2, lane 6). Comparing the total amount of impurities (Figure 2, lane 3) with the amount of impurities present in the supernatant after the addition of avidin (Figure 2, lane 7) indicates that 95% were excluded from the pellet, prior to the washing step. Since no DB-ProA was observed by Coomassie staining in the eluted IgG (lane 6), the degree of leached DB-ProA was assessed by silver staining to be below 1%.

Porcine Thyroglobulin and Glucose Oxidase. Similar results, of target protein purification in high yield and high purity, were obtained for porcine thyroglobulin and glucose oxidase. In this case, the ligand was DB-ConA. The recovery yields of porcine thyroglobulin and glucose oxidase were 70−75% and the purity above 95% (by densitometry). Glucose oxidase and porcine thyroglobulin were not precipitated in the presence of native concanavalin A and avidin. The modified ligand (DB-ConA) was regenerated in 86%.

The purification data of the three target proteins are summarized in Table 1.

The Effect of Increased Background Contamination on the Purification Process. To study the effect of increased background contamination on the yield and purity of the purification process, identical amounts of rabbit IgG, avidin, and DB-ProA were added to increasing concentrations of either BSA (Figure 3, A) or cell lysate (Figure 3, B). All pellets were washed once with identical volumes of fresh buffer (200 μL) regardless of their contamination background and the IgG was eluted. The eluted IgG solutions exhibited similar purity and yield (Figure 3, A, lanes 2P−5P; B, lanes 3P-5P) whether BSA or the cell lysate served as the background contamination. Similar results were obtained with DB-ConA and the glycoproteins porcine thyroglobulin and glucose oxidase (data not shown).

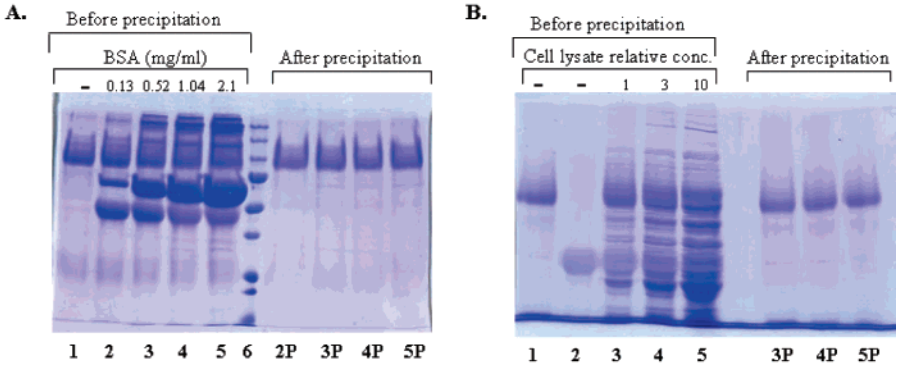

Figure 3. The effect of increased background contamination on the precipitation process. A. Lane 1 rabbit IgG; lanes 2−5 constant concentration of rabbit IgG and DB-ProA in the presence of increased BSA concentration; lane 6 Biorad prestained protein standards; lanes 2P−5P recovered IgG from pellets generated in lanes 2−5, respectively. B. Lane 1 rabbit IgG; lane 2 DB-ProA; lanes 3−5 constant concentration of rabbit IgG and DB-ProA in the presence of increased cell lysate concentration; lanes 3P−5P recovered IgG from pellets generated in lanes 3−5, respectively.

Table 1. Recovery Yields and Purity of the Target Proteins and the Modified Ligands

target protein	desthiobiotinylated ligand	recovery yield of target protein, %	purity of target protein, %	recovery yield of desthiobiotinylated ligand, %
rabbit IgG	protein A	80−86	97	80
thyroglobulin	concanavalin A	70−75	95	85−89
glucose oxidase	concanavalin A	70−75	95	85−89

Catalytic Activity of Recovered Glucose Oxidase. The purified glucose oxidase was assayed for its catalytic activity and was found to be 98 ± 3% active. This result emphasizes the mildness and lack of denaturation by the process.

DISCUSSION

It has been argued that the ideal strategy for large-scale purification of proteins would utilize a highly specific precipitation process rather than a chromatographic methodology (*4*, *19*). Therefore, we aimed at developing a simple precipitation approach (which we call affinity sinking, AS) that would lead to highly purified proteins while eliminating the need for sophisticated instrumentation (e.g. HPLC).

To the best of our knowledge, all known chromatographic and precipitation techniques require ligands covalently bound to various polymeric supports, while AS uses ligands at their free nonimmobilized state. The use of free ligands would circumvent the need for immobilizing ligands to polymers and would exclude polymers from the purification process. Figure 1 illustrates the differences in chemical architecture of well-established approaches (e.g. affinity chromatography, affinity precipitation) with that of AS. In AS, precipitation of the target protein requires two water soluble entities: a modified ligand and an interconnecting entity. The modified ligands used in this study were desthiobiotinylated protein A (DB-ProA) and desthiobiotinylated concanavalin A (DB-ConA). Incubation of the modified ligand with the target protein and addition of the interconnecting entity (free avidin) generated a precipitate, composed primarily of the [modified ligand−target protein−avidin] multicomplex (Figure 1, C). The target protein is then eluted from the generated sediment (i.e. pellet) under conditions that essentially do not dissociate the [modified ligand−avidin] multicomplex.

Since antibody purification is a major scientific and industrial need, we tested the ability of the approach to specifically capture and purify rabbit IgG from cell lysate, utilizing DB-ProA as the ligand (Figures 2 and 3). The high purity (97%) and yield (80−86%) of the recovered IgG demonstrates the feasibility of the approach. The majority of impurities are excluded from the pellet already in the precipitation step (Figure 2, lane 7), prior to the washing step. This emphasizes the advantage of the present purification approach, which lack any polymeric matrix onto which impurities would probably have been adsorbed nonspecifically.

Similar precipitation and recovery behavior was observed with a desthiobiotinylated concanavalin A derivative (DB-ConA), used for the capture of glucose oxidase and porcine thyroglobulin (Table 1). These consistent results with two distinct ligands indicate that other ligands may be similarly utilized and lead to highly purified proteins with good recovery yields. Native protein A or concanavalin A lacking bound desthiobiotin (DB) did not lead to precipitation of the target proteins (data not shown). The use of nonimmobilized ligands may raise the concern of ligand leaching. Nevertheless, leaching was not observed by Coomassie staining (Figure 2 lane 6; Figure 3, A, lanes 2P−5P, B, lanes 3P−5P). Therefore, gels were visualized by silver staining and the degree of leached DB-ProA was found to be less than 1% (data not shown). Since these values were obtained under highly acidic conditions (pH 3), one would expect lower levels of leaching under milder eluting conditions. These observations suggest that target proteins can be eluted directly from the generated precipitates, while keeping the [modified ligand−avidin] multicomplex intact in the precipitate. This feature may be advantageous for large-scale protein purification, where obtaining a relatively pure protein in high concentration by direct elution of the target protein from the pellet is a major advantage (*2*).

Furthermore, since all ligands according to AS are modified with a complexing entity (e.g. desthiobiotin, metal chelator), removal of minute amounts (<1%) of leached ligand can be accomplished by passing the sample containing primarily the eluted protein through an appropriate affinity column that would remove traces of leached modified ligand rather than the target protein. For example, a desthiobiotinylated-ligand could be re-

moved from a solution containing the target protein by an avidin column.

Generally, as background contamination increases, greater volumes of buffer are needed to remove impurities that bind nonspecifically to the polymeric matrix. Since no polymer matrix is present in AS, we postulated that a major increase in the contamination background would not affect the purity of the eluted protein. Thus, to demonstrate such a phenomenon, all pellets must be washed with minimum and identical volume of buffer, regardless of their background contamination. The results in Figure 3 (A, lanes 2P−5P; B, lanes 3P−5P) support our speculation and show that a 10- or 16-fold increase in the contamination background has no significant effect on either the purity or the yield of the target protein. Moreover, when pellets were not washed after their generation and the IgG was eluted, high purity was obtained, thus providing additional supporting data to the "nonstickiness" nature of the precipitates (data not shown). These results may imply that other contaminants (e.g. endotoxins, viruses, host DNA) could be excluded within the precipitation step, thereby reducing the number of purification steps in the downstream process.

In the preferred scenario, where the target protein has been eluted from the pellet, regeneration of the modified ligand could be accomplished by a simple dialysis procedure (which is supported by our experimental results). Since desthiobiotin has a lower association constant for biotin binding proteins ($K_a \sim 5 \times 10^{13}$ M^{-1} for streptavidin) than biotin ($K_a \sim 1 \times 10^{15}$ M^{-1}), the pellet will dissociate upon addition of biotin (*30*, *31*). Dialysis will remove excess of unbound biotin, leaving the modified ligand (DB-ProA or DB-ConA) and the [avidin-$(biotin)_4$] complex in the dialysis container. This mixture (devoid of free biotin) could be used directly in the next batch, since the free [avidin-$(biotin)_4$] complex is blocked (essentially irreversibly) with four biotins, cannot participate in network formation, and thus can be considered as an additional contaminant which will be excluded together with all impurities of the next cycle. This procedure was performed for the regeneration of both DB-ProA and DB-ConA (Table 1).

The nonimmobilized state of the modified ligand might possess additional theoretical advantages which include higher yields of purified product due to anticipated (a) faster and more efficient binding to the target protein in homogeneous solutions where no additional steric hindrances are imposed by the polymeric matrix. The nonimmobilized ligand is expected to be more available for binding, while in its immobilized state may also interact with the polymeric matrix making itself less available for binding (*1*); (b) the measured affinity of the modified ligand should represent its affinity upon use, enabling easier judgment as to the most appropriate modified ligand derivative to be utilized in a particular purification process. It has been argued that once a ligand is immobilized its affinity may be reduced by up to a factor of 1000 (*32*). Such a concern is not relevant to the present approach since no ligand immobilization is required; (c) the amount of added modified ligand to the medium is (theoretically) not limited, whereas affinity columns are characterized by their specific capacity. Therefore, more protein can be purified per batch. Additional benefits deriving from the nonimmobilized state may result in (a) higher purity of the end product due to the absence of a polymeric matrix onto which impurities can adsorb; (b) implementation of harsh sanitizing procedures without risking ligand functionality (i.e. the modified ligand can be removed from any instrumentation prior to sanitation); (c) the dramatic volume reduction within a single precipitation step would enable further purification manipulations with lab-scale machinery.

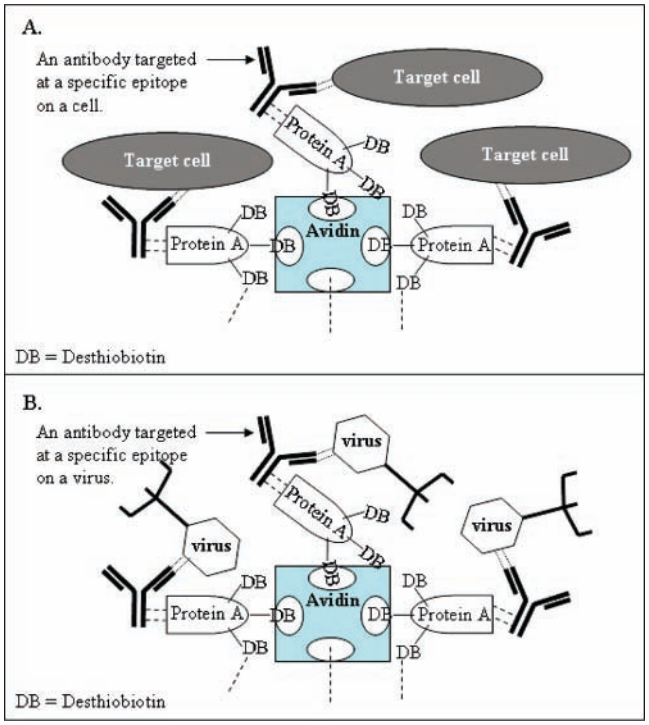

Figure 4. Schematic illustration of positive or negative cell selection (A) and virus depletion (B), utilizing a core complex composed of [DB-ProA−avidin].

A fundamental difference exists between AS and immunoprecipitation. In the latter, antibody−antigen complexes are removed from solution in the presence of an insoluble form of an antibody binding protein such as protein A or an immobilized second antibody, while in AS all components (i.e. the modified ligand and the interconnecting entity) are water soluble and are not immobilized.

Essentially, our approach does not introduce a new chemical principle but rather a different chemical architecture which could utilize any ligand, provided that specificity and affinity are preserved after ligand modification. The possibility of generating equivalent precipitates utilizing other types of modified ligands (e.g. ligand−chelator, ligand−antigen, ligand−nucleotide sequence) (Figure 1, C) emphasizes the wide scope of the presented approach. Furthermore, the [DB-ProA−avidin] complex may serve as a "core complex" for additional applications such as (a) positive/negative cell selection: target cells could be purified (or depleted) with the above "core complex" and an antibody targeted at an epitope on the target cell (Figure 4, A); (b) depletion of viruses could be performed with an antibody targeted at the virus (Figure 4, B).

CONCLUSIONS

This work presents a novel approach for simple and fast, high-yield and high-purity protein purification. It is based on nonimmobilized ligands, circumventing the use of polymeric supports. The new approach may provide an alternative route to obtain highly purified, concentrated protein preparations for crystallization trials. Its economical value for the bioseparation of therapeutics can only be assessed at industrial scales where the cost of regeneration and degree of leaching would be evaluated

together with the postulated advantages and simplicity of the process.

ACKNOWLEDGMENT

We are greatly indebted to Prof. E. Goldberg, Tufts University, for invaluable comments on the manuscript. We thank Prof. K. A. Jacobson, National Institutes of Health, for helpful suggestions.

Bioactive Thin Film of Acidic Fibroblast Growth Factor Fabricated by Layer-by-Layer Assembly

Zhengwei Mao, Lie Ma, Jie Zhou, Changyou Gao,* and Jiacong Shen

Department of Polymer Science and Engineering, Zhejiang University, Hangzhou 310027, China.
Received October 10, 2004; Revised Manuscript Received June 24, 2005

A new class of bioactive thin films using growth factors as building blocks has been fabricated via layer-by-layer assembly (LBL) technique. Acid fibroblast growth factor (aFGF) in the presence of heparin was used as negatively charged polyelectrolytes, while poly(ethyleneimine) (PEI) was chosen as a positively charged counterpart. The self-deposition process and surface morphology of the resultant multilayers were monitored and detected by UV−vis absorbance spectra, advanced contact angle measurements, and scanning force microscopy (SFM) observations. Cell culture was performed to assess the efficiency of the growth factors. The fibroblasts proliferated faster on the surface assembled with five bilayers of (aFGF/heparin)/PEI with apparent higher cytoviability than on those surfaces modified by one bilayer of (aFGF/heparin)/PEI, five bilayers of aFGF/PEI, or five bilayers of heparin/PEI, and tissue culture polystyrene. Enhanced secretion of collagen type I and interleukin 6 (IL-6) by the fibroblasts seeded on the five bilayers of (aFGF/heparin)/PEI was also verified by immunohistochemical examination. The bioactivity of the (aFGF/heparin)/PEI multilayers could be largely preserved when stored at −20 °C.

INTRODUCTION

The field of tissue engineering exploits living cells in a variety of ways to restore, maintain, or enhance tissues and organs (*1*). New developments in biomaterials, innovative cell culture technique, and newly discovered growth factors open novel avenues to engineering living tissues in vitro for fundamental research and clinical applications (*2*). Many kinds of polymers, e.g. poly(lactide) (PLA)[1] and poly(lactide-*co*-glycotide) (PLGA), have been widely used in medical fields because of manipulable properties such as biodegradability and good mechanical properties (*3*). Yet their drawbacks such as poor cytocompatibility lead to inefficiency in constructing a bioactive interface with living cells.

Layer-by-layer assembly (LBL) technique, which is based on the alternating physiosorption of oppositely charged polyelectrolytes, has been extended from fundamental studies to practical applications, in particular surface modification of biomaterials. Sequential adsorptions of anionic and cationic polyelectrolytes allow the construction of multilayer films on most types of substratum. The method has many important advantages over other techniques; for example, the assembly is based on spontaneous adsorptions and can proceed under mild conditions without involvement of harmful organic solvent, and the assembled molecular films exhibit a much larger thermal and mechanical stability and can be prepared up to hundreds of layers (*4*). Moreover, the method is valid whatever the shape and the inner structure of substratum. By this technique, many charged biopolymers including a lot of extracellular matrix (ECM) and extracellular matrix-like molecules have been incorporated for the purpose of ameliorating biocompatibility of polymers (*5*−*7*).

Growth factors, which are generally soluble signaling proteins, play an important role in tissue regeneration and differentiation. Acidic fibroblast growth factor (aFGF) is a paradigm of a group of nine closely related, multifunctional proteins known as the fibroblast growth factor family (FGFs). FGFs induce mitosis, migration, and differentiation in most mesoderm and neuroectoderm-derived cells, influence angiogenesis, and regulate various biological responses (*8*−*10*). For instance, T. Imaizumi et al. find that 1 ng/mL of human recombinant basic fibroblast growth factor (bFGF, another paradigm of FGFs) in collagen gel can accelerate the proliferation of fibroblasts and decrease the contraction of collagen fibers induced by the fibroblasts (*11*). Owing to their powerful bioactivity, the FGFs are being tested to treat surgical, burn, and periodontal tissue wounds, gastric ulcers, segmental bony defects, and ligament and spinal cord injury (*12*). Toshi Fujisato et al. observed that the composite of chondrocytes and the collagen scaffold impregnated with bFGF is very promising for cartilage reconstruction (*13*). Ichiro Ono reports that administration of bFGF at the time of wound closure significantly increases the breaking strength after a full thickness incisional wound operation (*14*).

But unfortunately, successful use of growth factors for human tissue regeneration has been notoriously difficult, since they typically have half-lives only on the order of

minutes (*15*−*17*) and may cause uncontrolled cell growth when overdosed, as that which occurs in carcinoma (*18*, *19*). To prolong the lives of growth factors and decrease their side effects, alot of controlled release systems for growth factors including microspheres, hydrogels, and matrixes have been widely explored in tissue engineering. Katsuya Kawai et al. reported that bFGF incorporated in gelatin microspheres is gradually released in artificial dermis, which exhibits a remarkably enhanced angiogenic effect to that of free bFGF (*20*). Xanthe M. Lam et al. encapsulated insulin-like growth factor-I in PLGA microspheres. The growth factor maintains its bioactivity and can be sustained release for up to 14 days in vivo (*21*).

The heparin family is nearly ubiquitous in animal tissues as heparan sulfate proteoglycans on cell surfaces and in ECM. They possess a linear anionic polysaccharide chain and are typically heterogeneously sulfated on alternating L-iduronic acid and D-glucosamino sugars. Recently, Ram Sasisekharan et al. reported that the activation and protection of FGFs requires heparin-like molecules (*22*). Heparin and aFGF can form a complex in solution even at ultralow concentrations (~pmol/L). Both the life and bioactivity of aFGF are improved in the complex. J. Feijen et al. immobilized heparin on collagen matrixes for the loading of bFGF. The incorporated bFGF exhibited sustained release over a prolonged period of time (*23*). Yoshihiro Ito et al. built micropattern-immobilized heparin for guiding cell growth. After treatment in FGF solution, they found that mouse fibroblasts have enhanced bioactivity on the heparin-immobilized regions (*24*).

Herein, we intend to extend the LBL technique to build a new class of bioactive thin films by using growth factors as building blocks. aFGF with the protection of heparin is used as a negatively charged polyelectrolyte, while poly(ethyleneimine) (PEI) is chosen as the positively charged counterpart. Culture of fibroblasts in vitro demonstrates that the activity of aFGF in multilayers is largely preserved in the presence of heparin. This would provide a new strategy to immobilize cell growth factors in a more controllable manner, for example, the amount, stability, and durability of the growth factors. Because the charge interaction is nonspecific and not restricted to the macroscopic shape of the substratum, this method can also be extended to tissue regeneration scaffolds with porous and/or irregular inner structure.

EXPERIMENTAL SECTION

Materials. Acidic fibroblast growth factor (aFGF, M_w =16 000, 3 mg/mL, in phosphate buffer solution) was kindly donated by Wanxing Bio-Pharmaceutical Co., Ltd. China. Poly(ethyleneimine) (PEI, M_w = 750 000, 50 wt %) and heparin (sodium salt) were purchased from Sigma-Aldrich. All the chemicals were used as received. Triple distilled water was used throughout the experiments.

aFGF (0.2 mg/mL) and PEI (1 mg/mL) were labeled with 1 mg/mL fluorescein isothiocyanate (FITC, Sigma) at 4 °C for 48 h, followed by dialysis with water for 4 weeks. To label the heparin molecules with FITC, hexamethylenediamine (HMDA) was first coupled to introduce active amino groups. For this to occur, 1 mg/mL heparin was reacted with 1 mg/mL HMDA (heparin: HMDA = 1:100 mol) in 20 mM/10 mM 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC) and *N*-hydroxysuccinimide (NHS) solution for 24 h, followed by dialysis with water for 1 week to obtain aminolyzed heparin, which was then labeled with FITC similarly to that of PEI.

Multilayer Preparation. Multilayer thin films were deposited on a tissue culture polystyrene (TCPS) (Nunc, Denmark) sheet. The sheet was incubated in PEI solution (1 mg/mL with 0.15 M NaCl) for 20 min to adsorb a layer of PEI and then rinsed with phosphate buffer (PBS) three times. In the next step, the surface charge of the sheet was reversed by the adsorption of a layer of aFGF/heparin mixture (aFGF 0.2 mg/mL and heparin 0.4 mg/mL in PBS), followed by rinsing with PBS three times. Repeating this cycle produced self-organized multilayer films.

Characterization of the Multilayers. UV−vis spectra were measured on a UV−visible spectrophotometer (CARY 100 BIO, America). Water contact angle was measured at room temperature using a sessile drop technique on a DSA10-MK2 contact angle measuring system from Krüss. Advancing contact angle was measured to reveal the surface wettability. Before the measurement, all the samples were dried at 25 °C under reduced pressure overnight and then were equilibrated in ambient air for 1 day. The scanning force microscopy (SFM) image was obtained on a scanning probe microscope (SPA400, Seiko) in a dynamic mode.

Human Fibroblasts Culture. The human fibroblasts were isolated from foreskins (*25*) and routinely cultured on TCPS. The cells of 5−10 passages were then seeded on the TCPS wells assembled previously with (aFGF/heparin)/PEI multilayers, heparin/PEI multilayers, and aFGF/PEI multilayers as well as on the blank TCPS. The fibroblasts were incubated in a culture medium consisting of 10% (v/v) fetal calf serum (FCS, Sijiqing Biotech.Co., China) and 90% (v/v) DMEM (Gibcobrl Co.) supplemented with 100 units/mL of penicillin and 100 μg/mL of streptomycin in humidified air containing 5% CO_2 at 37 °C. The culture medium was changed every 2 days. The cell numbers were averaged from three parallel measurements by trypsinization of the fibroblasts and counting the cell number under a hemocytometer at every 2 days, respectively. The cell viability was measured using methylthiazoletetrazolium (MTT) method according to refs (*26*, *27*). The absorbance that has a proportional relationship with the number of living cells and cell viability is recorded at a wavelength of 570 nm. To observe the cell morphology under confocal laser scanning microscopy (CLSM, Bio-Rad 2100), the fibroblasts were stained with 5 μg/mL fluorescein diacetate (FDA, Aldrich) solution in the incubator for 15 min after being cultured for 8 days. Each value was averaged from three parallel experiments and expressed as mean±standard deviation.

Measurement of Secreted Collagen Type I. After being cultured for 10 days, the fibroblasts were fixed with 4% paraformaldehyde/PBS solution for 30 min at room temperature, followed by five washings with PBS. Then they were challenged with rabbit polyclonal antibodies against human type I collagen (The immunoreagents were purchased from Zhongshan Golden Bridge Co., Ltd., Beijing, China) overnight at 4 °C. After washing with PBS, poly-HRP anti-mouse/rabbit IgG detection system was used to stain collagen type I (brown color). After rinsing with PBS, the specimens were observed under a microscope. Negative controls of the same specimen were incubated with rabbit normal serum or directly reacted with poly-HRP anti-mouse/rabbit IgG detection system in the absence of primary antibody, and then they were processed as outlined above (*28*). No positive immunoreactivity was found in these negative controls.

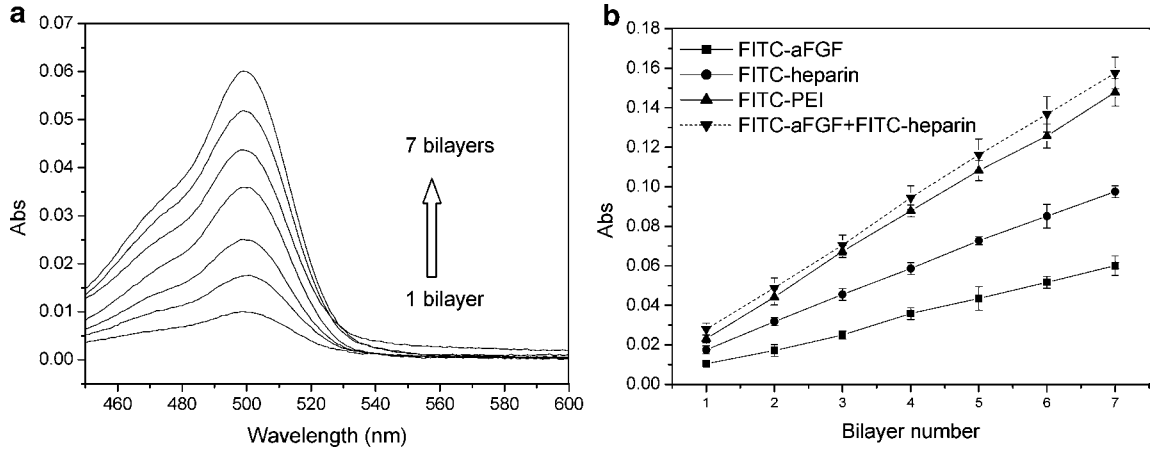

Figure 1. (a) UV−vis spectra of FITC-aFGF to show the layer growth process of (aFGF/heparin)/PEI multilayers. (b) Absorbance maximum at 490 nm to show the linear increase of layer thickness. The multilayers were deposited directly onto TCPS surfaces. For detail, see the text.

Measurement of Released Interleukin 6. Secretion of the interleukin 6 (IL-6) was measured in the supernatant of the cultured fibroblasts by IL-6 enzyme linked immunosorbent assay (ELISA, The Fourth Military Medical University, Xi'an, China). Spectrophotometric readings were performed at 405 nm. For detail measuring process, see refs 29 and 30. Final results were obtained by comparison with a standard curve constructed using dilutions of standard human IL-6. Each value was averaged from three parallel experiments.

The Stability of the Multilayers. Multilayer thin films deposited on the TCPS sheet were incubated in PBS at 37 °C. The normalized maximum absorbance at 490 nm was plotted as a function of incubation time to approximately depict the reservation of the building blocks. Each value was averaged from three parallel experiments.

Evaluation of Multilayer Activity after Storage. Five bilayers of (aFGF/heparin)/PEI were built on TCPS and then were incubated in culture medium at 37 °C for 24 h or 48 h, or stored at −20 °C for 3 months. Fibroblast cultures were similarly performed and evaluated as described above. Each value was averaged from three parallel experiments.

RESULTS AND DISCUSSION

Monitoring the LBL Deposition Process. In each LBL assembly, one of the normal aFGF, heparin, or PEI was substituted by a FITC-labeled counterpart for the purpose of monitoring layer growth by UV−vis spectroscopy. Total of three kinds of multilayer films were assembled with only one labeling component in each film. The spectra of all the multilayers exhibit a maximum absorbance at 490 nm arising from the fluorescein groups (Figure 1a). The maximum absorbance of all the labeled components increased linearly along with the increase of layer number (Figure 1b), demonstrating the homogeneous growth of the layer thickness or the total amount of the building blocks. Interestingly, the slopes of each component are different, with PEI being the sharpest and aFGF being the flattest. This would mean that the ratio of heparin to aFGF in the multilayers increased along with the layer number, e.g. more heparin will be incorporated into the multilayers compared with aFGF. However, this would not mean that the relative amount of PEI in each layer is larger than that of the negative components, since it equilibrates with both negative building blocks. Theoretically, the total absorbance of the negative layer can be derived from the summary of the corresponding value of heparin and aFGF, since the multilayers are assembled under identical conditions. The summarized values (dashed line in Figure 1b) indeed exhibit the same slope as that of the polycation, demonstrating the steady increase of both positive and negative layer thickness. The reason the relative mass of heparin increased faster than aFGF is not very clear at present. One possible reason is that the stronger charge property of heparin arises from its sulfate groups.

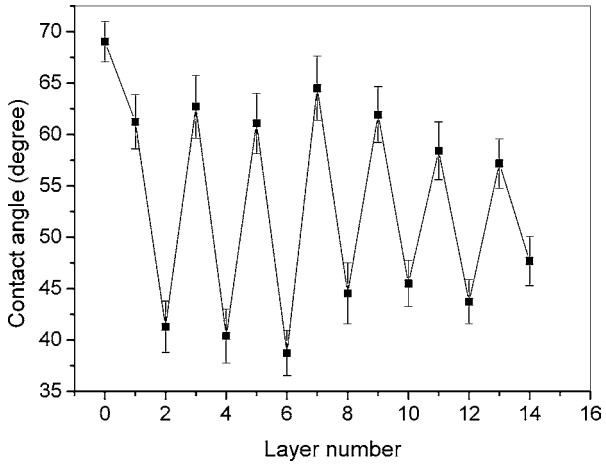

Figure 2. Advancing contact angle as a function of the layer number of (aFGF/heparin)/PEI multilayers. Odd numbers represent films with PEI as the outermost layer, whereas even number films have aFGF/heparin as the outermost layer.

The surface wettability of the sequentially layered PEI and aFGF/heparin as a function of layer number (Figure 2) also confirmed the occurrence of LBL assembly. The measurement of contact angle has been widely employed to diagnose the surface chemistry of synthesized surfaces such as a self-assembled monolayer. The surface wettability measured by an advancing contact angle is controlled primarily by the outermost layer if the layer is uniform (*31*, *32*). Thus, it is possible to monitor the deposition process by determining how surface wettability changes in a LBL manner. In the present case, samples with an odd number of layers have PEI as the outermost layer, whereas samples with an even number of layers have aFGF/heparin as the outermost layer. The advancing contact angle of the raw TCPS sheet was determined to be 69.1°. Figure 2 shows that the contact angles of the (aFGF/heparin)/PEI multilayers displayed

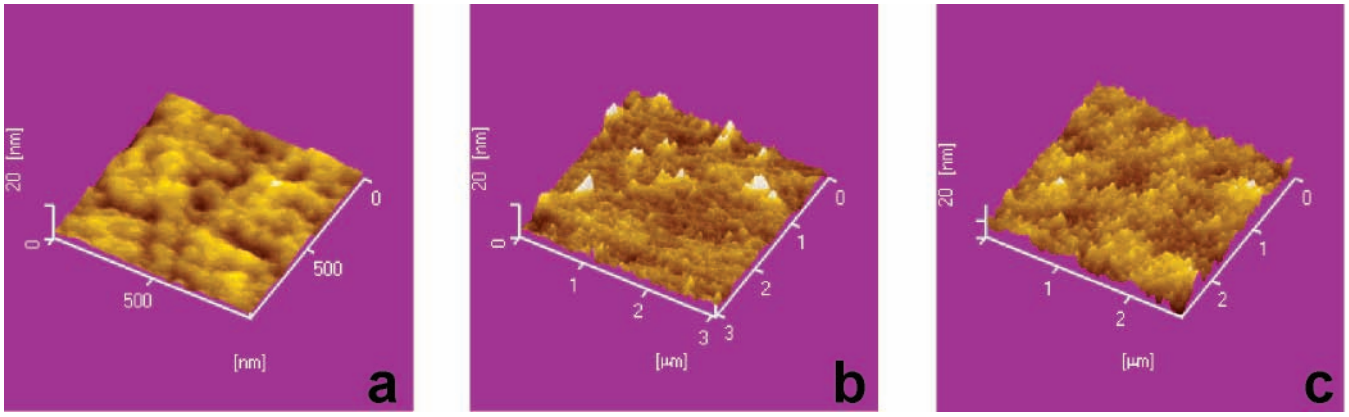

Figure 3. SFM images of (a) the TCPS surface, (b) deposited by one bilayer of (aFGF/heparin)/PEI and (c) by five bilayers of (aFGF/heparin)/PEI.

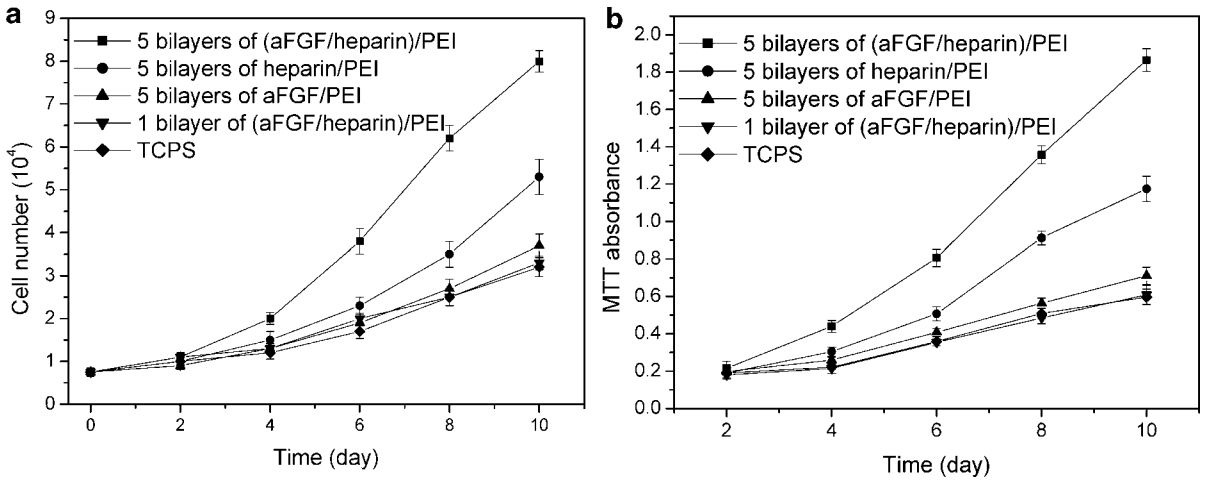

Figure 4. (a) Fibroblast proliferation and (b) cell viability seeded on multilayers (PEI being the outmost layers) or TCPS control.

a distinct oscillation as the outermost layer changed from PEI to aFGF/heparin, demonstrating the increased hydrophilicity of samples having aFGF/heparin as the outermost layer than that with PEI. However, the same outermost layer did not present the same contact angle. There was some fluctuation in a range of about 3−7°. This might be caused by the layer interpenetration between neighboring PEI and aFGF/heparin layers where the segments of the underlying layer are able to influence the surface hydrophilicity (*32*). It is worth noting that a more hydrophobic surface was found when heparin was partially substituted by aFGF, since a contact angle of 42° was measured for (aFGF/heparin)/PEI multilayers (the outmost layer is aFGF/heparin) and 28° for PEI/heparin multilayers (the outmost layer is heparin), respectively (*33*). This should be caused by the fact that aFGF is comparatively more hydrophobic than heparin.

It is known that the surface morphology of biomaterials also has a big influence on cell attachment, proliferation, and function in addition to the surface chemistry. Figure 3 shows that there exist minimal fluctuations on both the TCPS and the multilayer surface, which are in the range of nanometers as revealed by the roughness (RMS) measurements. The RMS increased from 1.38 nm (TCPS) to 1.90 nm (one bilayer) and to 4.52 nm (five bilayers). Some aggregates appeared on the first bilayer (Figure 3b), while some holes in a range of nanometers could be visualized after deposition of five bilayers (Figure 3c). This would mean that defects were formed either during layer assembly or drying process, or both. Yet compared with the fluctuation of the original TCPS, the alteration of the surface morphology after multilayer deposition is rather minimal. It is worth noting that these images measured in the dry state could only reflect the surface morphology to some extent, since multilayer swelling cannot be avoided in hydrated state, e.g. in the cell culture medium.

Cell Response to the (aFGF/Heparin)/PEI Multilayers. The aFGF built in the multilayers provides the possibility of promoting the mitosis of cells and inducing a series of signal pathways. Exemplified here with human fibroblasts, the cell culture results indeed showed a more positive cell response to the aFGF-assembled films in the presence of heparin (Figure 4). Both the cell proliferation ratio and the viability were substantially improved on the surface assembled with five bilayers of (aFGF/heparin)/PEI (with PEI being the outmost layer if not otherwise indicated), especially at longer culture time, while the multilayers composed of five bilayers of heparin/PEI exhibited somewhat improvement of cell proliferation and viability. On the other hand, during all the culture time no significant difference was found between the surfaces modified with five bilayers of aFGF/PEI, one bilayer (aFGF/heparin)/PEI, and an unmodified one, i.e., TCPS control.

The results that no difference was found between the aFGF/PEI and TCPS control would mean that the aFGF had lost its effect upon being assembled into the multilayers, which most possibly caused by the denaturation of aFGF or tight bonding (see below). Therefore, a strategy to ensure its bioactivity should be adopted during the LBL assembly process. We used here the heparin as a co-building block with aFGF. In the presence of heparin (*22*−*24*), the aFGF could actually act on the

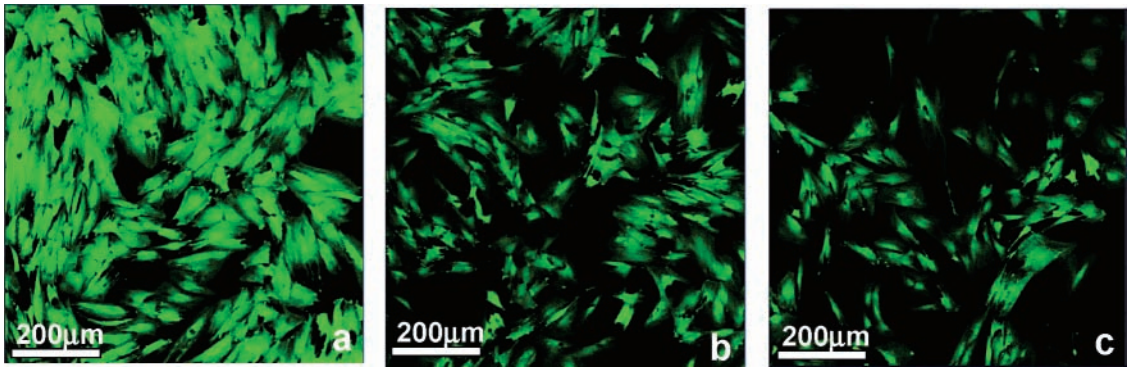

Figure 5. The morphology of fibroblasts observed under CLSM after being cultured for 8 days and stained with FDA. (a) Deposited by five bilayers of (aFGF/heparin)/PEI, (b) deposited by five bilayers of heparin/PEI, and (c) TCPS control.

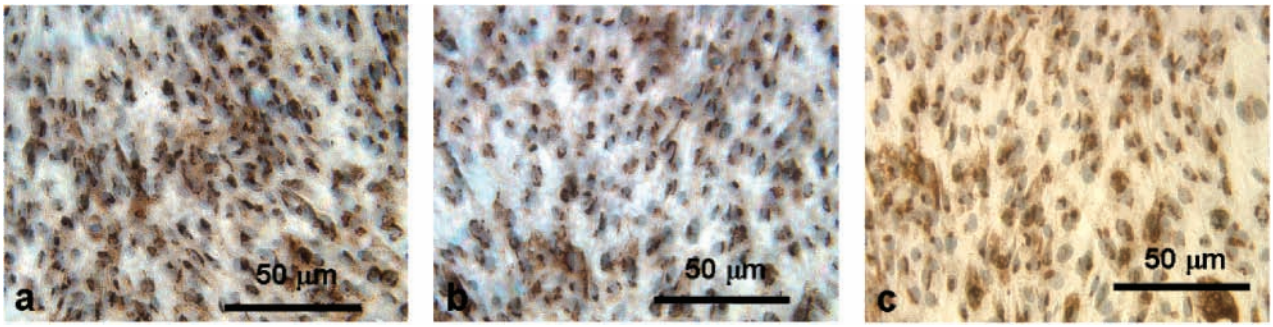

Figure 6. The immunohistorical stain of collagen type I secreted by fibroblasts after cultured for 8 days. (a) Deposited by five bilayers of (aFGF/heparin)/PEI, (b) deposited by five bilayers of heparin/PEI, and (c) TCPS control.

fibroblasts as shown in Figure 4. It is worth noting that PEI has similar ability to support cell attachment and growth as TCPS since no difference was observed for PEI-covered TCPS and TCPS control in our results (data not shown).

At the first 2 days, the fibroblasts cultured on five bilayers of (aFGF/heparin)/PEI did not show apparent difference with others in terms of cell number and viability. This may attribute to the facts that it takes 12 to 20 h for the fibroblasts to attach and spread on the culture substrate, and the main function of aFGF is inducing cell mitosis rather than cell attachment and spread. At longer culture time, the aFGF can then act on the fibroblasts to yield a higher proliferation ratio and viability than others. The fibroblasts cultured on five bilayers of (aFGF/heparin)/PEI for 10 days eventually reached 2.5 times the cell number and 3.1 times the MTT absorbance than that of TCPS control, respectively.

However, aFGF in only one bilayer of (aFGF/heparin)/PEI had not shown an effect on acceleration of fibroblast growth. This is attributed to the minimal amount of aFGF that existed on the material surface, leading to no obvious effect on the cells.

The fibroblasts cultured on the heparin/PEI multilayers also presented a higher proliferation ratio and viability. Heparin is also a kind of active factor which can stimulate cell proliferation at low concentration (*9*).

Observed under CLSM after culturing for 8 days, all the fibroblasts were spread well with their typical shapes. The cells on the five bilayers of (aFGF/heparin)/PEI displayed the highest density, and most of them reached confluence (Figure 5). Hence, one can conclude that the fibroblasts presented a larger number, higher viability, and normal morphology on the surface modified with five bilayers of (aFGF/heparin)/PEI than those on the heparin/PEI multilayers and TCPS control.

A regulated synthesis of interstitial collagens, the most abundant being type I collagen, is important during development and wound healing but also in a number of pathological conditions. Studies on these diseases as well as various in vitro models have shown that collagen synthesis and deposition are influenced by cytokines, growth factors, and mechanical tension (*34*, *35*). aFGF is one of the important regulatory factors for collagen synthesis in cultured fibroblasts. In the present case, human collagen type I (brown color, Figure 6) secreted by fibroblasts on all the substrates existed in the extracelluar matrix, in the cytoplasm, and in the nucleus. However, fibroblasts on the five bilayers of (aFGF/heparin)/PEI obviously secreted the greatest extent of collagen type I (Figure 6a), proving that aFGF built in the multilayers in the presence of heparin can stimulate the synthesis of collagen type I in fibroblasts.

aFGF not only induces fibroblast proliferation and influences collagen synthesis, but also acts as a multifunctional regulator of other water soluble factors such as interleukins (ILs), platelet-derived growth factor (PDGF), tumor necrosis factors (TNFs), and transforming growth factors (TGFs), etc. (*36*). Interleukin 6 (IL-6) which can be produced by human fibroblasts is a molecule that has both proinflammatory and antiinflammatory function, a modulator of bone resorption, a promoter of hematopoiesis, and an inducer of plasma cell development (*37*). Figure 7 shows that at first 4 days, fibroblasts on the surface covered by five bilayers of (aFGF/heparin)/PEI produced 2.9 times IL-6 of others. This value decreased to 1.3 at a still longer culture time. This is attributed to the limited life of aFGF which is only a few days in vitro/in vivo even stabilized by heparin. Although heparin can accelerate cell proliferation, very similar IL-6 secretion level was determined on both surfaces of heparin/PEI multilayers and unmodified TCPS, implying that heparin cannot stimulate the synthesis of IL-6 in human fibroblasts.

The (Bio)stability of the Multilayers. The stability of the multilayers in the culture conditions takes an

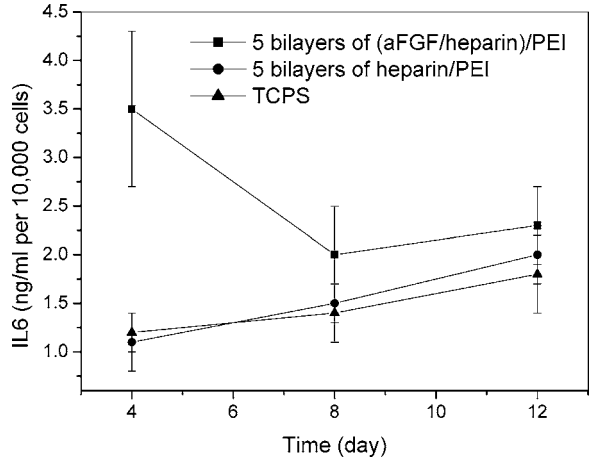

Figure 7. The IL-6 secretion of fibroblasts cultured on TCPS assembled with five bilayers of (aFGF/heparin)/PEI, five bilayers of heparin/PEI, or TCPS control.

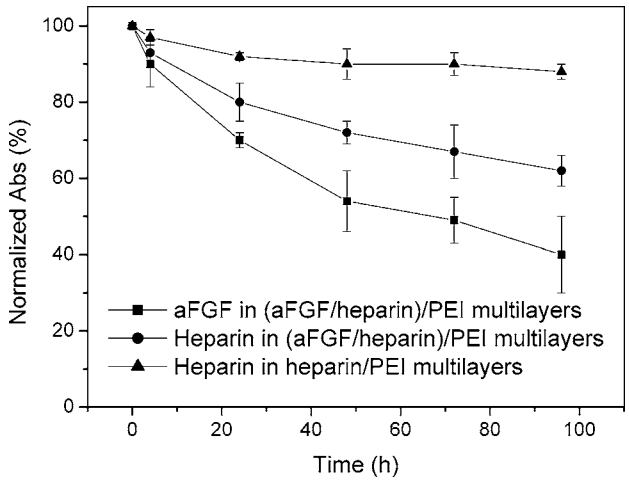

Figure 8. The normalized Abs as a function of incubation time in PBS at 37 °C.

important role in retaining their function. The multilayers were incubated in PBS at 37 °C to mimic the culture conditions. Figure 8 shows that the absorbance of the multilayers was reduced gradually as a function of incubation time, revealing that aFGF and heparin were released into the solution. For example, approximately 46% aFGF and 28% heparin had been released from the (aFGF/heparin)/PEI multilayers after incubated for 48 h, respectively. By contrast, heparin in heparin/PEI multilayers was rather stable. This proved that the structure of the (aFGF/heparin)/PEI multilayers was largely destroyed in a few days. As PEI/heparin multilayers were stable over several weeks (*33*), the damage of the (aFGF/heparin)/PEI multilayers must be caused by the introduction of aFGF. Therefore, this instability should be reasonably caused by the weak binding strength of PEI and aFGF/heparin complex. Consequently, the multilayers may swell in the buffer to enable the release of the building blocks, noting that hydrolysis of the biomacromolecules might also have partial contribution.

Hence, suitable storage is of practical importance since the materials may not be used immediately in many cases. Several storage conditions were determined with respect to bioactivity reservation. Figure 9 shows that stored at −20 °C even for 3 months the fibroblasts on the multilayers still behaved like those on the freshly made substrate, although a limited decrease in proliferation ratio and viability was detected. This result indicates that −20 °C is a suitable storage condition to keep the activity of the thin films. However, when the multilayers were incubated in vitro for 24 h, the activity largely decreased. A still longer incubation, e.g. for 48 h, had deteriorated the bioactivity dramatically, whose value was even lower than freshly made heparin/PEI multilayers. Besides the partial dissociation of the bioactive components from the multilayers, the denaturing of the native factors may also be one important reason.

CONCLUSIONS

We show here that the bioactive aFGF has been successfully deposited onto the TCPS sheet surface in the presence of heparin via a layer-by-layer manner. The aFGF built in the multilayers obviously enhances fibroblast proliferation and viability and regulates the secretion of collagen type I and IL-6. The bioactivity of the multilayers can be largely preserved when stored at −20 °C even for 3 months, while being diminished in vitro after a few days. In conclusion, herein a practical and simple technique has been provided to immobilize bioactive growth factors on a material surface with preserved bioactivity.

An Efficient Synthesis of a Heterobifunctional Coupling Agent

Rajarathnam E. Reddy,* Yon-Yih Chen, Donald D. Johnson, Gangamani S. Beligere, Sushil D. Rege, You Pan, and John K. Thottathil

Core R&D Chemistry Group (Department 09MD, Building AP20), Diagnostics Division, Abbott Laboratories, 100 Abbott Park Road, Abbott Park, Illinois 60064-6016. Received October 18, 2004; Revised Manuscript Received June 8, 2005

An efficient synthesis of 4-[(2,5-dioxo-2,5-dihydro-1*H*-pyrrol-1-yl)methyl]-*N*-(6-{[6-({6-[(2,5-dioxopyrrolidin-1-yl)oxy]-6-oxohexyl}amino)-6-oxohexyl]amino}-6-oxohexyl)cyclohexanecarboxamide (**12**), a heterobifunctional coupling agent, was developed, which is critical for chemoselective conjugation of proteins and enzymes. The synthesis involved seven steps starting from 6-{[(benzyloxy)carbonyl]-amino}hexanoic acid (**1**), and multigram quantities of coupling agent (**12**) were prepared using this protocol in excellent overall yield and 99.6% purity by reversed phase HPLC. The new method is suitable for the synthesis of coupling agent **12**, consistently with purity >99%, and is useful for the preparation of other analogous coupling agents.

INTRODUCTION

Recent advances in the field of bioconjugate chemistry have spurred the construction of biomolecules based on chemoselective coupling for a variety of applications (*1*−*3*). The native physical properties of the protein and enzyme components are typically preserved in the resulting conjugate, when the coupling is carried out under the selective conditions (*3*−*6*). Use of such well-defined conjugates for applications in biology and medical fields is critical for implementation of quality control as well as for reliable interpretation of biological results (*7*). Heterobifunctional coupling agents containing reactive groups, such as succinimidyl ester and maleimide, are important for cross-coupling of proteins and enzymes. The succinimidyl active ester can be chemoselectively reacted with an amine on one protein, and the resulting adduct can then be conjugated to the second unit, e.g., protein or enzyme, containing a thiol via the maleimide group present in linking agent. This controlled conjugation process is quite selective when compared to other groups, e.g., iodoacetyl group, and can be carried out at physiological pH.

Bieniarz and co-workers (*8*) have described the synthesis of four heterobifunctional reagents with varying lengths, e.g., 9, 16, 23, and 30 atoms long, and their application for the preparation of alkaline phosphatase conjugates, in a α-fetoprotein assay. They observed that the antibody−alkaline phosphatase conjugate prepared using the coupling agent with 30-atom long **12** gave 300% enhancement in the signal, when compared to the conjugate prepared with the corresponding 9-atom long analogue. The observed differences in performance of the conjugates was attributed to the improved antibody binding and lowered steric hindrance to the complementarity-determined region of the antibody, when a 30-atom long coupling agent (**12**) was used (*8*). Subsequently, the coupling agent **12** was found to be critical in the preparation of antibody−alkaline phosphatase conjugates for applications in the development of clinical assays, such as thyroid stimulating hormone (TSH) (*9*), prostate specific antigen (PSA) (*10*), troponin-1 (*11*), and progesterone (*12*), as well as in the preparation of thermally stabilized immunoconjugates (*13*).

However, the synthetic protocol described for the preparation of heterobifunctional coupling agent **12** is not practical and produced the material in very low overall yield (0.16−2.5%) (*8*). In addition, the quality of coupling agent **12** was varied significantly from batch to batch, ranging from 89 to 98% purity, as determined by analytical reversed phased HPLC method. We needed gram quantities of a good and consistent quality of coupling agent **12**, to prepare protein−enzyme conjugates, useful for diagnostic and medical applications. In this paper, we describe an efficient and convenient method for the preparation of heterobifunctional coupling agent **12**.

EXPERIMENTAL SECTION

General Methods and Materials. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury Plus 400 spectrometer with an Oxford AS400 magnet. The chemical shifts (δ) were reported in ppm relative to TMS, and coupling constants (J) were reported in hertz. Electrospray ionization mass spectrometry (ESI-MS) was carried out on a Perkin-Elmer (Norwalk, CT) Sciex API 100 benchtop system employing a Turbo Ionspray ion source. All chemicals were purchased either from Aldrich Chemical Co. (Milwaukee, WI) or NovaBiochem (San Diego, CA). Analytical reversed phase (RP) HPLC was performed using a Waters (Milford, MA) NovaPak (C18, 60 Å, 4 μm, 3.9 × 150 mm) reversed phase (RP) column (solvents ratio v/v reported). The final product, coupling agent **12**, was analyzed using an Akzonobel (Ferry, NY) kromasil reversed phased (RP) column (5.0 μm, 100 Å, 4.6 × 250 mm) (solvents ratio v/v reported). Melting points were recorded in open capillary tubes on an Electrothermal melting point apparatus and were uncorrected. Infrared spectra (IR) and elemental analysis were carried out by Roberson Microlit Laboratories, Inc. (Madison, NJ). IUPAC names of all compounds were obtained using the ACD/Ilab Web service version 3.5 at http://www.acdlabs.com/ilab.

Methyl 6-[(6-{[(Benzyloxy)carbonyl]amino}hexanoyl)amino]hexanoate (3). An oven-dried 2.0 L three-neck round-bottom flask was equipped with a mechanical stirrer and nitrogen inlet/outlet. To this flask were added 6-{[(benzyloxy)carbonyl]amino}hexanoic acid (**1**, 75.0 g, 282.7 mmol, 1.0 equiv) and methyl 6-aminohexanoate hydrochloride (**2**, 51.4 g, 282.7 mmol, 1.0 equiv) followed by anhydrous dichloromethane (1.1 L) at room temperature under nitrogen atmosphere. To the resulting suspension were added sequentially 1-hydroxybenzotriazole (HOBt, 45.8 g, 339.2 mmol, 1.2 equiv), diisopropylethylamine (DIEA, 123.1 mL, 706.8 mmol, 2.5 equiv), and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDAC, 65.0 g, 339.2 mmol, 1.2 equiv), and the mixture was stirred at room temperature (21−23 °C) for 5−6 h. After completion of the reaction, as determined by the analysis of an aliquot by using HPLC, the reaction mixture was transferred into a separatory funnel and diluted with dichloromethane (1.0 L). The mixture was washed vigorously with 1.0 N hydrochloric acid (4 × 1.0 L), followed by 1.0 N sodium hydroxide (4 × 1.0 L) and finally with 3.5 M sodium chloride solution (2 × 1.0 L). The organic layer was dried with anhydrous $MgSO_4$ and filtered, and the solvent was removed on a rotary evaporator. The resulting solid material was dried on a vacuum pump at room temperature for 24 h to afford 105.5 g of ester **3** as a colorless (white) powder in 95% yield. Mp: 74−75 °C [Lit. (*15*) 73−74 °C]; Analytical reversed phase (RP) HPLC: MeCN:water:0.5% aqueous trifluoroacetic acid/35:55:10/1.0 mL/min at 215 nm, t_R: 7.4 min, 98%; IR (KBr): 3347, 3310, 2949, 1730, 1684, 1635, 1533, 1271, 1175, 734, 724 cm^{-1}; ^1H NMR ($CDCl_3$): δ 7.37−7.29 (m, 5 H), 5.58 (br s, 1 H), 5.09 (s, 2 H), 4.88 (br s, 1 H), 3.67 (s, 3 H), 3.26−3.16 (m, 4 H), 2.31 (t, 2 H, J = 7.2 Hz), 2.15 (t, 2 H, J = 7.6 Hz), 1.69−1.59 (m, 4 H), 1.55−1.46 (m, 4 H), 1.38−1.29 (m, 4 H); ^{13}C NMR ($CDCl_3$): δ 174.4, 173.1, 156.8, 137.0, 128.8, 128.4, 66.9, 51.8, 41.1, 39.5, 36.9, 34.2, 30.0, 29.6, 26.7, 26.6, 25.5, 24.8; ESI-MS (*m/z*): 393.3 $(M + H)^+$, 410.3 $(M + NH_4)^+$, 786.0 $(2 \times M + H)^+$, 802.5 $(2 \times M + NH_4)^+$; Elemental analysis: Calcd for $C_{21}H_{32}N_2O_5$, C, 64.26; H 8.22; N, 7.14, Found: C, 64.20; H, 8.48; N, 7.26.

Methyl 6-[(6-Aminohexanoyl)amino]hexanoate Hydrochloride (4). In a dry 2.0 L hydrogention flask equipped with a stir bar was dissolved methyl 6-[(6-{-[(benzyloxy)carbonyl]amino}hexanoyl)amino]hexanoate (**3**, 102.2 g, 260.0 mmol, 1.0 equiv) in anhydrous methanol (675 mL). To this solution were added 1.25 M hydrochloric acid in methanol (625 mL, 780.0 mmol, 3.0 equiv) and 10% palladium on activated carbon (10.4 g, wet, Degussa type E101 NE/W), and the mixture was stirred under hydrogen atmosphere (20−30 psi) at room temperature (21−23 °C). The reaction flask was re-filled with hydrogen gas periodically, and the progress of the reaction was monitored by HPLC for consumption of starting material **3**. After 5 h, an additional amount of Pd/C catalyst (2.6 g) was added, and the hydrogenation was continued for an additional 2 h. After completion of the reaction, as determined by the analysis of an aliquot by using HPLC, the mixture was filtered using a funnel containing a Celite bed (about 4−5 mm thickness). The filter cake was washed with an additional amount of methanol (50 mL), and the combined filtrates were evaporated on a rotary evaporator (bath temp: 35−40 °C). The residue was redissolved in methanol (200 mL) and toluene (400 mL), and the residual amount of water, which originated from the catalyst, was removed azeotropically on a rotary evaporator. The redissolving/azeotropic concentration was repeated two more times, and the resulting white solid was dried under vacuum at room temperature (21−23 °C) for 24 h to afford 81.2 g of methyl 6-[(6-aminohexanoyl)amino]hexanoate hydrochloride (**4**) as colorless gummy material in quantitative yield. IR (KBr): 3299, 2949, 1724, 1635, 1545, 1256, 1197, 1167, 978, 885, 732 cm^{-1}; ^1H NMR (CD_3OD): δ 3.68 (s, 3 H), 3.25 (t, 2 H, J = 7.2 Hz), 2.97 (t, 2 H, J = 8.0 Hz), 2.37 (t, 2 H, J = 7.2 Hz), 2.36−2.30 (m, 2 H), 1.76−1.62 (m, 6 H), 1.61−1.52 (m, 2 H), 1.50−1.42 (m, 2 H, 1.42−1.34 (m, 2 H); ^{13}C NMR (CD_3OD): δ 177.1, 176.7, 41.4, 41.3, 37.1, 35.5, 30.7, 29.1, 28.3, 27.8, 27.2, 26.5; ESI-MS (*m/z*): 259.2 $(M + H)^+$, 517.8 $(2 \times M + H)^+$.

Methyl 3,10,17-Trioxo-1-phenyl-2-oxa-4,11,18-triazatetracosan-24-oate (5). An oven-dried 2.0 L three-neck round-bottom flask was equipped with a mechanical stirrer and nitrogen inlet/outlet. To this flask was added 6-{[(benzyloxy)carbonyl]amino}hexanoic acid (**1**, Z-ϵ-Ahx-OH, 72.0 g, 271.3 mmol, 1.0 equiv) followed by a solution of methyl 6-[(6-aminohexanoyl)amino]hexanoate hydrochloride (**4**, 22.1 g, 75 mmol, 1.0 equiv) in anhydrous dichloromethane (1.2 L) at room temperature under nitrogen atmosphere. To the resulting suspension were added sequentially 1-hydroxybenzotriazole (HOBt, 44.0 g, 325.6 mmol, 1.2 equiv), diisopropyl ethylamine (DIPA, 118.2 mL, 678.4 mmol, 2.5 equiv), and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDAC, 62.4 g, 325.6 mmol, 1.2 equiv). The resulting pale yellow clear solution was stirred at room temperature (21−23 °C) for 5−6 h. After completion of the reaction as determined by the analysis of an aliquot by using HPLC, the reaction mixture was transferred into a separatory funnel and diluted with a mixture of 5% methanol in dichloromethane (1.5 L). The mixture was washed vigorously with 1 N hydrochloric acid (3 × 1.0 L), followed by 1 N sodium hydroxide (4 × 1.0 L) and finally with 3.5 M sodium chloride solution (1 × 1.0 L). The organic layer was dried with anhydrous $MgSO_4$ and filtered, and the solvent was removed on a rotary evaporator. The resulting material was dried under vacuum for 60 h to afford 128.7 g of ester **5** as a colorless (white) powder in 94% yield. Mp: 121−24 °C [Lit. (*15*) 124−25 °C], IR (KBr): 3327, 2944, 2866, 1732, 1687, 1633, 1533, 1269, 733 cm^{-1}; Analytical reversed phase (RP) HPLC: MeCN:water:0.5% aqueous trifluoroacetic acid/35:55:10/1.0 mL/min at 215 nm, t_R: 5.85 min, 94−98.5%, ^1H NMR ($CDCl_3$): δ 7.38−7.28 (m, 5 H), 5.76 (m, 2 H), 5.08 (s, 2 H, 4.97 (m, 1 H), 3.66 (s, 3 H), 3.26−3.16 (m, 6 H), 2.31 (t, 2 H, J = 7.2 Hz), 2.15 (t, 4 H, J = 7.2 Hz), 1.68−1.58 (m, 6 H), 1.58−1.46 (m, 6 H), 1.38−1.28 (m, 6 H); ^{13}C NMR ($CDCl_3$): δ 174.4, 173.2, 156.8, 137.0, 128.8, 128.4, 128.3, 66.9, 51.8, 41.2, 39.5, 39.4, 36.8, 36.7, 34.2, 30.0, 29.6, 29.5, 26.7, 26.6, 26.5, 25.6, 25.4, 24.8; ESI-MS (*m/z*): 506.3 $(M + H)^+$, 523.8 $(M + NH_4)^+$, 1029.1 $(2 \times M + NH_4)^+$; Elemental analysis: Calcd for $C_{27}H_{43}N_3O_6$, C, 64.13, H; 8.57, N, 8.31, Found: C, 63.84, H, 8.57, N, 8.24.

3,10,17-Trioxo-1-phenyl-2-oxa-4,11,18-triazatetracosan-24-oic Acid (6). In a 3.0 L three-neck round-bottom flask equipped with mechanical stirrer was suspended the methyl 3,10,17-trioxo-1-phenyl-2-oxa-4,-11,18-triazatetracosan-24-oate (**5**, 125.0 g, 247.2 mmol, 1.0 equiv) in tetrahydrofuran (THF, 1.5 L). In a separate 1.0 L beaker, lithium hydroxide monohydrate (20.8 g, 494.4 mmol, 2.0 equiv) was dissolved in water (0.75 L), and the solution was added to the ester (**5**)−THF suspension at room temperature (21−23 °C). After the addition was complete, the white suspension slowly dissolved and a clear solution formed in about 10 min. The reaction mixture was stirred for an additional 2 h, and after completion of the reaction, as determined by the analysis

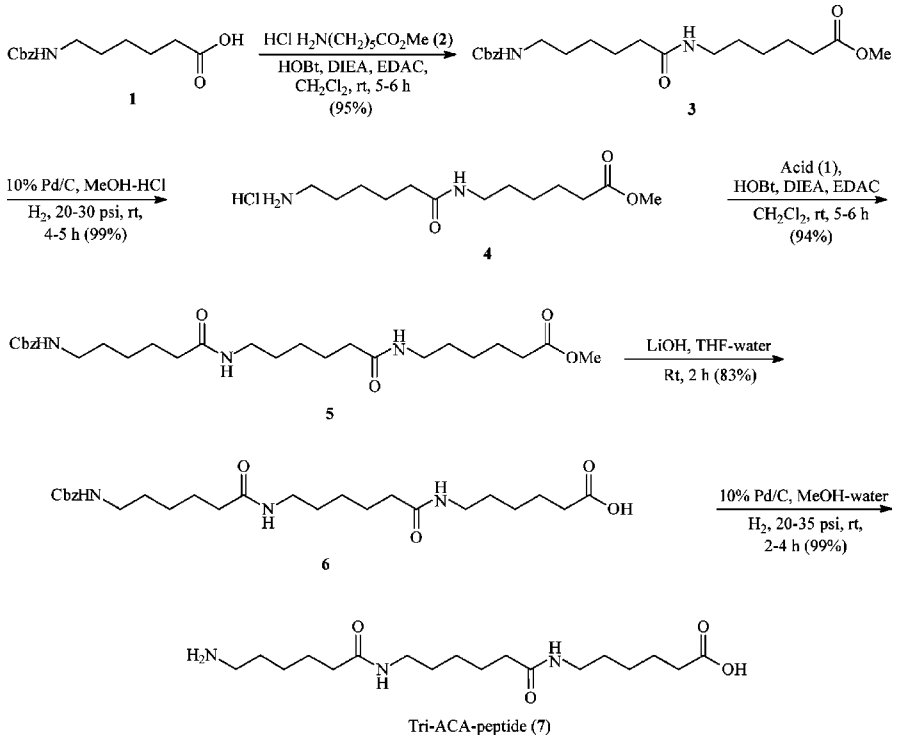
of an aliquot by using HPLC, the mixture was concentrated on a rotary evaporator to about 1.5 L final volume. The mixture was then diluted with water (750 mL), and the suspension was acidified to pH ~3.5 with 6.0 N hydrochloric acid (85 mL), while the mixture was continuously stirred. The resulting precipitate was filtered, and the solid was washed three times with water (3 × 1.5 L). The material was transferred into crystallizing dish and dried in an oven at 45−50 °C under vacuum for 14 h. The crude acid (110.0 g) was crystallized from ethanol (700 mL) and ethyl acetate (1.6 L). The resulting white solid material was filtered and dried under vacuum at room temperature over 18−24 h to afford 100.3 g of acid **6** as a colorless (white) powder in 83% yield. Mp: 136−37 °C [Lit. (*16*) 133−34 °C]; Analytical reversed phase (RP) HPLC: MeCN:water:0.5% aqueous trifluoroacetic acid/25:75:10/1.0 mL/min at 215 nm, t_R: 5.28 min, 99.9%; IR (KBr): 3533, 3140, 2250, 1578, 1460, 1392, 1253, 1180, 1126, 1033, 851 cm^{-1}; ^1H NMR (CD_3OD): δ 7.95 (dist t, 2 H), 7.39−7.28 (m, 5 H), 7.01 (dist t, 1 H), 5.09 (s, 2 H), 3.22−3.12 (m, 6 H), 2.32 (t, 2 H, J = 7.6 Hz), 2.20 (t, 4 H, J = 7.6 Hz), 1.68−1.60 (m, 6 H), 1.57−1.48 (m, 6 H), 1.43−1.34 (m, 6 H); ^{13}C NMR (CD_3OD): δ 178.3, 176.9, 176.8, 139.4, 130.3, 129.8, 129.6, 68.2, 42.5, 41.0, 41.1, 37.9, 37.8, 35.7, 31.5, 31.0, 28.4, 28.3, 28.2, 27.6, 27.5, 26.6, ESI-MS (*m/z*): 492.3 $(M + H)^+$, 509.3 $(M + NH_4)^+$; Elemental analysis: Calcd, $C_{26}H_{41}N_3O_6$, C, 63.52, H, 8.41, N, 8.55, Found, C, 63.54, H, 8.54, N, 8.54.

6-({6-[(6-Aminohexanoyl)amino]hexanoyl}amino)-hexanoic Acid (7). In a 2.0 L dry hydrogenation flask equipped with a stir bar was suspended the 3,10,17-trioxo-1-phenyl-2-oxa-4,11,18-triazatetracosan-24-oic acid (**6**, 50.0 g, 101.7 mmol) in methanol (900 mL). The mixture was gently heated to about 55 °C to dissolve the material, and then water (450 mL) was added. To the resulting clear solution was added 10% palladium on activated carbon (5.0 g, wet, Degussa type E101 NE/W) while the solution was still warm, and the mixture was stirred under hydrogen atmosphere (20−30 psi) for 2 h. The flask was refilled with hydrogen periodically, and the progress of the reaction was monitored by HPLC for the consumption of starting material, acid **6**. An additional amount of catalyst (2.5 g) was added, and the hydrogenation was continued for an additional 2 h. After completion of the reaction, as determined by the analysis of an aliquot by using HPLC (total time: 4 h), the mixture was then filtered over a Celite bed. The filter cake was washed with an additional methanol (100 mL), and the combined filtrates were evaporated on a rotary evaporator. The resulting solid was transferred into a crystallizing dish and dried in oven at 45−50 °C under vacuum for 36 h to afford 36.5 g of 6-({6-[(6-aminohexanoyl)-amino]hexanoyl}amino)hexanoic acid (Tri-ACA-peptide**,** **6**) as a colorless (white) powder in 99% yield. Mp: 218−20 °C [Lit. (*16*) 203−204 °C]; IR (KBr): 3366, 3026, 2886, 1846, 1488, 1444, 1340, 1289, 1230, 1184, 1111, 985, 940 cm^{-1}; ^1H NMR (D_2O + CD_3OD): δ 3.19 (t, 4 H, J = 6.8 Hz), 3.01 (t, 2 H, J = 7.6 Hz), 2.26 (t, 2 H, J = 7.6 Hz), 2.25 (t, 2 H, J = 6.8 Hz), 2.20 (t, 2 H, J = 7.2 Hz), 1.74−1.49 (m, 12 H), 1.45−1.29 (m, 6 H); ^{13}C NMR (D_2O + CD_3-OD): δ 185.0, 177.0, 177.8, 40.8, 40.7, 40.6, 40.0, 37.1, 37.0, 29.6, 29.5, 28.0, 27.6, 27.0, 26.9, 26.6, 26.5, 26.4; ESI-MS (*m/z*): 358.2 $(M + H)^+$, 715.9 $(2 \times M + H)^+$; Elemental analysis: Calcd for $C_{18}H_{35}N_3O_4$, C, 60.48, H, 9.87, N, 11.75, Found: C, 59.89, H, 9.81, N, 11.58.

Pentafluorophenyl 4-[(2,5-Dioxo-2,5-dihydro-1*H*-pyrrol-1-yl)methyl]cyclohexanecarboxylate (FMCC, 10). In a dry three-neck 2.0 L round-bottom flask equipped with mechanical stirrer and a nitrogen inlet, the powdered maleic anhydride (31.2 g, 318.1 mmol, 1.0 equiv) was dissolved in acetonitrile (500 mL) under nitrogen atmosphere. To this clear solution was added *trans*-4-(aminomethyl)cyclohexanecarboxylic acid (**8**, 50.0 g, 318.1 mmol, 1.0 equiv) at room temperature (21−23 °C). After the reaction mixture was stirred for 6 h, the resulting suspension was cooled to 2−5 °C with an ice bath. To this cold mixturewas added quickly diisopropylethylamine (DIEA, 150.0 mL, 858.9 mmol, 2.7 equiv) followed by pentafluorophenyl trifluoroacetate (**9**, 132.7 mL, 795.5 mmol, 2.5 equiv) slowly using an additional funnel over 20−25 min period. During this period, the temperature of the reaction mixture was maintained below 10 °C. After the addition was complete, the resulting pale brown color reaction mixture was stirred for 1.5 h at low temperature (<10 °C) and the cooling bath was removed. The reaction mixture was then allowed warm to room temperature, and the stirring was continued overnight, for 18 h. The resulting thick brown suspension was diluted with water (2.0 L) and extracted with dichloromethane (3 × 2.0 L). The combined dichloromethane extracts were washed with water (1 × 2.0 L), dried with anhydrous $MgSO_4$, and filtered. The solvent was removed using a rotary evaporator (bath temp: 35−40 °C), and the residue was dried on vacuum pump (0.1−0.3 mm/Hg) at room temperature for 5 h. The resulting solid (202 g) was crystallized from ethyl acetate (750 mL) and hexanes (200 mL) to afford 55.4 g of FMCC (**10**). The mother liquor was concentrated and recrystallized from ethyl acetate (500 mL) and hexanes (150 mL) to afford an additional 10.0 g of FMCC (**8**). Crops 1 and 2 were combined to give 65.3 g of FMCC (**8**) as a colorless crystalline solid in 51% yield. Mp: 157−59 °C [Lit. (*17*) 157−58 °C], Analytical reversed (RP) HPLC: Gradient: MeCN:water:1.0% aqueous trifluoroacetic acid/10:80:10 to 90:0:10 ratio from 0 to 15 min/1.0 mL/min at 220 nm, t_R: 10.61 min, 99.2%, ^1H NMR ($CDCl_3$): δ 6.68 (s, 2 H), 3.37 (d, 2 H, J = 7.2 Hz), 2.62−2.53 (m, 1 H), 2.15 (d, 2 H, J = 11.2 Hz), 1.84−1.66 (m, 3 H), 1.58−1.46 (m, 2 H), 1.16−1.10 (m, 2 H); ^{13}C NMR ($CDCl_3$): δ 171.5, 170.9, 134.0, 43.4, 42.4, 36.2, 29.4, 28.0; ESI-MS (*m/z*): 404.3 $(M + H)^+$, 422.3 $(M + NH_4)^+$; Elemental analysis: Calcd for $C_{18}H_{14}F_5NO_4$, C, 53,61, H, 3.50, N, 3.47, F, 23.55; Found: C, 53.64, H, 3.40, N, 3.42, F, 23.71.

6-{[6-({6-[({4-[(2,5-Dioxo-2,5-dihydro-1*H*-pyrrol-1-yl)methyl]cyclohexyl}carbonyl)amino]hexanoyl}-amino)hexanoyl]amino}hexanoic Acid (11). In a dry, 2.0 L three-neck round-bottom flask equipped with mechanical stirrer was added the 6-({6-[(6-aminohexanoyl)amino] hexanoyl}amino)hexanoic acid (tri-ACA-peptide, **7**, 64.0 g, 179.03 mmol, 1.0 equiv) followed by anhydrous-degassed DMF [1.5 L, which was stirred under vacuum (0.1−0.3 mm/Hg) for 30 min] at room temperature. To this suspension was added FMCC (**10**, 72.2 g, 179.03 mmol, 1.0 equiv), and the mixture was gently heated to 55 °C under nitrogen atmosphere for 7 h. During this period, the suspension gradually dissolved, and the mixture became a pale yellow clear solution. After completion of the reaction, as determined by the analysis of an aliquot by using HPLC, the mixture was concentrated on a rotary evaporator (bath temp: 50−55 °C) and the resulting material was further dried on a vacuum pump (0.1−0.5 mm/Hg) for 18 h. The resulting solid (239 g) was suspended in acetonitrile (1.5 L), stirred for 10 min, and filtered. The washing−filtration process with acetonitrile was repeated two more times (2 × 1.5 L), and the resulting solid was dried in oven at 45−50 °C under vacuum for 3 h. After being dried, the resulting crude product (97.7 g) was dissolved in a mixture of

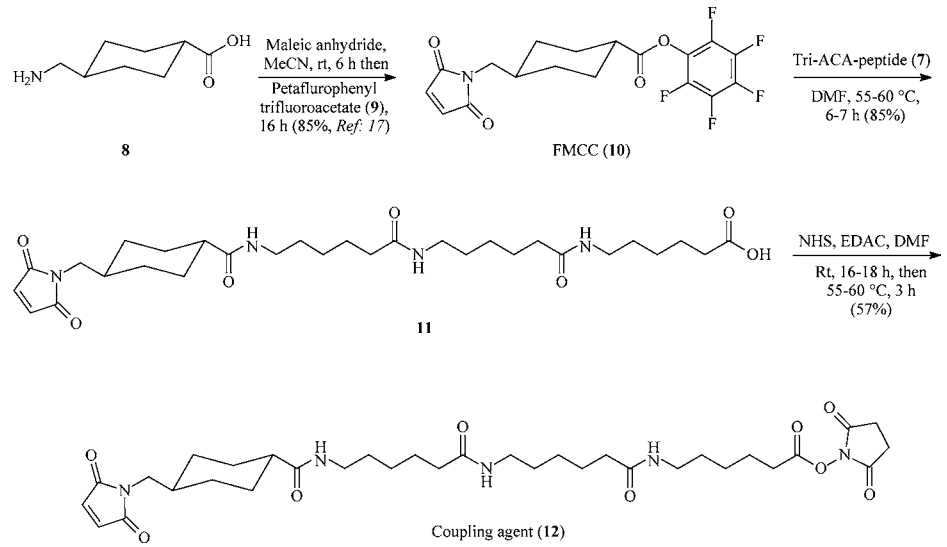
Scheme 1. Synthesis of 6-({6-[(6-Aminohexanoyl)amino]hexanoyl}amino)hexanoic Acid (7)



ethanol (1.4 L) and water (1.4 L) and treated with preactivated carbon (9.6 g) at 70−75 °C. The carbon was removed by filtration, and the crystallized solid was filtered and dried in oven at 45−50 °C under vacuum for 48 h to afford 81.7 g of acid **11** as a colorless powder in 79% yield. Mp: 170−72 °C, IR (KBr): 3533, 3342, 3144, 1759, 1586, 1457, 1381, 1183, 1085, 1028, 978, 880 cm^{-1}; Analytical reversed phase (RP) HPLC: MeCN:water:0.5% aqueous trifluoroacetic acid/25:65:10/1.0 mL/min at 215 nm, t_R: 4.79 min, 98.9%, ^1H NMR (DMSO-d_6): δ 7.75 (t, 1 H, J = 5.2 Hz), 7.73 (t, 1 H, J = 5.2 Hz), 7.66 (t, 1 H, J = 5.6 Hz), 7.04 (s, 2 H), 3.27 (d, 2 H, J = 7.2 Hz), 3.06−2.98 (m, 6 H), 2.22 (t, 2 H, J = 7.6 Hz), 2.08−2.02 (m, 4 H), 2.00 (dist t, 1 H), 1.75−1.60 (m, 5 H), 1.58−1.42 (m, 8 H), 1.42−1.33 (m, 6 H), 1.32−1.18 (m, 6 H), 0.98−0.86 (m, 2 H); ^{13}C NMR (DMSO-d_6): δ 175.6, 175.5, 172.7, 172.2, 135.3, 44.7, 44.0, 39.2, 39.2, 39.1, 37.1, 36.3, 34.5, 30.4, 29.9, 29.8, 29.8, 29.5, 27.1, 27.0, 26.9, 26.0, 25.1; ESI-MS (*m/z*): 577.9 $(M + H)^+$, 594.9 $(M + NH_4)^+$, 1171.2 $(2 \times M + NH_4)^+$; Elemental analysis: Calcd for $C_{30}H_{48}N_4O_7$, C, 62.48, H, 8.39, N, 9.71; Found, C, 62.33, H, 8.49, N, 9.64.

4-[(2,5-Dioxo-2,5-dihydro-1*H*-pyrrol-1-yl)methyl]-*N*-(6-{[6-({6-[(2,5-dioxopyrrolidin-1-yl)oxy]-6-oxohexyl}amino)-6-oxohexyl]amino}-6-oxohexyl)cyclohexanecarboxamide (12). In a dry three-neck 2.0 L round-bottom flask equipped with a mechanical stirrer and nitrogen inlet was added the acid (**11**, 70.0 g, 121.4 mmol, 1.0 equiv) followed by anhydrous-degassed DMF [1.2 L, which was stirred under vacuum (0.1−0.3 mm/Hg) for 30 min] at room temperature. To this suspension were added sequentially *N*-hydroxysuccinimide (NHS, 27.9 g, 242.8 mmol, 2.0 equiv) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDAC, 46.6 g, 242.8 mmol, 2.0 equiv). After the addition was complete, the reaction mixture was stirred overnight at room temperature (21−23 °C) under nitrogen atmosphere. After 18 h, the mixture was heated to 55 °C for 3 h under nitrogen atmosphere. After completion of the reaction, as determined by the analysis of an aliquot by using HPLC, the reaction mixture was concentrated on a rotary evaporator (bath temp: 50−55 °C) using a vacuum. The resulting solid material was further dried overnight under vacuum, and 173.6 g of solid residue was obtained. This material was suspended in acetonitrile (1.4 L) and stirred for about 10 min. The white suspension was filtered, and the washing with acetonitrile (1.4 L) was repeated. After filtering the material, the trituration−filtration process was carried out using water (2 × 1.4 L) and finally again with acetonitrile (1.4 L). The solid material (127.5 g) was then transferred into a crystallizing dish and dried in an oven at 45−50 °C under vacuum for 14 h to give 67.1 g of coupling agent **12** with 97−98% purity by HPLC. Crystallization of a 60 g portion of this material from absolute ethanol (1.5 L) and acetonitrile (900 mL) gave 51.4 g of material, which was recrystallized from ethanol (1.28 L) and acetonitrile (765 mL). After filtration and drying the solid in oven at 45−50 °C under vacuum for 24 h, 47.0 g of coupling agent **12** was obtained as a colorless powder in 58% yield. Mp: 189−92 °C [Lit. (*8*) 170−73 °C, Analytical reversed phase (RP) HPLC (Kromasil column): Gradient solvent system (MeCN:water:1.0% aqueous trifluoroacetic acid/10:80:10 to 40:50:10 in 30 min) with flow rate of 1.0 mL/min at 220 nm, t_R: 19.28 min, 99.6%; IR (KBr): 3459, 3081, 1777, 1556, 1434, 1391, 1300, 1247, 1211, 1119, 998, 927, 865; ^1H NMR (DMSO-d_6): δ 7.75 (t, 1 H, J = 5.6 Hz), 7.73 (t, 1 H, J = 6.0 Hz), 7.66 (t, 1 H, J = 5.6 Hz), 7.05 (s, 2 H), 3.27 (d, 2 H, J = 6.8 Hz), 3.08−2.98 (m, 6 H), 2.85 (s, 4 H), 2.69 (t, 2 H, J = 7.2 Hz), 2.08−2.02 (m, 4 H), 2.00 (dist t, 1 H), 1.75 − 1.61 (m, 5 H), 1.58−1.44 (m, 8 H), 1.44−1.32 (m, 6 H), 1.32−1.18 (m, 6 H), 0.98−0.86 (m, 2 H); ^{13}C NMR (DMSO-d_6): δ 175.4, 172.5, 172.4, 172.0, 170.9, 169.6, 135.1, 44.5, 43.8, 39.0, 38.9, 38.8, 36.8, 36.1, 30.8, 30.1, 29.7, 29.6, 29.3, 29.2, 26.8, 26.7, 26.1, 25.7, 24.6; ESI-MS (*m/z*): 674.9 $(M + H)^+$, 691.4 $(M + NH_4)^+$; Elemental analysis: Calcd for, $C_{34}H_{51}N_5O_9$, C, 60.61, H, 7.63, N, 10.39; Found, C, 60.60, H, 7.62, N, 10.38.

Scheme 2. Completion of the Synthesis of Coupling Agent 12



RESULTS AND DISCUSSION

Our strategy for the synthesis of the coupling agent **12** is based on a convergent approach, in which the tri-ACA-peptide **7** was assembled first, and then the cyclohexane-unit-containing maleimide group was introduced in the final stages. This strategy was envisioned not only for advantages of the convergent approach during scale-up, but also to avoid the formation of byproducts based on the reaction of maleimide group, from early stages of synthesis, as observed with the reported procedure (*8*). Accordingly, 6-{[(benzyloxy)carbonyl]amino}hexanoic acid (**1**) was coupled (Scheme 1) with methyl 6-aminohexanoate (**2**) in the presence of HOBt and EDAC in dichloromethane to afford methyl ester **3** (*14*−*15*) in 95% yield and 98% purity by HPLC. The next step in the synthesis was to remove the Cbz group in **3** by hydrogenolysis using 10% Pd/C, which was carried out in the presence of hydrochloric acid to prevent the formation any self-condensation products. The hydrogenation reaction was worked-up by filtration to give methyl 6-[(6-aminohexanoyl)amino]hexanoate (**4**) as its hydrochloride salt in quantitative yield. The hydrochloride salt **4** was then subjected to a second coupling reaction with acid **1** in the presence of HOBt and EDAC in dichloromethane to afford the ester **5** (*15*), which was also isolated by extractive workup in 94% yield. The methyl ester in **5** was then hydrolyzed using lithium hydroxide in methanol−water, and the resulting crude product was crystallized from ethanol−ethyl acetate to afford the acid **6** in 83% yield and 99.9% purity by HPLC. Subsequent hydrogenation of acid **6** in the presence of 10% Pd/C in a mixture of methanol−water gave the desired tri-ACA-peptide **7** (*16*) in quantitative yield, as a colorless solid. In the absence of water during hydrogenation, the tri-ACA-peptide **7** was precipitated in methanol and 2−3% of starting material **6** was still present, even after carrying out the reaction at higher pressure (50−60 psi) and for longer period (14−18 h).

The cyclohexanecarboxylic acid unit containing a maleimide group, FMCC (**10**), was synthesized on a 65 g scale by modifying the procedure reported by Adamczyk and Johnson (*17*). The reaction was carried out in acetonitrile solvent, which facilitated the aqueous extractive workup on a large scale, and the product **10** was isolated by crystallization. With FMCC (**10**) in hand, its coupling (Scheme 2) with the tri-ACA-peptide **7** was carried out in anhydrous DMF at 55 °C for 7 h. The crude product was crystallized from ethanol−water to afford the desired acid **11** in 79% yield and 99.4% purity. The acid **11** was then converted into the corresponding succinimidyl ester **12** by treatment with *N*-hydroxysuccinimide and EDAC in anhydrous DMF. The crude product **12**, which was isolated by removal of DMF and subsequent washing with acetonitrile and water, had 97−98% purity by HPLC consistently from different batch size reactions. The crude product **12**, with 97−98% purity, was further crystallized from a mixture of ethanol−acetonitrile to afford to the desired coupling agent **12** in 58% and 99.6% purity, as a colorless powder. The only impurity present in the crystallized coupling agent **12** was identified to be the acid **9**, in approximately 0.4% by HPLC (Figure 1).

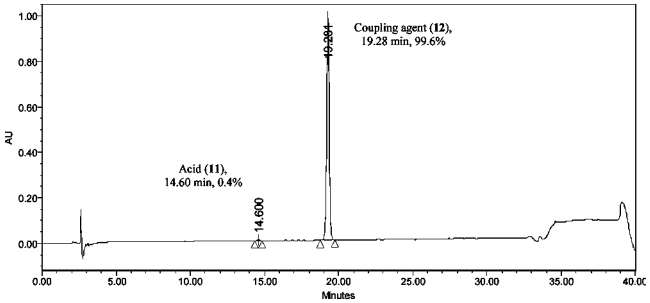


Figure 1. Analytical HPLC of heterobifunctional coupling agent **12**.

In summary, an efficient method for the preparation of a heterobifunctional coupling agent **12** was developed and the product was isolated in excellent over all yield (32%) and quality (99.6% purity). The method is suitable for synthesis of multigram quantities (47 g) of coupling agent **12** with consistent purity, >99% by HPLC, and can be useful for preparation of other analogous coupling agents, which are critical for bioconjugation.

^{18}F-labeling of proteins and peptides is important for positron emission tomography (PET). Although there are many methods for the labeling of proteins with ^{18}F, most of these are characterized by complicated procedures or low yields. Here, we report a novel and simple method which includes the preparation of [^{18}F]fluorobenzaldehyde ([^{18}F]FBA) and successive conjugation with hydrazinonicotinic acid−human serum albumin conjugate (HYNIC−HSA) via hydrazone formation. HYNIC−HSA, which can also be used for labeling with ^{99m}Tc, was prepared via reaction with *N*-hydroxysuccinimide (NHS) or tetrafluorophenyl (TFP) esters of HYNIC with HSA. No-carrier-added [^{18}F]FBA was prepared by the nucleophilic substitution of [^{18}F]fluoride to 4-trimethylammonium benzaldehyde triflate in the presence of tetrabutylammonium bicarbonate. [^{18}F]FBA was purified by passing ion exchange cartridges (IC-H and QMA) and was adsorbed to a C_{18} Sep-Pak cartridge. The adsorbed [^{18}F]FBA was then eluted with 50% ethanol. HYNIC−HSA was added to the solution and conjugated with [^{18}F]FBA via hydrazone formation. ^{18}F-HSA was purified with a PD10 column. Biodistribution of ^{18}F-HSA, ^{99m}Tc-HSA, and [^{18}F]FBA in mice were investigated at 10, 20, and 60 min after intravenous injection. The number of conjugated HYNIC molecules per HSA ranged from 5.2 to 23.2 depending on the reaction conditions. The labeling efficiency of ^{18}F-FBA was 67 ± 15.7%. The radiochemical purity after purification was over 99%. The conjugation efficiency of HYNIC−HSA with [^{18}F]FBA was between 25% and 90%. The conjugation efficiency was observed to increase with increases in the number of conjugated HYNIC, the HYNIC−HSA concentration, or temperature. ^{18}F-HSA exhibited a biodistribution pattern similar to that of ^{99m}Tc-HSA while [^{18}F]FBA showed much lower blood activity than that of ^{18}F-HSA and ^{99m}Tc-HSA. We concluded that ^{18}F-HSA was successfully labeled using a novel method which involves hydrazone formation between [^{18}F]FBA and HYNIC−HSA. This method can be applied to the ^{18}F-labeling of other proteins or peptides.

INTRODUCTION

The application of bioactive proteins labeled with radionuclides for diagnostic imaging has emerged as a useful and interesting field in nuclear medicine (*1*−*4*). In particular, ^{18}F-labeled proteins or peptides bear a great deal of clinical and research potential due primarily to their favorable nuclear characteristics with regard to positron emission tomography (PET) that has high resolution and sensitivity (*5*−*7*).

Specially designed synthons are essential for the ^{18}F labeling of proteins or peptides because the biomolecules cannot be directly labeled by nucleophilic [^{18}F]-fluorination. A variety of ^{18}F-labeled synthons have been developed and successfully applied to a host of peptides and proteins for ^{18}F labeling (*8*−*12*). With a few exceptions (*8*), the most effective procedures for the synthesis of ^{18}F-labeled synthons are all multistep procedures. Among these synthons, *N*-succinimidyl 4-[^{18}F]fluorobenzoate ([^{18}F]SFB) remains the most widely applied agent for many bioactive molecules with regard to in vivo stability and radiolabeling yields. However, [^{18}F]SFB can be obtained via a time-consuming three-step synthesis method (*5*, *6*). Therefore, it is necessary to develop simpler and more efficient ^{18}F labeling methods with proteins or peptides for clinical routine use.

Here, we report a novel and simple method for the preparation of ^{18}F-labeled proteins. In this paper, we evaluated the efficacy of this method using human serum albumin (HSA) as a test protein. The resulting product, ^{18}F-HSA, might be used in blood pool imaging. The whole procedure is shown in Scheme 1. First, hydrazinonicotinic acid (HYNIC) was conjugated with HSA yielding HYNIC−HSA. [^{18}F]fluorobenzaldehyde ([^{18}F]FBA) was then prepared via the nucleophilic substitution of [^{18}F]fluoride. Finally, [^{18}F]FBA was conjugated to HYNIC−HSA via hydrazone formation. HYNIC−HSA might be used not only for ^{18}F-labeling but also for ^{99m}Tc-labeling.

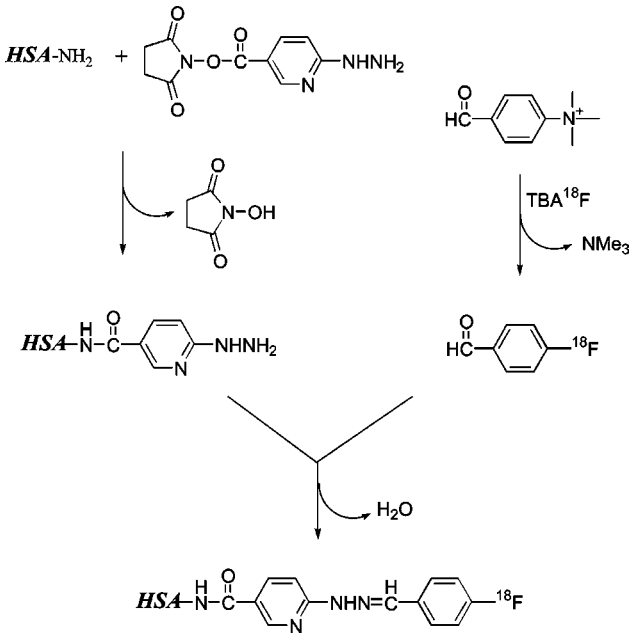
Scheme 1. Synthesis of ^{18}F-Labeled HSA via Formation of Hydrazone



were obtained with a Applied Biosystems/MDS Sciex API 3000 LC/MS/MS System. A DU650 Spectrophotometer (Beckman Coulter) was used for absorbance measurements. A NaI well counter (Packard, Canberra Co.) and dose calibrator (Atomlab 100, Medical Systems Inc.) were used to measure the low and high levels of radioactivity, respectively. A Bio-Scan System 2000 imaging scanner was used to perform the Radio-TLC scan. For TLC, we purchased aluminum-backed silica gel 60 F_{254} from the E. Merck Company (Germany) and ITLC-SG plates from the Gelman Company. PD10 size-exclusion columns were from Amersham Biosciences (Sweden), C_{18} and QMA Sep-Pak cartridges were obtained from Waters (Milford, MA), IC-H Maxi-Clean cartridges were purchased from Alltech (Deerfield, IL), and BCA kit for the protein assay was from Pierce (Rockford, IL). [^{18}F]Fluoride was produced by the ^{18}O (p, n) ^{18}F reaction on ^{18}O-enriched (95%) water using a 13 MeV proton beam generated by a TR-13 cyclotron (Ebco Technologies, Vancouver, Canada). The ^{99}Mo/^{99m}Tc-generator was purchased from the DuPont Company. HSA kit for ^{99m}Tc-labeling was obtained from Daiichi Radioisotope Laboratories, LTD (Japan). All other reagents and solvents, if not specified, were purchased from Aldrich, Sigma, or Fluka and were used with no further purification.

Synthesis of HYNIC and 4-*N*,*N*,*N*-Trimethylammonium Benzaldehyde Triflate. *N*-Hydroxysuccinimide ester of hydrazinonicotinic acid (NHS−HYNIC) and tetrafluorophenyl ester of hydrazinonicotinic acid (TFP−HYNIC) compounds were synthesized according to previously reported methods (*14*, *15*). 4-*N*,*N*,*N*-Trimethylammonium benzaldehyde triflate was also synthesized according to a method published in the literature (*16*). Briefly, *N*,*N*-dimethylalininobenzaldehyde (100 mg, 0.44 mmol) was added to an evacuated and argon-purged 25 mL sidearm flask with a stirring bar. Methylene chloride (7 mL) was added to the flask with stirring, which produced a clear slightly greenish-yellow solution. Methyl trifluoromethanesulfonate (53.75 μL, 0.475 mmol) was then added, which resulted in an immediate color change to intense yellow. After stirring overnight, the crude product was obtained by addition of diethyl ether as a white powder (0.14 g). Recrystallizaiton from methylene chloride/diethyl ether produced a fine white crystalline powder. mp 105−107 °C; ^{1}H NMR (DMSO-d_6) δ: 3.64 (s, 9H, 3CH_3), 8.18 (q, 4H, J = 6.8 Hz, aromatic), 10.1 (s, 1H, CHO); ^{13}C NMR (DMSO-d_6) δ: 55.3, 120.7, 129.9, 135.8, 150.1, 191.2; ESI-MS (*m*/*z*): 165.1 [M + H]$^+$.

Preparation of HYNIC−HSA. HYNIC−HSA was prepared by reacting HSA with various amounts of NHS−HYNIC or TFP−HYNIC, according to the published method with some modifications (*17*). To 1 mL of 2% HSA solution in 0.05 M phosphate buffer (pH 7.5) we added 20 μL of NHS−HYNIC or TFP−HYNIC solution in dimethyl sulfoxide (DMSO). The molar ratios of HYNIC to HSA varied ranging from 8:1 to 32:1. After incubation for 2 h at room temperature, the unreacted HYNIC was removed with a PD10 size-exclusion column. HYNIC−HSA was eluted with 0.05 M phosphate buffer (pH 7.5). The protein concentration of purified HYNIC−HSA was determined using a BCA protein assay kit. The amount of conjugated HYNIC was determined by measuring optical density at 385 nm after conjugation with 0.5 mM *p*-nitrobenzaldehyde (extinction coefficient: 2.53 $\times$ 10^4 L mol^{-1} cm^{-1}) for 5 h at room temperature thereby forming hydrazone (*15*, *18*).

Preparation of [^{18}F]FBA. An aqueous solution of [^{18}F]fluoride in ^{18}O-enriched water was captured on a QMA light Sep-Pak cartridge which had been preconditioned with 5 mL of 0.5 M potassium bicarbonate and washed with 10 mL of deionized water. The [^{18}F]fluoride on the cartridge was eluted with 1 mL of 2.3% tetrabutylammonium bicarbonate in 83.8% acetonitrile. Azeotropic distillation was conducted twice, each at 90 °C after addition of 1 mL acetonitrile under a gentle stream of argon gas.

[^{18}F]FBA was prepared via the nucleophilic substitution of [^{18}F]fluoride to 4-*N*,*N*,*N*-trimethylaminebenzaldehyde triflate (*16*). To the above dried [^{18}F]fluoride in tetrabutylammonium bicarbonate (16 mg, 52.7 μmol) was added 5 mg of 4-*N*,*N*,*N*-trimethylammonium benzaldehyde triflate in DMSO (0.5 mL) and reacted for 6 min at 100 °C. The reaction mixture was diluted with deionized water and passed through a set of ion exchange cartridges (two IC-H Maxi-Clean cartridges for cation exchanger and a QMA Sep-Pak cartridge for anion exchanger) to remove ionic components. The labeled product was then adsorbed to a C_{18} Sep-Pak light cartridge. The adsorbed [^{18}F]FBA was eluted with 50% ethanol. Labeling efficiency was measured by a thin-layer chromatography with a Radio-TLC scanning (silica gel TLC/ethyl acetate:hexane = 1:3; R_f values: [^{18}F]fluoride ion = 0.0 and [^{18}F]FBA = 0.7).

Preparation of ^{18}F-HSA. HYNIC−HSA was conjugated with [^{18}F]FBA via hydrazone formation (Scheme 1). Purified [^{18}F]FBA solution (0.3 mL) was added to the HYNIC−HSA solution (the concentration of HSA was 3 mg/1.2 mL 0.05 M phosphate buffer (pH 7.5)), and the solution was incubated for 30 min at room temperature, 50 °C or 60 °C. The labeled ^{18}F-HSA was then purified with a PD10 column. Radiochemical purity was verified using ITLC-SG and normal saline or acetone. (ITLC−SG/normal saline; R_f values: ^{18}F-HSA = 0.0 and [^{18}F]FBA = 1.0; ITLC−SG/acetone; R_f values: ^{18}F-HSA = 0.0 and [^{18}F]FBA = 1.0).

Stability Test of ^{18}F-HSA. The labeled and purified ^{18}F-HSA was then stored at room temperature, and the radiochemical purity was determined by chromatography as described in the Preparation of ^{18}F-HSA section. The radiochemical purity was determined at 10 min, 30 min, 1 h, 2 h, 3 h, 4 h, 5 h, and 6 h.

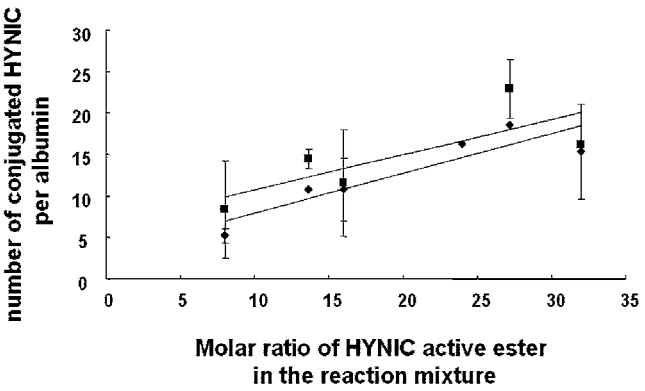


Figure 1. Conjugation of HYNIC to albumin as a function of the molar ratio of active HYNIC ester and HSA; NHS−HYNIC (◆) or TFP−HYNIC (■). Protein concentration of HYNIC−HSA was determined using a BCA protein assay kit, and the amount of conjugated HYNIC was determined by measuring OD385 after conjugation with *p*-nitrobenzaldehyde (extinction coefficient: 2.53×10^4 L mol^{-1} cm^{-1}).

Preparation of ^{99m}Tc-HSA. ^{99m}Tc-HSA was prepared and tested according to the protocols provided by the supplier.

Biodistribution Study in Mice. All animal studies were conducted in compliance with the local regulations. Male ICR mice (n = 3 or 4/group, 28 ± 1.9 g) were injected with 37 kBq (100 μL) of ^{18}F-HSA, ^{99m}Tc-HSA, or [^{18}F]FBA through the tail vein. The mice were subsequently sacrificed by cervical dislocation after 10, 20, and 60 min, respectively. The weight and radioactivity of the blood, muscle, fat, heart, lung, liver, spleen, stomach, intestine, kidney, brain, and bone from the sacrificed mice were then measured with electronic balance and gamma scintillation counter, respectively. Results were expressed as a percentage of injected dose per gram of tissue (% ID/g).

RESULTS

Preparation of HYNIC−HSA. The reaction of HSA with NHS−HYNIC or TFP−HYNIC resulted in the introduction of a number of hydrazinonicotinyl sidechains. The amount of conjugated HYNIC increased with increases in the molar ratio of the active ester of HYNIC to HSA (Figure 1). The amount ranged from 5.2 to 23.2 according to the reaction conditions utilized. When TFP−HYNIC was used, the amount of conjugated HYNIC molecules per HSA was slightly higher than that observed when NHS−HYNIC was used, but this difference was not significant (Figure 1).

Preparation of [^{18}F]FBA. [^{18}F]FBA was synthesized via the nucleophilic substitution of [^{18}F]fluoride to *N*,*N*,*N*-trimethylammonium benzaldehyde in the presence of tetrabutylammonium bicarbonate. The labeling efficiency of [^{18}F]FBA was about 67 ± 15.7%. The radiochemical purity of [^{18}F]FBA after purification was more than 99%.

Preparation of ^{18}F-HSA. HYNIC−HSA was conjugated with the purified [^{18}F]FBA via hydrazone formation, and the labeling efficiency was verified by an ITLC-SG chromatogram. As the HYNIC−HSA concentration increased, the radiochemical yield also increased (Figure 2). The conjugation yield of HYNIC−HSA with [^{18}F]FBA ranged from 25% to 90%. The more highly hydrazinonicotinylated HYNIC−HSA exhibited a higher conjugation yield. The radiochemical yield of the control HSA was less than 10% (Figure 3). The reaction temperature also influenced the radiochemical yield. This was determined to increase at higher temperatures (Figure 4).

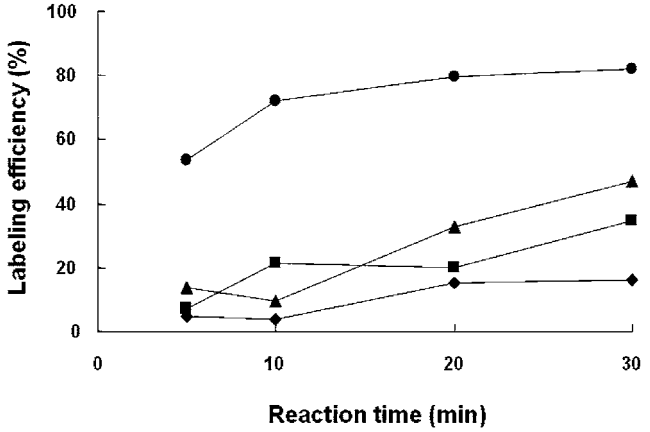

Figure 2. Conjugation efficiency of HYNIC−HSA with [^{18}F]-FBA as a function of time. The protein concentrations are 3 mg/1.5 mL (●), 2 mg/1.5 mL (▲), 1 mg/1.5 mL (■), and 0.5 mg/1.5 mL (◆).

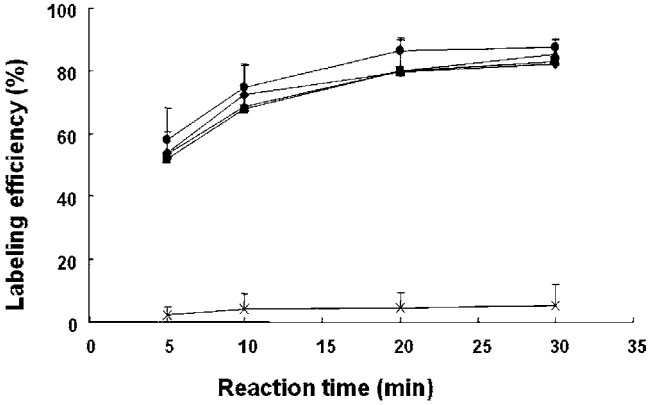

Figure 3. Conjugation efficiency of HYNIC−HSA with [^{18}F]-FBA as a function of time. The number of conjugated HYNIC per HSA on used HYNIC−HSA are 0 as a control (*), 5 (◆), 12 (■), and 23 (●).

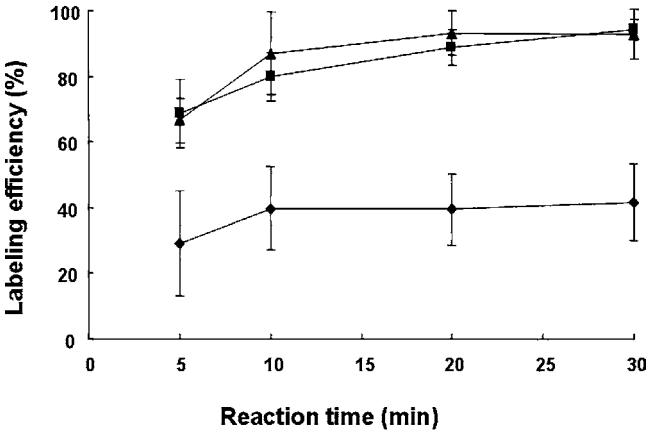

Figure 4. The effects of reaction temperature on conjugation efficiency of HYNIC−HSA with [^{18}F]FBA. The reaction temperatures are room temperature (◆), 50 °C (■), and 60 °C (▲).

Stability Test of ^{18}F-HSA. ^{18}F-HSA was very stable for 6 h both in 0.05 M phosphate buffer (pH = 7.4) at room temperature and in human serum at 37 °C (Figure 5).

Biodistribution Study in Mice. Biodistribution experiments using ^{18}F-HSA, ^{99m}Tc-HSA and [^{18}F]FBA were performed on normal mice (Figure 6). ^{18}F-HSA and ^{99m}Tc-HSA exhibited similar blood activities, while [^{18}F]FBA exhibited much lower blood activity. The bone

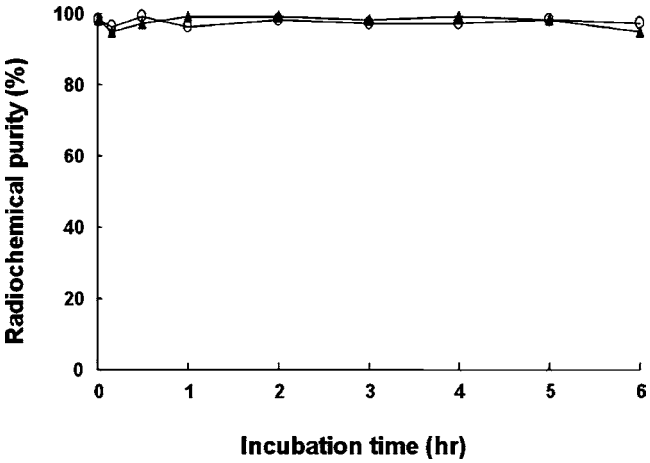

Figure 5. Stability test of ^{18}F-HSA in 0.05 M phosphate buffer (pH = 7.4) at room temperature (○) and in human serum at 37 °C (▲).

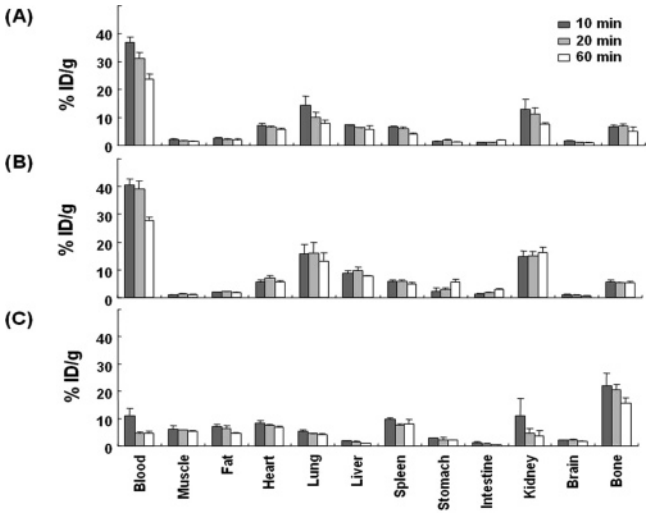

Figure 6. Biodistribution of (A) ^{18}F-HSA, (B) ^{99m}Tc-HSA, and (C) [^{18}F]FBA. The labeled agents were injected through the tail veins of mice.

uptake of ^{18}F-HSA was not increasing by time, which indicated that defluorination did not occur from ^{18}F-HSA in vivo. In the other organs, ^{18}F uptake was similar to or less than those observed with ^{99m}Tc-HSA.

DISCUSSION

HYNIC is a famous bifunctional chelating agent, which is used for the labeling of proteins with ^{99m}Tc (*1*, *2*, *13*, *15*, *17*). A variety of functional groups, including active esters, isothiocyanates, maleimides, hydrazides, and α-haloamides, have been developed in order to conjugate bifunctional chelating agents to proteins (*2*). Hydrazides have been demonstrated to react with aldehyde groups via the formation of stable hydrazone bonds with high yields. Thus, the hydrazone formation reaction for the coupling of aldehyde and/or hydrazide-containing proteins and/or bifunctional chelating agents has been applied to the preparation of protein−protein or protein−bifunctional chelating agent conjugates (*18*, *19*).

To determine the number of conjugated HYNIC per HYNIC-conjugated proteins, *p*-nitrobenzaldehyde is used, as it reacts with HYNIC−protein quantitatively with generation of a specific hydrazone, which exhibits a characteristic absorption at 385 nm. Actually, the protocols of this experiment are inspired from the quantification method used for HYNIC-protein. We used [^{18}F]FBA instead of *p*-nitrobenzaldehyde in this novel and simple method for the labeling of proteins or peptides with ^{18}F. This method proved to significantly reduce radiolabeling steps and reaction time relative to the other reported methods (*5*, *8*).

[^{18}F]FBA is a famous synthon which is used for the synthesis and ^{18}F-labeling of a variety of radiopharmaceuticals (*16*, *20*). In general, either *N*,*N*,*N*-trimethylammonium benzaldehyde or nitrobenzaldehyde can be used as a precursor for the synthesis of [^{18}F]FBA. We used *N*,*N*,*N*-trimethylammonium benzaldehyde because the positively charged quaternary ammonium can easily be removed from the neutral hydrophobic product using a combination of ion exchange and reverse phase cartridges. In this manner, [^{18}F]FBA can be produced in a no-carrier-added state which provides high specific activity.

Tetrabutylammonium bicarbonate, rather than crown ether such as Kryptofix 2.2.2, was used as a base to activate [^{18}F]fluoride in a nucleophilic substitution reaction in order to facilitate the next purification step in this experiment. Crown ether is difficult to remove as both it and [^{18}F]FBA are hydrophobic whereas the tetrabutylammonium ion can easily be removed by ion exchange cartridges together with precursor.

The prepared ^{18}F-HSA exhibited a high labeling efficiency and stability. Biodistribution studies in mice revealed that introduction of the HYNIC into HSA had no significant effects on the biological properties of HSA or on its in vivo stability as compared to ^{99m}Tc-HSA a verified and commercialized blood pool imaging agent.

A recent report reveals a chemoselective formation of oxime between unprotected aminooxy-functionalized peptides and [^{18}F]FBA with a high yield (*21*). They asserted that this method allowed for the fast and straightforward large-scale production of ^{18}F-labeled peptides for clinical routine PET application. Their method and our HYNIC method have a mechanism in common—namely, that some ammonia derivatives including hydroxylamine, hydrazine, phenylhydrazine, or semicarbazide form stable conjugates with either aldehydes or ketones. In our lab, the application of the HYNIC method proved to be more favorable than the oxime method as HYNIC has been already verified with regard to its application as a bifunctional chelating agent for the labeling of proteins or peptides with ^{99m}Tc. In addition, HYNIC−protein can be applied directly not only for ^{18}F labeling but also for ^{99m}Tc labeling.

There are some ^{18}F-labeling synthons those react with thiols (*22*) or contain thiols (*23*). Although these thiol-related synthons show high labeling efficiencies, highly reactive and unstable thiols can be a cause of problems in storage or preparation.

Our biodistribution study confirmed that ^{18}F-HSA labeled by this technique can be used for blood pool imaging, as it exhibited biodistribution pattern similar to that seen with ^{99m}Tc-HSA, which is an approved blood pool imaging agent, in the majority of the organs. [^{18}F]FBA, a small hydrophobic molecule, exhibited a very different biodistribution pattern as expected.

CONCLUSION

We developed a novel and simple method for the preparation of ^{18}F-HSA using a hydrazone formation mechanism between [^{18}F]FBA and HYNIC−HSA. The generated ^{18}F-HSA exhibited excellent in vitro and in vivo properties as a blood-pool imaging agent. This method

might prove quite applicable to the labeling of other proteins with ^{18}F as well.

Lipid Phase Control of DNA Delivery

Rumiana Koynova,*,† Li Wang, Yury Tarahovsky,‡ and Robert C. MacDonald

Biochemistry, Molecular & Cell Biology, Northwestern University, Evanston, Illinois 60208. Received July 27, 2005; Revised Manuscript Received October 5, 2005

Cationic lipids form nanoscale complexes (lipoplexes) with polyanionic DNA and can be utilized to deliver DNA to cells for transfection. Here we report the correlation between delivery efficiency of these DNA carriers and the mesomorphic phases they form when interacting with anionic membrane lipids. Specifically, formulations that are particularly effective DNA carriers form phases of highest negative interfacial curvature when mixed with anionic lipids, whereas less effective formulations form phases of lower curvature. Structural evolution of the carrier lipid/DNA complexes upon interaction with cellular lipids is hence suggested as a controlling factor in lipid-mediated DNA delivery. A strategy for optimizing lipofection is deduced. The behavior of a highly effective lipoplex formulation, DOTAP/DOPE, is found to conform to this "efficiency formula".

Efficient delivery of genetic material into biological systems is needed for tasks of utmost importance in laboratory and clinic, such as gene transfection and gene silencing. Synthetic cationic lipids can be used as DNA carriers and are now considered the most promising nonviral gene carriers (*1*). They form complexes (lipoplexes) with polyanionic DNA. Understanding the mechanism of lipid-mediated DNA delivery (lipofection) is of paramount significance for their effective application, as well as for rational design and synthesis of novel cationic lipid compounds that are promising for superior gene delivery. Here we advance the concept that the controlling factor in lipofection is the structural evolution of lipoplexes upon interaction with cellular (anionic) lipids.

The unbinding of DNA from a cationic lipid carrier when the lipoplex gets inside the cell has been identified as one of the key steps in lipofection. According to the current understanding, the unbinding is a result of charge neutralization by cellular anionic lipids; indeed, experiments have revealed that addition of negatively charged liposomes to lipoplexes results in dissociation of DNA from the lipid (*2*−*6*). A set of significant recent findings suggest that the structure of cationic lipid carriers changes dramatically upon interaction with cellular lipids, and furthermore that such changes may critically affect the delivery efficiency.

Hydrated lipids are known for their ability to form an impressive variety of polymorphic and mesomorphic phases, lamellar and nonlamellar, brought about by the optimization of the hydrophobic effect in conjunction with various intra- and intermolecular interactions and geometric packing constraints (*7, 8*). These phases are generally differentiated by the curvature of their lipid−water interface. The lipid phase state is a key physical

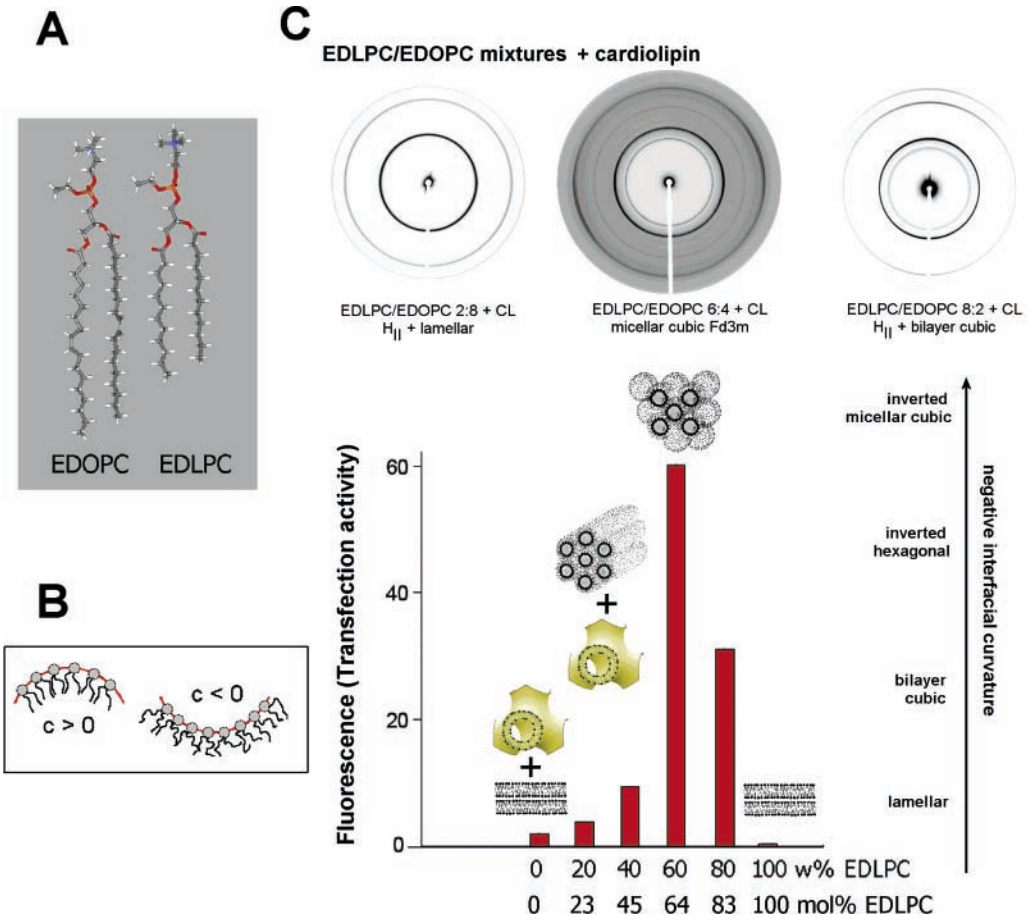

Figure 1. A. Molecular structures of the cationic phospholipids dioleoyl- and dilauroyl-*O*-ethylphosphatidylcholine. B. Illustration of lipid monolayers with positive (left) and negative (right) curvature. C. Correlation between the transfection efficiency (red bars) of ethyldilauroylphosphatidylcholine (EDLPC)/ethyldioleoylphosphatidylcholine (EDOPC) lipoplexes, as reported in ref 19 (quantified by expression of β-galactosidase in human umbilical artery endothelial cells) and the phase structure of their mixtures with the anionic lipid cardiolipin (CL). Cartoons of the phases are arranged vertically to give a qualitative notion about the increase of the interfacial curvature. Top row: diffraction patterns of mixtures of EDLPC/EDOPC lipoplex dispersions of different compositions with CL dispersions. The charge ratio of the cationic/anionic lipids in the samples is 1:1. Similar patterns were recorded also for mixtures of EDLPC/EDOPC with the anionic phosphatidylglycerol.

attribute because it mediates virtually all properties of lipid dispersions. Correlations between the mesomorphic phase state of the lipoplexes (lamellar vs inverted hexagonal) and their DNA delivery activity have been sought, but so far there is no clear consensus as to whether the hexagonal phase per se is beneficial for transfection (*9*−*14*).

It was recently reported that mixtures of cationic lipids with anionic lipids of the type found in cell membranes are unusually prone to form nonlamellar phases, even when the pure components form only the lamellar phase: even small amounts of anionic lipid added to certain cationic lipids generate virtually the entire panoply of possible lipid arrays (*15*−*17*). Since escape of DNA from the lipoplexes must involve neutralization of cationic lipid by cellular anionic lipids, most likely by fusion of cell membranes with lipoplexes, a wide variety of nonlamellar arrays can potentially appear in treated cells. Could the efficiency of transfection depend on which of those phases is preferred? This now seems very likely: in a previous study on this topic we demonstrated that DNA release measured after treating lipoplexes with anionic membrane lipids varies widely for the different cationic and anionic lipid combinations and, remarkably, showed an unambiguous correlation between the DNA unbinding and the phases formed by the mixtures of the anionic lipids with the cationic lipid of the lipoplexes (*18*). Specifically, the higher the negative interfacial curvature (polar/nonpolar interface curved toward the water, see Figure 1B) of the phase assumed by the cationic/anionic lipid mixture, the faster and more complete the release of DNA. We thus hypothesized that the structural evolution of lipoplexes upon interaction with cellular (anionic) lipids is a controlling factor in lipid-mediated DNA delivery. To test this suggestion, we compared the lipofection efficiency of certain lipoplexes with their phase behavior in mixtures with several anionic membrane lipids.

In our study we used lipoplex formulations comprising mixtures of the dilauroyl and dioleoyl derivatives of cationic ethylphosphatidylcholine (*2*), EDLPC/EDOPC (Figure 1A). It was discovered recently that delivery efficiency of such lipoplex formulations could be strongly modulated by merely varying the ratio of the two components (*19*). For example, the EDLPC/EDOPC mixture delivered DNA into cells more than 30-fold more efficiently at certain intermediate compositions than either compound separately (*19*). Given this astonishing synergy, we applied synchrotron X-ray diffraction to study the structural correlates of the lipoplex formulations and their mixtures with anionic lipids. The widely explored lipid transfection formulation, DOTAP/DOPE 1:1 (both from Avanti Polar Lipids) was also examined.

EDLPC/EDOPC cationic lipid dispersions were prepared by mixing lipids as chloroform solutions, with

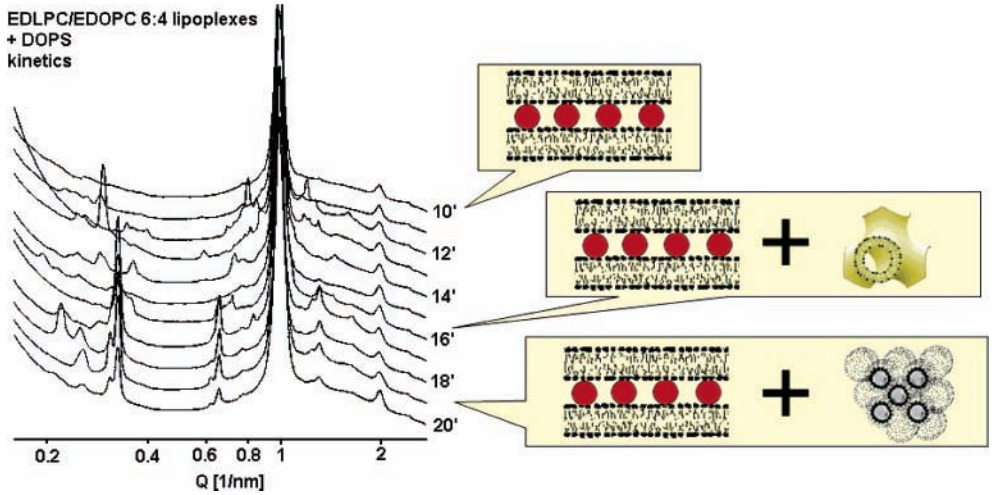

Figure 2. Kinetics of phase changes in the EDLPC/EDOPC lipoplexes of the highest activity (6:4 wt ratio (*19*)), upon addition of the anionic lipid DOPS, in the time interval 10 min to 30 min after the addition: bilayer cubic *Pn*3*m* phase forms initially in parallel to the lamellar phase; later, micellar cubic *Fd*3*m* could be distinguished. The charge ratio of the cationic/anionic lipids in the sample is 1:1.

subsequent chloroform evaporation under vacuum and overnight hydration in PBS (*17*). Lipoplexes were prepared by adding aqueous solution of herring sperm DNA (Invitrogen, Carlsbad, CA) to the cationic lipid dispersion at isoelectric ratio, vortexing, and overnight equilibration (*17, 20*). Anionic lipid dispersions were prepared from dioleoylphosphatidylserine (DOPS), dioleoylphosphatidylglycerol (DOPG), or tetraoleoylcardiolipin (CL) (Avanti Polar Lipids), as described in ref 18, and added to the lipoplexes. These mixed dispersions were then equilibrated for 1−2 days, filled into glass capillaries, and flame-sealed. For kinetic measurements, lipoplexes and anionic lipid dispersions were mixed and immediately mounted on the X-ray beamline for measurement. Small-angle X-ray diffraction (SAXD) measurements were performed at Argonne National Laboratory, Advanced Photon Source, BioCAT (beamline 18-ID) and DND-CAT (beamline 5-IDD), using 12 keV X-rays. A Linkam thermal stage (Linkam Sci Instruments, Surrey, England) provided temperature control. Linear heating scans were performed at rates of 0.8−2 °C/min. Exposure times were typically ∼0.5−1 s.

Both the lipid dispersions and the lipid/DNA complexes of the EDLPC/EDOPC mixture arrange into lamellar arrays at all compositions; the same is valid for the anionic lipid dispersions (not illustrated). When anionic lipids interact with the lipoplexes however, precisely those lipoplex compositions that exhibit particularly high transfection efficiency, EDLPC/EDOPC 60:40 w/w, formed the inverted micellar cubic phase, *Fd*3*m*, while either components and mixtures of other compositions all formed phases of lower curvature (Figure 1C), as revealed by our small-angle X-ray diffraction data. The micellar cubic phase exhibits even higher interfacial curvature than the more familiar inverted hexagonal phase (*8*). In the case of the anionic lipid cardiolipin (CL), in a sample of 1:1 cationic/anionic lipid charge ratio, this phase is identified by 11 diffraction maxima with reciprocal spacings fitting the ratio: $\sqrt{8}$: $\sqrt{11}$: $\sqrt{12}$: $\sqrt{16}$: $\sqrt{24}$: $\sqrt{32}$: $\sqrt{35}$: $\sqrt{36}$: $\sqrt{48}$: $\sqrt{51}$: $\sqrt{56}$, characteristic for the cubic aspect #15 (*21*). The anionic lipid dioleoylphosphatidylglycerol similarly formed micellar cubic phase when mixed with the most efficient EDLPC/EDOPC 6:4 formulation (not illustrated). Another anionic membrane lipid, phosphatidylserine, was found to form the micellar cubic phase transiently when mixed extempore with the EDLPC/EDOPC 6:4 formulation, as revealed by our kinetic synchrotron X-ray experiments (Figure 2). The pure cationic lipid components (EDLPC, EDOPC) and their mixtures of other, less effective compositions, formed phases of lower curvature: inverted hexagonal, bilayer cubic, and/or coexisting lamellar (Figure 1C).

Thus, transfection outcome appears to corellate with the propensity of the cationic/anionic lipid mixture to evolve into highly curved mesomorphic structure when they interact. According to our earlier study, DNA unbinding after treating lipoplexes with anionic lipids also unambiguously correlated with the disposition of the cationic/anionic lipid mixtures to form assemblies of highly curved topologies (*18*). The propensity of lipid bilayers to form nonlamellar phases has been described by the concept of bilayer "frustration" brought about by the imbalance of forces in the bilayer and which imposes a nonzero intrinsic curvature of the two opposing monolayers (*8, 22, 23*). In terms of this concept, those cationic lipid formulations, which tend to easily transform into curved nonlamellar arrays when mixed with anionic lipid, presumably retain higher degree of "frustration". The stored curvature elastic energy in a "frustrated" bilayer seems to be comparable to the cationic lipid-DNA binding energy: the same magnitude of $\sim 1-2k_BT$ has been estimated for both the binding free energy of lipoplexes (*24*−*26*) and the curvature elastic energy stored in a flat DOPE-dominated membrane (*27, 28*). The release of stored curvature elastic energy upon lamellar−nonlamellar phase transition and the balance between these energy terms could therefore play a significant role in lipoplex−membrane interactions and DNA unbinding energetics. This result corroborates our hypothesis that structural evolution of lipoplexes upon interaction with cellular lipids is the controlling factor in lipid-mediated DNA delivery. Here we recall that, for effective delivery, DNA must be retained until the lipoplex is inside the cell; thus, initial lamellar lipoplex structures are likely responsible for the successful import of DNA into cells.

Juxtaposing our results, a strategy for optimizing lipofection can be deduced: lamellar lipoplex formulations with compositions close to the lamellar−nonlamellar phase boundary, which could easily undergo phase transition upon mixing with cellular anionic lipids (Figure 3), are predicted to be especially efficient because they would be equally successful in transporting DNA into

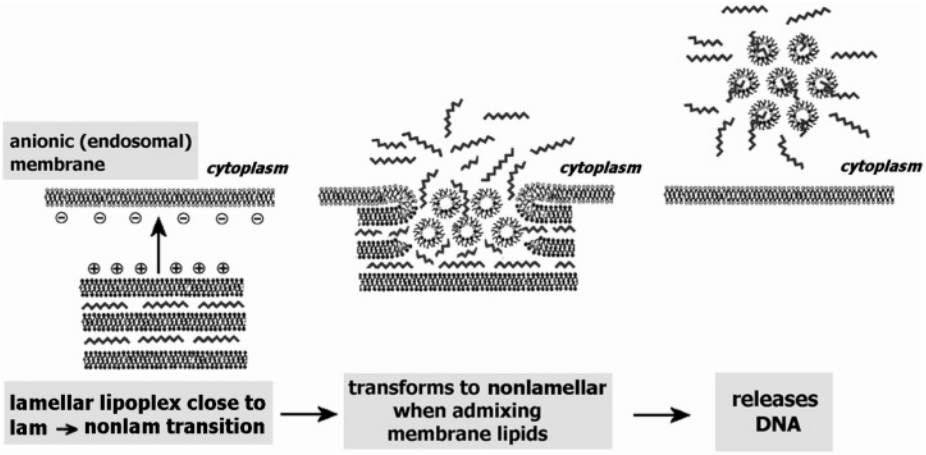

Figure 3. Hypothetical scheme for efficiency of DNA delivery: Lamellar lipoplexes residing close to the lamellar−nonlamellar phase transition form nonlamellar structures upon contacting the cellular lipids and thus exhibit optimum delivery efficiency (alternatively, lipoplexes retaining their lamellar structure after contacting the endosomal membrane may not efficiently release DNA; on the other hand, nonlamellar lipoplexes may release DNA prematurely).

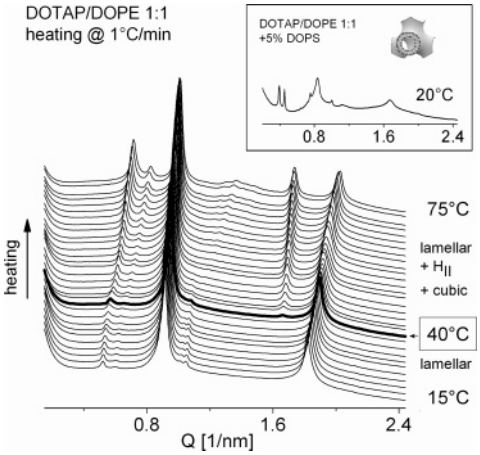

Figure 4. Small-angle X-ray diffraction patterns of DOTAP/DOPE (1:1 mol/mol) dispersion recorded during heating at 1 °C/min (exposure time 1 s): at low temperatures, the sample forms lamellar phase (with minor traces of cubic). Upon heating, hexagonal phase starts to form at ∼39−40 °C, which coexists with the lamellar phase. Inset: Upon addition of 5% of the anionic membrane lipid DOPS, cubic phase dominates in the dispersion at room and physiological temperatures.

cells (since lamellar phase optimally protects DNA (*18*)) and in releasing it subsequently.

Indeed, our X-ray diffraction experiments have now provided explicit support for this "efficiency formula": we found that one of the very effective and widely explored lipid transfection formulations, DOTAP/DOPE 1:1 (mol/mol), exhibits precisely this behavior: Samples prepared at low (below physiological) temperature form the lamellar phase, whereas upon heating, lamellar → inverted hexagonal phase transition begins just above physiological temperature, at ∼39−40 °C (Figure 4). Addition of a minor proportion (≤5%) of the anionic lipid phosphatidylserine was enough to convert the lipoplex structure into a predominantly cubic bicontinuous *Pn*3*m* phase at physiological temperature (Figure 4, inset). Thus, after uptake into the cell, these lipoplexes would very easily be converted into nonlamellar arrays that allow the DNA release, which is the likely reason for their effectiveness. Therefore, rational design of cationic lipid formulations residing close to the lamellar−nonlamellar phase transition may bring about superior delivery efficiency, especially if that phase transition is facilitated by acquisition of minor amounts of anionic lipids and/or elevation of the temperature to 37 °C.

Polyketal Nanoparticles: A New pH-Sensitive Biodegradable Drug Delivery Vehicle

Michael J. Heffernan and Niren Murthy*

The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332. Received June 20, 2005; Revised Manuscript Received August 17, 2005

In this report, we present an acid-sensitive drug delivery vehicle, termed polyketal nanoparticles, which are designed to target therapeutics to the acidic environments of tumors, inflammatory tissues, and phagosomes. The polyketal nanoparticles are formulated from poly(1,4-phenyleneacetone dimethylene ketal) (PPADK), a new hydrophobic polymer which contains ketal linkages in its backbone. The polyketal nanoparticles undergo acid-catalyzed hydrolysis into low molecular weight hydrophilic compounds and should therefore release encapsulated therapeutics at an accelerated rate in acidic environments. Importantly, the polyketal nanoparticles do not generate acidic degradation products after hydrolysis, as with polyester-based biomaterials. Dexamethasone-loaded nanoparticles, 200−600 nm in diameter, were fabricated with PPADK via an emulsion procedure using chloroform and water. The hydrolysis half-life of PPADK was measured to be 102 h at pH 7.4 and 35 h at pH 5.0. PPADK was synthesized by a new polymerization strategy based on the acetal exchange reaction. This new delivery system should find numerous applications in the field of drug delivery because of its ease of synthesis and excellent degradation properties.

Drug delivery vehicles based on polyesters and polyanhydrides have been widely used for the sustained release of therapeutics because of their excellent biocompatibility profiles and slow hydrolysis rates (*1*−*4*). However, numerous medical applications, such as targeting the acidic environment of lysosomes and tumors, require drug delivery systems that undergo rapid, pH-sensitive degradation (*5*, *6*). The majority of degradable polymers used for drug delivery cannot fulfill this requirement because they are composed of ester linkages, which degrade by base-catalyzed hydrolysis at physiological pH values. Recently, pH-sensitive hydrophobic microparticles based on poly(ortho esters) and poly(β-amino esters) have been successfully used for intracellular drug delivery and tumor targeting, thus demonstrating the potential of acid-sensitive biomaterials for drug delivery (*7*−*10*). Consequently, there is great interest in developing new strategies for the synthesis of pH-sensitive biodegradable polymers.

In this communication, we present an acid-sensitive hydrophobic nanoparticle based on a new polymer, poly(1,4-phenyleneacetone dimethylene ketal) (PPADK), which complements existing biodegradable nanoparticle technologies. This polymer has ketal linkages in its backbone and degrades via acid-catalyzed hydrolysis into low molecular weight compounds that can be easily excreted. PPADK forms micro- and nanoparticles, via an emulsion procedure, and can be used for the delivery of hydrophobic drugs and potentially proteins. In contrast to polyester-based biomaterials (*11*), the hydrolysis of polyketal nanoparticles does not generate acidic degradation products. Also, PPADK decomposes on a time scale that is faster than PLGA, but slower than poly(ortho esters) and poly(β-amino esters), and therefore provides the drug delivery community with a greater ability to tailor drug release kinetics to a particular application.

PPADK was synthesized via a new polymerization strategy based on the acetal exchange reaction. The acetal exchange reaction (*12*) is generally used to introduce protecting groups onto low molecular weight alcohols (*13*). However, we demonstrate here that the acetal exchange reaction can be used to generate acid labile polymers through the step growth polymerization of 1,4-benzenedimethanol and 2,2-dimethoxypropane (Scheme 1). This polymerization begins with an equilibrium reaction between 1,4-benzenedimethanol and 2,2-dimethoxypropane, generating dimers and trimers, which can further combine to form polymers. The formation of polymers is favored by distilling off the methanol byproduct formed during the polymerization reaction.

A representative polymerization of 2,2-dimethoxypropane and 1,4-benzenedimethanol gave PPADK with a 48% yield.[1] Figure 1A shows the GPC trace from one batch in which M_w = 4000 was obtained, corresponding to a degree of polymerization of 22.5 repeating units, with a polydispersity index of 1.54. The ^{1}H NMR spectrum

[1] The polymerization was carried out in a 25 mL two-necked flask connected to a short-path distilling head. 1,4-Benzenedimethanol (1.0 g, 7.3 mmol, Aldrich) dissolved in 10 mL of warm ethyl acetate was added to 10 mL of distilled benzene kept at 100 °C. Recrystallized *p*-toluenesulfonic acid (5.5 mg, 0.029 mmol, Aldrich) dissolved in 550 μL of ethyl acetate was then added. After allowing the ethyl acetate to distill off, distilled 2,2-dimethoxypropane (900 μL, 7.4 mmol, Aldrich) was added to initiate the reaction. Five additional doses of 2,2-dimethoxypropane were added via a metering funnel, with each dose consisting of 2 mL of benzene plus 300 to 500 μL of 2,2-dimethoxypropane. Each dose was added over a 30 to 40 min period with a 30 min interval in between. The total duration of the reaction was 7 h. The reaction was stopped with the addition of 100 μL of triethylamine and was precipitated in cold hexanes. The crude product was vacuum filtered, rinsed with ether and hexanes, and vacuum-dried to yield 600 mg of white solid product (48% yield). The recovered polymer was analyzed by GPC and ^{1}H NMR.

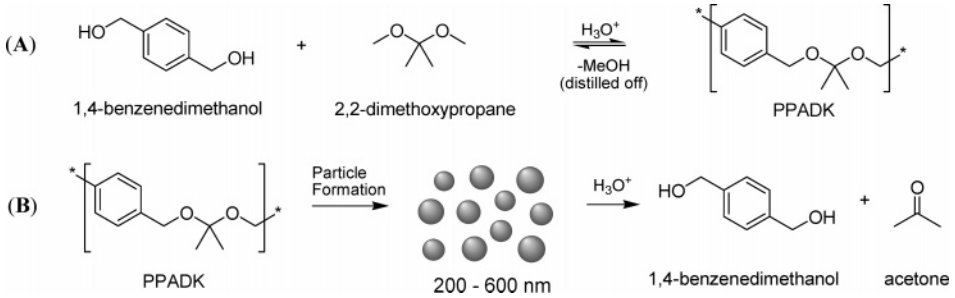
Scheme 1. Synthesis of the Polyketal, Poly(1,4-phenyleneacetone dimethylene ketal) (PPADK), via the Acetal Exchange Reaction[a]



[a] (A) Stepwise polymerization based on the acetal exchange reaction between 1,4-benzenedimethanol and 2,2-dimethoxypropane to produce PPADK. (B) Formation of drug-loaded nanoparticles by the solvent evaporation method. Particles exhibit pH-sensitive degradation into low molecular weight excretable compounds.

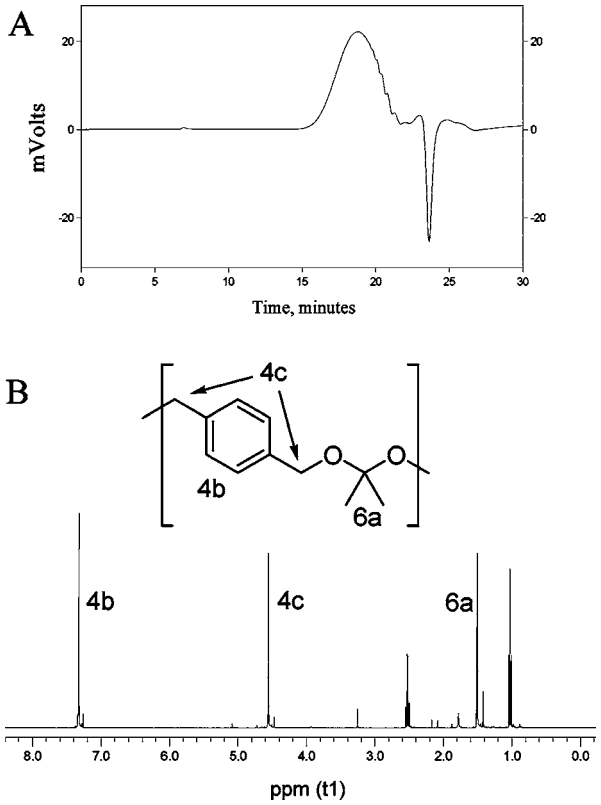


Figure 1. (A) GPC trace of PPADK in THF (Shimadzu SCL-10A). $M_w = 4000$, $M_w/M_n = 1.54$ based on a polystyrene standard (Polymer Laboratories, Inc.) (1060 M_w, 20.8 min; 2970 M_w, 19.0 min; 10,680 M_w, 16.5 min). *Y*-axis indicates relative absorbance at 262 nm. (B) ^{1}H NMR spectrum of PPADK in $CDCl_3$ (Varian Mercury Vx 400); repeating unit peaks at 7.3 ppm (4b), 4.5 ppm (4c), and 1.5 ppm (6a). Peaks at 2.5 and 1.0 are due to triethylamine added to prevent ketal hydrolysis.

(Figure 1B) confirms that the repeating unit of PPADK contains a ketal group ('6a'). Together, the GPC and ^{1}H NMR data provide evidence for the successful synthesis of PPADK.

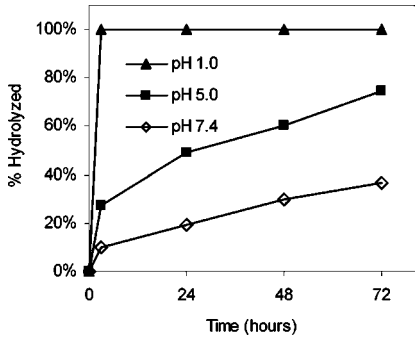

Figure 2. Hydrolysis kinetics of PPADK (finely ground powder) at pH 1.0, 5.0, and 7.4 (37 °C). Exponential decay half-lives are 102 h (pH 7.4) and 35 h (pH 5.0). The pH 1.0 control batch was completely hydrolyzed before the first time point.

The hydrolysis kinetics of PPADK was measured at pH values corresponding to lysosomes (pH 5.0) and the bloodstream (pH 7.4). The hydrolysis rates were measured by grinding PPADK into a fine powder and adding it to deuterated solutions at pH 7.4 (phosphate buffer), pH 5.0 (acetate buffer), and pH 1.0 (DCl).[2] Exponential decay half-lives were calculated to be 102 h at pH 7.4 and 35 h at pH 5.0, representing a 3-fold rate increase from pH 7.4 to 5.0 (Figure 2). The pH sensitivity of PPADK is significantly less than the 250-fold increase from pH 7.4 to 5.0 reported by Kwon et al. (*14*) for a water-soluble ketal. We hypothesize that the lower pH sensitivity of PPADK is due to its water insolubility, which limits the diffusion of water and creates another rate-limiting step that is pH-independent.

[2] The suspensions were stirred at 37 °C, and data points were taken at 3, 24, 48, and 72 h. Each suspension was centrifuged for 4 min at 1800*g*, and the supernatant was analyzed by ^{1}H NMR. The spectra contained peaks for 1,4-benzenedimethanol (7.24 and 4.47 ppm) and acetone (2.05 ppm). The average of the two 1,4-benzenedimethanol peak integrals was used to determine the relative degree of hydrolysis. The percent hydrolysis was calculated as the 1,4-benzenedimethanol peak average of the pH 7.4 or 5.0 sample divided by the 1,4-benzenedimethanol peak average of the pH 1.0 control batch.

[3] DLS samples were prepared by diluting the particle suspension in 10 mL of pH 9 buffer and allowing the larger particles to settle out. An aliquot from the liquid portion of each vial was then diluted for DLS particle sizing (Brookhaven 90Plus particle sizer). An SEM sample was made with the 0.2:1 ratio of PVA: PPADK by centrifuging the nanoparticle suspension for 10 min (5000*g*, 4 °C), washing with distilled water, and lyophilizing the recovered pellet.

[4] Control batches were prepared with PPADK/PVA only and Dex only. To measure Dex encapsulation, each particle batch was resuspended in pH 9 buffer, and an aliquot was then further diluted. A portion was filtered through a 0.1 μm Supor membrane Acrodisc syringe filter (Pall Corp.), and the 242 nm absorbance of the filtrate was recorded with a Shimadzu UV-1700 spectrophotometer. The encapsulation efficiency was calculated as $(A_{Dex} - A_{DexPoly})/(A_{Dex} - A_{Poly})$, where A is the absorbance at 242 nm and the subscripts 'Poly', 'Dex', and 'DexPoly' refer to the 'PPADK only', 'Dex only', and 'Dex + PPADK' samples, respectively. These calculations resulted in a Dex encapsulation efficiency of 43% to 53% for various samples.

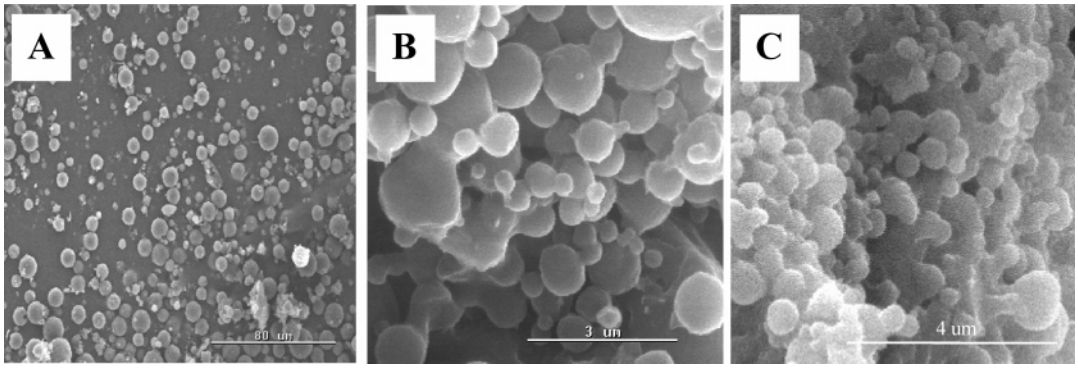

Figure 3. SEM images of particles made with PPADK. (A,B) Microparticles using 0.2:1 ratio of PVA to PPADK. (C) Dexamethasone-loaded nanoparticles made using 1:1 PVA:PPADK. Scale bars are (A) 80 μm, (B) 3 μm, and (C) 4 μm. SEM images were generated with a Hitachi S4100 by Dr. Lisa Detter-Hoskin of the Georgia Tech Research Institute, Atlanta, GA.

Micro- and nanoparticles were synthesized with PPADK using an oil-in-water emulsion method (*15*). Briefly, 50 mg of PPADK dissolved in 1 mL of $CHCl_3$ (with 0.1% triethylamine) was added to 5 mL of pH 9 buffer (10 mM $NaHCO_3$) containing various amounts of poly(vinyl alcohol) (PVA, 31−50 kDa, Aldrich) as the emulsifier. The oil−water mixture was shaken briefly and then sonicated for 2 to 3 min at 40 W (Branson Sonifier 250) to form a fine oil/water emulsion. The emulsion was stirred under N_2 flow for at least 3 h to evaporate the solvent and produce a nanoparticle suspension.

Particle sizes were analyzed by dynamic light scattering (DLS) and SEM.[3] As expected, the particle size was sensitive to the ratio of PVA to PPADK. The DLS particle diameters were 520, 290, and 280 nm for samples containing 0.2:1, 0.8:1, and 2:1 mass ratios of PVA:PPADK, respectively. The SEM images of the 0.2:1 batch (Figures 3A and 3B) confirm that PPADK does form micron-sized particles, with particle size distribution ranging from 0.5 to 30 μm in diameter.

The antiinflammatory drug dexamethasone (Dex, Sigma) was encapsulated into nanoparticles made with PPADK. Dex-loaded particles were formulated using the same procedure as that described above, except that the oil phase contained a 5 mg/mL concentration of Dex and the mass ratio of PVA:PPADK was 1:1. SEM images of these particles demonstrate that they are 200−600 nm in diameter (Figure 3C). Particle sizing by DLS indicated an effective diameter of 250 nm for the Dex-loaded particle batches. The Dex encapsulation efficiency ranged between 43 and 53%.[4]

In summary, we have developed a new pH-sensitive biodegradable polymer for drug delivery, synthesized via the acetal exchange reaction between 2,2-dimethoxypropane and 1,4-benzenedimethanol. This polymer is unique in that it contains ketal linkages in the polymer backbone, allowing for acid-catalyzed hydrolysis into low molecular weight, water soluble compounds. Dexamethasone-loaded nanoparticles were fabricated in the 200 to 600 nm range, which is suitable for applications involving phagocytosis by macrophages. The relative ease of polymer synthesis and particle formation, as well as its rapid pH-sensitive degradation into low molecular weight excretable compounds, suggest that this new polyketal will find numerous applications in the field of drug delivery.

Current interest in biomaterials for tissue engineering and drug delivery applications have spurred research into self-assembling peptide amphiphiles (PAs). Nanofiber networks formed from self-assembling PAs can be used as biomaterial scaffolds with the advantage of specificity by the incorporation of peptide-epitopes. Imaging the materials noninvasively will give information as to their fate in vivo. We report here the synthesis and in vitro MR images of self-assembling peptide amphiphile contrast agents (PACAs) that form nanofibers. At 400 MHz using a 0.1 mM Gd(III) conjugate of the PA we observed a T_1 three times that of a control gel. The PA derivative was doped into various epitope bearing PA solutions and upon gelling resulted in a homogeneous biomaterial as imaged by MRI.

INTRODUCTION

Current interest in human tissue repair has prompted the development of biomaterial scaffolds where the goal is to envelop cells in an environment mimicking extracellular matrix and mediate processes such as cell proliferation and differentiation (*1*−*4*). Tissue repair in mature organisms can be crippled because many of the molecular cues present in early development are absent. Peptide sequences (epitopes) can be used to influence specific cell matrix interactions leading to tissue formation (*5*). Therefore, providing a synthetic scaffold with epitopes affords the possibility of in vivo tissue regeneration (*4, 5*).

Nanofiber networks derived from self-assembling peptide amphiphiles (PAs) have been used to mimic bone extracellular matrix and provide a scaffold to direct the differentiation of neural progenitor cells in vitro (*6, 7*). PA molecules contain a peptide sequence at one terminus that is hydrophilic relative to the hydrophobic alkyl segment (Figure 1). The PA's charge and amphiphilic nature allows for solubility and promotes self-assembly in aqueous media into long cylindrical structures that are nanometers in diameter and up to microns in length (*6*−*11*). These supramolecular structures can form fibrous strands because of hydrogen bond formation between the amino acids of adjacent PA molecules. In our case, the β-sheet-forming sequence of LLLAAA together with the hydrophobic alkyl tail's collapse is thought to be the driving force in extended structures, rather than spherical micelles (9−*11*). The high aspect ratio nanofibers form a three-dimensional network trapping water, to create a self-supporting gel that is 99% water by mass (*6, 11*). Since the hydrophilic portion of the PA contains charged amino acids and are accessible to the aqueous environment, the self-assembled nanofibers can present a high density of epitopes on the periphery (*6, 10, 11*) of the nanofibers to interact with cells trapped within (*7*). To understand the scaffolds properties in vivo, it is necessary to elucidate the structural degradation and migration of the self-assembled materials postimplantation (*12*−*16*).

Magnetic resonance imaging (MRI) is a noninvasive technique for in vivo imaging and is an ideal tool for fate mapping of tissue scaffolds at near cellular resolution (*15, 17, 18*). We have chosen this modality to image self-assembled gels that integrate into their structure PA molecules conjugated to Gd(III) contrast agents (PACAs). Recently, we reported on the synthesis and characterization of PACA derivatives of PA molecules that were capable of self-assembling into nanofibers or spherical micelles (*19*). Here, we report on the synthesis and in vitro images of two PACA derivatives mixed with a variety of epitope bearing PA biomaterials. A number of reports have described the use of MRI to track implants in vivo (*12, 14, 15, 20*−*23*); however, to our knowledge this is the first demonstration that self-assembled biomaterials conjugated with MR contrast agents can be imaged.

MATERIALS AND METHODS

Preparation of 1−3. Amino acids were purchased from NovaBiochem. All other reagents were purchased from Sigma-Aldrich and used without further purification unless otherwise stated. The branched PAs **1**, **2** (*19*), **3** were prepared by 9-fluorenylmethoxycarbonyl (Fmoc) solid-phase peptide synthesis (SPPS) on a 0.1 mmol scale. **1** was prepared by SPPS, and branching of the peptide

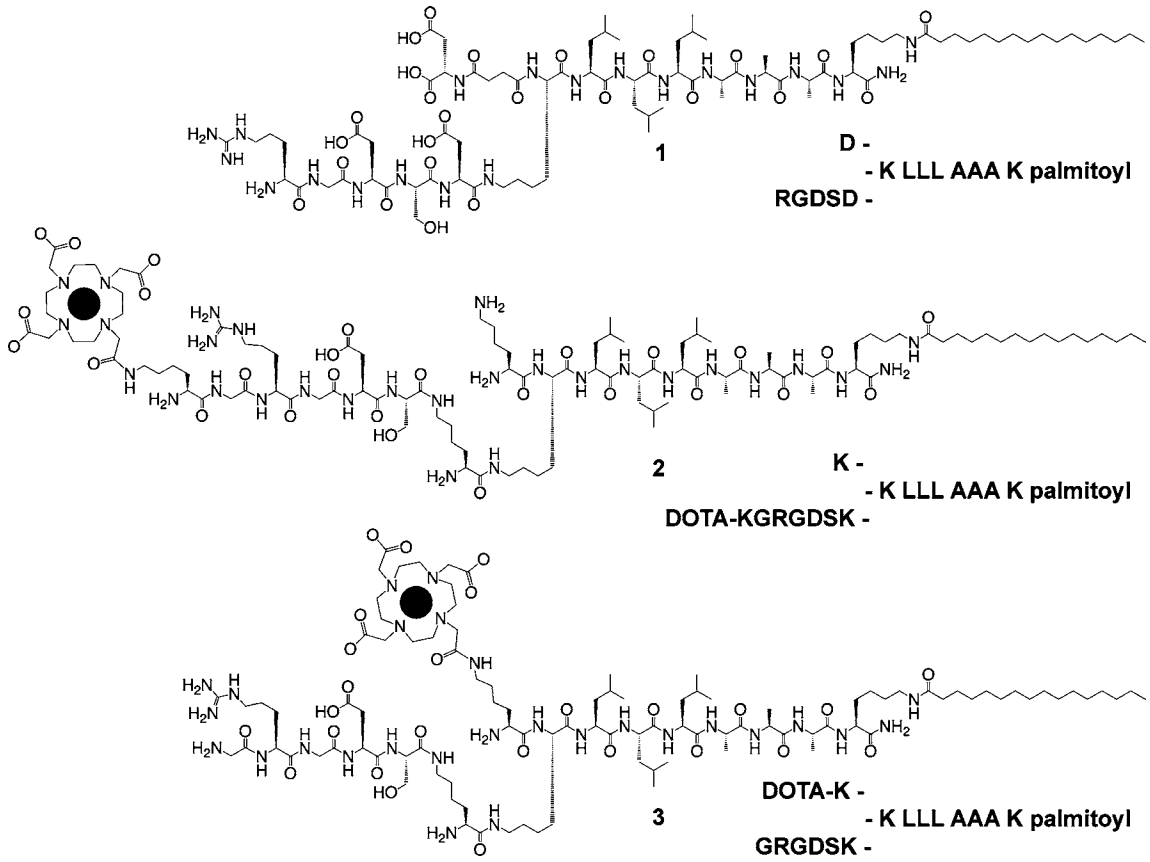

Figure 1. Structures of the PA molecules with the black circles representing the Gd(III) ion. **1** is an example of a filler PA and does not contain the Gd(III) chelate. **2** and **3** are the PACA molecules used in this study containing Gd(III). The basic structure of the PA contains three sections: a headgroup, body, and an alkyl tail. The headgroup is composed of an epitope for specific cell interaction and is presented on the outside of the supramolecular fibers. The body is structural in function by use of the hydrogen bond formation between molecules and is the driving force for fiber formation. The palmitoyl tail of the PA is used to drive self-assembly by initiating a hydrophobic collapse in an aqueous environment.

headgroup was achieved using orthogonal protecting group chemistry for the amines at the α and ϵ positions of the lysine residue (*19, 24*). Fmoc-Lys(Mtt)-OH (Mtt: 4-methyltrityl) was coupled to MBHA Rink Amide resin, followed by cleavage of the Mtt protecting group on the ϵ-amine to couple palmitic acid without affecting Fmoc protection with a 5% TFA in DMF solution for 5 min. This was followed by Fmoc removal on the α-amine to grow the LLLAAA peptide segment of the PA using 30% piperidine/DMF solution for 10 min. The branching point was introduced at a lysine dendron using Fmoc-Lys(Mtt)-OH. To grow the first arm of the PA, Fmoc on the α-amine was removed before Mtt. L-Aspartic acid di-*tert*-butyl ester hemiscucinate residue was coupled to the first branch. Mtt on the ϵ-amine of the lysine residue was removed, and bioactive peptide sequence RGDS was grown. Aspartic acid residue before the RGDS was coupled to increase solubility of the molecule in water. **1** was cleaved from the resin in 95:2.5:2.5 TFA:TIS:H_2O. Excess TFA was evaporated under reduced pressure and crude PA solutions were triturated using cold ether. MALDI-TOF mass spectroscopy 1810.40 (calcd 1810.14)

2 and **3** were synthesized using orthogonal protection group chemistry for the amines at the α and ϵ positions of the lysine residue. Fmoc-Lys(Mtt)-OH was coupled to MBHA Rink Amide resin, followed by cleavage of the Mtt protecting group on the ϵ-amine for palmitic acid coupling without affecting the Fmoc protection. This was followed by Fmoc removal on the α-amine to extend the peptide segment of the PA. The branching point in the PAs was introduced at a lysine dendron using Fmoc-Lys(Mtt)-OH. To extend the first arm of PAs, Fmoc on the α-amine was removed before Mtt. For molecule **2**, Boc-Lys(Boc)-OH was coupled at the end of the first branch. Both α and ϵ-amine positions of the lysine were blocked with Boc protection as it is more stable under the cleavage conditions employed for the removal of Fmoc and Mtt. For **3**, Boc-Lys(Fmoc)-OH was coupled as the first branch. Fmoc was deprotected and tris-*tert*-butyl-protected 1,4,7,10-tetraazacyclododecane-1,4,7,10 tetraacetic acid (DOTA) (purchased from Macrocyclics) was coupled at the end of the first branch. Mtt was removed, and the other branch was grown using Boc-Lys(Fmoc)-OH. The peptide sequence RGDS (important in cell adhesion) was coupled to the ϵ-amine in order to combine bioactivity and MR functionality. For **2**, the DOTA moiety was coupled on SPPS to the N-terminus of the peptide sequence by using a *tert*-butyl ester-protected DOTA molecule. **2** and **3** were cleaved from the resin in 95:2.5:2.5 TFA:TIS:H_2O. Excess TFA was evaporated under reduced pressure, and crude PA solutions were triturated using cold ether. **2** and **3** were dried under vacuum and characterized by MALDI-MS with a single peak found at 2308.66 (calcd 2308.87) and 2180.02 (calcd 2179.69), respectively. The final product was obtained by the addition of $GdCl_3$ with stirring at pH 6.5 for 72 h and purified by dialysis in deionized water (1000MWC Spectrum Laboratories Inc.). Samples were then lyophilized into a white powder. MALDI-MS showed peaks at 2464.40 (calcd 2463.09) and 2336.08 (calcd 2335.61) corresponding to **2** and **3** M + H, respectively.

Inductively Coupled Plasma Mass Spectrometry. Inductively coupled plasma mass spectrometry (ICP-MS) was performed on a Thermo Jarrell Ash Atomscan Model

25 Sequential ICP Spectrometer. Samples were prepared by taking an aliquot of **2** and **3** from the stock solution used for relaxivity and T_1 measurements and placed in 600 μL of neat nitric acid. Five milliliters of deionized water was added, and the solution was ultrasonicated for 3 min. The volume was brought up to 9990 μL with deionized water, and 10 μL of an indium standard was added to bring the total volume to 10 mL.

Relaxivity Measurements. Relaxivity measurements were performed on **2** and **3** by reconstituting the samples in deionized water to form stock solutions, and the relaxivity experiments were performed on a Bruker mq60 NMR Analyzer (Bruker Canada, Milton, Ont., Canada) in pH 7.41 (*25*) buffer at 37 °C. Four samples were prepared of each **2** and **3** at concentrations of about 0.005, 0.01, 0.015, 0.02 mM (actual concentrations of Gd(III) were calculated from ICP-MS). Measurements were performed in quadruplicate and plotted as $1/T_1$ vs mM Gd(III). The slope of this line provides the molar relaxivity.

T_1 Measurements. T_1 measurements were performed on a 9.4 T Oxford superconducting magnet (Bruker). The samples were prepared by making a 4 wt % solution of **1** in water. This solution was then aliquoted into four separate 3-dram vials. The appropriate amount of Gd(III)-containing molecules in aqueous solution was added to each vial to bring the concentration of Gd(III) to 0.1 mM (*26*). Excess water was added to bring the total volume to 250 μL. These solutions were ultrasonicated for 30 s and transferred to 5 mm NMR tubes. Fifty microliters of 0.1 M calcium carbonate buffer was added to each tube to increase the pH and induce gelation. Four sample tubes were bound together using Parafilm wax and inserted into the magnet. Images were acquired using a spin−echo pulse sequence with TR of 152, 200, 400, 750, 1000, 1400, 1800, 2500, 4000, 10 000 ms, TE 12 ms, slice thickness of 1 mm (eight slices taken), and FOV of 2 cm.

Circular Dichroism. Circular dichroism (CD) was performed on a Jasco J-715 CD spectrophotometer using a 2 mm quartz cuvette. Samples were prepared from the stock solution in water to a final concentration of 3.33×10^{-6} M at a pH of 7.4 in PBS buffer. Five spectra from 190 to 260 nm were averaged together.

AFM. AFM preparation was from the same stock solutions of **1**−**3** (0.005 mM) that were used to determine relaxivity, diluted 1:10 with deionized water. Samples were prepared by drop casting 5 μL of the diluted solutions onto freshly cleaved mica substrates. Samples were allowed to rest for 2 min before excess solution was wicked away. After drying in air, AFM was performed with a Digital Instruments MultiMode III SPM with a Quadrex extender and Olympus AC240TS cantilevers in tapping mode. Height measurements were taken on 149 straight fiber segments using the cross-sectional averaging tool included in Digital Instruments Nanoscope III acquisition analysis software.

RESULTS

Description of 1−3 and Molar Relaxivity. The Gd(III) chelator is a DOTA derivative selected because of its high binding constant for lanthanides and synthetic versatility (*27*). **1** (filler PA) is a self-assembling PA that forms self-supporting gels and is similar in sequence to **2** and **3** but does not contain the Gd(III) chelator and thus was used as a standard to compare to the MR images of the gels with Gd(III). Gels of **1** and **2**, or **1** and **3**, were prepared to demonstrate the minimal concentration of peptide amphiphile contrast agent (PACA) needed to obtain good MR contrast, leaving the remaining PA molecules free to present different epitopes on the nanofibers. Varying the position of the tethered DOTA derivative on the PAs induces changes in the molecule's relaxivity (efficiency) and imaging utility (*19*). The PACA derivatives described contain the RGD peptide sequence, a well-known epitope in integrin-binding domains of extracellular proteins that is critical for adhesion of many types of cells to the extracellular matrix (*28*). We have observed that positioning the chelate close to the hydrophobic end of the molecule results in a higher relaxivity (*19*). **2** and **3** differ in the position of the Gd(III) chelator, that results in a change in relaxivity in the self-assembled state from 14.7 mM^{-1} s^{-1} (*19*) to 21.5 mM^{-1} s^{-1}, respectively (*26*) in a buffer solution at pH 7.41 (*25*). The difference in relaxivity between **2** and **3** is likely due to a difference in the rotational correlation time, τ_r, arising from decreased internal flexibility and increased steric hindrance of the chelator in **3** as compared to **2** (*18, 29*).

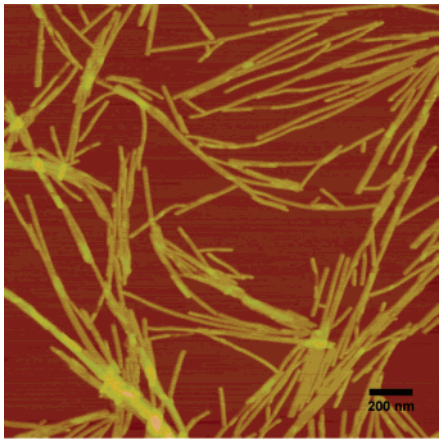

Figure 2. AFM micrograph of nanofibers formed from **3**. This image depicts the supramolecular assembly of the PACAs into fibers. These high aspect fibers then form a network trapping water and creating a gel. The fiber heights correspond to 6.0 ± 0.1 nm.

Supramolecular Properties of Nanofibers. Transmission electron microscopy (TEM) and atomic force microscopy (AFM) reveal the supramolecular structural aggregates from **1** (*30*), **2** (*19*), and **3** (Figure 2). Both **2** and **3** self-assemble into fibers at pH greater than 7.0 and **1**−**3** form uniform nanofibers microns in length. The fiber diameter of structures formed by **3** was calculated from AFM height measurements to be 6.0 ± 0.1 nm with 95% confidence. A self-supporting gel is formed upon mixing **2** or **3** with **1**, followed by ultrasonication and buffer addition. Circular dichroism (CD) spectroscopy was used to probe the hydrogen bonding interaction in the supramolecular polymer to compare with the structural observations in dried films obtained by TEM and AFM. The minima of **2** and **3** without Gd(III) reveal a peak at 212 nm, signifying a β-sheet like hydrogen bonding character (*31*), which supports fiber formation in the samples seen by AFM and TEM. These shifts in spectra from ideal β-sheets are thought to be from the change in hydrogen bonding caused by both the chelator and the branching motif used in synthesis.

Utility of PACAs. We found that mixing PACAs **2** or **3** with filler PA **1** could be successfully imaged by MR (Figure 3). The gels are homogeneous in image intensity throughout the samples, which implies uniform mixing of the PACA molecules within the filler PA at MR resolution. If heterogeneous mixing of PAs occur on a

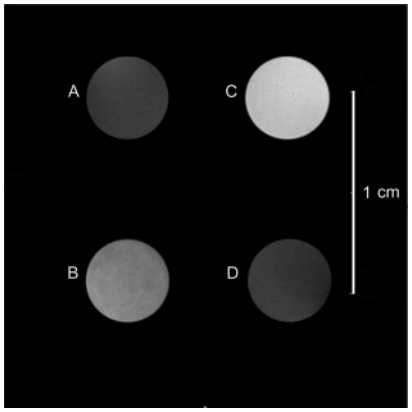

Figure 3. MR images of the phantom gels formed from **1**, **1** and **2**, **1** and **3**, and a Gd(III) DTPA standard corresponding to A, B, C, and D, respectively. The contrast arising from **3** is the greatest due to a change in τ_r of the Gd(III) chelator (*33*).

large enough scale, domains of bright and dark intensity would be observed (*30*). Figure 3 shows the difference in observed contrast between **1** (without Gd(III)), **2** mixed with **1**, **3** mixed with **1**, and a standard small molecule MR contrast agent diethylenetriaminepentaacetate (DTPA) doped into **1** (0.1 mM Gd(III)) (*26, 32*). The T_1 of these gels were measured at 3.03 ± 0.05 s, 1.89 ± 0.06 s, 1.08 ± 0.06 s, and 2.81 ± 0.05 s, respectively, the faster T_1's resulting in higher contrast. This clearly demonstrates the utility of using a contrast agent with a high relaxivity for imaging biomaterials.

Mixing of 3 with Various Epitope-Bearing PAs. A PACA that is able to mix homogeneously with a variety of different epitope containing PAs is important for biomaterial specificity. Using a PACA that universally mixes with other PAs simplifies the in vivo tests for fate mapping of different gels and allows for differing bioactivity without synthesizing a new PACA for every material. We tested the ubiquitous nature of **3**, owing to its higher relaxivity, with differing types of PA. We used a variety of PAs similar and different in structure and sequence (Figure 4) (*30*). The filler PAs were chosen based on their structure, epitopes, and sequence terminus (either C-terminus or N-terminus). Figure 4, **h**–**j**, are all linear PAs synthesized C- to N-terminus with an IKVAV

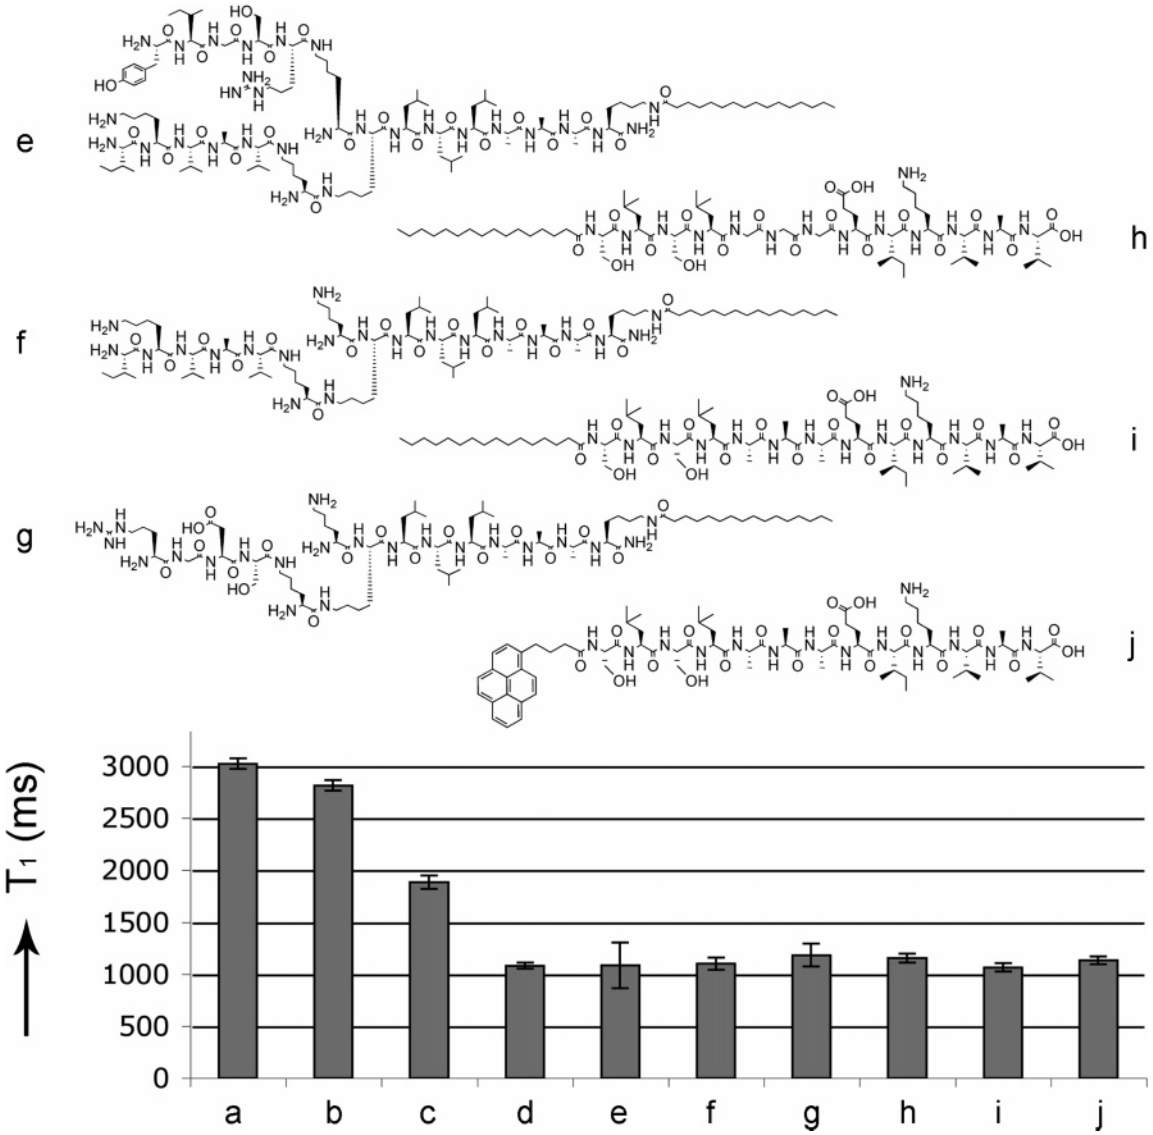

Figure 4. Results of T_1 study of PA gels and mixed PA gels. The concentration of Gd(III) is 0.1 mM in all samples except a and the concentration of filler PA is 1 wt % in each case (all samples form self-supporting gels). a corresponds to **1** alone and is used as a standard, b refers to **1** mixed with DTPA, c refers to **1** mixed with **2**, d refers to **1** mixed with **3**, e through j are mixed with **3** and their structures are depicted above. Error bars represent one standard deviation.

epitope (*7*) used for neuronal stem cell differentiation. **e** and **f** are branched PAs containing the IKVAV epitope, and **e** contains the YIGSR epitope as well also for use in neuronal stem cell differentiation. **g** is branched and contains the RGD epitope for cell adhesion. All samples formed aqueous self-supporting gels at 1 wt % and were imaged in a 400 MHz magnet. All of the gels imaged were of homogeneous signal intensity, and the T_1's of the gels were all similar values when doped with equal amounts of **3** (Figure 4). This finding shows the robustness and consistency of **3** and its ability to be used in differently structured and epitope presenting biomaterials.

DISCUSSION

The ability to noninvasively image gels formed by scaffolds of PA nanofibers doped with self-assembling PACA molecules provides a means for in vivo fate mapping of these new biomaterials. Our study compared two PACA molecules differing in the position of the Gd(III) chelator and used a variety of mixed systems to elucidate the minimal amount of PACA needed to achieve a homogeneous and significant signal intensity throughout the gel. We discovered that placing the Gd(III) closer to the hydrophobic region of the self-assembling molecules provides an increase in relaxivity and that **3** can be used with a variety of different PA gels. Further studies will explore the possibility of noninvasive three-dimensional imaging of the degradation and or migration of these PA bioactive gels in vivo are underway.

BC050153H

Transition from a Normal to Inverted Cylinder for an Amidine-Bearing Lipid/pDNA Complex and Its Excellent Transfection

Kazunori Koiwai,[†] Kenji Tokuhisa,[‡] Ryouji Karinaga,[‡] Yasuya Kudo,[‡] Shota Kusuki,[‡] Yoichi Takeda,[‡] and Kazuo Sakurai*,[‡]

Received June 10, 2005; Revised Manuscript Received August 23, 2005

A cationic lipid (TRX) having an amidine headgroup was synthesized, and a lipoplex (i.e., plasmid DNA+lipid complex) was prepared from the mixture of TRX and two other neutral colipids. Small-angle X-ray scattering showed that the addition of DNA induced a structural transition from normal to inverted hexagonally packed cylinders. Transmission electron microscopy showed a threadlike micelle was transformed to a spherical micelle about 50−200 nm in diameter by adding DNA. A combination of these results leads to the conclusion that the complexed DNA is hexagonally packed (or condensed) into spherical aggregates. The size and morphology are believed suitable for endocytosis uptake or vesicle fusion. The complex made from pDNA (pEGFP-C1) and TRX was transfected to Hep G2. Flow cytometry and confocal microscopy showed that the present system expressed green fluorescence protein (GFP) more than a conventional transfection reagent. Additionally, TRX was less cytotoxic than other transfection reagents. This paper presents the attractive possibility of the amidine group for a transfection device.

A lipoplex is an ionic complex made from cationic surfactants and pDNA and well-known for excellent performance in the transfection of bound DNA (*1*). It is involved in almost 20% of current clinical trials of gene therapy (*2*). In the lipoplex formulations, the cation-to-anion ratio is carefully adjusted so that the resultant lipoplex is positively charged overall, and this positive charge can induce cellular uptake. The cation also plays a crucial role in condensing DNA into a compact form. Of all the amines, tertiary amines are the most efficient in both transfection and condensation (*1*, *3*). However, cytotoxicity of the amines has been pointed out as a drawback.

Most lipoplex formulations require inclusion of a significant amount of a neutral colipid. Recent studies showed that the addition of colipids can control the morphology of the complex, which is strongly correlated to transfection efficiency. Small-angle X-ray scattering (SAXS) revealed that the inverted hexagonal phase, in which the cylinders consisting of DNA coated with a lipid monolayer are arranged on a hexagonal lattice, is more transfectant than the lamella phase where DNAs are sandwiched between cationic bilayers (*4*−*6*). Interestingly, the addition of pDNA to the lamella phase induces transition to the inverted hexagonal phase. The excellent transfection can be related to the fact that inverted hexagonal structures are often observed in the region where membranes fuse (*1*, *7*).

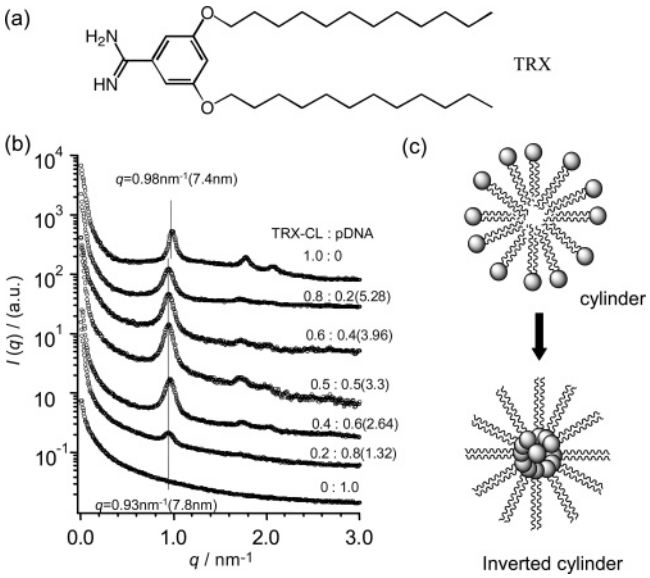

Figure 1. Chemical structure of TRX (a), SAXS profiles when TRX-CL was mixed with pDNA (pEGFP−C1) (b), and a schematic illustration for the morphological changes upon mixing TRX-CL and pDNA (c).

Recently, Aoyama et al. (*8*) reported a micellar glycocluster nanoparticle that can condense DNA into approximately 50 nm diameter spheres and showed excellent transfection. Their particle size seems to perfectly match the desirable dimension for transfection. Meanwhile, Engberts et al. (*9*), who synthesized a sugar-based cationic gemini surfactant, showed that their lipoplex

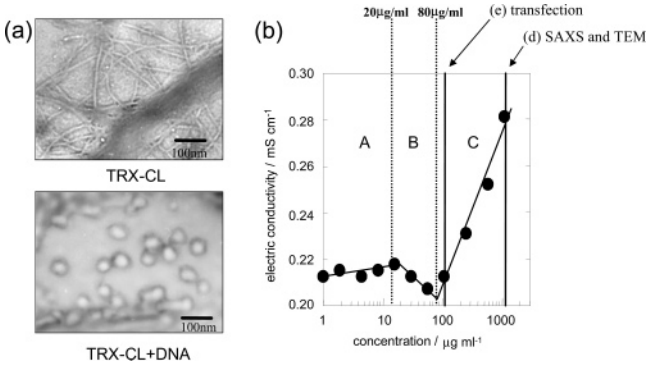

Figure 2. Comparison of TEM images between TRX-CL and TRX-CL+ pDNA where bar size is 100 nm (a) and the concentration dependence of the electric conductivity to relate the micelle structural changes (b). The concentration in b is defined by the total weight of TRX-CL+ pDNA. The transfection and SAXS and TEM were carried out at the concentrations indicated by e and d, respectively.

undergoes a pH-induced structural transition and interpreted the excellent transfection based on this transition. On the other hand, amidine has drawn attention as an alternative headgroup (*10*−*13*); however, the transfection efficiency has not been improved so much. Here, we report a novel gemini-type cationic surfactant (US Patent 6,228,391, 2001) having an amidine headgroup (denoted by TRX; the chemical structure is shown in Figure 1a) to show an excellent transfection and low cytotoxicity. In fact, the present report shows that the transfection efficiency and the cytotoxicity of TRX are much better than those of conventional transfection reagents. The major difference between TRX and the previous amidine derivative lies in the chemical structure of amidine, i.e., the amidine of TRX is protonated, while the previous one is alkylated. Therefore, TRX is considered to have a greater affinity for the phosphoric acid of DNA than the previous one.

Figure 1b presents SAXS profiles when TRX was mixed with pDNA (pCAG-luc, pEGFP-C1, 4731 base pairs) (*14*) in the presence of the colipids (DOPE and DLPC). Before the addition of the DNA to the lipid mixtures (denoted by TRX-CL), SAXS profiles show three distinctive peaks at $q = 0.98$, 1.74, and 2.02 nm^{-1}. The relation of these peaks satisfies the radio of $1:\sqrt{3}:2$, indicating the presence of hexagonally packed cylinders. After addition of DNA, the first peak position shifted to the lower q of 0.93 nm^{-1} and further addition did not change the peak position at all. It is clearly shown that the hexagonal cylinder still exists in the TRX-CL and DNA mixtures, although the unit cell length becomes longer than that of TRX-CL itself by about 3%. This increment of the unit cell length can be interpreted by the assumption that DNA molecules are included into the cylinder. Once DNA is included in the lipid cylinder, cationic TRX should form ion pairs with anionic DNA. Although further investigation is necessary to reach a definite conclusion, the changes in Figure 1b suggest the structural transition from a cylinder to an inverted cylinder. This feature is quite different from the results of Cherezov et al. (*10*−*12*) and Safinya and Koltover (*4*−*6*), in which the transitions of lamellae to inverted cylinders were observed by addition of DNA. This difference, especially from the previous amidine system, can be ascribed to the presence of the aromatic group attaching the headgroup, because this bulky headgroup may bend the bilayer surface to make the cylinder more thermodynamically favorable than lamellae.

The morphologies of TRX-CL and TRX-CL+DNA (1:1) were observed with transmission electron microscopy (TEM) (Figure 2a). Rodlike images and their bundles

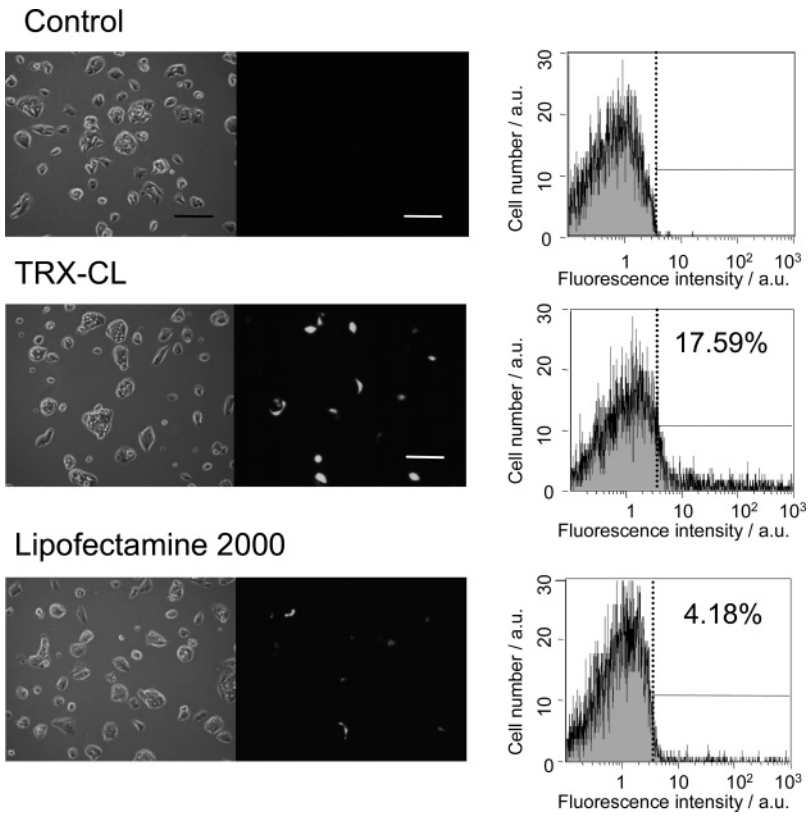

Figure 3. Comparison of the fluorescence microscopic images and the number of the cell distribution expressing GFP between TRX-CL and Lipofectamine 2000.

were observed in TRX-CL, which are quite similar to the image of other hexagonally packed molecules such as organogelators (*15*) or rodlike micelles. Once DNA was added, the morphology was completely different as presented in Figure 2a. Here, globular particles are observed and their diameters are about 50−200 nm, which can be interpreted as the amidine groups of TRX binding to the phosphoric groups of pDNA to lead to compaction of the DNA. Judging from the size, there are only a few DNA molecules present in one particle. The radius of gyrations obtained from SAXS was consistent with the TEM results. According to the literatures (*16*), this particle size seemed ideal for cellular uptake through an endocytosis pathway. Presence of such a small particle is one of the characteristics of the TRX system. Combining the SAXS and TEM results, we conclude that DNA molecules are condensed in the globular particle, and inside the particle the hexagonally packed inverted cylinders are formed as illustrated in Figure 1c. There seem to be discrepancies in size between SAXS and TEM; 50 nm from TEM and 50−200 nm from SAXS. We are in the middle of clarifying the size of the particles with dynamic light scattering and further SAXS and TEM measurements.

Figure 2b presents the relation between the concentration of TRX-CL+DNA and the electric conductivity of the solution. There appears to be three different regimes, denoted by A, B, and C. The range A should be the homogeneous solution and the range C, where we carried out TEM and SAXS, can be characterized by the inverted hexagonal cylinders phase. At this moment, however, we do not know what is happening in the range B. When we carried out the in vitro transfection experiment, the concentration indicated by e was used. The TRX-CL+DNA complex at e should have the same morphology as that of d where TEM and SAXS was done, because the concentrations of d and e were in the same regime of C. The complex made from pEGFP-C1 and TRX-CL was transfected to Hep G2. After 72 h, the cells were observed with fluorescence microscopy, and the number of the cells that expressed green fluorescent protein (GFP) was counted with a flow-cytometer (FCM) (Figure 3). The same experiments were carried out for Lipofectamine 2000. In the microscopic images, it seems that TRX-CL+pEGFP−C1 has more green cells (i.e., expressing GFP) than Lipofectamine 2000+pEGFP−C1. FCM indicates that 17.59% in the total cells are transfected in TRX-CL+pEGFP−C1, while 4.18% for Lipofectamine 2000. On the basis of the doubling time of Hep G2 being about 30 h, about 81% of the cells seemed to be transfected in the initial stage. Furthermore, when we examined the carrier concentration dependence of proliferation, comparing TRX-CL with Lipofectamine 2000, the results clearly showed that TRX-CL was less cytotoxic than Lipofectamine 2000 (see Supporting Information).

In summary, a new cationic lipid bearing an amidine headgroup is presented as a new transfection reagent, showing structural transition from a cylinder to inverted cylinder upon mixing with pDNA and showing excellent transfection ability as well as less cytotoxicity.

ACKNOWLEDGMENT

This work is finically supported by SORST of JST and a Grant-in-Aid for Scientific Research (No. 16350068 and 16655048). SAXS was performed at SPring-8 BL40B2 (2004A0425-NL2b-np and 2004B0135-NL2b-np).

Received July 20, 2005; Revised Manuscript Received August 22, 2005

Most covalent protein labeling schemes require a choice between visual and affinity properties, requiring the use of multiple fusion systems where both attributes are needed. While not disruptive at the single experiment level, this detail becomes critical when addressing high-throughput experimentation. Here we develop a uniform site-specific protein tag for use in both fluorescent and affinity screening. Covalent protein tagging with a stilbene reporter via promiscuous phosphopantetheinyltransferase (PPTase) modification enables a switchable, antibody-elicited fluorescent response in solution or on affinity resin. For demonstration purposes, VibB, a natural fusion protein harboring a carrier protein domain, was labeled with a stilbene tag through PPTase modification with a stilbene-labeled coenzyme A analogue. Analysis of the resulting stilbene-tagged VibB was accomplished by fluorescent and Western blot analysis with anti-stilbene monoclonal antibody EP2-19G2. The illustration of this method for general application to fusion protein analysis offers a dual role in assisting both solution-based fluorescent analysis and surface-based affinity detection and purification.

Site-specific protein labeling plays a major role in contemporary biomolecular research as a means to manipulate or visualize individual proteins. Tagged proteins are commonly generated for expression profiling, isolation, and cellular localization of targeted protein entities (*1*−*3*). In choosing an appropriate labeling system, function-specific properties are currently selected from a small list of available reporters, few of which serve more than one purpose. Of the established systems, labels such as histidine-fusion (*4*, *5*) and biotin-ligation (*6*) do not offer access to both optical and affinity applications. While systems such as dye and anti-dye antibody combinations (i.e., BODIPY and anti-BODIPY) provide dual functionality, these systems fail to correlate antibody binding with the generation of a fluorescent signal (*7*). Although several antibody-dye pairs undergo a net quenching of fluorescence upon binding (*8*, *9*), this loss of signal cannot be directly associated with a binding event, as such responses can arise from a number of external factors. To avoid this problem, additional control and regulatory elements, such as those common to immunofluorescent staining or fluorescent in situ hybridization (FISH) methods, are often favored for quantitative analyses (*10*−*12*). A practical solution arises through dye−antibody interactions that fluoresce upon binding. The combination of a site-specific vehicle for probe attachment and affinity-specific fluorometric gain presents an enhanced affinity tool with practical utility for molecular and cellular studies.

Posttranslational modification of carrier protein domains by a phosphopantetheinyltransferase (PPTase) provides a robust entry for site-specific transfer of both affinity and fluorescent probes (*13*). This technique has been shown to be viable with fusion proteins for both in vitro and in vivo analyses (*14*−*17*). While this technique tolerates an array of reporter species (*13*), we reasoned that the chosen reporter system should provide access to both affinity manipulation and optical analysis. An elegant choice for such a ligand was demonstrated with stilbene in its functional use with stilbene-binding antibodies (*18*−*21*). Here, a stilbene hapten becomes a visible fluorophore as it binds to a complementary monoclonal antibody (mAb).

Carrier protein-PPTase modification tools are derived from posttranslational modification of carrier proteins found in fatty acid, polyketide, and nonribosomal peptide biosynthetic pathways (*22*−*24*). As illustrated in Scheme 1, *apo*-carrier proteins (CP) may be labeled using reporter-modified coenzyme A (CoA) derivative **1** and a PPTase to yield the *crypto*-carrier protein (**1-CP**) bearing a stilbene-probe covalently tethered via a 4′-phosphopantetheine linkage (*13*). The scope of this technique is guided by the specificity of enzymatic transformation and the ability to chemically synthesize CoA derivatives (*25*−*27*). We reasoned that the application of a stilbene probe to this labeling scheme could provide an affinity tool with switchable optical response, and as such, sought to create a stilbene-tagged CoA derivative in order to develop this technique.

The synthesis of maleimide-terminal stilbene **6** was considered a key element of our strategy. In this con-

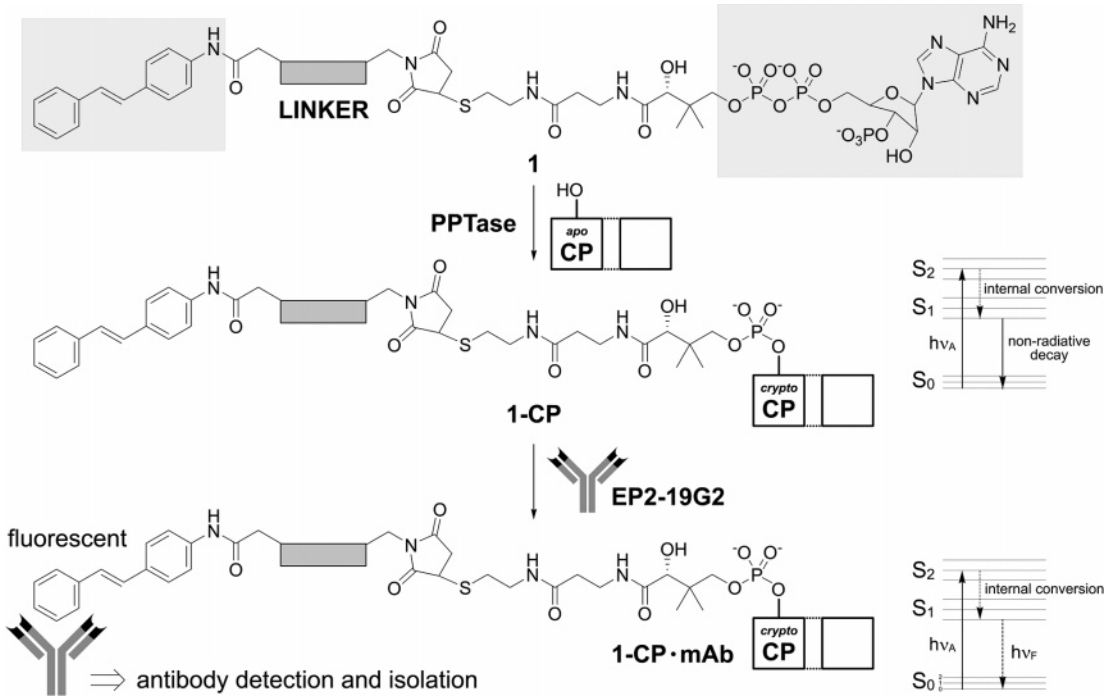
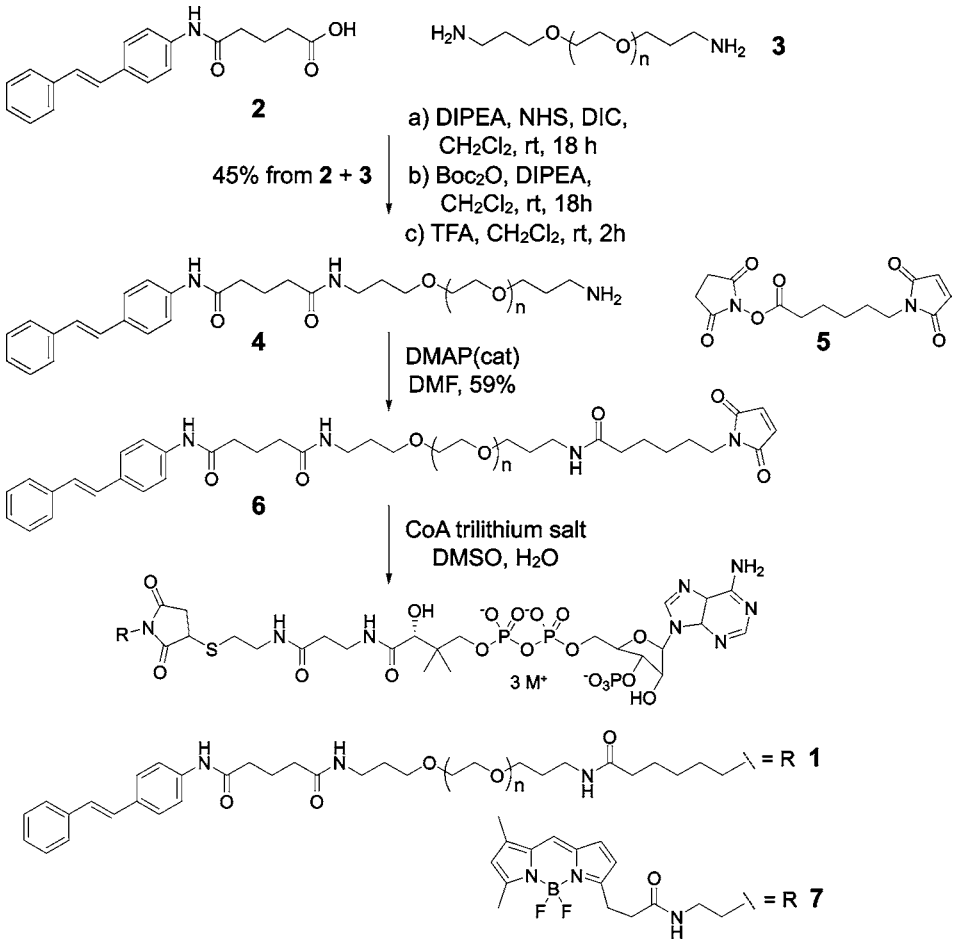
Scheme 1. Labeling of VibB, a Carrier Protein Fusion (CP) by CoA Analogue 1 and a PPTase Provides a Site-Specific-Labeled Protein 1-CP[a]



[a] Analysis of this *crypto*-state carrier protein **1-CP** can be done either by fluorescence or affinity methods using EP2-19G2, a stilbene-selective monoclonal antibody (mAb). Binding of EP2-19G2 to **1-CP** yields a fluorescent state.

Scheme 2. Synthesis of a Stilbene-Tagged Coenzyme A Analogue 1[a]



[a] Boc = *tert*-butoxycarbonyl, CoA = coenzyme A, DIPEA = *N,N*-diisopropylethylamine, DMF = *N,N*-dimethylformamide, NHS = *N*-hydroxysuccinimide, DIC = *N,N′*-diisopropylcarbodiimide, TFA = trifluoroacetic acid. n = 16−32, with an average of 25.

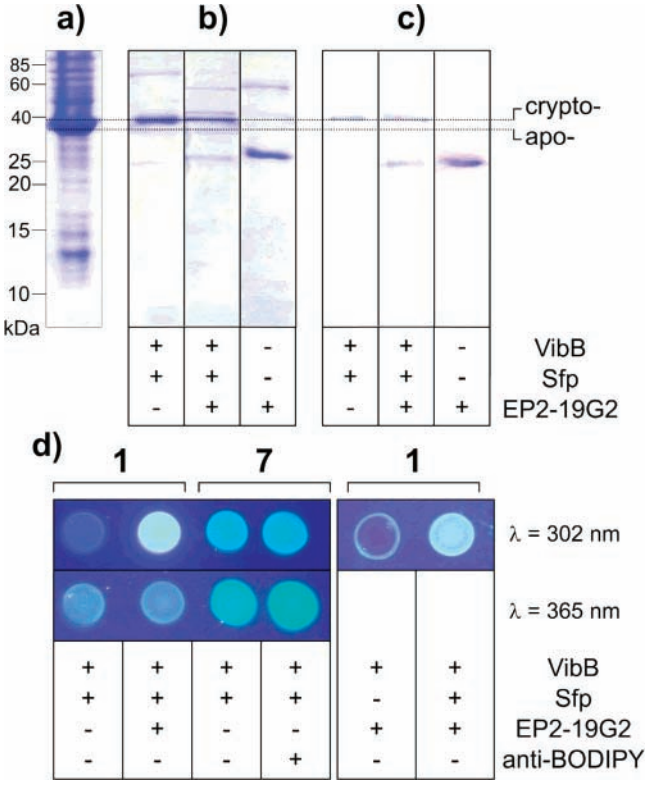


Figure 1. Fluorescent and affinity analysis of *crypto*-carrier protein (**1-CP**). (a) Coomassie stained gel depicting crude *E. coli* lysate containing overexpressed *apo*-VibB. (b) Affinity purification from crude *E. coli* lysate using EP2-19G2 appended to agarose beads. (left) Prepurified stilbene-*crypto*-VibB as positive control. (center) Eluate from EP2-19G2-bound agarose beads after exposure to a reaction containing crude cell lysate with recombinant VibB, Sfp, and **1**. (right) Eluate from affinity resin with no VibB. (c) Western blot of identical gels from b depicting the purification of VibB from lysate. Nitrocellulose was incubated with EP2-19G2 and followed by anti-mouse antibody reporter. The band at ~25 kDa in the center and right lanes was due to decomposition of mAb EP2-19G2. (d) Droplet analysis. (Left) Prepurified stilbene-*crypto*-VibB treated with either CoA analogue **1** or **7** after exposure to a Sfp. mAb EP2-19G2, mAb anti-BODIPY, or water was added to the spots, and UV light was irradiated from below. Droplets were ~2 mm in diameter. (top right) Droplets with *apo*-VibB or stilbene-*crypto*-VibB and mAb EP2-19G2.

struct, the appendage of a long PEG-spacer (16−32 ethylene glycol units) provides a linkage with maximum distance of 8.6 ± 2.8 nm, thereby allowing simultaneous analyses to be conducted on both native and denatured proteins (*27*). The synthetic route involved the conversion diamino PEG **3** (*18*) to the stilbene-labeled CoA analogue **1**. The synthesis began with the coupling of **2** to **3** by activation with *N*-hydroxysuccinimide and diisopropylcarbodiimide to give crude **4** in 60% yield (Scheme 2). To purify **4**, the resulting product was *N*-protected as its *tert*-butyl carbamate and purified by silica gel chromatography. Subsequent deprotection and precipitation yielded stilbene-PEG amine **4**. Selective functionalization of the terminal amine of **4** with *N*-succinimidyl-6-maleimidohexanoate **5** provided maleimide-derivatized stilbene **6**. Incubation of CoA with **6** followed by a rapid DEAE cellulose purification with an ammonium formate gradient (50 mM to 500 mM) offered pure stilbene-CoA **1**.

Stilbene-CoA **1** was incubated with purified recombinant vibriobactin synthase carrier protein domain (VibB), from *Vibrio cholerae*, and purified recombinant surfactin PPTase (Sfp), from *Bacillus subtilis*, as modifying enzymes. The reaction was separated via SDS−PAGE and electroblotted onto nitrocellulose. The resulting blot was incubated with anti-stilbene monoclonal antibody (mAb) EP2-19G2, followed with anti-mouse-alkaline phosphatase secondary antibody and developed with 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium (BCIP/NBT). The appearance of a band of an apparent molecular weight of 36 kDa indicated a gel shift of 2.5 kDA relative to *apo*-VibB (Figure 1c). This may be compared to the Coomassie stain of the same gel (Figure 1b), where stilbene-linked *crypto*-VibB runs at 36 kDa, while *apo*-VibB runs at 33.5 kDa (Figure 1a).

Stilbene-labeled molecules have been shown to fluoresce when bound to mAb EP2-19G2 (*18*−*21*). To verify the use of this protein modification scheme for both affinity and visualization applications, we quantified the fluorescence generated by antibody binding with stilbene-tagged protein **1-CP** in solution. Purified *apo*-VibB was modified by Sfp and stilbene-CoA **1**. The labeled protein, stilbene-*crypto*-VibB, was purified via size-exclusion chromatography and concentrated to 11 μM via spin concentration, mixed with mAb EP2-19G2 (1.67 μM), and fluorescence intensity was analyzed at the optimal wavelengths for mAb EP2-19G2 ($\lambda_{ex} = 327$ nm, $\lambda_{em} = 410$ nm) (*18*−*21*). Titration of mAb EP2-19G2 against stilbene-labeled *crypto*-VibB verified that maximal fluorescence arose from a 1:1 dependence of antibody binding sites to labeled protein.

To demonstrate cooperative affinity and fluorescence properties of the stilbene label, we also isolated labeled protein by affinity chromatography. Heterologously expressed *apo*-VibB was stilbene-tagged in vitro and purified from crude cell lysate using immobilized anti-stilbene mAb. The crude solution of *apo*-VibB from recombinant *Escherichia coli* lysate was incubated with **1** and recombinant Sfp. The resulting crude solution of stilbene-*crypto*-VibB **1-CP** was applied to agarose resin conjugated with mAb EP2-19G2. The progress of binding by stilbene-tagged *crypto*-VibB **1-CP** was readily visualized by the confinement of blue fluorescence to the agarose bead pellet. The affinity resin was then washed to remove unmodified cellular proteins. Conjugate **1-CP** was removed from the beads by heat denaturation in SDS buffer. The presence and purity of **1-CP** in the eluted fraction was confirmed by polyacrylamide gel electrophoresis and Western blotting (Figure 1c,d).

Droplet experiments were performed to demonstrate switchable fluorescence in solution. Two 20 μL droplets containing prepurified stilbene-*crypto*-VibB **1-CP** were placed on a transparent surface, and 2 μL of mAb EP2-19G2 (11.5 mg/mL) were added to one of the droplets. Similarly, two droplets of purified BODIPY-*crypto*-VibB, generated by incubation of BODIPY-CoA **7** with recombinant Sfp and recombinant *E. coli* lysate and purified by nickel chromatography (*13*), were placed on the surface, and 2 μL of anti-BODIPY monoclonal antibody (11 mg/mL) were added to one droplet. The droplets were visualized by UV illumination at $\lambda_{ex} = 302$ nm and $\lambda_{ex} = 365$ nm (Figure 1d). **1-CP** shows evident fluorescent gain at $\lambda_{ex} = 302$ nm in the presence of mAb EP2-19G2, indicating the switchable visualization as a result of antibody binding to the stilbene reporter. BODIPY-*crypto*-VibB (*13*) shows no change upon antibody addition with excitation at either wavelength. No fluorescence quenching was visualized as a result of anti-BODIPY mAb binding to BODIPY-labeled protein. As a control, mAb EP2-19G2 was added to each of two additional droplets, one with *apo*-VibB and the other with stilbene-*crypto*-VibB **1-CP** (Figure 1d, right). Fluorescence is seen at $\lambda = 302$ nm only in the stilbene-tagged protein,

demonstrating a modulated fluorescence gain through stilbene-tagged proteins in solution by selective binding of anti-stilbene mAb.

Using this stilbene-fusion/antibody technique, individual proteins may be screened in solution in a high-throughput format, analyzed by conventional SDS–PAGE and Western blotting techniques, and purified using immobilized antibodies. Fluorescence gain may be evaluated by a number of bioanalytical methods, including fluorescence spectroscopy, fluorescence microscopy, and biochemical methods such as immunoprecipitation and affinity chromatography. The combination of fluorescence and affinity methods presents a uniform reporter, and its application to carrier protein modification schemes provides a streamlined tagging-system for in vivo and in vitro protein analysis. Adaptation to carrier protein fusion systems provides a general tool for protein analysis.

Controlled Recovery of the Transcription of Nanoparticle-Bound DNA by Intracellular Concentrations of Glutathione

Gang Han, Nandini S. Chari,[§] Ayush Verma, Rui Hong, Craig T. Martin, and Vincent M. Rotello*

Department of Chemistry, University of Massachusetts, Amherst, Massachusetts 01003. Received June 16, 2005

Positively charged trimethylammonium-functionalized mixed monolayer protected clusters (MMPCs) bind DNA through complementary electrostatic interactions, resulting in complete inhibition of DNA transcription of T7 RNA polymerase. DNA was released from the nanoparticle by intracellular concentrations of glutathione, resulting in efficient transcription. The restoration of RNA production was dose-dependent in terms of GSH, with considerable control of the release process possible through variation in monolayer structure. This work presents a new approach to controlled release of DNA, with potential applications in the creation of transfection vectors and gene regulation systems.

Synthetic DNA-binding scaffolds are of great interests in bioorganic (*1*, *2*), biomedical (*3*), and materials chemistry (*4*, *5)* owing to numerous applications as DNA sensors (*6*), transcription regulators (*7*), nonviral transfection vectors (*8*), and biomaterials (*9*). These receptors offer the opportunity to directly regulate and control cellular activity by inhibiting or promoting DNA transcription based on either intercalative, major/minor groove binding, or complementary electrostatic interaction (*7*). Additionally, such nonviral gene transfection vectors based on these synthetic DNA-binding scaffolds have been widely used owing to their facile production and the reduced risk of cytotoxicity and immune and inflammatory responses (*10*).

Controlled release of functional DNA is required for efficient regulation of DNA transcription. The temporal and spatial control of DNA and corresponding RNA products is critical to the modulation of gene expression and is a fundamental issue in designing anticancer drugs (*11*) and potential therapeutic materials. Although some synthetic systems such as cisplatin (*12*) and polyamides (*13*) have been designed to bind with DNA to block the recognition between DNA and transcription factor proteins, controlled transcription has not been extensively studied. Additionally, while photoinduced transcription recovery of caged oligonucleotides has been reported (*14*), the tunable transcription of DNA using intracellular components provides new directions for the design of bioactive systems.

In addition to regulation, tunability is also essential in designing synthetic gene delivery systems: the process of unpackaging of DNA is a complicated process and vectors must be stable in the extracellular environments and then selectively unpackaged for transcription (*15*). Although a series of DNA trigger release mechanisms have been explored, which include either external means (e.g. photochemical (*16*)) or through differential cellular environment (e.g. pH (*17*) or the level of enzyme (*18*)), new release mechanisms may provide a means for overcoming current hurdles in gene therapy (*19*).

[§] Present address: Department of Chemistry and Biochemistry, University of Texas, Austin, TX 78712.

We reasoned a unique mechanism of release MMPC bound DNA would involve glutathione (GSH), a tripeptide which is involved in many important physiological functions, in particular the control of the redox environment in cells (*20*). The large concentration differential of intracellular glutathione (e.g. ~2 mM in erythrocytes (*21*)) compared to extracelluar level (e.g. 2 μM in red blood plasma (*22*)) provides a unique opportunity for mediation of DNA release. Additionally, the wide range of the intracellular levels of glutathione (from ~500 μM to 10 mM, e.g. 10 mM in liver cells (*23*)) provides a potential control over both in vitro and in vivo gene delivery applications.

Recently, we have demonstrated that cationically modified mixed monolayer protected gold clusters (MMPCs) interact electrostatically with DNA, providing an effective tool for gene delivery in mammalian cells (*24,* 25). MMPCs show much higher transfection efficiency than polyethyleneimine (PEI), a widely used synthetic transfection agent. One potential mechanism for unpackaging DNA from MMPCs in our system is GSH incorporation onto the particle surface (*26*). The cationic particles would lose their electrostatic affinity for the DNA backbone resulting in release of DNA. Previously, we have shown that GSH can release and reactivate the enzyme bound to MMPCs by place-exchange reaction (*27*). Here, we report that MMPC−DNA complexes are dissociated by GSH to release DNA (Figure 1). Further, we demonstrate that DNA transcription inhibited by DNA−MMPC complexes (*28*) is rescued by addition of reduced glutathione (GSH) at intracellular concentrations. The recovery of DNA transcription is found to be dependent on the chain length of the MMPC monolayer: enhanced recoveries of transcription were observed using a MMPC featuring a shorter chain length relative to MMPCs with a longer monolayer.

An ethidium bromide (EtBr) fluorescence assay was performed to investigate the release of DNA 37mer from the nanoparticles by GSH (*30*). At a ratio of MMPC:DNA of 4:1, EtBr was completely quenched, demonstrating complete complexation of the DNA by MMPC. GSH was then added into preincubated (5 min) DNA−MMPC solutions to give final concentrations corresponding to extracellular and intracellular GSH levels. The intensity

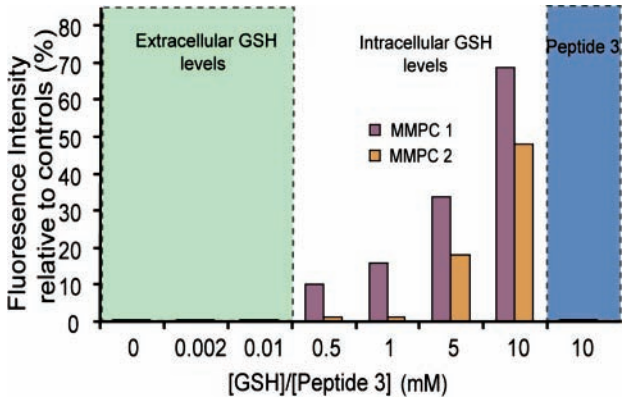

Figure 2. EtBr dye release obtained by addition of GSH and peptide **3** to MMPC/37mer DNA complexes followed by 1 h incubation at 37 °C. Normalized fluorescence intensities are relative to control experiments with corresponding concentrations of GSH or peptide **3** in absence of MMPCs (λ_{em} 595 nm).

of fluorescence was monitored after 1 h of incubation at 37 °C (Figure 2). No fluorescence recovery was observed at extracellular concentrations of GSH for both MMPCs. However, fluorescence for both MMPC **1** and **2** increased in a dose-dependent fashion with increasing GSH concentration. Significantly, enhanced fluorescence recovery was observed with the shorter chain MMPC **1** relative to MMPC **2**, consistent with the increased accessibility of the core of MMPC **1** with concomitantly faster place exchange (*29*). No fluorescence recovery was observed with peptide **3** (*30*), demonstrating that thiol−gold interaction is the operative mechanism for DNA release (*31*). Overall, these results indicate that the DNA−MMPC complexes are stable and intact in the extracellular GSH concentrations but are rapidly disrupted at intracellular GSH concentrations.

In our dye release studies we demonstrated that GSH has the ability to mediate unloading DNA from DNA−MMPC complexes. To determine the reversal of MMPC inhibition DNA transcription, premixed (5 min) DNA−MMPC (molar ratio DNA:MMPC = 1:4) solutions were incubated with different concentrations of GSH (from extracellular to intracellular levels) and peptide **3** for 1 h at 37 °C. The incubation was followed by addition of the T7 RNA polymerase (1:1 enzyme:DNA, 0.2 μM) and excess nucleotide triphosphates (including ^{32}P-labeled GTP for isotopic detection). The mixture was incubated for 5 min before being quenched with 15 mmol of EDTA in 95% formamide. The 20mer runoff RNA transcripts were quantified to determine the extent of reactions, with the transcription levels attained in the absence of MMPCs at corresponding GSH and peptide **3** concentrations set to 100% transcription (Figure 3b). No 20mer RNA transcripts were observed at extracellular concentrations of GSH for both of MMPCs. However, transcription was observed at intracellular GSH levels, reaching ~100% recovery for MMPC **1** and 83% recovery for MMPC **2** (10mM). A higher level of selectivity was also observed at intermediate GSH concentrations between MMPC **1** and **2** at typical intracellular concentrations (2−5 mM). Significantly higher levels of transcription recovery were observed relative to the fluorescence release experiments described above. In our previous studies it was shown that partially complexed DNA was efficiently transcribed; the present results are consistent with partial removal of MMPCs from the DNA strand. As expected, control experiments with peptide **3** resulted in a negligible DNA transcription level.

Our hypothesis for the glutathione-mediated release of DNA is that place exchange of the cationic residues of the nanoparticles with anionic GSH diminishes the overall positive charge of the particles. This decrease in charge would then be expected to reduce/or eliminate the affinity of the particles for DNA. This hypothesis was validated through zeta potential measurement (Figure 4). In these studies, MMPC **1** and **2** (0.8 μM) were incubated with 10 mM of GSH and peptide **3** separately for 1 h at 37 °C in PBS buffer (pH 7.8). Upon addition of GSH, the zeta potential of MMPC **1** decreased significantly from 26 ± 1 mV to 2 ± 4 mV. Interestingly, MMPC **2** showed a smaller but still significant decrease from 25 ± 2 mV to 17 ± 3 mV, indicating that the binding process is quite sensitive to particle charge. As expected, no significant change of the zeta potentials were observed with addition of peptide **3**. These data directly reflected the thiol-mediated incorporation of GSH onto gold surface, resulting in proportional positive charge attenuation of monolayer depending on the monolayer chain length.

Taken together, these results demonstrate the following processes: the original cationic MMPCs electrostatically bind the DNA with high affinity, forming supramolecular DNA−MMPC complexes that block the interaction between T7 polymerase and DNA. Anionic glutathione then place-exchanges onto the gold core, diminishing or eliminating the cationic charge of the MMPCs. An important aspect of this research is that recovery of transcription proceeds with greater efficacy than EtBr

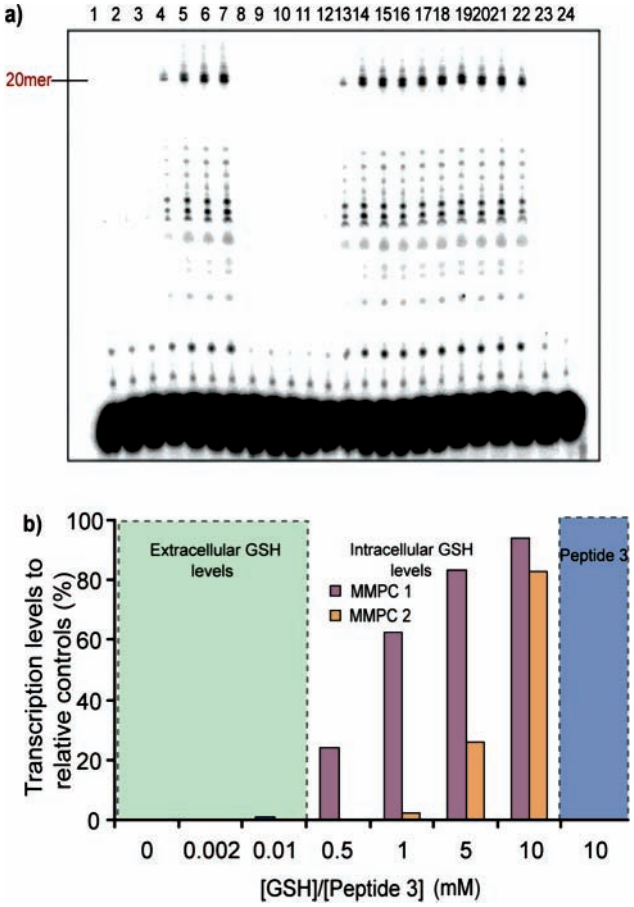

Figure 3. (a) Acrylamide gel electrophoresis of RNA products produced in the T7 RNA polymerase transcription assay. Lanes 1−7: Transcription recoveries in the presence of MMPC **1** by preincubation at 37 °C for 1 h with an increasing amount of GSH from extracellular concentrations (1) 0 μM, (2) 2 μM, (3) 10 μM to intracellular concentrations (4) 500 μM, (5) 1 mM, (6) 5 mM, and (7) 10 mM. Lanes 8−14: Transcription recoveries in the presence of MMPC **2** with (8) 0 μM, (9) 2 μM, (10) 10 μM, (11) 500 μM, (12) 1 mM, (13), 5 mM and (14) 10 mM GSH. Lanes 15−21: Control assays in absence of MMPCs with GSH (15) 0 μM, (16) 2 μM, (17)10 μM, (18) 500 μM, (19) 1 mM, (20) 5 mM, and (21) 10 mM. Lanes 22−24: Control assays with 10 mM peptide **3** and (22) no MMPCs, (23) MMPC **1**, (24) MMPC **2**. (b) The amount of 20mer runoff RNA detected relative to that produced in the absence of MMPCs at varying concentrations of GSH and peptide **3**.

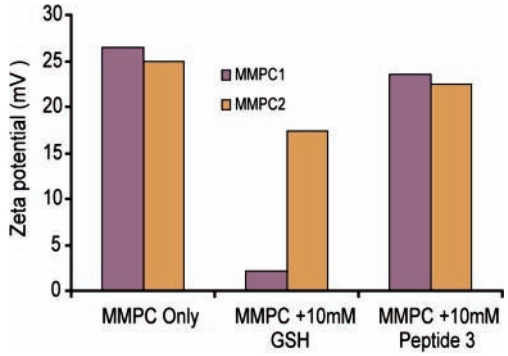

Figure 4. Zeta potential values of MMPCs upon addition of 10 mM GSH/peptide **3** followed by 1 h incubation at 37 °C.

release. The higher level of transcription recovery can be explained by the fact that transcription requires only the ability of the T7 RNA polymerase to anchor to the DNA. Once anchored, the polymerase can displace the nanoparticles from the DNA surface during the course of transcription. (Figure 5). In the case of EtBr displacement, however, there is a direct competition between the still partially cationic particles and the EtBr for DNA binding.

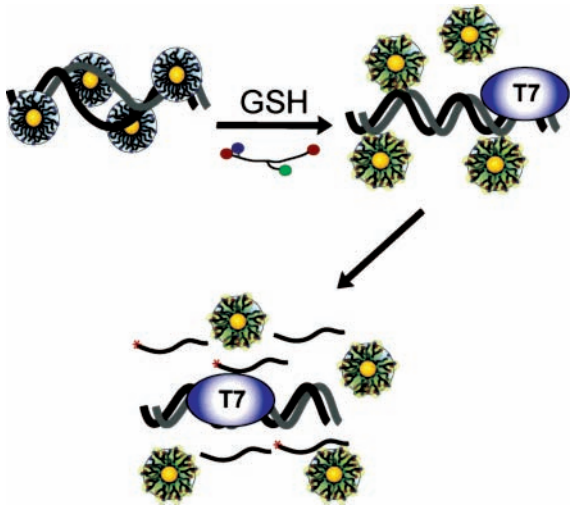

Figure 5. Proposed mechanism of GSH-triggered transcription recovery.

In summary, we have demonstrated glutathione-controlled DNA transcription. DNA−MMPC complexes are stable at extracellular GSH concentrations and labile at intracellular GSH levels, resulting in DNA release and transcription. The release of DNA and recoveries of DNA transcription can be tuned through the choice of monolayer coverage and intracellular GSH levels. This release mechanism provides potential strategies for the creation of MMPC-based DNA delivery vectors featuring new and unique properties.

ACKNOWLEDGMENT

Support for this research from the NIH (EB 004503 (VR) and GM55002 (C.T.M.)). We thank Prof. Jochen Weiss for assistance with zeta potential determination.

A Hydrophilic Azobenzene-Bearing Amino Acid for Photochemical Control of a Restriction Enzyme *Bam*HI

Koji Nakayama, Masayuki Endo, and Tetsuro Majima*

The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567-0047, Japan. Received November 15, 2004; Revised Manuscript Received August 12, 2005

A novel hydrophilic and negatively charged azobenzene-bearing amino acid, 4′-carboxyphenylazophenylalanine (azoAla **1**), has been designed and synthesized for investigation of the photochemical regulation of the enzyme activity. The properties of photoisomerization and thermal stability of the cis-isomer were similar to those of a commonly used phenylazophenylalanine (azoAla **2**). For photochemical control of the enzyme, these two azobenzene-bearing amino acids were incorporated into the specific position at the dimer interface of a restriction enzyme *Bam*HI. These *trans*-azobenzene derivatives in the *Bam*HI suppressed the enzymatic activity, and the following photoirradiation at 366 nm induced the recovery of its activity. Although the activities of both azoAla-*Bam*HI mutants were same level after a long time irradiation, the recovery of the activity of azoAla **1**-*Bam*HI was faster than that of azoAla **2**-*Bam*HI with a short time irradiation. This result suggests that the negatively charged carboxylate group introduced into an azobenzene moiety affects the behavior of azoAla in the protein scaffold during the trans−cis photoisomerization.

INTRODUCTION

The artificial and selective activation of an enzyme is one of the most important issues for the investigation of the specific biological phenomena in living cells. Caged compounds such as *o*-nitrobenzyl derivatives are widely used for regulation of the enzymatic activity by introduction of these compounds into an enzyme, which are then uncaged with photoirradiation for activation (*1*−*7*). These caged molecules unavoidably release the reactive nitroso derivatives after photoirradiation, which may cause a negative side-effect in the cells. In contrast, photochromic molecules, which change their conformations by photoirradiation, do not produce a side-product (*8*−*15*). When a photochromic moiety is incorporated into polymers and biomolecules, the mechanical movement of the photochromic molecules by irradiation at specific wavelengths can induce structural changes, which produces novel physical and biochemical properties (*8*−*15*). From this point of view, the use of photochromic molecules is a better choice for control of the activity of enzymes and the subsequent expression of biological phenomena.

The most commonly used and reliable photochemical switches for the functionalization of polymers and biomolecules are azobenzene derivatives, which have excellent features; i.e., the simplest chemical structure, rapid photoisomerization in both the trans−cis directions, a large structural motion, and a thermally stable cis isomer (*16*, *17*). However, for incorporation of phenylazophenylalanine into the proteins and enzymes, the hydrophobic property of the azobenzene moiety may cause the exclusion of water in the solvent-accessible surface of the proteins, which may result in a negative effect such as an unexpected missfolding of the proteins around the incorporated sites. One of the simplest solutions for water-accessibility is the introduction of a hydrophilic property into an azobenzene derivative.

In this report, we synthesized a negatively charged 4′-carboxyphenylazophenylalanine moiety and incorporated it into the dimer interface of a restriction enzyme *Bam*HI. In the previous study, we controlled the activity of *Bam*HI, which is activated through the dimer formation (*18*−*21*), by arranging the specific amino acids involved in the dimer interface by introducing the photoremovable *o*-nitroveratryl groups (*22*). At this dimer interface, side chains of four amino acids, K132, H133, E167, and E170, consist of a salt bridge network to maintain the conformation of the *Bam*HI dimer in the active form (Figure 1) (*18*−*21*). Especially, K132 in the dimer interface is the key position for the activity, since the K132 on the α-helix faces two glutamate side chains (E167 and E170) on the counterpart α-helix. We previously discovered that phenylazophenylalanine (azoAla **2**) incorporated into the 132 position can regulate the activity of *Bam*HI (*23*). For further investigation of relationship between the photochemical switching of azobenzene derivative and the expression of the enzymatic activity, we introduced a negatively charged 4′-carboxyphenylazophenylalanine (azoAla **1**) into the 132 position for changing the solvent-accessibility in the surface of *Bam*HI. We examined whether the negative charge affects the behavior of the azobenzene moiety during the trans−cis photoisomerization in the dimer interface, which may accompany local structural change around the azoAla residue for effective inactivation and photochemical activation of *Bam*HI.

EXPERIMENTAL PROCEDURES

Materials. The reagents used in the experiment were purchased from the following companies: 4-nitrobenzoic acid methyl ester, N^{α}-*tert*-butoxycarbonyl-4-nitro-L-phenylalanine, *tert*-butyl hypochlorite, chloroacetonitrile, Wako Chemicals (Osaka, Japan); 4-nitrobenzoic acid methyl ester, Tokyo Kasei (Tokyo, Japan); restriction endonucleases, New England BioLabs (Beverly, MA); pET26b, Novagen (Madison, WI); *Pfu* DNA polymerase, Stratagene (LaJolla, CA); nucleoside triphosphates and L-[^{35}S]-methionine, Amersham Pharmacia Biotech (Piscataway, NJ); T4 RNA ligase, Takara Shuzo (Kyoto, Japan); T4 DNA ligase, T7 RNA polymerase, and RNase inhibitor, Toyobo (Osaka, Japan); RNeasy Project Mini Kit, Qiagen (Hilden, Germany); *E. coli* S30 Extract System, Promega (Madison, WI). Purification of the nucleotide derivatives was performed using a JASCO LC-2000Plus series HPLC system (Tokyo, Japan). Photoirradiation was carried out using an ultrahigh-pressure mercury lamp (Ushio USH-500D; 500 W) equipped with a monochromator (Ritsuoyo Kogaku MC-10N) which can control the specific wavelength within a 4 nm full-width at half-maximum. Visualization and quantification of the gels were performed using a Fujix BAS1000 imaging analyzer (Tokyo, Japan).

4-Nitrobenzoic Acid *tert*-Butyl Ester (3). *n*-Butyllithium (0.10 mol, 65 mL of 1.58 M hexane solution) was slowly added to a mixture of the 4-nitrobenzoic acid methyl ester (9.05 g, 50 mmol) and distilled *tert*-butyl alcohol (9.5 mL, 0.10 mol) in anhydrous THF (30 mL) at 0 °C under an argon atmosphere (*24*). The reaction mixture was warmed to room temperature and stirred at room temperature. After 18 h, diethyl ether (200 mL) and a saturated ammonium chloride aqueous solution (200 mL) were added to the mixture, and the organic layer was extracted and washed twice with a saturated sodium chloride aqueous solution and dried over anhydrous sodium sulfate. The resulting brown solid was purified by silica gel chromatography with toluene/hexane (1:1) to give compound **3** (3.48 g, 31%) as a yellow solid; ^{1}H NMR [270 MHz, $CDCl_3$ (TMS)]: δ 8.15 (d, 2H, J = 8.1 Hz), 7.96 (d, 2H, J = 8.1 Hz), 1.63 (s, 9H).

***tert*-Butyl 4-Hydroxylaminebenzoate (4).** Zinc powder (90%, 205 mg, 3.2 mmol) was slowly added to a mixture of **3** (352 mg, 1.6 mmol) and ammonium chloride (84.4 mg, 1.6 mmol) in MeOH/water (10:1, 20 mL) over a period of 5 min (*25*). The reaction mixture was stirred at room temperature for 3 h under an argon atmosphere. The insoluble precipitate was removed by filtration, and the filtrate was dried under reduced pressure. The resulting orange solid was diluted with methylene chloride (200 mL) and a saturated aqueous sodium bicarbonate solution, and the organic layer was washed twice with saturated aqueous sodium chloride. The organic layer was dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure. The orange solid was purified by silica gel chromatography with CH_2Cl_2/MeOH (100:2) to give compound **4** (220 mg, 67%) as a yellow solid. ^{1}H NMR [270 MHz, $CDCl_3$ (TMS)]: δ7.91 (d, 2H, J = 8.6 Hz), 6.97 (d, 2H, J = 8.6 Hz), 5.21 (s, 1H), 1.63 (s, 1H), 1.58 (s, 9H).

4-*tert*-Butoxycarbonyl-N^{α}-Boc-phenylazophenylalanine (5). *tert*-Butyl hypochlorite (114 mg, 1.05 mmol) was added to a solution of **4** (220 mg, 1.05 mmol) in THF (5 mL) at −78 °C (*26*). The reaction mixture was stirred under argon at −78 °C for 10 min and then allowed to react at −20 °C for 1 h. The reaction proceeded more than 90% based on TLC monitoring. The solvent was removed under reduced pressure at 10 °C, and the brown solid was dried under reduced pressure. The crude product was dissolved in 10 mL of 10% AcOH/MeOH. This solution was added to a 10% AcOH/MeOH solution (10 mL) of N^{α}-Boc-4-aminophenylalanine (263 mg, 0.94 mmol) under argon at 0 °C. The reaction mixture was allowed to react at room temperature for 2 h. After removal of the solvent under reduce pressure, the brown solid was dissolved in CH_2Cl_2 (200 mL), and then a saturated aqueous sodium bicarbonate solution was added. The organic layer was washed twice with a saturated aqueous sodium chloride solution and then dried over anhydrous sodium sulfate. The resulting orange solid was purified by silica gel column chromatography with CH_2Cl_2/MeOH (100:8) to give compound **5** (335 mg, 76%) as an orange solid. ^{1}H

NMR [270 MHz, $CDCl_3$(TMS)]: δ 8.15 (d, 2H, J = 8.1 Hz), 7.88, (dd, 4H, J = 8.1 Hz), 7.35 (d, 2H, J = 8.1 Hz), 5.04 (s, 1H), 4.64 (s, 1H), 3.22 (m, 2H), 1.62 (s, 9H), 1.41 (s, 9H).

4-*tert*-Butoxycarbonyl-N^{α}-Boc-phenylazophenylalanine Cyanomethyl Ester (6). Chloroacetonitrile (24 mg, 0.32 mmol) was added to a mixture of compound **5** (77 mg, 0.16 mmol) and triethylamine (24 mg, 0.24 mmol) in dry acetonitrile (20 mL). The reaction mixture was stirred at room temperature for 12 h under argon. After removal of the solvent under reduced pressure, the product was purified by silica gel column chromatography with CH_2Cl_2/MeOH (100:2) to give compound **6** (46 mg, 57%) as an orange solid. ^{1}H NMR [$CDCl_3$ (TMS)]: δ 8.13 (d, 2H, J = 8.1 Hz), 7.91, (dd, 4H, J = 8.1 Hz), 7.33 (d, 2H, J = 8.1 Hz), 5.00 (d, 2H, J = 7.8 Hz), 4.77 (dd, 2H, J = 15.8 Hz), 4.71 (s, 1H), 3.21 (m, 2H), 1.63 (s, 9H), 1.43 (s, 9H). FAB-MS (positive), *m/z* calcd for $C_{27}H_{33}N_4O_6$ 509.2 $[M+H]^+$, found 509.0.

4-*tert*-Butoxycarbonyl-N^{α}-Boc-phenylazophenylalanyl pdCpA (7). Compound **6** (1.25 μmol) was added to a dry DMF solution of pdCpA tetra-*n*-butylammonium salt (*27*) (20 μL, 0.25 μmol) in a microtube. The reaction mixture was incubated at room temperature for 3 h, and the reaction was monitored by a reversed-phase HPLC [linear gradient; 0−80% acetonitrile−50 mM ammonium acetate buffer (pH 4.8) over 30 min, flow rate 2 mL/min, Chemcobond C18 column (7.5 × 150 mm), detection at 260 nm]. After the reaction, the mixture was diluted with 50 mM ammonium acetate solution (pH 4.5, 1 mL), and the product was purified by HPLC. The retention time of compound **7** was 22.8 min. The product was concentrated under reduced pressure and then lyophilized. 67% yield. ESI-MS (negative), *m/z* calcd for $C_{40}H_{46}N_{11}O_{18}P_2$ 1030.3 $[M - H]^-$, found 1030.5.

Preparation of 4′-Carboxyphenylazophenylalanyl-tRNA$_{CCCG}$ (azoAla 1-tRNA$_{CCCG}$). Deprotection of compound **7** was performed in trifluoroacetic acid (20 μL) on ice for 10 min, and then the trifluoroacetic acid was removed by flowing nitrogen gas. The pellet was washed twice with ether and then dried under reduced pressure. The pellet was dissolved in DMSO to make a 0.5 mM solution and stored at −20 °C. The tRNA$_{CCCG}$ (-CA) was obtained according to a previous method (*22*, *23*). Ligation of aminoacyl-pdCpA to tRNA$_{CCCG}$(-CA) was carried out in a 20 μL solution containing 5 μg of tRNA$_{CCCG}$(-CA), 0.5 mM aminoacyl-pdCpA, 50 mM Tris-HCl (pH 7.5), 10 mM $MgCl_2$, 10 mM DTT, 1 mM ATP, 0.01% BSA, 10% DMSO, and T4 RNA ligase (40 units). The reaction mixture was incubated at 4 °C for 2 h, and then the reaction was quenched by the addition of 2 μL of sodium acetate (3 M, pH 5.2). The aminoacyl-tRNA$_{CCCG}$ was precipitated with ethanol, rinsed with 70% ethanol, and dried under reduced pressure. The aminoacyl-tRNA$_{CCCG}$ was dissolved in RNase-free water to a final concentration of 1 μg/μL.

In Vitro Translation of Wild-Type and azoAla-*Bam*HI. Preparation of a plasmid containing the *Bam*HI gene and its mutant was performed according to a previous method (*22*). The preparation of mRNA was carried out in a solution (50 μL) containing the template DNA (5 μg), T7 RNA polymease (147 units), RNase inhibitor (40 units), 2.5 mM NTP, 40 mM Tris-HCl (pH 7.5), 20 mM $MgCl_2$, and 5 mM DTT at 37 °C for 6 h, and then the mRNA was purified using an RNeasy Protect Mini Kit (Qiagen). The *E. coli* S30 Extract System (Promega) was employed for the in vitro protein synthesis following the reported method (*28*, *29*). The translation reaction was carried out in a 10 μL of reaction mixture containing mRNA (2 μg), aminoacyl-tRNA$_{CCCG}$ (1 μg), 0.10 mM amino acid mixture (lacking methionine and arginine), a 0.01 mM arginine, premix (4 μL), *E. coli* S30 extract (3 μL), and L-[^{35}S]-methionine (3 μCi) at 30 °C for 2 h. The wild-type *Bam*HI was prepared by the same method without aminoacyl-tRNA$_{CCCG}$. The reaction was quenched by the addition of a mixture containing 50 mM Tris-HCl (pH 6.8), 0.1 M DTT, 2% SDS, and 10% glycerol and loaded onto an 15% SDS-polyacrylamide gel for electrophoresis. The SDS−PAGE gels were visualized and quantified using an imaging analyzer. For the cold samples, the same procedure described above was employed by just replacing the [^{35}S]-methionine with 0.1 mM methionine, and the concentration was quantified by Western blotting using a hexahistidine antibody as the primary antibody. The generation of the full-length proteins was about 10 ng from a 10 μL scale synthesis of the in vitro translation system.

Photoirradiation to Phenylazophenylalanine Derivatives. The phenylazophenylalanine derivatives (azoAla) **1** and **2** were prepared by treatment of the N^{α}-Boc-phenylazophenylalanine and compound **5** with TFA, respectively. After removal of TFA under reduced pressure, the deprotected azoAla **1** and **2** were dissolved in DMSO. Photoirradiation was carried out using a 500 W ultrahigh-pressure mercury lamp equipped with a monochromator. Samples (1 mL) containing azoAla **1** or **2** (0.01 mM), 10 mM Tris-HCl (pH 8.0), and 10% DMSO were placed in a quartz cell with a 1 cm path length.

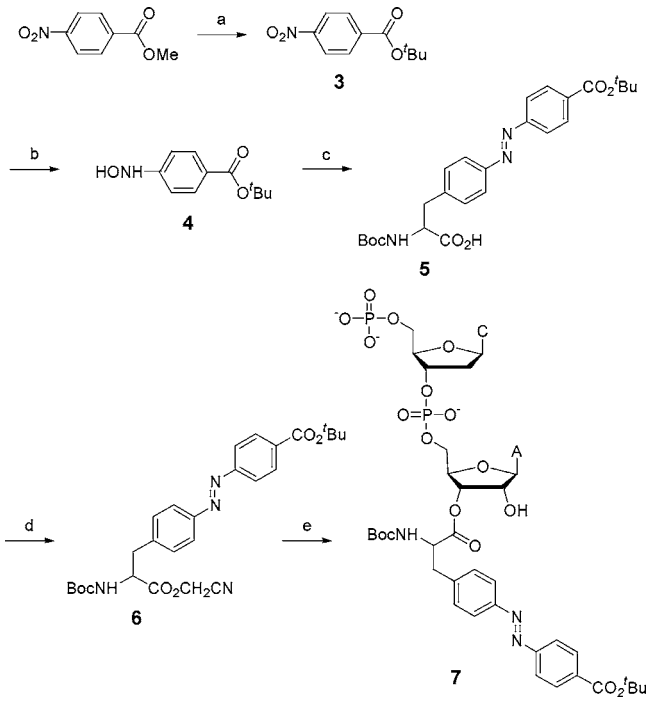
Photoirradiation and Measurements of the *Bam*HI Activities. Photoirradiation was carried out using the same instrument as described above. The trans to cis photoisomerization was carried out using the translation mixture prepared above by irradiation with 366 nm light on ice for 10 min. The translation mixtures (0.25 μL) before or after the photoirradiation were diluted by a reaction buffer containing 10 mM Tris-HCl (pH 8.0), 10 mM $MgCl_2$, 100 mM NaCl, 0.01% BSA, and 1 mM DTT, and then linearized pBR322 (6 nM) digested by *Nde*I was added. The reaction mixtures were incubated at 30 °C for 1 h. The reaction mixtures were loaded onto a 1.2% agarose gel in TBE buffer. The gels were visualized by ethidium bromide staining and quantified by the ImageJ program (NIH).

RESULTS AND DISCUSSION

Synthesis of 4′-Carboxyphenylazophenylalanine. The synthesis of the active ester of 4′-carboxyphenylazophenylalanine (azoAla **1**) was carried out according to Scheme 1. The transesterification of the 4-nitrobenzoic acid methyl ester to the *tert*-butyl ester was carried out by reaction with *n*-butyllithium and *tert*-butyl alcohol to give **3** (*24*). The reduction of the nitro group of **3** was carried out using Zn in ammonium hydroxide to produce **4** (*25*). For production of the azo group, compound **4** was oxidized to *tert*-butyl nitrosobenzoate using *tert*-butyl hypochlorite in THF at −20 °C (*26*), and the crude product was then coupled with N^{α}-Boc-4-aminophenylalanine in 10% AcOH/MeOH solution to yield **5**. The esterification of compound **5** with chloroacetonitrile gave the 4′-*tert*-butoxycarbonyl-N^{α}-Boc-phenylazophenylalanine cyanomethyl ester **6**. The active ester **6** was coupled with a nucleoside dimer 5′-phospho-2′-deoxycytidylyl-(3′-5′)-adenosine (pdCpA) tetrabutylammonium salt at room temperature for 3 h to give aminoacyl-pdCpA **7**.

Photochemical Properties of Phenylazophenylalanine Derivatives. To characterize the photochemical behaviors of the azoAla **1** and azoAla **2** monomers, the

Scheme 1[a]



[a] Reagents and conditions: (a) *tert*-BuOH, *tert*-BuLi, THF, rt; (b) Zn, NH_4OH, MeOH, H_2O, rt; (c) i. *tert*-BuOCl, THF, −20 °C, ii. N^{α}-Boc-4-aminophenylalanine, AcOH, MeOH, rt; (d) chloroacetonitrile, CH_3CN, Et_3N, rt; (e) pdCpA tetra-*n*-butylammonium salt, DMF, rt.

absorption changes by photoirradiation were examined. 4′-*tert*-Butoxycarbonyl-N^{α}-Boc-azoAla **1** (compound **5**) and N^{α}-Boc-azoAla **2** were treated with TFA for deprotection. Due to the introduction of carboxylate to the 4′-position, azoAla **1** was solubilized in water at neutral pH, while azoAla **2** needed at least 10% DMSO for solubilization in water. The azoAla derivatives (0.01 mM) were dissolved in 10% DMSO and 10 mM Tris-HCl buffer (pH 8.0), and photoirradiation was carried out at 25 °C using a high-pressure mercury lamp equipped with a monochromator. Photoisomerization was monitored by a UV/vis spectrometer. The spectrum of the untreated azoAla **1** showed two major peaks at 242 and 334 nm, which are identified as the characteristic $\pi-\pi^*$, and at 432 nm as the characteristic $n-\pi^*$ absorption band of the trans isomer of the azobenzene derivatives, respectively (Figure 2A) (*16*, *17*).

By photoirradiation to azoAla **1** at 366 nm, the peak at 334 nm rapidly decreased and largely shifted to 310 nm, while the peak at 432 nm increased and shifted to 429 nm (Figure 2A). The reaction were completed within 20 min. When irradiation to this product (*cis*-azoAla **1**) was carried out using 436 nm light, the increasing peak at 310 nm shifted to 334 nm and the decreasing one at 429 nm shifted to 432 nm (Figure 2B). This behavior is also characteristic of the cis to trans isomerization of the azobenzene derivatives, indicating that the reversible trans−cis photoisomerization of azoAla **1** occurred under this condition. In the case of azoAla **2**, a similar photoisomerization was observed by the photoirradiation. The ratios of the cis isomers of azoAla **1** and **2** after the 20 min irradiation at 366 nm were 81% and 79% under this condition (quantified by HPLC), respectively.

The half-lives for the trans to cis and cis to trans isomerizations of the azoAla **1** and azoAla **2** monomers are summarized in Table 1. They show similar values, indicating that the substitution of the 4′-position by a carboxylate does not change the basic behavior of the photoisomerization as compared to the normally used azoAla **2**. *cis*-azoAla **1** showed a good thermal stability at 30 °C ($\tau_{1/2} = 27$ h) as similar to the *cis*-azoAla **2** ($\tau_{1/2} = 35$ h), meaning that most of the cis isomer is retained under the reaction conditions of the *Bam*HI with a DNA substrate (30 °C, 1 h) when these azoAla derivatives were incorporated into the enzyme. The photochemical properties of these azoAla derivatives indicate that these have substantial potentials for photochemical switches in the protein.

Preparation of Phenylazophenylalanyl-*Bam*HI. The incorporation of the modified amino acids was performed using a four-base codon−anticodon method according to a previously reported method (*28*, *29*). The protected azoAla **1**-pdCpA and azoAla **2**-pdCpA were treated with TFA followed by ligation onto a $tRNA_{CCCG}$-(-CA) using T4 RNA ligase to give azoAla **1**-$tRNA_{CCCG}$ and azoAla **2**-$tRNA_{CCCG}$.

The azoAla derivatives were incorporated into the specific positions of *Bam*HI. The introduction of the modified amino acids into the specific positions of *Bam*HI was carried out by employing the cell-free translation system with the mutant mRNA containing a four base codon and the synthesized aminoacyl-$tRNA_{CCCG}$. In vitro translation was carried out in a mixture containing the mutant mRNA, unnatural aminoacyl-$tRNA_{CCCG}$, *E. coli* S30 extract, and amino acid with [^{35}S]-methionine at 30 °C for 2 h. After the reaction, the mixtures were loaded onto a 18% SDS−PAGE, and the gel was visualized using an imaging analyzer (Figure 3). Wild-type *Bam*HI was expressed as a full-length form at 27 kDa (lane 1). For the translation with the mutant mRNA containing a four-base codon mutation, an incomplete length of *Bam*HI was observed in the absence of aminoacyl-$tRNA_{CCCG}$ (lane 2). In contrast, the full-length *Bam*HI was obtained in the presence of the specific aminoacyl-$tRNA_{CCCG}$ (lanes 3 and 4). The efficiencies of incorporation of azo-Ala **1** and azo-Ala **2** at position 132 were 40% and 36% quantified by the radioactivity of [^{35}S]-methionine, respectively. The incorporation efficiencies for both azoAla derivatives were similar, indicating that the steric hindrance and negative charge of the carboxyl group in the 4′-position did not affect the protein synthesis using this cell-free translation system. We employed these azoAla-*Bam*HI mutants for the investigation of the photochemical control of the enzymatic activities without further purification.

Photochemical Control of the Activity of Phenylazophenylalanine-Bearing *Bam*HI Mutants. To examine the properties of the azoAla functionalized *Bam*HI mutants, photoirradiation was performed at 0 °C for 10 min using a high-pressure mercury lamp (500 W) equipped with a monochromator for generating the 366 nm light. The photoirradiated enzymes were incubated with a substrate DNA to examine the activity. As shown in Figure 4, both azoAla **1** and azoAla **2** mutants suppressed the activities after the preparation of the protein without irradiation (lanes 3 and 5, respectively). In addition, the intrinsic activities were recovered (both 44% substrate cleaved) in the azoAla **1** and **2** mutants after photoirradiation (lanes 4 and 6, respectively). This sequence selectivity was similar to that of the wild-type *Bam*HI (lane 2). The results show that the activities of the azoAla **1** and azoAla **2** mutants can be regulated through the photoisomerization of the azobenzene moiety.

In the previous study, we identified that the key amino acid regulating the *Bam*HI activity is the K132 residue using the protection and deprotection of the ϵ-amino group with a photoremovable group (*22*). The result

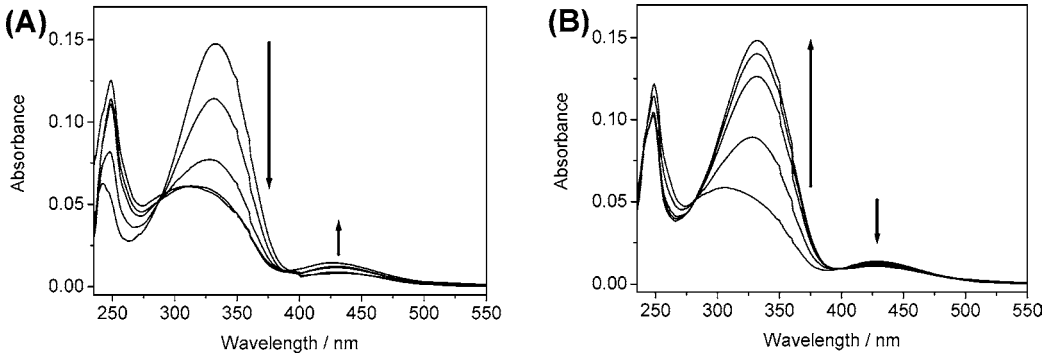


Figure 2. Absorption spectral changes of azoAla **1** with photoirradiation at 25 °C in pH 8.0 solution (water/DMSO = 9/1 v/v). (A) Trans to cis photoisomerization was carried out using 366 nm light for 0, 2, 5, 10, and 20 min. (B) Cis to trans isomerization was carried out. After the 20 min irradiation at 366 nm, the cis to trans photoisomerization was performed using 436 nm light for 0, 2, 5, 10, and 20 min.

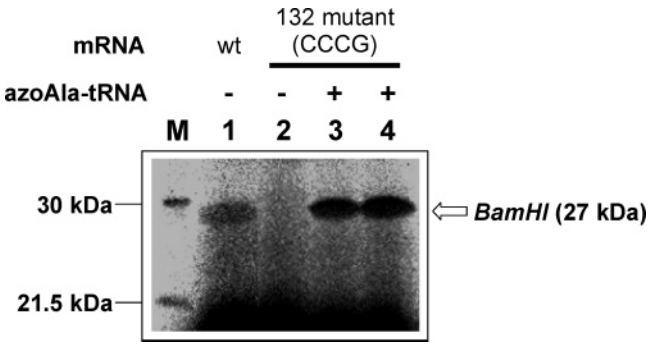

Figure 3. In vitro translation of azoAla-*Bam*HI mutants labeled with [^{35}S]-methionine. Lane 1, wild-type *Bam*HI; lane 2, translation with K132 mutant mRNA in the absence of aminoacyl-tRNA$_{CCCG}$; lane 3, translation with K132 mutant mRNA in the presence of azoAla **1**-tRNA$_{CCCG}$; lane 4, translation with K132 mutant mRNA in the presence of azoAla **2**-tRNA$_{CCCG}$.

obtained in this experiment indicates that both trans isomers of azoAlas **1** and **2** would induce a local structural change of the dimer interface to the inactive form. The *Bam*HI mutant having an *o*-nitroveratry group at the K132 position employed in the previous study showed activity, suggesting that the flexible *n*-butyl side chain of lysine would be excluded to outside of the dimer interface (*22*). The activities of azobenzene-bearing mutants after photoirradiation (366 nm, 10 min) were evaluated by kinetic parameters according to the previously reported method (*30*). Using the pBR322 restriction fragment as a substrate, kinetic parameters were obtained and summarized in Table 2. Although the *cis*-azoAla-*Bam*HI mutants showed lower activity than the wild-type, these mutants preserved the same level of the affinity and activity as compared to the H133A *Bam*HI mutant (*22*).

We tried the cis to trans photoisomerization using the cis forms of both azoAla-*Bam*HI mutants which were generated by irradiation with 366 nm light for 20 min. When these *cis*-azoAla-*Bam*HI mutants were irradiated

with 436 nm, suppression of the DNA cleavage was not observed. In the previous study, the enzyme activity of Horseradish peroxidase was successfully controlled in switchable way using the site-selectively incorporated azophenylalanine (*12*). In this case, the phenylazophenylalanine introduced close to the substrate binding site effectively controls the binding and activity for the small substrate. In our case, once the cis forms of the azoAla derivatives are removed from the dimer interface for formation of the active dimer complex, the regenerated *trans*-azobenzene moieties would not be forced to change the conformation of the dimer to an inactive conformation.

Effect of the Carboxylate Group in the Azobenzene on the Recovery of the Activity. We examined the relationship between the recovery of the activities and irradiation time for the azoAla-*Bam*HI mutants during the trans to cis photoisomerization using 366 nm light. The irradiation time-dependent activitation of the enzyme was observed for both the azoAla **1** and azoAla **2** *Bam*HI mutants (Figure 5). During photoirradiation for 5 min, the activity of the enzymes gradually increased, and the trans to cis photoisomerization in both azoAla

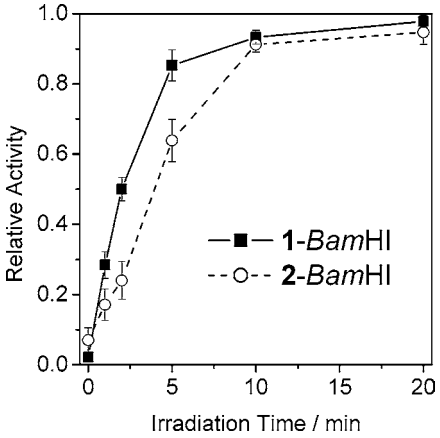

Figure 5. Recovery of the activity of the azoAla **1**-*Bam*HI and azoAla **2**-*Bam*HI mutants by photoirradiation (366 nm). Photoirradiation was carried out at 0 °C for 0, 1, 2, 5, 10, and 20 min, and then the samples were incubated with a substrate DNA at 30 °C for 1 h.

monomers was completed in 20 min. For an irradiation of more than 10 min, the activities reached the saturated level. Thus, the activity level of these azobenzene-functionalized enzymes can be regulated depending on the irradiation time within 10 min. The cis−trans thermal isomerization at 30 °C is slow enough to retain the cis form azoAla during the enzymatic reactions with substrates at 30 °C for 1 h (see Table 1). Therefore, the activity of the enzymes depends on the population of the active (cis isomer) and the inactive (trans isomer) *Bam*HI, namely the concentration of active *Bam*HI, can be purposely controlled by photoirradiation time.

Effect of the negatively charged carboxylate group on the azobenzene moiety for the activity was examined. As shown in Figure 5, we observed a faster recovery of the activity of azoAla **1**-*Bam*HI in shorter irradiation times (1−5 min) as compared to that of azoAla **2**-*Bam*HI. This means that the negatively charged azoAla **1** can rapidly produce the active *Bam*HI with correct dimer formation after photoirradiation. Since the properties of the photoisomerization between azoAla **1** and **2** were basically the same as the monomer level in solution (Table 1), the expression of the enzyme activity using the azoAla derivatives would be affected by the environment of the protein surface when the azoAla derivatives possessing different electrostatic properties were incorporated into the 132 position of the dimer interface.

In the present case, there are two possibilities for the regulation of the enzyme activity using the trans−cis photoisomerization of the azobenzene. One possibility is that the azobenzene moiety directly interferes the interaction between the two *Bam*HI monomers for the correct formation of the dimer. The short methylene chains of the azoAla residues constrain the orientations of the bulky *trans*-azobenzene moieties, which would cause the steric hindrance between the azobenzene moieties and the counterpart α-helix for consequent suppression of the activity. Recovery of the activities after the photoirradiation means the correct formation of the *Bam*HI dimer with the cis isomers. The compact *cis*-azobenzene moieties may reduce the steric interference in the dimer interface and exhibit the activity after the correct *Bam*HI dimer formation. The negatively charged carboxylate in the cis-isomer of the azoAla **1**-*Bam*HI would cause rapid dimer formation in the dimer interface as compared to the neutral azoAla **2**-*Bam*HI.

The other possibility is that the azobenzene moiety would change the local structure of the monomer around the azobenzene residue because of the interaction of the aromatic ring with the protein surface in order to avoid the water-accessible environment. The short methylene chains of the azoAla residues limit the movement of the *trans*-azobenzene moieties, and aromatic azobenzene may interact with the surface of *Bam*HI, which induces local structural changes for misalignment of the dimer structure and consequent suppression of the activity. Since the possible contact area of the *cis*-azobenzene moiety with the protein surface is smaller than that of the trans form, the cis isomer may weaken the interaction with the protein surface, and the *Bam*HI dimer forms an active one. Negative charge of the cis-isomer would work on the correct dimer formation in the environment on the surface of the *Bam*HI monomer. In these possibilities, the carboxylate group in the azobenzene affects the rapid expression of the activity in the protein scaffold as compared to the neutral azobenzene moiety without changing the potential of the activity of both *cis*-azoAla-*Bam*HI after a long time irradiation.

CONCLUSIONS

We designed and synthesized a novel hydrophilic and negatively charged azobenzene-bearing amino acid, 4′-carboxyphenylazophenylalanine, and investigated the photochemical regulation of *Bam*HI where the azobenzene derivatives were selectively incorporated. We found that the negative charge of the azobenzene moiety affects the initial activation of the enzyme in the trans−cis photoisomerization. The result suggests that these azobenzene derivatives may be a new tool for investigation of the environment such as solvent-accessibility, hydrophobicity, and electrostatic state in the protein.

Received January 10, 2005; Revised Manuscript Received September 25, 2005

We prepared block copolymers of (2-ethoxy)ethoxyethyl vinyl ether (EOEOVE) and octadecyl vinyl ether (ODVE) with the number average molecular weights of 6900, 9300, and 16 700 by living cationic polymerization. The poly(EOEOVE) block acts as a temperature-sensitive moiety, and the poly(ODVE) block acts as an anchor moiety. We also investigated the effect of chain length of the copolymer poly(EOEOVE) block on the ability to sensitize liposomes. The copolymers underwent a coil−globule transition at ∼36 °C in the presence of a membrane of egg yolk phosphatidylcholine (EYPC), detected using differential scanning calorimetry (DSC). Liposomes encapsulating calcein, a water-soluble fluorescent dye, were prepared from mixtures of dioleoylphosphatidylethanolamine, EYPC, and the copolymers. While the copolymer-modified liposomes released little calcein below 30 °C, release was enhanced above 35 °C, indicating that dehydrated copolymer chains destabilized the liposome membrane. In addition, copolymers with a longer poly(EOEOVE) block induced a more drastic enhancement of contents release in a narrow temperature region near the transition temperature of the poly(EOEOVE) block. As a result, the copolymer with an average molecular weight of 16 700 generated highly sensitive liposomes that produced rapid and dramatic release of the contents in response to temperature.

1. INTRODUCTION

Liposomes are highly attractive materials for drug delivery because of their biocompatibility, ability to encapsulate both hydrophilic and hydrophobic drugs, and size controllability (*1*). Therefore, studies to modify their functions have been conducted to increase their usefulness. While various functional liposomes have been developed, temperature-sensitive liposomes have received much attention (*2*−*4*). Temperature-sensitive liposomes have been produced by modifying liposomes with thermosensitive polymers according to methods by Kono et al. (*5*, *6*) and other groups (*7*−*10*).

The water solubility and conformation of thermosensitive polymers change at a specific temperature, called the lower critical solution temperature (LCST). These changes in water solubility and conformation provide temperature-sensitive properties to liposomes (*6*). Poly(*N*-isopropylacrylamide) [poly(NIPAM)] and copolymers of NIPAM, prepared via free radical polymerization, have been used for temperature-sensitization of liposomes (*5*−*7*, *9*, *11*−*13*). Highly hydrated polymer chains conjugated to the liposome surface increase the stability of liposomes below the LCST (*13*, *14*). In contrast, above the LCST, dehydrated polymer chains interact with the liposome membrane and induce release of the liposome contents (*6*). However, polymers and copolymers produced by this technique can have disadvantages, such as lack of control over molecular weight, high polydispersity, and limited freedom in choosing the architecture of the polymer chain, although efforts have been made recently to synthesize homopolymer and block copolymers of NIPAM with a defined structure by atom transfer polymerization (*15*) or reversible addition−fragmentation chain transfer polymerization (*16*−*18*).

Living cationic polymerization is an attractive technique for the synthesis of thermosensitive polymers with precisely controlled molecular architecture and molecular weight. In fact, a variety of thermosensitive polymers and block copolymers with controlled molecular structures have been prepared using this polymerization system (*19*−*21*). Aoshima et al. have shown that living cationic polymerization of 2-(2-ethoxy)ethoxyethyl vinyl ether (EOEOVE) gives a thermosensitive polymer, which allows control of molecular weight and a low polydispersity (*19*).

In this study, synthesis of block copolymers of EOEOVE and octadecyl vinyl ether (ODVE) for the sensitization of liposomes was examined (Figure 1). The poly(EOEOVE) block behaves as a thermosensitive moiety, whereas the poly(ODVE) block acts as an anchor for fixing the copolymer chain onto a liposomal membrane through hydrophobic interaction between its octadecyl chains and the liposome membrane. Temperature-sensitive content release or related behaviors were investigated for liposomes modified with the block copolymers having a poly(EOEOVE) block of varying chain lengths. The effect of chain length of the thermosensitive block

on the ability of block copolymers to sensitize liposomes is described.

2. EXPERIMENTAL SECTION

2.1. Materials. Egg yolk phosphatidylcholine (EYPC) and dioleoylphosphatidylethanolamine (DOPE) were kindly donated by Nippon Oil and Fats Co. (Tokyo, Japan). Octadecyl vinyl ether (ODVE) was obtained from BASF (Germany). 2-(2-Ethoxy)ethoxyethyl vinyl ether (EOEOVE) was purchased from Maruzen Petrochemical (Tokyo, Japan). Calcein, pyrenecarboxaldehyde (PyCHO) 1,6-diphenyl-1,3,5-hexatriene (DPH), and 8-anilino-1-naphthalenesulfonic acid (ANS) were obtained from Sigma-Aldrich Japan (Tokyo, Japan). $Et_{1.5}AlCl_{1.5}$ (1.0 M solution in toluene) and toluene were obtained from Wako Pure Chemical Industries (Osaka, Japan). Ethyl acetate was supplied from Nacalai Tesque (Kyoto, Japan). ODVE was distilled over calcium hydride under reduced pressure (150 °C/3 mmHg). EOEOVE was washed with 10% aqueous sodium hydroxide and then with water, dried overnight over potassium hydroxide pellets, and distilled twice over metallic sodium before use. Ethyl acetate was distilled at least twice over calcium hydride. Toluene as a polymerization solvent was washed by the usual method and distilled at least twice over calcium hydride and then metallic sodium just before use. Cationogen, 1-isobutylethyl acetate (IBEA) ($CH_3CH(OiBu)OCOCH_3$), was prepared from isobutyl vinyl ether (IBVE) and acetic acid and was distilled over calcium hydride under reduced pressure (*22*). All monomers, the $Et_{1.5}AlCl_{1.5}$ solution, and IBEA were stored in a brown ampule under dry nitrogen.

2.2. Polymerization Procedures. Polymerization was carried out at 0 °C under a dry nitrogen atmosphere in a glass tube equipped with a three-way stopcock baked at 240 °C for 10 min before use. The reaction was initiated by the addition of $Et_{1.5}AlCl_{1.5}$ solution in toluene into a mixture of a monomer, an added base, and the cationogen IBEA in toluene at 0 °C by a dry medical syringe. For block copolymerization, a typical example is as follows. EOEOVE (0.13 M, 0.11 mL) was first polymerized in the presence of $CH_3COOC_2H_5$ (1.0 M, 0.5 mL) as an added base ($[IBEA]_0 = 4.0$ mM; $[Et_{1.5}AlCl_{1.5}]_0 = 20$ mM in toluene). After 2.5 h, the second monomer, ODVE (0.04 M in toluene, 5.0 mL), was added to the reaction mixture at a given conversion of EOEOVE. After 2 h, ODVE had been consumed quantitatively (total 4.5 h). When the polymerization was finished, it was quenched with methanol containing a small amount of aqueous ammonia. The quenched reaction mixture was diluted with dichloromethane and then sequentially washed with dilute hydrochloric acid and with water to remove the initiator residues. The product polymer was recovered from the organic layer by evaporation of the solvent under reduced pressure and vacuum-dried overnight. Poly(NIPAM)s with different molecular weights were obtained by polymerization of NIPAM in tetrahydrofran using azobisisobutyronitrile as a free radical initiator as previously reported (*5*, *12*) and subsequent fractional precipitation by adding diethyl ether into poly(NIPAM) dissolved in tetrahydrofran.

2.3. Liposome Preparation. The liposomes were prepared as previously reported (*23*, *24*). A mixture of DOPE and EYPC (7:3, mol/mol) (4.4 mg) and varying amounts of the copolymer were dissolved in chloroform, and the solvent was removed by evaporation. The obtained thin lipid/copolymer-mixed membrane was further dried under vacuum overnight and dispersed in 0.75 mL of an aqueous calcein solution (63 mM, pH 7.4) or in 10 mM Tris-HCl-buffered solution containing 140 mM NaCl and 1 mM EDTA solution (pH 7.4). The obtained liposome suspension was extruded through a polycarbonate membrane with a pore diameter of 100 nm in an ice-cooled water bath. The free calcein and free copolymer were removed by gel permeation chromatography (GPC) on a Sepharose 4B column at 4 °C using a 10 mM Tris-HCl-buffered solution containing 140 mM NaCl and 1 mM EDTA solution (pH 7.4). The liposomes suspensions were kept at 5 °C until the measurements were made.

2.4. Calcein Release from Liposome. The release measurements were performed according to the method previously reported (*23*, *24*). An aliquot of dispersion of the calcein-loaded liposomes was added into 2 mL of 10 mM Tris-HCl, 140 mM NaCl, and 1 mM EDTA solution (pH 7.4) in a quartz cell (final concentration of the lipids, 10 μM) at a given temperature, and the fluorescence intensity of the solution was monitored using a spectrofluorometer (Shimadzu RF-5000). The excitation and monitoring wavelengths were 490 and 520 nm, respectively. The percent release of calcein from the liposomes was defined as

$$\%\ \text{release} = \frac{F^t - F^i}{F^f - F^i} \times 100$$

where F^i and F^t mean the initial and intermediary fluorescence intensities of the liposome suspension, respectively. F^f is the fluorescent intensity of the liposome suspension after the addition of Triton X-100 (final concentration of 0.15%).

2.5. Estimation of the Amount of Copolymer Bound to Liposome. The amount of the copolymer bound to the liposome was estimated using high-performance liquid chromatography as previously reported (*12*, *13*). The liposomes bearing the copolymer were dried under vacuum and then dissolved in methanol/water (7:3, v/v). The solution was filtered through a poly(tetrafluoroethylene) membrane with a pore size of 0.25 μm. The filtrate (20 μL) was injected into a KB-8501 column (Showa Denko), and the amount of the copolymer was evaluated using a refractive index detector (Jasco, RI-930). Also, the lipid amount was determined by the method of Bartlett (*25*).

2.6. Fluorescence Measurements. Emission spectra of PyCHO were obtained on a spectrofluorometer with excitation at 365.5 nm. Fluorescence polarization (P) of DPH and ANS was measured as reported previously (*26*). Fluorescence polarization of DPH and ANS was measured as reported previously (*24*, *27*). ANS and DPH were excited at 395 and 360 nm, respectively, and the fluorescence intensities of ANS and DPH were monitored at

467 and 428 nm, respectively. The P value was evaluated using

$$P = \frac{I_p - I_v}{I_p + I_v}$$

where I_p and I_v represent the intensities of parallel polarized fluorescence and vertically polarized fluorescence, respectively.

2.7. Retention of Fluorescein Isothiocyanate (FITC)−Dextran in Liposomes. The liposomes containing FITC−dextran was prepared by suspending a dry membrane of EYPC (10 mg) or a mixture (9 mg) of DOPE and EYPC (7/3, mol/mol) in a solution of FITC−dextran (6 mg) dissolved in 10 mM Tris-HCl and 140 mM NaCl solution (1.5 mL, pH 7.4) at varying temperatures for 30 min. Then, the liposomes were applied to a Sepharose 4B column to remove FITC−dextran released from the liposomes during the incubation. The percent of FITC−dextran remaining after the incubation was calculated from

$$\text{FITC−dextran remaining (\%)} = \frac{F^0 - F^t}{F^0} \times 100$$

where F^0 and F^t mean the fluorescence intensities of FITC-dextran-loaded liposomes per liposomal lipid before and after 30 min of incubation and subsequent GPC using a Sepharose 4B column, respectively. The excitation and monitoring wavelengths of FITC−dextran were 490 and 520 nm, respectively.

2.8. Other Methods. The molecular weight distribution of poly(EOEOVE) and poly(EOEOVE-*block*-ODVE) was measured by size exclusion chromatography (SEC) in chloroform at 40 °C on three polystyrene gel columns [TSK gel G-2000HXL (molecular range of 1×10^2 to 1×10^4 (PSt)), 3000HXL (6×10^3 to 6×10^4), and 4000HXL (1×10^4 to 4×10^5); 7.8 mm i.d. × 300 mm; flow rate, 1.0 mL/min] connected to a Tosoh DP-8020 dual pump and a RI-8020 refractive detector. The number-average molecular weight (M_n), the weight-average molecular weight (M_w), and the polydispersity index (M_w/M_n) were calculated from SEC curves on the basis of a polystyrene calibration. M_n and M_w of poly(NIPAM)s were determined using SEC on a system equipped with a Shodex KF-805L and KD-803 column (Showa Denko) with differential refractive index detection (Jasco, RI-930) using DMF as an eluent and poly(ethylene glycol) as the standard. ^{1}H NMR and ^{13}C NMR spectra were recorded on a JEOL JNM-EX270 (270 MHz). Differential scanning calorimetry (DSC) was performed with a DSC 120 microcalorimeter (Seiko Electronics). The size of liposomes was evaluated by dynamic light scattering using a Nicomp 380 ZLS instrument (Particle Sizing Systems).

3. RESULTS AND DISCUSSION

3.1. Characterization of Polymers and Copolymers. Three types of poly(EOEOVE) with different molecular weights were prepared by controlling the molar ratio of monomer EOEOVE to initiator IBEA for the polymerization (Figure 1). Polymerization at EOEOVE/IBEA (mol/mol) ratios of 32, 60, and 120 gave polymers with average molecular weights of 5300, 8300, and 15 800, respectively, within narrow molecular weight distributions (Table 1). The degree of polymerization for these polymers was estimated to be 33, 52, and 99, respectively. We also prepared three poly(EOEOVE)s with an oligo(ODVE) block, which acts as an anchor for fixing the polymer chain onto a liposomal membrane, through sequential living copolymerization of EOEOVE and ODVE (Table 1). When the poly(EOEOVE) segments of the block copolymers and homopolymers of EOEOVE were prepared at the same monomer/initiator ratio, they contained essentially the same number of EOEOVE units in the polymer and copolymer chains. In addition, these block copolymers contained approximately the same number of ODVE units (four or five) at the terminal moiety of the copolymer chain. We have already shown that two dodecyl groups fix chains of NIPAM copolymers stably onto liposome membranes (*23*, *24*). Therefore, highly hydrophobic octadecyl groups of the ODVE block at the terminal moiety of the copolymer should fix the copolymer chain onto the liposome surface tightly through hydrophobic interactions.

0.13	0	33	0	6000	5300	1.14
0.24	0	52	0	9500	8300	1.15
0.48	0	99	0	18300	15800	1.16
0.13	0.04	31	5	7800	6900	1.13
0.24	0.04	52	4	10800	9300	1.16
0.48	0.04	99	4	19000	16700	1.14

An endotherm is associated with the LCST of thermosensitive polymers, such as poly(NIPAM) and poly(vinyl methyl ether) (*28*, *29*), mainly because of the destruction of water around the hydrophobic groups upon a coil-to-globule transition of the polymer chain at the LCST (*30*). Therefore, we conducted microcalorimetric analyses to estimate the LCST of poly(EOEOVE) and to determine the influence of polymer chain length (Figure 2). Despite differences in molecular weight, these polymers showed similar endotherms of 14−15 J/g for the conformational transition, indicating that the destruction of water associated with the polymers occurred with a similar efficiency. However, the molecular weight affected the transition temperature of the polymers. The polymers with molecular weights of 5300, 8300, and 15 800 exhibited endotherms centered at 45, 41, and 40 °C, respectively. Apparently, the polymer with a higher molecular weight underwent a transition at a lower temperature. It is likely that a longer polymer chain enhances dehydration through efficient intramolecular interactions in addition to intermolecular interactions, resulting in a transition in a lower temperature region.

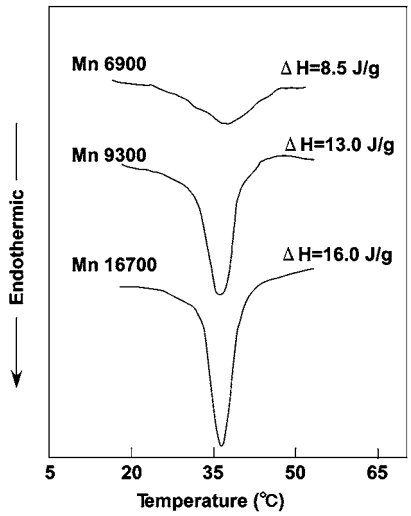

Figure 3. Microcalorimetric endotherms for copoly(EOEOVE−ODVE) with M_n of 6900, 9300 and 16 700 in the presence of EYPC in water. Copolymer/lipid (w/w) ratio was 1/1.

A microcalorimetric analysis was also performed for mixtures of EYPC and copoly(EOEOVE-*b*-ODVE) suspended in water to obtain information about the transition of poly(EOEOVE) chains fixed onto the lipid membrane (Figure 3). As shown in Figure 3, these copolymers on the surface of the lipid membrane showed endotherms in approximately the same temperature region of 36−39 °C, irrespective of the difference in poly(EOEOVE) chain length. In comparison with the transition in aqueous solution, it is apparent that the poly(EOEOVE) chain undergoes a phase transition at a lower temperature. The hydrophobic environment of the lipid membrane periphery may enhance dehydration of the polymer chain, enabling the polymer chain to undergo a transition at a low temperature. In addition, a comparison of endotherms for transitions of these copolymers with the EYPC membrane revealed that the copolymer with a higher molecular weight underwent the transition in a narrow temperature region with a large transition enthalpy, indicating that the longer polymer chain undergoes more efficient transition on the lipid membrane.

3.2. Characterization of Copolymer-Modified Liposomes. We used a mixture of DOPE and EYPC (7:3, mol/mol) as the liposomal lipids because inclusion of DOPE into EYPC liposomes modified with NIPAM copolymers improved their temperature sensitivity (*31*). The liposomes were prepared from mixtures of the lipids and block copolymers. The copolymer/DOPE/EYPC liposomes were extruded through a polycarbonate membrane with a pore size of 100 nm and purified by GPC using a Sepharose 4B column. The amounts of copolymers fixed onto the liposomes are listed in Table 2. Irrespective of poly(EOEOVE) chain length, generally more than 90% of the copolymer added for preparation of the liposome was retained in the liposome after purification by GPC, indicating that four or five octadecyl groups connected to the terminal moiety of the copolymer chain could fix the poly(EOEOVE) chains, although a slightly lower fixation efficiency was observed for liposomes prepared using the copolymer with an M_n of 16 700 and copolymer/lipid ratio of 1.5. The mean diameters of the copolymer-modified liposomes also are listed in Table 2, which possess slightly larger diameters than the pore size of the filter membrane used for the preparation of the liposomes. Since the liposomes containing the copolymer with higher M_n tend to have larger diameters, the chain length of the copolymer may increase the apparent size of the liposomes by assuming an extended conformation on the liposome surface.

Table 2. Characterization of Copoly(EOEOVE−ODVE)-Modified Liposomes[a]

M_n of copolymer	copolymer added (mg/mg lipid)	copolymer fixed (mg/mg lipid)	mean diameter (nm)
6900	0.5	0.44	132
	1.0	0.93	126
	1.5	1.36	132
9300	0.5	0.49	142
	1.0	0.96	139
	1.5	1.47	131
16700	0.5	0.40	157
	1.0	0.89	157
	1.5	1.25	151

[a] Measurements were performed at 20 °C.

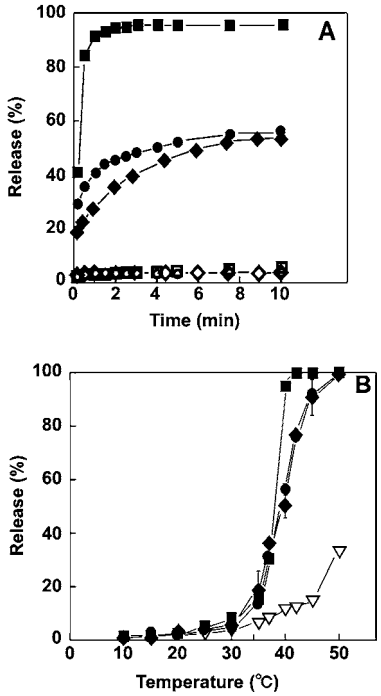

Figure 4. Release of calcein from the copolymer-modified DOPE/EYPC (7/3, mol/mol) liposomes: (A) profiles of calcein release from DOPE/EYPC (7/3, mol/mol) liposomes modified with copoly(EOEOVE-*b*-ODVE) with M_n of 6900 (diamonds), 9300 (circles), and 16 700 (squares) in 10 mM Tris-HCl, 140 mM NaCl, and 1 mM EDTA at 40 °C (solid symbols) and 25 °C (open symbols); (B) percent release of calcein from DOPE/EYPC (7/3, mol/mol) liposomes modified with copoly(EOEOVE-*b*-ODVE) with M_n of 6900 (diamonds), 9300 (circles), and 16 700 (squares) or unmodified DOPE/EYPC (7/3, mol/mol) liposome (triangles) after 10 min of incubation as a function of the incubation temperature. The liposomes were prepared from a copolymer/lipid (0.5/1, w/w) mixture.

3.3. Calcein Release from Copolymer-Modified Liposomes. To estimate first the ability of these block copolymers to sensitize the liposome to temperature and then to understand the effect of chain length of the copolymer on their ability for temperature sensitization of the liposome, we examined the content release behavior of liposomes modified with copoly(EOEOVE-*b*-ODVE) of varying molecular weights. Calcein (formula weight, 622.5) was used as a permeant because this water-soluble dye exhibits considerable self-quenching when entrapped in a liposome at high concentration but fluoresces when released into the outer phase (*31*). Figure 4A shows calcein release profiles from EYPC/DOPE liposomes modified with copolymers at 25 and 40 °C. As shown in Figure 4A, the liposomes did not release calcein at 25

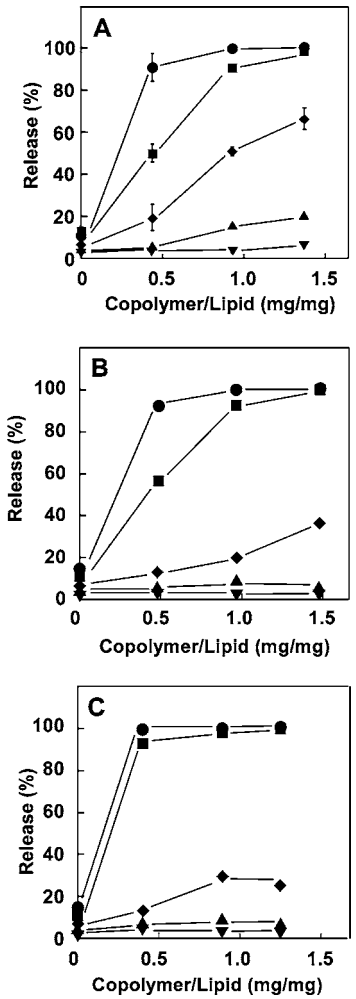

Figure 5. Percent release of calcein from DOPE/EYPC (7/3, mol/mol) liposomes after 10 min of incubation at 25 (▼), 30 (▲), 35 (◆), 40 (■), and 45 (●) as a function of content of copoly(EOEOVE-*b*-ODVE)s with M_n of 6900 (A), 9300 (B), and 16 700 (C).

°C; however, strong release was induced at 40 °C. As shown earlier, the poly(EOEOVE) segment of the copolymer changes its nature from hydrophilic to hydrophobic near 36 °C (Figure 3). Thus, these results imply that a hydrated chain of poly(EOEOVE) does not destabilize the liposomal membrane, but a dehydrated chain interacts with the membrane, enhancing permeation of calcein through the membrane. In addition, liposomes modified with copolymers of higher M_n exhibited more significant content release at 40 °C, indicating that the ability of the poly(EOEOVE) chain to sensitize liposomes increases with chain length. It is noteworthy that the copolymer with a M_n of 16 700 conferred a high degree of temperature sensitivity to liposomes, which achieved complete content release within 1 min.

As shown in Figure 4A, significant release was induced within the first 1 or 2 min. However, the release gradually slowed and approached a constant value after 10 min. The extent of content release after 10 min at varying temperatures was plotted as a function of incubation temperature (Figure 4B). The content release was clearly enhanced above 36 °C, where dehydration of poly(EOEOVE) presumably occurred on the lipid membrane, indicating that the change of the polymer chain from hydrophilic to hydrophobic triggered content release.

Figure 5 depicts the effect of copolymer content of the liposome membrane on calcein release behavior of the liposomes. No remarkable difference in calcein release was observed in liposomes modified with copolymers of different M_n below 30 °C or at 45 °C. These results suggest that highly hydrated or well-dehydrated polymer chains interact with membranes in a similar manner, irrespective of the difference in chain length. In contrast, a significant difference was observed in calcein release at 35 and 40 °C among these copolymer-modified liposomes. The copolymer with an M_n of 6900 possessed significant ability to enhance release at 35 °C, whereas the copolymer with an M_n of 16 700 exhibited a much lower ability to enhance release at the same temperature. In contrast, at 40 °C the copolymer with a high M_n achieved complete release even at a copolymer/lipid ratio of 0.5, whereas the copolymer with a low M_n induced only 50% release at the same copolymer/lipid ratio. As seen in Figure 3, dehydration of the poly(EOEOVE) segment was not complete at these temperatures. For the short chain of poly(EOEOVE), dehydrated segments of the polymer chain may interact with and destabilize the liposome membrane, although the degree of dehydration might be limited at 35 °C. However, for the longer polymer chain, because of its higher conformational freedom, dehydrated segments could associate with each other, resulting in weak interaction with the membrane. In contrast, at 40 °C, the longer polymer chain enables its dehydration more efficiently because of its larger freedom of conformation, resulting in a stronger interaction with the liposome and more significant release of calcein.

3.4. Interaction of Copolymers with Liposome Membrane. The influence of the copolymer on membrane fluidity of the liposome was investigated to obtain information about interactions with the lipid membrane using the fluorescent probes ANS and DPH. These fluorescent molecules are used widely to estimate membrane fluidity and provide information about the surface (ANS) and hydrophobic region (DPH) of the membrane (*32*). The inverse polarization of fluorescence probes (1/*P*) indicated the membrane fluidity (*32*).

For simplicity, EYPC was used as the liposomal lipid for estimation of membrane fluidity. Figure 6A depicts the temperature dependence of membrane fluidity of the liposomes as monitored by ANS. For unmodified liposomes, membrane fluidity increased with temperature. Similarly, the membrane fluidity of liposomes modified with the copolymer with an M_n of 6900 increased with temperature; no change in the temperature dependence of membrane fluidity was observed near the transition temperature. For liposomes modified with copolymers with M_n of 9300 and 16 700, the membrane fluidity increased monotonically up to 40 °C; this increase in membrane fluidity was slightly suppressed near 40 °C. Since this temperature is close to that at which significant enhancement of content release occurred, it is likely that the dehydrated chains of poly(EOEOVE) interact with the lipid membrane and suppress mobility of the lipid molecules. Because suppression was observed only with copolymers of higher molecular weights, the interaction of the copolymer with the membrane may increase with chain length of the poly(EOEOVE) segment. However, a previous study showed more significant suppression of the EYPC membrane upon modification with NIPAM copolymers (*24*, *27*); thus, the interaction of poly(EOEOVE) with the membrane may be relatively weak.

A similar tendency was seen for membrane fluidity as monitored by DPH (Figure 6B). Membrane fluidity of the unmodified EYPC liposome increased monotonically with temperature, whereas increase in membrane fluidity was

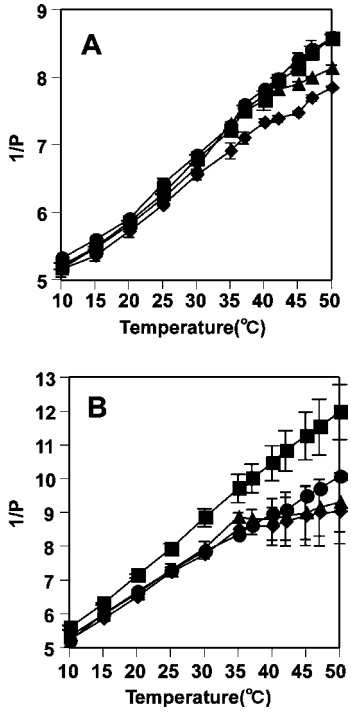

Figure 6. Temperature dependence of membrane fluidity (1/*P*) of EYPC liposomes modified with copoly(EOEOVE-*b*-ODVE)s with M_n of 6900 (●), 9300 (▲), and 16 700 (◆), and unmodified EYPC liposome (■) in 10 mM Tris-HCl and 140 mM NaCl solution (pH7.4) as monitored by ANS (A) and DPH (B). The concentrations of EYPC, ANS, and DPH were 0.4 mM, 4.4 μM, and 0.44 μM, respectively. Copolymer/lipid (w/w) ratio of the liposomes was 0.5/1.

suppressed above 37 °C for membranes having poly(EOEOVE) chains. More significant suppression was observed for membranes modified with copolymers of higher M_n. As mentioned earlier, copolymer chains with higher M_n underwent conformational transition more efficiently than did copolymers with a low M_n. Therefore, the longer chains of poly(EOEOVE) could form a more hydrophobic domain upon the transition and interact more strongly with the membrane. A comparison between membrane fluidities monitored by ANS and DPH showed that the latter indicated more pronounced suppression by the copolymers, implying that the copolymers interact with the hydrophobic region of the membrane more strongly than with the peripheral region of the membrane.

3.5. Retention of Dextran in Copolymer-Modified Liposomes. We examined the effect of temperature on retention of dextran in copolymer-modified liposomes to obtain information about the mechanism of content release induced by the copolymers. The copolymer-modified EYPC or DOPE/EYPC (7/3, mol/mol) liposome containing FITC−dextran with an average molecular weight of 4400 was incubated for 30 min at varied temperatures. Figure 7 shows the percent FITC−dextran remaining in the liposomes after a 30 min incubation as a function of incubation temperature. For copolymer-modified EYPC liposomes, more than 75% of the content was retained in the liposomes even at 50 °C, where the poly(EOEOVE) chain becomes fully dehydrated, indicating that the polymer chain causes only limited defects in the EYPC membrane. In contrast, for copolymer-modified liposomes containing DOPE, only a small portion of the contents remained after incubation above the transition temperature of poly(EOEOVE). Considering that a large molecule with an average molecular weight

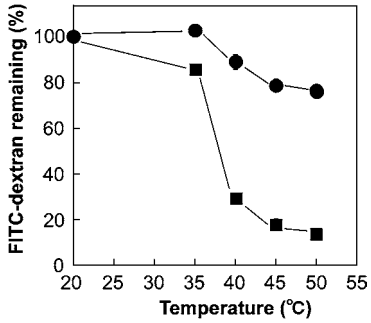

Figure 7. Retention of FITC−dextran from copoly(EOEOVE-*b*-ODVE) (M_n of 16 700) modified EYPC (●) and DOPE/EYPC (7/3, mol/mol) (■) liposomes after 30 min of incubation as a function of incubation temperature. Copolymer/lipid (w/w) ratio was 0.5/1.

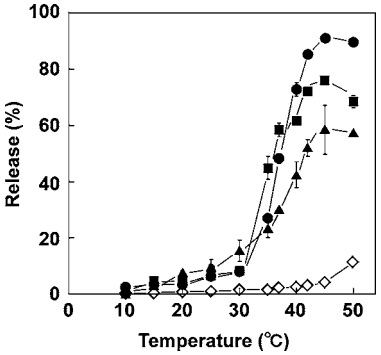

Figure 8. Percent release of calcein from EYPC liposomes modified with copoly(EOEOVE-*b*-ODVE) with M_n of 6900 (triangles), 9300 (squares), and 16 700 (circles) or unmodified EYPC liposome (diamonds) after 10 min of incubation in 10 mM Tris-HCl, 140 mM NaCl, and 1 mM EDTA as a function of the incubation temperature. The liposomes were prepared from a copolymer/lipid (1.5/1, w/w) mixture.

of 4400 was released effectively to the outer phase, it is likely that disintegration of the liposome was induced by the dehydrated polymer chain in the DOPE-containing liposome. It is well-known that EYPC forms a stable bilayer membrane under physiological condition, whereas DOPE has a tendency to form a hexagonal II structure (*33*, *34*). Therefore, it is likely that the interaction with the dehydrated chain of poly(EOEOVE) did not induce a significant defect in the stable bilayer membrane of EYPC but enhanced the transition of the DOPE-containing membrane from a lamellar to a nonlamellar phase, resulting in rupture of the liposome.

3.6. Sensitization of EYPC Liposomes by Copolymer-Modified Liposomes. It has been shown that the interaction between poly(NIPAM) and phosphatidylcholine membranes is not strong enough to induce significant release from the liposomes (*5*, *6*, *35*). Inclusion of DOPE has been shown to improve temperature-sensitive release properties of poly(NIPAM)-modified liposomes (*27*). At the same time, however, the stability of the liposomes decreases because DOPE has a high tendency to form a nonbilayer structure. Therefore, it is highly desired to provide highly temperature-sensitive properties to stable phosphatidylcholine liposomes. Thus, we examined the ability of these copolymers to sensitize EYPC liposomes. As is seen in Figure 8, EYPC liposomes modified with poly(EOEOVE-*b*-ODVE) enhanced release of calcein above 35 °C, indicating that these polymers have an ability to sensitize liposomes with a stable phosphatidylcholine membrane to temperature. In addition, the extent of enhancement of the contents release became more significant for the liposomes modified with the copolymer

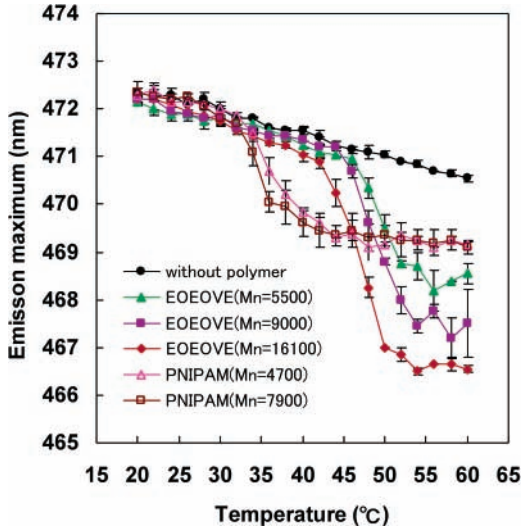

Figure 9. Emission maxima for PyCHO in the absence or presence of poly(NIPAM) or poly(EOEOVE) with varying molecular weights in water. The concentrations of PyCHO and the copolymers were 1 μM and 0.2 mg/mL, respectively. Poly(NIPAM)s with M_n of 4700 and M_w of 10 000 and with M_n of 7900 and M_w 23 000 were used. Poly(EOEOVE)s with M_n of 5500 and M_w of 6300, M_n of 9000 and M_w of 10 400, and M_n of 16100 and M_w of 18 400 were used.

of a higher molecular weight. In particular, the liposomes having a copolymer with a molecular weight of 16 700 exhibited a sharp and intensive contents release around the polymer transition temperature. This result clearly indicates that the poly(EOEOVE-*b*-ODVE) is very useful for obtaining stable phosphatidylcholine liposomes with temperature-sensitive properties.

The poly(EOEOVE-*b*-ODVE) was shown to be able to sensitize EYPC liposomes. This implies that poly(EOEOVE) forms a more hydrophobic domain than poly(NIPAM) does after their conformational transition because the contents release from the liposomes would be induced mainly by hydrophobic interaction between the liposome membrane and the dehydrated polymer chains. To confirm it, we further examined the hydrophobicity of domains formed by these polymers above the transition temperature using PyCHO. This molecule is known to change the wavelength of the emission maximum (λ_{max}) of the fluorescence, depending on polarity of the solvent (*26*). By using this property of PyCHO, Schild and Tirrell detected collapse of the backbone of the homopolymer and copolymers of NIPAM (*26*).

Two poly(NIPAM)s with M_n of 4700 and M_w of 10 000 and with M_n of 7900 and M_w of 23 000 were compared with three poly(EOEOVE)s with M_n of 5500 and M_w of 6300, M_n of 9000 and M_w of 10 400, and M_n of 16 100 and M_w of 18 400. As is seen in Figure 9, λ_{max} of PyCHO dissolved in an aqueous solution slightly decreased with increasing temperature in the absence of the polymer. In contrast, in the presence of the polymers, a marked blue shift above the LCST was observed around 35 °C for poly(NIPAM)s and at 44−46 °C for poly(EOEOVE)s, indicating that these polymers formed hydrophobic domains at these temperatures. As judged from the extent of emission blue shift, hydrophobicity of domains formed by poly(NIPAM)s is hardly affected by their molecular weights. In contrast, hydrophobicity of domains formed by poly(EOEOVE) increased with increasing molecular weight. This is consistent with the fact that the liposomes having longer chains of poly(EOEOVE) exhibited more intensive contents release (Figures 4 and 8) because polymer chains with greater hydrophobicity could destabilize liposome membrane more strongly and cause more intensive permeation of the contents through the membrane. In addition, when the extent of blue shift is compared between poly(NIPAM) and poly(EOEOVE), apparently the latter showed a more significant blue shift. For example, the poly(EOEOVE) with M_n of 5500 exhibited a larger blue shift than poly(NIPAM) with M_n of 7900. This result indicates that poly(EOEOVE) is more potent for sensitization of liposomes to temperature than poly(NIPAM), which has been used for the same purpose.

4. CONCLUSIONS

We synthesized three types of copoly(EOEOVE-*b*-ODVE) with varying chain lengths of poly(EOEOVE) segments, which become hydrophilic or hydrophobic depending on the local temperature, via living cationic polymerization. We also investigated the influence of chain length of the poly(EOEOVE) segments on their ability to sensitize liposomes. Irrespective of poly(EOEOVE) chain length, the copolymers on the surface of the liposomes enhanced the release of calcein entrapped in the EYPC/DOPE liposomes above 35°C, which corresponds to the transition temperature of the poly(EOEOVE) segment of the copolymer on the lipid membrane. However, a longer chain possessed a greater ability to enhance content release within a narrow temperature region near the transition temperature. Thus, the copolymer with an M_n of 16 700, which is the highest molecular weight among the copolymers prepared in this study, produced sharp and rapid control of content release at the transition temperature of the poly(EOEOVE) segment. NIPAM copolymers have been used for the sensitization of liposomes (*6*−*9*). However, we have shown that poly(EOEOVE-*b*-ODVE) can also be used to sensitize liposomes to temperature. Because the copolymers used in this study were prepared by living cationic polymerization, they have the advantage of allowing control of the molecular architecture. In addition, the thermosensitive moiety of poly(EOEOVE-*b*-ODVE) shares a common structural unit with poly(ethylene glycol), which is a widely used, biocompatible polymer. In addition, it is suggested that the block copolymers have greater ability to sensitize stable liposomes than poly(NIPAM). The localized hyperthermia can be achieved by the use of microwave or radiofrequency energy or phased array ultrasound; energy focused on the tumor results in an increase in local temperature (*36*). Therefore, when coupled with local hyperthermia, these liposomes are expected to deliver anticancer drugs specifically to the target tumor. We are currently studying heat-induced control of delivery of anticancer drugs, such as doxorubicin, using the copolymer-modified liposomes and evaluating their usefulness as a site-specific delivery system of anticancer drugs.

Received January 11, 2005; Revised Manuscript Received October 13, 2005

Inefficient release of polymer/DNA complexes from endocytic vesicles into the cytoplasm and the cytotoxic nature of cationic polymers are two of the primary causes of poor gene delivery. EG−polyurethane [poly(ethylene glycol)−PU, **Poly 1**], EGDM−polyurethane [poly(ethylene glycol), 2-(dimethylamino)ethylamine−PU, **Poly 2**], and MDEADM−polyurethane [*N*-methyldiethanolamine, 2-(dimethylamino)ethylamine−PU, **Poly 3**] were designed in this study to overcome these obstacles. The structural characteristics of polyurethanes and physicochemical properties of their formed complexes with DNA were determined to correlate their transfection efficiency. The results revealed that **Poly 2** and **Poly 3** could bind with plasmid DNA and yield positively charged complexes with a size required for transfection. **Poly 3** showed the best in buffering capacity and its formed complexes with DNA could transfect COS-7 cells better than those of **Poly 2** and **Poly 1**. This study reveals that the amine groups in the polymeric structure and the buffer capacity of a polymeric transfectant would affect its potential in DNA delivery. Also the size and binding properties of DNA and polymeric transfectants can be in correlation to the transfection efficiency of resulting DNA/polymer complexes.

INTRODUCTION

Gene therapy (the introduction of an extraneous gene into a cell with the aim of replacing a lost cellular utility or introducing a new functionality) requires a gene delivery system that is efficient and has no or low cytotoxic side effects. Several polycations have been proposed for the delivery of DNA into mammalian cells (*1*−*8*). These polycations not only can condense DNA into structures small enough to enter cells through endocytosis but also afford protection from nuclease degradation. It has been demonstrated that the presence of polycations mediates transfection, but they were also associated with a considerable degree of cytotoxicity (*5*, *7*, *9*). As a result, the successful design of polycations for a gene vector application generally requires a balance between transfection efficiency and short-term or long-term cytotoxicity.

Polyurethane is a class of biodegradable polymer with urethane linkages in the backbone. It has been studied as a biomaterial in tissue engineering (*10*−*12*). Recently, we have first demonstrated that cationic polyurethane can introduce DNA into cells (*13*). Besides the evaluation of the buffer capacity of transfectants for better transfection efficiency, we also systemically investigated the correlations between the structure of polymers, the physicochemical characteristics of polymer/DNA complexes, and their transfection efficiency. To study these crucial factors of polymers and complexes efficient for gene delivery, for example, size distribution of polyurethane/plasmid DNA complexes and structural effect of polyurethane, three polymers with different structures of the polyurethane (e.g., tertiary amine groups in side chain or backbone) were prepared in this article. This insight of correlation can shed light on the preferred in vitro properties of DNA−polymer particles to achieve optimum transfection efficiency.

EXPERIMENTAL PROCEDURES

Materials. *N*-Methyldiethanolamine (MDEA), glutaraldehyde, 2-dimethylaminoethylamine (DMAE), and poly(ethylene glycol) (PEG, M_w = 200), which were vacuum-dried before use, were obtained from Fluka. L-Lysine methyl ester diisocyanate (LDI) was from Kyowa Hakko Kogyo co. (Japan). Polyethylenimine (branched PEI, M_w = 25 000), poly(L-lysine) (PLL, M_w = 25 600), ethidium bromide, bovine serum albumin, 5-bromo-4-chloro-3-indoyl-β-galacto-pyranoside (X-Gal), Triton X-100, dibutyltin dilaurate, and *N*-[2-hydroxyethyl] piperazine-*N*′-[2-ethaneslfonic acid] (HEPES) were purchased from Sigma co. (USA). *N*-Methyl dibenzopyrazine methyl sulfate (electron-coupling reagent) and sodium (2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2*H*-tetrazolium-5-carboxanilide) (XTT) were purchased from Roche co. (USA). *Kpn*I was purchased from Promega co. (USA). Solvent *N*,*N*-dimethylformamide (DMF, Tedia co., USA) was dried over calcium hydride and distilled just before use.

Polymer Characterization. The structures of polymers were characterized by nuclear magnetic resonance (NMR, Bruker AMX-400 spectrometer) and Fourier transform infrared (FT-IR, Mattson Galerxy Series 5000 spectroscopy). All of the chemical shifts in ^{1}H NMR and ^{13}C NMR spectra were reported in parts per million (ppm). A 99.8% pure DMSO-d_6 was used as the solvent to characterize polymers. IR spectra were recorded on a

spectrometer as KBr pellets. The molecular weights of polymers were determined by high-performance liquid chromatography/gel permeation chromatography analysis (GPC, Waters model LC-2410). THF was used as the eluent and polystyrene as the reference. The weight- and number-average molecular weights (M_w and M_n, respectively) were calibrated with standard polystyrene samples. The sample concentration in the THF was 8.0 mg/mL, and the flow rate was 1.0 mL/min.

Preparation of pCMV-βgal and Cell Culture. The plasmid pCMV-LacZ (pCMV-βgal), which contained a CMV promoter to drive the β-galactosidase (LacZ) gene expression, was used (*7*, *9*, *13*, *14*). The plasmid DNA was amplified in *Escherichia coli* (DH5α strain) and purified by column chromatography (Qiagen Plasmid Mega kit, Germany). The purified plasmid DNA was dissolved in tris(hydroxymethyl) methylamine−ethyldiaminetetraacetic acid (Tris-EDTA) buffer (pH 8.0) and determined by the ratio of UV absorbance at 260 nm. Agarose gel electrophoresis analysis using restriction enzymes showed that the plasmid was in supercoiled form. The same analysis further indicated that a size of 7.8 kb of DNA was visible by using a restriction enzyme.

The cell line COS-7 (SV 40 virus transformed African green monkey cell line, ATCC CRL-1651) was cultured in Dulbecco's modified Eagle's medium (DMEM, Gibco-BRL Co., Ltd.) with 4 mM L-glutamine adjusted to 10% fetal serum albumin, 1.5 g/L sodium bicarbonate, and 4.5 g/L glucose at 37 °C in a humidified atmosphere of 5% CO_2.

Polymer Synthesis. The LDI and MDEA or PEG with a NCO/OH molar ratio of 1.1/1 were mixed in anhydrous DMF solvent within the three-necked reaction flask under dry nitrogen purge and then heated to 70 °C to react for 6 h with 0.5 wt % dibutyltin dilaurate included as a catalyst. And then an excess amount of methanol was slowly added into the reaction mixture until no unreacted isocyanate groups were detected. The **Poly 1** was precipitated in ethyl ether and then dried at 40 °C under vacuum. **Poly 2** and **Poly 3** were synthesized using the aminolysis reaction (*13*). The polymers were characterized by FT-IR, ^{1}H NMR, and ^{13}C NMR.

*EG−Polyurethane (**Poly 1**).* ^{1}H NMR(400 MHz, DMSO-d_6, ppm) δ: 1.3−1.8 (6H, −CH_2CH_2CH_2−), 2.9 (2H, −CH_2NHCOO−), 3.1 (1H, −C*H*NHCOO−), 3.3 (3H, −NHCOOCH_3), 3.6 (−CH_2− of PEG), 4.05 (3H, −COOCH_3), 5.2 (1H, −CH$_2$N*H*COO−), 5.5 (1H, −CHN*H*COO−). ^{13}C NMR (400 MHz, DMSO-d_6, ppm) δ: 22.3, 29.1, 31.4 (−*C*H$_2$*C*H$_2$*C*H$_2$−), 40.5 (−*C*H$_2$NHCOO−), 52.4 (−NHCOO*C*H$_3$), 56.3 (−*C*HNHCOO−), 60.9(−COO*C*H$_3$), 63.6−70.1 (−*C*H$_2$− of PEG), 156.6 (−CH$_2$NH*C*OO−), 158.1 (−CHNH*C*OO−), 173.8 (−*C*OOCH$_3$). *EGDM−Polyurethane (**Poly 2**).* ^{1}H NMR(400 MHz, DMSO-d_6, ppm) δ: 1.3−1.8 (6H, −CH_2CH_2CH_2−), 2 (6H, −N(CH_3)$_2$), 2.5 (2H, −CH$_2$CH_2N(CH$_3$)$_2$), 2.9 (2H, −CH_2NHCOO−), 3.1 (1H, −C*H*NHCOO−), 3.3 (3H, −NHCOOCH_3), 3.5 (2H, −CH_2-NHCO−), 3.6 (−CH_2- of PEG), 5.2 (1H, −CH$_2$N*H*COO−), 5.5 (1H, −CHN*H*COO−), 7.0 (1H, −N*H*CO−). ^{13}C NMR (400 MHz, DMSO-d_6, ppm) δ: 22.3, 29.1, 31.4 (−*C*H$_2$*C*H$_2$-*C*H$_2$−), 38.9 (−*C*H$_2$NHCO−), 40.5 (−*C*H$_2$NHCOO−), 45.8 (−N(*C*H$_3$)$_2$), 52.4 (−NHCOO*C*H$_3$), 56.1 (−CH$_2$*C*H$_2$N(CH$_3$)$_2$), 56.3 (-*C*HNHCOO−), 63.6−70.1 (−*C*H$_2$− of PEG), 156.6 (−CH$_2$NH*C*OO−), 158.1 (−CHNH*C*OO−), 162.8 (−NH*C*O−).

*MDEADM−Polyurethane (**Poly 3**).* ^{1}H NMR(400 MHz, DMSO-d_6, ppm) δ: 1.3−1.8 (6H, −CH_2CH_2CH_2−), 2 (6H, −N(CH_3)$_2$), 2.3 (3H, −CH$_2$CH$_2$N(CH_3)CH$_2$CH$_2$−), 2.5−2.8 (2H, −CH$_2$CH_2N(CH$_3$)$_2$; 4H, −CH$_2$CH_2N(CH$_3$)CH_2CH$_2$−), 2.9 (2H, −CH_2NHCOO−), 3.1 (1H, −C*H*NHCOO−), 3.3 (3H, −NHCOOCH_3), 3.5 (2H, −CH_2NHCO−), 4.1 (4H, −CH_2CH$_2$N(CH$_3$)CH$_2$CH_2−), 5.2 (1H, −CH$_2$N*H*COO−), 5.5 (1H, −CHN*H*COO−), 7.0 (1H, −N*H*CO−). ^{13}C NMR (400 MHz, DMSO-d_6, ppm) δ: 22.3, 29.1, 31.4 (−*C*H$_2$*C*H$_2$-*C*H$_2$−), 38.9 (−*C*H$_2$NHCO−), 40.5 (−*C*H$_2$NHCOO−), 44.1 (−CH$_2$CH$_2$N(*C*H$_3$)CH$_2$CH$_2$−), 45.8 (−N(*C*H$_3$)$_2$), 52.4 (−NHCOO*C*H$_3$), 56.1 (−CH$_2$*C*H$_2$N(CH$_3$)$_2$), 56.3 (−*C*HNHCOO−), 56.8 (−CH$_2$*C*H$_2$N(CH$_3$)*C*H$_2$CH$_2$−), 59.1 (−*C*H$_2$CH$_2$-N(CH$_3$)CH$_2$*C*H$_2$−), 156.6 (−CH$_2$NH*C*OO−), 158.1 (−CHNH*C*OO−), 162.8 (−NH*C*O−).

Acid−Base Titration. Acid−base titration was used to evaluate the buffering capacity of synthesized cationic polyurethanes. In this assay, 10 mg of polymer was dissolved in 10 mL of 150 mM NaCl, and then 100 μL of 1 N NaOH was added to the solution to adjust the pH to the alkaline range at 11.6. HCl (0.1 N) was used as the titratant to lower the pH to acidic conditions at around 2−2.5. Titration increment size = 100 μL.

Preparation and Characterization of Polymer/Plasmid DNA Complexes. *Formation of Polymer/Plasmid DNA Complexes.* **Poly 1**, **2**, and **3** (10 mg/mL) were dissolved in the 20 mM HEPES buffer (pH 7.4), and serial dilutions were made in which the mass ratio of polymer/DNA (w/w) was from 1/2 to 300/1.

Particle Size, ζ-Potential, and Atomic Force Microscopy (AFM) Measurements of Polymer/Plasmid DNA Complexes. The particle sizes and surface charges of the polymer/DNA complexes were determined by dynamic light scattering (Nicomp 380 system, USA) at 25 °C using a 5-mW He−Ne laser (λ = 633 nm) as the incident beam at a scattering angle of 90° and electrophoretic mobility with a ζ-potential system (Nicomp Instrument, USA) at 25 °C. The image of the **Poly 3**/DNA complexes coated on the ruby mica surface was observed on a nanoscope II (Digital Instruments, Santa Barbara, CA) as described previously (*13*).

Stability of the Polymer/DNA Complexes in the Presence of Bovine Serum Albumin. The stability studies of the complexes in the presence of bovine serum albumin were evaluated by agarose gel retardation. The complexes were prepared at a mass ratio of 150/1 for 30 min, and bovine serum albumin was added into the solution of complexes to make final albumin concentrations of 5, 25, and 50 mg/mL. The DNA released from complexes was determined after 12 h at room temperature and 37 °C.

DNA Gel Retardation and Restriction Endonuclease Protection Assay. The polymer/DNA complexes were loaded into a 0.7% agarose gel containing ethidium bromide (0.3 μg/mL) in a tris−acetate−EDTA (TAE) buffer and electrophoresed at 100 V for 45 min. After electrophoresis, the DNA bands were visualized by UV-irradiation. The MDEA−PU/DNA polyplexes at ratios of 1/1, 5/1, and 50/1 (w/w) were incubated with *Kpn*I at a concentration of 10 U/μL at 37 °C for 90 min in the provided reaction buffer. After the restriction endonuclease digests, samples were analyzed by 0.7% agarose gel electrophoresis in the same manner as described above.

Transfection Studies and β-Galactosidase Assay. The COS-7 cells were used to evaluate the transfection efficiency of the polymer/DNA complexes. The cells were seeded in a 96-well plate (1.0×10^4 cells per well) in complete DMEM and incubated for 24 h before transfection. The polymer/DNA complexes (volume 200 μL) then were added to the cells. The DNA concentration was kept constant at 5 μg/mL (1.0 μg/well), and the amounts of polymer/DNA were expressed as mass ratios. After 1 h at 37 °C, the transfection mixture was removed and replaced with complete DMEM for an additional 48 h.

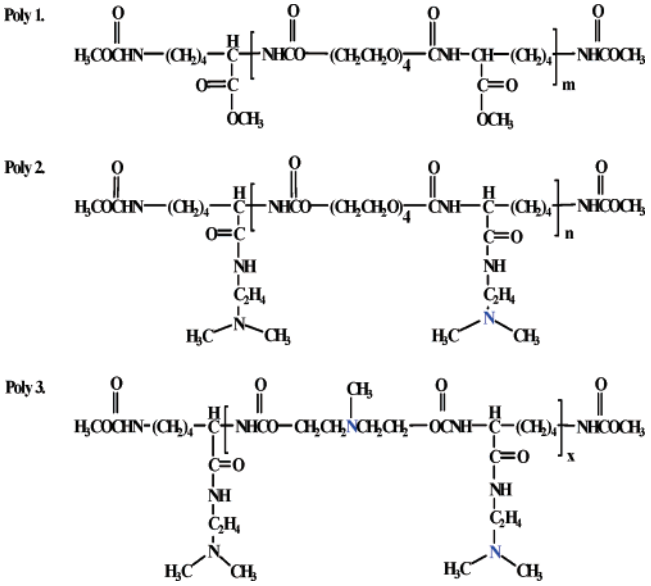

Figure 1. The structures of **Poly 1** (EG−polyurethane; EG−PU), **Poly 2** (EGDM−polyurethane; EGDM−PU), and **Poly 3** (MDEADM−polyurethane; MDEADM−PU).

Then a series of tests were performed for reporter gene expression (β-galactosidase) by histochemical staining with X-Gal, essentially as described previously (*7*, *9*, *13*, *15*).

Determination of the Cytotoxic Effect of Polymers and Polymer/DNA Complexes. Cytotoxicity of **Poly 1**, **Poly 2**, and **Poly 3** in comparison with a commonly used gene carrier, PEI, was evaluated using the XTT assay (*7*, *9*, *13*, 16). In a 96-well plate, COS-7 cells were cultured in complete DMEM then seeded at a density of 1.0×10^4 cells/well. The cells were incubated at 37 °C and 5% CO_2 in humidified atmosphere for 24 h. Subsequently, the cells were incubated for 1 h in 200 mL of FBS-free DMEM containing a polymer only (**Poly 1**, **Poly 2**, **Poly 3**, and PEI) or complexes at various concentrations. The cells incubated in DMEM were only for a negative control. After 1 h, the cells were washed with 200 μL of PBS solution and replaced by complete DMEM. After 48 h incubation, 50 μL of XTT labeling mixture was added to each well and incubated at 37 °C for 1 h. Results were expressed as the relatively cell viability (%) with respect to control wells containing culture medium cells.

RESULTS AND DISCUSSION

Structural Characterizations of Polymers. The structures of EG−polyurethane, EGDM−polyurethane, and MDEADM−polyurethane (**Poly 1**, **Poly 2**, and **Poly 3**, respectively) were shown in Figure 1. The resulting polyurethane (**Poly 3**) with tertiary amines ($-CH_2CH_2N(CH_3)CH_2CH_2-$) and ($-N(CH_3)_2$) in the backbone and side chain was isolated in up to 90% yield with weight average molecular weight of 37 000 and a polydispersity of 1.8 relative to polystyrene standards in THF. **Poly 2**, with tertiary amines ($-N(CH_3)_2$) in the side chain, and **Poly 1** showed that the weight-averaged molecular weights were 35 000 and 39 000 with a polydispersity of 1.7 and 1.8, respectively. The structures of **Poly 1**, **Poly 2**, and **Poly 3** were confirmed by FT-IR, ^{1}H NMR, and ^{13}C NMR. From the FT-IR spectra, the peaks at 1720 cm^{-1} (C=O stretching, urethane), 1651 cm^{-1} (C=O stretching, amide), 1553 cm^{-1} (N−H bending, amide), and 3320 cm^{-1} (N−H stretching, urethane) represent the absorptions of urethane links in **Poly 1**, **Poly 2**, and **Poly 3** (data not shown). In the ^{1}H NMR spectra of **Poly 1**, **Poly 2**, and **Poly 3**, two distinct peaks at 5.9 and 5.2 ppm were assigned to the NH protons derived from the α- and ϵ-amine groups of L-lysine respectively (*13*). Chemical shifts of 2.0 and 7.0 ppm, observed in the **Poly 2** and **Poly 3**, derived from the methyl and amide protons of the pendant group, respectively. In ^{13}C NMR spectra, there was an accompanied disappearance of chemical shift at 173.8 ppm, which represented the ester carbon of the pendent group in the **Poly 1**. The FT-IR, ^{1}H NMR, and ^{13}C NMR characterizations of the synthesized polymers provided clear evidence that **Poly 1**, **Poly 2**, and **Poly 3** had been successfully synthesized.

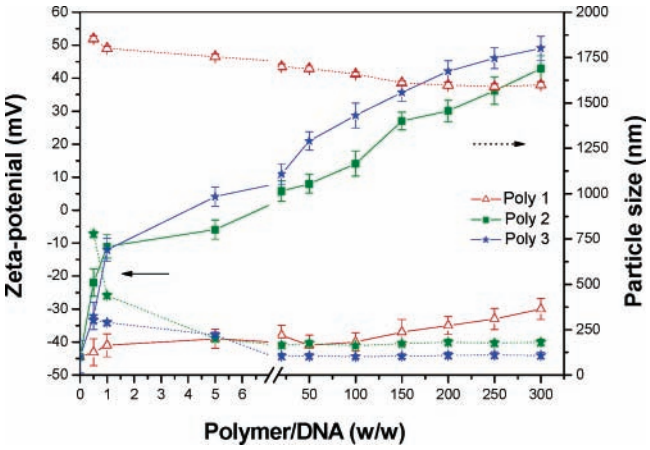

Figure 3. Sizes and ζ-potentials of polymer/pCMV-βgal complexes prepared at different mass ratios. Results are presented as mean ± SD (n = 3).

Buffering Capacity of Polymers. Titration studies were performed to determine the buffering capacities of the various polymers within the endosomal/lysosomal compartments of the cell (Figure 2). All of the polycation solutions had pH 11.5−11.8 after addition of 100 μL of 1.0 N NaOH. PEI showed the best buffering capacity with a wide pH range. **Poly 1**, containing no amine group in the structure, demonstrated a poor buffering range from pH 11.5 and 10. The buffering properties of the polymers were improved through the incorporation of tertiary amine groups into the backbone or side chain. **Poly 2**, bearing tertiary amines in the side chain, and **Poly 3**, with tertiary amines in the backbone and side chain, showed buffering capacities from pH 11.5−7.0 and 11.7−

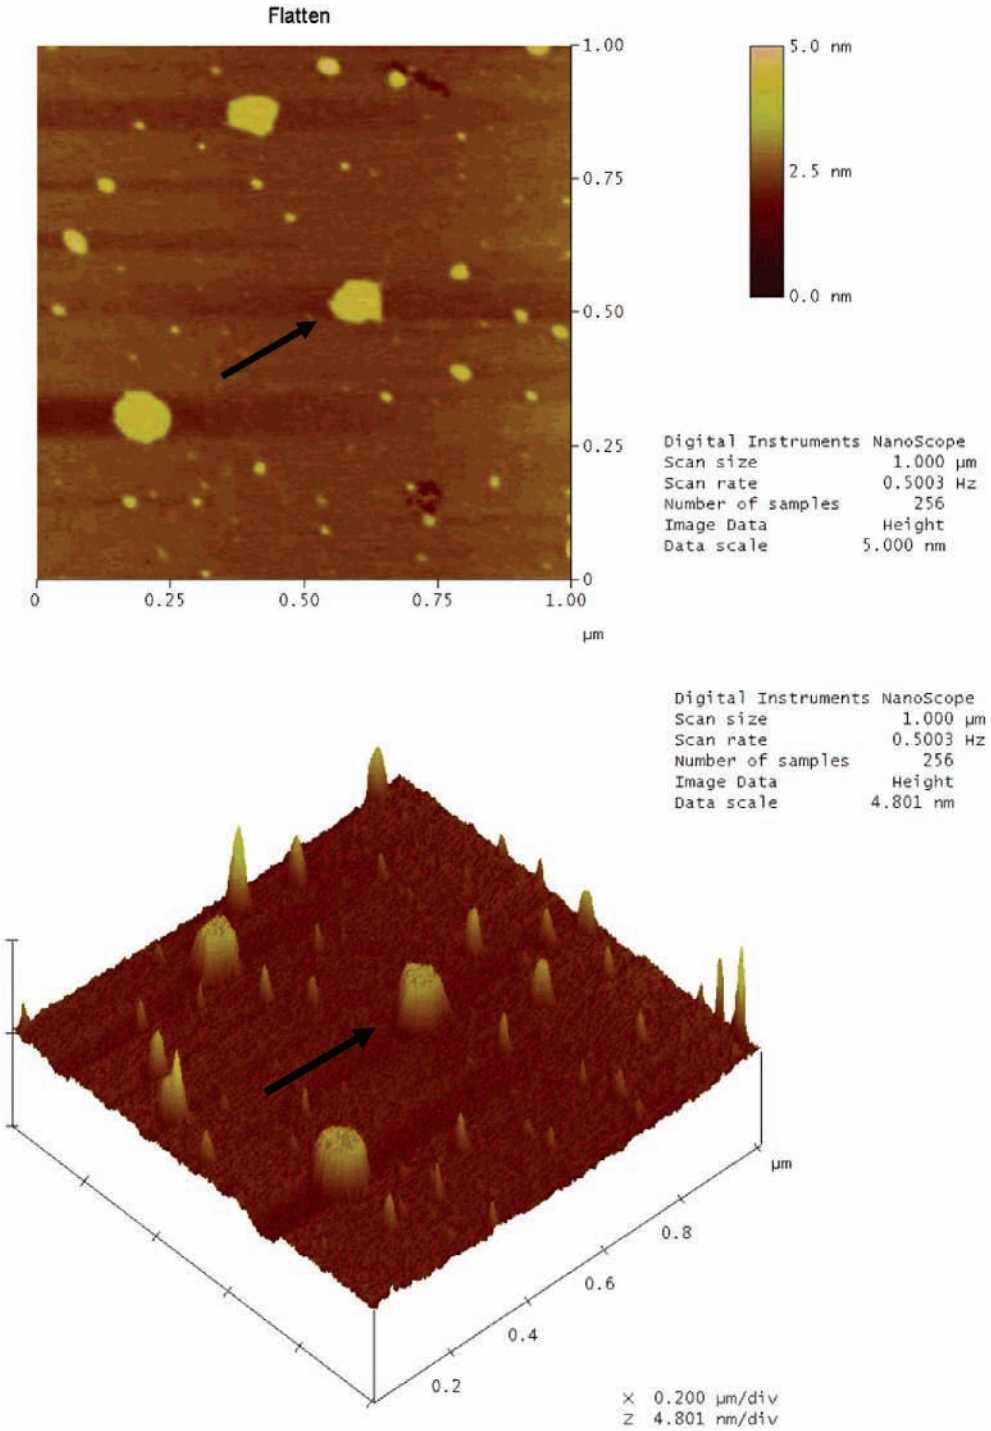

Figure 4. The AFM images of **Poly 3**/pCMV-βgal complexes (w/w), 150/1. The height of the AFM image is represented by a graded brown−yellow scale with the yellow color indicating a height more than 10 nm above the ruby mica. The x and y dimensions are scaled as shown.

5.0, respectively. It was found that **Poly 3** possessed excellent properties in DNA condensing and buffering abilities.

Self-Assembly of Polymer with Plasmid DNA and Restriction Endonuclease Protection Assay of Polymer/DNA Complexes. Figure 3 shows the size and ζ-potential of the **Poly 1**/DNA complexes, **Poly 2**/DNA complexes, and **Poly 3**/DNA complexes at various mass ratios ranging from 1/2 to 300/1. The results show that the average diameter (100−110 nm) of the **Poly 3**/DNA complexes and the average diameter (170−180 nm) of the **Poly 2**/DNA complexes fall within the general size required for cellular endocytosis (<0.2 μm). The DNA condensing ability of **Poly 1** was very weak as the average diameter (1550−1750 nm) of **Poly 1**/DNA complexes was formed because the backbone and side chain present no tertiary amines. The results demonstrated that tertiary amines in only the side chain of **Poly 2** were sufficient to condensed DNA into complexes and that introduction of tertiary amines in the backbone and side chain of **Poly 3** provided even better electrostatic interactions between **Poly 3** and DNA. Figure 4 shows the atomic force microscopy (AFM) images of **Poly 3**/DNA complexes at mass ratios of 150/1. The ζ-potential of the resulting complexes was changed from a negative charge to a positive charge when the amounts of **Poly 2** and

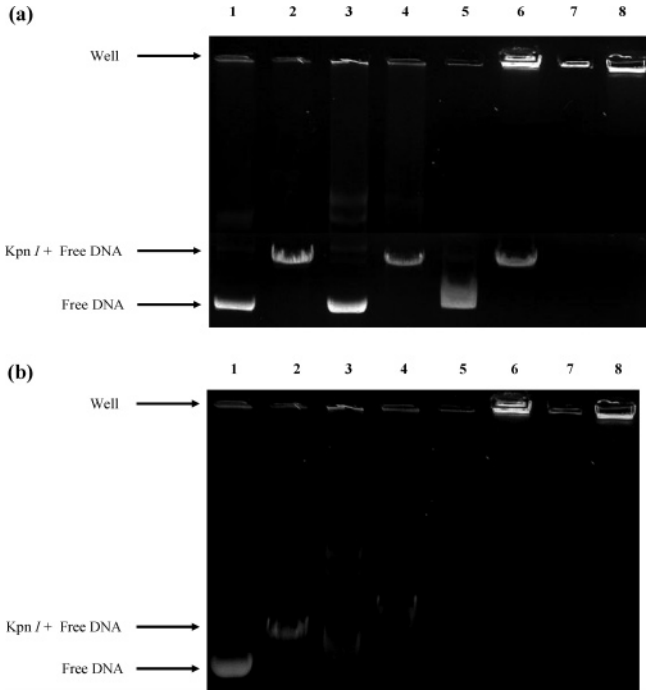

Figure 5. DNA gel retardation and restriction endonuclease protection assay of **Poly 2** (a) and **Poly 3** (b). Lanes: (1) 400 ng of pCMV-βgal; (2) 400 ng of pCMV-βgal treated with *Kpn*I; (3) polymer/pCMV-βgal (w/w), 1/1; (4) polymer/pCMV-βgal (w/w), 1/1, treated with *Kpn*I; (5) polymer/pCMV-βgal (w/w), 5/1; (6) polymer/pCMV-βgal (w/w), 5/1, treated with *Kpn*I; (7) polymer/pCMV-βgal (w/w), 50/1; (8) polymer/pCMV-βgal (w/w), 50/1, treated with *Kpn*I.

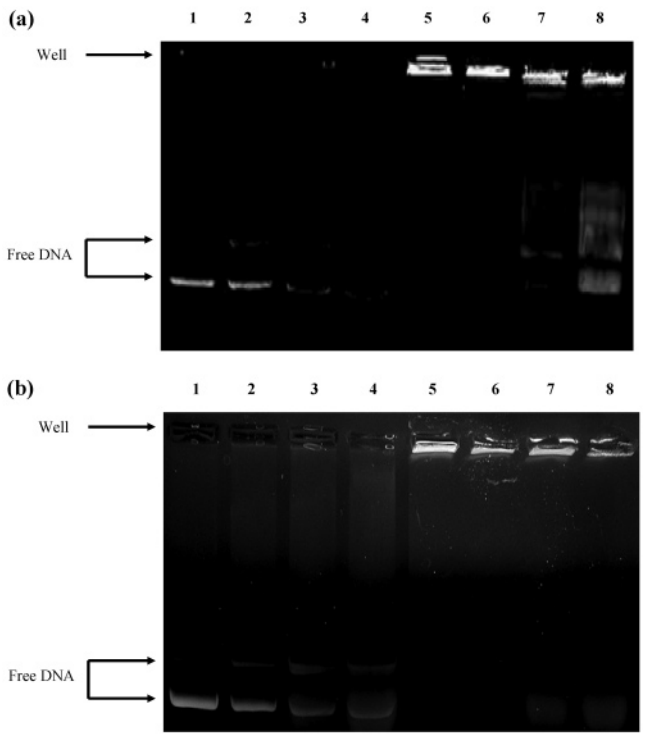

Figure 6. Stability of complexes based on **Poly 2** (a) and **Poly 3** (b) after 12 h incubation with albumin at 37 °C. The polymer/DNA complexes were prepared at mass ratio of 150/1, incubated with serum albumin, and analyzed on a 0.7% (w/v) agarose gel for 45 min at 100 V. Lanes: (1) 625 ng of pCMV-βgal; (2) 625 ng of pCMV-βgal treated with 5 mg/mL BSA; (3) 625 ng of pCMV-βgal treated with 25 mg/mL BSA; (4) 625 ng of pCMV-βgal treated with 50 mg/mL BSA; (5) polymer/pCMV-βgal (w/w), 150/1; (6) polymer/pCMV-βgal (w/w), 150/1, treated with 5 mg/mL BSA; (7) polymer/pCMV-βgal (w/w), 150/1, treated with 25 mg/mL BSA; (8) polymer/pCMV-βgal (w/w), 150/1, treated with 50 mg/mL BSA.

Poly 3 were increased. From particle size characterization and ζ-potential analysis, it was found that these properties varied with the number of amino groups in the polyurethanes and that the tertiary amine moieties within the backbone enhanced the electrostatic interaction between DNA and cationic polymers.

The ability of the polycation to interact electrostatically with DNA was indicated by a reduction in DNA electrophoretic mobility. In addition, the relative ability of the polymers to retain DNA within the complex was indicated by the formation of a DNA streak in the gel. This streak is caused by separation of the DNA and the polycation during electrophoresis induced by the electrophoretic force. Figure 5 shows that all polycations can condense DNA into nanosized complexes and afford protection from nuclease degradation (endonuclease *Kpn*I). At the low mass ratio 5/1 of **Poly 3**/DNA, plasmid DNA was totally retained, as indicated in lane 5 (Figure 5b). Plasmid DNA was partially retained in the presence of **Poly 2** at a mass ratio of 1/1 and 5/1 (lane 3 and 5) and totally retained at a mass ratio of 50/1 (lane 7 of Figure 5a). **Poly 1** was not completely bound with DNA at all mass ratios (data not shown). The higher efficiency of **Poly 3** in DNA complexation relative to **Poly 2** may be due to the further introduction of tertiary amines into the backbone of **Poly 3**.

The plasmid DNA (or polymer/DNA) was incubated with the restriction endonuclease *Kpn*I, which can cleave the plasmid DNA in the CMV-promoter region, at a concentration of 10 U/μL. Pure linear DNA was observed when the plasmid DNA was treated with *Kpn*I, in Figure 5a lane 2. **Poly 2** was unable to protect the plasmid DNA from enzyme degradation at the lower mass rations of 1/1 and 5/1 (shown in lanes 4 and 6 of Figure 5a). However, it was found that the plasmid DNA was completely protected against *Kpn*I at the higher mass ratios of **Poly 2**/DNA (shown in lanes 7 and 8 of Figure 5a). **Poly 3** showed excellent protective ability for DNA (shown in lane 6 of Figure 5) due to the existence of tertiary amino groups in the backbone and side chain.

Stability of the Polymer/DNA Complexes in the Presence of Bovine Serum Albumin. The interaction of bovine serum albumin with the complexes was investigated by means of agarose gel electrophoresis. The naked DNA and complexes were prepared at a mass ratio of 150/1, and subsequently bovine serum albumin was added to a final concentration of 5, 25, and 50 mg/mL. The DNA release was assessed after 12 h. It is clear that DNA was released through the interaction of albumin with the **Poly 2**/DNA complexes in lanes 7 and 8 (Figure 6a). Although **Poly 2** could self-assemble DNA into complexes, the electrostatic force between **Poly 2** and DNA was not stable toward bovine serum albumin. In lanes 5−8 (Figure 6b), the formation of stronger electrostatic complexes was suggested between the **Poly 3** and DNA. The **Poly 3**/DNA complexes were then more stable toward bovine serum albumin.

Cellular Delivery of Plasmid DNA via Polymer/DNA Complexes. The well-studied COS-7 cell line was transfected in vitro (*7*, *9*, *16*) with polymer/DNA complexes. The transfection efficiency of polymer/DNA complexes was assessed by an indication of β-galactosidase expression. Transfection with **Poly 1** was not observed because the particle size (1550−1750 nm) was large and the buffering capacity was low. The numbers of transfected cells showed a bell-shaped trend for the **Poly 2**/DNA and **Poly 3**/DNA (w/w) ratios above 100/1 (w/w)

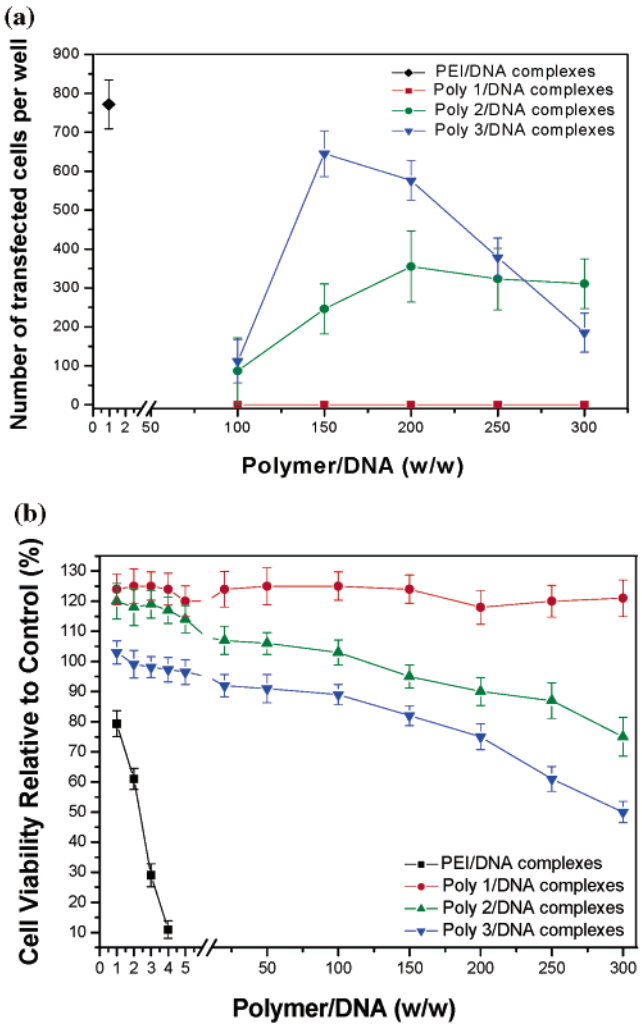

Figure 7. (a) Effect of polymer concentration on the number of transfected cells. Transfection was performed in COS-7 cells for 1 h at a 1 μg of DNA per well in DMEM, and then cells were incubated for an additional 48 h in fresh media with 5% FBS. Results are presented as mean ± SD ($n = 3$). (b) Cytotoxicity of polymer/pCMV-βgal complexes in COS-7 cells. Results are presented as mean ± SD ($n = 3$).

as observed previously for other polycation-based transfection systems (*7*, *13*, *17*). The highest transfection efficiency of **Poly 3**/DNA was reached at a mass ratio of 150/1, and **Poly 3** displays the highest gene delivery efficacy (equivalent to branched PEI made with the optimal transfection efficiency at a mass ratio of 1/1 (*18*), shown in Figure 7a). In addition, it was demonstrated that the transfection efficiency of **Poly 3** was greater than that of **Poly 2**. This may be due in part to the particle size and "proton sponge" hypothesis (*5*, *8*, *19*). Although **Poly 2** with tertiary amines in the side chain has been shown to effectively condense plasmid DNA into complexes (170−180 nm), mostly the amine groups of **Poly 2** have already been protonated under pH 11.5−7.0. This result suggests that endosomal buffering effect could be limited from the **Poly 2**/DNA complexes when the pH in the activated endosome drops to 5. And the size of **Poly 3**/DNA complexes (100−110 nm) and **Poly 3** buffering capacity between pH 11.7 and 5.0, due to introduction of tertiary amines in the backbone and side chain, are capable of buffering the endosomal pH and increasing the endosomal release of the **Poly 3**/DNA complexes.

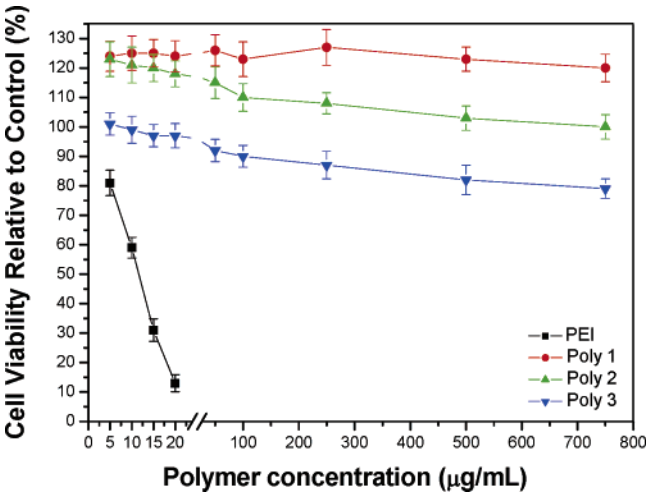

Figure 8. Cytotoxicity of polymers in COS-7 cells.

Relative cell viability in the presence of **Poly 1**/DNA, **Poly 2**/DNA, and **Poly 3**/DNA complexes in comparison with PEI/DNA complexes was shown in Figure 7b. It was found that the cell viability in the presence of PEI/DNA complexes rapidly decreased with an increase of polymer concentration, whereas cell viability in the presence of **Poly 1**/DNA, **Poly 2**/DNA, and **Poly 3**/DNA complexes was slightly changed with an increase of polymer concentration, indicating much less toxicity than PEI.

Cytotoxicity of Polymers. To determine the cytotoxicity of **Poly 1**, **Poly 2**, and **Poly 3** in comparison with PEI, we performed an XTT assay using the COS-7 cell line. Cells were incubated with increasing amounts of **Poly 1**, **Poly 2**, and **Poly 3** (ranging from 5 to 750 μg/mL) or PEI (ranging from 5 to 20 μg/mL). The results show that **Poly 1**, **Poly 2**, and **Poly 3** exhibited substantially lower toxicity on COS-7 cells than PEI in Figure 8. The IC_{50} [defined as the concentration resulting in 50% inhibitory activity (cell death)] for the PEI was around 15 μg/mL, whereas **Poly 1**, **Poly 2**, and **Poly 3** showed more than 80% viable cells even at a higher dose (750 μg/mL) with no significant change in cell morphology and proliferation relative to controls. We infer that the polyurethanes can provide better cytotoxicity profiles than presently used gene carrier (PEI) due to the introduction of amino groups and urethane units in the polycation backbone alternately to reduce the high charge density of the polycation.

CONCLUSION

It was found that the positive charge on pendent amine groups or within the backbone of the polymer can condense DNA to form DNA−polycation complexes due to the electrostatic force between the DNA and the polycation. Stronger electrostatic interaction between DNA and cationic polymer could make nanosized DNA/polymer complexes and resist endonuclease and albumin degradations, resulting a better bioactivity in transfection efficiency. Besides the existence of positive charges in polymer being crucial, optimal buffering capacity was needed for the release of DNA/polymer complexes from endosomes. Having a high transfection efficiency and low cytotoxicity, the new biodegradable polyurethane is an interesting candidate for a nonviral gene delivery system.

Received January 12, 2005; Revised Manuscript Received August 7, 2005

We present the design, synthesis, and biochemical and spectroscopic characterization of five functional fluorescent conjugates of kabiramide C (KabC), a small molecule biomimetic of gelsolin. The tetramethylrhodamine (TMR), rhodol green (RG), IC5, dapoxyl (DAP), and fluorescein diester (FDE) conjugates of KabC bind specifically to actin at the barbed end in a 1:1 complex. These probes are shown to function in an indistinguishable manner to the unmodified KabC. Various modalities of the fluorescence emission of these KabC probes, including fluorescence anisotropy and fluorescence resonance energy transfer, are used for the development of assays for the rapid determination of G-actin concentration in solution. The TMR−KabC and FDE−KabC probes are cell permeable and provide unique imaging information on the distribution and dynamics of actin filament within living cells.

INTRODUCTION

Cell protrusion is characterized by fluctuations in the concentrations and activities of, and/or interactions between, membrane receptors, Rac1, Ca^{2+}, PIP_2, cofilin, and actin filament barbed-end capping protein—these dynamic events are usually confined to lamellipodia and are coupled to the rapid and polarized polymerization of actin filaments in the vicinity of the activated membrane receptor (*1*−*2*). A major challenge in cell motility research is to develop innovative approaches and techniques that permit the study of the temporal and spatial regulation of these events within the lamellipodium. The critical concentration for the in vitro polymerization of pure G-actin is ∼100 nM, yet as much as 50% of the ∼200 μM concentration of actin within an eukaryotic cell exists as G-actin (*2*). The large amount of unpolymerized G-actin results from the sequestering activity of monomer binding proteins that include thymosin β4 and profilin, which reduce the free concentration of G-actin to ∼100 nM; filament capping proteins such as tropomodulin (pointed-end) (*3*) and gelsolin, capping protein (CP), and CapG (fast growing, barbed-end) also block actin polymerization from existing filaments (*4*−*6*). However, during cell protrusion, a rise in membrane-associated PIP_2 dissociates barbed-end capping proteins from these filaments and is accompanied by an explosive polarization of actin facilitated by the nucleating proteins ARP2/3-WASP and formins (*2*, *7*−*11*).

Given the central role of the barbed-end in regulating actin filament polymerization, a better understanding of cell protrusion will require knowledge of molecular events at the barbed-end of the filament and how they are regulated within cells. These are challenging studies since the protomer at the barbed-end of an actin filament accounts for only 1 in 10^4 of actin monomers within a 10 μM solution of pure F-actin (average filament length of 2.5 μm) or 1 in 10^6 of all protomers in a typical cell. While certain actin-directed probes such as GFP−actin (*12*) and TMR−phalloidin (*13*) are useful in quantifying total actin and the average rate of actin filament dynamics in a cell, they do not provide specific information on molecular events at the barbed-end. Furthermore, the linkage of large, aromatic, charged fluorescent probes such as TMR−maleimide to Cys-374 of actin can impair or inhibit polymerization (*25*). We have recently shown that a family of actin-targeted trisoxazole macrolides typified by kabiramide C (KabC) (*14*, *15*) function in vitro and in living cells as small molecule biomimetics of the barbed-end capping proteins, gelsolin, and CapG (*15*). Since correct regulation of the barbed-end of the actin filament is essential to many cellular processes, it is no wonder that KabC and related macrolides exhibit potent cytotoxic effects (*15*). We argue that the binding specificity of KabC-related drugs to the cleft between subdomans 1 and 3 of actin (the barbed-end) provides an opportunity to develop a new class of optical probes that serve as an indicator of molecular events associated with actin polymerization. Here, we describe the preparation and characterization of several new fluorescent KabC probes and show that they bind to G-actin with high specificity—this interaction can be quantified using a variety of changes in the fluorescence emission of the probe (quantum yield, polarization, lifetime, and Foerster resonance energy transfer). Finally, we show using confocal imaging

of living cells that the tetramethylrhodamine− and the fluorescein diester−KabC derivatives (TMR−KabC and FDE−KabC, respectively) are cell permeable and can be used to image and quantify actin filament dynamics in living cells.

EXPERIMENTAL PROCEDURES

Instrumentation. ESI mass spectra were carried out on a Micromass LCT for exact mass measurement**.** Absorption spectra were recorded using a Shimadzu 1601PC instrument. An SLM-Aminco AB2 fluorometer was used to record emission and excitation spectra of fluorescent dyes and their conjugates. Fluorescence emission spectra were recorded using excitation and emission polarizers aligned at 0 and 54°, respectively, and corrected for the instrument response (*16*). Fluorescence resonance energy transfer (FRET) between 6-proprionyl-2-dimethylaminonaphthalene (Prodan) labeled to G-actin to the bound fluorescent KabC probes was performed by exciting Prodan at 385 nm and recording the emission from the complexes between 400 and 650 nm for rhodol green and for TMR and 400−750 nm for *N*-ethyl-*N*′-[5-(*N*″-succininmidyloxycarbonyl)pentyl]-3,3,3′,3′-tetramethyl-2,2′-indodicarbocyanine chloride (IC5, a de-sulfated derivative of the better known Cy5). Fluorescence anisotropy (FA) was measured according to Heidecker et al. (*17*). All spectra were recorded at room temperature.

Syntheses. 5-(and-6)-Carboxytetramethylrhodamine, succinimidyl ester (C-1171), dapoxyl carboxylic acid, succinimidyl ester (D-10161), and rhodol green carboxylic acid, succinimidyl ester (mixed isomer, R-6108) were purchased from Molecular Probes. *N*-Ethyl-*N*′-[5-(*N*″-succininmidyloxycarbonyl)pentyl]-3,3,3′,3′-tetramethyl-2,2′-indodicarbocyanine chloride (IC5−OSu) was purchased from Dojindo, and 5(6)-carboxyfluorescein diacetate *N*-succinimidyl ester was purchased from Fluka. Dichlorometane (CH_2Cl_2) was dried over CaH_2, and dimethyl sulfoxide (DMSO) was opened immediately before use. 7-(4-Aminomethyl-1*H*-1,2,3-triazol-1-yl)kabiramide C (AMT−KabC) was synthesized from KabC as described in Petchprayoon et al. (*18*). Silica gel 60 F_{254} thin-layer chromatography (TLC) plates were purchased from Merck (250 μm thick), and C_{18}-silica gel F_{254} TLC plates were purchased from Fisher Scientific (Analtech UNIPLATES; 250 μm thick).

Synthesis of the Tetramethylrhodamine Derivative of 7-(4-Aminomethyl-1*H*-1,2,3-triazol-1-yl)kabiramide C (TMR−KabC). To a solution of AMT−KabC (1 mg, 0.98 μmol) in dry CH_2Cl_2 (100 μL), a solution of 5-(and-6)-carboxytetramethylrhodamine, succinimidyl ester (0.6 mg, 1.14 μmol) in DMSO (100 μL) was added. The reaction mixture was stirred at room temperature in the dark under N_2 atmosphere. After 8 h, the mixture was concentrated and isolated by silica gel TLC (CH_2Cl_2/MeOH = 20:3) and C_{18}-silica gel TLC (MeOH/H_2O = 7:3) to give TMR−KabC. ESIMS *m/z*: $[M + Na]^+$ 1456.6838 (calcd for $C_{76}H_{95}N_{11}O_{17}Na$, 1456.6805).

Synthesis of the Rhodol Green Derivative of 7-(4-Aminomethyl-1*H*-1,2,3-triazol-1-yl)kabiramide C (RG−KabC). To a solution of AMT−KabC(1 mg, 0.98 μmol) in dry CH_2Cl_2 (100 μL), a solution of rhodol green carboxylic acid, succinimidyl ester (0.5 mg, 1.06 μmol) in DMSO (100 μL) was added. The mixture was stirred at room temperature in the dark under N_2 atmosphere for 8 h. The mixture was concentrated and purified by silica gel TLC (CH_2Cl_2/MeOH = 8:2) to give RG−KabC. ESIMS *m/z*: $[M + Na]^+$ 1401.6028 (calcd for $C_{72}H_{86}N_{10}O_{18}Na$, 1456.6019).

Synthesis of the IC5 Derivative of 7-(4-Aminomethyl-1*H*-1,2,3-triazol-1-yl)kabiramide C (IC5−KabC). To a solution of AMT−KabC(1 mg, 0.98 μmol) in dry CH_2Cl_2 (100 μL), a solution of IC5−OSu (0.7 mg, 1.11 μmol) in DMSO (70 μL) was added and stirred at room temperature in the dark under N_2 atmosphere. After being stirred for 8 h, the mixture was concentrated and purified by silica gel TLC (CH_2Cl_2/MeOH = 10:1) to give IC5−KabC. ESIMS *m/z*: $[M + H]^+$ 1501.8665 (calcd for $C_{84}H_{115}N_{11}O_{14}$, 1501.8619).

Synthesis of the Dapoxyl Derivative of 7-(4-Aminomethyl-1*H*-1,2,3-triazol-1-yl)kabiramide C (DAP−KabC). To a solution of AMT−KabC(1 mg, 0.98 μmol) in dry CH_2Cl_2 (100 μL), a solution of dapoxyl carboxylic acid, succinimidyl ester (0.5 mg, 1.23 μmol) in DMSO (100 μL) was added and stirred at room temperature in the dark under N_2 atmosphere. After 8 h, the mixture was concentrated and purified by silica gel TLC (CH_2Cl_2/MeOH = 10:1) to give DAP−KabC. ESIMS *m/z*: $[M + Na]^+$ 1334.6503 (calcd for $C_{69}H_{89}N_{11}O_{15}Na$, 1334.6437).

Synthesis of the Fluorescein Diester Derivative of 7-(4-Aminomethyl-1*H*-1,2,3-triazol-1-yl)kabiramide C (FDE−KabC). To a solution of AMT−KabC(1 mg, 0.98 μmol) in dry CH_2Cl_2 (100 μL), a solution of 5(6)-carboxyfluorescein diacetate *N*-succinimidyl ester (0.8 mg, 1.44 μmol) in dry CH_2Cl_2 (100 μL) was added and stirred at room temperature in the dark under N_2 atmosphere. After 8 h, the mixture was purified by silica gel TLC (CH_2Cl_2/MeOH = 20:1) to give FDE−KabC. ESIMS *m/z*: $[M + Na]^+$ 1486.6056 (calcd for $C_{76}H_{89}N_9O_{21}Na$, 1486.6071).

G-Actin. G-actin was prepared from rabbit skeletal muscle using a standard protocol developed in the principal investigator's laboratory (*16*). The purity and activity of actin was analyzed using SDS−PAGE, polymerization assays, and a motility assay (*17*).

Prodan−Actin. Rabbit muscle G-actin was labeled with the thiol reactive, environmentally sensitive probe, acrylodan (Molecular Probes, Eugene, OR), according to our earlier publication (*16*). Briefly G-actin was dialyzed at 20 μM against dialysis buffer (DB, 2 mM Tris, 0.2 mM $CaCl_2$, and 0.2 mM ATP, pH 8.0) overnight and further treated with a 2-fold excess of acrylodan freshly prepared to 20 mM in DMF. The reaction was left in the dark for 1 h at 20 °C and then dialyzed overnight at 4 °C against DB containing 1 mM DTT (G-buffer). The labeled conjugate was polymerized for 90 min at 20 °C by adding $MgCl_2$ and KCl to 2 mM and 0.1 M, respectively, and centrifuged at 4 °C for 90 min at 100 000*g* in a Beckman ultracentrifuge. The pelleted fluorescent actin conjugate was resuspended in G-buffer and dialyzed against 0.5 L G-buffer as described above. Prodan-labeled G-actin was recovered from the supernatant fraction following a 100 000*g* spin at 4 °C. Absorption spectroscopic analysis routinely showed that the labeling ratio of Prodan/actin monomer was 1. The emission maximum of Prodan−actin shifted during the polymerization of G-actin from 496 to 465 nm and was accompanied by an 8-fold increase in intensity at 465 nm (*16*). Prodan−actin behaved as unlabeled actin in all functional assays tested (*16*, *19*).

Live Cell Imaging of TMR−KabC and FDE−KabC. Live cell imaging of barbed-end dynamics using TMR−KabC and FDE−KabC was performed using a Zeiss 510 confocal microscope. NIH 3T3 cells (a gift from Dr. Anna Huttenlocher, UW-Madison) shown on a 24 mm acid-washed coverslip housed in a sample chamber (*12*) were incubated with 100 nM FDE−KabC or TMR−KabC for 10 min at 37 °C. Following exchange of the cell

medium, the cells were imaged using the appropriate excitation and emission wavelengths according to Choidas et al. (*12*).

RESULTS AND DISCUSSION

Design of Fluorescent KabC Probes. Previous analyses of the structural and binding properties of KabC suggested that bulky groups linked to the terminal aldehyde of the tail region of KabC would interfere with its binding to the cleft between subdomains 1 and 3 of G-actin (*15*, *20*). Correspondingly, a 2,5-dimethylamino-naphthalenehydrazide-linked KabC derivative was found to be inactive when tested in our cytotoxicity assay (data not shown) (*15*). This result agrees with a finding by Wada et al. (*21*) who showed that biotin attached to the aldehyde group of mycalolide failed to stain actin within living cells.

On the basis of our previous studies (*15*, *20*), we reasoned that optical probes introduced into KabC via the 7-hydroxyl would face the solvent and therefore not interfere with KabC binding to G-actin. After considering several different approaches for the preparation of C-7-directed optical probes, we elected to synthesize the key intermediate, 7-(4-aminomethyl-1*H*-1,2,3-triazol-1-yl)-kabiramide C (AMT−KabC) from KabC (*18*). The long linker between the C-7 of KabC and the optical probe minimizes effects of the bulky probe on actin binding. Furthermore, the introduction of a terminal amino group on KabC allows for the facile synthesis of optical and capture group derivatives using commercially available carboxy-activated fluorescence probes that include the succinimidyl esters of tetramethylrhodamine (TMR), rhodol green (RG), IC5, fluorescein diester (FDE), and dapoxyl (DAP). The structures of the fluorescent KabC

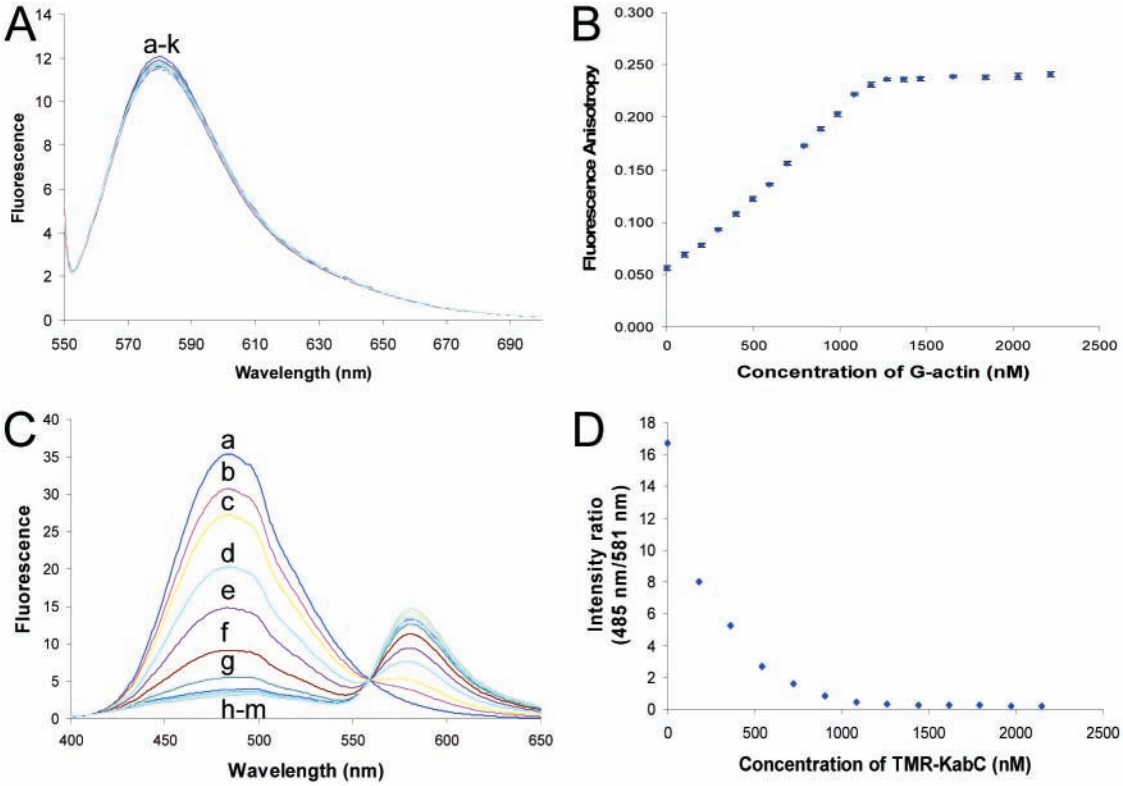

Figure 2. Spectroscopic and actin-binding properties of the TMR−KabC probe. (A) Fluorescence emission spectra of 1 μM TMR−KabC in G-buffer as a function of unlabeled G-actin concentrations: (a) 0 nM, (b) 144 nM, (c) 286 nM, (d) 423 nM, (e) 564 nM, (f) 700 nM, (g) 835 nM, (h) 968 nM, (i) 1099 nM, (j) 1228 nM, and (k) 1356 nM. Excitation wavelength was 546 nm (±4 nm bandwidth), and emission was collected over 550−700 nm (±4 nm bandwidth). (B) Fluorescence anisotropy values of 1 μM TMR−KabC in G-buffer as a function of unlabeled G-actin concentrations. Excitation wavelength was 546 nm (±4 nm bandwidth) and emission was collected over 575−585 nm (±4 nm bandwidth) for the four measurements of polarized emission. (C) Fluorescence emission spectra of 1 μM Prodan−G-actin in G-buffer as a function of TMR−KabC concentrations: (a) 0 nM, (b) 182 nM, (c) 364 nM, (d) 545 nM, (e) 725 nM, (f) 905 nM, (g) 1084 nM, (h) 1263 nM, (i) 1441 nM, (j) 1618 nM, (k) 1800 nM, (l) 1971 nM, and (m) 2147 nM. Excitation wavelength was 385 nm (±4 nm bandwidth), and emission was collected over 400−650 nm (±4 nm bandwidth). (D) Fluorescence intensity ratio of Prodan−G-actin (485 nm, 1 μM) to TMR−KabC (581 nm) as a function of TMR−KabC concentrations. The binding of TMR−KabC was monitored using the fluorescence intensity decrease in Prodan resulting from KabC-mediated quenching of Prodan fluorescence, and the donor quenching and TMR-sensitized emission due to FRET.

probes shown in Figure 1 were determined by their exact molecular weights obtained from ESI mass spectral analyses. The interactions of the fluorescent KabC probes and G-actin were characterized using spectroscopic and binding assays as described in the following sections for each probe.

Characterization of Fluorescent KabC Probes. *TMR*−KabC. Neither the fluorescence quantum yield nor the average emission energy of the TMR group of TMR−KabC changes upon binding to unlabeled G-actin (Figure 2A). This result suggests that the molecular environment of the TMR group is similar in both the free and bound states and that the linker is sufficiently constrained by the triazole ring to prevent interactions between the polar TMR group with the protein. However, the binding of TMR−KabC to G-actin substantially increases the hydrodynamic volume of the bound TMR−KabC compared to free TMR−KabC. This change is accurately quantified by measuring the steady-state FA (*22*) of free TMR−KabC and increasing amount of unlabeled G-actin (Figure 2B). The FA values increase linearly under the stoichiometric binding condition, and analysis of the FA data shows that TMR−KabC binds to G-actin in a 1:1 complex (Figure 2B) (*15*). Further support for this conclusion is provided in a FRET study of the interaction between TMR−KabC and Prodan (Cys-374)-labeled G-actin shown in Figure 2C. Excitation of Prodan on G-actin generates a strong fluorescence centered at 496 nm that decreases significantly upon adding increasing amounts of TMR−KabC, which is caused by KabC-mediated quenching as was previously reported (*15*) and by FRET from Prodan to TMR−KabC, which is also seen by the sensitization of TMR fluorescence. The increase in TMR-sensitized fluorescence emission and decrease in Prodan fluorescence as a function of added TMR−KabC provide a signal to analyze the stoichiometry of the complex; thus, the plateau region of the titration occurs at a KabC−TMR concentration of 1 mM, which is the same as that of Prodan−actin and suggests that, over the concentration range studied, TMR−KabC binds stoichiometrically to G-actin in a 1:1 complex (Figure 2D).

The fact that the quantum yield of the TMR emission, and by implication the lifetime of excited state, is constant in the free and bound states was exploited in the development of a simple and quantitative FA-based assay for G-actin. Thus, the change in FA value of TMR−KabC is directly related to the fractions of the probe in a sample that exist in the free state (r of 0.056 ± 0.002) and the G-actin-bound state (r of 0.236 ± 0.002) according to the equation $r = F_f r_f + F_b r_b$, where $F_f + F_b = 1$, r is the observed FA value, F_f and F_b are fractions of free and bound fluorescent ligand, and r_f and r_b are FA of free and bound fluorescent ligand, respectively. The relatively low FA value (0.236 ± 0.002) found for TMR−KabC in the G-actin complex suggests that the TMR group experiences a considerable degree of local motion. Furthermore, the FA value is unchanged when the TMR−KabC−G-actin complex is added at a substoichiometric level to a

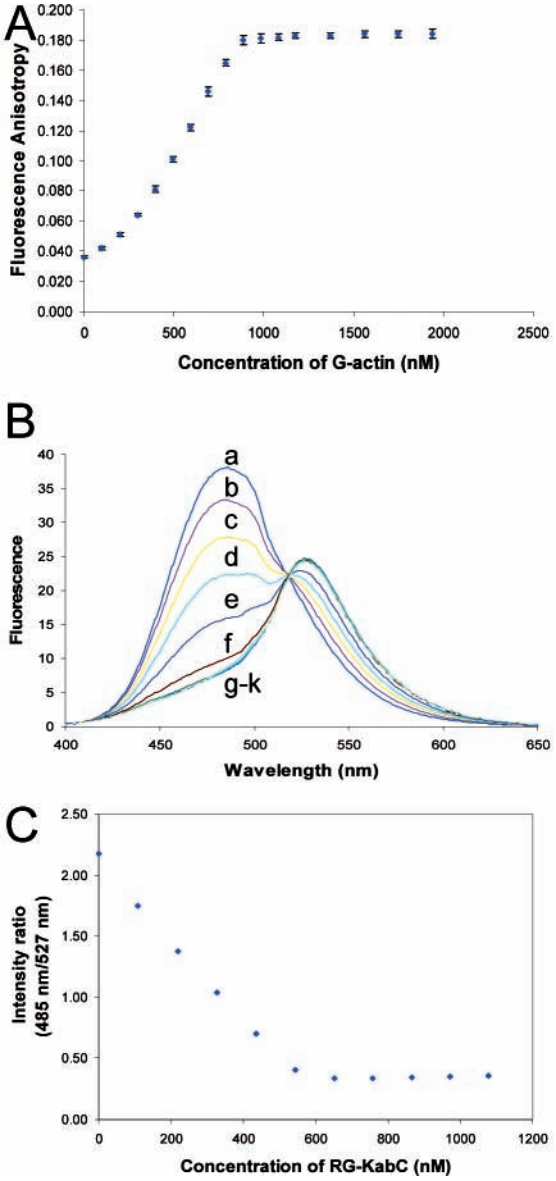

Figure 3. Spectroscopic and actin-binding properties of the RG−KabC probe. (A) Fluorescence anisotropy values of 1 μM RG−KabC as a function of unlabeled G-actin concentrations. Excitation wavelength was 499 nm (±4 nm bandwidth), and emission was collected over 520−530 nm (±4 nm bandwidth) for the four measurements of polarized emission. (B) Fluorescence emission spectra of 1 μM Prodan−G-actin in G-buffer as a function of RG−KabC concentrations: (a) 0 nM, (b) 109 nM, (c) 218 nM, (d) 327 nM, (e) 435 nM, (f) 543 nM, (g) 651 nM, (h) 758 nM, (i) 865 nM, (j) 971 nM, and (k) 1071 nM. Excitation wavelength was 385 nm (±4 nm bandwidth), and emission was collected over 400−650 nm (±4 nm bandwidth). (C) Fluorescence intensity ratio of Prodan−G-actin (485 nm, 1 μM) to RG−KabC (527 nm) as a function of RG−KabC concentrations. The binding of RG−KabC was monitored using the fluorescence intensity decrease in Prodan resulting from KabC-mediated quenching of Prodan fluorescence, and the donor quenching and RG-sensitized emission due to FRET.

polymerizing solution of actin, where it forms TMR−KabC-capped, barbed-ends (*15*). These results support our view that the TMR probe in KabC complex with both G- and F-actin is fully exposed to the solvent where it experiences considerable rotational freedom.

RG−KabC. The rhodol green derivative of KabC exhibits an excitation spectrum centered at 488 nm and emission at 517 nm. The fluorescence spectrum of RG−KabC does not change upon binding to G-actin, which suggests that the molecular environments of the probe

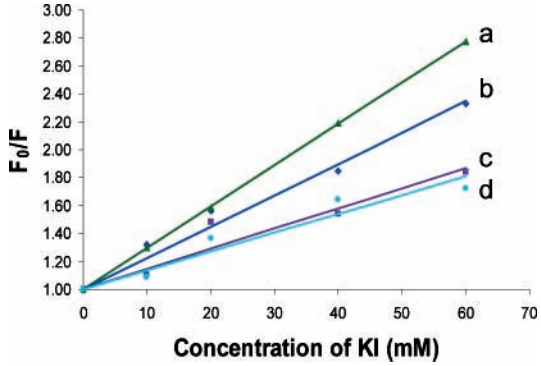

Figure 4. Stern−Volmer plot of iodide quenching behaviors of TMR−KabC, RG−KabC, and G-actin complexes in G-buffer as a function of potassium iodide concentrations: (a) TMR−KabC, (b) RG−KabC, (c) TMR−KabC−G-actin complex, and (d) RG−KabC−G-actin complex.

in the free and bound states are similar. The FA value of RG−KabC changes from a value of 0.036 ± 0.001 in the free state to 0.180 ± 0.003 when bound to G-actin (Figure 3A). As we saw with TMR−KabC, this anisotropy value suggests that the probe exhibits considerable rotational freedom when bound to G-actin and confirms our suggestion that the short linker between the C-7 of KabC and the probe prevents the RG group from interacting with the protein. The similarity of the molecular environments for the RG−KabC within G-actin and capped to the (+)-end of actin filaments is implied from the unchanged FA value of RG−KabC in these two preparations. The higher degree of spectral overlap between Prodan emission on G-actin and the absorption spectrum of RG−KabC results in an efficient FRET process (Figure 3B,C), which can be used to determine properties of the interaction including the formation of a 1:1 complex.

Iodide Quenching of TMR−KabC and RG−KabC. To learn more about the molecular environment of the RG and TMR groups in their G-actin complexes, we performed a potassium iodide-mediated collision quenching study. The IC5 probe was found to be irreversibly quenched by KI, presumably by iodination, and was not included in these studies. The quenching curves for free and bound RG− and TMR−KabC show two quenching modes with the faster rate accounting for the greater degree of quenching (Figure 4). Analysis of the rapid quenching mode was achieved by restricting the linear regression of fluorescence quenching data to 60 mM KI (Figure 4). Free KabC probes were found to exhibit collision molar quenching constants of 29.6 M^{-1} (R^2 of 0.999) for TMR−KabC and 22.5 M^{-1} (R^2 of 0.976) for RG−KabC. These corresponding values for TMR−KabC and RG−KabC bound to G-actin are 13.5 M^{-1} (R^2 of 0.929) and 14.5 M^{-1} (R^2 of 0.914), respectively. Given a fluorescence lifetime for both TMR−KabC and RG−KabC of 4 ns (*17*), we calculate that the unbound probes are quenched at 7.4×10^9 M^{-1} s^{-1} and 5.6×10^9 M^{-1} s^{-1}, respectively, which are very close to the diffusion-controlled rate of 8×10^9 M^{-1} s^{-1} (*16*). Since the lifetimes of the TMR−KabC and RG−KabC probes do not change on binding to G-actin, the quenching rate constants calculated for the bound probes are very similar at 3.38×10^9 M^{-1} s^{-1} and 3.63×10^9 M^{-1} s^{-1}, respectively. The analysis of these quenching data supports the conclusion reached from the spectral and FA analyses showing that the TMR−KabC and RG−KabC probes are fully exposed to the solvent and experience a considerable degree of rotational freedom.

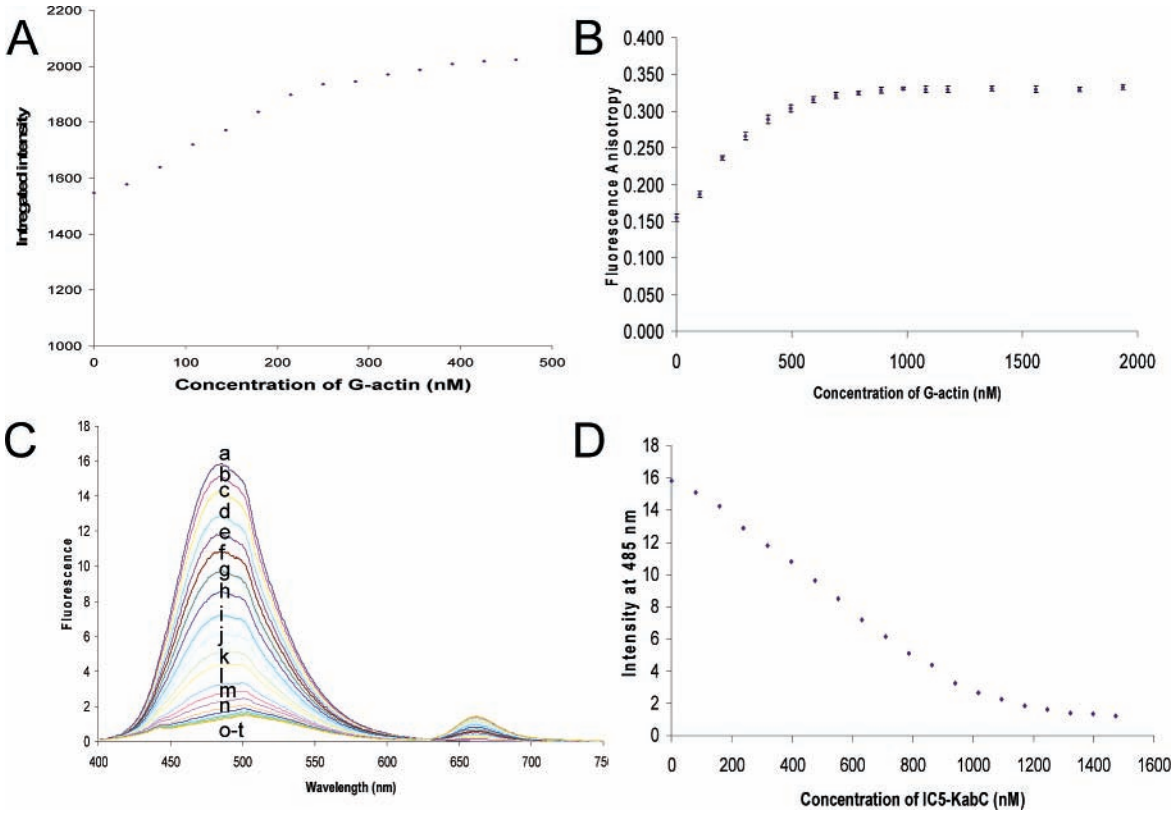

Figure 5. Spectroscopic and actin-binding properties of the IC5−KabC probe. (A) Fluorescence intensity of IC5−KabC binding to G-actin. The binding of IC5−KabC was monitored using the increase in the integrated emission intensity of IC5−KabC (200 nM, in G-buffer) upon binding to actin as a function of G-actin concentrations. (B) Fluorescence anisotropy values of 1 μM IC5−KabC in G-buffer as a function of unlabeled G-actin concentrations. Excitation wavelength was 630 nm (±4 nm bandwidth), and emission was collected over 655−665 nm (±4 nm bandwidth) for the four measurements of polarized emission. (C) Fluorescence emission spectra of 1 μM Prodan−G-actin in G-buffer as a function of IC5−KabC concentrations: (a) 0 nM, (b) 80 nM, (c) 160 nM, (d) 239 nM, (e) 318 nM, (f) 397 nM, (g) 475 nM, (h) 554 nM, (i) 632 nM, (j) 709 nM, (k) 787 nM, (l) 864 nM, (m) 941 nM, (n) 1018 nM, (o) 1095 nM, (p) 1171 nM, (q) 1247 nM, (r) 1323 nM, (s) 1398 nM, and (t) 1473 nM. Excitation wavelength was 385 nm (±4 nm bandwidth), and emission was collected over 400−750 nm (±4 nm bandwidth). (D) Fluorescence intensity of 1 μM Prodan−G-actin at 485 nm as a function of IC5−KabC concentrations. The binding of IC5−KabC is detected mainly from the decrease in Prodan fluorescence resulting from KabC-mediated quenching of Prodan fluorescence and donor quenching due to FRET to IC5.

IC5−KabC. The relative fluorescence quantum yield of IC5−KabC increases ~20% upon binding to G-actin and does not involve any significant spectral shift (Figure 5A). As expected, the binding of IC5−KabC to G-actin substantially increases the hydrodynamic volume sensed by the IC5 probe compared to free IC5−KabC. Steady-state FA measurements of IC5−KabC increase from 0.155 ± 0.005 in the free state to 0.331 ± 0.002 when stoichiometrically bound to G-actin (Figure 5B). Both the integrated fluorescence intensity of the emission spectrum and the FA value increase linearly with increasing G-actin concentration—analysis of these data shows that IC5−KabC binds stoichiometrically (1:1) to G-actin. This result was confirmed from a FRET-based analysis of Prodan−actin emission at 485 nm as a function of IC5−KabC concentration (Figure 5C,D). The FA value of IC5−KabC in the complex (0.331) does not change in the presence of a large excess of the (+)-end binding protein, CapG (data not shown), which suggest that the complex has a long complex lifetime to prevent competition binding from CapG. Since the FA value for IC5−KabC bound to the terminal protomer at the (+)-end of an actin filament does not increase compared to the G-actin complex, we ascribe the small difference in the FA of the IC5−KabC−G-actin complex (0.331) to the limiting anisotropy (0.4) in terms of a low amplitude local motion of the IC5−KabC within the complex.

The high value of the steady-state FA measured for IC5−KabC compared to the RG− and TMR−KabC probes on actin is expected (a) if the lifetime of IC5−KabC in the G-actin complex was short compared to the RG−KabC- and TMR−KabC-bound probes or (b) if the longer link between the IC5 group and the C-7 of KabC allows the IC5 probe to double-back and engage in interactions with the protein surface that restrict local motion. Since the relative quantum yield of IC5−KabC emission is already high, then the fluorescence lifetime would if anything increase on binding to G-actin; on the basis of this argument, it is possible to rule out the first possibility. On the other hand, the emission spectrum of the IC5 probe (*23*) is slightly red-shifted in the G-actin complex compared to the free probe, which is evidence that the probe engages in different interactions in the G-actin complex compared to water. Taken together, we propose that the very high FA value measured for IC5−KabC-bound G-actin results from a significant reduction in local motion of the probe that is brought about by interactions between the IC5 probe and the G-actin.

DAP−KabC. Dapoxyl group has been reported to be sensitive to changes in its molecular environment, and accordingly, the relative fluorescence quantum yield of DAP−KabC decreased upon binding to G-actin (Figure 6A). These data were used to confirm that the KabC probe binds to G-actin in a 1:1 complex. While the fluorescence of the DAP probe is severely quenched in the complex, we expect that the bound probe may prove to be sensitive to the presence of ternary protein and

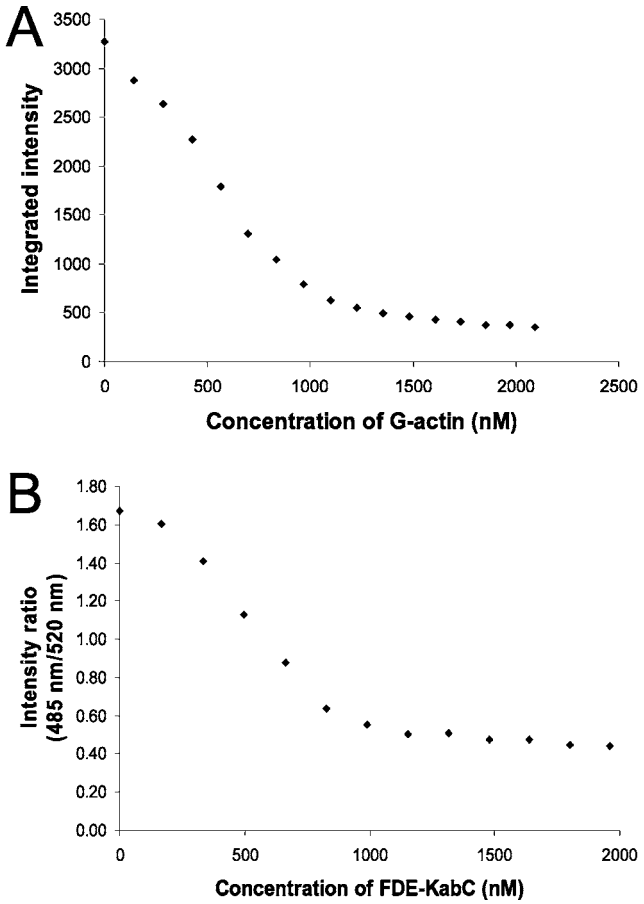

Figure 6. Spectroscopic and actin-binding properties of DAP−and FDE−KabC probes. (A) Fluorescence intensity of DAP−KabC binding to G-actin. The binding of DAP−KabC (1 μM, in G-buffer) was monitored using the decrease in the integrated emission intensity of DAP−KabC upon binding to actin as a function of G-actin concentrations. (B) Fluorescence intensity ratio of Prodan−G-actin (485 nm, 1 μM) to FDE−KabC (520 nm) as a function of FDE−KabC concentrations. The binding of FDE−KabC is monitored using the fluorescence intensity decrease in Prodan resulting from KabC-mediated quenching of Prodan fluorescence, and the donor quenching and FDE-sensitized emission due to FRET.

ligand interactions within G-actin or the terminal actin protomer at the (+)-end of the filament.

FDE−KabC. The binding of the nonfluorescent FDE−KabC probe to G-actin was confirmed by monitoring of Prodan−actin/FDE−KabC emission ratio at 485/520 nm as a function of FDE−KabC concentrations. Excitation of the Prodan fluorophore in G-actin leads to a strong emission centered at 496 nm that decreases upon the addition of increasing amount of FDE−KabC due to KabC-mediated quenching of Prodan fluorescence and the donor quenching and FDE-sensitized emission due to FRET. Analysis of these data confirms that the FDE−KabC probe binds to G-actin in a 1:1 complex (Figure 6B).

Imaging of the Fluorescent KabC Probes in Living Cells. Having shown that all of the fluorescent KabC derivatives bind in vitro to the barbed-end of actin in a tight, long-lived, and stoichiometric complex, we next sought to use TMR−KabC and FDE−KabC as optical probes in a confocal fluorescence image microscopy to image sites within living cells that are undergoing actin filament dynamics, i.e., uncapping of barbed-ends. The FDE−KabC optical probe has three key features that make it suitable for in vivo imaging studies: (1) the probe readily permeates the plasma membrane of living cells; (2) the fluorescein is nonfluorescent until one or both

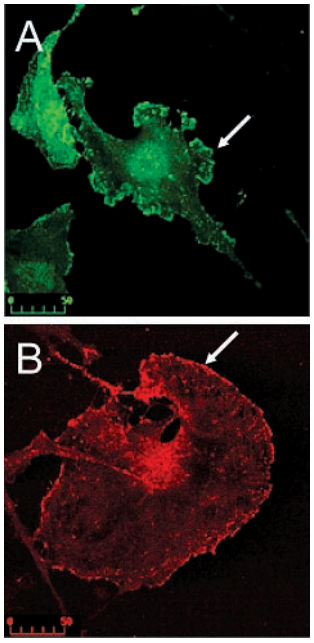

Figure 7. The confocal images of FDE−KabC−G-actin (A) and TMR−KabC−G-actin (B) in actin filament at protrusion site (arrow) of live NIH 3T3 cells.

acetate groups are hydrolyzed by intracellular esterases; and (3) once cleaved, the FDE−KabC probe remains trapped within the cell. Cells treated with medium containing 100 nM FDE−KabC display robust fluorescence within a few minutes. Confocal imaging of FDE−KabC within live NIH-3T3 cells shows two categories of staining. The first is a diffuse fluorescence that associates with FDE−KabC−G-actin existing in complex with G-actin-sequestering proteins such as thymosin β4 (*19*); the second is a far more intense fluorescence of FDE−KabC−G-actin in actin filament and is found at the cell cortex, especially at sites of cell protrusion (Figure 7A). The brilliantly fluorescent TMR−KabC also crosses the plasma membrane where it becomes trapped within the cytoplasm. After washing cells with fresh medium, fluorescence imaging also shows that the distribution of the entrapped probe is similar to that described for FDE−KabC (Figure 7B). The red-shifted excitation and emission spectra of the TMR probe together with its increased photostability generate images that are of higher contrast than FDE−KabC.

SUMMARY

We have previously shown that KabC acts as a functional, unregulated biomimetic of gelsolin and CapG, which bind to the (+)-end of the actin filament. In this study, we demonstrate the design, synthesis, and spectroscopic, functional, and biochemical characterization of five new fluorescent derivatives of KabC. We introduced a rigid triazole linker group terminated with a primary amine to facilitate the synthesis of a diverse range of fluorescence probes using commercially available succinimidyl esters. The probes were characterized by exact molecular weight obtained from ESIMS. All fluorescent KabC probes formed a high stable, 1:1 complex with G-actin. The fluorescent KabC probes are truly unique among the commonly used optical probes for actin (*25*) in that the irreversible binding can be used to titrate actin that is present in complex mixtures.

The specific binding of the five fluorescent KabC probes to G-actin provides an unparalleled opportunity to study

the structural and structural dynamic properties of actin in the critical region between subdomains 1 and 3 and to map molecular events around this critical region. The rapid rate of iodide quenching of TMR−KabC and RG−KabC fluorescence in the G-actin complex supports the conclusion of the FA and spectral data that the KabC probes experience considerable rotational freedom in the G-actin complex and are exposed to solvent molecules. On the other hand, spectroscopic characterization of the IC5−KabC complex with G-actin shows that the longer linker in the probe allows the IC5 group to associate with the surface of actin as seen in the restriction of the rotational freedom of the probe causing the slightly red-shifted emission spectrum in the complex.

The fluorescence property of each KabC probe was largely unaffected following the polymerization of G-actin to F-actin. The extremely tight molecular complex between the fluorescent KabC and G-actin, together with the fact that this complex can only associate with actin filaments at the (+)-end in an unregulated manner, fulfills a major objective of this study, which was to design probes that can map and quantify molecular events at the (+)-end of the filament. The family of fluorescent, membrane permeable, unregulated (+)-end KabC-based capping probes described herein, as well as KabC probes based on quantum dots (*26*), will provide the necessary contrast to map molecular events occurring at the (+)-end of actin filaments in motile cells and should be useful to advance our understanding of the regulation of actin filament dynamics in cell protrusion (*2*, *10*, *11*).

Received March 31, 2005; Revised Manuscript Received October 4, 2005

Novel, multifunctional polymers remain an attractive objective for drug delivery, especially for hydrophilic macromolecular drugs candidates such as peptides, proteins, RNA, and DNA. To facilitate intracellular delivery of DNA, new amine-modified poly(vinyl alcohol)s (PVAs) were synthesized by a two-step process using carbonyl diimidazole activated diamines to produce PVAs with different degrees of amine substitution. The resulting polymers were characterized using NMR, thermogravimetric analysis (TGA), and gelpermation chromatography (GPC). Atomic force microscopy (AFM), dynamic light scattering photon correlation spectroscopy (PCS), and zeta-potential were used to investigate polyplexes of DNA with PVA copolymers. These studies suggest an influence of the polycation structure on the morphology of condensed DNA in polyplexes. Significant differences were observed by changing both the degrees of amine substitution and the structure of the PVA backbone, demonstrating that both electrostatic and hydrophobic interactions affect DNA condensation. DNA condensation measured by an ethidium bromide intercalation assay showed a higher degree of condensation with pDNA with increasing degrees of amine substitution and more hydrophobic functional groups. These findings are in line with transfection experiments, in which a good uptake of these polymer DNA complexes was noted, unfortunately, with little endosomal escape. Co-administration of chloroquine resulted in increased endosomal escape and higher transfection efficiencies, due to disruption of the endosomal membrane. In this study, the structural requirements for DNA complexation and condensation were characterized to provide a basis for rational design of nonviral gene delivery systems.

INTRODUCTION

Delivery of hydrophilic molecules such as proteins and DNA is generally considered as the Achilles heel for their therapeutic application (*1*−*3*). These molecules are rapidly degraded by enzymes found under in vivo conditions both intracellularly at the site of application as well as in the general circulation, causing low bioavailabilities and requiring frequent injections (*4*−*6*). Because of their size and lability, uptake through the epithelium of the gastrointestinal tract is low and thus necessitates parenteral administration (*7*, *8*). To overcome these problems, carrier systems are necessary to allow efficient, safe, and convenient delivery to patients (*9*−*20*).

In this context, nanoscale carriers such as nanoparticles and nanocomplexes have reached increasing attention, since they can be administered by various routes, including the intravenous and intranasal routes (*9*, *21*, *22*). Controlled and sustained release of these drug candidates can be accomplished using microspheres and implants from biodegradable polymers (*1*, *14*, *20*, *23*). The classic copolyesters of lactic and glycolic acid (PLGA) are not ideal for protein and DNA delivery since inactivation and uncontrolled release is a consequence of poor compatibility between lipophilic polymers and hydrophilic drug candidates (*7*, *24*−*27*). This is especially the case for DNA, where the complexation capabilities and protecting abilities of the carrier substance are very important. We hypothesized that comblike polyesters consisting of both lipophilic and hydrophilic components could be beneficial for drug delivery.

We selected PVA with a molecular weight of 15 000 g/mol, which is considered biocompatible and can be eliminated from the body by renal excretion (*28*−*30*). To this polymer backbone, amine groups were covalently coupled in a polymer-analogous reaction using carbonyl diimidazole (CDI) to introduce cationic charges under physiological conditions (*31*−*33*). This modification was thought to affect colloidal stability of carrier systems by imparting positive surface charges on one hand (*34*) and increasing the protein or DNA loading by electrostatic interactions on the other hand (*35*, *36*). As the secondary and tertiary amino-groups functions possess lower cytotoxicity, diamines, and PVA were coupled via the hydrolytically stable urethane bond (*38*). The resulting PVA could be used in different ratios to complex DNA.

EXPERIMENTAL SECTION

Materials. Diethylaminoethylamine (*purum*, >98%), Diethylaminopropylamine (*purum*, >98%), Dimethylaminopropylamine (*purum*, >98%), PVA (MW 15000; degree of polymerization 300 (P = 300); degree of hydrolysis 86−89%), CDI (*purum*, ∼97%), *N*-methyl pyrrolidone (NMP) (absolute), dimethylacetamide (DMAc) (for HPLC, 99.8% and 1,3-dimethyl-3,4,5,6-tetrahydro-2(1H)-pyrimidinone

[a] Feed (mass/g): m(PVA)/m(amine-CI)/m(DMPU)/days of reaction. [b] Calculated by ^{1}H NMR depending on the degree of polymerization of PVA (P = 300). [c] Measured by GPC-MALLS.

(DMPU) (*puriss.*, absolute, over molecular sieve) were purchased from Fluka GmbH (Germany) and used as received. Lithium bromide (extra pure) (Merck) was used as received. Tetrahydrofuran (THF) (BASF, Germany) was dried over sodium and distilled under nitrogen before use. All other chemicals were used as received without further purification.

Synthesis of Amine Carbonylimidazoles. A total of 90 mL of dry THF was distilled under nitrogen into a rigorously dried 100 mL round-bottomed flask equipped with gas inlet, a septum cap, and a magnetic stir bar. Then, 16.72 g (0.10 mol) of CDI was dissolved, and the diamine (at a 1:1 molar ratio) was injected by syringe, while the temperature in the flask was monitored to ensure that it did not exceed 55 °C (*31*).

After stirring of the sample for 16 h at room temperature, the resulting imidazole/amine-carbonylimidazole solution was isolated by evaporation of THF. The resulting oily, slight yellow mixture was used without further purification after the amount of amine-CI was quantitated by ^{1}H NMR spectroscopy. Yields: >90%.

Synthesis of Amine-Modified PVAs. Poly(vinyl (dialkylamino)alkylcarbamate-*co*-vinyl acetate-*co*-vinyl alcohol): A 250 mL round-bottomed flask with gas inlet and magnetic stirring bar was rigorously dried and filled with PVA and anhydrous NMP. During heating to 80 °C, the PVA was dissolved. After complete dissolution (dialkylamino)alkyl)-1H-imidazole-1-carboxamide was added, and finally DMPU was injected. The mixture was heated to 80 °C under stirring for 4.5 days (Table 1).

The resulting amine-modified PVA was purified by ultrafiltration using an YM1 membrane (cut off 1000 g/mol, Millipore). During filtration, the solvent was substituted by demineralized water. After filtration of 2.5 L water, the volume in the cell was reduced to 50 to 100 mL. The solution was frozen at −20 °C and dried by lyophilization (Edward Freeze Dryer Modulyo, standard conditions). The polymers were milled and stored until use at 40 °C in a vacuum to minimize water uptake during storage. The polymers are obtained as slightly yellowish hygroscopic powders. Yields: ∼83%.

Nomenclature. The source-based IUPAC nomenclature for these polymers lead to the designation: poly(vinyl 3-(alkylamino)alkylcarbamate-*co*-vinyl acetate-*co*-vinyl alcohol). As an abbreviation the short form of the amine followed by a number in brackets was used. (e.g., DEAPA(x) = 3-diethylaminopropylamine; while x the number displays the modified vinyl alcohol monomers in the chain, for example, DMAPA(13), etc.)

Sample Characterization. ^{1}H and ^{13}C NMR spectroscopic data were collected using a JEOL Eclipse+ 500 and a Joel GX 400 D at a frequency of 500 respective 400 MHz for ^{1}H NMR and 126 respective 101 MHz for ^{13}C NMR at 50 °C in DMSO-d_6 (euriso-top, <0.02% HDO+D_2O). A 40−50 mg sample was used for each measurement. ^{1}H NMR was performed with 64 scans. The ^{13}C NMR was performed with 4096 scans.

[a] Degree of amine substitution/% calculated form ^{1}H NMR measurements. [b] Mass loss during the first degradation step. [c] Mass loss calculated from NMR data.

The amine substitution (AS) was evaluated by calculating the ratio between the integral of the CH_3 end group of the amine and the integral of the methylene protons of PVA on the basis of the degree of polymerization. $(100/(I_{PVA}/2))(I_{amine}/3) = DS$; DS*3 = AS.

Fourier transform-infrared spectroscopy (FT-IR) was performed on a Nicolet 510P FTIR spectrometer (range between 4000 and 400 cm^{-1}, resolution: 2 cm^{-1}). All powder samples were compressed into KBr pellets.

CHN analysis was performed with a Hewlett-Packard autoanalyser 185.

Gelpermation chromatography in combination with a multi-angle-laser-light scattering detector (GPC-MALLS) was employed for the determination of absolute molecular weights and weight distributions using a Duratec DDG-75 degasser, a Merck-Hitachi L-6000 pump and an AS-2000A autosampler, a Merck T-6300 Column Thermostat, a Wyatt DAWN Eos multiangle-laser-light-scattering detector (normalized with PSS (Polymer Standard Service, Mainz) PMMA 200k standard). The separation was performed using an Optilab DSP together with a PSS SDV linear M (8 × 300, 5μ) column with a precolumn of the same type (8 × 50, 5μ). The measurements were performed at 60 °C column temperature at a flow rate of 0.5 mL min^{-1} using dimethylacetamide (DMAc) and 2.5 g lithium bromide /L (LiBr) as eluent. The molecular weights of the samples were determined using the Wyatt software Astra V4.73. To calculate the molecular weights total mass recovery was used (third-order fit).

Differential scanning calorimetry (DSC) was performed on a Perkin-Elmer DSC7 calibrated against indium and gallium. Using ca. 5 mg of polymer the sample was scanned between −10 and 200 °C at a heating rate of 10 °C/min. Glass transition temperatures were calculated from the second run.

Thermogravimetric Analysis (TGA). About 5 mg of polymer was used for thermogravimetric analysis in a TGA7 (Perkin-Elmer) (under nitrogen, heating rate of 20 °C/min, run 30−600 °C) (Table 2).

DNA. The plasmid DNA pBR322 (4363 bp) (Sigma-Aldrich, Poole, Dorset, UK) was diluted to a stock solution of 10 μg mL^{-1} w/v in deionized water (resistivity of about 18.2 MΩ cm) obtained from an ELGA purification system (Maxima USF ELGA, High Wycombe, UK) and 10% phosphate buffered saline (PBS) (Sigma-Aldrich PLC);

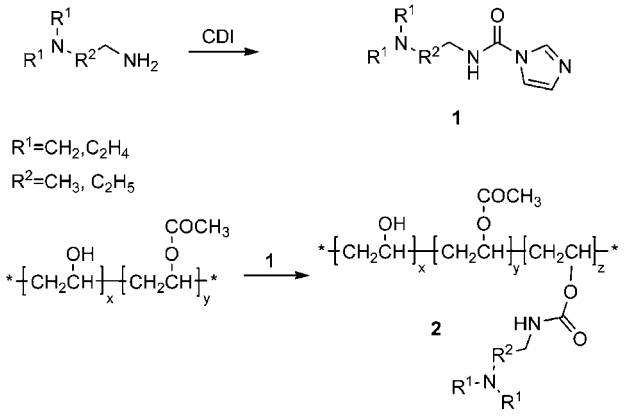
these stocks were further diluted with deionized water to give a concentration of 1 μg mL^{-1} DNA in 1% PBS (pH 5.5).

Atomic Force Microscopy (AFM) Instrumentation. A Multimode AFM (Veeco Instruments, Santa Barbara, CA) operating with a NanoScope IIIa controller with a size E scanner was used throughout this study. For imaging in liquid, silicon nitride, oxide sharpened, triangular cantilevers (Veeco Instruments) were selected, operating at resonant frequencies of approximately 8 kHz. All imaging was conducted in tapping mode at 512 × 512 pixel resolution, with scan speeds of approximately 3.05 Hz. We chose optimal set-points to reduce sample distortion. Post-imaging analysis, unless otherwise indicated, was carried out on either NanoScope IIIa software, version 5.12b48 or SPIP version 3.0.0 (Image Metrology, Lyngby, Denmark). The background slope was removed from image data using a first- or second-order polynomial function, and some images were subjected to a median filter of 3 × 3. All lateral cross-sectional measurements acquired from AFM images were taken at half-maximum height (*39*).

Grain size analysis was conducted using the Nanoscope Software. Using such software, the average (mean) surface area (nm^2) was calculated for each selected condensate. To reduce the effect of noise and substrate defects on the analysis, height thresholds were optimized. First, a height threshold was chosen such that unwanted pixels were removed and second, each individual particle was selected, giving either its grain size (projected two-dimensional area) or the mean grain size of particles of similar dimension, followed by the standard deviation (Table 3).

Scheme 1. Synthesis of Amine-Substituted PVA



In Vitro Cytotoxicity Using (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl Tetrazolium Bromide (MTT) Assay. L929 mouse fibroblasts were grown in Dulbecco's modified Eagle's medium (DMEM) (Gibco, Eggenstein, Germany) supplemented with 10% fetal calf serum (Cytogen, Sinn, Germany) and 2 mM glutamine.

In vitro cytotoxicity of the polymers was evaluated using the MTT assay as described previously (*13*). L929 were seeded into 96-well microtiter plates (Nunclon, Nunc, Germany) at a density of 8000 cells/well. After 24 h, the culture medium was replaced with 100 μL/well of

serial dilutions of polymer stock solutions in DMEM (n = 7). After an incubation period of 24 h, MTT (Sigma-Aldrich, Germany) was dissolved in phosphate buffered saline at 5 mg/mL and 20 μL was added to each well reaching a final concentration of 0.5 mg of MTT/mL. After an incubation time of 4 h, unreacted dye was removed by aspiration and the purple formazan product was dissolved in 200 μL/well dimethyl sulfoxide and quantitated by a plate reader (Titertek Plus MS 212, ICN, Germany) at wavelengths of 570 and 690 nm. The relative cell viability [%] related to control wells containing cell culture medium without polymer was calculated by [A] test/[A] control × 100. Poly(ethylene imine) 25 kDa (BASF, Germany) was used as a positive control.

Transfection. Transfection experiments were carried out as reported earlier (*40*). In brief, polymer (in isotonic NaCl solution) was mixed in the intended ratio with 4 μg of pCMV-Luc (c = 5 μg/ μL) in 100 μL of isotonic NaCl solution resulting a final volume of 200 μL.

NIH/3T3 mouse fibroblasts were seeded onto 12-well plates, 50 000/well (n = 3). After 24 h medium (DMEM with 10% FKS) was exchanged against polymer/DNA complex solution and chloroquine (10.32 μL, 10 μg/μL, final concentration 100 μmol/L (*41*). After 4 h, the medium was changed, and after 44 h cells were washed and lysed. (Growth conditions: 8.5% CO_2, 90% rel. humidity, 37 °C.) *For assays of luciferase activity:* 20 μL of cell lysis medium was mixed with 100 μL of luciferase assay reagent (Promega) and measured in a luminometer (calibration: 8.33 × 10^5 RLU = 1 ng/mL Luciferase).

Confocal Laser Scanning Microscopy (CLSM). Labeling: 10 mg of polymer was dissolved in $NaHCO_3$ buffer (pH 9.0) and 0.26 mg of (5-(4,6-dichlorotriazinyl)-aminofluoresceine (5-DTAF) in DMSO (c = 0.01 mg/μL) was added. The mixture was heated to 70 °C. The conjugate was purified by size exclusion chromatography on a PD-10 column (SEC-column, cutoff 10 kDa, Amersham Biosciences, Sweden) and subsequently freeze-dried.

Preparation of Polyplexes. Labeled polymer was mixed with YOYO1-DNA (*42*) at a N/P ratio of 20 and incubated in chamber-slides with 20 000 NIH/3T3 cells for 4 h. Then PBS buffer was used to wash the cells. The cells were fixed with formalin and stained with 4′,6-diamidine-2-phenylindol (DAPI). Images were recorded using confocal laser scanning microscopy (CLSM) (Zeiss Axiovert 100 M coupled to Zeiss LSM 510 scanning device).

RESULTS AND DISCUSSION

Different diamines were used to synthesize amine-modified PVA with different degrees of substitution ranging between 0.02 and 0.35. PVA with a molar mass of 15 000 g/mol (M_n) (P = 300, degree of hydrolysis 87−89%) was used as starting material. CDI chemistry was used to modify PVA with tyramine (*32*). Here we present a modified way to couple amines to PVA. To avoid cross-linking, we used substituted diamines such as N^1,N^1-diethylpropane-1,3-diamine activated with CDI (Scheme 1) (*31*). The amines were injected into solution/suspension of CDI in THF to prevent disubstitution. The resulting amine-carbonylimidazole (amine-CI) is less reactive than CDI. No further purification of the resulting amine-CI/imidazole mixture was necessary, and ^{1}H NMR spectroscopy was used to determine the concentration of amine-CI in the reaction mixture. On the basis of these calculations, amine-modified PVAs with degrees of amine substitution of 0.02, 0.04, 0.11, 0.23, and 0.35 were synthesized (Table 1). Substitution was determined by setting the signals of PVA at δ = 1.87−1.17 ppm

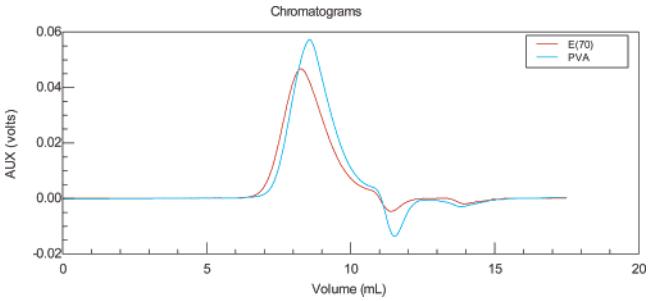


Figure 2. GPC: elugram of E(70) in comparison to unmodified PVA.

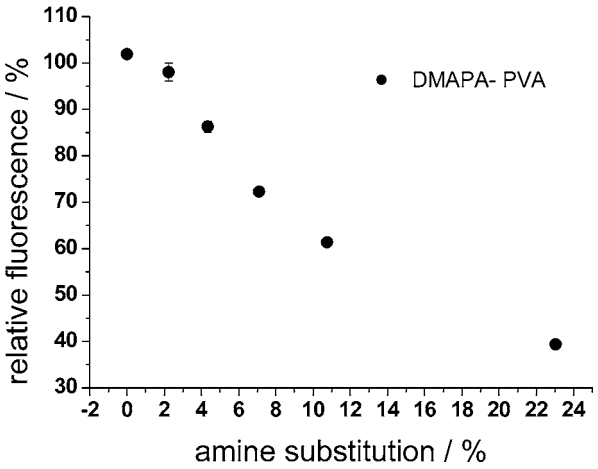

Figure 3. Ethidium bromide assay of DMAPA(x) (x = 0.0, 2.3, 4.4, 7.1, 10.8, 23.0) and salmon testis DNA at the same N/P ratio.

(methylene protons) into relation to a clearly separated signal of the amine substitution, e.g., at δ = 0.95 ppm for DEAPA modification. On the basis of the known degree of polymerization of PVA, the stoichiometric amount of substituted hydroxyl groups could be calculated. To achieve higher degrees of amine substitution, it is necessary to use an excess of amine-CI (Table 1). The resulting amine-modified PVAs are water soluble. Their hygroscopic properties increase with increasing amine substitution as demonstrated by a shift of the glass transition temperature (T_g) shown in Figure 1.

The postulated structure of the amine-modified PVA was in accordance with NMR and FT-IR spectra and was confirmed by CHN elemental analysis. These results are in good agreement with NMR and TGA data (Table 2). NMR, FT-IR, and CHN data are presented as Supporting Information. Previously, we have confirmed the covalent attachment of amines to PVA backbone using two-dimensional NMR spectroscopy. Mainly isotactic triads of the precursor PVA react with the amine reactant and form a polymer with an average block length of nine vinyl alcohol monomer groups between each amine-modified monomer region for polymer DMAPA (*32*). Further, the three-dimensional structure and the tacticity of amine-modified PVA was verified (*43*). GPC measurements demonstrate a monomodal distribution of molecular weights in good correspondence to values calculated from NMR measurements (Table 1, Figure 2).

Because of their amino functions which were protonated under physiological conditions these polymers formed complexes with DNA through electrostatic interactions (*44*, *45*). We hypothesized that polyplex formation could influenced by the degree of amine substitution as well as by the type of the amine function (*46*). The tertiary amino function was substituted dimethyl or

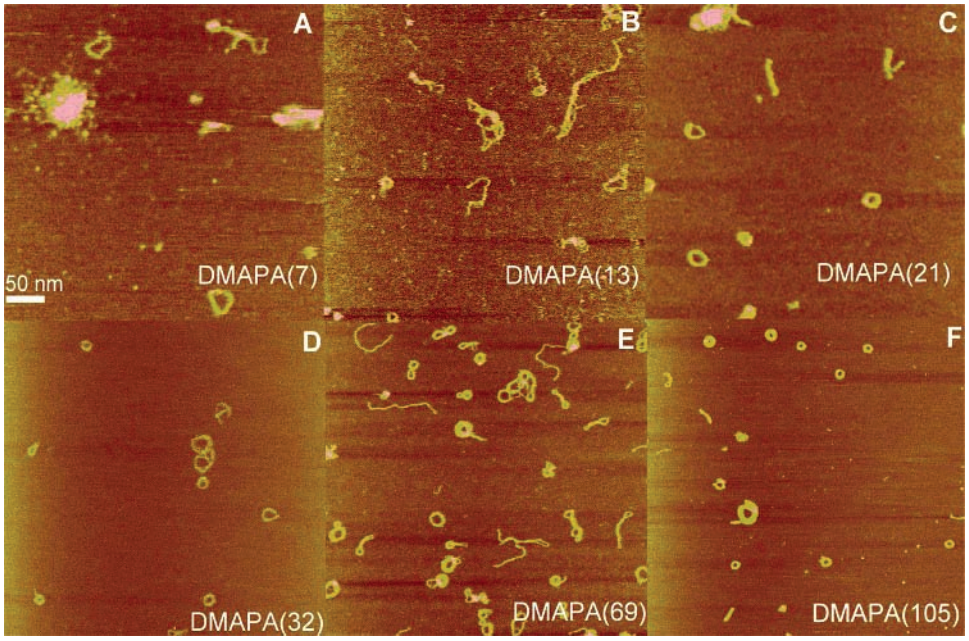

Figure 4. (A−F) Changes in the morphology of the DNA/polymer complexes due to different amine substitution of DMAPA-modified PVA (N/P ratio 12).

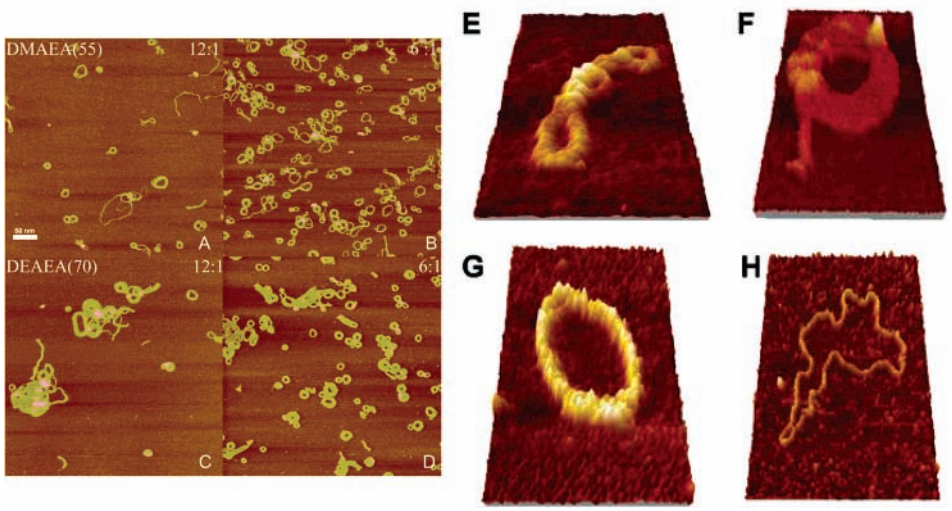

Figure 5. Panels A−D depict various AFM topographical images of both DMAEA(55) and DEAEA(70) highlighting different morphologies of DNA with 12:1 ratios, compared to 6:1 ratios (A, B, C and D, respectively). These data suggest a 6:1 ratio of DMAEA forms partially condensed toroids and plectonomics, whereas 6:1 DEAEA forms complete toroids. $Z = 10$ nm; (E−G) highlights different morphologies of the DNA/polymer complexes which are compared to naked DNA (H).

diethyl moieties, and different spacer length were realized for coupling to PVA backbone. Both factors are thought to contribute to polyplex size and structure.

To test this hypothesis, we investigated polyplex formation with DNA using DMAPA−PVA with different degrees of amine substitutions. Polyplex formation was monitored by an ethidium bromide exclusion assay at constant N/P ratios (Figure 3). Higher degrees of amine substitution resulted in decreased fluorescence intensities, compatible with an increasing complexation and condensation of DNA as a function of the degree of substitution. Obviously, increasing amine densities lead to an increase in charge density and hence to stronger complexation at a constant N/P ratio. There was no significant difference between diethyl and dimethylamine-modified PVA showing similar complexation behavior (data not shown). Therefore, condensation and complexation of the DNA seem to be mainly dominated by charge density and not by the chemical structure of charge carrying groups.

The interaction between DNA and the polymers was directly observed using AFM, which provides useful information on polyplex size, morphology, and mechanisms of condensation (*39*, *47*−*50*). Differences in the morphology of the polyplexes formed by different polymers are recognizable. Figures 4 and 5A−D depict the changing of morphology of condensed DNA with increasing amine substitution and at different N/P ratios. The complexes formed between DNA and DMAPA(7) are very diffuse and not clearly defined (Figure 4A). Increasing the amine substitution leads to further refinement of morphology (Figure 4B−F), where these diffuse particles are transformed into toroids, plectonomic rods, and other highly condensed morphologies (Figure 5, right E−G). These shapes are totally different from noncondensed DNA (Figure 5, right H), and they highlight the PVA/

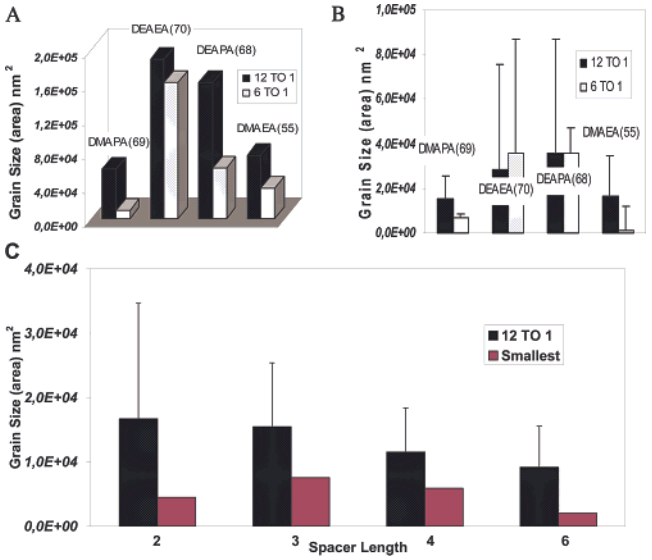

Figure 6. (A) Max grain sizes for each polymer (nm^2) both 6:1 and 12:1; (B) mean particle size for each polymer + S/D; (C) mean particle size for each polymer + S/D.

DNA interaction very clearly. Previous publications suggest distinct pathways for the formation of these morphologies; starting with neutralization of 89−90% of the charge of naked DNA (*45*), where toroid formation is concerned, the formation of a nucleus or "static loop" precedes charge neutralization, where the dimensions of this static loop directly affect the diameter of the toroid formed (*51*, *52*). AFM has identified possible mechanisms for the formation of ringlike and flowerlike DNA (*49*) and have identified possible intermediary structures that may be precursors to the final product of condensation (*53*, *54*).

Many factors are believed govern the morphology and dimension of condensed DNA, including hydrophobicity (*55*, *56*), polymer charge, and solution pH (*57*). With such knowledge of DNA condensation, an ideal nonviral gene delivery candidate is yet to be synthesized. To this end, we investigated possible structure activity relationships of different amine-modified PVAs to investigate how they affect DNA condensation and transfection.

Our data suggest that the elongation of spacer length leads to a reduction in the mean grain size of particles (Figure 6). As the tertiary amine groups of the amine-PVA are largely responsible for the binding of polymer to DNA and subsequent condensation of DNA, it is reasonable to believe that the distance between the amine functionalities and the polymer backbone has the ability to affect these interactions. It would be expected that a long flexible spacer results in easily accessible amino functionality and hence a better adaptation to DNA. Finally, less polymer is necessary to complex the DNA, and because of the better compatibility between both components smaller particles are formed. Consistent with this view is that a polymer having shorter spacers (such as ethyl) form larger mean particles than those of hexyl spacer type (Figure 6, Table 3). Further, AFM image

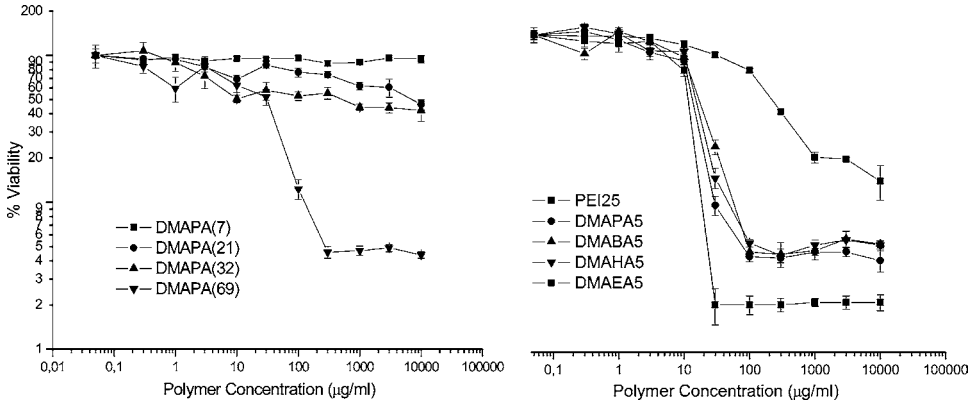

Figure 7. MTT test on L929 mouse fibroblasts: amine-modified PVA with degrees of substitution smaller than 0.2 are nontoxic (left); higher DS results in toxicity at polymer concentrations above 10 μL/mL (right).

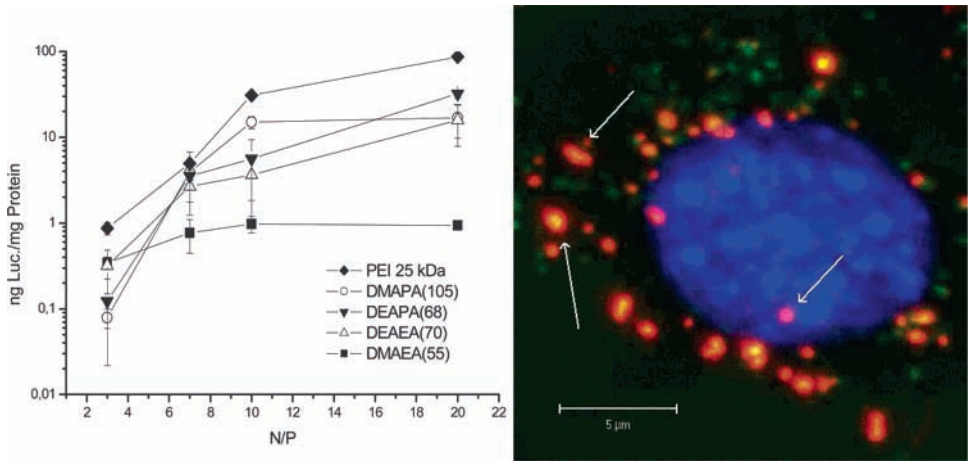

Figure 8. (Left) Transfection abilities of amine-modified PVA in the presence of chloroquin: higher degrees of amine substitution results in higher transfection abilities of the polymer; (right) the CLSM image indicates endosomes filled with PVA/DNA complexes (orange) in the nucleus plane within a NIH/3T3 cell (nucleus (DAPI, blue), polymer (FITC, green), DNA (YOYO1-DNA, red) (scale: 5 μm).

analysis demonstrated the influence of the amino protecting group where, independent of the N/P ratio, the methyl protecting groups enable amine-modified PVA to form smaller polymer/DNA particles than ethyl-protected ones (Figure 6). This effect could be a result of better accessibility to methyl protected amino groups due to lower steric hindrance. The effect of amino protecting groups on particle size seems to be more significant than that of the spacer length on particle size. These data suggest that optimal condensation would be achieved with a higher degree of amine substitution, a smaller amino-protecting group, and a longer spacer.

In MTT tests amine-modified polymers with degrees of substitutions (DS) smaller than 0.2 (20%) are nontoxic. Any increase in the DS above 0.2 results in an increased toxicity at polymer concentrations > 10 μg/mL (Figure 7). This toxicity seems to be independent of the amine type and is only dependent on DS. Apparently, charge density is the decisive factor in determining toxicity, which does not appear to be affected by the means in which it is introduced to the cell. Toxicity is therefore unspecific and a function of charge and not of structure (*58*).

Investigation of the transfection abilities of these polymers are shown in Figure 8. Increasing DS of amine leads to an overall better transfection in comparison to lower-substituted polymers. Increasing the N/P ratio leads to increasing transfection in the presence of chloroquine. Without addition of chloroquine, there is no detectable transfection. In contrast, CLSM images demonstrate an uptake of polymer/DNA particles into the cell but no release into the cytoplasm. The particles stay intact in the endosomes but they cannot leave them without the addition of chloroquine. Positive charges of polymers enable particles formed by these substances and DNA to enter cells. Indeed, this uptake process is only a part of the whole transfection mechanism. It is necessary that something enables the particles to leave the endosomes and to reach the cytoplasm and lastly the nucleus. In the literature, it is discussed that polymers such as poly(ethylene imine) (PEI) open the endosomes by a so-called proton sponge effect (*40*). This effect is based on the buffering capacity of the polymer. Because of its high density of amino groups, PEI has a huge buffer capacity and leads to an increasing influx of protons and water into the endosomes. This process finally results in a breakdown of the vesicles and release of its content into the cytoplasm. The low amine density in the synthesized PVA results in insufficient proton buffering. As a result, polyplexes are not released from the endosomes, resulting in very poor transfection. This result is not unexpected and in line with transfection efficiencies observed with other polycations such as poly-L-lysine (*59*). Further modifications of the PVA backbone using PLGA grafting have led to surprisingly efficient gene delivery systems reported elsewhere (*60*).

In conclusion, this study underscores the necessity to establish more detailed structural-activity relationships between polycations as demonstrated here for the amine-modified PVA structure and DNA morphology. Such a relationship was highlighted using PCS, AFM, and zeta-potential. Our transfection data demonstrate that the rate-limiting step for gene expression seems to be associated with endosomal escape of PVA−DNA polyplexes. The addition of chloroquine appears to circumvent this process and achieves superior luciferase expression. The results of this study clarifies that an effective transfection device needs more functionality than simply positive charges. It must also be able to leave the endosomes without addition of further substances. As demonstrated by Oster et al., the grafting of these PVA will lead to transfection efficiencies even higher than with PEI/DNA complexes (*60*).

Received April 25, 2005; Revised Manuscript Received September 8, 2005

Attempts to unravel the cell translocation mechanism of a growing number of cell-penetrating peptides (CPP) have revealed molecular determinants essential for internalization ability. The peptide sequence and the charge have been proposed to be the major factors in determining the membrane interaction mode and subsequent internalization pathway. Recent research in this field has shifted to search and design of novel CPPs with predefined vectorial properties and elucidation of the mechanism of cell entry of CPPs with high cargo delivery efficiency. Here we present a map of interaction modes with cell surface and intracellular traffic of transportan and its analogue TP10 complexed with fluorescently labeled avidin or streptavidin−gold conjugates. The protein cargo complexed with either peptide is transduced into HeLa and Bowes cells mostly in the endocytic vesicles with heterogeneous morphology and size as demonstrated by transmission electron microscopy (TEM) and confocal laser scanning fluorescence microscopy. Most of the induced vesicles are large, with 0.5−2 μm diameter, probably macropinosomes, but the complexes are present also in smaller vesicles, suggesting involvement of different pathways. Later the majority of complexes are translocated from the cell periphery into vesicles of perinuclear region and partly to lysosomes. A fraction of transportan−streptavidin complexes is present also freely in cytoplasm, both in the close vicinity of plasma membrane and more centrally, suggesting the escape from endosomal vesicles, since vesicles with discontinuous membrane were also detected by TEM. The cell-translocation process of transportan−protein complexes is temperature dependent and strongly inhibited at 8−10 °C and blocked at 4 °C when only interaction with the plasma membrane takes place.

INTRODUCTION

One of the major bottlenecks in introduction of oligonucleotide and peptide or protein-based drugs is the poor uptake of hydrophilic compounds by cells. For a decade, great expectations to overcome this obstacle were connected with cell-penetrating peptides (CPP) (also called protein transduction domains, membrane translocating sequences, or Trojan peptides), a class of 10−30 amino acid long peptides. Cationic and hydrophilic CPPs of natural and synthetic origin were first suggested to cross cellular membrane in a receptor- and temperature-independent mode (*1*−*3*). The model of direct passage of CPPs across the plasma membrane, however, has been displaced by the more cell-centered concept of mainly endocytic uptake. Evidence that the cellular uptake of CPPs and their cargoes is highly dependent on physical parameters such as temperature (*4*−*7*), charge of the peptide (*8*−*10*), and experimental conditions (*4*, *11*, *12*) has been accumulated rapidly during the past years. Taking into consideration that more than 200 peptide sequences have shown cellular delivery properties and the number is still growing, one has to assume that the details of internalization mechanisms might vary. The rapidly growing number of examples of successful CPP-mediated cargo delivery (*13*) demonstrates the potential and development in the field of application of peptidic delivery vectors for biotechnological applications. The detailed knowledge about the internalization mechanism and intracellular trafficking of CPPs and their cargoes is still of fundamental significance. Efforts to define the intracellular pathway used by different CPP−protein complexes and fusion proteins have provided controversial results. It has been shown that Tat−GFP fusion proteins are taken up by HeLa and Jurkat cell lines via lipid raft-dependent caveolar endocytosis (*14*, *15*). On the other hand, rapid internalization by lipid raft-dependent macropinocytosis without the involvement of caveolar marker protein caveolin has been demonstrated for Tat−Cre fusion protein in mouse lymphocytes (*16*). Recently, Nakase and co-workers demonstrated that the uptake of penetratin is not mediated by macropinocytosis in HeLa cells (*7*). On the other hand, slightly improved oligoarginine uptake was observed when coapplied to HeLa cells with epidermal growth factor (*7*) suggesting a macropinocytic mechanism. Macropinocytosis is an actin-mediated endocytic process initiated usually by growth factors and characterized by the membrane ruffles and outgrowth of protrusions, which collapse and fuse with the plasma membrane generating large endocytic vesicles (*17*). Macropinosomes might be dissimilar, it has been reported about the different translocation speed of Adenovirus type 2 virus (Ad2)-containing and EGF-induced macropinosomes and the shorter lifetime of former (*18*). The same group also observed the increase of Ad2 uptake by clathrin-mediated endocytosis and the reduction of viral escape from endosomes as a response

to the inhibition of macropinocytosis (*18*). It is not clear yet, whether the CPP-containing vesicular structures are of the same character/type as adenovirus- or EGF-induced macropinosomes and if the CPPs switch between the endocytic routes. The CPP-containing vesicular structures could be disrupted leading to the initiation of escape and the increased functional activity of delivered proteins as demonstrated by including membrane destabilizing sequences into fusion protein or exposing cells to multifunctional peptides containing both a CPP and the membrane disrupting motif (*16*, *19*). The polyarginine−peptide conjugates labeled with the fluorescent dye molecule are released from vesicular structures upon irradiation at an appropriate wavelength (*20*). Although it might provide a potentially useful technique for increasing the efficiency of CPP-mediated delivery of active cargoes, the mechanism of photo-destabilization of vesicular membranes is not well understood and the putative toxic effects of this method are not evaluated yet. Therefore, application of CPPs with intrinsic membrane-destabilizing properties is still of interest. One of the potential membrane-interacting peptides is transportan, a 27 amino acid long chimeric peptide (*21*), the C-terminal part of which has helical structure both in the aqueous environment and in the presence of lipid vesicles (*10*) and interacts with phospholipids using the hydrophobic face of the α-helix (*22*). Transportan has been demonstrated to be an efficient carrier for PNA (*23*), fluorophore-labeled peptide (*24*), and protein (*12*). One possibility to explain the high delivery efficiency of MAP (*24*) and transportan is the more efficient escape from vesicular structures as compared to penetratin and Tat peptide due to stronger interaction with membrane lipids. Therefore, the more detailed analysis of internalization and cellular trafficking of transportan are of interest. Since transportan modulates the activity of membranous G-proteins at high concentration (*21*), an analogue TP10, with no effect on the activity of GTPases, was designed (*25*). The cellular uptake and fate of CPPs and their cargoes has been mainly studied by using fluorescence or activity-based methods. The vesicular structures mediating the cell entry of CPPs are specified either by looking for colocalization with the respective marker proteins or by specifically inhibiting a certain type of endocytic process. Visualization on ultrastructural level might be helpful in characterizing the sites of initial interaction of CPPs with the plasma membrane or membrane-bound extracellular structures, changes of membrane morphology, size and shape of vesicular structures hiding CPPs, etc. Therefore, we used a preembedding labeling procedure and transmission electron microscopy (TEM) to visualize protein cellular delivery by transportan and TP10. The cellular uptake and trafficking of biotin−CPP complexes with colloidal-gold-labeled streptavidin was characterized after fixation and embedding of cells by TEM. The results obtained by electron microscopy in fixed cells were compared with confocal laser scanning microscopy (CLSM) data in living cells using analogous experimental setup, i.e., by using the complexes of biotin−CPP with fluorescently labeled avidin.

MATERIALS AND METHODS

Peptide Synthesis. Transportan (GWTLNSAGYLLGKINLKALAALAKKIL-amide) and TP10 (AGYLLGKINLKALAALAKKIL-amide) were synthesized stepwise on a 0.1 mmol scale on an automated peptide synthesizer (Applied Biosystems Model 431A) using the *t*-Boc solid-phase peptide synthesis strategy. *tert*-Butyloxycarbonyl amino acids were coupled as hydroxybenzotriazole esters to a *p*-methylbenzylhydrylamine resin (Neosystem, Strasbourg, France) to obtain C-terminally amidated peptides. Biotin was coupled to the side-chain of Lys^{13} or Lys^{7} in transportan and transportan 10, respectively, as previously described (*12*). The final cleavage and purification of peptides was performed, as described (*12*). The molecular weights of biotinylated peptides were determined by MALDI-TOF mass spectroscopy (Voyager STR).

Cell Cultures. The human breast cancer cell line HeLa (ATCC CCL-2) and the human Bowes melanoma cells (ATCC CRL-9607) were cultivated in a humidified atmosphere containing 5% CO_2 at 37 °C in Iscove's Modified Dulbecco's Medium (IMDM) or in Dulbecco's Modified Eagle's Medium (DMEM), respectively. Culture medium was supplemented with 10% fetal calf serum (FCS), 100 IU/mL penicillin, and 100 μg/mL streptomycin.

Delivery of Streptavidin−Gold into Cultured Cells by Biotinyl−Transportan and Biotin−TP10. The cells used for experiments were grown for 2 days on round Thermanox tissue culture coverslips (diam 13 mm, Electron Microscopy Science, Fort Washington, PA) in 24-well plates to 80−100% confluence. The stock solution of biotin−transportan (1 mM) was treated with 10 mg/mL L-leucine in a minimal volume for 5 min at room temperature in order to dissociate the multimers of peptide. The biotinylated transportan or TP10 was complexed with streptavidin−gold (d 10 nm, Amersham Pharmacia Biotech, UK) for 3 min, diluted with the respective culture medium and applied to cells. Cells were incubated with the complexes of 25 or 5 μM biotin−transportan or -TP10 and streptavidin−gold (1:50 dilution) at 10, 20, or 37 °C for 20 min to 72 h depending on the experiment.

Labeling of Transferrin with Colloidal Gold. The colloidal gold solution of particles with 20 nm diameter was prepared, and absorption of transferrin was performed essentially as described earlier by Bendayan (*26*). Briefly, the gold sol was prepared by adding 1.5 mL of 1% sodium citrate solution to 100 mL of boiling solution of 0.01% $HAuCl_4$ dropwise over 5 min and boiling the mixture for 5 min. The resulting gold colloid was coated with 2.5 mg transferrin (Sigma, dissolved in 2 mL of water) at room temperature for 30 min. Transferrin−gold was stabilized with 1 mg/mL PVP40, 0.5 mg/mL PEG20000, and 0.5 mg/mL BSA and harvested by centrifugation at 10000*g* for 1 h at 4 °C. The residual free protein and aggregated material was removed by centrifugation at 5000 rpm for 45 min in discontinuous gradient of 10, 30, and 50% glycerol in PBS in a SW41 rotor. The most intensely colored fraction of transferrin−gold with homogeneous particle size was collected and stabilized for storage with 2% PVP (poly(vinylpyrrolidone)), 0.2 mg/mL PEG and 0.05% NaN_3.

Comparative Uptake of Transferrin and Transportan−Streptavidin Complexes by HeLa Cells. HeLa cells were grown on Thermanox coverslips in 24-well plates as described above. The nearly confluent cell layer was washed twice with serum-free IMDM and incubated in serum-free culture medium for 1 h in order to upregulate the transferrin receptors on plasma membrane (*27*). The starved cells were incubated with complexes of 25 or 5 μM biotin−TP and 1:50 dilution of streptavidin−gold (10 nm) along with the transferrin−gold complex (20 nm) at 1:50 dilution in serum-free IMDM in CO_2 incubator at 37 °C for 30 min. In some experiments cells were first incubated with TP−streptavidin complexes for 30 min, and then the solution

containing complexes was removed and replaced with the culture medium with gold-labeled transferrin and incubated for an additional 30 min. An analogous experiment with reversed order, first transferrin followed by TP−streptavidin complexes, was also carried out.

Electron Microscopy. Cells were fixed for transmission electron microscopy with 3% glutaraldehyde in 0.1 M sodium cacodylate-HCl buffer (pH 7.3) containing 0.05 M sucrose for 1−2 h. After being rinsed with cacodylate buffer, the cells were postfixed with 1.5% osmium tetraoxide in the same buffer containing 0.7% potassium ferrocyanate at 4 °C for 30 min and dehydrated in ethanol series from 50% up to 96%. Cells on Thermanox coverslips were embedded in epoxy resin, and the material was cut into ultrathin sections of 40−60 nm by using the Reichert Om U2 ultramicrotome. The sections were collected on grids and stained with 2% uranyl acetate in 50% ethanol and lead citrate according to instruction (*28*). Microtomed sections on the grids were examined and the images recorded by using a JEM-100S (JEOL, Japan) electron microscope. The scanned electron microphotos were analyzed and processed with Adobe Photoshop version 7.0 software.

Fluorescence Microscopy Experiments with Live Cells. HeLa cells (8×10^3) were seeded onto eight-well chambered coverglasses (Nalge Nunc International, Rochester, NY) 2 days before uptake experiments. The glasses were coated with collagen−fibronectin solution (10 μg/mL fibronectin, 30 μg/mL collagen, 0.01% bovine serum albumin, 100 IU/mL penicillin, and 100 μg/mL streptomycin in DMEM) for 30 min before seeding the cells. Cells were incubated with the complexes of 0.15 μM Alexa Fluor (AF) 488 labeled avidin (Molecular Probes, Leiden, Netherlands) and 0.5 or 1 μM biotin−CPP in serum free IMDM for 1 h at 37 °C. The incubation solution was supplemented with 25 μg/mL transferrin (labeled with AF 594, Molecular Probes) or 150 nM Lyso Tracker Red DND-99 (Molecular Probes) depending on experiment. For visualizing the Golgi apparatus, the cells were incubated with 0.5 μM BODIPY-TR-C_5 ceramide complex with BSA (prepared according to manufacturer's instructions, Molecular Probes) in serum free IMDM for 30 min before applying peptide−avidin complexes into the same medium. After 1 h incubation, the medium with CPP−avidin complexes and the markers of cellular organelles was removed and the cells were rinsed with PBS (containing 1 mM of $CaCl_2$ and 0.5 mM $MgCl_2$) followed by a brief rinse with 0.05% trypan blue in PBS and two additional washing steps with PBS. Cells were covered with calcium and magnesium-supplemented PBS, and the serial images from live cells were recorded using the laser confocal scanning microscope MRC-1024 with excitation at 488 and 568 nm (Bio-Rad Laboratories, Hercules, CA). To avoid cross-talk between the channels, emission signals were collected independently. Obtained images were processed with Adobe Photoshop version 6.0 software.

Fluorescence Microscopy Experiments with Fixed Cells. HeLa cells (2×10^4) were seeded 2 days before experiment on round glass coverslips into 24-well plate. Incubation with peptide−protein complexes was performed in serum-containing (10% FCS) medium. For the pulse-chase study, the medium with complexes was replaced after 1 h by media containing no complexes for 4 or 24 h according to the experiment. Before applying fresh media, the cells were rinsed twice in PBS to completely remove the nonassociated complexes. Cells were fixed for 20 min in 4% paraformaldehyde on ice, followed by 5 min permeabilization in 0.1% Triton X-100 in PBS. Nonspecific binding sites were blocked with 10% (w/v) nonfat dry milk solution in PBS for 30 min. Lysosomes were visualized with 1:50 (hybridoma supernatant) solution of LAMP2 primary antibody and 10 μg/mL AF 594-labeled goat anti-mouse secondary antibody. For revealing the actin fibers, cells were stained with 30 nM Texas Red-labeled phalloidin. Images were recorded using the laser confocal scanning microscope or Olympus BX61 microscope equipped with CCD camera DX70.

RESULTS

Association of Transportan−Streptavidin Complexes with the Cell Surface. To characterize the cellular delivery of proteins by transportan peptides, we followed the uptake of noncovalent complexes of biotin−transportan (or biotin−TP10) with streptavidin−gold by electron microscopy. The complexes between the biotin−CPP and gold-labeled streptavidin form quickly and were assembled by coincubating the respective components before applying to cells. The association of transportan− and TP10−protein complexes with the cell surface was examined in HeLa and human Bowes melanoma cells, which slightly differ in morphology. The surface of HeLa cells was usually more structured, possessing protrusions, long filopodia, and smaller microvillar extensions, whereas Bowes cells had a rather smooth plasma membrane with fewer protrusions and long extensions spread only between adjacent cells. The peptide−protein complexes associated quickly with the surface of the cells, already upon a 5−10 min incubation and were detectable by electron microscopy between the cells mostly as elongated structures of 0.4−2 μm on the electron dense background (Figure 1A−C). The initial interaction of transportan−streptavidin complexes induced formation of a small pit in the plasma membrane (Figure 1A). The aggregates were more typical for the complexes with transportan rather than with TP10. Formation of big peptide−protein aggregates was reduced by hindering the multimerization of transportan during formation of complexes with gold-labeled streptavidin by using leucine. The cells incubated with such "dissociated" complexes at 3 μM peptide concentration resembled the complexes of TP10 and showed significantly lower degree of aggregation (Figure 1D). The smaller aggregates but not the extensive agglomerates still formed, and the complexes were distributed more diffusely on the protrusions of cells. The peptide−protein complexes preferentially associated with filopodia and extensions of plasma membrane in HeLa cells. A smaller fraction of complexes associated with the flat areas, and most of these seemed to be in close contact with the lipids of the plasma membrane.

Transportan−Avidin Complexes Associate with Membrane Protrusions and Actin Cytoskeleton. The nature of membrane protrusions involved in the transportan-mediated protein internalization was further assessed by confocal microscopy in cells with visualized actin. Staining of actin cytoskeleton with Texas Red-labeled phalloidin revealed highly structured morphology of HeLa cells' plasma membrane with numerous protrusions. The protrusions were most abundant between the neighboring cells and oriented parallel bridging the cells, whereas thinner and more heterogeneous microspikes were observed in other regions of cellular membrane (Figure 2A). Transportan−avidin complexes docked to the intercellular membrane protrusions starting from 5 min incubation (data not shown). After 1 h incubation, the complexes were detected as punctate structures abundantly decorating the actin-filament-containing mem-

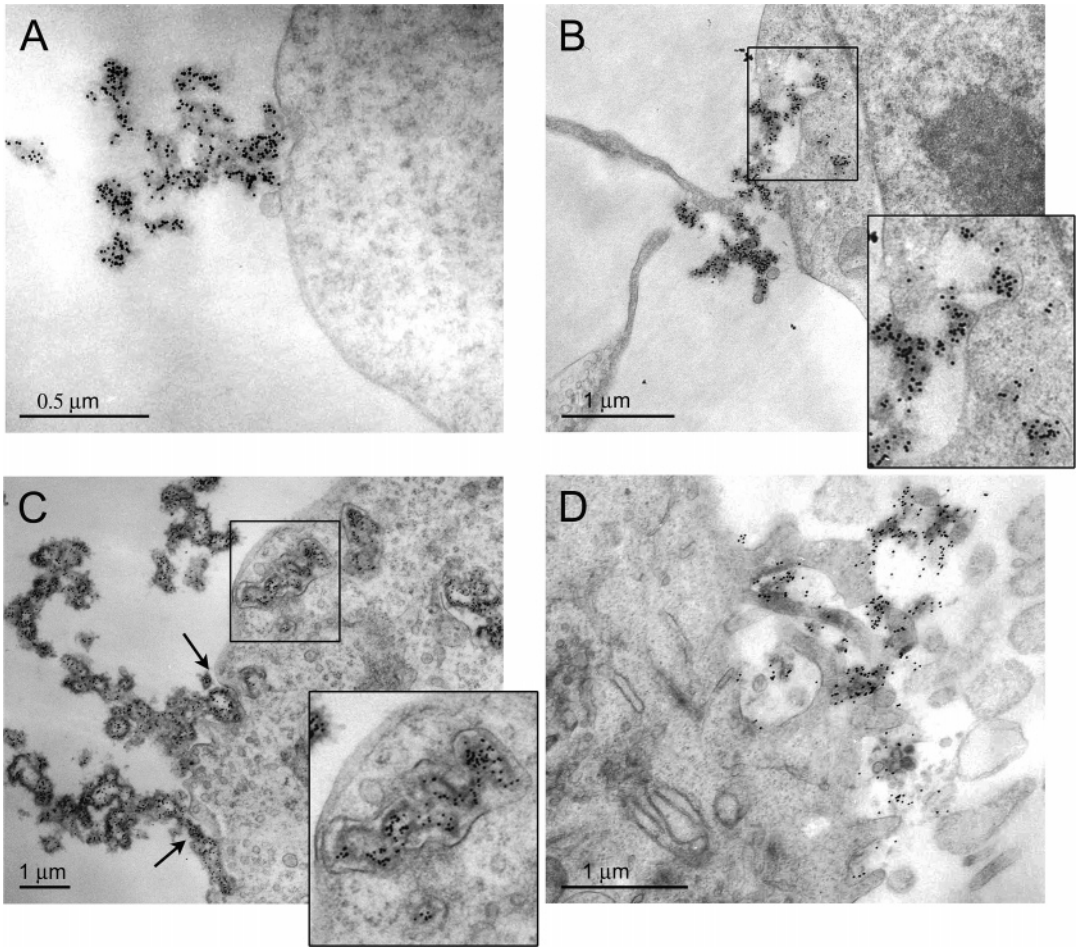

Figure 1. Interaction of CPP−protein agglomerates at the plasma membrane of cells. Human Bowes melanoma cells incubated with the complexes of gold-labeled streptavidin (10 nm, dilution 1:50) and 5 μM biotin−transportan for 30 min (A, B) or 2 h (C). HeLa cells (D) incubated for 1 h with the complexes of streptavidin−gold (10 nm, 1:50) and 2.5 μM biotin−transportan, treated with leucine (10 mg/mL) before complexing with protein−gold.

brane protrusions. The colocalization of peptide−protein complexes with actin fibers was detected also in the cortical cytoplasm of cells where actin filaments were packed less densely (Figure 2A). This suggests that intracellular translocation of peptide−avidin complexes might at least partially be mediated by actin cytoskeleton.

Morphology of the Plasma Membrane Changes upon Internalization of Transportan−Streptavidin Complexes. Streptavidin−gold complexes with transportan or TP10 entered the cells by using at least two morphologically clearly distinguishable mechanisms. First, docking of larger CPP−protein aggregates induced morphological changes in the plasma membrane leading to the formation of membrane invaginations (Figure 1B−D). Later the complexes shifted deeper into the cytoplasm, being finally fully engulfed by the cell into endocytic vacuoles (arrows in Figure 1C and enlarged sections of Figure 1B and C). The membrane bound aggregates seemed to repulse or force the indentation of plasma membrane. Various cell surface extensions were frequently involved in the translocation process as demonstrated in Figure 1B and D. The second mode of internalization was characteristic for smaller complexes containing few or a single gold particle, which did not induce detectable changes in the membrane morphology upon interaction with the plasma membrane (arrows in Figure 3A and the enlarged section of Figure 3A and B). Later the complexes with a single gold particle were also detectable in cortical cytoplasm, and changes in morphology of plasma membrane were not observed (Figure 3C). The second mode was not the major cell entry mechanism of streptavidin−gold complexes and was more characteristic for TP10 than transportan complexes and at the lower concentrations of peptide. It has to be mentioned that despite the differences in HeLa and Bowes cells morphology, both internalization modes were observed in both cell lines.

Distribution of Protein Delivered into Cells by Transportans. Streptavidin−gold complexes with transportan or TP10 were detectable in the cortical cytoplasm of Bowes and HeLa cells already after 10 min of incubation with complexes at 37 °C. Later in 1−2 h, transportan−streptavidin complexes spread over the cytoplasm, including the perinuclear region. The cell-transduced peptide−protein aggregates resided mainly in vesicular structures of irregular shape and varying diameter of 0.5−2.0 μm, which primarily seemed to depend on the size of internalized aggregate (Figure 4). The gold particles localized mostly in large vacuoles of 0.5−1.0 μm and in the multivesicular relatively spherical structures of 200−300 nm in diameter (large arrows in Figure 4A and B), the latter resembling the structures of endosomal−lysosomal pathway. Some complexes were present in long tubulovesicular structures, which were more typical for Bowes cells (Figure 4C and small arrow in Figure 4A). The complexes containing vesicles in HeLa cells were more homogeneous and spherical with maximal diameter of 0.3−0.5 μm. A small fraction of peptide−protein complexes was also present in small caveosome-

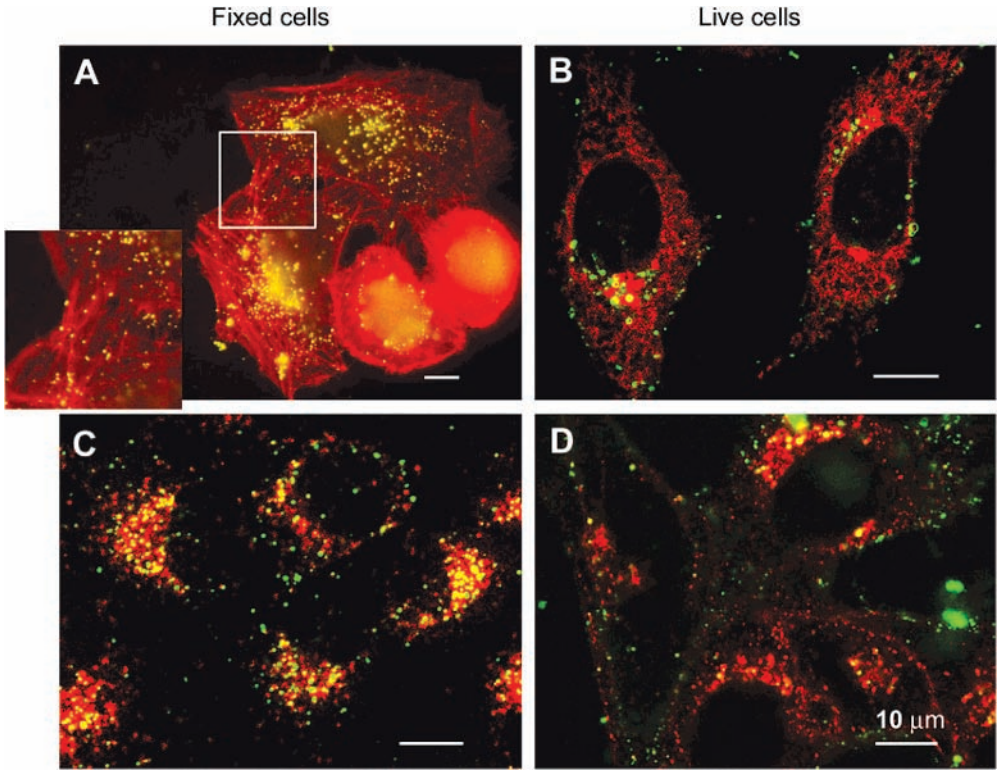

Figure 2. Localization of peptide−avidin complexes in relation to the actin cytoskeleton and organelles. Complexes of 1 μM (A) or 0.5 μM (B−D) biotinylated transportan with 0.15 μM AF 488-labeled avidin in HeLa cells after 1 h incubation (green). Actin fibers were stained with 30 nM phalloidin−Texas Red (A). Coincubation of cells with TP−avidin complexes with 0.5 μM BODIPY-TR-C_5 ceramide (B) or 50 μg/mL AF 594-labeled transferrin (D) was performed to reveal Golgi apparatus, and endosomes, respectively. Pulse-chase study: cells were incubated for 1 h with TP−avidin complexes, followed by a 24 h chase period. Lysosomes were visualized by staining with LAMP2 antibody and AF 594-labeled anti mouse antibody (red) (C). Colocalized structures are visible as yellow. Fluorescence microphoto of HeLa cells (A) and confocal sections at the equatorial level of nuclei (B−D).

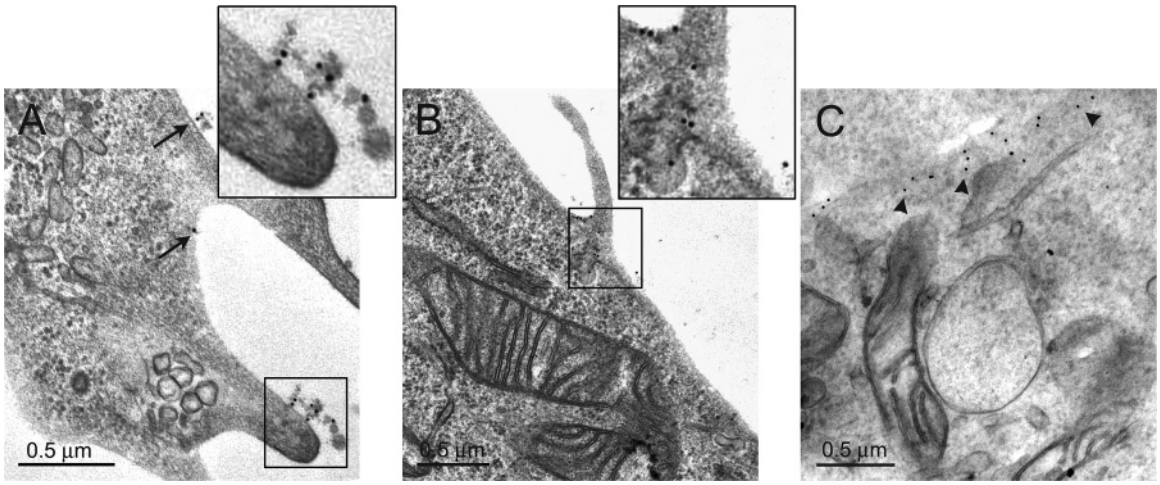

Figure 3. Nonaggregated CPP−protein complexes associate directly with the plasma membrane. HeLa cells incubated for 1 h with streptavidin−gold (10 nm, 1:50) complexed with 2.5 μM biotin−transportan (A, B) or biotin−TP10 (C) in the presence of leucine.

like vesicles of about 100 nm diameter or less (arrowhead in Figure 4A). Most of the complexes containing vesicles in HeLa cells were intact and surrounded by a continuous membrane. However, some of the vesicles that contained peptide−protein complexes had a discontinuous membrane, and the electron density of the vesicle content was undistinguishable from that of cytosol (arrows in Figure 4C). Moreover, considerable part of gold particles was spread apparently free in cytosol, often in the close proximity of vesicles with discontinuous membrane as indicated by the arrowheads in the enlarged section of Figure 4C. One might assume that the membrane was destabilized by transportan or TP10, and some vesicles were broken enabling the escape of complexes into cytosol.

Data obtained by electron microscopy were complemented by analogous experiments using the confocal laser scanning microscopy for analyzing the localization of biotinylated transportan complexed with AF 488-labeled avidin. After 1 h incubation, the transportan−avidin complexes localized in living cells in a punctate manner mostly at the cellular membrane or in the cortical cytoplasm but also in the perinuclear area (Figure 2B−D). However, fluorescent punctate structures

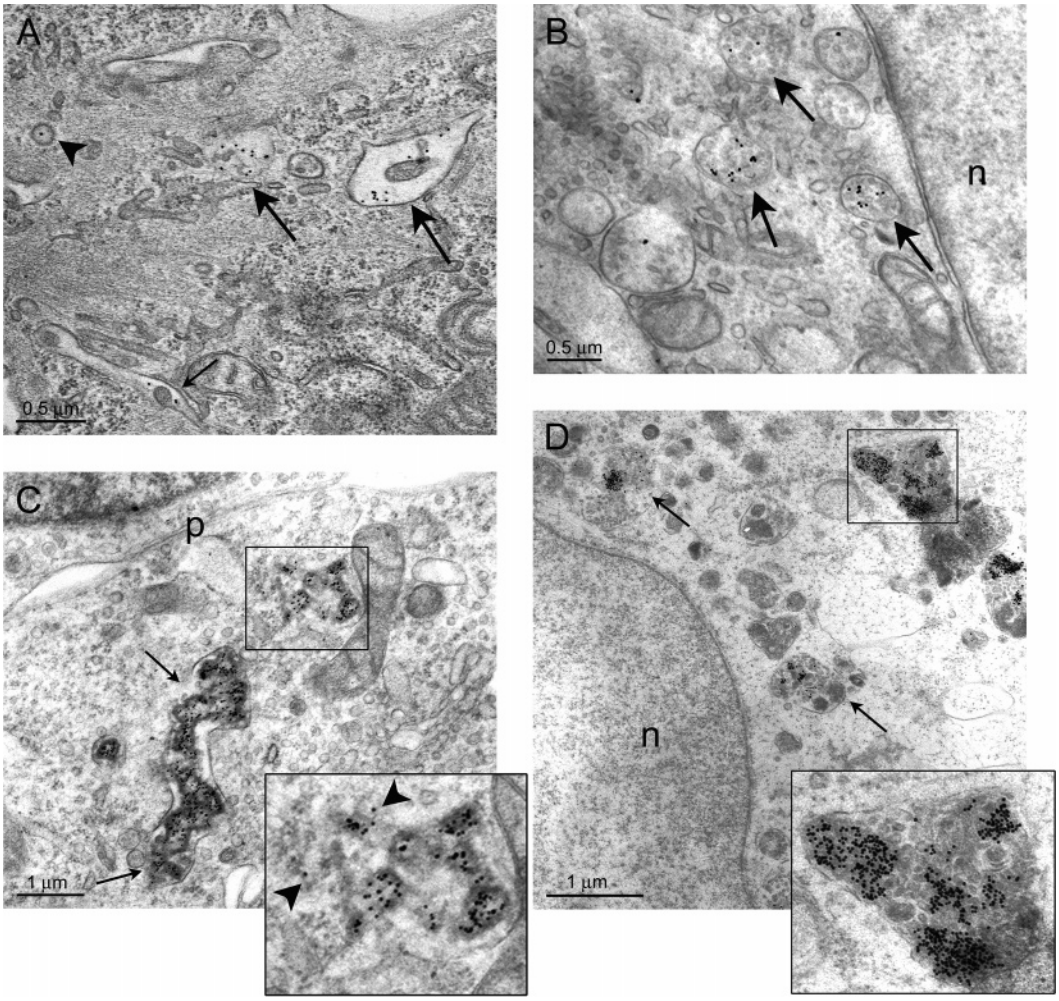

Figure 4. Localization of CPP−protein complexes in the cells after incubation at 37 °C. HeLa cells (A, B) incubated for 1 h with streptavidin−gold (10 nm, 1:50) complexed with 3 μM biotin−transportan (A) or 2.5 μM biotin−TP10 (B) in the presence of leucine. Bowes cells (C, D) incubated with the complexes of streptavidin−gold (10 nm, 1:50) and 5 μM biotin−transportan for 2 h (C) and 72 h (D). p = plasma membrane; n = nucleus.

were different—spherical aggregates with the higher diameter concentrated to the perinuclear area into one or two centers, whereas smaller dots were distributed in the cortical cytoplasm (Figure 2A−D). Some big fluorescent aggregates were attached to the cellular membrane, and very few were occasionally moving freely in the extracellular media. Large aggregates probably resulted from the multimerization of the peptide and the assembly of the formed complexes into bigger agglomerates, which was observed also at higher peptide concentrations in electron microscopy experiments (Figure 1A−C). Some agglomerates were not in contact with the cells, and their presence in the media after many washing steps suggests that initially membrane-bound aggregates could detach during treatment/visualization.

CPP−Protein Complexes Accumulated in the Perinuclear Area of Cells upon Extended Incubation at 37 °C. To find out whether the cell-transduced protein is later mainly directed to the cellular degradative pathway or remains in the cytoplasm, we extended the incubation of Bowes cells with transportan−streptavidin complexes to 2 days or longer. After 20−72 h, peptide−protein complexes were concentrated in structures resembling late endosomes and lysosomes as observed by electron microscopy (enlarged section and arrows in Figure 4D). However, some gold particles were still scattered diffusely in the cytoplasm. Upon extended incubation of the cells with the complexes, the amount of gold particles was significantly increased, especially in the perinuclear region, confirming the continuous uptake for more than 4 h (*12*). Our data indicated that some complexes of CPP−protein retained intactness for at least several hours before accumulation to the degradative organelles after 20 h. The intracellular trafficking of peptide−protein complexes in relation to structures of the degradative pathway was studied by visualizing the plasma membrane and Golgi complex with BODIPY TR C_5-labeled ceramide and acidic intracellular vesicles, including lysosomes, with Lyso Tracker Red DND-99. Fluorescent ceramide derivative inserts into the plasma membrane of live cells and is preferentially targeted to the Golgi apparatus. After incubating HeLa cells with TR−ceramide, the whole cell cytoplasm exhibited reticular staining reminiscent with the endoplasmic reticulum. Labeled ceramide concentrated also into one or two perinuclear centers probably in Golgi apparatus (Figure 2B). The transportan−avidin complexes showed, after translocation into the HeLa cells, a partial colocalization with TR−ceramide in perinuclear areas (Figure 2B). Specific accumulation of transportan−avidin complexes in the reticular structures of cytoplasm was not observed. Lyso Tracker intensely stained the perinuclear area of the HeLa cells and some cortically localized vesicles, but the entire cell area fluoresced weakly red probably due to nonspecific interaction with other membranous structures. Localization of transportan−avidin complexes

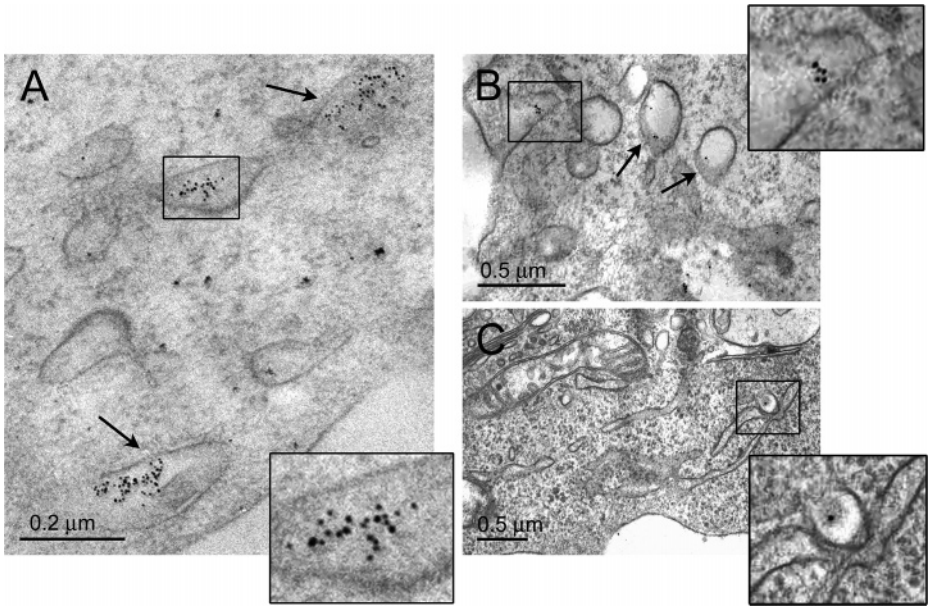

Figure 5. Interaction of CPP−protein complexes with plasma membrane of cells and internalization at 10 °C. Bowes (A) or HeLa (B, C) cells were incubated with complexes of 5 μM biotin−transportan (A, B) or 3 μM biotin−TP10 (C) with 5 nm (A) or 10 nm (B, C) streptavidin−gold (1:50) for 1 h at 10 °C.

taken up by the cells and Lyso Tracker overlapped partially only in large vesicles of the perinuclear area (data not shown). A more specific staining of lysosomes in HeLa cells was achieved with antibody specific to lysosome-associated membrane protein-2 (LAMP2). For enlightening the intracellular targeting of peptide−protein complexes in time, we performed pulse-chase experiments by growing the cells for 4 or 24 h in culture media after a 1 h pulse with complexes of transportan and avidin. After a 4-h chase, the fraction of complexes in lysosomes was not substantial (data not shown). However, after a 24-h chase, the amount of complexes inside the HeLa cells had markedly increased, suggesting the continuing accumulation of internalized complexes (Figure 2C) corroborating the data obtained by electron microscopy. Colocalization of transportan−avidin complexes with lysosomes was detected mostly in the perinuclear region including some very big vesicular structures. However, even after a 24 h chase, a fraction of complexes-containing vesicles retained their localization distinct from the degradative organelles marked by LAMP2 antibody (Figure 2C).

Translocation of CPP−Streptavidin Complexes into HeLa and Bowes Cells Is Not Blocked at 10 °C. The pinocytosis and receptor-mediated endocytosis are the potential cellular uptake mechanisms of large molecular structures. Endocytosis occurs usually within minutes to several hours and is cellular-energy-dependent. In general, if the temperature is lowered below 18 °C, endocytosis is considered to be blocked, and also the flexibility and the fluidity of plasma membrane is drastically reduced (*29*) and the membrane traffic is slowed (*30*). We evaluated whether peptide−protein complexes could enter the cultured cells at the endocytosis abolishing temperatures, e.g. 8−10 °C. After incubation of Bowes or HeLa cells with complexes of biotin−transportan and streptavidin−gold for 1 h at 10 °C, the gold particles were clearly detectable attached at the plasma membrane but also in the vesicular structures of cortical cytoplasm. The amount of internalized complexes at 10 °C was markedly lower compared to the complexes visible at the physiological conditions but still clearly detectable by electron microscopy. As demonstrated in Figure 5, transportan−streptavidin complexes resided mainly in rather small spherical vesicles of 0.2−0.3 μm diameter (arrows in Figure 5A and B) and localized at the plasma membrane of cells (enlarged section of Figure 5B). TP10−protein complexes were mostly localized randomly as single particles near the plasma membrane or very rarely in vesicles in the peripheral cytoplasm (enlarged section of Figure 5C). In addition, no big agglomerates of peptide−protein complexes formed nor were large cell surface invaginations observed at 8−10 °C. Thus, under the conditions of cellular energy deficiency, the cellular uptake of biotin−transportan complexes with streptavidin−gold was not completely abolished, but the formation of very big vesicular structures and their further translocation toward the cell center were strongly inhibited, as the complexes were detected only in the cortical cytoplasm. On the contrary, at 20 °C, the transportan−streptavidin complexes were distributed in the cells in vesicular structures analogously as observed at the physiological temperature. Still, the amount of complexes in cells was lower, and the large membrane invaginations so typical to physiological temperature were almost missing (data not shown).

Cellular Uptake of Transportan−Streptavidin Complexes Is Abolished at 4 °C and Lower Temperature. Although the internalization of CPP−protein complexes was diminished at 8 °C, we assessed whether transportan or TP10 could transduce streptavidin−gold into cells at 0−4 °C also. After incubation of the cells with transportan−streptavidin complexes on ice for 1 h, only a negligible amount of gold particles had associated with the plasma membrane. Association of transportan−streptavidin complexes with the plasma membrane was rather rare, and no complexes were detected in the cells. The absence of uptake at 4 °C suggests the prevalence of energy-dependent processes in the internalization of peptide−protein complexes. However, some complexes of streptavidin−gold with transportan or TP10 translocated into cells even at 10 °C support the ideas about uptake pathways that are active at low temperatures (*31*) also.

Cellular Uptake of Transportan−Streptavidin Complexes in Parallel with Transferrin. Our results indicate that CPP−protein complexes are taken up by

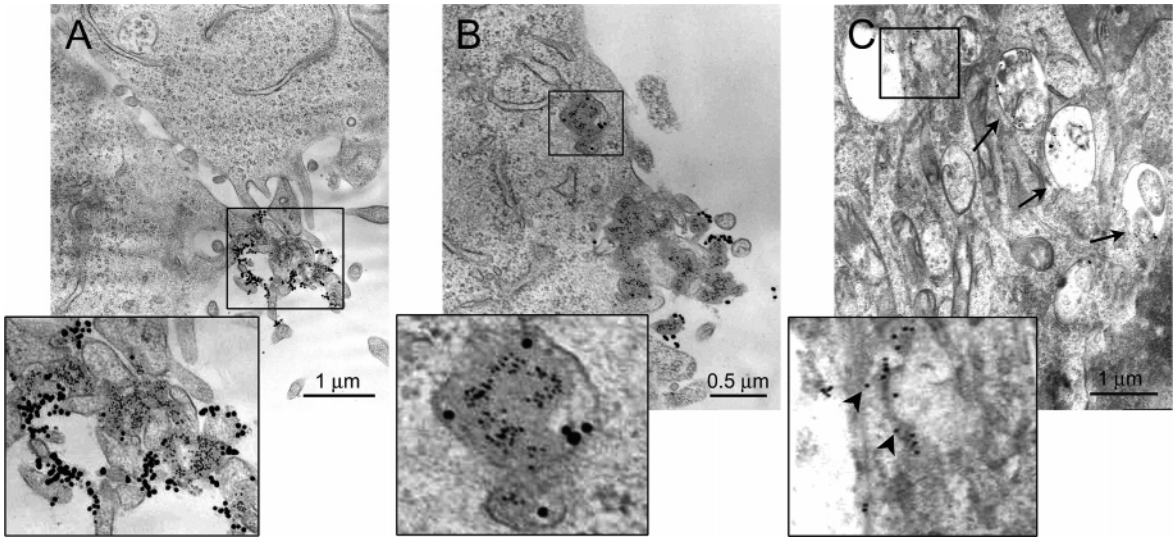

Figure 6. Colocalization of transferrin and CPP−protein complexes in HeLa cells. Cells were incubated in serum free culture medium containing the complexes of streptavidin−gold (10 nm, 1:50) with 5 μM (A, B) or 2.5 μM (C) biotin−transportan, and 20 nm gold-labeled transferrin (1:50) at 37 °C for 1 h.

the cells mainly via temperature-dependent endocytic pathways that originate from the cell membrane invaginations and result in the formation of cellular vesicles of different shape and size. Transferrin, an iron-transport protein, is known to be internalized via clathrin-coated pits and vesicles (*32*). To assess whether this endocytic pathway is involved in the internalization of transportan−streptavidin complexes, we tested the putative colocalization of internalized complexes with transferrin. Prior to the addition of the peptide−protein complexes, HeLa cells were first incubated with serum-free culture medium for 30 min to induce the targeting of transferrin receptors to the plasma membrane (*27*). Transferrin, tagged with colloidal gold, induced the formation of clathrin-coated pits and the respective vesicles and in addition associated with the terminals of microvilli and filopodia. Cells incubated with the peptide−streptavidin complexes labeled with a 10 nm gold particle along with a 20 nm gold particle-tagged transferrin in serum-free medium for 30 min revealed no specific colocalization of these proteins. Still, in some areas at the plasma membrane and cellular vesicles, location of transferrin and transportan−streptavidin complexes overlapped. Complexes of streptavidin with TP10 showed less colocalization with transferrin than transportan complexes. The ultrastructural analysis, however, revealed that if transportan−protein complexes and transferrin were used at high concentrations (respectively 5 μM biotin−transportan and 1:25 transferrin−gold), colocalization on the plasma membrane was prevailing. As shown in Figure 6A and B, transferrin associated mainly with the regions of plasma membrane where peptide−protein complexes had concentrated—preferentially at the protrusions and also on smooth areas. Inside the cell, both the peptide−protein complexes and transferrin molecules were usually confined to the same big vacuoles of 0.5−1 μm diameter in the cortical and perinuclear cytoplasm (enlarged section of Figure 6B and arrows in Figure 6C). Some peptide−protein complexes localized in cytoplasm/cells without transferrin as indicated by arrowheads on the enlarged section of Figure 6C. Distribution of peptide−protein complexes in the cells coincubated with the gold-labeled transferrin was very similar to that observed in cells treated with the complexes only, whereas the localization of transferrin at the plasma membrane and inside the cells was radically altered by coincubation with transportan−streptavidin complexes. The colocalization of CPP−protein complexes with transferrin was observed mainly at higher concentrations. Surprisingly, a considerably lower number of transferrin−gold particles associated with the cells incubated with transferrin only as compared to the cells coincubated with transportan−streptavidin complexes (data not shown). In addition to peptide-streptavidin complexes, transportan also induced increased association of transferrin with the plasma membrane and subsequent uptake. In principle the cationic transportan might associate at high concentration with anionic transferrin and increase association with the plasma membrane and the uptake of transferrin by cells.

To exclude the putative association of transportan with transferrin in solution or at the plasma membrane, we incubated cells with these consecutively. Cells were first incubated with TP−streptavidin complexes for 30 min, washed several times, and then incubated with transferrin−gold complexes for an additional 30 min. An analogous experiment with reversed order of incubations was also performed. Under these conditions, no noticeable colocalization was detected between transferrin and transportan−protein complexes (data not shown). In the cells, transferrin and peptide−protein complexes localized mainly to different vesicular compartments, whereas a fraction of both was colocalizing in a certain type of vesicular structures, probably in late endosomes. This suggests that transportan−streptavidin complexes are taken up to large vesicular structures and that this pathway does not overlap with the well-characterized clathrin-mediated endocytic pathway of the transferrin receptor. However, during later targeting, the structures containing peptide−protein complexes may fuse with multivesicular bodies on their way to lysosomes.

The involvement of receptor-mediated endocytosis in the internalization of peptide−avidin complexes was proven by confocal microscopy as well, following their cellular uptake in the culture medium containing AF 594-labeled transferrin. After 1-h incubation, transferrin had concentrated in a punctate manner in the cytoplasm of cells with more intense signal in the vesicular structures of perinuclear area (Figure 2D). Structures containing transportan−avidin complexes rarely overlapped with

the transferrin-positive vesicles in the cortical cytoplasm and were usually less abundant, whereas in larger perinuclear vesicles the colocalization with transferrin was more common but still not prevailing (Figure 2D).

DISCUSSION

The power of cell-penetrating peptides to transduce various payloads of very different nature and size into living cells in culture and in animal models has found rapidly growing application (*13*). Despite intense studies during the past decade, the cell entry mechanism of "Trojan peptides" has remained elusive (*33*), though several cellular pathways have been demonstrated to be involved in the uptake of CPPs (*4*, *14*−*16*, *31*, *34*−*37*). We characterized the uptake and cellular whereabouts of proteins complexed with delivery peptides transportan and TP10 by transmission electron microscopy and confocal fluorescence microscopy. Electron microscopy reveals that the complexes of gold-labeled streptavidin with biotin−transportans are mostly detectable as elongated agglomerates on the electron-dense background associating with the plasma membrane of the cells frequently at the cell surface extensions, microspikes and filopodia. Since large aggregates of peptide−protein complexes formed only at higher peptide concentration (5 μM) and were more typical for transportan rather than TP10−protein complexes, the aggregation might be caused by multimerization in solution (*21*). Complexation of biotin−transportan at 0.5−1 μM concentration with avidin did not induce formation of aggregates as observed by fluorescence microscopy, whereas by increasing the peptide concentration the size of cell-associating assemblages also increased. Peptide−protein complexes associated with the cellular surface were mostly on the electron dense background, which was not present when the complexes were assembled in solution in the absence of the cells. Therefore, the electron dense material is obviously of cellular origin and may represent exoplasmic membrane proteins or cell surface proteoglycans. Considering the role of proteoglycans in cell−cell and cell−matrix interactions (*38*, *39*), in peptide-mediated cellular transduction (*35*, *40*, *41*) and strong interaction of cationic CPPs with heparan sulfates (*42*), the interaction of transportan−protein complexes with the cell surface proteoglycans is highly probable.

The mechanisms used by CPPs to translocate into mammalian cells may vary in different cells and between peptides; so far endocytosis via clathrin-coated pits (*34*, *43*) and via lipid rafts (*14*, *40*) have been suggested. In parallel, macropinocytosis has been proposed as a route for CPPs translocation (*7*, *16*). Macropinocytosis is a lipid raft-mediated, clathrin- or caveolae-independent endocytic process (*44*), which starts with the induction of actin-dependent lamellipodia and membrane ruffling leading internalization of extracellular material into the macropinosomes of 1 μm or greater. The results obtained by electron microscopy reveal that transportan−streptavidin complexes associated with the extensions of cell surface and induced invaginations of the plasma membrane are reminiscent of the changes preceding the macropinocytosis of some pathogenic bacteria (*45*, *46*). The vacuoles formed in the cytoplasm could fuse with lysosomes or release their content into the cytosol (*17*). Our results demonstrate that the cell-transduced gold-tagged streptavidin localized mainly in intracellular vesicular structures with different size (0.5−2 μm) and in Bowes cells the vesicular membrane was not always intact (*47*). On the basis of these considerations, it seems probable that transportan-mediated cellular uptake of protein molecules proceeds at least partially by macropinocytosis and transportan is able to destabilize the macropinosomes.

The peptide−protein complexes marked by gold particles were also found in vesicles characteristic to receptor-mediated endocytic pathway, e.g. multivesicular bodies and endosomal-lysosomal structures suggesting the involvement of clathrin-dependent endocytosis. In most animal cells, the clathrin-dependent pathway guarantees the uptake of specific macromolecules, nutrients, and ions from the extracellular fluid (*48*). Transferrin, a typical marker of clathrin-dependent endocytosis, and transportan−protein complexes colocalized partially on the plasma membrane of the HeLa cells and later in the endocytic vacuoles. Colocalization of transportan−streptavidin complexes and transferrin was more characteristic at higher concentrations of substances and less obvious at lower concentration. The results of confocal laser scanning microscopy confirmed that vesicular structures containing transportan−avidin complexes rarely overlapped with transferrin-AF 594 positive vesicles, suggesting that a small fraction of transportan−protein complexes was cointernalized with transferrin or targeted into the same vesicles intracellularly. At high concentrations weak electrostatic interaction of cationic transportan complexes with anionic transferrin might be envisaged, leading to the increase of transferrin uptake and altering its intracellular distribution.

Different endocytic pathways target the ingested material to specific cellular destinations: degradative organelles, the plasma membrane, ER, Golgi apparatus. The destination of the protein molecules translocated into cells by CPPs is of primary importance both from the view of mechanisms and application. Neither electron- nor fluorescence microscopy revealed accumulation of transportan−protein complexes to endoplasmic reticulum or Golgi apparatus, though some colocalization with the respective markers was detected by fluorescence microscopy in perinuclear area. On the contrary, part of transportan−protein complexes was targeted to late endosomes and lysosomal structures, especially after 20 h or later. However, a substantial amount of labeled complexes was detectable in the cytoplasm or vesicles of nondegradative character after 24 or even 48 h of incubation.

Caveolae-mediated endocytosis which starts from cholesterol and sphingolipid rich membrane rafts has been proposed for the cellular translocation of Tat fusion proteins (*14*, *15*). Electron microscopy revealed that streptavidin complexed with transportans was occasionally present also in caveosome-like structures, mainly in the cortical cytoplasm. This internalization mechanism is not prevailing since by confocal fluorescence microscopy we did not observe the accumulation of peptide−protein complexes to the Golgi apparatus, but it suggests that complexes can use different endocytic pathways simultaneously.

Apparently all endocytic pathways have been shown to be used to gain access into eukaryotic cells by viruses (*49*). Cell-entry of peptide−protein complexes has several features similar to internalization of Simian Virus 40 (SV40). We detected peptide−protein complexes in vesicles of different size and morphology with little overlap with clathrin-coated vesicles, indicating other transduction modes; for example, SV40 is known to enter cells dynaminII-independently (*50*) and the recruitment of caveolae seems not to be obligatory (*51*). Moreover, like the infectivity of SV40, internalization of transportan/TP10−(strept)avidin complexes can be blocked by actin depo-

lymerization and depletion of cholesterol from the plasma membrane (Säälik and Padari, unpublished data). It has to be assessed if the same or different inducible actin- and cholesterol-dependent endocytic processes lead to internalization of some viruses, bacteria, and peptide−cargo complexes and which receptors are involved, if any.

In parallel to translocation into cells in membrane-surrounded vesicles, transportan−streptavidin complexes with a single gold particle were detectable in the cortical cytoplasm of cells in the close proximity of the intact plasma membrane, suggesting direct passage across the membrane. The amount of complexes that seemingly directly crossed the plasma membrane was very small compared to that in vesicles and was higher for TP10 rather than transportan complexes. The presence of transportan−streptavidin complexes with a single (or few) gold particle in the cortical cytoplasm could be caused by redistribution of complexes from the cell surface into cells upon fixation (*4*, *11*) or an embedding procedure. Neither can we exclude that those complexes are encompassed by the membrane, which remains undetectable by electron microscopy, in analogy with SV40 particles internalization within the vesicles devoid of the visible coat (*51*), which were found when studying a novel clathrin-, caveolae-, and dynaminII-independent cholesterol-sensitive endocytic pathway (*51*, *52*). On the other hand, we cannot completely ignore the possibility that a small fraction of transportan−protein complexes translocates into cells by inducing a pore-like structure in the plasma membrane hypothesized for complexes of carrier peptides MPG and Pep-1 with cargo molecules (*36*) or the nondefined mechanism observed in studies of Seelig and collaborators (*31*). Presence of oligoarginine both in cytoplasmic and vesicular fraction after fractionation of CHO cell material (*53*, *54*) and the activity of biological cargo delivered into cells by transportan and/or TP10 (*55*, *56*) supports the cytoplasmic localization of peptide−protein complexes observed in our experiments. The translocation mode has been also suggested to depend on the size of the particle as proposed by Morris and co-workers (*57*) which could be the case for transportan/TP10-streptavidin complexes of different size. However, until now this hypothesis has not found unambiguous affirmation.

The contribution of endocytosis in the cellular uptake process of CPPs is often estimated after blocking this pathway by lowering temperature, which has sometimes led to the contradicting results. Cellular translocation of gold-tagged streptavidin−transportan complexes was highly temperature/energy-dependent. Lowering temperature to endocytosis-permissive 20 °C markedly reduced amount of internalized complexes. Minimal uptake of transportan−streptavidin complexes was detected also at endocytosis nonpermissive 8−10 °C but not at 0−4 °C. Unexpectedly, the internalization detected at 8−10 °C was mainly vesicular and cortical; the vesicles had not translocated markedly toward perinuclear region in 1 h. It has been demonstrated earlier that FITC-labeled avidin complexes with biotin−Tat and biotin−penetratin cannot enter CHO cells at 0−4 °C (*41*). Very recently, transduction of Cy3-tagged streptavidin into HEK293 cells after complexing with biotin−maurocalcine, a 33 amino acid long scorpion toxin (*58*), was shown, but only after fixation of cells. Our results are in line with the suggestion of mainly endocytic uptake of CPP−protein complexes (*41*). Reduction of uptake at 20 °C and ceasing at 0−4 °C suggests that the decrease in fluidity of the membrane has also considerable effect on the internalization of CPPs and their constructs as proposed earlier for penetratin peptide (*29*). The reduced association of CPP−avidin/streptavidin complexes with cell surface structures at 0−4 °C observed by Console and collaborators (*41*) and by us might be also partly ascribed to the increased rigidity of the plasma membrane.

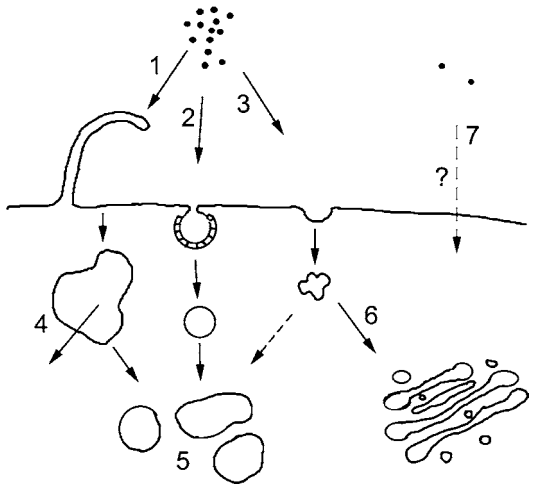

Figure 7. Internalization and intracellular routing of CPP−protein complexes. Internalization via macropinosomes (1), clathrin-coated vesicles (2) and caveosomes (3) leading to different cellular compartments: escape from macropinosomes (4), targeting to lysosomes (5) and partial direction to Golgi complex (6). Putative translocation of peptide−protein complexes across plasma membrane without induction of vesicular structures (7).

Summing up, as we schematically represent in Figure 7, complexes of transportan and TP10 with protein can translocate into cells by different mechanisms in parallel, mainly by endocytic processes using diverse vesicles and probably also by translocation without inducing the membrane invagination and vesicle formation. The latter mode could be more common for CPPs alone than detected here for constructs with proteins. The morphology and size of formed vesicles suggests that macropincytosis is the main mechanism of transportan−protein complexes' uptake by Bowes and HeLa cells. It seems also that the size (degree of concentration) of complexes on the cell surface influences the size of the forming vesicle, the mode of internalization and further cellular targeting.

In Vitro Lipofection with Novel Asymmetric Series of 1,2-Dialkoylamidopropane-Based Cytofectins Containing Single Symmetric Bis-(2-dimethylaminoethane) Polar Headgroups

Michalakis Savva,* Pensung Chen, Ahmad Aljaberi, Bilge Selvi, and Michael Spelios

Division of Pharmaceutical Sciences, Arnold & Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, 75 Dekalb Avenue, Brooklyn, New York 11201. Received May 11, 2005; Revised Manuscript Received August 31, 2005

Novel *N*,*N*′-diacyl-1,2-diaminopropyl-3-carbamoyl[bis-(2-dimethylaminoethane)] bivalent cationic lipids were synthesized and evaluated for in vitro transfection activity against a murine melanoma cell line. In the absence of the helper lipid DOPE (1,2-dioleoyl-sn-glycero-3-phosphoethanolamine), only the dioleoyl derivative **22** (1,2lb5) elicited transfection activity. The transfection activity of this lipid was reduced when formulated with DOPE. Contrary to that, the dimyristoyl derivative **19** (1,2lb2) mediated no activity when used alone but induced the highest levels of marker gene expression in the presence of DOPE. In an effort to correlate the transfection activity with cationic lipid structures, the physicochemical properties of cationic lipids in isolation and of lipoplexes were studied with surface tensiometry, photon correlation spectroscopy, gel electrophoresis mobility shift assay, and fluorescence techniques. In regard to the lipoplex properties, gel electrophoresis mobility shift assay and EtBr exclusion fluorescence assay revealed that the 1,2lb5 was the only lipid to associate and condense plasmid DNA, respectively. Photon correlation spectroscopy analysis found that 1,2lb5/DNA complexes were of relatively small size compared to all other lipoplexes. With respect to the properties of isolated lipids, Langmuir monolayer studies and fluorescence anisotropy on cationic lipid dispersions verified high two-plane elasticity and increased fluidity of the transfection competent dioleoyl derivative 1,-2lb5, respectively. The results indicate that high transfection activity is mediated by cationic lipids characterized by an expanded mean molecular area, high molecular elasticity, and increased fluidity.

INTRODUCTION

Gene delivery reagents comprising a variety of recombinant replication deficient viruses (*1*, *2*), positively charged synthetic polymers and peptides and cationic lipids (*3*−*5*), are currently being used to treat genetic diseases (*6*) and a wide variety of cancers (*7*). These delivery systems have their pluses and minuses. Viral vectors unambiguously induce much higher transgene expression levels than their nonviral rivals. Their in vivo application, however, is severely compromised by the innate immunity and by the more refined adaptive immunity, as provided by the natural killer cells, biochemicals and cellular proteins of the patient, and neutralizing antibodies, respectively. On the other hand, cationic lipids are a particularly attractive alternative to the viral vectors because they do not induce any humoral responses. Moreover, it is possible to design and synthesize a wide variety of cationic lipids that, depending on their structural features, promote gene expression by affecting one or more of the essential requirements for transfection, i.e., efficient compaction of plasmid DNA, lipoplex internalization, fusion of the internalized lipoplex with lysosome membrane, and translocation of the plasmid DNA to the nucleus. Unfortunately, the transfection activity of nonviral vectors is currently very low to permit disease treatment. Thus, for gene therapy to become common medicine therapeutics, current vehicles have to be improved significantly. Nevertheless, despite the present lack of clinical success of gene therapy, the promise that it holds to eradicate the cause of a disease rather than to treat the symptoms of it has kept the drive for discovering efficient cationic transfection lipids active, for more than 17 years.

Toward this effort, we have recently launched a systematic investigation of the transfection potency of a series of positively charged lipids containing primary and tertiary amine groups attached to the 2-position of the 1,3-diamino-2-propanol backbone, whereas the acyl chains were linked to the backbone at the 1- and 3-positions via amide bonds (*8*, *9*). Herein, we report on the synthesis and transfection activity of novel cationic lipids of the 1,2-diamino-3-propanol series, in which the polar headgroup bis-(2-dimethylaminoethane) is attached via a carbamate spacer at the 3-position of the 1,2-diaminopropan-3-ol, whereas the hydrophobic alkyl chains are bonded to the nitrogen atoms at the 1- and 2-position of the diaminopropanol backbone through acyl linkers. The physicochemical properties of the cationic lipids in isolation were investigated in an effort to correlate structures with transfection activity.

MATERIALS AND METHODS

Materials. Bis-(2-chloroethyl)amine hydrochloride, 98%, 2,3-diaminopropionic acid monohydrochloride 98%, lauroyl chloride 98%, myristoyl chloride 97%, palmitoyl chloride 98%, stearoyl chloride 99%, oleoyl chloride technical grade (∼85%), 4-nitrophenyl chloroformate 97%, hydrogen chloride gas anhydrous 99+%, lithium borohydride 2.0 M solution in THF, tetrahydrofuran (THF) anhydrous 99.9%, triethylamine 99.5% (TEA), ethyl alcohol 99.5%, *N*,*N*-dimethylformamide (DMF) 99%,

and pyridine 99+% were purchased from Aldrich. Dimethylamine 40% was purchased from ACROS ORGANICS. Methanol (anhydrous) and all other reagents used were from VWR. All tissue culture reagents were purchased from Life Technologies Inc. (Rockville, MD), unless otherwise specified.

Synthesis. The synthesis of the bivalent cationic lipids is summarized in Figure 1. Mobile phase systems v/v for thin layer chromatography (TLC) (A) $CH_3OH/CHCl_3$ (1:1), (B) $CH_3OH/CHCl_3$ (1:4), (C) $CH_3OH/CHCl_3$ (1:9), (D) $CH_3OHCHCl_3$ (1: 20), (E) $CH_3OH/CHCl_3/NH_4OH$ (1:2:0.15).

Bis-(2-(dimethylamino)ethyl)amine. Solid bis-(2-chloroethyl)amine hydrochloride (17.85 g, 0.10 mol) was dissolved in a 500 mL round-bottom flask with addition of 152 mL of dimethylamine (54 g, 1.20 mol). After a 72 h of rigorous stirring at room temperature, the mixture was made alkaline with 6 M NaOH (100 mL) and further saturated with anhydrous potassium carbonate. Upon alkalization an oily liquid separates on the upper layer. The mixture was stirred for one-half hour and then transferred to a 500 mL separation funnel where the crude product was extracted with 4 × 150 mL of ethyl ether (ninhydrin test of the organic phase turns negative). The extracts were collected and dried ($MgSO_4$) overnight. $MgSO_4$ was removed by suction filtration and the organic solvent was eliminated under diminished pressure at 45 °C to give a total of 5.0 g of colorless oil (yield 31%). Further purification of the triamine was performed by chromatography with 50% recovery (*10*). MS (FAB and ES) *m/z* 160.2 $[M + H]^+$; ^1H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 2.60−2.63 (t, 4H, J = 6.2 Hz, $NCH_2CH_2N(CH_3)_2$), 2.31−2.34 (t, 4H, J = 6.2 Hz, $CH_2N(CH_3)_2$), 2.13 (s, 12H, $N(CH_3)_2$); ^{13}C NMR (100 MHz, $CDCl_3$, 20 °C, TMS) δ 59.21 ($2CH_2$), 47.48 ($2CH_2$), 45.60 ($4CH_3$).

Methyl 2,3-Diaminopropionate Dihydrochloride (2). 2,3-Diaminopropionic acid monohydrochloride (2.0 g, 14.2 mmol) was pulverized and transferred to a 500 mL round-bottom flask containing 50 mL of anhydrous methanol. Bound water was removed by evaporating the solvent several times at low pressure at 75 °C. The dry powder was finally dissolved in fresh anhydrous methanol (100 mL) saturated with anhydrous hydrogen chloride gas. The mixture was refluxed at 85−90 °C for 17 h. Methanol was eliminated under diminished pressure to give 2.85 g as a yellowish crystal of 86−90% purity, depending on the batch, as determined by ^1H NMR. R_f = 0.86 (A). ^1H NMR (400 MHz, D_2O, 20 °C, TMS) δ 4.26−4.34 (t, 1H, $CH_2CH(NH_2)CO$), 3.66 (s, 3H, $COOCH_3$), 3.22−3.44 (m, 2H, CH_2CH).

Methyl 2,3-Dilauroylamidopropionate (3). Methyl 2,3-dilauroylamidopropionate was synthesized using a procedure similar to that described by Sunamoto and coworkers (*11*). Briefly, to a 100 mL anhydrous DMF solution of methyl 2,3-diaminopropionate dihydrochloride (1.36 g, 7.11 mmol) in a 250 mL round-bottom flask was added 10.0 mL of TEA (71.1 mmol) immediately followed by dropwise addition of 7.0 mL of lauroyl chloride (28.4 mmol). The mixture was stirred at 60 °C for 6 h. DMF was evaporated with the aid of a rotary evaporator at 90 °C under reduced pressure, and the crude material was transferred with 100 mL of $CHCl_3$ to a 500 mL separation funnel where it was washed once with HCl and once with Na_2CO_3. The organic phase was collected in a 250 mL round-bottom flask, and the $CHCl_3$ was removed under reduced pressure with the aid of a rotary evaporator. The dried crude was dissolved in a minimum amount of hot methanol and left overnight for crystallization. The product was collected by suction filtration as a white crystalline powder (2.1 g, 61.3%). R_f = 0.76 (C). ^1H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.89 (d, 1H, *H*NCH), 6.25 (t, 1H, $HNCH_2$), 4.57 (m, 1H, $CHCOOCH_3$), 3.72 (s, 3H, $COOCH_3$), 3.60 (t, 2H, $HNCH_2CH$), 2.11−2.21 (m, 4H, $COCH_2$), 1.58 (m, 4H, $COCH_2CH_2$), 1.21 (b, 32H, $(CH_2)_8CH_3$), 0.82−0.85 (t, 6H, CH_3).

2,3-Dilauroylamidopropan-3-ol (8). To a 100 mL solution of methyl 2,3-dilauroylamidopropionate (3.52 g, 7.29 mmol) in absolute ethanol in a 250 mL round-bottom flask was added 10.9 mL (21.87 mmol) of 2.0 M lithium borohydride solution in THF. Hydrogenation was performed in a dry N_2 gas environment at 50−60 °C for 3 h and then at 23 °C for an additional 12 h. Ethanol was removed, and the crude material was taken with 100 mL of chloroform, transferred to a 500 mL separation funnel, and washed once with 100 mL of 1.0 N HCl and once with Na_2CO_3. The organic phase was concentrated to an oil of high viscosity, which was applied to a silica gel column (3.2 cm × 30 cm). Elution was performed with 100 mL of $CHCl_3$ and 1%, 1.5%, 2%, 2.5%, 3%, 10%, 20%, and 50% MeOH/$CHCl_3$. Fractions between 2% and 20% were pooled and concentrated to give a total of 2.94 g of 2,3-dilauroylamidopropanol as a white powder (89% yield). R_f = 0.27 (D). ^1H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.25−6.50 (b, 2H, $HNCH_2HNCH$), 3.60−3.90 (m, 2H, $HNCH_2CH$), 3.40−3.55 (m, 2H, $CH(NH)CH_2OH$), 3.20−3.30 (m, 1H, C*H*), 2.12−2.22 (m, 4H, $COCH_2$), 1.59

(b, 4H, $COCH_2CH_2$), 1.23 (b, 32H, $(CH_2)_8CH_3$), 0.83−0.86 (t, 6H, CH_3).

2,3-Dilauroylamidopropane-1-(*p*-nitrophenyl) Carbonate (13). 2,3-Dilauroylamidopropanol (2.94 g, 6.47 mmol) was suspended with continuous stirring in 100 mL of anhydrous THF in a 250 mL capacity round-bottom flask. The mixture was kept at 25 °C with the aid of an oil bath. To the suspension was added 4-nitrophenyl chloroformate (1.30 g, 6.47 mmol) followed by a dropwise addition of pyridine (0.52 mL, 6.47 mmol). The reaction was stopped after 5 h. THF was removed under diminished pressure, and the crude was transferred with 100 mL of chloroform to a 500 mL separation funnel and washed once with 100 mL of 1.0 N HCl and once with 100 mL of Na_2CO_3. The organic phase was concentrated to a viscous oil with the aid of a rotary evaporator and purified by chromatography on a silica gel column, eluting with 100 mL of 1%, 2%, 3%, 4%, 5%, 20%, 50% MeOH/$CHCl_3$. Fractions between 3% and 20% were pooled and dried to give a total of 3.9 g (6.28 mmol, 97% yield) of 2,3-dilauroylamidopropane-1-(*p*-nitrophenyl) carbonate as a white crystalline material. R_f = 0.49 (D). ^{1}HNMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 8.27−8.24, 7.37−7.23 (two d, each J = 9.1 Hz, 4H, C_6H_4), 6.64 (d, 1H, *H*NCH), 6.02 (t, 1H, *H*NCH_2), 4.18−4.40 (m, 3H, NHC*HCH*$_2$OCOO), 3.42−3.57 (m, 2H, HNC*H*$_2$CH), 2.14−2.20 (m, 4H, $COCH_2$), 1.57−1.79 (m, 4H, $COCH_2CH_2$), 1.0−1.24 (bs, 32H, $(CH_2)_8CH_3$), 0.82−0.90 (t, 6H, CH_3).

1,2-Dilauroylamidopropane-3-[bis-(2-dimethylaminoethane)] Carbamate (18, 1,2lb1). To a solution of 2,3-dilauroylamidopropane-1-(*p*-nitrophenyl) carbonate (3.9 g, 6.28 mmol) in 100 mL of chloroform was added bis-(2-dimethylaminoethyl)amine (1.7 mL, 9.42 mmol). The mixture was stirred at room temperature for 17 h. The reaction mixture was then transferred to a 500 mL separation funnel where it was washed once with 100 mL of 1.0 N Na_2CO_3. The organic phase was concentrated to an oil, which was chromatographed on a silica gel column, eluting with 100 mL of 2%, 4%, 200 mL of 5%, 100 mL of 7%, 10%, and 200 mL of 15%, 20%, 25%, 30%, 35%, 40% MeOH/$CHCl_3$. Fractions between 15% and 40% were pooled and dried to obtain a total 2.95 g (73%). R_f = 0.46 (E). Anal. Calcd for $C_{36}H_{73}N_5O_4$ (MW 639): C, 67.56; H, 11.50; N, 10.94. Found: C, 66.97; H, 11.77; N, 10.90. MS (ESI) *m/z* 662.5 $[M + Na]^+$; ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 7.15 (d, 1H, *H*NCH), 6.70 (t, 1H, *H*NCH_2), 4.13 (m, 3H, NHC*HCH*$_2$OCO), 3.20−3.50 (m, 6H, NHC*H*$_2$CH(NH)CH_2OCON$(CH_2)_2$−), 2.35−2.42 (m, 4H, $CH_2N(CH_3)_2$), 2.19−2.20 (d, 12H, $N(CH_3)_2$), 2.05−2.18 (m, 4H, $COCH_2$), 1.45−1.60 (m, 4H, $COCH_2CH_2$), 1.187 (b, 32H, $(CH_2)_8CH_3$), 0.80−0.90 (t, 6H, CH_3); ^{13}C NMR (100 MHz, $CDCl_3$, 20 °C) δ 176.04 (NHCO), 175.34 (NHCO), 157.47 (OCO), 65.30, 58.63, 46.83, 37.75, 32.96, 30.68, 30.41, 27.35, 23.73, 15.17.

Methyl 2,3-Dimyristoylamidopropionate (4). Methyl 2,3-dimyristoylamidopropionate was crystallized from methanol analogously to compound **3** to afford a total of 1.3 g as white crystals (68%). R_f = 0.89 (B), R_f = 0.82 (C). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.77 (d, 1H, *H*NCH), 6.15 (t, 1H, *H*NCH_2), 4.55 (m, 1H, C*H*COO), 3.72 (s, 3H, $COOCH_3$), 3.60 (t, 2H, HNCH_2), 2.11−2.21 (m, 4H, $COCH_2$), 1.56 (m, 4H, $COCH_2CH_2$), 1.22 (b, 40H, $(CH_2)_{10}CH_3$), 0.82−0.85 (t, 6H, $(CH_2)_{10}CH_3$); ^{13}C NMR (100 MHz, $CDCl_3$, 20 °C) δ 175.77 (NHCO), 174.95 (NHCO), 171.82 (COO), 54.72, 51.74, 46.64, 37.60, 37.48, 32.93, 30.68, 30.38, 26.55, 26.71, 23.70, 15.11.

2,3-Dimyristoylamidopropanol (9). This compound was prepared similarly to compound **8** with lithium borohydride at 60 °C for 5 h and gave the product as a white powder (2.23 g, 99%). R_f = 0.27 (D). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.44−6.55 (m, 2H, *H*NCH_2-*H*NCH), 3.40−3.90 (m, 4H, HNCH_2CH(NH)CH_2OH), 3.20−3.30 (m, 1H, $HNCH_2CH$), 2.13−2.21 (m, 4H, $COCH_2$), 1.56 (m, 4H, $COCH_2CH_2$), 1.21 (b, 40H, $(CH_2)_{10}$-CH_3), 0.82−0.85 (t, 6H, CH_3).

2,3-Dimyristoylamidopropane-1-(*p*-nitrophenyl) Carbonate (14). Compound **14** was prepared analogously to **13** and purified by silica gel column chromatography (70−230, 3.2 cm × 30 cm), eluting with 100 mL of 1%, 1.5%, 2%, 2.5%, 3%, 3.5%, 4%, 5%, 40% MeOH/$CHCl_3$. The 2−4% fractions were pooled to give 1.16 g (1.7 mmol, 79.5%) of the product as a white solid. R_f = 0.71 (D). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 8.26−8.23, 7.36−7.34 (two d, each J = 9.1 Hz, 4H, C_6H_4), 6.77 (d, 1H, *H*NCH), 6.25 (t, 1H, *H*NCH_2), 4.20−4.38 (m, 3H, NHC*HCH*$_2$OCOO), 3.30−3.60 (m, 2H, HNC*H*$_2$CH), 2.16−2.18 (m, 4H, $COCH_2$), 1.56 (m, 4H, $COCH_2CH_2$), 1.20 (b, 40H, $(CH_2)_{10}CH_3$), 0.81−0.85 (t, 6H, CH_3).

1,2-Dimyristoylamidopropane-3-[bis-(2-dimethylaminoethane)] Carbamate (19, 1,2lb2). 19 was prepared analogously to **18** on a 1.5 mmol scale to give upon purification the product as a white solid (0.6 g, 0.87 mmol, 57%). R_f = 0.76 (E). Anal. Calcd for $C_{40}H_{81}N_5O_4$ (MW 695): C, 69.02; H, 11.73; N, 10.06. Found: C, 68.74; H, 11.99; N, 9.98. MS (FAB) *m/z* 697.1 $[M + H]^+$. ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 7.15 (d, 1H, *H*NCH) 6.70 (t, 1H, *H*NCH_2), 4.13 (m, 3H, *CH*(NH)*CH*$_2$OCO), 3.24−3.46 (m, 6H, NHCH_2CH(NH)CH_2OCON$(CH_2)_2$), 2.36−2.47 (m, 4H, $CH_2N(CH_3)_2$), 2.21−2.23 (d, 12H, $N(CH_3)_2$), 2.12 (m, 4H, $COCH_2$), 1.56−1.58 (m, 4H, $COCH_2CH_2$), 1.24 (b, 40H, $(CH_2)_{10}CH_3$), 0.80−0.90 (t, 6H, CH_3); ^{13}C NMR (100 MHz, $CDCl_3$, 20 °C) δ 176.16 (NHCO), 175.34 (NHCO), 157.35 (OCO), 65.76, 58.63, 46.83, 46.37, 46.25, 37.69, 32.96, 30.71, 30.41, 27.05, 23.73, 15.20.

Methyl 2,3-Dipalmitoylamidopropionate (5). This compound was prepared similarly to **4** and gave the product as white crystals (2.9 g, 4.9 mmol, 68%). R_f = 0.76 (C). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.80 (d, 1H, *H*NCH), 6.18 (t, 1H, *H*NCH_2), 4.58 (m, 1H, C*H*$COOCH_3$), 3.73 (s, 3H, $COOCH_3$), 3.61 (m, 2H, HNCH_2-CH), 2.14−2.20 (m, 4H, $COCH_2$), 1.57−1.58 (m, 4H, $COCH_2CH_2$), 1.24 (b, 48H, $(CH_2)_{12}CH_3$), 0.83−0.86 (t, 6H, $(CH_2)_{12}CH_3$).

2,3-Dipalmitoylamidopropan-3-ol (10). Compound **10** was prepared analogously to **9** on a 4.9 mmol scale and gave the product, after chromatography ($CHCl_3$/MeOH), as a white powder (2.5 g, 89%). R_f = 0.37 (D). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.24−6.36 (b, 2H, *H*NCH_2*H*NCH), 3.40−3.90 (m, 4H, HNCH_2CH(NH)-CH_2OH), 3.20−3.30 (m, 1H, $HNCH_2CH$), 2.15−2.19 (m, 4H, $COCH_2$), 1.58−1.59 (m, 4H, $COCH_2CH_2$), 1.23 (b, 48H, $(CH_2)_{12}CH_3$), 0.84−0.87 (t, 6H, CH_3).

2,3-Dipalmitoylamidopropane-1-(*p*-nitrophenyl) Carbonate (15). This compound was prepared similarly to **14** and was recovered as a white powder (2.3 g, 3.1 mmol, 72%). R_f = 0.71 (D). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 8.27−8.25, 7.38−7.36 (two d, each J = 9.1 Hz, 4H, C_6H_4), 6.69 (m, 1H, −*H*NCH−), 6.13 (m, 1H, *H*NCH_2), 4.23−4.36 (m, 3H, NHC*HCH*$_2$OCOO), 3.38−3.59 (m, 2H, HNCH_2CH), 2.15−2.20 (m, 4H, $COCH_2$), 1.57−1.58 (m, 4H, $COCH_2CH_2$), 1.24 (b, 48H, $(CH_2)_{12}$-CH_3), 0.82−0.86 (t, 6H, CH_3),

1,2-Dipalmitoylamidopropane-3-[bis-(2-dimethylaminoethane)] Carbamate (20, 1,2lb3). 20 was prepared similarly to **19** as a white sticky powder (1.9 g, 2.5 mmol, 58%). R_f = 0.52 (E). Anal. Calcd for $C_{44}H_{89}N_5O_4$ (MW 751): C, 70.26; H, 11.92; N, 9.31. Found: C, 70.14;

H, 11.97; N, 9.32. MS (ESI) *m*/z 774.7 $[M + Na]^+$; ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 7.15 (d, 1H, OC*H*NCH) 6.70 (t, 1H, OC*H*NCH$_2$CH), 4.13 (m, 3H, NHC*HCH*$_2$OCO), 3.20−3.50 (m, 6H, C*H*$_2$CHCH$_2$OCON-(C*H*$_2$)$_2$), 2.40−2.50 (m, 4H, C*H*$_2$N(CH$_3$)$_2$), 2.22−2.25 (d, 12H, N(C*H*$_3$)$_2$), 2.10−2.20 (m, 4H, COC*H*$_2$), 1.45−1.60 (m, 4H, COCH$_2$C*H*$_2$), 1.21 (b, 48H, (C*H*$_2$)$_{12}$CH$_3$), 0.82−0.86 (t, 6H, (CH$_2$)$_{12}$C*H*$_3$); ^{13}C NMR (100 MHz, $CDCl_3$, 20 °C) δ 176.04 (NHCO), 175.34 (NHCO), 157.44 (OCO), 65.67, 58.61, 46.83, 46.58, 37.72, 32.96, 30.74, 30.41, 26.74, 23.73, 15.20.

Methyl 2,3-Distearoylamidopropionate (6). Compound **6** was prepared analogously to **3** on a 6.6 mmol scale to give upon crystallization from methanol the product **6** as a brownish powder (2.4 g, 3.7 mmol, 56%). R_f = 0.92 (A), R_f = 0.68 (C). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.78 (d, 1H, *H*NCH), 6.08 (s, 1H, *H*NCH$_2$), 4.58 (m, 1H, C*H*COOCH$_3$), 3.72 (s, 3H, COOC*H*$_3$), 3.60 (m, 2H, HNC*H*$_2$), 2.13−2.19 (m, 4H, COC*H*$_2$), 1.56−1.68 (m, 4H, COCH$_2$C*H*$_2$), 1.20 (b, 56H, (C*H*$_2$)$_{14}$CH$_3$), 0.82−0.85 (t, 6H, (CH$_2$)$_{14}$C*H*$_3$).

2,3-Distearoylamidopropanol (11). Compound **11** was prepared by reducing **6** with lithium borohydride in anhydrous THF at 50−60 °C for 25 h. The crude was worked up similarly to **8** to give the product **11** as white crystals (1.0 g, 1.6 mmol, 47%). R_f = 0.5 (D). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.40 (m, 2H, *H*NCH$_2$-(*H*N)CH), 3.20−3.90 (m, 5H, HNC*H*$_2$C*H*(NH)C*H*$_2$OH), 2.15−2.19 (m, 4H, COC*H*$_2$), 1.59 (m, 4H, COCH$_2$C*H*$_2$), 1.23 (b, 56H, (C*H*$_2$)$_{14}$CH$_3$), 0.85 (t, 6H, C*H*$_3$).

2,3-Distearoylamidopropane-1-(*p*-nitrophenyl) Carbonate (16). This compound was prepared similarly to **13** with *p*-nitrophenylchloroformate and gave the product as white solid (1.2 g, 1.6 mmol, 96%). R_f = 0.63 (D). ^{1}HNMR (400 MHz, $CDCl_3$, 20°C, TMS) δ 8.25−8.23, 7.37−7.35 (two d, each J = 9.1 Hz, 4H, C_6H_4), 6.64 (s, 1H, *H*NCH), 6.02 (s, 1H, *H*NCH$_2$CH), 4.08−4.40 (m, 3H, NHC*HCH*$_2$OCOO), 3.42−3.75 (m, 2H, HNC*H*$_2$CH), 2.20 (m, 4H, COC*H*$_2$), 1.58−1.59 (m, 4H, COCH$_2$C*H*$_2$), 1.23 (b, 56H, (C*H*$_2$)$_{14}$CH$_3$), 0.84−0.87 (t, 6H, C*H*$_3$).

1,2-Distearoylamidopropane-3-[bis-(2-dimethylaminoethane)] Carbamate (21, 1,2lb4). 21 was prepared similarly to **20** with bis-(2-dimethylaminoethyl) amine and gave the product as a half-white sticky solid (0.6 g, 0.7 mmol, 48%). R_f = 0.48 (E). Anal. Calcd for $C_{48}H_{97}N_5O_4$ (MW 807): C, 71.32; H, 12.09; N, 8.66. Found: C, 71.38; H, 11.92; N, 8.18. MS (ESI) *m/z* 830.7 $[M + Na]^+$; ^{1}H NMR (400 MHz, $CDCl_3$, 20°C, TMS) δ 7.00 (d, 1H, *H*NCH), 6.67 (t, 1H, *H*NCH$_2$CH), 4.13 (m, 3H, NHC*HCH*$_2$OCON), 3.33 (m, 6H, C*H*$_2$CHCH$_2$OCON-(C*H*$_2$)$_2$−), 2.10−2.40 (m, 20H, C*H*$_2$N(C*H*$_3$)$_2$, COC*H*$_2$-CH$_2$(CH$_2$)$_{14}$CH$_3$), 1.55−1.57 (m, 4H, COCH$_2$C*H*$_2$), 1.22 (s, 56H, (C*H*$_2$)$_{14}$CH$_3$), 0.84 (t, 6H, C*H*$_3$).

Methyl 2,3-Dioleoylamidopropionate (7). Compound **7** was prepared as a brown oil (impure mixture) analogously to compound **6** on a 6.8 mmol scale. R_f = 0.94 (A). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 6.80 (b, 1H, *H*NCH), 6.18 (b, 1H, *H*NCH$_2$), 5.3 (m, 4H, C*H*=C*H*), 3.5−4.7 (m, 6H, HNC*H*$_2$HNC*H*COOC*H*$_3$), 1.4−2.4 (b, 16H, COC*H*$_2$C*H*$_2$(CH$_2$)$_4$C*H*$_2$CH=CHC*H*$_2$(CH$_2$)$_6$CH$_3$), 1.24 (b, 40H, CH$_2$(C*H*$_2$)$_4$CH$_2$CH=CHCH$_2$(C*H*$_2$)$_6$CH$_3$), 0.83−0.86 (t, 6H, (CH$_2$)$_6$C*H*$_3$).

2,3-Dioleoylamidopropan-3-ol (12). Compound **12** was prepared analogously to **11** on a 1.8 mmol scale to give upon purification (column chromatography, $CHCl_3$/MeOH) the product as a yellow solid (0.49 g, 0.8 mmol, 44%). R_f = 0.5 (D). ^{1}H NMR (400 MHz, $CDCl_3$, 20 °C, TMS) δ 7.33 (s, 1H, *H*NCH), 6.80 (s, 1H, *H*NCH$_2$CH), 5.27 (m, 4H, C*H*=C*H*), 3.20−3.80 (m, 5H, HNC*H*$_2$(HN)-C*H*CH$_2$OH), 2.14 (m, 4H, COC*H*$_2$), 1.95 (m, 8H, C*H*$_2$CH=CHC*H*$_2$), 1.56 (m, 4H, COCH$_2$C*H*$_2$) 1.23 (b, 40H, COCH$_2$-(C*H*$_2$)$_4$CH$_2$CH=CHCH$_2$(C*H*$_2$)$_6$CH$_3$), 0.8−0.83 (t, 6H, (CH$_2$)$_6$-CH$_3$).

2,3-Dioleoylamidopropane-1-(p-nitrophenyl) Carbonate (17). Compound **17** was prepared analogously to **16** on a 5.8 mmol scale to give upon purification (column chromatography, $CHCl_3$/MeOH) the product as a yellow-brown oil (2.9 g, 3.7 mmol, 63%). R_f = 0.73 (D). ^{1}H NMR (400 MHz, $CDCl_3$, 20°C, TMS) δ 8.25−8.23, 7.37−7.35 (two d, each J = 9.1 Hz, 4H, C_6H_4), 7.0 (b, 1H, *H*NCH), 6.82 (b, 1H, *H*NCH$_2$CH), 5.31 (m, 4H, C*H*=C*H*), 4.18−4.40 (m, 3H, NHC*HCH*$_2$OCOO), 3.22−3.57 (m, 2H, HNC*H*$_2$CH), 2.17 (m, 4H, COC*H*$_2$), 1.97 (m, 8H, C*H*$_2$CH=CHC*H*$_2$), 1.55 (m, 4H, COCH$_2$C*H*$_2$), 1.23 (b, 40H, COCH$_2$-(C*H*$_2$)$_4$CH$_2$CH=CHCH$_2$(C*H*$_2$)$_6$CH$_3$), 0.82−0.86 (t, 6H, (CH$_2$)$_6$C*H*$_3$).

2,3-Dioleoylamidopropane-1-[bis-(2-dimethylaminoethane)] Carbamate (22, 1,2lb5). 22 was prepared similarly to **21** with bis-(2-dimethylaminoethyl)amine and gave the product as a yellow oil (0.9 g, 1.1 mmol, 35%). R_f = 0.5 (E). Anal. Calcd for $C_{48}H_{93}N_5O_4$ (MW 803): C, 71.68; H, 11.65; N, 8.71. Found: C, 71.03; H, 11.85; N, 7.73. MS (ESI) *m/z* 826.7 $[M + Na]^+$; ^{1}H NMR (400 MHz, $CDCl_3$, 20°C, TMS) δ 7.3 (b, 1H, *H*NCH), 6.89 (b, 1H, *H*NCH$_2$), 5.28 (m, 4H, C*H*=C*H*), 4.16 (m, 3H, HNC*HCH*$_2$OCO), 3.39 (m, 6H, HNC*H*$_2$(HN)CHCH$_2$OCON-(C*H*$_2$−)$_2$), 1.97−2.42 (m, 28H, COC*H*$_2$; C*H*$_2$CH=CHC*H*$_2$, C*H*$_2$N(C*H*$_3$)$_2$), 1.21−1.55 (m, 44H, COCH$_2$C*H*$_2$(CH$_2$)$_4$CH$_2$-CH=CHCH$_2$(CH$_2$)$_6$), 0.80−0.83 (t, 6H, CH$_2$C*H*$_3$); ^{13}C NMR (100 MHz, $CDCl_3$, 20 °C) δ 175.40 (NHCO), 174.10 (NHCO), 157.38 (OCO), 130.86−129.50 (C=C), 58.24, 46.852, 37.69, 32.96, 30.80, 30.38, 28.25, 26.80, 23.76, 15.17.

Lipoplex Formation. Solutions of cationic lipids in chloroform were prepared on a weight to volume basis. Aliquots of cationic lipids, DOPE, and cholesterol were transferred with the aid of graduated glass syringes to 12 mm × 75 mm borosilicate glass tubes (pyrex, Corning Inc., NY) in appropriate amounts to provide the relative lipid concentrations desired upon reconstitution with 1 mL of 40 mM Tris buffer, pH 7.1. Bulk organic solvent was removed with a stream of nitrogen gas, and residual solvent was removed under high vacuum (0.40 mmHg) for 4−5 h. The dried lipids were hydrated with 40 mM Tris buffer, pH 7.1, for 30−45 min at 50−60 °C with occasional vortexing. Lipid dispersions were further diluted in serum-free RPMI media (0.3 μmol/mL) and mixed with pUC19-CMV-β-gal plasmid DNA (0.2 μg/mL), as described elsewhere (*8*). Lipoplexes were added to the cells within 1 h after mixing.

Transfection Assays. Approximately 50 000 B16F0 cells (CRL-6322, ATCC, Rockville, MD) in 0.5 mL of 10% FBS/90% RPMI, supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, 4 mM L-glutamine, and 1 mM sodium pyruvate were seeded into each well of 48-well plates and cultured overnight in a 5% CO_2 incubator at 37 °C. After 12−14 h, the medium was removed, and 250 μL of the lipoplexes in serum-free RPMI was added. Lipoplexes were aspirated after 3 h, and 0.5 mL of 10% FBS/90% RPMI was added to each well. After a total of 48 h, the medium was removed and 150 μL of lysis buffer (0.1% Triton X-100 in 0.1 M Tris and 2 mM EDTA, pH 8) was added to lyse the cells. The cell lysate was centrifuged, and an amount of 120 μL was collected and assayed for β-galactosidase activity using a microplate colorimetric assay that employed the substrate *o*-nitrophenyl-β-D-galactopyranoside (*12*).

Cytotoxicity Assay. B16F0 cells were subjected to lipoplex formulations and further incubated for 44 h, as described above in the in vitro transfection studies. MTT was dissolved in PBS at 5 mg/mL and filtered through a 0.22 μm membrane to remove insoluble material. The 50 μL of MTT solution was added into each well, and the cells were incubated for 4 h at 37 °C in 5% CO_2. The medium was then flicked out, the cells were washed once with cold PBS, and 250 μL of DMSO was added to each well. The cells were subsequently shaken for 30 min at room temperature using an orbital shaker to ensure complete dissolution of the formazan crystals. The emerged deep-purple color was measured at 630 nm with a multiwell scanning spectrophotometer (El_x 800 UV, Bio-Tek Instruments, Inc.).

Agarose Gel Electrophoresis. Agarose powder (400 mg) was added to 50 mL of TAE buffer (0.8% dispersion) in an Erlenmeyer flask. The mixture was boiled for a minute until it became clear. To the solution, 2.5 μL (10 mg/mL) of ethidium bromide (dye) was added. The solution was allowed to cool to 50−60 °C, then poured into the electrophoresis apparatus and allowed to solidify. The lipoplexes were prepared as 0.5, 1.0, 2.0, 4.0, 6.0, and 8.0 +/− charge ratios. Calculations were based on a nucleotide average molecular weight of 330 g/mol. The ratio for cationic lipids mixed with neutral lipids was kept constant at cationic lipid/ DOPE/cholesterol 3:2:1 mol/ mol.

A fixed quantity of DNA of 0.2 μg was added to each microfuge. Aliquots of cationic liposomes were then added to provide the desired +/− charge ratio. The total volume was brought to 8 μL by addition of appropriate buffer. The microfuges were briefly centrifuged (10−20 s), and they were allowed to stand at room temperature for at least 15 min. The complexes were then loaded into the wells of the gel sequentially with proper mixing. Naked DNA was loaded on the outermost lanes as a control experiment. After loading the complexes in the wells, the gel tank was filled with TAE buffer, pH 7.4, to a few millimeters above the gel surface and the lipoplexes were subjected to an electrophoretic field of 5 V/cm for 25−30 min. Migration of naked DNA and lipoplexes was noted with the aid of a BioRad minitransluminator.

Particle Size Determination. Size determination was carried out using a 90° fixed scattering angle nanoparticle analyzer (Nicomp 370, PCS Inc., CA). All measurements were performed at room temperature with a 5 min run time. Particle size measurements were done using buffers of pH 7.2 and pH 8.0, 40 mM Tris buffer. All buffers were filtered using 0.22 μm filters. Lipid dispersions were prepared as described under the Lipoplex Formation section and subsequently diluted with a dust-free buffer to a final concentration of 1.5 mM in borosilicate tubes, 12 mm × 75 mm (KIMAX 51, VWR). Lipoplexes were prepared at a cationic lipid-to-DNA molar ratio of 1:1 (+/− ratio of 2) from 0.3 mM lipid dispersions. Lipoplexes were always freshly prepared by simply adding DNA to the lipid dispersions with gentle agitation. Preparation and manipulation of the liposomes were performed in a dust-free environment. "Equilibration time" was set to 2 min and "run time" to 10 min. Mean particle size and standard deviation reported are the cumulative average and cumulative standard deviation of five consecutive scans as calculated from intensity-weighted Gaussian analysis (C370, version 12.4). Despite the high polydispersity index of some samples, individual scans were highly reproducible.

Ethidium Bromide Displacement Assay. The studies were performed on a Cary Eclipse spectrofluorometer at an excitation wavelength of 515 nm (band-pass = 5 nm, linear reciprocal dispersion D^{-1} = 2 nm/mm, slit width = 2.5 mm) and an emission wavelength of 595−605 nm (band-pass = 10 nm, D^{-1} = 2 nm/mm, slit width = 5 mm). The amount of DNA added was set to 22.5 μg, and ethidium bromide was added in aliquots in order to identify the concentration that gave the maximum signal-to-noise ratio. In a typical titration experiment, ethidium bromide (0.8 μg, 1.01 μM) was added to the quartz cuvette that contained a small magnetic stirrer and diluted to 3 mL with appropriate buffer. Addition of 22.5 μg (67.5 nmol, by nucleotide equivalent) of plasmid DNA with continuous gentle stirring yielded a 27−29 times increase in fluorescence intensity. Cationic lipids (1.5 mM) were then added in aliquots (4.5 μL) under continuous stirring at ambient temperature, and fluorescence was monitored continuously until the reading became stable. To minimize the effects of light source fluctuation and to provide a more accurate measurement, the light intensity emitted by the sample was always ratioed with the reference signal from the excitation light source. Processing of the fluorescence values as described before (*13, 14*) provided the relative ethidium bromide displacement from the plasmid DNA. The binding profiles of cationic reagents to plasmid DNA were modeled as parabolas on a domain and range [0, +∞) and [0, −∞), respectively, with the aid of PSI-Plot (version 7, Polysoftware International, NY). Vertical shifting of the curves yielded parabolas of the form $y = ax^b$, the slopes of which can easily be compared. Instantaneous rates (dF/dr, where r stands for charge ratio) were calculated either by taking the first derivative of the best fit parabolic equation or from the experimental data for 0.2 charge ratio intervals, using $dF/dc = (F_n - F_{n-1})/0.2$. The two methods correlated well. The cumulative average rates were calculated from the experimental data for 0.2 charge ratio intervals using $\Delta F/\Delta c = (F_{in} - F_{final})/\Delta c$.

Monolayers Studies. The studies were conducted on a KSV Minitrough, Langmuir-type film balance equipped with symmetric barriers (KSV Instruments Ltd., Helsinki, Finland) and thermostated with the aid of a circulating water bath (VWR brand, model 1162, PolyScience, IL). Stock solutions of pure cationic lipids were prepared by dissolving lipids in chloroform at concentrations less than 0.5 mg/mL. The buffer (40 mM Tris, pH 7.2) was prepared with HPLC grade water, the surface tension of which was 72.0−72.8 dynes/cm. All experiments were performed in an open-air vibration-free environment. Prior to each experiment, the platinum plate was rinsed with ethanol and burned with a strong flame for 1 min and the barrier and trough were washed with soap and rinsed with distilled water. The proper volume of buffer was poured into the trough, and the platinum plate was adjusted at one-third of its height immersed in the buffer. The balance and barrier position were zeroed before any addition of the lipid. The 10−25 μL of the lipid dissolved in chloroform were applied through a microsyringe drop by drop on the surface of the buffer. After the chloroform was evaporated (15−20 min), the barriers were closed at constant speed of 9.99 mm/min. The data were collected using the proprietary KSV software (WinLB, version 1.61) and were plotted as surface pressure (mN/m) against mean molecular area (Å^2/molecule). The apparatus was validated using DPPC as a standard (*15*).

The data were subsequently imported into an Excel spreadsheet, and the compressibility modulus was cal-

culated from the first derivative of the monolayer force−area isotherms using

$$K = -A(\partial\Pi/\partial A)_T$$

where K is the isothermal compressibility modulus of the monolayer and where A is the area per molecule at the corresponding surface pressure Π. Values of the compressibility moduli at monolayer collapse pressure were calculated from the plots of the compressibility modulus as a function of the mean molecular area.

Fluorescence Polarization Studies. Fluorescence anisotropies of lipid dispersions were measured using a Cary Eclipse spectrofluorometer (Varian Inc., Victoria, Australia) equipped with motorized polarizers. The slit widths of both excitation and emission were 5 nm. Samples of lipid doped DPH dispersions (0.5 mM lipid, lipid/DPH molar ratio of 100:1) in a standard 1 cm × 1 cm square fluorescence cuvette were placed in a thermoelectric temperature-controlled four-window cuvette holder with a magnetic stirrer (temperature control precision of ±0.02 °C) and illuminated with a beam at 351 nm. The fluorescence intensities (λ_{max} = 430 nm) of the emitted light polarized parallel (I_h) and perpendicular (I_v) to the excited light were recorded at different temperatures. Anisotropy values at each temperature were calculated by the Eclipse software according to the equation

$$r = \frac{I_v - GI_h}{I_v + 2GI_h}$$

where G is the instrumental grating factor that corrects for the anisotropy introduced by the optical components of the detection system. A 5 min equilibration time was left between each temperature. The anisotropy−temperature curves were fitted to

$$r = A - \frac{B}{1 + e^{-C(T-D)}}$$

where A, B, C, and D are constant parameters to be determined. The parameter D represents the gel to liquid crystalline phase transition temperature, T_m. Nonlinear fitting of the experimental data was done in an iterative fashion using the Prostat (Poly Software Intenational, version 3, New York). Initial parameters for A and B were r_{max} and $r_{max} - r_{min}$, respectively, where r_{max} is the maximum anisotropy or average of the upper third and r_{min} represents the minimum anisotropy value or the average of the lower third of the anisotropy values of data points. The initial value of D (or T_m) is the average of the temperature values of the crossover area. Best fit parameters were assessed within a 95% confidence interval.

RESULTS

Biological Results. To establish the effect of varying the alkyl chain length on transfection efficiency, the ability of cationic lipids to mediate DNA transfection in the absence and presence of helper lipids DOPE and cholesterol was evaluated in B16F0 cells. Figure 2 illustrates the transfection properties of lipoplexes at cationic lipid-to-DNA charge ratios ranging from 1 to 4. As shown in Figure 2A, only the dioleoyl derivative, 1,-2lb5, mediated efficient transfection that increased with increasing charge ratio. At charge ratio 8:1 the transfection activity of cationic lipids decreased dramatically

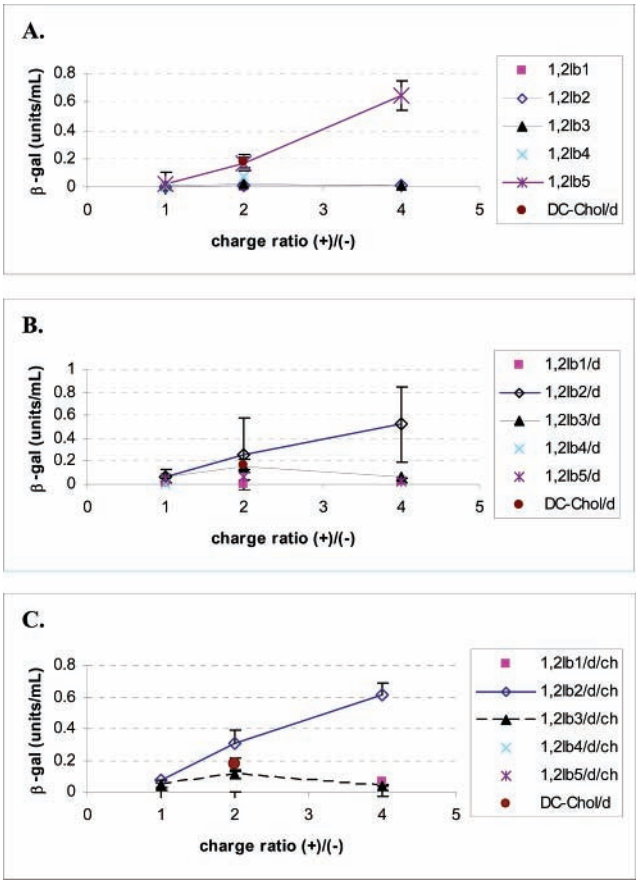

Figure 2. Transfection activity of cationic lipids in B16F0 cells: (A) 1,2lb lipoplexes; (B) 1,2lb/d lipoplexes; (C) 1,2lb/d/ch lipoplexes. The *o*-nitrophenol formation was converted to units, using a standard curve obtained with commercial β-galactosidase. The data presented are the average of values obtained from seven wells (n = 7) of two independent experiments performed at different times.

because of toxicity (not shown). Also, it is noted that the transfection potency of complexes containing 1,2lb5 at 2:1 +/− charge ratio is comparable to the potency of complexes containing the commercially available cationic lipid DC-chol, and it is much greater at higher charge ratios. Surprisingly, the activity of the 1,2lb5 is greatly diminished in the presence of helper lipids (Figure 2B,C). Contrary to that, the dimyristoyl derivative 1,2lb2 induced high levels of β-galactosidase when used with DOPE and DOPE/cholesterol (Figure 2). Lipoplexes made by the dilauroyl derivative 1,2lb1 and the distearoyl analogue 1,2lb4 were devoid of activity at all charge ratios and compositions. The dipalmitoyl derivative 1,-2lb3 mediated low levels of gene expression at all +/− ratios when it was combined with DOPE and DOPE and cholesterol (Figure 2B,C).

The cytotoxicity of the cationic lipids alone or in combination with DOPE and DOPE and cholesterol was tested by the MTT reduction method. All lipoplex formulations were well tolerated with cell survival greater than 75% at all different charge ratios (not shown).

Physicochemical Properties. Agarose Gel Electrophoresis. Since DNA condensation is considered a requirement for efficient in vitro internalization of lipoplexes by the cells, techniques that provide information about lipid−DNA interaction are useful tools to provide insight about the mechanism of transfection. One such technique is agarose gel electrophoresis, in which lipoplexes are subjected to an electric field and the electrostatic and hydrophobic interactions of cationic

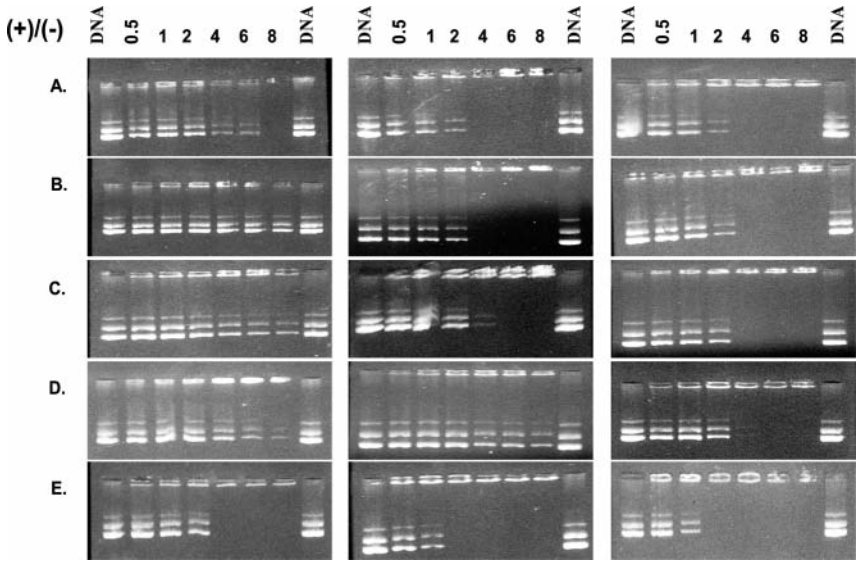

Figure 3. Gel retardation assay (from left to right): (A) 1,2lb1, 1,2lb1/d, 1,2lb1/d/ch; (B) 1,2lb2, 1,2lb2/d, 1,2lb2/d/ch; (C) 1,2lb3, 1,2lb3/d, 1,2lb3/d/ch; (D) 1,2lb4, 1,2lb4/d, 1,2lb4/d/ch; (E) 1,2lb5, 1,2lb5/d, 1,2lb5/d/ch. All gels were repeated at least once. Details of the assay are as described in Materials and Methods.

lipids with DNA can be evaluated from the migration pattern of the plasmid DNA. Electrophoretic migration of molecules is dependent on both molecular charge and size. Thus, retardation of plasmid DNA on agarose gel can occur because of its encapsulation by cationic lipids or because of charge neutralization and compaction to small particles. Plasmid DNA compaction by cationic lipids is ordinarily accompanied by ethidium bromide exclusion yielding DNA bands of reduced intensity. This is the basis for differentiating compacted DNA from encapsulated DNA that has precipitated in the slots of the gel.

Figure 3 illustrates the effect of bivalent cationic lipids on plasmid DNA electrophoretic migration. In the absence of helper lipids only the dioleoyl derivative 1,2lb5 promoted complete DNA retardation at charge ratios relevant to those used in the transfection experiments (Figure 3E, left lane). The results suggest that lack of activity of lipoplexes composed of saturated cationic lipids is due to their extremely weak interaction with the plasmid DNA. Moreover, the complete retardation of plasmid DNA promoted by 1,2lb5 at charge ratios of >2 suggests that the higher levels of gene expression observed at the highest charge ratio (Figure 2A) is due to a larger population of DNA associated with the lipid or due to a greater degree of plasmid condensation induced by the cationic lipid.

The presence of DOPE in the formulations greatly facilitated association of plasmid DNA with the cationic lipids. The sole exception was the distearoyl derivative 1,2lb4, where DOPE had no effect (Figure 3D, middle lane). The binding profiles of 1,2lb1/d and 1,2lb2/d were similar with a full retention of the plasmid in the slots of the gel occurring at +/− ratio of ≥4. The results are in agreement with the high transfection activity of the 1,2lb2/d and 1,2lb2/d/ch, but they contradict the lack of activity of the 1,2lb1 formulated with DOPE and DOPE and cholesterol. The binding efficiency of the dipalmitoyl derivative 1,2lb3 also increases when formulated with helper lipids (Figure 3C), and the transfection activity of these lipoplexes increases accordingly (Figure 2C). In contrast, although plasmid DNA migration is inhibited by the 1,2lb4/d/ch (Figure 3D, right lane), its transfection activity is practically zero. A similar contradiction between the gel electrophoresis and transfection activity occurred with the 1,2lb5/d and 1,2lb5/d/ch. Although the binding efficiency of the cationic lipids to the DNA is increased compared to the 1,2lb5 alone, their transfection activity is reduced (Figure 2B,C).

Ethidium Bromide Displacement Assay. Another approach used to characterize lipid−DNA complexes is the EtBr displacement assay. The distinct fluorescence enhancement of intercalated EtBr allows accurate spectrofluorometric quantification of its exclusion from the double helix of plasmid DNA by cationic lipids. This method is used to determine the exact charge ratio at which cationic lipids fully displace EtBr from plasmid DNA.

Figure 4A shows that none of the cationic lipids totally displaces EtBr at charge ratios ranging from 0.5 to 2 at physiological pH and ambient temperature. In fact, the only lipid that was appreciably bound to DNA is the 1,2lb5. At a charge ratio of 2, this lipid had accomplished 66% EtBr exclusion. Fitting the experimental data into a parabolic equation as described in the methods section suggested that complete exclusion of EtBr by the 1,2lb5 analogue takes place at a +/− charge ratio equal to 2.7. This is in agreement with the agarose gel electrophoresis results that indicated that complete retention of plasmid DNA in the slots occurred at charge ratios greater than 2. Binding of cationic lipids bearing a tertiary amine as the polar headgroup was also dependent on the pH of the media. Figure 4B signifies the cooperative nature of DNA binding of the 1,2lb5 at both pH values; i.e., the binding rate increases with charge ratio exponentially. As expected, DNA binding of the lipid at pH 7.2 was more effective than at pH 8.0. Paradoxically, binding cooperativity at pH 8 was higher as signified by the higher curvature of the neutralization curve (Figure 4B) and the higher slope of the average binding rate in the +/− range of 0.2−1.2 (Figure 4C). Specifically, at a +/− charge ratio of 0.2, the lipid quenched 4.2% of the total fluorescence at pH 7.2 as opposed to only 0.87% fluorescence quenching at pH 8.0. The average rate difference at the two pH values was 4.9. At a +/− ratio equal to 2, the lipid quenched 66.4% of the total fluorescence at pH 7.2 as opposed to 43.0% fluorescence quenching at pH 8.0, thus reducing the rate difference between the two pH values to 1.5. To explain the higher curvature of the plasmid DNA binding curve at pH 8, one has to account for the

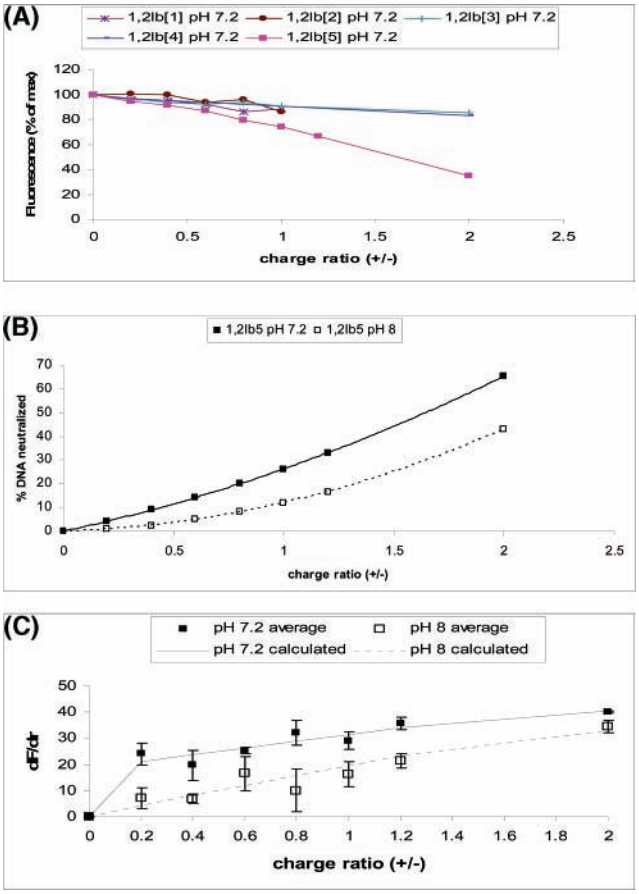

Figure 4. (A, B) Titration of plasmid DNA with cationic lipids in the presence of ethidium bromide. Fluorescence is reported relative to the fluorescence in the absence of cationic lipids, after subtracting the baseline of ethidium bromide alone, for each of the buffer conditions examined. (C) The noncumulative average rates d*F*/d*r* were calculated from the data shown in (B), as described in Methods.

forces responsible for EtBr exclusion. The main two forces that play a major role in plasmid DNA condensation by cationic lipids are the electrostatic and hydrophobic ones. Electrostatic forces are long range and are responsible for the initial approach of the cationic lipids to the DNA. Neutralization of the negative charges of the double helix causes its collapse and its compaction to a random coil configuration identified in our case with EtBr displacement. The collapse of the double helix is accompanied by a reduction of the water of hydration; a condition that encourages the cationic lipids to surround the plasmid DNA in greater numbers and pack tighter around it, thus facilitating further dehydration and compaction of the DNA. It appears that the electrostatic interactions are weaker at pH 8 than at pH 7.2, whereas dehydration-mediated DNA condensation due to hydrophobic attractive interactions plays a bigger role at pH 8.

Dynamic Light Scattering. Hydration of cationic lipids in Tris buffer, pH 7.2, resulted in liposome formation of quite heterogeneous size, as indicated by the large coefficient of variation (Table 1). The size of liposomes made by 1,2lb1 and 1,2lb2 was above 1 μm, whereas dispersions made of the 1,2lb3 and 1,2lb4 had an average particle size of 0.5 μm. Upon addition of DNA, the diameter of all the complexes composed of saturated cationic lipids increased, with the only exception being the complex made of the dioleoyl derivative 1,2lb5. The results of the particle size distribution suggest that, in agreement with the gel electrophoresis and the EtBr displacement assay, saturated cationic lipids failed to electrostatically interact and effectively condense the plasmid DNA. In addition, the results verify the dependence of DNA binding on the pH. The very big particle size of the 1,2lb5−DNA complex measured at pH 8, as opposed to the compact particle of the complex at pH 7.2, validates the results obtained from the EtBr displacement assay and suggests that at pH 8, the lipid is loosely associated with plasmid DNA mainly through hydrophobic forces.

Table 1. Summary of Particle Size Distribution of Lipid Dispersions and Lipoplexes at a +/− Charge Ratio Equal to 2

	pH	mean diameter ± SD (nm)	coefficient of variation	macroscopic appearance
		Particle Size Distribution of Cationic Lipid Dispersions[a]		
1,2lb1	7.2	5698 ± 5800	1.018	turbid
1,2lb2	7.2	990 ± 704	0.712	turbid

[a] All of the lipid concentrations are 1.5 mM. [b] All of the lipid concentrations are 0.1 mM.

Monolayer Studies. Studies performed on spread monolayer at the air−water interface enabled investigation of surface properties of the novel cationic lipids. Cationic lipids 12lb1 and 1,2lb5 exist at liquid-expanded phases at both 23 and 37 °C, exhibiting almost identical monolayer collapse areas and pressures at corresponding temperatures (Figure 5 and Table 2). Contrary to the 1,-2lb1 and 1,2lb5, 1,2lb2 monolayers were at a liquid condensed state at high compressions at 23 °C while monolayers of this lipid displayed an all-liquid expanded behavior at 37 °C, as indicated by the absence of a phase transition in the force−area isotherm of the 1,2lb monolayers and its larger mean molecular area at 37 °C (Table 2).

Monolayers composed of the 1,2lb3 derivative were at liquid expanded states at low surface pressures and at liquid condensed phases at high surface pressures, at both temperatures. The distearoyl derivative 1,2lb4 displayed only liquid-condensed behavior at 23 °C as concluded by the relatively small molecular area at monolayer collapse, the high value of the compressibility modulus *K*, and the absence of any discontinuities in the Π−*A* isotherm. Isotherms of this cationic lipid at 37 °C displayed two discontinuities at two different surface pressures and mean molecular areas. The first discontinuity was centered at the mean molecular area and surface pressure of approximately 93 Å^2 and 10 mN/m, respectively, while the second one occurred at smaller molecular dimensions (63 Å^2) and higher compression forces (18 mN/m). Although the exact nature of these two transitions is not known, it is possible that the lower pressure transition is related to the merging of several lipid islets (2D micelles on the interface) into a more uniform surface, whereas the discontinuity that occurred at higher pressure represents an L_1-to-L_2 phase transition. Nevertheless, the small average cross-sectional molecular areas (Table 2) of this lipid at monolayer

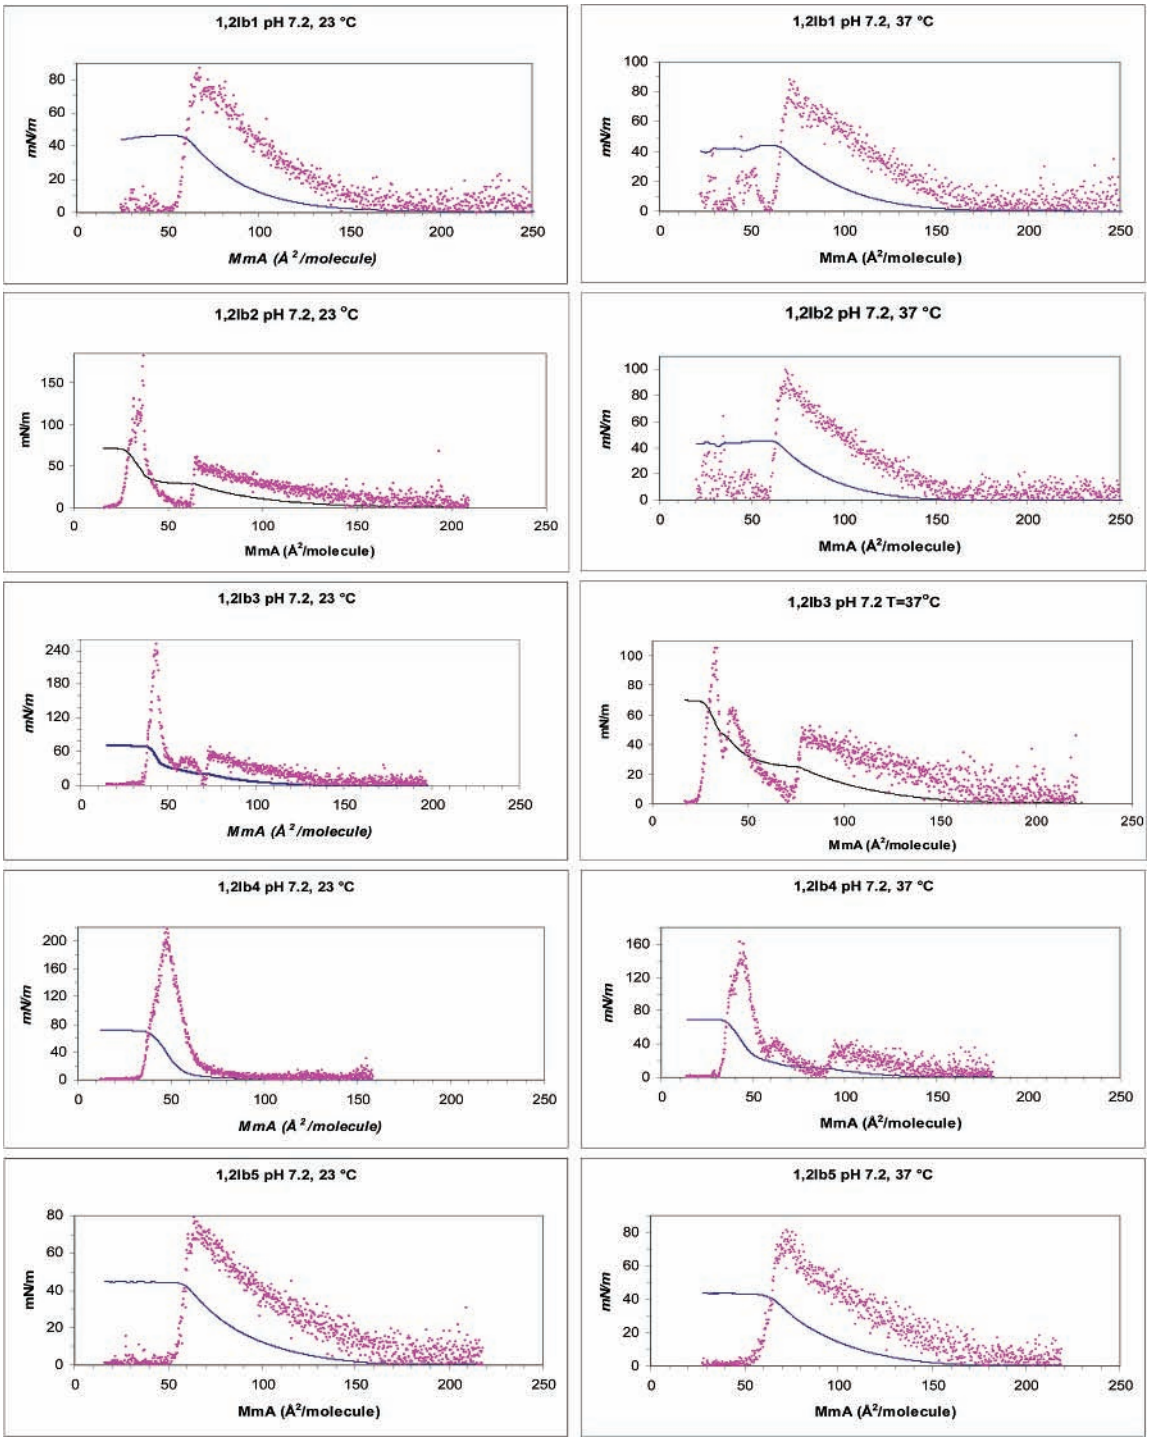

Figure 5. Representative compression isotherms of 1,2lb cationic lipids spread on 40 mM Tris buffer, pH 7.2, at 23 °C (left) and 37 °C (right). Line represents the Π−*A* isotherm, while dots represent calculated *K*−*A* isotherm.

collapse argue in favor of a compact assembly of the 1,-2lb4 at both temperatures.

Fluorescence Anisotropy Studies. As shown in Figure 6, the nature and length of the acyl chain affected the dependence of fluorescence anisotropy of cationic lipid/DPH dispersions on the temperature profoundly. All lipids exhibited one or more inflections in their profile with the exception of dioleoyl derivative 1,2lb5, suggesting that this monounsaturated derivative existed at the liquid crystalline state within the temperature range studied in agreement with the monolayer studies (Figures 5 and 6). For the DPPC, a phase transition temperature of 41.3 °C was obtained that agrees well with literature values (*16*). Not surprisingly, the phase transition of DPPC was strikingly sharp compared to the much broader phase transitions of the other saturated cationic lipids. Specifically, the temperature span of the DPPC phase transition was only 1 °C, compared to approximately 18, 38, 44, and 36 °C for 1,2lb1, 1,2lb2, 1,2lb3, and 1,2lb4, respectively. The larger temperature span of the transition signifies the uncooperative nature of the phase transition of cationic lipids compared to the highly cooperative gel-to-liquid crystalline phase transition of DPPC.

As shown in Table 3, the midpoint of the phase transition temperature for 1,2lb1 was found to be equal

Table 2. Monolayer Parameters of 1,2lb Series[a]

	mean molecular area (Å^2)		Πc (mN/m)		K (mN/m)		dΠ/dA		phase state[c]

to 32.9 °C. However, as shown in Figure 5, compression isotherms of 1,2lb1 indicated an all-liquid expanded state of this lipid at 23 °C. Similar to the 1,2lb1, the compression isotherm of 1,2lb2 monolayers indicated the liquid expanded state of this lipid at 37 °C, contrary to the anisotropy experiments that indicated a fluid phase of this lipid existing above 44 °C. This monolayer−bilayer inconsistency of the short-chain derivatives appeared to start breaking down with the dipalmitoyl derivative 1,-2lb3.

In view of this inconsistency between the 2D and 3D experiments and the wide onset−offset temperature range of the phase transitions of the cationic lipids, an attempt was made to determine the onset 3D phase transition temperatures of cationic lipids from the derivative profile of the anisotropy temperature plot (Figure 7). The values tabulated in Table 3 are not very different from the corresponding transition midpoints and reinforce the very different behavior of the saturated cationic lipids observed in 2D monolayers as opposed to their 3D bilayers assemblies.

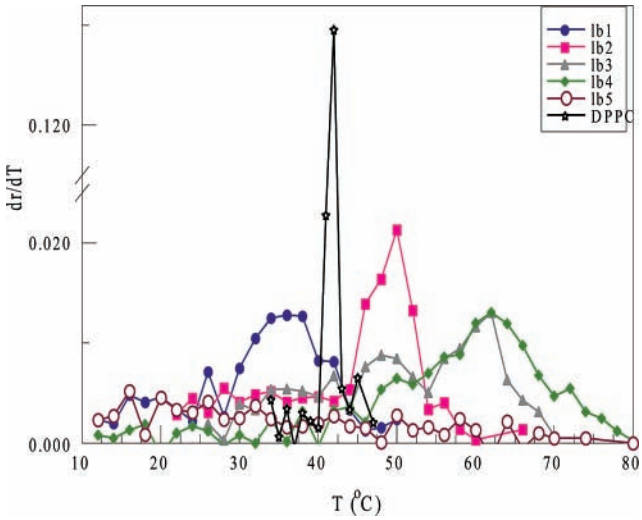

Figure 7. Derivative data of fluorescence anisotropy (r) against temperature plots for cationic lipid dispersions at pH 7.2.

DISCUSSION

The transfection activity of *N*,*N*′-diacyl-1,2-diaminopropyl-3-carbamoyl(dimethylaminoethane) amphiphilic monovalent derivatives was recently correlated with a low compressibility modulus recovered from monolayer studies (*12*). Assessment of the interfacial compressibility moduli (K) as a function of cross-sectional area has provided valuable insights into lipid in-plane elastic interactions in the past (*17*−*19*). As shown in Table 2, the liquid-condensed states of saturated cationic lipids with the exception of the 1,2lb1 were characterized with high K values at 23 °C. In sharp contrast, monolayers of the transfection potent dioleoyl derivative 1,2lb5 exhibited the lowest compressibility modulus, 84.6 mN/m, at 23 °C. Low values of the compressibility modulus are indicative of a more compressible packing state of lipid molecules with enhanced in-plane elasticity and larger mean cross-sectional average area. Interestingly, the only lipid that mediated high levels of gene expression in the absence of helper lipids was the 1,2lb5. The larger mean molecular area of 1,2lb5 allows efficient protonation of the amine headgroup and plasmid DNA charge neutralization, thus initiating the process of compaction. Increased hydration and elasticity of the 1,2lb5 help the lipid navigate through, pack nicely, and dehydrate the plasmid DNA in a cooperative fashion, thus leading to small stable lipoplex particles (Table 1).

Using the Henderson−Hasselbach equation, one could calculate the apparent pK_a of the cationic lipid under the assumption that complete neutralization of the "visible" negative charges of the plasmid DNA occurs somewhere

within the range of 80−100% of fluorescence quenching. The percent of maximum fluorescence values, at pH 7.2 and pH 8, at the lowest charge ratio where the contribution to the displacement of EtBr due to any other forces other than electrostatic ones was minimum (Figure 4 B), was applied to the equation. Interestingly, the apparent average pK_a was calculated to be in the range 6.63−6.75, which is significantly lower than the pK_a of the isolated triamine (pK_{a1} = 8.959, pK_{a2} = 9.592) (*20*). The difference between the apparent pK_a of the lipids and those of the free amine is obviously due to reduced hydration and due to the spatial dispersion of the charge of one molecule to the immediate neighbors promoted by the tight packing of the hydrophobic long acyl chains. Nevertheless, according to the calculation above, the amine polar headgroup of the 1,2lb5 is only 20−25% protonated at pH 7.2, thus implying that DNA charge neutralization would occur with 4−5 excess amount of 1,2lb5 cationic lipid. However, as mentioned in the Results section, complete EtBr exclusion from plasmid DNA occurs at a +/− charge ratio of 2.7. These two results suggest that a minimum of 32.5% contribution to DNA condensation is due to the cooperative hydrophobic forces of the acyl chains of the cationic lipid. Furthermore, the results indicate that association of plasmid DNA with the cationic lipid is extremely important, since maximum transfection activity occurred at +/− ratios high enough (+/− ratio of 4/1) to ensure association of the whole DNA population with the lipid.

It was furthermore shown that the presence of DOPE consistently reduced the transfection activity of the 1,-2lb5 (Figure 2). Although its presence increased the binding efficacy of the cationic lipid to the DNA (Figure 3), EtBr exclusion assay indicated that this increased association did not lead to increased compaction (Figure 4A). DOPE has been shown before to adversely affect the in vivo performance of cationic lipids (*21*, *22*) but never the in vitro transfection activity, especially in the absence of serum proteins. The values of the compressibility modulus of the 1,2lb1 at 23 and 37 °C were also low: 88.4 and 86.3 mN/m, respectively. Nonetheless, lipoplexes composed of 1,2lb1 failed to induce marker gene expression. A possible reason for the lack of activity of the dilauroyl derivative 1,2lb1 can be found in the early work of Minsky and co-workers (*23*). They have suggested that fatty acid chains of 12 carbons are not long enough to create the hydrophobic environment required for efficient dehydration and compaction of plasmid DNA. Another reason could be that the shorter double-chained dilauroyl derivative does not cause sufficient cell membrane perturbation to enable the DNA to gain access to the cytoplasm (*24*).

Unlike the 1,2lb5, the transfection activity of the dimyristoyl derivative 1,2lb2 has increased tremendously in the presence of DOPE. This increase was correlated with an enhanced association of this lipid with plasmid DNA in the presence of DOPE, as verified by gel electrophoresis (Figure 3) and EtBr exclusion assay (Figure 4A). Perhaps the presence of DOPE increased the hydration and fluid properties of 1,2lb2 vesicles, thus increasing its binding to plasmid DNA and cell surfaces.

The discontinuity present in the compression isotherm, the small mean molecular area, and the high surface pressure of 1,2lb2 at monolayer collapse suggest that this lipid exists at a liquid condensed state at 23 °C (Figure 5). The large "lift off" areas (150−220 Å^2), however, imply that this lipid exists at an extremely expanded spread state at low compressions, contrary to the corresponding *N*,*N*′-dimyristoyl-1,2-diaminopropyl-3-carbamoyl(dimethylaminoethane) monovalent derivative (*12*). In fact, all 1,2lb derivatives had large "lift off" areas compared to their monovalent counterparts (*12*). It appears that the presence of the branched symmetric diamine imposes steric hindrance and prevents close lipid apposition at low surface pressures. At high compressions, the headgroup steric barrier is overcome; thus, all monovalent and bivalent analogues but the shorter chain 1,2lb1 (R = 12C) have similar mean molecular dimensions at monolayer collapse.

The increased two-plane elasticity of the transfection incompetent 1,2lb1 derivative prompted investigation of the physical properties of cationic lipids in bilayer assemblies. Surprisingly, fluorescence anisotropy studies demonstrated that vesicles made of saturated shorter chain 1,2lb derivatives, i.e., 1,2lb1 and 1,2lb2, behave very differently from the corresponding monolayer surfaces (Figure 6, Table 3). Extreme caution needs to be exercised when correlating the liquid expanded properties measured in lipid monolayers with fluid properties of lipid dispersion.

In summary, it has been shown repeatedly in the past that the exterior of lipoplexes is predominantly composed of cationic lipid alone (*25, 26*). There have been many attempts in the past to relate physicochemical properties of cationic lipids in isolation with transfection potency in an effort to derive meaningful structure−activity relationships (*27*). Several of the physicochemical properties that were found to play a role in the transfection activity are gel-to-liquid crystalline phase transition below 37 °C (*28*−*31*), induction of the nonbilayer H_{II} structure (*32*), and extent of lipid hydration (*33*). These parameters contain indirect information about physical properties such as hydrogen bonding and surface activity that may be relevant to the transfection activity mediated by one kind of lipid structure but not by another. For example, the transfection potency of glycerol backbone monovalent cationic lipids appears to be related to their main phase transition temperature but that does not necessarily apply to polyvalent cationic lipids (*34*). The results of this investigation indicated a correlation between the transfection activity of these bivalent cationic lipids and high two-dimensional elasticity and fluidity of corresponding cationic lipid vesicles.

Preparation and Evaluation of Thiol-Modified Gelatin Nanoparticles for Intracellular DNA Delivery in Response to Glutathione

Sushma Kommareddy and Mansoor Amiji*

Department of Pharmaceutical Sciences, School of Pharmacy, Northeastern University, 110 Mugar Life Sciences Building, Boston, Massachusetts 02115. Received May 20, 2005; Revised Manuscript Received August 18, 2005

To enhance the intracellular delivery potential of plasmid DNA using nonviral vectors, we have developed thiolated gelatin nanoparticles that can release the payload in the highly reducing environment, such as in response to glutathione. Thiolated gelatin was synthesized by covalent modification of the primary amino groups of Type B gelatin using 2-iminothiolane (Traut's reagent). The degree of thiolation of the polymers ranged from 0 to 43.71 mmol of reduced sulfhydryl (SH) groups when the amount of 2-iminothiolane was increased up to 100 mg per gram of the biopolymer. Cytotoxicity evaluations carried out by the formazan (MTS) assay showed that the thiolated gelatin prepared with 20 mg and 40 mg of 2-iminothiolane (SHGel-20 and SHGel-40) per gram of gelatin had comparable cell viability profile to that of the unmodified gelatin. In vitro release studies of fluorescein isothiocyanate (FITC)-labeled dextran (mol wt. 70 000 Da), when encapsulated in gelatin and thiolated gelatin nanoparticles (150−250 nm in diameter), was found to be affected by the presence of glutathione (GSH) in the medium. The presence of GSH was found to enhance the release by about 40% in case of thiolated gelatin and about 20% in gelatin nanoparticles under similar conditions of temperature and GSH concentrations. Qualitative and quantitative analysis of transfection in NIH-3T3 murine fibroblast cells by the nanoparticles carrying plasmid DNA encoding for enhanced green fluorescent protein (EGFP-N1) was done by fluorescence confocal microscopy and fluorescence-activated cell sorting (FACS). Qualitative results showed highly efficient expression of GFP that remained stable for up to 96 h. Quantitative results from FACS showed that the thiolated gelatin nanoparticles (SHGel-20) were significantly more effective in transfecting NIH-3T3 cells than other carrier systems examined. The results of this study show that thiolated gelatin nanoparticles would serve as a biocompatible intracellular delivery system that can release the payload in a highly reducing environment.

INTRODUCTION

In recent years, there has been an enormous interest in ex vivo and in vivo gene therapy approaches, which necessitates the formulation of DNA into vectors for targeting a specific population of cells either locally or systemically. The gene delivery to target cells can be achieved by either viral or nonviral methods (*1*−*6*). Viral vectors, although efficient in transfection, are plagued by issues of integration with the host genome, self-replication, recombination potential, and immunogenicity. There are several reported incidents of insertional mutagenesis with viral vector administration in humans leading to serious safety concerns (*7*−*9*). Viral vectors are also relatively expensive to manufacture and have difficulties in bypassing the immune defense mechanism.

The nonviral vectors for gene delivery applications are increasingly popular owing to several advantages, such as ease of production and administration and lack of immunogenicity and mutagenesis. An ideal vector used in gene therapy needs to be inert while in circulation and release its payload at the target site resulting in an efficient transfection of the cells. The vector used should have sufficiently small size and stability, minimal aggregation in blood, and the ability to efficiently target cells. Once in the cell, the system should disassemble and release intact DNA in the supercoiled state for nuclear uptake and transcription. Cationic lipids and biodegradable polymers have been synthesized to condense DNA and promote efficient intracellular delivery (*10*). However, the design of an ideal vector is still a limiting step, and various strategies are needed for achieving effective nonviral gene therapy (*11*).

Polymeric nanoparticles offer an attractive alternative for intracellular gene delivery because of their high surface-to-volume ratio and their ability to encapsulate DNA without a precondensing step (*12*). In addition, these colloidal carriers are stable and can be prepared and modified with relative ease. Tissue- and cell-targeted polymeric nanocarriers can be obtained by attaching specific ligands such as antibodies or lectins in order to achieve site-specific delivery, and the surface can be modified with hydrophilic polymers, such as poly(ethylene glycol) (PEG), resulting in long circulating properties in the systemic circulation. Due to the small size these nanoparticles can be used to achieve tumor targeting by the enhanced permeability and retention (EPR) effect (*13*−*15*).

For the past several years, our group has been engaged in exploring the use of gelatin and modified gelatin-based nanoparticles for intracellular drug and gene delivery. The nanoparticulate carriers of gelatin have been used for efficient intracellular delivery of the encapsulated payload. Kaul and Amiji (*16*, *17*) have shown that Type-B gelatin and PEG-modified gelatin nanoparticles loaded with TMR-dextran, as a model hydrophilic macromolecule, can be used for cell trafficking (BT-20 cells). Also, from the trafficking experiments, using colloidal gold-

Published on Web 09/28/2005

encapsulated gelatin nanoparticles, it was evident that nanoparticles were efficiently taken up by the cells through nonspecific endocytosis and accumulated in the perinuclear region. Furthermore, it was reported that plasmid-encapsulated gelatin and PEG-modified gelatin nanoparticles were internalized in NIH-3T3 fibroblast cells within the first 6 h of incubation, and the transfection results are quantified by flow cytometry at different time points up to 96 h (*18*). Kaul and Amiji also showed the biodistribution and tumor targeting results of gelatin and PEG-modified gelatin nanoparticles, labeled with iodine-125, upon intravenous administration in mice bearing Lewis lung carcinoma (LLC) (*19*). From the radioactivity in plasma, tumor mass, and various organs collected, it was evident that the majority of PEGylated nanoparticles were present either in the blood pool or taken up by the tumor mass and liver. The plasma and the tumor half-lives, the mean residence time, and the area-under-the-curve of the PEGylated gelatin nanoparticles were significantly higher than those for the gelatin nanoparticles. The results of this study showed that PEGylated gelatin nanoparticles do possess long circulating properties and can preferentially distribute in the tumor mass after systemic delivery (*19*). Last, it has been shown that the in vivo transgene expression in LLC tumor bearing C57BL/6J mice administered with plasmid DNA encoding β-galactosidase (pCMV-β) encapsulated in gelatin and PEG-modified gelatin nanoparticles. Qualitative and quantitative analysis has shown a significantly greater transfection efficiency with the use of PEG-modified gelatin nanoparticles following systemic administration (*20*).

It is the unique physical, chemical, and biological properties of the gelatin and its modified derivatives that make this system suitable for systemic gene delivery and other therapeutic applications (*16*, *18*, *19*, *21*−*26*). Despite numerous advantages of gelatin, it is still sometimes necessary to chemically modify the biopolymer so that it remains stable during blood circulation which can lead to efficient expression at the target site. Based on the fact that the free thiol groups can form disulfide bonds within the polymer, the added thiol groups can be used in strengthening the tertiary and quaternary protein structure. The disulfide bonds also stabilize the nanoparticles, and when they are broken, the polymer unfolds, releasing the encapsulated payload. This mechanism is environment-sensitive and is enhanced by the presence of glutathione (GSH) or other redox enzymes that are present in high concentrations in the hypoxic regions, such as the tumor cells. The cells generally contain majority of the glutathione in the cytosol and at concentrations ranging from 1 to 11 mM, while the extracellular concentration is about 1000-fold less (*27*−*29*).

On the basis of the differences in the intracellular and extracellular GSH concentrations, we hypothesize that thiolated gelatin nanoparticles will provide a unique platform for intracellular DNA delivery in response to GSH levels. In the present study, therefore, we describe the synthesis of thiolated gelatin and preparation of nanoparticulate systems for intracellular plasmid DNA delivery. Transgene expression efficiencies, using enhanced green fluorescent protein (EGFP-N1) plasmid, were examined by qualitative and quantitative analysis.

EXPERMENTAL PROCEDURES

Materials. Type-B gelatin (225 bloomstrength) with 100−115 mmol of carboxylic acid per 100 g of protein, an isoelectric point of 4.7−5.2, and an average molecular weight 40 000−50000 Da was purchased from Sigma-Aldrich (St Louis, MO). 2-Iminothiolane (Traut's reagent) and 5,5′- dithiobis(2-nitrobenzoic acid) (Ellman's reagent) were purchased from Pierce Biotechnology Inc., (Rockford, IL). CellTiter 96 AQ_{ueous} one solution cell proliferation assay was obtained from Promega Corporation (Madison, WI). Ethyl alcohol, absolute, 200 proof, 99.5% ACS reagent, was obtained from Acros Chemicals (Pittsburgh, PA). Glyoxal 40% w/v and glycine were purchased from Fisher Scientific (Fair Lawn, NJ). Poly(ethyleneimine) (PEI, M_n = 10 000 Da) and fluorescein isothiocyanate (FITC) dextran with a molecular weight 70 000 Da and degree of substitution of 0.004 mol of FITC per mole of dextran were obtained from Sigma as well. The NIH-3T3, mouse embryonic fibroblast cell line, was obtained from American Type Culture Collection (ATCC, Rockville, MD) and maintained in Dulbecco's modified Eagle medium (DMEM) with 4 mM L-glutamine, 1.5 g/L sodium bicarbonate, and 4.5 g/L glucose and supplemented with 10% fetal bovine serum and 1% each of penicillin−streptomycin, HEPES buffer, and sodium pyruvate. General purpose serum-free medium (UltraCulture) was obtained from BioWhittaker (Walkersville, MD). Lipofectin lipid transfection reagent was obtained from Invitrogen (Carlsbad, CA). All aqueous solutions and reagents were prepared in deionized distilled water from Nanopure II (Barnstead/Thermolyne, Dubuque, IA).

Synthesis and Purification of Thiolated Gelatin. Thiolated gelatin was synthesized by covalent modification of the primary amino groups of gelatin by the addition of sulfhydryl moieties, and the chemistry involved in thiolation is shown in Figure 1. For the synthesis, 1 g of gelatin was dissolved in 100 mL of deionized water and then incubated with varying amount of 2-iminothiolane hydrochloride, 20 mg (SHGel-20), 40 mg (SHGel-40), and 100 mg (SHGel-100) at room temperature for 15 h (*30*). Any unreacted 2-iminothiolane was removed by repeated dialysis against 5 mM HCl followed by 1 mM HCl solution for 24 h each. The purified thiolated gelatin was dried in vacuo and stored at −80 °C for further use.

Determination of the Degree of Thiolation. To determine the degree of thiolation, the control gelatin and thiolated gelatin derivatives were dissolved in 0.1 M sodium phosphate buffer (pH 8.0) containing 1 mM EDTA. The colorimetric reaction was carried out by mixing 500 μL of the sample solutions with 100 μL of Ellman's reagent (4 mg/mL) and 5 mL of buffer. After 15 min of reaction at room temperature, the absorbance of the solution was measured at 412 nm by Shimadzu UV160U spectrophotometer (Columbia, MD) (*31*). The degree of thiolation was calculated by extrapolating the results obtained to that of the standard curve of cysteine and expressed in terms of millimoles of free sulfhydryl groups per gram of gelatin.

Preparation of Nanoparticles. Nanoparticles of the control gelatin and thiolated gelatin derivatives were prepared by desolvation using ethanol under controlled conditions of temperature and pH as previously described (*16*). Briefly, a 1% (w/v) solution in water was prepared by dissolving 200 mg of the control or thiolated gelatin in a temperature controlled water bath at 37 °C. The pH of the resulting solution was adjusted to 7.0 with 0.2 M sodium hydroxide. Nanoparticles were formed when the solvent composition was changed from 100% water to 75 vol % hydro-alcoholic solution, upon gradual addition of ethanol, under continuous stirring conditions. The formed nanoparticles were further cross-linked with 0.1 mL of

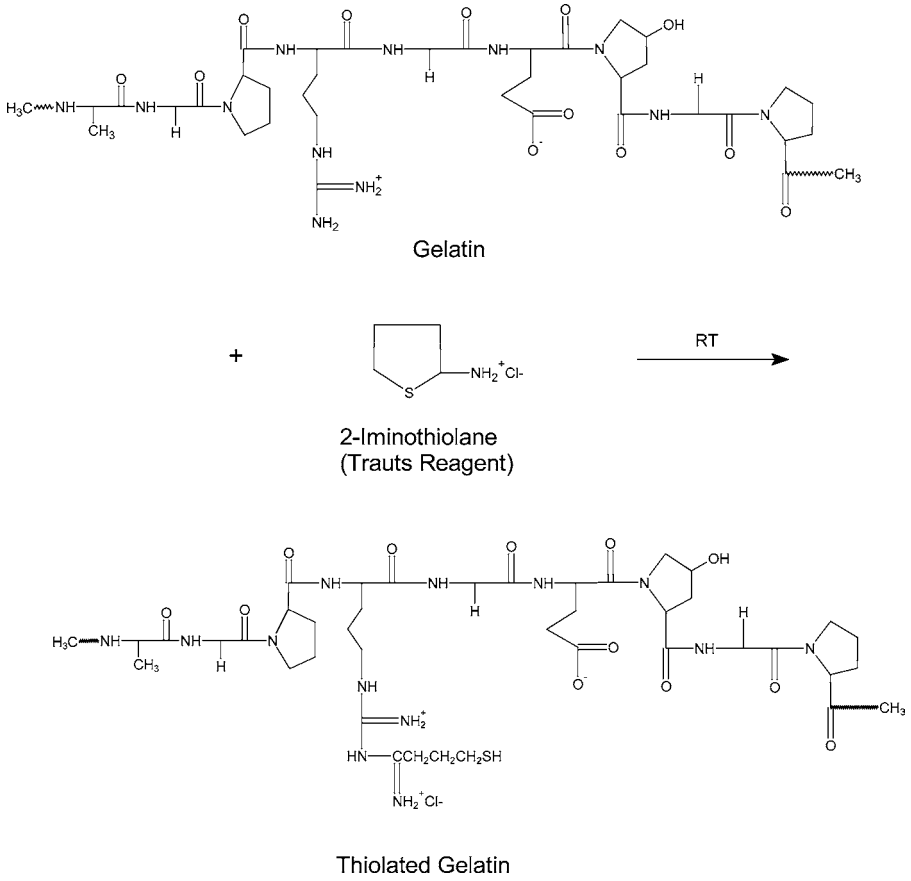

Figure 1. Schematic illustration of the synthesis of thiolated gelatin by reacting Type-B gelatin with 2-iminothiolane (Traut's Reagent).

40% (v/v) aqueous solution of glyoxal for desired time interval, and any unreacted aldehyde was quenched with 0.2 M glycine solution. The particles obtained were centrifuged either before or after cross-linking at 16 000 rpm for 30 min. The nanoparticles were washed twice with deionized distilled water and lyophilized.

Characterization of Nanoparticles. *Particle Size Analysis.* The resulting non-cross-linked and cross-linked systems of the control and thiolated gelatin nanoparticles were analyzed for mean particle size by ZetaPALS, 90Plus (Brookhaven Instruments Corporation, Holtsville, NY). The colloidal suspension of the nanoparticles was diluted with deionized distilled water, and the particle size analysis was carried out at a scattering angle of 90° and a temperature of 25 °C.

Scanning Electron Microscopy. The gelatin and thiolated gelatin nanoparticles were separated from suspension by centrifugation at 16 000 rpm for 30 min and lyophilized. The freeze-dried nanoparticles were mounted on an aluminum sample mount and sputter-coated with gold−palladium to enhance conductivity and minimize the buildup of charges. The samples were then observed for surface morphology under a Hitachi 4800 field emission scanning electron microscope.

Surface Charge Measurements. Zeta potential (ξ) measurements of the control and thiolated gelatin nanoparticles (both non-cross-linked and cross-linked systems) in suspension in deionized water were performed using a ZetaPALS (Brookhaven Instruments Corporation, Holtsville, NY). The nanoparticles were dispersed in deionized water and the zeta potential values measured at the default parameters of dielectric constant, refractive index, and viscosity of water.

Cell Viability Studies with Thiolated Gelatin. The NIH-3T3 murine fibroblast cells were grown in 96-well plates at an initial seeding density of 10 000 cells per well in 150 μL of supplemented DMEM. The cells were allowed to grow for 24 h, and the growth medium was replaced by serum free media containing gelatin and thiolated gelatins in aqueous solutions at a concentrations ranging from 0 to 200 μg/mL along with negative control (serum free media alone). PEI, a known cytotoxic cationic polymer, was used as a positive control. The cells were treated with the control and test materials for 6 h and then replaced by 20 μL of MTS along with 100 μL of culture media per well. The cells were incubated for ~2 h along with the reagent at 37 °C in a 5% CO_2 incubator, and the absorbance of the purple colored formazan product formed was measured at 490 nm with a Biotek SynergyHT plate reader (Winooski, VT). The percent viability of the cells was expressed as the ratio of absorbance of the polymer-treated cells relative to those in serum alone multiplied by 100 and plotted as a function of the polymer concentration.

Glutathione-Responsive In Vitro Release Studies. FITC-dextran of molecular weight 70 000 Da with a degree of substitution of 0.004 mol of FITC per mole of dextran was used as a model of hydrophilic macromolecular drugs. A 1.0% (w/v) solution of gelatin and thiolated gelatins (SHGel-20 and SHGel-40) in water were prepared and adjusted to pH 7.0, followed by addition of FITC-dextran at a concentration of 1.0% (w/w) to the polymer. Using this solution FITC-dextran loaded nanoparticles were prepared by desolvation process as described above. The free FITC-dextran was separated from the loaded by a series of centrifugation

and washing steps, and the loading efficiency in the nanoparticulate formulations was determined by dissolving the nanoparticles in PBS containing protease (0.2 mg/mL) at 37 °C. The resulting solution was filtered through a 0.22 μm filter, and the fluorescence intensity was measured at 490 nm excitation and 520 nm emission wavelengths, using a Biotek SynergyHT plate reader (Winooski, VT). The efficiency of FITC-dextran loading in the nanoparticle formulations was determined using a standard curve of FITC-dextran in protease-containing PBS.

The in vitro release of FITC-dextran from the nanoparticles was performed in varying concentrations of glutathione (GSH) in PBS at 37 °C and compared with the release in PBS alone. The study was carried out in PBS and 0.1, 1.0, and 5.0 mM GSH containing PBS at 37 °C. Twenty milligrams of the FITC-dextran-loaded control gelatin and thiolated gelatin nanoparticulate samples were weighed into microcentrifuge tubes with 1.5 mL of the buffer solutions. The samples were placed in a temperature-controlled bath, and 0.5 mL of the supernatant was removed at specified intervals following centrifugation at 10 000 rpm for 5 min. Sink conditions were maintained by replacing an equal volume of the release medium each time. The fluorescence intensity of the released FITC-dextran in the samples was measured using a plate reader, and the percentage of dye released was calculated from calibration curves constructed in PBS containing various concentrations of glutathione. The release studies were repeated for both cross-linked and non-cross-linked systems.

Preparation and Characterization of Plasmid DNA-Encapsulated Nanoparticles. Nanoparticles encapsulating plasmid DNA expressing enhanced green fluorescent protein (EGFP-N1) were prepared by desolvation using ethanol under controlled conditions of temperature and pH as previously described. The pH of the 1% (w/v) solution of control gelatin or thiolated gelatin (SHGel-20, SHGel-40, and SHGel-100) was adjusted to 7.0, and 1 mL of the plasmid DNA at a concentration of 1 mg/mL was added. The nanoparticles encapsulated with plasmid DNA were formed by controlled precipitation of the aqueous gelatin solution with ethanol under continuous stirring. The nanoparticles were centrifuged at 16 000 rpm for 30 min either before or after cross-linking and were analyzed for mean particle size, size distribution, and zeta potential by ZetaPALS (Brookhaven Instruments Corporation, Holtsville, NY).

DNA Encapsulation Efficiency. The pDNA-loaded nanoparticles were separated from the free pDNA by a series of centrifugation and washing steps. The loading efficiency of pDNA in the nanoparticle formulations was determined by dissolving the nanoparticle sample in protease (0.2 mg/mL)-containing PBS at 37 °C. The pDNA concentrations were estimated in solution using the PicoGreen dsDNA reagent (Molecular Probes, Eugene, OR), a one step, sensitive, fluorescent, quantitation kit for double-stranded DNA (dsDNA). The reagent was incubated with the samples for 5 min, and the fluorescence intensity was measured at 480 nm excitation and 520 nm emission wavelengths, using a Bio-Tek plate reader.

Stability of Encapsulated Plasmid DNA. The stability of the encapsulated plasmid DNA was confirmed by running the extracted DNA on precast gels. The nanoparticles were digested using protease containing PBS, diluted, and mixed with 5-fold diluted loading buffer (1×). The samples were then loaded onto 1.2% agarose gels (E-Gel, Invitrogen, Carlsbad, CA) prestained with ethidium bromide at a concentration of 100 ng/well in a 15 μL volume per well. Naked plasmid DNA and DNA encapsulated in gelatin nanoparticles were used as control and the gel was run at 65 V for 30 min using a Biorad model 200/2 power supply, and the bands were visualized using KODAK Gel logic 100 imaging system (Scientific Imaging, New Haven, CT). The process was repeated for both cross-linked and non-cross-linked nanoparticles.

In Vitro Transfection Studies. *Qualitative Analysis of Transfection.* NIH-3T3 cells, murine fibroblast cells, were grown in six-well cell culture plates containing a Corning's circular glass cover-slip with 2×10^5 cells seeded per well. The cells were grown to semi-confluence in an incubator at 37 °C and 5% CO_2 atmosphere. The plasmid DNA encapsulated non-cross-linked and cross-linked nanoparticles prepared from control gelatin, and thiolated gelatins were dispersed in serum-free medium. Twenty micrograms of EGFP-N1 plasmid DNA complexed with 20 μL of Lipofectin, a cationic lipid transfection reagent, was used as a positive control and untreated cells were used as a negative control. After filtration, the DNA-containing nanoparticle suspension was added at a concentration equivalent to 20 μg of plasmid DNA per well and incubated with the cells at 37 °C for a period of 6 h. The media was removed from each well and replaced with the DMEM. The cover slips were washed three times with sterile PBS at time intervals of 12, 24, 48, and 96 h postincubation and mounted on to microscopic slides containing a drop of fluorescence-free mounting medium (Fluoromount-G, Southern Biotech Associates, Birmingham, AL). The expression of GFP in the cells was observed by a fluorescence microscope. Differential interference contrast (DIC) and fluorescence images acquired using Olympus BX61 microscope and the digital images were processed with Adobe Photoshop software.

Quantitative Analysis of Transfection. NIH3T3 cells were grown to semi-confluence in a six-well cell culture plate and transfected with EGFP-N1 plasmid DNA encapsulated non-cross-linked and cross-linked systems of gelatin, SHGel-20, and SHGel-40 nanoparticles and compared with the Lipofectin−plasmid DNA transfected cells and cells treated with serum free media alone. The nanoparticles carrying pDNA and the Lipofectin−DNA mixture were dispersed in serum free media and added to each of the six wells at a concentration of 20 μg of plasmid DNA per well. The cells are allowed to incubate for a period of 6 h at 37 °C in a 5% CO_2 incubator and then replaced by fresh growth medium. The adherent cells are trypsinized at 12, 24, and 48, and 96 h postincubation, centrifuged, and resuspended in 0.5 mL of DMEM before fixing with 100 μL of 4% formalin buffer solution. The fluorescence of the GFP produced in the transfected a cell was detected by a Beckman Coulter (Epics/Altra) (FACS) equipped with an argon 488 laser. The FL1 channel was used to detect the cells expressing GFP fluorescence, and the results obtained were analyzed using Expo 32 software.

RESULTS AND DISCUSSION

Synthesis and Characterization of Thiolated Gelatin. The degree of thiolation was calculated by determining the number of free sulfhydryl groups using Ellman's reagent. The results obtained were extrapolated to that of the standard curve of cysteine and expressed in terms of millimoles of free sulfhydryl groups per gram of the polymer and are shown in Table 1. There was an increase

Table 1. Characterization of the Control and Thiolated Gelatin Nanoparticles

amount of iminothiolane (mg) per gram of gelatin	degree of thiolation (mM/g gelatin)	mean diameter of nanoparticles (nm)		zeta potential (mV)	
		non-cross-linked	cross-linked	non-cross-linked	cross-linked
0 mg (gelatin)	0	151.3 ± 53.8[a]	230 ± 11.5	−8.86 ± 0.78	−8.45 ± 0.45
20 mg (SHGel-20)	6.08 ± 0.7[b]	156.6 ± 60.7	244 ± 6.8	−9.09 ± 0.81	−9.36 ± 0.64
40 mg (SHGel-40)	16.41 ± 0.14	165.3 ± 45.0	232.8 ± 6.4	−9.83 ± 0.74	−11.88 ± 0.72
100 mg (SHGel-100)	43.71 ± 0.35	150.9 ± 58.4	253.7 ± 8.9	−11.97 ± 1.20	−12.98 ± 0.77

[a] Mean ± SE (n = 8). [b] Mean ± SD (n = 4).

in the degree of thiolation with increasing amounts of iminothiolane, with SHGel-20 containing 6.08 mmol/g followed by SHGel-40 (16.4 mmol/g) and SHGel-100 (43.7 mmol/g). The increasing amounts of iminothiolane resulted in an increase in thiolation at the free amino groups present on gelatin.

Preparation and Characterization of the Control and Thiolated Gelatin Nanoparticles. The nanoparticles prepared by desolvation were characterized for particle size and zeta potential. The average size and surface charge of the particles prepared from thiolated gelatins with different degrees of thiolation are listed in Table 1. The mean particle size for both non-cross-linked control and thiolated gelatin nanoparticles was found to be around 150 nm and that of cross-linked nanoparticles at 200 nm. The net charge on the gelatin nanoparticles was found to be negative, and there was no significant difference in the values between the cross-linked and non-cross-linked nanoparticles. The control gelatin nanoparticles were found to have a zeta potential value of −8.86 mV as compared to the −11.97 mV for the thiolated gelatin (SHGel-100) nanoparticles. The slight difference in zeta potential values between control and thiolated gelatin nanoparticles could be due to the fact that a hydrochloride salt of 2-iminothiolane was used. The surface presence of chloride ions would result in the nanoparticles having a greater negative zeta potential value with increasing amount of 2-iminothiolane used. The net negative charge on the surface adds to the stability of these colloidal particles. On the basis of these results, we find that the solvent exchange method can still be used to make nanoparticles from thiolated gelatin with different degrees of thiolation. Also, from these studies, we find that there was no significant difference in the particle size of the formed nanoparticles between gelatin and thiolated gelatin. Cross-linking of the nanoparticles did increase the size, probably due to disulfide bridging of two or more nanoparticles. Lastly, the surface charge on nanoparticles was also not affected by the degree of thiolation.

SEM images shown in Figure 2 reveal the surface morphology and spherical shape of the control and thiolated gelatin nanoparticles. The actual diameter of the nanoparticles observed by SEM was around 200 nm and was found to be similar to the values obtained by measurements based on light scattering. From the studies of Jain and co-workers, it is known that molecular size is one of the key determinants of vascular transport in tumors and that tumor vessels are permeable and have pores with a cutoff size of around 400−600 nm. Therefore, the thiolated gelatin nanoparticles with a mean particle size of around 200 nm would be effective in delivering DNA to solid tumors in vivo.

The in vitro toxicity studies of the control and thiolated gelatins were conducted by MTS assay with NIH3T3 cells. The percent viability of the polymer-treated cells was compared with PEI (mol wt 10 kDa), a known cytotoxic DNA-condensing gene carrier, as a positive control. The results of the cell viability profile as seen in

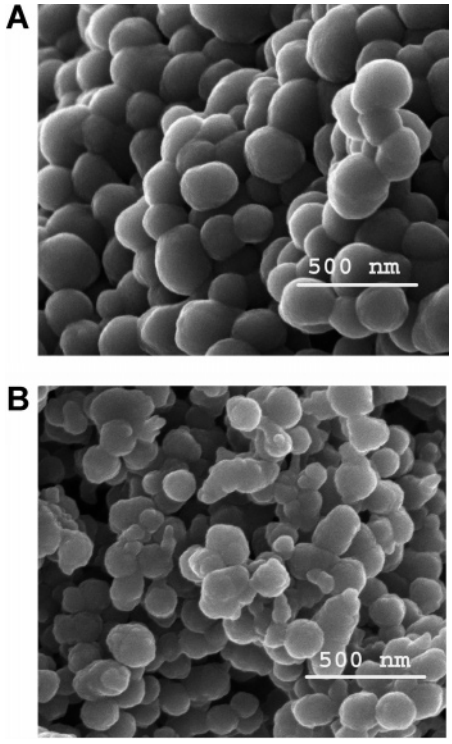

Figure 2. Scanning electron micrographs of non-cross-linked gelatin (A) and thiolated gelatin nanoparticles prepared by reacting 20 mg of 2-iminothiolane per gram of gelatin (SHGel-20) (B).

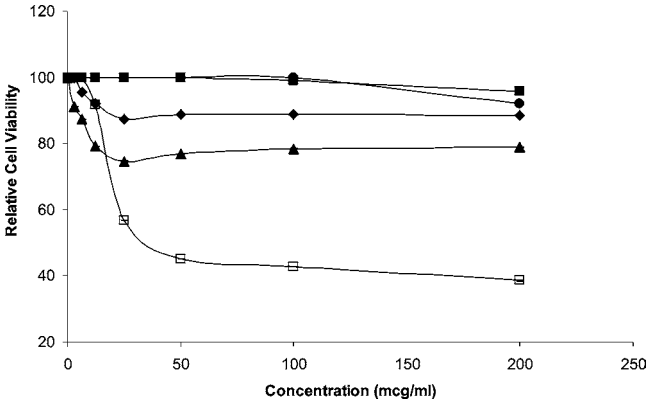

Figure 3. Cytotoxicity profiles of the control gelatin (■), and thiolated gelatin prepared with 20 mg of 2-iminothiolane (SHGel-20) (●), 40 mg of 2-iminothiolane (SHGel-40) (◆), and 100 mg of 2-iminothiolane (SHGel-100) (▲) per gram of gelatin. Poly(ethyleneimine) (mol wt 10 000 Da) (□) was used as a positive control. The relative cell viability was determined in NIH-3T3 murine fibroblast cells by the MTS assay and plotted against the polymer concentration in aqueous solution at 37 °C.

Figure 3 indicate that gelatin was highly biocompatible and nontoxic showing 100% viability at all concentrations tested. At the highest concentration of 200 μg/mL, SHGel-20 showed 92% viability, SHGel-40 showed 88%, and SHGel-100 showed 79% relative cell viability. Increase in the amount of 2-iminothiolane used in thiolation did

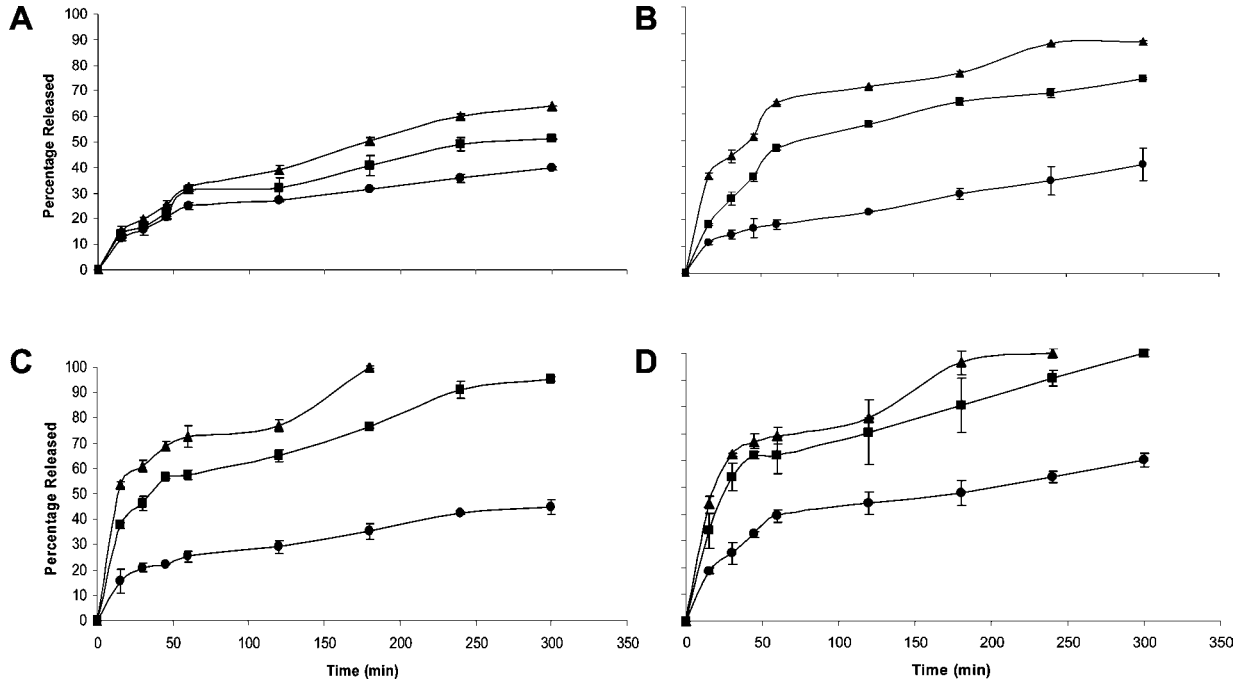

Figure 4. Release profile of fluorescein isothiocyanate-labeled dextran (mol wt 70 000 Da) from non-cross-linked nanoparticles of control gelatin (●) and thiolated gelatin prepared with 20 mg of 2-iminothiolane (SHGel-20) (■) and 40 mg of 2-iminothiolane (SHGel-40) (▲) in phosphate-buffered saline (PBS, pH 7.4) (A) and in the presence of increasing glutathione (GSH) concentrations: 0.1 mM GSH (B), 1.0 mM GSH (C), and 5.0 mM GSH (D) containing PBS at 37 °C.

result in an increase in the cytotoxicity that has been observed from the relative cell viability profiles. Based on these cytotoxicity results, further studies were carried out with SHGel-20 and SHGel-40 nanoparticles only.

In Vitro Release of FITC-Dextran in Response to Glutathione. Fluorescein isothiocyanate-conjugated dextran (FITC-dextran) was used as a model for hydrophilic macromolecular drugs, as it can be encapsulated into nanoparticles by a simple process, impermeable to cellular membranes unless taken up by endocytosis and can be easily visualized under a florescence microscope. In addition, unlike other fluorophores such as rhodamine, the fluorescence of FITC is not affected by the presence of high glutathione concentration in solution. The loading efficiency was determined using FITC-dextran at a concentration of 1.0% w/w to that of the polymer. The non-cross-linked systems had a loading efficiency of 86.7% in case of nanoparticles prepared from gelatin followed by SHGel-20 and SHGel-40 with a loading efficiency of 91.9% and 99.7%, respectively. A similar trend was observed in loading efficiencies of cross-linked systems with gelatin nanoparticles having 84.6% followed by SHGel-20 with 86.1% and SHGel-40 with 99.6%.

The in vitro release of FITC-dextran from the nanoparticles was performed in the presence of varying concentrations of GSH, which was included in the release medium to evaluate its nonenzymatic reducing action on the thiolated gelatin nanoparticles versus control gelatin nanoparticles. Also, we were interested in determining differences in the release behavior between non-cross-linked and cross-linked systems. As seen in Figures 4 and 5, the release of FITC-dextran from the non-cross-linked nanoparticles was significantly greater than from the cross-linked nanoparticles both in the presence and absence of glutathione in the release medium. The release from the thiolated gelatin nanoparticles was found to be faster in the presence of 5 mM GSH than in 1.0 mM GSH or 0.1 mM GSH containing PBS or PBS alone. In 5 mM GSH-containing PBS, the SHGel-20 nanoparticles released 100% of the payload content from the non-cross-linked and 73.6% from the cross-linked system within 5 h. Similar results were obtained from SHGel-40 were 100% and 74% of FITC-dextran released from non-cross-linked and cross-linked nanoparticles in a span of 4 h, with cross-linked nanoparticles releasing up to 87.8% of their payload in 5 h. The presence of GSH was found to enhance the release by about 40% in case of thiolated gelatin and 20% in the case of gelatin nanoparticles. The predominant difference in the release characteristics can be attributed to the nonenzymatic reducing properties of GSH which cleaves off the disulfide bonds leaving the free thiol groups. Thus, the disulfide bonds formed within the thiolated gelatins could be used for achieving rapid release system in a highly reducing environment.

Plasmid DNA Encapsulation in the Control and Thiolated Gelatin Nanoparticles. Nanoparticles encapsulating plasmid DNA expressing green fluorescent protein (pEGFP-N1) were prepared by desolvation using ethanol under controlled conditions of temperature and pH. The particles formed were harvested either before or after cross-linking and were characterized for particle size and zeta potential. Both the cross-linked and non-cross-linked nanoparticles encapsulated with plasmid DNA were found to have mean particle size similar to that of the empty nanoparticles, with non-cross-linked control and thiolated gelatin nanoparticles around 150 nm and that of cross-linked nanoparticles at 200 nm. The zeta potential of the plasmid DNA encapsulated nanoparticles had values ranging from −9.01 for gelatin to −11.78. The net charge was found to be negative, and there was no significant difference in the values between the cross-linked and non-cross-linked nanoparticles as well as between the empty and DNA containing nanoparticles, indicating the encapsulation rather than adsorption of DNA on the surface of the particles.

The loading capacity and efficiency of plasmid DNA in the nanoparticle formulations was determined using a standard curve of DNA in protease-containing PBS. The results as seen in Figure 6 indicate that cross-linking of gelatin does not affect the loading capacity of the nano-

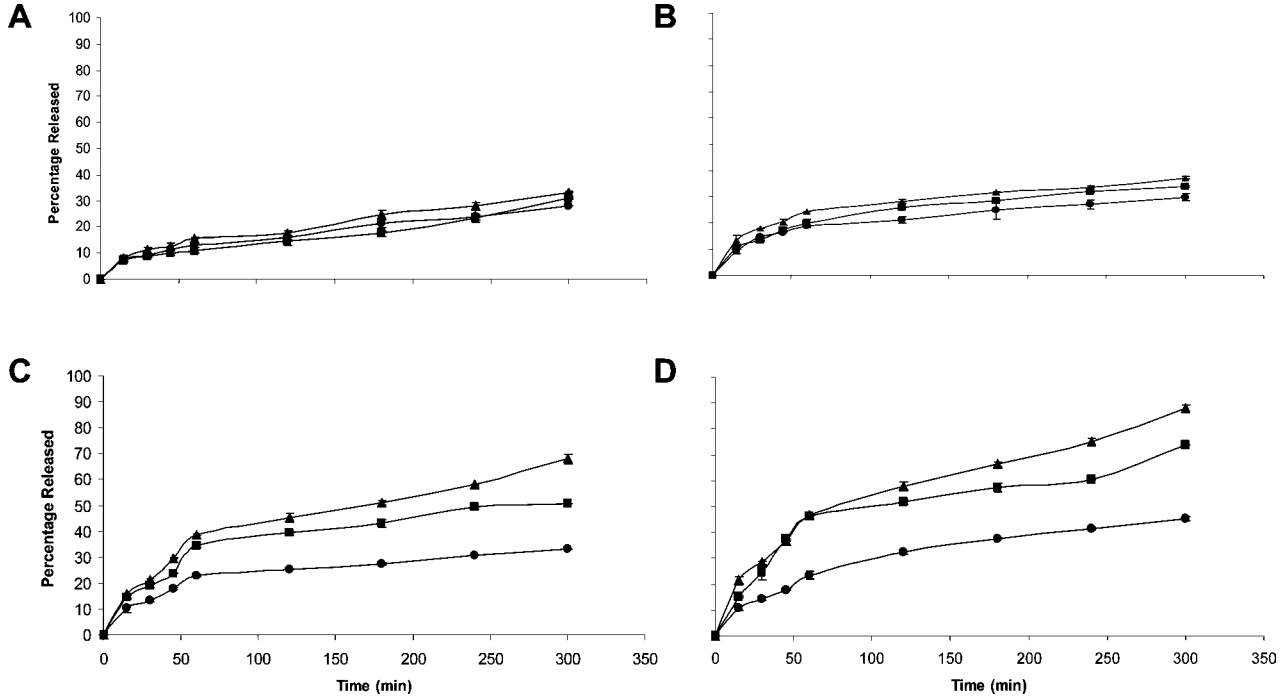

Figure 5. Release profile of fluorescein isothiocyanate-labeled dextran (mol wt 70 000 Da) from cross-linked nanoparticles of control gelatin (●) and thiolated gelatin prepared with 20 mg of 2-iminothiolane (SHGel-20) (■) and 40 mg of 2-iminothiolane (SHGel-40) (▲) in phosphate-buffered saline (PBS, pH 7.4) (A) increasing glutathione (GSH) concentrations: 0.1 mM GSH (B), 1.0 mM GSH (C), and 5.0 mM GSH (D) containing PBS at 37 °C.

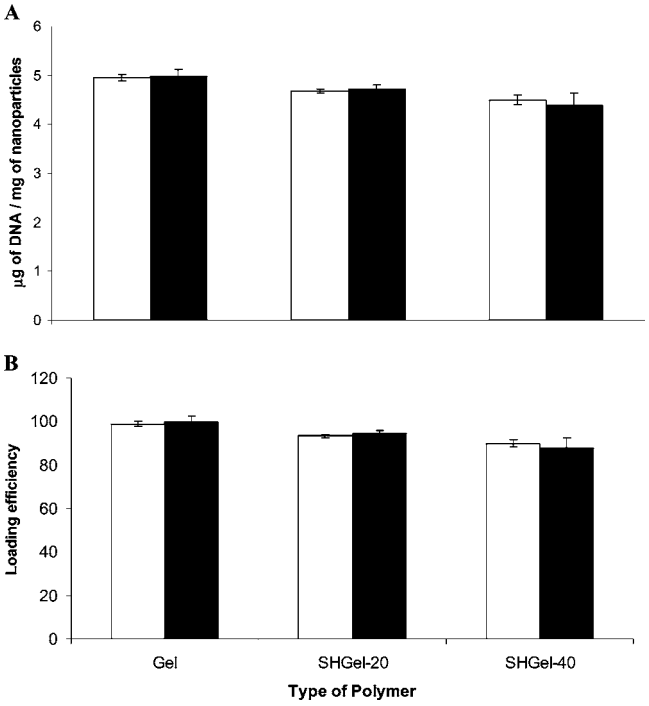

Figure 6. The encapsulation of plasmid DNA encoding for enhanced green fluorescent protein (EGFP-N1) in control gelatin and thiolated gelatin nanoparticles. Loading studies of pDNA (pEGFP-N1) from non-cross-linked (□) and cross-linked (■) nanoparticles prepared using control gelatin and thiolated gelatin prepared with 20 mg of 2-iminothiolane (SHGel-20) and 40 mg of 2-iminothiolane (SHGel-40) per gram of gelatin. The DNA encapsulation was expressed in terms of capacity as μg of DNA loaded per mg of nanoparticles (A) and efficiency as percent encapsulated (B). DNA encapsulation was determined by digesting the nanoparticles in the presence of 0.2 mg/mL protease-containing in phosphate buffered saline at 37 °C.

particulate systems. The gelatin nanoparticles had a loading efficiency of 99% as compared to SHGel-20, which had the loading efficiency of 94%, and SHGel-40, which had the loading efficiency of 90%. The slight decrease in DNA loading with an increase in the degree of thiolation could be explained by the fact that DNA is negatively charged, and with increase in the negative charge of the thiolated gelatin there was a slight decrease in encapsulation efficiency which could be attributed to electrostatic repulsion.

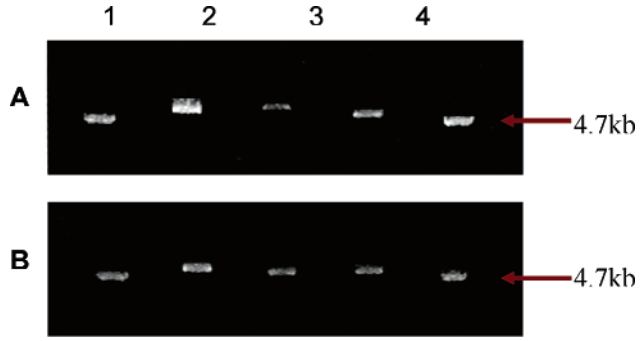

Figure 7. Stability of encapsulated plasmid DNA encoding for enhanced green fluorescent protein (EGFP-N1) by agarose gel electrophoresis. Gel electrophoresis of DNA encapsulated in non-cross-linked (A) and cross-linked (B) nanoparticles. Lane 1 and 5 represent naked plasmid DNA (pEGFP-N1) as a control, lane 2 is DNA band from control gelatin nanoparticles, lane 3 is DNA band from thiolated gelatin nanoparticles prepared with 20 mg of 2-iminothiolane (SHGel-20), and lane 4 is DNA band from thiolated gelatin nanoparticles prepared with 40 mg of 2-iminothiolane (SHGel-40) per gram of gelatin. For the nanoparticle systems, the encapsulated plasmid was extracted by digesting the matrix in 0.2 mg/mL protease-containing phosphate-buffered saline (pH 7.4) at 37 °C.

Stability of Encapsulated Plasmid DNA. The effect of thiolated gelatin and process parameters on the stability of DNA was detected by gel electrophoresis. The results, as seen in Figure 7, show that the plasmid DNA encapsulated in SHGel-20 and SHGel-40 are stable and are comparable to that encapsulated in gelatin nanopar-

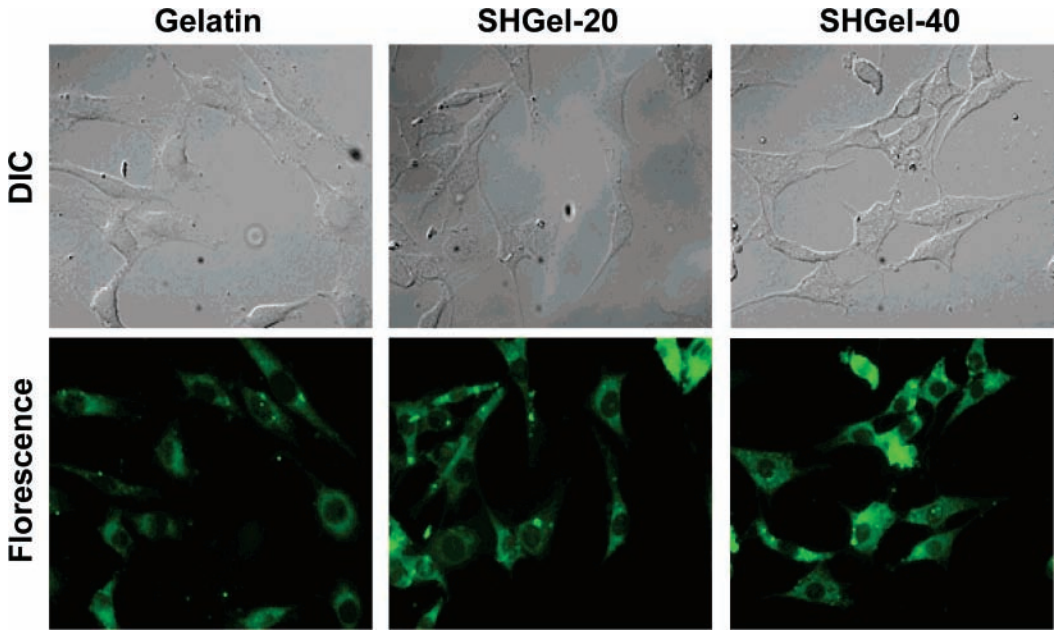

Figure 8. Qualitative evaluation of enhanced green fluorescent protein (EGFP-N1) transgene expression in NIH-3T3 murine fibroblast cells with non-cross-linked control gelatin and thiolated gelatin nanoparticles prepared with 20 mg of 2-iminothiolane (SHGel-20) and 40 mg of 2-iminothiolane (SHGel-40) per gram of gelatin. Differential interference contrast (DIC) and fluorescence confocal images of the cells were obtained after 96 h upon incubation of DNA-containing nanoparticles with the cells in culture at 37 °C.

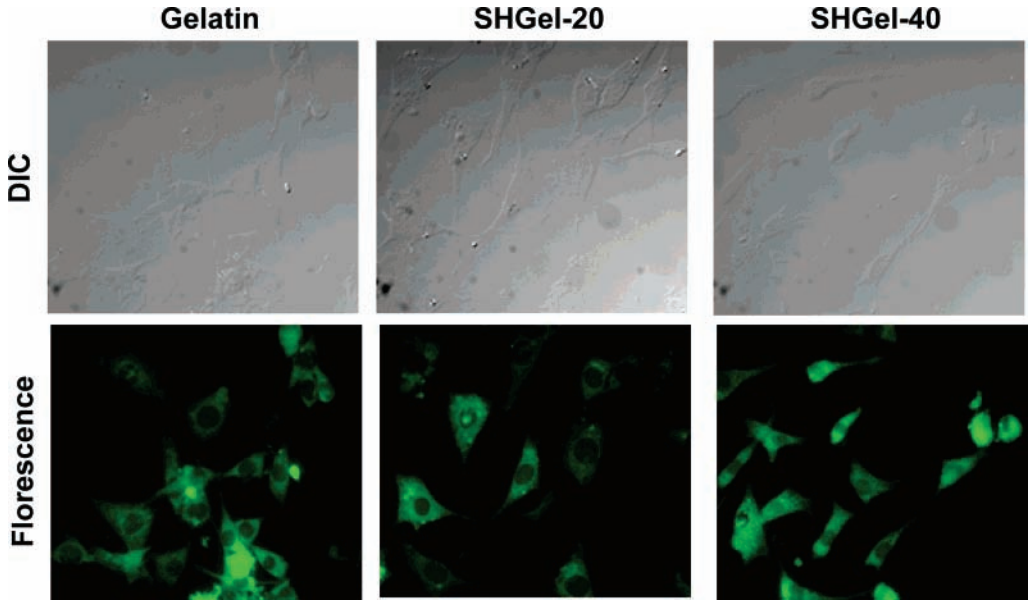

Figure 9. Qualitative evaluation of enhanced green fluorescent protein (EGFP-N1) transgene expression in NIH-3T3 murine fibroblast cells with cross-linked control gelatin and thiolated gelatin nanoparticles prepared with 20 mg of 2-iminothiolane (SHGel-20) and 40 mg of 2-iminothiolane (SHGel-40) per gram of gelatin. Differential interference contrast (DIC) and fluorescence confocal images of the cells were obtained after 96 h upon incubation of DNA-containing nanoparticles with the cells in culture at 37 °C.

ticles and naked plasmid DNA. The processes of cross-linking and protease digestion did not have any detectable effect on the DNA encapsulated and the polymers have a protective action on the plasmid.

Qualitative and Quantitative Transgene Expression Studies. The qualitative analysis of GFP expression upon transfection in NIH3T3 cells was evaluated by florescence microscopy. The Figures 8 and 9 show the DIC and fluorescence images of cells transfected with cross-linked and non-cross-linked nanoparticles prepared from the control gelatin and thiolated gelatins. The images show that the polymeric nanoparticles carrying the plasmid DNA were able to transfect the cells and the protein expression was seen as early as 6 h (data not shown) and was stable for as long as 96 h posttransfection. The fluorescence images show that these nanoparticles protect the plasmid DNA during its transport which are later taken up by the cells through the endosomal pathway and released into the cytosol. The released DNA molecules would then diffuse into the nucleus through the nuclear pores and bring about transfection of the transgene. From the results it can also be noted that cross-linking and thiolation did not affect the ability of transfection of these plasmid DNA carrying nanoparticles.

The quantitative analysis of transfection efficiency was carried out by flow cytometry. The transfection results at various time points for gelatin and the two thiolated gelatins were compared in non-cross-linked and cross-linked systems by plotting percentage of transfected cells

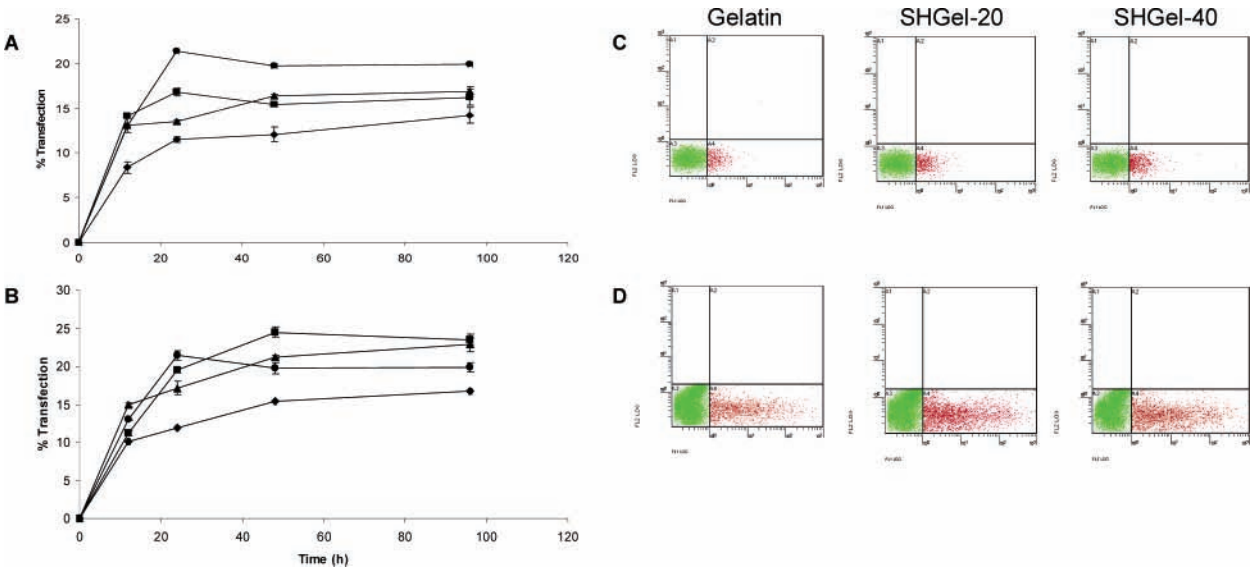

Figure 10. Quantitative evaluation of enhanced green fluorescent protein (EGFP-N1) transgene expression in NIH-3T3 murine fibroblast cells as a function of time as measured by flow cytometric analysis. Percent cell transfection with non-cross-linked (A) and cross-linked (B) nanoparticles encapsulated with EGFP-N1 plasmid DNA were prepared from control gelatin (◆), and thiolated gelatin prepared with 20 mg of 2-iminothiolane (SHGel-20) (■) and 40 mg of 2-iminothiolane (SHGel-40) (▲) per gram of gelatin. The flow cytometric scatter plots were obtained at 96 h posttransfection using non-cross-linked (C) and cross-linked nanoparticle systems (D). Plasmid DNA-complexed with Lipofectin, a commercially available cationic lipid transfection reagent was used as a control.

as a function of time as seen in the Figures 10A and 10B. The corresponding scatter plots of the transfected and normal cells at 96 h time point were represented in the form of pixels in regions A1 to A4 in Figures 10C and 10D. The transfected cells were expressed as a percentage of the total cells present in quadrants A3 and A4. Among the non-cross-linked systems the two thiolated gelatins showed better transfection than the gelatin nanoparticles but lower than the Lipofectin−pDNA-treated cells. Upon cross-linking, the SHGel-20 nanoparticles showed better transfection properties than either SHGel-40 or Lipofectin−pDNA. The results can be explained by the fact that cross-linking resulted in a stable particle, which probably provided stability to the payload in the cells by protecting it until the DNA reached the perinuclear region. In the case of SHGel-40 nanoparticles, the polymer would probably be slightly more cytotoxic than the SHGel-20 and showed lesser transfection efficiency due to its effect on cell viability. When incubated for longer periods of time the protein expressed is cytotoxic to the cells resulting in apoptosis or cell death, which led to a decrease in the percentage of transfected cells.

CONCLUSIONS

Gelatin was thiolated successfully using the 2-iminothiolane reagent, and the thiolated biopolymer was used to prepare nanoparticles by desolvation method. A well-characterized nanoparticulate system with a size of about 200 nm and negative surface charge was achieved. The in vitro release studies resulted in a significantly greater release of encapsulated macromolecular payload (FITC-dextran) from the non-cross-linked as compared to the cross-linked nanoparticles both in the presence and absence of GSH. The release from thiolated gelatin nanoparticles was enhanced in the presence of GSH-containing PBS than PBS alone. Both the non-cross-linked and cross-linked thiolated and control gelatin nanoparticles carrying the EGFP-N1 transgene were internalized by the NIH-3T3 cells, and the expression of the green fluorescent protein was observed as early as 6 h after transfection. Upon quantitative analysis, the cross-linked nanoparticles prepared from thiolated gelatin, namely the SHGel-20, was found to have greater transfection efficiency than the other nanocarriers as well as Lipofectin−pDNA complexes. The results of the study indicate that the thiolation resulted in faster release of their payload in the cells and cross-linking resulted in a particle that remains stable during its transport, and hence these cross-linked, thiolated gelatin nanoparticles could be used for rapid delivery of drugs and genes in vitro. Further, these particles can be used as vectors for systemic delivery of DNA in order to target tissues with a highly reducing environment.

ACKNOWLEDGMENT

This study was supported by a grant RO1-CA095522 from the National Cancer Institute of the National Institutes of Health. The flow cytometry studies were performed at the Forsyth Dental Institute (Boston, MA). We deeply appreciate the assistance of Dr. Jean Eastcott with the flow cytometric experiments and results interpretation.

Near-Infrared Fluorescent RGD Peptides for Optical Imaging of Integrin $\alpha_v\beta_3$ Expression in Living Mice

Zhen Cheng,[†] Yun Wu,[†] Zhengming Xiong,[†,‡] Sanjiv Sam Gambhir,[†] and Xiaoyuan Chen*[,†]

Molecular Imaging Program at Stanford (MIPS), Department of Radiology and Bio-X Program, Stanford University, California, California, 94305-5344, and Department of Pediatrics, Tongji Medical College, Huazhong University of Science and Technology & Tongji Hospital, Wuhan, China, 430030. Received June 14, 2005; Revised Manuscript Received August 25, 2005

Near-infrared fluorescence optical imaging is a powerful technique for studying diseases at the molecular level in preclinical models. We recently reported that monomeric RGD peptide c(RGDyK) conjugated to the NIR fluorescent dye specifically targets integrin receptor both in cell culture and in living subjects. In this report, Cy5.5-conjugated mono-, di-, and tetrameric RGD peptides were evaluated in a subcutaneous U87MG glioblastoma xenograft model in order to investigate the effect of multimerization of RGD peptide on integrin avidity and tumor targeting efficacy. The binding affinities of Cy5.5-conjugated RGD monomer, dimer, and tetramer for $\alpha_v\beta_3$ integrin expressed on U87MG cell surface were determined to be 42.9 ± 1.2, 27.5 ± 1.2, and 12.1 ± 1.3 nmol/L, respectively. All three peptide−dye conjugates had integrin specific uptake both in vitro and in vivo. The subcutaneous U87MG tumor can be clearly visualized with each of these three fluorescent probes. Among them, tetramer displayed highest tumor uptake and tumor-to-normal tissue ratio from 0.5 to 4 h postinjection. Tumor-to-normal tissue ratio for Cy5.5-conjugated RGD monomer, dimer, and tetramer were found to be 3.18 ± 0.16, 2.98 ± 0.05, and 3.63 ± 0.09, respectively, at 4 h postinjection. These results suggest that Cy5.5-conjugated monomeric, dimeric, and tetrameric RGD peptides are all suitable for integrin expression imaging. The multmerization of RGD peptide results in moderate improvement of imaging characteristics of the tetramer, compared to that of the monomer and dimeric counterparts.

INTRODUCTION

Near-infrared fluorescence (NIRF)[1] optical imaging is emerging as a powerful technology for studying diseases at molecular level in small animal models (*1*−*5*). Water and biological tissues have minimal absorbance and autofluorescence in the NIR window (650−900 nm), thus allowing efficient photon penetration into, and out of tissue with low intra-tissue scattering. Recent advances in the field of molecular imaging have demonstrated that this technology can be used for monitoring the biological activity of a wide variety of molecular targets such as intracellular enzymes (*6*−*10*), cell surface receptors (*11*−*16*), and antigens (*17*−*18*), as well as other targets (*19*−*20*), providing a unique opportunity to achieve insight into the biological events involved with these molecules of interest. Moreover, NIR optical imaging technology is a highly sensitive imaging modality, which does not require use of ionizing radiation or radioactive materials (*1*−*5*). It is expected that NIR optical imaging will make a significant impact in disease detection and staging, drug development, and treatment assessment.

The cell adhesion molecule integrin $\alpha_v\beta_3$ is a very important factor involved in angiogenesis and metastasis in many tumor types (*20*−*22*). It is found that $\alpha_v\beta_3$ is significantly up-regulated in activated endothelial cells and fast-growing solid tumor cells, compared to its minimum expression in quiescent blood vessels and most normal tissues (*22*, *23*). The ability to noninvasively image the integrin $\alpha_v\beta_3$ expression in living subjects would render a novel approach to diagnose tumor and its metastasis and to help to better understand tumor biology of angiogenesis, as well as to greatly facilitate the development of integrin targeted therapy. For this purpose, numerous molecular probes have been developed for imaging integrin expression using different modalities such as magnetic resonance imaging (*24*), ultrasound (*25*−*27*), optical imaging (*28*−*30*), positron emission tomography (PET) (*31*−*40*), and single-photon emission computed tomography (SPECT) (*41*−*44*).

We reported recently that NIRF dye Cy5.5-labeled monomeric arginine-glycine-aspartic acid (RGD) peptide c(RGDyK) specifically targets integrin $\alpha_v\beta_3$ both in cell culture and in living subjects (*28*). Cy5.5-c(RGDyK), however, had only moderate integrin binding affinity and thus might provide suboptimal tumor targeting efficacy. We and others found that dimeric and multimeric RGD peptides, consisting of multiple cyclic RGD monomer appropriately linked together, have significantly higher integrin avidity than the monomeric counterpart, presumably due to the polyvalency effect (*35*−*37*, *43*, *44*). It was hypothesized that the receptor binding of one RGD cyclic peptide moiety will significantly enhance the "local concentration" of the other RGD peptide moieties in the vicinity of the receptor, which may lead to a faster rate of receptor binding or a slower rate of dissociation of the oligomer from the integrin $\alpha_v\beta_3$ receptor. In this report, we evaluate the effect that multimerization of RGD

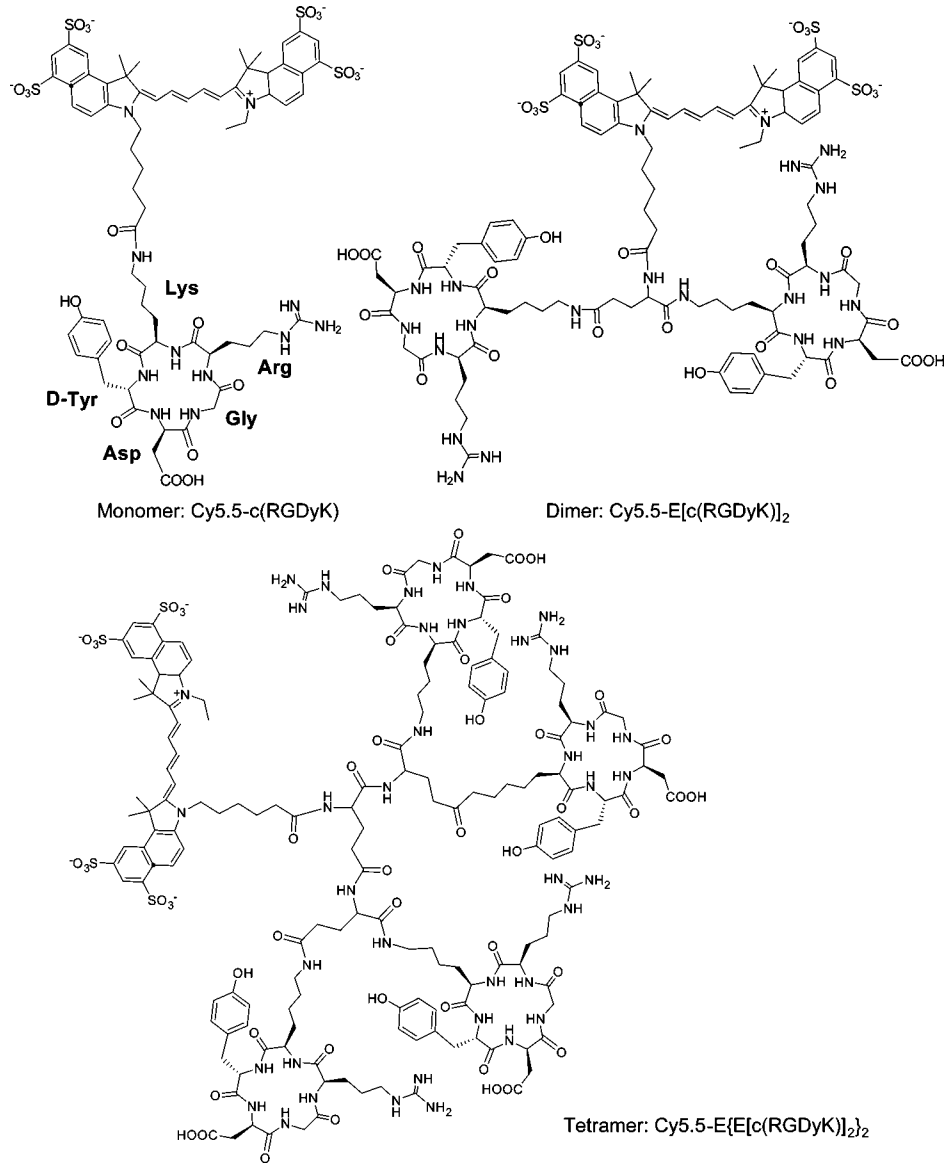

Figure 1. Schematic structures of Cy5.5-conjugated RGD monomer Cy5.5-c(RGDyK), dimer Cy5.5-E[c(RGDyK)]$_2$, and tetramer Cy5.5-E{E[c(RGDyK)]$_2$}$_2$.

peptide has on integrin binding affinity and tumor targeting efficacy in three novel NIRF probes: Cy5.5-labeled monomer c(RGDyK), dimer E[c(RGDyK)]$_2$, and tetramer E{E[c(RGDyK)]$_2$}$_2$ (structures are shown in Figure 1).

MATERIALS AND METHODS

General. All commercially available chemical reagents were used without further purification. 9-Fluorenylmethoxycarbonyl (Fmoc) amino acids and 2-chlorotrityl chloride resin were purchased from Novabiochem (San Diego, CA). Arginine and lysine were protected by the 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl (Pbf) and *tert*-butoxycarbonyl (Boc) groups, respectively, while D-tyrosine and aspartic acid were protected as a *tert*-butyl ester. Cy5.5 monofunctional *N*-hydroxysuccinimide (NHS) ester (Cy5.5-NHS) and ^{125}I-echistatin labeled by the lactoperoxidase method to a specific activity of 2000 Ci/mmol were purchased from Amersham Biosciences (Piscataway, NJ). Echistatin was purchased from Sigma (St. Louis, MO). The purification of the crude product was carried out on a semipreparative reversed-phase high-performance liquid chromatography (HPLC) system equipped with a 170U 4-Channel UV−Vis absorbance detector (Dionex Summit HPLC system, Dionex Corporation, Sunnyvale, CA) using a Vydac protein and peptide column (218TP510, 5 μm 250 × 10 mm). The flow was 5 mL/min, with the mobile phase starting from 95% solvent A (0.1% TFA in water) and 5% solvent B (0.1% TFA in acetonitrile) (0−3 min) to 35% solvent A and 65% solvent B at 33 min. The analytical HPLC method was performed with the same gradient system, but with a Vydac 218TP54 column (5 μm, 250 × 4.6 mm) and flow rate of 1 mL/min.

Peptide Synthesis. Monomeric cyclic RGD peptide c(RGDyK) (MW = 617.6) was synthesized via solution cyclization of the fully protected linear pentapeptide H-Gly-Asp(OtBu)-D-Tyr(OtBu)-Lys(Boc)-Arg(Pbf)-OH, followed by trifluoroacetic acid (TFA) deprotection (*45*). Dimeric RGD peptide, E[c(RGDyK)]$_2$, was prepared according to the literature method (*37*). The tetrameric RGD peptide E{E[c(RGDyK)]$_2$}$_2$ was obtained by coupling Boc-protected glutamic acid activated ester Boc-E(OSu)$_2$ with RGD dimer E[c(RGDyK)]$_2$ in the presence of diisopropylethylamine (DIPEA) (pH = 8.5−9) followed by semipreparative HPLC purification (*46*).

Cy5.5-RGD Conjugates Synthesis. Appropriate RGD peptide (monomer, dimer, or tetramer) (5 μmol) was dissolved in 1 mL of 0.1 M sodium borate ($Na_2B_4O_7$) buffer (pH = 8.3) and then mixed with 1.2 equiv of Cy5.5-NHS (6.7 mg, 6 μmol) in H_2O (1 mL). The reaction mixture (pH = 8.1) was incubated in the dark at 4 °C overnight and then quenched by adding 200 μL of 5% acetic acid (HOAc). The crude product was purified by a semipreparative reversed-phase HPLC and characterized by an analytical HPLC and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS). α-Cyano-4-hydroxycinnamic acid (α-CHCA, prepared as 10 g/L in 33.3% CH_3CN: 33.3% EtOH: 33.3% H_2O: 0.1% TFA) was used as solid matrix. Fractions containing RGD-Cy5.5 conjugates were collected, lyophilized, redissolved in saline at a concentration of 1 mg/mL, and stored in the dark at −20 °C until use.

U87MG Glioblastoma Xenograft Model. U87MG human glioblastoma cell line was obtained from American Type Culture Collection (Manassas, VA) and was maintained at 37 °C in a humidified atmosphere containing 5% CO_2 in Iscove's modified Dulbecco's medium and 5% fetal bovine serum (Life Technologies, Inc., Grand island, NY). Animal procedures were performed according to a protocol approved by the Stanford University Administrative Panels on Laboratory Animal Care (APLAC). Female athymic nude mice (*nu*/*nu*), obtained from Charles River Laboratories, Inc. (Cambridge, MA) at 4−6 weeks of age, were injected subcutaneously in the right foreleg with 5×10^6 U87MG glioblastoma cells suspended in 100 μL of phosphate-buffered saline (PBS). The tumor bearing mice were subjected to in vivo imaging studies when the tumors reached 0.4−0.6 cm in diameter (14−21 d after implant).

Receptor Binding Assay. The $\alpha_v\beta_3$ receptor binding assay was performed to determine binding affinities of NIR fluorescent RGD conjugates. Briefly, 2×10^5 U87MG cells/well in a 96-well plate were incubated with ^{125}I-echistatin (0.06 nM) in the binding buffer [25 mM 2-amino-2-(hydroxymethyl)-1,3-propanediol, hydrochloride (Tris-HCl), pH 7.4, 150 mM NaCl, 1 mM $CaCl_2$, 0.5 mM $MgCl_2$ and 1 mM $MnCl_2$, 0.1% bovine serum albumin (BSA)] in the presence of different concentrations of Cy5.5-RGD conjugates at room temperature for 3 h. After incubation, the plate was washed three times with binding buffer, and the radioactivity was solubilized with 2 N NaOH followed by γ-counting. Nonspecific binding of ^{125}I-echistatin to $\alpha_v\beta_3$ was determined in the presence of 100 nM echistatin. The IC_{50} values were calculated by nonlinear regression analysis using the GraphPad Prism computer-fitting program (GraphPad Software, Inc., San Diego, CA). Each data point is a result of the average of triplicate wells.

Fluorescence Microscopic Studies. For fluorescence microscopic studies, 1×10^4 cells were cultured on 35 mm MatTek glass bottom culture dishes (cat. no.: P35G-0-14-C, Ashland, MA). After 24 h, the cells were washed with PBS and then incubated at 37 °C with appropriate Cy5.5-RGD conjugate (10 nM) for 30 min. Integrin specificity of the RGD-Cy5.5 conjugates in cell culture was verified by incubating U87MG cells with or without blocking dose of the nonfluorescent monomeric RGD peptide c(RGDyK) (10 μmol/L). After the incubation period, cells were washed three times with ice-cold PBS. The fluorescence signal of the cells was recorded using an Axiovert 200M fluorescence microscope (Carl Zeiss MicroImaging, Inc., Thornwood, NY) equipped with a Cy5.5 filter set (Exciter, HQ 650/20 nm; Emitter, HQ 675/35 nm). An AttoArc HBO 100W microscopic illuminator was used as a light source for fluorescence excitation. Images were taken using a thermoelectrically cooled charge-coupled device (CCD) (Micromax, model RTE/CCD-576, Princeton Instruments Inc., Trenton, NJ) and analyzed using MetaMorph Software version 6.2r4 (Molecular Devices Corporation, Downingtown, PA).

In Vivo Optical Imaging of Tumors. In vivo fluorescence imaging was performed with an IVIS 200 small animal imaging system (Xenogen, Alameda, CA). A Cy5.5 filter set was used for acquiring Cy5.5-conjugated RGD monomer, dimer, and tetramer fluorescence in vivo. Identical illumination settings (lamp voltage, filters, f/stop, field of views, binning) were used for acquiring all images, and fluorescence emission was normalized to photons per second per centimeter squared per steradian (p/s/cm^2/sr). Images were acquired and analyzed using Living Image 2.5 software (Xenogen, Alameda, CA). For the control experiment, mice ($n = 3$ for each probe) were injected via tail vein with 500 pmol Cy5.5-RGD (monomer, dimer, or tetramer) and subjected to optical imaging at various time points postinjection (pi). For the blocking experiment, mice ($n = 3$ for each probe also) were injected with the mixture of 10 mg/kg of c(RGDyK) and 500 pmol Cy5.5-conjugated RGD peptides. All NIRF images were acquired using 1 s exposure time (f/stop = 4). The mice in the control experiment were euthanized at 24 h pi. The tumor and major tissues and organs were dissected, wet weighted, and placed on black papers. The fluorescence images were acquired, and total fluorescence flux (p/s/cm^2/sr) for each sample was obtained. Aliquots with known amount of the injectates were also put on the black papers and imaged together with the samples. The results were presented as the percentage injected dose per gram (%ID/g). Values were quoted as mean ± standard deviation (SD) for a group of three animals.

Data Processing and Statistics. All the data are given as means ± SD of n independent measurements. Statistical analysis was performed using a Student's t-test. Statistical significance was assigned for P values < 0.05. For determining tumor contrast, mean fluorescence intensities of the tumor area (T) at the right foreleg of the animal and of the area (N) at the right flank (normal tissue) were calculated by the region-of-interest (ROI) function of Living Image software integrated with Igor (Wavemetrics, Lake Oswego, OR). Dividing T by N yielded the contrast between tumor tissue and normal tissue.

RESULTS

Conjugation and Purification of Cy5.5-RGD Conjugates. The synthesis of Cy5.5-RGD conjugates was achieved through conjugation of Cy5.5-NHS ester with the ϵ-amino group of the lysine residue (in the case of monomer) or glutamate amine (in the case of dimer and tetramer) of the RGD peptides. The desired products were purified by semipreparative HPLC. The purity of Cy5.5-labeled peptides were over 95% from analytical HPLC analysis. The retention times on analytical HPLC for monomer, dimer, and tetramer are found to be: 15.5, 15.8, and 16.2 min, respectively. The yields of Cy5.5-RGD conjugates were typically over 70%. The purified RGD-Cy5.5 conjugates were characterized by MALDI-TOF-MS. Cy5.5-c(RGDyK) (monomer): $m/z = 1518.4$ for $[M + H]^+$ ($C_{68}H_{83}N_{11}O_{21}S_4$, Calculated MW= 1518.7); Cy5.5-E[c(RGDyK)]$_2$ (dimer): $m/z = 2249.0$ for $[M + H]^+$ ($C_{100}H_{129}N_{21}O_{31}S_4$,calculated MW= 2249.5); Cy5.5-E{E[c(RGDfK]$_2$}$_2$ (tetramer): $m/z = 3711.8$ for $[M + H]^+$ ($C_{165}H_{222}N_{40}O_{51}S_4$, calculated MW = 3710.02); The absorption and fluores-

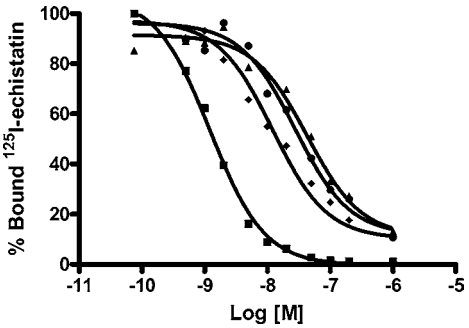

Figure 2. Competitive integrin receptor assay of unlabeled echistatin (■), monomer Cy5.5-c(RGDyK) (▲), dimer Cy5.5-E[c(RGDyK)]$_2$ (●), and tetramer Cy5.5-E{E[c(RGDyK)]$_2$}$_2$ (◆) to U87MG human glioma cells. All experiments were done in triplicate. The IC_{50} values for echistatin, Cy5.5-monomer, dimer, and tetramer were determined to be 1.2 ± 0.1, 12.1 ± 1.3, 27.5 ± 1.2, and 42.9 ± 1.2 nmol/L, respectively.

cence emission characteristics of Cy5.5-RGD conjugates were identical to those of free Cy5.5, as apparent from the spectrums measured in H_2O (data not shown).

Integrin Binding Characteristics in Vitro. The receptor binding affinity study of Cy5.5-RGD conjugates for integrin $\alpha_v\beta_3$ was carried out using $\alpha_v\beta_3$ positive U87MG cells. We compared the receptor binding affinity of the three probes by performing competitive displacement studies with ^{125}I-echistatin as radioligand (Figure 2). All the peptides inhibited the binding of ^{125}I-echistatin to U87MG cells in a dose dependent manner. The IC_{50} values for echistatin, Cy5.5-E{E[c(RGDyK)]$_2$}$_2$, Cy5.5-E[c(RGDyK)]$_2$, and Cy5.5-c(RGDyK) were 1.2 ± 0.1, 12.1 ± 1.3, 27.5 ± 1.2, and 42.9 ± 1.2 nmol/L, respectively.

To demonstrate the $\alpha_v\beta_3$ integrin specificity and subcellular localization of the Cy5.5-RGD conjugates, cyanine dye-labeled RGD peptides were incubated with U87MG tumor cells and images taken with a fluorescent microscope. Receptor-mediated endocytosis of the fluorescent dye was observed for all three RGD peptide conjugates (Figure 3 A−C) after 30 min of incubation at 37 °C as indicated by the appearance of fluorescence in the perinuclear region. Integrin receptor specificity of the Cy5.5-RGD conjugates was further demonstrated by the absence of the cell associated fluorecscence in the presence of a blocking dose of monomeric RGD peptide c(RGDyK) (1 μmol/L) (Figure 3D−F).

Imaging of U87MG Tumor in Vivo. Whole-body imaging of subcutaneous U87MG tumor xenografted mice was accomplished by using tungsten−halogen lamp light source to excite the probe at 610−665 nm wavelength and monitoring the distribution of the imaging agents with IVIS200 system equipped with a cooled charged-coupled device (CCD) camera. Figure 4A shows typical NIRF images of athymic nude mice bearing subcutaneous U87MG glioblastoma tumor after intravenous (iv) injection of 500 pmol of Cy5.5-RGD monomer, dimer, and tetramer, respectively. For all three probes, the subcutaneous U87MG tumor could be clearly visualized from the surrounding background tissue from 30 min to 24 h pi. Quantification analysis of these images was performed using software Living Image2.5. The fluorescence intensities in the tumor and the normal tissues as a function of time for monomer, dimer, and tetramer are depicted in Figure 4B−D, respectively. Monomer, dimer, and tetramer all exhibited fast tumor targeting character in vivo. The tumor uptake reached a maximum at 30 min pi and slowly washed out over time. Most importantly, at early time points (from 0.5 to 4 h) pi, both tetramer and dimer had significantly higher accumulation in tumor than monomer ($P < 0.05$). Tetramer also showed higher tumor uptake than dimer, although the difference is not significant ($P > 0.05$). The differences in tumor uptakes among the three probes were minimal at 24 h pi. The fluorescence intensity ratio between the tumor and normal tissue (*T*/*N*) for Cy5.5-conjugated RGD peptides were calculated and shown in Figure 4E. The tetramer shows significantly higher *T*/*N* value than both monomer and dimer at early time points (0.5, 1, 2, and 4 h) ($P < 0.05$). For example, *T*/*N* ratio for tetramer, dimer, and monomer are found to be 3.63 ± 0.09, 2.98 ± 0.05, and 3.18 ± 0.16, respectively, at 4 h pi, while the difference diminished at 24 h time point ($P > 0.05$). No significant difference in *T*/*N* is observed between dimeric and monomeric peptide probes ($P > 0.05$ for all time

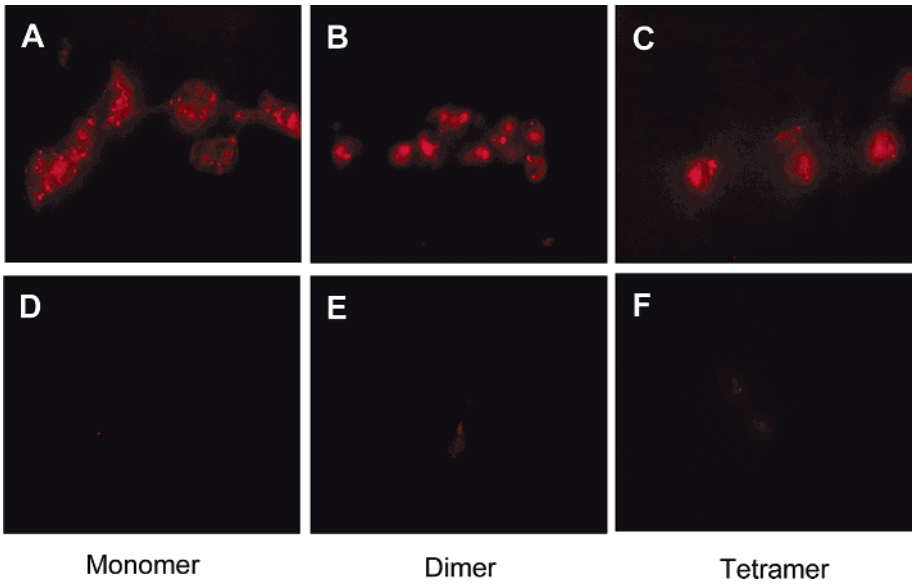

Figure 3. Specific binding and endocytosis of the Cy5.5-labeled cyclic RGD peptides. NIRF images of U87MG were obtained after the cells were incubated for 30 min at 37 °C in the presence of 10 nmol/L monomer Cy5.5-c(RGDyK), dimer Cy5.5-E[c(RGDyK)]$_2$, tetramer Cy5.5-E{E[c(RGDyK)]$_2$}$_2$ with (D, E, F) or without (A, B, C) blocking dose of nonfluorescent RGD peptide c(RGDyK) (10 μmol/L). Complete blocking of NIR fluorescence of U87MG cells demonstrating high $\alpha_v\beta_3$ integrin specificity of these NIR dye-labeled RGD peptides.

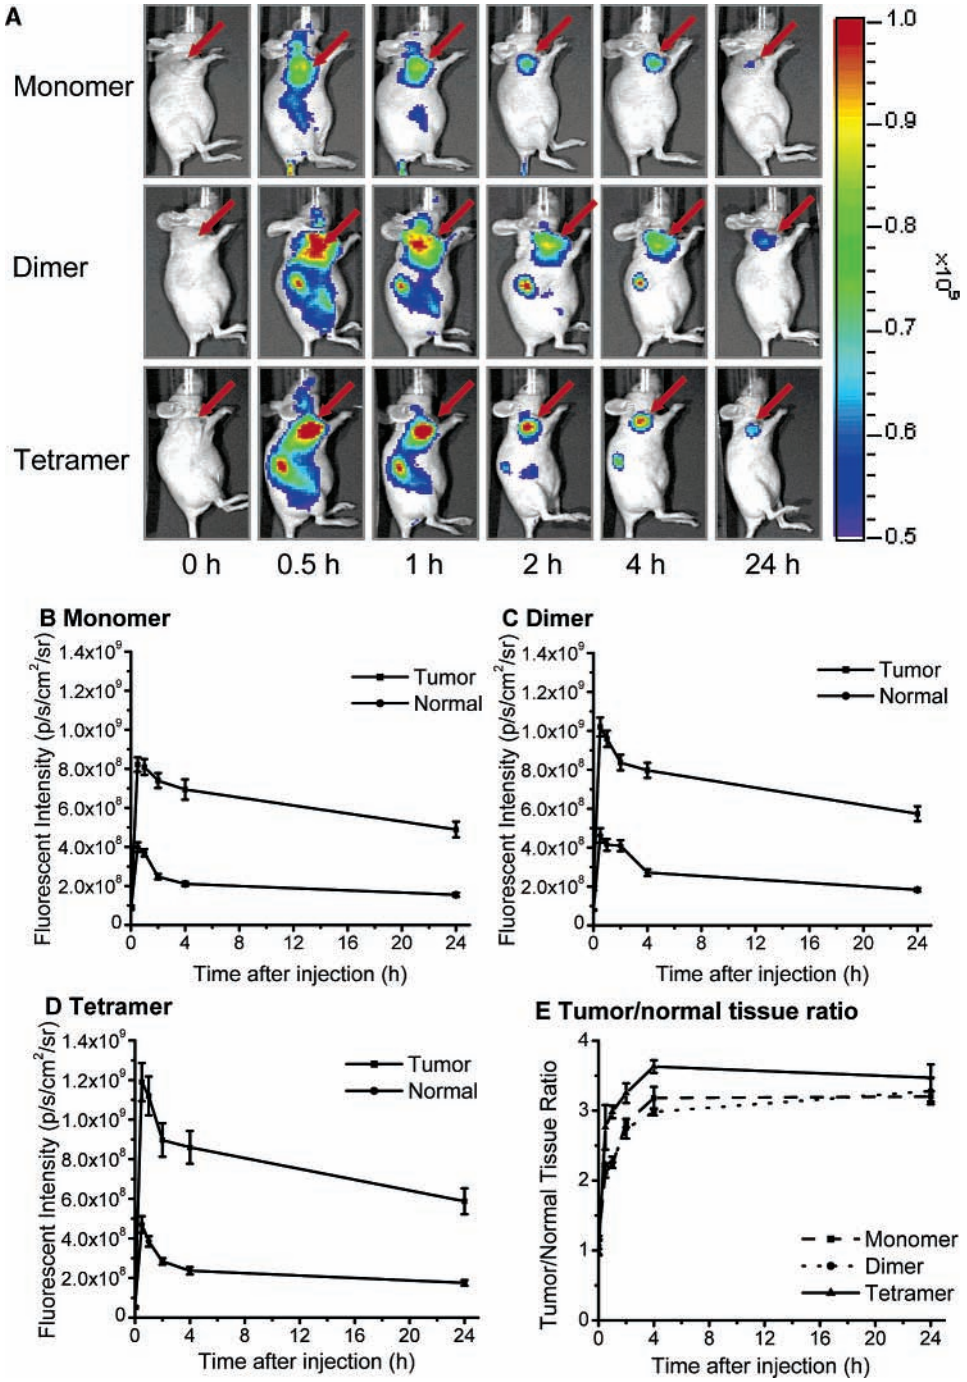

Figure 4. (A) In vivo fluorescence imaging of athymic nude mice bearing subcutaneous U87MG glioblastoma xenografts after intravenous injection of 500 pmol Cy5.5-RGD monomer, dimer, or tetramer. The location of the tumor was indicated by an arrow. Fluorescence signal from Cy5.5 was pseudo-colored red. The tetramer and dimer displayer higher tumor uptake and tumor/normal contrast than that of monomer from 0.5 to 4 h pi. (B−D) In vivo targeting characters of Cy5.5-RGD monomer, dimer, and tetramer, respectively. Both tetramer and dimer had significantly higher accumulation in tumor than monomer ($P < 0.05$) at early time points (from 0.5 to 4 h) pi. But the differences in tumor uptakes among the three probes were minimal at 24 h pi. (E) Tumor contrast (tumor-to-normal tissue ratio) as a function of time post-administration of Cy5.5-RGD monomer (■), dimer (●), and tetramer (▲). The fluorescence intensity for the region of interest was recorded as photons per second per centimeter squared per steradian (p/s/cm²/sr). The tumor contrast of Cy5.5-RGD-tetramer from 0.5 to 4 h postinjection is significantly higher than that of Cy5.5-RGD-dimer and monomer ($P < 0.05$).

points examined in this experiment). Kidneys were clearly visualized for dimeric and tetarmeric peptides, indicating that dimer and tetramer have significantly higher renal activity accumulation than the monomer.

Receptor specificities of these probes were validated by a blocking experiment. Unlabeled monomeric RGD peptide, c(RGDyK), successfully reduced tumor contrast for all three tracers (Figure 5). Tumor contrast as quantified by ROI analysis of noninvasive optical imaging indicated that the *T*/*N* was reduced from 2.22 ± 0.04 to 1.27 ± 0.05 for monomer, 2.26 ± 0.27 to 1.28 ± 0.02 for dimer, and 2.98 ± 0.09 to 1.09 ± 0.18 for tetramer, respectively.

To further characterize the distribution of RGD peptide−dye conjugates in U87MG in vivo, the tumor-bearing mice were sacrificed right after noninvasive imaging at 24 h pi. Tumors and other normal organs and tissues were removed and subjected to IVIS200 imaging

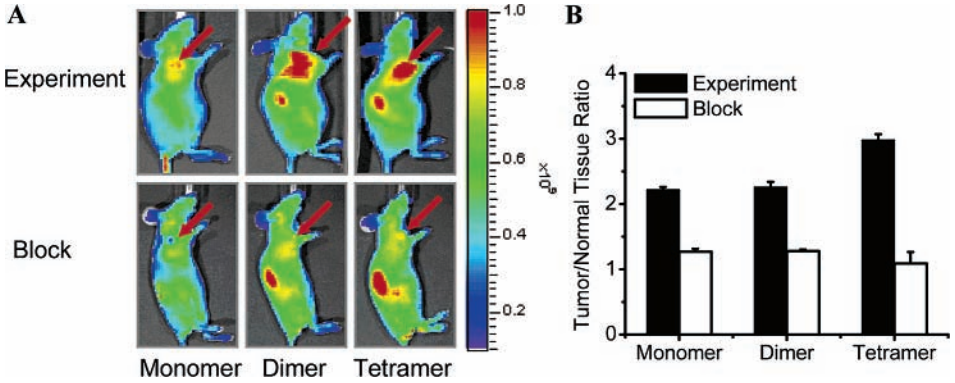

Figure 5. Representative NIRF images of mice bearing subcutaneous U87MG tumor on the right foreleg demonstrating blocking of Cy5.5-RGD conjugates (500 pmol) uptake in the tumors by coinjection with 10 mg/kg of c(RGDyK). Pseudo-color fluorescence images of tumor-bearing mice were acquired 1 h after intravenous injection of Cy5.5-RGD conjugates (experiment) or Cy5.5-RGD conjugates + c(RGDyK) (block). (B) Tumor contrast (tumor-to-normal tissue ratio) calculated from region of interest measurement at 1 h postadministration of Cy5.5-RGD conjugates.

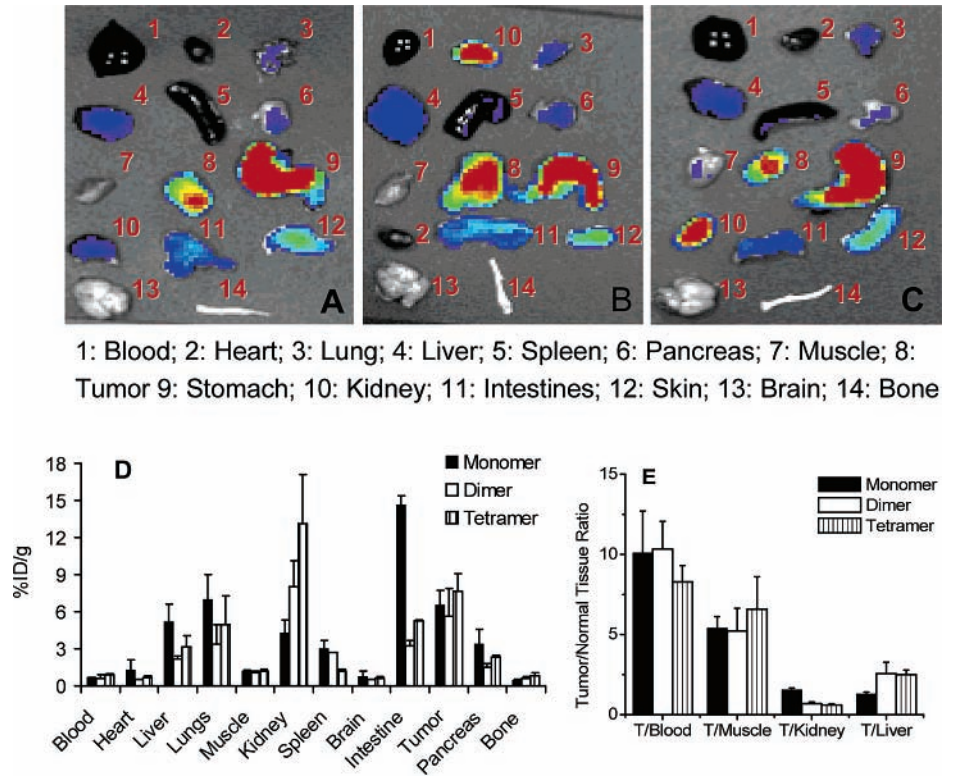

Figure 6. Representative images of dissected organs of mice bearing U87MG tumor sacrificed 24 h after intravenous injection of Cy5.5-RGD monomer (A), dimer (B), and tetramer (C) at a dose of 500 pmol per mouse. (D) Biodistribution of the probes at 24 h postinjection. (E) Tumor-to-normal organ ratios.

(Figure 6). The total fluorescence of the whole organ was obtained, and %ID/g was calculated for each organ. The biodistribution of the probes at 24 h pi is shown in the Figure 6B. Tumor-to-blood, tumor-to-muscle, tumor-to-kidney, and tumor-to-liver ratios are illustrated in Figure 6C. The renal uptake for tetramer and dimer are much higher than monomer, consistent with the imaging data obtained in living mice. The tumor accumulation and tumor/muscle and tumor/blood ratios for monomer are similar to that of dimer and tetramer. This corroborated the noninvasive imaging data obtained in living mice.

DISCUSSION

NIRF imaging, which uses neither ionizing radiation nor radioactive materials, is emerging as a complement to nuclear imaging methods. A relatively low-cost, safe, and easy-to-use NIRF imaging system has been proven to be a very powerful tool for noninvasive imaging diseases in preclinical models such as rodents (*3*). Furthermore, NIRF imaging may provide both surgical anatomy and functional/molecular information when exogenous fluorescent probes are used; thus, it has a potential in the clinical setting by allowing easy visualization and guidance in surgery (*47*). We are very interested in applying this NIRF imaging technique for studying an important molecular target integrin $\alpha_v\beta_3$, so we can better understand tumor angiogenesis and eventually develop methods for integrin-directed tumor therapy. To achieve this goal, a highly specific and sensitive NIRF agent needs to be developed first.

We have previously demonstrated that Cy5.5-labeled monomeric RGD peptide c(RGDyK) targets integrin $\alpha_v\beta_3$-expressed tumor in vivo (*28*). However, this agent only provides moderate tumor contrast in a highly integrin

positive U87MG tumor model. Cell receptor binding assay using ^{125}I-echistatin as radioligand indicated that the IC_{50} value for c(RGDyK) was approximately 50 nM. Because the cyclic pentatpeptide c(RGDyK) has already been optimized for receptor−ligand interactions (*48*), it is very unlikely that one can significantly improve receptor avidity of monomeric RGD peptide by fine-tuning of the peptide configuration. An alternative is to apply the concept of multivalency or multimerization and to develop oligomeric RGD peptide probes. In principle, the introduction of a homogeneous multimeric RGD peptide system is expected to improve integrin targeting by cooperative receptor interactions and receptor shielding to endogenous competition. We and others have previously reported that suitably labeled dimeric RGD peptide tracers had incremental improvement on tumor targeting efficiency and pharmacokinetics, compared to the monomeric RGD peptide analogues (*35*−*37*, *43*, *44*). We hypothesize that multimerization to introduce tetrameric RGD peptides might further increase the receptor binding affinity. In this study, we designed a new Cy5.5-labeled tetrameric RGD peptide with repeating c(RGDyK) units connected through glutamate linkers (Figure 1). As expected, integrin affinity followed the order of tetramer > dimer > monomer. Fluorescence microscope imaging studies also confirmed the effectiveness of all three probes for integrin positive U87MG cell staining and receptor mediated endocytosis.

We recently radiolabeled DOTA-conjugated RGD monomer, dimer, and tetramer with ^{64}Cu and compared their tumor targeting efficacy and in vivo kinetics (*33*, *37*, *46*). Tetrameric RGD peptide tracer had almost twice as much tumor uptake than the corresponding dimer. The dimer also had significantly higher tumor uptake than the monomeric counterpart. Renal and hepatic activity accumulation of tetramer was also somewhat higher than that of dimer and monomer. In agreement with these data, we observed significant ($P < 0.05$) increase of tumor fluorescence intensity for Cy5.5-conjugated tetramer and dimer, compared to the monomic analogue at early time points (from 0.5 to 4 h) pi (Figure 4). However, between tetramer and dimer, no significant difference in tumor accumulation is observed. Another important finding in this research is that tetramer demonstrated the highest *T/N* contrast from 0.5 to 4 h pi (Figure 4). This attribute is apparent from the high tumor uptake and relatively low normal tissue uptake. The monomer displayed low uptake in the tumor, but it was quickly cleared from normal tissue. This results in a moderate *T/N* contrast. For the dimer, although it showed a higher tumor uptake thanthat of the monomer, the relatively high uptake in normal tissue reduced its *T/N* contrast. We did not observe significant differences in the magnitude of tumor uptake or *T/N* contrast at 24 h after administration of the NIRF probes by which most of the tumor uptake has been cleared. Moreover, the tumor uptake of NIRF RGD peptides could be specifically inhibited by the unlabeled c(RGDyK) (Figure 5). This demonstrates that Cy5.5-conjugated monomeric, dimeric, and tetrameric RGD peptides are all specific agents for NIR fluorescence imaging of integrin expression. Overall, these data suggest that based on the highest tumor uptake and contrast at early time points pi, the tetramer appears to be the best integrin $\alpha_v\beta_3$ targeting agent among these three compounds. However, only moderate improvement was achieved through multimerization of the peptide strategy. Compared to the monomer, the tetramer only shows 1.20−1.45-fold increase in tumor accumulation and 1.08−1.30-fold increase in *T/N* ratio at different time points postinjection.

The small animal optical imaging studies above also highlight the importance of evaluation of polyvalency effects of the contrast agents in vivo. Initially we expected that higher tumor uptake, retention, and *T/N* ratio would be achieved for Cy5.5-labeled RGD multimers due to their increased binding affinities. However, although it was found that the absolute tumor uptake of Cy5.5-labeled RGD probes was generally enhanced with increasing number of RGDs in each probe, multimerization of RGD also changes the molecular size, overall molecular charge, and hydrophilicity of the resulting peptides, thus altering their in vivo pharmacokinetics and clearance from nontarget tissues. These results are consistent with the data reported in the literature (*43*, *46*). In both reports, the multlimeric RGD peptides showed significantly higher IC_{50} values in vitro and the magnitude of tumor uptake in vivo; however, the improvement of tumor-to-background ratio is marginal. Apparently, for applying the strategy of peptide multmerization extensively and efficiently, more studies are needed to investigate what the essential effects are required to improve the biodistribution and achieve greater targeting selectivity.

Fluorescence intensities of the dissected tumors and normal organs and tissues agreed well with the aforementioned in vivo observations, except that the ex vivo tumor-to-muscle ratio was substantially higher than that observed noninvasively, which might be attributed to the minimal loss of excitation and emission of light density without the need of penetration in and out of skin in addition to the scatter caused by the skin. Quantification analysis verified there were no significant differences in tumor/blood and tumor/muscle ratios for these NIRF probes at 24 h pi. Furthermore, both dimer and tetramer had much lower tumor-to-kidney ratios than the monomer, likely reflecting the more net positive charge character of the dimer and tetramer than the monomer. The membranes of the renal tabular cells contain negatively charged sites to which the positively charged groups (such as guanidines in the RGD sequence) are expected to bind. There is no significant difference in liver uptake of the three probes.

To further optimize the NIRF RGD probes, it also should carefully choose fluorescent labels itself. The emission maximum of Cy5.5 at 694 nm is at the lower limit of NIRF window. It is expected that fluorescent dyes with more red-absorbing character may provide deeper tissue penetration and thus a closer reflection of an actual distribution of the probe in vivo. Another major problem with Cy5.5 dye is the very small Stokes shift (20 nm). Development of fluorescent dyes with a large Stokes shift would provide better fluorescence detection sensitivity by eliminating the interference with the excitation source, minimizing the rejection of excitation light by the emission filter, and reducing the error by excitation light and scattered light. A good alternative to the fluorescent dyes would be quantum dots (QDs) as fluorescent biolabeling reagents. In comparison with organic fluorophores, QDs have unique optical and electronic properties, such as size- and composition-tunable fluorescence emission from visible to NIR wavelengths, a large absorption coefficient across a wide spectral range, and very high level of brightness and photostability (*49*). Because of their broad excitation profiles and narrow, symmetric emission spectra, high-quality QDs are suited for optical multiplexing. Whether conjugation of RGD peptides with novel reporter components such as fluorescent dyes with a large Stokes

shift or QDs could generate better NIRF imaging agents for integrin $\alpha_v\beta_3$ requires further investigation.

Initially we also expected that NIRF imaging using Cy5.5-labeled RGD peptides might provide the opportunity for rapid and cost-effective structure−activity studies to screen newly developed ligands, rather than the more costly radionuclide-based imaging studies such as SPECT and PET. However, this hypothesis oversimplifies the complex effect that a fairly bulky Cy 5.5 label has on the pharmacokinetics of a probe. The in vivo behavior is the combination of many factors, including, but not limited, to the receptor affinity and specificity, molecular size, overall molecular charge, hydrophilicity, and metabolic stability. Cy5.5 is a rather large chromophore with a molecular weight of ca. 1000. Tumor contrast obtained with a Cy5.5-RGD conjugate may not truly reflect the same RGD peptide labeled with a radionuclide. Additional studies to evaluate the impact of cyanine dye structure on the receptor targeting properties of RGD peptide in vivo is needed to elucidate the discrepancy between NIRF imaging and radionuclide imaging.

CONCLUSION

Cy5.5-RGD monomer, dimer, and tetramer all exhibit specific uptake in the U87MG glioblastoma both in vitro and in vivo. Among these three probes, Cy5.5-RGD tetramer displays the highest tumor uptake and tumor-to-background ratio up to 4 h postinjection and as such appears to be the most promising probe for integrin receptor NIRF imaging. However, the improvement of imaging character of tetramer is only moderate, compared to that of monomer. More research is needed to further optimize such probes.

University, Budapest 112, POB 32, H-1518 Hungary, and Department of Genome Sciences, University of Washington, HSB K-116, Box 357710, 1959 NE Pacific Street, Seattle, Washington 98195. Received June 14, 2005; Revised Manuscript Received August 18, 2005

Selective delivery of antiparasitic or antibacterial drugs into infected macrophages could be a promising approach for improved therapies. Methotrexate conjugate with branched chain polypeptides exhibited pronounced anti-*Leishmania* activity in vitro and in vivo as reported here earlier. To identify structural requirements for efficient uptake of branched polypeptides, we have studied murine bone marrow culture-derived macrophages (BMMϕ) from 129/ICR mice. We report on the translocation characteristics of structurally closely related compounds labeled with 5(6)-carboxyfluorescein. We found that this process is dependent on experimental conditions (e.g. polypeptide concentration, incubation time, and temperature). Using specific inhibitors as well as macrophages from wild-type and class-A scavenger receptor knockout (SR-A −/−) mice, we demonstrated that SR-A was involved in the endocytosis of some polypeptides depending on their charge. Uptake could be blocked by unlabeled polypeptide, by SR-A inhibitors, and by specific anti-SR-A monoclonal antibody. The polyanionic polypeptide poly[Lys(Succ-Glu$_{1.0}$-DL-Ala$_{3.8}$)] (SuccEAK) with high charge density translocated more efficiently than poly[Lys(Ac-Glu$_{1.0}$-DL-Ala$_{3.8}$)] (AcEAK), which had a lower anionic charge density. On the basis of experimental data presented, SuccEAK can be considered as a potential candidate for the design of a macromolecular carrier for specific drug delivery of bioactive entities into macrophages via SR-A.

INTRODUCTION

A number of intracellular pathogens including *Mycobacterium tuberculosis* (*1*) and the unicellular parasite *Leishmania* (*2*) are capable of surviving intracellularly in macrophages within phagosomes. Macrophage-selective delivery of antibacterial or antiparasitic drugs by endocytosis via specific receptors could be an attractive strategy for more efficient therapies. This approach would require the development of therapeutic macrophage receptor-specific carriers of macromolecular nature. Scavenger receptors play a crucial role in the uptake of bacteria (*3*, *4*), apoptotic cells, and modified lipoproteins (*5*). Scavenger receptors are structurally varied transmembrane proteins binding mainly polyanions with diverse chemical composition (e.g. sulfated polysaccharides, poly(I) and poly(G)) (*6*). Reports published earlier described successful introduction of antimycobacterial *p*-aminosalicylic acid (*7*) and phthalocyanine derivatives (*8*) into macrophages or macrophage cell lines by using maleylated BSA (mal-BSA). The conjugate of *p*-aminosalicylic acid was taken up by peritoneal macrophages infected in culture by *M. tuberculosis* and was 100 times more effective in killing the intracellular organisms (*7*). J774 macrophages treated with the conjugate of phthalocyanine derivatives with mal-BSA exhibited phototoxicity higher than in nonphagocytic EMT-6 cells (*8*). Mukhopadhyay et al. found that daunomycin coupled to mal-BSA entered daunomycin resistant J774A.1 cells (*9*) in vitro. When injected into mice, the daunomycin−mal-BSA conjugate was cleared rapidly from the circulation and accumulated in the macrophage-rich tissues, liver, lung, and spleen (*10*). The same group described also that the conjugate of methotrexate and mal-BSA delivered the drug into *Leishmania donovani*-infected macrophages (*11*). Also, Prasad and colleagues coupled antisense oligonucleotide to a 10-mer poly(G) and introduced this into the J774E macrophage cell line (*12*).

Very few systematic studies have been reported on structural and functional factors required for delivery/targeting of bioactive entities by macromolecules. To this end we have initiated systematic structure−function studies for rational selection of polypeptides as synthetic macromolecular carriers. For this we prepared several groups of branched chain polypeptides with the general formula of poly[Lys(X$_i$−DL-Ala$_m$)] (XAK) (Figure 1), where $i \cong 1$, $m \cong 3-4$, and X represents an additional optically active amino acid residue (*13*, *14*). These polypeptides characterized by chemical (primary structure, conformation) and biological (in vitro cytotoxicity, biodegradation, immunoreactivity, and biodistribution) properties (*13*−

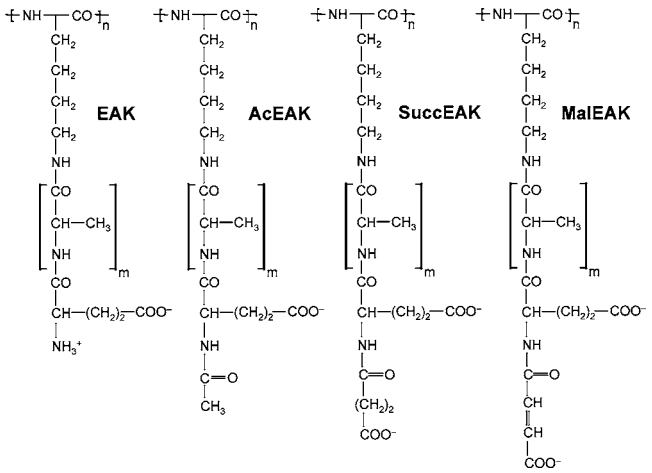

Figure 1. Chemical structure of the amphoteric EAK and its polyanionic derivatives.

15) had a marked effect on phospholipid model membranes depending on their side chain structure (*16*−*18*).

Recently we prepared several highly active bioconjugates in which an antitumor agent (*19*), radionucleide (*20*), or epitope peptide (*21*) was covalently attached to selected branched polypeptides.The coupling of an acid labile derivative of daunomycin to poly[Lys(Glu_i−DL-Ala_m)] (EAK) resulted in compensation of the immunosuppressive effect of the drug, and this conjugate in vivo was very effective in mice bearing L1210 leukemia producing 66−100% long-term (>60 days) survivors (*22*). Recently, a pronounced anti−*Leishmania donovani* effect of methotrexate (MTX) branched polypeptide conjugates was observed in vitro and in vivo (*23*). We demonstrated that the leishmanicidal activity was carrier dependent and the covalent bond between the carrier and MTX is essential. On the basis of in vitro observations, we postulated that the MTX conjugate exhibited an effect through uptake by macrophages, which was different from that of the free drug.

The aim of this work was to analyze the uptake of structurally related branched polypeptides by murine bone marrow culture-derived macrophages (BMMϕ) from 129/ICR mice. We found that polypeptides labeled with 5(6)-carboxyfluorescein are taken up and that the process was dependent on experimental conditions (e.g. polypeptide concentration, incubation time, and temperature). Furthermore, comparing polypeptide uptake by wild-type and class A macrophage scavenger receptor (SR-A)-deficient macrophages, we demonstrated that SR-A played a crucial role in the uptake of some of the polypeptides tested. SR-A-dependent recognition and endocytosis of the polypeptides was dependent on their charge properties. Taken together, our data indicate that the polypeptide poly[Lys(Succ-$Glu_{1.0}$-DL-$Ala_{3.8}$)] (SuccEAK) could be a potential candidate for the design of a macromolecular carrier for specific drug delivery of bioactive entities into macrophages via SR-A.

EXPERIMENTAL PROCEDURES

Abbreviations. Abbreviations of amino acids and their derivatives follow the revised recommendation of the IUPAC−IUB Committee on Biochemical Nomenclature entitled "Nomenclature and Symbolism for Amino Acids and Peptides" (recommendations of 1983). Nomenclature of branched chain polypeptides was used in accordance with the recommended nomenclature of graft polymers (*24*). For the sake of brevity, codes of branched chain polypeptides were constructed by us using the one-letter codes of amino acids. All amino acids are L configuration unless otherwise stated. The other abbreviations in this paper are the following: Z: benzyloxycarbonyl, Boc: *tert*-butyloxycarbonyl, Pcp: pentachlorophenyl, NCA: *N*-carboxy anhydride, HOBt: 1-hydroxybenzotriazole, DMF: *N,N*-dimethylformamide, DMSO: dimethyl sulfoxide, TEA: triethylamine, DCM: dichloromethane, NMM: 4-methylmorpholine, TEA: triethylamine, TFA: trifluoracetic acid PBS: phosphate-buffered saline, Ac: acetyl, Succ: succinyl, Mal: maleyl, CF: 5(6)-carboxyfluorescein, DiI: 1,1′-dioctadecyl-1−3,3,3′,3′-tetramethylindocarbocyanine perchlorate, LDL: low-density lipoprotein.

Branched Chain Polypeptides. *Reagents and Solvents.* Amino acids used for this study, HCl, trifluoracetic acid, acetic acid anhydride, and succinic anhydride, were purchased from REANAL (Budapest, Hungary). Benzyloxycarbonyl chloride, pentachlorophenol, *N,N′*-dicyclohexylcarbodiimide, HOBt, TEA, DMSO, and NMM were from Fluka (Buchs, Switzerland). Acetonitrile was from Merck (Darmstadt, Germany). 5(6)-Carboxyfluorescein succinimide ester was obtained from Sigma-Aldrich (Budapest, Hungary).

Synthesis of Poly[Lys]·HBr. The synthesis was carried out from N^{α}-carboxy-N^{ϵ}-benzyloxycarbonyl-lysine anhydride under conditions to obtain an average degree of polymerization of approximately 100 (monomer: diethylamine initiator molar ratio = 50:1), as reported previously (*25*). Protecting groups were cleaved by HBr in glacial acetic acid (35%, m/V) and poly[Lys]·HBr was precipitated using diethyl ether. The polypeptide was purified by dialysis against distilled water using visking casing and was isolated by freeze-drying. The average relative molar masses (M_w, M_z) were determined by sedimentation equilibrium using a short column technique at 25 °C (MOM 3180 type analytical ultracentrifuge, Hungary). The number average of the relative molar mass (M_n), the polydispersity factor (M_z/M_w), and the average degree of polymerization (DP_n) values were calculated from data described earlier (*26*).

Synthesis of Poly[Lys(X_i-DL-Ala_m)] (XAK) Type Polypeptides and the Polyanionic Derivatives of Poly[Lys(Glu_i-DL-Ala_m)], (EAK). Poly[Lys(DL-Ala_m)] (AK) (*27*) and poly[Lys(X_i-DL-Ala_m)] (XAK) polypeptides, where X = Glu or Ser, were prepared as described earlier (*28*). Briefly, AK polypeptide was synthesized by grafting short oligomeric DL-Ala chains to the $^{\epsilon}NH_2$ group of lysine residues using *N*-carboxy-DL-Ala-anhydride. The terminal amino acids (X) were coupled to the $^{\alpha}NH_2$-groups of the side chains as Z−X-OPcp, where X = Glu or Ser. The reaction was performed by an in situ active ester method using an equivalent amount of HOBt dissolved in DMF as activating reagent. The pH of the solution was adjusted to 8.0 by adding NMM. Stirring was continued at room-temperature overnight. Z-protecting groups were removed with HBr using acetic acid containing 35% HBr. The polypeptides were purified by dialysis against distilled water for 2 days using a Visking tube (cutoff = 12000−14000 Da) and isolated by freeze-drying.

Poly[Lys(AcGlu$_i$-DL-Ala_m)] (AcEAK) was prepared by acetylation of poly[Lys(Glu_i-DL-Ala_m)] (EAK) as follows. 85 mg (159 μmol) of EAK was dissolved in 2 mL of distilled water and diluted with 10 mL of DMF under cooling at 0 °C. 27 μL (198 μmol) of TEA was added to this solution to neutralize the polymer. Five equivalents of freshly prepared imidazolyl-acetate was used for the acetylation (*29*), and then the product was dialyzed against distilled water followed by freeze-drying.

Poly[Lys(Succ-Glu_i-DL-Ala_m)] (SuccEAK) was prepared by succinylation and poly[Lys(Mal-Glu_i-DL-Ala_m)] (MalEAK) by maleylation of poly[Lys(Glu_i-DL-Ala_m)],(EAK) as follows. 10 mg (18.5 μmol) EAK) was dissolved in 2 mL of 0.1 M carbonate buffer (pH = 9.2). 220 μL (220 mmol) of succinic anhydride or 219 μL (220 mmol) maleic anhydride, respectively, was dissolved in DMSO (c = 100 mg/mL) and was added to this solution with continuous stirring for 30 min at RT (*30*). The pH was maintained between 9.0 and 9.2 with 0.1 M NaOH. The reaction was continued for 4 h followed by dialysis against distilled water for 2 days and then freeze-drying.

Amino Acid Analysis. The amino acid composition of the polymeric polypeptides was determined by amino acid analysis using a Beckman 6300 analyzer (Fullerton, CA). Prior to analysis, the samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 105 °C for 24 h.

Labeling of Branched Polypeptides with 5(6)-Carboxyfluorescein. 10 mg (6×10^{-7} to 1.9×10^{-7} mol) amounts of polypeptides were dissolved in 2 mL of Na_2CO_3 buffer (0.1 M; pH 9.4). The amino-reactive dye 5(6)-carboxyfluorescein succinimide ester (5(6)-CF-SE) was dissolved in DMF (c = 10 mg/mL, 0.21 mM) and was added to the polypeptide solution in 20 μL aliquots. The reaction was continued for 1 h at room temperature with continuous stirring. The product was purified on a PD10 Sephadex G25 column using distilled water as eluent. The samples were then freeze-dried and they were resolved in PBS (0.1 M, pH 7.4) before use.

Determination of 5(6)-Carboxyfluorescein Content of Conjugates. Labeled polypeptide samples and 5(6)-carboxyfluorescein succinimide ester were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h. HCl was removed, and the hydrolysate was dissolved in DMSO. The hydrolyzed samples (20 μL) were analyzed by RP-HPLC using reversed phase Eurospher C_{18} column (3.9 × 250 mm; packed with spherical 5 μm silica with 100 Å pore size [Knauer, Bad Homburg, Germany] and gradient elution consisted of 0.1% TFA in water [eluent A] and 0.1% TFA in acetonitrile/water = 80/20 v/v [eluent B]). During chromatography the eluent B content was between 25 and 45%, in 20 min, 45−99%, in 10 min. The flow rate was 1 mL/min at room temperature. The average sample concentration applied was 0.65 μg/mL. Peaks were detected at λ_{ex} = 419 nm and λ_{em} = 519 nm using a fluorescence detector (Shimadzu, Japan). A calibration curve was constructed using 5(6)-carcoxyfluorescein in the 4.8×10^{-5} M to 1.2×10^{-5} M concentration range.

Functional Studies. *Reagents.* 1,1′-Dioctadecyl-1−3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI)-labeled acetylated LDL (DiI-AcLDL) was obtained from Autogen Bioclear, and poly(I) from Signa (Reading, UK). OptiMEM medium and all other culture media were from Invitrogen (Paisley, United Kingdom). Rat anti-mouse SR-A antibody 2F8 was prepared at the Sir William Dunn School of Pathology, Oxford, as described previously (*33*). CAMPATH rat anti-mouse IgG, an isotype-control for 2F8, was a kind gift from H. Waldmann, Sir William Dunn School of Pathology, Oxford. Cy3-labeled donkey anti-rat IgG was from Jackson ImmunoResearch (Soham, UK), and rabbit and goat sera were from Sigma. Fluorescent Mounting Medium was from DakoCytomation (Glostrup, Denmark). Plastic products were purchased from Becton Dickinson Labware (Oxford, UK).

Animals. Mice deficient in SR-AI and II (SR-A −/−) were produced as previously described (*31*). SR-A −/− and SR-A +/+ control 129/ICR mice of the same sex were used at 8−12 weeks of age. All animals were handled in accordance with guidelines issued by the Home Office, United Kingdom.

Cell Isolation and Culture. BMMϕ were obtained and cultured by standard procedures described previously (4). The cells were maintained in 15 cm bacteriologic plastic (BP) Petri dishes containing RPMI 1640 with 50 IU/mL penicillin G, 50 μg/mL streptomycin, 2 mM glutamine (PSG), 10% fetal calf serum (FCS), and 15% (vol/vol) L-cell conditioned medium (LCM) as a source of macrophage colony-stimulating factor (*32*). The macrophages were harvested with PBS (0.1 M, pH 7.4) containing 10 mM EDTA and 4 mg/mL lidocaine·HCl and plated onto six-well BP plates (Greiner, Gloucester, United Kingdom). The cells were maintained in the six-well plate for further 24 h at 37 °C. The bone marrow from the femurs and tibias of one mouse gave $(1-5) \times 10^7$ Mϕ after 7 days in culture.

Cytotoxicity Assay. Prior to the experiment, cells were washed three times with PBS. Each polypeptide was added in OptiMEM at a concentration of 1 μg/mL or 20 μg/mL. BMMϕ were incubated with the polypeptide solution for 1 h and then harvested with lidocaine/EDTA. The number of living cells was determined by counting the cells in a Neubauer haemocytometer after staining with 0.4% trypan blue dissolved in PBS. The statistical significance of data was determined by Student's t test at the 95% confidence level.

Flow Cytometry Analysis of Cellular Uptake. Polypeptides labeled with 5(6)-CF dissolved in OptiMEM were used. Before adding CF-labeled polypeptides, the cells were washed three times with PBS. The CF-labeled polypeptides were incubated with the cells for 1 h at 37 °C or 4 °C. For the inhibition experiments poly(I) at 50 μg/mL (4) or 2F8 at 15 μg/mL was used (*33*). Prior to the addition of polypeptides, cells were preincubated for 30 min with inhibitor which was also maintained throughout the experiment. In some experiments unlabeled polypeptides were added at 10 times excess of labeled molecule concentration. The increase in macrophage fluorescence following incubation with labeled molecules was analyzed by flow cytometry. Data were analyzed with CellQuest 3.0 software. The mean fluorescence of untreated control cells was subtracted from the mean fluorescence obtained with treated samples under all different assay conditions applied. Statistical analysis of data was performed using Student's t test at the 95% confidence level.

Analysis of the Cellular Uptake by Confocal Microscopy. Wild-type 129/ICR BMMϕ were plated on sterile glass coverslips in 24-well tissue-culture dishes in RPMI 1640 medium supplemented PSG; 10% FCS; and 15% (vol/vol) LCM at 5×10^4 macrophages per well 24 h prior to the experiment. The cells were washed three times with PBS. CF-labeled polypeptides were incubated with the cells for 5, 15, 30, and 60 min at 37 °C. Cells were fixed with 4% formaldehyde/PBS for 15 min at room temperature then permeabilized using a blocking buffer containing 1% (m/V) BSA, 0.25% (m/V) saponin, and 1% goat and 1% rabbit serum. The cells were incubated with 2F8 (c = 10 μg/mL) or with an isotype-matched control antibody (CAMPATH 1G) in parallel for 1 h at room temperature followed by washing three times with blocking buffer. After incubation with Cy3 labeled anti-rat IgG antibody for 1 h in the dark, the coverslips were mounted on glass microscopy slides using DakoCytomation Fluorescent Mounting Medium. Cells were analyzed in a BIO RAD Radiance 2000 confocal microscope (λ_{ex} = 488 nm).

Table 1. Characteristics of Polylysine Based Branched Chain Polymeric Polypeptides with Poly[Lys(X_i-DL-Ala_m)] Formula

polypeptide	code[a]	amino acid composition[b] Lys	Ala (m)	X (i)	$\overline{DP_n}$[c]	$\overline{M_w}$[d] ± 5%	CF [%][e]
poly[Lys]	-	1.00	-	-	130	16700	-
poly[Lys(Glu_i-DL-Ala_m)]	EAK	1.00	3.80	1.00	60	31600	2.91
poly[Lys(Ac-Glu_i-DL-Ala_m)]	AcEAK	1.00	3.80	1.00	60	34500	0.46
poly[Lys(Succ-Glu_i-DL-Ala_m)]	SuccEAK	1.00	3.80	1.00	60	37900	0.53
poly[Lys(Succ-Glu_i-DL-Ala_m)]	MalEAK	1.00	3.80	1.00	60	37800	0.72

[a] Code of branched chain polymeric polypeptides, based on one-letter symbol of amino acids. [b] Amino acid composition was determined by amino acid analysis as after hydrolysis in 6 M HCl at 105 °C for 24 h. [c] Number of average degree of polymerization determined by sedimentation equilibrium measurements. [d] Average molecular mass of polymers; calculated from the average degree of polymerization (DP_n) of poly[Lys] and of the side chain composition. [e] Average degree of substitution for 5(6)-carboxyfluorescein (CF) was determined by reverse phase HPLC after hydrolysis of the samples in 6 M HCl at 105 °C for 24 h.

RESULTS

Branched Polypeptides. Branched polypeptides with the general formula poly[Lys(X_i-DL-Ala_m)], ($m \cong 4$, $i \cong 1$), which were used for these studies have short oligo-(DL-Ala) side chains and Glu at the *N*-terminal of the branches. The terminal amino acid X was coupled to the $^{\alpha}NH_2$ groups of the terminal alanine by an in situ active ester method (*28*). EAK bearing $^{\alpha}NH_2$ and also free carboxyl groups at the end of the branches possess an amphoteric character. The three additional polypeptides that were also included in our studies were the polyanionic derivatives of poly[Lys($Glu_{1.0}$-DL-$Ala_{3.8}$)] (EAK) prepared by acetylation, succinylation or maleylation of the $^{\alpha}NH_2$ groups of the terminal glutamic acid residues (Figure 1). Poly[Lys($AcGlu_{1.0}$-DL-$Ala_{3.8}$)] (AcEAK) side chains contain only one negative charge per monomer unit under conditions used for the present studies. The charge density of the succinylated (poly[Lys($SuccGlu_{1.0}$-DL-$Ala_{3.8}$)], SuccEAK) and maleylated (poly[Lys($MalGlu_{1.0}$-DL-$Ala_{3.8}$)], MalEAK) polypeptides were higher, since two negative charges were present per unit. Thus, we investigated this group of structurally related polypeptides built on a polylysine backbone with systematically altered chemical properties (charge, conformation (*13*, *30*)). The polypeptides were characterized according to their relative average molar mass, determined by sedimentation equilibrium analysis (*26*), and the composition of their side chain. The chemical characteristics of the polypeptides are shown in Table 1.

Cytotoxic Effect of Polypeptides on BMMϕ. The cytotoxicity of polypeptides labeled with CF was studied on BMMϕ cells from wild-type mice at two different concentrations (1 μg/mL and 20 μg/mL). The cytotoxicity of the polypeptides was determined by counting live cells by trypane blue exclusion. Polylysine was included as a control. Results are expressed as a percentage of untreated cells and summarized in Figure 2. We found that after 1 h incubation none of the polypeptides had a significant toxic effect on the macrophages at 1 μg/mL concentration. At 20 μg/mL poly[Lys] proved to be highly toxic, but no cytotoxic effect of the other polypeptides was observed.

Uptake of polypeptides by BMMϕ. We studied the endocytosis of polypeptides by BMMϕ from wild-type mice under different conditions. The effects of polypeptide concentration, incubation time, and temperature on uptake were analyzed. Furthermore we investigated the influence of unlabeled polypeptides on the internalization of CF-polypeptides in inhibition assays.

Influence of the Polypeptide Concentration on the Uptake. BMMϕ from wild-type mice were incubated with varying concentrations (0.1−100 μg/mL) of the CF-labeled polypeptides, and the rate of uptake was detected by flow cytometry. The amphoteric EAK and polyanionic AcEAK were internalized only at 100 μg/mL concentration. In the case of polyanionic SuccEAK, uptake was proportional with the increasing concentration in the concentration range tested, while MalEAK was taken up effectively only at 50 and 100 μg/mL (Figure 3).

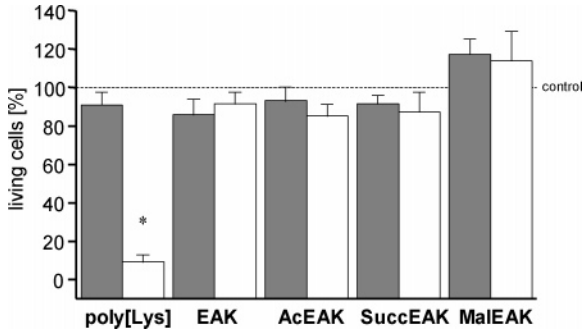

Figure 2. The effect of the branched CF-polypeptides on the survival of BMMϕ. Columns represent the number of living cells as a percentage of untreated control ± SD. Polylysine ($\overline{DP_n}$ = 130, $\overline{M_w}$ = 17000) was used as control polypeptide. ■: c = 1 μg/mL, □: c = 20 μg/mL. Statistical analysis of data was performed by Student's t test; *: p<0.05. Poly[L-Lys] (M_w = 17000, DP_n = 130) was used as control.

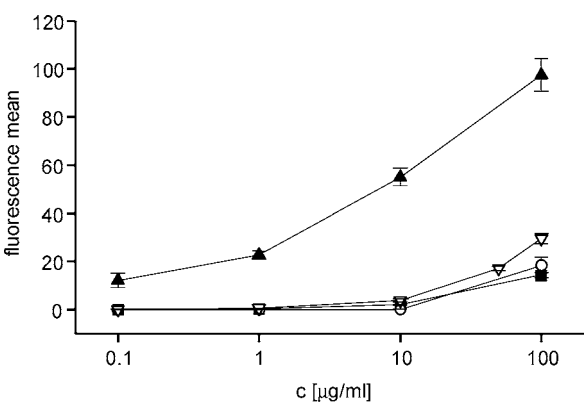

Figure 3. Concentration dependence of the uptake of the CF-polypeptides by BMMϕ after 60 min incubation with the polypeptides. Symbols represent the average of mean fluorescence values of a representative experiment of three independent assays ± SD after subtracting the control. ■: CF-EAK, ○: CF-AcEAK, ▲: CF-SuccEAK, ▽: CF-MalEAK.

Time Dependence. Time dependence of uptake was examined by flow cytometry after 1, 5, 10, 20, 30, 45, and 60 min incubation with the polypeptides (Figure 4). The internalization of the polyanionic polypeptides by the cells was in direct proportion to the duration of incubation. The uptake of neither the scavenger receptor ligand DiI-AcLDL (c = 5 μg/mL) used as positive control (6, 34) nor the CF-polypeptides was saturable during the 1 h

study period, and the polyanionic polypeptides were taken up continuously by the BMMϕ during this time (Figure 4).

Temperature Dependence. The uptake of the polypeptides was also investigated at 4 °C versus 37 °C by flow cytometry. The results are summarized in Figure 5. In the case of the amphoteric EAK no significant uptake could be observed at 37 °C or 4 °C. Two polyanionic polypeptides, AcEAK and SuccEAK, were internalized only at 37 °C. In the case of MalEAK a significant difference could be observed between the uptake at 4 °C or at 37 °C.

The Effect of Pretreatment with Unlabeled Polypeptides. In this experiment the endocytosis of CF-SuccEAK was examined at the lowest concentration that could be easily detected. Macrophages were pretreated with unlabeled polypeptides at a concentration 10 times higher than the labeled polypeptide for 30 min prior to the incubation of the cells with the respective CF-polypeptides. The polyanionic polypeptides, AcEAK and SuccEAK, significantly inhibited the uptake of the labeled SuccEAK into the macrophages (Figure 6). Pretreatment of the macrophages with c = 10 μg/mL unlabeled SuccEAK inhibited the uptake of CF-SuccEAK (c = 1 μg/mL) to the control levels. After 60 min incubation with the labeled polypeptide, mean fluorescence was 1.43 ± 0.15 in the presence and 10.77 ± 0.65 in the absence of the unlabeled SuccEAK, p < 0.01. To a

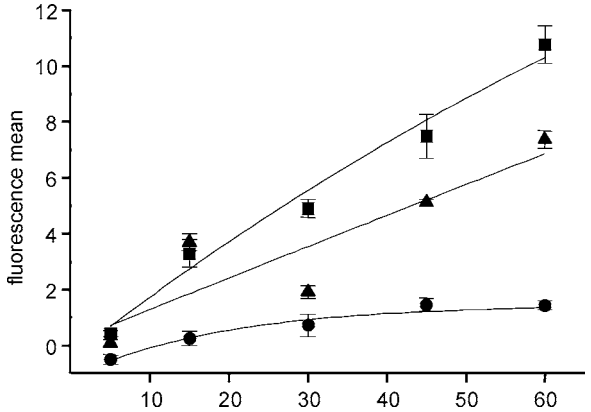

Figure 6. Effect of pretreatment with unlabeled polypeptides of similar chemical character. Symbols represent the average of mean fluorescence values of a representative experiment of three independent assays ± SD after subtracting the control. ■: uptake of CF-SuccEAK, c = 1 μg/mL; ●: uptake of CF-SuccEAK pretreated with unlabeled SuccEAK, c = 10 μg/mL, ▲: uptake of CF-SuccEAK pretreated with unlabeled AcEAK, c = 10 μg/mL.

lesser extent, unlabeled AcEAK also elicited a statistically significant inhibition of the internalization of CF-SuccEAK (mean fluorescence [%] = 7.36 ± 0.31 in the presence of AcEAK, $p < 0.01$).

The Role of the Scavenger Receptor in the Uptake of Polyanionic Polypeptides. To clarify the potential involvement of the SR-A, we examined the uptake of the polypeptides by BMMϕ from SRA −/− mice. In these studies in order to block the receptor we utilized a known general SR-A ligand, poly(I), and a specific anti-SR-A monoclonal antibody, 2F8.

Uptake of Polypeptides by Wild-Type and SR-A −/− Macrophages. The uptake of polyanionic polypeptides CF-AcEAK, CF-SuccEAK, and CF-MalEAK was tested. The scavenger receptor ligand DiI-AcLDL was used as a positive control (*34*), and the amphoteric CF-EAK polypeptide as negative control. The three polyanionic polypeptides were internalized by wild-type macrophages, but to a lower extent compared with DiI-AcLDL (Figures7 and 8). The uptake of CF-SuccEAK, with higher negative charge density, by wild-type BMMϕ was greater than CF-AcEAK having less negative charges and CF-MalEAK containing a double bond in its anionic end-group. In all cases we observed that the internalization of these polypeptides was significantly diminished in SR-A −/− cells (Figure 7). In the case of CF-SuccEAK (c = 50 μg/mL) we detected a thirteen-fold difference between the fluorescence intensities of the internalized polypeptide by the wild-type and SRA −/− BMMϕ (mean fluorescence = 52.49 ± 1.34 and 3.77 ± 0.01 respectively, $p < 0.001$). With CF-AcEAK (c = 100 μg/mL) a statistically significant difference could be demonstrated between the uptake of the wild-type and of the SR-A −/− macrophages, a 8-fold decrease in the uptake could be observed (mean fluorescence = 10.195 ± 1.43 for the wild-type and 1.235 ± 0.26 for the SRA −/− cells, $p < 0.001$) (Figure 8).

Blocking of Scavenger Receptor-A with Poly(I) and MAb 2F8. Next, wild-type and SR-A −/− BMMϕ were pretreated with the scavenger receptor ligand poly(I) (c = 50 μg/mL) (*4*, *6*) or the SR-A specific monoclonal antibody 2F8 (at c = 15 μg/mL) for 30 min before the addition of the polypeptides. Data are presented in Figure 8. We observed that the presence of these SR-A scavenger receptor ligands significantly reduced the uptake of the

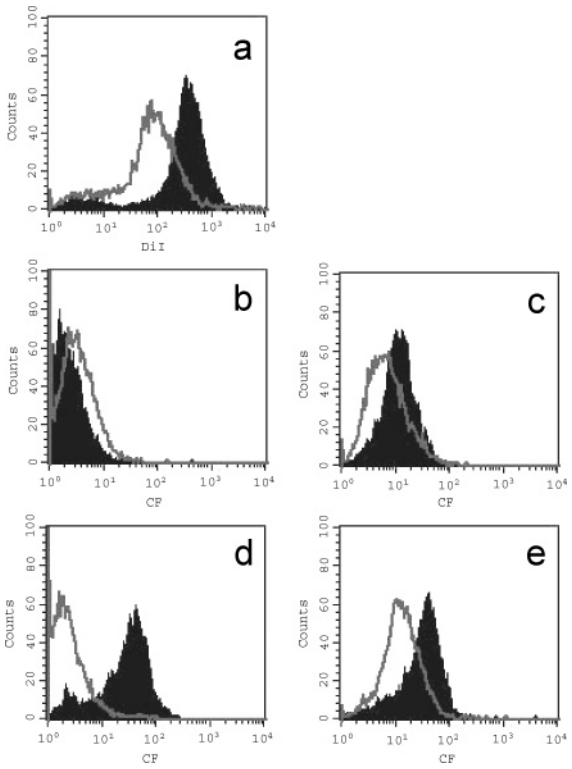

Figure 7. Uptake of polyanionic polypeptides by wild-type and SR-A −/− BMMϕ. Cells were fixed with 2% formaldehyde. Diagrams were recorded by measurig 10000 cells. Data were analyzed by CellQuest 3.0. a. Filled diagrams represent wild-type macrophages, while open lines represent *SR-A* −/− cells. (a) DiI-AcLDL, $c = 5$ μg/mL, (b) CF-EAK, $c = 100$ μg/mL, (c) CF-AcEAK: $c = 100$ μg/mL, (d) CF-SuccEAK, $c = 50$ μg/mL, (e) CF-MalEAK, $c = 50$ μg/mL.

polyanionic polypeptides and of DiI-AcLDL used as positive control.

Colocalization of SR-A and CF-polypeptides in the Cells. The time-dependence of the uptake of CF-SuccEAK and its colocalization with SR-A were further investigated by confocal microscopy. We detected SR-A in cells, using 2F8- and Cy3-labeled anti-rat IgG secondary antibody. We found that CF-SuccEAK was internalized by the cells. Vesicles containing the polypeptide were observed in the cytoplasm (Figure 9). We detected colocalization of CF-SuccEAK (green) and SR-A (red) within 5 min of incubation.

DISCUSSION

Class A scavenger receptors are membrane glycoproteins that are present mainly on cells of the macrophage lineage (*35*). Therefore these receptors are potential targets for macrophage-specific delivery of macromolecules and their drug or epitope conjugates. The scavenger receptor ligands described in the literature are polyanionic compounds with diverse chemical structure and composition (e.g. sulfated polysaccharides such as fucoidin, AcLDL, maleylated proteins, poly(I), and poly(G) (*6*).

The present studies are the first attempt at systematic examination of the interaction between SR-A-bearing cells and a chemically related polypeptide family with different charge and structure. Our previous results with these polypeptides imply that chemical structure, the charge and length of the side chains, have a pronounced effect on various biological and physicochemical properties (*16*, *17*). Results presented in this paper indicate that the uptake of branched polypeptides by murine BMMϕ depends on the composition of the branches, indicating the importance of both charge and the structure of the terminal amino acid derivative. As assessed by the fluorescence intensity of CF-labeled polypeptides, we found a significant difference between the rate of uptake of the polyanionic polypeptides. Although both SuccEAK and MalEAK contain two carboxyl groups at the end of the side chain, whereas AcEAK possesses only one in the terminal glutamic acid, SuccEAK was internalized by BMMϕ to a greater extent than MalEAK. This observation could be explained by the presence of a C−C double bond in MalEAK, which is in conjugation with the C−O double bond influencing the charged state of the terminal carboxyl group.

To analyze the mechanism of uptake we performed inhibition studies with the polypeptide internalized most efficiently. The translocation of CF-SuccEAK was investigated in the presence of unlabeled SuccEAK and also AcEAK. The results of this study showed that unlabeled SuccEAK markedly inhibited the internalization of the CF-labeled polypeptide compound, but AcEAK exhibited only a partial inhibitory effect. These data suggest that AcEAK and SuccEAK share the same receptor, but AcEAK binds with lower affinity or that there are multiple receptors for SuccEAK some of which are shared.

To clarify if SR-A was involved in the endocytosis, we investigated the uptake of the polyanionic polypeptides on wild-type and SR-A −/− BMMϕ. Results show that SR-A −/− macrophages internalize these compounds at a substantially lower level compared with wild-type cells. Blocking of the SR-A with receptor antagonist, poly(I), or with an anti-SR-A monoclonal antibody, resulted in a clear reduction in uptake. In addition, confocal microscopic studies provided independent evidence of colocalization of CF-SuccEAK with SR-A soon after internalization into cells. Taken together, these results suggest that CF-SuccEAK is taken up by SR-A-mediated endocytosis and indicate that the receptor recognizes polyanionic polypeptides and has an important role in their uptake.

It is known that not all polyanionic molecules are able to bind SR-A due to the presence of an undetermined structural requirement for recognition by the receptor. Using our systematic modification of polylysine, we were able to demonstrate that we could enhance binding to SR-A. Thus, the use this approach provides us a powerful new tool to study SR-A binding in further detailby structural manipulation of the polylysine to enhance or reduce binding to the receptor and by modeling how the changes alter the charge distribution and spatial arrangement.

We showed that SuccEAK had higher accumulation in macrophages compared to AcEAK. Interestingly, our previous data on the blood clearance and biodistribution of branched polypeptides showed that AcEAK had prolonged blood survival in Balb/c mice, while SuccEAK was cleared rapidly from the circulation (*36*). This difference in the blood clearance, which was not due to enzymatic degradation, could be related to the difference of macrophage uptake between AcEAK and SuccEAK. Thus, the enhanced uptake by macrophages, mainly through SR-A, could contribute to the rapid clearance of SuccEAK.

Several previous papers have reported on the uptake of modified proteins and conjugates by macrophages. Majumdar et al. demonstrated that the binding of PAS-MalBSA labeled with ^{125}I to peritoneal macrophages was saturable, indicating a limited number of binding sites. Addition of unlabeled conjugate to medium of the macrophages eliminated binding of the labeled compound.

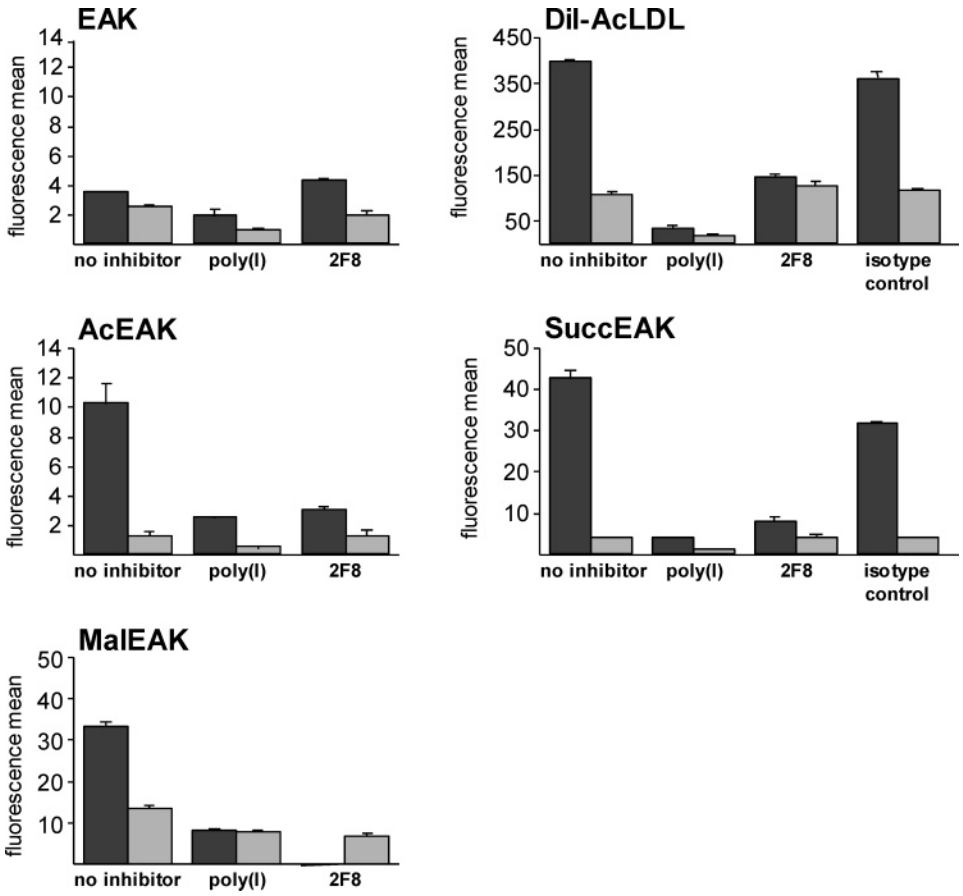

Figure 8. Uptake of polyanionic polypeptides by wild-type and SR-A −/− BMMϕ, CF-AcEAK: $c = 100$ μg/mL. CF-SuccEAK, $c = 50$ μg/mL,MalEAK, $c = 50$ μg/mL DiI-AcLDL, $c = 5$ μg/mL. Figure 9. Colocalization of SR-A (red) and CF-SuccEAK (green). SR-A was detected by the SR-A specific monoclonal antibody 2F8 and a Cy3-labeled secondary antibody. The cells were analyzed by confocal microscopy ($\lambda_{ex} = 488$ nm). (a) isotype control of 2F8, (b) CF-SuccEAK 5 min, (c) CF-SuccEAK 15 min, (d) CF-SuccEAK 30 min, (e) CF-SuccEAK 60 min, (f) control cells not reated with polypeptide, SR-A detected by 2F8 and a Cy3 labeled secondary antibody, (g) CF-SuccEAK 5 min and SR-A: merge, (h) CF-SuccEAK 15 min and SR-A: merge, (i) CF-SuccEAK 30 min and SR-A: merge, (j) CF-SuccEAK 60 min and SR-A: merge. Arrows show examples of colocalization.

The authors also demonstrated the uptake of the conjugate at 37 °C, which was followed by its lysosomal degradation (*7*). Brasseur et al. described the specific uptake of phthalocyanine-malBSA conjugates followed by photoinactivation of J774 macrophages. The receptor binding was demonstrated by competition assay between labeled and nonlabeled conjugates (*8*). These studies showed no direct evidence of the involvement of scavenger receptors in the processes described. Similarly, the articles of Mukhopadhyay et al. contained no experimental data on the involvement of scavenger receptors in the uptake and cytotoxicity of daunomycin or methotrexate conjugates with mal-BSA (*9*−*12*). Recognition of a 10-mer poly(G)-tethered antisense oligonucleotide by scavenger receptors was assessed by a competition assay. In this the degradation of ^{125}I-labeled mal-BSA by J774E

cells in the presence or absence of different polyanionic molecules as competitors exhibited the characteristic scavenger receptor profile (*12*).

To the best of our knowledge this is the first report to show that systematic chemical modification of polylysine-based polypeptides greatly influences the rate and mechanism of uptake by BMMϕ. We also demonstrated for the first time that the internalization of polyanionic synthetic polypeptides, especially SuccEAK, could be considered a SR-A mediated process. Thus, this polypeptide seems to be appropriate as a macromolecular carrier for specific drug delivery into macrophages and they can become the basis for development of further carrier molecules and bioconjugates.

ACKNOWLEDGMENT

Experimental work summarized in this paper was supported by grants from the British-Hungarian Intergovernmental Program (2/2003), from the Hungarian Research Fund (OTKA No. T-045679), and from the Hungarian Ministry of Education (Medichem 2, NKFP). Work in the laboratory of S.G. was supported by a grant from the Medical Research Council, UK. The authors thank Dr. Hedvig Medzihradszky-Schweiger for the amino acid analyses.

Combined Physical and Chemical Immobilization of Glucose Oxidase in Alginate Microspheres Improves Stability of Encapsulation and Activity

Huiguang Zhu,*,† Rohit Srivastava,† J. Quincy Brown,† and Michael J. McShane†,‡,§

Institute for Micromanufacturing and Biomedical Engineering Program, Louisiana Tech University, 911 Hergot Avenue, Ruston, Louisiana 71272. Received June 16, 2005; Revised Manuscript Received September 13, 2005

Chemical sensors utilizing immobilized enzymes and proteins are important for monitoring chemical processes and biological systems. In this study, calcium-cross-linked alginate hydrogel microspheres were fabricated as enzyme carriers by an emulsification technique. Glucose oxidase (GOx) was encapsulated in alginate microspheres using three different methods: physical entrapment (emulsion), chemical conjugation (conjugation), and a combination of physical entrapment and chemical conjugation (emulsion−conjugation). Nano-organized coatings were applied on alginate/GOx microspheres using the layer-by-layer self-assembly technique in order to stabilize the hydrogel/enzyme system under biological environment. The encapsulation of GOx and formation of nanofilm coating on alginate microspheres were verified with FTIR spectral analysis, ζ-potential analysis, and confocal laser scanning microscopy. To compare both the immobilization properties of enzyme encapsulation techniques and the influence of nanofilms with uncoated microspheres, the relationship between enzyme loading, release, and effective GOx activity (enzyme activity per unit protein loading) were studied over a period of four weeks. The results produced four key findings: (1) the emulsion−conjugation technique improved the stability of GOx in alginate microspheres compared to the emulsion technique, reducing the GOx leaching from microsphere from 50% to 17%; (2) the polyelectrolyte nanofilm coatings increased the GOx stability over time, but also reduced the effective GOx activity; (3) the effective GOx activity for the emulsion−conjugation technique (about 3.5×10^{-5} AU μg^{-1} s^{-1}) was higher than that for other methods, and did not change significantly over four weeks; and (4) the GOx concentration, when compared after one week for microspheres with three bilayers of poly(allylamine hydrochloride)/sodium poly(styrene sulfonate) ({PAH/PSS}) coating, was highest for the emulsion−conjugation technique. As a result, the comparison of these three techniques showed the emulsion−conjugation technique to be a potentially effective and practical way to fabricate alginate/GOx microspheres for implantable glucose biosensor application.

INTRODUCTION

Chemical sensors utilizing immobilized enzymes and proteins are important for monitoring of chemical processes and biological systems. They have been widely used for the processing of a variety of products from food to environmental control, and even for biomedical applications (*1*−*3*). The main goal behind enzyme immobilization is to entrap the protein in a semipermeable support material, which prevents the enzyme from leaching while allowing its substrate(s) to pass at an appropriate rate (*4*). Some essential features of the immobilization matrix are nondegradability and compatibility with the enzymes. Because of the three-dimensional structure of enzymes that determines their specific function, it is critical that the encapsulation matrix and procedures have minimal effect upon the structure and function of the proteins.

In search of suitable matrices for enzyme immobilization, polysaccharides such as alginate and chitosan (*5*−*8*) have been found to be among the top candidates due to their biocompatibility and processability. Ionically cross-linked alginate encapsulation has been reported as suitable for many biological components including cells (*9*−*18*), owing to the relatively inert aqueous environment within the matrix, the mild room temperature encapsulation process, and high gel porosity allowing high diffusion rates of macromolecules (*19*, *20*). Chemical immobilization, in which the enzyme is covalently linked to the hydrogel matrix, has been employed to stably entrap the enzyme, but this approach often results in significant loss of enzymatic activity (*21*). In contrast, simple one-step coating procedures have been applied to decrease enzyme leaching (*22*−*25*).

The layer-by-layer (LbL) self-assembly technique enables polyelectrolytes of opposite charge to be deposited onto charged templates, forming a stable multilayer with each component layer being 1−10 nm thick (*26*, *27*). These nanofilm coatings applied to negatively charged alginate matrix provide a protective shell for encapsulated biomolecules and prolong the life span of alginate microspheres in a biological environment. Multilayer coatings involving chitosan/alginate, poly(lysine)/alginate, and other polyelectrolyte coatings have been used as barrier membranes for alginate microspheres to slow release of the encapsulated macromolecule (*28*−*33*).

Recent work in our lab has shown that the application of self-assembled ultrathin film coatings can reduce leaching of macromolecules from alginate microspheres (*34*, *35*). Diffusion of the enzyme from the gel matrix depends upon porosity of the gel and concentration gradients, as well as the permeability of the thin-film coatings to the enzyme. The nanofilm coatings also slow down the decomposition of alginate microspheres in PBS buffer or biological environments relative to bare alginate microspheres without coatings, which make the structures useful for long-term biomedical applications. Coimmobilization of glucose oxidase and an oxygen-quenched fluorescent compound (such as ruthenium or porphyrin compound) within alginate hydrogel microspheres coated with specialized biocompatible ultrathin films has been proposed as an approach to realize optical glucose microsensor systems (*3*). The nanofilms provide stabilization of the hydrogel spheres in addition to a transport barrier. These ratiometric sensors respond to glucose transients via local oxygen changes, which can be transduced by the fluorescence intensity of the oxygen quenched fluorescent compound.

The work described here is a comparison of glucose oxidase encapsulation in alginate microspheres using three different encapsulation techniques, with the integration of the LbL self-assembly nanofilm coating to stablize alginate/enzyme microspheres, with an effort to maximize the enzyme loading in alginate hydrogel microspheres while retaining its catalytic activity. In this work, alginate microspheres with a diameter of $<10\ \mu$m were used, due to their intended application as implantable glucose sensors for diabetic monitoring (*3*). To compare the immobilization properties of enzyme encapsulation techniques and the influence of nanofilm thickness for coated and uncoated microspheres, the relationship between enzyme loading, release, and effective activity was studied over a period of four weeks. These fundamental results should provide useful information for further investigations, including testing of enzymatic sensors in in vitro and in vivo studies, toward practical implantable biosensors.

EXPERIMENTAL PROCEDURES

Materials. Sodium alginate (low viscosity, 250 cps, MW 12−80k) and anhydrous calcium chloride were obtained from Aldrich. Sorbitan trioleate (SPAN 85) and polyoxyethylene sorbitan trioleate (TWEEN 85) were purchased from Sigma. OmniSolv 2,2,4-trimethylpentane (isooctane) was purchased from EMD Chemicals Inc. 1,6-Diaminohexane, *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC), and *N*-hydroxysulfosuccinimide sodium salt (NHSS) were obtained from Fluka. Sodium poly(styrene sulfonate) (PSS, MW ∼70 000), poly(allylamine hydrochloride) (PAH, MW ∼70 000) were obtained from Aldrich. Glucose oxidase (GOx, from *Aspergillus niger* type VII, lyophilized powder, 198 000 units/g solid (without added oxygen)) was obtained from Sigma. Peroxidase (Sigma), *o*-dianisidine (Aldrich), and β-D-glucose (Sigma) were used for the GOx activity test. Fluorescein isothiocyanate (FITC, isomer I) and rhodamine B isothiocyanate (RITC) were obtained from Sigma. For confocal fluorescence microscopy, PAH was labeled with FITC in pH 8.5 sodium bicarbonate buffer and precipitated in acetone. GOx was labeled with RITC or FITC in pH 8.5 sodium bicarbonate buffer and purified through a Sephadex G-25M column (Amersham Pharmacia Biotech AB). All chemicals were reagent grade and used as received.

Synthesis of FITC-Alginate Derivative. Sodium alginate (120 mg) was mixed with EDC/NHSS (50 mg/30 mg) for the activation of carbonyl groups on alginate in pH 5.0 sodium acetic buffer for 30 min, followed by addition of 1,6-diaminohexane (60 mg) for another 4 h. The mixture was precipitated in 2-propanol to remove unreacted diamine. The alginate-amine derivative was reacted with FITC (0.5 mg) in pH 8.5 sodium bicarbonate solution for 4 h and precipitated in acetone to remove unreacted FITC. The resulting FITC-alginate derivative was dissolved in DI water, and absorbance was measured with a UV−vis spectrometer (Lambda 45, PerkinElmer), and then the labeled alginate was mixed with 50 g of 3 wt % unlabeled sodium alginate solution and made into microspheres using the following process.

Fabrication of Alginate Hydrogel Microspheres. Alginate hydrogel microspheres were prepared by an emulsification method (*36*−*38*). Briefly, 50 g of 3 wt % sodium alginate aqueous solution was dispersed in 75 g of isooctane containing 1.7 g of SPAN 85 using an ultrasonicator (Cole Palmer, CPX-750) at 60% power for 5 min. A solution containing 0.9 g of TWEEN 85 in 5 g of isooctane was then added to the emulsion and ultrasonicated at the same power for another 5 min to achieve stable water/oil emulsion droplets. After this, 20 mL of aqueous solution containing 10 wt % of calcium chloride was added to allow formation of ionic cross-links while stirring for 20 min. The microspheres were then rinsed three times with DI water by successive centrifugation cycles and stored in DI water at room temperature. FITC-alginate derivative was added into alginate solution to facilitate the confocal microscopy (Leica TCS SP2) investigation. The number and size distribution of alginate microspheres were measured with a Coulter counter (Beckman Coulter Z Series).

Conjugation of GOx to Alginate Microspheres. GOx was first mixed with alginate solution followed by alginate cross-linking by calcium ions, as described above, in which case the GOx was physically entrapped in alginate microspheres. This GOx encapsulation method is named the "emulsion technique" in this study and is a commonly used technique for materials encapsulation in alginate hydrogel microspheres. However, there is severe limitation for this technique, as the entrapped molecules can easily leach out from the hydrogel microspheres after fabrication, causing substantial loss of the enzyme from the matrix.

Two conjugation methods were used to improve the stability of GOx in alginate microspheres. For the first method, alginate microspheres (200 μL, without enzyme) were incubated in 1 mL of pH 5.0 buffer for 30 min, and then 2.0 mg of EDC and 1.2 mg of NHSS were added to activate the alginate microspheres for another 30 min. The activated alginate microspheres were centrifuged and rinsed with DI water to remove unreacted EDC and NHSS. Next, 1 mL of GOx solution (5 mg/mL in DI water) was added to react with alginate microspheres for another 4 h. The microspheres were centrifuged and triple rinsed with DI water to remove unreacted GOx, followed by slowly adding 200 μL of 1 M $CaCl_2$ to strengthen the alginate hydrogel microspheres and avoid de-cross-linking during the following LbL assembly procedure. In this case, GOx will only react with activated alginate. This GOx encapsulation method is named the "conjugation technique" in this study. For the second method, alginate microspheres already containing GOx (from the emulsion step) were also reacted with EDC/NHSS in pH 5.0 buffer for 4 h, which is named the "emulsion−conjugation" technique. In this case, GOx

should react with not only alginate but also the enzyme itself, since enzyme contains both amine groups and carboxylic acid groups. Fourier transform infrared spectroscopy (Nexus 470 FTIR) was used to analyze the unmodified alginate microspheres and alginate/GOx microspheres. Confocal micrographs were taken with a Leica TCS SP2 equipped with a 63× oil-immersion objective, using the 488/514 nm lines of an Ar/Kr laser for FITC/RITC excitation, respectively.

Layer-by-Layer Assembly of PAH/PSS Nanofilm Coating on Alginate Microspheres. The PSS and PAH solutions used for alternating adsorption of {PAH/PSS} multilayers on alginate (or alginate/GOx) microspheres were prepared at a concentration of 2 mg/mL in DI water containing 0.1 M $CaCl_2$. For deposition of each coating, 1 mL of polyelectrolyte solution was added to a microcentrifuge tube containing 100 μL of microsphere suspension. Adsorption was allowed to proceed for 20 min, after which the suspension was centrifuged at 3000 rpm to separate the spheres from remaining unadsorbed polyelectrolyte. The microspheres were then triple-rinsed with DI water by successive centrifugation cycles. The process was repeated for the oppositely charged polyelectrolyte, and then alternated until a total of three bilayers of {PAH/PSS} films were obtained. The assembly of polyelectrolyte layers on alginate microspheres was monitored by electrophoretic mobility measurements (ZetaPlus ζ-potential analyzer, Brookhaven Instrument Corp.).

Enzyme Stability in Alginate/GOx Microspheres. For wet storage loss experiments, alginate/FITC-GOx microspheres prepared by the emulsion, conjugation, and emulsion−conjugation techniques, with zero (uncoated alginate) and three bilayers of {PAH/PSS} coatings, were suspended in individual cuvettes containing 1.5 mL of 0.01 M PBS buffer at pH 7.4, which were stored at room temperature, covered and in the dark. Leaching analysis was performed by removing the supernatant by centrifugation and recording the fluorescence from the supernatant with a scanning spectrometer (Photon Technologies Inc, QM-1), allowing determination of the relative supernatant enzyme concentration by comparison to a standard FITC-dextran emission (7 μM in 2 mL of PBS buffer) at each point of time. This supernatant was then placed back with the sphere suspension. The relative fluorescence resulting from leaching through different coatings was then used to compare final total enzyme lost from the microspheres with each coating.

Enzyme Activity in Alginate/GOx Microspheres. Glucose oxidase activity was monitored through a colorimetric assay, based on the oxidation of *o*-dianisidine through a peroxidase-coupled system.

$$\beta\text{-D-glucose} + O_2 + H_2O \xrightarrow{\text{glucose oxidase}} \text{D-gluconic acid} + H_2O_2$$

$$H_2O_2 + o\text{-dianisidine (reduced)} \xrightarrow{\text{peroxidase}} o\text{-dianisidine (oxidized)} + H_2O$$

The GOx activity assay comprised 2.4 mL of *o*-dianisidine solution (0.21 mM in 0.01 M PBS buffer pH 7.4), 0.5 mL of β-D(+)-glucose solution (100 mg/mL in 0.01 M PBS buffer), and 0.1 mL of peroxidase solution (60 purpurogallin units/mL in DI water). During continuous stirring with a magnetic bar at 25 °C (Peltier temperature controlled cell holder, Quantum Northwest), a 100 μL aliquot of GOx-loaded alginate microspheres suspended in DI water (approximately 10^6 spheres) was added to the assay and the absorbance at 500 nm was monitored as a function of time, resulting in a catalytic profile of the encapsulated GOx. The experiment was repeated for the different alginate/GOx microspheres (different preparation techniques, bare and three bilayer coating spheres) after a period of 0, 1, and 4 weeks, and the results were compared by calculating the slopes of the activity curves. In each case, the experiments were performed in triplicate, and results were normalized to the mass of glucose oxidase present in the spheres, as determined using the Lowry assay. The effective GOx activity (AU μg^{-1} s^{-1}, enzyme activity per unit protein loading) is expressed as total GOx activity (absorbance units/second) divided by the mass of GOx (micrograms) encapsulated in alginate microspheres.

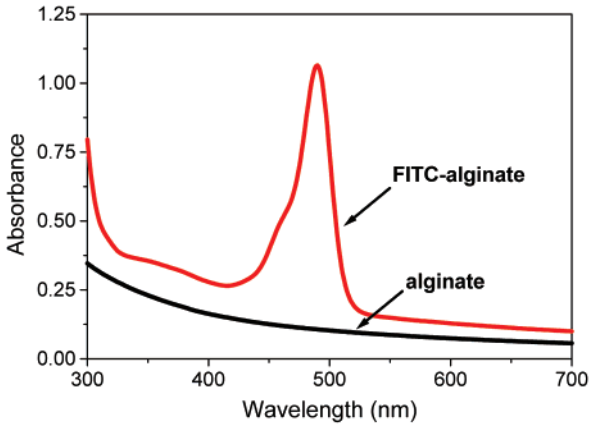

Figure 1. UV−vis absorbance spectrum of alginate and FITC-alginate derivative.

RESULTS AND DISCUSSION

Synthesis of FITC-Alginate Derivative. Figure 1 contains the UV−vis absorbance spectrum of unmodified alginate and FITC-labeled alginate. The unmodified alginate material does not display any characteristic absorbance between 300 and 700 nm. However, the FITC-alginate derivative possessed strong absorbance at 488 nm, which corresponds to the absorbance of FITC and verifies the successful synthesis of the FITC-alginate derivative. For quantitative analysis of FITC-alginate derivative, a series of solutions of known concentration of FITC were measured with UV−vis spectroscopy, which gives the relationship between FITC absorbance and concentration. The FITC content was calculated to be 1.7 wt % in FITC-alginate derivative. The FITC-labeled alginate was therefore mixed with alginate and made into microspheres for confocal imaging.

Characterization of Alginate Microspheres. The emulsion technique used for fabrication of alginate hydrogel microspheres is illustrated in Figure 2a. Calcium ions were used to cross-link the alginate microspheres while in the emulsion. By adjusting the ultrasonicator power, ratio of surfactant, or concentration of alginate solution, different sizes (1−200 μm) of alginate microspheres can be obtained. Figure 2b is an image of typical alginate microspheres obtained by confocal microscopy, with FITC-labeled alginate showing green fluorescence. Coulter counter measurements revealed that the process resulted in a typical alginate microsphere mean diameter of 4.25 ± 0.49 μm (N > 5000 spheres counted). The microspheres were found to be stable in DI water after removal of the surfactant, and the microspheres exhibited the expected negative surface charge, which therefore

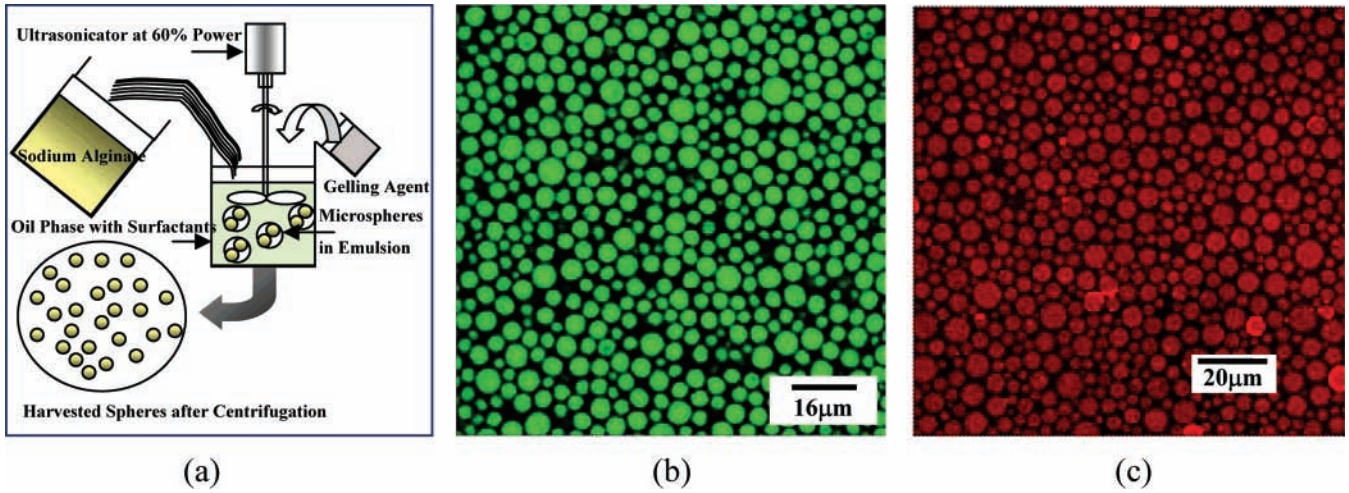

Figure 2. (a) Emulsion technique for the production of alginate microspheres. (b) Confocal images of alginate microspheres, alginate labeled with FITC. (c) Confocal images of alginate microspheres with physically embedded GOx, where GOx was labeled with RITC.

could be used for polyelectrolyte LbL assembly to provide protective shells. It was also found, as illustrated in Figure 2c, that the RITC-labeled GOx was uniformly distributed in the alginate hydrogel microspheres made by the emulsion technique.

Conjugation of Enzyme to Alginate Microspheres. Alginates are linear chains of 1,4′-linked residues of β-D-mannuronic acid (β-DMA) and α-L-guluronic acid (α-LGA). A key property of sodium alginate is the formation of ionically cross-linked gel in the presence of multivalent cations. Thus, when sodium alginate is exposed to $CaCl_2$ solution, the carboxylic acid groups on polyguluronate units from different alginate molecules form a cross-linked structure with calcium ions called an "egg-box" junction with interstices in which the cations may pack and be coordinated. Because the carboxylic acid groups will not be depleted during the ionic-cross-linking procedure, the residual carboxylates in alginate microspheres could be activated by EDC/NHSS and bind to amine-containing molecules such as enzymes. Under biological conditions, the calcium-cross-linked structure may be replaced and de-cross-linked slowly by monovalent cations such as sodium ions and therefore are not stable for long-term application (*39*); however, polyelectrolyte coatings can provide protective shells and improve the stability of the alginate microspheres to some extent. A schematic diagram of enzyme conjugated to alginate microspheres and subsequent coating with polyelectrolytes is shown in Scheme 1.

Since alginate and GOx (pI = 4) exhibit the same negative charge around neutral pH, it is difficult for GOx to be stable within alginate microspheres when only physical entanglement between alginate and GOx exists. Similary, it is also difficult for free GOx to diffuse into alginate microspheres and interact with alginate. To improve the stability of GOx in alginate microspheres for long-term applications, two different conjugation techniques were applied, which are called the "conjugation technique" and the "emulsion−conjugation technique". To verify conjugation-made alginate/GOx microspheres, alginate microspheres were mixed with GOx solution for 4 h, without adding EDC/NHSS. Both treated alginate microspheres and bare microspheres were triple rinsed with DI water before FT-IR measurement (Figure 3). The spectrum of alginate microspheres mixed with GOx solution was exactly the same as that of alginate microspheres, with strong absorbance at 1600 cm^{-1} contributed by carbonyl groups. This result shows that GOx cannot become entrapped in alginate microspheres by simply mixing GOx with the spheres after fabrication. In contrast, the spectrum for conjugation-made alginate/GOx microspheres possesses two shoulders beside the 1600 cm^{-1} carbonyl peak, related to amide I (1750 cm^{-1}) and amide II (1550 cm^{-1}) bonds. The amide signal may be contributed by amide bonds on the enzyme or amide bonds formed between carboxylic acid groups on alginate and amine groups on enzyme; in either case, this result demonstrates that the GOx could be chemically conjugated to alginate microspheres by using EDC/NHSS activation process.

The LbL assembly of polyelectrolyte layers on alginate (or alginate/GOx) microspheres was monitored by electrophoretic mobility measurements. Three bilayers of {PAH/PSS} were deposited on alginate microspheres and

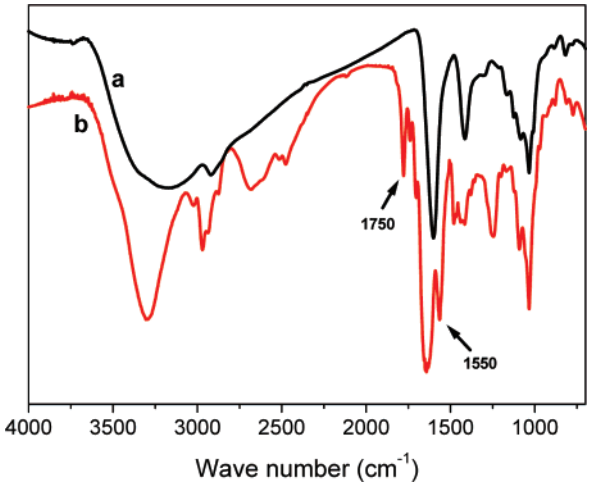

Figure 3. FTIR spectrum of (a) alginate microspheres and (b) conjugation-made alginate/GOx microspheres.

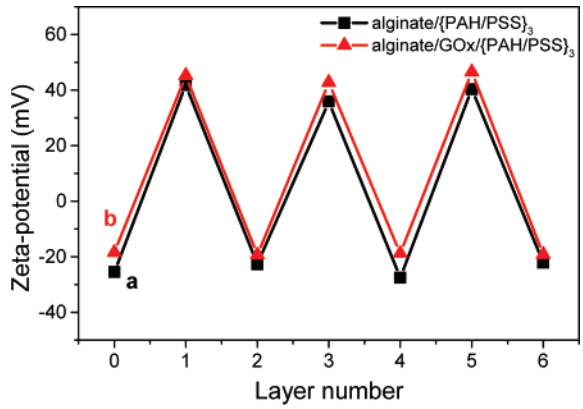

Figure 4. ζ-Potential measurements for deposition of {PAH/PSS}$_3$ on (a) alginate microspheres and (b) alginate/GOx microspheres. The first measurement (layer 0) is the surface potential of uncoated alginate microspheres.

GOx-encapsulated alginate microspheres. It was found that there was no significant difference between alginate cores and alginate cores with encapsulated GOx. The surface potential of the microspheres was observed to change regularly from −25 mV for alginate (or alginate/GOx) and PSS to +40 mV for PAH (Figure 4), indicating the formation of the desired {PAH/PSS}$_3$ wall architecture. This result shows that the alginate microspheres still have strong negative surface charge after calcium gelation, which makes polyelectrolyte nanofilm deposition onto alginate microspheres straightforward. The polyelectrolyte multilayer wall may serve multiple purposes, including providing a protective shell for encapsulated biomolecules and stabilizing alginate microspheres against dissolution in a biological environment, as well as a necessary barrier to control substrate mass transport in the development of enzymatic glucose sensors (*3*, *40*).

Confocal microscopy was used to image conjugated alginate/GOx microspheres, and coating of {PAH/PSS} on microspheres (Figure 5), which clearly shows that the GOx was uniformly distributed in the alginate microspheres, no matter whether the conjugation (Figure 5a) or the emulsion−conjugation (Figure 5b) technique was used. RITC-labeled GOx solution was also mixed with bare alginate microspheres, however they exhibit no RITC fluorescence under confocal microscopy after rinsing with DI water. Three bilayers of {FITC-PAH/PSS} were coated on emulsion−conjugation-made alginate/GOx microspheres, as illustrated in Figure 5c, which shows that the GOx was still uniformly distributed in alginate microspheres after coating with polyelectrolytes. It should be noted that the GOx cannot be conjugated into alginate microspheres once they have been coated with polyelectrolytes, although GOx is able to penetrate through the {PAH/PSS} multilayer wall (data not shown); this is because most of the GOx becomes entrapped in the polyelectrolyte wall, rather than diffusing into the sphere and reacting with alginate.

Enzyme Stability in Alginate/GOx Microspheres. Fluorescence spectroscopy was employed to investigate and compare the stability of GOx in alginate microspheres made by the emulsion, conjugation, and emulsion−conjugation techniques, with 0 and 3 bilayers of {PAH/PSS} nanofilm coating. The result of the leaching study (Figure 6) showed the percentage of GOx leached out from alginate microspheres over one week. It can be seen that the emulsion-made alginate/GOx microspheres leach approximately 50% of the standard concentration in 1 week. This may be attributed to relatively large pores in alginate hydrogel microspheres, which allow large and small molecules to pass through, and charge repulsion between alginate and GOx in pH 7.4 PBS buffer. As expected, three bilayers {PAH/PSS} of nanofilm decreased the GOx leaching substantially, from 50.0% to 17.8%.

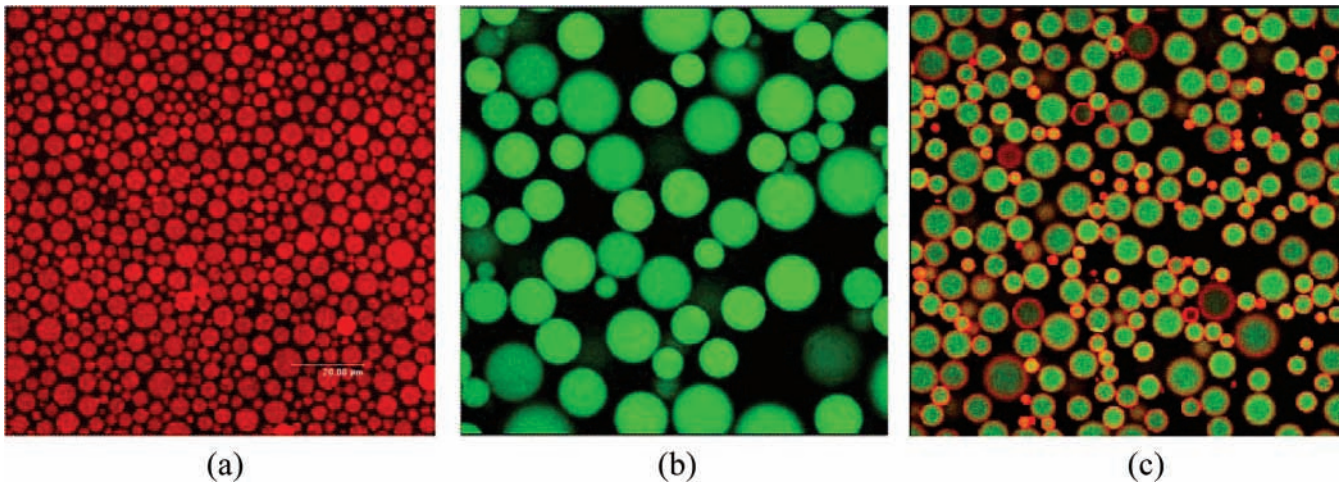

Figure 5. Confocal images of alginate/GOx microspheres. (a) Conjugation-made alginate/GOx microspheres, GOx labeled with RITC. (b) Emulsion−conjugation-made alginate/GOx microspheres, GOx labeled with FITC. (c) Emulsion−conjugation-made alginate/GOx microspheres with 3 bilayers of {PAH/PSS}, GOx labeled with FITC and PAH labeled with RITC.

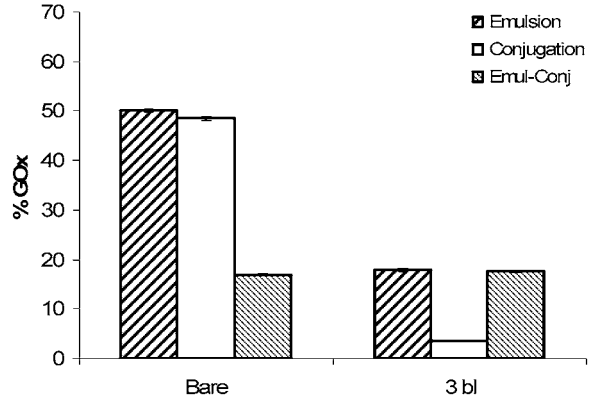

Figure 6. GOx stability in alginate-templated microspheres one week after fabrication.

Unexpectedly, the GOx in conjugation-made alginate/GOx microspheres was found to be unstable in PBS buffer (48.5% leaching), although GOx has been verified to chemically conjugate to alginate. The reason for this may be that the cross-linked alginate hydrogel was decomposed via ion-exchange since PBS buffer contains many monovalent cations (Na^+, K^+) and polyvalent anions (PO_4^{3-}). The calcium ions on alginate hydrogel microspheres may be replaced by those monovalent cations and form insoluble calcium phosphate. Alginate−GOx conjugate, rather than GOx, was therefore leached from the alginate microspheres. For bare alginate microspheres without polyelectrolyte coating, the microspheres will be decomposed and eventually disappear over 2−3 months in PBS buffer. The polyelectrolyte nanofilm coatings were proved to prevent the alginate hydrogels from decomposing substantially, as seen from the leaching result of conjugation-made alginate/GOx microspheres with three bilayers of {PAH/PSS} (3.5% leaching).

The emulsion−conjugation technique also improved the stability of GOx in alginate microspheres. The leaching data for uncoated and three bilayers of {PAH/PSS} alginate microspheres indicated 16.9% and 17.6% loss, respectively. Compared with the conjugation technique, the emulsion−conjugation technique increased the GOx stability for uncoated microspheres, which is especially important since most of the enzyme leaching occurs in the first few hours after the fabrication of alginate microspheres, and substantial loss even occurs during the polyelectrolyte coating process.

Enzyme Activity in Alginate/GOx Microspheres. Since the primary function of enzymes is catalysis, it is ideal to preserve as much activity as possible when encapsulated in alginate microspheres. To determine the effect, if any, of different encapsulation techniques and nanofilm assembly on activity of encapsulated enzyme, the activity of the alginate/GOx microspheres was studied over four weeks of wet storage (0.01 M PBS buffer, room temperature). Figure 7 contains a summary of the experimental results to determine the effect of three different encapsulation techniques and nanofilms on the effective catalytic activity per unit mass of encapsulated GOx (determined by Lowry assay).

For the emulsion technique (Figure 7a), the results show that uncoated alginate microspheres exhibited an 80% reduction in initial activity after one week, with no further notable reduction in activity after four weeks. Coating of {PAH/PSS} nanofilm was observed to reduce the GOx activity from 3.5×10^{-5} to 2.7×10^{-5} AU μg^{-1} s^{-1}; however, reduction of enzyme activity over time for nanofilm coated microspheres was decreased substantially. As seen from Figure 7a, the GOx activity for uncoated microspheres at 4 weeks is about 0.75×10^{-5} AU μg^{-1} s^{-1}, while the GOx activity for the three bilayers of {PAH/PSS} coated microspheres at 4 weeks remains 2.0×10^{-5} AU μg^{-1} s^{-1}.

Table 1. Enzyme Concentration in Alginate/GOx Microspheres

	uncoated spheres (mM)		$\{PAH/PSS\}_3$-coated spheres (mM)	
	0 week	1 week	0 week	1 week
emulsion	66.7	33.4	61.5	50.4
conjugation	3.38	1.69	0.45	0.43
emulsion−conjugation	86.0	68.8	70.1	58.2

For the conjugation technique (Figure 7b), the enzyme activity test results show that increasing nanofilm thickness leads to increased enzyme activity after one week, with the enzyme activity also increasing over time. These unexpected results may arise from two possible explanations: The first is that the total enzyme activity before normalization (division by enzyme mass) is much lower (about 60 times lower than uncoated microspheres at 0 week) than the activity from the emulsion technique. According to our observations, low activity due to low enzyme concentration will still result in relatively high normalized enzyme activity, with larger standard deviation, using the peroxidase assay. A second reason for increasing enzyme activity may be the decomposition of alginate microspheres, in which case the GOx or alginate−GOx conjugates should regain activity as the steric barrier from the cross-linked hydrogel is reduced, providing greater access of substrate to enzyme. A combination of these reasons may cause the result shown in Figure 7b, which needs further studies in the future.

For the emulsion−conjugation technique (Figure 7c), increasing the nanofilm thickness generally decreased the enzyme activity. Furthermore, the enzyme activity also decreased over time. These results are similar with those of the emulsion technique. However, the overall effect on effective activity of nanofilm thickness and time is slight, relative to the emulsion technique. As a result, the enzyme activity of alginate/GOx with three bilayers of {PAH/PSS} made by the emulsion−conjugation technique is almost double that made by the emulsion technique.

All the above results showed the effective GOx activity (GOx activity per unit mass of encapsulated enzyme). It is also important to know the total GOx amount left in alginate microspheres, which is related with enzyme stability. The total enzyme activity could therefore be calculated from the effective GOx activity and amount in the alginate microsphere, which is responsible for the function of glucose biosensor. Table 1 presents the enzyme concentration (determined by Lowry assay) in the alginate/GOx microspheres over 1 week. The GOx is found to be stable in conjugation-made alginate/GOx microspheres, although the enzyme concentration is very low; therefore, the conjugation technique may not be practically useful for large enzymes such as GOx to be encapsulated for biosensors. However, it should be useful to encapsulate small molecules with amine groups (such as peptides) in microspheres where other techniques are difficult to achieve and only a small amount of molecules is needed for encapsulation in this case. The GOx is also stable in the microspheres coated with three bilayers of nanofilm, however, most of the GOx leaching took place before the microspheres were coated with polyelectrolytes. The "emulsion−conjugation" technique greatly

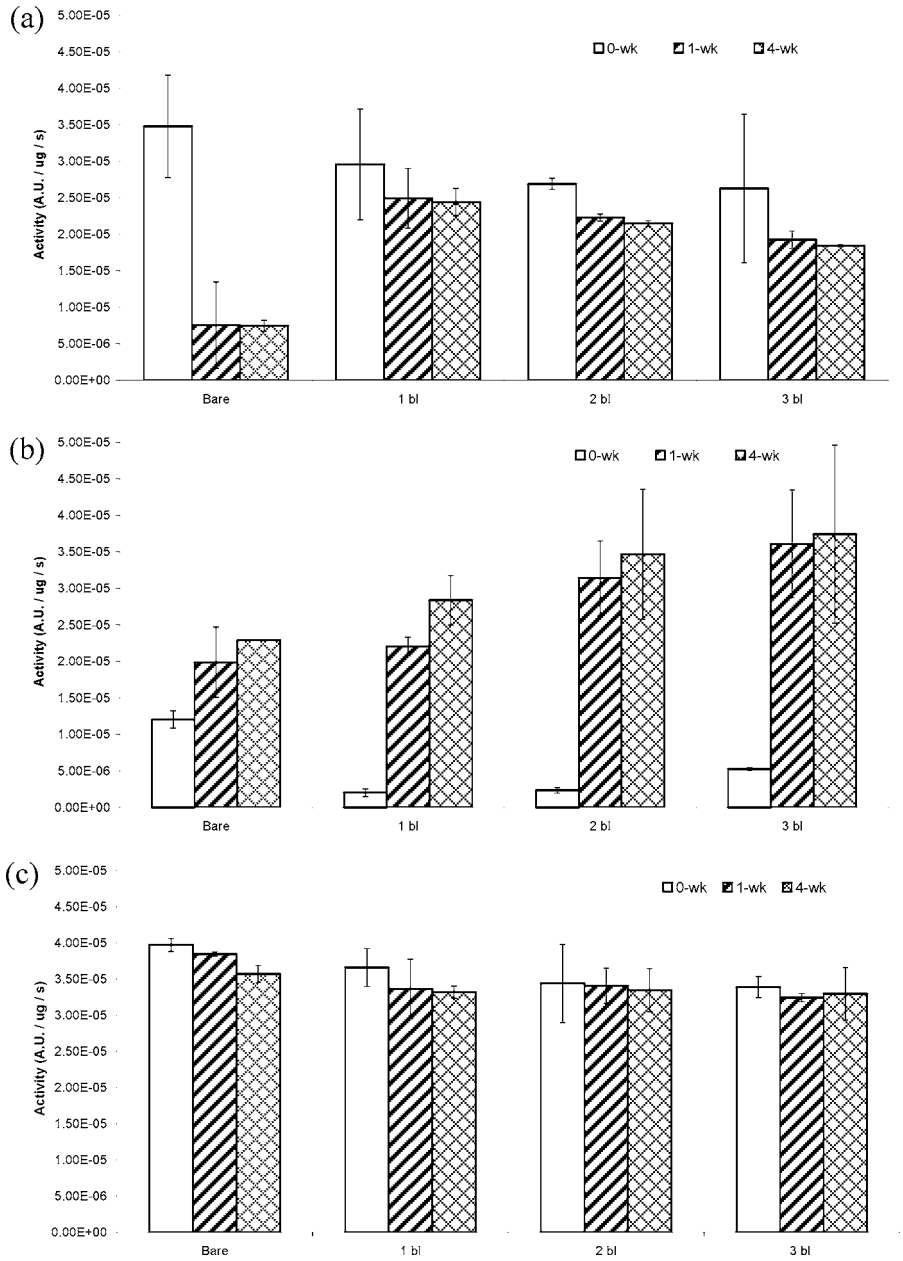

Figure 7. Enzyme activity of alginate/GOx microspheres over time. (a) Emulsion technique. (b) Conjugation technique. (c) Emulsion–conjugation technique.

improved the GOx stability right after the alginate microsphere fabrication. High concentration of GOx and enzyme activity were retained after nanofilm assembly on microspheres. Among the three techniques investigated in our study, emulsion–conjugation was shown to be the most efficient and practical way for GOx encapsulation in alginate microspheres.

CONCLUSIONS

Glucose oxidase (GOx) was successfully encapsulated into calcium-cross-linked alginate hydrogel microspheres via three different techniques, the emulsion, conjugation, and emulsion–conjugation techniques, to be used as implantable glucose biosensors. FTIR, ζ-potential analyzer, and confocal microscopy were used to verify the encapsulation of GOx and formation of nanofilm coating on alginate microspheres. The stability and effective activity of GOx were also investigated to compare these three techniques, with and without polyelectrolyte multilayer nanofilms over 4 weeks. GOx concentration in alginate microspheres was also given to compare the total enzyme activity over time for these three techniques. Of these, the emulsion–conjugation technique was shown to be a practical and effective way to fabricate GOx-encapsulating alginate microspheres for future use as implantable glucose biosensors.

Most members of the tumor necrosis factor (TNF) ligand family occur in both a membrane-bound and a soluble form, which can possess differential bioactivities. The aim of this work was the construction of a synthetic−biological hybrid system consisting of chemically nanostructured core−shell particles with a diameter of 100 nm, 1 μm, or 10 μm and the cytokine TNF to obtain a tool that mimics the bioactivity of naturally occurring membrane-bound TNF. Synthetic core−shell nanoparticles consisting of an inorganic silica core and an ultrathin organic shell bearing a maleimide group at the shell surface which allowed for a covalent and site-directed coupling of CysHisTNF mutants were prepared. The TNF mutants were modified at the N-terminus by PCR cloning by introducing a His-Tag for purification and a free cysteine group for reaction with the particle-attached maleimide group. The resulting nanostructured hybrid particles initiated strong TNF receptor type 2 specific responses, otherwise only seen for the membrane-bound form of TNF, but not the soluble cytokine, thus clearly demonstrating new and membrane TNF-like properties of the bioconjugated soluble TNF.

INTRODUCTION

Nano- to micrometer-sized particles made of inorganic and organic materials have been used in the past for different biological applications. Micrometer-sized particles for example were used to bind biological targets from biological samples, as has been published for cell sorting (Bildirici and Rickwood, 2001; Kruger et al., 2000) or protein enrichment and purification (Hurst et al., 1999). Furthermore, particles were functionalized with peptides for promoting cellular uptake of the bioconjugated particles (Becker et al., 2004), as a DNA carrier (Maruyama et al., 1997), for drug delivery (Lockman et al., 2002), or for mammalian cell transformation (Sandhu et al., 2002). In addition, fluorescent-labeled particles decorated with affinity ligands such as antibodies were successfully used for cell imaging (Willard, 2003; Gao et al., 2005). Particles exposing streptavidin on their surface to allow coating of the particles with biotin-conjugated proteins were shown to represent a valuable tool for spatially restricted receptor-selective stimulation of cells (Verveer et al., 2000).

In multicellular organisms, receptor ligands are often presented at the surface of cells. Such cell membrane-bound ligands bind highly specific to their corresponding interaction partners, based on molecular recognition processes. This type of intercellular communication is essential to sustain homeostasis in all higher organisms. The inflammatory cytokine tumor necrosis factor (TNF, also termed TNFα) is the representative member of a large homologous protein ligand family, mirrored by a respective family of cell surface membrane receptor proteins (Locksley et al., 2001; Aggarwal, 2003). TNF is crucially involved in inflammatory responses to elicit effective innate immune responses but is also a key player in many pathological situations such as septic shock, rheumatoid arthritis, and neurodegenerative diseases, e.g. multiple sclerosis (Grell and Scheurich, 1999; Wajant et al., 2003). In addition, TNF is capable of inducing apoptosis and is a promising candidate for new strategies in cancer therapy under conditions where systemic side effects can be avoided, as demonstrated in isolated limb perfusion (Eggermont and ten Hagen, 2001). Most studies with TNF have been performed with the soluble cytokine (sTNF). However, typical for the members of the TNF ligand family, TNF is a genuine type 2 transmembrane protein (memTNF) and initially expressed at the cell membrane. From this membrane-bound protein sTNF is subsequently derived from proteolytic processing by the metalloproteinase TACE (tumor necrosis factor alpha-converting enzyme) (Black et al., 1997). Both memTNF and sTNF bind to two different cell membrane receptors, termed TNFR1 (CD120a) and TNFR2 (CD120b) (Locksley et al., 2001). Whereas TNFR1 is ubiquitously expressed in all tissues, TNFR2 is highly

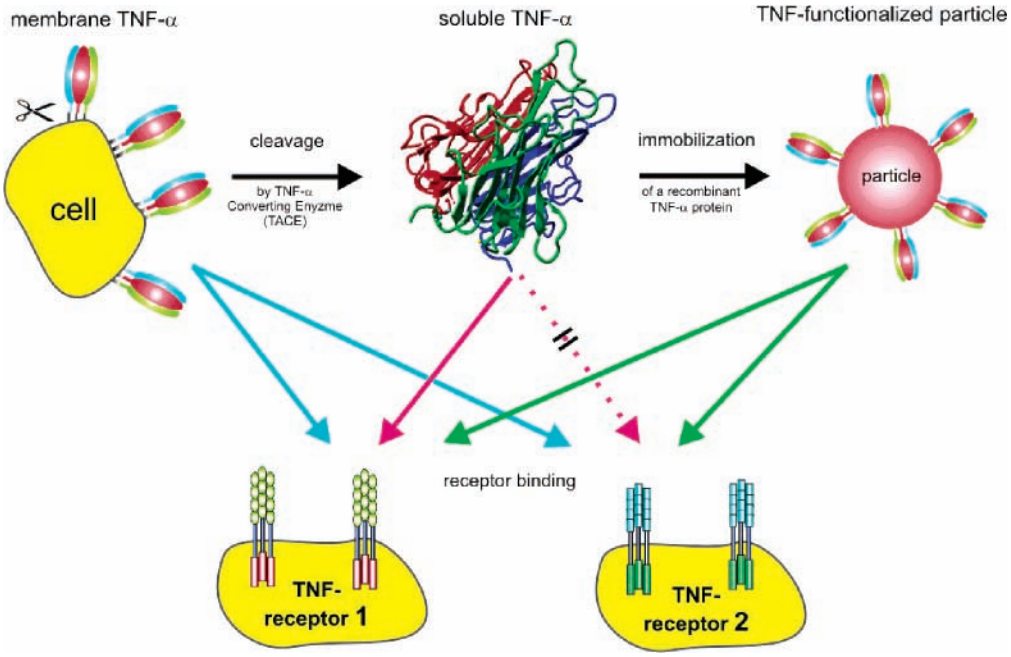
Scheme 1. TNF-α Signaling Capabilities[a]



[a] TNF is a transmembrane protein (membrane or memTNF) and initially expressed at the cell surface. From this membrane-bound form the soluble TNF (sTNF) is proteolytically derived by action of the metalloproteinase TACE (tumor necrosis factor alpha-converting enzyme). Both memTNF and sTNF bind to two different cell membrane receptors, termed TNF receptor (TNFR) 1 and 2. Membrane TNF strongly activates both receptors, whereas sTNF is capable to only stimulate TNFR1 but not TNFR2. Functionalized particles with a recombinant TNF protein bind to and strongly activate both receptors, thus mimicking the action of memTNF.

regulated in expression and mainly found in immune cells and endothelial cells but also in neuronal tissue.

The two TNF forms possess differential capabilities for the induction of larger signaling complexes. Whereas sTNF binding enforces receptor trimerization only, cell-associated memTNF might subsequently cause the formation of larger complexes by induction of capping of the membrane-bound ligand molecules and the receptors at the respective interacting cellular sites.

In light of these data, it is very likely that the physiological role of TNFR2 is largely underestimated, simply because sTNF has been used in by far the most studies. Accordingly, there is a need for a memTNF-adequate stimulus that can be easily applied in experimental systems in vitro but also in animal model systems in vivo. To overcome the lack of an appropriate memTNF-like stimulating reagent, we have here constructed silica-based particles covalently coupled with mutated functional TNF derivatives (here also termed as muteins), forming bioactive homotrimers at the particle surface (Scheme 1). These novel particles are able to initiate memTNF-resembling cellular responses.

EXPERIMENTAL PROCEDURES

Particle Synthesis and Characterization. Nano- and microparticles of three different mean particle sizes (100 nm, 1 μm, and 10 μm) and consisting of silica were used as core material for organic modification. The smaller sized silica particles (100 nm and 1 μm) were synthesized following the method of Stober (Stober et al., 1968) as described elsewhere (Schiestel et al., 2004). Briefly, to obtain particles with a mean particle diameter of 100 nm, a mixture of 1.37 mL ammonia (25 wt. %, SAF, Taufkirchen, Germany), 2 mL of H_2O, and 500 mg of tetraethoxysilane (TEOS; ABCR, Karlsruhe, Germany) in 40 mL of ethanol (HPLC-grade, SAF, Taufkirchen, Germany) were stirred for 24 h at room temperature (RT). Afterward they were separated by centrifugation (13000 rpm, 15 min) and suspended in 10 mL of ultrapure water, then put into dialysis until conductance was below 1.3 μS/cm. Particle sizes and ζ-potentials were routinely monitored by photocorrelation spectroscopy and microelectrophoresis using a Zetasizer 3000 HSA (Malvern Instruments, Herrenberg, Germany). ζ-Potentials of the 100 nm and 1 μm particles were determined at pH 4.7 in acetate buffer. The ζ-potential of 10 μm particles was not determined by microelectrophoresis due to instability toward sedimentation during the measurements. To generate particles with a mean diameter of 1 μm, a mixture of 1.44 g of ammonia, 1.04 g of TEOS, and 10 mL of ethanol were stirred for 3.5 h at RT. The resulting particles were washed with 100% ethanol and suspended in 10 mL of 100% ethanol prior to any further modification. The 10 μm particles were purchased from Kisker (Steinfurt, Germany) and washed in the particular solvent before use.

Preparation of Fluorescent Shell. An ultrathin fluorescent shell for confocal microscopy studies was covalently attached to the 100 nm, 1 μm, and 10 μm particles according to the following method. *N*-Hydroxysuccinimide ester Alexa dye 546 or 568 (MoBiTec, Göttingen, Germany) (500 μg) was incubated for 3 h at RT with 111 μg of (3-aminopropyl)triethoxysilane (ABCR, Karlsruhe, Germany) in 64 μL of ethanol. An amount of 50 mg of silica particles in 1.6 mL of 100% ethanol, 3.3 μL (3.05 mg) of TEOS, and 167 μL of ammonia were added, and the mixture was stirred for 20 h at RT. To avoid photobleaching, all steps involving fluorescence markers were performed in the dark. The resulting particles were washed five times with 100% ethanol and once with acetate-buffered solution (pH 4.7) and suspended in acetate buffer.

Particle Surface Modification. An amount of 100 mg of silica particles (in acetate buffer) was stirred with 100 μL of ammonia, 6.8 mg of TEOS, and 20.4 mg of APS for 24 h at room temperature. The resulting particles

were washed intensively and suspended in water. An amount of 1 mg of APS-modified particles was suspended in PP72 (183 μL of 10 mM phosphate buffer pH 7.2), 817 μL of a 3.06 mM sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC; Perbio Science, Bonn, Germany) solution in PP72 was added, and the reaction mixture was shaken for 1 h. All steps were performed under sterile conditions. The resulting particles were collected by centrifugation at 4 °C, washed with 1 mL of ice-cold PP72, suspended in 1 mL of ice-cold PP72, and then immediately used for protein coupling reactions.

Construction and Purification of CysHisTNF and Derived Muteins. Expression constructs optimized for bacterial codon usage of a histidine-tagged soluble TNF (HisTNF) was originally obtained from Philippe Holliger, Cambridge, UK. The CysHisTNF expression construct, pQE5 CysHisTNF, was produced by site-directed mutagenesis introducing the coding sequence of a cysteine residue as well as a factor Xa cleavage site (IEGR) and a His tag. This generated an N-terminal sequence tag (MGELIEGR**C**AGGSGHHHHHHGSDGAS) fused to serine 79 of human TNF. Receptor specific TNF muteins (CysHisTNF143N/145R and CysHisTNF32W/86T) were also generated by site-directed mutagenesis using pQe5CysHisTNF as template. All constructs generated by PCR were verified by sequencing. For the production of CysHisTNF, *E.coli* XL1 blue cells transformed with CysHisTNF expression constructs were grown overnight. The following day the cultures were diluted 1:10, grown to a density of $OD_{600\ nm}$ 0.5−0.7, and then induced by 1 mM IPTG for 6 h at 30 °C. Cells were washed in phosphate-buffered saline (PBS) and centrifuged, and the pellet was frozen at −20 °C. The cell pellet was resuspended in PBS (3 mL PBS/g pellet), cells were lysed by sonification on ice, and the cell debris was pelleted at 12000 g for 15 min at 4 °C.

CysHisTNF was purified using a HiTrap column (1 mL; Pharmacia) following the instructions of the manufacturer. Briefly, the column was connected to a peristaltic pump with a flow rate of 1 mL/min and equilibrated with 10 mL of buffer 1 (20 mM NaH_2PO_4 pH 7.4, 0.5 mM NaCl, 10 mM imidazole), and then the supernatant was loaded and the column was washed with 10 mL of buffer 2 (20 mM NaH_2PO_4 pH 7.4, 0.5 mM NaCl, 30 mM imidazole) followed by elution of CysHisTNF using 7 mL of buffer 3 (20 mM NaH_2PO_4 pH 7.4, 0.5 mM NaCl, 500 mM imidazol). Fractions of 500 μL were collected and analyzed for their CysHisTNF content by Coomassie gel analysis as described in Grunwald et al. (2003). Positive fractions were pooled and dialyzed against PBS at 4 °C. Protein concentration was determined by Bradford method (BioRad, Germany) and the protein stored at 4 °C.

TNF-Coupling to Core−Shell Particles. Similar to wildtype TNF, CysHisTNF exists in its bioactive form as a noncovalently linked homotrimer, with each monomer carrying a free Cysteine residue near its N-terminus, all three located close together. Accordingly, CysHisTNF tends to form disulfide bridges, one type linking two of its monomers and a second type bridging two CysHisTNF homotrimers. To reduce these cysteine bridges, CysHisTNF or its derivatives were pretreated with 10 mM dithiothreitol (DTT) overnight at 4 °C. DTT was removed by dialysis for 3 h against PBS, and the solution was sterilized by filtration. DTT-treated CysHisTNF showed the same bioactivity as the native protein, indicating that the reduction of the N-terminal cysteines does not influence the disulfide bridges within the TNF monomers (data not shown).

Nanostructured particles with a diameter of 100 nm, 1 μm, or 10 μm and bearing a sulfoSMCC-shell (1 mg beads/mL) were incubated with 25 μg (1 μm, 100 nm beads) of CysHisTNF in PBS or 50 μg (10 μm beads) of CysHisTNF in PBS for 1 h at RT in vials which were constantly being rolled. Control beads were prepared by addition of 200 mM β-mercaptoethanol to 1 mg of beads in PBS. Labeled beads were centrifuged at 14000 g for 10 min at 4 °C. The supernatant with surplus CysHisTNF was discarded, and the beads were washed twice (centrifugation step between the washings) with sterile cell culture medium to remove unligated CysHisTNF. The final preparation was resuspended in 200 μL of culture medium and stored at 4 °C, protected from light. Bioactivity of the particles was determined in a cytotoxicity assay as described.

Cell Lines. HeLa cells stably transfected with human TNFR2 (HeLa80) or immortalized mouse fibroblasts (MF) from TNFR1/TNFR2 double knockout mice stably transfected with TNFR1-Fas or TNFR2-Fas expression plasmids (MF TNFR1-Fas, MF TNFR2-Fas) have been described elsewhere (Weiss et al., 1997; Krippner-Heidenreich et al., 2002). The human rhabdomyosarcoma cell line KYM-1 was supplied by M. Sekiguchi (University of Tokyo, Tokyo, Japan), and the human HeLa cell line was obtained from the American Type Culture Collection. HeLa cells, KYM-1 cells, and the immortalized mouse fibroblasts MF TNFR1-Fas and MF TNFR2-Fas were grown in RPMI 1640 medium supplemented with 5% (v/v) heat-inactivated fetal calf serum and 2 mM L-glutamine. The expression of the receptor fusion proteins TNFR1-Fas and TNFR2-Fas in fibroblasts was controlled routinely by FACS analysis (Krippner-Heidenreich et al., 2002).

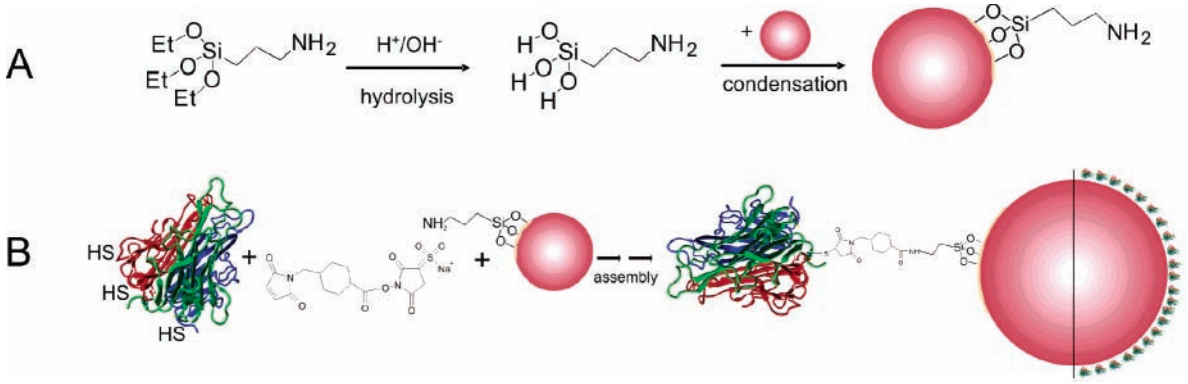
Transient Transfection and Live Imaging by Confocal Laser Scanning Microscopy. Cells were harvested and transiently transfected with 6 μg of pFADD-EGFP or pTNFR2-EGFP expression plasmids by electroporation. An amount of 10^6 cells per 800 μL of culture medium was electroporated at 250 V and 1800 μF in a 0.4 cm cuvette (Peqbio Easyject Plus, Peqlab). An amount of 3×10^5 cells was seeded immediately after electroporation into 3.5 cm coated glass bottom dishes (Mattek Corp., Ashland, MA) and cultured for 24 h before stimulation. Cells were then treated with CysHisTNF-labeled particles of different sizes. Images were taken at the indicated time points using a TCS SL confocal laser scanning microscope (Leica).

Cytotoxicity Assays. Mouse fibroblasts or KYM-1 cells (1×10^4 cells/well) were grown in 96-well plates overnight. Cells were then treated as indicated and cultivated overnight. The next day cells were washed three times with PBS followed by crystal violet staining (20% methanol, 0.5% crystal violet) for 15 min. The wells were washed with H_2O and air-dried. The dye was resolved with methanol for 15 min, and optical density at 550 nm was determined with an ELISA plate reader (SPECTRAmax 340PC, Molecular Devices Corp., Sunnyvale, CA).

RESULTS

Functionality of Organically Activated Core−Shell Particles. Core−shell nanoparticles and microparticles were prepared consisting of an inorganic core and an organic shell bearing both fluorescent markers and functional surface groups suitable for the coupling of TNF muteins. The inorganic core of the particles consisted of silica prepared via sol−gel chemistry (Scheme

Scheme 2. Synthesis, Modification and Assembling of the TNF-Functionalized Particles[a]



[a] Core particles are generated in a reaction mixture containing tetraethoxysilane, ammonia, water, and ethanol. Subsequently the silica particles are surface-modified using APS, ammonia, and TEOS (A). The particles are then surface activated using the heterobifunctional cross-linker SMCC (B) which is coupled to the amino groups of the modified particles. The maleimide group of the cross-linker then reacts with the free sulfhydryl groups of the TNF molecule, generating stable thioether bonds. The schemes are not drawn at the same scale (calculated sizes are: SMCC ~ 0.13 nm, TNF ~5.5 × 4.4 nm and nanoparticle ~ 100 nm) with the exception of the right part of the functionalized particle in B.

2A) and showed a negative ζ-potential of −(13.9 ± 1.6) mV for the 100 nm particles and −(13.7 ± 3.3) mV for the 1 μm particles. The ζ-potential was shifted toward highly positive values during the preparation of the organic shell consisting of APS (Scheme 2B) and fluorescent markers and resulting values of (40.1 ± 4.2) mV for the 100 nm particles and (43.2 ± 6.5) for the 1 μm particles. The colloidal stability of the core−shell particles was high enough that in this case the ζ-potential of the 10 μm particles was detectable by microelectrophoresis, rendering a value of ~52.3 mV. The organic shell was further modified by the bifunctional organic cross-linker SMCC, bearing one chemical group for reaction with the particles' amino surface and a maleimido group as second functional group for formation of a shell surface suitable for later protein coupling reactions to the shell surface. The shell modification by SMCC led to a slightly negative ζ-potential with −(3.4 ± 6.0) mV for the 100 nm particles.

Functionality of TNF-Coupled Nanoparticles. For covalent binding on the activated silica particles, CysHisTNF was used, a TNF mutein containing a His tag for purification purposes and a cysteine residue near its N-terminus (Scheme 2B). Under nonreducing conditions CysHisTNF rapidly forms covalently linked dimers (calculated M_r 39 × 10^3; Figure 1A, lane 1). To obtain reduced CysHisTNF, the TNF mutein was treated with DTT overnight and subsequently dialyzed against PBS (Figure 1A, lane 2). This protein shows a slightly higher apparent molecular weight as compared to soluble human TNF, in accordance with the added CysHis tag (Figure 1A, lane 3).

Mouse fibroblasts derived from TNFR1 and TNFR2 double knockout animals stably expressing TNF receptor/Fas chimeras rapidly develop apoptosis when adequately stimulated. The TNFR1-Fas chimera positive cells respond to both sTNF and memTNF, whereas the TNFR2-Fas chimera only responds to the membrane-bound form of the ligand (Krippner-Heidenreich et al., 2002). TNFR2-Fas positive cells were used for an initial characterization of the bioactivity of TNF-coated particles. Soluble CysHisTNF was inactive on these cells over a wide dose range and induced only at high concentrations a weak cytotoxic effect (Figure 1B), presumably caused by the presence of a minor proportion of higher molecular weight aggregates, e.g. hexamers comprised of three covalently linked dimers (data not shown). In the presence of the TNFR2-specific antibody 80M2, however, known to develop a membrane TNF-like activity when combined with soluble TNF (Grell et al., 1993; Grell et al., 1995), a strong cytotoxic activity toward TNFR2-Fas positive cells was observed (Figure 1B). These data demonstrate that CysHisTNF bioactivity resembles wildtype sTNF, i.e., the introduction of the N-terminal tags did not significantly affect sTNF's function. When coupled to beads, the parental TNFR1/TNFR2 knockout fibroblasts were fully unresponsive to treatment with CysHisTNF positive particles, similar to unconjugated control beads (Figure 1C). However, when TNFR2-Fas-expressing mouse fibroblasts were used, CysHisTNF beads induced a strong and dose-dependent cytotoxic effect, whereas control beads were ineffective (Figure 1D). These results demonstrate a memTNF-like bioactivity of CysHisTNF positive beads.

Receptor Selectivity of Beads Coated with CysHisTNF Mutants. Various mutants of human TNF have been produced that exert a pronounced selectivity for one of the two TNF receptors (Van, X et al., 1993; Loetscher et al., 1993). A high selectivity for TNFR1 and TNFR2, respectively, can be obtained by exchange of only two amino acids, leading to the TNF mutants TNF32W/86T (TNFR1 selective) and TNF143N/145R (TNFR2 selective), that have been characterized quite extensively in the past (Beyaert and Fiers, 1994). CysHis-variants of these two TNF muteins were constructed, produced, and coupled to activated beads. CysHisTNF32W/86T shows a bioactivity on TNFR1-Fas chimeric receptors comparable to wild-type TNF but is inactive on TNFR2. CysHisTNF143N/145R possesses a mild memTNF-like bioactivity on TNFR2-Fas molecules while inactive on TNFR1-Fas (Krippner-Heidenreich et al., 2002). As expected, a marked receptor selectivity could be observed when applied to cells expressing TNFR1-Fas or TNFR2-Fas receptor chimera. Similar to control beads, CysHisTNF143N/145R positive beads induced no cytotoxic response in TNFR1-Fas-expressing mouse fibroblasts, whereas CysHisTNF32W/86T positive beads were strongly cytotoxic (Figure 2A). Vice versa, the TNFR2-Fas chimera expressing cells were responsive to treatment with CysHisTNF143N/145R positive beads only (Figure 2B).

Stability of CysHisTNF-Labeled Beads. To test for the stability of generated TNF-beads, CysHisTNF-coupled particles of 10 μm diameter were produced washed and their cytotoxic activity was quantified using

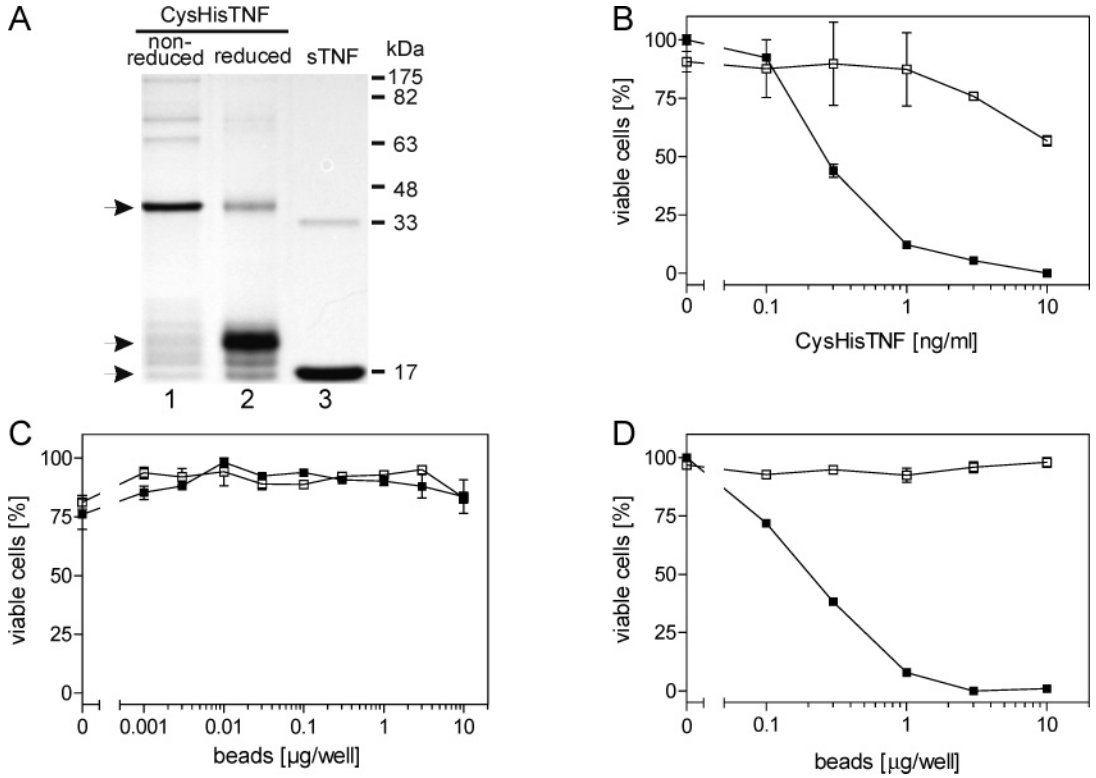


Figure 1. Characterization and bioactivity of soluble CysHisTNF and CysHisTNF coupled beads. CysHisTNF was incubated overnight with 10 mM DTT to reduce covalently linked dimers and dialyzed for 3 h against PBS. A**.** An amount of 5 μg of protein per lane was analyzed using a 15% nonreducing SDS−PAGE. Lane 1: CysHisTNF before DTT treatment, lane 2: CysHisTNF treated with DTT, lane 3: wild-type soluble TNF. The arrows at the left indicate dimeric CysHisTNF, monomeric CysHisTNF, and wild-type sTNF monomers, respectively. Numbers at the right indicate molecular weight markers. B, C, and D. Cell viability was determined in a standard cytotoxicity assay using crystal violet staining. Results are expressed as mean values of duplicates, representative results from three independent experiments are shown. B. TNFR2-Fas expressing mouse fibroblasts were stimulated with soluble CysHisTNF alone (□) or after preincubation with the mAb 80M2 (■; 1 μg/mL). C and D. DTT-treated CysHisTNF was coupled onto activated 1 μm beads. TNF-coated particles (■) and uncoated beads (□) as a negative control were used to stimulate TNFR1/TNFR2 double knockout mouse fibroblasts (C) or TNFR2-Fas expressing cells (D).

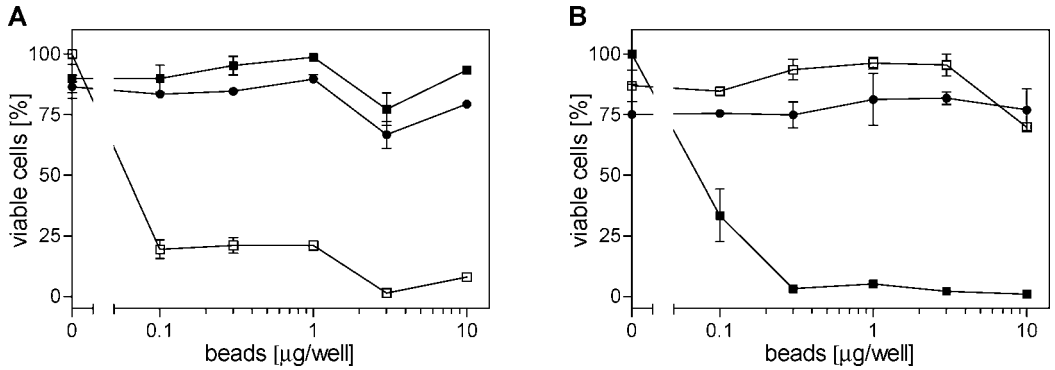

Figure 2. Receptor selectivity of beads coated with CysHisTNF mutants. The TNF derived muteins CysHisTNF32W/86T (□) and CysHisTNF143N/145R (■) were pretreated with DTT to reduce covalently linked dimers, dialyzed, and coupled onto activated beads. Bioactivity and receptor-selectivity were determined using TNFR1-Fas (A) and TNFR2-Fas (B) chimera expressing mouse fibroblasts in comparison to TNF negative control beads (●). Cell viability was quantified using crystal violet staining. Mean values of duplicates are shown.

the rhabdomyosarcoma cell line KYM-1 (Figure 3A). An aliquot was stored at a concentration of 5 μg particels/μL in fetal calf serum containing cell culture medium for five weeks at 4 °C. Thereafter, the beads were washed once to remove unbound CysHisTNF, and their bioactivity was tested in a cytotoxicity assay (Figure 3B). Whereas control beads induced no significant cytotoxic effect in both experiments, the CysHisTNF positive beads induced a strong cytotoxic effect with half-maximum efficiency at a concentration of about 0.5 μg/well, indicating no significant loss of bioactivity during the storage period of five weeks (Figures 3, A and B).

Specific Bioactivity of CysHisTNF-Labeled Beads. The LD_{50} value of CysHisTNF coated beads of 1 μm size was found to be in the order of 0.2 μg beads/well (1.0 μg/mL) in a standard cytotoxicity assay using TNFR2-Fas positive mouse fibroblasts (Figure 1D). From these values it can be calculated that about 2×10^5 particles induced half-maximum apoptosis in a single well containing 20000 cells, or 10 beads per cell (1 mg of beads with 1 μm size equals to 9.55×10^8 particles). This method to assess the bioactivity of the beads might be inadequate, however, since the particles might come into contact with their target cells only statistically. More reliable informa-

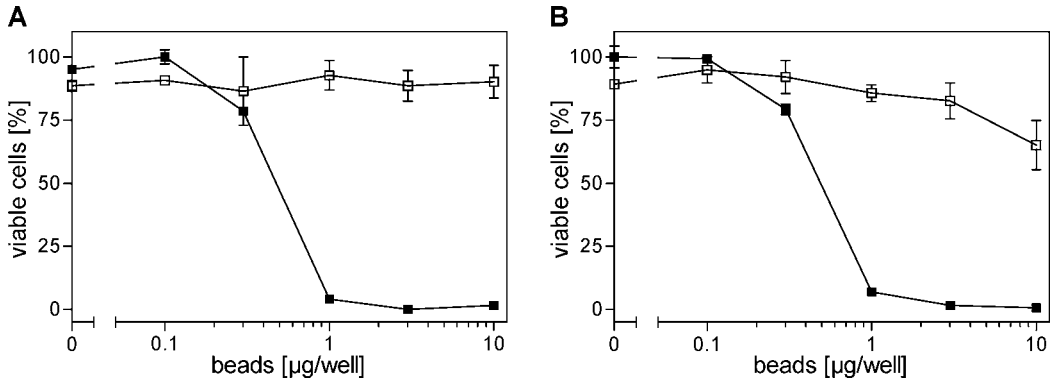

Figure 3. The bioactivity of TNF-coated particles remains stable upon storage at 4 °C. CysHisTNF-coupled beads (■) were stored at a concentration of 5 μg particles/μL for five weeks in FCS-containing culture medium. Subsequently they were washed, resuspended in fresh culture medium, and tested on KYM-1 cells in a standard cytotoxicity assay in comparison to control beads negative for TNF (□). A. Freshly prepared particles. B. Beads after storage for 5 weeks at 4 °C in RPMI/FCS 5%. Results are expressed as the mean values of duplicates.

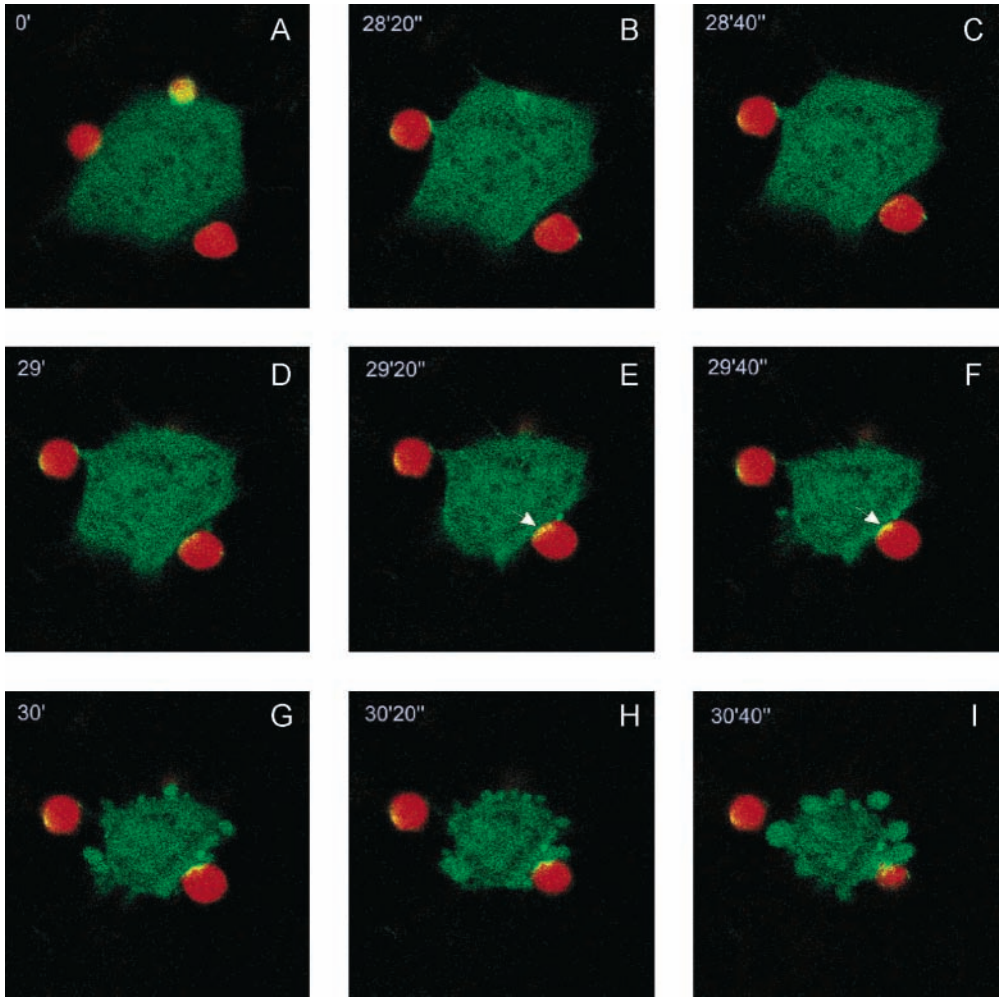

Figure 4. Induction of apoptosis in TNFR2-Fas positive mouse fibroblasts.Alexa-Fluor-568 stained beads of 10 μm diameter had been coated with CysHisTNF. 10^6 TNFR2-Fas mouse fibroblasts were transiently transfected with human pEGFP−FADD and grown overnight in glass bottom culture dishes. An amount of 100 μg of beads was added to the cells, and a particular cell was chosen for further observation ($t = 0$) using a confocal laser scanning microscope. Images were taken every 10 s over a time period of 40 min (A−I). The white arrows indicate FADD recruitment. Note that the development of the apoptotic phenotype takes place within only about 2 min after a lag time of about 29 min (F−I).

tion regarding the potency of TNF-coupled beads could be obtained from data at the single cell level. Large CysHisTNF-coated particles of 10 μm diameter, prelabeled with Alexa-Fluor-568-dye, were used for live cell imaging experiments using confocal microscopy. These beads were added to TNFR2-Fas positive mouse fibroblasts overexpressing human FADD (Fas-associated death domain protein)-EGFP. The cells were then observed regarding their contact with one or more beads. In Figure 4, a single TNFR2-Fas-expressing mouse fibroblast is shown to undergo apoptosis after stimulation by three 10 μm CysHisTNF beads. As a receptor-proximal event, FADD-EGFP recruitment into the death-inducing signaling complex (DISC) was evident from induced membrane

colocalization with beads (yellow color; see white arrows). Cell shrinking, the first optically visible sign of cell death, was observed after 29 min. Blebbing and fragmentation of the cell into smaller vesicles followed rapidly within the next 2 min (Figure 4).

To perform statistical analyses, we used particles of 1 μm diameter. TNFR2-Fas positive mouse fibroblasts expressing human FADD-EGFP were treated with 25 μg of red fluorescent beads that had been coupled with CysHisTNF. After an incubation time of 5 min, single cells were identified with beads in contact and observed for the next 30 min. Twenty-seven cells from nine different sample preparations were observed to develop apoptosis. These cells had been in contact, in average, with six beads (6.3 ± 3.2, $n = 27$; data not shown). Approximately 600 cells from six different dishes were subsequently counted to determine the total percentage of apoptotic cells (66%). Accordingly, at a beads dose close to the LD_{50} value, the apoptotic cells had been in contact, on average, with six beads. This value is very similar to that determined in dose−response assays applying serial dilution of beads, where the observed LD_{50} value of 0.2 μg/well corresponds to 10 beads/cell (Figure 1D).

Within a size ranging from 100 nm to 10 μm in diameter, the beads had been estimated to bind on average 4.5 μg of CysHisTNF per mg of carrier material (3.2−5.5 μg/mg beads; $n = 11$; data not shown). These results indicate some limiting factor in the coupling procedure independent of the surface size of the beads, which varies by a factor of hundred within the used size range. Accordingly, a single particle of 1 μm diameter has bound about 50000 molecules of TNF (trimers) at the surface, a number which is in good agreement with the specific binding capacity calculated earlier (Schiestel et al., 2004). We estimated from microscopical analyses that one-third of the particle surface would be in direct contact with the cell, i.e., capable to engage receptors. From these estimations, it follows that, with an average of six beads contacting the cell surface at a LD_{50} dose, about 100000 TNF molecules are available for signaling. However, the receptor number available at the contact site of the cell is much lower. We assume that the 45000 TNFR2-Fas molecules expressed per cell are homogeneously distributed at the cell surface, as indicated from confocal microscopy data (Krippner-Heidenreich et al., 2002). The cellular contact site with the six beads covers about 5.6 μm^2, or about 0.6% of the cell surface (with an estimated available cell surface of about 900 μm^2), i.e., only about 270 receptor molecules would be directly targeted. Although the number of engaged receptors might increase somewhat due to lateral diffusion of more molecules into the contact site, these data indicate that particle-mediated activation of less than 1000 receptors is sufficient to kill a cell. These estimations indicate a very high memTNF-like potential of the carrier coupled CysHisTNF.

DISCUSSION

Most of the members of the TNF-ligand superfamily exist in two bioactive forms: a membrane-bound form and its soluble counterpart, processed from the membrane-bound TNF by metalloproteases and/or produced by alternative splicing (Black et al., 1997; Grell and Scheurich, 1999). Both soluble and membrane-bound TNF do bind and stimulate TNFR1. Although TNFR2 also binds sTNF and memTNF, only the latter is capable to strongly activate this receptor (Grell et al., 1995). Therefore, the investigation of TNFR2 signaling pathways has long been hampered by the lack of adequate memTNF-mimicking tools. In this work, we have produced nano- and microparticles with directedly and covalently coupled TNF derivatives at their surface (Scheme 1). As core particles, silica-based beads have been used that can be easily activated for covalent coupling (Schiestel et al., 2004). Silica particles of various sizes were coated with CysHisTNF, exposing a free SH-group in their N-terminal cysteine residue to generate a memTNF equivalent. In average, about 5 μg of CysHisTNF could be coupled per mg of beads, independent of its size ranging between 0.1 μm and 10 μm. This indicates a decreasing density of the coupled TNF molecules with decreasing particle size. In any case the resulting particles contained a much higher density of CysHisTNF molecules on their surface as compared to a typical receptor density of a TNF responsive cell (approximately 16000 molecules of CysHisTNF per μm^2 on a 1 μm particle versus an about 100 fold lower cellular receptor density).

Beside covalent coupling, some adsorption of CysHisTNF was also observed in our experiments, although the particles had been intensively washed to remove unligated CysHisTNF. This was estimated to be 10% or less of the covalently coupled material, as calculated from control experiments with wild-type TNF (data not shown). CysHisTNF-coated beads could be stored at 4 °C for several weeks without significant loss in bioactivity, although small amounts of bioactive, soluble TNF was detectable in supernatants of pelleted particles. This minor leakiness of the conjugated particles can be explained by a slow release of passively adsorbed material and/or by reversible dissociation of TNF trimers that are covalently linked to the particle surface by only one or two of its monomers, rather than all three monomers of the homotrimer (Scheme 1, Figure 3, and data not shown).

The oriented presentation of CysHisTNF at the surface of the beads, with its N-terminus forming a covalent bond with sulfoSMCC, permits the formation of biologically active trimers possessing a bioactivity comparable to the membrane-expressed ligand. This could be demonstrated by the effective induction of apoptosis in cells expressing wild-type TNF receptors (Figure 3) as well as TNFR2-Fas chimera (Figure 4), the latter being responsive to membrane-bound TNF only but fully resistant to soluble TNF (Krippner-Heidenreich et al., 2002). Induction of apoptosis was preceded by recruitment of FADD to the membrane-bound receptor chimeras (Figure 4), further supporting the formation of a functional death inducing signaling complex. Similarly, in cells expressing wild-type TNFR2 molecules, stimulation of the cells with CysHisTNF positive beads induced receptor clustering, recruitment of TRAF2-EGFP, and translocation of p65/relA into the nucleus (data not shown).

Cells from various human tissues have been shown to typically express between 300 and a few thousand endogenous TNF receptors (Scheurich et al., 1986; Kull, Jr. et al., 1985). Accordingly, the receptor density at the cell surface is rather low, provided that TNF receptors are distributed homogeneously, which is supported for TNFR2 by confocal microscopy analyses of ectopically expressed TNFR2-EGFP and of TNFR2-Fas chimeric receptors (Krippner-Heidenreich et al., 2002). In the case of the TNFR2-Fas chimera we could estimate the efficiency of the beads in comparison to the most efficient tool for TNFR2 stimulation so far available, the combination of sTNF with the TNFR2 specific mAb 80M2 (Grell et al., 1993; Grell et al., 1995). A comparable cytotoxic activity (50 and 66% of maximum apoptosis) could be

obtained with about 6500 sTNF molecules per cell in the presence of the mAb 80M2 or 6 CysHisTNF positive 1 μm beads. These beads present a large number of TNF molecules (about 100000 per particle) but are likely to interact with only a few hundred cellular receptor molecules. Accordingly, particle-coupled TNF proved to be superior in bioactivity when compared to sTNF plus 80M2 by approximately 1 order of magnitude.

Human TNF-derived muteins with high receptor selectivity have been described (Van, X et al., 1993; Loetscher et al., 1993). We were questioning whether receptor selectivity would be preserved after coupling of the respective receptor-selective CysHisTNF mutants to the beads or whether subtype specificity would be overcome by a positive cooperativity of the surface-bound ligands in terms of an increased avidity. The results shown in Figure 2, however, clearly show that receptor selectivity remains preserved, and therefore TNFR2-selective, strongly activating agonists can be produced on the basis of nano/microparticles covalently coupled with the TNFR2-selective mutein CysHisTNF143N/145R.

In summary, we have generated TNF-functionalized particles capable to efficiently stimulate TNFR2, thus mimicking the action of membrane-bound TNF. Moreover, these tools can be used for selective and spatially restricted activation of either of the two TNF receptors and allows live imaging of receptor proximal events and apoptosis events. Future areas of application for similar but biodegradable (nano)particles might include the in vivo usage of particles carrying more than a single effector/targeting protein for therapeutic treatment.

Preparation and Characterization of a DOTA−Lysine−Biotin Conjugate as an Effector Molecule for Pretargeted Radionuclide Therapy

James Hainsworth,[†] Peter Harrison,[‡] and Stephen J. Mather*,[†]

Cancer Research UK, Nuclear Medicine Group, St. Bartholomew's Hospital, London, and Bioventix Ltd., 7 Romans Business Park, East Street, Farnham, Surrey GU9 7SX. Received June 28, 2005; Revised Manuscript Received September 5, 2005

Pretargeted radionuclide therapy depends on the establishment of a high concentration of secondary binding sites at a tumor to which low-molecular weight radiolabeled effector molecules can be directed. This study describes the simple synthesis of an effector molecule and its subsequent characterization to determine the extent to which it complied with the ideal requirements of such a compound. (ϵ)-DOTA−(α)-biotinamidolysine (DLB) was synthesized in high yield and purity using conventional SPPS methodology. High radiochemical purities were obtained when labeled with several potentially useful radionuclides. The radiolabeled analogue bound to streptavidin efficiently with a stoichiometry similar to that of native biotin and showed high stability in serum and upon challenge with acid conditions. Biodistribution studies in normal animals showed a rapid rate of clearance from the blood and low retention of radioactivity by normal tissues. This design of effector molecule therefore shows promise for further pretargeted radionuclide therapy studies.

INTRODUCTION

Despite the recent successes in the application of targeted radionuclide therapy for treatment of lymphoma, the relative lack of success of RIT[1] in the treatment of solid tumors has led many researchers to look for alternative strategies, one of the most promising of which is pretargeted radionuclide therapy (for a recent review see ref 1). This involves the preadministration of an antibody conjugate to establish secondary binding sites on the tumor which can then be more efficiently targeted by low molecular weight radiolabeled effector molecules. To prevent these effector molecules from interacting with molecules of antibody conjugate still circulating in the blood, it may be necessary to inject a clearing agent between the first and last reagents in order to reduce the amount of circulating antibody conjugate.

The most widely explored system to date is that based on the biotin−(strept)avidin interaction. Thus the first administration might be that of an antibody−streptavidin conjugate or fusion protein, a suitable clearing agent would be a macromolecular biotin conjugate which remains confined to the vasculature, and the final effector molecule might be a small radiolabeled biotin analogue which is able to diffuse rapidly into the extravascular space surrounding the tumor and bind to the pretargeted antibody−streptavidin conjugate.

It has become clear in recent years that each stage of this targeting regimen needs to be optimized. Not only the reagents themselves but the doses used and the timing between the different stages have all been extensively studied in order to increase the efficacy of the treatment as a whole. This publication is concerned with developments in the design of the last stage in the process, the radiolabeled effector molecule (EM).

The ideal EM should maximize the delivery of a therapeutic radionuclide to the tumor and minimize its uptake by nontarget organs in the body. To achieve this it should have (a) a high affinity for streptavidin, (b) a high stability in vivo, and (c) a favorable pharmacokinetic profile which ensures that it is cleared rapidly from the blood and excreted through the kidneys without any significant retention by organs of excretion and metabolism such as the kidneys and liver. Supplementary benefits include the ability to radiolabel with a range of potentially useful radionuclides and a simple and efficient synthetic route.

The most successful therapies have been achieved using biotin-based EMs which have been labeled with metallic radioisotopes, most commonly yttrium-90. This is achieved by conjugating a chelating agent such as diethylenetraminepentaacetic acid (DTPA) or tetraazacyclododecanetetraacetic acid (DOTA) to biotin. Both bifunctional chelators have the ability to complex a variety of potentially useful metallic radionuclides including those of yttrium, indium, gallium, and lutetium, but DOTA is generally preferred because higher stability metal complexes can be obtained (*2, 3*). In the first DTPA−biotin conjugates to be employed for pretargeting purposes, one of the carboxylic acid groups of DTPA was condensed with the ϵ-amino group of biocytin as shown in Figure 1A (*4*). However, a significant disadvantage of this design is the fact that the amido bond so formed can

be cleaved by biotinidase, a ubiquitous enzyme present in mammalian serum (*5*) . A number of strategies have been formulated to overcome this problem including the use of reduced or sterically hindered amide bonds to render the linkage stable to biotinidase. Examples are shown in Figures 1B (*6*) and 1C (*7*). A second possible route of instability relates to dissociation of the metal core from the complex in vivo. It is important that the radionuclide remains firmly bound in the complex to ensure that it is not scavenged by other metabolic pathways in the body which would result in an increased radiation dose to normal tissues. The main question in relation to DOTA conjugate design is whether to attach the DOTA chelate to biotin via one of the four pendant carboxylic acid groups or to engineer a point of attachment into one of the ethylene backbones in the molecule. The former approach has the advantage of simpler and easier synthesis but the latter the advantage of potentially greater stability.

For reasons discussed below, we were interested in preparing DOTA conjugates of L-biotin [the mirror image of naturally occurring D-biotin] for use in a novel pretargeting strategy. The synthesis of L-biotin is a complex, six-step procedure, and the material is therefore in limited supply. We therefore wished to develop a simple but efficient route to the preparation of a DOTA−L-biotin conjugate which retained all of the prerequisite properties discussed above. Our preferred design for this molecule is shown in Figure 1D. This molecule has the advantage that it can be prepared using conventional solid-phase peptide synthetic (SPSS) procedures, in high yield. A full characterization of the properties of this EM and the extent to which they complied with our list of requirements was performed.

EXPERIMENTAL PROCEDURES.

Chemicals and Reagents. All reagents were purchased from Sigma-Aldrich unless otherwise indicated**.** Indium chloride ($^{111}InCl_3$) was sourced from Mallinckrodt Medical b.v (Petten, Netherlands), yttrium chloride ($^{90}YCl_3$) from MDS Nordion (Fleurus, Belgium), lutetium chloride ($^{177}LuCl_3$) from Perkin-Elmer Life Sciences, Inc. (Boston, Massachusetts), and cobalt chloride ($^{57}CoCl_2$) from ICN (Basingstoke, Hamps, UK).

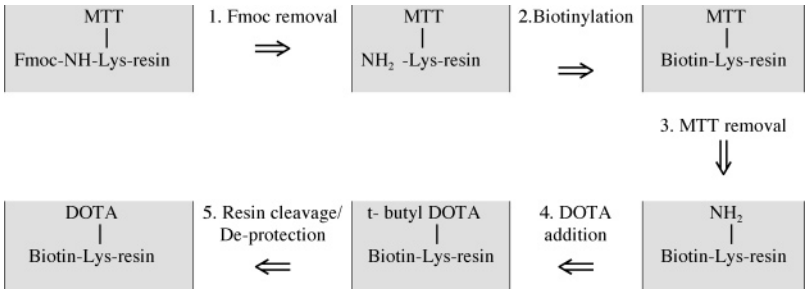
Reverse-Phase Chromatography. HPLC analysis was performed using a Beckman 126 solvent-module pump system with a Beckman 168 diode array detector and a sodium iodide flow through radiochemical detector attached to a Raytest gamma radioactivity monitor. Preparative HPLC was performed using a an Agilent Zorbax 300SB-C8 preparative column (21.2 mm × 25 cm) while for analysis a Galaxy Jupiter 5μ C_{18} column, 300 Å; 4.6 × 250 mm i.d. was used (Phenomenex, Cheshire, England). Data collection was handled by a PC running System Gold Nouveau (Beckman, High Wycombe, England). A mobile phase system comprising water and acetonitrile containing 0.05% TFA was used at a flow-rate of 1 mL per minute.

(ϵ) DOTA−(α)-Biotinamidolysine (DLB) Synthesis. Classical SPPS methods were used to synthesize the conjugate as described in Scheme 1. Ninhydrin assays were performed at each stage to check completion of the reactions. The starting point was an Fmoc-Lys(MTT)-Wang resin (Novabiochem). Briefly, after removal of the Fmoc protection with 20% piperidine, biotinylation on the α-amino group was performed overnight using a 4-fold molar excess of HOBT activated D- or L-biotin. The ϵ-MTT protection was removed with 1% TFA, 5% TIS in dichloromethane, and DOTA conjugation to the lysine side chain was performed overnight by addition of a 4-fold molar excess of HOBT-activated DOTA-tris(*tert*-butyl) ester (Macrocyclics, TX). Cleavage from the resin and removal of the *tert*-butyl protection was performed with 2.5% TIS, 2.5% water in TFA. The resin was removed by filtration, the DLB precipitated in cold diethyl ether, washed, redissolved in water, and lyophilized. The crude product was purified by reverse-phase HPLC using a C_8 column. The samples were analyzed by reverse-phase HPLC to check their purity, and matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (Lasermat 2000, Finnigan-Mat, Thermo Electron Corp) was used to verify their molecular mass.

Radiolabeling of DOTA−Biotin Conjugates. The DLB was labeled with indium-111, yttrium-90, and lutetium-177 using the same reaction conditions. Typically, a volume of 10 μL (7 MBq) of the radionuclide was added to an equal volume of 2 M ammonium acetate, pH 5.4, in a 2 mL polypropylene vial. This was followed by 5 μL of a 1 mg/mL solution of DLB in water. The volume was made up to 100 μL with water, and the reaction vial was sealed, heated in a boiling bath for 30 min, and finally quenched with 10 μL of 50 mM EDTA before further analysis. Sodium ascorbate was added to ^{90}Y-labeled solutions at a final concentration of 100 μg/mL to prevent radiolysis.

Assay of DOTA−Lysine Biotin. Because of inaccuracies in weighing small amounts and to compensate for the presence of residual water, the concentration of DLB was confirmed by labeling a sample with $^{57}CoCl_3$ of a known specific activity (*8*). A range of concentrations was labeled with ^{57}Co, quenched with EDTA, and analyzed by ITLC (Pall Life Sciences, Portsmouth, UK) using 10 mM EDTA in 0.1 M ammonium acetate as mobile

Scheme 1. Solid-Phase Synthesis of DLB[a]



[a] Step 1: A volume of 3 mL of 20% piperidine/DMF was mixed with 50 mg of peptidyl resin and incubated for 1 h at room temperature. The reacted sample was centrifuged at 6500 rpm for 1 min, and the supernatant was discarded and replaced with a further 3 mL of 20% piperidine/DMF to ensure complete reaction for another 1 h. The supernatant was discarded, and the pellet evaporated to dryness in a Savant SpeedVac Plus. The resin was washed three times with 1 mL of dimethylformamide and twice with 1 mL of dichloromethane before drying in the SpeedVac. Step 2: The deprotected lysine resin beads were preswollen with 250 μL of NMP, and the excess supernatant was removed. A 4:1 molar excess of biotin (0.12 mmol) to lysine was dissolved in 1 mL of DMSO and 400 μL of NMP. Then 200 μL of 1 M HOBT in NMP was added to the D-biotin solution and left for 3 min. A volume of 200 μL of diisopropylcarbodiimide activator (1 M in NMP) was added to the D-biotin solution and reacted for 30 min. The activated D-biotin solution was then added to the resin and mixed overnight on a 4RT-rocking table (Luckham, Ltd., Burgess Hill, UK). The next day the beads were washed three times with 1.5 mL of NMP. A volume of 500 μL of DCM was used to shrink and dry the beads. Step 3: The resin was washed four times for 3 min with 2 mL of a solution containing 1% TFA, 5% TIS, and 94% DCM. Initially the solution became a fluorescent yellow color, indicating the presence of MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide) in solution. Washing was continued until the wash solution became colorless again. The beads were then washed in DCM. Step 4: The resin beads were preswollen with 200 μL of NMP. A mass of 115 μg (0.2 mmols) (6× excess) of DOTA-tris(*tert*-butyl ester) (Macrocyclics, Dallas, TX) was dissolved in 700 μL of DMF, and a 200 μL aliquot of 1 M HOBT in NMP was added and mixed for 3 min. A volume of 50 μL of diisopropylcarbodiimide (1 M in NMP) was added and incubated for 30 min at room temperature. The "Activated DOTA" was added to the swollen resin and gently mixed overnight. The resin beads were then washed five times with DMF and twice with DCM. Step 5: A 1 mL aliquot of a cleavage solution containing 2.5% water, 2.5% TIS, and 95% TFA was added to the resin, and the suspension was slowly filtered through a microtube filter over a period of 2 h. The solute was precipitated with 1 mL of cold diethyl ether and centrifuged for 1 min and the supernatant discarded. The pellet was washed with a second 1 mL of ether, the supernatant discarded, and the compound dried in the SpeedVac. The resultant solid was weighed in a microfuge tube on a Sartorius analytical balance (Goettingen, Germany) and then redissolved in water for preparative HPLC purification.

phase. Under these conditions, DLB-bound ^{57}Co has an $R_f = 0$ while unbound ^{57}Co has an $R_f = 1$. A graph of bound cobalt concentration vs estimated DLB concentration was drawn and the gradient determined by linear correlation from which the true concentration of the DLB was calculated.

Streptavidin Binding of Labeled DOTA−Biotin Conjugates. ^{111}In-labeled DLB was incubated with a series of dilutions of streptavidin (ICN, MP Biomedicals, Irvine CA) ranging from 0.2 pM to 2 μM corresponding to DLB:streptavidin ratios of 10^{-5} to 100:1. The reaction mixtures were incubated for 30 min at 37 °C, and samples were taken and analyzed using Sephadex G-50 spin columns (Amersham Biosciences, Amersham UK) to determine the degree of streptavidin binding.

Serum Stability. To asses the stability of DLB to biotinidase and other serum proteases, 50 μL of ^{111}In-labeled DLB (containing 1 μg of labeled EM) was diluted 10-fold in fresh human serum and incubated with gentle mixing at 37 °C for up to 24 h. Samples were taken at 0, 1, 2, 6, and 24 h, serum proteins were precipitated with an equal volume of acetonitrile, and the supernatant was analyzed by reverse-phase HPLC.

Stability of DOTA−Metal Complexes. The stability of the ^{111}In- and ^{90}Y-DLB complexes were compared with those of the unconjugated DOTA and DTPA radiometal complexes by assessing their resistance to competition by hydrogen ions. The complexes were prepared and diluted with a 10-fold excess of 0.1 M glycine·HCl buffers ranging in pH from 0.5 to 5. After incubation at room temperature for 30 min, the solutions were neutralized by addition of phosphate buffer and analyzed by ITLC using 10% aqueous ammonium hydroxide:methanol (1:1) as mobile phase. Under these conditions, any complexed radioisotope has an $R_f = 1$ while that which has been lost from the complex has an $R_f = 0$.

Biodistribution of ^{111}In-Labeled DLB. The biodistribution of labeled DOTA−biotin conjugate was determined after intravenous administration to normal mice. Twelve normal adult balb/c mice were injected with 35 ng of conjugate labeled with 70 kBq of ^{111}In. Two, six, and twenty-four hours after injection, groups of four mice were killed, and a sample of their blood, a sample of muscle, a femur, both kidneys, the liver, the complete intestine, and the spleen were transferred to preweighed tubes and counted in a suitably calibrated gamma counter together with a series of dilutions of the injected material in order to allow the percentage of the injected dose in each sample to be calculated.

RESULTS

Synthesis of the DOTA−lysine−biotin (DLB) proceeded without difficulty. A practical yield of around 80% was obtained. Although our synthesis was performed manually starting with only 50 mg (0.03 mmol) of loaded resin, no difficulty in scaling the synthesis up to the levels normally performed by automated peptide synthesizers would be expected. The DLB produced was pure as assessed by analytical HPLC (see Figure 2 upper trace) and showed the expected mass of 759 on MS (see Figure 3). Radiolabeling of the effector molecule consistently produced complexes with radiochemical purities greater than 99% as assessed by RP-HPLC (see Figure 2 lower trace). The complexes remained stable in aqueous solution for at least 48 h provided that (in the case of ^{90}Y-labeled DLB) sodium ascorbate was added to prevent radiolysis.

To perform an accurate assessment of the properties of the radiolabeled DLB solution, in particular the stoichiometry of its binding to streptavidin, an accurate assessment of its concentration was required. Since only very small amounts of the DLB were required for each assay, very small quantities were weighed out on most

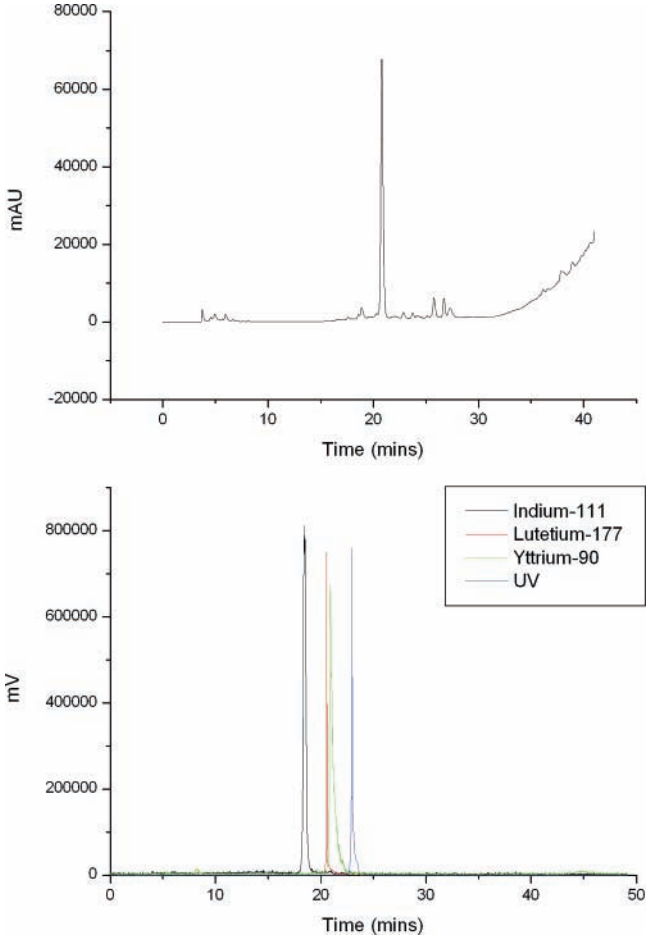


Figure 2. Reverse phase HPLC analysis of DLB. Upper trace UV detection of unlabeled compound. Lower trace radioactive detection of DLB labeled with ^{111}In, ^{90}Y, and ^{177}Lu.

occasions, and, in the knowledge that many peptides are hygroscopic, it was considered likely that this could lead to inaccuracies in the estimated concentrations of the DLB solutions prepared. An accurate assessment was therefore performed by titrating the DLB solution with a known concentration of $^{57}CoCl_3$ solution and plotting the concentration of bound ^{57}Co against the estimated DLB concentration. An example is shown in Figure 4. If the estimated concentration of DLB was correct, then the slope of the line would be 1. In this example the slope is 0.64, indicating that the real concentration of DLB was 1/0.64 or 1.56 times greater than that estimated.

Using a precisely known concentration of ^{111}In-DLB, a titration was performed with a range of streptavidin solutions and the extent of streptavidin binding measured by size-exclusion spin columns. The results show a sigmoidal pattern of binding as seen in Figure 5. With a large molar excess of streptavidin, up to 99% of the ^{111}In-DLB was protein bound. At a DLB:streptavidin ratio of 4:1 (the expected stoichiometric ratio of biotin binding), about 93% of the DLB is protein bound.

A high level of stability of the effector molecule in vivo is required. Two main routes of instability are likely: degradation by serum proteases such as biotinidase and transchelation of the radiometal from the DOTA complex. The first route of degradation was studied by incubating the labeled DLB in fresh human serum for up to 72 h and analyzing the mixture by reverse-phase HPLC. The rate of breakdown was compared with that of ^{111}In-DTPA α,ω-bis(biocytinamide) which is a known biotinidase substrate. No significant breakdown of the ^{111}In-DLB was observed over a 72 h incubation period. This contrasted with a loss of 46% of ^{111}In DTPA α,ω-bis(biocytinamide) in 24 h and a ~100% loss in 72 h. The level of serum protein binding of ^{111}In-DLB after 24 h incubation was found by size-exclusion spin column analysis to be 5%.

Although the high stability of the ^{111}In- and ^{90}Y-DOTA complexes are well documented, it is possible that the removal of one of the pendant carboxylic acid side chains may sufficiently reduce the stability to permit transchelation of the radiolabel in vivo. The stability of ^{111}In- and ^{90}Y-labeled DLB were therefore compared with that of ^{111}In- and ^{90}Y-labeled DOTA as well as ^{111}In- and ^{90}Y-labeled DTPA and ^{111}In- and ^{90}Y-labeled DTPA α,ω-bis(biocytinamide) using a modification of the approach described by Stimmel et al. (*9*). This was performed by diluting the complexes with an excess of glycine·HCl buffers of pH ranging from 0.5 to 5. Under low pH conditions, the high concentration of hydrogen ions would be expected to compete more effectively with the metal, and any loss in stability would result in a more rapid rate of transchelation than that which would be observed at higher pH. The results are shown in Figure 6. It can be seen that at least down to pH 0.5, no difference in stability between ^{111}In- and ^{90}Y-labeled DLB and DOTA complexes can be seen, indicating that the loss of one carboxylate arm has no profound effect upon the rate of loss of metal from the complex. By contrast the DTPA complexes and especially the DTPA α,ω-bis(biocytinamide) complexes (in which two carboxylate groups are used for conjugation) show a much greater rate of metal loss.

The biodistribution of ^{111}In-labeled DLB conjugates was studied in normal mice 2, 6, and 24 h after intravenous administration. The results are shown in Table 1. These show a rapid rate of clearance from the blood with very low retention in all tissues except kidney and bone where values ranged from 1 to 2% per gram.

DISCUSSION

Our aim in this exercise was to develop a simple efficient synthesis of a biotin-based effector molecule which provides high, reproducible labeling efficiency, high stability in a biological environment, effective interaction with its streptavidin target, and low nonspecific retention by normal organs and tissues in vivo. The results show that these aims have been largely achieved. The design of our DOTA–lysine–biotin was based on the results of a number of previous pivotal publications. In 1987 Hnatowich and co-workers (*4*) based their initial pretargeting studies on a DTPA–biocytin analogue. Although this firmly established the proof of principle, this effector molecule suffered from a number of shortcomings. The same group subsequently described the preparation of a DOTA–biotin analogue (*10*) and Chinol later showed that DOTA was a superior chelator for this purpose (*11*). The realization that a simple biocytin conjugate was a substrate for biotinidase led to the development of a number of more stable designs (*6, 7*). Wilbur et al. have explored in detail the effects of different substitutions on biotinidase stability (*12, 13*). In particular they showed that substitutions alpha to the biotinamide bond inhibited the activity of the enzyme through steric hindrance (*14*). Wilbur et al. have also studied the effect of different lengths of spacer between the radionuclide and the biotin. Because of their desire to radiolabel with halogens, they developed a series of ether-containing linkers to maintain the hydrophilicity of the molecule. Since DOTA itself confers a high degree of hydrophilicity on the structure,

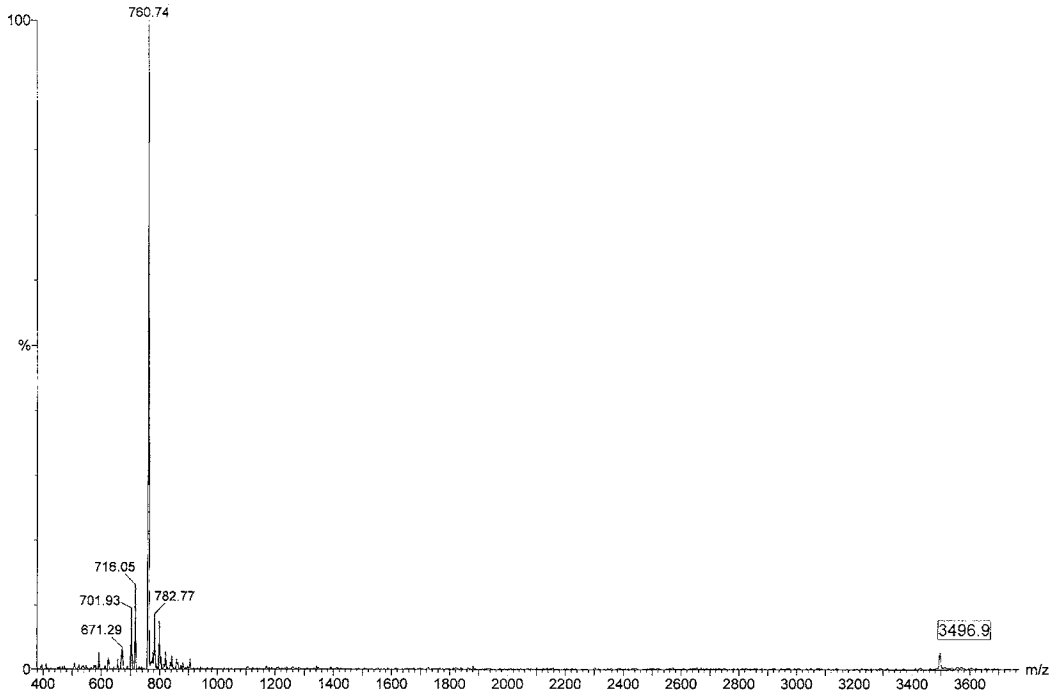

Figure 3. DLB matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometric analysis of DLB. M + H^+ of 760 corresponds to the expected mass of DLB of 759.

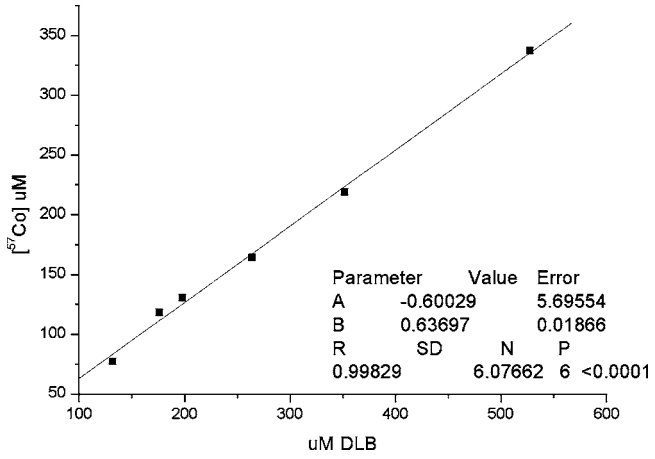

Figure 4. ^{57}Co titration to determine accurate concentration of DLB. A range of concentrations was labeled with ^{57}Co, quenched with EDTA, and analyzed by ITLC. A graph of bound cobalt concentration vs estimated DLB concentration was drawn and the gradient determined by linear correlation from which the true concentration of the DLB was calculated.

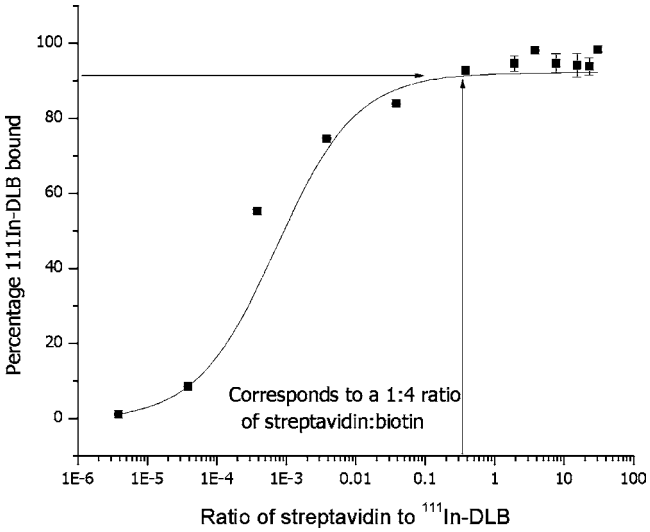

Figure 5. Binding of ^{111}In-DLB to streptavidin. ^{111}In-labeled DLB was incubated with a series of dilutions of streptavidin. After 30 min at 37 °C, samples were taken and analyzed using Sephadex G-50 spin columns to determine the degree of streptavidin binding.

we were not so constrained. For that reason we chose to use lysine as a linker since this would allow us to use standard SPPS chemistry to prepare the effector molecule. By substituting the biotin at the α- rather than the more usual ϵ-amino group of the lysine we ensured that the terminal carboxylate of the peptide provided the necessary steric hindrance of the biotinamide bond (see Figure 1D).

No difficulties were encountered in the synthesis of the effector molecule in acceptable yields. As well as preparing the DOTA−L-lysine−D-biotin described above we also prepared DOTA−L-lysine−L-biotin and achieved similar yields and purities. L-Biotin does not bind to streptavidin, but the rationale for our interest in this compound stems from a desire to combine the advantages of the streptavidin−biotin pretargeting system with those of the bispecific antibody approach (*15*). The streptavidin−biotin system has two significant drawbacks. The first is that streptavidin itself can be highly immunogenic (*16*), and this limits the number of potential administrations that can be made. The second drawback is the likelihood that endogenous biotin present in the blood will compete with the radiolabeled biotin for the limited number of binding sites on the pretargeted streptavidin conjugate (*17*). As effector molecules based on the D-isomer of biotin have many ideal properties (high specific activity, low toxicity, favorable stability, rapid renal excretion), it is expected that compounds based on the L-isomer would retain these advantages. We have therefore raised high affinity antibodies to L-biotin that do not cross-react with D-biotin and would, therefore, not be affected by endogenous biotin in the blood. The work presented in this publication stems from a desire to be able to perform studies directly comparing the two approaches in our laboratory. One of

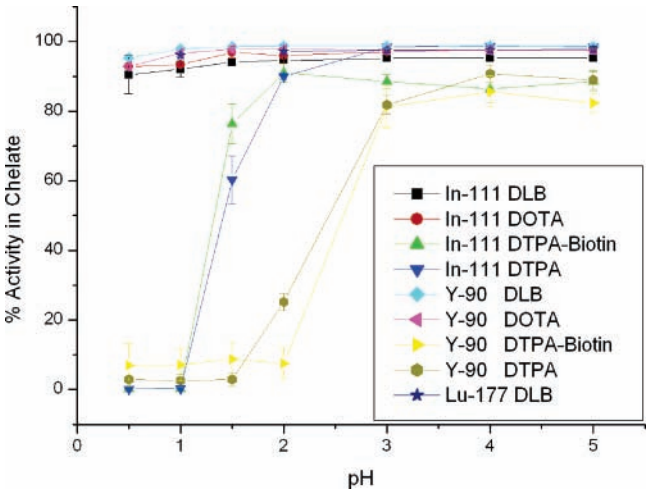

Figure 6. Dissociation of radiometal complexes under challenge at varying pH. The stability of the ^{111}In- and ^{90}Y-DLB complexes were compared with those of the unconjugated DOTA and DTPA radiometal complexes by assessing their resistance to competition by hydrogen ions. The complexes were prepared and diluted with a 10-fold excess of 0.1M glycine·HCl buffers at pH ranging from 0.5 to 5. After 30 min, the solutions were analyzed by ITLC to determine the proportion of intact complex remaining.

Table 1. Biodistribution of ^{111}In-DLB in Normal balb/c Mice

	% of injected dose/g tissue (SD) at time point (h)		
tissue	2	6	24
BLOOD	0.09 (0.02)	0.08 (0.02)	0.02 (0)
MUSCLE	0.21 (0.13)	0.41 (0.31)	0.11 (0.07)
BONE	1.31 (0.52)	1.39 (0.91)	0.1 (0.03)

LIVER	0.29 (0.19)	0.22 (0.11)	0.13 (0.03)
GUT	0.61 (0.51)	0.61 (0.14)	0.27 (0.17)
SPLEEN	0.22 (0.17)	0.24 (0.09)	0.3 (0.32)

the difficulties in exploiting L-biotin as an effector molecule is its difficult synthesis. We obtained the material from an expensive commercial custom synthesis (CMS Chemical, Abingdon, UK) which synthesized the compound from L-mannose according to the method of Ohrui (*18*). Although our DLB synthesis was performed manually on a small scale in order to limit the amount of the expensive L-biotin required, no difficulty in scaling the synthesis up to the levels normally performed by automated peptide synthesizers would be expected. It would also be possible to prepare the corresponding D-lysine analogues (*19*) if desired.

High levels of purity of the DLB and its radiolabeled counterparts were achieved. The molecule was able to bind efficiently to streptavidin in solution with a stoichiometry similar to that of native biotin indicating that the lysine spacer did not significantly inhibit this interaction.

In vitro measures of stability were encouraging. HPLC analysis of the radiolabeled effector molecule after incubation in serum for up to 3 days indicated no loss in purity over this time, indicating that the α-amino-linked molecule was not cleaved by serum proteases such as biotinidase. This is in contrast to the radiolabeled DTPA–ϵ-amino-linked control biotin analogue which was completely degraded over the same time period. However, it is possible that a proportion of this loss can be attributed to transchelation from the DTPA to transferrin present in the serum.

The stability of the radiometal–DOTA complexes were studied by comparing their rate of acid-assisted dissociation in a modification of the method described by Stimmel et al. (*9*). While Stimmel studied the dissociation of various chelates at pH 2 over a period of several days, we chose to study the effect of a range of pH (0.5–5) at a single time of 30 min. The results show that while the yttrium–DTPA complexes start to show dissociation at pH 3, the yttrium–DOTA complexes show no significant dissociation even at pH 0.5. As expected the indium–DTPA complexes are rather more stable than their yttrium counterparts while the indium–DOTA complexes are as stable as the yttrium analogues under the conditions studied. Although it has been shown that DOTA lacking one of the *N*-acetate side chains has a lower thermodynamic stability constant than DOTA itself (*20*), the most important issue in radiopharmaceutical design is that of kinetic stability since the great majority of the yttrium-90 will either clear from the body or decay within a few days. These results suggest that, from a practical point of view, the convenience of using the SPSS-friendly commercially available reagent DOTA-tris(*tert*-butyl) ester is not outweighed by a large decrease in the kinetic stability of the complex and taken together with the serum stability study indicate that this effector molecule would have a suitable stability profile for pretargeting studies.

The final stage of the characterization of the DOTA–lysine–biotin was to study its biodistribution in normal animals. The dose of compound chosen for this study (1.4 μg/kg) was within the range of those chosen for clinical pretargeting studies – 0.7 to 30 μg/kg (*21–23*). The ideal effector molecule would show no significant retention by any normal tissues or organs. With the exception of the bone and kidney, all tissues showed a retention of 0.5% or less. Bone showed an initially quite high value of around 1% but declined to only 0.1% by 24 h while kidney uptake varied between 1 and 2%. With the exception of the high initial bone uptake, these results are similar to those published from similar studies of alternative effector molecules. Goodwin et al. (*24*) showed very similar results with a DOTA–C-linked-isothiocyanatobenzylbiotin analogue in most tissues but only around 0.1% bone uptake at 2 h pi, while Sharkey et al. (*25*) showed similar results but a rapidly clearing kidney retention with DOTA–N-linked (D)-ϵ-lysine–biotin. The biodistribution of a DOTA–N-linked-*N*-methylglycyl-biotin (*26*) is presented in graphical form only but appears to follow a similar pattern of biodistribution.

In conclusion we consider that the design and simple synthetic method described above is suitable for the preparation of radiolabeled effector molecules for pretargeted radionuclide therapy.

Stable phosphoinositide (PIP_n)-containing liposomes were prepared using polydiacetylene photochemistry. Tethered pentacosadiynyl inositol polyphosphate ($InsP_n$) analogues of Ins(1,3,4)P_3, Ins(1,4,5)P_3, and Ins(1,3,4,5)P_4 were synthesized, incorporated into vesicles made up of diyne-phosphatidylcholine and -phosphatidylethanolamine, and polymerized by UV irradiation. The polymerized liposome nanoparticles showed markedly increased stability over conventional PIP_n-containing vesicles as a result of the covalent conjugated ene-yne network in the acyl chains. The polymerized liposomes were specifically recognized by PIP_n binding PH domains in liposome overlay assays and amplified luminescent proximity homogeneous assays. Moreover, the biotin moiety allowed attachment of the nanoparticles to a streptavidin-coated sensor chips in surface plasmon resonance (SPR) sensor. The PIP_n headgroups displayed on SPR sensors showed higher affinities for PH domains and PIP_n monoclonal antibodies than did monomeric PIP_n-analogues with biotinylated acyl chains.

INTRODUCTION

Phosphatidylinositol polyphosphates (PIP_ns) are important second messengers for a diverse array of cellular functions (*1*, *2*). These charged lipids are minor components of cellular membranes and are biosynthesized by the interplay of kinases (*3*), lipases, and phosphatases (*4*). PIP_ns are essential elements in tyrosine kinase growth factor receptor and G-protein receptor signaling pathways (*5*). Furthermore, they have important roles in membrane traffic (*6*), including endocytosis, exocytosis, Golgi vesicle movement and protein trafficking (*7*), in cell adhesion and migration, in remodeling of the actin cytoskeleton, and in mitogenesis and oncogenesis (*8*, *9*). Activation of cellular signaling pathways often results from specific PIP_n production in response to stimuli.

The common mechanism employed by PIP_ns appears to be localized signal generation and the spatially localized recruitment of effector proteins (*1*, *10*). Recruitment generally occurs through a specific PIP_n binding domain on the protein. For example, pleckstrin homology (PH) domains bind to PIP_ns with varying affinities and specificities and are present in over 110 proteins (*11*, *12*). Other domains include PX and FYVE, both of which predominantly bind PI(3)P (*13*, *14*), and the COOH-terminal domain of the tubby protein which binds to PI(4,5)P_2 (*15*). Finally, the first known PIP_n-binding nuclear receptor ING2, a putative tumor suppressor protein that promotes p53 acetylation, predominantly binds to the rare species, PI(5)P by a plant homeodomain (PHD) zinc finger (*16*). The association of ING2 with chromatin is modulated by phosphoinositides and it was shown that ING2-dependent p53 acetylation and transactivation requires an intact PIP_n-binding domain.

An example of the importance of PIP_n binding domains is that of the PH domains of PDK1 and Akt (protein kinase B) and their involvement in the PI-3 kinase pathway and cancer. Both PDK1 and Akt are sequestered to the membrane by binding to PI(3,4,5)P_3 and Akt possibly undergoes a conformational change thought to make it susceptible to activation through phosphorylation on Ser^{473} by PDK1 (*17*). Activated Akt then inhibits apoptosis by phosphorylating a critical serine residue (Ser^{136}) which suppresses pro-apoptic activity of BAD leading to subsequent cell death (*18*). Rationally designed PI analogues have been prepared that act as specific Akt PH domain inhibitors with low μM activities and increasing apoptosis 20−30 times in cancer cells with high Akt activity and 4−5 times in those with low activity (*19*, *20*). Results such as these demonstrate the importance of PIP_n-protein interactions in disease and suggest that small molecule modulators of these processes are an attractive new avenue for therapeutics (*21*, *22*).

Presentation of the PIP_n ligand in liposomes has been a common technique employed to mimic the cell membrane for binding studies. For example, binding between the effector domain of the myristoylated alanine-rich C kinase substrate (MARCKS) and PI(4,5)P_2 has been measured using sucrose laden vesicles (*23*) and vesicles containing spin labeled (*24*) and fluorescently labeled PI(4,5)P_2 analogues (*25*). PIP_n-containing liposomes have found extensive use in surface plasmon resonance (SPR) measurements of the PHD finger of ING2 (*16*), mammalian PH domains (*26*), and a recent genome-wide analysis of yeast PH domains (*27*). However, liposomes have some drawbacks, in particular, their instability and short lifetime. After 24−48 h at 4 °C, the carefully

prepared unilamellar liposomes begin to fuse and form an irregular mixture of sizes. Thus, new batches need to be frequently prepared leading to potential inconsistencies and difficulties in experimental reproducibility. To make more robust liposomes capable of providing in highly reproducible data we report herein the preparation of stable, polymerized, PIP_n-containing liposomes. These new nanoparticles show properties similar to those of conventional liposomes and monomeric PIP_ns in three binding assays: liposome overlays, the amplified luminescence proximity homogeneous assay (ALPHA), and SPR.

EXPERIMENTAL PROCEDURES

General. Thin-layer chromatography was performed on 0.25 mm precoated glass plates (Merck silica gel $60F_{254}$) with detection by phosphomolybdic acid (5% in EtOH). Flash column chromatography (FCC) used Merck silica gel 60 (230−400 mesh). ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on a Varian INOVA 400 instrument. Coupling constants are recorded in Hz and chemical shifts in ppm. Mass spectra were measured at the University of Utah Medicinal Chemistry Department using matrix-assisted laser desorption ionization (MALDI). Bis-10,12-tricosadiynoyl-phosphatidylcholine and -phosphatidyletheanolamine (diyne-PC and diyne-PE) were purchased from Avanti Polar Lipids (Alabaster, AB). Biotin-X, succinimide ester was purchased from Invitrogen (Eugene, OR). All other reagents were purchased from Aldrich or Acros and used without further purification. *N*-Succinimidyl-10,12-pentacosadiynoate was prepared from 10,12-pentacosadiynoic acid (GFS Chemicals Inc) as previously described (*28*). Aminopropyl-Ins(1,3,4)-P_3, −Ins(1,4,5)P_3, and −Ins(1,3,4,5)P_4 were synthesized according to established protocols (*29*−*31*). DiC_8-PIP_ns, acyl-biotinylated PIP_ns, and anti-PIP_n mAbs were from Echelon. PH domain GST fusions were prepared at Echelon except for Akt-PH (Upstate Biotech).

1-*O*-(10,12-Pentacosadiynylaminopropyl-1-phospho)-*myo*-inositol-4,5-diphosphate (triethylammonium salt) (1a). A solution of *N*-succinimidyl-10,12-pentacosadiynoate (7.0 mg, 14.8 mmol) in DMF (0.6 mL) was added to a solution of (3-aminopropyl-1-phospho)-*myo*-inositol-4,5-diphosphate, sodium salt (5.8 mg, 9.8 mmol) in TEAB (0.5 M, 0.6 mL, pH 7.8). THF (∼10 drops) was added to the suspension to dissolve solids, and the reaction was stirred in the dark for 16 h. The reaction mixture was dried in vacuo, and the solid residue was washed with acetone (5 × 1.5 mL). The product was dissolved in water, passed through a short column (4 × 40 mm) of DOWEX 50 × 8−100 (triethylammonium form) to convert the product from the sodium salt, then lyophilized. Yield: 10.6 mg (77%). ^1H NMR (400 mHz, D_2O, free acid) δ 0.79 (m, 3H), 1.20 (m, 26H), 1.43 (m, 4H), 1.72 (m, 2H), 1.88 (quin, J = 6.0 Hz, 2H), 2.10 (m, 6H), 3.04 (t, J = 7.2 Hz, 2H), 3.58 (dd, J = 9.6, 2.8 Hz, 1H), 3.77−3.98 (m, 5H), 4.10−4.17 (m, 2H). ^{31}P NMR (D_2O, 162 MHz) δ 0.61, 3.20, 3.66 (1:1:1). MALDI-TOF MS: 832.0 $(M - H)^-$ (free acid).

1-*O*-(10,12-Pentacosadiynylaminopropyl-1-phospho)-*myo*-inositol-3,4-diphosphate (triethylammonium salt) (1b). The same procedure was followed as for **1a**. ^1H NMR (400 MHz, CD_3OD, 3-$TEAH^+$ salt) δ 0.89 (t, J = 6.4 Hz, 3H), 1.28 (m, 24H), 1.30 (t, J = 7.6 Hz, 27H), 1.50 (quin, J = 6.8 Hz, 4H), 1.59 (m, 2H), 1.79 (quin, J = 5.6 Hz, 2H), 2.15−2.21 (m, 2H), 2.23 (t, J = 8.0 Hz, 4H), 3.19 (quart, J = 7.6 Hz, 18H), 3.47 (t, J = 8.4 Hz, 1H), 3.86 (t, J = 9.2 Hz, 1H), 3.95 (m, 3H), 1.38 (m, 4H), 4.10 (t, J = 9.2 Hz, 1H), 4.41 (quart, J = 8.8 Hz, 1H). ^{31}P NMR (162 MHz, CD_3OD) δ 1.50, 1.79, 2.87 (1:1:1). MALDI-TOF MS: 832.1 $(M - H)^-$ (free acid).

1-*O*-(10,12-Pentacosadiynylaminopropyl-1-phospho)-*myo*-inositol-3,4,5-trisphosphate (triethylammonium salt) (1c). The same procedure was followed as for **1a**. ^1H NMR (400 MHz, CD_3OD) δ 0.89 (J = 6.8 Hz, t, 3H), 1.28 (m, 26 H), 1.30 (J = 6.8 Hz, t, 45H), 1.49 (J = 7.2 Hz, quin, 4H), 1.79 (m, 2H), 2.19 (J = 8.0 Hz, t, 2H), 1.58 (m, 2H), 2.23 (J = 6.8 Hz, t, 4H), 3.19 (J = 7.2 Hz, quart, 30H), 3.91−4.19 (m, 5H), 4.41 (m, 2H), 4.56 (m, 1H). ^{31}P NMR (162 MHz, CD_3OD) δ 1.33, 1.87, 2.20 (2:1:1). MALDI-TOF MS: 912.2 $(M - H)^-$ (free acid).

Biotin-diyne-PE. NEt_3 (10 μL, 72 μmol) was added to a solution of Biotin-X, succinimde ester (11.6 mg, 25 μmol) and diyne-PE (17.7 mg, 20 μmol) in chloroform (2 mL), and the reaction was stirred at room temperature for 2 h. The solution was evaporated to half the volume and purified by flash column chromatography (70:20:4 $CHCl_3$:MeOH:concentrated NH_4OH). Yield: 22.8 mg (95%). ^1H NMR (400 MHz, $CDCl_3$) δ 0.87 (t, J = 6.8 Hz, 6H), 1.22−1.76 (m, 70H), 2.20 (m, 4H), 2.23 (t, J = 7.2 Hz, 8H), 2.28 (q, J = 7.2 Hz, 4H), 2.75 (d, J = 12.8 Hz, 1H), 2.89 (dd, J = 12.8, 4.8 Hz, 1H), 3.01−3.12 (m, 3H), 3.14 (q, J = 4.4 Hz, 1H), 3.21 (q, J = 6 Hz, 2H), 3.46 (d, J = 4.0 Hz, 2H), 3.92−4.06 (m, 5H), 4.26−4.39 (m, 2H), 4.51 (dd, J = 4.8 Hz, 1H), 5.21 (m, 1H), 6.73 (bs, 1H), 6.94 (bs, 1H), 7.39 (bs, 1H). ^{13}C NMR (101 MHz $CDCl_3$) δ 8.79, 14.32, 19.42, 22.89, 25.03, 25.07, 25.37, 25.74, 26.52, 27.96, 28.06, 28.55, 28.57, 29.02, 29.08, 29.16, 29.31, 29.34, 29.51, 29.69, 29.77, 32.10, 32.68, 34.25, 34.43, 35.71, 36.34, 39.41, 40.85, 45.90, 55.97, 60.49, 62.10, 64.21, 65.18, 65.44, 65.54, 173.62, 173.63, 173.72, 173.97. ^{31}P NMR (162 MHz, $CDCl_3$) δ 0.88. MALDI-TOF MS: 1209.3 $(M - H)^-$ (free acid).

Polymerized Liposome Preparation The following details a typical preparation of polymerized liposomes. Lipid constituents 1,2-bis(10,12-tricosadiynoyl-*sn*-glycero-3-phosphatidylcholine (diyne-PC), 1,2-bis(10,12-tricosadiynoyl-*sn*-glycero-3-phosphatidylethanolamine (diyne-PE) (Avanti Polar Lipids,), $InsP_n$-diyne, and biotin-diyne-PE) were dissolved in $CHCl_3$/MeOH (9:1) and dried to a film on a rotary evaporator then dried further under high vacuum for 2 h. The proportions were typically 65:24:10:1 or 65:29:5:1 diyne-PC:diyne-PE:$InsP_n$-diyne:biotin-diyne-PE [mol %]. Deionized water was added to give a 1 mM (total lipid) suspension. The mixture was heated to 70 °C and probe sonicated (Fisher Scientific 60 Sonic Dismembrator, setting 8) for 30 min, forming a clear solution. The solution was cooled to 4 °C for 2 h and then polymerized by UV irradiation (254 nm) at the same temperature using a handheld lamp. The faintly red solutions were filtered through 0.45 μm cellulose acetate syringe filters to remove any insoluble aggregates. Liposome solutions were stored at 4 °C in amber vials with 0.02% sodium azide to prevent bacterial growth.

Liposome Overlay Assays. Aliquots of the desired protein solutions were spotted on a piece of nitrocellulose membrane (Hybond-C, Amersham Life Sciences) by hand and the membrane was allowed to dry for 5 min. The membrane was blocked for 2 h in blocking buffer (PBS (10 mM sodium phosphate, 138 mM NaCl, 2.7 mM KCl, pH 7.4), 3% BSA) at room temperature. The membrane was incubated in the polymerized liposome solution (5 μg/mL in PBS, 3% BSA) for 1 h at room temperature. The membrane was washed (4 × 10 min) in blocking buffer, then incubated in streptavidin-horseradish peroxidase (1:50 000) (Biosource International) in blocking buffer for 30−60 min at room temperature. Finally, the

membrane was washed with blocking buffer (5 × 10 min), and then visualized with enhanced chemiluminescence (ECL, Amersham plc). Exposure times varied from 5 s to 2 min.

Far Western/Liposome Overlay. Samples of PLCδ1-, Grp1-, LL5α-, and FAPP−PH domains (5, 1, or 0.1 μg) were dissolved in 13.3 μL of Laemilli buffer (Bio Rad Laboratories Inc.) then diluted to 20 μL with water. The samples were applied to the lanes of a 12% polyacrylamide gel, electrophoresed for 1.25 h at 100 V, and then electrotransferred to nitrocellulose in tris/glycine/SDS buffer at 300 mA for 70 min. The membrane was washed with PBS (2 × 5 min) and then subsequently treated with 6, 3, 1, and 0.1 M guanidine buffers (25 mM NaCl, 10% glycerol, 1 mM DTT) for 1 h each to renature the proteins followed by incubating with the blocking buffer overnight at 4 °C. The membrane was treated with 3 μg/mL PI-(4,5)P_2 liposomes in blocking buffer for 1 h, and the subsequent steps were identical to those described above for the overlay assay.

Alphascreen Assays. Alphascreen assays were performed on a Fusion instrument (Perkin-Elmer, Inc.) using standard settings and the recommended buffer (50 mM Tris pH 7.5, 150 mM NaCl, 0.1% Tween-20, 0.1% BSA). In a 384-well microplate was added 10 μL of buffer followed by 5 μL each of the GST-PH domain ([PLCδ1-PH] = 7.5 nM, [Akt-PH] = 92 nM, [Grp1-PH] = 8.4 nM final concentrated) and liposomes (0.01−10 uM PIP_n ligand). A solution of anti-GST acceptor beads and streptavidin donor beads (5 μL, 5 μg/mL) were added, the plate was gently shaken, stored for 2 h in the dark, and read on the Fusion instrument. For competition experiments, solutions of diC_8-PIP_ns (Echelon Biosciences Inc.) or biotin-free liposomes at varying concentrations were incubated with PLCδ1-PH (7.52 nM final concentrated) in buffer (10 μL) for 1 h in a 384-well microplate followed by addition of liposomes (0.20 μM final concentrated) and acceptor and donor beads (5 μL, 5 μg/mL). The plate was incubated in the dark for another hour and the luminescence was measured. Data were graphed and analyzed (nonlinear regression) using GraphPad Prism version 4.00 for Windows (GraphPad Software).

Surface Plasmon Resonance. Interaction analysis was conducted at 20 °C using a Biacore 2000 biosensor (Biacore AB) equipped with a CM5 sensor chip. Streptavidin was immobilized onto the sensor surface (CM5) at 23 °C using a standard three step amine-coupling approach in HBS running buffer (10 mM HEPES pH 7.4, 150 mM NaCl). First, all flow cells were activated by injecting a freshly mixed solution of 50 mM NHS in 200 mM EDC for 7 min. Second, streptavidin (ImmunoPure grade, Pierce Biotechnology, Inc.) was reconstituted in 10 mM sodium acetate at pH 5.0 to ~1 mg/mL and injected for 7 min. Finally, excess activated esters were blocked by treating them with 1 M sodium ethanolamine at pH 8.5, using a 7-min pulse. Liposome solutions (100 nM in HBS) and biotin-PIP_ns (200−250 nM in HBS) were diluted 10-fold in HBS running buffer and injected across individual flow cells at a flow rates of 5 or 10 μL/min until the desired loading was obtained. Fresh ligand surfaces were post-conditioned by injecting three 30 s pulses of 5 mM NaOH at 100 μL/min. Unmodified streptavidin flow cells served as reference and control surfaces. Antibodies were diluted into HBS running buffer supplemented with 0.5 mg/mL BSA and injected at 100 μL/min. The surfaces were regenerated with a single 15 s pulse of 10 mM H_3PO_4. PH domain samples were diluted into modified running buffer (10 mM HEPES pH 7.4, 150 mM NaCl, 2% v/v glycerol, and 0.1 or 0.5 mg/mL BSA (for PLCδ1-PH and Grp1-PH, respectively)) and injected at 30 or 100 μL/min (for PLCδ1-PH and Grp1-PH respectively) across all surfaces. A single pulse of 5 mM NaOH was used to regenerate the surfaces. Binding responses were referenced by subtracting the response generated across an unmodified streptavidin flow cell, and double referenced by subtracting an average buffer response (from at least two blank injections). The kinetic parameters were obtained by fitting globally to a mass transport model ($[A_0] = [A]$, $[A] + [B] = [AB]$, where A_0 = injected analyte, A = analyte concentration at surface, B = immobilized ligand, AB = bound complex).

RESULTS AND DISCUSSION

Polymerized liposomes (vesicles) offer an attractive method of presenting multiple ligands in a stable membrane mimetic system. In a highly ordered state, diacetlyenes can be polymerized by UV light (254 nm) to form a conjugated enyne system (Figure 1A). Thus, when diacetylene amphiphiles are formed into vesicles and irradiated, polymerized vesicles are created (*32*). Poly(diacetylene) (PDA) liposomes are not disrupted by organic solvents or osmotic shock and show no evidence of fusion into larger aggregates over time (*32*, *33*).

Polymerizable inositol polyphosphate ($InsP_n$)-diynes (**1a**−**c**) were synthesized from the aminopropyl analogues of Ins(1,4,5)P_3, Ins(1,3,4)P_3, and Ins(1,3,4,5)P_4 via the *N*-hydroxysuccinimide ester of 10,12-pentacosadiynoic acid as shown in Figure 1B. $InsP_n$s rather than acyl-labeled PIP_ns were chosen for two reasons. First, using a simple aminopropyl linker shortens the synthesis facilitates handling of the required headgroup. Since the headgroup will be anchored to the membrane through the diyne acyl group, incorporating the diacylglycerol seemed unnecessary. Second, $InsP_n$ probes have demonstrated effectiveness in mimicking a biologically relevant context (*21*). For instance, Ins(1,4,5)P_3- and Ins(1,3,4,5)-P_4-tethered resins have been used in affinity purification of PI(4,5)P_2 and PI(3,4,5)P_3 binding proteins with equal to or greater efficacy than PI(4,5)P_2 or PI(3,4,5)P_3 resins (*21*, *34*). Similar results have been observed for photolabeling proteins with PIP_n vs $InsP_n$ probes (*21*, *35*). To act as a detection tag, biotin-diyne-PE was synthesized from commercially available diyne-PE by condensation with the active ester of biotin-X (Figure 1C). Sonication of aqueous dispersions of the lipids at 70 °C gave liposomes, appearing as clear or slightly opaque solutions at concentrations of 1 mM (total lipid). The PIP_n component constituted 1−10 mol % of the total lipids. Irradiation of the cooled solutions at 254 nm polymerized the acyl chains resulting in a faintly red color. Liposome suspensions up to 5 mM total lipid could be prepared but at that point, the viscosity increased dramatically when polymerized. For the remainder of this report, the polymerized liposomes will often be referred to simply as liposomes unless otherwise indicated.

PI(4,5)P_2 and PI(3,4,5)P_3 liposomes were analyzed using a liposome overlay assay with immobilized PIP_n-binding proteins. In this assay, the polymerized liposomes are incubated with proteins bound on a membrane and binding interactions are detected via the biotin tag (a scheme of the steps is shown in Figure 2A). First, solutions of GST fusions of the PH domains of PLCδ1, Grp1, LL5α, DAPP, and/or FAPP were spotted on nitrocellulose in varying amounts (0.021−21 pmol). Next, the membranes were incubated with a solution of polymerized liposomes in PBS containing 3% BSA (to prevent nonspecific binding to nitrocellulose), followed by treat-

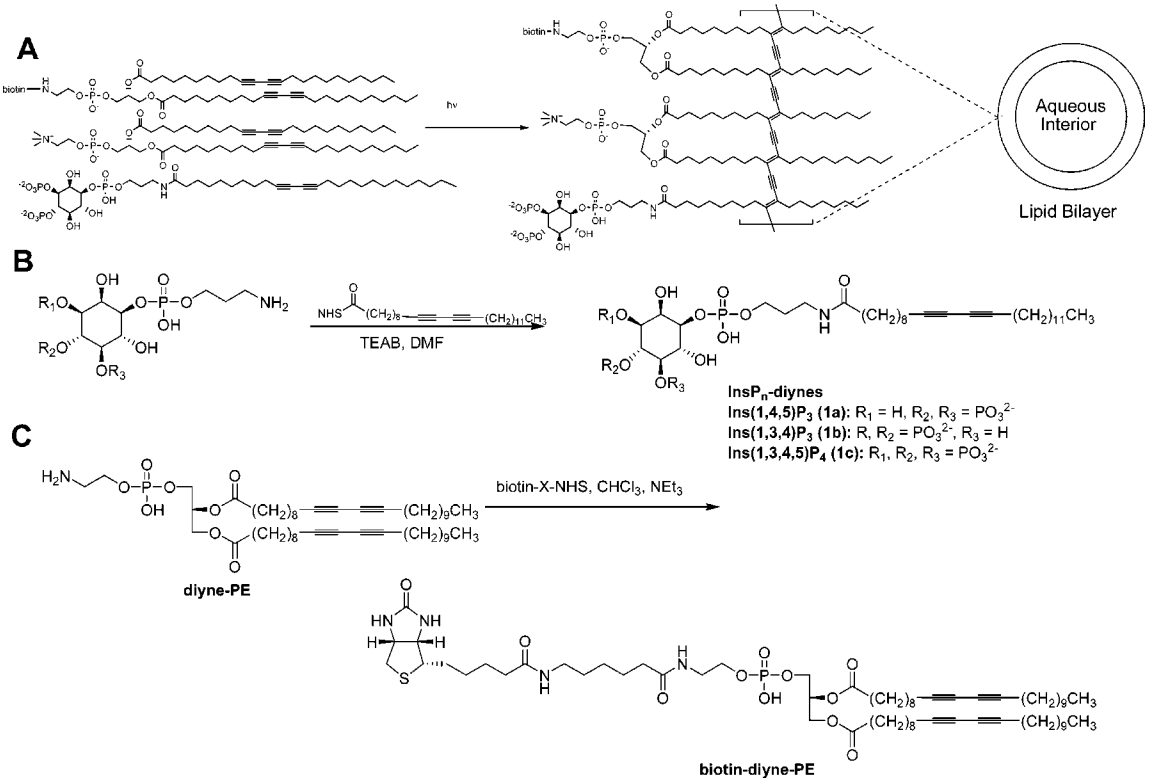

Figure 1. (A) Schematic representation of the polymerization of monomeric lipids in the outer layer of a liposome, (B) synthesis of InsP$_n$-diynes, and (C) synthesis of diyne-PE-biotin.

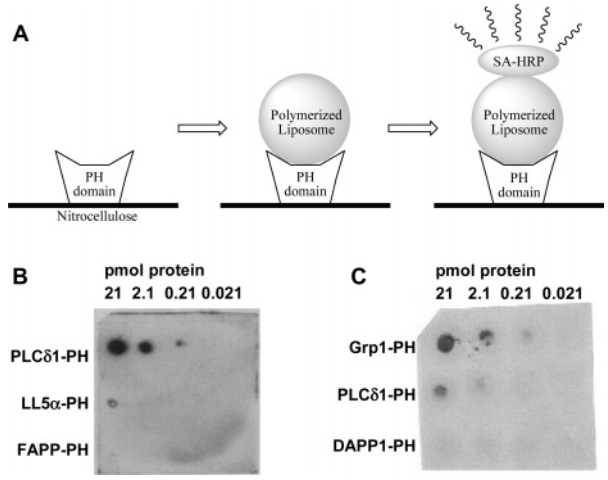

Figure 2. Detection of nitrocellulose immobilized PH domains by polymerized liposomes in liposome overlay assays. (A) Schematic of steps in the liposome overlay assay. (B) PLCδ1-PH was selectively recognized by PI(4,5)P$_2$ liposomes. (C) Grp1-PH was selectively detected by PI(3,4,5)P$_3$ liposomes.

ment with streptavidin−horseradish peroxidase (SA-HRP) and chemiluminescent detection. As shown in Figure 2B, PLCδ1-PH was detected preferentially by the PI(4,5)P$_2$ liposomes down to 0.21 pmol (10 ng) while FAPP-PH which binds PI(4)P was not detected. LL5α-PH is a promiscuous PIP$_n$ binder and was recognized at 21 pmol, which is consistent with its weaker affinity for all PIP$_n$s. PI(3,4,5)P$_3$ liposomes bound preferentially to Grp1-PH down to 0.21 pmol (10 ng) but did show some cross reactivity with PLCδ1-PH (Figure 2B). Importantly, binding was not observed using liposomes prepared without Ins(1,4,5)P$_3$-diyne clearly demonstrating that the observed interactions are due to the PIP$_n$ headgroups (data not shown). Similar experiments with conventional liposomes showed essentially identical specificity but

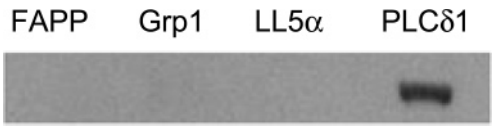

Figure 3. Detection of electrophoresed PH domains by polymerized liposomes. PH domain proteins were electrophoresed and electrotransferred to nitrocellulose and PLCδ1-PH (5 μg) was selectively recognized by PI(4,5)P$_2$ liposomes in a liposome overlay assay.

approximately 10-fold greater sensitivity than polymerized liposomes (data not shown). Nonetheless, the anticipated benefit of the polymerized liposomes was their stability compared with conventional liposomes. Thus, no appreciable differences in specificity or detection limits were observed between freshly prepared PI(4,5)P$_2$ polymerized liposomes and an older batch that had been stored at 4 °C for six months.

The polymerized liposomes could also be used to specifically detect electrophoretically separated proteins in a fashion analogous to a Western blot. PH domains were separated on SDS−PAGE, electrotransferred onto nitrocellulose, and partially renatured in guanidinium hydrochloride, and then the membrane was treated as described above for the overlay experiments. As shown in Figure 3, PLCδ1-PH (5 μg) was selectively detected using PI(4,5)P$_2$ liposomes compared with FAPP−PH and Grp1-PH; however, LL5α-PH was not detected likely due to lower affinity. As little as 1 μg of protein could be detected, and this sensitivity was increased when DTT was replaced with a glutathione redox pair at the expense of an increase in background. The detection limit was not as low as the overlays described above which we attribute to incomplete renaturation of the PH domains. In a related application, Elkin et al. employed the polymerized liposomes in liposome pull-down assays to confirm the PIP$_n$ binding specificity of the PHD finger containing RAG2 (*36*). RAG2 is essential for generating

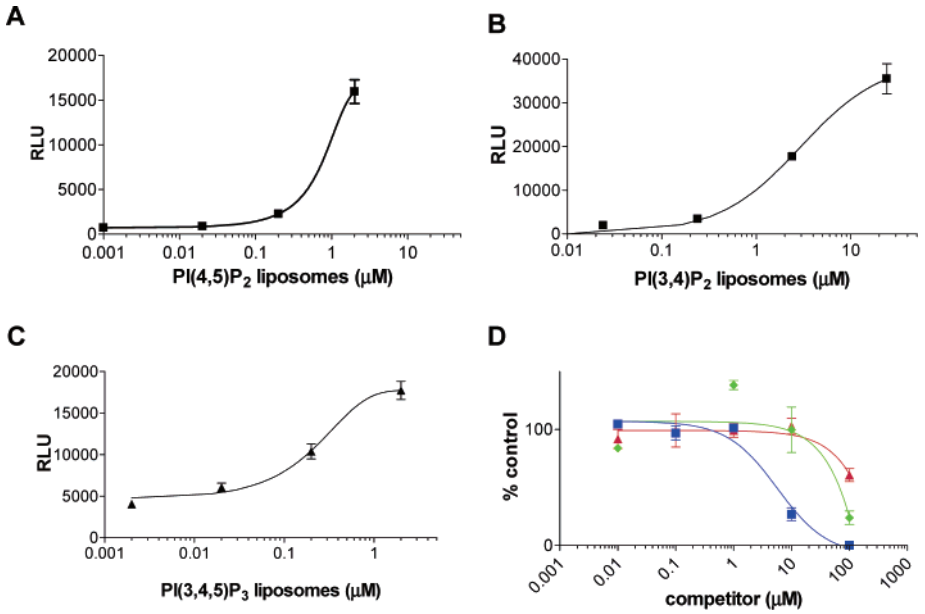

Figure 4. Alphascreen binding and competition assays for liposome-PH domain interactions. Dose-dependent binding was demostrated for: (A) $PI(4,5)P_2$ liposomes and PLCδ1-PH (7.5 nM), (B) $PI(3,4)P_2$ liposomes and Akt-PH (92 nM), and (C) $PI(3,4,5)P_3$ liposomes and Grp1-PH (8.4 nM). X-axes represent the concentration of PIP_n ligand in the assay well. (D) Competition of PIP_ns with $PI(4,5)P_2$ liposomes for binding to PLCδ1-PH. DiC_8−$PI(4,5)P_2$ (■) preferentially competed compared with diC_8-$PI(3,4)P_2$ (▲) and diC_8-$PI(3,4,5)P_3$ (◆). RLU = Relative light units.

effective immune responses by catalyzing V(D)J recombination, and it is suggested that mutations in the PIP_n-binding PHD finger alter the recombination activity leading to immunodeficiency. Additional control experiments in the report demonstrated the proteins PLCδ1-PH [$PI(4,5)P_2$], ING2-PHD [PI(5)P], p40-PX [PI(3)P], and FAPP1-PH [PI(4)P] specifically bound their known PIP_n partners [in brackets].

The second technique used to analyze the binding characteristics of polymerized liposomes was ALPHA, a bead-based platform developed by Packard Biosciences for detecting biological interactions. The AlphaScreen system uses photosensitive donor beads, which convert ambient oxygen to singlet oxygen when irradiated at 680 nm. When the donor bead comes in close proximity to an acceptor bead, through a binding event, chemiluminescent receptor and fluorescent acceptor molecules in the acceptor bead are activated by the diffusion of singlet oxygen. The resulting emission shift from 580 to 620 nm can be measured as a luminescent signal. The pairing of acyl labeled biotin-PIP_ns and PH domains in this format have been demonstrated and implemented in assays for PI 3-kinase and PTEN (*22*, *37*) suggesting that this technique would be suitable for validating the utility of the polymerized liposomes. The first experiment was designed to determine if binding occurred in this format and optimize a ratio of lipid to protein. A solution of GST-PLCδ1-PH in assay buffer was incubated with increasing amounts of $PI(4,5)P_2$-containing polymerized liposomes. Streptavidin-coated donor and anti-GST-coated acceptor beads were added and allowed to incubate for 120 min, followed by measurement of the luminescence output. Increasing luminescence was observed with increasing amount of $PI(4,5)P_2$-containing nanoparticles indicating dose-dependent binding to PLCδ1-PH (Figure 4A). The concentration on the *X*-axis represents the concentration of $PI(4,5)P_2$ ligand in the assay well. In addition, $PI(3,4)P_2$- and $PI(3,4,5)P_3$-containing polymerized liposomes bound to Akt-PH and Grp1-PH domains respectively in a dose-dependent manner (Figures 4B and 4C). At higher liposome concentrations, the luminescence dropped off, likely due to saturation of the donor beads and competition by unbound vesicles.

A second experiment examined the ability of small soluble PIP_ns to compete with liposomes for protein binding. As observed in Figure 4D, diC_8-$PI(4,5)P_2$ preferentially competed with $PI(4,5)P_2$ liposomes compared with diC_8-$PI(3,4)P_2$ and $PI(3,4,5)P_3$ for binding to PLCδ1-PH. Similarly, $PI(4,5)P_2$ liposomes, prepared without diyne-PE-biotin, caused a decrease in luminescence by competing with biotinylated-$PI(4,5)P_2$ liposomes while nonbiotinylated $PI(3,4)P_2$ liposomes could not compete at concentrations up to 500 pmol/well confirming specificity (data not shown). Both experiments show that $PI(4,5)P_2$ liposomes are selectively recognized in solution by PLCδ1-PH.

The final technique employed SPR to analyze the polymerized liposomes. SPR measurements of PIP_n-protein interactions have typically used two methods of immobilizing lipids to chip surfaces to mimic membranes: (i) trapping liposomes onto a hydrophobic dextran surface (e.g. L1 chip from Biacore), or (ii) collapsing liposomes to form a lipid monolayer on the chip (e.g. HPA chip from Biacore). Initial experiments with $PI(4,5)P_2$-polymerized liposomes used a hydrophobic L1 chip for direct capture of vesicles. Although the vesicles were captured and protein binding was observed, the results were not reproducible, but some clues as to optimum running and regeneration conditions were elucidated.

In contrast, streptavidin-coated sensor chips gave outstanding results with the biotinylated nanoparticles. Thus, the biotinylated polymerized liposomes were compared with acyl-biotinylated PIP_ns for binding to PIP_n-specific monoclonal antibodies (mAbs) and PH domains. Two anti-PIP_n mAbs, an anti-$PI(3,4)P_2$ IgG and anti-$PI(4,5)P_2$ IgM, were analyzed against their respective cognate ligands. As shown in Figure 5A−D the anti-$PI(3,4)P_2$ IgG bound to both $PI(3,4)P_2$ surfaces as did the anti $PI(4,5)P_2$ IgM to the $PI(4,5)P_2$ surfaces. The responses for the liposomes are concentration-dependent and reproducible for both cases. Binding was undetectable over an unmodified streptavidin control surface

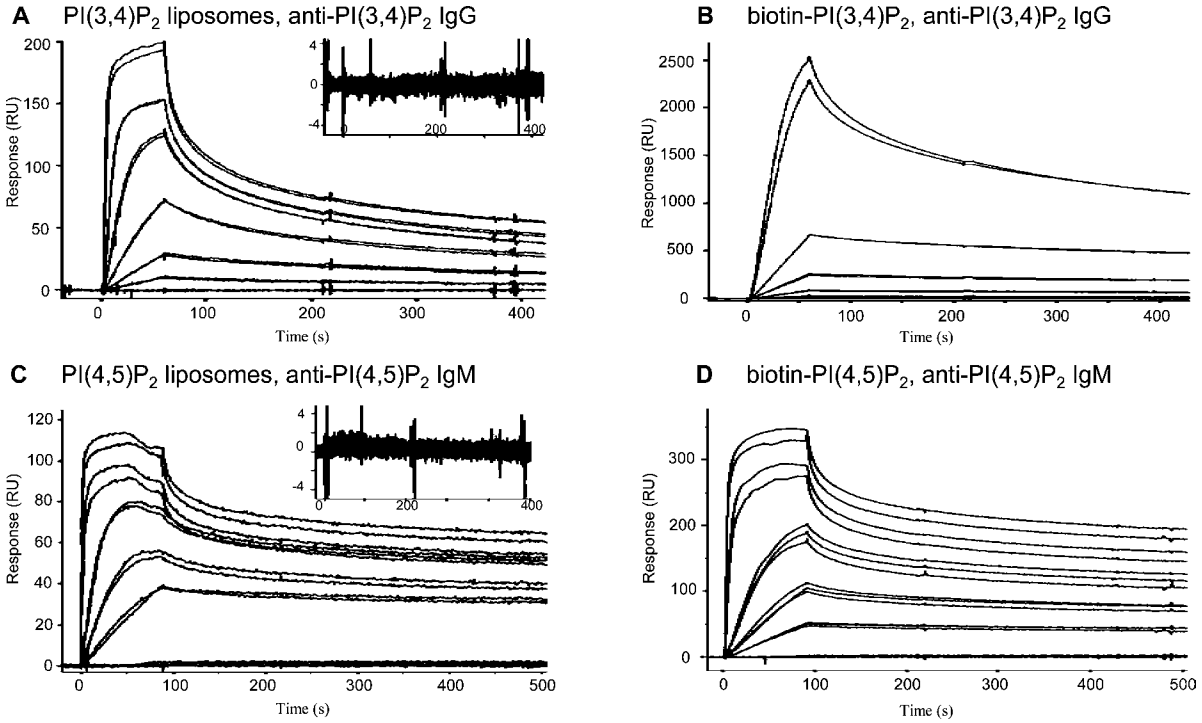

Figure 5. Sensorgrams comparing anti-PIP_n mAbs binding to polymerized liposome and biotin-PIP_n surfaces. Binding of anti-PI(3,4)P_2 IgG (0.3, 0.8, 2.4, 7.3, 22, and 66 nM) to (A) PI(3,4)P_2-liposome and (B) biotin-PI(3,4)P_2-coated streptavidin chips at 20 °C (100 μL/min). Anti-PI(4,5)P_2 IgM (0.8, 2.5, 7.4, 22.4, 66.6, and 200 nM) binding to (C) PI(4,5)P_2 liposome and (D) biotin-PI(4,5)P_2 at 20 °C (100 μL/min). The insets in parts A and C show the lack of binding to control surfaces. Surfaces were regenerated with single pulses of 10 mM H_3PO_4 (15 s.).

(insets, Figures 5A and C), demonstrating that the binding signals detected over the biotin PIP_n and liposome surfaces are specific to the PIP_n surfaces (0.5 mg/mL BSA was included in the running buffer to minimize nonspecific binding to unmodified sensor chip surfaces). Kinetically, the interactions are limited by mass transport as described by the linear slopes during the association phase. The shapes appear slightly different between the PI(3,4)P_2-containing polymerized liposome vs biotin-PI(3,4)P_2 surfaces due to mass transport. The biotin-PIP_n surface has a much higher capacity and is therefore limited more by mass transport. The bivalent nature of the mAbs contributes to avidity effects making it challenging to determine binding rate constants. No binding was detected when anti-PI(3,4,5)P_3 IgM was injected over the PI(4,5)P_2 surfaces at 200 nM indicating specific interactions between the anti-PI(4,5)P_2 mAb and the PI(4,5)P_2 liposomes (data not shown).

PH domain binding was analyzed under slightly modified conditions, 2% glycerol was included in the running buffer which helped stabilize the protein in addition to BSA. High-resolution data were collected across similar capacity PI(4,5)P_2-liposome and biotin-PI(4,5)P_2 surfaces by randomly injecting PLCδ1-PH ranging in concentration from 200 to 3.1 nM in duplicate at 30 μL/min (Figure 6A and B). After each run, the sensor chips were regenerated with single pulse of 5 mM NaOH. Binding responses were concentration dependent and reproducible. At concentrations above 100 nM, protein appeared to saturate all binding sites on the liposome surface, but not the biotin-PI(4,5)P_2 surface. The reactions were analyzed globally using a mass transport model, which provided a reasonable fit to the measured data. As shown in Table 1A, PLCδ1-PH bound with a sixteen-fold higher affinity to the liposome surface than to the biotin-PI(4,5)-P_2 surface. The on-rates (k_a) for the two surfaces were fairly similar but the off-rate (k_d) was 8.5-fold slower for the liposome surface. The slower off-rates could be due to hydrophobic interactions between proteins and the bilayer interior and/or an avidity effect of close proximity of multiple headgroups on the vesicle surface.

Table 1. Kinetic Studies into the Binding of (A) PLCδ1-PH and (B) Grp1-PH to Monomeric PIP_ns and Polymerized Liposomes by SPR[a]

	k_a (M^{-1} s^{-1})	k_d (s^{-1})	K_D(nM)
	(A) PLCδ1-PH		
PI(4,5)P_2 liposomes	1.2×10^6	7.9×10^{-3}	6.6
Biotin-PI(4,5)P_2	8.9×10^5	9.3×10^{-2}	104
	(B) Grp1-PH		
PI(3,4,5)P_3 liposomes	3.9×10^5	9.5×10^{-4}	2.5
Biotin-PI(3,4,5)P_3	1.7×10^5	2.1×10^{-3}	12

[a] The kinetic parameters were obtained by fitting globally to a mass transport model. This gave the association rate constant (k_a) and the dissociation rate constant (k_d) which yielded the equilibrium dissociation constant (K_D).

Grp1-PH was assayed under essentially identical conditions, except that BSA was increased to 0.5 mg/mL and the flow rate was increased to 100 μL/min (Figure 6C and D). Data were fit globally using a mass transport model (Table 1B) and revealed that Grp1-PH bound biotin-PI(3,4,5)P_3 probe with a 5-fold lower affinity (K_D = 12 nM) than the PI(3,4,5)P_3 liposome surface (K_D = 2.5 nM). As with the PLCδ1-PH/PI(4,5)P_2 interactions, the liposome surfaces interacted more strongly with the protein. However, the on- and off-rates were both approximately 2.3-fold faster and slower respectively for the liposome surface, both contributing equally to the increase in affinity. The improved binding to the liposome surfaces for both proteins could be due to hydrophobic interactions between proteins and the bilayer interior and/or an avidity effect of close proximity of multiple headgroups on the vesicle surface, both of which would be missing from the acyl-linked surfaces.

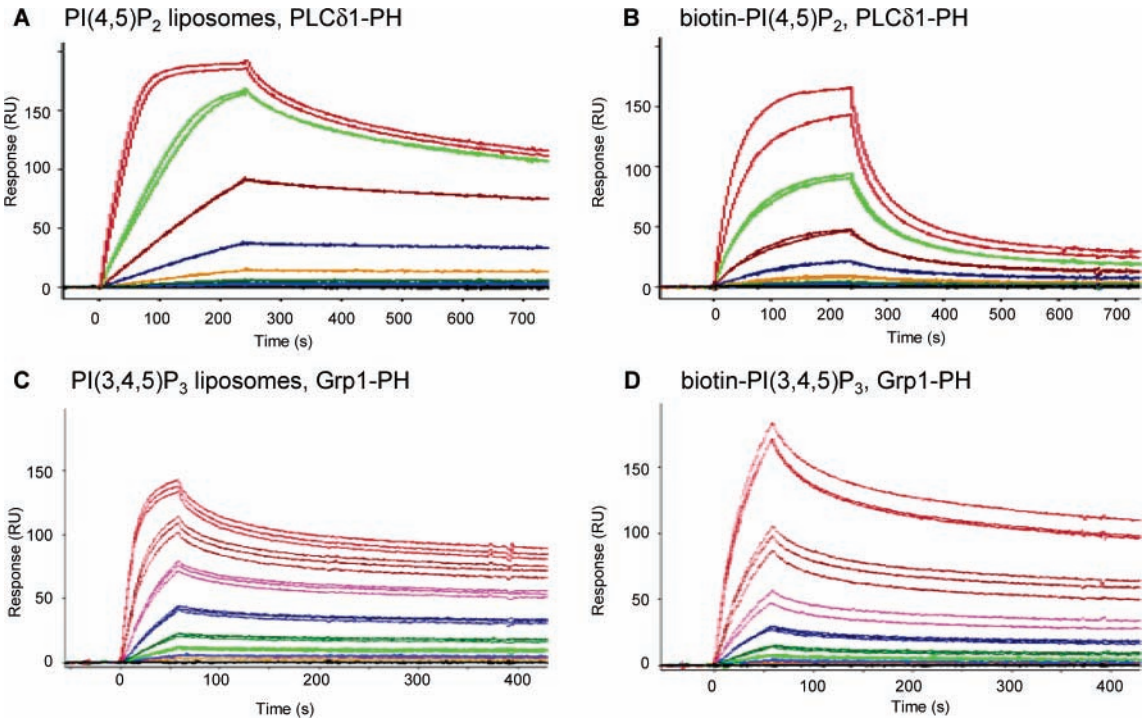

Figure 6. Sensorgrams comparing PH domain binding to polymerized liposome and biotin-PIP$_n$ surfaces. PLCδ1-PH (0, 3.1, 6.3, 12.5, 25, 50, 100, 200 nM) binding to (A) PI(4,5)P_2-liposome and (B) biotin-PI(4,5)P_2-coated streptavidin chips at 20 °C (30 μL/min). Grp1-PH (1.4, 2.7, 5.4, 10.9, 21.8, 43.5, 87, 173 nM) binding to (C) PI(3,4,5)P_3-liposome and (D) biotin-PI(3,4,5)P_3-coated streptavidin chips at 20 °C (100 μL/min). Surfaces were regenerated with pulses of 5 mM NaOH.

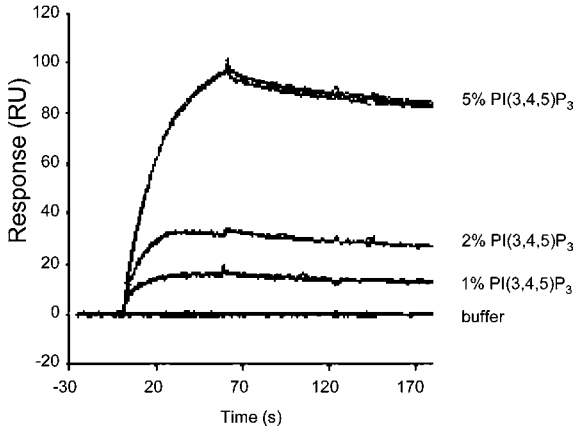

Figure 7. Grp1-PH binding to varying mol % PI(3,4,5)P_3-liposome surfaces by surface plasmon resonance. The overlay plot of 173 nM Grp1-PH injected across three polymerized liposome surfaces (1, 2, and 5% PIP_3) at 20 °C (100 μL/min) shows increasing signal comparable to the increasing PI(3,4,5)-P_3 composition in the liposomes. Probe surfaces were regenerated with a single 30-s pulse of 25 mM NaOH.

To examine the effect of varying ligand concentrations within the vesicles, additional liposomes were prepared with 1, 2, and 5 mol % PI(3,4,5)P_3 and analyzed (for the previous experiment, the PI(3,4,5)P_3 proportion in the vesicles was 10 mol %). As expected, the binding capacity increased with mol % PI(3,4,5)P_3 (Figure 7). Of these probes, results with the 5% preparation were superior as these polymerized liposomes afforded surfaces that were the easiest to regenerate between runs. The affinities of the two other preparations were judged to be comparable but did not regenerate as well, requiring a 5-fold increase in NaOH to 25 mM. For all of the SPR experiments conducted, the data deviated from the simulated data, most notably in the dissociation phase. This suggested that, as expected for a multivalent ligand, the mechanism was complex and that simple bimolecular models were not applicable.

Finally, to investigate the selectivity of PI(3,4,5)P_3 liposomes for Grp1-PH, competition studies were undertaken using water soluble diC_8-PI(3,4,5)P_3 and diC_8-PI-(4,5)P_2. The competitors at varying concentrations were preincubated with the protein and then passed over the PI(3,4,5)P_3-liposome chip surface. As shown in Figure 8, increasing diC_8-PI(3,4,5)P_3 competed with the liposome surface to bind Grp1-PH causing a decrease in response with almost complete competition at 87 nM. DiC_8−PI-(4,5)P_2 did not effectively compete until much higher concentrations, with essentially complete competition at 21 μM. This demonstrates the strong selective affinity of Grp1-PH for the PI(3,4,5)P_3-liposome surface as it is only interrupted by the presence of an analogue of the natural ligand.

In this report, we describe the preparation of stable polymerized PIP$_n$-containing vesicles. InsP_n ligands containing a pentacosadiynyl acyl chain were synthesized for Ins(1,4,5)P_2, Ins(1,3,4)P_2, and Ins(1,3,4,5)P_4, and a diyne-PE-biotin was prepared as a detection tag. Vesicles were prepared and polymerized at 254 nm and were validated in a number of formats. Liposome overlay assays using PI(4,5)P_2- and PI(3,4,5)P_3-polymerized liposomes showed selectivity comparable to that of conventional liposomes when binding to nitrocellulose-immobilized PH domains. In addition, PLCδ1-PH that had been electrophoretically separated and electrotransferred was recognized specifically by PI(4,5)P_2 liposomes in the presence of other PH domains. Polymerized liposomes were applicable the ALPHA assays, binding was observed between PI(4,5)P_2/PLCδ1-PH, PI(3,4)P_2/Akt-PH, and PI-(3,4,5)P_3/Grp1-PH. The interaction of PI(4,5)P_2/PLCδ1-PH was specifically disrupted by soluble PI(4,5)P_2. Finally, the interactions of with anti-PIP$_n$ mAbs and PLCδ1-PH and Grp1-PH were validated using SPR. The polymerized liposome nanoparticles proved to be robust

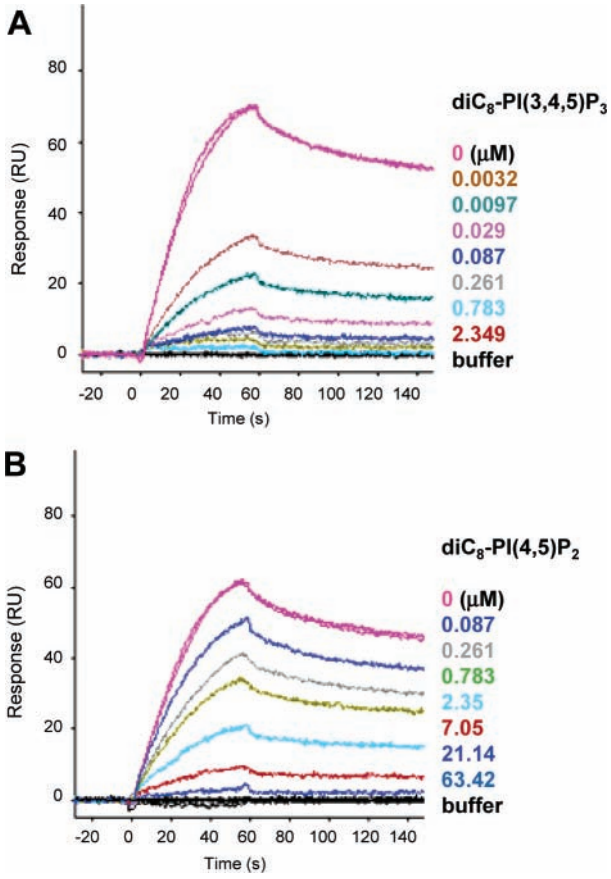

Figure 8. Sensorgrams of Grp1-PH binding to $PI(3,4,5)P_3$-liposome surfaces in the presence of water soluble PIP_ns. Grp1-PH (87 nM) was incubated with varying concentrations of competitors: (A) diC_8-$PI(3,4,5)P_3$ and (B) diC_8-$PI(4,5)P_2$ and injected over $PI(3,4,5)P_3$-liposome-coated surfaces at 20 °C (100 μL/min). Probe surfaces were regenerated with a single 30 s pulse of 5 mM NaOH. DiC_8-$PI(3,4,5)P_3$ competed at approximately 250-fold lower concentration than diC_8-$PI(4,5)P_2$.

coatings for streptavidin-coated chips and bound the PH domain proteins more strongly than the corresponding monomeric PIP_n ligands. Polymerized PIP_n-containing liposomes are thus appropriate, convenient, and biologically informative tools for studying protein lipid interactions.

ACKNOWLEDGMENT

The work in this paper was supported by a grant (R43 GM685683 to C.G.F.) from the National Institutes of Health. Additional help provided by Dr. Randy Booth (UUtah) and Ms. Heather Hudson (Echelon) were greatly appreciated

Fabrication and Application of Enzyme-Incorporated Peptide Nanotubes

Lingtao Yu, Ipsita A. Banerjee, Xueyun Gao, Nurxat Nuraje, and Hiroshi Matsui*

Department of Chemistry and Biochemistry at Hunter College and the Graduate Center, The City University of New York, New York, New York 10021. Received July 8, 2005; Revised Manuscript Received August 23, 2005

Enzyme engineering is a fast-growing field in the pharmaceutical and food markets. For those applications, various substrates have been examined to immobilize and stabilize enzymes. In this report, we examined peptide nanotubes as supports for enzymes. When a model enzyme, *Candida rugosa* lipase, was encapsulated in peptide nanotubes, the catalytic activity of nanotube-bound lipases was increased 33% as compared to free-standing lipases at room temperature. At an elevated temperature, 65 °C, the activity of lipases inside the nanotubes was 70% higher than free-standing lipases. The activity enhancement of lipases in the peptide nanotubes is likely induced by the conformation change of lipases to the open form (the enzymatically active structure) as lipases are adsorbed on the inner surfaces of peptide nanotubes.

INTRODUCTION

Enzymes are versatile biocatalysts that control specific chemical reactions effectively in vivo and in vitro (*1*−*3*). To make enzymes cost-effective, long-lived, and highly active, supports, such as sol−gels (*4, 5*), polymer membranes (*6*), silica (*7, 8*), and zeolites (*9, 10*), have been utilized to immobilize enzymes. While there are supports that enhance enzymatic activity, lifetime, and thermal stability (*4, 6, 10, 11*), some supports also decrease the lifetime and the activity of enzymes (*8, 12*). Nanometer-scale materials have potential to serve as superior enzyme supports due to their large surface-to-volume ratios in comparison with traditional macroscale materials while the reduction of substrate size may induce the deactivation and the desorption of enzymes in the processes of enzymatic reactions (*12*). Recently, the catalytic activity and the thermal stability of enzymes were reported to be enhanced when they were immobilized on magnetic nanoparticle supports (*11, 13*). To evaluate the effectiveness of nanoscale enzymatic supports, more studies in various types of nanosupports are desirable.

In this report, we explored a new nanoscale support, peptide nanotube, to immobilize enzymes inside the nanotubes. Peptide nanotubes have an advantage to immobilize enzymes on the nanotube surfaces with a simple incubation process via hydrogen bonding between amide groups of the nanotube and the complementary functional groups of proteins (*14, 15*). It is also advantageous that the adsorption of enzymes can be limited inside the peptide nanotubes via capillary effect (*16*). Previously, the coating location of peptides and nanocrystals, inside or outside the nanotubes, was controlled by optimizing concentrations of adsorbents and functionalities of nanotube surfaces (*16, 17*). In this report, a *Candida rugosa* lipase was chosen as a model enzyme to test the peptide nanotube support because the *Candida rugosa* lipase has previously shown enhancement of the enzymatic activity on other supports (*11, 13*). The enzymatic activity of *Candida rugosa* lipases inside the peptide nanotube was enhanced not only at room temperature but also at elevated temperatures as compared to free-standing lipases.

EXPERIMENTAL PROCEDURES

First, 10 mM of bis(*N*-α-amido-glycylglycine)-1,7-heptane dicarboxylate, bolaamphiphile peptide, was self-assembled into peptide nanotubes in a pH 4.5 citric acid/NaOH solution. Methods for the bolaamphiphile peptide synthesis and the nanotube self-assembly are described elsewhere (*18, 19*). After the peptide nanotubes were washed with deionized water several times, 200 μL of nanotubes in a phosphate buffer solution (pH = 7.4) was mixed with 1−20 μL of *Candida rugosa* lipase solutions, respectively. The enzyme in the peptide nanotube was protected during the incubation time of a week by keeping the sample in a refrigerator at 4 °C. After these samples were washed twice with centrifugation for 3 h to remove excess lipases in the supernatant solutions, the immobilization of lipases inside the peptide nanotubes was confirmed by transmission electron microscopy (TEM, JEOL 1200EX) at 100 kV acceleration voltage. The TEM samples were prepared by dropping 10 μL of the sample solution on carbon membrane 300 mesh copper grids and then the samples were dried completely in air. The loaded amount of lipase inside the nanotubes was determined by the colorimetric protein assay with a Bio-Rad reagent. After lipases and peptide nanotubes in the solution were separated by centrifugation, the lipase concentration in the supernatant was determined by the assay. The amount of lipases bound in the nanotubes was calculated by subtracting the lipase concentration in the supernatant from the initial lipase concentration. In this measurement, bovine serum albumin was applied as a standard. The resulting nanotubes, whose lipase loadings were determined by the assay, were used to study their activities and thermal stabilities after washing these nanotubes. To study the activities of those peptide nanotubes, 30 μL of *p*-nitrophenyl butyrate solution (13.8 mg/mL in 2-propanol) was added to 200 μL of the lipase−nanotube solution, and the mixture was balanced to 1

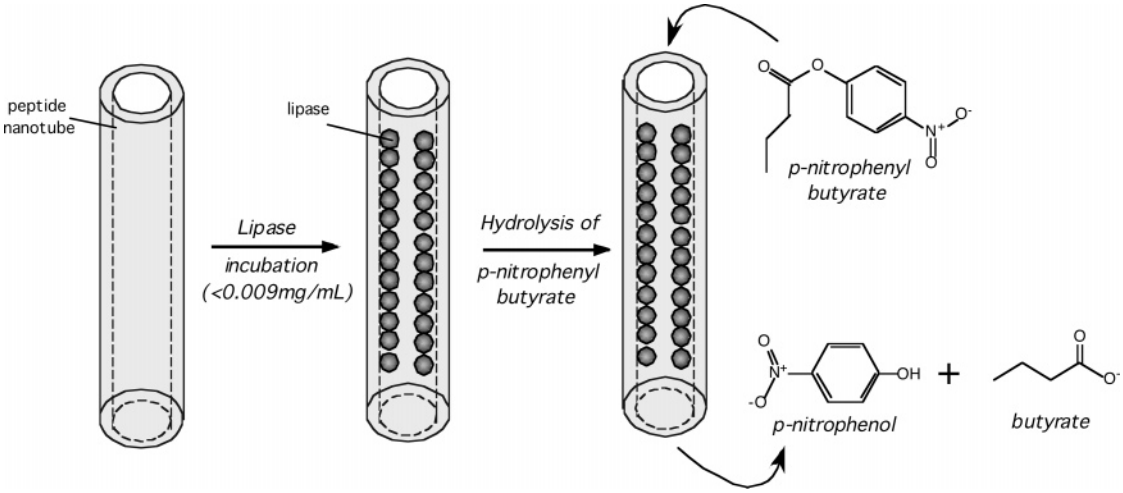

Figure 1. Illustration of lipase nanotube fabrication and its enzymatic application.

mL by a pH 7.4 buffer solution. The hydrolysis rates of *p*-nitrophenyl butyrate solutions were monitored by the product concentration, [*p*-nitrophenol], by means of UV−vis spectroscopy (Varian Cary 300 Bio). These processes are summarized in Figure 1. The thermal stability of lipases was also investigated at various reaction temperatures from 25 °C to 75 °C. In this thermal experiment, 6 μL of lipase solution was mixed with 200 μL of the nanotube solution at 4 °C for one week. After the resulting solution was diluted to 1 mL by a pH 7.4 buffer solution, the thermal stability of lipases were examined. Fluorescence studies of free-standing lipases and nanotube-bound lipases were carried out with a Jobin Ybin-SPEX, FL3-11 fluorometer. The excitation wavelength was 310 nm, and the bandwidth was 3 nm for both excitation and emission. This protocol allowed us to observe the tryptophan peak shift around 339 nm.

RESULTS AND DISCUSSION

A model enzyme, *Candida rugosa* lipase, was encapsulated within peptide nanotubes and its catalytic activity in hydrolysis of *p*-nitrophenyl butyrate was examined, as shown in Figure 1. The peptide nanotube was synthesized with the previously published method (*18, 19*). We used the peptide nanotube with the inner diameter of 160 nm, large enough to introduce substrates and lipases inside the nanotube while the ideal porous diameter of nanotube for lipase incorporation is not completely investigated yet.

After lipases were incubated in the nanotube solutions for one week, the inner wall of the nanotube was coated by lipases, as shown in Figure 2. Figure 2a shows TEM image of the peptide nanotube without incorporating lipases. Figure 2b is TEM image of the nanotube with 0.002 mg/mL of lipases. As shown in this TEM image, lipases appeared as darker areas in the nanotube because they were crystallized inside when the samples were dried on TEM grids (*20*). Figure 2c is TEM image of the lipase nanotube with 0.006 mg/mL of lipases. This TEM image shows that the inner wall of nanotube was fully coated by lipases. When the lipase concentration exceeded 0.009 mg/mL, the lipases were coated outside the nanotubes because the saturation of lipase binding on the inner wall induced the outside coating with the excess lipases. While we do not have direct evidence to explain this inside-coating mechanism, various nanoparticles were observed to coat inside the peptide nanotubes at lower nanoparticle concentrations via capillary effect (*16, 21*) and the trend of lipase incorporation at the lower

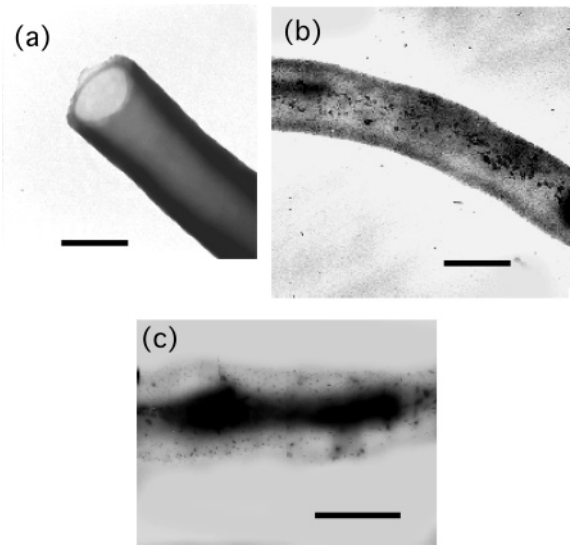

Figure 2. TEM images of peptide nanotubes incorporating *Candida rugosa* lipase at (a) [lipase] = 0 mg/mL (b) [lipase] = 0.002 mg/mL (c) [lipase] = 0.006 mg/mL. Scale bar = 200 nm.

concentrations is consistent with these previous outcomes. Another possible mechanism is the hydrophobic interaction between the nanotubes and the lipases. In general, the hydrophobic nonpolar residues of lipase spread on the outer shell while the enzymatic active sites are clustered (*9, 22, 23*), and then lipases aggregate on hydrophobic surfaces (*24, 25*). Therefore, the incorporation of lipases in the peptide nanotubes may also be due to the hydrophobicity of the inner surface of the peptide nanotube.

Enzymatic activities of lipases immobilized inside the peptide nanotubes were studied by monitoring the hydrolysis rate of *p*-nitrophenyl butyrate via the concentration change of a product, *p*-nitrophenol (Figure 1). To obtain their activities, the initial slopes of *p*-nitrophenol concentration changes over the reaction time were used. Figure 3 shows that the hydrolysis rate of lipases inside the peptide nanotubes increased linearly as a function of the lipase concentration. This feature indicates that the peptide nanotube support could maintain the enzymatic function of lipase, and the binding inside the nanotube did not hinder the catalytic reaction (*26*). Since the peptide nanotube itself has amino groups that may react with the resulting esters to affect the observed hydrolysis rates, the extent of the *p*-nitrophenyl ester

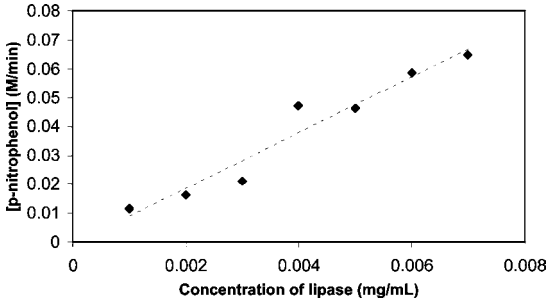

Figure 3. Hydrolysis rate of lipid catalyzed by lipases inside the nanotubes. A dotted line is a fit for experimental data points.

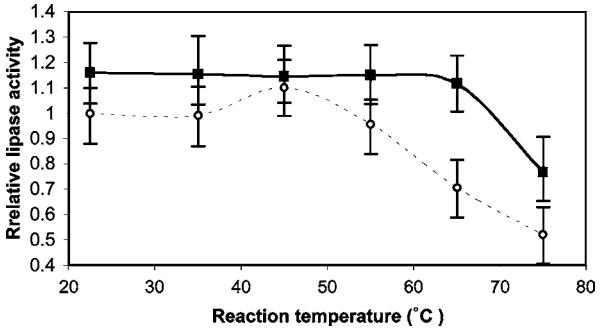

Figure 4. Thermal stability of lipases. The solid line and ■ represent lipases inside the nanotubes and the dotted line and ○ represent free-standing lipases.

hydrolysis by the neat peptide nanotubes without the enzyme was examined. This control experiment showed that the product concentration was 10^3 times lower as compared to the one by the peptide nanotubes with the enzyme, which means that the peptide nanotube itself cannot hydrolyze *p*-nitrophenyl ester efficiently. Since the product formation by the neat peptide nanotubes was negligible, the observed hydrolysis rates in Figure 3 are solely contributed by the lipases in the nanotubes.

The thermal stabilities of lipases (0.006 mg/mL) inside the nanotubes and free-standing lipases were compared in the temperature range, 25 °C to 75 °C, as shown in Figure 4. In this figure, the activity of the lipase was obtained by its initial slope of the *p*-nitrophenol concentration change over the reaction time, and the lipase activities were normalized by the hydrolysis rate of free-standing lipase at 22 °C. In the temperature range of 25−50 °C, the yield of *p*-nitrophenol by the nanotube-bound lipases is 33% higher than the one by the free-standing lipases. In the higher temperature range, the nanotube-bound lipases still maintained its activity up to 65 °C (a solid line in Figure 4); however the free-standing lipases lost their activity rapidly (a dotted line in Figure 4). As a result, the activity of nanotube-bound lipases was observed to be 70% higher as compared to the activity of free-standing lipases at 65 °C. The similar magnitude of the activity enhancement of nanotube-bound lipases was still observable at 75 °C. The drop of the activity for the lipases in the nanotubes at 75 °C (Figure 4) was not caused by the destruction of the peptide nanotube because the nanotube structure was observed to be rigid up to 200 °C (*18*). It is also unlikely that the activity decrease was caused by the lipase desorption since no lipases were released from the nanotubes in all temperature range during the activity measurement.

This outcome indicates that the noncovalent binding between the inner nanotube surfaces and lipases is strong enough to hold lipases during the enzymatic reaction even in the elevated temperatures. The increase of lipase

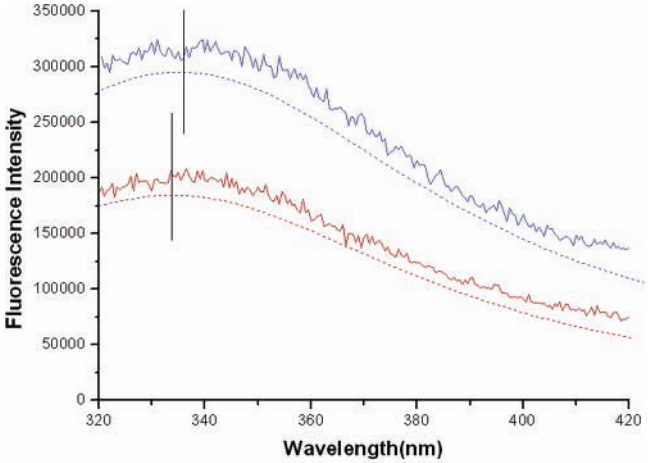

Figure 5. Fluorescence spectra of lipases bound the inside wall of peptide nanotubes (a blue line) and free-standing lipases (a red line). Dotted lines are the Lorentzian fits for these spectra and the computed peak positions by these fittings are also marked in this plot.

activity is also likely contributed by the conformation change of lipases, which exposes the catalytic active sites of lipases as lipase molecules are attached on the peptide nanotubes. For example, when lipases were attached on an oil−water interface, their catalytic activity was enhanced dramatically because lipases could undergo the conformation change from a closed form (i.e., enzymatically inactive) to a more open form (i.e., enzymatically active) (*27*). This type of conformation change has been detected by monitoring intrinsic fluorescence intensity of tryptophan in lipases (*28, 29*). When lipases were unfolded to the open conformation, the hydrophobic pockets of lipases were exposed, which increased the fluorescence intensity of tryptophan. If the activity of lipases on the peptide nanotubes is increased with the same mechanism via the conformation change induced by the nanotube−water interface, the increase of the Trp fluorescence intensity of nanotube-bound lipases should be observed as compared to free-standing lipases. Figure 5 shows the fluorescence intensity change of lipases before and after adding the peptide nanotube solution. The exact peak positions of these spectra was determined by the Lorenztian fits, as shown in dotted lines in Figure 5. Indeed, the increase of the tryptophan fluorescence intensity at 339 nm (blue) was observed after lipases bound the nanotubes, which is consistent with the enhancement mechanism observed in the lipase system at the oil−water interface. The red-shift of the tryptophan peak from 333 nm (a peak of the red line in Figure 5) to 339 nm (a peak of the blue line in Figure 5) after the nanotube solution was added to lipases, is also consistent with the red-shift of the tryptophan's fluorescence spectra in polar environments. When we added the substrate to a solution of the peptide nanotubes without lipase and measured the amount of substrate remaining in solution by UV−vis absorption, the resulting substrate concentration was identical to the initial concentration of the substrate. Since there is no partitioning of substrates in the nanotubes over 24 h, the observed enhancement of lipase activity in the peptide nanotubes is not due to simply local increase of the substrate concentration inside the nanotube. The conformation change of lipases may also indicate that the inner surface of the peptide nanotube facilitates lipases on the nanotube surfaces in the favorable orientation to maximize the contact with the substrate, *p*-nitrophenyl butyrate (*9, 23*).

In conclusion, peptide nanotubes were applied as supports for enzymes. We encapsulated a model enzyme inside peptide nanotubes, and the catalytic activity of nanotube-bound lipases was 33% higher as compared to free-standing lipases at room temperature. It was remarkable that the peptide nanotubes behaved as even better enzyme supports at higher temperature. At the elevated temperature, 65 °C, the activity of lipases inside the nanotubes was 70% higher as compared to free-standing lipases. The activity enhancement of lipases in the peptide nanotubes is likely induced by the conformation change of lipases to the open form (the enzymatically active structure) as lipases are adsorbed on the inner surfaces of peptide nanotubes. The stable binding between the nanotubes and lipases may also contribute to maintain the open (enzymatically active) form of lipases, which keeps the high catalytic activity at elevated temperature. It is advantageous to apply these peptide nanotubes as enzyme supports because the nanotubes can immobilize enzymes on the surfaces with a simple procedure and provide an appropriate environment for the active conformation of lipases (*15, 17*). The peptide nanotube can also be decorated by magnetic materials, which is beneficial to develop recyclable sensors and high-throughput catalysts (*21*).

Nonspecific binding is a frequently encountered problem with fluorescent labeling of tissue cultures when labeled with quantum dots. In these studies various cell lines were examined for nonspecific binding. Evidence suggests that nonspecific binding is related to cell type and may be significantly reduced by functionalizing quantum dots with poly(ethylene glycol) ligands (PEG). The length of PEG required to give a significant reduction in nonspecific binding may be as short as 12−14 ethylene glycol units.

INTRODUCTION

Fluorescence is a tool widely employed in biological assays. Current organic dyes suffer from many limitations including narrow excitation spectra, broad emission spectra, and photobleaching. Fluorescent semiconducting nanocrystals, also known as quantum dots, are beginning to find their way into the tool box of many biologists, chemists, and biochemists. Quantum dots are an attractive alternative to the traditional organic dyes due to their broad excitation spectra, narrow emission spectra, and photostability which allows for multiplexed experiments (*1*−*10*). During the synthesis of quantum dots, the size and composition can be varied in order to obtain emission wavelengths from blue to near-IR (*1*, *3*, *4*). Additionally, through the judicious choice of an appropriate excitation source, multiple color quantum dots may be excited simultaneously.

Typically prepared CdSe/ZnS quantum dots are limited for biological uses because they are soluble only in nonpolar solvents making them incompatible with biological systems (*5*). This is overcome by an additional polymer shell consisting of amphiphilic poly (acrylic acid) (AMP) (*6*). The AMP coating can subsequently be conjugated, through a 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) coupling (*7*) reaction, to biological molecules. Though the AMP-coated quantum dots are compatible with biological assays, studies are still needed to refine this functionalization strategy. Additional studies are also needed to investigate their stability in biological conditions, such as highly concentrated electrolyte solutions, and to minimize background fluorescence due to nonspecific binding.

Currently, quantum dots are being explored as biological imaging agents in vitro (*11*, *12*) and in vivo (*13*, *14*). A number of groups have attached small molecules (*15*−*18*), peptides (*19*), proteins (*20*), antibodies (*21*−*24*), and DNA (*25*) to quantum dots and imaged their binding. It has been reported that the carboxyl groups on the surface of quantum dots lead to nonspecific binding to oligonucleotides (*25*), and we have observed nonspecific binding of mercaptoacetic acid-conjugated quantum dots to human epithelial kidney cells (HEK). While other studies have optimized labeling using quantum dots for their own particular applications, presented here are generalized strategies to reduce nonspecific binding of quantum dots through PEG functionalization of the quantum dot surface that can be utilized in a variety of applications.

To advance studies of conjugated quantum dots for live cell applications, it is necessary to address the issue of nonspecific binding. It has been previously reported that quantum dots conjugated to methoxy-terminated PEG^{5000} (5000 g molecular wt) reduces nonspecific binding in mouse animal models (*26*). We assessed the degree of nonspecific binding of AMP-coated quantum dots (AMP dots) to cell surfaces of six different cell lines. We report that cell type is an important factor in the degree of nonspecific binding that is exhibited with quantum dots. The optimal conjugation conditions of PEG to AMP dots were investigated to ensure maximum fluorescence quantum yield after conjugation. The effect of ligand coverage of the quantum dot and PEG lengths required to sufficiently reduce background fluorescence caused by nonspecific binding of quantum dots was also evaluated in live cell assays.

MATERIALS AND METHODS

Reagents. Poly(ethylene glycol) (PEG) 2000 monomethyl ether, 550 monomethyl ether, and 350 mono methyl ether were obtained from Fluka. Tosyl chloride, *N*-hydroxysuccinamide (NHS), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), tetraethylene glycol, and methyl iodide were obtained from Aldrich. Potassium hydroxide was purchased from EM Science, Potassium phthalimide was obtained from Lancaster, and hydrazine hydrate was purchased from VWR. Borate buffer was obtained from Polysciences Inc (Warrington PA 18976); Sephadex G-50 was obtained from Amersham Biosciences (AB SE 751 84 Uppsala Sweden). All reagents were used as supplied without further purification.

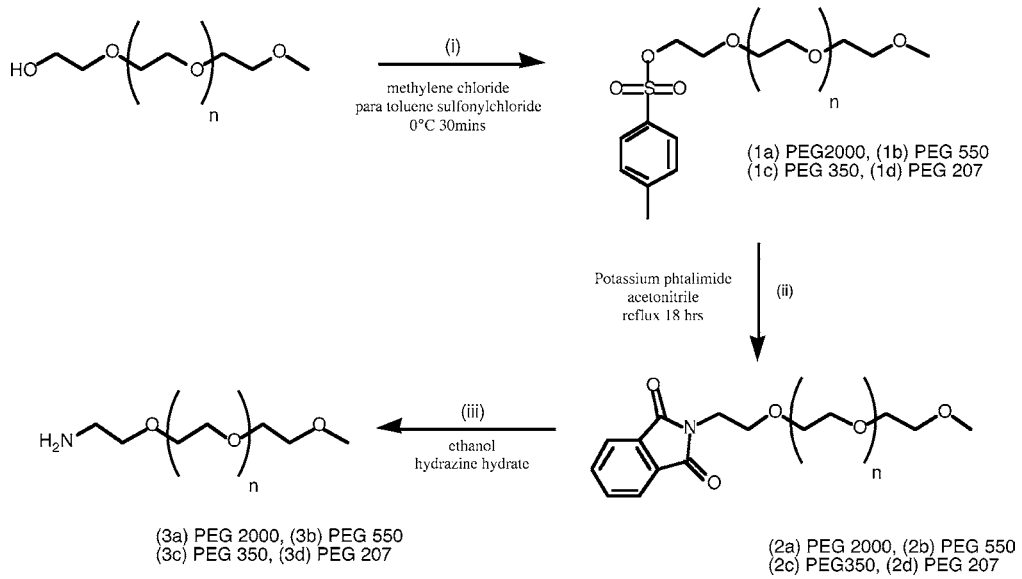
Scheme 1. Synthetic Route for Creating Methoxy-Terminated Amino PEGs



Quantum Dots. Amphiphilic poly(acrylic acid) polymer-coated quantum dots (AMP dots) were a gift from the Quantum Dot Corporation (Hayward, CA 94545). Core shell cadmium selenide/zinc sulfide quantum dots emitting at 605 nm were used in this study. Concentrations of quantum dots were measured using a Carey 50 UV−visible spectrophotometer. Their absorbance at 600 nm was measured, and the concentration was calculated based upon an extinction coefficient of 650 000.[1]

Spectroscopic Characterization. The PEG intermediates and the final product were characterized by NMR and MALDI mass spectroscopy. All NMR data was obtained using $CDCl_3$ as a solvent unless otherwise stated and analyses were performed using a Brucker 300 MHz instrument. Chemical shifts were measured relative to TMS, and coupling constants are measured in Hz.

Mass Spectroscopy. MALDI-TOF mass spectra were recorded on an Applied Biosystems Voyager mass spectrometer equipped with a 337 nm nitrogen laser. For each spectrum, 30 to 64 scans were averaged using an acceleration voltage of 25 kV. Samples were prepared, using a standard DBA matrix. A PEG standard prepared in the same manner as the other samples was used for mass calibration of the instrument.

PEG Synthesis. Four methoxy terminated amino PEGs were used in this study. These were methoxy-terminated amino PEG 2000, 550, 350 and the methoxy-terminated amino PEG derived from tetra PEG (PEG 207). The synthetic route used to synthesize these compounds is shown in Scheme 1. The mono methoxy PEG derivative of tetra PEG was synthesized as described by Masci (*27*).

Initially the PEG mono methyl ether was converted to a tosylate using the method described by Kegstra (*28*) resulting in tosylates **1a**−**d**. The tosylate was displaced using potassium phthalimide by refluxing in acetonitrile for 18 h resulting in **2a**−**d**. These were subsequently converted to the amino PEG derivative by stirring in ethanol with hydrazine hydrate giving **3a**−**d**. Compounds **1a**−**d**, **2a**−**d**, **3a**−**d** were characterized by NMR. Compounds **3a**−**d** were further characterized by MALDI mass spectroscopy.

The tosylates of the four PEG lengths were prepared as follows:

Mono Tosyl Poly(ethylene glycol) 2000 Mono Methyl Ether (1a). PEG 2000 monomethyl ether (20 g) was dissolved in methylene chloride (200 mL) and cooled to 0 °C in an ice/acetone bath. *p*-Toluenesulfonyl chloride (2 g, 0.01 mol) was added, and the mixture was stirred at 0 °C for 30 min. Freshly powdered potassium hydroxide (4.5 g, 0.08 mol) was added, and the mixture was stirred at 0 °C for 6 h (*28*). After warming to room temperature, the solution was washed with water (2 × 20 mL) and dried over magnesium sulfate. The methylene chloride was removed under reduced pressure, and the product was purified by washing with hexanes (5 × 200 mL). This yielded 18 g of the product as a waxy solid. ^{1}H NMR ($CDCl_3$) δ 2.42 (3H), 3.39 (3H), 3.60 (*n*H), 3.82−3.86 (2H), 4.10−4.14 (2H), 7.31 (2ArH), 7.75 (2 ArH).

Mono Tosyl Poly(ethylene glycol) 550 Mono Methyl Ether (1b). An amount of 22 g of PEG 550 mono methyl ether gave 26 g of crude mono tosyl poly(ethylene glycol) 550 mono methyl ether, and this was purified by column chromatography on silica gel eluted with methylene chloride then methylene chloride/methanol (5%), giving 24 g of the product as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 2.40 (3H), 3.33 (3H), 3.60 (*n*H), 4.10−4.12 (2H), 7.29 (2ArH), 7.76 (2 ArH).

Mono Tosyl Poly(ethylene glycol) 350 Mono Methyl Ether (1c). An amount of 14 g of mono methyl PEG 350 gave 18 g of crude tosylate which was purified using column chromatography on silica gel eluted with methylene chloride and then a methylene chloride (98%)/methanol (2%) mixture, resulting in 17.3 g of the product as colorless oil. ^{1}H NMR ($CDCl_3$) δ 2.37 (3H), 3.28 (3H), 3.46 (*n*H), 4.05 (2H), 7.27 (2ArH), 7.70 (2ArH).

Toluene-4-sulfonic Acid 2-{2-[2-(2-Methoxyethoxy)-ethoxy]ethoxy}ethyl Ester (1d). An amount of 10.4 g of 2-{2-[2-(2-methoxyethoxy)ethoxy]ethoxy}ethanol gave 9.5 g of tosylate after column chromatography on silica gel eluted with methylene chloride 98%/methanol 2%. Mass spectroscopy indicated that this material was contaminated with 1-methoxy-2-{2-[2-(2-methoxyethoxy)-ethoxy]ethoxy}ethane (**I**). Attempts to remove this contaminant using column chromatography failed, and the product was used without further purification in the next synthetic step. ^{1}H NMR ($CDCl_3$) δ 2.27 (3H), 3.17 (*n*H), 3.47 (*n*H), 3.96 (2H), 7.19 (2ArH), 7.61 (2ArH).

Mono Phthalimido Poly(ethylene glycol) 2000 Monomethyl Ether (2a). Mono tosyl PEG 2000 mono

[1] Brucez, M. Private communication.

methyl ether (18 g) was dissolved in acetonitrile (200 mL) and heated at reflux with stirring for 18 h. The mixture was cooled and evaporated and dissolved in methylene chloride (200 mL). The organic solution was washed with water (2 × 50 mL) and dried over magnesium sulfate. After filtration and evaporation under reduced pressure, the product was purified by washing the crude product with hexanes (5 × 200 mL). This gave 7.7 g of the product as a colorless wax. ^{1}H NMR ($CDCl_3$) δ 3.36 (3H), 3.52 (*n*H), 3.68 (2H), 3.82 (2H), 7.69 (2ArH), 7.79 (2ArH).

Mono Phthalimido Poly(ethylene glycol) 550 Monomethyl Ether (2b). The phthalimide was prepared as previously described for the phthalimide of mono methyl PEG 2000. Thus, 20 g of tosylate gave 15 g of crude phthalimide which was purified using column chromatography on silica gel eluted with a gradient system running from methylene chloride to 95% methylene chloride/5% methanol. This gave 14 g of the purified phthalimide as a yellow oil. ^{1}H NMR ($CDCl_3$) δ 3.20 (3H), 3.48 (*n*H), 3.56 (2H), 3.71 (2H), 7.57 (2ArH), 7.66 (2ArH).

Mono Phthalimido Poly(ethylene glycol) 350 Monomethyl Ether (2c). An amount of 17.3 g of tosylate gave 8.7 g of phthalimide, after purification on silica gel eluted with a gradient system eluted with a solvent system from methylene chloride to methylene chloride (98%)/methanol (2%). ^{1}H NMR ($CDCl_3$) δ 3.30 (3H), 3.46 (*n*H), 3.66 (2H), 3.82 (2H), 7.65 (2ArH), 7.76 (2ArH).

2-(2-{2-[2-(2-Methoxyethoxy)ethoxy]ethoxy}ethyl)-isoindole-1,3-dione (2d). An amount of 9.5 g of tosylate gave 3.9 g of phthalimide, after purification on silica gel eluted with a gradient system eluted with a solvent system from methylene chloride to methylene chloride (98%)/methanol (2%). Mass and NMR spectroscopy indicated that this material was contaminated with 1-methoxy-2-{2-[2-(2-methoxyethoxy)ethoxy]ethoxy}ethane (**I**) and was used without further purification.^{1}H NMR ($CDCl_3$) 2.22 (*n*H), 3.45 (*n*H), 3.75 (2H), 7.57 (2ArH), 7.68 (2ArH).

Mono Amino Poly(ethylene glycol) 2000 Monomethyl Ether (3a). Mono phthalimido PEG 2000 monomethyl ether (7.7 g) was dissolved in ethanol (200 mL), and hydrazine mono hydrate (10 mL) was added. The mixture was stirred at room temperature for 18 h and then evaporated under reduced pressure. The crude product was dissolved in methylene chloride and stirred for 18 h at room temperature. The solution was filtered and washed with water (2 × 50 mL) and dried over magnesium sulfate. After filtration and evaporation, the product was purified by washing with hexanes (5 × 200 mL). This gave the product as a colorless wax (5.9 g). ^{1}H NMR ($CDCl_3$) δ 3.32 (3H), 3.56 (nH), 3.69 (NH_2).

Mono Amino Poly(ethylene glycol) 550 Monomethyl Ether (3b). Mono amino poly(ethylene glycol) 550 monomethyl ether was prepared as previously described for mono amino poly(ethylene glycol) 2000 monomethyl ether. Thus 10 g of phthalimide resulted in 7.5 g of the desired product as colorless oil. ^{1}H NMR ($CDCl_3$) δ 2.73 (2H), 3.32 (3H), 3.44 (*n*H).

Mono Amino Poly(ethylene glycol) 350 Monomethyl Ether (3c). Mono amino poly(ethylene glycol) 350 monomethyl ether was prepared as previously described for mono amino poly(ethylene glycol) 2000 monomethyl ether. Thus 8.7 g of phthalimide resulted in 7.5 g of the desired product as a colorless oil. ^{1}H NMR ($CDCl_3$) δ 2.81 (2H), 3.09 (3H), 3.36 (*n*H).

2-{2-[2-(2-Methoxyethoxy)ethoxy]ethoxy}ethylamine (3d). 2-{2-[2-(2-Methoxyethoxy)ethoxy]ethoxy}-ethylamine (mono amino poly(ethylene glycol) 207 monomethyl ether) was prepared as previously described for mono amino poly(ethylene glycol) 2000 monomethyl ether. Thus, 3.9 g of phthalimide resulted in 1.0 g of the desired product as colorless oil after distillation under reduced pressure at 1 mmHg (bp 115−125 °C). NMR and mass spectroscopy of this material indicated that it was a mixture of the desired product (70%) and 1-methoxy-2-{2-[2-(2-methoxyethoxy)ethoxy]ethoxy}ethane (**I**) (30%). As 1-methoxy-2-{2-[2-(2-methoxyethoxy)ethoxy]ethoxy}-ethane is inert it was decided to couple this material to AMP dots without further purification. ^{1}H NMR ($CDCl_3$) δ 1.3 (NH_2), 2.71 (2H), 3.22 (*n*H), 3.40 (*n*H).

Coupling PEG Ligands to AMP Dots. During the course of our studies, we tried several different coupling methodologies using different ratios of EDC, NHS, and AMP dots. We observed that the best methodology used a ratio of 2000 PEGs, 1500 EDCs, 1500 NHS, and 1 dot. Thus, in a typical ligand exchange, 0.1 mL of a 8.9 μM solution of AMP dots was placed in a vial equipped with a stir bar. Mono methyl PEG 2000 amine (3.6 mg, 1.8 μM) was dissolved in borate buffer (0.3 mL) at pH 8.4, and this was added to the solution of the AMP dots. This mixture was stirred for 10 min at room temperature, and then N-hydroxysuccinamide (0.15 mg, 1.3μM) dissolved in borate buffer (0.1 mL) was added. The mixture was stirred for a further 10 min at room temperature, and then 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (0.25 mg, 1.3 μM) was added. The solution was stirred at room temperature for 2 h, and the pegylated dots were purified via size exclusion chromatography using sephadex (G50).

Gel Electrophoresis. Conjugation was confirmed by gel electrophoresis. Gels were 1% agarose in Tris-EDTA acetate (TEA) buffer. Gels were run at 80 V for 80 min with TEA buffer as the running buffer. Gel images were taken on an AlphaImager 2000 imaging station (Alpha Innotech Corp.).

Quantification of PEG on the Surface. The number of PEG molecules coupled to each quantum dot was determined by using the fluorescamine assay. An excess of fluorescamine (3 mg/mL) in acetone was added to each reaction mixture and vortexed for 15 min at room temperature. The fluorescence at 480 nm was measured and compared to the fluorescence produced by the same reaction mixture without EDC. The ratio of the fluorescence of these two reactions is the percentage of PEG still in solution, unconjugated to the quantum dots. This is subtracted by the amount of initial PEG and then divided by the number of quantum dots used in the reaction to give the number of PEG molecules conjugated to each quantum dot (equation given in Supporting Information).

Cell Cultures. Several cell lines were chosen to compare the nonspecific binding of AMP dots to PEG conjugated AMP dots (PEG dots). These cell types were as follows: mouse fibroblasts (3T3); African green monkey kidney cells (COS7); Chinese hamster ovary (CHO), a gift from Dr. Tad Inagami (Vanderbilt University, Nashville, TN); human epithelial kidney (HEK); porcine renal epithelial (LLC); human epithelial larynx carcinoma (HEp-2). Approximately 5000 cells/well of 3T3 cells were plated in black/clear bottom 96-well plates and grown to confluency in DMEM (Gibco) containing 9% bovine serum, 5 units/mL penicillin, and 5 μg/mL streptomycin media. Approximately 10−15 000 cells/well of COS7, CHO, HEK, and LLC cells were plated in black/clear bottom 96-well plates and grown to confluency in DMEM containing 10% fetal bovine serum, 2 mM glutamine, 100 units/mL penicillin, and 100 mg/mL streptomycin media. Approximately 10 000 cells/well of

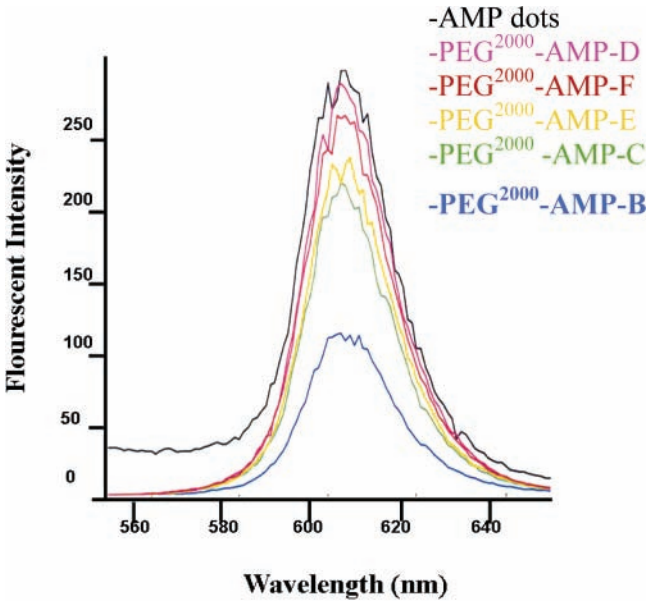


Figure 1. Fluorescent spectra used to determine relative quantum yield of PEGylated AMPdots with varied ratios of PEG:NHS:EDC. PEG^{2000}-AMP-D (purple) and PEG^{2000}-AMP-F (red) are 2000 equivalents of PEG to 1500 equivalents of NHS and EDC (separate reactions). PEG^{2000}-AMP-E (yellow) is 2000 equivlaents of PEG, NHS and EDC. PEG^{2000}-AMP-C (green) is 2000 equivalents of PEG to 1000 equivalents of NHS and EDC. PEG^{2000}-AMP-B (blue) is 1000 equivalents of PEG to 3000 equivalents of NHS and EDC.

HEp-2 cells were plated in black/clear bottom 96-well plates and grown to confluency in OPTI-MEM containing 2% fetal bovine serum, 200 mM glutamine, 250 μg/mL of amphotericin-B, and 10 mg/mL gentamicin media. All cells were incubated at 37 °C with 5% CO_2.

Microscopy. Images of labeled cells were taken using a Nikon Diaphot epifluorescent microscope equipped with phase/fluorescent/camera and a Quixell automated micromanipulator on a Nikon D100 digital camera.

Quantification of Nonspecific Binding. The nonspecific binding of the AMP dots and PEG dots to each cell type was quantified by fluorescence measurements of cell cultures grown in 96-well plates. Concentrations of PEG and AMP dots ranging from 1 nM to 50 nM were tested against each cell type by incubating three wells with each concentration for 30 min and then washing with excess KRH buffer. The fluorescent intensity of each well was measured using a BIO-TEK Synergy HT plate reader (excitation 250 nm/10, emission filter 590 nm/35, top optic position with a vertical offset of 1 mm and sensitivity = 88.)

RESULTS AND DISCUSSION

Conjugating PEG to the surface of the AMP dots was employed to reduce nonspecific binding in live cell assays. Previous studies indicated that the quantum efficiencies of the 605 nm AMP dots were affected by the conjugation chemistry (data not shown). Ratios of methoxy terminated amino PEG^{2000}, NHS, and EDC were varied to determine the optimal conditions for coupling PEG to the surface of AMP dots without compromising the probe's quantum yield. The relative quantum yields of 50 nM solutions of each of the PEG dots were determined by comparison of their emission intensity at 605 nm. The ratio 2000:1500:1500 of PEG/NHS/EDC equivalents per quantum dot (purple and red) (Figure 1) exhibited the least amount of quenching after conjugation. An excess of NHS and EDC (blue) displayed less than half of the original fluorescent emission, while lower ratios resulted in nonoptimal PEG coupling. The pH of the reactions was monitored to determine if the decrease in fluorescent intensity was due to etching of the quantum dot surface by hydrochloric acid liberated from EDC hydrolysis. Etching of the surface from HCl does not appear to be the cause of decreased fluorescence since the borate buffer maintained a pH of 8.5−8.2 throughout the 2 h coupling. All subsequent conjugations of PEG to AMP dots were carried at the 2000:1500:1500 ratio of PEG/NHS/EDC equivalents per quantum dot.

Six common cell lines, 3T3, LLC, COS7, CHO, HEp-2, and HEK, were chosen in order to determine the degree of nonspecific binding of AMP dots in live cell assays. Each cell line was incubated with 50 nM AMP dots for 30 min, washed, and imaged. While all cell lines showed some degree of nonspecific binding, the amount varied with each cell line (Figure 2: A1−F1). HEK cells (Figure 2: C1) displayed the most nonspecific binding while 3T3 cells exhibited the least (Figure 2:E1). The reduction of nonspecific binding was evaluated in parallel experiments by incubating the cell lines with 50 nM PEG functionalized AMP dots. PEG-conjugated quantum dots significantly reduced the nonspecific binding with all the selected cell types. Controls indicated that there was no binding of the AMP dots or the PEG conjugated quantum dots to the surface of the 96-well microtiter plates used for cells seeding, therefore, all binding was attributed to the cell surfaces. In cell lines that did not exhibit much nonspecific binding initially, like 3T3, there was a reduction of 18% when using 50 nM PEG dots. In cell lines like HEK, where there were very significant amounts of nonspecific binding PEG dots reduced nonspecific binding by as much as 90% at working concentrations of 50 nM (Supporting Information). While nonspecific bind-

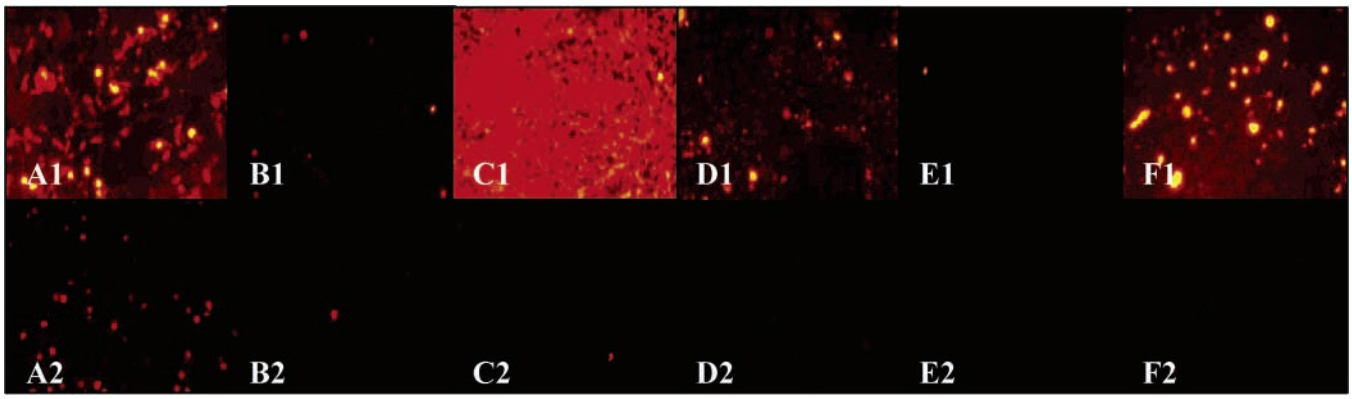

Figure 2. Comparison of the nonspecific binding of 50 nM AMP dots (A1−F1) to PEGylated AMP dots (A2−F2). The comparison was done in six different cell lines: HEp-2 (A), LLC (B), HEK (C), COS7 (D), 3T3 (E), and CHO (F).

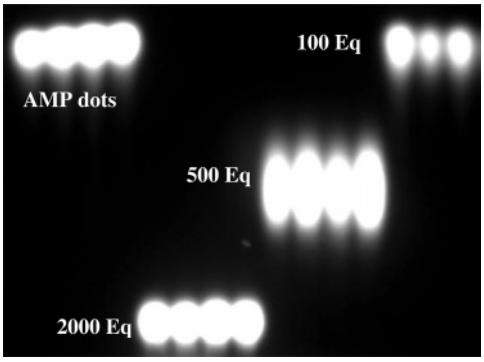

Figure 3. Electrophoretic gels (1% agarose) of AMP dots and PEGylated AMP dots. The gel was run at 80 V for 80 min. The gel indicates that the conjugation was successful and that the AMP dots have been PEGylated with different equivalents of PEG^{2000}. As expected, the more equivalents of PEG used the less electrophoretic movement.

ing is clearly related to the surface chemistry of the cells, the nature of the interaction that causes nonspecific binding likely arises from a variety of different interactions.

It is possible to envision hydrophobic interactions occurring between tri-*n*-octylphosphine oxide (TOPO) on the surface of the quantum dot and lipids in cellular membranes. These hydrophobic interactions might occur from an incomplete coverage of the core/shell with the AMP coating. Different cell types express a variety of proteins or lipids on their surfaces that allow for interaction with exposed hydrophobic regions of the quantum dots. This variation of proteins and lipids expressed in a cell type dependent manner would give rise to some cell lines displaying larger amounts of nonspecific binding than others.

Another possibility for nonspecific binding is the electrostatic interactions between the surfaces of cells and the carboxylic acids on the surfaces of the AMP-coated quantum dots. PEG reduces the ability of the quantum dots to form these interactions with the surface of the cell or proteins expressed in the extra cellular matrix, resulting in a reduction of nonspecific binding. Consequently, PEG functionalization yields an essentially passivated surface that minimizes cellular interaction. Further surface modifications of quantum dots with PEG will change the electrical double layer surrounding the quantum dots and this may also reduce the nonspecific binding. PEG is able to solvate cations in a manner similar to crown ethers (*27*). It is possible that cations surrounding the quantum dot are solvated by the PEGs on the surface of the quantum dot. Thus these cations may be less able to form interactions such as salt bridges between negatively charged groups on the cell surface and the quantum dot.

Since HEK cells exhibited the most nonspecific binding and 3T3 cells the least, these cells lines were selected as the subjects for focused study of the effects of both the coverage and length of the PEG modulator on nonspecific cellular binding. The effect of ligand coverage was studied by coupling 2000, 500, and 100 equivalents of PEG^{2000} to AMP dots. Quantitation of the number of PEGs coupled to the surface was determined by a fluorescamine difference assay. The fluorescamine assay produces a fluorescent species when it reacts with primary amines thereby giving you the amount of amino PEGs that still have primary amines (*26*). Controls for Qdot interference and issues of solvent incompatibilities (i.e. presence of acetone) showed no interference. Assay results indicated approximately 380, 106, and 11 PEG modulators per quantum dot in the 2000, 500, and 100 equivalent reactions, respectively (Supporting Information). In the 2000 equivalent reaction it is expected that all surface accessible carboxyl groups of the AMP coating on the quantum dot are funtionalized. Subsequent characterization with gel electrophoresis (Figure 3) confirmed the coupling reaction and was consistent with the fluorescamine quantitation.

Quantum dots with 380 PEG^{2000} displayed little to no nonspecific binding (Figure 4). Very little increase in nonspecific binding to HEK and 3T3 cells was observed with quantum dots which had about 106 PEG^{2000}. However, when only 11 PEG^{2000} were coupled to the quantum dot, the nonspecific binding to HEK cells increased. Nevertheless, even though the surface has very few PEG molecules on it, it is still apparent that the nonspecific binding is reduced by about 50%. These results suggest that it may not be necessary to functionalize every site on the surface of the quantum dot with PEG to reduce nonspecific binding but the more complete functionalization of the AMP surface the better the reduction of nonspecific binding. There was little effect on the nonspecific binding of the quantum dots with only 11 PEG to the 3T3 cells, which had originally shown the least nonspecific binding to the AMPdots.

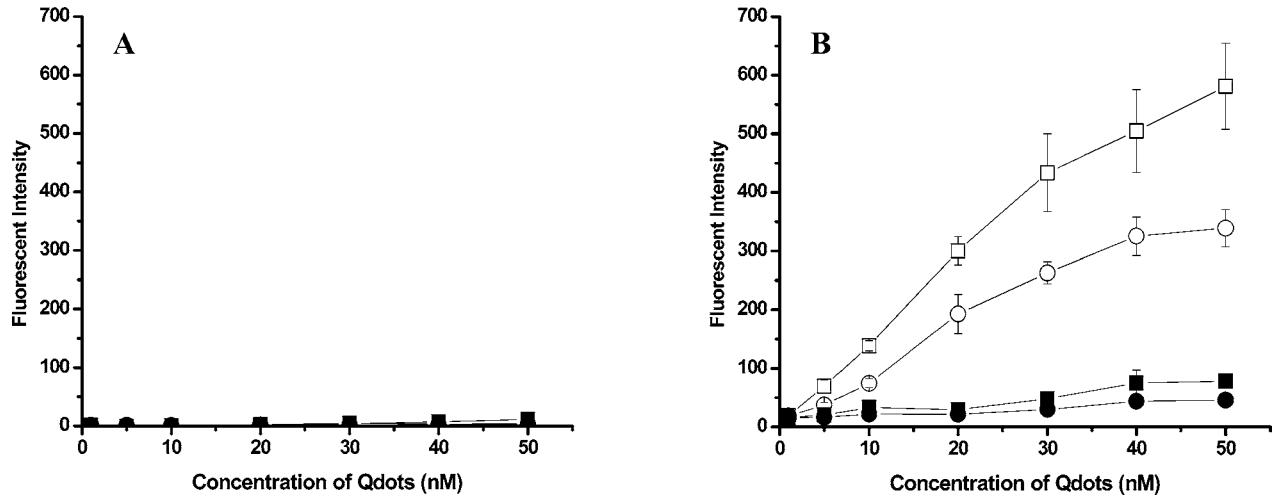

Figure 4. Graphs of the fluorescent intensity of AMP dots (□) and AMP dots PEGylated with 100 equivalent of PEG^{2000} (○), 500 equivalents of PEG^{2000} (■), and 2000 equivalents of PEG^{2000} (●) for 3T3 (A) and HEK (B).

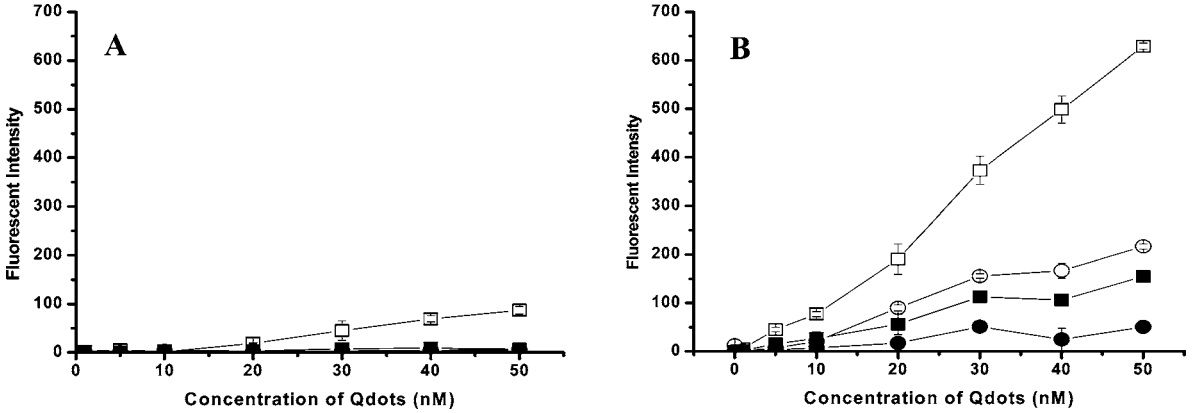

Figure 5. Graphs of the fluorescent intensity of AMP dots (□) and AMP dots PEGylated with 2000 equivalents of PEG^{350} (○), PEG^{550} (■), and PEG^{2000} (●) for 3T3 (A) and HEK (B).

The effect of PEG length was determined by comparing the amount of nonspecific binding AMPdots functionalized with PEG^{2000}, PEG^{550}, and PEG^{350} with uniform coverage (Figure 5). To ensure that nonspecific binding in these assays was a product of PEG length, all conjugations were done with 2000 equivalents of PEG as described above so that all surface available carboxyl groups were utilized. It has been observed by Ballou (*26*) et al. that when methoxy amino PEG^{5000} was attached to AMP dots only 100 PEGs were observed to bind, but when PEG^{750} was attached, 300 PEGs were observed to bind. Electrophoretic gels indicate that the mobility of PEG conjugated to quantum dots appear to behave as a function of the PEG length (Supporting Information). Consequently, with lengths shorter than PEG^{2000}, steric hindrance does not appear to affect PEG conjugation but may be a factor in the reduced number of conjugations with longer PEGs.

The length of the PEG chain does not seem to be important until it is shorter than about 14 units, and even PEG^{350} was able to eliminate most nonspecific binding. All lengths of PEG dots used reduced the nonspecific binding in both HEK cells and 3T3 cells. In the 3T3 cells, which had originally shown the least nonspecific binding to the AMP dots, length of the PEG had no effect on nonspecific binding. However, nonspecific binding of PEG dots to HEK cells did increase with decreasing PEG length (Figure 5). In HEK cells, the PEG^{2000} eliminated the nonspecific binding over the concentration range investigated by approximately 90%. While the PEG^{550} and PEG^{350} did show an increase in nonspecific binding, they still provide a significant reduction of 70% and 60%, respectively, over most concentrations examined. For most biological assays the working concentration of quantum dots will be around 10 nM, where the nonspecific binding for all lengths is very low.

CONCLUSIONS

The nonspecific binding of AMP dots to cell surfaces is dependent upon the cell type. In our study, HEK cells exhibited the most nonspecific binding at concentrations of 50 nM. When AMP dots are conjugated to methoxy amino PEG^{2000}, the nonspecific binding at 50 nM concentrations is greatly reduced. The PEG may be shortened to approximately 12−14 units without increasing nonspecific binding. While it may not be necessary to coat the entire quantum dot surface with PEG to reduce nonspecific binding, complete coverage of the AMP surface on the dots is optimal.

While PEG coated dots do not provide a biologically interesting probe, this study shows that a small number of PEGs are sufficient to reduce nonspecific binding. A coligand strategy could be implemented utilizing some of the available conjugation sites for PEG while other sites may be filled with ligands of biological relevance. Another strategy would be to fill available conjugation sites with customized ligands consisting of a PEG linker arm attached to a biologically relevant moiety.

ACKNOWLEDGMENT

We would like to thank Quantum Dot Corporation for supplying the core/shell nanocrystals used in this study. We would like to thank David Hercules and Matthew Vergne for doing the MALDI mass spectrometry studies used in this work, and Marcus Voeler and Brian O. Bachman for providing the equipment to run and study agarose gels. This work was supported by the NIH under grant RO1 EB003728.

Synthesis and Cellular Studies of Porphyrin−Cobaltacarborane Conjugates

Erhong Hao, Timothy J. Jensen, Brandy H. Courtney, and M. Graça H. Vicente*

Department of Chemistry, Louisiana State University, Baton Rouge LA, 70803. Received July 15, 2005; Revised Manuscript Received August 25, 2005

The total syntheses of five new porphyrin−cobaltacarborane conjugates (**1**−**5**) have been achieved in 88−98% yields in a single-step reaction between a nucleophilic *meso*-pyridyl-containing porphyrin and zwitterionic cobaltacarborane [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)]. These unique zwitterionic compounds have one to four cobaltabisdicarbollide anions conjugated to the porphyrin macrocycle via $(CH_2CH_2O)_2$ chains. The X-ray structure of one of these conjugates (**1**) is presented and discussed. The cellular uptake, cytotoxicity, and subcellular localization of cobaltacarboraneporphyrins **1**−**5** were investigated in human HEp2 cells. The number and distribution of cobaltacarborane residues linked to the porphyrin macrocycle has a significant effect on the cellular uptake of the conjugates.

INTRODUCTION

Boron neutron capture therapy (BNCT), a binary modality for cancer treatment based on the ability of ^{10}B nuclides to capture low-energy neutrons with subsequent production of high linear energy transfer particles ($^4He^{2+}$ and $^7Li^{3+}$), has attracted much interest in the past decades because it can selectively target and destroy malignant cells in the presence of normal cells (*1*−*3*). The success of BNCT depends on the availability of nontoxic boron-containing compounds that can selectively target and accumulate in tumors with high tumor:normal tissues and tumor:blood boron concentration ratios. Among all BNCT agents reported to date, porphyrins are particularly promising due to their known ability to selectively incorporate into tumor cells in high amounts and their subsequent persistence within tumors (*3*−*5*). Furthermore, porphyrins are highly fluorescent, thus enabling tumor diagnosis and facilitating treatment planning. The timely discovery of borane clusters in the late 1950s (*6*) has made possible the syntheses of porphyrins with high percentages of boron by weight, able to deliver therapeutic concentrations of boron (∼20 μg ^{10}B/g tumor) to target tumors. Several porphyrins carrying multiple boron clusters have been synthesized and evaluated in both cellular and animal studies (*4*, *5*, *7*−*10*), but to date there is still limited availability of boron-containing porphyrins because of lengthy synthetic routes and overall low reaction yields. Consequently, there is a lack of structure/activity relationships conducted for this type of compound that could allow the identification of the best candidates for application in BNCT (*11*). Such studies have been much more extensively reported in the development of porphyrins for application in the photodynamic therapy (PDT) of tumors, another binary therapy that uses red light for the activation of a tumor-localized photosensitizer (*4*, *12*, *13*). These studies show that the uptake of porphyrins by tumors is highly dependent upon their physicochemical properties, such as structural features (nature of peripheral side chains), charge and charge distribution, hydrophobic character, and aggregation state.

Metallacarboranes, first reported in 1965 (*14*), belong to the large family of metallocene-type complexes. Among these, the cobaltabisdicarbollide anion [3,3′-Co(1,2-$C_2B_9H_{11}$)$_2$]$^-$ was among the first to be synthesized, and its chemistry has been extensively investigated (*15*, *16*). In the 1980s Spryshkova et al. showed that the potassium salt of [3,3′-Co(1,2-$C_2B_9H_{11}$)$_2$]$^-$ had low toxicity (LD_{50} = 0.08750 mg/kg) in tumor-bearing rats (*17*, *18*). This property, along with the remarkable thermal, kinetic, and photochemical stabilities of cobaltacarborane and some of its derivatives, has led to their investigation as radiotherapeutic (*19*, *20*) and as BNCT agents (*21*−*23*). The bisdicarbollide complexes contain a larger number of boron atoms than the carboranes and the *closo*-dodecaborate anions and are water-soluble in the form of sodium or potassium salts while still maintaining hydrophobic character needed for crossing cellular membranes. Since the discovery of a convenient synthesis of the zwitterionic [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] (*24*, *25*), several new cobaltacarborane-substituted molecules have been reported (*26*−*30*). The dioxane ring of [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] readily undergoes a ring-opening reaction in the presence of a variety of nucleophilic reagents, including halide and hydroxide anions (*26*), phthalimide ions and amines (*27*), phenolate ions and phosphines (*28*), pyrrolyl salts (*29*), and pyridine and phenol (*30*). Using this methodology, a nucleoside−cobaltacarborane conjugate was recently synthesized and found to have low cytotoxicity toward Vero and A549 cells (IC_{50} > 80 μM), using an MTT-based assay (*23*).

With the aim to investigate structure/activity relationships in porphyrin−carborane conjugates, we report herein the synthesis and in vitro evaluation of a series of five conjugates (**1**−**5**) containing one to four cobaltabisdicarbollide anions linked to the porphyrin macrocycle via $(CH_2CH_2O)_2$ chains. An efficient one-step ring-opening reaction between cobaltacarborane **6** and five pyridylporphyrins (**7**−**11**) afforded the target conjugates

in 88−98% yields. We have previously shown that this reaction also proceeds with phenol-substituted porphyrins as the nucleophilic species (*30*). Since cobaltacarborane−porphyrins contain twice as many boron atoms as *nido*-carboranylporphyrins while still bearing a delocalized negative charge, we anticipate that the conjugates reported herein will be very promising boron carriers for BNCT.

EXPERIMENTAL PROCEDURES

Syntheses. All reactions were monitored by TLC using 0.25 mm silica gel plates with or without UV indicator (Merck 60F-254). Silica gel from Sorbent Technologies 32−63 μm was used for flash column chromatography. ^{1}H and ^{13}C NMR were obtained on either a DPX-250 or a ARX-300 Bruker spectrometer. Chemical shifts (δ) are given in ppm relative to acetone-d_6 (2.05 ppm, ^{1}H; 207.07 ppm, ^{13}C) unless otherwise indicated. Electronic absorption spectra were measured on a Perkin-Elmer Lambda 35 UV−Vis spectrophotometer, and fluorescence spectra were measured on a Perkin-Elmer LS55 spectrometer. Mass spectra were obtained on an Applied Biosystems QSTAR XL. All solvents were purchased from Fisher Scientific (HPLC grade) and used without further purification. Zwitterionic [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{11}$)(1′,2′-$C_2B_9H_{11}$)] (**6**) was prepared from the cesium salt of cobaltabisdicarbollide, obtained from Katchem Ltd (Czech Republic), as described in the literature (*25*). The 5-(4′-pyridyl)-10,15,20-triphenylporphyrin (**7**), *trans*-5,15-di-(4′-pyridyl)-10,20-diphenylporphyrin (**8**), *cis*-5,10-di(4′-pyridyl)-15,20-diphenylporphyrin (**9**), and 5,10,15-tri(4′-pyridyl)-20-phenylporphyrin (**10**) were prepared according to the literature (*31*). 5,10,15,20-Tetra(4′-pyridyl)porphyrin (**11**) was obtained from Sigma-Aldrich and recrystallized from chloroform/methanol before use.

General Procedure for Conjugate Synthesis. Cobaltacarborane **6** and the 4-pyridylporphyrin were dissolved into a 1:1 (v/v) mixture of chloroform and acetonitrile (Scheme 1). The reaction was stirred at 60 °C under an argon atmosphere until the reaction was complete (monitored by TLC and ^{1}H NMR). The reaction mixture was cooled to room temperature and the solvent evaporated under vacuum. The remaining residue was washed with diethyl ether (3 × 5 mL) and with methanol (3 × 5 mL). Finally, the product was dried overnight under vacuum to afford the targeted conjugate.

5-(4′-Cobaltacarboranepyridyl)-10,15,20-triphenylporphyrin (1). Porphyrin **7** (61.6 mg, 0.10 mmol) and compound **6** (61.5 mg, 0.15 mmol) were heated in 40 mL of chloroform/acetonitrile 1:1 for 12 h. The title conjugate was obtained in 98.4% yield (101.0 mg) as a purple solid. UV−Vis (acetone) λ_{max} (ϵ/M^{-1} cm^{-1}) 418 (157 600), 515 (10 100), 551(5300), 590 (3400), 646 (2600). ^{1}H NMR (acetone-d_6): δ 9.73 (d, 2H, J = 6.7 Hz, *o*-PyrH), 9.10−9.07 (m, 4H, β-H), 9.00 (d, 2H, J = 4.8 Hz, *m*-PyrH), 8.90 (s, 4H, β-H), 8.28−8.24 (m, 6H, *o*-PhH), 7.86−7.76 (m, 9H, *m,p*-PhH), 5.34−5.30 (m, 2H, NCH_2), 4.51−4.42 (m, 2H, OCH_2), 4.06−4.03 (m, 4H, OCH_2), 3.84−3.82 (br s, 4H, carborane-H), 1.6−3.0 (br, 17H, BH), −2.74 (s, 2H, NH). ^{13}C NMR (acetone-d_6): δ 160.1, 144.8, 142.2, 135.1, 133.6, 128.9, 127.7, 123.0, 122.1, 113.3, 73.0, 69.7, 61.8, 52.5, 46.9. 5,10,15,20-Tetra(4′-cobaltacarboranepyridyl)porphyrin (5). Porphyrin **11** (17.0 mg, 0.027 mmol) and compound **6** (62.0 mg, 0.15 mmol) were heated in 40 mL of chloroform/acetonitrile 1:1 for 3 days, affording 53.3 mg (87.7%) of the title conjugate. UV−Vis (acetone) λ_{max} (ϵ/M^{-1} cm^{-1}) 427 (210 000), 517 (15 600), 553 (5880), 590 (5630), 645 (1500). ^1H NMR (acetone-d_6): δ 9.80 (d, 8H, J = 6.3 Hz, *o*-PyrH), 9.26 (s, 8H, β-H), 9.15 (d, 8H, J = 6.3 Hz, *m*-PyrH), 5.36 (br s, 8H, NCH_2), 4.43 (br s, 8H, OCH_2), 4.05 (br s, 8H, OCH_2), 4.00 (br s, 8H, OCH_2), 3.86−3.84 (m, 16H, carborane-H), 1.6−3.0 (br, 68H, BH), −2.89 (s, 2H, NH). ^{13}C NMR (acetone-d_6): δ 159.4, 145.9, 134.1, 117.4, 74.0, 70.6, 70.5, 62.9, 53.3, 47.9. HRMS (MALDI-TOF) *m/z* 2262.5566, calculated for $C_{72}H_{142}N_8O_8B_{72}Co_4$ 2262.5509.

Molecular Structure. The crystal structure of porphyrin−cobaltacarborane conjugate **1** was determined using data collected at T = 110 K with Mo Kα radiation on a Nonius KappaCCD diffractometer. Crystal data: $C_{51}H_{58}B_{18}CoN_5O_2$, triclinic space group $P\bar{1}$, a = 6.941(5), b = 10.982(7), c = 35.48(3) Å, α = 89.46(2), β = 86.86(3), γ = 75.03(4)°, V = 2609(3) Å^3, Z = 2, R = 0.125 ($F^2 > 2\sigma$), Rw = 0.359 (all F^2) for 7181 unique data and 324 refined parameters. Due to the limited quality of the crystal, anisotropic refinement was not possible, except for the Co atom. Disorder was present in the chain connecting the porphyrin to the cobaltacarborane, and two atoms were modeled as pairs of half-populated sites. The N−H hydrogen atoms could not be located.

Cell Culture. Human HEp2 cells were obtained from the ATCC and maintained in a 50:50 mixture of DMEM: Advanced MEM (Gibco) supplemented with 5% FBS (Gibco). Phosphate buffered saline (PBS), FBS and trypsin were purchased from Gibco. All conjugate solutions were filter sterilized using a 0.22 μm Pal syringe filter.

Cellular Uptake. HEp2 cells were seeded at 10 000 cells per well in a Costar 96 well plate and incubated overnight. Solutions of the conjugates 10 mM in DMSO (Sigma) were prepared and further diluted to 1 mM by adding Cremophor EL (Fluka) to give final concentrations of 90% DMSO and 10% Cremophor EL. These solutions were then diluted 50-fold into medium and filter-sterilized to give 2× stock solutions. Equal volumes of conjugate stocks were added to the wells containing cells, giving a final concentration of 10 μM, and incubated for 0, 1, 2, 4, 8, and 24 h. The conjugate uptake was stopped by removing the loading medium and washing the cells with 200 μL of PBS. The cells were solubilized in 0.25% Triton X-100 (Calbiochem) in PBS. Conjugate concentration was determined by measuring the conjugate fluorescence using a BMG FLUOstar Optima plate reader at 410/650 nm excitation/emission. Cell counts were performed using the CyQuant cell proliferation assay reagent (Molecular Probes) as described by the manufacturer.

Dark Cytotoxicity. Cells were plated in 96-well plates and incubated overnight. Conjugate was added to

a final concentration of 10 μM as described above and incubated overnight. The conjugate was then removed and replaced with medium containing Cell Titer Blue (Promega) viability reagent. The cytotoxicity was assayed as per the manufacturer's instructions. The controls consist of cells not treated with either conjugate or vehicle, but incubated under the same conditions to provide a 100% viable reference point. Cells were also treated with 0.2% saponin overnight to provide a 100% dead control, and with vehicle alone (0.9%DMSO/0.1% Cremophor EL) to test residual toxic effects of the delivery vehicle.

Microscopy. Cells were trypsinized and plated on LabTek 2 chamber coverslips (Nunc) and allowed to attach overnight. Lipofectamine liposomes were used as a delivery vehicle. The conjugate stocks were first prepared in DMSO to a concentration of 1 mM, and 1 μL of this stock was mixed with 5 μL of Lipofectamine (Invitrogen), vortexed, and incubated for 15 min. Serum free AMEM (100 μL) was then added, and the mixture was vortexed and incubated for 30 min at room temperature. During this incubation, the cells were washed once with serum free AMEM. The liposome complex was then diluted with 900 μL of serum free AMEM and the mixture transferred to the cells and incubated for 4 h. At the end of the incubation period, 1 mL of medium containing 2 $\times$ FBS was added, and the cells were incubated overnight. The cells were then washed five times with medium supplemented with 50 mM HEPES pH 7.4 and viewed using a Zeiss Axiovert 200M inverted microscope fitted with standard FITC and Texas Red fluorescent filter sets (Chroma). For the colocalization experiments, LysoSensor Green and MitoTracker Green (Molecular Probes) were diluted into medium to a final concentration of 50 nM (LysoSensor Green) and 250 nM (MitoTracker Green). The cells were incubated concurrently with conjugate for 30 min before being washed and viewed by microscopy as described above.

RESULTS

Synthesis and Characterization. Cobaltacarborane **6** was prepared from the reaction of cobaltabisdicarbollide anion $[Co(C_2B_9H_{11})_2]^-$ with 1,4-dioxane in the presence of $BF_3{\cdot}Et_2O$, according to the literature procedure (*25*). Pyridylporphyrins **7**−**11**, synthesized using an Adler-Longo mixed condensation in boiling propionic acid (*31*), were used as the nucleophilic species in the dioxane ring-opening of **6**. Conjugates **1**−**5** were prepared in 88−98% yield in a single-step reaction between the corresponding 4-pyridylphenylporphyrin and an excess of cobaltacarborane **6**, in a mixture of chloroform and acetonitrile at 60 °C (*30*). At higher temperatures (e.g. at 80 °C or in refluxing chloroform) small amounts of green byproducts were also obtained, due to substitution reactions at the porphyrin core (*32*). The targeted conjugates were isolated in pure form upon washing the resulting reaction residues with ethyl ether to remove the excess of compound **6**, without need of chromatography. The molecular structure of conjugate **1** is shown in Figure 1. The porphyrin core is reasonably planar, having mean deviation of 24 atoms from their best plane of only 0.07 Å and maximum deviation 0.18(2) Å. The two dicarbollide moieties coordinate the Co atom with their five-membered rings parallel. The Co atom is equidistant from the two five-membered rings, having a perpendicular distance of 1.463(2) Å to the untethered dicarbollide and 1.464(2) Å to the tethered one. The centroid−Co−centroid angle is 178.3(1)°.

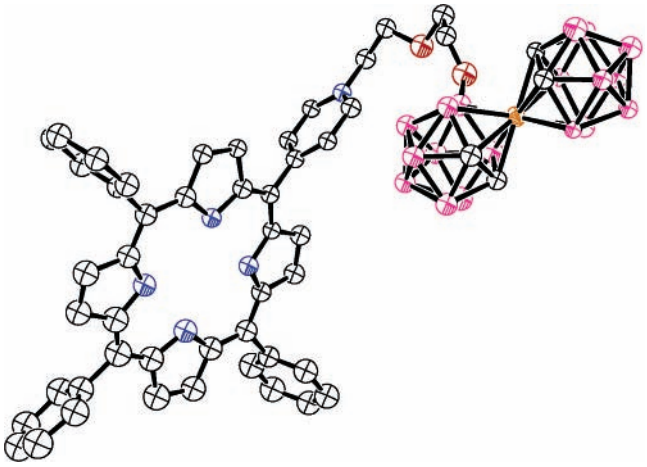

Figure 1. Molecular structure of porphyrin−cobaltacarborane **1**.

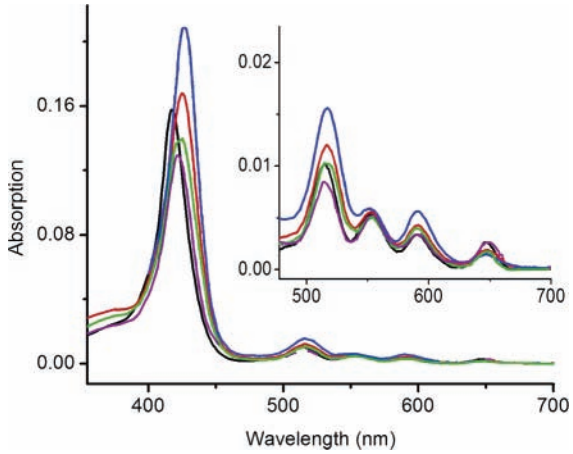

Figure 2. Optical spectra of conjugates **1** (black), **2** (purple), **3** (green), **4** (red), and **5** (blue) at 1 μM in acetone solution.

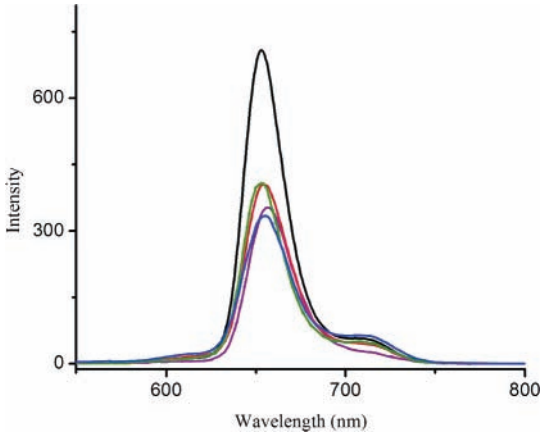

Figure 3. Fluoresence emission spectra of conjugates **1** (black), **2** (purple), **3** (green), **4** (red), and **5** (blue) at 1 μM in acetone solution upon excitation at 416 nm at room temperature.

The zwiterionic porphyrin conjugates **1**−**5** are soluble in polar aprotic solvents, such as acetonitrile, acetone, ethyl acetate, THF, DMF, and DMSO but are not soluble in methanol or water. Their observed low extinction coefficients in acetone solution compared with the corresponding starting porphyrins (Figure 2) indicates the formation of small aggregates even at micromolar concentrations and may explain their poor solubility in protic solvents. Interestingly, 2−3 nm red-shifts of the conjugate Soret bands were observed with increasing number

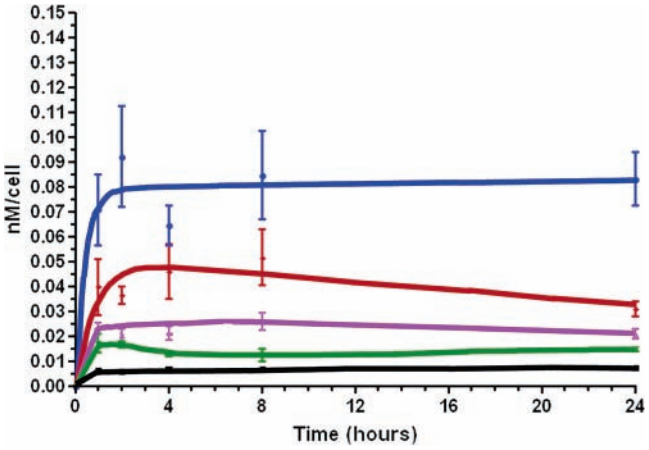

Figure 4. Time-dependent uptake of conjugates **1** (black), **2** (purple), **3** (green), **4** (red), and **5** (blue) at 10 μM by HEp2 cells.

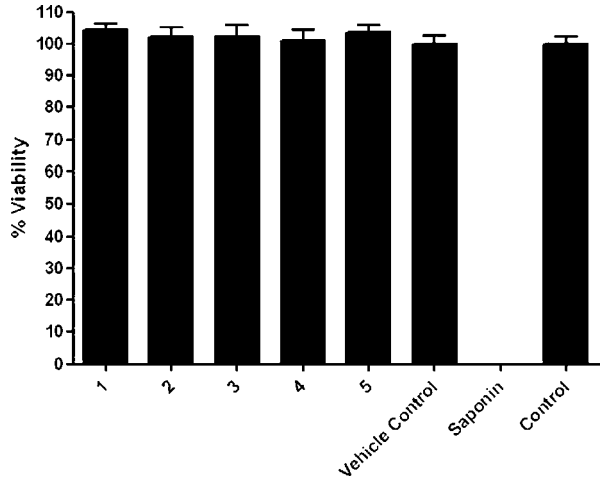

Figure 5. Dark cytotoxicity of conjugates **1**–**5** and controls toward HEp2 cells using the Cell Titer Blue assay.

of cobaltacarborane moieties linked to the porphyrin macrocycle; for example, the Soret bands of conjugates **1** and **5** appear at 418 and 427 nm, respectively. The fluorescence spectra of conjugates **1**–**5** (Figure 3) all display emissions at ~653 nm in acetone solution, upon excitation at 512 nm. The most intense fluorescence band was observed for conjugate **1**, containing only one cobaltacarborane substituent on the porphyrin macrocycle.

Cellular Studies. The time-dependent uptake of conjugates **1**–**5** was evaluated in HEp2 cells at a concentration of 10 μM (Figure 4). Since the conjugates were poorly soluble in water, DMSO and Cremophore EL were used as the delivery vehicles (0.9%DMSO/0.1% Cremophor EL). At 10 μM concentration all conjugates were found to be nontoxic to the cells, as evaluated using the Cell Titer Blue assay (Figure 5). Higher concentrations were not investigated due to the poor solubility of the conjugates in aqueous solutions. At the low concentration used, the DMSO/Cremophor EL vehicle was nontoxic to cells (Figure 5, vehicle control), while 0.2% saponin provided 100% cell death, and the control cells (in the absence of both conjugate and vehicle) showed 100% cell viability (Figure 5). The cellular uptake of conjugates **1**–**5** significantly increased with the number of cobaltacarborane moieties linked to the porphyrin macrocycle, as shown in Figure 4. Conjugate **5**, bearing four cobaltacarboranes, accumulated the most within cells, approximately 16 times more than **1**, bearing only one cobaltacarborane, at all time points. Conjugate **3**, with two cobaltacarboranes linked to adjacent *meso*-pyridyl rings, was taken up by HEp2 cells to a significantly higher extent (~25%) than **2**, bearing two cobaltacarboranes linked to opposite pyridyls. The uptake kinetics were similar for all conjugates, proceeding rapidly in the first 1–2 h after which a plateau was reached.

The intracellular localization of conjugates **1**–**5** in HEp2 cells was investigated by fluorescence microscopy, using Lipofectamine liposomes as the delivery vehicle (Figure 6). In the absence of liposomes the fluorescent signal for the conjugates was too weak to be clearly detected above the background autofluorescence, due to their poor water solubility. Using liposomes as the delivery vehicle, we observed a very punctate fluorescence for all conjugates, as seen in Figure 6, indicating that they all localize within vesicles. Colocalization experiments with LysoSensor Green and Mitotracker Green, as seen in Figure 7 for conjugate **3** (similar figures are available for conjugates **1**, **2**, **4**, and **5** in the Supporting Information), indicate that some of the conjugates' fluorescence correlates with the cell lysosomes.

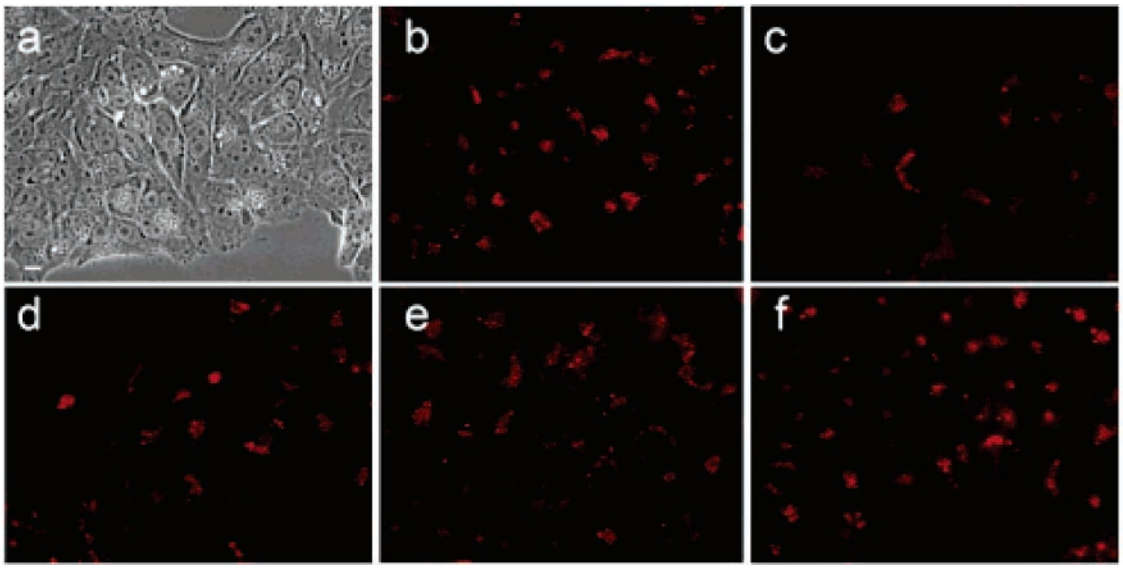

Figure 6. Subcellular localization of conjugates **1**–**5** in HEp2 cells at 1 μM in liposomes for 18 h. (a) Phase contrast, (b) **1** fluorescence, (c) **2** fluorescence, (d) **3** fluorescence, (e) **4** fluorescence, (f) **5** fluorescence. Scale bar: 10 μm.

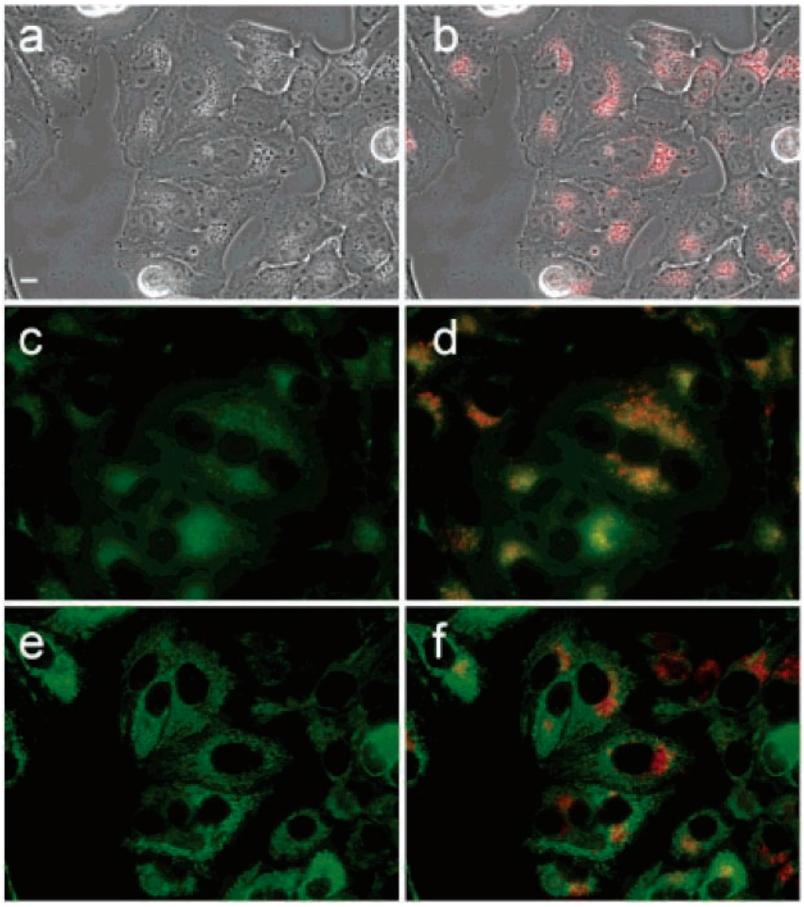

Figure 7. Subcellular localization of conjugate **3** in HEp2 cells at 1 μM in liposomes, for 18 h. (a) Phase contrast, (b) overlay of **3** fluorescence and phase contrast, (c) LysoSensor Green fluorescence, (e) MitoTracker Green fluorescence, (d), (f) overlays of organelle tracers with **3** fluorescence. Scale bar: 10 μm.

DISCUSSION

Cobaltacarborane−porphyrin conjugates **1**−**5** were synthesized in 88−98% yields in a single-step reaction between cobaltacarborane **6** and pyridylporphyrins **7**−**11**. This methodology allows the easy and expeditious preparation of the target porphyrin conjugates, in gram amounts. N-Alkylated pyridylporphyrins, in particular *meso*-tetra(*N*-methylpyridyl)porphyrin, have been extensively studied as DNA and RNA binding probes (*33*−*37*) and as antibacterial and antiviral agents (*38*−*41*). The biological activity of this type of compound depends on the size and distribution of the macrocycle periphery groups, the molecule charge and its distribution, and on the nature of the centrally chelated metal ion and associated axial ligand(s) (*42*). The new zwiterionic porphyrin conjugates **1**−**5** bearing one to four *N*-cobaltacarboranepyridyl moieties were synthesized in order to study their biological activity and to correlate their structure and charge distribution with their cellular uptake and preferential sites of intracellular localization. All conjugates display absorption spectra characteristic of porphyrin macrocycles (Figure 2) and fluorescence emissions in the red region of the optical spectrum (Figure 3).

The cellular uptake of all conjugates in the presence of a DMSO/Cremophor EL delivery vehicle was studied in HEp2 cells at a concentration of 10 μM. The amount of conjugate accumulated by cells depended significantly on the number of cobaltacarborane residues linked to the porphyrin macrocycle, and on its distribution about the ring (conjugates **2** and **3**). Compound **5**, bearing four cobaltacarboranes, accumulated the most within cells, while conjugate **1**, bearing a single cobaltacarborane, accumulated the least (Figure 4). Although conjugate **1**, with only one positive and one negative charges, is expected to be more hydrophobic than **5**, which bears four positive and four negative charges, the latter showed decreased solubility in polar solvents and increased tendency for aggregation, as indicated by its lower emission intensity of all conjugates studied (Figure 3). Porphyrin aggregates are potentially taken up to a higher extent by cells in culture, via an endocytic pathway (*43*). We have previously observed that free-base carboranylporphyrins accumulated within cells to a higher extent than their Zn(II) counterparts, as a result of their higher tendency for forming aggregates and consequently higher hydrophobicity (*10*, *44*). We have also observed that a porphyrin bearing eight *nido*-carborane groups was taken up by T98G cells to a lower extent than a related tetra(*nido*-carboranyl)porphyrin, although in this case the overall molecule charge changed from −8 to −4 and the octa-anionic porphyrin was more hydrophilic than the tetra-anionic derivative (*10*). On the other hand, the overall molecule charge for all conjugates **1**−**5** is zero, and their tendency for aggregation likely increases with the number of charges. The charge distribution about the porphyrin ring was also found to affect cellular uptake; conjugate **3**, bearing two cobaltacarboranes on adjacent pyridyl rings, accumulated to a higher extent within cells compared with **2**, bearing the charges and substituents on opposite pyridyl rings. It is expected that conjugate **3**, with two distinctive charged/hydrophobic moieties, will have different aggregation behavior from **2**. In agreement with these results, we have recently discovered that two

(*N*-trimethylaminophenyl)porphyrins, bearing two positive charges on either adjacent or opposite *meso*-phenyl rings, display different photodynamic efficacy, possibly as a result of their different interactions with biological substrates (*45*).

All porphyrin−cobaltacarborane conjugates localized into vesicles within HEp2 cells, when delivered by Lipofectamine liposomes (Figure 6). Colocalization experiments showed that these vesicles correlated to some extent with the cell lysosomes (Figure 7). Our group and others have previously observed that carboranylporphyrins preferentially localize in the cell lysosomes (*10*, *44*, *46*). However, the use of liposomes as delivery vehicle could potentially alter the subcellular distribution of porphyrin sensitizers, as we have recently reported (*47*, *48*). This could in part explain the vesicle localization observed in this study for conjugates **1**−**5** and its partial correlation with the cell lysosomes.

ACKNOWLEDGMENT

The authors thank Dr. Frank Fronczek for assistance with the molecular structure determination and Dr. Martha Sibrian-Vazquez for assistance with HPLC. This work was supported by the National Institutes of Health, grant number R01 CA098902.

Supporting Information Available: Additional spectroscopic data including HRMS and NMR spectra for all conjugates synthesized, HPLC conditions, and subcellular localization figures for conjugates **1**, **2**, **4**, and **5** is available free of charge via Internet at http://pubs.acs.org. Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 272582. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, (fax: +44-(0)1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

The inhibition of the caspase-3 enzyme is reported to increase neuronal cell survival following cerebral ischemia. The peptide Z-DEVD-FMK is a specific caspase inhibitor, which significantly reduces vulnerability to the neuronal cell death. However, this molecule is unable to cross the blood−brain barrier (BBB) and to diffuse into the brain tissue. Thus, the development of an effective delivery system is needed to provide sufficient drug concentration into the brain to prevent cell death. Using the avidin (SA)−biotin (BIO) technology, we describe here the design of chitosan (CS) nanospheres conjugated with poly(ethylene glycol) (PEG) bearing the OX26 monoclonal antibody whose affinity for the transferrin receptor (TfR) may trigger receptor-mediated transport across the BBB. These functionalized CS−PEG−BIO−SA/OX26 nanoparticles (NPs) were characterized for their particle size, zeta potential, drug loading capacity, and release properties. Fluorescently labeled CS−PEG−BIO−SA/OX26 nanoparticles were administered systemically to mice in order to evaluate their efficacy for brain translocation. The results showed that an important amount of nanoparticles were located in the brain, outside of the intravascular compartment. These findings, which were also confirmed by electron microscopic examination of the brain tissue indicate that this novel targeted nanoparticulate drug delivery system was able to translocate into the brain tissue after iv administration. Consequently, these novel nanoparticles are promising carriers for the transport of the anticaspase peptide Z-DEVD-FMK into the brain.

INTRODUCTION

The blood−brain barrier (BBB) is a diffusion barrier essential for the normal function of the central nervous system. The BBB endothelial cells differ from endothelial cells in the rest of the body by the absence of fenestrations, more extensive tight junctions (TJs), and sparse pinocytic vesicular transport. Endothelial cell tight junctions limit the paracellular flux of hydrophilic molecules across the BBB (*1*). In fact, only nonionic, lipophilic, and low molecular weight molecules can diffuse freely through the endothelial membrane and may passively cross the BBB. On the other hand, a large number of drugs that possess a favorable lipophilicity, which normally should enable an easy transport across these cells, are rapidly pumped back into the bloodstream by effective efflux pump systems (*2*, *3*). These efflux pump systems include multiple organic anion transporter (MOAT) and especially P-glycoprotein (P-gp) sometimes referred to as multidrug resistance protein (mdr). Other essential compounds such as amino acids, hexoses, neuropeptides, and proteins need specific carriers or transporter systems to permeate the brain (*2*). Consequently, very few molecules may be transported efficiently into the brain which may compromise the efficient treatment of neurological and psychiatric disorders.

Vector-mediated drug delivery to the brain employs the chimeric peptide technology, wherein the drug is conjugated to a molecular carrier of protein nature (i.e. cationized albumin or OX26 monoclonal antibody). Although this approach has been found useful for the brain delivery of a vasoconstrictive intestinal peptide analogue (VIP), the amount of drug transported with the aid of this technology remains generally limited since the ratio

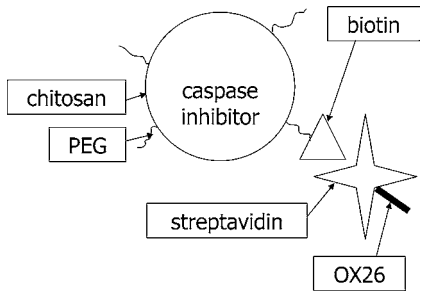
of drug to carrier protein is usually not above 1:1. This is the reason, poly(ethylene glycol) or span 80-coated polymeric nanoparticles have been proposed as an interesting alternative for targeted brain delivery (*3*). It is hypothesized that with such types of hydrophilic coatings, the natural blood opsonization process of the particles is reduced; hence, a relative avoidance of the recognition by macrophages in the liver and spleen is conferred. This steric repulsion augments particle blood half-life and therefore extravasation to nonreticuloendothelial system organs, including the brain, especially when brain pathologies occur together with an increase in the endothelial permeability (*4*, *5*).

Transferrin receptor (TfR), which is highly concentrated in brain capillary endothelium, may trigger receptor-mediated transport across the BBB since it undergoes trancytosis through the BBB (*6*, *7*). Because the circulating concentration of transferrin is manyfold greater than the dissociation (K_D) of the BBB transferrin receptor (*8*), it appears more efficient to use the OX26 mouse monoclonal antibody to the rat transferrin receptor to target the brain. Transferrin itself is limited as a brain drug transport vector since the transferrin receptors are almost saturated under physiologic conditions due to high endogenous plasma concentrations of transferrin. However, the antibodies that bind to the TfR have been shown to selectively target BBB endothelium due to the high levels of TfR expressed by these cells. Therefore, these antibodies are potential carriers for the delivery of therapeutic agents to the central nervous systems. With a mouse monoclonal antibody against the rat TfR, OX26, a high abundance of transferrin receptors at the brain microvascular endothelium has been detected. The OX26 monoclonal antibody against the rat TfR is likely to be a candidate in the delivery of therapeutic agents to the brain (*9*).

Chitosan (CS) is obtained from the deacetylation of chitin, a naturally occurring and abundantly available biocompatible polysaccharide which is obtained from crabs. However, applications of chitin are limited compared to CS, since it is chemically inert (*10*). CS, on the otherhand is a cationic polysaccharide in neutral or basic pH conditions and contains free amino groups which can go undergo protonation, thus making it soluble in water. CS is biocompatible with living tissues since it does not cause allergic reactions and rejection. It is degraded into nontoxic amino sugars under fermentation. The biocompatibility and nontoxic properties of chitosan make this polymer a good candidate for pharmaceutical applications such as targeted drug delivery. The primary amine groups render special properties that make CS very useful in pharmaceutical applications. Compared to many other natural polymers, CS has a positive charge and is mucoadhesive (*11*). Therefore, CS has been used for widespread applications such as colon targeted drug delivery, mucosal delivery, cancer theraphy, gene delivery, topical delivery, and ocular delivery (*12*−*17*). Another advantage of this type of NPs is that due to the hydrophilic nature of chitosan, it can be prepared under exceptionally mild conditions (*18*, *19*), thus being particularly attractive for the association of delicate compounds such as peptides and proteins.

It has been reported that, in focal as well as global brain ischemia, the caspase-3 enzyme is induced and its pro form is activated in ischemic neurons. Caspase-3 activation precedes and its regional distribution correlates with cell death. Furthermore, caspase-3 inhibitors increase cell survival after ischemia which strongly supports a cell death effector role for the caspase-3 protease in ischemic brain injury. Similarly, knocking out the caspase-3 gene confers resistance to brain ischemia. Thus, inhibition of caspase-3-like protease activity is of great interest and may have therapeutic significance in the treatment of stroke and related neurological disorders (*20*). Supporting this view, Ma et al. (*21*) showed that the combined administration of subthreshold doses of basic fibroblast growth factor (bFGF) and caspase inhibitors reduced infarct volume as well as neurological deficit after focal ischemia.

Scheme 1. The Schematic View of Novel Drug Delivery System for Brain Delivery of Chitosan−PEG Nanoparticles Functionalized with the Monoclonal Antibody OX26



On the basis of these considerations, we describe here a new nanotechnology for the brain delivery of the caspase inhibitor peptide Z-DEVD-FMK. This technology consists of PEG-overcoated chitosan (CS) nanoparticles conjugated with the monoclonal antibody OX26, using the avidin−biotin approach. These addressed CS nanoparticles combine (i) the ability of cationic CS to interact with the negative charges of the brain endothelium and (ii) the affinity of OX26 for the transferrin receptor to trigger receptor-mediated transport across the BBB (Scheme 1).

EXPERIMENTAL SECTION

Materials. The CS Protasan Cl 113 (Mw < 150 kD, deacetylation degree: 75−90%) and the caspase inhibitor peptide Z-DEVD-FMK were purchased from FMC Biopolymers (Norway) and Enzyme Systems (Livermore, CA), respectively. Pentasodium tripolyphosphate (TPP), streptavidin−FITC, trifluoroacetic acid (TFA), maleimidobenzoyl *N*-hydroxy-
succinimide ester (MBS), and Traut's Reagent (2-iminothiolane) were purchased from Sigma-Aldrich (St. Louis, MO). Antihuman CD71 (OX26) was received from Cymbus Biotechnology (Hants, UK). Acetonitrile was purchased from Carlo Erba Reagenti (Italy). All other reagents used were of analytical or pharmaceutical grade.

Synthesis of Chitosan-PEG (CS−PEG). Chitosan·HCl [80 mg, 0.40 mmol, degree of acetylation 13.7%, M_w 113650, (Protasan UP CL113)] was dissolved in H_2O (11.5 mL). MeO-PEG-CH_2CO_2H (14.2 mg, 2.77 μmol, M_n 5114 by MALDI-TOF) and NHS (1.63 mg, 0.014 mmol) were added to the solution. Then, EDC (21.7 mg, 0.113 mmol) was added gradually due to its instability. The resulting solution was stirred at room temperature for 22 h and then ultrafiltered (Amicon, YM30), and lyophilized to give chitosan-PEG (CS−PEG) as a white foam [74 mg, degree of substitution (DS) 0.56% determined by ^{1}H NMR]. ^{1}H NMR (500 MHz, D_2O) δ (ppm): 2.07 (s, 41.1 H, $COCH_3$), 3.10−3.30 (m, 84 H, H2 from $GluNH_2$), 3.30−4.30 (m, 778 H, H2 from GluNHAc; H3, H4, H5, H6 from $GluNH_2$ and GluNHAc; CH_3O, CH_2O from PEG), 4.55−4.70 (m, H1 from GluNHAc) 4.80−4.95 (m, H1 from $GluNH_2$).

Synthesis of Chitosan−PEG−Biotin (CS−PEG−BIO). The copolymer made of chitosan and PEG−biotin

(CS−PEG−BIO) was synthesized in two steps from a heterobifunctional PEG as described below.

Synthesis of HO_2C−PEG-Biotin. [$HO_2C(CH_2)_3CONH$-$(CH_2CH_2O)_nCH_2CH_2CONH(CH_2CH_2O)_2CH_2CH_2NHCO$−biotin]: $FmocHN(CH_2CH_2O)_nCH_2CH_2CONHS$ ($M_n = 3837$, M_w=3890 determined by MALDI-TOF, Nektar) was treated with $H_2N(CH_2CH_2O)_2CH_2CH_2NHCO$−biotin in $CHCl_3$. The resulting product was subjected to Fmoc deprotection and reaction with glutaric anhydride to give the desired HO_2C−PEG−biotin in 76% combined yield ($M_n = 4009$, $M_w = 4030$ by MALDI-TOF). ^{1}H NMR (400 MHz, CD_3Cl, 333 K) δ (ppm): 1.35−1.55 (m, 2H, CH_2), 1.57−1.90 (m, 4H, CH_2), 1.95 (q, $J = 6.9$ Hz, 2H, CH_2), 2.15 (t, $J = 6.7$ Hz, 2H, CH_2CONH), 2.22 (t, $J = 7.1$ Hz, 2H, CH_2CO), 2.32 (t, $J = 6.8$ Hz, 2H, CH_2CO), 2.41 (t, $J = 5.5$ Hz, 2H, CH_2CONH), 2.75 (d, $J = 12.8$ Hz, 1H, CH_2), 2.93 (dd, $J = 4.9$ Hz, $J = 12.8$ Hz, 1H, CH_2), 3.00−3.20 (m, 1H, CH), 3.25−3.90 (m, 325H,CH_2O, CH_2NH), 4.25−4.35 (m, 1H, CH), 4.35−4.50 (m, 1H, CH), 4.67 (br s, 1H, NH), 6.16 (br s, 2H, NH), 6.64 (br s, 1H, NH).

Synthesis of Chitosan−PEG−Biotin. CS−PEG−BIO was synthesized as described above for CS−PEG (under the title of Synthesis of Chitosan−PEG (CS−PEG)) from chitosan·HCl [53.3 mg, 0.27 mmol (Protasan UP CL113)], HO_2C-PEG−biotin (7.8 mg, 1.94 μmol), NHS (1.0 mg, 8.59 μmol), and EDC (14.4 mg, 0.075 mmol). The desired CS−PEG−BIO was obtained as a white foam (60.8 mg, DS 0.55% determined by ^{1}H NMR). ^{1}H NMR (500 MHz, D_2O) δ (ppm): 2.07 (s, 41.1 H, $COCH_3$), 3.10−3.30 (m, 87 H, H2 from $GluNH_2$), 3.30−4.30 (m, 691 H, H2 from GluNHAc; H3, H4, H5, H6 from $GluNH_2$ and GluNHAc; CH_3O, CH_2O from PEG), 4.62 (m, H1 from GluNHAc) 4.91 (m, H1 from $GluNH_2$).

Preparation of Chitosan and Surface-Modified Chitosan Nanoparticles. CS, CS−PEG, or CS−PEG−BIO nanoparticles were prepared by the ionic gelation of TPP and CS, CS−PEG, or CS−PEG−BIO according to the procedure previously developed by P. Calvo et al. for the preparation of CS nanoparticles (*18*, *19*).

Preliminary experiments were performed in order to identify the optimal concentrations of CS and TPP for NP formation. Practically, CS nanoparticles were formed upon dropwise addition of 1 mL TPP aqueous solution (0.4 mg/mL) to 1 mL of CS aqueous solution (1.75 mg/mL). Likewise, CS−PEG and CS−PEG−BIO (1 mg/mL each) nanoparticles were prepared by dropwise addition of 0.4 mL TPP aqueous solution (0.84 mg/mL) to 1 mL of each of the corresponding aqueous polymer solutions. These solutions were then stirred under magnetic stirring at medium speed and room temperature.

Z-DEVD-FMK-loaded nanoparticles were obtained according to the same procedure, and the ratio of polymer/TPP remaining unchanged. Z-DEVD-FMK was incorporated in the polymer solution before the addition of the TPP. The initial concentration of the peptide in the NP suspension was 800 ng/mL. Although the previous study (*22*) showed that the optimum loading concentration was 400 ng/mL, the 800 ng/mL concentration was used in the present study since the released amount would be higher compared to the former loading concentration.

The resulting mixtures were broadly characterized as either a clear solution, an opalescent suspension displaying a tyndall effect (NPs), or aggregates. Nanoparticles were isolated by ultracentrifugation (10 000 rpm, 4 °C, 60 min in the presence of 10 μL of glycerol) and then resuspended in water by manual shaking.

Preparation of the Streptavidin/OX26 Conjugate (SA/OX26). The SA/OX26 conjugates were prepared according to the procedure described by Yoshikawa and Pardridge (*23*). Briefly, 1 mg of streptavidin−FITC (SA−FITC) was dissolved in 100 μL of borate buffer containing 0.1 M EDTA (0.1 M) and 5 μL of 2-iminothiolane (4 mg/mL). After stirring for 90 min at room-temperature nonthiolated streptavidin was removed by dialysis in 0.05 M phosphate buffer (pH 6.5). Then, 100 μL of OX26 solution was added to 100 μL of SA−FITC solution. After stirring for 30 min, nonreacted OX26 was discarded by dialysis.

Preparation of OX26-Conjugated Nanoparticles (CS−PEG-BIO−SA/OX26). 10 μL of SA/OX26 conjugate was added to 1 mg of lyophilized CS−PEG−BIO NP previously resuspended in deionized water (100 μL); this suspension was incubated for 30 min. The CS−PEG−BIO−SA/OX26 nanoparticles obtained were lyophilized for further use.

Characterization of Nanoparticles. Measurements of particle size and zeta potential of the NPs were performed in triplicate by photon correlation spectroscopy and laser doppler anemometry, respectively, using a Zetasizer Nanosystems 3000 HS (Malvern Instruments, UK). The size measurements were carried out at 25 °C at a 90° scattering angle and recorded for 180 s for each measurement. After staining with 1% (w/v) phosphotungstic acid, the morphological characterization of the CS NPs was done using a transmission electron microscope (TEM; CM12 Philips).

Quantitative Analysis of Z-DEVD-FMK. Z-DEVD-FMK was analyzed by reversed-phase (RP) HPLC utilizing a Hewlett-Packard Agilent 1100 apparatus with HP CHEMSTATION software and a C18 RP column (250 × 4.6 mm; particle size 5 μm; Waters Assoc.). Water:acetonitrile (80:20) containing 0.1% TFA was used as the mobile phase with a flow rate of 1 mL/min. Column effluent was monitored by UV absorption at 215 nm. Total run time was 6 min and the injection volume was 50 μL. The retention time of the peptide was 2.8 min. A calibration curve was constructed using standard Z-DEVD-FMK solutions prepared in the incubation medium. The calibration curve was linear between 25 and 150 ng/mL ($y = 2.6309x - 20.542$, $R^2 = 0.9975$). The limit of detection was 10 ng/mL. Peptide solution was found to be stable both at room temperature and at 4 °C for 1 day.

Evaluation of the Peptide Association Efficiency. The NPs loaded with Z-DEVD-FMK anticaspase peptide were subjected to ultracentrifugation (10 000 rpm at 4 °C for 1 h). Then, the amount of free peptide was measured in the clear supernatant by RP-HPLC as described above (under the title of Quantitative Analysis of Z-DEVD-FMK). The peptide loading capacity (LC) and the association efficiency (AE) of the nanoparticle were calculated according to the following equations:

$$\%\ \mathrm{LC} = 100 \times (\text{total peptide amount} - \text{free peptide amount})/\text{nanoparticle weight}$$

$$\%\ \mathrm{AE} = 100 \times (\text{total peptide amount} - \text{free peptide amount})/\text{total peptide amount}$$

Evaluation of in Vitro Z-DEVD-FMK Release. The NPs were collected by centrifugation at 10 000 rpm for 1 h on a glycerol bed, and an aliquot of NPs (1 mg) was then resuspended and incubated in 1 mL of PBS (pH 7.4) at 37 °C under light agitation. At varying time points, supernatants were isolated by centrifugation at 10 000 rpm for 20 min, and the amount of Z-DEVD-FMK released was measured by RP-HPLC as described earlier. All measurements were performed in triplicate.

The stability of the peptide in the release medium was checked by a 24 h stability assay. Practically, peptide solutions in PBS with three concentrations (25, 50, and 150 ng/mL) were prepared, each solution being divided into three equal portions. The first portion was immediately analyzed, while the remaining two portions were kept at room temperature and at 4 °C prior to HPLC analysis.

In Vivo Brain Uptake of the CS−PEG−BIO−OX26/SA Nanoparticles. Swiss albino mice weighing 30−33 g were housed under diurnal lighting conditions (12 h darkness and 12 h light) and fasted overnight but allowed free access to water before the experiment. Animal housing, care and application of experimental procedures were all done in accordance with institutional guidelines. Mice ($n = 9$) were anesthetized intraperitoneally (ip) with 50 mg/kg ketamin (Ketalar, Parke-Davis) and 10 mg/kg xylasine (Rompun, Bayer). Body temperature was monitored with a rectal probe and maintained at 37.0 ± 0.2 °C by a homeothermic blanket.

FITC-labeled NPs were detected with fluorescence microscopy (Nikon Eclipse E600, λ_{Ex} 450−490 nm). In preliminary experiments, to observe the appearance of FITC-labeled NPs, microscopic slides prepared from nanoparticle containing suspensions (1 mg in 200 μL of saline) were examined under the microscope. Later, the NPs (1 mg in 200 μL of saline) were injected intracerebrally with a microsyringe to the right frontal cortex, and mice were immediately sacrificed and decapitated ($n = 2$). NPs not conjugated to OX26 were administered as control ($n = 4$). Coronal cryosections of 20 μm thickness obtained from 2 mm posterior of the frontal pole and coverslipped with mounting medium containing Hoechst-33258 to counterstain the nuclei were examined. After determining how FITC-labeled nanospheres appeared in the brain, coronal sections obtained by the same method were examined from mice brains administered with the same nanoparticle suspensions via the tail vein. Mice were sacrificed and decapitated one ($n = 2$) and two ($n = 4$) hours after the iv injection of the NPs.

Histological specimens (1 mm^3) were obtained from the frontal cortex, striatum, and the occipital cortex of both hemispheres for examination under transmission electron microscope. They were fixed in 2.5% gluteraldehyde for 24 h, washed in phosphate buffer (pH 7.4), postfixed in 1% osmium tetroxide in phosphate buffer (pH 7.4), and dehydrated in increasing concentrations of alcohol for TEM examination. Then the tissues were washed with propylene oxide and embedded in epoxy-resin embedding media. Semithin sections about 2 μm in thickness and ultrathin sections about 60 nm in thickness were cut with a glass knife on a LKB−Nova (Sweden) ultramicrotome. Semithin sections were stained with methylene blue and examined by a Nikon Optiphot (Japan) light microscope. After trimming procedure of these semithin sections, ultrathin sections were taken, collected on copper grids, stained with uranyl acetate and lead citrate, and examined with a JEOL JEM 1200 EX (Japan) transmission electron microscope.

RESULTS AND DISCUSSION

Characterization of Chitosan−PEG, PEG−Biotin, and Chitosan−PEG−Biotin. In Figure 1A the ^{1}H NMR spectrum of the starting CS is depicted. In the ^{1}H NMR spectra of CS−PEG and CS−PEG−BIO (Figures 1B and 1C), the presence of PEG is clearly established by the big intense signal at 3.7 ppm. Also, the differences in the spectra between unfunctionalized PEG and PEG−biotin (Figures 1D and 1E) demonstrate the attachment of biotin to PEG. Noteworthy is that the signal corresponding to biotin in the CS−PEG−BIO ^{1}H NMR spectrum (Figure 1C) could not be observed due to the very low proportion of PEG−BIO in this polymer (DS 0.56%). We can also confirm the formation of PEG−BIO prior to the synthesis of CS−PEG−BIO from the molecular weight of PEG−BIO as shown in Figure 2A. Thus, the presence of a signal at 3.7 ppm in the ^{1}H NMR spectrum of CS−PEG−BIO (Figure 1C) indicates with no doubt the efficient linkage of PEG−BIO to CS.

Nanoparticle Preparation and Characterization. The formation of the Z-DEVD-FMK-loaded CS, CS−PEG, CS−PEG−BIO NPs occurred spontaneously upon incorporation of the counteranion TPP into the corresponding CS, CS−PEG, and CS−PEG−BIO polymer solutions. Nanoparticle construction resulted from the ionic interactions between the negative TPP and the positively charged amino groups of CS. The ratio of CS/TPP was established according to the preliminary studies. Confirmation of the conjugates CS−PEG and CS−PEG−BIO was made by utilizing MALDI-TOF and NMR analyses. However the MALDI-TOF analysis of the CS−PEG−BIO/SA−OX26 could not be achieved due to the high molecular weight of the final product.

TEM images of blank CS and PEG-CS NPs are shown in Figures 3A and 3B, respectively. The particles showed a dense and generally spherical structure. It can be seen that the hydrodynamic diameter of the particles measured by light scattering (PCS) is higher than the size estimated from microscopy (TEM) as observed in the previous study of our group (*22*). This may be attributed to the high swelling capacity of the CS NPs. It is worth mentioning that the NPs studied by TEM were dried samples whereas NPs studied by light scattering were aqueous suspensions. In the latter case the NPs were swollen in aqueous medium while in the former case there was a shrinkage of the NPs. This situation may have led to a difference in particle size obtained by light scattering and by TEM. As shown in Table 1, blank CS NPs displayed a zeta potential of +28.4 mV. The addition of the negatively charged Z-DEVD-FMK resulted in a significant lowering of the zeta potential values of the NPs. It was observed that the size of PEG-CS NPs was smaller as compared to CS NPs. This may be explained by the colloid stabilization exerted by the PEG. On the other hand, when the NPs were surface-modified with either PEG−BIO or PEG−BIO−SA/OX26, an important increase in size was observed. This may be attributed to an increase in the hydrophobicity of the surface of the NPs leading to some aggregation due to presence of bulky groups on the surface. Confirmation of the conjugates CS−PEG and CS−PEG−BIO was made by utilizing Maldi-TOF and NMR analyses. However the Maldi-TOF analysis of the CS−PEG−BIO/SA−OX26 could not be achieved due to the high molecular weight of the final product.

Z-DEVD-FMK Encapsulation. Results in Table 1 show the significant increase in the Z-DEVD-FMK encapsulation efficiency for the conjugated NPs as compared with the nonconjugated CS NPs. There are several factors which could affect the encapsulation of the peptide in the CS NPs, such as CS/TPP ratio, auxiliary molecules, and interaction between the peptide and CS (*24*). In this study, the % AE and % LC could be correlated with the surface modification of the CS. However, the association efficiency of the peptide Z-DEVD-FMK in CS NPs was

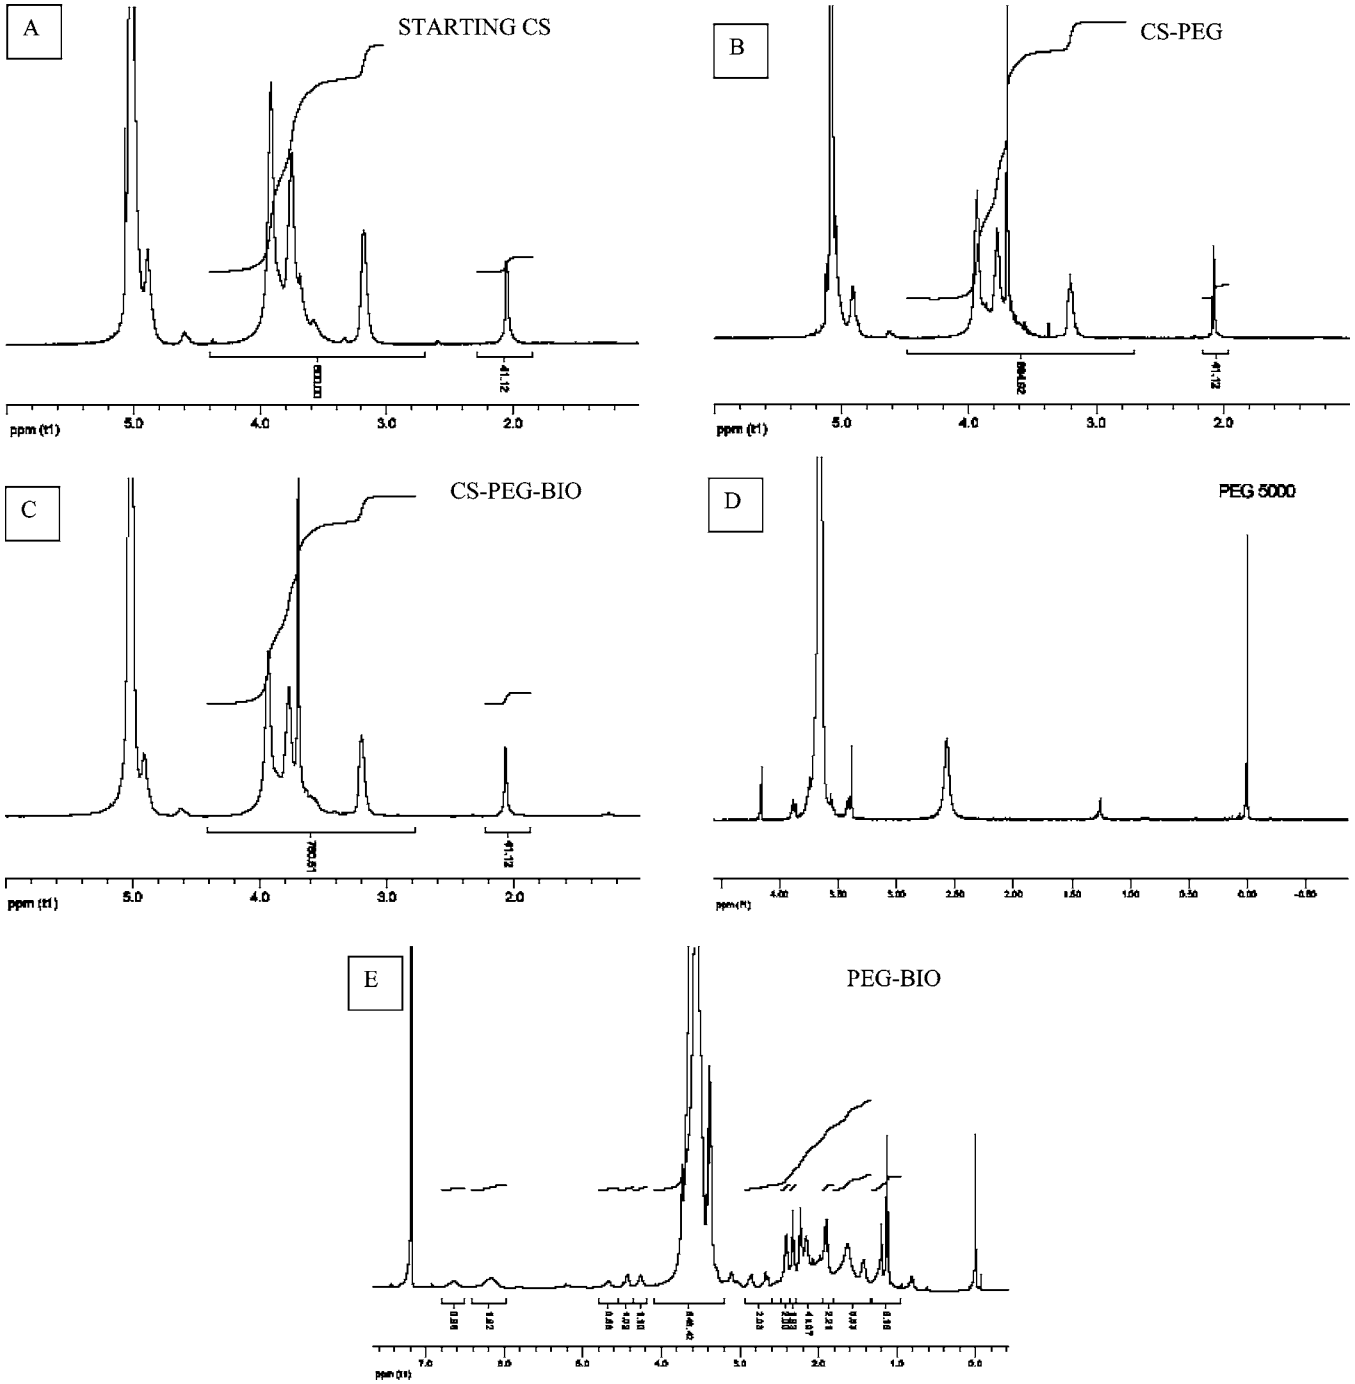


Figure 1. ^{1}H NMR spectra of (A) CS; (B) CS−PEG; (C) CS−PEG−BIO; (D) PEG; (E) PEG−BIO. The identification of the conjugates were determined on the basis of the presence of PEG which gave a signal at 3.7 ppm.

surprisingly low if we take into account the anionic structure of the peptide and its expected tendency to interact with the positively charged chitosan molecules. In fact, the association efficiency reported until now for acidic peptides and proteins such as insulin (*25*), BSA (*19*), and tetanus toxoid (*26*) has always been higher than 30%. It was additionally surprising that CS−PEG NPs exhibited a higher encapsulation efficiency (248 ng per mg nanoparticle) than CS NPs. Further modification of the nanocarrier with BIO and BIO−SA−OX26 led to minor reductions in the amount of peptide associated (188 ng per mg nanoparticle). The fact that the PEGylation of the polymer leads to an increase in the association of the peptide to the NPs suggests that the ionic interaction between the acidic peptide and the positively charged molecules is not the main force involved in the association process. However, more experiments are needed in order to fully clarify the association mechanism of the peptide to the different nanocarriers.

In Vitro Release of Z-DEVD-FMK from Nanoparticles. Figure 4 shows the release profiles in PBS of Z-DEVD-FMK from the different types of CS NPs. A fast initial release (25−45% in 60 min) suggests that some of the peptide could be located onto the surface of the NPs. Release rate constants of different NP types are given in Table 2. For the CS, CS−PEG, and CS−PEG−BIO NPs, similar release profiles were observed despite different peptide loadings. Interestingly, whereas the burst release of Z-DEVD-FMK from CS−PEG−BIO−SA−OX26 NPs was reduced, likely due to the steric

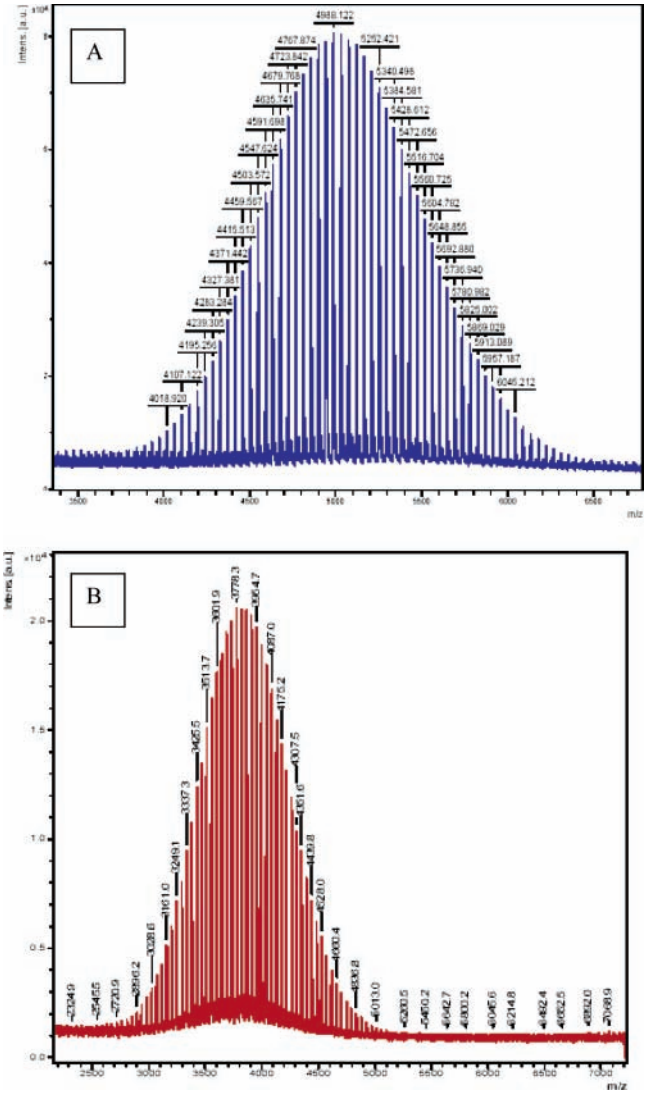

Figure 2. MALDI-TOF mass spectra of (A) PEG−BIO; (B) PEG. The solvent was CH_3Cl for both compounds. The resulting product; PEG−BIO had a combined yield of 76% (M_n = 4009, M_w = 4030).

hindrance induced by the SA/OX26 molecules at the surface of the NPs, CS−PEG−BIO−SA−OX26 NPs exhibited then a much faster second phase release than the other NPs. Thus, surface modification of the CS NPs was observed to have a dramatic impact on the release profile of the peptide. It appears that conjugation of OX26 not only leads to an increase in particle size but also facilitates the faster release of the peptide from the NPs. Although unexpected, this release profile observed with OX26-decorated NPs was very reproducible as confirmed in separate independent experiments. The hypothesis that the OX26 monoclonal antibody may account for a more regular leakage of Z-DEVD-FMK from the nanoparticle will deserve further investigation. Finally, the total amount of the peptide released at the end of 24 h is much higher with CS−PEG−BIO−SA/OX26 NPs (80 ng/mL) than with the others (35−40 ng/mL). This could be an advantage for the intervention to prevent brain ischemia within the very first few hours of brain damage. Additionally, it was calculated that 80 ng of the peptide would be available upon the injection of only 1 mg of the CS−PEG−BIO−SA/OX26 NPs, which is in the range of the therapeutic dose (*27*). In other words, the therapeutic dose of the peptide could be achieved utilizing this technology.

In Vivo Evaluation of the Brain Uptake of CS−PEG−BIO−OX26/SA Nanoparticles. FITC-labeled NPs either OX26-not bearing (Figure 5A) or bearing (Figure 5B) were microscopically detected discretely or as small aggregates in saline solution. The suspensions of OX26-

Table 1. Physicochemical Properties of Different Types of Chitosan NPs

NP type	particle size (nm)	zeta potential (mV)	% AE[a]	% LC[b]	% Z-DEVD-FMK theoretical loading	encapsulated amount (ng)
CS-blank	339.03 ± 5.67	+28.39 ± 0.18	-	-	-	-
CS	383.43 ± 4.60	+20.25 ± 4.60	7.87 ± 0.77	$0.011 \pm 0.014 \times 10^{-3}$	74.4×10^{-3}	112.96

Inset demonstrates the release profiles for the same formulations during the 0−1 h time period. The data points of CS−PEG and CS−PEG−BIO are superimposed.

Table 2. Release Rate Constants ± (SD) of Different Types of Chitosan NPs

NP type	release rate constant (ng·mL·h^{-1})
CS−PEG−BIO−SA/OX26	2.7460 ± 0.0213
CS−PEG−BIO	0.6098 ± 0.0118
CS−PEG	0.4755 ± 0.0090
CS	0.4639 ± 0.0103

free NPs were injected intravenously to mice; the mice were then decapitated and the brains were removed. The brains were checked under a fluorescent microscope. As expected, no fluorescent NP was observed in the brain (Figure 5C). When mice were injected OX26-bearing formulation intravenously (iv), the horizontal sections showed the fluorescent particles scattered all over the hemispheres and were identified again as the same fine, spherical particles, sometimes forming aggregates (Figure 5D). When the vascular lumen was identified with oval-shaped endothelial nuclei linings on both sides (Hoechst staining), no particles were observed inside the lumen of the vessels, most of them being located outside of the intravascular space (Figure 5E). When mice were injected intracerebrally to the right frontal cortex, microscopic observations of horizontal sections have shown that the green fluorescent particles were localized close to the injection site and were identified as fine, spherical particles sometimes forming aggregates as they did in the saline solution (Figure 5F). It is important to note that the appearance of OX26-free formulation administered to the mice brain did not differ from the control brain (Figure 5G). The results indicate that the OX26-conjugated NPs could penetrate into the brain whereas the OX26-free NPs could not, since only the FITC-labeled CS−PEG−BIO/SA−OX26 NPs could be observed under the fluorescence microscope whereas FITC-labeled CS−PEG/SA NPs could not.

In the transmission electron microscopic examination of the ultrathin serial sections, CS−PEG−BIO−OX26/SA NPs having a diameter of approximately 200 nm were observed in the lumen of the blood vessels together with erythrocytes (Figure 6A) and also in the brain interstitium (Figure 6B). The NPs seen in the lumen of the blood vessels were located very close to the endothelial layer. Additionally they were forming groups inside the lumen of the vessels. In the ultrastructural examination of the perivascular tissue, an edema was observed around the blood vessels. On the other hand, the NPs which were observed in the brain interstitium were sparsely distributed inside the tissue. However, in the ultrastructural examination of the control specimens, netiher NPs nor ultrastrcutural changes were observed (Figure 6C). On the contrary CS−PEG−BIO nanospheres could not be observed in the brain of the corresponding animals. These

results showed that the OX26 adressed NPs have the capability to translocate into the brain tissue.

CONCLUSION

In this study, the design of OX26 functionalized chitosan-PEG NPs has been successfully achieved, using the avidin−biotin system. This novel nanocarrier showed a capacity for the association of the peptide Z-DEVD-FMK. In addition, it was shown that the functionalization of the NPs with the OX26 antibody was critical for facilitating their translocation into the brain tissue after iv administration. Since therapeutic doses of the anti-caspase peptide Z-DEVD-FMK may be transported and released utilizing this technology, experiments are underway in order to investigate the pharmacological activity of Z-DEVD-FMK-loaded NPs on experimental models of brain ischemia.

Local anesthetics are useful for reducing acute pain, but their short duration precludes them from use in solely managing postoperative pain. To prolong the duration of local anesthesia, we conjugated bupivacaine to native hyaluronan (HA) and divinyl sulfone cross-linked Hylan A (Hylan B particles) using a hydrolyzable linker incorporating an imide. Bupivacaine was prepared for conjugation to HA by forming the acryl imide derivative. Separately, the carboxyl group of HA was reacted with nipsylethylamine (NEA) using carbodiimide-mediated coupling to provide HA-NEA that was subsequently reduced with tris(2-carboxyethylphosphine) hydrochloride to yield HA carrying a free sulfhydryl (HA-SH). The HA−bupivacaine conjugate was assembled by reacting HA-SH with acrylbupivacaine. Characterization of the conjugates showed 22% degree of modification by 1 mol of carboxyl. In vitro release studies comparing bupivacaine admixed in HA with bupivacaine conjugated to HA showed half-lives of 0.4 ± 0.1 h, and 16.9 ± 0.2 h, respectively, and the bupivacaine was released chemically unaltered as confirmed by LC-MS. In vivo studies to assess the duration of anesthetic activity were performed in a rat sciatic nerve blockade model. For these studies, bupivacaine was conjugated to Hylan B following a similar procedure, and the degree of modification obtained was 14%. Free bupivacaine (3 and 16 mg/kg) and free bupivacaine (3 mg/kg) admixed with Hylan B particles showed nerve block over 4, 9, and 6 h, respectively. Free bupivacaine (3 mg/kg) admixed with bupivacaine (13 mg/kg) conjugated to Hylan B particles showed a four to 5-fold longer impairment of motor function over the free bupivacaine formulations with a total block time of 19 h. Bupivacaine conjugated to Hylan B particles has the potential to prolong the duration of local anesthesia.

INTRODUCTION

Minimizing postoperative surgical recovery periods has become one of the major goals of hospitals to contain and reduce health care costs (*1*−*3*). Optimized local and regional anesthesia regimens improve postoperative rehabilitation by modulating the postoperative stress response thereby improving pulmonary and gastrointestinal function and facilitating postoperative rehabilitation. In treatments such as total knee arthroplasty, accelerating the postoperative convalescence time has been shown to benefit the functional operation outcome while minimizing postoperative complications (*4*). Given the increasing number of older patients with higher comorbidity, this is of particular therapeutic importance as well as considerable economic implications (*5*).

Continuous techniques of regional anesthesia such as indwelling catheters, continuous infusions and repeated, fractional dosing are used to provide several days of effective postoperative analgesia. While these drug delivery approaches have proven their utility at accelerating postoperative recovery and preventing postoperative adverse outcomes, they are often cumbersome, prone to complications, time-consuming, and costly. For example, epidural catheters require the need for subcutaneous tunneling and fixation of the catheter, bacterial filters, frequent changes of tubing, catheter site protection and monitoring to prevent infection, and training for caretakers (*6*). External drug delivery devices and fractional dosing regimens are further challenged by the pharmacokinetic profiles of analgesics, as most widely used anesthetic agents are hydrophilic, small molecules that are rapidly distributed and eliminated from the administration site. For example, local infiltration of bupivacaine shows rapid distribution and elimination with peak systemic levels occurring in 30 to 40 min, followed by a decline to insignificant levels during the next 3 to 6 h (*7*). Therefore, there exists a clinical need for a long-acting local anesthetic that can be simply administered to the patient prior to discharge and can provide 1 to 3 days of local pain management (*8*).

In recent years, several studies investigated approaches to prolong the duration of local anesthetics. Lipids and liposomes (*9*−*11*), microspheres (*12*−*14*), polymeric implants (*15*, *16*), sodium channel toxins (*17*, *18*), butamben formulations (*19*), and new molecules that target sodium channel subtypes (*20*) are all examples of formulations that have shown modest extension of anesthetic duration. Of these, the most promising demonstration of long-term motor blockade was achieved using microspheres combining bupivacaine and an antiinflammatory steroid that showed nerve blockade lasting 2 to 7 days, depending on the species, dosing, and site of administration (*21*).

Hyaluronan (HA) is a naturally occurring linear polysaccharide of alternating β-1,3-D-glucuronic acid and β-1,4-*N*-acetyl-D-glucosamine units found in the extracellular matrix and synovial fluid (*22*). HA is hydrophilic and

forms gels of varying viscosity depending on its molecular weight and concentration. HA that is free of contaminating proteins and nucleotide is nonimmunogenic and therefore an ideal candidate for surgical applications that involve sensitive areas, including nerves and muscles. In addition, HA can be modified using a variety of cross-linkers generating novel copolymeric materials and can be used also for tissue engineering (*23*). As an example, cross-linkers may contain disulfide bonds that can be reduced by dithiothreitol to yield thiol-modified HA that in turn can be reacted with poly(ethylene glycol) diacrylate and other thiol-modified polymers to generate copolymers capable of controlled release of basic fibroblast growth factor (*24*, *25*).

Particular interest has been devoted to HA as a potential delivery vehicle for bupivacaine. Prolongation of bupivacaine's effect by viscous HA formulations was observed in rabbits with the duration of action and pharmacological effects being dependent directly on viscosity (*26*). During these studies it was stated that the influences of ionic interactions between bupivacaine free base and HA were difficult to assess since viscosity masked the electrostatic feature. HA derivatives (i.e., cross-linked) were also used to prolong the duration of action of bupivacaine. In a recent study an in situ cross-linked HA derivative was tested in rats as a vehicle for bupivacaine. Although cross-linked HA appeared to be a safe and effective means for delivery, the curing process used in this method imposed a need for a rapid injection technique to avoid needle blockage during administration (*27*).

The aim of this study is to investigate the release rate and efficacy of bupivacaine tethered via a reversible covalent bond to HA. We hypothesized that a reversible covalent bond may be more effective in maintaining the drug in the carrier for a longer period of time. We used a cross-linked form of HA that did not require an in situ curing process. It is known that HA cross-linked with divinyl sulfone (DVS) to form the derivative, Hylan B, shows longer residence time at the injection site compared to un-cross-linked HA (*28*). Thus, bupivacaine was conjugated via a linker containing a hydrolytically labile bond (i.e. imide) to HA. Moreover, a sulfide bond was included in the proximity of the imide to favor the hydrolysis rate in a fashion similar to the one observed when conjugating the drug paclitaxel to poly(ethylene glycol) (*29*).

This report describes a method to prepare the tethered bupivacaine to HA and Hylan B particles. This HA–bupivacaine conjugate had a significantly slower release rate compared to free bupivacaine in an infinite sink in vitro release system. The HA–bupivacaine conjugate was compared against free bupivacaine, and bupivacaine–hylan B particles admixture formulations in a rat model using the sciatic nerve blockade of motor function.

EXPERIMENTAL PROCEDURES

Materials and Methods. Low molecular weight HA (130 kDa) was prepared by gamma-irradiation of bacterially fermented HA (*30*). HA cross-linked with DVS (Hylan B particles) was prepared following a method in the literature (*31*). Anhydrous solvents and starting materials were purchased from Sigma-Aldrich Co. and used without further purification. ^{1}H and ^{13}C NMR spectra were obtained on a Varian spectrometer (400 MHz) against tetramethylsilane (δ = 0.0 ppm). Mass spectra and high-resolution mass spectra (HRMS) were obtained on a Applied Biosystems Qstar XL spectrometer with Turbolonspray source. Thin-layer chromatography (TLC) was performed on Silica Gel 60 F_{254} precoated on aluminum sheets (EM Separation Technology) using CH_3OH:CH_2Cl_2 (1:19). Dialyses were performed using either membrane tubing (7 kDa MWCO, Spectrum) or tangential flow cassette (10 kDa MWCO, Pierce). Phosphate-buffered saline (PBS) contained 137 mM NaCl, 2.7 mM KCl, 10 mM phosphate buffer, pH = 7.3–7.5, and was purchased as a 10-fold concentrate (EMD Chemicals, Inc.) and diluted to a working concentration with deionized water. UV/visible measurements were obtained using a Varian Cary 50 Probe spectrometer. The molecular weight and degree of modification of HA conjugates were determined using size exclusion chromatography and multiangle laser light scattering (SEC-MALLS) analyzer (model DAWN-EOS, Wyatt Technology). A SEC-MALLS analyzer was connected to refractive index and UV/visible (model UVIS-205, Perkin-Elmer) detectors. Separation was performed using a size exclusion column (300 Å, 7.5 × 300 mm, Macrosphere, Alltech), and the mobile phase was a 0.05 M Na_2SO_4 solution. HA degree of modification was defined as the molar percentage of conjugated repeating dimeric units in HA. The quantitation of bupivacaine rate of release in vitro was determined by high performance liquid chromatography using a C18 reverse-phase column (100 Å, 4.6 × 150 mm, Waters Symmetry) and mobile phase consisting of 55% 10 mM Na_2HPO_4 in 0.1% H_2PO_4 and 45% acetonitrile (pH 2.9–3.0). The purity of bupivacaine released in vitro was determined by high performance liquid chromatography (HPLC model Waters 2690) connected to a UV/visible detector (model Waters 2487) reading at 210 nm and a mass spectrometer (model Waters ZQ-2000) with positive ion electrospray interface. The column used for the separation was a C8 reverse-phase (100 Å, 4.6 × 250 mm, Ace 5, Mac-Mod Analytical). The separation was performed at a column temperature of 25 °C ± 2 °C. Mobile Phase A = 0.1% HCOOH + 0.01% trifluoroacetic acid (TFA) in water. B = 0.1% HCOOH + 0.01% TFA 60% CH_3CN 20% CH_3OH 20% H_2O. Flow rate: 1 mL/min split to 0.2 mL/min after the UV/visible detector into the mass spectrometer. A linear gradient was used: 5–100% B over 10 min, followed by 100% B for 5 min.

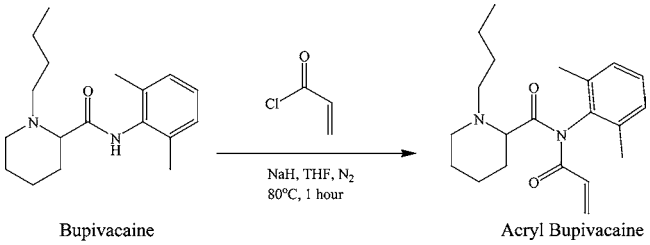

Figure 1. Synthesis of acrylbupivacaine.

Synthesis of Acryl Bupivacaine (Figure 1). Bupivacaine (**1**, 500 mg, 1.74 mmol) was placed in a 100-mL round-bottom flask and dried by azeotropic removal of water with toluene under reduced pressure. Anhydrous THF (5 mL) was added under a nitrogen atmosphere. A suspension of 60% NaH in mineral oil (140 mg, 3.48 mmol) was added, gradually allowing for venting. The resulting mixture was allowed to stir for 30 min at room temperature. Acryloyl chloride (157 μL, 1.92 mmol) was subsequently added. The reaction flask was equipped with a condenser and placed in an oil bath, and the reaction mixture was allowed to stir under reflux for 1 h under nitrogen. After completion of the reaction, as monitored by TLC, the mixture was allowed to cool to

room temperature and the reaction quenched by addition of MeOH (1 mL). The solvents were removed under reduced pressure, and the crude product was dissolved in dichloromethane (50 mL), transferred into a separatory funnel and washed with water (100 mL). The organic phase was collected, dried with Na_2SO_4, and concentrated under reduced pressure. An aliquot was further purified by chromatography over silica using 5% MeOH in dichloromethane. The product acryl bupivacaine (**2**, 162 mg) was obtained as a white solid after removal of solvent under reduced pressure. R_f (methanol/dichloromethane, 1/19): 0.43. ^{1}H NMR (DMSO-d_6): δ = 0.83 (t, 3Hs, J = 7.6 Hz, CH_3 alkyl), 1.2−1.3 (m, 3Hs, CH_2), 1.4−1.5 (m, 5Hs, CH_2), 1.7−1.8 (m, 2Hs, CH_2), 1.9 (s, 3Hs, CH_3 aromatic), 2.0 (s, 3Hs, CH_3 aromatic), 2.3−2.4 (m, 2Hs, CH_2), 5.7 (d, 1H, J = 10.0 Hz, acryl), 5.8 (dd, 1H, J = 10.0, 16.0 Hz, acryl), 6.3 (d, 1H, J = 16.0 Hz, acryl), 7.1−7.3 (m, 3Hs, aromatic) ppm; ^{13}C NMR (DMSO-d_6): δ = 14.3, 14.5, 18.0, 18.6, 20.6, 21.6, 25.6, 28.7, 29.5, 49.5, 55.4, 63.2, 129.0, 129.5, 132.2, 136.4, 136.5, 136.9, 137.2, 167.2, 167.3 ppm HRMS calculated for $C_{21}H_{31}N_2O_2$ (M + H^+): 343.2386; found: 343.2386.

Synthesis of HA-NEA. 3-Nitro-2-pyridinesulfenylethylamine (NEA) was prepared according to a published procedure (*32*, *33*). To a solution of HA (1.5 g, 3.74 mmol, 130 kDa MW) in water (375 mL) was added 1-hydroxybenzotriazole (1.0 g, 7.48 mmol) followed by NEA (1.5 g, 5.61 mmol). The pH of the reaction mixture was adjusted to 4.5 using 2 N HCl. Subsequently, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (2.15 g, 11.22 mmol) was added, and the reaction was allowed to stir at room temperature for 2 h. The resulting HA carrying NEA (**3**) was purified by exhaustive dialysis using a 7 kDa MWCO membrane against PBS, followed by dialysis against water overnight. HA-NEA was recovered by lyophilization as yellow foam (95% yield). Molecular weight and degree of modification of carboxy-modified HA-NEA were determined by SEC-MALLS analysis with detection at 350 nm.

Synthesis of HA-SH (Figure 2). Compound **3** (1.0 g, 2.5 mmol, 130 kDa MW, and 22% degree of modification) was treated with a 50 mM tris(2-carboxyethylphosphine) hydrochloride (TCEP) solution (250 mL) at 4 °C for 4 h. The resulting HA carrying free sulfhydryl (**4**) was purified by exhaustive dialysis using a 7 kDa MWCO membrane against 30 mM succinate buffer containing 120 mM NaCl (pH = 4.5) followed by dialysis against water overnight. HA-SH was recovered by lyophilization as off-white foam (90% yield). Free sulfhydryl group was quantitated colorimetrically using Ellman's reagent (*34*, *35*).

Synthesis of HA−Bupivacaine (Figure 2). A solution of compound **4** (50 mg, 0.130 mmol of HA, 0.032 mmol of free SH) in water (10 mL) was pH adjusted to 8.0 using triethanolamine and the solution cooled using an ice−water bath. A solution of compound **2** (14 mg, 0.038 mmol) in dimethylformamide (DMF, 130 μL) was added to the solution of **4**. Additional DMF (5 mL) was added to maximize the solubility of both compounds **2** and **4**. The solution was stirred at 4 °C overnight. The consumption of the free sulfhydryl groups was monitored colorimetrically (Ellman's reagent). At the end of the reaction, the mixture was transferred into a 7 kDa MWCO membrane and dialyzed at 4 °C against PBS overnight, followed by dialysis against water for 6 h. The retentate was lyophilized to give a white solid product (40 mg, 80% yield). The results of the SEC-MALLS and UV/visible spectroscopy were consistent with the HA−bupivacaine conjugate, **5a**.

Synthesis of Hylan B−Bupivacaine (Figure 2). Bupivacaine was conjugated to Hylan B following a similar procedure to the one described above for compound **5a**. The synthesis was performed starting from sterile Hylan B particles and operating under aseptic conditions. Hylan B particles (378 mL, 5.3 mg/mL in 0.9% NaCl solution) were functionalized with NEA and reduced to the free sulfhydryl form. Degree of modification was 14% as determined colorimetrically using Ellman's reagent (*34*, *35*). Hylan B particles carrying free sulfhy-

dryl group were reacted with **2**. The Hylan B−bupivacaine conjugate particles (**5b**) were transferred into a 7 kDa MWCO membrane and dialyzed at 4 °C against PBS overnight, followed by dialysis against water for 6 h. The retentate was lyophilized to give a white solid product (1.9 g, 94% yield). Degree of modification was 14% as determined by UV/visible spectroscopy with detection at 260 nm, using bupivacaine as a standard.

Release Rate of Bupivacaine In Vitro. The release rate of bupivacaine in vitro (infinite sink) from the compound **5a** was compared to an admixture of free bupivacaine in a HA solution. To prepare the test sample, compound **5a** was dissolved at 5% w/w in distilled water. The admixed control sample was prepared by dissolving one part bupivacaine hydrochloride in 99 parts of a 5% aqueous solution of HA (MW 130 kDa). Aliquots (approximately 1 to 1.5 g) of each solution were weighed in triplicate into tangential flow cassettes (10 kDa MWCO, Pierce). The cassettes were then placed individually in 0.1 M PBS (250 mL) at 37 °C with stirring. The composition of the receptor phase over time was analyzed by HPLC.

In Vivo Studies, Sciatic Blockade Technique, and Evaluation. Female Sprague Dawley rats weighing 250 to 300 g were acclimated with free access to food and water for a minimum of 5 days prior to the procedure. Three days prior to each experiment, rats were acclimated to stainless steel cages with mesh flooring. Anesthesia was induced with 2−3% isoflurane in 100% oxygen in a sealed chamber. The skin of the dorsal thigh was shaved, and 200 μL of either a control solution or test formulation was injected into the perineural space of the sciatic nerve. Animals were allowed to recover and were returned to their cages. Immediately following recovery, all animals were observed for the onset of motor block. Motor block was defined as loss of local motor function, exhibited by foot dragging, curling of toes, weight bearing on the lateral margin of the foot, and inability to grab the bars of the cage. The extent of nerve blockade was assessed by monitoring the rats over time using a three-point scoring system (Table 1).

The approximate time to onset was recorded. Animals were evaluated every hour until motor block was observed. If no evidence of motor block was observed for more than three consecutive hours, animals were considered unaffected. The experimenter was blinded as to which formulation was injected.

Histology. One week after injection, the animals were sacrificed and the sciatic nerves and surrounding tissues were removed, fixed in formalin, and processed for histology by hematoxylin and eosin staining. Slides containing the tissue sections were examined by a board certified pathologist and blinded to the treatment, and microscopic findings were graded according to the intensity and extent of change.

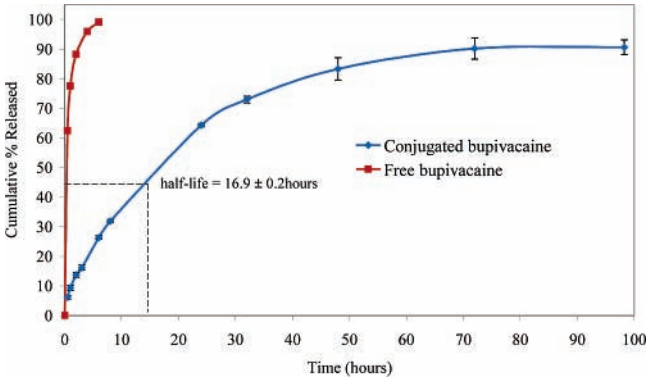

Figure 3. Release profiles of free and conjugated bupivacaine (**5a**) into receptor phase.

RESULTS AND DISCUSSION

Bupivacaine lacks reactive sites (e.g. primary amine, hydroxyl group) for mild chemical modification; however, it possesses an amide bond that could potentially be a site for acylation after deprotonation to give an imide conjugate. The hydrolysis of the imide bond in the resulting HA−bupivacaine conjugate (**5a**) may either regenerate authentic bupivacaine or produce an undesirable side-product depending on which of the two imide bonds undergoes hydrolytic cleavage. With this possibility in mind, we designed the synthesis of the linker to include a sulfide group in proximity to one of the imide functional groups to favor the hydrolysis toward the regeneration of bupivacaine (*29*). Using this approach described in Figures 1 and 2, bupivacaine was conjugated to HA (**5a**) with a 22% degree of modification and an overall yield of 80%. To avoid premature hydrolysis and consequent loss of bupivacaine from the conjugate, PBS and water used for dialysis were chilled to 4 °C before use and maintained in the cold room (4 ± 2 °C) during workup.

The in vitro release rate of bupivacaine from compound **5a** was compared to a physical admixture of bupivacaine in HA (MW 130 kDa). Figure 3 shows the release profiles obtained from this experiment. Bupivacaine hydrochloride admixed to HA quickly eluted into the receptor phase, with half of the drug eluting within 1 h and 100% of the drug eluting within 6 h. In contrast, the HA−bupivacaine conjugate (**5a**) showed more prolonged delivery with half the drug eluting within 17 h and 100% of the drug eluting within 2−3 days. The release profile follows approximately first-order kinetics consistent with the expected pseudo-first-order hydrolysis reaction.

LC-MS analysis of the hydrolysis solution from compound **5a** showed that 95% of the molecules in the receptor phase were authentic bupivacaine (Figure 4). The remaining peaks present in the chromatogram were attributed to impurities generated during the preparation of the conjugate and were also observed in the control samples without bupivacaine.

This result agrees with our initial design hypothesis that the thioether moiety on the methylene β to the acyl group would render this imide bond more susceptible to hydrolysis relative to the other imide bond (Figure 5). The preferential acceleration of the hydrolysis of this bond is due perhaps to a combination of favorable factors. One possible factor is the stabilization of the tetrahedral intermediate by the overlap of low lying empty d orbitals of the sulfur atom with the nonbonded electrons on one of the two oxygen atoms. Another contributing factor that may influence the carbonyl cleavage site is the steric hindrance of the substituents around the two tetrahedral transition states. In particular, inspection of the putative

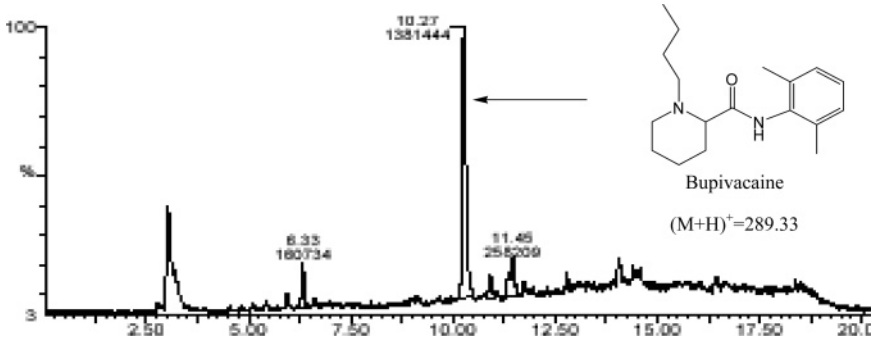

Figure 4. LC-MS analysis of the hydrolysis solution in the receptor phase.

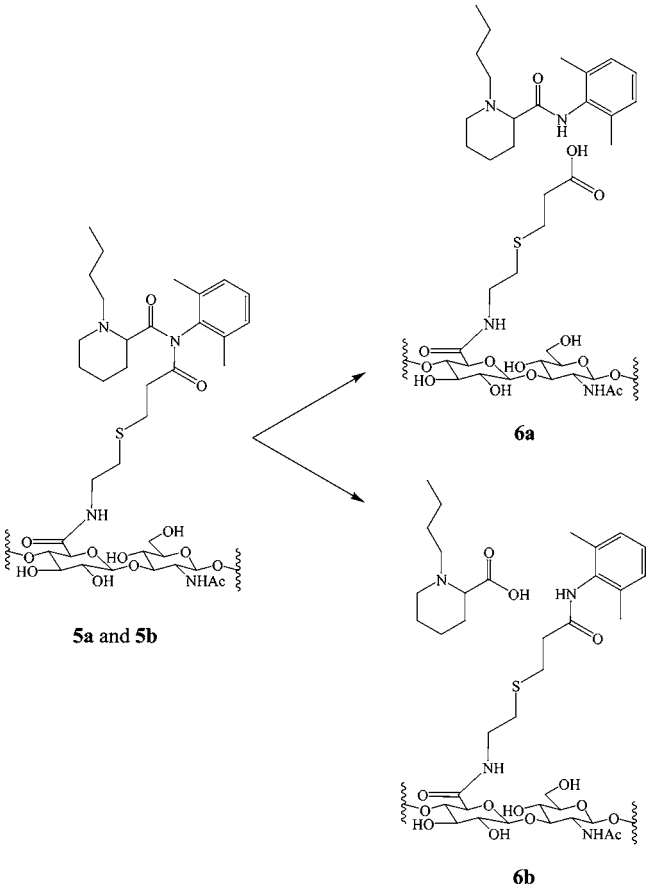

Figure 5. **6a**, major product of hydrolysis observed. **6b**, side product.

tetrahedral intermediate for the hydrolysis of the two carbonyls shows that the tetrahedral intermediate that gives free bupivacaine is less sterically hindered and therefore more stable. This greater stability would lead to a higher equilibrium concentration and in turn faster subsequent hydrolysis rate. These explanations work synergistically to favor the desired hydrolysis.

Unmodified HA has a short residence time at most placement sites in the body due to its rapid uptake and degradation by cells (*36*). To create an HA-based drug carrier that can persist for several days at the placement site we used the insoluble divinyl sulfone (DVS) cross-linked HA. This HA derivative is used in several approved HA products and has a well-established safety profile (*37*, *38*). Thus we conjugated bupivacaine to DVS cross-linked HA, Hylan B particles (*31*), using the same synthetic approach described for the soluble HA conjugate described above to give the bupivacaine conjugate (**5b**) with a 14% degree of modification and an overall yield of 94%.

Table 2. Amounts of Free Bupivacaine and Bupivacaine from the Conjugate 5b Injected in Each Rat

	free bupivacaine (mg/kg)	conjugated bupivacaine[a] (mg/kg)	N^b
saline	3	0	5
Hylan B particles admixture	3	0	10
Hylan B conjugate particles	3	13	9
saline	16	0	9

[a] Hylan B−bupivacaine particles (**5b**) 14% degree of modification. [b] N = number of animals for each group.

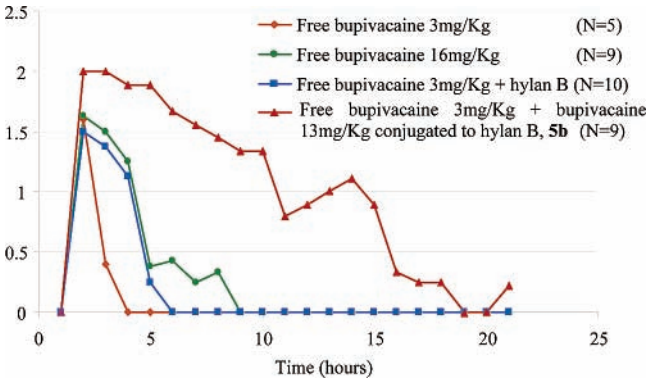

Figure 6. Nerve blockade scores as a function of time. Scoring methods shown in Table 1. N = number of animals for each group. Values are means.

In vivo studies were conducted using an adaptation of the rat sciatic nerve model (*39*). The duration of efficacy of bupivacaine conjugate (**5b**) relative to bupivacaine free in solution was assessed in vivo by injecting the conjugate in the proximity of the rat sciatic nerve and by observing the loss and recovery of motor function over time. Control rats were injected with either a 0.5% solution of bupivacaine in saline or an admixture of bupivacaine and Hylan B particles. Table 2 summarizes the amounts of free and conjugated bupivacaine injected per kilogram of animal for each of the controls and test samples.

Rats injected with bupivacaine next to the sciatic nerve generally lost their ability to ambulate as a consequence of the nerve blockage. They dragged the injected leg, gathered the forepart of the foot, and lost their grasping ability.

The onset time for each rat generally showed nerve blockage within the first 15 min. Figure 6 shows that the duration of motor loss for the bupivacaine control or bupivacaine admixed with Hylan B particles was about 5 h for either sample. This observation is consistent with published findings with similar formulations in the same rat model (*40*). This result shows that the presence of an insoluble HA gel did not significantly affect the loss of motor function in this model.

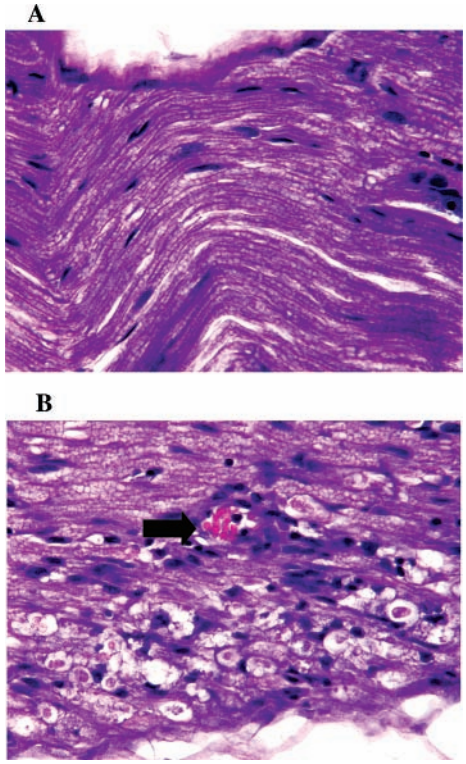

Figure 7. (A) Representative histology of a **5b** treated animal and (B) tissue taken from one of the nine treated animals showing extensive regions of vacuolation indicative of dilated axon sheaths. Axon/myelin debris from degenerating axons within the dilated spaces are indicated by the arrow.

Rats injected with a combination of 13 mg/kg of conjugated bupivacaine and 3 mg/kg of free bupivacaine showed a 4- to 5-fold longer impairment of motor function compared to those animals injected with free bupivacaine and free bupivacaine in Hylan B particles.

Histological evaluation of each of the injection sites revealed minimal to mild epineurial inflammation with fibroplasia in each of the treatment groups (Figure 7A). The incidence and severity appeared to be somewhat increased in the Hylan B−bupivacaine conjugate particle-treated nerves relative to their respective untreated controls. Axonal degeneration characterized by locally extensive regions of dilated axon sheets filled with axon/myelin debris and associated with inflammatory cell infiltrates and Schwann cell hypertrophy was observed in one of the nine animals (Figure 7B).

CONCLUSION

Tethering bupivacaine to HA sustained release in vitro and extended the duration of effect in a sciatic nerve blockage model in vivo. Although nerve blockage was significantly extended by conjugation, there was asymptomatic moderate nerve degeneration in one of the nine animals injected with compound **5b**. The extension of motor block with compound **5b** is very encouraging, although the axonal degeneration observed in one of the nine animals suggests further evaluation before it is used perineurally. This may not be a concern for local anesthesia at the incision line following surgery. Some degree of inflammation and myotoxicity was also reported for other controlled-release formulations for similar applications (*12*, *27*). This study identifies an additional utility of HA as a drug carrier and deserves further investigation.

SialylTn-mAb17-1A Carbohydrate–Protein Conjugate Vaccine: Effect of Coupling Density and Presentation of SialylTn

Ralf Kircheis,* Petra Vondru, Andreas Nechansky, Renate Ohler, Hans Loibner, Gottfried Himmler, and Geert C. Mudde

igeneon AG, Immunotherapy of Cancer, Vienna, Austria. Received June 1, 2005

Carbohydrate antigens resulting from aberrant glycosylation of tumor cells, such as SialylTn, represent attractive targets for cancer vaccination. However, T-cell-independent carbohydrate antigens are poorly immunogenic and fail to induce memory and IgG class switch. Clustered expression patterns of some carbohydrates on the cell surface add further complexity to the design of carbohydrate-based vaccines. We describe here a vaccine consisting of SialylTn carbohydrate epitopes coupled to a highly immunogenic carrier molecule, mAb17-1A, adsorbed on alhydrogel and coformulated with a strong adjuvant, QS-21. The SialylTn–mAb17-1A conjugate vaccine was administered in Rhesus monkeys, and the immune responses against mAb17-1A, SialylTn, ovine submaxillary mucin, and tumor cells were analyzed. The data demonstrate that the density of carbohydrate epitopes on the carrier is an essential parameter for induction of anti-carbohydrate specific memory IgG immune responses. Furthermore, the influence of different types of presentation of SialylTn (monomeric vs trimers vs clustered via a branched polyethylenimine linker) on antibody titers and specificity was studied. High-density coupling of SialylTn epitopes to mAb17-1A induced the strongest immune response against synthetic SialylTn and showed also the highest reactivity against natural targets, such as OSM and tumor cells.

INTRODUCTION

Accumulating data indicate that tumor-recognizing antibodies and immune effector cells may play a deciding role for the long-term benefit of cancer therapy. Elimination of circulating tumor cells and eradication of micrometastases which remain after surgery or radiotherapy are considered primary targets for immune cancer therapy. Therefore, identification and selection of the appropriate target antigen(s) on the tumor cells is essential for therapy efficacy. Cell surface-exposed carbohydrate and mucin antigens resulting from aberrant glycosylation of tumor cells may provide attractive targets. In animal models (*1*–*3*) as well as cancer patients the presence of natural or vaccine-induced antibodies against carbohydrates such as GM_2 and SialylTn was found to correlate with prolonged survival (*4*–*6*). The mucin-derived SialylTn is expressed in more than 80% of cancers of breast, colorectal, prostate, and ovarian origin showing no or very limited expression on the corresponding normal tissues (*7*–*9*). SialylTn expression by various epithelial cancers correlates with a more aggressive phenotype and poor prognosis (*10*, *11*). Recent data indicate that mucin-derived O-glycosylated truncated carbohydrates, such as the monosaccharide Tn or the disaccharides TF or SialylTn, are predominantly expressed as molecular clusters on the surface of tumor cells (*9*, *12*–*17*). The exact pattern of these clusters is still under debate; clustering in trimers has been suggested as one favorable pattern for antibody recognition found on ovine submaxillary mucin (OSM) and on the surface of some tumor cells (*14*–*17*). However, it is rather likely that in different tumors slightly different predominant expression patterns exist, and coexpression of monomeric and clustered forms (*13*–*15*) as well as heteroclusters consisting of different types of carbohydrates are likely (*18*).

Our strategy consists of coupling tumor-associated carbohydrate epitopes to a highly immunogenic murine antibody with intrinsic antitumor activity (*19*) in order to (i) use an immunogenic carrier protein to increase the immunogenicity of the carbohydrate antigen and (ii) to benefit from the antitumor immune response induced by the carrier molecule itself (*20*, *21*). IGN402 is a first candidate of this type of conjugate vaccine consisting of SialylTn carbohydrate epitopes chemically coupled to mAb17-1A. The murine 17-1A antibody, a monoclonal antibody recognizing EpCAM (*19*–*21*), adsorbed on aluminum hydroxide has been used as vaccine antigen in the cancer vaccine candidate IGN101 and has recently been reported to prolong survival in metastatic colorectal cancer patients (*22*). Recently we have shown that the SialylTn carbohydrate conjugate vaccine IGN402, coformulated with QS-21 adjuvant, can induce an IgG response against the SialylTn moiety (*23*).

In the present study we investigated the effect of the SialylTn coupling density on the immune response. Furthermore, different types of presentation of SialylTn (monomeric vs trimers vs clustered via a branched polyethylenimine linker) were studied. High-density coupling of SialylTn epitopes to mAb17-1A induced the strongest immune response against synthetic SialylTn as well as against natural targets such as OSM and tumor cells. IGN402 may provide an attractive prototype for further development toward multi-epitope vaccines with multiple carbohydrate epitopes coupled to an immunogenic murine antibody.

EXPERIMENTAL PROCEDURES

Coupling of SialylTn Carbohydrate to mAb17-1A at Different Ratios. The SialylTn carbohydrate antigen was coupled to the murine monoclonal antibody 17-1A (mIgG2a) at different molar ratios (i.e. 4.5:1; 18:1; and 36:1) to produce SialylTn−mAb17-1A carbohydrate−protein conjugate vaccines with low, medium, and high SialylTn density, respectively. Coupling was performed by reacting 4.5, 18, or 36 mol of nitrophenylated spacered SialylTn, Neu5Acα2-6GalNAcα-O$(CH_2)_3$ NHCO$(CH_2)_4$-COO-(*p*-$NO_2C_6H_4$) (mw 819 g/mol, Lectinity, Finland), to 1 mol of mAb17-1A. Briefly, 70 mg of mAb17-1A was dialyzed twice against coupling buffer (0.1 M $NaPO_4$, 0.15 M NaCl, pH 8.5) using a Slide-A-Lyzer dialysis cassette MWCO 10K (Pierce). Concentration of mAb17-1A was determined by size exclusion chromatography (SEC) on a Zorbax GF-250. Dialyzed mAb17-1A was diluted to a final concentration of 4 mg/mL and stored on ice. The following amounts were transferred to 15 mL vials (Falcon): 3.5 mL for IGN402 'high SialylTn', 4.6 mL for IGN402 'medium SialylTn', and 4.6 mL for IGN402 'low SialylTn'. In parallel, 5 mg of SialylTn-O$(CH_2)_4$NHCOO-pNp was dissolved in 250 μL of DMF, giving a final concentration of 20 mg/mL. SialylTn (dissolved in DMF) was added to ice cold mAb17-1A as follows: 22 μL to IGN402 (low), 90 μL to IGN402 (medium), and 138 μL to IGN402 (high). The reaction mixture was rotated at +4 °C. After 53 h, the reaction was stopped by dialyzing the reaction mixtures against formulation buffer (1 mM $NaPO_4$, 0.86% NaCl, pH 6) using Slide-A-Lyzer dialysis cassette 3.5K (Pierce) at 4 °C. For comparison, uncoupled mAb17-1A was treated in parallel.

To get a very high carbohydrate density, SialylTn was coupled to mAb17-1A at a molar ratio of 100:1. Briefly, 20 mg of nitrophenylated spacer SialylTn, Neu5Acα2-6GalNAcα-O$(CH_2)_3$NHCO$(CH_2)_4$COO-(*p*-$NO_2C_6H_4$), was dissolved in 500 μL of DMF, and 423 μL of this solution was added to ice cold, dialyzed mAb17-1A (31 mg in 7.75 mL of coupling buffer). The reaction mixture was incubated 74 h under rotation at +4 °C. The coupling product was dialyzed twice against formulation buffer.

Coupling of SialylTn Carbohydrate Trimers to mAb17-1A. The SialylTn carbohydrate antigen trimers attached to one linker molecule having a nitrophenyl group, [Neu5Acα2-6GalNAcα-O$(CH_2)_3$NHCO$(CH_2)_4$CO-Gly_3-$NHCH_2$-]$_3$ [(*p*-$NO_2C_6H_4$)O-CO$(CH_2)_4$CO-Gly_3-$NHCH_2$-)]$_1$C (mw 3105 g/mol, Lectinity, Finland), was coupled to the mAb17-1A at a molar ratio of 33:1 (calculation based on trimers). Five milligrams of [Neu5Acα2-6GalNAcα-O$(CH_2)_3$NHCO$(CH_2)_4$CO-Gly_3-$NHCH_2$-]$_3$[(*p*-$NO_2C_6H_4$)O-CO$(CH_2)_4$CO-Gly_3-$NHCH_2$-)]$_1$C was dissolved in 300 μL of DMF and added to 8.1 mg of ice cold, dialyzed mAb17-1A. The reaction mixture was incubated 72 h under rotation at +4 °C. The coupling product was dialyzed twice against formulation buffer.

Mimicing SialylTn Clusters on mAb17-1A by Using a Branched PEI Linker. The coupling procedure consisted of coupling the branched polyethylenimine (PEI) linker molecule to mAb17-1A, followed by the coupling of nitrophenylated spacer SialylTn to the mAb17-1A−PEI conjugate

Coupling of Branched PEI Linker to mAb17-1A. Branched PEI (25 kDa, Aldrich) was coupled to mAb17-1A via the heterobifunctional cross-linker SPDP (*N*-succinimidyl 3-(2-pyridyldithio)propionate, Pierce, Rockford, IL). Briefly, mAb17-1A (2.7 mg, 10 mg/mL) and PEI (4.9 mg, 1 mg/ml) were dialyzed against PBS using Slide-A-Lyzer dialysis cassettes. Concentration was measured using SEC and ninhydrin assay for mAb17-1A and PEI, respectively.

Coupling of SPDP to mAb17-1A and PEI, Respectively. mAb17-1A (26 mg, 10 mg/mL in PBS) was coupled with 65 μL of SPDP (20 mM in DMSO) for 60 min at RT. PEI (4.2 mg, 1 mg/mL in PBS) was coupled with 65 μL of SPDP (20 mM in DMSO) for 60 min at RT. The SPDP conjugates were dialyzed against PBS. PEI−SPDP (4.2 mg in 2.1 mL PBS) was reduced with 55 mg of DTT for 30 min at RT. The reduced PEI−SPDP was dialyed against PBS.

Reaction of mAb17-1A−SPDP with Reduced PEI−SPDP. Reduced PEI−SPDP (3.95 mg) and mAb17-1A−SPDP (24.4 mg) were reacted at a molar ratio of 1:1 for 24 h at +4 °C. The reaction mixture was dialyzed against PBS using SpectraPor Float-A-Lyzer (MWCO 60 kDa). The mAb17-1−PEI coupling product was confirmed by LDS−PAGE, WesternBlot, BioRAD protein assay, and ninhydrin assay.

Coupling of SialylTn to mAb17-1A−PEI. Ten milligrams of nitrophenylated spacered SialylTn, Neu5Acα2-6GalNAcα-O$(CH_2)_3$NHCO $(CH_2)_4$COO-(*p*-$NO_2C_6H_4$), were dissolved in 200 μL of DMF, and added to ice cold mAb17-1A−PEI conjugate (18 mg/7.2 mL). The reaction mixture was incubated 75 h under rotation at +4 °C. The coupling product was dialyzed twice against formulation buffer.

Analysis of Final Coupling Products. *Size Exclusion Chromatography.* Concentrations of SialylTn−mAb17-1A coupling products were quantified by size exclusion chromatography (SEC) on a ZORBAX GF-250 column in a Dionex system and on a TSKgel G3000SW column in a HP1100 system.

IEF, LDS−PAGE, and Western Blots. SialylTn−mAb17-1A coupling products were analyzed by SERVALYT PRECOTES horizontal flatbed IEF electrophoresis pH 3−10 (SERVA) followed by Coomassie blue staining (Invitrogen) and by lithium dodecyl sulfate polyacrylamide gel electrophoresis (LDS−PAGE, NuPAGE Electrophoresis System, Bis-Tris-Gel, 4−12%) under both nonreducing and reducing conditions (50 mM DTT, 1,4-dithiothretiol) followed by SilverXpress staining (Invitrogen).

For Western blot analysis, samples following LDS−PAGE were transferred (25 V, 1.1 W, 1.5 h) to Immobilon membranes (PVDF 0.45 μm, Millipore). Membranes were blocked with 3% skim milk and stained with rabbit anti-mouse IgG (H+L)−HRP (1:1000, Zymed) or alternatively with anti-SialylTn CD175s (IgG1) (10 μg/mL, DAKO) and rat anti-mouse IgG1−HRP (1:1000, Becton Dickinson).

Quantification of Sialic Acid by the Resorcinol Assay. Amount of sialic acid in the coupling products was quantified by the resorcinol-HCl reaction in the presence of $CuSO_4$, and spectrophotometric measurement of absorbance at 562 nm. Briefly, 0.15 mL of samples and 0.15 mL of resorcinol reagent (2% resorcinol, 2.5 mM $CuSO_4$, HCl (37%)) were mixed in tightly closed glass vials and incubated at 100 °C for 1 h. The optical density (OD) of the developing color was measured by adsorption at 562 nm (Spectrophotometer Ultrospec II, LKB Biochrom). As a standard, a 'SialylTn mix' (consisting of sialic acid (i.e. *N*-acetylneuraminic acid) and GalNAc at a molar ratio 1:1), 1.25−25 μg/mL, was used for calibration.

Quantification of Sialic Acid by HPLC. Quantification of amount of sialic acid in the coupling products was performed by HPLC analysis and fluorescence detection of DMB derivatives of sialic acid (DMB = 1,2-diamino-4,5-methylenedioxybenzyl). Briefly, samples were treated with 2 M acetic acid at 80 °C for 3 h and derivatized with DMB. Derivatized samples were analyzed by reversed

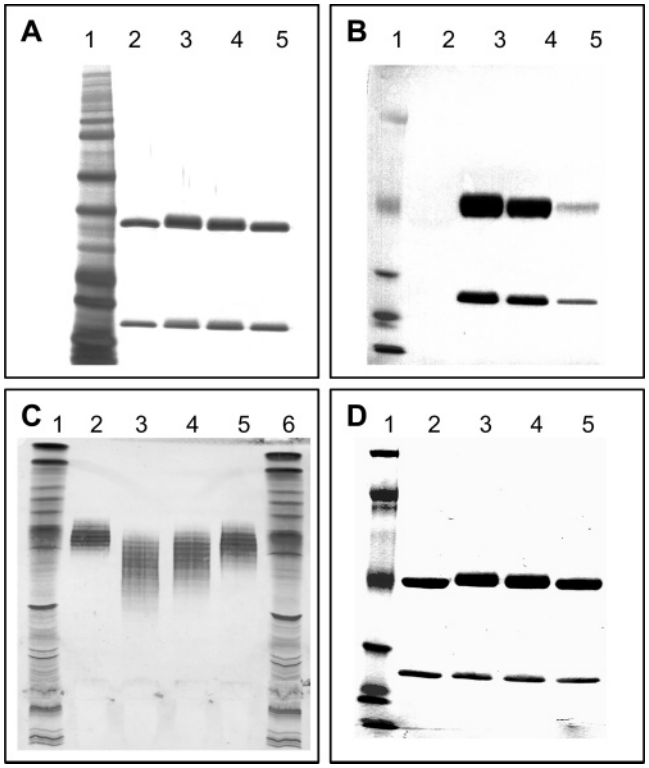

Figure 1. Characterization of SialylTn−mAb17-1A coupling products with high, medium, or low SialylTn density by IEF, LDS−PAGE, and Western Blots. Unconjugated mAb17-1A (lane 2) and SialylTn−mAb17-1A conjugates with high (lane 3), medium (lane 4), and low SialylTn density (lane 5) were subjected to LDS−PAGE under reducing conditions followed by silver staining (A), or blotted and stained with anti-SiaTn CD175s (mIgG1) and rat-anti-mouse IgG1−HRP (B) or rabbit-anti-mouse IgG (H+L)−HRP (D), or subjected to IEF−PAGE and stained by Coomassie blue (C). Heavy and light chains of mAb17-1A or conjugated SialylTn−mAb17-1A under reducing conditions (A, B, D) can be seen.

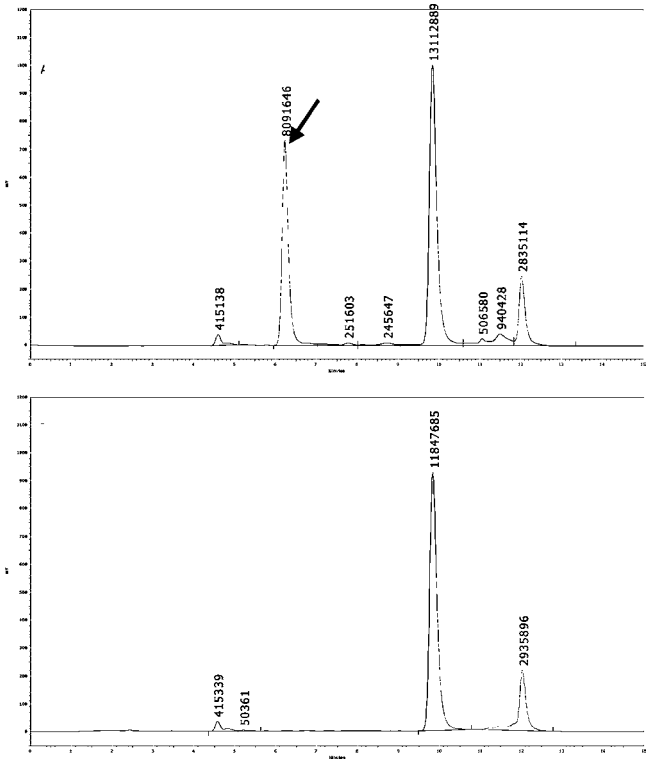

Figure 2. Quantification of sialic acid by reverse phase HPLC. Quantification of amount of sialic acid in the coupling products was performed by HPLC analysis and fluorescence detection of DMB derivatives of sialic scid. Derivatized samples were injected into reversed phase HPLC with fluorescence detection. Quantification was done by measuring the peak area of *N*-acetylneuraminic acid (NANA). HPLC profile of SialylTn−mAb17-1A conjugate (upper panel) and nonconjugated mAb17-1A (lower panel) are shown. The arrowhead points to the peak corresponding to NANA in the sample. Synthetic NANA (Sigma), 1.25−25 μg/mL, was used for calibration.

phase HPLC with fluorescence detection. Quantification was done by the peak area of *N*-acetylneuraminic acid. Synthetic *N*-acetylneuraminic acid (Sigma), 1.25−25 μg/mL, was used for calibration.

IGN402 Vaccine Formulations. SialylTn−mAb17-1A conjugate (500 μg) was adsorbed on 1.67 mg of aluminum hydroxide in 0.5 mL of formulation buffer (1 mM $NaPO_4$, 0.86% NaCl, pH 6) and coformulated with 100 μg of QS-21 adjuvant (Antigenics Inc., Lexington, MA).

LAL Assay and Pyrogenicity Test in Rabbits. Amounts of endotoxin in the vaccine formulations were estimated by Limulus Amebocyte Lysate−Endochrome Assay (Charles River Endosafe). None of the final vaccine formulations contained detectable amounts of endotoxin.

Furthermore, the final vaccine formulations were subjected to pyrogenicity test by iv application in rabbits. The formulations used for this study were negative regarding pyrogenicity testing.

Rhesus Monkey Immunization Study. Safety, tolerability, and immunogenicity of multiple subcutaneous injections of IGN402 were evaluated in a vaccination study in Rhesus monkeys. All animal studies were performed under controlled and documented conditions in accordance with animal health care standards at Biotest Ltd., Konarovice, Czech Republic. Each SialylTn−mAb17-1A conjugate was tested in groups each consisting of four Rhesus monkeys (sex and age matched). In a first comparative study animals were vaccinated with four initial immunizations on days (d) 1, 15, 29, and 57. Blood samples were taken before (d −15, −11, −6) and after immunization (d 15, 22, 29, 36, 57; 71 and 85).

In a second Rhesus monkey study, four animals per group were vaccinated with four initial immunizations on days (d) 1, 21, 49, and 76. Blood samples were taken before (d −13 and −6) and after immunization (d 27, 49, 52, 70, 79, and 91). All immunizations were well tolerated by the animals with no signs of systemic or local toxicity related to immunization. One animal (no. 83 from the SialylTn[tri]−mAb17-1A group), however, had to be euthanized during the course of the study because of moribund conditions. The pathological and histopathological examinations of the animal showed pathologies in blood coagulation (thrombus in liver vein, embolus in lungs) most probably not related to the vaccination.

ELISA for Immune Reactivity against mAb17-1A. Presera and immune sera were analyzed regarding the induced immune response against mAb17-1A by ELISA. Briefly, ELISA plates (F96 Maxisorp, NUNC) were coated with 10 μg/mL mAb17-1A. ELISA plates were blocked with 2% HSA in PBS (1 h, 37 °C), and samples were prediluted in PBS with 0.5% HSA and were incubated for 1.5 h at 37 °C. A positive control serum with known reactivity against mAb17-1A was tested in parallel and used for normalization between different ELISA plates. For detection, plates were incubated with a sheep anti-human IgG-(γ-chain)−HRP conjugate (1:2000, Chemicon) for 30 min at 37 °C. Staining with substrate OPD (10 mg OPD dissolved in 25 mL + 10 μL 30% H_2O_2) was stopped by adding 50 μL of H_2SO_4 (30%) and measured

Table 1. Molar Ratios of SialylTn to mAb17-1A[a]

coupling product	molar ratio SialylTn to mAb17-1A	
	resorcinol	HPLC (NANA)
mAb17-1A	–	–
SiaTn-mAb17-1A (high)	16.2 (0.5)	12.9
SiaTn-mAb17-1A (medium)	9.1 (0.4)	7.1
SiaTn-mAb17-1A (low)	2.8 (0.1)	1.9

[a] Quantification of sialic acid in the different SialylTn−mAb17-1A coupling products were estimated by the resorcinol assay. The resorcinol assay is based on the resorcinol-HCl reaction in the presence of $CuSO_4$ and spectrophotometric measurement of absorbance at OD562 nm. Mean and standard deviation (SD) are shown.

at 492/620 nm. The titer was defined as reciprocal serum dilution yielding an absorbance of OD = 1.0 on a titration curve. Curve fitting was done using GraphPad Prism program version 4.0.

SialylTn−PAA ELISA. Preserum and immune sera were analyzed concerning the immune response against the synthetic SialylTn carbohydrate antigen (coupled to polyacrylamide) by SialylTn−PAA ELISA. Briefly, ELISA plates (F96 Maxisorp, NUNC) were coated 10 μg/mL SialylTn−PAA (Lectinity). ELISA plates were blocked with PBS containing 2% HSA for 1 h at 37 °C. Serum samples were prediluted in PBS containing 0.5% HSA and 5% glucose and incubated for 2 h at 37 °C. A positive control serum with known reactivity against SialylTn was used for normalization between different ELISA plates. For detection, plates were incubated with mouse anti-human IgM−HRP conjugate (1:2000, SB, Southern Biotechnology) or sheep anti-human IgG-(γ-chain)−HRP conjugate (1:2000, Chemicon), respectively, for 30 min at 37 °C. Staining with substrate OPD (10 mg OPD dissolved in 25 mL + 10 μL of 30% H_2O_2) was stopped by adding 50 μL of H_2SO_4 (30%) and measured at 492/620 nm. Titers were defined as the reciprocal of serum dilutions yielding an absorbance of OD = 1.0 and OD = 0.5 for IgM and IgG, respectively. Curve fitting was done using GraphPad Prism program version 4.0.

Ovine Submaxillary Mucin (OSM) ELISA. Presera and immune sera were analyzed regarding the immune response to OSM which is a natural substrate highly expressing SialylTn. Briefly, ELISA plates (F96 Maxisorp, NUNC) were coated with 10 μg/mL OSM (Accurate Chemical, Westbury, NY). ELISA plates were blocked with 2% HSA for 1 h at 37 °C, followed next by a washing step. Samples were prediluted in PBS with 0.5% HSA and incubated for 2 h at 37 °C. A positive control serum with known reactivity against OSM was tested in parallel and used for normalization between different ELISA plates. For detection, plates were incubated with mouse anti-human IgM−HRP conjugate (1:2000, SB, Southern Biotechnology) or sheep anti-human IgG-(γ-chain)−HRP conjugate (1:2000, Chemicon), respectively, for 30 min at 37 °C. Staining with substrate OPD (10 mg OPD dissolved in 25 mL + 10 μL of 30% H_2O_2) was stopped by adding 50 μL of H_2SO_4 (30%) and measured at 492/620 nm. Titers were defined as reciprocal of serum dilutions yielding an absorbance of OD = 1.0 and OD = 0.5 for IgM and IgG, respectively. Curve fitting was done using GraphPad Prism program version 4.0.

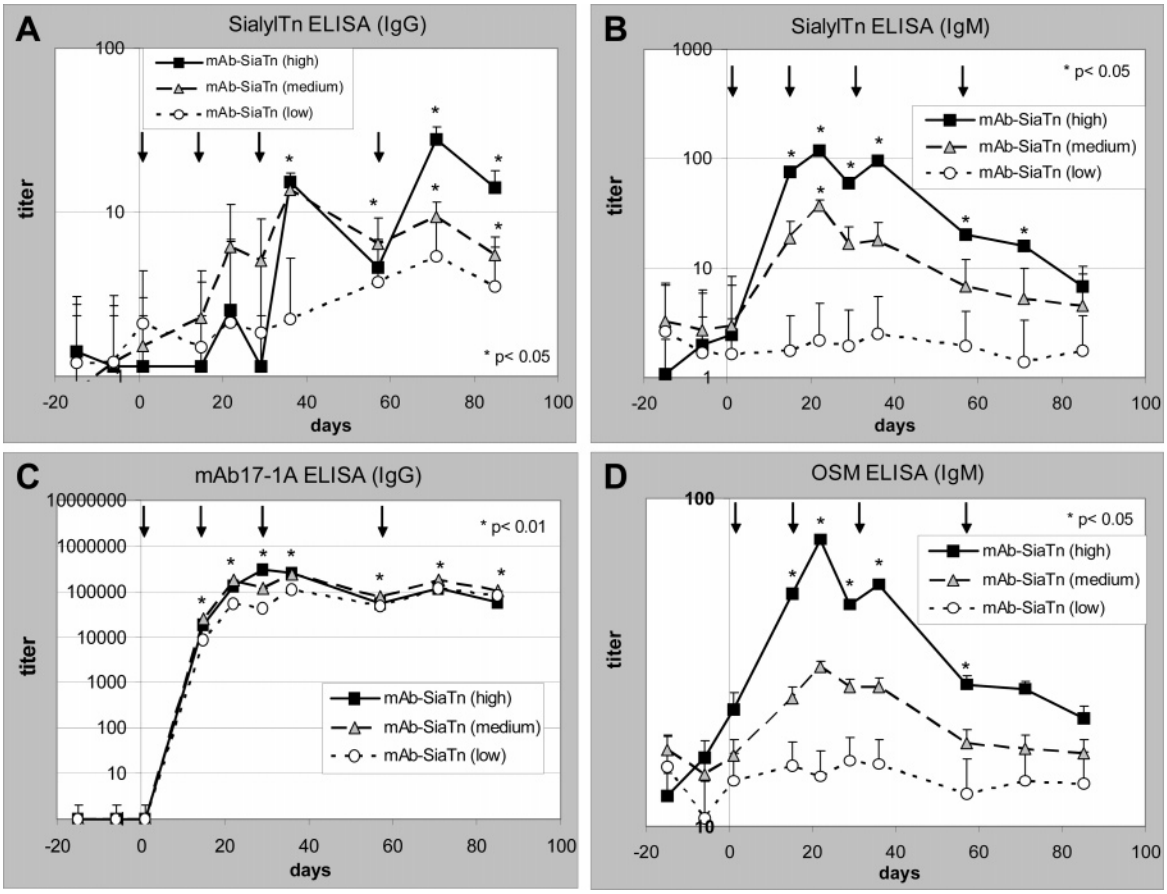

Figure 3. Effect of SialylTn coupling density on immune responses induced against SialylTn, mAb17-1A, and OSM. Rhesus monkeys were immunized with SialylTn−mAb17-1A plus QS-21 vaccines containing high, medium, or low SialylTn coupling density. Preserum and immune sera at a time kinetic were analyzed for immune response against mAb17-1A carrier protein and SialylTn carbohydrate antigen and ovine submaxillary mucin by ELISA. Antibody titers (geomean and Scatter factor) against SialylTn (IgG) (A), IgM (B), mAb17-1A (IgG) (C), and OSM (IgM) (D) are shown. Statistics: *p < 0.05 vs preserum (one-tailed, paired t-test).

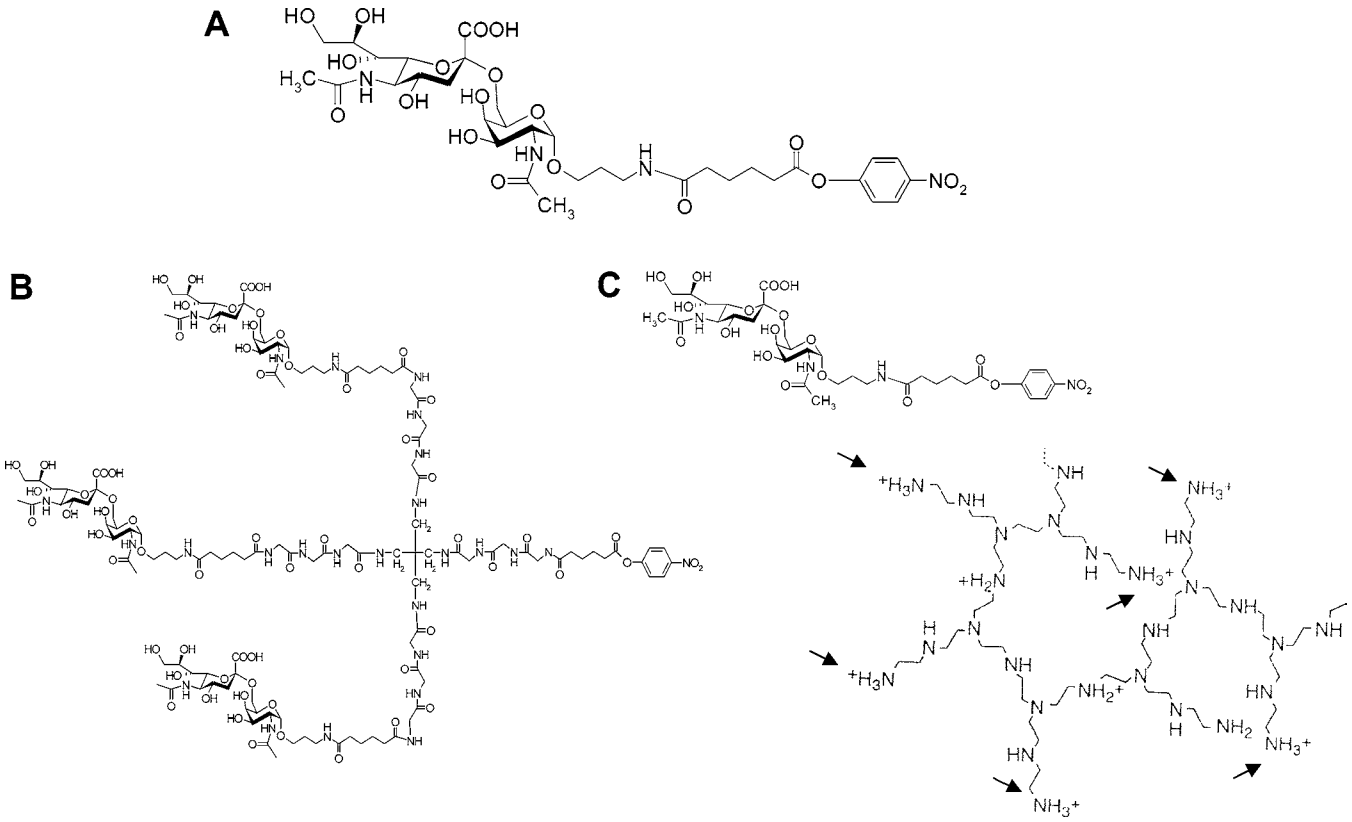

Figure 4. Different presentation of SialylTn epitope: monomeric; trimers; clustered via branched linker. The following SialylTn−mAb17-1A variants with different presentations of SialylTn were designed and tested in a Rhesus monkey study: monomeric presentation of SialylTn (A) at high and very high coupling ratios (33:1 and 100:1, respectively); SialylTn presentation as trimers (ratio 33 [tri]:1) (B); clustered presentation of SialylTn on mAb17-1A−PEI (SialylTn coupling ratio 100:1) (C).

Immune Response against Tumor Cells (FACS analysis). Binding of immune sera to tumor cells was measured by cell surface staining using a FACScan (Becton Dickinson). OVCAR-3 human ovary adenocarcinoma cells (ATCC, HTB-161) were incubated with serum (diluted 1:40 in PBS with 2% FCS) for 2 h on ice. For detection, a goat $F(ab')_2$ anti-human IgG (H+L)−PE conjugate (1:100, Immunotech, Marseille, France) was used. Mean fluoresence intensities (MFI) values obtained for binding of preserum were compared to binding of the corresponding immune serum. For better comparison, the binding of preserum of each individual animal was set at 10% positive cells.

Antibody-Dependent Cellular Cytotoxicity, ADCC. Preserum and immune serum was tested for ADCC against SialylTn positive OVCAR-3 cells. Human PBMCs were used as effector cells and incubated with the ^{51}Cr-labeled target cells at different E:T ratios, i.e., 60:1 and 20:1 for 14 h. ^{51}Cr -release was measured by a γ-counter.

RESULTS

Effect of SialylTn Coupling Density on Immune Responses Induced against mAb17-1A, SialylTn, and OSM. Nitrophenyl-activated SialylTn carbohydrates were coupled to mAb17-1A at three different molar ratios of SialylTn to mAb17-1A (4.5:1; 18:1; and 36:1) resulting in three SialylTn−mAb17-1A conjugate vaccines with low, medium, and high SialylTn density, respectively. SialylTn−mAb17-1A coupling products analyzed by LDS−PAGE under reducing conditions followed by Silver staining are shown in Figure 1A. LDS−PAGE showed an increase in the molecular weight of the heavy chains (50 kDa) and the light chains (25 kDa) in the coupling products (lanes 3−5, compared to uncoupled mAb17-1A, lane 2) indicating that SialylTn has been coupled to both heavy and light chains of mAb17-1A. Western blot analysis of the SialylTn−mAb17-1A coupling products with either anti-SialylTn CD175s (mIgG1)) and rat anti-mouse IgG1−HRP (Figure 1B) or alternatively with rabbit anti-mouse IgG (H+L)−HRP (Figure 1D) demonstrated that SialylTn was detectable in the SialylTn−mAb17-1A coupling products but not in the mAb17-1A (Figure 1B vs 1D). The amount of SialylTn detectable in the coupling product correlated with the coupling ratio (lane 3: high, lane 4: medium, lane 5: low). Coupling of the negatively charged SialylTn to mAb17-1A resulted also in a shift of the isoelectric point (pI) in the coupling products as shown by IEF (Figure 1C). The pI shift correlated with the coupling SialylTn ratio (lane 3: high; lane 4: medium, lane 5: low SialylTn).

The molar ratios of SialylTn to mAb17-1A in the coupling products were quantified by Recorcinol assay or HPLC of N−Acetylneuraminic acid (NANA). In the resorcinol assay the amount of sialic acid (as part of SialylTn) in the coupling products is quantified by the resorcinol-HCl reaction. Molar ratios of SialylTn to mAb17-1A for the high, medium, and low ratio coupling product as determined by the resorcinol assay are shown in Table 1. Quantification of amount of sialic acid in the coupling products was also performed by reverse phase HPLC followed by fluorescence detection of DMB derivatives of sialic acid. Quantification is based on the peak area of *N*-acetylneuraminic acid (Figure 2). Molar ratios of SialylTn to mAb17-1A for the high, medium, and low ratio coupling product as determined by HPLC of NANA correlate well with those estimated by the resorcinol assay (Table 1).

The SialylTn−mAb17-1A coupling products (i.e. with final SialylTn to mAb17-1A ratios of 3:1, 9:1, and 16:1,

respectively, as determined by the resorcinol assay) were adsorbed on aluminum hydroxide (i.e. 500 μg coupling product coupled to 1.67 mg aluminum hydroxide) and coformulated with 100 μg QS-21 adjuvant. Addition of strong adjuvants, such as QS-21, was previously found to be essential for induction of switching carbohydrate specific IgM antibodies to the IgG isotype (*23*).

Rhesus monkeys, four animals per group, were immunized with SialylTn−mAb17-1A vaccines with high, medium, or low SialylTn coupling density, respectively. The time kinetics of the immune responses against mAb17-1A carrier protein, the SialylTn carbohydrate antigen, and OSM, a natural substrate with high SialylTn expression, were analyzed by ELISA (Figure 3, Panels A to D). The induced immune responses against SialylTn (Panel A: IgG, Panel B: IgM) and OSM (Panel D: IgM) were found to correlate with the density of coupled SialylTn. Highest responses against SialylTn (IgM, IgG) and OSM (IgM) were induced at the highest coupling density (i.e. 16:1), while only low IgG titers against OSM were found (data not shown). With the low SialylTn density (i.e. 3:1) vaccine formulation, generally only marginal reactivity against SialylTn and no reactivity with OSM were found. In contrast, all three vaccines induced comparable IgG responses against the mAb17-1A carrier protein (Panel C). The data demonstrate a clear correlation between SialylTn ligand density and the efficacy to induce an anti-carbohydrate immune response, with the highest tested density showing highest efficacy of immune response against SialylTn or OSM.

Mimic of Clustered Presentation of SialylTn. Recent data from the literature indicate that mucin-derived, truncated carbohydrates, such as Tn or SialylTn, are recognized by antibodies preferably as clusters on the surface of tumor cells rather than as single molecule epitopes (*12*−*17*). To address this issue, the following variants of vaccines with different presentations of SialylTn were designed: monomeric SialylTn (Figure 4A) coupled at a ratio of 33:1 (corresponding to the highest ratio of the previous experiment) was compared with a conjugate coupled at very high SialylTn to mAb17-1A ratio, i.e. 100:1. Furthermore, a trimer SialylTn with three SialylTn moieties attached to one linker, SialylTn[tri], was coupled to mAb17-1A at a ratio of 33:1 (trimer-to-carrier ratio) (Figure 4B). Finally SialylTn was coupled to a mAb17-1A−PEI conjugate at a coupling ratio of 100:1. The branched polyethylenimine linker molecule, PEI 25 kDa, is a polycation with a high density of primary amino groups, and coupling of SialylTn to the mAb17-1A−PEI conjugate aimed to mimic highly clustered SialylTn presentation (Figure 4C). SialylTn−mAb17-1A coupling products were analyzed using LDS−PAGE under reducing conditions (Figure 5A). An increase in molecular weight of the heavy and the light chains was found in all coupling products. The SialylTn[tri]−mAb17-1A conjugate (lane 5) showed a peculiar ladder pattern with several distinct bands for both heavy and light chains. Western blot analysis with anti-SialylTn CD175s (IgG1) and rat anti-mouse IgG1−HRP demonstrated that SialylTn was detectable in all coupling products, but not in mAb17-1A (Figure 5B). All coupling products showed a pI shift compared to mAb17-1A (lane 2) due to the coupling of negatively charged SialylTn. Different to all other coupling products, the SialylTn−PEI-mAb17-1A conjugate repeatedly showed a very peculiar IEF pattern (lane 6) which may be due to superimposing effects of the negatively charged SialylTn and the positively charged PEI (Figure 5C).

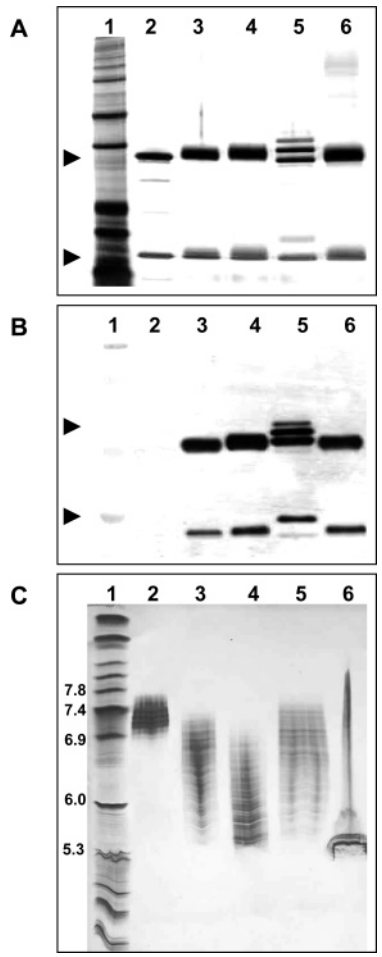

Figure 5. Characterization of different SialylTn−mAb17-1A coupling products by IEF, LDS−PAGE, and Western Blots. Unconjugated mAb17-1A (lane 2) and SialylTn−mAb17-1A conjugates, monomeric at coupling ratio 33:1 (lane 3), monomeric at coupling ratio 100:1 (lane 4), SialylTn[tri] at coupling ratio 33:1 (lane 5), and SialylTn−PEI-mAb17-1A (lane 6) were subjected to LDS−PAGE under reducing conditions followed by silver staining (A), or blotted and stained with anti-SiaTn CD175s (mIgG1) x rat-anti-mouse IgG1−HRP (B), or subjected to IEF−PAGE and stained by Coomassie blue (C). Heavy and light chains of mAb17-1A or conjugated SialylTn−mAb17-1A under reducing conditions (A, B) can be seen.

Table 2. Molar Ratio of SialylTn to mAb in Different Coupling Products[a]

coupling product	molar ratio SialylTn to mAb17-1A (resorcinol)
SialylTn-mAb17-1A 33:1	19
SialylTn-mAb17-1A 100:1	75
SialylTn-mAb17-1A 33[tri]:1	65
SialylTn-mAb17-1A 100:1	27

[a] Quantification of sialic acid in the different SialylTn−mAb17-1A coupling products were estimated by the resorcinol assay. The resorcinol assay is based on the resorcinol-HCl reaction in the presence of $CuSO_4$ and spectrophotometric measurement of absorbance at OD562 nm.

SialylTn to mAb17-1A ratios in the final coupling products were quantified by the resorcinol assay, and the following ratios (calculated on monomeric SialylTn) were estimated: 19:1, 75:1, 65:1, and 27:1 for the monomeric SialylTn−mAb17-1A (reacted at 33:1 and 100:1), SialylTn[tri]-mAb17-1A, and SialylTn−PEI-mAb17-1A, respectively (Table 2). While the molar SialylTn to mAb17-1A ratios in the 100:1 monomeric SialylTn−mAb17-1A (final ratio 75:1) and SialylTn[tri]−mAb17-1A (final ratio 65:1) showed, as expected, an approximately 3-fold higher

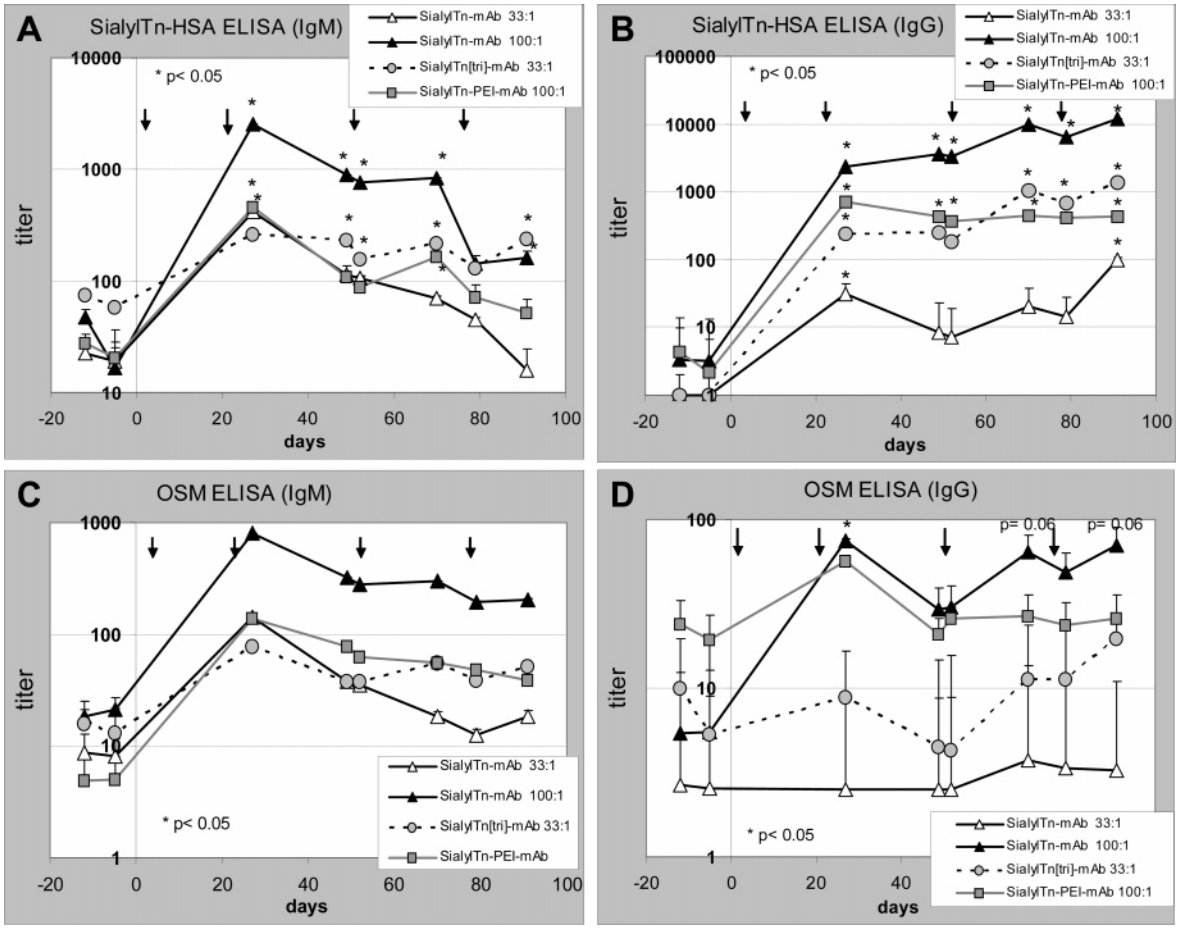

Figure 6. Effect of SialylTn coupling density and presentation on immune responses induced against synthetic SialylTn and ovine submaxillary mucin. Rhesus monkeys were immunized with the different SialylTn−mAb17-1A vaccines, adsorbed on alhydrogel, and coformulated with QS-21 adjuvant. Preserum and immune sera at a time kinetic were analyzed for immune response against SialylTn carbohydrate antigen and OSM by ELISA. Antibody titers (geomean and Scatter factor) against SialylTn (IgM) (A), IgG (B), and OSM (IgM) (C), (IgG) (D), are shown.

ratio compared to the 33:1 coupled conjugate (final ratio 19:1); a lower ratio (27:1) was measured in the SialylTn−PEI-mAb17-1A coupling product. The SialylTn−mAb17-1A conjugates were adsorbed on aluminum hydroxide, coformulated with QS-21 adjuvant and tested in a Rhesus monkey vaccination study. Presera and the corresponding immune sera were tested for reactivity against SialylTn−HSA and OSM by ELISA (Figure 6). The time kinetics for the immune responses against SialylTn (Panel A: IgM, Panel B: IgG) and OSM (Panel C: IgM, Panel D: IgG) are shown. Again, a strong correlation between density of coupled SialylTn and the immune responses against both synthetic SialylTn and OSM was found. Regarding induced titers, the high coupling product of monomeric SialylTn to mAb17-1A (coupling ratio at 100:1, i.e. final ratio 75:1) was found superior to all other coupling products. The SialylTn[[tri]−mAb17-1A and the SialylTn−PEI−mAb17-1A conjugates were significantly more efficient than the monomeric SialylTn (33:1, final 19:1), but were inferior when compared to the 75:1 monomeric coupling product. The superior efficacy of the high density coupling product was particularly dramatic concerning the response against OSM, a natural substrate with high SialylTn content (Figure 6C,D).

Immune Response against SialylTn Positive Tumor Cells. Finally, the immune response against the natural target, SialylTn positive tumor cells, was tested. Preserum and immune sera of Rhesus monkeys immunized with SialylTn−mAb17-1A plus QS-21 were analyzed for binding to SialylTn positive OVCAR-3 cells by FACS analysis. Histograms of IgG and IgM binding to OVCAR-3 cells are shown for the 75:1 high-density SialylTn−mAb17-1A vaccine (Figure 7A,B). A statistically significant increase in cell binding to OVCAR-3 cells (both IgG and IgM) was found for the high coupling product ($p < 0.05$, paired t-test). A less consistent reactivity was found with the other coupling products (data not shown).

Finally, presera and immune sera of animals immunized with the high-density SialylTn−mAb17-1A vaccine were tested for ADCC against SialylTn positive OVCAR-3 cells. Human PBMCs were used as effector cells and incubated with the target cells at two E:T ratios, i.e., 60:1 and 20:1. While different initial levels of lytic activity were found in the different animals, a clear increase in ADCC activity was found in the immune sera of all animals in comparison to the corresponding presera (Figure 7C).

DISCUSSION

A panel of synthetic cancer vaccine formulations based on SialylTn carbohydrate antigens chemically coupled to an immunogenic protein carrier molecule were designed and tested in Rhesus monkeys. Coupling of the SialylTn carbohydrate epitopes to mAb17-1A aims to increase the immunogenicity of the SialylTn carbohydrate antigen and to provide with the mAb17-1A carrier an additional antigen that is thought to mediate an immune response against epithelial cancer. The murine 17-1A antibody, a monoclonal antibody (mAb) recognizing the epithelial cell

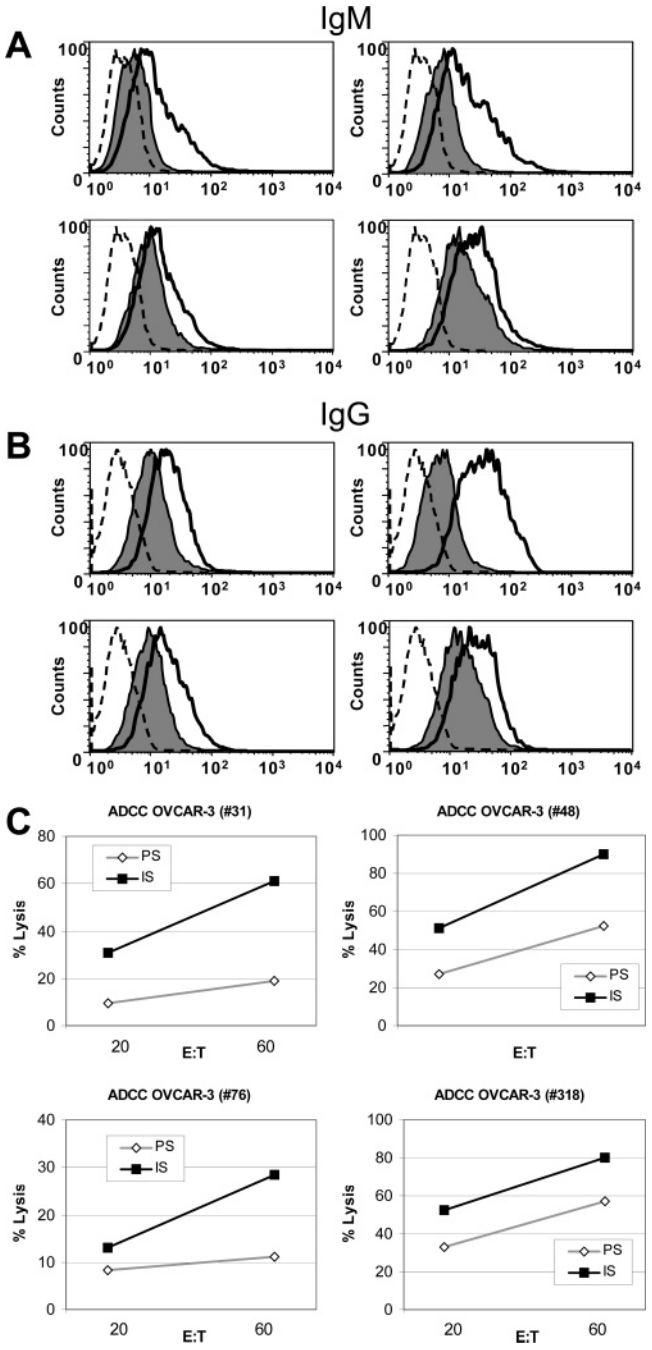

Figure 7. Rhesus monkeys were immunized with the SialylTn–mAb17-1A vaccines. Preserum (grey line filled) and immune sera (bold blank line) (both diluted 1:40 in PBS + 2% FCS) were analyzed for cell binding by FACS analysis (dotted line: unstained control). Cell binding to SialylTn positive OVCAR-3 tumor cells is shown for immunization with the high-density SialylTn coupling product (IgM (A), IgG (B)). Preserum and immune serum was tested for ADCC against SialylTn positive OVCAR-3 cells. Human PBMCs were used as effector cells and incubated with the ^{51}Cr-labeled target cells at E:T ratio of 60:1 and 20:1 for 14h. ^{51}Cr -release was measured using a γ-counter (C).

adhesion molecule (EpCAM), has been used for passive cancer therapy in patients with epithelial carcinomas (*19*) whereby part of the observed efficacy has been attributed to the induction of anti-idiotypic and anti-anti-idiotypic antibodies (*20*, *21*). In the cancer vaccine candidate IGN101 mAb17-1A adsorbed on aluminum hydroxide is being used as vaccine antigen to induce an immune response against epithelial cancer. IGN101 has demonstrated an excellent safety profile and has recently been shown to improve survival in metastatic colorectal cancer patients (*22*).

In the present study, we investigated the effect of various SialylTn coupling densities and different ways of carbohydrate presentation on the carrier molecule on the induced immune response. Recent data have indicated that the monosaccharide Tn or the disaccharide SialylTn are predominantly present as molecular clusters on the surface of tumor cells (*9*, *12*, *17*). Therefore, increasing the coupling density of SialylTn on the carrier molecule and mimicking various types of clustered presentation was tested in this study. Our results demonstrate that at least for this type of carbohydrate–protein conjugate vaccine, the coupling density of SialylTn is an essential parameter determining the efficacy of the induced immune response against the carbohydrate antigen. While only marginal anti-SialylTn responses were generated at a very low carbohydrate to mAb17-1A carrier ratio of 3:1, a ratio of ~16:1 resulted in significant anti-SialylTn IgG titers. At the highest coupling density achieved in this study of 75:1, the highest IgG titers against SialylTn were induced. In contrast, the immune response against mAb17-1A was not significantly affected by the SialylTn to mAb17-1A ratio. However, the magnitude of the immune response against OSM was again strongly dependent on the SialylTn coupling density in the vaccine. In particular IgG antibodies (indicative for an isotype switch from IgM to IgG) specific for OSM were found at significant levels only with high SialylTn coupling densities in the vaccine. Induction of a significant IgG response against OSM and tumor cells indicates that SialylTn in its natural presentation is also recognized by the induced immune response, although to a lesser degree than the synthetic SialylTn immunogen. Alternatively designed clustered presentation of SialylTn as trimers or on a branched PEI linker did not further improve the induced immune response against SialylTn, OSM, or tumor cells compared to the highest monomeric SialylTn coupling density. This result was somewhat unexpected as trimeric presentation of SialylTn on an immunogenic carrier has been shown by others to be a better mimic of the natural presentation (*9*, *12*, *17*). One explanation may be that the recognition of the trimer SialylTn in the present study is negatively influenced by the use of longer and more flexible linker molecules in the trimer conjugate, thus perhaps placing the three SialylTn moieties at an unfavorably large distance to each other for recognition. Furthermore, recent data indicate that it is not only the clustered carbohydrate but also the context with the peptide anchor which can affect the immune response (*16*, *17*). It is currently still under investigation whether the native mucin glycopeptide architecture (*16*) or rather the more immunogenic non-native carbohydrate–peptide linkage (*17*) would be better suited for induction of therapeutic efficacy in tumor patients. Finally, it is known that different tumor cell lines, depending on the growth conditions, but also primary tumors and metastatic cells can differ in their carbohydrate clusters. A trimeric cluster may be typical for certain cells; for others different types of clusters may prevail (*13*, *14*, *18*).

On the basis of its amino acid sequence, the mAb17-1A carrier, a murine monoclonal IgG2a antibody, contains a total of 98 lysine residues which present potential primary amino groups for coupling, depending on the accessibility. Lysines, due to their positive charge and extended, rather rigid structure, are generally surface exposed (*25*). To get insight in the three-dimensional distribution of the lysine residues within the murine

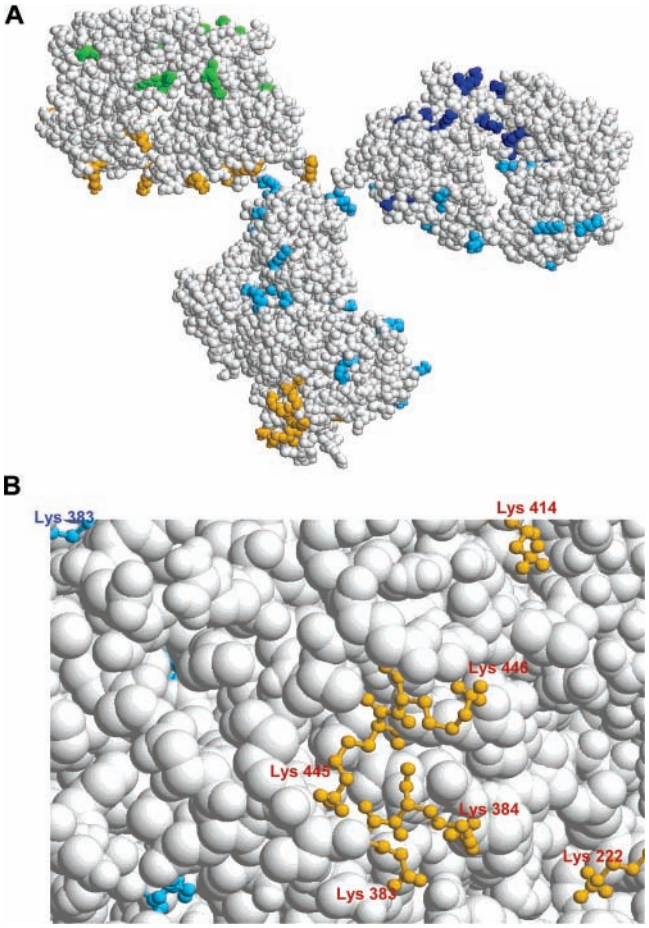

Figure 8. Spatial distribution of lysine residues in a 3D-model of muIgG2a The three-dimensional distribution of the lysine residues within the murine IgG2a molecule (anti-canine lymphoma mAb 321 (*26*)) was obtained from the Brookhaven Protein Data Bank (code: 1IGT), and for visualization the Rasmol computer software version 2.7.1.1 (ftp://ftp.dcs.ed.ac.uk/pub/rasmol) was used. The lysines, shown in yellow and light blue for the two heavy chains, and in green and dark blue for the two light chains, respectively, appear to be dispersed over the whole antibody molecule (Panel A: overview on the muIgG2a molecule in "space-fill" mode). Panel B: a cluster of four lysines is shown at higher magnification (lysines in ball-stick mode; all other amino acids in space-fill mode).

IgG2a molecule, the published structure of the anti-canine lymphoma mAb 321 (*26*) was chosen as a model system. Atomic coordinates for mAb 321 were obtained from the Brookhaven Protein Data Bank (code: 1IGT), and for visualization, the Rasmol computer software version 2.7.1.1 (ftp://ftp.dcs.ed.ac.uk/pub/rasmol) was used. According to this model (Figure 8, Panel A), the majority of these lysines (shown in yellow and light blue for the two heavy chains, and in green and dark blue for the two light chains, respectively) appear to be dispersed over the whole antibody molecule (shown in the "space-fill" mode). In contrast, some of them, especially in the Fc part of the molecule, are present in spatial proximity to other lysine residues thus forming clusters (Figure 8, Panel B). As the free amino groups on accessible lysine side chains are used for coupling of the sugar moieties to the protein carrier, clustered lysines may allow for a clustered coupling and subsequent presentation of carbohydrates. It should be stressed here that, although mAb321 (muIgG2a) serves only as a model for the mAb17-1A (muIgG2a) used as the carrier molecule in the present study, still, based on the high homology, we believe that this approach is justified. Alignment of the amino acid sequence of the heavy chain constant regions reveals 100% homology whereas for the variable regions the homology is, as expected, lower due to the unique complementary determining regions.

Coupling of carbohydrate epitopes to mAb17-1A may provide the advantage of creating different types of presentation for the carbohydrate epitopes, both monomeric as well as different kinds of clusters. Furthermore, the data of the present study demonstrate that it is feasible to design a synthetic cancer vaccine which is adjustable to a controlled and reproducible, large scale manufacturing process. The SialylTn−mAb17-1A conjugate vaccine may provide a prototype for development of vaccines with several different carbohydrate epitopes coupled to the same immunogenic carrier molecule. The need for high density coupling may limit the number of different types of carbohydrate epitopes which can be coupled to the carrier. However, immune recognition of clustered carbohydrates has been shown so far only for a selected group of carbohydrates such as Tn and SialylTn and is probably not typical for recognition of larger carbohydrates, such as GM2 and GloboH. Therefore, combining carbohydrate epitopes which are recognized as monomers with epitopes with clustered presentation on one carrier molecule should be feasible (*18*). Alternatively, using a mixture of different types of carbohydrate-carrier conjugates coformulated in one vaccine formulation might be another pragmatic solution for the generation of a sufficiently broad panel of tumor-associated carbohydrate recognizing IgG antibodies. Strategies for cancer vaccines which target multiple tumor antigens (*18*, *24*) can be expected to provide higher therapeutic efficacy and to minimize the risk for tumor escape, two key parameters for the successful treatment of cancer patients.

ACKNOWLEDGMENT

We thank Dr. C. R. Kensil from Antigenics Inc., Lexington, MA, for kindly providing the QS-21 adjuvant and for critical review of the manuscript.

Novel Thermosensitive 5-Fluorouracil–Cyclotriphosphazene Conjugates: Synthesis, Thermosensitivity, Degradability, and in Vitro Antitumor Activity

Yong Woo Cho,† Jeong-Ryel Lee, and Soo-Chang Song*

Division of Life Science, Korea Institute of Science and Technology, Seoul 130-650, Korea. Received December 22, 2004; Revised Manuscript Received August 18, 2005

A novel thermosensitive macromolecular prodrug of 5-fluorouracil (5-FU) was synthesized using cyclotriphosphazene, and its thermosensitivity, degradability, and in vitro antitumor activity were studied. A series of α-substituted glycine derivatives of 5-FU containing carboxylic groups were prepared, and cyclotriphosphazenes with amino groups were synthesized via the stepwise substitution of hexachlorocyclotriphosphazene $(NPCl_2)_3$ with methoxy-poly(ethylene glycol) (MPEG) or alkoxy ethylene oxide and lysine ethyl ester (LysOEt). The coupling reaction of the two derivatives, and their subsequent deprotection, yielded a thermosenstive 5-FU–cyclotriphosphazene conjugate, which exhibited a unique octopus-shaped molecular structure, in which the three hydrophilic PEG groups (or alkoxy ethylene oxides) were oriented in one direction, opposing the other three hydrophobic groups containing 5-FU, with respect to the trimer ring plane. This conjugate exhibited a reversible and thermosensitive phase transition in an aqueous medium, from soluble to insoluble states. The lower critical solution temperature (LCST) of the conjugate was controlled by substitution with different hydrophilic/hydrophobic side groups, and a few of the conjugates displayed LCSTs which were just below body temperature. This, of course, implies possible applications for local drug delivery by direct intratumoral injection. The conjugate exhibited gradual degradation at 37 °C in both neutral and acidic buffer solutions, and high temperature significantly facilitated its hydrolytic degradation. All of the conjugates displayed dose-dependent cytotoxicity against the leukemia L1210 cell line and exhibited more pronounced cytotoxic effects than did 5-FU.

INTRODUCTION

One of the limitations inherent in current cancer chemotherapy is the lack of specificity with regard to anticancer drugs. Most anticancer drugs exert prohibitively cytotoxic effects on normal cells. The systemic administration of a chemotherapeutic agent results in its spread throughout the body, leading to serious side effects from nonspecific toxicity. A common approach to localize a chemotherapeutic agent into tumor tissues is the target-specific drug delivery with polymer–drug conjugates bearing specific ligands capable of being recognized by the target cells or with particulate drug carriers passively accumulated in tumor tissues by the enhanced permeability and retention (EPR) effect (*1*–*6*). Since Ringsdorf's landmark work (*7*) in 1975 introduced the concept of targetable polymer–drug conjugates, a number of polymer–drug conjugates have been developed (*1*), some of which are now being tested clinically (*8*, *9*). Much effort has been devoted to the search for specific ligands and their conjugation with appropriate polymeric carriers (*1*, *2*, *10*–*14*).

Another promising approach for the localization of a chemotherapeutic agent is the injectable drug delivery system, which utilizes a thermosensitive polymer which undergoes a phase transition from a soluble to an insoluble state at around body temperature. Typical biodegradable and thermosensitive polymers for such an injectable drug delivery system include triblock copolymers of poly(ethylene glycol) and poly[(D,L-lactide)-*co*-glycolide] (PEG–PLGA–PEG) (*15*–*17*), chitosan (*18*–*21*), and poly(organophosphazenes) (*22*–*25*) with PEG and amino acid ester side groups. These polymers are readily soluble in water at room temperature, and their aqueous solutions undergo a phase transition to gel or insoluble precipitate under increased temperatures. The local administration of these systems could be performed by simple intratumoral injection of the aqueous solution, thereby circumventing the necessity of surgery.

Our group has reported a series of biodegradable and thermosensitive poly(organophosphazenes) (*22*–*25*) and cyclotriphosphazenes (*26*, *27*) bearing PEG and amino acid esters as side groups. Temperature-triggered intermolecular associations between the hydrophobic amino acid ester side groups result in the thermosensitive phase transitions of the aqueous polymer solutions. At lower temperatures, these polymers are readily soluble in water and are fully hydrated. As the temperature rises, however, the hydrogen bonds between the water molecules and the polymers weaken gradually, and the hydrophobic associations of the side groups become more pronounced, thereby resulting in the formation of hydrogels or precipitate. The thermosensitive phase transitions of these polymer solutions are completely reversible. The gels or precipitates formed at high temperatures rehydrate when cooled, reverting to the original soluble state.

In recent years, our group has also developed biodegradable and thermosensitive polymer–platinum(II) conjugates via the complexation of cisplatin with cyclotriphosphazenes, through chelate-type coordination bonds

(*28*). The conjugates exhibited thermosensitivity at lower critical solution temperatures (LCST), during which phase transitions from solution to precipitate occurred (sol-to-prep). Our thermosensitive conjugates evidenced outstanding antitumor activity, both in vitro and in vivo, against the murine leukemia L1210 cell line. This study prompted us to develop a series of thermosensitive anticancer drug conjugates, such as 5-fluorouracil(5-FU)-cyclotriphosphazene conjugates and doxorubicin−poly(organophosphazene) conjugates. We herein report our development of a series of biodegradable and thermosensitive 5-FU−cyclotriphosphazene conjugates with variable LCSTs. A series of α-substituted glycine derivatives of 5-FU with carboxylic groups were prepared, in addition to a group of functionalized cyclotriphosphazenes with amino groups. Their coupling reaction yielded a set of 5-FU−cyclotriphosphazene conjugates with a unique, octopoidal molecular structure. Thereafter, the conjugates were assessed in terms of thermosensitivity, biodegradability, and in vitro antitumor activity.

EXPERIMENTAL SECTION

Materials. Hexachlorocyclotriphosphazene (Aldrich) was used without further purification. Dicylohexylcarbodimide (DCC), *N*-hydroxysuccinimide (NHS), $Pb(OAc)_4$, 5-FU, and different amino acid derivatives from Acros were used as received. Methoxy-poly(ethylene glycol) (MPEG), 2-(2-methoxyethoxy)ethanol (MEE), 2-(2-ethoxyethoxy)ethanol (EEE), and 2-(2-buthoxyethoxy)ethanol (BEE) were azeotropically dried with benzene, followed by vacuum-drying, and then stored over molecular sieve 4A. Tetrahydrofuran (THF), ethyl acetate (EA), triethylamine (TEA), and dimethyl formamide (DMF) were freshly distilled prior to use.

Instruments. Proton-decoupled ^{31}P NMR spectra were recorded with a Varian Gemini-300 spectrometer, operating at 121.4 MHz, and using triphenyl phosphate as an external standard. ^1H NMR spectra were recorded with the same spectrometer, but operating at 300 MHz in Fourier transform mode. Elementary analysis was performed with a Fisons 1108 CHNS Microanalyzer and a Polyscan 61E ICP. HPLC was performed on a C18 column (3.9 × 300 mm) at 25 °C. Pure methanol was used as a mobile phase, with a flow rate of 1.0 mL/min.

Synthesis of α-Substituted Glycine Derivatives of 5-FU. Different α-substituted glycine derivatives of 5-FU were prepared through slight modifications of the protocol described by Putman and Kopeček (*29*).

Synthesis of Cyclotriphophazenes with Amino Groups. $N_3P_3(MPEG350)_3(LysOEt)_3$. A sodium salt of methoxy-poly(ethylene glycol) ($M_w = 350$, MPEG350) was prepared by the reaction of MPEG350 (7.05 g, 20.1 mmol) with 1.5 equiv of sodium metal in THF (230 mL) at refluxing temperature, for 24 h. After filtration for the removal of excess sodium, the solution was cooled to −60 °C in a dry ice−acetone bath and added to a solution of hexachlorocyclotriphosphazene (2.00 g, 5.75 mmol) in THF. The reaction was stirred for 5 h at −60 °C. Meanwhile, L-lysine ethyl ester dihydrochloride (12.8 g, 51.8 mmol) was suspended in anhydrous THF (150 mL) containing TEA (28.7 mL, 207 mmol). The trimer solution was added to the L-lysine ethyl ester solution, which was then stirred for 24 h at room temperature. The reaction mixture was filtered, and the filtrate was concentrated under reduced pressure. The filtrate was then poured into a large amount of hexane, to obtain precipitates. The polymer was further purified by LCST separation, as described below. The other polymers were prepared in a similar manner, using different substituents and molar ratios. Yield: 6.45 g (60%). ^1H NMR (D_2O), δ (ppm): 1.3 (t, 3H, ester CH_3), 1.4 (br m, 2H, lysine γ CH_2), 1.6 (br m, 2H, lysine β CH_2), 1.7 (br m, 2H, lysine δ CH_2), 2.9 (br m, 2H, lysine ϵ CH_2), 3.4 (s, 3H, methoxy CH_3), 3.6 (t, 1H, lysine α CH_2), 3.7 (br m, 26H, MPEG CH_2), 4.1 (m, 2H, MPEG CH_2), 4.2 (q, 2H, ester CH_2). ^{31}P NMR (D_2O), δ (ppm): 42.42.

LCST Separation (27). Trifluoroethanol was used as an LCST-lowering agent. Trifluoroethanol was slowly added to a trimer solution (5 w/v %) in water, until the solution became turbid. The turbid solution was moved to an ice bath, yielding a transparent solution, and it was then incubated in a water bath, with agitation, for 15 min at the desired temperatures (20−30 °C). The reprecipitated trimer was then centrifugally separated and freeze-dried.

$N_3P_3(MEE)_3(LysOEt)_3$. Yield: 73%. ^1H NMR (D_2O), δ (ppm): 1.3 (t, 3H, ester CH_3), 1.4 (br m, 2H, lysine γ CH_2), 1.6 (br m, 2H, lysine β CH_2), 1.7 (br m, 2H, lysine δ CH_2), 2.9 (br m, 2H, lysine ϵ CH_2), 3.4 (s, 3H, methoxy CH_3), 3.6 (t, 1H, lysine α CH), 3.7 (br m, 6H, MEE CH_2), 4.1 (m, 2H, MEE CH_2), 4.2 (q, 2H, ester CH_2). ^{31}P NMR (D_2O), δ (ppm): 42.47.

$N_3P_3(EEE)_3(LysOEt)_3$. Yield: 57%. ^1H NMR (D_2O), δ (ppm): 1.2 (t, 3H, EEE CH_3), 1.3 (t, 3H, ester CH_3), 1.4 (br m, 2H, lysine γ CH_2), 1.6 (br m, 2H, lysine β CH_2), 1.7 (br m, 2H, lysine δ CH_2), 2.9 (br m, 2H, lysine ϵ CH_2), 3.6 (t, 1H, lysine α CH), 3.7 (br m, 8H, EEE CH_2), 4.1 (m, 2H, EEE CH_2), 4.2 (q, 2H, ester CH_2). ^{31}P NMR (D_2O), δ (ppm): 42.46.

$N_3P_3(BEE)_3(LysOEt)_3$. Yield: 48%. ^1H NMR (D_2O), δ (ppm): 1.2 (t, 3H, BEE CH_3), 1.3 (t, 3H, ester CH_3), 1.4 (br m, 2H, lysine γ CH_2), 1.6 (m, 4H, buthoxy CH_2), 1.6 (br m, 2H, lysine β CH_2), 1.7 (br m, 2H, lysine δ CH_2), 2.9 (br m, 2H, lysine ϵ CH_2), 3.5 (t, 2H, buthoxy CH_2), 3.6 (t, 1H, lysine α CH), 3.7 (br m, 4H, BEE CH_2), 4.1 (m, 2H, BEE CH_2), 4.2 (q, 2H, ester CH_2). ^{31}P NMR (D_2O), δ (ppm): 44.68.

Synthesis of 5-Fluorouracil/Cyclotriphophazenes Conjugates. N_3P_3(MPEG350)$_3$(Leu-Gly(5-Fu)-Lys)$_3$ (conjugate 1). DCC (0.219 g, 10.6 mmol) and NHS (0.122 g, 10.6 mmol) were added to a solution of L-1 (0.477 g, 10.6 mmol) dissolved in dry THF (30 mL) and stirred for 24 h. N_3P_3(MPEG350)$_3$(LysOEt)$_3$ (0.500 g, 0.294 mmol) in $CHCl_3$ (30 mL) was added dropwise to the reaction mixture and stirred for 4 h. The reaction was monitored using ninhydrin. The solvents were evaporated under reduced pressure, and the resulting product was purified by LCST separation. The obtained polymer, N_3P_3(MPEG350)$_3$(CBZ-Leu-Gly(5-Fu)-Lys)$_3$ (0.640 g, 0.213 mmol), was then dissolved in 15 mL of methanol and added to a suspension of 10% Pd/C (0.192 g) in 1 mL of dry methanol. The reaction mixture was stirred at room temperature for 4 h, under H_2 gas. After completion of the reaction, the catalyst was removed by filtration through a 0.45 μm membrane filter. The organic filtrate was evaporated under reduced pressure. The resulting polymer was dissolved in a small amount of water and then freeze-dried. The other polymers were prepared in a similar manner, using different substituents. Yield: 0.530 g (67%). ^{1}H NMR (D_2O), δ (ppm): 1.0 (6H, CH_3), 1.3 (3H, CH_3), 1.5∼1.9 (9H, CH, CH_2), 3.0 (2H, CH_2), 3.35 (3H, CH_3), 3.6 (27H, CH_2, CH), 4.0∼4.2 (4H, CH_2), 4.3∼4.5 (1H, CH), 6.4 (1H, CH), 8.2 (1H, CH). ^{31}P NMR (D_2O, ppm): 43.65. HPLC: 99.82%. Elem. anal. (%) calcd: C (46.6), H (7.06), N (10.9). Found: C (46.7), H (7.38), N (10.8).

N_3P_3(MPEG350)$_3$(Phe-Gly(5-Fu)-Lys)$_3$ (conjugate 2). 10.6 mmol of L-3 and 0.294 mmol of N_3P_3(MPEG350)$_3$-(LysOEt)$_3$. Yield: 62%. ^{1}H NMR (D_2O), δ (ppm): 1.2 (3H, CH_3), 1.5∼1.9 (6H, CH_2), 2.9 (2H, CH_2), 3.2 (2H, CH_2), 3.3 (3H, CH_3), 3.65 (27H, CH_2, CH), 4.1 (2H, CH_2), 4.2 (2H, CH_2), 4.4 (1H, CH), 6.4 (1H, CH), 7.3 (5H, CH), 7.6∼7.8 (1H, CH). ^{31}P NMR (D_2O, ppm): 43.76. HPLC: 99.71%. Elem. anal. (%) calcd: C (49.2), H (7.02), N (10.5). Found: C (49.0), H (7.00), N (9.62).

N_3P_3(MEE)$_3$(Leu-Gly(5-Fu)-Lys)$_3$ (conjugate 3). 17.8 mmol of L-1 and 0.495 mmol of N_3P_3(MEE)$_3$(LysOEt)$_3$ Yield: 44%. ^{1}H NMR (D_2O, ppm): 0.9 (6H, CH_3), 1.2 (3H, CH_3), 1.4∼1.9 (9H, CH_2, CH), 2.85 (2H, CH_2), 3.35 (3H, CH_3), 3.7 (7H, CH_2, CH), 4.0 (2H, CH_2), 4.2 (2H, CH_2), 4.4 (1H, CH), 4.5 (1H, CH), 6.5 (1H, CH), 7.8 (1H, CH). ^{31}P NMR (D_2O, ppm): 42.30. HPLC: 99.95%. Elem. anal. (%) calcd: C (45.5), H (7.00), N (14.9). Found: C (45.6), H (6.86), N (14.6).

N_3P_3(MEE)$_3$(Phe-Gly(5-Fu)-Lys)$_3$ (conjugate 4). 17.8 mmol of L-3 and 0.495 mmol of N_3P_3(MEE)$_3$(LysOEt)$_3$. Yield: 52%. ^{1}H NMR (D_2O, ppm): 1.2 (3H, CH_3), 1.5∼1.9 (6H, CH_2), 2.9 (2H, CH_2), 3.2 (2H, CH_2), 3.3 (3H, CH_3), 3.7 (7H, CH_2, CH), 4.1 (2H, CH_2), 4.2 (2H, CH_2), 4.4 (1H, CH), 6.4 (1H, CH), 7.3 (5H, CH), 7.6∼7.8 (1H, CH). ^{31}P NMR (D_2O, ppm): 42.37. HPLC: 99.99%. Elem. anal. (%) calcd: C (46.5), H (6.56), N (13.6). Found: C (46.5), H (5.98), N (13.1).

N_3P_3(MEE)$_3$(Ala-Gly(5-Fu)-Lys)$_3$ (conjugate 5). 17.8 mmol of L-2 and 0.495 mmol of N_3P_3(MEE)$_3$(LysOEt)$_3$. Yield: 40%. ^{1}H NMR (D_2O, ppm): 1.2 (3H, CH_3), 1.5 (3H, CH_3), 1.4∼1.9 (6H, CH_2), 2.85 (2H, CH_2), 3.35 (3H, CH_3), 3.65 (7H, CH_2, CH), 4.0 (2H, CH_2), 4.2 (2H, CH_2), 4.4 (1H, CH), 4.5 (1H, CH), 6.5 (1H, CH), 7.9 (1H, CH). ^{31}P NMR (D_2O, ppm): 42.35. HPLC: 99.99%. Elem. anal. (%) calcd: C (40.1), H (6.79), N (14.9). Found: C (39.8), H (6.16), N (14.4).

N_3P_3(EEE)$_3$(Leu-Gly(5-Fu)-Lys)$_3$ (conjugate 6). 17.1 mmol of L-1 and 0.474 mmol of N_3P_3(EEE)$_3$(LysOEt)$_3$. Yield: 43%. ^{1}H NMR (D_2O, ppm): 0.9 (6H, CH_3), 1.2∼1.3 (6H, CH_3), 1.5∼1.9 (9H, CH, CH_2), 2.9 (2H, CH_2), 3.5 (9H, CH, CH_2), 4.0 (2H, CH_2), 4.2 (2H, CH_2), 4.4 (1H, CH), 6.5 (1H, CH), 7.9 (1H, CH). ^{31}P NMR (D_2O, ppm): 42.18. HPLC: 99.96%. Elem. anal. (%) calcd: C (44.0), H (7.35), N (13.8). Found: C (43.9), H (6.83), N (13.2).

N_3P_3(EEE)$_3$(Val-Gly(5-Fu)-Lys)$_3$ (conjugate 7). 17.1 mmol of L-4 and 0.474 mmol of N_3P_3(EEE)$_3$(LysOEt)$_3$. Measurement of LCST. The phase transition of the aqueous solution of a conjugate was detected visually, in a closed glass tube immersed in an oil bath. The LCST was identified as the temperature at which the solution became turbid.

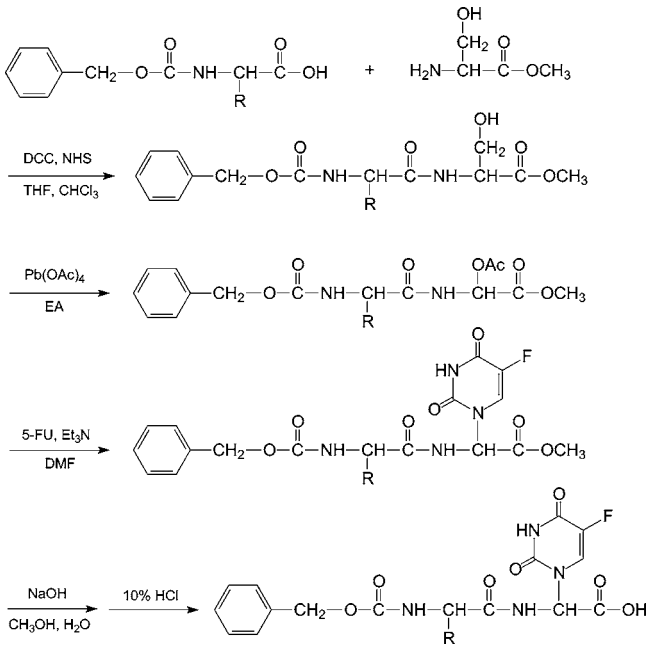
In Vitro Hydrolytic Degradation. The time-dependent degradation of 5-FU–cyclotriphosphazene conjugates was assessed in different pH buffer solutions at different temperatures. The conjugates (50 mg) were dissolved in 1 mL of 0.5 M concentrations of different buffer solutions (pH 5 acetate buffer, pH 7.4 tris buffer, and pH 10 carbonate buffer), which were incubated in a water bath at different temperatures. The hydrolytic degradation behaviors were determined by ^{31}P NMR spectroscopy.

In Vitro Antitumor Activity. The in vitro antitumor activity of 5-FU–cyclotriphosphazene conjugates was assessed using leukemia L1210 cells, which were maintained in RPMI 1640 medium supplemented with 10% fetal bovine serum. Cell suspensions containing 1×10^5 cells/mL in culture medium were distributed onto a 24-well plate and incubated with the conjugates in a 5% CO_2 atmosphere at 37 °C for 24, 48, or 72 h. The number of viable cells was determined by means of MTT [3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide] enzyme assay, using a microplate reader (SOFTmax PRO, Molecular Device Corp.), and the concentration of the conjugate exhibiting 50% inhibition of cell growth (ED_{50}) was determined.

RESULTS AND DISCUSSION

Synthesis of 5-FU–Cyclotriphosphazene Conjugates. The 5-FU–cyclotriphosphazene conjugates were synthesized by the following stepwise reactions, syntheses of α-substituted glycine derivatives of 5-FU, and cyclotriphosphazenes with functional groups, and their conjugations. α-Substituted glycine derivatives of 5-FU were prepared for coupling with cyclotriphosphazenes

Scheme 1. Synthetic Pathway to 5-FU Derivatives[a]

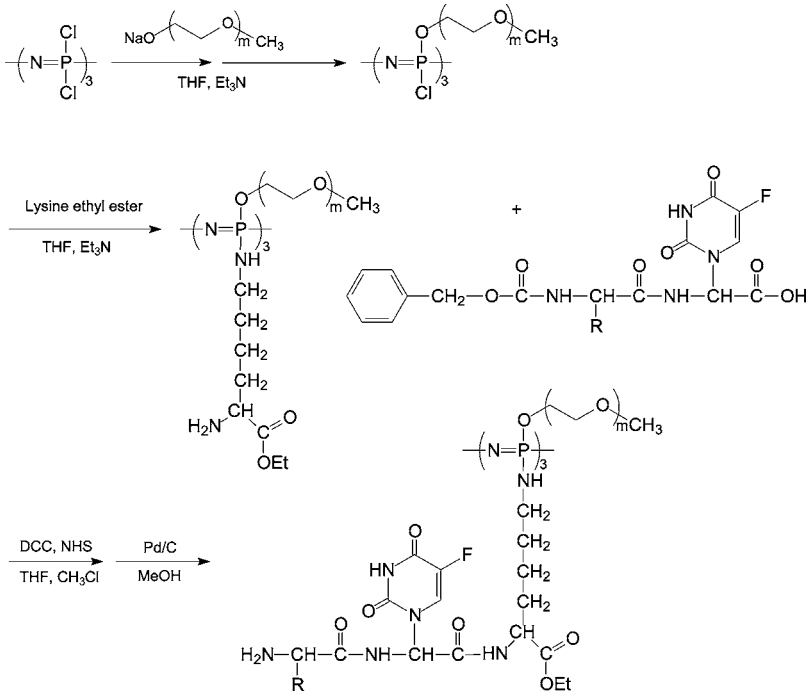


[a] R is $CH_2CH(CH_3)_2$ for L-1, CH_3 for L-2, $CH_2C_6H_5$ for L-3, $CH(CH_3)_2$ for L-4, and H for L-5.

with amino groups via a slightly modified version of the protocol described by Putman and Kopeček (*29*), as shown in Scheme 1. An excellent description of the synthesis and release of 5-FU from the derivative is given in the literature. Substitution at the α-carbon of glycine with the secondary amine of 5-FU results in an intrinsically unstable glycine derivative, which undergoes spontaneous decomposition into the α-substitutent and a glyoxylate. However, the acylation of the glycyl derivative through peptide bond formation stabilizes the α-substituted glycine derivative. Free 5-FU can then be liberated by peptide bond cleavage through enzymatically catalyzed hydrolysis by aminopeptidases.

The synthesis of thermosensitive cyclotriphosphazenes has been previously reported by our group (*26*, *27*). Themosensitive cyclotriphosphazenes are synthesized by the stepwise substitution of hexachlorocyclotriphosphazene $(NPCl_2)_3$ with alkoxy-poly(ethylene glycol) (APEG) and amino acid esters (AAEs). The initial substitution of the chlorotrimer with 3 mol of sodium salt of APEG follows a cis-nongeminal pathway. Successive substitution with AAE yields trimeric derivatives, which exhibit a unique, octopoidal molecular configuration, in which the three hydrophilic APEG groups are oriented in one direction, opposing the other three hydrophobic AAE groups, with respect to the trimer ring plane (*26*). In our present study, the intermediate $N_3P_3(MPEG350)_3(LysOEt)_3$ was synthesized for conjugation with 5-FU by the stepwise substitution of hexachlorocyclotriphosphazene $(NPCl_2)_3$ with methoxy-poly(ethylene glycol) (MPEG) and lysine ethyl ester (LysOEt). Then, the intermediate $N_3P_3(MPEG350)_3(LysOEt)_3$ with amino groups was coupled with an α-substituted glycine derivative of 5-FU with a carboxylic group. All the compounds were fully characterized by means of elementary analysis and H NMR spectroscopy. For the structural characterization of cyclotriphosphazene derivatives, the substitution reactions were monitored by P NMR spectrospcopy (data not shown). P NMR spectroscopy is one of the most powerful tools for the structural study of cyclotriphosphagene derivatives since most critical structural information is available from the chemical shifts and spin−spin coupling data of their ^{31}P NMR spectra. In general, when hexachlorocyclotriphosphazene $(NPCl_2)_3$ is substituted by 3 mol of a substituent, three isomers (geminal 2,2,4; nongeminal *cis*-2,4,6; nongeminal *trans*-2,4,6) may be formed (*26*, *27*). Unreacted hexachlorocyclotriphosphazene exhibits a sharp singlet of ^{31}P resonance, but the addition of MPEG to the chlorotrimer resulted in a mixture of partially substituted products, including mono-, di-, and trisubstituted products. More MPEG was added to the reaction mixture until the peak due to the trisubstituted product became predominant, coupled with

Scheme 2. Synthetic Pathway to 5-FU−Cyclotriphosphazene Conjugates[a]



[a] R is $CH_2CH(CH_3)_2$ for L-1, CH_3 for L-2, $CH_2C_6H_5$ for L-3, $CH(CH_3)_2$ for L-4, and H for L-5.

the disappearance of the peaks due to the partially substituted isomers. The major single peak became complex upon the addition of LysOEt. However, as the reaction progressed, the side peaks disappeared, finally culminating after 24 h in a singlet peak. This sharp singlet ^{31}P resonance clearly indicates that the final product, $N_3P_3(MPEG350)_3(LysOEt)_3$, is a cis-nongeminal isomer. After purification by LCST separation, its isomeric purity was over 99.0%, as determined by HPLC.

The conjugation of α-substituted glycine derivatives of 5-FU to cyclotriphosphazene with amino groups was carried out via coupling reaction, using DCC and NHS. A carboxylic group in a 5-FU derivative is activated to form an ester intermediate, which subsequently reacts with a primary amino group in cyclotriphosphazene, via reaction with NHS, to form an amide bond. After the coupling reaction, the deprotection of an amino group of 5-FU derivative residues from a benzyloxycarbonyl group was carried out by catalytic hydrogenolysis. The chemical structure of the final 5-FU–cyclotriphosphazene conjugate was verified via ^{1}H NMR and ^{31}P NMR spectroscopy in conjunction with elemental analysis. In ^{1}H NMR spectra, the 5-FU signals in the final conjugates were clearly observed at 7.6–8.2 ppm. In ^{31}P NMR spectra, all of the 5-FU–cyclotriphosphazene conjugates exhibited sharp singlet ^{31}P resonances at 40∼45 ppm, and their isomeric purities were over 99%, as determined by HPLC.

Thermosensitivity of 5-FU–Cyclotriphosphazene Conjugates. The thermosensitive behavior of cyclotriphosphazenes with hydrophilic ethylene oxide chains and hydrophobic amino acid esters was previously commented on by our group (*26*, *27*). The cyclotriphosphazene exhibited a reversible and thermosensitive phase transition in an aqueous medium, from a soluble to an insoluble state.

The present 5-FU conjugates also exhibited a reversible and thermosensitive sol-to-prep transition in aqueous media, as shown in Figure 1. The phase transition with LCST is illustrated in Figure 2, and the LCSTs of the conjugates were listed in Table 1. Below LCST, the 5-FU–cyclotriphosphazene conjugate is readily soluble in aqueous media. Water molecules form hydrogen bonds with the fully extended side chains of the conjugates. As the temperature rises, however, the hydrogen bonds gradually degenerate and the hydrophobic groups are exposed, leading to physical association between the hydrophobic groups of the amino acid esters. As the temperature increases further, water molecules surrounding hydrophilic ethylene oxide chains are also excluded, leading to precipitation of the conjugate from the solution. This thermosensitive phase transition process is completely reversible, in that the polymer solutions precipitate upon warming and then are able to revert upon cooling to the original sol state. The rates of the phase transitions, both sol-to-prep and prep-to-sol, are fairly fast. A transparent solution in water became turbid in less than 10 s at 10 °C above LCST, and the turbid solution reverted to transparency in less than 10 s at 10 °C below LCST.

The LCST was greatly affected by the hydrophobic–hydrophilic balance of the conjugate. More hydrophobic

[a] MPEG: methoxy poly(ethylene glycol), MEE: 2-(2-methoxyethoxy)ethanol, EEE: 2-(2-ethoxyethoxy)ethanol, BEE: 2-(2-buthoxyethoxy)ethanol. [b] The concentration of the conjugate exhibiting 50% inhibition of cell growth.

tripeptide side groups resulted in lower LCST values. Comparing conjugates **1** and **2**, the LCST of the conjugate containing phenylalanine ($CH_2C_5H_5$) was 56 °C, while no LCST was observed in the conjugate containing leucine [$CH_2CH(CH_3)_2$]. The LCST could be also lowered by increasing the alkyl chain lengths of the alkoxy groups, due to increases in hydrophobicity. The LCSTs of conjugates **3** (methoxy) and **6** (ethoxy) were 27 and 17 °C, respectively. On the contrary, the conjugates with longer ethylene oxide chains (conjugates **1** and **2**) exhibited high LCSTs due to their high hydrophilicity. These results are consistent with previous studies of poly(organophosphazenes) or cyclotriphosphazenes with PEG and amino acid esters as side groups (*22*, *26*, *27*). The attached 5-FU did not significantly affect the thermosensitive behavior of cyclotriphosphazene. Considering over 20 different naturally occurring amino acids with different hydrophobicities, the LCST of a 5-FU−cyclotriphosphazene conjugate could be readily manipulated by substitution with different amino acid side groups. Among the present 5-FU−cyclotriphosphazene conjugates, conjugate **3** exhibited an LCST which was just slightly below body temperature. Therefore, it would appear to have great potential with regard to direct drug delivery to a tumor site. Upon intratumoral injection and subsequent warming to body temperature, the drug−polymer conjugate will precipitate from solution, hopefully functioning as a depot for the sustained release of 5-FU into tumor tissues.

Hydrolytic Degradation of 5-FU−Cyclotriphosphazene Conjugates. The in vitro hydrolytic degradation behaviors of 5-FU−cyclotriphosphazene conjugates were assessed under varying conditions of pH and temperature. The hydrolysis of the conjugate was monitored by ^{31}P NMR spectroscopy for 20 days (data not shown). The conjugate was relatively stable in a basic buffer solution. However, the conjugate demonstrated gradual degradation in neutral and acidic buffer solutions, and high temperature greatly facilitated its hydrolytic degradation. The conjugate before hydrolytic degradation exhibited a sharp singlet ^{31}P resonance. After 10 days incubation in neutral and basic buffer solutions, the small peaks appeared around the main peak, implying the ring opening of the cyclotriphosphazene conjugate due to hydrolytic degradation. The main resonance upfield-shifted with increasing incubation time, and the ring cleavage-associated peaks became more pronounced, suggesting gradual hydrolytic degradation in neutral and acidic buffer solutions. These results are inconsistent with those of the previous study (*27*), in that the hydrolysis of cyclotriphosphazene with MPEG and amino acid ester was faster in a basic solution than in acidic or neutral solutions. Two possible mechanisms underlying the hydrolytic degradation of cyclotriphosphazene derivatives have been proposed by Allcock and colleagues (*30*). One is the protonation of the nitrogen atom in the skeleton or in the side group, resulting in ring cleavage. The other is carboxylic acid-catalyzed degradation. The initial step in this process is the hydrolysis of a pendant ester group, with a consequent protonation of the nitrogen atom in the skeleton or in the side group. It appears that the present cyclotriphosphazene derivatives underwent hydrolytic degradation through the first pathway, whereas the cyclotriphosphazenes (*27*) with MPEG and amino acid esters were hydrolyzed via the second pathway.

In Vitro Antitumor Activity of 5-FU−Cyclotriphosphazene Conjugates. The in vitro cytotoxicity of 5-FU−cyclotriphosphazene conjugates was assessed by MTT assay, with regard to its action against the murine leukemia L1210 cell line. Table 1 lists the ED_{50} values, representing the concentration of the conjugate necessary to inhibit 50% of tumor cell growth. All of the conjugates displayed dose-dependent cytotoxicity against the tumor cell line, and all exhibited more pronounced cytotoxicity than did 5-FU, implying that the macromolecular prodrug of 5-FU should retain its antitumor activity, even after derivatization. However, the effect of thermosensitivity with the LCST of the prodrug on antitumor activity could not be definitively determined in the in vitro study. The in vivo study using tumor-bearing mice is still underway, and its results will be reported soon.

CONCLUSIONS

Novel macromolecular prodrugs of 5-FU were synthesized and assessed with regard to their ability to undergo thermosensitive phase transition from a soluble to an insoluble state. The LCSTs of these compounds appeared to be dependent on the hydrophilic−hydrophobic balance of the 5-FU−cyclotriphosphazene conjugate. More hydrophobic side groups resulted in lower LCST values. The LCST of the conjugate could be readily manipulated by the application of different ethylene oxide chains and amino acids with different hydrophobicities. The conjugate was gradually degraded in neutral and acidic buffer solutions, but relatively stable in a basic buffer solution. The conjugate exhibited effective antitumor activity against the murine leukemia L1210 cell line. This thermosensitive, polymeric drug delivery system is a very appealing option for a future drug delivery system, in which, by a simple injection rather than a surgical operation, a depot for drug release may be created.

"Clickable" Agarose for Affinity Chromatography

Sreenivas Punna, Eiton Kaltgrad, and M. G. Finn*

Department of Chemistry and The Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037. Received August 8, 2005; Revised Manuscript Received August 12, 2005

Successful purification of biological molecules by affinity chromatography requires the attachment of desired ligands to biocompatible chromatographic supports. The Cu(I)-catalyzed cycloaddition of azides and alkynes—the premier example of "click chemistry"—is an efficient way to make covalent connections among diverse molecules and materials. Both azide and alkyne units are highly selective in their reactivity, being inert to most chemical functionalities and stable to wide ranges of solvent, temperature, and pH. We show that agarose beads bearing alkyne and azide groups can be easily made and are practical precursors to functionalized agarose materials for affinity chromatography.

INTRODUCTION

Biological processes depend on specific interactions between molecules, such as between antibodies and antigens, carbohydrates and lectins, and enzymes and inhibitors. Affinity chromatography (*1*) exploits these various interactions for the analysis and purification of mixtures of biomolecules. One of the members of the interacting pair is immobilized on an insoluble support and is used to "fish out" the complementary agent from a solution passed through or over the column. In many cases, affinity chromatography is a crucial step in the isolation of desired species, for example, providing the only practical means for the separation of tagged or functional proteins from cellular extracts.

Beaded agarose bearing functional groups such as amine ($-NH_2$), carboxylic acid ($-COOH$), aldehyde ($-CHO$), thiol ($-SH$), and hydroxyl ($-OH$) is the support of choice for most ligands of interest (*2*) due to its inexpensive and biocompatible nature. For selective immobilization, a ligand should possess a functional group for attachment to the support that is not essential to its binding property. Ligands can be immobilized in ways detrimental to their intended function when more than one of the attachment units is present in a ligand or when other reactive functional groups on the ligand compete in the immobilization chemistry. A matched pair of groups which is selective in reacting with each other while being unreactive to other functional groups in the molecule would therefore be highly useful in the preparation of functional agarose beads. Organic azides and terminal alkynes fit this description, being inert to most chemical functionalities and stable to wide ranges of solvent, temperature, and pH. While their uncatalyzed [3+2] dipolar cycloaddition is typically very slow at room temeperature (*3*), Cu(I) catalysts accelerate the reaction to a great degree (*4*, *5*). Here we report the first use of azides, alkynes, and their "click reaction" (*6*) for the convenient immobilization of ligands on agarose for affinity chromatography and related purposes.

EXPERIMENTAL PROCEDURES

General. ^1H and ^{13}C NMR spectra were recorded on Bruker DRX-500, AMX-400, or Varian Mercury 200 spectrometers, using $CDCl_3$ or CD_3OD as solvents. Mass spectra were obtained on an Agilent 1100 LC/MS spectrometer (model G1946A). Melting points were measured in a Mel-Temp II capillary melting point apparatus and are uncorrected. Infrared spectra were recorded on a MIDAC EM200 instrument with horizontal attenuated total reflectance accessory from Pike Instruments or in KBr pellets. Column chromatography was performed on EM Science silica gel (40−63 μm mesh). TLC analysis was facilitated by the use of phosphomolybdic acid or $KMnO_4/H_2O$ stains in addition to UV light with fluorescent-indicating plates. Anhydrous sodium sulfate was used for drying solutions. Carboxy Link coupling gel (50% aqueous slurry, 16 μmol of amine groups per milliliter), biotin-PEG-amine, and avidin-HABA complex were purchased from Pierce. All other commercially available reagents were purchased from Acros or Aldrich. Compounds **6** and **7**, kindly provided by Mr. Warren G. Lewis, have been previously described (*5*). Reactions requiring anhydrous conditions were performed under nitrogen.

5-Azidopentanoic Acid 4-Nitrophenyl Ester (2). 1-(3-Dimethylaminopropyl)-3-ethylcarbodimide hydrochloride (EDCI·HCl, 703.8 mg, 3.67 mmol) was added to a solution of *p*-nitrophenol (510.5 mg, 3.67 mmol) and 5-azidopentanoic acid (500 mg, 3.49 mmol) in CH_2Cl_2 (25 mL) at room temperature and stirred overnight, followed by the addition of water and excess EtOAc. The separated organic phase was washed with H_2O and brine solution, dried over Na_2SO_4, and evaporated. The crude product was purified by silica gel column chromatography (1:4 EtOAc/hexane) to give **2** (514 mg) as a pale yellow oil in 52% yield. ^1H NMR ($CDCl_3$) δ 1.62−1.92 (m, 4H), 2.60 (t, J = 6.6 Hz, 2H, $-CH_2N_3$), 3.34 (t, J = 6.6 Hz, 2H), 7.25 (d, J = 9.2 Hz, 2H), 8.23 (d, J = 8.8 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ 22.1, 28.4, 33.9, 51.2, 60.6, 122.6, 125.4, 145.5, 155.5, 170.8; IR (thin film, cm^{-1}): 2946, 2100 (azide), 1768, 1593, 1534, 1345, 1211, 1130, 910, 865, 748; ESMS *m/z* (relative intensity) 287 $(M + Na)^+$ (75), 237 (100), 223 (70).

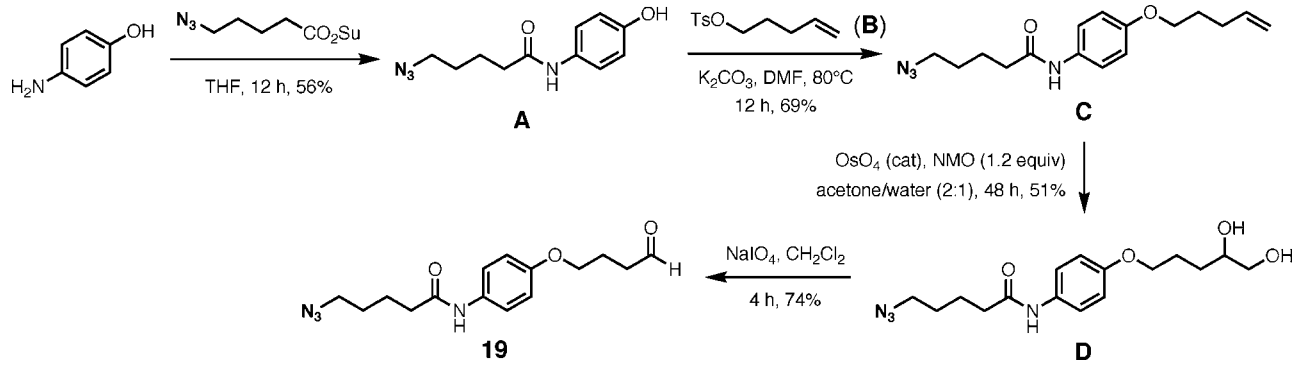
Scheme 1



Agarose Azide and Alkyne Beads (4 and 5). CarboxyLink gel (8 mL, maximum of 64 μmol of amine groups) was transferred to a disposable frit, allowed to settle for 30 min, and equilibrated with 5 column volumes of pH 4.7 MES buffer (0.1 M). To the gel was added *p*-nitrophenyl ester **2** (143.4 mg, 64 mmol, 16 μmol/mL) dissolved in DMF with 5% of the MES buffer (8.4 mL), and the capped fritted tube was rotated gently at room temperature for 2 days. Phosphate buffer (600 μL, pH 7, 1.5 M) was added to the reaction mixture, which was then drained into a clean scintillation vial and the absorbance at 412 nm was measured directly. An agarose sample lacking the amine group was used in a control experiment to correct for residual hydrolysis of **2**, which was negligible under these conditions. The amount of attached azide was assumed to be equivalent to the amount of released *p*-nitrophenol, which was determined with the aid of an extinction coefficient measured by the addition of authentic *p*-nitrophenol to the same mixture of DMF, pH 4.7 MES, and pH 7 phosphate (ϵ = 432 M^{-1} cm^{-1}). Agarose **5** was prepared and analyzed by the same procedure, using *p*-nitrophenyl ester **3**.

Fluorescein-alkyne (8). To fluorescein NHS ester (97 mg, 0.205 mmol) in THF (30 mL) was added propargylamine (32 μL, 0.451 mmol), and the reaction was stirred under nitrogen atmosphere at room temperature overnight. After the sample was filtered to remove a small amount of insoluble material, the solvent was evaporated and the residue was washed with CH_2Cl_2 and then Et_2O to afford **8** as a yellow solid in quantitative yield (87 mg). ESMS *m/z* (relative intensity) 414 (M^+, base peak).

Typical Immobilization Procedure. Stock solutions (50 mM) of the following reagents were prepared: 2,6-lutidine (DMF), 2,2′-bipyridine (DMF), CuBr (DMF), and sodium ascorbate (water). A slurry of agarose-azide/alkyne beads (1.0 equiv) in DMF in a disposable frit was treated with the molecule to be attached bearing the complementary (alkyne or azide) group (4.0 equiv), followed by 2,6-lutidine (8.0 equiv), 2,2′-bipyridine (8.0 equiv), cuprous bromide (4.0 equiv), and finally sodium ascorbate (8.0 equiv). The resulting suspension was bubbled with a gentle flow of nitrogen for 1 min, capped, and rotated at room temperature for 12−18 h. The reaction mixture was drained and washed sequentially with approximately 5 column volumes each of DMF, H_2O, MeOH, 0.1 M aq EDTA, H_2O, and DMF.

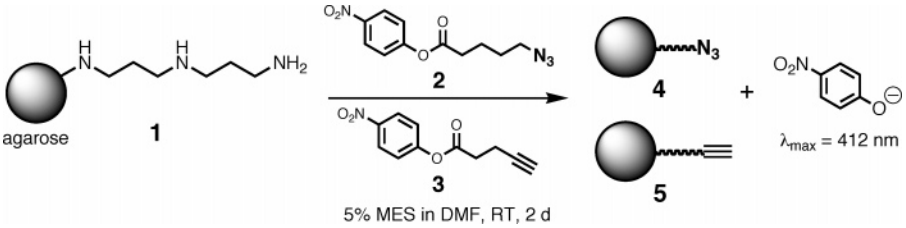
Biotin-PEG-alkyne (12). To a solution of biotin-PEG-amine (**11**, 33 mg, 0.079 mmol) in CH_2Cl_2 (5 mL) was added 4-pentynoic acid (7.4 mg, 0.045 mmol) followed by 1-(3-dimethylaminopropyl)-3-ethylcarbodimide hydrochloride (EDCI·HCl; 704 mg, 3.67 mmol). The mixture was stirred at room temperature overnight and was then partitioned between EtOAc (10 mL) and water. The organic layer was dried (Na_2SO_4) and evaporated to give compound **12** (9 mg) as a colorless syrup. A further 11 mg was recovered from the aqueous layer by stirring in the presence of additional EtOAc and excess NaCl (overall yield 51%). ^{1}H NMR ($CDCl_3$) δ 1.49−1.55 (m, 2H), 1.86−1.88 (m, 4H), 2.25−2.85 (m, 2H), 2.36 (s, 1H), 2.49−2.60 (m, 6H), 2.75−2.85 (m, 2H), 2.92−3.02 (m, 2H), 3.25−3.30 (m, 1H), 3.40 (m, 2H), 3.41−3.50 (m, 4H), 3.58−3.64 (m, 4H), 3.67−3.70 (m, 2H), 4.35−4.40 (m, 1H), 4.55−4.60 (m, 1H), 8.20 (br s, 1H), 8.4 (br s, 1H);^{13}C NMR ($CDCl_3$) δ 14.7, 25.8, 28.5, 28.7, 34.9, 35.7, 40.0, 56.03, 60.64, 62.4, 68.9, 69.5, 70.2, 70.27, 70.6, 74.4, 82.5, 175.2, 177.7, 178.05; IR (film, cm^{-1}): 3287 (CCH), 3084, 2864, 2114 (alkyne), 1629, 1553, 1265, 1140, 951, 879, 726; ESMS *m/z* (relative intensity) 521 $(M+Na)^+$ (100), 499 $(M+1)^+$ (25), 375 (60).

HIV-Protease Peptide Alkyne (15). Standard Fmoc-based solid phase peptide synthesis techniques were employed (*7*), starting with Wang resin bearing the C-terminal amino acid (Fmoc-Phe-OH, 0.77 mmol/g). Fmoc deprotection was accomplished with two treatments of 20% piperidine in DMF, and amino acid coupling was typically performed with 5.5 equiv of Fmoc-amino acid, 5.0 equiv of HBTU, and excess *i*Pr_2NEt. Fmoc-propargylglycine (CSPS Chemicals, San Diego) was installed as the final (*N*-terminal) amino acid, using DIC/HOBt (5.0 equiv) in CH_2Cl_2. The crude peptide containing the N-terminal Fmoc protecting group was obtained by treating the resulting resin with 94/2.5/2.5/1 CF_3CO_2H/H_2O/1,2-ethanedithiol/SiH(*i*Pr)$_3$ mixture for 3 h at room temperature. The desired peptide was identified by MALDI-MS of fractions from analytical HPLC of the crude product, and then purified by preparative HPLC. The final purified product (peptide G*QCTLNF, where G* = propargylglycine) was obtained in approximately 9% yield, calculated from the weight of the isolated material relative to the amount of amino acid on the starting resin.

After attachment of **15** to **4** by the above procedure, the resulting beads (**16**) were treated with 20% piperidine (4 mL) at room temperature for 10 min. The solution was drained, and the absorbance at 300 nm was measured against a blank composed of 20% piperidine in DMF. Using the measured fluorene molar extinction coefficient of 7800 M^{-1} cm^{-1} determined under identical conditions, the attached peptide concentration was found to be 0.71 μmol/mL, representing approximately 39% conversion of the available azides on the resin (measured as above at 1.84 μmol/mL). Attachment of Fmoc-propargylglycine alone proceeded in 63% yield by the same assay. A contributing factor to the relatively poor attachment of the peptide is its poor solubility, even in DMF, causing it to aggregate and precipitate slowly during the reaction.

4-Azido-*N*-[4-(4-oxobutoxy)phenyl]butyramide (19, Scheme 1). To the *N*-hydroxysuccinimide (Su) ester of

Scheme 2



4-azidobutyric acid (2.2 g, 18.32 mmol) in THF (20 mL) was added *p*-aminophenol (1.0 g, 18.32 mmol), and the mixture was stirred overnight at room temperature. The solvent was evaporated and the resulting residue was partitioned between equal volumes of 1 M HCl and EtOAc. The aqueous layer was extracted twice more with EtOAc and the combined organic layers were washed with 1 N HCl, H_2O (2×), brine, dried, and evaporated. The crude product (designated as compound **A**) was purified by column chromatography (1:3 EtOAc/hexanes) to give a brown solid (1.19 g, 57% yield). mp 67−69 °C; ^{1}H NMR ($CDCl_3$) δ 1.50−1.57 (m, 2H), 1.63−1.71 (m, 2H), 2.26 (t, J = 7.5 Hz, 2H), 6.68 (d, J = 8.0 Hz, 2H), 7.19 (dd, J = 8.5, 3.5 Hz), 8.37 (s, 1H); ^{13}C NMR (CD_3OD) δ 24.3, 29.6, 37.2, 52.3, 116.3, 123.6, 131.7, 155.5, 173.9; IR (KBr, cm^{-1}): 2959, 2465, 2096 (azide), 1665, 1449, 1238, 839; ESMS *m/z* (relative intensity) 257 $(M + Na)^+$ (22), 235 $(M+H)^+$ (100).

To a solution of 4-pentene-1-ol (3.0 g, 35 mmol), Et_3N (14.5 mL, 105 mmol), and DMAP (425 mg, 3.5 mmol) in THF (50 mL) was added *p*-TsCl (6.64 g, 34.88 mmol), and the reaction was stirred for 6 h at room temperature. The resulting mixture was filtered through a sintered funnel, the solid was washed with additional THF, and the combined solution was evaporated. The crude product was purified by column chromatography (silica gel, 1:4 EtOAc/hexanes) to obtain the desired tosylate **B** (Scheme 1) as a colorless liquid (6.6 g, 79% yield). ^{1}H NMR ($CDCl_3$) δ 1.58−1.72 (m, 2H), 1.92−2.08 (m, 2H), 2.36 (s, 3H), 3.96 (t, J = 6.4 Hz, 2H), 4.80−4.94 (m, 2H), 5.50−5.73 (m, 1H), 7.27 (d, J = 8.0 Hz, 2H), 7.70 (d, J = 7.8 Hz); ^{13}C NMR ($CDCl_3$) δ 13.9, 21.3, 27.7, 29.1, 69.6, 115.5, 127.6, 132.8, 136.4, 144.6; IR (thin film, cm^{-1}): 3075 (olefin), 2981, 1926, 1643, 1598, 1449, 1346, 1185, 920, 825, 749; ESMS *m/z* (relative intensity) 241 $(M + H)^+$ (10).) This material (720 mg, 3.00 mmol) was combined with compound **A** (702 mg, 3.00 mmol) and K_2CO_3 (1.24 g, 9.0 mmol) in DMF (5.0 mL), and the mixture was stirred at 80 °C for 12 h. Saturated aqueous NH_4Cl solution (25 mL) and EtOAc (25 mL) were added, and the organic layer was separated and washed with additional NH_4Cl solution, water, and brine. The solution was dried and evaporated, and the residue was purified by column chromatography (silica gel, 1:4 EtOAc/hexanes) to give the ether-amide intermediate **C** (627 mg, 69% yield) as a red solid. mp 60−62 °C; ^{1}H NMR ($CDCl_3$) δ 1.63−1.69 (m, 2H), 1.75−1.82 (m, 2H), 1.82−1.89 (m, 2H), 2.22 (q, J = 7.0 Hz, 2H), 2.35 (t, J = 7 Hz, 2H), 3.30 (t, J = 6.5 Hz, 2H, $-CH_2N_3$), 3.93 (t, J = 6 Hz), 4.98−5.08 (m, 2H), 5.84 (m, 1H), 6.83 (d, J = 10.0 Hz), 7.37 (d, J = 8.5 Hz, 2H), 7.41 (br s, 1H); ^{13}C NMR ($CDCl_3$) δ 22.3, 27.9, 29.6, 36.2, 50.7, 66.9, 114.3, 115.0, 121.4, 130.3, 137.3, 155.4, 170.15; IR (KBr, cm^{-1}): 2950, 2100 (azide), 1650, 1310, 1250, 820, 760; ESMS *m/z* (relative intensity) 303 $(M + H)^+$ (100).

To a cooled (ice bath) solution of olefin **C** (500 mg, 1.65 mmol) in 2:1 acetone/water (6 mL) was added a small crystal of OsO_4. After 5 min, *N*-methylmorpholine *N*-oxide (193.3 mg, 1.65 mmol) was added, and the mixture was stirred at room temperature for 2 days. EtOAc and brine were added, and the aqueous layer was further extracted with EtOAc (2 × 25 mL). The crude product obtained from the combined organic layers was purified by column chromatography (silica gel, EtOAc) to give the desired diol (**D**, Scheme 1, 248 mg, 51% yield) as a white solid. Approximately 65 mg of the starting material was also recovered. mp 82−84 °C; ^{1}H NMR ($CDCl_3$) δ 1.50−1.90 (m, 8H), 2.34 (t, J = 7.0 Hz, 2H), 2.70 (br s, −OH), 3.29 (t, J = 5.5 Hz, 2H, $-CH_2N_3$), 3.40−3.44 (m, 1H), 3.60−3.85 (m, 2H), 3.92 (s, 2H), 6.79 (d, J = 9.5 Hz), 7.36 (dd, t, J = 7.0, 5.0 Hz, 2H), 8.32 (br s, 1H); ^{13}C NMR ($CDCl_3$) δ 23.9, 26.5, 29.3, 30.8, 36.9, 52.0, 67.2, 69.0, 72.8, 115.4, 122.9, 132.6, 157.1, 173.6; IR (thin film, cm^{-1}): 2945, 2869, 2132 (azide), 1661, 1490, 1301, 1238, 1018, 830; ESMS *m/z* (relative intensity) 337 $(M + H)^+$ (100).

To a solution of diol **D** (100 mg, 0.297 mmol) in CH_2Cl_2 (5 mL + 2 drops of MeOH) was added saturated aqueous $NaHCO_3$ (0.5 mL) followed by $NaIO_4$ (127 mg, 0.60 mmol). After the sample was stirred at room temperature for 4 h, anhydrous Na_2SO_4 (approximately 1 g) and CH_2Cl_2 (25 mL) were added and the mixture was stirred for a further 30 min. Filtration, washing of the solid with CH_2Cl_2, and evaporation of the combined organic solutions provided compound **19** (67 mg, 74% yield) as a thick colorless syrup. ^{1}H NMR ($CDCl_3$) δ 1.60−1.70 (m, 2H), 1.74−1.85 (m, 2H), 2.08−2.15 (m, 2H), 2.34 (t, J = 6.4 Hz, 2H), 2.65 (t, J = 5.8 Hz, 2H), 3.28 (t, J = 5.6 Hz, 2H, $-CH_2N_3$), 3.95 (t, J = 5.4 Hz, 2H), 6.8 (d, J = 10.8 Hz, 2H, ArH), 7.38 (d, J = 10.8 Hz, 2H, ArH), 7.74 (s, 1H), 9.8 (s, 1H, −CHO); ^{13}C NMR ($CDCl_3$) δ 21.3, 22.0, 27.6, 35.8, 39.9, 50.4, 66.2, 113.9, 121.2, 130.6, 154.7, 170.3, 201.4; IR (film, cm^{-1}): 2949, 2877, 2096 (azide), 1727, 1664 (C=O), 1301, 1233, 959, 833, 743; ESMS *m/z* (relative intensity) 305 $(M+1)^+$ (85).

Test of Affinity Chromatography Function with Aldehyde 19. Functionalized agarose **20**, prepared in the standard manner from **19**, was poured into a column (Amersham Tricom, 5 mm × 50 mm; 1 mL volume; cat#18−1163−09). At pH 7, the column was found to retain the catalytic antibody 84G3 originally obtained by Barbas and co-workers (*8*, *9*) and not an unrelated antibody; details can be found in Figure 5.

RESULTS AND DISCUSSION

Commercially available Carboxy-Link agarose (**1**), which bears addressable amine groups, was treated with the *p*-nitrophenyl ester of 5-azidopentanoic acid (**2**) and 5-pentynoic acid (**3**) to give azide- and alkyne-functionalized beads **4** and **5**, respectively (Scheme 2). The degree of acylation was determined by measurement of the concentration of released *p*-nitrophenol. Loadings of between 3.3 and 4.6 μmol/mL of gel were typical, representing approximately 20−30% of the available amine groups according to the commercial specifications of the gel. However, the standard Kaiser (ninhydrin) test (*10*) gave a positive signal for **1** and negative signals for **4** and **5**, suggesting that most or all of the accessible amine groups of **1** were acylated by **2** and **3**.

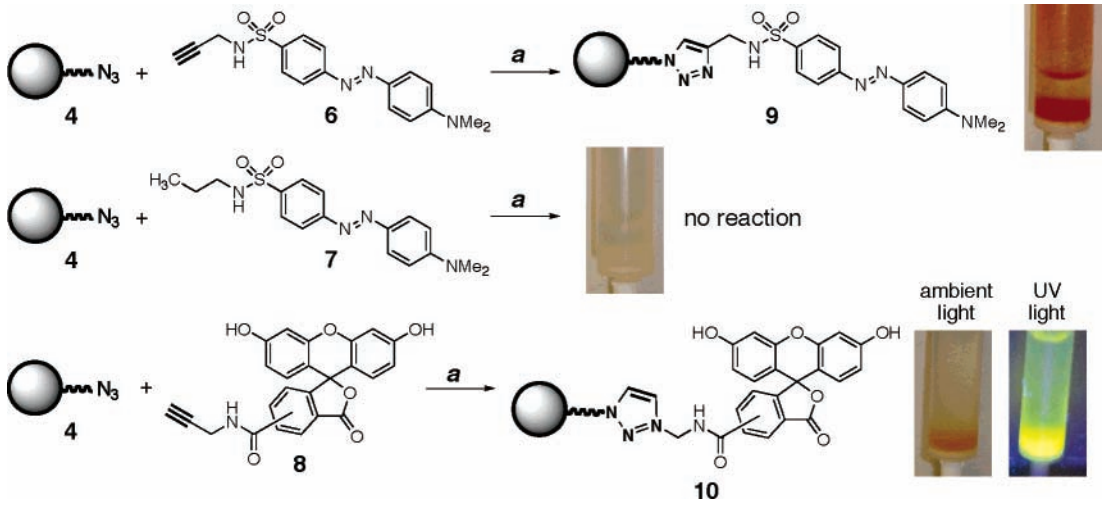


Figure 1. CuAAC coupling of dye reagents to agarose azide and alkyne; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions.

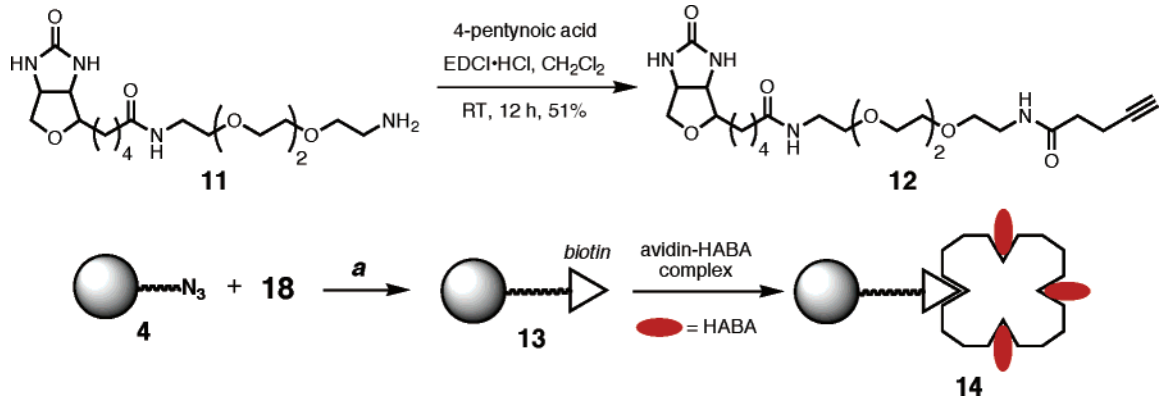

Figure 2. Biotinylation of agarose azide; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions.

To test the feasibility of resin attachment by the Cu-mediated azide-alkyne cycloaddition (CuAAC) reaction, agarose-azide beads **4** were treated with a dabsyl-alkyne derivative (**6**) and the corresponding dye with an *n*-propyl group in place of the alkyne (**7**), in the presence of cuprous bromide, 2,2′-bipyridine as accelerating ligand (*5*), sodium ascorbate to maintain a reducing environment, and 2,6-lutidine as mild base (Figure 1). The dye was successfully attached with **6**, as indicated by the production of an intense and permanent red color in the resulting beads (**9**). Use of the control **7** or omission of Cu(I) from the reaction of **6** gave colorless beads. In addition, no dye could be washed from **9** even upon extensive treatment with DMF; these observations show that the dye does not adsorb to the resin. Similarly, **4** was treated with fluorescein alkyne **8** under CuAAC conditions to give yellow beads that were strongly fluorescent under ultraviolet light. The same successful results were obtained with agarose-alkyne **5** and the complementary azide-substituted dabsyl compound (data not shown).

Biotinylated supports are a mainstay of protein immobilization and therefore of experimental biochemistry. The CuAAC reaction provides a convenient addition to the many methods already in use for constructing such materials. Biotin alkyne **12** was prepared from commercially available biotin-PEG-amine **12** and 4-pentynoic acid (Figure 2). Immobilization on agarose azide beads gave **13**, which was treated with a red solution of avidin-HABA (HABA = 2-(4′-hydroxyphenyl)azobenzoic acid) complex. Tight avidin−biotin interaction gave the resulting beads a persistent red color (**14**), whereas a mixture of avidin-HABA with agarose-azide **4** resulted in no such binding.

The immobilization of peptides is a common application of activated agarose supports. To demonstrate the ease and convenience of clickable agarose in this endeavor, we prepared a derivative of the C-terminal sequence of HIV protease (QCTLNF), which contains primary amide, carboxylic acid, thiol, and alcohol functional groups which would otherwise complicate the choice of attachment stragtegy. An extra alkyne-containing amino acid was used to end the standard solid-phase peptide synthesis sequence, and the final oligopeptide was cleaved from the resin retaining its N-terminal Fmoc protecting group (compound **15**, Figure 3). Purification by reversed-phase chromatography was followed by reaction with agarose azide **4** by the method described above. Fmoc deprotection of **16** with piperidine revealed the amine-terminated immobilized peptide **17** and showed by quantitation of the released fluorene chromophore a capture of 39% of the azide groups installed on the agarose support. The resulting peptide concentration is more than enough to be useful for applications such as aptamer selection and binding studies, which are currently underway.

Affinity purification of enzymes and antibodies by reversible interaction with a binding site or reactive tag is enabled by attachment of the complementary group to the solid support with a chemically compatible linker. An example is shown in Figure 4. Certain monoclonal antibodies generated against diketone **20** (Figure 5) have been shown to possess crucial active-site lysine residues

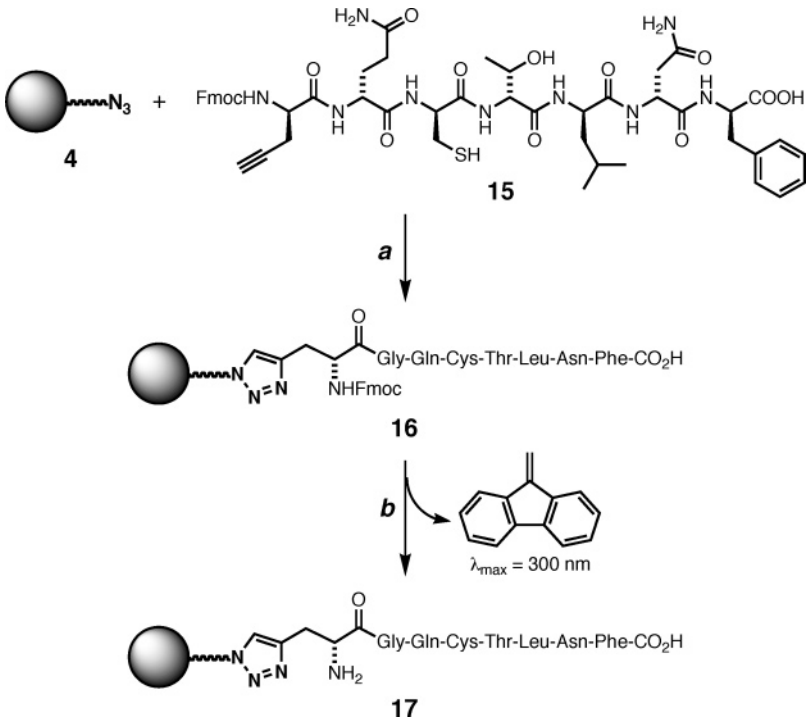

Figure 3. Peptide immobilization on agarose azide; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions; b, 20% piperidine in DMF, RT, 10 min.

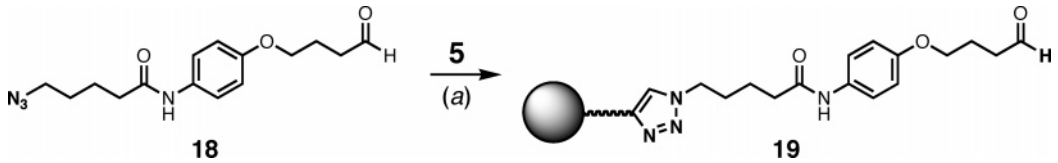

Figure 4. Aliphatic aldehyde immobilization on agarose azide; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions.

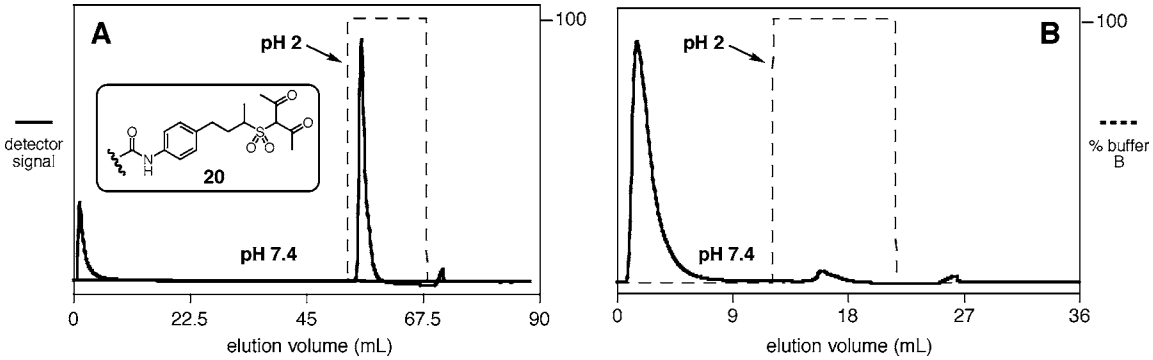

Figure 5. Elution profiles on a column of agarose **19** of (A) antibody 84G3 and (B) IgY isolated from chicken eggs obtained prior to an immunization. A greater wash volume at pH 7.4 was used in A, but the patterns were reproducible. The antibody isolated from chromatograph A was found to be catalytically active in a standard retro-aldol reaction. The structure of the hapten used to generate 84G3 (**20**) is shown.

which catalyze asymmetric aldol and retro-aldol reactions by the formation of enamine intermediates from aldehyde substrates (*8*, *11*). It was envisioned that an immobilized aldehyde could be used to purify such antibodies by virtue of reversible imine formation. The attachment of such an aldehyde to agarose by standard amide or ether bond-forming methods would usually require protection/deprotection steps, which are avoided by the use of the CuAAC process. Thus, azidoaldehyde **18** was ligated without difficulty to agarose-alkyne **5** by the standard protocol to give **19**. The presence of the aldehyde group was confirmed by treatment of agarose **19** with *p*-nitrophenylhydrazine to give a yellow color consistent with the formation of the corresponding hydrazone. As shown in Figure 5, agarose **19** did indeed bind an antibody raised against **20**, but not an unrelated polyclonal antibody.

The results described here illustrate the convenient use of a single pair of functionalized agarose materials, azide **4** and alkyne **5**, for the attachment of a chemically diverse set of functional molecules. While we produced **4** and **5** for this study from a commercial "specialty" agarose-amine, it should be possible to access similar materials from agarose itself and much less expensive reagents; such large-scale production of clickable agarose materials is underway in our laboratory. Given the established applicability of the CuAAC reaction to a widely diverse set of building blocks in organic, materials, and biological chemistry, we believe that there are few limitations to

the nature of structures that can be married to soluble or insoluble supports in this manner for a wide variety of applications.

ACKNOWLEDGMENT

We thank the Skaggs Institute for Chemical Biology and the National Institutes of Health (GM48870) for support of this work, Dr. Sayam Sen Gupta for helpful discussions, and Dr. Diane Kubitz for a sample of antibody 84G3.

"Clickable" Agarose for Affinity Chromatography

Sreenivas Punna, Eiton Kaltgrad, and M. G. Finn*

Department of Chemistry and The Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037. Received August 8, 2005; Revised Manuscript Received August 12, 2005

Successful purification of biological molecules by affinity chromatography requires the attachment of desired ligands to biocompatible chromatographic supports. The Cu(I)-catalyzed cycloaddition of azides and alkynes—the premier example of "click chemistry"—is an efficient way to make covalent connections among diverse molecules and materials. Both azide and alkyne units are highly selective in their reactivity, being inert to most chemical functionalities and stable to wide ranges of solvent, temperature, and pH. We show that agarose beads bearing alkyne and azide groups can be easily made and are practical precursors to functionalized agarose materials for affinity chromatography.

INTRODUCTION

Biological processes depend on specific interactions between molecules, such as between antibodies and antigens, carbohydrates and lectins, and enzymes and inhibitors. Affinity chromatography (*1*) exploits these various interactions for the analysis and purification of mixtures of biomolecules. One of the members of the interacting pair is immobilized on an insoluble support and is used to "fish out" the complementary agent from a solution passed through or over the column. In many cases, affinity chromatography is a crucial step in the isolation of desired species, for example, providing the only practical means for the separation of tagged or functional proteins from cellular extracts.

Beaded agarose bearing functional groups such as amine ($-NH_2$), carboxylic acid ($-COOH$), aldehyde ($-CHO$), thiol ($-SH$), and hydroxyl ($-OH$) is the support of choice for most ligands of interest (*2*) due to its inexpensive and biocompatible nature. For selective immobilization, a ligand should possess a functional group for attachment to the support that is not essential to its binding property. Ligands can be immobilized in ways detrimental to their intended function when more than one of the attachment units is present in a ligand or when other reactive functional groups on the ligand compete in the immobilization chemistry. A matched pair of groups which is selective in reacting with each other while being unreactive to other functional groups in the molecule would therefore be highly useful in the preparation of functional agarose beads. Organic azides and terminal alkynes fit this description, being inert to most chemical functionalities and stable to wide ranges of solvent, temperature, and pH. While their uncatalyzed [3+2] dipolar cycloaddition is typically very slow at room temeperature (*3*), Cu(I) catalysts accelerate the reaction to a great degree (*4*, *5*). Here we report the first use of azides, alkynes, and their "click reaction" (*6*) for the convenient immobilization of ligands on agarose for affinity chromatography and related purposes.

EXPERIMENTAL PROCEDURES

General. ^1H and ^{13}C NMR spectra were recorded on Bruker DRX-500, AMX-400, or Varian Mercury 200 spectrometers, using $CDCl_3$ or CD_3OD as solvents. Mass spectra were obtained on an Agilent 1100 LC/MS spectrometer (model G1946A). Melting points were measured in a Mel-Temp II capillary melting point apparatus and are uncorrected. Infrared spectra were recorded on a MIDAC EM200 instrument with horizontal attenuated total reflectance accessory from Pike Instruments or in KBr pellets. Column chromatography was performed on EM Science silica gel (40−63 μm mesh). TLC analysis was facilitated by the use of phosphomolybdic acid or $KMnO_4/H_2O$ stains in addition to UV light with fluorescent-indicating plates. Anhydrous sodium sulfate was used for drying solutions. Carboxy Link coupling gel (50% aqueous slurry, 16 μmol of amine groups per milliliter), biotin-PEG-amine, and avidin-HABA complex were purchased from Pierce. All other commercially available reagents were purchased from Acros or Aldrich. Compounds **6** and **7**, kindly provided by Mr. Warren G. Lewis, have been previously described (*5*). Reactions requiring anhydrous conditions were performed under nitrogen.

5-Azidopentanoic Acid 4-Nitrophenyl Ester (2). 1-(3-Dimethylaminopropyl)-3-ethylcarbodimide hydrochloride (EDCI·HCl, 703.8 mg, 3.67 mmol) was added to a solution of *p*-nitrophenol (510.5 mg, 3.67 mmol) and 5-azidopentanoic acid (500 mg, 3.49 mmol) in CH_2Cl_2 (25 mL) at room temperature and stirred overnight, followed by the addition of water and excess EtOAc. The separated organic phase was washed with H_2O and brine solution, dried over Na_2SO_4, and evaporated. The crude product was purified by silica gel column chromatography (1:4 EtOAc/hexane) to give **2** (514 mg) as a pale yellow oil in 52% yield. ^1H NMR ($CDCl_3$) δ 1.62−1.92 (m, 4H), 2.60 (t, J = 6.6 Hz, 2H, $-CH_2N_3$), 3.34 (t, J = 6.6 Hz, 2H), 7.25 (d, J = 9.2 Hz, 2H), 8.23 (d, J = 8.8 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ 22.1, 28.4, 33.9, 51.2, 60.6, 122.6, 125.4, 145.5, 155.5, 170.8; IR (thin film, cm^{-1}): 2946, 2100 (azide), 1768, 1593, 1534, 1345, 1211, 1130, 910, 865, 748; ESMS *m/z* (relative intensity) 287 $(M + Na)^+$ (75), 237 (100), 223 (70).

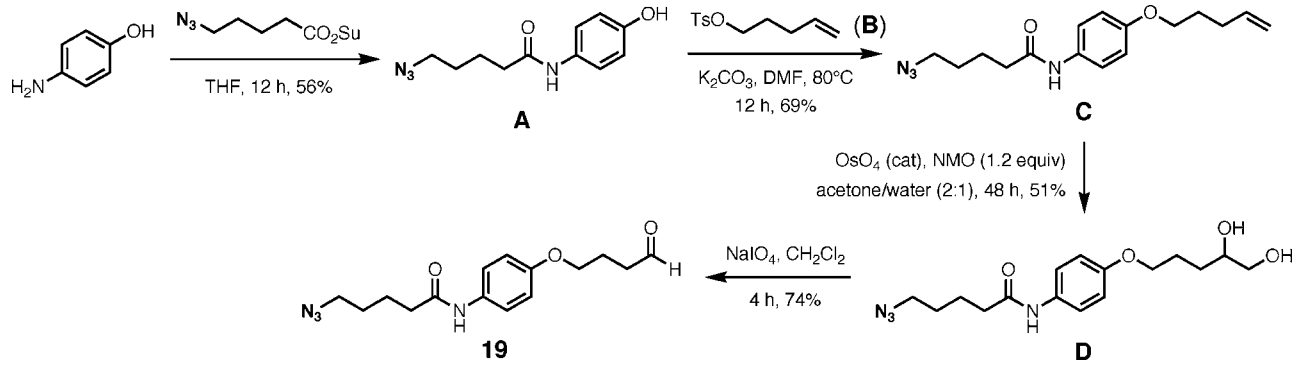
Scheme 1



Agarose Azide and Alkyne Beads (4 and 5). CarboxyLink gel (8 mL, maximum of 64 μmol of amine groups) was transferred to a disposable frit, allowed to settle for 30 min, and equilibrated with 5 column volumes of pH 4.7 MES buffer (0.1 M). To the gel was added *p*-nitrophenyl ester **2** (143.4 mg, 64 mmol, 16 μmol/mL) dissolved in DMF with 5% of the MES buffer (8.4 mL), and the capped fritted tube was rotated gently at room temperature for 2 days. Phosphate buffer (600 μL, pH 7, 1.5 M) was added to the reaction mixture, which was then drained into a clean scintillation vial and the absorbance at 412 nm was measured directly. An agarose sample lacking the amine group was used in a control experiment to correct for residual hydrolysis of **2**, which was negligible under these conditions. The amount of attached azide was assumed to be equivalent to the amount of released *p*-nitrophenol, which was determined with the aid of an extinction coefficient measured by the addition of authentic *p*-nitrophenol to the same mixture of DMF, pH 4.7 MES, and pH 7 phosphate (ϵ = 432 M^{-1} cm^{-1}). Agarose **5** was prepared and analyzed by the same procedure, using *p*-nitrophenyl ester **3**.

Fluorescein-alkyne (8). To fluorescein NHS ester (97 mg, 0.205 mmol) in THF (30 mL) was added propargylamine (32 μL, 0.451 mmol), and the reaction was stirred under nitrogen atmosphere at room temperature overnight. After the sample was filtered to remove a small amount of insoluble material, the solvent was evaporated and the residue was washed with CH_2Cl_2 and then Et_2O to afford **8** as a yellow solid in quantitative yield (87 mg). ESMS *m/z* (relative intensity) 414 (M^+, base peak).

Typical Immobilization Procedure. Stock solutions (50 mM) of the following reagents were prepared: 2,6-lutidine (DMF), 2,2′-bipyridine (DMF), CuBr (DMF), and sodium ascorbate (water). A slurry of agarose-azide/alkyne beads (1.0 equiv) in DMF in a disposable frit was treated with the molecule to be attached bearing the complementary (alkyne or azide) group (4.0 equiv), followed by 2,6-lutidine (8.0 equiv), 2,2′-bipyridine (8.0 equiv), cuprous bromide (4.0 equiv), and finally sodium ascorbate (8.0 equiv). The resulting suspension was bubbled with a gentle flow of nitrogen for 1 min, capped, and rotated at room temperature for 12−18 h. The reaction mixture was drained and washed sequentially with approximately 5 column volumes each of DMF, H_2O, MeOH, 0.1 M aq EDTA, H_2O, and DMF.

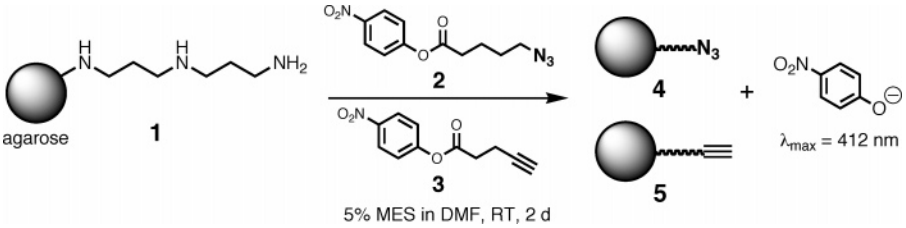
Biotin-PEG-alkyne (12). To a solution of biotin-PEG-amine (**11**, 33 mg, 0.079 mmol) in CH_2Cl_2 (5 mL) was added 4-pentynoic acid (7.4 mg, 0.045 mmol) followed by 1-(3-dimethylaminopropyl)-3-ethylcarbodimide hydrochloride (EDCI·HCl; 704 mg, 3.67 mmol). The mixture was stirred at room temperature overnight and was then partitioned between EtOAc (10 mL) and water. The organic layer was dried (Na_2SO_4) and evaporated to give compound **12** (9 mg) as a colorless syrup. A further 11 mg was recovered from the aqueous layer by stirring in the presence of additional EtOAc and excess NaCl (overall yield 51%). ^{1}H NMR ($CDCl_3$) δ 1.49−1.55 (m, 2H), 1.86−1.88 (m, 4H), 2.25−2.85 (m, 2H), 2.36 (s, 1H), 2.49−2.60 (m, 6H), 2.75−2.85 (m, 2H), 2.92−3.02 (m, 2H), 3.25−3.30 (m, 1H), 3.40 (m, 2H), 3.41−3.50 (m, 4H), 3.58−3.64 (m, 4H), 3.67−3.70 (m, 2H), 4.35−4.40 (m, 1H), 4.55−4.60 (m, 1H), 8.20 (br s, 1H), 8.4 (br s, 1H);^{13}C NMR ($CDCl_3$) δ 14.7, 25.8, 28.5, 28.7, 34.9, 35.7, 40.0, 56.03, 60.64, 62.4, 68.9, 69.5, 70.2, 70.27, 70.6, 74.4, 82.5, 175.2, 177.7, 178.05; IR (film, cm^{-1}): 3287 (CCH), 3084, 2864, 2114 (alkyne), 1629, 1553, 1265, 1140, 951, 879, 726; ESMS *m/z* (relative intensity) 521 $(M+Na)^+$ (100), 499 $(M+1)^+$ (25), 375 (60).

HIV-Protease Peptide Alkyne (15). Standard Fmoc-based solid phase peptide synthesis techniques were employed (*7*), starting with Wang resin bearing the C-terminal amino acid (Fmoc-Phe-OH, 0.77 mmol/g). Fmoc deprotection was accomplished with two treatments of 20% piperidine in DMF, and amino acid coupling was typically performed with 5.5 equiv of Fmoc-amino acid, 5.0 equiv of HBTU, and excess *i*Pr_2NEt. Fmoc-propargylglycine (CSPS Chemicals, San Diego) was installed as the final (*N*-terminal) amino acid, using DIC/HOBt (5.0 equiv) in CH_2Cl_2. The crude peptide containing the N-terminal Fmoc protecting group was obtained by treating the resulting resin with 94/2.5/2.5/1 CF_3CO_2H/H_2O/1,2-ethanedithiol/SiH(*i*Pr)$_3$ mixture for 3 h at room temperature. The desired peptide was identified by MALDI-MS of fractions from analytical HPLC of the crude product, and then purified by preparative HPLC. The final purified product (peptide G*QCTLNF, where G* = propargylglycine) was obtained in approximately 9% yield, calculated from the weight of the isolated material relative to the amount of amino acid on the starting resin.

After attachment of **15** to **4** by the above procedure, the resulting beads (**16**) were treated with 20% piperidine (4 mL) at room temperature for 10 min. The solution was drained, and the absorbance at 300 nm was measured against a blank composed of 20% piperidine in DMF. Using the measured fluorene molar extinction coefficient of 7800 M^{-1} cm^{-1} determined under identical conditions, the attached peptide concentration was found to be 0.71 μmol/mL, representing approximately 39% conversion of the available azides on the resin (measured as above at 1.84 μmol/mL). Attachment of Fmoc-propargylglycine alone proceeded in 63% yield by the same assay. A contributing factor to the relatively poor attachment of the peptide is its poor solubility, even in DMF, causing it to aggregate and precipitate slowly during the reaction.

4-Azido-*N*-[4-(4-oxobutoxy)phenyl]butyramide (19, Scheme 1). To the *N*-hydroxysuccinimide (Su) ester of

Scheme 2



4-azidobutyric acid (2.2 g, 18.32 mmol) in THF (20 mL) was added *p*-aminophenol (1.0 g, 18.32 mmol), and the mixture was stirred overnight at room temperature. The solvent was evaporated and the resulting residue was partitioned between equal volumes of 1 M HCl and EtOAc. The aqueous layer was extracted twice more with EtOAc and the combined organic layers were washed with 1 N HCl, H_2O (2×), brine, dried, and evaporated. The crude product (designated as compound **A**) was purified by column chromatography (1:3 EtOAc/hexanes) to give a brown solid (1.19 g, 57% yield). mp 67−69 °C; ^{1}H NMR ($CDCl_3$) δ 1.50−1.57 (m, 2H), 1.63−1.71 (m, 2H), 2.26 (t, J = 7.5 Hz, 2H), 6.68 (d, J = 8.0 Hz, 2H), 7.19 (dd, J = 8.5, 3.5 Hz), 8.37 (s, 1H); ^{13}C NMR (CD_3OD) δ 24.3, 29.6, 37.2, 52.3, 116.3, 123.6, 131.7, 155.5, 173.9; IR (KBr, cm^{-1}): 2959, 2465, 2096 (azide), 1665, 1449, 1238, 839; ESMS *m/z* (relative intensity) 257 $(M + Na)^+$ (22), 235 $(M+H)^+$ (100).

To a solution of 4-pentene-1-ol (3.0 g, 35 mmol), Et_3N (14.5 mL, 105 mmol), and DMAP (425 mg, 3.5 mmol) in THF (50 mL) was added *p*-TsCl (6.64 g, 34.88 mmol), and the reaction was stirred for 6 h at room temperature. The resulting mixture was filtered through a sintered funnel, the solid was washed with additional THF, and the combined solution was evaporated. The crude product was purified by column chromatography (silica gel, 1:4 EtOAc/hexanes) to obtain the desired tosylate **B** (Scheme 1) as a colorless liquid (6.6 g, 79% yield). ^{1}H NMR ($CDCl_3$) δ 1.58−1.72 (m, 2H), 1.92−2.08 (m, 2H), 2.36 (s, 3H), 3.96 (t, J = 6.4 Hz, 2H), 4.80−4.94 (m, 2H), 5.50−5.73 (m, 1H), 7.27 (d, J = 8.0 Hz, 2H), 7.70 (d, J = 7.8 Hz); ^{13}C NMR ($CDCl_3$) δ 13.9, 21.3, 27.7, 29.1, 69.6, 115.5, 127.6, 132.8, 136.4, 144.6; IR (thin film, cm^{-1}): 3075 (olefin), 2981, 1926, 1643, 1598, 1449, 1346, 1185, 920, 825, 749; ESMS *m/z* (relative intensity) 241 $(M + H)^+$ (10).) This material (720 mg, 3.00 mmol) was combined with compound **A** (702 mg, 3.00 mmol) and K_2CO_3 (1.24 g, 9.0 mmol) in DMF (5.0 mL), and the mixture was stirred at 80 °C for 12 h. Saturated aqueous NH_4Cl solution (25 mL) and EtOAc (25 mL) were added, and the organic layer was separated and washed with additional NH_4Cl solution, water, and brine. The solution was dried and evaporated, and the residue was purified by column chromatography (silica gel, 1:4 EtOAc/hexanes) to give the ether-amide intermediate **C** (627 mg, 69% yield) as a red solid. mp 60−62 °C; ^{1}H NMR ($CDCl_3$) δ 1.63−1.69 (m, 2H), 1.75−1.82 (m, 2H), 1.82−1.89 (m, 2H), 2.22 (q, J = 7.0 Hz, 2H), 2.35 (t, J = 7 Hz, 2H), 3.30 (t, J = 6.5 Hz, 2H, $-CH_2N_3$), 3.93 (t, J = 6 Hz), 4.98−5.08 (m, 2H), 5.84 (m, 1H), 6.83 (d, J = 10.0 Hz), 7.37 (d, J = 8.5 Hz, 2H), 7.41 (br s, 1H); ^{13}C NMR ($CDCl_3$) δ 22.3, 27.9, 29.6, 36.2, 50.7, 66.9, 114.3, 115.0, 121.4, 130.3, 137.3, 155.4, 170.15; IR (KBr, cm^{-1}): 2950, 2100 (azide), 1650, 1310, 1250, 820, 760; ESMS *m/z* (relative intensity) 303 $(M + H)^+$ (100).

To a cooled (ice bath) solution of olefin **C** (500 mg, 1.65 mmol) in 2:1 acetone/water (6 mL) was added a small crystal of OsO_4. After 5 min, *N*-methylmorpholine *N*-oxide (193.3 mg, 1.65 mmol) was added, and the mixture was stirred at room temperature for 2 days. EtOAc and brine were added, and the aqueous layer was further extracted with EtOAc (2 × 25 mL). The crude product obtained from the combined organic layers was purified by column chromatography (silica gel, EtOAc) to give the desired diol (**D**, Scheme 1, 248 mg, 51% yield) as a white solid. Approximately 65 mg of the starting material was also recovered. mp 82−84 °C; ^{1}H NMR ($CDCl_3$) δ 1.50−1.90 (m, 8H), 2.34 (t, J = 7.0 Hz, 2H), 2.70 (br s, −OH), 3.29 (t, J = 5.5 Hz, 2H, $-CH_2N_3$), 3.40−3.44 (m, 1H), 3.60−3.85 (m, 2H), 3.92 (s, 2H), 6.79 (d, J = 9.5 Hz), 7.36 (dd, t, J = 7.0, 5.0 Hz, 2H), 8.32 (br s, 1H); ^{13}C NMR ($CDCl_3$) δ 23.9, 26.5, 29.3, 30.8, 36.9, 52.0, 67.2, 69.0, 72.8, 115.4, 122.9, 132.6, 157.1, 173.6; IR (thin film, cm^{-1}): 2945, 2869, 2132 (azide), 1661, 1490, 1301, 1238, 1018, 830; ESMS *m/z* (relative intensity) 337 $(M + H)^+$ (100).

To a solution of diol **D** (100 mg, 0.297 mmol) in CH_2Cl_2 (5 mL + 2 drops of MeOH) was added saturated aqueous $NaHCO_3$ (0.5 mL) followed by $NaIO_4$ (127 mg, 0.60 mmol). After the sample was stirred at room temperature for 4 h, anhydrous Na_2SO_4 (approximately 1 g) and CH_2Cl_2 (25 mL) were added and the mixture was stirred for a further 30 min. Filtration, washing of the solid with CH_2Cl_2, and evaporation of the combined organic solutions provided compound **19** (67 mg, 74% yield) as a thick colorless syrup. ^{1}H NMR ($CDCl_3$) δ 1.60−1.70 (m, 2H), 1.74−1.85 (m, 2H), 2.08−2.15 (m, 2H), 2.34 (t, J = 6.4 Hz, 2H), 2.65 (t, J = 5.8 Hz, 2H), 3.28 (t, J = 5.6 Hz, 2H, $-CH_2N_3$), 3.95 (t, J = 5.4 Hz, 2H), 6.8 (d, J = 10.8 Hz, 2H, ArH), 7.38 (d, J = 10.8 Hz, 2H, ArH), 7.74 (s, 1H), 9.8 (s, 1H, −CHO); ^{13}C NMR ($CDCl_3$) δ 21.3, 22.0, 27.6, 35.8, 39.9, 50.4, 66.2, 113.9, 121.2, 130.6, 154.7, 170.3, 201.4; IR (film, cm^{-1}): 2949, 2877, 2096 (azide), 1727, 1664 (C=O), 1301, 1233, 959, 833, 743; ESMS *m/z* (relative intensity) 305 $(M+1)^+$ (85).

Test of Affinity Chromatography Function with Aldehyde 19. Functionalized agarose **20**, prepared in the standard manner from **19**, was poured into a column (Amersham Tricom, 5 mm × 50 mm; 1 mL volume; cat#18−1163−09). At pH 7, the column was found to retain the catalytic antibody 84G3 originally obtained by Barbas and co-workers (*8*, *9*) and not an unrelated antibody; details can be found in Figure 5.

RESULTS AND DISCUSSION

Commercially available Carboxy-Link agarose (**1**), which bears addressable amine groups, was treated with the *p*-nitrophenyl ester of 5-azidopentanoic acid (**2**) and 5-pentynoic acid (**3**) to give azide- and alkyne-functionalized beads **4** and **5**, respectively (Scheme 2). The degree of acylation was determined by measurement of the concentration of released *p*-nitrophenol. Loadings of between 3.3 and 4.6 μmol/mL of gel were typical, representing approximately 20−30% of the available amine groups according to the commercial specifications of the gel. However, the standard Kaiser (ninhydrin) test (*10*) gave a positive signal for **1** and negative signals for **4** and **5**, suggesting that most or all of the accessible amine groups of **1** were acylated by **2** and **3**.

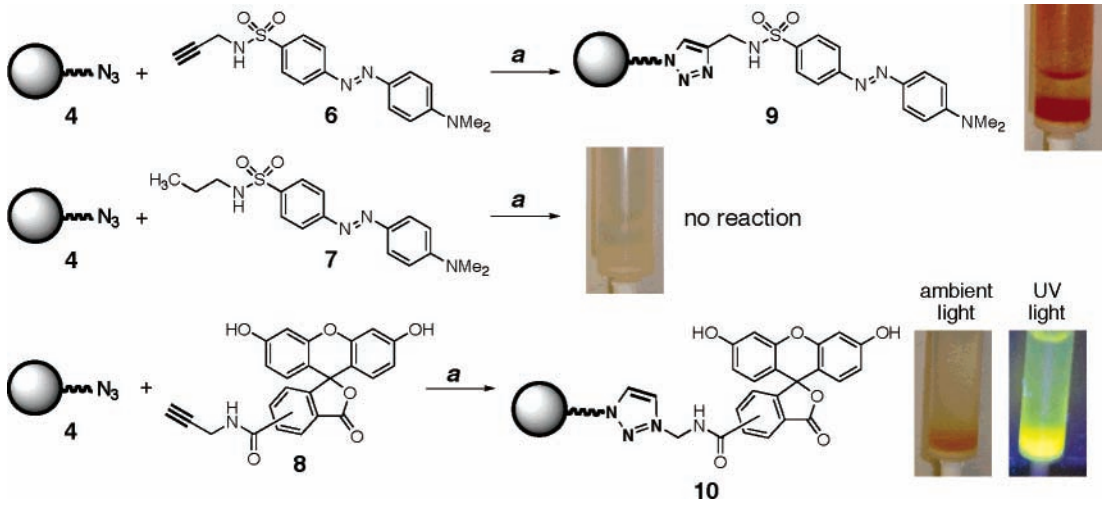


Figure 1. CuAAC coupling of dye reagents to agarose azide and alkyne; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions.

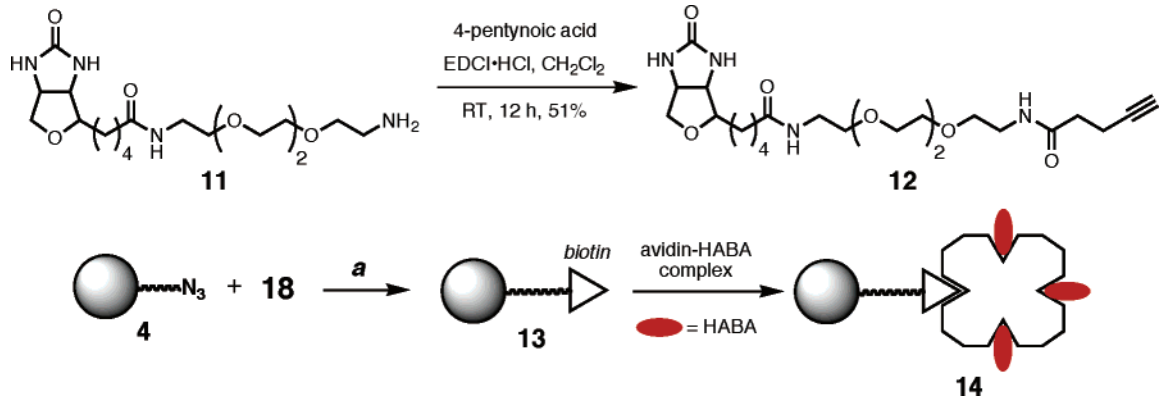

Figure 2. Biotinylation of agarose azide; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions.

To test the feasibility of resin attachment by the Cu-mediated azide-alkyne cycloaddition (CuAAC) reaction, agarose-azide beads **4** were treated with a dabsyl-alkyne derivative (**6**) and the corresponding dye with an *n*-propyl group in place of the alkyne (**7**), in the presence of cuprous bromide, 2,2′-bipyridine as accelerating ligand (*5*), sodium ascorbate to maintain a reducing environment, and 2,6-lutidine as mild base (Figure 1). The dye was successfully attached with **6**, as indicated by the production of an intense and permanent red color in the resulting beads (**9**). Use of the control **7** or omission of Cu(I) from the reaction of **6** gave colorless beads. In addition, no dye could be washed from **9** even upon extensive treatment with DMF; these observations show that the dye does not adsorb to the resin. Similarly, **4** was treated with fluorescein alkyne **8** under CuAAC conditions to give yellow beads that were strongly fluorescent under ultraviolet light. The same successful results were obtained with agarose-alkyne **5** and the complementary azide-substituted dabsyl compound (data not shown).

Biotinylated supports are a mainstay of protein immobilization and therefore of experimental biochemistry. The CuAAC reaction provides a convenient addition to the many methods already in use for constructing such materials. Biotin alkyne **12** was prepared from commercially available biotin-PEG-amine **12** and 4-pentynoic acid (Figure 2). Immobilization on agarose azide beads gave **13**, which was treated with a red solution of avidin-HABA (HABA = 2-(4′-hydroxyphenyl)azobenzoic acid) complex. Tight avidin−biotin interaction gave the resulting beads a persistent red color (**14**), whereas a mixture of avidin-HABA with agarose-azide **4** resulted in no such binding.

The immobilization of peptides is a common application of activated agarose supports. To demonstrate the ease and convenience of clickable agarose in this endeavor, we prepared a derivative of the C-terminal sequence of HIV protease (QCTLNF), which contains primary amide, carboxylic acid, thiol, and alcohol functional groups which would otherwise complicate the choice of attachment stragtegy. An extra alkyne-containing amino acid was used to end the standard solid-phase peptide synthesis sequence, and the final oligopeptide was cleaved from the resin retaining its N-terminal Fmoc protecting group (compound **15**, Figure 3). Purification by reversed-phase chromatography was followed by reaction with agarose azide **4** by the method described above. Fmoc deprotection of **16** with piperidine revealed the amine-terminated immobilized peptide **17** and showed by quantitation of the released fluorene chromophore a capture of 39% of the azide groups installed on the agarose support. The resulting peptide concentration is more than enough to be useful for applications such as aptamer selection and binding studies, which are currently underway.

Affinity purification of enzymes and antibodies by reversible interaction with a binding site or reactive tag is enabled by attachment of the complementary group to the solid support with a chemically compatible linker. An example is shown in Figure 4. Certain monoclonal antibodies generated against diketone **20** (Figure 5) have been shown to possess crucial active-site lysine residues

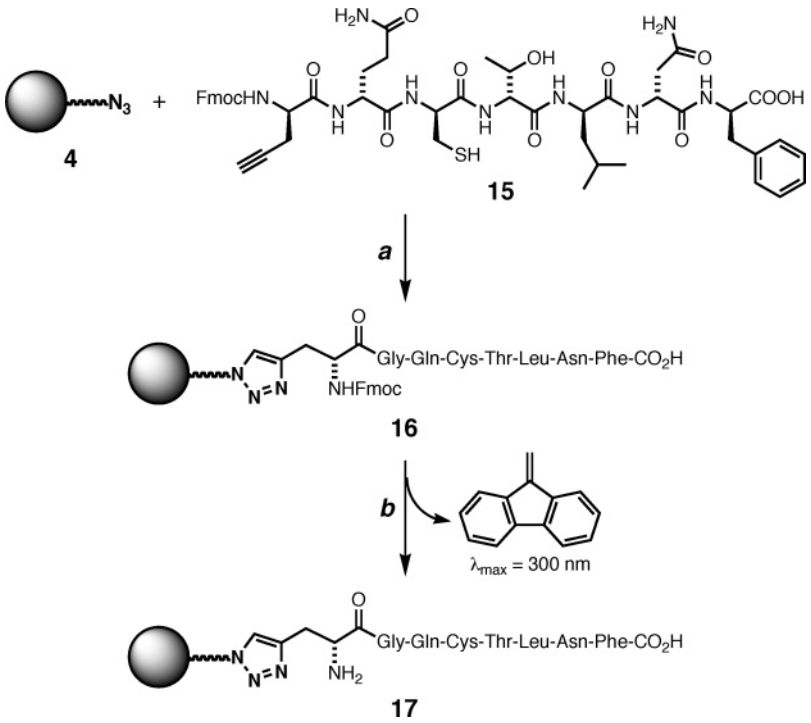

Figure 3. Peptide immobilization on agarose azide; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions; b, 20% piperidine in DMF, RT, 10 min.

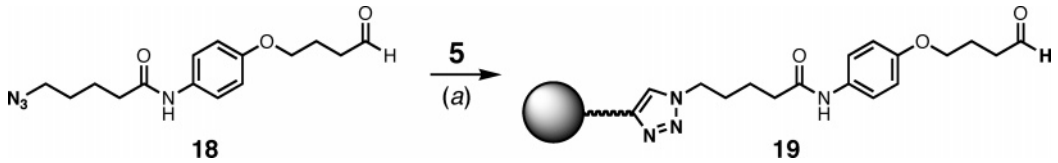

Figure 4. Aliphatic aldehyde immobilization on agarose azide; a, standard Cu·bipy-mediated coupling conditions (see Experimental Procedures), followed by a wash procedure including 0.l M EDTA to remove Cu ions.

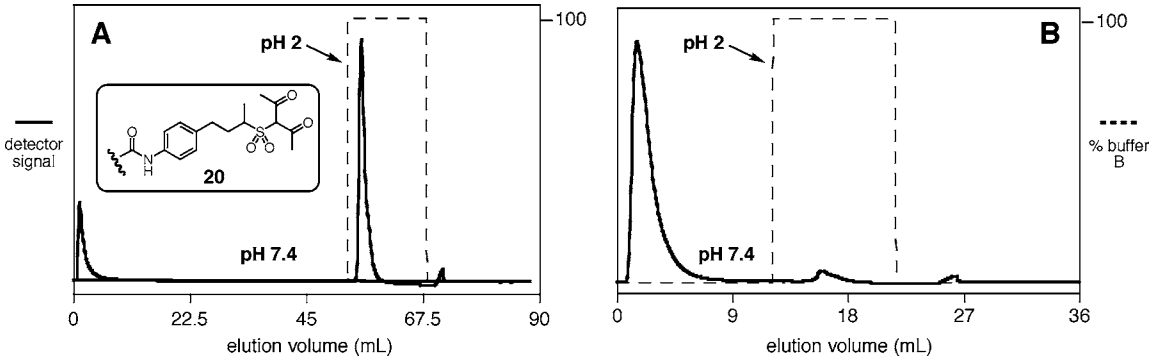

Figure 5. Elution profiles on a column of agarose **19** of (A) antibody 84G3 and (B) IgY isolated from chicken eggs obtained prior to an immunization. A greater wash volume at pH 7.4 was used in A, but the patterns were reproducible. The antibody isolated from chromatograph A was found to be catalytically active in a standard retro-aldol reaction. The structure of the hapten used to generate 84G3 (**20**) is shown.

which catalyze asymmetric aldol and retro-aldol reactions by the formation of enamine intermediates from aldehyde substrates (*8*, *11*). It was envisioned that an immobilized aldehyde could be used to purify such antibodies by virtue of reversible imine formation. The attachment of such an aldehyde to agarose by standard amide or ether bond-forming methods would usually require protection/deprotection steps, which are avoided by the use of the CuAAC process. Thus, azidoaldehyde **18** was ligated without difficulty to agarose-alkyne **5** by the standard protocol to give **19**. The presence of the aldehyde group was confirmed by treatment of agarose **19** with *p*-nitrophenylhydrazine to give a yellow color consistent with the formation of the corresponding hydrazone. As shown in Figure 5, agarose **19** did indeed bind an antibody raised against **20**, but not an unrelated polyclonal antibody.

The results described here illustrate the convenient use of a single pair of functionalized agarose materials, azide **4** and alkyne **5**, for the attachment of a chemically diverse set of functional molecules. While we produced **4** and **5** for this study from a commercial "specialty" agarose-amine, it should be possible to access similar materials from agarose itself and much less expensive reagents; such large-scale production of clickable agarose materials is underway in our laboratory. Given the established applicability of the CuAAC reaction to a widely diverse set of building blocks in organic, materials, and biological chemistry, we believe that there are few limitations to

the nature of structures that can be married to soluble or insoluble supports in this manner for a wide variety of applications.

ACKNOWLEDGMENT

We thank the Skaggs Institute for Chemical Biology and the National Institutes of Health (GM48870) for support of this work, Dr. Sayam Sen Gupta for helpful discussions, and Dr. Diane Kubitz for a sample of antibody 84G3.

A Peptide Sequence Controls the Physical Properties of Nanoparticles Formed by Peptide–Polymer Conjugates That Respond to a Protein Kinase A Signal

Tatsuhiko Sonoda,[†] Takashi Nogami,[†] Jun Oishi,[†] Masaharu Murata,[†] Takuro Niidome,[†] and Yoshiki Katayama*[,†,‡]

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan, and CREST, Japan Science and Technology Agency, Japan. Received December 3, 2004; Revised Manuscript Received August 19, 2005

We previously reported that poly(*N*-isopropylacrylamide) grafted with Peptide 1 (-GLRRASLG) and poly(ethylene glycol) changed its physical properties in response to an intracellular protein phosphorylation signal, protein kinase A (PKA) (Katayama, Y. et al. (2001) *Macromolecules 34*, 905). In this study, we investigated the effect of changing peptide structure on the lower critical solution temperature (LCST) of peptide–polymer conjugates, before and after phosphorylation with PKA. For Peptide 2 (Ac-LRRASL-), which has a formal net charge of +2 at physiological pH, the LCST of the conjugate decreased on phosphorylation. In contrast, the LCSTs of the conjugates with Peptide 3 (-ALRRASLE) and Peptide 4 (Ac-DWDALRRASL-), which have neutral net charges, were greatly increased. This suggests that the LCST of the polymer was mainly governed by two factors: the change in hydration around the polymer chain and the interpeptide electrostatic repulsion, resulting from phosphorylation. These polymers have potential for use as drug capsules that respond to cellular conditions.

INTRODUCTION

The intracellular signal transduction system plays an important role in regulating various cellular events such as cellular proliferation (*1*), hormone secretion (*2*), gene transcription (*3*), and cell differentiation (*4*). Control of these events is mainly achieved by the regulation of a protein's activation or inactivation as caused by a conformational change of the protein. Protein phosphorylation is one of the most versatile ways of changing protein conformation. Incorporation of a phosphate group into a target protein leads to the following three effects: (i) enhancement of hydration around the phosphorylation site, (ii) introduction of anionic charges, and (iii) introduction of an additional hydrogen bonding site. Such protein phosphorylation is catalyzed by protein kinases. A living cell possesses nearly 800 kinds of protein kinases to regulate cellular events. Of those protein kinases, cyclic AMP-dependent protein kinase (PKA) is one of the most important enzymes (*5*–*7*). Its extraordinary continuous activation is related to various diseases such as colon cancer (*8*), melanoma (*9*), and prostate cancer (*10*). In a previous paper, we reported that two types of thermo-responsive polymer, NIPAM–PEP and NIPAM–PEPEP, responding to protein kinase A (PKA) (*11*). In this paper, we termed them NIPAM–PEP1 and NIPAM–PEPEP1, respectively. NIPAM–PEP1 is synthesized by copolymerization of *N*-isopropylacrylamide and a methacryloyl derivative of a PKA substrate peptide (GLRRASLG). NIPAM–PEPEP1 is another type of copolymer, which has some extra poly(ethylene glycol) (PEG) units. These polymers possessed lower critical solution temperatures (LCSTs), and we found that their LCSTs increased with the phosphorylation, by PKA, of incorporated peptides. This was due to enhancement of the hydration around the polymer backbone by introduced phosphate groups. The phosphorylation caused an increase in the temperature at which NIPAM–PEP1 is isolated from its aqueous solution and caused disintegration of the polymer micelle which was formed by NIPAM–PEPEP1 above its LCST (Figure 1a). This type of material, especially the 'nanoparticle' formed by NIPAM–PEPEP1, is potentially useful as a drug capsule which releases drugs in response to PKA levels in cells. However, the increase in the LCST in these polymers after phosphorylation was still insufficient. In the present work, we developed new polyNIPAM–peptide conjugate derivatives that have a greater response to PKA activity than NIPAM–PEP1 and NIPAM–PEPEP1, by changing the peptide sequence in the polymer. We also clarified that the formal net charge of the polymer before and after PKA phosphorylation and the extent of hydration around the ionic parts of the peptide are the key factors controlling the response of the NIPAM–peptide conjugate to the PKA signal.

EXPERIMENTAL PROCEDURES

Materials. Fmoc-amino acids were purchased from Calbiochem-Novabiochem AG (Laufelfingen, Switzerland) and Watanabe Chemical Ind., Ltd. (Hiroshima, Japan). DMF for peptide synthesis and acetonitrile and trifluoroacetic acid (TFA) for HPLC (HPLC grade) were obtained from Kanto Chemical Co., Ltd. (Tokyo, Japan). α-Methoxy-ω-aminopoly(ethylene oxide) was kindly donated by Nippon Oil & Fats Co. Ltd. (Tokyo, Japan). PKA C-subunit was purchased from Promega Co. Ltd. (Madison, WI).

Synthesis of Peptide Monomers and Poly(ethylene glycol) Macromonomer. Substrate peptide monomer 1 (Peptide 1: CH_2=C(CH_3)CO-GLRRASLG) was

synthesized by an automatic peptide synthesizer by Fmoc chemistry using the corresponding Fmoc amino acids and *N*-methacryloyl-L-glycine, as reported previously.[11] Substrate peptide monomer 2 and 4 (Peptide 2: CH_3CO-LRRASL-Dpr($COC(CH_3)=CH_2$)-NH_2, Peptide 4: CH_3CO-DWDALRRASL-Dpr($COC(CH_3)=CH_2$)-NH_2) were prepared in a manner similar to that for Peptide 1, using the corresponding Fmoc amino acids and N^{α}-Fmoc-N^{β}-1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)-3-methylbuthyl-L-diaminopropionic acid (Fmoc-Dpr(ivDde)-OH) as the residue to incorporate the vinyl group. Vinylation of the peptide was accomplished by selective deprotection of ivDde from Dpr, by incubating the peptide-loaded resin for 5 min with DMF/2% hydrazine and subsequently coupling it with the *N*-methacryloyloxysuccinimide in DMF. Substrate peptide monomer 3 (Peptide 3: $CH_2=C(CH_3)CO$-ALRRASLE) was also synthesized in a manner similar to that of Peptide 1, using *N*-methacryloyl-L-alanine as an N-terminus amino acid. The obtained peptides were purified by reverse-phase high performance liquid chromatography (HPLC) using a mobile phase of acetonitrile/water containing 0.1% TFA (20% v/v to 27.5–50% v/v) and then lyophilized. The *N*-methacryloyl-PEG was prepared by stirring a mixture of *N*-methacryloyloxysuccinimide (90 mg, 0.5 mmol) and α-methoxy-ω-aminopoly(ethylene oxide) (600 mg, MW 12 000) in chloroform (5 mL) overnight at room temperature. The obtained *N*-methacryloyl-PEG was purified by column chromatography on Sephadex LH-20 using methanol as the eluting solvent.

Preparation of NIPAM–PEPs and NIPAM–PEPEPs. NIPAM–PEP1–3 were synthesized by radical copolymerization of *N*-isopropylacrylamide and the corresponding substrate peptide monomer, in distilled water at 25 °C for 1.5 h under a nitrogen atmosphere, using ammonium persulfate (2.8 mM) and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (5.78 mM) as the redox initiator couple. The total monomer concentration was 72.3 mM. The NIPAM–PEPs were purified by dialysis using a semipermeable membrane bag (with a molecular weight cutoff of 10 000) against water for 1–3 days, followed by lyophilizing. NIPAM–PEPEP1–4 were synthesized similarly to the NIPAM–PEPs, using *N*-methacryloyl-PEG, the appropriate substrate peptide monomer and *N*-isopropylacrylamide. In this case, a semipermeable membrane bag with a molecular weight cutoff of 50 000 was used for the dialysis. The chemical structures of these conjugates are shown in Figure 1b. The mole fractions of each peptide and PEG unit are shown in Table 1. This information was obtained by elemental analysis and ^1H NMR.

Table 1. Mole Fraction of Each Peptide and PEG Unit in NIPAM–PEPs and NIPAM–PEPEPs

	mole fraction (mol %)				
	peptide		PEG		
	in feed	observed	in feed	observed	yield (%)
NIPAM–PEP1	1.9	1.3	-	-	67

NIPAM–PEP3	38.0	46.5	8.5

Gel Permeation Chromatography (GPC) Analysis. GPC of NIPAM–PEPs and NIPAM–PEPEPs was performed using a Viscotek model 300 TDA system equipped with refractive index, viscosity, and light scattering detectors operating at 25 °C. TSKgel α - M columns (TOSOH Co. Ltd., Tokyo, Japan) were used, with DMF containing 10 mM LiBr as the eluent. The flow rate was 0.8 mL/min.

Light Transmittance Measurement. Light transmittance was measured using a UV-2550 UV–Visible spectrophotometer (Shimadzu Co. Ltd., Kyoto, Japan). 50 mM MOPS buffer solution (pH 7.0) containing 0.3 mg/mL NIPAM–PEP1–3, 0.2 mM ATP, and 10 mM $MgCl_2$ was prepared to a final volume of 500 μL. The light transmittance of each solution at 500 nm was monitored from 30 °C to 45–55 °C at a heating rate of 0.5 °C/min. For the experiment using the phosphorylated NIPAM–PEP, 25 U PKA C-subunit was added to the above solution 2 h before the measurements.

Fluorescence Measurement. Fluorescence spectra were measured using a RF-5300PC spectrofluorophotometer (Shimadzu Co. Ltd., Kyoto, Japan). Dansyl-aniline (final concentration 20 μM) was dissolved in 50 mM MOPS buffer solution (pH 7.0) containing 10 mM $MgCl_2$ and 0.2 mM ATP in the presence of 0.3 mg/mL NIPAM−PEPEP1−4. Fluorescence spectra were then measured at an excitation wavelength of 340 nm at various temperatures. For the experiment using phosphorylated NIPAM−PEPEPs, 25 U PKA C-subunit was added to the above solution 2 h before the fluorescence measurements. Measurement of the release of dansyl-aniline encapsulated in the nanoparticle formed by NIPAM−PEPEP4 was also performed under similar conditions, except for the use of PBS(−) instead of MOPS buffer solution.

Laser Light Scattering. A modified commercial LLS spectrometer (DLS-7000, Ohtsuka Electronics Co. Ltd., Osaka, Japan) and an argon laser (output power ca. 20 mW at $\lambda = 488$ nm) were used. The incident light beam was vertically polarized with respect to the scattering plane. NIPAM−PEPEP2 (final concentration 0.3 mg/mL) was dissolved in 50 mM MOPS buffer (pH 7.0) containing 10 mM $MgCl_2$ and 0.2 mM ATP. This solution was filtered before DLS measurement.

RESULTS AND DISCUSSION

GPC Analysis of Polymers. The average molecular weights of the polymers were evaluated using GPC. The results suggested that all NIPAM−PEPs and NIPAM−PEPEPs had similar molecular weights in the range 270 000−300 000.

Effect of Phosphorylation on Physical Properties of NIPAM−PEPs. In our previous report (*11*), we showed that the LCST of NIPAM−PEP1 was raised in response to phosphorylation by PKA (Figure 2a). To construct a polymer-peptide conjugate which shows a larger difference than NIPAM−PEP1 in the LCST as a result of PKA treatment, we designed two types of substrate peptides for PKA. Peptide 2 has a methacryloyl group at the carboxyl terminus. It means that a serine residue of the phosphorylation site is located closer to the polymer backbone than that in NIPAM−PEP1 (Figure 1b). It is expected that the enhancement of the hydration around the polymer backbone is greater than for NIPAM−PEP1. We evaluated the effect of NIPAM−PEP2 phosphorylation by PKA on the LCST of this polymer (Figure 2b). Surprisingly, light transmittance of NIPAM−PEP2 was 80% even at 45 °C; that is, this polymer was water-soluble over the full range of temperatures we tested, while phosphorylated NIPAM−PEP2 had a LCST of 37 °C. This result indicates that the LCST in NIPAM−PEP2 was lowered on the introduction of phosphate groups into the polymer, contrary to our expectation. The major reason the effects of phosphorylation in the two polymers were entirely different can be found in the net charge of the peptide in both polymers at neutral pH. In the case of NIPAM−PEP1, the net charge of Peptide 1 is considered to be +1, and this changes to −1 after the phosphorylation. In this case, the interpeptide electrostatic repulsion is scarcely changed, and the LCST of NIPAM−PEP1 was increased due to the enhancement of the hydration around the polymer chain by the phosphorylation. On the other hand, the net charge of Peptide 2 in NIPAM−PEP2 is +2 at pH 7. In this case, the interpeptide electrostatic repulsion will be larger than for Peptide 1. Such repulsion would completely disappear as a result of the neutralization of the charges on Peptide 2 on modification with the phosphate group. Thus, the LCST of NIPAM−PEP2 decreased, even though the effect of the enhanced hydration resulting from phosphorylation could be greater in NIPAM−PEP2 than that in NIPAM−PEP1. These results suggest that the change in water solubility of the NIPAM−peptide conjugate is mainly governed by the change in the net charge of the peptide on phosphorylation.

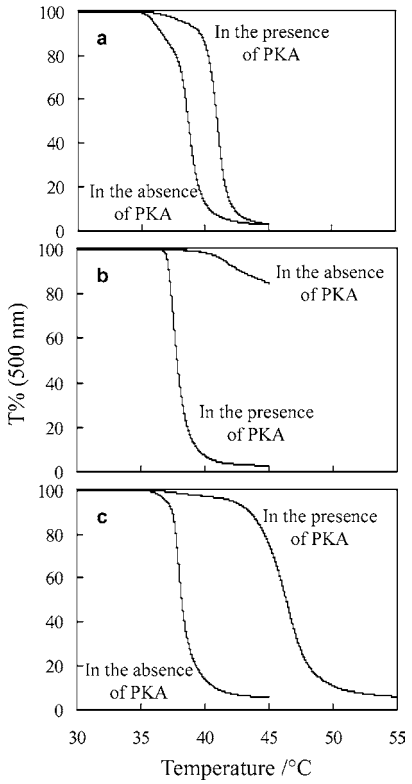

Figure 2. Temperature dependence of the light transmittance of the NIPAM−PEP solution before and after phosphorylation with activated PKA. The experiment was performed in 50 mM MOPS buffer (pH 7.0) containing 0.3 mg/mL each of NIPAM−PEP, 0.2 mM ATP, and 10 mM $MgCl_2$. In the case of phosphorylated NIPAM−PEP, light transmittance was measured after 2 h of incubation of the solution with PKA C-subunit (25 U). (a) NIPAM−PEP1, (b) NIPAM−PEP2, (c) NIPAM−PEP3.

We designed another substrate peptide for PKA, Peptide 3, and synthesized NIPAM−PEP3 (Figure 1b). The light transmittance of the NIPAM−PEP3 solution indicates that the LCST of NIPAM−PEP3 increased as a result of phosphorylation by PKA to a greater degree than in the case of NIPAM−PEP1 (Figure 2c). The LCST of NIPAM−PEP3 was increased from 38 °C to 46 °C by phosphorylation. The net charge of Peptide 3 changes from 0 to −2 on phosphorylation by PKA. It was expected that the physical properties of NIPAM−PEP3 would change a large amount as a result of phosphorylation, because the phosphotransfer into Peptide 3 causes great enhancement of the hydration around the polymer backbone and the electrostatic repulsion between the peptides. It is reasonable to suppose that the change in the physical properties of the conjugates due to phosphorylation is mainly governed by the change in the formal net charge on the pendant peptide.

Modification of NIPAM−PEPs with PEG Chain. As described in our previous paper (*11*), NIPAM−PEP1 containing a PEG chain (NIPAM−PEPEP1) forms polymer micelles above the LCST without precipitation. We synthesized NIPAM−PEPEP2 and NIPAM−PEPEP3 by radical copolymerization in a manner similar to that for

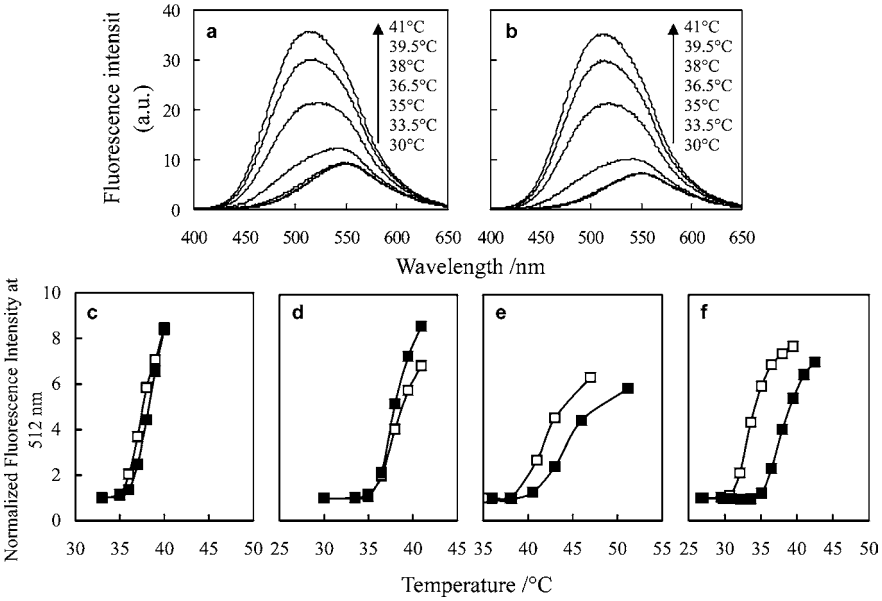

Figure 3. Temperature dependence of fluorescence spectra of dansyl aniline with NIPAM−PEPEP2 before (a) and after (b) phosphorylation, and the change in the fluorescence intensity of dansyl aniline at 512 nm in the presence of NIPAM−PEPEPs (c−f). Closed and open squares indicate the phosphorylated and unphosphorylated polymer, respectively. (c) NIPAM−PEPEP1, (d) NIPAM−PEPEP2, (e) NIPAM−PEPEP3, (f) NIPAM−PEPEP4. Dansyl aniline (20 μM final concentration) was dissolved in 50 mM MOPS (pH 7.0) containing 0.3 mg/mL of NIPAM−PEPEP2, 0.2 mM ATP and 10 mM $MgCl_2$. Phosphorylation was performed by the addition of 12.5 U of PKA C-subunit.

the preparation of NIPAM−PEPEP1 (Figure 1b) (*11*). To study the effect of phosphorylation on their physical properties, the fluorescence intensity of dansyl aniline, which has a fluorescence spectrum that is sensitive to the polarity of its environment, was monitored at various temperatures in the presence of the phosphorylated or unphosphorylated NIPAM−PEPEPs (Figure 3a,b). The dye tends to be encapsulated into the hydrophobic core of the NIPAM−PEPEPs polymer micelles above their LCSTs. In the case of the phosphorylated and unphosphorylated NIPAM−PEPEP2, the fluorescence intensity started to increase at the same temperature (36 °C) regardless of the phosphorylation (Figure 3c). This means that the phosphorylation of NIPAM−PEPEP2 did not affect the temperature at which particle formation began. However, the hydrophobicity of the polymer micelle core increased with phosphorylation, because the increase in the fluorescence intensity of the dansyl aniline at 512 nm is larger in the presence of the phosphorylated polymer than in the presence of the unphosphorylated polymer.

The size distribution of NIPAM−PEPEP2 micelles was evaluated at 38 °C, before and after treatment with PKA (Figure 4). The average diameter of the unphosphorylated micelles was 86.7 nm. After addition of PKA, the particle size was decreased within 6 min, simultaneous to the increase in the fluorescence intensity of the dansyl aniline. These results indicate that the collapse of the polyNIPAM chain in NIPAM−PEPEP2 accelerated as a result of the phosphorylation due to disappearance of the interpeptide electrostatic repulsion on phosphorylation.

A similar fluorescent measurement was performed for NIPAM−PEPEP3 (Figure 3c). Here, the temperature at which the polymer micelle was formed increased more remarkably on phosphorylation than for NIPAM−PEPEP1. This result indicates that the polymer micelle of NIPAM−PEPEP3 disintegrated in the presence of PKA much more readily than the polymer micelle of NIPAM−PEPEP1. Thus, the change in the net charge of the pendant peptide and the extent of the hydration around

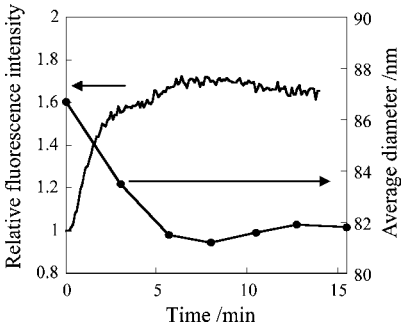

Figure 4. Time course of the change in the average hydrodynamic radius (circles) of the NIPAM−PEPEP2 particle, and of the fluorescence intensity at 512 nm (solid line) of dansyl aniline after PKA addition. The NIPAM−PEPEP2 (0.3 mg/mL) was dissolved in 50 mM MOPS (pH 7.0) containing 0.2 mM ATP and 10 mM $MgCl_2$, and dansyl aniline was added to a final concentration of 20 μM only in the fluorescence measurement. The light scattering intensity was monitored at 37 °C with a 90° detection angle. The change in the fluorescence intensity at 512 nm was estimated as the ratio of the intensity at each time to that at 0 min.

the polymer chain are key factors in the NIPAM−PEPEP-type conjugates.

In this experiment, unphosphorylated NIPAM−PEPEP3 began to form polymer micelles at 38 °C. This temperature was higher than that for NIPAM−PEPEP1 (35 °C). It is likely that a larger quantity of hydrophilic substrate peptides was introduced in NIPAM−PEPEP3 (2.7 mol %) than in NIPAM−PEPEP1 (1.6 mol %).

Further Sophisticated Peptides. These findings encouraged us to design NIPAM−PEPEP-type conjugates which provide a greater response than NIPAM−PEPEP1−3. We designed and synthesized NIPAM−PEPEP4 as an ideal material that exhibited sufficient response to PKA activity (Figure 1b). The net charge of the pendant Peptide 4 is the same as that of Peptide 3, so that the change in the net charge of the peptide should be able to increase the LCST. In addition, a serine residue as a phosphorylation site is located closer to the polymer main

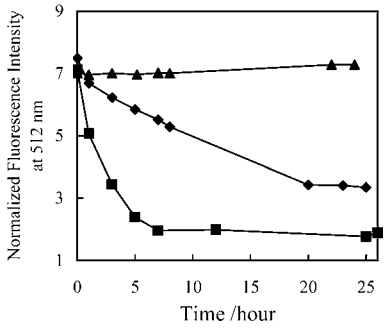

Figure 5. Time course of the release of dansyl aniline encapsulated in nanoparticles of NIPAM−PEPEP4 at 34 °C. Dansyl aniline (20 μM final concentration) was dissolved in PBS(−) (pH 7.2) containing 0.3 mg/mL of NIPAM−PEPEP4, 0.2 mM ATP and 10 mM $MgCl_2$. The fluorescence intensity at 512 nm was then monitored in the absence (triangles) or presence (diamonds: 60 U, squares: 300 U) of PKA.

chain than in Peptide 3. It was expected that the enhancement of the hydration on PKA phosphorylation could be greater than that for NIPAM−PEPEP3. Figure 3c shows the fluorescence measurement results for NIPAM−PEPEP4. The temperature at which polymer micelles were formed increased by ca. 5 °C on phosphorylation by PKA. This was the greatest change of all the peptide-polymer conjugates developed. Although it is not clear the reason LCST of NIPAM−PEPEP4 was lower than that of other NIPAM−PEPEPs, the increase of the hydrophobicity of the peptide side chains introduced in NIPAM−PEPEP4 may contribute to the phenomenon. This polymer will be more suitable than other NIPAM−PEPEPs in the use at physiological temperatures.

Next, the potential of NIPAM−PEPEP4 as a drug capsule responding to a PKA signal was investigated. The fluorescence of dansyl aniline encapsulated in NIPAM−PEPEP4 stayed at its initial level for over 25 h at 34 °C, indicating that the fluorescence dye did not leak from the micelles into the solvent, while leakage of the dye from the micelles was observed in the presence of PKA (Figure 5). When 300 U PKA was added, the fluorescence intensity at 512 nm reached a minimum at 5 h. Addition of 60 U PKA showed a more gradual release of the dansyl aniline. NIPAM−PEPEP4 will be applicable for use in drug capsules to achieve the selective release of drugs in response to cellular conditions, because PKA activation occurs in various diseases.

CONCLUSION

In this work we reported on the physical properties of polyNIPAM−peptide conjugates containing a new type of PKA substrate peptide. The assembly of our designed PKA-responding polymers could be regulated by phosphorylation at temperatures above their LCSTs. The synthesized polymers all responded differently to phosphorylation by PKA. This difference can be accomplished by making a small change in the substrate peptide sequence. In the case of the polymers containing Peptide 1 and Peptide 3, an increase in the LCST was observed on phosphorylation by PKA. On the other hand, the LCST for Peptide 2 was lowered on phosphorylation. Our findings suggest that two major factors contribute to determining the direction and degree of the change in the LCST resulting from phosphorylation of the polymer−peptide conjugates reported here. One factor is the enhancement of the hydration around the polymer-chain backbone, and the other is a change in the formal net charge of the peptide due to the introduction of the anionic charge of the phosphate group on its serine residue. By controlling these two factors, we succeeded in designing a new material, NIPAM−PEPEP4, that forms a polymer micelle-type capsule that disintegrated with a much greater response to PKA phosphorylation than other materials. We recently reported an artificial gene regulation system for the new concept of gene delivery and termed this system D-RECS, which stands for drug-delivery system responding to cellular signals.[12] The polymer micelle formed by NIPAM−PEPEP4 will be another tool for use in D-RECS.

Department of Chemistry, Organic Chemistry, Uppsala University, Uppsala, Sweden, Affibody AB, Bromma, Sweden, and Unit of Biomedical Radiation Sciences, Rudbecklaboratoriet, Uppsala University, S-751 85, Uppsala, Sweden. Received February 28, 2005; Revised Manuscript Received August 7, 2005

Affibody molecules are a new class of small phage-display selected proteins using a scaffold domain of the bacterial receptor protein A. They can be selected for specific binding to a large variety of protein targets. An affibody molecule binding with high affinity to a tumor antigen HER2 was recently developed for radionuclide diagnostics and therapy in vivo. The use of the positron-emitting nuclide ^{76}Br ($T_{1/2}$ = 16.2 h) could improve the sensitivity of detection of HER2-expressing tumors. A site-specific radiobromination of a cysteine-containing variant of the anti-HER2 affibody, $(Z_{HER2:4})_2$-Cys, using ((4-hydroxyphenyl)ethyl)maleimide (HPEM), was evaluated in this study. It was found that HPEM can be radiobrominated with an efficiency of 83 ± 0.4% and thereafter coupled to freshly reduced affibody with a yield of 65.3 ± 3.9%. A "one-pot" labeling enabled the radiochemical purity of the conjugate to exceed 97%. The label was stable against challenge with large excess of nonlabeled bromide and in a high molar strength solution. In vitro cell tests demonstrated that radiobrominated affibody binds specifically to the HER2-expressing cell-line, SK-OV-3. Biodistribution studies in nude mice bearing SK-OV-3 xenografts have shown tumor accumulation of 4.8 ± 2.2% IA/g and good tumor-to-normal tissue ratios.

INTRODUCTION

Radionuclide tumor targeting uses molecular recognition of tumor-associated structures for the selective delivery of diagnostic or therapeutic nuclides to tumor sites. Molecular recognition has mainly been associated with the use of monoclonal antibodies and their products or of peptide receptor ligands and their analogues. During last years, nonpeptide small molecular weight ligands for receptors and enzymes attracted attention as potential targeting agents as well. Development in this area has enabled the production of targeting molecules with excellent specificity and high binding affinity. Still, each approach has its disadvantages. Monoclonal antibodies are relatively bulky proteins, and this bulkiness limits blood clearance rate, extravasation, and tumor penetration. The use of receptor ligands is restricted in terms of target selection to receptors that are overexpressed in tumors. Sometimes, receptor ligands possess strong agonistic action, and efforts should be made in order to develop antagonistic analogues or provide high specific radioactivity of targeting conjugates.

A possible alternative in creating new targeting vectors is to use phage display technology (*1*). One variant of phage display proteins, termed affibody molecules (*2*, *3*), uses the domain scaffold of the immunoglobulin-binding Staphylococcal receptor protein A. This 58-amino acid-long cysteine-free protein provides a robust framework, independent of disulfide bonds for its folding. The small size (about 7 kDa in monomeric and about 15 kDa in dimeric form) of affibody molecules enables fast blood clearance and good tumor penetration. Randomization of 13 solvent-accessible surface residues of the protein A domain was used to create a library containing about 10^9 members, enabling the isolation of high-affinity ligands for virtually any tumor-associated protein target. The selection of the affibody $Z_{HER2:4}$, which binds with high specificity and affinity of 50 nM to the HER2/neu receptor, was recently reported by Wikman and co-workers (*4*). Dimerization of $Z_{HER2:4}$ enabled to obtain affinity of 3 nM (*22*). This HER2/neu receptor is often overexpressed in a number of carcinomas, such as breast, ovarian, and urinary bladder cancer (*5*−*7*). The prognostic and predictive values of HER2/neu receptor overexpression are well documented (*6*, *8*, *9*), and HER2 imaging can provide important information that can influence patient management. Preliminary biodistribution and imaging data for $Z_{HER2:4}$ derivatives labeled with ^{125}I (*10*) confirmed the utility of affibody molecules for tumor diagnostics.

It is reasonable to assume that the use of positron-emitting labels may improve quality of targeted diagnostics due to the better sensitivity and resolution of positron emission tomography (PET) in comparison to those of other radionuclide imaging modalities (*11*). A possible candidate radionuclide for labeling affibody molecules is ^{76}Br. Its half-life of 16.2 h matches the fast kinetics of affibody molecules well, and it can easily be produced using cyclotrons available at PET centers (*12*).

When a radionuclide is to be selected as a label, its labeling chemistry should be carefully considered. Though the radiobromination of proteins or peptides is not as

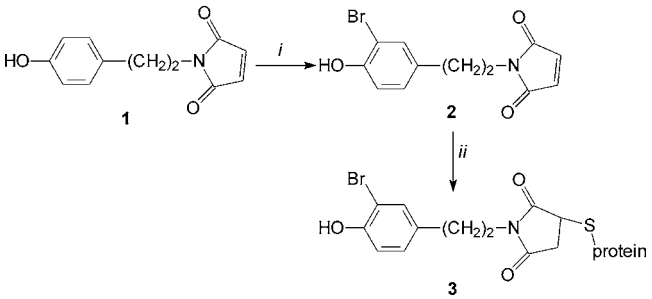
Scheme 1. Labeling of HPEM and Conjugation of the Labeled Product, 2, to His_6-$(Z_{HER2:4})_2$-Cys[a]



[a] Reagents and conditions: (i) $^{76}Br^-$, Chloramine-T, MeOH/HOAc, RT; (ii) His_6-$(Z_{HER2:4})_2$-Cys, pH 6.

well-studied as is radioiodination, some experience has been amassed pertaining to bromine-75, bromine-76, and bromine-77. Radiobromine can be attached to proteins either *directly* to tyrosine residues, using peroxidases (*13*−*15*) and Chloramine-T (*16*) as oxidants, or *indirectly* by labeling several precursors and subsequent coupling to the ϵ-amino groups of lysine residues (*17*−*21*). However, both lysines and tyrosines can appear in the binding regions of the selected affibody candidates, and their modification may therefore reduce the binding affinity. In fact, direct radioiodination of $Z_{HER2:4}$ led to loss of HER2 binding (*22*), while some labeling methods directed to lysines decreased such binding. For this reason, it would be useful to develop a method for conjugating radiobromine to affibody molecules in a site-specific manner.

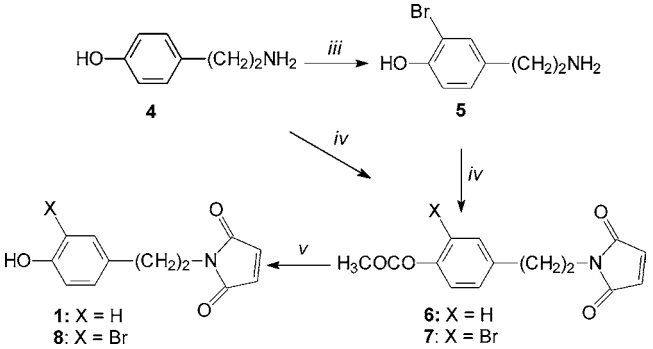
The approach used in this study exploits the fact that cysteine residues have been excluded from the affibody selection library. This allows us to introduce, using genetic engineering, a unique cysteine residue at C-terminal of the selected affibody molecules and to use the thiol group for the coupling of a radiobrominated precursor. As a model, a dimeric cysteine-containing variant of $Z_{HER2:4}$, $(Z_{HER2:4})_2$-Cys, was created for this study. A maleimide derivative of tyramine, ((4-hydroxyphenyl)ethyl)maleimide (HPEM) (*1*) (see Scheme 1), was selected as a bifunctional linker for attaching radiobromine to the cysteine-containing affibody. Use of this compound for the radioiodination of radioimmunoconjugates was reported in an abstract (*23*), but no details concerning synthesis or characterization were provided.

The present study explores the labeling chemistry of the indirect site-specific radiobromination of cysteine-containing affibody molecules using HPEM and evaluates the tumor-targeting properties of cysteine-containing $(Z_{HER2:4})_2$-Cys, both in vitro and in vivo.

EXPERIMENTAL PROCEDURES

Material. Organic solvents were purchased from Merck (Darmstadt, Germany), and Chloramine-T (CAT) and sodium metabisulfite from Sigma Chemical Company (St. Louis, MO); all chemicals were of analytical grade or higher. Acetate buffer (0.1 M, pH 5) was prepared using sodium acetate and acetic acid (Merck, Darmstadt, Germany). Phosphate-buffered saline (PBS, 5 mM, pH 7.4) was prepared from $Na_2HPO_4 \cdot 10H_2O$, $NaH_2PO_4 \cdot H_2O$, and NaCl, all of analytical grade (Merck, Darmstadt, Germany). High-quality Milli-Q water (resistance > 18 MΩ/cm) was used in preparing solutions and buffers. Solutions of CAT, sodium metabisulfite, and ((4-hydroxyphenyl)ethyl)maleimide were prepared immediately before use. Merck silica gel 60 (230−400 mesh) was used for column chromatography. Thin-layer chromatography

Scheme 2. Synthesis of HPEM, 1, and the Chromatography Standard, 8[a]



[a] Reagents and conditions: (iii) Br_2, AcOH, RT; (iv) maleic anhydride, acetic anhydride, KOAc, THF; (v) Amberlyst-15, MeOH.

(TLC) was performed using Merck Silica 60 F_{254} gel, and compounds were visualized with UV (254 nm) or by developing the plates with ninhydrin/acetic acid (0.4/4 w/w% in *n*-butanol) followed by heating. Tetrahydrofuran (THF) was dried according to standard methods.

Instrumentation. Radioactivity measurements were carried out with an ultrapure germanium detector (ORTEC, Oak Ridge, TN) connected to a 8192-channel, PC-based multichannel analyzer (The Nucleus Inc., Oak Ridge, TN). The detector was calibrated for energy and efficiency with a standard ^{152}Eu source. Dead-time losses were always below 10% during measurements. Alternatively, the radioactivity was measured with the automatic 1480 WIZARD 3" Gamma Counter (Wallac) equipped with 3-in. NaI(Tl) well detector using a measurement protocol with an energy window of 300−2047 keV. The ^1H and ^{13}C spectra were recorded in $CDCl_3$ (7.26 ppm ^1H, 77.0 ppm ^{13}C) on a Varian Unity 400 spectrometer operating at 400 and 100.6 MHz, respectively, or on a Varian Unity 500 spectrometer operating at 500 and 125 MHz, respectively. Melting points were determined on a Buchi capillary melting point apparatus and are uncorrected. High-resolution mass spectroscopy (HRMS) was conducted at the Organisch Chemisches Institut der Universitaet Muenster, Germany, for compounds **1**−**7** and on a Thermoquest GCQ GC/MS instrument, using the electron impact (EI), direct inlet mode for compound **8**. High-performance liquid chromatography (HPLC) was conducted with a Gilson Model 322 pump and UV/VIS-152 detector. HPLC chromatography was carried out using an ODS C-18 HPLC column 150 × 20 mm ID, 5 μm at a flow rate of 5 mL/min. Spectrophotometer analysis of the HPLC effluent was performed by means of UV detection at 254 nm. Distribution of radioactivity along the TLC and instant thin-layer chromatography (ITLC) strips was measured using the Cyclone Storage Phosphor System and analyzed with the OptiQuant image analysis software. Size-exclusion chromatography was performed on disposable NAP-5 columns (Amersham Pharmacia Biotech AB, Uppsala; Sweden) according to the manufacturer's instructions.

Synthesis of HPEM (1) and of the Chromatography Standard, 1-[2-(3-Bromo-4-hydroxyphenyl)-ethyl]-1*H*-pyrrole-2,5-dione (8) (Scheme 2). *4-(2-Aminoethyl)-2-bromophenol (**5**).* A solution (0.7 M) of bromine in carbon tetrachloride (1.51 g, 9.46 mmol) was added dropwise to a stirred solution of tyramine (0.649 g, 4.73 mmol) in 15 mL acetic acid over 13 min. Analysis by means of nuclear magnetic resonance (NMR) indicated that the tyramine was fully consumed after 20 min at RT. The solvent was evaporated, and the residue was

dissolved in 0.5 g K_2CO_3/MeOH and stirred for 10 min; thereafter the salt was filtered off and the mixture was concentrated under a vacuum. The crude product was filtered through a short plug of silica to afford a white solid of bromide **5** along with a dibromide, (4-(2-aminoethyl)-2,6-dibromophenol). This was further purified by RP-HPLC, holding 100% (0.05% formic acid in water) for 5 min, followed by a gradient of 100% (0.05% formic acid in water)/0% acetonitrile (0.05% formic acid in acetonitrile), changing to 100% acetonitrile (0.05% formic acid in acetonitrile) over 35 min, to give 0.394 g of compound **5** as white crystals, mp = 152−155 °C, in 41% yield. ^{1}H NMR (CD_3OD): δ 7.39 (d, 1H, benz), 7.07 (dd, 1H, benz), 6.87 (d, 1H, benz), 3.10 (t, 2H, NCH_2), 2.84 (t, 2H, CH_2); ^{13}C NMR (CD_3OD): δ 153.5, 133.1, 129.1, 128.8, 116.4, 109.9, 40.7, 32.2. HRMS(*m/z*): calcd for [$C_8H_{10}BrNO$ + H^+], 216.0019; found, 215.9988.

*4-[2-(2,5-Dioxo-2,5-dihydro-1H-pyrrol-1-yl)ethyl]phenyl Acetate (**6**).* Maleic anhydride (0.452 g, 4.63 mmol) was added to a stirred solution of tyramine (0.529 g, 3.86 mmol) in 50 mL of dry THF at 40 °C. The solution mixture was stirred overnight at 40 °C under an argon atmosphere. The solvent was then evaporated under reduced pressure. Acetic anhydride (125 mL) and potassium acetate (1.47 g, 15.3 mmol) were added to the white solid residue, and the mixture was stirred at 90 °C for 1 h. After this, the black reaction mixture was stirred at RT overnight. The solvent was evaporated under reduced pressure, and the residue was dissolved in CH_2Cl_2 and then washed three times with water and once with saturated $NaHCO_3$. The organic phase was dried over anhydrous Na_2SO_4 and filtered, and then the solvent was removed under reduced pressure. The resulting crude product was purified by flash chromatography (10:1%, CH_2Cl_2:Et_2O as the mobile phase) to afford 0.660 g of **6** as white crystals, mp = 96−97 °C, in 66% yield. ^{1}H NMR ($CDCl_3$): 7.21 (2H, m, AA′ part of AA′XX′, benz), 7.01 (2H, m, XX′ part of AA′XX′, benz), 6.66 (s, 2H, CH=CH-), 3.75 (t, 2H, NCH_2), 2.90 (t, 2H, CH_2), 2.28 (s, 3H, $COCH_3$); ^{13}C NMR ($CDCl_3$): δ 170.7, 169.6, 149.7, 135.6, 134.3, 130.0, 121.9, 39.2, 34.1, 21.3. HRMS(*m/z*): calcd for [$C_{14}H_{13}NO_4$ + Na^+], 282.0737; found, 282.0711.

*2-Bromo-4-[2-(2,5-dioxo-2,5-dihydro-1H-pyrrol-1-yl)ethyl]phenyl Acetate (**7**).* Compound **7** was synthesized using the same procedure as for compound **6**, except that 4-(2-aminoethyl)-2-bromophenol (0.135 g, 0.63 mmol) replaced tyramine and a temperature of 60 °C and a reaction time of 11 h were used. The crude product was purified using flash chromatography using neat $CHCl_3$ as a mobile phase to produce **7** with some impurities; this was then further purified using RP-HPLC, holding 100% (0.05% formic acid in water) for 5 min, followed by a gradient of 100% (0.05% formic acid in water)/0% acetonitrile (0.05% formic acid in acetonitrile), changing to 100% acetonitrile (0.05% formic acid in acetonitrile) over 60 min, to provide 0.098 g of **7**, as a white solid, in 46% yield. ^{1}H NMR ($CDCl_3$): δ 7.47 (d, 1H, benz), 7.18 (dd, 1H, benz), 7.05 (d, 1H, benz), 6.68 (s, 2H, CH=CH), 3.74 (t, 2H, NCH_2), 2.88 (t, 2H, CH_2), 2.34 (s, 3H, $COCH_3$); ^{13}C NMR ($CDCl_3$): δ 170.7, 168.8, 147.2, 137.6, 134.3, 133.8, 129.1, 123.9, 116.4, 38.9, 33.9, 21.0. HRMS(*m/z*): calcd for [$C_{14}H_{12}BrNO_4$ + Na^+], 359.9842; found, 359.9834.

*1-[2-(4-Hydroxyphenyl)ethyl]-1H-pyrrole-2,5-dione (**1**).* Amberlyst-15 (0.400 g) was added to a stirred solution of compound **6** (0.300 g, 1.16 mmol) in MeOH (30 mL), and the mixture was stirred at 55 °C for 4 h. The starting material was fully consumed according to TLC. The catalyst was filtered off and washed with MeOH/CH_2Cl_2 (2 × 3 mL). The filtrate was concentrated under reduced pressure. The resulting crude product was purified using flash chromatography with a dichloromethane−diethyl ether gradient (100% CH_2Cl_2:0% Et_2O to 90% CH_2Cl_2: 10% Et_2O) as a mobile phase to give 0.244 g of **1** as white crystals, mp = 144−145 °C, in 97% yield. ^{1}H NMR ($CDCl_3$): 7.05 (2H, m, AA′ part of AA′XX′, benz), 6.75 (2H, m, XX′ part of AA′XX′, benz), 6.65 (s, 2H, CH=CH), 3.72 (t, 2H, NCH_2), 2.82 (t, 2H, CH_2); ^{13}C NMR ($CDCl_3$): δ 170.9, 154.5, 134.3, 130.3, 130.2, 115.6, 39.5, 33.8. HRMS-(*m/z*): calcd for [$C_{12}H_{11}NO_3$ + Na^+], 240.0631; found, 240.0613.

*1-[2-(3-Bromo-4-hydroxyphenyl)ethyl]-1H-pyrrole-2,5-dione (**8**).* Compound **8** was synthesized using the same procedure as was used for compound **1**, except that compound **7** (34 mg, 0.10 mmol) was used as the starting material. The crude product was purified by means of flash chromatography using neat $CHCl_3$ as a mobile phase to give 26 mg of compound **8**, as a white solid, in 87% yield. ^{1}H NMR ($CDCl_3$): δ 7.32 (d, 1H, benz), 7.10 (dd, 1H, benz), 6.95 (d, 1H, benz), 6.69 (s, 2H, CH=CH), 3.73 (t, 2H, NCH_2), 2.83 (t, 2H, CH_2); ^{13}C NMR ($CDCl_3$): δ 170.7, 151.2, 134.3, 132.3, 131.7, 129.8, 116.3, 39.2, 33.6. MS(*m/z*): calcd for [$C_{12}H_{10}BrNO_3$ + H^+], 295.99; found, 294.52.

Production of $(Z_{HER2:4})_2$-Cys. The selection of a novel affibody ligand, denoted $Z_{HER2:4}$, binding to HER2, was previously described (*10*). The dimeric form of $Z_{HER2:4}$, from now on called $(Z_{HER2})_2$, was constructed by subcloning the gene fragment encoding the Z_{HER2} protein (*10*) into the expression vector pAY81-Z_{HER2}. The fragment was then digested with *Xho*I (ER0691, Fermentas, Vilnius, Lithuania) and *Sal*I (ER0641, Fermentas) and ligated into the pAY81-Z_{HER2} vector, previously restricted with *Sal*I to form pAY321 (*22*). In the present study, a C-terminal cysteine was introduced to form the clone pAY393 (pAY243-$(Z_{HER2})_2$-Cys) in the following way. A PCR product of the affibody molecule was generated from plasmid pAY321 (pAY81-$(Z_{HER2})_2$) with forward primer AFFI-77 (5′gccgctcgaggtagacaacaaattcaacaaag), introducing a *Xho*I restriction site, and reverse primer AFFI-223 (5′gatctgctgcagttagcatttcggcgcctgagcatcatttag), introducing a C-terminal cysteine and a *Pst*I restriction site downstream. Using as template a dimer consisting of two repetitive monomers, the PCR generated a monomeric and a dimeric version of the affibody molecule corresponding to Z_{HER2}. The dimer band was extracted from a preparative agarose gel using the QIAquick gel extraction kit (QIAGEN GmbH, Germany).

The affibody fragment, $(Z_{HER2})_2$-Cys, and the expression vector, pAY243, were digested using *Xho*I and *Pst*I, purified with the QIAquick PCR purification kit (QIAGEN GmbH, Germany), subsequently ligated with T4 DNA ligase, and transformed into the *Escherichia coli* strain BL21(DE3). The cells were plated on TBAB plates supplemented with 50 μg/mL kanamycin, and positive clones containing the introduced $(Z_{HER2})_2$-Cys fragment were verified by means of DNA sequencing on an ABI PRISM 3100 Genetic Analyzer (Applied Biosystems, Foster City, CA). *Escherichia coli* strain RRI$\Delta M15$[10] was used as bacterial host during the cloning procedure. The resulting vector, pAY393 (pAY243-$(Z_{HER2})_2$-Cys), encodes the bivalent affibody, $(Z_{HER2})_2$, fused to a C-terminal cysteine for thiol coupling and an N-terminal hexahistidyl (His_6) tag, allowing purification by immobilized metal ion affinity chromatography (IMAC).

The bivalent affibody protein was expressed as an His_6-tagged fusion protein in *E. coli* strain BL21(DE3) and recovered by means of IMAC purification on a TALON Metal Affinity Resin (8901-2, BD Biosciences, CA) column

under denaturing conditions, as described earlier (*22*). Renaturation of the purified fusion protein, the bivalent affibody, was performed by gel filtration using PD-10 columns, equilibrated with PBS (10 mM phosphate, 154 mM NaCl, pH 7.1), according to the manufacturer's protocol (Amersham Biosciences, Uppsala, Sweden). Protein concentration was calculated from absorbance measurements made at 280 nm using the extinction coefficient (30440 M^{-1} cm^{-1}). The purified protein was further analyzed by SDS−PAGE on a Tris-Glycine 16% homogeneous gel, using a Novex system (Novex, CA).

Radiobromine Production. A mixture of bromine radioisotopes was used for the radiobromination study. These nuclides were produced by irradiating copper(II) selenide of natural isotopic composition with 40-MeV protons. Radioactivity measurements of the irradiated targets and produced radiobromine were carried out using gamma-spectroscopy, as it was described in the Instrumentation section. The proton bombardment induces the bromine isotopes ^{77}Br, ^{76}Br, and ^{82}Br, as well as a number of radioisotopes of copper, zinc, selenium, and arsenic, in the target material. Radiobromine was separated from the target by dry distillation coupled with on-line thermochromatography purification (*12*) and was obtained as a no-carrier-added bromide solution in 200−400 μL of ultrapure Milli-Q water. No radioactive nuclides other than bromine isotopes were found in the product. Typical production batch contained 290 MBq ^{77}Br, 228 MBq ^{76}Br, and 6 MBq ^{82}Br at the end of separation. Measurements of specific radioactivity were not performed for this preparation. Earlier, we produced ^{76}Br using the same technique. The specific activity of the product was about 40 times lower than theoretical value, 200 GBq/μmol (*24*). Presence of fairly long-lived ^{77}Br ($T_{1/2}$ = 57 h) enabled the use of the radioactivity of a single batch for up to several days after radionuclide production.

Radiobromination of ((4-Hydroxyphenyl)ethyl)-maleimide (HPEM). The precursor molecule was radiobrominated using CAT as oxidant. An initial series of experiments was performed using 0.1% acetic acid in water, 1% acetic acid in methanol, and 5% acetic acid in methanol as reaction media. Typically, 3 μL of radiobromide were mixed with 10 μL of solvents and 5 μL of HPEM solution in methanol (varying concentrations), and CAT was added in 10 μL of water (varying concentrations). The reaction proceeded for a predetermined time and then was quenched by a double excess of sodium metabisulfite in 10 μL of water. Since the use of 5% acetic acid in methanol provided the best yields, this solvent was selected for further experiments. Labeling-yield dependence on the amount of added CAT and HPEM, and on reaction time, was determined by varying one parameter at a time. Typical reaction conditions were as follows: 5 μL of HPEM solution in 5% acetic acid in methanol was mixed with 3 μL of ^{76,77}Br in Milli-Q water in an Eppendorf tube (1.5 mL). To this mixture was added 10 μL of CAT solution in 5% acetic acid in methanol. The HPEM amount varied between 0.031 and 20 μg (0.144 and 92 nmol), and the CAT amount varied between 0 and 80 μg (283 nmol). The tube was agitated throughout the reaction time, which ranged from 5 to 20 min. The reaction was terminated by adding 10 μL of sodium metabisulfite solution in water, given in double molar excess to CAT. All experiments were made at least in duplicate.

Varying CAT Amount. When the amount of CAT was varied, the amount of added HPEM remained constant at 5 μg and the reaction time was 5 min.

Varying ((4-Hydroxyphenyl)ethyl)maleimide Amount. When the amount of HPEM was varied the amount of added CAT remained constant at 40 μg and the reaction time was 15 min. Blank experiments were performed, when 5% acetic acid in methanol was used instead of HPEM.

Varying Reaction Time. When the reaction time was varied the amount of added HPEM remained constant at 5 μg and the amount of added CAT was 40 μg.

Silica gel 60 F_{254} TLC plates (20 × 100 mm, elution path 80 mm, E. Merck, Darmstadt, Germany) were used for analysis. Neat acetonitrile was used for elution. For the analysis, 1−2 μL of the reaction mixture was applied on a TLC plate, which was then left to evaporate spontaneously before being developed in freshly prepared eluent.

Conjugation of Radiobrominated ((4-Hydroxyphenyl)ethyl)maleimide to His_6-$(Z_{HER2:4})_2$-Cys. Before labeling, affibody solution was treated with dithiothreitol (DTT, E. Merck, Darmstadt, Germany) in order to reduce spontaneously formed disulfide bonds. Typically, 0.5 mL of stock affibody solution (1 mg/mL in citrate-phosphate buffer, pH 4.5) was mixed with 10 μL of DTT (1 M solution in water, freshly prepared) and incubated for 40 min at 37 °C. Thereafter, the mixture was applied to NAP-5 size-exclusion columns, preequilibrated, and eluted with well-degassed 0.1 M acetate buffer, pH 6.0; the first 900 μL of the high-molecular-weight (HMW) fraction were used for labeling. Reduced affibody was used for labeling within 10−15 min after reduction.

((4-Hydroxyphenyl)ethyl)maleimide was radiobrominated for conjugation as previously described. A small sample (0.5 μL) of the reaction mixture was taken for radio-TLC analysis. $(Z_{HER2:4})_2$-Cys was added in an equimolar amount to HPEM, and the mixture was incubated at RT. At predetermined times (10 and 30 min), aliquots were taken, and the overall labeling yield was determined by size-exclusion chromatography as the ratio of radioactivity in the HMW fraction to the sum of the radioactivity in the HMW fraction, in the low-molecular-weight fraction (LMW) and on the column. Conjugation yield was calculated by correcting overall labeling yield for the yield of HPEM radiobromination. All experiments were performed in duplicate. Radiochemical purity of the labeled affibody was controlled using the ITLC SG strip (Pall Life Sciences, New York, NY) eluted with 70% acetone in water.

To verify that the labeling was associated with HPEM, blank experiments were performed in duplicate. In this case, 5% acetic acid in methanol was used instead of the HPEM solution, but all manipulations were the same as in the case of HPEM labeling.

To verify that coupling of radiobrominated ((4-hydroxyphenyl)ethyl)maleimide is directed to SH-group of cysteine, a control experiment was performed using subclone $(Z_{HER2:4})_2$, which does not contained cysteine. All other manipulations were the same as for $(Z_{HER2:4})_2$-Cys.

Stability Test. The in vitro stability of radiobromine binding to $(Z_{HER2:4})_2$-Cys was assessed by using 8 M urea to achieve high ion strength and 1 M NaBr to challenge with an excess of nonradioactive bromine. The labeling was performed according to the method described above. To Eppendorf tubes (1.5 mL) containing 1 mL of each of the stability test solutions was added 100 μL of radiobrominated $(Z_{HER2:4})_2$-Cys. The tubes were shaken vigorously for 15 s. The NaBr and urea solutions were kept at RT for 1.5 h of gentle agitation, and a fraction of 100 μL was taken for analysis. The samples were analyzed using size-exclusion chromatography, and the portion of

radioactivity in the LMW fraction was assumed to have resulted from release of the label. All tests were performed in duplicate.

Binding Specificity of Labeled Conjugates to HER2-Expressing Cells. Binding specificity of the obtained conjugates was tested on HER2-expressing SK-OV-3 ovarian cancer cells. Labeled conjugate was added to two groups of Petri dishes (3−4 dishes, ∅ 3.5 cm, 2−5 × 10^5 cells per dish). One group of dishes in each experiment was presaturated with a 1000-fold excess of nonlabeled affibody 10 min before the labeled affibody was added. Cells were incubated with labeled conjugate for 2 h at 37 °C; the incubation media was then collected. Cell dishes were washed 6 times with cold serum-free medium and then treated with 0.5 mL of trypsin-EDTA solution (0.05% trypsin, 0.02% EDTA in buffer, Flow Irvine, UK) for 10 min at 37 °C. When cells were detached, 1 mL of complete medium was added to every dish and the cells were resuspended. Of this cell suspension, 0.5 mL was used for cell counting and 1 mL for radioactivity measurements, along with 1 mL of the corresponding incubation medium.

Biodistribution Studies. The animal study was approved by the local Ethics Committee for Animal Research. Female outbreed BALB/c nu/nu mice (10−12 weeks old at arrival) were acclimatized for one week at the Rudbeck Laboratory animal facility before subcutaneous (sc) injection of ∼5 × 10^6 SK-OV-3 cells in the left hind leg. Xenografts were allowed to become established for two months.

Groups of four animals were used for the biodistribution study. All mice were subcutaneously injected with ∼50 μL (approximately 100 kBq, 0.8 μg) of radiolabeled affibody. After 4 h, the mice were anesthetized and sacrificed by heart puncture. Blood was collected using heparinized syringes (heparin 5000 IE/mL, from Leo Pharma, Köpenhamn, Denmark), while organs (heart, lung, liver, spleen, pancreas, kidney, stomach, muscle, and brain) and tumors were excised, and their radioactivity content was measured. Percent of injected dose per gram tissue (%IA/g) was calculated by dividing the radioactivity in a tissue by the average radioactivity in three control syringes, minus the radioactivity left in the syringe after injection and divided by the organ weight.

Since results of biodistibution study have demonstrated unusually low uptake of radioactivity in kidneys, a control experiment was performed with no-cysteine-containing clone $(Z_{HER2:4})_2$, which has been indirectly radiobrominated using *N*-succinimidyl 4-bromobenzoate (PBrB-$(Z_{HER2:4})_2$). Labeling was done according to Höglund and co-workers (*18*). Study protocol was the same as for HPEM-labeled affibody, but no-tumor-bearing nude mice were used in this study.

RESULTS

The synthesis of HPEM (**1**) and the chromatography standard 1-[2-(3-bromo-4-hydroxyphenyl)ethyl]-1*H*-pyrrole-2,5-dione (**8**) was carried out as outlined in Scheme 2 (see Material and Methods). Electrophilic bromination of commercially available tyramine (**4**) with bromine in carbon tetrachloride in the presence of acetic acid gave bromide, **5**, along with the dibromide, (4-(2-aminoethyl)-2,6-dibromophenol). Compound **5** (yield 41%) was isolated by reverse phase (RP). Tyramine (**4**) and 4-(2-aminoethyl)-2-bromophenol) (**5**) were reacted with maleic anhydride in dry tetrahydrofurane (THF) above room temperature (RT). The crude product was purified using column chromatography to give a 66% yield of compound

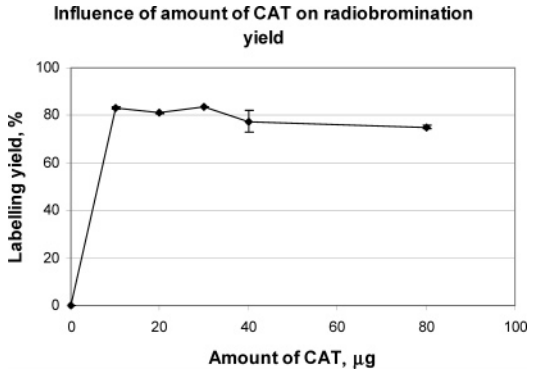


Figure 1. Dependence of bromination yield on amount of CAT. Other conditions: HPEM 5 μg; reaction time 5 min.

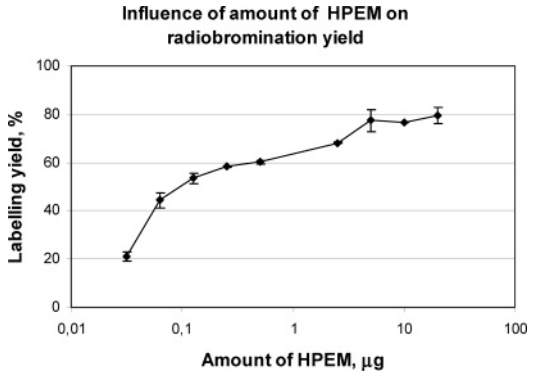

Figure 2. Dependence of bromination yield on amount of HPEM. Note the logarithmic scale. Other conditions: CAT 40 μg; reaction time 15 min.

6. Compound **7** (yield 46%) was isolated using RP-HPLC. The aryl acetates, **6** and **7**, were converted to the corresponding phenols, **1** and **8**, respectively, by means of methanolysis in the presence of Amberlyst-15, using the methodology developed by Das and co-workers (*25*). After completion of the reaction, Amberlyst-15 was easily removed from the reaction mixture by filtration to give a high yield of the parent phenols.

The following solutions were evaluated as reaction media for radiobromination of HPEM: 0.1% acetic acid in water, 1% acetic acid in methanol, and 5% acetic acid in methanol. The use of 0.1% acetic acid in water provided yields of about 40%, and increasing either amount of oxidant or reaction time resulted in no increase of labeling yield. The use of acidified methanol solutions enabled us to obtain, while using the same reactant concentration, yields of about 60% using 1% acetic acid in methanol and of about 70% using 5% acetic acid in methanol. Further experiments were performed using 5% acetic acid in methanol as a solvent.

Influence of oxidant amount on HPEM radiobromination efficiency is shown in Figure 1. The use of 10 μg of CAT provided a maximum labeling efficiency of 83 ± 0.4% when 5 μg of HPEM was radiobrominated for 5 min. Increasing the amount of oxidant to 40 μg did not increase yield. Further increase of CAT even decreased the yield somewhat (Figure 1), presumably due to the overoxidation of radiobromine.

Dependence of radiobromination yield on amount of substrate showed two distinct segments (Figure 2). Up to approximately 5 μg of HPEM, labeling yield increased proportionally to the amount of substrate. Thereafter, even a 4-fold increase in the amount of HPEM caused no significant improvement in labeling yield. An important feature of this is that the ascendant part of the curve

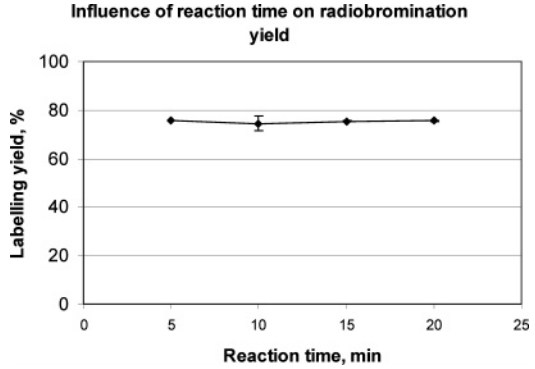

Figure 3. Dependence of bromination yield on reaction time. Other conditions: CAT 40 μg; HPEM 5 μg.

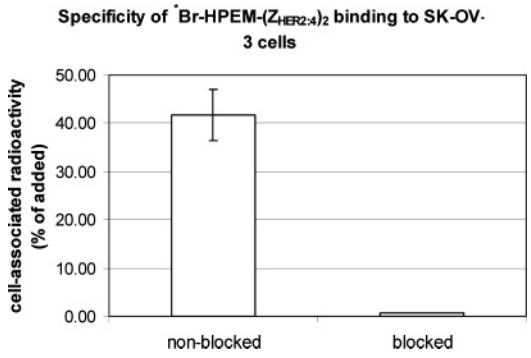

Figure 4. Antigen binding test. The test was performed on the ovarian cancer cell line, SK-OV-3. For presaturation of antigens, a 1000-fold molar excess of nonradioactive affibody was added. Cells were incubated with radiobrominated $(Z_{HER2:4})_2$ for 2 h and then washed six times. Data are presented as mean values from three dishes and maximum errors.

is rather shallow, with yields exceeding 50% even with the use of sub-microgram amounts of substrate. No peak corresponding to brominated HPEM was observed when neat 5% acetic acid in methanol was added to the reaction mixture instead of to the HPEM solution. This blank experiment confirms our interpretation of the radio-TLC data.

Electrophilic radiobromination of HPEM seems to be a rather rapid reaction at RT (Figure 3). For 5 μg of HPEM, the maximum yield of 75.9% was obtained in 5 min. Prolongation of reaction time did not increase the yield.

Coupling to the affibody molecule was performed without intermediate purification of radiobrominated HPEM. Freshly prepared reduced His_6-$(Z_{HER2:4})_2$-Cys in acetate buffer, pH 6.0, was added to the reaction mixture and incubated at RT. With approximately equimolar amounts of HPEM and His_6-$(Z_{HER2:4})_2$-Cys, conjugation yield was 29.3 ± 2.4% after 10 min of incubation and 65.3 ± 3.9% after 30 min. According to ITLC analysis, the radiochemical purity of the conjugate was >97%. Blank experiments, where no HPEM was added into the reaction mixture, or no-cysteine-containing affibody variant His_6-$(Z_{HER2:4})_2$ was used, did not show any labeling. It can be concluded that labeling was HPEM-mediated and cysteine-specific.

Stability of the label was tested by challenge with a high concentration of cold sodium bromide and by exposure to a high molar strength solution (8 M urea). After separating the test mixture on a NAP-5 size-exclusion column, radioactivity in the LMW fraction was 3.8 ± 0.9% for the sodium bromide test and 2.2 ± 0.35% for the urea test. Given the results of the ITLC testing (radiochemical purity of 98%), we can conclude that radiobromine was stably attached to affibody.

To ensure that the HER2 binding capacity of the affibody was retained after labeling, the labeled affibody was incubated with SK-OV-3 cells, which express HER2/neu antigen (as described in Experimental Procedures). The data concerning the cell-binding test are given in Figure 4. It was found that 41.6 ± 5.3% and 0.64 ± 0.02% of added radioactivity was bound to the nonblocked and blocked cells, respectively ($p < 0.001$). The results of the test demonstrated the specific binding of the antibody to antigen-expressing cells, since it can be displaced by nonradioactive antibody.

Biodistribution of radiobrominated affibody dimer in nude mice with grafted HER2-expressing SK-OV-3 tumors was performed at 4 h postinjection (pi). Radioactivity uptake in the tumors was 4.88 ± 1.59% IA/g. The blood level of radioactivity was low at 0.54 ± 0.03% IA/g. Radioactivity accumulation in other organs and tissues was also low, typically <1% IA/g, which resulted in a high tumor-to-normal organ ratio. Interestingly, radioactivity uptake in the kidney was low at 1.04 ± 0.17% IA; this is unusual for small proteins, which undergo renal excretion. The renal uptake in this study was much lower than renal uptake of $(Z_{HER2:4})_2$, which was radioiodinated using *N*-succinimidyl 4-iodobenzoate (*10*). A biodistribution study on non-tumor-bearing nude mice was performed to confirm that the use of HPEM reduced renal uptake also in comparison with the use *N*-succinimidyl 4-bromobenzoate. It was shown that the use site-specific HPEM-mediated labeling reduced kidney uptake from 7.43 ± 1.64% IA/g to 1.04 ± 0.17% IA/g. Significant difference in radioactivity concentration was observed in blood and liver, which were, in case of HPEM labeling, 1.5- and 5.9-fold higher, respectively.

Table 1. Biodistribution of *Br-HPEM-His_6-$(Z_{HER2:4})_2$-cys and *Br-benzoyl-His_6-$(Z_{HER2:4})_2$ in Nude Mice, 4 h pi[a,b]

	HPEM-$(Z_{HER2:4})_2$-Cys	PBrB-$(Z_{HER2:4})_2$	*p* value
blood	0.54 ± 0.03	0.34 ± 0.05	0.0004
heart	0.44 ± 0.11	0.30 ± 0.18	
lung	0.56 ± 0.07	0.45 ± 0.10	
liver	1.32 ± 0.31	0.22 ± 0.03	0.0004
spleen	0.36 ± 0.06	0.29 ± 0.04	
pancreas	0.27 ± 0.09	0.27 ± 0.10	
kidney	1.04 ± 0.17	7.43 ± 1.64	0.0003
stomach	0.76 ± 0.69	0.39 ± 0.06	
tumor	4.88 ± 1.59	no tumors	
muscle	0.17 ± 0.05	0.20 ± 0.09	
brain	0.14 ± 0.04	0.11 ± 0.02	

[a] Biodistribution of *Br-HPEM-His_6-$(Z_{her2:4})_2$-cys was performed on BALB/c nu/nu mice bearing SK-OV-3 xenograft. Average tumor weight was 0.029 ± 0.12 g. Biodistribution of *Br-PBrB-His_6-$(Z_{HER2:4})_2$ was performed on tumor-free animals of the same strain. [b] Each data point represents an average from four animals, ± standard deviation, and expressed as percent of injected radioactivity per gram of organ or tissue.

DISCUSSION

The site-specific labeling of tumor-targeting proteins is an attractive approach, as it provides well-defined conjugates. With this approach, a label can be placed some distance from the binding site of the affibody molecule, thus not interfering with recognition of the target structure. Introducing a cysteine appends a unique reactive thiol group to the affibody molecule, enabling such site-specific labeling. However, a linker molecule is required for the attachment of radiohalogen to cysteine-containing affibody. Such a linker molecule should be bifunctional, i.e., contain one part that can be easily and

stably radiohalogenated, and another part that can be quickly and stably attached to the SH group.

Wilbur's excellent review of protein radiohalogenation methods (*26*) indicates that the two most promising thiol-reactive groups are maleimides and acyl halides. The same review suggests two major ways to attach radiohalogens to organic compounds: to use molecules containing a strongly activated aromatic ring, or to exploit organometallic intermediates. Though no thiol-reactive radiobrominating agents have been reported so far, information concerning radioiodinating analogues was very helpful due to the close chemical similarity of these two heavy halogens. Of a number of candidates, ((4-hydroxyphenyl)ethyl)maleimide (HPEM) was especially attractive for two reasons. First, its synthesis seemed to be straightforward. Second, our previous experience with the direct radiobromination (*16*) of antibodies suggested that the activated aromatic ring could be efficiently radiobrominated.

An important aspect of electrophilic radiohalogenation of activated aromatic rings is that high labeling yields may be obtained using rather small amounts of substrate. This factor is decisive when choosing a radiolabeling strategy. Indirect radiohalogenation of proteins includes two major steps: labeling the pendant group, and attaching it to proteins. Often, a radiolabeled pendant group is purified from nonlabeled precursor and other components of the first-step reaction mixture (see, e.g., refs 18, 27, 28). In this case, the labeled pendant group can be obtained free of nonlabeled precursor, which would otherwise compete for the same binding groups in a protein molecule. For this reason, the amount of protein to be labeled can be decreased, and a higher specific radioactivity of radiolabeled conjugate can be obtained. On the other hand, introducing an extra step, and, in most cases, subsequently changing the solvent after purification, increases the probability of operator error. This decreases the overall reliability of the labeling procedure, a factor that might be important in mass producing the conjugate.

An alternative is the "one-pot" procedure, in which no intermediate purification is performed and conjugation of the labeled pendant group is carried out in the same vial as is the labeling (*19*−*21*, *29*). This labeling procedure is simpler and reduces the risk of human error. However, a nonseparated, nonlabeled precursor would require more protein substrate in order to obtain the same degree of modification. It may be that overall labeling efficiency should be sacrificed to a certain extent in order to obtain a more robust procedure and a product of higher specific radioactivity. In fact, in this study 2.3 nmol (0.5 μg) of HPEM was labeled at 60% efficiency, while labeling reproducibility was very good. In comparison, the same molar amount of *N*-succinimidyl *p*-trimethylstannyl-bromobenzoate was labeled under similar conditions at an average efficiency of 47%, and with rather large labeling yield variation (*18*). Under optimal conditions, the radiobromination yield of HPEM (83%) was similar to the radioiodination yield of trialkylstannyl derivatives of maleimide-conjugated aromatic rings (*29*, *30*).

The coupling of maleimide to free thiol in this study was efficient, with maximum coupling yield obtained within 30 min. The coupling efficiency of 65.3 ± 3.9% was in the same range as the efficiency reported for radioiodinated maleimides or acyl halides (*30*−*32*). Though increasing the cysteine-to-maleimide ratio may increase coupling efficiency, this would undesirably reduce specific radioactivity. Blank experiments confirmed that the labeling was HPEM-mediated and cysteine-specific. Both bromide challenge and exposure to a high-ion-strength solution failed to cause dissociation of radiobromine from the affibody molecule, thus confirming that the attachment is mediated by stable covalent bonds.

As expected, the site-specific labeling of the affibody molecule preserved its ability to bind HER2, which was demonstrated in vitro. Biodistribution of radiobrominated $(Z_{HER2:4})_2$-Cys showed its ability to accumulate in HER2-expressing SK-OV-3 xenografts. The combination of quick extravasation and good tumor binding with fast clearance from blood and normal organs provided high tumor-to-normal tissue ratios. For example, the radioactivity concentration in tumors 4 h pi exceeded the radioactivity concentration in blood, liver, and muscle by 9.1 ± 2.9, 3.7 ± 0.8, and 31 ± 10 times, respectively. Such high tumor-to-normal tissue ratios in combination with the high registration efficiency of PET may enable the highly sensitive detection of HER2 expression in small tumors, if positron-emitting nuclide ^{76}Br is used. An interesting finding was the low accumulation of radioactivity in kidneys. In our previous studies, when [^{125}I] *N*-succinimidyl 4-iodobenzoate was used for labeling of $(Z_{HER2:4})_2$, kidney uptake 4 h pi was found to be appreciably higher (*10*). Much higher kidney uptake is typical, for example, of radioiodinated scFv, which has a similar molecular weight and also undergoes renal excretion (*33*). To investigate if reduction of the kidney accumulation is dependent on the linker molecule, or on radionuclide, a biodistribution of cysteine-free variant $(Z_{HER2:4})_2$ labeled using *N*-succinimidyl 4-bromobenzoate was performed. The results have demonstrated that the use of HPEM reduced kidney accumulation more than 7-fold. It should be noted that at the same time, a significant increase of radioactivity concentration in blood and liver, in the case of HPEM labeling, was observed. Though high renal accumulation of radioactivity is generally not considered to be a major problem in diagnostics, it creates serious problems in therapeutic applications. Therefore, further investigation of the use of HPEM to reduce kidney uptake when using small proteins labeled with ^{131}I for therapy is warranted.

As Srivastava and co-workers have indicated (*23*), the same method can be applied, after some reoptimization of labeling chemistry, in radioiodinating affibody molecules. This opens up the possibility of the site-specific labeling of affibody molecules with ^{123}I for SPECT, with ^{124}I for PET, and with ^{131}I for therapy. In this way, a variety of labels with different emissions and half-lives are made available, and adjustment of such properties for a given clinical application is possible. A limitation of HPEM labeling is that it cannot be applied in attaching the promising alpha-emitting therapeutic nuclide ^{211}At to thiol-containing proteins; this is because the astatine−carbon bond in activated aromatic rings is weak and undergoes spontaneous dissociation (*34*).

In conclusion, the indirect radiobromination of anti-HER2 affibody using HPEM provides site-specific stable labeling at a level of efficiency similar to that of the thiol-specific radioiodination of targeting proteins. The radiobrominated affibody molecule preserves its capacity to bind HER2 both in vitro and in vivo. Importantly, HPEM-radiobrominated His_6-$(Z_{HER2:4})_2$-Cys provides for low accumulation of radioactivity in kidneys. This is promising for the development of positron-emitting anti-HER2 conjugates labeled with ^{76}Br. This method may also be used for the site-specific radiobromination of other affibody molecules, of various genetically engineered peptides or proteins, and of Fab′ fragments.

ACKNOWLEDGMENT

This work was financially supported by grants from the Swedish Cancer Society (Cancerfonden) and from Affibody AB (Bromma, Sweden). The authors are grateful to Prof. Jörgen Carlsson (Division of Biomedical Radiation Sciences, Uppsala University) and Prof. Stefan Ståhl (Department of Biotechnology, AlbaNova University Center, Kungliga Tekniska Högskolan—KTH, Stockholm, Sweden) for initiating research into tumor targeting using anti-HER2 affibody molecules in our laboratories; their efforts have provided much inspiration for this study. The authors also thank the personnel of the Svedberg Laboratory, Uppsala, Sweden, and especially Mr. Lars Einarsson for technical support in radiobromine production.

Hydrophobic Transmembrane-Peptide Lipid Conjugations Enhance Membrane Binding and Functional Activity in T-Cells

Marina Ali,† Michael Amon,† Veronika Bender, and Nicholas Manolios*

Rheumatology Department, Westmead Hospital, Westmead, NSW Australia 2145. Received April 26, 2005; Revised Manuscript Received August 22, 2005

Application of different delivery methods for therapeutic peptides has gained much attention in recent years. In this paper we conjugated a transmembrane hydrophobic peptide (core peptide; CP) derived from the T-cell antigen receptor α-chain sequence with either one (LP1), two (LP2), or three (LP3) palmitic acids through a Tris linkage. The effect of these lipopeptides (LPs) were compared to CP's activity both in vitro and in model membrane binding experiments using surface plasmon resonance. The influence of charged amino acids, arginine and lysine, within the CP sequence was examined by synthesizing analogues where arginine and lysine were replaced by the neutral amino acid alanine and these analogues were subsequently Tris-lipid conjugated with either one (XP1), two (XP2), or three (XP3) palmitic acids through a Tris linkage. The results indicated that the amount of irreversible binding for LPs were all greater than that of the underivatized CP in model membranes. None of the LPs could be dissociated from the liposome membranes, even after prolonged washing. Binding results for the neutral conjugates showed that only the XP1 bound to model membranes. This binding was 20% as efficient compared to LP1. In biological assays it was found that LP1 and XP1 were toxic to cells. LP3 inhibited IL-2 production more effectively than CP. Control lipopeptides (XP2, XP3) did not inhibit IL-2 production. These results demonstrate that the number of lipids conjugated to peptide, and the charged amino acids of CP, are both essential factors for peptide function and activity that can be enhanced by lipidation.

INTRODUCTION

The T cell receptor (TCR)[1] serves a critical function in the immune system and represents one of the most complex receptor structures in biology. The ability to inhibit pathogenic T-cells by blocking the TCR represents a novel means to treating autoimmune conditions such as rheumatoid arthritis, psoriasis, and lupus at a very early phase in disease progression. This opens the door to more selective treatment options than are currently available with the multipotent cytokine related drugs.

We have previously identified and subsequently shown in vitro that a nonapeptide derived from the TCR-α transmembrane region was able to inhibit IL-2 production in T-cells following antigen recognition. This hydrophobic transmembrane peptide (core peptide, CP) contains two positively charged amino acids, which are critical for receptor assembly (*1*, *2*). Extending these studies in vivo, CP given subcutaneously or intraperitoneally significantly reduced the induction of T-cell mediated inflammation in animal models with adjuvant-induced arthritis, allergic encephalomyelitis, and delayed type contact hypersensitivity (*3*, *4*). In preliminary studies by Gollner et al. (*5*), when CP was tested in humans it was noted that CP was effective in the treatment of autoimmune skin conditions. More recently, Mahnke et al. (*6*) have genetically engineered dendritic cells to secrete this peptide and thereby reduce inflammation in the T-cell dependent, experimental allergic encephalomyelitis animal disease model. The therapeutic effect was demonstrated to be antigen specific.

To increase CP's bioavailability we undertook to conjugate lipids to CP using the previously reported 2-amino-2-(hydroxymethyl)-1,3 propanediol (Tris) technology (*7*). The advantages of using Tris technology for such a linking function are, first, the hydroxy methyl groups in Tris are all symmetrically arranged around a central carbon atom, thereby removing the problems of stereoisomerization. Second, with the molecule of interest coupled to the amino group of Tris, all three hydroxymethyl groups are available for coupling to lipophilic groups. Peptides have been coupled to Tris by the formation of an amide bond between the amino group of Tris and the carboxyl group of the peptide.

Tris technology was used by Wells et al. (*8*) to prepare fatty acid conjugates of the analgesic morphine, nonsteroidal antiinflammatory drug indomethacin, antiviral drug 3′-azido-3′-deoxythymidine (AZT), and antineoplastic drugs methotrexate and chlorambucil. In their studies they demonstrated that biological properties such as cellular uptake, delivery profiles, skin retention, and toxicity of these conjugates could be altered.

Tris-lipidation may also provide a useful way of manipulating the pharmacokinetic properties of drugs. Lockett et al. (*9*) demonstrated that Tris-lipidated con-

jugates of the widely used cytotoxic and antiinflammatory drug methotrexate, using a mouse melanoma model, displayed improved potency in the local treatment of tumors and reduced systemic toxicity when compared with the unconjugated drug. They also showed that Tris-lipidated cationic peptides could efficiently deliver (transfect) DNA into cells in culture.

To determine the effect of Tris-lipidation on a drug's cytoxicity in multidrug resistant cells, Davey et al. (*10*) also investigated the effect and cytotoxicity of various Gly-Tris-Palmitate (GTP1, GTP2, and GTP3) derivatives of the cancer chemotherapeutic drugs chlorambucil and methotrexate, and of the anti-HIV drug AZT in comparison to parent drugs.

In this study CP was C-terminally attached to the amino group of the Tris molecule, and the hydroxyl group of the Tris was attached to long chain fatty acyl molecules in order to produce lipopeptides. The effect of lipopeptides on modulation of T-cell function was examined in vitro by measuring IL-2 production and it was found that the biological activity of certain lipopeptides increased compared to the parent peptide. We therefore decided to investigate some of the aspects of the mode of action of these compounds using surface plasmon resonance (SPR). The biophysical findings were then correlated with the biological effects of these lipopeptides on T-cell IL-2 production reflecting T-cell activation. To examine the importance of amino acid charge (arginine, lysine) within the lipopeptide's sequence (LP1, LP2, and LP3) a set of neutral analogues were synthesized by replacing arginine and lysine with alanine (XP1, XP2, XP3). The biological and biophysical properties of these lipopeptides are reported in this paper.

EXPERIMENTAL PROCEDURES

Materials. Phospholipids dimyristoyl phoshatidyl choline (DMPC), dimyristoyl phosphatidyl glycerol (DMPG), and *N*-octyl β-D-glucopyranoside were purchased from Sigma (St. Louis, MO). Pioneer sensor L1 chips were purchased from Biacore (Uppsala, Sweden).

Peptides. Protected peptides with greater than 80% purity were purchased from Auspep with an amino acid analysis and HPLC data supplied (Melbourne, Australia). The lysine residue and the N-terminal amino group of CP (GLRILLLKV) was *tert*-butyloxycarbonyl (Boc)-protected, and the arginine residue was protected with 2,2,5,7,8-pentamethylchroman-6-sulfonyl (Pmc). In the control peptide (GLAILLLAV) the lysine and arginine residues of CP were replaced with alanine and the N-terminal amino group was Boc protected.

High Performance Liquid Chromatography (HPLC). Analytical HPLC was carried out on a Millipore Waters HPLC equipment, comprising of a 6000A series solvent delivery system. The separations were performed on a NovapakC18 reverse phase column (100 × 8 mm). Elution was carried out at a flow rate of 2 mL/min. Detection was at 260 nm using a Waters Lambda Max Spectrophotometer, Model 480. The lipopeptide conjugates were analyzed on a C18 column with a linear gradient from 40% water: 50% acetonitrile: 10% THF to 50% acetonitrile: 50% THF containing 0.1% TFA over 5 min. at a flow rate of 2 mL/min.

Preparative HPLC. Briefly, separations were carried out on a Millipore Waters DeltaPrep 4000 HPLC using PrepPak C4 or C18 reverse phase columns (Prep Nova-Pak HR 40 × 100 mm) with flow rates of 20 mL/min, or Prep-Pak C4 semipreparative cartridges 25 × 10 mm with an extension cartridge of the same size. Flow rates for these conditions were 6 mL/min. Elution was with linear gradients using the same eluent buffer systems as for the analytical HPLC.

Thin Layer Chromatography (TLC). These were performed on Alufolien Kieselgel 60 F_{254} plates (Riedel-de Haen) of 0.2 mm thickness in petroleum ether:ethyl ether:acetic acid (50:50:1 and 70:30:1), methanol:chloroform (1:9), and in ethyl acetate:hexane (60:40). Visualization of spots was under UV light, 5% solution of ninhydrin in butan-1-ol, 2′,7′-dichlorofluorescein (TCI, Japan) in ethanol, and 10% phosphomolybdate in ethanol.

Synthesis of Lipopeptides. All lipid conjugates were synthesized as per the method published by Whittaker et al. (*7*). Briefly, benzyloxycarbonyl (Z)-protected gly-Tris mono-, di-, and tripalmitates (ZGTP1, ZGTP2, and ZGTP3, respectively) were synthesized by reacting Z-gly-Tris (6.4 mmol) with palmitic acid (12.8 mmol) in the presence of DCC (12.8 mmol) and catalytic amounts of (dimethylamino)pyridine (DMAP). The purity of Z-gly-Tris was confirmed by comparison of its ^{1}H NMR spectrum to previously published data (*11*). The mixture of ZGTP1, ZGTP2, and ZGTP3 were separated on a silica column using gradient elution with ethyl acetate and hexane (20% to 80% ethyl acetate) and further purified by HPLC on a C4 column using THF/acetonitrile system to give chromatographically pure compounds with single peaks on analytical HPLC. These compounds coeluted with previously described samples of ZGTP1, ZGTP2, and ZGTP3, respectively (*11*). After removal of the Z group by hydrogenation each GTP1, GTP2, and GTP3 (1 equiv) were coupled to protected CP (1 equivalent) or the control peptide (1 equiv) in the presence of 4 equiv of *O*-(1,2-dihydro-2-oxo-1-pyridyl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TPTU) at apparent pH 9. Lipopeptides were purified by preparative HPLC to give the mono-, di-, and tripalmitates in 55%, 31%, and 74% yields, respectively. Analytical HPLC showed single peaks at t_R 7.92 for monopalmitate, 8.8 for dipalmitate, and 9.8 for tripalmitate derivatives. After appropriate purity was demonstrated by HPLC using solvent systems described above, the protecting groups were then removed using trifluoroacetic acid (TFA) and scavenger mixture. TLC was used to confirm the presence of a single spot, which visualized with ninhydrin, dichlorofluorescein, and the phosphomolybdate spray. The resulting lipopeptides shown in Figure 1 were recovered by repeated lyophylization from tertiary butanol and characterized by Perkin-Elmer AP365 LC-MS-MS with an electrospray source.

Lipopeptides were dissolved in dimethyl sulfoxide (DMSO) as 10 mM, 5 mM, 2 mM, and 1 mM stock solutions and diluted with the *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES)-buffered saline (HBS-N) running buffer prior to the SPR studies and with culture media for the bioassays to give concentrations of 50 μM, 25 μM, 10 μM, and 5 μM as required.

Antigen Activation Assay. IL-2 assays were carried out using 2B4.11 hybridoma cells as previously described by Manolios et al. (*3*). Briefly, 2B4.11 hybridoma (5×10^4cells) and LK35.2 (5×10^4) were incubated with pigeon cytochrome C (50 μM) in 96-well microtiter plates for 24 h in the presence and absence of peptides. An aliquot of each supernatant (100 μL) was removed and serial 2-fold dilutions prepared using RPMI medium. Diluted supernatant was then incubated with CTLL-2 cells (2×10^4) for 18 h in microtiter plates. [^{3}H]-Thymidine (0.5 μCi) was added for 6 h, and the CTLL cells were collected onto glass fiber filter paper using a cell harvester (TiterTek, Packard Bioscience). [^{3}H]-

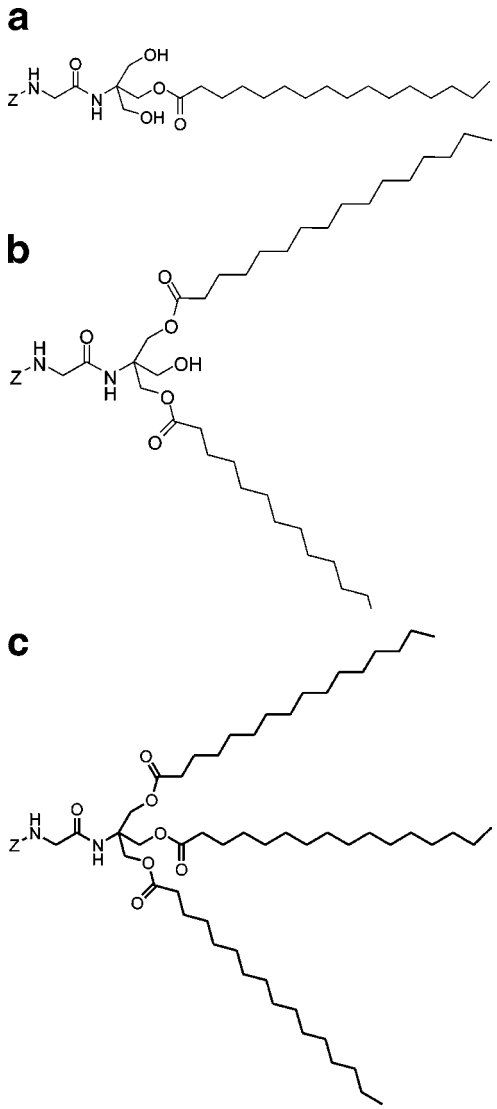

Figure 1. Structure of peptide conjugates with mono-, di-, and tripalmitate (a, b, and c) where Z = GLRILLLKV or GLAILLLAV.

Thymidine uptake was measured by scintillation counting (Packard Bioscience) and compared to standard curves to determine the amount of IL-2 produced. All lipopeptides and CP were tested at 50 μM, 25 μM, 10 μM, and 5 μM in 0.5% DMSO. IL2 production results were analyzed and expressed in terms of the concentration resulting in 50% IL2 production relative to a control of 0.5% DMSO (IC-50). All errors presented is standard error of the mean (SEM).

Cell Proliferation and Viability Assays. Mouse T-cell hybridoma 2B4.11 cells (1×10^5) were cultured in microtiter wells in the presence of lipopeptides at various concentrations. After 20 h, 30 μL of the 50 μM culture was removed and assessed for viability by trypan blue exclusion. The remaining cells in culture were pulsed with 0.5 μCi [^{3}H] thymidine for 5 h, harvested, and quantitated for [^{3}H]-thymidine uptake as per the antigen presentation assay described above. Proliferation results were analyzed and expressed in terms of the concentration resulting in 50% cell proliferation relative to a control of 0.5% DMSO (IC-50).

Preparation of Small Unilamellar Vesicles (SUV). Model membranes composed of zwitterionic and anionic phospholipids and their mixtures were produced. Briefly, DMPC was dissolved in dry chloroform and DMPG in chloroform:methanol (2:1) to give 10 mg/mL solutions.

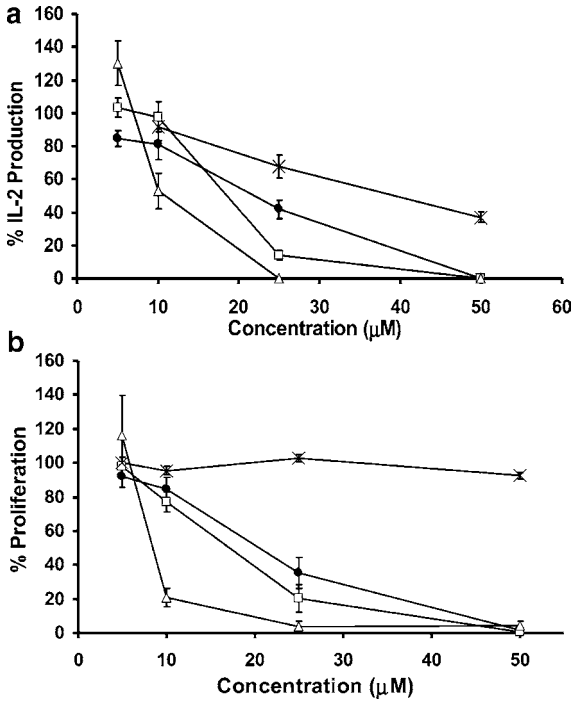

Figure 2. IL-2 production and cell proliferation dose curves of the monopalmitate conjugations. LP1 (filled circles), XP1 (open squares), unconjugated GTP1 (open triangles), and unconjugated CP (×). % IL-2 production (a) and % proliferation (b) are calculated relative to a control of 0.5% DMSO set to 100%. Each graph represents the mean ± SEM of three sets of triplicate experiments.

These were mixed in appropriate proportions before being evaporated under reduced pressure and the resulting lipid films dried overnight in vacuo. Lipids were then hydrated by resuspending in HEPES buffer for 60 min at 34 °C to give 0.5 mM concentration in respect of phospholipids. The solution was then sonicated in an ultrasonic bath for 20 min. Eight cycles of freeze/thawing was followed by extrusion through polycarbonate filters, first 100 nm (21 times) then 50 nm (21 times) pore diameter, using a Liposofast apparatus (Avestin,-Ottawa,Canada) and SUV were used immediately.

Binding Analysis by Surface Plasmon Resonance. SPR was carried out on a BIAcore 2000 instrument using Pioneer Sensor Chip L1 and HBS-N (Biacore, Upssala, Sweden) as running buffer. The chip surface was cleaned with 40 mM octyl glycoside (30 μL, 10 μL/min) followed by running buffer (100 μL, 10 μL/min). Liposomes (SUV) were injected (100 μL, 5 μL/min) giving a response of approximately 8000 RU. 10 mM NaOH (40 μL, 10 μL/min) removed any multilamellar vesicles from the surface, which was followed by 10 mM glycine pH 2.2 (10 μL, 10 μL/min) before injecting the peptide/lipopeptide of interest (100 μL, 5 μL/min). After peptide injection, the dissociation phase was commenced by replacing the peptide solution with elution buffer (5 μL/min) for 1200 s. Complete regeneration of the sensor chip was difficult. All SPR experiments were run at 25 °C, and all analyses were performed using the BIAevaluation software (Biacore, Upssala, Sweden).

RESULTS

IL 2 and Proliferation Assays. The monopalmitate conjugations demonstrated a greatly increased ability to inhibit IL-2 production in the antigen presentation model (Figure 2a). The monopalmitate conjugated CP (LP1) resulted in an IC-50 value of 21.92 μM, the control

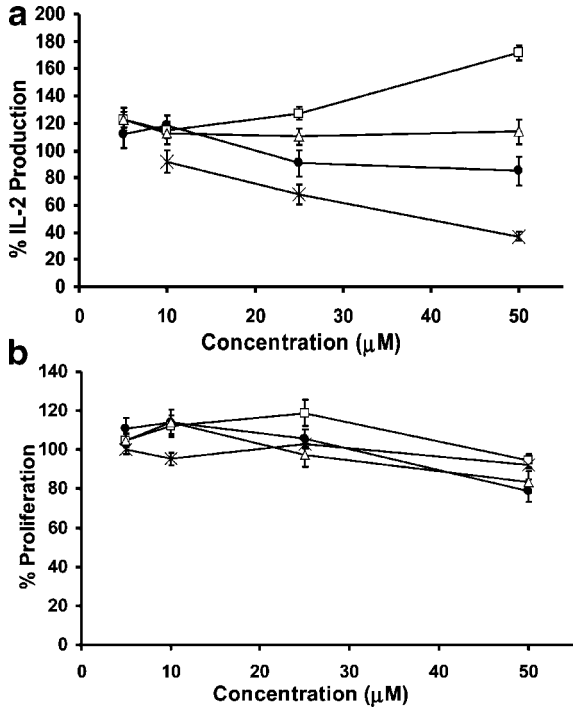

Figure 3. IL-2 production and cell proliferation dose curves of the dipalmitate conjugations. LP2 (filled circles), XP2 (open squares), unconjugated GTP2 (open triangles) and unconjugated CP (×). % IL-2 production (a) and % proliferation (b) are calculated relative to a control of 0.5% DMSO set to 100%. Each graph represents the mean ± SEM of three sets of triplicate experiments.

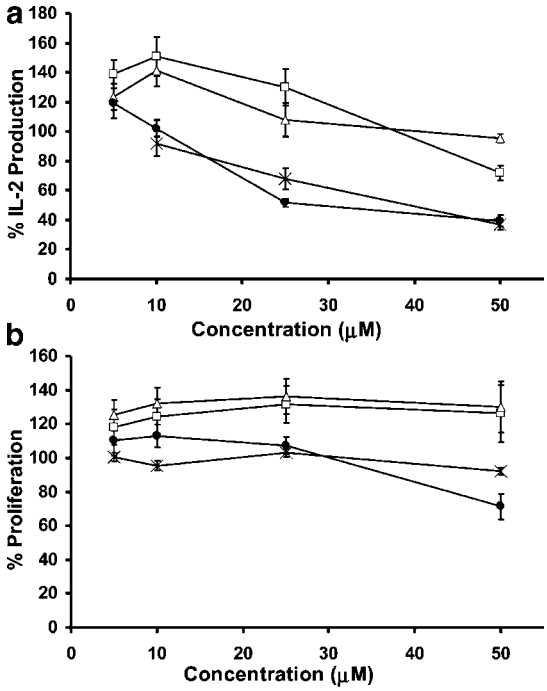

Figure 4. IL-2 production and cell proliferation dose curves of the tripalmitate conjugations. LP3 (filled circles), XP3 (open squares), unconjugated GTP3 (open triangles), and unconjugated CP (×). % IL-2 production (a) and % proliferation (b) are calculated relative to a control of 0.5% DMSO set to 100%. Each graph represents the mean ± SEM of three sets of triplicate experiments.

peptide conjugation (XP1) resulted in an IC-50 of 18.57 μM, and the building block of the monopalmitate Tris-conjugates, GTP1, resulted in an IC-50 value of 10.85 μM. The parent peptide displayed an IC-50 value of 39.52 μM in the IL2 assay. The proliferation results shown in Figure 2b mirror the IL-2 data. The IC-50 values calculated from Figure 2b showed that all monopalmitate conjugations increased CP's cytotoxicity. The IC-50 value of GTP1 was found to be 8.47 μM, 17.15 μM for XP1, and 20.50 μM for LP1, whereas that of CP was greater than 50 μM.

Each of the dipalmitate conjugations tested resulted in a marked increase in all IC-50 values to greater than 50 μM, meaning that the activity of the unconjugated CP had been effectively lost (Figure 3a and b).

The tripalmitate conjugations gave more interesting results (Figure 4a and b). LP3 resulted in an IC-50 value of 28.23 μM for the IL-2 production experiments, whereas each of the other tripalmitate conjugations resulted in IC-50 values above 50 μM. The corresponding IC-50 values for the proliferation experiments, were all well above the 50 μM mark. IC-50 values for all conjugations tested in the antigen presentation assay and the cell proliferation assay are summarized in Table 1.

Viability. Cell viability was performed by trypan blue exclusion to determine if the observed changes in proliferation were due to possible cytotoxic effects of each conjugation. When the effect of CP, control peptide, and their lipidated derivatives were examined on cell viability by trypan blue exclusion, both LP1 and XP1 were found to be toxic to cells (Figure 5), with viability at 14.72% ± 9.89 for LP1, and 8.92% ± 3.04 for XP1 at 50 μM. The di- and tripalmitate conjugates showed minimal toxicity, resulting in 90.06% ± 4.31 and 93.64% ± 2.85 viability, respectively. The control peptide's di- and tripalmitate conjugates also appeared nontoxic at 50 μM, presenting

Table 1. IC-50 Values for IL-2 Production and Cell Proliferation Assays[a]

	IC-50, μM	
conjugation	IL-2 production	proliferation
CP	39.52	>50
LP1	21.92	20.50
XP1	18.57	17.15
GTP1	10.85	8.47
LP2	>50	>50
XP2	>50	>50
GTP2	>50	>50
LP3	28.23	>50
XP3	>50	>50
GTP3	>50	>50

[a] IC-50 values are calculated from Figures 2−4. IC-50 is taken as the value in which the amount of IL-2 produced (or cell proliferation) is equal to 50% of that obtained in control experiments of 0.5% DMSO.

at 99.40% ± 1.61 and 100.93% ± 1.96 cell viability relative to control. The parent peptide, CP, resulted in 97.14% ± 1.96 cell viability.

Surface Plasmon Resonance Measurements of Lipopeptide Binding to Model Membranes. Membrane binding behavior of CP and the lipidated derivatives was examined on immobilized liposomes consisting of mixtures of DMPC:DMPG and are shown in Figure 6. Figure 6a shows the comparative binding sensorgrams of CP and lipopeptides to model membranes where the zwitterionic to anionic phospholipid ratio (DMPC:DMPG) is 70:30. The sensorgram revealed that LP1 and LP2 exhibit stronger binding to this model membranes than LP3 and the underivatized CP, with LP1 showing close to a 10-fold increase in irreversible binding. None of the lipopeptides could be dissociated from the liposomes even after extended washing with running buffer.

Figure 6b shows comparative binding of lipopeptides to membranes prepared from DMPC:DMPG mixtures in

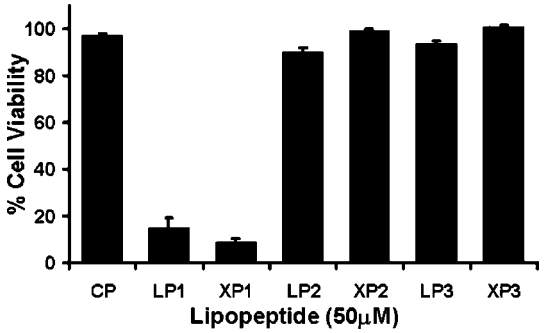

Figure 5. Viability of 2B4 cells (1×10^5) following overnight incubation with CP, LP, and XP series. Viability was assessed by trypan blue exclusion at a peptide or lipopeptide concentration of 50 μM. Results are shown relative to control (0.5% DMSO).

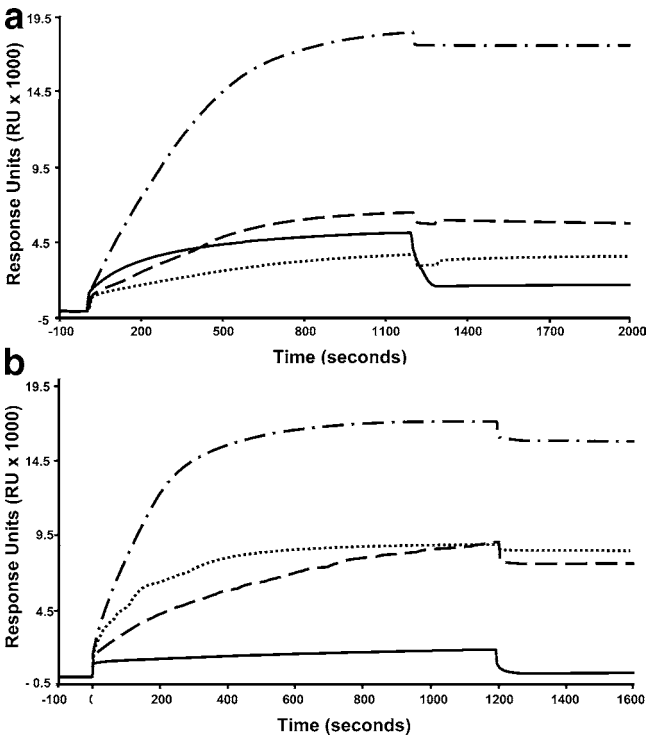

Figure 6. Sensorgrams showing the binding of CP (—), LP1 (— · —), LP2 (- — -), and LP3 (···) to (a) DMPC:DMPG 70:30 and (b) DMPC:DMPG 50:50 liposomes immobilized on an L1 sensor chip. Concentration for both CP and lipopeptides were 50 μM. Binding is expressed as the difference in signal between points before sample injection and after the dissociation phase.

the proportion of 50:50. Lipopeptides bound irreversibly to these liposomes as well. Under these conditions, LP1 continued to exhibit strong binding to liposomes, close to 15000 response units (RU) while LP2 and LP3 showed binding in the vicinity of 8000 RU.

In control lipopeptides, where CP's positively charged amino acids arginine and lysine were replaced with alanine, sensorgrams showing the binding of these lipopeptides to model membranes composed of 50:50 DMPC:DMPG revealed a dramatic loss of binding with both the di- and tripalmitate conjugates (XP2 and XP3 respectively). This was not so for the neutral monopalmitate conjugate (XP1), which was shown to bind, but to a lesser degree, when compared to that shown by the monopalmitate of CP-lipopeptide (Figure 7). Figure 8 graphically summarizes these results showing the relative binding of all lipopeptides to a 50:50 DMPC:DMPG liposome bilayer.

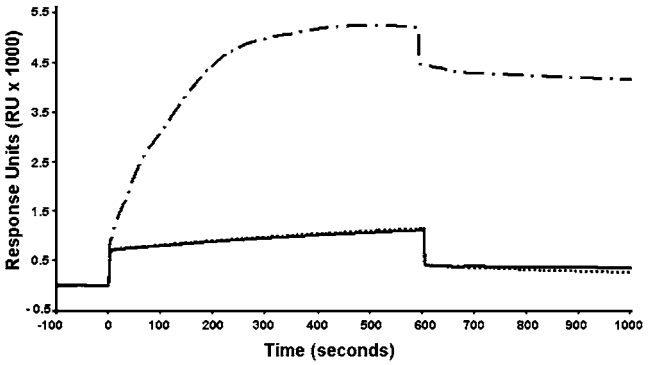

Figure 7. Sensorgram showing the binding of XP1 (— · —), XP2 (—), and XP3 (···) to DMPC:DMPG 50:50 liposomes immobilized on an L1 sensor chip. Lipopeptide concentration was 50 μM. Binding was expressed as the difference in signal between points before sample injection and after the dissociation phase.

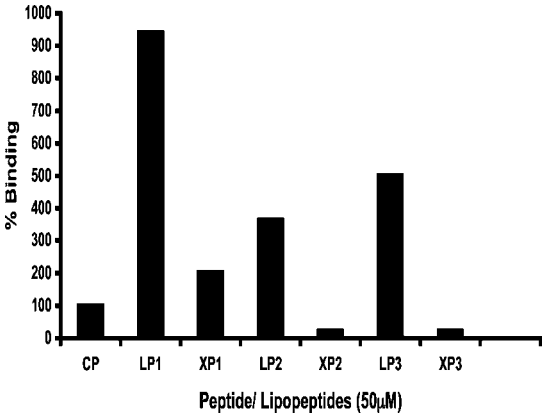

Figure 8. Bar graph representation of data shown in Figure 6b and Figure 7 showing comparative binding of CP and lipopeptide analogues to DMPC:DMPG 50:50 liposomes immobilized onto L1 sensor chip. Peptide concentrations were all the same at 50 μM.

DISCUSSION

The Tris-lipidation method makes use of the observation that the three hydroxyl groups of the Tris molecule may be acylated while the amino group provides a convenient attachment site for the formation of a covalent linkage of amino acids/peptides to the molecule (*7*). The structural similarity of the Tris molecule to glycerol enables fatty acyl groups to be attached to mimic naturally occurring mono-, di-, and triglycerides. The central carbon atom in the multifunctional Tris molecule is symmetrical and lends itself to derivatization without structural isomerization. Both synthesis and purification are less difficult than those of the glycerol derivatives and the three hydroxyl groups are all equal in reactivity. In contrast to glycerol, Tris enables the formation of triacyl derivatives of lipopeptides.

Earlier work involving Tris conjugation (*7*–*10*, *12*) has given interesting and important results concerning the design and potential therapeutic application of this system. In one study, one, two, or three palmitic acid groups were conjugated to three different drugs, chlorambucil, AZT, and methotrexate, whereupon the cytotoxicity of each compound was compared in various multidrug resistant cell lines(*10*). In general, Davey et al. (*10*) noted a trend in which the cytoxicity of each conjugated compound decreased with increasing numbers of palmitic acid groups. Furthermore, it was noted that the same type of conjugation (mono-, di-, or tripalmitate) could

result in different toxicity trends depending on the nature of the parent molecule. A monopalmitate conjugation of either chlorambucil or AZT both resulted in an increase in cytotoxicity relative to the parent compound, while the same conjugation to methotrexate resulted in a drop in cytotoxicity relative to the unconjugated methotrexate-(*10*). Overall, this paper demonstrated that conjugating various numbers of palmitates using Tris technology not only has the potential to dramatically alter a drug's performance in vitro, but that the parent drug itself remains an important component as it continues to exert a strong and directing influence on the behavior of the overall conjugate.

In the present study, a known immunosuppressant (CP) has been conjugated using Tris-lipidation with one, two, or three palmitic acid groups to try and increase the cellular uptake of CP and thereby increase its bioavailability. Each conjugate was then tested for its ability to inhibit T-cell activation in an antigen presentation model, results of which were then correlated with toxicity and membrane binding data using cell culture based assays and surface plasmon resonance.

Surface plasmon resonance (SPR) is a proven technique used to study interactions between peptides and lipopeptides with phospholipid membranes (*13*−*16*). The advantages of using SPR to study peptide−membrane interactions is that it not only allows real-time monitoring of a peptide binding and dissociating from model membranes, but it overcomes the need to use labeled peptides and/or cumbersome separation procedures employed in other techniques. Recently, CP and several sequence analogues have been analyzed using SPR and the antigen presentation assay described herein. A remarkable correlation was observed between each peptide's ability to bind to model membranes and their ability to inhibit T cell activation (*15*). In that study, it was noted that replacement of one or both of CP's basic residues with acidic residues led to a loss of peptide binding to both DMPC and DMPG model membrane systems. In addition, by changing the position of the charged amino acids in the sequence, the number of hydrophobic amino acids between the charged residues, and substitution of one or both basic residues to neutral amino acids, were found to negatively affect binding. Each loss of peptide−membrane binding was mirrored by a corresponding loss of activity in the antigen presentation assay thereby adding further evidence to CP's reliance not only on the presence of it's two positively charged residues, but also on their specific location.

To determine if CP's reliance on it's two positively charged residues behaves in the context of Tris-lipidation as it did in the nonlipidated peptide experiments of Bender et al. (*15*), a control peptide was synthesized in which CP's arginine and lysine residues have been switched to the neutral alanine residue.

In the antigen presentation assay, the monopalmitate conjugation of CP resulted in the highest degree of IL-2 inhibition with an IC-50 value of 21.92 μM. Comparing this value to that obtained from the proliferation experiments, 20.50 μM, it would appear that LP1 exerted its inhibitory effect in the antigen presentation assay through cytotoxicity. This was confirmed through viability experiments, which resulted in 14.72% ± 4.42 cell viability at 50 μM. XP1 followed a similar trend as that of LP1, in which the IC-50 value for the IL-2 production approximated that of the proliferation experiments. This suggests that the monopalmitate conjugations acted nonspecifically. The results of monopalmitate building block GTP1 confirmed this, as it was roughly twice as toxic as the LP1 conjugation, with IC-50 values of 10.85 μM for IL-2 production, and 8.47 μM for cell proliferation.

The di-palmitate conjugations (LP2, XP2, and GTP2) all presented with IC-50 values above 50 μM, whereas upon analysis of the tripalmitate conjugations, a significant difference was observed. The IC-50 value for LP3 in the IL-2 assay was 28.23 μM, whereas that of the proliferation assay was greater than 50 μM. Besides the parent CP this is the only compound which shows a significant difference between the IC-50 values obtained from the IL-2 production and cell proliferation curves. This suggests that LP3 is acting on the T-cells in a mechanism that does not affect cell proliferation, as further confirmed by the viability results (93.64% ± 1.27 viability at 50 μM). The XP3 and GTP3 conjugations presented with IC-50 values for both the IL-2 and proliferation assays above 50 μM.

Table 1 highlights these results, and the utility of Tris-lipidation as a means to alter a peptide's activity by regulating its lipophilicity. In accordance with what was observed by others (*10*), Table 1 and Figure 5 show that all of the monopalmitate conjugations were more toxic than their di- or tripalmitate counterparts. Figure 5 further suggests that the toxicity of CP is not largely affected by Tris conjugation with two or three palmitate groups. T-cells treated with CP display a viability of 97%, which only drops by 7% to 90% when treated with LP2, or by 3% to 94% when treated with LP3. This again agrees with work presented by Davey et al. who have found toxicity to decrease with increasing lipophilicity in this Tris-lipidation system (*10*).

Comparing the results of the CP conjugations to those of the XP peptide, the only difference lies in the results for the tripalmitate conjugation. XP1 behaves similar to LP1, and appears to be cytotoxic, which as discussed earlier, is likely nonspecific and due to the cytotoxicity of the GTP1 starting complex. As with LP2, XP2 is not active in any of the biological assays used. The tripalmitate conjugate, XP3, remains inactive in the IL-2 assay, proliferation assay, and the viability assay, whereas LP3 is active in the IL-2 assay with an IC-50 value of 28.23 μM. Since the main difference between CP and XP is that CP has its two basic charges, arginine and lysine, switched to the neutral alanine in the XP peptide, these results suggest that the charges present in CP are still important for activity. These results are in agreement with those found by Bender et al. (*15*) discussed earlier, where it was observed that altering CP's charges renders the peptide biologically inactive in the antigen stimulation model.

The general trend of decreasing toxicity noted with increasing lipophilicity may be the result of a notable decrease in solubility when more lipids are conjugated to an already hydrophobic peptide. It is also possible, as has been discussed by other groups using this system (*8*−*10*), that the structure of the resulting lipopeptides likely alters the degradative steps these peptides undergo when delivered in their unconjugated forms. It is possible that the degradation products of the monopalmitate conjugations result in a compound that is more toxic to cells than that which may be produced by the degradation of the di- and tripalmitate conjugations. However, it is interesting to note the results of the tripalmitate conjugation of CP, which, despite its poor solubility, LP3 was more active than the unconjugated CP in the IL-2 assay, while displaying the smallest effect on cell viability of all the CP conjugations (Figure 5). This combines to suggest that despite poor solubility, LP3 has succeeded in improving CP's immunomodulatory behavior.

Variable CP lipidation was performed in this study to help CP bind more effectively to a cell's membrane, thereby increasing its bioavailability within the cell membrane and decreasing its effective dosage. Covalent attachment of lipids such as palmitic, myristic, and prenyl groups to proteins and peptides and the role of the lipid group in partitioning the lipopeptides to membranes has been the subject of several excellent reviews (*17*, *18*). Myristic acid is generally found in amide linkage to the N-terminal group of certain proteins and peptides while in nature palmitic acid is more often found in a thioester linkage to a Cys side chain (*19*). The properties of a family of synthetic lipopeptides with agonist properties were described by Gras-Masse (*18*).

In one study using fluorescently labeled Tris conjugated peptides, Bender et al. (*20*) have shown that Tris conjugates are capable of passing through a cell's membrane, but also that conjugations containing only one lipid group enter cells much more rapidly than their di- or trilipidated counterparts. We have previously labeled LP1, LP2, and LP3 conjugates with fluorescein isothiocyanate to study their ability to enter cells (*3*). These conjugates were added to COS cells and/or the murine cytochrome *c*-specific T-cell hybridoma, 2B4, and their intracellular localization was determined by confocal microscopy. It was found that lipopeptides crossed cell membranes and localized within the cellular cytoplasm, reaching as far as the endoplasmic reticulum. The extent of cellular penetration was found to be influenced by lipid moieties attached. LP1 showed the most ability to permeate the fibroblasts and T cell reaching the nucleus. These observations have led us to consider this as a potential reason for the toxicity observed in all of the monopalmitate conjugations observed in this study. It is possible that LP1 and XP1 are cytotoxic because they are binding to such a high degree, causing lysis as shown in Table 1 and Figure 5. It is also possible that the degree of self-association is an important consideration in this matter. Cameron et al. (*12*) have shown with the help of transmission electron microscopy that the transfection ability of their Tris conjugations depended upon their ability to self-associate into membranous structures (*12*). What might be occurring is differential self-association and differential membrane preference between each of the lipidated compounds.

To confirm that Tris-lipidation improves a peptide's ability to bind to lipid membranes and to explore differential membrane preference between each of the lipid conjugations synthesized herein, each Tris compound was examined using surface plasmon resonance in order to quantify the amount of lipopeptide that binds to various lipid membrane bilayers. The results in Figure 6 indicate that all of the lipopeptide derivatives of CP, bind very strongly to both model membranes tested, DMPC:DMPG 70:30 (6a) and 50:50 (6b). Although the di- and tripalmitate conjugations of CP demonstrated a preference for membranes consisting of a higher anionic proportion (DMPC:DMPG = 50:50), the monopalmitate conjugate LP1 bound to both 70:30 and 50:50 membranes at roughly the same level. The most interesting finding in these SPR studies was the lack of dissociation of all three bound lipopeptides from the model membranes. None of the lipopeptides could be removed from the liposome surfaces at the concentration examined (50 μM), even after extensive washing with elution buffer. This indicates that at this stage, the lipopeptides might be irreversibly bound to membranes, presumably through strong hydrophobic forces/interactions.

The binding of the XP conjugations to liposomes consisting of DMPC:DMPG at a 50:50 ratio (Figure 7) show that, as is the case with the CP series, the monopalmitate conjugation results in the highest level of membrane binding. The CP conjugation, LP1, exhibited more than a 10-fold increase in irreversible binding when compared to CP (Figure 8), adding weight that this high affinity for lipid membranes is a factor in the cytotoxicity observed in the biological studies. In a study of N-terminally lipid conjugated magainin analogues (*21*) self-association of these constructs in solutions and in membranes were demonstrated and a direct correlation between oligomerization of the lipopeptides in solution and potent antifungal activity were found.

We have shown previously (*15*) that CP displays association to, and dissociation from, both zwitterionic and anionic liposomes. CP, like several other cationic hydrophobic peptide sequences reported (*22*−*25*), binds to liposomes with a rapid initial association. However, the dissociation was found to be slower and the signal does not return to baseline even after extensive washing with buffer, indicating that some of the peptide bound irreversibly to both membranes. We reported earlier (*15*) that while some binding by various CP neutral analogues was exhibited to the zwitterionic DMPC membranes, binding to the anionic DMPG was completely abolished. The above results showing that the neutral XP1, XP2, and XP3 bind poorly to membranes, whereas the di-basic CP conjugations LP1, LP2, and LP3, bind much stronger, indicate that lipid conjugation alone is not sufficient to alter this requirement.

In an investigation to deliver reporter genes into various cultured cells Cameron et al. (*12*) studied tri-lysine-Ala-Tris -mono, -di- and -tripalmitate (K_3 ATP_1, K_3 ATP_2, and K_3 ATP_3). These compounds differed in their level of palmitoylation similar to the lipopeptides in our study. Cameron et al. found that although the dipalmitate derivative of tri-lysine-Ala-Tris compound gave the highest transfection levels under optimal conditions compared to the tripalmitate (P3) compound in at least two cell types, this effect was limited to a narrow lipid:DNA ratio and concentration range whereas the P3 compound was quite effective over a broad range. It was therefore the P3 construct chosen to be the prototype molecule in their transfection studies. In our studies of the CP-lipopeptides, we found the dipalmitate derivative the least efficient in inhibiting IL-2 levels in T-cell function following antigen recognition as well as poorly binding to the model membrane mixtures in our SPR studies. Unlike the above transfection agent K3ATP3, where the headgroup carries four positive charges, LP3 has two positively charged amino acids giving a total of three positive charges including the amino terminus of the peptide of this molecule.

This study has given important insights into the types of modifications Tris-lipidation can have on peptide drugs, as well as the importance of the inherent properties found in the unconjugated peptide itself. We have examined the biological and biophysical outcomes of conjugating a peptide with known immunomodulating effects to one, two, or three palmitoyl groups via the Tris-lipidation strategy. In this study, we have found that monopalmitate conjugation results in a compound with greatly increased cytotoxicity and a 10-fold increase in membrane binding potential relative to the parent compound. Di- and tripalmitate conjugations resulted in minimal toxicity and greater binding potential with LP3, demonstrating an improved biological activity in the T-cell activation assay. The importance of the peptide in

each conjugation was further examined by removing the two essential basic residues of CP, replacing them with alanine, and then analyzing their biological and biophysical properties as well (XP series). This alteration effectively removed all biological activity and greatly reduced the membrane binding potential of each conjugation tested. These data combine to show that although Tris-lipidation has the potential to dramatically alter this peptide's function, the peptide's inherent properties still remain a deciding factor in the conjugate's overall activity.

ACKNOWLEDGMENT

We express our sincere appreciation to Dr. Eve Diefenbach for her expert advice on SPR analysis and Mr Jim Keegan from the University of Technology Sydney for the LC-MS-MS data acquisition. M. Amon and Dr. M Ali were supported by the Barbara Cameron Memorial Scholarship Sydney University, and a Grant-in-Aid from the Arthritis Foundation of Australia, respectively. A grant-in-aid from the Rebecca Cooper Medical Research Foundation is appreciated.

2,2-Bis(ethoxycarbonyl)- and 2-(Alkylaminocarbonyl)-2-cyano-Substituted 3-(Pivaloyloxy)propyl Groups as Biodegradable Phosphate Protections of Oligonucleotides

Päivi Poijärvi,* Petri Heinonen, Pasi Virta, and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received May 18, 2005; Revised Manuscript Received August 22, 2005

Oligonucleotides bearing biodegradable phosphate protecting groups have been synthesized on a solid support. For this purpose, two dimeric building blocks, viz. 5′-*O*-(4,4′-dimethoxytrityl)-(R_P,S_P)-O^P-[2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl]-*P*-thiothymidylyl-(3′,5′)-thymidine 3′-[*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite] (**1**) and 5′-*O*-(4,4′-dimethoxytrityl)-(R_P,S_P)-O^P-[2-cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl]thymidylyl-(3′,5′)-thymidine 3′-(*H*-phosphonate) (**2**), were prepared. Phosphoramidite **1** was incorporated into an phosphorothioate oligothymidylate sequence on a base-labile hydroquinone-*O*,*O*′-diacetic acid linker (Q-linker) and on a photolabile 4-alkoxy-5-methoxy-2-nitrobenzyl carbonate linker (**11**). *H*-Phosphonate **2** was, in turn, incorporated into an oligothymidylate sequence only on the photolabile linker. Kinetics of the removal of the protecting groups by porcine liver esterase and subsequent retro aldol condensation/phosphate elimination were then studied. While the pro-oligonucleotide that contained only one phosphate protection gave the deprotected phosphorothioate oligonucleotide in a quantitative yield, the enzymatic step was markedly decelerated upon increasing the number of protection groups, and hence chain cleavage started to compete.

INTRODUCTION

Antisense oligonucleotides have long been studied as potential chemotherapeutic agents, with which gene expression could be inhibited in a highly selective manner (*1*−*4*). Unfortunately, oligonucleotides as polyanions exhibit only poor cellular uptake. Temporary masking of the negative charges with biodegradable phosphate protections has been suggested to enhance the cytoplasmic transfection (*5*, *6*). A similar approach has given promising results with monomeric nucleotides. The 5′-monophosphates of numerous nucleoside analogues have been protected as bis[(pivaloyloxy)methyl] (*7*), bis{[(isopropoxy)carbonyloxy]methyl} (*8*), bis[2-(acylthio)ethyl] (*9*), [2-(acylthio)ethyl] aryl (*10*), and cyclosaligenyl (*11-15*) triesters, and as cyclic (*16*) or acyclic O,N-disubstituted phosphoramidates (*17-19*). However, at oligonucleotide level only two biodegradable protecting groups have been tested so far, viz. the *S*-acyl-2-thioethyl (*20*−*24*) and acyloxymethyl (*25*) groups. The cellular uptake of *S*-acyl-2-thioethyl protected pro-oligonucleotides (*26*, *27*) and their complete release in cell extracts (*28*) have been verified.

We have recently reported on two novel biodegradable groups that are expected to find applications as temporary protections of internucleosidic phosphorothioate linkages (*29*). Studies with thymidylyl-(3′,5′)-thymidine phosphorothioate bearing an *S*-[2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl] or *O*-[2-cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl] protection have shown that the pivalic acid ester undergoes a carboxyesterase-mediated hydrolysis and the remaining 2,2-disubstituted 3-hydroxypropyl group is readily cleaved by retro aldol condensation and concomitant phosphate elimination (*30*, *31*). We now report on solid-supported synthesis of oligothymidylates and their phosphorothioate analogues bearing internucleosidic *O*-[2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl] or *O*-[2-cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl] protections and on partial success of the removal of these groups by treatment with porcine liver carboxyesterase.

EXPERIMENTAL SECTION

General Methods and Materials. The ^{1}H and ^{31}P NMR spectra were recorded at 400, 500, or 600 MHz. The chemical shifts are given in ppm referenced to internal $SiMe_4$ and external ortophosphoric acid. The mass spectra were recorded by ESI and MALDI ionization.

High-Performance Liquid Chromatography (HPLC). The pro-oligonucleotides prepared were analyzed and purified on an analytical Butyl Hypersil C-4 column (4.6 × 150 mm, 5 μm) using a linear gradient elution from A to B in 40 min (flow rate 1 mL min^{-1}, buffer A = 10 mmol L^{-1} TEAA, buffer B = buffer A containing 65% MeCN).

5′-*O*-(4,4′-Dimethoxytrityl)-(R_P,S_P)-O^P-[2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl]-*P*-thiothymidylyl-(3′,5′)-thymidine 3′-[*O*-(2-cyanoethyl)-(*N*,*N*-diisopropyl)]phosphoramidite (1). To a solution of 5′-*O*-(4,4′-dimethoxytrityl)thymidine 3′-(*N*,*N*,*N*′,*N*′-tetramethylphosphorodiamidite (*29*) (**3**, 2.50 g, 4.59 mmol) in MeCN (10 mL) were added 0.9 equiv of 3′-*O*-(levulinyl)-thymidine (**4**, 1.25 g, 3.76 mmol) and 1.5 equiv of tetrazole (15 mL, 6.89 mmol), and the mixture was agitated for 24 h at room temperature. 2,2-Bis(ethoxycarbonyl)-3-hydroxypropyl pivalate (*29*) (**5a**, 1.12 g, 3.76 mmol) and tetrazole dissolved in MeCN (0.45 mol L^{-1}, 15 mL, 6.75 mmol) were added, and the agitation was continued for 24 h. The phosphite triester was not isolated, but

sulfurization with S_8 (0.60 g, 18.78 mmol) was carried out by allowing the reaction to proceed for 20 h. The reaction was quenched by water (20 mL), a CH_2Cl_2/H_2O workup was performed, the organic phase was dried (Na_2SO_4), and the solvent was evaporated. The residue was purified by column chromatography (silica gel, MeOH/CH_2Cl_2 1:9, *v/v* containing 0.1% Et_3N) to yield 2.68 g (51%) of **6a**. ^{1}H NMR ($CDCl_3$, 600 MHz): 7.57 (m, 1H, *H*6); 7.24−7.41 (m, 10H, 9H of ODMTr, 1H, *H*6); 6.83−6.87 (m, 6H, 4H, of ODMTr, 2H of *H*1′); 5.42 (m, 1H, *H*3′ of the 3′-linked Thy); 4.43−4.61 (m, 5H, *H*′5′, *H*″5′ of the 5′-linked Thy, *H*4′ of the 3′-linked Thy, C*H*$_2$O); 4.12−4.37 (m, 10H, *H*′5′, *H*″5′ of the 3′-linked Thy, *H*4′ of the 5′-linked Thy, C*H*$_2$OPiv, 2 × C*H*$_2$CH$_3$, *H*3′ of the 5′-linked Thy); 3.80 (m, 6H, (*Me*O)$_2$Tr); 3.41−3.52 (m, 2H, COC*H*$_2$); 2.93−3.13 (m, 2H, C*H*$_2$CO); 2.10−2.67 (m, 4H, 2 × *H*′2′, 2 × *H*″2′); 2.19 (s, 3H, COC*H*$_3$); 1.95 (s, 3H, 5-C*H*$_3$); 1.24 (t, 6H, CH$_2$C*H*$_3$); 1.16 (s, 3H, 5-C*H*$_3$); 1.13 (s, 9H, COC(C*H*$_3$)$_3$). ^{31}P NMR ($CDCl_3$, 600 MHz): 67.45, 67.65. MS (ESI) $[M + H]^+$ calcd 1249.0, obsd 1249.6, $[M + Na]^+$ calcd 1271.0, obsd 1271.9.

The levulinyl group was removed by hydrazinium acetate treatment. Accordingly, a solution of **6a** (0.76 g, 0.61 mmol) in 0.5 mol L^{-1} $NH_2NH_2 \cdot H_2O$ Py/AcOH (4:1, *v/v*, 5 mL) was stirred at 0 °C for 1.5 h and at room temperature for 11 h. The reaction was quenched with aq NaH_2PO_4 solution (0.1 mol L^{-1}, 20 mL). The mixture was extracted with CH_2Cl_2, washed with water and dried with Na_2SO_4. The solvent was removed under reduced pressure and the residue was chromatographed on a silica gel column eluting with MeOH/CH_2Cl_2 1:9, *v/v* containing 0.2% Et_3N to obtain **7a** in 77% yield (0.54 g). ^{1}H NMR ($CDCl_3$, 500 MHz): 7.59 (d, $J = 1.0$ Hz, 1H, *H*6); 7.21−7.40 (m, 10H, 9H of ODMTr, 1H, *H*6); 6.83−6.86 (m, 4H, ODMTr); 6.30−6.35 (m, 2H, *H*1′); 5.31 (m, 1H, *H*3′ of the 3′-linked Thy); 4.42−4.57 (m, 5H, *H*′5′,*H*″5′ of the 5′-linked Thy, *H*4′ of the 3′-linked Thy, C*H*$_2$O); 4.12−4.31 (m, 9H, *H*′5′, *H*″5′ of the 3′-linked Thy, *H*4′ of the 5′-linked Thy, C*H*$_2$OPiv, 2 × C*H*$_2$CH$_3$); 4.04 (m, 1H, O*H* of the 5′-linked Thy); 3.79 (m, 6H, (*Me*O)$_2$Tr); 3.44 (m, 1H, *H*3′ of the 5′-linked Thy); 2.11−2.68 (m, 4H, 2 × *H*′2′, 2 × *H*″2′); 1.93 (s, 3H, 5-C*H*$_3$); 1.43 (s, 3H, 5-C*H*$_3$); 1.16 (t, $J = 5.8$ Hz, 6H, CH$_2$C*H*$_3$); 1.13 (s, 9H, COC(C*H*$_3$)$_3$). ^{31}P NMR ($CDCl_3$, 500 MHz): 67.14, 67.64. MS (ESI) $[M + H]^+$ calcd 1151.0, obsd 1151.8, $[M + Na]^+$ calcd 1172.9, obsd 1173.8, $[M + K]^+$ calcd 1189.1, obsd 1189.9.

Dinucleoside triester **7a** was then converted into a phosphoramidite building block (**1**). The phosphitylation was carried out with 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite. 5′-*O*-Protected dinucleoside (0.25 g, 0.22 mmol) was dissolved in 1 mL of dry MeCN, and 90 μL of the diamidite (0.28 mmol) and tetrazole dissolved in MeCN (0.45 mol L^{-1}, 490 μL, 0.22 mmol) were slowly added. The mixture was stirred 3 h at room temperature and evaporated to dryness. The reaction mixture was partitioned between 25 mL $NaHCO_3$ and 25 mL CH_2Cl_2. The organic layer was separated, washed with $NaHCO_3$, and dried with Na_2SO_4, and the solvent was evaporated to obtain **1** as white powder. ^{1}H NMR ($CDCl_3$, 500 MHz): 7.56 (m, 1H, *H*6); 7.24−7.42 (m, 10H, 9H of ODMTr, 1H, *H*6); 6.86 (d, 4H, ODMTr); 6.41 (m, 1H, *H*1′); 6.29 (m, 1H, *H*1′); 5.42 (m, 1H, *H*3′ of the 3′-linked Thy); 4.42−4.63 (m, 5H, *H*′5′,*H*′5′ of the 5′-linked Thy, *H*4′ of the 3′-linked Thy, C*H*$_2$O); 4.12−4.40 (m, 10H, *H*′5′,*H*′5′ of the 3′-linked Thy, *H*4′ of the 5′-linked Thy C*H*$_2$OPiv, 2 × C*H*$_2$CH$_3$, *H*3′ of the 5′-linked Thy); 3.81 (m, 6H, (*Me*O)$_2$Tr); 3.38−3.58 (m, 4H, C*H*$_2$C*H*$_2$CN); 2.76−2.79 (m, 1H, C*H*N); 2.64−2.70 (m, 1H, C*H*N); 2.53−2.60 (m, 1H, *H*′2′); 2.25−2.51 (m, 2H, *H*′2′,*H*″2′); 2.14−2.29 (m, 1H, *H*″2′); 1.93 (m, 3H, 5-CH$_3$); 1.40 (m, 3H, 5-CH$_3$); 1.23−1.32 (t and m, 18H, 2 × CH$_2$C*H*$_3$, 4 × C*H*$_3$CH); 1.17, 1.14 (2s, 9H, COC(C*H*$_3$)$_3$). ^{31}P NMR ($CDCl_3$, 500 MHz): 68.03, 67.83, 67.77, 67.56 (4 s); 149.7, 149.6, 149.3, 149.1 (4 s, phosphoramidite). MS (ESI) $[M + H]^+$ calcd 1285.2, obsd 1285.5.

5′-*O*-(4,4′-Dimethoxytrityl)-(R_P,S_P)-*O*^{P}-[2-cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl]thymidylyl-(3′,5′)-thymidine 3′-(*H*-phosphonate) (2). 5′-*O*-(4,4′-Dimethoxytrityl)thymidine 3′-(*N*,*N*,*N*′,*N*′-tetramethylphosphorodiamidite (*29*) (**3**, 2.00 g, 3.02 mmol), 0.9 equiv of 3′-*O*-(levulinyl)thymidine (**4**, 0.93 g, 2.72 mmol) and 1.5 equiv of tetrazole dissolved in MeCN (0.45 mol L^{-1}, 10 mL, 4.53 mmol) were dissolved in dry MeCN (10 mL). After overnight stirring at room temperature, 2-cyano-3-hydroxy-2-pivaloyloxymethyl-*N*-(2-phenylethyl)propanamide (**5b**) (*29*) (0.89 g, 2.67 mmol) and tetrazole dissolved in MeCN (0.45 mol L^{-1}, 10 mL, 4.53 mmol) were added and the agitation was continued for 25 h. Oxidation with I_2 (2.07 g, 8.15 mmol in THF/H_2O/lutidine 4:2:1, *v/v/v*) was carried out in situ by allowing the reaction proceed for 21 h. The reaction was quenched by 5% aqueous $NaHSO_3$ solution (20 mL), a CH_2Cl_2/aq 5% $NaHSO_3$ workup was performed, the organic phase was dried (Na_2SO_4), and the solvent was evaporated. The residue was chromatographed on a silica gel column (MeOH/CH_2Cl_2 1:99 → 20:80, *v/v* containing 0.1% Et_3N) giving 5′-*O*-(4,4′-dimethoxytrityl)-3′-*O*-levulinyl-(R_P,S_P)-*O*^{P}-[2-cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl]thymidylyl-(3′,5′)-thymidine (**6b**) in a 56% yield (1.9 g). ^{1}H NMR (DMSO-d_6, 400 MHz): 8.61 (m, 1H, CON*H*); 7.09−7.54 (m, 14H, 9H of ODMTr, 5H of *Ph*); 7.01 (s, 1H, *H*6); 6.99 (s, 1H, *H*6); 6.83−6.88 (m, 4H, ODMTr); 6.16−6.28 (m, 2H, *H*1′); 5.17 (m, 1H, *H*3′ of the 3′-linked Thy); 4.35−4.62 (m, 4H, *H*′5′, *H*″5′ of the 3′-linked Thy and C*H*$_2$O); 4.21−4.27 (m, 3H, *H*3′ of the 5′-linked Thy and C*H*$_2$NH); 4.13 (m, 1H, *H*4′ of the 3′-linked Thy); 3.72 [s, 6H, (*Me*O)$_2$Tr]; 3.69 (s, 2H, C*H*$_2$OPiv); 3.20−3.34 (m, 5 H, *H*4′ *H*′5′, *H*″5′ of the 5′-linked Thy, C*H*$_2$-Ph); 2.70 (m, 2H, *H*′2′, *H*″2′ of the 3′-linked Thy); 2.23−2.34 (m, 2H, *H*′2′, *H*″2′ of the 5′-linked Thy); 1.74 (s, 3H, 5-C*H*$_3$); 1.42 (m, 3H, 5-C*H*$_3$); 1.12 (s, 9H, COC(C*H*$_3$)$_3$). ^{31}P NMR (DMSO-d_6, 161.8 MHz): −3.16, −3.09, −2.73, −2.68 (4 s). MS (ESI) $[M - H]^-$ calcd 1260.5, obsd 1260.6; (MALDI) $[M + Na]^+$, calcd 1283.5, obsd 1288.6.

The levulinyl group was removed by dissolving **6b** (1.90 g, 1.51 mmol) in 0.5 mol L^{-1} $NH_2NH_2 \cdot H_2O$ in Py/AcOH (4:1, *v/v*, 10 mL). The mixture was stirred at 0 °C for 1.5 h and at room temperature for 1 h. The reaction was quenched with aq NaH_2PO_4 solution (0.1 mol L^{-1}, 20 mL), and the mixture was subjected to CH_2Cl_2/H_2O workup. The organic phase was dried with Na_2SO_4, and the solvent was removed under reduced pressure. Purification by silica gel chromatography (MeOH/CH_2Cl_2 1:99 → 10:90, *v/v* containing 0.1% Et_3N) afforded 5′-*O*-(4,4′-dimethoxytrityl)-(R_P,S_P)-*O*^{P}-[2-cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl]thymidylyl-(3′,5′)-thymidine (**7b**) in an 85% yield (1.49 g). ^{1}H NMR (DMSO-d_6, 400 MHz): 8.56−8.62 (m, 3H, CON*H*, 2 N1*H*); 7.07−7.54 (m, 14H, 9H of ODMTr, 5H of *Ph*); 7.02 (s, 1H, *H*6); 7.00 (s, 1H, *H*6); 6.83−6.89 (m, 4H, ODMTr); 6.13−6.27 (m, 2H, *H*1′); 5.13 (m, 1H, *H*3′ of the 3′-linked Thy); 4.35−4.48 (m, 4H, *H*′5′,*H*″5′ of the 3′-linked Thy and C*H*$_2$O); 4.19 (m, 3H, *H*3′ of the 5′-linked Thy and C*H*$_2$NH); 3.92 (m, 1H, *H*4′ of the 3′-linked Thy); 3.72 (s, 6H, (*Me*O)$_2$Tr); 3.69 (s, 2H, C*H*$_2$OPiv); 3.17−3.31 (m, 5H, *H*4′, *H*′5′, *H*″5′ of the 5′-linked Thy, C*H*$_2$Ph); 2.69 (m, 2H, *H*′2′, *H*″2′ of the 3′-linked Thy); 2.04−2.09 (m, 2H, *H*′2′, *H*″2′ of the 5′-linked Thy); 1.73 (s, 3H, 5-C*H*$_3$); 1.42 (m, 3H, 5-C*H*$_3$);

1.12 (s, 9H, COC(CH_3)$_3$). ^{31}P NMR (DMSO-d_6, 161.8 Hz): −3.10, −3.01, −2.61, −2.56 (4 s). MS (ESI) [M − H]$^-$ calcd 1162.5, obsd 1162.5; (MALDI) [M + Na]$^+$ calcd 1285.5, obsd 1282.9.

7b was converted to its 3′-(*H*-phosphonate) as follows (*32*). The 5′-*O*-protected dinucleoside phosphoriester (**7b**, 1.49 g, 1.28 mmol) was dissolved in 6.4 mL of 2 mol L^{-1} solution of H_3PO_3 in pyridine (12.8 mmol), and 864 μL of pivaloyl chloride (7.04 mmol) was slowly added. The mixture was stirred overnight at room temperature and after completion quenched with aq TEAB (2 mol L^{-1}, 1 mL). The reaction mixture was partitioned between 75 mL CH_2Cl_2 and 50 mL of 2 mol L^{-1} TEAB. The organic layer was separated and dried with Na_2SO_4, and the solvent was evaporated to obtain the product as white foam. The crude product mixture was purified by silica gel chromatography using MeOH/CH_2Cl_2 (1:9, *v*/*v*, containing 0.2% Et_3N) to elute the product (**2**) in a 44% yield (0.74 g). ^{1}H NMR (acetone-d_6, 500 MHz): 7.24−7.60 (m, 16H, 9H of ODMTr, 5H of *Ph*, 2 *H*6); 6.90 (s, 4H, ODMTr); 6.35 (m, 2H, *H*1′); 5.36 (m, 1H, *H*3′ of the 3′-linked Thy); 4.51 (m, 10H, *H*3′ of the 5′-linked Thy, CH_2-NH, *H*′5′, *H*″5′ of the 3′-linked Thy, CH_2O, *H*4′ of the 3′-linked Thy, *H*′5′, *H*″5′ of the 5′-linked Thy); 3.77 (s, 6H, (*Me*O)$_2$Tr); 3.50 (m, 5H, CH_2OPiv, *H*4′ of the 5′-linked Thy, *H*′2′, *H*″2′ of the 3′-linked Thy); 2.44 − 2.62 (m, CH_2-Ph, *H*′2′, *H*″2′ of the 5′-linked Thy); 1.80 (s, 3H, 5-CH_3); 1.42 (m, 3H, 5-CH_3); 1.19 (s, 9H, COC(CH_3)$_3$). ^{31}P NMR (Acetone-d_6, 161.8 Hz): 0.14 (average, set of signals caused by 3 diastereomeric centers, *H*-phosphonate), −3.04 (average, set of signals caused by 3 diastereomeric centers). MS (MALDI) [M + Na]$^+$ calcd 1226.1, obsd 1222.7.

Synthesis of 2,2-Bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl-Protected Oligodeoxyribonucleotide Phosphorothioates on a CPG-Q-Thymidine Support. The oligonucleotide phosphorothioates bearing one or two 2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl groups were assembled on an Applied Biosystems 3400 DNA synthesizer on a 1.0 μmol scale using 500 Å CPG-Q-thymidine support and phosphoramidite chemistry. The phosphoramidite building block **1** was used as a 0.15 mol L^{-1} solution, the coupling time being 600 s. For thymidine 3′-phosphoramidite the coupling time was 60 s. Based on the DMTr-cation report of the synthesizer, 95, 96, and 97% average coupling efficiencies were obtained for pro-oligonucleotides **8**, **9**, and **10**, respectively. The internucleosidic phosphorothioate linkages were generated using 3*H*-1,2-benzodithiole-3-one-1,1-dioxide (*33*) as an oxidant (0.1 mol L^{-1} in MeCN, 420 s). The removal of the 2-cyanoethyl phosphate protecting groups was carried out by DBU treatment (1.5% in dry MeCN, 30 min), and the cleavage of oligonucleotides (**8**, **9** and **10**) from the support was performed using K_2CO_3 (0.05 mol L^{-1}, MeOH, rt, 1 min). Finally, the desired sequences were purified by RP HPLC (Butyl Hypersil, 150 × 4.6 mm, 5μm) with gradient solvent system (from A to B in 40 min, A: 10 mmol L^{-1} TEAA, B:10 mmol L^{-1} TEAA, 65% MeCN, flow rate 1 mL/min) and identified by ESI-MS. Observed masses (**8**): *m/z* 1384.37 [M − 2H]$^{2-}$, 922.28 [M − 3H]$^{3-}$, 691.45 [M − 4H]$^{4-}$ calculated masses: 1384.66, 922.77, 691.82, respectively. Observed masses (**9**): *m/z* 2007.12 [M − 2H]$^{2-}$, 1338.73 [M − 3H]$^{3-}$, 1003.33 [M − 4H]$^{4-}$ 802.84 [M − 5H]$^{5-}$ calculated mass: *m/z* 2007.61, 1338.07, 1003.30, 802.44, respectively. Observed masses (**10**): *m/z* 1444.64 [M − 3H]$^{3-}$, 1083.25 [M − 4H]$^{4-}$, 866.74 [M − 5H]$^{5-}$, 721.80 [M − 6H]$^{6-}$, 618.55 [M − 7H]$^{7-}$, 541.12 [M − 8H]$^{8-}$ calculated mass: *m/z* 1444.97, 1083.47, 866.58, 721.98, 618.70, 541.23, respectively.

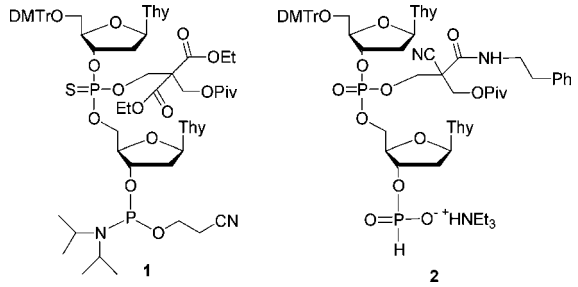
Pro-oligodeoxyribonucleotide Synthesis on Photolabile Support 11. Commercially available Tentagel resin (Novabiochem, 250 mg, 0.07 mmol) bearing a photolabile 5-(4-hydroxymethyl-6-methoxy-3-nitrophenoxy)butanoyl linker (*34-38*) was suspended in CH_2Cl_2 (2 mL), and 10 equiv of *N*-methylmorpholine (77 μL) and *p*-nitrophenyl chloroformate (10 equiv, 141 mg, 0.70 mmol) were added at 0 °C. The suspension was shaken overnight, and the resin was then washed on filter with CH_2Cl_2 and Et_2O and finally dried under diminished pressure for 30 min. To a suspension of the activated support in DMF (2 mL) were added 10 equiv of 5′-*O*-(4,4′-dimethoxytrityl)thymidine (385 mg, 0.70 mmol) and 2 equiv of DMAP (1.4 mmol, 17 mg), and the mixture was shaken overnight. The resin was washed on the filter with DMF, CH_2Cl_2, and MeOH. The unreacted, active carbonate groups were deactivated with MeOH (1 mL) in DMF (2 mL) in the presence of catalytic amount of DMAP. Since this treatment reduces also the loading by cleaving the carbonate bonds, no longer than 45 min reaction time at RT was used. After this deactivation, the remained OH-groups of the support were finally capped by treating the support with a mixture of Ac_2O, lutidine, *N*-methylimidazole, and THF (5:5:8:132, *v*/*v*/*v*/*v*) for 15 min. The support was washed on filter with DMF, CH_2Cl_2, and MeOH and dried under vacuum. A loading of 170 μmol g^{-1}, determined by the standard dimethoxytrityl cation assay (*39*), was obtained.

The protected oligonucleotide **12** was assembled on an Applied Biosystems 392 DNA synthesizer in a 1.0 μmol scale using support **11** and the *H*-phosphonate chemistry. The *H*-phosphonate protocol was generated for the Applied Biosystems 392 DNA synthesizer on the basis of previous reports (*40*,*41*). The *H*-phosphonate building block (**2**) was used as a 50 mmol L^{-1} solution in dry Py/MeCN (1:3, *v*/*v*), the coupling time being 240−300 s. The monomeric thymidine 3′-(*H*-phosphonate) was used as a 30 mmol L^{-1} solution in dry Py/MeCN (1:3, *v*/*v*), the coupling time being 30−60 s. Pivaloyl chloride was used as an activator (120 mmol L^{-1} Py/MeCN 1:3, *v*/*v* solution). Despite the prolonged coupling time used for **2**, the coupling yield of this block remained surprisingly low, below 80%. The support-bound material was treated with I_2 (0.1 M, Py/H_2O, 98:2, *v*/*v*) at RT for 30 min, washed with MeCN and MeOH, and dried on the filter. The supports were exposed to light at 20 °C (Hg-lamp, 250 W) for 26 h to release the desired pro-oligonucleotide (MeOH/H_2O, 1:9, *v*/*v*, 2 mL). After the solvent evaporation, the product mixture was dissolved in water and purified by RP HPLC (Butyl Hypersil, 150 × 4.6 mm, 5 μm) using gradient elution (from A to B in 40 min, A: 10 mmol L^{-1} TEAA, B:10 mmol L^{-1} TEAA, 65% MeCN, flow rate = 1 mL/min). Fractions were identified with ESI-MS and the desired sequence was further purified to yield **12** as a diastereomeric mixture. Observed masses (**12**): *m/z* 1499.64 [M − 2H]$^{2-}$, 999.77 [M − 3H]$^{3-}$, 749.83 [M − 4H]$^{4-}$, 599.86 [M − 5H]$^{5-}$ calculated masses: *m/z* 1499.04, 999.02, 749.01, 599.01, respectively.

The synthesis of **8** was also carried out on support **11** applying the phosphoramidite chemistry and similar methods as described above for the synthesis on the Q-linker. Observed masses (**8**): *m/z* 1384.96 [M − 2H]$^{2-}$, 922.30 [M − 3H]$^{3-}$, 691.73 [M − 4H]$^{4-}$ calculated masses: *m/z* 1384.66, 922.77, 691.82, respectively.

Enzymatic Hydrolysis. The pivaloyl groups were removed from oligonucleotides **8**, **9**, **10**, and **12** with porcine liver esterase (PLE, Sigma) in HEPES buffer

Chart 1. Synthesized Building Blocks 1 and 2



(0.01/0.01 mol L^{-1}) at pH 7.5, $t = 25$ °C, $I = 0.1$ mol L^{-1} (NaCl). To start the enzymatic cleavage, 0.33 mg of the PLE enzyme as an aqueous solution (1.5 μL, 4.8 units) was dissolved in 300 μL of the HEPES buffer and 3 OD (90 μg, 38 nmol) of the protected oligonucleotide was added. Aliquots of 20 μL were withdrawn at appropriate intervals, made acidic (pH 2) with aqueous hydrochloride, and cooled on an ice-bath. The samples were analyzed immediately by HPLC on a Butyl Hypersil column eluted with triethylammonium acetate buffer (0.01 mol L^{-1}, pH = 7.0) containing MeCN (0−65%, *v*/*v*).

RESULTS AND DISCUSSION

Synthesis of the Building Blocks. Chart 1 shows the two building blocks used to assemble the pro-oligonucleotides. The phosphoramidite building block **1** was obtained by replacing the dimethylamino ligands from tris(dimethylamino)phosphine one after another with 5′-*O*-(4,4′-dimethoxytrityl)thymidine (**3**), 3′-*O*-levulinylthymidine (**4**), and 2,2-bis(ethoxycarbonyl)-3-hydroxypropyl pivalate **5a** (*29*), using MeCN as a solvent and tetrazole as an activator (Scheme 1). The resulting phosphite ester was sulfurized with S_8 to phosphoromonothioate **6a** and the 3′-levulinyl protection was removed to obtain **7a**. The exposed 3′-hydroxy function was finally phosphitylated with 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite to obtain **1**.

Building block **2** was prepared in an analogous manner (Scheme 1). 2-Cyano-3-hydroxy-2-(pivaloyloxymethyl)-*N*-(2-phenylethyl)propanamide (**5b**) (*29*) was used to create the biodegradable moiety. Oxidation with I_2 gave phosphotriester **6b**, which after removal of the levulinyl protection (**7b**) was converted by a standard procedure to *H*-phosphonate triethylammonium salt **2**. Reverse phase HPLC analysis showed the presence of two isomers, in all likehood the R_P and S_P stereoisomers of the phosphate triester.

Synthesis of Oligodeoxyribonucleotides Bearing 2,2-Bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl Groups (8, 9, 10). The internucleosidic phosphotriester groups of 2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl protected oligonucleotides, as well as the ester linkages of the protecting group itself, may be expected to be susceptible to nucleophiles (*29*). For this reason, these oligonucleotides were assembled on a hydroquinone-*O*,*O*′-diacetic acid linker (Q-linker) that is considerably more base labile than the conventional succinyl linker (*42*). The 2-cyanoethyl protections were removed from the phosphate groups by weakly nucleophilic DBU in an inert solvent (*22*) instead of ammonolysis.

A T_6-sequence containing the dimeric phosphotriester block **1** at the 5′-end of the chain was first assembled on a CPG-Q-thymidine support to test the coupling efficiency of **1** and the applicability of the developed protocol. The standard phosphoramidite protocol for phosphorothioates was applied, except that prolonged coupling times, 60s and 600s, were used for the thymidine 3′-phosphoramidite and the dimeric building block **1**, respectively. Additionally, a 0.1 mol L^{-1} solution of 3*H*-1,2-benzodithiol-3-one 1,1-dioxide and a waiting step of 420 s were used for sulfurization. On the basis of the DMTr-cation report given by the synthesizer, an acceptable 95% coupling efficiency was obtained. The cyanoethyl groups were removed by 30 min treatment with 1.5% DBU in dry acetonitrile (*22*). Standard potassium carbonate treatment (0.05 mol L^{-1} K_2CO_3 in methanol, 1 min) released the pro-oligonucleotide **8** (Figure 1). No signs of hydrolysis or degradation products were observed during either of these treatments. The crude pro-oligonucleotide **8** was purified by RP HPLC (see Figure 1 and Table 1).

Longer T-sequences (**9**, **10** Figure 2) containing two building blocks **1** either in the central part of the chain (**9**) or close to the ends of chain (**10**), were then synthesized in a similar manner on a CPG-Q-thymidine support. The average coupling yields were 96% (**9**) and 97% (**10**). The crude pro-oligonucleotides **9** and **10** were purified by RP HPLC (see Figure 2 and Table 1). The authenticity of pro-oligonucleotides **8**, **9** and **10** was verified by ESI-MS.

[a] RP HPLC; for detailed chromatographic conditions, see Experimental Section. [b] Percentage of the pro-oligonucleotide in the crude reaction mixture on the basis of the HPLC peak areas.

The synthesis of pro-oligonucleotide **8** was also attempted on the Tentagel-immobilized photolabile linker (**11** Chart 2) described below. The overall yield of the synthesis was 67%, and the sulfurization was not complete. Accordingly, the CPG-Q-support turned out to be superior to the **11** for the present purpose.

Synthesis of the Oligodeoxyribonucleotides Bearing 2-Cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl Groups. It has been shown previously (*29*) that *O*-[2-cyano-2-(2-phenylethylaminocarbonyl)-3-pivaloyloxypropyl] group is readily cleaved from internucleosidic phosphorothioate linkage under basic conditions. At pH 12, the half-life of this reaction is about 5 min. The cleavage proceeds by retention of configuration around the phosphorus atom, probably by formation of a β-lactam by intramolecular attack of the deprotonated amide nitrogen on the phosphate bound carbon. To avoid basic conditions, oligonucleotide **12** bearing this protecting group was assembled on photolabile linker **11** (Chart 2) by the *H*-phosphonate chemistry. A prolonged coupling time (240−300 s) was used for building block **2**. An 8-mer sequence containing two phosphotriester blocks (**12**, Figure 3) was assembled. The concentration of the dimeric building block (**2**) was 50 mmol L^{-1} and that of the activator 120 mmol L^{-1}. The oxidation was performed by 30 min treatment with 0.1 mol L^{-1} I_2 in Py/H_2O (98:2, *v*/*v*) solution. The resin suspended in MeOH/H_2O solution (1:9, *v*/*v*, 2 mL) was then exposed to the light filtered with a Pyrex glass for 26 h at 20 °C (Hg-lamp, 250 W) to release the crude pro-oligonucleotide. The cleavage was monitored by analyzing the aliquots of the solution by reversed-phase HPLC. No sign of photodimer formation between thymidine residues was observed. RP HPLC analysis of the crude product mixture showed the desired sequence to be the main product. The crude pro-oligonucleotide **12** was purified by RP HPLC (see Figure 3 and Table 1) and it was identified by ESI-MS.

Enzymatic Hydrolysis of the Pro-oligonucleotides. The pro-oligonucleotides prepared (**8**, **9**, **10**, **12**) were treated with porcine liver esterase (PLE) to demonstrate that both 2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl and 2-(phenylethylaminocarbonyl)-2-cyano-3-pivaloyloxypropyl protecting groups could really be removed by a reaction trigged by enzymatic hydrolysis of the pivalic ester moiety and that the desired T-sequence is released. During the enzymatic hydrolysis of **8**, accumulation of an intermediate was observed by HPLC analysis. In all likehood this intermediate is the oligo-

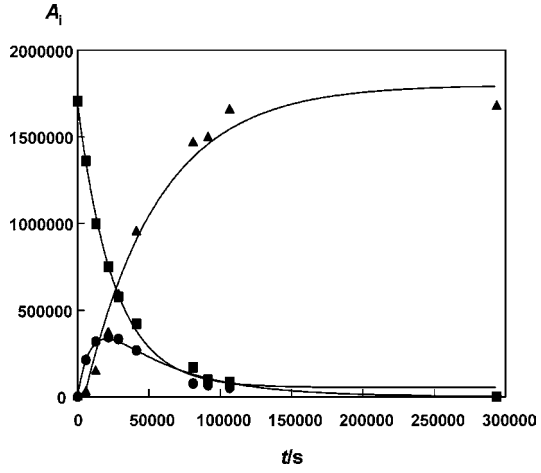

Figure 4. Time-dependent product distribution for the PLE-trigged deprotection of pro-oligonucleotide **8.** A_i is the peak area in the HPLC chromatogram for the enzymatic hydrolysis of **8** in 0.02 mol L^{-1} HEPES buffer at pH 7.5 and 25 °C. The ionic strength was adjusted to 0.1 mol L^{-1} with NaCl. [Notation: **8** (■), intermediate (●) and T_8 (▲)].

nucleotide triester having the pivaloyloxy group hydrolyzed to a hydroxyl function. The data obtained from the enzymatic hydrolysis of **8** is given as an illustrative example in Figure 4. The situation is very similar to the previously reported PLE-triggered deprotection of thymidylyl-(3′,5′)-thymidine phosphorothioate bearing the same protecting group on the sulfur atom (*29*). The intermediate was finally converted quantitatively to T_8-phosphorothioate, which was identified by ESI-MS analysis and spiking with an authentic sample. The rate of the PLE-triggered deprotection was relatively slow; a complete release of phosphorothioate was observed in 30 h.

Pro-oligonucleotide **9** bearing two biodegradable 2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl groups was also subjected to carboxyesterase-mediated hydrolysis, and again HPLC analysis revealed accumulation of an intermediate. However, the deprotection was found to be much slower than with **8**. Consequently, a prolonged treatment with PLE resulted in partial degradation of the phosphorothioate backbone concurrent with release of the deprotected oligomer. Since the distance between the two

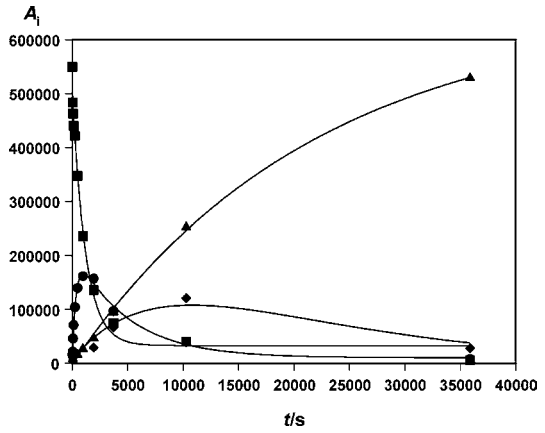

Figure 5. Time-dependent product distribution of the PLE-triggered deprotection of pro-oligonucleotide **12**. A_i is the peak area in the HPLC chromatogram for the enzymatic hydrolysis of **12** in 0.02 mol L^{-1} HEPES buffer at pH 7.5 and 25 °C. The ionic strength was adjusted to 0.1 mol L^{-1} with NaCl. [Notation: **12** (■), intermediates (● and ◆) and thymidine (▲)].

protecting groups could play a role, a 12-mer bearing two 2,2-bis(ethoxycarbonyl)-3-(pivaloyloxy)propyl groups (**10**) apart from each other was prepared and subjected to PLE triggered hydrolysis. The deprotection was now faster than with **9** and accumulation of the desired full-length phosphorothioate could be verified by spiking. However, also with this pro-oligonucleotide the chain cleavage to a marked extent competed with the removal of the phosphate protections.

Pro-oligonucleotide **12**, bearing two 2-cyano-2-(2-phenylethylaminocarbonyl)-3-(pivaloyloxy)propyl groups initially behaved similarly: intermediates exhibiting HPLC signals at a shorter retention time than the starting material appeared (Figure 5). These intermediates were, however, finally converted not to T_8, as expected, but to thymidine. In other words, the enzyme employed quite readily cleaved the phosphodiester bonds, although it did not cleave phophorothioate linkages of **8**. When the PLE-mediated hydrolysis of unmodified T_8 in water was followed with RP HPLC, it turned out that within 1 day T_8 was completely hydrolyzed to thymidine.

CONCLUDING REMARKS

Pro-oligonucleotides containing two different biodegradable protecting groups have been prepared, and their carboxyesterase-mediated hydrolysis has been studied. Both protecting groups contain a pivalic ester moiety in their structure. Hydrolysis of this ester linkage by porcine liver esterase (PLE) triggers a retroaldol condensation/phosphate elimination reaction that releases the oligonucleotide. Treatment of a pro-oligonucleotide bearing one 2,2-bis(ethoxycarbonyl)-3-pivaloyloxypropyl group (**8**) with porcine liver esterase released the phosphorothioate T_8 in an intact form. Presence of more than one such protection (**9**, **10**), however, markedly retarded the enzymatic deprotection, and hence the phosphorothioate backbone was partially degraded concurrent with release of the deprotected oligomer. In vivo experiments are needed to find out whether the situation is the same with intracellular esterases. Oligonucleotides bearing the 2-cyano-2-(2-phenylethylaminocarbonyl)-3-pivaloyloxypropyl groups were not phosphorothioates, and hence enzymatic hydrolysis to thymidine took place concurrent with the cleavage of the protecting groups. The attractive feature of the present protecting groups is that they allow temporary attachment of conjugate groups to the oligonucleotide backbone, since the ethoxy and 2-phenylethyl-

amino groups in their structure may in all likelihood be replaced by other conjugate groups. Hence, both of these groups appear as viable candidates for biodegradable linkers through which various conjugate groups facilitating the cellular uptake could be attached.

Accelerated Bioorthogonal Conjugation: A Practical Method for the Ligation of Diverse Functional Molecules to a Polyvalent Virus Scaffold

Sayam Sen Gupta,[†] Jane Kuzelka,[†] Pratik Singh,[‡] Warren G. Lewis,[†] Marianne Manchester,[‡] and M. G. Finn*,[†]

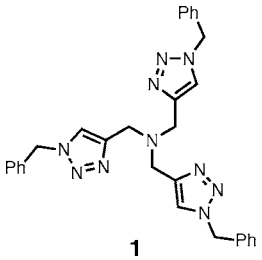
Department of Chemistry and The Skaggs Institute for Chemical Biology, and Department of Cell Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037. Received May 23, 2005; Revised Manuscript Received August 12, 2005

Covalent bond formation to proteins is made difficult by their multiple unprotected functional groups and normally low concentrations. A water-soluble sulfonated bathophenanthroline ligand (**2**) was used to promote a highly efficient Cu^{I}-mediated azide−alkyne cycloaddition (CuAAC) reaction for the chemoselective attachment of biologically relevant molecules to cowpea mosaic virus (CPMV). The ligated substrates included complex sugars, peptides, poly(ethylene oxide) polymers, and the iron carrier protein transferrin, with routine success even for cases that were previously resistant to azide−alkyne coupling using the conventional ligand tris(triazolyl)amine (**1**). The use of 4−6 equiv of substrate was sufficient to achieve loadings of 60−115 molecules/virion in yields of 60−85%. Although it is sensitive to oxygen, the reliably efficient performance of the Cu·**2** system makes it a useful tool for demanding bioconjugation applications.

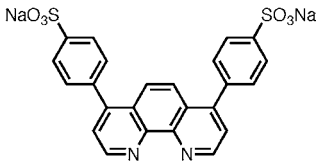
INTRODUCTION

Chemoselective ligation, a process whereby unprotected molecular fragments couple through uniquely complementary reactive functional groups, is a powerful technique for bioconjugation (*1*, *2*). The azide group in particular has emerged as a very useful chemical handle for this purpose, participating in the Staudinger ligation with phosphines (*1*) as well as the [3 + 2] cycloaddition reaction with strained (*3*) and terminal (*4*) alkynes. Under the influence of copper(I) catalysis (*4*), the latter process has permitted the selective modification of virus particles (*5*, *6*), enzymes (*7*), cells (*8*), and proteins from complex tissue lysates (*9*). The unreactive nature of both azides and alkynes with the functional groups of biomolecules, as well as their small size and therefore unobtrusive presence when appended to enzymatic substrates, makes improved methods for their ligation of interest for a wide range of biomolecular applications.

The successful execution of the Cu-catalyzed azide−alkyne cycloaddition (CuAAC) reaction at mild temperatures and low concentrations requires the presence of a copper-binding ligand. The ligand must accelerate the reaction, maintain the +1 oxidation state of the metal, and preserve the integrity of the biological scaffold by sequestering the copper ions away from proteins and polynucleotides. To this end, tris(triazolyl)amine ligand (**1**) (*10*) has been utilized for the conjugation of a variety of molecules to protein surfaces. Although **1** strongly accelerates the CuAAC process when the reaction is homogeneous, the ligand is not very soluble in water, and there have been some indications that proteins may be damaged if insufficient amounts of the ligand are available in solution (*3*). Most importantly, the reaction in water in the presence of **1** is too slow to eliminate the need for large excesses of substrate, on the same order of concentrations as are needed for the more conventional reactions of cysteine residues with maleimides. In other words, bioconjugation reactions catalyzed by Cu·**1** are too demanding of precious or expensive coupling partners to be routinely useful for preparative applications.



1



2

For several years, we have developed the use of icosahedral virus particles as chemical building blocks for studying the role of polyvalency in diagnostic and therapeutic applications (*11*, *12*). As a prototypical scaffold, we have employed cowpea mosaic virus (CPMV), which is a stable and crystallographically characterized particle available in large quantities. The range of target functions is broad, requiring the attachment of such structures as carbohydrates, peptides, organic polymers, and proteins. A single common attachment methodology would greatly assist synthetic access to diverse particles. However, the aforementioned deficiencies of the Cu·**1** system constrained our initial efforts to obtain such materials in relatively large amounts. We describe here an improved procedure for the CuAAC process that makes it a truly general method for polyvalent scaffold decoration and, by extension, for the creation of functionalized surfaces of almost any kind. Importantly, this

system permits the chemoselective bioconjugation of molecules that were hitherto unreactive to azide−alkyne coupling.

EXPERIMENTAL PROCEDURES

Materials. Fluorescein-PEG-NHS-3400 (NHS = *N*-hydroxysuccinimide) was obtained from Nektar (Huntsville, AL). The water-soluble sulfonated bathophenanthroline ligand **2** was purchased from GFS. Human holotransferrinn (98%) was supplied by Sigma. The resins Fmoc-Phe-Wang (0.77 mmol/g, 100−200 mesh) and Fmoc-Lys(Boc)-Wang (0.12 mmol/g, 100−200 mesh), as well as other Fmoc-protected amino acids were purchased from Chem-Impex International. Compounds **5** (*13*), **6** (*13*), and $[Cu(MeCN)_4](OTf)$ (*14*) were prepared as previously described; **7a** and **8a** were provided by the Consortium for Functional Glycomics at The Scripps Research Institute. CPMV−alkyne and −azide conjugates **3** and **4** were prepared as previously described (*13*) using purified NHS esters of the acid-bearing linkers. Fmoc-L-propargylglycine was purchased from CSPS (San Diego, CA). All other chemical reagents were obtained from commercial suppliers and used as received, unless indicated otherwise.

Instrumentation. Air-sensitive manipulations were performed under nitrogen in a Vacuum Atmospheres glovebox. Preparative HPLC was performed with a Dynamax/Rainin Preppy SD-1 instrument and a Vydac protein and peptide reverse phase column, eluting with a gradient solvent mixture (solvent A = H_2O/0.1% TFA; solvent B = CH_3CN/0.1% TFA). MALDI-TOF analyses were performed by the Mass Spectrometry Facility at The Scripps Research Institute. FPLC analyses were performed on an AKTA Explorer (Amersham Pharmacia Biotech) equipped with a Superose-6 size exclusion column. Samples for transmission electron microscopy (TEM) were obtained by deposition of 20 μL sample aliquots onto 100-mesh carbon-coated copper grids, followed by staining with 20 μL of 2% uranyl acetate. Images were obtained using a Philips CM100 electron microscope.

Modification of CPMV with NHS Esters. Reagents were introduced into a solution of CPMV, such that the final mixture contained ≤20% DMSO. Unless otherwise specified, the buffer used was 0.1 M phosphate, pH 7.0. Purification of derivatized virus (>1 mg) was performed by ultracentrifugation over a 10−40% sucrose gradient, pelleting of the recovered virus, and dissolution of the resulting material in Tris buffer (0.1 M, pH 8). Mass recoveries of derivatized viruses were typically 60−80%; all such samples were composed of >95% intact particles as determined by analytical size-exclusion FPLC. Virus concentrations were measured by absorbance at 260 nm; virus at 0.10 mg/mL gives a standard absorbance of 0.80. Fluorescein concentrations were obtained by measurement of absorbance at 495 nm, applying an extinction coefficient of 70 000 M^{-1} cm^{-1}. Each data point is the average of values obtained from three independent parallel reactions; loading values (the number of substrate molecules attached to the virus) are subject to an experimental error of ±10%. The average molecular weight of the CPMV virion is 5.6×10^6 g/mol.

Compounds 7b and 8b. To a solution of **7a** (10 mg, 12.4 μmol) in H_2O (1 mL) was added **9** (70 mg, 0.125 mmol) in THF (1 mL). *t*-BuOH (1 mL) was added, followed by sodium ascorbate (0.5 M in H_2O, 72 μL, 36 μmol) and $CuSO_4$ (0.5 M in H_2O, 24 μL, 12 μmol). The reaction mixture was stirred in a closed vial for 48 h at room temperature, followed by removal of the volatile solvents by rotary evaporation and addition of 5 mL of H_2O. Excess **9** was largely removed by extraction with EtOAc. The reaction was monitored by TLC (R_f = 0.6 in 8:3:3:2 EtOAc/MeOH/AcOH/H_2O,) as well as by disappearance of the azide peak (2100 cm^{-1}) using FT-IR spectroscopy. The aqueous phase was concentrated by evaporation and residual **9** was removed by column chromatography (Sephadex G-15, 95:5 H_2O/BuOH), giving a yellow solid (11 mg, 65% yield) upon lyophilization of the collected fraction. MALDI-TOF: $[M + H]^+ = 1361$, $[M + Na]^+ = 1383$, $[M + K]^+ = 1399$. Compound **8b** was synthesized in 55% yield from **8a** using the same procedure. MALDI-TOF: $[M + Na]^+ = 1472$, $[M + K]^+ = 1488$.

Compound 9. A mixture of fluorescein amine (1.57 g, 4.54 mmol) and sodium bicarbonate (1.57 g, 1.87 mmol) in dry THF (30 Ml) was cooled in an ice bath and stirred under N_2 for 15 min. 3,5-Bis-prop-2-ynyloxy-benzoyl chloride (1.15 g, 4.99 mmol) in dry THF (30 mL) was added dropwise and the mixture was stirred overnight at room temperature. The solid bicarbonate was removed by filtration, and the solvent was evaporated to give **4** as an orange solid, which was purified by column chromatography (silica gel, 95:5 EtOAc/MeOH). ^1H NMR (CD_3OD, δ) 8.4 (s, 1H), 8.2 (d, 2H), 7.3 (m, 3H), 6.8−7 (m, 3H), 6.6−6.8 (m, 4H), 4.8 (d, 4H) (s, 6 H), 3.1 (t, 2H). ESI-MS *m/z* = 560.1 (MH^+); UV−vis (0.1 M phosphate, pH 7) λ_{max} 494 nm, ϵ = 64 000.

Peptides 10 and 11. Compound **10** was prepared by standard techniques of solid-phase Fmoc peptide synthesis using 0.2 mmol of Fmoc-Phe-Wang resin. Coupling of Fmoc-L-propargylglycine was performed as reported elsewhere (*15*). Conjugation of fluorescein to the N-terminus of the peptide chain was accomplished by addition of a DMF/*i*Pr_2Net (2:1 v/v) solution containing 5(6)-carboxyfluorescein (414 mg, 1.1 mmol) and HBTU (417 mg, 1.1 mmol) to the drained resin. The mixture was agitated overnight and purified by reverse phase HPLC after cleavage from the resin. MALDI-TOF: $[M + H]^+ = 1579$. Peptide **11** was obtained from the analogous procedure using 0.1 mmol of Fmoc-Lys(Boc)-Wang resin. MALDI-TOF: $[M + H]^+ = 1571$, $[M + Na]^+ = 1593$.

Polymer 12. A toluene solution of 3-azido-1-propylamine (0.66 M, 334 μL, 0.22 mmol) was added to a solution of fluorescein-PEG-NHS-3400 (150 mg, 0.044 mmol) in dry CH_2Cl_2 (5 mL). The mixture was stirred overnight, followed by removal of the solvents under reduced pressure. H_2O (10 mL) was added and the solution was extracted with EtOAc to remove the excess azide compound. The aqueous solution was lyophilized to afford **12** as a yellow powder (135 mg, 90% yield).

Polymer 13. To a solution of fluorescein-PEG-NHS-3400 (150 mg, 0.044 mmol) in dry CH_2Cl_2 (5 mL) was added propargylamine (12.1 mg, 0.22 mmol). The mixture was stirred overnight and worked up as described for **12**. Compound **13** was isolated as a yellow powder (135 mg, 90% yield).

Transferrin−Alkyne Conjugate 14. To human holotransferrin (50 mg, 0.625 μmol) in phosphate buffer (0.1 M, pH 7, 2 mL) was added *N*-(*N*-(prop-2-ynyl)hexanamidyl)maleimide (3.9 mg, 9.1 μmol) in DMSO (500 μL), and the mixture was incubated overnight at room temperature. Purification through a G-15 Sephadex coloumn followed by dialysis and lyophilization afforded **14** as a pink powder (30 mg).

Modification of CPMV by CuAAC Reaction. CPMV conjugate **3** or **4** (1 mg as a 2 mg/mL solution) was incubated with complementary azide or alkyne compound (concentrations given in Table 1) in Tris buffer (0.1 M, pH 8, 0.5 mL) containing **2** (3 mM) and $[Cu(MeCN)_4](OTf)$

Scheme 1

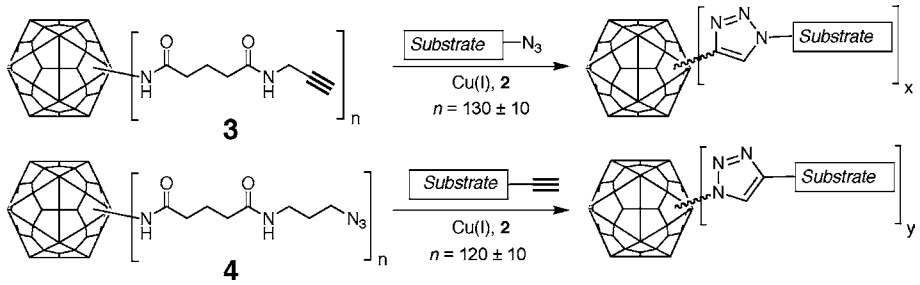

Table 1. Azide−Alkyne Cycloaddition on CPMV[a] with Various Substrates

entry	substrate	CPMV derivative	[substrate] (μM)	loading	yield (%)
1	7b	4	200	115	85
2	8b	4	200	105	85
3	10	4	120	60	85
4	11	4	250	115	80
5	12	3	500	60	60
6	13	4	250	90	75
7	14	4	260	*b*	*b*

[a] 2 mg/mL; 47 μM in alkyne for **3**, 43 μM in azide for **4**. [b] not determined.

(1 mM) for 12 h at room temperature with rigorous exclusion of dioxygen. CPMV−**12**, CPMV−**13**, and CPMV−**14** conjugates were purified by sucrose gradients and pelleting as described above. All other CPMV conjugates were purified by size exclusion chromatography using Bio-Spin disposable chromatography columns filled with Bio-Gel P-100 as described elsewhere (*16*).

RESULTS AND DISCUSSION

Optimization of Reaction Conditions. Our recent discovery of sulfonated bathophenanthroline **2** as a highly efficient ligand in a fluorescence quenching catalysis assay (*17*) prompted us to further investigate **2** for the coupling of compounds to suitably derivatized CPMV particles. The viral capsids were labeled with alkynes (**3**) or azides (**4**) at surface-exposed lysine residues using standard NHS ester chemistry (Scheme 1) (*5*). Initial experiments were performed using functionalized fluorescein dyes as substrates because the success of the bioconjugation could be readily monitored using UV−vis spectroscopy. Thus, fluorescein derivatives **5** and **6** (Figure 1) (*5*) were condensed with **3** and **4**, respectively, in the presence of Cu·**2** in Tris buffer (pH 8) under inert atmosphere, to give CPMV−dye conjugates with good loading in a concentration-dependent fashion. In all cases, the reaction yield (the percent of virus recovered after purification of protein away from small molecules) and purity (intact virus particles vs disassembled viral protein) was high. Thus, >85% of the protein was recovered in each case, and size-exclusion FPLC indicated that >95% of the virons were intact particles (*18*). SDS−PAGE analysis visualized under ultraviolet light revealed two dye-labeled bands corresponding to the small and large subunits of CPMV, indicating that both subunits of the virus were chemically modified (data not shown). No attachment was found to occur in the absence of Cu^{I}, ruling out nonspecific adsorption of dye to virus. It should also be noted that the use of phosphate buffer diminishes the effectiveness of the reaction, while HEPES buffer is at least as good or better than Tris.

The dependence of the observed loading (dye attachments per virion) on substrate concentration is shown in Figure 2. Upon treatment of 2 mg/mL **4** (0.36 μM in virus particles) with 200 μM **6**, corresponding to a 5-fold molar excess with respect to azide groups on **4**, the CPMV particles were found to be fully labeled (in other words, all of the attached azide groups converted to triazoles, approximately 110 per particle). Similar results were obtained with **3** + **5**. In contrast, the use of ligand **1** under otherwise identical conditions required a 5 mM concentration of **6** (250 equiv) to achieve such dye loadings. Furthermore, the reaction of opposite "polarity" (**3** + **5**) mediated by Cu·**1** was significantly worse than **4** + **6**.

The same results with each ligand were obtained using $[Cu(MeCN)_4](OTf)$, $[Cu(MeCN)_4](PF_6)$, or CuBr as the source of Cu^{I}. The optimal copper concentration was found to be 1 mM; lower concentrations significantly decreased the coupling efficiency. The ligand-to-metal ratio is also important. A 3:1 ratio of **2** to Cu^{I} afforded the best results; a lower ratio resulted in significant degradation of the viral capsid, whereas a larger excess of ligand slowed the reaction to provide incomplete labeling. The efficiency of the Cu·**2** mediated AAC process thereby far exceeds that of standard NHS and maleimide coupling reactions with lysine and cysteine side chains, respectively. For example, the addition of a 10-fold excess of fluorescein NHS ester to CPMV under similar conditions results in the attachment of approximately 20 dyes to each capsid (*19*), and fluorescein maleimide deposits between 10 and 25 dye molecules on CPMV mutants bearing surface cysteine residues, depending on the local environment of the sulfhydryl groups (*20*). While the linker used to attach azides and alkynes to CPMV may make these groups more accessible than the lysine or cysteine side chains of native and mutant forms of the particle, we believe that the differences will be small given the highly solvent-exposed nature of many of the surface peptide residues.

Preparation of CPMV−Carbohydrate Conjugates. With the optimal reaction conditions thus established, biologically relevant substrates were attached to the CPMV capsid as shown in Figure 1 and Table 1. Carbohydrate **7a** binds the protein galectin-4, an early marker of breast cancer cells (*21*). Sialyl Lewis X, an azide derivative of which is **8a**, is overexpressed on cancer cells and also plays a role in inflammation (*22*). We envisioned that the attachment of these two compounds to the surface of a virus particle could be useful for drug targeting, as well as for the elusive goal of antibody production against carbohydrate epitopes (*23*). To allow for ready quantitation of the attachment of these nonfluorescent compounds, the azides were subjected to a CuAAC reaction with fluorescein dialkyne reagent **9** to provide dye−alkyne derivatives **7b** and **8b**. Using the Cu·**2** system, **7b** and **8b** were then successfully grafted to virus−azide **4** with loadings of 115 and 105 per virion, respectively. Only 4 equiv of **7b** or **8b** per azide group on **2** was necessary to reach this level of loading at a virus

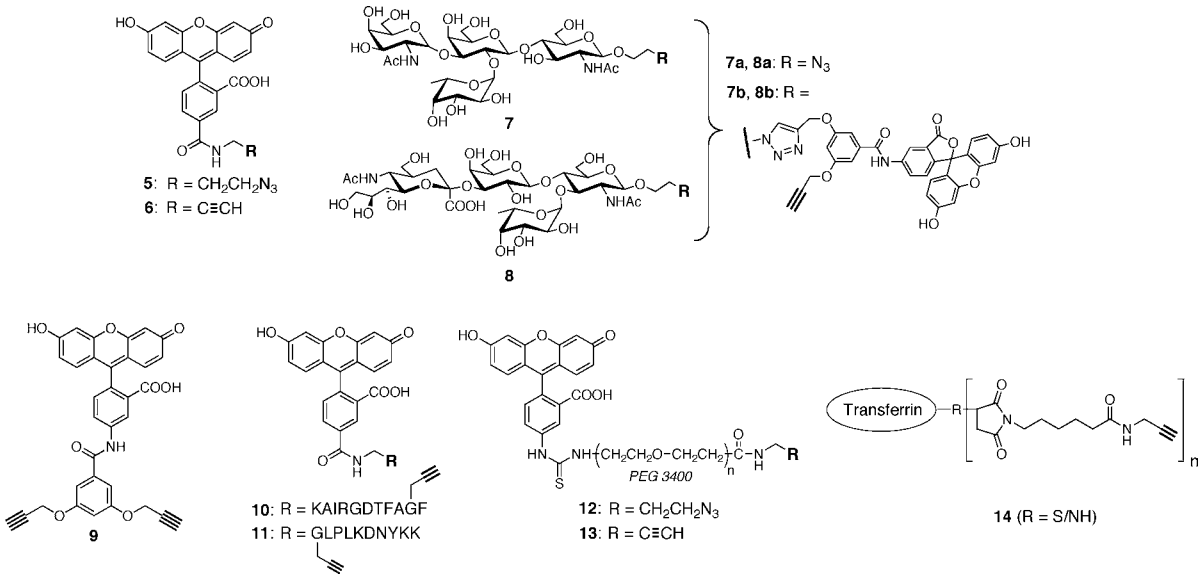

Figure 1. Substrates used in CuAAC attachment to CPMV.

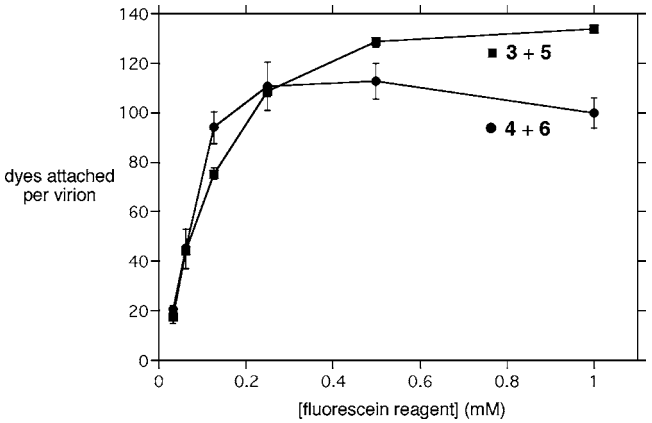

Figure 2. Dependence of dye loading on reagent concentration. Conditions used: 2 mg/mL **3** or **4**, complementary fluorescein derivatives **5** or **6**, 1 mM $[Cu(MeCN)_4](Otf)$, 3 mM **2**, Tris-HCl buffer (pH 8), r.t., 14 h.

concentration of 1−2 mg/mL. The integrity of polyvalently displayed **7** and the retention of the activity of the carbohydrate was verified by the formation of a gel upon the addition of CPMV−$(\mathbf{7b})_{115}$ to dimeric galectin-4 (*18*). The use of **7a** and **8a** with particle **3** under similar conditions likewise gave intact derivatized virions in high yield with the ability to efficiently crosslink a solution of galectin-4. We assume in these cases that the loading of small molecules lacking the fluorescein tag is approximately the same as for their fluorescent counterparts since we have established with extensive studies that the nature of the substrate has little effect on the efficiency of the CuAAC reaction.

This facile attachment of complex, unprotected sugars to proteins by CuAAC ligation represents a significant advancement over existing methodologies employing a bifunctional linker on the carbohydrate for standard bioconjugation reactions. Typically, squarates (*24*) and maleiimide-hydrazide or maleiimide-NHS ester linkers have been employed for this purpose (*23*, *25*), and the additional synthetic steps required to functionalize the sugars in the appropriate fashion result in poor overall coupling yields. In contrast, azides can be readily incorporated into the carbohydrate scaffold early in the synthesis and rarely interfere in subsequent synthetic steps.

Attachment of Peptides to CPMV. Although the genetic incorporation of peptide loops into selected regions of the CPMV capsid structure is well established (*26*), the production of such chimeras suffers from restrictions in terms of size, position, and sequence. Given the great importance of cyclic and linear peptides to a wide variety of targets in biochemistry, molecular recognition, and drug development, robust methods for the attachment of natural and nonnatural oligopeptides to polyvalent scaffolds are of interest. To demonstrate the virtues of the CuAAC reaction in this regard, we chose peptides containing carboxylic acid or amine side chain functional groups and which would therefore require protection/deprotection strategies to be incorporated in standard peptide coupling procedures. To date, the decoration of full proteins with functional peptides has been accomplished predominantly with native chemical ligation (*27*) or maleimide-cysteine reactions. Both of these strategies require the presence of accessible cysteine residues in the protein, the former at the N-terminus (*28*).

We tested the Cu·**2** system with two functional peptides. The arginine-glycine-aspartate (RGD) sequence of **10** is derived from an adenovirus serotype that binds α_v integrins, extracellular matrix receptors that are overexpressed on many cancer cells (*29*). The amino acid sequence of **11** comes from a portion of the protective antigen (PA) of anthrax toxin, a moiety that binds edema factor (EF) and lethal factor (LF) and permits cell entry of the toxin (*30*). Peptide **10** was successfully attached to **4** with a loading of 60 peptides per viral particle using only a 6-fold excess of substrate and standard Cu·**2** conditions. Significantly, no peptide attachment was obtained when ligand **1** was employed with up to 5 mM substrate present. The attachment of **11** afforded a loading of 115 peptides/virion, and SDS−PAGE analysis by UV irradiation indicated that both small and large subunits of CPMV were modified with the PA peptide (data not shown). The ready incorporation of alkyne groups into synthetic peptides (*15*) permits the Cu·**2**-mediated AAC reaction to serve as a general strategy for the attachment of peptides to biomolecular scaffolds.

Preparation of Virus−Polymer Constructs. CPMV was previously derivatized with poly(ethylene oxide) (PEG) using an NHS ester derivative to give well-controlled loadings of the polymer on the outer coat-

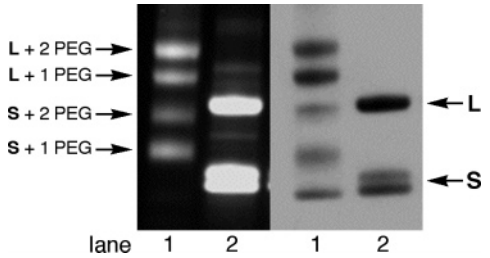

Figure 3. SDS−PAGE of CPMV−(**13**)$_{90}$ (lane 1) and CPMV−(**5**)$_{110}$ (lane 2). On the right (light background) is shown the gel visualized after SimplyBlue staining; the two extra bands corresponding to each subunit arise from modification by 1 or 2 PEG-3400 moieties. On the left (dark background) is the gel illuminated by UV light prior to protein staining. Because PEG-3400 is labeled with fluorescein, only the modified subunits are visible in lane 1. The two small-subunit bands appearing in lane 2 arise from incomplete C-terminal peptide cleavage in vivo and are unrelated to the present experiments.

protein assembly (*12*). Compared with wild-type CPMV, the PEGylated particle showed altered physical properties and a reduced immunogenic response in mice. Lysine reactivity with activated ester derivatives of PEG allowed us to reach a maximum of only 30 attached PEG molecules per virion. Attempts to boost the loading past this value required such high concentrations of PEG reagents that the virus particle precipitated before the reaction could occur. The enhanced activity of the Cu·**2** catalyst allowed us to improve on this prior result. Thus, fluorescein end-functionalized PEG reagents **12** and **13** were coupled to their complementary CPMV alkyne and azide scaffolds to give loadings of 60 and 90 PEG chains per virion, respectively, using easily accessible concentrations in which the virus particles were stable (Table 1). The resulting particles were again less dense on sucrose gradient sedimentation and larger as indicated by size-exclusion FPLC (*18*). Figure 3 shows the denaturing gel of CPMV−(**13**)$_{90}$ and CPMV−(**5**)$_{110}$ visualized by UV irradiation and protein staining. In both cases, both large (L) and small (S) subunits of the CPMV coat protein were labeled, as expected. The PEG conjugate CPMV−**13** gave rise to two higher molecular weight bands for each subunit, corresponding to single and double labeling of the subunits by the polymer. Protein staining of this conjugate also revealed the presence of a small proportion of unmodified subunits.

Attachment of the Transferrin Protein. As a final example of the ability of Cu·**2** to efficiently promote the AAC reaction, the coupling of a large protein to the outer surface of CPMV was performed. Receptors for transferrin (Tfn), an iron carrier protein in vertebrates, are overexpressed on a variety of cancer cells. Polyvalent assemblies of Tfn on such scaffolds as liposomes and iron oxide nanoparticles have therefore been prepared for cancer cell targeting (*31*). The display of multiple copies of Tfn on CPMV could similarly afford a particle that binds tightly and selectively to receptor-bearing cells.

Human holo-transferrin, an 80 kDa bilobed glycoprotein, was incubated at high concentration (20 mg/mL) with 15 equiv of a maleimide-alkyne linker at pH 7 to afford the alkyne-derivatized protein **14**, with attachments made at one or more accessible cysteines (and perhaps, to a lesser extent, lysine) residues. The successful conjugation of alkyne to Tfn was verified by the

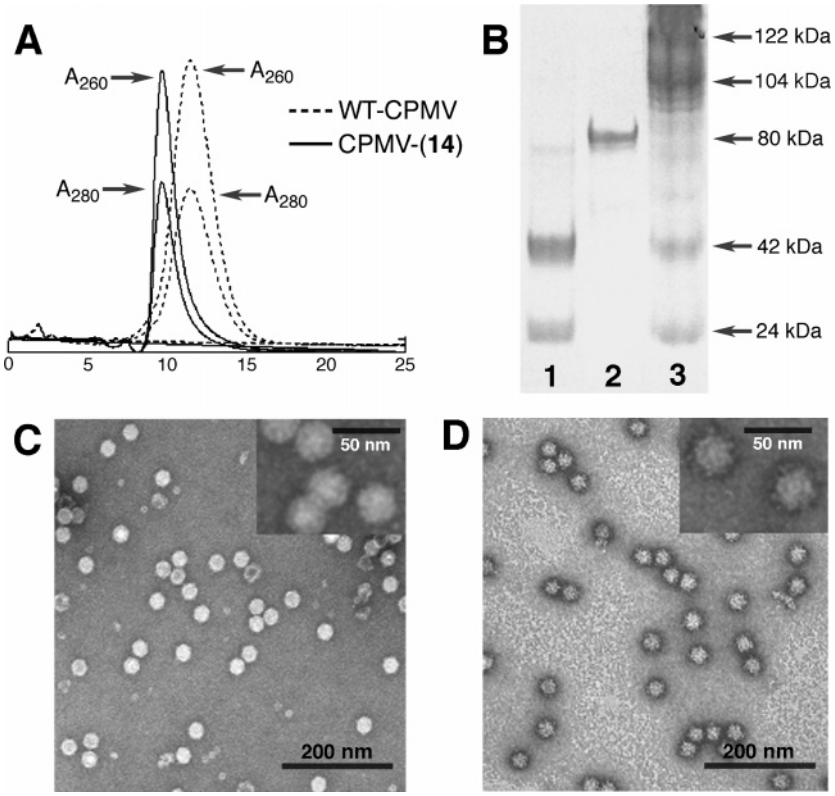

Figure 4. (A) Size-exclusion FPLC of wild-type CPMV and CPMV−(**14**)$_n$. Protein from disassembled particles would appear at longer retention times than the peaks observed here, and the A_{260}/A_{280} ratios are characteristic of intact, RNA-containing capsids for both samples. The more rapid elution of CPMV−(**14**)$_n$ indicates a substantial size increase in the particle, as 10 mL is approximately the void volume of the column. (B) SimplyBlue-stained gel (4−12% bis-tris) of wild-type CPMV (subunits at 42 and 24 kDa) (lane 1), Tfn (80 kDa) (lane 2), and CPMV−(**14**)$_n$ (lane 3). Note the appearance of two strong bands of approximately 102 and 122 kDa in the lane 3, corresponding to the CPMV subunits conjugated with Tfn. (C) Negative-stained TEM of wild-type CPMV. (D) Negative-stained TEM of CPMV−(**14**)$_n$. Automated measurement of the particles showed the average diameters to be 30 ± 1 nm for wild-type and 46 ± 5 nm for CPMV−(**14**)$_n$.

reaction of **14** with the fluorescein derivative **5** under CuAAC conditions. Analysis by SDS−PAGE confirmed that all of the Tfn was covalently labeled with at least one fluorescein molecule (data not shown).

The CPMV−Tfn conjugate CPMV−(**14**)$_n$ was then prepared by reaction of **4** with **14** using Cu·**2**. Examination of the product by FPLC, SDS−PAGE, TEM (Figure 4), and Western immunoblotting (*18*) indicated that a significant number of Tfn molecules were arrayed on the particle. Importantly, the virus−protein conjugates were isolated as individual particles, with no evidence of aggregation that might be expected if Tfn species bearing more than one alkyne were to couple to polyvalent CPMV azides. In negative-stained electron microscopy, individual CPMV−(**14**)$_n$ particles were larger than wild-type CPMV by approximately 16 nm in diameter, and displayed a clear knobby appearance contrasting with the smooth hexagonal shape of the wild-type virion. These observations confirm that Tfn molecules were covalently attached evenly over the CPMV surface. Preliminary measurements show the attached Tfn molecules to be active in binding the target receptor.

A recent report employing thiol-maleimide chemistry for the attachment of proteins (up to 22 kDa) to CPMV required the use of a 50-fold excess of protein with respect to the viral asymmetric unit, as well as subsequent chromatographic purification of the desired conjugate (*32*). We have obtained many similar results for NHS ester-lysine as well as thiol-electrophile reactions. In contrast, protein conjugation is achieved by the CuAAC reaction with efficiencies comparable to those of native chemical ligation (NCL) (*27*). Here, only a 6-fold excess of Tfn was required, and the relatively small amount of Tfn employed allowed for simple purification by sucrose gradients and pelleting. While NCL reactions are typically conducted with nearly equimolar ratios of coupling reagents, the concentrations of thioester and *N*-terminal cysteine reaction partners are typically much higher (0.1−1 mM) than the CPMV azides and alkynes used here (*33*). The Cu·**2**-mediated AAC protocol is therefore an excellent alternative for the coupling of suitably functionalized proteins (*34*).

In summary, we have developed a highly efficient azide−alkyne cycloaddition protocol using a simple copper(I) salt and sulfonated bathophenanthroline (**2**) for chemoselective ligation. This catalytic system permits the attachment of complex carbohydrates, peptides, polymers, and proteins to biomacromolecules in yields and substrate loadings far superior to those possible with previously established procedures. Advantages to the Cu·**2**-mediated AAC method include the use of modest excesses of the desired coupling partners and simple purification. The unfortunate tendency of copper ions to speed the hydrolytic cleavage of peptides and polynucleotides is largely controlled by the use of enough ligand to restrict access to the metal center. We anticipate that the improved CuAAC reaction will be particularly beneficial to those wishing to join substrates that are expensive or available in only small quantities and for biological molecules in which azides or alkynes are incorporated by biosynthetic procedures (*6*, *35*). The single drawback to this system is the requirement that the reaction be performed under inert atmosphere; ligands designed to solve this problem are currently being developed.

ACKNOWLEDGMENT

This work was supported by the NIH (EB00432 and N01-CO-27181), The David and Lucille Packard Foundation Interdisciplinary Science Award program, and The Skaggs Institute for Chemical Biology; S.S. and W.G.L. are Skaggs Postdoctoral and Predoctoral Fellows, respectively. We thank Dr. Wendy Ochoa for obtaining the TEM images, Dr. Ola Blixt for generous gifts of **7a** and **8a**, and Mr. Eiton Kaltgrad for assistance with the preparation of **7b** and **8b**.

Received June 13, 2005; Revised Manuscript Received September 16, 2005

This report describes biodistribution characteristics of three ternary ligand complexes [^{99m}Tc(SQ168)-(tricine)(L)] (SQ168 = [2-[[[5-[carboonyl]-2-pyridinyl]hydrazono]methyl]-benzenesulfonic acid]-Glu-(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}; L = TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate), ISONIC (isonicotinic acid) and PDA (2,5-pyridinedicarboxylic acid)) in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts. Ternary ligand complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) were prepared and were analyzed by a reversed HPLC method. Surprisingly, coligands have little impact on log *P* values of their ternary ligand ^{99m}Tc complexes even though HPLC retention times suggest that [^{99m}Tc(SQ168)(tricine)(PDA)] and [^{99m}Tc(SQ168)(tricine)(ISONIC)] are more hydrophilic than [^{99m}Tc(SQ168)(tricine)(TPPTS)]. The results from biodistribution studies indicated that excretion kinetics of the ^{99m}Tc-labeled cyclic RGDfK dimer can be modified by the choice of coligand. The fact that all three radiotracers show high tumor uptake during the 2 h study period suggests that the coligand has minimal effect on the tumor targeting capability of the ^{99m}Tc-labeled cyclic RGDfK dimer. Results from the blocking experiment suggest that the tumor localization of the ^{99m}Tc-labeled cyclic RGDfK dimer is integrin $\alpha_v\beta_3$-mediated. On the basis of their liver uptake and tumor/liver ratios, we believe that PDA has the advantage over TPPTS and ISONIC for the ^{99m}Tc-labeling of HYNIC−biomolecule conjugates.

INTRODUCTION

For the last several years, we have been using cyclic RGD peptide dimers, such as E[c(RGDfK)]$_2$, for development of the integrin $\alpha_v\beta_3$-targeted diagnostic (^{64}Cu, ^{99m}Tc and ^{111}In) and therapeutic (^{90}Y and ^{177}Lu) radiopharmaceuticals (*1*−*10*). For the ^{99m}Tc-labeling, we have been using 6-hydrazinonicotinic acid (HYNIC) as the bifunctional coupling agent, and tricine and a water-soluble phosphine or pyridine analogue as coligands to prepare ternary ligand complexes [^{99m}Tc(HYNIC−BM)-(tricine)(L)] (Figure 1: BM = biomolecule; L = TPPDS, TPPMS, ISONIC, NIC, PA, PDA and PSA) (*11*−*21*). In these complexes, the ^{99m}Tc chelate (HYNIC, tricine and L) contributes greatly to their overall molecular weight and charge. It was reported that the use of different phosphine coligands caused a significant change in both distribution patterns and excretion routes of the ^{99m}Tc-labeled GPIIb/IIIa receptor antagonist (*12*). Similar coligand effects have also been observed for a variety of binary and ternary ligand ^{99m}Tc complexes of HYNIC-conjugated small biomolecules, including chemotactic peptides (*22*, *23*), somatostatin analogues (*24*−*26*), antisense DNA (*27*), interleukin-8 (*28*) and cholecystokinin (CCK8) peptides (29). It was found that the combination of tricine with NIC reduced the protein binding of the ^{99m}Tc-labeled HYNIC-conjugates (*30*−*32*). The complex [^{99m}Tc(HYNIC−IL-8)(tricine)(NIC)] (IL-8 = interleukin-8) was shown to have the highest abscess uptake (~6.5 ± 1.3% ID/g at 6 h postinjection) and abscess/muscle ratio (248 ± 69) while the use of TPPTS as coligand resulted in the complex [^{99m}Tc(HYNIC−IL-8)(tricine)(TPPTS)] with a significant reduction of receptor binding affinity, low abscess uptake (1.1 ± 0.1% ID/g at 6 h postinjection), and high liver uptake (0.28 ± 0.01% ID/g at 6 h postinjection) (*29*). It was also found that the combination of tricine with NIC gave the best ^{99m}Tc-labeling efficiency, tumor uptake and excretion characteristics for the ^{99m}Tc-labeled cholecystokinin (CCK8) peptides (*29*).

In our previous communication (*1*), we reported the ^{99m}Tc-labeled cyclic RGDfK peptide dimer (Figure 2: SQ168 = [2-[[[5-[carboonyl]-2-pyridinyl]hydrazono]methyl]benzenesulfonic acid]-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}). We prepared [^{99m}Tc(SQ168)(tricine)(TPPTS)] and its ^{99}Tc analogue, [^{99}Tc(SQ168)(tricine)(TPPTS)] using tricine and TPPTS as coligands. We found that [^{99m}Tc(SQ168)(tricine)-(TPPTS)] was stable and exists in solution as two detectable diastereomers. [^{99}Tc(SQ168)(tricine)(TPPTS)] has the integrin $\alpha_v\beta_3$ binding affinity comparable to that of SQ168 in an in vitro assay, suggesting that attachment of the Tc chelate had minimal effect on the integrin $\alpha_v\beta_3$ binding affinity (*1*).

As an extension of our previous studies, we evaluated the biodistribution characteristics of three ternary ligand complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC, and PDA) in athymic nude mice bearing the MDA-MB-435 human breast cancer xenografts. The objective of this study is to explore the impact of coligands (TPPTS, ISONIC and PDA) on the tumor uptake, excretion

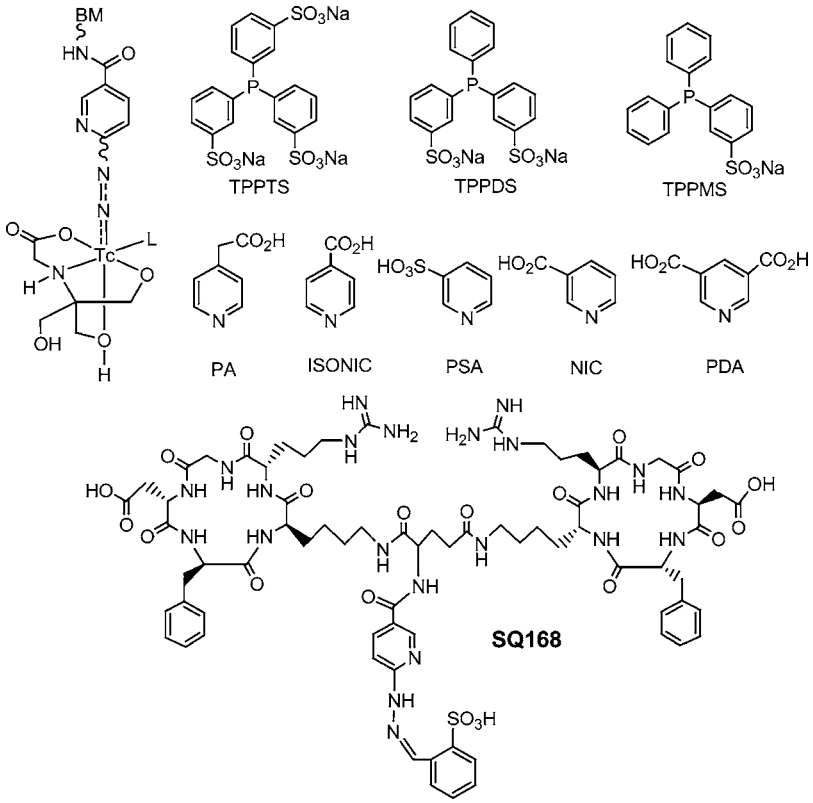

Figure 1. Structures of coligands and their ternary ligand complexes [^{99m}Tc(HYNIC−BM)(tricine)(L)] (BM = biomolecule; L = TPPTS, TPPDS, TPPMS, ISONIC, NIC, PA, PDA and PSA). SQ168 is a HYNIC-conjugated cyclic RGDfK dimer.

kinetics and metabolic fate of the ^{99m}Tc-labeled cyclic RGDfK dimer. Results from biodistribution studies will allow us to select an optimal coligand (TPPTS, ISONIC or PDA) for the ^{99m}Tc-labeling of cyclic RGDfK dimer or other HYNIC-conjugated biomolecules.

EXPERIMENTAL SECTION

Materials. Dicyclcohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), isonicotinic acid (ISONIC), 1,5-pyridinedicarboxylic acid (PDA), succinic acid, trisodium triphenylphosphine-3,3′,3″-trisulfonate (TPPTS), and tricine were purchased from Aldrich Chemical Co. The cyclic pentapeptide, cyclo(RGDfK), was prepared according to the literature method (*33*). Na^{99m}TcO$_4$ was obtained from a commercial DuPont Pharma ^{99}Mo/^{99m}Tc generator, N. Billerica, MA.

Instruments and Methods. The NMR (^{1}H and ^{13}C) data were obtained using a Bruker ARX 300 MHz FT NMR spectrometer, and chemical shifts as δ are reported in ppm relative to TMS. Mass spectral data were collected on a Finnigan LCQ classic mass spectrometer, School of Pharmacy, Purdue University. The semi-prep HPLC method (Method 1) used a LabAlliance semi-prep HPLC system equipped with a UV/vis detector (λ = 254 nm) and Zorbax C$_{18}$ semi-prep column (9.4 mm × 250 mm, 100 Å pore size) for peptide purification. The flow rate was 2.5 mL/min. The mobile phase was isocratic with 90% solvent A (0.1% acetic acid in water) and 10% solvent B (0.1% acetic acid in acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 90% solvent A and 10% solvent B at 5 min to 60% solvent A and 40% solvent B at 20 min. The radio-HPLC method (Method 2) used the LabAlliance HPLC system equipped with a β-ram IN-US detector and Zorbax C$_{18}$ column (4.6 mm × 250 mm, 300 Å pore size). The flow rate was 1 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM ammonium acetate buffer, pH = 5.0) and 10% solvent B (acetonitrile) at 0−2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min.

Synthesis of Boc-Glu(OSu)$_2$. To a solution of the Boc-protected glutamic acid (0.247 g, 1.0 mmol) in 5 mL *N*,*N*-dimethylforamide (DMF) were added *N*-hydroxysuccinimide (0.253 g, 2.2 mmol) and DCC (0.453 g, 2.2 mmol). The mixture was stirred at room temperature for 10 h. After filtration, the filtrate was evaporated to dryness to give crude product, which was then taken up in 3 mL of methylene chloride. The insoluble solid was filtered off. The filtrate was concentrated to about 1 mL. The solution was added dropwise into 30 mL of diethyl ether. The desired product was precipitated as white solid, which was dried in vacuo. The yield was 0.27 g (∼61%). ^{1}H NMR (in CDCl$_3$): 5.23 (br s, 1H, NH), 4.82 (m, 1H, CH), 2.85 (m, 8H, succinimide group), 2.44−2.25 (m, 2H, CH$_2$CO), 1.52 (m, 2H, *CH*$_2$CH$_2$CO), 1.46 (s, 9H, *t*-Bu).

Synthesis of Cyclic RGDfK Peptide Dimer E[c(RGDfK)]$_2$. Boc-Glu(OSu)$_2$ (24.7 mg, 100 μmol) and c(RGDfK) (124 mg, 205 μmol) were dissolved in dry DMF (2 mL). Upon addition of triethylamine (1 mmol), the reaction mixture was stirred at room-temperature overnight. The mixture was diluted with 3 mL of 0.5 M ammonium acetate buffer (pH = 5.0), and the resulting solution was filtered with a Millex-LG syringe driven filter unit to remove any precipitate or particles. The product was separated by HPLC (Method 1). Collections of the fraction at 15 min were combined. Lyophilization of the solution gave a white powder. The yield was ∼75%. ES-MS for Boc-E[c(RGDfK)]$_2$: *m/z* = 1419 for [M + H]$^+$ (C$_{64}$H$_{95}$N$_{19}$O$_{18}$) and 710.3 for [M + 2H]$^{2+}$. Boc-E[c(RGDfK)]$_2$ (50 mg) was dissolved in anhydrous TFA (1.0 mL), and was stirred at room temperature for 5 min. Excess

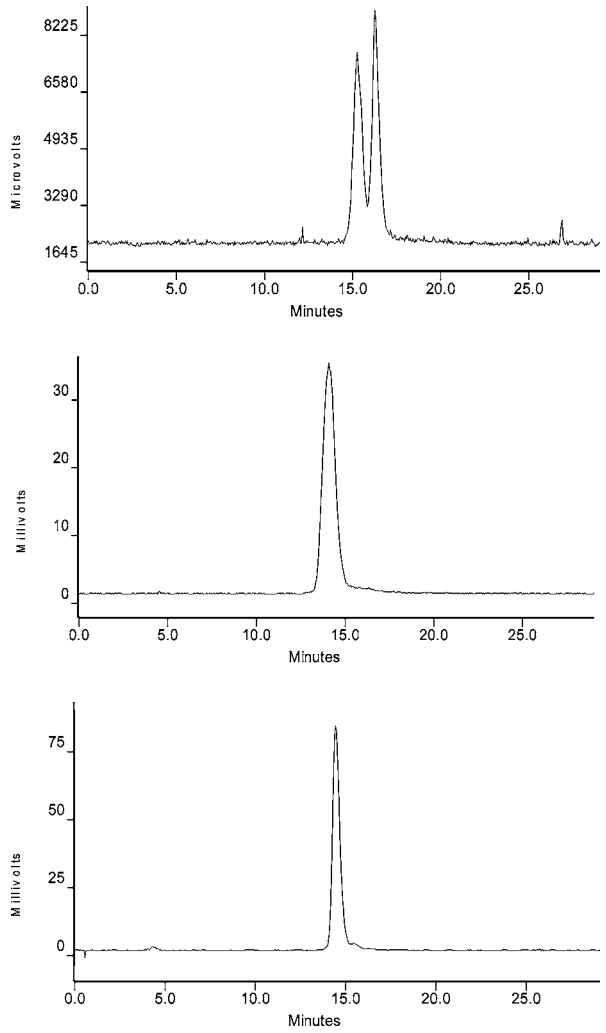

Figure 2. Radio-HPLC chromatograms of [^{99m}Tc(SQ168)-(tricine)(TPPTS)] (top) and [^{99m}Tc(SQ168)(tricine)(ISONIC)] (middle) and [^{99m}Tc(SQ168)(tricine)(PDA)] (bottom) using Method 2.

TFA was removed under reduced pressure and the residue was purified by HPLC (Method 1). Collections of the fraction at ~12 min were combined, and the combined solution was then lyophilized give a white powder. The yield was 28 mg (~60%) with the purity > 95% by HPLC (Method 1). ES-MS for E[c(RGDfK)]$_2$: m/z = 1319.5 for $[M + H]^+$ ($C_{59}H_{87}N_{19}O_{16}$).

Synthesis of HYNIC-E[c(RGDfK)]$_2$ (SQ168). HYNIC-OSu was prepared according to literature method (*34*). HYNIC-OSu (4.17 mg, 10 μmol) and E[c(RGDfK)]$_2$ (14.0 mg, 10.6 μmol) were dissolved in a mixture of DMF and water (50:50 = v:v). The pH was adjusted to 8.5−9.0 with 0.1 N NaOH. The reaction mixture was allowed to incubate overnight at room temperature. The product was purified by HPLC (Method 1). The peak of interest at ~14 min was collected. The collected fractions were combined. Lyophilization of the solution gave a pale yellow powder. The yield was 11 mg (~65%) with the purity > 95% by HPLC (Method 1). The HPLC retention time was 14.5 min (Method 1). ES-MS for HYNIC-E[c(RGDfK)]$_2$ (SQ168): m/z = 1621.7 for $[M + H]^+$ ($C_{72}H_{97}N_{22}O_{20}S$).

Synthesis of [^{99m}Tc(SQ168)(tricine)(TPPTS)]. To a vial filled with 1.0 mL of a solution containing 5 mg of TPPTS, 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, and 12.7 mg of succinic acid (pH = 4.8) were added 0.2 mL of SQ168 solution (100 μg/mL in water) and 0.3 mL of Na[^{99m}TcO$_4$] solution (30 mCi/mL) in saline. The vial was heated at 100 °C for 10−25 min in a lead-shielded water bath. After heating, the vial was placed back into the lead pig and allowed to stand at room temperature for ~10 min. A sample of the resulting solution was analyzed by the radio-HPLC. The radiochemical purity (RCP) was >95%. The HPLC retention time was ~15.5 min (Method 2).

Synthesis of [^{99m}Tc(SQ168)(tricine)(ISONIC)]. To a clean vial filled with 1.0 mL of a solution containing 15 mg of ISONIC, 20 mg of tricine, 38.5 mg of disodium succinate hexahydrate, and 12.7 mg of succinic acid (pH = 4.8) were added 0.2 mL of SQ168 solution (100 μg/mL in water) and 0.3 mL of Na[^{99m}TcO$_4$] solution (30−60 mCi/mL) in saline. The vial was sealed and heated at 100 °C for 15 min. A sample of the resulting solution was analyzed by radio-HPLC. The RCP was >95%. The HPLC retention time was ~15.5 min (Method 2). The solution stability of [^{99m}Tc(SQ168)(tricine)(ISONIC)] was monitored by radio-HPLC for 24 h.

Synthesis of [^{99m}Tc(SQ168)(tricine)(PDA)]. To a clean vial filled with 1.0 mL of solution containing 15 mg of PDA, 20 mg of tricine, 38.5 mg of disodium succinate hexahydrate, and 12.7 mg of succinic acid (pH = 4.8) were added 0.2 mL of SQ168 solution (100 μg/mL in water) and 0.3 mL of Na[^{99m}TcO$_4$] solution (30−60 mCi/mL) in saline. The vial was sealed and heated at 100 °C for 15 min. A sample of the resulting solution was analyzed by radio-HPLC. The RCP was >95%. The HPLC retention time was ~15.5 min (Method 2). The solution stability of [^{99m}Tc(SQ168)(tricine)(PDA)] was monitored by radio-HPLC for 24 h.

Doses Preparation for Animal Studies. Doses for animal studies were prepared by dissolving the HPLC-purified ternary ligand complex [^{99m}Tc(SQ168)(tricine)-(L)] (L = TPPTS, ISONIC and PDA) in saline to give a concentration of ~10 μCi/mL. For the blocking experiment, E[c(RGDfK)]$_2$ was used as the blocking agent. Doses were prepared by dissolving E[c(RGDfK)]$_2$ in the solution containing [^{99m}Tc(SQ168)(tricine)(ISONIC)] (~10 μCi/mL) to give a final concentration of 7.5 mg/mL. Each tumor-bearing mouse was injected with 0.1 mL of solution, which corresponds to a dose of 30 mg/kg.

Determination of Log *P* Values. Log *P* values of complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) were determined using the following procedure: the ternary ligand complex [^{99m}Tc(SQ168)-(tricine)(L)] (L = TPPTS, ISONIC and PDA) was prepared and purified by HPLC. Volatiles were removed under reduced pressure, and the residue was dissolved in a mixture of equal volume (3 mL:3 mL) of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). After vertex mixing for at least 20 min, samples (in triplets) from *n*-octanol and aqueous layers were counted in a gamma counter (Beckman Gama 8000). Partition coefficients were calculated using the following equation: P = (activity concentration in *n*-octanol)/(activity concentration in aqueous layer). The log P value was measured three different times and reported as an average of three different measurements.

Animal Studies. Biodistribution and imaging studies were performed according to the literature procedures (*3*). These studies were carried out using the athymic nude mice bearing the MDA-MB-435 human breast cancer xenografts in compliance NIH animal experiment guidelines (*Principles of Laboratory Animal Care*, NIH Publication No. 86-23, revised 1985). The animal protocol for the animal studies has been approved by the Purdue University Animal Care and Use Committee (PACUC).

[a] The organ uptake is expressed %ID/g. Each data point represents an average of biodistribution data in four animals.

Tumor-Bearing Mice. Female athymic nu/nu mice were purchased from Harlan (Indianapolis, IN) at 4−5 weeks of age. The mice were orthotopically implanted with 5×10^6 cells of MDA-MB-435 estrogen receptor-negative human breast cancer cells into the mammary fat pad. Tumor cells were grown at 37 °C in Minimal Essential Medium (Alpha Modification) containing 3.7 g of sodium bicarbonate/L and 10% fetal bovine serum v/v, in a humidified atmosphere of 5% carbon dioxide. Four weeks after inoculation, animals were used for biodistribution studies.

Biodistribution. Sixteen tumor-bearing mice (20−25 g) were anesthetized with ip injection of ketamine (40−100 mg/kg) and xylazine (2−5 mg/kg). Once the animal was in the surgical plane of anesthesia, as noted by lack of pain response, the radiotracer (∼1 μCi) dissolved in 0.1 mL of saline was administered via the tail vein. Four animals were sacrificed by exsanguinations and opening of thoracic cavity at 5, 30, 60, and 120 min postinjection. Organs were excised, washed with saline, weighed, and counted on a gamma counter. Organs of interest included tumor, blood, brain, eyes, spleen, lungs, liver, kidneys, muscle and intestine. The organ uptake was calculated as a percentage of the injected dose per organ (%ID/organ) and a percentage of the injected dose per gram of wet tissue (%ID/g). For the blocking experiment, four tumor-bearing mice (20−25 g) were used, and each animal was administered with 0.1 mL of saline solution containing ∼1 μCi of the test agent and 750 μg (∼ 30 mg/kg) of E[c(RGDfK)]$_2$, a known integrin $\alpha_v\beta_3$ antagonist. At 1 h postinjection, all four animals were sacrificed for organ biodistribution using the same procedure above. The results were compared to those obtained in animals without the coinjection of E[c(RGDfK)]$_2$. Biodistribution data were analyzed using the one-way ANOVA test, and the level of significance was set at $p = 0.05$ (Tables 1−3).

Metabolism. Each tumor-bearing mouse was administered with the radiotracer at a dose of 100 μCi/mice. The urine samples were collected at 2 h postinjection by manual void and were mixed with equal volume of acetonitrile. The mixture was centrifuged at 8000 rpm. The supernatant was collected and filtered through a 0.20 μm Millex-LG syringe driven filter unit. The filtrate was analyzed by radio-HPLC. The feces samples were collected at ∼120 min postinjection. The sample was suspended in a mixture of 50% acetonitrile aqueous solution, and the resulting mixture was vertexed for 5−10 min. After centrifugation, the supernatant was collected and passed through a 0.20 μm Millex-LG syringe driven filter unit. The filtrate was analyzed by radio-HPLC.

RESULTS AND DISCUSSION

Synthesis and HPLC Analysis. Synthesis of SQ168 was straightforward by conjugation of the Boc-protected bis(*N*-hydroxysuccinmide) glutamic acid ester with 2 equiv of c(RGDfK), followed by TFA deprotection of the Boc-protecting group and conjugation with HYNIC-OSu in a mixture of water and DMF. SQ168 was purified before being used for the ^{99m}Tc-labeling. Ternary ligand ^{99m}Tc complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) were prepared according to literature methods (*1*, *13*) and were analyzed using a reversed phase radio-HPLC method (Method 2). Figure 2 shows their typical HPLC chromatograms. Using this method, the HPLC retention times were 16.5, 14.0 and 14.5 min for [^{99m}Tc(SQ168)(tricine)(TPPTS)], [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)], respectively. It seems that [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)] are more hydrophilic than [^{99m}Tc(SQ168)(tricine)(TPPTS)] according to their HPLC retention times.

To further explore the impact of coligands on lipophilicity of their ternary ligand complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA), we also determined their distribution coefficients in a mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). The log *P* values are −2.66 ± 0.25, −2.70 ± 0.24 and −2.62 ± 0.17 for [^{99m}Tc(SQ168)(tricine)(TPPTS)], [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)], respectively. Surprisingly, there is no significant difference in log *P* values of three radiotracers within the experimental error, even though their HPLC retention times suggest that [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)] might be more hydrophilic than [^{99m}Tc(SQ168)(tricine)(TPPTS)]. This is probably related to the low pH value of the HPLC mobile phase. Complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) may have different degrees of protonation in the HPLC mobile phase (pH = 5.0 in the 25 mM

succinate buffer) as compared to pH 7.4 for the log *P* value determination

It is interesting to note that [^{99m}Tc(SQ168)(tricine)(TPPTS)] always shows two peaks due to its two diastereomers, which are formed because of chiral centers on the Tc chelate and the RGDfK dimer (*1*). However, ternary ligand complexes [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)] show only one radiometric peak under the same chromatographic conditions (Figure 2). Attempts to separate diastereomers of [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)] were not successful most likely due to the fact that the size of Tc chelate becomes much smaller with ISONIC and PDA as coligands, and two diastereomers are more difficult to separate than those of [^{99m}Tc(SQ168)(tricine)(TPPTS)].

Solution Stability. The solution stability of [^{99m}Tc(SQ168)(tricine)(TPPTS)] has been described in our previous report (*1*). [^{99m}Tc(SQ168)(tricine)(TPPTS)] is stable for at least 12 h even in the presence of cysteine. The solution stability of [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)] was monitored by radio-HPLC after purification. It was found that both of them remained stable in the ammonium acetate buffer (pH = 5) for more than 12 h, which is completely consistent with the results obtained from our previous report (*13*) and their in vivo stability in tumor bearing mice as described in this study.

Choice of Animal Model. To evaluate the impact of coligands on biological properties (tumor uptake and excretion kinetics), we performed the biodistribution studies on complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) using athymic nude mice bearing the MDA-MB-435 human breast cancer xenografts. The orthotopically growing tumors in the axillary mammary fat pad give rise to spontaneous metastasis that resemble the clinical behavior of the original human tumor (*35*, *36*). This animal model has been used for evaluation of radiolabeled RGD peptides (*3*, *37*).

Biodistribution Characteristics. For biodistribution studies, all three radiotracers were purified by HPLC to remove excess "unlabeled" SQ168 that may compete with the radiotracer in binding to the integrin $\alpha_v\beta_3$ expressed in both tumor and normal tissues. The biodistribution data for ternary ligand complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) are summarized in Tables 1−3. Figure 3 shows the direct comparison of their organ uptake and excretion kinetics of from blood, liver and kidneys at 5, 30, 60 and 120 min postinjection. The T/B ratios in several selected organs are illustrated in Figure 4.

In general, all three radiotracers displayed a rapid clearance via the renal route. Their blood clearance

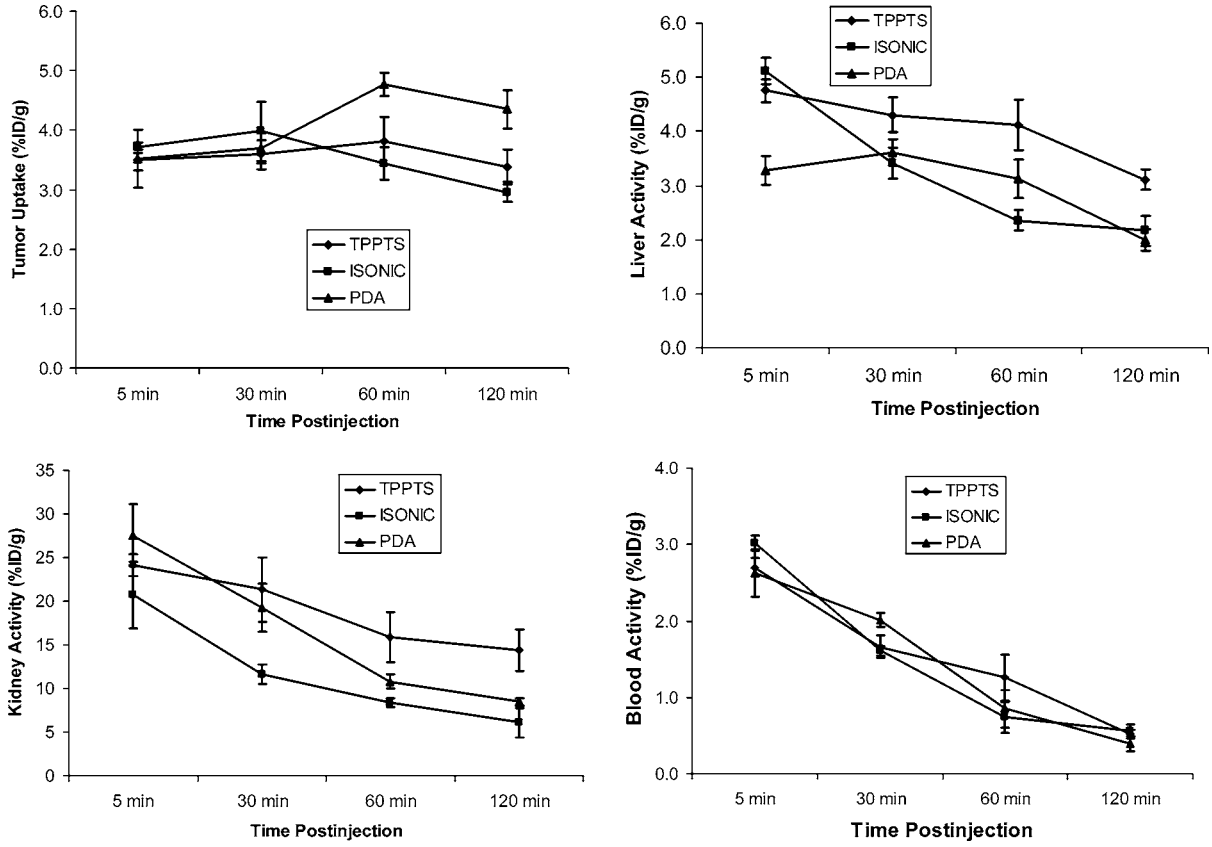

Figure 3. Comparison of excretion kinetics between [^{99m}Tc(SQ168)(tricine)(TPPTS)] (■), [^{99m}Tc(SQ168)(tricine)(ISONIC)] (◆), and [^{99m}Tc(SQ168)(tricine)(PDA)] (▲) in nude mice bearing the MDA-MB-435 human breast cancer xenografts.

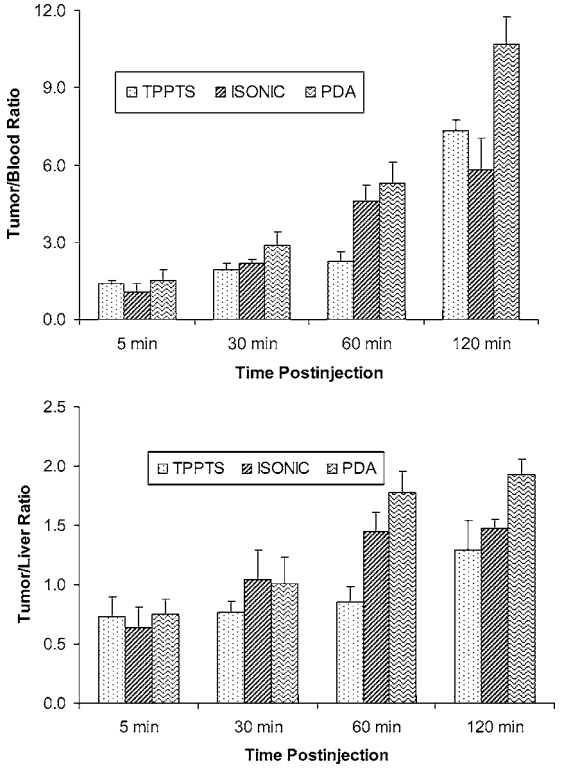

Figure 4. The tumor/background ratios for [^{99m}Tc(SQ168)(tricine)(TPPTS)], [^{99m}Tc(SQ168)(tricine)(ISONIC)], and [^{99m}Tc(SQ168)(tricine)(PDA)] in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts.

curves were almost identical (Figure 3), suggesting that coligands have little impact on their protein binding capability. The tumor uptake of [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) was comparable at 5−30 min postinjection. While the tumor uptake of [^{99m}Tc(SQ168)(tricine)(TPPTS)] remained relatively unchanged over 2 h, the complex [^{99m}Tc(SQ168)(tricine)(ISONIC)] showed a slow washout between 60 and 120 min postinjection (Figure 3). In contrast, the tumor uptake of [^{99m}Tc(SQ168)(tricine)(PDA)] peaked at 60 min postinjection (4.77 ± 0.19%ID/g), and remained relatively unchanged at 120 min postinjection (4.35 ± 0.33%ID/g). As a result, there was a significant increase in the tumor/blood ratio during 2 h study period (Figure 4). The initial kidney uptake of all three radiotracers was high; but it was significantly lower than that reported for a ^{99m}Tc-labeled cyclic RGDfK peptide monomer (*39*). [^{99m}Tc(SQ168)(tricine)(TPPTS)] was cleared very slowly from kidneys. The kidney clearance of [^{99m}Tc(SQ168)(tricine)(ISONIC)] and [^{99m}Tc(SQ168)(tricine)(PDA)] is much faster. The liver uptake of [^{99m}Tc(SQ168)(tricine)(TPPTS)] was high (4.75 ± 0.21% ID/g at 5 min postinjection), and the liver clearance was slow. [^{99m}Tc(SQ168)(tricine)(ISONIC)] also showed a higher initial liver uptake (5.41 ± 0.24%ID/g at 5 min postinjection), but it cleared faster from the liver than [^{99m}Tc(SQ168)(tricine)(TPPTS)]. [^{99m}Tc(SQ168)(tricine)(PDA)] had a lower liver uptake than [^{99m}Tc(SQ168)(tricine)(TPPTS)] at all four time points. As a result, it has a better tumor/liver ratio than [^{99m}Tc(SQ168)(tricine)(TPPTS)] at 120 postinjection (Figure 4).

Excess E[c(RGDfK)]$_2$ on Biodistribution Characteristics. The blocking experiment by coinjecting a known receptor ligand is often used to demonstrate the tumor-specificity of a radiotracer (*3*, *38*). In this study, we used E[c(RGDfK)]$_2$ (~30 mg/kg corresponding to ~750 μg/mouse), the IC$_{50}$ value of which was 15.1 ± 1.1 nM against ^{125}I-echistatin binding to integrin $\alpha_v\beta_3$ on U87MG tumor cells (*38*), as the blocking agent. We used such as a high dose to make sure that integrin $\alpha_v\beta_3$ is almost completely blocked. Figure 5 shows a comparison of organ uptake for [^{99m}Tc(SQ168))(tricine)(NIC)] at 60 min postinjection with/without the excess E[c(RGDfK)]$_2$. Obviously, coinjection of excess E[c(RGDfK)]$_2$ resulted in a significant reduction in the uptake of [^{99m}Tc(SQ168))(tricine)(NIC)] in tumor, lungs, liver, spleen, and intestine. The muscle and kidney uptake was also inhibited (to a much lesser degree) by the presence of excess E[c(RGDfK)]$_2$. The blood activity in the presence of excess E[c(RGDfK)]$_2$ was higher than that without E[c(RGDfK)]$_2$. This is probably caused by the saturation effect of E[c(RGDfK)]$_2$ in distribution and transport mechanism. Similar results were obtained for [^{99m}Tc(SQ168)(tricine)(TPPTS)] and ^{111}In-DOTA-E[c(RGDfK)]$_2$ in the BALB/c mice bearing ovarian carcinoma (*2*), and for ^{64}Cu-DOTA-E[c(RGDfK)]$_2$ in the nude mice bearing the MDA-MB-435 human breast cancer xenografts (*3*).

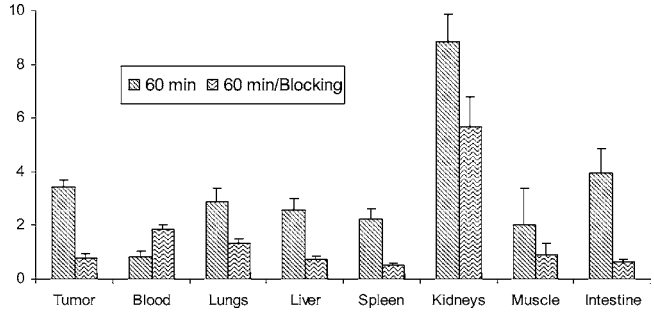

Figure 5. Comparison of the organ uptake (%ID/g) for [^{99m}Tc(SQ168)(tricine)(ISONIC)] at 60 min postinjection in the absence/presence of excess cyclic RGDfK dimer, E[c(RGDfK)]$_2$. Biodistribution was performed in nude mice bearing the MDA-MB-435 human breast cancer xenografts. Each data point represents an average of biodistribution data in four animals.

It is very important to note that the athymic tumor-bearing mice used in this study were all at their rapidly growing stage. Recently, the integrin $\alpha_v\beta_3$ expression in microvessels of lungs and, to a lesser extent, the liver of the rat has also been documented (*40*). It is not surprising to see a high uptake in nontumor organs (such as liver, lungs, spleen, and kidneys) when small rodent tumor-bearing animals are used to evaluate biodistribution patterns of the integrin $\alpha_v\beta_3$-targeted radiotracers. Thus, caution must be taken when using the biodistribution data obtained from small animals to predict the radiotracer distribution patterns in humans.

Metabolic Properties. The in vivo distribution characteristics of a radiolabeled small biomolecule are determined by the size and type of the targeting biomolecule, the metal chelate (radiometal plus bifunctional chelator), and the overall molecular charge, lipophilicity, and protein binding affinity. Radiolabeled small peptides (such as cyclic RGD peptide monomers, dimers and tetramers) often accumulate in kidneys. Extensive metabolic degradation has been observed for the ^{99m}Tc-labeled cyclic RGDfK monomer (*39*) and the ^{64}Cu-labeled cyclic RGDfK tetramer in both kidneys and urine samples (*38*). Since all three complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC and PDA) are excreted mainly from the renal system, we analyzed urine samples from tumor-bearing mice. To our surprise, [^{99m}Tc(SQ168)(tricine)(TPPTS)] shows a significant metabolism at 30 min postinjection while [^{99m}Tc(SQ168)(tricine)(PDA)] remains intact over 120 min postinjection (Figure 6). The complex [^{99m}Tc(SQ168))(tricine)(ISONIC)] has a very similar meta-

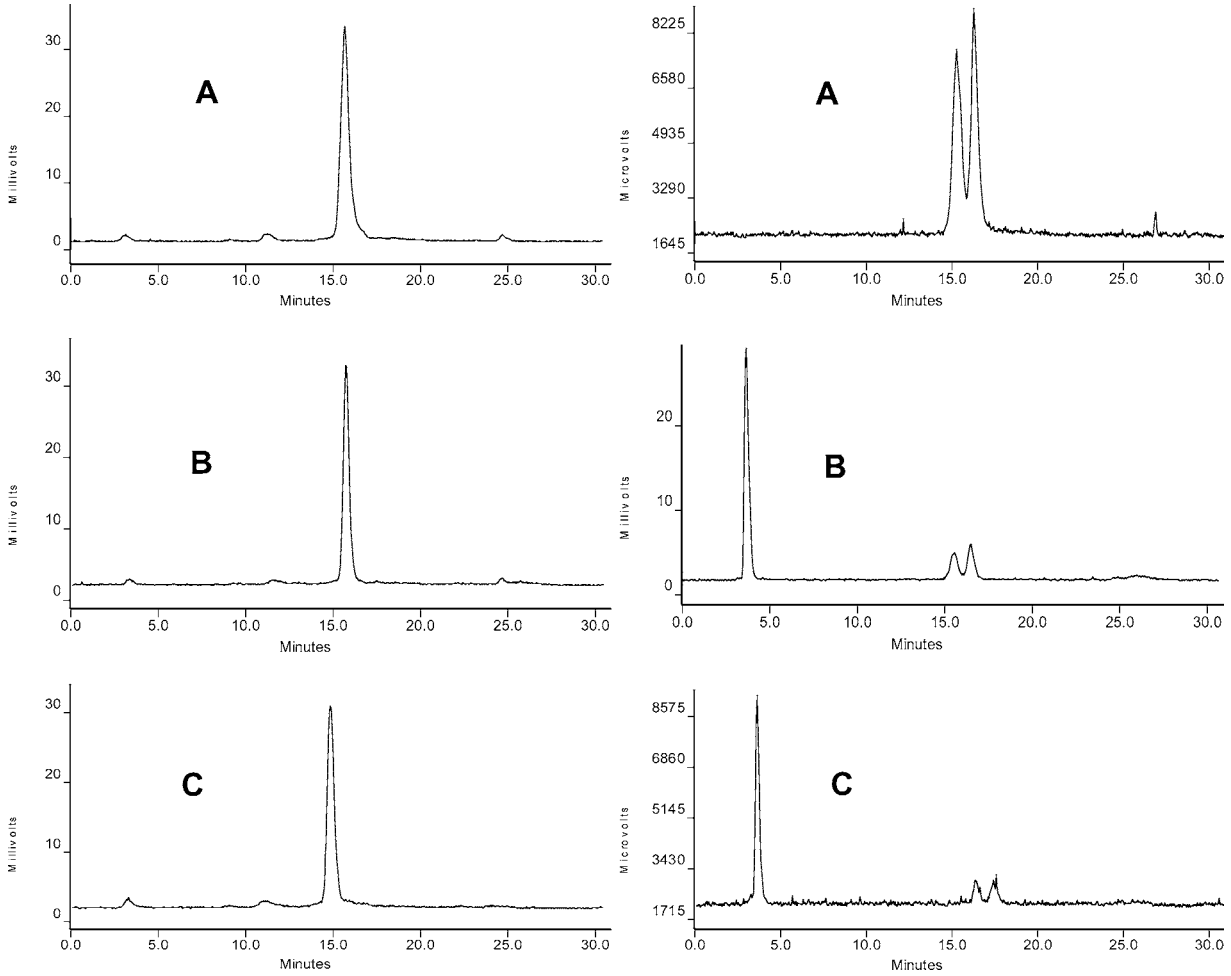

Figure 6. Radio-HPLC chromatograms of [^{99m}Tc(SQ168)(tricine)(PDA)] (left) and [^{99m}Tc(SQ168)(tricine)(TPPTS)] (right) in the kit matrix before injection (A), in the urine at 30 min postinjection (B), and in the urine at 120 min postinjection (C). The metabolic pattern of [^{99m}Tc(SQ168)(tricine)(ISONIC)] in the urine is similar to [^{99m}Tc(SQ168)(tricine)(TPPTS)]. Each tumor-bearing mouse was administered with ~100 μCi of radiotracer. Two tumor-bearing mice were used for each radiotracer.

bolic pattern to that of [^{99m}Tc(SQ168))(tricine)(TPPTS)]. We tried to extract the radioactivity from the feces samples, but the activity level was so low that we were unable to detect either intact ternary ligand ^{99m}Tc complexes or their metabolites. It has been suggested that extensive metabolic degradation is caused by the cyclic RGDfK peptide (*39*). Since all three radiotracers used in this study share the same HYNIC-conjugated cyclic RGDfK dimer, the difference in their metabolic fate is likely related to the coligand and the Tc chelate. At this moment, we cannot explain the different metabolic fate of these three radiotracers according to chemical stability of the Tc chelate. It is also important to note that these data are very preliminary (two tumor-bearing mice for each radiotracer), and more detailed metabolic studies are still in progress. Results from these studies will be reported as a separate account.

Coligand Effect. Since HYNIC can occupy only one coordination site, glucoheptonate and tricine are often used as coligands to complete the Tc coordination sphere. The choice of coligands allows easy modification of biological properties of the ^{99m}Tc-labeled biomolecules. Fischman and co-workers have been using the ^{99m}Tc-labeled fMLFK−HYNIC to image acute infection (*22*, *23*, *41*, *42*). Different biodistribution properties were observed for binary ligand complexes [^{99m}Tc(fMLFK−HYNIC)(L)$_2$] (L = glucoheptonate, mannitol, and glucamine) (*22*). Although the biological data from animal and clinical studies show that the binary ligand complexes [^{99m}Tc-(HYNIC−BM)(L)$_2$] (BM = chemotactic peptides, somatostatin analogues, DNA oligonucleotides, and a folate receptor antagonist; L = tricine and EDDA) are able to localize at the disease site (*43*−*47*), it would be still difficult to develop them for routine clinical use due to their solution instability and the presence of multiple species in solution (*11*, *14*).

To solve the problem, we have developed several ternary ligand systems (Figure 1) that form complexes [^{99m}Tc(HYNIC−BM)(tricine)(L)] (L = TPPTS, TPPDS, TPPMS, ISONIC, NIC, PA, PDA and PSA) with extremely high solution stability (*1*, *11*, *13*). The effect of coligands on biological properties has been reported for the ^{99m}Tc-labeled HYNIC−BM conjugates, including a glycoprotein IIB/IIIa receptor antagonist (*12*), somatostatin analogues (*24*−*26*), interleukin-8 (*28*), and cholecystokinin (CCK8) peptides (*29*). It is very important to note that the coligand effect is largely dependent on the targeting biomolecule. For the ^{99m}Tc-labeled HYNIC−IL-8 conjugate, the use of TPPTS coligand results in the complex [^{99m}Tc(HYNIC−IL-8)(tricine)(TPPTS)] that has the significantly reduced in vitro receptor binding affinity, low abscess uptake, and high liver uptake (*28*). The best coligands for the ^{99m}Tc-labeled HYNIC−IL-8 and CCK8 peptides are NIC and ISONIC (*28*, *29*). For the ^{99m}Tc-labeled cyclic RGDfK dimer, changing the coligand had a minimal effect on their lipophilicity and tumor-targeting capability, which is consistent with that fact that [^{99}Tc(SQ168)(tricine)(TPPTS)] has almost the same

integrin $\alpha_v\beta_3$ binding affinity as the "unlabeled" SQ168 in an in vitro assay (*1*). Thus, caution must be taken when comparing the coligand effect for different HYNIC−biomolecule conjugates.

One of the factors in selecting an optimal coligand (L) is the liver and tumor/liver ratio uptake of the radiotracer. Despite its faster liver clearance (Figure 3), the tumor/liver ratio of [^{99m}Tc(SQ168)(tricine)(ISONIC)] was comparable to that of [^{99m}Tc(SQ168)(tricine)(TPPTS)] due to its slow tumor washout. The complex [^{99m}Tc(SQ168)-(tricine)(PDA)] has a lower liver uptake than [^{99m}Tc(SQ168)(tricine)(TPPTS)] at all four time points and has a better tumor/liver ratio than [^{99m}Tc(SQ168)(tricine)-(TPPTS)] at >60 min postinjection (Figure 4). From this viewpoint, PDA has the advantage over TPPTS and ISONIC. However, for other ^{99m}Tc-labeled HYNIC-conjugated biomolecules, the choice of coligand should be confirmed according to their distribution characteristics.

CONCLUSION

In this report, we described biodistribution characteristics of ternary ligand complexes [^{99m}Tc(SQ168)(tricine)-(L)] (L = TPPTS, ISONIC and PDA) in athymic nude mice bearing the MDA-MB-435 human breast cancer xenografts. The key finding of this study is that the excretion kinetics of the ^{99m}Tc-labeled RGDfK dimer can be modified by the choice of coligand. The fact that all three radiotracers show relatively high tumor uptake during a 2 h study period suggests that changing the coligand has minimal effect on the integrin $\alpha_v\beta_3$ targeting capability of the ^{99m}Tc-labeled RGDfK dimer. On the basis of the liver uptake and tumor/liver ratio of ternary ligand complexes [^{99m}Tc(SQ168)(tricine)(L)], we believe that PDA has the advantage over TPPTS and ISONIC for the ^{99m}Tc-labeling of HYNIC-biomolecule conjugates.

Received June 21, 2005; Revised Manuscript Received September 15, 2005

We studied prototypes of platelet substitutes that bear on their surface a dodecapeptide, HHLGGAKQAGDV (H12). The peptide is a fibrinogen γ chain carboxy-terminal sequence (γ400−411) and recognizes specifically the active form of glycoprotein (GP) IIb/IIIa on the surface of activated platelets. We conjugated H12 to the end of poly(ethylene glycol) chains on the surface of a phospholipid vesicle with an average diameter of 220 nm to prepare H12−PEG−vesicles. The half-life of the H12−PEG−vesicles was significantly prolonged by PEG modification, and the ability of H12 on the surface of the vesicle to recognize GPIIb/IIIa was maintained even though the surface was modified with PEG chains. The H12−PEG−veiscles enhanced the in vitro thrombus formation of platelets that were adhering to a collagen-immobilized plate, when thrombocytopenia-imitation blood was passed over the plate. Based on the flow cytometric analyses of PAC-1 binding and P-selectin expression, the H12−PEG−vesicles were shown not to cause platelet activation. Furthermore, the H12−PEG−vesicles dose-dependently shortened the tail bleeding time of thrombocytopenic rats. It was confirmed that the H12−PEG−vesicles had a hemostatic effect and may be a suitable candidate for an alternative to human platelet concentrates transfused into thrombocytopenic patients.

INTRODUCTION

Platelet transfusion plays an important role in prophylactic therapy for patients with thrombocytopenia caused by hematologic malignancies or intensive chemotherapy for solid tumors or as a result of surgical procedures and radiotherapy. However, due to the short storage life of platelets (3 days in Japan), the shortage has become a serious concern in an aging society. Furthermore, the risk of viral and bacterial infections accompanied by transfusion is also a serious issue. To solve these problems, various platelet substitutes (*1*) have been developed, such as, solubilized platelet membrane protein-conjugated liposomes (Plateletsome) (*2*), infusible platelet membranes (IPM) (*3*), fibrinogen-coated albumin microcapsules (Synthocyte) (*4*), fibrinogen-bonded red blood cells (*5*), liposomes bearing fibrinogen (*6*), and arginine-glycine-aspartic acid (RGD) peptide-bound red blood cells (Thromboerythrocyte) (*7*). These platelet substitutes consist of materials derived from blood components.

We have developed platelet substitutes using polymerized albumin particles (polyAlb) (*8*−*11*) and phospholipid vesicles (*12*−*15*) as biocompatible and biodegradable carriers and shown that those carriers carrying recombinant fragments of platelet membrane proteins (rGPIbα (*16*, *17*) and rGPIa/IIa complex (*18*, *19*)) specifically interact with a surface that mimics the site of bleeding injury, such as von Willebrand factor (VWF) and collagen immobilized on a surface under flow conditions in vitro. Moreover, we demonstrated that rGPIa/IIa-conjugated polyAlb reduced the tail bleeding time of thrombocytopenic mice (*8*). These carriers have the ability to induce platelet hemostasis; however, they cannot recruit flowing platelets to induce platelet aggregation.

When platelets are made to adhere to collagen immobilized on a surface and activated, the conformation of GPIIb/IIIa which exists on the platelet membrane changes from a silent form to an activated form (*20*−*22*). The activated form acts as a receptor for fibrinogen and VWF (*23*−*25*), which is followed by platelet aggregation (*26*, *27*). This is because fibrinogen contains three putative platelet interaction sites, namely, a tetrapeptide containing RGD sequences such as RGDF and RGDS at α95−98 and α572−575, respectively, and a dodecapeptide (HHLGGAKQAGDV, H12) at a γ chain carboxy-terminal segment (γ400−411) (*28*).

To study the usefulness of fibrinogen as a recognition site of platelet substitutes, we prepared fibrinogen-conjugated polyAlb, and we confirmed that the polyAlb enhanced adhesion of the flowing platelets to an activated platelet-immobilized surface in vitro (*9*). However, fibrinogen is derived from human blood and when isolated in solution tends to precipitate at 4 °C within a few hours (*29*).

Recently, we have focused on the stable dodecapeptide, H12, instead of fibrinogen (*28*, *30*−*33*). Based on our results obtained from flow cytometric analyses of agglutination, H12-conjugated latex beads showed minimal interaction with nonactivated platelets in comparison

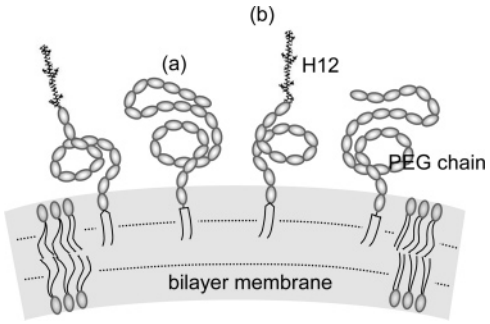

Figure 1. The structure of H12−PEG−vesicles: (a) PEG−DSPE (PEG 5.0 kDa) and (b) H12−PEG−Glu2C18 (PEG: 3.1 kDa, H12: 1.3 kDa) are incorporated into the bilayer membrane.

with RGD-conjugated latex beads (*34*). Furthermore, the H12-conjugated latex beads enhanced in vitro thrombus formation on the collagen-immobilized plate when thrombocytopenia-imitation blood was passed over the plate (*34*).

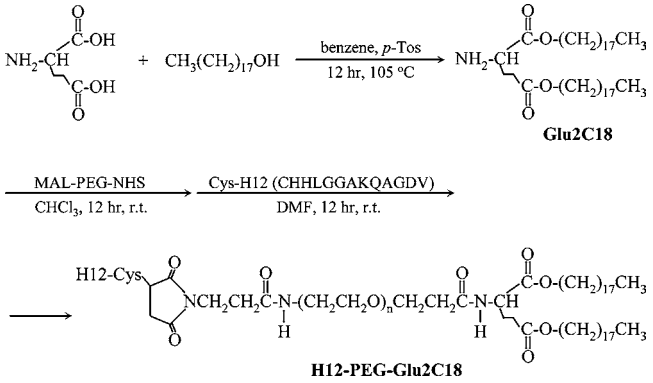
Phospholipid vesicles have been extensively studied as carriers for biologically important substances such as drugs, hemoglobin, enzymes, hormones, and DNA. In particular, recognition proteins such as antibodies and various ligands have been conjugated to the surface of vesicles to bind and interact with tissue epitopes or specific cells. Recently, it was reported that H12-liposomes enhanced platelet aggregation and specifically adhered to the platelets activated on the collagen surface in a state of rest (*35*). On the other hand, poly(ethylene glycol) (PEG) modification of the surface of the vesicles has been widely used to prolong the half-life or to stabilize their dispersion states (*36*−*40*). We previously reported that PEG modification of the vesicles was effective in preventing intervesicular access and aggregation as determined using a capillary viscosimeter and optical microscopy. Also, subcutaneous microvascular studies showed that PEG conjugates significantly improved microcirculation (flow rate, functional capillary density, and vessel diameter) (*38*, *39*).

In this study, we prepared phospholipid vesicles carrying both H12 and PEG chains to enhance the biocompatibility as a platelet substitute and to enhance the stabilization of the vesicles in vitro and in vivo, as noted above. Our purpose was to produce a platelet substitute for the indication of prophylactic transfusion. However, the excluded volume effect of the neighboring PEG chains might shield the recognition ability of H12. Therefore, we conjugated H12 to the end of the PEG chain by using PEG−lipids and prepared the PEG-modified vesicles carrying H12 (H12−PEG−vesicles, Figure 1). Then we studied the recognition ability toward platelets activated on collagen immobilized on a surface when thrombocytopenia-imitation blood was passed over the surface. Furthermore, we intravenously administered the H12−PEG−vesicles into thrombocytopenic rats and measured the tail bleeding time for evaluation of the hemostatic ability of the vesicles.

MATERIALS AND METHODS

Materials. All reagents were used without further purification. L-Glutamic acid, *p*-toluenesulfonic acid monohydrate (*p*-Tos), stearyl alcohol, and *N*,*N*′-dicyclohexylcarbodiimide were purchased from Kanto Chemical (Tokyo). 1,2-Distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-[monomethoxy poly(ethylene glycol)] (5000) (PEG−DSPE, M_w = 5.1 kDa), and α-maleimidyl-ω-hydroxy succinimidyl poly(ethylene glycol) (MAL−PEG−NHS, M_w = 3.5 kDa) were purchased from NOF (Tokyo). 1,2-Dipalmitoyl-*sn*-glycero-3-phosphatidylcholine (DPPC) and cholesterol were purchased from Nippon Fine Chemical (Osaka). 1,5-Dihexadecyl-*N*-succinyl-L-glutamate (DHSG) was synthesized in our laboratory (*41*, *42*). A fibrinogen γ chain dodecapeptide (C-HHLGGAKQAGDV, Cys-H12) was synthesized with a solid-phase synthesizer by BEX (Tokyo). 3,3′-Dihexyloxacarbocyanine iodide ($DiOC_6$), which is a platelet fluorescent dye, and dioctadecyloxacarbocyanine perchlorate ($DiOC_{18}$), which is a vesicle fluorescent dye, were purchased from Molecular Probes (Eugene, OR). Collagen I-A (Cellmatrix) was purchased from Nitta Gelatine (Osaka). D-Phe-Pro-Arg-chloromethyl ketone (PPACK) was purchased from Calbiochem (San Diego, CA). FITC-labeled PAC-1, which is anti-GPIIb/IIIa antibody, and FITC-labeled anti-P-selectin (CD62P) antibody were obtained from Becton Dickinson (San Jose, CA) and BD-Pharmingen (San Diego, CA), respectively. Both busulfan and poly(ethylene glycol) (average molecular weight 400) were purchased from Sigma-Aldrich (St Louis, MO).

Scheme 1. Syntheses of H12−PEG-Glu2C18 (PEG 3.1 kDa, H12 1.3 kDa)



Synthesis of H12−PEG−Glu2C18. The syntheses were performed according to Scheme 1. L-Glutamic acid (2.96 g, 20 mmol) and *p*-Tos (4.56 g, 24 mmol) were dissolved in benzene and refluxed for 1 h at 105 °C. Stearyl alcohol was added to the solution, and the solution was refluxed for 12 h at 105 °C. The crude product was washed with an aqueous solution of saturated Na_2CO_3 and then distilled water. After recrystallization from methanol at 4 °C, 1,5-distearoyl-L-glutamate (Glu2C18) was obtained (9.5 g, yield 80%). Glu2C18 (115 mg, 176 μmol) and MAL−PEG−NHS (300 mg, 88 μmol) were dissolved in chloroform and stirred for 12 h at room temperature (rt). The crude product was purified by reprecipitation from diethyl ether. After recrystallization from ethanol, the MAL−PEG−Glu2C18 was obtained as a white solid (265 mg, yield 64%). MAL−PEG−Glu2C18 (100 mg, 25 μmol) and Cys-H12 (33 mg, 25 μmol) were reacted in *N*,*N*-dimethylformamide (DMF) for 12 h at rt. The crude product was purified by reprecipitation from diethyl ether and extracted with distilled water. The H12−PEG−Glu2C18 was obtained as a white solid (63 mg, 12 μmol, 47%).

Physicochemical Properties of H12−PEG−Glu2C18. TLC (silica gel, chloroform/methanol = 4/1, v/v): R_f 0.17. IR (film; cm^{-1}): 1736($\nu_{C=O}$, ester). ^1H NMR ($CDCl_3$, 500 MHz, δ ppm): 0.89 (t, 6H, $-CH_3$), 1.26 (br, 60H, $-CH_2-$), 1.63 (m, 4H, $-COOCH_2\mathbf{CH}_2-$), 2.00 (m, 2H, $-\mathbf{CH}_2CHCON-$), 2.46 (m, 2H, $-CH_2COO-$), 4.08 (m, 4H, $-COOCH_2-$), 3.63 (br, 360H, PEG).

Preparation of H12−PEG−vesicles. DPPC (100 mg, 136 μmol), cholesterol (52.7 mg, 136 μmol), DHSG (18.9

mg, 27.2 μmol), PEG−DSPE (5.2 mg, 0.90 μmol), and H12−PEG−Glu2C18 (0, 0.47, 1.57, 4.7, or 9.4 mg; 0, 0.090, 0.30, 0.90, or 1.8 μmol, respectively) were dissolved in benzene and then freeze-dried. The resulting white powder was hydrated with distilled water and extruded with membrane filters (pore sizes 3.00, 0.80, 0.65, 0.30, or 0.22 μm, FM filter, Fuji Film, Tokyo). The vesicles were washed with phosphate-buffered saline (PBS, pH 7.4) by suspension and centrifugation (100 000*g*, 30 min, 4 °C, twice). The particle diameter was analyzed by a dynamic light scattering method (N4 PLUS, Beckman-Coulter, Fullerton, FL). We prepared PEG−vesicles or vesicles using lipids in the absence of H12−PEG−Glu2C18 or H12−PEG−Glu2C18 and PEG−DSPE, respectively.

Measurement of the Stability of H12−PEG−vesicles. For the measurement of the incorporation ratio of H12−PEG−Glu2C18 to the vesicle, the H12−PEG−vesicles dispersion was freeze-dried to dissolve in $CDCl_3$. The peak area ratio (R_1) of the choline methyl proton of DPPC (3.37 ppm) to the methylene proton of the PEG chain in H12−PEG−Glu2C18 (3.64 ppm) was measured by ^{1}H NMR spectroscopy (JNM-Lambda 500, JEOL, Tokyo) to determine the incorporation ratio of the H12−PEG−Glu2C18. To study the change of the incorporated PEG lipids in the vesicles, the 30-fold diluted sample dispersion ([lipid] = 0.58 M in PBS, pH 7.4) was incubated at 37 °C, and R_1 was calculated from the ^{1}H NMR spectrum as described above. The peak area ratio before the incubation was defined as R_0. The incorporation ratio was calculated from a percentage of R_1 to R_0.

Preparation of Collagen Immobilized on a Surface. Collagen I-A (3.0 mg/mL) was suspended in PBS at 4 °C (30 μg/mL), and glass plates (diameter 24 mm, thickness 0.5 mm) were immersed into the collagen suspension at 4 °C for 8 h. The glass plates were carefully rinsed with PBS and immersed in a bovine serum albumin solution (20 mg/mL) at rt for 2 h before perfusion studies were performed, as described below.

Preparation of Platelets Immobilized on a Surface. Blood withdrawn from three healthy volunteers was mixed with a 10% volume of 3.8% (w/v) sodium citrate. Platelet-rich plasma (PRP) was prepared by centrifugation (100*g*, 15 min, 22 °C). The PRP was mixed with a 15% volume of acid−citrate−dextrose composed of 2.2% (w/v) sodium citrate, 0.8% (w/v) citric acid, and 2.2% (w/v) glucose (ACD) containing 1 μM prostaglandin E_1 (PGE_1, Sigma, St. Louis, MO). The suspension was centrifuged (2200*g*, 10 min, 22 °C), and the plasma was replaced with a Ringer's−citrate−dextrose solution (RCD solution, composition 0.76% (w/v) citric acid, 0.090% (w/v) glucose, 0.043% (w/v) $MgCl_2$, 0.038% (w/v) KCl, 0.60% (w/v) NaCl, pH 6.5) containing 1 μM PGE_1. After the pellets were resuspended in the RCD solution, the suspension was centrifuged (2200*g*, 10 min, 22 °C), and the concentrated platelets were resuspended at $2.0 \times 10^5/\mu$L in a Hepes−Tyrode buffer (H−T buffer, pH 7.4). The platelet counts were determined using an automated hematology analyzer (K-4500, Sysmex, Kobe, Japan). A collagen-coated glass plate was immersed into the platelet suspension for 1 h at 37 °C and carefully rinsed with PBS.

Measurement of Interaction of the H12−PEG−vesicles with Platelets Immobilized on a Glass Plate using Reconstituted Blood. Blood containing a 10% volume of 3.8% (w/v) sodium citrate was centrifuged (100*g*, 15 min, 22 °C) to replace PRP with an equal volume of a 0.9% (w/v) NaCl solution containing 10% (v/v) ACD (10% ACD−saline). The red blood cell suspension was centrifuged (2200*g*, 10 min, 22 °C) and washed with 10% ACD−saline three times to remove the buffy coat and plasma completely. After the final centrifugation, the red blood cells were resuspended in a H−T buffer to adjust the hematocrit (Hct) to 50%. The residual platelet counts were determined to be $(5.0 \pm 2.0) \times 10^3/\mu$L.

A solution of $DiOC_{18}$ in DMSO (10 mM, 50 μL) was added to the H12−PEG−vesicle suspension (20 mg/mL, 5 mL), and the suspension was incubated at rt for 30 min. The free $DiOC_{18}$ was separated by washing with PBS and centrifugation at 100 000*g* for 30 min at 4 °C twice, and the $DiOC_{18}$-labeled H12−PEG−vesicles were collected.

The reconstituted blood and the $DiOC_{18}$-labeled H12−PEG−vesicle mixtures were placed in a recirculating chamber mounted on an epifluorescent microscope (ECLIPS TE300, Nikon, Tokyo) equipped with a CCD camera, and the interaction of the H12−PEG−vesicles with the platelets immobilized on the surface was observed. All perfusion studies were performed at 37 °C. Single-frame images of the H12−PEG−vesicles on the plates were obtained with an image processor, Argus-50 (Hamamatsu Photonics, Hamamatsu).

Measurement of the Dynamic Interaction of Platelets in Thrombocytopenia-Imitation Blood with a Collagen-Coated Surface in the Presence of the H12−PEG−vesicles. Blood containing PPACK (40 μM), a thrombin inhibitor, was filtered with a leukocyte removal filter (NEO1J, Nihon Poll, Tokyo), which can remove both leukocytes and platelets from whole blood. The residual platelet count in the blood was $(6.0 \pm 2.0) \times 10^3/\mu$L. The platelet count was adjusted to $5.0 \times 10^4/\mu$L with PRP. This blood preparation was termed thrombocytopenia-imitation blood.

Platelets in the blood were labeled with $DiOC_6$ (final concentration, 2 μM), and the H12−PEG−vesicles were added to the blood for 5 min at 37 °C ([lipid] = 0.89 mM). The blood was placed in a recirculating chamber mounted on an epifluorescent microscope as described above, and the interaction of platelets with the collagen immobilized on the surface was observed. The surface coverage of the platelets that adhered on the plate was calculated with an image processor, Argus-20 (Hamamatsu Photonics).

Measurement of PAC-1 Binding and P-Selectin Expression of Resting Platelets in the Presence of the H12−PEG−vesicles Using Flow Cytometry. H12−PEG−vesicles or PEG−vesicles (final lipid concentration 0.82 μM) were added to PRP ([platelet] = $5.0 \times 10^4/\mu$L), and the mixtures were stirred at 37 °C for 30 min. Before and after stirring, FITC-labeled anti-P-selectin antibody (approximately 0.5 μg) was added to the mixture, incubated at 37 °C for 10 min, and then fixed with formaldehyde (final concentration 1.5% (v/v)). Alternatively, FITC-labeled PAC-1 (approximately 0.5 μg) was added to the mixture of platelets and samples and stirred at 37 °C for 10 min, followed by fixing with formaldehyde. As a positive control, ADP-stimulated platelets (final concentration of ADP; 20 or 100 μM) were prepared from PRP. The platelets were gated according to their characteristic forward versus side scatter, and 20 000 platelets were analyzed using a FACSCalibur flow cytometer (Nihon Becton Dickinson, Tokyo). PAC-1 binding or P-selectin expression was quantified as a fraction of the fluorescent-positive platelets. Each experiment was performed at least three times.

Measurement of Tail Bleeding Time and Half-Life of H12−PEG−vesicles Using Thrombocytopenic Rats. All animal studies were approved by the Animal Subject Committee of Keio University School of Medicine and performed according to NIH guidelines for the care

and use of laboratory animals. Experiments were carried out using male Wistar rats (230−250 g, CLEA Japan, Tokyo). A busulfan solution was prepared at a final concentration of 5 mg/mL in poly(ethylene glycol) (average molecular weight 400) (*11*, *43*, *44*). Rats were anesthetized with diethyl ether and injected on day 0 and day 3 with 10 mg/kg on each dosing day to produce a total dosage of 20 mg/kg of busulfan. On day 10, thrombocytopenic rats were anesthetized with sevofrane, and the sample suspension was infused into the tail vein. The samples were the H12−PEG−vesicles and the PEG−vesicles at a dose of 4 mL/kg; saline was used for control. Five minutes after administration, a template-guided incision (Quikheel, Becton-Dickinson, San Jose, CA) 2.5 mm in length and 1.0 mm in depth was made 1 cm from the tip of the tail. The tail was immersed in a 50 mL cylinder of saline, and the time taken for bleeding to stop was measured. In addition, blood was sampled from ether-anesthetized rats 5 min before and 30 min after sample injection by inserting a 25-gauge needle into the tail vein, and the cell counts were determined using an automated hematology analyzer (K-4500).

Half-life was measured from the β-phase of the clearance curve as follows: the $DiOC_{18}$-labeled H12−PEG−vesicles, PEG−vesicles, or vesicles were infused into the tail vein of thrombocytopenic rats at a dose of 40 mg/kg (equivalent lipid concentration). Following this, 400 μL of blood was collected from the tail vein of the rats at time intervals and centrifuged (2200*g*, 10 min, 22 °C), and 200 μL of plasma containing vesicles was collected. The plasma was mixed with deca(oxyethylene) dodecyl ether ($C_{12}E_{10}$) and was heated at 42 °C for 2 min to enhance the solubilization of the vesicles. The fluorescent intensity was then measured (E_x = 485 nm, E_m = 500 nm), and the half-life was calculated using a spectrofluorometer (FP-750, JASCO, Tokyo).

Statistical Analysis. Statistical significance of the results for H12−PEG−vesicles group vs the PEG−vesicles group was tested with Tukey−Kramer tests (Figure 4). A P value of less than 0.05 was considered to be statistically significant. Statistical analyses were performed using Stat View software (SAS Institute).

RESULTS

Characterization of H12−PEG−vesicles. L-Glutamic acid was selected as a connector to synthesize PEG−lipid derivatives as shown in Scheme 1. Each of the two carboxyl groups of the glutamic acid were bonded to a stearyl alcohol molecule by an ester bond to produce a hydrophobic moiety. The product, Glu2C18, was obtained after reprecipitation and recrystallization with a yield of 80%. MAL−PEG−Glu2C18 was obtained from the reaction of MAL−PEG−NHS and Glu2C18 with a yield of 64%. Cys-H12, where cysteine was introduced at the N terminal end of H12, was reacted with MAL−PEG−Glu2C18 in DMF to obtain H12−PEG−Glu2C18. In the ^{1}H NMR spectrum of H12−PEG−Glu2C18, the peak (δ = 6.70 ppm) that was attributed to the maleimide group of MAL−PEG−Glu2C18 disappeared, indicating the bonding of the thiol group of the cysteine with the maleimide group of MAL−PEG−Glu2C18 (yield 47%).

Next, we prepared H12−PEG−vesicles (220 ± 70 nm), DPPC/cholesterol/DHSG = 5/5/1, by molar ratio (Figure 1), which were modified with PEG−DSPE (0.3 mol %) and H12−PEG−Glu2C18 (from 0.03 to 0.6 mol %). The molecular weights of the PEG chain of the PEG−DSPE and H12−PEG−Glu2C18 were 5.0 and 3.1 kDa, respectively. The incorporated ratio (R_1/R_0) of the H12−PEG−Glu2C18 (0.3 and 0.6 mol %) was measured after incubation at 37 °C in a 30-fold dilution to analyze the stability of the lipids in the vesicle. From the ^{1}H NMR analyses, the R_1/R_0 of the H12−PEG−Glu2C18 did not change after the incubation for 12 h at 37 °C. The endotoxin concentration in the H12−PEG−vesicle suspension ([lipid] = 53.5 mM) was below 0.2 EU/mL. Furthermore, the half-life of H12−PEG−vesicles was estimated to be 200 ± 23 min from the β-phase of the clearance curve. In the cases of the control PEG−vesicles and the bare vesicles, the half-life was calculated to be 268 ± 2 min and 29 ± 1 min, respectively.

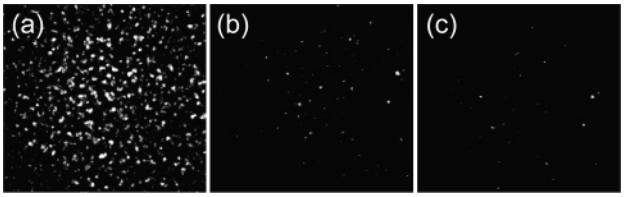


Figure 2. Specific adhesion of H12−PEG−vesicles in the reconstituted blood (Hct. 50%, platelet counts = (5.0 ± 2.0) × $10^3/\mu$L) to platelets activated on the collagen surface at a shear rate of 150 s^{-1}: (a) H12−PEG−vesicles; (b) H12−PEG−vesicles in the presence of PAC-1; (c) PEG−vesicles. Images a−c were obtained after blood was circulated for 500 s ([lipid] = 0.89 M).

Interaction of the H12−PEG−vesicles with Platelets Immobilized on a Surface under Flow Conditions. $DiOC_{18}$-prelabeled H12−PEG−vesicles (modification ratio of H12 0.3 mol %) were mixed with the reconstituted blood, and the mixture was allowed to flow over the activated platelets that were adhering to the collagen surface at a shear rate of 150 s^{-1}. The vesicles adhered and accumulated on the surface in a time-dependent manner, whereas the control PEG−vesicles did not adhere (Figure 2). The adhesion of the H12−PEG−vesicles was suppressed in the presence of PAC-1, an inhibitor of GPIIb/IIIa of the activated platelets.

Platelet Adhesion to a Collagen-Coated Surface in Thrombocytopenia-Imitation Blood Containing the H12−PEG−vesicles. We prepared a thrombocytopenia-imitation blood and adjusted the platelet counts to 5.0 × $10^4/\mu$L. The platelets were labeled with a fluorescent reagent, $DiOC_6$, to observe the dynamic interactions of the platelets with the collagen-coated surface at a shear rate of 150 s^{-1}. In this case, vesicles were not labeled. In the presence of the control PEG−vesicles, the surface coverage of platelets gradually increased to 10.6% ± 1.3% after 300 s of flow (Figure 3A, filled triangle). The value was not appreciably different (9.1% ± 0.4%) in the absence of the PEG−vesicles (Figure 3A, filled circle). When the H12−PEG−vesicles (modification ratio of H12 0.3 mol %) were added to the blood in the same way, the initial adhesion rate was comparable to that obtained with the PEG−vesicles; however, the adhesion rate increased dramatically with time, and the surface coverage reached 17.2% ± 1.9% (Figure 3A, opened circle).

We carried out the same experiments using the H12−PEG−vesicles with various modification ratios of the H12−PEG−Glu2C18 from 0 to 0.6 mol % (Figure 3B). The surface coverage of the PEG−vesicles and the H12−PEG−vesicles having the modification ratio of 0.1 mol % was 8.8% ± 1.8% and 9.5% ± 4.2% after 300 s of flow, respectively. When the H12-modification ratio was higher than 0.3 mol %, the surface coverage increased significantly to 17.2% ± 1.9% and then saturated.

PAC-1 Binding to and P-Selectin Expression of Platelets in the Presence of the H12−PEG−vesicles.

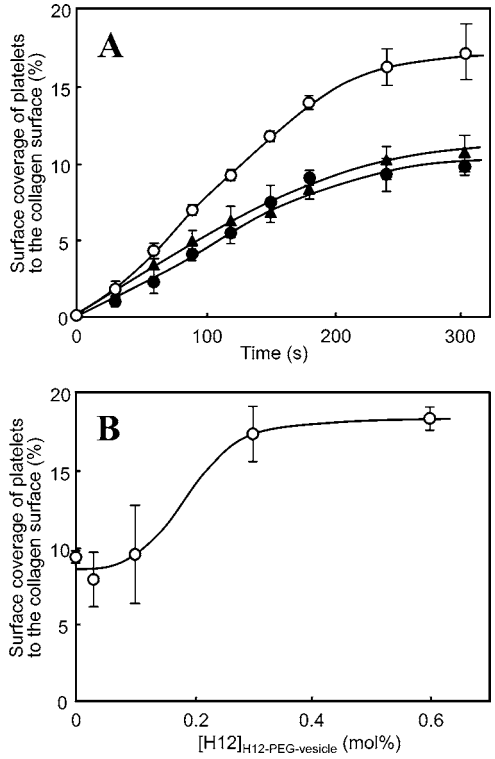

Figure 3. (A) Time course studies of surface coverage of platelets in the thrombocytopenic-imitation blood on the collagen surface after addition of (○) H12−PEG−vesicles, (●) PEG−vesicles, and (▲) PBS and (B) comparison between surface coverage of platelets and modification ratio of H12 on the surface of vesicles (shear rate 150 s^{-1}, [platelets] = $5.0 \times 10^4/\mu$L, [lipid] = 0.89 M, $N = 3$). The surface coverage was measured after 300 s.

Table 1. Binding Ratios of PAC-1 and Anti-P-selectin Antibody to the Resting Platelets in the Presence of H12−PEG−vesicles ($N = 3$)

stirring time (min)	PAC-1 binding (%)		P-selectin expression (%)	
	0	10	0	10
PBS	0.37 ± 0.12	3.77 ± 0.89	0.35 ± 0.11	2.52 ± 0.52
PEG−vesicles	0.52 ± 0.11	3.35 ± 0.32	0.50 ± 0.09	2.27 ± 0.54
H12−PEG−vesicles ([H12] = 0.3 mol %)	0.34 ± 0.16	3.72 ± 0.53	0.40 ± 0.10	2.43 ± 0.21
	89.80 ± 10.90[a]		33.42 ± 6.87[b]	

[a] ADP = 100 μM. [b] ADP = 20 μM.

We measured the ratios of PAC-1 binding to platelets and the P-selectin expression of platelets in the presence of the H12−PEG−vesicles (modification ratio of H12 0.3 mol %) (Table 1). In the ADP-stimulated and the resting platelets, the PAC-1 binding ratio was 89.8% ± 10.9%, and 0.37% ± 0.12%, respectively. When the resting platelets were stirred for 10 min at 37 °C, the ratio increased slightly to 3.77% ± 0.89%. Before and after mixing with the H12−PEG−vesicles, the ratio was 0.34% ± 0.16% and 3.72% ± 0.53%, respectively. In the case of the PEG−vesicles, the values (before 0.52% ± 0.11%, after 3.35% ± 0.32%) were approximately the same as those of the H12−PEG−vesicles.

On the other hand, the P-selectin expression ratios before and after mixing with the H12−PEG−vesicles were 0.40% ± 0.10% and 2.43% ± 0.21%, respectively, whereas in the PEG−vesicles, the values did not change (before 0.50% ± 0.09%, after 2.27% ± 0.54%). The positive and negative controls were 33.42% ± 6.87% and 0.35% ± 0.11%, respectively.

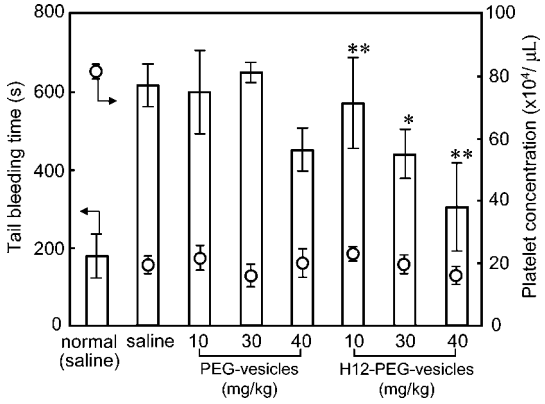

Figure 4. Effects of the administration of H12−PEG−vesicles on tail bleeding time. The administered amount of H12−PEG−vesicles was 10, 30, or 40 mg/kg equivalent of lipid. ○ indicates the platelet concentration in the rats ($N = 6-10$); ∗ indicates $P < 0.05$ or ∗∗ indicates not significant for H12−PEG−vesicles vs PEG−vesicles group at the same dose.

Measurement of the Tail Bleeding Time of Thrombocytopenic Rats in the Presence of the H12−PEG−vesicles. Thrombocytopenic rats were prepared by administering busulfan at a total dose of 20 mg/kg as described in our previous study (*11*). The tail bleeding times of normal rats ([platelet] = $(8.1 \pm 0.9) \times 10^5/\mu$L) and thrombocytopenic rats ([platelet] = $(2.0 \pm 0.3) \times 10^5/\mu$L) were 178 ± 56 and 618 ± 51 s, respectively (Figure 4). The bleeding time of the thrombocytopenic rats was about 3.5 times longer than that of the normal rats. Intravenous administration of the H12−PEG−vesicles at a dose of 10 mg/kg slightly reduced the bleeding time to 573 ± 127 s in comparison with those of a saline group (618 ± 51 s) or a control PEG−vesicle group at the same dose of the H12−PEG−vesicles (598 ± 115 s). At doses of 30 and 40 mg/kg, we confirmed a dose-dependent reduction of the bleeding time as shown in Figure 4; the time decreased significantly to 441 ± 66 and 335 ± 96 s, respectively. By comparison, the bleeding times of the control PEG−vesicles groups at doses of 30 and 40 mg/kg were 662 ± 21 and 432 ± 22 s, respectively. At the dose of 30 mg/kg, H12−PEG−vesicles significantly reduced the bleeding time in comparison with controls, whereas the H12−PEG−vesicles tended to reduce the bleeding time at the dose of 40 mg/kg.

DISCUSSION

We previously showed that fibrinogen-related dodecapeptide (H12) did not interact with the nonactivated platelets and did not cause platelet activation by using H12-latex beads (*34*). This indicated that H12 is a promising candidate as a key material of platelet substitutes. In this paper, we prepared H12−vesicles modified with PEG to obtain information about the possibility of constructing biocompatible and biodegradable particles with hemostatic ability in thrombocytopenic conditions. On the other hand, PEG-conjugated phosphatidylethanolamines (PEG−phospholipids) have been widely used for modification of the surface of vesicles to prolong the blood circulation time or to stabilize their dispersion states (*40*−*44*). Furthermore, PEG−phospholipids in which the terminus has an active group such as maleimido and pyridyl disulfide groups were also utilized to conjugate receptor proteins or ligands. We are proposing the use of amino acid-based lipids instead of phospholipid because various modifications are possible by simple syntheses. In this study, we used the PEG-conjugated amino acid-based lipid, as in our previous studies (*41*,

42). L-Glutamic acid was used as a connector between the PEG chain and two hydrophobic chains, in this case, stearyl alcohol (Glu2C18). The length of the alkyl chain is important because shorter alkyl chains should result in the dissociation of the PEG−lipid from the surface of the vesicle. The amino group of Glu2C18 reacted with the NHS group of MAL−PEG−NHS to produce MAL−PEG−Glu2C18 with a yield of 64%. The low yield is understandable because the NHS group was degraded before or during the reaction by hydrolysis. H12−PEG−Glu2C18 was thus obtained in a relatively high yield via an addition reaction between the maleimido and the mercapto groups of H12.

Next, we prepared vesicles consisting of DPPC/cholesterol/DHSG/PEG−DSPE at a molar ratio of 5/5/1/0.033. The vesicles with this composition were confirmed to be very stable in the state of aqueous dispersion and had excellent blood compatibility with an adequate blood circulation time (*41*). In the case of the PEG modification ratio of 0.3 mol %, the PEG chain is considered to take a so-called mushroom structure on the surface of the vesicle (*45*). For example, if 0.3 mol % of PEG−DSPE (M_w 5.0 kDa) and 0.3 mol % of H12−PEG−Glu2C18 (M_w of PEG chain 3.4 kDa) were incorporated in the surface of the vesicle, the excluded volume of the PEG chains would be estimated from the globular polymer chain as a radius of 6.2 and 4.9 nm, respectively, and the linear dodecapeptide (ca. 4.5 nm) was conjugated to the end of the PEG chain. This means that the H12 should locate on the more outer side more than the neighboring PEG chains, and therefore, the H12 has a possibility to be recognized by the platelets activated on the collagen plate.

The H12−PEG−Glu2C18 was incorporated into the bilayer membrane of the H12−PEG−vesicles in an equilibrium state. We have to determine whether the PEG−lipid tends to dissociate from the vesicular surface after dilution of the H12−PEG−vesicle suspension. We measured the incorporated ratio of H12−PEG−Glu2C18 (0.3 and 0.6 mol %) after incubation at 37 °C in a 30-fold dilution to analyze the stability of the lipids incorporated in the vesicles. From the ^{1}H NMR analyses, the incorporated ratio of the H12−PEG−Glu2C18 did not change. This indicated that the H12−PEG−Glu2C18 with the molecular weight of 4.4 kDa could be tethered to the vesicular surface with two stearoyl chains of Glu2C18. Therefore, the H12−PEG−vesicles would circulate stably in vivo without dissociation of the PEG−lipids. Furthermore, we confirmed that the half-life of the H12−PEG−vesicles was approximately 7-fold longer than that of the bare vesicles due to the effect of PEG modification, indicating that the H12−PEG−vesicles were useful for prophylactic transfusion. We are now studying the prolongation of the hemostatic effects at 180 min and longer after the intravenous administration of the H12−PEG−vesicles.

We prepared the immobilized-platelet surface and reconstituted blood to determine whether the H12−PEG−vesicles specifically bind to the immobilized platelets. In our previous studies, the flowing platelets specifically tethered and adhered to the platelets immobilized on the collagen plate, and the adhesion was suppressed in the presence of PAC-1 (*46*), soluble RGD, or soluble H12, which are GPIIb/IIIa antibodies or inhibitors, indicating that the immobilized-platelet plate should have GPIIb/IIIa exposed on the surface (*9*, *47*) (data not shown). Especially, PAC-1 recognizes an epitope on the GPIIb/IIIa complex of activated platelets at or near the platelet fibrinogen receptor (*46*). In reconstituted blood flowing over the immobilized-platelet plate, the H12−PEG−vesicles adhered and accumulated on the surface, whereas the control PEG−vesicles did not adhere as shown in Figure 2. When PAC-1 was added to the blood containing the H12−PEG−vesicles, the adhesion of the H12−PEG−vesicles was completely inhibited, indicating that the H12−PEG−vesicles were specifically bound to the activated GPIIb/IIIa on the surface of the platelets even with PEG modification. This was supported by the results showing that the number of the adherent H12−PEG−vesicles increased with increasing H12-modification ratio to the vesicle from 0.03 to 0.6 mol % (data not shown).

To determine whether the H12−PEG−vesicles have an ability to reinforce thrombus formation under thrombocytopenic conditions, we prepared a thrombocytopenic blood and adjusted the number of platelets to $5.0 \times 10^4/\mu$L (one-fifth of normal). When the thrombocytopenic blood flowed over the collagen surface, the control PEG−vesicles did not influence the surface coverage of platelets as shown in Figure 3A (filled circle). In the case of the H12−PEG−vesicles having 0.3 mol % H12, the enhancement of the platelet thrombus formation was confirmed as shown in Figure 3A (opened circle). These results suggest that the H12−PEG−vesicles cross-link the activated platelets to enhance the platelet aggregation. In the initial 30 s, the adhesion rate of platelets in the presence of the H12−PEG−vesicles was similar to that of the PEG−vesicles, and then the surface coverage increased dramatically with time in the case of the H12−PEG−vesicles. Furthermore, we confirmed that the H12−PEG−vesicles labeled with rhodamine were involved in the platelet thrombus labeled with $DiOC_6$ by a double-stain method (data not shown). The above results suggest that (1) the adhesion of the H12−PEG−vesicles could be initiated by the activated platelets, which had already adhered on the surface of the immobilized-collagen plate, (2) the H12−PEG−vesicles adhering to the surface of the platelet could act as binding sites for the activated platelets, and (3) the H12−PEG−vesicles could accelerate the formation of the thrombus of the remaining flowing platelets in the thrombocytopenic blood.

Figure 3B summarized the results of the surface coverage of platelets after 300 s in the presence of the H12−PEG−vesicles in which the modification ratio of H12 is from 0 to 0.6 mol % in thrombocytopenic blood. From 0 to 0.1 mol %, the constant surface coverage in the region of the modification ratios suggests that the recognition ability of the H12−PEG−vesicles to the GPIIb/IIIa on the activated platelets was very low because of the low modification density of H12. Surprisingly, the surface coverage increased significantly when the modification ratio was raised above 0.3 mol %. This indicated that the H12−PEG−vesicles had the ability to cross-link the activated platelets. Therefore, we adopted the H12 modification ratio of 0.3 mol %.

Before in vivo studies, we used platelet-activation markers, PAC-1 or anti-P-selectin antibody (*48*), to determine whether the H12−PEG−vesicles caused the activation of platelets. P-selectin is a membrane glycoprotein existing in the α granules of platelets and Weibel−Palade bodies of vascular endothelial cells, and following cellular activation, it becomes surface-expressed by exocytosis (*48*). When a mixture of platelets and the control PEG−vesicles was stirred with PAC-1 or anti-P-selectin antibody, the binding ratios of both antibodies to the platelets were slightly increased after stirring as shown in Table 1. These phenomena were also observed in the absence of the control PEG−vesicles or in the

presence of H12−PEG−vesicles as shown in Table 1. This suggested that the increase was caused by stirring and was within the error limit in comparison with that of PAC-1 binding and P-selectin expression to ADP-stimulated platelets. We concluded that the H12−PEG−vesicles did not activate platelets and did not interact with the nonactivated platelets under flow and that the adhesion of the H12−PEG−vesicles was induced by the platelets activated by the collagen surface. Therefore, H12−PEG−vesicles have the potential to be a candidate for platelet substitutes.

Next, we evaluated the hemostatic ability of the H12−PEG−vesicles using thrombocytopenic rats. In our previous studies, we succeeded in preparing thrombocytopenic rats by busulfan administration and getting the extinction curve of platelets reproducibly (*11*). From the data of hematologic indices, where the platelet counts were sufficiently decreased and the erythrocyte and leukocyte counts were maintained, we determined that the appropriate total dosage of busulfan for the rats (8 weeks) was 20 mg/kg. The incision of the tail was to be made on Day 10 after busulfan infusion. We also confirmed that the bleeding time correlated with their platelet concentration, indicating that the tail bleeding time was an effective evaluation parameter for measuring the hemostatic capability of the platelet substitutes.

As shown in Figure 4, the bleeding time of the thrombocytopenic rats was significantly extended in comparison with that of normal rats 5 min after the intravenous administration of saline, and we determined that it was possible to evaluate the hemostatic effect of the H12−PEG−vesicles in vivo using thrombocytopenic rats. The circulating H12−PEG−vesicles at the dose of 30 mg/kg significantly reduced the bleeding time of the thrombocytopenic rats, whereas at a lower concentration of 10 mg/kg, the hemostatic effect did not reach a significant level. At a higher concentration of 40 mg/kg, however, the bleeding time was significantly reduced in comparison with that of the saline group but not with the control PEG−vesicles group (40 mg/kg). This suggested that the PEG−vesicles themselves possessed a hemostatic activity at the higher concentration, because the PEG−vesicles having negative charge at pH 7.4 might nonspecifically bind to site of bleeding injury.

We estimated that the hemostatic ability of the H12−PEG−vesicles at a dose of 30 mg/kg (approximately 2.0×10^{12} particles) would correspond to 1/500th of the hemostatic ability in particle base, which was based on the bleeding time of the thrombocytopenic rats and platelet concentration. Furthermore, we confirmed that hematologic indices such as the platelet and leukocyte counts did not change before and after the administration of the H12−PEG−vesicles.

In conclusion, we demonstrated that the H12−PEG−vesicles did not interact with nonactivated platelets, and the vesicles were shown to preferentially interact with an activated platelet surface via GPIIb/IIIa receptors and to facilitate platelet accumulation at sites of hemostasis. Furthermore, the H12−PEG−vesicles could reduce the tail bleeding time of thrombocytopenic rats. Thus, the H12−PEG−vesicles may be a suitable candidate for an alternative to human platelet concentrates infused into thrombocytopenic patients.

ACKNOWLEDGMENT

The authors thank Drs. M. Murata and K. Yokoyama at Keio University for useful discussion about the functional evaluation of H12 peptide. Received June 23, 2005; Revised Manuscript Received August 23, 2005

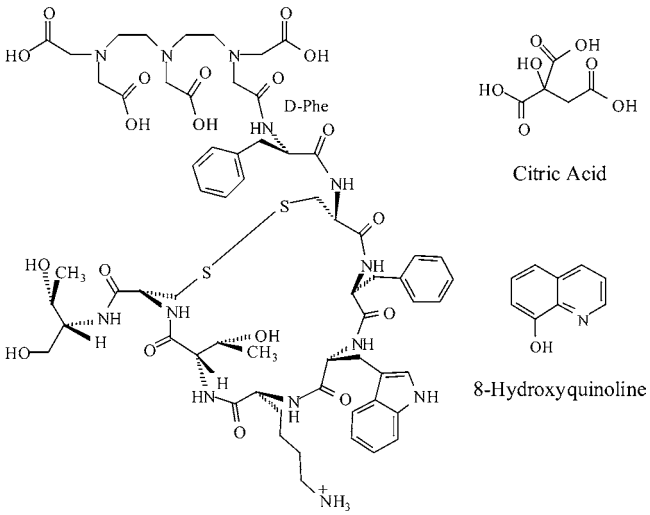
Gallium and indium complexes with pendant carbohydrates have been prepared and examined for their potential as radiopharmaceuticals. Carbohydrate-bearing 3-hydroxy-4-pyridinone ligand precursors and their tris(ligand)gallium(III) and -indium(III) complexes were synthesized and characterized by mass spectrometry, elemental analysis, and ^{1}H and ^{13}C NMR spectroscopy, and in the case of one intermediate, by X-ray crystallography. With three equivalents of ligand, neutral complexes formed with the bidentate hydroxypyridinone moiety complexing the gallium(III) and indium(III) metal centers.

INTRODUCTION

Isotopes of gallium and indium have been used in diagnostic nuclear medicine for decades (*1*–*5*). The gamma-emitting isotopes ^{67}Ga ($t_{1/2}$ = 78 h, γ = 93, 185, 300 keV) and ^{111}In ($t_{1/2}$ = 68 h, γ = 245, 172 keV) are the most common radionuclides of gallium and indium used in nuclear medicine. Another promising gallium radionuclide with the ideal characteristics for generator technology is the positron-emitting ^{68}Ga ($t_{1/2}$ = 68 min) produced from a $^{68}Ge/^{68}Ga$ couple. Advantages of this radionuclide are that the long half-life of ^{68}Ge ($t_{1/2}$ = 280 d) gives the generator a life of at least one year and ^{68}Ga has a short half-life and can also be used for quantitative PET imaging; an on-site cyclotron is not required for production.

Currently, gallium citrate is the most used gallium radiopharmaceutical for diagnostic imaging; however, the coordinating citrate ligands are readily displaced by transferrin which complexes the gallium(III) ions, thus facilitating the biodistribution of the isotope ^{67}Ga (*6*, *7*). For a metal complex to remain intact it must be kinetically and thermodynamically stable in comparison to other biological chelators. A high stability constant for a metal complex indicates its thermodynamic stability and is one criterion considered for radiopharmaceutical evaluation. Chelators such as 8-hydroxyquinoline (Chart 1) are used to form gallium and indium complexes with high stability constants that are used in radiopharmaceutical applications (*6*). More recent efforts include the use of a pendant peptide linked to DTPA (pentetreotide, Chart 1). This is a bifunctional chelate approach: the DTPA portion of the molecule chelates the gallium or indium metal center, and the peptide portion helps to direct the metal complex to somatostatin receptors in vivo (*8*).

Chart 1. Selected Relevant Compounds That Form Gallium and Indium Complexes



Recently FDA-approved, this ^{111}In radiopharmaceutical (OctreoScan) is being used for diagnostic imaging.

To expand further the types of gallium and indium radiopharmaceuticals, metal complexes stable under in vivo conditions are needed. 3-Hydroxy-4-pyridinones also have high stability constants with gallium(III) and indium(III) ions (*9*–*11*). These ligands form neutral tris(ligand)gallium(III) and indium(III) complexes that predominate from pH 4.5 to 9 and have high thermodynamic stabilities (log β_3 ~36–38 for Ga(III) and ~31–33 for In(III)). The pyridinone moiety also has a number of sites where it can be functionalized with the addition of biomolecules such as carbohydrates.

In this work, we report carbohydrate-bearing pyridinone complexes of gallium and indium. Several novel

3-hydroxy-4-pyridinone ligands bearing pendant glucose derivatives are described as well as an improved synthesis of the previously published Feralex-G (*12*). The glucose-bearing ligands will likely direct the metal complexes in vivo, as carbohydrates have extensive transport and metabolic pathways. The corresponding radioactive gallium or indium complexes may have applications in diagnostic nuclear medicine (^{67}Ga, ^{68}Ga, ^{111}In) and radiotherapy (^{111}In) related to metabolic glucose imaging such as tumor, myocardial, or brain imaging or perhaps in imaging of glucose transport receptors. Several studies of carbohydrate pendant metal complexes using the SPECT radioisotope ^{99m}Tc have been reported (*13*−*16*), but none with gallium or indium radioisotopes.

RESULTS AND DISCUSSION

Ligand Preparations. The conditions for pyridinone synthesis from the corresponding pyranone often require heating for extended periods of time in slightly acidic or rather basic conditions. Larger amino substituents typically hinder pyridinone formation resulting in very low or no yields. For these reasons the strategy was to form the pyridinone-linker system first using relatively smaller amines and then couple this linker to the glucose moiety. The linkers include the carboxylic acid substituent as in **3** and a phenolic substituent as in **17**. The point of glucose attachment was chosen to give some variety in structure that was relatively straightforward to synthesize.

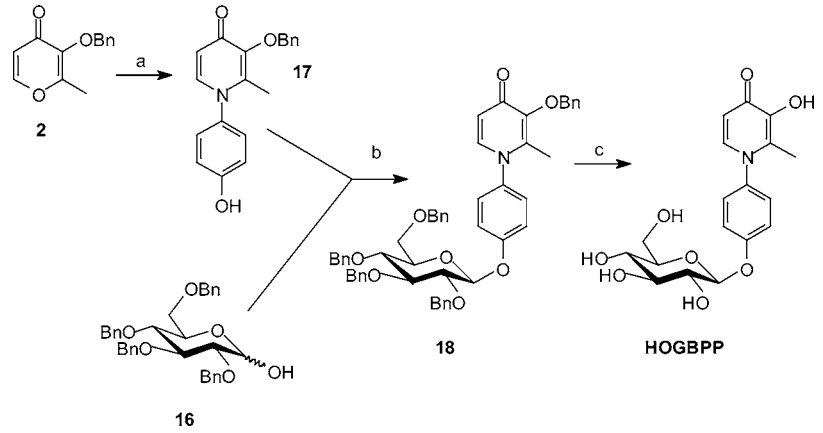
All six ligand precursors **HOG6GP**, **HOG2GP**, **HOGBAP**, **HOGBPP**, **HAG6GP**, and **HAGBAP** were prepared by various routes from maltol (**1**). The hydroxyl group of maltol was benzyl-protected using benzyl chloride to produce **2**. Glycine was reacted with **2** under basic conditions to produce the corresponding pyridinone **3**. DCC was used to activate the carboxylic acid group of **3** as the NHS ester, which was then reacted in situ with amines **7**, **13**, and glucosamine to produce the amide-coupled compounds **8** (Scheme 1), **14** (Scheme 2), and **19**, respectively. Debenzylation of **8**, **14**, and **19** was accomplished by hydrogenolysis using 10% Pd/C to produce **HOG6GP**, **HOGBAP**, and **HOG2GP (Feralex-G)**, respectively.

Amine **7** (Scheme 1) was prepared starting from methyl α-D-glucopyranoside (**4**) that was tosylated to produce **5** and further reacted with sodium azide, according to literature preparations (*17*), to afford **6**. Hydrogenation of the azide was accomplished at 60 atm using palladium black as a catalyst producing amine **7**.

Amine **13** (Scheme 2) was prepared from 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (**10**); Koenigs−Knorr conditions (*18*) with silver carbonate were used to convert **10** to 4-nitrophenyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**11**). Deacetylation with sodium methoxide produced 4-nitrophenyl β-D-glucopyranoside (**12**), and the nitro group was hydrogenated with 10% Pd/C as a catalyst to produce the amine **13** that was recrystallized as the hydrochloride.

The synthesis of **HOGBPP** is shown in Scheme 3. 4-Aminophenol was reacted with benzyl-protected maltol **2** under slightly acidic conditions to produce 3-benzyloxy-

Scheme 3. Synthesis of HOGBPP[a]



[a] (a) 4-Aminophenol, H_2O/MeOH, 29%; (b) ADDP, Bu_3P, dichloromethane, 66%; (c) 10% Pd/C, 1 atm H_2, MeOH/H_2O, 86%.

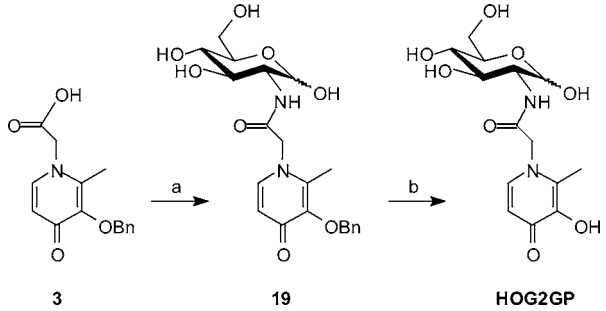
1-(4-hydroxyphenyl)-2-methyl-4(1*H*)-pyridinone (**17**). ADDP and tributylphosphine were used to couple the phenolic moiety of **17** to 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose (**16**) under Mitsunobu conditions (*19*) which produced the β-glucoside (**18**) after column chromatography. Debenzylation of **18** with H_2 and 10% Pd/C afforded **HOGBPP**.

The syntheses of **HAG6GP** and **HAGBAP** are shown in Schemes 4 and 5, respectively. Compounds **8** and **14** were acetylated using acetic anhydride in pyridine to produce **9** and **15**, respectively. Debenzylation of **9** and **15** with H_2 and 10% Pd/C afforded **HAG6GP** and **HAGBAP**, respectively.

A synthesis of **HOG2GP**, also known as Feralex-G, has been previously reported. In the literature preparation, the nonbenzylated analogue of **3**, 1-carboxymethyl-2-methyl-4(1*H*)-pyridinone, is coupled to glucosamine (*12*). Although the reported synthesis gives good yields, purification of the product posed difficulties. Easier purification was afforded by preparing the benzyloxy-protected **HOG2GP** (**19**). The greater lipophilicity of **19** facilitated its silica gel purification, and a protected pyridinone also prevented adventitious metal chelation from the silica. Debenzylation of **19** with H_2 and 10% Pd/C afforded high purity **HOG2GP** (Scheme 6).

Scheme 6. Synthesis of HOG2GP[a]



[a] (a) Glucosamine hydrochloride, DCC, NHS, DMF, 80 °C, 54% (b) 10% Pd/C, 1 atm H_2, MeOH/H_2O, 100%.

All ligands were thoroughly characterized by elemental analysis and mass spectrometry, and complete ^1H and ^{13}C NMR spectral assignments were made using 2D techniques. The ^1H NMR spectrum of **HOG2GP** has been previously reported, but only for the α anomer (*12*). As a hemiacetal, **HOG2GP** can mutarotate and is present as a 7:3 α:β ratio in water (at RT). The other five ligands were designed as single anomers.

Tris(3-oxy-4-pyridinato)gallium(III) and -indium-(III) Complexes. The neutral gallium(III) and indium-(III) complexes were prepared by addition of gallium or indium nitrate solutions to solutions containing the precursor ligands. The acidic solutions containing the reaction mixtures were adjusted to neutral pH with sodium hydroxide, and subsequent column purification (G10) or precipitate collection yielded the metal complexes (Scheme 7).

Elemental analyses of all the metal complexes were consistent with the calculated values. All metal complexes included 1 to 5 waters of hydration that were not eliminated after drying for at least 48 h in a vacuum desiccator at RT. These waters are consistent with other gallium and indium pyridinone complexes with 0.5−5.5 waters of hydration often being reported (*9*), although up to 12 waters of hydration have been reported in some solid-state structures (*20*, *21*). Drying some gallium and indium pyridinone complexes at 85 °C in vacuo for 24 h failed to remove all waters of hydration from these complexes (*9*). The mass spectra (+ESI) for the metal

complexes revealed protonated, sodiated, or sometimes potassiated parent molecules. These parent ions had the expected fragmentation patterns and isotopic distributions.

^{1}H and ^{13}C NMR Spectra. ^{1}H NMR spectra indicated that the pyridinone ring protons had the most prominent changes in chemical shift upon metal complexation. The largest coordination induced shift (CIS) was observed for H5, (see Table 1 for pyridinone ring numbering) where metal complexation resulted in downfield shifts of 0.11−0.19 ppm for the complexes studied. These are close to the 0.19−0.32 ppm downfield shifts observed for other (crystallographically characterized) gallium and indium pyridinone complexes in $CDCl_3$ and $(CD_3)_2SO$ (*9*). Significant shifts were also observed in this work for H6 with upfield shifts from 0.04 to 0.11 ppm.

Gallium(III) and indium(III) ions have the potential to coordinate alkoxy groups from citric acid (*22*, *23*) or gluconic acid (*24*). The overlap of the glucose protons in some of the ^{1}H NMR spectra in this work (3.4−3.7 ppm) made it difficult to ascertain whether there were any interactions between the hydroxyl groups of glucose and the gallium or indium metal centers. ^{13}C NMR spectra were obtained and assigned using 2D techniques to aid

[a] Only the pyridinone and glucose moieties are considered. A positive/negative value indicates a downfield/upfield shift for the metal complexes compared to the free ligand.

in determining whether any glucose−metal direct interactions take place. Also, a comparison of the pyridinone ^{13}C NMR region upon complexation to gallium and indium has not been previously undertaken (to our knowledge). The ^{13}C NMR coordination induced shifts for **HOG6GP**, **HOGBAP**, and **HOGBPP** are listed in Table 1. There are very small chemical shift differences for the glucose carbon atoms (all less than 0.1 ppm shifts), indicating clearly that the hydroxyl groups of glucose do not coordinate to the gallium or indium metal centers; one would expect more dramatic shifts if the glucose hydroxyl groups coordinated gallium or indium. When gluconic acid complexes gallium(III), the C2−C4 hydroxyl groups deprotonate/coordinate to gallium and the resulting ^{13}C NMR shifts for C2−C4 range from −0.3 ppm (upfield shift) to +0.6 ppm (downfield shift) in 9:1 H_2O:D_2O (*23*−*25*). Citrate complexation of gallium at neutral pH results in a 1.1 ppm upfield ^{13}C CIS for the tertiary hydroxyl group that deprotonates/coordinates gallium(III).

While there are small changes in the glucose ^{13}C NMR chemical shifts, all of the pyridinone ring carbon atoms shift by −5 ppm to +8 ppm, indicating that the pyridinone moiety is complexing gallium and indium. A representative ^{13}C NMR spectrum is shown in Figure 1. The largest CIS occurs for the pyridinone C3 atom, where a downfield shift of 6.5−8.3 ppm occurs upon formation of the gallium or indium complex. Each indium complex has a slightly larger downfield CIS for C3 (∼0.3−0.5 ppm) compared to that for the corresponding gallium complex. In contrast, upfield shifts are observed for the C4 pyridinone carbonyl ranging from ∼0.4 to 2.3 ppm. Each gallium complex has a slightly larger CIS for C4 (∼0.5−0.7 ppm) compared to the corresponding indium complex. The C5 and C6 atoms have upfield shifts from 2.5 to 4.9 ppm after metal complexation, while only the indium complexes show a consistent downfield CIS of 1.3−2.3 ppm for the C2 atom.

So far, attempts to recrystallize the metal complexes or the precursor ligands have failed to produce X-ray quality crystals. Vapor diffusion of alcohols into water or slow evaporation of water or MeCN were the most common methods employed. Sugars are notoriously difficult to crystallize; however, X-ray quality crystals of a benzylated pyridinone-glucose compound (**8**) were grown by slow evaporation of a 3:1 ethyl acetate:methanol solution (Figure 2). The bond lengths and angles (Table 2) are typical for pyridinones. The torsional angles indicate the near-planarity of the pyridinone ring, and the first carbon atom of the N2-substituent (C9) is also close to the plane of the pyridinone ring, both characteristics of other pyridinone structures. The α-anomer of glucose is also displayed in the structure of **8** which concurs with the coupling constant and chemical shift in the ^{1}H NMR spectrum (Supporting Information). Intermolecular hydrogen bonds form a tight net in the unit cell (Supporting Information). The amide H-atom (H26) is 1.931(19) Å from O2 of the glucose ring, the amide O-atom (O6) is 1.83(2) Å from H23, and the pyridinone carbonyl O-atom (O7) is 1.81(3) Å from H24.

Typically, aromatic- or alkyl-substituted pyridinone ligands and their complexes have low water solubility. The solubility of the complexes is usually less of an issue in radiopharmaceutical chemistry due to the low concentrations of the tracers; however, the ligand solubility may influence the efficiency of radiolabeling. Interestingly, the presence of the attached carbohydrates increases the solubility of both the ligands and the complexes compared to those of other pyridinone-based ligands. The water solubilities of **Ga(OG6GP)$_3$, In(OG6GP)$_3$, Ga(OGBPP)$_3$, In(OGBPP)$_3$, Ga(OG2GP)$_3$, In(OG2GP)$_3$, Ga(AG6GP)$_3$**, and **In(AG6GP)$_3$** were all greater than 10 mM at RT. **Ga(OGBAP)$_3$** and **In(OGBAP)$_3$** have water solubilities of ∼2.5−3 mM at RT while **Ga(AGBAP)$_3$** and **In(AGBAP)$_3$** have quite low water solubilities (<0.5 mM). Mixtures of water and EtOH improve the solubilities of **Ga(AGBAP)$_3$** and **In(AGBAP)$_3$**, and depending on the study, EtOH content may be acceptable for injection.

Enzymatic Cleavage. The glycoside linkage has the potential to be cleaved in vivo by a number of β-glycosidases, some of which are found naturally occurring in

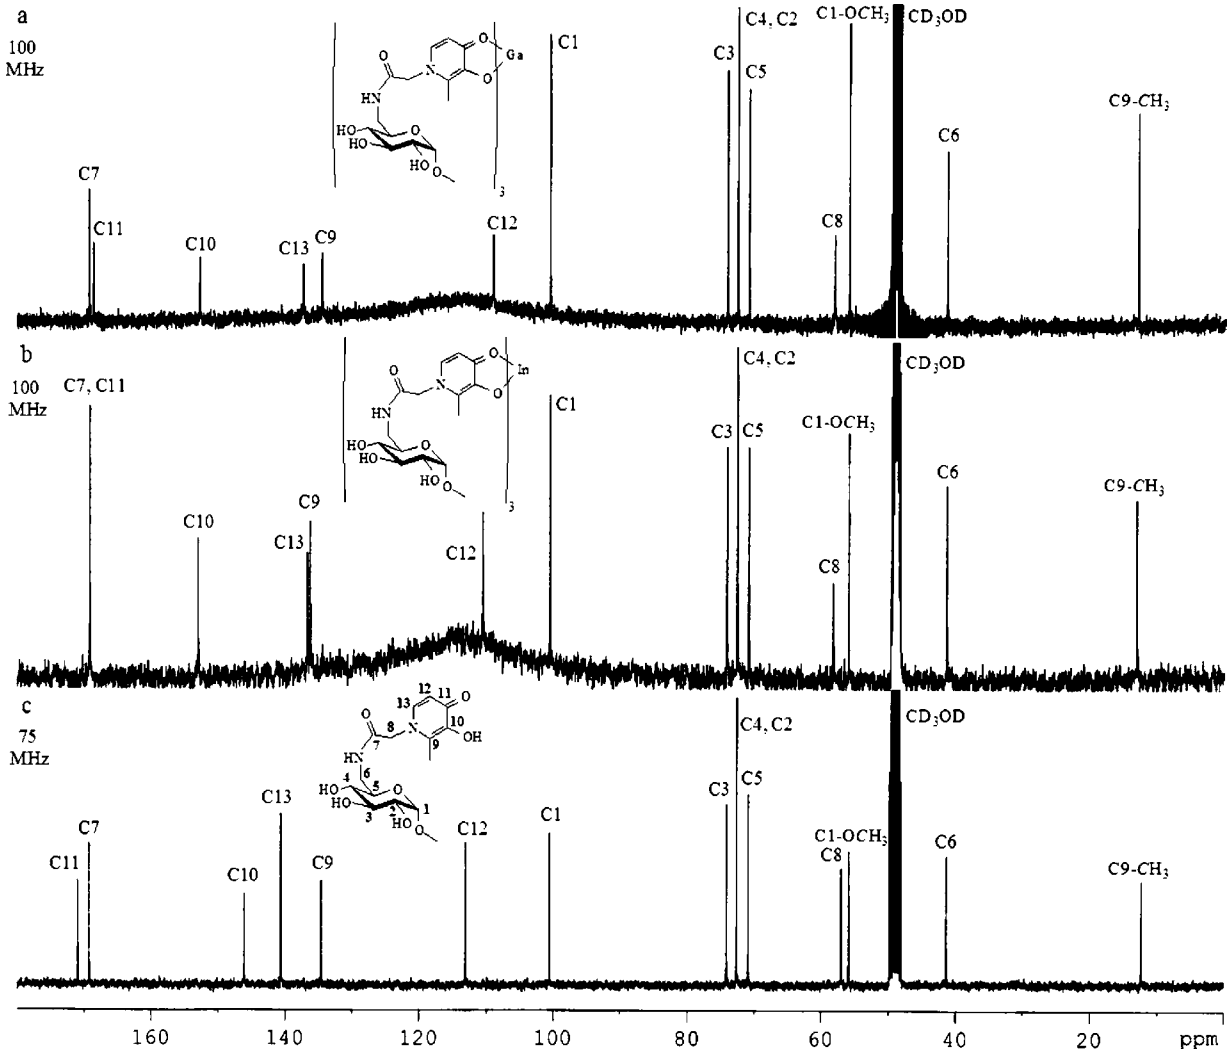

Figure 1. ^{13}C NMR spectra in 1:1 $CD_3OD:D_2O$ for (a) **Ga(OG6GP)$_3$** (100 MHz), (b) **In(OG6GP)$_3$** (100 MHz), and (c) **HOG6GP** (75 MHz).

the brain (*26*, *27*). Cleavage of the β-glucosides to produce pyridinone complexes without the attached carbohydrates may allow accumulation of activity in target sites, such as the brain. One of the metal complexes that contained β-glucose linkages (**Ga(OGBPP)$_3$**) was randomly chosen as a substrate for a broad-specificity β-glucosidase, Abg (*28*). After addition of Abg to a buffered solution containing **Ga(OGBPP)$_3$**, a white precipitate formed within a few minutes at RT. The mass spectrum of this precipitate is identical to that of an authentic sample of **Ga(hpp)$_3$** indicating that three β-glucose molecules were cleaved to produce **Ga(hpp)$_3$**. If **Ga(OGBPP)$_3$** were to come in contact with a similar specificity β-glucosidase enzyme in vivo, this suggests that the β-glucose linkages would be cleaved.

EXPERIMENTAL PROCEDURES

Materials. All solvents were purchased from Fisher except anhydrous pyridine which was purchased from Aldrich. MeOH, MeCN, and ethyl acetate solvents were

HPLC grade, and all other solvents were ACS grade or higher. Dry DMF was obtained by stirring over 4 Å molecular sieves followed by distillation. Other anhydrous solvents were dried according to standard procedures (*29*). All chemicals were from Aldrich unless otherwise stated. 3-Hydroxy-2-methyl-4-pyranone (maltol, **1**) was obtained from Pfizer (New York). H_2 and N_2 gases were from Praxair. Palladium black was obtained from Alfa Aesar. *Agrobacterium sp.* β-glucosidase (Abg) (*28*) was generously provided by Prof. S. G. Withers (UBC).

Methods. All pH measurements were made using an Accumet 950 pH/ion Meter with a Metrohm Porotrode micro-combination glass electrode. A Parr series 4750 (200 mL) split ring high-pressure reactor was used for higher pressure hydrogenations. A thick-walled glass insert (test tube shaped) was made (UBC Chemistry Glass Shop) that inserted into the Parr apparatus and held 100 mL of solvent when full. Vacuum desiccators contained phosphorus pentoxide as a desiccant.

NMR spectral data are contained in the Supporting Information. NMR spectra of samples were recorded on Bruker Avance 300, Avance 400, or AMX 500 instruments at room temperature (RT). NMR spectra were calibrated with the deuterated solvent, and in the case where mixtures were used, CD_3OD was chosen as the reference. Two-dimensional NMR techniques such as COSY, HMQC, and HMBC were used to aid in the characterization of all the final products and a number of intermediates. Mass spectra were obtained with either a Kratos Concept II H32Q instrument (Cs^+-LSIMS) or a Macromass LCT (electrospray ionization, ESI). Microanalyses for C, H, and N were done in this department (Mr. P. Borda or Mr. M. Lakha) or by Delta Microanalytical Services (Delta, BC).

X-ray data for **8** were collected and processed (*30*) using a Rigaku/ADSC CCD diffractometer and are shown in the Supporting Information. The X-ray structure was solved using direct methods (*31*) and expanded using Fourier techniques (*32*). The non-hydrogen atoms were refined anisotropically. Some hydrogen atoms were refined isotropically, the rest were included in fixed positions. All calculations were performed using the teXan crystallographic software package (*33*).

Synthesis. *3-Benzyloxy-2-methyl-4-pyranone (**2**) (benzyl maltol).* This compound was prepared in a manner similar to a previously published procedure (*34*) with some modifications. Maltol (**1**) (151.3 g, 1.2 mol) was dissolved in 1 L of MeOH and 120 mL of 10.5 M NaOH (50.4 g, 1.26 mol) was added. Benzyl chloride (160 mL, 1.39 mol) was added, and the reaction mixture was refluxed for 6 h. Then additional benzyl chloride (40 mL, 0.35 mmol) and NaOH (2.5 g, 0.062 mmol) (predissolved in 10 mL water) were added to the reaction mixture which was refluxed for an additional 12 h. The bright yellow solution containing white precipitate was reduced using a rotary evaporator (50 °C), then redissolved in 700 mL of water and 350 mL of dichloromethane. The water layer was discarded, and the dichloromethane was washed with 3 × 250 mL of 5% NaOH and 100 mL of water. The organic layer was dried (Na_2SO_4) and filtered, and the solution was removed using a rotary evaporator (40 °C), which produced a yellow oil. The oil was recrystallized in the freezer from 500 mL of EtOH. The crystals formed were filtered out and washed with a minimum of cold EtOH to remove the smell of benzyl chloride. The volume of the filtrate was reduced to ~200 mL using a rotary evaporator, and the product was crystallized as above with the addition of seed crystals. A third recrystallization from the mother liquor was also performed; all the crystals were combined and dried under vacuum 24 h to produce a white solid (183.0 g, 71% yield). Mp 52−54 °C.

*3-Benzyloxy-1-(carboxymethyl)-2-methyl-4(1H)-pyridinone (**3**).* Sodium glycinate (58.2 g, 600 mmol) and benzyl maltol (**2**) (86.5 g, 400 mmol) were dissolved in water and MeOH (125 mL each). After 36 h of reflux the volume of the red-brown solution was reduced to ~100 mL using a rotary evaporator (50 °C). An additional 200 mL of water was added, the solution was heated to dissolve all the material and cooled, and unreacted benzyl maltol was extracted with 4 × 100 mL dichloromethane. The water layer was stirred, and the pH was adjusted from 10.2 to 2.2 by adding 2 M HCl. A fine light yellow precipitate started to form at pH ~5. After being cooled on ice, the precipitate was filtered and rinsed with 2 × 30 mL cold water. The light yellow solid was dried 30 h on the vacuum line and weighed (108.5 g). This solid was recrystallized by refluxing in 83:17 MeOH:water (21 mL/g solid), then cooling. The yellow crystalline solid was filtered, rinsed with 2 × 30 mL cold water, and dried at least 48 h in the vacuum desiccator (52.32 g, 48% yield based on **2**). Anal. ($C_{15}H_{15}NO_4$) C, H, N. MS (+LSIMS): *m/z* 274 $[M + H]^+$.

*Methyl 6-O-Tosyl-α-D-glucopyranoside (**5**).* This compound was prepared using a previously published procedure (*17*) starting from methyl α-D-glucopyranoside (**4**) (Sigma) (30% yield).

*Methyl 6-Azido-6-deoxy-α-D-glucopyranoside (**6**).* This compound was prepared from **5** using a previously published procedure (*35*). After the solvent was removed, a light yellow syrup was produced that was dried 24 h in a vacuum desiccator (97% yield).

*Methyl 6-Amino-6-deoxy-α-D-glucopyranoside (**7**).* Palladium black has been used previously for azide reductions on carbohydrates (*36*). Compound **6** (2.92 g, 13.3 mmol) was dissolved in 50 mL of MeOH and transferred to a Parr reactor with glass insert. Palladium black (142 mg, 1.33 mmol) was wetted with ~0.5 mL of water and added to the reactor using ~5 mL of MeOH. A stir bar was added, and the reaction mixture was stirred rapidly. The reactor was sealed and pressurized to 60 atm with H_2 gas and stirred for 20 h. The reaction mixture was filtered through a medium frit, and the filtrate was removed using a rotary evaporator, which produced a viscous oil. A tacky white solid formed from the oil after drying 48 h in the vacuum desiccator. After the product was cooled in the freezer, the white solid was scraped into a vial (1.412 g, 73% yield) and used without further purification. The remaining oil was dissolved in water, the pH was adjusted to ~5 using 2 M HCl solution, and the solvent was removed using a rotary evaporator. This was recrystallized in a freezer from a minimum amount of hot MeOH producing the hydrochloride which was characterized. MS (+LSIMS): *m/z* 194 $[M + H]^+$.

*3-Benzyloxy-1-{[((2R,3S,4S,5R,6S)-3,4,5-trihydroxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-2-methyl-4(1H)-pyridinone (**8**).* The reaction used was typical of activated ester reactions in the literature (*37*) and was done under dry conditions using Schlenk line techniques. *N*-Hydroxysuccinimide (NHS) (575 mg, 5.0 mmol) and compound **3** (1.4 g, 5.0 mmol) were dissolved in 65 mL of dry DMF. In a separate vessel dicyclohexylcarbodiimide (DCC) (1.08 g, 5.25 mmol) was dissolved in 10 mL of DMF. The DCC solution was added to the other stirring reaction mixture via cannula. This reaction mixture was left to stir for 24 h at RT under positive N_2 pressure. The activated ester that formed was filtered into a flask containing **7** (1.01 g, 5.25 mmol). The filtrate

dissolved **7**, and the solution was stirred under N_2 for 4 h at RT. The reaction mixture was rotovaporated to dryness (55 °C, ~30 min). Purification was done by silica chromatography using 3:1 ethyl acetate:MeOH. The solid obtained was dried in a vacuum desiccator 48 h to yield a white product (1.70 g, 76% based on **3**). X-ray quality crystals were grown from slow evaporation in ~3:1 ethyl acetate:MeOH. Anal. ($C_{22}H_{28}N_2O_8$) C, H, N. MS (+LSIMS): *m/z* 449 $[M + H]^+$.

*1-{[((2R,3S,4S,5R,6S)-3,4,5-Triacetoxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-3-benzyloxy-2-methyl-4(1H)-pyridinone Hemihydrate (**9**·0.5H_2O).* This reaction was done under dry conditions using Schlenk line techniques. Compound **8** (448 mg, 1.00 mmol), dry pyridine (12 mL), and 1.7 mL of acetic anhydride (18 mmol, 6 equiv per OH) were left to stir under a positive N_2 pressure for 8 h at RT. The reaction mixture was evaporated at reduced pressure on the vacuum line while being stirred for 17 h. The solid was redissolved in a minimum of hot 1:1 EtOH:water and recrystallized. After cooling the reaction flask on ice, the precipitate was filtered, rinsed with 2 × 3 mL of cold water, and dried in a vacuum desiccator at least 48 h to yield a white solid (447 mg, 77% yield). Anal. ($C_{28}H_{35}N_2O_{11.5}$) C, H, N. MS (+ESI): *m/z* 597 $[M + Na]^+$, 575 $[M + H]^+$.

*4-Nitrophenyl 2,3,4,6-Tetra-O-acetyl-β-*D*-glucopyranoside (**11**).* This compound was prepared in a manner similar to other previously published Koenigs−Knorr procedures (*18*) with a number of modifications. 4-Nitrophenol (2.78 g, 20.0 mmol), silver carbonate (5.51 g, 20.0 mmol), activated 4 Å molecular sieves (~10 g), 100 mL of dry MeCN, and 2,6-dimethylpyridine (2.5 mL, 21.0 mmol) were combined. In a separate vessel 4.112 g (10.0 mmol) of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (**10**) (Aldrich) was dissolved in 40 mL of dry MeCN, and the solution was transferred to the reaction mixture via a cannula. The reaction mixture was stirred for 1 h at RT in the dark, filtered through Celite, and rinsed with 30 mL of dichloromethane. The solvents were removed using a rotary evaporator (40 °C), producing an oil that was placed on the vacuum line for 2 h. The resulting syrup was dissolved with 150 mL of dichloromethane and washed with water (100 mL), 5% NaOH (3 × 100 mL), 5% HCl (100 mL), and water (2 × 100 mL). The organic layer was dried and filtered, and the solvent was removed from the filtrate using a rotary evaporator (40 °C). The product was recrystallized from a minimum of hot ethyl acetate/hexanes, filtered, and dried 16 h on the vacuum line to produce a white solid (3.20 g, 68% yield).

*4-Nitrophenyl β-*D*-Glucopyranoside (**12**).* This deacetylation was typical of other deacetylations in the literature (*38*). The reaction was done under dry conditions. Compound **11** (22.5 g, 48.0 mmol) was dissolved in dry MeOH (~500 mL) and dry dichloromethane (~200 mL). Sodium methoxide (260 mg, 4.8 mmol) was added, and the reaction mixture was stirred for 3 h at RT. The dichloromethane was removed using a rotary evaporator (35 °C), an additional 100 mL of MeOH was added, and the solution was heated to dissolve any precipitate. Upon cooling (~30−40 °C), strongly acidic cation-exchange resin (Rexyn 101, Fisher) was added (5 g of resin was activated with 6 M HCl and rinsed with water until the solution was neutral in pH). The resin was stirred for 30 min and filtered out through a Buchner funnel, and the filtrate was recrystallized at RT for a few hours before it was placed in the freezer. The precipitate was filtered, washed with cold MeOH, and dried 24 h on the vacuum line (12.3 g). A second crop of crystals was obtained from a minimum amount of hot MeOH as above (1.96 g), and these products were combined (14.3 g, 99% yield). MS (+LSIMS): *m/z* 302 $[M + H]^+$.

*4-Aminophenyl β-*D*-Glucopyranoside, Hydrochloride (**13**).* This hydrogenation setup is similar to that described for **HOG6GP**. In a flask compound **12** (9.64 g, 32.0 mmol) was dissolved in 150 mL of MeOH and 220 mL of water. The 10% Pd/C (3.405 g, 3.2 mmol Pd) was wetted and rinsed into the flask with water (~30 mL). About 5 drops of 0.5 M HCl were added, and the adaptor was opened to the balloon containing hydrogen gas. After 3 h, 2 mL of 2 M HCl solution was added to the reaction mixture. An additional 2 mL of 2 M HCl solution was added after 6 h, the hydrogen balloon was refilled, and the reaction mixture was left to stir an additional 18 h. The reaction mixture was suction filtered through a medium frit, and the Pd/C was rinsed with 10 mL of water. To the light yellow filtrate was added 2 M HCl solution with stirring until the pH meter read ~4. The solvent was removed using a rotary evaporator (45 °C, ~2 h) and placed on the vacuum line for 24 h. The precipitate was recrystallized from a minimum amount of hot MeOH, filtered, and rinsed with cold MeOH (2 × 15 mL) to give a white solid. The mother liquor was reduced to a minimum amount using a rotary evaporator, and the remaining residue was recrystallized a second time as above. The white solids were combined and dried in a vacuum desiccator at least 48 h before weighing to determine the yield (8.55 g, 87% yield). MS (+LSIMS): *m/z* 272 $[M + H]^+$.

*3-Benzyloxy-1-{[4-(β-*D*-glucopyranosyloxy)phenylcarbamoyl]methyl}-2-methyl-4(1H)-pyridinone (**14**).* This was prepared in a similar fashion as **8** with the following changes: 1.91 g (7.0 mmol) **3**, 0.80 g NHS, 1.47 g DCC (9.1 mmol), and 2.80 g (9.1 mmol) **13**·HCl were used with 250 mL round-bottom flasks. Dry DMF (~140 mL) dissolved the NHS and **8**. The DCC was dissolved in ~15 mL of dry DMF, and a minimum amount of dry DMF was used to dissolve **13**·HCl (250 mL round-bottom flask with septum), followed by the addition of triethylamine (1.9 mL, 9.1 mmol) just prior to Schlenk filtering of the activated ester. After 12 h at 50 °C, the DMF was removed using a rotary evaporator (55 °C, ~1.5 h), taken up in a minimum amount of warm MeOH, filtered, and purified on a silica column run in 4:1 ethyl acetate: MeOH. A small amount of product coeluted with a slight red-brown color. These fractions were recrystallized from hot EtOH to afford a white product. The white solids were combined and dried in a vacuum desiccator at least 48 h (2.63 g, 71% based on **3**). Anal. ($C_{27}H_{30}N_2O_9$) C, H, N. MS (+LSIMS): *m/z* 527 $[M + H]^+$.

*1-{[4-(2,3,4,6-Tetra-O-acetyl-β-*D*-glucopyranosyloxy)-phenylcarbamoyl]methyl}-3-benzyloxy-2-methyl-4(1H)-pyridinone Hemihydrate (**15**·0.5 H_2O).* This reaction was carried out in a similar fashion as for **9** with the following changes: **14** (0.71 g, 1.34 mmol) was dissolved in 15 mL of dry pyridine, and acetic anhydride (2.0 mL, 21 mmol) was used. After 12 h stirring at RT, the reaction mixture was evaporated to dryness using a rotary evaporator (50 °C, <30 min) and dried 12 h on the vacuum line. After recrystallization and filtration, the product was dried in a vacuum desiccator at least 48 h to obtain a white solid (699 mg, 74% yield). Anal. ($C_{35}H_{39}N_2O_{13.5}$) C, H, N. MS (+ESI): *m/z* 717 $[M + Na]^+$, 695 $[M + H]^+$.

*3-Benzyloxy-1-(4-hydroxyphenyl)-2-methyl-4(1H)-pyridinone (**17**).* To a 2 L round-bottom flask were added 4-aminophenol (49.11 g, 450 mmol), benzyl maltol (**2**) (64.9 g, 300 mmol), 1.2 L of water, and 250 mL of MeOH. The reaction mixture was stirred and heated in an oil bath at 90 °C for 72 h. The solution was filtered hot and rinsed with cold water and MeOH (25 mL each), yielding

a white precipitate which was dried in a vacuum desiccator for 16 h (13.2 g). The warm filtrate was left at RT to cool and allow for further precipitation. The precipitate was filtered and dried for 3 h in a vacuum desiccator (22.4 g). The precipitate was refluxed in 50 mL of MeOH, and a red-brown solution was decanted. This was repeated four more times, with the last decant having a slight yellow color. The remaining solid was recrystallized from refluxing MeOH (~800 mL) followed by cooling in the freezer for 16 h. The crystals were dried in a vacuum desiccator 24 h to produce a white solid (13.7 g). The ^{1}H NMR spectra and TLC in 9:1 ethyl acetate:MeOH looked identical for the precipitated and recrystallized products; they were combined (26.9 g, 29% yield). Mp 240−242 °C. Anal. ($C_{19}H_{17}NO_3$) C, H, N. MS (+LSIMS): *m/z* 308 [M + H]$^+$.

*1-[4-(2,3,4,6-Tetra-O-benzyl-β-*D*-glucopyranosyloxy)-phenyl]-3-benzyloxy-2-methyl-4(1H)-pyridinone (**18**).* This reaction was typical of Mitsunobu reactions in the literature (*19*) and was done under dry conditions using Schlenk line techniques. 2,3,4,6-Tetra-*O*-benzyl-D-glucopyranose (**16**, Aldrich) (5.41 g, 10.0 mmol) and **17** (3.69 g, 12.0 mmol) were combined in 240 mL of dry dichloromethane. Tributylphosphine (3.74 mL, 15.0 mmol) was added via a syringe, and the reaction mixture was stirred for 5 min. Separately, azodicarboxylic acid dipiperidide (ADDP) (3.79 g, 15 mmol) was dissolved with 20 mL of dichloromethane and transferred to the reaction mixture via a syringe, followed by rinsing with 10 mL of dichloromethane. The reaction mixture was light orange in color. All material dissolved after ~1 h. The flask was stirred for 10 h at RT. The dichloromethane was removed using a rotary evaporator (45 °C), and the reaction mixture was redissolved in hot ethyl acetate (~120 mL) and then cooled in the freezer. A white solid recrystallized (ADDP byproduct), was filtered with a course frit, and was rinsed with 2 × 10 mL of cold ethyl acetate. The ethyl acetate filtrate was removed using a rotary evaporator (45 °C) to form an orange-brown oil. The oil was purified on a silica column eluting with ethyl acetate. A bright yellow band elutes just ahead of the product. The product was dried in vacuo 48 h to produce a yellow viscous oil (6.01 g, 66% yield). MS (+LSIMS): *m/z* 830 [M + H]$^+$.

*3-Benzyloxy-1-{[((2R/S,3R,4R,5S)-6-hydroxymethyl-2,4,5-trihydroxy-tetrahydropyran-3-yl)carbamoyl]methyl}-2-methyl-4(1H)-pyridinone (**19**).* Prepared in a similar manner to that of **8**, this reaction was done under dry conditions using Schlenk line techniques. To a 100 mL flask were added **3** (769 mg, 2.8 mmol), glucosamine hydrochloride (728 mg, 3.4 mmol), DCC (744 mg, 3.6 mmol), and NHS (377 mg, 3.3 mmol). DMF (10 mL) was added via a syringe and the mixture stirred into a slurry. Diisopropylethylamine (1.3 mL, 7.5 mmol) was added to the stirring mixture, and the reaction was heated at 80 °C for 16 h. The solvent and excess base were removed on a rotary evaporator, and the resulting dark residue was redissolved in water. Insoluble impurities were removed by filtration, and the filtrate was reduced to a thick orange syrup, which was purified by silica chromatography eluting with 2:2:1 ethyl acetate:CH_3CN:MeOH. Fractions containing the product were recrystallized in MeOH to give a white solid (675 mg, 54%). Anal. ($C_{21}H_{26}N_2O_8$) C, H, N. MS (+ESI): *m/z* 457 [M + Na]$^+$, 435 [M + H]$^+$.

*3-Hydroxy-1-{[((2R,3S,4S,5R,6S)-3,4,5-trihydroxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-2-methyl-4(1H)-pyridinone (**HOG6GP**).* **8** (1.34 g, 3.0 mmol) was dissolved in MeOH (60 mL) with stirring in a round-bottom flask. Water (40 mL) was added to prevent the product from precipitating when formed. 10% Pd/C (319 mg, 0.3 mmol Pd) was wetted with water (5 mL) and poured into the flask. An 11 L latex balloon was filled with H_2 gas and fitted to a stopcocked adaptor which was opened to the round-bottom flask. After stirring at RT for 12 h, the H_2 atmosphere was removed. The solution was suction filtered through a medium frit, the Pd/C was washed with 10 mL of water, and the filtrate was syringed through a nylon filter (25 mm, 0.2 μm) to remove fine Pd/C. This light orange solution was reduced in volume using a rotary evaporator (50 °C, <30 min) and recrystallized by adding 3 mL of water and 4 mL of methanol, heating until dissolved, and cooling at RT. The precipitate was cooled on ice, filtered out, and rinsed with 2 × 3 mL of cold MeOH to produce a white solid and a red-orange colored filtrate. The solid was dried in a vacuum desiccator at least 48 h (568 mg, 53%). Anal. ($C_{15}H_{22}N_2O_8$) C, H, N. MS (+LSIMS): *m/z* 359 [LH + H]$^+$; (+ESI): *m/z* 359 [LH + H]$^+$.

*Tris(1-{[((2R,3S,4S,5R,6S)-3,4,5-trihydroxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)gallium(III) Tetrahydrate (**Ga(OG6GP)$_3$·4H$_2$O**).* Gallium nitrate nonahydrate (41.8 mg, 0.1 mmol) was dissolved in 3 mL of water. This solution was added dropwise to a stirring solution of **HOG6GP** (358 mg, 0.315 mmol) in 4 mL of water. The initial pH of the reaction mixture was 1.6. A 1% NaOH solution was added dropwise to the reaction mixture until the pH was 7.0, and the solvent was then removed using a rotoevaporation (50 °C, <30 min) to produce an off-white precipitate. The precipitate was redissolved in 3 mL of water and applied on a Sephadex G10 size exclusion column; the column was eluted with deionized water. Silica TLC of the fractions was conducted (1:1 ethyl acetate:MeOH) to determine the presence of product. Salts remained white on a charred TLC plate, and the ligand had a higher R_f value than did the metal complex. The fractions containing the desired compound were combined, and the solvent was removed using a rotary evaporator (50 °C, <30 min) to produce an off-white solid. The solid was dried in a vacuum desiccator at least 48 h (115.6 mg, 95%). Anal. ($C_{45}H_{71}N_6O_{28}Ga$) C, H, N. MS (+ESI): *m/z* 1163/1165 [$^{69/71}GaL_3Na$]$^+$ 1141/1143 [$^{69/71}GaL_3H$]$^+$ (with similar isotopic distribution as that calculated for $C_{45}H_{64}GaN_6O_{24}$), 783/785 [$^{69/71}GaL_2$]$^+$, 381 [LH + Na]$^+$, 359 [LH + H]$^+$; (+LSIMS): *m/z* 783/785 [$^{69/71}GaL_2$]$^+$, 359 [LH + H]$^+$.

*Tris(1-{[((2R,3S,4S,5R,6S)-3,4,5-trihydroxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)indium(III) Hydrate (**In(OG6GP)$_3$·H$_2$O**).* This reaction was carried out in a similar fashion as for the analogous gallium complex except that indium nitrate trihydrate was used (35.5 mg, 0.1 mmol). The off white solid obtained was dried in a vacuum desiccator for 48 h (108 mg, 89% yield). Anal. ($C_{45}H_{65}InN_6O_{25}$) C, H, N. MS (+ESI): *m/z* 1225 [$^{115}InL_3$ + K]$^+$ (with similar isotopic distribution as that calculated for $C_{45}H_{63}N_6O_{24}KIn$), 1209 [$^{115}InL_3$ + Na]$^+$, 867 [$^{115}InL_2K(-H)$]$^+$, 851 [$^{115}InL_2Na(-H)$]$^+$, 829 [$^{115}InL_2$]$^+$, 397 [LH + K]$^+$, 381 [LH + Na]$^+$.

*1-{[4-(β-*D*-Glucopyranosyloxy)phenylcarbamoyl]methyl}-3-hydroxy-2-methyl-4(1H)-pyridinone Hemihydrate (**HOGBAP·0.5H$_2$O**).* This reaction was carried out in a similar fashion as for **HOG6GP** with the following changes: the starting material (**14**, 790 mg, 1.5 mmol) was dissolved in MeOH (40 mL) followed by the addition of water (20 mL) and 10% Pd/C (160 mg, 0.15 mmol). After the solvent was removed using a rotary evaporator,

a minimum amount of 2:1 MeOH:water (~10−15 mL) was added to redissolve the product under reflux and was left to recrystallize at RT. The product obtained from recrystallization was dried in a vacuum desiccator (394.8 mg, 59%). Anal. ($C_{20}H_{25}N_2O_{9.5}$) C, H, N. MS (+ESI): *m/z* 475 $[LH + K]^+$, 459 $[LH + Na]^+$.

*Tris(1-{[4-(β-*D*-glucopyranosyloxy)phenylcarbamoyl]-methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)gallium(III) Dihydrate (**Ga(OGBAP)$_3$·2H$_2$O**).* To a 100 mL flask were added **HOGBAP**·0.5H_2O (122.4 mg, 0.315 mmol) and water (15 mL). A solution of 1% HCl was added dropwise with stirring until the pH was 1.0, at which time all the ligand dissolved. Gallium nitrate nonahydrate (42 mg, 0.1 mmol) was dissolved in 3 mL of water and added dropwise to the solution in the flask; this solution was clear and colorless (pH 1.4). 1% NaOH solution was added dropwise with stirring. At pH ~ 4 a white precipitate formed and was redissolved upon warming (~50 °C). Continued addition of 1% NaOH to the cooling solution (until pH ~ 6.5) resulted in more precipitate formation. The pH was adjusted to 7.0 after cooling to RT, and the solution was left to stir for 15 min. The precipitate was filtered and washed with cold water (5 mL). The filtrate was reduced to a few mL using a rotary evaporator (50 °C, <30 min). Purification was done on a Sephadex G10 column. TLC of the fractions (1:1 ethyl acetate:MeOH) was used to verify product fractions as described above. ^{1}H NMR spectra were identical for both the precipitated and column purified product. The product was dried in a vacuum desiccator at least 48 h to yield precipitate: 56.6 mg; column: 60.2 mg (116.8 mg combined, 83% yield). Anal. ($C_{60}H_{73}GaN_6O_{29}$) C, H, N. MS (+ESI): *m/z* 1397/1399 $[^{69/71}GaL_3 + Na]^+$ (consistent isotopic distribution), 961/963 $[^{69/71}GaL_2 + Na(-H)]^+$, 939/941 $[^{69/71}GaL_2]^+$, 777/779 $[^{69/71}GaL_2(-C_6H_{10}O_5$ for one glucose molecule$)]^+$, 459 $[LH + Na]^+$.

*Tris(1-{[4-(β-*D*-glucopyranosyloxy)phenylcarbamoyl]-methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)indium(III) Pentahydrate (**In(OGBAP)$_3$·5H$_2$O**).* This reaction was carried out in a similar fashion as for the analogous gallium complex except that indium nitrate trihydrate was used (35.5 mg, 0.1 mmol). The product was dried in a vacuum desiccator at least 48 h to yield precipitate: 61.1 mg; column: 68.2 (129.3 mg combined, 86% yield). Anal. ($C_{60}H_{79}InN_6O_{32}$) C, H, N. MS (+ESI): *m/z* 1443 $[^{115}InL_3 + Na]^+$ (consistent isotopic distribution), 1007 $[^{115}InL_2 + Na(-H)]^+$, 985 $[^{115}InL_2]^+$, 823 $[^{115}InL_2-(-C_6H_{10}O_5$ for 1 glucose molecule$)]^+$, 661 $[^{115}InL_2-(-C_{12}H_{20}O_{10}$ for two glucose molecules$)]^+$, 459 $[LH + Na]^+$.

*1-[4-(β-*D*-Glucopyranosyloxy)phenyl]-3-hydroxy-2-methyl-4(1H)-pyridinone Hydrate (**HOGBPP·H$_2$O**).* This reaction was carried out in a similar fashion as for **HOG6GP** with the following changes: **18** (1.66 g, 2.0 mmol) was dissolved with MeOH (40 mL). The 10% Pd/C (2.13 g, 2.0 mmol Pd) was wetted with water (10 mL) and rinsed with MeOH (~10 mL). The reaction was stirred vigorously under H_2 gas at RT for 24 h. Following filtering and filtrate solvent removal with a rotary evaporator, the product was dissolved in 50 mL of water and washed with 3 × 15 mL of dichloromethane. The water was removed using a rotovaporator (50 °C) to produce an off-white solid, which was dried in a vacuum desiccator at least 48 h (652 mg, 86%). Anal. ($C_{18}H_{23}NO_9$) C, H, N. MS (+ESI): *m/z* 402 $[LH + Na]^+$; (+LSIMS): *m/z* 380 $[LH + H]^+$.

*Tris{1-[4-(β-*D*-glucopyranosyloxy)phenyl]-2-methyl-3-oxy-4(1H)-pyridinonato}gallium(III) Dihydrate (**Ga(OGBPP)$_3$·2H$_2$O**).* This reaction was carried out in a similar fashion as for **Ga(OG6GP)$_3$** with substitution of the ligand (**HOGBPP**·H_2O, 125 mg, 0.315 mmol) and the pH after addition of the gallium nitrate solution was 1.4. After drying in the vacuum desiccator at least 48 h, an off-white solid was produced (117 mg, 95% yield). Anal. ($C_{54}H_{64}GaN_3O_{26}$) C, H, N. MS (+ESI): *m/z* 1226/1228 $[^{69/71}GaL_3 + Na]^+$ (consistent isotopic distribution), 825/827 $[^{69/71}GaL_2]^+$, 402 $[LH + Na]^+$.

*Tris{1-[4-(β-*D*-glucopyranosyloxy)phenyl]-2-methyl-3-oxy-4(1H)-pyridinonato}indium(III) Tetrahydrate (**In(OGBPP)$_3$·4H$_2$O**).* This reaction was carried out in a similar fashion as for the analogous gallium complex, with the exception that indium nitrate trihydrate was used (35.5 mg, 0.1 mmol) and the pH after its addition to the ligand was 1.8. After drying in the vacuum desiccator at least 48 h, an off-white solid was obtained (120 mg, 91% yield). Anal. ($C_{54}H_{68}InN_3O_{28}$) C, H, N. MS (+ESI): *m/z* 1272 $[^{115}InL_3 + Na]^+$ (consistent isotopic distribution), 871 $[^{115}InL_2]^+$, 402 $[LH + Na]^+$.

*1-{[((2R,3S,4S,5R,6S)-3,4,5-Triacetoxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-3-hydroxy-2-methyl-4(1H)-pyridinone Hydrate (**HAG6GP·H$_2$O**).* This reaction was carried out in a similar fashion as for **HOG6GP** with the following changes: **9**·0.5H_2O (950 mg, 1.63 mmol) was dissolved in MeOH (40 mL), 10% Pd/C (175 mg, 0.164 mmol) was used (wetted with 5 mL of H_2O, rinsed with 5 mL of MeOH), and the reaction was stopped after 20 h at RT. The filtered Pd/C was rinsed with 3 × 10 mL of MeOH taking care not to completely dry the Pd/C in the frit. After filtering through a 0.2 μm filter, the filtrate solvent was removed using a rotary evaporator (40 °C, <30 min). The solid was redissolved in a minimum amount of hot 1:1 water:EtOH and recrystallized at RT. Filtering the precipitate and rinsing with 2 × 3 mL of cold ethanol produced a white solid and an orange filtrate. The product was dried in a vacuum desiccator for at least 48 h (321 mg, 71%). Anal. ($C_{21}H_{30}N_2O_{12}$) C, H, N. MS (+ESI): *m/z* 507 $[LH + Na]^+$, 485 $[LH + H]^+$.

*Tris(1-{[((2R,3S,4S,5R,6S)-3,4,5-triacetoxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)gallium(III) Hydrate (**Ga(AG6GP)$_3$·H$_2$O**).* This reaction was carried out in a similar fashion as for **Ga(OG6GP)$_3$** with the following changes: **HAG6GP**·H_2O (157 mg, 0.315 mmol) was dissolved in 4 mL of 1:1 EtOH:water. Gallium nitrate nonahydrate (41.8 mg, 0.1 mmol) was dissolved in 2 mL of 1:1 H_2O:EtOH and added dropwise to the solution containing the ligand. The initial pH was 2.4 for this reaction mixture, and a 1% NaOH solution was added dropwise until the pH was 7.0. The solvent was removed using a rotary evaporator at 50 °C (<30 min) to produce a white precipitate. The precipitate was purified on a Sephadex G10 size exclusion column run in 1:1 EtOH:water. The relevant fractions were combined, and the solvent was removed using a rotary evaporator (50 °C, <30 min). The resulting solid was dried in a vacuum desiccator at least 48 h (139 mg, 90%). Anal. ($C_{63}H_{83}GaN_6O_{34}$) C, H, N. MS (+ESI): *m/z* 1541/1543 $[^{69/71}GaL_3 + Na]^+$ (consistent isotopic distribution), 1035/1037 $[^{69/71}GaL_2]^+$, 507 $[LH + Na]^+$, 485 $[LH + H]^+$.

*Tris(1-{[((2R,3S,4S,5R,6S)-3,4,5-triacetoxy-6-methoxy-tetrahydropyran-2-yl-methyl)carbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)indium(III) Tetrahydrate (**In(AG6GP)$_3$·4H$_2$O**).* This reaction was carried out in a similar fashion as for the analogous gallium complex, with the exception that indium nitrate trihydrate was used (35.5 mg, 0.1 mmol). After drying in the vacuum desiccator at least 48 h, a white solid was produced (172

mg, 93% yield). Anal. ($C_{63}H_{89}InN_6O_{37}$) C, H, N. MS (+ESI): *m/z* 1587 $[^{115}InL_3 + Na]^+$ (consistent isotopic distribution), 1081 $[^{115}InL_2]^+$, 507 $[LH + Na]^+$, 485 $[LH + H]^+$.

*1-{[4-(2,3,4,6-Tetra-O-acetyl-β-*D*-glucopyranosyloxy)-phenylcarbamoyl]methyl}-3-hydroxy-2-methyl-4(1H)-pyridinone Hydrate (**HAGBAP·**H_2O).* This reaction was carried out in a similar fashion as for **HAG6GP** with the following changes: **11** (507 mg, 0.71 mmol) and 10% Pd/C (76 mg, 0.071 mmol) were used, and the reaction was stopped after 24 h at RT. The product was recrystallized from hot 1:1 MeOH:water (10 mL). After filtering out a white solid, an orange filtrate remained. The white solid was dried (321 mg, 71%). Anal. ($C_{28}H_{32}N_2O_{13}$) C, H, N. MS (+ESI): *m/z* 627 $[LH + Na]^+$, 605 $[LH + H]^+$.

*Tris(1-{[4-(2,3,4,6-tetra-O-acetyl-β-*D*-glucopyranosyloxy)phenylcarbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)gallium(III) Tetrahydrate (**Ga(AGBAP)$_3$·**$4H_2O$).* This reaction was carried out in a similar fashion as for **Ga(AG6GP)$_3$** with the following changes: **HAGBAP·**$1H_2O$ (196 mg, 0.315 mmol) was dissolved in 1:1 EtOH:water (10 mL). After the addition of gallium nitrate, the pH was 2.2. When dropwise addition of 1% NaOH produced a precipitate, the reaction mixture was heated to ~40 °C. As the reaction mixture cooled, 1% NaOH solution was added until pH 7 and more precipitate formed. The solution was cooled on ice 15 min, and the precipitate was filtered and rinsed with 5 mL of cold water. The solid was dried in a vacuum desiccator at least 48 h (172 mg, 88%). Anal. ($C_{84}H_{101}GaN_6O_{43}$) C, H, N. MS (+ESI): *m/z* 1879/81 $[^{69/71}GaL_3 + H]^+$ (consistent isotopic distribution), 1275/1277 $[^{69/71}GaL_2]^+$, 605 $[LH + H]^+$.

*Tris(1-{[4-(2,3,4,6-tetra-O-acetyl-β-*D*-glucopyranosyloxy)phenylcarbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)indium(III) Dihydrate (**In(AGBAP)$_3$·**$2H_2O$).* This reaction was carried out in a similar fashion as for the analogous gallium complex, with the exception that indium nitrate trihydrate was used (35.5 mg, 0.1 mmol). After drying, a white solid was produced (178 mg, 91% yield). Anal. ($C_{84}H_{97}InN_6O_{41}$) C, H, N. MS (+ESI): *m/z* 1947 $[^{115}InL_3 + Na]^+$ (consistent isotopic distribution), 1925 $[^{115}InL_3 + H]^+$, 1321 $[^{115}InL_2]^+$, 627 $[LH + Na]^+$, 605 $[LH + H]^+$.

*3-Hydroxy-1-{[((2R/S,3R,4R,5S)-6-hydroxymethyl-2,4,5-trihydroxy-tetrahydropyran-3-yl)carbamoyl]methyl}-2-methyl-4(1H)-pyridinone Hydrate (**HOG2GP·**H_2O or **Feralex-G·**H_2O).* This reaction was carried out in a similar fashion as for **HOG6GP** with the following changes: the starting material **19** (450 mg, 1.0 mmol) was dissolved in MeOH (30 mL) and water (30 mL), and 10% Pd/C (115 mg, 0.11 mmol) was used. The solvent was removed on a rotary evaporator (40 °C) to give a quantitative yield of white crystalline product (358 mg, 100%). Anal. ($C_{14}H_{22}N_2O_9$) C, H, N. MS (+ESI): *m/z* 345 $[LH + H]^+$.

*Tris({[((2R/S,3R,4R,5S)-6-hydroxymethyl-2,4,5-trihydroxy-tetrahydropyran-3-yl)carbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)gallium(III) Pentahydrate (**Ga(OG2GP)$_3$·**$5H_2O$).* Gallium nitrate hexahydrate (11 mg, 0.03 mmol) was dissolved in 3 mL of water and added to **HOG2GP** (32 mg, 0.093 mmol) dissolved in 3 mL of water. The pH of the resulting solution was adjusted to 7 with 0.1 M NaOH. The solution volume was reduced on a rotary evaporator (30 °C) and the residue purified on a Sephadex G10 column. Precipitation with acetone from a minimal amount of water gave a white solid, which was dried 48 h in a vacuum desiccator (30 mg, 91% yield). Anal. ($C_{42}H_{67}Ga\ N_6O_{29}$) C, H, N. MS (+ESI): *m/z* 755 $[GaL_2]^+$.

*Tris({[((2R/S,3R,4R,5S)-6-hydroxymethyl-2,4,5-trihydroxy-tetrahydropyran-3-yl)carbamoyl]methyl}-2-methyl-3-oxy-4(1H)-pyridinonato)indium(III) Tetrahydrate (**In(OG2GP)$_3$·**$4H_2O$).* This reaction was carried out in a similar fashion as for the analogous gallium complex except indium nitrate trihydrate was used (20 mg, 0.045 mmol) and 59 mg of **HOG2GP** (0.17 mmol). The product was a white solid (45 mg, 70% yield). Anal. ($C_{42}H_{65}InN_6O_{28}$) C, H, N. MS (+ESI): *m/z* 801 $[InL_2]^+$.

*3-Hydroxy-1-(4-hydroxyphenyl)-2-methyl-4(1H)-pyridinone (**Hhpp**).* This reaction was carried out in a similar fashion as for **HOG6GP** with the following changes: the starting material **17** (1.53 g, 5.0 mmol) was dissolved in MeOH (50 mL) and DMF (50 mL). The 10% Pd/C (532 mg, 0.50 mmol Pd) was wetted and transferred to the flask using ~10 mL of water. The reaction was stopped after 12 h at RT. The filtered Pd/C was rinsed with 3 × 10 mL of warm MeOH (taking care not to completely dry the Pd/C) and 3 × 10 mL of warm DMF (~60 °C). The solvent of the light pink-orange filtrate was removed using a rotary evaporator (50 °C, ~1.5 h) and the residue dried in vacuo for 2 h. The resulting light pink solid was dissolved in a minimum of hot MeOH, ~25% more MeOH was added, and a fine precipitate formed on cooling. The precipitate was filtered and rinsed with 2 × 3 mL of cold MeOH to produce a white solid and orange filtrate. A second crop of white precipitate was obtained from the orange filtrate. The precipitates were combined and dried in a vacuum desiccator for at least 48 h (381 mg, 35%). Anal. ($C_{12}H_{11}NO_3$) C, H, N. MS (+ESI): *m/z* 218 $[LH + H]^+$.

Tris(1-(4-hydroxyphenyl)-2-methyl-3-oxy-4(1H)-pyridinonato)gallium(III) Sesquihydrate (Ga(hpp)$_3$·1.5H_2O). Method A: Synthesis from Hhpp. Gallium nitrate nonahydrate (208.9 mg, 0.50 mmol) was dissolved in DMF (5 mL). This solution was added dropwise to a stirring solution of **Hhpp** (330 mg, 1.52 mmol) at RT in 40 mL of DMF. A 1.0% NaOH solution (6.2 mL) was added dropwise to the reaction mixture, and the solvent was removed using a rotary evaporator at 55 °C. After drying on the vacuum line for 16 h, the precipitate was transferred to a medium frit, stirred with warm water, and filtered (3 × 20 mL). The resulting white precipitate was dried in a vacuum desiccator for at least 48 h (319.2 mg, 86%). Anal. ($C_{36}H_{33}GaN_3O_{10.5}$) C, H, N. MS (+ESI): *m/z* 718/720 $[^{69/71}GaL_3 + H]^+$ (consistent isotopic distribution), 501/503 $[^{69/71}GaL_2]^+$, 218 $[LH + H]^+$.

Method B: Enzymatic Cleavage of Ga(OGBPP)$_3$. To a 1 mL Eppendorf tube were added 30 μL of 50 mM solution of **Ga(OGBPP)$_3$** and 65 μL of 75 mM sodium phosphate buffer (pH 6.8). The solution was mixed briefly (vortex mixer) and 5 μL of a buffered solution containing 3.98 mg/mL of Abg was added to start the reaction. A white precipitate formed within a few minutes. After 30 min at RT, the reaction mixture (with some white precipitate) was spotted on a TLC plate (dried at RT between spotting). TLC in 1:1 ethyl acetate:MeOH was run ~45 min. after addition of enzyme. The TLC indicated a new spot with the same R_f value (0.55) as the **Ga(hpp)$_3$** precipitate from Method A. After ~1 h, the white precipitate was filtered. TLC of the supernatant and filtered precipitate indicated that free glucose ($R_f = 0.35$) was present in the supernatant. The precipitate was dried 2 h in a vacuum desiccator producing ~1 mg of a white solid. MS (+ESI): *m/z* 740/742 $[^{69/71}Ga(hpp)_3 + Na]^+$ (consistent isotopic distribution), 501/503 $[^{69/71}Ga(hpp)_2]^+$, 218 $[Hhpp + H]^+$.

CONCLUSIONS

A number of glucose-bearing tris(pyridinonato)gallium and indium complexes were synthesized and characterized by mass spectrometry and ^{1}H and ^{13}C NMR spectroscopy. With three equivalents of ligand, neutral complexes formed, with the pyridinone moiety complexing the gallium and indium metal centers. There are no indications that the glucose moiety coordinates to, or interacts with, the gallium or indium metal centers. How the glucose moieties interact in vivo will dictate the biodistribution of the metal complexes and their potential for use in diagnostic nuclear medicine. Labeling studies with suitable gallium isotopes are now in progress.

ACKNOWLEDGMENT

We thank the Natural Sciences and Engineering Research Council (NSERC) of Canada for support and Ryan Moslin and Sherwin Sattarzadeh for technical/experimental assistance.

Supporting Information Available: ^{1}H NMR and ^{13}C NMR spectral assignments for all compounds and selected NMR spectra. This material is available free of charge via the Internet at http://pubs.acs.org/BC.

Received July 20, 2005; Revised Manuscript Received September 5, 2005

Renal localization of radiolabeled antibody fragments presents a problem in targeted imaging and radiotherapy. We recently reported that Fab fragments labeled with 3′-[^{131}I]iodohippuryl N^{ϵ}-maleoyl-L-lysine (HML) demonstrated markedly low renal radioactivity levels from early postinjection in mice. Previous studies suggested that low renal radioactivity levels were attributable to cleavage of the glycyl-lysine sequence in HML by the action of renal brush border enzymes, followed by urinary excretion of the resulting *m*-iodohippuric acid. In this study, an in vitro system using brush border membrane vesicles (BBMVs) isolated from the rat kidney cortex was developed to estimate renal brush border enzyme(s)-mediated cleavage of the peptide linkage. Low molecular weight HML derivatives, 3′-[^{125}I]iodohippuryl L-lysine (HL), 3′-[^{125}I]iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine (HBL), and their D-amino acid counterparts, were synthesized and incubated in BBMVs. Both [^{125}I]HL and [^{125}I]HBL generated *m*-[^{125}I]iodohippuric acid after incubation in BBMVs at 37 °C while the latter liberated significantly higher amounts of the metabolite. [^{125}I]D-HL and [^{125}I]D-HBL failed to release the metabolite under similar conditions. The liberation of *m*-[^{125}I]iodohippric acid from [^{125}I]HL was significantly facilitated or completely inhibited by the addition of an activator or an inhibitor for carboxypeptidase M. The release of *m*-[^{125}I]iodohippuric acid from [^{125}I]HBL increased by the addition of the activator, whereas the inhibitor partially inhibited the release of the metabolite from [^{125}I]-HBL. The BBMV-mediated release of *m*-[^{125}I]iodohippuric acid from [^{125}I]HBL was not impaired by the addition of inhibitors for neutral endopeptidase or renal dipeptidase. These findings showed that the glycyl-L-lysine sequence in HML would be recognized and cleaved by metalloenzymes and nonmetalloenzymes on the renal brush border even when iodine was incorporated into a benzene ring and the N^{ϵ}-amine residue of lysine was chemically modified, which supported the hypothesis that low renal radioactivity levels of HML-conjugated Fab fragments would be attributed to the release of *m*-iodohippuric acid by renal brush border enzymes. This study suggested that this in vitro system using BBMVs would be useful to estimate radiolabeling reagents of antibody fragments or peptides designed to reduce renal radioactivity with a variety of radionuclides.

INTRODUCTION

Recent clinical studies of ^{90}Y- and ^{131}I-labeled intact antibodies against CD20 demonstrated significant response rates in patients with chemotherapy-refractory non-Hodgkin's lymphoma (*1*). Although the ^{90}Y-labeled antibodies caused myelosuppresion as a result of long circulation times, this could be reduced by using antibody fragments in place of intact antibodies, due to the faster clearance of antibody fragments from the systemic circulation. The uniform intratumor distribution of antibody fragments would also be advantageous to increase the therapeutic efficacy (*2*). However, radiolabeled antibody fragments showed high and persistent localization of radioactivity in the kidneys from early postinjection onward, which causes therapeutic limitations (*3*−*6*).

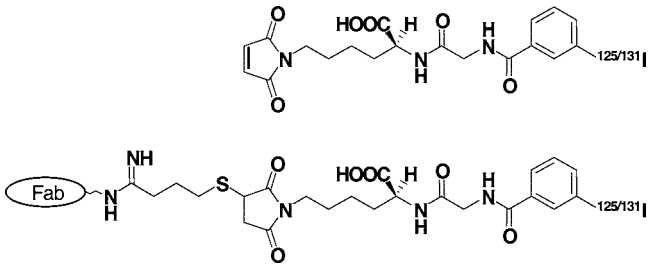

Figure 1. Chemical structures of [$^{125/131}$I]HML and [$^{125/131}$I]-HML-conjugated Fab fragments.

To circumvent this problem, we recently developed a radioiodination reagent, 3′-iodohippuryl N^{ϵ}-maleoyl-L-lysine (HML, Figure 1) based on the hypothesis that glycyl-lysine linkage in HML would be cleaved by brush border enzyme(s) present on the lumen of the renal tubule while the antibody fragments are taken up by renal cells (*7*). In tumor-bearing nude mice, [^{131}I]HML-conjugated Fab fragments (Figure 1) significantly reduced renal radioactivity levels from early postinjection onward without impairing radioactivity levels in the

tumor (*7*, *8*). A follow-up in vivo study showed that cleavage of the glycyl-lysine sequence in [$^{125/131}$I]HML-conjugated Fab fragments occurred at the membrane fractions of renal cells from an early postinjection time (*9*). These in vivo studies supported the validity of this chemical design to prepare radiolabeled antibody fragments of low renal radioactivity levels. However, it remains uncertain whether a renal enzyme(s) on the brush border membrane was responsible for cleavage of the glycyl-lysine sequence in HML-conjugated antibody fragments. In addition, since the ability of HML to release *m*-iodohippuric acid was only estimated by biodistribution studies after conjugation with antibody fragments, an in vitro experimental system is highly warranted to estimate the release of *m*-iodohippuric acid prior to conjugation with antibody fragments. Such an experimental system would provide an insight into better understanding the mechanism of releasing *m*-iodohippuric acid from HML-conjugated antibody fragments. Such an in vitro system would also be useful to develop new radiolabeling reagents for antibody fragments or peptides with a variety of radionuclides.

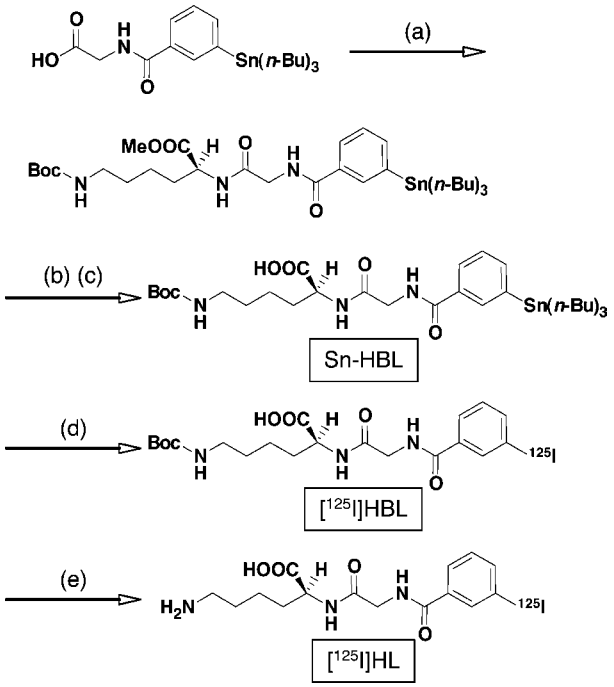
Renal brush border membrane vesicles (BBMVs) have been used to investigate the transport mechanisms of drugs in the renal brush border membrane (*10*, *11*). BBMVs have a predominantly luminal side-out orientation with a variety of enzymes on their surface (*10*, *12*). Furthermore, enzymes in renal lysosomes can be separated from those on BBMVs during preparation (*12*). Such characteristics rendered BBMVs attractive as an in vitro system to estimate the radiolabeling reagents for antibody fragments or peptides of low renal radioactivity levels utilizing enzymes on renal brush border membrane.

In this study, 3′-[^{125}I]iodohippuryl L-lysine ([^{125}I]HL), 3′-[^{125}I]iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine ([^{125}I]-HBL), and their D-lysine counterparts, 3′-[^{125}I]iodohippuryl D-lysine ([^{125}I]D-HL) and 3′-[^{125}I]iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-D-lysine ([^{125}I]D-HBL) were synthesized as HML derivatives, and the brush border enzyme-mediated release of *m*-[^{125}I]iodohippuric acid was investigated using BBMVs prepared from the rat kidney cortex. The BBMV-mediated release of *m*-[^{125}I]iodohippuric acid was also determined by the presence of an activator for carboxypeptidase M (CPM) or inhibitors of some enzymes on BBMVs. The findings in this study showed that the in vitro system using BBMVs would be useful to evaluate newly developed radiolabeling reagents designed to liberate radiometabolites by the action of renal brush border enzymes prior to conjugation to antibody fragments.

MATERIALS AND METHODS

Reagents and Chemicals. Na[^{125}I]I was purchased from Biomedicals, Inc. (California). Reversed phase high-performance liquid chromatography (RP-HPLC) was performed with a Cosmosil 5C_{18}-AR-300 column (4.6 × 150 mm, Nacalai Tesque, Kyoto, Japan) eluted at a flow rate of 1 mL/min with a gradient mobile phase starting from 100% water to 100% acetonitrile in 30 min (solvent system 1) or from 80% A (0.1% aqueous trifluoroacetic acid; TFA) and 20% B (acetonitrile with 0.1% TFA) to 20% A and 80% B in 30 min (solvent system 2). Size-exclusion high-performance liquid chromatography (SE-HPLC) was performed with a Cosmosil Diol-120 column (7.5 × 600 mm, Nacalai Tesque, Kyoto) eluted with 0.1 M phosphate buffer (pH 6.8) at a flow rate of 1 mL/min. Each eluent was collected with a fraction collector (Redi-Frac; Pharmacia Biotech, Tokyo) at 30-s intervals, and

Scheme 1[a]



[a] Reagents: (a) 1-hydroxybenzotriazole, triethylamine, N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester hydrochloride, 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride; (b) NaOH; (c) HCl; (d) *N*-chlorosuccinimide, Na[^{125}I]I; (e) TFA.

the radioactivity levels in each fraction (500 μL) were determined with an auto well counter (ARC-2000; Aloka, Tokyo). TLC analyses were performed with silica plates (Merck Art 5553) developed with a mixture of chloroform, methanol, and water (15:8:1) (solvent system 3) or a mixture of chloroform, methanol, and acetic acid (50:10:1) (solvent system 4). ^{1}H NMR spectra were recorded on a Bruker AC-200 spectrometer, and chemical shifts are reported in ppm downfield from an internal tetramethylsilane standard. Mass spectra were obtained with the JMS−HX/HX110 A model (JEOL Ltd., Tokyo), API III model (Perkin-Elmer Sciex Instruments, Canada), or LCMS-QP8000α model (Shimadzu, Kyoto). Sn-HML was synthesized according to the procedure of Wakisaka et al. (*13*). DL-2-Mercaptomethyl-3-guanidinoethylthiopropanoic acid (MGTA), phosphoramidon, and tienam were purchased from Calbiochem (La Jolla, CA), Peptide Institute (Osaka, Japan) and Banyu Pharmaceutical Co., Ltd. (Tokyo), respectively. L-γ-Glutamyl-*p*-nitroanilde, L-leucine-*p*-nitroanilide, *p*-nitrophenyl-β-D-galactopyranoside, and glycyl-D-phenylalanine were obtained from Wako Pure Chemical Industries Ltd. (Osaka), ICN Pharmaceutical Inc. (Costa Mesa, CA), Nacalai Tesque, and Bachem AG (Bubendorf, Switzerland), respectively. Other reagents were of reagent grade.

Synthesis of 3′-(Tri-*n*-butylstannyl)hippuryl N^{ϵ}-*tert*-Butoxycarbonyl-L-lysine (Sn-HBL). 3-(Tri-*n*-butylstannyl)hippuric acid was synthesized as described previously (*13*). 3-(Tri-*n*-butylstannyl)hippuric acid (300 mg, 0.64 mmol), 1-hydroxybenzotriazole (118 mg, 0.77 mmol), triethylamine (143 mg, 1.41 mmol), and N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester hydrochloride (190 mg, 0.64 mmol) were dissolved in dry chloroform (10 mL) (Scheme 1). After the mixture was cooled to 0 °C, a solution of 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (147 mg, 0.77 mmol) in 3 mL of dry chloroform was added to the solution. After being stirred for 12 h at 0 °C, the reaction mixture was washed with

5% aqueous citrate (10 mL × 3), saturated $NaHCO_3$ (10 mL × 3), and saturated NaCl (10 mL × 3) successively before drying over anhydrous calcium sulfate. The organic layer was removed in vacuo to produce 3′-(tri-*n*-butylstannyl)hippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester (250 mg, 55%) as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 0.85−1.94 (33H, m, $SnBu_3$, $(CH_2)_3$), 1.42 (9H, s, Boc), 3.10 (2H, q, NHCH_2), 3.74 (3H, s, $COOCH_3$), 4.19 (2H, d, NHCH_2), 4.62 (1H, q, NHC*H*), 7.39 (1H, t, aromatic), 7.60 (1H, d, aromatic), 7.70 (1H, d, aromatic), 7.90 (1H, t, aromatic). Electro spray ionization mass spectra (ESI-MS) calcd for $C_{33}H_{58}N_3O_6Sn$ (MH^+): *m/z* 712. Found: 712.

3′-(Tri-*n*-butylstannyl)hippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester (250 mg, 0.35 mmol) in methanol (10 mL) was added to a solution of 1 N NaOH (2 mL), and the mixed solution was refluxed with stirring for 1 h. After removal of methanol in vacuo, the solution was neutralized with 1 N HCl at 0 °C before extraction with ethyl acetate (10 mL). The organic layer was dried over anhydrous calcium sulfate before removing the solvent in vacuo to produce 3′-(tri-*n*-butylstannyl)hippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine (138 mg, 56%) as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 0.85−1.82 (33H, m, $SnBu_3$, $(CH_2)_3$), 1.42 (9H, s, Boc), 3.08 (2H, q, NHCH_2), 4.25 (2H, d, NHCH_2), 4.55 (1H, q, NHC*H*), 7.31 (1H, t, aromatic), 7.58 (1H, d, aromatic), 7.72 (1H, d, aromatic), 7.91 (1H, t, aromatic). Fast atom bombardment mass spectra (FAB-MS) calcd for $C_{32}H_{55}N_3O_6Sn$ (MH^+): *m/z* 698. Found: 698.

Synthesis of 3′-(Tri-*n*-butylstannyl)hippuryl N^{ϵ}-*tert*-Butoxycarbonyl-D-lysine (D-Sn-HBL). This compound was synthesized by the reaction of N^{ϵ}-*tert*-butoxycarbonyl-D-lysine methyl ester hydrochloride with 3-(tri-*n*-butylstannyl)hippuric acid as described above. ^{1}H NMR ($CDCl_3$): δ 0.85−1.88 (33H, m, $SnBu_3$, $(CH_2)_3$), 1.42 (9H, s, Boc), 3.01 (2H, q, NHCH_2), 4.26 (2H, d, NHCH_2), 4.50 (1H, q, NHC*H*), 7.32 (1H, t, aromatic), 7.57 (1H, d, aromatic), 7.66 (1H, d, aromatic), 7.85 (1H, t, aromatic). ESI-MS calcd for $C_{32}H_{55}N_3O_6Sn$ (MH^+): *m/z* 698. Found: 698.

Synthesis of 3′-Iodohippuryl N^{ϵ}-*tert*-Butoxycarbonyl-L-lysine (HBL). 3-Iodohippuric acid was synthesized as described previously (*13*). A mixture of 3-iodohippuric acid (305 mg, 1.00 mmol), 1-hydroxybenzotriazole (184 mg, 1.20 mmol), triethylamine (223 mg, 2.20 mmol), and N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester hydrochloride (297 mg, 1.00 mmol) dissolved in dry acetonitrile (10 mL) was cooled to 0 °C. A solution of 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (230 mg, 1.20 mmol) in 10 mL of acetonitrile was added, and the reaction mixture was stirred for 7 h at 0 °C. After removal of the solvent in vacuo, the residue was dissolved in ethyl acetate (10 mL) and the organic phase was washed with 5% aqueous citrate (10 mL × 3), saturated $NaHCO_3$ (10 mL × 3), and saturated NaCl (10 mL × 3) successively. After the solvent was dried over anhydrous calcium sulfate, the organic layer was removed in vacuo to produce 3′-iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester (443 mg, 81%) as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 1.12−1.95 (6H, m, $(CH_2)_3$), 1.42 (9H, s, Boc), 3.10 (2H, q, NHCH_2), 3.75 (3H, s, $COOCH_3$), 4.19 (2H, d, NHCH_2), 4.60 (1H, q, NHC*H*), 7.18 (1H, t, aromatic), 7.78 (1H, d, aromatic), 7.85 (1H, d, aromatic), 8.17 (1H, t, aromatic). FAB-MS calcd for $C_{21}H_{30}N_3O_6I$ (MH^+): *m/z* 548. Found: 548. Anal. ($C_{21}H_{30}N_3O_6I$) C, H, N.

3′-Iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester (425 mg, 0.78 mmol) was added to a mixture of 1 N NaOH (1.55 mL) and methanol (10 mL), and the solution was refluxed with stirring for 1 h. After removal of methanol in vacuo, the solution was neutralized with 1 N HCl at 0 °C before extraction with ethyl acetate (10 mL). The organic layer was dried over anhydrous calcium sulfate before removing the solvent in vacuo to produce 3′-iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine (290 mg, 70%) as a colorless oil. ^{1}H NMR (CD_3OD): δ 1.12−1.99 (6H, m, $(CH_2)_3$), 1.42 (9H, s, Boc), 3.02 (2H, q, NHCH_2), 4.05 (2H, d, NHCH_2), 4.41 (1H, q, NHC*H*), 7.25 (1H, t, aromatic), 7.84 (1H, d, aromatic), 7.89 (1H, d, aromatic), 8.22 (1H, t, aromatic). ESI-MS calcd for $C_{20}H_{28}N_3O_6I$ (MH^+): *m/z* 534. Found: 534. Anal. ($C_{20}H_{28}N_3O_6I \cdot 1/2H_2O \cdot 1/4CH_3COOC_2H_5$) C, H, N.

Synthesis of 3′-Iodohippuryl N^{ϵ}-*tert*-Butoxycarbonyl-D-lysine (D-HBL). D-HBL was synthesized by the reaction of N^{ϵ}-*tert*-butoxycarbonyl-D-lysine methyl ester hydrochloride with 3-iodohippuric acid as described above. ^{1}H NMR (CD_3OD): δ 0.88−1.98 (6H, m, $(CH_2)_3$), 1.42 (9H, s, Boc), 3.03 (2H, q, NHCH_2), 4.07 (2H, d, NHCH_2), 4.42 (1H, q, NHC*H*), 7.22 (1H, t, aromatic), 7.85 (1H, d, aromatic), 7.90 (1H, d, aromatic), 8.25 (1H, t, aromatic). ESI-MS calcd for $C_{20}H_{28}N_3O_6I$ (MH^+): *m/z* 534. Found: 534.

Synthesis of 3′-Iodohippuryl L-Lysine (HL). 3-Iodohippuric acid (450 mg, 1.48 mmol), 1-hydroxybenzotriazole (239 mg, 1.77 mmol), triethylamine (328 mg, 3.25 mmol), and N^{ϵ}-*tert*-butoxycarbonyl-L-lysine *tert*-butyl ester hydrochloride (500 mg, 1.48 mmol) were dissolved in dry acetonitrile (10 mL). After the mixture was cooled to 0 °C, a solution of 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (339 mg, 1.77 mmol) in 15 mL of acetonitrile was added to the solution. After being stirred for 7 h at 0 °C, the solvent was removed in vacuo and the residue was dissolved in ethyl acetate (10 mL). The organic phase was washed with 5% aqueous citrate (10 mL × 3), saturated $NaHCO_3$ (10 mL × 3), and saturated NaCl (10 mL × 3) successively. After the solvent was dried over anhydrous calcium sulfate, the organic layer was removed in vacuo to produce 3′-iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine *tert*-butyl ester (679 mg, 78%) as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 1.26−2.04 (6H, m, $(CH_2)_3$), 1.44 (9H, s, *t*-Bu), 1.47 (9H, s, Boc), 3.13 (2H, q, NHCH_2), 4.17 (2H, d, NHCH_2CO), 4.50 (1H, q, NHC*H*), 7.18 (1H, t, aromatic), 7.79 (1H, d, aromatic), 7.85 (1H, d, aromatic), 8.18 (1H, t, aromatic). Electron Impact mass spectra (EI-MS) calcd for $C_{21}H_{30}N_3O_6I$: *m/z* 589. Found: 589. Anal. ($C_{24}H_{36}N_3O_6I$) C, H, N.

3′-Iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine *tert*-butyl ester (180 mg, 0.31 mmol) was dissolved in TFA (15 mL) containing anisole (66 μL) and stirred for 1 h at room temperature. After removal of TFA in vacuo, the residue was treated with ether to precipitate 3′-iodohippuryl L-lysine (102 mg, 59%) as a white crystal. ^{1}H NMR (DMSO-d_6): δ 1.05−2.04 (6H, m, $(CH_2)_3$), 3.44 (2H, q, NHCH_2), 4.04 (2H, d, NHCH_2CO), 4.22 (1H, q, NHC*H*), 7.30 (1H, t, aromatic), 7.91 (1H, d, aromatic), 8.08 (1H, d, aromatic), 8.29 (1H, t, aromatic). EI-MS calcd for $C_{15}H_{20}N_3O_4I$: *m/z* 433. Found: 433. Anal. ($C_{15}H_{20}N_3O_4I \cdot 7/4CF_3COOH \cdot 1/2H_2O \cdot 1/2C_2H_5OC_2H_5$) C, H, N.

Synthesis of 3′-Iodohippuryl D-Lysine (D-HL). 3′-Iodohippuryl D-lysine was synthesized by the reaction of N^{ϵ}-*tert*-butoxycarbonyl-D-lysine *tert*-butyl ester hydrochloride with 3-iodohippuric acid as described above. ^{1}H NMR (CD_3OD): δ 1.05−2.02 (6H, m, $(CH_2)_3$), 3.28 (2H, q, NHCH_2), 4.09 (2H, d, NHCH_2CO), 4.49 (1H, q, NHC*H*), 7.22 (1H, t, aromatic), 7.85 (1H, d, aromatic), 7.91 (1H, d, aromatic), 8.23 (1H, t, aromatic). ESI-MS calcd for $C_{15}H_{21}N_3O_4I$ (MH^+): *m/z* 434. Found: 434.

Synthesis of [^{125}I]HL and [^{125}I]HBL. Sn-HBL was radioiodinated in the presence of *N*-chlorosuccinimide (NCS) as an oxidant. Sn-HBL was dissolved in dry methanol containing 1% acetic acid (0.5 mg/mL), and 44.6 μL of this solution was mixed with 9.9 μL of NCS in methanol (0.5 mg/mL) in a sealed vial, followed by the addition of Na[^{125}I]I (2 μL). After incubation for 25 min at room temperature, [^{125}I]HBL was purified by RP-HPLC (solvent system 1). The radiochemical yield and purity of [^{125}I]HBL were determined by RP-HPLC (solvent system 2) and TLC (solvent system 4), respectively.

[^{125}I]HL was prepared by treating RP-HPLC-purified [^{125}I]HBL with TFA (100 μL). After standing for 10 min at room temperature, [^{125}I]HL was purified by RP-HPLC (solvent system 1). The radiochemical yield and purity of [^{125}I]HL were determined by RP-HPLC (solvent system 2) and TLC (solvent system 3), respectively.

Synthesis of D-[^{125}I]HL and D-[^{125}I]HBL. D-[^{125}I]HL and D-[^{125}I]HBL were prepared from D-Sn-HBL as described above.

Preparation of BBMVs. BBMVs were isolated from the renal cortex of male Wistar rats according to the Mg/EGTA precipitation method reported previously (*11*). All steps were performed on ice or at 4 °C. The cortex was homogenized with a Polytron homogenizer (PT10-35, Kinematica GmbH Littau, Switzerland) at full speed for 2 min in an appropriate volume of 300 mM mannitol, 12 mM Tris-HCl (pH 7.1), and 5 mM ethylenebis(oxyethylenenitrilo)tetraacetic acid (EGTA), followed by the addition of the same buffer to make a 10% homogenate. After the mixture was diluted with distilled water (1:1), $MgCl_2$ was added to a final concentration of 10 mM, and the homogenate was allowed to stand for 15 min. The homogenate was centrifuged at 1900*g* for 15 min in a Hitachi High-Speed Refrigerated Centrifuge SCR 20B (rotor RPR20-2). The supernatant was centrifuged at 24 000*g* for 30 min. The pellet was resuspended in an appropriate volume of buffer composed of 150 mM mannitol, 6 mM Tris-HCl (pH 7.1), and 2.5 mM EGTA and homogenized in a Potter-Elvehjem homogenizer with a Teflon pestle at 1000 rpm (10 strokes). $MgCl_2$ was added to a final concentration of 10 mM, and the suspension was centrifuged at 1900*g* for 15 min. The supernatant was centrifuged at 24000*g* for 30 min. The final pellet (purified brush border membrane) was resuspended in a 0.1 M phosphate buffer (pH 7.0) by 10 passages through a fine needle (0.4 × 19 mm) attached to a plastic syringe. For incubation studies, the vesicles were diluted with 0.1 M phosphate buffer (pH 7.0) to give a final protein concentration of 10 mg/mL. The γ-glutamyltransferase, aminopeptidase, and renal dipeptidase activities on BBMVs, determined according to the procedures of Glossmann et al. (*14*), Kramers et al. (*15*), and Hooper et al. (*16*), using L-γ-glutamyl-*p*-nitroanilide, L-leucine-*p*-nitroanilide, and glycyl-D-phenylanaline as substrates, were found to be 5.22 μmol/min/mg protein, 893 and 6.22 nmol/min/mg protein, respectively. The β-galactosidase activity on BBMVs, determined accoroding to the procedure of Wallner et al. using *p*-nitrophenyl β-D-galactopyranoside (*17*), was not detectable, which indicated that BBMVs were free from cross-contamination by lysosomal enzymes.

Preparation of Cilastatin. One gram of tienam (a mixture of imipenem 0.5 g and sodium cilastatin 0.5 g) was stirred in 20 mL of ethanol for 3 min at room temperature. After filtration, the filtrate was removed *in* vacuo to produce 120 mg of cilastatin as a sodium salt. ^{1}H NMR (D_2O); δ 0.71−0.87 (2H, m, $(CH_3)_2C-CH_2$), 0.95−1.04 (6H, m, $C(CH_3)_2$) 1.38−1.55 (5H, m, $(CH_2)_2$, $(CH_3)C-CH$), 1.96 (2H, q, CH_2CH_2S), 2.47 (2H, t, SCH_2-CH), 2.85−2.96 (2H, m, $CHCH_2CH_2$), 3.75 (1H, q, CH-COOH), 6.31 (1H, t, $CCHCH_2$). FAB-MS calcd for $C_{16}H_{25}N_2NaO_5S$ $(MH)^+$: *m/z* 381. Found: 381.

In Vitro Studies. Synthetic substrates were incubated with BBMVs as follows: a solution of BBMVs (20 μL) was preincubated for 2 h at 4 °C, followed by the addition of each substrate solution (20 μL) in 0.1 M phosphate buffer (pH 7.0). After incubation for 3 and 6 h at 37 °C, samples were taken from the solution and analyzed immediately by TLC (solvent system 3 or 4). Each sample was also analyzed by RP-HPLC (solvent system 2) after ultrafiltration with a 10-kDa cutoff membrane (Microcon-10, Millipore). A solution of Co^{2+}, MGTA, and phosphoramidon or cilastatin in 0.1 M phosphate buffer (pH 7.0) was added to preincubating solution with a final concentration of 1 mM, and the release of [^{125}I]iodohippuric acid from [^{125}I]HL or [^{125}I]HBL was estimated by TLC and RP-HPLC as described above.

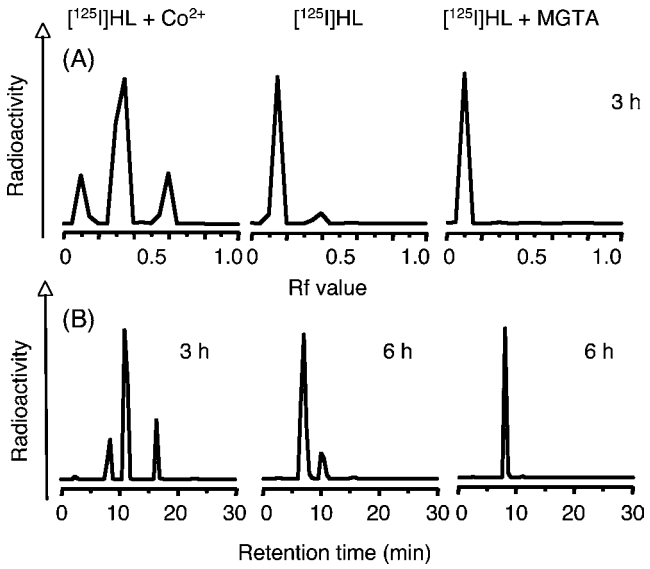


Figure 2. Radioactivity profiles of [^{125}I]HL after incubation in BBMVs (center panels) in the presence of 1 mM Co^{2+} (left panels) or 1 mM MGTA (right panels) at 37 °C as determined by (A) TLC (solvent system 3) or (B) RP-HPLC (solvent system 2). Under these conditions, *m*-iodohippuric acid and *m*-iodobenzoic acid had an R_f value of 0.35−0.40 and 0.60, and a retention time of 11 and 16 min, respectively.

RESULTS

Figure 2 shows TLC radiochromatograms of [^{125}I]HL after incubation in BBMV solution at 37 °C using solvent system 3. Under this condition, HL had an R_f value of 0.1, whereas *m*-iodohippuric acid and *m*-iodobenzoic acid had R_f values of 0.35−0.4 and 0.6, respectively. After 3 h incubation, a radioactivity peak at an R_f value of 0.35−0.4 was observed. On the other hand, this was not detected when [^{125}I]HL was incubated in BBMVs at 4 °C or in the absence of BBMVs at 37 °C (data not shown). The radioactivity peak at an R_f value of 0.35−0.4 significantly increased when [^{125}I]HL was incubated with BBMVs at 37 °C in the presence of Co^{2+}. A radioactivity peak at an R_f value of 0.6 was also observed; however, no radioactivity peak other than [^{125}I]HL was observed when [^{125}I]HL was incubated in BBMV solution at 37 °C in the presence of MGTA. Similar results were obtained when the reactions were analyzed by RP-HPLC as shown in Figure 2. Under these conditions (solvent system 2), HL and *m*-iodohippuric acid had a retention time of 7.5 and 11 min, respectively. Figure 3 summarizes the

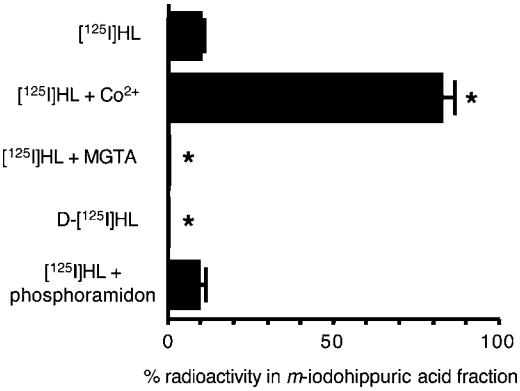

Figure 3. Liberation of *m*-[^{125}I]iodohippuric acid from [^{125}I]-HL after incubation in BBMVs at 37 °C for 3 h in the presence of an activator of CPM, or an inhibitor of CPM (MGTA), neutral endopeptidase (phosphoramidon), or dipeptidase (cilastatin), respectively. Columns and bars show the means and SD of three experiments. Significance was determined by unpaired Student's *t*-test [(*) $p < 0.01$ compared to [^{125}I]HL].

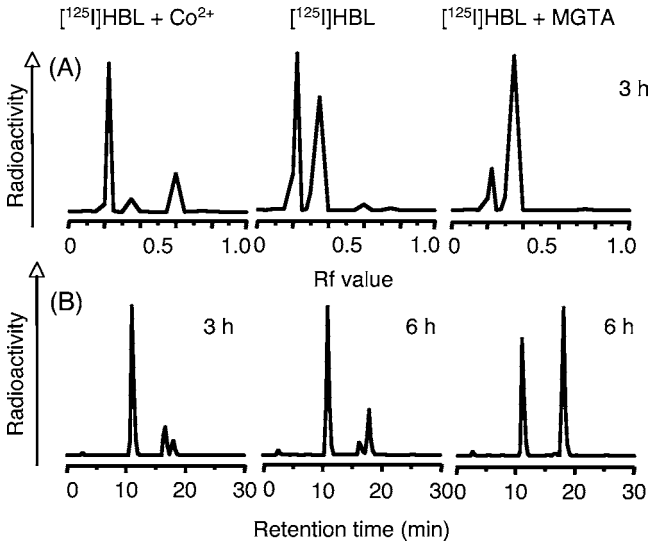

Figure 4. Radioactivity profiles of [^{125}I]HBL after incubation in BBMVs (center panels) or in the presence of 1 mM Co^{2+} (left panels) or 1 mM MGTA (right panels) at 37 °C, as determined by (A) TLC (solvent system 4) or (B) RP-HPLC (solvent system 2). Under these conditions, *m*-iodohippuric acid and *m*-iodobenzoic acid had an R_f value of 0.20 and 0.60 on TLC, and a retention time of 11 and 16 min, respectively.

amount of radioactivity in *m*-iodohippuric acid fractions after [^{125}I]HL incubation in the presence of BBMVs at 37 °C for 3 h, as determined by TLC. The addition of an inhibitor of neutral endopeptidase (phosphoramidon) had no effect on the generation of a radioactivity peak at an R_f value of 0.35−0.4. D-[^{125}I]HL remained unchanged when incubated in BBMV solution in the presence or absence of Co^{2+}.

TLC radiochromatograms of [^{125}I]HBL after incubation in BBMV solution at 37 °C are depicted in Figure 4. Under these conditions (solvent system 4), HBL, *m*-iodohippuric acid, and *m*-iodobenzoic acid had an R_f value of 0.35, 0.2, and 0.6, respectively. No radiometabolites were detected when [^{125}I]HBL was incubated in BBMVs at 4 °C or in the absence of BBMVs at 37 °C (data not shown). The radioactivity peak at an R_f value of 0.2 increased when [^{125}I]HBL was incubated in the presence of Co^{2+} (Figure 4). An additional radioactivity peak was observed at an R_f value of 0.6 in the presence of Co^{2+}. Contrary to [^{125}I]HL, [^{125}I]HBL generated a radioactivity peak at an R_f value of 0.2 when incubated in the presence

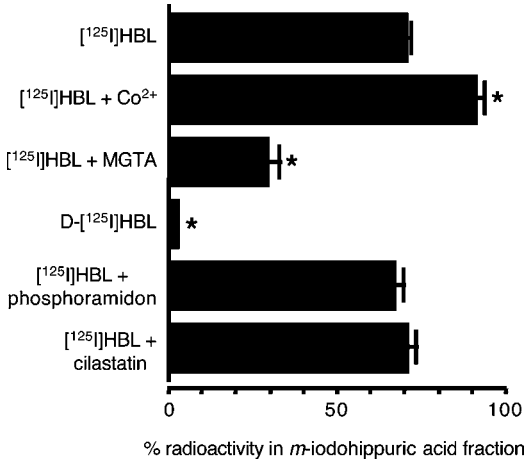

Figure 5. Liberation of *m*-[^{125}I]iodohippuric acid from [^{125}I]-HBL after incubation in BBMVs at 37 °C for 3 h in the presence or absence of an activator of CPM (Co^{2+}), or an inhibitor of CPM (MGTA), neutral endopeptidase (phosphoramidon) or dipeptidase (cilastatin), respectively. Columns and bars show the means and SD of three experiments. Significance was determined by unpaired Student's *t*-test [(*) $p < 0.01$ compared to [^{125}I]HBL].

of MGTA although the amount of the radioactivity at this R_f value was significantly reduced (Figure 5, right panel). Similar results were observed by RP-HPLC analyses where [^{125}I]HBL and *m*-[^{125}I]iodohippuric acid had a retention time of 18 and 11 min (solvent system 2), respectively (Figure 4). Figure 5 summarizes the amount of radioactivity in the *m*-[^{125}I]iodohippuric acid fraction after incubation of [^{125}I]HBL in BBMV solution at 37 °C for 3 h, when determined by TLC. [^{125}I]HBL generated a significantly higher amount of radioactivity in *m*-iodohippuric acid fractions than did [^{125}I]HL. The amount of radioactivity in *m*-iodohippuric acid fractions increased with the presence of Co^{2+}, as also observed with [^{125}I]-HL. However, radioactivity fractions were still observed when [^{125}I]HBL was incubated in the presence of MGTA. Both phosphoramidon and cilastatin had no effect on the generation of *m*-[^{125}I]iodohippuric acid from [^{125}I]HBL. D-[^{125}I]HBL hardly liberated any radiometabolites when incubated in BBMV solution at 37 °C in the presence or absence of Co^{2+}.

DISCUSSION

HML was designed based on the hypothesis that the glycyl-lysine sequence in HML would be recognized and cleaved by CPM on the renal brush border membrane during the internalization process of the antibody fragment, since it is well-known that glycyl-lysine is one of the substrates for CPM on the renal brush border membrane (*18*). Although hippuryl lysine is also recognized and cleaved by CPM (*18*), HML differs from hippuryl-lysine in that the former has an iodine atom at the meta-position of hippuric acid and the N^{ϵ}-amine residue of HML is converted to the maleoyl group, which is further converted to the succinimidyl group after conjugation to thiolated Fab fragments. The latter modification would significantly affect CPM recognition since the presence of a positive charge in the side-chain of the C-terminal lysine residue of glycyl-lysine prefers CPM recognition (*19*).

To estimate the effect of iodination at the meta-position of hippuric acid on CPM recognition, [^{125}I]HL was incubated in BBMVs in the presence or absence of Co^{2+} or MGTA, an activator and inhibitor of the enzyme, respectively (*18*, *20*). As summarized in Figure 3, the BBMV-

mediated release of *m*-[^{125}I]iodohippuric acid from [^{125}I]-HL showed temperature dependency. D-[^{125}I]HL was not recognized as a substrate for enzymes on BBMVs. Both Co^{2+} and MGTA were effective to facilitate and inhibit the hydrolysis reaction. These results suggested that CPM recognized the glycyl-lysine sequence of hippuryl-L-lysine when iodine was introduced at the meta-position of hippuric acid.

To investigate the effect of the modification of N^{ϵ}-amine residue of L-lysine on CPM recognition, [^{125}I]HBL was incubated in the presence of BBMVs. [^{125}I]HBL liberated much higher amounts of *m*-[^{125}I]hippuric acid than [^{125}I]-HL (Figures 3 and 5). The hydrolysis reaction of [^{125}I]-HBL also showed temperature dependency. D-[^{125}I]HBL was hardly recognized as a substrate by enzymes on BBMVs. Although the addition of Co^{2+} facilitated the hydrolysis reaction, MGTA acted as a partial inhibitor of the reaction (Figure 5). These studies implied that chemical modification of the N^{ϵ}-amine residue of HL made the resulting compound, HBL, a substrate for more than two enzymes on BBMVs at the expense of reduced specificity for CPM. Enzymes on the renal brush border membrane are classified into two types: transmembrane enzymes and glycophosphatidylinositol (GPI)-anchored enzymes. Since the N^{ϵ}-amine residue in [^{125}I]HBL was modified with the lipophilic Boc group, [^{125}I]HBL would gain access to not only GPI-anchored enzymes but also transmembrane enzymes on BBMVs, which may account for the significantly higher release of *m*-[^{125}I]iodohippuric acid from [^{125}I]HBL compared with [^{125}I]HL. Antibody fragments are internalized into renal cells through the brush border of renal tubules. Thus, the iodohippuryl-lysine moiety in HML-conjugated Fab fragments would also gain access to both types of enzymes during the internalization process. This suggested that a variety of enzymes on BBMVs were involved in the in vivo cleavage of the glycyl-lysine sequence in HML-conjugated Fab fragments.

To further investigate the enzymes responsible for the release of *m*-iodohippuric acid from HML-conjugated antibody fragments, [^{125}I]HBL was incubated in BBMVs in the presence of representative inhibitors for enzymes that cleave the C-terminal peptide sequence. The lack of inhibition of the BBMV-mediated release of *m*-[^{125}I]-iodohippuric acid from [^{125}I]HBL by phosphoramidon and cilastatin indicated that neither neutral endopeptidase nor renal dipeptidase catalyzed the hydrolysis reaction. The acceleration or partial inhibition of the BBMV-mediated hydrolysis of [^{125}I]HBL by the presence of Co^{2+} or MGTA showed that both metalloenzymes and non-metalloenzymes were involved in the release of *m*-[^{125}I]-iodohippric acid from [^{125}I]HBL and HML-conjugated Fab fragments. These results suggested the involvement of CPM in the hydrolysis of the glycyl-lysine sequence in HBL- and HML-conjugated antibody fragments although the N^{ϵ}-amine residues of the two compounds were chemically modified. However, since both activation by Co^{2+} and inhibition by MGTA are not specific to CPM but rather typical to a variety of metalloenzymes (*21*, *22*), further studies are required for confirmation.

In conclusion, the findings in this study suggested that N^{ϵ}-modified iodohippuryl-lysine would be recognized as a substrate by enzymes on the renal brush border membrane, which supported our hypothesis that low renal radioactivity levels of [^{125}I]HML-conjugated Fab would be attributable to enzyme-mediated hydrolysis during the internalization process of the conjugate into renal cells. Thus, this study showed that this in vitro system using renal BBMVs would constitute a useful approach to the development of radiolabeling reagents for antibody fragments and peptides based on the notion of the renal brush border enzyme-mediated release of radiometabolites for low renal radioactivity levels.

Site-Specific Cross-Linking of Proteins through Tyrosine Hexahistidine Tags

R. Scott Stayner, Dong-Joon Min,‡ Patrick F. Kiser, and Russell J. Stewart*

Department of Bioengineering, 20 South 2030 East, Room 506, University of Utah, Salt Lake City, Utah 84112.
Received August 12, 2005

The genetic addition of hexahistidine (H_6) tags is widely used to isolate recombinant proteins by immobilized metal-affinity chromatography (IMAC). Addition of a tyrosine residue to H_6 tags enabled proteins to be covalently cross-linked under mild conditions in a manner similar to the natural, site-specific cross-linking of tyrosines into dityrosine. A series of seven hexahistidine tags with tyrosines placed in various positions (H_6Y tags) were added to the amino terminus of the I28 immunoglobulin domain of the human cardiac titin. The H_6Y-tagged I28 dimerized in the presence of excess Ni^{2+} with a K_D of 200 μM. Treatment of Ni^{2+}-dimerized H_6Y-I28 with an oxidant, monoperoxyphthalic acid (MMPP) or sodium sulfite, resulted in covalent protein multimerization through chelated Ni^{2+}-catalyzed cross-linking of the Y residues engineered into the H_6 tag. The protein oligomerization was observed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE). The presence of dityrosine in the cross-linked proteins was confirmed by fluorescence emission at 410 nm. Proteins lacking the Y residue in the H_6 tag treated with the same oxidative conditions did not cross-link or exhibit dityrosine fluorescence, despite the presence of an endogenous Y residue. The method may have potential uses in other protein conjugation applications such as protein labeling and interfacial immobilization of proteins on artificial surfaces.

INTRODUCTION

The expanding use of recombinant proteins in several major industries feeds a growing need for new technologies for labeling, cross-linking, and interfacial immobilization of active proteins. Current protein conjugation and cross-linking methods have several major limitations. Most rely on diffusible reagents that react somewhat specifically with a particular class of nucleophilic functional group, such as the thiol of cysteines or primary amine of lysines. One problem with this approach is the lack of selectivity where all accessible groups of a particular class are modified. This can create multiple compounds, and if one of the targeted functional groups is in or near the active site, the target protein can be inactivated. For purposes of interfacial immobilization, this lack of selectivity can lead to random orientations and conjugation inefficiency. A further drawback of nonselectively modifying an entire class of functional groups is that specific protein modification cannot be carried out in a mixture with several other proteins. Therefore, relatively large quantities of purified protein are required for chemical modifications. All of these problems could be overcome with the development of a conjugation chemistry that utilizes nondiffusible, reactive groups at a genetically specified site on the target protein.

Looking to nature, one can find many examples of natural materials composed of highly cross-linked proteins and other biopolymers (*1*−*7*). The extensive covalent cross-linking gives these materials their impressive tensile strength, elasticity, tear resistance, toughness, and other critical material properties. A common natural strategy to cross-link biopolymers is the localized oxidation of specific amino acid side chains by metalloenzymes to form reactive intermediates that then spontaneously form cross-links within a restricted space. An example of this strategy is the oxidative deamination by lysyl oxidase of specific lysine residues that then condense with vicinal nucleophiles to covalently cross-link collagen and elastin (*8*, *9*). Another example is oxidative coupling of the phenolic moiety of two tyrosines, which is catalyzed by several structurally and mechanistically distinct categories of metalloenzymes, including peroxidases, tyrosinases, and laccases (*10*−*13*). Dityrosine protein linkages have been found in many structural proteins including elastin (*1*), silk, and plant cell wall extensin (*3*, *4*), and in hardened fertilization membranes of insect and sea urchin eggs (*7*).

Tyrosine residues are not a common target for site-specific chemical modification of proteins in vitro because they are generally unreactive under physiological pH. However, there have been reports of in vitro dityrosine cross-linking based on metal-catalyzed oxidation of tyrosine phenolic side chains that are reminiscent in some respects to the natural tyrosine cross-linking process described above (*14*−*17*). Peptidic complexes of Ni^{2+} in the presence of peracid oxidizing agents catalyze the formation of tyrosine free radicals that then react with proximal tyrosine residues to form dityrosine or isodityrosine cross-links (*9*, *14*−*17*). Brown and co-workers (*9*) found that Ni^{2+} complexed with the tripeptide GGH catalyzed the cross-linking of dimeric proteins in the presence of the relatively strong oxidant monoperoxyphthalic acid (MMPP) through natural tyrosine residues. Similarly, when GGH was genetically appended to the dimeric protein, ecotin, intermolecular cross-linking occurred between tyrosine residues in the presence of

MMPP and Ni^{2+} (*8*). The tyrosine cross-linking efficiency was shown to be dependent on the distance between tyrosines in these experiments. In wild-type ecotin, in which natural tyrosines at the dimer interface are separated by 20 Å, the cross-linking efficiency was 15%. In ecotin genetically modified to move the tyrosines to within 5 Å of one another at the dimer interface, the cross-linking efficiency was 60%.

Similarly, the hexapeptide H_6, which is routinely used as a tag for purification of recombinant proteins by immobilized metal affinity chromatography (*18*, *19*), has also been shown to be redox active when complexed with Ni^{2+}. The dimer of H_6-tagged glutathione S-transferase (H_6GST) was covalently cross-linked by dityrosine formation in the presence of Ni^{2+} and MMPP (*14*). Proteins that do not naturally associate with H_6GST were not cross-linked, demonstrating that H_6-mediated cross-linking did not proceed through a highly diffusible reactant but instead was localized to the vicinity of the H_6 tag. Going further, the same research group demonstrated that, in the presence of MMPP and Ni^{2+}, H_6GST mediated the formation of dityrosine from free tyrosine, that the mutagenic removal of tyrosine residues from H_6GST decreased cross-linking efficiency, and that chemical addition of tyrosine-like residues, using the Bolton–Hunter reagent, increased cross-linking efficiency.

In this paper, we take this biomimetic strategy a step further by developing methods for site-specific dityrosine cross-linking of proteins that do not normally associate in solution. Using the I28 immunoglobulin domain from human cardiac titin as a model protein, we show that H_6-tagged I28 domains reversibly self-associate in solution in the presence of Ni^{2+} and that the complexed Ni^{2+} will catalyze the formation of dityrosine cross-links between Y residues strategically placed in or near the H_6 tag (Figure 1).

EXPERIMENTAL PROCEDURES

Preparation of the H_6(Y) Titin I28 Plasmids. The construction of the double H_6 tagged protein, H_6-titin I28–H_6 pET24a was previously published (*20*). The constructs containing the various H_6-tyr (H_6Y) tags (Table 1) were prepared by amplifying the I28 region with PCR primers, in separate reactions, that incorporated the DNA sequence of the H_6Y tag into the 5′ end of the PCR product along with *Nde*I and *Xho*I restriction sites for cloning. The PCR products were ligated into pET 26b (Novagen, Inc.) after digestion with *Nde*I and *Xho*I and transformed into DH5α. The constructs were verified by DNA sequencing.

Expression and Purification of H_6YI28 Proteins. For expression, the pET26b-I28 plasmids were transformed into *E. coli* strain BL21(DE3) (Novagen, Inc.) by electroporation (EPX Genetics, ECM 395). Single colonies from agar plates containing 50 μg/mL kanamycin were grown overnight at 37 °C in 5 mL LB media with 50 μg/mL kanamycin. LB cultures (500 mL) with 50 μg/mL kanamycin were then inoculated with the overnight cultures and grown at 37 °C until A_{600} was between 0.6 and 1.0 (about 2 h). Expression of the target protein was induced by adding isopropyl β-D-thiogalactoside (IPTG) to a final concentration of 0.1 mM followed by shaking for 4 h at 37 °C. The cells were then centrifuged (Beckman JA 10 rotor) at 4500 rpm for 15 min at 4 °C. The cell pellets were stored at −70 °C. Frozen pellets were resuspended in 5 mL of binding buffer (50 mM NaH_2PO_4, 500 mM NaCl, pH 7.5) per gram of pellet. Phenylmethanesulfonyl fluoride (PMSF) and Triton ×100 were added to concentrations of 1 mM and 0.1% v/v, respectively. The cell suspension was sonicated (Fisher 550 Sonic Dismembranator) at power level 4 on ice for 10 s followed by 1 min of cooling, which was repeated six times. The insoluble cell components were pelleted by centrifugation at 20 000 g (Beckman J2-HS Centrifuge, JA-17 rotor) for 45 min at 4 °C. The supernatant was mixed with 2 mL of Ni^{2+} nitrilotriacetic acid (NTA) agarose beads (Qiagen) equilibrated with binding buffer, allowed to settle in a column and drained by gravity. The collected flow-through was reapplied to the Ni–NTA column. The column was washed with several column bed volumes of the washing buffer (15 mM NaH_2PO_4, 500 mM NaCl, 60 mM imidazole, pH 7.5). H-tagged proteins were eluted into1 mL aliquots of the elution buffer (15 mM NaH_2PO_4, 500 mM NaCl, 300 mM imidazole, pH 7.5). The purity of the protein fractions was determined by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE) using 15% polyacrylamide gels. Combined fractions were desalted into phosphate-buffered solution (PBS) (50 mM NaH_2PO_4, 150 mM NaCl, pH 7.5) on PD 10 sepharose columns (Pharmacia). After desalting, the proteins were aliquoted and stored at −70 °C. I28 proteins were concentrated using a 3000 MW cutoff centrifuge filter (Amicon). Protein concentrations were measured using a Coomasie protein assay (Biorad) with bovine serum albumin (BSA) as a standard. Each protein sample was concentrated so that the subsequent cross-linking reactions could be performed in a total volume of 20 μL, with a total protein concentration of 20 μM (4 nmol).

Sedimentation Equilibrium. Sedimentation equilibrium experiments were conducted in a Beckman Optima XL-A analytical ultracentrifuge, with an AnTi60 rotor at 20 °C, using six-channel, 12 mm thick, charcoal-epon centerpieces. Prior to the analysis, the protein samples were dialyzed against fresh PBS for 20 h. The three sample channels in each cell contained three

different concentrations (1.4 μM, 4.3 μM, and 13 μM) of either the H_6GY-titin I28 protein without added nickel or that had been incubated overnight at 4 °C with 10-fold excess nickel(II) acetate. The reference channels contained PBS. Samples were centrifuged until sedimentation and chemical equilibrium were attained. Values of v-bar and the extinction coefficients for each protein were calculated from the amino acid sequence using the method of Laue (*21*). Various models describing the concentration distribution were fit to final absorbance versus radius data using nonlinear least squares techniques and the analysis program NONLIN (*22*, *23*). NONLIN performs simultaneous nonlinear least-squares fits to one or more sets of ultracentrifuge data.

Oxidative Cross-Linking of H_6Y-I28 Proteins. All cross-linking reactions were performed in PBS (50 mM NaH_2PO_4, 150 mM NaCl, pH 7.5). The nickel(II) acetate, monoperoxyphthalic acid (MMPP), and Na_2SO_3 stock solutions were prepared in DDI H_2O. To determine the effect of the position of Y on cross-linking efficiency, the series of H_6Y-I28 proteins (Table 1) were mixed in a final volume of 20 μL with nickel(II) acetate, 20 μM, and MMPP at final concentrations of 20, 200, or 200 μM. After addition of nickel(II) acetate, the solution was left on ice for 30 min, then warmed to room temperature before the addition of MMPP to initiate cross-linking. After 2 min, the cross-linking reaction was quenched by addition of 5 μL of 5× SDS−PAGE sample buffer (0. 25 M Tris pH 6.8, 1% SDS, 2% bromophenol blue, 50% glycerol, 10% β-mercaptoethanol). The samples were then analyzed using SDS PAGE. The extent of cross-linking of H_6GY-I28 as a function of oxidant and oxidant concentration was determined by cross-linking in 4 mM, 400 μM or 40 μM MMPP, or 40 mM, 4 mM, or 400 μM Na_2SO_3. The reactions were quenched by the addition of 5 μL of 5× sample buffer containing 10% β-mercaptoethanol. The samples were then analyzed by SDS PAGE.

Fluorescence Spectroscopy. The formation of dityrosine in the Ni^{2+}/Na_2SO_3 treated H_6GY-I28 proteins was verified using fluorescence spectroscopy. The cross-linking reactions were performed in a 1 mL quartz crystal cuvette at room temperature in a final volume of 400 μL PBS using 15 μM H6GY-I28 and 150 μM of nickel(II) acetate. With an excitation wavelength of 325 nm the fluorescence emission was scanned from 350 to 600 nm with an excitation slit width of 10 nm, emission slit width of 5 nm, and a scan speed of 500 nm/min on a Perkin-Elmer LS 55 fluorimeter. As a control, fluorescence emission was scanned in the absence of Ni^{2+}. To verify that the fluorescence of cross-linked H_6GY-I28 was due to dityrosine, the emission spectrum was compared to the emission spectrum of dityrosine produced by a laccase enzyme purified from pleurotus ostreatus, (Earthfax Development,7324 South Union Park Ave, Midvale, UT 84047, 938 units of activity/mg laccase). Laccase, at a final concentration of 0.3 mg/mL (281 U/mL) was reacted with 1.25 mM L-tyrosine in 600 μL PBS. Dityrosine formation catalyzed by the GGH/Ni^{2+} complex and Na_2SO_3 was also analyzed. L-Tyrosine (15 μM) in DDI H_2O was combined with a solution of GGH and Ni(II) acetate (150 μM each, DDI H_2O) such that the concentration of the GGH tripeptide and the Ni^{2+} concentration was 10 times that of the L-tyrosine concentration. The solution was allowed to sit at room temperature for 10 min, after which Na_2SO_3 was added for a final concentration of 1.5 mM. Dityrosine formation was followed using fluorescence spectroscopy. As a control, the preceding experiment was performed in the absence of the GGH tripeptide to demonstrate that Ni^{2+} and Na_2SO_3 alone are not sufficient to catalyze the reaction.

RESULTS

Self-Association of H_6-Tagged I28 Immunoglobulin Domains. It has been reported that a H_{10}-tagged fusion protein oligomerizes in the presence of Ni^{2+} (*24*). SDS PAGE analysis showed a ladder of proteins oligomerized into high molecular species that had a stoichiometry of three and six with respect to the monomeric protein. The oligomers were readily converted to the monomeric species by using excess EDTA to remove Ni^{2+} or by boiling.. Control experiments in which the protein was incubated in the buffer without added Ni^{2+} did not result in oligomerization. Enzymatic removal of the H_{10} tags from the fusion protein prevented oligomerization, indicating that oligomer formation involved Ni^{2+}/H_{10}-tag coordination complexes.

The titin I28 protein used in these experiments is an Ig domain found in cardiac titin (*26*). In muscle the physical properties of I28, and other Ig domains, help titin act as an elastic spring that keeps the sarcomere in register (*27*) by partially unfolding when the muscle is subjected to tensile stress (*28*). Previous SDS PAGE analysis of I28 have shown that the protein does not self-associate in vitro (*28*). To investigate if H_6- I28 dimerizes through the H_6 tags in the presence of Ni^{2+}, the native molecular weight of I28 was determined by equilibrium sedimentation in the absence and presence of Ni^{2+}. As titin Ig domains are not known to spontaneously associate in vivo (*27*) or in vitro (*29*) it was not unexpected that in the absence of Ni^{2+}, an H_6-I28 protein behaved as a 12.3 ± 1 kDa monomer (Figure 2A), which is consistent with the sequence derived molecular weight of 11.7 kDa. The H6GY-titin I28 protein in the presence of a 10-fold excess of Ni(II) acetate is weakly associated into a dimer with a dissociation constant of approximately 200 μM (Figure 2B).

Oxidative Cross-Linking through H_6Y-tags. The known redox activity of the H_6Ni^{2+} complex and the H_6-

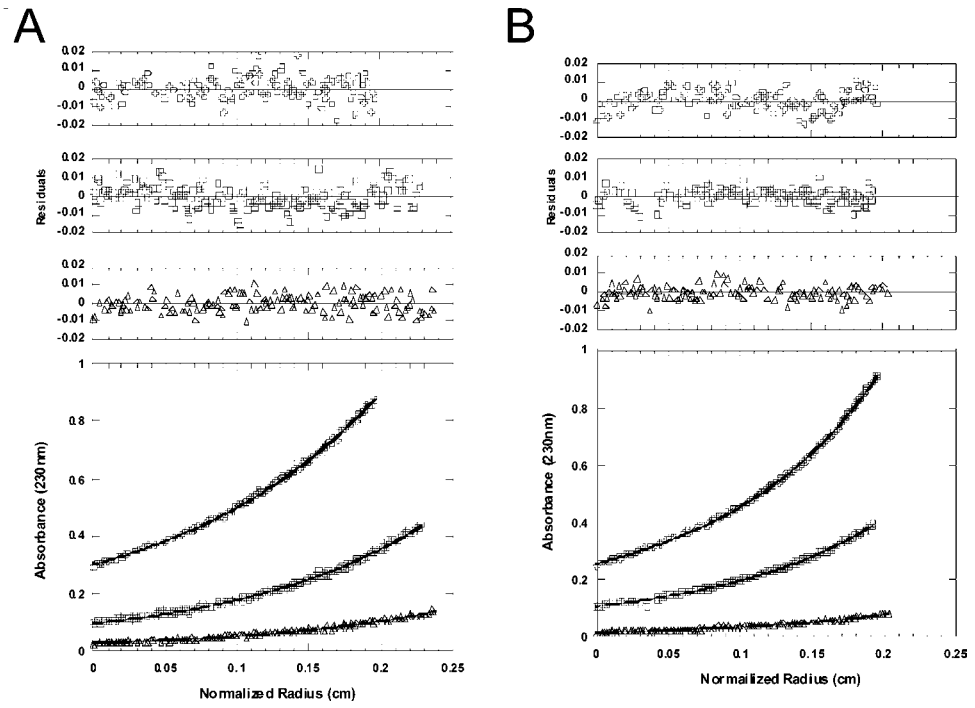

Figure 2. A. Sedimentation equilibrium of H6GY-titin I28 protein without Ni_2^+. The lower panels show experimental data points for three different loading concentrations of each protein with the corresponding calculated curve fit (solid line). The H_6GY-titin I28 protein is fit to a monomer model, MW = 12.3 ± 1 kDa. The upper panels show the residuals for these fits, which are small and random indicating a good fit to the monomer model. B. Sedimentation equilibrium data H_6GY-titin I28 protein with a 10-fold molar excess of Ni_2^+. The lower panels show experimental data points for three different loading concentrations of each protein with the corresponding calculated curve fit (solid line). In the presence of Ni_2^+, the H_6GY-titin I28 protein fit a monomer−dimer model with an equilibrium KD of approximately 200 μM. The upper panels show the residuals for these fits, which indicate a good fit to the monomer−dimer model.

Ni^{2+}-mediated self-association of I28 suggested that the ternary Ni^{2+} complex might catalyze site specific oxidative cross-linking of I28 if Y residues were placed near the H_6-tags (Figure 1). To investigate this possibility and to optimize Y placement, a series of H_6-I28 proteins were constructed that had Y residues strategically positioned within or adjacent to the H_6-tags (Table 1). Solutions of I28 in the presence of Ni^{2+} were treated with the oxidizing agent MMPP and the efficiency of I28 cross-linking was investigated by SDS−PAGE (Figure 3). The H_6Y-tags in which the Y residues were on the inside, or carboxyl end, of the H_6 tag (lanes 4 and 5) were covalently cross-linked into dimers predominantly, but also into trimers and higher molecular weight species. These multimers remained intact after vigorous boiling and in the presence of the reducing agent, β-mercaptoethanol, indicating that neither metal-mediated complexes nor disulfide bonds were responsible for the observed inter-protein cross-linking. The H_6-tags in which the Y residues are on the outside, or amino end, of the H_6 tag (lanes 1−3 and 6−7) underwent little cross-linking. In the absence of Ni^{2+} or MMPP, no cross-linking occurred. A control I28 protein that did not have a Y residue in the H_6 tag was not cross-linked in the presence of Ni^{2+} and MMPP although it does have a single endogenous Y residue (lane 8). These results demonstrate first that H_6-complexed Ni^{2+} will catalyze covalent cross-linking between HY-tagged I28, and second that the position of the Y residue relative to the H_6-tag has a profound effect on the covalent cross-linking efficiency.

Covalent cross-linking of H_6GY-I28 protein was also induced by sodium sulfite (Na_2SO_3) in the presence of Ni^{2+} (Figure 4). Although the precise mechanism of this process is unknown, XXH peptide/Ni^{2+} complexes in the presence of SO_3^- and dioxygen have been shown to

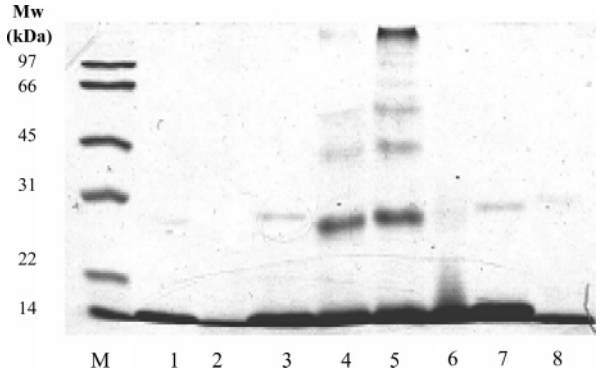

Figure 3. Protein cross-linking efficiency depends on the placement of the Y residue(s) near the H_6 tag. Proteins with the Y residue on the inside of the H_6 tag, lanes 4 (MH_6GY-titin I28) and 5 (MH_6GYGY-titin I28) showed efficient cross-linking when treated with MMPP. However, those versions of the protein in which Y residue(s) were placed within or on the amino side of the H_6 tag underwent little or no cross-linking when subjected to the same conditions: lanes 1 (YH_6-titin I28), 2 (YGH_6-titin I28), 3 (MNSYGYGH_6-titin I28), 6 (YGH_6GY−Titin I28), 7 (H_3GYGH_3−Titin I28). generate sulfur oxyradicals, e.g. $SO_3^{\bullet-}$, $SO_5^{\bullet-}$, and $SO_4^{\bullet-}$ (*30*). The sulfite radical anion $SO_3^{\bullet-}$ is known to react rapidly with dioxygen to form the short-lived monoperoxysulfite radical anion $SO_5^{\bullet-}$ which can then dimerize to form the more stable sulfate radical anion $SO_4^{\bullet-}$ (for a detailed discussion of the metal-catalyzed redox chemistry of Na_2SO_3 see ref 30). Alternatively, an oxidized nickel metal complex (Ni^{3+}/Ni^{2+}) may also be acting as the phenolic oxidizing agent. One or more of these reactive intermediate species could then oxidize the Y

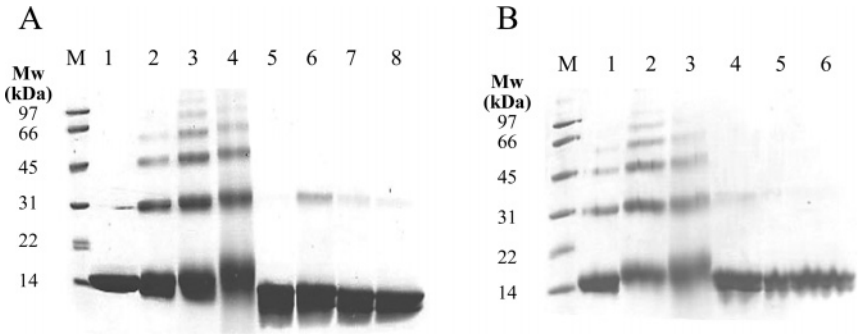

Figure 4. Effect of oxidant concentration on I28 cross-linking. (A). MMPP-induced cross-linking. Lanes 1−4: H_6GY-titin I28. Lanes 5−8: H_6-titin I28-H6 no Y control. The final concentration of MMPP was 0 in lanes 1 and 5, 40 μM in lanes 2 and 6, 400 μM in lanes 3 and 7, and 4 mM in lanes 4 and 8. (B) Na_2SO_3 induced cross-linking. Lanes 1−3: H_6GY-titin I28. Lanes 4−6: H_6-titin I28-H_6 control. The final concentration of Na_2SO_3 was 400 μM in lanes 1 and 4, 4 mM in lanes 2 and 5 with 40 mM in lanes 3 and 6. Lane M: molecular weight markers.

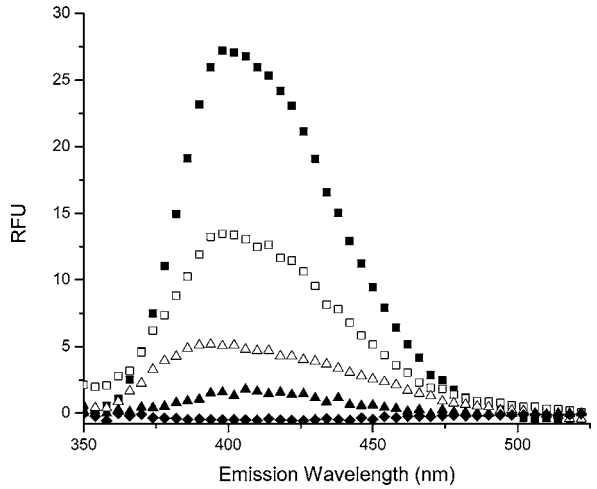

Figure 5. Dityrosine fluorescence. (■) L-Tyrosine and laccase enzyme. (□) H6GYG-titin I28 treated with Ni_2^+ and Na_2SO_3, (△) L-tyrosine treated with GGH/Ni_2^+/Na_2SO_3, (▲) H_6GYG-titin I28 treated with Na_2SO_3 (no Ni_2^+ control), (◆) L-tyrosine treated with Ni_2^+ and Na_2SO_3 (no ligand control).

phenol ring residue, resulting in the formation of a phenolic free radical species, which could then undergo oxidative cross-linking with an adjacent phenolic moiety. This scheme is thermodynamically possible as the one-electron redox potential of [(XXH)Ni^{2+}]-Ni^{3+}/Ni^{2+} (∼+800 mV) (*30*), $SO_3^{\bullet-}$/SO_3^{2-} (+390 mV) (*31*), $SO_5^{\bullet-}$/SO_5^{2-} (+840 mV) (*31*), and $SO_4^{\bullet-}$/SO_4^{2-} (+2900 mV) (*30*) are all potent enough oxidizing agents to oxidize phenolic residues (+300 mV) (*32*).

Dityrosine Formation. As further evidence that covalent cross-linking was occurring through the formation of dityrosine bonds, the cross-linked H_6Y-I28 proteins were analyzed by fluorescence spectroscopy. Dityrosine has an excitation maximum at 325 nm and a fluorescence maximum at 410 nm (*34*). Laccase is an enzyme that catalyzes the polymerization of phenol derivatives in nature, such as urushiol found in oriental lacquers (*35*). Laccase has been used to create dityrosine linkages in Y-containing peptides(*36*) and to polymerize free phenol, the functional group on tyrosine (*11*). Reaction of L-tyrosine with laccase to create an internal dityrosine standard resulted in a broad peak of fluorescence at about 400 nm (Figure 5). As an additional control, dityrosine was formed by reacting L-tyrosine with Ni^{2+} complexed by the tripeptide, GGH, which has been shown previously to generate dityrosine (*8*, *37*).

The oxidatively cross-linked H_6Y-tagged I28 proteins had fluorescence spectra similar to dityrosine formed from L-tyrosine with laccase. In the absence of oxidant or Ni^{2+} there was little or no fluorescence (Figure 5). These results confirm that the covalent cross-linking in the H_6Y-I28 proteins was due, at least in part, to the formation of dityrosine near the H-tags. Furthermore, the relative fluorescence intensity of the oxidatively cross-linked H_6Y-I28 proteins correlated with the degree of cross-linking observed by SDS−PAGE; the most cross-linked protein (Figure 3) had the highest fluorescence (Table 1).

DISCUSSION

The goal of this work was to develop an alternative method to modify proteins in a site-specific manner under mild conditions. Our approach was predicated on two previously reported observations. First, H-tagged proteins can associate through a ternary complex formed between the H-tags and Ni^{2+} (*24*). Second, H_6 complexed Ni^{2+} catalyzes oxidative covalent cross-linking of tyrosine residues into dityrosine (*9*, *14*, *16*). We reasoned that it should be possible to use H_6-tags to first form a metal-mediated complex between H_6-tagged proteins and that the metal complex could then be used to catalyze the localized cross-linking of tyrosine residues placed in the vicinity of the metal complex.

That H_6-tagged proteins associate in solution in the presence of Ni^{2+} was confirmed by sedimentation equilibrium analysis. H_6-tagged I28 existed in a monomer−dimer equilibrium in solution with a K_D of approximately 200 μM (Figure 2). The Ni^{2+}-mediated association through H_6-tags brings genetically placed Y residues into close proximity to one another and the catalytic Ni^{2+} H_6 complex. Addition of an oxidant generates reactive oxidative species, which then generate tyrosine free radicals that react with proximal tyrosines and other residues. By localizing two tyrosine residues in space by the ternary complex, we envisioned the possibility of observing enhanced rates of reaction as the local concentration of tyrosine could be higher than what could be obtained in solution. This rate enhancement affect has been recently observed in reactants tethered to DNA dimers (*38*, *39*). Additionally, the ternary metal complex prevents the reactive free radicals from diffusing away and thereby localizes the cross-linking reaction.

The position of the Y residue in the H_6-tag had a profound effect on the cross-linking efficiency of the reaction (Figure 3). Placement of the Y residue(s) on the carboxy side of the H_6 tag facilitates the cross-linking whereas the placement of Y residue(s) near the amino terminus resulted in little or no cross-linking. Although the mechanism that leads to this difference is not known,

it may be related to the half-life of the Y free radical generated in the reaction which can vary considerably depending on the local environment of the radical (*40*, *41*).

Our data indicates that the His-tagged proteins were dimerized via the formation of Y−Y cross-links, there is also evidence of side reactions. Metal-catalyzed oxidation has been reported to induce peptide bond cleavage in proteins (*42*−*44*), sometimes near Y residues (*45*, *46*). Mass spectrometry analysis after trypsin digestion of the H_6GY I28 proteins subjected to the oxidative treatment revealed the presence of small peptides conjugated to the H_6GY tag digest fragment (data not shown). Peptides containing Y residues generated by the cleavage of the protein near Y residue in the H_6 tag likely cross-linked with intact proteins, which accounts for the increased width of the monomer band in the SDS PAGE results (Figure 4). These same results, however, indicate that though the protein cleavage does occur the predominant product is protein cross-linking. It is conceivable that assay conditions such as oxidizing species, oxidant concentration, dioxygen concentration, and the reaction time could be optimized to enhance cross-linking while reducing protein cleavage.

The presence of dityrosine was detected by fluorescence spectroscopy in the cross-linked proteins (Figure 5). However, other residues in the H_6 tag region are likely to have reacted with the Y free radical. Of the residues vicinal to the Y in the H_6 tag, G is a likely candidate since it was shown previously to react with Y in proteins subjected to metal-catalyzed oxidation (*37*). The strong fluorescence observed indicates that the ladder of high molecular weight proteins observed in the SDS−PAGE studies is mainly due to the formation of Y−Y cross-linking; however, other Y-amino acid cross-links likely contributed to the oligomerization as well.

We demonstrated that the H_6 tag in conjunction with Ni^{2+} caused the protein to associate weakly into dimers. However, the association was transient and therefore only observable by sedimentation equilibrium studies. There are a number of residues that can participate in metal binding complexes: E, Y, H, R, K, D, M, C (*47*). Combinations of these residues in protein tags have the potential to yield stronger metallopeptide complexes than polyhistadine tags. For example, it has been reported that the HNRYGCGCC protein tag was shown to have a stronger metal binding capacity when compared to the common hexahistadine tag and yielded 20% more protein after purification during immobilized metal affinity chromatography (*48*). The focus of future research will be to develop methods to screen for additional peptides for the propensity to form metal-mediated complexes and catalyze oxidative dityrosine cross-linking triggered by low concentrations of a mild oxidant.

In conclusion, the metal-catalyzed oxidative cross-linking system described with further optimization to limit side reactions may circumvent some of the major limitations of conventional protein chemical modification methods. First, the conjugation site is preestablished as a ternary complex before functional groups are created by a mild oxidant. The conjugation site itself catalyzes the creation of the reactive species, which localizes covalent bond formation to the intended region. Therefore, the target functional group is not active in mild reaction conditions, unlike the C residues sometimes used in protein conjugation reactions (*49*, *50*), and the site limits random modifications that may damage or inactivate the target protein. Second, the conjugation site on the protein is genetically encoded in the form of a metal chelating peptide. Therefore, it is unnecessary to purify the target protein as a prerequisite for modification; it can be modified within a complex mixture of proteins. The implication for protein array applications is that recombinant proteins may be selectively captured onto a solid support from a crude lysate of cells expressing the protein. Purification and posttranslational chemical modification will be unnecessary.

TECHNICAL NOTES

Synthesis of Chemical Probes to Map Sulfenic Acid Modifications on Proteins

Cysteine sulfenic acids in proteins can be identified by their ability to form adducts with dimedone, but this reagent imparts no spectral or affinity tag for subsequent analyses of such tagged proteins. Given its similar reactivity toward cysteine sulfenic acids, 1,3-cyclohexadione was synthetically modified to an alcohol derivative and linked to fluorophores based on isatoic acid and 7-methoxycoumarin. The resulting compounds retain full reactivity and specificity toward cysteine sulfenic acids in proteins, allowing for incorporation of the fluorescent label into the protein and "tagging" it based on its sulfenic acid redox state. Control experiments using dimedone further show the specificity of the reaction of 1,3-diones with protein sulfenic acids in aqueous media. These new compounds provide the basis for an improved method for the detection of protein sulfenic acids.

INTRODUCTION

Interest in the identification of cysteine sulfenic acids in proteins by biochemists has grown substantially over the past decade as their biological roles in redox regulation and catalysis within an array of cellular proteins have become better defined (*1*, *2*). Despite their importance, only a limited set of tools to identify these species exist, and most of these are only applicable to in vitro studies of pure, isolated proteins (*3*, *4*). Chemical modification of cysteine sulfenic acids by dimedone (5,5-dimethyl-1,3-cyclohexanedione) provides a useful way to "tag" these species with a specific, irreversible alkylating agent, but the lack of any spectral or affinity label associated with dimedone requires that the detection of this tag be undertaken by mass spectrometry(*4*−*7*). A recently reported method involving biotin tagging of nascent cysteine thiols following cysteine sulfenic acid-specific reduction of cell extracts by sodium arsenite (*8*) has provided a new way to detect and isolate sulfenic acid proteins in a whole cell, proteomics format, although limitations of this method due in particular to cysteine sulfenic acid instability indicate that a rapid trapping and labeling method directed toward the unique chemistry of cysteine sulfenic acid would still be preferable.

To provide a new tool for identifying and isolating sulfenic acid-containing proteins and peptides, we designed and synthesized a functionalized derivative of 1,3-cyclohexadione (**3**, Scheme 1), a dimedone-like compound. Linkage of the alcohol functional group of this derivative to two different fluorophores, isatoic acid and 7-methoxycoumarin, yields fluorescent, sulfenic acid-reactive compounds (**6** and **7**, Scheme 3). Data presented herein confirm the utility of these reagents in specifically and rapidly labeling sulfenic acid groups in proteins. Further, the synthetic methods should be generally useful for linking other types of fluorescent or affinity tags to sulfenic acid-containing proteins for analysis and isolation.

EXPERIMENTAL PROCEDURES

3-Ethoxy-6-(3-*tert*-butyldimethylsilyloxypropyl)-cyclohex-2-enone (2). To a lithium diisopropylamide (LDA) solution [prepared from diisopropylamine (3.82 mL, 27 mmol) and ^{n}BuLi (7.26 mL of a 2.5M solution in hexanes, 18 mmol) in tetrahydrofuran (THF, 12 mL)[1] at 0 °C] at −78 °C was added 3-ethoxy-2-cyclohexen-1-one (2.64 mL, 18 mmol) in THF (6 mL), dropwise, over 40 min. After stirring for an additional 30 min at −78 °C, hexamethyl phosphoramide (HMPA, 3.16 mL, 18 mmol) was added followed by the dropwise addition of 3-iodo-1-*tert*-butyldimethylsiloxypropane (5.45 g, 18 mmol) in THF (8 mL). The resultant mixture was allowed to warm to room temperature, stirred for 6 h, and then quenched by the addition of water (10 mL). The reaction mixture was then partitioned between dichloromethane (DCM, 100 mL) and sat. NH_4Cl (40 mL). The aqueous phase was extracted with DCM (3 × 50 mL), and the organic phases were combined and washed with brine (50 mL), dried over anhydrous $MgSO_4$, and reduced to dryness. The resultant syrup was purified by flash column chromatography (hexanes/EtOAc 8/2) to yield **2** as a pale yellow oil (2.92 g, 51.2%). R_f 0.21 (hexanes/EtOAc 8/2); ^{1}H NMR (300 MHz, $CDCl_3$) δ 5.26 (1H, s), 3.83 (2H, q, J = 7.0 Hz), 3.59 (1H, t, J = 6.5 Hz), 3.58 (H, t, J = 6.5 Hz), 2.38 (2H, t, J = 6.2 Hz), 2.20−1.99 (2H, m), 1.85−1.35 (5H, m), 1.31 (3H, t, J = 7.0 Hz), 0.84 (s, 9H), 0.00 (s, 6H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 201.6, 176.7, 102.3, 64.2, 63.4, 45.0, 30.5, 28.0, 26.4, 26.0 (×2), 18.4, 14.2, −5.2.

3-Ethoxy-6-(3-hydroxypropyl)cyclohex-2-enone (3). To a solution of **2** in THF (20 mL) was added TBAF (23.2 mL of a 1.0 M solution in THF, 23.2 mmol) and NEt_3 (3.2 mL, 23.2 mmol). After stirring at room temperature for 2 h, the reaction was quenched by the addition of water (20 mL) and sat. NH_4Cl (20 mL). The mixture was extracted with DCM (3 × 80 mL), and the combined organic phases were dried over anhydrous $MgSO_4$ and reduced to dryness. The resultant syrup was purified by flash column chromatography with gradient elution (DCM/diethyl ether 1/1 to 3/7) to yield **3** as a pale yellow oil (1.85 g, 100%). R_f 0.37 (hexanes/EtOAc/MeOH 6/3/1); ^{1}H NMR (300 MHz, $CDCl_3$) δ 5.32 (1H, s), 3.89 (2H, q, J = 7.1 Hz), 3.64 (2H, t, J = 6.2 Hz), 2.44 (2H, 2d, J = 7.1 Hz), 2.24 (1H, m), 2.06 (1H, m), 1.92−1.49 (5H, m), 1.36 (3H, t, J = 7.1 Hz); ^{13}C NMR (75 MHz, $CDCl_3$) δ 202.0, 177.2, 102.3, 64.4, 62.6, 44.9, 30.3, 28.4, 26.8, 25.8, 14.3.

3-(4-Ethoxy-2-oxocyclohex-3-enyl)propyl 2-(methylamino)benzoate (4). Alcohol **3** (180 mg, 0.89 mmol), NEt_3 (0.56 mL), and catalytic DMAP were added to a solution of *N*-methylisatoic anhydride (220 mg, 0.89 mmol) in dry DMF (2.0 mL) at room temperature. After stirring overnight, the solution was warmed to 65 °C for 3 h. After cooling to room temperature, water was added and this mixture was extracted with ethyl acetate (5 × 50 mL). The combined organic layers were washed with brine, dried over Na_2SO_4, filtered, and evaporated to give the crude product, which was purified by flash column chromatography to afford 87.0 mg (45% yield) of **4** as a white solid: ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.85 (1H, m), 7.33 (1H, m), 6.56 (2H, m), 5.27 (1H, s), 4.22 (2H, t, J = 5.2 Hz), 3.85 (2H, q, J = 7.0 Hz), 2.86 (3H, s), 2.39 (2H, t, J = 5.3 Hz), 2.04−1.41 (7H, m), 1.31 (3H, t, J = 7.0 Hz); ^{13}C NMR (75 MHz, $CDCl_3$) δ 201.1, 176.8, 168.7, 151.7, 134.7, 131.7, 115.0, 111.3, 110.6, 102.5, 101.9, 64.7, 64.5, 64.3, 44.9, 30.0, 28.2, 26.6, 26.5, 26.4, 14.3; ESI MS *m/z* 354 ($M^+ + Na^+$).

3-(4-Ethoxy-2-oxocyclohex-3-enyl)propyl-7-methoxy-2-oxo-2*H*-chromen-3-ylcarbamate (5). A solution of 7-methoxy-3-carboxycoumarin (335 mg, 1.5 mmol), NEt_3 (1.05 mL, 7.6 mmol), and DPPA (0.36 mL, 1.7 mmol) in benzene (15 mL) was stirred at 65 °C for 4 h. A solution of **3** (260 mg, 1.3 mmol) in benzene (2 mL) was then added and the mixture stirred at 65 °C for 16 h. Upon cooling, water (40 mL) was added and the mixture extracted with DCM (3 × 40 mL). The combined organic phases were washed with sat. $NaHCO_3$ (30 mL) and brine (30 mL), dried over anhydrous $MgSO_4$, and reduced to dryness. The resultant solid was purified by flash column chromatography (×2, gradient elution with DCM/EtOAC (8/2) to DCM/EtOAc/MeOH (8/1/1), and then DCM/MeOH (9/1)) to yield **5** as an off-white solid (270 mg, 49.5%). R_f 0.63 (hexanes/EtOAc 1/2); mp 131−134 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.22 (1H, s), 7.34 (2H, m), 6.84 (1H, dd, J = 8.6 Hz, 2.4 Hz), 6.79 (1H, d, J = 2.4 Hz), 5.29 (1H, s), 4.18 (2H, t, J = 6.3 Hz), 3.85 (2H, 2q, J = 7.0 Hz), 3.82 (3H, s), 2.42 (2H, 2d, J = 7.1 Hz), 2.22 (1H, m), 2.08 (1H, dq, J = 14.2 Hz, 5.0 Hz), 1.94−1.85 (1H, m), 1.78−1.66 (3H, m), 1.52−1.42 (1H, m), 1.33 (3H, t, J = 7.0 Hz); ^{13}C NMR (75 MHz, $CDCl_3$) δ 201.0, 176.9, 161.1, 158.9, 153.6, 151.3, 128.4, 122.0, 121.9, 113.3, 113.2, 102.4, 100.8, 66.0, 64.4, 55.9, 44.9, 28.3, 26.6 (×2), 26.2, 14.3; ESI MS *m/z* 438 ($M^+ + Na^+$).

3-(2,4-Dioxocyclohexyl)propyl 2-(methylamino)-benzoate (DCP-MAB, compound 6). Compound **4** was stirred in a mixture of THF/3 N HCl (1/1) at room temperature for 3 h, and the mixture was concentrated. The crude product was washed with EtOAc/hexane/MeOH (1/2/0.5) to afford **6** as a white solid: ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.83 (1H, m), 7.34 (1H, m), 6.55 (2H, m), 4.22 (2H, t, J = 6.3 Hz), 3.60 (2H, m), 2.84 (3H, s), 2.52−1.50 (9H, m); ^{13}C NMR (75 MHz, $CDCl_3$) δ 204.3, 203.8, 168.6, 151.6, 134.9, 131.7, 131.5, 115.2, 111.6, 110.5, 64.1, 58.4, 49.1, 39.9, 30.1, 26.4, 26.0, 24.7; ESI MS *m/z* 326 ($M^+ + Na^+$).

3-(2,4-Dioxocyclohexyl)propyl 7-Methoxy-2-oxo-2*H*-chromen-3-ylcarbamate (DCP-MCC, compound 7). Compound **5** (240 mg, 0.58 mmol) was stirred in a mixture of THF/DCM (3/1 v/v, 4 mL) and 3 N HCl (4 mL) for 1 h. The reaction mixture was diluted with water (10 mL) and extracted with DCM (3 × 30 mL). The combined organic phases were dried over anhydrous $MgSO_4$, and reduced to dryness to yield the crude product, which was purified by flash column chromatography (EtOAc/acetone 4/1) to yield **7** as an off-white solid (133 mg, 59.4%). R_f 0.62 (hexanes/EtOAc/MeOH 6/3/1); mp 154−156 °C; ^{1}H

Generation of Pure, Sulfenic Acid-Containing C165S AhpC. The C165S mutant of AhpC was expressed in bacteria and purified in the presence of 5 mM 1,4-dithiothreitol (added to all buffers) essentially as described previously (*9*). Purification of wild type AhpC was also carried out as previously described (*10*). For generation of the sulfenic acid form of C165S AhpC, thawed enzyme in 25 mM phosphate buffer at pH 7, containing 1 mM EDTA, was washed free of the dithiothreitol and transferred into fresh buffer using a PD-10 column (Amersham Biosciences), and pooled fractions were transferred to an anerobic cuvette. The protein solution (160 nmol in 0.60 mL) was made anaerobic by repeated cycles of argon and vacuum over about 30 min, then rapidly titrated with 11 mM hydrogen peroxide to give a maximal absorbance signal at ~367 nm for the sulfenate anion as described previously (*3*, *4*). In subsequent experiments, optimal sulfenic acid formation was observed by adding and mixing the hydrogen peroxide much more slowly (additions of about 0.05 equiv and thorough mixing every ~1 min) and quantitating the sulfenic acid formed using a freshly prepared 2-nitro-5-thiobenzoate (TNB) solution (0.28 mL) and a 60 μL aliquot of the protein removed anaerobically from the cuvette (*3*, *4*). Using this method, ~73% of the protein was converted to the sulfenic acid form after addition of 1.08 equiv of hydrogen peroxide. Protein was kept in the anaerobic cuvette at room temperature for several hours before conducting experiments with no loss in sulfenic acid content.

Labeling of Sulfenic Acid-Containing C165S AhpC for Spectral and Mass Spectrometric Analysis. The pure, oxidized enzyme (32 μL, 6 nmol each) from the anaerobic cuvette was added to argon-flushed 500 μL Eppendorf tubes containing the compound of choice (either dimethyl sulfoxide alone, or dimethyl sulfoxide into which dimedone, 1,3-cyclohexanedione, **6**, or **7** had been dissolved) to give a final concentration of 5 mM for the added reagent in final volumes of 50 μL, and the tubes were flushed again with argon before closing. Other redox forms of C165S AhpC or the wild-type enzyme were also tested for reactivity with one or more of these four compounds. Approximate 100 mM stock solutions of **6** or **7** in dimethyl sulfoxide were standardized using expected extinction coefficients of 5700 M^{-1} cm^{-1} at 353 nm or 25000 M^{-1} cm^{-1} at 334 nm, respectively, for the esterified isatoic acid conjugate or the methoxycoumarin conjugate in methanol (*11*). Samples were incubated at room temperature for 60 min, then transferred to Apollo ultrafiltration devices (30K cutoff, Orbital Biosciences, Topsfield, MA), washed with 5.5 mL of 10 mM ammonium bicarbonate and reconcentrated to about 50 μL, for a total of four washes (>10^8-fold dilution of the initial small molecule components).

Mass Spectrometric and Spectral Analyses of Adducts with the Sulfenic Acid-Containing Form of C165S AhpC. For mass spectrometric analyses, 60 μL of the ammonium bicarbonate buffer containing 1−2 nmol of labeled or unlabeled protein was submitted to the Mass Spectrometer Facility at Wake Forest University School of Medicine for infusion analysis on a Micromass Quattro II triple quadrupole mass spectrometer equipped with a Z-spray source. Just prior to analysis, samples were diluted 1:1 with acetonitrile and 1% formic acid was added. The data were processed and analyzed using MassLynx Version 3.5.

Labeled protein samples washed (with Apollo concentrators) into potassium phosphate or ammonium bicarbonate buffers were also analyzed for their UV−visible spectroscopic and fluorescence properties using a Beckman DU7500 diode array spectrophotometer or a SLM Aminco-Bowman Series 2 luminescence spectrophotometer, respectively. By comparison with the reported extinction coefficients for each of the free reagents in methanol (5700 M^{-1} cm^{-1} for esterified isatoic acid, and 25000 M^{-1} cm^{-1} for methoxycoumarin) (*11*), the free and presumably protein-bound reagents in neutral pH phosphate buffer exhibited average extinction coefficients of ~4500 and ~21800 M^{-1} cm^{-1}, respectively, for **6** and **7**. These measured values were subsequently used to standardize **6** and **7** and to estimate the labeled protein concentrations.

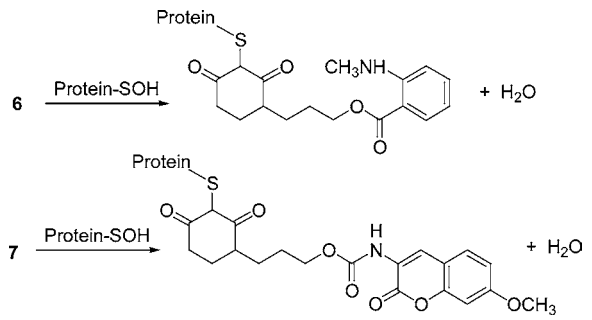
RESULTS AND DISCUSSION

Synthesis. As preliminary biochemical results revealed that 1,3-cyclohexadione reacts in a manner similar to dimedone, the protected version of 1,3-cyclohexadione, 3-ethoxy-2-cyclohexen-1-one (**1**, Scheme 1), was chosen as the initial starting material for the preparation of fluorescently labeled probes. Starting with **1**, which readily hydrolyzes to 1,3-cyclohexadione under acidic conditions, removes any synthetic complications from the highly acidic (pK_a = 5.15) (*12*) active methylene group of dimedone. Alkylation of the anion of commercially available 3-ethoxy-2-cyclohexen-1-one with *tert*-butyldimethylsilyl (TBDMS) (*13*)-protected 3-iodo-1-propanol yields **2** (51% yield, Scheme 1). Treatment of **2** with tetra-*n*-butylammonium fluoride (TBAF) removes the silyl group to give the alcohol (**3**, 100%, Scheme 1). The alcohol group of **3** provides an attachment site for the fluorescent groups.

Condensation of **3** with *N*-methylisatoic anhydride yields the protected 1,3-cyclohexadione derivative (**4**, 45%, Scheme 2). Heating 7-methoxycoumarin-3-carboxylic acid in the presence of diphenyl phosphorazidate (DPPA) and **3** gives the protected derivative (**5**, 50%, Scheme 2), presumably through the Curtius rearrangement of the acyl azide to the isocyanate followed by condensation of **3**. Treatment of **4** and **5** with aqueous HCl cleanly produces 3-(2,4-dioxocyclohexyl)propyl 2-(methylamino)benzoate (**6,** DCP-MAB, Scheme 3**)** and 3-(2,4-dioxocyclohexyl)propyl 7-methoxy-2-oxo-2*H*-chromen-3-ylcarbamate **(7**, DCP-MCC, Scheme 3) in 96 and 59% yield, respectively. Both the ester linkage of **6** and the carbamate linkage of **7** appear generally stable to these acidic deprotection conditions.

Reactivity of New Compounds toward Cysteine Sulfenic Acids in Proteins. To test for the reactivity of **6** and **7** toward protein sulfenic acids, a mutant, cysteine-dependent peroxidase enzyme was used in which the oxidized, sulfenic acid form of the cysteinyl redox center is stabilized, yet accessible (the C165S mutant of AhpC from *Salmonella typhimurium*, a peroxiredoxin) (*3, 9, 13*). Both compounds, dissolved initially in dimethyl sulfoxide and diluted 20-fold to a final concentration of 5 mM in aqueous, neutral pH buffer, gave covalent

Scheme 4



adducts with the sulfenic, but not sulfinic or sulfonic, acid forms of the peroxidase (Scheme 4).

The thiol group of the reduced protein and the oxidized, disulfide-bonded form of wild type AhpC were also unreactive toward these compounds, as confirmed by electrospray ionization mass spectrometry (ESI-MS) of the ammonium bicarbonate-washed proteins following incubations with the labeling agents (Figure 1 and data not shown). As illustrated in Figure 1 and summarized in Table 1, mass spectrometry results were completely consistent with the expected reactivity and products generated with the sulfenic acid-containing protein using dimedone, 1,3-cyclohexadione, and our two new labeling agents (**6** and **7**). Where sulfenic acid and hence adduct generation was substoichiometric due to the rapid addition of excess hydrogen peroxide (converting much of the enzyme to the sulfinic and perhaps sulfonic acid forms), additional peaks for thiol (unoxidized) and hyperoxidized (RSO_2^- and RSO_3^-) protein were observed (Figure 1). Under the conditions used, the sulfenic acid form of the protein either reacts with the reagent or is further oxidized during the workup or analysis of the sample and is therefore not observed. In a subsequent experiment where sulfenic acid formation was measured at ~73%, an equivalent amount of **6** or **7** (74 and 67%, respectively) was incorporated into the protein as observed by ESI-MS (Table 1).

The fluorescence properties of **7** ($\lambda_{ex,max} = 341$ nm and $\lambda_{em,max} = 414$ nm) were unchanged upon reaction with the cysteine sulfenic acid**,** while small shifts in both the excitation and emission wavelength maxima were observed upon adduct formation with **6**, the isatoic acid derivative (from $\lambda_{ex,max} = 353$ nm to $\lambda_{ex,max} = 357$ nm, and from $\lambda_{em,max} = 440$ nm to $\lambda_{em,max} = 430$ nm, Figure 2). This fluorescence difference may allow for the monitoring of the protein reaction with the fluorophore, although apparent bleaching of the fluorophore during measurements makes such experiments technically difficult. Protein adduct amounts assessed by ESI-MS analyses of the intact proteins indicate approximately equal labeling of the protein with the two reagents when 1:1 mixtures of the **6** and **7** are added, suggesting similar rates of reaction for these two compounds. While it is unlikely that all protein sulfenic acids react with these compounds at the same rate due in part to varying accessibility of the reactive group, it is probable that, under denaturing and anaerobic conditions, reaction rates will be similar to those with the model protein sulfenic acid.

Specificity of Dimedone and/or Fluorescent, Cyclohexadione-Derived Reagents toward Sulfenic Acids in Proteins. The known reactivity of the nucleophilic center of dimedone is toward cysteine sulfenic acids and aldehydes (*14, 15*). Amines have also been shown to condense with dimedone (*16*). As described above, control

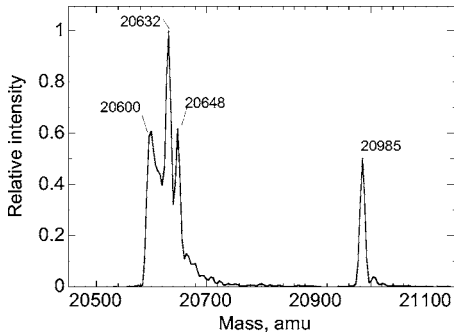


Figure 1. Electrospray ionization mass spectrometry analysis of adducts with the sulfenic acid form of C165S AhpC. The mutant of the bacterial peroxidase AhpC (C165S) containing only the peroxidatic cysteine (Cys46) but not the resolving cysteine (Cys165) that participates in disulfide bond formation was treated with hydrogen peroxide to yield the relatively stabilized sulfenic acid form of the protein under anaerobic conditions, then incubated with DCP-MCC (**7**) to yield the covalent protein adduct. The treated protein sample was concentrated and rediluted four times into 10 mM ammonium bicarbonate buffer using a 30K cutoff Apollo ultrafiltration device (>10^8-fold dilution of the initial small molecule components). Just prior to analysis, samples were diluted 1:1 with acetonitrile, made 1% in formic acid, and then infused at 5 μL/min. The capillary voltage was 3.5 kV; the cone voltage was ramped (30−120 V) and the spectrum scanned from *m/z* 600−1800 in 2.1 s. Eight to twenty scans were acquired for each sample. The data were processed using MassLynx 3.5 to generate the absolute molecular weight of the protein ± 2.1 Da. Shown are the transformed data that represent the relative abundance (shown as both the predicted and observed masses, see Table 1 for more detailed mass information) of four prominent species of C165S AhpC: the protein with the active site Cys46 in the thiol (20600 amu), sulfinic acid (20632 amu), or sulfonic acid (20648 amu) states, or in a covalent complex with **7** (20985 amu). In this case the initial method described in the Experimental Section (based on maximal A_{367} and rapid hydrogen peroxide addition) was used to generate the sulfenic acid form of C165S AhpC, resulting in approximately 1/5 of the protein being stabilized in this redox state at the time of reaction with **7**.

Table 1. Observed and Predicted Masses of Products Following Sulfenic Acid-Directed Labeling of Target Protein (C165S AhpC)

reagent	observed increase in mass of product compared with RSH form[a]	predicted additional mass of product[b]
1,3-cyclohexadione	109.2	110.1
DCP-MAB (**6**)	300.7	301.4
DCP-MCC (**7**)	384.5	385.4
dimedone	137.3	138.2

[a] Mass from electrospray ionization mass spectrometry on a Micromass Quattro II triple quadrapole mass spectrometer of the modified product from which was subtracted the mass for the oxidized sulfinic acid product (RSO_2^-) present in each sample, adjusted 32 amu for the two oxygen atoms. [b] Mass of labeling agent minus 2.016 for loss of hydrogens during adduct formation.

reactions of thiol, disulfide, or hyperoxidized forms of AhpC (wild type or C165S) demonstrated their lack of reactivity toward **6**, **7**, and dimedone based on the lack of ESI-MS-detectable adduct formation. To test for general cross-reactivity of these reagents with other oxidized sulfur-containing functional groups, we tested the reactivity of dimedone, as a model reagent, with a *S*-nitrosothiol and two sulfoxides. Dimedone fails to react with *S*-nitrosoglutathione (GSNO) as judged by absorbance spectroscopy over 1 h at room temperature. Nuclear magnetic resonance (NMR) and spectroscopic and chemical isolation experiments show that dimedone does not

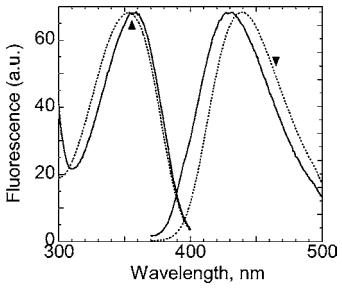

Figure 2. Fluorescence spectra of DCP-MAB (**6**) before (solid) and after (dotted) reaction with cysteine sulfenic acid-containing protein. Labeled C165S AhpC was prepared as described in the Experimental Section with the cysteine sulfenic acid form of the protein incubated anaerobically with 5 mM of **6** for 60 min, then washed free of the unreacted reagent and buffer components into a final buffer of 50 mM Tris-HCl at pH 8 using an Apollo concentrator. The absorbance at 347 nm of this sample was 0.14, and the fluorescence measurements were taken using a semi-microcuvette with the 0.4 mm cuvette width directed toward the excitation beam and the 1.0 mm internal width directed toward the emission detector at 90°. Emission scans (370 to 500 nm) were collected at an excitation wavelength of 353 or 357 nm, respectively, for the free and protein-bound **6**, and excitation scans (250 to 400 nm) were collected at an emission wavelength of 440 or 430 nm, respectively. Arrows indicate excitation and emission wavelengths used in attempts to monitor rates of reaction of cysteine sulfenic acid-containing C165S AhpC with **6**; technical problems were encountered with these measurements, and reproducible rates were not obtained.

react with aqueous solutions of either dimethyl sulfoxide or methionine sulfoxide (Supporting Information).

As reported, dimedone demonstrates reactivity with both aldehydes and amines (*15, 16*). Control reactions show that dimedone reacts with butyraldehyde in the presence of piperidine at 50 °C in aqueous ethanol but fails to react with the same aldehyde at room temperature in the absence of base. In addition, while dimedone condenses with benzylamine to form an imine in organic solvent, no reaction occurs in aqueous ethanol. The failure of **6** and **7** to react with either reduced or oxidized wild type or reduced C165S AhpC proteins also indicates that these compounds do not react with protein amine groups under these conditions. Taken together, these results demonstrate the relative specificity of the reaction of these compounds for sulfenic acids in proteins in aqueous buffers.

CONCLUSIONS

Functionalization of 1,3-cyclohexadione derivatives with an alcohol group and subsequent coupling to fluorophores has successfully generated two sulfenic acid-reactive compounds that specifically incorporate a fluorescent label into a sulfenic acid-containing model protein. Compounds such as these should prove useful in tagging protein sulfenic acids for their detection and isolation from complex protein mixtures in the future.

ACKNOWLEDGMENT

The authors thank Drs. Larry Daniel and Jacquelyn Fetrow for experimental and editorial guidance and acknowledge financial support from the American Heart Association Established Investigatorship program (to both L.B.P., 0140175N, and S.B.K., 0140020N), from the Cross Campus Collaborative Research Program at Wake Forest University (to S.B.K. and L.B.P.), and from the National Institutes of Health to L.B.P., with S.B.K. as coinvestigator (R21 CA112145). The Quattro II tandem mass spectrometer was purchased, updated, and supported in part with funds from National Science Foundation BIR-9414018, the North Carolina Biotechnology Center (9903IDG-1002), the Winston-Salem Foundation, and the Comprehensive Cancer Center of Wake Forest University. The NMR spectrometers used in this work were purchased with partial support from NSF (CHE-9708077) and the North Carolina Biotechnology Center (9703-IDG-1007).
