
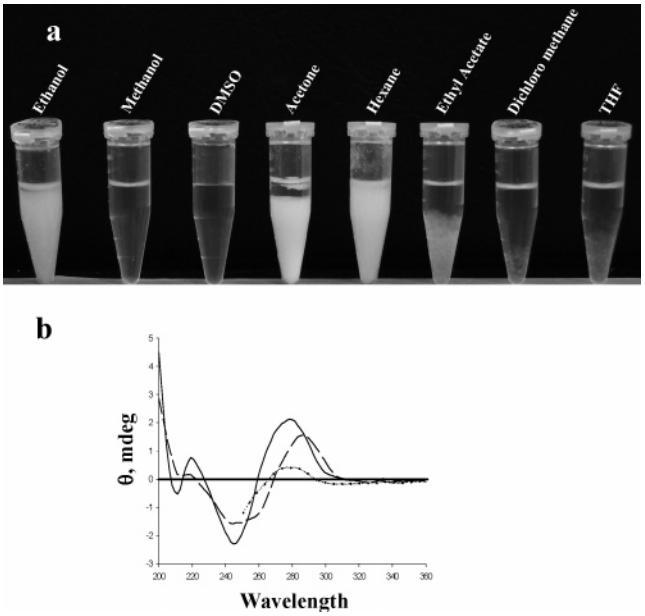

Figure 1. (a) Photograph of DNA solubilization in various organic solvents. (b) Circular dichroism spectra of plasmid DNA in DW (solid line), PEG/plasmid DNA complex (weight ratio PEG/DNA = 15) in DMSO (dotted line), and PEG/plasmid DNA in methanol (dashed line).

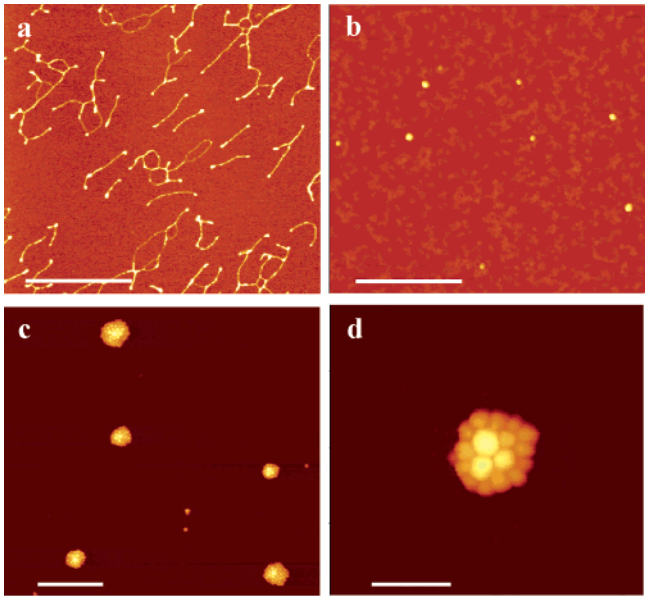

Figure 2. AFM images of (a) plasmid DNA in water, (b) PEG/DNA nanocomplex (PEG/DNA weight = 15) in DMSO, and (c,d) cross-linked PEG/DNA nanogels in water. Scale bars: (a−c) = 1 μm, (d) = 250 nm.

seen that DNA exhibits different extents of solubilization depending on organic solvents, but it is completely dissolved in methanol, dimethylsulfoxide (DMSO), and dimethylformamide (DMF). The DNA solubility in DMSO was determined by measuring the concentration of DNA in the supernatant after centrifugation at 14 000 rpm. Since the PEG/DNA nanocomplexes were spontaneously formed in DMSO without showing any turbidity, they could not be spun down. As shown in Figures S1−2 (Supporting Information), almost 100% transmittance and 100% solubility values were attained for PEG/DNA nanocomplexes dispersed in DMSO. When testing the effect of PEG/DNA weight ratio on the DNA solubilization in DMSO, the transmittance value reached 97.1 ± 1.0% at a PEG/DNA weight ratio of 5. Thus, we defined that plasmid DNA was soluble in a state of nanoparticulate in the DMSO phase. In circular dichroism (CD) spectra as shown in Figure 1b, it can be seen that a positive ellipticity peak of plasmid DNA solubilized in DMSO and methanol exhibits a red-shift while maintaining a duplex helical structure, indicating that DNA in organic solvents was in a highly compacted and collapsed state (*3*, *15*).

The state of DNA in the DMSO phase was visualized with atomic force microscopy. Figure 2a,b shows the conformation of DNA in water and DMSO in the presence of PEG (PEG/DNA weight ratio = 15), respectively. Figure S3 (Supporting Information) shows DNA conformation in DMSO at the PEG/DNA weight ratio of 1. Plasmid DNA in water is in a relaxed and stretched form with a contour length of ∼1 μm in water, but in DMSO containing PEG, it is collapsed and dispersed in a nanoscale of ∼100 nm. PEG is known to condense protein or DNA in an aqueous solution when PEG is added at a higher concentration above 7 w/v % (*16*, *17*). The effect of concentrated PEG on the DNA condensation in the aqueous phase occurs mainly via dehydrating water molecules from dissolved DNA, which results in DNA aggregation and precipitation. In this work, co-lyophilized PEG and salt-free DNA were dissolved together in an organic DMSO phase to produce individually well dispersed PEG/DNA complex nanoparticles. This indicates that the shrunken and compact DNA conformation in DMSO is likely due to the formation of hydrogen bonding between PEG and DNA. Previously, it was reported that nonionic polymers such as poly(*N*-vinylpyrrolidone) could interact with DNA by hydrogen bonding to form complex nanoparticles in an aqueous solution (*18*, *19*). It is conceivable that an oxygen atom in the ether linkage of the PEG chain can interact with −NH in the base of DNA by hydrogen bonding in an aprotic solvent such as DMSO. When redissolved in water, DNA regained its original conformation and stretched form as shown in Figure 2a, suggesting that water molecules broke up the hydrogen bonds between PEG and DNA. To prepare stable PEG nanogels containing DNA inside, a thiol-functionalized six-arm branched PEG derivative was used to condense plasmid DNA in DMSO, and then −SH groups present in the PEG/DNA nanocomplex were covalently cross-linked by a maleimide-functionalized crossinker, dithio-bis-maleimidoethane (DTME) (Scheme 1). Although air-induced and/or DMSO-induced oxidation of thiol groups also resulted in the disulfide cross-linking reaction (*20*, *21*), a bifunctional DTME cross-linker was used to facilitate the formation of PEG/DNA nanogels with more controllable cross-linking density. Plasmid DNA containing polyelectrolyte complex nanoparticles (polyplexes) cross-linked with disulfide bonds that are cleavable to cytosolic reductive conditions have been reported previously (*22*, *23*). The polyplexes formed between DNA and cationic polymers bearing −SH groups were cross-linked via disulfide linkages to stabilize the structure for improve gene transfection efficiency. In this study, plasmid DNA was first condensed with a thiol-functionalized multiarm PEG to form polyplexes in organic solvent and then free −SH groups in PEG cross-linked to form stable plasmid DNA encapsulating PEG nanogels in an aqueous solution without using any cytotoxic polycationic condensing agents.

The resultant PEG/DNA nanogels were spherical and very stable in aqueous solution (Figure 2c,d and Figure S4 (Supporting Information)). When the molar ratio of DTME/PEG-SH was adjusted at 15, the average size was 315.4 ± 91.3 nm (polydispersity 0.12 ± 0.06) and the surface charge value was −16.3 ± 2.8 mV, as determined by dynamic light scattering method. Under this condition, about 80% of the −SH groups were cross-linked as analyzed with Ellman's assay for free thiol groups (21.6 ± 13.6%). The amount of encapsulated DNA in the PEG nanogels was 5.3 ± 0.9% (w/w). The size of −S−S− cross-linked PEG nanogels could be readily controlled by varying the molar ratio of DTME/PEG-SH (Figure 3a).

Scheme 1. Schematic of PEG-assisted DNA Solubilization in Organic Solvent and Preparation of PEG/DNA Nanogels[a]

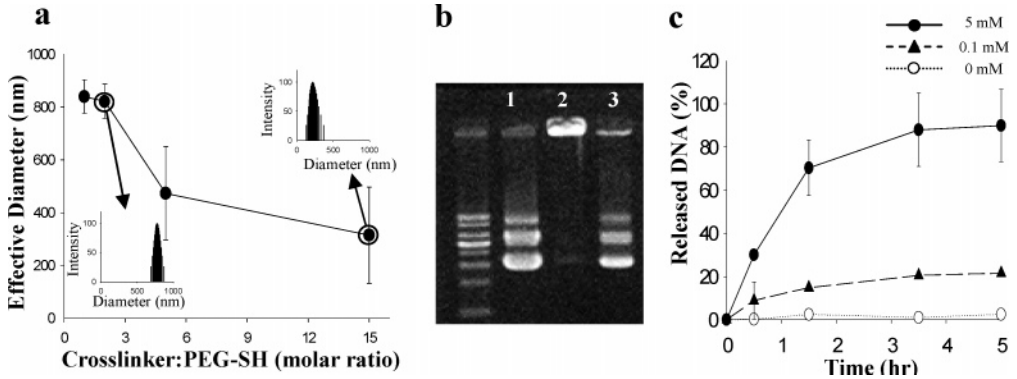

Figure 3. (a) Diameter of PEG nanogels at various molar concentrations of cross-linker, (b) gel retardation assay, and (c) DNA release profiles from PEG nanogels at various GSH concentrations of 0 (○), 0.1 (▲), and 5 (●) mM.

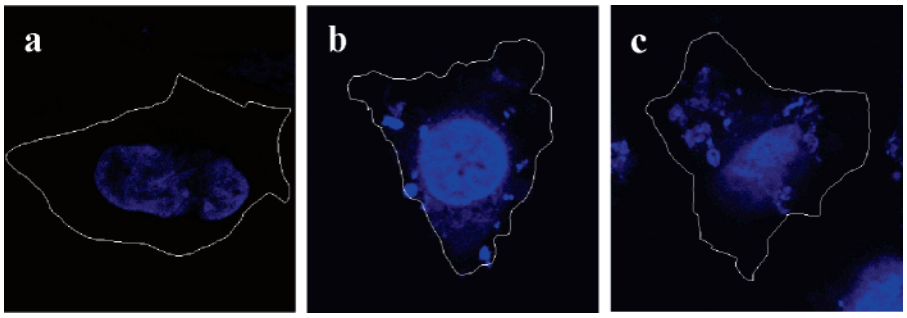

Figure 4. Confocal microscopy images of uptaken PEG nanogels within HeLa cells after (a) 0 h, (b) 1 h, and (c) 5 h post-transfection.

To prove that plasmid DNA was indeed encapsulated within cross-linked PEG nanogels, gel retardation assay was performed before and after treating a reducing agent, 100 mM dithiothreitol (DTT). Figure 3b shows that DNA encapsulated within PEG nanogels is primarily located in the loading zone (lane 2), but after treating with DTT for cleaving −S−S− linkage, supercoiled, circular, and linear DNA fractions appear in an intact form in the agarose gel (lane 3), in the same manner as those of naked plasmid DNA (lane 1). This suggests that no structural and conformational damage to DNA occurred during encapsulation, cross-linking, and degradation processes of PEG nanogels. To examine whether the PEG/DNA nanogels were degradable in an intracellular reduced environment where the concentration of glutathione (GSH) is maintained at 1−8 mM (*24*), they were exposed to 5 mM of glutathione (GSH). Figure 3c exhibits DNA release profiles from PEG/DNA nanogels at GSH concentrations of 0 (open circle), 0.1 (closed triangle), and 5 mM (closed circle). At a GSH concentration of 5 mM, the PEG nanogels released the encapsulated DNA almost completely after 4 h incubation. In contrast, at lower GSH concentrations, they were very stable without releasing DNA. This suggests that, in an extracellular condition, PEG/DNA nanogels maintained their structural integrity, but in a reductive cytosolic environment, they completely degraded and dissolved with subsequent release of entrapped DNA in the cytosol.

To prove that plasmid DNA was released from PEG nanogels in an intracellular environment, PEG/DNA nanogels were transfected to HeLa cells. To enhance the extent of cellular uptake, a positively charged KALA peptide was coated on the surface. The KALA peptide has a fusogenic effect to induce destabilization of endosomal membrane after endocytosis (*19*). To visualize DNA within the cells, intracellular DNA was stained with DAPI (4′,6-diamidino-2-phenylindole) dye, a double-strand DNA-specific marker. As shown in Figure 4, DNA is still collapsed after 1 h, but it appears to be more diffusive after 5 h in a cytosol area. This indicates that DNA release from PEG nanogels can be modulated in response to a reductive cellular environment. The transfected cells exhibited

appreciable GFP protein expression as shown in Figure S5 (Supporting Information), but the level of GFP transfection efficiency was still lower than those of commercially available transfection agents (Lipofectamine or PEI-based formulations). Thus, PEG/DNA nanogels would be usefully applied for locally delivering naked DNA in ischemic, muscular, and mucosal tissue sites. Naked plasmid DNA has been successfully administered to those tissues to treat various genetic diseases (*25*).

In conclusion, we demonstrate for the first time that plasmid DNA can be solubilized in selected polar organic solvents in the presence of PEG without using cationic polymers and surfactants. PEG-assisted DNA solubilization in organic solvents enabled plasmid DNA to be encapsulated within degradable PEG nanogels cross-linked via disulfide linkages. DNA release from the nanogels could be triggered upon exposure to reductive environments. The current formulation strategy of DNA is expected to have a wide range of applications for gene therapy including DNA vaccine.

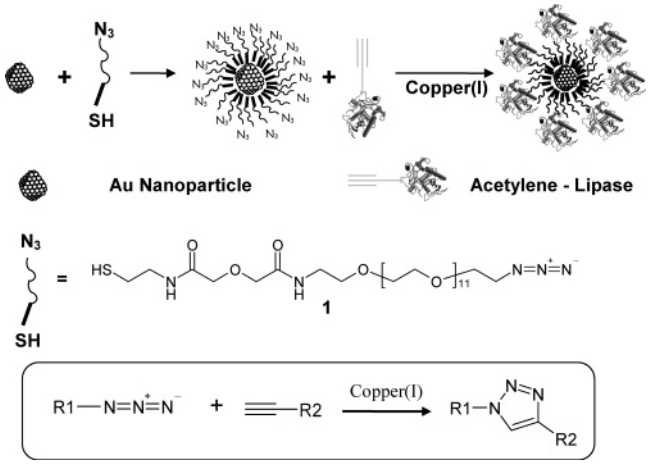
Received April 21, 2006; Revised Manuscript Received July 31, 2006

A simple and versatile method for the preparation of functional enzyme−gold nanoparticle conjugates using "click" chemistry has been developed. In a copper-catalyzed 1,2,3-triazole cycloaddition, an acetylene-functionalized *Thermomyces lanuginosus* lipase has been attached to azide-functionalized water-soluble gold nanoparticles under retention of enzymatic activity. The products have been characterized by gel electrophoresis and a fluorometric lipase activity assay. It is estimated that the equivalent of approximately seven fully active lipase molecules are attached to each nanoparticle.

The integration of biological with nonbiological materials and structures in functional devices is an interdisciplinary multiscale task of great practical importance (*1*). Its main challenge often lies in understanding and controlling the interface between biological and nonbiological materials on the molecular scale. The attachment of functional biomolecules to nonbiological nanoparticles, which is of relevance, for example, to biosensors, drug and gene delivery, tissue engineering, and the manipulation and study of single biomolecules, creates such an interface at the smallest possible scale (*1*−*9*). Here, we present a versatile preparative route to gold nanoparticle bioconjugates, which uses lipase enzymes as covalently attached biofunctional components. Only very few examples of covalently linked enzyme−gold nanoparticle conjugates have been reported (*10*−*14*), while most approaches rely on the nonspecific attachment of enzymes to nanoparticles (*15*−*20*). We now introduce the use of click chemistry (*21*−*26*) for the facile covalent coupling of adequately functionalized nanoparticles and enzymes to each other, utilizing the copper(I)-catalyzed 1,2,3-triazole formation between azides and terminal acetylenes. Click chemistry is appealing due to its dependability, specificity, and compatibility with both organic and aqueous reaction systems (*23*−*26*). As a result of this approach, the attachment of acetylene-functionalized lipase molecules to azide-functionalized gold nanoparticles under retention of enzymatic activity is demonstrated. The binding of lipase to nanoparticles via this reaction has been demonstrated by agarose gel electrophoresis and by the lipase activity of the purified conjugates.

Azide-functionalized gold nanoparticles were prepared by treating standard, citrate-stabilized gold hydrosols (*27*, *28*) with an aqueous solution of ligand **1** to directly yield thiolate-capped, azide-functionalized particles (AzNPs; Scheme 1), which were

Scheme 1. Functionalization of Gold Nanoparticles with 1, and Linking of Lipase to These Nanoparticles Using Click Chemistry



purified by repeated centrifugation and redispersion in water. They exhibit a characteristic plasmon absorption band at 523 nm, and their size is that of the original citrate-stabilized particles, 14 ± 1 nm (by TEM; Supporting Information). The number of capping ligands per nanoparticle can be estimated as 2250 ± 190 from the experimental gold, sulfur, carbon, hydrogen, and nitrogen content of the product and assuming an average nucleation number on the order of 85 000 gold atoms per particle (*29*). The particles are extremely stable and can be centrifuged, dried, and resuspended in aqueous solution several times without significant loss of material. They are stable for up to 3 months when stored at 4 °C in the dark in deionized water. Metal nanoparticles in biological systems always require ligand protection to prevent them from aggregating in the relatively high salt environment of biological buffers. As long as these ligands are reasonably short, i.e., within the limit of approximately half the diameter of the metal core, they do not affect the optical biosensing ability (distance probes) of the particles. While larger ligands may indeed prevent significant color changes upon particle aggregation, biosensing based on

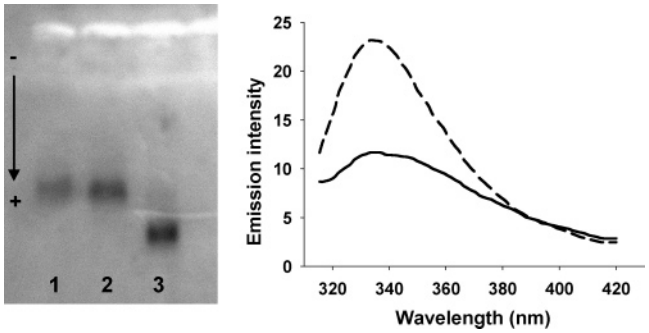

Figure 1. LHS: 1.5% agarose gel electrophoresis of AzNPs after click reaction with acetylene−lipase and following purification to remove excess lipase and copper salt. Lane 1: AzNPs. Lane 2: AzNPs reacted with acetylene−lipase without copper catalyst (blank). Lane 3: AzNPs reacted with acetylene−lipase with copper catalyst. RHS: Fluorometric lipase assay emission spectra recorded after 1 min (solid line) and 5 min (dashed line) of incubation with lipase-labeled AzNPs.

light scattering or photothermal effects is still possible (*2*−*4*). The particles described here are indeed compatible with biological buffers, tolerating salt concentrations up to 0.2 M before aggregation occurs. These properties are attributed to the structure of the ligand derived from **1**, containing a thiolate group for strong bonding to the gold nanoparticle surface and a water-soluble oligo(ethylene glycol) portion, which should also prevent denaturation of covalently bound enzymes and reduce nonspecific binding of enzymes to the particles (*30*, *31*).

These AzNPs were clicked to acetylene-functionalized lipase molecules (Scheme 1). The lipase was a 30 000 Da globular recombinant protein of fungal origin (*Thermomyces lanuginosus*), genetically altered to express only one solvent-accessible surface lysine residue (*32*, *33*). This lysine was modified using standard carbodiimide coupling chemistry (*34*) to yield a lipase with a freely accessible acetylene moiety.[1] This acetylene labeling step is facile to achieve on any protein with accessible lysines, for example, enzymes such as glucose oxidase (*34*), horseradish peroxidase (*35*), or alkaline phosphatase (*36*). Where no accessible lysines exist, standardized reagents and protocols are available to introduce amine groups without significant loss of biological activity, via modification of carboxyl or sulfhydryl amino acid functional groups or the carbohydrates of glycoproteins (*36*).

The acetylene-labeled lipase was clicked to gold nanoparticles by incubating an excess of lipase and Cu(I) catalyst with the nanoparticle suspensions at room temperature for 3 days. Although prolonged reaction times are required, this novel approach is very appealing, since no byproducts are formed. Following extensive purification by centrifugation to remove excess lipase and copper catalyst, the products were analyzed by gel electrophoresis (1.5% agarose gel, 100 V, 60 min). Figure 1 shows a gel comparing the purified reaction product (lane 3) to two control samples of as-prepared AzNPs (lane 1) and AzNPs treated with lipase in the absence of the Cu(I) catalyst (lane 2), respectively. The result indicates qualitatively the successful formation of protein−nanoparticle conjugates by click chemistry. The higher mobility of the reaction product in lane 3 is due to the covalent attachment of negatively charged lipase molecules to the gold particles. The increase in negative charge overcompensates here the effect of the increased hydrodynamic radius of the particles. The identical mobility of the two different control samples indicates the absence of nonspecifically bound lipase in the sample that has been exposed to the enzyme solution. While such nonspecific binding is usually quite common (*31*, *37*), and can indeed also be observed in our system (Supporting Information, Figure S3), this experiment demonstrates that the purification method used here is sufficient to remove all nonspecifically bound protein from the nanoparticle surface.

[1] Note that, while we have chosen here to site-specifically acetylate our enzyme, this is not a requirement to achieve click chemistry bioconjugation and simply depends on the desired application for the bioconjugate material.

Table 1. Supernatant Activity Tests during Removal of Unbound Lipase from Nanoparticle Samples Using Centrifugation[a]

sample	activity ($\times 10^{-3}$ U mL^{-1})[c]
wash 1[b]	224.57
wash 2	67.06
wash 3	3.77
wash 4	0.72
wash 5	0.39
wash 6	0.00
wash 7	0.00
wash 8	0.00
blank NPs[d]	0.00
lipase-labeled NPs	1.82

[a] Nanoparticles are washed until no activity is measured in the last three wash supernatants. [b] Refers to supernatant removed from nanoparticle pelleted by centrifugation. [c] 1 activity unit (U) is equivalent to 1 μmol of 5-OH-indole liberated per minute. [d] Lipase reacted with nanoparticle without copper catalyst.

To investigate whether the bound lipases retain their activity, the lipase-labeled and blank AzNP samples were tested using a modified fluorometric lipase activity assay (*38*). In the presence of lipase, a newly synthesized nonfluorescent ester, 5-*O*-palmitoylindole, is cleaved to a highly fluorescent 5-*OH*-indole product (λ_{max} 333 nm, synthesis in Supporting Information). Product emission is monitored at intervals of 1 and 5 min after sample addition. Activity is expressed as activity units per milliliter (U mL^{-1}), with 1 unit equivalent to 1 μmol of 5-*OH*-indole liberated per minute. Emission spectra for the lipase-labeled AzNP sample (Figure 1) demonstrate the observed increase in emission when the sample is incubated with substrate. Enzymatic activity is therefore retained when lipase is bound to the AzNP, with an enzyme activity of 1.82×10^{-3} U mL^{-1}. On the basis of the calibration curve of lipase activity versus lipase concentration for the free enzyme (Supporting Information), the measured activity of the hybrids corresponds to an average loading of seven lipase molecules per nanoparticle. This is valid only under the assumption that enzymatic activity is neither increased nor decreased upon attachment to the particles. As expected, zero activity is observed for the blank NP sample. Lipase activity assays were also performed on the supernatants from the centrifugation/washing procedure used to purify the AzNP samples, to ensure that all unbound lipase was removed from the nanoparticle suspensions. Table 1 shows the drop in supernatant lipase activity to zero as the particles are repeatedly cleaned, indicating the absence of solution free lipase in the system.

In conclusion, we have introduced the use of click chemistry for the conjugation of biomaterials to metal nanoparticles. Employing water-soluble, azide-functionalized gold nanoparticles and an acetylene-functionalized lipase as "clickable" precursor units has resulted in a new hybrid nanomaterial consisting of active lipase molecules covalently attached to the PEGylated ligand shell of a gold nanoparticle. Importantly, the coupling chemistry used here is very general and independent of the chemical nature of the nanoscopic subunits. This will allow the creation of similar composites containing a range of different biomolecular functionalities, which in the future may be used in applications such as biosensing, molecular electronics, catalysis, and controlled delivery.

Receptor-mediated endocytosis can be exploited for improving the transcellular delivery of therapeutic proteins. Insulin conjugated to transferrin by forming disulfide bonds has been shown to improve insulin oral bioavailability in diabetic rats. We are developing a combination strategy involving complexation hydrogels as delivery vehicles for insulin−transferrin conjugates. The complexation hydrogels developed in our laboratory have been shown to be promising carriers for oral delivery of proteins and peptides. Integrating the strategies based on the complexation hydrogels and insulin−transferrin conjugates may prove to be a novel approach for oral delivery of insulin and other therapeutic proteins. In this work, electrospray ionization mass spectrometry (ESI-MS) was used to study the modification of insulin during its reaction with transferrin. The stability of the conjugated insulin to enzymatic degradation was also studied. ESI-MS studies confirmed the site-specific modifications of insulin. The transferrin conjugation of insulin was also shown to increase the stability of insulin to enzymatic degradation.

INTRODUCTION

Complexation hydrogels developed in our laboratory have emerged as one of the most promising methods for orally delivering therapeutic proteins (*1*−*3*). These hydrogels are hydrogen bonding, copolymer networks of poly(methacrylic acid) grafted with poly(ethylene glycol), henceforth designated as P(MAA-*g*-EG) hydrogels. Their pH-responsive behavior resulting from the hydrogen-bonding complexation/decomplexation characteristics makes them ideal carriers for oral delivery of proteins, such as insulin. Insulin entrapped inside the polymer network is protected in the harsh gastric environment before it is released in the upper small intestine, from which it is absorbed into the systemic circulation. Further, the polymer network can inhibit the activity of Ca^{2+}-dependent proteolytic enzymes. Both in vitro and in vivo studies with insulin-loaded polymer carriers have demonstrated the efficacy of these hydrogels as vehicles for oral administration of insulin (*1*, *4*, *5*).

One of the other effective strategies for enhancing bioavailability of proteins exploits the receptor-mediated endocytotic pathway used by the cells for selective and efficient uptake of specific macromolecules required for various cell processes. By coupling proteins and peptides to ligands that can recognize specific receptors on the epithelial cells, transcellular delivery of macromolecular biopharmaceuticals may be achieved. Since only those molecules that are conjugated to the ligands are transcytosed, this process eliminates potential side effects associated with the unspecific transport via the paracellular pathway.

Transferrin is a widely investigated protein for enhancing the cellular uptake of therapeutic agents. It is a naturally occurring protein involved in iron transport. Absorptive uptake of the iron-bound transferrin has been used to enhance the transcytosis of therapeutic agents and drug carriers across polarized cells such as the epithelial cells (*12*, *13*) and the endothelial cells (*6*−*9*). Transferrin receptor (TfR)-mediated cellular uptake has also been explored for targeted delivery of anticancer drugs, proteins, and therapeutic genes into primary proliferating malignancies (*10*, *11*).

In one promising application of TfR-mediated drug delivery, Shen and co-workers (*12*, *13*) recently demonstrated improved efficacy of orally administered insulin by conjugating insulin with transferrin through disulfide linkages (*12*). Shah and Shen (*13*) showed that insulin conjugated to transferrin via disulfide linkages can be transported across enterocytes-like Caco-2 cells. Further, Xia et al. (*12*) showed that orally administered insulin−transferrin conjugate exhibited a slow but prolonged hypoglycemic effect compared to that of the native human insulin in streptozotocin-induced diabetic rats. One important consideration relating to the use of TfR-conjugated proteins for improved oral bioavailability is that the TfR is primarily present in the basolateral membrane of the epithelial cells (*14*). This may limit the desired apical to basolateral transcytosis of the conjugated molecule. Despite this limitation, successful studies conducted by Shen and co-workers have demonstrated that insulin and granulocyte-colony stimulating factor (GCSF) conjugated to transferrin were transported across Caco-2 cell monolayers (*13*, *15*). Transcytosis experiments with radiolabeled insulin demonstrated 15-fold (apical-to-basolateral) and 5-fold (basolateral-to-apical) increases in insulin transport compared with unmodified insulin across Caco-2 cells (*13*). This transport was TfR-mediated because it was efficiently inhibited by unlabeled Tf (*13*). This indicates that the distribution of the TfRs on the apical side may be sufficient to cause significant enhancement in the transport of insulin across the epithelial cell barrier.

In our laboratory, we are developing a delivery system consisting of the complexation hydrogels acting as delivery vehicles for insulin−transferrin conjugates. The use of P(MAA-*g*-EG)-based microparticles as delivery vehicles for the insulin−transferrin conjugates may constitute a superior transmucosal delivery system for insulin. The system may improve the efficacy of oral insulin administration since (i) insulin in the conjugated form may be further protected from enzymatic degradation due to steric hindrance created by the conjugated transferrin, (ii) owing to the potential of complexation hydrogels to act as mucoadhesive carriers, most of the conjugate will be released within the localized microenvironment of the small intestine's filamentous brush border creating a high local concentration of the conjugate, (iii) the conjugate will have larger residence time in the small intestine, and (iv) the insulin−transferrin conjugate can cross the intestinal barrier by TfR-mediated transcellular pathway, which may further increase the efficiency of insulin absorption.

In this work, we discuss the synthesis of insulin−transferrin conjugates, analysis of the intermediate products, and characterization of the reaction products. Detailed analysis of the insulin modification reaction and determination of stability to enzymatic degradation of the conjugated insulin are important steps in developing the proposed combination strategy.

EXPERIMENTAL SECTION

Materials. The heterobifunctional cross-linker succinimidyl 3-(2-pyridyldithio)propionate (SPDP) and dithiothreitol (DTT) were purchased from Pierce (Rockford, IL). Dimethylmaleic anhydride (DMMA) was purchased from Sigma-Aldrich (Chemie, Steinheim, Germany). Bovine insulin, trypsin, and 4-phenylspiro[furan-2(3*H*),1′-phthalan]-3,3′-dione (fluorescamine) were purchased from Sigma (St. Louis, MO). Float-a-Lyzer dialysis tubings were purchased from Spectrum Laboratories (Rancho Dominguez, CA). Slide-A-Lyzer mini dialysis units, D-Salt Dextran desalting columns and immobilized trypsin, TPCK, were purchased from Pierce Biotechnology, Inc. (Rockford, IL). *N*-Ethylmaleimide (NEM) was obtained from MP Biomedicals (Aurora, OH). C18 ZipTips were purchased from Millipore (Billerica, MA).

Synthesis of Insulin−Transferrin Conjugates. The protein conjugation method described here has been developed by Carlsson et al. (*16*) and was modified for preparation of insulin−transferrin conjugates by Shah and Shen (*13*). Insulin (Ins) was conjugated to transferrin (Tf) through disulfide linkages using SPDP, according to the method described by Shah and Shen (*13*) with some modifications as described below.

Insulin Modification by DMMA (Step I). Insulin was reacted with (DMMA) to block the primary amine groups at the N-terminal ends of the insulin chains, which can potentially react with SPDP (Figure 1A). A sample of 25 mg of bovine insulin was added to a solution containing 1.5 mL of 1 N HCl and 3 mL of phosphate-buffered saline (PBS) solution (pH 6.9). After completely dissolving insulin, the pH of the solution was adjusted to 6.9 by addition of 1.5 mL of 1 N NaOH solution. Dissolved insulin was then reacted with 3.5 mg of DMMA under constant stirring for 0.5 h. The pH of the solution was maintained at 6.8 to 6.9 by addition of 1 M Na_2CO_3 solution. Reaction with DMMA was repeated two more times so that a total of 10.5 mg of DMMA was added to insulin at the controlled pH of 6.8−6.9. A micro-pH meter (IQ Scientific Instruments, San Diego, CA) was used to monitor the pH of the solution during the reaction. The reaction mixture was transferred to Float-a-Lyzer dialysis tubings (MWCO 3500) and dialyzed against PBS buffer (pH 6.9) for 24 h to remove unreacted DMMA.

Insulin Modification with SPDP (Step II). Following dialysis, the DMMA-modified insulin was reacted with SPDP to introduce disulfide bonds at primary amine group of lysine at the B29 position of insulin (Figure 1B). The pH of modified insulin solution was raised to 9.0 by addition of 1 M Na_2CO_3 and 6.0 mg of SPDP dissolved in 150 μL of dimethyl formamide (DMF) was added to this solution. The reaction was constantly stirred at 4 °C for 2 h. The pH of the reaction was maintained at 8.8−9.0 during the course of the reaction.

The modified insulin was then dialyzed against PBS buffer (pH 8.0) for 24 h to remove unreacted SPDP reagent. To measure the average number of moles of 2-pyridyl disulfide groups attached per mole of insulin (PDP/Ins ratio), 700 μL of Ins−PDP solution was reduced by 25 mM DTT. PDP-modified protein on reduction with DTT releases of 2-pyridinethione chromophore, which can be quantitated by measuring the absorbance at 343 nm (A_{343}). A molar extinction coefficient of 8.08×10^3 M^{-1} cm^{-1} at 343 nm ($\epsilon_{343,2-TP}$) and 5.10×10^3 $M^{-1}cm^{-1}$ at 280 nm ($\epsilon_{280,2-TP}$) was used for the calculations (*16, 17*). Protein concentration was determined by measuring the absorbance at 280 nm (A_{280}). The molar extinction coefficient of 5.8×10^3 M^{-1} cm^{-1}at 280 nm was used for insulin. A sample of 40 μL of DTT-reduced modified insulin solution was diluted to 700 μL, and the absorbance was measured in triplicate at 343 and 280 nm with a microplate reader (Synergy HT, Bio-Tech Instruments, Winooski, VT). The PDP/protein ratio was determined by the following formula.

$$\text{PDP/protein} = \frac{A_{343}\epsilon_{280,\text{protein}}}{(A_{280}\epsilon_{343,2-TP} - A_{343}\epsilon_{280,2-TP})} \quad (1)$$

Transferrin Modification with SPDP (Step III). Transferrin was dissolved in 4 mL of phosphate buffer (pH 7.0, 30 mM) at a concentration of 20 mg/mL. Four-fold molar excess of SPDP dissolved in 100 μL of DMF and added to the transferrin solution under constant stirring. The reaction mixture was stirred for 2 h at 4 °C. The modified transferrin was then dialyzed (MWCO 50000) against phosphate buffer (pH 8.0, 30 mM, 3 mM EDTA) for 24 h to remove unreacted SPDP reagent. Following dialysis, entire transferrin solution was reduced by 25 mM DTT for 1 h to generate thiol-containing transferrin, Tf-SH (Figure 1C). The PDP/Tf modification ratio was determined by using molar extinction coefficient of 93.0×10^3 M^{-1} cm^{-1} at 280 nm ($\epsilon_{280,Tf}$) as described above.

Conjugation of Modified Proteins (Step IV). The reaction solution from step III containing Tf-SH was immediately purified by elution on D-Salt Dextran desalting columns (MWCO 5000). Four columns were connected in series to achieve the desired purification. Phosphate buffer (pH 8.0, 30 mM, 3 mM EDTA) was used to elute the protein from the columns. Fractions with A_{280} values greater than 0.2 were collected.

Purified Tf-SH was then reacted with Ins−PDP (Figure 1D) in a molar ratio of 1:2 of Tf-SH/Ins−PDP. To follow the progress of the reaction, 40 μL of the reaction samples was withdrawn at predetermined time intervals and diluted to 700 μL with phosphate buffer. Reaction of each mole of insulin with Tf-SH is accompanied by the release of 1 mol of 2-pyridinethione. Hence, A_{343} values of the samples were measured with a microplate reader to determine the concentration of 2-pyridinethione. To determine the average number of moles of insulin attached to 1 mol transferrin (Ins/Tf ratio), concentration of the 2-pyridinethione was divided by transferrin concentration in the samples. When approximately 2 mol of 2-pyridinethione were released per mole of transferrin, the reaction was stopped by addition of 4 mg of NEM to prevent further cross-linking of transferrin molecules via oxidation of unreacted thiols (*13*). Following the reaction, the conjugate was purified by dialysis

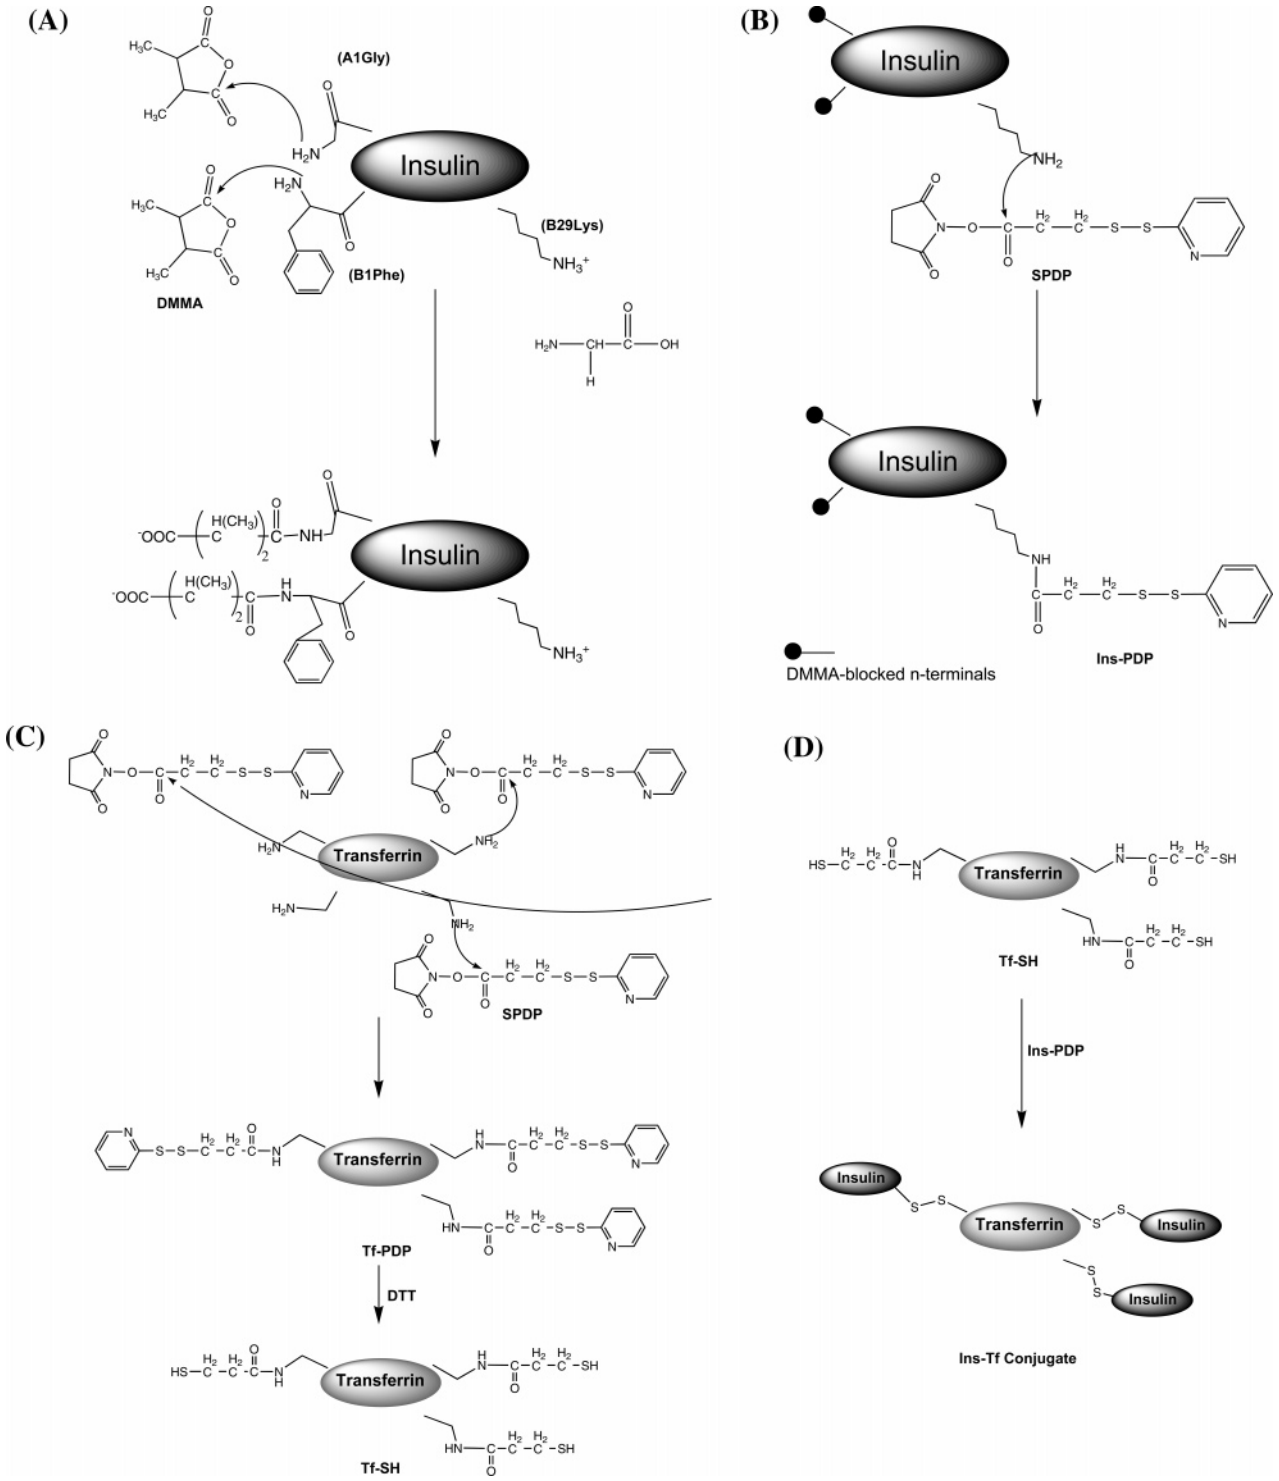

Figure 1. (A) Conjugation reaction, step I (DMMA blocking of the N-terminal amine groups). DMMA reaction with insulin at pH of 6.8−6.9. Only the primary amines at the N-terminal are deprotonated and are able to react with DMMA. Most of the primary amines at B29 lysine residue are protonated and do not react with DMMA. (B) Conjugation reaction, step II (SPDP reaction with DMMA-modified insulin). SPDP reacts with DMMA-modified insulin at pH 9.0 to form insulin−PDP. (C) Conjugation reaction, step III (SPDP modification of transferrin). SPDP reacts with transferrin at pH 7.0 to form Tf−PDP. The modification ratio can be controlled by altering the amount of SPDP reacted with transferrin. Purified Tf−PDP is then reacted with DTT to generate free thiol groups on transferrin (Tf-SH). (D) Conjugation reaction, step IV (Ins−PDP reaction with Tf−SH). Purified Tf−SH reacts with Ins−PDP obtained from step II to form Ins−Tf conjugate.

(MWCO 25 000) against phosphate buffer (pH 8.0, 30 mM, 3 mM EDTA) until no free insulin was detected in the solution by HPLC. Total protein concentration of the final purified conjugate solution was determined by Quick Start Bradford assay (Bio-Rad Laboratories, Hercules, CA) using BSA or unmodified transferrin as a reference standard (*18*).

Analysis of the Insulin Modification Reaction. Modifications of the primary amines of insulin due to DMMA reaction (step I) and SPDP modification (step II) were studied by quantitatively measuring the amount of free primary amine groups of the protein using fluorescamine assay and by identifying the sites of insulin modification by mass spectrometry. This was important since improper modifications of the protein may lead to decrease in its bioactivity (*19*).

Fluorescamine Assay for Measurement of Free Amine Groups of Insulin. A primary amine assay utilizing fluores-

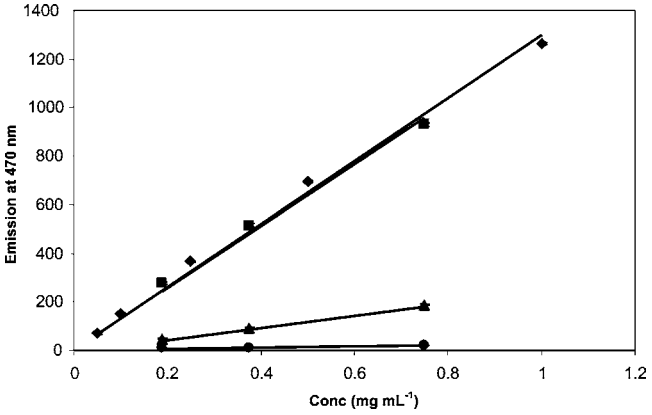

Figure 2. Fluorescamine assay for determination of free amine groups of insulin. Fluorescamine (50 μL of 1.08 mM) in acetone was added to 150 μL of protein samples in a microplate reader: insulin standard (◆), unmodified insulin (■), DMMA-modified insulin (▲), or SPDP-modified insulin (●). The fluorescence associated with the samples was measured with a microplate reader. Excitation was at 390 nm and emission at 470 nm. Error bars are smaller than the symbols; $n = 3$.

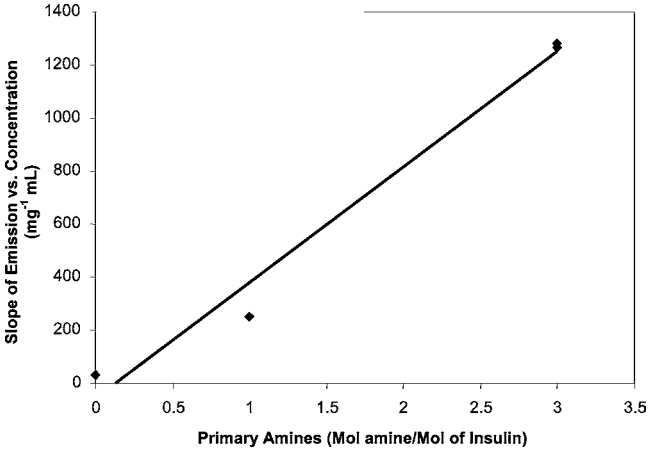

Figure 3. Fluorescamine assay for determination of free amine groups of insulin. Slopes of the linear relationship between emission at 470 nm and concentration for various insulin samples (Figure 2) plotted against the expected number of moles of free amine groups per mole of insulin.

camine was performed to estimate insulin primary amine modification by DMMA and by SPDP. Fluorescamine stock solution (1.08 mM) was prepared by dissolving 0.9 mg of fluorescamine in 3 mL of acetone. Insulin standard solutions were prepared containing 0.05, 0.1, 0.25, 0.5, 1, and 2 mg/mL native, unmodified insulin in PBS buffer. Fifty microliters of fluorescamine stock solution was added to 150 μL of insulin standard solutions in 96 well plates, and the fluorescence measurements were performed a microplate reader (*20*). The excitation wavelength for measurements was 390 nm, and the emission wavelength was 470 nm. A standard curve of emission at 470 nm (Em470) vs insulin concentration (mg/mL) was prepared (Figure 2).

Samples were taken from the modification reaction before modification with DMMA (after step I), after purification of the DMMA-modified insulin, and after purification of the SPDP-modified insulin intermediate (after step II). The concentrations of the samples were adjusted to account for the dilution caused by dialysis of the modified intermediate products, so the final concentration in all the samples was 0.75 mg/mL. A plot of Em470 vs concentration (mg/mL) was prepared for all three samples. The slopes of standard curve and plots for three samples were calculated and plotted against the expected number of moles of free amines present per mole of insulin samples (Figure 3).

Mass Spectrometry Analysis of the Insulin Modification Reaction. Sample aliquots were taken before and after the DMMA and SPDP modification steps. Dialysis of each aliquot was performed with Slide-A-Lyzer Mini Dialysis units (3500 MWCO) against 0.5 L of deionized water with triethylamine (TEA) at pH 7.5 for 30 min. The dialysis was repeated before dilution for ESI-MS analysis. SPDP-modified insulin was first dialyzed than digested with immobilized trypsin beads treated with 0.1 M ammonium acetate buffer (pH 8.5) for 18 h at 37 °C. The trypsin digest samples were desalted and concentrated with C_{18} ZipTips. ESI-MS and MS^n experiments were performed on an LCQ Duo quadrupole ion trap mass spectrometer (ThermoFinnigan, San Jose, Ca). All the samples were diluted to 10 μM and run at 3 μL/min for ESI-MS analysis in 99/1/1 methanol/water/TEA (MeOH/H_2O/TEA) by volume for negative mode or 99/1/1 methanol/water/acetic acid (MeOH/H_2O/HoAc) by volume for the positive mode unless otherwise noted. All the chemicals were purchased from Sigma (St. Louis, MO) without any further purification unless otherwise noted.

HPLC Analysis of the Insulin−Transferrin Conjugates. A reversed phase HPLC method was established for analysis of the conjugates to be used in quantification of the conjugates in later studies. The same method was used for measurement of insulin and transferrin concentrations. The HPLC system was a Waters 2695 Alliance separation module (Waters, Milford, MA) equipped with Waters 2487 Dual λ absorbance detector (Waters, Milford, MA). All the data were collected utilizing the Millenium Software Empower Application. A Symmetry300 C4 column (particle size 5 μm, 3.9 mm i.d. $\times$ 150 mm length) (Milford, MA) was used for the separations. The solvents used for the analysis were solvent A (water, 0.1% trifluoroacetic acid (TFA)) and solvent B (HPLC-grade acetonitrile, 0.08% TFA). The mobile phase for the analysis consisted of a linear gradient of 70% of solvent A to 40% of solvent A in 6 min. The gradient was controlled by the Empower software. The column temperature was set at 40 °C. The flow rate of the mobile phase was set at 0.6 mL/min, and the peaks were detected at 215 nm.

Analysis of Stability of the Insulin−Transferrin Conjugates to Enzymatic Degradation. The degradation profile of the conjugates was studied in comparison with insulin and transferrin in the presence of trypsin, a major proteolytic enzyme present in the intestine. The enzyme solution was prepared by dissolving trypsin in 50 mM phosphate buffer solution with pH of 7.4 and ionic strength of 154 mM. Insulin and transferrin stock solutions were prepared in the reaction buffer. Conjugate solution was diluted with the reaction buffer to achieve desired concentration. All the solutions were prewarmed at 37 °C for 15 min. The protein and the trypsin concentrations in the stock solutions were adjusted so that after adding trypsin solution to the insulin, transferrin, and conjugate stock solutions, the initial protein concentration in the reaction mixture was 1 mg/mL and the trypsin concentration was 3.2 mg/mL. At time $t = 0$, trypsin stock solution was added to insulin, transferrin, and the conjugate solutions at 37 °C under continuous mixing. Samples (50 μL) were withdrawn at predetermined time intervals, and the enzyme activity in the samples was stopped by addition of 50 μL of ice-cold acetic acid solution (50% (v/v) acetic acid in DI water). The samples were then analyzed by HPLC as described previously. Degradation rate constants were determined from the slope of the semilog plot of the percentage of initial protein remaining vs time.

RESULTS AND DISCUSSION

Synthesis of Insulin−Transferrin Conjugates. Insulin was conjugated to transferrin using SPDP, a heterobifunctional, cleavable cross-linker that reacts with primary amines and sulfhydryl groups (*21*) (Figure 1). Upon SPDP reaction with

the accessible primary amines of a protein, a mixed disulfide is formed that has free 2-pyridyldithio groups, which can react with free sulfhydryl groups from other proteins. This results in formation of conjugates of different proteins (heteroconjugates) without unwanted cross-reaction products such as the homoconjugates of individual proteins. This cross-linker is especially applicable to this research since the disulfide linkages are inherently unstable in the plasma (*22*). Hence disulfide linkages linking the two proteins may be cleaved once the conjugate reaches systemic circulation (*18*, *23*, *24*). Xia et al. (*12*) showed that free insulin was released within 5 min of incubation of the insulin−transferrin conjugates with rat liver slices. Free insulin was also detected in the rat serum 4 h after oral administration of the insulin−transferrin conjugates (*12*).

Step I of the conjugation involves modification of the N-terminal primary amines of insulin by reaction with DMMA. Insulin has three primary amine moieties: at A1-glycine (A1Gly), at B1-phenylalanine (B1Phe), and at B29-lysine (B29-Lys) (Figure 7). All the primary amines can potentially react with SPDP reagent at a pH where most of the amine groups are deprotonated so that the $-NH_2$ group can act as a nucleophile and react with the electron-deficient carbon atom of the succinimidyl group of SPDP. However, Lindsay and Shall (*25*) reported that acetylation of insulin at the A1Gly position resulted in decrease in the biological activity of insulin. Hence insulin modifications involving primary amines are usually directed to either B1Phe or B29Lys positions. In this work, SPDP modification was carrier out at the B29 lysine group of insulin. Hence it was necessary to block the N-terminal primary amines before reacting insulin with SPDP. This was done by reacting insulin with DMMA at a controlled pH of 6.8−6.9 (*12*). At this pH, most of the terminal amine groups were in their deprotonated state and were able to react with DMMA through nucleophilic attack. However, since the pH was about two units below the pK_a of the lysine residue, most of the lysine residues remained unreacted. The DMMA modification of insulin is acid-labile and the amino acid residues can be regenerated by making the solution slightly acidic.

SPDP modification of the purified intermediate from step I was carried out at the pH of 9.0 to generate the Ins−PDP intermediate. The modification was measured by UV spectroscopy after reducing a small aliquot of purified Ins−PDP with 25 mM DTT. The modification ratio (PDP/Ins) calculated from eq 1 was approximately 1:1. Modification ratio for transferrin (PDP/Tf) was approximately 4:1.

After reduction of the Tf−PDP intermediate to generate thiol-containing transferrin (Tf-SH), the intermediate was purified by size exclusion chromatography. Two moles of Ins−PDP were then added per mole of Tf-SH. When added, Ins−PDP was almost entirely reacted releasing 2 mol of 2-pyridinethio per mole of transferrin; the reaction was stopped by addition of NEM to prevent cross-linking of the Ins−Tf conjugates due to oxidation of excess −SH on insulin-conjugated transferrin. The conjugation ratio of 2:1 Ins/Tf was chosen since excessive modification of transferrin by insulin attachment will result in a bulky complex, which may adversely affect the diffusion characteristics of the conjugate in the polymer network reducing loading and release efficiencies of the conjugate.

Little or no insulin was detected in the reaction mixture by HPLC at the end of the reaction. The conjugate was extensively dialyzed to remove any unreacted residual insulin. The concentration of purified conjugate was determined using Bradford assay (*18*). Because many proteins have nearly identical response curve in this assay, the methods can be applied widely using a single set of standards (*18*). BSA and transferrin were used as standards to calculate the concentration of conjugate in the purified conjugate solution.

Analysis of the Insulin Modification Reaction. Cellular studies performed by Shah and Shen (*13*) showed that conjugate molecules containing up to three insulin molecules per molecule of transferrin were able to be transported across the Caco-2 cell monolayers by a transcellular mechanism. This means that the SPDP modification of the surface-exposed lysine residues of transferrin did not decrease its ability to bind the transferrin receptors on the cell surfaces nor inhibit transport across the cell monolayers by receptor-mediated transcytosis. However, improper modification of insulin by DMMA or SPDP may result in inhibition of its physiological activity. Hence sites of modification of insulin were verified here by fluorescamine assay and mass spectrometry analysis of the insulin modified by step I (DMMA modification) and step II (SPDP modification).

Fluorescamine Assay for Quantification of the Primary Amine Groups. Fluorescamine, a nonfluorescent compound, reacts rapidly with primary amines in proteins, such as the terminal amino groups and the ϵ-amino groups of lysine residues, to form fluorophors, which are excited at 390 nm and fluoresce at 475 nm (*26*). The reaction is completed in 100−500 ms, and excess reagent is quickly hydrolyzed to nonfluorescent products. The fluorescent product is stable for several hours.

Figure 2 shows the plot of Em470 vs concentration for insulin standards, unmodified insulin (before step I), DMMA-modified insulin (after step I), and SPDP-modified insulin (after step II). As can be seen from the figure, the calibration plots for standard curve and unmodified insulin overlap and have comparable slopes. The slopes of the curves are greatly reduced after DMMA modification, indicating that the number of free amino groups per mole of insulin has decreased. Fluorescence values for corresponding concentrations of the SPDP-modified insulin are even lower indicating that the SPDP-modified derivative of insulin had fewer amino groups that are free to react with fluorescamine than the DMMA-modified insulin.

Ideally, PDP−insulin should not react with fluorescamine since a successfully modified insulin molecule should not have any free amino groups. But in actual reaction, some unreacted amino groups are to be expected that can react with fluorescamine to form the fluorophors. The slopes of the calibration plots from Figure 2 were proportional to the expected number of free amino groups per mole of insulin for various samples (Figure 3), indicating that the decrease in fluorescence correlated well with the conversion of free amino groups into intermediates that were unreactive toward fluorescamine.

This was an important finding since it established that the primary amines were indeed being converted into intermediates owing to DMMA and SPDP modifications. However this assay did not provide much information about the reaction site specificity of the modification agents. Hence, mass spectrometry analysis was performed on the insulin intermediates to confirm the modifications and to evaluate the specificity of the reagents for reaction with the primary amines.

Mass Spectrometry Analysis of the Insulin Modifications. Figure 4 shows the mass spectrum of unmodified bovine insulin in the negative ESI mode. The mass to charge ratio (m/z) for the −4 charge state is 1432.2 corresponding to the molecular weight of 5732.8 Da. Figure 5 shows the ESI mass spectrum for DMMA-modified insulin sprayed from a 99/1/1 MeOH/H_2O/TEA solution. As seen from the mass spectrum, the 1:1 and 2:1 DMMA/insulin species are major products, and there is a minor amount of unreacted insulin apparent. Importantly, no peaks corresponding to the 3:1 derivative of insulin were found, supporting that nonspecific modification of insulin did not occur and consistent with restriction of the modification sites to the two N-terminal amines (A- and B-chains). The ESI-mass

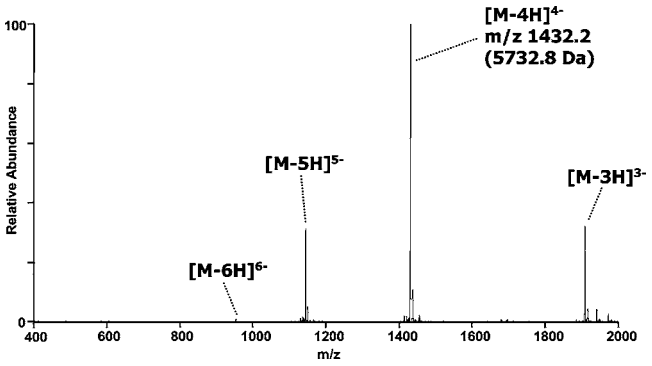

Figure 4. ESI-mass spectrum of unmodified bovine insulin showing various charge states. The −4 charge state at *m*/*z* 1432.2 corresponds to a species with a molecular weight of 5732.8 Da. The spectrum was obtained in 99/1/1 MeOH/H_2O/TEA by volume.

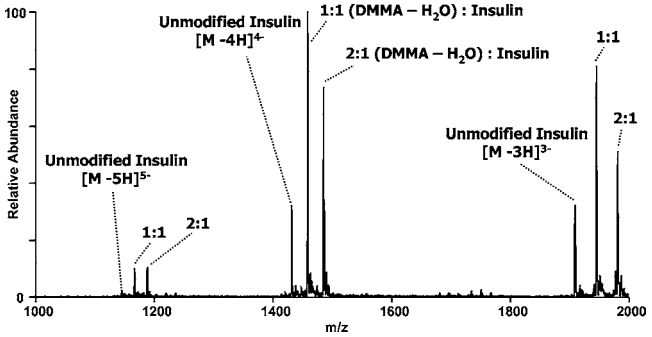

Figure 5. ESI-mass spectrum of the DMMA-modified bovine insulin in 99/1/1 MeOH/H_2O/TEA by volume. The stoichiometry values (1:1 or 2:1) represent the number of (DMMA−H_2O) modifications per insulin molecule. The −4 charge state of the 2:1 (DMMA−H_2O)/insulin species is observed at *m*/*z* 1486.3.

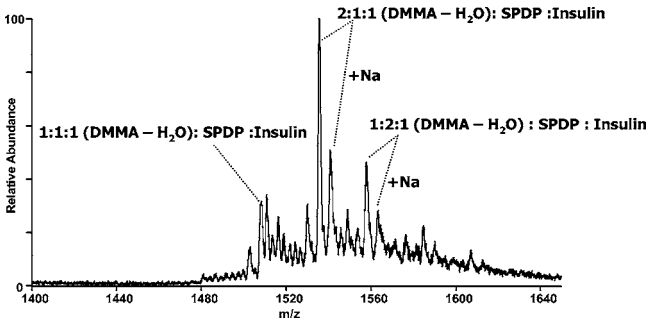

Figure 6. ESI-mass spectrum of the SPDP-modified bovine insulin (−4 charge state) in 99/1/1 MeOH/H_2O/TEA by volume. The $[M - 4H]^{4-}$ and $[M - 5H + Na]^{4-}$ ions of the 2:1:1 DMMA/insulin/PDP species are observed at *m*/*z* 1535.6 and 1540.9, respectively. Other minor peaks are attributed to various degrees of metal adduction from the ESI process.

spectrum of the SPDP-modified insulin intermediate is shown in Figure 6. The 2:1:1 DMMA/insulin/PDP species is identified at *m*/*z* 1535.6 and is shown to be the major reaction product from the mass spectrum.

To further pinpoint the sites of DMMA and SPDP modifications of insulin, ESI-MS was used to analyze the DMMA/SPDP−insulin product mixture after trypsin digestion. Figure 7 summarizes the potential sites of DMMA and SPDP modifications and the amide bonds expected to be cleaved by trypsin. Trypsin can cleave insulin at the amide bond between the B22Arg and B23Gly residues, yielding a 43 amino acid peptide (Ins-43) containing both the A- and B-chain N-termini and a smaller eight amino acid peptide (Ins-8) containing the B-chain C-terminus of insulin. The trypsin cleavage site between B29Lys and B30Ala is not accessible since the normally protonated side

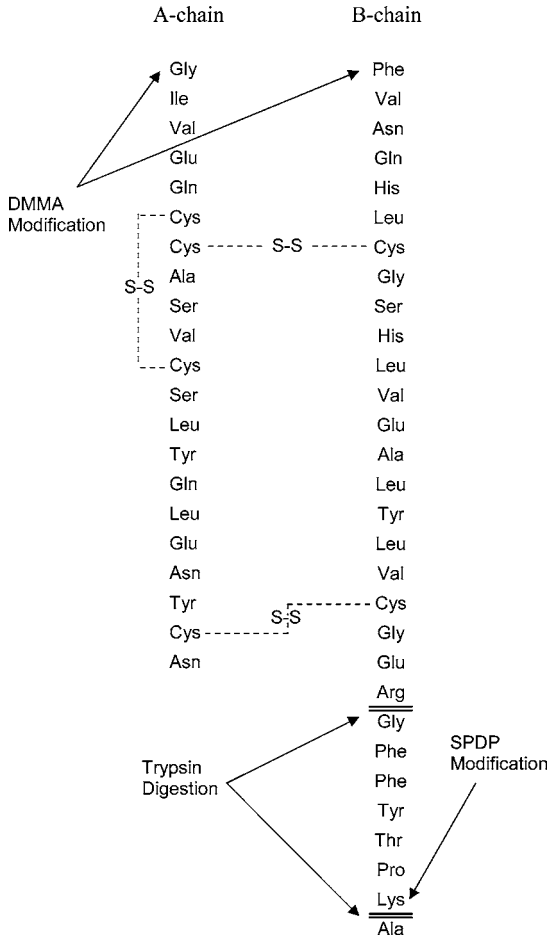

Figure 7. Insulin primary structure showing modification sites of DMMA and SPDP and sites of trypsin digestion.

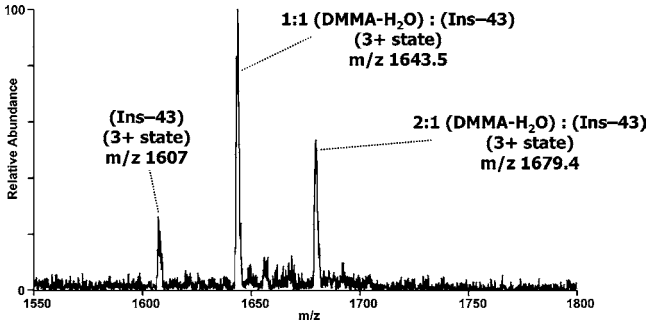

Figure 8. Expansion of the ESI-mass spectrum of the +3 charge state region for the larger peptide formed after trypsin digestion of modified insulin (Ins-43). The spectrum was obtained in 50/50/1 H_2O/MeOH/HoAc by volume. No peak for the PDP derivative of Ins-43 was identified in the mass spectrum.

chain of lysine, which signals tryptic cleavage, is blocked by the PDP modification. The two resulting tryptic peptides were structurally characterized by tandem mass spectrometry. Figure 8 shows the ESI-mass spectrum of the Ins-43 tryptic peptide (+3 charge state). As expected, peaks corresponding to both 1:1 and 2:1 DMMA/In-43 were identified in the mass spectrum, but no peaks were found for the corresponding PDP attachment to Ins-43, which would be observed at *m*/*z* 1672.7, 1708.3, or 1744.0 depending on the degree of DMMA modification. This confirms that the PDP did not attach to the N-terminal primary amines of the A or B chains.

Collisional activated dissociation (CAD), a method used to provide structural information based on the fragmentation pattern of a selected ion in the gas phase, was used for further

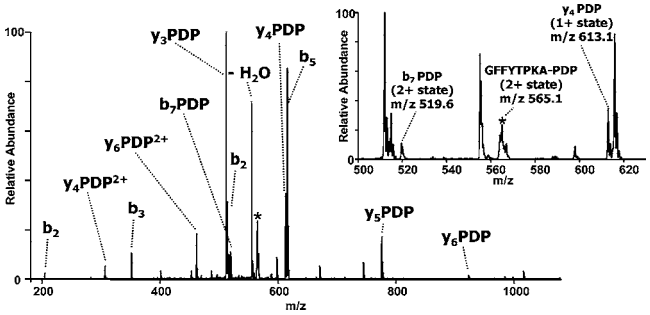

Figure 9. ESI-MS/MS spectrum of the smaller peptide (*m*/*z* 565.1, Ins-8) formed after trypsin digestion of modified insulin. The insert shows the expanded region from the middle portion of the spectrum, which contains two key diagnostic ions, $(b_7\text{-PDP})^{2+}$ at *m*/*z* 519.6, and $(y_4\text{-PDP})^{1+}$ at *m*/*z* 613.1.

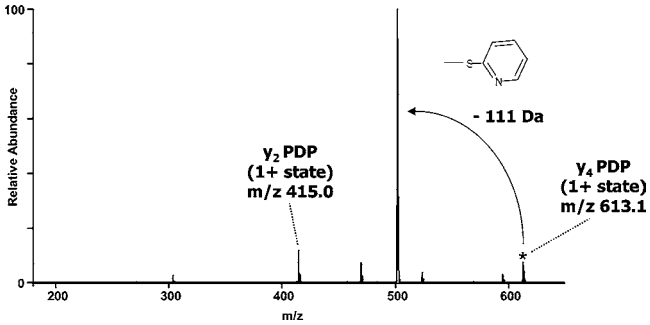

Figure 10. ESI-MS^3 spectrum of the y_4-PDP peptide fragment at *m*/*z* 613.1. The y_2-PDP fragment is observed at *m*/*z* 415.0; this ion combined with the observation of b_7-PDP in Figure 9 provides confirmation of the B29Lys position as the specific site of modification. The major peak at *m*/*z* 502 is the loss of the thiopyridyl moiety from the PDP modification.

characterization of the smaller of the two tryptic peptides (Ins-8). The ESI tandem mass spectrum for the eight amino acid peptide, Ins-8, is shown in Figure 9. The parent ion at *m*/*z* 565 corresponds to diprotonated Ins-8 with a single PDP modification and is consistent with the synthetic strategy outlined in Figure 1B and the predicted product shown in Figure 7. An array of b and y sequence ions is observed, which confirms the amino acid sequence of the Ins-8 species, and the sequence ions that are mass-shifted by 197 Da indicate the incorporation of the PDP group. From the series of fragments generated by CAD, two critical sequence ions were identified: y_4 (TPKA)−PDP and b_7 (GFFYTPK)−PDP (see inset of Figure 9), with each one containing the B-chain 29Lys residue. The *m*/*z* values of these two key sequence ions confirm the presence of PDP in both species and thus narrow the possible PDP modification sites to the residues B27Thr, B28Pro, and B29Lys because these are the only amino acids common to the two sequence ions and the Ins-8 precursor. Further dissociation of the selected y_4 (TPKA)−PDP species via a second stage of CAD yields the y_2 (KA)−PDP ion at *m*/*z* 415.0 as shown in Figure 10, along with the dominant loss of the thiopyridyl moiety, 111 Da, from the PDP group of the y_4 (TPKA)−PDP parent ion, which results in the abundant ion at *m*/*z* 502. The presence of y_2 (KA)−PDP species from this MS^3 experiment and the b_7 (GFFYTPK)−PDP species from the prior MS/MS experiment confirms B29Lys as the sole site of PDP modification because it is the only amino acid found in both species. All other peaks observed in these mass spectra support this modification site without contradiction.

The data from mass spectrometry and the fluorescamine assay together provide evidence that the SPDP modification is primarily at B29Lys and the DMMA modification sites are A1Gly and B1Phe. These are important results since improper

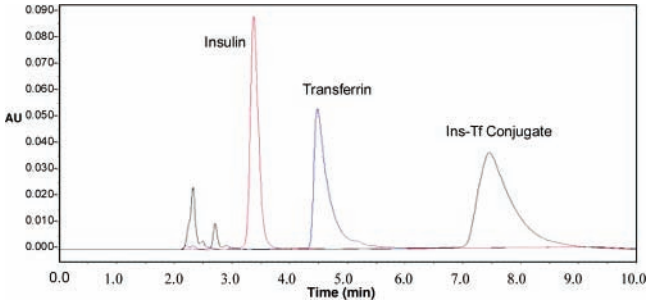

Figure 11. HPLC chromatograms of insulin, transferrin, and insulin−transferrin conjugate. The mobile phase for the analysis consisted of a linear gradient of 70% of solvent A to 40% of solvent A in 6 min. A Symmetry300 C4 column (particle size 5 μm, 3.9 mm i.d. × 150 mm length) was used for the separation.

modification may result in reduction or complete loss of insulin activity.

HPLC Analysis of the Insulin−Transferrin Conjugates. Figure 11 shows the HPLC chromatogram for insulin, transferrin, and the purified conjugate. The insulin eluted from the C4 column due to the applied gradient with a retention time of approximately 3.4 min, where as the transferrin and the conjugates eluted at around 4.5 and 7.5 min respectively. More importantly, the chromatogram of the purified conjugate did not show any peak for transferrin or insulin (data not shown), indicating that the conjugate was essentially pure and did not contain either of the unmodified proteins.

Analysis of the Stability of Insulin−Transferrin Conjugates to Enzymatic Degradation. Intact insulin−transferrin conjugate has been shown to reach systemic circulation in diabetic rats (*12*). In these studies, insulin and insulin−transferrin conjugates were orally administered in diabetic rats in a 30 mg/mL $NaHCO_3$ solution to neutralize the gastric acidity and to protect digestion of proteins in the stomach (*12*). However there was no mechanism to reduce the degradation of insulin or the conjugate in the intestinal milieu. Even in the absence of such a mechanism, the conjugate was able to reach the systemic circulation without being completely degraded. This provides an indirect evidence of the increased stability of the conjugated insulin against tryptic and chymotryptic attack. However this improvement in the stability of the conjugate in enzyme solution has not been demonstrated experimentally.

Hence in this study, the degradation profiles of insulin, transferrin, and the conjugate were evaluated in a solution containing trypsin based on HPLC analysis. As can be seen from Figure 12, most of the insulin degraded due to tryptic attack within 15−20 min of incubation, whereas transferrin was significantly more stable at the same enzyme concentrations. The conjugate degraded at a faster rate as compared to transferrin but was more stable than the unmodified insulin. The degradation rate constants were calculated from the slopes of the semilog plot of the percentage of initial protein remaining vs time at early time points (Figure 13 and Table 1). The degradation rate constant calculated was 21.1×10^{-3} min^{-1} for insulin and 0.73×10^{-3} and 6.17×10^{-3} min^{-1} for transferrin and the conjugate, respectively. These data indicated that the stability of insulin was significantly increased due to its conjugation with transferrin. This may be one of the important factors contributing to the observed hypoglycemic effect of the orally administered conjugates (*12*). Although the reasons behind the observed increase in stability of the conjugate are not clearly understood, this may be due to the shielding effect of the transferrin, which limits enzymatic degradation of insulin. Transferrin has been shown to be resistant to tryptic and chymotryptic digestion (*13*). Thus the large transferrin molecule

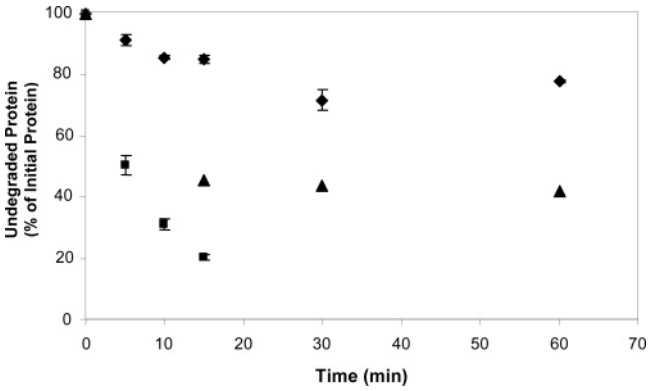

Figure 12. Protein degradation profiles in the presence of trypsin. Initial protein concentration in the reaction was 1 mg/mL, and the trypsin concentration was 3.2 mg/mL. The total reaction volume was 5 mL, and the pH was 7.4. Samples (50 μL) were withdrawn at different time intervals, and the trypsin activity in the samples was stopped by addition of equal volumes of 50% acetic acid solution. For insulin (■) and transferrin (◆) samples, $n = 3$; for the conjugate (▲) sample, $n = 1$.

may stabilize the conjugated insulin against enzymes by creating a hindrance for the enzymatic attack.

CONCLUSIONS

An insulin−transferrin conjugate was synthesized by site-specific modification of insulin and modification of transferrin by a heterobifunctional cross-linker. Proper modification of the insulin molecule, which is critical to its physiological function, was verified through fluorescence photometry and mass spectrometry. The conjugation resulted in a macromolecular heteroconjugate consisting of two insulin molecules and one transferrin molecule. Insulin in the conjugated form exhibited enhanced stability against proteolytic attack. The insulin−transferrin conjugates synthesized here exhibit beneficial characteristics for oral delivery applications. This system when used in conjunction with the complexation hydrogels developed in our laboratory may result in a efficacious system for oral delivery of insulin.

Induction of apoptosis in endothelial cells is considered an attractive strategy to therapeutically interfere with a solid tumor's blood supply. In the present paper, we constructed cytotoxic conjugates that specifically target angiogenic endothelial cells, thus preventing typical side effects of apoptosis-inducing drugs. For this purpose, we conjugated the potent antimitotic agent monomethyl-auristatin-E (MMAE) via a lysosomal cleavable linker to human serum albumin (HSA) and further equipped this drug−albumin conjugate with cyclic c(RGDfK) peptides for multivalent interaction with $\alpha_v\beta_3$-integrin. The RGD-peptides were conjugated via either an extended poly(ethylene glycol) linker or a short alkyl linker. The resulting drug-targeting conjugates RGDPEG−MMAE−HSA and RGD-MMAE−HSA demonstrated high binding affinity and specificity for $\alpha_v\beta_3$-integrin expressing human umbilical vein endothelial cells (HUVEC). Both types of conjugates were internalized by endothelial cells and killed the target cells at low nM concentrations. Furthermore, we observed RGD-dependent binding of the conjugates to C26 carcinoma. Upon i.v. administration to C26-tumor bearing mice, both drug-targeting conjugates displayed excellent tumor homing properties. Our results demonstrate that RGD-modified albumins are suitable carriers for cell selective intracellular delivery of cytotoxic compounds, and further studies will be conducted to assess the antivascular and tumor inhibitory potential of RGDPEG−MMAE−HSA and RGD-MMAE−HSA.

INTRODUCTION

Excessive angiogenesis, the formation of new blood vessel out of pre-existing capillaries, is a prominent feature during the pathogenesis of cancer. Solid tumors rely on angiogenesis to guarantee a continuous supply of oxygen and nutrients. Vascular-directed therapies are therefore extensively investigated for combating cancer (*1*). Induction of apoptosis in endothelial cells is one way to destroy tumor vessels. However, most cytotoxic compounds are neither selective for endothelial cells in general nor for angiogenic endothelial cells. As a consequence, they produce severe side effects limiting their applicability in cancer therapy. We propose targeting of the antimitotic agent monomethyl auristatin E (MMAE) to angiogenic blood vessels in tumor tissue. MMAE, a synthetic analogue of the natural product dolastatin 10, is a potent inhibitor of tubulin polymerization in dividing cells (*2*, *3*). Previously, MMAE has been conjugated via a valine−citrulline linker to monoclonal antibodies (mAb) for drug targeting purposes (*3*−*6*). The valine−citrulline linker is highly stable in serum but is cleaved by lysosomal enzymes like cathepsin B after internalization of the conjugate by target cells (*7*, *8*, *9*). We now present a novel type of MMAE conjugate, in which the drug is bound via the valine−citrulline linker to human serum albumin (HSA). HSA is readily available in gram amounts and can serve as a natural and therefore biocompatible and biodegradable carrier with a lower polydispersity than any artificial polymeric carrier. Selectivity for angiogenic endothelial cells is introduced into the albumin backbone by conjugation of multiple cyclic RGD-peptides, which bind to $\alpha_v\beta_3$-integrin (*10*). We applied either a short alkyl linker to introduce a maximum of RGD-peptide or an extended polyethylene glycol linker to infer an increased circulation time and shielding of the modified albumin from the immune system. The $\alpha_v\beta_3$-integrin target receptor is expressed in high amounts on angiogenic endothelium, but expression is minimal on quiescent endothelial cells and highly limited in other healthy tissues. The restricted expression profile and the good accessibility of endothelial cells make it an ideal target for drug delivery purposes (*11*). We have previously described that RGD-equipped carriers bind with high avidity to proliferating endothelial cells, and that they are internalized and lysosomally degraded (*12*−*14*).

In the present study, we first describe the synthesis and characterization of the two types of RGD-equipped MMAE−albumin conjugates. Second, we report on the binding, uptake and cell killing properties of the conjugates, and we compared the tumor vasculature homing potential in C26 tumor bearing mice.

MATERIALS AND METHODS

Synthesis and Purification of MMAE−HSA. HSA (Sanquin, Amsterdam, The Netherlands) was thiolated with 2-iminothiolane (2-IT) at pH 8, 37 °C. Thiolation was monitored by DTNB of PD10-purified analytical samples. When the desired

thiolation level was reached (4.1 SH/albumin), the modified albumin was purified over a G25 gel filtration desalting column. The thiol/albumin mole ratio was determined by measuring the thiol concentration with Ellman's assay and the albumin concentration by UV absorbance at 280 nm. Thiolated albumin was treated with a 20% excess (over measured thiols) of MC−val-cit−PAB−MMAE. Ellman's assay was performed on the reaction mixture to ensure complete alkylation. Excess maleimide-drug-linker was quenched, and removed with solid-phase resin-bound-DTT (BioVectra cat. #3505), and the product was purified by gel filtration chromatography.

Characterization of MMAE−HSA. The concentration of the MMAE−HSA conjugates was measured using the BCA assay kit from Pierce. The MMAE−HSA conjugate was analyzed by size exclusion chromatography for percentage of monomer using a Tosoh Bioscience TSKgel G3000SW (7.8 cm × 30 cm, 5 μm) size exclusion chromatography (SEC) column. The conjugates were more than 91% monomer. To check for residual drug-linker, a sample of conjugate was treated with MeOH and separated in a microconcentrator to precipitate the protein, and the supernatant was analyzed by reverse phase (RP) HPLC (Synergi C12 column with a linear gradient from 5 mM ammonium phosphate, pH 7, to 100% acetonitrile). No free drug-linker was detectable, compared to spiked controls and a standard curve with a quantitation limit of <0.5% of bound drug. The MMAE−HSA conjugates were tested for endotoxin contaminant using BioWhitaker-Cambrex LAL QCL-1000 kit. Endotoxin was below the limit of detection (~0.2 EU/mg).

The drug to HSA ratio was estimated by treating 300 μg of conjugate with cathepsin B to release free MMAE from the MC−val-cit−PAB linker. The protein was removed by precipitation with TCA/MeOH, heated at 37 °C for 10 min and centrifuged at high speed to pellet. The released drug in the supernatant was analyzed by RP-HPLC as described above for drug-linker and quantitated by comparison to a standard curve. The drug/albumin values agreed closely (±5%) with the thiol/albumin ratios determined prior to conjugation. A change in the OD250/OD280 ratio commensurate with the conjugation of PAB-containing moieties qualitatively corroborated the measured drug load. Thereafter MMAE−HSA was subjected to MALDI-TOF analysis. HSA and MMAE−HSA were dissolved in 50:50:0.1 methanol:water:acetic acid at a concentration of 1 mg/mL. 1 μL was mixed with 1μL of matrix (20 mg/mL sinapinic acid in 60:40:0.1 water:acetonitrile:trifluoroacetic acid), transferred onto a stainless steel sample holder, and dried before being introduced into a Voyager-DE PRO workstation (Applied Biosystems). Mass spectra were obtained by averaging the signals from 100 laser shots. Correction of data was performed using BSA as a control. Average molecular weights received by MALDI-TOF analysis were used to calculate differences in mass of HSA to MMAE−HSA.

Synthesis of RGDPEG−MMAE−HSA. MMAE−HSA (59.1 nmol) dissolved in PBS was incubated with a 50-fold molar excess of vinylsulfone-poly(ethylene glycol)-*N*-hydroxysuccinimide ester (VNS-PEG-NHS; Nektar, AL; 20 mg/mL in water, 2.96 μmol), which was added dropwise. The mixture was protected from light with aluminum foil and incubated for 1h at room temperature while gently shaking on a spiramix. Meanwhile, the RGD−peptide c(RGDf(ϵ-*S*-acetylthioacetyl)K) (Ansynth Service, Roosendaal, The Netherlands) was dissolved at 10 mg/mL in a 1:4 acetonitrile/water mixture. The peptide (3.25 μmol) was added dropwise to the reaction mixture at a peptide to protein molar ratio of 55:1, after which hydroxylamine was added to a final concentration of 50 mM. Reaction was carried out over night at room temperature while protected from light. Remaining VNS groups were quenched by addition of cysteine (3.25 μmol; 55-fold molar excess over the amount of HSA), after which the product was dialyzed against PBS and finally purified by SEC using a Superdex200 column on an Äkta System (GE Healthcare, Uppsala, Sweden). The final product RGDPEG−MMAE−HSA was stored at −20 °C. A control conjugate RADPEG−MMAE−HSA was prepared according to the same protocol with the control peptide c(RADf(ϵ-*S*-acetylthioacetyl)K).

Synthesis of RGD−MMAE−HSA. MMAE−HSA (59.1 nmol) dissolved in PBS was incubated with a 22-fold molar excess of iodoacetic acid *N*-hydroxysuccinimide ester (SIA-linker; Sigma, St. Louis, MO; 10 mg/mL in DMF, 1.3 μmol), which was added dropwise. The mixture was protected from light with aluminum foil and incubated for 1 h at room temperature while gently shaking on a spiramix. RGD−peptide (1.48 μmol) was added in a mole:mole ratio of 25:1 followed by hydroxylamine addition as described above. Reaction was carried out within 6 h at room temperature while protected from light. Products are purified by dialyzing three times against PBS using Slide-A-Lyzer dialysis cassettes (Pierce, MWCO 10 kDa). The final products RGD−MMAE−HSA and the control conjugate RAD−MMAE−HSA were stored at −20 °C.

Characterization of RGDPEG−MMAE−HSA and RGD−MMAE−HSA. Protein content of synthesis products was estimated by BCA protein assay kit (Pierce). Both the intermediate and final products were subjected to analytical SEC to reveal increase in size, purity, and grade of aggregation. SDS-PAGE (12%, Ready Gel; Bio-Rad, Veenendaal, The Netherlands) and Western blotting were performed to corroborate covalent binding of the RGD−peptide. Duplicate gels were either stained for protein (Coomassie Brilliant Blue staining) or blotted on a PVDF membrane (Roche, Mannheim, Germany). The membrane was blocked with BSA and subsequently incubated with an in-house prepared rabbit anti-RGD antiserum (*12*). The signal was amplified with a polyclonal goat anti rabbit IgG conjugated with horse radish peroxidase (GARPO, DAKO). Peroxidase was visualized by incubation with 3-amino-9-ethylcarbazole (AEC, Sigma). The amount of RGDPEG and RGD bound per HSA was determined by MALDI-TOF analysis, as explained earlier in this section.

Cells. HUVEC were obtained from the UMCG Endothelial Cell Facility. Primary isolates were cultured in 1% gelatin-coated tissue culture flasks (Costar, Cambridge, MA) at 37 °C under 5% CO_2/95% air. The culture medium, hereafter referred to as EC medium, consisted of RPMI 1640 (BioWittaker, Verviers, Belgium) supplemented with 20% heat inactivated fetal calf serum (Integro, Zaandam, The Netherlands), 2 mM L-glutamine (Invitrogen, Breda, The Netherlands), 5 U/mL heparin (Leo Pharmaceutical Products, Weesp, The Netherlands), 100 U/mL penicillin (Yamanouchi Pharma, Leiderdorp, The Netherlands, 100 μg/mL streptomycin (Radiumfarma-Fisiopharma, Italy), and 50 μg/mL EC growth factor supplement extracted from bovine brain. After attaining confluence, cells were detached from the surface by trypsin EDTA (0.5/0.2 mg/mL in PBS) treatment and split in 1:3 ratio. Cells were used up to passage four. C26 mouse carcinoma cells were cultured under the same conditions as described for HUVEC, in DMEM medium (Gibco) containing 10% fetal calf serum.

Endothelial Cell Binding Affinity of RGD-Equipped Conjugates. Binding affinity of RGDPEG−MMAE−HSA and RGD−MMAE−HSA to $\alpha_v\beta_3$-integrin expressed on the surface of HUVEC was determined by competitive binding studies using ^{125}I-labeled echistatin as radioligand for $\alpha_v\beta_3$-integrin (*15*). Echistatin was radiolabeled using the chloramine T method (*16*). On the day of the experiment, ^{125}I-echistatin was purified using a PD-10 column (GE Healthcare). Confluent monolayers of HUVEC in a 24-well plate (Costar) were incubated with 100 000 cpm ^{125}I-echistatin in the presence of serial dilutions of the

conjugates in binding buffer (50 mM Tris-HCl, pH 7.4, 150 mM NaCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mM $MnCl_2$ and 1% BSA) at 4 °C for 4 h (*13*). Subsequently, the supernatant was harvested, and cells were washed three times with binding buffer and lysed with 1 M NaOH. Radioactivity was counted in a Packard RIASTAR multiwell gamma counter (GMI). Data were analyzed by nonlinear regression using the GraphPad Prism program (GraphPad Software Inc).

Binding Specificity of RGD-Equipped Conjugates to Endothelial Cells and Tumor Cells. HUVEC were incubated with ^{125}I-radiolabeled RGDPEG−MMAE−HSA and RGD−MMAE−HSA, which had been radiolabeled using the chloramine T method, and purified on the day of the experiment. Radiochemical purity as determined by trichloroacetic acid precipitation was above 96%, and specific activity was respectively 690 kBq/μg and 570 kBq/μg. Confluent monolayers of HUVEC in 24-well plates were incubated with 100 000 cpm of radiolabeled conjugate in presence of excess of c(RGDfK)-Ata (10 μM), C(RADfK)-Ata (10 μM), and RGD−HSA (0.5 μM) in binding buffer. Cell-bound radioactivity was harvested and counted as described above.

Both radiolabeled conjugates were also incubated with confluent C26 carcinoma cells in the absence and presence of an excess of c(RGDfK)-Ata (10 μM). Incubation conditions and analysis of cell-bound radioactivity were as describe above.

Uptake of RGD-Equipped Conjugates into Endothelial Cells. HUVEC were incubated with ^{89}Zr-radiolabeled RGD-PEG−MMAE−HSA or RGD−MMAE−HSA to determine uptake of the products. The ^{89}Zr-radiolabel will remain trapped inside the cells after degradation of the carrier, in contrast to the ^{125}I-radiolabel. For radiolabeling, 3.7 nmol RGDPEG−MMAE−HSA or RGD−MMAE−HSA was mixed with 18.6 nmol of the chelator TFP-N-succinyldesferal-Fe (desferal) at pH 8.5. After an incubation period of 30 min, the reaction mixture was purified on a Hitrap desalting column (GE Healthcare). UV absorbance at 430 nm was used to assess conjugation of Fe^{3+}-containing desferal. Fe^{3+} was replaced with radioactive ^{89}Zr at pH 6.8 as described (*17*), and the product was purified using a centricon filter unit (MWCO 10 kDa; Millipore, Billerica, MA). Radiochemical purity was 96% or higher, as determined by trichloroacetic acid precipitation, and specific activity was 17.75 MBq/mg and 2.1 MBq/mg for RGDPEG−MMAE−HSA and RGD−MMAE−HSA. Confluent cell layers were incubated with 250 000 cpm ^{89}Zr-RGDPEG−MMAE−HSA or 50 000 cpm ^{89}Zr-RGD−MMAE−HSA at either 4 °C or 37 °C for 4 and 8 h. Supernatant and cell associated radioactivity were harvested as described above, and radioactivity was counted on a 1282 COMPUGAMMA CS (Perkin-Elmer, Boston, MA).

***In Vitro* Killing Efficacy of RGD-Equipped Conjugates.** HUVEC were plated on 96-well plates (Costar) at 5000 cell/well and exposed to a graded titration of RGDPEG−MMAE−HSA and RGD−MMAE−HSA. RAD-equipped conjugates were tested at a concentration of 1 and 10 μg/mL. After 72 h of incubation, cell viability was determined by MTS cell viability assay (Promega, Madison, WI) (*18*). Absorption was measured on a Thermomax microplate reader (Molecular Devices, Sunnyvale, CA) at 490 nm after 2 h of incubation at 37 °C. Data were analyzed by nonlinear regression using GraphPad Prism.

Tumor Accumulation of RGD-Equipped Conjugates in Subcutaneous C26 Tumor Model. All animal experiments were performed according to the national law on animal experiments and were approved by the Animal Ethics Committee of the University of Groningen. Upon arrival, male Balb/C mice were housed in a temperature-controlled room with a 12 h light/dark cycle and offered ad libitum intake of tap water

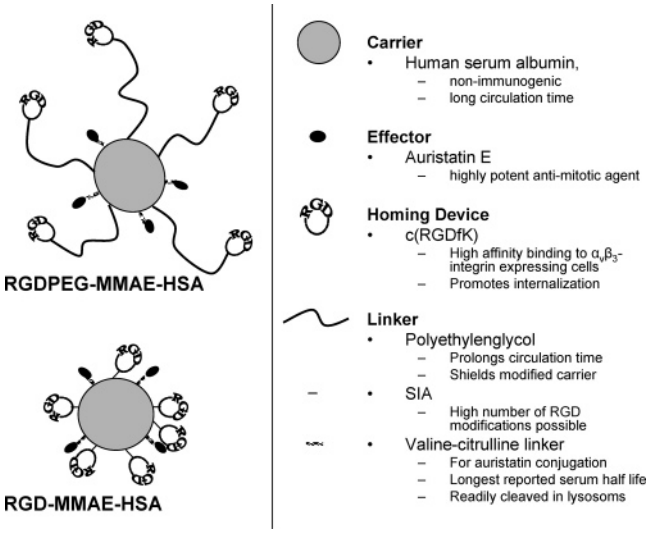

Figure 1. Schematic representation of RGD-equipped MMAE−albumin conjugates.

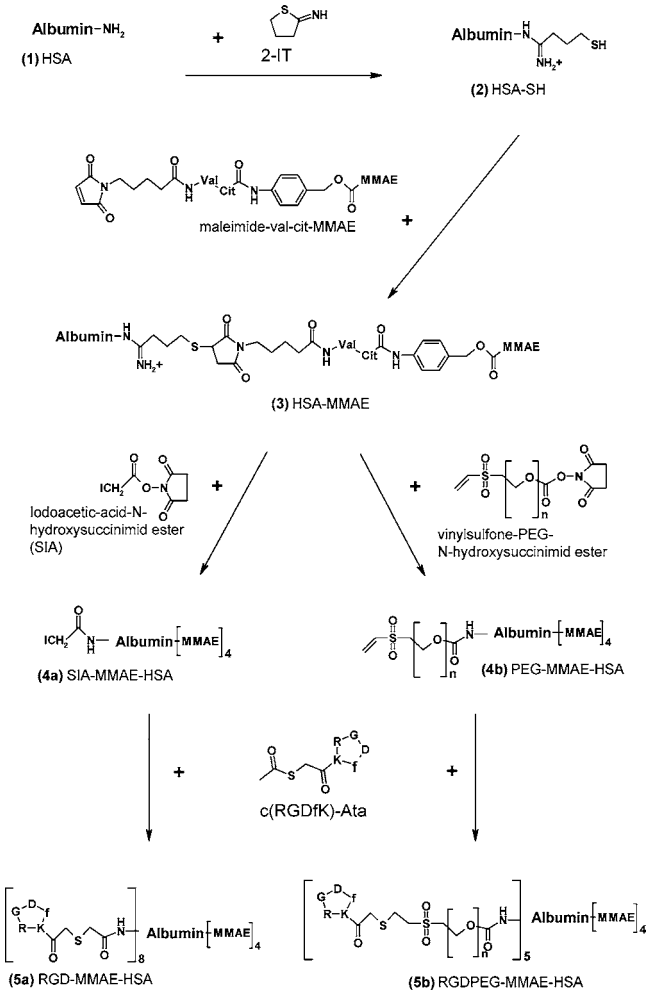

Figure 2. Reaction scheme for the synthesis of RGDPEG-MMAE−HSA and RGD−MMAE−HSA.

and standard rodent chow. Mice were anesthetized by Forene (Abbott B.V. Hofddorp, The Netherlands) inhalation in combination with N_2O (600 mL/min) and O_2 (300 mL/min). C26 murine colon carcinoma cells (1×10^6) were inoculated subcutaneously in the flank of the mice and allowed to grow to a size of approximately 8 × 8 mm. Thereafter a single dose of 30 μg of RGDPEG−MMAE−HSA or RGD−MMAE−HSA was injected in the penis vein under Forene/N_2O/O_2 anesthesia.

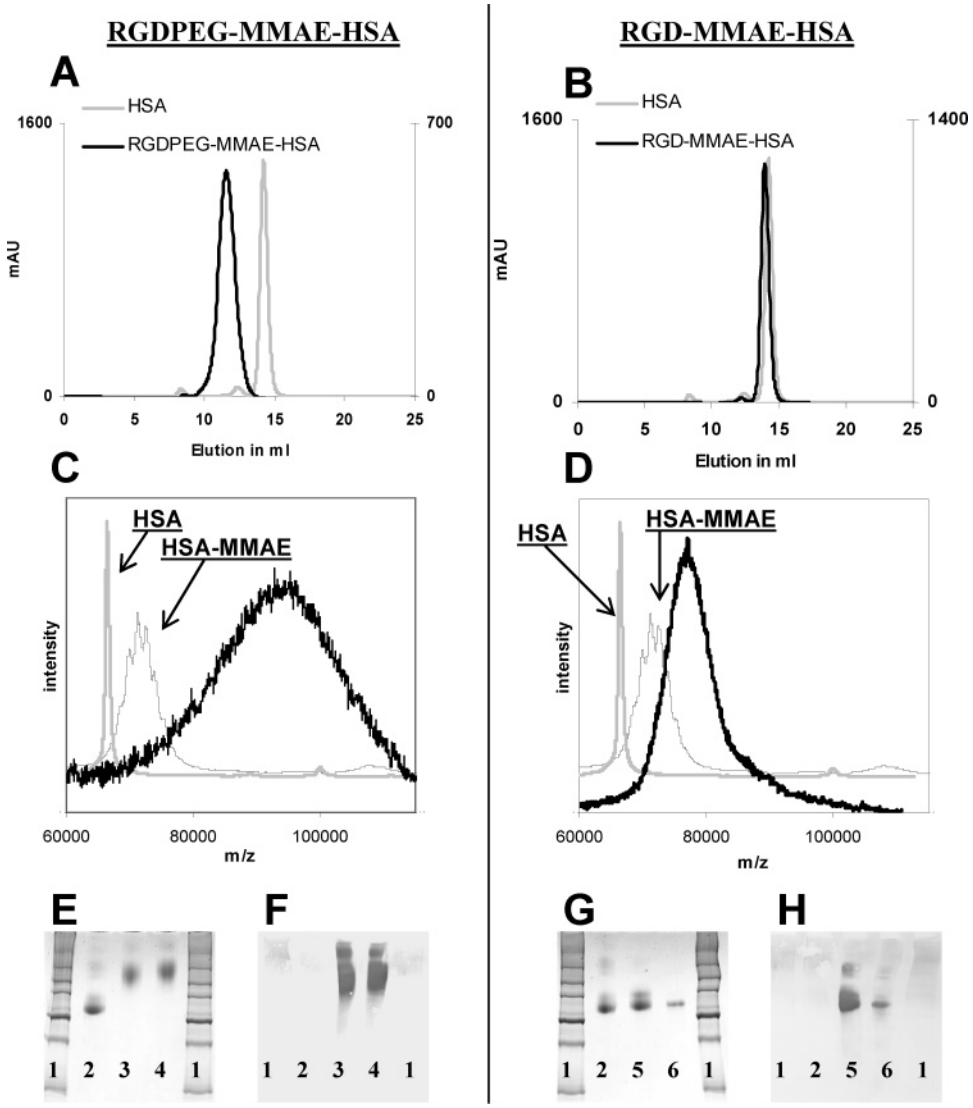

Figure 3. A,B: Size exclusion chromatography of RGDPEG-MMAE−HAS (A) and RGD−MMAE−HSA (B) revealed increase in size due to coupling of RGD−peptide via a PEG-linker (A) or a short alkyl linker (B). No aggregates had been formed. C,D: MALDI-TOF has been used to estimate molecular weight of RGDPEG-MMAE−HSA (C) and RGD−MMAE−HSA (D). HSA and MMAE−HSA are shown for comparison. E−H: SDS-PAGE (E, G) had been performed with a molecular weight marker (*1*), MMAE−HSA (*2*), RGDPEG-MMAE−HSA (*3*), RGDPEG−HSA (*4*), RGD−MMAE−HSA (*5*), and RGD−HSA (*6*). Identical gels have been blotted on a membrane and were immunostained using anti-RGD antibody (F, H).

Mice were sacrificed at 3 h after injection or at 24 h after injection. Tumor, liver, kidney, and spleen were collected and snap frozen in liquid nitrogen.

Immunohistochemical Detection of Conjugates. Cryostat sections (5 μm) prepared from tumor, liver, kidney, and spleen were fixed in acetone and stained for the presence of the conjugates. For this purpose, a rabbit anti-HSA antibody was applied to the sections in a 1:1500 dilution. After removal of endogenous peroxidase activity, staining was amplified with a peroxidase-conjugated goat anti-rabbit IgG (GARPO, DAKO) followed by a peroxidase-conjugated rabbit anti-goat IgG (RAGPO, DAKO). Peroxidase was visualized by incubation with 3-amino-9-ethylcarbazole (AEC, Sigma), and sections were counterstained with Mayers hematoxylin (Merck, Darmstadt, Germany) according to standard laboratory protocols.

Colocalization of conjugates with either tumor endothelium or tumor cells was investigated by fluorescent immunohistochemistry. Deposited conjugate was stained by rabbit anti-HSA antibody (1:1000 dilution), followed by secondary staining with FITC-conjugated goat anti-rabbit IgG (DAKO). Nuclei were stained using 4′-6-Diamidino-2-phenylindole (DAPI, Sigma). Nuclei of endothelial cells and tumor cells were discriminated by phenotypical differences (endothelial nuclei are flattened, as compared to big tumor cell nuclei).

Table 1. Characterization of Drug-Targeting Conjugates by MALDI-TOF

	number of modifications per HSA		
	MMAE	RGDPEG or RGD	MW in kDa
RGDPEG-MMAE−HSA	4.1	5.4	94.5
RGDPEG−HSA	-	7.1	96.1
RGD−MMAE−HSA	4.1	7.6	77.3
RGD−HSA	-	13.2	76.2

RESULTS

Synthesis and Characterization. We developed RGD-equipped auristatin conjugates that are directed to $\alpha_v\beta_3$-integrin on angiogenic endothelium (Figure 1). These drug-targeting conjugates were prepared by coupling MMAE and RGD or RGDPEG to an albumin backbone (Figure 2). Both, HPLC and MALDI-TOF analysis demonstrated an average of four MMAE per albumin (Table 1, Figure 3). RP-HPLC revealed that the products did not contain free drug or linker molecules. The short

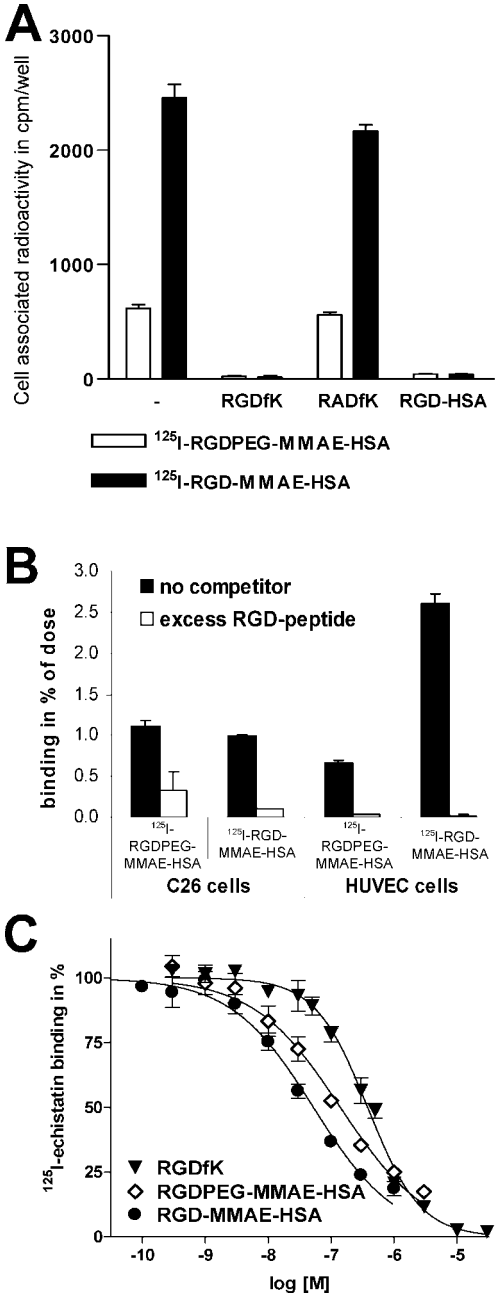

Figure 4. Binding properties of drug-targeting conjugates. **(**A**)** Binding specificity was tested by coincubation of radiolabeled drug-targeting conjugates with excess of c(RGDfK)-Ata (10 μM), c(RADfK)-Ata (10 μM), and RGD−HSA (0.3 μM) on $\alpha_v\beta_3$-expressing HUVEC. **(**B**)** Radiolabeled drug-targeting conjugates were incubated with C26 carcinoma cells and HUVEC. Specificity of binding was determined by conincubation with excess of c(RGDfK)-Ata (10 μM). **(**C**)** Binding affinity is detected by competition between ^{125}I-echistatin and increasing concentrations of drug-targeting conjugates for $\alpha_v\beta_3$-integrin on HUVEC. Concentrations are expressed in mol/L.

SIA linker allowed more RGD to be coupled per HSA compared to the extended PEG linker. Furthermore, RGD numbers were higher in conjugates prepared with parental albumin, not equipped with MMAE (Table 1). SEC analysis demonstrated an increase in size due to the modification, especially for PEGylated products (Figure 3). In addition, it was shown that little aggregation of products occurred, comparable to aggregation found for nonmodified HSA. Aggregation hampered further use of drug-targeting conjugates only when drug loads of eight MMAE per albumin were tested (data not shown). Coupling of RGD−peptide onto the distal end of PEG was demonstrated by anti-RGD western blot. Both products as well as their

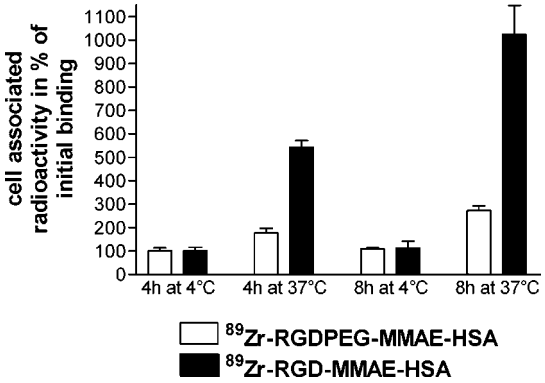

Figure 5. ^{89}Zr-RGDPEG-MMAE−HSA and ^{89}Zr-RGD−MMAE−HSA were incubated with HUVEC at 4 and 37 °C for 4 or 8 h to determine uptake of the drug-targeting conjugates.

Table 2. Binding and Cell Killing Potency of Drug-targeting Conjugates

		binding		fold
	RGD−peptides per HSA	EC_{50} in nM	IC_{50} in nM	increase vs RGD
RGDPEG-MMAE−HS A	5.4	41.1	141	2.7
RADPEG-MMAE−HS A		>150[a]	>1000[a]	-
RGDPEG−HSA	7.1		18.6	21
RGD−MMAE−HSA	7.6	6.64	52.6	7.3

respective control products RGDPEG−HSA and RGD−HSA were positively stained by anti-RGD antibody, while MMAE−HSA was not stained (Figure 3).

Binding Specificity of RGD-Equipped Conjugates to Endothelial Cells and C26 Carcinoma Cells. Binding specificity was evaluated using ^{125}I-labeled drug-targeting conjugates. Both conjugates bound to $\alpha_v\beta_3$-integrin expressing HUVEC and could be completely displaced by excess of RGD−peptide or RGD−HSA but not by RAD−peptide (Figure 4A). This demonstrated that binding was mediated exclusively by the introduced RGD-moiety. Remarkably, a 4 times higher binding of ^{125}I-RGD−MMAE−HSA than of ^{125}I-RGDPEG−MMAE−HSA was observed. Both conjugates bound also to C26 cells but in contrast to HUVEC no difference in the quantity of binding could be detected. Binding to C26 cells was as well mediated by the introduced RGD-moiety, as could be concluded from the complete displacement by RGD−peptide (Figure 4B).

Binding Affinity of RGD-Equipped Conjugates to Endothelial Cells. Binding affinity of drug-targeting conjugates was determined in competition experiments with the known $\alpha_v\beta_3$-integrin ligand ^{125}I-echistatin as shown in Figure 4C. Both conjugates displaced ^{125}I-echistatin in the low nanomolar range, with the binding affinity of RGD−MMAE−HSA being higher than of RGDPEG−MMAE−HSA. The respective control conjugate RGDPEG−HSA and RGD−HSA displayed higher affinities (Table 2). All conjugates possessed an increased affinity for $\alpha_v\beta_3$-integrin as compared to the single c(RGDfK) peptide. Furthermore, a clear relationship was observed between the average number of RGD/albumin and affinity for the target cells. The observation that multivalent RGD-carriers bind with higher affinity than monovalent carriers has been made before (*12, 19, 20*).

Uptake of RGD-Equipped Conjugates into Endothelial Cells. Drug-targeting conjugates were labeled with ^{89}Zr to study intracellular uptake. ^{89}Zr, captured by the chelator desferal, is highly stable, and its hydrophilicity will lead to its entrapment

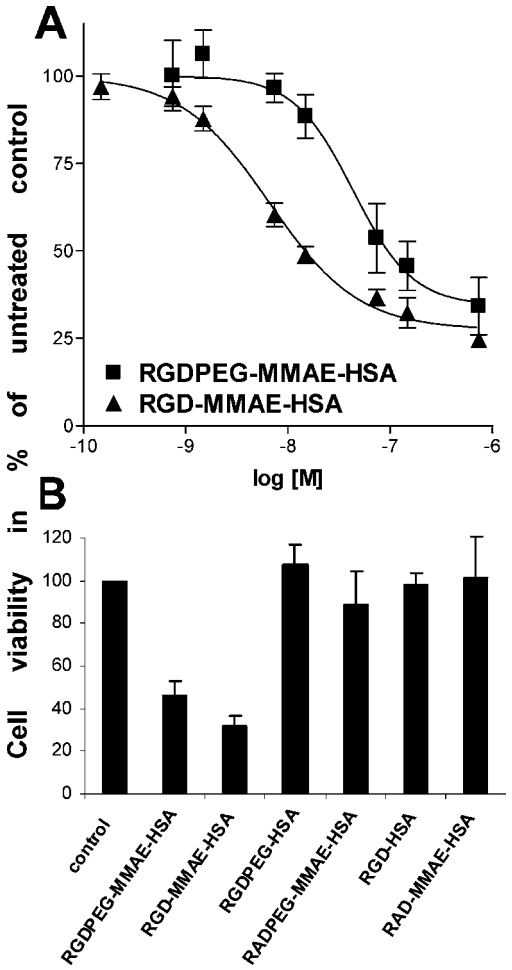

Figure 6. **(A)** HUVEC have been incubated with increasing concentrations of drug-targeting conjugates to determine killing efficacy. Concentrations are expressed in mol/L. (EC_{50}s: RGDPEG-MMAE−HSA 41 nM; RGD−MMAE−HSA 6.6 nM). **(B)** Viability of HUVEC treated with 150 nM of drug targeting and control conjugates.

inside the cells after degradation of the carrier (*21*, *22*). As such, it is an ideal label for uptake studies since this will prevent redistribution of the radiolabel. In spite of all previous modifications, we were able to attach 1.2 (RGDPEG−MMAE−HSA) and 0.9 (RGD−MMAE−HSA) desferal per conjugate. ^{89}Zr labeled conjugates were incubated with HUVEC at 4 °C and 37 °C degrees. Energy dependent uptake processes take place at 37 °C, at which more cell associated radioactivity was found than at 4 °C (Figure 5), at which these processes are inhibited. The cell-associated radioactivity increased further upon longer incubation at 37 °C but not at 4 °C. Taken together, these results indicated uptake of the drug-targeting conjugates via an active process. Uptake was more pronounced for ^{89}Zr-RGD−MMAE−HSA than for ^{89}Zr-RGDPEG−MMAE−HSA (black versus white bars).

***In Vitro* Killing Efficacy of RGD-Equipped Conjugates.** Monomethyl auristatin E has been shown to inhibit the polymerization of tubulin in dividing cells and thus to induce apoptosis (*3*). To study the effect of intracellularly delivered MMAE, HUVEC were exposed for 72 h to serial dilutions of both drug-targeting conjugates and their respective control. Regression analysis of the concentration−cytotoxicity curves in Figure 6A revealed EC_{50}s (effective concentrations) of 44 nM for RGDPEG−MMAE−HSA and 6.6 nM for RGD−MMAE−HSA. In contrast, the RAD-containing control conjugates and the control conjugates without MMAE showed no effect at concentration as high as 150 nM (Figure 6B).

Preliminary *In Vivo* Evaluation. To determine whether the RGD-equipped drug carriers accumulate in the tumor endothelium, we administered RGDPEG−MMAE−HSA and RGD−MMAE−HSA to C26 murine colon carcinoma-bearing mice. Anti-HSA staining of sections of organs and tumors showed the presence of both conjugates in the tumor, 3 h after injection (Figure 7A,F). In contrast, hardly any drug-targeting conjugate was found in the spleen and kidneys. A clear staining was detected in the liver. Higher magnification revealed the presence of the drug-targeting conjugates in the hepatic sinusoids, not confined to any sinusoidal cell type.

This distribution pattern changed after 24 h. RGD−MMAE−HSA could not be detected in any of the three control organs (Figure 7H−J) while a clear accumulation in the tumor could be detected (Figure 7G). RGDPEG−MMAE−HSA was also absent in kidneys and spleen but showed some residual staining in the liver (Figure 7C−E), apart from the pronounced tumor accumulation (Figure 7B).

To identify which cell types had accumulated the auristatin−albumin conjugates, we investigated the colocalization of the albumins with either endothelial cells or tumor cells. Since endothelial cells display typically flattened nuclei in contrast to bigger nuclei for C26 cells, DAPI nuclear staining could be used to discriminate between vasculature and tumor cells. Figure 8 shows the typical fluorescent staining for cell nuclei (blue) and HSA (green) of a tumor 24 h after injection of RGD−MMAE−HSA (8A) and RGDPEG−MMAE−HSA (8B). A blood vessel with two typically flattened endothelial nuclei is pointed out by red arrows, while some of the larger tumor cell nuclei are indicated by yellow arrows. HSA was found along the vessel wall, but also colocalized with tumor cells within the tumor mass.

DISCUSSION

Immunotoxins are an attractive strategy to kill specific cell types without affecting other cells in the body. Typically, such conjugates have been prepared by conjugating cytotoxic agents to antibodies (*23*). We now report on a different type of target-cell specific toxin containing conjugate, in which RGD−peptides facilitate recognition of angiogenic endothelial cells (Figure 1). The RGD-motif is a highly conserved receptor binding ligand and allows studying RGD-equipped drug targeting in different species without further modification of the homing ligand. This is not possible for antibodies that commonly are species specific. RGD-equipped albumin conjugates are a versatile platform that can be readily modified with drugs and tailored with other moieties such as PEG. HSA functions in this context as a monomeric polymer featuring low immunogenicity, high biocompatibility, and excellent biodegradability. Furthermore, renal filtration of drug is prevented by the high molecular size of albumin enabling prolonged exposure of the target cells to the conjugates. Here we report the development of RGD−MMAE−HSA and RGDPEG−MMAE−HSA, in which MMAE−HSA is equipped with RGD−peptide via a short alkyl linker or via an extended PEG linker (Figure 2). MALDI-TOF analysis of synthesis products demonstrated that both conjugates were modified with multiple RGD−peptides. It has been recognized that RGD-based drug-targeting conjugates need to be equipped with multiple RGD−peptides in order to obtain optimal binding to and uptake into the target cell (*11*, *24*) and current research focuses on various multivalent carriers for delivery of therapeutic or diagnostic agents (*25*−*29*). The presently developed drug-targeting conjugates both demonstrated multivalent binding, as they bind with higher affinity than single RGD−peptide, and they are also taken up, thus fulfilling these criteria. However, application of the short alkyl linker resulted in a higher average RGD/carrier ratio than the PEG linker. As a consequence,

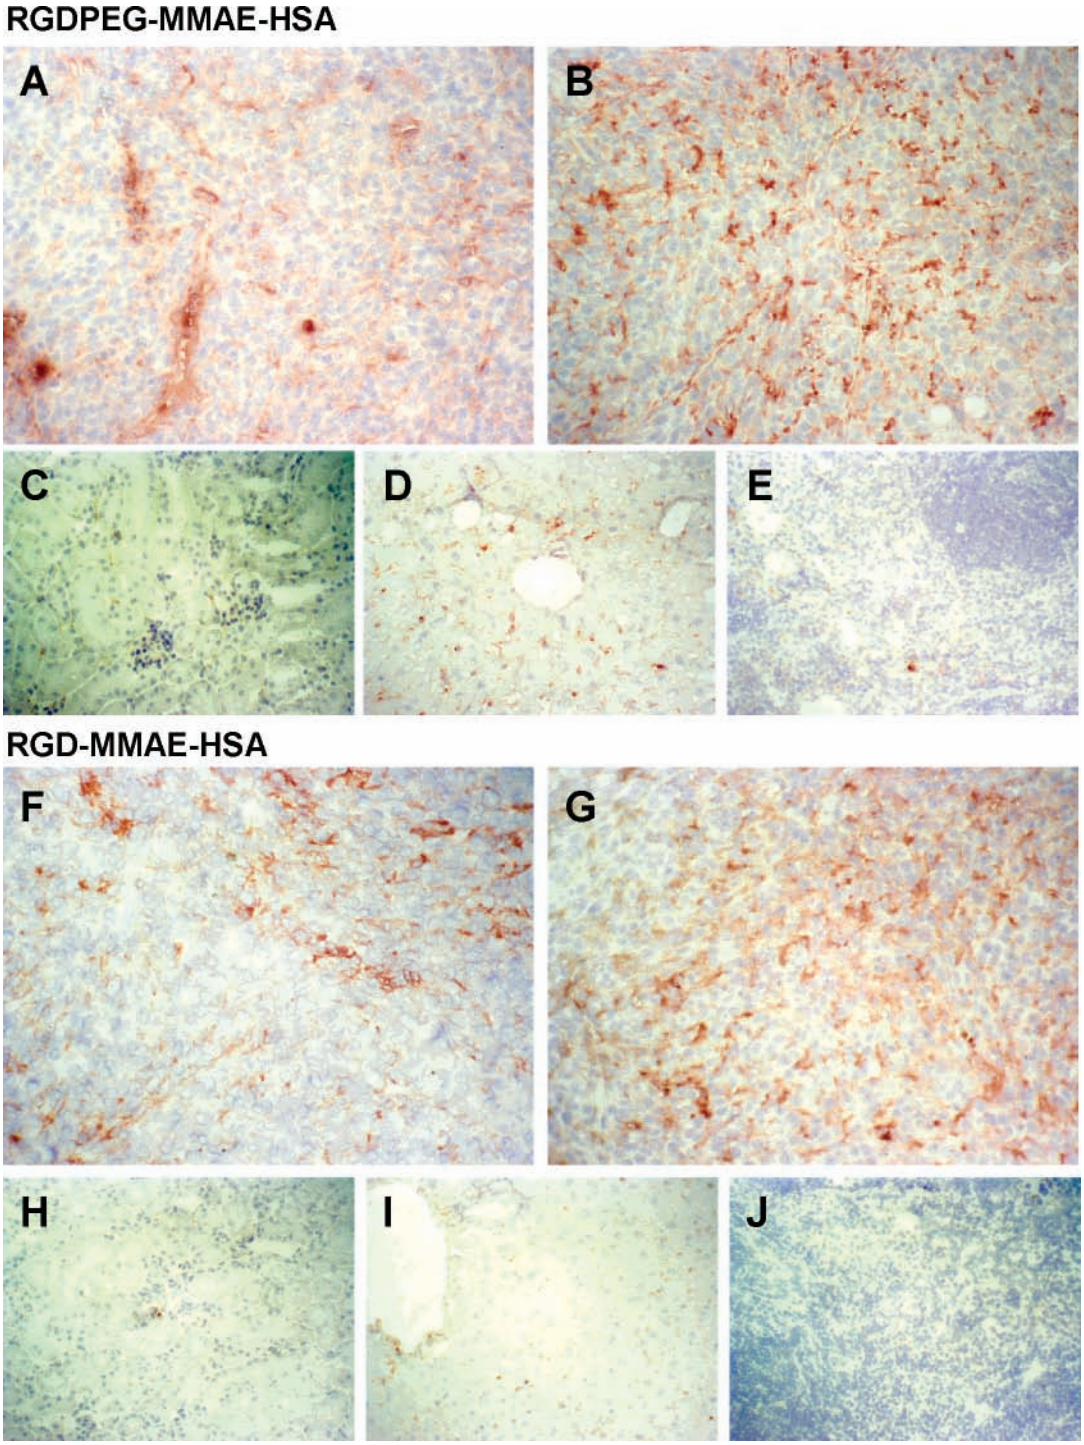

Figure 7. C26 tumor bearing mice had been injected with either 30 μg RGDPEG-MMAE−HSA (A-E) or RGD−MMAE−HSA (F−J). Sections were stained with rabbit antiHSA antibody. Both drug-targeting conjugates localized in C26 tumors 3 h (A, F) and 24 h (B, G) after i.v. administration. Sections of kidney (C, H), liver (I), and spleen (E, J) at 24 h time point are stained negative. All pictures are taken at magnification of 200×; C−E and H−J are reduced to 45% of the size of A, B, F, and G.

RGD−MMAE−HSA bound with higher affinity and in higher quantity to $\alpha_v\beta_3$-expressing HUVEC than RGDPEG−MMAE−HSA. We did not fractionate our products further into batches with a narrow RGD/HSA ratio, and it can be conceived that individual RGDPEG−MMAE−HSA with high RGD loading will bind stronger to the target cells. Another explanation for the difference in affinity might be a different spatial presentation of RGD−peptides due to the extended PEG linker, or differences in hydrophobicity between the two linkers.

In line with the observed higher affinity and higher uptake efficiency, RGD−MMAE−HSA demonstrated superior EC_{50} in cell killing as compared to the PEGylated conjugates. This result was corroborated upon testing of RGD−MMAE−HSA bearing an average of six MMAE molecules but less RGD−peptides per carrier, since only little improvement in EC_{50} was found (data not shown). Taken together, these data indicate that a high number of RGD−peptides and efficient internalization is more important than a high drug load.

Both drug-targeting conjugates demonstrated efficient killing of the target cells at nanomolar concentrations. The EC_{50} values (Table 2) are in a similar range as EC_{50} values of MMAE modified antibodies against E-selectin (*6*), CD20 on non-Hodgkin's lymphoma (*4*), TMEFF2, a plasma membrane protein overexpressed in prostate cancer (*5*), and the glycoprotein NMB

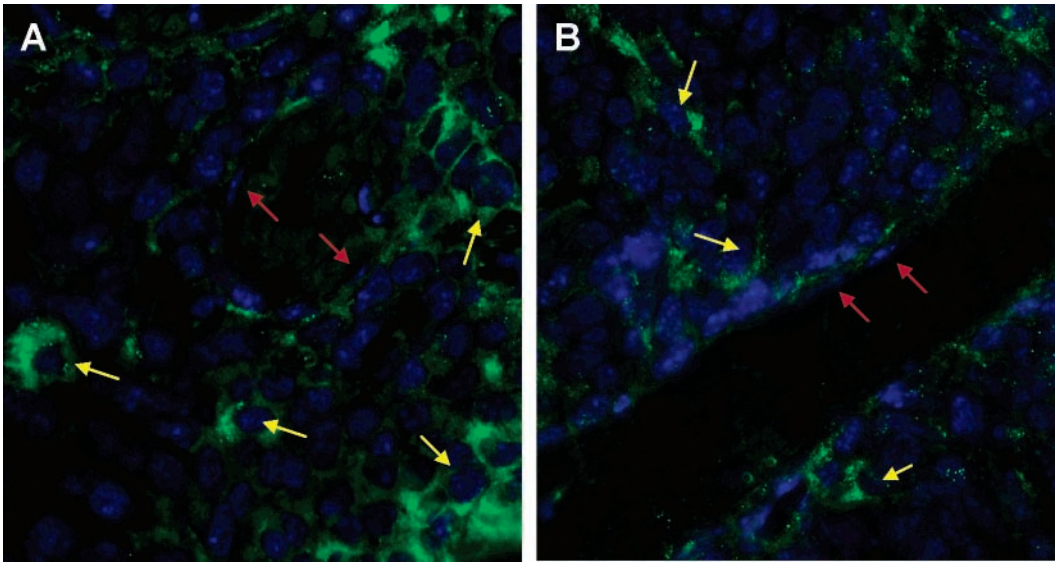

Figure 8. Colocalization of auristatin−albumin conjugates with tumor vasculature and tumor cells. C26 tumor section of RGDPEG-MMAE−HSA (A) and RGD−MMAE−HSA (B) treated mice (24 h postinjection) were stained with DAPI (blue) to visualize endothelial cells (flattened nuclei) or tumor cells (big nuclei). Accumulated conjugate was visualized by anti-HSA staining (green). Red arrows point at the typically flattened nuclei of endothelial cells and identify a blood vessel, colocalizing with HSA. Examples for tumor cells nuclei that colocalize with HSA are pointed out using yellow arrows. Magnification 400×.

found on melanoma (*30*). *In vitro* cell killing assays showed that a fraction of the cells survived treatment with highest concentrations of immunoconjugates (*6*, *31*, *5*). Identical observations were made for our RGD-based conjugates. Most likely, this fraction represented not dividing cells, which therefore do not respond to MMAE.

The short alkyl linker was chosen to modify MMAE−HSA with a maximum of RGD−peptides but the extended PEG linker was chosen for its known ability to shield the modified HSA, to prolong circulation time, and to increase passive targeting by the enhanced permeability and retention (EPR) effect (*32*, *33*). These advantages cannot be detected in in vitro assays. In the C26 tumor bearing mice, both conjugates accumulated to a similar extent in the tumors in time, with a stronger and more widespread localization for the conjugates after 24 h compared to localization at 3 h. At the later time point, kidney, liver, and spleen were almost devoid of drug-targeting conjugates. Thus, the concentration of drug-targeting conjugate increased in the tumor, and at the same time the concentration in organs decreased. Mitra et al. (*34*) reported similar findings in which a RGD-equipped polymer accumulated in the course of 3 days in prostate tumors.

RGDPEG−MMAE−HSA was still detectable in the liver 24 h after injection. A possible explanation for this might be a longer circulation time and delayed degradation compared to RGD−MMAE−HSA due to the PEG moiety. A remarkably strong staining at both time points and for both conjugates was observed in tumor tissue. It is important to note that not a tracer dose but a therapeutic dose (30 μg/ mouse) was given, thus reflecting the distribution pattern during treatment. In the future experiments, we will use the here prepared ^{89}Zr-labeled conjugates in combination with positron emission tomography (PET) to gain more insight in organ distribution of RGD-equipped drug−albumin conjugates. In those studies, tumor accumulation of RGD-based carriers will also be compared to carriers that accumulate in tumors by enhance-permeability retention (EPR), such as for instance the above presented RAD-modified albumins. ^{89}Zirkonium captured by the chelator desferal is the ideal label for these studies, as it is highly stable, hydrophilic enough to prevent redistribution, and equipped with a half-life that allows PET scans for longer than 48 h.

The preliminary distribution data of our product indicated that the accumulation in the tumor was widespread and did not reflect a vascular staining pattern. Fluorescent staining of nuclei demonstrated colocalization of the conjugates with both endothelial cells and tumor cells. We therefore investigated binding of ^{125}I-labeled conjugates to C26 tumor cells. Indeed, both RGDPEG−MMAE−HSA and RGD−MMAE−HSA bound to C26 cells and were displaceable by coincubation with an excess of free RGD−peptide. This indicated that binding was mediated via the RGD−peptide to C26 carcinoma cells, and binding presumable took place via $\alpha_v\beta_3$-integrin or related α_v integrins. Thus angiogenic endothelium and tumor cells were both targeted in the chosen tumor model, explaining the staining pattern. An $\alpha_v\beta_3$-integrin-expressing tumor is likely to be more responsive than a $\alpha_v\beta_3$-integrin-negative tumor. Although this may perturbate the selectivity of the RGD-equipped conjugates for the tumor vasculature per se, this will even enhance the potential antitumor effects of the compounds. Similarly, many of the studies employing RGD−peptides for either imaging or drug delivery have been conducted in tumor models that express $\alpha_v\beta_3$ integrin at the tumor cells (*11*).

In conclusion, two types of RGD-equipped auristatin−albumin conjugates have been developed, demonstrating the versatility of such a targeting approach. Both drug-targeting conjugates displayed excellent binding and cell killing properties, and strongly accumulate in a C26 tumor in mice. These results indicate that RGD-mediated targeting of auristatin E is a promising strategy for delivery of a proapoptotic payload to tumor vasculature and carcinoma cells and a valid alternative to current immunoconjugates. In the future pharmacokinetics and tumor growth inhibition of these promising compounds will be evaluated in detail.

ACKNOWLEDGMENT

J. H. Pol from the Department of Nuclear Medicine is kindly acknowledged for radiolabeling of proteins, H. E. Moorlag from the Endothelial Cell Facility UMCG for skillful isolation and culturing of HUVEC, and Annemiek van Loenen-Weemaes for assistance with animal experiments. We also acknowledge Prof.

G. A. M. S. van Dongen and Ir. L. R. Perk of the VU Medical Center for providing the desferal labeling technology. This work was made possible by grants from Marie Curie (HPMI-CT-2002-00218) and SenterNovem (TSGE1083).

Multiblock Reducible Copolypeptides Containing Histidine-Rich and Nuclear Localization Sequences for Gene Delivery

Devika Soundara Manickam and David Oupický*

Department of Pharmaceutical Sciences, Wayne State University, Detroit, Michigan 48202. Received April 23, 2006; Revised Manuscript Received September 3, 2006

Polyplexes sensitive to redox potential gradients represent promising gene delivery vectors. High molecular weight polypeptides containing disulfide bonds in the backbone were synthesized by an oxidative copolymerization of a histidine-rich peptide (HRP) and a nuclear localization sequence (NLS) peptide. The synthetic approach allowed an easy synthesis of reducible copolypeptides (rCPP) with different relative contents of the HRP and NLS sequences. Cytotoxicity and transfection activity of rCPP-based DNA polyplexes were evaluated in vitro. In comparison with control polyethylenimine (PEI), only minimum toxic effects of rCPPs were observed on the metabolic activity and membrane integrity of human endothelial cells. These findings are predominantly ascribed to favorable structural features like lower charge density and higher chain rigidity of the rCPPs compared to PEI and also to a reductive intracellular and plasma membrane degradation. Transfection activity in all tested cell lines increased with increasing content of the HRP sequence in the rCPPs, while no clearly measurable effect of the NLS sequence was found.

INTRODUCTION

Polyelectrolyte complexes of nucleic acids with polycations (polyplexes) are investigated as promising delivery vectors for a variety of nucleic acid therapeutics. In particular, polyplexes capable of responding to environmental changes or stimuli by altering their properties and behavior promise a significant improvement of the efficacy of the delivery process. One of the several microenvironmental features, which could be exploited for improving the efficiency of nucleic acid delivery, is the redox potential gradient existing between extracellular environment and various subcellular organelles in normal as well as pathological states. The existence of such gradients has been exploited by incorporating disulfide bonds into the structure of a variety of delivery vectors to provide them with a capability to release the therapeutic cargo selectively in the subcellular reducing space (*1*−*5*).

The easy intracellular reversibility of disulfide bonds in redox-sensitive polyplexes proved to be a highly advantageous feature for delivering a variety of nucleic acids, including plasmid DNA, mRNA, antisense oligonucleotides, and siRNA. Delivery of plasmid DNA has been by far the most investigated application of the redox-sensitive polyplexes. A number of studies in a variety of cell lines showed transfection activities comparable to or better than those observed for polyethylenimine (PEI) and/or commercially available lipid formulations (*6*−*10*). The benefits of intracellular reduction of disulfides in the redox-sensitive polyplexes for efficient delivery of nucleic acids have been demonstrated also for mRNA, siRNA, and antisense oligonucleotides (*4*, *11*).

Redox-sensitive polyplexes based on cationic peptides are attractive vectors because of the possibility of combining DNA condensation capability with an inherent biological activity of the peptides (*12*−*14*). Here, we synthesized reducible copolypeptides (rCPP) composed of two cationic peptide sequences that should provide the copolymers with endosomal buffering capability and nuclear localization capability. It is hypothesized that the combination of the two features in a single carrier will improve the overall efficiency of the gene delivery process. The copolypeptides are synthesized by an oxidative polycondensation using an engineered histidine-rich peptide (HRP) and a nuclear localization sequence (NLS) derived from the SV40 virus. The copolypeptides show minimal cytotoxicity and transfection activity comparable to or better than control PEI polyplexes.

EXPERIMENTAL PROCEDURES

Materials. Peptides, NLS (CGAGPKKKRKVC, Mr 1274), and HRP (CKHHHKHHHKC, Mr 1431) were custom-synthesized by Sigma-Genosys. Branched PEI (25 000 g/mol), poly-L-lysine (PLL, 240 000 g/mol), dithiothreitol (DTT), chloroquine, genistein (Gen) and bafilomycin A1 (Baf.A1) were from Sigma-Aldrich. Plasmid DNA vectors, gWiz high-expression luciferase (gWiz-Luc) containing luciferase reporter gene, and gWiz high-expression GFP (gWiz-GFP) containing enhanced green fluorescent protein reporter gene were from Aldevron (Fargo, ND). Dulbecco's modified Eagle medium (DMEM), fetal bovine serum (FBS), and Roswell Park Memorial Institute 1640 (RPMI 1640) medium were from Invitrogen. All other chemicals were obtained from Fisher Scientific unless otherwise noted.

Synthesis of Reducible Copolypeptides. The rCPPs were synthesized by DMSO-mediated oxidative polycondensation described previously (*15*). Five rCPPs were prepared using NLS and HRP peptides at different molar ratios in the reaction mixture. Relative content of the NLS and HRP peptides in the synthesized copolypeptides was determined by amino acid analysis (Michigan State University Macromolecular Core) using the average ratio of histidine residues of HRP to valine and alanine residues of NLS peptide. The concentration of the polypeptides in solution was estimated from the amino acid analysis by adding L-norleucine as an internal standard.

Formulation of DNA Polyplexes. DNA solution (20 μg/mL) in 10 mM HEPES buffer (pH 7.4) was used to prepare complexes with PEI, and DNA solution in 30 mM sodium acetate buffer (pH 5) was used to prepare polyplexes with rCPPs at the desired N/P mixing ratio (*c*(basic amino acid residues of a peptide or amino groups of PEI)/*c*(DNA phosphates)) and mixed by vigorous vortexing for 10 s.

Hydrodynamic Radius and ζ Potential Determination. The determination of hydrodynamic diameters and ζ potentials of polyplexes was performed using ZetaPlus Particle Size and Zeta Potential analyzer (Brookhaven Instruments Inc.) as described previously (*14*).

Salt Dissociation Assay. Polyplexes were formulated as described above and incubated in 25 mM DTT for 1 h at 37 °C. Then, increasing concentration of NaCl (0−1 M) was added and samples were loaded onto 0.8% agarose gel containing 0.5 μg/mL ethidium bromide and run for 90 min at 120 V in 0.5× TBE buffer. The amount of DNA released from the polyplexes at a given NaCl concentration was analyzed using Kodak 1D image analysis software.

Cell Lines. Murine melanoma cell line B16F10, mouse mammary tumor cell line 4T1, human cervical cancer cell line HeLa, human breast carcinoma MCF-7, and African green monkey kidney fibroblasts COS-7 were obtained from ATCC. Human endothelial cell line EA.hy926, derived by a fusion of human umbilical vein endothelial cells with a lung carcinoma A549, was a kind gift from Dr. Edgell (University of North Carolina). B16F10, HeLa, EA.hy926, and COS-7 were maintained in DMEM and MCF-7 and 4T1 in RPMI 1640. Both media were supplemented with 4 mM L-alanyl-L-glutamine and 10% FBS.

Cytotoxicity Evaluation. Cytotoxicity of rCPPs and control PEI in EA.hy926 cells were determined by MTS and LDH assays using commercially available kits. The MTS assay was performed using the CellTiter 96 aqueous cell proliferation assay (Promega). Twenty-thousand cells seeded in a 96-well plate 2 days before the experiment were incubated with increasing concentration of the polycations in 150 μL of DMEM/FBS. The medium was removed after 16 h and replaced with a mixture of 100 μL of fresh DMEM and 20 μL of MTS reagent solution. The cells were incubated for 1 h at 37 °C in a CO_2 incubator. The absorbance of each sample was then measured at 505 nm to determine cell viability. The results are expressed as the mean percentage cell viability relative to untreated cells ± SD. The cytotoxicity of the polycations was also determined by a CytoTox 96 nonradioactive cytotoxicity assay, an assay that measures LDH release from damaged cells. EA.hy926 cells were incubated with increasing concentrations of the polycations in DMEM/FBS lacking phenol red. After 2 h of incubation at 37 °C, the medium was removed and centrifuged at 250*g* at 4 °C for 5 min. An amount of 50 μL of the supernatant was diluted with 50 μL of DMEM/FBS without phenol red. The LDH substrate (50 μL) was added to each sample and incubated for 30 min in the dark. An amount of 50 μL of the stop solution was added to each sample, and the absorbance was measured at 490 nm. The maximum LDH release was quantified by freeze−thaw lysis of untreated cells followed by medium processing as described above. The results are expressed as the mean % LDH release ± SD.

Transfection Efficiency in Vitro. Transfection activity was tested using polyplexes prepared as described above at the indicated N/P ratio. All transfection studies were performed in 48-well plates with cells plated 24 h before transfection at a seeding density of 30 000 cells per well using previously described protocols (*10*, *14*). On a day of transfection, the cells were incubated with the complexes in 150 μL of FBS-supplemented media or medium lacking FBS as indicated. After 3 h of incubation, the transfection mixture was completely removed and the cells were cultured for an additional 24 h in fresh media supplemented with 10% FBS prior to analysis of reporter gene expression. Transfections in the presence of chloroquine and Baf.A1 were performed in the same way except that the drug was added to the culture medium before addition of the polyplexes. Caveolae inhibition experiments were conducted by preincubating the cells for 30 min with the respective inhibitor or combination of inhibitors (200 μM genistein, 100 nM bafilomycin A1) before the addition of polyplexes. The inhibitors were present in the transfection medium throughout the 3 h of incubation. The luciferase transfection results are expressed as relative light units (RLU) per milligram of cellular protein ± SD of triplicate experiments. The GFP transfection results are expressed as the percentage of GFP-positive cells determined by flow cytometry ± SD of triplicate experiments.

rCPP-E	100	100	∼200 000

[a] Determined from amino acid analysis.

RESULTS

Synthesis of rCPP and Characterization of rCPP/DNA Polyplexes. To combine two functional peptides into a single polymeric carrier, multiblock reducible copolypeptides were synthesized by randomly connecting HRP and NLS peptides via disulfide bonds into a linear polypeptide chain (Figure 1). Mild oxidation of the terminal Cys residues with DMSO was used as described in our earlier work (*14*, *15*). Five different compositions of the rCPP were prepared by varying the amount of the NLS and HRP peptides in the polycondensation reaction (Table 1). Amino acid analysis was used to determine the relative content of the two peptides in the rCPPs. Molecular weights of selected rCPPs were estimated by size exclusion chromatography and were found to range from ∼60 000 to ∼200 000 (Table 1). The ability of the rCPP polycations to condense DNA was confirmed by ethidium bromide exclusion (data not shown) and gel retardation assays (Figure 2a). All rCPPs were able to fully condense DNA in buffers at pH 7.4 and 5 at N/P ratios of ≥2. Hydrodynamic size and ζ potential of the rCPP polyplexes were measured by dynamic light scattering using optimized polyplex compositions determined in the transfection assay (Table 2). All rCPPs formed polyplexes with sizes and ζ potentials fully comparable to those of control PEI. The sensitivity of the rCPP/DNA polyplexes to reducing environment was tested by following the polyplex dissociation with NaCl (*16*). No detectable dissociation was observed under nonreducing conditions up to 1 M NaCl (Figure 2b, data shown for rCPP−C/DNA only). Reduction of the disulfide bonds in rCPP-C in 25 mM DTT resulted in the polyplex dissociation already starting in ∼0.3 M NaCl.

Cytotoxicity of rCPP Polycations. The cytotoxicity of the rCPP polycations was evaluated using MTS and LDH assays in human endothelial cells (Figure 3). The results show that the rCPP polycations exhibit only a negligible cytotoxicity in the MTS assay after 16 h of incubation in the concentration range 0−300 μg/mL, while control PEI shows an IC_{50} value less than 10 μg/mL (Figure 3a). The LDH release assay, which was used to estimate the early-stage cytotoxicity associated with

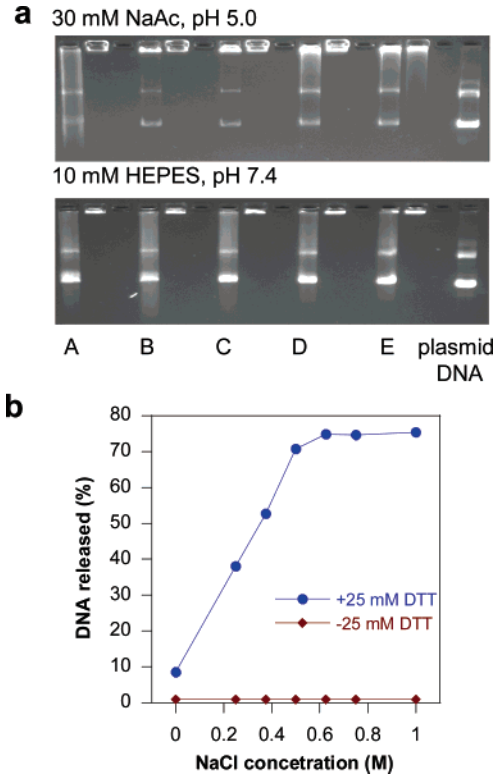

Figure 2. (a) DNA condensation by rCPPs. Polyplexes were prepared at N/P ratios of 0.5 and 2.0 (left and right lanes) in 30 mM sodium acetate buffer (pH 5.0) (upper panel) and 10 mM HEPES buffer (pH 7.4) (lower panel). (b) Salt dissociation of rCPP-C/DNA polyplexes under reducing conditions of 25 mM DTT.

Table 2. Molecular Parameters of rCPP-Based DNA Polyplexes[a]

polycation	hydrodynamic diameter (nm)	ζ potential (mV)
rCPP-A	105 ± 3	47 ± 1
rCPP-B	125 ± 1	49 ± 4
rCPP-C	145 ± 2	43 ± 1
rCPP-D	135 ± 1	46 ± 1
rCPP-E	96 ± 1	55 ± 1
PEI	115 ± 1	47 ± 5

[a] The polyplexes were formulated at optimum molar mixing ratios. Results are presented as the mean ± SD ($n = 3$).

plasma membrane disruption, shows results similar to the MTS data. When the LDH is measured after 2 h of incubation with the polycations, PEI exhibits a similar IC_{50} value as in case of the MTS assay. The rCPPs show minimal LDH release at concentrations below 100 μg/mL, but unlike in the MTS assay considerable cytotoxicity is observed at the highest concentration (300 μg/mL) tested (Figure 3b). Light transmission micrographs were obtained after a 16 h incubation of the cells with the polycations to directly document the differential effects of PEI and rCPP on the human endothelial cells (Figure 3c). The images show the cells incubated with the rCPP polycations as healthy, attached to the surface, and of similar appearance as untreated cells. The cells incubated with PEI, on the other hand, show clear signs of toxicity indicated by changed morphology and a large number of rounded and detached cells.

Transfection Activity of rCPP/DNA Polyplexes. Initial transfection experiments were conducted to determine the optimum N/P ratio for each rCPP/DNA formulation to achieve maximum transgene expression levels in B16F10 cells (Figure 4). The N/P ratio that resulted in maximum luciferase expression was then used in all subsequent experiments. The N/P dependence of the transfection activity is mostly influenced by the content of the pH-buffering HRP peptide. For example, transfection activity of rCPP-B with 27% of HRP gradually decreases with increasing N/P ratio, while the activity of rCPP-E (100% HRP) peaks at N/P = 8 and then slowly declines, similar to the control PEI/DNA.

The transfection activity of the optimized rCPP/DNA formulations was further tested in a panel of six cell lines (Figure 5). A general trend of gradual increase in the transfection activity with increasing content of HRP is observed in all the cell lines. The best performing rCPP-E polyplexes exhibit between 2- and 7-fold higher transfection activity than control PEI polyplexes depending on the cell line. It is worth noting that the difference between the lowest and the highest observed transfection is almost 5 orders of magnitude. Similar results were obtained across the same panel of cell lines in GFP transfection experiments (data not shown).

The effect of chloroquine on the luciferase reporter expression of the rCPP/DNA polyplexes is plotted in Figure 6a as a chloroquine enhancement ratio ([RLU/mg protein with chloroquine]/[RLU/mg protein without chloroquine]). In fast-growing B16F10 cells, the presence of 100 μM chloroquine results in an almost 10000-fold increase in the transfection activity of rCPP-A, which consists of 100% NLS and thus lacks any buffering capability. As expected, increasing the HRP content in the polypeptides leads to a decrease in the potentiation of the transfection activity by chloroquine. The two other cell lines tested show a slightly different pattern of chloroquine effect, with maximum enhancement seen for rCPP-C/DNA polyplexes. Complementary results are obtained for the GFP reporter plasmid in B16F10 cells (Figure 6b).

The dependence of transfection activity of polyplexes on pH-buffering capability of the polypeptides was examined by conducting transfections in the presence of Baf.A1, a potent inhibitor of vacuolar ATPases (Figure 7). It has been reported that, depending on the cell line used, the transfection activity of PEI can be reduced 7- to 74-fold in the presence of 175 nM Baf.A1 (*17*). Unexpectedly, rCPP-A polyplexes that lack any buffering capability exhibited almost a 1000-fold increase in the transfection activity in the presence of 100 nM Baf.A1 in B16F10 cells (Figure 7a). A decreasing effect of Baf.A1 on transfection enhancement is observed when moving from rCPP-A to rCPP-E. The transfection activity of control PEI/DNA increased almost 2-fold under the same conditions. Baf.A1 has a smaller but similar enhancing effect on the transfection of rCPP-A polyplexes in HeLa cells (Figure 7b). A 2- to 4-fold, statistically insignificant, increase in the transfection activity of the remaining four rCPP polyplexes is observed in the presence of 10% FBS and 175 nM Baf.A1 (Figure 7b). There was a 2-fold decrease in the transfection activity of control PEI, which is in close agreement with the results reported previously (*17*). Unlike HeLa and B16F10 cells, Baf.A1 has no enhancing effect on the transfection activity of rCPP polyplexes in MCF-7 cells (Figure 7c).

In experiments conducted in the absence of FBS (Figure 7d–f), Baf.A1 causes the expected decrease of transfection activity of polyplexes capable of endosomal pH buffering. Especially in the HeLa and MCF-7 cells, the Baf.A1 effect is directly correlated with the content of HRP (Figure 7e,f). For example, the decrease in the transfection activity of rCPP-E polyplexes in HeLa cells is almost 2 orders of magnitude. In addition, Baf.A1 has a more pronounced effect on the transfection activity of rCPP-E than PEI polyplexes. No significant differences were observed in the transfection activity of control PLL polyplexes in the presence and absence of Baf.A1 (data not shown). In B16F10 cells, the enhancing effect of Baf.A1 was preserved for polyplexes with no (rCPP-A) or minimum buffering capability (rCPP-B) (Figure 7d). There was almost a 10-fold increase in the transfection activity of rCPP-A. In agreement with the

original expectations, polycations with significantly higher buffering capabilities (rCPP-D and rCPP-E) demonstrated a decrease in the transfection activity of the polyplexes in the presence of Baf.A1, 3- and 5-fold, respectively.

Since the effects of Baf.A1 in B16F10 cells showed a strong dependence on the presence or absence of serum, we conducted transfections using medium supplemented with gradually increasing concentrations of bovine serum albumin (BSA) (Figure 8a). The results show that in the presence of Baf.A1, rCPP-A with no buffering capability exhibits a gradual increase in the transfection activity with increasing concentration of BSA in the incubation medium and rCPP-E with the maximum buffering capability among the tested compositions shows no significant increase. Additional transfection studies were conducted to further probe the unexpected effect of Baf.A1 on the activity of rCPP-A polyplexes. It has been reported that cellular uptake of polyplexes proceeds via a clathrin- or caveolae-dependent endocytic pathway (*18*). To determine an involvement of an alternative endocytosis pathway, caveolae inhibition studies were carried out using genistein, a specific inhibitor of tyrosine kinase involved in receptor-induced formation of caveolae (Figure 8b) (*19*, *20*). In the presence of Baf.A1, there was a 100-fold increase in transfection activity of rCPP-A polyplexes, an 8-fold increase in the case of rCPP-C polyplexes, while no effect was observed for rCPP-E polyplexes (Figure 8b). Unlike Baf.A1, genistein had no marked effect on the transfection activity of the NLS-containing rCPP polyplexes, but it led to a decrease of transfection activity of rCPP-E polyplexes. It has been

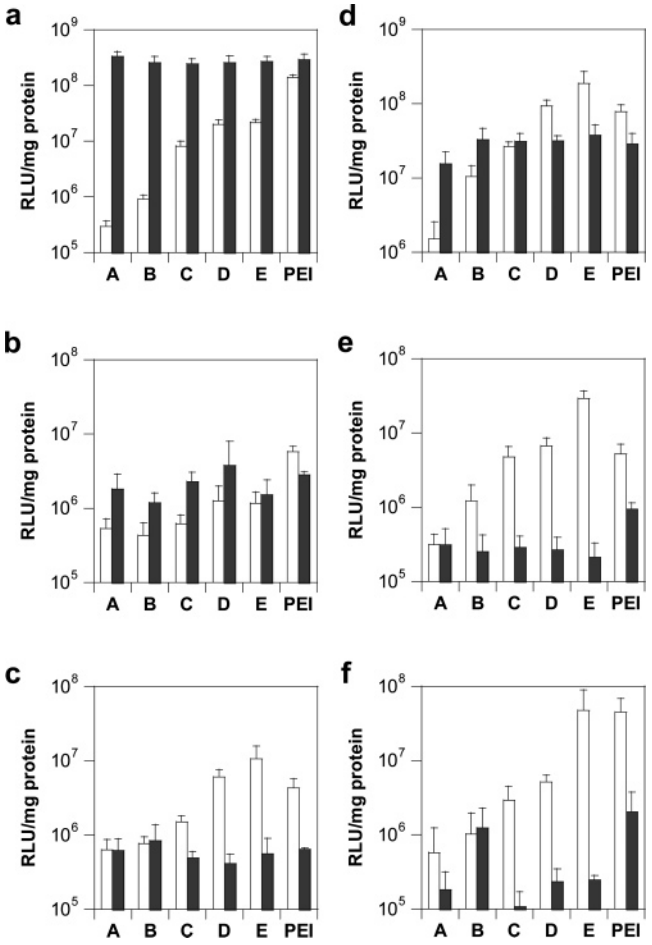

Figure 7. Effect of Baf.A1 on transfection activity of rCPP polyplexes. Transfections were performed in the presence (a) or absence (d) of 10% FBS in B16F10 cells, in the presence (b) or absence (e) of 10% FBS in HeLa cells, and in the presence (c) or absence (f) of 10% FBS in MCF-7 cells. Luciferase activity was measured after 24 h, and results are shown as mean RLU per milligram of cellular protein and SD from triplicate samples (empty bars, absence of Baf.A1; solid bars, presence of Baf.A1).

reported that transfection activity of polyplexes is mediated by both clathrin-dependent and caveolae-dependent endocytosis pathways whereas lipoplex transfection is mediated only by the clathrin endocytosis pathway and is unaffected by inhibiting the caveolae endocytosis pathway (*18*). DOTAP lipoplexes were therefore included as a control (not shown) to verify if the observed decrease in the transfection activity of rCPP-E polyplexes in the presence of genistein was due to inhibition of the caveolae endocytosis pathway. The transfection activity of DOTAP lipoplexes was not affected by genistein, confirming published observations (*18*). Treatment of cells with both genistein and Baf.A1 prevented the Baf.A1-induced increase in the transfection activity of rCPP-A polyplexes. The transfection activity of NLS-containing (rCPP-A and rCPP-C) polyplexes was almost equal to levels mediated in inhibitor-free conditions. However, there was a significant decrease in the transfection activity of rCPP-E polyplexes in the presence of both genistein and Baf.A1.

DISCUSSION

Polyplexes sensitive to redox potential gradients represent promising gene delivery vectors because of a favorable safety profile and flexibility for use in delivery of a wide range of nucleic acids. Reducible polypeptides used in the preparation of such polyplexes are typically based on a single peptide

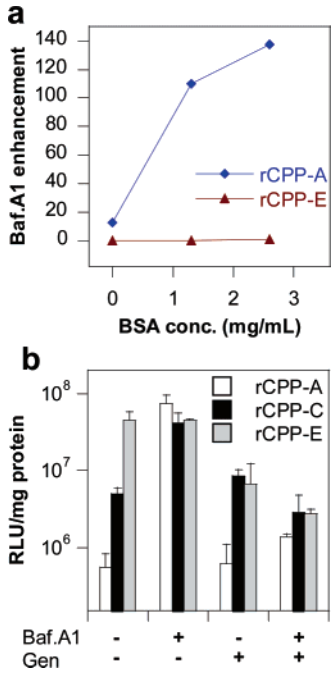

Figure 8. (a) Effect of BSA on Baf.A1-induced enhancement of luciferase expression in B16F10 cells (Baf.A1 enhancement = [RLU/mg with Baf.A1]/[RLU/mg without Baf.A1]). (b) Effect of Baf.A1 and caveolae inhibitor genistein (Gen) on the transfection activity of polyplexes in B16F10 cells. Luciferase activity was measured after 24 h, and results are shown as mean RLU per milligram of cellular protein and SD from triplicate samples.

sequence and are prepared either by DNA-template polymerization or by DMSO-mediated polycondensation (*7*, *11*, *14*, *21*). The only example of a reducible polypeptide composed of several peptides of different amino acid sequences was reported by Rice et al. and used the DNA-template polymerization (*22*). Here, we use a polycondensation approach to demonstrate the feasibility of synthesizing reducible sequential polypeptides consisting of two peptides with distinct biological functions (Figure 1). This approach represents a viable alternative of preparing high molecular weight repetitive polypeptides with a better control over the amino acid sequence and molecular weight than traditional chemical synthesis and an easier alternative to polypeptide synthesis using genetic engineering methods, which provide the ultimate control over the properties of polypeptides (*23*).

Peptide selection for the synthesis of rCPPs was based on recognizing the importance of endosomal escape and nuclear transport for the efficacy of DNA polyplexes. To enable endosomal escape of the polyplexes, HRP peptide containing histidyl residues capable of buffering in the endo/lysosomal pH range was used. The sequence of the HRP peptide was selected on the basis of previous findings that high His content is required for efficient transfection (*7*, *24*). Two trihistidyl blocks were separated by lysyl residues to improve DNA binding capability. To provide the polyplexes with potential nuclear localization capability, NLS peptide was used that was derived from the importin α binding SV40 T antigen sequence (*13*, *25*). Neither of the two peptides used here requires a free terminus for their activity. In cases where the N- or C-terminus of a peptide is required for its activity, a single Cys residue can be placed at the opposite end and used in the oxidative polycondensation scheme as an end-capping functionality. The copolymerization proceeded readily for all five HRP/NLS ratios tested and resulted in the formation of high molecular weight linear polypeptides. No information could be obtained about the distribution of the HRP and NLS blocks in the polypeptides. The fact that the content of the two peptides in rCPP is close to that in the

reaction mixture (Table 1) suggests similar reactivity of both peptides, and therefore, it is likely that HRP and NLS blocks are randomly distributed in the rCPPs.

As expected, the HRP-containing rCPPs exhibited better DNA condensation ability at slightly acidic pH of 5 because of higher protonation levels of the His residues. The principle of the redox sensitivity of rCPP/DNA polyplexes was demonstrated in cell-free conditions by determining the concentration of NaCl required to dissociate the polyplexes in reducing and non-reducing environment. It is assumed that the disulfide bonds in the backbone of the rCPP chains are cleaved in the reducing environment of DTT. The resultant short cationic HRP and NLS peptide residues then display lower affinity to the DNA and allow subsequent dissociation of the polyplexes at lower NaCl concentration. The concentration of NaCl required to dissociate the polyplexes is directly related to the affinity between DNA and polycations, which in turn depends, among other factors, on the molecular weight of the polycations (*16*, *26*). Because of the cooperative nature of polycation binding to DNA, the molecular weight dependence of the dissociating NaCl concentration is especially strong in the low-to-medium molecular weight range of the polycations and is therefore highly suitable to follow the degradation of rCPPs in the polyplexes. The observed NaCl concentration required to dissociate the polyplexes in reducing conditions (~0.3 M) was close to that of polyplexes based on control small peptides, confirming that reduction of the disulfide bonds of the rCPPs proceeds readily in the polyplexes.

Cellular delivery of intact nucleic acids is not the only goal in designing a successful delivery vector. The vector should be able to accomplish this without negatively affecting normal functions of the cell. The toxicity of polycations like PEI and their DNA polyplexes has been reported by a number of investigators in both in vitro and in vivo experiments. The studies suggest two types of cytotoxic action of PEI. The first type of toxicity originates from compromised plasma membrane integrity and occurs in the early stages of incubating the cells with PEI. The first phase of the cytotoxic activity of PEI is then followed by apoptosis caused by PEI-induced channel formation in the mitochondrial membrane (*27*, *28*). Structural features that most affect the way polycations interact with cells include charge density, molecular weight, molecular flexibility, and type of charged center. Rigid molecules have more difficulties attaching to the membranes than flexible molecules. Therefore, high cationic charge densities and highly flexible polymers, such as PEI, are expected to cause greater cytotoxic effects than those with low cationic charge density and more rigid chains. We have hypothesized that intracellular degradation of rCPP into short cationic fragments will significantly reduce the cytotoxicity because of the dependence of polycation toxicity on the molecular weight. The results obtained from the MTS assay, which measures metabolic activity of cells, seem to confirm the hypothesis because no significant toxicity was observed for any of the tested rCPPs up to 300 μg/mL, while PEI showed $IC_{50} \approx 10$ μg/mL.

To further assess the short-term acute cytotoxicity of rCPPs, studies were performed to measure the amount of LDH released in the early stages of incubation. It is expected that during the early stages of incubation, the plasma membrane disruption by extracellular polycations will be the main contributing factor to the observed LDH release. Even though the reducible polycations are not degraded in the cell culture medium, their acute toxicity measured in the LDH assay is minimal when compared to control PEI. Only at the highest rCPP concentrations (300 μg/mL) do the levels of LDH release suggest substantial membrane perturbation. Because of the strong dependence of polycation toxicity on their molecular weight, it is important to analyze possible cellular sites of rCPP degradation before drawing any conclusions. The intracellular reduction of disulfide bonds of rCPPs is most likely mediated by small redox molecules like glutathione (GSH), either alone or with the help of redox enzymes. GSH is the most abundant intracellular sulfhydryl present in millimolar concentrations inside the cell but only in micromolar concentrations in the blood plasma (*29*). The intracellular glutathione concentration is an additive function of both the oxidized (GSSG) and the reduced forms (GSH) of glutathione. The glutathione concentration and redox ratio (GSH/GSSG) are different in the various subcellular compartments, with the lowest redox potential in the cell usually found in the nucleus, where it is required for DNA synthesis and DNA repair as well as to maintain a number of transcription factors in a reduced state. The concentration of GSH has been reported to be about 4 mM in the cytoplasm and about 20 mM in the nucleus (*30*, *31*). The subcellular distribution of GSH suggests that intracellular reduction of disulfide bonds will proceed preferentially in the cytoplasm and nucleus. Even though some evidence also suggests the possibility of endosomal and lysosomal reduction of disulfide bonds (*32*), a recent report indicates that both the endosomal and lysosomal environments are oxidizing and that disulfide bond reduction proceeds rather inefficiently (*33*). Despite the oxidizing nature of the extracellular environment, the presence of redox-active sulfhydryl groups in numerous proteins on the cellular plasma membrane suggests that at least the microenvironment of the cell surface can also support redox reactions in and between certain surface proteins (*34*, *35*).

On the basis of our data and the above analysis, we assume that the reduced cytotoxicity of the rCPP polycations observed in the MTS assay is due to the intracellular reduction of the disulfide bonds resulting in short fragments with decreased binding affinity to membranes, nucleic acids, and vital proteins inside the cell. The limited ability of rCPPs to damage cell membrane and release the LDH is predominantly due to favorable (compared to PEI) structural features such as lower charge density and higher chain rigidity. It might be also possible that plasma membrane reduction of rCPPs contributes to their favorable cytotoxic properties. To enable more direct and unambiguous evaluation of the contribution of disulfide bond reduction to the cytotoxicity of reducible polycation, reducible and nonreducible polycations with similar chemical structures should be used instead of comparing peptide-based polycations with PEI. Such studies are currently underway in our lab using reducible and nonreducible forms of poly(L-lysine) (*15*).

One of the disadvantages in employing short bioactive cationic peptides as carriers in gene delivery lies in their nonspecific interactions with nucleic acids, which can hinder their biological activity. Polyplexes formed using short cationic peptides also show less efficient transfection (*7*) and are less stable because of the less prominent cooperative effect (*16*). These major limitations in utilizing bioactive peptides can be overcome by the use of reversible polymeric forms of the peptides, such as demonstrated here. Analysis of the transfection data of the rCPP/DNA polyplexes reveals that of the two peptides used in rCPP synthesis, HRP is more important than NLS for the transfection activity. The activity increases in all cell lines with increasing content of HRP. The increase in transfection activity of HRP-rich polyplexes with increasing N/P ratio suggests an important contribution of the free polypeptides to the polyplex activity (*36*). It was expected that an optimum HRP/NLS composition might exist at which maximum transfection activity would be observed. The results, however, suggest no clearly measurable effect of an NLS role in the rCPP/DNA activity. The apparent lack of NLS contribution to enhanced activity of the rCPP may be explained by several factors. The

NLS activity in DNA polyplexes is limited, as suggested by numerous reports demonstrating only modest enhancing effect on the transfection (*25*, *37*−*39*). The large size of the plasmid DNA and the large particle size of the polyplexes might be another factor, which limits the nuclear delivery. The notion that the size of the nucleic acid may play a role in the nuclear transport of polyplexes is supported by recent findings that rCPP containing the NLS sequence (rCPP A, B, C, D) can mediate nuclear delivery of siRNA (*40*). Yet another reason for the apparent lack of NLS effect on the rCPP activity may lie in the loss of NLS sequences from the surface of the polyplexes in the reducing environment of cytosol by the cleavage of the disulfide bonds. Finally, it may be possible that even if a small increase in efficiency of nuclear delivery mediated by the NLS is achieved, it may not manifest itself by a significant enhancement of reporter gene expression (*41*, *42*).

The contribution of the buffering capability of HRP to the overall transfection activity of rCPP polyplexes was tested by conducting the experiments in the presence of chloroquine and Baf.A1. The lysosomotropic activity of chloroquine is known to preferentially enhance activity of polyplexes based on polycations with no buffering potential, and as such, the chloroquine-mediated enhancement of transfection can serve as a measure of the importance of the buffering component in the polyplexes. This is clearly documented especially in the fast-growing B16F10 cells where the chloroquine enhancement ratio decreases with increasing HRP content. In the other two cell lines tested, the same effect is observed only in the three rCPPs with the highest HRP content. To complement the chloroquine data, we conducted the transfection experiments also in the presence of the inhibitor of vacuolar type H^+ ATPases, Baf.A1. Since polycations with pH buffering properties require exposure to an acidic environment for their activity (*43*), inhibition of the vacuolar ATPases by Baf.A1 should inhibit activity of the polyplexes based on such polycations (*17*). Dependent on the cell line and conditions used, our data show great qualitative and quantitative differences in the effect of Baf.A1 on the transfection activity of rCPP polyplexes. When the experiments were conducted under our standard transfection conditions (i.e., in the presence of 10% FBS), only the results in MCF-7 cells confirm the expected effect of Baf.A1 and show a significant decrease of levels of transgene expression for polyplexes with high HRP content and control PEI polyplexes (Figure 7c). Qualitatively different results are observed in B16F10 cells where a large increase of luciferase expression induced by Baf.A1 is observed, especially for rCPP with no or limited buffering capability, while no significant effect is seen for control PEI (Figure 7a). Most previous studies on the effects of Baf.A1 on transfection activity of polyplexes were conducted in serum-free conditions. Under serum-free conditions in B16F10 cells (Figure 7d), we observed that Baf.A1 exhibited the expected effect on the transfection activity of rCPP/DNA polyplexes in compositions containing comparatively higher amounts of the HRP peptide (D and E), which was compatible with a mechanism of action that depends on proton capture during the acidification process during endocytosis. Also, in HeLa and MCF-7 (Figure 7e,f), Baf.A1 demonstrated the expected effect on transfection activity of rCPP/DNA complexes compatible with the mechanism mentioned above. In all three cell lines, Baf.A1 decreases the luciferase expression of the polyplexes with the highest HRP content. The effect is best shown in HeLa and MCF-7 cells, while the data obtained in B16F10 cells are less clear and a Baf.A1-mediated increase of luciferase expression is still observed for rCPP-A even in serum-free conditions. This effect seems to be at least partially dependent on the amino acid sequence of the NLS peptide because no effect of such magnitude was observed for similar nonbuffering reducible polypeptides based on CKKKK-KKKKKKC or CGRKKRRQRRRGC peptides (data not shown). In addition, Baf.A1 caused no increase in cellular uptake of the polyplexes in B16F10 (data not shown). As shown in Figure 7, the Baf.A1 effect on the activity of rCPP-A polyplexes in B16F10 cells is strongly associated with the presence of serum. To determine if there is a specific component of the serum responsible for the observed effect, we have conducted the experiment in the presence of bovine serum albumin (BSA) (Figure 8a). Increasing the albumin concentration leads to increased transfection induced by Baf.A1 in rCPP-A polyplexes but has almost no effect on rCPP-E polyplexes. As reported previously, Baf.A1 is toxic to the B16F10 cells and causes significant levels of apoptotic cell death at 100 nM (*44*). To limit the adverse toxic effects of Baf.A1, control experiments were also conducted at 20 nM Baf.A1. In the presence of 10% FBS, the observed results showed similar effects of Baf.A1 on the transfection activity of rCPP-A demonstrated by ∼75-fold increase of luciferase expression (data not shown). The data obtained with the caveolae inhibitor genistein (Figure 8b) seem to suggest that Baf.A1 treatment may redirect at least some of the NLS-containing polyplexes to a caveolae-mediated uptake mechanism. Since this mechanism of cellular uptake avoids routing to the lysosomal degradative environment, it may be possible that avoidance of the lysosomal degradation of the polyplexes may be the reason for the observed Baf.A1 effect (*45*). It should be noted, however, that detailed understanding of the unexpected behavior of the NLS-containing polyplexes in the presence of Baf.A1 is not available at this moment and further detailed investigation of this phenomenon is beyond the scope of this manuscript.

CONCLUSION

In conclusion, the present studies demonstrate that reducible multiblock copolypeptides can be readily synthesized by an oxidative polycondensation. This synthetic approach allows an effective control of the relative content of individual building blocks of the copolypeptides, which is demonstrated here on the copolypeptides of the histidine-rich and NLS peptides. As such, this versatile approach should be suitable for generation of chemical libraries of copolypeptides consisting of a variety of bioactive peptide sequences. By use of the reducible copolypeptides, polyplexes sensitive to redox potential gradients can be formulated as promising gene delivery vectors. In comparison with control polyethylenimine, only minimum toxic effects of rCPPs are observed on the metabolic activity and membrane integrity of human endothelial cells. These findings are explained by a reductive intracellular and plasma membrane degradation and lower charge density and higher chain rigidity of the rCPPs than PEI. Transfection activity in all tested cell lines increases with increasing content of the HRP sequence in the rCPPs, while no clearly measurable effect of the NLS sequence is found. Overall, we believe that reducible co-polypeptides possess a number of advantageous features to make them an attractive tool for gene delivery.

The emergence of small interfering RNA (siRNA) opened a new opportunity to study gene functions in a genome. However, large-scale loss-of-function analyses further require cell-based high-throughput methods that allow simultaneous silencing of the huge number of genes by siRNA. In this study, we aim at fabricating the cell-based siRNA arrays that facilitate parallel introduction of multiple siRNAs into cultured mammalian cells. The siRNA arrays were prepared using surface chemical processes including the micropatterning of a self-assembled monolayer and the layer-by-layer assembly of siRNA and cationic lipid. We examined the feasibility of the siRNA array for the sequence-specific gene silencing in an array format. Furthermore, the effects of siRNA loading and culture period after transfection were studied to optimize cell-based assays on the siRNA arrays. The results obtained in this study demonstrated that our method provides the siRNA arrays with spatial specificity in gene silencing, which will serve to obtain a quantitative data set from the cell-based screens on siRNA arrays.

INTRODUCTION

Small interfering RNA (siRNA) have recently been recognized as a powerful tool for analyzing gene functions in mammalian cells (*1*). When introduced into cytoplasm, double-stranded RNA of ~21 nucleotides triggers RNA interference (RNAi) by which specific genes having homologous sequences are transiently silenced to yield mutants. The abnormal phenotypes caused by RNAi provide the biological readouts from which we can infer the functions of particular genes. Recently, we have gained deep insights into the cellular mechanism involved in siRNA-triggered gene silencing (*2, 3*), while advances in siRNA technology opened a new opportunity to study gene functions genome-wide (*4*−*7*).

The genome-wide RNAi screens require several methodological arrangements: A library of siRNA clones must be implemented to cover the huge number of genes. Efficient cell reporting systems are further needed to monitor phenotypic alterations on living cells. In addition, it is practically important especially for high-throughput screens to develop efficient and flexible platforms that permit parallel introduction of siRNA clones into living cells. Because the number of genes has reached a few tens of thousands, this is not straightforward by conventional microplate formats. To solve this problem, a number of groups have developed the cell-based arrays that allow parallel introduction of multiple siRNAs into cultured mammalian cells (*8*−*11*).

The idea of cell-based arrays for large-scale genetic screens was derived from the pioneering study by Ziauddin and Sabatini (*12*). In that study, expression constructs for defined cDNAs were printed together with cationic lipid and gelatin onto a glass slide in an array format. It was shown that, when cultured directly on the slide, cells were successfully transfected with released DNA to express individual cDNAs within the defined areas. This technology was immediately extended to the parallel transfection of siRNA into living cells (*8*−*11, 13*). In most cases, siRNA arrays were fabricated in a similar way to the plasmid DNA array as mentioned above, but simply replacing DNA with siRNA.

Although early studies (*8*−*11, 13*) succeeded in demonstrating the feasibility of the cell-based arrays for RNAi screens, further improvements are considered necessary to obtain quantitative and accurate data for finding out specific phenotypes from a large data set. First of all, it is obvious that low transfection efficiency would make experimental data difficult to interpret. Other important factors include deviation of transfection efficiency between different siRNAs on separate spots on a single array. Such deviation would make it difficult to distinguish small difference in phenotypic readouts, such as fluorescent intensity in an assay combined with a reporter system using mutants with green fluorescent protein (GFP). In addition, the efficiency of gene silencing at the different regions within a single spot is also a matter of utmost concern in quantitative analysis. Because the extent of gene silencing is expressed as a reduction rate of protein expression in total transfected cells, siRNA should be introduced to the cells on precisely restricted regions and, at the same time, homogenously to the entire cells over the spot.

Here, we present our attempts to fabricate cell-based siRNA arrays using surface chemical processes including the micropatterning of a self-assembled monolayer (SAM) (*14*−*16*) and the layer-by-layer (LBL) assembly (*17*) of siRNA and cationic lipid. In our previous study, cell-based arrays for the efficient overexpression of defined cDNAs were successfully fabricated using the LBL process on the micropatterned SAM (*18*). It was demonstrated that these processes provide an effective way to reproducibly introduce plasmid DNA into cells at the restricted regions on the array. The present study is therefore the extension of our outstanding method for the array-based loss-of-function assays using siRNA. In this study, photoassisted micropatterning of SAM was employed to create an array of small anionic dots on a glass substrate. The array was then utilized as a platform for loading siRNA with cationic lipid and plasmid DNA by the LBL process to obtain siRNA arrays. We examined the feasibility of our siRNA arrays for the sequence- and site-specific gene silencing. Furthermore, the effects of siRNA loading and culture period after transfection were studied to

optimize cell-based assays on the siRNA arrays. We show that the method used in this study provides the siRNA arrays with spatial specificity in gene silencing, which will serve to obtain a quantitative data set from the cell-based screens on siRNA arrays.

EXPERIMENTAL SECTION

Preparation of Patterned SAM. A glass plate ($22 \times 26 \times 0.5$ mm^3, Matsunami Glass Industries, Ltd., Osaka, Japan) was immersed in piranha solution (7:3, v/v 96% H_2SO_4/30% H_2O_2) for 5 min at room temperature to remove impurities and then washed with 2-propanol and MilliQ water. Thin layers of chromium (thickness: 1 nm) and gold (thickness: 49 nm) were sequentially deposited onto the purified glass plate in a continuous process with a vacuum evaporator (V-KS200, Osaka Vacuum Instruments, Osaka, Japan) operated at a pressure of $3-4 \times 10^{-4}$ Pa. Immediately after deposition, the plate was immersed in 1 mM 1-hexadecanethiol (Tokyo Kasei Kogyo Co., Tokyo, Japan) solution in ethanol at room temperature for 24 h to allow the formation of a methyl-terminated SAM (CH_3-SAM) on gold. The plate was washed with ethanol and water to remove unreacted alkanethiols, and dried under a stream of dried N_2 gas.

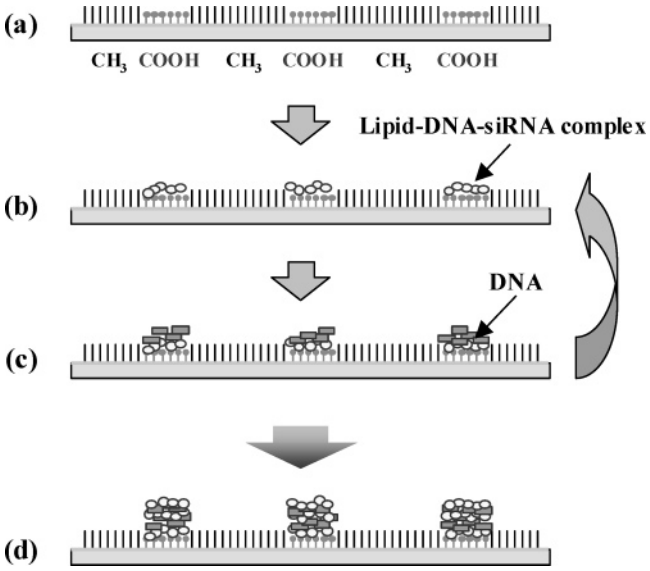
For micropattterning, the glass plate having a CH_3-SAM was radiated by ultraviolet light through a photomask (*15*). The photomask was made of a quartz plate deposited with a thick chromium layer having 5×5 circular holes with a diameter of 1 mm. The SAM surface was overlaid with the photomask and irradiated with ultraviolet light through the photomask from an ultrahigh-pressure mercury lamp (500 W, Optical Modulex SX-UI500HQ, Ushio Inc., Osaka, Japan). After 2 h irradiation, the plate was washed with ethanol and water to remove photocleaved alkanethiols and immediately immersed in a 1 mM solution of 11-mercapto-1-undecanoic acid (Aldrich Chemical Co., Milwaukee, WI) in ethanol. The plate was kept in the solution for 2 h at room temperature to allow the formation of a carboxylic acid terminated SAM (COOH-SAM) within the UV-radiated spots. Finally, the plate was washed with ethanol and water to remove unreacted alkanethiols and dried under a stream of N_2 gas.

siRNA and Plasmid DNA. Synthetic siRNAs of 21 or 22 nucleotides were purchased from Qiagen, Hilden, Germany, and Dharmacon, Inc., Colorado, U.S.A.: Specific siRNA for enhanced GFP (EGFP-siRNA): sense, 5′-GCAAGCUGACCCUGAAGUUCAU-3′; antisense, 5′-GAACUUCAGGGUCAGCUUG CCG-3′ (Qiagen). For *Discosoma* sp. red fluorescent protein (DsRed-siRNA): sense, 5′-AGUUCCAGUACGGCUCCAAUU-3′; antisense, 5′-UUGGAGCCGUACUGGAACUUU-3′ (Dharmacon). Nonspecific siRNA (control-siRNA): sense, 5′-UUCUCCGAACGUGUCACGUdTdT-3′; antisense, 5′-ACGUGACACGUUCGGAGAAdTdT-3′ (Qiagen). EGFP-siRNA conjugated with rhodamine at the 3′-end (EGFP-siRNA-Rho): sense, 5′-GCAAGCUGACCCUG AAGUUCAU-3′; antisense, 5′-GAACUUCAGGGUCAGCUUGCCG-3′ (Qiagen).

Plasmids used were pEGFP-C1 and pDsRed2-C1 (Clontech Laboratories, Palo Alto, CA), which encoded, respectively, EGFP and DsRed, under the control of the immediate early promoter of human cytomegalovirus. We refer to these plasmids as pEGFP and pDsRed, respectively. These plasmids were amplified in *Escherichia coli* DH5α and purified using a Plasmid Maxiprep Kit (Qiagen). A rhodamine labeled plasmid, pGeneGrip Rhodamine/GFP, was purchased from Gene Therapy Systems, California, and used as received.

Loading of siRNA and Plasmid DNA. The outline of array preparation is shown in Scheme 1. Opti-MEM (Gibco Life Technologies, Grand Island, NY), containing siRNA (0−20 μg/mL) and plasmid DNA (10 μg/mL), and lipofectAMINE2000

Scheme 1. Loading of siRNA by LBL Assembly To Individual Dots on the Micropatterned SAM[a]



[a] (a) Micropatterned alkanethiol SAM. (b) Adsorption of LDR complex. (c) Adsorption of plasmid DNA. The procedures (b) and (c) were repeated to obtain a siRNA-loaded array (d).

(30 μg/mL; Invitrogen Corp., Carlsbad, CA) was prepared and kept at room temperature for 20 min to form an electrolyte complex between the anionic nucleic acids (siRNA and plasmid DNA) and the cationic lipid. We refer hereafter to this lipid−DNA−RNA complex as LDR complex. The solution (approximately 200 nL) of LDR complex was manually pipetted to COOH-terminated dots on the patterned SAM and kept for 5 min to adsorb the complex to the dot surface. After aspiration of the LDR complex solutions, 200 nL of a plasmid DNA solution (10 μg/mL) in Opti-MEM was then pipetted to the LDR-adsorbed dots and kept for 5 min to adsorb DNA to the dots. These procedures were repeated to form a multilayer consisting of LDR−DNA−LDR−DNA−LDR. Finally, the entire surface of the array was washed with PBS and immediately used for further experiments without drying.

To determine the amount of plasmid DNA and siRNA loaded to the dots, either the rhodamine conjugate of plasmid DNA (pGeneGrip Rhodamine/GFP) or siRNA (EGFP-siRNA-Rho) was loaded to the patterned SAM together with unlabeled siRNA or plasmid DNA, respectively, in the same manner as described above. The dots were observed with a fluorescence stereomicroscope (MZ FLIII, Leica, Switzerland) equipped with a cooled-CCD camera (ORCA-ER; Hamamatsu Photonics K.K., Shizuoka, Japan). A fluorescence intensity was measured for the entire area within a single dot using an AQUA-Lite digital imaging software (Hamamatsu Photonics). The fluorescence intensity was converted to the amount of DNA or siRNA using a calibration curve obtained by depositing the rhodamine-labeled DNA and siRNA of known amount to a dot. The data was expressed as mean ± standard deviation for $n = 5$.

Gene Silencing on siRNA Array. Human embryonic kidney cell, HEK293, was obtained from Health Science Research Resources Bank, Tokyo, Japan, and grown in minimal essential medium (MEM; Gibco) containing 10% fetal bovine serum (FBS), 100 U/mL penicillin, and 0.1 mg/mL streptomycin at 37 °C under 5% CO_2. The cells were harvested by trypsin treatment and suspended in antibiotics-free MEM with or without 10% FBS. The siRNA-loaded array was placed in a 35-mm Petri dish, and the cells were seeded onto the array at a density of 6.7×10^4 cells/cm^2. The cells were incubated at 37 °C under 5% CO_2 to allow cell adhesion and cotransfection of plasmid DNA and siRNA. Then, the medium was replaced

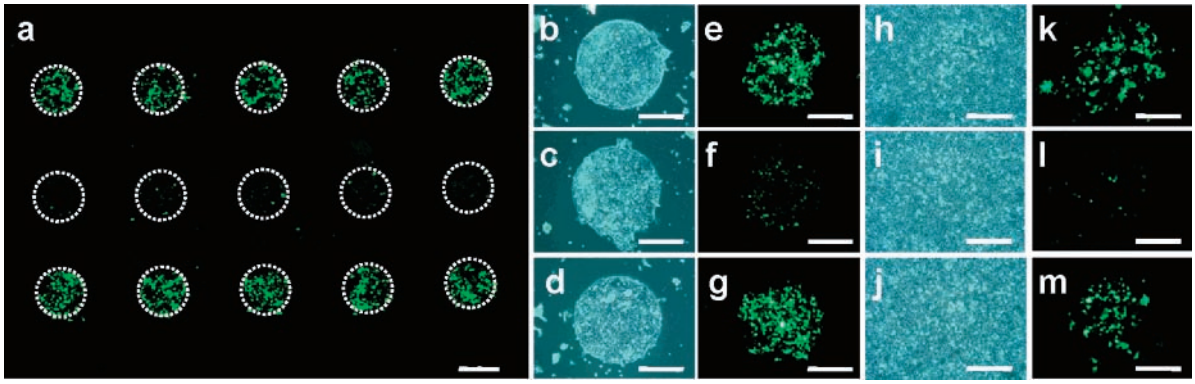


Figure 1. Gene silencing on the siRNA array. (a) Fluorescent image of the array on which HEK293 cells were seeded in the presence of FBS. The images were recorded 48 h after cell seeding. The position of dots is indicated in the image with dotted circles. (b−m) Higher-magnification images of selected dots. Cells were seeded in (b−g) the presence and (h−m) the absence of FBS. Phase contrast (b−d, h−j) and the corresponding fluorescent (e−g, k−m) images are shown for three cases: (top) pEGFP alone, (middle) pEGFP + EGFP-siRNA, (bottom) pEGFP + control-siRNA. Bar = (a) 1 mm, (b−m) 500 μm.

with a fresh MEM containing 10% FBS and antibiotics 6 h (for cells seeded without FBS) or 24 h (for cells seeded with FBS) after cell seeding. During culture, cells were observed with an epifluorescence microscope (Olympus, Tokyo, Japan). The fluorescence intensity of EGFP or DsRed was measured 48 h after cell seeding for the entire area of a dot using a fluorescence stereomicroscope (MZ FLIII, Leica). The efficiency of gene silencing (suppression efficiency) was determined according to the following equation

$$\text{Suppression efficiency (\%)} = [1 - (I_{\text{specific}}/I_{\text{control}})] \times 100$$

where I_{specific} is the fluorescent intensity of EGFP measured for the dot on which plasmid DNA and the specific siRNA were cotransfected, and I_{control} is that for the dot on which either of the plasmids were cotransfected with control siRNA. All the data presented in this paper were the average of three independent experiments.

RESULTS

Preparation of siRNA Array. The photoassisted patterning of CH_3-SAM and the subsequent formation of COOH-SAM within the radiated areas gave rise to the patterned SAM which possessed hydrophilic dots (COOH-SAM) surrounded by the hydrophobic regions (CH_3-SAM). Thanks to the difference in hydrophilicity, a liquid droplet pipetted was readily positioned to the hydrophilic dot. This feature served to confine siRNA to the dots, and eventually to produce well-formatted siRNA arrays.

Our previous study (*18*) revealed that the complex consisting of plasmid DNA and excess cationic lipid (lipofectAMINE2000) was attracted by the negatively charged surface of COOH-SAM through electrostatic interactions. From an analogy to the previous observation, it is plausible that the LDR complex employed in this study adsorbed ionically to the COOH-SAM surface. Similarly, alternate adsorption of LDR complex (cationic assembler) and free plasmid DNA (anionic assembler) is expected to produce a multilayer comprising siRNA, plasmid DNA, and cationic lipid. The amount of adsorbed siRNA and plasmid DNA reached, respectively, 38 ± 11 ng/cm^2 and 150 ± 67 ng/cm^2, when determined for a multilayer formed using 1 μg/mL siRNA solution after 5 adsorption procedures, i.e., a multilayer with LDR−DNA−LDR−DNA−LDR.

Sequence-Specific Gene Silencing on siRNA Array. Figure 1 shows the representative results of sequence-specific gene silencing on the siRNA-loaded array. When seeded in the presence of FBS, adhesion of HEK293 cells were restricted to the dots (Figure 1b−d), probably due to preferential adsorption of abundant serum proteins such as albumin and globulin onto hydrophobic regions between dots (*19*−*22*), which might suppress cell adhesion to these areas. The cell adhesion within dots may be promoted by the cationic nature of the uppermost surface, because the LBL process was always ended with the LDR complex. The typical number of cells was approximately 2500 cells per dot under the conditions employed here. EGFP expression was observed on the dots loaded with the EGFP-coding plasmid but lacking siRNA (5 dots on the upper line in Figure 1a) with a similar extent between the spots. Cells on the dots with both plasmid and control siRNA (5 dots on the bottom line in Figure 1a) also expressed EGFP, indicating the insignificant effect of nonspecific siRNA on protein synthesis. In contrast, a lower level of EGFP expression was observed on the dots with EGFP-coding plasmid and EGFP-siRNA (5 dots on the middle line in Figure 1a), indicating the suppression of EGFP synthesis. The fluorescence intensities were determined to be 0.19 ± 0.09 (EGFP-siRNA), 2.30 ± 0.31 (control-siRNA), and 2.36 ± 0.86 (no siRNA). The observed small deviations denote the reproducibility of transfection. These results suggested that both plasmid and siRNA were transferred from the array into the cells to reproducibly silence EGFP synthesis in sequence- and region-specific manners.

Similar to the case in which cells were seeded in the presence of FBS, sequence- and region-specific gene silencing was observed in the absence of FBS (Figure 1h−m). In the absence of FBS, however, cells adhered and grew on the entire surface of the array.

In order to gain deeper insights into the interactions operated in the LBL process, an amine-terminated SAM (NH_2-SAM) having a positively charged surface was used instead of a COOH-SAM. When the LDR complex (lipid/pEGFP/control siRNA) was adsorbed as the first assembler to obtain five-layered LDR−DNA composites, EGFP was expressed in HEK293 cells to a lower extent compared to the case with COOH-SAM (Supporting Information Figure S1), indicating that the combination of the COOH-SAM having an anionic surface and the LDR complex plays an important role in efficient transfection. This finding supports our hypothesis that the LDR complex bares cationic charges and that electrostatic interactions are predominant forces operated in the LBL assembly process. It seems that the cationic NH_2-SAM surface inefficiently attracts the LDR complex with the same sign of charges.

To clarify the mechanism by which the array functions, two different plasmids, pEGFP and pDsRed, were used respectively as a component of the LDR complex and anionic assembler, or vice versa. GFP-siRNA and control siRNA were used as a RNA component in the LDR complex. As shown in Figure 2, the plasmid contained in the LDR complex was efficiently expressed

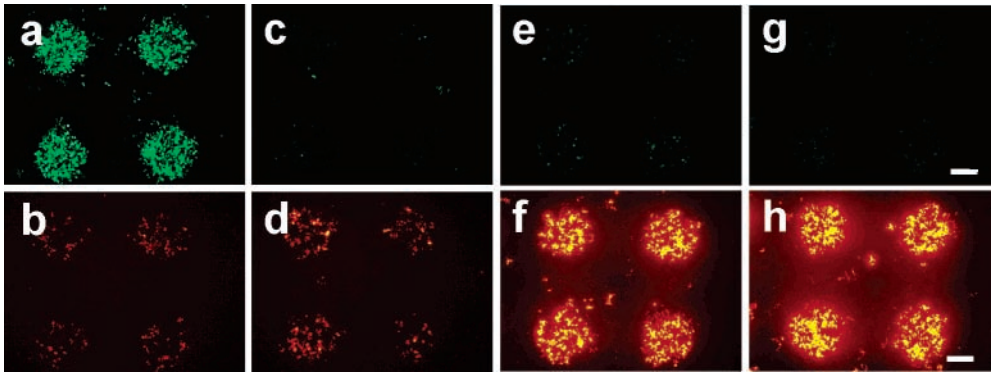

Figure 2. Fluorescent images of HEK293 cells transfected on siRNA arrays prepared from different compositions of siRNAs and plasmid DNAs. Plasmid DNA: (a−d) LDR; pEGFP, D; pDsRed, (e−h) LDR; pDsRed, D; pEGFP. siRNA: (a,b,e,f) control-siRNA, (c,d,g,h) GFP-siRNA. Bar = 500 μm.

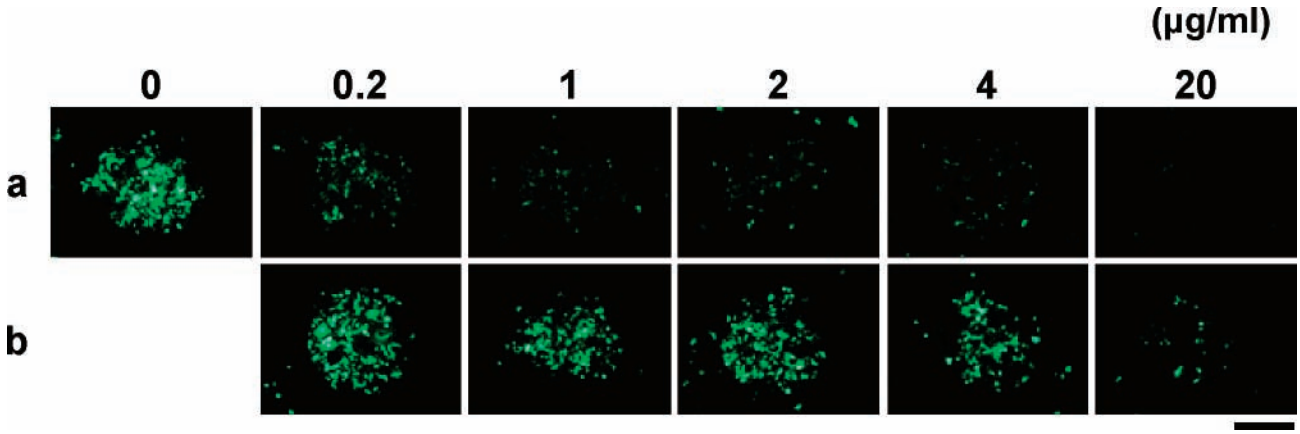

Figure 3. Fluorescent images showing the effect of siRNA loading on the silencing of EGFP expression. EGFP-siRNA (a) and control siRNA (b) were cotransfected with pEGFP. The concentration of siRNA used in the preparation of LDR complex is indicated above the corresponding photographs. Bar = 500 μm.

in the cells (Figure 2a,f), but that used as an anionic assembler was not (Figure 2b,e). The expression of GFP was efficiently suppressed by the GFP-siRNA incorporated to the LDR complex (Figure 2c,g). The DsRed expression was not influenced by GFP-siRNA, as expected (Figure 2d,h). These results demonstrate that plasmid contained in the LDR complex is transfected more efficiently than that used as an anionic assembler.

Attempts were further made to examine the feasibility of the SAM array for silencing endogenous targets. The LBL assembly was conducted using the complex consisting of GFP-siRNA and the lipid as cationic assembler and GFP-siRNA as anionic assembler. HEK293 cells stably transformed with GFP gene were plated to the array. It was found that the expression of GFP was efficiently reduced in a sequence-specific manner (data not shown).

Effect of siRNA Loading. Figure 3 shows the effect of siRNA loading on the suppression of EGFP expression. The LDL complex was prepared using different concentrations of siRNA together with the fixed concentration of plasmid DNA and cationic lipid. As is seen from the series of fluorescent images, silencing by specific siRNA (Figure 3a) was evident at a siRNA concentration of 0.2 μg/mL with a suppression efficiency of 76%. The highest suppression efficiency (=90%) was achieved at a siRNA concentration of more than 1.0 μg/mL. When a siRNA solution of relatively high concentration (>4 μg/mL, Figure 3b) was used, EGFP expression was impaired in the cells transfected with both EGFP-specific and control siRNAs. This is partly because of nonspecific inhibition of protein synthesis by highly concentrated exogeneous RNA (*23*). Another factor that affects EGFP expression may be altered charge balance in the LDR complex, which would affect introduction of plasmid DNA into cells. These results suggest that the most efficient, sequence-specific gene silencing can be achieved with 1.0−2.0 μg/mL siRNA under the experimental conditions employed here, while nonspecific effects are insignificant.

Time Dependence of Gene Silencing. As shown in Figure 4a, EGFP expression on the dots without siRNA and with control siRNA increased during the initial 4 days after cell seeding in the presence of FBS, reached the maximal expression level at day 4, and then gradually decreased afterward, most likely due to plasmid metabolism (*24*). In contrast, a low level of EGFP expression was observed on the dots loaded with EGFP-siRNA throughout the culture period. The highest suppression was achieved 48 h after cell seeding, with a suppression efficiency of 91% compared to the fluorescence intensity determined at the same time points for cells transfected with control siRNA. Similar time dependence was observed in the experiments in which cells were seeded in the absence of FBS (Figure 4b): The highest efficiency of gene silencing (80−90% compared to the results with control siRNA) was achieved after 48 h of culture on the array. When control siRNA was transfected, the expression of EGFP was lower in the absence of serum than in the presence of serum (open bars in Figure 4a,b). Although we do not have a clear explanation for this result at this moment, the composition of lipid/siRNA/DNA might not be optimal for transferring pEGFP under the serum-free condition. However, we also cannot rule out the possibility that control siRNA might cause nonspecific inhibition particularly in the absence of serum.

Parallel and Dual Silencing. We examined the feasibility of the array method for the parallel experimentation in which

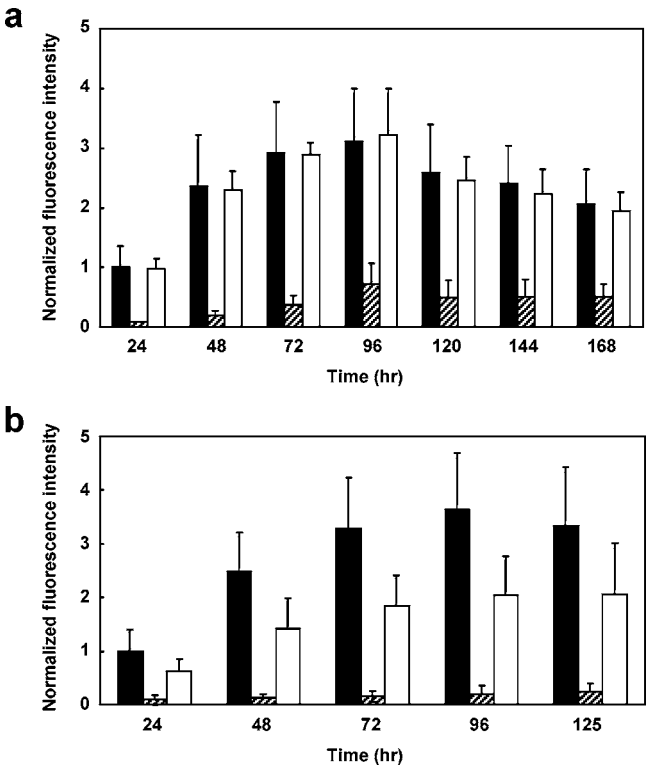

Figure 4. Time dependence of EGFP expression on the siRNA array. Cells were seeded in (a) the presence and (b) the absence of FBS (see Materials and Methods for details). Fluorescent intensities measured on the dots at various time points were normalized by that of control dot (no siRNA transfected) at 24 h. Closed bar: no siRNA transfected. Hatched bar: transfected with EGFP-siRNA. Open bar: transfected with control siRNA. The data are expressed as mean ± standard deviation for $n = 3$.

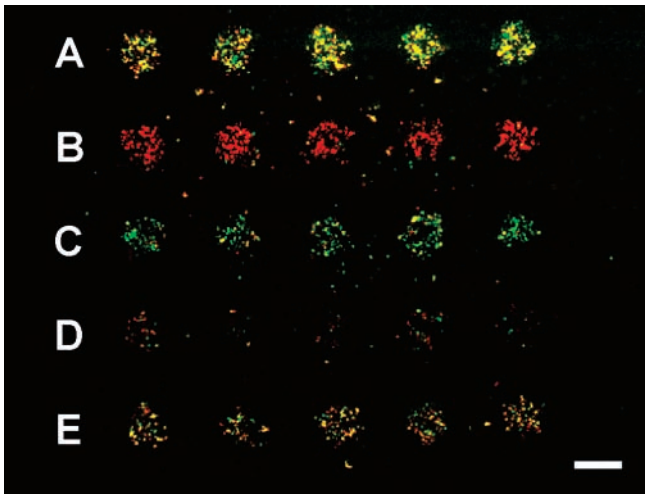

Figure 5. Parallel and dual silencing of gene expression on the siRNA array. The fluorescent images acquired using an interference filter for EGFP and DsRed were pseudo-colored and merged. Two plasmids, pEGFP and pDsRed, were loaded to all the dots (a) without any siRNA or together with (b) EGFP-siRNA, (c) DsRed-siRNA, (d) EGFP-siRNA plus DsRed-siRNA, and (E) control siRNA. Bar = 500 μm.

two different siRNAs are introduced separately to the cells on different dots on a single array. In addition, attempts were made to simultaneously introduce different siRNAs to the cells on a single dot. The result is shown in Figure 5. All the dots were loaded with both plasmids, pEGFP and pDsRed. The siRNAs used here (EGFP-siRNA and DsRed-siRNA) were specific for the distinct sequences in the respective cDNA, and hence are not expected to interfere with each other. As shown in Figure 5, transfection of siRNA resulted in the reasonable gene expression profiles expected from the combinations of siRNAs and plasmids. This simple demonstration shows the feasibility of our method for use in parallel and/or dual silencing analysis on a single array platform.

DISCUSSION

In order to conduct array-based large-scale RNAi screens to distinguish peculiar phenotypes from the multitude of negative backgrounds, it is primarily important that the reliability and accuracy of phenotypic readouts are guaranteed. To realize such an assay method, we prepared cell-based siRNA arrays using processes for micropatterning and LBL assembly. As demonstrated in the present study, our siRNA arrays allowed us to silence specific genes in a spatially restricted manner, which enabled us to quantitatively determine silencing efficiency. The silencing efficiency determined for cotransfected EGFP gene reproducibly reached ca. 90% under the optimum conditions.

A key technology in our siRNA array preparation is an alkanethiol SAM that provides well-characterized functional surfaces for further modifications (*14*, *25*). In combination with micropatterning techniques, the SAM finds a great opportunity to be applied in micro- and nanobiotechnology, especially in cell-based array technology (*26*−*31*). The UV-assisted patterning process used here is a simple and reproducible technique. The flexibility in pattern size and shape is of great advantage in restricting regions for siRNA loading over other methods such as, for instance, spotting by means of robotic arrayers. Using SAM, one can readily design distinctive surface chemistry between the patterns and the surrounding areas, which consequently affords higher restrictions on the regions of siRNA loading and, in particular cases, cell adhesion.

The spots created on the SAM had an area of 0.79 mm^2 (1 mm in diameter), on which approximately 2500 HEK293 cells were grown at confluence. Although this size is rather large for the conventional microarrays, much smaller spots will probably affect the reliability of quantitative data obtained from a single spot. For a quantitative study, the spot size should be carefully optimized depending on the cells used, because the confluent density is also a subject of cell types. In micropatterning of SAM, the size as well as the density of the spot can be easily changed by appropriately designing a photomask using the standard lithography-based technique.

One of the most important requirements for siRNA arrays is that nucleotides must be transiently loaded on the array before cell seeding. They were realized in this study by employing the LBL assembly process. The surface of COOH-SAM, possessing the negative charge under neutral conditions, attracts the LDR complex probably through electrostatic interactions, because the complexes formed with siRNA, plasmid DNA, and excess cationic lipid are expected to bear net positive charge. It is likely that the adsorption of the LDR complex overcompensates to generate cationically charged surface which, in turn, attracts excess anionic DNA to generate again an anionically charged surface. These alternate adsorptions were repeated to obtain 5 layers consisting of the LDR complex and plasmid DNA. It was shown that the silencing of the EGFP expression was restricted to the cells within the dot loaded with EGFP-siRNA, whereas EGFP expression in the cells at the surrounding regions outside the dot as well as those on the neighboring dots were not affected by released EGFP-siRNA. This observation suggests that the leaching of siRNA out of the dot was not significant until cells were seeded and that the concentration of siRNA was too low to silence gene expression in the adjacent cells.

The concentration of siRNA in a solution used for LDR complex formation had a large effect on the level of gene

silencing, with the optimum concentration of 1.0 μg/mL (Figure 3). This effect is most likely due to the fact that higher concentration of siRNA gives rise to the larger loading on the dot. The loading of too much siRNA might enhance the introduction of siRNA into cells, initiating nonspecific inhibition of protein synthesis as in the case with control siRNA. However, the large amount of siRNA seems to weaken the cationic nature of the LDR complex, which in turn would retard transfection of cells with plasmid DNA, reducing the level of EGFP expression.

It was further demonstrated that the micropatterned SAM-based siRNA array allowed parallel and dual silencing of specific genes (Figure 5). Taking into account the high silencing efficiency as well as the possibility of silencing endogenous genes, the array method presented here has potential as an excellent platform for large-scale RNAi screens. Moreover, assays using the siRNA array require neither the large number of cells nor the extremely expensive robotic machine for dispensing liquid. In addition, there is no difficulty in microscopic observation of living cells with an array format, in marked contrast to the assays using the conventional microplates.

In conclusion, the siRNA arrays prepared by means of micropatterning and LBL assembly processes enable us to precisely restrict regions of gene silencing. This feature will facilitate obtaining quantitative data from cell-based RNAi screens on mammalian cells. The flexibility of array design and the capability of controlling the cell adhesion area expand the future application of the siRNA arrays.

Cellular Uptake Mechanism of an Inorganic Nanovehicle and Its Drug Conjugates: Enhanced Efficacy Due To Clathrin-Mediated Endocytosis

Jae-Min Oh,[§] Soo-Jin Choi,[§] Sang-Tae Kim,[§] and Jin-Ho Choy*

Center for Intelligent Nano-Bio Materials, Division of Nanoscience and Department of Chemistry, Ewha Womans University, Seoul 120-750, Korea. Received May 23, 2006; Revised Manuscript Received September 4, 2006

We present the mechanism for the cellular uptake of layered double hydroxide (LDH) nanoparticles that are internalized into MNNG/HOS cells principally via clathrin-mediated endocytosis. The intracellular LDHs are highly colocalized with not only typical endocytic proteins, such as clathrin heavy chain, dynamin, and eps15, but also transferrin, a marker of the clathrin-mediated process, suggesting their specific internalization pathway. LDHs loaded with an anticancer drug (MTX−LDH) were also prepared to confirm the efficacy of LDHs as drug delivery systems. The cellular uptake of MTX was higher in MTX−LDH-treated cells than in MTX-treated cells, giving a lower IC_{50} value for MTX−LDH than for MTX only. The inhibition of the cell cycle was greater for MTX−LDH than for MTX only. This result clearly shows that the internalization of LDH nanoparticles via clathrin-mediated endocytosis may allow the efficient delivery of MTX−LDH in cells and thus enhance drug efficacy.

INTRODUCTION

Nanomaterials such as nanoparticles, nanohybrids, or nanocomposites, as well as nanoporous materials, have been widely studied in the view point of physics, chemistry, biosciences, and materials engineering (*1*−*6*). Among these nanomaterials, the use of nanoparticles as nanomedicines (*7*) for alternative drug delivery vehicles (*8*−*12*) or molecular diagnostics (*13*−*15*) has attracted much interest. Designing nanomedicines with enhanced and intentional functionalities required an understanding of the intracellular trafficking pathway of nanoparticles so that their fate in the cell can be predicted. Recently, it has been reported that certain nanoparticles, such as iron oxide and silica, as well as carbon nanotubes, are internalized in cells via the endocytic pathway (*11*, *16*−*21*). Endocytosis is a conserved process in eukaryotes by which extracellular components are taken up into cells by invagination of the plasma membrane to form vesicles that enclose these materials.

In the present study, we have used layered double hydroxide (LDH) to investigate the cellular interaction and uptake of nanoparticles, since LDH is considered as a candidate for drug delivery nanovehicles (*4*, *11*, *12*). LDHs are positively charged metal hydroxide layers in which solvated exchangeable anions are stabilized to compensate for the positive layer charges (*22*). Due to their hydrolysis behavior in acidic media and their anionic exchange capacity, LDHs are already used as antiacid and antipepsin agents (*23*). More recently, we have successfully demonstrated that the positively or neutrally charged LDHs which encapsulate anionic molecules are easily attached to the surface of a negatively charged plasma membrane, and in such a way their internalization into cells could be facilitated. Thus, LDHs may prove useful as gene or drug delivery vectors (*11*, *12*).

EXPERIMENTAL PROCEDURES

Preparation of LDHs. All reagents, $Mg(NO_3)_2{\cdot}6H_2O$, $Al(NO_3)_3{\cdot}9H_2O$, NaOH, $NaHCO_3$, methotrexate (MTX), and fluorescein 5′-isothiocyanate (FITC) were purchased from Aldrich Co. Ltd. An LDH with the formula $Mg_{0.68}Al_{0.32}(OH)_2(CO_3)_{0.16}{\cdot}0.1H_2O$ was prepared by coprecipitation at room temperature by titration to pH ∼ 9.5 with NaOH/$NaHCO_3$ solution (0.5 M/0.5 M). The obtained mixed solution was then hydrothermally treated at 100 °C for 24 h to give even particle size distribution (CO3−LDH), as described previously (*24*). LDH loaded with the anticancer drug MTX (MTX−LDH), and FITC-loaded LDH (FITC−LDH) were also prepared by respectively coprecipitation and anion exchange, as previously reported (*12*). Powdered MTX was dissolved in decarbonated water, and 0.5 M NaOH solution was added carefully to give a 0.032 M solution of MTX at pH 7. A mixed solution of $Mg(NO_3)_2{\cdot}6H_2O$ (0.032 M) and $Al(NO_3)_3{\cdot}9H_2O$ (0.016 M) was then added. The pH of the mixture was adjusted to 9.5 by NaOH titration. For FITC−LDH, a 0.032 M solution of FITC was prepared with decarbonated water and NaOH titration. LDH particles ($Mg_{0.68}Al_{0.32}(OH)_2(NO_3)_{0.32}{\cdot}0.1H_2O$) dispersed in decarbonated water were then added to the FITC solution. Both the MTX and FITC mixtures were left to stand for 48 h at room temperature. Each LDH sample (CO3−LDH, MTX−LDH, and FITC−LDH) was thoroughly washed with decarbonated water and dried in vacuum to give a powder, which was then redispersed in decarbonated water for the next step. The prepared LDHs were analyzed by powder X-ray diffraction (PXRD; Phillips PW3710 diffractometer with Ni-filtered Cu Kα radiation ($\lambda = 1.5418$ Å)) and by scanning electron microscopy (SEM; HITACHI S-4300).

Immunofluorescence/Confocal Microscopy. MNNG/HOS cells were seeded on 12-well slides (5×10^3 cells/well) and incubated with 50 μg/mL FITC−LDH for 10 min, 1, 2, or 3 h. The effects of a membrane entry inhibitor were examined by incubating the cells with 10 μg/mL chlorpromazine for 1 h at 37 °C followed by treatment with FITC−LDH as described above. The cells were washed several times with ice-cold PBS, fixed by incubation with freshly made 3% formaldehyde (containing 1.5% methanol) in PBS (pH 7.4) for 15 min, and permeabilized by incubation with 0.1% Triton X-100 in PBS for 10 min. The cells were incubated with primary antibodies against mouse clathrin, caveolin-1, eps15, dynamin, and Trans-

ferrin (Tf) for 1 h, washed, and then incubated with secondary antibodies conjugated to Texas Red (TR : Molecular Probe) or Alexa fluor 594 (Molecular Probe). The cells were then stained by incubation with 2 μg/mL DAPI dye for 10 min at room temperature in the dark. The cells were washed and visualized by fluorescence microscopy using an Axioplan Zeiss microscope and photographed with a digital camera (CCD). For laser scanning confocal microscopy (LSCM), the cells were visualized using a Zeiss LSM 510 confocal microscope (Carl Zeiss Inc., Germany) equipped with Argon (488 nm) and HeNe (543 nm) lasers for fluorescence. Image acquisition and analysis was done using LSM 510 software. Each experiment was repeated three times on separate days.

MTX Quantification by HPLC. Cells (1×10^6) were seeded on a 60 mm culture dish and treated with 50 μM/mL MTX or the equivalent amount of MTX−LDH with respect to MTX

concentration. After 0.5, 1, 2, 4, 8, and 24 h, the cells were washed twice with PBS, harvested by trypsin−EDTA treatment, and cell pellets were collected by centrifugation. After the pellets were washed twice with PBS, cell lysis buffer (20 mM Tris-HCl, pH 7.5, 1% Triton X-100, 150 mM NaCl, and 1 mM EDTA) was added and the pellets were incubated on ice for 20 min followed by ultrasonication for 20 s (Sonics & Materials Inc.) The crude cell lysates were then centrifuged at 10 000*g* for 5 min. Two volumes of acetonitrile were added to the cell supernatants and mixed vigorously to precipitate proteins. After centrifugation at 10 000*g* for 3 min, four volumes of chloroform were added to the supernatant to remove lipids. The supernatants were then collected by centrifugation at 2000*g* for 10 min and analyzed by high performance liquid chromatography (HPLC). MTX was quantified by HPLC using an Agilent 1100 series HPLC system on a C18 column (Nucleosil, 250 × 4.6 mm, Alltech). The mobile phase was 0.05 M KH_2PO_4, 10% acetonitrile, pH 6.6, and flow rate was 1 mL/min. Column temperature was maintained at a constant 40 °C and MTX was detected by UV absorption at 304 nm. Each experiment was repeated three times on separate days.

In Vitro Cell Viability/Cytotoxicity Studies. Cells were seeded onto 96-well plates at a density of 5×10^3 cells/well and incubated overnight at 37 °C in a 5% CO_2 atmosphere. The medium in the wells was then replaced with the fresh medium containing nanoparticles (CO3−LDH or MTX−LDH) in a concentration range of 0 to 2 mg/mL. After 72 h, cell viability and cytotoxicity were monitored by counting viable (trypan blue excluding) cells in a hemacytometer.

Flow Cytometric Analysis of the Cell Cycle. Cells (1×10^6) were treated with indicated concentrations of drugs for 20 h. They were then harvested by trypsin treatment, washed with PBS, and fixed by incubation with cold 70% ethanol on ice for 1 h. The fixed cells were washed with PBS and incubated with PI (40 μg/mL PI, 320 μg/mL RNase-A in PBS) at 4 °C for 30 min. Flow cytometric measurement was done on a flow cytometer (FACS Calibur, Becton Dickinson BD). For each analysis, 20 000 events were monitored.

RESULTS AND DISCUSSION

We used three different kinds of LDHs in this study. Pristine LDH with a formula of $Mg_{0.68}Al_{0.32}(OH)_2(CO_3)_{0.16}\cdot 0.1H_2O$ (CO3−LDH) and fluorescein isothiocyanate (FITC)-loaded LDH (FITC−LDH) were used to check, by electron and fluorescence microscopy, the cellular uptake pathway of the drug delivery vector, LDH. LDH loaded with the anticancer drug methotrexate (MTX) (MTX−LDH) was used to confirm the increased efficacy of drug delivery by LDH encapsulation. The powder X-ray diffraction patterns showed that each LDH had a typical LDH structure (Figure 1A), and the *d*-spacing of each LDH determined was 7.6, 20.8, and 18.8 Å, respectively, upon

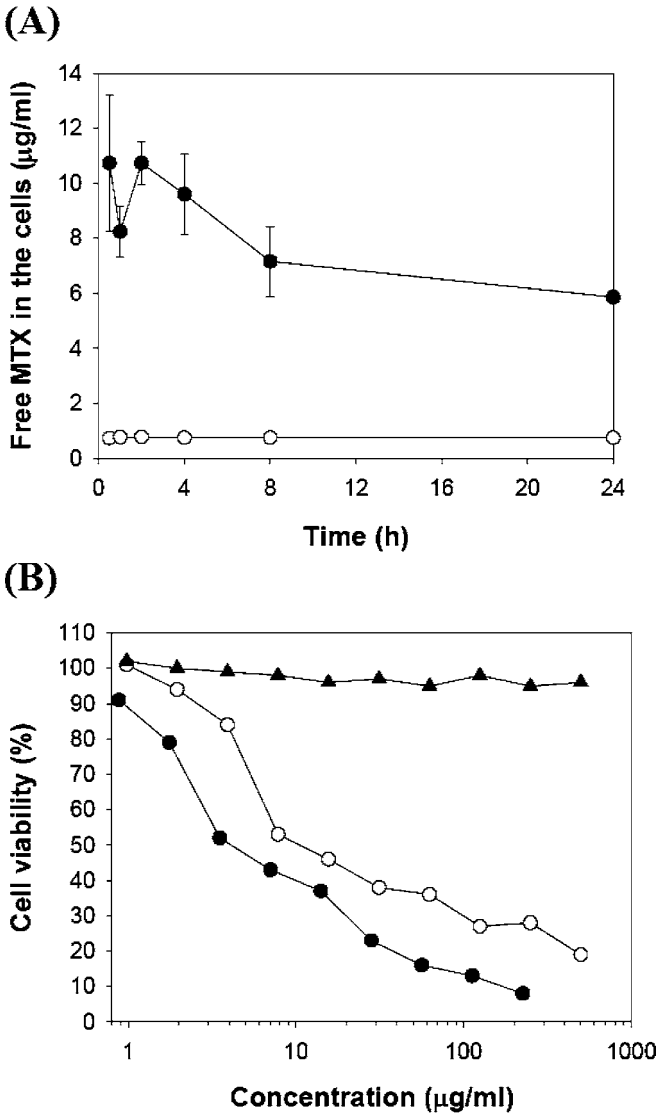

Figure 4. Cellular accumulation of free MTX molecules in MNNG/HOS cells treated with either MTX (○) or MTX−LDH (●), as quantified by HPLC analysis (see Experimental Procedures). (A). Cell viability/cytotoxicity of MNNG/HOS cells treated with LDH (▲), MTX (○), and MTX−LDH (●), as monitored by trypan blue exclusion, with respect to drug concentration (see Experimental Procedures) (B).

molecular size of interlayer anions such as CO_3^{2-}, MTX, and FITC (Figure 1B), as previously reported (*11*, *12*, *24*). The SEM results (Figure 1C) showed that all the LDH particles have characteristic hexagonal plate like morphology with uniform size. When dispersed in water (neutral pH), the particle size of approximately 150 nm was determined with narrow distribution as shown in Table 1, and the zeta potential of each colloidal LDH was positive or neutral. The LDH particle should have positive layer charge due to the isomorphous substitution of Mg^{2+} ions by Al^{3+} ions. This is the reason why negatively charged organic molecules such as MTX and FITC could be intercalated into the interlayer space of LDH. In this way, charge neutralization of the reaction could be satisfied (Table 1).

There are several possible endocytic pathways for internalizing LDH nanoparticles, such as clathrin-mediated endocytosis, caveolae-mediated endocytosis, and clathrin-caveolae-independent endocytosis. We determined the specific endocytic pathway used by the LDH nanoparticles for membrane entry by immunofluorescence and confocal microscopic studies. We used tumorogenic osteosarcoma MNNG/HOS cells treated with the fluorescent FITC−LDH to measure the intracellular fluorescence intensity with respect to time. The fluorescence microscopic images (Figure 2A) showed an increasingly strong fluorescent signal inside the cell as the incubation time increased to 2 h. For the immunofluorescence study, the cells were treated with FITC−LDH for 2 h, during which the maximum fluorescence intensity was attained, and stained with either anti-clathrin antibody or anti-caveolin-1 antibody both conjugated to TR. The immunofluorescence microscopic images showed that both the clathrin staining red fluorescence (TR) and the LDH green one (FITC) overlapped each other perfectly. Though the red immunofluorescent caveolin-1 was observed but faintly, no clear merged image could be seen when treated with the LDH fluorescence as shown in Figure 2B. MNNG/HOS cells treated with FITC−LDH and the anti-clathrin antibody showed that, as expected, FITC−LDHs were mainly located in the cytosol, with a perinuclear distribution and was highly colocalized with clathrin (Figure 2C). The magnified image (Figure 2D) revealed that the green FITC fluorescence (LDH) and the red fluorescent clathrin staining overlapped well to produce a yellow fluorescence. This result clearly suggests that clathrin-mediated endocytosis is the principal mechanism for the cellular internalization of LDH nanoparticles. Caveolae-mediated endocytosis does not appear to be responsible for LDH uptake.

We confirmed the clathrin-mediated cellular uptake of LDH nanoparticles by determining the involvement of certain accessory proteins related to clathrin-mediated endocytosis. Thus, we investigated whether FITC−LDH colocalized with typical endocytic proteins such as dynamin and eps15. Dynamin regulates endocytic vesicle formation in different endocytic pathways (*25*), and eps15 is involved in regulating clathrin-coated pit assembly (*26*). We incubated MNNG/HOS cells with FITC−LDH and stained them with antibodies against clathrin, dynamin, and eps15, with the red Alexa Fluor 594 conjugated to the secondary antibodies as the probe (Figure 3A). We found that FITC−LDH was well colocalized with clathrin, dynamin, and eps15. eps15 plays a critical role only in clathrin-mediated endocytosis by associating with the plasma membrane adaptor, the AP-2 protein (*26*), which is essential for receptor-mediated endocytosis. As a positive control, we also compared the internalization of FITC−LDH with that of Tf, which is well-known to undergo the clathrin-mediated endocytosis through the transferrin receptor (*27*). Intracellular FITC−LDH was highly colocalized with the Tf labeled with Alexa Fluor 594 (Figure 3B). This is consistent with the results seen for clathrin, dynamin, and eps15, confirming the clathrin-mediated internalization of LDH nanoparticles.

We confirmed LDH entry via clathrin-coated vesicles biochemically by studying the effect of chlorpromazine (CPZ), a clathrin inhibitor, on LDH entry. CPZ is a cationic amphiphilic drug that prevents clathrin-mediated endocytosis by disrupting the assembly of the clathrin adaptor protein at the cell surface (*28*). Thus, we incubated MNNG/HOS cells with CPZ before observing the cellular uptake of FITC−LDH. Unsurprisingly, clathrin inhibition gave rise to a considerable reduction of the uptake of the LDH particles (Figure 3C). Altogether, it is concluded that LDH nanoparticles are transported into MNNG/HOS cells principally via clathrin-mediated endocytosis.

The targeted entry of nanoparticles into cells is important in nanomedicines, as their specific intracellular delivery can considerably reduce drug toxicity and increase therapeutic effects. Drugs conjugated with a ligand that can be efficiently and specifically recognized by receptor-mediated endocytosis have been already used to deliver drugs into cells; for example, transferrin/transferrin receptor-mediated drug delivery (*29*, *30*). Thus, our results showing that LDH nanoparticles primarily select the clathrin-mediated process such as the transferrin ligand/receptor interaction for cellular entry suggest that they may prove promising as nanomedicines and drug delivery

Figure 5. G1 phase arrest of MNNG/HOS cells exposed to either MTX or MTX−LDH at different concentrations for 20 h. The cell cycle was studied by FACS analysis of PI-stained cells. DNA histograms are shown, with the *x*-axis representing the DNA content and the *y*-axis representing the cell number. Note that 10 and 320 μg/mL MTX are equivalent to 22 and 704 μg/mL of MTX−LDH, respectively, based on MTX content in MTX−LDH.

nanovehicles. Their intracellular trafficking mechanism may also be predicted, being transported to endosomes, and subsequently to the Golgi complex or/and lysosomes after uptake (*31*).

From our results, we would expect an enhanced internalization of the drug in vitro due to their being encapsulated in the LDH nanoparticles. Thus, we investigated the applicability of LDH nanoparticles as drug delivery nanovectors for anticancer chemotherapy using a well-known anticancer drug, MTX, a folate antagonist. MTX binds competitively and reversibly to dihydrofolate reductase and inhibits important biochemical pathways, including the syntheses of thymidine, purine, DNA, RNA, and proteins (*32*). MTX is used in patients with certain forms of leukemia, and also in patients with various malignant diseases, such as lymphoma, choriocarcinoma, osteosarcoma, and uterus, breast, lung, head, neck, and ovarian cancers. However, high doses of MTX are required because of the antifolate properties of MTX, which is one of the major disadvantages of MTX medication (*33*). Thus, new chemotherapeutic approaches are urgently needed to limit its toxic effects.

We prepared MTX−LDH and quantified the level of intracellular "free MTX in the cells" by HPLC to determine its accumulation in cells (Figure 4A). The concentration of MTX within MTX−LDH-treated cells was considerably higher than in the cells treated with MTX only at all incubation times. This result strongly suggests that in an osteosarcoma cell culture line, the clathrin-mediated endocytosis of LDH nanoparticles enhances the internalization of conjugated drug molecules. As shown in Figure 4B, MTX−LDH was more toxic than MTX only as demonstrated that the IC_{50} value of MTX−LDH in the cells was about 2.5 lower than that of MTX only which means that MTX−LDH penetrates the cell membrane more effectively than MTX only, resulting in a better efficacy. This result indicates that the drug efficacy of MTX−LDH significantly increased over MTX only, resulting from effective internalization of MTX−LDH. Furthermore, LDH alone does not influence the cell viability at levels up to 500 μg/mL (Figure 4 B).

We also investigated the effect of MTX and MTX−LDH on cell cycle distribution to confirm further the efficacy of MTX−LDH. The cell cycle consists of interphases (G1, S, and G2) and mitosis (M). During the G1 period, cells increase in size, produce RNA, and synthesize proteins for DNA formation. During the S phase, DNA replication occurs and the cells continue to grow, producing new proteins at the G2 phase. Nuclear and cytoplasmic division occurs at the M stage. We used fluorescence-activated cell sorting (FACS) analysis to study propidium iodide (PI)-stained cells treated with either MTX or MTX−LDH (Figure 5). Over 20 h, MTX and MTX−LDH treatments resulted in an accumulation of cells in the G1 phase and a decrease in the number of cells in the S and G2 phases versus control cells. This is probably due to inhibition of DNA synthesis and blockage at the G1/S boundary. However, the

inhibition of G1/S transition was more evident in MTX−LDH-treated cells than in MTX-treated cells at the same concentration (63.87% versus 75.09% at 10 μM/mL) and was considerably increased at higher concentrations of MTX−LDH. This suggests that using LDH as drug delivery vector effectively enhances MTX efficacy, consistent with above results (Figure 4A,B). LDH alone did not affect the cell cycle at concentrations between 1.5 and 384 μg/mL. The G1 checkpoint stops replication of cells with DNA damage and is involved the development of cancer. Proteins involved in the G1 checkpoint, such as p53, a tumor suppressor protein, and cyclin-dependent kinases may be targets for cancer therapeutics (*34*).

We have shown using immunofluorescence and confocal microscopy that LDH nanoparticles are internalized in MNNG/HOS cells via clathrin-mediated endocytosis. FITC−LDHs were highly colocalized with clathrin and Tf, and also clathrin-mediated endocytosis substrates, such as dynamin and eps15. We also studied the efficacy of MTX−LDH as a potential drug delivery nanovector. The cellular uptake of MTX−LDH was found to be considerably higher than that for MTX only, resulting in lower IC_{50} values and an increased inhibition of the G1 cell cycle.

LDH nanoparticles can stabilize MTX during cell permeation and intracellular trafficking by encapsulation and can release it in the cytoplasm in a stable and constant manner due to its anion exchange capacity in acidic pH. The most common endocytic pathway, the clathrin-coated pit process, for LDH uptake may contribute to the efficient delivery of MTX−LDH in the cells and thus enhance drug efficacy.

These results allow us to propose new directions in designing target-specific nanomedicine. Our research, particularly in designing drug delivery nanovehicles based on metal hydroxide nanoparticles, may provide a new strategy based on a better understanding of their cellular uptake pathways and intracellular delivery mechanism.

Binding, Electrochemical Activation, and Cleavage of DNA by Cobalt(II) Tetrakis-*N*-methylpyridyl Porphyrin and Its β-Pyrrole Brominated Derivative

Shivaraj Yellappa, Jaldappagari Seetharamappa,† Lisa M. Rogers, Raghu Chitta, Ram P. Singhal,* and Francis D'Souza*

Department of Chemistry, Wichita State University, 1845 Fairmount, Wichita, Kansas 67260-0051. Received June 5, 2006; Revised Manuscript Received September 26, 2006

The binding of nucleic acids by water-soluble cobalt(II) tetrakis-*N*-methylpyridyl porphyrin, (TMPyP)Co, and its highly electron-deficient derivative cobalt(II) tetrakis-*N*-methyl pyridyl-β-octabromoporphyrin, (Br_8TMPyP)Co, was investigated by UV−visible absorption, circular dichroism (CD), and electrochemical and gel electrophoresis methods. The changes of the absorption spectra during the titration of these complexes with polynucleotides revealed a shift in the absorption maxima and a hypochromicity of the porphyrin Soret bands. The intrinsic binding constants were found to be in the range of 10^5-10^6 M^{-1}. These values were higher for the more electron-deficient (Br_8TMPyP)Co. Induced CD bands were noticed in the Soret region of the complexes due to the interaction of these complexes with different polynucleotides, and an analysis of the CD spectra supported a mainly external mode of binding. Electrochemical studies revealed the cleavage of polynucleotides by (TMPyP)Co and (Br_8TMPyP)Co in the presence of oxygen preferentially at the A−T base pair region. Gel electrophoresis experiments further supported the cleavage of nucleic acids. The results indicate that the β-pyrrole brominated porphyrin, (Br_8TMPyP)Co, binds strongly and cleaves nucleic acids efficiently as compared with (TMPyP)Co. This electrolytic procedure offers a unique tool in biotechnology for cleaving double-stranded DNA with specificity at the A−T regions.

INTRODUCTION

Macrocyclic compounds that bind and cleave nucleic acids have gained importance as reagents to retrieve structural and genetic information and also to develop efficient chemical nucleases (*1*, *2*). Several metal ions and complexes have been attached to DNA-interactive groups to produce DNA chain scission. For example, Fe(II)−EDTA covalently bound to methidium as an intercalator (*3*) to oligonucleotides (*4*, *5*) and to oligopeptides/proteins (*6*, *7*) in the presence of dioxygen and a reducing agent efficiently cleaves DNA. Nuclease activity has been observed for complexes of porphyrins of Fe(III), Mn(III), Co(III), Cu(II), and Zn(II) under chemical and photochemical conditions (*2*, *8*−*17*). Hence, the porphyrin and its metal complexes have been extensively studied as models of DNA-reactive complexes (*18*, *19*). The majority of reports have concentrated on *meso*-tetra(4-*N*-methylpyridyl) porphyrin (TMPyP) and its metal complexes by spectroscopic methods. The cationic TMPyP has a high binding affinity for anionic DNA strands with association constants in the range of 10^5-10^7 M^{-1} (*20*−*22*). The DNA binding mechanism is dependent on both the sequence of the DNA strands and the structure perturbation of the porphyrin molecules (*23*, *24*). Additionally, the ionic strength of the solution is also known to influence the binding modes (*25*, *26*).

The interaction of porphyrins with DNA can occur through three types of binding modes, namely, intercalation, outside binding in the groove, and outside binding with self-stacking along the DNA surface. DNA footprinting investigations have revealed that Mn^{3+}, Fe^{3+}, Zn^{2+}, and Co^{2+} metal complexes of TMPyP bind to the A−T-rich regions of DNA in the minor groove while Ni^{2+} and Cu^{2+} complexes of TMPyP intercalate in the G−C-rich regions and bind in the A−T-rich regions by an outside binding mode (*27*, *28*). These metal derivatives of TMPyP were found to cleave DNA in the presence of oxygen and either a reducing or an oxidizing agent, namely, ascorbate, superoxide, and iodosobenzene (*27*). Fiel et al. (*29*) have reported that Fe^{III}−TMPyP can nick DNA without any added activating agent, while the studies by Praseuth et al. (*13*) have indicated that the photoactivation of Co^{III}−TMPyP (but not Mn^{III}−TMPyP) in the presence of O_2 can induce DNA cleavage. They have also demonstrated that Fe^{III}−TMPyP can degrade DNA in a few minutes without light irradiation but that the extent of degradation increased with exposure to light. The possible mechanism of the chemically activated cleavage process includes the generation of a reduced form of oxygen produced in a redox reaction of the metal ion with oxygen.

Among the different porphyrins employed for DNA binding studies, the positively charged (TMPyP)M is the most efficient in terms of binding and cleaving DNA as compared with either the neutral or negatively charged porphyrins. One way of improving the processes of binding and cleavage of DNA by porphyrins is by making the porphyrin ring more electrophilic while keeping the positive charges on the porphyrin macrocyle for its intrinsic affinity for DNA. This can be achieved by introducing one or more peripheral electron-withdrawing substituents like halogens at the β-pyrrole positions of the TMPyP macrocycle. The first part of this study addresses this issue by employing a highly electron-deficient, water-soluble β-brominated cobalt porphyrin (*30*−*32*) as a DNA binding and cleaving agent (Scheme 1).

Electrochemical methods can also be used to study binding and cleavage of DNA (*33*). Electrochemical methods offer several advantages for probing metalloporphyrin binding and DNA cleavage and can provide a useful complement to the widely used spectroscopic methods. These advantages include

the following: (i) Metal ion complexed macrocyclic compounds that are not amenable to spectroscopic methods, either because of weak absorption bands or because of overlap of electronic transitions with those of the DNA molecule, can potentially be studied via electrochemical techniques. (ii) Multiple oxidation states of the same species as well as mixtures of several interacting species can be observed simultaneously by electrochemical methods. (iii) Equilibrium constants (*K*) for the interaction of the metal complexes with DNA can be obtained from the shifts of peak potentials. (iv) Electrochemical analysis is a cleaner method that does not require addition of a reductant and, hence, makes the analysis of the reaction products easier. (v) Electrochemical methods also offer a wider range of potentials to activate molecules with different binding specifications that may not be activated by chemical methods and may also be useful in following the formation and consumption of electroactive species to study reaction mechanisms. (vi) Finally, the activation process can be studied using metalloporphyrin- or DNA-modified electrode surfaces. The modified electrodes offer distinct advantages of requiring smaller amounts of samples and well understood surface electrochemical phenomenon. In spite of all these advantages, utilization of electrochemical techniques to study DNA interaction and cleavage has been scarce (*33*−*36*). In the present study, we have also explored electrochemical methods to activate and cleave DNA by cobalt porphyrins. As shown here, the β-pyrrole brominated porphyrin exhibits better binding and cleavage of DNA under electrochemical conditions.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. (TMPyP)Co as a tetrachloride salt was purchased from Mid-Century Chemicals Co., Illinois, and used as received, while (Br_8TMPyP)Co as tetrachloride salt was prepared by following the reported procedure (*30*). Calf thymus DNA (CT-DNA), double-stranded (ds) poly[d(G·C)] and ds poly[d(A·T)], sodium dihydrogen phosphate, sodium phosphate dibasic, and cacodylic acid were obtained from Sigma Aldrich, while phi-X174 DNA was purchased from Promega. Tris base, boric acid, and EDTA were received from Fischer Scientific Chemicals Ltd., New Jersey.

Stock solution of CT-DNA was prepared by sonication at 0−5 °C. Concentration of DNA was determined by UV absorbance at 260 nm ($\epsilon_{260} = 6.6 \times 10^3$ M^{-1} cm^{-1}). Stock solutions of ds poly[d(G·C)] and ds poly[d(A·T)] were prepared in different buffers as mentioned in the text. A 0.05 M phosphate buffer of pH 10.5 and a cacodylic buffer of pH 7.0 were used in the study. Tris−borate−EDTA buffer of pH 8.3 was used as a loading buffer in electrophoresis experiment. Stock solutions of 1 μM each of (TMPyP)Co and (Br_8TMPyP)Co were prepared separately in deionized water. High purity nitrogen was used for deaeration.

Instrumentation. Electrochemical measurements were performed on a PAR electrochemical instrument model PARSTAT 2273 (Ametek, PAR, Oak Ridge, TN). The standard cell consisted of three electrodes that include the working electrode (platinum or glassy carbon electrode), the reference electrode (Ag/AgCl/3 M KCl), and an auxiliary electrode (Pt wire). In order to obtain reproducible results, the electrodes were cleaned with soft emery paper (600 Å), polished with 0.05 μm alumina, then sonicated (ultrasound bath) for 3 min and rinsed with deionized water before making a measurement.

The CD measurements were made on a 70 JASCO-J-810 spectropolarimeter (Tokyo, Japan) using a 0.1 cm cell at 0.2 nm intervals with five scans averaged for each CD spectrum.

The absorption spectra were recorded on a double beam UV−visible spectrophotometer (Shimadzu UV-1650 PC). A quartz cell of 1.00 cm was used for measurements.

Gel electrophoresis experiments were carried out on a Mini-Sub Cell GT from Bio-Rad and Bio-Rad Power PAC 1000 as power source.

Hypochromicity and Evaluation of Binding Constant. The hypochromicity in the Soret band of the cationic porphyrins caused by their interaction with CT-DNA/ds poly[d(A·T)]/ds poly[d(G·C)] was determined by performing absorption titration experiments wherein the concentration of the metal porphyrin complex is kept constant and the concentration of nucleic acid/polynucleotide was varied in cacodylic buffer of pH 7. Absorbance values were recorded at room temperature after each successive addition of CT-DNA/ds poly[d(A·T)]/ds poly[d(G·C)] [0.25−0.3 μL of CT-DNA or 1 μL of ds poly[d(A·T)]/ds poly[d(G·C)]] to (TMPyP)Co (0.005 μM for ds poly[d(A·T)] and ds poly[d(G·C)] or 0.05 μM for CT-DNA) or (Br_8TMPyP)Co (0.083 μM for ds poly[d(A·T)] and ds poly[d(G·C)] or 0.01 μM for CT-DNA) and equilibration (ca. 0.5 min). Buffer blanks were used to compensate for the dilution effect. The percentage of hypochromicity was determined from eq 1.

$$((I_f - I_b)/I_f) \times 100 \quad (1)$$

where I_f and I_b represent the optical density of the free porphyrin complex and the mixture of free porphyrin complex and that bound to DNA/ds poly[d(A·T)]/ds poly[d(G·C)], respectively. The absorbance data were fit to a Benesi−Hildebrand plot (*37*) of $I/\Delta I$ *versus* $1/C$ to evaluate the binding constant of (TMPyP)Co/(Br_8TMPyP)Co−DNA/ds poly[d(A·T)]/ ds poly[d(G·C)].

Circular Dichroism Measurements. CD spectra of CT-DNA/ds poly[d(A·T)]/ds poly[d(G·C)] were recorded in the presence of increasing amounts of (TMPyP)Co and (Br_8TMPyP)Co complexes (0.005−0.03 μM), separately in cacodylic buffer of pH 7.

Modification of Glassy Carbon Electrode. Stock solutions of CT-DNA, ds poly[d(G·C)] and ds poly[d(A·T)] were prepared in Tris-HCl buffer of pH 7.3 containing 0.1 M NaCl. These solutions were used for making the CT-DNA and ds poly[d(A·T)]/ds poly[d(G·C)] modified electrodes. To prepare a drop-coated electrode, 5 μL of CT-DNA solution was transferred to cover the glassy carbon (GC) electrode's surface, and then warm air (about 50 °C) was blown from a distance of 10 cm to dry the electrode's surface to make a film. Later,

(TMPyP)Co/(Br_8TMPyP)Co was transferred on the DNA film modified electrode and dried by warm air. Electrochemical deposition was performed by holding the potential at a suitable reduction potential for the metalloporphyrin film. Stable GC/DNA/metalloporphyrin films can also be prepared by keeping the potential of the DNA-modified electrode at −40 mV (*versus* Ag/AgCl) in a metalloporphyrin aqueous solution as is done in consecutive cyclic voltammetry (*38*).

Solutions were thoroughly deoxygenated, unless otherwise indicated, by bubbling with nitrogen that had been previously saturated with water. During the data acquisition, a nitrogen atmosphere was maintained over the solution in the cell.

Bulk Electrolysis. In order to conserve the nucleic acid and ds poly[d(A·T)]/ds poly[d(G·C)], it becomes essential to carry-out the bulk electrolysis experiments on a small scale. A homemade microcell assembly consisting of an outer working electrode compartment and an inner compartment with a porous Vycor plug containing the reference and counter electrodes was used to electrolyze different amounts of the metalloporphyrins with phi-X174 DNA, ds poly[d(G·C)], and ds poly[d(A·T)] at a concentration of 0.6 μg. The reaction mixture was placed in the working electrode compartment. The other compartment consisted of supporting electrolyte, phosphate buffer of pH 10.5. The working solution compartment volume was maintained at 120 μL. The electrolysis was carried out in the dark for 10 h at −450 mV in the presence of (TMPyP)Co or (Br_8TMPyP)Co. During electrolysis, O_2 was bubbled into the solution. The working, counter, and reference electrodes used were Pt foil, Pt wire, and Ag/AgCl, respectively.

Gel Electrophoresis. A sample (120 μL) of either phi-X174 DNA or ds poly[d(G·C)] or ds poly[d(A·T)] each with (TMPyP)Co or (Br_8TMPyP)Co was electrolyzed for 10 h in the presence of oxygen. From this, a fraction of the reaction mixture (20 μL) containing phi-X174 DNA (0.1 μg), (TMPyP)Co (8.3 μL, 1 μM), and phosphate buffer of pH 10.5 (10 μL) was added followed by 2 μL of the loading dye (bromophenol blue dye and sucrose) into the wells of a 1% horizontal agarose gel containing 1 μg/mL ethidium bromide. The gel electrophoresis was carried out at 4 V/cm for 1 h in 89 mM Tris base, 89 mM boric acid, 2 mM EDTA buffer of pH 8.3. After electrophoresis, the DNA bands were visualized and photographed under ultraviolet light.

RESULTS AND DISCUSSION

Absorption Studies. Absorption spectroscopy is one of the convenient tools for examining the interaction between ligands and nucleic acids. The different modes of interaction of a metal complex with DNA can be studied not only by this technique but also by circular dichroism (CD) spectroscopy. Binding of (TMPyP)Co or (Br_8TMPyP)Co to native and synthetic polynucleotides induces changes of the absorption spectrum in the Soret band. The extent of the shift and hypochromism depends on the nature of the polynucleotide, the porphyrin, and the binding mode. Generally, the change is large for intercalation and small for a groove binding or stacking mode. The absorption spectra of both (TMPyP)Co and (Br_8TMPyP)Co were recorded separately in the presence of increasing amounts of nucleic acid/ds poly[d(G·C)]/ds poly[d(A·T)] in cacodylic buffer of pH 7. The representative absorption spectra of (TMPyP)Co−ds poly-[d(A·T)] and (Br_8TMPyP)Co−ds poly[d(A·T)] are shown in Figure 1, panels a and b, respectively. Upon successive addition of ds poly[d(A·T)], ds poly[d(G·C)], and CT-DNA, the Soret bands of (TMPyP)Co were red-shifted from 433.9 to 440.3 nm, from 434 to 436 nm, and from 433.5 to 437.4 nm, respectively, while in the case of (Br_8TMPyP)Co, a blue shift in Soret band was observed from 468.5 to 462.7 nm, from 467.8 to 464.7 nm, and from 469.8 to 468.2 for ds poly[d(A·T)],

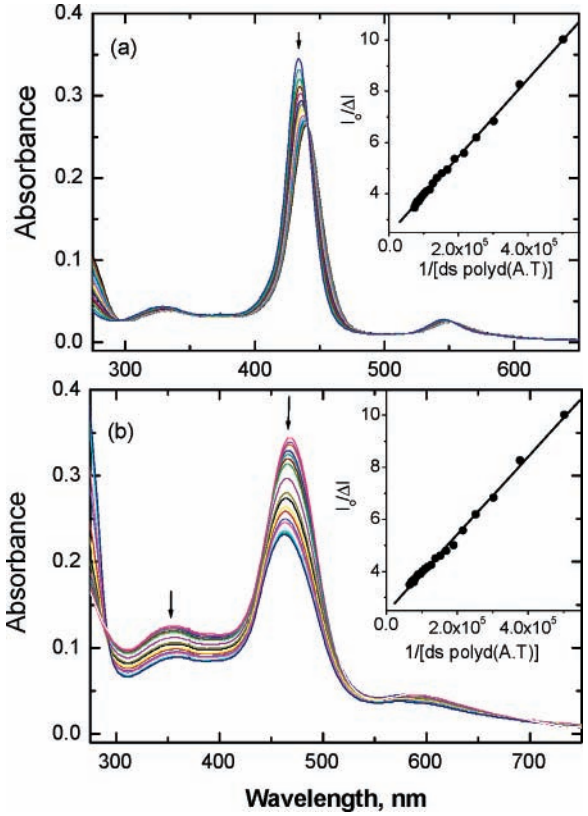

Figure 1. UV−visible spectrum of (a) (TMPyP)Co and (b) (Br_8TMPyP)Co on increasing addition of ds poly[d(A·T)] (0.004 μM each addition). The inset shows the Benesi−Hildebrand plot of $I/\Delta I$ *versus* $1/C$ constructed for the determination of binding constant.

ds poly[d(G·C)], and CT-DNA, respectively. (TMPyP)Co exhibited 9.25−13.58%, 3.71−24.18%, and 2.94−46.93% hypochromism, while (Br_8TMPyP)Co showed 3.43−6.49%, 3.50−35.0%, and 4.05−36.85% hypochromism with CT-DNA, ds poly[d(A·T)], and ds poly[d(G·C)], respectively. These results reveal that both porphyrin complexes interact with nucleic acid, ds poly[d(G·C)], and ds poly[d(A·T)].

In order to compare quantitatively the binding strength of the complexes, the intrinsic binding constants, K_b, of (TMPyP)Co and (Br_8TMPyP)Co with ds poly[d(A·T)], ds poly-[d(G·C)], and CT-DNA were determined from their spectral changes monitored in the Soret region. The intrinsic binding constants as evaluated from Benesi−Hildebrand plots (*37*) (see Figure 1 inset) were found to be 1.5×10^5, 7.0×10^5, and 8.0×10^5 M^{-1} for (TMPyP)Co and 8.0×10^5, 9.0×10^5, and 7.0×10^6 M^{-1} for (Br_8TMPyP)Co with ds poly[d(A·T)], ds poly-[d(G·C)], and CT-DNA, respectively. These results indicate that the (Br_8TMPyP)Co binds more strongly to ds poly[d(A·T)], ds poly[d(G·C)], and CT-DNA as compared with (TMPyP)Co.

Circular Dichroism Studies. Circular dichroism is a powerful technique for distinguishing the three main DNA-binding modes, namely, intercalation (negative CD), outside groove binding (positive CD), and outside stacking (bisignate CD) (*39*, *40*). The metalloporphyrin derivatives considered here do not display CD spectra in the absence of nucleic acid/ds poly[d(G·C)]/ds poly[d(A·T)], but CD spectra are induced in the Soret region when they are bound to nucleic acids/ds poly[d(G·C)]/ds poly[d(A·T)] due to the interaction between the transition moments of the achiral porphyrin and chirally arranged DNA base transitions. Representative induced CD spectra in the visible region for unbrominated and brominated cobalt porphyrins recorded in the presence of CT-DNA and ds poly[d(A·T)] are shown in Figure 2. The mole ratio of porphyrin to DNA base pairs, R value, was varied from 6.3 to 19.

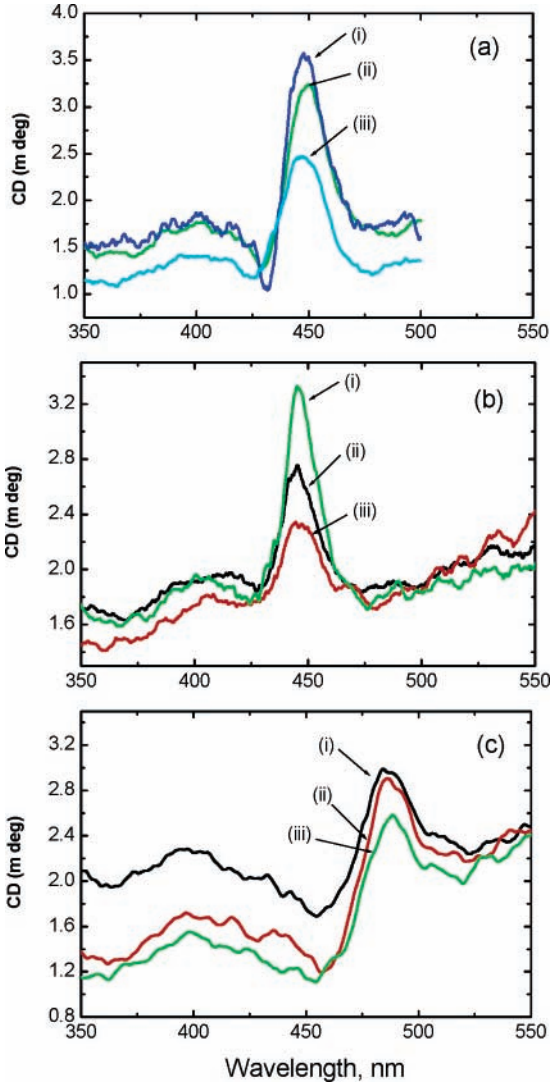

Figure 2. Circular dichroism spectrum of (a) CT-DNA interacting with (TMPyP)Co (i−iii represents 0.01 μM each addition), (b) poly[d(A·T)$_2$] interacting with (TMPyP)Co (i−iii represents 0.01 μM each addition), and (c) poly [d(A·T)$_2$] interacting with (Br_8TMPyP)Co (i−iii represents 0.01 μM each addition). All the spectra were recorded in cacodylic acid buffer at pH 7.0.

(TMPyP)Co examined in the present study displayed two positive induced CD signals in the Soret region at 402 and 447 nm in presence of CT-DNA (Figure 2a), at 400 and 444 nm in presence of ds poly[d(A·T)] DNA (Figure 2b), and at 397 and 485 nm for ds poly[d(G·C)]. The CD spectra of (Br_8TMPyP)Co exhibited positive bands at 398 and 487 nm for CT-DNA, at 398 and 485 nm for ds poly[d(A·T)] (Figure 2c), and at 397 and 483 nm for ds poly[d(G·C)]. These results reveal that the interaction is not through intercalation (*41*) but through an external binding mode at these investigated *R* values. It is important to note that although the macrocycle of the brominated cobalt porphyrin is severely distorted (up to 2 Å as estimated from computational calculations), it effectively interacts with CT-DNA/ds poly[d(A·T)].

The CD spectrum of CT-DNA (not shown) recorded in the absence of the porphyrin complex shows a positive band at 275 nm due to base stacking and a negative band at 245 nm due to helicity and is characteristic of DNA in the right-handed B form (*42*). The conformational changes observed in the UV region may be due to the effect of nucleobase or porphyrin (since porphyrin has weak absorption in the same region where the nucleobase moiety absorbs). In the presence of (TMPyP)Co or (Br_8TMPyP)Co, the negative band at 245 nm decreases while

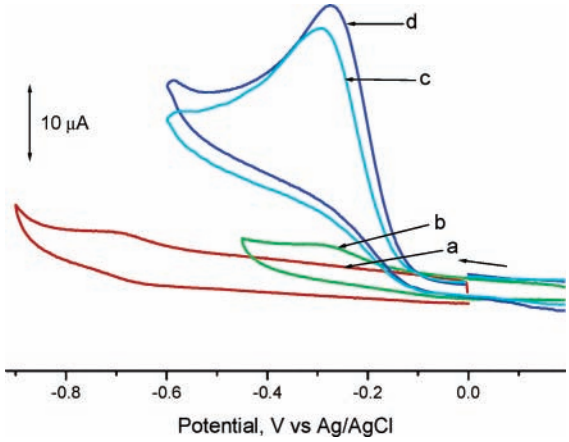

Figure 3. Cyclic voltammograms of (a) (TMPyP)Co and (b) (Br_8TMPyP) in nitrogen atmosphere and (c) (TMPyP)Co and (d) (Br_8TMPyP)Co in oxygen atmosphere. Solution composition was phosphate buffer at pH 10.5. Scan rate = 50 mV s^{-1}.

the positive band at 275 nm disappears and a negative peak appears at the same wavelength. These observations also indicate that the CT-DNA interacts with both (TMPyP)Co and (Br_8TMPyP)Co through an external binding mode. Both porphyrin complexes exhibited a strong negative band around the 280 nm region when bound to ds poly[d(A·T)] and a positive peak around 275 nm when bound to ds poly[d(G·C)]. These observations are in agreement with the reported literature (*43*).

Electrochemistry of (TMPyP)Co and (Br_8TMPyP)Co. Both cyclic voltammetry (CV) and differential pulse voltammetry (DPV) were employed to probe the binding of metalloporphyrins to DNA in solution. The selection of CV and DPV techniques is based on their different time scales (*44*). The time scale, τ, for a typical CV experiment is around 250 ms ($\tau \approx RT/(\nu F)$, R = molar gas constant, F = faraday constant, ν = scan rate, and T = temperature), while for a DPV under the same conditions, this value is 17 ms. As a result, the reversibility of heterogeneous electron-transfer kinetics will be different for these two techniques. DPV data were used to obtain quantitative information about the interaction of these metalloporphyrins with CT-DNA and phi-X174 DNA.

Figure 3 shows the cyclic voltammograms of (TMPyP)Co and (Br_8TMPyP)Co in the absence and presence of oxygen. The electroreduction behavior of these porphyrins is reversible to quasi-reversible. The potentials corresponding to the reduction processes are located at $E_{1/2} = -0.67$ and $E_{pc} = -0.29$ V vs Ag/AgCl, respectively, for (TMPyP)Co and (Br_8TMPyP)Co under the given solution conditions of pH 10.5. It is evident that the redox potentials for the brominated porphyrin are shifted positively as compared with that of the corresponding unbrominated derivative. Both metalloporphyrins reduce dioxygen as shown by the voltammograms in Figure 3c,d. In a previous study, we have shown the occurrence of a two-electron reduction leading to the formation of H_2O_2 by these porphyrins (*30*). The peak potentials for the catalytic reduction are located at $E_{pc} = -0.29$ and -0.27 V vs Ag/AgCl for (TMPyP)Co and (Br_8TMPyP)Co, respectively, while that of free O_2 is observed at -0.56 V. That is, the dioxygen reduction was easier by 20 mV by the more electron-deficient β-pyrrole brominated cobalt porphyrin. It may be mentioned here that a similar electrocatalytic reduction of dioxygen was observed when electrodes modified by drop coating the cobalt porphyrins were used.

As shown in Figure 4, DNA binding to metalloporphyrins yields diminished currents as a result of reduced diffusion of the porphyrin−DNA complex. This change is also accompanied by a shift in the redox potential values as a result of complex formation. The magnitude of this potential shift is dependent

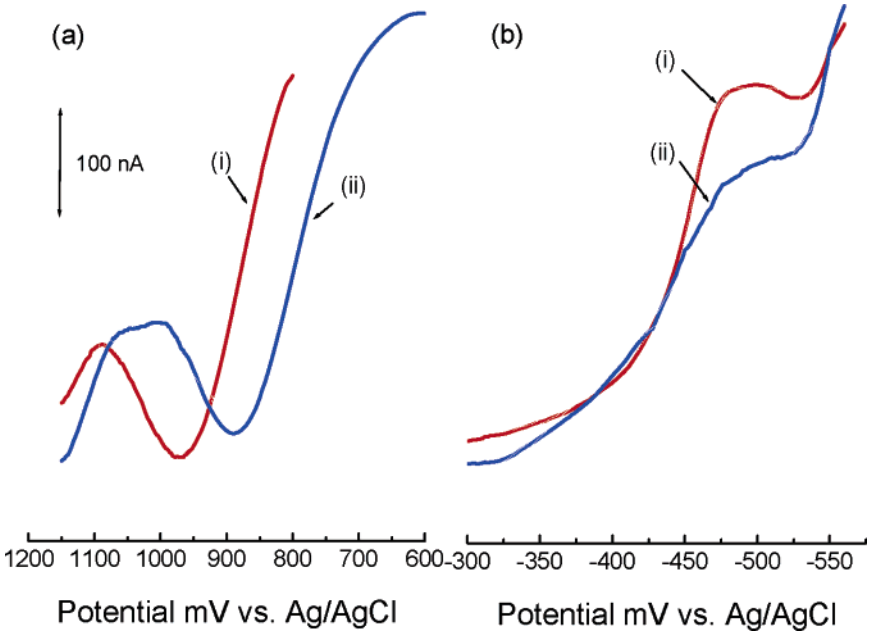

Figure 4. Differential pulse voltammograms for (a) the first oxidation and (b) the first reduction of (TMPyP)Co in the absence (curve i) and presence of ~10 equiv of calf thymus DNA (curve ii) in pH 7.4 buffer solution. Ionic strength = 0.1 M. Scan rate = 2 mV s^{-1}, pulse width = 0.50 s, and pulse height = 0.025 V.

upon the oxidation state of the metal ion. That is, a cathodic shift of ~0.1 V is observed for Co^{3+} (oxidized species) binding to DNA, while this shift is <20 mV for Co^{+} (reduced species) binding to DNA in Figure 4a,b. These results indicate a higher binding power of porphyrins having metal ions in higher oxidation state, a novel property that could be probed easily by electrochemical techniques.

DNA Cleavage by an Electrochemical Method. The DNA cleavage studies were performed by drop coating the electrode surfaces with the catalyst and DNA in order to conserve the catalyst and the substrate. In a typical cleavage experiment, a modified electrode of glassy carbon/DNA/(Br_8TMPyP)Co or (TMPyP)Co was immersed in phosphate buffer of pH 10.5, and voltammograms were recorded under nitrogen atmosphere. Thereafter the modified electrode was taken out of the solution. A stream of oxygen was bubbled through the phosphate buffer for 2 min. The electrode was then dipped into the aerated buffer, and voltammograms were recorded.

Figure 5, panels a and b, shows representative CV and DPV for (TMPyP)Co in the presence of CT-DNA in oxygen-saturated solution and (Br_8TMPyP)Co in the presence of ds poly[d(A·T)] in oxygen-saturated solution, respectively. The potential of the cyclic voltammogram was scanned, first, in the negative direction, and after crossing the potential corresponding to the catalytic reduction of dioxygen, the scan direction was changed into the positive direction. That is, oxygen was *in-situ* reduced, and its effect on the DNA cleavage was simultaneously monitored by following oxidative waves corresponding to the cleavage products. Two oxidative cleavages were noticed at the potentials of +0.72 and +1.01 V for CT-DNA (Figure 5a), at +0.73 and +1.02 V for phi-X174 DNA, and at +0.69 and +1.09 V for ds poly[d(A·T)] in presence of (TMPyP)Co and at +0.67 and +1.02 V for CT-DNA, at +0.65 and +0.99 V for phi-X174 DNA, and at +0.71 and +0.99 V for ds poly[d(A·T)] (Figure 5b) with (Br_8TMPyP)Co. Almost similar behavior was observed for rest of the nucleic acids and ds poly[d(A·T)]/cobalt porphyrins. In all of these experiments, currents of the second oxidation wave were found to be much larger than those of the first one suggesting occurrence of other oxidation processes at this potential. In order to identify the nucleobase pair of the nucleic acid at which the cleavage has

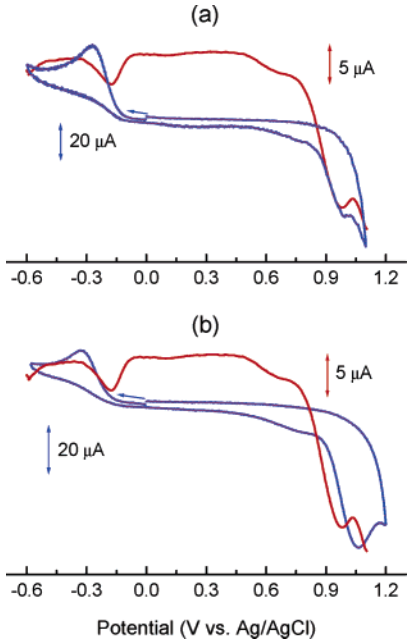

Figure 5. Cyclic (blue lines) and differential pulse (red lines) voltammograms of (a) (TMPyP)Co in the presence of CT-DNA in oxygen-saturated solution and (b) (Br_8TMPyP)Co in the presence of ds poly[d(A·T)] in oxygen-saturated solution. Conditions: phosphate buffer (pH 10.5); scan rate = 50 and 5 mV s^{-1} for CV and DPV, respectively.

occurred, in a control experiment we recorded the voltammograms by external addition of monomer nucleobases (adenine, guanine, thymine, and cytosine) into the electrochemical cell used above. Addition of adenine increased the intensity of the peak at ~0.67 V, while thymine increased the intensity of the peak at ~1.0 V suggesting that the DNA cleavage takes place at adenine and thymine base pairs. It may be mentioned here that when the potential was scanned initially in the positive direction, no wave at ~0.67 V corresponding to the oxidation of adenine was observed. However, the wave at ~1.0 V was observed with diminished currents. These results suggest that the wave at ~1.0 V may involve currents from reoxidation of

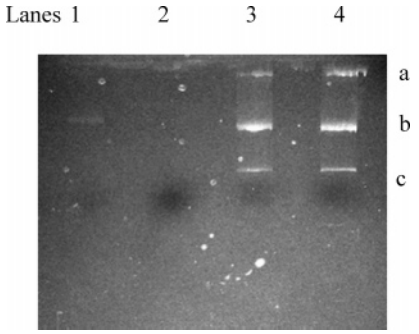

Figure 6. Electrophoresis results showing cleavage of phi-X175 DNA by electrolysis carried out in the presence of (TMPyP)Co and oxygen: Lane 1, nonelectrolyzed phi-X174 DNA, 0.1 μg; lane 2, bromophenol blue dye (2 μL); lane 3, electrolyzed plasmid phi-X174 DNA, 0.1 μg; lane 4, electrolyzed phi-X174 DNA, 0.125 μg. Conditions: agarose gel 1.0%; ethidum bromide 10 μL (1 μg/mL); potential applied = 40 V; loading dye 2 μL; electrophoresis time 1 h. Bulk electrolysis conditions: phi-X174 DNA with (TMPyP)Co and 0.05 M phosphate buffer of pH 10.5 with 10 μL of 10% of SDS at −0.45 V with continuous oxygen purging for 10 h.

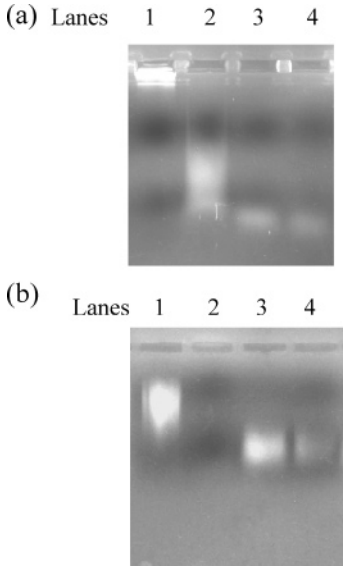

Figure 7. (a) Electrophoresis results showing cleavage of ds poly[d(A·T)] by electrolysis carried out in the presence of (TMPyP)Co and oxygen: lane 1, nonelectrolyzed ds poly[d(A·T)], 0.05 μg; lane 2, ds poly[d(A·T)], 0.075 μg, electrolyzed for 30 min; lane 3, ds poly[d(A·T)], 0.075 μg, electrolyzed for 45 min; lane 4, ds poly[d(A·T)], 0.05 μg, electrolyzed for 45 min. Conditions: agarose gel 1.0%; ethidum bromide 10 μL (1 μg/mL); potential applied = 40 V; loading dye 1 μL; electrophoresis time 1 h. (b) Electrophoresis results showing cleavage of ds poly[d(A·T)] by electrolysis carried out in the presence of (Br_8TMPyP)Co and oxygen: lane 1, nonelectrolyzed ds poly[d(A·T)], 0.05 μg; lane 2, loading dye, 2 μL; lane 3, electrolyzed [ds poly[d(A·T)], 0.075 μg, (TMPyP)Co, 1 μM, and phosphate buffer, pH 10.5; lane 4, electrolyzed [ds poly[d(A·T)], 0.075 μg, (Br_8TMPyP)Co, 1 μM, and phosphate buffer, pH 10.5. Electrolysis time = 45 min. Conditions: agarose gel 1.0%; ethidum bromide 10 μL (1 μg/mL); potential applied = 40 V; loading dye 1 μL; electrophoresis time 1 h.

the peroxide generated during the catalytic reduction of oxygen or direct oxidation of the nucleic acid and polynucleotide at this potential or both. Moreover, it was noticed that the ds poly[d(G·C)] did not show significant cleavage with (TMPyP)Co and (Br_8TMPyP)Co. That is, no peaks corresponding to guanine or cytosine were observed indicating cleavage preference over ds poly[d(A·T)] by the cobalt porphyrins. These results were further confirmed by gel electrophoresis experiments of electrolyzed ds poly[d(A·T)] and ds poly[d(G·C)] with (TMPyP)Co and (Br_8TMPyP)Co, discussed below.

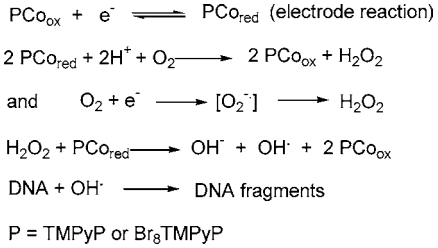
In order to understand the role of the electro-active cobalt in the DNA cleavage process, control experiments were performed utilizing free-base porphyrin, (TMPyP)H_2, and zinc porphyrin, (TMPyP)Zn (zinc is an electro-inactive metal), in the presence of oxygen and DNA. Under these experimental conditions, no peak corresponding to DNA oxidation products around +0.7 V was observed suggesting the absence of DNA cleavage by these porphyrins (see Supporting Information for figures). Similarly, the electrolysis products of the above reaction mixture revealed no DNA fragments by the agorose gel electrophoresis indicating the absence of a DNA cleavage process.

Electrophoresis Study—Cleavage of DNAs and Polynucleotides. Samples containing phi-X174 DNA and (TMPyP)Co in a phosphate buffer of pH 10.5 were submitted to voltammetric electrolysis at −0.45 V for 10 h with continuous oxygen purging. Figure 6 shows the gel electrophoresis of phi-X174 DNA with (TMPyP)Co. Bromophenol blue dye (2 μL) was injected at lanes 1−4 and nonelectrolyzed DNA was injected at lane 1. At lanes 3 and 4, 0.1 and 0.125 μg of electrolyzed reaction mixture of DNA with (TMPyP)Co were injected, respectively. After gel electrophoresis experiments, though no separations of phi-X174 DNA were observed in lane 1, there was a prominent band representing a supercoiled form of DNA at position a. A dark band in lane 2 is caused by the run dye. In lanes 3 and 4, form I of DNA (supercoiled form) of phi-X174 DNA observed at position a gradually disappeared, and form II (relaxed circular form) at position b was observed. It was only when the number of single-strand breaks become sufficient that the band corresponding to form III (linear form) was seen on electrophoresis gels. Thus, the double-strand breaks in DNA responsible for these linear forms of DNA have to be considered as resulting from coincidence of two random single-strand breaks. More predominant bands were observed with larger amount of electrolyzed reaction mixture (lane 3).

Figure 7, panels a and b, shows the cleavage of ds poly[d(A·T)] by (TMPyP)Co and (Br_8TMPyP)Co, respectively. In Figure 7a, the electrolysis was carried out at the potential of −0.45 V for 30 and 45 min separately with continuous oxygen purging. A broad band was observed with the reaction mixture that was electrolyzed for 30 min indicating incomplete cleavage of ds poly[d(A·T)] by (TMPyP)Co. However, complete cleavage of ds poly[d(A·T)] was noticed with the reaction mixture electrolyzed for 45 min. Hence, the electrolysis was carried out for 45 min in all subsequent experiments. Further, the band intensity varied with the concentration of ds poly[d(A·T)] in lanes. Similar behavior was observed with ds poly[d(A·T)] in the presence of (Br_8TMPyP)Co as shown in Figure 7b. A comparison between the cleaving behavior of (TMPyP)Co and (Br_8TMPyP)Co in Figure 7b (lanes 3 and 4) clearly shows that (Br_8TMPyP)Co is as good if not better than (TMPyP)Co. Similar experiments carried out for ds poly[d(G·C)] in the presence of either (TMPyP)Co or (Br_8TMPyP)Co revealed no cleavage products corresponding to guanine or cytosine. This confirms the earlier electrochemical claim that the cleavage of phi-X174 DNA and CT-DNA occur at A·T bases but not at G·C bases.

A possible mechanism for binding and cleavage of dsDNA (natural or synthetic) by the studied cobalt porphyrins is shown in Scheme 2. The initial step involves electroreduction of cobalt porphyrin to a reduced state. Based on the electrochemical data in Figure 3, one could assign Co^{II} as the species responsible for dioxygen binding in the case of (TMPyP)Co, while a Co^{I} species is responsible for dioxygen binding in the case of (Br_8TMPyP)Co. The reduced cobalt porphyrin binds dioxygen and catalytically reduces it to hydrogen peroxide. The hydrogen peroxide thus generated reacts with the reduced cobalt porphyrins generating hydroxyl radicals, which in turn cleave the DNA/ds poly[d(A·T)] at the A·T region. Although the present

Scheme 2. Proposed Mechanism of Electrochemically Activated Cobalt Porphyrin−Dioxygen-Induced DNA Cleavage



investigation could not fully explain the observed A·T selectivity, previous studies have confirmed such behavior of metalloporphyrin in the presence of chemical reducing agents (*27*, *28*). Currently, we are involved in covalently linking intercalators such as acridine to the β-brominated metalloporphyrins to probe the binding and cleavage studies by electrochemical techniques.

CONCLUSIONS

Cobalt(II) tetrakis-*N*-methylpyridyl porphyrin and its β-pyrrole brominated derivative have been successfully utilized for nucleic acid/ds poly[d(G·C)]/ds poly[d(A·T)] binding studies. UV−vis and CD studies have been carried out to determine the nature of binding between metalloporphyrin complexes and nucleic acid/ds poly[d(G·C)]/ds poly[d(A·T)]. The shift in the wavelength maxima, percent hypochromicity, and binding constant values indicate that the behavior of both cobalt porphyrins with nucleic acid/ds poly[d(G·C)]/ds poly[d(A·T)] is the same; however, the more electron-deficient brominated porphyrin binds more strongly when compared with unbrominated porphyrin. Circular dichroism studies revealed that the mode of binding is the same for both porphyrins and it is through an external binding mode. Electrochemical studies revealed that the cobalt porphyrins bind and catalytically reduce dioxygen to hydrogen peroxide and indicated that they complex with the employed nucleic acid, ds poly[d(G·C)], or ds poly[d(A·T)] as evidenced by the shift in the potentials and reduced peak currents. In the presence of dioxygen, the cobalt porphyrins electrochemically cleave nucleic acid and ds poly[d(A·T)]. Gel electrophoresis experiments were carried out to investigate the cleavage of DNA base pairs, ds poly[d(G·C)], and ds poly-[d(A·T)]. The electrochemical studies coupled with the gel electrophoresis results clearly suggest that the cleavage occurs at the A·T base pairs and not at the G·C base pairs. The procedure offers a unique tool to cleave dsDNA at A−T specific bonds in molecular biology.

A Comparison of the Emission Efficiency of Four Common Green Fluorescence Dyes after Internalization into Cancer Cells

Yukihiro Hama,[†] Yasuteru Urano,[‡] Yoshinori Koyama,[†] Marcelino Bernardo,[§] Peter L. Choyke,[†] and Hisataka Kobayashi*,[†]

Molecular Imaging Program, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20892-1088, Graduate School of Pharmaceutical Sciences, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan, and Research Technology Program, Science Applications International Corporation (SAIC)-Frederick, Frederick, Maryland 21702 Received June 9, 2006; Revised Manuscript Received August 9, 2006

In vivo optical imaging to enhance the detection of cancer during endoscopy or surgery requires a targeted fluorescent probe with high emission efficiency and high signal-to-background ratio. One strategy to accurately detect cancers is to have the fluorophore internalize within the cancer cells permitting nonbound fluorophores to be washed away or absorbed. The choice of fluorophores for this task must be carefully considered. For depth of penetration, near-infrared probes are ordinarily preferred but suffer from relatively low quantum efficiency. Although green fluorescent protein has been widely used to image tumors on internal organs in mice, green fluorescent probes are better suited for imaging the superficial tissues because of the short penetration distance of green light in tissue and the highly efficient production of signal. While the fluorescence properties of green fluorophores are well-known in vitro, less attention has been paid to their fluorescence once they are internalized within cells. In this study, the emission efficiency after cellular internalization of four common green fluorophores conjugated to avidin (Av−fluorescein, Av−Oregon green, Av−BODIPY-FL, and Av−rhodamine green) were compared after each conjugate was incubated with SHIN3 ovarian cancer cells. Using the lectin binding receptor system, the avidin−fluorophore conjugates were endocytosed, and their fluorescence was evaluated with fluorescence microscopy and flow cytometry. While fluorescein demonstrated the highest signal outside the cell, among the four fluorophores, internalized Av-rhodamine green emitted the most light from SHIN3 ovarian cancer cells both in vitro and in vivo. The internalized Av-rhodamine green complex appeared to localize to the endoplasmic vesicles. Thus, among the four common green fluorescent dyes, rhodamine green is the brightest green fluorescence probe after cellular internalization. This information could have implications for the design of tumor-targeted fluorescent probes that rely on cellular internalization for cancer detection.

INTRODUCTION

In vivo optical imaging during endoscopy or surgery requires targeted fluorescence probes with high signal-to-background ratios to detect cancer on the surface of tissues such as the peritoneum or colon. Although green fluorescent protein has been used to image tumors on internal organs in mice (*1*, *2*), green fluorescent probes are ordinarily used less for in vivo imaging than near-infrared probes because of their short penetration distance within tissue; however, when the surface is being imaged, green fluorophores hold considerable advantages over fluorophores that emit at higher wavelengths due to their higher emission efficiency and the ability to distinguish them from the background autofluorescence. There is a growing list of green fluorophores available for probe development (*3*, *4*). Fluorescein, a well-established bright green fluorescence dye, is approved for human use to perform retinal angiography and therefore has advantages based on its known safety profile in humans (*5*). More recently, three other green fluorescence dyes, Oregon green (OreG), rhodamine green (RhodG), and 4,4-difluoro-4-bora-3*a*,4*a*-diaza-*s*-indacene (BODIPY; BODIPY-FL), have been developed and are commercially available (Figure 1). Each of these has similar emission spectra to that of fluorescein, and it is not immediately clear which of these agents is preferred.

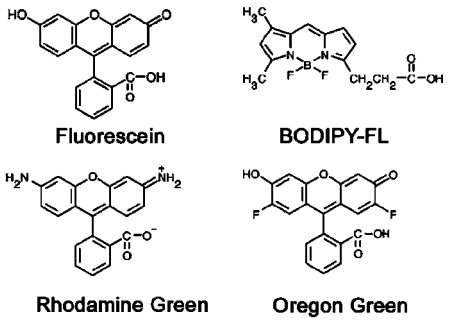

Figure 1. The chemical structures of the four green fluorescence dyes compared in this study.

In theory, one has only to look at the relative brightness of these fluorophores in vitro to determine which is the most desirable from the standpoint of optical probe development. However, it has recently been shown that there are considerable advantages if the fluorophore can be internalized within the cancer cell rather than simply remaining on its surface. For internalizing probes, noninternalized fluorophores are either washed away or absorbed, leading to a very high signal emanating from the cells and negligible background signal. For instance, when avidin-conjugated fluorescein was instilled in the peritoneum of mice bearing implanted ovarian cancers, it was either internalized within the cancers or absorbed through

the peritoneum, making it possible to detect submillimeter cancer implants (*6*). The specific uptake of avidin was based on its affinity for asialo-receptors found in abundance on the cell surface of various cancers, especially those which can form metastatic implants in the peritoneal space such as ovarian, colorectal, gastric, and pancreatic cancers (*7*). However, it is uncertain whether the optical properties of fluorophores change in the unique chemical environment of the cell (e.g., acidic pH, oxidation, aggressive proteolysis), and it is possible that the newer dyes might yield greater signal within cancer cells than fluorescein. This could impact the detectability of minute cancer implants at a time when they are most curable. In the present study, we conjugated four widely available green fluorescent dyes to avidin to study them both in vitro and in vivo before and after uptake into ovarian cancer cells and compared their emission efficiency and brightness.

EXPERIMENTAL PROCEDURES

Synthesis of Avidin-Conjugated Green Fluorescence Dyes. Avidin was purchased from Pierce Biochemical, Inc. (Milwaukee, WI); amido-reactive fluorescein, BODIPY (BODIPY-FL), OreG, and RhodG were purchased from Molecular Probes, Inc. (Eugene, OR). At room temperature, 400 μg (5.9 nmol) of avidin in 198 μL of Na_2HPO_4 was incubated with 12 nmol (2 μL/6 mM) of isothiocyanatobenzyl−fluorescein or BODIPY−, OreG−, or RhodG−succinoimidyl ester, respectively, in DMSO for 15 min. The mixture was purified with Sephadex G50 (PD-10; GE Healthcare, Milwaukee, WI). Avidin-conjugated fluorescein, BODIPY, OreGr, and RhodG samples (Av−FITC, Av−BODIPY, Av−OreG, and Av−RhodG, respectively) were kept at 4 °C in the refrigerator as stock solutions.

The protein concentrations of Av−FITC, Av−BODIPY, Av−OreG, and Av−RhodG samples were determined with Coomassie Plus protein assay kit (Pierce Chem Co., Rockford, IL) by measuring the absorption at 595 nm with a UV−vis system (8453 Value UV-Bis system, Agilent Technologies, Palo Alto, CA) using standard solutions of known concentrations of avidin (100, 200, and 400 μg/mL). Then, the concentration of fluorescein, BODIPY, OreG, and RhodG were measured by the absorption at 497, 508, 500, and 503 nm, respectively, with a UV−vis system (8453 Value UV-Bis system, Agilent Technologies, Palo Alto, CA) to confirm the number of fluorophore molecules conjugated with each avidin molecule. By changing the concentration of avidin solution, the number of fluorophore molecules per avidin was adjusted to be approximately 0.8.

Cell Culture. An established ovarian cancer cell line SHIN3 (*8*) was used for in vitro fluorescence microscopy, flow cytometry, and in vivo optical imaging for intraperitoneal disseminated cancer implants. The cell lines were grown in RPMI 1640 medium (Gibco, Gaithersburg, MD) containing 10% fetal bovine serum (FBS) (Gibco, Gaithersburg, MD), 0.03% L-glutamine at 37 °C, 100 units/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2.

Fluorescence Microscopy. SHIN3 cells (1×10^4) were plated on a cover glass bottom culture well and incubated for 16 h. Av−FITC, Av−BODIPY, Av−OreG, or Av−RhodG was added to the medium (30 μg/mL), and the cells were incubated for 1 h. Cells were washed one time with PBS, and fluorescent microscopy was then performed immediately and at 4 and 8 h after washing with PBS. Cells were incubated in RPMI 1640 medium without dyes after wash with PBS. Fluorescence microscopy was performed using an Olympus BX51 microscope (Olympus America Inc., Melville, NY) equipped with the following filters: excitation wavelength 470−490 nm, emission wavelength 515 nm long pass.

Flow Cytometry. One-color flow cytometry was performed for the assessment of fluorescing capability of Av−FITC, Av−BODIPY, Av−OreG, and Av−RhodG in SHIN3 cancer cells. SHIN3 cells (1×10^4) were plated on a 12-chamber culture well and incubated for 16 h. Av−FITC, Av−BODIPY, Av−OreG, or Av−RhodG was added to the medium (30 μg/mL), and the cells were incubated for 96 h. Cells were washed twice with PBS and incubated in RPMI 1640 medium without fluorophores. Cells were washed once with PBS, trypsinized, and flow cytometry was performed immediately and at 24 h after washing with PBS. The argon ion 488 nm laser was employed for excitation. Signals from cells were collected using a 530/30 nm band-pass filter. Cells were analyzed in a FACScan cytometer (Becton Dickinson, Franklin Lakes, NJ), and all data were analyzed using *CellQuest* software (Becton Dickinson, Franklin Lakes, NJ). The fluorescing capability of each fluorophore was referred to as mean fluorescence index (MFI).

Fluorescence Intensity of Four Dyes before Intraperitoneal Injection. To compare the fluorescing capability of the four fluorophore conjugates before intraperitoneal injection, fluorescence intensity and emission spectra of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were measured by the Maestro In-Vivo Imaging System (CRi, Inc., Woburn, MA) in arbitrary units. Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG (5 μg/390 μL PBS) were put in a nonfluorescent 96-well plate, and spectral fluorescence imaging was performed. The ratio of BODIPY, fluorescein, OreG, or RhodG molecules to avidin molecules was 0.8. To study the fluorescing capability under the acidic condition, 5 μg Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were diluted in 390 μL buffer mixture consisting of sodium dihydrogen phosphate and phosphate (pH 3.3). A band-pass filter from 445 to 490 nm and a long-pass filter over 515 nm were used for emission and excitation light, respectively. The tunable filter was automatically stepped in 10 nm increments from 500 to 800 nm, while the camera captured images at each wavelength interval with constant exposure. Spectral unmixing algorithms were applied to create the unmixed image of the four green dyes distinguished from background autofluorescence. A region of interest (ROI) as large as each well was drawn to determine the fluorescence intensity as well as the emission spectra of each of the four dye conjugates in order to exclude a dye that had the emission peak different from the fluorescein peak.

Tumor Model. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), National Research Council, and approved by the local Animal Care and Use Committee. The intraperitoneal tumor implants were established by intraperitoneal injection of 2×10^6 cells suspended in 200 μL of PBS in female nude mice (National Cancer Institute Animal Production Facility, Frederick, MD). Experiments with tumor-bearing mice were performed at 14 days after injection of the cells.

In Vivo Spectral Fluorescence Imaging. 50 μg each of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were diluted in 300 μL PBS and injected into the peritoneal cavities of mice with peritoneally disseminated cancer implants. Three hours after injection of each dye, each mouse was sacrificed at a time with carbon dioxide. Immediately after sacrifice, the abdominal cavity was exposed, and the four mice, each with a different fluorophore instilled in the peritoneum, were placed side-by-side on a nonfluorescent plate to compare the fluorescence intensity of tumors simultaneously. Spectral fluorescence images were obtained using the Maestro In-Vivo Imaging System (CRi, Inc., Woburn, MA). Whole abdominal images as well as close-up peritoneal membrane images were obtained. A band-pass filter from 445 to 490 nm and a long-pass filter over 515 nm were used for emission and excitation light, respectively. The tunable filter was automatically stepped in 10 nm increments from 500 to 800 nm, while the camera captured images at each wavelength

interval with constant exposure. The spectral fluorescence images consisting of autofluorescence spectra and a spectrum from each of the four green dyes were obtained and then unmixed on the basis of their spectral patterns using commercial software (*Maestro* software, CRi, Inc., Woburn, MA). The experiment was repeated three times ($n = 3$ mice per fluorophore).

Using the unmixed fluorescence images of the peritoneal membranes, fluorescence intensity of the cancer implants was semiquantitatively compared among the four dyes. An ROI as large as the peritoneal membrane was drawn inside the bowel, and a histogram (number of pixels at specific fluorescence intensity) was created using *ImageJ* software (http://rsb.info.nih.gov/ij/plugins/mri-analysis.html). Then, a threshold was set in the fluorescence intensity above which a pixel is counted. The total number of pixels (N) within the threshold range was calculated at a threshold value of t (eq 1).

$$N_{(t)} = \sum_{i=t}^{\infty} n_{(i)} \quad (1)$$

where i is the fluorescence intensity in arbitrary units, n is the number of pixels at the fluorescence intensity of i, t is the threshold value, and N is the total number of pixels within the threshold range ($i \geq t$). The common logarithm (log) values of N were calculated and plotted as a function of t. The regression line and the correlation coefficient (r) were calculated from these data sets (t and log N) by Microsoft *Excel 2003* (Microsoft, Redmond, WA). For comparison of the fluorescing capability or the "brightness" of each dye, the slopes of the regression line were compared among the four dyes. If the absolute value of r was less than 0.9, then slope values were not included.

RESULTS AND DISCUSSION

Optical Characteristics of Avidin-Conjugated Dyes. To investigate the optical characteristics of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG ex vivo, fluorescence intensity and emission spectra were measured under the same conditions: total dose, concentration of the solution, number of fluorophore conjugated per avidin, excitation/emission filters, and exposure time. All four spectra contained an emission peak at a wavelength of 550 nm when stepped in 10 nm increments at pH 7.4 (Figure 2a). The fluorescence intensities of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were 28, 238, 170, and 159 in arbitrary units, respectively (Figure 2b). Thus, ex vivo, the Av−FITC demonstrated the highest signal and the Av−BODIPY the lowest in PBS solution at pH 7.4. When these four dyes were put into the phosphate buffer at pH 3.3, the fluorescence intensities of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were 35, 33, 122, and 199 in arbitrary units, respectively (Figure 2b). That is, when the pH changed from 7.4 to 3.3, the fluorescence intensities of Av−BODIPY and Av−RhodG increased by 25% and 25%, respectively, although BODIPY emitted over $^1/_5$-fold less fluorescence than the other three dyes, when conjugated with avidin. In contrast, Av−FITC and Av−OreG decreased by 86% and 28%, respectively.

Intracellular Av−RhodG Demonstrates Progressive Fluorescence after Internalization. SHIN3 cells were incubated with each of the four fluorophores for 1 h, and fluorescent microscopy was then performed immediately and at 4 and 8 h after washing with PBS (Figure 3). No visual differences were seen among the different fluorophores at any of these time points except for the 8 h image obtained using Av-RhodG, which showed very bright fluorescent dots within the cytoplasm and was so intense that exposure times were halved to create the image to avoid overwhelming the dynamic range of the camera (Figure 3). The images also revealed that the Av−RhodG was clearly internalized within the endoplasmic vesicles within the cytoplasm. These data suggest that Av−RhodG behaves differently than the other three dyes regarding fluorescent intensity and the stability within the cells.

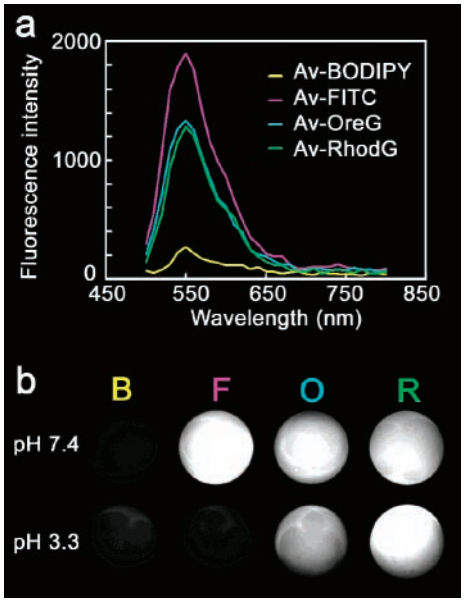

Figure 2. Optical characteristics of avidin-conjugated BODIPY, FITC, OreG, and RhodG. 5 μg Av−BODIPY, Av−FITC, Av−OreG, or Av−RhodG in 390 μL PBS (pH 7.4) or the mixture of sodium dihydrogen phosphate and phosphate (pH 3.3) were placed in a nonfluorescent 96-well plate and spectral fluorescence image was obtained. The ratio of BODIPY, FITC, OreG, or RhodG molecules to avidin was 0.8 in all cases. (a) Emission spectra. All four dyes had the same emission peak at a wavelength of 550 nm, but the fluorescence intensity was different, with Av−FITC the highest, followed by Av−OreG, Av−RhodG, and Av−BODIPY. (b) Fluorescence intensities of Av−BODIPY (B), Av−FITC (F), Av−OreG (O), and Av−RhodG (R) were 28, 238, 170, and 159, respectively, in arbitrary units (a.u.), with Av−FITC the highest and Av−BODIPY the lowest under pH 7.4. However, under the acidic condition (pH 3.3), fluorescence intensities of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were 35, 33, 122, and 199 (a.u.), respectively, with Av−FITC the lowest and Av−RhodG the highest.

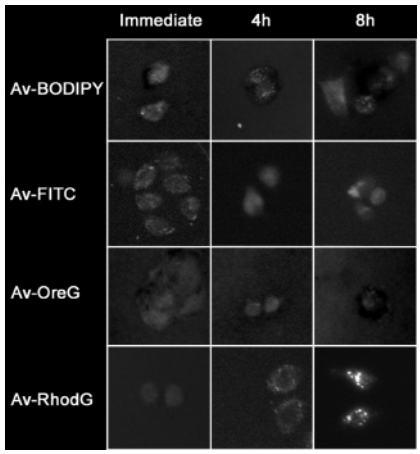

Figure 3. Serial fluorescence microscopy images of SHIN3 ovarian cancer cells. SHIN3 cells were incubated with each of the four fluorophores for 1 h, and fluorescent microscopy was then performed immediately and at 4 and 8 h after washing with PBS. Av−RhodG showed that the size of intracellular fluorescent dots as well as the fluorescence intensity progressively increased with time, while the other three dyes showed a minimal change. Original magnification: 200× Photographic exposure times: Av−BODIPY, Av−FITC, and Av−OreG (immediate, 4 h, and 8 h) = 2 s; Av−RhodG (immediate and 4 h) = 2 s; Av−RhodG (8 h) = 1 s.

Intracellular Av−RhodG Demonstrates Significantly Higher Fluorescence on FACS than Other Fluorophores. After 96

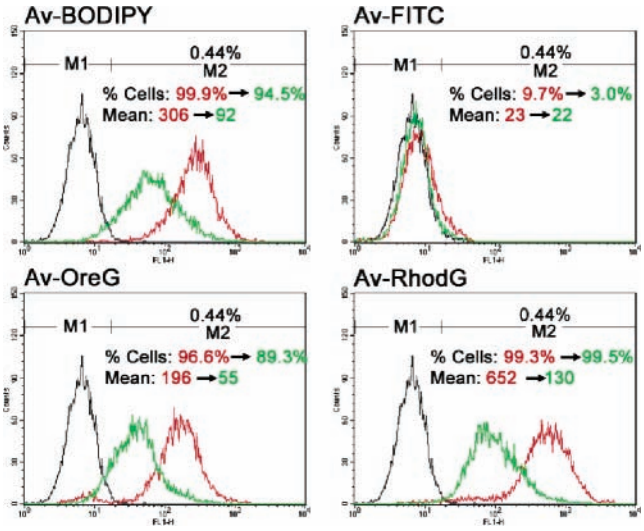

Figure 4. Histograms for flow cytometric analysis of SHIN3 cancer cells immediately (red) and at 24 h (green) after washout of each of the four green dyes as well as the control SHIN3 cells without treatment with dye (black). Samples with Av−BODIPY, Av−OreG, and Av−RhodG showed a significant rightward shift both immediately and at 24 h after washing dyes compared with the untreated control samples. Av−RhodG demonstrated the highest fluorescence both immediately (MFI 652) and 24 h after (MFI 130) washing. The percent cells in M2 increased from 0.44% to 99.9% for Av−BODIPY, 96.6% for Av−OreG, and 99.3% for Av−RhodG after 96 h incubation with each of the four dyes. Av−FITC did not show a significant rightward shift with percent cells in M2 from 0.44% to 9.7%.

h incubation with each of the fluorophores, flow cytometry was performed immediately and 24 h following washing on SHIN3 cells. Immediately after washing, Av−BODIPY, Av−OreG, and Av−RhodG showed a significant shift (>one order shift) as compared with unstained SHIN3 control cells (Figure 4). Among the four agents, Av−RhodG showed significantly higher mean fluorescence intensity (MFI) despite suboptimal excitation wavelength for Av−RhodG ($p < 0.001$). However, Av−FITC demonstrated minimal rightward shift (from 0.4% to 9.7%), and the MFI did not increase significantly. The cells were evaluated 24 h later for MFI, and Av−RhodG still demonstrated the highest fluorescence among the four fluorophores.

Av-RhodG Demonstrated the Highest Fluorescence on in Vivo Spectral Fluorescence Imaging. Three hours after intraperitoneal injection of 50 μg Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG, spectral fluorescence images of the whole abdominal cavity as well as close-up images of the peritoneal membranes were obtained by placing four mice, each with a different fluorophore, side by side on a nonfluorescent plate. Using spectral unmixing algorithm, the fluorescence signals of tumors were clearly distinguished from the autofluorescence from the intestine and the other organs. Unmixed images of the peritoneal cavities demonstrated that Av−BODIPY, Av−OreG, and Av−RhodG depicted the tumor foci; however, Av−FITC failed to visualize the tumors due to the insufficient fluorescence intensity compared to the other fluorophores at the same exposure times (Figure 5). Unmixed images of the peritoneal membranes clearly visualized lesions as small as 1 mm in diameter in all mice (Figure 5). However, the fluorescence intensity of Av−RhodG was the highest and that of Av−FITC was the lowest of all when compared visually.

To make an objective comparison of fluorescence intensity of the peritoneal implants among the four dyes, an ROI encompassing the peritoneal membrane was drawn inside the intestine using the unmixed green fluorescence image (Figure 6a), and a histogram depicting the distribution of pixel intensities was created (Figure 6b). The dynamic range of signal intensity

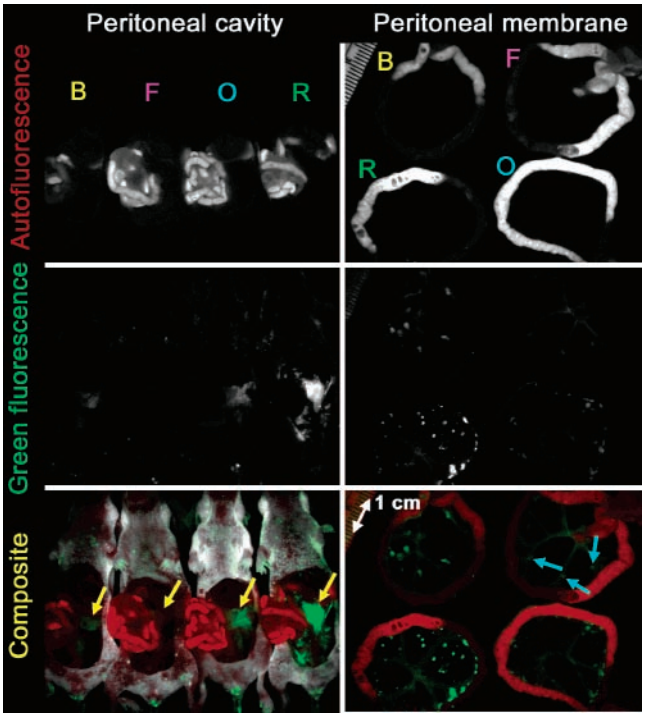

Figure 5. In vivo spectral fluorescence images of tumor-bearing mice 3 h after intraperitoneal injection with Av−BODIPY (B), Av−FITC (F), Av−OreG (O), and Av−RhodG (R). Upper: Autofluorescence image. Middle: Green dye fluorescence image. Lower: Composite image (red, autofluorescence; green, green dye fluorescence). Spectral fluorescence image of the peritoneal cavities clearly visualized the disseminated tumor foci (yellow arrows) in mice incubated with Av−BODIPY, Av−OreG, or Av−RhodG; whereas Av−FITC failed to visualize tumor foci (yellow arrow) due to insufficient fluorescence intensity. Close-up image of the peritoneal membranes demonstrates peritoneal implants histologically confirmed to be metastatic deposits as small as 1 mm in diameter in all mice including Av−FITC injected mouse (blue arrows). The fluorescence intensity of Av−RhodG was the highest, and that of Av−FITC was the lowest of all when compared visually.

in the unmixed fluorescence image was set from 1 to 256 in arbitrary units (a.u.), and the threshold value (t) was changed from 41 to 241 in increments of 10, because the background signals, such as the normal peritoneal membrane excluding tumors and the nonfluorescent plate, were mostly less than 40 (a.u.). Then, the total number of pixels (N) within the threshold range was calculated as a function of threshold (t), and a regression line was calculated in each ROI (Figure 6c). The correlation coefficients of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were −0.982, −0.989, −0.989, and −0.965, respectively. The slopes of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were −0.022, −0.056, −0.028, and −0.006, respectively. These results indicate that internalized Av−RhodG not only had the highest fluorescence, but above a specific threshold, only Av−RhodG was capable of detecting tumors. Among the other fluorophore, Av−FITC had the lowest internalized fluorescence, and Av−BODIPY and Av−OreG had intermediate fluorescence in vivo. Contrary to the preinjection fluorescence intensity, where Av−FITC was the highest (Figure 2), internalized Av−RhodG demonstrated much higher fluorescence than Av−FITC in vivo indicating that the two agents had changed fluorescence properties after internalization. With the use of Av−RhodG, submillimeter SHIN3 ovarian cancer implants on the perioneum were depicted with intense green fluorescence, which was able to overwhelm the background autofluorescence and visualize tiny tumors in close-up views without the use of the wavelength-resolved spectral imaging technique (Figure 7). On the basis of these in vitro and in vivo

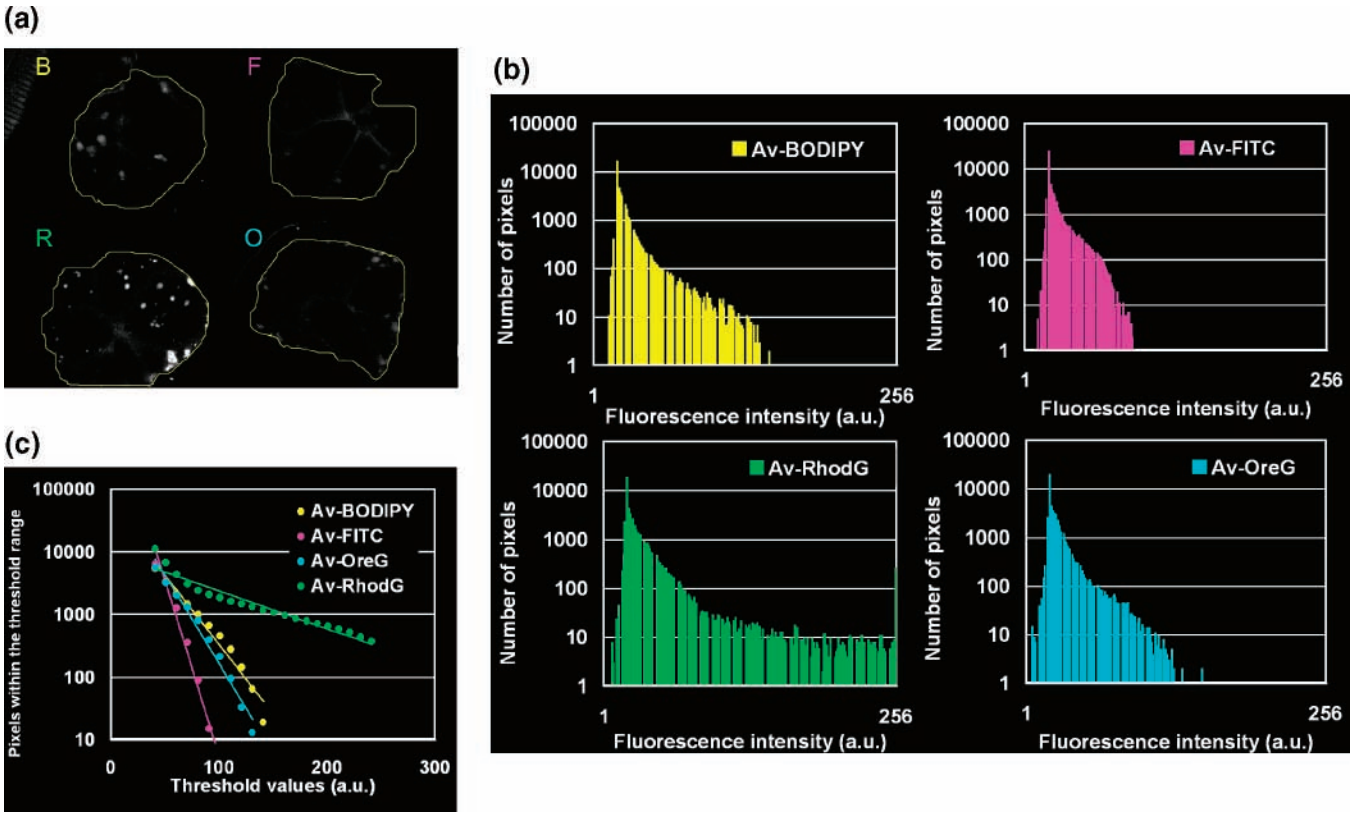

Figure 6. Semiquantitative assessment of in vivo fluorescence intensity. (a) ROI was drawn inside the intestine on the unmixed green fluorescence image (the same image as the unmixed green fluorescence image of Figure 5). B: Av−BODIPY. F: Av−FITC. O: Av−OreG. R: RhodG. (b) Histogram of fluorescence intensity of an ROI drawn on each of the peritoneal membranes instilled with 4 green dyes, Av−BODIPY, Av−FITC, Av−OreG, and RhodG. The dynamic range of the fluorescence intensity was split into 256 equal-sized bins (1−256). Then, for each bin (horizontal axis), the number of pixels from the data set that fall into each bin (vertical axis) are counted. The shape of the plot distribution ≤40 in arbitrary unit (a.u.) is almost the same among the 4 histograms. (c) Regression lines of 4 green dyes. The regression lines were calculated from the data sets (fluorescence threshold values 41−241, total number of pixels within the threshold rage 10−100 000 in common logarithm). The slopes of Av−BODIPY, Av−FITC, Av−OreG, and Av−RhodG were −0.022, −0.056, −0.028, and −0.006, respectively. Av−RhodG has the highest slope value, consistent with it being the brightest fluorophore, whereas Av−FITC had the lowest slope value, and Av−BODIPY and Av−OreG were intermediate.

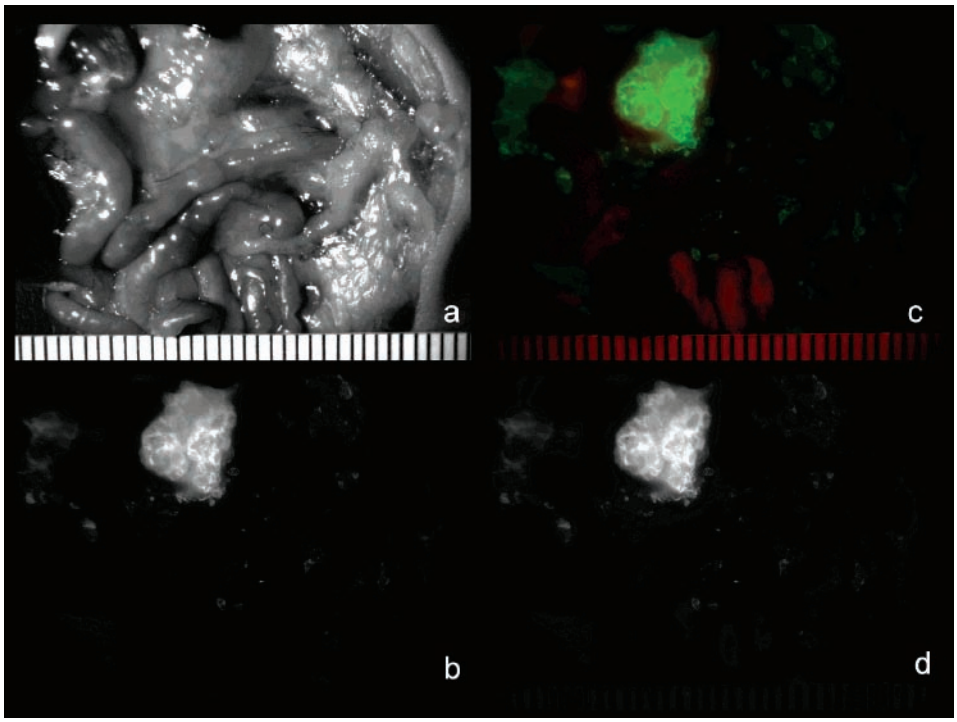

Figure 7. In vivo spectral fluorescence close-up images of a peritoneally disseminated SHIN3 ovarian cancer-bearing mouse 6 h after intraperitoneal injection with Av−RhodG. A white light image (a), a green fluorescence image (b), a composite image of green fluorescence (green) and autofluorescence (red) (c), and an uncalculated image obtained with a 545−555 nm band-pass filter. Strong green florescence derived from Av−RhodG allow visualization of SHIN3 ovarian cancer submillimeter implants in an uncalculated image taken with a 545−555 nm band-pass filter without the use of the wavelength-resolved technique (d) as well as in a spectrally calculated green fluorescence image (b).

results, Av−RhodG was considered the most compelling choice for a cellular targeting optical probe.

When the fluorescent dyes are conjugated with proteins, it is well-known that fluorescence emission of each dye is generally altered differently in each combination of dyes and proteins. Additionally, this study demonstrated that the in vivo characteristics of fluorophores, once internalized within cells, could be very different from their extracellular behavior. When four green dyes were conjugated with avidin, Av−BODIPY had the lowest signal intensity in the solution at physiological pH and remained low at acidic pH. Av−FITC, which clearly had the highest signal intensity in the solution at physiological pH, demonstrated minimal fluorescence once it was internalized, probably because of acidic pH in the endoplasmic vessicles. Conversely, Av−RhodG, which had modest fluorescence extracellularly, remain unchanged or even progressively increased in fluorescence once it had been internalized. Thus, in designing optical fluorescence probes, it is important to consider whether the agent will end up intracellular or will remain in the extracellular environment.

On the basis of its biocompatibility and efficacy, fluorescein is the most feasible green dye for clinical translation, since it has been used in clinical practice for the past three decades (*9*, *10*). Fluorescein emits in the green wavelength (fluorescence emission maximum around 520 nm) at physiological pH. However, fluorescein is known to decrease its emission signal at lower pH (*11*, *12*). Thus, when SHIN3 cancer cells were targeted by an avidin conjugate (or another targeting ligand) conjugated to a fluorophore, the agent was internalized and catabolized. The low pH conditions found within the endosome and lysosome might rapidly compromise the signal of the fluorescein, especially when we utilize a quickly internalizing ligand−receptor system such as the avidin−lectin system. The other three dyes, BODIPY, OreG, and RhodG, have been reported to emit photons in a less pH-independent fashion than fluorescein. Therefore, we hypothesized that, if pH-independent alternative dyes were used instead of pH-dependent fluorescein, we could achieve better targeting of the cancer due to the stronger signals from internalized reagents in cancer cells.

Non-FITC green fluorescent dyes were designed to resist the photobleaching associated with the fluorescein dyes (*13*, *14*). Since fluorescein is sensitive to photobleaching, RhodG and BODIPY-FL were synthesized as photobleaching-resistant alternatives to fluorescein. However, to the best of our knowledge, the changes in fluorescence in vivo and their comprehensive comparison among green fluorophores in response to internalization have not been reported. In our results, RhodG is the most suitable dye to be conjugated with quickly internalizing receptor ligands or antibodies such as avidin or trastuzumab (Herceptin) (*15*), although the exact reason why Av−RhodG was brighter than Av−OreG or Av−BODIPY-FL in the endoplasmic vesicles is still unknown.

The rate at which Av−fluorophore complexes, such as Av−RhodG, are internalized and catabolized can be determined by examining the combined fluorescence of these agents. In theory, such agents could be used to measure internalization rates, and the effect of various drugs and interventions on internalization could be measured using fluorescence to monitor the process (*16*, *17*).

CONCLUSION

Whereas Av−FITC demonstrated the brightest fluorescence in vitro, once the fluorophores were internalized, Av−RhodG demonstrated the brightest fluorescence. Chemical change in the fluorophores induced by the low pH of the lysosome/endosome is one of the likely reasons. Therefore, RhodG is a suitable fluorescence dye for internalized in vivo spectral fluorescence imaging to detect cancer.

Enzymatic Activation of Second-Generation Dendritic Prodrugs: Conjugation of Self-Immolative Dendrimers with Poly(ethylene glycol) via Click Chemistry

Anna Gopin,[†] Sharon Ebner,[‡] Bernard Attali,[‡] and Doron Shabat[†,*]

School of Chemistry, Raymond and Beverly Sackler Faculty of Exact Sciences, and Department of Physiology and Pharmacology, Sackler Faculty of Medical Sciences, Tel-Aviv University, Tel Aviv 69978 Israel. Received June 26, 2006; Revised Manuscript Received September 21, 2006

Single-triggered disassemble dendrimers were recently developed and introduced as a potential platform for a multi-prodrug. These unique structural dendrimers can release all of their tail units through a self-immolative chain fragmentation initiated by a single cleavage at the dendrimer's core. There are several examples for the bioactivation of first-generation self-immolative dendritic prodrugs. However, enzymatic activation failed for second-generation self-immolative dendrimers. The hydrophobic large molecular structure of the dendritic prodrugs results in aggregation under aqueous conditions and prevented the enzyme from reaching the triggering substrate. Here we show a simple solution for the enzymatic activation of second-generation self-immolative dendrimers. Poly(ethylene glycol) (PEG) was conjugated to the dendritic platform via click chemistry. The poly(ethylene glycol) tails significantly decreased the hydrophobic properties of the dendrimers and thereby prevented aggregate formation. We designed and synthesized a dendritic prodrug with four molecules of the anticancer agent camptothecin and a trigger that can be activated by penicillin-G-amidase. The PEG5000-conjugated, self-immolative dendritic prodrug was effectively activated by penicillin-G-amidase under physiological conditions and free camptothecin was released to the reaction media. Cell-growth inhibition assays demonstrated increased toxicity of the dendritic prodrug upon incubation with the enzyme.

INTRODUCTION

Recently, three groups, almost simultaneously, reported the design and synthesis of novel dendritic structures. These dendrimers include a trigger that initiates the fragmentation of the molecule in a self-immolative manner with the consequent release of the tail-high-group units (*1*−*3*). All three groups exploited the fact that the dendrimer skeleton can be constructed in such a way that it will disintegrate into known molecular fragments once the disintegration process has been initiated. These unique structural dendrimers can release all of their tail units through a domino-like chain fragmentation, initiated by a single cleavage at the dendrimer's core (*4*). Incorporation of drug molecules as the tail units and use of an enzyme substrate as the trigger generates a multi-prodrug unit that is activated with a single enzymatic cleavage. We have shown significant advantage in tumoral cell-growth inhibition by our single-triggered dendritic prodrugs in comparison with classic monomeric prodrugs (*5*, *6*). In another report, we designed and synthesized fully biodegradable dendrimers that disassemble through multienzymatic triggering followed by self-immolative chain fragmentation (*7*). A practical application for such multitriggered self-immolative dendrons was recently demonstrated by the concept of prodrug activation through a molecular OR logic trigger (*8*).

Two options for the triggering/activation of self-immolative dendrimers were proposed. One approach is based on chemical triggering whereas the other is based on enzymatic bioactivation. While chemical activation of first and second generation self-immolative dendrimers was achieved by all three groups, only ours successfully demonstrated the enzymatic approach with incorporation of substrate triggers for catalytic antibody 38C2 (*9*−*11*) and penicillin-G-amidase (*12*) (PGA). However, when second-generation self-immolative dendrimer were tested for enzymatic activation, no fragmentation was observed at all. We assumed that the hydrophobic structure of the dendritic prodrugs generates aggregation under aqueous conditions, which prevented the enzyme from accessing the triggering substrate (*13*). Here we report a simple solution to this problem. Enzymatic activation of second-generation self-immolative dendrimers was achieved through conjugation of poly(ethylene glycol) (PEG) to the dendritic platform via click chemistry. The PEG tails significantly decreased the hydrophobicity of the dendrimers and thereby prevented aggregate formation.

EXPERIMENTAL PROCEDURES

General. All reactions requiring anhydrous conditions were performed under argon or N_2 atmosphere. Chemicals and solvents were either A.R. grade or purified by standard techniques. Thin layer chromatography (TLC): silica gel plates Merck 60 F_{254}; compounds were visualized by irradiation with UV light and/or by treatment with a solution of 25 g phosphomolybdic acid, 10 g $Ce(SO_4)_2{\cdot}H_2O$, 60 mL concd H_2SO_4, and 940 mL H_2O, followed by heating. Flash chromatography (FC): silica gel Merck 60 (particle size 0.040−0.063 mm), eluent given in parentheses. ^{1}H NMR: Bruker AMX 200 or 400. The chemical shifts are expressed in δ relative to TMS (δ = 0 ppm) and the coupling constants J in hertz. The spectra

were recorded in $CDCl_3$ or CD_3OD as a solvent at room temp. All reagents, including salts and solvents, were purchased from Sigma-Aldrich. PEG_{400}-azide was received from Polypure (Norway). TBTA was received from the Sharpless laboratory (Scripps, La Jolla).

Compound 2. Commercially available 4-hydroxybenzoic acid (2.0 g, 14.5 mmol) was dissolved in DMF. Then EDC (3.3 g, 17.4 mmol), HOBT (1.0 g, 7.3 mmol), and propargyl amine (1.0 mL, 14.5 mmol) were added. The mixture was stirred overnight and monitored by TLC (EtOAc:He = 2:3). After completion of the reaction, the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc:He = 2:3) to give compound **2 (**1.8 g, 70%) in the form of yellowish oil.

^{1}H NMR (200 MHz, $CDCl_3$) δ = 7.70 (2H, d, J = 6.8 Hz); 6.81 (2H, d, J = 6.8); 4.11 (2H, d, J = 2.5); 2.71 (1H, t, J = 2.5). ^{13}C (400 MHz, $CDCl_3$) δ = 167.9, 160.6, 128.8, 124.4, 114.5, 79.5, 70.3, 28.3. MS (FAB): calculated for $C_{10}H_9NO_2$ 176.0 [M + H $^+$], found 176.0.

Compound 3. To a cool 12% NaOH (12 mL) compound **2** (1.8 g, 10.2 mmol) was added while being cooled to 0 °C. Formaldehyde 37% in water (10 mL) was added. The reaction was stirred at 55 °C for 3 days and monitored by TLC (EtOAc: MeOH = 95:5). After completion the reaction was diluted with EtOAc and washed with ammonium chloride saturated solution. The aqueous layer was washed twice with EtOAc. The combined organic layer was dried over magnesium sulfate and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc: MeOH = 95:5) to give compound **3 (**1.9 gr, 80%) in the form of a white solid.

^{1}H NMR (200 MHz, CD_3OD) δ = 7.80 (2H, s); 4.91 (4H, s); 4.26 (2H, d, J = 2.5); 2.70 (1H, t, J = 2.5). ^{13}C (400 MHz, CD_3OD) δ = 168.1, 156.7, 126.8, 126.0, 124.4, 79.4, 70.2, 60.3, 28.3. MS (FAB): calculated for $C_{12}H_{13}NO_4$ 236.0 [M + H $^+$], found 236.0.

Compound 4. Compound **3** (713 mg, 3.0 mmol) was dissolved in DMF and cooled to 0 °C. Imidazole (408 mg, 6.0 mmol) and TBSCl (910 mg, 6.0 mmol) were added. The reaction was stirred at room temp for 2 h and monitored by TLC (EtOAc: He = 2:8). After completion, the reaction was diluted with ether and washed with ammonium chloride saturated solution. The organic layer was dried over magnesium sulfate, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc:He = 15:85) to give compound **4 (**1.12 g, 80%) in the form of a colorless oil.

^{1}H NMR (400 MHz, $CDCl_3$) δ = 7.57 (2H, s); 4.87 (4H, s); 4.23 (2H, dd, J = 2.5, J = 2.6); 2.17 (1H, t, J = 2.5); 0.95 (18H, s); 0.13 (12H, s). ^{13}C (400 MHz, $CDCl_3$) δ = 166.7, 156.4, 126.1, 124.5, 79.6, 71.7, 62.7, 29.6, 25.8, 25.6, 18.2, −5.5. MS (FAB): calculated for $C_{24}H_{41}NO_4Si_2$ 464.2 [M + H $^+$], found 464.2.

Compound 5. Compound **4** (1.12 g, 2.4 mmol) was dissolved in dry THF, Et_3N (1.0 mL, 7.2 mmol) was added, and the mixture was cooled to 0 °C. Then, *p*-nitrophenyl chloroformate (581 mg, 2.9 mmol) dissolved in dry THF (10 mL) was added dropwise, and the reaction was stirred for 1 h at room temp and monitored by TLC (EtOAc:He = 2:8). After completion, the reaction was filtered, the solvent was evaporated, and the crude product was purified by column chromatography on silica gel (EtOAc:He = 15:85) to give compound **5 (**1.35 g, 90%) in the form of a colorless oil.

^{1}H NMR (200 MHz, $CDCl_3$) δ = 8.43 (2H, d, J = 8.1); 8.02 (2H, s); 7.63 (2H, d, J = 8.1); 7.01 (1H, m); 4.91 (4H, s); 4.38 (2H, dd, J = 2.5, J = 2.6); 2.41 (1H, t, J = 2.5); 1.08 (18H, s); 0.29 (12H, s). ^{13}C (400 MHz, $CDCl_3$) δ = 166.4, 155.2, 149.4, 147.7, 145.5, 133.9, 132.2, 126.3, 125.3, 121.5, 79.2, 71.8, 60.3, 31.5, 25.8, 18.2, −5.5. HRMS (MALDI-TOF): calculated for $C_{31}H_{44}N_2O_8Si_2$ 651.2528 [M + Na^+], found 651.2562.

Compound 6. Compound **5** (1.5 g, 2.3 mmol) was dissolved in DMF. Mono-Boc-N,N′-dimethylethylenediamine (541 mg, 2.9 mmol) was added. The reaction was stirred at room temperature for 1 h and monitored by TLC (EtOAc:He = 1:1). After completion, the solvent was removed under reduced pressure and the crude product was purified by column chromatography on silica gel (EtOAc:He = 2:8) to give compound **6** (1.45 g, 90%) in the form of a colorless oil.

^{1}H NMR (400 MHz, $CDCl_3$) δ = 7.79 (2H, s); 6.32 (1H, m); 4.68−4.67 (4H, m); 4.27−4.25 (2H, m); 3.61−3.43 (4H, m); 3.24 (2H, s); 3.12 (1H, s); 2.96 (3H, s); 2.32 (1H, bs); 1.51−1.46 (9H, m); 0.92 (18H, s); 0.08 (12H, s). ^{13}C (400 MHz, $CDCl_3$) δ = 167.2, 153.1, 153.0, 134.6, 130.8, 125.1, 80.2, 78.8, 72.0, 59.9, 46.4, 46.1, 36.4, 35.9, 35.1, 29.8, 28.3, 25.7, 18.2, −5.5. MS (FAB): calculated for $C_{34}H_{59}N_3O_7Si_2$ 700.4 [M + Na $^+$], found 700.3.

Compound 7. Compound **6** (1.5 g, 2.2 mmol) was dissolved in 10 mL of methanol, and amberlist 15 was added. The reaction was stirred at room temperature for 2 h and monitored by TLC (EtOAc:MeOH = 95:5). After completion, the amberlist was filtered out and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc:MeOH = 95:5) to give compound **7 (**500 mg, 56%) in the form of a white solid.

^{1}H NMR (200 MHz, CD_3OD) δ = 7.78 (2H, s); 4.57 (4H, bs); 4.25−4.23 (2H, m); 3.6−3.4 (4H, m); 3.2 (2H, s); 3.1 (1H, s); 2.96 (3H, s); 2.40 (1H, bs); 1.59−1.54 (9H, m). ^{13}C (400 MHz, CD_3OD) δ = 169.8, 158.9, 157.5, 152.1, 134.1, 130.3, 130.0, 83.2, 83.0, 74.4, 62.5, 50.3, 49.0, 38.7, 37.9, 37.6, 31.3. HRMS (MALDI-TOF): calculated for $C_{22}H_{31}N_3O_7$ 472.2015 [M + Na^+], found 472.2059.

Compound 8. Triphosgen (57 mg, 2 mmol) was dissolved in 10 mL of dry THF and was cooled to 0 °C. A mixture of *p*-nitroaniline (614 mg, 4.5 mmol) and Et_3N (622 μL, 4.5 mmol) dissolved in 20 mL dry THF was added dropwise. The reaction was stirred for 20 min, and afterward a mixture of compound **7** (400 mg, 0.9 mmol) and DMAP (274 mg, 2.3 mmol) in dry THF was added dropwise. The reaction was stirred at room temperature overnight and monitored by TLC (EtOAc:He = 1:1). After completion, the mixture was diluted with EtOAc and was washed with 1 M HCl. The organic layer was dried over magnesium sulfate, and the solvent was removed under reduced pressure. Then, the crude product was dissolved in a small amount of DCM and filtered. The filtrate was concentrated, and the product was purified by column chromatography to give compound **8** (478 mg, 68%) in the form of a yellow solid.

^{1}H NMR (400 MHz, $CDCl_3$) δ = 8.11 ppm (4H, d, J = 9 Hz); 7.9 (2H, s); 7.61 (4H, d, J = 9); 5.2 (4H, bs); 4.13 (2H, s); 3.66−3.64 (1H, m); 3.4−3.2 (4H, m); 3.2 (2H, s); 3.1 (1H, s); 2.96 (3H, s); 2.46 (1H, bs); 1.37 (9H, s). ^{13}C NMR (400 MHz, $CDCl_3$) δ = 166.2; 156.4; 155.9; 153.8; 153.5; 144.6; 142.5; 131.2; 130.2; 129.9; 129.8; 124.9; 117.8; 80.6; 79.2; 71.7; 61.6; 46.6; 45.5; 34.3; 34.0; 29.6; 28.3. HRMS (MALDI-TOF): calculated for $C_{36}H_{39}N_7O_{13}$ [M + Na^+] 800.2498; found 800.2454.

Compound 10. Previously reported compound **9** (344 mg, 0.9 mmol) was deprotected with 1 mL TFA to remove the Boc group. The excess of the acid was removed under reduced pressure, and the residue was dissolved in 1 mL DMF. Linker **12** (305 mg, 0.75 mmol) was added followed by addition of Et_3N (374 μL, 2.7 mmol). The reaction was stirred at room temperature for 1 h and monitored by TLC (EtOAc:He = 3:1). After completion, the solvent was removed under reduced

pressure, and the crude product was purified by column chromatography to give compound **10** (380 mg, 69%) in the form of a sticky foam.

^{1}H NMR (200 MHz, $CDCl_3$) δ = 7.4−7.1 ppm (11H, m); 5.11 (2H, bs); 4.5 (4H, s); 3.7 (2H, s); 3.6−3.46 (4H, m); 3.15 (1H, s); 3.01−2.93 (4H, m); 2.3 (3H, s). ^{13}C NMR (200 MHz, $CDCl_3$) δ = 169.3; 156.1; 137.6; 134.5; 133.4; 132.7; 132.4; 130.8; 130.4; 129.9; 129.6; 128.9; 127.8; 120.0; 67.2; 60.8; 47.6; 46.7; 45.2; 31.6; 21.0. HRMS (MALDI-TOF): calculated for $C_{30}H_{35}N_3O_7$ [M + Na^+] 572.2367, found 572.2349

Compound 11. Compound **10** (370 mg, 0.67 mmol) was dissolved in 10 mL of dry THF and cooled to 0 °C. Then DIPEA (692.5 mg, 5.36 mmol) was added followed by *p*-nitrophenyl chloroformate (814 mg, 4.04 mmol) and pyridine (26 mg, 0.34 mmol). The reaction was allowed to warm to room temperature and monitored by TLC (EtOAc:He = 35:65). After completion, the reaction was diluted with EtOAc and washed with 1 M HCl and with saturated $NaHCO_3$ solutions. The organic layer was dried over magnesium sulfate, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc:He = 35:65) to give compound **11** (547 mg, 93%) in a form of a white solid.

^{1}H NMR (200 MHz, $CDCl_3$) δ = 8.39 ppm (4H, d, J = 8); 7.52−7.39 (15H, m); 5.38 (4H, s); 5.19 (2H, s); 3.7 (2H, s); 3.6−3.46 (5H, m); 3.15 (1H, s); 3.01−2.93 (6H, m); 2.3 (3H, s). HRMS (MALDI-TOF): calculated for $C_{44}H_{41}N_5O_{15}$ [M + Na^+] 902.2491; found 902.2475

Compound 1. Compound **8** (200 mg, 0.26 mmol) was deprotected with 1 mL TFA to remove the Boc group. The excess of the acid was removed under reduced pressure, and the residue was dissolved in 1 mL DMF. Compound **11** (75 mg, 0.09 mmol) was added followed by addition of Et_3N (50 μL, 0.36 mmol). The reaction was stirred at room temperature for 1 h and was monitored by TLC (EtOAc:He = 85:15). After completion, the solvent was removed under reduced pressure, and the crude product was purified by column chromatography to give compound **1** (158 mg, 89%) in the form of a light yellow solid. ^{1}H NMR (200 MHz, $CDCl_3$) δ = 8.23−8.17 ppm (8H, m); 7.8−8.1 (4H, m); 7.7−7.6 (8H,m), 7.5−7.25 (11H, m); 5.25−4.8 (14H, m); 4.3 (4H, bs); 3.8 (2H, bs); 3.75−3.4 (14H, m); 3.25−2.8 (18H, s); 2.4 (3H, bs); 2.3 (2H, s). HRMS (MALDI-TOF): calculated for $C_{94}H_{93}N_{17}O_{31}$ [M + Na^+] 1978.6116; found 1978.6293.

Compound 15. Compound **14** (226 mg, 1.28 mmol) was dissolved in DCM. NHS (162 mg, 1.4 mmol) and EDC (269 mg, 1. 4 mmol) were added, and the mixture was stirred at room temp for 15 min and monitored by TLC (EtOAc:He = 4:6). After completion, the solvent was evaporated and the crude product was purified by column chromatography to give product **15** (310 mg, 88%) in the form of a white solid.

^{1}H NMR (200 MHz, $CDCl_3$) δ = 8.16 ppm (2H, d, J = 8.2); 7.47 (2H, d, J = 8.2); 4.4 (2H, s); 2.91 (4H, s). ^{13}C (400 MHz, $CDCl_3$) δ = 169.1; 161.4; 131.1; 131.0; 128.1; 126.9; 54.0; 25.6. HRMS (MALDI-TOF): calculated for $C_{12}H_{10}N_4O_4$ [M + Na^+] 297.0572, found 297.0572.

Compound 16. PEG_{5000}-amine (500 mg, 0.1 mmol) was dissolved in DMF. Compound **15** (42 mg, 0.15 mmol) was added. The reaction was stirred for 2 h and monitored by TLC (DCM: MeOH = 9: 1). After completion, the solvent was removed under reduced pressure and the crude product was purified by column chromatography, dissolved in water, filtered and lyophilized to give compound **16** (67%) in the form of a white powder.

^{1}H NMR (200 MHz, $CDCl_3$) δ = 7.93 ppm (2H, d, J = 8.2); 7.43 (2H, d, J = 8.2); 4.4 (2H, s); 3.8−3.2 (multiplet signal of PEG).

Compound 17. Compound **7** (300 mg, 0.67 mmol) was deprotected with 1 mL TFA to remove the Boc group. The excess of the acid was removed under reduced pressure, and the residue was dissolved in 1 mL DMF. Compound **11** (196 mg, 0.22 mmol) was added followed by addition of Et_3N (185 μL, 1.34 mmol). The reaction was stirred at room temperature overnight and monitored by TLC (EtOAc 100% then EtOAc: MeOH = 8:2). After completion, the solvent was removed under reduced pressure and the crude product was purified by column chromatography (EtOAc:MeOH = 8:2) to give compound **17** (154 mg, 54%) in the form of sticky foam.

^{1}H NMR (200 MHz, MeOD) δ = 8.04 ppm (4H, s); 7.65 (2H, m); 7.47−7.20 (9H, m); 5.2−5.0 (6H, m); 4.68−4.5 (8H, m); 4.28 (4H, d, J = 2.4); 3.78−3.61 (14H, m); 3.27 (3H, s); 3.18−3.03 (15H, m); 2.72 (2H, t, J = 2.4); 2.31−2.29 (3H, m). HRMS (MALDI-TOF): calculated for $C_{66}H_{77}N_9O_{19}$ [M + Na^+] 1322.5228; found 1322.5360.

Compound 18. Compound **17** (154 mg, 0.11 mmol) was dissolved in 10 mL of dry THF at 0 °C. Then, DIPEA (254 mg, 1.97 mmol) was added followed by *p*-nitrophenyl chloroformate (290 mg, 1.44 mmol) and pyridine (10 mg, 0.13 mmol). The reaction was allowed to warm to room temperature and monitored by TLC (EtOAc:He = 85:15). After completion, the reaction was diluted with EtOAc and washed with 1 M HCl and with saturated $NaHCO_3$ solutions. The organic layer was dried over magnesium sulfate. The solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc:He = 85:15) to give compound **18** (156 mg, 69%) in the form of a white solid.

^{1}H NMR (400 MHz, $CDCl_3$) δ = 8.25 ppm (8H, d, J = 8.3); 8.0 (4H, s); 7.37−7.03 (17H, m); 5.3 (8H, bs); 5.18 (2H, s); 5.1 (6H, m); 4.28 (4H, s); 3.8−3.5 (16H, m); 3.3 (4H, s); 3.0−2.8 (16H, m); 2.3 (2H, s); 2.1−2.0 (3H, m). HRMS (MALDI-TOF): calculated for $C_{94}H_{89}N_{13}O_{35}$ [M + Na^+] 1982.5476; found 1982.5429.

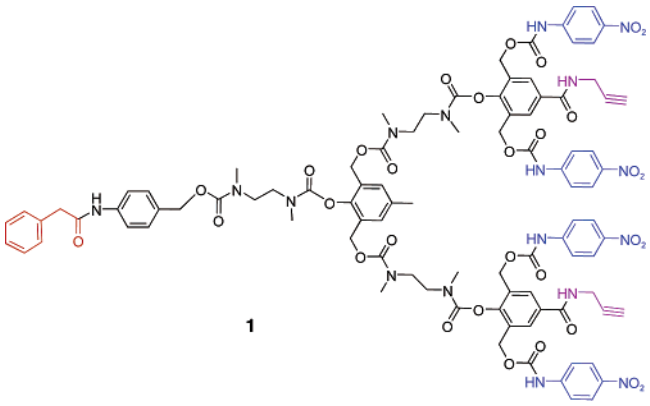
Compound 20. Previously reported CPT-amine-Boc unit **19** (259 mg, 0.5 mmol) was deprotected with 1 mL TFA to remove the Boc group. The excess of the acid was removed under reduced pressure and the residue was dissolved in 1 mL DMF. Compound **18** (150 mg, 0.077 mmol) was added followed by addition of Et_3N (140 μL, 1 mmol). The reaction was stirred at room temperature overnight and was monitored by TLC (EtOAc: MeOH = 8:2). After completion, the solvent was removed under reduced pressure, and the crude product was purified by column chromatography to give compound **20** (188 mg, 75%) in the form of a yellowish solid.

^{1}H NMR (200 MHz, $CDCl_3$) δ = 8.5 ppm (4H, s); 8.32 (4H, d, J = 8.4); 8.07−8.03 (6H, m); 7.9 (6H, t, J = 7); 7.7 (6H, t, J = 7); 7.6−7.5 (2H, m); 7.4−7.2 (14H, m); 5.9−5.7 (4H, m); 5.5 (4H, m); 5.3−5.1 (19H, m); 4.3−4.2 (4H, m); 3.75−3.5 (25H, m); 3.4−3.25 (14H, m); 3.25−2.99 (25H, m); 2.8−2.75 (3H, m); 2.5−2.25 (18H, m); 1.4 (16H, s); 1.1−0.95 (12H, m). HRMS (MALDI-TOF): calculated for $C_{170}H_{173}N_{25}O_{43}$ [M + Na^+] 3275.2011, found 3275.2221.

General Procedure for the "Click Chemistry". Corresponding PEG-azide (2.2 equiv) was dissolved in DMF. Corresponding dendrimer (1 equiv) was added followed by addition of copper sulfate (0.5 equiv) and TBTA (1equiv). Then, few copper turnings were added, and the reaction was stirred overnight at room temperature. The reaction was monitored by HPLC and after completion the mixture was filtered, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (DCM: MeOH = 9:1) to give desired product.

Compound 1a. HPLC conditions: C18 reverse phase column, λ = 348 nm, flow rate 1 mL/min, gradient program: t = 0 (30% ACN: 70% H_2O); t = 20−25 min (100% ACN).

Scheme 1. Molecular Structure of Second-Generation Self-Immolative Dendron with a Trigger Designed for Activation by PGA (red), Reporter Groups of 4-Nitroaniline (blue), and Acetylene Functional Groups (purple) for Click Conjugation



t_R(compound **1**) = 18.5 min, t_R(compound **1a**) = 15.5 min. The yield after column chromatography is 52%. HRMS (MALDI-TOF): calculated for $C_{126}H_{159}N_{23}O_{47}$ 2769.0651 [M + Na^+], found 2769.0859.

Compound 13. HPLC conditions: C18 reverse phase column, λ = 360 nm, flow rate 1 mL/min, gradient program: t = 0 (30% ACN: 70% H_2O); t = 20−25 min (100% ACN). t_R(compound **20**) = 14 min, t_R(compound **13**) = 11 min (broad peak). After the column chromatography, the product was dissolved in mixture of water:MeOH = 9:1, filtered, and lyophilized to give pure product (50.4%) in a form of a yellowish powder.

Solubility Determination. Compound **13** (2 mg) was suspended in 100 μL of distilled water. The mixture was stirred for 1 h and filtered. The concentration of the filtrate was determined by spectroscopic assay (wavelength 360 nm) with CPT solution as a reference. The observed concentration of solution was 11 mg/mL.

Cell-Growth Inhibition Assays. The human embryonic kidney HEK293 cell line was maintained in DMEM (Biological Industries, Beit Haemek, Israel) supplemented with 10% fetal calf serum, 2 mM L-glutamine, and penicillin (10 U/mL)−streptomycin (0.01 mg/mL). The human Molt3 and Jurkat leukemia cell lines were maintained in RPMI 1640 (Biological Industries, Beit Haemek, Israel) supplemented with 20% FCS, 1 mM L-glutamine, and penicillin (10 U/mL)−streptomycin (0.01 mg/mL). Cells were grown in Nunclon Flasks in a humidified atmosphere at 37 °C in 5%CO_2.

For measurements of growth inhibition by CPT and prodrug **13**, the Quick cell Proliferation Assay was used (Biovision). Briefly, Jurkat and Molt3 cells were cultured in 96-well microtiter plate at an initial density of 15 000 cells per well in a final volume of 200 μL medium. Various concentrations of the cytotoxic substance were added to the wells in triplicates, and the extent of cell proliferation was determined 3 days later using the WST-1 reagent. The WST-1 reagent is cleaved to a formazan dye via the mitochondrial dehydrogenase, and the dye produced by viable cells was quantified by measuring absorbance of the dye solution at 440 nm. HEK293 cell line proliferation was evaluated in a similar manner, except that the initial culture density was 2500 cells per well. The cytotoxicity effect of prodrug **13** was evaluated in the presence/absence of 1 μM of the enzyme PGA.

RESULTS AND DISCUSSION

Synthesis and Bioactivation of Second-Generation Dendritic Model System. In order to test our approach, we designed and synthesized second-generation dendritic molecule **1** (Scheme 1). The molecule has an enzymatic trigger that is activated by PGA (red), four reporter groups of 4-nitroaniline (blue), and two acetylene functional groups that are ready to be coupled to various PEG-azide units (purple). The synthesis of dendritic molecule **1** was achieved as illustrated in Schemes 2 and 3. 4-Hydroxybenzoic acid was coupled with propargylamine to give amide

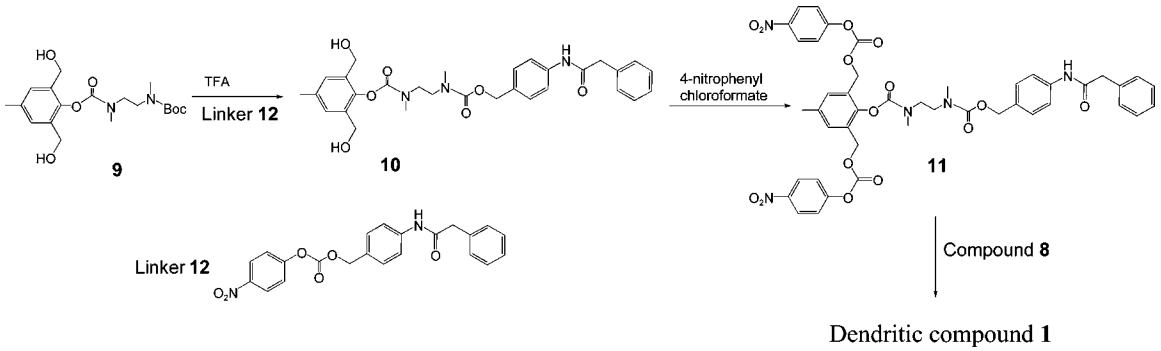
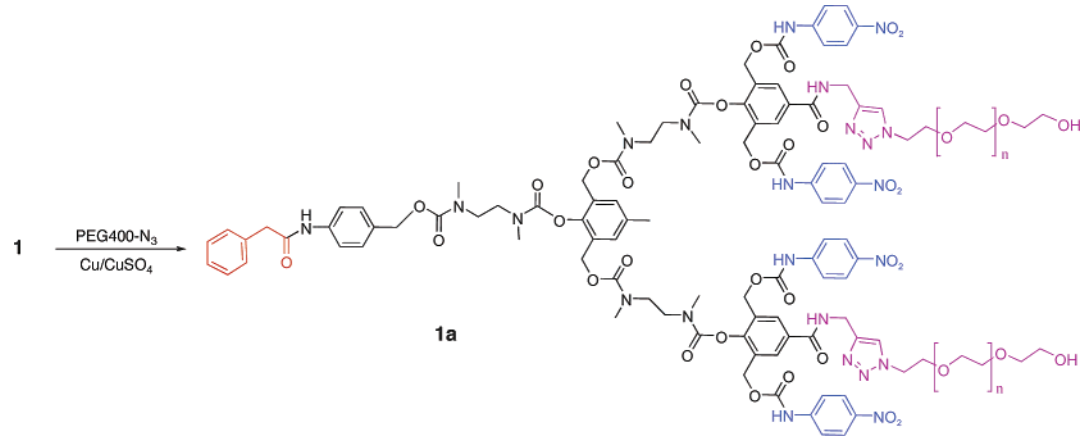
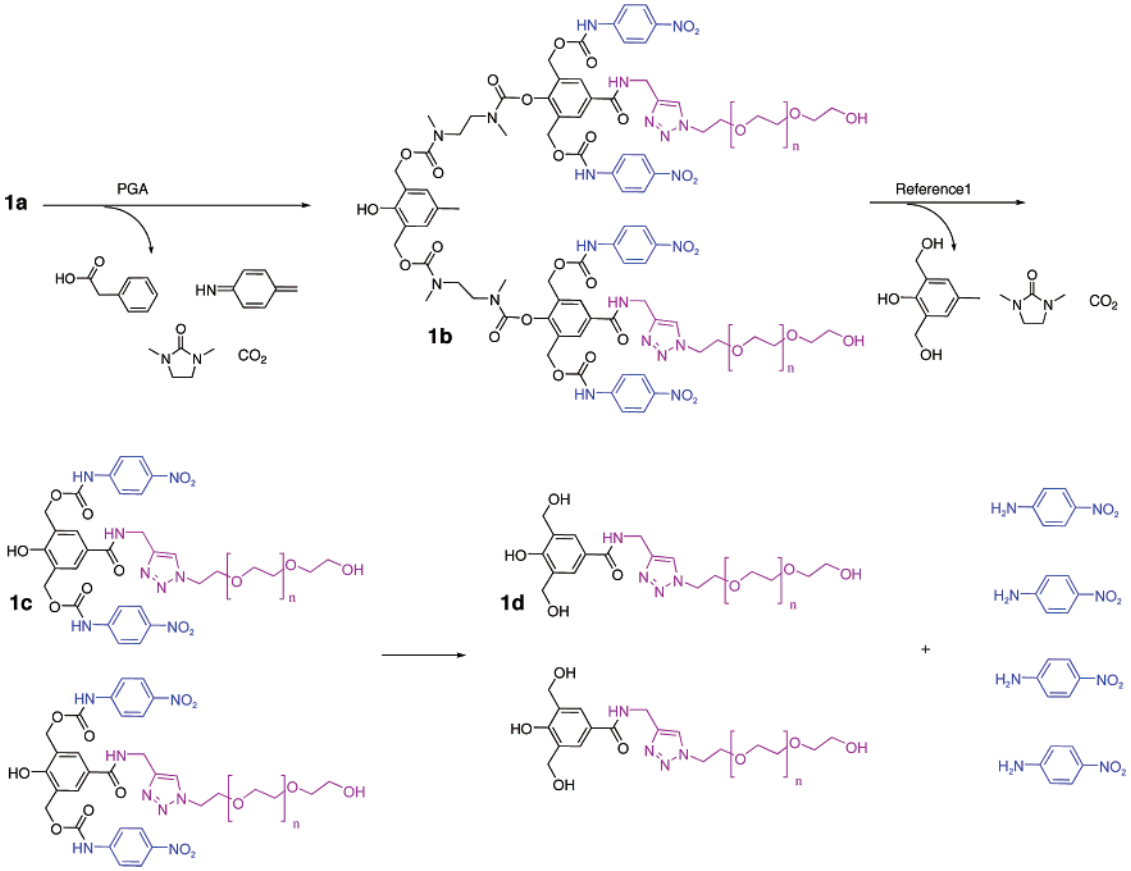


Scheme 4. Conjugation of Dendritic Molecule 1 with PEG400-azide



Scheme 5. Disassembly Pathway of Second-Generation Dendritic Molecule 1a Triggered by Enzymatic Activation of PGA



2, which was further reacted with formaldehyde under aqueous basic conditions to afford compound **3**. The latter was selectively protected with two equivalents of *tert*-butyl-dimethylsilyl chloride to generate phenol **4**, which was then activated with *p*-nitrophenyl chloroformate to give carbonate **5**. Reaction of mono-Boc-*N*,*N*′-dimethylethylenediamine with carbonate **5** afforded carbamate **6**, which was stirred with amberlist 15 in methanol to generate compound **7**. The latter was reacted with 4-nitrophenyl isocyanate (generated *in situ* from 4-nitrophenyl and triphosgene) to give compound **8**. Carbamate **9** (*1*) was then deprotected with trifluoroacetic acid (TFA) and directly reacted with linker **12** to generate compound **10**, which was activated with *p*-nitrophenyl chloroformate to give dicarbonate **11**. Compound **8** was deprotected with TFA and immediately reacted with dicarbonate **11** to afford dendritic molecule **1**.

Dendritic molecule **1** was conjugated with 2 equiv of commercially available PEG400-azide via the copper-catalyzed click reaction (*14*) to give conjugate **1a** (Scheme 4). The location of the PEG tails in the dendron's periphery was highly important for aqueous solubility during the dendritic platform fragmentation as presented in Scheme 5. The PEG tails remained attached to the dendron fragments until the reporter groups of 4-nitroaniline were released. Cleavage of the phenylacetamide group by PGA triggered the disassembly of dendron **1a** through a known self-immolative reaction sequence (*1*).

Following the enzymatic cleavage, azaquinone methide was rapidly eliminated and decarboxylation occurred, leading to internal cyclization that released a urea derivative and phenol **1b**. The latter was disassembled as previously described (*1*) to generate 2 equiv of phenol **1c**, which was further fragmented to release the four reporter groups.

In order to prepare aqueous solutions of **1** and **1a**, the compounds were initially dissolved in DMSO/Cremophor EL (4/1) and then diluted into water. The final composition of the

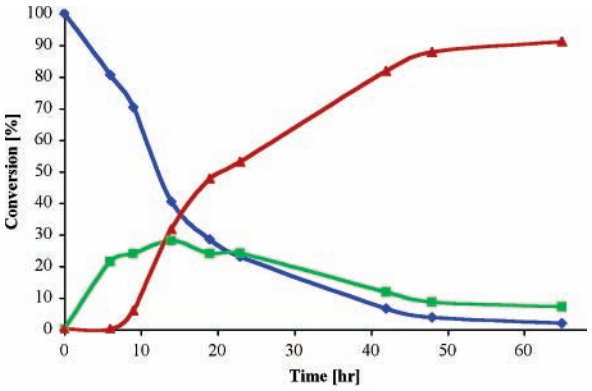


Figure 1. Bioactivation of dendron **1a** by PGA: (blue) dendron **1a**, (green) intermediates, (red) 4-nitroaniline.

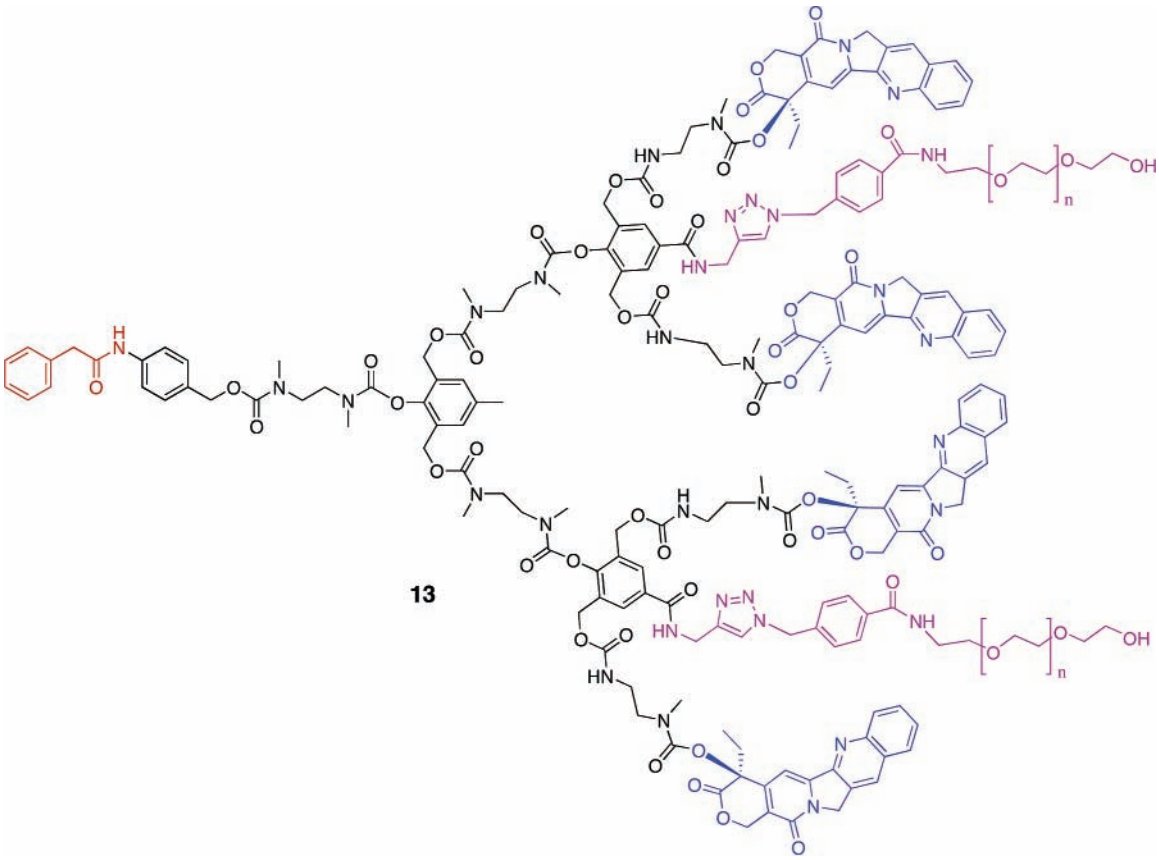
solution was 10% organic and 90% aqueous. Dendritic molecules **1** and **1a** were then incubated with PGA in phosphate-buffered saline (PBS, pH 7.4) at 37 °C. Control solutions were composed of buffer without the enzyme. The sequential fragmentation illustrated in Scheme 5 was monitored by observing the disappearance of dendrons **1** or **1a** and the release of 4-nitroaniline by RP-HPLC. As expected, dendron **1** could not be activated by PGA and remained intact for 72 h (data not shown). However, dendron **1a** showed clear activation upon incubation with PGA, and its corresponding peak completely disappeared from the HPLC chromatogram as 4-nitroaniline appeared (Figure 1). No 4-nitroaniline was observed in the control experiment when dendron **1a** was incubated in the buffer without PGA.

Synthesis and Bioactivation of Second-Generation Dendritic Prodrug System. Motivated by the results obtained with the model system, we evaluated the enzymatic activation of a second-generation dendritic prodrug with camptothecin (CPT), an anticancer agent, in place of the reporter groups (dendron **13**). The antitumor activity of 20(*S*)-camptothecin, a pentacyclic plant alkaloid, was recognized more than 20 years ago. It was first isolated from the Asian tree *Camptotheca acuminata* by Wall and co-workers in 1966 (*15*). CPT exerts its antitumor activity mainly through inhibition of topoisomerase I (*16*). This enzyme, which is found in all mammals, binds preferentially to double-stranded DNA, cleaving one strand and forming an enzyme−DNA covalent bond between a tyrosine residue and the 3′ phosphate of the cleaved DNA. Drug-induced accumulation of topoisomerase I−DNA complexes was identified as an essential step in the effects of CPT, ultimately leading to cell death by apoptosis (*17*).

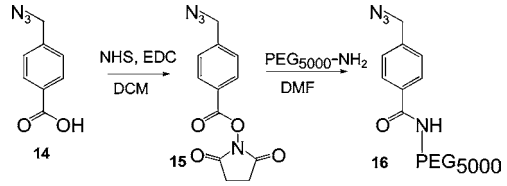
There are two problems associated with CPT therapy: the instability of the 20-hydroxy lactone and the insolubility of CPT in aqueous and organic media. Both the lactone ring and the 20-hydroxy group of CPT are critical for its antitumor activity. The 20-hydroxy lactone is readily hydrolyzed at neutral pH, yielding the inactive carboxylate. The 20-hydroxyl generates an intramolecular hydrogen bond with the carbonyl moiety of the lactone, accelerating the hydrolysis of the otherwise stable lactone ring. Masking of the 20-hydroxy group of CPT results in increased stability of the lactone ring, but also in reduced activity of the drug (*18*). However, a prodrug can be generated from CPT by masking the 20-hydroxyl by a chemical linker that can be selectively removed (*19*). The masking linker serves two purposes: (*1*) removal of the intramolecular hydrogen bond, resulting in a stable lactone, and (*2*) increased solubility of CPT. These circumstances make CPT an ideal drug candidate for the evaluation of our dendritic prodrug system.

Second-generation CPT dendritic prodrug **13** was prepared with a trigger that is activated by PGA and PEG5000 tails to allow sufficient aqueous solubility (Scheme 6). The synthesis

Scheme 6. Molecular Structure of Second-Generation, Self-Immolative, Dendritic CPT (blue) Prodrug with a Trigger Designed for Activation by PGA (red)



Scheme 7. Synthesis of PEG5000 Azide Derivative



is outlined in Schemes 7 and 8. In order to conjugate PEG5000 with the dendritic platform via a click reaction, we had initially prepared a PEG-azide derivative. Hence, compound **14** was synthesized as previously reported (*20*) and its *N*-hydroxysuccinimide ester **15** was prepared (Scheme 7). The latter was reacted with commercially available PEG5000-amine to afford the PEG5000-azide derivative **16**. Then, compound **7** (Scheme 8) was deprotected with TFA and directly reacted with linker **12** to generate compound **17**, which was activated with *p*-nitrophenyl chloroformate to give tetracarbonate **18**. Four equivalents of CPT derivative **19** (prepared according to published procedure (*21*)) was reacted with **18** to afford dendritic molecule **20**. Click conjugation of azide **16** (2 equiv) with diacetylene **20** afforded conjugate **13**.

The aqueous solubility of dendritic prodrug **13** was measured as described in the experimental section and found to be over 11 mg/mL. The bioactivation of the CPT dendritic prodrugs **20** and **13** by PGA was then evaluated. The prodrugs were incubated in PBS (pH 7.4) at 37 °C with and without PGA and the release of free CPT was monitored by RP-HPLC. As in the model system described above, the PEG-conjugated prodrug **13** was efficiently activated by PGA, whereas its parent prodrug **20** (without the PEG) remained intact. The release of CPT from dendritic prodrug **13** as a function of time is plotted in Figure 2. No release was observed when prodrug **13** was incubated in the buffer without PGA.

Cell-Growth Inhibition Assays. Next we evaluated the ability of dendritic prodrug **13** to inhibit cell proliferation in

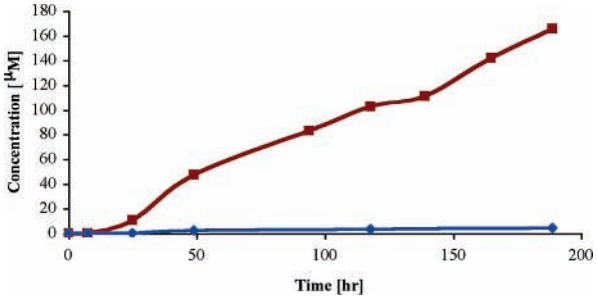


Figure 2. CPT release from dendritic prodrug **13** with PGA (red) and without PGA (blue).

Table 1. IC_{50} (nM) Values from Cell-Growth Inhibition Assays

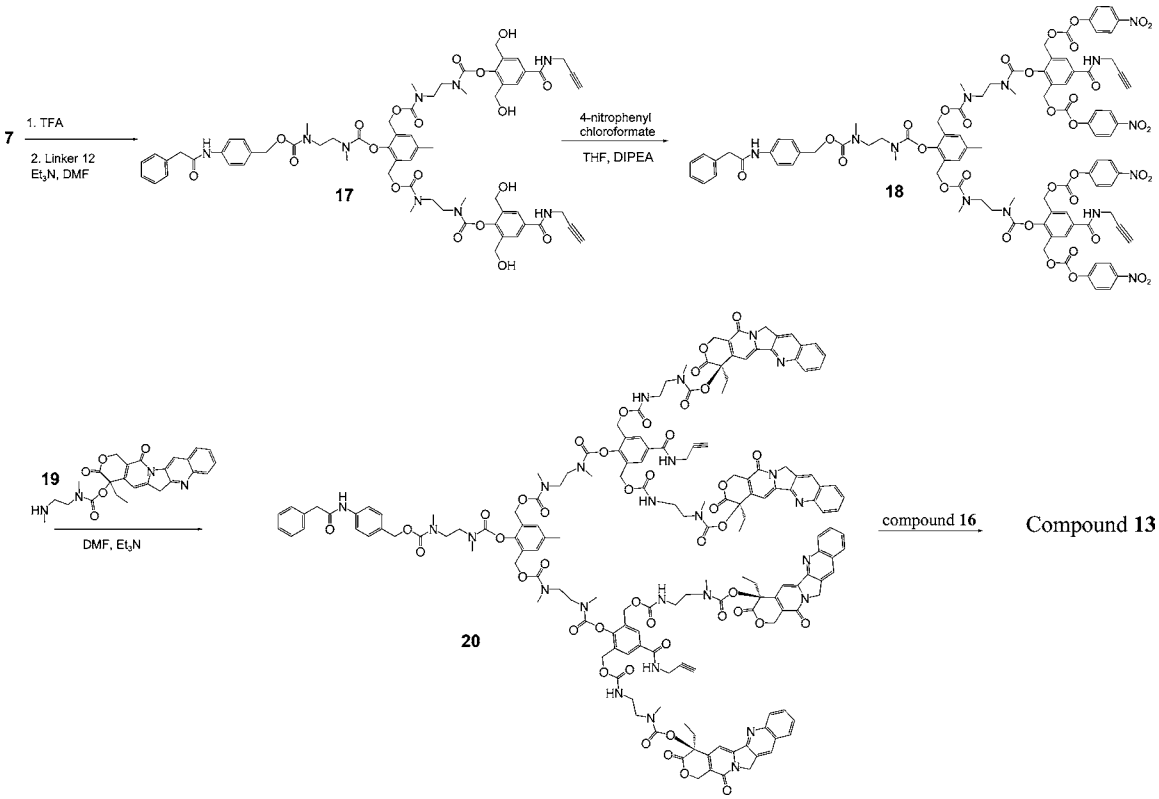
[a] Cells were incubated in medium with drug/prodrug. [b] Cells were incubated in medium with drug/prodrug + 1 μM of PGA.

the presence of PGA using three different cell lines: the human T-lineage acute lymphoblastic leukemia cell line MOLT-3, the human leukemia T cell line JURKAT, and the human kidney embryonic HEK-293 cell line. The results are summarized in Table 1, and the full data from the cell assays are presented in Figure 3. PGA effectively activated dendritic prodrug **13**, and its toxicity was significantly increased in the cell-growth inhibition assays of three cancerous cell lines. The IC_{50} of prodrug **13** was between 100- and 1000-fold less than free CPT. When PGA was added, the prodrug was activated and its toxicity approached that of free CPT. The 2−3 log difference between the drug and the prodrug cytotoxicity suggests that relatively high concentration of prodrug may be applied for tumor therapy, decreasing the negative side-effect of chemotherapeutic drugs.

Scheme 8. Synthesis of Second-Generation Dendritic Prodrug 13



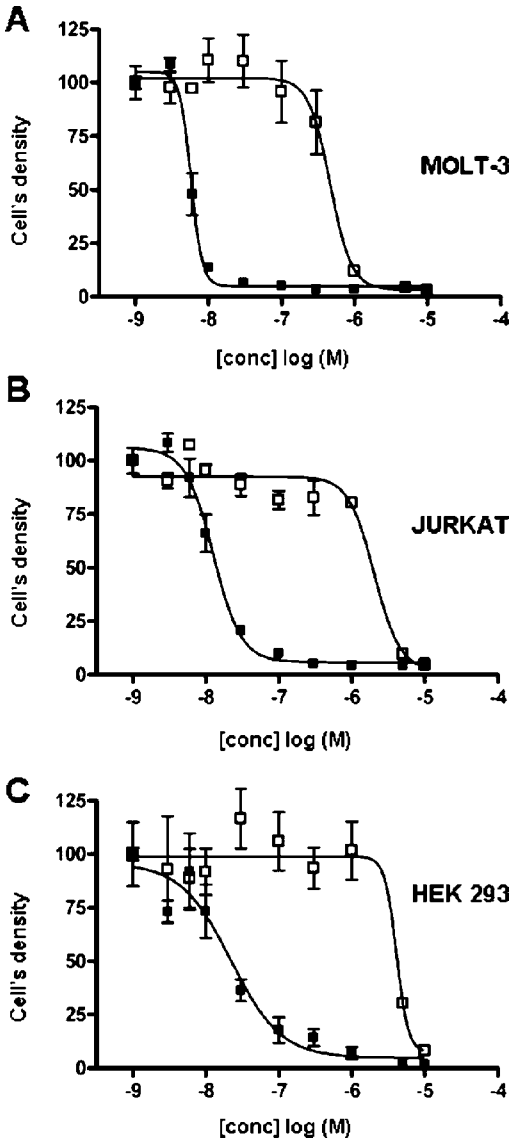


Figure 3. Growth inhibition assay of three human cancerous cell lines, with dendritic prodrug **13** in the presence (■) and absence (□) of PGA; cells were incubated for 72 h.

A dramatic 75% decrease in subcutaneous (s.c.) tumor size has been observed in mice that received a combination of intratumoral injections of activator protein (catalytic antibody 38C2) and systemic treatments with an etoposide prodrug that was 500-fold less toxic than its parent drug (*10*).

It has been previously demonstrated that PEG conjugation prevents protein precipitation by two possible mechanisms (*22*). One possibility is that the PEG group poses a steric hindrance to protein−protein association. A second possibility is that the PEG group shields hydrophobic patches on the protein. Both would significantly reduce protein aggregation and enhance solubility of hydrophobic molecules in water. In the present study even two short PEG400 oligomers were sufficient to permit access of the enzyme to substrate in the dendron's focal point and allow the bioactivation of the system. However, the PEG400 oligomers were large enough to significantly affect to dendrons' aqueous solubility. We assumed that the conjugation PEG oligomers with higher mass should achieved sufficient hydrophilicity to solubilize the dendritic prodrug system in water. Indeed, when PEG5000 was conjugated to a second-generation dendritic prodrug bearing four molecules of the hydrophobic drug CPT, the conjugate had significant aqueous solubility and PGA efficiently activated it.

CONCLUSIONS

In summary, we have demonstrated the first enzymatic activation of second-generation self-immolative dendrimers. We designed and synthesized a dendritic prodrug with four molecules of the anticancer agent camptothecin and a trigger that allows activation by PGA. Two molecules of PEG5000 were conjugated via click chemistry to the dendritic platform in order to gain aqueous solubility. The second-generation self-immolative dendritic prodrug was effectively activated by PGA under physiological conditions, and free CPT was released to the reaction media. Cell-growth inhibition assays demonstrated toxicity of the dendritic prodrug dependent upon incubation with PGA. Incorporation of a specific enzymatic substrate, cleaved by a protease that is overexpressed in tumor cells, could generate a cancer-cell-specific dendritic prodrug activation system.

Received June 26, 2006; Revised Manuscript Received September 12, 2006

2,2′-Bipyridine (bpy) or 1,10-phenanthroline (phen) metal-binding domains were covalently attached to oligonucleotides, and the influence of metal ions on the hybridization of the conjugates was investigated. Metal-binding domains were attached to oligonucleotides at 3′- and 5′-terminal positions, thus placing them in juxtaposed positions after hybridization to a common target strand. While the ligands alone had a positive effect (increased T_m) on hybrid stability, the duplex was further stabilized by the addition of copper(I) and/or copper(II) through the formation of a metal complex in which the two short sequences are linked through {Cu(bpy)$_2$}, {Cu(phen)$_2$}, or {Cu(bpy)(phen)} domains. The increase in T_m, due to formation of the {Cu(bpy)$_2$}, {Cu(phen)$_2$}, or {Cu(bpy)(phen)} motifs is reversed upon addition of EDTA, consistent with the stripping of copper from the ligands. The effect of metal complex formation on the duplex strength was shown to be highest if the two metal-coordinating ligand strands are placed as close to each other as possible.

INTRODUCTION

There is currently significant interest in the development of short oligonucleotides, which bind to nucleic acid targets with high selectivity as well as high affinity (*1*, *2*). Different strategies have been adopted for this purpose, including the conjugation of oligonucleotides with affinity-enhancing moieties and the synthesis of oligonucleotide analogs with enhanced binding properties (*3*, *4*). An additional approach consists of the use of molecular or supramolecular interactions in assisting the hybridization of nucleic acids (*5*−*8*). One possible type of cooperativity is coordination to metal ions to produce metal-linked oligonucleotide strands. When two short oligonucleotide sequences are coupled by coordination to a single metal center, the so-formed, metal-linked oligonucleotide will be capable of recognizing a long complementary sequence with enhanced binding characteristics. The binding of metal ions, taking place concomitantly to the hybridization process, offers a powerful and selective methodology for nucleotide recognition. It is well-known that metal ions can interact with donor atoms of both the backbone and the bases of nucleic acids, and the importance of metal ions in controlling the structure and function of nucleic acids is well-documented (*9*−*12*). Transition metal ions are also of interest in controlling and developing the molecular architecture of nucleic acids and their analogs. Metal-mediated hybridization of various types of DNA analogs has been reported (*13*−*18*), and specific modification through the incorporation of metal-binding domains has been used for the synthesis of DNA-based nanostructures (*19*−*22*). Furthermore, metal-derived hairpin mimics have been described (*23*−*25*), and different types of transition metal complexes have found applications in the context of artificial ribonucleases (*26*−*28*). Due to their compatibility with nucleic acids, metal ions are ideal candidates for the development of systems in which DNA hybridization and metal complex formation can act in a cooperative way. The feasibility of metal cooperative complex formation in assisting nucleic acid hybridization has been demonstrated by Balasubramanian and co-workers, who reported that the coordination of gadolinium(III) to two short oligonucleotides modified with iminodiacetic acid donors leads to enhanced target affinity (*8*). Important in this general context are the recent observations of Sasaki and co-workers (*29*), who showed that copper-induced dimerization of a minor groove-binding ligand increases its affinity to DNA. Stimulated by this work, we have studied the effect of copper ion complexation by metal-binding domains attached to complementary oligodeoxynucleotides in DNA hybridization. For this purpose, oligonucleotide conjugates incorporating 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen) metal-binding domains were synthesized, and the influence on the structure and stability of duplexes formed with complementary target strands in the absence and presence of copper(I) and copper(II) was investigated (illustrated in Figure 1). The findings are reported herein.

EXPERIMENTAL PROCEDURES

General. Reactions were carried out under N_2 atmosphere using distilled, anhydrous solvents. Flash column chromatography was performed using silica gel 60 (63−32 μM, Chemie Brunschwig AG). If compounds were sensitive to acid, the silica was pretreated with solvent containing 2% Et_3N. Oligonucleotides were synthesized on a 392 DNA/RNA Synthesizer (Applied Biosystems). Nucleoside phosphoramidites were from Transgenomic (Glasgow G20 OUA, Scotland); universal solid support used for the reverse synthesis was from Glen/Research (Sterling, Virginia). The solvents (CH_3CN and CH_2Cl_2) were of analytical grade from Proligo GmbH (Hamburg) and reagents (3% TCA/DCM deblock solution, 30 mg/mL activator solution, oxidizing solution, capping solutions A and B) used for the synthesis were from Transgenomic (Glasgow G20 OUA, Scotland). Experiments with EDTA involved the use of a 0.5 M aqueous EDTA stock solution (titrated to pH 8.0 with NaOH). CD experiments were performed using a Jasco J-715 spectropolarimeter with a 150 W Xe high-pressure lamp. A Jasco PDF-

350S-Peltier unit, coupled with a Colora K5 ultrathermostat, controlled the temperature of the cell holder. All NMR spectra were measured at room temperature on a Buker AC-300 spectrometer. ^{1}H NMR spectra were recorded at 300 MHz. Chemical shifts (δ) are reported in parts per million relative to the residual undeuterated solvent ($CDCl_3$, 7.27 ppm; CD_3CN, 1.94 ppm). Coupling constants *J* are in hertz. Multiplicities are abbreviated as follows: s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet. ^{13}C NMR spectra were recorded at 75 MHz. Chemical shifts are reported in parts per million relative to the residual nondeuterated solvent ($CDCl_3$, 77.00 ppm; CD_3CN, 1.32 ppm). ^{31}P NMR spectra were recorded at 162 MHz. Chemical shifts are reported in parts per million relative to 85% H_3PO_4 as an external standard. Electrospray ionization mass spectra (ESI-MS) were recorded on VG platform Fisons instruments.

2-Cyanoethyl (6′-Methyl-2,2′-bipyridin-6-yl)methyl *N*,*N*-Diisopropylphosphoramidite (2). Cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (*30*) (360 mg, 1.2 mmol) was added to a mixture of **1** (200 mg, 1 mmol) and diisopropylammonium tetrazolide (171 mg, 1 mmol) in dry CH_2Cl_2 (10 mL) under a nitrogen atmosphere. The mixture was stirred at room temperature (rt) for 1 h. After evaporation of the solvent, the residue was purified by flash chromatography (hexane/EtOAc 2:1 + 2% Et_3N) to afford **2** (280 mg, 70%). ^{1}H NMR (300 MHz, CD_3CN): δ = 1.26 (m, 12H); 2.61 (s, 3H); 2.73 (m, 2H); 2.77 (m, 2H); 3.95 (m, 2H); 4.91 (m, 2H); 7.30 (d, *J* = 7.72, 1H); 7.56 (d, *J* = 7.72, 1H); 7.82 (t, *J* = 7.73, 1H); 7.95 (t, *J* = 7.73, 1H); 8.33 (d, *J* = 7.53, 1H); 8.36 (d, *J* = 7.92, 1H). ^{13}C NMR (75 MHz, CD_3CN): δ = 20.37; 20.45; 21.80; 22.39; 24.58; 24.63; 24.73; 43.19; 43.35; 47.32; 47.38; 58.52; 48.78; 66.32; 118.18; 119.64; 120.61; 123.19; 137.00; 137.42; 155.62. ^{31}P NMR (161.9 MHz, CD_3CN): δ = 148.71. ESI-MS (positive mode): *m*/*z* = 401.

2-Cyanoethyl (9-Methyl-1,10-phenanthrolin-2-yl)methyl *N*,*N*-Diisopropylphosphoramidite (4). 2-Cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (*30*) (242 mg, 0.8 mmol) was added to a mixture of **3** (150 mg, 0.67 mmol) and diisopropylammonium tetrazolide (114 mg, 0.67 mmol) in dichloromethane (6 mL) under nitrogen atmosphere. The mixture was stirred at rt for 1 h. After concentration, the product was purified by flash column chromatography using hexane/EtOAc (1:2) + 2% Et_3N as eluant to afford **4** (214 mg, 75%). TLC (hexane/EtOAc 1:2 + 2% Et_3N): R_f = 0.7. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.08−1.25 (m, 18H); 2.64 (t, *J* = 6.4, 3H); 2.87 (s, 3H); 3.42−357 (m, 2H); 3.63−3.71 (m, 3H); 3.82−3.94 (m, 2H); 5.08−5.27 (m, 2H); 7.45 (d, *J* = 8.29, 1H); 7.68 (s, 2H); 7.85 (d, *J* = 8.29, 1H); 8.09 (d, *J* = 8.29, 1H); 8.22 (d, *J* = 8.45, 1H). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 20.38; 21.76; 22.39; 24.66; 25.96; 43.24; 47.31; 58.62; 120.45; 125.57; 126.02; 136.33; 136.83. ^{31}P NMR (161.9 MHz, $CDCl_3$): δ = 149.11.

Oligonucleotide Synthesis and Purification. Oligonucleotides were synthesized according to the standard phosphoramidite solid-phase chemistry. The 5′-conjugated oligonucleotide sequences were elongated from the 3′-end using normal nucleoside phosphoramidites, whereas the 3′-conjugated oligonucleotide sequences were elongated from the 5′-end using universal-Q solid support (*31*) and reverse nucleoside phosphoramidites. The standard synthetic procedure ("trityl-off" mode) and standard condition (i.e., a coupling time of 90 s) were used to incorporate the phosphoramidite building blocks **2** and **4** into oligonucleotide sequences. Detachment of the oligonucleotides from the solid support and deprotection after the synthesis were performed using standard procedures (conc NH_3 solution, 55 °C, 16 h), followed by filtration through Spritzenfilter (nylon, 0.17 mm/0.45 μm, Semadeni AG). All crude oligonucleotides were purified by ion-exchange HPLC, using Tricorn column−Source 15Q 4.6/100PE−15 μm from Amersham Biosciences (Freiburg, Germany). The collected fractions were desalted over Sep-Pak cartridges (Waters, Milford, U.S.A.). Optical densities (ODs) of the purified oligonucleotides were measured at 260 nm with a NanoDrop ND-1000 spectrophotometer, and the masses determined by electrospray mass spectroscopy: VG Platform single quadrupole ESI-MS. Sequences and data are shown in Table 1.

UV Melting Experiments. If not indicated otherwise, all experiments were carried out under the following conditions: oligonucleotide concentration 1.5 μM; 10 mM phosphate buffer, pH = 7.5 (23 °C); 100 mM NaCl. For experiments with metals, 1 mM stock solutions (in milliQ-H_2O) of the following metals were used: $ZnCl_2$; $CuCl_2 \cdot 2H_2O$; $[Cu(CH_3CN)_4][PF_6]$. The latter was prepared as described in the literature (*32*). The solution of $[Cu(CH_3CN)_4][PF_6]$ was always freshly prepared, and argon bubbled through it for at least 10 min to avoid rapid oxidation of copper(I) to copper(II). This procedure was also used to degas the buffers or solution used in all the experiments involving copper(I).

Thermal denaturation experiments were performed on a Varian Cary 3e UV−vis spectrophotometer equipped with a Peltier block temperature controller, and Varian *WinUV* software was utilized to determine the melting curves at 260 nm; a heating−cooling−heating cycle in the temperature range 0−90 °C or 10−90 °C was applied with a temperature gradient of 0.5 °C/min. To avoid H_2O condensation on the UV cells at temperatures ≤20 °C, the cell compartment was flushed with N_2. Data were collected and analyzed with *Kaleidagraph* software from Synergy Software. T_m values were determined as the maximum of the first derivative of the melting curve; each T_m is the average of three independent experiments; exptl error: ±0.5 °C.

RESULTS AND DISCUSSION

Synthesis of the Phosphoramidite Building Blocks. The required phosphoramidite building blocks were obtained from

Scheme 1. Conditions: (a) $(iPr_2N)_2P(OCH_2CH_2CN)$, *N,N*-diisopropylammonium 1*H*-tetrazolide, CH_2Cl_2, rt, 1 h.

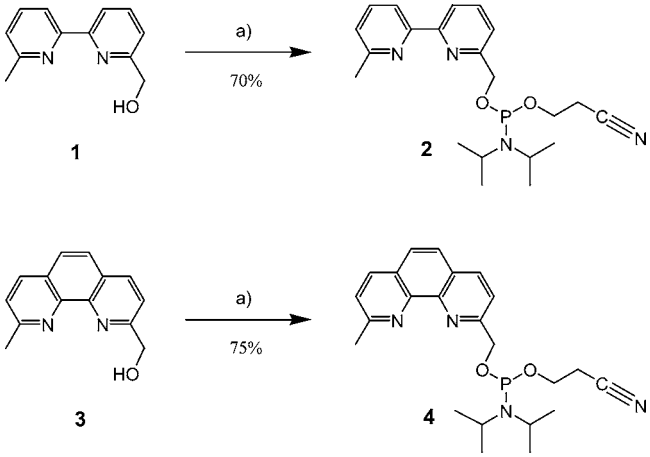

Table 2. Effect of Terminal bpy and phen Ligands on Hybrid Stability.

entry	hybrid [a]	Tm (°C)	ΔTm [b] (°C)
2-1	**T0** + **R1** + **R2**	49.0	-
2-2	**T0** + **C1-bpy** + **C2-bpy**	53.5	+ 4.5
2-3	**T0** + **C1-phen** + **C2-phen**	56.5	+ 7.5

[a] Conditions: Na_2HPO_4 (10 mM; pH = 7.5); NaCl (100 mM); oligonucleotides (1.5 μM); T_m values were determined as the first derivative of the melting curve. [b] Difference in T_m relative to reference (entry 2−1).

known precursors (*33*−*35*). Thus, 6-methyl-2,2′-bipyridine (**1**) was converted to the bpy−phosphoramidite **2** in 70% via the intermediate 6-hydroxymethyl derivative. Similarly, 2-methyl-1,10-phenanthroline (**3**) yielded the phen−phosphoramidite **4** (75%) as shown in Scheme 1.

Oligonucleotide Synthesis. The phosphoramidites **2** and **4** were incorporated into the oligonucleotides (Table 1) using standard oligonucleotide technology (*36*, *37*). The metal-binding domains were incorporated at the 5′-end of a 13-mer sequence (**C1-bpy** and **C1-phen**) and at the 3′-end of an 8-mer sequence (**C2-bpy** and **C2-phen**). For the synthesis of the **C1** conjugates, conventional deoxynucleoside phosphoramidites were used. The **C2** conjugates were synthesized using reverse phosphoramidites (*38*, *39*). Standard conditions were applied, with the exception that prolonged (5 min) coupling time was allowed for the modified building blocks to ensure maximal coupling efficiency. The **C1** conjugates were designed to be complementary to the 5′-end and the **C2** conjugates complementary to the 3′-end of the target (**T0**). Oligonucleotides **R1** and **R2** were prepared as reference oligonucleotides. Detachment of the oligonucleotides from the solid support and deprotection involved standard conditions (conc NH_3 solution, 55 °C, 16 h). Oligonucleotides were purified using ion-exchange HPLC and characterized by electron spray mass spectrometry.

Effect of bpy and phen Metal-Binding Domains on the Duplex Stability in the Absence of Metal Ions. We first examined the influence on the stability of the duplex of the bpy- and phen-modified oligonucleotides with the target complementary strand **T0** in the absence of metal ions. T_m values obtained from thermal denaturation experiments are shown in Table 2. The introduction of metal-binding domains leads to an increase in stability in comparison to the native duplex (Table 2). Thus, an increase in the T_m value of 4.5 and 7.5 °C, respectively, for bpy- (entry 2−2) and phen-modified (entry 2−3) oligonucleotide hybrids with **T0** was observed. The increase in the stability of the modified duplexes (in comparison to the unmodified duplex, which possesses a nicked sequence in the molecule structure) may be the result of stacking interaction between the two diimine ligands facing each other or between the diimine ligands and the adjacent nucleobases.

Table 3. Thermal Denaturing Experiments with bpy and phen Conjugate in the Presence and Absence of Metal.

3-10	**T0** + **C1-bpy** + **C2-phen** + Cu(I)	61.0	+ 10.0

[a] Conditions: Na_2HPO_4(10 mM; pH = 7.5); NaCl (100 mM); oligonucleotides (1.5 μM); T_m values were determined as the first derivative of the melting curve. [b] Difference in T_m relative to the respective metal-free experiment.

Effect of Metal Coordination on Duplex Stability. We next investigated the influence of copper(I) and copper(II) salts on the stability of the modified duplexes. The thermal denaturing experiments with the modified duplex in the presence of these metal ions showed a further remarkable increase in the T_m values by the presence of copper(II) and/or copper(I) (Table 3). For the bpy conjugates (**C1**−**bpy** and **C2**−**bpy**, entries 3−2 and 3−3) an increase of approximately 7 °C was observed upon addition of either of the two metals. In aqueous solution, simple copper(I) salts are unstable with respect to oxidation or disproportionation, and copper(II) species are expected at equilibrium. However, in the case of bpy ligands bearing substituents at the 6- or 6,6′-positions or phen ligands bearing substituents at the 2- or 2,9-positions, copper(I) $\{CuL_2\}^+$ complexes are stabilized by about 3 lgK units to give water-stable copper(I) complexes (*40*−*44*). Furthermore, with 6,6′-disubstituted 2,2′-bipyridine or 2,9-disubstituted 1,10-phenanthroline ligands, reaction with copper(II) or copper(I) leads to the same copper(I) solution species. This phenomenon is discussed in detail elsewhere (*45*). On the other hand, no effect was observed with zinc(II) (Table 3, entry 3−4) as expected from the observations that (i) zinc(II) complexes of bpy and phen ligands are less stable than copper complexes following the Irving−Williams series and (ii) zinc(II) complexes of bpy ligands bearing substituents at the 6- or 6,6′- positions or phen ligands bearing substituents at the 2- or 2,9-positions are less stable than those with bpy and phen. These findings can be interpreted in terms of a common copper(I) complex and

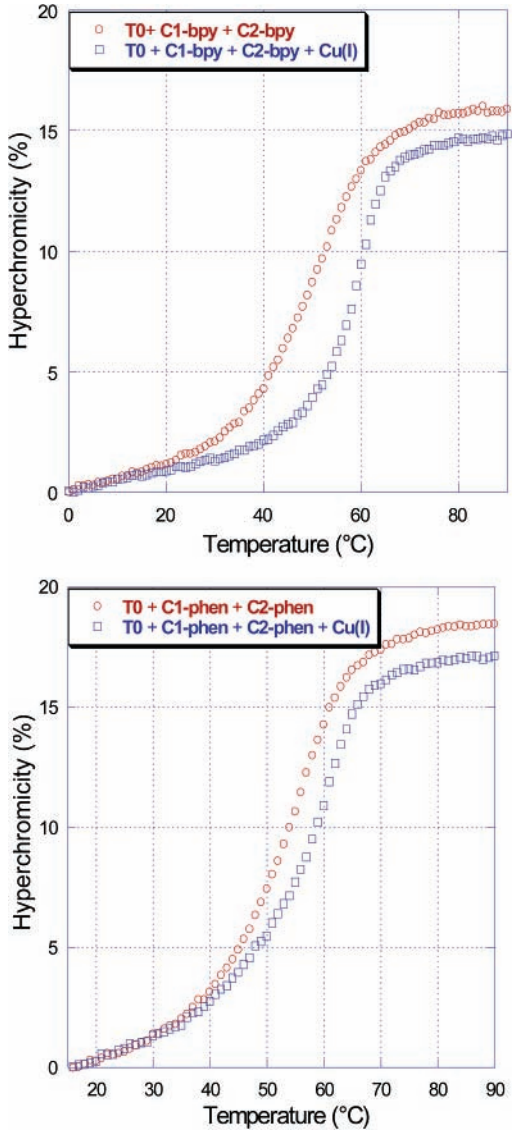

Figure 2. Thermal denaturing curves of hybrids formed by target and conjugates in the presence and absence of metals. Conditions: Na_2HPO_4 (10 mM; pH = 7.5); NaCl (100 mM); oligonucleotides (1.5 μM); heating and cooling rate, 0.5 °C/min; each of the curves shown corresponds to the second of three ramps.

minimal binding of Zn^{2+} to conjugate ligands under the experimental conditions. The phen conjugates (**C2−phen**) showed an increase of 4.5 °C in T_m upon addition of copper(I). The thermal denaturation curves for the hybrids in the absence and presence of copper(I) for both types of conjugates, i.e., bpy and phen, are shown in Figure 2. In all cases, a single transition is observed. Hyperchromicities in the presence and absence of the metals are comparable. Copper(I) and copper(II) ions interact with two bpy or phen ligands to form a stable tetrahedral $\{CuL_2\}$ species (*46*−*48*). Although initial studies utilized both copper(I) and copper(II), we subsequently only investigated interactions with copper(I). The formation of these metal complexes leads to a linking of the two conjugate strands and the formation of a single metallonucleotide strand and, hence, an increase in hybrid stability. The addition of transition metal salts had no experimentally significant influence on the T_m of any control duplex (see Supporting Information). Thus, we can rule out that the effects observed in the case of modified duplexes are due to general metal coordination to the nucleic acid—DNA and RNA are well-known to have a large variety of sites for metal interaction (*36*−*40*)—but rather to specific complex formation with the bpy and phen ligands. Formation of the copper(I) complex does not have an influence on the general B-form structure of the DNA as verified by circular dichroism analysis (see Supporting Information).

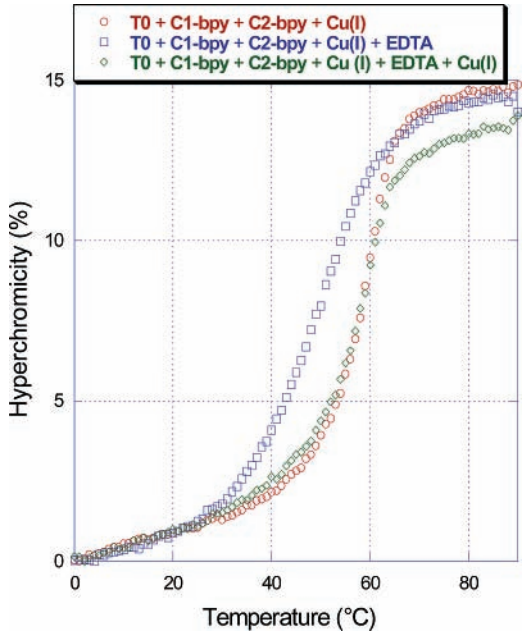

Figure 3. Thermal denaturing curves of hybrids formed by bpy conjugated duplex with consecutive metal and EDTA additions. Conditions: see Figure 2; each of the curves shown corresponds to the second of three ramps.

Effect of Mixed-Ligand Complexes on Hybrid Stability. Mixed-ligand duplexes were formed by hybridizing one bpy and one phen oligonucleotide probe to the target **T0** (Table 3, entries 3−7 and 3−9). With a difference of 6 °C between these two duplexes (57.0 °C and 51.0 °C, respectively) in the absence of metal, the stability of the mixed-ligand duplex depends considerably on the relative positions (3′ or 5′) of the bpy or phen metal-binding domains. Upon the addition of copper(I) (Table 3, entries 3−8 and 3−10), this difference between the two heteroleptic duplexes disappears (T_m = 61 °C in both cases), consistent with the formation of two very similar metal complexes. Furthermore, for both mixed-domain complexes, the hybrid stability is, not unexpectedly, very similar to that of the homocomplexes (entries 3−2 and 3−6).

Effect of EDTA on the Duplex Stabilization. Experiments involving EDTA were performed in order to test the strength of the bpy−metal complexes and the reversibility of metal-induced duplex formation. The denaturation curves are shown in Figure 3. The addition of EDTA to the metalloduplex leads to a T_m which is equal to the one obtained in the absence of metal—in other words, the copper is removed quantitatively upon treatment with the chelating ligand EDTA. The T_m value of the metal-coordinated duplex is restored upon treatment with additional copper(I) or copper(II), establishing the complete reversibility of the formation of the metal linkage between the oligonucleotides.

Influence of Gap Size at the Site of Metal-Complex Formation. In order to investigate the influence of the gap between the two metal-binding domains facing each other—at the complexation site—on duplex stability, hybridization to targets **T1**−**T3**, containing one, two, and three additional cytidines at the junction of the two complementary functionalized oligomers (Table 4), was examined. These oligonucleotides are formally derived from **T0** by sequential addition of the respective numbers of cytosines after position 13. In this way, the relative distance between the metal-binding bpy or phen

[a] Conditions: Na_2HPO_4 (10 mM, pH = 7.5); NaCl (100 mM); oligonucleotides (1.5 μM); T_m values were determined as the first derivative of the melting curve. [b] Difference in T_m relative to the metal-free reference. [c] Gap size was varied by increasing the number (0−3) of cytidine nucleotides in the target strand.

domains was gradually increased, while the total number of base pairs formed in each hybrid was kept constant. Thermal denaturing experiments were performed with the bpy conjugates **C1**−**bpy** and **C2**−**bpy**, and the results are summarized in Table 4. In the absence of copper, an elongation of the gap between the two ligands leads to a slight increase (2−3 °C) in the T_m value of the duplex. This stabilization may well be attributed to steric requirements of the bpy or phen substituents. With increasing gap size, the metal-free functionalized oligonucleotides are better accommodated with a reduction of repulsion between the metal-binding domains, and hence hybrid stability increases. Upon the addition of the metal ion, however, formation of the metal complex becomes the dominant aspect. Apparently, close proximity facilitates the coordination of the metal by the two terminal metal-binding domains. In this context, the relatively short and inflexible methylene linker further supports this interpretation of the data: the stability of the hybrids is highest if the gap is minimal, i.e., if the two metal-binding domains are juxtaposed, as is the case with target **T0**.

CONCLUSIONS

The influence of metal complex formation on hybridization of oligodeoxynucleotides was investigated. Oligonucleotides containing 3′- and 5′-linked 6′-methyl-2,2′-bipyridine- and 2-methyl-1,10-phenanthroline-derived metal-binding domains were synthesized. Pairs of oligonucleotide conjugates were designed to hybridize to a target DNA sequence, such that the two copper-binding domains are arranged head-to-head in the ternary hybrid to create an N_4 metal-binding site. Incorporation of the metal-binding domains had a positive influence on hybrid stability per se (ΔT_m = 4.5−7.5 °C). Addition of copper(I) or copper(II) sources results in the formation of metal complex and leads to substantial further stabilization (up to 10 °C increase in T_m). While the placement of the metal-free ligands had no influence on the extent of the stabilization, the stabilizing effect obtained by metal coordination was found to be distance-dependent, i.e., the largest increase is observed upon placement of the ligands as close to each other as possible. While the stability of the hybrid is substantially influenced by metal coordination, the overall B-form structure of the DNA is not affected. This study shows that hybridization of relatively short (13- and 8-mer) oligonucleotides modified with bpy or phen metal-binding domains to a complementary target DNA is assisted by formation of {$Cu(bpy)_2$}, {$Cu(phen)_2$}, or {Cu(bpy)-(phen)} metal complexes.

Engineering an Arginine Catabolizing Bioconjugate: Biochemical and Pharmacological Characterization of PEGylated Derivatives of Arginine Deiminase from *Mycoplasma arthritidis*

Maoliang Wang, Amartya Basu, Thomas Palm, Jack Hua, Stephen Youngster, Lisa Hwang, Hsien-Ching Liu, Xiguang Li, Ping Peng, Yue Zhang, Hong Zhao, Zhihua Zhang, Clifford Longley, Mary Mehlig, Virna Borowski, Prakash Sai, Manickam Viswanathan, Eun Jang, Gerald Petti, Sam Liu, Karen Yang, and David Filpula*

Enzon Pharmaceuticals, 20 Kingsbridge Road, Piscataway, New Jersey 08854-3969. Received July 5, 2006; Revised Manuscript Received August 31, 2006

Arginine is an important metabolite in the normal function of several biological systems, and arginine deprivation has been investigated in animal models and human clinical trials for its effects on inhibition of tumor growth, angiogenesis, or nitric oxide synthesis. In order to design an optimal arginine-catabolizing enzyme bioconjugate, a novel recombinant arginine deiminase (ADI) from *Mycoplasma arthritidis* was prepared, and multi-PEGylated derivatives were examined for enzymatic and biochemical properties in vitro, as well as pharmacokinetic and pharmacodynamic behavior in rats and mice. ADI bioconjugates constructed with 12 kDa or 20 kDa monomethoxy-poly(ethylene glycol) polymers with linear succinimidyl carbonate linkers were investigated via intravenous, intramuscular, or subcutaneous administration in rodents. The selected PEG−ADI compounds have 22 ± 2 PEG strands per protein dimer, providing an additional molecular mass of about $0.2-0.5 \times 10^6$ Da and prolonging the plasma mean residence time of the enzyme over 30-fold in mice. Prolonged plasma arginine deprivation was demonstrated with each injection route for these bioconjugates. Pharmacokinetic analysis employed parallel measurement of enzyme activity in bioassays and enzyme assays and demonstrated a correlation with the pharmacodynamic analysis of plasma arginine concentrations. Either ADI bioconjugate depressed plasma arginine to undetectable levels for 10 days when administered intravenously at 5 IU per mouse, while the subcutaneous and intramuscular routes exhibited only slightly reduced potency. Both bioconjugates exhibited potent growth inhibition of several cultured tumor lines that are deficient in the anabolic enzyme, argininosuccinate synthetase. Investigations of structure−activity optimization for PEGylated ADI compounds revealed a benefit to constraining the PEG size and number of attachments to both conserve catabolic activity and streamline manufacturing of the experimental therapeutics. Specifically, ADI with either 12 kDa or 20 kDa PEG attachments on 33% of the primary amines retained about 60% or 48% of enzyme activity, respectively; the K_m and pH profiles were nearly unchanged; IC_{50} values were diminished by less than 30%; while stability studies demonstrated full retention of activity at 4 °C for 5 months. A comparison of the enzymatic properties of a second ADI from *Pseudomonas putida* illustrated the superior characteristics of the *M. arthritidis* ADI enzyme.

INTRODUCTION

Enzymes have inherent utility as pharmaceuticals, owing to their substrate specificity, catalytic efficiency, and favored function under physiological environments (*1*−*7*). Unlike antibodies, receptors, or ligands, enzymes have the capacity to permanently alter their target, rather than merely act as its antagonist or agonist. Yet enzymes, as a drug category, have demonstrated insufficient progress in recent years, due to the considerable challenges of (*1*) identifying and manufacturing the optimal enzyme, (*2*) employing the best drug delivery formulation, and (*3*) recognizing the correct patient population whose genotype correlates with a metabolic difference which the enzyme therapy may exploit.

While the target specificity of enzymes makes them attractive drug candidates, protein therapeutics also have disadvantages including immunogenicity, limited stability and circulating life, and suboptimal biodistribution/bioavailability. Advances in drug delivery systems for protein therapeutics have increased interest in enzyme therapy as a strategy for disease management (*8, 9*). The pioneering research on the antineoplastic activity of L-asparaginase led to the establishment of this bacterial enzyme as a major component in the treatment of acute lymphoblastic leukemia—the first FDA licensed heterologous enzyme therapy for cancer (*7, 10, 11*). Asparaginase therapy exploits a difference in asparagine auxotrophy between normal and leukemic cells. Unfortunately, few tumor-specific metabolic targets have been well-established.

One promising metabolic target which has shown promise in experimental therapies for the treatment of cancer is arginine, an amino acid which plays an important role in many metabolic pathways (*12*−*14*). Arginine is a nonessential amino acid for the growth of most normal and tumor cells, which are able to convert citrulline into arginine. The apparent arginine auxotrophy of melanoma and hepatocellular carcinoma (HCC) cells may offer an effective method for selective growth inhibition by enzymatic depletion of plasma arginine (*15*−*18*). Arginine is synthesized from citrulline by two urea cycle enzymes, argininosuccinate synthetase (AS) and argininosuccinate lyase (AL). In humans, the AS gene is expressed in all normal cells and tissues except circulating humoral cells. The AS gene appears to be regulated by metabolite repression, and the cultivation of human cells in arginine free medium, supplemented with citrulline, increases the expression of AS by 3- to 150-fold (*12*). AL, the second enzyme involved in the conversion of citrulline

to arginine, appears to be constitutively expressed in all tissues (*12*). Recently, it has been shown that human melanomas and hepatocellular carcinomas are frequently deficient in AS expression (*15*, *19*, *20*), which may be the underlying mechanism that rendered these cells susceptible to growth inhibition by arginine deprivation.

Arginine deiminase (ADI[1]; L-arginine iminohydrolase, EC 3.5.3.6) catalyzes the conversion of L-arginine into L-citrulline and ammonia. Although not present in humans, ADI is expressed in many microbial organisms, such as mycoplasma, yeast, bacteria, and protozoa. The best-studied of these enzymes are obtained from *Pseudomonas aeruginosa*, *Mycoplasma arginini*, and *Mycoplasma hominis* (*21*−*27*). These enzymes, as well as mammalian arginase, have been shown to be effective in inhibiting growth of cancer cell lines in vitro and in experimental tumors in rodents (*28*−*34*), as well as exhibiting antiviral effects (*35*), anti-angiogenesis activity (*36*), and decreasing nitric oxide production (*37*). Early clinical studies suggest arginine deprivation may be a significant therapy for selected carcinomas (*34*, *38*, *39*). These arginine catabolizing enzymes are not ideal therapeutics, however. Reported K_m values of 0.2−2 mM are not well matched to the task of total elimination of plasma arginine (∼100 μM), and the enzymes are not optimally active at physiological pH (*33*). Furthermore, all of these enzymes present drug delivery and immunogenicity challenges that may be addressed by bioconjugate chemistry.

PEGylation, the covalent attachment of poly(ethylene glycol) polymers to compounds, has become one of the best-validated drug delivery methods for extension of serum half-life and the reduction of immunogenicity (*1*, *9*, *40*−*47*), and at least six PEGylated protein therapeutics are now on the market (*8*). In general, activated PEG polymers reacted with primary amines have been employed in multiple attachments with catabolic enzymes and other macromolecules which recognize small substrates. Several different chain lengths of PEG have been examined with various linker chemistries in previous reports (*40*, *44*, *46*). While bioconjugates of enzymes with PEG have demonstrated some of the expected benefits in pharmacological behavior, there has been insufficient focus in bioconjugate science on first engineering a superior active pharmaceutical protein and also matching that compound to the best linkage and the preferred degree of modification.

The goals of our current studies were to develop a new arginine-catabolizing bioconjugate which would (1) demonstrate superior pharmacological properties in vivo, (2) offer a practical manufacturing process, and (3) exhibit improved stability and potency in vitro. Our work plan focused on development of a new arginine deiminase from *Mycoplasma arthritidis*. Several reports describe *M. arthritidis* ADI as a novel enzyme in this category (*48*−*50*), with a distinct physiological pH optimum, suitable activity, very low K_m, and unusual disulfide content that might be ideal as an in vivo therapeutic. We purified and characterized recombinant *M. arthritidis* ADI and employed a stable succinimidyl carbonate linker with a parsimonious PEGylation strategy to preserve enzyme activity and antitumor potency in cell culture, while achieving excellent pharmacokinetics and pharmacodynamics in rodent studies.

EXPERIMENTAL PROCEDURES

Materials. Hiload Superdex 200, Q Sepharose FF (QSFF), and Arginine Sepharose 4B resins were supplied by GE Healthcare (Piscataway, NJ), and Poros HS was supplied by Applied Biosystems (Foster City, CA). YM-100 (100 kDa MWCO) CentriPlus devices were from Millipore (Billerica, MA). Precast 4−20% Tris-glycine SDS−PAGE gels and cell culture media were obtained from Invitrogen (Carlsbad, CA). Titrisol iodine solution was obtained from EM Science (Gibbstown, NJ). 2,3-Butanedione monoxime was purchased from Alfa Aesar (Ward Hill, MA). Antipyrine and jack bean urease were supplied by Sigma. Anti-ADI rabbit serum was produced by BioSynthesis (Lewisville, TX). *P. putida* ADI (25 IU/mg) was obtained from Enzon Pharmaceuticals, Inc.

Synthesis of SC−PEG. A solution of 12 kDa mPEG-OH (12.3 g, 1.03 mmol) was azeotroped in 450 mL of toluene for 2 h while removing 150 mL of toluene/water, followed by cooling to 50 °C. To this was added triphosgene (0.31 g, 1.04 mmol) and pyridine (0.61 g, 7.6 mmol), and the mixture was stirred for 3 h at 50 °C, followed by the addition of *N*-hydroxyl succinimide (NHS, 0.36 g, 3.13 mmol) and pyridine (0.39 g, 5.0 mmol). This mixture was stirred overnight at 50 °C, followed by partial removal of the solvent by rotary evaporation under reduced vacuum and precipitation of the product with ether. The solid was collected, washed with ether, and recrystallized from DMF/IPA to yield the SC−PEG product (11.6 g, 0.97 mmol, 94%). ^{13}C NMR analysis was conducted: (75.4 MHz, $CDCl_3$) δ 168.14, 151.09, 71.54−67.95 (PEG), 56.65, 25.13. Other SC−PEG polymers with differing masses were synthesized by comparable steps (*51*).

Expression of *M. arthritidis* ADI gene in *E. coli*. *M. arthritidis* strain 14152 was obtained from the American Type Culture Collection. The ADI gene was isolated by PCR using the primer pair 5′-GGCAATCGATGTCTGTATTTGACAGTA-3′ and 5′-TGAGGATCCTTACTACCACTTAACATCTTTACG-3′ derived from the ADI sequence of *M. arginini* LBIF (GenBank Accession X54312). Thirty cycles were carried out (94 °C, 60 s; 37 °C, 180 s; 72 °C, 120 s). A single 1.2 kb fragment was cloned and sequenced and confirmed to have sequence similarity to ADI. The N-terminal region of the *M. arthritidis* gene was confirmed by inverse PCR methods. The five TGA codons in the isolated ADI gene which encode tryptophan in *Mycoplasma* were changed to TGG codons by oligonucleotide-directed mutagenesis. The gene was inserted into vector pET 27b+ (Novagen) and expressed in host BLR(DE3). The GenBank Accession Code has been assigned BD056868. DNA sequence confirmation of all ADI genes was performed on an ABI PRISM 310 Genetic Analyzer.

Purification of *M. arthritidis* ADI. Recombinant ADI was purified from inclusion bodies as described (*21*) with the following modifications. Inclusion bodies were resuspended in 6 M guanidine−HCl buffer containing 10 mM DTT and diluted 20-fold with refolding buffer containing 0.5 M arginine, and allowed to refold for at least 16 h at 4 °C. Chaotropic agent and reducing agent were then removed by diafiltration. The diafiltered ADI solution was applied to a Q Sepharose FF column which was pre-equilibrated with buffer A (20 mM sodium phosphate, pH 7.2). The loaded column was washed with 5 CV buffer A, and ADI was eluted with a 10−50% gradient of buffer B (20 mM sodium phosphate, pH 7.2, 1.0 M NaCl). The active peak fractions from QSFF were pooled and applied to an Arginine Sepharose 4B column which was pre-equilibrated with 20% buffer B. Any nonspecifically bound protein was removed from the column with 20% buffer B (5 CV), and ADI was eluted with a 20−50% gradient of buffer B.

[1] Abbreviations: ADI, arginine deiminase; AUC, area under the curve; CV, column volume; ELISA, enzyme-linked immunosorbent assay; HAc, acetic acid; HRP, horseradish peroxidase; i.m., intramuscular; i.v., intravenous; LOQ, limits of quantification; mAb, monoclonal antibody; mPEG, monomethoxy-PEG; MRT, mean retention time; MW, molecular weight; NHS, *N*-hydroxysuccinimide; PBS, phosphate-buffered saline; PD, pharmacodynamics; PEG, poly(ethylene glycol); PK, pharmacokinetics; RP, reversed phase; s.c., subcutaneous; SC, succinimidyl carbonate; SE-HPLC, size-exclusion high-performance liquid chromatography; $t_{1/2}$, serum half-life; TFA, trifluoroacetic acid; TNBS, trinitrobenzene sulfonic acid; UF/DF, ultrafiltration/diafiltration.

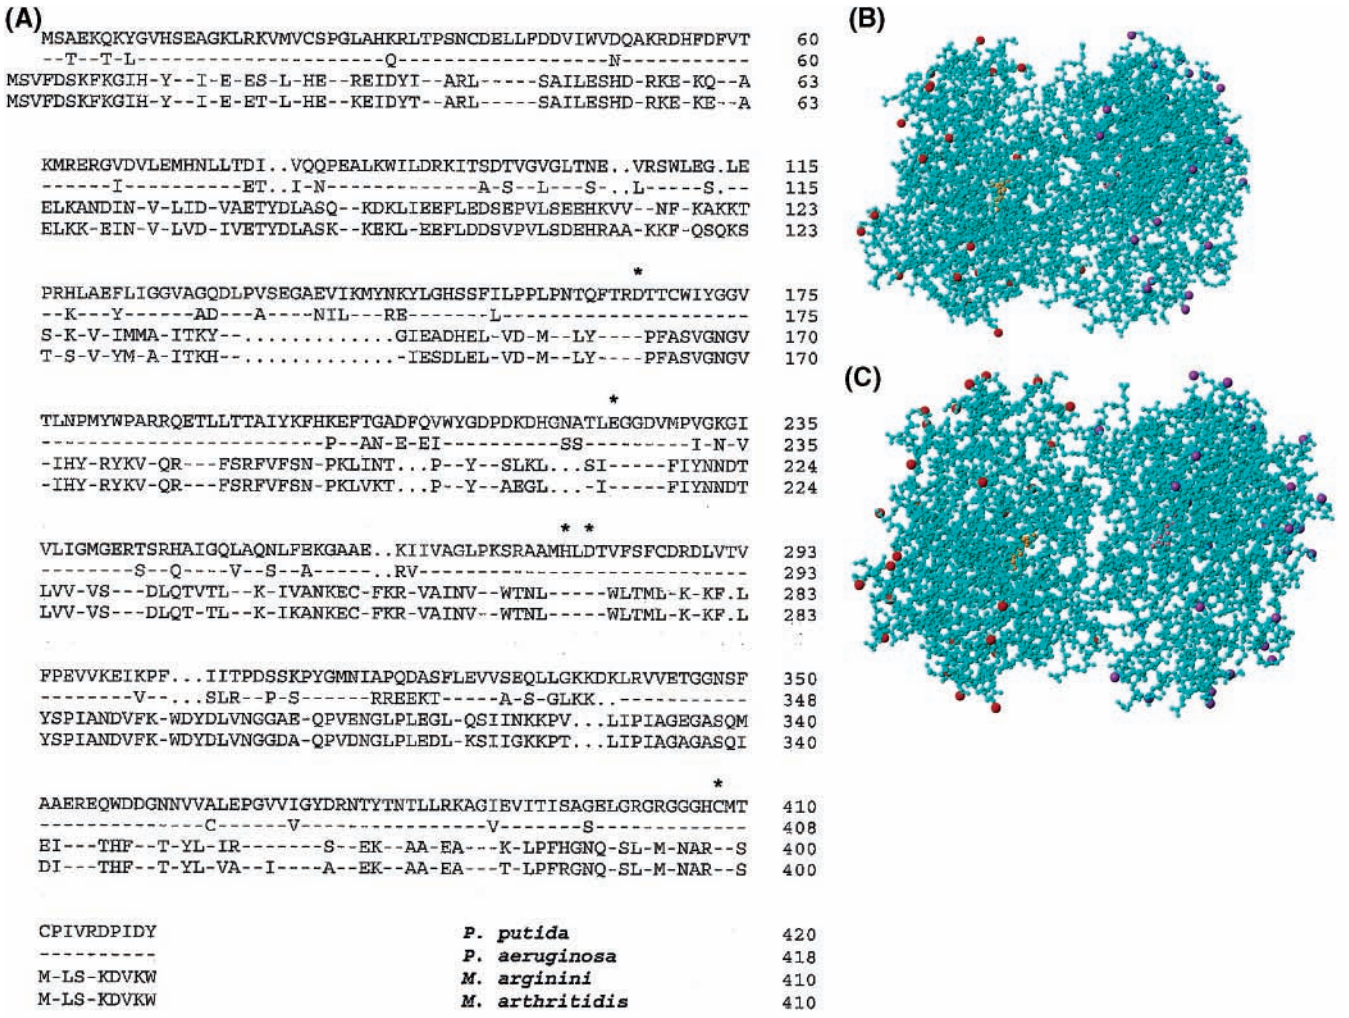

Figure 1. (A) Amino acid coding sequences of ADI from *P. putida* (U07185), *P. aeruginosa* (X14694), *M. arginini* (X54312), and *M. arthritidis* (AR112900) Putative active site catalytic residues are highlighted (*), and residues identical to the *P. putida* sequence (- - -) or residues missing in the aligned sequence (⋯) are indicated. (B) Molecular architecture of *M. arginini* ADI dimer (*23*) (PDB file name 1LXY) with lysine N-atoms highlighted by purple and red spheres in the two subunits. Citrulline covalently attached at the active site is depicted by orange and pink spheres, respectively. (C) Molecular modeling of *M. arthritidis* lysine positions based on *M. arginini* dimer structure with lysine N-atoms symbolized by purple and red spheres and the product citrulline covalently attached at the active site depicted in orange and pink spheres.

Table 1. Purification of Recombinant *M. arthritidis* ADI from Inclusion Bodies

purification step[a]	volume (mL)	protein concn (mg/mL)	total protein (mg)	specific activity (U/mg)	total activity[b] (IU)	purity[c] (%)
inclusion body solution	200	3.00	600			60.6
Q-sepharose-FF	450	0.43	198	22.0	4356	95.0
arginine sepharose	225	0.78	175	22.9	4007	99.9

[a] From 2 g of inclusion bodies. [b] 1 IU of ADI produces 1 μmol of citrulline per min at 37 °C. [c] From scanning densitometry of SDS-PAGE.

Purification and Gene Cloning of *P. putida* ADI. The ADI gene of *P. putida* ATCC 4359 was isolated by screening a genomic library of HindIII fragments in Lambda ZAP (Stratagene) with the *P. aeruginosa*-derived oligonucleotide 5′-CACTCCGAAGCCGGCAAACT-3′ as a ^{32}P-phosphorylated probe. The nonrecombinant ADI protein was also purified from the same strain to about 95% purity by published methods (*26*, *52*).

ADI Enzyme Assays. The ADI assay was modified from previous reports (*53*, *54*). The determination of citrulline (the product of ADI activity) in 96-well microplates utilized a colorimetric enzyme activity assay based on the Bagrel et al. method (*54*) using antipyrine, ferric chloride, and butanedione monoxime, which is well-suited to measure low citrulline concentrations in the range 0−0.25 mM; this assay was also used for K_m determinations. Another assay based on the Oginsky method (*53*) using only butanedione monoxime is less sensitive but better suited to measure citrulline in the range of ≥0.2−2.5 mM. Data were analyzed with *SigmaPlot*. ADI activity assays for blood plasma samples included urease (1 mg/mL) in the assay buffer (0.2 M Na phosphate, 0.2% BSA, pH = 7.3 ± 0.1) with 2.5 mM arginine. Plates were read at 490 nm, and the data were analyzed using Microsoft *Excel*.

PEGylation of ADI. The PEGylation of *M. arthritidis* ADI (1−20 mg/mL; 0.1 M sodium phosphate, pH = 8.0 ± 0.1, 145 mM NaCl) with 12 kDa PEG−SC and 20 kDa PEG−SC followed identical procedures. Reaction stoichiometries with 10-fold to 50-fold molar excess of PEG to ADI subunit were examined. The SC−PEG polymers were dissolved at a concentration of 125 mg/mL in 2 mM hydrochloric acid and added to a solution of, e.g., 5 mg/mL native ADI in 100 mM phosphate buffer. After 60 min reaction time at 22 °C, free glycine was added in 15-fold molar excess to PEG to terminate the reaction, and residual free PEG compound was removed by repeated

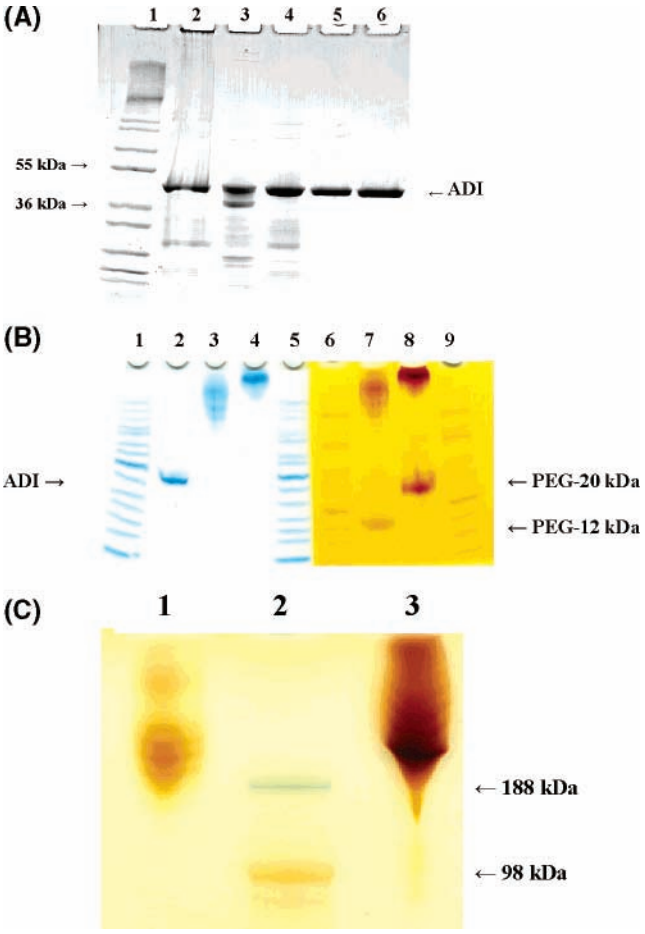

Figure 2. (A) SDS-PAGE analysis of purification steps for *M. arthritidis* ADI: lane 1, mark-12 molecular weight markers; lane 2, inclusion bodies in guanidine hydrochloride; lane 3, refolded ADI solution; lane 4, diafiltration; lane 5, eluate from QSFF; lane 6, eluate from arginine−sepharose 4B. The samples (1 μg per lane) were denatured by heating at 85 °C for 3 min in the presence of 12 mM β-mercaptoethanol. (B) SDS-PAGE (4−20%) analysis of multi-PEGylated *M. arthritidis* ADI with either 12 kDa or 20 kDa SC-PEG polymers. Lanes 1 and 5, molecular weight markers (Fermentas); lane 2, native ADI; lane 3, 12 kDa PEG−ADI; lane 4, 20 kDa PEG−ADI; lanes 6 and 9, molecular weight markers (Bio-Rad); lane 7, 12 kDa PEG−ADI; lane 8, 20 kDa PEG−ADI. Lanes 1−5 are stained with Coomassie Blue; lanes 6−9 are stained with iodine. (C) PEG staining of PEG−ADI compounds after extended run on SDS-PAGE. Lane 1, 12 kDa PEG−ADI (1 μg); lane 2, molecular weight markers (Invitrogen SeeBlue Plus2); lane 3, 20 kDa PEG−ADI (2 μg). Gel staining is with iodine to identify PEG bands.

dilution of the reaction mixture with formulation buffer and concentration using a 100 kDa molecular weight cutoff (MWCO) centrifugal filter unit. While PEGylated ADI was retained by the device, free PEG compound passed through the pores. Several rounds of dilution and concentration resulted in higher than 20 mg/mL PEGylated ADI protein that contained a minor amount (<0.1 mg/mL) of the free PEG polymer. All samples were recovered in high yield (70−90%) and filtered through a 0.22 μm filter. In some studies, PEG−ADI was purified with Superdex-200 SEC with a mobile phase of 50 mM Na phosphate, pH = 6.5, 140 mM NaCl.

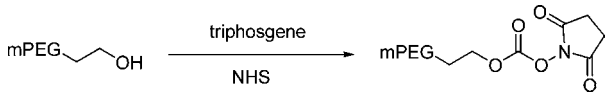
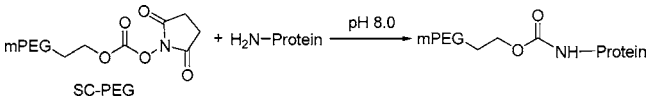


Scheme 2. Reaction of SC-PEG with Amine of Protein to Form a Urethane Linkage



Cell Culture Studies. The cell lines used in these experiments were as follows: CCRF S-180 II (mouse sarcoma), SK-MEL-2 (human melanoma), SK-HEP-1 (human liver adenocarcinoma), PC-3 (human prostate adenocarcinoma), and KHOS/NP (human osteosarcoma), which were obtained from the American Type Culture Collection. RT-PCR analysis confirmed AS deficiency in these cells. All cells were cultured in Minimal Essential Medium with Earle's salts, supplemented with 10% (v/v) fetal bovine serum, 0.1 mM nonessential amino acids, and 1 mM sodium pyruvate. Quantitative cell proliferation assays by the MTT or Alamar Blue methods were performed with published procedures (*41*, *43*) to determine IC_{50} values. Typically, cells (2.5×10^3) in a volume of 0.1 mL of growth medium were added to each well of a 96-well plate. ADI was diluted by 2-fold serial dilutions into the growth medium (0.1 mL). The 96-well plates were incubated for 72 h at 37 °C, before dye addition, processing, and analysis using *SOFTmax PRO 4.0* template and Microsoft *Excel*.

Amino Acid Analysis. Arginine levels in mouse or rat plasma were determined by derivatization with FMOC-Cl followed by RP-HPLC with fluorescence detection using a Phenomenex Synergi Max-RP column at 40 °C. Mobile phase A was 0.1% TFA in water; mobile phase B was 0.1% TFA in 80% acetonitrile and 20% water. The limits of quantification were 2.3 μM arginine.

Analytical Characterization of ADI and PEG−ADI. Protein concentrations were determined by the bicinchoninic acid assay (BCA) (*55*) using a BSA standard and confirmed by UV absorbance at 280 nm. TNBS (*56*) and fluoresamine (*57*) assays for determination of primary amines were conducted as described. N-terminal protein sequencing was performed on PROCISE (Applied Biosystems).

IEF was conducted on Invitrogen precast vertical Novex pH 3−10 mini gels. Western blot analysis was performed with anti-ADI rabbit antiserum as a primary antibody and goat anti-rabbit HRP as a secondary antibody with a TMBM peroxidase substrate. Iodine staining (*43*) of SDS-PAGE gels was performed after gels were rinsed with distilled water and placed in 5% barium chloride solution. After 10 min of gentle mixing, the gels were again rinsed with water and placed in 0.1 M Titrisol iodine solution for color development.

Table 2. Features and Analysis of *M. arthritidis* ADI and Bioconjugates[a]

compound	sp. act. (IU/mg)	linker	PEG (%) TNBS[b]	PEG (%) Fl[b]	PEG mass (kDa)	K_m (μM)	pI	mass[c]	SEC[d] (kDa)	SDS-PAGE (kDa)	IC_{50}[e] (ng/mL)
ADI	22.9 ± 1.4	none	0	0	0	10.4	5.35	46182	92.5	46	11 ± 1
12 kDa PEG-ADI	13.6 ± 0.7	SC	32.9 ± 4.3	33.7 ± 3.5	264	8.8			>700	>200	13 ± 1
20 kDa PEG-ADI	10.9 ± 0.6	SC	33.3 ± 2.4	35.5 ± 1.3	452	11.9			>700	>200	14 ± 1

[a] The described conjugates were prepared at 17.5:1 PEG/ADI subunit reaction ratio and used in PK/PD studies. [b] PEG (%) is the fraction of available ADI amines modified by PEG and corresponds to 22 PEGs per ADI dimer for either bioconjugate. [c] LC/MS and sequence calculated mass are identical, and protein sequence analysis confirmed N-terminal methionine removal. [d] ADI is ≥98% dimer in gel filtration. [e] ADI protein concentration providing 50% inhibition of CCRF S-180 II mouse sarcoma cultures.

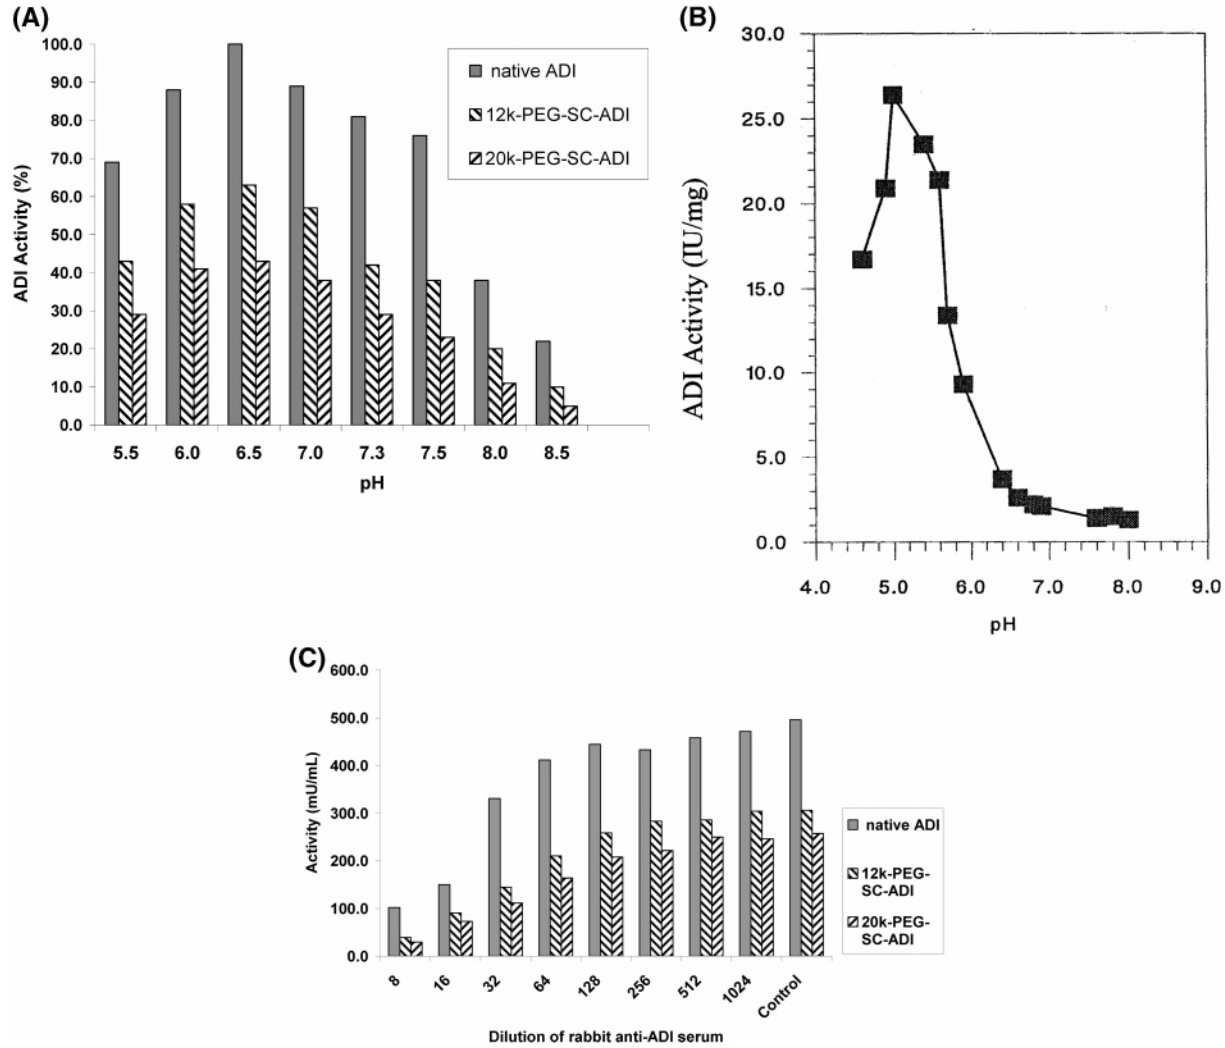


Figure 3. pH dependence of *M. arthritidis* ADI and PEG−ADI activity. (A) ADI, 12 kDa PEG−ADI, and 20 kDa PEG−ADI activity are measured at eight pH values. Values (%) are shown relative to native ADI at pH = 6.5 (100%). (B) pH profile of specific activity of *P. putida* ADI. (C) Stability studies in rat plasma for *M. arthritidis* ADI, 12 kDa PEG−ADI, and 20 kDa PEG−ADI stored at 4, 25, and 37 °C, and assayed at 10 min, 18 h, or 5 days. Relative activity is shown with 100% corresponding to the 4 °C stock solution.

Mass values of ADI were determined with liquid chromatography/mass spectrometry (LC/MS). Apparent molecular weights (Stoke radius) of the compounds were estimated using Superdex 200 HR 10/30 gel filtration column chromatography. The mobile phase was composed of 100 mM sodium phosphate, pH 6.8, at 24 °C. Evaporative light scattering detection (ELSD; Sedere, Inc.) allowed free PEG detection. Additionally, analysis of molecular masses on 4−20% SDS-PAGE gels was performed using protein and PEG−protein standards.

Pharmacokinetic Analysis of PEG−ADI in Mice and Rats. Single i.v., i.m., or s.c. injections of 5, 0.5, or 0.05 IU/mouse of ADI, 12 kDa PEG−ADI, or 20 kDa PEG−ADI were administered to female Balb/c mice on day 0. A total of 171 mice were assigned into 9 groups, with 3 mice/timepoint. The mice were bled at the following timepoints: −1 h, 1 h, 24 h, and 3, 6, 10, and 15 days. Animals were bled through cardiac puncture, and plasma samples were isolated. Plasma concentration of native or PEGylated ADI was determined by enzyme assay and by cell-based cytotoxicity assay, and plasma arginine concentration was determined by an HPLC assay. Descriptive statistics (mean, SD) and noncompartmental analysis were used to calculate pharmacokinetic parameters using *WinNonlin* version 4.0.1 (Pharsight Corp.). The pharmacokinetic parameters estimated were $AUC_{0-\infty}$ (the AUC from time 0 to infinity), C_{max} (maximum plasma concentration), T_{max} (the time to reach maximum concentration), and half-life of λ_z (first-order elimination rate constant). The $AUC_{0-\infty}$ values were calculated using the linear trapezoidal method. Statistical comparisons between data sets were performed using paired *T*-test in *Excel* software.

Rat PK analysis was conducted with similar methods. Single i.v. injection of 8, 2.5, or 0.8 IU/kg of ADI, 12 kDa PEG−ADI, or 20 kDa PEG−ADI was administered to female CD rats on day 0. The rats (3/timepoint) were bled at the following timepoints: −1 h, 1 h, 24 h, and 5, 7, 10, and 15 days. Animals were bled through retro-orbital plexus, and plasma samples were isolated for enzyme, bioassay, and HPLC analysis.

RESULTS AND DISCUSSION

Recombinant ADI from *M. arthritidis*. The gene for *M. arthritidis* ADI was cloned from the same ATCC deposit 14152 as previously used for nonrecombinant ADI characterization (*48*−*50*). We also cloned and sequenced the ADI gene from *P. putida* for an extended comparison of primary structures in the ADI family. As shown in Figure 1A, it appears that the *M. arthritidis* ADI and *P. putida* ADI sequences conform overall to previously reported ADI primary structures, with conservation also of key catalytic residues, when compared to *M. arginini* and *P. aeruginosa* ADI (86% and 84% identity, respectively, among common genus). Modeling of the exposed lysine residues

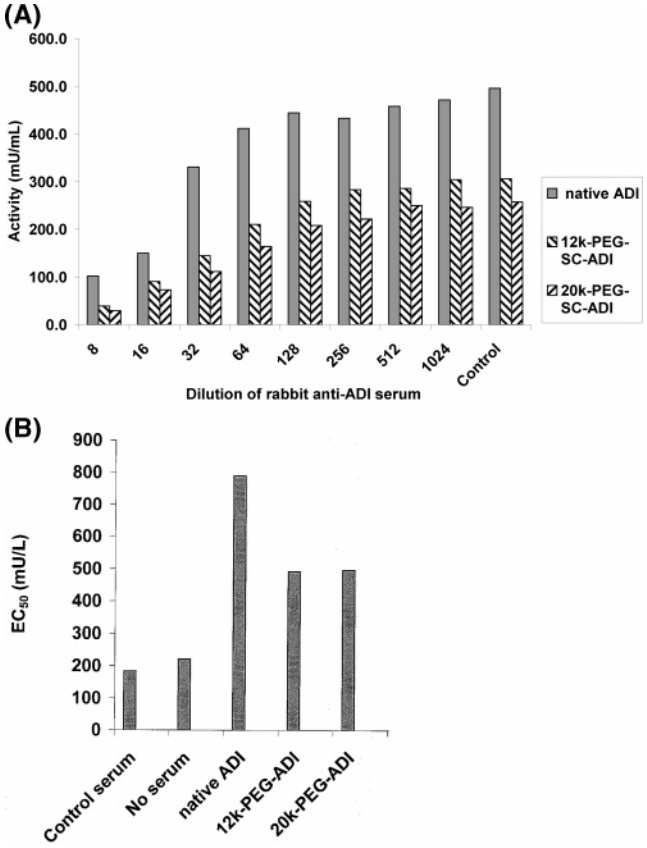

Figure 4. Neutralizing anti-ADI antibodies of rabbit antiserum raised against native *M. arthritidis* ADI. (A) Enzyme activity of ADI, 12 kDa PEG−ADI, and 20 kDa PEG−ADI were measured in the presence of increasing dilutions of rabbit antiserum. The control assay contained an 8-fold dilution of preimmunized rabbit serum. (B) Cell culture assays with ADI-sensitive tumor line CCRF S-180 II determined the EC_{50} values of ADI, 12 kDa PEG−ADI, and 20 kDa PEG−ADI using serial dilutions of the ADI compounds in the presence of a 250-fold dilution of rabbit anti-ADI serum. The control serum is from preimmunized rabbits. Control and serum-free samples contained native ADI; the PEG−ADI samples contained only conjugates; all samples included the rabbit antiserum (1:250 dilution).

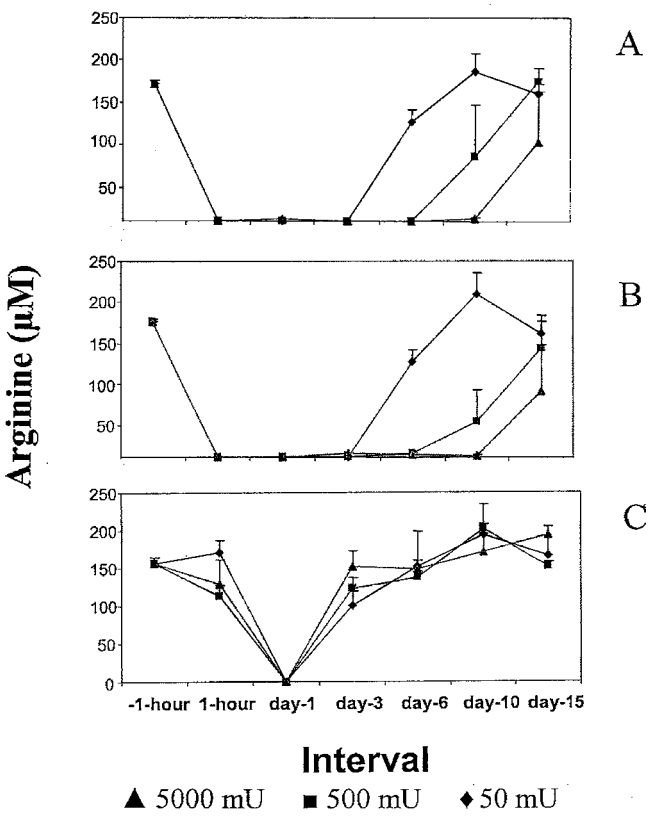

Figure 5. Pharmacodynamics of *M. arthritidis* ADI and PEG−ADI in mice following single i.v. administration. (A) 20 kDa PEG−ADI. (B) 12 kDa PEG−ADI. (C) unmodified ADI. Arginine levels in plasma (mean ± SD) are measured at the indicated durations following 5000 mU (▲), 500 mU (■), or 50 mU (♦) doses.

on the surface of *M. arginini* ADI (29 lysines/subunit; Figure 1B) or *M. arthritidis* ADI (32 lysines/subunit; Figure 1C) reveals numerous positional substitutions of the primary amines available for conjugation, and this may influence the properties of these bioconjugates. Of these four ADI proteins, the *M. arthritidis* ADI dimer has both the greatest number and the least clustering of the surface lysine residues, providing a potential advantage for conjugation. However, an understanding of biochemical properties of the enzymes will follow purification of the recombinant proteins. This was achieved as summarized in Table 1 and Figure 2A for recombinant *M. arthritidis* ADI. Specific activity of this enzyme was about 30% higher than previous preparations of recombinant *M. arginini* ADI prepared and assayed by a similar protocol (Filpula, D. Unpublished results). Moreover, the K_m of *M. arthritidis* ADI (10.4 μM) is notably lower than for any other reported ADI enzyme (*25*, *26*, *29*, *30*, *33*, *52*). Nonetheless, the *M. arthritidis* ADI clearly resides in the same structure−function design of previously described ADI. Although we used the same ATCC deposit as reported for the prior *M. arthritidis* nonrecombinant ADI characterization (*48*−*50*), we cannot exclude the possibility that there exists another modified or distinct ADI enzyme not identified in our present studies; alternatively, our current thorough studies on this recombinant enzyme may define the only ADI enzyme in this species. As summarized in Table 2, *M. arthritidis* ADI is a homodimer of 40 182 Da subunits, and its IEF-determined pI agrees with the predicted pI = 5.35 for this protein. Potent growth inhibition of cultured sarcoma (Table 2), hepatoma, and melanoma tumor cells was demonstrated. Investigations of the capacity of this enzyme to inhibit the growth of several tumor cell lines (including CCRF S-180 II, SK-MEL-2, KHOS/NP, SK-HEP-1, and PC-3) demonstrated about 50% lower IC_{50} values than for similar recombinant *M. arginini* ADI preparations (data not shown).

In comparison, we observed that *P. putida* ADI, also an apparent homodimeric enzyme, exhibited suitable specific activity (25 IU/mg) at pH 5.5. However, this enzyme was not a potent inhibitor of growth in these tumor cell lines and exhibited IC_{50} values 100- to 1000-fold higher than the *M. arthritidis* enzyme. This may be explained in part by the higher K_m value of the *P. putida* enzyme (K_m = 1.8 mM without $MgCl_2$; K_m = 0.2 mM with $MgCl_2$). However, another significant factor is the pH profile for enzyme activity of *P. putida* ADI whereby only 5−10% of enzyme activity is retained at physiological pH when compared to its pH optimum of 5.5. Therefore, the *P. putida* ADI was not successfully developed as a lead pharmaceutical in either its native or PEGylated format.

PEGylated *M. arthritidis* ADI. The development of foreign proteins as therapeutics frequently requires the employment of controlled release technology, and most frequently PEGylation (*8*). It was certain from pilot experiments that unmodified ADI protein would clear too rapidly from animals and also exhibit profound immunogenicity. Therefore, we focused our investigations on the optimal development of a PEGylated *M. arthritidis* ADI, which conserved the attractive catalytic parameters of the enzyme, while introducing the desired pharmacokinetic and pharmacodynamic features in animal models. Although multiple attachment of 5 kDa PEG polymers has been the best developed approach for pharmaceutical enzymes, such as ADAGEN and

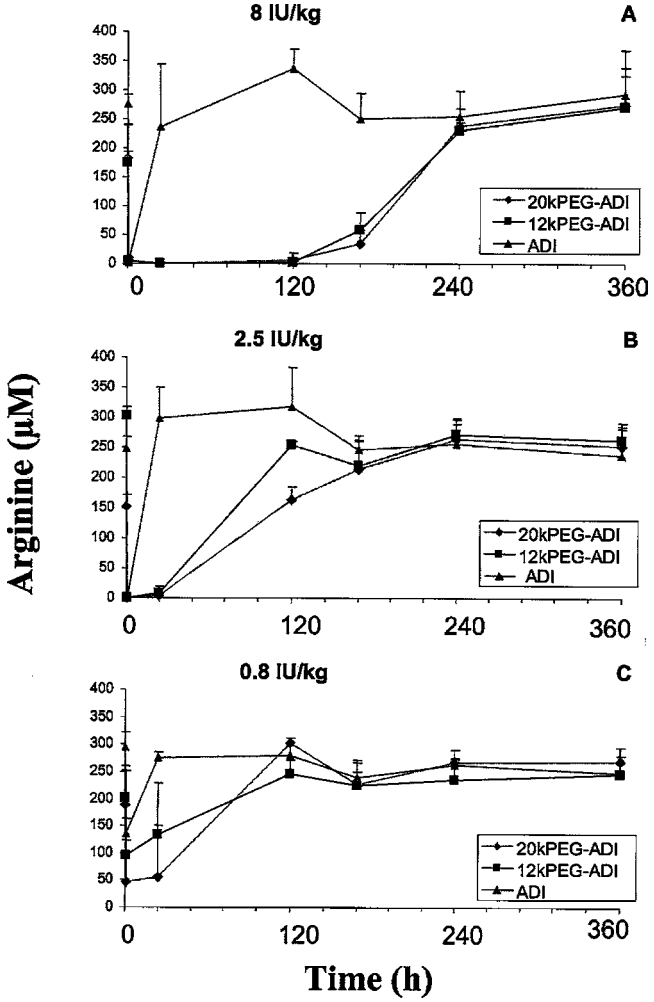

Figure 6. Pharmacodynamics of *M. arthritidis* ADI and PEG−ADI in rats following single i.v. administration. (A) 8 IU/kg dose. (B) 2.5 IU/kg dose. (C) 0.8 IU/kg dose. Arginine levels in plasma are measured at the indicated durations following injection of ADI (▲), 12 kDa PEG−ADI (■), or 20 kDa PEG−ADI (◆).

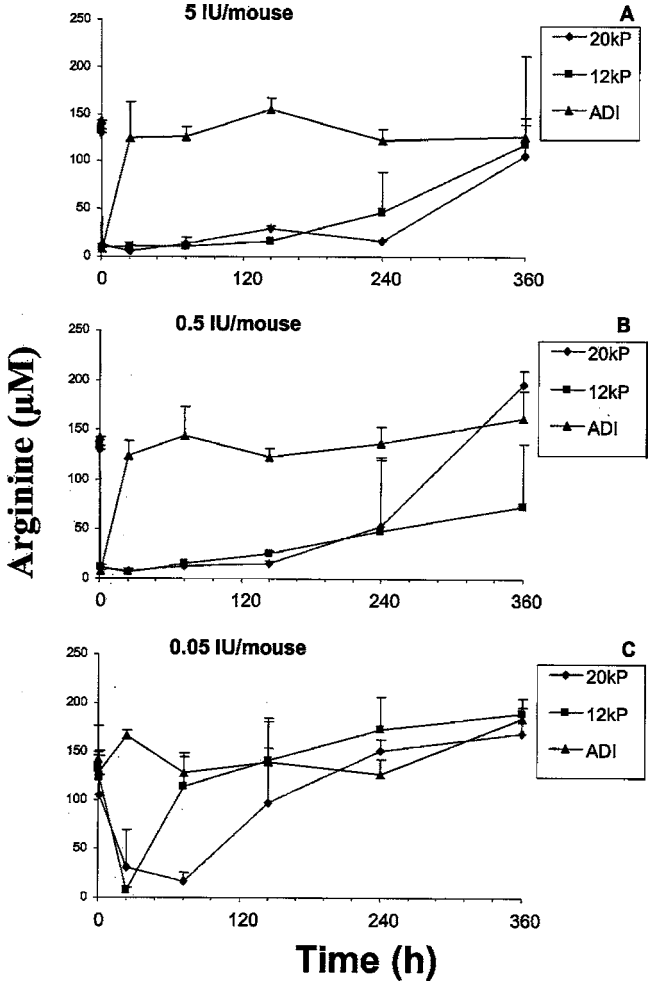

Figure 7. Pharmacodynamics of *M. arthritidis* ADI and PEG−ADI in mice following single i.m. administration. (A) 5000 mU. (B) 500 mU. (C) 50 mU. Arginine levels in plasma are measured at the indicated durations following injection of ADI (▲), 12 kDa PEG−ADI (■), or 20 kDa PEG−ADI (◆).

ONCASPAR (*10*), our studies and published reports (*27*, *31*) demonstrated a benefit to employment of larger PEG polymers to extend the PK/PD and AUC performance of the arginine-depleting compounds. Nonetheless, we wished to limit the quantities of the attached PEG to the extent possible due to process design, potency, and cost of goods considerations. Therefore, we sought to revisit the prior conclusions that multi-PEGylation of ADI with the largest PEG polymers is necessary for optimal performance. Specifically, we have undertaken a rigorous in vitro and in vivo comparative investigation of two multi-PEGylated *M. arthritidis* ADI bioconjugates having either 12 kDa PEG polymers or 20 kDa PEG polymers.

Succinimidyl carbonate (SC) linkers were chosen for this study on the basis of their confirmed chemical stability (*42*, *51*) in contrast to the hydrolytically labile succinimidyl succinate linkers employed in other PEG−ADI reports (*31*, *37*). The synthesis of SC-PEG-12 kDa or SC-PEG-20-kDa is shown in Scheme 1, while the reaction of these activated polymers with primary amines of ADI is shown in Scheme 2. The PEGylation reactions were performed at an elevated ADI concentration (5 mg/mL) and a diminished reactant stoichiometry with only 17.5:1 molar excess of activated PEG over ADI subunit, in contrast to prior conjugate studies which utilized low protein concentrations (1 mg/mL) and a 40-fold excess of activated PEG (*27*, *31*). The current approach provided complete conversion of ADI to multi-PEGylated derivatives using a manageable concentration of polymers in the reaction while retaining excellent activity as shown in Table 2. Further increases in PEG reactant concentrations provided only a marginal increase in PEG attachments, which plateau at about 40% modification of available amines, while further diminishing the specific activity of the compounds. Since both the optimized 12 kDa and 20 kDa PEG−ADI compounds exhibited about 33% modification, which was verified by both TNBS and fluoresamine methods, a direct comparison of biochemical and pharmacological performance for the conjugates is possible. SDS-PAGE analysis of the PEG−ADI preparations is also shown in Figure 2B,C which illustrate the total conversion of the protein into multi-PEGylated compounds, the degree of product heterogeneity, and the large apparent molecular weights of the bioconjugates. Figure 2B also illustrates the retention of significant amounts of free PEG (16% and 5% of the total PEG in the preparations for 20 kDa and 12 kDa reactions, respectively) following two rounds of dilution and concentration through a 100 kDa molecular weight cutoff filtration membrane. Although the free PEG can be completely removed by size exclusion chromatography, smaller PEGs prove easier to separate in standard UF/DF manufacturing processes.

Key biochemical properties are summarized in Table 2. Retention of ADI specific activity is 59% and 48% for the 12 kDa and 20 kDa PEG−ADI compounds, respectively, and K_m determinations were not notably altered by PEGylation. The improvement in PEG−ADI specific activity relative to other

examined formulations might provide an opportunity for reduced dosing of these compounds. The total PEG mass differs by nearly 200 kDa between these two PEG−ADI compounds; yet, both are enormous molecules in hydrodynamic volume as demonstrated by the size exclusion chromatography analysis. A critical measurement of the biological potency of the two PEG−ADI conjugates was performed by evaluation of the inhibitory activity in cell culture proliferation assays of several tumor cell lines known to be sensitive to arginine deprivation. For example, the IC_{50} values for native ADI and the two PEG−ADI conjugates differ by only 20−30% with the CCRF S-180 II mouse sarcoma tumor cell line (Table 2). Other sensitive tumor lines exhibited comparable results. These data confirm that the intrinsic catalytic characteristics of *M. arthritidis* ADI are well-preserved in these bioconjugates.

The pH profile for enzymatic activity may be crucial for the suitability of enzymes as successful therapeutics. Therefore, we examined these characteristics both for the native enzyme and the two PEGylated derivatives. As shown in Figure 3A, *M. arthritidis* ADI activity exhibits a broad pH range; although activity is maximal at pH 6.5, about 80% of the activity is retained at pH 7.5. The 12 kDa and 20 kDa PEG−ADI derivatives demonstrated very similar pH dependence that confirms that extensive lysine derivatization does not appear to alter the catalytic profile of the enzyme. For comparison, Figure 3B displays the determined pH dependence for *P. putida* ADI activity. Less than 10% of maximal activity remains at physiological pH for this *Pseudomonas* enzyme which is most active at pH 5.5. PEG derivatives of this ADI exhibited similar profiles (data not shown). Although enzymes with unfavorable K_m and pH profile characteristics may produce pharmacological effects, the required elevated dosing regimen discourages development of these compounds.

Since stability is another crucial concern for the PEG−ADI compounds, we investigated enzyme activity over a period of 5 months stored in PBS buffer, pH 7.4, at 4 °C. Both native ADI and PEG−ADI compounds retained full activity (±10%) for the duration of this study. Further, both PEG−ADI compounds retained full activity (±10%) in mouse plasma over a 5 day incubation at 4, 25, or 37 °C, while native ADI exhibited slight (20−30%) activity losses at 37 °C. Interestingly, the PEG−ADI compounds were not completely stable in rat plasma under the same stability parameters. As shown in Figure 3C, about half of the activity of these compounds was lost in rat plasma at 37 °C over 5 days. The root cause of this instability was not determined but may correspond to proteolysis. While these conjugates are extensively shielded with PEG polymers, the density of attachment sites may not preclude all protein−protein interactions in solution, as suggested by the molecular model in Figure 3C.

Immunogenicity is another important concern in the development and drug monitoring of protein therapeutics, including PEGylated proteins. Binding antibodies are commonly encountered, and neutralizing antibodies versus PEGylated enzymes have been investigated (*5*, *9*, *41*, *58*, *59*). It is well-established that proteins, including ADI proteins, demonstrate markedly diminished immunogenicity following PEGylation (*8*, *27*, *58*; Filpula, D. Unpublished results). We wished to address here a more specific question on the antigenicity of the PEG−ADI compounds. Rabbit antisera versus unmodified *M. arthritidis* ADI were produced with complete Freund's adjuvant. As shown in Figure 4A, at very high titers (<1:50 dilution), rabbit antibodies versus ADI are able to significantly neutralize the enzyme activity of ADI and, to a lesser extent, the activity of either PEG−ADI compound. Figure 4B shows that this effect may also be observed when bioassays of serially diluted ADI compounds are conducted with arginine requiring cell cultures

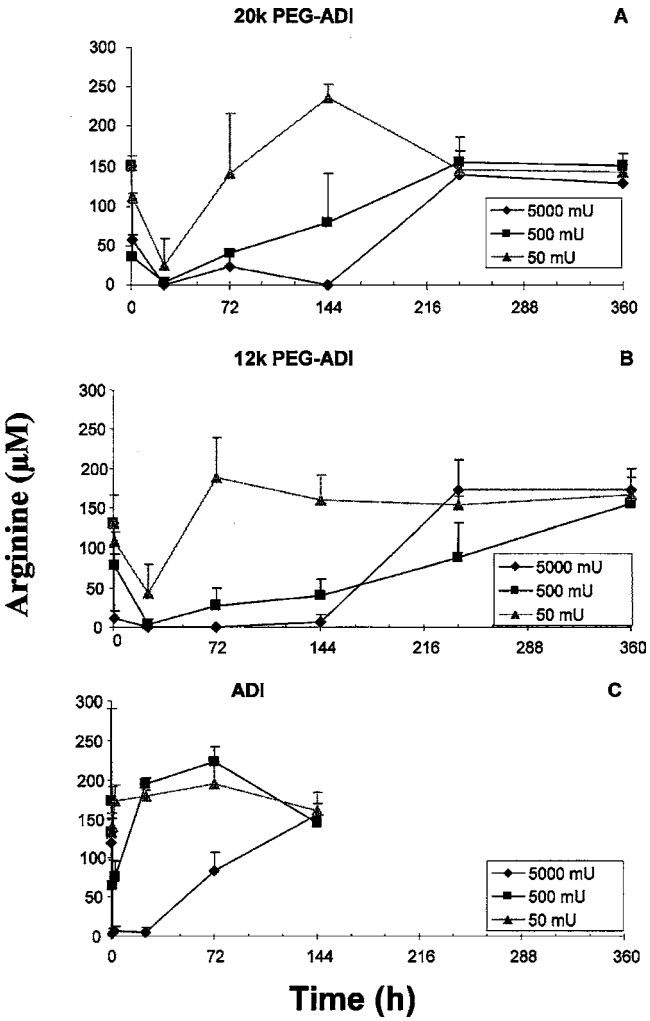

Figure 8. Pharmacodynamics of *M. arthritidis* ADI and PEG−ADI in mice following single s.c. administration. (A) 20 kDa PEG−ADI. (B) 12 kDa PEG−ADI. (C) unmodified ADI. Arginine levels in plasma are measured at the indicated durations following 5000 mU (◆), 500 mU (■), or 50 mU (▲) doses.

in the presence of a fixed concentration of neutralizing antiserum. The greater sensitivity of unmodified ADI to the antiserum compared to the conjugates reverses the slight potency advantage of the native ADI over the conjugates when measured in the absence of the antiserum, and this may suggest another benefit for the PEG−ADI compounds in an in vivo setting. In contrast, a previous study suggested neutralizing antibodies versus *M. hominis* ADI were not generated by immunization (*27*). Although the effects of neutralizing antibodies in our present study were not of high potency, these data once again illustrate that the PEGylated ADI compounds, although chemically shrouded in their molecular environment, are not expected to be totally secluded from protein−protein interactions in vivo.

Pharmacodynamics of PEG−ADI. A hallmark of the beneficial effects of PEGylation is an increased blood residency time of the bioconjugates. In order for PEG−ADI to exhibit prolonged pharmaceutical effects in therapy of oncological disease or inflammatory disorders, a potent and sustained pharmacodynamic effect is desired, whereby arginine concentrations in blood, and ultimately in the diseased tissues, are reduced to undetectable levels. We examined the pharmacodynamic potency of our experimental PEG−ADI compounds in rodent studies. As shown in Figure 5A,B, i.v. administration of 5 IU (5000 mU) of either 20 kDa PEG−ADI or 12 kDa PEG−ADI per mouse depleted plasma of detectable arginine within 1 h and maintained undetectable levels through 10 days (LOQ =

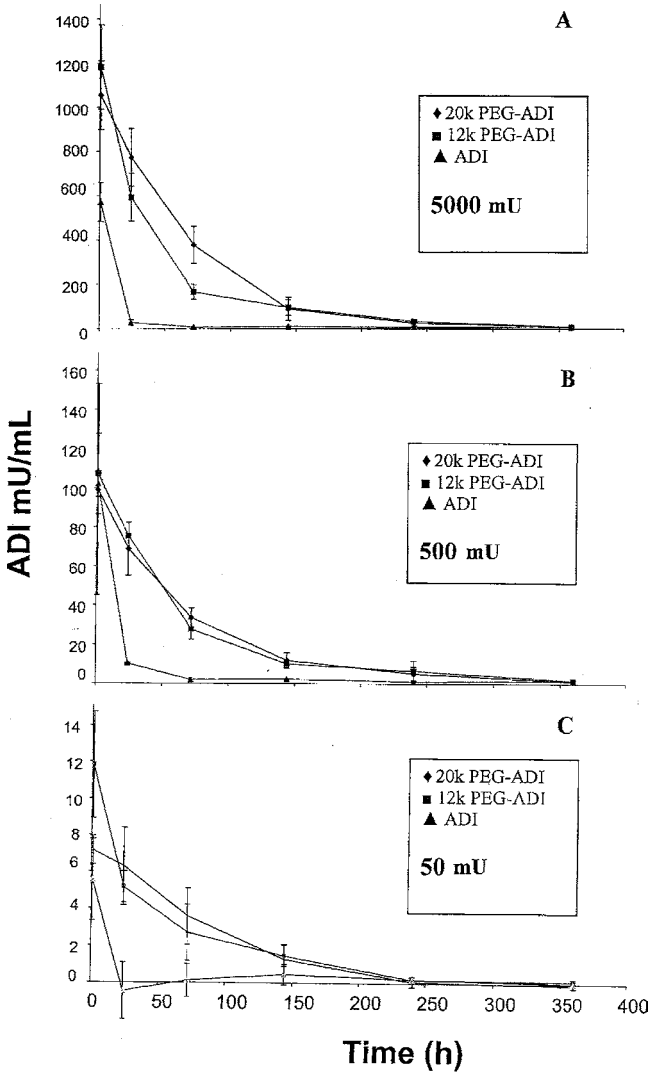

Figure 9. Pharmacokinetics of *M. arthritidis* ADI and PEG−ADI in mice following single i.v. administration. (A) 5000 mU. (B) 500 mU. (C) 50 mU. ADI concentrations (activity) in plasma (mean ± SD) are measured by enzyme assay at the indicated durations following injection of ADI (▲), 12 kDa PEG−ADI (■), or 20 kDa PEG−ADI (◆).

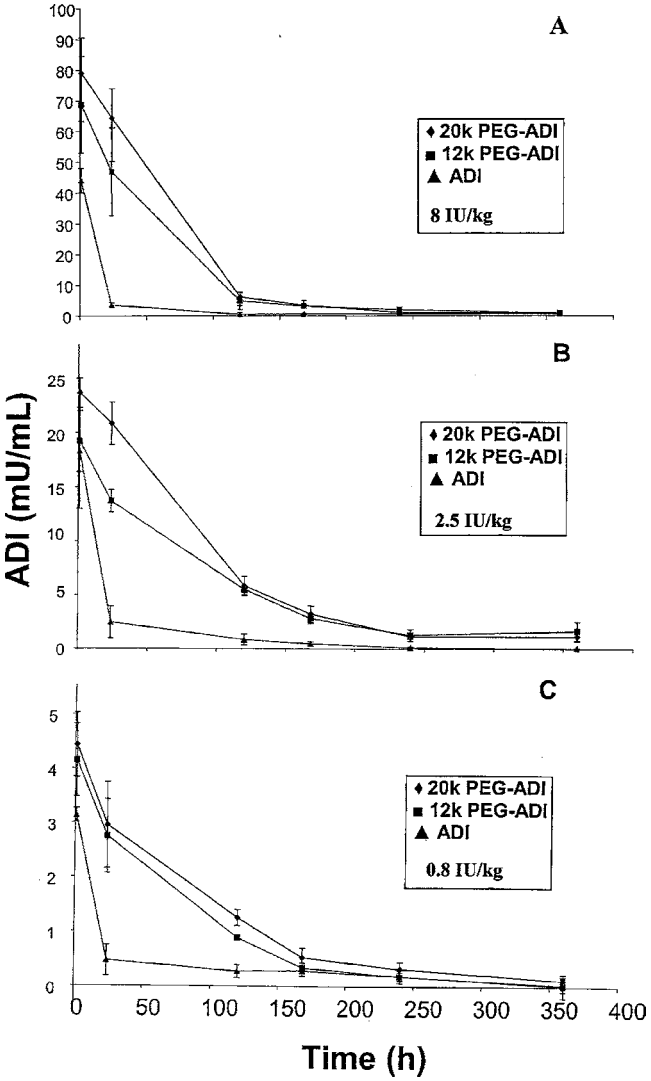

Figure 10. Pharmacokinetics of *M. arthritidis* ADI and PEG−ADI in rats following single i.v. administration. (A) 8 IU/mg dose. (B) 2.5 IU/mg dose. (C) 0.8 IU/mg dose. ADI activity in plasma is measured by enzyme assay at the indicated durations following injection of ADI (▲), 12 kDa PEG−ADI (■), or 20 kDa PEG−ADI (◆).

2.3 μM arginine in these studies). These PD effects compare favorably to prior reports with i.v. administration of other ADI formulations (*27*, *31*). The unmodified ADI protein at any dose produced only transient arginine depletion for no more than 1 day (Figure 5C; data not shown), whereas the PEG−ADI compounds suppressed arginine plasma levels in a dose-dependent manner (Figure 5A,B), with both conjugates demonstrating comparable dose−response effects. Additional studies demonstrated that the PD effects are rapid for both ADI and PEG−ADI, with elimination of all detectable plasma arginine occurring within 10 min of compound administration. Since the ADI dose was based on units of activity, the 12 kDa PEG−ADI compound produced similar PD effects at about 75% of the protein dose of the 20 kDa PEG−ADI conjugate (see Table 2).

In Figure 6, similar PD investigations were conducted in rats. Since arginine has been reported to be an essential amino acid in rats, but not mice, a reduced dosing schedule for the compounds was utilized, and no toxicity was observed in the animals under these conditions. At the highest i.v. dose (8 IU/kg = 1.6 IU/rat), both the 12 kDa and 20 kDa PEG−ADI compounds eliminated detectable arginine from plasma rapidly and sustained this condition for 5 days (Figure 6A). This dose−response study also revealed a comparability of the two conjugates at lower doses (Figure 6B,C). The necessity for PEGylation in development of this enzyme therapeutic is evident from the short-lived PD effect of unmodified ADI even at the highest dose, both in these rat studies and in all of the mouse investigations.

Administration of PEG−ADI in a clinical setting may benefit from the convenience of intramuscular (i.m.) or subcutaneous (s.c.) injection. As shown in Figure 7, the dosing schedule employed for i.v. administration in mice produced a less pronounced PD effect via i.m. administration. Although arginine levels in plasma remained severely diminished for 10 days, concentrations of this amino acid were within the limits of detection and quantitation. The 12 kDa and 20 kDa PEG−ADI again produced comparable dose-dependent PD effects. Investigation of PD effects of PEG−ADI using this same dosing schedule by s.c. administration in mice (Figure 8) revealed comparable outcomes but with two interesting differences. The s.c. route of injection of both PEG−ADI compounds did result in diminution of plasma arginine levels to essentially undetectable levels for about 6 days; however, the duration of the PD effect was actually shortened when compared to i.m. administration. These pharmacological effects may have a biological basis relating to biodistribution of the compounds under different

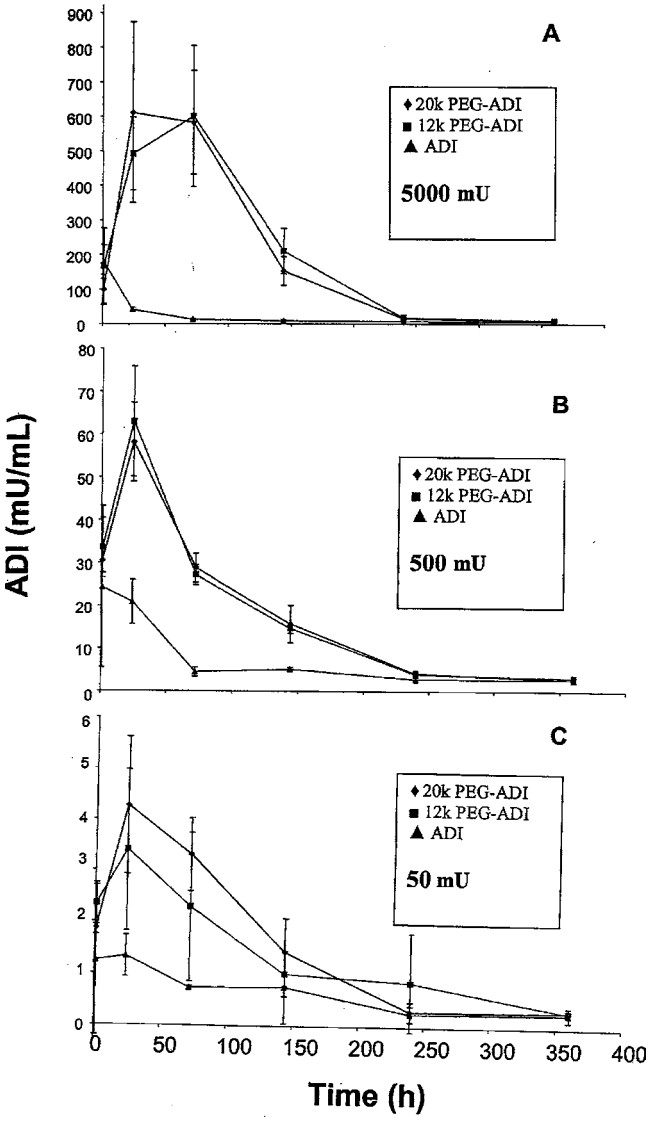

Figure 11. Pharmacokinetics of *M. arthritidis* ADI and PEG−ADI in mice following single i.m. administration. (A) 5000 mU. (B) 500 mU. (C) 50 mU. ADI activity in plasma is measured by enzyme assay at the indicated durations following injection of ADI (▲), 12 kDa PEG−ADI (■), or 20 kDa PEG−ADI (◆).

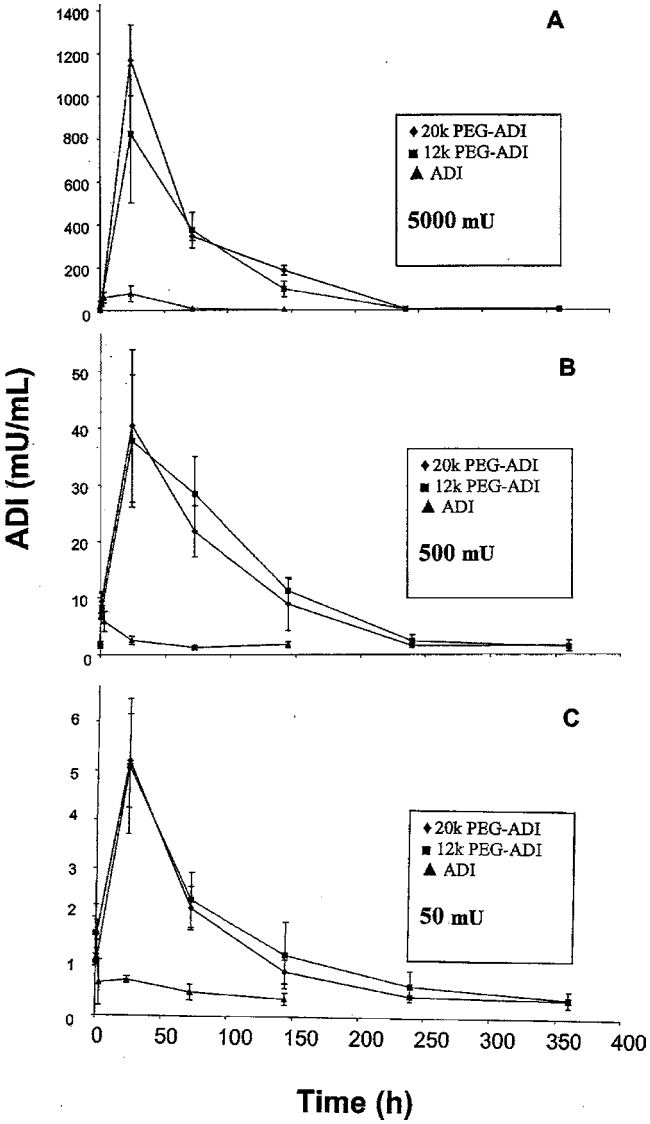

Figure 12. Pharmacokinetics of *M. arthritidis* ADI and PEG−ADI in mice following single s.c. administration. (A) 5000 mU. (B) 500 mU. (C) 50 mU. ADI activity in plasma is measured by enzyme assay at the indicated durations following injection of ADI (▲), 12 kDa PEG−ADI (■), or 20 kDa PEG−ADI (◆).

injection routes or may relate to the innate metabolism of the tissue types and biological response to compound bolus injection. Possibly arginine synthesis is stimulated in a differential manner dependent on injection site. The overall conclusion from these PD studies is that both 12 kDa and 20 kDa PEG−ADI potently catabolized arginine by each parenteral route of administration, and, as expected, i.v. administration provided the most sustained elimination of plasma arginine.

Pharmacokinetics of PEG−ADI. Completion of the pharmacological studies of *M. arthritidis* ADI and PEG−ADI compounds also required a thorough understanding of the pharmacokinetics (PK) of these compounds. Therefore, PK analyses were conducted as companion studies with the above PD investigations. Measurements of PK profiles for multi-PEGylated proteins present special challenges due to the effects of PEG polymers on physically shielding the protein. Three assays were evaluated for the PK studies. Immunoassays were determined to lack sufficient sensitivity for PEG−ADI detection. Enzyme assays were instead developed by modifying the citrulline detection method for plasma samples as described in Experimental Procedures. Finally, we also conducted, as a confirmatory though less sensitive method, bioassays of the PK samples using IC_{50} determinations for the growth inhibition of the S-180 II mouse sarcoma tumor cell line in vitro.

As shown in Figure 9, using the enzyme method, the PK profiles for the 12 kDa and 20 kDa PEG−ADI compounds following i.v. administration in mice were shown to be comparable, as anticipated from the companion PD study results shown in Figure 5. Native ADI is rapidly eliminated from circulation. Similarly, as shown in Figure 10, i.v. administration of these compounds in rats revealed comparability in PK profiles for the 12 kDa and 20 kDa PEG−ADI which correlates with PD effects (Figure 6). In this experiment, as well as the other current pharmacological studies, there was no statistically significant difference in the PK and PD effects of the two conjugates. Figures 11 and 12 record the PK profiles of the ADI and PEG−ADI compounds by i.m. and s.c. administration, respectively. An absorption phase is observed, followed by clearance, and both PEG−ADI compounds demonstrated similar PK profiles. In comparison to the corresponding PD profiles (Figures 7 and 8), the i.m.-administered PEG−ADI compounds demonstrated a similar C_{max} while exhibiting a slower elimination phase when compared to s.c. administration, which appears to correlate with the observed PD effects. When PK profiles

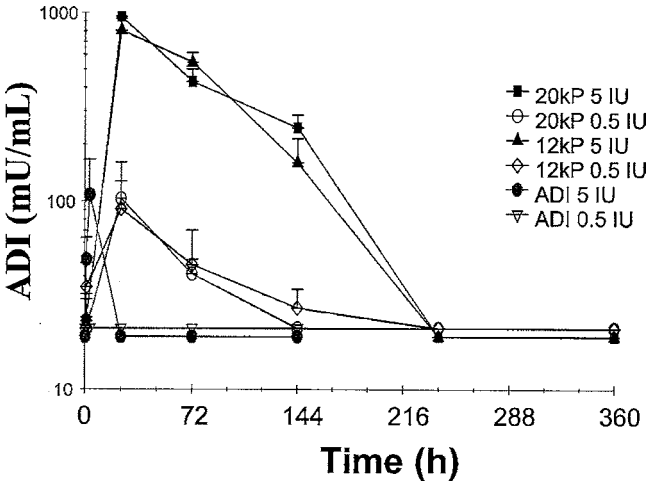

Figure 13. Pharmacokinetics via bioassay of *M. arthritidis* ADI and PEG−ADI in mice following single s.c. administration. ADI activity in plasma (mean ± SD) is measured by S-180 II cell culture growth inhibition assay at the indicated durations following injection of ADI (5 IU, ●; 0.5 IU, ▼), 12 kDa PEG−ADI (5 IU, ▲; 0.5 IU, ◇), or 20 kDa PEG−ADI (5 IU, ■; 0.5 IU, ○).

Table 3. Pharmacokinetic Parameters of ADI Compounds in Mice (5 IU/mouse)

route	HL (h)	C_{max} (IU/mL)	T_{max} (h)	AUC (h×IU/mL)	MRT (h)	CL (mL/h)	bioavailability (%)
				20k PEG−ADI			
i.v.	50.0	2.57		176.4	66.9	0.03	
i.m.	36.8	0.86	24	101.9	80.4	0.05	57.7

i.m.	4.84	0.35	1	4.4	2.4	1.12	15.0

were examined by bioassay methods rather than enzyme assay measurements, comparable results were observed, except that the bioassay limits of quantitation allowed evaluation of only the higher two of the three doses in the dose range studies. An example of this approach is shown in Figure 13 for s.c. administration in mice, which may be compared to the enzyme method of Figure 12.

Pharmacological parameters from the mouse studies employing 5 IU doses/mouse were compiled and are presented in Table 3. Biological half-lives for the PEG−ADI compounds do not vary greatly when comparing the 12 kDa and 20 kDa derivatives or when comparing injection routes. However, PEGylation imparts nearly 10-fold increased half-life in the bioconjugates. C_{max} is about 2.5-fold higher for the PEG−ADI compounds by i.v. administration compared to the s.c. or i.m. routes. AUC values are markedly similar between the two bioconjugates and over 5-fold greater than for the unmodified ADI. Bioavailability via the i.m. route of administration appeared about 30% higher than s.c. administration in these investigations, and a suitable overall bioavailability (∼50%) was achieved for either the 20 kDa PEG−ADI or 12 kDa PEG−ADI compound.

CONCLUSIONS

We describe investigations of the physical and functional properties of a new arginine-degrading ADI enzyme from *M. arthritidis*, which exhibited most of the favored characteristics for therapy, including low K_m, high specific activity, near physiological pH optimum, prolonged stability in vitro and in vivo, together with retention of these desired properties in multi-PEGylated formulations.

Our investigations in PEGylation optimization of *M. arthritidis* ADI evaluated both in vitro and in vivo performance, and these studies provided the basis for selection of developmental drug candidates which differ in composition from most conventional and experimental PEG enzymes. Specifically, although a multi-PEGylated enzyme format is beneficial in addressing immunogenicity concerns, as illustrated by ADAGEN and ONCASPAR, employment of PEG polymers larger than 5 kDa is required to optimize PK and PD of ADI. However, in contrast to other studies (*27*, *31*), we do not observe a benefit to increasing total PEG mass to the upper limits of conjugation and polymer dimensions, although it is uncertain to what extent the use of an unstable succinimidyl succinate linker employed in prior reported studies influenced in vivo pharmacological behavior. We chose to instead construct the present conjugates with the highly stable succinimidyl carbonate linker (*42*, *51*). PD effects of multi-PEGylated ADI with either 12 kDa or 20 kDa polymers and equivalent numbers of attachments demonstrated comparable outcomes. However, the 12 kDa polymers provide advantages in processing due to reduced viscosity and easier separation on ultrafiltration/diafiltration, as well as potential cost of goods advantages, a lower protein dose, and possibly better tumor penetration. Our studies also streamlined PEGylation reaction conditions, providing a manageable amount of polymer to be consumed while still approaching maximal modification. The PD performance of the PEG−ADI compounds in eliminating detectable plasma arginine from mice for 10 days with a 5 IU single dose is outstanding for this category of enzyme conjugates (*27*−*31*). Further development of these lead compounds in preclinical studies is ongoing to determine the dosing regimen for oncological indications.

ACKNOWLEDGMENT

We thank Enzon colleagues for assistance in purification and characterization of *P. putida* ADI. Stanford Lee, Srijata Sarkar, and Alahari Arunakumari made key contributions in advancing this overall program. Dechun Wu and Yoany Lozanguiez contributed in chemical synthesis of linkers; Ramesh Chintala, Ahsen Janjua, and Magda Mendez supported the bioconjugate purifications; Qing Dong, Qing-Hong Dai, Kavitha Kumar, Michelle Boro, and Julia Zhu assisted in analytical assays. We thank Uli Grau and Gerrit Borchard for their encouragement and support and Lee Greenberger and Ivan Horak for a critical review of the manuscript.

Biologically Active Amphotericin B-Calix[4]arene Conjugates

Valérie Paquet, Andreas Zumbuehl, and Erick M. Carreira*

Laboratorium für Organische Chemie, ETH Hönggerberg, CH-8093 Zürich, Switzerland. Received July 10, 2006; Revised Manuscript Received September 24, 2006

In order to provide tools for investigations of amphotericin B ion channels, new conjugates bearing a calix[4]-arene scaffold covalently linked to four amphotericin B molecules were synthesized. These macromolecules adopt a cone conformation that mimics the structure of a transmembrane pore. The antifungal activity of the conjugates **3** and **4** was superior or similar to that of native amphotericin B, with minimal inhibitory concentration values of 0.10 and 0.25 μM, respectively. Furthermore, the hemotoxicity of the new conjugates was considerably lower (at least 10 times) than the hemotoxicity of monomeric amphotericin B. Finally, the formation of ion channels in the lipid bilayer by the amphotericin B tetramer was monitored by measuring the K^+ efflux from various liposomes.

INTRODUCTION

Over the past 50 years, amphotericin B (AmB, **1**) has remained the drug of choice against systemic fungal infections especially because of its broad spectrum of activity (*1*, *2*). However, although AmB (**1**) has been the subject of many studies, its mechanism of action has not been clearly elucidated and is still a subject of debate (*3*). The most widely accepted model refers to the formation of a barrel-stave structure in the membrane that serves as an ion channel causing electrolyte loss that ultimately leads to cell death (Figure 1) (*4*). AmB (**1**) molecules are believed to organize in a fashion such that the hydrophilic hydroxylated portion of each molecule faces the inside of the pore, forming a hydrophilic channel, while correspondingly the polyene section of the molecule interacts with the lipid bilayer by being oriented toward the outside of the channel.

Even though this model is a classic in membrane biology, both the formation sequence and the precise structure of the channel remain to be confirmed. For instance, several pore sizes have been reported where the number of AmB (**1**) molecules required to form a channel ranged from 4 to 12, albeit 8 molecules is generally accepted (*5*). Moreover, the mechanism of pore formation is sometimes described as independent of the sterol located in the membrane (ergosterol in yeast cells and cholesterol in mammalian cells) (*6*). However, it is more often asserted that channel formation is sterol-dependent, but again, the reported values for the stoichiometry between the sterol and AmB (**1**) varies considerably in the literature from 0.7 to 3.9 (*7*). Furthermore, until recently no evidence was available as to whether a single-length or a double-length barrel was formed in the membrane (*8*). The myriad of mechanistic hypotheses argues for the necessity of designing and synthesizing AmB (**1**) conjugates with the purpose of providing additional insight.

In an attempt to elucidate the nature of the structure of the AmB (**1**) channel in lipid bilayers, we sought to assemble AmB (**1**) molecules on a scaffold that would mimic a single-length ion channel structure (*9*). In such a system, AmB (**1**) molecules would be preorganized and covalently bound; consequently the number of AmB units forming the pore is clearly defined. Calixarenes were chosen because they are a class of compound that is already known to form synthetic cation channels in lipid membranes (*10*). Furthermore, calix[4]arenes are well-defined scaffolds because of their rigidity, particularly with respect to the cone shape, and practical to work with because they are readily synthesized and functionalized (*11*). Herein, we report the synthesis of a preformed AmB (**1**) channel bearing four AmB (**1**) molecules covalently bound to a calix[4]arene core (Figure 2). When compared to monomeric AmB (**1**), the novel conjugates retain the ability to induce K^+ leakage as well as antifungal activity. Investigation of the hemotoxicity also revealed that these macromolecules are 10 times less toxic than native AmB (**1**).

EXPERIMENTAL PROCEDURES

Susceptibility Assays. The minimal inhibitory concentration (MIC) values were determined for the *Saccharomyces cerevisiae* wild type (BY4741, a derivative of S288C) (*12*). The assays were inspired by the standard protocol approved by the National Committee of Clinical Laboratory Standards (NCCLS) but using

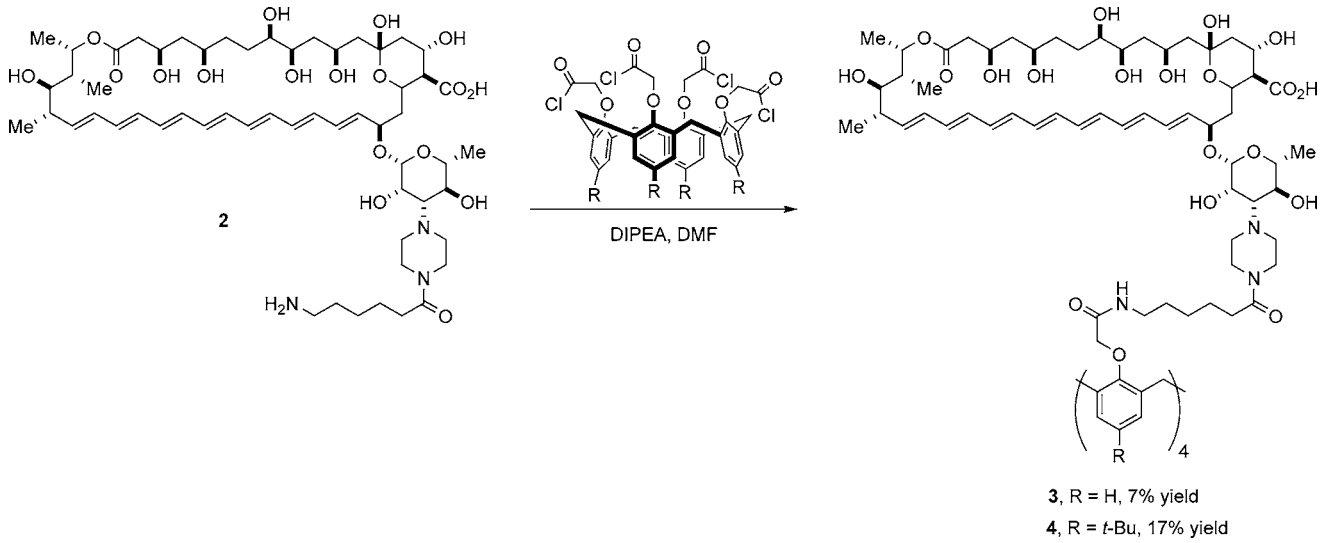
Scheme 1



YEPD liquid medium instead of the RPMI-1640 medium (*13*). The strains were cultivated overnight in 5 mL of YEPD liquid medium at 30 °C with constant shaking. The saturated cultures were diluted to an ODB_{600B} of 0.1 (3×10^7 cells/mL). For the 24-well plate, each well was prepared by adding 1% (12 μL) of DMSO solution of the tested compound with 1% (12 μL) yeast cells solution and completed with YEPD (1.176 mL). The plates were sealed with Parafilm and then incubated for 18 h at 30 °C. The optical density was read at 600 nm using 1.5 mL cuvettes. The MIC value was defined as the drug concentration needed to inhibit growth at less than 5% compared to a drug-free culture.

Hemolytic Assays (*14*). Human blood, anticoagulated with citrate or EDTA, was centrifuged (2000*g*) at 4 °C for 10 min. The pellets were washed three times with PBS buffer (pH 7.2 with 2 g/L glucose) and then diluted to a concentration of 4% (4×10^8 cells/mL). All experiments were done in triplicate, and the total volume for the hemolysis tubes was 1.4 mL. The solutions were prepared by adding 1% (14 μL) of DMSO solution of the tested compound with 736 μL of PBS buffer and completed with 750 μL of 4% erythrocytes. After 1 h of incubation at 37 °C, the samples were centrifuged (1500*g*) at 4 °C for 5 min and the absorbance of the supernatant was measured at 560 nm. The concentration that led to 50% hemolysis (EH_{50}) was interpolated graphically. The value for the 100% hemolysis was obtained by the treatment with 100 μM AmB.

K^+ Efflux Assays. The K^+ efflux measurements were made following a procedure previously described (*15*). The appropriate liposome suspensions were prepared using POPC, cholesterol, and ergosterol. Then the liposomes were sized by extrusion through two 400, 200, and finally 100 nm pore size membranes (10 times for each pore size). The resultant "100 nm" unilamellar liposomes were dialyzed against 600 mL of 150 mM NaCl, 5 mM HEPES (pH 7.4) buffer. Afterward, the suspension was diluted with 150 mM NaCl, 5 mM HEPES (pH 7.4) buffer to 1 mM overall lipid concentration (phospholipids + sterols). For each efflux measurement 10 mL of this liposome suspension was placed in a small beaker. Potentiometric measurements were performed every second with a 16-channel electrode monitor in magnetically stirred solutions at ambient temperature. The reference electrode was a Metrohm double-junction Ag/AgCl reference electrode with 3 M KCl as the reference electrolyte and 1 M LiOAc as the bridge electrolyte. After recording the amphotericin-induced potassium efflux, liposomes were lysed by adding sodium cholate (172 mg). The resulting reading (taken after 1 h) was used to quantify the 100% K^+ release.

Table 1. MIC and EH_{50} Values for AmB (1) and Conjugates 3 and 4

compd	MIC BY4741 (μM)[a]	EH_{50} (μM)[b]
1 (AmB)	0.30	4.0
3	0.10	50
4	0.25	40

[a] Assayed with *S. cerevisiae* (BY4741) following the NCCLS protocol. See Supporting Information for details. [b] Determined according to the procedure in ref 14. EH_{50}: concentration causing 50% hemoglobin release in human erythrocytes. MIC: minimal inhibitory concentration.

RESULTS AND DISCUSSION

Our group has previously reported the synthesis of a readily accessible piperazine linker as a synthetic anchor for the conjugation of various entities to AmB (**1**), such as fluorescein (*15*). On the basis of this approach, we envisioned the use of the AmB derivative **2** in a series of amide coupling reactions with a calix[4]arene precursor bearing several acyl chloride functionalities (Scheme 1). This synthetic route conveniently allows the use of natural and unprotected AmB (**1**) because the four coupling reactions are chemoselective. The yields reported correspond to pure single isomers of the calixarene AmB conjugates as shown. The conical shape of the calix[4]arene scaffold is preserved throughout the synthesis because it was fixed during a prior alkylation step (*16*). The conical conformation in the final products was also confirmed by the symmetry found in the aromatic region of the ^1H NMR spectra of the conjugates **3** and **4**.

After the isolation of conjugates **3** and **4**, we could then examine if such a preorganized macromolecular arrangement of AmB (**1**) molecules would display biological activity. First, to evaluate the antifungal activities of **3** and **4**, the minimal inhibitory concentrations (MIC, the concentration needed to inhibit growth at less than 5% compared to a drug-free culture) against *Saccharomyces cerevisiae* were determined (Table 1). Interestingly, there was no diminution in the antifungal activity observed for the conjugates in comparison to native AmB (**1**). In fact, both MIC values for **3** and **4** (0.10 and 0.25 μM, respectively) were slightly better than for monomeric AmB (**1**) (MIC = 0.30 μM). These results are consistent with the ion channel mechanism because the AmB conjugate that mimics pore structure retains good antifungal activity. However, they do not rule out completely the possibility of other mechanisms

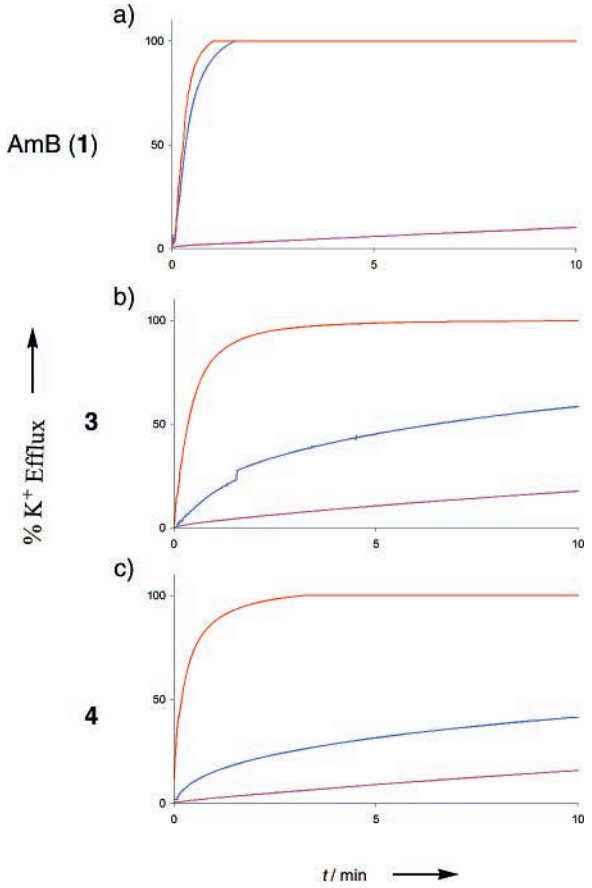


Figure 3. K^+ efflux from vesicles ($LUVET_{100}$) prepared from 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) (pink line), POPC with 13% ergosterol (red line), and POPC with 30% cholesterol (blue line) caused by AmB (**1**), **3**, and **4**, added in DMSO to a suspension of vesicles to give a final concentration of 1.0 μM (a−c).

such as internalization, membrane disruption, and peroxidation. However, in contrast to the prevailing models, which call for 8−12 AmB staves, it would seem that a large number of AmB (**1**) molecules are not required to form an active ion channel because an arrangement containing only four AmB (**1**) units is sufficient to preserve activity in the calixarene that forms the basis of our study.

The toxicity of the AmB (**1**) derivatives toward erythrocytes was next examined (Table 1), for which an EH_{50} value (the concentration of an agent that causes 50% hemoglobin release) can be measured using an established assay (*14*). AmB derivative **3** ($EH_{50} = 50\ \mu$M) was 10 times less toxic than AmB (**1**) ($EH_{50} = 4.0\ \mu$M), while **4** displayed even less toxicity ($EH_{50} = 40\ \mu$M). Previous observations have shown that AmB aggregates were more toxic for mammalian cells than the corresponding monomer. However, our results suggest that the spatial arrangement of the complex might be an important factor for controlling the toxicity, with head-to-tail complexes showing higher toxicity than head-to-head complexes such as seen in this communication (*17*).

Differential interactions between ergosterol found in fungal membranes and cholesterol in mammalian cells and the concurrent membrane preorganization are often considered the basis for the selectivity of AmB (**1**) as an antifungal agent. A convenient assay for studying the channel formation process involves the measurement of induced K^+ efflux in liposomes (*18*). We then studied the ability of derivatives **3** and **4** to lead to K^+ efflux from large unilamellar vesicles (LUVs) prepared from POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine) admixed with sterols, mimicking conditions found in natural biomembranes (Figure 3) (*19*). In accordance with the MIC values previously observed, all compounds rapidly induce complete K^+ efflux from vesicles containing ergosterol (red line). The channel formation process seems unaffected by the nature of the substituent distally substituted on the calixarene because both conjugates **3** and **4** retain the ability to induce K^+ leakage in the same fashion as a free monomeric AmB (**1**) molecule. However, derivatives **3** and **4** caused significantly reduced efflux with cholesterol-containing vesicles (blue line), indicating improved selectivity over AmB (**1**). This superior differentiation between ergosterol and cholesterol containing lipid bilayers is consistent with the observation that compounds **3** and **4** are less hemotoxic than AmB (**1**), since the nonselective binding of AmB (**1**) in membranes incorporating ergosterol (fungal) and cholesterol (mammalian) has been considered the main cause of toxicity.

In conclusion, the first preorganized AmB single-length ion channels based on a calix[4]arene scaffold were synthesized. Conjugates **3** and **4** not only are as active as native AmB (**1**) against *S. cerevisiae* but also retain the ability to induce K^+ leakage from vesicles, suggesting an efficient channel formation in the membrane. The fact that these molecules are active is unusual, as previous assumptions have called for 8−12 AmB molecules per channel, while the compounds reported herein consist of only 4 AmB units. Moreover, the minimal hemotoxicity observed for these tetramers is noteworthy. Finally, molecular architectures such as AmB−calix[4]arene discussed herein can serve as an interesting starting point for transmembrane pore models.

Dendrimer Versus Linear Conjugate: Influence of Polymeric Architecture on the Delivery and Anticancer Effect of Paclitaxel

Jayant J. Khandare,[†] Sreeja Jayant,[†] Ajay Singh,[‡] Pooja Chandna,[†] Yang Wang,[†] Nicholi Vorsa,[‡] and Tamara Minko*,[†]

Department of Pharmaceutics, Rutgers, The State University of New Jersey, Piscataway, New Jersey 08854, and Department of Plant Biology and Pathology, The State University of New Jersey, New Brunswick, New Jersey 08854. Received August 1, 2006; Revised Manuscript Received September 25, 2006

The relative difference in polymeric architectures of dendrimer and linear bis(poly(ethylene glycol)) (PEG) polymer in conjugation with paclitaxel has been described. Paclitaxel, a poorly soluble anticancer drug, was covalently conjugated with PAMAM G4 hydroxyl-terminated dendrimer and bis(PEG) polymer for the potential enhancement of drug solubility and cytotoxicity. Both conjugates were characterized by ^{1}NMR, HPLC, and MALDI/TOF. In addition, molecular conformations of dendrimer, bis(PEG), paclitaxel, and its polymeric conjugates were studied by molecular modeling. Hydrolysis of the ester bond in the conjugate was analyzed by HPLC using esterase hydrolyzing enzyme. In vitro cytotoxicity of dendrimer, bis(PEG), paclitaxel, and polymeric conjugates containing paclitaxel was evaluated using A2780 human ovarian carcinoma cells. Cytotoxicity increased by 10-fold with PAMAM dendrimer−succinic acid−paclitaxel conjugate when compared with free nonconjugated drug. Data obtained indicate that the nanosized dendritic polymer conjugates can be used with good success as anticancer drug carriers.

INTRODUCTION

Paclitaxel (Taxol) is a diterpenoid obtained from the bark of the pacific yew tree *Taxus brevifolia* (*1*) and is one of the most promising chemotherapeutic agents acclaimed by the National Cancer Institute (*2*). The drug promotes tubulin polymerization by forming a hyperstabilized structure, disrupting the normal tubule dynamics essential in cellular division, thereby inducting cell death (*3*). Due to low aqueous solubility of paclitaxel (about 0.3 μg/mL), numerous attempts are being made to increase solubility of the drug using various formulations and prodrug conjugates (*4*−*8*). Among the latter, poly(ethylene glycol) (PEG) prodrugs have been the most promising, providing for an increased aqueous solubility, enhanced pharmacological activity, lowered systemic toxicity, reduced immunogenicity, and prolonged plasma lifetime. Greenwald et al. proposed several relatively high molecular weight PEG prodrugs to render paclitaxel more soluble and increase its systemic circulation time (*9*).

Various polymers with different architectures have been used for the delivery of therapeutic agents (*10*−*19*). Only a few of these polymers, such as *N*-(2-hydroxypropylmethacrylamide) (HPMA), PEG, and poly(glutamic acid) (PGA), and their polymeric prodrug conjugates have shown promise in clinical applications for the delivery of anticancer drugs. Among these, only PGA is a biodegradable polymer. In the case of PEG and HPMA copolymers, molecular weights have been limited to 40 kDa to ensure their renal elimination (*20*).

Recently, novel branched polymers (e.g., dendrimers) have been introduced as carriers of therapeutic agents. Such branched carriers are characterized by *nanosized*, monodispersed peripheral multiend sites that allows for conjugation of multiple drug molecules per one molecule of the carrier. In addition, dendrimers possess unique characteristics including specific shape, branch length-to-density ratio, and surface functionality, which distinguish them from conventional linear polymers (*21*−*23*). Moreover, these polymers have entered into therapeutics with successful human clinical (Phase I) trials, namely, dendrimer-based nanopharmaceuticals (VivaGel), nanodiagnostics (Stratus), DNA delivery vectors (Superfect), and other drug delivery/polyvalency prototypes (*24*).

Many attempts have been made to improve the solubility of the highly water insoluble paclitaxel using formulations, surfactants, PEGylated polymers, Cremophor, solid dispersions, micro-nanoparticles, and complexation with cyclodextrins (*25*). Another strategy involves prodrug conjugation using small molecules or polymers as solubilizing entities at either C2′primary or C7 secondary hydroxyl positions in paclitaxel (*26*−*30*). Such conjugates can potentially improve aqueous solubility of the drug and thereby enhance its antitumor activity. However, polymeric carriers with different architectures have not been compared on the similar experimental conditions in order to assess the effectiveness of the various architectural elements in the delivery of anticancer drug by the carrier (i.e., by linear or branched).

The present work is aimed at comparing the ability of carriers with two different polymeric architectures, i.e., (a) polyamidoamine (PAMAM) G4 hydroxyl-terminated dendrimer and (b) conventional linear PEG polymer to deliver anticancer drug paclitaxel. Paclitaxel was covalently conjugated with bis-(carboxymethyl) PEG and dendrimer by the condensation method. To study the cellular entry dynamics by confocal microscopy, fluorescent probe fluoroisothiocynate (FITC) was covalently conjugated with paclitaxel, polymers, and polymeric conjugates containing paclitaxel. Conjugates were characterized by ^{1}HNMR, MALDI/TOF, and HPLC methods. The rate of hydrolysis of the ester bond in the conjugates was analyzed by

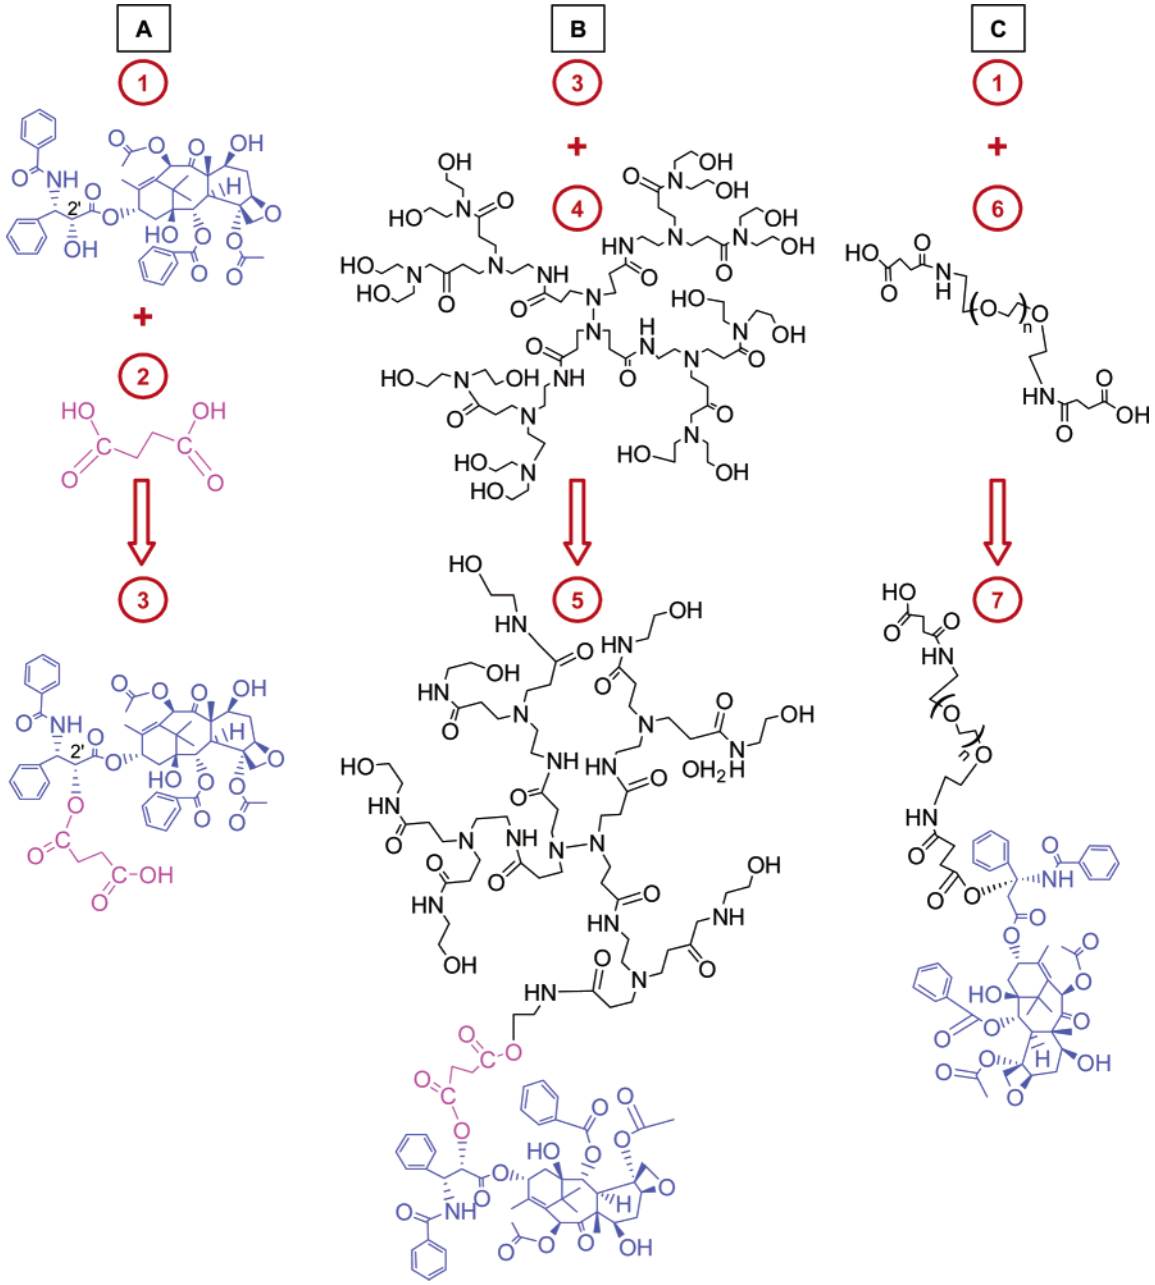

Figure 1. Synthesis of conjugates. (A) Paclitaxel (**1**) was first bound to succinic acid (**2**, SA) forming paclitaxel−SA conjugate (**3**). (B) PAMAM G4 hydroxyl-terminal dendrimer (**4**) was further coupled with paclitaxel−SA conjugate (**3**) to form paclitaxel−dendrimer conjugate (**5**). (C) bis-(PEG) (**6**) was joined with paclitaxel (**1**) to yield PEG−paclitaxel conjugate (**7**).

HPLC using esterase enzyme. In addition, polymers and conjugates with paclitaxel were studied for molecular conformations by the molecular modeling method. In vitro cytotoxicity (IC_{50}) of the conjugates was evaluated.

EXPERIMENTAL SECTION

Materials. Paclitaxel (M_w ~853.9 Da) was obtained from Sigma Chemical Co. (Atlanta, GA); α,ω-bis(2-carboxyethyl)-poly(ethylene glycol) (M_w ~10 000 Da) and fluorescein isothiocyanate (FITC) were obtained from Fluka (Allentown, PA). PAMAM−G4-OH (M_w ~14 279 Da, 64 end groups) dendrimers, *N*,*N*-diisopropylethylamine (DIEA), 4-(methylamino)pyridine (DMAP), and succinic acid (SA) were purchased from Sigma-Aldrich (St. Louis, MO). *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide HCl (EDC.HCl) was purchased from Fluka. Dialysis membrane of the molecular weight cutoff of 3500 Da (Spectra Pore), dimethyl sulfoxide (DMSO), dimethyl formamide (DMF), dichloromethane (DCM) acetone, ethanol, and diethyl ether were purchased from Fischer Scientific. Jupiter C5 column was purchased from Phenomenex (Torrance, CA).

Cell Line. The human ovarian carcinoma A2780 cell line was obtained from Dr. T. C. Hamilton (Fox Chase Cancer Center, PA). Cells were cultured in RPMI 1640 medium (Sigma Chemical Co., St. Louis, MO) supplemented with 10% fetal bovine serum (FBS) (HyClone, Logan, UT). Cells were grown at 37 °C in a humidified atmosphere of 5% CO_2 (v/v) in air. All experiments were performed on cells in the exponential growth phase.

Synthesis of Paclitaxel−Succinic acid (SA) Conjugate (Figure 1A). SA (**2**) is a bis(carboxylic acid) moiety and is reacted on an equimolar basis with the hydroxyl group in paclitaxel (**1**) to form a paclitaxel−SA conjugate (**3**), leaving one free carboxyl group for further conjugation with hydroxyl-terminal dendrimer. Briefly, paclitaxel (10.0 mg, 0.0118 mM)

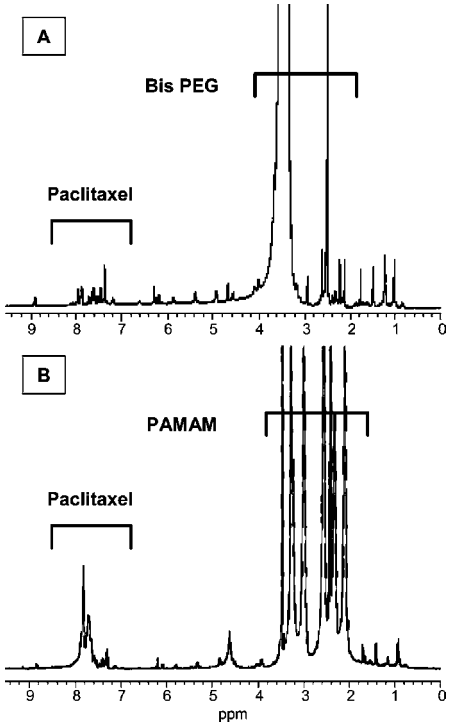

Figure 2. Proton nuclear magnetic resonance (^{1}H NMR) spectra of bis(PEG)−paclitaxel conjugate (A) and paclitaxel−SA−PAMAM dendrimer conjugate (B). ^{1}H NMR spectra were recorded on 400 MHz spectrophotometer using DMSO-d_6 as a solvent.

and succinic acid (1.4 mg, 0.0118 mM) were dissolved in 3.0 mL of anhydrous DMSO and 10.0 mL of anhydrous DCM. To the resulting mixture, *N*-(3- dimethylaminopropyl)-*N*-ethylcarbodiimide HCl (EDC.HCl, 2.30 mg, 0.0118 mM) and DMAP (1.0 mg) were used as a catalyst. The reaction was carried out with continuous stirring for 24 h at room temperature. The resulting solution was filtered to remove dicyclohexilurea (DCU) obtained as a byproduct during the reaction. Paclitaxel−SA conjugate (**3**) was precipitated using diethyl ether and dried under vacuum.

Synthesis of PAMAM-G4−Succinic Acid−Paclitaxel Conjugate (Figure 1B). Conjugation of succinic acid to paclitaxel resulted in the formation of monocarboxylic acid conjugate (**3**), which was further conjugated with hydroxyl groups in PAMAM-G4-OH dendrimer (**4**). Briefly, dendrimer (88 mg, 0.0061 mM) and paclitaxel−succinic acid conjugate (**3**) (6.0 mg, 0.0061 mM) were dissolved in 4.0 mL of anhydrous DMSO and 10.0 mL of anhydrous DCM. The mole ratio of dendrimer to paclitaxel−SA conjugate was maintained at 1:1. EDC.HCl (1.2 mg, 0.0062 mM) was added as a coupling agent, and DMAP (1.0 mg) was used as a catalyst. The reaction was stirred continuously for 24 h at room temperature. The resulting solution was filtered to remove DCU, and the filtrate was dialyzed extensively with anhydrous DMSO using dialysis membrane of molecular weight cutoff of 2000 Da for 24 h to remove unreacted paclitaxel−SA conjugate and EDC.HCl. Further, the conjugate was purified by size exclusion chromatography to remove unreacted paclitaxel−SA conjugate and excess EDC.HCl. Conjugate was dried under vacuum at room temperature. ^{1}H NMR was recorded in DMSO-d_6 on a 400 MHz NMR spectrophotometer and characterized for the peaks of dendrimer and paclitaxel (Figure 2B). Dendrimer, bis(PEG), and paclitaxel conjugates were analyzed for molecular mass by MALDI/TOF (Figure 3A,B) and HPLC (Figure 3D−F).

Synthesis of α,ω-Bis((2-carboxyethyl)PEG)−Paclitaxel Conjugates (Figure 1C). α,ω-Bis($PEG_{10\,000}$)−citric acid (**6**) containing carboxyl end groups at the terminals was coupled with hydroxyl groups in paclitaxel to form an ester conjugate (**1**). Briefly, bis((2-carboxyethyl)PEG) (50 mg, 0.005 mM) and paclitaxel (4.2 mg, 0.005 mM) were dissolved in 5.0 mL of anhydrous dimethylformamide (DMSO) and 15 mL of anhydrous dichloromethane (DCM). To this solution, 1-[3-(dimethylaminopropyl]-3-ethylcarbodiimide HCl (EDC.HCl, 1.0 mg, 0.0052 mM) was added as a coupling agent and 4-(methylamino)pyridine (DMAP, 0.5 mg, 0.004 mM) was used as a catalyst. The reaction solution was stirred continuously for 24 h at room temperature. The reaction yields formation of carbodiimide urea, which was removed by filtration. The conjugate was purified to remove unreacted paclitaxel and EDC.HCl by the dialysis method using a Spectra/Por membrane (M_w cutoff ∼2000 Da) in DMSO as a solvent. After the additional purification by size exclusion chromatography, α,ω-bis((2-carboxyethyl)PEG−paclitaxel conjugate was dried under vacuum at room temperature. ^{1}H NMR spectra were recorded in DMSO-d_6 on a 400 MHz NMR spectrophotometer and characterized for the peaks of bis(PEG) polymer and paclitaxel (Figure 2A). In addition, the molecular mass was measured by MALDI/TOF (Figure 3C) and characterized by HPLC (Figure 3F).

FITC Labeling of Bis(PEG), PAMAM Dendrimer, Free Paclitaxel, PEG−Paclitaxel, and PAMAM Dendrimer−SA−Paclitaxel Conjugates. FITC possesses carboxyl as well as hydroxyl groups for chemical conjugation with either hydroxyl or carboxyl group-possessing compounds. The reacting components were used in the following proportions: carboxyl-terminated bis(PEG) (60.0 mg, 0.006 nM) and FITC-OH (2.33 mg, 0.006 nM); PAMAM dendrimer (45 mg, 0.0032 nM) and FITC (5.0 mg, 0.0128 nM); paclitaxel (5.0 mg, 0.0058 nM) and FITC (2.28 mg, 0.0058 nM); PEG−paclitaxel conjugate (27 mg, 0.0025 nM) and FITC (1.0 mg, 0.0025 nM); PAMAM dendrimer−SA−paclitaxel conjugate (25 mg, 0.00163 nM) and FITC (2.5 mg, 0.0064 nM). All the components were dissolved separately in a round-bottom flask, and anhydrous DMSO and dichloromethane (DCM) were added. EDC.HCl was added with equivalent moles of FITC to be conjugated, and the reaction was carried out for 24 h at room temperature. Urea salt was precipitated and removed by filtration. All the FITC-labeled components (except paclitaxel−FITC conjugate) were dialyzed extensively using anhydrous DMSO (dialysis membrane of molecular weight cutoff of 2000 Da) for 24 h to remove unreacted FITC and EDC.HCl. Further, the conjugates were purified using size exclusion chromatography to remove unreacted FITC and excess EDC.HCl. All the conjugates were precipitated three times in acetone to remove free FITC.

HPLC. Quantitative evaluations of individual samples were obtained using Water Empower HPLC consisting of an in-line degasser, a 600E multisolvent delivery pump, a 717plus autosampler, and a Photodiode array detector 996. The separations were performed using a Jupiter column (C5, 4.6 × 250, 5−300 A) from Phenomenex (Torrance, CA). Two solvent systems were used. Solvent system A consisted of 99.9% water with pH 3.5 (adjusted with formic acid) and 10% methanol. Solvent B consisted of 20% water with pH 3.5 (adjusted with formic acid), 20% methanol, and 60% acetonitrile. The flow rate was maintained at 1 mL/min using step gradients of 0 min solvent A 100%; 10 min solvent A 100%; 20 min solvent A 0%, and 30 min solvent A 0%, 32 min solvent A 100%. The spectra were recorded ranging from 210 to 600 nm at 1.5 nm step. The spectra of each peak were superimposed with corresponding spectra and retention times. Only peaks which showed no more than 1.0% difference were used for integration and evaluation. Twenty microliters of each sample and standard were injected. The stock solutions (1 mg/mL) of analyzed substances were prepared using methanol as a solvent. The calibration standards of paclitaxel (0.24 mg/mL to 0.000296 mg/

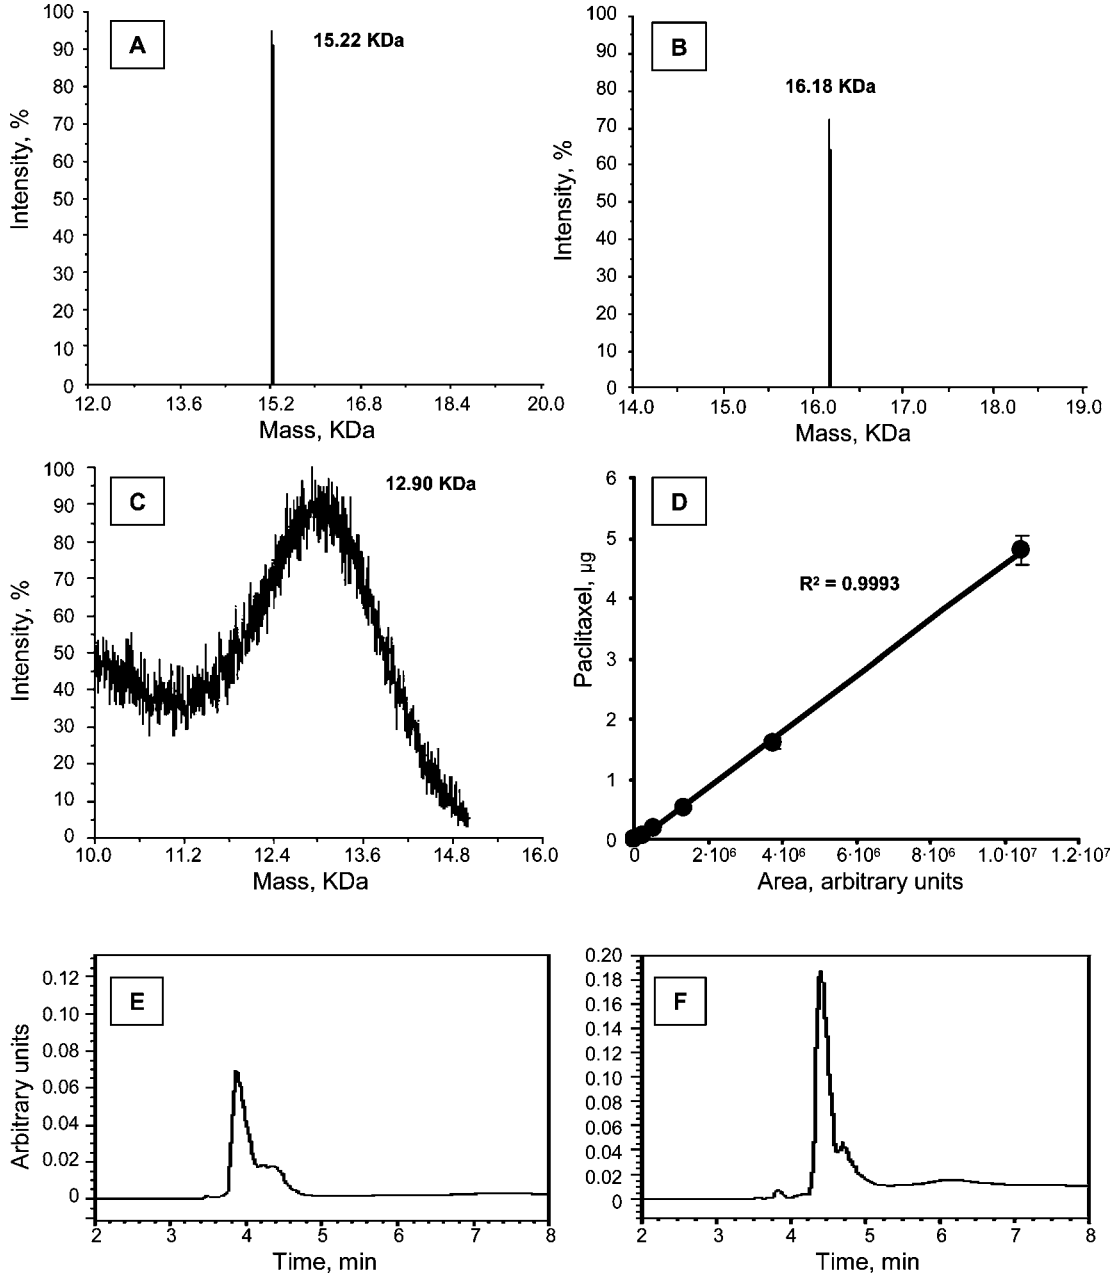

Figure 3. Characterization of synthesized polymer conjugates. Mass of PAMAM G4 OH dendrimer (A, 15.22 KDa), paclitaxel−SA−PAMAM dendrimer (B, 16, 18 KDa) and paclitaxel−bis(PEG) conjugates (C, 12.90 KDa) were measured by MALDI/TOF (Voyager De-Pro) system using sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid) as a matrix. The total mass of the components indicate the appropriate formation of the paclitaxel conjugates. Calibration curve for paclitaxel (D) and typical HPLC chromatograms (E,F) of paclitaxel−SA−PAMAM dendrimer conjugate and PEG−paclitaxel conjugate, respectively. Peaks from 3.5 to 5 min retention time indicate the formation of high molecular weight conjugates.

mL) were prepared by serial dilution to achieve the nominal concentrations in reaction mass and hydrolyzed reaction mass.

Release of Paclitaxel from the Conjugates. The release of drug from the conjugates was assessed by HPLC method using esterase as hydrolyzing enzyme at pH 7.4. The standard curve of paclitaxel (Figure 3D) was obtained in a special series of HPLC experiments and used for calculating drug release from the conjugates. The data are presented as a percentage of total bound of paclitaxel, which is released from the conjugates (Figure 5).

Molecular Modeling. The studies were focused on analysis of conformational structures, energy minima, and molecular dynamics of bis(PEG) polymer, PAMAM dendrimer, free paclitaxel, and paclitaxel containing polymeric conjugates. The chemical structures were built using *ChemDraw 9.0 Pro* (Cambrigesoft Corp., Cambridge, MA). Free PEG and its bioconjugate with paclitaxel were built to represent seven ethylene repeat ($-CH_2-O-CH_2-$) units. The settings for energy minima and molecular dynamics were of the order reported by us earlier: 1.000 step interval, 2.0 fs; frame interval, 10 fs; terminated after 10 000 steps; heating/cooling rate, 1.000 kcal/atom/ps; target temperature, 300 K. Distance between the first and last carbon atom was measured for the molecular dynamics structures of bis(PEG) and its conjugation with paclitaxel. *RasTop* molecular visualization software (Philippe Valadon, San Diego, CA) was used for obtaining lengths of free drug, polymer, and its conjugates.

Cellular Internalization (Confocal Microscopy). Cellular internalization of FITC-labeled PEG−polymer, dendrimer, paclitaxel, PEG−paclitaxel, and PAMAM−dendrimer−paclitaxel conjugates was studied by confocal microscopy. To assess intracellular distribution of the substances, six optical sections, known as a *z*-series, were scanned sequentially along the vertical (*z*) axis from the top to the bottom of the cell.

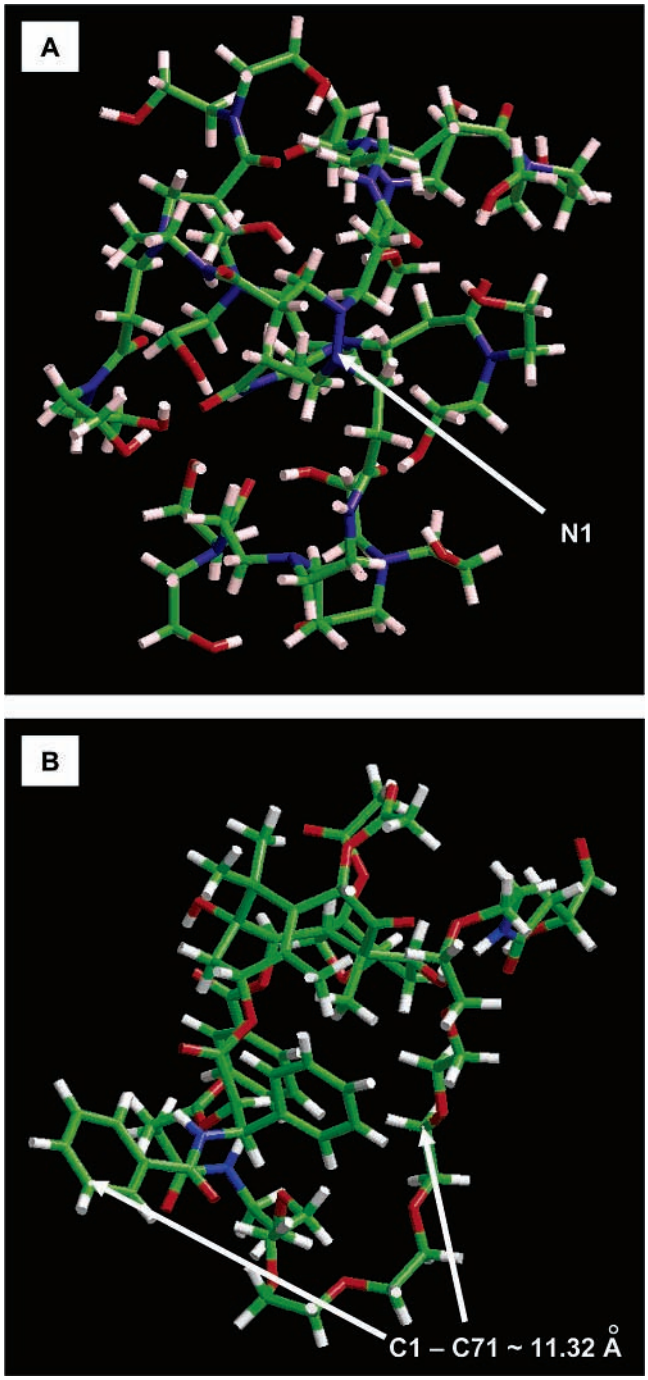

Figure 4. Molecular modeling studies of paclitaxel−SA−PAMAM dendrimer (A) and PEG−paclitaxel conjugate (B). Polymeric structures were built in *Chemdraw* software and allowed to undergo conformational stabilization for energy minima. The stabilized structure of PEG−paclitaxel conjugate was exported to *RasTop* software to estimate the distances between the first and last carbon atoms (here, C1−C71). The distance was measured to be 11.32 Å for energy-minimized molecule.

In Vitro Cytotoxicity. The cytotoxicity of paclitaxel conjugates and free paclitaxel was assessed by using a modified MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay as previously described (*31*, *32*). To measure cytotoxicity, cells were separately incubated in a microtiter plate with different concentrations of free paclitaxel, PEG−paclitaxel, and PAMAM dendrimer−paclitaxel conjugates. Control cells received an equivalent volume of fresh medium. The duration of incubation was 24 h. On the basis of these measurements, IC_{50} doses of free paclitaxel and its polymeric conjugates (the concentrations of active ingredients necessary to inhibit the cell growth by 50%) were calculated. A decrease in the IC_{50} dose indicates an increase in drug toxicity.

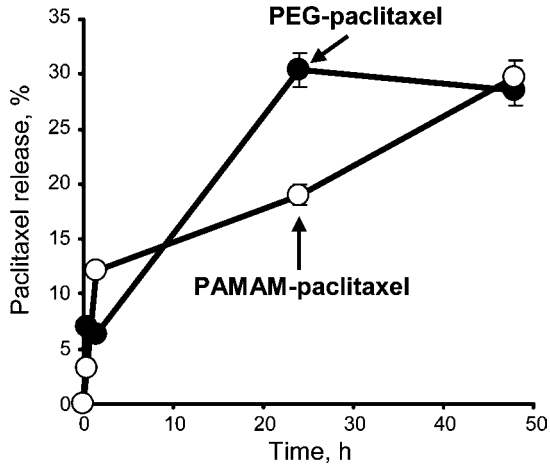

Figure 5. A release profile of paclitaxel from the conjugates determined by HPLC after enzymatic hydrolysis using esterase as the enzyme at pH 7.4. After 24 h, the release of paclitaxel in the PEG conjugate was observed to be 30%. In the case of paclitaxel−SA−PAMAM dendrimer conjugate, the 30% release of the drug was achieved after 48 h, indicating slower release.

Statistics. All in vitro experiments were performed in quadruplicate. The results are expressed as mean ± SD from 4−8 independent measurements. Statistical analysis was performed as a one-way analysis of variance (ANOVA) and comparisons among groups were performed by independent sample *t*-tests.

RESULTS

Synthesis and Characterization of Paclitaxel Conjugates. α,ω-Bis(PEG)−paclitaxel and dendrimer−SA−paclitaxel conjugates were prepared by using EDC.HCl as a coupling agent. Conjugates were purified by membrane dialysis using the molecular weight cutoff method and by size exclusion chromatography. Each of the conjugates was characterized by ^{1}H NMR on 400 MHz spectrophotometer. Proton peaks arising from paclitaxel, bis(PEG), and PAMAM dendrimer were analyzed (Figure 2A,B), and the peak area was integrated and compared for the conjugation ratio (integration values not shown in proton spectra). Both the conjugates and free paclitaxel were further analyzed and characterized by HPLC. In addition, the masses of the PAMAM dendrimer, bis(PEG) polymer, and their conjugates having paclitaxel were characterized by MALDI/TOF. FITC was covalently labeled with paclitaxel, polymers, and their paclitaxel conjugates, for evaluating cellular dynamics using confocal microscopy.

NMR Peaks Characterization and Estimation of Conjugation Ratios. *PEG−Paclitaxel Conjugate.* ^{1}H NMR spectrum (Figure 2A) showed the broad peaks from 3.2 to 3.9 ppm indicating protons for $-CH_2CH_2O-$ in bis(PEG) polymer. A peak at 8.85 ppm shows the presence of two hydrogen atoms arising from the phenyl ring in paclitaxel at the C2′ position (*33*). Proton peaks from δ 3.2 to 3.9 ppm corresponded to PEG and have the integrated peak area of 639 arbitrary units (integration values not shown in proton spectra). Bis(PEG) polymer with molecular weight 10 000 Da has approximately 257 protons in this region. So, each proton corresponds to a value of 2.49 units (639/257). On the other hand, a peak at δ 8.85 ppm corresponds to a value of 0.025 units for a single proton in the phenyl ring of paclitaxel (integration for value ∼0.05/2 = 0.025). Therefore, the ratio of protons of PEG to paclitaxel is inferred to be around 0.99.

Dendrimer−SA−Paclitaxel Conjugate. ^{1}H NMR spectrum (Figure 2B) showed the multiplets between δ 2.0 and 3.6 ppm

corresponding to the presence of 985 protons of CH_2 of PAMAM-G4-OH (integration values not shown in the proton NMR spectra) (*34*). On the other hand, a peak at 8.85 ppm showed the presence of two hydrogen atoms on the phenyl ring in paclitaxel at the C2′ position. The integrated peak areas for protons in dendrimer and paclitaxel are 104.17 and 0.18, respectively. Since the value for each proton in dendrimer and paclitaxel corresponds to 0.105 and 0.09, respectively (i.e., 104.17/985 = 0.105 and 0.18/2 = 0.09), the ratio of paclitaxel molecules per dendrimer is ~0.857 (0.09/0.105 = 0.857). The proton NMR provides evidence for the formation of PEG−paclitaxel and PAMAM dendrimer−paclitaxel conjugates.

Characterization of Conjugates. *MALDI/TOF* (Figure 3A−C). Masses of PAMAM-G4-OH dendrimer, paclitaxel−SA−PAMAM dendrimer, and paclitaxel−bis(PEG) conjugates were measured by MALDI/TOF Voyager DE-Pro system (Applied Biosystems, Foster City, CA) using sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid) as a matrix. The molecular masses were found to be 15.22 KDa for PAMAM-G4-OH dendrimer (Figure 3A), 16, 18 KDa for paclitaxel−SA−PAMAM dendrimer (Figure 3B), and 12.90 KDa for paclitaxel−bis(PEG) conjugate (Figure 3C). The total mass of the compounds indicates formation of the paclitaxel conjugates. In addition, HPLC data confirmed the peaks between 3.5 and 5 min (Figure 3E,F) indicating high molecular weight conjugate formation for both PAMAM−SA−paclitaxel and PEG−paclitaxel.

HPLC. In this study, we used HPLC for analysis of paclitaxel in conjugates and free form. Quantification of free and polymer-bound paclitaxel was achieved using the reverse-phase HPLC method preceded by C5 column (4.6 × 250, 5−300 A, Phenomenex, Torrance, CA). Paclitaxel has an absorbance spectrum with the maximum at 280 nm allowing quantitative determination of polymer−drug conjugates. The use of the C5 column improved the retention time of polymer-bound paclitaxel when compared with C18 and C8 columns (Figure 3E,F). The chromatogram represents the broad peak which may arise from conjugation formed at primary as well as secondary hydroxyl positions. The stability of the bond in paclitaxel−polymer conjugates was investigated by measuring the release of free paclitaxel in stock solution. The conjugates were stored at 4 and −20 °C for 1 month, and no significant release of free drug was observed. In addition, the release of paclitaxel from the conjugates after enzymatic hydrolysis was determined using esterase as enzyme at pH 7.4 (Figure 5). Data obtained showed that about 30% of paclitaxel were released from PEG−paclitaxel conjugate after 24 h of incubation. In contrast, less than 20% of the drug was released after 24 h of incubation from PAMAM−SA−paclitaxel dendrimer, reaching 30% only after 48 h of the experiment. Although dendrimer−SA−paclitaxel conjugate has two ester sites for hydrolysis (Figure 1A,B), its enzymatic degradation was slower when compared with PEG conjugate, which has only one ester site (Figure 1C). This may be a result of specific nanosized dendrimer architecture which exhibits higher steric hindrance for esterase degradation at macromolecular ester sites when compared with linear PEG conjugate.

Enhanced Aqueous Solubility of Paclitaxel Using Dendritic and PEG Conjugates. Both of these polymers increased aqueous solubility of the drug. Solubility was higher for dendrimer−paclitaxel conjugate when compared to PEG−paclitaxel conjugates. While the aqueous solubility of paclitaxel is limited to 0.3μg/mL, the solubility of paclitaxel−bis(PEG) conjugate was observed to be 2.5 mg/mL. Moreover, the solubility for PAMAM−paclitaxel conjugate was further improved and was found to be 3.2 mg/mL.

Molecular Modeling Studies. We compared the structural stability of the linear PEG polymer with the well-defined molecular structure of PAMAM dendrimer, built structures, and evaluated the energy minima and molecular dynamics of paclitaxel, bis(PEG), PAMAM dendrimer, and polymeric conjugates containing paclitaxel. An example of molecular modeling of PAMAM dendrimer is shown in Figure 4. The energy minima conformational distance for paclitaxel was observed to be 8.24 Å (C1 to C47, the figure not shown). On the other hand, the molecular dynamics structure showed a distance of 7.99 Å (figure not shown). Energy minima conformation for paclitaxel−SA−PEG conjugate (Figure 4B) was observed to be 11.32 Å (C1 to C71). On the other hand, the molecular conformation of PAMAM dendrimer was found to be more stable than that of its paclitaxel conjugate, indicating conformational bulkiness of the resulting conjugate due to addition of the drug (Figure 4A).

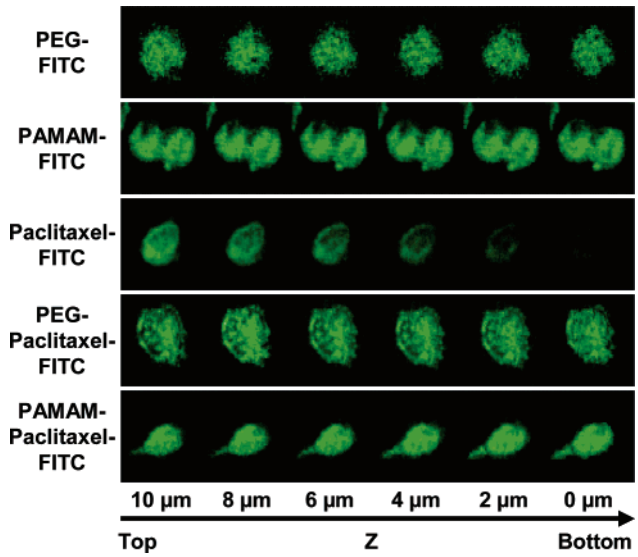

Figure 6. Confocal microscopy fluorescent images of human A2780 ovarian carcinoma cells incubated for 24 h with FITC-labeled substances (*z*-series, from the top of the cell to the bottom).

Cellular Localization of Labeled FITC Having Bis(PEG) and Dendrimer with Paclitaxel. Theoretically, high molecular weight drug conjugates could adhere to the surface of cancer cells and erroneously be visualized on microscopic images as internalized within cells. To exclude such errors, we analyzed the distribution of FITC-labeled polymers, polymer−drug conjugates, and free paclitaxel in different cellular layers from the upper to the lower of the fixed cell using confocal fluorescent microscopy (*z*-sections, Figure 6). In these experiments, the studied components were labeled with FITC and incubated with A2780 human ovarian carcinoma cells. The cells were fixed and subjected to confocal microscopy. The *z*-sections of single cells showed the homogeneous and uniform distribution of labeled polymers with or without paclitaxel. In contrast, the distribution of free paclitaxel inside the cancer cell was highly inhomogeneous both within the one layer and through different layers of a single cell. Free paclitaxel accumulated mainly in the cytoplasm near the plasma membrane and predominantly on the top of the cell in the place of cellular contact with the medium containing the drug (the bottom surface of the cell was attached to the flask wall). These data suggest that both linear PEG polymer and PAMAM dendrimer enhance the penetration of paclitaxel into cancer cells, resulting in a more homogeneous drug distribution inside the single cells.

In Vitro Cytotoxicity. Conjugation of paclitaxel to linear PEG polymer and PAMAM dendrimer substantially influenced its cytotoxicity (Figure 7). While linear PEG−paclitaxel conjugate showed more than 25-fold lower toxicity (IC_{50} dose increased), PAMAM−dendrimer−paclitaxel conjugate showed

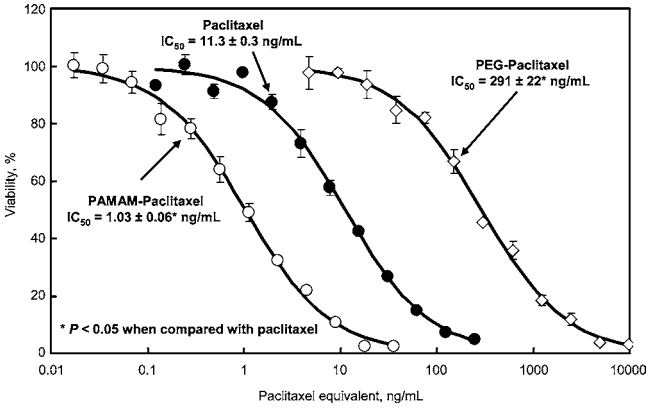

Figure 7. In vitro cytotoxicity of free paclitaxel, PEG−paclitaxel, and paclitaxel−SA−PAMAM dendrimer conjugates toward A2780 human ovarian carcinoma cells. PAMAM−SA dendrimer substantially enhances toxicity of paclitaxel by decreasing the dose of the drug required to kill 50% of cells (IC_{50} dose). Means ± SD are shown. *$P < 0.05$ when compared with free paclitaxel.

significantly ($P < 0.05$) higher toxicity (IC_{50} dose was more them 10 times lower) when compared with free drug.

DISCUSSION

Polymeric architecture, molecular weight, and molecular charge play important roles in delivering drugs (*35*). This is especially true when the polymeric materials have linear, branched, and graft architectures. In addition, such polymers exhibit high steric hindrance for cellular internalization and might often result in delayed cellular entry. For instance, PEGylated adenovirus vectors exhibit longer plasma half-life when compared with free adenovirus, and their entry into cells has been prevented by steric hindrance by poly(ethylene glycol) (PEG) chains (*36*). Moreover, linear PEG polymer may possess higher polydispersity, and theoretical size may range greater than 300−500 nm even for lower molecular weight polymer. In contrast, hyperbranched polymers, e.g., dendrimers, due to their well-defined monodispersity (PI ≈ 1.0), controlled architecture, nanosize (20−40 nm), and shape, are often considered most promising vehicles for the delivery of drugs, proteins, and other therapeutic agents (*21*, *37*−*39*). Dendrimers in conjugation with FITC have been reported to achieve rapid cellular entry even in 5 min (*34*). Dendrimers have unique architecture, as they are prepared through controlled synthetic methods: either by divergent or convergent method having control over the branching architecture. Therefore, in a short time, they have emerged as the most promising drug delivery carriers. In this work, we compared the difference in delivery ability of these polymers with the conventional linear PEG polymers.

Conjugation of a low-solubility drug with high-solubility polymers bears an additional advantage of forming a prodrug with enhanced aqueous solubility. Such soluble prodrugs further increase the bioavailability of the drug and therefore have a potential to enhance its activity (cytotoxicity in the case of an anticancer drug). Recently, polyglycerol dendrimers (PGDs) with 4−5 generations were used to investigate the effect of dendritic architecture and its generation on the aqueous solubilization of paclitaxel (*7*). It was shown that the increase in the paclitaxel solubility by PGDs was dependent on the dendrimer generation. In the present study, both polymers increased the aqueous solubility of the drug. However, the increase in the solubility was higher for the dendrimer−paclitaxel conjugate when compared with the PEG−paclitaxel conjugate. The aqueous solubility of paclitaxel−bis(PEG) was equal to 2.5 mg/mL, while that of PAMAM−SA−paclitaxel conjugate was 3.2 mg/mL. The aqueous solubility of free paclitaxel was about 0.3 μg/mL. Such a dramatic enhancement in paclitaxel solubility allowed dissolving of conjugates in buffer for our in vitro cytotoxicity studies, while the free drug was dissolved in ethanol.

Besides solubility and size, the bioavailability and anticancer activity of conjugated drug substantially depend on the type of bond between the drug and a carrier. Specific spacers are often used to control the rate of drug release from the conjugate. We used succinic acid as a spacer to bind paclitaxel to PAMAM dendrimer. SA is a bis functional carboxylic acid and therefore can be conjugated with hydroxyl groups in paclitaxel, thereby resulting in forming an ester bond with the drug, and yet leaves one free carboxyl group for further conjugation with another component. Paclitaxel−SA conjugate was coupled with hydroxyl-terminal PAMAM dendrimer to obtain dendrimer−SA−paclitaxel conjugate. In the past, the role of bis functional spacers (e.g., glutaric acid) has been established in increasing the reactivity of the low-reactivity drugs with the hyperbranched polymers (*34*). Additionally, bis functional spacers such as succinic acid may decrease the steric hindrance for conjugation with polymers, especially with the hyperbranched polymers, due to crowded functional groups (*34*). This is especially important when the dendrimer conjugate is expected to obtain a high payload of drug in the conjugate. It should be noted that, in the present conjugation reaction, two ester bonds are formed, i.e., one with the drug and another with the dendrimer, thereby providing two sites for hydrolysis to release the free drug. It is expected that free paclitaxel will be released from the conjugated drug following hydrolysis of this bond after internalization of the whole complex into the cancer cell. On the other hand, α,ω-bis($PEG_{10\,000}$) polymer contains carboxyl end groups at the terminals and therefore can be coupled directly with 2′ hydroxyl groups in paclitaxel. Although the bis(PEG) polymer consists of two reactive sites, only one molecule of paclitaxel was coupled using equivalent moles of drug and EDC.HCl as a condensing agent. It has been reported in the past that the most suitable position for structural conjugation in paclitaxel is either C2′ or C7′ hydroxyl (*33*). It has been well-realized that usually the primary hydroxyl C2′ site is a more active site than the secondary hydroxyl C7′ site due to less steric hindrance, and esterification is preferentially formed at C2′. However, it is possible to form more than one conformation of the conjugates reacting either at C2′ or at C7′. The second free carboxyl group available on the bis(PEG)−paclitaxel conjugate was utilized for coupling with the hydroxyl group in FITC, allowing for visualization of the conjugate by fluorescent/confocal microscopy.

A polymer and its reaction with bulkier drug molecules undergo steric hindrance due to higher molecular mass and unstable conformations (*35*). The net result may lead to lower yields or may even form by-products through incomplete conjugation reactions with free and unreacted drug and polymer chains. Prodrug conjugation reactions may be studied using modeling through the conformations and minima energies. In addition, the reactivity of both polymers as well as drugs could be increased by incorporating spacer molecules. One of the objectives of the present study was to compare the structural stability of the linear PEG polymer with well-defined, monodispersed PAMAM dendrimers. In the past, polymeric conformations with a glycine spacer have been evaluated using modeling studies to estimate the spacer length and molecule stability (*40*, *41*). More recently, few studies suggest applications of modeling in prodrug bioconjugates, involving incorporation of spacers and strategies to reduce the steric hindrance in prodrug synthesis (*42*). The author has demonstrated steric hindrance associated with conjugation of an anticancer drug with PEG polymer by a molecular modeling method to determine

the most suitable bicarboxylic amino acid that possesses the least steric hindrance.

Recently, we reported molecular structures of bis(PEG) polymer with multiple copies of the drug camptothecin (CPT) using molecular modeling tools (*40*). The minima represented the minimum energies (kcal) indicating the degree of conformational freedom for (a) seven repeating units of bis(PEG) polymeric chain conjugate, (b) generation 2 hydroxyl-terminated PAMAM dendrimer, and (c) its conjugate with paclitaxel. The minimum-energy conformational distance for paclitaxel was observed to be 8.24 Å (C1 to C47). On the other hand, the molecularly dynamic structure showed a distance of 7.99 Å. The minimum-energy conformation for paclitaxel−SA−PEG conjugate was observed to be 11.32 Å (C1 to C71). On the other hand, molecular confirmation of PAMAM dendrimer was found to be more stable than its paclitaxel conjugate, indicating conformational bulkiness of the resulting conjugate due to addition of the drug. Previously, we reported the results of molecular modeling studies which support our synthetic strategies in selecting reactive peptides, polymers, drugs, and spacers to reduce steric hindrance, especially prodrug conjugates involving multiple components (*35*, *40*).

Although conjugation of paclitaxel to both traditional PEG polymer and PAMAM G4−SA dendrimer improve the bioavailability of the drug, the influence of the conjugation on anticancer activity of paclitaxel depended on the type of drug carrier. Conjugation to PEG polymer significantly decreased the toxicity of paclitaxel. In fact, the IC_{50} dose of PEG−paclitaxel conjugate was more than 25 higher when compared with free drug. Such a decrease in anticancer activity might be explained by the increase in molecular mass of the whole complex, which in turn changed the mechanism of the cellular internalization of PEG−paclitaxel polymer from diffusion (free drug) to endocytosis. In contrast, conjugation of paclitaxel to PAMAM G4−SA dendrimer substantially enhanced cytotoxicity of the drug leading to the decrease in the IC_{50} dose more than 10-fold when compared with free drug.

CONCLUSIONS

Taken together, the data obtained suggest that PAMAM G4−SA dendrimer represents a promising vehicle for intracellular delivery of low-solubility drugs such as paclitaxel. The developed dendrimer provides both cytoplasmic and nuclear delivery of therapeutics and enhances anticancer activity of paclitaxel.

Covalent binding of bioligands to atomic force microscope (AFM) tips converts them into monomolecular biosensors by which cognate receptors can be localized on the sample surface and fine details of ligand−receptor interaction can be studied. Tethering of the bioligand to the AFM tip via a ∼6 nm long, flexible poly(ethylene glycol) linker (PEG) allows the bioligand to freely reorient and to rapidly "scan" a large surface area while the tip is at or near the sample surface. In the standard coupling scheme, amino groups are first generated on the AFM tip. In the second step, these amino groups react with the amino-reactive ends of heterobifunctional PEG linkers. In the third step, the 2-pyridyl-S-S groups on the free ends of the PEG chains react with protein thiol groups to give stable disulfide bonds. In the present study, this standard coupling scheme has been critically examined, using biotinylated IgG with free thiols as the bioligand. AFM tips with PEG-tethered biotin-IgG were specifically recognized by avidin molecules that had been adsorbed to mica surfaces. The unbinding force distribution showed three maxima that reflected simultaneous unbinding of 1, 2, or 3 IgG-linked biotin residues from the avidin monolayer. The coupling scheme was well-reproduced on amino-functionalized silicon nitride chips, and the number of covalently bound biotin-IgG per μm^2 was estimated by the amount of specifically bound ExtrAvidin−peroxidase conjugate. Coupling was evidently via disulfide bonds, since only biotin-IgG with free thiol groups was bound to the chips. The mechanism of protein thiol coupling to 2-pyridyl-S-S-PEG linkers on AFM tips was further examined by staging the coupling step in bulk solution and monitoring turnover by release of 2-pyridyl-SH which tautomerizes to 2-thiopyridone and absorbs light at 343 nm. These experiments predicted 10^3-fold slower rates for the disulfide coupling step than actually observed on AFM tips and silicon nitride chips. The discrepancy was reconciled by assuming 10^3-fold enrichment of protein on AFM tips via preadsorption, as is known to occur on comparable inorganic surfaces.

INTRODUCTION

Microscopy of biomolecules and subcellular structures has made invaluable contributions to modern bioscience. While this field wasoriginally dominated by electron microscopy, the invention of atomic force microscopy (AFM)[1] has opened new fields of investigation, because AFM can operate in aqueous solution under physiological conditions of ionic strength, pressure, and temperature (for a review, see ref 1) and thereby reveal submolecular details not resolved by electron microscopy (*2*). Moreover, the AFM tip can be converted into a specific biosensor by stable attachment of a bioligand which has the ability to specifically bind to a complementary molecule on the biological specimen which is scanned by this functionalized AFM tip. The bioligand can itself be a biomolecule (antibody, hormone, single- or double-strand nucleic acid, etc.) or a synthetic molecule or whatever structure that is being recognized by a complementary molecule on the surface of the biological sample to be studied. In single molecule recognition force microscopy (SMRFM), specific binding of the ligand on the tip to a single immobile target molecule is followed by specific unbinding when the tip moves on (*3*, *4*), and the unbinding occurs with a defined force that is highly dependent on the biochemical state of the interacting molecules; thus, unique mechanistic details can be revealed by single molecule force spectroscopy (*5*).

Linear PEG chains have frequently been used to attach one or a few sensor molecules to an AFM tip, because the PEG itself is chemically and physically inert and it allows for rapid and free reorientation of the sensor molecule when the AFM tip approaches the surface (*6*−*15*). Thus, even a single sensor molecule on the tip can recognize its cognate molecule on the target surface with up to 25% probability in one force−distance cycle with 50−200 nm amplitude and 1 s cycle time (*16*). Furthermore, the 6−8 nm long PEG linker between the tip and the probe molecule facilitates data analysis in SMRFM, because the nonlinear elasticity of PEG allows for easy discrimination

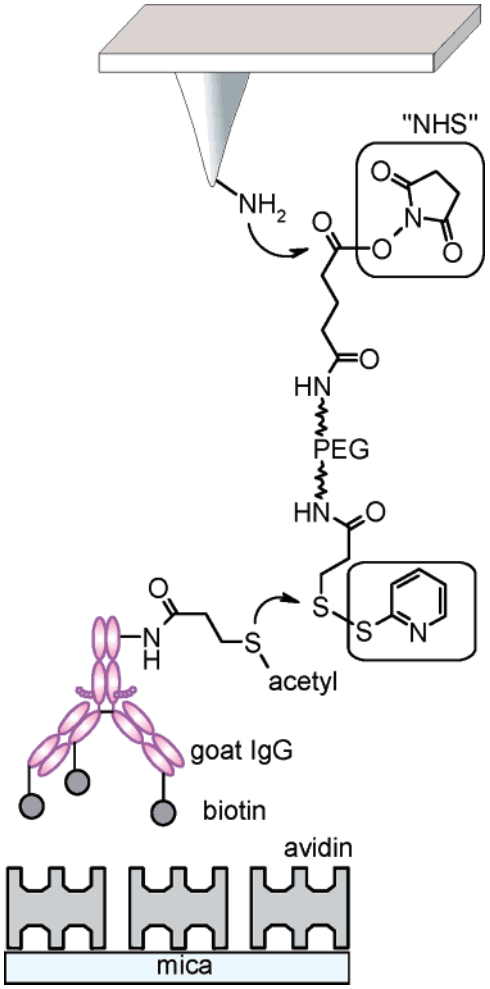

Figure 1. Schematic representation of the testing system for tip−antibody linking via disulfide bond formation. In the first step, the crosslinker PDP-PEG-NHS reacts with an amino group on the tip, with concomitant loss of the NHS leaving group. Hydroxylamine-induced de-acetylation of the SATP group on the antibody exposes a free SH group which reacts with the 2-pyridyldithio group on the free crosslinker end. When brought into contact with avidin-covered mica, the biotin residues on the model antibody showed reversible binding to, and unbinding from, immobilized avidin.

of specific unbinding events which are preceded by nonlinear PEG stretching from nonspecific tip adhesion (*16*−*18*). Moreover, 6−8 nm long PEG linkers are indispensable for a new method in which surface topography and a map of recognition sites are simultaneously acquired in one fast surface scan (*19*−*21*). Finally, the PEG-linked sensor molecule appears to regularly escape the danger of being crushed between tip and sample surface in each force−distance cycle, as is deduced from preservation of single sensor molecules over many thousands of cycles.

Our standard method of tip functionalization (*9*, *10*) involves three steps (see Figure 1): (i) generation of NH_2 groups on the silicon nitride tip, (ii) attachment of a heterobifunctional PEG linker with one end by amide bond formation, and (iii) linking of a sulfhydryl-containing sensor molecule to the outer end of the PEG tentacle on the tip by disulfide bond formation. The first two steps have been analyzed and optimized in a recent model study (*16*) in which the third step had been eliminated by using a PEG linker already carrying a bioligand (*d*-biotin) on its outer end. With respect to the first step, gas-phase aminosilanization with APTES or silanol group esterification with ethanolamine hydrochloride proved to be equally suitable to create a sufficient number of grafting sites for attachment of up to $2 \times 10^3\ \mu m^{-2}$ PEG-biotin tentacles on silicon nitride chips, as estimated from specific binding of ExtrAvidin−peroxidase with colorimetric peroxidase quantitation, using OPD and hydrogen peroxide as chromogenic substrates. When using the same functionalization conditions for AFM tips, the tip-bound PEG-biotin tentacles exhibited a binding probability of 10−20% to a dense monolayer of avidin on mica, i.e., about 10−20% of the force distance cycles showed a specific unbinding event, and specificity was proven by block with *d*-biotin.

In the present study, the third step of tip functionalization (attachment of an antibody molecule to the outer end of a tip-bound PEG linker) has been investigated in detail, using biotinylated goat IgG as a model antibody (see Figure 1). Besides biotin residues, the IgG molecule needed to carry protected thiols (*S*-acetylated thiopropionyl residues). These were deprotected in situ with hydroxylamine to allow for disulfide bond formation with the pyridine-S-S group on the outer end of PEG on the AFM tip (see Figure 1). The interaction of tip-tethered biotin-IgG with mica-bound avidin was studied with SMRFM, and the specificity of interaction was demonstrated by specific block with *d*-biotin. In parallel, silicon nitride chips were functionalized in the same sequence, and chip-tethered biotin-IgG was measured by specific binding of ExtrAvidin−peroxidase which was quantified by enzymatic color production from chromogenic substrates. In addition, the kinetics of disulfide bond formation between a thiolated protein and a PDP-PEG linker in bulk solution was monitored spectrophotometrically, and valuable clues on the mechanism of protein coupling to tip-bound PEG tentacles were obtained.

EXPERIMENTAL PROCEDURES

Materials. Analytical-grade materials were used as long as they were commercially available. The starting materials were of highest available purity. NH_2-PEG-COOH and PDP-PEG-NHS were synthesized as described (*22*), using multistep extraction for purification of PDP-PEG-COOH (see Supporting Information). Muscovite mica sheets were supplied by Christine Gröpl Elektronenmikroskopie (Tulln, Austria). Si_3N_4 measuring tips were bought from Veeco Instruments (Dourdan, France) and Si_3N_4 chips from Wacker-Chemitronic GmbH (Germany). Pyr-S-S-PEG-NHS was purchased from Polypure (Oslo, Norway).

Protein Modifications. Biotin-IgG and biotin-IgG-SATP were prepared by reacting goat IgG (10 mg/mL in buffer D) with a 10-fold excess of biotin-cap-NHS (from a 66 mM stock solution in DMSO), lowering the pH to 7.5, and adding a 10-fold excess of SATP (from a 66 mM stock solution in DMSO), followed by removal of unbound reagent by gel filtration in buffer A (100 mM NaCl, 50 mM NaH_2PO_4, 1 mM EDTA, pH 7.5 adjusted with NaOH), as described in the Supporting Information.

Functionalization of AFM Tips with PEG Linkers and Antibodies. AFM tips (Si_3N_4) were amino-functionalized as described before, using the room-temperature method for reaction with ethanolamine hydrochloride (*16*). Attachment of the PEG linkers (Pyr-S-S-PEG-NHS or PDP-PEG-NHS; see Figures 1 and 2) was accomplished by incubating the tip for 2 h with 1 mg/mL (or 10 mg/mL, as indicated) of PEG linker in chloroform containing 0.5% (v/v) of triethylamine. After rinsing with chloroform, the tip was stored in a desiccator for less than 5 days. For coupling of antibody, 40 μL of biotin-IgG-SATP (2.2 mg/mL) was mixed with 380 μL of buffer A and 80 μL of 500 mM hydroxylamine reagent (500 mM hydroxylamine hydrochloride, 25 mM EDTA, titrated to pH 7.5 with Na_2CO_3) (*9*). Tips with PEG linkers were immersed in this solution for 1 h, washed in buffer A (2×) and PBS (2×) and stored in PBS at 4 °C until used (up to 3 days). Detailed descriptions of all steps can be found in the Supporting Information.

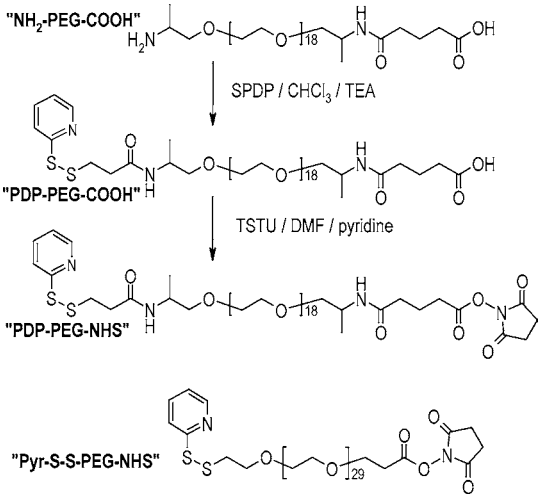

Figure 2. Synthesis of PDP-PEG-NHS from NH_2-PEG-COOH and structural comparison with the commercial crosslinker Pyr-S-S-PEG-NHS.

Monitoring of Single Unbinding Events between Tip-Bound Biotin-IgG and Mica-Bound Avidin by Force Spectroscopy. Avidin (1 mg/mL in PBS, 150 mM NaCl, 5 mM NaH_2PO_4, pH 7.4 adjusted with NaOH) was diluted with 9 volumes of water and adsorbed to freshly cleaved mica. After 15 min, the substrate was rinsed with a 1/9 mixture of PBS and water and imaged in PBS. Force measurements with biotin-IgG-functionalized AFM tips were performed in the fluid cell of a commercial AFM (Pico-SPM, Molecular Imaging, Phoenix, AZ) using a Nanoscope IIIA controller (Digital Instruments, Santa Barbara, CA). Force−distance cycles (conventional force calibration mode) were recorded at a 1 Hz vertical scan rate and 300 nm *z*-range. The measurements were done in PBS at a constant trace and retrace velocity of 100 nm/s. The spring constants of the levers were determined by the thermal noise method (*23*, *24*). Further details can be found in the Supporting Information.

Functionalization of Silicon Nitride Chips with Amines, PEG Linkers, and Biotin-IgG-SATP, and Quantitative Assay for Chip-Bound Biotin-IgG-SATP. Silicon nitride chips were precut, weighed for calculation of the effective surface area, precleaned, and amino-functionalized in a DMSO solution of ethanolamine hydrochloride (16 h), using the room-temperature method (*16*). After washing in DMSO (3×) and ethanol (3×), the chips were dried with nitrogen and derivatized with Pyr-S-S-PEG-NHS or PDP-PEG-NHS exactly as described above for AFM tips. After binding of the PEG linkers, the chips were washed in chloroform (3×), dried with nitrogen, and placed in a plastic petri dish. Biotin-IgG-SATP (2.2 mg/mL) or biotin-IgG (3.2 mg/mL) was mixed with buffer A and 500 μL hydroxylamine reagent to adjust final concentrations of 0.5 mg/mL for IgG and 50 mM for hydroxylamine, and 50 μL of this solution was pipetted onto the surface of each chip. The petri dishes were covered with a lid and incubated for 60 min. The chips were removed and washed in buffer A (3 × 10 min) and PBS (3 × 10 min).

For quantification of chip-bound biotin-IgG-SATP or biotin-IgG, most of the buffer was removed from the chips and they were placed on Teflon plates (prewashed with ethanol and dried well) which were lying in disposable petri dishes. Unblocked EAP reagent (50 μL, prepared by dilution of commercial EAP solution, Sigma/Austria, with 19 volumes of PBS containing 0.5% Tween 20) was placed on each chip and incubated in the closed chamber for 60 min. In parallel controls, 50 μL portions of blocked EAP reagent were used which contained 1 mM of biotin in addition. The chips were removed and washed in PBS containing 0.5% Tween 20 (3 × 10 min) and PBS (3 × 10 min). For measurement of chip-bound ExtrAvidin−peroxidase, 3 mL of citrate buffer (50 mM citric acid, pH adjusted to 5.5) containing OPD (0.8 mg/mL) was mixed with 30 μL of 3% H_2O_2 and stirred in a photometer cuvette. The chip was immersed in the cuvette for 1 min and then stored in the same buffer while reading A_{490}. In the case of small absorbance values, the chip was reimmersed in the cuvette for a longer time period. The amount of enzyme on the chip was calculated by comparison with calibration series in which known amounts of soluble enzyme were added to the chromogenic mixture and color production was also monitored over defined time intervals. A detailed description can be found in the Supporting Information.

RESULTS AND DISCUSSION

Syntheses of PDP-PEG-NHS, SPDP, and Biotin-cap-NHS. The synthesis of PDP-PEG-NHS followed our standard scheme (Figure 2), i.e., the general precursor NH_2-PEG-COOH was first acylated with SPDP, yielding the intermediate PDP-PEG-COOH, the carboxyl function of which was activated as NHS ester to give PDP-PEG-NHS (*22*). The published procedure has often been reproduced with good success, but in some batches, complete removal of unreacted and/or hydrolyzed SPDP from the intermediate PDP-PEG-COOH has been a problem. Now, this problem has been eliminated by a multistep extraction procedure, as described in the Supporting Information. In addition, the published procedures for synthesis of SPDP have been optimized for reliability and convenience, and the same applies to the synthesis of biotin-cap-NHS (see Supporting Information).

Since PDP-PEG-NHS is not commercially available, a comparable commercial linker (Pyr-S-S-PEG-NHS, purchased from Polypure, Oslo, Norway; see Figure 2) was tested in the same way as PDP-PEG-NHS. As shown in the Supporting Information (Figure 14S), it gave very similar results and thus appears well-suited for AFM tip functionalization by the scheme shown in Figure 1.

Recognition Force Microscopy with AFM Tip-Bound Biotin-IgG and Mica-Bound Avidin. In a preceding model study on AFM tip functionalization (*16*), the amino-functionalized tips were reacted with the NHS ester function of biotin-PEG-NHS, resulting in tip-bound PEG tentacles which already carried a specific bioligand (biotin) on their outer ends. The ligand function of tip-bound biotin residues was particularly easy to study by SMRFM, because the complementary acceptor protein (avidin) can easily be immobilized on mica by electrostatic adsorption (*16*), as exemplified in Figure 3. Due to the high density of avidin on the surface, the probability for specific recognition of tip-tethered biotin by an immobilized avidin molecule in a single approach-and-retraction cycle was found to be ≤20% (*16*). It is important to take into account the published correction note of reference (*16*), according to which a very low salt concentration (e.g., 15 mM NaCl as used here) is required for rapid adsorption of positively charged avidin (isoelectric pH ∼10; see ref 25) to the negatively charged mica surface (*26*), in contrast to lysozyme (isoelectric pH ∼11.2; see ref 27) which quickly adsorbs to mica in PBS (*11*). Once the avidin monolayer is formed, however, it can be exposed to PBS (150 mM NaCl) without dissociation of avidin (*16*).

In the present study, the previous model system was modified to study the tethering of antibodies, rather than biotin residues, to AFM tips via long, flexible PEG linkers. We adhered to our standard coupling scheme for antibody coupling (*9*) but used biotinylated IgG in place of some specific antibody (see Figure 1). As a consequence, we could take advantage of the well-known rupture force of the avidin−biotin bond and of specific block with minute concentrations of *d*-biotin (*16*, *28*, *29*).

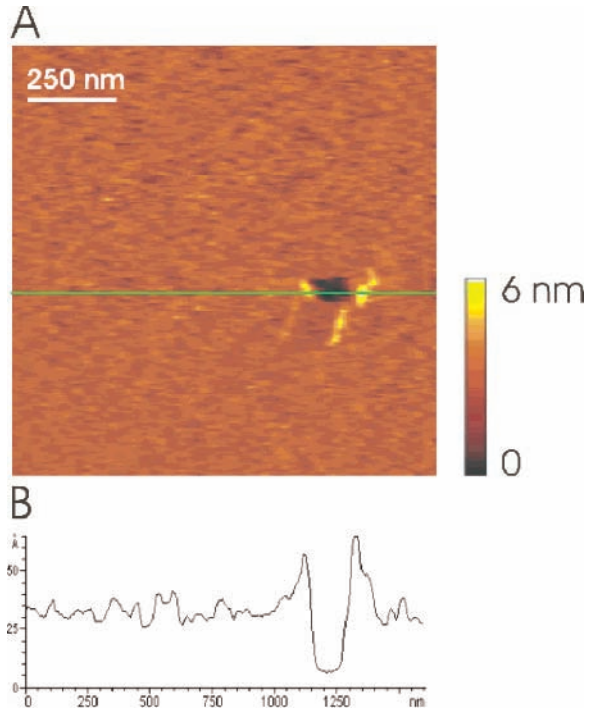

Figure 3. Topographical image of a dense avidin monolayer on mica support, formed by incubation (15 min) of freshly cleaved mica in 15 mM NaCl containing 0.1 mg/mL of avidin. Before the image in panel A was taken (at a force of 200 pN), a small rectangular area (100 nm × 100 nm) was scraped free of avidin with high force (10 nN) in order to expose bare mica. The straight line in panel A indicates the location of the cross section shown in panel B. The height of the avidin monolayer was observed to be 3−4 nm.

Consequently, IgG was statistically labeled with both biotin and SATP, resulting in at least 5 biotin and at least 5 protected thiol groups per IgG (see Supporting Information). The acetyl protecting groups on the latter were removed with hydroxylamine, liberating free thiols which reacted with the 2-pyridyl-S-S group on the tip-bound PEG linker (see Figure 1) to form a stable disulfide bond, with concomitant loss of 2-mercaptopyridine ("leaving group").

Tips with such PEG-linked biotin-IgG were tested for function by repeated approach to, and retraction from, mica densely covered with a monolayer of avidin (see Figure 3), measuring the repulsive and attractive forces by SMRFM. Typical results are shown in Figure 4. The vertical distance between tip and support is plotted on the *X*-axis and cantilever deflection on the *Y*-axis. Before plotting, the deflection amplitudes had been converted into force values after having measured the spring constant of the cantilever (see legend to Figure 4). Panel A shows a force−distance cycle with a specific unbinding event. The gray, dotted trace was measured during cantilever approach. Upon contact (at distance = 0 nm), the cantilever starts to bend upward. The constant slope shows that the cantilever obeys Hook's law, and the same is true for retraction to the point of zero force (solid, black trace) which again occurs at a vertical distance of 0 nm. Upon further retraction, however, the cantilever is bent downward until the force acting on the cantilever has reached −55 pN. At this point, the connection between the tip and the mica substrate suddenly breaks and the cantilever jumps back to the resting position, where it remains during further retraction.

The vertical jump from −55 pN to zero force can be attributed to the sudden unbinding of one biotin residue (of tip-bound biotin-IgG) from mica-bound avidin, for the following reasons: (i) Under identical conditions, the same unbinding force had previously been measured for tip-bound biotin and immobilized avidin, or vice versa (*16*, *28*). (ii) The nonlinear bending of the cantilever before the unbinding event is known to reflect the nonlinear elasticity of the PEG tether (*18*). (iii) The probability of observing such an unbinding event in one force−distance cycle was reduced from 44% in the absence of biotin to 3.0% in the presence of *d*-biotin, resulting in mostly "event-free" force−distance cycles, as shown in panel C. (iv) In the absence of *d*-biotin, the unbinding force distribution showed a maximum at 59 pN (solid line in panel D), which is the typical value expected for the avidin−biotin bond at the applied loading rate (*16*, *28*). In the presence of biotin, however, no such prominent peak was observed in the force distribution profile. (v) Specific unbinding events (as in panel A) were easily differentiated from direct tip−substrate adhesion (shown in panel B). While specific unbinding was preceded by the nonlinear stretching of PEG (solid line in panel A), the cantilever showed only linear deflection before rupture of direct adhesion (black

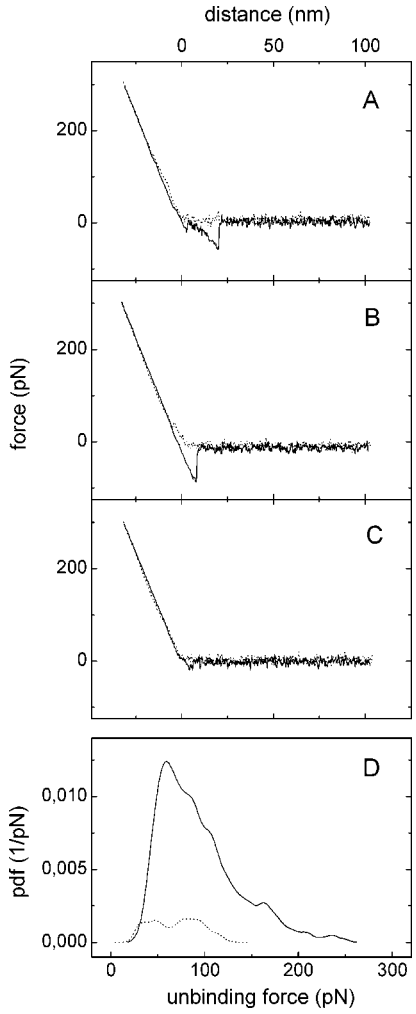

Figure 4. Force measurements of single avidin−biotin interactions. The tip was functionalized with PDP-PEG_{800}-NHS and with biotin-IgG-SATP, and avidin was irreversibly adsorbed to mica, as depicted in Figure 1. The piezo movement in the approach-and-retraction cycles was ±300 nm in 1 s and the force constant of the cantilever was 17 pN/nm, thus the loading rate was 10.2 nN/s. (A) Example of a force−distance cycle showing specific avidin−biotin unbinding in the absence of *d*-biotin. Unbinding occurred at a rupture force of 56 pN. (B) Example of a force−distance cycle in which the tip was directly stuck to the mica substrate by electrostatic adhesion. (C) Example of a force−distance cycle performed in the presence of free *d*-biotin (0.1 mg/mL). (D) Probability density function (pdf) of the unbinding forces observed in 435 out of 980 force−distance cycles (solid line). In the presence of free *d*-biotin (dotted line), only 29 out of 980 force−distance cycles appeared to reflect specific unbinding.

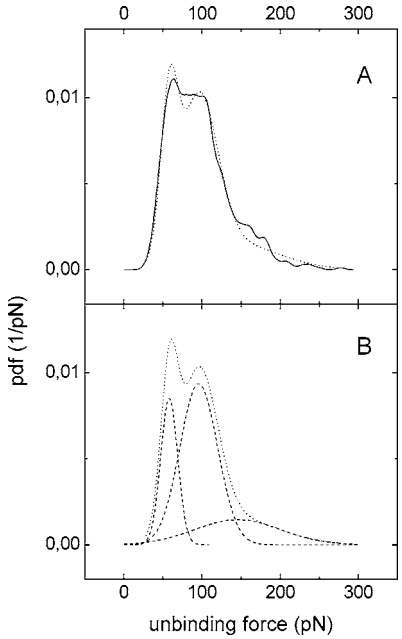

Figure 5. Multicomponent analysis of the unbinding force distribution obtained with the identical tip as used in Figure 4. (A) The solid curve is the unbinding force distribution from 643 recognition events obtained with the same tip as used in Figure 4D but in another location on the avidin-covered mica. The dotted line is a fit as explained in B. (B) The experimental profile (i.e., the solid line in (A)) was fitted by the sum of three Gaussian peaks with the force maxima 58 pN, 96 pN, and 150 pN (dashed lines). For an easier comparison between experiment (A) and mathematical fit (B), the sum of the three Gaussian components (dotted line) is shown both in (B) and in (A).

solid line in panel B), with the same slope as observed in the contact region of the gray dotted line panel B.

The AFM tip used in Figure 4 was moved to another spot of the avidin-covered mica, and another 999 force−distance cylces were acquired. The force distribution of the 208 unbinding events seen on site no. 2 (not shown) was added to the force distribution of the 435 unbinding events seen on site no. 1, which is shown in Figure 4 (panel D, solid line). The sum of the two force distributions is depicted in Figure 5 (panel A, solid line). It could well be fitted to the sum (dotted line in panel A and B) of three individual Gaussian peaks (dashed curves in panel B). The three Gaussian curves were found to peak at 58 pN, 96 pN, and 150 pN. The large width of the third curve is likely to result from implicit inclusion of a fourth curve with an even higher force maximum in the actual data. The amplitude of this putative component, however, was too small for explicit fitting. Since the 58 pN value is known to be the typical unbinding force of a single biotin residue from avidin, the peak maxima at 96 and 150 pN probably reflect the simultaneous unbinding of two or three biotin residues, respectively, from immobilized avidin molecules. The two or three biotin residues may have been located on a single tip-bound IgG or on two different tip-bound biotin-IgG molecules, albeit the latter situation seems less likely to cause such simultaneous unbinding events with twice or thrice the unbinding force of one avidin−biotin bond. In any case, Figure 5 can be taken as additional confirmation for successful tip−PEG-IgG linking by the scheme in Figure 1 and for proper function of the functionalized tip.

Imitation of AFM Tip Functionalization by Analogous Functionalization of Silicon Nitride Chips for Semiquantitative Analysis of Efficiency. In our preceding model study on the linking of biotin-PEG-NHS to amino-functionalized AFM tips (*16*), the AFM data were complemented with parallel macroscopic experiments in which silicon nitride chips (same material as the tips) were amino-functionalized and reacted with biotin-PEG-NHS. The chip-bound biotin-PEG residues were then quantified with the help of a conjugate between avidin and a marker enzyme (ExtrAvidin−peroxidase), similar as in other solid phase assays such as ELISA. By analogy, we have now reacted amino-functionalized silicon nitride chips with PDP-PEG-NHS and subsequently coupled biotin-IgG-SATP via disulfide bond formation, thereby also simulating AFM tip functionalization (see Figure 1) on a macroscopic scale (see Figure 15S in the Supporting Information for a schematic illustration of these steps, as well as of the quantification of bound biotin-IgG).

The covalently bound probe molecules (biotinylated IgG) were again labeled with ExtrAvidin−peroxidase, the amount of which was estimated from its enzymatic activity, i.e., from the rate of color production in a solution containing OPD and H_2O_2 when the chip was immersed in a stirred solution (3 mL) for a defined time interval (1 min, or several minutes if the response was low). The measured absorbance increase (A_{490}) per minute was compared to the absorbance increase measured with a known number of ExtrAvidin−peroxidase molecules in the total assay volume in order to calculate the number of enzymes bound on the chip (expressed as sites/μm^2; see Table 1).

Admittedly, ExtrAvidin−peroxidase is not a stoichiometric conjugate of one avidin and one enzyme molecule; therefore, the supplier's specifications were used to estimate the number of aggregates, both in the calibration series with ExtrAvidin−peroxidase in bulk solution and in the samples with chip-bound ExtrAvidin−peroxidase. Due to the high number of biotin-binding sites per aggregate, one aggregate can bind many PEG-linked biotin residues within reach; thus, the number of bound avidin−enzyme conjugates is expected to level off at higher numbers of binding sites per μm^2.

Nonspecific adsorption of ExtrAvidin−peroxidase was measured in the presence of *d*-biotin and subtracted from the total amount of ExtrAvidin−peroxidase bound in the absence of *d*-biotin to calculate the extent of specific binding (see Table 1). Moreover, 0.5% of Tween-20 was used to minimize the extent of nonspecific binding of ExtrAvidin−peroxidase.

As can be seen from Table 1, both the commercial linker Pyr-S-S-PEG-NHS and our standard linker PDP-PEG-NHS gave similar densities of specific binding sites for ExtrAvidin−peroxidase. Moreover, the concentration of PEG linker had little influence on the number of linkers bound to the amino-functionalized surface. The last two lines represent a separate data set with a new batch of amino-functionalized chips in which a critical control was included to prove that binding of biotin-IgG-SATP was indeed accomplished by disulfide bond formation (as indicated in Figure 1), rather than by some unknown mechanism. For this purpose, biotin-IgG was used in place of biotin-IgG-SATP, i.e., without the protected thiol (3-[acetylthio]-propionyl) functions shown in Figure 1. As can be seen from the last two lines of Table 1, the binding of biotin-IgG was indeed crucially dependent on the presence of SATP residues on IgG, since biotin-IgG-SATP was bound at a high density, whereas no detectable amount of simple biotin-IgG was bound on chips from the same batch of amino-functionalization.

In conclusion, the marker enzyme assay previously used to "count" the number of biotin-PEG tentacles on amino-functionalized silicon nitride chips also proved useful for examination of covalent binding of a thiolated protein to chips with covalently bound pyridine-S-S-PEG tentacles on a semiquantitative scale. Specific binding to biotin residues was easily discriminated from nonspecific binding, the extent of which was low anyway, and coupling was fully dependent on a free thiol; thus, the protein was indeed bound by the coupling scheme shown in Figure 1 and not via some unknown mechanism.

Table 1. Tethering of Antibodies to Silicon Nitride Chips via PEG Linkers[a]

linker type	[linker] (mg/mL)	antibody	total sites (μm^{-2})	nonspecific sites (μm^{-2})	specific sites (μm^{-2})
Pyr-S-S-PEG-NHS	10	biotin-IgG-SATP	2800 ± 100	90	2700 ± 200
	1	biotin-IgG-SATP	2800 ± 100	110	2700 ± 200
PDP-PEG-NHS	10	biotin-IgG-SATP	2900 ± 100	110	2800 ± 200
	1	biotin-IgG-SATP	1900 ± 100	170	1700 ± 200
PDP-PEG-NHS	1	biotin-IgG-SATP	2100 ± 300	130	2000 ± 400
	1	biotin-IgG	130 ± 40	120	0 ± 100

[a] The chip surface was amino-functionalized with ethanolamine hydrochloride and reacted with the NHS-ester function of the PEG linker molecule (see Figure 1). For coupling of protein, the chips were incubated in aqueous solutions of biotin−IgG−SATP or biotin−IgG and washed. The number of biotinylated IgG molecules per μm^2 surface was estimated from the amount of bound ExtrAvidin−peroxidase and measured in the absence (total sites) or presence (nonspecific sites) of free *d*-biotin.

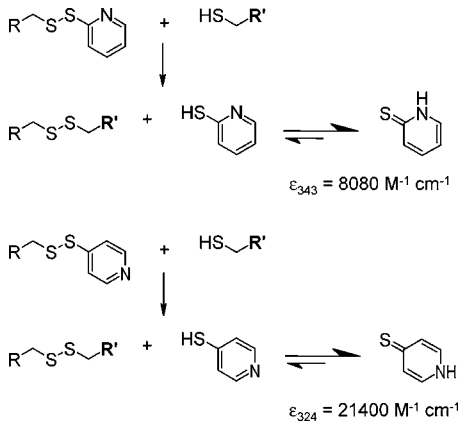

Figure 6. Reaction of 2-pyridyldithio or 4-pyridyldithio groups with aliphatic thiols, yielding stable disulfides and 2- or 4-mercaptopyridine which are quickly converted into 2- or 4-thiopyridone, respectively, by tautomerism. The latter have intense UV absorption bands in the near UV region (343 and 324 nm, respectively).

Hypothesis on Protein Preadsorption as the Main Accelerator of Protein Coupling to AFM Tips. Having demonstrated that protein coupling to silicon nitride surfaces with 2-pyridyl-S-S-PEG tentacles is indeed via disulfide bond formation (see previous paragraphs and Table 1), it was of interest to compare the observed disulfide coupling on surfaces with the rate of disulfide bond formation between a thiol component and a second component which carried 2-pyridyl-S-S groups (*30*). As shown in Figure 6, this reaction can easily be followed spectrophotometrically because it is accompanied by release of 2-mercaptopyridine, which quickly tautomerizes into 2-thiopyridone which has an absorption maximum at 343 nm (molar extinction coefficient $\epsilon_{343} = 8080\ M^{-1}\ cm^{-1}$) (*31*). By analogy, 4-pyridyldithio groups release 4-thiopyridone, which has an absorption maximum at 324 nm ($\epsilon_{324} = 21\,400\ M^{-1}\ cm^{-1}$) (*32*).

For monitoring of disulfide bond formation in bulk solution, a quartz cuvette with 1 cm light path was filled with buffer A (pH 7.5, same as used for disulfide coupling to AFM tips and silicon nitride chips) containing an excess of a pyridyldithio component (e.g., 80 μM), and this solution was continuously stirred. Disulfide bond formation was started by sudden addition of a small quantity of thiol component (e.g., at 20 μM final concentration), and the time course of 2- or 4-thiopyridone release was monitored by the change in A_{343} or A_{324}, respectively, as exemplified in the Supporting Information (Figure 8S). Table 2 lists the pairs of thiol components (third column) and pyridyldithio components (second column) for which the reaction rate was determined in the way described above. The data were analyzed as described in the Supporting Information, in order to estimate the bimolecular kinetic constant k_2 for each of these pairs.

For easier understanding of the results, the k_2 values were used to predict half-time values ($t_{1/2}^{calc}$, last two columns of Table 2) of the apparent monoexponential time course of pyridyldithio component turnover if it is reacted with a large excess of thiol component. In one model situation, the concentration of the thiol excess component is assumed to be 1 mM (next-to-last column in Table 2); in the other model situation, the thiol concentration is assumed to be 1 μM (last column in Table 2).

The first three lines of Table 2 show that the reaction rate is only weakly influenced if 2-mercaptoethanol is replaced by a BSA carrying 3-mercaptopropionyl residues. However, comparison with line 11 shows that the reaction is dramatically slowed down if the 2-pyridyl-S-S group is also linked to BSA via the short propionyl spacer. In the first three lines of Table 2, charge effects are absent since the pyridyldithio component is uncharged at the pH of the reaction (7.5). In contrast, the reaction of cationic 2-(2-pyridyldithio)-ethylamine (line 4) with anionic BSA-SH is accelerated by electrostatic attraction. By the same rationale, the reaction is decelerated by electrostatic repulsion between anionic pyridyldithiopropionate (2- and 4-isomer, lines 5 and 6) and the negatively charged protein.

Line 7 describes the reaction of BSA-SH with 2-pyridyl-S-S-PEG_{800}-COO^-. It is of particular interest since the latter is almost identical with PDP-PEG-NHS, which we have used to link thiolated protein to AFM tips (see Figures 1 and 2). As can be seen from a comparison of line 5 with line 7, the PEG_{800} linker did not slow down the reaction with a thiolated protein. Rather, the reaction was even accelerated by a factor of 2, which is attributed to elimination of electric repulsion by the long PEG_{800} spacer (line 7). The same effect of PEG chain length is seen in the corresponding set of with 4-pyridyldithio groups (lines 6 and 8), taking into account the usual observation that 4-pyridylditho groups are somewhat more reactive (*33*).

Most interesting for the purpose of this study is the comparison between line 7 and line 9 (or line 8 and line 10 for the corresponding 4-isomers). In line 7, the 2-pyridyl-S-S group sits on one end of a PEG_{800} chain, the other end of which is free to diffuse in solution; whereas in line 9, the other end of the PEG chain (1 kDa) is anchored on the relatively large BSA molecule (65 kDa). This difference caused a deceleration by a factor of <10, and the same was observed with the 4-isomers (lines 8 and 10). It is therefore justified to assume that a similar reaction rate should hold for disulfide bond formation between a thiolated protein (which is in excess) and a single 2-pyridyl-S-S-PEG_{800} tentacle that is anchored on the apex of an AFM tip. In this situation, the predicted monoexponential time course no longer means actual turnover but instead the probability that the single 2-pyridyl-S-S-PEG reacts with a thiolated protein. In this study, we applied 0.2 mg/mL of biotin-IgG-SATP for disulfide bond formation with the AFM tip which corresponds to a molar concentration of 1.4 μM. Taking into account the slower diffusion of biotin-IgG-SATP (150 kDa), we can assume the *calculated* half-time to be similar to that given in line 9 for 1 μM of BSA-SH ($t_{1/2}^{calc} = 5$ days). In reality, however, disulfide coupling has proven quite successful in the time

Table 2. Kinetics of Disulfide Bond Formation between PDP Groups and Free Sulfhydryls Attached to Various Kinds of Molecules[a]

line	pyridyldithio component (minute concentration)	thiol component (in excess, 1 mM or 1 mM)	$t_{1/2}^{calc}$ at excess of 1 mM	$t_{1/2}^{calc}$ at excess of 1 μM
1	2-pyridyl-S-S-CH_2-CH_2-OH	HO-CH_2-CH_2-SH	0.3 min	5 h
2	4-pyridyl-S-S-CH_2-CH_2-OH	HO-CH_2-CH_2-SH	0.1 min	2 h
3	2-pyridyl-S-S-CH_2-CH_2-OH	BSA-SH	0.7 min	11 h
4	2-pyridyl-S-S-CH_2-CH_2-NH_3^+	BSA-SH	0.07 min	1 h

12	2-pyridyl-S-S-propionyl-NH-BSA	G-SH	4 min	3 d

[a] After mixing of the components, the rate of disulfide bond formation was monitored in a UV−vis spectrophotometer via release of 2-thiopyridone (at 343 nm, $\epsilon_{343} = 8080\ M^{-1}\ cm^{-1}$) (*28*) or 4-thiopyridone (at 324 nm, $\epsilon_{324} = 21400\ M^{-1}\ cm^{-1}$) (*32*), and the kinetic parameters were calculated, as described in the Supporting Information.

window of 1 h, both on the AFM tip (see Figure 4) and on silicon nitride chips (see Table 1), even at 0.2 μM IgG (30 μg/mL) (*7*, *9*−*11*, *14*, *15*). On the basis of the kinetic data from bulk solution (see Table 2), the half-time for coupling of 0.2 μM IgG to a 2-pyridyl-S-S-PEG tentacle on the AFM tip should be 1 month, not to speak of the five half-times needed to reach 97% probability for coupling.

The big discrepancy between the slow disulfide coupling in bulk solution when working at 1 μM thiolated protein (Table 2) and efficient coupling to AFM tips and silicon nitride chips (Table 1) within 1 h allows for two alternate explanations: The uneasy hypothesis would mean that our actual success of biotin-IgG-SATP coupling to AFM tips and silicon nitride chips were not via disulfide coupling but by some other mechanism. The more favorable explanation means that some additional mechanism is in operation which greatly accelerates coupling of thiolated proteins to 2-pyridyl-S-S-PEG tentacles on AFM tips.

Fortunately, the first hypothesis can be dismissed on the following grounds: (i) The last two lines of Table 1 demonstrate without any doubt that the coupling to chip-bound 2-pyridyl-S-S-PEG tentacles is solely via disulfide bond formation, since only biotin-IgG-SATP but not simple biotin-IgG was covalently bound. (ii) All specific unbinding events (as in Figure 4A) were preceded by the typical nonlinear stretching behavior of the PEG linker (*18*); thus, the ligand molecule (biotin-IgG) necessarily must have been bound to the outer end of the PEG linker. (iii) Before coupling of protein, the outer end of the PEG had been a 2-pyridyl-S-S group, which is known for its exceptionally high selectivity for thiol over amino groups (*34*) (also exemplified by very slow reaction with 10 mM ethanolamine, even at pH 8.6 and 37 °C; see Figure 1B in ref 35). (iv) The number of lysine residues per IgG (∼80 to 90) (*36*) is only 1 order of magnitude higher than the number of deprotected SATP groups per IgG (>5; see Supporting Information) which is by far too little to override the much higher reactivity of deprotected SATP groups for 2-pyridyl-S-S functions.

From the previous paragraph, it is concluded that incubation of tips or chips with 2-pyridyl-S-S-PEG tentacles with micromolar concentrations of biotin-IgG-SATP actually results in disulfide coupling as depicted in Figure 1 (and Figure 15S in the Supporting Information). Consequently, the unexpectedly high rate of coupling to surface-bound 2-pyridyl-S-S-PEG tentacles at micromolar protein concentrations must be caused by some catalytic effect which accelerates coupling by about 3 orders of magnitude in comparison to bulk solution kinetics. As explained in the following, preadsorption of protein to the tip/chip surface must be assumed as the only plausible effect which appears to enrich the effective protein concentration from micromolar in bulk solution to millimolar at the site of action, i.e., next to a tip/chip-bound PEG linker.

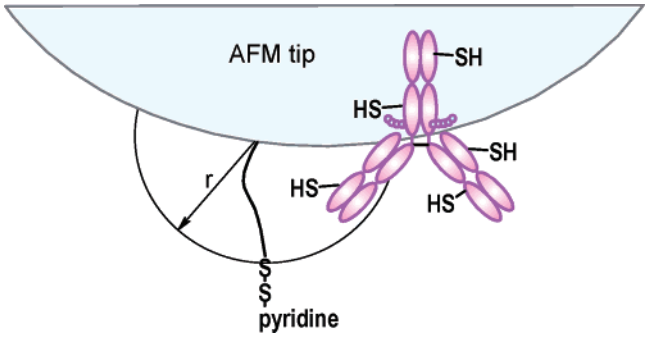

Figure 7. Model for acceleration of antibody linking to tip-bound PDP-PEG tentacles, due to preadsorption of protein next to the PEG linker. The free end of a 6 nm long, surface-bound PEG linker can reach all locations in a hemisphere with $r = 6$ nm. One particle per hemisphere (450 nm^3) corresponds to a formal concentration of 3 mM. Tip radius, antibody dimensions, and PEG length were drawn roughly to scale.

As depicted in Figure 7, the 2-pyridyl-S-S group on the outer end of a tip-bound PEG_{800} chain can reach every point in a hemisphere with the radius $r \approx 6$ nm (*16*−*18*). The volume of this hemisphere is ∼450 nm^3; consequently, the concentration of a single 2-pyridyl-S-S group per hemisphere corresponds to a formal concentration of ∼3 mM. The next question concerns the effective concentration of protein within the hemisphere. As long as proteins only transiently collide with the surface and continue to diffuse, the concentration of protein will be similar to that in bulk solution, i.e., micromolar. However, the surface of the tip used in SMRFM usually consists of superficially oxidized silicon nitride (or silicon), which is known to get largely covered with protein when in contact with a protein solution, with desorption being induced only upon washing with protein-free buffer (*27*, *37*, *38*). In addition, amino-functionalization causes coverage of the tip surface with organic material (detected by AFM imaging) (*16*), which is known for enhanced protein adsorption (*39*). Moreover, amino-functionalization induces some cationic charges which are known to further promote protein adsorption (*39*). In conclusion, it is safe to assume that the amino-functionalized AFM tip will get largely covered with protein when immersed in buffer with micromolar protein concentrations. Consequently, at least one IgG molecule should be adsorbed near each individual PEG linker on the tip (see Figure 7), and the effective protein thiol concentration next to the PEG linker should be at least 1 mM, taking into account the number of at least 5 SATP residues per IgG (see Supporting Information) which compensates for the large dimensions of the IgG molecule.

With an effective protein thiol concentration of >1 mM within reach of each tip-bound PEG chain having been estimated, Table 2 can again be consulted for prediction of the

time course of disulfide coupling between the protein thiol and the 2-pyridyl-S-S-PEG on the tip. As argued before, line 9 describes that situation in bulk solution which is closest to the situation on the AFM tip (Figure 7). For >1 mM thiol component, a half-time of <7 min can be assumed for protein coupling to the AFM tip. This finally explains why the majority of AFM tips actually gets functionalized within 1 h with at least one IgG molecule per tip when using the coupling scheme shown in Figure 1, even when the bulk solution contains only micromolar concentrations of IgG, as used in typical applications (*7*, *9*−*11*, *14*, *15*).

In conclusion, preadsorption of protein next to the pyridine-S-S-PEG tentacle on the tip surface appears to be the key parameter which helps to raise protein concentration even from submicromolar concentrations in bulk solution to millimolar concentration at the site of linking (see Figure 7). This is the only plausible hypothesis which can explain why coupling of a thiol protein to a 2-pyridyl-S-S-PEG linker on an AFM tip (Figure 1 and Figure 7) takes 1 h only, rather than months, as would have been predicted for a collisional mechanism of coupling (as in Table 2) when reacting at micromolar protein concentrations.

The above model has important consequences for practical application. It warns against mixing of the thiol protein with excess of non-thiol protein, e.g., for the sake of physical stabilization during storage or freezing. The non-thiol protein is likely to be equally preadsorbed and over-represented next to the surface-bound PEG linkers, thereby inhibiting coupling of thiol protein to the PEG linker. Another warning is that preadsorption will not occur with many small thiol ligands, in which case higher concentrations and/or longer reaction times will be required. At the same time, there is an upper limit for the concentration of a small thiol ligand which should be observed: Too-high concentrations and/or too-long reaction times will obviously cause the coupling product "ligand-S-S-PEG-tip" to be attacked by another HS-ligand, resulting in release of "ligand-S-S-ligand" from "HS-PEG-tip". The question is which concentration of a small ligand-SH will ensure coupling without subsequent cleavage. Fortunately, the last line of Table 2 allows estimation of the concentration and reaction time needed for collisional coupling of a small thiol ligand. Line 12 reports a half-time of 4 min for coupling of 1 mM glutathion (G-SH, a small tripeptide) to 2-pyridyl-S-S-PEG_{800}-BSA, which resembles coupling to PEG_{800} on the AFM tip. Incubation for five half-times (20 min) at 1 mM small ligand thiol concentration, therefore, should be appropriate for a 97% probability of coupling to 2-pyridyl-S-S-PEG on the AFM tip. Accordingly, 200 min or longer times will be required when working at 100 μM or lower ligand thiol concentrations. Although these numbers are meant as rough estimates, they still appear helpful to choose reasonable starting conditions from which tip functionalization can further be optimized in a particular case.

CONCLUSIONS

In this study, the coupling of a thiolated antibody to 2-pyridyl-S-S-PEG_{800} linkers on AFM tips and silicon nitride chips was demonstrated by use of biotin-IgG-SATP in place of some specific antibody. Accordingly, SMRFM experiments were performed with avidin as a partner molecule, which was particularly easy to immobilize on mica by electrostatic adsorption (*16*). The observed unbinding events were easily assigned to rupturing of single avidin−biotin bonds, because (i) the unbinding force was the same as previously measured under the same loading rate (*16*, *28*) and (ii) binding was efficiently blocked by low concentrations of free biotin. Blocking with such a small molecule appears more convincing than by addition of protein which might be suspected to block an AFM tip by nonspecific adsorption. In conclusion, tip-bound biotin-IgG-SATP and mica-bound avidin appear particularly suited as a start-up and testing system in SMRFM, due to simplicity, low cost, and easy differentiation between specific and nonspecific data.

Blocking with free biotin was also employed to distinguish specific from nonspecific binding of ExtrAvidin−peroxidase to biotin-IgG-SATP which had been coupled to 2-pyridyl-S-S-PEG_{800} linkers on silicon nitride chips. Specific binding indicated a density of $\sim$2000 μm^{-2} for chip-bound biotin-IgG-SATP, which nicely explained the observation that 1−2 functional antibodies were typically found on the apex of a functionalized AFM tip (*16*). Tethering of antibodies to silicon nitride tips by the scheme shown in Figure 1 was thus reproduced on silicon nitride chips in a semiquantitative way, and the disulfide coupling step was proven, because only biotin-IgG *with* free thiols was able to couple at all.

Finally, the mechanism of thiol protein coupling to tip-bound 2-pyridyl-S-S-PEG_{800} linkers was elucidated by staging the coupling reaction in bulk solution and measuring the reaction rates photometrically. Surprisingly, the coupling of micromolar protein was $\sim 10^3$-fold slower in bulk solution than on tips or chips. The only conceivable reason to explain $\sim 10^3$-fold faster coupling on the surfaces was found in preadsorption of protein next to the surface-bound PEG linkers which raises the effective protein concentration from micromolar (or lower) in bulk solution to millimolar on the surface. Taken together, the insights from this study provide for a rational approach to biofunctionalization of scanning probes with single molecules.

Photocrosslinking/Label Transfer: A Key Step in Mapping Short α-Neurotoxin Binding Site on Nicotinic Acetylcholine Receptor

Pascal Kessler,* Robert Thai, Fabrice Beau, Jean-Luc Tarride, and André Ménez

CEA, DSV, DIEP, Gif-sur-Yvette, F-91191, France. Received June 19, 2006; Revised Manuscript Received August 23, 2006

We developed a novel radioactive short bifunctional photoprobe, which could be coupled through a cleavable bond to an engineered cysteinyl residue on an analogue of a nicotinic acetylcholine receptor-specific α-neurotoxin. This cysteine was put on the tip of loop II in place of Arg33, a major residue for the interaction with the receptor. To facilitate the purification of the nAChR labeled subunits, we tagged the ligand with a desthiobiotin moiety. After irradiation of the photosensitive toxin−nAChR complex, gel electrophoresis showed that most of the radioactivity was attached to the α subunit (59%), followed by the γ subunit (28%), with the δ subunit (13%) being less labeled. On a preparative scale, the labeled subunits were purified on streptavidin beads before separation on SDS-PAGE. "In-gel" CNBr cleavage of the labeled α subunit followed by Edman degradation of the purified peptides showed that αTyr190 and αTyr198 were the most labeled residues, with a less important labeling on αCys192. We believe that the novel photoactivatable probe will be of great use to identify key residues of ligands interacting with macromolecules.

INTRODUCTION

With relation to the discovery of soluble acetylcholine binding proteins (AChBP's[1]) in various snails, the recent past has been quite rich in structure descriptions of complexes between nicotinic ligands and the surrogate of the acetylcholine receptor. These data brought new insights on the interactions between agonists/antagonists and their intrinsic acetylcholine protein target. X-ray crystallography of complexes between AChBP and agonists, such as nicotine, carbamylcholine (*1*), epibatidine, or lobeline (*2*) showed that the critical C loop, classically harbored by α-subunits on nAChRs, wraps these ligands, occluding the binding site. In contrast to these data, structures of complexes with peptidic antagonists, such as α-conotoxin ImI (*2*), α-conotoxin PnIA (*3*), or α-cobratoxin (*4*) showed a more or less extended C loop, its position depending on the steric hindrance of the antagonist.

Three finger curaremimetic snake α-neurotoxins can be divided into long-chain and short-chain toxins. α-Bungarotoxin and α-cobratoxin belong to the first group, which binds with high affinity to the neuronal α7 receptor and to AChBP. Crystals and X-ray data of a complex between AChBP and α-cobratoxin have been obtained recently by Bourne and colleagues (*4*), revealing an unpredicted conformation of the toxin-bound AChBP, especially of loop C on the α subunit.

NmmI, erabutoxin-a, NTII, and the α-neurotoxin of *Naja nigricollis* belong to the short-chain group, which is specific to the muscle-type nAChR. This family of toxins do not bind with high affinity to AChBP (*4*, *5*), and no structure of a complex with AChBP has ever been published. However, by checking the ability of making ternary complexes between nAChR, streptavidin, and biotinylated analogues of *Naja nigricollis* α-neurotoxin, it was concluded that short and long curaremimetic toxins share a similar overall topology of interaction when bound to nicotinic receptors (*6*). Moreover, by comparing the structure of the α-cobratoxin−AChBP complex to data obtained by double mutant cycle analysis of a muscle nAChR and the short-chain α-neurotoxin NmmI (*7*, *8*), Bourne and colleagues suggested that NmmI binds at the subunit interface of the muscle-type nAChR in a somewhat different orientation than α-cobratoxin, with Arg33 acting as a pivot. More recently, an in silico study suggested that the way of entry into the nAChR binding pocket of the second loop of NTII, another short-chain α-neurotoxin, differs from that of α-cobratoxin (*9*).

In order to test these proposals, we mapped the binding area of the tip of the second loop of a short-chain α-neurotoxin on the acetylcholine receptor by photoaffinity labeling. Unfortunately, with such ligands, this technique almost never led to the characterization of the labeled residues on the targeted protein, due essentially to the noncleavable nature of the covalent bond linking the photoprobe to the toxin. Actually, a labeled residue could only be characterized once (*10*), when the radioactive label was transferred from the ligand to the receptor. However, the 16.5 Å long linker did not lead to a precise mapping of the binding site. To overcome this drawback, we designed here a novel short bifunctional tritiated aryldiazonium photoprobe.

This paper describes the synthesis of the photoprobe followed by its coupling, through a cleavable disulfide bond, to an engineered cysteinyl residue at the putative pivotal position 33 of an analogue of a short-chain α-neurotoxin. Photoaffinity experiments, using this new toxin photoprobe in complex with nAChR on *Torpedo marmorata* membranes, showed a preferential labeling of the α and γ subunits compared to the δ subunit. Edman degradation of the α-subunit-labeled peptides showed that αTyr190, αTyr198, and, to a lesser extent, αCys192 reacted with the photoprobe. Our results reinforce the idea that long and short α-neurotoxins bind to their receptors in a similar manner, at least with the critical Arg33 residue.

EXPERIMENTAL PROCEDURES

For the sake of clarity, we decided to use erabutoxin numbering for the amino acids of *Naja nigricollis* α-neurotoxin as we did in previous papers (*6*, *11*, *12*).

Peptide synthesis was achieved on an Applied Biosystems 433 apparatus. The Fmoc-protected amino acids were obtained from Novabiochem or Advanced Chemtech. All the chemicals were of the highest purity commercially available. Live *Torpedo marmorata* were purchased from the Station Biologique d'Arcachon (France). Western blots were carried out using Advance-ECL from Amersham Biosciences. Monoclonal antibodies mAb140, mAb155, and mAb165 were a generous gift of Dr. Tzartos (Hellenic Pasteur Institute, Athens). Goat anti-rat IgG peroxidase $F(ab')_2$ fragment (H + L) conjugate was purchased from Jackson ImmunoResearch Laboratories (West Grove, PA). Synthesis of *Naja nigricollis* R33C toxin analogue was achieved as described earlier (*11*). Electrospray mass spectrometry was achieved on a Quattro II from Micromass. NMR spectra were recorded on a Bruker Avance 250 MHz. Melting points were taken on a Kofler device. The irradiating device was composed of a 1000 W mercury lamp (Osram), an aperture, and a series of lenses focusing the polychromatic light to a monochromator (Jobin-Yvon), after which a series of lenses focused the monochromatic light to a thermostatic quartz cuvette containing the nAChR. The light intensity was measured with a radiometer IL1700 (International Light, Newburyport, MA). Each experiment involving photoactivatable compounds was done under sodium light, safe for aryldiazonium derivatives.

2-Hydroxymethyl-6-iodo-4-nitrophenol (1). 2-Hydroxy-5-nitrobenzoic acid (10.2 g, 55.7 mmol) was selectively reduced with BH_3-THF (2.2 equiv) in dry THF (150 mL), at reflux for 1 h. The borates were solvolyzed in dry MeOH, added to destroy the excess of borane. The mixture was evaporated to dryness. The residue was then solubilized again in dry MeOH, evaporated to dryness, and dissolved in a mixture of $MeOH/H_2O$ (200 mL/50 mL). After treatment with Na_2CO_3 (1.5 g), ICl (1 equiv) was added. The mixture was stirred for half an hour and then acidified with citric acid. Iodine was reduced with an excess of sodium thiosulphate. The mixture was then concentrated and extracted with EtOAc. The organic phase was washed with water and brine, dried over $MgSO_4$, and purified by silica gel chromatography (gradient: *n*-hexane 7/EtOAc 3 to *n*-hexane 5/EtOAc 5), giving orange oil, which was crystallized in $CHCl_3$. The final yield was 14 g (85%) of orange needles, mp 87 °C. ^{1}H NMR (acetone-d_6): δ (ppm) 4.97 (s, 2H), 5.58 (s_{broad}, 1H), 8.15 (d, $J = 2.7$ Hz, 1H), 8.50 (d, $J = 2.7$ Hz, 1H), 10.07 (s_{broad}, 1H). ^{13}C NMR (acetone-d_6): δ (ppm) 61.8, 83.6, 123.0, 127.0, 133.2, 141.1, 160.8. Anal. ($C_7H_6INO_4$) calcd %: C 28.50, H 2.05, N 4.75, I 43.02. Found %: C 28.74, H 2.06, N 4.72, I 43.11.

1-Iodo-2-methoxy-3-[(4-methoxyphenyl)diphenylmethoxymethyl]-5-nitrobenzene (2). Compound (**1**) (1.475 g, 5 mmol) was dissolved in pyridine (10 mL) with (4-methoxyphenyl)-diphenylmethoxymethyl chloride (2.4 g, 1.5 equiv) and heated to 65 °C for 1.5 h. The mixture was then evaporated, and the residue was dissolved in EtOAc and washed with H_2O, a saturated solution of NH_4Cl, and a 10% citric acid solution. The organic phase was dried over $MgSO_4$ and evaporated. The residue was taken in DMF (20 mL). Following the addition of $NaHCO_3$ (2.35 g, 28 mmol) and CH_3I (2 mL, 32 mmol), the mixture was stirred for 1 day, after which it was concentrated and taken into EtOAc. The organic phase was washed with water and brine, dried over $MgSO_4$, and purified by silica gel chromatography (eluent: *n*-hexane 95/EtOAc 5), yielding a white solid (2.33 g, 80%), mp 143 °C. ^{1}H NMR ($CDCl_3$): δ (ppm) 3.65 (s, 3H), 3.79 (s, 3H), 4.33 (s, 2H), 6.85 (dd, $J =$ 6.8 Hz, $J = 2.1$ Hz, 2H), 7.24−7.52 (m, 12H), 8.45 (d, $J = 2.7$ Hz, 1H), 8.55 (d, $J = 2.7$ Hz, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 55.2, 60.7, 61.3, 87.5, 91.0, 113.3, 124.7, 127.2, 128.0, 128.3, 130.3, 133.5, 134.7, 135.0, 143.9, 144.6, 158.8, 162.3. Anal. ($C_{28}H_{24}INO_5$) calcd %: C 57.84, H 4.16, N 2.41, I 21.83. Found %: C 57.77, H 4.77, N 2.48, I 21.98.

{3-Iodo-4-methoxy-5-[(4-methoxyphenyl)diphenylmethoxymethyl]phenyl}carbamic Acid *tert*-Butyl Ester (3). Nitro compound (**2**) (1.63 g, 2.5 mmol) was selectively reduced with an excess of fresh NaSH, xH_2O (8 g) in a mixture of MeOH (50 mL) and THF (20 mL), under reflux for 2 h. After an evaporation step, the product was dissolved in EtOAc, washed with water and brine, and dried over $MgSO_4$. The amine was then taken in THF (10 mL) and protected with ditertiobutyldicarbonate (1.1 g, 2 equiv) at 50 °C, overnight. Finally, it was purified by silica gel chromatography (eluent: *n*-hexane 9/EtOAc 1), yielding 1.24 g of a white powder (76.5%), mp 201 °C. ^{1}H NMR (acetone-d_6): δ (ppm) 1.51 (s, 9H), 3.52 (s, 3H), 3.80 (s, 3H), 4.20 (s, 2H), 6.92 (dd, $J = 6.8$ Hz, $J = 2.2$ Hz, 2H), 7.26−7.58 (m, 12H), 7.89 (d, $J = 2.6$ Hz, 1H), 8.17 (d, $J = 2.6$ Hz, 1H), 8.55 (s_{broad}, 1H). ^{13}C NMR (acetone-d_6): δ (ppm) 28.5, 55.5, 61.4, 61.9, 80.4, 87.8, 91.7, 114.0, 120.2, 127.8, 128.1, 128.7, 129.2, 131.2, 134.1, 136.2, 138.2, 145.5, 153.1, 153.7, 159.8. Anal. ($C_{33}H_{34}INO_5$) calcd %: C 60.83, H 5.26, N 2.15, I 19.48. Found %: C 60.98, H 5.30, N 2.18, I 19.57.

(3-Hydroxymethyl-5-iodo-4-methoxyphenyl)carbamic Acid *tert*-Butyl Ester (4). Compound (**3**) (1.55 g, 2.4 mmol) was dissolved in THF (50 mL), and the mixture was diluted with H_2O (10 mL) and AcOH (50 mL) and refluxed for 3 h. The solvents were evaporated, and the product was purified by silica gel chromatography (gradient: *n*-hexane 8/EtOAc 2 to *n*-hexane 7/EtOAc 3), yielding a colorless oil which turned to a white solid (641 mg, 71%), mp 146 °C. ^{1}H NMR ($CDCl_3$): δ (ppm) 1.50 (s, 9H), 3.17 (s_{broad}, 1H), 3.75 (s, 3H), 4.65 (s, 2H), 6.87 (s_{broad}, 1H), 7.27 (d, $J = 2.6$ Hz, 1H), 7.80 (d, $J = 2.6$ Hz, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 28.2, 60.7, 61.4, 80.8, 91.5, 119.5, 128.4, 135.0, 135.8, 152.7, 152.8. Anal. ($C_{13}H_{18}INO_4$) calcd %: C 41.17, H 4.78, N 3.69, I 33.47. Found %: C 41.27, H 4.87, N 3.71, I 33.59.

Thioacetic Acid *S*-(5-*tert*-butoxycarbonylamino-3-iodo-2-methoxybenzyl) Ester (5). Methanesulfonyl chloride (107 μL, 1.5 equiv) was added to a mixture of compound (**4**) (350 mg, 0.92 mmol) and Et_3N (195 μL, 1.5 equiv) in dry THF (10 mL) and stirred for 15 min. A mixture of thioacetic acid (294 μL, 4 equiv) and Et_3N (570 μL, 4 equiv) in EtOAc (3 mL) was added to the mesylate, and the solution was stirred for 1 h, at room temperature. After concentration, the residue was dissolved in EtOAc and washed with water and brine, dried over $MgSO_4$, and purified by silica gel chromatography (eluent: *n*-hexane 9/EtOAc 1), yielding 345 mg (85.5%) of yellowish oil. ^{1}H NMR ($CDCl_3$): δ (ppm) 1.50 (s, 9H), 2.35 (s, 3H), 3.80 (s, 3H), 4.13 (s, 2H), 6.49 (s_{broad}, 1H), 7.18 (d, $J = 2.6$ Hz, 1H), 7.88 (d, $J = 2.6$ Hz, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 28.2, 28.5, 30.2, 61.4, 80.7, 91.6, 121.0, 128.6, 131.6, 135.7, 152.5, 153.3, 195.0. Anal. ($C_{15}H_{20}INO_4S$) calcd %: C 41.20, H 4.61, N 3.20, I 29.02, S 7.33. Found %: C 40.47, H 4.56, N 3.10, I 27.75, S 7.34.

Thioacetic Acid *S*-(5-*tert*-butoxycarbonylamino-2-methoxybenzyl) Ester (6). Iodide (**5**) (490 mg, 1.12 mmol) was hydrogenated ($P(H_2) = 2$ bar) for 1 h in EtOAc (10 mL) in the presence of Pd black (1.3 g) and Et_3N (700 μL). The mixture was filtered and washed with water and brine, dried over $MgSO_4$, and purified by silica gel chromatography (eluent: *n*-hexane 9/EtOAc 1), yielding 240 mg (69%) of colorless oil. ^{1}H NMR ($CDCl_3$): δ (ppm) 1.50 (s, 9H), 2.31 (s, 3H), 3.81 (s, 3H), 4.09 (s, 2H), 6.40 (s_{broad}, 1H), 6.77 (d, $J = 8.8$ Hz, 1H), 7.19 (d, $J = 2.7$ Hz, 1H), 7.34 (dd, $J = 8.8$ Hz, $J = 2.7$ Hz, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 28.2, 28.3, 30.3, 55.8, 80.2, 110.9, 119.4, 121.7, 126.2, 131.1, 153.1, 153.4, 195.7. Anal.

($C_{15}H_{21}NO_4S$) calcd %: C 57.85, H 6.80, N 4.50, S 10.30. Found %: C 57.50, H 6.91, N 4.42, S 10.58.

[4-Methoxy-3-(pyridin-2-yldisulfanylmethyl)phenyl]carbamic Acid *tert*-Butyl Ester (7). Thioacetate (**6**) (102 mg, 0.33 mmol) was solvolyzed in a mixture of dry MeOH (4 mL) and NaOMe (80 mg, 4 equiv) for 4 h, at room temperature. The fraction of disulfide formed during the methanolysis was then reduced with TCEP (100 mg, 1 equiv) dissolved in a mixture of H_2O (1 mL) and pyridine (600 μL). 2,2′-Dithiopyridine (480 mg, 6.6 equiv) was then added to this mixture and stirred overnight. After evaporation, the residue was dissolved in EtOAc and washed with water and brine and dried over $MgSO_4$. The product was purified by silica gel chromatography (eluent: CH_2Cl_2 97/EtOAc 3), yielding 98 mg (79%) of a white powder, mp 122 °C. MS (ES-MS): $M + H^+ = 379.2$ [$C_{18}H_{22}N_2O_3S_2$ (378.5)]. ^{1}H NMR ($CDCl_3$): δ (ppm) 1.50 (s, 9H), 3.81 (s, 3H), 4.01 (s, 2H), 6.26 (s_{broad}, 1H), 6.75 (d, $J = 8.8$ Hz, 1H), 6.98−7.04 (m, 1H), 7.09 (d, $J = 2.7$ Hz, 1H), 7.25 (m, 1H), 7.49−7.55 (m, 1H), 7.60 (dd, $J = 8.8$ Hz, $J = 2.7$ Hz, 1H), 8.40 (d, $J = 4.0$ Hz, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 28.3, 38.5, 55.7, 80.1, 110.9, 119.2, 119.7, 120.2, 122.0, 125.1, 131.1, 136.7, 149.1, 153.0, 153.3, 160.6. Anal. ($C_{18}H_{22}N_2O_3S_2$) calcd %: C 57.11, H 5.86, N 7.40, S 16.94. Found %: C 57.01, H 5.92, N 7.40, S 16.91. UV: $\lambda_{max} = 287$ nm, $\epsilon = 5900$ $M^{-1}.cm^{-1}$.

4-Methoxy-3-(pyridin-2-yldisulfanylmethyl)benzenediazonium Trifluoroacetate (8). The aromatic amine of compound (**7**) (19 mg, 50 μmol) was deprotected in trifluoroacetic acid (2 mL) for 15 min. The mixture was cooled down to about 0 °C, and sodium nitrite (1.1 equiv) dissolved in water (100 μL) was added dropwise. The solution was evaporated to dryness, taken into H_2O, and purified by reverse-phase HPLC on a Vydac C4 preparative column (22 × 250 mm; flow rate 15 mL.min^{-1}; linear gradient: 0% B to 10% B in 5 min, then isocratic at 10% B. A: H_2O, 0.1% TFA. B: CH_3CN) yielding aryldiazonium (**8**) (26%). MS (ES-MS): $M = 262.87$ ($M - N_2$) [$C_{13}H_{12}N_3S_2^+$ (290.4)]. ^{1}H NMR (CD_3OD): δ (ppm) 4.09 (s, 3H), 4.11 (s, 2H), 7.20−7.23 (m, 1H), 7.42 (d, $J = 9.3$ Hz, 1H), 7.66−7.75 (m, 2H), 8.33−8.35 (m, 1H), 8.38 (d, $J = 2.6$ Hz, 1H), 8.49 (dd, $J = 9.3$ Hz, $J = 2.6$ Hz, 1H). ^{13}C NMR (CD_3OD): δ (ppm) 37.1, 58.6, 103.0, 115.1, 121.8, 122.8, 131.2, 135.3, 137.5, 139.2, 150.3, 160.4, 160.9, 161.5, 169.3.

[4-Methoxy-3-(pyridin-2-yldisulfanylmethyl)-5-[^{3}H]-phenyl]carbamic Acid *tert*-Butyl Ester (7bis). Iodide (**5**) (44 mg, 0.1 mmol) was hydrogenated ($P(^3H_2) = 2$ bar) for 1 day in EtOAc (1 mL) in the presence of Pd black (120 mg) and Et_3N (60 μL). The mixture was centrifuged and the catalyst washed with EtOAc (5 mL). The organic phase was concentrated to 1 mL and purified by thin layer silica gel chromatography (eluent: *n*-hexane 8/EtOAc 2), yielding 18 mg (58%) of colorless oil, coeluting on TLC with the equivalent non-radioactive compound (**6**). The tritiated derivative was then dissolved in dry MeOH and reacted with an excess of NaOMe (15 mg) for 3 h, at room temperature. The mixture was then buffered by adding 75 μL of pyridine in 150 μL H_2O. Treatment with an excess of TCEP (20 mg) reduced the formed disulfide. An excess of 2,2′-dithiopyridine (60 mg) was then added to this mixture, which was evaporated after 10 min. The remaining oil was diluted in 1.5 mL CH_3CN and 750 μL H_2O and purified by HPLC on a Vydac C18 analytical column (4.8 × 250 mm; flow rate 1 mL.min^{-1}; isocratic: 55% B. A: H_2O without TFA. B: CH_3CN), yielding 61% of pure radioactive product (**7bis**). It coeluted with the non-radioactive compound on HPLC, and their ^{1}H NMR spectra were identical. However, as expected, the integration of the proton in the ortho position of the methoxy group in **7bis** corresponded to about 40% of the expected value on the non-radioactive compound, due to the replacement of part of the proton by tritium. Its radioactive specificity (12.5 Ci.mmol^{-1}) was determined by UV spectroscopy ($\lambda_{max} = 287$ nm, $\epsilon = 5900$ $M^{-1}.cm^{-1}$) and β-counting and corresponded to the proton integration in ^{1}H NMR. This compound was stable for months in a $^1/_4$ mixture of $CDCL_3$/toluene, in liquid N_2.

4-Methoxy-3-(pyridin-2-yldisulfanylmethyl)-5-[^{3}H]-benzenediazonium Trifluoroacetate (8bis). The aromatic amine of compound **7bis** (3 μmol) was deprotected in trifluoroacetic acid (500 μL) for 2 h. The mixture was cooled down to about 0 °C, and sodium nitrite (1.1 equiv) dissolved in water (10 μL) was added. The solution was evaporated to dryness, taken into H_2O, and purified by reverse-phase HPLC on a bondasorb C18 (10 μm) analytical column (4.8 × 250 mm; flow rate 1 mL.min^{-1}; linear gradient: 0% B to 40% B in 20 min. A: H_2O, 0.01% TFA. B: CH_3CN) yielding aryldiazonium (**8bis**) (25%). The pure tritiated compound coeluted on a C18 column (conditions mentioned above) with the same non-radioactive derivative and had identical UV spectra. The concentrated HPLC fraction of compound **8bis** was stable for months in liquid N_2. UV: $\lambda_{max} = 313$ nm, $\epsilon = 20\,000$ $M^{-1}.cm^{-1}$; the molar absorption coefficient was determined using the radioactive compound **8bis**, by correlating its UV spectrum and its radioactive specificity (12.5 Ci.mmol^{-1}).

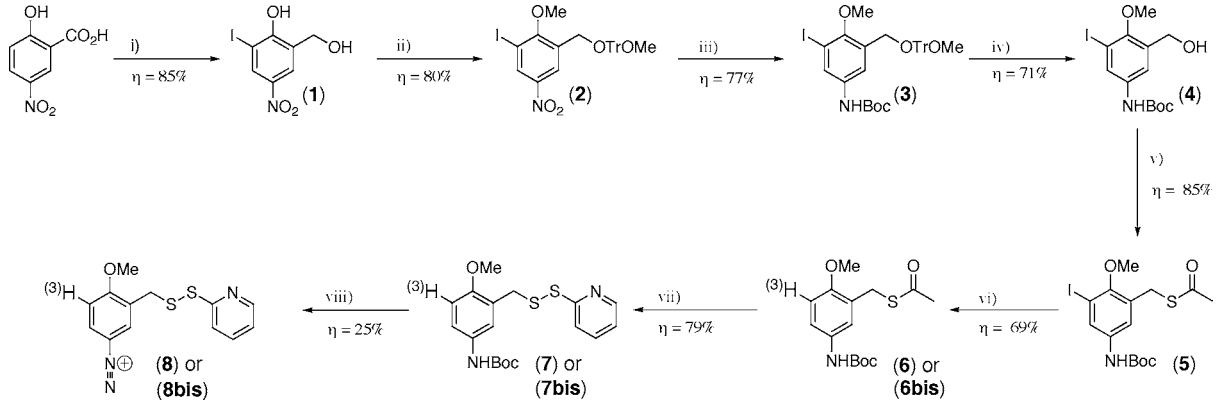
N-Terminal Modification of *Naja nigricollis* R33C Toxin Analogue with Desthiobiotin. After the automated peptide synthesis of the precursor of *Naja nigricollis* R33C toxin analogue (*11*), 6-fmoc-aminohexanoic acid was coupled to the N-terminus of the peptide still linked to the resin, using a standard HATU/diisopropylethylamine overnight activation in *N*-methylpyrrolidone. The fmoc group was released by piperidine treatment. Desthiobiotin was then coupled in the same way than the aminohexanoic linker. After deprotection for 1.5 h in TFA/triisopropylsilane/water (9/0.5/0.5), the peptide was precipitated in cold terbutyl ethyl ether and centrifuged. The pellet was dissolved in 10% acetic acid overnight. The linear peptide was purified as described earlier (*11*) and then refolded at 10 μM, in Tris-HCl 100 mM, pH 7.8, oxidized DTT 5 mM, for 1 day. Purification was carried out as described earlier (*11*) and afforded pure dtb-R33C toxin analogue, which was checked by electrospray mass spectrometry. $M_{calcd} = 7043.2$; $M_{found} = 7043.0$.

Coupling of Aryldiazonium Salt (8bis) to dtb-R33C. A solution of 1.3 mg (190 nmol) of dtb-R33C in 250 μL of 1.6 M sodium citrate buffer (pH 2.2) was mixed, under rapid stirring, with 2.2 equiv of diazonium (**8bis**) diluted in 250 μL of the same buffer. The mixture was allowed to stand at room temperature in the dark for 1 day. The toxin derivative [^{3}H]-dtb-R33C-ArN_2^+ was then purified by HPLC on a Vydac C4 analytical column (4.8 × 250 mm; flow rate 1 mL.min^{-1}; linear gradient: 10% B to 10% B in 10 min, then 10% to 18% B in 6 min, then 18% to 24% B in 19 min. A: H_2O, 0.1% TFA. B: CH_3CN), and checked by electrospray mass spectrometry. M_{calcd} (dtb-R33C-ArN_2^+) = 7222.25; $M_{found} = 7222.35$. UV: $\lambda_{max} = 314$ nm, $\epsilon = 20\,000$ $M^{-1}.cm^{-1}$; toxin concentration was determined by acidic hydrolysis and subsequent quantification of the contained amino acids.

Preparation of nAChR-Rich Membranes. nAChR-rich membranes from the electric tissue of *Torpedo marmorata* were prepared as previously described (*13*). The concentration of acetylcholine binding sites was typically between 0.9 and 1.4 nmol per milligram of proteins.

Analytical Scale Photolabeling. *Torpedo* membranes (2 μM, 500 pmol α-bungarotoxin sites) were incubated in $NaPO_4$ 250 mM, pH 6.9, at room temperature in the dark for 15 min with [^{3}H]-dtb-R33C-ArN_2^+ (0.95 equiv). The mixture was then stirred in a quartz cuvette and irradiated at 323 nm (200 μW.cm^{-2}) for 10 min, at 10 °C. The size of the light beam was approximately 2 mm × 12 mm. For protection experiments,

Scheme 1. Synthesis of the Aryldiazonium Salts (8) and (8bis)[a]



[a] Reagents and conditions: (i) (a) BH_3-THF, (b) Na_2CO_3, ICl, MeOH/H_2O; (ii) (a) ClTrOMe, pyridine, 100 °C, (b) CH_3I, $NaHCO_3$, DMF; (iii) (a) NaSH, MeOH/THF, reflux, (b) *tert*-butyl dicarbonate; (iv) (a) THF, H_2O, AcOH; (v) (a) CH_3SO_2Cl, Et_3N, THF, (b) CH_3COSH/Et_3N, THF; (vi) H_2 or $^3H_2$ (2 bar), Pd black; (vii) (a) NaOMe, MeOH, (b) TCEP, (c) 2,2′-dithiodipyridine; (viii) TFA, $NaNO_2$. Yields are given for non-radioactive products.

membranes were incubated with 20 equiv of α-bungarotoxin at room temperature for 1 h, before adding the tritiated photoactivatable toxin analogue. Following irradiation, the membranes were centrifuged at 22 000 g for 30 min, at 4 °C, and the pellets were solubilized in Laemmli buffer to be run on a 10% SDS-PAGE. The gels were then transferred to PVDF-membranes, which were exposed to a *β*-imager in order to visualize the labeled bands. These bands were compared to the one obtained by Western blotting of the same PVDF-membranes with mAbs 155, 165, and 140, which are specific for the α, *γ*, and *δ* subunits, respectively.

Preparative Scale Photolabeling and Isolation of the Labeled α Subunit. Large quantities of torpedo membranes (30 nmol) were irradiated in the same conditions as for analytical scale experiments, except that the size of the light beam was 5 mm × 12 mm, and the energy was equal to 300 $\mu W.cm^{-2}$. Following irradiation, the membrane suspension was centrifuged at 22 000 g for 30 min, at 25 °C, and the pellet solubilized in buffer A (Tris-HCl 50 mM, pH 8, LiDS 1%, LiCl 2 M). The mixture was then centrifuged as described before. The supernatant was poured onto streptavidin Sepharose beads (Amersham Biosciences), equilibrated with buffer A. The beads were washed with buffer A (2 × 10 mL) and with Tris 50 mM pH8, SDS 0.2% (3 × 10 mL). The labeled subunits were then recovered by incubating the beads twice (2 mL and 1 mL) in buffer B (Tris-HCl 2M pH 8, SDS 0.2%, biotin 50 mM) at 70 °C for 30 min. The subunits were reduced with TCEP (20 mM) at 25 °C overnight, and the sulfydryls were blocked with iodoacetamide (35 mM) at 25 °C for 15 min. The mixture was concentrated on centricon-30 and washed with Tris-HCl 20 mM pH 7. The solubilized and labeled subunits were subjected to 10% SDS-PAGE. The gel was covered with a dry PVDF-membrane for 15 min, which enabled the location of the radioactive bands after exposing the membrane on a *β*-imager (Beta Imager 2000 from Biospace). The labeled subunits could then be excised from the gel without any staining. The gel fraction containing the α-subunit was cut into small pieces, transferred to an Eppendorf tube, and washed twice with a 50% aqueous solution of CH_3CN (2 × 1 mL) for 10 min.

"In Gel" CNBr Cleavage of the α Subunit and Peptide Purification. Cleavage of the α subunit and extraction of the labeled peptides were done as described in Grutter et al. (*14*), except that extraction of the peptides from the gel was carried out only with a mixture of H_2O − 0.1% TFA/CH_3CN (50/50). The extract was purified on a Vydac C4 narrow-bore column by HPLC (2.1 × 250 mm; flow rate 0.2 $mL.min^{-1}$; linear gradient: 5% B to 5% B in 10 min, then 5% to 25% B in 10 min, then 25% to 35% B in 155 min, then 35% to 100% B in 30 min, then 100% to 100% B in 15 min, then 100% to 5% B in 5 min. A: H_2O, 0.1% TFA. B: 70% CH_3CN, 30% *n*-propanol, 0.095% TFA). UV absorbance was monitored at 220 nm. Fractions (400 μL) were collected, and aliquots were counted for radioactivity.

Peptide Sequencing. HPLC fractions were concentrated (speedvac) and loaded onto a biobrene-pretreated filter of the sequencer. Automated Edman degradation was performed on an Applied Biosystems Procise sequencer. The HPLC output from each cycle was collected and counted for radioactivity quantification.

RESULTS

Synthesis of the Bifunctional Photoprobe (8bis) (Scheme 1). The aryldiazonium salt (**8**) was synthesized in fourteen steps, with an overall yield of about 4%. A radioactive version was obtained by treating the aryliodide (**5**) with tritium gas leading to the thioacetate (**6bis**). Its radioactive specificity was 12.5 $Ci.mmol^{-1}$. The main secondary reaction observed in this step (radioactive or not) was the concomitant desulfurization of (**5**). The methanolysis of the thioacetate (**6bis**) followed by the reduction of the formed disulfide and the dithiopyridinylation of the thiol were made one-pot. We thus obtained the precursor (**7bis**) of the bifunctional photoprobe (**8bis**). This precursor was kept in a mixture of toluene and chloroform (4/1) in liquid nitrogen and was stable for months. Diazotization of (**7bis**) led to the aryldiazonium salt (**8bis**), which was purified by HPLC. After concentration, the HPLC fractions were stable for months in liquid nitrogen.

As was the case for a previous non-radioactive bifunctional photoprobe (*12*), this novel tritiated molecule carries an aryldiazonium salt, which can be photodecomposed at wavelengths which are safe for proteins (above 300 nm). Consistent with earlier data (*15*), replacing the dimethylamino group on the para position of the diazonium moiety (*12*) by a methoxy group (this work) shifted the maximal wavelength from 391 to 313 nm.

Coupling of the Bifunctional Photoprobe to dtb-R33C. We synthesized a previously described analogue of the α-neurotoxin of *Naja nigricollis* (*11*) in which Arg33, at the tip of loop II, is replaced by a cysteine residue (Figure 1). This residue was shown to be a major hot spot for the interaction with the nAChR (*16*). Following automated peptide synthesis, we coupled manually a desthiobiotin through an aminohexanoic linker to the N-terminus of the peptide, in order to enable a prepurification of labeled subunits on streptavidin beads. In contrast to biotin, desthiobiotin binds reversibly to streptavidin (*17*), a huge advantage in such a study, as it enables the recovery of the purified labeled subunits.

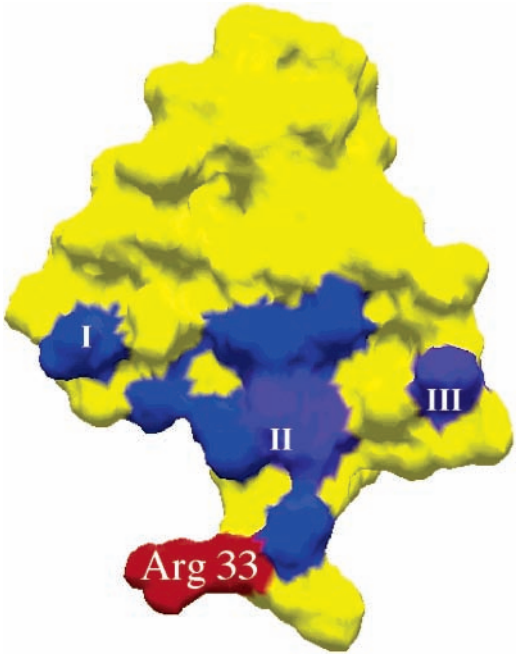


Figure 1. *Naja nigricollis* α-neurotoxin. The structure has been taken from Zinn-Justin et al. (*33*). The molecular surface has been represented in yellow, showing the binding surface in blue and highlighting the critical Arg33 residue in red on tip of loop II. Note that the numbering of the residue corresponds to erabutoxin numbering.

We tried to couple the unique free cysteine of the refolded toxin to our bifunctional photoprobe at the same conditions as previously described for the achievement of R33C-DABD (*12*). Unfortunately, we obtained a mixture of the expected product and a molecule derived from the attack of the cysteine thiolate on the diazonium moiety (data not shown). This undesired reaction showed that, in the absence of light, the methoxy group renders the *p*-diazonium moiety more sensitive to nucleophilic attack than the dimethylamino group did. Lowering the pH from 7 to 4.5, during such coupling reaction, accelerates the disulfide exchange on the pyridyl disulfide, by protonation of the pyridine nitrogen (*18*). As the pK_a value of 2,2′-pyridyl disulfide is 2.45 (*18*), we observed that decreasing the pH to 2.2 enabled the expected reaction to happen with the robust snake toxin, without any side reaction but with longer reaction times, as the cysteine residue is almost fully protonated.

The maximum wavelengths of the obtained toxin photoprobe and of the initial bifunctional photoprobe (**8 bis**) were almost identical (Figure 2). This aryldiazonium toxin was stable for months in acidic conditions (HPLC fractions) in liquid nitrogen in the dark. However, the stability of the diazonium group at physiological pH (half-life = 5 h at 17 °C in 250 mM sodium phosphate, pH 6.9, in the dark, data not shown) was not sufficient for equilibrium binding experiments in order to determine the inhibition constant of the modified toxin on the torpedo receptor. Nevertheless, a similar but more stable modified toxin (R33C-DABD), in which only the *p*-methoxy group on the bifunctional photoprobe was replaced by a *p*-dimethylamino moiety (*12*), showed an almost wild-type affinity for the nicotinic receptor.

This novel toxin photoprobe had various specific characteristics (Scheme 2). The desthiobiotin tag enables purification of the labeled subunits of the nAChR. The disulfide bond, linking the toxin to the radioactive photoprobe, can easily be reduced, allowing the release of the toxin at will after photolabeling and, therefore, the transfer of radioactivity from the ligand to the receptor. This feature facilitates the purification and the analysis of the labeled peptides (*10*), as we have then to deal with standard labeling with a small non-peptidic molecule. The length

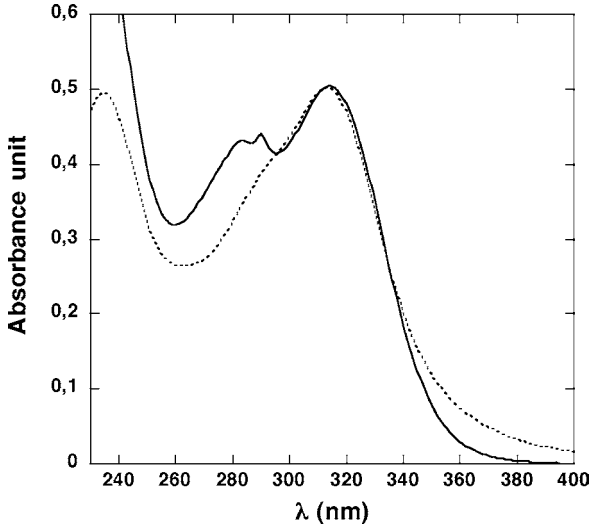

Figure 2. UV/visible spectrum of compound (**8**) (·····) and dtb-R33C-ArN_2^+ in water (—).

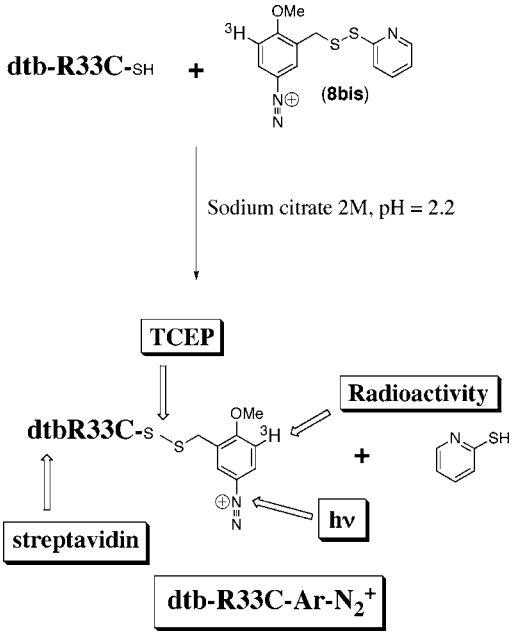
Scheme 2. Coupling of Aryldiazonium Salt (8bis) to dtb−R33C



(8.5 Å) between the α-carbon attached to the photosensitive moiety and the reactive carbon on the arylcation, produced by UV irradiation, is almost as short as the replaced arginine residue, enabling a precise mapping of the binding site. It is also positively charged, therefore probably being a better mime than standard azido, diazirine, and benzophenone photoprobes on position 33 of the toxin.

Photolabeling of *Torpedo marmorata* Membranes. The nAChR was irradiated in the presence of about 1 equiv of photosensitive toxin (dtb-R33C-ArN_2^+) at 323 nm, which is farther from the protein absorption band than the maximum wavelength of the photoprobe (314 nm). However, at this wavelength, the molar absorption coefficient is still close to the highest (Figure 2).

For analytical experiments, labeled membranes were centrifuged, and the pellets taken in Laemmli buffer and run on a 10% SDS-PAGE. The gel was then transferred onto a PVDF-membrane. Once dry, the latter was exposed on a β-imager (Figure 3). Mainly four bands could be seen for the pellet dissolved in nonreducing Laemmli buffer (lane 5). Their apparent molecular weights were consistent with those of the

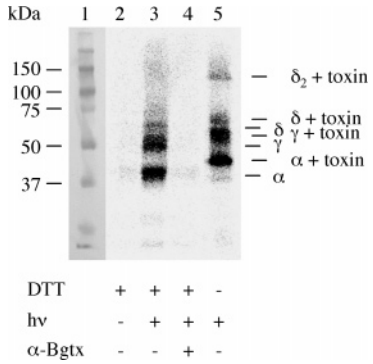


Figure 3. Detection of the nAChR labeled subunits by β-imaging. *Torpedo* membranes (2 μM α-bungarotoxin sites) were incubated with dtb-R33C-ArN_2^+ (0.95 equiv) and irradiated at 323 nm for 10 min, at 10 °C (see Experimental Procedures). Following irradiation, the membrane suspension was centrifuged at 22 000 g for 20 min at 4 °C, and the pellets solubilized in Laemmli sample buffer and run on 10% SDS-PAGE. Lane 1, molecular weight markers; lane 2, nonirradiated nAChR−photoprobe complex; lane 3, nAChR irradiated in the presence of dtb-R33C-ArN_2^+; lane 4, nAChR, preincubated with a large excess of α-bungarotoxin (20 equiv) and irradiated in the presence of dtb-R33C-ArN_2^+; samples corresponding to lanes 1−4 were dissolved in reducing Laemmli buffer; lane 5, nAChR irradiated in the presence of dtb-R33C-ArN_2^+ (nonreducing Laemmli buffer). After SDS-PAGE, the proteins were transferred to a PVDF-membrane and exposed to a β-imager.

α, γ, and δ subunits coupled to a toxin molecule, with the highest weight being consistent with the dimer δ_2 coupled to at least one toxin molecule. These two bands for the δ subunit show that, as is often the case, a mixture of monomers and dimers of nAChR were present in the torpedo membranes used. Three radioactive bands (lane 3) could be observed for the pellet dissolved in reducing Laemmli buffer. Their apparent molecular weights (38, 56, and 65 kDa) were consistent with those of the α, γ, and δ subunits, as expected after reduction of the disulfide bond linking the toxin to the receptor, leaving the radioactive probe on the receptor side.

The labeling yield was determined on a similar polyacrylamide gel, which was cut in 1 mm pieces and counted for $[^3H]$-radioactivity. The band at 38 kDa was the most labeled (59% of the total labeling, 7.6% of the added toxin), due probably, in part, to the presence of two α subunits, followed by the band at 56 kDa (28% of the total labeling, 3.2% of the added toxin), with the last one being the band at 65 kDa, which was the least labeled subunit (13% of the total labeling, 1.2% of the added toxin). As expected, controls (i) with no irradiation of the toxin−receptor complex (lane 2) or (ii) with preincubation of the nAChR with an excess of α-bungarotoxin before the addition of dtb-R33C-ArN_2^+ (lane 4) showed no incorporation of radioactivity, demonstrating the total specificity of photolabeling.

Desthiobiotin coupled to the N-terminus of the toxin analogue enabled purification on streptavidin beads of the whole set of labeled subunits (data not shown). Photolabeled membrane pellets were solubilized and denatured in lithium dodecyl sulfate, in order to purify the subunits covalently linked to the toxin by affinity chromatography on streptavidin Sepharose beads. Lithium chloride and lithium dodecyl sulfate were chosen instead of the sodium salts for solubility reasons, as sodium dodecyl sulfate precipitates rapidly in the presence of a high concentration of sodium chloride in buffers. Unexpectedly, recovery of the labeled subunits was not efficient enough when the disulfide bond linking the toxin to the irradiated photoprobe was directly reduced on the beads. To be quantitative, it required many repetitive reducing steps, preventing the recovery of the labeled subunits in a small volume. This was also the case when the beads were only incubated with an excess of biotin at room temperature. Thus, after many washings, the labeled subunits

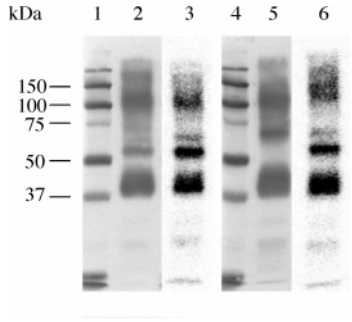

Figure 4. Labeling specificity of dtb-R33C-ArN_2^+. After irradiation, the solubilized dtb-toxin-nAChR covalent complex was purified on streptavidin Sepharose beads and run on SDS-PAGE, using reducing Laemmli buffer. The proteins were then transferred from the gel to another PVDF-membrane, which was incubated with mAb155 + mAb165 or mAb155 + mAb140 to visualize the α and γ, respectively, the α and δ subunits of the *Torpedo* nAChR (see Experimental Procedures). Lanes 1 and 4, prestained molecular weight markers; lane 2, immunoblot with mAb155 + mAb165 (α + γ); lane 3, β-imaging of lane 2; lane 5, immunoblot with mAb155 + mAb140 (α + δ); lane 6, β-imaging of lane 5.

were recovered by heating the beads at 70 °C in the presence of an excess of biotin, and then reduced and alkylated. The radioactivity was hence transferred from the ligand to the subunits by release of the toxin from the photoprobe. The labeled subunits were then separated by 10% SDS-PAGE.

On an analytical scale, the polyacrylamide gel was transferred on a PVDF-membrane, which was then exposed on a β-imager, followed by a Western blot with monoclonal antibodies mAb155, mAb165, and mAb140 directed against the α, γ, and δ subunits, respectively. This blot coupled to the $[^3H]$-image demonstrated unambiguously that the labeled bands were indeed the formerly cited subunits (Figure 4). As expected, no labeling of the β subunit was observed. However, a varying amount of aggregates could be observed by β-imaging as well as by Western blotting. These aggregates depended on the quality of the torpedo membrane preparation but might also form in part during the treatment of the streptavidin beads at 70 °C.

On a preparative scale (30 nmol of binding sites), the affinity purified subunits were run on three 1.5-mm-thick one-well SDS-PAGE. The labeled subunits were detected without any staining. Actually, we covered the gel for about 15 min with a dry PVDF-membrane. This contact was sufficient to transfer enough molecules to be detected on a β-imager. Superimposing this image to the gel enabled cutting of the labeled subunits.

Characterization of the Labeled Residues on the α Subunit. The gel fractions corresponding to the α subunit were digested "in-gel" with CNBr as described earlier (*14*). The extracted peptides were purified by HPLC on a Vydac C4 narrow-bore column (Figure 5). One major radioactive peak could be observed (fractions 39 to 44) corresponding to many poorly separated UV-detected peaks.

The 4 fractions containing most of the radioactivity (**40**, **41**, **42**, and **43)** were analyzed separately by sequential Edman degradation for ^3H and mass release on 28 cycles (Figure 6). For fraction **40**, 4 peptides beginning at αTrp118 (I_o = 124 pmol, R = 86%), αGlu172 (first 6 residues detected, I_o = 73 pmol, R = 58%), αLys179 (I_o = 81 pmol, R = 88%), and αVal405 (I_o = 45 pmol, R = 74%) could be detected. For fraction **41**, five peptides from the nAChR α-subunit were detected: the first sequence began at αTrp118 (I_o = 50 pmol, R = 92%), the second at αLys145 (I_o = 41 pmol, R = 79%), the third at αGlu172 (first 20 residues detected, I_o = 39 pmol, R = 83%), the fourth at αLys179 (I_o = 70 pmol, R = 88%), and the fifth at αPro309 (I_o = 55 pmol, R = 87%). For fraction **42**, 4 peptides beginning at αGlu172 (first 25 residues detected,

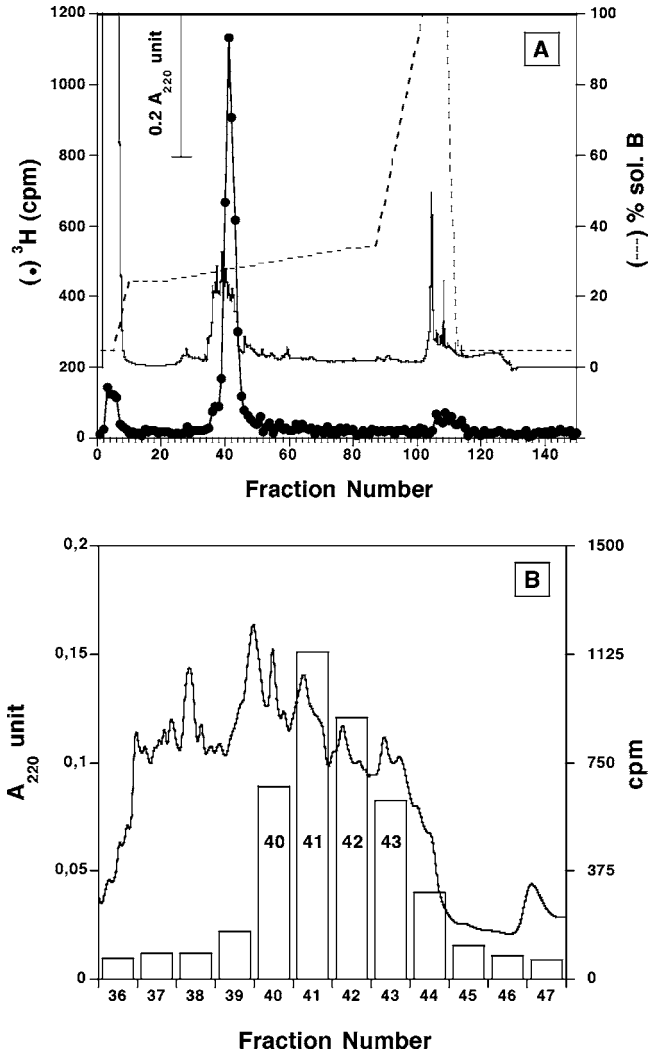

Figure 5. Reversed-phase HPLC of CNBr digests of the labeled α-subunit. *Torpedo* membranes (30 nmol, 2 μM α-bungarotoxin sites) were irradiated at 323 nm (300 μW.cm^{-2}) for 10 min, at 10 °C in the presence of [^{3}H]-dtb-R33C-ArN_2^+ (0.95 equiv). Following irradiation, the membrane suspension was centrifuged (22 000 g for 30 min, 25 °C), and the pellet solubilized in buffer A (Tris-HCl 50 mM, pH 8, LiDS 1%, LiCl 2 M). The labeled subunits were prepurified by affinity chromatography on streptavidin Sepharose beads (Amersham Biosciences) (6 mL), and the disulfide bonds were then reduced with TCEP and the cysteine blocked with iodoacetamide (see Experimental Procedures). The mixture was then concentrated on centricon-30 and subjected to 10% SDS-PAGE (three 1.5-mm-thick minigels). The labeled subunits were then excised from the gel, cut into small pieces, and cleaved "in gel" with CNBr. The extracted peptides were purified on a Vydac C4 narrow-bore column (2.1 × 250 mm; flow rate, 0.2 mL.min^{-1}; linear gradient, 5% B to 5% B in 10 min, then 5% to 25% B in 10 min, then 25% to 35% B in 155 min, then 35% to 100% B in 30 min, then 100% to 100% B in 15 min, then 100% to 5% B in 5 min. A: H_2O, 0.1% TFA. B: 70% CH_3CN, 30% *n*-propanol, 0.095% TFA). UV absorbance was monitored at 220 nm. Fractions (400 μL) were collected, and aliquots were counted for radioactivity in a scintillation counter. (A) (-----) Gradient profile, (—) UV profile, (-●-) [^{3}H] profile. (B) Zoom between fractions 36 and 47; (—) UV profile; ^{3}H profile has been represented as a histogram.

I_o = 28 pmol, R = 89%), αLys179 (I_o = 63 pmol, R = 87%), αPro309 (I_o = 116 pmol, R = 85%), and αLys330 (I_o = 35 pmol, R = 91%) were detected. For fraction **43**, 3 peptides from the α-subunit were detected: the first primary sequence began at αGlu172 (first 10 residues detected, I_o = 24 pmol, R = 93%), a second at αLys179 (I_o = 57 pmol, R = 87%), and a third at αLys330 (I_o = 75 pmol, R = 86%).

As can be seen, the two unique peptides common to fractions **40**, **41**, **42**, and **43** extend from αGlu172 and αLys179 and harbor the critical C loop of the α-subunit, which occludes the ligand binding site and wraps agonists. However, only the peptide extending from αLys179 could be detected during the 28 cycles; the other peptide was already undetectable from cycles 7 and 11 for fractions **40** and **43**, respectively. The 4 fractions also share 2 common positions of radioactive release, on cycles 12 and 20, corresponding to αTyr190 and αTyr198, respectively, on the peptide extending from αLys179. A third radioactive amino acid could be detected at cycle 14 for fractions **42** and **43**, corresponding to αCys192 on the same peptide, as αAla343, which belongs to the peptide extending from αLys330, is cytoplasmic. As observed in fractions **40**, **41**, and **42**, a very faint labeling could be seen on cycle 19 which might correspond to αTyr190 on the peptide beginning at αGlu172. Such an increase in radioactive detection was also visible on cycle 21, in fractions **42** and **43**, and might correspond to αCys192 on the same peptide.

It must be noted that a small radioactive peak was repeatedly detected at the third cycle. It would correspond to a faint labeling of αTyr181 on the peptide starting at αLys179 or of αGly174 on the peptide starting at αGlu172, which seems unreasonable considering their orientation and their distance to the ligand binding site (*19*). Moreover, repetitive experiments showed that the intensity of this peak was always low and not related to the intensity of the peaks at positions 12, 14, and 20 (data not shown). Further studies are necessary to explain its presence. Hence, the labeled residues are unambiguously primarily αTyr190, followed by αTyr198, with αCys192 being less labeled.

DISCUSSION

Despite numerous photolabeling experiments of the muscle-type nicotinic acetylcholine receptor with α-neurotoxins in these past decades (*10*, *20*−*29*), no labeled residue belonging to the toxin-binding site could be characterized. The only success (*10*) managed a label-transfer technique with a commercial derivative. However, the linker between the photoactivatable moiety and the toxin was, at that time, too long to explore the binding site.

Recently, we described the synthesis of a novel short cleavable photoactivatable probe with dual functionality, which can be selectively linked to any natural or engineered cysteinyl residue in peptides or proteins through a disulfide bond (*12*). This probe was coupled to a synthetic analogue of *Naja nigricollis* α-neurotoxin, in which a cysteine residue replaced Arg33 on the tip of loop II (Figure 1). Chemical synthesis of this toxin analogue allowed modification on a critical position, which could not be modified using wild-type toxins. This new photosensitive toxin analogue efficiently coupled to the receptor α subunit, but unfortunately, we could not get through the characterization of the labeled residues, as the synthesis of a radioactive version of this probe appeared impossible.

We developed here a novel aryldiazonium photoprobe, in which a *p*-methoxy group replaced the stabilizing *p*-dimethylamino moiety (Scheme 1). This modification enabled the synthesis of a bifunctional cleavable tritiated photoactivatable probe via an iodinated derivative. The aryldiazonium salt showed long stability when stored in acidic conditions. The use of tritium makes it safe against irradiation and radioactively stable for years. However, the pH needed for coupling the aryldiazonium to the ligand restricts its use to acid-stable ligands. To our knowledge, no commercial molecule is shorter than 14 Å (compared to 8 Å here), and only one other short radioactive photocrosslinking/label-transfer probe was described (*30*). It harbors a benzophenone photosensitive moiety, is radioiodinatable, and has about the same length than our probe, but is more bulky. However, the authors did not get through the character-

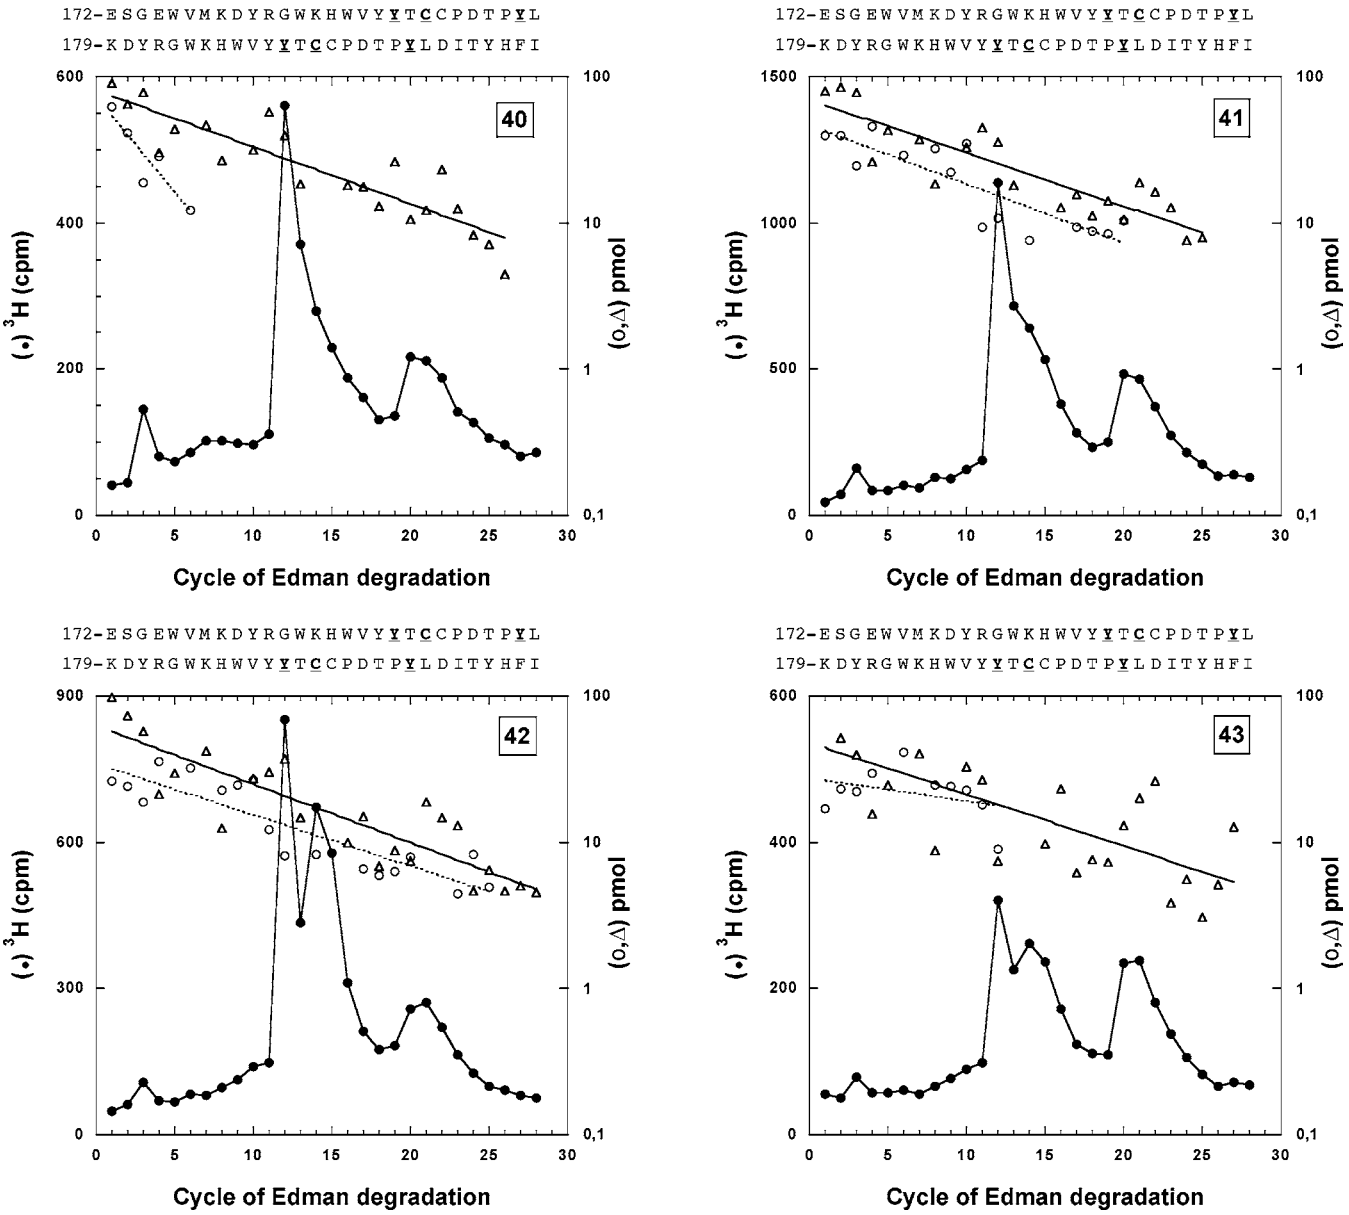

Figure 6. Identification of nAChR α-subunit amino acids photolabeled by [^{3}H]-dtb-R33C-ArN_2^+: ^{3}H and mass release at each cycle upon sequential Edman degradation of HPLC fractions **40**, **41**, **42**, and **43** (see Figure 5B). For fraction **40**, 2.6×10^4 cpm was loaded on the filter. After 28 cycles, 16% of the radioactivity (4200 cpm) remained on the filter and 17% (4300 cpm) was recovered. Four peptides from the nAChR α-subunit were detected: the first primary sequence began at αTrp118 (I_o = 124 pmol, R = 86%), a second at αGlu172 (I_o = 73 pmol, R = 58%), a third at αLys179 (I_o = 81 pmol, R = 88%), and a fourth at αVal405 (I_o = 45 pmol, R = 74%). For fraction **41**, 4.4×10^4 cpm was loaded on the filter. After 28 cycles, 17% of the radioactivity (7500 cpm) remained on the filter and 18% (7,800 cpm) was recovered. Five peptides from the nAChR α-subunit were detected: the first primary sequence began at αTrp118 (I_o = 50 pmol, R = 92%), a second at αLys145 (I_o = 41 pmol, R = 79%), a third at αGlu172 (I_o = 39 pmol, R = 83%), a fourth at αLys179 (I_o = 70 pmol, R = 88%), and a fifth at αPro309 (I_o = 55 pmol, R = 87%). For fraction **42**, 3.5×10^4 cpm was loaded on the filter. After 28 cycles, 14% of the radioactivity (4800 cpm) remained on the filter and 16% (5800 cpm) was recovered. Four peptides from the nAChR α-subunit were detected: the first primary sequence began at αGlu172 (I_o = 28 pmol, R = 89%), a second at αLys179 (I_o = 63 pmol, R = 87%), a third at αPro309 (I_o = 116 pmol, R = 85%), and a fourth at αLys330 (I_o = 35 pmol, R = 91%). For fraction **43**, 2.4×10^4 cpm was loaded on the filter. After 28 cycles, 14% of the radioactivity (3300 cpm) remained on the filter and 15% (3600 cpm) was recovered. Three peptides from the nAChR α-subunit were detected: the first primary sequence began at αGlu172 (I_o = 24 pmol, R = 93%), a second at αLys179 (I_o = 57 pmol, R = 87%), and a third at αLys330 (I_o = 75 pmol, R = 86%). The mass release curves were only represented for the two unique common peptides to fractions **40**, **41**, **42**, and **43** extending from αGlu172 and αLys179. Their primary sequences are shown on top of the figures. Labeled residues are indicated in bold underlined characters.

ization of the labeled residues. Our probe showed also good labeling yields and is potentially dual, as the aryldiazonium moiety can be changed easily in an arylazido group, just by working in buffers containing sodium azide (*12*).

The aryldiazonium photoprobe was subsequently coupled to a previously described (*11*) cysteine analogue of *Naja nigricollis* α-neurotoxin, through a cleavable disulfide bond. Moreover, to facilitate the purification of the labeled subunits, we tagged the N-terminus of the toxin with desthiobiotin. Assembly on the same toxin probe of a tag and a cleavable disulfide bond linking the toxin to a radioactive photoprobe allowed us to characterize for the first time the labeled residues of the toxin-binding site on the α subunit of the nAChR.

This tagged photoactivatable toxin labeled the torpedo nicotinic acetylcholine receptor with a 12% overall yield on the α (7.6%), γ (3.2%), and δ (1.2%) subunits, showing a small preference for the α subunit (3.8% on one α subunit at least). This may be due in part to the presence on this subunit of a higher number of aromatic amino acids, which are preferentially targeted by the arylcation formed through irradiation of an

aryldiazonium moiety. Edman degradation of purified CNBr fragments of the α subunit showed that three residues (αTyr190, αTyr198, and αCys192) were labeled. They all belong to the C loop, which wraps the agonists and occludes the binding site. They also belong to the group of residues labeled by another aryldiazonium antagonist named DDF (*31*, *32*). But, in contrast to DDF, no labeling of αTrp149 could be detected, as we did not see any radioactive peak on cycle five when the CNBr fragments of HPLC fraction **41**, containing a sequence beginning at αLys145, were submitted to Edman degradation.

αTyr190, αCys192, and αTyr198 are located at less than 10 Å from the toxin backbone at position 33, as the reactive carbon of the photoprobe is located at about 8.5 Å, at most, from the Cys33 α-carbon. This is about the length of residue Arg33, meaning that the labeled residues are in close contact to Arg33 in the receptor/wild-type toxin complex. Our data corroborate double mutant cycle analysis with another short toxin (NmmI) (*8*), showing the proximity of αTyr190 and αTyr198 to Arg33. Notably, our results, obtained with a short α-neurotoxin, also fit well to the structure of the complex between a long neurotoxin and AChBP (*4*), where the shortest distances between the α-carbon of Arg33 and the side chains of the equivalent residues of αTyr190, αCys192, and αTyr198 on AChBP are close to 4−6 Å. This confirms a similar binding mode for short and long neurotoxins, at least at position 33, where the arginine residue may possibly act as a pivot. In contrast, our results do not agree with the recently proposed model of interaction between the short toxin NTII and the nAChR (*9*) in which the orientation of the toxin would hardly allow the labeling of αTyr190 and αCys192.

In a prospective way, if we suppose that short- and long-chain toxins bind in a similar manner, the AChBP/α-cobratoxin complex structure may also give a possible explanation of the different labeling yields between the γ and δ subunits, as (i) the common Trp55 would be too far away (>11 Å) to be labeled and (ii) γTyr116, which would be located as close to Arg33 as the three labeled α residues, is replaced by the nonaromatic δThr119, which is not a preferential target of aryldiazonium photoprobes. However, these conclusions need further work in the characterization of the γ- and δ-subunit labeled residues.

The novel cleavable photoprobe described in this paper may be of great use for photocrosslinking/label transfer experiments between macromolecules and peptidic ligands. The literature shows no general rule to choose the best photosensitive moiety, when a photoaffinity labeling experiment on a given ligand−receptor complex is planned. Therefore, two and potentially three radioactive label transfer probes with various reactivity are welcome in the "photocrosslinking/label transfer kit".

ACKNOWLEDGMENT

We thank Dr. Tzartos for a generous gift of monoclonal antibodies directed against the nAChR subunits and Gilles Mourier for technical support and fruitful discussion on peptide synthesis.

NOTE ADDED AFTER ASAP PUBLICATION

This manuscript was released ASAP on October 19, 2006 with missing information in the list of authors. The correct version was posted on October 25, 2006.

Site-Specific Attachment of Polyethylene Glycol-like Oligomers to Proteins and Peptides

Yoann Marsac,† Janina Cramer,† Diana Olschewski, Kirill Alexandrov, and Christian F. W. Becker*

Max-Planck Institute of Molecular Physiology, Department of Physical Biochemistry, Otto-Hahn Str. 11, 44227 Dortmund, Germany. Received July 3, 2006; Revised Manuscript Received October 2, 2006

Modification of proteins with polymers is a viable method to tune protein properties, e.g., to render them more water-soluble by using hydrophilic polymers. We have utilized precision-length, polyethylene glycol-based oligomers carrying a thioester moiety in transthioesterification and native chemical ligation reactions with internal and N-terminal cysteine residues in proteins and peptides. These reactions lead to uniquely modified proteins with an increased solubility in chaotrope- and detergent-free aqueous systems. Polymer modification of internal cysteines is fully reversible and allows generation of stable protein−polymer conjugates for enzymatic manipulations as demonstrated by proteolytic cleavage of a protein construct that was only soluble in buffers incompatible with protease activity before polymer modification. The permanent polymer modification of a Rab protein at its N-terminal cysteine produced a fully active Rab variant that was efficiently prenylated. Thus, PEGylation of prenylated proteins might be a viable route to increase water solubility of such proteins in order to carry out experiments in detergent- and lipid-free systems.

INTRODUCTION

Polymer modifications of proteins have become a major focus of protein drug development (*1*, *2*). The attachment of polymers such as polyethylene glycol (PEG) to side chain groups of certain amino acids improves the behavior of proteins with regard to their biomedical properties. These modifications lead to an increase in solubility, which enhances bioavailability, help to resist proteolytic degradation, reduce immunogenicity, and prolong plasma circulation times (*3*, *4*). However, PEG modifications are desirable not only for certain medicinal applications for the above-mentioned reasons, but also for functional analysis of proteins in biophysical or biochemical studies. Site-selective and reversible attachment of polymers leads to proteins with new properties with regard to their aggregation propensity or their propensity to absorb to glass or plastic surfaces. Proteins modified with polymers could help to overcome experimental limitations when proteins are needed at specific concentrations well beyond their solubility in aqueous systems. This point is of special interest whenever integral membrane proteins or membrane-attached proteins are used in solution-based assays that do not allow the use of detergents or liposomes (*5*). Furthermore, such solubilizing modifications can help to process peptides and proteins in proteolytic digests and other enzyme-based assays that otherwise cannot be used due to their limited solubility in chaotrope-free buffers.

Additionally, the introduction of such polymers increases the hydrodynamic radius of proteins and might facilitate separation from smaller impurities by dialysis or ultrafiltration (*6*). Biophysical probes can be attached to proteins by exploiting the polymers as inert linker molecules that can be uniquely modified with diverse functionalities.

A variety of methods for the amino acid specific modification of proteins and peptides has been suggested that allow the irreversible as well as the reversible modification of specific residues such as lysine and cysteine by using chemistry that leads to secondary amines, thioethers, or disulfides (*7*−*9*). Recently, a procedure was introduced that leads to site-specific PEGylation of native disulfide bonds by bisalkylation of the two thiol groups involved (*10*). However, thioester chemistry has experienced only very limited use for side chain modification of proteins, even though this type of chemistry is heavily used in protein synthesis via native chemical and expressed protein ligation, as well as by nature for posttranslational attachment of lipid groups (*11*, *12*). During NCL and EPL, a nucleophilic attack of the thiol group of a cysteine residue with an unblocked amino group leads to an initial transthioesterification of a thioester-containing compound, which can be a small molecule or a large protein. Upon formation of this intermediate, the amino group is in close proximity to the thioester and can easily undergo a rearrangement to form an amide bond via a 5-membered transition state (Scheme 1B). This reaction is driven by the final S-to-N acyl shift that leads to the formation of an amide bond between the two reaction partners and can be exploited to attach non-natural groups such as PEG-based polymers to the N- and C-termini of proteins via a stable amide bond. Generally, an excess of exogenous thiols such as thiophenol, mercaptoethanesulfonic acid (Mesna), or, as recently suggested, 4-mercaptophenyl acetic acid MPAA (*13*) has to be added to the reaction mixture in order to form reactive thioester species, keep the cysteine residues in a reduced state, and reverse transthioesterification with internal cysteine residues (Scheme 1A). Such transthioesterification reactions lead to the attachment of thioester species to unblocked thiol groups of internal cysteines in peptides and proteins and have been observed for reactions with small molecule thioesters (*14*, *15*). Therefore, thioester bond formation with thiol groups of cysteine side chains can potentially be used to selectively modify peptides and proteins. These thioester bonds are stable at physiological and acidic pH and have been utilized in chemical protein synthesis to successfully link peptide segments (*16*, *17*).

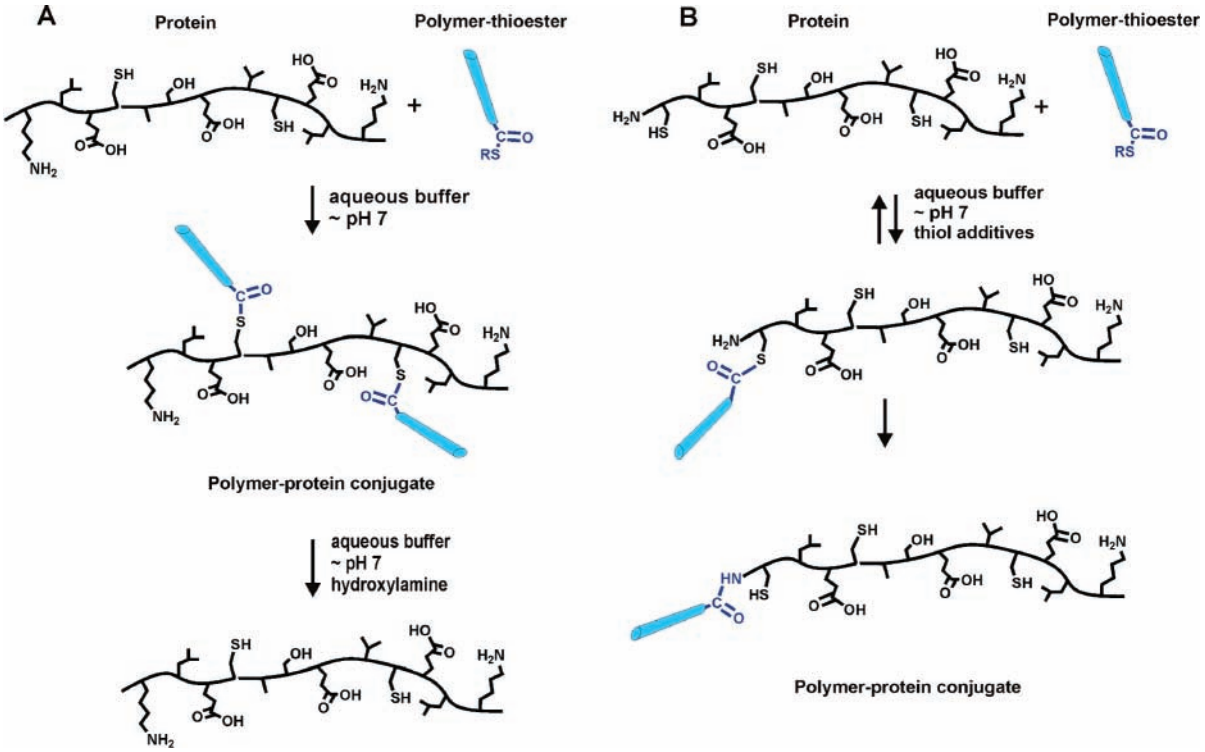
Scheme 1. Reactions of Polymer Thioesters with Cysteine Residues in Peptides and Proteins[a]



[a] (A) Reaction with internal thiol groups to form reversibly polymer-modified polypeptides. Polymer modifications can be removed by treatment with a strong nucleophile or at pH > 8.5. (B) Native chemical ligation reaction of polymer thioester with an N-terminal cysteine residue to give an irreversibly polymer modified protein/peptide.

EXPERIMENTAL PROCEDURES

Materials. *tert*-Butyloxycarbonyl (Boc)-protected amino acids, 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), and the Boc-amino acyl-OCH_2-phenylacetamidomethyl resins were purchased from Novabiochem (Schwalbach). Trifluoroacetic acid was from Roth (Karlsruhe). Hydrogen fluoride was obtained from Merck (Darmstadt). All other chemicals were obtained from Sigma-Aldrich at the highest purity available.

Peptide Synthesis. Solid-phase peptide synthesis was performed on a custom-modified 433A peptide synthesizer from Applied Biosystems, using Boc-chemistry, *in situ* neutralization, and HBTU activation protocols (*18*). The peptides were deprotected and simultaneously cleaved from the resin using anhydrous HF. Subsequently, they were precipitated with ether, and the crude products were dissolved in 50% aqueous acetonitrile (0.1% TFA) and lyophilized. The peptide segments were purified by RP-HPLC on a C4-column from Vydac (Hesperia, CA) using linear gradients of solution B (acetonitrile with 0.08% trifluoroacetic acid) in solution A (water with 0.1% trifluoroacetic acid). The elution of the peptide was monitored at 214 nm.

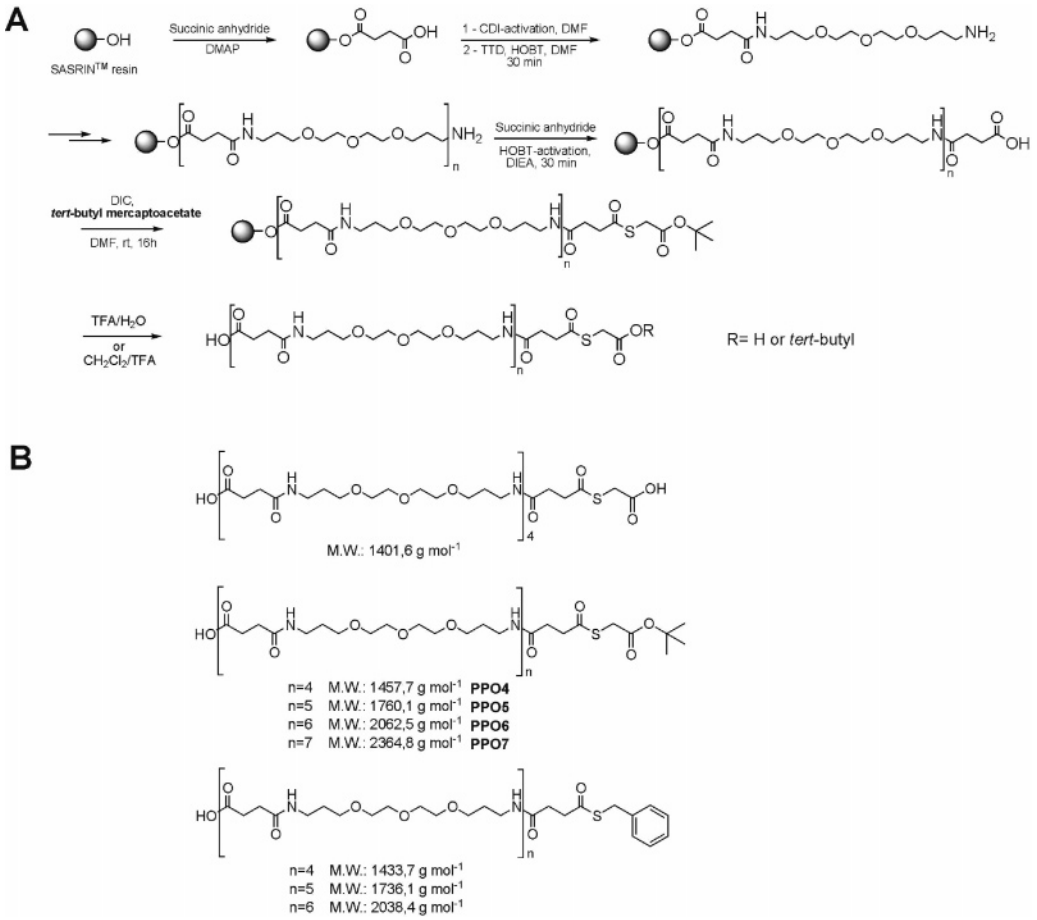
Polymer Synthesis. Polyethylene glycol polyamide oligomers (PPOs) were synthesized on SASRIN resin (Bachem) starting with the coupling of succinic anhydride (10 equiv) in the presence of *N*,*N*-dimethyl-4-aminopyridine (10 equiv) for 30 min. The resin was washed with dimethylformamide (DMF) and treated with a 0.5 M of 1,1′-carbodiimidazole in DMF for 30 min and then washed with DMF. (4,7,10)-Trioxa-1,13-tridecanediamine (TTD) was activated with a 0.5 M 1-hydroxybenzotriazole (HOBT) solution in DMF and added to the resin for 30 min. After washing the resin with DMF, another succinic anhydride unit was added to the resin activated with 0.5 M HOBT solution and diisopropylethylamine (DIEA) for 30 min. Further extension of the oligomer chain was achieved as described. For synthesis of the thioester, after drying the resin, *tert*-butyl mercaptoacetate (4 equiv) and 1,3-diisopropylcarbodiimide (4 equiv) were combined in DMF in a solid-phase vessel. After one night, the PPO−resin was washed by DMF (1 min) and CH_2Cl_2 (1 min) and then dried in vacuo for cleavage. Different conditions of cleavage reaction were attempted: For R = H, a 95/5 TFA/H_2O mixture was used for 15 min to deprotect the *tert*-butyl group and cleave the thioPEG from the resin. For R = *tert*-butyl, the CH_2Cl_2/TFA 97/3 mixture used for 20−30 min led to efficient cleavage of the PPO from the resin without deprotection of *tert*-butyl.

HPLC and Mass Spectrometry. HPLC analysis of PPOs and peptides was performed on an analytical RP-C4-column (Vydac) at a flow rate of 1 mL/min over 30 min with a gradient from 5% to 65% (v/v) buffer B (CH_3CN + 0.08% TFA) in buffer A (H_2O + 0.1% TFA). Peak areas were used to determine peptide concentrations in solution. Polyethylene glycol polyamide oligomer and peptide/protein masses were determined by electrospray ionization mass spectrometry on an LCQ Advantage Max (Finnigan) operating in positive ion mode. The molecular masses were deconvoluted from the charged ion spectra.

PPO Modifications. *N-Terminal Modification.* Peptides and proteins with N-terminal cysteines were dissolved in HEPES or NaPi buffered solutions (pH ∼7.5) at concentrations of 100 μM up to 1 mM and a solution containing 15 equiv TCEP (tris-(2-carboxyethyl)phosphine hydrochloride), 80 equiv Mesna (sodium 2-mercaptoethanesulfonate), and 10 equiv PPO−thioester was added. The reaction mixture was gently agitated overnight at room temperature.

Modification of Internal Cysteine Side Chains. Peptides and proteins with internal cysteines were dissolved in HEPES or NaPi buffered solutions (pH ∼7.5) at concentrations of 30 μM up to 1 mM. 15 equiv of TCEP and a 5−10-fold excess of PPO thioester over every sulfhydryl group was added. The reaction

Scheme 2. Synthesis Scheme and Structure of Precision-Length Polymer Thioesters Used in Peptide and Protein Modification Reactions



mixture was incubated overnight at room temperature. Excess PPO_n was removed either by RP-HPLC for peptides or by dialysis using a 10 kDa molecular weight cutoff. If necessary, buffers containing 6 M guanidine were used to solubilize peptides and proteins.

PPO Removal with BME and Hydroxylamine. A 50 mM hydroxylamine solution (NaPi buffered at pH ~7.5) was added to the PPO-modified protein or peptide to adjust a final hydroxylamine concentration of 12.5 mM. The reaction mixture was gently shaken and incubated at room temperature. Complete conversion was achieved between 1 and 5 h, depending on the protein/peptide used. Similar results were obtained by treating PPO-modified protein or peptide with 50 equiv of BME for 1 to 4 h at room temperature and gentle shaking.

Protein Expression. The coding sequences for Tev_Ras_Mxe (H-Ras, aa 51−180 with an N-terminal His-tag and a Tev site) and Tev_PrP (mouse Prion protein, aa 134−232 with an N-terminal His-tag and a Tev site), respectively, were cloned into the pTXB3-vector (New England Biolabs) and expressed in *E. coli* BL21(DE3) RIL as fusion proteins with the *GyrA* intein from *Mycobacterium xenopis* and a chitin-binding domain.

Protein expression was induced with IPTG. The cells were harvested by centrifugation and lysed in a M110S Microfluidizer (Microfluids Corporation, Newton). Cell debris and insoluble proteins were removed by centrifugation, and the supernatant was loaded onto Ni-NTA superflow matrix (Qiagen) for purification. Tev_PrP and Tev_Ras_Mxe were deposited in inclusion bodies during expression and had to be dissolved in 6 M guanidine prior to Ni-NTA purification.

Expression Rab6. Expression and purification of recombinant Rab6 containing an N-terminal cysteine residue instead of methionine was described elsewhere (*14*).

TEV Digest. PPO_7-modified His_8TEV_PrP134−232 was dialyzed into a buffer consisting of 1 M urea, 50 mM NaPi, 0.5 mM EDTA, and 1 mM TCEP. Proteolysis was achieved with an addition of $^1/_{60}$ equiv of TEV protease for 16 h at RT. Removal of TEV protease and the cleaved-off N-terminal protein segment was achieved by Ni-NTA purification.

Prenylation Assay. Time course of fluorescence change upon prenylation catalyzed by RabGGTase (0.02 μM) on Rab6:REP-1 complex (6 μM) in the presence of NBD−FPP (4 μM) at 37 °C was monitored by a change in fluorescence excited at 479 nm and recorded at 520 nm. Assay conditions: 50 mM HEPES, pH 7.2, 50 mM NaCl, 5 mM DTE, 2 mM $MgCl_2$, 10 μM GDP.

RESULTS AND DISCUSSION

Here, we report the use of polyethylene glycol-like oligomers equipped with a thioester moiety in native chemical ligation reactions with N-terminal cysteine residues as well as in transthioesterification reactions with cysteine side chains within proteins to generate stable protein−thioester species (Scheme 1).

The polyethylene glycol polyamide oligomers (PPO) were synthesized by stepwise solid-phase synthesis using (4,7,10)-trioxa-1,13-tridecanediamine (TTD) and succinic anhydride as building blocks. Discrete oligomers and polymers composed of these building blocks have been used as inert peptide linkers and solubilizing modifications as well as enhancers of pharmacokinetic properties of protein pharmaceuticals (6, *19*, *20*). The obtained PPOs were furnished with a variety of thioesters and varied in length from 3 to 7 TTD subunits and therefore from 1154 to 2365 Da in molecular weight (Scheme 2). All of them were produced in high yields (50−75%) and with excellent

purity of ∼92−95%. Formation of mercaptoacetate, *tert*-butyl-mercaptoacetate, and benzylmercaptane thioesters was achieved on the solid support by treatment with mercaptoacetate, *tert*-butyl mercaptoacetate, or benzylmercaptane, respectively, in the presence of DIC (*21*). Closely related polyethylene glycol (PEG)−thioesters are commercially available and could, in principle, be used in a similar way as described below. However, since these commercially available PEG−thioesters are polymerization products and therefore not monodisperse, characterization of the resulting protein−polymer conjugates would be more difficult.

Modified Peptides. The obtained PPO thioesters were initially tested in native chemical ligation reactions with a N-terminal cysteine containing synthetic peptide mimicking the last 36 amino acids of the Ras-binding domain (RBD) of cRaf1 kinase (*22*, *23*). The reactions were highly specific and produced the peptide carrying one polymer modification at its N-terminus (Figure 1A). A typical peptide−oligomer conjugate consisting of the RBD peptide and PPO_7 exhibited a 10-fold increase in solubility in chaotrope-free aqueous systems (0.5 mg/mL compared to 0.05 mg/mL) and a distinct change toward a lower retention time on a RP-C4 column (Figure 1B). This indicates the increase in hydrophilicity induced by the attached PPO_7.

To demonstrate that sulfhydryl groups of internal cysteine residues are accessible to transthioesterification reactions, we chose a 45 amino acid long fully reduced synthetic human β-defensin (hBD-3, 45 amino acids) (*24*) that contains 6 internal cysteine residues. After 12 h incubation at room temperature of PPO_7 with hBD-3, a mixture of different PPO_7-modified species was obtained that exhibits an ambivalent solubility behavior with high water solubility as well as a dramatically increased solubility in organic solvents such as ethanol and tetrahydrofurane (Figure 2). The hBD-3−PPO_7 conjugates were used to study the stability of the thioester linkage between the polymers and the peptide. After up to 24 h at RT and at pH values ranging from 4.0 up to 8.0, no significant thioester hydrolysis was found. However, at a pH above 8.5, a shift to hBD-3 species with less PPO_7 moieties attached was observed, which leads to the conclusion that thioester hydrolysis above pH 8 is accelerated (Figure 2B). In the presence of low concentrations of thiols such as Mesna and DTT (0.5 to 2 mM) that, in principle, can undergo transthioesterification reactions with the polymer−protein thioester conjugate, only very slow removal of polymer modifications was observed. Efficient removal was achieved by addition of strong nucleophiles such as hydroxylamine that lead to release of the polymers and produces unmodified peptide after 1 to 5 h at RT. Hydrolysis of the thioester bonds at pH > 8.5 as well as treatment with thiols was slower and led to less homogeneous samples. Since the PPO modifications are stable at conditions commonly used for biochemical and biophysical analysis of proteins but can be easily removed with protein-friendly reagents, this approach for the (transient) PEGylation of proteins could prove to be a highly

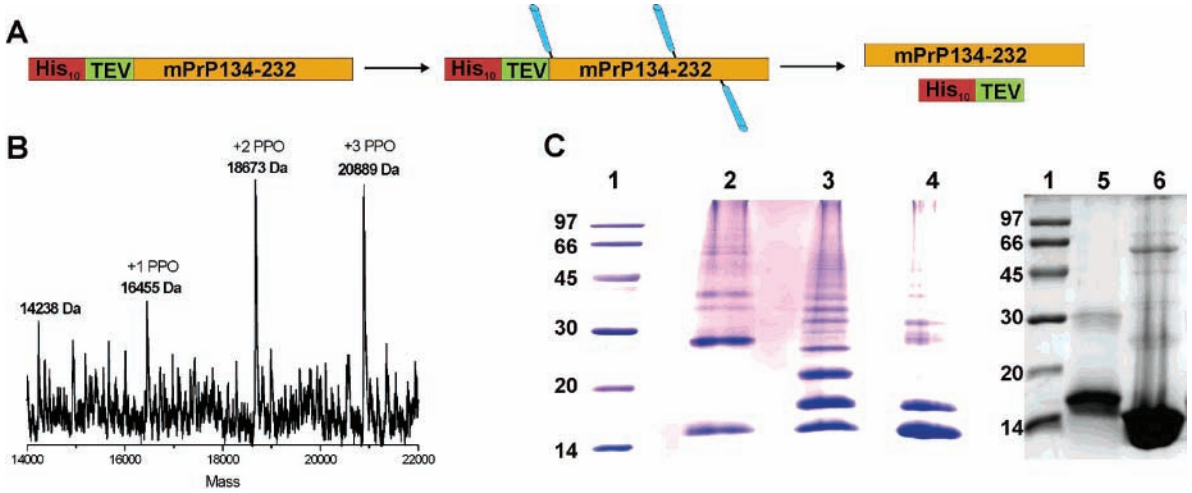

Figure 3. Characterization of PPO-modified Tev_PrP. (A) Polymer modification reaction followed by protease cleavage and removal of polymers. (B) Deconvoluted mass spectrum of PEG-modified TEV_PrP (M = 14 235 Da, 3 Cys) after 16 h of reaction with 5 equiv/Cys of PPO_7 thioester in denaturating buffer (6 M GdmCl, 50 mM Tris pH 8.0). (C) Coomassie-stained SDS-PAGE of TEV_PrP PEGylation reaction; lane 1, protein marker; lane 2, TEV_PrP; lane 3, crude PEGylation showing a mixture of conjugates containing $(PEG_7)_n$−protein species with n = 0, 1, 2, and 3; lane 4, incubation of PPO_7-modified Tev_PrP diluted 10-fold with 50 mM hydroxylamine in 6 M GdmCl, 100 mM sodium phosphate, pH 7.2 for 2 h; lane 5, TEV_PrP; lane 6: PrP134−232 after treatment with TEV protease.

valuable tool for purification and analysis of otherwise insoluble proteins. It should be noted that the different polymer thioester species exhibited a marked difference in reactivity with the *tert*-butylmercaptoacetate thioester giving the most efficient labeling yields when compared to the mercaptoacetate and benzylmercaptane thioester polymers. This behavior is difficult to explain but might be due to favorable electronic and steric conditions of the *tert*-butylmercaptoacetate thioester, which render this variant more reactive.

Modified Proteins. As a first application, we chose a segment of the mouse Prion protein comprising residues 134−232 with an N-terminal octa-histidine tag and a TEV protease cleavage site that in our experience was difficult to solubilize and handle (Figure 3) (*25*, *26*). This protein construct contains three cysteine residues that are available for reaction with thioester-tagged polymers. The transthioesterification reaction was carried out under denaturing conditions by using a 5-fold excess of polymer over every cysteine residue in the protein and yielded polymer-modified protein (Figure 3A). These modifications could be removed by a brief treatment with hydroxylamine (1 h at RT). The mixture of Tev_PrP modified with 1, 2, or 3 PEGs respectively was easily transferred into buffer conditions (1 M urea at pH 8) that allowed proteolytic removal of the N-terminal His-tag and protease recognition site with excellent yields. In contrast to this behavior, the non-polymer-modified counterpart could only be solubilized at high chaotrope concentrations (6 M Gdn or 8 M urea), which prevents enzymatic processing of the target protein. A brief treatment (1 h at RT) with hydroxylamine gave the desired PrP134−232 with an overall yield of 60% (Figure 3B).

Similar modification experiments were performed with a Tev_Ras51−180_GyrA construct with an N-terminal hexahistidine tag, a TEV-protease site, and a C-terminal fusion to the GyrA intein of *Mycobacterium xenopi* (*27*, *28*). This protein contains 7 internal cysteines and was modified with PPO_7 using similar conditions as described above (data not shown). The resulting protein−polymer conjugate could be transferred into low chaotrope buffer as well, even though it did not solubilize as efficiently as the PrP construct. However, modification of proteins containing multiple internal cysteine residues appears to be incomplete in most cases. This problem cannot be easily overcome by increasing the amount of PPO−thioester and might be related to secondary structure effects and/or formation of disulfide bonds under the reaction conditions used. The addition of phosphine-based reducing agents during the modification reaction might help to overcome this problem, as well as the use of strongly denaturing conditions that could be induced by heating of the reaction mixture or addition of denaturing detergents.

The procedure described here establishes access to transiently polymer modified proteins that are, prior to polymer modification, insoluble in chaotrope-free buffers. We demonstrate that the solubilized PPO−protein conjugates can be processed by specific proteases. Furthermore, removal of the polymer modifications is efficient and provides an unaltered polypeptide chain that could again form essential disulfide bonds during oxidative refolding.

Modified Rab Protein. Rab proteins are central regulators of vesicular transport and are involved in vesicular budding, targeting, and fusion (*29*). These proteins are attached to their resident membranes by virtue of C-terminal geranylgeranyl group(s). This modification is attached posttranslationally to one or two C-terminal cysteine residues by Rab geranylgeranyl transferase (RabGGTase) (*30*). RabGGTase is a multimeric enzyme consisting of catalytic α/β heterodimer and an accessory factor termed Rab escort protein (REP). REP functions as a molecular chaperone that delivers newly synthesized Rab proteins to the catalytic α/β heterodimer and then upon catalysis delivers the prenylated protein to the target membrane. Central to the function of REP protein is its ability to maintain in solution otherwise insoluble lipidated RabGTPases (*31*). In order to study the interaction of Rab GTPases and other prenylated proteins with their interaction partners and membranes, it would be very desirable to obtain them soluble in prenylated form without the native chaperones attached to them. We surmise that this could be achieved by site-selective PEGylation. This approach would provide a protein−PPO conjugate with a well-defined molecular structure and a potentially increased solubility in water.

Initial attempts to modify Rab proteins with commercially available PEGs functionalized with maleimide groups did not produce any site-specifically modified proteins and always interfered with subsequent prenylation assays, since sulfhydryl groups are nonspecifically modified by this reaction and, in particular, the C-terminal cysteine residues were no longer available for prenyl transfer. In order to circumvent this problem, we applied the above-described procedure that leads to reversible

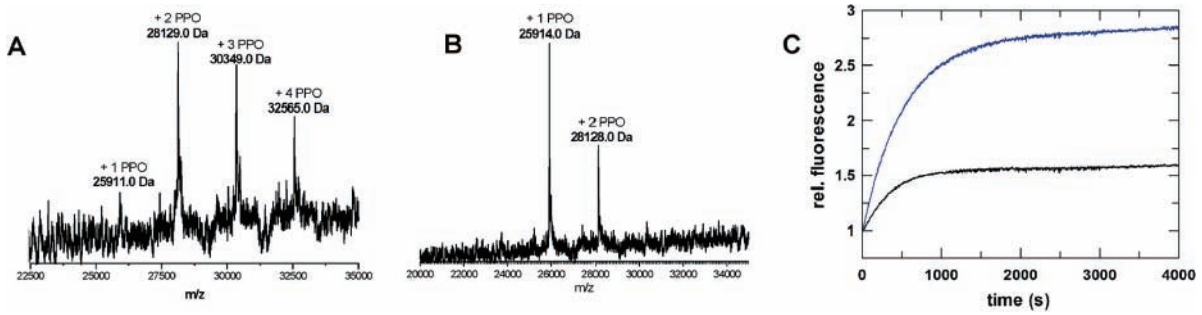

Figure 4. PPO_7 modification of Rab6 and its use in a prenylation assay. (A) Deconvoluted ESI-MS of PPO_7-modified Rab6 prior to hydroxylamine treatment. (B) Deconvoluted ESI-MS of PPO_7-modified Rab6 after hydroxylamine treatment (1 h at RT). PPO modification of internal cysteine residues and nonreversible PPO attachment to N-terminal cysteines.

Rab6 is a well-studied Rab GTPase involved in control of vesicular trafficking from early endosomes to the trans-Golgi network, through the Golgi apparatus, and from the Golgi to the endoplasmatic reticulum, and appears to be involved in a complex network of protein−protein interactions (*32*). We used its recombinant variant that contains 3 cysteine residues with 1 positioned at the N-terminus and 2 within the last 3 C-terminal amino acids (*14*). The protein was treated with 10 equiv of PPO_7 under conditions that kept all cysteines in a reduced state and in the absence of any additional thiol. After 16 h incubation at 4 °C, we observed a complete conversion Rab6 to product carrying 2, 3, and 4 PPO_7 moieties (Figure 4A). The observed polymer modification pattern was stable for several hours, and the protein could be stored for up to 3 days at 4 °C without detectable changes. However, incubation of the PPO_7-modified Rab6 with β-mercaptoethanol at pH 8.0 or hydroxylamine for 1 h at 4 °C efficiently removed the PPO_7 moieties from the C-terminal cysteine residues. Following this treatment, the major fraction of Rab6 contained 1 PPO_7 unit attached to its N-terminus via an amide bond. The other PPO_7 units, bound to the protein via a thioester bond, were removed by transthioesterification with BME or by nucleophilic attack of the strong nucleophile hydroxylamine (Figure 4B). A small fraction of Rab6 still carried a second PPO_7 unit, but subsequent prenylation experiments demonstrated that this modification did not interfere with prenyl transfer onto the C-terminal cysteine residues of Rab6.

In vitro prenylation assays were carried out in the presence of a fluorescently labeled (NBD) farnesyl pyrophosphate analog as the limiting substrate for the prenyl transfer reaction and with PPO_7-modified Rab6 as well as with unmodified Rab6 (*33*). In both cases, isoprenoid transfer was observed, as evidenced by an increase of NBD fluorescence over time. Similar rates were observed for PPO_7-modified Rab6 and unmodified Rab6, but a large increase in overall fluorescence intensity (amplitude) was found for PPO_7-modified Rab6 (Figure 4C). This effect could be explained either by a change in the NBD environment in prenylated, PPO_7-modified Rab6 when compared to the prenylated wild-type protein or by release of the prenylated, PPO_7-modified Rab6 from the ternary complex with RabGGTase and REP-1 due to an increased solubility of the prenylation product. However, further evidence is needed to confirm either one of these two explanations.

CONCLUSIONS

Site-selective PEGylation of proteins via amide bond formation and reversible modification by transthioesterification are valuable tools for the production of defined protein−polymer structures that carry a chemically inert solubilization helper. Such conjugates have proven useful in converting peptides and proteins that can only be solubilized under strongly denaturing conditions into protein−polymer conjugates that can be enzymatically processed under rather mild conditions. The solubilizing polymers are easily removed subsequent to any protein manipulation and allow the recovery of desired native protein segments for further studies. Native disulfide bonds in proteins can remain intact during the polymer modification reaction, and such disulfides will not be modified. Reducing conditions can be applied to the polymer−protein conjugates; however, reducing agent carrying a free thiol group led to transthioesterification and, depending on the concentration, to slow or fast polymer removal.

Rab6, N-terminally modified with PPO_7, was fully active in prenylation experiments when compared to wild-type protein.

The high selectivity of the described modification reactions and the resulting well-defined molecular structures in combination with the freedom to introduce a variety of orthogonal reactive groups into the polymers render this approach highly interesting for targeting protein−polymer conjugates to specific cells, surfaces, or nanoparticles.

ACKNOWLEDGMENT

The authors are thankful to Ralf Seidel for providing the expression plasmid of TevRas51-166 and to Jörg Tatzelt for the mPrP gene. We are also grateful to Yoawen Wu for help with the prenylation assay, and we would like to thank Martin Engelhard and Roger Goody for continuous support. This work was funded in part by the VCI (C.F.W.B.), grant DFG AL 484/5-2, and grant I/77 977 of the Volkswagen foundation to K.A.

Impact of PKM Linkers on Biodistribution Characteristics of the ^{99m}Tc-Labeled Cyclic RGDfK Dimer

Shuang Liu,* Zhengjie He, Wen-Yuan Hsieh, Young-Seung Kim, and Young Jiang

School of Health Sciences, Purdue University, 550 Stadium Mall Drive, West Lafayette, Indiana 47907. Received July 31, 2006; Revised Manuscript Received September 27, 2006

This report describes synthesis of three new cyclic RGDfK peptide conjugates, HYNIC−PKM−SU016 (PKM = E, K and PEG4) and in vivo evaluation of the impact of PKM linkers on biodistribution characteristics of their ternary ligand complexes [^{99m}Tc(HYNIC−PKM−SU016)[1](tricine)(TPPTS)] in athymic nude mice bearing the MDA-MB-435 human breast cancer xenografts. Results from biodistribution studies show that PKM linkers have minimal impact on the integrin $\alpha_v\beta_3$ binding capability of radiotracers. Even though they have different charges under physiological conditions, all three linkers (E, K, and PEG4) are able to reduce the uptake of ^{99m}Tc-labeled E[c(RGDfK)]$_2$ in blood, kidneys, liver, and lungs, and increase target-to-background (*T*/*B*) ratios at >30 min postinjection. E and K may have advantages over PEG4 due to a combination of relatively low liver uptake and high tumor/liver and tumor/lung ratios of ternary ligand complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)-(TPPTS)] (PKM = E and K).

INTRODUCTION

For the past several years, we and others have been using multimeric cyclic RGD peptides, such as E[c(RGDfK)]$_2$ (SU016), to develop integrin $\alpha_v\beta_3$-targeted radiotracers for imaging rapidly growing and metastatic tumors (*1*−*11*). The RGD peptide serves as "vehicles" to carry radionuclide (^{99m}Tc, ^{18}F, and ^{64}Cu) to the integrin $\alpha_v\beta_3$ overexpressed on tumor cells and activated endothelial cells of the tumor neovasculature. ^{99m}Tc is the choice of radionuclide for single photon emission computed tomography (SPECT) and planar imaging due to its optimal nuclear properties (half-life, abundance, and energy of γ photons) and easy availability at low cost (*12*−*14*). For the ^{99m}Tc-labeling, 6-hydrazinonicotinic acid (HYNIC) has been used as a bifunctional coupling agent, while tricine and a water-soluble phosphine or pyridine analog are used as coligands to prepare ternary ligand ^{99m}Tc complexes [^{99m}Tc(HYNIC−SU016)(tricine)(L)] (L = ISONIC (isonicotinic acid), TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate, and PDA (2,5-pyridinedicarboxylic acid)) (*1*−*3*).

Recently, we studied the effect of coligands on biodistribution characteristics of ternary ligand complexes [^{99m}Tc(HYNIC−SU016)(tricine)(L)] (Figure 1; L = ISONIC, TPPTS, and PDA) in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts (*2*). It was found that the coligand has a significant impact on the radiotracer excretion kinetics from nontumor organs, such as liver and lungs, while maintaining their tumor targeting capability. Similar results were observed for [^{99m}Tc(HYNIC−SU016)(tricine)(L)] (L = TPPTS and ISONIC) and [^{99m}Tc(HYNIC−SU016)(EDDA)] (EDDA = ethylenediamine-*N*,*N*′-diacetic acid) in BALB/c mice bearing human U87MG glioma xenografts (*3*). Among several radiotracers evaluated, [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)] shows a great potential as a new radiotracer for imaging the integrin $\alpha_v\beta_3$-positive tumors.

It is highly desirable for the radiotracer to clear from noncancerous organs, such as liver and lungs, so that a high target-to-background (*T*/*B*) ratio can be achieved and clinically useful images of tumor can be obtained in a short period of time. In the past several years, a variety of pharmacokinetic modifying (PKM) linkers have been used to improve excretion kinetics of radiolabeled cyclic RGD peptides. For example, a sugar moiety was used to increase *T*/*B* ratios of the ^{125}I- and ^{18}F-labeled cyclic RGD peptides (*15*−*20*). Small peptides sequences, such as di(cysteic acid), Asp$_3$, and Ser$_3$, have been used to improve blood clearance and to minimize liver accumulation of radiolabeled nonpeptide integrin $\alpha_v\beta_3$ antagonists (*21*, *22*) and ^{18}F-labeled c(RGDfK) (*23*, *24*). The hexaethylene glycol (HEG) linker has been used in the ^{18}F-labeled RGDfE dimer and tetramer (*11*, *12*, *23*, *24*). It was reported that introduction of the polyethylene glycol (PEG) linker can improve not only tumor uptake but also excretion kinetics of ^{125}I- and ^{18}F-labeled c(RGDyK) and ^{64}Cu-labeled E[c(RGDyK)]$_2$ (*25*−*28*). PKM linkers and their applications to improve the excretion kinetics of radiolabeled small biomolecules have been reviewed recently (*13*, *24*, *29*−*31*).

To explore the impact of PKM linkers on tumor uptake and excretion kinetics of the ^{99m}Tc-labeled E[c(RGDfK)]$_2$, we have prepared three HYNIC conjugates, HYNIC−PKM−SU016 (Figure 1; PKM = glutamic acid (E), lysine (K), and PEG4), and their ternary ligand complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E, K, and PEG4). These three PKM linkers were chosen due to their different charge under physiological conditions. In this report, we present synthesis and in vivo evaluation of biodistribution characteristics of complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E, K, and PEG4) in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts. The main objective of this study is to select an optimal PKM linker (E, K, or PEG4) for the ^{99m}Tc-labeled small biomolecules, which is very

important in successful development of target-specific radiopharmaceuticals.

EXPERIMENTAL SECTION

Materials. Dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), succinic acid, trisodium triphenylphosphine-3,3′,3″-trisulfonate (TPPTS), and tricine were purchased from Sigma-Aldrich (St. Louis, MO). Boc-Glu(OSu)OH and lys(Boc)-OH were from Bachem Biosciences, Inc. (Prussia, PA). The Boc-protected PEG4 was obtained from Quanta BioDesign, Ltd. (Powell, OH). Cyclic pentapeptide, c(RGDfK), was obtained from Peptides International, Inc. (Louisville, KY). The cyclic RGDfK dimer, E[c(RGDfK)]$_2$ (SU016), was prepared according to the procedure described in our previous communication (*2*). Sodium succinimidyl 6-(2-(2-sulfonatobenzaldehyde)hydrazono)-nicotinate (HYNIC−NHS) was prepared according to literature procedure (*32*). Na^{99m}TcO$_4$ was obtained from a DuPont Pharma ^{99}Mo/^{99m}Tc generator, N. Billerica, MA.

Instrument and Methods. The ^{1}H NMR data were obtained using a Bruker ARX 300 MHz FT NMR spectrometer and chemical shifts as δ are reported in ppm relative to TMS. Mass spectral data were collected on a Finnigan LCQ classic mass spectrometer, School of Pharmacy, Purdue University. The semi-prep HPLC method (method 1) used a LabAlliance semi-prep HPLC system equipped with a UV/vis detector (λ = 254 nm) and Zorbax C_{18} semi-prep column (9.4 mm × 250 mm, 100 Å pore size) for peptide purification. The flow rate was 2.5 mL/min. The mobile phase was isocratic with 90% solvent A (0.1% acetic acid in water) and 10% solvent B (0.1% acetic acid in acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 90% solvent A and 10% solvent B at 5 min to 60% solvent A and 40% solvent B at 20 min. The radio-HPLC method (method 2) used the LabAlliance HPLC system equipped with a β-ram IN-US detector and Zorbax C_{18} column (4.6 mm × 250 mm, 300 Å pore size). The flow rate was 1 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM ammonium acetate buffer, pH = 5.0) and 10% solvent B (acetonitrile) at 0−2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min. The ITLC method used GelmanSciences silica-gel paper strips and a 1:1 mixture of acetone and saline as eluant. By this method, ^{99m}Tc complexes migrate to the solvent front, while ^{99m}TcO$_4^-$ and [^{99m}Tc]colloid remain at the origin.

Boc−E(OBu-t)−SU016. To a solution of Boc−E(OBu-t)−NHS (8.0 mg, 0.02 mmol) in DMF (1.0 mL) was added diisopropylethylamine (DIEA) to adjust pH of the reaction mixture to 8.0−8.5. SU016 (13.8 mg, 0.01 mmol) was added, and the resulting mixture was stirred for 30 min. The reaction was stirred at room temperature overnight, and the pH was maintained at 8.0−8.5 with DIEA. The crude product was dissolved in 2 mL of 0.5 N NH_4OAc buffer (pH = 7.0) and was purified by HPLC (method 1). The fraction at ∼16 min was collected. Lyophilization of the collected fractions afforded Boc−E(OBu-t)−SU016. The yield was 10 mg (∼60%). ESI-MS (positive mode): m/z = 1603.9 for $[M + H]^+$ (1603.82 calcd. for $[C_{73}H_{111}N_{20}O_{21}]^+$).

E−SU016. Boc−E(OBu-t)−SU016 (10 mg) was treated with 1.0 mL of trifluoroacetic acid (TFA), and the resulting mixture was stirred at room temperature for 30 min. Excess TFA was removed. The crude product was dissolved in 0.5 N NH_4OAc buffer (pH = 7.0) and purified by HPLC (method 1). The fraction at ∼11 min was collected. Lyophilization of the combined collections afforded E−SU016. The yield was 6.4 mg (∼71%). ESI-MS (positive mode): m/z = 1447.5 for $[M + H]^+$ (1447.70 calcd. for $[C_{64}H_{95}N_{20}O_{19}]^+$).

HYNIC−E−SU016. HYNIC−NHS (1.3 mg, 3 μmol) and E−SU016 (3.1 mg, 2 μmol) were dissolved in 1.0 mL of DMF. The mixture was stirred at room temperature for 12 h with pH being maintained at 8.0−8.5. The resulting mixture was subjected to HPLC purification (method 1). The fraction at ∼14 min was collected. Lyophilization of the collected fractions afforded HYNIC−E−SU016 as a white powder. The yield was

2.0 mg (~60%). ESI-MS (positive mode): m/z = 1750.5 for $[M + H]^+$ (1750.74 calcd. for $[C_{77}H_{103}N_{23}O_{23}S]^+$).

HYNIC−K(Boc)OH. To a solution of HYNIC−NHS (200 mg, 0.5 mmol) in 10 mL of DMF were added K(Boc)OH (123 mg, 0.5 mmol) and triethylamine (~60 μL, 0.5 mmol). The mixture was stirred at room temperature for 24 h. After filtration, the filtrate was evaporated to dryness. The residue was washed with diethyl ether. The crude product was purified by HPLC (method 1). Fractions at ~14 min were collected. Lyophilization of the combined collections gave an off-white powder. The yield was 200 mg (~73%). ^{1}H NMR (DMSO-d_6, chemical shifts in ppm relative to TMS): 1.34 (s, 9H, Boc group); 1.36 (m, 4H, CH_2); 1.78 (m, 2H, CH_2); 2.90 (q, 2H, *CH*$_2$NH-Boc); 4.35 (m, H, *CH*); 6.75 (t, 1H, *NH*-Boc); 7.10−8.50 (m, 8H, aromatic); 8.52 (s, 1H, =*CH*); 8.75 (bs, 1H, *NH*CO); and 11.90 (s, 1H, *NH*N=CH). ESI-MS (positive mode): m/z = 550.2 for $[M + H]^+$ (549.19 calcd. for $[C_{24}H_{32}N_5O_8S]^+$).

HYNIC−K(Boc)−NHS. To a solution of HYNIC−K(Boc)-OH (170 mg, 0.31 mmol) and NHS (41 mg, 0.36 mmol) in DMF (5 mL) was added DCC (74 mg, 0.36 mmol). The mixture was stirred at room temperature for 24 h. To the mixture was added 100 μL of acetic acid, and the solution was stirred for 5 h. After filtration, the filtrate was evaporated to dryness. The residue was dissolved in CH_2Cl_2 (10 mL), and the mixture was filtered to remove insoluble solid. To the filtrate was added 20 mL diethyl ether to give an off-white precipitate, which was collected, washed with diethyl ether, and dried under vacuum. The yield was 165 mg (~82%). ^{1}H NMR (DMSO-d_6, chemical shifts in ppm relative to TMS): 1.35 (s, 9H, Boc group); 1.50 (m, 4H, *CH*$_2$); 1.80 (m, 2H, *CH*$_2$); 3.32 (m, 2H, *CH*$_2$NH-Boc); 4.30 (m, 1H, *CH*); 7.20−8.10 (m, 8H, aromatic); 8.30 (t, 1H, *NH*-Boc); 8.58 (d, 1H, *NH*CO); 9.00 (s, 1H, =*CH*); and 11.31 (s, 1H, *NH*). ESI-MS (positive mode): m/z = 647.2 for $[M + H]^+$ (647.21 calcd. for $[C_{28}H_{35}N_6O_{10}S]^+$).

HYNIC−K(Boc)−SU016. HYNIC−K(Boc)−NHS (1.3 mg, 2 μmol) and SU016 (3.1 mg, 2 μmol) were dissolved in 1.0 mL of anhydrous DMF. The pH was maintained at 8.0−8.5 with DIEA, and the reaction mixture was stirred at room temperature for 12 h. After addition of 2 mL of 0.5 M NH_4OAc buffer (pH = 7.0), the product was isolated by HPLC (method 1). The fraction at ~16 min was collected. Lyophilization of the combined collections afforded the expected product, HYNIC−K(Boc)−SU016. The yield was 6.4 mg (~60%). ESI-MS (positive mode): m/z = 1849.9 for $[M + H]^+$ (1849.85 calcd. for $[C_{83}H_{117}N_{24}O_{23}S]^+$).

HYNIC−K−SU016. HYNIC−K(Boc)−SU016 (2 mg) was treated with 1.0 mL of TFA, and the mixture was stirred at room temperature for ~30 min. Excess TFA was removed under vacuum. The residue was dissolved in 3 mL of 0.5 N NH_4OAc buffer (pH = 7.0). The product was purified by HPLC (method 1). Lyophilization of the collected fractions at ~11 min afforded the expected product, HYNIC−K−SU016. The yield was 1.2 mg (~63%). ESI-MS (positive mode): m/z = 1749.9 for $[M + H]^+$ (1749.78 calcd. for $[C_{78}H_{109}N_{24}O_{21}S]^+$).

Boc−PEG4−SU016. To a solution of Boc−PEG4−OH (5.5 mg, 0.015 mmol) in 1 mL of DMF were added NHS (3.5 mg, 0.03 mmol) and DCC (6.2 mg, 0.03 mmol). After the mixture was stirred at room temperature for 2 h, SU016 (26.3 mg, 0.02 mmol) was added into the mixture above. The pH was adjusted to 8.0−8.5 using DIEA (~8 μL). The reaction mixture was stirred at room temperature overnight. To the reaction mixture was added 3 mL of 0.5 M NH_4OAc buffer (pH = 7.0). The cloudy solution was filtered, and the filtrate was subjected to HPLC purification (method 1). The fraction at ~14 min was collected. Lyophilization of the combined fractions afforded Boc−PEG4−SU016. The yield was 7.5 mg (~30%). ESI-MS (positive mode): m/z = 1665 for $[M + H]^+$ (1665.85 calcd. for $[C_{75}H_{117}N_{20}O_{23}]^+$).

PEG4−SU016. Boc−PEG4−SU016 (10 mg, 6 μmol) was treated with TFA (3.0 mL) at room temperature for 30 min. The TFA was removed under the reduced pressure. The residue was dissolved in 2 mL of ammonium acetate buffer (pH = 7.0) and was then purified by HPLC to afford the expected product PEG4−SU014. The yield was 7.0 mg (~74%). ESI-MS (positive mode): m/z = 1565.2 for $[M + H]^+$ (1565.80 calcd. for $[C_{70}H_{109}N_{20}O_{21}]^+$).

HYNIC−PEG4−SU016. In a 5 cm^3 vial, HYNIC−NHS (1.3 mg, 3 μmol) and PEG4−SU016 (3.0 mg, 2 μmol) were mixed with 1 mL of anhydrous DMF. After the mixture was stirred at room temperature for 10 min, the pH was adjusted to 8.0−8.5 with DIEA. The reaction mixture was stirred for 6 h at room temperature, and was then mixed with 3 mL of 0.5 M NH_4OAc buffer (pH = 7.0). The resulting solution was subjected to HPLC purification. The desired product HYNIC−PEG4−SU016 was collected after lyophilization. The yield was 2.0 mg (~54%). ESI-MS (positive mode): m/z = 1869.0 for $[M + H]^+$ (1868.83 calcd. for $[C_{83}H_{118}N_{23}O_{25}S]^+$).

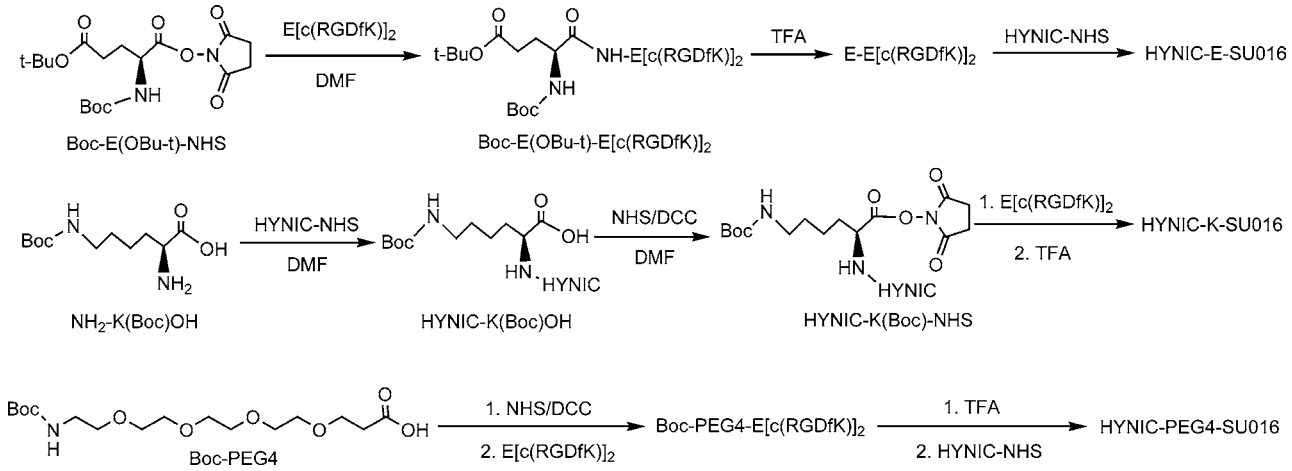
General Procedure for Preparation of Ternary Ligand ^{99m}Tc Complexes: [^{99m}Tc(HYNIC−PKM−SU016)(tricine)-(TPPTS)] (PKM = E, K, and PEG4). To a 5 cm^3 vial filled with 1.0 mL solution (pH = 4.8) containing 5 mg of TPPTS, 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, and 12.7 mg of succinic acid were added 0.2 mL of the solution containing HYNIC−PKM−SU016 (100 μg/mL in water) and 0.3 mL of Na[^{99m}TcO$_4$] solution (30−100 mCi/mL) in saline. The vial was heated at 100 °C for 20 min in a lead-shielded water bath. After radiolabeling, the vial was placed back into the lead pig and allowed to stand at room temperature for 5−10 min. A sample of the resulting solution was analyzed by the radio-HPLC (method 2) and TLC. The radiochemical purity (RCP) was >95%. The [^{99m}Tc]colloid was minimal (<0.5%) using the non-$SnCl_2$ formulation.

Dose Preparation for Animal Studies. For biodistribution studies, ternary ligand complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E, K, and PEG4) were first prepared and then purified by radio-HPLC (method 2). Volatiles in the HPLC mobile phases were completely removed under the reduced pressure. Doses were made by dissolving the HPLC-purified radiotracer in saline to give a concentration of ~10 μCi/mL. Each tumor-bearing mouse was administered intravenously 0.1 mL of the prepared dose solution.

Determination of Log *P* Values. Log *P* values of ternary ligand ^{999m}Tc complexes [^{99m}Tc(HYNIC−PKM−SU016)-(tricine)(TPPTS)] (PKM = E, K, and PEG4) were determined using the following procedure: the radiotracer was prepared and purified by HPLC (method 2). Volatiles were completely removed under the reduced pressure. The residue was dissolved in a mixture of equal volume (3 mL/3 mL) *n*-octanol and 25 mM phosphate buffer (pH = 7.4). After stirring vigorously for 20−25 min, the mixture was centrifuged for 5 min at a speed of 8000 rpm. Samples (in triplets) from *n*-octanol and aqueous layers were obtained and were counted in a γ counter (Beckman Gama 8000). The partition coefficient was calculated using the following equation: P = (activity concentration in *n*-octanol)/(activity concentration in aqueous layer). The log *P* values were reported as an average of three different measurements plus the standard variation.

Animal Studies. Biodistribution and metabolism studies were performed using the athymic nude mice bearing MDA-MB-435 human breast cancer xenografts in compliance with NIH animal experiment guidelines (*Principles of Laboratory Animal Care*, NIH Publication No. 86-23, revised 1985). The animal

Chart 1. Synthesis of HYNIC-Conjugated Cyclic RGDfK Conjugates



protocol for animal studies has been approved by the Purdue University Animal Care and Use Committee (PACUC).

Tumor-Bearing Mice. Female athymic nu/nu mice were purchased from Harlan (Indianapolis, IN) at 4−5 weeks of age. Tumor cells were grown at 37 °C in minimal essential medium (alpha modification) containing 3.7 g of sodium bicarbonate/L, and 10% fetal bovine serum v/v, in a humidified atmosphere of 5% carbon dioxide. The nude mice were implanted with ∼5 × 10^6 cells of MDA-MB-435 estrogen-receptor-negative human breast cancer cells into the mammary fat pad. Four weeks after inoculation, animals were used for biodistribution and metabolism studies.

Biodistribution. Sixteen tumor-bearing mice (20−25 g) were anesthetized with IP injection of Ketamine (40−100 mg/kg) and Xylazine (2−5 mg/kg). Once the animal was in the surgical plane of anesthesia, as noted by lack of pain response, the radiotracer (∼1 μCi) dissolved in 0.1 mL saline was administered via the tail vein. Four animals were sacrificed by exsanguinations and opening of thoracic cavity at 5, 30, 60, and 120 min postinjection. Organs (tumor, blood, brain, eyes, spleen, lungs, liver, kidneys, muscle, and intestine) were excised, washed with saline, weighed, and counted on a γ counter. The organ uptake was calculated as a percentage of the injected dose per organ (% ID/organ) and a percentage of the injected dose per gram of wet tissue (% ID/g).

Metabolism. Two tumor-bearing mice were used for each radiotracer. Each tumor-bearing mouse was administered the radiotracer at a dose of 100 μCi/mice. Urine samples were collected at 2 h postinjection by manual void and were mixed with equal volume of acetonitrile. The mixture was centrifuged at 8000 rpm. The supernatant was collected and filtered through a 0.20 μm Millex-LG syringe-driven filter unit to remove any precipitate and large proteins. The filtrate was analyzed by radio-HPLC. Feces samples were collected at ∼120 min postinjection. The sample was suspended in a mixture of 50% acetonitrile aqueous solution, and the resulting mixture was vortexed for 5−10 min. After centrifuging at 8000 rpm for 5 min, the supernatant was collected and passed through a 0.20 μm Millex-LG syringe-driven filter unit. The filtrate was analyzed by radio-HPLC.

Data and Statistical Analysis. The biodistribution data and *T*/*B* ratios are reported as an average plus the standard variation based on the results from four animals at each time point. Comparison between two different radiotracers was also made using the one-way ANOVA test. The level of significance was set at $p = 0.05$.

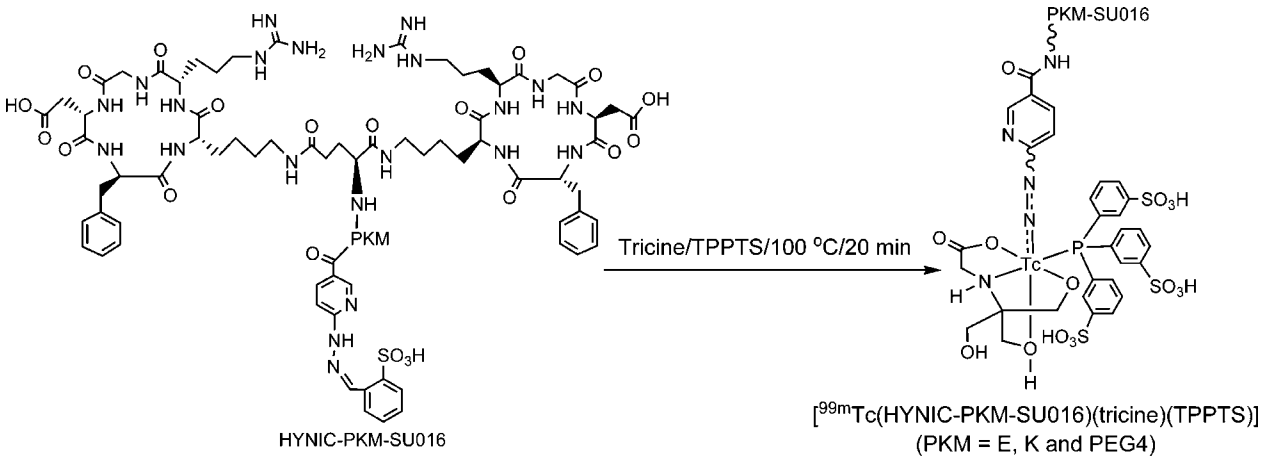
RESULTS

HYNIC−PKM−SU016 Conjugates. HYNIC−E−SU016 was prepared (Chart 1) by conjugation of Boc−E(OBu-t)−NHS with 1 equiv of E[c(RGDfK)]$_2$ (SU016), followed by deprotection of the Boc-protecting group in TFA, and conjugation with HYNIC−NHS in DMF. HYNIC−K−SU016 was prepared (Chart 1) by conjugation of HYNIC−NHS with 1 equiv of K(Boc)OH, followed by activation of the carboxylic group in HYNIC−K(Boc)OH, conjugation of HYNIC−K(Boc)−NHS with SU016 in DMF, and deprotection of the Boc-protecting group. For HYNIC−PEG4−SU016 (Chart 1), Boc−PEG4 was first activated to form the activated ester Boc−PEG4−NHS, which was then allowed to react with SU016 to afford Boc−PEG4−SU016. The Boc-protecting group was removed by treating Boc−PEG4−SU016 with anhydrous TFA. Conjugation of PEG4−SU016 with HYNIC−NHS in DMF produced HYNIC−PEG4−SU016. The HYNIC−PKM−SU016 (PKM = E, K, and PEG4) conjugates were purified by a semi-prep HPLC method. Their HPLC purity was >95% before being used for the ^{99m}Tc-labeling.

Radiochemistry. [^{99m}Tc(HYNIC−PKM−SU016)(tricine)-(TPPTS)] (PKM = E, K, and PEG4) were prepared according to Chart 2. TPPTS was chosen as the coligand due to the high solution stability of its ternary ligand ^{99m}Tc complexes (*1*−*4*) and the availability of the non-$SnCl_2$ formulation (*33*−*35*). The radiochemical purity (RCP) of all three radiotracers was >95% with minimal amount (<0.5%) of [^{99m}Tc]colloid using non-$SnCl_2$ formulation. It was also found that all three radiotracers remained stable in 25 mM ammonium acetate buffer (pH = 5) for more than 12 h, which is consistent with the results obtained from our previous studies (*1*, *2*).

All three radiotracers were analyzed by the same HPLC method (method 2). Figure 2 shows their representative HPLC chromatograms in the kit matrix. Small radioimpurities were formed during the radiolabeling process. No identification was made for these radioimpurities. The HPLC retention times for [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)], [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)] and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(PDA)] were 12.2, 15.0, and 13.5 min, respectively, under identical chromatographic conditions. It is interesting to note that [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)] shows two peaks, which are often observed for ternary ligand complexes [^{99m}Tc(HYNIC−biomolecule)(tricine)(TPPTS)] due to chirality of the Tc chelate and presence of chiral center(s) in the targeting biomolecule (*35*−*38*). However, [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)] and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] both show one radiometric peak under the same chromatographic conditions (Figure 2). Attempts to separate the two diastereomers in [^{99m}Tc(HYNIC−E−SU016)-(tricine)(TPPTS)] and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)-(TPPTS)] were not successful. It is obvious that the introduction

Chart 2. Synthesis of Ternary Ligand ^{99m}Tc Complexes



of E or PEG4 linker between HYNIC and E[c(RGDfK)]$_2$ makes it much more difficult to separate these two diastereomers.

To further explore the linker effect on lipophilicity of ternary ligand complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)-(TPPTS)] (PKM = E, K, and PEG4), we also determined their partition coefficients (*P* values) in an equal volume mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). The log *P* values are −3.13 ± 0.20, −3.41 ± 0.14, and −3.56 ± 0.16 for [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)], [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)], and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)], respectively. As expected, complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E, K, and PEG4) are more hydrophilic than [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)] (log *P* = −2.66 ± 0.25) (*2*). There is no significant difference in log *P* values of all three new radiotracers within experimental error, even though their HPLC retention times suggest that [^{99m}Tc(HYNIC−E−SU016)(tricine)-(TPPTS)] might be more hydrophilic than [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)] and [^{99m}Tc(HYNIC−PEG4−SU016)-(tricine)(TPPTS)] (Figure 2).

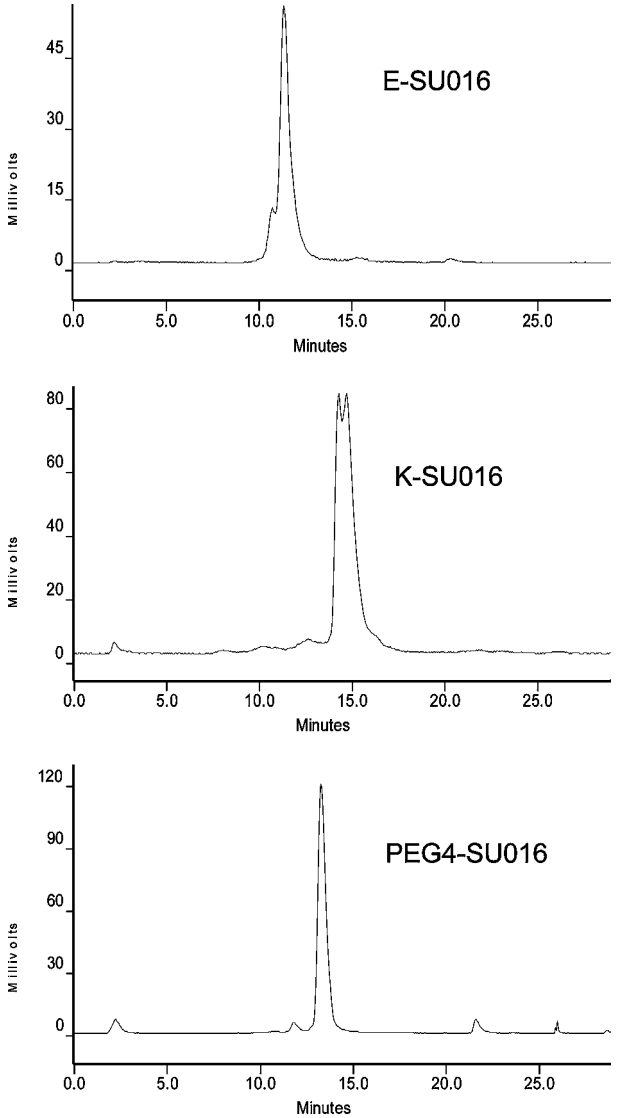


Figure 2. Radio-HPLC chromatograms of [^{99m}Tc(HYNIC−E−SU016)-(tricine)(TPPTS)] (top), [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)] (middle), and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] (bottom) in the kit matrix.

Biodistribution Characteristics. For biodistribution studies, all three radiotracers were purified by HPLC to remove excess "unlabeled" HYNIC−PKM−SU016 conjugate that may compete with the radiotracer in binding to the integrin $\alpha_v\beta_3$. Biodistribution data for complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E, K, and PEG4) are summarized in Supporting Information Tables 1−3, respectively. Figure 3 shows direct comparison of their tumor uptake and excretion kinetics from blood, liver, and kidneys at 5, 30, 60, and 120 min postinjection. The *T*/*B* ratios in selected organs are illustrated in Figure 4. The biodistribution data and *T*/*B* ratios for [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)] were obtained from our previous studies (*2*).

In general, [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = K and PEG4) have the tumor uptake (3−4% ID/g) very similar to that of [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)] (Figure 3). Their tumor uptake remains constant over the 2 h study period. The tumor uptake of [^{99m}Tc(HYNIC−E−SU016)-(tricine)(TPPTS)] is comparable to that of [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = K and PEG4) and [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)] over the first 30 min, but it increases from 4.07 ± 0.19% ID/g at 30 min postinjection to 6.33 ± 0.55% ID/g at 60 min postinjection and remains almost unchanged between 60 and 120 min postinjection. Compared to [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)], all three new radiotracers show faster clearance from blood, liver, muscle, lungs, and kidneys (Supporting Information Tables 1−3). As a result, there is a steady increase in *T*/*B* ratios over the 2 h study period. Among the three radiotracers evaluated in this study, [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)] has the best tumor/liver and tumor/lung ratios at 120 min postinjection, while [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)] has the best tumor/blood and tumor/muscle ratios (Figure 4). The tumor/muscle ratio of [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)]

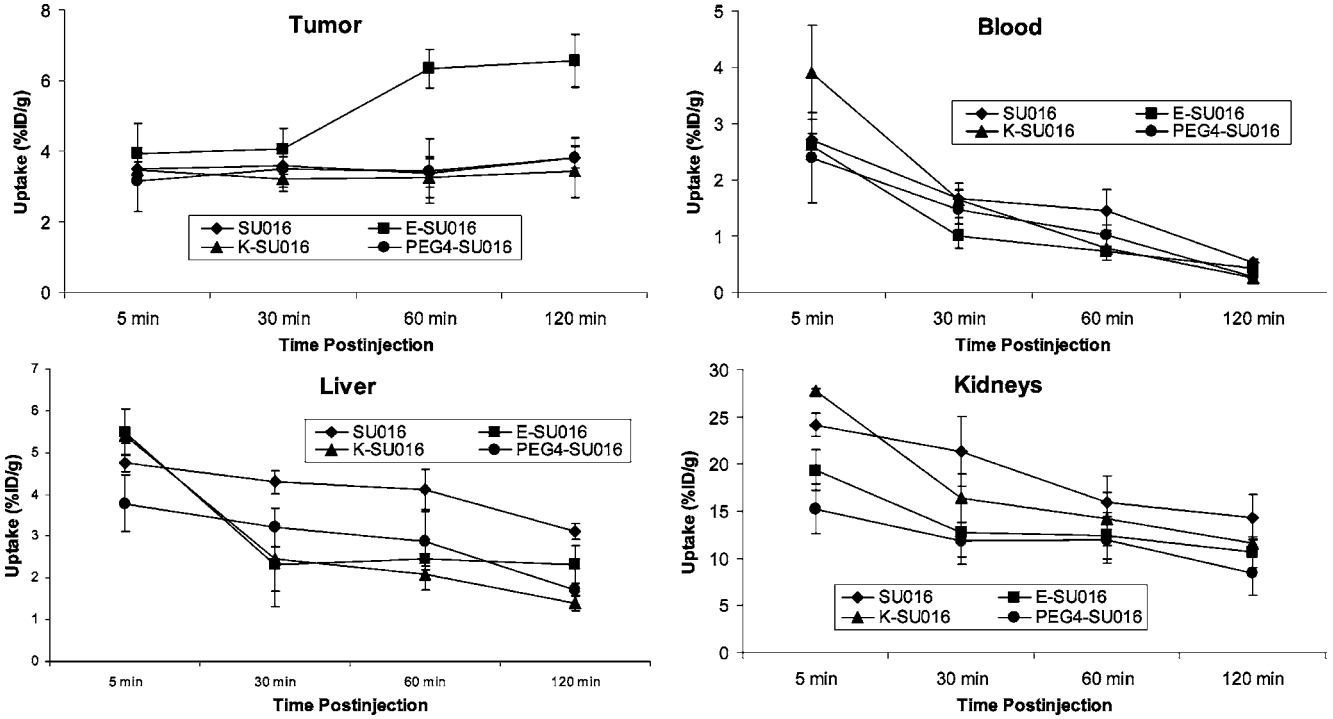

Figure 3. Comparison of organ uptake (% ID/g) among [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)], [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)], [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)], and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts.

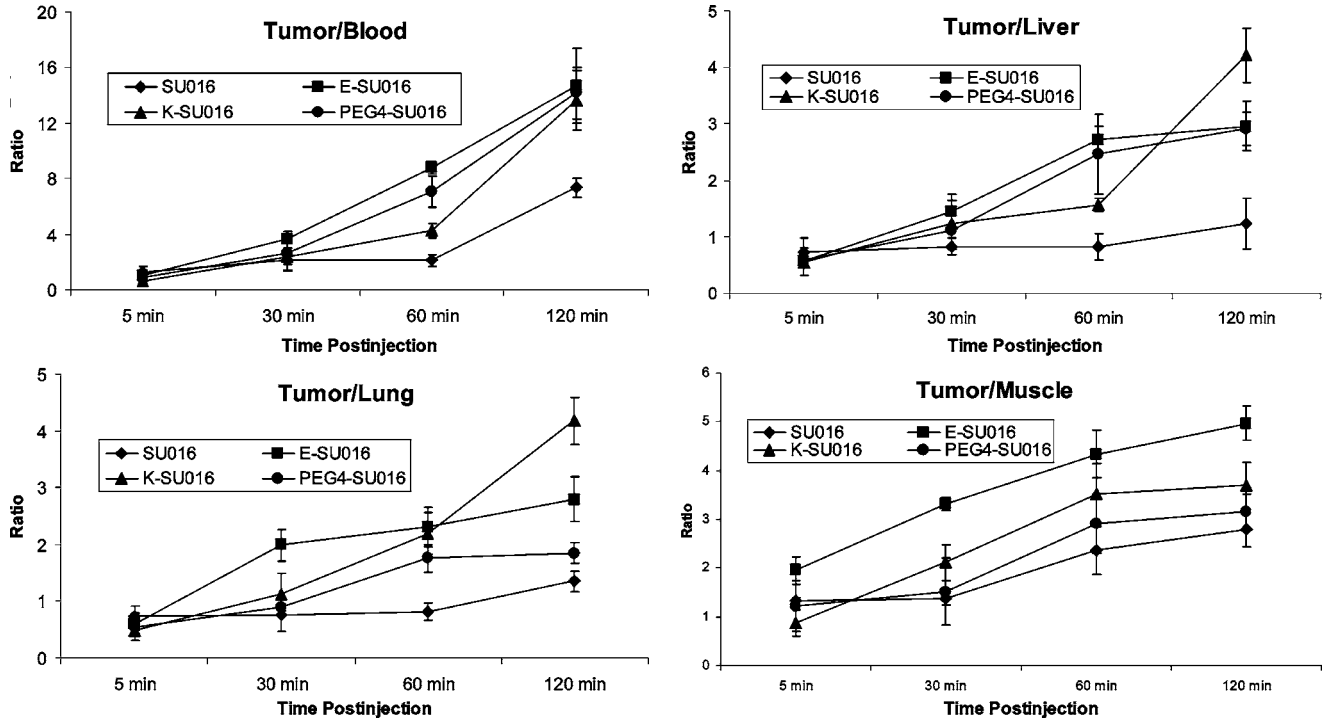

Figure 4. Comparison of *T*/*B* ratios among [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)], [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)], [^{99m}Tc(HYNIC−K−Su016)(tricine)(TPPTS)], and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts.

are almost the same as that of [^{99m}Tc(HYNIC−SU016)(tricine)-(TPPTS)]. Its tumor/liver ratio is comparable to that of [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] within experimental error over the 2 h study period.

Metabolism. We performed metabolism studies on all three new radiotracers using athymic tumor-bearing nude mice. Since they are excreted from renal and hepatobiliary (to a much lesser degree) routes, we tried to collect samples from both feces and urine and determine if these radiotracers retain their chemical integrity at 2 h postinjection. Figure 5 shows radio-HPLC chromatograms of [^{99m}Tc(HYNIC−PKM−SU016)(tricine)-(TPPTS)] (PKM = E, K, and PEG4) in the urine at 120 min postinjection. It is quite clear that these three radiotracers have different metabolic patterns. For example, [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)] had no significant metabolism (<1.0%) over the 2 h study period. The percentage of "metabolized component" (at ∼3 min) for [^{99m}Tc(HYNIC−K−SU016)-(tricine)(TPPTS)] was <10% at 120 min postinjection, and

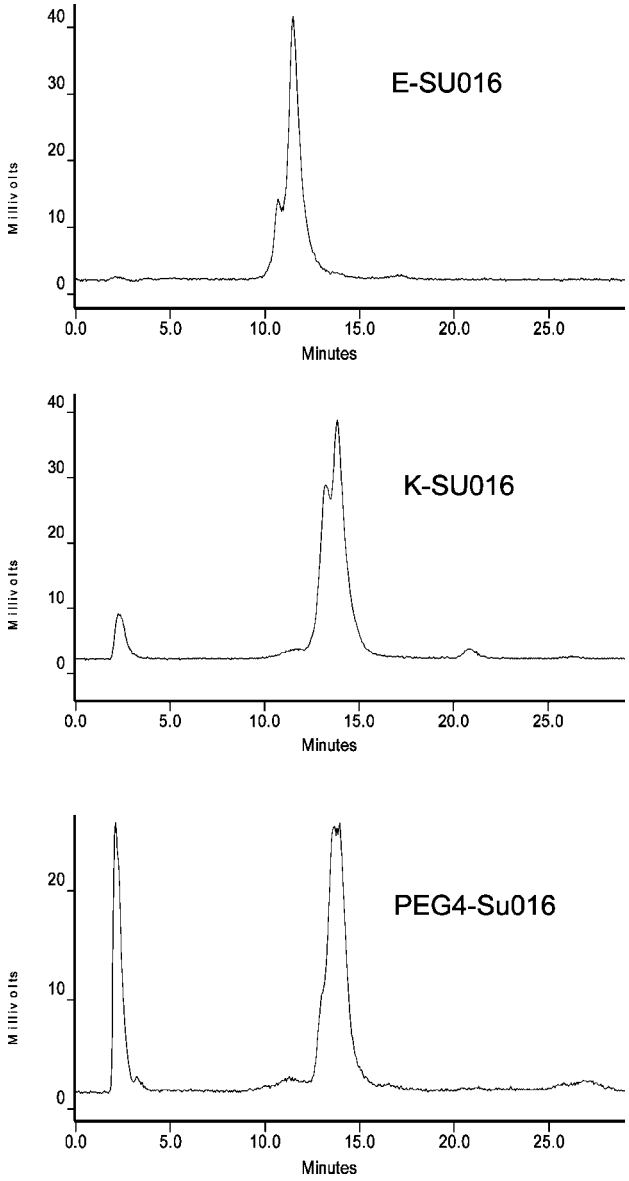

Figure 5. Radio-HPLC chromatograms of [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)] (top), [^{99m}Tc(HYNIC−K−SU016)(tricine)(TPPTS)] (middle), and [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] (bottom) in the urine at 120 min postinjection. Each tumor-bearing mouse was administered 100−120 μCi of radiotracer. Two tumor-bearing mice were used for each radiotracer.

>70% of [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] remained intact over 2 h postinjection (Figure 5). The presence of two overlapped peaks in the HPLC chromatogram of [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] is probably due to chromatographic artifact. We also tried to extract radioactivity from feces samples, but the activity level in feces samples was so low that we were unable to detect either intact ternary ligand ^{99m}Tc complexes or their metabolites.

DISCUSSION

For a new integrin $\alpha_v\beta_3$-targeted radiotracer to be successful, it should be able to have a high tumor uptake with diagnostically useful *T*/*B* ratios in a short period of time (*28*, *29*). Since most high-incidence tumors (namely, lung, colorectal, and breast cancers metastatic to the lymphatic system) occur in the torso, it is necessary to avoid radioactivity accumulation in the gastrointestinal tract, which may interfere with interpretation of tumor activity in the abdominal region. Therefore, efforts have been directed toward optimization of excretion kinetics so that the radiotracer has a fast clearance from nontumor organs (such as blood, liver, and lungs) while maintaining its high tumor uptake.

There are several approaches to increase the renal clearance of radiotracers (*13*, *29*, *30*). These include (*1*) the use of hydrophilic amino acid residues in targeting biomolecules; (*2*) the use of hydrophilic chelators or coligands for the ^{99m}Tc-labeling; and (*3*) the use of charged PKM linkers between the ^{99m}Tc-chelator and the targeting biomolecule (namely, E[c(RGDfK)]$_2$ or SU016 in this study). Incorporation of different amino acid residues into small biomolecules, such as cyclic RGD pentapeptides, often leads to alteration of their receptor-binding affinity. Thus, it is common to use PKM linkers and chelators or coligands to modify pharmacokinetics of radiotracers while keeping the cyclic pentapeptide framework intact so that the integrin $\alpha_v\beta_3$ binding affinity is not adversely affected.

Recently, we examined the coligand effect on biodistribution characteristics of [^{99m}Tc(HYNIC−SU016)(tricine)(L)] (L = ISONIC, TPPTS, and PDA) in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts and found that the coligand has a significant impact on excretion kinetics of the ^{99m}Tc-labeled E[c(RGDfK)]$_2$ from blood, liver, and lungs (*2*). In this study, we studied the impact of three PKM linkers (E, K, and PEG4) on lipophilicity, tumor uptake, and excretion kinetics of the ^{99m}Tc-labeled E[c(RGDfK)]$_2$. It was found that all three radiotracers [^{99m}Tc(HYNIC−PKM−SU016)(tricine)-(TPPTS)] (PKM = E, K, and PEG4) (log P = −3.13 ± 0.20, −3.41 ± 0.14, and −3.56 ± 0.16, respectively) are more hydrophilic than [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)] (log P = −2.66 ± 0.25). On the basis of biodistribution characteristics, it seems that PKM linkers have minimal impact on tumor-targeting capability, as indicated by their similar tumor uptake (Figure 3). Even though they may have different charges under physiological conditions, all three PKM linkers (E, K, and PEG4) are able to reduce the uptake of ^{99m}Tc-labeled E[c(RGDfK)]$_2$ in blood, liver, and lungs and increase their *T*/*B* ratios, particularly at >60 min postinjection (Figure 4). E and K are especially useful to minimize radioactivity accumulation in liver and lungs.

Small peptides in blood plasma are filtered through glomerular capillaries in the kidneys and subsequently reabsorbed by proximal tubular cells by carrier-mediated endocytosis. The membranes of renal tabular cells contain negatively charged sites to which the positively charged groups, such as guanidine moieties in cyclic RGD peptides, are expected to bind. In this respect, the negatively charged small peptides, such as E, can be used as PKM linkers to reduce renal uptake of ^{99m}Tc-labeled E[c(RGDfK)]$_2$ since the extra carboxylic groups are expected to be deprotonated under physiological conditions. In this way, the interaction between membranes of renal tabular cells and the positively charged guanidine groups in E[c(RGDfK)]$_2$ can be minimized, thereby reducing renal uptake of the ^{99m}Tc-labeled E[c(RGDfK)]$_2$. This assumption is supported by the lower kidney uptake of [^{99m}Tc(HYNIC−E−SU016)(tricine)(TPPTS)] than that of [^{99m}Tc(HYNIC−SU016)(tricine)(TPPTS)] (Figure 3). The use of negatively charged E linker also decreases the radiotracer accumulation in blood and liver (Figure 3), which results in high tumor/blood and tumor/liver ratios for [^{99m}Tc-(HYNIC−E−SU016)(tricine)(TPPTS)] (Figure 4). Similar results were also reported for ^{99m}Tc−DKCK−c(RGDfK) (*39*). Therefore, the negatively charged PKM linkers are particularly useful to enhance the radiotracer elimination from the body without prolonged retention in kidneys.

Harris et al. reported the use of a PEG4 linker to improve *T*/*B* ratios of the ^{99m}Tc-labeled nonpeptide integrin $\alpha_v\beta_3$ antagonists (*21*, *22*). Chen et al. also found that introduction of

the PEG linker (Mw = 2000 or 3400 Da) can improve tumor uptake and excretion kinetics of the radiolabeled RGD peptides (*25*−*28*). In this study, we found that the PEG4 linker significantly enhances the radiotracer excretion from blood, liver, and kidneys. Among three radiotracers evaluated in this study, [^{99m}Tc(HYNIC−PEG4−SU016)(tricine)(TPPTS)] has the lowest kidney uptake (Figure 3). Even though PEG linkers are neutral, they are useful tools for optimization of pharmacokinetic parameters of target-specific radiotracers.

Extensive metabolic degradation has been observed for the ^{99m}Tc-labeled c(RGDfK) (*39*), [^{99m}Tc(HYNIC−SU016)(tricine)-(TPPTS)] (*2*), and the ^{64}Cu-labeled c(RGDfK) tetramer (*7*). In this study, we found that all three radiotracers have a different degree of metabolism. For example, [^{99m}Tc(HYNIC−E−SU016)-(tricine)(TPPTS)] has little metabolism (<1.0%), while [^{99m}Tc-(HYNIC−K−SU016)(tricine)(TPPTS)] has <10% metabolism during the 2 h study period. The majority (>70%) of [^{99m}Tc-(HYNIC−PEG4−SU016)(tricine)(TPPTS)] remained intact at 2 h postinjection (Figure 5). Since all three radiotracers used in this study share the same Tc chelate and the same cyclic RGDfK dimer, the difference in their metabolic patterns is likely related to the PKM linker.

The pharmacokinetic requirement for an optimal radiotracer depends largely on its medical applications (diagnostic or therapeutic). For therapeutic radiopharmaceuticals, the high uptake in kidneys and prolonged kidney retention of radiotracers will impose a serious challenge for the radiolabeled cyclic RGD peptides (*12*, *30*, *31*). For tumor imaging, however, the most important factor in selecting an optimal radiotracer is its excretion kinetics from the liver and lungs (*29*, *30*). Although all three linkers are able to increase the excretion rate of ^{99m}Tc-labeled E[c(RGDfK)]$_2$ from nontumor organs, E and K may have advantages over PEG4 due to a combination of low liver uptake and high tumor/liver and tumor/lung ratios (Figure 4) of [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E and K).

CONCLUSION

In this report, we described the in vivo evaluation of biodistribution characteristics of complexes [^{99m}Tc(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E, K, and PEG4) in nude mice bearing MDA-MB-435 human breast cancer xenografts. The results from biodistribution studies show that excretion kinetics of the ^{99m}Tc-labeled E[c(RGDfK)]$_2$ can be modified with various PKM linkers. The fact that [^{99m}Tc-(HYNIC−PKM−SU016)(tricine)(TPPTS)] (PKM = E, K, and PEG4) have a tumor uptake comparable to that of [^{99m}Tc-(HYNIC−SU016)(tricine)(TPPTS)] during the 2 h study period suggests that changing PKM linkers has no adverse effect on the integrin $\alpha_v\beta_3$ binding capability of the ^{99m}Tc-labeled E[c(RGDfK)]$_2$. Among the three linkers, E and K linkers are especially useful in minimizing the radioactivity accumulation in liver and lungs. For other ^{99m}Tc-labeled small biomolecules, the choice of PKM linker must be confirmed by their distribution characteristics.

ACKNOWLEDGMENT

Authors would like to thank Lee Ann Grote, Carol Dowell, and Cheryl Anderson from the Department of Veterinary Clinical Sciences, Purdue University, for their assistance with biodistribution studies. Influence of Carrier Proteins on the Immunologic Response to Haptenic Antitetrodotoxin Vaccine

Qin-Hui Xu,* Xiu-Nan Zhao, Jun-Ping Cheng, Chang-Hua Wei, Qin-Hua Zhang, and Kang-Tai Rong

Beijing Institute of Pharmacology and Toxicology, 27 Taiping Road, Beijing 100850, P.R. China. Received April 4, 2006; Revised Manuscript Received August 29, 2006

Tetrodotoxin (TTX) is a haptenic, highly toxic neurotoxin with no specific antidote available yet. Anti-TTX vaccine is being studied for antitoxin development. The effectiveness of the carrier protein in eliciting TTX-specific antibody response was comparatively studied. TTX was conjugated to *Tachypleus tridentatus* hemocyanin (TTH), *Limulus polyphemus* hemocyanin (LPH), tetanus toxoid (TT), diphtheria toxoid (DT), and bovine serum albumin (BSA) chemically to form artificial antigens TTH−TTX, LPH−TTX, TT−TTX, DT−TTX, and BSA−TTX, respectively, with which BALB/c mice were immunized, and the antibody response and antitoxic efficacy were detected. The serum anti-TTX antibody response and antitoxic efficacy varied markedly with adopted carrier protein. TTH−TTX elicited the best and BSA−TTX the worst TTX-specific antibody response. The proportion of the immunized mice surviving a 3× lethal dose (LD) dose of TTX challenge was 92%, 75%, 42%, 8%, and 0% for TTH−, TT−, LPH−, DT−, and BSA−TTX conjugates, respectively. The rank order of total efficacy of carrier protein for both anti-TTX antibody response and antitoxic effect was TTH > TT > LPH > DT > BSA. As a result of formaldehyde treatment in coupling of TTX carriers, the relative immunogenicity of TTX *vs* carrier, that is, the ratio of TTX- to carrier-specific antibody response, evidently varied with respective carrier adopted, in a rank order of TT > BSA > TTH > DT > LPH. The results suggest that the carrier protein used in haptenic TTX vaccine is greatly important in eliciting potent anti-TTX antibody, and both TTH and TT are the preferred carriers for development of excellent experimental TTX vaccine.

INTRODUCTION

A small molecular chemical is immunologically inert. So it has to be chemically modified by covalent linking to a large molecular weight carrier protein (CP)[1] to form an artificial antigen before it can act as an immunogen (*1*−*6*). The selection of the carrier molecule of the haptenic vaccine is paramount for the successful production of hapten-specific antibody, although special research on selection of CP for a haptenic vaccine is very rare (*7*, *8*).

Tetrodotoxin (TTX), mainly found in the organs of puffer fish, is one of the highly toxic haptenic neurotoxins. TTX blocks diffusion of sodium through the sodium channel, preventing depolarization and propagation of action potentials in nerve cells. Poisoning with TTX usually occurs after ingestion of improperly prepared TTX-containing puffer fish in China and Japan where the puffer fish is considered a delicacy. Death in seriously poisoned humans often occurs from respiratory failure (*9*−*11*). Management of clinical TTX poisoning disease is often difficult, and the main treatment is meticulous supportive care, but it is usually inefficient in serious cases. So far no specific antidote for TTX poisoning has been available (*12*, *13*). Immunological protection, especially the passive immunotherapy of antitoxin, has been considered as a unique measure capable of conquering TTX diseases; studies in this field have been published with varying degrees of success (*14*−*19*). As a first stage to producing a potential anti-TTX antitoxin for treating victims, a chemo-experimental vaccine of TTX that could highly effectively protect animals from TTX intoxication has been developed (*20*−*22*), and a preliminary attempt of passive immunization research for TTX has been performed (*23*) in our lab.

The purpose of this report is to present an anterior research on the selection of CP in anti-TTX experimental vaccine in order to obtain a potent antibody response and then excellent antitoxic effect from TTX vaccine and further to develop a potential anti-TTX antitoxin. Five experimental vaccines constructed by coupling TTX to different proteins have been compared in their immunogenic potency and antitoxic efficacy in mice, the possible cause for the effect differences among vaccines has been analyzed experimentally, and the optimal carriers adopted in TTX vaccine have been validated.

MATERIALS AND METHODS

Materials. TTX (M_r 319.3) was purchased from Fisheries Research Institute of Hebei Province (Qinhuangdao, China); the product was prepared by freeze-drying the original solution containing citrate buffer with pH 4.8−4.9 and with purity of 98%. Bovine serum albumin (BSA, M_r 67 000) and *Limulus polyphemus* hemocyanin (LPH, M_r 3 300 000) were purchased from Sigma; diphtheria toxoid (DT, M_r 63 000) and tetanus toxoid (TT, M_r 67 000) were obtained from Changchun Institute of Biological Products (Changchun, China); *Tachypleus tridentatus* hemocyanin (TTH) with molecular weight of 3 000 000 Da by ultracentrifugation analysis was prepared by our lab. All these proteins were lyophilized.

Mice. Female BALB/c mice, aged 6−8 weeks, Grade II, Certificate No. SCXK 2003-001, were obtained from the Institute of Jing-Feng Medical Laboratory Animals (IJM) (Beijing, China) and were housed under standard laboratory conditions and fed *ad libitum* diet and water. All animal study

procedures were approved by the Center on Experimental Animal Care and Research from our Institute.

Preparation of Artificial Antigen. TTX was conjugated to CP via formaldehyde as the coupling agent to form artificial antigen as described previously with modification (*22*−*24*). Briefly, 1 mg of lyophilized TTX was dissolved in 1 mL of distilled water to yield an aqueous solution consisting of citrate buffer, pH 4.9. CP (8 mg), that is, TTH, TT, LPH, DT, or BSA, was dissolved in 2.0 mL of 20 mM phosphate-buffered saline (PBS) (pH 6.8), and TTX solution was added to yield a weight ratio of TTX to CP of 1:8. Then formaldehyde was added up to final concentration of 1.5%. The reagents were thoroughly mixed and slowly shaken in a 30 °C water bath for 72 h, and then dialyzed for 48 h at 4 °C against six 1 L changes of PBS (pH 7.2) to remove residual free TTX. TTX−CP conjugates, that is, TTH−TTX, TT−TTX, LPH−TTX, DT−TTX, and BSA−TTX, were obtained, and conjugate aliquots were stored at −20 °C before use. In addition, the formal-treated control CPs, that is, f−TTH and f−BSA, were prepared by the above procedure with omission of TTX.

Immunization of Mice. Mice were randomly divided into groups of 12 and immunized intraperitoneally (ip) with 50 μg of TTX−CP, emulsified by mixing it with an equal volume of complete Freund's adjuvant. Booster immunizations were administered at the 15th day after the primary immunization (d15), d30, d55, d85, d115, and d150 with 50 μg of TTX−CP per injection, emulsified in incomplete Freund's adjuvant or in saline solution alternatively. Each mouse received a total of 350 μg of artificial antigen in terms of the amounts of CP. In addition, mice were immunized with representative CPs instead, that is, DT, TT, and TTH, according to the same scheme acting as control.

Determination of TTX-Specific Antibody Response. The antisera were collected on schedule during the immunization and the TTX challenge course by tail-bleeding and stored at −20 °C until tested. Antibody quality, expressed by parameters antibody titer and apparent affinity, was tested as described before (*22*, *23*). Briefly, test antigen BSA−TTX, at a concentration of 2 μg/mL, 100 μL/well, was coated onto 96-well microtiter plates for detection of antibody against all TTX conjugates except BSA−TTX itself, and instead, TTX−DT was used for detection of TTX−BSA, in order to avoid the false positive reaction from the antibody against CP of immunogen reacting on the same CP in test antigen. DT−TTX acting as test antigen was certified essentially identical with BSA−TTX in preliminary experiments.

The antisera were tenfold serially diluted in PBS (pH 7.2) containing 1% BSA, and the antibody reactivity with test antigen (BSA−TTX or DT−TTX) was detected by enzyme-linked immunosorbent assay (ELISA). TTX-specific antibody level was expressed as antibody titer (**n**). The **n** value was defined as the logarithm of specimen dilution at which the positive reaction was certificated as a result of $A_{490\ nm}$ read on a Bio-Rad model 550 microplate reader (Bio-Rad), exceeding those in normal mice sera control 3-fold.

Apparent affinity (K_{ap}) was assayed by competition-inhibited enzyme immunoassay. Briefly, the mixtures of a series of molar concentrations of TTX solution and antibody specimens in fixed dilutions ranging from 10^2−10^5 were incubated with test antigen at 37 °C for 0.5 h. Then anti-TTX antibody reactivity was determined as above, and IC_{50}, the TTX concentration (M) inhibiting 50% of antibody binding activity to test antigen, was calculated. The apparent affinity, K_{ap}, was defined as the negative logarithm of IC_{50} ($K_{ap} = pIC_{50}$).

Determination of CP-Specific Antibody Response. CP-specific antibody in antisera was determined by ELISA procedure same as the above by a modification of using respective CP alone, that is, TT, DT, or TTH, instead of BSA−TTX or DT−TTX conjugate as a test antigen.

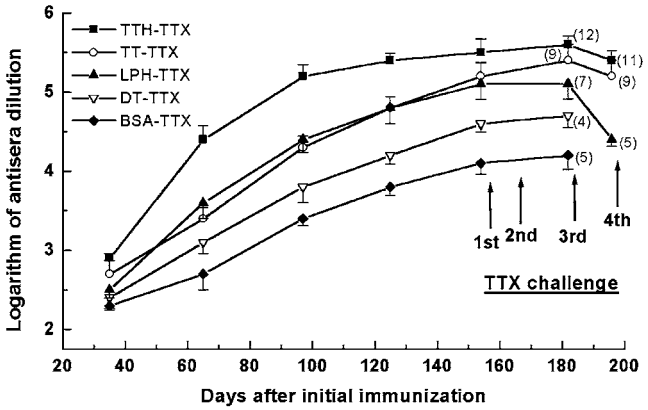

Figure 1. Comparison of the dynamic course of TTX-specific antibody level among TTX vaccines. BALB/c mice in groups were immunized with different TTX−carrier conjugates, and the antiserum specimens were prepared on schedule, initially at day 35 after initial immunization. Antibody titer (**n**), defined as the negative logarithm of the final dilution of antisera at which positive antibody reactivity appeared, was detected by ELISA procedure and expressed as mean ± SEM, $n = 12$ per group initially, and thereafter the survival number is indicated otherwise in parentheses.

Calculation of Relative Immunogenicity of TTX *vs* CP. The relative immunogenicity of TTX *vs* CP was reflected by relative antibody response intensity and expressed as the ratio of TTX- to carrier-specific antibody response in $A_{490\ nm}$ read assayed as above.

TTX Challenge Experiment. To compare the antitoxic effect of different CP−TTX vaccines, 12 immunized mice from each group were challenged repeatedly with 1× lethal dose (LD) of TTX for the first challenge at d157, 2×LD for the second at d167, 3×LD for the third at d183, and 4×LD for the fourth at d198. Referring to a previous report (*25*), a dose of 13.5 μg/kg of TTX in 10 mL/kg of normal saline solution was defined as 1×LD of TTX intraperitoneal (ip) challenge for female BALB/c mice in this study. The survivals were determined 24 h after TTX exposure, and the lethal time in the case of decedents was recorded.

Statistical Analysis. All replicate data were expressed as mean ± S.E.M. The differences among groups were determined by using Student's *t*-test, and $P < 0.05$ was considered significant as compared with the corresponding control.

RESULTS

Comparison of the Dynamic Course of TTX-Specific Antibody Level among Different Vaccines. The circulating TTX-specific antibody level (**n**) was increased gradually within 3−6 months (Figure 1). Among the five TTX vaccines, the quickest antibody-raising rate occurred in the TTH−TTX group; a moderate rate occurred in both the TT− and LPH−TTX groups; a slower rate occurred in the DT−TTX group; and the slowest rate occurred in the BSA−TTX group. A 3-month period for TTH group but a 5−6-month period for the others was necessary for the antibody titer to ascend to its top level. As a result, the antibody titer difference between the highest in the TTH−TTX and the lowest in the BSA−TTX group approximated two units of **n** value during the antibody-raising course. The **n** value from the fourth assay (d125) exemplified in Table 1 statistically differed from each other for all paired comparisons between groups, except TT−TTX *vs* LPH−TTX. The sequence of final antibody level magnitude was accordant with the antibody-raising rate, keeping rank as TTH−, TT−/LPH−, DT−, and BSA−TTX groups (Figure 1). After repeated

		statistical significance of difference between groups[b]				
immunogen	titer (**n**)[a]	BSA−TTX	DT−TTX	LPH−TTX	TT−TTX	TTH−TTX
TTH−TTX	5.4 ± 0.1	***	***	*	**	
TT−TTX	4.8 ± 0.1	***	**	†		
LPH−TTX	4.8 ± 0.2	***	*			
DT−TTX	4.2 ± 0.1	*				
BSA−TTX	3.8 ± 0.1					

[a] Antisera were collected at day 125 after initial immunization. The titer (**n**) was detected as note in Figure 1 and expressed as mean ± SEM, $n = 12$ per group. [b] Asterisks and daggers indicated statistical significance of difference in **n** values: † $P > 0.05$, * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$, compared with each other group by *t*-test.

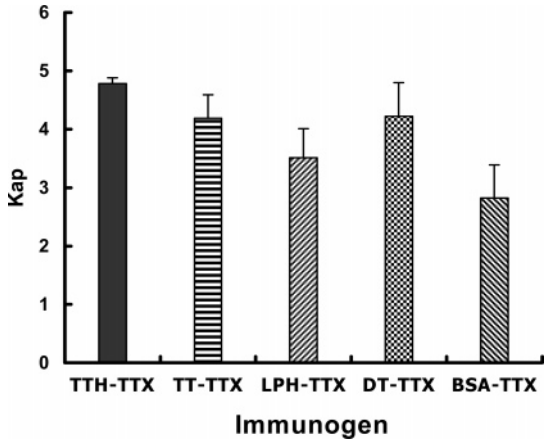

Figure 2. Comparison of TTX-specific antibody affinity among TTX vaccines. Antisera were prepared before the first TTX challenge in groups. Apparent affinity, K_{ap}, defined as the negative logarithm of IC_{50}, the TTX concentration (M) inhibiting 50% of antisera binding activity to test antigen ($K_{ap} = pIC_{50}$), was tested by competition-inhibited enzyme immunoassay procedure and expressed as mean ± SEM, $n = 12$ per group.

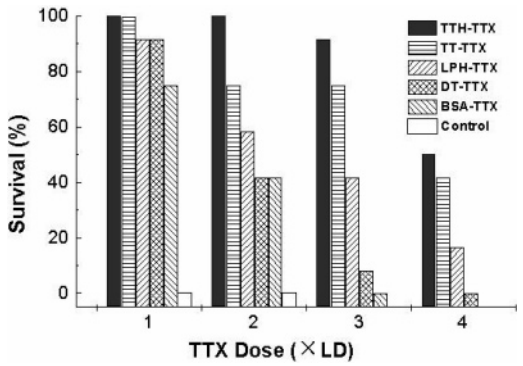

Figure 3. Comparison of antitoxic efficiency among TTX vaccines. Immunized mice in groups of 12 were intraperitoneally challenged repeatedly with 1×LD of TTX for the first challenge at the 157th day after initial immunization (d157), 2×LD for the second at d167, 3×LD for the third at d183, and 4×LD for the fourth at d198. All control mice, uninoculated or inoculated with TTH or TT alone, died of 1×LD ($n = 22$) and 2×LD ($n = 6$) TTX challenge; 1×LD = 13.5 μg/kg, in 10 mL/kg of normal saline. The survivors were counted 24 h after TTX exposure.

TTX challenges, the antibody level declined slightly in both the TTH and TT vaccines and sharply in the LPH vaccine, while all mice in the DT− and BSA−TTX groups had died off, implying that the circulating antibody had been neutralized by TTX *in vivo* (Figure 1). No TTX-specific antibody certainly was detected in the sera from mice immunized with CP alone.

Comparison of Antibody Affinity among TTX Vaccines. The apparent affinity (K_{ap}) for TTX-specific antibody, assayed before the first TTX challenge, also varied with CP adopted in these vaccines (Figure 2). The difference between the highest in the TTH−TTX and the lowest in BSA−TTX group was as high as approximately two units of K_{ap} value; the average magnitude of K_{ap} sequenced basically same as that of antibody level with the exception of the DT−TTX group, which showed slightly higher K_{ap} value. In the TTH−TTX group, a lower standard deviation of K_{ap} value implied that the antibody affinity matured more rapidly and then more readily tended to uniformity than in other four vaccines.

Comparison of Antitoxic Efficacy among TTX Vaccines. TTX challenge experiments began at d157 when the antibody level in all tested groups approximately approached the top level and was repeated at intervals of 10−16 days with gradually increasing doses (Figure 3). The majority of the immunized mice were able to tolerate more than one TTX exposure. The group TTH−TTX showed the most excellent effect, all mice surviving a 2×LD single dose and the majority surviving increasing TTX doses, and the group TT−TTX showed a slightly lower effect, all surviving a 1×LD single TTX dose. In turn, LPH−TTX presented a moderate antitoxic potency, the majority surviving 1×LD and the survival rate descending sharply with the increasing TTX doses. The DT−TTX showed a poorer effect; and especially, the BSA−TTX showed the poorest effect, none surviving the 3×LD TTX dose. The survival proportion of the immunized mice, for example, challenged with a single TTX dose of 3×LD, was 92%, 75%, 42%, 8%, and 0% for TTH−, TT−, LPH−, DT−, and BSA−TTX, respectively. The group sequence in anti-TTX poisoning effect was approximately consistent with that for both antibody-raising rate and antibody level (Figure 1), that is, in the order TTH, TT, LPH, DT, and BSA carrier. All control mice, uninoculated or immunized with TTH or TT alone, died of 1× or 2×LD TTX exposure.

Table 2. Comparison of Lethal Time for Victims among TTX Vaccines

immunogen	number of mice	TTX dose[a] (×LD)	lethal time[b] (min)
uninoculated control	12	1	13 ± 2
	6	2	5 ± 0
TTH or TT control	10	1	10 ± 1
TTH−TTX	6	3−4	22 ± 3*,‡
TT−TTX	7	2−4	56 ± 26*,†
LPH−TTX	10	1−4	20 ± 6
DT−TTX	12	1−4	21 ± 4†
BSA−TTX	12	1−3	10 ± 1

[a] The animals were challenged as described in Figure 3. [b] Lethal times are means ± SEM. *$P < 0.05$ vs control of 1×LD and †$P < 0.05$, ‡$P < 0.01$ vs BSA−TTX by *t*-test.

In addition, the decedents in all groups except BSA−TTX, especially in TTH− and TT−TTX groups, survived longer than those in control groups, even those who were challenged with higher TTX doses, whereas the victims in the BSA−TTX group behaved almost the same as the control (Table 2).

Influence of Formaldehyde Treatment of CP on Its Antigenicity. In an attempt to explain the cause of the difference in TTX-antibody response among TTX vaccines, the influence of formaldehyde treatment in coupling of TTX−CP on CP

TTH−TTX	−	−	0.98 ± 0.06

[a] $A_{490\ nm}$ values are means ± SEM; n indicates the number of specimens tested. **$p < 0.01$ vs respective CP and ‡$p < 0.01$ vs TTH, by t-test; − denotes a value of $A_{490\ nm} < 0.1$, same as that in normal mice sera control. [b] f−BSA and f−TTH refer to formaldehyde-treated BSA and TTH, the procedure being the same as the preparation of CP−TTX conjugates by omission of TTX. [c] Antisera, collected at day 120 from mice immunized with CP, were tested by ELISA procedure at a dilution of 1:1000.

antigenicity and the cross-antigenicity between CPs have been assayed using mice antisera elicited by three representative CPs, that is, TT, DT, and TTH (Table 3). The anti-TT antisera reacted with TT−TTX far more weakly than with TT alone, whereas both anti-TTH and anti-DT antisera reacted similarly with their respective TTX conjugates and CP alone. Moreover, the anti-TTH antisera reacted very weakly with f−TTH, a product from aggregation of TTH molecules by formaldehyde treatment. These results indicated that the change of antigenicity for CP involved in the TTX conjugate due to formaldehyde treatment varied markedly, that is, significant loss in the case of TT and negligible change in DT and TTH, and that formaldehyde might bring on the loss of most antigenicity in free TTH but had negligible effect on TTH involved in its TTX conjugate.

In addition, except anti-TTH antisera, which reacted with LPH and LPH−TTX, no positive cross-reaction occurred between individual anti-CP antisera and unrelated CP, implying that only TTH and LPH may share common antigenicity.

Cross-Reactivity of Anti-TTX Vaccine Antisera to CP and TTX. To compare the relative immunogenicity of TTX *vs* CP in individual TTX vaccines, both CP-specific and TTX-specific antibodies contained in antisera were measured by the ELISA procedure (Table 4). The antisera elicited by the TT−TTX vaccine strongly reacted with TTX ligand but weakly with TT carrier. Similarly, the anti-TTH−TTX antisera reacted very strongly with TTX but considerably less strongly with TTH, and anti-BSA−TTX antisera moderately to TTX but negligibly to BSA. In contrast, the antisera against both LPH−TTX and DT−TTX reacted with the respective CPs more strongly than with TTX. Furthermore, the antisera from both TTH−TTX and LPH−TTX obviously cross-reacted each other, whether the CP was in a free or coupled state, which was somewhat consistent with the case of anti-TTH antisera being cross-reactive to LPH or LPH−TTX (Table 3).

Based on these data, the relative intensity of anti-TTX to anti-CP antibody response was analyzed (Table 5). The ratio of TTX- to CP-specific antibody response ranks in sequence of TT−, BSA−, TTH−, DT−, and LPH−TTX vaccine.

DISCUSSION

It is considered that proteins of large molecular size and originating from outside the mammalian order are strongly immunogenic and could be preferred as CPs of haptenic vaccine. Among the proteins studied, both TTH and LPH are excellent immunogenic agents themselves (*26*−*28*) and have been effectively used as carriers of other haptenic poisons (*29*, *30*); TT and DT have been clinically used as active immunizing agents for a long time; BSA has the advantage of being easily available in pure form and proven to be an effective carrier (*4*, *31*, *32*), whereas some reports showed it being a weak carrier in other poison conjugates (*33*, *34*).

The present research showed that the anti-TTX antibody response elicited by TTX vaccines varied greatly with vaccine-

Table 4. Cross-Reactivity ($A_{490\ nm}$) of Antisera Elicited by TTX Vaccines to Both Haptenic TTX and CP[a]

	antisera-eliciting immunogen				
test antigen	BSA−TTX ($n = 8$)	DT−TTX ($n = 9$)	LPH−TTX ($n = 10$)	TT−TTX ($n = 12$)	TTH−TTX ($n = 12$)
BSA−TTX	0.75 ± 0.15	0.66 ± 0.14	1.02 ± 0.15	1.20 ± 0.08	1.69 ± 0.07

BSA	0.20 ± 0.02	−	−	−	−
DT	−	1.12 ± 0.15	−	−	−
LPH	−	−	1.85 ± 0.11	−	1.66 ± 0.12
TT	−	−	−	0.25 ± 0.02	−
TTH	−	−	1.17 ± 0.07	−	1.20 ± 0.10
f−TTH	−	−	−	−	0.18 ± 0.02

[a] Cross-reactivity was assayed by ELISA procedure in which antisera were diluted 1000-fold with PBS containing 1% BSA (pH 7.2). The results ($A_{490\ nm}$) are means ± SEM; the control value of nonspecific binding of normal mice sera (1:1000) to test antigens was 0.09 ± 0.00, $n = 22$. †, not detected; − denotes a value of $A_{490\ nm} < 0.1$, same as that in normal mice sera control. No TTX-antibody reaction was detected from antisera from control mice inoculated with TTH or TT alone ($n = 12$). f−TTH refers to formaldehyde-treated TTH.

Table 5. Analysis for Relative Intensity of Antibody Reaction to TTX and CP

	antisera-eliciting immunogen				
	BSA−TTX	DT−TTX	LPH−TTX	TT−TTX	TTH−TTX
reactivity to CP[a]	±/+	+++	++++	+	+++
reactivity to TTX[a]	++	++	+++	+++	++++
reactivity ratio of TTX/CP[b]	4.3 ± 1.0	0.8 ± 0.2	0.5 ± 0.1	5.0 ± 0.4	1.6 ± 0.1
sequence of ratio[c]	2	4	5	1	3

[a] The grade of intensity was defined according to data in Table 4: ±, $A_{490\ nm} < 0.2$; +, $0.2 < A_{490\ nm} < 0.5$; ++, $0.5 < A_{490\ nm} < 1.0$; +++, $1.0 < A_{490\ nm} < 1.5$; ++++, $A_{490\ nm} > 1.5$. [b] The reactivity ratio means the ratio of TTX-specific antibody reaction with test antigen in which the CP was different from that in immunogen vs CP-specific antibody reaction with respective CP alone. Values are means ± SEM; $n = 8$−12 per group. [c] The numbers denote the sequence of ratios listed above, indicating relative potency of TTX-specific antibody response as $1 > 2 > 3 > 4 > 5$.

constituting CP species. The TTH−TTX was excellent, showing strong antibody response and high antitoxic efficacy; the TT−TTX was just slightly inferior to TTH−TTX in turn; the DT−TTX showed a weak immune effect and some toxic side effects; and the BSA−TTX showed poor immune response. The LPH−TTX vaccine showed only a moderate anti-TTX effect, although LPH is also macromolecular and shares common antigenicity with TTH, as proved by cross-reactivity to anti-TTH antisera (Table 3). Previous reports demonstrated that only 46% of the amino acid sequence of the N-terminal segment of the LPH molecule is identical with that of the α-chain of TTH (*35*, *36*) and that their characteristics are different in ultracentrifugation, chromatography, electrophoresis, electron microscopy, and immunogenicity (*26*−*28*, *37*, *38*). These differences in structure and characteristics might be responsible for their different effect in application to TTX vaccines. Consequently, TTH chiefly and also TT were selected as optimal CP candidates and approved by further study (*22*).

The antitoxic potency for all TTX vaccines was basically consistent with the respective antibody response. The highest antibody quality induced the best antitoxic efficacy in TTH−TTX; the lowest antibody response produced the poorest antitoxic potency in BSA−TTX. This fact demonstrated that the antibody response was consequentially the basis of the antitoxic effect. The results also suggested that an early quick antibody response must result in a higher final circulating antibody level and quicker affinity maturation.

Usually the CP involved in an artificial antigen conjugate may be more immunogenic than the hapten, and the conjugate could induce inhomogeneous antisera containing both CP- and hapten-specific antibodies. So the binary antitoxic sera, for example, against both TT or DT and TTX, would be possibly elicited by immunization with TT− or DT−TTX conjugates. Nevertheless, the results in this study showed that the relative intensity of antibody response to CP and to TTX varied with CP species used in the vaccine (Table 5). Animals responded strongly to the TTX ligand but weakly to the TT carrier for the TT vaccine. Similarly, higher TTX/CP antibody response ratio appeared both in the TTH vaccine, very powerful response, and in the BSA vaccine, very weak response. But, in a contrary mode, a stronger response to CP than to TTX was observed in DT and LPH vaccines. The phenomenon that the immunogenicity of some proteins involved in artificial antigens was inferior to that of haptenic TTX is interesting and inexplicable yet. Whether it is true for other CP−hapten conjugates remains to be studied. The experiments on cross-reactivity of anti-CP antisera showed that formaldehyde treatment caused the majority of antigenicity of free TTH to be lost. Probably some immunologically active group becomes inactive because of intra- and intermolecule cross-linking (*39*, *40*). But, in the case of the TTX−CP conjugate coupled via formaldehyde, the change in CP antigenicity varied according to adoptive protein species, decreasing for TT, invariable for TTH, and increasing for DT and LPH (Table 3). This was even consistent with and thereby might be able partially to interpret the sequence of TTX/CP antibody response ratios (Table 5). The decrease of CP antigenicity might be beneficial to the prominence of anti-TTX antibody response. This imbalance of immune response against CP and TTX may be one of the direct causes of diverse TTX-specific antibody production. There is much more to be learned whether and how the species and structure of CPs bring on different haptenic stimulus properties. This first work will serve as a basis for further elucidation of influences of CP on haptenic vaccine.

The classical coupling technique of TTX to proteins by formaldehyde treatment in which amino groups of proteins were cross-linked with guanidyl groups of the TTX molecule (*24*, *41*) was to some extent reversible; thereby the free toxin resulting from possible decomposition during the storage, management, or even after injection would poison animals as indicated by the early case of paralytic shellfish poison (*24*). By virtue of improvement of preparation and storage of vaccine, all TTX vaccines except DT−TTX showed no perceivable side effects. The majority of mice in the DT−TTX group became thin ($P < 0.01$ *vs* control), developed sag and lackluster hair, and quivered, whereas no visible side effects were found in mice immunized with DT itself. The results suggested that the side effects were induced by the DT vaccine; perhaps it might release free toxin more easily than other CP conjugates by reversible decomposition. The variability in rates of decomposition might be very different from protein to protein.

In conclusion, The TTX vaccines constructed with various CPs brought on obviously different TTX- to CP-specific antibody response ratios. The CP functionally affected the TTX-specific antibody intensity and then the antitoxic effect. The rank order of total efficacy of CP for these respects is TTH > TT > LPH > DT > BSA. Both TTH and TT were selected as optimal CP candidates for a TTX vaccine because of their excellent TTX-specific antibody-eliciting capacity and few side effects. The use of optimal CP may be able greatly to improve the effect of an anti-TTX vaccine and be beneficial to anti-TTX antitoxin research.

ACKNOWLEDGMENT

This work was supported by both the ninth and tenth Five-year Plan Foundation of Military Medical Science, the Chinese P.L.A. The authors are highly grateful to Dr. Z. G. Xue for her help with preparation of TTH and to Prof. Y. F. Ren for critical review of this manuscript.

Biotin Reagents for Antibody Pretargeting. 7. Investigation of Chemically Inert Biotinidase Blocking Functionalities for Synthetic Utility

D. Scott Wilbur,* Donald K. Hamlin, and Ming-Kuan Chyan

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195. Received April 6, 2006; Revised Manuscript Received August 10, 2006

An investigation was conducted to evaluate three biotin derivatives designed to block biotinidase cleavage of the biotinamide bond. Difficulties in multistep syntheses of molecules containing *tert*-butyl protected hydroxymethyl and carboxylate groups positioned α to a biotinamide bond led to the investigation of alternative biotinidase-blocking moieties that do not require protection and deprotection. The targeted biotin derivatives contained serine-*O*-methyl ether, 2-aminobutyric acid, and valine moieties conjugated to the biotin carboxylate functionality. Those derivatives were further modified with a radioiodinated aryl ring to study their biotinidase stability. As a comparison to previously studied biotin derivatives, radioiodinated versions of biotin conjugates that contained (a) no biotinidase stabilizing group, (b) an *N*-methyl (sarcosine) stabilizing group, (c) an α-carboxylate (aspartate) stabilizing group and hydroxymethyl (serine) stabilizing group were also prepared and tested. When tested in human serum, all of the radioiodinated biotinidase-stabilized biotin derivatives had <1% biotinamide cleavage. Thus, under the conditions studied, all of the tested biotinidase blocking moieties appeared to be equal with regards to protection from biotinidase cleavage. Further testing of the biotin derivatives included a HPLC assay to determine their relative dissociation from recombinant streptavidin (rSAv). The dissociation of cyanocobalamin (CN-Cbl) adducts of biotin−serine-*O*-methyl ether, biotin−aminobutyric acid, and biotin−valine were compared with the CN-Cbl adduct of biotin−sarcosine. The relative rates of dissociation found were biotin−sarcosine−CN-Cbl > biotin−valine−CN-Cbl > biotin−serine-*O*-methyl ether−CN-Cbl > biotin−aminobutyric acid−CN-Cbl. Due to the high cost of serine-*O*-ethyl ether (and its N-Boc derivative) and difficulty in syntheses of its biotin derivatives, that adduct is not an attractive candidate for application to compounds used in vivo. The higher lipophilicity and diminished binding of the biotin−valine adduct also makes its use in vivo less attractive. Thus, the biotin−aminobutyric acid adduct appears to be the best candidate for incorporation into biotin derivatives used in vivo, as it simplifies the synthetic procedures, has low cost, and provides effective blocking of biotinidase while retaining high binding affinity.

INTRODUCTION

This laboratory has been involved in the development of radiohalogenated biotin derivatives for therapy of cancer using the monoclonal antibody-based "pretargeting" approach (*1*−*3*). As part of those studies, we have investigated structural requirements in biotin derivatives to block the activity of the enzyme biotinidase (*4*−*7*). Biotinidase functions in a biotin salvage pathway, where it cleaves the biotinamide bond in the biotin−lysine adduct biocytin, which is present from peptidase degradation of biotin-containing carboxylases and histones (*8*, *9*). Biotinidase may also function as a biotin carrier (*10*) to transfer biotin to other proteins such as histones (*11*, *12*). The biotinamide cleavage by biotinidase is not specific for biocytin, as it occurs with biotin conjugates of other alkyl and aromatic amino compounds. This nonspecificity has allowed the development of colorimetric assays with *p*-aminobenzoic acid and aminoquinoline adducts of biotin (*13*), and radiometric assays with biotin adducts of *p*-[^{14}C]aminobenzoic acid (*14*) and [^{125}I]-iodotyramine (*15*), for measuring bioactivity of biotinidase in clinical assays. Indeed, biotinidase may not be highly specific for biotin adducts either, as data has been published which indicates that it can cleave structurally similar desthiobiotinyl-*p*-aminobenzoic acid (*16*) and lipoic acid−lysine adducts (*8*, *17*, *18*).

* Address correspondence to: D. Scott Wilbur, Ph.D., Department of Radiation Oncology, University of Washington, Box 359658, 325 Ninth Ave., Seattle, WA 98104, Phone: 206-341-5437, FAX: 206-341-5438, E-mail: dswilbur@u.washington.edu.

The nonspecific nature of the cleavage of biotinamide bonds in biotin conjugates has made it imperative that biotin derivatives employed in vivo be designed in a manner that blocks the enzyme activity. For this reason, a number of investigators (*19*−*21*), including ourselves (*22*, *23*), have studied biotin conjugates for use in pretargeting applications which have structural features designed to block biotinidase action. Our studies initially followed the lead reported by other investigators in which it was found that the *N*-methylglycine (sarcosine) adduct of biotin fully blocked the action of biotinidase (*24*). However, we felt it was important that the high binding affinity of biotin with avidin or streptavidin be retained, so competitive binding studies were conducted with biotin. From those studies, some biotin adducts were identified which were stable to biotinidase and retained the high binding affinity of the biotin−(strept)avidin system (as measured by a slow dissociation rate). The biotin adducts identified contained either a carboxylate (e.g., biotin−aspartate, biotin−lysine, biotin−cysteine) or hydroxymethyl (e.g., biotin−serine) on the carbon α to the biotinamide bond (*25*).

Subsequently, we have conducted a number of synthetic studies incorporating aspartate, lysine, and serine in the targeted biotin-containing compounds. In most synthetic studies, biotin−aspartate or biotin−lysine was used, and the biotinidase-blocking carboxylate was protected as a *tert*-butyl ester. Unfortunately, unwanted side reaction products were obtained with the *t*-Bu ester protecting group. The problems encountered in synthetic procedures led us to investigate alternate biotinidase blocking

groups that are chemically inert or functionalized in a manner that a protecting group does not have to be removed after the synthesis. The studies focused on three biotin−amino acid conjugates that have steric, but nonreactive, functional groups α to the biotinamide bond. The biotin derivatives were synthesized and evaluated for biotinidase stability and binding with streptavidin. The derivatives studied included biotin conjugates of (a) L-serine-methyl ether, (b) D,L-2-aminobutyric acid and (c) L-valine, which contain methyl hydroxymethyl, ethyl and isopropyl functional groups (respectively) α to the biotinamide functionality.

Stability of the biotin−amino acid conjugates toward biotinidase cleavage in human serum was evaluated by preparing radioiodinated biotin derivatives from arylstannyl-biotin derivatives (*22*, *23*). The structures of the biotin derivatives prepared, radioiodinated, and evaluated are shown in Figure 1. Changes in the binding affinity of two of the three biotin−amino acid adducts with recombinant streptavidin (rSAv) was evaluated using a size-exclusion HPLC assay (*26*). In that assay, relative rates of dissociation of biotin derivatives from rSAv can be observed after challenge with a large excess of biotin. The assay required preparation of CN-Cbl conjugates shown in Figure 2. The preparation of biotin derivatives, radioiodination of biotin−arylstannanes, and evaluation of radioiodinated biotin derivatives in the biotinidase assay and biotin−CN-Cbl derivatives in the HPLC dissociation assay are described herein.

EXPERIMENTAL PROCEDURES

General. Most chemicals were purchased from Sigma-Aldrich Corporation (St. Louis, MO, and Milwaukee, WI) as analytical grade and were used without further purification. Boc-serine(Me)-OH DCHA salt was obtained from Bachem Bioscience Inc. (King of Prussia, PA). Biotin *N*-hydroxysuccinimide ester, **11**, was obtained as a gift from Quanta BioDesign, Ltd (Powell, OH). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Silica gel chromatography was conducted with 70−230 mesh 60 Å silica gel (Aldrich Chemical Co.). Microcon-30 centrifugation concentrators were obtained from Amicon (Beverly, MA). Melting

[1] Abbreviations: Av, avidin; BSA, bovine serum albumin; CN-Cbl, cyanocobalamin; cpm, counts per minute; DCHA, dicyclohexylammonium salt; EDC, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide; HOHgBz, hydroxymercuribenzoic acid; NCS, *N*-chlorosuccinimide; NHS, *N*-hydroxysuccinimide; PBS, phosphate-buffered saline; rt, room temperature; rSAv, recombinant streptavidin; SAv, streptavidin; t-Boc, *tert*-butyloxycarbonyl; TFA, trifluoroacetic acid; TFP, tetrafluorophenyl; TFP-OTFA, tetrafluorophenyl trifluoroacetate.

points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected.

Spectral Analyses. ^{1}H NMR were obtained on either a Bruker AV 300 (300 MHz) or Bruker AV 500 (500 MHz) instrument. Chemical shifts are expressed as ppm using tetramethylsilane as internal standard (δ = 0.0 ppm). High-resolution mass spectral (HRMS) data were obtained on a Bruker APEX III 47e Fourier transform mass spectrometer using electrospray ionization. For analysis, the samples were dissolved in 50/50 MeOH/H_2O and were introduced by an integral syringe infusion pump (Cole Parmer Series 74900).

Radioactive Materials. Standard methods for safely using radionuclides of iodine were employed (*27*). Na[^{125}I]I was purchased from Perkin-Elmer Life Sciences (Billerica, MA) as high pH, high concentration solutions in 0.1 N NaOH. Measurement of ^{125}I was accomplished on the Capintec CRC-15R or a Capintec CRC-6A Radioisotope Calibrator. Radioactive samples were counted in a Wallac 1480 Wizard Gamma Counter (Perkin-Elmer Life and Analytical Services, Wellesley, MA).

Chromatography. HPLC separations of nonradioactive compounds were obtained on Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 nm) and a Varex ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. All reactions were monitored by HPLC. Reversed-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μm, 250 mm × 4.6 mm) using a gradient solvent system at a flow rate of 1 mL/min. A gradient of MeOH and H_2O/0.1% HOAc was used. Starting with 40% MeOH, the initial solvent mixture was held for 2 min, the gradient was increased to 100% MeOH over the next 10 min, and then held at 100% MeOH for 8 min. Retention times (t_R) under these conditions for biotin conjugates are provided with the compound experimental.

HPLC separations of radioiodinated biotin derivatives were conducted using a gradient system consisting of a HP 1050 quaternary pump, a Waters Model 481 UV detector (254 nm), and a Beckman model 170 radioisotope detector. The separations were obtained using HPLC conditions described for Gradient I, above, except water was used in the place of the H_2O/0.1% HOAc.

Size-exclusion HPLC analyses used in the rSAv binding (dissociation) experiments were conducted on a system consisting of a Hewlett-Packard 1050 Multiple Wavelength Detector (280 and 362 nm), isocratic pump, and a Waters Protein-Pak 300SW glass column. The mobile phase was an aqueous solution containing 50 mM potassium phosphate (pH 6.8), 300 mM NaCl, 1 mM EDTA, and 1 mM NaN_3. A flow rate of 1.0 mL/min was used. Retention time for rSAv and bound biotin−cyanocobalamin derivatives was 10.5 min and free biotin−cyanocobalamin derivatives was 14.0 min.

The following compounds were prepared as previously described: **1a**, **1b**, [^{125}I]**1b**, **2a**, **2b**, [^{125}I]**2b** (*22*); **3a**, **3b**, [^{125}I]-**3b**, **4a**, **4b** [^{125}I]**4b** (*23*); **8** (*26*); **18** (*28*); **25**, **26** (*22*); **27** (*26*).

General Procedure for Synthesis of Biotin−Amino Acid−Trioxatridecanediaminebenzamide Adducts, 5a/b−7a/b. A quantity of **19**, **20**, or **21** was dissolved in neat TFA (3−5 mL) and stirred at room temperature for 10 min. Then the TFA was evaporated under a stream of argon. The amine **22**, **23**, or **24** (TFA salt) was washed with EtOAc (3 × 20 mL) and dried under vacuum for 2 h. The crude amine TFA salt was dissolved in a solution of anhydrous DMF (10 mL) and Et_3N (0.25 mL, 1.79 mmol), and then 1.3 equiv of the *p*-tri-*n*-butylstannylbenzoate TFP ester **25** or *p*-iodobenzoate TFP ester **26** was added and stirred at room temperature for 10 min to 1 h. The volatile materials were removed under vacuum. The residue was purified by a silica gel column (1.5 cm × 25 cm), eluting with a mixture of MeOH/EtOAc to give the desired product **5a**, **5b**, **6a**, **6b**, **7a**, or **7b**.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-(tri-*n*-butylstannyl)benzoylamino)-4′,7′,10′-trio xatridecanamino)-L-serine-*O*-methyl Ether, 5a. Following the general procedure (stirring for 30 min), **5a** was obtained after silica gel chromatography (20% MeOH/EtOAc) as a colorless solid in 87% yield, mp = 137−139 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.91 (t, J = 7.3 Hz, 9H), 1.13 (t, J = 8.1 Hz, 4H), 1.32−1.51 (m, 10H), 1.55−1.81 (m, 14H), 1.88−1.96 (m, 2H), 2.32 (t, J = 7.3 Hz, 2H), 2.73 (d, J = 12.5 Hz, 1H), 2.92−2.99 (m, 1H), 3.19−3.35 (m, 4H), 3.37 (s, 3H), 3.49−3.54 (m, 4H), 3.56−3.71 (m, 9H), 4.33 (dd, J = 4.4, 7.9 Hz, 1H), 4.49−4.54 (m, 2H), 7.59 (d, J = 8.2 Hz, 2H), 7.78 (d, J = 8.2 Hz, 2H). HRMS (ES^+) calcd for $C_{43}H_{75}N_5NaO_8SSn$ $(M + Na)^+$: 964.4256. Found: 964.4274. HPLC: t_R = 16.7 min.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-iodobenzoylamino)-4′,7′,10′-trioxatridecaneam ino)- L-serine-*O*-methyl Ether, 5b. Following the general procedure (stirring for 1 h), **5b** was obtained after silica gel chromatography (40% MeOH/EtOAc) as a colorless solid in 83% yield, mp = 152−154 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 1.34 (t, J = 7.3 Hz, 3H), 1.41−1.52 (m, 2H), 1.56−1.82 (m, 5H), 1.86−1.95 (m, 2H), 2.32 (t, J = 7.3 Hz, 2H), 2.73 (d, J = 12.6 Hz, 1H), 2.94 (dd, J = 5.0, 12.6 Hz, 1H), 3.24 (q, J = 7.3 Hz, 3H), 3.33−3.35 (m, 2H), 3.37 (s, 3H), 3.47−3.54 (m, 3H), 3.56−3.70 (m, 9H), 4.33 (dd, J = 4.4, 8.0 Hz, 1H), 4.49−4.54 (m, 2H), 7.60 (d, J = 8.5 Hz, 2H), 7.87 (d, J = 8.5 Hz, 2H). HRMS (ES^+) calcd for $C_{31}H_{48}IN_5NaO_8S$ $(M + Na)^+$: 800.2166. Found: 800.2157. HPLC: t_R = 11.9 min.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-(tri-*n*-butylstannyl)benzoylamino)-4′,7′,10′-trio xatridecanamino)aminobutyramide, 6a. Following the general procedure (stirring for 30 min), **6a** was obtained after silica gel chromatography (15% MeOH/EtOAc) as a colorless solid in 91% yield, mp = 130−132 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.90−0.99 (m, 10H), 1.14 (t, J = 8.1 Hz, 4H), 1.32−1.51 (m, 10H), 1.55−1.83 (m, 14H), 1.86−1.96 (m, 2H), 2.29 (t, J = 7.3 Hz, 2H), 2.72 (d, J = 12.4 Hz, 1H), 2.94 (dd, J = 5.0, 12.9 Hz, 1H), 3.19−3.35 (m, 6H), 3.51 (t, J = 6.1 Hz, 4H), 3.56−3.70 (m, 9H), 4.16−4.24 (m, 1H), 4.32 (dd, J = 4.4, 7.9 Hz, 1H), 4.51 (dd, J = 4.4, 7.9 Hz, 1H), 7.59 (d, J = 8.3 Hz, 2H), 7.77 (d, J = 8.3 Hz, 2H). HRMS (ES^+) calcd for $C_{43}H_{75}N_5NaO_7SSn$ $(M + Na)^+$: 948.4307. Found: 948.4302. HPLC: t_R = 16.8 min.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-iodobenzoylamino)-4′,7′,10′-trioxatridecanam ino)aminobutyramide, 6b. Following the general procedure (stirring for 10 min), **6b** was obtained after silica gel chromatography (30% MeOH/EtOAc) as a colorless solid in 88% yield, mp = 80−82 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.96 (t, J = 7.5 Hz, 3H), 1.41−1.51 (m, 2H), 1.55−1.83 (m, 8H), 1.86−1.97 (m, 2H), 2.29 (t, J = 7.3 Hz, 2H), 2.72 (d, J = 12.5 Hz, 1H), 2.95 (dd, J = 5.0, 12.7 Hz, 1H), 3.19−3.35 (m, 4H), 3.50 (q, J = 6.4 Hz, 4H), 3.56−3.69 (m, 9H), 4.19 (dd, J = 5.9, 8.3 Hz, 1H), 4.32 (dd, J = 4.5, 7.9 Hz, 1H), 4.52 (dd, J = 4.5, 7.9 Hz, 1H), 7.60 (d, J = 8.6 Hz, 2H), 7.87 (d, J = 8.6 Hz, 2H). HRMS (ES^+) calcd for $C_{31}H_{48}IN_5NaO_7S$ $(M + Na)^+$: 784.2217. Found: 784.2205. HPLC: t_R = 12.2 min.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-(tri-*n*-butylstannyl)benzoylamino)-4′,7′,10′-trio xatridecanamino)-L-valine, 7a. Following the general procedure (stirring for 30 min), **7a** was obtained after silica gel chromatography (15% MeOH/EtOAc) as a colorless solid in 89% yield, mp = 134−136 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.92 (t, J = 7.4 Hz, 6H), 0.97 (dd, J = 2.6, 6.5 Hz, 6H), 1.14 (t, J = 8.0 Hz, 3H), 1.34 (t, J = 7.3 Hz, 6H), 1.39−1.51 (m, 4H), 1.55−1.82 (m, 10H), 1.87−1.96 (m, 2H),

1.99−2.11 (m, 1H), 2.30 (t, J = 7.3 Hz, 2H), 2.72 (d, J = 12.9 Hz, 1H), 2.94 (dd, J = 5.0, 12.7 Hz, 1H), 3.24 (q, J = 7.3 Hz, 6H), 3.29−3.35 (m, 4H), 3.51 (t, J = 6.4 Hz, 4H), 3.55−3.70 (m, 9H), 4.11 (dd, J = 1.8, 7.7 Hz, 1H), 4.32 (dd, J = 4.4, 7.9 Hz, 1H), 4.51 (dd, J = 4.4, 7.9 Hz, 1H), 7.58 (d, J = 8.2 Hz, 2H), 7.77 (d, J = 8.2 Hz, 2H). HRMS (ES$^+$) calcd for $C_{44}H_{77}N_5NaO_7SSn$ (M + Na)$^+$: 962.4463. Found: 962.4453. HPLC: t_R = 16.8 min.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-iodobenzoylamino)-4′,7′,10′-trioxatridecanam ino)-L-valine, 7b. Following the general procedure (stirring for 10 min), **7b** was obtained after silica gel chromatography (15% MeOH/EtOAc) as a colorless solid in 85% yield, mp = 144−146 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.97 (dd, J = 2.9, 6.7 Hz, 6H), 1.41−1.51 (m, 2H), 1.56−1.82 (m, 6H), 1.87−1.95 (m, 2H), 1.97−2.11 (m, 1H), 2.31 (t, J = 7.3 Hz, 2H), 2.73 (d, J = 12.6 Hz, 1H), 2.95 (dd, J = 5.0, 12.7 Hz, 1H), 3.19−3.35 (m, 4H), 3.51 (q, J = 6.3 Hz, 4H), 3.56−3.70 (m, 9H), 4.11 (dd, J = 1.8, 7.8 Hz, 1H), 4.32 (dd, J = 4.5, 7.9 Hz, 1H), 4.52 (dd, J = 4.5, 7.9 Hz, 1H), 7.60 (d, J = 8.7 Hz, 2H), 7.87 (d, J = 8.7 Hz, 2H). LRMS (ES$^+$) calcd for $C_{32}H_{51}IN_5O_7S$ (M + H)$^+$: 776.2554. Found: 776.2563. HPLC: t_R = 12.6 min.

General Procedure for Synthesis of Biotin−Cyanocobalamin Derivatives 9, 10, and 11. To a solution of 48 μmol biotin amino acid adduct **15**, **16**, or **17**, and Et_3N (9 μL, 64 μmol) in anhydrous DMF (2 mL), at room temperature was added 48 μmol trifluoroacetate tetrafluorophenyl ester (TFP-OTFA). The mixture was stirred at room temperature for 0.5 h, and then 32 μmol of the cyanocobalamin-trioxadiamine adduct **27** was added. That mixture was stirred at room temperature for 0.5 h, and EtOAc (15 mL) was added and stirred for an additional 5 min. The crude product was filtered, washed with EtOAc (3 × 10 mL), and then purified by TLC plate (RP-18 F_{254S}, 20 × 20, Merck) eluting with 1:1 MeOH/H_2O.

Biotin−Serine-OMe−Cyanocobalamin Conjugate, 9. Following the general procedure, **9** was obtained as a red solid in 40% yield, mp 183−186 °C. ^{1}H NMR 500 MHz (CD_3OD): d −.49 (s, 3H), 1.23 (s, 6H), 1.28−1.42 (m, 6H), 1.49 (s, 3H), 1.63−1.86 (m, 10H), 1.91 (s, 6H), 1.95−2.26 (m, 6H), 2.29 (d, J = 3.4 Hz, 6H), 2.33−2.42 (m, 6H), 2.50 (s, 3H), 2.59 (s, 6H), 2.63 (s, 3H), 2.85−2.97 (m, 2H), 3.10−3.30 (m, 6H), 3.37 (2xs, 3H), 3.41−3.45 (m, 3H), 3.52−3.71 (m, 14H), 3.79 (dd, J = 3.7, 12.7 Hz, 1H), 3.93 (dd, J = 3.6, 12.6 Hz, 1H), 4.09−4.22 (m, 2H), 4.32−4.38 (m, 1H), 4.50−4.54 (m, 1H), 6.08 (s, 1H), 6.31 (d, J = 3.0 Hz, 1H), 6.54 (s, 1H), 7.17 (s, 1H), 7.28 (s, 1H). HRMS (ES$^+$) calcd for $C_{87}H_{129}CoN_{18}Na_2O_{22}PS$ (M−H+2Na)$^+$: 1945.8115. Found: 1945.8079. HPLC: t_R = 7.8−7.9 min.

Biotin−2-Aminobutyrate−Cyanocobalamin Conjugate, 10. Following the general procedure, **10** was obtained as a red solid in 90% yield, mp 196−199 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.48 (s, 3H), 0.96−1.03 (m, 3H), 1.22 (s, 3H), 1.28 (d, J = 5.5 Hz, 3H), 1.34 (t, J = 7.3 Hz, 2H), 1.40 (d, J = 5.7 Hz, 6H), 1.49 (s, 3H), 1.59−1.82 (m, 8H), 1.91 (s, 2H), 1.97−2.26 (m, 10H), 2.30 (s, 6H), 2.41 (s, 1H), 2.51 (s, 3H), 2.53−2.61 (m, 2H), 2.64 (s, 3H), 2.69 (s, 6H), 2.75−3.19 (m, 5H), 3.24 (q, J = 7.3 Hz, 2H), 3.30−3.38 (m, 2H), 3.41−3.46 (m, 2H), 3.52−3.73 (m, 9H), 3.79 (dd, J = 4.5, 12.8 Hz, 1H), 3.94 (dd, J = 3.1, 12.5 Hz, 1H), 3.91−3.97 (m, 1H), 4.08−4.22 (m, 3H), 4.31−4.35 (m, 1H), 4.51 (dd, J = 4.5, 8.0 Hz, 1H), 4.65−4.74 (m, 2H), 6.07 (s, 1H), 6.31 (d, J = 2.8 Hz, 1H), 6.54 (s, 1H), 7.17 (s, 1H), 7.28 (s, 1H), 7.85 (s, 1H); LRMS (ES$^+$) calcd for $C_{87}H_{130}N_{18}O_{21}PSCoNa$ (M + Na)$^+$: 1907.8. Found: 1907.9. HPLC: t_R = 8.5 min.

Biotin−Valine−Cyanocobalamin Conjugate, 11. Following the general procedure, **11** was obtained as a red solid in 86% yield, mp 200−203 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.48 (s, 3H), 0.97 (dd, J = 2.8, 6.9 Hz, 6H), 1.17−1.29 (m, 6H), 1.41 (d, J = 8.7 Hz, 6H), 1.49 (s, 3H), 1.60−1.84 (m, 8H), 1.87−2.12 (m, 10H), 2.19 (s, 1H), 2.22−2.26 (m, 1H), 2.29 (s, 6H), 2.50 (s, 3H), 2.55−2.60 (m, 2H), 2.63 (s, 3H), 2.90 (s, 6H), 3.15 (t, J = 6.4 Hz, 3H), 3.25 (t, J = 7.2 Hz, 3H), 3.32−3.35 (m, 2H), 3.41 (s, 6H), 3.45 (s, 3H), 3.51−3.72 (m, 9H), 3.84−3.96 (m, 3H), 4.09−4.23 (m, 3H), 4.31−4.39 (m, 1H), 4.50−4.58 (m, 1H), 4.68−4.76 (m, 1H), 6.07 (s, 1H), 6.31 (d, J = 2.8 Hz, 1H), 6.54 (s, 1H), 7.17 (s, 1H), 7.28 (s, 1H), 7.85 (s, 1H); LRMS (ES$^+$) calcd for $C_{88}H_{133}N_{18}O_{21}PSCo$ (M + H)$^+$: 1899.9. Found: 1899.9. HPLC: t_R = 9.1 min.

General Procedure for Synthesis of Biotin−Amino Acid Adducts, 15−17. A quantity of the amino acid **12** (see below), **13**, or **14** dissolved in a solution of water (15 mL) and sodium hydrogen carbonate (0.50 g, 6.24 mmol), then biotin *N*-hydroxysuccinimide ester (0.71 g, 2.08 mmol) and acetone (15 mmol) were added respectively. The resultant solution was stirred at room temperature for 16 h, then the solution was evaporated to dryness under vacuum. The residue was redissolved in water (50 mL), and the aqueous solution was acidified to pH 2.0 by 1 N HCl. The white precipitate was filtered, washed with water (300 mL), and dried under vacuum to afford the compound **15**, **16** or **17**.

***N*-Biotinoyl-L-serine-*O*-methyl Ether, 15.** *N*-(*tert*-Butoxycarbonyl)-L-serine-*O*-methyl ether DCHA salt (1.0 g, 2.50 mmol) was used rather than 12. To prepare 12, the tBoc protected amino acid was dissolved in neat trifluoroacetic acid (3 mL) and stirred at rt for 10 min. After volatile materials were removed under a stream of argon, the residue was washed with ethyl acetate (3 × 20 mL), then dried under vacuum for 1 h. The dried residue was used directly in the synthesis. Following the general procedure, 15 was obtained as a colorless solid in 81% yield, mp = 245−247 °C. ^{1}H NMR 300 MHz (D_2O/NaOD): d 1.39−1.50 (m, 2H), 1.56−1.81 (m, 4H), 2.35 (t, J = 7.4 Hz, 2H), 2.79 (d, J = 13.4 Hz, 1H), 3.01 (dd, J = 5.0, 13.1 Hz, 1H), 3.33−3.39 (m, 1 H), 3.37 (s, 3H), 3.73−3.75 (m, 2H), 4.40 (2xd, J = 4.1, 4.3 Hz, 1 H), 4.44 (dd, 4.3, 8.0 Hz, 1H), 4.62 (dd, J = 4.3, 8.0 Hz, 1H). HRMS (ES$^+$) calcd for $C_{14}H_{23}N_3NaO_5S$ (M + Na)$^+$: 368.1256. Found: 368.1259. HPLC 4.4 min.

***N*-Biotinoyl-2-aminobutyric Acid, 16.** Following the general procedure, **16** was obtained as a colorless solid in 95% yield, mp 216−218 °C dec. ^{1}H NMR 500 MHz (DMSO-d_6): δ 0.87 (t, J = 7.2 Hz, 3H), 1.27−1.37 (m, 2H), 1.41−1.65 (m, 4H), 1.66−1.74 (m, 1H), 2.10−2.14 (m, 2H), 2.56, 2.59 (2xs, 2H), 2.80, 2.83 (2xd, J = 5.0 Hz, 1H), 3.07−3.12 (m, 1H), 4.07−4.14 (m, 2H), 4.31 (dd, J = 4.3, 8.0 Hz, 1H), 6.35 (s, 1H), 6.40 (s, 1H), 8.02 (s, 1H). HRMS (ES$^+$) calcd for $C_{14}H_{24}N_3O_4S$ (M + H)$^+$: 330.1488. Found: 330.1493. HPLC: t_R = 6.5 min.

***N*-Biotinoyl-L-valine, 17.** Following the general procedure, **17** was obtained as a colorless solid in 86% yield, mp 207−209 °C dec [lit. 215−216 °C] (*29*). ^{1}H NMR 300 MHz (DMSO-d_6): δ 0.87 (d, J = 6.8 Hz, 6H), 1.24−1.38 (m, 2H), 1.40−1.68 (m, 4H), 1.97−2.08 (m, 1H), 2.16 (t, J = 7.2 Hz, 2H), 2.57 (d, J = 12.5 Hz, 1H), 2.82 (dd, J = 5.0, 12.4 Hz, 1H), 3.06−3.12 (m, 2H), 4.10−4.15 (m, 2H), 4.30 (dd, J = 5.1, 7.8 Hz, 1H), 6.38 (d, J = 15.9 Hz, 2H), 7.91 (d, J = 8.5 Hz, 1H). HRMS (ES$^+$) calcd for $C_{15}H_{26}N_3O_4S$ (M + H)$^+$: 344.1644. Found: 344.1645. HPLC: t_R = 8.1 min.

General Procedure for Syntheses of Biotin−Amino Acid−Trioxadiamine Adducts, 19−21. To a solution containing 0.7 mmol of **15**, **16** or **17** and 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (0.9 mmol) in anhydrous DMF (8 mL) was added 0.9 mmol of **18**. The reaction was stirred at room temperature for 4 h to 5 days. After that period, DMF was removed under vacuum and the crude residue was purified

by silica column (1.5 cm × 25 cm) eluted with a MeOH/EtOAc mixture to obtain **19**, **20**, or **21**.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*tert*-butoxycarbonylamino)-4′,7′,-10′-trioxatrideca neamino)-L-serine-*O*-methyl Ether, 19. Following the general procedure (stirring for 5 d), **19** was obtained after silica gel chromatography (40% MeOH/EtOAc) as a colorless solid product in 77% yield, mp 142−144 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 1.49 (s, 9H), 1.62−1.92 (m, 8H), 1.96−2.04 (m, 1H), 2.33−2.45 (m, 2H), 2.77 (d, J = 12.8 Hz, 1H), 2.99 (dd, J = 4.8, 12.8 Hz, 1H), 3.14−3.20 (m, 4H), 3.24−3.38 (m, 3H), 3.41 (s, 3H), 3.55−3.61 (m, 4H), 3.63−3.75 (m, 9H), 4.38 (dd, J = 4.5, 7.7 Hz, 1H), 4.52−4.59 (m, 2H). HRMS (ES^+) calcd for $C_{29}H_{53}N_5NaO_9S$ $(M + Na)^+$: 670.3462. Found: 670.3449. HPLC: t_R = 11.0 min.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*tert*-butoxycarbonylamino)benzoylamino)-4′,7′,10′-trioxatri-decaneamino)aminobutyramide, 20. Following the general procedure (stirring for 4 h), **20** was obtained after silica gel chromatography (20% MeOH/EtOAc) as a colorless solid in 83% yield, mp 125−127 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 0.99 (t, J = 7.3 Hz, 3H), 1.47 (s, 9H), 1.60−1.87 (m, 10H), 2.31 (t, J = 7.2 Hz, 2H), 2.74 (d, J = 12.6 Hz, 1H), 2.96 (dd, J = 4.9, 12.8 Hz, 1H), 3.16 (t, J = 7.9 Hz, 2H), 3.21−3.35 (m, 4H), 3.52−3.57 (m, 4H), 3.60−3.69 (m, 9H), 4.17−4.25 (m, 1H), 4.34 (dd, J = 5.0, 7.9 Hz, 1H), 4.53 (dd, J = 5.0, 7.9 Hz, 1H). HRMS (ES^+) calcd for $C_{29}H_{53}N_5NaO_8S$ $(M + Na)^+$: 654.3513. Found: 654.3505. HPLC: t_R = 11.4 min.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*tert*-butoxycarbonylamino)benzoylamino)-4′,7′,10′-trioxatri-decaneamino)-L-valine, 21. Following the general procedure (stirring for 16 h), **20** was obtained after silica gel chromatography (15% MeOH/EtOAc) as a colorless solid in 88% yield, mp 133−135 °C. ^{1}H NMR 300 MHz (CD_3OD): δ 1.08 (dd, J = 2.3, 6.7 Hz, 6H), 1.56 (s, 9H), 1.69−1.94 (m, 8H), 2.10−2.22 (m, 1H), 2.41 (t, J = 7.3 Hz, 2H), 2.83 (d, J = 12.8 Hz, 1H), 3.05 (dd, J = 4.9, 12.8 Hz, 1H), 3.25 (t, J = 6.8 Hz, 2H), 3.30−3.46 (m, 4H), 3.62−3.67 (m, 4H), 3.70−3.78 (m, 9H), 4.21 (dd, J = 1.8, 7.8 Hz, 1H), 4.43 (dd, J = 4.9, 7.8 Hz, 1H), 4.62 (dd, J = 4.9, 7.8 Hz, 1H). HRMS (ES^+) calcd for $C_{30}H_{56}N_5O_8S$ $(M + H)^+$: 646.3850. Found: 646.3856. HPLC: t_R = 11.9 min.

Radioiodination. To 100 μL of a 1 mg/mL solution of **5a**, **6a**, or **7a** was added 1−5 μL of Na[^{125}I]I in 0.1 N NaOH, followed by 15 μL of a 1 mg/mL solution of *N*-chlorosuccinimide in MeOH/5% HOAc. After 5 min, 15 μL of a 1 mg/mL aqueous sodium metabisulfite solution was added. The reaction mixture was then drawn into a syringe for purification by HPLC. The radioiodinated [^{125}I]**5b**, [^{125}I]**6b**, or [^{125}I]**7b** was obtained from the HPLC effluent, collecting the peak that had a retention time 0.2 min later than the nonradioactive **5b**, **6b**, or **7b** (this compensation is made due to the difference in UV and radioactivity detectors).

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-[^{125}I]iodobenzoylamino)-4′,7′,-10′-trioxatrideca neamino)-L-serine-*O*-methyl Ether, [^{125}I]-5b. This compound was obtained in 13% isolated radiochemical yield.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-iodobenzoylamino)-4′,7′,10′-trioxatridecaneam ino)amino-butyramide, 6b. This compound was obtained in 39% isolated radiochemical yield.

2-(*N*-Biotinoyl)-1-(*N*′-(13′-*p*-iodobenzoylamino)-4′,7′,10′-trioxatridecaneam ino)-L-valine, 7b. This compound was obtained in 19% isolated radiochemical yield.

Biotinidase Cleavage Assay. The same experimental conditions were used as previously reported (*22*). Briefly; the radiolabeled biotin derivative (isolated from HPLC effluent) was diluted to obtain approximately 500 000 cpm per 10 μL in a well counter. To each set of three 0.5 mL aliquots of diluted serum (1:10 with 20 mM phosphate buffer, pH 6.8) was added 10 μL of the HPLC purified radiolabeled biotin derivative in MeOH. Each tube was lightly vortexed and placed in a 37 °C heating block. After the desired time (e.g., 2 h), the vials were removed and 40 μL of 2 mM 4-(hydroxymercuri)benzoic acid (HOHgBz), sodium salt in H_2O, was added to inhibit biotinidase. To that solution was added an excess of rSAv (40 μL; 0.24 mg), and it was incubated at 37 °C for another 30 min. A 200 μL aliquot of each triplicate sample was transferred to a Microcon-30 filter and centrifuged at 3000*g* for 10 min. The material remaining on the filter was washed with 4 × 100 μL phosphate buffer, concentrating by centrifugation each time. The top and bottom (containing filtrate and washes) of the Microcon-30 were counted in a gamma counter. The ratio of nonbound counts (bottom) to the total counts (top and bottom) was calculated to determine the percent of the biotin derivative that had been cleaved. As a control, this procedure was repeated as above except that the 4-(hydroxymercuri)benzoic acid was added prior to the radiolabeled biotin derivative to inhibit biotinidase activity.

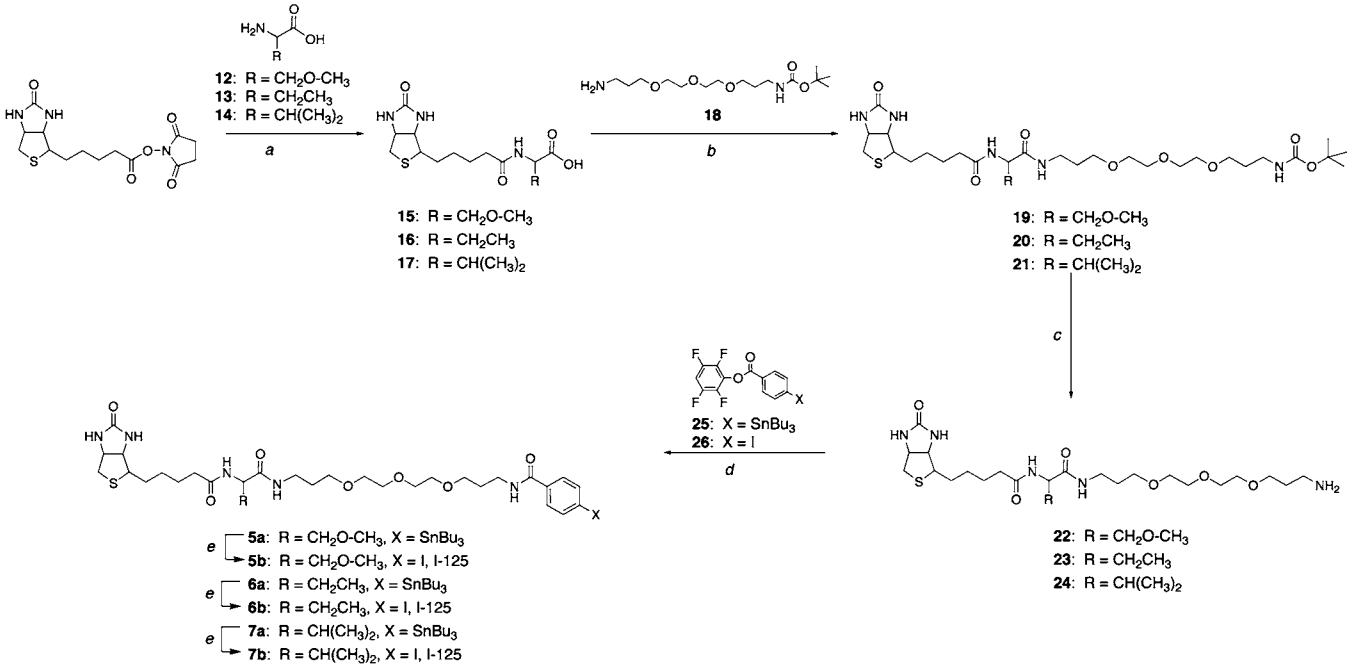
HPLC Biotin Derivative Dissociation Measurements. The same experimental conditions were used as previously reported (*26*). Briefly, to 400 μL of a 0.5 mg/mL solution of rSAv (200 μg; 3.8 nmol) in a microcentrifuge vial was added ∼4 equiv (16 nmol) of a biotin conjugate (**8**, **9**, or **10**) dissolved in 20 μL of a 10% aqueous DMSO solution. The rSAv/biotin derivative mixture was incubated for 1 h at room temperature, and 100 μL of the solution was injected onto the SE-HPLC column and eluted to assay binding. To the remaining avidin/biotin derivative solution was added 60 μL of a 0.575 mg/mL solution of biotin (34.5 μg; 141 nmol) in 10% aqueous DMSO. That solution was incubated for 1 h, and 100 μL was removed for analysis by HPLC. The remaining solution was incubated for an additional 2−3 h, and then another 100 μL was removed and analyzed by HPLC.

RESULTS

Synthesis of Biotin Derivatives. Biotin derivatives that contain an unprotected biotinamide bond (**1a/b**), a *N*-methyl-substituted biotinamide bond (**2a/b**), a carboxylate α to the biotinamide bond (**3a/b**), and a hydroxymethyl group α to the biotinamide bond (**4a/b**) were prepared as previously described (*23*). The synthetic route to obtain biotin derivatives that contain a methoxymethyl (**5a/b**), an ethyl (**6a/b**), or an isopropyl (**7a/b**) group α to the biotinamide bond is shown in Scheme 1. 2-Aminobutyric acid, **13**, and valine, **14**, are commercially available, but the serine-*O*-methyl ether, **12**, was not readily obtained, so an alternate, the N-*t*-Boc protected derivative, was used instead. The *t*-Boc protecting group was readily removed to provide **12**, and all three amino acids (**12**, **13**, **14**) were conjugated with biotin *N*-hydroxysuccinimidyl ester to give the desired adducts in 81−95% yields. The resulting biotin derivatives **15**, **16**, and **17** were coupled with mono-*t*-Boc protected trioxadiamine, **18**, to provide adducts **19**, **20**, and **21** in 77−88% yields. Deprotection of **19**, **20**, and **21** was essentially quantitative in neat trifluoroacetic acid (TFA) to provide the free amine derivatives **22**, **23**, and **24**. The biotin−amine derivatives were used without isolation in reactions with benzoate esters **25** and **26**. Iodobenzamide derivatives **5b**, **6b**, and **7b**, used as HPLC standards, were prepared in 83−88% yield by reaction of *p*-iodobenzoate tetrafluorophenyl (TFP) ester **26** with **22**, **23**, or **24** (respectively). Similarly, the stannylbenzoate-containing biotin derivatives **5a**, **6a**, and **7a**, used as intermediates for radioiodination, were prepared in 87−91% yields by reaction of the tri-*n*-butylstannylbenzoate TFP ester, **25**, with **22**, **23**, or **24**.

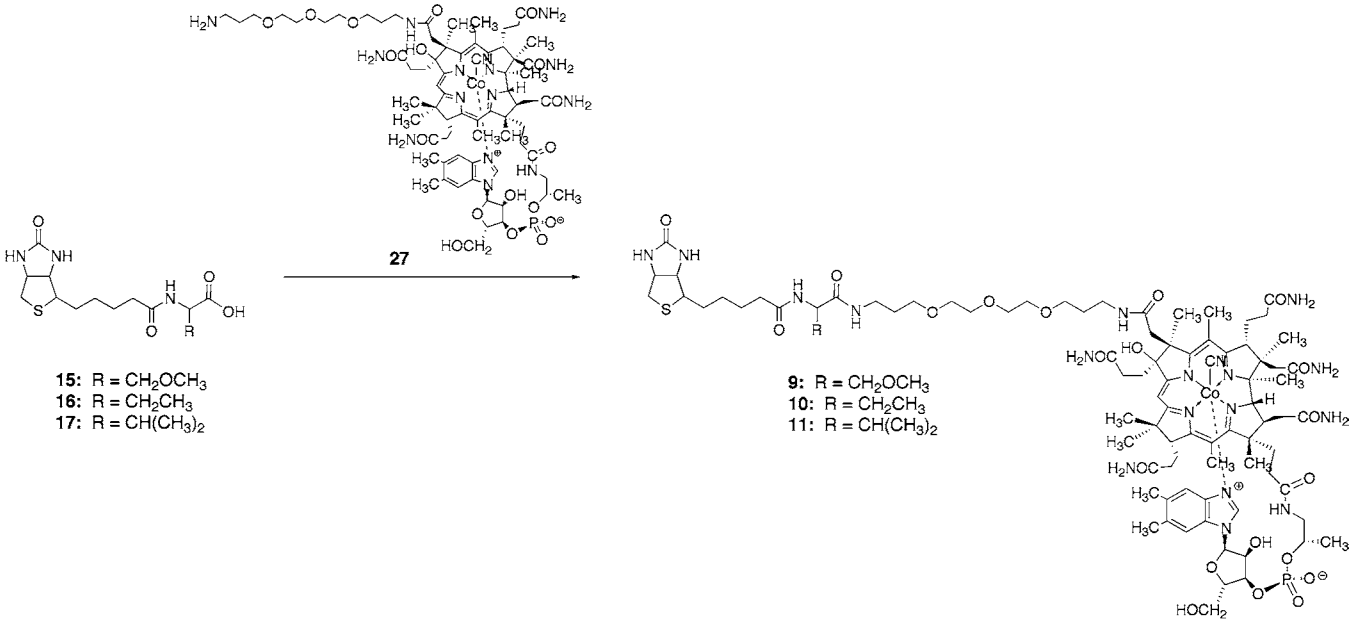
Four biotin−cyanocobalamin derivatives (**8**, **9**, **10**, **11**) were prepared for evaluation of their relative binding with rSAv.

Scheme 1. Synthetic Route for Preparation of Iodinated and Radioiodinated Biotin Derivatives 5b, 6b, and 7b[a]



[a] (a) H_2O, Na_2CO_3, **12**, **13**, or **14**, acetone, rt, 16 h; (b) DMF, EDC, **15**, **16**, or **17**, 4 h to 5 d; (c) TFA, rt, 10 min; (d) DMF, Et_3N, **25** or **26**, rt, 10 min to 1 h; (e) MeOH/5% HOAc, **5a**, **6a**, or **7a**, NCS, 2 min.

Scheme 2. Reaction for Preparation of Biotin−Cyanocobalamin Derivatives 9, 10, and 11[a]



[a] (a) DMF, **15**, **16**, or **17**, TFP-OTFA, rt, 0.5 h; (b) **27**, rt, 30 min.

Biotin cyanocobalamin **8** was prepared as previously described (*26*). Biotin−cyanocobalamin derivatives **9**, **10**, and **11** were prepared using the same synthetic route, as shown in Scheme 2. Reaction of biotin adducts **15**, **16**, and **17** with trifluoroacetate tetrafluorophenyl ester (TFA-OTFP) to form the corresponding biotin TFP esters in situ, followed by reaction with the trioxadiamine adduct of cyanocobalamin **27** provided **9**, **10**, and **11** in 40%, 90%, and 86% yield (respectively). Cyanocobalamin derivative **27** was prepared by reaction of 1,13-diamino-4,7,-10-trioxatridecane as previously described (*26*).

Radioiodination of Biotin Derivatives. The radioiodinated derivatives [^{125}I]**1b**, [^{125}I]**2b**, [^{125}I]**3b**, [^{125}I]**4b**, [^{125}I]**5b**, [^{125}I]-**6b**, and [^{125}I]**7b** were prepared in 13−80% yield from the corresponding tri-*n*-butylstannylbenzamide derivatives **1a**, **2a**, **3a**, **4a** **5a**, **6a**, or **7a** in MeOH/1% HOAc using *N*-chlorosuccinimide (NCS) as the oxidant as previously described (*22*, *23*). The radioiodinated derivatives were purified by collection from the HPLC effluent. Identification was accomplished by co-injection of the isolated radioiodinated derivative with the HPLC standards. The radiochemical yields were not optimized, as only a small amount of material was required for the biotinidase evaluations.

Assessment of Biotinidase Activity. In this study, as in our previous studies, incubation of the radioiodinated samples in a 1 to 10 dilution of fresh human serum was used to assess biotinidase activity. Cleavage of the biotinamide bond is demonstrated as a lack of binding of radioactivity with rSAv. In the experiment, parallel sets of triplicate samples (for most

Table 1. Estimates of Biotinamide Cleavage in Biotin Derivatives[a]

compound no. [blocking group]	% bound[b] (serum)	% bound[c] (serum+HOHgBz)	% cleaved[d] by biotinidase
1b [H]	8.34 ± 0.50	98.52 ± 0.41	91.5
2b [N-CH_3]	96.93 ± 0.07	97.76 ± 0.23	0.8
3b [CO_2H]	92.47 ± 0.04*	92.57 ± 0.14	0.1
4b [CH_2OH]	86.92 ± 0.07	87.13 ± 0.07	0.2
5b [CH_2OCH_3]	90.57 ± 0.21	91.43 ± 0.05*	0.9
6b [CH_2CH_3]	92.92 ± 0.10	93.42 ± 0.10	0.5
7b [$CH(CH_3)_2$]	91.84 ± 0.31	91.66 ± 0.16	0.0

[a] Values were obtained from percent [^{125}I]iodophenyl-biotin derivative bound to rSAv after incubation with human serum or human serum treated with 4-(hydroxymercuri)benzoic acid (HOHgBz). All % bound values represent the percentage of total radioactivity remaining in a Microcon-30 centrifugation unit (bound with rSAv or nonspecifically bound) after repeated (3×) centrifugations/washes at 2000 rpm for 5 min. Values are an average of three analyses ± SD, except those denoted by * which are from two analyses. Human serum was obtained on the day of the experiments. [b] Radiolabeled biotin was placed in 10% human serum for 2 h at 37 °C, rSAv was added, and an aliquot was spun in Microcon-30 centrifugation unit. [c] Radiolabeled biotin was placed in HOHgBz-treated 10% human serum for 2 h at 37 °C, rSAv was added, and an aliquot was spun in a Microcon-30 centrifugation unit. [d] Percentages are derived from the formula (100 − [% bound for noninhibited/% bound after HOHgBz inhibition] × 100]). Values for percent biotinamide cleaved that are less than 1% may be reflective of experimental error and not actual biotinidase cleavage.

compounds) either were treated with the sulfhydryl-reactive HOHgBz to block biotinidase activity (as a control) or were untreated to measure biotinidase cleavage. All samples were incubated at 37 °C for 2 h, then samples previously untreated with HOHgBz were treated with that reagent to quench the enzyme activity. Following that, rSAv was added to all samples and they were incubated at 37 °C for 30 min. Ultrafiltration was then conducted on each sample using Microcon-30 filters to separate the rSAv-bound radioactivity from the nonbound radioactivity. The results obtained are shown as percent bound radioactivity in Table 1. The control group (serum + HOHgBz) provides a value for the amount of radiolabeled biotin that will bind with rSAv under the conditions of the study. In theory, this value should be 100%, but other factors may cause a decrease in the binding of the radiolabeled biotin derivatives with rSAv. One such factor is production of biotin sulfoxide under the radioiodination conditions (*30*). To assess the percent biotinamide bond cleaved, the percent bound values obtained after incubation with serum is subtracted from the control binding values (serum + HOHgBz). At least 90% of the unprotected biotinamide bond in **1b** was cleaved by biotinidase, demonstrating the activity of the enzyme. All of the other samples evaluated had less than 1% cleaved, indicating that they are very stable to biotinidase activity. It is likely that the <1% values are within experimental error and all samples are stable to biotinidase over the time period (2 h) of the study.

Biotin Derivative Dissociation Assay. The results of the competitive binding assay conducted with biotin−CN-Cbl derivatives **8**, **9**, **10**, and **11** are shown in Table 2. The values at $t = 0$ in theory should be 100%. An attempt was made to have a small excess (i.e., > 4 equiv) of the biotin−cyanocobalamin reagent prior to the competitive reaction so that both protein-bound activity and free biotin derivative could be seen on the chromatogram (UV trace). Thus, the percent bound values observed at $t = 0$ are less than 100%. It should be noted that the variance in free biotin−CN-Cbl will potentially askew the values at the later time points, so caution must be used in comparing data between studies. However, the data in Table 2 clearly show the differences in dissociation of the biotin−CN-Cbl derivatives tested. The *N*-methylbiotinamide derivative **8** was included in the assay as a control to compare with the rates of dissociation of **9**, **10**, and **11**. The data indicate that the release of the α-isopropyl (biotin−valine) derivative **11** is slower than

Table 2. Percent Biotin−Cyanocobalamin Derivatives 8, 9, 10, and 11 Bound with rSAv before and after Challenged by a Large Excess of Biotin[a]

compound no. [blocking group]	$t = 0$ (%)[b]	$t = 1$ h (%)	$t = 3$ h (%)	$t = 5$ h (%)
8 [N-CH_3]	86	42	11	4
8 [N-CH_3][c]	100	53	15	4
9 [CH_2OCH_3][c]	89	77	56	47

11 [$CH(CH_3)_2$]	93	65	42	32

[a] Biotin derivative (4+ equiv) was incubated for 1 h with rSAv ($t = 0$), 50 equiv of biotin was added, and aliquots of the mixture were taken at 1, 3, and 5 h for analysis by size exclusion HPLC. Samples were covered from light and kept at room temperature during the experiment. Values from $t = 0$ are not 100% due to an excess of the reagent being present. [b] Percent values were obtained from analysis of peak areas from size exclusion HPLC chromatograms. UV traces were obtained for 280 and 362 nm, where the protein and vitamin B_{12}, respectively, have strong absorbances. The % bound values were obtained from the 362 nm traces and represent the [area of protein-bound peak divided by the area of protein bound peak + free biotin derivative] × 100. [c] Analysis of binding run at a separate time from cyanocobalamin derivatives **8**, **9**, and **10**. Cyanocobalamin derivative **8** was run a second time as control.

the N-Me (biotin−sarcosine) derivative **8**, but is faster than the α-methylmethyl ether and the smaller α-ethyl derivative **10** (i.e., dissociation rates are: **8** > **11** > **9** > **10**).

DISCUSSION

Animals and humans have significant amounts of biotinidase in serum and tissues (*8*), raising the possibility that biotinylated compounds used in vivo will be degraded (biotin released) before the intended binding with avidin or streptavidin can occur. For this reason, all of the biotin derivatives prepared for in vivo application in our laboratory incorporate biotinidase-stabilizing functionalities as a precautionary measure to assure that no cleavage (release) of the biotin occurs. It should be noted that there may be in vivo applications where biotinidase stabilization is not required, or even desirable. For example, in some applications, modification for biotinidase stabilization may impart undesirable properties to biotinylated molecules, such as increasing the lipophilicity. Additionally, there may be instances where biotinidase cleavage offers an advantage for blood and tissue clearance, particularly if an avidin or streptavidin binding of the biotinylated compound postinjection is not required. Another example where biotinidase stabilization may not be required is in vivo use of biotinylated proteins such as monoclonal antibodies. In studies of biotinylated antibodies in this laboratory no difference was observed in avidin column capture of monoclonal antibodies biotinylated with biotinidase stabilized or nonstabilized biotin reagents after subjecting to human serum (unpublished results). These results do not necessarily indicate that biotinidase is incapable of acting on biotinylated antibodies, but rather that the rate of cleavage from the (usual) multi-biotinylated protein is slow enough that the biotinylated protein can be captured on an avidin column after incubation in serum. In fact, published data suggests that intact proteins can be debiotinylated by biotinidase (*9*), and biotinidase stabilizing groups can block the cleavage (*31*).

It became apparent in our early studies that biotinidase-blocking functional groups were essential for optimal pretargeting of therapeutic radionuclides. In those studies, we identified biotin conjugates that contain carboxylate and hydroxymethyl functionalities on the carbon α to the biotinamide bond as derivatives of choice for in vivo application (*25*). However, later synthetic studies to prepare dendrimers and dendrons with multiple biotin conjugates containing these functionalities were fraught with difficulties. Importantly, in some examples, unexpected side reactions prevailed, and in other

examples, removal of the *t*-Bu protecting group was problematic. Further, the cost of the protected amino acids (e.g., aspartate *t*-Bu ester and serine-*O*-*t*-Bu ether) used in the syntheses was perceived as a potential roadblock to their widespread application. These shortcomings led us to consider alternate biotinidase-blocking functionalities that were inert to most chemical transformations and could be obtained at a lower cost.

A primary goal of the studies was to identify biotinidase-blocking moieties that were inert to most reaction conditions, such that they did not have to be protected and deprotected in the syntheses of targeted biotin derivatives. We reasoned that it was best to incorporate functional groups just large enough to block the biotinidase without dramatically affecting avidin/streptavidin binding or other properties of the conjugates. A nonreactive derivative previously tested had a methyl group α to the biotinamide bond. Unfortunately, the methyl group did not fully block biotinidase cleavage, only decreased its rate of cleavage. Since it appeared that the α-methyl group was not large enough to fully block biotinidase activity, slightly larger nonreactive functional groups adjacent to the biotinamide were sought. We chose to incorporate 2-aminobutyric acid and valine as biotin adducts as those amino acid adducts have either an ethyl or isopropyl group α to the biotinamide bond. The ethyl and isopropyl group are inert to most reaction conditions and are similar in steric size of a hydroxymethyl and carboxylate functionality (respectively), which have been previously shown to be stable to biotinidase activity. We also chose to include the biotin adduct of serine-*O*-methyl ether in the study, as it is nonreactive under most reaction conditions and has a similar steric size but would be expected to be less lipophilic.

Radioiodinated derivatives of the serine-*O*-methyl ether, 2-aminobutyric acid, and valine adducts of biotin, ([^{125}I]**5b**, [^{125}I]-**6b**, and [^{125}I]**7b**) were prepared and evaluated in a biotinidase assay. As controls, radioiodinated derivatives of biotin without an amino acid blocking group ([^{125}I]**1b**) or containing the amino acids sarcosine, aspartate, and serine ([^{125}I]**2b**, [^{125}I]**3b**, [^{125}I]-**4b**) were also prepared and tested. All of the biotin derivatives containing an amino acid conjugated with the biotin carboxylate were found to be very stable toward biotinidase cleavage (Table 1). On the basis of the theory that blockage of the enzyme is controlled by steric bulk, one might expect the steric isopropyl group in valine to block biotinidase more effectively. However, under the conditions studied there was essentially no difference between the compounds. More concentrated serum samples or longer incubation times may be required to determine if there are small differences in the biotinidase-blocking capacity of the various derivatives. It should be noted that biotin derivatives of interest for our studies have a very short half-life in blood (i.e., 4 min in α-phase and 1 h in *β*-phase (*33*)], making the 2 h incubation time adequate to assess their in vivo use. Biotin derivatives of molecules that have long biological half-lives in blood may require further studies of biotinidase stability.

In addition to biotinidase stability, we believe it is very important to retain the high binding affinity in the biotin derivatives used in vivo to alleviate the potential for displacement from streptavidin by endogenous biotin (*34*, *35*). While there are methods for decreasing biotin concentrations in blood, it appears that some biotin will always be present to compete for the biotin-binding pockets on SAv. To assess the relative retention of biotin derivatives bound with rSAv, a simple size-exclusion HPLC assay has been developed (*26*). In that assay, 4 equiv of a biotin−CN-Cbl derivative are bound with rSAv and then challenged with a large excess (50 equiv) of biotin. Under these conditions, any biotin−CN-Cbl derivative that is dissociated will be replaced with biotin. Thus, the relative rate of dissociation of a biotin derivative can be estimated by the quantity of free biotin−CN-Cbl derivative versus rSAv-bound biotin−CN-Cbl derivative. The use of biotin−CN-Cbl derivatives makes HPLC analysis possible, as UV detection of the protein can be measured at 280 nm and the biotin−cyanocobalamin derivative at 362 nm, where there is very little absorption by the protein. Significant differences in the rate of dissociation were measured between the biotin derivatives (Table 2). As in previous studies, nearly all biotin−sarcosine-CN-Cbl, **8**, is displaced within 5 h at room temperature. The biotin−valine−CN-Cbl, **11**, has the second fastest rate of dissociation, with the biotin−serine-*O*-methyl ether−CN-Cbl, **9**, a little slower, and the biotin−2-aminobutyric acid−CN-Cbl, **10**, having the slowest dissociation. It is interesting to note that the rate of dissociation correlates with the steric bulk of the substituent on the carbon α to the biotinamide bond. While the differences in amount of biotin−amino acid adduct dissociated by 5 h is fairly large, this may not be important for in vivo application. Indeed, it is likely that all three new biotin derivatives would provide adequate binding to be useful in most in vivo applications. This statement is made based on the fact that highly successful pretargeting of rSAv conjugates on tumors in vivo has been accomplished with a biotin−sarcosine derivative (*36*), which has the fastest dissociation from SAv out of the compounds studied.

CONCLUSION

Problems encountered in prior studies employing *t*-Bu protected hydroxyl and carboxylate biotinidase stabilizing groups led to this investigation to develop alternate biotinidase stabilizing functionalities. In the investigation, new functionalized biotin derivatives were targeted that retained criteria set previously, i.e., that they effectively block biotinidase while retaining high binding affinity with rSAv but had the additional criteria that they (*1*) are chemically inert, (*2*) do not require protection/deprotection in the syntheses, and (*3*) have a low cost such that they can be applied widely. While all three of the biotin−amino acid derivatives tested were found to be stable to biotinidase, the cost of serine-*O*-methyl ether and difficulties encountered in syntheses using it makes that derivative less attractive than the 2-aminobutyric acid and valine adducts. The data obtained indicate that biotin−valine adduct could be used for in vivo studies, but higher lipophilicity and faster dissociation than that of the 2-aminobutyric acid adduct make it a second choice. The low cost and high binding affinity of the biotin−2-aminobutyric acid derivative make it particularly attractive for development of reagents to be used in vivo. While there is little doubt that other untested functional groups can also provide biotinidase blockage, it seems likely that a relatively small number would meet all of the criteria set. It is anticipated that a majority of our subsequent synthetic studies with biotin derivatives will incorporate the 2-aminobutyric acid moiety to block biotinidase.

ACKNOWLEDGMENT

We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, OHER (DE-FG03-98ER62572), and National Cancer Institute, NIH (5 RO1 CA113431). We thank Quanta BioDesign (Powell, OH) for providing the biotin *N*-hydroxysuccinimide ester as a gift.

Received April 17, 2006; Revised Manuscript Received September 23, 2006

Sophorolipids (SLs) are extra cellular glycolipids produced by *Candida bombicola* ATCC 22214 when grown in the presence of glucose and fatty acids. These compounds have a disaccharide head group connected to a long-chain hydroxyl−fatty acid by a glycosidic bond. To explore structure−activity of modified SLs, a new family of amino acid−SL derivatives was prepared. Synthesized analogs consist of amino acids linked by amide bonds formed between their α-amino moiety and the carboxyl group of ring-opened SL fatty acids. Their preparation involved the following: (i) hydrolysis of a natural SL mixture with aqueous alkali to give SL free acids, (ii) coupling of free acids to protected amino acids using dicarbodiimide, and (iii) removing amino acid carboxyl protecting groups. These conjugates were evaluated for their antibacterial, anti-HIV, and spermicidal activity. All tested analogs showed antibacterial activity against both gram +ve and gram −ve organisms. Leucine-conjugated SL was most efficient. For example, the minimum inhibitory concentrations (MIC) for *Moraxella* sp. and *E. coli* were 0.83 and 1.67 mg/mL, respectively. Among the alkyl esters of amino acid conjugated SLs, the ethyl ester of leucine−SLs was most active. Against *Moraxella* sp., *S. sanguinis*, and *M. imperiale*, MIC values are 7.62×10^{-4}, 2.28×10^{-3} and 1.67 mg/mL, respectively. All compounds displayed virus-inactivating activity with 50% effective concentrations (EC_{50}) below 200 μg/mL. The EC_{50} of leucine−SL ethyl ester was 24.1 μg/mL, showing that it is more potent than commercial spermicide nonoxynol-9 ($EC_{50} \approx 65$ μg/mL).

INTRODUCTION

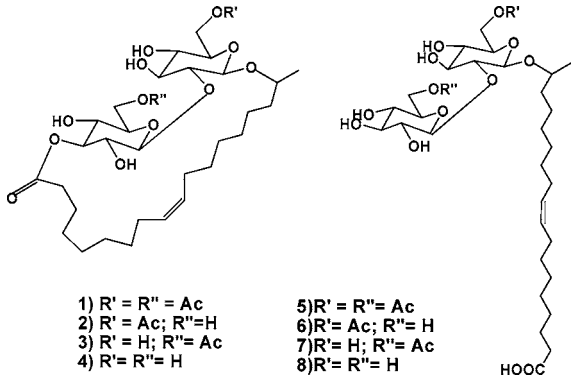
Sophorolipids (SLs) are glycolipids produced by the yeast *Candida bombicola* when cultured on carbohydrate and lipidic substrates. Structurally, SLs are composed of dimeric sophorose (2′-*O*-*β*-D-glucopyranosyl-*β*-D-glucopyranose) linked to the hydroxyl group at the penultimate position of, most often, a monounsaturated C18 fatty acid (*1*). First described by Gorin et al. (*2*), SLs exist as mixtures of eight major components (lactone and acid forms) with varying degrees of acetylation at the 6′- and 6″-positions of the sophorose moiety (Chart 1).

Our ongoing research with SLs and their derivatives have shown that they have immense potential as therapeutic agents that can function as septic shock antagonists (*3*), anticancer agents (*4*), and antibacterial (*5*), antiviral (*6*, *7*), spermicidal (*6*, *7*), and antifungal agents (*8*). However, more structural derivatives of SLs are needed to better define structural−biological activity relationships and thereby enhance SL efficacy and its spectrum of action.

Attempts have been made to perform in vivo modifications of SL structure during biosynthesis. Selective feeding during fermentations of lipophilic substrates such as alkanes and fatty acids did bring about changes in the sophorolipid structure (*9*−*11*). Although this approach is promising, thus far it has affected a change in only a small fraction of the SLs produced.

Thus far, in vitro modification of SLs has been most successful. Earlier reports from our laboratories described SL modifications by chemoenzymatic strategies (*12*, *13*). Bisht et al. synthesized several alkyl esters of SLs using sodium alkoxide/alkanol mixtures under reflux conditions. The resulting

Chart 1. Structures of Sophorolipids Produced by *Candida bombicola*



SL alkyl esters were subjected to Novozyme 435 catalyzed acylation in anhydrous THF to furnish C-6′ and C-6″ acylated compounds in high yields with excellent chemoselectivity (*13*). Singh et al. synthesized SL−amide derivatives by lipase-catalyzed amidation of SL ethyl ester in dry THF. Amines used included phenethylamine, tyramine, and 2-(*p*-tolyl)ethylamine (*12*). Recently, Nunez et al. reported the synthesis of galactose conjugated SL ester. They successfully transesterified SL methyl ester with 1,2-3,4-di-*O*-isopropylidene-D-galactopyranose in THF using an immobilized lipase catalyst (*14*).

In this paper, a new family of SL derivatives consisting of SL−amino acid and SL−amino acid ethyl ester conjugates were prepared by linking the α-NH_2 group of amino acids to the carboxyl terminus of SL fatty acids. These compounds were assayed to ascertain their antibacterial, anti-HIV, and spermicidal activities. The results of this work provide important insights that expand our knowledge of SL structure−bioactivity relationships.

EXPERIMENTAL SECTION

General Chemicals and Procedures. Anhydrous solvents, methylene chloride, *N*,*N*-dimethylformamide, hydrochloride form of carboxyl group protected amino acids, dicyclohexylcarbodiimide (DCC), 1-hydroxybenzotriazole (HOBt), and 4-(dimethylamino)pyridine (DMAP) were purchased from Aldrich Chemical Company in the highest available purity and were used as received unless otherwise noted. Amino acid alkyl ester hydrochlorides were converted to the free-amine form by treatment with an equivalent amount of *N*-methylmorpholine. All liquid reagents were transferred by syringe under N_2 atmosphere. Proton (^{1}H) NMR spectra were recorded on Bruker-300 and Varian 400 M spectrometers at 300 and 400 MHz, respectively. Carbon (^{13}C) NMR spectra were recorded on a Bruker-300 spectrometer at 75 MHz. Chemical shifts are reported in parts per million downfield from 0.00 ppm using trimethylsilane (TMS) as the internal standard. Coupling constants are expressed in hertz (Hz). Column chromatographic separations were conducted with silica gel 60 (Aldrich Chemical Co.). Analytical thin layer chromatography (TLC) were performed on Merck silica gel $^{60}F_{254}$ plates. The spots were developed by spraying with α-naphthol/sulfuric acid (for 100 mL solution, 500 mg of α-naphthol in 5% sulfuric acid solution in ethanol) detecting system. IR spectra were recorded using a Perkin-Elmer FT-IR 1600 series. The samples were dissolved in THF and deposited as thin films on KBr discs. Optical rotations were determined at 598 nm on a Perkin-Elmer 241 digital polarimeter with a 2 dm cell. Values of $[\alpha]_D$ are given in units of 10^{-1} deg cm^2 g^{-1}.

Sophorolipids Synthesis. SLs were synthesized by fermentation of *Candida bombicola* (*12*, *13*). The fermentation media contained glucose (100 g), yeast extract (10 g), urea (1 g), and oleic acid (40 g) per 1000 mL water. After 10 day fermentations, SLs were extracted three times with ethyl acetate. The extracts were pooled and the solvent removed. The resulting product was washed with hexane to remove residual fatty acids.

Isolation of SL-COOH (structure 8). Acidic SLs were synthesized from the natural mixture by alkaline hydrolysis following a literature procedure (*12*, *13*). The hydrolyzed SLs were acidified, the solution was cooled in an ice bath, and the precipitate was further purified by silica gel column chromatography using a chloroform/methanol gradient (3:22 to 4:22, v/v). The product was identified by NMR and LC-MS, which were identical to previously published spectra.

General Procedure for DCC Coupling of SL-COOH (structure 8) with C-Terminal Protected Amino Acids (structures 9−13, 19−21). Amino acid alkyl ester hydrochloride (1 mmol) was suspended in a 4:1 mixture of DCM/DMF (15 mL). The hydrochloride salt was neutralized with *N*-methylmorpholine (1 mmol, 108 μL) and stirred for 15 min giving a clear solution. SL-COOH (**8**, 622 mg, 1 mmol), HOBt (135 mg, 1 mmol), DCC (1.2 mmol, 244 mg), and DMAP (0.1 mmol, 12 mg) were then added to the clear solution. Stirring was continued at room temperature for 24 h. Water (2 mL) was added, and the reaction was stirred for an additional 10 min. Filtration of DCU followed by solvent evaporation gave a transparent syrup which was diluted with ethyl acetate and subsequently washed with cold 0.1 N HCl (20 mL). The ethyl acetate layer was dried over $MgSO_4$, filtered, and concentrated. Purification was performed by flash chromatography to give the desired compounds in 72−78% yields.

Removal of *tert*-Butyl Protecting Group. A solution of **13** (500 mg, 0.58 mmol) in 10 mL CH_2Cl_2/TFA (7:3) was stirred at 0 °C for 30 min. After completion of the reaction, the solution was concentrated under vacuum and twice evaporated with anhydrous toluene to give **14** (380 mg, 87% yield).

Removal of Benzyl Protection and Hydrogenation of cis Double Bond. A solution of **9−12** in 5 mL dry ethanol was stirred at room temperature under H_2 atmosphere in the presence of 10% pd/C (50 mg) for 72 h. Reaction progress was monitored by TLC, and on completion, the solids were removed from the reaction mixture by passing it through a celite pad. The filtrate was concentrated by rotoevaporation under vacuum to give compounds **15−18** in quantitative yields.

Liquid Chromatography−Mass Spectrophotometry Analysis of SLs. A Waters ZQ LC/MS system was used for analysis and identification of individual sophorolipids and amino acid conjugated sophorolipids. The system includes 2795 Alliance HT separation module, 2996 photodiode array detector, and

Waters (Micromass) ZQ 2000 online mass detector. Separation was carried out on a 250 × 4.6 mm polymeric reversed-phase PLRP-S column (particle size 8 μm, pore size 1000 Å, Polymer Laboratories). The water/acetonitrile mobile phase was programmed as follows: 60% water to 50% water in 20 min, then 60% water for 5.0 min (re-equilibration). The HPLC eluent (1 mL/min) was split at the outlet of the column by means of a zero-dead-volume tee splitter to introduce eluent to PDA detector and mass spectrometer. LC-MS was operated with an atmospheric pressure chemical ionization (APCI) probe in positive ion mode. Probe and source temperature were set to 450 and 50 °C, respectively. Cone voltage, corona current, and nebulizer gas flow were set at 60 V, 0.66 μA, and 300 L/h, respectively. Sophorolipids were detected in scan mode with a scan duration of 2.0 s, interscan delay of 0.1 s, and scan range 170−850 *m*/*z*. Data acquisition and mass spectrometric evaluation were performed with *MassLynx Software 4.0*. The samples for LC/MS were dissolved in 50:50 acetonitrile/water at a concentration of 40−200 μg/mL and were passed through a 0.45 μm PTFE filter before injection.

LC/APCI-MS: R_t 4.1 min, *m*/*z* 716.38 $[M + Na]^+$ and 4.3 min, *m*/*z* 716.38 $[M + Na]^+$.

Antimicrobial Assay. To determine antimicrobial activities, *Escherichia coli*, *Bacillus subtilis*, *Salmonela cholerasesuis*, *Microbacterium imperiale* (obtained from ATCC, U.S.A.), *Moraxella* sp., *Streptococcus agalactiae*, and *Streptococcus sanguinis* (obtained as gift cultures from Dr. Maja Nowakowski, SUNY downstate medical center, NY) were used.

The minimum inhibitory concentrations (MIC) of the amino acid conjugated SLs were determined by the broth serial dilution method performed in 96-well microtiter plates. A stock solution of SL (15 mg/mL) was prepared in 200 mg/mL sucrose solution (pH 9.0). Cultures were grown o/n and diluted to 0.1 OD before experiments. Serial dilutions (50 μL) of each sample were made in the broth, and plates incubated at 30 °C. After 18−24 h, the plates were examined for growth of the organisms. The concentration that inhibited more then 90% growth of the organism was record as the MIC. Positive control (cells plus medium) and negative control (medium only) were performed with each experiment. Percent inhibition was calculated by comparing the experimental readings with the positive control. Three replicates were performed for each SL derivative against each test organism.

Spermicidal Assay. The spermicidal activity of SLs was evaluated using a modification of the method by Sander and Cramer (*15*). Semen samples were collected from normal donors by masturbation, allowed to liquefy at room temperature, and assessed for motility. The protocol was approved by the Eastern Virginia Medical School Institutional Review Board. Stock solutions, typically 10 mg/mL, were prepared in DMSO. Serial 2-fold dilutions in 0.9% NaCl of test compounds were incubated with semen aliquots for 30 s. Motility was evaluated under the microscope during the first incubation and after dilution in buffer and further incubation for 1 h. Only those dilutions that immobilized 100% of the spermatozoa pass the test. Results were expressed as minimum effective concentrations (MEC or ED100).

HIV Inactivation Assay. Anti-HIV activity was evaluated by incubating serial dilutions of the SL compounds with HIV-1 (IIIB) and CD4/*β*-galactosidase-expressing HeLa cells for 2 h in 12-well plates (*16*). After this incubation, virus and compounds were washed away, and the cells were resuspended and cultured in fresh RPMI 1640 medium supplemented with 10% fetal bovine serum for 48 h at 37 °C and 5% CO_2. These cells express *β*-galactosidase under the control of the HIV long terminal repeat (LTR). Thus, expression of this enzyme is linked to HIV infection. After the 48 h incubation, cells were washed in PBS, and *β*-galactosidase activity was measured using the Galacto-Star *β*-galactosidase reporter gene assay (Applied Biosystems, Foster City, CA). Briefly, the cells were lysed and their contents incubated with Galacto-Star substrate. Chemiluminescence was quantified in a luminometer. Cells incubated with virus and no compounds provided values representing 100% infection. Fifty percent effective concentrations (EC_{50}) were calculated using a linear regression model.

RESULTS AND DISCUSSION

Synthesis. SL mixture produced by the fermentation of *C. bombicola* on glucose/oleic acid contains at least fourteen different compounds that exist mainly in the lactonic and acidic forms. These compounds also have a variable degree of acetylation at the primary hydroxyl groups at 6′ and 6″ positions. The aliphatic component of SLs is composed of 17-hydroxyoleic acid that exists in hydrogenated and non-hydrogenated forms. To free carboxylic groups of lactonic sophorolipids as well as to reduce natural sophorolipid mixture heterogeneity, alkaline hydrolysis was performed according to a published procedure (*17*). During alkaline hydrolysis, acetate groups of sophorose units were removed with concomitant opening of the lactonic ring to give 17-L-[(2′-*O*-*β*-D-glucopyranosyl-*β*-D-glucopyranosyl)oxy]-*cis*-9-octadecenoic acid (SL-COOH, **8**). The downfield shift (δ 3.66) for the C-1 carbon of **8** (δ 178.42), when compared to the cyclic form (δ 174.76), confirmed that opening of the lactonic ring occurred (*18*). All peaks due to carbohydrate protons match well with other ring-open derivatives synthesized in the past and for which rigorous assignments had been made using ^{1}H−^{1}H COSY NMR and DEPT 135 experiments (*12*, *13*). Finally, before conjugation, purity of the SL-COOH was determined by LC/APCI (*m*/*z* 645.39 and 645.41). Two peaks of the same mass at different retention times were observed. This is attributed to attachment of dimeric sophorose to the hydroxyl group at either the penultimate or terminal fatty acid carbon where the later is the minor component (*19*).

The free carboxylic group was used as a handle to anchor various amino acids using DCC coupling. The coupling was performed without protecting free hydroxyl groups of sophorose moieties. SL-COOH is sparingly soluble in DCM; however, addition of anhydrous DMF renders the compound completely soluble, yielding a homogeneous solution. Conjugation of amino acids to sophorolipids was confirmed by identifying relevant NMR signals of the amino acid moiety. For example, coupling of dibenzylaspartic ester to SL-COOH gave a double doublet at 2.90 ppm (2H) that corresponds to the aspartate methylene of the side chain. Furthermore, ^{13}C NMR showed three peaks in the carbonyl region, two at 171.83 and 171.59 ppm due to esters and one at 176.05 ppm due to newly formed amide. Deprotection of sophorolipid−amino acid conjugates with benzyl ester protecting groups was performed in dry ethanol by hydrogenation over Pd/C. This method resulted in both the removal of benzyl ester groups and the reduction of cis double bonds of the SL fatty acid moiety. Removal of *tert*-butyl protecting groups was carried out in DCM/TFA at 0 °C. Performing this reaction under mild acidic conditions avoided the hydrolysis of anomeric linkages of SLs.

To further broaden the range of SL−amino acid conjugates for bioactivity studies, amino acid ethyl esters were coupled to SL-COOH. SL−amino acid conjugates where the amino acid carboxylate groups are ethyl esters increases compound hydrophobicity relative to its corresponding carboxylate salt form. Furthermore, introduction of ethyl esters was not considered problematic, since liberation of ethanol by metabolism gives readily metabolized byproducts.

[a] MAEE-SL = ethyl 17-L-([2′-*O*-*β*-D-glucopyranosyl-*β*-D-glucopyranosyl]oxy)-*cis*-9-octadecenoate-6′,6″-diacetate. The compound was synthesized using protocol described elsewhere.[13] [b] ND = not determined.

This family of new SL−amino acid conjugates was assessed to understand structure−bioactivity relationships by performing studies of antibacterial, anti-HIV, and spermicidal activity.

Biological Activity. Biosurfactants represent an emerging class of important compounds in biomedical science that offer antifungal, antibacterial, antimycoplasmal, and antiviral properties (*20*). The proposed primary mechanism of action of these surfactants is membrane lipid order perturbation, which compromises the viability of microorganisms (*21*). Some amino acid conjugated SLs display bactericidal and virucidal activity. However, none of these compounds are significantly spermicidal, showing a certain degree of membrane specificity in their lytic action.

Antibacterial Activity. All tested analogues showed antibacterial activity against both gram +ve and gram −ve organisms (Table 1). Comparing the efficiencies of amino acid conjugated SLs shows that leucine-conjugated SL is most efficient with MIC of 5 mg/mL or less for all seven of the organisms tested. MIC for *Moraxella* sp. was 0.83 mg/mL, and for *E. coli*, it was 1.67 mg/mL. This derivative was also the most effective of those tested against *B. subtilis* and *S. sanguinis* (5 mg/mL and 2.5 mg/mL, respectively). Among the alkyl esters of amino acid conjugated SLs, the ethyl ester of leucine−SLs was most active. It is also the most effective compound of those evaluated against *Moraxella* sp., *S. sanguinis*, and *M. imperiale* with MIC values of 7.62×10^{-4}, 2.28×10^{-3}, and 1.67 mg/mL, respectively. In earlier studies by our laboratory, monoacetylated ethyl ester SL (MAEE-SL) was identified as an efficient antibacterial compound.[5] After comparing the activity of ethyl ester leucine−SL to that of MAEE-SL, it is evident that ethyl ester−leucine SL is more potent against *Moraxella* sp. However, the antibacterial activity of MAEE relative to ethyl ester−leucine SL was higher against the other microorganisms tested. Therefore, future experiments will be directed toward preparing amino acid−SLs whose sophorose head group contains various extents of acetylation.

Anti-HIV Activity. As shown in Table 2, all compounds displayed virus inactivating activity with 50% effective concentrations (EC_{50}) below 200 μg/mL. Comparing potencies of amino acid conjugated SLs and their alkyl esters showed that esterified derivatives were more effective than corresponding non-esterified compounds. The ethyl ester of leucine-conjugated SL was most potent with an EC_{50} of 24.1 μg/mL. This analogue was more potent than the commercial spermicide nonoxynol-9, which displays virucidal anti-HIV activity with an $EC_{50} \approx$ 65 μg/mL. Dimethyl sulfoxide (DMSO) did not display antiviral activity at the concentrations present in the tested compound dilutions.

Spermicidal Activity. Spermicidal activity was measured using a modified Sander−Cramer test. None of the compounds displayed significant spermicidal activity beyond that shown by the solvent (DMSO) control. In contrast, nonoxynol-9 (N-9) and MAEE, included as positive controls, revealed the minimum effective concentration (MEC) values of around 300 and 500 μg/mL, respectively.

Table 2. Anti-HIV and Spermicidal Activity of Different Amino Acid Conjugated SLs

SL sample	anti-HIV activity EC_{50} (μg/mL)	spermicidal activity MEC*a* (mg/mL)

SUMMARY OF RESULTS

By changing the amino acid from hydrophilic (L-glutamic, L-aspartic, L-serine) to hydrophobic (L-phenylalanine, L-leucine), improved antimicrobial properties were achieved. The leucine-conjugated SL ethyl ester derivative was the most potent bactericidal and HIV-1 virucidal compound studied herein. Nevertheless, the potency of this analog must be further enhanced before it can be considered as an important candidate for advanced therapy. The results of structure−activity relationships from this work provide important guidance in how to engineer SL derivatives to achieve effective new therapeutics. Work is in progress to determine how the length of leucine alkyl esters conjugated to SL, and acetylating sophorose head groups of amino acid−SL conjugates, modulates SL biological properties.

Synthesis and in Vitro Evaluation of Glutamide-Containing Cationic Lipids for Gene Delivery

Vijaya Gopal,[†] Tekkatte K. Prasad,[‡,§] Nalam M. Rao,*[,†] Makoto Takafuji,[‡] Mohammed M. Rahman,[‡] and Hirotaka Ihara*[,‡]

Centre for Cellular and Molecular Biology, Uppal Road, Hyderabad, India 500 007, and Department of Applied Chemistry and Biochemistry, Faculty of Engineering, Kumamoto University, 2-39-1 Kurokami, Kumamoto, Japan, 860-8555. Received April 22, 2006; Revised Manuscript Received July 20, 2006

A novel series of cationic amphiphiles based on dialkyl glutamides with cationic pyridinium head group were synthesized as potential gene delivery agents. Four cationic lipids with glutamide as linker and varying chain lengths were tested for their transfection efficiency in three cell lines. The DNA−lipid complexes were characterized for their ability to bind to DNA, protection from nuclease digestion, size, ζ-potential, and toxicity. All four lipids demonstrated efficient transfection in MCF-7, COS, and HeLa cells, and the reporter gene expression was much higher with DOPE as the helper lipid in the formulation when compared to cholesterol. Among these 14-carbon lipids, lipid **2** has shown the highest transfection efficiency, complete protection of DNA from nuclease digestion, and low toxicity. Interestingly, lipid **2** has also shown remarkable enhancement in transfection in the presence of serum.

INTRODUCTION

Carriers that can deliver nucleic acids into cells have immense potential to investigate the properties of gene sequences and in gene therapy (*1*−*4*), and broadly fall into viral and nonviral classes. Among the nonviral carriers, the successful strategies are mainly based on cationic lipids, cationic peptides, or polymers and cationic dendrimers (*5*). Cationic lipids have several advantages including simplicity of method, clinical grade manufacturing, lack of ability to elicit immune response, and capacity to carry large fragments of DNA (*6*, *7*). Several clinical trials employing cationic lipids are in progress (*8*).

Cationic lipids are amphiphilic in nature and carry a positive charge at physiological pH (*9*, *10*). The cationic nature of the lipids allows them to bind to the nucleic acids and also to the negatively charged cell membrane. Besides being cationic, the long hydrophobic moiety of these lipids allows self-assembly into vesicles to entrap the nucleic acids, thus protecting DNA from nucleases (*9*). The synthesis, chemistry, and biology of the cationic lipids have been extensively reviewed (*10*−*15*). Essentially, a cationic lipid has a cationic head group that is connected to a hydrophobic moiety by a linker. Glycerol, with ether or ester bonds with fatty acids, is the most popular linker, though other groups such as phosphonates and aromatic groups have also been used (*16*). We report here the synthesis and transfection efficiencies of cationic lipids based on glutamic acid as the linker. These glutamide-derived dialkyl lipids form self-assembled lamellar and non-lamellar structures based on intermolecular hydrogen bonding among amide moieties (*17*−*20*). Four cationic pyridinium amphiphiles with different alkyl chain lengths (C12 to C18) with glutamide as a linker were synthesized. The physical properties of these lipids have been characterized and were tested for their DNA binding and transfection ability in the presence of serum on three cell lines.

EXPERIMENTAL PROCEDURES

Plasmid/Chemicals. pCMV.SPORT-β-gal plasmid, Lipofectamine, and Lipofectin were purchased from Invitrogen. DOTAP, cholesterol, and DOPE were purchased from Avanti Polar Lipids, Inc. Dulbecco's Modified Eagle's Medium (DMEM) and cholesterol was obtained from Sigma Chemicals, U.S.A. All other reagents used were of high-quality grade.

Preparation of Liposomes. The methods employed here have been described earlier (*21*, *22*). In the preparation of lipid−DNA complex (Lipoplex) cationic lipids were either mixed with DOPE or cholesterol as the helper lipid. Liposomes were prepared at 1:1 (mol/mol) ratio of cationic lipid and helper lipid, by drying the chloroform stock solutions in 1.5 mL glass tubes under nitrogen gas. Tubes were dried under vacuum to remove traces of chloroform for about 2 h. Sterile MilliQ was added to dried lipid film and hydrated overnight by incubating the tubes at 55 °C in water bath. The sample was vortexed for about 3 min and sonicated using a microprobe until the solution became clear.

Cell Culture. MCF-7, COS-1, and HeLa cells were maintained in DMEM containing 10% fetal bovine serum and 500 μg/mL penicillin, 600 μg/mL streptomycin, and 1 mg/mL kanamycin.

Cell Transfections. For quantitating the transient transfections in cell lines, the β-gal activity was measured 24 h after the transfections (*23*). Lipoplexes with different lipid/DNA charge ratios were prepared by mixing different amounts of liposomes with plasmid DNA (0.3 μg per well) in DMEM and incubated at room temperature for about 15 min. Complexes were incubated with cells for about 3 h, after which lipoplex-containing medium was replaced with 10% serum containing DMEM medium. After 24 h, the medium was removed, and cells were washed with PBS and lysed with 50 μL lysis buffer (250 mM Tris-HCl pH 8.0 containing 0.5% NP40) for 10 min at room temperature. Cell lysate was used for protein estimation

Published on Web 10/04/2006

by Lowry's method and 50 μL was used for the β-galactosidase activity. Absorbance at 410 nm was read in a SPECTRA Max ELISA plate reader. β-Galactosidase activity was calculated from a standard graph constructed from commercial β-galactosidase enzyme. β-Galactosidase activity was normalized against milligrams of cell protein. For transient transfections done in the presence of varying serum concentrations, CLDC was prepared in the absence of serum, and serum was added to the complex at the required final concentration, after which they were added to the cells. Data is represented as β-gal activity per well (~20 000 cells).

Binding of Lipid to DNA and DNaseI Protection Assay. pCMVβ-gal was complexed with cationic lipids at charge ratios varying from 0.3:1 to 3:1 (lipid/DNA) in order to measure the DNA binding ability and, second, to evaluate the susceptibility of the DNA in these complexes to DNaseI digestion. In a typical binding assay, 0.6 nmol of DNA was complexed with lipids in MQ water to obtain the above charge ratios and incubated for 25 min at room temperature (RT) prior to electrophoresis on an agarose gel. For the DNaseI protection assay, the complexes were prepared in 0.5× PBS (pH 7.5). Subsequently, the complexes were treated with 0.2 units of DNaseI and incubated at RT for 20 min, followed by heat inactivation at 60 °C for 7 min. The reactions were then halted with EGTA added to a final concentration of 30 mM. Lipids from the lipoplex were extracted with a phenol−chloroform mixture. Equal volumes of the aqueous phase was treated with DNA loading dye and electrophoresed on a 0.8% agarose gel in TAE buffer at a constant voltage (80 V). The gel was stained with ethidium bromide postelectrophoresis and the bands visualized on a transilluminator.

Cytotoxicity Assay. MCF-7 cells were grown in 96-well plates at about 70% confluency (*24*). After incubating the lipoplexes with the cells for 3 h, the lipoplexes were removed from the well, washed once with PBS, and replaced with 100 μL of DMEM containing 10% serum and antibiotics per well. To this, 100 μL of MTT (5 mg/mL in PBS) solution was added to each well, and the cells were incubated in the incubator for additional 2 h. At the end of 2 h, the medium was removed, and 100 μL of DMSO/methanol (1:1 vol/vol) was added per well. The plate was gently rocked and kept at room temperature for 5 min and then read at 540 nm in the SPECTRA Max ELISA plate reader. Data were represented as percentage cell viability.

Lipoplex Size. The sizes of lipoplexes were measured by photon correlation spectroscopy on a Zeta sizer 3000HSA (Malvern, U.K.) in DMEM and HEPES buffer, pH 7.4, using a sample refractive index of 1.59 and a viscosity of 0.89. The system was calibrated by using the 200/5 nm polystyrene polymer (Duke Scientific Corporation, Palo Alto, CA).

Synthesis of Lipids. Structures and the synthesis scheme of glutamide-derived lipids having cationic pyridinium head groups with different alkyl chain lengths are shown in Figure 1. The synthesis processes of lipid **1** are given below.

N′,N″-Didodecyl-N-benzyloxycarbonylglutamide (2C12-Gln-(Z)). *N*-Benzyloxycarbonylglutamic acid (Glu(Z)) (7.0 g, 25 mmol), *n*-dodecylamine (12 mL, 53 mmol), and triethylamine (8.9 g, 63 mmol) were dissolved in THF (400 mL) (*23*). The solution was cooled to 0 °C, and diethylphosphorocyanidate (DEPC) (10 mL, 64 mmol) was added to the solution and stirred for 1 h at this temperature. After stirring for 1 day at room temperature, the solution was concentrated in vacuo, and the residue was dissolved in 350 mL of chloroform. The solution was washed with 10% $NaHCO_3$, 0.1 mol/L HCl, and water. The solution was dried over Na_2SO_4, concentrated, and finally recrystallized from ethanol, which gave a white solid powder: yield 10.7 g (68%, 17 mmol); mp 141−143 °C; FT-IR (KBr)/3287, 2917, 2850, 1686, 1637, and 1539 cm^{-1}; ^1H NMR

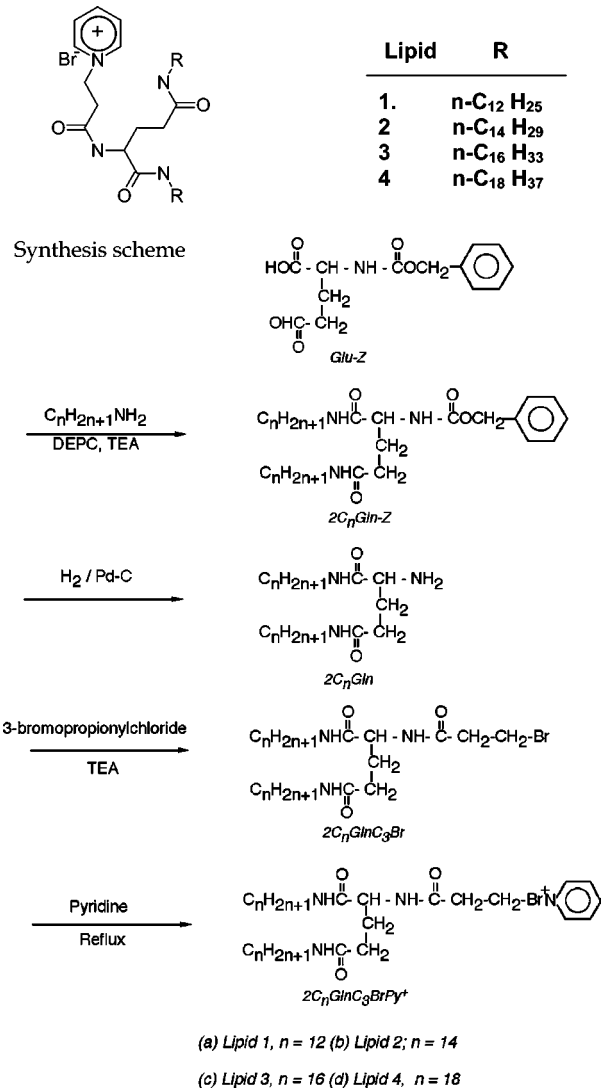

Figure 1. Structures and the synthesis scheme of the glutamide lipids used in this study.

($CDCl_3$) δ 0.862−0.896 (t, 6H, C*H*$_3$), 1.257 (m, 36H, CH_3-(CH_2)$_9$), 1.486 (m, 4H, C*H*$_2$CH$_2$NHC(=O)), 1.980 (m, ^1H, C*HC*H$_2$), 2.091 (m, 1H, C*HC*H$_2$), 2.297 (m, 2H, C*HCH$_2$-C*H*$_2$C(=O)), 3.221 (m, 4H, C*H*$_2$NHC(=O)), 4.144 (m, 1H, C**H*), 5.098 (s, 2H, C*H*$_2$Ph), 7.328 (s, 5H, C$_6$*H*$_5$). N′,N″-Didodecylglutamide (2C$_{12}$-Gln). 2C$_{12}$-Gln(Z) (10.0 g, 16 mmol) was dissolved in 400 mL ethanol with heating, and Pd carbon (1 g) was added to the solution. H_2 gas was bubbled slowly into the solution for 10 h at 60 °C. Pd carbon was removed by filtration. The solution was concentrated, recrystallized from methanol, and dried in vacuo to give a white solid powder: yield 6.76 (88%, 14 mmol); mp 117.0−118.5 °C; FT-IR (KBr)/3318, 2934, 2874, 1647, and 1553 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.88 (t, 6H, C*H*$_3$), 1.26 (m, 36H, CH_3(C*H*$_2$)$_9$), 1.50 (m, 4H, C*H*$_2$CH$_2$NHC(=O)), 1.95 (m, 2H, C*HC*H$_2$CH$_2$C-(=O)), 2.31 (m, 2H, C*HCH$_2$C*H*$_2$C(=O)), 3.23 (m, 4H, C*H*$_2$-NHC(=O)), 3.41 (m, 1H, C**H*). Anal. Found: H, 12.2; C, 72.1; N, 8.74. Calcd. for $C_{29}H_{59}N_3O_2$: H, 12.3; C, 72.3; N, 8.72.

N′,N″-Didodecyl-N-bromopropionylglutamide (2C$_{12}$-GlnC$_3$Br). 2C$_{12}$-Gln (1.45 g, 3.0 mmol) was dissolved in THF (100 mL); 3-bromopropionylchloride (0.77 g 4.5 mmol) and triethylamine (0.91 g, 9.0 mmol) were also added into the solution. The solution was cooled to 0 °C and stirred for 1 h at this temperature. After being stirred for 1 day at room temperature,

the solution was concentrated, and the residue was dissolved in chloroform. The solution was washed with 10% $NaHCO_3$, 0.1 mol/L HCl, and water. The solution was dried over Na_2SO_4, concentrated, and finally recrystallized from ethyl acetate, which gave a white solid powder: yield 0.93 g (49%, 1.51×10^{-3} mol); mp 164−166 °C; FT-IR (KBr)/3316, 2933, 2875, 1648, and 1555 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.73 (t, 6H, CH_3), 1.23 (m, 36H, $CH_3(CH_2)_9$), 1.33 (m, 2H, C*HC$H_2$$CH_2$C(=O)), 1.43 (m, 4H, C$H_2CH_2$NH), 2.43 (m, 2H, C*$HCH_2CH_2$C(=O)), 2.83 (t, 2H, C(=O)C$H_2CH_2Br^-$), 2.93 (m, 4H, CH_2CH_2NH), 3.28 (t, 2H, C(=O)$CH_2CH_2Br^-$), 4.73 (m, 1H, C*H). Anal. Found: H, 10.3; C, 63.1; N, 6.94. Calcd. for $C_{32}H_{62}N_3O_3Br$: H, 10.13; C, 62.32; N, 6.81.

*N′,N″-Didodecyl(pyridinium-N-propionyl)glutamide Bromide ($2C_{12}$-GlnC$_3$Py$^+$Br$^-$), Lipid **1**.* $2C_{12}$-$GlnC_3Br$ (0.50 g, 0.81 mmol) was dissolved in 50 mL of pyridine and stirred at reflux temperature for 2 days. After cooling to room temperature, a white crystal appeared, and unreacted pyridine was removed by filtration. The white crystal was dissolved in methanol and filtered. The white crystals in this step were dried in vacuo: yield 0.31 g (54%, 0.44 mmol); mp 180−182 °C; FT-IR (KBr)/3295, 2928, 2865, 1650, and 1541 cm^{-1}; ^1H NMR (CD_3OD) δ 0.87−0.91 (t, 6H, CH_2), 1.28 (m, 36H, $(CH_2)_3(CH_2)_9$), 1.47 (m, 4H, CH_2CH_2C(=O)), 1.80−1.85 (m, 2H, C*HCH_2CH_2C(=O)), 1.94−1.99 (t, 2H, C*HCH_2CH_2C(=O)), 2.16−2.20 (t, 2H, C(=O)C$H_2CH_2Py^+$), 3.02−3.04 (t, 2H, C(=O)$CH_2CH_2Py^+$), 3.13−3.15 (m, 4H, CH_2CH_2C(=O)), 4.19−4.22 (m, 1H, C*H), 8.07−8.10 (m, 2H, pyridine ring), 8.56−8.60 (t, 1H, pyridine ring), 8.98−9.00 (d, 2H, pyridine ring). Anal. Found: H, 9.85; C, 62.8; N, 7.75. Calcd. for $C_{37}H_{67}N_4O_3Br$: H, 9.70; C, 63.86; N, 8.05. The others (lipids **2**, **3**, and **4**) were also synthesized, and the structures of the compounds in each step were characterized using procedures employed in the synthesis of lipid **1**. The results of elemental analysis, melting points, and MALDI-TOF-MS data for all four lipids are provided in Table 1.

RESULTS AND DISCUSSION

DNA Binding of the Lipids 1−4. To quantify the binding strength of the four lipids to DNA, the lipid-bound DNA was separated from the free or unbound DNA by agarose gel electrophoresis. Figure 2 shows that, in phosphate-buffered saline (PBS), complete binding of DNA was observed with all four lipids when the helper lipid was DOPE. With cholesterol as the helper lipid, only lipids **1** and **4** has shown complete binding, while the binding of lipids **2** and **3** to DNA was comparatively lower. Also, the presence of lipid at charge ratio of 2:1 was sufficient to achieve complete binding. However, when the complexes were prepared in water, all the lipids bind DNA strongly, indicating an ionic basis of DNA interaction with the cationic lipids (data not reported).

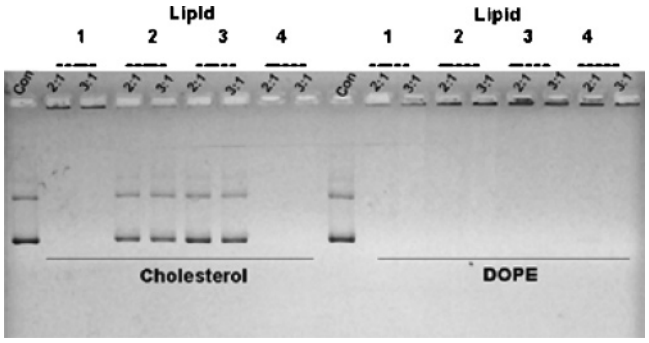

Figure 2. Binding of DNA with lipids **1**−**4**/0.8% agarose gel electrophoresis of plasmid pCMVβ-gal complexed with lipids **1**−**4** at two charge ratios, i.e., 2:1 and 3:1. The helper lipid is either cholesterol or DOPE. Free DNA was loaded in the first well and the tenth well.

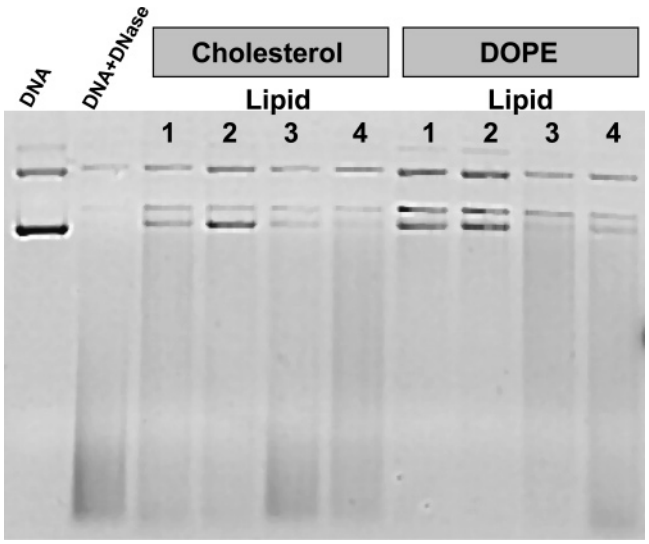

Figure 3. Sensitivity of DNA in lipid−DNA complexes to DNaseI/0.8% agarose gel electrophoresis of lipid−DNA complexes treated with DNaseI. Lane 1: Control plasmid pCMVβ-gal. Lane 2: Control DNA + DNaseI. Lanes 3−6: Lipids **1**−**4** with cholesterol as the co-lipid at 3:1 lipid/DNA. Lanes 7−10: Lipids **1**−**4** with DOPE as the co-lipid at 3:1 lipid/DNA.

In addition to the DNA binding assay, the susceptibility of bound DNA to DNaseI was performed to assess the protective ability of the lipid. Presence of DOPE as helper lipid offers better protection of DNA from DNase I digestion compared to cholesterol (Figure 3). Although all the eight formulations showed protection to DNA from DNaseI treatment to some extent, complete protection was seen only with lipid **2** with either of the helper lipids. Lipid **1** also showed compete protection with DOPE alone but not with cholesterol as the helper lipid.

Size of the Lipoplexes Prepared with Lipids 1−4 and Plasmid DNA. Transfection efficiency of lipoplexes was known to depend strongly on the size and the surface charge of the lipoplex (*25*, *26*). We measured these parameters on lipoplexes with DOPE as the helper lipid in DMEM, since this medium is relevant to the transfection protocol. The data presented in Table 2 demonstrate that the size of the complex increases with the increase in charge ratio with all four lipids. Chain length of the lipid does not influence the size of the complex with varying charge ratios, though longer chain-length lipids have resulted in vesicles of larger size. Surface charge as measured by ζ-potential has negative values across all the lipids and at all

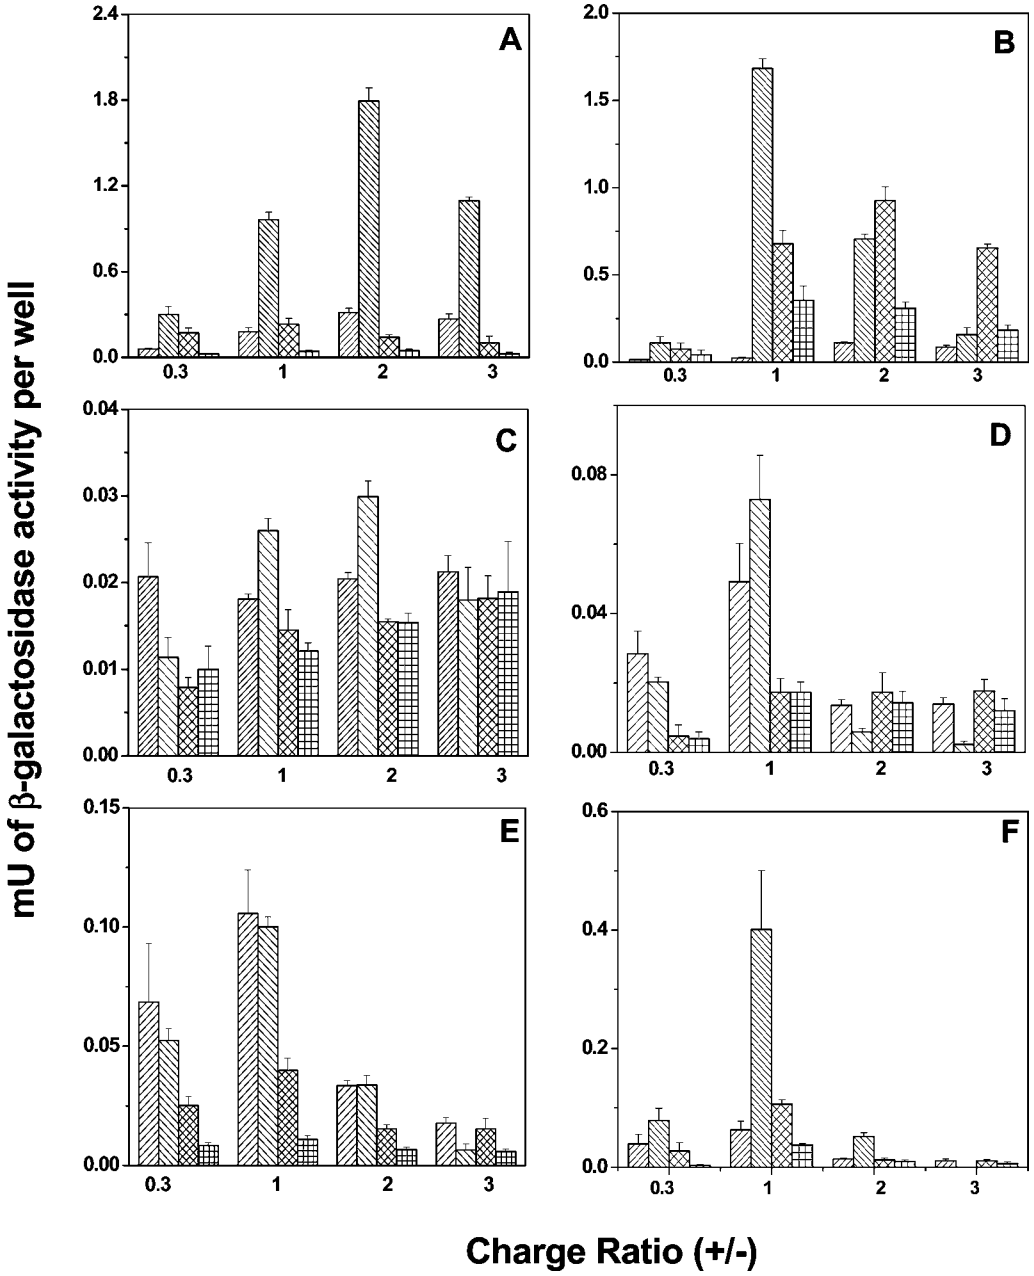

Figure 4. Transfection efficiencies of lipids **1**−**4** on MCF-7 (A, B), HeLa (C, D), and COS (E, F) cell lines. The four lipids were tested with either cholesterol (A, C, E) or DOPE (B, D, F) as the helper lipid. Bar fills are as follows: Lipid **1**, left slanting lines; lipid **2**, right slanting lines; lipid **3**, angled mesh; and lipid **4**, square mesh.

Table 2. Size of the Lipoplexes of Lipids 1−4:

charge ratio (±)	size, nm			
	0.3	1	2	3
lipid **1**	214 ± 4.7	242 ± 1.5	361 ± 14.7	956 ± 65.5
lipid **2**	267 ± 6.3	894 ± 592	367.7 ± 24	1036 ± 109
lipid **3**	441 ± 25	719 ± 52	1379 ± 41	2043 ± 91
lipid **4**	489 ± 13	561 ± 39	913 ± 60	1426 ± 113

charge ratios except in the case of **1** at 3:1 charge ratio (data not reported). Generally, lipoplexes achieve maximum size when the net charge is zero, and the size decreases when the particle is either net positive or net negative (*27*−*29*). The net charge with glutamide lipids even at 3:1 charge ratio was negative in DMEM, suggesting charge neutralization did not occur at these charge ratios. Though the cationic charge is far in excess compared to the charge on the nucleic acids, the negative ζ-potential indicates that components of the medium DMEM may bind to the complexes and render them anionic. However, if the potential measurements were made in water, the potential was found to be positive above a 1:1 charge ratio (data not reported).

Transfection Studies with Lipids 1−4. We have tested the four dialkyl pyridinium glutamides for their transfection efficiencies with two helper lipids in three different cell lines, viz., MCF7, COS, and HeLa. Since non-cationic lipid additives in the formulations were known to enhance the transfection efficiency, we have used either DOPE or cholesterol as the helper lipid to investigate if the transfection efficiency is helper-lipid-dependent (*30*). Since the transfection efficiency depends on the ratio of the positive "lipid" charges to negative phosphate charges in the DNA, we have also tested the efficiency at various charge ratios (*23*). The reporter gene expression as measured by monitoring β-galactosidase activity is shown in Figure 4A−F to compare transfection efficiency among the three cell lines. MCF-7 cells showed maximum transfection compared to COS and HeLa cells. Between the two helper lipids, DOPE enhanced

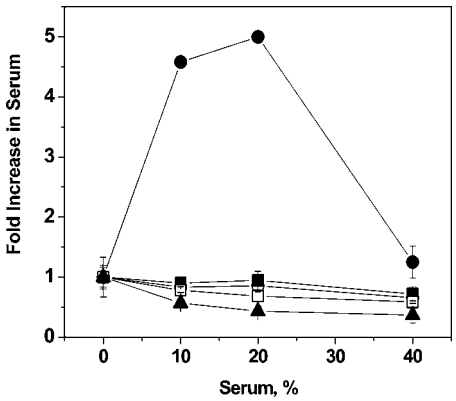

Figure 5. Transfection efficiency of lipid **2** in MCF-7 cells in the presence of serum. Transfection efficiency (fold increase) of lipid **2** + DOPE (●), with varying concentrations of serum compared with Lipofectamine (1 mg/mL) used at 1 μL (■), 2 μL (□), 4 μL (▲), and 8 μL (○) with 0.9 μg of DNA.

transfection in COS and HeLa cell lines compared to cholesterol; however, such differences were not apparent in the MCF-7 cell line where both the helper lipids elicited similar transfection efficiencies. Though the optimum charge ratio was dependent on the lipids and also on cell lines, a charge ratio of approximately 1:1 or 2:1 was found to be optimal. Very high (3:1) or low (0.3:1) charge ratios were not effective in transfection (*31*). Lipid **2** showed maximum transfection in all three cell lines at a 1:1 charge ratio with DOPE as the helper lipid. The observed maximum transfection with a 14-carbon lipid is in agreement with the reported literature that a 12- to 16-carbon length hydrophobic domain is optimally suited for transfection (*25*, *32*). Lack of transfection with shorter-chain lipids was suspected to be due to poor vesicle-forming abilities and toxicity to the cells. Long-chain lipids would probably result in stable and rigid vesicles unsuitable for transfection. Some lipids were reported to be efficient when the chain length was 18-carbon (*16*).

Transfection Efficiency in the Presence of Serum. Serum stability of the lipoplexes is very important for their in vivo efficacies (*33*, *34*). We have tested the transfection efficiency of lipids, initially in the presence of 10% serum, and found that only lipid **2** shows significant transfection efficiencies in the presence of serum (Figure 5). The other lipids showed decreased transfection efficiency in the presence of serum (data not shown). Serum contains nucleases, which would degrade the plasmid DNA, and also contains several proteins, including albumin, which would reduce the cell association properties of the lipoplex (*35*). We further tested lipid **2** with both the helper lipids in MCF-7 cells, in the presence of 0−40% serum along with a commercial transfecting agent Lipofectamine (Figure 5). We observed nearly a 5-fold increase in the transfection efficiency with lipoplexes with lipid **2** and DOPE in the presence of 20% serum (Figure 5). Unlike the small decrease in transfection efficiency observed with Lipofectamine, the transfection efficiency of lipid **2** has in fact enhanced by 5-fold in the presence of serum. Such increases in transfection efficiency by cationic lipids in the presence of serum have not been reported to our knowledge. This suggests that lipid **2** demonstrates a very interesting stability to serum and also a serum-mediated enhancement of transfection efficiency.

Toxicity of the Formulations on MCF-7. Since toxicity of the formulations to the cells is critical for transfection, we have tested the viability of MCF-7 cells in the presence of formulations prepared with the four lipids along with two helper lipids. Lipoplexes with cholesterol were found to be very toxic to the cell by decreasing the cell viability by more than 50% even at

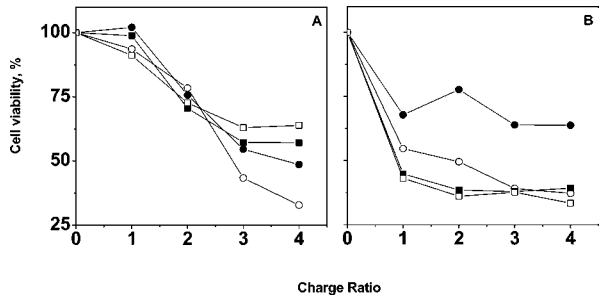

Figure 6. Cytotoxicity of lipids **1**−**4** on MCF-7 cells. Toxicity, measured as percent viability, was evaluated with lipids **1** (●), **2** (○), **3** (■), and **4** (□) with DOPE (A) and cholesterol (B) as helper lipids. The absorption values obtained using reduced formazon with cells in the absence of lipids were taken to be 100.

a 1:1 charge ratio. In comparison, DOPE marginally affects the viability at a 1:1 charge ratio and by 20% at a 2:1 charge ratio (Figure 6).

Four dialkyl glutamides of varying chain lengths were synthesized and characterized. The data presented here demonstrate that these lipids efficiently transfect three cell lines tested in this study. These lipids have significant binding to DNA at charge ratios above 2:1 when the helper lipid in the formulation is DOPE. In line with this observation, the DNaseI protection was also higher in the presence of DOPE compared to cholesterol. Cholesterol apparently does not form stable lipoplexes strongly for occluding the DNA inside the lipoplex. Even at a 3:1 charge ratio, the lipoplexes have a net negative charge leading to a continuous increase in size. Among the four lipids, lipid **2** with DOPE as the helper lipid shows very promising transfection efficiencies on all three cell lines tested. The efficiency of the cationic lipids with chain length in the range 12−16 carbons in length is well-documented, and often 14-carbon-length lipids are most efficient among several cationic lipids with differing chemistries (*15*). The balance between the stability of the liposome in the medium and the readiness of the liposome to release the DNA is important for good transfection efficiency (*36*). Short-chain lipids may not result in stable liposomes, and long-chain lipids may form very stable particles for release of the DNA. Lipid **2** with DOPE as the helper lipid has good DNA binding ability, provides DNaseI protection, and is also less toxic. All these properties together elicited high transfection efficiencies. The converse is true with cholesterol in most of the cases. The size of the lipoplexes does not show any correlation with the transfection efficiency, indicating that factors in addition to size play a role in lipoplex and cell interactions. The role of biophysical properties of the lipid−DNA complex in its association and uptake by cells is still poorly understood (*37*, *38*). The remarkable enhancement of transfection of lipoplexes prepared with lipid **2** in the presence of serum suggests the potential of this lipid for in vivo transfections.

Tetraalkyldiglutamides with long spacers were synthesized by alkylating the free amino group into tertiary amine (*39*). These lipids with charge on the glutamate, called as lipopeptides, were shown to transfect cells with efficiencies lower than Lipofectin on 293 cells. Pyridinium head groups have been made popular with the publication of the Saint series of lipids, though the pyridinium was bonded to a linker at C3 and an R group was attached to the nitrogen (*40*−*42*). Cationic lipids with a heterocyclic trimethylpyridinium as the polar head linked to two alkyl chains via a propyl group have shown good transfection in both in vitro and in vivo experiments (*43*). Unlike the Saint lipids, in the lipids described here, the pyridine is N-linked to the linker, i.e., glutamic acid. Dialkyl glutamides were tested for their ability to form supramolecular structures due to the presence of a chiral center (*19*). The intermolecular hydrogen

bonding among the amide moieties of the lipids contributes to self-assembly and thus stabilizes the liposome (*17*, *44*). As a linker molecule, glutamic acid offers a synthetic flexibility to design various cationic lipids. To the best of our knowledge, this is the first report where dialkyl glutamides have been shown to transfect several cell lines efficiently.

CONCLUSIONS

Four cationic lipids based on glutamide as a linker were synthesized. Formulations with DOPE as the helper lipid show excellent transfection in three different cell lines. Although DNA binding and protection from nuclease, size, or surface potential measurements of lipoplexes of these lipids show variation, there is no apparent correlation with their transfection abilities. Very remarkably, one of the lipids, lipid **2,** demonstrates enhanced transfection in the presence of serum, suggesting its physiological relevance and suitability for in vivo applications.

Improving the Antigenicity of sTn Antigen by Modification of Its Sialic Acid Residue for Development of Glycoconjugate Cancer Vaccines

Jian Wu and Zhongwu Guo*

Department of Chemistry, Wayne State University, 5101 Cass Avenue, Detroit, Michigan 48202. Received April 22, 2006; Revised Manuscript Received September 20, 2006

Sialyl Tn (sTn) antigen is a sialylated disaccharide abundantly expressed by many tumors. To search for effective cancer immunotherapies based on sTn antigen, we designed and synthesized a series of unnatural *N*-acyl derivatives of sTn and studied their immunological properties. For this purpose, an efficient method was developed to synthesize the natural and unnatural forms of sTn antigen and their protein conjugates. The resultant glycoconjugates were used to immunize C57BL/6 mice, and the immune response was assessed by enzyme-linked immunosorbent assay (ELISA). Whereas the keyhole limpet hemocyanin (KLH) conjugate of sTn elicited low levels of IgM antibodies, the KLH conjugates of *N*-*iso*-butanoyl sTn and *N*-phenylacetyl sTn, especially the latter, induced high titers of antigen-specific IgG antibodies, showing a T-cell-dependent response that is critical for the antitumor activity. The results suggest that the modified forms of sTn, especially *N*-phenylacetyl sTn, have improved antigenicity and promising immunological properties for use as cancer vaccines.

INTRODUCTION

Many tumors express certain unique carbohydrates termed tumor-associated carbohydrate antigens (TACAs), and the TACAs are closely correlated with cancer cell adhesion and metastasis (*1*, *2*). TACAs are also useful molecular targets in the design and development of novel strategies for cancer diagnosis and therapy, such as cancer vaccines (*3*−*9*). Among numerous TACAs identified (*2*−*5*), sialyl Tn antigen (sTn, Figure 1), an *O*-linked disaccharide [NeuAcα(2→6)GalNAc], is of particular interest. First, sTn is relatively tumor-specific. Even though sTn antigen is richly expressed on a number of tumors, such as breast, prostate, colorectal, and ovarian cancer (*10*−*13*), it is rarely observed on normal tissues. Second, the expression of sTn has been identified as an independent indicator for poor prognosis of cancer (*11*−*14*). Consequently, sTn antigen and relevant mucins that are aberrantly glycosylated with sTn have been extensively investigated for the immunotherapy of cancer (*15*−*20*). The protein conjugates of sTn antigen could indeed elicit humoral immune response that showed remarkable specificity for cancer cells (*21*). The keyhole limpet hemocyanin (KLH) conjugate of sTn antigen (*19*, *20*) has been developed and tested as a therapeutic vaccine (Theratope) for treatment of metastatic breast cancer (*22*, *23*). Unfortunately, at the Phase III clinical trial Theratope failed to meet the endpoints of time-to-disease progression and overall survival rate (*23*), which was largely because it cannot induce strong T-cell-mediated immune response in patients. In fact, most natural TACAs elicit IgM antibodies rather than IgG antibodies (*24*), while T-cell dependent IgG response is critical for immunotherapy of cancer (*25*, *26*). The problem of the lack of a T-cell-dependent immune response to TACAs has severely hindered further progress of TACA-based cancer vaccines.

To overcome such problems, our group has recently developed a novel strategy for immunotherapy (*27*), which is based on metabolic engineering of cell surface *N*-acetylneuraminic acid (Neu5Ac) (*28*, *29*). The concept is to immunize cancer patients with a synthetic vaccine made of an artificial *N*-acyl derivative of a natural sialyl TACA. After a specific immune response is established, the patients will be treated with correspondingly *N*-acylated D-mannosamine to induce the expression of this artificial antigen on tumor cells in place of the natural TACA. The provoked immune system will then eliminate the bioengineered tumors. As sTn antigen contains a sialic acid residue at its nonreducing end, we anticipated that the new strategy should be applicable to it for the development of useful cancer immunotherapy.

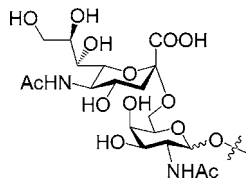

Figure 1. The structure of sTn antigen.

For the new strategy to work, an important condition is an effective vaccine that can induce a T-cell-dependent immune response. The other condition is a method that can effectively bioengineer tumor cells (*30*). The main aim of this work is to study the influence of chemical modification of the sialic acid residue of sTn on its antigenicity and to identify a derivative that may be used as a vaccine to induce robust T-cell-dependent immune responses. For this purpose, we have synthesized the natural and unnatural *N*-acyl derivatives of sTn, linked them to KLH, and studied the immunological properties of the resultant glycoconjugates.

EXPERIMENTAL PROCEDURES

2-Azidoethyl *O*-[Methyl 4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-5-trifluoroacetamido-D-*glycero*-α-D-*galacto*-non-2-ulopyranosylonate]-(2→6)-*O*-2-acetamido-2-deoxy-*β*-D-galactopyranoside (16). A mixture of **14** (400 mg, 1.21 mmol), **15** (700 mg, 1.21 mmol), and activated molecular sieves (4 Å, 2.0 g) in anhydrous acetonitrile (5.0 mL) was stirred at rt for 2 h under an atmosphere of argon. After the mixture was cooled to −35 °C, *N*-iodosuccinamide (NIS) (1.1 g, 4.84 mmol) and triflic acid (TfOH) (53 μL, 0.61 mmol) were added with stirring. The mixture was kept at −35 °C for 30 min and then diluted with

DCM (20 mL). The solid material was filtered off and washed with DCM (10 mL). The combined filtrates were washed with aqueous $Na_2S_2O_3$ (20%) and water. The organic phase was dried over Na_2SO_4 and concentrated under reduced pressure. The residue was purified on a silica gel column (EtOAc/hexane 2:1) to give a mixture of α-/β-disaccharide (680 mg, 65%, α/β 4:1) as a white foamy solid. $R_f = 0.19$ (EtOAc/hexane 2:1); HR FABMS (*m*/*z*): cacld for $C_{33}H_{46}F_3N_5NaO_{18}$ ($M + Na^+$) 880.2688, found 880.2685. This mixture was directly used in the next step of the reaction without further purification.

A solution of the above product (600 mg, 0.7 mmol) in 65% $HOAc/H_2O$ (v/v, 6 mL) was stirred at 60 °C for 1.5 h. Thin layer chromatography (TLC) showed the complete consumption of the starting material. The mixture was concentrated and coevaporated with toluene (3 × 5 mL). The residue was purified by flash column chromatography (DCM/MeOH 18:1) to afford compound **16** (420 mg, 70%) as a white solid ($R_f = 0.27$, DCM/MeOH 12:1) and its β-anomer (100 mg, 17%, $R_f = 0.32$, DCM/MeOH 12:1). Compound **16**: $[\alpha]_D$ −42.4 (*c* 1.0, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 600 MHz): δ 6.72 (d, *J* 9.6 Hz, 1H), 6.17 (d, *J* 3.6 Hz, 1H), 5.37−5.26 (m, 2H), 5.21 (dd, *J* 7.8, 1.8 Hz, 1H), 4.99−4.93 (m, 1H), 4.50 (d, *J* 8.4 Hz, 1H, H-1), 4.36 (dd, *J* 12.6, 3.0 Hz, 1H), 4.27 (dd, *J* 10.8, 2.4 Hz, 1H), 4.10 (dt, *J* 10.8, 3.6 Hz, 1H), 4.00 (dd, *J* 12.6, 6.6 Hz, 1H), 3.98−3.93 (m, 2H), 3.82 (s, 3H), 3.79−3.67 (m, 6H), 3.59−3.54 (m, 1H), 3.28 (dt, *J* 13.2, 3.0 Hz, 1H), 2.91 (s, 1H), 2.63 (dd, *J* 12.6, 4.2 Hz, 1H, H-3′e), 2.15, 2.14, 2.05, 2.03, 2.01 (5s, 5 × 3H, Ac), 1.96 (t, *J* 12.6 Hz, 1H, H-3′a). HR FABMS (*m*/*z*) calcd for $C_{30}H_{42}F_3N_5O_{18}$ ($M + H^+$) 818.2555, found 818.2552.

***N*-{2-*O*-{[Methyl 4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-5-trifluoroacetamido-D-*glycero*-α-D-*galacto*-non-2-ulopyranosylonate]-(2→6)-*O*-2-acetamido-2-deoxy-β-D-galactopyranosyl}-ethyl} 4-Pentenamide (17).** A solution of **16** (330 mg, 0.404 mmol) in MeOH (15 mL) was stirred with 10% Pd/C under a H_2 atmosphere at rt for 1 h. After the catalyst was filtered off, to the filtrate that contained glycosyl amine was added 4-pentenoic anhydride. The mixture was stirred at rt overnight. The solution was condensed, and the crude product was purified by flash chromatography (DCM/MeOH 10:1) to afford compound **17** (270 mg, 80%) as a white solid. $R_f = 0.19$ (DCM/MeOH 12:1). $[\alpha]_D$ −39.5 (*c* 1.0, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 600 MHz): δ 7.08 (d, *J* 9.0 Hz, 1H), 6.99 (d, *J* 5.4 Hz, 1H), 6.41 (s, 1H), 5.86−5.78 (m, 1H, CH_2=C<u>H</u>-), 5.38−5.32 (m, 1H), 5.25 (dd, *J* 7.8, 1.2 Hz, 1H), 5.08 (d, *J* 16.8 Hz, 1H, C<u>H</u>$_2$=CH-), 5.02 (d, *J* 10.2 Hz, 1H, C<u>H</u>$_2$=CH-), 4.98 (dt, *J* 11.4, 4.2 Hz, 1H), 4.50 (d, *J* 8.4 Hz, 1H, H-1), 4.39 (dd, *J* 12, 1.8 Hz, 1H), 4.31 (dd, *J* 10.8, 1.8 Hz, 1H), 4.04−3.98 (m, 2H), 3.94 (d, *J* 3.6 Hz, 1H), 3.88−3.74 (m, 7H), 3.70−3.64 (m, 3H), 3.26−3.20 (m, 1H), 2.65 (dd, *J* 12.6, 4.8 Hz, 1H, H-3′e), 2.41−2.36 (m, 2H), 2.33−2.28 (m, 2H), 2.16, 2.15, 2.09, 2.03, 2.02 (5s, 5 × 3H, Ac), 1.96 (t, *J* 12.6 Hz, 1H, H-3′a). HR FABMS (*m*/*z*) calcd for $C_{35}H_{50}F_3N_3NaO_{19}$ ($M + Na^+$) 896.2888, found 896.2896.

Compounds 18−21. To a stirred solution of **17** (220 mg, 0.252 mmol) in methanol (10 mL) was added a sodium methoxide solution in methanol (0.1 M, 1.8 mL). After the mixture was stirred at rt for 5 h, it was neutralized with Amberlite IR-120 (H^+) resin. The resin was filtered off and washed with methanol. The filtrate and washings were combined and concentrated to a small volume (ca. 10 mL), to which was added an aqueous NaOH solution (1 N, 3 mL). After the reaction finished within 24 h, as indicated by TLC, the mixture was neutralized with diluted HCl to pH 7. Then, the reaction mixture was concentrated in a vacuum to give the fully deprotected disaccharide, which was directly used in the next step. $[\alpha]^{20}_D$ −23.2 (c 1.0, MeOH); ^{1}H NMR (D_2O, 600 MHz): δ 5.86−5.78 (m, 1H, CH_2=C<u>H</u>-), 5.04 (dd, *J* 17.4, 1.8 Hz, 1H, C<u>H</u>$_2$=CH-), 4.97 (dd, *J* 10.2, 1.8 Hz, 1H, C<u>H</u>$_2$=CH-), 4.33 (d, *J* 8.4 Hz, 1H, H-1), 3.94−3.76 (m, 6H), 3.74−3.46 (m, 8H), 2.81 (t, *J* 9.6 Hz, 1H), 2.76 (dd, *J* 12.6, 4.8 Hz, 1H, H-3′e), 2.36−2.24 (m, 4H), 1.97 (s, 3H, C<u>H</u>$_3$CONH), 1.55 (t, *J* 12.0 Hz, 1H, H-3′a). HR FABMS (*m*/*z*) calcd for $C_{24}H_{40}N_3Na_2O_{14}$ ($M + Na^+$) 640.2306, found 640.2324.

To a solution of the above product (40 mg, 0.065 mmol) in MeOH (6 mL) was added an acyl anhydride (Ac_2O 0.1 mL, Pr_2O 0.12 mL, *i*Bu_2O 0.14 mL, or $PhAc_2O$ 100 mg). After the reaction finished within 4 h, as indicated by TLC, the mixture was condensed under reduced pressure. The residue was purified on a Biogel P-2 column with H_2O as the eluent. Fractions containing the expected product were combined and freeze-dried to afford *N*-acyl sTn derivatives **18−21.**

General Procedure for the Coupling between 22 and 25 and KLH or Human Serum Albumin (HSA). A solution of **22**, **23**, **24**, or **25** (8 mg), KLH or HSA (6 mg), and $NaBH_3CN$ (6 mg) in 0.1 M $NaHCO_3$ (0.2 mL, pH 7.5−8.0) was allowed to stand at rt in the dark for 3 days with occasional shaking. The reaction mixture was then loaded onto a Biogel A0.5 column (1 × 15 cm) and eluted with 0.1 M phosphate buffered saline (PBS) buffer (I = 0.1, pH = 7.8). The fractions containing the glycoconjugate, characterized by a bicinchoninic acid (BCA) assay for proteins and by the Svennerholm method for sialic acid, were combined and dialyzed against distilled water for 2 days. It was then lyophilized to give a white powder of the expected glycoconjugates **4**−**11** (5−6 mg).

Analysis of the Carbohydrate Loading Levels of the Glycoconjugates (*31*, *32*). After the solution of an exactly weighed sample of the glycoconjugate (0.5 mg) in distilled water (1.0 mL) was mixed with the resorcinol reagent (2.0 mL), the mixture was heated in a boiling water bath for 30 min. It was cooled to rt, and to this mixture was then added an extraction solution (1-butanol acetate and 1-butanol, 85:15 v/v, 3.0 mL). The mixture was shaken vigorously before it was allowed to stand still for ca. 10 min to allow the organic layer to separate well from the inorganic layer. The organic layer was transferred to a 1.0-cm cuvette, and its absorbance at 580 nm was determined by an UV−vis spectrometer, using a blank organic solution as the control. The sialic acid content of the glycoconjugate was determined against a calibration curve created with the standard NeuNAcyl (Acyl = Ac, Pr, iBu, PhAc) solutions analyzed under the same condition. The carbohydrate loading of each glycoconjugate was calculated according to the following equation.

$$N\text{-Acyl sTn loading (\%)} = \frac{\text{amount of sialic acid (mg) in the sample}}{\text{weight of the glycoconjugate sample (mg)}} \times \frac{\text{molecular weight of sTn}}{\text{molecular weight of sialic acid}} \times 100\%$$

Immunization of Mice. Five female C57BL/6 mice at the age of 8 weeks (Jackson Laboratories, Bar Harbor, ME) were immunized for each sTn−KLH conjugate. Immunizations were intraperitoneal with the glycoconjugate containing 2 μg of carbohydrate in 200 μL of saline mixed with 200 μL of MPL/TDM Ribi adjuvant (Sigma Chemical, St. Louis, MO) following the manufacturer's protocol. The mice were boosted with identical immunizations on days 15 and 22 following the initial immunization. The mice were bled by tail vein prior to the initial immunization on day 0 and after immunization on day 14 and day 31. Bleed was clotted to obtain sera, which were stored at −80 °C.

Protocols for Enzyme-Linked Immunosorbent Assay (ELISA) Analysis. ELISA plates were first treated with 100 μL solution of KLH or the HSA conjugate of sTn or sTn derivatives (1 μg/mL 0.1 M bicarbonate buffer) overnight at 4 °C, followed by washing with PBS. Pooled sera from each group of mice were diluted 1:300 to 1:72900 in serial half-log dilutions in PBS with 0.02% azide and incubated overnight in the coated ELISA plates (100 μL/well). The plates were then washed and incubated with 1:1000 dilution of alkaline phosphatase linked anti-κ, anti-IgM, or anti-IgG2a antibodies or with a 1:2000 dilution of anti-IgG1 or anti-IgG3 antibodies (Southern Biotechnology, Buckingham, AL) for 1 h at rt. Plates were washed and developed with PNPP substrate for colorimetric readout using a BioRad 550 plate reader at 405 nM wavelength.

For titer analysis, optical density (OD) values were plotted against dilution values, and a best-fit line was obtained. The equation of this line was employed to calculate the dilution value at which an OD of 0.5 was achieved, and the antibody titer was calculated at the inverse of this dilution value.

RESULTS AND DISCUSSION

In the design of sTn analogues, we focused on the modification of the sialic acid residue because previous studies have demonstrated that cells can be readily bioengineered to express unnatural sialic acids following the uptake of *N*-acyl mannosamines as biosynthetic precursors (*30*, *33*−*36*). The sTn derivatives synthesized and studied in this work were *N*-propionyl sTn (sTnNPr, **1**), *N*-*iso*-butanoyl sTn (sTnN*i*Bu, **2**), and *N*-phenylacetyl sTn (sTnNPhAc, **3**) (Figure 2). The same *N*-acyl derivatives of sialic acid proved to be more antigenic than Neu5Ac itself (*37*); therefore, we expected that **1**, **2**, and **3** would be better antigens than sTn. On the other hand, it has been reported that *N*-propionyl and *N*-phenylacetyl mannosamines could efficiently glycoengineer tumor cells (*30*, *31*). It is thus reasonable to expect the feasibility of achieving glycoengineered modification of sTn on tumors by these functional groups, which is necessary for the new immunotherapeutic strategy. Consequently, if certain glycoconjugates designed above show desired immunological properties, they will have great potential for use as vaccines in the exploration of new cancer immunotherapies.

To form effective vaccines, sTn and its *N*-acyl derivatives were coupled to a carrier protein. We chose KLH for this purpose, since KLH has shown useful immunological properties (*15*, *38*). Alternatively, to avoid the detection of antibodies

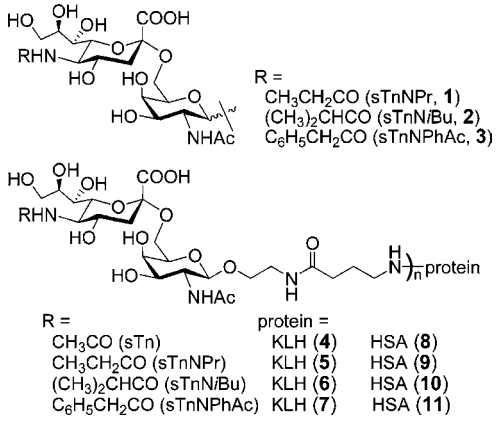

Figure 2. Structures of *N*-modified sTn antigens and the glycoconjugate vaccines studied.

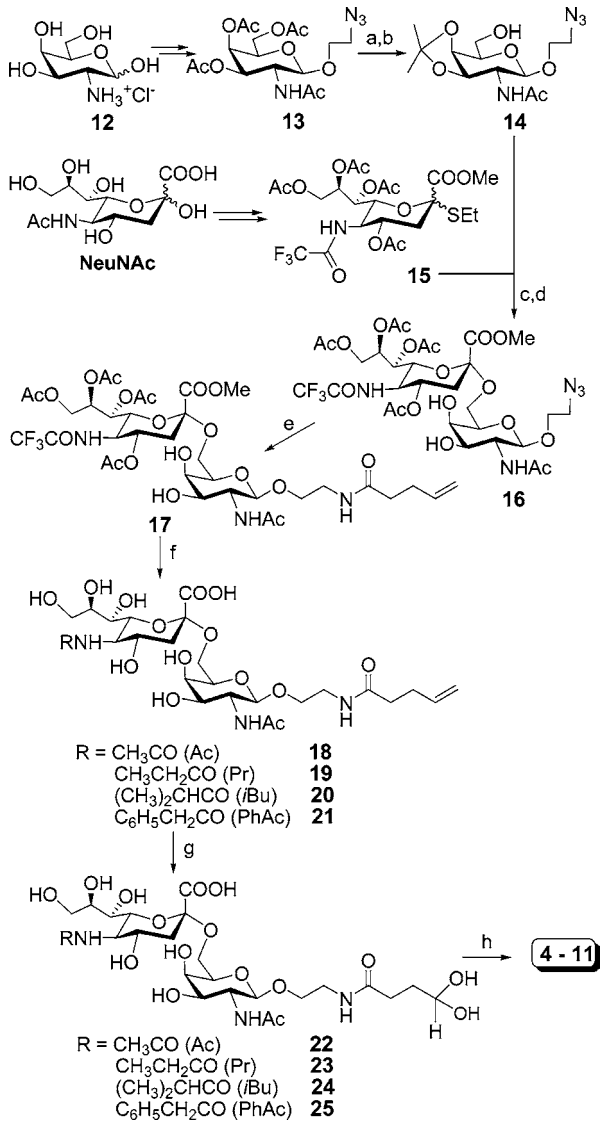
specific for KLH in ELISA, HSA was employed as the carrier protein of the capture reagents. The antigens and carrier proteins were coupled together by a convenient and efficient method based on the pentenoyl group (*39*). An additional advantage of this coupling method is that the linker itself does not cause an immune response (*40*).

The synthesis of natural sTn antigen, its unnatural *N*-acyl derivatives, and their protein conjugates is outlined in Scheme 1. The glycosyl acceptor **14** was prepared from D-galactosamine (**12**) after a series of transformations including conversion of **12** into a 2-azidoethanol glycoside **13** followed by complete *O*-deacetylation and then selective protection of the 3,4-hydroxyl groups as an acetonide. A major issue in this synthetic scheme is the sialylation reaction, which is one of the most difficult glycosylation reactions in carbohydrate chemistry. We used the method of Boons and co-workers (*41*) to achieve this transformation, in which an *N*-trifluoroacetyl derivative of neuraminic acid was employed as the glycosyl donor to offer the desired α-glycoside. The trifluoroacetyl group as a protecting group was easily removable to facilitate N-deprotection and subsequent modification with various acyl groups, offering a highly convergent route to the target structures. Thus, after the required sialyl donor **15** was prepared from Neu5Ac following a literature procedure (*41*), it was used to glycosidate **14** using *N*-iodosuccinamide (NIS) and triflic acid (TfOH) as the promoters. This reaction afforded the disaccharide in a good yield (65%) and a reasonable stereoselectivity (α/β: 4/1), but the two anomers were almost inseparable by column chromatography. However, we found that after the acetonide was removed, the diol products were easily separated to afford pure **16**. The α-configuration of its sialic acid was determined by the unique, downfield-shifted NMR signal of H-3e (δ 2.63, compared to δ 2.35 of β-linked sialic acid), which was further confirmed by structural analysis of subsequent products. Compound **16** was then converted into *N*-acyl derivatives of sTn and linked to the carrier proteins.

The pentenoyl group used to couple carbohydrate antigens to carrier proteins was introduced upon selective reduction of the azido group to form a primary amine and then selective acylation of the amino group with pentenoic anhydride. The product **17** was a common intermediate in the synthesis of sTn and its *N*-acyl derivatives. The *N*-trifluoroacetyl group and all *O*-acetyl groups were selectively removed by treatments with a methanolic solution of NaOMe and a methanolic aqueous solution of NaOH, in the presence of an *N*-pentenoyl group. To the exposed amino group were then regioselectively introduced acyl groups in methanol by reactions with acetic, propionic, *iso*-butyric, and phenylacetic anhydrides to afford **18**−**21**, respectively. These products were purified on a Biogel P2 column. Their identity and purity were supported by NMR

Scheme 1[a]



[a] Reagents and conditions: (a) NaOMe, MeOH, 99%; (b) dimethoxypropane, *p*-TsOH, DMF, 65 °C, 90%; (c) NIS, TfOH, MS 4 Å, MeCN, −35 °C, 65%; (d) 60% HOAc, 65 °C, 87%; (e) 10% Pd/C, H_2, MeOH, 1 h; then 4-pentenoic anhydride, overnight, 80%; (f) 0.1 N MeONa/MeOH; then 1 N NaOH, 24 h; finally various anhydrides, rt, >95%; (g) O_3, MeOH, −70 °C, 0.5 h; then Me_2S, to rt, 2 h, 85−90%; (h) KLH or HSA, $NaBH_3CN$, 0.1 N $NaHCO_3$, rt in dark, 3 days.

and HR MS. At this stage, the α-configuration of sialic acid was further confirmed by a downfield-shifted H-3e NMR signal (δ 2.59) compared to the β-anomer (δ < 2.40).

Finally, sTn and its derivatives were coupled to the carrier proteins by a two-step procedure (*39*). First, **18**−**21** were treated with ozone in methanol to selectively oxidize their carbon−carbon double bond and produce hydrated aldehydes **22**−**25** that were purified on a Biogel P2 column. The ^1H NMR spectra of **22**−**25** clearly showed the hydrated aldehyde signal at δ 5.2, whereas the signals of protons linked to carbon−carbon double bond disappeared completely. Next, **22**−**25** were coupled to the carrier proteins, KLH and HSA, by reductive amination carried out in a 0.1 M $NaHCO_3$ buffer in the presence of $NaBH_3CN$. The sTn derivatives **22**−**25** were employed in excess, and the unreacted **22**−**25** were readily separated from the glycoconjugate products on a Biogel A0.5 column. Fractions containing the glycoconjugate, which was the first eluted component, were combined and dialyzed against distilled water. Freeze drying of the aqueous solution afforded glycoconjugates **4**−**11** as white fluffy solids.

Table 1. Antigen Loading Level of the Glycoconjugates

	KLH conjugates				HSA conjugates			
sample	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**
loading (%)	8	10	9	10	11	14	10	13

The sialic acid contents of resultant glycoconjugates **4**−**11** were analyzed by the Svennerholm method (*32*). The contents were converted into carbohydrate loading levels according to the equation presented in Experimental Procedures. As shown in Table 1, the coupling reactions yielded glycoconjugates containing 8−13% (w/w) of carbohydrates. The loading level of HSA conjugates was slightly higher than that of KLH conjugates, which might be determined by the property of carrier proteins. Nevertheless, the level of antigen loading in these glycoconjugates is typical for glycoconjugate vaccines.

The immunological properties of glycoconjugates **4**−**7** as vaccines were studied in C57BL/6 mice. For immunizations, each glycoconjugate containing ca. 2 μg of carbohydrates mixed with MPL/TDM Ribi adjuvant (*42*) was injected intraperitoneally in mice. These mice were then boosted with the same glycoconjugate on day 15 and day 22 following the initial immunization. On day 14 and day 31, animal sera were withdrawn and pooled with respect to the individual group and date. The titer of total antigen-specific antibody or a specific antibody isotype including IgM, IgG1, IgG2a, and IgG3 of the pooled sera was assessed by ELISA.

In ELISA, plate wells were first coated with a derivatized sTn−HSA conjugate or KLH alone as the capture antigen and then treated with the pooled day −1, day 14, or day 31 sera of five immunized mice in a glycoconjugate group. Pooling the sera of immunized mice in each group gave a mean serum antibody concentration. Antibodies captured by the coating antigen on plates were detected with goat anti-mouse kappa light chain specific and horseradish peroxidase (HRP) conjugated antibody, which would reflect about 95% of the total antibody response (*26*). Using sTn−HSA conjugates as the capture antigens allowed us to detect antibodies that were specific for the modified sTn component of KLH conjugates without detection of anti-KLH antibodies. The assays using KLH as the capture antigen served as a positive control, since KLH is well established as a strong immunogen to elicit high titers of antibodies. The sera obtained after the primary immunization, namely, obtained on day 14, gave low ELISA titers, so only the ELISA data of sera obtained on day 31 are presented and discussed in detail here.

Figure 3A shows the total antibody titers with the OD plotted against pooled sera dilutions. Figure 3B gives the normalized titer analysis data (Experimental Procedures) which can quantify more accurately the antigenicity of the glycoconjugates. Although all of the tested glycoconjugates **4**−**7** were immunogenic, sTnNPhAc gave obviously the highest level of antigen-specific antibodies, and the natural sTn antigen gave the lowest concentration of sTn-specific antibodies. There was essentially no binding of preimmune serum to various sTn−HSA conjugates.

Figure 4 shows the titers of different isotypes of antibodies. All glycoconjugates produced relatively equivalent concentrations of IgM antibodies (panel A), but a significant difference was observed with IgG responses. Panel B reveals that the tested glycoconjugates induced low levels of IgG1 antibody, but sTnNPhAc and sTnN*i*Bu induced significant amounts of IgG2a antibodies (panel C). IgG3 titers (panel D) showed a hierarchy similar to that of antigenicity in Figure 3B.

Finally, we also examined the reactivity of antisera from modified sTn-immunized mice to the HSA conjugate of natural sTn (Figure 5). The antisera of sTnNPr and sTnN*i*Bu showed low binding titers, indicating some cross reactivity to sTn. Since

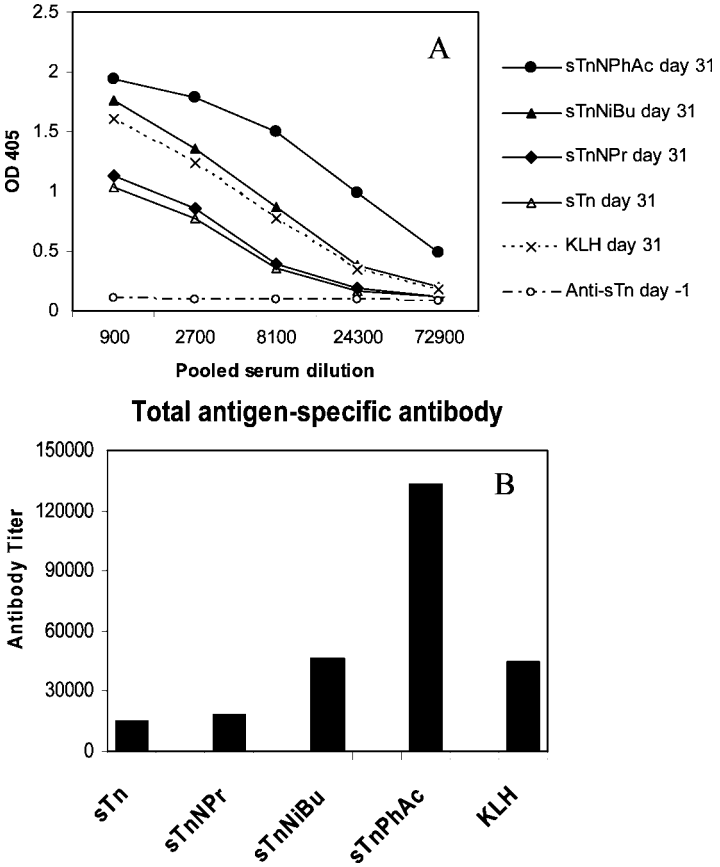


Figure 3. Antigen-specific total antibody contents in sera analyzed by ELISA. (A) Each line represents the antibody level in serum pooled from a group of five mice. Anti-sTn and anti-derivatized sTn antibody levels were obtained from mice immunized with glycoconjugates **4**−**7**. Anti-KLH antibody level was obtained from mice immunized with sTn, and anti-sTn antibody level of preimmune serum was obtained from the same group and used as the negative control (equivalent results were obtained from other groups). Error bars are smaller than the symbol width. (B) Normalized ELISA data of total antibodies. A best-fit line was obtained by plotting OD values against dilution values, and the equation of this line was used to calculate the dilution value at which an OD of 0.5 was achieved.

sTn is relatively tumor-specific, this cross reactivity may not have a major impact on normal tissues. In fact, under certain conditions the synthetic vaccines with improved immunological properties, combined with the cross reactivity of their immune responses to native sTn antigen as well as the unique presentation of sTn on tumor cells, may be useful for cancer immunotherapy. However, sTnNPr-KLH and sTnN*i*Bu-KLH are definitely not the ideal vaccines for our new strategy of cancer immunotherapy, due to the cross reactivity and relatively poor antigenicity. In contrast, the reactivity of sTnNPhAc sera to sTn was too low to be detected. This result suggests that the immune response induced by sTnNPhAc was specific.

Above ELISA data suggest that chemical modifications of sTn antigen could improve its antigenicity, which is consistent with the conclusions about other TACAs (*27*, *37*, *40*, *43*, *44*). Moreover, sTnNPhAc proved to be the most antigenic among the sTn derivatives investigated. Most importantly, although the natural sTn antigen induced exclusively IgM antibodies (Figures 3 and 4), sTnNPhAc induced significant titers of IgG antibodies, which indicates a T-cell-dependent immune response, such as antibody isotype switching, antibody affinity maturation, immunological memory, and the induction of cell-mediated cytotoxicity (*6*, *25*, *26*). The switch to T-cell-dependent immune response is important for the antitumor activity of cancer vaccines (*45*). The reasons for the antigenicity improvement of

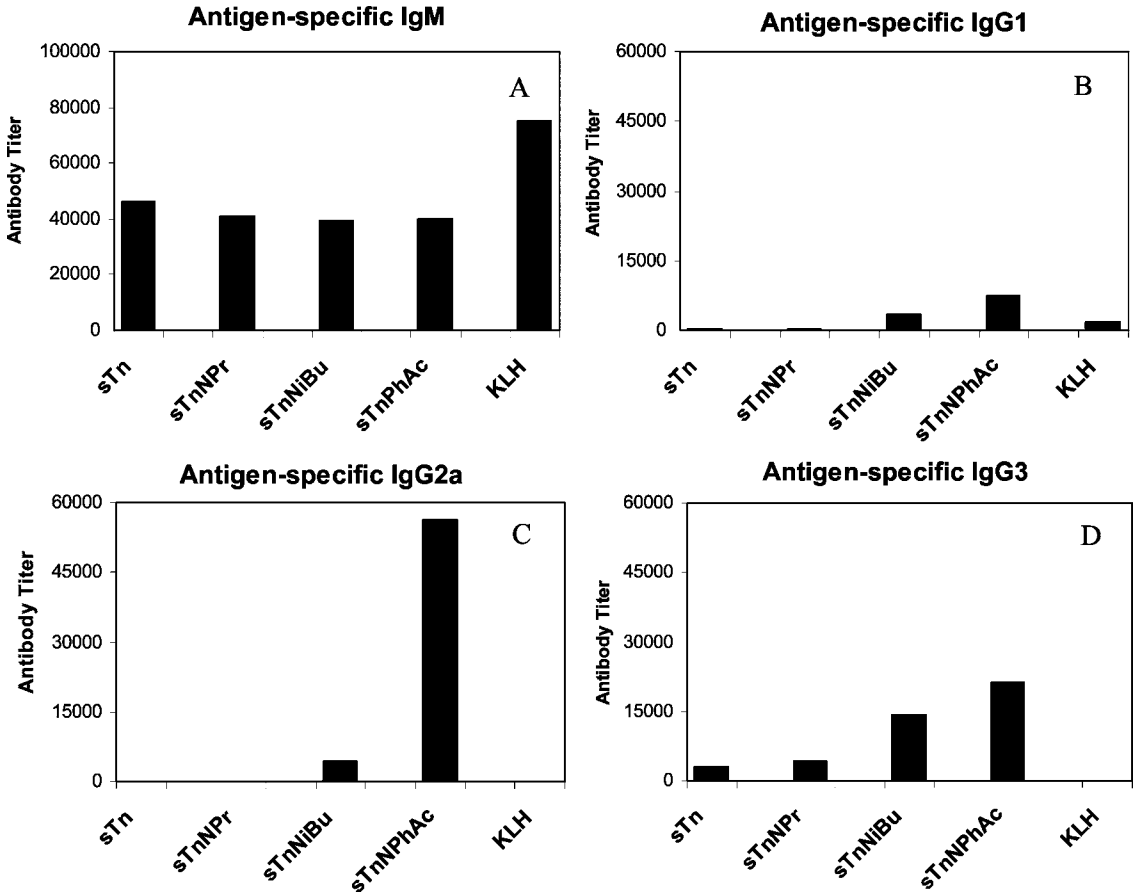

Figure 4. (A−D) Titer analysis of different isotypes of antigen-specific antibodies determined by ELISA assay. Each represents the titer in pooled serum obtained on day 31 after primary and booster immunizations from five replicate animals.

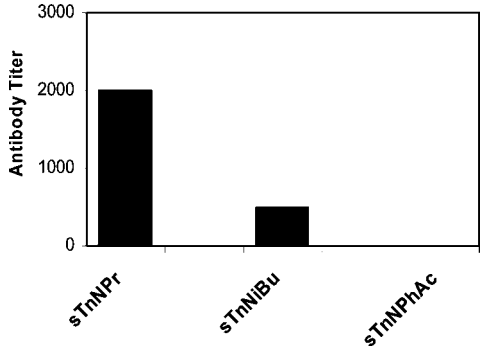

Figure 5. Titer analysis of the cross reactivity determined by ELISA. Each bar represents total anti-sTn reactivity in pooled sera from five replicate animals immunized with a derivatized sTn−KLH conjugate.

modified forms of sTn antigen and their capability to stimulate T-cell-dependent immune responses are not clear, but we think that the significant difference of the structure and chemical properties of sTnPhAc compared to native sTn, especially the increased hydrophobicity of the former, may play a critical role. For instance, this may facilitate the recognition and binding of sTnNPhAc by the immune system and immune cells. ELISA data of the reactivity of antisera obtained from mice immunized with modified sTn−KLH conjugates to native sTn antigen revealed that sTnNPhAc sera had essentially no cross reaction. This may well suggest that when being used as cancer vaccines the sTnNPhAc conjugate would cause no or relatively low autoimmune reactions. This result may be explained by the significant structural difference between the phenylacetyl group in sTnNPhAc and the acetyl group in native sTn. The high antigenicity of sTnNPhAc−KLH combined with its relatively low potential to cause autoimmune reactions makes it an excellent vaccine.

In summary, this paper has established an expedient method for synthesizing N-modified derivatives of sTn antigen and their protein conjugates. After careful analysis of the immunological properties of the synthetic glycoconjugates, we identified sTnNPhAc−KLH as a promising candidate for being developed into a functional cancer vaccine, not only because sTnNPhAc is highly antigenic, but also because it can induce IgG immune responses that are critical for the antitumor applications (*25, 26*). An effective glycoconjugate vaccine based on sTnNPhAc combined with the fact that cancer cell surface Neu5Ac can be readily and effectively engineered by *N*-phenylacetyl-D-mannosamine may provide a solution to the problem of immune tolerance to sTn and may be used for the immunotherapy of cancer, such as breast cancer, which expresses high levels of sTn antigen,

ACKNOWLEDGMENT

This work was supported by an NIH/NCI research grant (1R01 CA95142). The authors thank Dr. Clifford Harding, Dr. Peter Chefalo, and Ms. Nancy Nagy for allowing the use of their lab space and equipment for this study, as well as for their stimulating discussion and generous assistance with the immunological experiments.

Rigid Linkers for Bioactive Peptides

Josef Vagner,[†] Heather L. Handl,[‡] Yasunari Monguchi,[†] Umasish Jana,[†] Lucinda J. Begay,[†] Eugene A. Mash,[†] Victor J. Hruby,[†,‡] and Robert J. Gillies*[,‡]

Department of Chemistry, University of Arizona, Tucson, Arizona 85721, and Department of Biochemistry and Molecular Biophysics, Arizona Cancer Center, Tucson, Arizona 85724. Received June 5, 2006;
Revised Manuscript Received August 18, 2006

Rigid linkers of variable length were used to connect two high-affinity Nle[4]-D-Phe[7]-α-melanocyte stimulating hormone (NDP-α-MSH) or two low-affinity MSH(4) ligands. The linked peptides were synthesized by solid-phase methods. Control experiments indicate there is little or no effect of these linkers on NDP-α-MSH or MSH-(4) binding to the human melanocortin 4 receptor (hMC4R). Tethering two high-affinity ligands gave no binding enhancement, while tethering two low-affinity ligands resulted in binding enhancement that decreased with increased linker length. Furthermore, for the low-affinity ligands, the enhancement of affinity is inversely proportional to the estimated molecular moments of inertia. These results are consistent with a model wherein binding is enhanced when the rate of ligand reattachment to the receptor is fast relative to the rate of ligand diffusion.

INTRODUCTION

Early diagnosis is critical to the successful treatment of many human cancers. Noninvasive methods for early detection depend on the availability of nontoxic reagents that can seek out and selectively bind to cancer cells and report their existence and location by molecular imaging (*1*, *2*). We are engaged in a program to develop reagents that target human cancers that presently are difficult to detect, such as melanoma and pancreatic cancer. Our strategy involves linking together reporter moieties and ligands that bind to cell surface receptors that are expressed in cancer cells (*3*). The resulting multivalent molecules could display enhanced affinity for the targeted cells (*4*, *5*).

Factors that must be considered in designing linkers for bioactive multimeric ligands include the distance that must be spanned, availability, and ease of use. The distance that must be spanned between targeted receptors on the cell surface will vary depending on the number, kind, and mobility of the receptors, but it is expected to greatly exceed the typical dimensions of small molecules (*6*). Several small molecule linkers connected in series will therefore be necessary to span the distance between receptors. For peptide ligands, linkers should terminate in amine and/or carboxylic acid functional groups to facilitate incorporation by solid-phase peptide synthesis. Both flexible linkers (*7*, *8*) and rigid linkers (*9*) are of interest. Each new linker must be validated as noninterfering with the binding of the ligand. We report herein the use of rigid linkers **1**−**4** (Figure 1), which are of variable length (*10*) to join two "high-affinity" or two "low-affinity" α-melanocyte stimulating hormone (α-MSH) peptide ligands (*11*−*16*), and evaluations of the bioactivities of these linker-spliced peptides.

EXPERIMENTAL PROCEDURES

Materials and Methods. The *N*-9-fluorenylmethyloxycarbonyl (Fmoc) derivative **5** (Figure 1) was purchased from Torviq (Niles, MI). The *N*-trifluoroacetamide (TFA) derivatives **6**−**8** (Figure 1) were prepared as previously described (*17*). Other *N*-α-Fmoc-protected amino acids and Rink amide resin were purchased from SynPep (Dublin, CA) or from Novabiochem (San Diego, CA). *O*-[1*H*-6-Chlorobenzotriazol-1-yl)(dimethylamino)methylene]uranium hexafluorophosphate *N*-oxide (HCTU), 1-hydroxybenzotriazole (HOBt), and 6-chloro-1-hydroxybenzotriazole (HOCt) were purchased from IRIS Biotech (Marktredwitz, Germany). For the *N*-α-Fmoc-protected amino acids, the following side-chain protecting groups were used: Arg(N^{γ}-2,2,4,6,7-pentamethyldihydrobenzofuran-5-yl sulfonyl); Glu(O^{γ}-*t*Bu); His(N^{im}-triphenylmethyl); Lys(N^{ϵ}-*tert*-butyloxycarbonyl); Ser(*O*-*t*Bu); Trp(N^{i}-*tert*-butyloxycarbonyl). Peptide synthesis solvents, reagents, and acetonitrile for HPLC were reagent grade, were acquired from VWR (West Chester, PA) or Sigma-Aldrich (Milwaukee, WI), and were used without further purification unless otherwise noted. Solid-phase synthesis was performed in fritted syringes using a Domino manual synthesizer obtained from Torviq (Niles, MI).

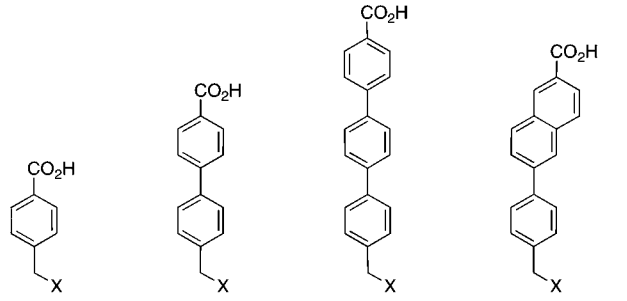

Figure 1. Rigid amino acid linkers **1**−**4** and *N*-protected derivatives **5**−**8**.

Purification of peptide products was achieved on a Waters 600 HPLC using a reverse-phase column (Vydac C-18, 15−20 m, 22 × 250 mm). Peptide products were eluted with a linear gradient of CH_3CN/0.1% CF_3CO_2H at a flow rate of 5.0 mL/min. Separation was monitored at 230 and 280 nm. The purity of the final peptide products was checked by TLC and by analytical PR-HPLC using a Waters Alliance 2695 separation

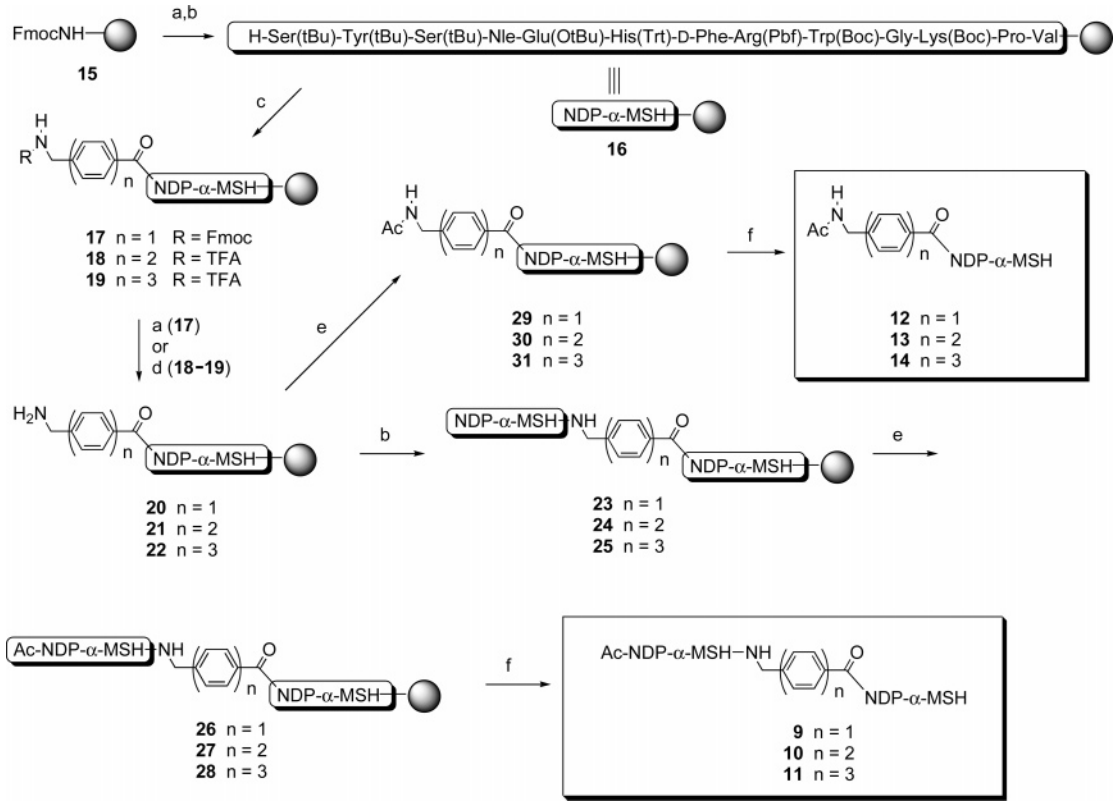
Scheme 1. Solid-phase Synthesis of Compounds 9−11 Containing Linked NDP-α-MSH Ligands and Control Compounds 12−14.



Reagents and conditions: (a) piperidine. (b) Fmoc/*t*Bu solid-phase synthesis (Refs 18 and 19). (c) *N*-protected linker (**5**, **6**, or **7**), HOCt-DIC, DMF. (d) THF/MeOH/N_2H_4 (70/15/15). (e) pyridine/Ac_2O (50/50). (f) CF_3CO_2H/$HSCH_2CH_2SH$/PhSMe/H_2O (91/3/3/3).

model with a Waters 2487 dual wavelength detector (220 and 280 nm) on a reverse-phase column (Waters Symmetry 4.6 × 75 mm, 3.5 μm). Peptide products were eluted with a linear gradient of 60% aqueous MeCN/0.1 M NH_4OAc or MeCN/0.1% CF_3CO_2H at a flow rate of 1.0 mL/min. Size exclusion chromatography was performed on a borosilicate glass column (2.6 × 250 mm, Sigma, St. Louis, MO) filled with medium-sized Sephadex G-25 or G-10. The compounds were eluted with an isocratic flow of 1.0 M aqueous AcOH.

Structures were characterized by ESI (Finnigan, Thermoquest LCQ ion trap instrument) or MALDI-TOF (Bruker Rexlex-III, α-cyanocinnamic acid as a matrix). For internal calibration, an appropriate mixture of standard peptides was used with an average resolution of 8000−9000.

Solid-Phase Synthesis (*18*−*19*)**.** Rink resin was washed with DMF, and the *N*-Fmoc protecting group was removed with 50% piperidine in DMF (1 × 2 min and 1 × 20 min). The resin was washed successively with DMF, 1.0 M HOBt in DMF, and DMF, and the next *N*-α-Fmoc amino acid was coupled using preactivated 0.3 M HOCt ester in THF (3 equiv of *N*-α-Fmoc amino acid, 3 equiv of HOCt, and 3 equiv of DIC). The resin slurry was stirred for 2 h or until the bromophenol test became negative. If the test failed, the resin was washed with DMF, and the amino acid was coupled again by the HCTU/2,4,6-lutidine procedure (0.3 M solution of 3 equiv of *N*-α-Fmoc amino acid, 3 equiv of HCTU, and 6 equiv of 2,4,6-lutidine in DMF) for 3 h or until the Kaiser test was negative. If a positive Kaiser test was observed after the second coupling, the resin was washed with DMF and any reactive amine groups capped by treatment with 50% Ac_2O in pyridine for 10 min.

After the first peptide segment had been assembled on the solid support (e.g., see Scheme 1), an N-protected linker (**5**, **6**, **7**, or **8**) was attached to the free N-terminal amine using the coupling methods previously described. The resin was then split into two portions. The first portion of the resin was treated either with 50% piperidine in DMF to remove the Fmoc protecting group or with 15% anhydrous N_2H_4 plus 15% MeOH in THF at room temperature for 6 h to remove the trifluoroacetyl protecting group, from the N-terminus of the resin-bound linker. The conditions for TFA cleavage were defined by an empirical study (see Table 1 and the accompanying discussion). The free amine was acetylated using 50% Ac_2O in pyridine for 10 min and the [peptide + linker] cleaved off the resin. A cleavage cocktail (10 mL per 1 g of the resin) consisting of CF_3CO_2H (91%), H_2O (3%), $HSCH_2CH_2SH$ (3%), and PhSMe (3%) was injected into the resin, and the mixture was stirred at room temperature for 3 h. The solution was filtered off, the resin was washed with CF_3CO_2H (2 × 3 min), the liquid phases were concentrated under a stream of nitrogen, and the product was precipitated using cold Et_2O. The peptide pellets were washed three times with cold Et_2O, lyophilized, purified, and characterized as described above. For the second portion of the resin, removal of the N-terminal Fmoc or TFA was carried out, and assembly of the second peptide segment was completed using the methods previously described. Following incorporation of the last amino acid, the N-terminal protecting group was removed and the free amine acetylated using 50% Ac_2O in pyridine for 10 min. The resin was then thoroughly washed with DMF and CH_2Cl_2, the [peptide + linker + peptide] was cleaved off the resin using the cleavage cocktail, and the product purified as described above. Mass spectral and HPLC characterization data for the peptide products are given in Table 2 and are discussed later.

Biological Assays. Ligand binding was evaluated using a previously described lanthanide-based binding assay (*20*). HEK293 cells overexpressing the human melanocortin 4 receptor (hMC4R) were used to assess ligand binding (*21*). The coding region of the hMC4R gene was expressed in pcDNA3.1 (Invitrogen, Carlsbad, California). HEK293/hMC4R cells were grown in Dulbecco's Modified Eagle Medium (DMEM) supple-

[a] NDP-α-MSH Rink resin **34** (30 μL of resin slurry in THF) was placed into a small fritted 2 mL syringe and washed with an *N*-TFA cleavage solvent mixture. After the treatment, the resin was washed with THF and CH_2Cl_2, and the peptide was cleaved off the resin and side-chain protecting groups removed as described in the Materials and Methods section. The peptide was then dissolved in 30% aqueous MeCN and analyzed by HPLC using a linear MeCN/0.1% CF_3CO_2H aqueous gradient (10% to 40% in 30 min) at a flow rate of 1.0 mL/min. [b] Yields were determined as ratios of peak areas at 280 nm on HPLC analyses; product **35** had a retention time of 16.1 min, and product **36** had a retention time of 24.2 min. [c] Unidentified impurities.

[a] MS found molecular peaks $(M+1)^{1+}$, $(M+2)^{2+}$, $(M+3)^{3+}$, and $(M+4)^{4+}$. One diagnostic peak is listed here for each compound. [b] Peptides were eluted with a linear MeCN/0.1% CF_3CO_2H aqueous gradient (10% to 40% in 30 min) at a flow rate of 1.0 mL/min.

mented with 10% fetal bovine serum (FBS). Cells were plated in Black & White Isoplates (Wallac, 1450−583) at a density of 12 000 cells/well and were allowed to grow for 3 days. On the day of the experiment, media was aspirated from all wells. Ligands of interest were diluted in binding buffer [DMEM, 1 mM 1,10-phenanthroline, 200 mg/L bacitracin, 0.5 mg/L leupeptin, 0.3% bovine serum albumin (BSA)] to result in final dilutions ranging from 10 μM to 4 pM. Eu-labeled NDP-α-MSH was used at a final concentration of 10 nM. 50 μL of the ligand of interest and 50 μL of Eu-NDP-α-MSH were added to each well, and plates were incubated for 40 min at 37 °C. Following the incubation, cells were washed four times with Wash Buffer (50 mM Tris-HCl, 0.2% BSA, 30 mM NaCl) using Molecular Devices SkanWasher. Enhancement solution (Perkin-Elmer, 1244−105) was added (100 μL/well), and the plates were incubated for 30 min at 37 °C prior to reading. The plates were read on a Wallac VICTOR[3] instrument using the standard Eu time-resolved fluorescence (TRF) measurement (340 nm excitation, 400 μs delay, and emission collection for 400 μs at 615 nm). Competition curves were analyzed with GraphPad *Prism* software using the sigmoidal dose−response classical equation for nonlinear regression analysis. Each data point represents the average of at least four samples, with the error bars indicating standard error of the mean.

RESULTS

Solid-Phase Synthesis. The synthesis of compounds **9**−**11** consisting of two linked "high-affinity" NDP-α-MSH ligands connected in a head-to-tail fashion by linkers **1**−**3** is depicted in Scheme 1. Also depicted is the synthesis of control compounds **12**−**14** which are composed of a single "high-affinity" NDP-α-MSH ligand and an N-terminally acylated linker.

The tridecapeptide NDP-α-MSH was constructed on PS−Rink resin (**15**, initial loading 0.17 mmol/g, 1% DVB). Resin

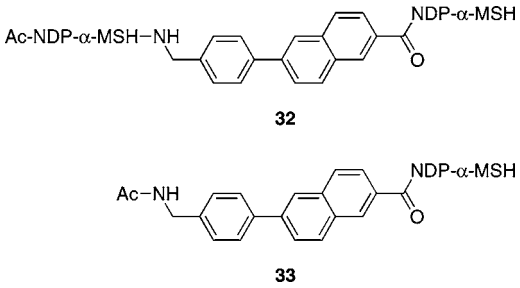

Figure 2. Dimeric and monomeric NDP-α-MSH compounds **32** and **33**.

16 retained all side-chain protecting groups. The N-protected linkers **5**−**7** were coupled to the N-terminus of **16**, giving resins **17**−**19**. The *N*-Fmoc group of **17** was cleaved by treatment with piperidine, and the *N*-TFA groups of **18** and **19** were cleaved by treatment with 15% hydrazine and 15% methanol in THF. The resulting resins **20**−**22** were each split into two portions. For the synthesis of **9**−**11**, the free amine groups of resins **20**−**22** were coupled with Fmoc−valine and solid-phase peptide synthesis continued to completion of the second NDP-α-MSH sequence, giving resins **23**−**25**. The peptide was then capped by N-acetylation, giving resins **26**−**28**. Simultaneous side-chain deprotection and cleavage of the peptides from the Rink resin was effected using a mixture of trifluoroacetic acid, 1,2-ethanedithiol, thioanisole, and water (91/3/3/3) that produced the desired compounds **9**−**11**. For the synthesis of **12**−**14**, resins **20**−**22** were terminally N-acetylated to give resins **29**−**31**. Treatment of these resins with the $CF_3CO_2H/HSCH_2CH_2SH/PhSMe/H_2O$ cocktail effected simultaneous side-chain deprotection and cleavage of the peptides from the resin, producing compounds **12**−**14**. Compounds **32** and **33** (Figure 2) that incorporate the phenylnaphthyl linker **4** were similarly prepared (see Scheme S1 in the Supporting Information).

N-TFA derivatives **6**−**8** were employed instead of the corresponding Fmoc derivatives of **2**−**4**, since this enhanced the solubility of these more hydrophobic linkers under the conditions employed for solid-phase synthesis.

The intermediate resin **34** was used to establish conditions for the cleavage of the TFA protecting group from resin-bound linkers (Table 1). Published conditions (*22*) for *N*-ϵ-trifluoroacetyl group deprotection in peptides (aqueous piperidine) gave poor results (Table 1, entry 1). DMF suppressed the cleavage of the *N*-ϵ-trifluoroacetyl group (entries 1, 3, and 4). Optimal conditions developed for the removal of the TFA protecting group from the resin-bound linker were treatment with 15% N_2H_4 and 15% MeOH in THF for 5 h at room temperature (entry 5).

A similar synthetic strategy was employed to synthesize molecules **37**−**40** containing linked "low-affinity" MSH(4) ligands (His-D-Phe-Arg-Trp; see Schemes S2 and S3 in the Supporting Information) and the corresponding controls **41**−**44** (Figure 3).

All products from solid-phase syntheses were purified by reverse-phase C_{18} preparative HPLC and were characterized by analytical HPLC, ESI-MS, and/or MALDI-TOF. Characterization data are listed in Table 2.

Biological Assays. Shown in Figure 4 are representative results from a competition binding assay, described in Handl et al. (*20*) This figure shows the reduction of Eu-NDP-α-MSH binding in the presence of increasing concentrations of compounds **10** and **13**. From these data, IC_{50} values were calculated as the concentration of test ligand that reduced Eu-NDP-α-MSH binding by 50%. These values can be quantitatively related to K_d by correcting for the ratio of the Eu-NDP-α-MSH concentration relative to its K_d (*11*). Similar data sets were obtained multiple times for all compounds. Table 3 lists the IC_{50} values (averaged over *n* experiments) for the dimeric and monomeric complexes of NDP-α-MSH and MSH(4). Compounds **9**−**11** and **32** contained dimeric NDP-α-MSH ligands, compounds **37**−**40** contained dimeric MSH(4) ligands, and compounds **12**−**14**, **33**, and **41**−**44** were the corresponding monomeric ligand controls. This table also shows the fold increase in avidity as the ratio of IC_{50} for the dimeric ligands relative to the corresponding monomeric ligands.

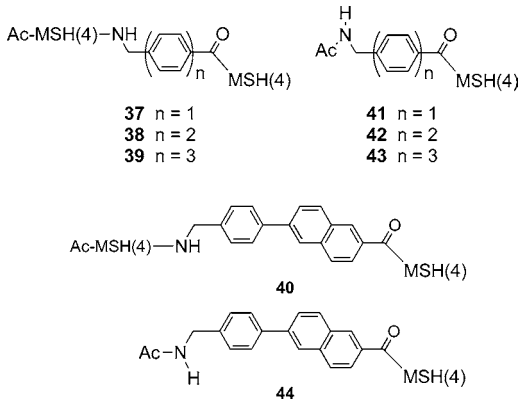

Figure 3. Dimeric and monomeric MSH(4) compounds **37**−**44**.

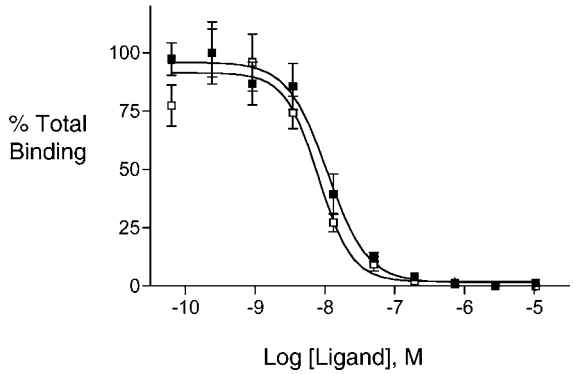

Figure 4. Representative ligand binding curves generated through competitive ligand binding analysis compare the binding affinities of ligands **10** (□) and **13** (■). The calculated IC_{50} for **10** is 8 nM with an R^2 value = 0.91 and for **13** 10 nM with an R^2 value = 0.93.

[a] Ph = phenyl linker **1**; BP = biphenyl linker **2**; TP = terphenyl linker **3**; and PN = phenylnaphthyl linker **4**. [b] The IC_{50} value given is the average of *n* independent binding experiments, each done in quadruplicate.

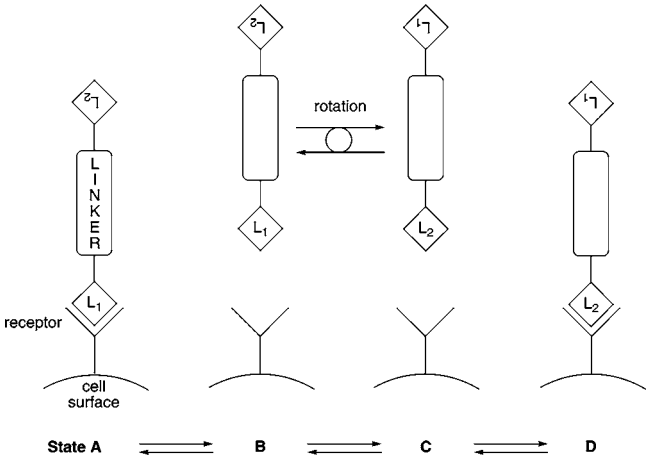

Figure 5. Binding of Linked MSH Ligands to hMC4R. **State A**: L_1 is bound, L_2 is unavailable for binding. **State B**: $L_1$and L_2 are unbound, L_1 is positioned for binding. **State C**: $L_1$and L_2 are unbound, L_2 is positioned for binding. **State D**: L_2 is bound, L_1 is unavailable for binding. **State E**: Compound is dissociated from cell surface (not shown).

DISCUSSION

The IC_{50} values for the [linker + NDP-α-MSH] control compounds **12**, **13**, and **33** were virtually the same as the IC_{50} for the parental NDP-α-MSH ligand. Similarly, the IC_{50} values for the [linker + MSH(4)] control compounds **41**, **42**, and **44** were very close to the IC_{50} for the parental MSH(4) ligand. These results indicate that attachment of the phenyl, biphenyl, and phenylnaphthyl linkers to the NDP-α-MSH and MSH(4) ligands had little or no effect on the binding of either ligand to hMC4R. In contrast, control compounds **14** and **43** that incorporate the terphenyl linker showed modest (3-fold and 2-fold, respectively) increases in IC_{50}. These results indicate that attachment of the terphenyl linker diminishes slightly NDP-α-MSH and MSH(4) ligand binding affinity to hMC4R.

The expected statistical halving of the IC_{50} for compounds that contain two ligands was observed only for terphenyl-containing NDP-α-MSH compounds **11** and **14** and for MSH-(4) compounds **39** and **43**. This is consistent with the observation that terphenyl-containing compounds bind less well to hMC4R. Tight binding in the cases of **9**, **10**, and **33**, presumably due to slow off-rates for the NDP-α-MSH ligand, effectively removes tethered, unbound ligands from the ligand pool (Figure 5), implying that states B, C, and D are insignificant. Poorer binding of the terphenyl-containing compounds **11** and **14** permits observance of statistical halving of the IC_{50} for these compounds (Figure 5), implying that states B, C, and D are significant.

A greater than stoichiometric increase in affinity for the hMC4R is observed relative to controls for compounds **37**, **38**, and **40** that contain two of the more weakly binding MSH(4) ligands joined by noninterfering linkers. This increase in affinity is inversely correlated (Figure 6) with an estimation of the molecular moments of inertia (I_M) calculated using eq 1 where *M* is the compound molecular weight and *R* is the linker length measured from one benzylic carbon to the other.

$$I_M = MR^2/2 \quad (1)$$

Compound **39** that incorporates the terphenyl linker is displaced from the best-fit line, possibly due to its inherently poorer binding to hMC4R. The existence of this correlation is consistent with a competition between diffusion of the compound away from the receptor (to give state E in Figure 5) and rotation of the compound necessary for presentation of the second ligand to the receptor (equilibration of states B and C).

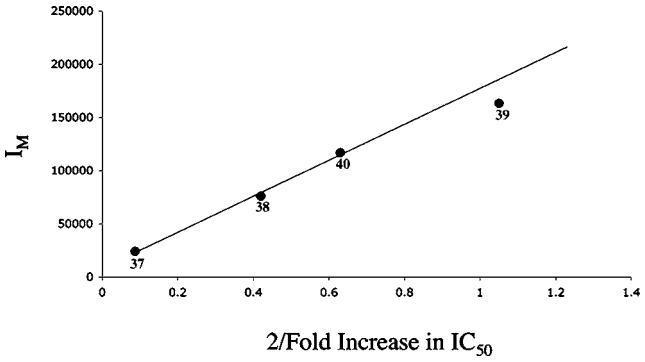

Figure 6. Inverse correlation of compound binding affinity and linker length.

The greater the moment of inertia, the longer this rotation will take, leading to an increased probability of diffusion away from the cell surface before rebinding (to states A and D) can occur.

CONCLUSION

Low- and high-affinity forms of melanocortin ligands were attached to rigid linkers in either monomeric or dimeric forms. Binding affinities of these ligands were tested in whole cells expressing the hMC4 receptor using a sensitive competition assay based on detection of lanthanide (europium) with time-resolved fluorescence. Consistent with previous results, addition of linkers resulted in a reduction in binding affinity that was dependent on the size of the linker. Notably, the short phenyl and biphenyl linkers did not adversely affect binding affinities of monomeric ligands. Also consistent with previous results, there was an increase in binding affinity in dimers compared to the corresponding monomers, and the increase was inversely related to the calculated moment of inertia for the molecules. We interpret these results to indicate that the increased affinity of dimers was due to increased local concentrations of ligand, also known as the statistical effect of Kiessling (*5*). Somewhat surprisingly, this enhancement of dimers was only observed for the low-affinity MSH(4) ligands and not for the high-affinity NDP-α-MSH ligands. We interpret this to suggest that the statistical effect enhancement is critically dependent on a low-affinity ligand, with potentially faster on-rates relative to the rate of diffusion.

Influence of the Linker on the Biodistribution and Catabolism of Actinium-225 Self-Immolative Tumor-Targeted Isotope Generators

Christophe Antczak, Jaspreet S. Jaggi, Clare V. LeFave, Michael J. Curcio, Michael R. McDevitt, and David A. Scheinberg*

Department of Molecular Pharmacology and Chemistry, Memorial Sloan Kettering Cancer Center, New York, New York 10021. Received June 7, 2006; Revised Manuscript Received August 24, 2006

Current limitations to applications of monoclonal antibody (mAb) targeted isotope generators in radioimmunotherapy include the low mAb labeling yields and the nonspecific radiation of normal tissues by nontargeted radioimmunoconjugates (RIC). Radiotoxicity occurs in normal organs that metabolize radiolabeled proteins and peptides, primarily liver and kidneys, or in radiosensitive organs with prolonged exposure to the isotope from the blood, such as the bone marrow. Actinium-225 nanogenerators also have the problem of released α-emitting daughters. We developed two new bifunctional chelating agents (BCA) in order to address these issues. Thiol−maleimide conjugation chemistry was employed to increase the efficiency of the mAb radiolabelings by up to 8-fold. In addition, one bifunctional chelating agent incorporated a cleavable linker to alter the catabolism of the α-particle-emitting mAb conjugate. This linker was designed to be sensitive to cathepsins to allow release and clearance of the chelated radiometal after internalization of the radioimmunoconjugate into the cell. We compared the properties of the cleavable conjugate (mAb−DOTA−G3FC) to noncleavable constructs (mAb−DOTA−NCS and mAb−DOTA−SH). The cleavable RIC was able to release 80% of its radioactive payload when incubated with purified cathepsin B. The catabolism of the constructs mAb−DOTA−G3FC and mAb−DOTA−NCS was investigated in vitro and in vivo. RIC integrity was retained at 85% over a period of 136 h in mouse serum in vivo. Both conjugates were degraded over time inside HL-60 cells after internalization and in mouse liver in vivo. While we found that the rates of degradation of the two RICs in those conditions were similar, the amounts of the radiolabeled product residues were different. The cleavable mAb−DOTA−G3FC conjugate yielded a larger proportion of fragments below 6kDa in size in mouse liver in vivo after 12 h than the DOTA−NCS conjugate. Biodistribution studies in mice showed that the mAb−DOTA−G3FC construct yielded a higher liver dose and prolonged liver retention of radioactivity compared to the mAb−DOTA−NCS conjugate. The accumulation in the liver seemed to be in part caused by the maleimide functionalization of the antibody, since the noncleavable mAb−DOTA−SH maleimide-functionalized control conjugate displayed the same biodistribution pattern. These results provide an insight into the catabolism of RICs, by demonstrating that the release of the radioisotope from a RIC is not a sufficient condition to allow the radioactive moiety to clear from the body. The excretion mechanisms of radiolabeled fragments seem to constitute a major limiting step in the chain of events leading to their clearance.

INTRODUCTION

In hematopoietic malignancies, the accessibility of tumor cells in the blood, marrow, spleen, and lymph nodes enables rapid targeting of specific antibodies. Several antigens have been identified that allow selective targeting of neoplastic hematopoietic cells while sparing other necessary hematopoietic lineage and progenitor cells. One of the most suitable targets for myeloid leukemias is CD33, an antigen whose expression is restricted to myelogenous leukemias and myeloid progenitor cells. This marker is absent from other normal tissues or ultimate bone marrow stem cells (*1*−*4*). The antibody HuM195, humanized version of the antibody M195 directed against CD33, has been developed and characterized by our group (*5*). M195 showed targeting to leukemia cells in humans (*6*) with the majority of the bound IgG being internalized into target cells in vivo (*7*, *8*). On the basis of this biology and pharmacokinetics, it has been proposed that mAb tagged with short-lived nuclides emitting short-ranged, high linear energy transfer (LET) α particles may be effective in therapy (*9*). These short-ranged particles may be capable of single-cell kill while sparing bystanders. High LET α-emitters used in radioimmunotherapy include bismuth-212 (*10*−*12*) and -213 (*13*−*15*), astatine-211 (*16*), and actinium-225. This latter isotope is an in vivo isotope generator, in that it has a long (10 day) half-life and decays via α-emission through three short-lived atoms, each of which yields an α particle (*12*, *14*). Previous work in our laboratory led to the synthesis, purification, and analysis of ^{225}Ac stably bound to the IgG via a bifunctional macrocyclic chelator DOTA (1,4,-7,10-tetraazacyclodoecane-1,4,7,10-tetraacetic acid) (*15*). These constructs specifically killed leukemia and cancer cells at becquerel (picocurie) levels in vitro. Injection of rodents bearing disseminated human lymphoma or solid carcinoma with single courses of the constructs at kilobecquerel (nanocurie) levels induced tumor regression and prolonged survival in a substantial fraction of animals without toxicity (*15*, *17*, *18*).

A first limitation to the use of targeted ^{225}Ac isotope generators is the poor yield of labeled antibody (*19*). Chelation of Ac-225 stably under physiological conditions requires the use the macrocyclic chelator DOTA with all four carboxylic groups available (Antczak et al., unpublished data). However, heating to 60 °C is necessary for complete and stable ^{225}Ac chelation by DOTA, a condition that is unsuitable for retention of mAb function (*19*). Therefore, a two-step procedure was developed to label the antibodies (*19*). The first step consisted

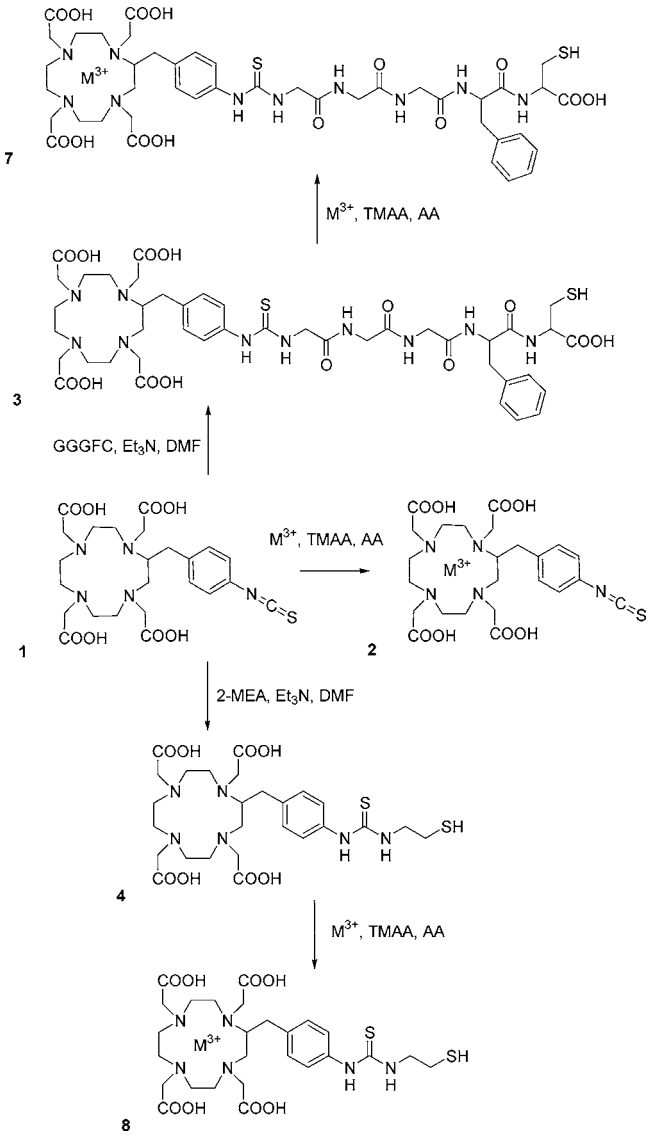
Scheme 1. Bifunctional Chelating Agents



of the chelation of ^{225}Ac by the bifunctional chelating agent DOTA−NCS **1** (Scheme 1). A low-yield second step of the process was the reaction of the ^{225}Ac−DOTA−NCS **2** with the IgG. HPLC studies showed that the first step largely degrades the isothiocyanate moiety required for the labeling of the antibody in the second step, thus reducing product yields (data not shown). Therefore, we based our new BCAs on novel thiol-based BCAs following the assumption that thiol groups would be more stable than isothiocyanates during the first step of the labeling process.

Another limitation to a more general application of tumor-targeted ^{225}Ac nanogenerators is the excessive radiation of normal tissues by the RIC. With the exception of antibodies targeting leukemias, most (>99%) of the injected antibody dose remains circulating in the blood or is not associated with the target tumor. The prolonged circulation time of untargeted antibodies, typically days to weeks, results in radiation exposure of normal organs that catabolize or retain proteins and peptides, primarily liver and kidneys (*20*, *21*). In the case of in vivo generators, an additional major potential obstacle to their safe use is the sequential release of three unchelated α-emitting daughter atoms following initial decay of the generator. Uptake into organs such as the kidney or the liver could induce toxicity (*22*).

One attractive approach to overcome the long circulation time of untargeted radioimmunoconjugates is the development of BCAs that allow conditional release of the chelated radioactive payload. The introduction of a cleavage site in the linkage between the radiochelate and the mAb is meant to permit the release of a low molecular weight radiochelate from its carrier mAb and its subsequent rapid clearance once the radioconjugate has accumulated in metabolizing organs. The chelated radiometal then rapidly clears the body through the kidneys, thereby reducing toxicity. This strategy has been attempted using disulfide, ester, tartramide, and peptide bonds (*23*, *24*). An optimal linker should (1) link the carrier mAb to the radiochelator without impairing the functionality of either, (2) provide a stable linkage in circulation, and (3) degrade under specific conditions. Stability in circulation has proven to constitute a particularly important factor for success using this strategy. Perhaps for this reason, peptide linkers, which are usually more stable than esters and disulfides in serum, have been most successful in RICs and in the design of antibody−drug conjugates (ADC) (*25*, *26*). The most extensively studied peptide linkers are sensitive to cathepsins. More precisely, ADCs incorporating the dipeptide valine−citrulline have been shown to enter the target cells and migrate to the lysosomes, where they release their drug specifically under the action of cysteine proteases (*27*).

The most advanced strategy for the release of a radionuclide from a RIC is the one followed by DeNardo et al., based on cathepsin-sensitive peptide linkers. On the basis of the hypothesis that intrahepatocyte cathepsins are responsible for most of the protein metabolism in hepatic lysosomes, a BCA was designed to incorporate a specific cathepsin B cleavage site. Even though human tumors express cathepsin B (*28*), studies from DeNardo et al. have demonstrated that the dose achieved at the xenograft after treatment with four cathepsin B labile radioconjugates was comparable to that achieved with a noncleavable control. This remained true for two different antibodies and for two human maligancies (an adenocarcinoma and a lymphoma) (*29*). The cathepsin B-sensitive conjugate glycylglycylglycyl-L-*p*-isothiocyanatophenylalanine-Lym-1 demonstrated great stability in human serum. This cleavable construct was compared to a noncleavable construct in human breast cancer xenografts, and a 30−70% decrease in the liver dose and a slightly increased tumor dose was observed (*29*, *30*). In patients with prostate and breast cancer, the pharmacokinetics and tumor dose were similar for both cleavable and noncleavable RICs, except for about a 30% decrease in the mean dose to the liver with the cleavable linker (*31*). In another clinical study with patients with breast and prostate cancer, the liver dose was consistantly lower with the cleavable RIC compared to a noncleavable conjugate, while the tumor dose was not significantly affected by the linker (*32*). Therefore, we applied a cathepsin-sensitive linker strategy to the ^{225}Ac nanogenerators.

EXPERIMENTAL PROCEDURES

Radionuclides, Reagents, and Monoclonal Antibodies. The ^{225}Ac was obtained from Oak Ridge National Laboratory (Oak Ridge, TN) as a nitrate salt. The ^{225}Ac salt was dissolved in 0.15 M Optima grade HCl (Fisher Scientific, Pittsburgh, PA). Metal-free water (MFW) used for this and all other solutions was obtained from a Purelab Plus system (US Filter Corp., Lowell, MA) and was sterile filtered. The parent ^{225}Ac activity was measured when it was in secular equilibrium with its daughters using a drop well dose calibrator (CRC-17; E.R. Squibb and Sons, Inc., Princeton, NJ) set at 775 and the reading multiplied by 5.

The chelating agent DOTA−NCS **1**, 2-(*p*-isothiocyanatobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracetic acid, was obtained from Macrocyclics (Dallas, TX). The heterobifunctional linker LC-SMCC and 2-mercaptoethylamine (2-MEA)

were provided by Pierce (Rockford, IL). Chemicals used in the radiolabeling and purification steps were ACS reagent grade or better. Dithiothreitol (DTT), tetramethylammonium acetate (TMAA), L-ascorbic acid (AA), sodium carbonate (Na_2CO_3), dimethylformamide (DMF), triethylamine (Et_3N), trishydroxymethylaminomethane hydrochloride (Tris-HCl), Triton X-100, trifluoroacetic acid (TFA), acetonitrile (CH_3CN), and ethylenediamine tetraacetic acid (EDTA) were obtained from Sigma-Aldrich (Saint Louis, MO). Sulfur-35 radiolabeled cysteine was provided by Perkin-Elmer (Wellesley, MA). Bovine spleen cathepsin B (E.C. 3.4.22.1), was obtained from Sigma-Aldrich. The protease inhibitor cocktail was provided by Roche Diagnostics Gmbh (Mannheim, Germany). The cation exchange resin Sephadex C-25 was purchased from Amersham Biosciences (Piscataway, NJ). Human serum albumin (HSA) (Swiss Red Cross, Bern, Switzerland) and 0.9% NaCl (Abbott Laboratories, North Chicago, IL) were used as received. A 10DG desalting column (Bio-Rad, Hercules, CA) was used for RIC purification.

The cell line HL-60 was obtained from the ATCC (catalog #CCL-240) and was cultured following the ATCC recommendations. The humanized murine monoclonal antibody HuM195 directed against the cell surface myelomonocytic differentiation antigen CD33 was generously provided by Protein Design Laboratories (Sunny View, CA). The mouse monoclonal antibody SJ25C1 directed against the CD19 antigen present on human B lymphocytes was provided by the monoclonal antibody core facility of the Sloan-Kettering Institute.

HPLC. Reversed-phase HPLC was performed using a Beckman Coulter System Gold Bioessential HPLC, equipped for analytical studies with a Varian C18 Inertsil ODS-3 5 μ 250 $\times$ 4.6 mm column, and with a Varian C18 Inertsil ODS-3 5 μ 250 $\times$ 10 mm column for semipreparative runs. Detection of the peaks was performed using a Beckman Coulter 168 diode array detector at 220 nm. Data was analyzed using the system's 32 Karat software.

Synthesis of 3-Mercapto-2-(3-phenyl-2-{2-[2-(2-{3-[2-*p*-(1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid)-benzyl]thioureido}acetylamino)acetylamino]acetylamino}-propionylamino)propionic Acid (*3*). To a solution of peptide GGGFC (16.5 mg, 37.6 μmol) and Et_3N (22 μL, 219.1 μmol) in dry DMF, a solution of DOTA−NCS **1** (17.2 mg, 31.3 μmol) in dry DMF was slowly added. After 1 h reaction at room temperature, the product DOTA−G3FC **3** was purified by semipreparative reversed-phase HPLC. The mobile phases consisted of A, 0.1% (v/v) trifluoroacetic acid (TFA) in water, and B, 0.1% TFA in acetonitrile (CH_3CN). The reaction mixture was solubilized in mobile phase A and injected for a 30-min run at 5.0 mL/min at room temperature. The column was previously equilibrated in eluent A with 5% eluent B. The gradient was 5−20% B in 20 min, 20−90% B in 10 min. After lyophilization, the desired product **3** was isolated as a white powder (26.5 mg, 26.8 μmol, 86% yield) and stored under vacuum. Analytical HPLC using the same gradient gave a single peak. HRMS (ESI): *m*/*z* 496.1860 $[M + 2H]^{++}$; calcd for $C_{42}H_{58}N_{10}O_{14}S_2$ 990.3575; found 990.3563.

Synthesis of 2-*p*-(2-mercaptoethylthioureido)benzyl-(1,4,-7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) (*4*). To a solution of 2-mercaptoethylamine (2-MEA) (1.3 mg, 11.5 μmol) and Et_3N (1.8 μL, 17.9 μmol) in dry DMF was slowly added a solution of DOTA−NCS **1** (4 mg, 7.3 μmol) in dry dimethylformamide (DMF). After 1 h reaction at room temperature, the product **4** was purified by semipreparative reversed-phase HPLC as previously described for compound **3**. After lyophilization, the desired compound **4** was isolated as a white powder (3.9 mg, 6.19 μmol, 85% yield) and stored under vacuum. Analytical HPLC using the same gradient gave a single peak. HRMS (ESI): *m*/*z* 629.2434 $[M + H]^{+}$; calcd for $C_{26}H_{40}N_6O_8S_2$ 628.2349; found 628.2356.

Functionalization and Characterization of Maleimide−Antibodies. The heterobifunctional linker LC-SMCC (0.375 mg, 833 nmol) was solubilized just prior to use in DMSO and added to 1 mL of the antibody solution in PBS (5 mg, 33.3 nmol). The pH was adjusted to 7.0 by adding a few microliters of a 200 mM Na_2CO_3 solution to the reaction mixture, and the reaction was carried out over 2 h at 24 °C. The modified antibody was purified by size-exlusion chromatogaphy (10-DG desalting column, Bio-Rad) in degassed PBS EDTA 5 mM, pH 6.4. Protein concentration was performed using Microcon YM-50 centrifugal filter devices (Millipore) in order to reach 3−5 mg/mL. The protein concentration was determined using the Bradford assay (Bio-Rad) before storage at −80 °C. The extent of maleimide functionalization was determined by trace-labeling with ^{35}S-labeled cysteine. The antibody solution in PBS EDTA 5 mM, pH 6.4 (100 μL, 0.3 mg, 2 nmol) was mixed with cysteine (0.07 mg, 400 nmol) containing trace amounts of ^{35}S-cysteine. The pH was adjusted to 7.0 by adding a few microliters of a 200 mM Na_2CO_3 solution, and after 30 min at room temperature, the protein was purified from the low molecular weight content by size-exclusion chromatography. After determination of the protein concentration, an aliquot was counted in a β scintillation counter (Beckman LS6000 IC), and by comparison with an aliquot of the ^{35}S-cysteine/cold cysteine solution, the total amount of cysteine bound to the protein was calculated. Using the protein concentration, the amount of maleimide residues per antibody was determined.

Preparation of Radioimmunoconjugates. The chelation of the radiometal during the first step to yield the chelates **2**, **7**, and **8** was performed as follows. All the reagent solutions were degassed by sonication under vacuum just prior to use. Depending on the scale of the subsequent conjugation reaction, a few microliters of $^{225}Ac(NO_{3)3}$ dissolved in 0.15 M HCl or $^{111}InCl_3$ at 0.1 mCi/mL were added to 50 μL of 2 M tetramethylammonium acetate (TMAA). To this solution was added 20 μL of 150 g/L ascorbic acid (AA) as a radioprotectant and 50−500 μL of the BCA solubilized at 1−10 mg/mL in freshly degassed metal-free water (MFW). If necessary, another 50 μL of the TMAA solution was added in order to reach pH 5.5. The pH was checked by testing an aliquot of the reaction mixture using pH test papers in the appropriate range (Micro Essential Laboratory, Inc., NY). The reaction mixture was incubated under argon at 60 °C over 30 min. The percentage of incorporation of the radiometal by the chelate was determined by loading 1−2 μL of the reaction mixture onto a 1 mL cation exchange resin (Sephadex C-25) equilibrated with 0.9% saline and eluting the column two times with 3 mL of saline. The eluate was collected, and the activity of the eluate and the column measured immediately for ^{111}In and when in equilibrium with its decay products in the case of ^{225}Ac. Chelated radiometals elute, whereas the free radiometals are retained on the column.

The second step of the labeling was achieved by adding 100 μL to 1 mL of the unmodified or maleimide-functionalized antibody in solution with 5 mM EDTA (3−5 mg/mL) to the reaction mixture. The pH was brought to 8.5 by adding a few microliters of a 200 mM Na_2CO_3 solution. The conjugation was allowed to proceed for 150 min at 37 °C. Purification of the conjugate was performed using a 10-DG desalting column using saline with 1% HSA as the mobile phase.

Characterization of the Radioimmunoconjugates. The radiochemical purity of the RICs was determined by instant TLC in triplicate (SG TLC plates; Gelman Sciences Inc., Ann Arbor, MI) using 10 mM EDTA as the mobile phase. The strips were analyzed immediately to detect ^{111}In or allowed to sit overnight before measuring ^{225}Ac. Analysis was performed using a gas

ionization detector (Ambis 4000; Ambis, San Diego, CA). The R_f of the radiolabeled antibody was 0, and both the free metal species and metal chelates were characterized by an R_f of 1.

The immunoreactivity of the purified RICs was determined by incubating the radiolabeled antibodies with AL67 (CD33-positive) or Daudi (CD33-negative) cells. First, cells were washed twice with ice-cold PBS and then blocked by incubation on ice with 2% rabbit serum. Then, 8 ng of the RICs of 1% HSA in PBS was added to 2.5×10^7 AL67 cells or 5×10^6 Daudi cells and incubated on ice for 30 min in a final volume of 20 μL. The cells were washed twice with ice-cold PBS, and the washes were saved and counted along with the cells after 20 h.

Radiometal Release by Cathepsin B and in Vitro Serum Stability. The cleavable RIC SJ25C1-DOTAG3FC **11** was used for these studies. Assay conditions were chosen to approximate the lysosomal medium. A stock solution of bovine spleen cathepsin B was prepared by dissolving the lyophilized solid at 15 U/mL in the cathepsin buffer, which consisted of 50 mM sodium acetate, 1 mM EDTA, pH 4.5. The enzyme was activated just prior use by incubation at 37 °C with 50 mM DTT for 30 min. The assay was performed at 37 °C using 25 μg conjugate, and the final enzyme concentration was 1.5 U/mL in a total volume of 150 μL. The control cathepsin buffer experiment was run in exactly the same conditions except no enzyme was added. The serum stability experiment was conducted at 37 °C with fresh human or mouse (Balb/c) serum prepared in the laboratory. The final serum concentration was 64% in saline, pH 7.6. The radiometal release was assessed by TLC. Preliminary studies using sodium hydroxide as the mobile phase allowed us to determine that the radiometal was released in a chelated form ($R_f = 1$). Kinetic studies were later performed by TLC using 10 mM EDTA as the mobile phase. The protein-bound ^{225}Ac was measured at $R_f = 0$ and expressed as a percentage of the total activity of the strip at equilibrium. Mean values and standard deviations were calculated from triplicate TLC experiments.

Animal Studies. Female Balb/c mice 10 weeks of age were obtained from Taconic (Germantown, NY). The studies were conducted according to the NIH Guide for the Care and Use of Laboratory Animals and were approved by the Institutional Animal Care and Use Committee at Memorial Sloan Kettering Cancer Center.

The mice were anesthetized and then injected i.v. (via the retroorbital venous plexus) with 0.5 μCi labeled antibody. The injected volume was 100 μL. Animals were sacrificed at different time points after injection by carbon dioxide asphyxiation, and the liver was removed. In addition, for the biodistribution studies, samples of blood (by cardiac puncture) and kidneys were removed. The organs were washed in distilled water, dried on gauze, and weighed, and the activities of ^{221}Fr (185−250 keV window) and ^{213}Bi (360−480 keV window) were measured using a γ counter (COBRA II, Packard Instrument Company, Meriden, CT). Samples of the injectate were used as decay correction standards. Percentage injected dose of ^{225}Ac per gram of tissue weight (% ID/g) was calculated for each animal at the time of sacrifice, using the equation described previously (*33*). The mean % ID/g was determined for each experimental group.

Radiometal Release in Cultured Cells and in Vivo. Assessment of RIC integrity was performed by protein A assay. The protein A resin (protein A sepharose CL-4B resin, Amersham Biosciences, Piscataway, NJ) was used according to the directions provided by the supplier. The beads were washed 3 times in PBS before use. For each experiment, a 100-fold excess of beads was used compared to the calculated amount of protein A necessary to bind the estimated amount of antibody.

For the cell internalization experiment, 2×10^6 HL-60 cells per milliliter were incubated for 30 min in RPMI 1640 with 10% fetal bovine serum with 30 ng of conjugate **9** or **11** labeled with ^{225}Ac in a total of 6 mL on ice. Each experiment was conducted in duplicate, and data values were averaged. After 2 washes with cold media, the cells were resuspended at 1×10^6 cells per milliliter in fresh media and incubated at 37 °C. At different time points, the cells were washed 2 times with cold media, and the pellet was lysed for 30 min at 4 °C in 100 mM NaCl, 10 mM Tris-HCl buffer, pH 8.0, containing 1% Triton and supplemented with the Roche protease inhibitor cocktail. The protein A resin in suspension in PBS was then added to the cell lysate, and the suspension was agitated for 30 min at 4 °C. The resin was then separated from the supernatant by quick centrifugation and washed 2 times. The radioactivity was measured in scintillation liquid using a β counter. The activity in the washes was negligible, and the activity associated to the beads was at least 25-fold superior to background. The antibody-bound activity was expressed as the percentage of the activity bound to the beads compared to the total activity found in the supernatant and associated with the resin.

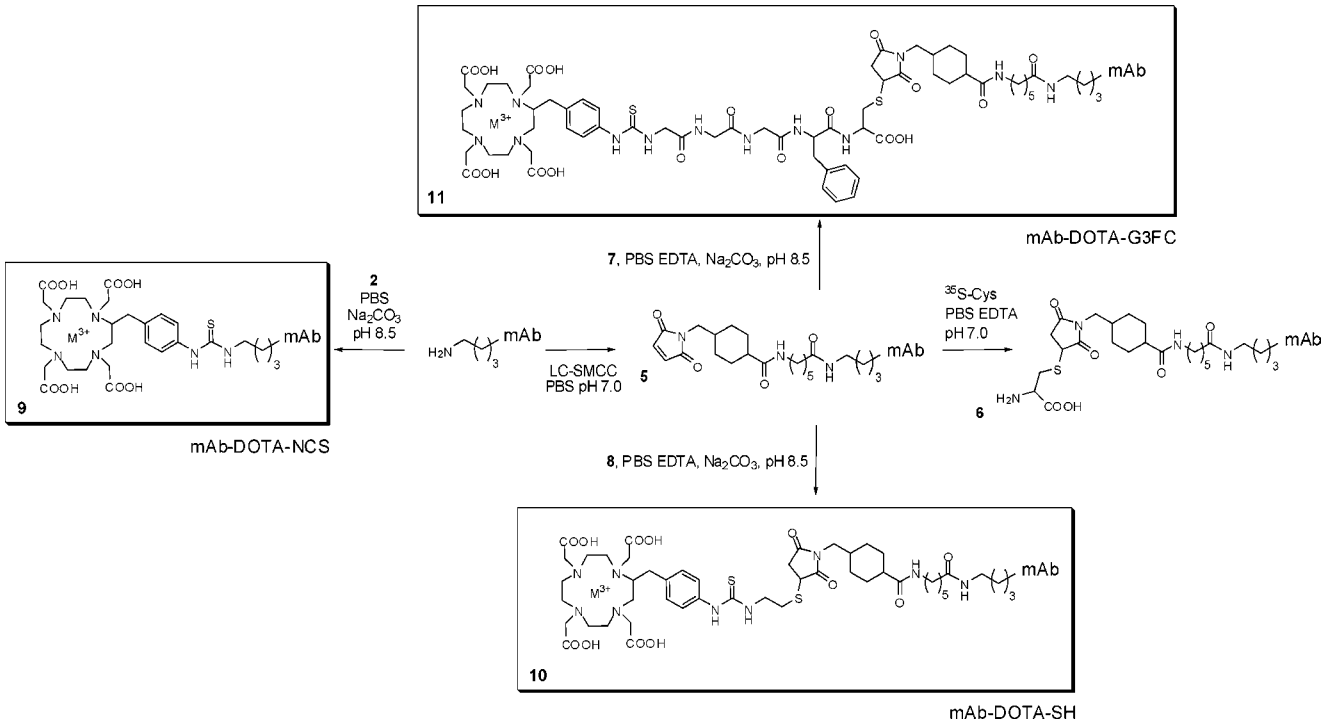
For the in vivo radiometal release experiments, the constructs **9** or **11** labeled with ^{225}Ac (0.1 mCi in saline 1% HSA) were injected ip to two groups of three Balb/c female mice. At different time points, the isolated livers were homogenized on ice in 10 mL of 10 mM Tris-HCL buffer at pH 8.0 containing 0.25 M sucrose and 1% Triton X-100, supplemented with the Roche protease inhibitor cocktail. After pelleting at 12 000 g at 4 °C for 10 min, the supernatant was submitted to the protein A beads assay as described above. In order to estimate the size of the antibody fragments carrying the radiolabel, the liver extracts were submitted to size-exclusion chromatography using 10-DG columns (Bio-Rad), which have a 6 kDA molecular weight cutoff. This type of column was previously calibrated in the laboratory using the following method. Fractions collected after the purification of the RIC HuM195−DOTA−NCS labeled with ^{225}Ac were analyzed by size-exclusion HPLC to determine the volume corresponding to the elution of high molecular weight molecules. The same protocol was later used to analyze the radiolabeled components of the liver homogenates, allowing separation of the high (>6 kDa) and low (<6 kDa) molecular weight content.

RESULTS

Design and Synthesis of the Bifunctional Chelating Agents. In order to achieve high labeling yields, we based our conjugation strategy on thiol/maleimide chemistry, because thiols would be resistant to the conditions used during the ^{225}Ac chelation step. Since all four carboxylic groups of DOTA need to be available for stable ^{225}Ac chelation, we decided to use the bifunctional DOTA−NCS **1** macrocyclic chelator as the starting material for the synthesis of the new linkers, because its *p*-benzylisothiocyanate moiety is directly linked to the macrocycle backbone rather than to one of the carboxylic groups.

We used a cathepsin B-sensitive linker in the design of our self-immolative nanogenerators on the basis that cathepsin B is a prominent enzyme implicated in the catabolism of proteins in the liver (*29*−*31, 34*). The cleavable BCA DOTA−glycyl-glycylglycyl−L-*p*-isothiocyanatophenylalanine used by DeNardo et al. was shown to be cleaved by cathepsin B before the phenylalanine residue (*35*). This residue was bound to the antibody through a thiourea moiety in the para position of the benzyl moiety. We hypothesized that this nonpeptidic bond was not required for recognition by the enzyme cathepsin B, and instead, we incorporated to our linker a regular phenylalanine residue. A terminal cysteine residue was added in order to provide the reactive thiol for conjugation to the maleimide-

Scheme 2. Radioimmunoconjugates



functionalized antibody. The synthesis of our cleavable BCA required a single step consisting of coupling the pentapeptide GGGFC to DOTA−NCS (Scheme 1). This was achieved in anhydrous DMF in the presence of triethylamine with a 86% yield; the resulting product DOTA−G3FC **3** was purified by semipreparative reversed-phase HPLC. Similarly, we synthesized the noncleavable control BCA DOTA−SH **4** by coupling DOTA−NCS with 2-mercaptoethylamine (2-MEA), with a 85% yield.

Preparation of the Radioimmunoconjugates. Our thiol−maleimide conjugation strategy requires the functionalization of the antibody with a maleimide moiety, which was readily achieved through the use of the commercially available bifunctional linker LC-SMCC (Scheme 2). The long chain (LC) version of this reagent was preferred in order to reduce the possible steric hindrance provided by the proximity of the antibody, therefore allowing maximum accessibility of the enzyme cathepsin to the linker. The protocol allowed derivatization of the antibody with a reproducible amount of maleimides. A 25-fold molar excess of LC-SMCC per antibody yielded about 8 mol maleimide per mole of HuM195 antibody (7.7 ± 0.9; $n = 8$). Purification of the functionalized antibody **5** was achieved by size-exclusion chromatography. This functionalization method was successfully applied to two different antibodies: HuM195 and SJ25C1. Using similar conditions as the one optimized for HuM195 led to the functionalization of SJ25C1 with a reproducible amount of about eight maleimide moieties per antibody. The degree of maleimide functionalization was assessed by ^{35}S-cysteine labeling of an aliquot of the prepared batch of antibody (Scheme 2). Specific activity was determined on the product, allowing determination of the number of of available maleimides per antibody. The storage buffer (freshly degassed PBS with 5 mM EDTA) at pH 6.4 was chosen because the slightly acidic pH is necessary for the stability of the construct. Upon storage at −80 °C in PBS/EDTA at pH 6.4, the functionalized mAbs suffered little loss of their maleimide moiety (1−9% over a period of 6 months). The presence of EDTA and the degassing are important for the second step, in order to prevent the oxidation of the reactive thiol on the BCAs **7** and **8**.

The chelation efficiencies of ^{225}Ac by the newly synthesized BCAs to yield the chelates **7** and **8** were similar to those obtained with DOTA−NCS **1**. Metal chelation efficiency was typically 95% to >99% when using a ^{225}Ac/DOTA ratio of 1:5000 or greater.

The noncleavable, control RIC mAb−DOTA−NCS **9** (*15*, *19*) was prepared using the commercially available BCA DOTA−NCS **1**. After completion of the first step, the reaction of **2** with the antibody afforded the RIC **9** with a radiochemical yield of 5−10%. Its radiochemical purity was typically 90% or greater. Previous studies have shown that an average of 5.4 DOTA per antibody are attached (*19*).

The conjugate mAb−DOTA−SH (**10**) (Scheme 2) was prepared using the novel, noncleavable BCA DOTA−SH (**4**). We optimized the conditions of the maleimide/thiol conjugation during the second step using the ^{225}Ac chelate DOTA−SH **8**. Increasing the pH up to 8.5 increased the radiochemical yields by up to 2-fold compared to pH 6.8. Similarly, incubating the reaction mixture at 37 °C instead of room temperature increased the efficiency by a factor of 1.8. The stoichiometry of the reaction also constituted an important parameter in the reaction, since using 0.5 mol equiv of BCA **8** per maleimide instead of a 2:1 DOTA−SH/maleimide ratio increased the radiochemical yield by another 2-fold. When combined, these parameters allowed the labeling of antibodies with ^{225}Ac through the noncleavable BCA **8** with radiochemical yields ranging from 30% to 40%. The purity of those constructs was 93% and greater, as assessed by thin layer chromatography (TLC). When applied to the labeling of antibodies with the cleavable BCA **7** and ^{225}Ac, those conditions afforded the same range of yields and purities.

Characterization of the RICs in Vitro. The immunoreactivity of the three different constucts HuM195−DOTA−NCS **9**, HuM195−DOTA−SH **10**, and HuM195−DOTAG3FC **11** labeled with ^{225}Ac were tested on the CD33-positive AL67 cells. All conjugates were active with immunoreactivities of 93%, 87%, and 82%, respectively. The amount of construct bound to the control CD33-negative Daudi cells ranged between 1% and 2%. Therefore, neither the maleimide functionalization of the mAb HuM195 nor its coupling to the newly synthesized

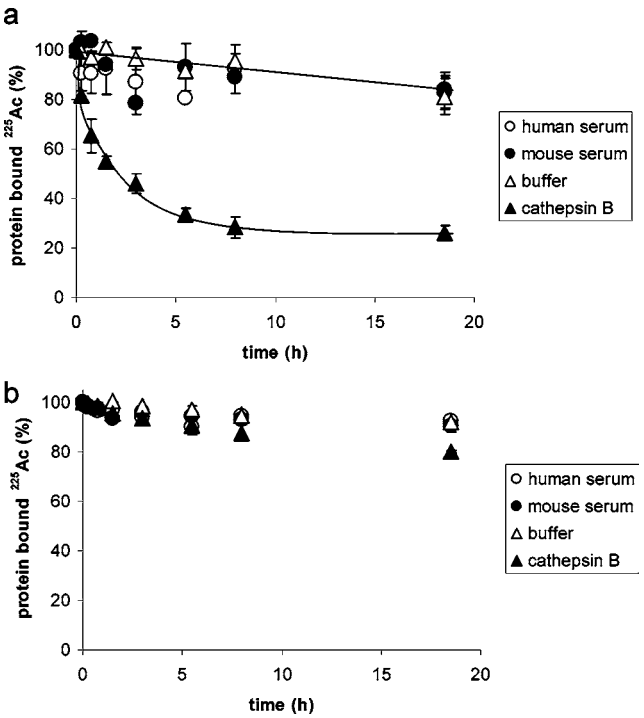


Figure 1. (a) Cathepsin B-mediated release of chelated ^{225}Ac from the cleavable RIC SJ25C1−DOTA−G3FC **11**. (b) Stability of the noncleavable RIC SJ25C1−DOTA−NCS **9**. The release of the radiometal from the conjugates was measured at 37 °C and assessed by thin layer chromatography.

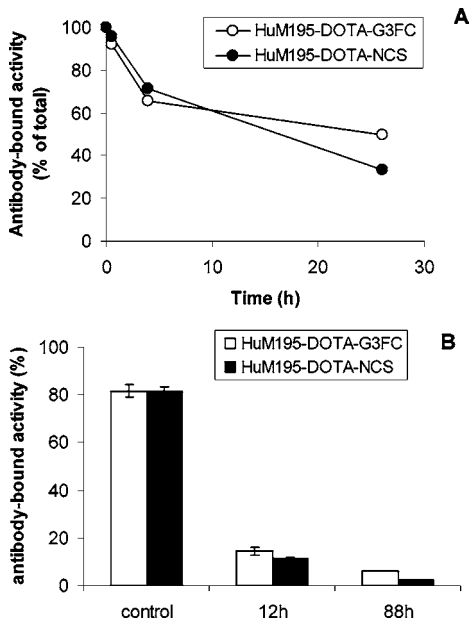

Figure 2. Comparison of ^{225}Ac release from HuM195−DOTA−G3FC **11** and HuM195−DOTA−NCS **9** after HL-60 cell internalization in vitro (A) or in mouse liver in vivo (B). The antibody-bound activity was measured after cell homogenization by using protein A beads.

BCAs significantly affected the immunoreactivity or specificity of the antibody in vitro.

The next step in the evaluation of the cleavable construct mAb−DOTA−G3FC **11** consisted of verifying the recognition of the inserted linker as a substrate of cathepsin B in vitro. As assessed by TLC, the construct released ^{225}Ac in a chelated form over time when incubated with purified cathepsin B at 37 °C (Figure 1a). The drug cleavage half-life was about 150 min, and up to 80% of its radioactive payload was released within 7 h. As a control, the RIC was incubated in the cathepsin buffer without cathepsin B, in order to test whether the acidic conditions (pH 4.5) were responsible for the degradation of the linker. No significant radioisotope release was observed within 10 h, indicating that the cleavage of the linker was cathepsin-dependent (Figure 1b). We showed that the cathepsin is cleaving the linker, rather than the IgG backbone by conductiong another control, which consisted of analyzing the noncleavable conjugate SJ25C1−DOTA−NCS **9** in the same conditions (Figure 1b). Only about 10% of the conjugated radiometal was released within 10 h, demonstrating that the degradation observed with the construct SJ25C1−DOTAG3FC **11** was linker-dependent and did not result of antibody metabolism by cathepsin B during that time frame.

The observed degradation of the RIC SJ25C1−DOTAG3FC in mouse and human serum was lower than 20% over 20 h at 37 °C, indicating that it was stable in these conditions (Figure 1a). When the in vitro cleavage of the cathepsin-sensitive RIC mAb−DOTA−G3FC (made with either the HuM195 antibody (data not shown) or the mouse SJ25C1 antibody) was tested, no difference in the degradation rate between the two constructs was observed. This indicated that the source of the antibody seemed not to interfere with the enzymatic cleavage of the DOTA−G3FC BCA.

We wanted to investigate whether the self-immolative RIC mAb−DOTA−G3FC was susceptible to degradation after cell internalization in vitro. For this purpose, we compared the fates of the cleavable HuM195−DOTA−G3FC **11** and of the noncleavable HuM195−DOTA−NCS **9**, each labeled with ^{225}Ac, in target HL-60 cells. After specific binding at 4 °C and internalization at 37 °C, both RICs were degraded inside the cells over time, as demonstrated by the increasing failure of the labeled construct to bind protein A beads (Figure 2A). The rates of degradation of both RICs were similar. This result suggested that both the noncleavable RIC HuM195−DOTA−NCS **9** and the cathepsin-sensitive RIC HuM195−DOTA−G3FC **11** are susceptible to protein catabolism after cell internalization, presumably inside the lysosomes. As the kinetics of loss of binding to protein A were similar, it appeared that both constructs were submitted to a protease activity that separated the radiolabel from the Fc portion of the IgG.

Characterization of the RICs in Vivo. A protein A bead assay was run on the serum of mice injected with the same constructs labeled with ^{111}In. The experiment showed that all three conjugates were stable in mouse serum in vivo, since between 80% and 85% of the serum activity was antibody-bound after 136 h.

The catabolism of the three RICs labeled with ^{225}Ac was investigated in vivo after iv injection in mice. Mouse livers from untreated animals were homogenized at different time points, and the integrity of the RICs was assessed using the protein A bead assay (Figure 2B). As a control, the intact RICs were mixed with a liver homogenate suplemented with a cocktail of protease inhibitors. In these control conditions, 80% of both RICs were able to bind the protein A beads. In contrast, at 12 and 88 h after injection, both RICs were significantly degraded, since their ability to recognize the beads was reduced to about 10%. Similar to the in vitro observation with HL-60 cells, both constructs had their radiolabel separated from a functional Fc at the same rate.

In order to estimate the sizes of the fragments carrying the radiolabel, at 12 h after injection, we passed the liver extracts through a size-exclusion column (10-DG). This analysis revealed that 84% (±3%) of the radioactivity was bound to fragments smaller than 6 kDa for the cleavable RIC, whereas those fragments represented only 62% (±3%) for the noncleavable RIC HuM195−DOTA−NCS.

We then compared the biodistribution in mice of ^{225}Ac after injection of the cleavable RIC HuM195−DOTA−G3FC **11** or

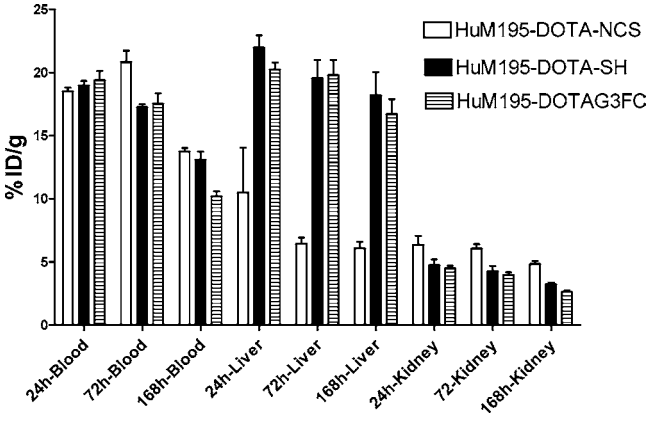

Figure 3. Comparison of the biodistribution in mice of the RICs HuM195−DOTA−NCS **9**, HuM195−DOTA−SH **10**, and HuM195−DOTA−G3FC **11** labeled with ^{225}Ac.

of the noncleavable RIC HuM195−DOTA−NCS **9** (Figure 3). For this study, we included another noncleavable control construct: HuM195−DOTA−SH **10**. The antibody in the latter conjugate was functionalized with maleimides the same way the degradable RIC **11** was, but the BCA DOTA−SH **4** used for its labeling is not sensitive to cathepsins. The biodistribution study revealed that all three constructs cleared from the blood in a similar way, approaching 10−14% of the injected dose at 168 h. A striking difference, however, was seen in the accumulation into the liver. Both the noncleavable HuM195−DOTA−SH and the cleavable HuM195−DOTA−G3FC constructs yielded a 2-fold higher liver accumulation at 24 h compared to the noncleavable HuM195−DOTA−NCS conjugate. Their slow clearance from the liver eventually yielded a 3-fold higher liver uptake at 168 h. The kidney accumulation for the two maleimide-functionalized constructs **10** and **11** was slightly lower, probably related to the increased liver uptake. Clearance was observed over time for all constructs.

DISCUSSION

This report describes the synthesis of two new BCAs that allow markedly improved yields for the labeling of antibodies with ^{225}Ac. By using the newly synthesized BCAs, chelation yields of 95% to >99% and labeling yields of up to 40% were routinely observed. This result constitutes a dramatic improvement compared to the typical yields using the isothiocyanate-functionalized macrochelator DOTA−NCS **2**, which average 5−10% (*19*). This difference is likely to be attributable to the sensitivity to hydrolysis of DOTA−NCS during the chelating step of ^{225}Ac at 60 °C. This hypothesis was in part confirmed by an HPLC stability study, which showed a half-life of DOTA−NCS of 30 min in those conditions (data not shown). We therefore demonstrate here that thiol/maleimide chemistry constitutes an alternative conjugation method that is preferrable when a high radiochemical yield is needed with ^{225}Ac. The yields might be further improved with additional process development and optimization.

The pharmacology of an in vivo isotope generator is complex. The three α-emitting daughters of ^{225}Ac pose a potential threat to injected patients if the elements cannot be controlled and cleared quickly. Strategies to decrease exposure to RICs of nontarget organs include antibody engineering, pretargeting, extracorporeal depletion, and cleavable conjugates (*25*). In this article, we describe the design of a self-immolative tumor-targeted isotope nanogenerator. Our intent was to develop a RIC capable of generating four high LET α particles at the tumor site, whose radioactive payload can be enzymatically disarmed in order to reduce damage to normal tissues should the RIC not target. The DOTA−G3FC BCA **3** incorporates a cleavage site for the enzyme cathepsin B allowing release of the radiometal from the carrier antibody in a chelated, safe form. The specific degradation of the linker by purified cathepsin B was demonstrated. The chemical half-life of the linker in those conditions was 150 min, whereas no significant radiometal release was observed during that time frame with buffer only. Furthermore, this peptide link proved to be stable in circulation in vivo, since the cleavable RIC HuM195−DOTA−G3FC **11** labeled with ^{225}Ac was found intact in mouse serum 136 h after injection.

When we investigated the fate of the cleavable RIC **11** after internalization in cultured HL-60 cells, we discovered that its rate of degradation (as measured by retention of the isotope on protein A-beads, which requires an intact Fc portion for binding) was similar to the noncleavable control construct **9**. This result was confirmed in vivo in the liver homogenate experiment. A rapid degradation of both constructs occurs in mouse liver, leaving less than 20% conjugate intact 12 h after injection. The nature of the degradation, however, cannot be determined by this assay. Other groups have reported that radiolabled antibodies are processed after cell internalization. Geissler at al. have shown that following cell surface binding, different radiolabeled antibodies are internalized and degraded in the lysosome (*36*, *37*). When injected in vivo, a large fraction of a radiolabeled murine antibody against a tumor glycoprotein accumulated in the liver. Its liver uptake is mediated by its Fc portion (*38*). The same authors observed the conversion in the liver of the ^{111}In−DTPA RIC into small radiolabeled fragments, presumably ^{111}In−DTPA bound to one or a few amino acids. This hypothesis was confirmed by several groups who identified the in vivo metabolite of different ^{111}In−DTPA−NCS labeled proteins as indium−DTPA−lysine (*39*−*41*). Therefore, it is likely that the noncleavable control construct HuM195−DOTA−SCN **9** undergoes a similar process, explaining the degradation we observed after cell internalization in vitro and in the liver in vivo.

On the basis of the protein A assay, the kinetics of degradation observed for the cleavable RIC **11** and the noncleavable construct **9** were similar within the studied time frame. However, the protein A assay does not provide information regarding the way the radiolabeled antibody was degraded, other than reporting the separation of the radiolabel from a functional Fc end of the IgG. We could therefore not rule out the possibility that the degradation of both constructs was qualitatively different and that the cathepsin-sensitive linker was degraded in addition to the catabolism of the antibody. For this reason, we investigated the size of the radiolabeled fragments in the liver. At 12 h after injection, the proportion of small radiolabeled fragments (<6 kDa) was significantly greater for the cleavable construct, suggesting that additional processing of the linker had occurred. It is also likely that a more significant difference may be observed at earlier time points. Indeed, a study using comparable cathepsin-sensitive RICs demonstrated processing of the radiolabeled conjugates in mice liver as early as 30 min postinjection. In particular, a RIC with a linker incorporating the sequence Gly-Phe-Gly showed little radioactivity associated with the intact antibody and most of the activity associated with the low molecular weight fragments in a gel filtration chromatography experiment after hepatic catabolism (*42*). Similar to our findings, a study was recently published that describes the unexpected activity of a control immunoconjugate not designed to be able to release an active drug (*43*). Drug release from this conjugate was shown to take place through mAb degradation. Taken together, these results suggest that the G3FC linker in the cathepsin-sensitive RIC **11** was cleaved in vivo and that catabolism of the antibody backbone took place for both the

cleavable and noncleavable constructs at the same time, obscuring the linker degradation.

When we investigated the biodistribution of the cathepsin-sensitive construct HuM195−DOTA−G3FC **11** in mice, we observed its accumulation in the liver, leading to 2- to 3-fold higher liver uptake compared to the noncleavable construct HuM195−DOTA−NCS **9**. A different noncleavable control construct HuM195−DOTA−SH **10** induced a similar liver accumulation of ^{225}Ac in the liver. Since the antibody in this conjugate was functionalized by maleimides the same way as the cleavable construct **11**, it is likely that the functionalization of HuM195 with LC-SMCC was responsible for its increased uptake. It was recently demonstrated that drug-load stoichiometry can significantly influence immunoconjugate pharmacokinetics (*44*). It is also known that the pI of an antibody or antibody fragment affects its biodistribution (*45*−*47*). Therefore, a difference in the number of modifed lysines between the constructs could account for different drug loading and a different overall charge of the conjugates, which could explain the difference in behaviors in vivo. Presumably, about eight lysines were modified during maleimide functionalization, which is comparable to the number of lysines derivatized with DOTA−NCS (*8*−*10*) using our protocols. However, we cannot rule out the possibility that the resulting amount of maleimides after reaction with LC-SMCC does not reflect the number of modified lysines, because some maleimide hydrolysis may have occurred. Another explanation for the different fate in vivo of the two noncleavable constructs could be a different localization of the radiochelate on the antibody due to the different chemistries used. Catabolism of the conjugates could then produce different labeled fragments, with nonsimilar excretion properties. The decreased kidney accumulation consistently observed for the two maleimide-functionalized constructs **10** and **11** probably resulted from to the increased liver uptake.

Although the cleavable construct HuM195−DOTA−G3FC **11** was demonstrated to be extensively catabolized, the organ distribution profile of the cleavable construct and of the noncleavable control conjugate HuM195−DOTA−SH **10** were similar. Both constructs showed prolonged retention of the radioactivity in the liver. The lack of accelerated liver isotope clearance by the cathepsin-sensitive linker on the cleavable construct raises questions about the fate of the radioconjugate once inside the liver. We speculate that the accumulation of ^{225}Ac in the liver, which was associated with the treatment with conjugate **11**, is the result of an absence of secretion of the radiolabeled metabolites, rather than an absence of cleavage. Lysosomes are known to be highly selective with respect to the release of molecules in the cytoplasm, and accumulation of certain compounds like weak bases results (*48*). Differences in the catabolism of different radiolabels on antibodies have been observed previously (*8*). Several authors have reported the accumulation of RIC metabolites in the liver (*38*) or in their lysosomes (*39*). Furthermore, not all cathepsin-sensitive linkers in RICs resulted in accelerated liver clearance. For example, while the previously described Ala-Leu-Ala-Leu peptide was beneficial in a daunorubicin conjugate (*49*), the linker did not significantly increase the liver clearance of a ^{111}In-labeled antibody (*50*). The authors concluded that the chelates were cleaved off in the liver but were trapped there (*50*). The difference in biodistribution with the previously reported result (*49*) was attributed to the different method used to attach the linker to the antibody, the different number of chelates, and possibly different positions of attachment. In another study, Meares et al. synthesized various peptide-derivatized DOTA compounds and selected the best substrates for cathepsin B and D (*51*, *52*). The most efficiently cleaved peptide sequences in vitro were not the linkers leading to the best clearance of the liver in vivo (*29*). This result most likely could be explained by the absence of correlation between rate of linker degradation by purified cathepsin and rate of liver clearance, which depends on other catabolic steps.

Together, these results show that cleavage of a linker by cathepsins is not necessarily the limiting step in the clearance of a self-immolative RIC. We postulate that the catabolism and release of the radiolabeled fragments from liver constitutes a major limiting step in the clearance of RIC metabolites. Therefore, similar cathepsin-sensitive linkers, for example, those reported here and those described by DeNardo et al., could display different biodistributions. Additional support for this hypothesis is derived from work with similar BCAs used to label F(ab′)2 antibody fragments with copper, in which slight modifications in the linker structure dramatically influenced the biodistribution and clearance of the radiometal (*42*). A better understanding of those mechanisms is required for the design of successful self-immolative RIC.

Triplex Staples: DNA Double-Strand Cross-Linking at Internal and Terminal Sites Using Psoralen-Containing Triplex-Forming Oligonucleotides

Hong Li,[†] Victoria J. Broughton-Head,[‡] Guomei Peng,[†] Vicki E. C. Powers,[†] Matthew J. Ovens,[‡] Keith R. Fox,[‡] and Tom Brown*[,†]

A method has been developed to attach 4′-(hydroxymethyl)-4,5′,8-trimethylpsoralen to the 5 position of thymine bases during solid-phase oligonucleotide synthesis. UV irradiation of triplex-forming oligonucleotides (TFOs) containing internally attached psoralens produces photoadducts at TpA steps within target duplexes, thus relaxing the constraints on selection of psoralen target sequences. Photoreaction of TFOs containing two psoralens, located at the 5′- and 3′-ends, has been used to create double-strand cross-links (triplex staples) at both termini of the TFO. Such complexes have no free single-stranded ends. TFOs containing 4′-(hydroxymethyl)-4,5′,8-trimethylpsoralen, 3-methyl-2-aminopyridine, and 5-(3-aminoprop-2-ynyl)deoxyuridine formed photoadducts with target duplexes under near-physiological conditions.

INTRODUCTION

Triplex-forming oligonucleotides (TFOs) bind in a sequence-specific manner to the major groove of double-stranded DNA (dsDNA). In the parallel motif, hydrogen bonds are formed with purine bases in the oligopurine strand through T•AT and C^+•GC Hoogsteen interactions, whereas in the antiparallel motif, A•AT, T•AT, and G•GC reverse Hoogsteen triplets are formed (*1*−*3*). TFOs can be used to modulate gene expression and as molecular tools to cause strand cleavage (*4*). They are also powerful tools for causing site-specific chemical damage at selected DNA sequences, thereby introducing mutations (*5*, *6*). Parallel triplexes are more stable than the antiparallel variants, but the affinity of the third strand for the duplex is relatively low at physiological pH due to the requirement for protonation of the third strand cytosine (*7*, *8*). Parallel TFOs constructed from normal bases are therefore not suitable for use in vivo.

Psoralens are bifunctional photo-cross-linking agents that have been used as probes of nucleic acid structure and function (*9*). When attached to the termini of TFOs as shown in Scheme 1 (structure **1**), psoralens intercalate into the neighboring duplex and stabilize the triple-stranded complex (*10*). Irradiation at 365 nm induces a [2 + 2] cycloaddition reaction between the intercalated psoralen and pyrimidine bases in the duplex to form adducts with one or both strands, principally at TpA steps (*11*, *12*). The 3,4-double bond of the pyrone ring and the 4′,5′-double bond on the furan ring of psoralen are involved (*10*). Double-strand cross-linking only occurs if the furan moiety undergoes reaction first (*9*). Such cross-links can inhibit replication and transcription by preventing opening of the double helix, and psoralen-modified oligonucleotides have been proposed as tools in molecular biology and as potential therapeutic agents (*13*, *14*).

The attachment of psoralen to the termini of TFOs limits the choice of duplex target, as efficient double-strand cross-linking requires a TpA step just outside the triplex binding site. This constraint could be relaxed if cross-linking was possible at TpA sites within the triplex binding site. With this in mind, we have studied the DNA binding and photochemical cross-linking properties of TFOs that contain an internal psoralen tethered to a uracil as shown in Scheme 1 (structure **2**). We have also synthesized a TFO containing two psoralens, one at the 5′-end (**1**) and one at the 3′-end (**2**) and have investigated its interactions with a duplex target. This double psoralen-labeled TFO acts as a triplex staple.

EXPERIMENTAL PROCEDURES

Materials. All reagents were purchased from Aldrich, Avocado, or Fluka and used without purification with the exception of the following solvents, which were purified by distillation: methanol (over iodine and magnesium), tetrahydrofuran (over sodium wire and benzophenone), dichloromethane, *n*-diisopropylethylamine, pyridine, and triethylamine (over calcium hydride). All reactions were carried out under an argon atmosphere using oven-dried glassware with purified and distilled solvents. Column chromatography was carried out under pressure using Fisher Scientific DAVISIL 60A (35−70 μm) silica. Thin layer chromatography was performed using Merck Kieselgel 60 F24 (0.22 mm thickness, aluminum backed). Compounds were visualized by ultraviolet light at 254 nm or by staining with 10% phosphomolybdic acid in ethanol (A′), or anisaldehyde (B′).

^{1}H NMR and ^{13}C NMR spectra were measured on a Bruker AC300 spectrometer or a Bruker DPX400 spectrometer. Chemical shifts are given in parts per million relative to tetramethylsilane, and *J* values in hertz. Multiplicities of ^{13}C signals were determined using the DEPT spectral editing technique and are described as s (quartenary carbon), d (CH), t (CH_2), and q (CH_3). Assignment was also aided by COSY (^{1}H−^{1}H), HMQC, and HMBC experiments. ^{31}P NMR spectra were recorded on a Bruker AV300 spectrometer at 121 MHz or 162 MHz on a Bruker DPX400 spectrometer and were externally referenced to 85% phosphoric acid in D_2O.

Low-resolution mass spectra were recorded by electrospray on a Fisons VG platform instrument in acetonitrile or a Waters

ZMD quadrupole mass spectrometer in methanol or water (HPLC grade). High-resolution mass spectra were recorded in acetonitrile, methanol, or water (HPLC grade) by electrospray on a Bruker APEX III FT-ICR mass spectrometer. Oligonucleotides were analyzed by MALDI-TOF MS using a ThermoBioAnalysis Dynamo MALDI-TOF mass spectrometer in positive ion mode using internal T_n standards.

Hex-5-ynyl-4-oxopentanoate. Levulinic acid (1.05 mL, 10.2 mmol) was added to a solution of dicyclohexyl carbodiimide (2.1 g, 10.2 mmol) in dichloromethane (10 mL). The slurry was stirred for 10 min at room temperature before adding further dichloromethane (10 mL), 5-hexyn-1-ol (0.55 mL, 5.1 mmol), and 4-dimethylaminopyridine (62 mg, 0.5 mmol). The reaction was stirred at room temperature for 2 h and filtered to remove dicyclohexylurea. The filtrate was washed with saturated sodium bicarbonate, 10% citric acid, and saturated potassium chloride, dried over sodium sulfate, filtered, and the solvent evaporated in vacuo. Purification by column chromatography (9.5:0.5 toluene/ethyl acetate) gave the title compound as a colorless oil in quantitative yield. R_f (9:1 toluene/ethyl acetate, A′) 0.43; δ_H (400 MHz, $CDCl_3$) 4.09 (2H, t, $J = 6.5$ Hz, **H**^{6}), 2.73 (2H, t, $J = 6.5$ Hz, **H**^{8}), 2.56 (2H, t, $J = 6.5$ Hz, **H**^{7}), 2.22 (2H, td, $J = 6.5$, 2.5 Hz, **H**^{4}), 2.18 (3H, s, C**H**$_3$), 1.94 (1H, t, $J = 2.5$ Hz, **H**^{6}), 1.71−1.78 (2H, m, **H**^{2}), 1.55−1.62 (2H, m, **H**^{3}); δ_C (100 MHz, $CDCl_3$) 206.6 (s, **C**O**)**, 172.9 (s, **C**O), 84.0 (s, **C**^{5}), 68.8 (d, **C**^{6}), 64.2 (t, **C**^{1}), 38.1 (t, **C**^{8}), 30.0 (q, **C**H_3), 28.1 (t, **C**^{7}), 27.8 (t, **C**^{2}), 25.0 (t, **C**^{3}), 18.2 (t, **C**^{4}); *m/z* LRMS [ES^+, MeOH] 219 ($M + Na^+$, 100%); *m/z* HRMS [ES^+, MeOH] found 415.2092 ($2M + Na^+$) $C_{22}H_{32}O_6Na$ requires 415.2090.

5′-*O*-(4,4′-Dimethoxytrityl)-5-(hex-5-ynyl-4-oxopentanoyl)-2′-deoxyuridine. 5′-*O*-(4,4′-Dimethoxytrityl)-5-iodo-2′-deoxyuridine (2.60 g, 3.96 mmol) was dissolved in anhydrous dimethylformamide (20 mL). Cu^I iodide (302 mg, 1.59 mmol) and triethylamine (5.52 mL, 39.6 mmol) were added, followed by hex-5-ynyl 4-oxopentanoate (1.72 g, 8.72 mmol) in dimethylformamide (5.0 mL). The reaction mixture was stirred under an argon atmosphere in the dark for 10 min before adding $Pd(PPh_3)_4$ (0.92 g, 0.79 mmol), then left to stir for a further 12 h in the dark at room temperature. The solvent was then removed in vacuo, and the residue partitioned between dichloromethane and saturated potassium chloride. The organic layer was washed with water, dried over sodium sulfate, filtered, and the solvent removed in vacuo. Purification by column chromatography (4:1 ethyl acetate/hexane, 1% pyridine) gave the title compound as a pale yellow foam (2.33 g, 81%). R_f (7:3 ethyl acetate/hexane, B′) 0.45; δ_H (400 MHz, d_6-DMSO) 11.6 (1H, s, N**H**), 7.91 (1H, s, **H**^{6}), 7.25−7.71 (9H, m, C**H**^{Ar}), 6.92 (4H, d, $J = 8.5$ Hz, C**H**^{Ar}), 6.16 (1H, t, $J = 6.5$ Hz, **H**^{11}), 5.34 (1H, d, $J = 4.5$ Hz,

O**H**$^{3'}$), 4.32 (1H, bs, **H**$^{3'}$), 3.94 (1H, app t, J = 6.5 Hz, **H**$^{4'}$), 3.77 (6H, s, OC**H**$_3$), 1.55 (1H, dt, J = 14.5, 6.5 Hz, **H**$^{2'}$), 1.35 (1H, dt, J = 15.0, 7.0 Hz, **H**$^{2'}$); δ_C (400 MHz, d_6-DMSO) 206.7 (s, **C**O), 172.2 (s, **C**O), 161.6 (s, **C**O), 158.0 (s, **C**O), 149.3, 144.7 (s, **C**^{Ar}), 141.9 (d, **C**H^6), 135.5, 129.6, 129.6, 128.8, 128.6, 128.1, 127.8 (d, **C**H^{Ar}), 127.6 (s, **C**^{Ar}), 113.1 (d, **C**H^{Ar}), 99.2 (s, **C**), 92.9 (s, **C**^{8}), 85.8 (d, **C**H$^{4'}$), 84.8 (d, **C**H$^{1'}$), 72.4 (s, **C**^{7}), 70.4 (d, **C**H$^{3'}$), 63.3 (t, $^{5'}$**C**H$_2$), 55.0 (q, O**C**H$_3$), 40.0 (t, ^{14}**C**H$_2$), 37.4 (t, ^{12}**C**H$_2$), 29.5 (q, **C**H$_3$), 27.5 (t, ^{13}**C**H$_2$), 27.3 (t, ^{10}**C**H$_2$), 24.4 (t, ^{11}**C**H$_2$), 18.3 (t, $^{2'}$**C**H$_2$); *m*/*z* LRMS [ES$^+$, MeCN] 747 (M + Na$^+$, 100%); *m*/*z* HRMS [ES$^+$, MeCN] found 747.2870 (M + Na$^+$) $C_{41}H_{44}N_2O_{10}Na$ requires 747.2888.

5′-*O*-(4,4′-Dimethoxytrityl)-5-(hex-5-ynyl-4-oxopentanoyl)-2′-deoxyuridine-3′-*O*-(2-cyanoethyl-*N*,*N*-disopropyl)phosphoramidite. 5′-*O*-(4,4′-Dimethoxytrityl)-5-(hex-5-ynyl-4-oxopentanoyl)-2′-deoxyuridine (2.28 g, 3.15 mmol) was dissolved in distilled tetrahydrofuran (20 mL) under argon. *N*,*N*-Diisopropylethylamine (1.4 mL, 7.87 mmol) was added, followed by 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite (0.77 mL, 3.46 mmol). The reaction mixture was left to stir at room temperature for 1 h, then transferred under argon (with degassed ethyl acetate washings, 2 × 20 mL) into a separating funnel containing degassed ethyl acetate (10 mL). This mixture was washed with saturated potassium chloride (20 mL), dried over sodium sulfate, filtered, and the solvent removed in vacuo. Purification by silica gel column chromatography (7:3 ethyl acetate/hexane, 1% pyridine, under argon pressure) gave the product as a colorless foam (2.49 g, 86%). This was dissolved in anhydrous acetonitrile and filtered through a Millipore Millex-FH syringe filter (0.45 μm, 25 mm diameter). The solvent was removed under reduced pressure, and the monomer was dissolved in freshly distilled dichloromethane. Aliquots of 100 μmol were transferred to monomer reagent bottles and dried in a desiccator overnight under high vacuum before being stored under a slight positive pressure of argon at −20 °C. R_f (4:1 ethyl acetate/hexane, B′) 0.5, 0.45 (diastereomers); δ_P (121 MHz, d_6-DMSO) 148.8, 148.4; *m*/*z* LRMS [ES$^+$, MeCN] 947 (M + Na$^+$, 100%); *m*/*z* HRMS [ES$^+$, MeCN] found 947.3978 (M + Na$^+$) $C_{50}H_{61}N_4O_{11}PNa$ requires 947.3967.

Oligonucleotide Synthesis and Purification. Standard DNA phosphoramidites, solid supports, and additional reagents were purchased from Link Technologies or Applied Biosystems, Ltd. The psoralen C6 phosphoramidite was purchased from Glen Research, Inc. All oligonucleotides were synthesized on an Applied Biosystems 394 automated DNA/RNA synthesizer using a 1.0 μmol phosphoramidite cycle of acid-catalyzed detritylation, coupling, capping, and iodine oxidation. Normal monomers (A, G, C, and T) were allowed to couple for 25 s and all other monomers for an additional 300 s. Stepwise coupling efficiencies and overall yields of monomers with DMT protection were determined by measuring trityl cation conductivity and in all cases were >98.0%.

The deprotection mixture for cleavage of the levulinoyl group from the lev dU monomer was prepared by adding hydrazine monohydrate (30.3 μL) to a stirred solution of distilled pyridine and acetic acid (4:1, 2.5 mL). Deprotection was achieved as follows: An empty 1 mL luer tipped syringe was fitted to one end of the column and a 1 mL luer tipped syringe filled with the deprotection mixture to the other end. The mixture was slowly pushed through the column from one syringe to the other and the process repeated every 3 min. After 12 min, the deprotection solution was removed by syringe, and the column was washed with acetonitrile (6 × 1 mL). It was then returned to the DNA synthesizer for addition of the psoralen C6 phosphoramidite.

5'-**Pso**-TMTMTPGPTPM**T**^{Pso}-prop-3'	13

[a] Oligonucleotides **5**·**6** form the duplex that contains the target site for the TFOs. The TpA steps in the target are shown in bold, and the binding site for the TFOs is underlined. Pso indicates 5′-psoralen (4′-(methoxyhexyl)-4,5′,8-trimethylpsoralen), while **T**^{Pso} corresponds to 5-(6-*O*-levulinoylhex-1-ynyl)-2′-deoxyuridine attached psoralen via an extended hexynyl linker. M and P correspond to 3-methyl-2-aminopyridine-2′-deoxyriboside and 5-(3-aminoprop-2-ynyl)deoxyuridine, respectively. **9** and **10** contain a 3′-phosphate, while **13** has a propanol attached to the 3′-phosphate.

Cleavage of the oligonucleotides from the solid support was carried out in a mixture of *t*-butylamine, methanol, and water (1:1:2) at room temperature for 20 h.

The sequences of the oligonucleotides used in this work are shown in Table 1

Oligonucleotide Purification. Purification of oligonucleotides was carried out by reversed-phase HPLC on a Gilson system using an ABI Aquapore column (C8), 8 mm × 250 mm, pore size 300 Å, controlled by *Gilson 7.12* software. The following protocol was used: Run time 30 min, flow rate 3 mL per minute. Binary system: time in minutes (% buffer B); 0 (0); 3 (0); 5 (20); 22 (100); 25 (100); 27 (0); 30 (0). Elution buffer A: 0.1 M ammonium acetate, pH 7.0. Buffer B: 0.1 M ammonium acetate with 50% acetonitrile pH 7.0 (modified oligomers). Buffer B: 0.1 M ammonium acetate with 25% acetonitrile pH 7.0 (unmodified oligomers). Elution was monitored by ultraviolet absorption at 295 nm (unmodified oligomers) or 305 nm (psoralen-containing oligomers). After HPLC purification, oligonucleotides were desalted using disposable NAP 10 Sephadex columns (Pharmacia) using the manufacturer's instructions, aliquoted into Eppendorf tubes, and stored at −20 °C in distilled deionized water.

Ultraviolet Melting Experiments. UV melting experiments were performed on a Varian Cary 400 Scan UV−visible spectrophotometer, in Hellma SUPRASIL synthetic quartz, 10 mm path length cuvettes, monitoring at 260 nm, at a 1 μM concentration of duplex strands and 10 μM of TFO, in a volume of 1.5 mL. The sample chamber was flushed with air pumped through a desiccant to prevent condensation of atmospheric water on the cells. Samples were prepared as follows: The third strand and duplex were mixed in a 2 mL Eppendorf tube, then lyophilized before resuspending in 1.5 mL of the appropriate buffer solution (50 mM sodium acetate at pH 5.0 containing 200 mM NaCl or 10 mM sodium phosphate at pH 7.0 or 7.5, containing 200 mM NaCl and 1 mM EDTA). The samples were then filtered into the cuvettes with Kinesis regenerated cellulose 13 mm, 0.45 μM syringe filters. Following an initial heating and cooling cycle (20−80−5 °C at 10 °C/min) to ensure uniform annealing of the strands, the UV−melting curves were recorded for three consecutive heating and cooling cycles (20 °C to 80 °C to 20 °C at 0.5 °C/min). Melting curves were then repeated over the triplex melting range at a slower rate of heating and cooling (0.12 °C/min) to eliminate hysteresis.

Fluorescence Measurements. Fluorescence measurements were carried out using a Perkin-Elmer LS 50B luminescence spectrometer. The samples were irradiated for 1 h using a 6 W

Table 2. Thermal Stability (T_m, °C) and Cross-Linking (%) of Triplexes Formed between Psoralen-Linked Oligonucleotides and Duplex 5·6[a]

[a] The reactions were performed in 50 mM sodium acetate pH 5.0 containing 200 mM NaCl.

UVGL-58 Mineralight lamp at 365 nm, with readings taken after 1, 2, 4, 10, 15, 30, and 60 min. The excitation wavelength for psoralen was 340 nm, the slit width was 4 nm, and the scan speed was 120 nm/min. Solutions were prepared using buffer solutions as mentioned above; the concentration of the TFO was 5 μM, and the concentration of the duplex was 25 μM.

Cross-Linking and Gel Electrophoresis. Synthetic oligonucleotides were radiolabeled at the 5′-end using [γ-^{32}P]ATP and polynucleotide kinase. Each radiolabeled oligonucleotide was annealed to its unlabeled complementary strand to generate a duplex in which one strand is labeled. Triplexes were prepared with radiolabeled oligonucleotide duplex (approximately 1 nM) and TFO (10 μM) in a total volume of 30 μL in 50 mM sodium acetate at pH 5.0, containing 200 mM NaCl, or 10 mM sodium phosphate at pH 7.0 or 7.5, containing 200 mM NaCl and 1 mM EDTA, and were incubated at 20 °C for 1 h before cooling on ice for 30 min. The samples (30 μL) were added to a 96-well plate on ice and irradiated with UV light (365 nm) at a distance of 2 cm for various times. At each time point, 4.5 μL was removed and added to 4 μL of 80% formamide containing 10 mM EDTA, 10 mM NaOH, and 0.2% (w/v) bromophenol blue. Samples were heated to 100 °C for 3 min, before rapidly cooling on ice and loading onto a 14% polyacrylamide gel containing 8 M urea. Polyacrylamide gels (40 cm long and 0.3 mm thick) were run at 1500 V for 2 h and then fixed in 10% (v/v) acetic acid. These were transferred to Whatman 3MM paper and dried under vacuum at 86 °C for 1 h. The dried gels were subjected to phosphorimaging using a Molecular Dynamics Storm phosphorimager. The intensity of bands was estimated using *ImageQuant* software. For each reaction, the amounts of monoadduct and bisadduct were expressed as a percentage of total radiolabeled DNA in the lane.

RESULTS AND DISCUSSION

Oligonucleotides. A 23-mer duplex (**5·6**) was used as a target for the psoralen-linked TFOs (**7**−**13**) (Table 1, in which the 12-base pair TFO binding site is underlined). This duplex contains three 5′-TpA-3′ sites (shown in bold) for psoralen cross-linking. These are located at the 5′-end, the center, and the 3′-end of the TFO binding site. Several TFOs with the same sequence but with different points of psoralen attachment were synthesized by automated solid-phase methods. In TFOs **7**−**11**, cytosine is used for recognizing GC base pairs and thymine for recognizing AT. The internal TA inversion is recognized using guanine forming a G.TA triplet. In TFO **8**, psoralen was attached at the 5′-end using 4′-(methoxyhexyl)-4,5′,8-trimethylpsoralen phosphoramidite (Pso C6) from Glen Research, Inc., (**1**, Scheme 1) in the final step of oligonucleotide assembly.

Psoralen was attached internally or at the 3′-end as follows: The modified nucleoside, 5-(6-*O*-levulinoylhex-1-ynyl)-2′-deoxyuridine, was introduced during oligonucleotide synthesis at the desired position as a phosphoramidite monomer. This is similar to a previously reported monomer 5-(*N*(6)-*O*-levulinoyl-1-aminohexyl)-3(*E*)acrylamido)-2′-deoxyuridine (*15*), but an alkynyl group has been introduced to stabilize triplexes (*16*). After oligonucleotide assembly, the levulinoyl group was removed by treatment of the solid support with hydrazine. The column was returned to the DNA synthesizer, and Pso C6 phosphoramidite was coupled to the free hydroxyl group of the modified thymine base (**2**, Scheme 1). The synthetic strategy for incorporating the psoralen internally (and 3′) in the TFO is outlined in Scheme 1. For TFO **9** and TFO **11**, the 5′-end of the TFO was capped with acetic anhydride and *N*-methylimidazole on the DNA synthesizer prior to levulinoyl deprotection to prevent double attachment. TFO **9** and TFO **10** were synthesized using phosphate solid support, which produces an oligonucleotide with a 3′-phosphate group. Subsequently, (in TFO **13**) this was changed for a 3′-hydroxypropylphosphate due to concerns that the bis-hydroxyethylsulfonyl linkage used to introduce a 3′-phosphate might be slightly labile during levulinoyl deprotection. All oligonucleotides were prepared on a 1.0 μmol scale on an ABI 394-08 synthesizer using cyanoethyl phosphoramidite chemistry. They were deprotected in a mixture of *t*-butylamine, methanol, and water (1:1:2) at room temperature for 20 h, then purified by reversed-phase HPLC (*17*). Characterization was carried out by MALDI-TOF mass spectrometry (*18*) (Supporting Information).

UV-Melting Studies. The interaction of unlabeled TFO **7** and psoralen-linked oligonucleotides **8**−**11** with the duplex DNA target **5·6** were initially studied by ultraviolet melting at pH 5.0, and the results are shown in the first two columns of Table 2. In the absence of any TFO, duplex **5·6** gave a single transition with a T_m of 56 °C, whereas in the presence of the unmodified control TFO **7** (without attached psoralen), two transitions were observed, the lower of which (25 °C) was due to triplex melting and the higher (56 °C) to duplex melting. Significant increases in thermal stability were observed for psoralen-labeled TFOs **8**−**10**, even before UV-irradiation. The increase in T_m was 8 °C for the 5′-labeled TFO (**8**), 5 °C for the 3′-labeled sequence (**9**), and 17 °C for the 5′−3′double label (**10**). The very large increase in T_m caused by the latter is particularly striking, suggesting that the psoralens are intercalated at both duplex−triplex junctions and produce a powerful cooperative enhancement of binding to this target. TFO **11**, containing a single internally attached psoralen, did not increase the T_m relative to the unmodified TFO **7**, either because intercalation did not occur or because internal intercalation does not increase triplex stability. These triplexes were then irradiated with UV light (365 nm, for up to 60 min at 0 °C) and subjected to further melting studies. In all cases except the unlabeled control, the melting curves were totally transformed (e.g., Figure 1, TFO **11**). After irradiation, the transition due to dissociation of the TFO disappeared. A minor transition, corresponding to that of the residual duplex, was present around 56 °C, and a new high-temperature transition was observed, which presumably reflects melting of the cross-linked triplex. Shorter irradiation times produced intermediate melting profiles with a significant transition at 55 °C and a high-melting species around 75 °C. It is known that short exposure of psoralen triplexes to UV light leads to the formation of monoadducts between the

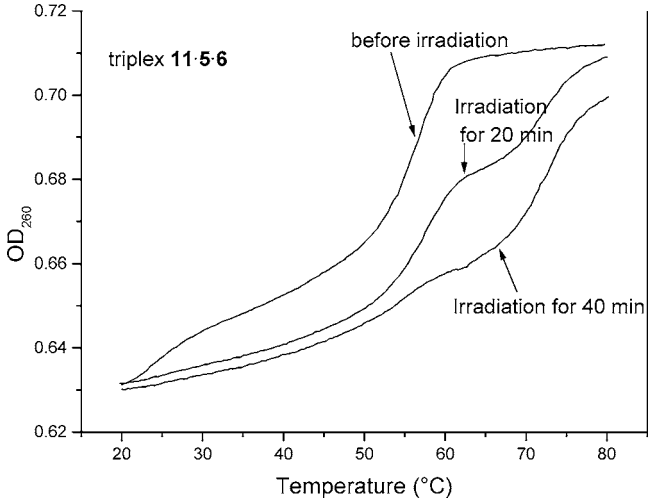

Figure 1. UV-melting profiles for the complex between TFO **11** and duplex **5·6.** The reaction was performed in 50 mM sodium acetate, 200 mM NaCl, pH 5.0. The duplex concentration was 1 μM, and the TFO concentration was 10 μM.

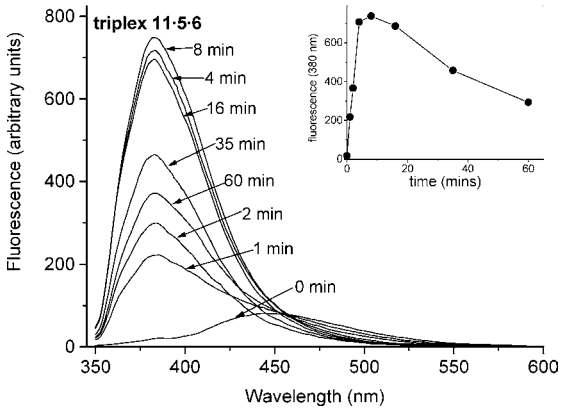

Figure 2. Fluorescence emission spectra of TFO **11** when complexed with duplex **5·6** after various emission times. The reaction was performed in 50 mM sodium acetate pH 5.0 containing 200 mM NaCl. The duplex concentration was 5 μM with a TFO concentration of 1 μM. The inset shows the time-dependent fluorescence intensity at 380 nm.

TFO and a single strand of the DNA target, and further irradiation converts these to bis-adducts (*13*). The changes in the UV-melting curves after irradiation of triplexes **8·5·6** and **9·5·6** were similar to those observed for triplex **11·5·6**. Interestingly, no melting transitions were observed after UV-irradiation of triplex **10·5·6** (Supporting Information). In this case, the psoralen moieties at both ends of the TFO can form double-strand cross-links with the duplex to produce a very stable species (a triplex staple) with no free ends to initiate the triplex melting processes. Such a species might have the added advantage of being resistant to enzymic degradation in vivo. These thermal stability measurements suggest that internally linked psoralen, as well as psoralen attached at the 3′- and 5′-ends of a TFO, can form photoreaction products with the duplex target.

Fluorescence Studies. Further proof of cross-linking between the intercalated psoralen and its target can be obtained from fluorescence measurements (*19*). TFO **11**, containing an internally attached psoralen, exhibited a weak fluorescence emission spectrum between 380 and 600 nm with maximum at 460 nm (Figure 2). Upon hybridization with the target duplex **5·6**, the intensity of the psoralen fluorescence dropped slightly, while the λ_{max} shifted from 460 to 450 nm due to fluorescence quenching of the excited state of the intercalated dye by the DNA bases. After irradiation at 365 nm to promote cross-linking, the fluorescence at 450 nm declined, and a new intense peak appeared at 380 nm due to formation of the monoadduct. Further irradiation produced a decline in fluorescence intensity due to the conversion of the monoadducts to bis-adducts (*19*). Fluorescence experiments with the other psoralen modified triplexes produced similar results. The final fluorescence intensity at 380 nm was lowest for the complex formed with TFO **8·5·6**, suggesting that the 5′-modification produces the greatest conversion to the bis-cross-linked adduct (Supporting Information).

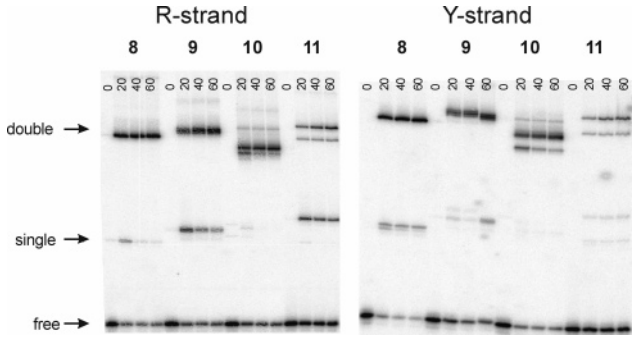

Figure 3. UV-induced cross-linking of the psoralen-linked oligonucleotides to duplex **5·6**. The target duplex was labeled on either the purine (**5**) or pyrimidine (**6**) strand. The reactions were performed in 50 mM sodium acetate pH 5.0 containing 200 mM NaCl. The concentration of the third strand was 10 μM; this was equilibrated with the duplex (approximate concentration 1 nM) for 1 h at 20 °C before irradiating for 0, 20, 40, and 60 min. The samples were then denatured and run on a 14% polyacrylamide gel containing 8 M urea. "free", "single", and "double" indicate the presence of a single DNA strand, the adduct(s) between the TFO and one strand of the duplex, and the adduct(s) between the TFO and both strands of the duplex, respectively.

Gel Electrophoresis. The propensity of psoralen-labeled TFOs to form double-strand cross-links with target duplexes was further investigated by gel-retardation analysis (*20*). One strand of the duplex was labeled at the 5′-end with [^{32}P] phosphate, and after irradiation at 365 nm, the reaction products were analyzed by denaturing polyacrylamide gel electrophoresis. Figure 3 shows the time dependence of typical experiments with TFOs **8**−**11**, and the relative intensities of the bands is shown in Table 2. With TFO **8**, the usual pattern of retarded bands is produced when the duplex is labeled on either the purine or pyrimidine strands (*20*). The lower retarded species corresponds to the monoadduct, with the TFO cross-linked to the labeled strand, while the upper (slower) band corresponds to the bis-adduct in which the TFO is linked to both strands of the duplex. The slower bis-adduct is the predominant species, and it increases with irradiation time. On the labeled purine strand, the intensity of the band due to the monoadduct decreases with longer irradiation times, suggesting that this is converted to the bis-adduct. In contrast, with the labeled pyrimidine strand, there are two monoadduct bands, the most intense of which remains constant and does not diminish with longer irradiation times. The banding pattern for the purine strand is consistent with previous observations that the furan side of the psoralen first reacts with the purine-labeled strand and that this initial cycloaddition product undergoes a second reaction involving the 3,4-double bond on the pyrone moiety of psoralen to produce the bis-adduct (*10, 21*). If the first reaction were to involve the pyrone 3,4-double bond, then this monoadduct could not be converted to the bis-adduct by further photolysis. In contrast, the small amount of stable monoadduct formed with the pyrimidine-labeled strand must correspond to reaction with the pyrone 3,4-bond, and this is not converted to the bis-adduct on further irradiation. The lower of the two pyrimidine monoadduct bands disappears with prolonged irradiation, suggesting that there is some degree of initial cross-linking of the furan moiety

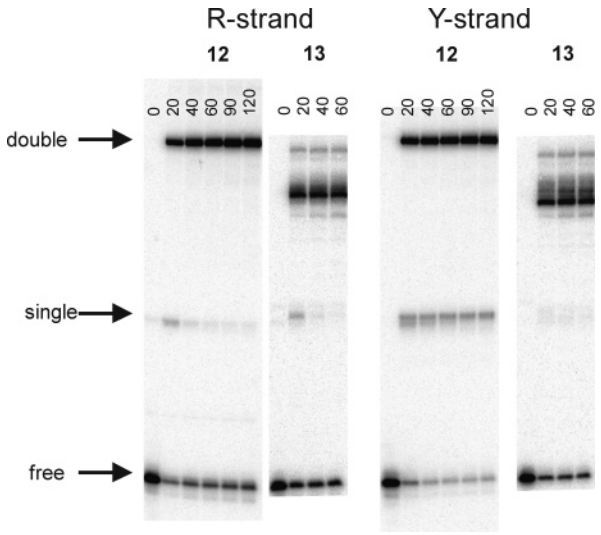

Figure 4. UV-induced cross-linking of psoralen-linked TFOs **12** and **13** to duplex **5·6**. The target duplex was labeled on either the purine-containing (**5**) or pyrimidine-containing (**6**) strand. The reactions were performed in 10 mM sodium phosphate pH 7.0 containing 200 mM NaCl and 1 mM EDTA. The concentration of the third strand was 10 μM; this was equilibrated with the duplex for 1 h at 20 °C before irradiating for 0, 20, 40, 60, and 120 min. The samples were then denatured and run on a 14% polyacrylamide gel containing 8 M urea. "free", "single", and "double" indicate the presence of a single DNA strand, the adduct(s) between the TFO and one strand of the duplex, and the adduct(s) between the TFO and both strands of the duplex, respectively.

of psoralen to the pyrimidine strand followed by cross-linking of the pyrone moiety to the purine strand. This complexity arises from the fact that there are two possible intercalation modes for psoralen at TpA sites. A similar effect is observed with TFOs **9**−**11**, though the yield of the fully cross-linked bis-adduct is lower. TFO **10**, containing two psoralen moieties, produced a more complicated pattern of cross-linked species. It is likely that the most intense band in the lanes for TFO **10** in both gels is due to a 5′,3′-double cross-link, whereas the band just below this arises from a 5′-double, 3′-single cross-link, which is almost completely converted to the upper band over the time course of the experiment. The very weak high running band has the same mobility as the double cross-links for TFOs **8**, **9**, and **11** and is probably due to a double cross-link at one end of the TFO and no cross-linking at the other end. This could arise from a minor intramolecular photoreaction between psoralen and a thymine base in the TFO, which renders the psoralen inert to reaction with the duplex. Indeed, TFO **10** has a 5′-thymine adjacent to psoralen. In TFOs **8**, **9**, and **11**, such a species would not be observed, as the inactivated TFOs would fail to interact with the duplex. Surprisingly, TFO **11** also produces a complex pattern of retarded bands, suggesting that this single central psoralen can react at more than one location, and this is the only case where a stable monoadduct is formed with the purine strand of the duplex.

Similar experiments were also performed with oligonucleotides in which the central psoralen was tethered by different length linkers (not shown). When psoralen C2 phosphoramidite was used in place of psoralen C6 in TFO **11**, only 0.5% double-strand cross-linking was observed after 60 min irradiation. A longer linker was then produced by synthesizing a TFO with hexaethylene glycol inserted between the oligonucleotide and Pso C6; this also produced a low level of cross-linking (4% double-strand cross-linking after 60 min irradiation).

These experiments were performed at pH 5.0 to ensure protonation of the third strand cytosine and therefore the formation of stable triplexes. No significant cross-linking was observed at pH 6.0 or 7.0. For nonbiological applications, e.g., in nanotechnology, TFOs can be used at low pH to reversibly attach functionality to double-stranded DNA scaffolds. However, in most biological applications, triplexes have to be stable under physiological conditions. We therefore prepared two psoralen-labeled TFOs containing modified bases (TFOs **12** and **13**) and investigated their photoreaction at pH 7.0. 3-Methyl-2-amino-pyridine-2′-deoxyriboside (M) (**3**, Scheme 1) (*22*, *23*) recognizes GC at elevated pH and 5-(3-aminoprop-2-ynyl)deoxyuridine (P) (**4**, Scheme 1) (*16*, *24*) produces stable recognition of AT. The results of experiments with these oligonucleotides at pH 7.0 are shown in Figure 4, and the relative cross-linking at pH 7.0 and 7.5 is presented in Table 3. As expected, these modified TFOs produce efficient cross-linking at pH 5.0 (not shown), which is also evident at pH 7.0 and higher.

Table 3. Cross-Linking (%) of Triplexes Formed between Psoralen-Linked Oligonucleotides Containing Modified Bases and Duplex 5·6[a]

	purine strand labeled		pyrimidine strand labeled	
TFO	monoadduct	bis-adduct	monoadduct	bis-adduct
		pH 7.0		
12	0.7 ± 0.1	80.9 ± 0.6	9.5 ± 0.5	83.2 ± 2.4
13	0.6 ± 0.2	52.9 ± 4.7	0.6 ± 0.2	60.8 ± 4.1
		pH 7.5		
12	0.8 ± 0.3	41.9 ± 13.9	4.4 ± 0.8	41.8 ± 7.2
13	0.2 ± 0.2	7.2 ± 3.3	0.0	11.3 ± 6.0

[a] The reactions were performed in 10 mM sodium phosphate pH 7.0 or 7.5, containing 200 mM NaCl and 1 mM EDTA and were irradiated for 60 min.

CONCLUSIONS

This new methodology provides a means for covalently attaching psoralen to any thymine within a triplex-forming oligonucleotide. This relaxes some of the constraints on selection of TFO target sequences. By using psoralen derivatives in combination with nucleotide analogues, triplex-directed double-stranded psoralen photoadduct formation can be achieved under near-physiological conditions.

Received July 12, 2006; Revised Manuscript Received September 22, 2006

In an approach to improve the pharmacological properties, safety and pharmacokinetic profiles, and their penetration into HIV reservoirs or sanctuaries, and consequently, the therapeutic potential of the current protease inhibitors (PIs) used in clinics, we investigated the synthesis of various mannose-substituted saquinavir, nelfinavir, and indinavir prodrugs, their in vitro stability with respect to hydrolysis, anti-HIV activity, cytotoxicity, and permeation through a monolayer of Caco-2 cells used as a model of the intestinal barrier. Mannose-derived conjugates were prepared in two steps, in good yields, by condensing an acid derivative of a protected mannose with the PIs, followed by deprotection of the sugar protecting group. With respect to hydrolysis, these PI prodrugs are chemically stable with half-life times in the 50−60 h range that are compatible with an in vivo utilization aimed at improving the absorption/penetration or accumulation of the prodrug in specific cells/tissues and liberation of the active free drug inside HIV-infected cells. These stabilities correlate closely with the low in vitro anti-HIV activity measured for those prodrugs wherein the coupling of mannose to the PIs was performed through the peptidomimetic PI's hydroxyl. Importantly, mannose conjugation to the PIs was further found to improve the absorptive transepithelial transport of saquinavir and indinavir but not of nelfinavir across Caco-2 cell monolayers, by contrast to glucose conjugation which had the opposite effect. The mannose-linked prodrugs of saquinavir and indinavir display therefore a most promising therapeutic potential provided that bioavailability, penetration into the HIV infected macrophages, and HIV-reservoirs of these PIs are improved.

INTRODUCTION

Combination therapy against AIDS using two types of inhibitors, HIV reverse transcriptase and protease inhibitors (PIs), has been remarkably successful in reducing viral load below the threshold of detectability and increasing T4 lymphocytes, leading to a decline in morbidity and mortality (*1*). However, despite these improvements, viral replication in infected patients persists, indicating the existence of reservoirs or sanctuaries for the virus, such as the lymphatic system and central nervous system (*2*−*4*), wherein the antivirals, and more particularly the PIs, do not penetrate at an inhibitory level (*5*, *6*).

To reduce total body viral replication, alternatives are to develop new more efficient PIs or to improve the pharmacological properties, safety and pharmacokinetic profiles, and, consequently, the therapeutic potential of the PIs already used in clinics. Aiming at this latter goal, we adopted the very efficient prodrug approach (*7*−*14*). This approach has been widely used for improving HIV reverse transcriptase inhibitors (*8*, *15*, *16*). It also has been applied to PIs (*9*, *17*−*19*), and successful results were obtained with the disclosure of the recently FDA-approved fosamprenavir, a phosphate ester prodrug of amprenavir (*20*−*24*). However, a number of shortcomings have still to be overcome for the PIs. Among others, the generation of "modified" PIs should display higher water solubility, increased bioavailability (plasma concentration, blood circulation time), and/or improved delivery into HIV sanctuaries. One should also be able with these "modified" PIs to (i) circumvent their inactivation resulting from their in vivo binding to mainly the plasma α_1-acid glycoprotein, (ii) limit their rapid metabolization and inactivation by the liver cytochrome P450 enzymes (mainly the 3A4 isoform), and/or (iii) inhibit their possible transport by the multi-drug-resistant P-glycoprotein (P-gp) responsible for their limited oral bioavailability and brain penetration (*25*, *26*).

In continuation of our previous studies that already showed the benefit of the prodrug approach (*27*−*30*), one of the remaining challenge is the targeting of HIV reservoirs and particularly the lymphatic system. It is well-known that macrophages and dendritic cells are professional antigen presenting cells, unique in their ability to initiate naive T cells, and primary targets for HIV-1 infection. The regeneration of these cells is of particular interest for helping the immune system to overcome the virus. Macrophages and dendritic cells abundantly express mannose receptors (*31*−*33*). Thus, receptor-mediated PIs transfer via mannose receptor offers a versatile tool for targeting PIs toward these cells (*34*−*37*). Therefore, we tagged PIs used in clinics, saquinavir (Saq), indinavir (Ind), and nelfinavir (Nelf), with a mannose residue. Although for successful and efficient targeting one should conjugate these entities to multivalent cluster glycoside moieties to obtain high-affinity ligands for the mannose receptor, as reported by several groups (*31*−*33*), we connected nevertheless the PIs to only a single and/or two mannose residues (in the case of indinavir and nelfinavir). Indeed, recognition of low molecular weight mannosides, even of monomers, by the mannose receptor was shown to be possible, albeit weak (*38*). This could be nevertheless sufficient to improve their absorption/penetration or accumulation into those reservoirs of HIV. Moreover, the development of cluster glycoside structures is a highly demanding and challenging strategy, leading to high-molecular weight compounds. This

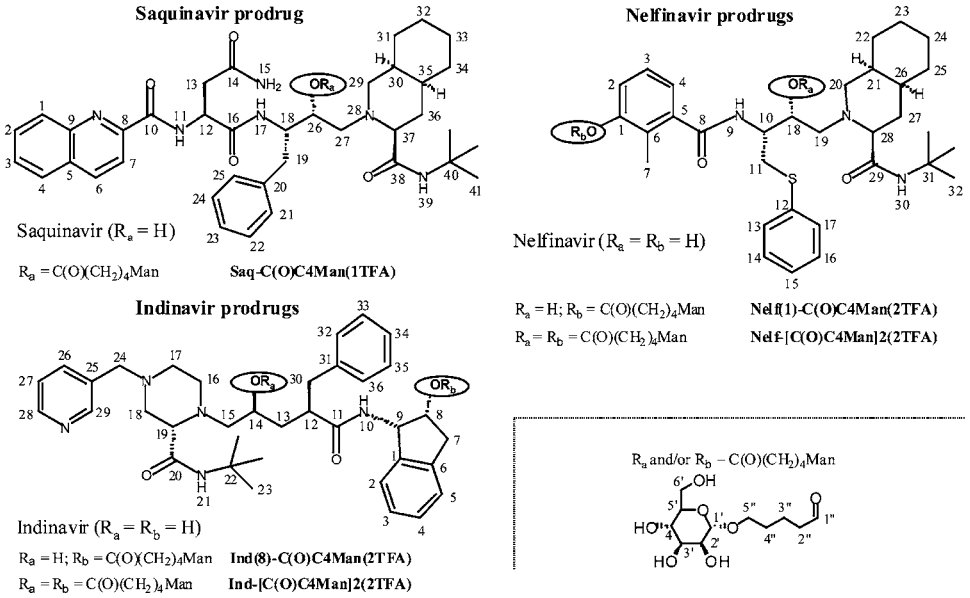

Figure 1. Chemical structures and code names of the mannose-containing protease inhibitor (PI = saquinavir, indinavir, and nelfinavir) prodrugs described in this study and atom numbering used in the description of their NMR spectra.

constitutes a drawback when the use of such high-value prodrugs as oral therapeutics against AIDS is contemplated and is also a reason for selecting mannose monovalent/divalent PI conjugates. The PI and mannose moieties were linked together through a hydrolyzable ester function. As esterases are ubiquitous in cells, in vivo hydrolysis of the ester prodrugs is expected to release the active parent drug. Although the mannose receptor tolerates ligands with large substituents at the mannose C-1 anomeric position (*39*), a spacer between the PI and mannose units was nevertheless introduced for the modulation of the chemical and biological stability of the prodrugs and for the accessibility of mannose, thus allowing a better recognition by its cellular receptors. For synthetic purposes, and as the impact of the anomeric mannosyl carbon atom on its recognition by the cellular receptor is not well established, the mannose unit was joined to the spacer through a glycoside bond of α/β configuration. This should further preserve its recognition (*39*−*42*).

This paper is dedicated to the synthesis of various mannose-derived PI prodrugs (Figure 1), their chemical stability with respect to hydrolysis under physiological conditions, and their in vitro anti-HIV activity. Using an in vitro model (i.e., Caco-2 cell monolayer) that mimics the human intestinal epithelium, we report also on their transepithelial transport. All these features are some of the prerequisites for further in vitro and in vivo investigations, including binding to and uptake into mannose receptor expressing cells and reservoirs of HIV, and pharmacokinetic studies.

EXPERIMENTAL PROCEDURES

Chemical Section. *General.* Unless otherwise indicated, the reactions were performed under anhydrous nitrogen using dry solvents and reagents. Anhydrous solvents were prepared by standard methods. Chlorotrimethylsilane, 2,2-dimethoxypropane, 1-(3-dimethylaminopropyl)-3-ethyl-carbodiimide hydrochloride (EDC), 4-dimethylaminopyridine (DMAP), lithium hydroxide, pyridine, triethylamine, *p*-toluenesulfonic acid (*p*-TsOH), and *N*,*O*-bis(trimethylsilyl)acetamide *δ*-valerolactone were purchased from Aldrich, and ammonium iodide, 2-chloropyridine, 2,6-dimethylpyridine, diphenyl sulfoxide, iodotrimethylsilane, mannose, 2-methoxypropene, trifluoroacetic acid (TFA), and trifluoromethanesulfonic anhydride were from Fluka. All these materials were used without further purification. Saquinavir, indinavir, and nelfinavir (as their methanesulfonate salt or sulfate salt) were a gift from Hoffmann-La Roche, E. Merck, and Agouron, respectively, and were deprotonated prior to their use in the synthetic processes ($CHCl_3$ or EtOAc extraction of the free base from a $NaHCO_3$ or Na_2CO_3 10% solution of the antiprotease).

Using previously described procedures, methyl 5-hydroxypentanoate was quantitatively prepared by the acid-catalyzed transesterification of *δ*-valerolactone with methanol (*43*, *44*). Because of its easy relactonization, the product was used without purification immediately after preparation [R_f 0.63 (AcOEt); ^{1}H NMR ($CDCl_3$): δ 3.80 (s, 1 H, OH), 3.38 (s, 3 H, OCH_3), 3.31 (t, *J* 6.1 Hz, 2 H, H-5), 2.07 (t, *J* 7.3, 2 H, H-2), 1.49−1.21 (m, 4 H, H-3, H-4); ^{13}C NMR ($CDCl_3$): δ 173.91 (C-1), 61.2 (C-5), 51.0 (OCH_3), 33.2 (C-2′), 31.4 (C-4), 20.8 (C-3)].

2,3;4,6-Di-*O*-isopropylidene-α-D-mannopyranoside **3α** (HO-ManP) was prepared from D-mannose in three steps consisting of the synthesis of benzyl α-D-mannopyranoside, then protection as the benzyl 2,3;4,6-di-*O*-isopropylidene-α-D-mannopyranoside, then benzyl deprotection (nearly 55% yields), as described in the literature (*45*−*47*) [R_f 0.26 (7:3 hexane-AcOEt); ^{1}H NMR (DMSO-d_6): δ 6.47 (s, 1 H, OH), 5.13 (s, 1H, H-1′), 4.70 (dd, 1 H, *J* 5.9, *J* 3.6 Hz, H-3′), 4.44 (d, 1H, *J* 5.9 Hz, H-2′), 4.24 (∼ q, 1 H, *J* 6.4, 5.8 Hz, H-5′), 4.01 (dd, 1 H, *J* 6.4, 3.6 Hz, H-4′), 3.96 (dd, 1 H, *J* 8.3, *J* 6.4 Hz, H-6′a), 3.82 (dd, 1 H, *J* 8.3, *J* 5.8 Hz, H-6′b), 1.34, 1.32, 1.26, and 1.23 (4 s, 12 H, CH_3C); ^{13}C NMR (DMSO-d_6): δ 111.3 and 107.9 ($CH_3\underline{C}$), 100.4 (C-1′), 85.5 (C-2′), 79.4 (C-3′), 79.2 (C-4′), 72.8 (C-5′), 65.9 (C-6′), 26.6, 25.7, 25.2, and 24.3 ($\underline{C}H_3$C)].

If not specified, column chromatography purifications were carried out on Silica Gel 60 (E. Merck, 70−230 mesh). The purity of all new compounds was checked by TLC, NMR, MS, and HPLC. TLC analyses were performed on precoated Silica Gel F254 plates (E. Merck) with detection by UV and by charring with 50% methanol−sulfuric acid solution, ninhydrin or $KMnO_4$. HPLC analyses of the synthesized prodrugs (flow of 1 mL/min) were performed using a HP1100 apparatus using a Lichrospher 100 RP-18 (5 μm) column (250 × 3.2 mm) with gradient A: H_2O-CH_3CN (v:v) 0.1% TFA gradient as eluent (from 80:20 to 0:100) over 30 min; UV detection at 210 nm. With these conditions, retention times (R_t) of indinavir, nelfinavir, and saquinavir are 10.4, 10.8, and 15.3 min, respectively. ^{1}H, ^{13}C, and ^{19}F NMR spectra were recorded with a Brucker AC 200 or AC 500 spectrometer at 200 (or 500), 50.3 (or 125.8),

and 188.3 MHz, respectively. Chemical shifts (δ) are given in ppm relative to the signal (i) of remaining $CHCl_3$ (δ 7.26) for ^1H, (ii) of $CDCl_3$ (δ 77.16) for ^{13}C, or of remaining water for ^1H (δ 4.87) and CD_3OD for ^{13}C (δ 49.00) when recorded in CD_3OD. Concerning the description of the prodrug NMR spectra, the atoms of the PI part are depicted as C-x and H-y, whereas those of the sugar part are depicted as C-x′ and H-y′ according to their standard nomenclature numbering and those of the linker part are depicted as C-x″ and H-y″ (see Figure 1 for numbering). COSY $^1H/^1H$, $^1H/^{13}C$ NMR correlation (on Brucker AC 500 spectrometer), ^{13}C DEPT, and/or mass spectrometry data fully confirm the signal assignments and structure of the isolated materials. The mannose-deprotected target compounds consisted of TFA salts, and the TFA anion quantification was assessed by ^{19}F NMR using 3,3,3-trifluoroethanol as an internal standard. Electron-spray ionization mass spectra (ESI-MS) were run on a Finnigan MAT TSQ 7000 apparatus equipped with an atmospheric pressure ionization source. This method used in positive mode gives either M^+, $[M + H]^+$ and/or $[M + Na]^+$ signals.

Syntheses. *Methoxycarbonylbutyl-α-D-mannopyranoside, **7α,β** and **7α**.* D-Mannose (5.0 g, 25 mmol) and *N,O*-bis(trimethylsilyl)acetamide (30 mL, 125 mmol) in anhydrous CH_2Cl_2 were stirred at room temperature for 12 h. The reaction mixture was evaporated under reduced pressure. The resulting mixture diluted in Et_2O (100 mL) was washed with 5% aq HCl, saturated aq $NaHCO_3$, and water. The organic layer was dried over Na_2SO_4 and concentrated giving a mixture of trimethylsilyl 2,3,4,6-tetra-*O*-trimetylsilyl-D-mannopyranoside **6α,β** as an oil (15 g, α:β = 79:21) [R_f 0.82 (CH_2Cl_2); ^1H NMR ($CDCl_3$): δ 4.88 (m, 1 H, H-1α); 4.62 (m, 0.27 H, H-1β); ^{13}C NMR ($CDCl_3$): δ 95.8 (C-1α), 95.7 (C-1β)]. Freshly distilled iodotrimethylsilane (1.5 mL, 11.0 mmol) was added to a solution of **6α,β** (5 g, 2.13 mmol) in dry CH_2Cl_2 (100 mL). After the sample was stirred at room temperature for 45 min, tetrabutylammonium iodide (6.75 g, 10.7 mmol) was added and stirred for 15 min more before adding a CH_2Cl_2 solution (50 mL) containing methyl 5-hydroxypentanoate (2.35 g, 16 mmol) and 2,6-lutidine (1.25 mL, 16 mmol). The reaction mixture was stirred at room temperature for 6 h, and then desilylation was performed in 30 min with MeOH (200 mL). After addition of Et_3N, the resulting solution was concentrated and purified by column chromatography (9:1 CH_2Cl_2-MeOH) affording **7α,β** as a yellow solid (2.3 g, 30% with α:β = 60:40).

R_f 0.56 (9:1 CH_2Cl_2-MeOH); ^1H NMR ($CDCl_3$): δ 5.15 (bs, 3 H, 3 OH), 4.78 (s, 0.6 H, H-1′α), 4.60 (s, 1 H, OH), 4.48 (s, 0.4 H, H-1′β), 4.10−3.72 (m, 5 H, H-2′, H-3′, H-4′, H-6′), 3.64 (s, 3 H, OCH_3), 3.64−3.18 (m, 3 H, H-5′, H-5″), 2.31 (t, *J* 7.1 Hz, 2 H, H-2″), 1.62 (m, 4 H, H-3″, H-4″); ^{13}C NMR ($CDCl_3$): δ 174.2 (C-1″), 100.2 (C-1′α,β), 77.4 (C-5′β), 74.0 (C-3′β), 72.5 (C-5′α), 71.6 (C-2′β), 71.3 (C-3′α), 71.0 (C-2′α), 69.4 (C-5″β), 67.3 (C-5″α), 66.4 (C-4′α), 66.3 (C-4′β), 61.0 (C-6′α,β), 51.7 (OCH_3), 33.8 (C-2″), 28.9 (C-4″), 21.7 (C-3″). ESI-MS (positive mode): $(M + Na)^+ = 316.9$ in agreement with the mass calculated for $M = C_{12}H_{22}O_8$ (294.13).

The same experimental procedure when applied to 1.0 g of **6α,β** gave, after several purifications by column chromatography (9:1 CH_2Cl_2-MeOH), **7α** as a yellow solid (0.46 g, 30%). R_f 0.56 (9:1 CH_2Cl_2-MeOH); ^1H NMR ($CDCl_3$): δ 5.06 (bs, 1 H, OH), 5.03 (bs, 1 H, OH), 4.95 (bs, 1 H, OH), 4.79 (s, 1 H, H-1′), 4.49 (bs, 1 H, OH), 3.94−3.88 (m, 3 H, H-2′, H-3′, H-6′a), 3.80−3.73 (m, 2 H, H-4′, H-6′b), 3.65 (bs, 4 H, H-5″a, OCH_3), 3.47 (m, 1 H, H-5′), 3.39 (m, 1 H, H-5″b), 2.32 (t, *J* 7.1 Hz, 2 H, H-2″), 1.66−1.57 (m, 4 H, H-3″, H-4″); ^{13}C NMR ($CDCl_3$): δ 174.2 (C-1″), 100.2 (C-1′), 72.4 (C-5′), 71.7 (C-3′), 71.1 (C-2′), 67.3 (C-5″), 66.4 (C-4′), 61.1 (C-6′), 51.7 (OCH_3), 33.8 (C-2″), 28.9 (C-4″), 21.8 (C-3″); ESI-MS (positive mode): $(M + Na)^+ = 316.9$ in agreement with the mass calculated for $M = C_{12}H_{22}O_8$ (294.13).

*2,3,4,6-Di-O-isopropylidene-1-(4-methoxycarbonylbutyl)-α-D-mannopyranoside, **4α**. Path A.* Trifluoromethanesulfonic anhydride (24 μL, 0.16 mmol) was added to a solution of **3α** (30 mg, 0.11 mmol) and diphenyl sulfoxide (65 mg, 0.32 mmol) in a mixture of 1:3 toluene−dichloromethane (4 mL) at −78 °C, and stirred for 5 min, then at −40 °C for 1 h. Chloropyridine (54 μL, 0.57 mmol) and methyl 5-hydroxypentanoate (43.6 mg, 0.33 mmol) were then added successively. The resulting solution was stirred at −40 °C for 1 h, at 0 °C for 30 min, and finally at 23 °C for 1 h before the addition of excess Et_3N (153 μL, 1.09 mmol). The solution diluted with CH_2Cl_2 (50 mL) was successively washed with saturated aq Na_2CO_3 and saturated aq NaCl. The organic layer was dried over Na_2SO_4 and concentrated, and the residue was purified by column chromatography (gradient elution: 10:0 to 1:1 hexane−ethyl acetate) to afford **4α** as a white solid (10 mg, 4%).

Path B. p-Toluenesulfonic acid (*p*-TsOH) (20 mg, 0.1 mmol) was added to a solution of **7α** (0.5 g, 1.70 mmol) and 2-methoxypropene (0.64 mL, 6.7 mmol) solubilized in CH_2Cl_2 (20 mL). After the sample was stirred for 6 h at room temperature, the resulting solution was made neutral with $NaHCO_3$ (8.4 mg, 0.1 mmol) and concentrated, and purification by column chromatography (98:2 CH_2Cl_2-AcOEt) afforded compound **4α** (400 mg, 63%).

R_f 0.71 (98:2 CH_2Cl_2-AcOEt); ^1H NMR ($CDCl_3$): δ 4.89 (s, 1 H, H-1′), 4.08−4.04 (m, 2 H, H-2′, H-3′), 3.81−3.57 (m, 7 H, H-4′−6′, OCH_3), 3.50−3.41 (m, 1 H, H-5″a), 3.37−3.27 (m, 1 H, H-5″b), 2.25 (t, *J* 7.0 Hz, 2 H, H-2″), 1.70−1.52 (m, 4 H, H-3″, H-4″), 1.44, 1.41, 1.32, and 1.25 (4 s, 12 H, CH_3C); ^{13}C NMR ($CDCl_3$): δ 173.6 (C-1″), 109.2 and 99.5 ($CH_3\underline{C}$), 97.7 (C-1′), 76.0 (C-2′), 74.8 (C-3′), 72.7 (C-5′), 67.2 (C-5″), 62.0 (C-6′), 61.2 (C-4′), 51.4 (OCH_3), 33.5 (C-2″), 28.7 (C-4″), 29.0, 28.1, 26.1, and 18.7 ($\underline{C}H_3C$), 21.6 (C-3″).

*2,3;4,6-Di-O-isopropylidene-1-(4-methoxycarbonylbutyl)-α,β-D-mannopyranoside, **4α,β**.* The same experimental procedure described above in path B for the preparation of **4α**, when applied to *p*-TsOH (86 mg, 0.5 mmol), **7α,β** (2.30 g, 7.82 mmol) and 2-methoxypropene (2.94 mL, 30.7 mmol) gave, after purification by column chromatography, compound **4α,β** (2.08 g, 71% with α:β = 53:47). R_f 0.71 (98:2 CH_2Cl_2-AcOEt); ^1H NMR ($CDCl_3$): δ 4.96 (s, 0.6 H, H-1′α), 4.89 (s, 0.4 H, H-1′β), 4.13−4.07 (m, 2 H, H-2′), 3.91−3.83 (m, 1 H, H-6′a), 3.79−3.65 (m, 7 H, H-3′, H-4′β, H-5′α, H-6′b, H-5″a, OCH_3), 3.58−3.49 (m, 1 H, H-4′α, H-5′β), 3.46−3.38 (m, 1 H, H-5″b), 2.32 (t, *J* 7.0 Hz, 2 H, H-2″), 1.92−1.80 (m, 2 H, H-3″), 1.73−1.59 (m, 2H, H-4″), 1.52, 1.49, 1.40 and 1.32 (4 s, 12 H, CH_3C); ^{13}C NMR ($CDCl_3$): δ 174.0 (C-1″), 109.5 and 99.8 ($CH_3\underline{C}$), 98.9 (C-1′β), 97.9 (C-1′α), 76.2 (C-3′β), 76.1 (C-2′α), 75.0 (C-3′α, C-2′β), 72.9, 72.8 (C-5′α, C-4′β), 67.4 (C-5″), 62.2 (C-6′α,β), 61.4, 61.3 (C-4′α, C-5′β), 51.6 (OCH_3), 33.8 (C-2″), 28.9 (C-4″), 29.1, 28.3, 26.2, and 18.8 ($\underline{C}H_3C$), 21.8 (C-3″).

*2,3;4,6-Di-O-isopropylidene-1-(4-carboxybutyl)-α-D-mannopyranoside, **5α**.* A 1 N LiOH aq solution (2 mL) was added to **4α** (200 mg, 0.53 mmol) in THF (2 mL) cooled at 0 °C. After 12 h at room temperature, the resulting solution was made neutral with 1 N HCl. After evaporation of THF, the product was extracted with CH_2Cl_2, dried over Na_2SO_4, filtered, and concentrated. **5α** was obtained almost quantitatively as a colorless oil (187 mg, 98%); R_f 0.38 (96:4 CH_2Cl_2−AcOEt); ^1H NMR (CD_3OD): δ 4.94 (s, 1 H, H-1′), 4.11 (d, *J* 5.7 Hz, 1 H, H-2′), 4.01 (dd, *J* 7.6, 5.7 Hz, 1 H, H-3′), 3.82−3.64 (m, 4 H, H-4′−6′), 3.50−3.38 (m, 2 H, H-5″), 2.28 (t, *J* 6.9 Hz, 2 H, H-2″), 1.58−1.55 (m, 4 H, H-3″, H-4″), 1.43 (s, 6 H, CH_3C), 1.26, and 1.24 (2 s, 6 H, CH_3C); ^{13}C NMR (CD_3OD): δ 177.6

(C-1″), 110.4 and 100.8 (CH_3**C**), 99.1 (C-1′), 77.5 (C-2′), 76.2 (C-3′), 74.1 (C-5′), 68.4 (C-5″), 63.0 (C-6′), 62.6 (C-4′), 34.8 (C-2″), 29.9 (C-4″), 29.4, 28.4, 26.5, and 19.2 (**C**H_3C), 22.9 (C-3″).

*2,3;4,6-Di-O-isopropylidene-1-(4-carboxybutyl)-*α,β*-*D*-mannopyranoside,* ***5α,β***. The same experimental procedure as described above for the preparation of **5α**, when applied to ***4α,β*** (2.0 g, 5.35 mmol) gave ***5α,β*** (1.77 g, 92%) as a white solid; R_f 0.38 (96:4 CH_2Cl_2-AcOEt); ^{1}H NMR (CD_3OD): δ 4.09 (dd, *J* 5.5, 2.3 Hz, 1 H, H-2′), 4.00 (m, 1 H, H-6′a), 3.81−3.36 (m, 7 H, H-4′−5′, H-6′b, H-5″), 2.13 (m, 2 H, H-2″), 1.59−1.50 (m, 4 H, H-3″, H-4″), 1.32, 1.28, 1.26, 1.20 (4s, 12 H, CH_3C); ^{13}C NMR (CD_3OD): δ 180.4 (C-1″), 110.5 and 100.9 (CH_3*C*), 100.1 (C-1′ *β*), 99.1 (C-1′α), 77.6 (C-3′ *β*), 77.4 (C-2′α), 76.3 (C-3′α, C-2′ *β*), 74.2, 74.1 (C-5′α, C-4′ *β*), 68.8 (C-5″), 63.1 (C-6′α,*β*), 62.6, 62,5 (C-4′α, C-5′*β*), 38.9 (C-2″), 30.5 (C-4″), 29.4, 28.4, 26.5, 24.3, 19.1 and 18.4 (**C**H_3C), 24.4 (C-3″).

Nelf(1)-C(O)C4Man and Nelf-[C(O)C4Man]2. General Esterification Method. EDC (101 mg, 0.53 mmol) was added to a solution of ***5α,β*** (190 mg, 0.53 mmol), DMAP (65 mg, 0.53 mmol), and nelfinavir (300 mg, 0.53 mmol) in CH_2Cl_2 (10 mL) at 0 °C. Then, the mixture was stirred for 15 min at 0 °C then for 19 h at room temperature. The reaction mixture was washed, and the organic layer was dried over Na_2SO_4 filtered, and evaporated under reduced pressure. Then, the residue was chromatographed three times on silica gel (100:0 to 98:2 CH_2Cl_2-EtOH) to give Nelf(1)-C(O)C4ManP (130 mg, 27% with α:*β* = 55:45) and Nelf-[C(O)C4ManP]2 (80 mg, 12% with α:*β* = 55:45) as white solids.

Deprotection of Ind-[C(O)C4ManP]2 (80 mg, 0.06 mmol) led, after chromatography (10:0 to 4:1 EtOAc-MeOH), to Ind-[C(O)C4Man]2 (2TFA) (78 mg, 95% with α:β = 60:40) as a white solid; R_f 0.48 (7:3 EtOAc−MeOH); R_t 9.0 min (gradient A); ^{1}H NMR (CD_3OD): δ 8.50 (m, 2 H, H-28, H-29), 7.85 (d, *J 7.7* Hz, 1 H, H-26), 7.45 (s, 1 H, H-21), 7.38 (m, 1H, H-27), 7.29−7.22 (m, 10 H, H-2−5, H-10, H-32−36), 5.62 (d, *J* 4.8 Hz, 1 H, H-9), 5.48 (m, 1 H, H-8), 5.16 (m, 1 H, H-14), 4.76 (1s, 0.6 H, H-1′αint), 4.71 (1s, 0.6 H, H-1′αext), 4.51 (1s, 0.4 H, H-1′βint), 4.39 (1s, 0.4 H, H-1′βext), 3.94−3.41 (m, 19.2 H, H-2′$\alpha\beta$, H-3′$\alpha\beta$, H-4′α, H-5′$\alpha\beta$, H-6′$\alpha\beta$, H-5″$\alpha\beta$, H-15, H-24), 3.26−3.17 (m, 2 H, H-7a, H-19), 3.00−2.87 (m, 4.8 H, H-4′β, H-7b, H-12, H-18a, H-30a), 2.72−2.39 (m, 13 H, H-2″, H-13a, H-15, H-16, H-17, H-18b, H-30b), 1.72−1.53 (m, 9 H, H-3″, H-4″, H-13b), 1.30 (s, 9 H, H-23); ^{13}C NMR (CD_3OD): δ 177.4 (C-11), 175.1 (C-1″int), 174.7 (C-1″ext), 172.8 (C-20), 150.9 (C-29), 149.0 (C-28), 141.5 (C-31), 141.1, 140.3 (C-1, C-6), 139.3 (C-26), 132.4 (C-25), 130.2 (C-32, C-36), 129.5 (C-33, C-35), 129.3 (C-2), 128.2, 127.6 (C-3, C-4), 125.9 (C-34), 125.3 (C-5, C-27), 101.68, 101.60, 101.56, and 101.48 (C-1′α and C-1′β), 78.22 and 78.16 (C-5′β), 76.9 (C-8), 75.31 and 75.23 (C-3′β), 74.62 and 74.55 (C-5′α), 72.68, 72.65, 72.56, and 72.48 (C-2′β, C-3′α), 72.2 (C-2′α), 71.1 (C-14), 70.1 and 70.0 (C-5″β), 68.65, 68.61, and 68.51 (C-19, C-4′$\alpha\beta$), 68.1 and 68.0 (C-5″α), 62.9, 62.8, and 62.7 (C-6′$\alpha\beta$), 60.4 (C-24), 59.9 (C-15), 56.8 (C-9), 56.3 (C-18), 53.1, and 52.1 (C-16, C-17), 51.8 (C-22), 45.2 (C-12), 40.7 (C-30), 38.3 (C-7), 35.1 (C-13) 34.9 and 34.7 (C-2″), 30.1 and 30.0 (C-4″$\alpha\beta$), 29.0 (C-23), 22.8, 22.6, and 22.5 (C-3″$\alpha\beta$). ESI-MS: *m*/*z* 1138.5 $[M + H]^+$, 1160.6 $[M + Na]^+$, in agreement with the calculated mass for [M] = $C_{58}H_{83}N_5O_{18}$ (1137.57).

Biological Section. *Materials.* 1-Pentanesulfonic acid sodium salt, sodium acetate trihydrate, and acetonitrile were high-performance liquid chromatography (HPLC) grade. Foetal bovine serum (FBS), Dulbecco's phosphate buffered saline (DPBS), penicillin−streptomycin solution (5000 U/mL:5000 μg/mL), trypsin-EDTA 0.25% solution (2.5 g trypsin and 0.2 g EDTA in 1 L DPBS), D-(+)-glucose, and *N*-[2-hydroxyethyl]-piperazine-*N*-ethanesulfonic acid (HEPES) were purchased from Sigma Chemical (St Quentin Fallavier, France). Dulbecco's modified eagle's medium (DMEM) and nonessential amino acids DMEM 100× (NEAA) were purchased from Gibco-Life Technologies (Cergy-Pontoise, France). Transport Medium (TM) consisted of DPBS containing 25 mM glucose and 10 mM HEPES (pH 7.4). Cell culture medium consisted of DMEM supplemented with 20% foetal bovine serum, 1% NEAA, and 2% penicillin−streptomycin.

HPLC Conditions for Chemical Stability and Transport Experiments. All HPLC analyses used for chemical stability and transport experiments were performed using a HP1100 apparatus with a Lichrospher 100 RP-18 (5 μm)-packed column (250 × 3.2 mm) with a flow rate of 1 mL/min. The isocratic mobile phase consisted of $CH_3COONa{\cdot}3H_2O$ (15 mM) and $CH_3(CH_2)_4SO_3Na$ (15 mM), 5 mM pH 6 buffer and CH_3CN: 59:41 for Ind, Ind(8)-C(O)C4Man and Ind-[C(OC4Man]2, 41:59 for Saq and Saq-C(O)C4Man, and 45:55 for Nelf, Nelf(1)-C(O)C4Man and Nelf(1)-[C(O)C4Man]2. The prodrugs and/or drugs were detected by measuring their UV absorption at 210 (Ind, Nelf, and their derivatives) or 254 nm (Saq and its derivative) and the signals (peak integration) were interpreted by the software provided. Under their respective HPLC conditions, the retention times measured for the different compounds were of 4.9 min for Ind, 3.5 min for Ind(8)-C(O)C4Man, 3.3 min for Ind-[C(OC4Man]2, 5.6 min for Saq, 5.0 min for Saq-C(O)C4Man, 12.5 min for Nelf, 5.2 min for Nelf(1)-C(O)C4Man, 4.8 min for Nelf-[C(OC4Man]2. The prodrug and/or drug concentration was determined from HPLC calibration curves. These curves were established under the same HPLC conditions, using standard calibrated prodrug and drug solutions that were prepared in the same hydrolysis medium as the sample under investigation. The calibration curves were linear (correlation coefficients from 0.9993 to 0.9998) in a concentration range of 0.4 to 1143 μM for Ind and its prodrugs, 0.1 to 300 μM for Saq and its prodrug, and 0.1 to 301 μM for Nelf and its prodrugs, the lower limit corresponding to the limit of detection that can be quantified with accuracy. Above the lower concentration limit, the analytical method was reproducible.

Hydrolysis. Hydrolysis experiments were performed by incubating 20 mL of a DMEM-MeOH solution (pH 7.3) of the prodrug (250 μg/mL) at 37 °C with stirring. The amount of MeOH (v/v) in these solutions was 4% for Ind(8)-C(O)C4Man, 5% for Ind-[C(OC4Man]2, 3% for Saq-C(O)C4Man, and 5% for Nelf(1)-C(O)C4Man. Hydrolysis was followed by HPLC monitoring of either the disappearance of the prodrug and appearance of the parent drug by injecting 40 μL of the solution onto the HPLC column (for HPLC conditions see above). Plots of $\ln([\text{prodrug}]_o - [\text{prodrug}(t)])$ and of $\ln[\text{drug}(t)]$ against time were linear within the concentration range studied, indicating that the hydrolysis is a first-order process with respect to the prodrug. The half-lives of hydrolysis ($t_{1/2}$) were measured, when possible, or calculated from these plots; $t_{1/2}$ is related to the slope, *K*, of these curves by the relation $t_{1/2} = (\ln 2)/K$.

Caco-2 Cell Monolayers. Caco-2 cells, clone TC7, were kindly provided by Dr. A. Zweibaum (INSERM U178, Villejuif, France). The cells were routinely maintained in 75 cm^2 culture flasks at 37 °C in an atmosphere containing 5% CO_2 and 95% relative humidity. Cells were split every 7 days at a density of 1.5×10^6 cells/flask. For the transepithelial transport experiments, Caco-2 cells (passage 60−65) were harvested with trypsin-EDTA and seeded on Anopore membrane inserts (0.2 μm pore diameter, 25 mm diameter; Nunc, Roskilde, Denmark) at a density of 5×10^5 cells/insert (cm^2). Apical (AP) and basolateral (BL) chamber volumes were maintained at 2 mL. Culture medium was changed every 3−4 days and cells were used for the experiments between days 14 and 27 post-seeding. Monolayer formation was monitored by measurement of trans-epithelial electrical resistance (TEER) using a Millicel ERS apparatus (Millipore).

Transport Experiments. Before the transepithelial transport experiments, the Caco-2 monolayers were rinsed twice with the transport medium (TM) (both chambers) and preincubated for 30 min in the TM. After this equilibration period, the monolayer integrity was checked by measuring its TEER. For the transport experiments, only monolayers displaying TEER values above 176 Ω·cm^2 and for which TEER values fell by less than 15% from the value measured at the end of the equilibration period were used. Under these conditions, the age of the cell monolayer within the 14−27 day's postseeding range did not affect the transport results. Transport was initiated by replacing the TM in the AP or in the BL "donor" compartment with 2 mL of the drug or prodrug solution. AP and BL chamber volumes were maintained at 2 mL. The test solutions were prepared by mixing a known amount of TM with a concentrated MeOH stock solution of the drug or prodrug under investigation to reach a final concentration of the drug or prodrug in the 230−300 μM, 280 μM, and 252−344 μM range for the indinavir, saquinavir, and nelfinavir derivatives, respectively (the exact concentrations used for each derivative are given in the figures showing their transepithelial transport). The final MeOH concentration in the drug or prodrug solutions in contact with the monolayers never exceeded 3% MeOH (TEER monitoring and transport experiments have shown that MeOH at concentrations up to 5% did not affect cell monolayer integrity during the 3-h period of transport experiment nor the amount of drug and/or prodrug transported, respectively). 200 μL samples were withdrawn from the "acceptor" compartment (opposite to the addition "donor" chamber) every 1 h over a period of 3 h and replaced by the same amount of fresh transport medium to maintain the same volume. The dilution was taken into account for the calculations. To prevent hydrolysis of the prodrugs, all these samples were stored at 4 °C awaiting prodrug and/or parent drug HPLC-analysis (see above section: HPLC conditions). At the end of the experiments (3 h), samples were also taken from the "donor" compartment for HPLC analysis, and the monolayers were checked for integrity by measuring TEER values. The concentrations of the prodrug and parent drug that were measured in the donor and acceptor chamber at the end of the transport experiment indicated that no nonspecific adsorption on glass or on plastic had occurred. The experiments for which TEER has decreased by more than 8% from the value measured at the beginning of the experiment were discarded. Transport was expressed as a percentage of the initial amount added to the donor compartment. All flux experiments were conducted at least in triplicate in the AP to BL and BL to AP directions. If possible, a concentration of the prodrug in the donor chamber the closest to that of the parent drug was preferred, but solubility issues of the prodrug (which needed in some cases the use of MeOH) and detection issues of the prodrug and/or parent drug in the acceptor chamber were also considered for the selection of the prodrug concentration.

Data Analysis for the Transport Experiments. The apparent permeability coefficients P_{app} (cm/s) were calculated by linear regression analysis on the time course plot of amount of (pro)-drug transported from equation $P_{app} = k(V_D/A)$, where k is the slope of the linear curve $\ln(C_t/C_o) = -kt$, C_t being the (pro)-drug concentration in the receiver chamber at time t, C_o is the initial concentration in the donor chamber, A is the membrane surface area (4.52 cm^2), and V_D is the volume of the donor chamber (2 cm^3). These calculations were performed for each transport experiment, and the values that are reported in Table 3 represent the means (±SD) of at least three independent experiments.

RESULTS AND DISCUSSION

Synthesis. The mannose-derived PI prodrugs shown in Figure 1 were prepared in two steps by condensing the saquinavir, indinavir, or nelfinavir with the key acid synthon **5α,*β***, a protected mannosylated derivative, followed by deprotection of the sugar protecting group (Scheme 1). Owing to the difficulties to prepare large amounts of pure **5α** or **5*β***, the synthon **5** was used as a mixture of α/*β* anomers. The esterification (first step) of the PI hydroxyl(s) was the limiting step. Indeed, the deacetalation of the protected mannose unit in the various saquinavir, indinavir, or nelfinavir was performed with 90−95% yields. Note that all the mono- and diester PI-prodrugs were isolated as mixtures of α,*β*-D-mannose anomers (see below).

Concerning saquinavir, acylation of its unique hydroxyl was performed in 71% yield using conventional EDC/DMAP as coupling reagent (*48*). Concerning indinavir and nelfinavir, which both contain two hydoxyls, and in line with previous work (*27*−*29*), a stochastic esterification, one to one equivalent, was preferred instead of a more tedious and time-consuming protection/deprotection strategy of one of these two hydoxyls. The stochastic esterification led into the formation of a mixture of mainly the monoester and diester resulting from the esterification of the C1-hydroxyl of nelfinavir and C8-hydroxyl of indinavir, and of both hydroxyls, respectively. Only tiny amounts (less than 2%) of the monoesters corresponding to the esterification of the C18-hydroxyl of nelfinavir and C14-hydroxyl of indinavir were detected. In the case of indinavir and nelfinavir esters, monoester versus diester formation was favored but only slightly by contrast with what we noticed for all nelfinavir or indinavir prodrugs synthesized so far, using the same reaction conditions (*27*−*29*). Indeed, acylation of indinavir (respectively nelfinavir) with acid **5α,*β*** led to a 1.5:1 (respectively 2.2:1) mixture of monoester Ind(8)-C(O)C4ManP (respectively Nelf-(1)-C(O)C4ManP) and diester Ind-[C(O)C4ManP]2 (respectively Nelf-[C(O)C4ManP]2). By contrast, and as reported elsewhere, reaction of indinavir with 1,2:5,6-di-*O*-isopropylidene-3-*O*-(4-carboxybutyl)-α-D-glucofuranose, a close analogue of the mannosylated acid **5α,*β***, produced a 4:1 mixture of the monoester and diester adducts (*29*). Deprotection of the mannose unit in the saquinavir, indinavir, or nelfinavir conjugates was performed using aqueous TFA and afforded almost quantitatively the target Saq-C(O)C4Man(TFA), Ind(8)-C(O)C4Man(2TFA), Ind-[C(O)-C4ManP]2(2TFA), Nelf(1)-C(O)C4Man(2TFA), and Nelf-[C(O)-C4ManP]2(2TFA) prodrugs, respectively.

Concerning the synthesis of the starting mannose-derived building block **5** and owing to the presence of several hydroxyl groups on mannose with close reactivity, protection/deprotection steps were needed to prepare this key synthon. Moreover, as this synthon was linked to the PI via an ester linkage, the use of protecting groups for the sugar part that are labile under basic conditions was precluded. Therefore, we selected the isopropylidene acid-labile acetal protection, which has further been shown to be highly compatible for similar glucosylated derivatives (*29*). To the best of our knowledge, examples of glycosylation with saccharides containing a 2,3-isopropylidene protecting group used as a glycoside donor are few (*49*−*54*), and only one concerns the mannopyranose moiety (*53*). In our hands, this latter strategy failed. Indeed, the glycosylation of methyl 5-hydroxypentanoate with 2,3;4,6-di-*O*-isopropylidene α-D-mannopyranose derivative **3α** (HO-ManP) (Scheme 1, path A) gave the target molecule **4α** in 4% yield only.

To overcome this drawback, another strategy was attempted where the diisopropylidene protection was performed after the glycosylation step using a more conventional procedure (Scheme 1, path B). The glycosylation was achieved using the very labile trimethylsilyl group as transient intermediate protecting group adapting a process described in literature for the preparation of an analogous mannosylated derivative (*55*). The transitory persilylated mannopyanose **6α,*β*** (obtained as a 80:20 α/*β*

[a] Refs *28* and *29*.

anomeric mixture, according to ^1H NMR) was prepared from D-mannose using either *N,O*-bis(trimethylsilyl)acetamide in dichloromethane or a mixture of chlorotrimethylsilane and 1,1,1,3,3,3-hexamethyldisilazane in pyridine, the former conditions being preferred. Then, action of iodotrimethylsilane gave the in situ persilylated mannopyranosyl iodide which, by reaction with methyl 5-hydroxypentanoate followed by desilylation, afforded methyl ester **7α,*β*** in 30% yield as a 60:40 α/*β* mixture according to ^1H NMR (see below). Pure **7α** could be separated and isolated from this mixture after several column chromatographies. The acetalation protection was then performed by action of 2-methoxypropene on **7α,*β*** giving **4α,*β*** in 71% yield. Saponification released almost quantitatively the acid intermediate **5α,*β*** (20% overall yield from D-mannose). In the same way, the anomeric material **5α** was obtained from **7α**.

The chemical structures of (i) all protected and deprotected PI prodrugs, which consist into mixtures of α,*β*-D-mannose anomers, (ii) anomeric mixtures of **4α,*β*/5α,*β*/7α,*β***, and (iii) pure **4α**/**5α**/**7α** were unambiguously ascertained by ^1H,^{13}C NMR and mass spectrometry. That each of the protected and deprotected PI prodrugs consisted of a mixture of α,*β*-D-mannose anomers was shown by the presence of anomeric H-1α and H-1*β* singlets in approximately 64:36 to 52:48, which are close to that of the 53:47 protected material **4α,*β***, and of anomeric C-1α and C-1*β* resonances in its ^1H and ^{13}C NMR spectrum, respectively (see Table 1). The α/*β* assignment was attested by comparison of these NMR signals with those collected for pure **4α**, **5α**, and anomeric **4α,*β*** or **5α,*β*** mixtures (see Table 1) and by comparison with the ^1H (*55*−*57*) and ^{13}C NMR data for similar derivatives (*55*, *56*, *58*). For instance, the α and *β* configurations of **4** are confirmed by the anomeric H-1α and H-1*β* singlets at 4.96 and 4.89 ppm, respectively, the C-13α and C-13*β* resonances determined by 2D experiments being at 97.9 and 98.9 ppm, respectively (*55*, *59*). The variations of α:*β* ratios of the various protected and deprotected PI prodrugs were essentially due to the purification steps which were performed by column chromatography.

That formation of the monoesters occurred on the C-26 saquinavir, C-8 indinavir, and C-1 nelfinavir hydroxyls is also unambiguously established by ^1H and ^{13}C NMR. As expected, the resonances of the corresponding H-26 (respectively H-8) proton and C-26 (respectively C-8) carbon atoms of the saquinavir (respectively indinavir) derivative, are deshielded ($|\Delta\delta| = 1.25-1.38$ ppm and $|\Delta\delta| = 3.7-7.6$ ppm, respectively) in comparison with those of the parent PI. For nelfinavir, acylation of its aromatic C-1 hydroxyl resulted in the shielding ($|\Delta\delta| = 5.9$ ppm) of the C-1 carbon resonance (*60*, *61*), as expected for phenyl esters. Furthermore, the resonances of the

[a] δ in ppm, *J* in Hz. [b] Singlet unless otherwise stated. [c] Hindered by the residual peak of water. [d] C-8/C-14 means that the mannosylated residues are connected to the indinavir C-8/C-14 atom, respectively. [e] Could not be assigned to the indinavir C-8 or C-14 connecting position [f] Could not be assigned to the nelfinavir C-1 or C-18 connecting position.

H-14/C-14 indinavir and H-18/C-18 nelfinavir atoms bearing the remaining "free" hydroxyl and of their vicinal β-carbon atoms are almost not affected. These resonances are deshielded in the diesters, confirming that acylation of the two hydroxyls of indinavir and nelfinavir has occurred. All these trends are in line with those reported for the C-14/C-8 indinavir and C-18/C-1 nelfinavir prodrugs (*27*−*29*).

Concerning the protected and deprotected diester prodrugs derived from indinavir or nelfinavir, their $^{1}H/^{13}C$ NMR spectra are very complex. This is due to the presence of four isomers consisting of the α/α-, α/β-, β/α-, and β/β- connection of the mannose moiety to each of the two hydroxyl groups of the PI. Indeed, their $^{1}H/^{13}C$ NMR spectra exhibit four signals for the α/β anomeric H/C atoms, two sets for each of the C14α/β- and C8-α/β-indinavir (respectively, C18- and C1-nelfinavir) α/β-anomers, as expected (see Table 1).

Mannose-deprotection is confirmed among others by the absence of the characteristic isopropylidene resonances in the NMR spectra of the isolated deprotected PI prodrugs.

Biological Activity and Chemical Stability. The saquinavir hydroxyl, the indinavir C-14 but not the C-8 hydroxyl, and the nelfinavir C-18 but not the C-1 hydroxyl, are involved in the peptidomimetic noncleavable transition state isostere responsible for the protease inhibitory potency of saquinavir, indinavir, and nelfinavir, respectively (*62*). Therefore, it is most important that these hydroxyls be accessible for antiviral activity. In the previous studies dedicated to the ester prodrugs of saquinavir, indinavir, and nelfinavir (*27*, *28*), a close correlation between their anti-HIV activity and the hydrolysis of their acylated "peptidomimetic" hydroxyl, hence the liberation of the active free drug during the time of incubation, was found: the faster the hydrolysis, the closer the anti-HIV activity level to that of the respective parent drug. Concomitantly, the level of HIV inhibition was very low for the prodrugs for which hydrolysis and release of this peptidomimetic hydroxyl was very slow. On the other hand, no correlation was found between the hydrolysis rate of the acylated C-8 indinavir prodrugs (C-8 hydroxyl is not part of the transition state isostere) and their anti-HIV activity (*27*). The HIV inhibition levels and cytotoxicities of D-mannose-containing saquinavir, indinavir, and nelfinavir prodrugs (as their TFA salt) were evaluated in vitro in CEM-SS and MT4 cells against HIV-1 according to published procedures (*63*−*65*). The data are collected in Table 2 together with those of saquinavir and nelfinavir (*66*) (as their methanesulfonate salt), and indinavir (as its sulfate salt).

The sensitivity to hydrolysis of the mannose prodrugs was checked using the same hydrolysis protocol as that described in previous studies from our laboratory. These hydrolysis experiments were performed in a pH 7.3 buffer at 37 °C and in the absence of serum, cells and virus using a prodrug concentration in the 476−1015 μM range. All compounds were hydrolyzed within a close interval of time, their hydrolysis $t_{1/2}$ being comprised between 30 and 60 h (Table 2). These results are close to those established for glucose prodrug analogues containing the same spacer with the striking exception of the glucose analogue Saq-C(O)C4Glc (Scheme 2) which was found to be quite unstable ($t_{1/2}$ = 3 h) (*29*). No obvious explanation may be found for the higher resistance to hydrolysis of the mannosylated saquinavir conjugates as compared with the glucosylated one.

The anti-HIV efficiency of saquinavir, indinavir, and nelfinavir is substantially reduced when D-mannose is conjugated to the peptidomimetic hydroxyl of these protease inhibitors as well as to the hydroxyl of indinavir and nelfinavir, which is not part of the transition state isostere. This is illustrated by the large *R* values (from ≥44 to 1060), which correspond to the ratio of the IC_{50} of the PI prodrug versus that of the parent PI (see Table 2). The lower anti-HIV activities of these PI prodrugs reflect to some extent their relative stabilities with respect to hydrolysis during the 4 day time-span of the antiviral assays.

Considering the sole masking of the "non-peptidomimetic hydroxyl" C-8 of indinavir and C-1 of nelfinavir, this modified also drastically the antiviral activity of nelfinavir ($R \sim 170$ and ~ 120 for Nelf(1)-C(O)C4Man) but not that of indinavir ($R \sim 7$ and ~ 12 for Ind(8)-C(O)C4Man). The activity found for this latter prodrug is in the same range than that of its glucose analogue, Ind(8)-C(O)C4Glc (Scheme 2) (*29*). These data indicate likely that C-8 indinavir conjugates themselves may possess an antiviral activity, which is lower than that of indinavir, and that the hydrolysis rate may also, to some extent, contribute to increasing their intrinsic antiviral potency. In addition, it appears that the nature of the substituent at the other end of the C(O)C4 spacer linked to the non-peptidomimetic C-8 indinavir or C-1 nelfinavir hydroxyl is also of importance for the anti-HIV activity. Indeed, anti-HIV activity is increasing along the mannose, glucose, and tyrosine series (Scheme 2), with these derivatives displaying comparable chemical stability ($t_{1/2}$ in the 40−60 h range, Table 2).

Transepithelial Transport. There is currently a considerable interest in increasing the intestinal absorption of the HIV

protease inhibitors and in reducing their recognition by the efflux P-gp carrier (*67*, *68*) which is a possible reason for their poor or variable uptake from the intestinal lumen into the blood circulation. In this regard, esterase-rich and efflux carrier-expressing Caco-2 cell line monolayers are widely accepted in vitro models of the intestinal epithelium for screening drug and prodrug candidates and thus for evaluating prodrug approaches for enhanced intestinal drug absorption (*69*−*73*). This human cell line forms indeed polarized monolayers, which have been shown to express most of the enzymatic, functional, and morphologic characteristics of the intestinal mucosa (*69*, *74*). They express, on the apical side of the monolayer, efflux carrier systems, such as the multidrug-resistant P-gp, which is responsible for the limited oral bioavailability and brain penetration of the protease inhibitors (*67*, *68*). Caco-2 cell line monolayers have already been used in numerous studies to characterize the permeation of various drugs and prodrugs, including indinavir, saquinavir, and nelfinavir (*67*, *68*) and prodrugs deriving therefrom which have been developed in our laboratory (*30*).

Translocation of the various mannosylated protease inhibitor prodrugs across Caco-2 cell monolayers was evaluated at a concentration where they are soluble. Transepithelial electrical resistance after confluence has been used to monitor the integrity of the cell layer (*75*). Translocation was then initiated by adding the test solution to the apical (AP) or basolateral (BL) side of the monolayer (donor chamber). Investigation of the transport across the polarized Caco-2 cell monolayer in the absorptive AP to BL direction and in the secretory BL to AP one constitutes a mean of evaluating the influence of P-gp and related efflux carriers which are located on the AP side of the monolayer. As Caco-2 cells are also rich in esterases, the hydrolysis of the ester prodrugs during their permeation across Caco-2 monolayers was carefully checked. Only the prodrugs were detected either in the donor or acceptor chamber, indicating that no hydrolysis occurred during the transport experiments.

The results of the bidirectional transport studies of D-mannose conjugated prodrugs and of their parent protease inhibitor are presented in Figure 2 (which illustrates the transport profiles) and Table 3. This table collects the percentages of (pro)drug that have been transported after the 3 h experiment and the apparent permeability coefficients P_{app} that were calculated from the slope of a plot of the cumulative receiver concentration with time. In addition, the P_{app} of mannose-conjugated derivatives are presented in Figure 3 in comparison with those of the closely related glucose-conjugated ones (*29*, *30*).

The bidirectional transport results of D-mannose-conjugated prodrugs were very contrasting depending on the PI concerned. Moreover, they contrast also very strongly with those reported for their D-glucose analogues (*30*). Most importantly, the mannosylated saquinavir and indinavir (but not nelfinavir)

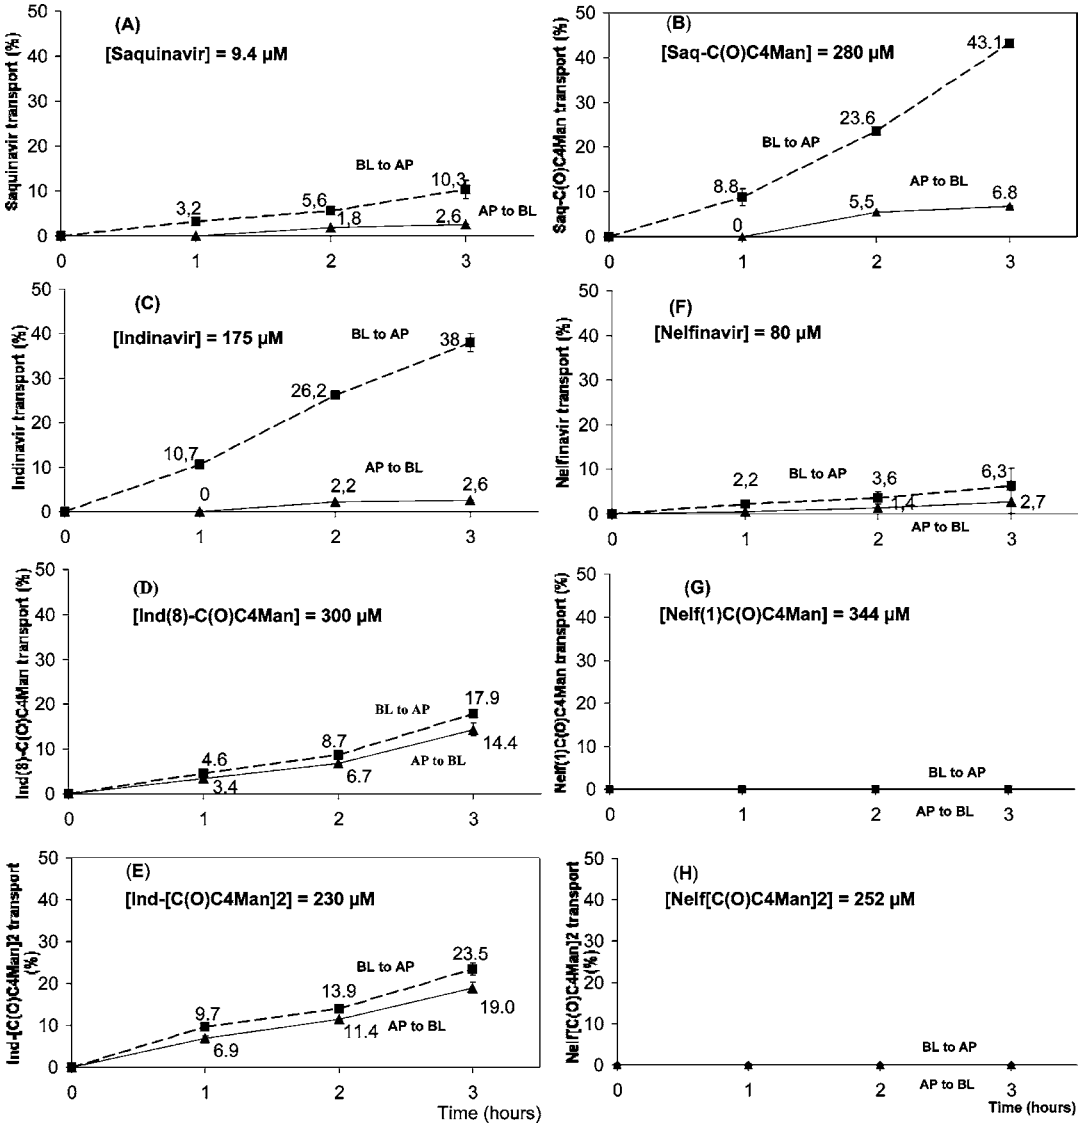

Figure 2. Bidirectional transepithelial transport across a monolayer of Caco-2 cells of mannose-conjugates of PIs (panels B, D, E, G, H) in comparison with their parent drugs (panels A, C, F) (data from ref *30*). Absorptive translocation [apical (AP) to basolateral (BL) compartment]: filled lozenges. Secretory translocation (BL to AP): filled squares. The results are expressed as prodrug transport percentages versus time. The percentage values represent the ratios of (pro)drug concentration in receiver vs donor chamber × 100. The initial concentration of the prodrug in the donor compartment is indicated on each panel. Results are means ± SD from three experiments. All incubations were performed at 37 °C and pH 7.4.

prodrugs were found to display very promising transport profiles that could improve the intestinal absorption of these two protease inhibitors.

Concerning the saquinavir derivative (Figure 2B), Saq-C(O)-C4Man showed an asymmetric permeation profile indicating that, as its parent PI, it is substrate of the apically localized efflux P-gp carrier (*67*, *68*). This highly asymmetric permeation profile was already observed for the D-glucose conjugate analogues [(i.e., Saq-C(O)C4Glc and Saq-C(O)NC4Glc (Scheme 2))]. However, it is noteworthy that the permeation of Saq-C(O)-C4Man in the absorptive AP to BL direction is significantly much higher than those of its glucose analogues for which no transport across the Caco-2 cell monolayer was observed (Table 3 and Figure 3). In comparison with that of its parent drug, permeation of Saq-C(O)C4Man is enhanced in the two directional transport: ∼3-fold in the absorptive AP to BL direction and ∼4-fold in the secretory BL to AP efflux (Table 3, Figure 2A). These absorptive and secretory transport enhancements are not only attributable to a lower affinity of the efflux carriers for this conjugate but also to an active transport mechanism involving a mannose carrier system located at the brush border side of the Caco-2 cell monolayer, if present. It could also arise from an improvement of passive permeation. However, this seems unlikely since conjugation of mannose to saquinavir induced a hydrophilicity increase, though tiny, as shown by the slight decrease of HPLC mobility and logP coefficient[76] (Table 4).

For the indinavir prodrugs, the monoester and diester conjugates, Ind(8)-C(O)C4Man and Ind-[C(OC4Man]2, presented similar and almost superimposable absorptive and secretory permeation profiles (Figure 2D,E). It appears also that, as for saquinavir, conjugation of indinavir to D-mannose improves substantially the absorptive permeation of indinavir (Figure 2C) across Caco-2 cell monolayers (∼5- and 7-fold increase, respectively), by contrast to its conjugation to D-glucose (Table 3 and Figure 3). It is further noticeable that the secretory permeations of these indinavir prodrugs are lower than that of indinavir, indicating that conjugation of D-mannose to indinavir decreases its passive diffusion, as expected from an increase of its hydrophilicity[76] (see Table 4). Therefore, the absorptive transport enhancements are more likely attributable to a substantial decrease of their efflux owing to a lower affinity

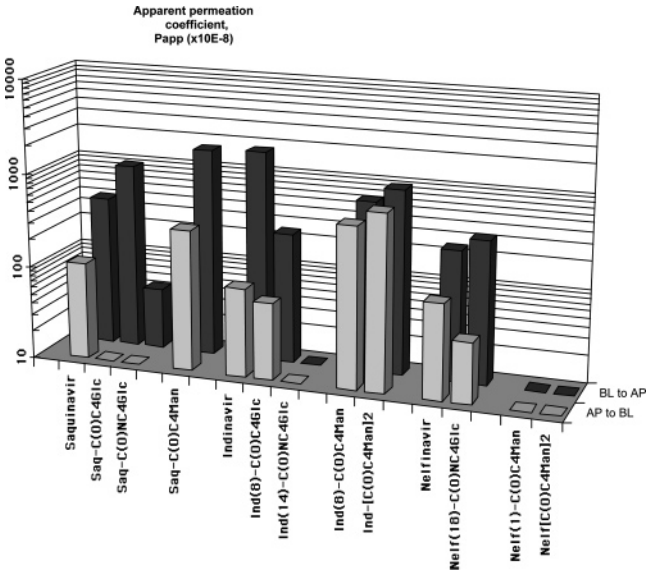

Figure 3. Caco-2 cell monolayer apparent permeation coefficients (P_{app}) in the absorptive (AP to BL; gray bars) and secretion (BL to AP; dark gray bars) direction of indinavir, saquinavir, nelfinavir, and of their mannose conjugates displayed in Scheme 1, and of their glucose conjugates (data from ref *30*), structures in Scheme 2.

Table 4. HPLC Mobility and LogP Data of PIs and Prodrugs

compound[a]	HPLC mobility[a] (in min)	log P[b]
Saquinavir	5.6	4.727 (4.73)[c]
Saq-C(O)C4Man	5.0	4.218
Indinavir	4.9	3.681 (3.68)[c]
Ind(8)-C(O)C4Man	3.5	3.216
Ind-[C(OC4Man]2	3.3	2.062
Nelfinavir	12.5	5.842 (5.84)[c]
Nelf(1)-C(O)C4Man	5.2	4.490
Nelf-[C(OC4Man]2	4.8	3.659

[a] Determined on a HP1100 apparatus with a Lichrospher 100 RP-18-packed column. The isocratic mobile phase consisted of a pH 6 buffer/CH_3CN mixture (41:59 for saquinavir and its prodrug; 59:41 for indinavir and its two prodrugs; 45:55 for nelfinavir and its two prodrugs (for more details, see experimental section). [b] Calculated using Chem 3D Ultra 8.0, CambridgeSoft, Cambridge, MA. [c] Data taken from ref 76 and calculated using CQSAR program.

of the efflux carriers for these conjugates and/or to an active transport mechanism involving a mannose carrier system located at the brush border side of the Caco-2 cell monolayer, if present. Such an absorptive transport improvement was already detected for valine conjugates of indinavir (*30*).

Concerning the mannose-nelfinavir prodrugs, the conjugation of D-mannose to nelfinavir, Nelf(1)-C(O)C4Man and Nelf-[C(OC4Man]2, was highly detrimental to its permeation across the Caco-2 cell monolayers. No detectable transport, at least above the detection limit for nelfinavir derivatives (0.1 μM), was observed whatever the AP to BL or BL to AP directional transport (Figure 2F−H). A similar behavior was also found for Nelf(1)-C(O)C4Tyr (*30*) (Table 3, Scheme 2), a tyrosine analogue prodrug of Nelf(1)-C(O)C4Man. However, it is in sharp contrast with a D-glucose analogue prodrug, i.e., Nelf-(18)-C(O)NC4Glc (Table 3, Figure 3, Scheme 2), for which transport in both direction was observed. These results indicate that the mannose-nelfinavir conjugates are not recognized and actively transported by a mannose carrier system, if present on the Caco-2 cells. The absence of any secretory transport supports further that conjugation of D-mannose to nelfinavir reduces drastically its passive permeation, as expected from an increase of its hydrophilicity. This is indeed reflected by the substantial much larger decrease of HPLC mobility and logP coefficient observed for nelfinavir (which of the three PIs investigated is the most lipophilic) than for saquinavir and indinavir[76] (Table 4).

CONCLUSION

Mannose-derived conjugates were prepared in two steps, in good yields, by condensing an acid derivative of the appropriate protected mannose with the PI, followed by deprotection of the sugar protecting group. With respect to hydrolysis, these PI prodrugs are chemically stable with half-life times in the 50−60 h range that are further compatible with an in vivo utilization aimed at improving the absorption/penetration or accumulation of the prodrug in specific cells/tissues and liberation of the active free drug inside HIV-infected cells. These stabilities correlate closely with the low in vitro anti-HIV activity measured for those prodrugs wherein the coupling of mannose to the PIs was performed through the peptidomimetic PI's hydroxyl. Ind(8)-C(O)C4Man, wherein the coupling of the mannosylated residue was performed onto the non-peptidomimetic PI hydroxyl, displayed a quite high antiviral activity and stability, indicating that this prodrug is also to some extent an antiviral drug by itself. Mannose conjugation to the PIs was further found to improve the absorptive transepithelial transport of saquinavir and indinavir, but not of nelfinavir, across Caco-2 cell monolayers used as a model of the intestinal barrier. These data indicate also that the conjugation of mannose to saquinavir and indinavir could constitute a mean to improve their intestinal absorption. It is noteworthy that mannose conjugation improved the absorptive transepithelial transport of saquinavir and indinavir by contrast to glucose conjugation which had the opposite effect. The mannose-linked prodrugs of saquinavir and indinavir display therefore a most promising therapeutic potential provided that bioavailability, penetration into the HIV infected macrophages and HIV-reservoirs of these PIs are improved. Further work aimed at a better understanding of the impact of D-mannose on the absorptive transepithelial transport of the PIs and of the transport mechanism of the mannosylated PI prodrugs, and at evaluating their uptake by macrophages is under progress and will be reported in due course.

A Bioconjugate Approach toward Squalamine Mimics: Insight into the Mechanism of Biological Action

Wen-Hua Chen,[†] Xue-Bin Shao,[†] Robert Moellering,[‡] Christine Wennersten,[‡] and Steven L. Regen*[,†]

Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania 18015, and Infectious Disease, BIDMC, Harvard Institutes of Medicine, 77 Avenue Louis Pasteur, Boston, Massachuestts 02115. Received July 19, 2006; Revised Manuscript Received July 20, 2006

A short and efficient synthesis has been devised for a family of squalamine mimics, based on the use of cholic acid, deoxycholic acid, lithocholic acid, putrescine, and spermine as starting materials. Those mimics that contain two facially amphiphilic sterol−spermidine conjugates show strong antibacterial activity against a broad spectrum of Gram-positive bacteria; their corresponding activities against a broad spectrum of Gram-negative bacteria are relatively moderate. Larger mimics, containing four such sterol−spermidine conjugates, exhibit very weak activities. Reversal of the pendent spermidine moiety and a putrescine linkage on the A- and D-rings had little consequence on the antibacterial activity for the most active of the squalamine mimics, which contained two sterol−polyamine units; similar results were obtained with squalamine mimics made from only one sterol unit. Detailed structure−activity measurements, in combination with kinetic studies carried out using liposomes as model membranes, support a mechanism of action involving noncovalent dimers as ion transporting species, most probably via the formation of pores or channels.

INTRODUCTION

The emergence of multidrug-resistant microorganisms, such as methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant *Enterococcus*, has prompted major efforts aimed at developing new classes of antibiotics (*1*−*6*). Squalamine, a compound that has been isolated from the stomach of the dogfish shark, possesses an unusual chemical structure that consists of a spermidine moiety that is attached to a sterol backbone (Chart 1) (*7*−*9*). The fact that it exhibits significant activity against Gram-negative and Gram-positive bacteria has led to the proposal that squalamine is likely to play a role in the immune defense system of the dogfish shark (*7*). It has also stimulated interest in such structures as therapeutic agents (*9*).

In previous work, we have shown that the placement of pendent spermidine and sulfate groups on the A- and D-rings can be reversed in a closely related sterol (i.e., **1**) with retention of significant antibacterial activity (Chart 1) (*10*). Using a bioconjugate approach toward even simpler analogues (e.g., **2**), we also found that the sulfate group is not essential for strong antibiotic activity (*11*, *12*). Although the mechanism of action of these squalamine mimics is not presently known, the fact that *subinhibitory* concentrations of **2** significantly enhance the activity of rifampin against Gram-negative bacteria suggested that they may act at the membrane level (*11*). Previous studies of **1** in model systems have lent support for the notion that such compounds are membrane-active agents. Specifically, a kinetic analysis of the activity of **1**, in discharging pH gradients across liposomal membranes, supports a model in which monomers of **1** are in equilibrium with transport-active dimers; they also imply that this equilibrium strongly favors the monomeric form (*13*, *14*). In this previous investigation, we also postulated that **1** may be operating via a H^+/Cl^- symport mechanism (*13*). In Figure 1, we provide a stylized illustration of two hypothetical transport-active dimers that could shuttle HCl across lipid bilayers. In model "A", two U-shaped forms of a sterol−polyamine conjugate lie side-by-side in a thinned region of a lipid bilayer. In model "B", one U-shaped conjugate lies adjacent to a second one in the adjoining monolayer to form a contiguous pathway for HCl transport across the bilayer.

In the work reported herein, we have carried out a detailed structure−activity investigation using a family of "connected" sterol−polyamine conjugates. Our primary aim was to gain further insight into the probable mechanism of biological action of this general class of compounds. For this purpose, we have used a design strategy that is related to one that we have previously employed in constructing "molecular umbrellas"; that is, bioconjugates derived from two or more naturally occuring facial amphiphiles (*15*−*17*). Conjugate **3** is a generalized structure that is illustrative of the types of molecular umbrellas that we have previously reported (Chart 2).

EXPERIMENTAL PROCEDURES

General Methods. ^{1}H NMR spectra were recorded in either CD_3OD or $CDCl_3$ using a Bruker 500 spectrometer and the solvent as a reference. MALDI-TOF mass spectra were recorded on a DE-STR mass spectrometer. Silica gel 60 (Fluka, particle size 0.035−0.070 mm, 220−440 mesh) was used for all column chromatographic purifications. Thin-layer chromatography (TLC) was performed on glass plates that were precoated with silica gel containing a fluorescence indicator (Whatman). Detection on TLC was made by use of 10% sulfuric acid in water, iodine, ninhydrin solution and UV (254 or 365 nm). All reagents and chemicals were obtained from commercial sources and used as received unless noted otherwise. *N*-Methyldeoxycholamide was prepared according to the reported procedures (*18*).

Synthesis of 8a. To a solution of cholic acid (1.0 g, 2.45 mmol) and *N*-hydroxylsuccinimide (324 mg, 2.81 mmol) in anhydrous THF (5 mL) was added DCC (759 mg, 3.68 mmol). The resulting mixture was stirred at room temperature for 6 h, filtered, and concentrated under reduced pressure. The residue was dissolved in $CHCl_3$ (100 mL) and washed with saturated aqueous $NaHCO_3$ (100 mL), water (100 mL), and brine (100

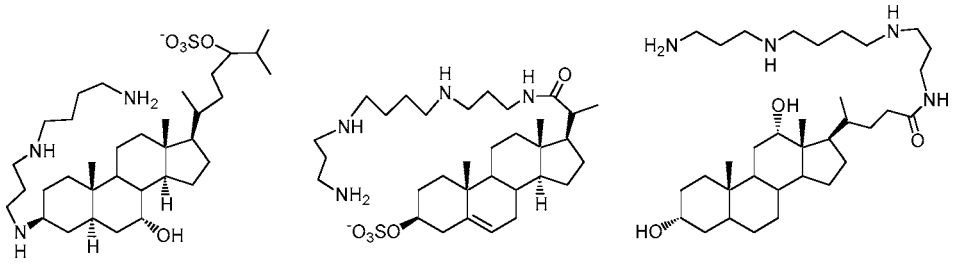
Chart 1



mL). The organic layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure to give crude cholic acid *N*-succinimidyl ester (1.20 g). To a solution of spermine (750 mg) in $CHCl_3$ (10 mL) was added dropwise a solution of the above crude ester in $CHCl_3$ (15 mL) over 20 min. The resulting mixture was stirred at room temperature overnight and then concentrated under reduced pressure. The obtained residue was dissolved in methanol (15 mL), and a solution of di-*tert*-butyl carbonate (3.24 g, 4 equiv) in methanol (10 mL) was added dropwise at 0 °C. The reaction mixture was warmed to room temperature and continued to stir at room temperature for 3 h. After concentration under reduced pressure, the obtained residue was purified by chromatography on a silica gel column ($CHCl_3$/MeOH, 10/1, v/v) to give **8a** (1.37 g, 67%) having ^{1}H NMR (CD_3OD, 500 MHz) δ 3.94 (s, 1 H), 3.78 (s, 1 H), 3.36 (m, 1 H), 3.20−3.15 (m, 10 H), 3.02 (t, J = 6.72 Hz, 2 H), 2.29−2.24 (m, 3 H), 2.10 (m, 1 H), 2.00−0.91 (m, 61 H), 0.70 (s, 3 H). MALDI-TOF MS: m/z 915 ($[M + Na]^+$).

Synthesis of 8b. Compound **8b** was synthesized from deoxycholic acid (1.0 g, 2.55 mmol) using procedures similar to those used for the preparation of **8a** except that $CHCl_3$/MeOH (20/1, v/v) was used as an eluting solvent. The desired product (1.61 g, 72%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 3.95 (s, 1 H), 3.52 (m, 1 H), 3.20−3.14 (m, 10 H), 3.03 (t, J = 6.74 Hz, 2 H), 2.24 (m, 1 H), 2.11 (m, 1 H), 1.89−0.92 (m, 65 H), 0.70 (s, 3 H). MALDI-TOF MS: m/z 899 ($[M + Na]^+$).

Synthesis of 9a. To a solution of **8a** (725 mg, 0.81 mmol) in a 16 mL of a mixture of $CHCl_3$/CH_3CH/ Et_3N (1/1/1.2, v/v/v) was added di-(*N*-succinimidyl)carbonate (DSC, 937 mg, 3.65 mmol). After stirring at 45 °C for 3 h, the reaction mixture was diluted with $CHCl_3$ (100 mL), washed with water (100 mL × 2) and dried over anhydrous sodium sulfate. Concentration under reduced pressure and drying under vacuum afforded residue (796 mg) that was used immediately in the subsequent reaction. To a solution of the residue in anhydrous DMF (5 mL) was added a solution of putrescine (22 mg, 0.25 mmol) and 4-methylmorpholine (1.0 mL). The resulting mixture was stirred at room temperature overnight and concentrated under reduced pressure. The residue was then partitioned between H_2O (150 mL) and $CHCl_3$ (150 mL). The organic layer was separated and dried over anhydrous sodium sulfate. After the solvent was removed under reduced pressure, the residue was purified by chromatography on a silica gel column ($CHCl_3$/CH_3OH, 15/1, v/v) to give **9a** (350 mg, 73%) having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.35 (m, 2 H), 3.95 (s, 2 H), 3.79 (s, 2 H), 3.21−3.15 (m, 20 H), 3.06−3.01 (m, 8 H), 2.39−2.36 (m, 2 H), 2.26−2.24 (m, 4 H), 2.10 (m, 2 H), 2.00−0.92 (m, 126 H), 0.70 (s, 6 H). MALDI-TOF MS: m/z 1949 ($[M + Na]^+$).

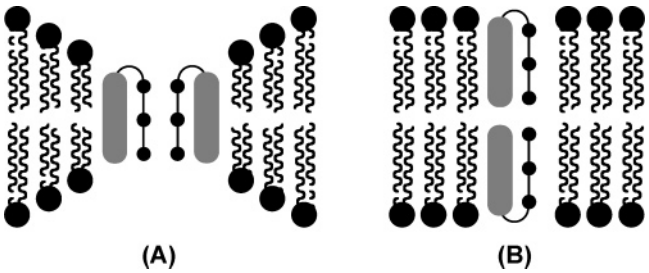


Figure 1. Stylized illustration showing hypothetical transport active dimers made from sterol−polyamine conjugates where (A) two monomers lie side-by-side in a thinned region of the lipid bilayer, and (B) two monomers are adjacent to one another in adjoining leaflets.

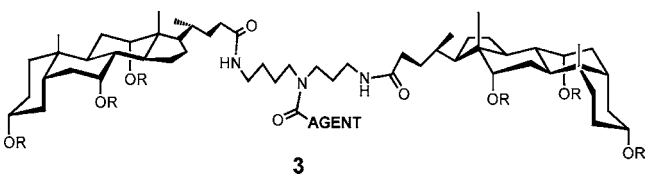
Chart 2



Synthesis of 9b. Compound **9b** was synthesized from **8b** (635 mg, 0.72 mmol) and putrescine (19 mg, 0.22 mmol) using procedures similar to those used for the preparation of **9a** except that $CHCl_3$/MeOH (30/1, v/v) was used as an eluting solvent. The desired product (240 mg, 59%) had ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.45 (m, 2 H), 3.88 (s, 2 H), 3.13−2.92 (m, 28 H), 2.17 (m, 2 H), 2.02 (m, 2 H), 1.80−0.81 (m, 134 H), 0.57 (s, 6 H). MALDI-TOF MS: m/z 1917 ($[M + Na]^+$).

Synthesis of 4a. To a solution that was prepared from **9a** (125 mg) in dichloromethane (2.0 mL) at 0 °C was added trifluoroacetic acid (2.0 mL). The reaction mixture was then stirred at room temperature for 12 h and concentrated under reduced pressure. The residue was dissolved in methanol (5 mL), adjusted to pH 10 with concentrated ammonium hydroxide and stirred at room temperature for 30 min. After concentration under reduced pressure, the residue was dissolved in water (5.0 mL) and dialyzed against pure water (250 mL, Micro Dispo-Dialyzer, MWCO 500) for 48 h. Concentration under reduced pressure and drying under vacuum gave **4a** (85 mg, *ca* 100%) having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.35 (s, 2 H), 3.95 (s, 2 H), 3.79 (s, 2 H), 3.27 (t, J = 6.42 Hz, 4 H), 3.12 (t, J = 7.62 Hz, 4 H), 3.07−2.98 (m, 20 H), 2.40−0.92 (m, 80 H), 0.70 (s, 6 H). MALDI-TOF MS: m/z 1326 ($[M + H]^+$).

Synthesis of 4b. Compound **4b** was prepared from **9b** (85 mg) using procedures similar to those used in the synthesis of **4a**, affording 56 mg (100%) of product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.49 (s, 2 H), 3.96 (s, 2 H), 3.27 (t, J = 6.51 Hz, 4 H), 3.12−2.97 (m, 24 H), 2.28 (m, 2 H), 2.15−2.05 (m, 6 H), 1.88−0.93 (m, 76 H), 0.70 (s, 6 H). MALDI-TOF MS: m/z 1294 ($[M + H]^+$).

Synthesis of 10. To a solution of deoxycholic acid methyl amide (708 mg, 1.75 mmol) in 16 mL of a mixture of $CHCl_3$/CH_3CH/Et_3N (1/1/1.2, v/v/v) was added DSC (2.01 g, 7.85 mmol). After stirring at 45 °C for 3 h, the reaction mixture was concentrated under reduced pressure. The residue was then partitioned between H_2O (150 mL) and $CHCl_3$ (150 mL). The organic layer was separated, washed with water, and dried over anhydrous magnesium sulfate. Concentration under reduced

pressure and drying under vacuum gave crude product (725 mg, 1.33 mmol) which was used in the subsequent reaction without further purification. To a solution of the above crude product (500 mg) in anhydrous DMF (5 mL) was added a solution of tri-Boc protected spermine (688 mg, 1.37 mmol) and 4-methylmorpholine (1.0 mL) in anhydrous DMF (5.0 mL). The resulting mixture was stirred at 50 °C overnight and concentrated under reduced pressure. The obtained residue was partitioned between H_2O (150 mL) and $CHCl_3$ (150 mL). The organic layer was separated and dried over anhydrous sodium sulfate. After the solvent was removed under reduced pressure, the residue was purified by chromatography on a silica gel column ($CHCl_3$/CH_3OH, 15/1, v/v) to give **10** (699 mg, 43%) having ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.48 (s, 1 H), 3.88 (s, 1 H), 3.14−3.00 (m, 12 H), 2.68 (s, 3 H), 2.15−2.13 (m, 1 H), 2.02−2.00 (m, 1 H), 1.75−0.82 (m, 65 H), 0.59 (s, 3 H). MALDI-TOF MS: *m*/*z* 957 ([M + Na]$^+$).

Synthesis of 5. To a solution that was prepared from **10** (100 mg) in dichloromethane (1.0 mL) at 0 °C was added trifluoroacetic acid (1.0 mL). The reaction mixture was then stirred at room temperature overnight and concentrated under reduced pressure. The resulting residue was dissolved in methanol (5 mL), adjusted to pH 10 with concentrated ammonium hydroxide, and stirred at room temperature for 30 min. After concentration under reduced pressure, the residue was purified by chromatography on a silica gel column (CH_3OH/NH_4OH, 2/1, v/v) to give **5** (59 mg, 87%) having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.50 (m, 1 H), 3.95 (s, 1 H), 3.16 (t, J = 6.65 Hz, 2 H), 2.85 (t, J = 6.98 Hz, 2 H), 2.78 (t, J = 7.16 Hz, 2 H), 2.75−2.72 (m, 6 H), 2.69 (s, 3 H), 2.21 (m, 1 H), 2.08 (m, 1H), 1.89−0.94 (m, 38 H), 0.70 (s, 3 H). MALDI-TOF MS: *m*/*z* 635 ([M + H]$^+$).

Synthesis of 11a. To a solution of cholic acid methyl ester (1.50 g, 3.55 mmol) in a 16 mL of a mixture of $CHCl_3$/CH_3CH/Et_3N (1/1/1.2, v/v/v) was added DSC (3.58 g, 14.0 mmol). After the mixture was stirred at 45 °C for 3 h, the product mixture was diluted with $CHCl_3$ (100 mL) and washed with water. The organic layer was then dried over anhydrous sodium sulfate and concentrated under reduced pressure. The residue was purified by column chromatography [silica gel, $CHCl_3$/CH_3CO_2Et (1/1, v/v)] to give 1.40 g (70%) of product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.57 (s, 1 H), 3.99 (s, 1 H), 3.86 (s, 1 H), 3.66 (s, 3 H), 2.82 (s, 4 H), 2.38−2.21 (m, 2 H), 1.94−0.91 (m, 28 H), 0.69 (s, 3 H).

Synthesis of 11b. Compound **11b** was prepared from deoxycholic acid methyl ester (2.00 g, 4.92 mmol) using procedures similar to that used in the preparation of **11a**, except that $CHCl_3$/CH_3CO_2Et (3/1, v/v) was employed as an eluting solvent. The desired product (1.71 g, 62%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 4.70 (s, 1 H), 3.98 (s, 1 H), 3.66 (s, 3 H), 2.82 (s, 4 H), 2.35−2.24 (m, 2 H), 2.04−0.92 (m, 30 H), 0.69 (s, 3 H).

Synthesis of 11c. Compound **11c** was prepared from lithocholic acid methyl ester (2.50 g, 6.40 mmol) using procedures similar to that used in the preparation of **11a** except that $CHCl_3$/CH_3CO_2Et (10/1, v/v) was used as an eluting solvent. The desired product (2.78 g, 82%) had ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.69 (s, 1 H), 3.64 (s, 3 H), 2.80 (s, 4 H), 2.33−2.19 (m, 2 H), 2.01−0.88 (m, 32 H), 0.62 (s, 3 H).

Synthesis of 12a. To a solution of **11a** (1.40 g, 2.56 mmol) in anhydrous DMF (5 mL) and DIPEA (0.83 mL, 5 mmol) was added tri-Boc protected spermine (1.30 g, 2.5 mmol). After stirring for 12 h at 50 °C, under a nitrogen atmosphere, the product mixture was concentrated under reduced pressure. The residue was then dissolved in $CHCl_3$ (100 mL), washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. Purification by column chromatography [silica gel, $CHCl_3$/CH_3CO_2Et (1/2, v/v)] afforded 1.69 g (71%) of the desired product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.35 (s, 1 H), 3.94 (s, 1 H), 3.79 (s, 1 H), 3.63 (s, 3 H), 3.21 (br, 8 H), 3.06−3.02 (m, 4 H), 2.37−2.26 (m, 4 H), 1.97−0.92 (m, 61 H), 0.70 (s, 3 H). MALDI-TOF MS: *m*/*z* 974 ([M + Na]$^+$).

Synthesis of 12b. Compound **12b** was prepared from **11b** (1.64 g, 3.08 mmol) in a manner that was similar to that described for the synthesis of **12a**, except that $CHCl_3$/CH_3CO_2Et (3/1, v/v) was used as an eluting solvent. The desired product (2.90 g, 98%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 4.50 (s, 1 H), 3.95 (s, 1 H), 3.64 (s, 3 H), 3.20 (br, 8 H), 3.07−2.99 (m, 4 H), 2.35−2.25 (m, 2 H), 1.89−0.94 (m, 65 H), 0.70 (s, 3 H). MALDI-TOF MS: *m*/*z* 958 ([M + Na]$^+$).

Synthesis of 12c. Compound **12c** was prepared from **11c** (1.37 g, 2.66 mmol) in a manner that was similar to that described for the synthesis of **12a**, except that $CHCl_3$/CH_3CO_2Et (10/1, v/v) was used as an eluting solvent. The desired product (1.96 g, 83%) had ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.57 (s, 1 H), 3.63 (s, 3 H), 3.27−3.06 (m, 12 H), 2.32−2.19 (m, 2 H), 1.95−0.87 (m, 67 H), 0.63 (s, 3 H).

Synthesis of 13a. To a solution of **12a** (2.30 g, 2.42 mmol) in methanol (30 mL) was added an aqueous Na_2CO_3 solution (10 wt %, 10 mL). The mixture was refluxed until thin layer chromatographic analysis showed the complete disappearance of the starting material. The product mixture was then acidified to pH 3 with dilute HCl at 0 °C and extracted with $CHCl_3$ (3 × 50 mL). The combined organic phase was dried over anhydrous sodium sulfate and concentrated under reduced pressure. The residue was then purified by column chromatography [silica gel, $CHCl_3$/MeOH (6/1, v/v)] to give 1.64 g (70%) of product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.38 (s, 1 H), 3.95 (s, 1 H), 3.79 (s, 1 H), 3.21 (br, 8 H), 3.07−3.01 (m, 4 H), 2.34−2.15 (m, 4 H), 2.00−0.93 (m, 61 H), 0.71 (s, 3 H). MALDI-TOF MS: *m*/*z* 960 ([M + Na]$^+$).

Synthesis of 13b. Compound **13b** was synthesized from **12b** (2.76 g, 2.95 mmol) in a manner that was similar to that used in the preparation of **13a** except that LiOH was used as the base and $CHCl_3$/CH_3CO_2Et (12/1, v/v) was used as an eluting solvent to give 2.03 g (73%) of product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.50 (s, 1 H), 4.00 (s, 1 H), 3.20 (br, 8 H), 3.08−3.00 (m, 4 H), 2.31−2.21 (m, 2 H), 1.90−0.94 (m, 65 H), 0.71 (s, 3 H). MALDI-TOF MS: *m*/*z* 944 ([M + Na]$^+$).

Synthesis of 13c. Compound **13c** was synthesized from **12c** (1.96 g, 2.13 mmol) in a manner that was similar to that used in the preparation of **13a** except that LiOH was used as the base and $CHCl_3$/CH_3CO_2Et (20/1, v/v) was used as an eluting solvent. The desired product (1.47 g, 83%) had ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.57 (s, 1 H), 3.25−3.00 (m, 12 H), 2.38−2.24 (m, 2 H), 1.93−0.86 (m, 67 H), 0.63 (s, 3 H). MALDI-TOF MS: *m*/*z* 928 ([M + Na]$^+$).

Synthesis of 14a. To a solution that was made from **13a** (400 mg, 0.42 mmol) and 3-hydroxy-4-oxo-3,4-dihydro-1,2,3-benzotriazine (DHBT, 86 mg, 0.53 mmol) in anhydrous DMF (5 mL) was added DCC (130 mg, 0.63 mmol). The mixture was stirred at room temperature for 3 h. A solution of putrescine (17.8 mg, 0.20 mmol) and DMAP (100 mg) in anhydrous DMF (1.0 mL) was then added, and the mixture was stirred for 12 h. After the solution was concentrated under reduced pressure, the resulting residue was partitioned between water (50 mL) and $CHCl_3$ (50 mL), and the aqueous phase then extracted with $CHCl_3$ (3 × 50 mL). The combined organic phase was washed with water (100 mL) and dried over anhydrous sodium sulfate. Removal of solvent under reduce pressure and purification by column chromatography [silica gel, $CHCl_3$/MeOH (13/1, v/v)] afforded 228 mg (59%) of **14a** having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.38 (s, 2 H), 3.95 (s, 2 H), 3.79 (s, 2 H), 3.21 (m, 20 H), 3.07−

3.01 (m, 8 H), 2.35−0.93 (m, 134 H), 0.70 (s, 6 H). MALDI-TOF MS: *m*/*z* 1949 ([M + Na]$^+$).

Synthesis of 14b. Compound **14b** was synthesized from **13b** (500 mg, 0.54 mmol) and putrescine (17 mg, 0.19 mmol) using procedures similar to those used for the preparation of **14a**, except that $CHCl_3$/MeOH (25/1, v/v) was used as an eluting solvent. The desired product (200 mg, 53%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 4.50 (s, 2 H), 3.94 (s, 2 H), 3.19−3.16 (m, 20 H), 3.07−3.03 (m, 8 H), 2.38−0.93 (m, 138 H), 0.66 (s, 6 H). MALDI-TOF MS: *m*/*z* 1917 ([M + Na]$^+$).

Synthesis of 14c. Conjugate **14c** was synthesized from **13c** (320 mg, 0.35 mmol) and putrescine (15 mg, 0.17 mmol) using procedures similar to those used for the preparation of **14a** except that $CHCl_3$/MeOH (50/1, v/v) was used as an eluting solvent. The desired product (234 mg, 74%) had ^{1}H NMR ($CD_3OD/CDCl_3$, 500 MHz) δ 4.43 (s, 2 H), 3.15−2.94 (m, 28 H), 2.15 (m, 2 H), 1.97−0.79 (m, 140 H), 0.52 (s, 6 H). MALDI-TOF MS: *m*/*z* 1885 ([M + Na]$^+$).

Synthesis of 6a. To a solution that was prepared from **14a** (100 mg) in dichloromethane (2.0 mL) at 0 °C was added trifluoroacetic acid (2.0 mL). The reaction mixture was then stirred at room temperature for 12 h and concentrated under reduced pressure. The residue was dissolved in methanol (5 mL), adjusted to pH 9−10 with concentrated ammonium hydroxide, and stirred at room temperature for 30 min. After concentration under reduced pressure, the residue was dissolved in water (5.0 mL) and dialyzed against pure water (250 mL, Micro DispoDialyzer, MWCO 500) for 48 h. Concentration under reduced pressure and drying under vacuum gave 70 mg (100%) of **5a** having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.38 (s, 2 H), 3.95 (s, 2 H), 3.79 (s, 2 H), 3.18−3.01 (m, 28 H), 2.40−0.93 (m, 80 H), 0.70 (s, 6 H). MALDI-TOF MS: *m*/*z* 1326 ([M + H]$^+$).

Synthesis of 6b. Compound **6b** was prepared from **14b** (117 mg) using procedures similar to those used in the synthesis of **6a**, affording 76 mg (100%) of product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.52 (s, 2 H), 3.96 (s, 2 H), 3.20−3.17 (m, 8 H), 3.03−2.93 (m, 20 H), 2.23 (m, 2 H), 2.00−0.88 (m, 82 H), 0.70 (s, 6 H). MALDI-TOF MS: *m*/*z* 1294 ([M + H]$^+$).

Synthesis of 6c. Compound **6c** was prepared from **14c** (130 mg) using procedures similar to those used for the synthesis of **6a**, affording 86 mg (100%) of product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.52 (s, 2 H), 3.20−3.00 (m, 28 H), 2.21 (m, 2 H), 2.09−0.95 (m, 86 H), 0.68 (s, 6 H). MALDI-TOF MS: *m*/*z* 1262 ([M + H]$^+$).

Synthesis of 15a. To a solution that was prepared from **13a** (1.60 g, 1.71 mmol) and DHBT (500 mg, 3.06 mmol) in anhydrous DMF (5 mL) was added DCC (610 mg, 2.97 mmol). After the mixture was stirred at room temperature for 4 h, spermine (61 mg, 0.30 mmol) and Et_3N (0.5 mL) were added. The reaction mixture was stirred for an additional 12 h and filtered. Concentration of the filtrate under reduced pressure gave a residue that was dissolved in methanol (20 mL). To this solution was then added an aqueous Na_2CO_3 solution (10 wt %, 5 mL). This solution was stirred at room temperature for 1 h and added, dropwise, into water. The resulting precipitate was collected by filtration and purified by column chromatography [silica gel, $CHCl_3$/MeOH (10/1, v/v)] to give 468 mg (40%) of product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.34 (s, 4 H), 3.94 (s, 4 H), 3.78 (s, 4 H), 3.34 (m, 8 H), 3.28 (br, 4 H), 3.19 (m, 32 H), 3.08−2.96 (m, 16 H), 2.36−0.69 (m, 268 H), 0.63 (s, 12 H). MALDI-TOF MS: *m*/*z* 3901 ([M + Na]$^+$).

Synthesis of 15b. Compound **15b** was prepared from **13b** (1.95 g, 2.12 mmol) and spermine (76 mg, 0.38 mmol) in a manner that was similar to that used in the preparation of **15a**, except that $CHCl_3$/MeOH (15/1, v/v) was used as an eluting solvent. The desired product (141 mg, 10%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 4.48 (s, 4 H), 3.93 (s, 4 H), 3.32 (m, 8 H), 3.28 (br, 4 H), 3.17 (m, 32 H), 3.04−3.00 (m, 16 H), 2.36−0.92 (m, 276 H), 0.67 (s, 12 H). MALDI-TOF MS: *m*/*z* 3839 ([M + Na]$^+$).

Synthesis of 15c. Compound **15c** was prepared from **13c** (650 mg, 0.72 mmol) and spermine (33 mg, 0.16 mmol) in a manner that was similar to that used in the preparation of **15a** except that $CHCl_3$/MeOH (50/1, v/v) was used as an eluting solvent. The desired product (422 mg, 69%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 4.51 (s, 4 H), 3.35 (m, 8 H), 3.20 (m, 36 H), 3.09−3.01 (m, 16 H), 2.25−0.97 (m, 284 H), 0.70 (s, 12 H).

Synthesis of 7a. To a cooled solution (0 °C) that was made from **15a** (60 mg) and dichloromethane (1.0 mL) was added trifluoroacetic acid (1.0 mL). The reaction mixture was then stirred at room temperature for 12 h and concentrated under reduced pressure. The residue was dissolved in methanol (5 mL), adjusted to pH 9−10 with concentrated ammonium hydroxide, and stirred at room temperature for 30 min. Removal of solvent under reduced pressure gave a residue, which was dissolved in water (5.0 mL) and dialyzed against pure water (250 mL, Micro DispoDialyzer, MWCO 500) for 48 h. Concentration under reduced pressure and drying under vacuum afforded 44 mg (100%) of the desired product having ^{1}H NMR (CD_3OD, 500 MHz) δ 4.38 (s, 4 H), 3.95 (s, 4 H), 3.79 (s, 4 H), 3.34 (m, 8 H), 3.18−3.12 (m, 20 H), 3.03 (br, 16 H), 2.38−0.93 (m, 160 H), 0.70 (s, 12 H). MALDI-TOF MS: *m*/*z* 2700 ([M + Na]$^+$).

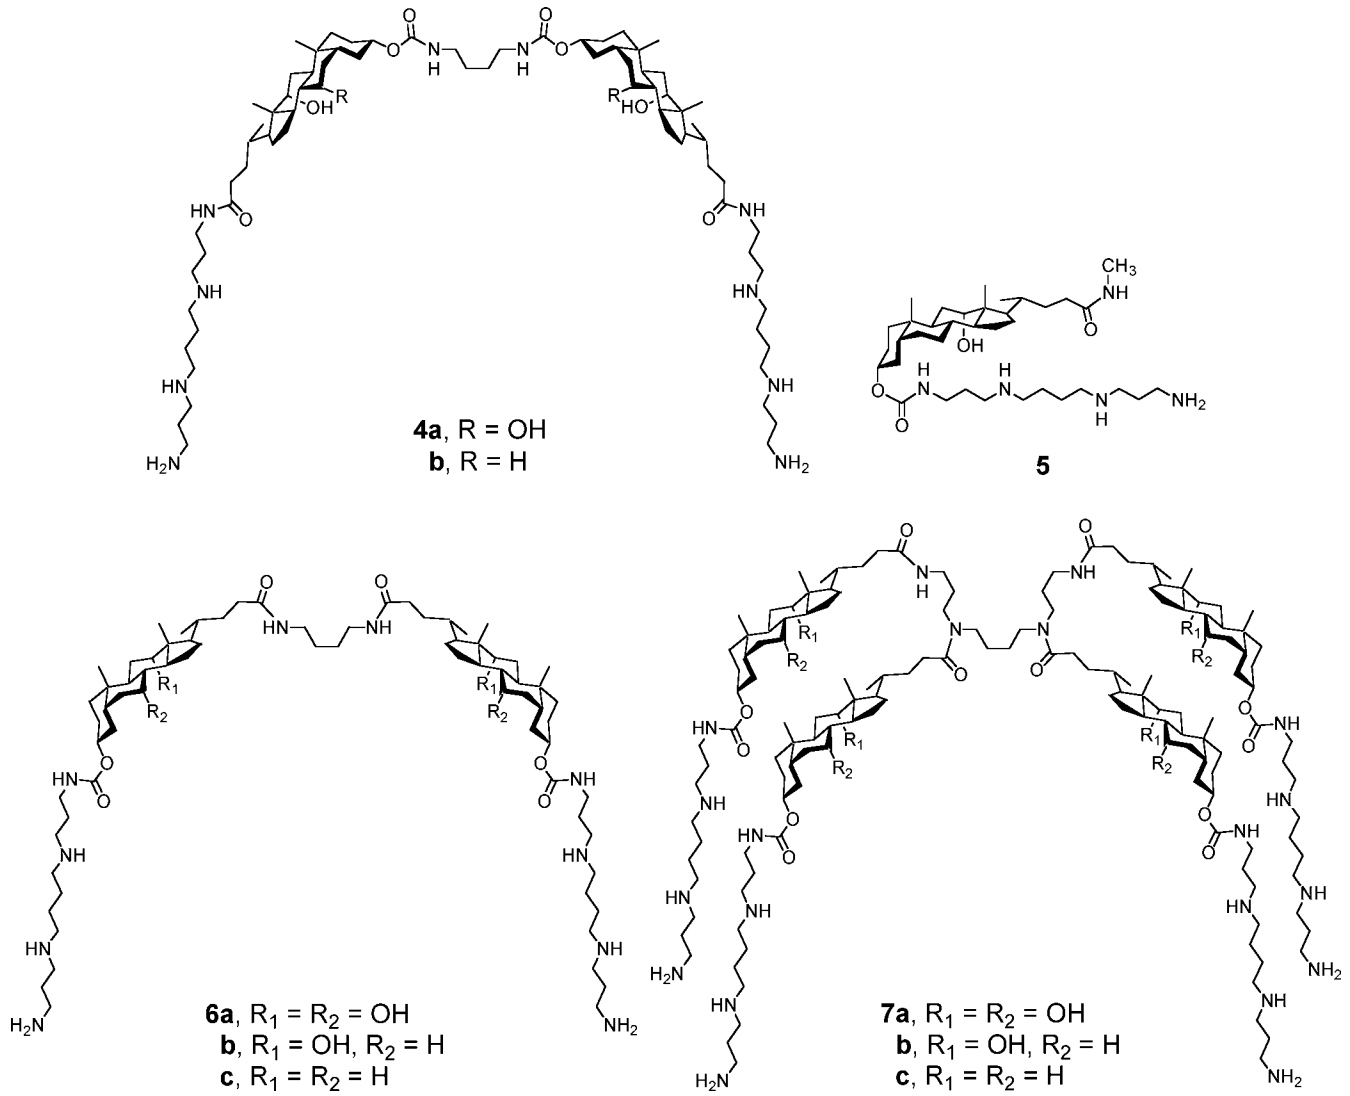
Synthesis of 7b. Compound **7b** was prepared from **15b** (70 mg) using a procedure that was similar to that used for the synthesis of **7a**. The desired product (48 mg, 100%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 4.52 (s, 4 H), 3.96 (s, 4 H), 3.34 (m, 8 H), 3.19−3.10 (m, 20 H), 3.03 (br, 16 H), 2.25−0.94 (m, 168 H), 0.70 (s, 12 H). MALDI-TOF MS: *m*/*z* 2636 ([M + Na]$^+$).

Synthesis of 7c. Compounds **7c** was prepared from **15c** (175 mg) using a procedure that was similar to that used for the synthesis of **7a**. The desired product (117 mg, 100%) had ^{1}H NMR (CD_3OD, 500 MHz) δ 4.52 (s, 4 H), 3.34 (m, 8 H), 3.19−3.10 (m, 20 H), 3.03 (br, 16 H), 2.24−0.96 (m, 176 H), 0.69 (s, 12 H). MALDI-TOF MS: *m*/*z* 2550 ([M + H]$^+$).

Partitioning between 1-Octanol and Water. A given conjugate (1 mg) was partitioned between an equal volume of water (1 mL) and 1-octanol (1 mL) at room temperature and allowed to equilibrate over 10 h. The aqueous and organic phases were then separated, and aliquots (5 μL) of each phase were deposited onto a thin layer chromatography plate, dried, and stained (ninhydrin solution). The density of each spot was analyzed by densitometry and used to calculate the partition coefficient P according to the equation $P = \log[\text{conjugate}]_{1-\text{octanol}}/[\text{conjugate}]_{\text{water}}$.

pH Discharge Measurements. Typically, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylglycerol (POPG) (0.5 mL, 20 mg/ mL in chloroform) was transferred to a pyrex test tube. While rotating the tube, the organic solvent was removed under a stream of nitrogen, resulting in a thin lipid film. The last traces of solvent were then removed under reduced pressure (25 °C, 12 h, <0.2 Torr). To the dried film was added 1.0 mL of a 0.1 mM pyranine in 25 mM HEPES buffer (pH 7.0, 50 mM NaCl), and the mixture was vortexed for 1 min. The dispersion was then incubated for 5 min, followed by another 1 min of vortexing and 20 min of incubation at ambient temperature. The sample was subjected to five freeze/thaw cycles (77 K/325 K), followed by sequential extrusion through a 400 nm Nuclepore membrane (10 times) and a 200 nm membrane (10 times). After extrusion, the dispersion was incubated at room temperature for 1.25 h. The non-entrapped pyranine was removed via gel filtration (Sephadex G-25, 1 × 32 cm, eluting with 25 mM HEPES buffer (pH 7.0, 50 mM NaCl)).

Chart 3



The vesicle dispersion (0.3 mL) was added to 1.7 mL of a 25 mM HEPES buffer (pH 8.0, 50 mM NaCl) that contained the desired amount of sterol−spermine conjugate. The appearance of fluorescence intensity was then monitored as a function of time (λ_{ex} 460 nm, em 510 nm, $\lambda_{ex}/\lambda_{em}$ 2.5 nm/2.5 nm) on a Perkin-Elmer Luminescence Spectrometer LS50B. After 60 min, an aqueous solution of Triton X-100 (50 μL, 5 wt %) was added. Pseudo first-order rate constants for pH discharge were calculated from the change in the fluorescence intensity of pyranine as a function of time using a curve-fitting procedure.

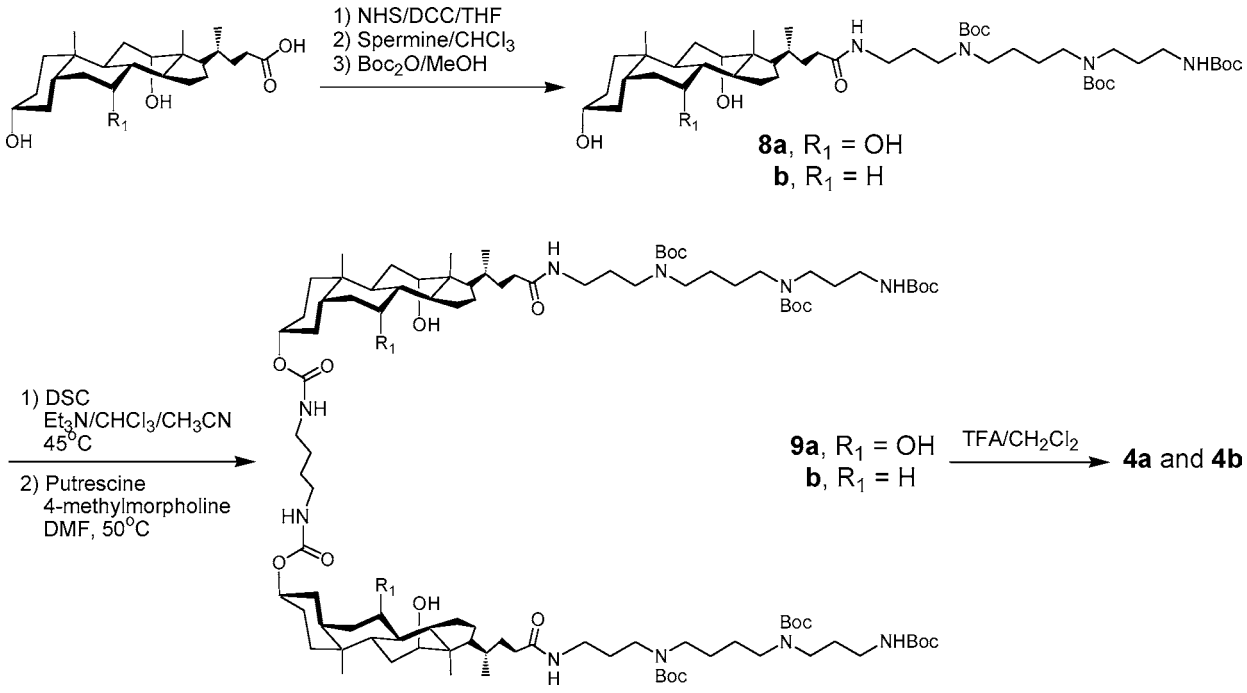
Determination of Minimum Inhibitory Concentrations (MICs). Bacteria used in this study were recent clinical isolates from the Beth Israel Deaconess Medical Center or Massachusetts General Hospital in Boston, with the following exceptions: Strains 1, 20, 24, 28, and 32 were standard strains from the American Type Culture Collection; strain 25 was a clinical isolate from Boston in 1969; strain 29 was a recent clinical isolate from New York and strain 31 was isolated in Spain.

Antimicrobial susceptibilities were done by the agar dilution method, incorporating Mueller-Hinton II agar (Becton, Dickenson, & Co., Sparks, MD) (*20*). Inocula of approximately 10^4 colony-forming units (CFU) per spot were applied with a multiprong replicator, and the plates were examined for growth after overnight incubation in room air at 35 °C.

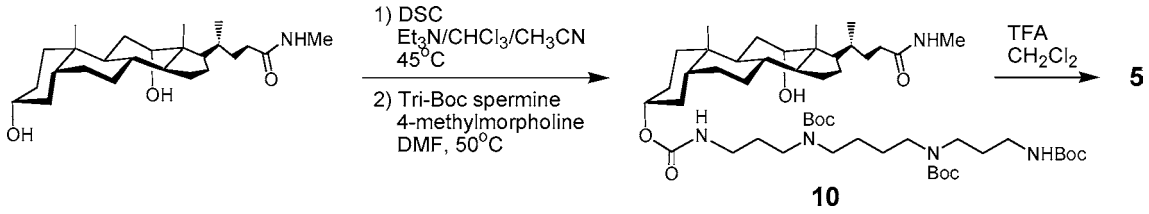
RESULTS

Molecular Design. In this investigation, we sought to devise short and efficient syntheses of a family of squalamine mimics, using fully biogenic starting materials. With this goal in mind, the specific synthetic targets that were chosen were conjugates **4a**, **4b**, **5**, **6a**, **6b**, **6c**, **7a**, **7b**, and **7c** (Chart 3). In essence, **4a** and **4b** are molecular umbrella-like analogues of **2**, in which two facially amphiphilic sterol−spermidine units have been connected through their A-ring. Comparison of **4a** with **4b**, bearing two and one hydroxyl groups on the α-face of the sterols, respectively, provides a means for judging the importance of facial hydrophilicity on antibacterial activity. Comparison of **6a** and **6b** with **4a** and **4b**, respectively, having the putrescine linkages and the pendent spermidine groups reversed, addresses the question of specificity; that is, if receptors were involved in their biological action, then it is highly unlikely that they would have similar activities. In addition, we sought to address this same question in monomeric squalamine mimics, by comparing the activities of **2** with a carbamate analog (i.e., **5**), in which the pendent spermidine unit is placed at the A-ring instead of the D-ring. Conjugate **6c** represents a control compound since it is devoid of facial amphiphilicity and molecular umbrella character. Finally, conjugates **7a**, **7b**, and **7c**, which can be viewed as larger versions of **6a**, **6b**, and **6c**, were chosen as synthetic targets to determine how the presence

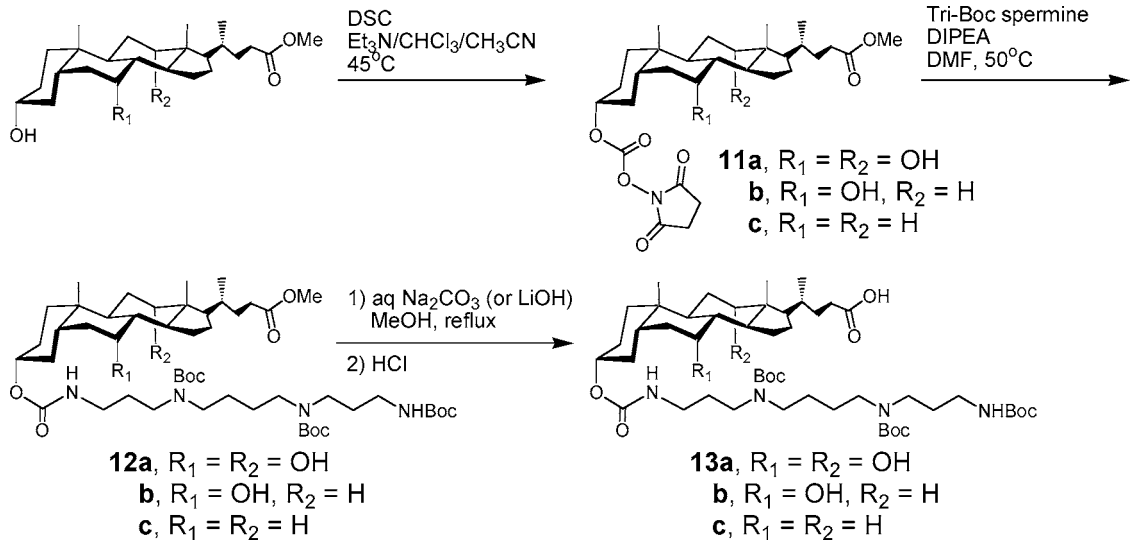
Scheme 1



Scheme 2



Scheme 3

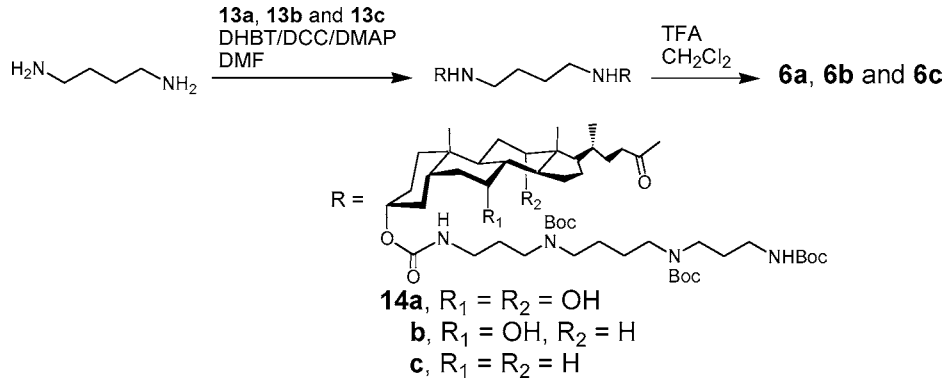


of additional facially amphiphilic-spermidine units influences the antibacterial properties of such squalamine mimics.

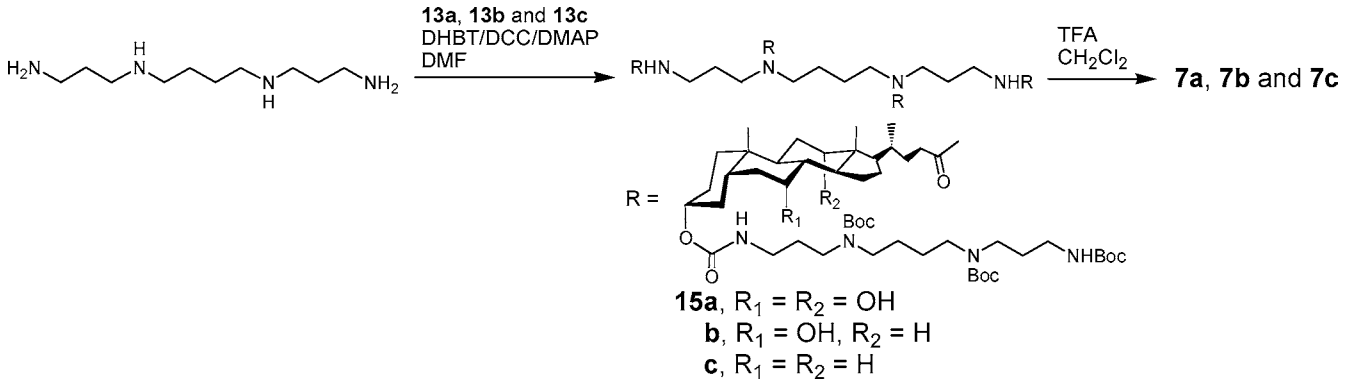
Molecular Synthesis. The general synthetic route that was used to prepare **4a** and **4b** is outlined in Scheme 1. In essence, both conjugates can be prepared via "two-pot" syntheses. Thus, monoacylation of spermine by cholic acid or deoxycholic acid, followed by Boc-protection of the remaining amino groups (one pot), afforded **8a** and **8b**. Subsequent activation of the C-3 hydroxyl group with di-(*N*-succinimidyl) carbonate (DSC) and condensation with putrescine (second pot) yielded **9a** and **9b**, which upon deprotection gave the desired conjugates **4a** and **4b**, respectively. The synthesis of **5** was readily accomplished by activating the C-3 hydroxyl group of deoxycholic acid methyl amide with DSC, condensing the product with tri-Boc-protected spermine to give **10**, followed by deprotection (Scheme 2).[18,19]

The syntheses of **6a**, **6b**, and **6c** were carried out using the strategies that are outlined in Scheme 3 and Scheme 4. In brief, the C-3 hydroxyl group of the methyl ester of cholic acid, deoxycholic acid, or lithocholic acid was activated by reaction with DSC to give **11a**, **11b**, and **11c**, followed by condensation with tri-Boc-protected spermine to yield **12a**, **12b**, and **12c** (Scheme 3) (*19*). Mild hydrolysis with Na_2CO_3 or LiOH and

Scheme 4



Scheme 5



acidification with HCl then afforded **13a**, **13b**, and **13c**. These sterols were then used to fully acylate putrescine to give **14a**, **14b**, and **14c** (Scheme 4). Finally deprotection with trifluoroacetic acid afforded the desired conjugates **6a**, **6b**, and **6c**.

A similar sequence of reactions was used to prepare **7a**, **7b**, and **7c**. In this case, spermine was exhaustively acylated with **13a**, **13b**, and **13c** (Scheme 5). Finally deprotection with trifluoroacetic acid afforded the desired conjugates **7a**, **7b**, and **7c**.

Activity in Discharging pH Gradients. To determine whether dimeric squalamine mimics are capable of discharging pH gradients across lipid bilayers, we examined the ability of **6a**, **6b**, and **6c** to eliminate a pH differential across vesicle membranes derived from 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylglycerol (POPG). For this purpose, a pH-sensitive dye (pyranine, pK_a = 7.2) was entrapped within large unilamellar vesicles (200 nm diameter, extrusion) and used as a fluorescence-responsive reporter of pH changes within the vesicle interior (*13*). Figure 2 shows the action of each of these conjugates on liposomal dispersions containing an internal pH of 7.0 and an external aqueous phase of pH of 8.0. In each case, apparent first-order kinetics was observed for the pH discharge. Of these three conjugates, **6a**, having the greatest facial hydrophilicity showed the highest activity. Further examination of the activity of **6a** was then carried out using varying mole percentages of the conjugate with a fixed liposome concentration. A plot of pseudo-first-order rate constants (k_{obsd}) versus the mol % of **6a** in the dispersion is presented in Figure 3. The solid line that appears in this figure represents a nonlinear least-squares fit of the data according to $k_{obsd} = k_0 + k_2(\text{mol \% } \mathbf{6a})^n/K$, where k_o is the background rate of pH discharge in the absence of the conjugate, and K is the dissociation constant of an aggregate composed of n molecules of **6a**, through which ions may pass. As discussed elsewhere, the basic assumptions that underlie this kinetic analysis are (i) that the conjugate exists primarily in its monomeric form, and (ii) the conconcentration of the conjugate in the membrane can be approximated by its *analytical* concentration; that is, its total concentration that is present in the dispersion (*13*). The fact that n is found to be equal to 1.93 implies that dimers of **6a** are the transport-active species. It also suggests, a priori, that such compounds might have biological activities that are comparable to those of **1** and **2** and that only a small percentage of **6a** is in its active-noncovalent, dimeric form.

Antibacterial Properties. Table 1 summarizes the antibacterial activities that were determined for squalamine mimics **2**, **4a**, **4b**, **5**, **6a**, **6b**, **6c**, **7a**, **7b**, and **7c** against a broad series of Gram positive and Gram negative bacteria. Similar to what we have observed previously, **2** was found to have significant activity against most of the microorganisms tested. Conjugate **5**, having the pendent spermidine moiety located at the C-3

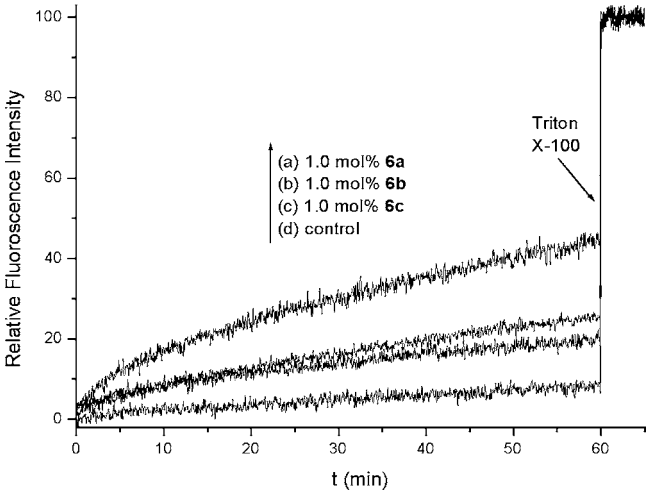


Figure 2. Discharge of a pH gradient (23 °C) across POPG-based liposomal membranes with an internal compartment containing 0.1 mM pyranine (pH 7.0) and an external aqueous phase of pH of 8.0 in the presence of (a) 1.0 mol % **6a**, (b) 1.0 mol % **6b**, and (c) 1.0 mol % **6c**; (d) a control experiment in which **6a** was not added to the dispersion.

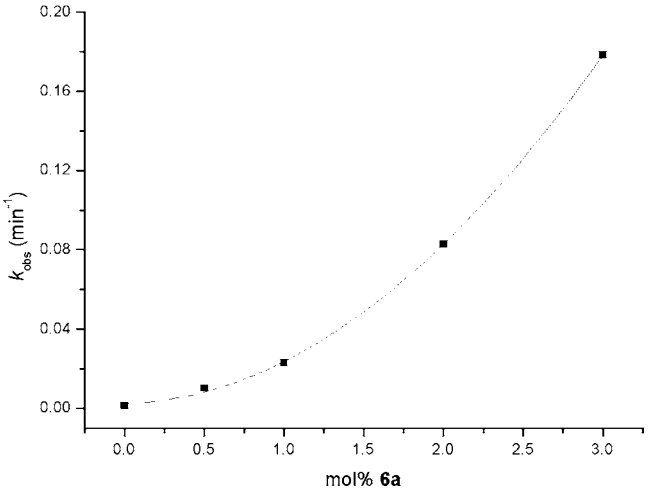

Figure 3. Plot of k_{obsd} versus (mol % **6a**) in POPG liposomes. The solid line represents a nonlinear least-squares fit of the data according to $k_{obsd} = k_0 + k_2(\text{mol \% } \mathbf{6a})^n/K$, where $n = 1.93$.

position of the A-ring, had antibacterial activities that were very similar to that of **2**. Squalamine mimic, **4a**, also had activities that were similar to that of **2**. Removal of the C-7 hydroxyl groups in both sterols (i.e., **4b**), which reduced its degree of facial hydrophilicity, showed a general decrease in activity. Similar removal of the C-7 hydroxyls, on going from **6a** to **6b**, also resulted in a general decrease in activity, but this change was only modest. In addition, conjugates **6a** and **6b** showed activities that were similar to those of **4a** and **4b**, respectively. Removal of facial amphiphilicity, in the case of **6c**, eliminated nearly all antibacterial activity. Finally, the larger squalamine mimics, **7a** and **7b**, showed relatively poor antibacterial activity. Removal of facial amphiphilicity within this series of conjugates (i.e., **7c**) resulted in the complete elimination of antibacterial activity. An analysis of the hydrophobic/hydrophilic balance for **6a** and **7a**, using conventional 1-octanol/water partition coefficients, *P*, where *P* is defined in eq 1, showed that **7a** was significantly more hydrophilic; that is, the values of *P* for **7a** and **6a** were -0.93 and -0.54, respectively.

$$P = \log(\text{conjugate})_{1-\text{octanol}}/(\text{conjugate})_{\text{water}} \qquad (1)$$

DISCUSSION

Four possible modes of action that seem most probable for this class of antibiotics, include (i) competitive binding to a specific receptor on a membrane surface, (ii) complexation with a protein or DNA in the cytoplasm, (iii) a carrier mechanism in which the conjugate shuttles ions across the membrane in both directions via an umbrella mechanism, and (iv) channel or pore formation in the plasma membrane. Taken together, all of our data point toward a mechanism that involves the formation of channels or pores. The fact that antibacterial activity is largely independent of the placement of the pendent polyamine chain at the A- or the D-ring (i.e., **2** versus **5**, **4a** versus **6a**, and **4b** versus **6b**) argues, strongly, against binding to a specific receptor. Additionally, the substantial loss in activity on going from **6a** to **7a**, together with the greater hydrophilicity of **7a** (the *P* values indicate 1-octanol/water partition coefficients that differ by a factor of ca. 2.5) argues against complexation within

the cytoplasm as being responsible for antibacterial activity. In particular, if the site of action were located in the cytoplasm, then the more hydrophilic conjugate, **7a**, would be expected to have greater apparent activity since less of it would be partitioned into the plasma membrane. An additional argument against complexation is the fact that **7a** has four sterol−polyamine units and **6a** has only two. One might expect, therefore, that **7a** would be a stronger complexing agent and exhibit greater activity due to cooperative forces, which is clearly not the case. The fact that the umbrella-like dimers and tetramers are not more active than the monomeric mimics of squalamine also argues against a carier mechanism of ion transport. Within each subclass (**4a** versus **4b**; **6a** versus **6b**, and **7a** versus **7b**), the general trend that we have observed is that the presence of both the C-7 and C-12 hydroxyl groups leads to higher activities as compared with analogues having only C-12 hydroxyls. This finding parallels, exactly, what we have observed in model systems, where **6a** exhibited greater activity in discharging a pH gradient relative to **6b**. Taken together, these results support the premise that these conjugates function as antibiotics by acting at the membrane level, most probably via the formation of pores or channels.

The fact that dimers of **6a** appear to be the species that are responsible for promoting pH discharge across liposomal membranes can also account for a level of antibiotic activity that is comparable with that found for monomeric mimics of squalamine. Thus, in both cases, the majority of the monomeric and dimeric squalamine mimics are present in the bacterial membrane in nonaggregated, inactive forms, and only a small fraction are appropriately clustered to promote ion transport. At the same time, these results suggest that the active species may not be of the type that are illustrated in Figure 1. In particular, one can envision an alternate structure in which both monomers fully span the bilayer but lie antiparallel. Here, the hydrophilic face of each sterol lies across from the polyamine moiety of a neighboring conjugate. If this structure is correct, then one might expect that head-to-tail dimers could be more active than the head-to-head (molecular umbrella-like) dimers reported herein. The reason for the relatively low activity of those conjugates bearing four sterols and four pendent spermine moieties (i.e., **7a**, **7b**, and **7c**) is not presently clear. One possibility is that adverse steric interactions with peripheral proteins may inhibit their effective insertion into the plasma membrane.

CONCLUSIONS

Short and efficient syntheses have been devised for the preparation of a series of dimeric mimics of squalamine. Those mimics having relatively high facial hydrophilicity exhibit generally strong antibacterial properties, especially toward Gram-positive bacteria. Structure−activity studies, along with kinetic measurements for pH discharge in model membranes, have provided inferential evidence, which point toward a mechanism of action that involves membrane perturbation, most probably pore or channel formation. The fact that dimeric mimics of squalamine have molecular umbrella-like features raises the intriguing possibility that their biodistribution may be quite different than squalamine, itself, or monomeric mimics of squalamine. Whether such differences can improve their therapeutic potential, however, remains to be established.

Received July 20, 2006; Revised Manuscript Received October 3, 2006

High-affinity nitrilotriacetic acids (NTA) have great potential in the molecular manipulation of His-tagged proteins. We have developed a facile method to synthesize multivalent NTA and its conjugates. Starting with appropriately protected lysine, we synthesized the mono-NTA synthons functionalized with either an amino group or a carboxylic group. We then obtained tri-NTA through the condensation of the amino NTA and the carboxylic NTA. Using amino tri-NTA as the key intermediate, we synthesized a series of tri-NTA conjugates with a variety of functional units including biotin, dialkyl, fluorescein, and a hydroxybenzimidate moiety. The biotin−tri-NTA was employed to convert a Biacore streptavidin chip into a high-affinity tri-NTA chip. The equilibrium dissociation constants of tri-NTA/His-tagged protein complexes measured by surface plasmon resonance are in the 20 nM range. Histidine-(6)-tagged yeast cytosine deaminase (His6-yCD) was incorporated onto the liposome surface by the lipid−tri-NTA conjugate without any activity loss. Fluorescein−tri-NTA formed a stable 1:1 complex with His6-yCD without significant fluorescence quenching. Specific tri-NTA derivatives for the radiolabeling and coupling of two His-tagged proteins to each other are described. Thus, we have added to the toolbox a number of high-affinity tri-NTA adaptors for the manipulation of His-tagged molecules.

INTRODUCTION

Generic chemical tools are highly sought for the selective and efficient modification of recombinant proteins. Nitrilotriacetic acid (NTA) has become a commonly used reagent for the purification of His-tagged proteins since the introduction of immobilized metal-affinity chromatography (IMAC) (*1*, *2*). Although the binding affinity of mono-NTA (K_D ca. 10 μM) (*3*, *4*) fulfills the need of IMAC, the molecular-level manipulation of His-tagged proteins requires tighter association to form stable complexes at low concentrations often found in biological systems. Theoretically, three NTAs will form exactly three coordination pairs with the hexahistidine (His6) tag, and provide sufficient binding affinity to form a tight NTA−protein complex. Indeed, multivalent NTAs have higher binding affinity (K_D ca. 20 nM) toward His-tagged proteins than mono-NTA (*5*). In the work of Lata and colleagues, tri-NTA had significantly higher affinity toward His-tagged proteins than bis-NTA, but tetra-NTA provided no additional binding advantage over tri-NTA. Thus, tri-NTA is a good choice for a multivalent adaptor to join a functional moiety to His6 recombinant proteins. We sought to develop an efficient method to synthesize tri-NTA conjugates and to use them for the analysis and modification of His-tagged proteins for use in diagnostic and delivery systems.

While mono-NTA has been mostly used in the purification of His-tagged proteins, it has also been applied to other manipulations of His-tagged proteins such as surface immobilization (*6*−*9*), biosensor detection (*10*−*12*), and fluorescence labeling (*3*, *13*, *14*). Multivalent NTA derivatives are better suited for these applications due to the stronger binding affinity. Recently, ditetradecylamine−tri-NTA (NTA_3−DTDA) was used to introduce His-tagged monoclonal antibody fragment onto a liposome surface for tumor immunotherapy (*15*). The synthesis of NTA_3−DTDA was not disclosed in this paper or in a later related publication (*16*). In the course of our present work, some fluorophore−tri-NTA conjugates have been reported for the specific and stable labeling of His-tagged proteins (*17*). Quantitative labeling was achieved with fluorophore−tri-NTA, while the fluorophore−mono-NTA-protein complex was hardly detectable. However, the load of Ni(II) on the fluorophore−tri-NTA resulted in significant fluorescence quenching due to possible electron and energy transfer (*18*, *19*). In this paper, we report the facile synthesis of a series of tri-NTA conjugates with improved yields. We illustrate a few examples of their applications for the creation of a modified Biacore surface and for the attachment of a His-tagged enzyme to the liposome surface.

EXPERIMENTAL PROCEDURES

General. H-Lys(Z)-OtBu.HCl was from BACHEM (Torrance, CA). Fluorescein−PEG-NHS was from Nektar, Inc. (Huntsville, AL). Phospholipids were purchased from Avanti Polar Lipids (Alabaster, AL). Phosphate buffered silane (PBS) was from UCSF Cell Culture Facility. Other reagents were from Aldrich (Milwaukee, WI). ^{1}H NMR (400 MHz) spectra were recorded on a Varian 400 MHz instrument. Chemical shifts are expressed as parts per million using tetramethylsilane as internal standard. *J* values are in hertz. MALDI-TOF mass spectra were obtained at the Mass Spectrometry Facility, University of California, San Francisco. TLC analyses were performed on 0.25-mm silica gel F_{254} plates. High-performance flash chromatography (HPFC) was carried out on a Biotage (Charlottesville, VA) Horizon HPFC system with pre-packed silica gel columns (60 Å, 40−63 μm). Unless noted otherwise, the ratios describing the composition of solvent mixtures represent relative volumes.

Compound ***1***. To a suspension of H-Lys(Z)-OtBu.HCl (14.64 g, 39.5 mmol) in DMF (300 mL) were added *tert*-butyl

bromoacetate (23.3 mL, 158 mmol) and diisopropylethylamine (33.7 mL, 198 mmol) under nitrogen. The reaction mixture was stirred overnight at 55 °C. The volatiles were evaporated under reduced pressure at 60 °C. The slurry residue was extracted with hexane−ethyl acetate (3:1) three times (200 mL × 3). The combined extracts were then concentrated and purified by high-performance flash chromatography (HPFC) with programmed elution gradient (25−40% ethyl acetate in hexane). Yield: 19.7 g, 88.3% with respect to (wrt) H-Lys(Z)-OtBu.HCl. TLC: $R_f = 0.46$ in hexane−ethyl acetate (3:1). ^{1}H NMR ($CDCl_3$), δ 1.42 (s, 18H); 1.45 (s, 9H); 1.53 (m, 4H); 1.62 (m, 2H); 3.20 (m, 2H); 3.31 (t, $J = 7.2$, 1H); 3.44 (dd, $J = 16$, 8.4, 4H); 5.08 (s, 2H); 7.34 (m, 5H). MALDI-MS calcd for $C_{30}H_{49}N_2O_8^+$ $[M + H]^+$ 565.35, found 565.39.

*Compound **2***. To a solution of **1** (15 g, 26.5 mmol) in methanol (200 mL) under nitrogen were added 10% Pd/C (1 g) and ammonium formate (13.6 g, 216 mmol) solution in 10 mL water and 90 mL methanol sequentially. The reaction mixture was vigorously stirred for 3 h under nitrogen at 40 °C. Pd/C was filtered off over celite, and the filtrate was evaporated under reduced pressure. The residual ammonium formate was removed by repeated evaporation with ethanol. The crude product was then purified by HPFC (10−18% methanol in chloroform). Yield: 10.5 g, 91.8% wrt **1**. TLC: $R_f = 0.5$ in chloroform−methanol (6:1). ^{1}H NMR ($CDCl_3$), δ 1.44 (s, 18H); 1.45 (s, 9H); 1.63 (m, 6H); 2.87 (t, $J = 7.2$, 2H); 3.29 (t, $J = 7.6$, 1H); 3.44 (dd, $J = 17.2$, 9.2, 4H). MALDI-MS calcd for $C_{22}H_{42}N_2O_6^+$ $[M + H]^+$ 431.35, found 431.30.

*Compound **3**.* To a solution of **1** (7 g, 12.3 mmol) in chloroform (40 mL) were added trifluoroacetic acid (TFA) (20 mL) and triisopropylsilane (1 mL). The reaction mixture was stirred at 23 °C and monitored by TLC. After 3 h, methanol (10 mL) and water (5 mL) were added to the reaction mixture. The volatiles were evaporated under reduced pressure. The residue was dried azeotropically with toluene and triturated with anhydrous ether. The white precipitate was collected and dried over high vacuum. Yield: 4.36 g, 89% wrt **1**. TLC: $R_f = 0.06$ in chloroform−methanol−water (65:25:4). ^{1}H NMR (MeOH-d_4), δ 1.48−1.53 (m, 4H); 1.66 (m, 1H); 1.78 (m, 1H); 3.15 (m, 2H); 3.45 (t, $J = 12.8$, 1H); 3.63 (dd, $J = 18$, 9.6, 4H); 5.08 (s, 2H); 7.36 (m, 5H). MALDI-MS calcd for $C_{18}H_{24}N_2NaO_8^+$ $[M + Na]^+$ 419.14, found 419.11.

*Compound **4***. To a solution of **3** (2.33 g, 5.87 mmol) in anhydrous DMF (50 mL) were added *N*-hydroxysuccinimide (NHS) (4.05 g, 35.22 mmol), 4,4-dimethylaminopyridine (DMAP) (1 g), and dicyclohexylcarbodiimide (DCC) (7.25 g, 35.22 mmol). The reaction was kept at 23 °C for 5 h, then a solution of **2** (11.37 g, 26.42 mmol) and anhydrous diisopropylethylamine (3 mL) in anhydrous methanol-free chloroform (25 mL) was added. After 24 h reaction, the mixture was filtered and the filtrate was evaporated to dryness under reduced pressure. The residue was loaded onto column and purified by HPFC (0−4% methanol in chloroform). Yield: 9 g, 93.8% wrt **3**. TLC: $R_f = 0.84$ in chloroform−methanol (9:1). ^{1}H NMR ($CDCl_3$), δ 1.44 (s, 54H); 1.46 (s, 27H); 1.53 (m, 16H); 1.63 (m, 8H); 3.20−3.31 (m, 12H); 3.44 (m, 16H); 5.08 (s, 2H); 7.34 (m, 5H).

*Compound **5***. To a solution of **4** (9 g, 5.5 mmol) in 95% methanol (120 mL) under nitrogen were added 10% Pd/C (0.69 g) and ammonium formate (4 g, 63.4 mmol) solution in 4 mL water and 20 mL methanol sequentially. The reaction mixture was vigorously stirred for 3 h under nitrogen at 40 °C. Pd/C was filtered off over celite, and the filtrate was evaporated under reduced pressure. The residual ammonium formate was removed by repeated evaporation with toluene. The crude product was then purified by HPFC (4−10% methanol in chloroform). Yield: 7.2 g, 90.6% wrt **4**. TLC: $R_f = 0.48$ in chloroform−methanol (9:1). ^{1}H NMR ($CDCl_3$), δ 1.44 (s, 54H); 1.46 (s, 27H); 1.53 (m, 8H); 1.63 (m, 8H); 1.78 (m, 4H); 1.94 (m, 4H); 3.20−3.31 (m, 12H); 3.44 (m, 16H). MALDI-MS calcd for $C_{77}H_{144}N_9O_{23}^+$ $[M + H + NH_4OOCH]^+$ 1563.04, found 1563.07.

*Compound **6***. To a solution of biotin (2.44 g, 10 mmol) in DMF (130 mL) were added NHS (1.38 g, 12 mmol), DMAP (0.2 g), and DCC (2.88 g, 14 mmol). The reaction was kept at 23 °C overnight, and the precipitate was filtered off. Then, 4,7,10-trioxatridecane diamine (22 mL, ca. 100 mmol) and diisopropylethylamine (5 mL) were added to the filtrate. After 16 h reaction, the volatiles were evaporated at reduced pressure, and the residue was triturated with diethyl ether (250 mL). The solid was dissolved in chloroform (150 mL) and filtered again. The filtrate was then evaporated and triturated with diethyl ether. The crude solid product was dissolved in the minimum amount of chloroform and purified by HPFC (chloroform to chloroform−methanol−ammonia, 65:35:5). Yield: 2.2 g, 49.2% wrt biotin. TLC: $R_f = 0.44$ in chloroform−methanol−ammonia (65:35:5). ^{1}H NMR ($CDCl_3$), δ 1.44 (m, 2H); 1.65 (m, 2H); 1.77 (m, 6H); 2.19 (t, $J = 7.2$, 2H); 2.60 (br, 2H); 2.72 (m, 2H); 2.85 (m, 2H); 3.15 (m, 1H); 3.34 (m, 2H); 3.55−3.63 (m, 12H); 4.30 (m, 1H); 4.49 (m, 1H); 5.47 (br, 1H); 6.37 (br, 1H); 6.96 (br, 1H). MALDI-MS calcd for $C_{40}H_{39}N_4O_5S^+$ $[M + H]^+$ 447.27, found 447.21.

*Compound **7***. To a solution of **6** (2.2 g, 4.92 mmol) in dry, ethanol-free chloroform (50 mL) was added succinic anhydride (1 g, 5 mmol) and anhydrous diisopropylethylamine (3 mL). The reaction mixture was stirred at 23 °C for 18 h, and evaporated to dryness. The residue was triturated with diethyl ether (100 mL) and purified by HPFC (chloroform to chloroform−methanol−ammonia, 65:25:4). Yield: 2.1 g, 78% wrt **6**. TLC: $R_f = 0.24$ in chloroform−methanol−ammonia (65:25:4). ^{1}H NMR ($CDCl_3$), δ 1.45 (m, 2H); 1.69−1.77 (m, 8H); 2.20 (t, $J = 7.2$, 2H); 2.48 (m, 2H); 2.66 (m, 2H); 2.92 (m, 2H); 3.04 (m, 2H); 3.17 (m, 1H); 3.35 (m, 2H); 3.55−3.63 (m, 12H); 4.35 (m, 1H); 4.51 (m, 1H); 6.61 (br, 1H); 6.87 (br, 1H); 6.99 (br, 1H). MALDI-MS calcd for $C_{24}H_{43}N_4O_8S^+$ $[M + H]^+$ 547.28, found 547.30.

*Compound **8***. To a solution of **7** (0.53 g, 0.97 mmol) in dry, methanol-free chloroform (15 mL), were added NHS (167.3 mg, 1.46 mmol), DMAP (50 mg), and DCC (300 mg, 1.46 mmol). The mixture was stirred at 23 °C for 3 h, and a solution of **5** (1.45 g, 0.97 mmol) in dry, ethanol-free chloroform (15 mL) was added. After overnight reaction, the precipitate was filtered off, and the filtrate was concentrated under reduced pressure. The residue was purified by HPFC (0−10% methanol in chloroform). Yield: 1.42 g, 72.2% wrt **7**. TLC: $R_f = 0.19$ in chloroform−methanol (9:1).^{1}H NMR ($CDCl_3$), δ 1.46 (m, 83H); 1.53−1.78 (m, 32H); 2.15 (m, 2H); 2.44 (m, 2H); 2.62 (m, 2H); 2.83 (m, 2H); 3.15−3.40 (m, 45H); 4.34 (m, 1H); 4.54 (m, 1H).

*Biotin−tri-NTA (**9**)*. To a solution of **8** (1.34 g, 0.637 mmol) in chloroform (27 mL) were added triisopropylsilane (2 mL) and TFA (9 mL). After 3 h reaction at 23 °C, the volatiles were evaporated at reduced pressure, and the residue was precipitated from 50 mL diethyl ether at −20 °C. The precipitate was dissolved in methanol, evaporated, and precipitated from ether again. The solid was then collected and dried over high vacuum. Yield: 0.88 g, 90.9% wrt **8**. ^{1}H NMR ($CDCl_3$), δ 1.45−1.80 (m, 34H); 2.20 (t, $J = 7.2$, 2H); 2.46 (m, 2H); 2.67 (m, 2H); 2.92 (m, 2H); 3.0−3.40 (m, 33H); 3.45−3.71 (m, 12H); 4.31 (m, 1H); 4.50 (m, 1H). MALDI-MS calcd for $C_{64}H_{107}N_{12}O_{28}S^+$ $[M + H]^+$ 1523.71, found 1523.77.

*Compound **10***. To a solution of dioctadecylamine (4.95 g, 9.48 mmol) in dichloromethane (100 mL) were added succinic anhydride (1.9 g, 2 equiv) and anhydrous triethylamine (12 mL). The reaction mixture was stirred at 23 °C overnight in the dark.

The mixture was then extracted consecutively with hydrochloric acid (1 M, 100 mL) and water (100 mL × 2), and dried over anhydrous sodium sulfate, filtered, and evaporated. The crude product was recrystallized from acetone (ca. 50 mL) twice. Yield: 5.0 g, 85% wrt dioctadecylamine. TLC: $R_f = 0.5$ in chloroform−methanol (9:1). ^{1}H NMR ($CDCl_3$), δ 0.89 (t, $J =$ 6.8, 6H); 1.26 (m, 60H); 1.54 (m, 4H); 2.68 (m, 4H); 3.23 (t, $J = 8.4$, 2H); 3.32 (t, $J = 8.0$, 2H). MALDI-MS calcd for $C_{40}H_{80}NO_3^+$ $[M + H]^+$ 622.62, found 622.64.

*Compound **11***. This compound was synthesized according to the same method as **8** but using **10** as the acid substrate. The crude product was purified by HPFC (0−4% methanol in chloroform). Yield: 86.3% wrt **10**. TLC: $R_f = 0.6$ in chloroform−methanol (9:1). ^{1}H NMR ($CDCl_3$), δ 0.89 (t, $J = 6.8$, 6H); 1.26 (m, 60H); 1.44 (s, 54H); 1.46 (s, 27H); 1.53−1.80 (m, 28H); 2.50 (t, $J = 6.8$, 2H); 2.61 (t, $J = 6.8$, 2H); 3.17−3.31 (m, 16H); 3.44 (m, 16H).

*DOD−tri-NTA (**12**)*. Compound **12** was synthesized according to the same method as **9** but using **11** as the substrate. The crude product was extracted with hexane twice at −20 °C and repeatedly dried with methanol, then dried over high vacuum. Yield: 90.8% wrt **11**. ^{1}H NMR (MeOH-d_4), δ 0.90 (t, $J = 6.8$, 6H); 1.28 (m, 60H); 1.48−1.80 (m, 28H); 2.68 (m, 4H); 3.17−3.34 (m, 16H); 3.44−3.70 (m, 16H). MALDI-MS calcd for $C_{80}H_{144}N_9O_{23}^+$ $[M + H]^+$ 1599.04, found 1599.10.

*Compound **13***. To a solution of fluorescein−PEG-NHS (500 mg, Mw 2000, ca. 0.25 mmol) in dry, ethanol-free chloroform (20 mL) was added **5** (0.38 g, 0.25 mmol) and diisopropylethylamine (anhydrous, 1 mL). The reaction mixture was purged with argon and stirred in the dark at 23 °C overnight. The volatiles were evaporated under reduced pressure, and the residue was purified by HPFC (2−9% methanol in chloroform). Yield: 215 mg, 25% wrt fluorescein−PEG-NHS. TLC: $R_f =$ 0.21 in chloroform−methanol (9:1). ^{1}H NMR ($CDCl_3$), δ 1.44 (s, 54H); 1.46 (s, 27H); 1.53−1.78 (m, 26H); 2.44 (t, $J = 6.4$, 2H); 3.24 (m, 14H); 3.45 (m, 16H); 3.60 (m, 180H); 6.59−6.78 (m, 5H); 7.05 (m, 1H); 7.64 (m, 3H).

*Fluorescein−tri-NTA (**14**)*. This compound was synthesized according to the same method as **9** but using **13** as the substrate. Yield: 90% wrt **13**. ^{1}H NMR ($CDCl_3$), δ 1.53−1.78 (m, 26H); 2.46 (t, $J = 6.4$, 2H); 3.06−3.31 (m, 14H); 3.48 (m, 16H); 3.60 (m, 180H); 6.51−6.80 (m, 5H); 7.06 (m, 1H); 7.64 (m, 3H). MALDI-MS calcd for $C_{155}H_{265}N_{10}O_{72}S^+$ $[M + H]^+$ 3450.84, found 3450.80.

*Compound **15***. Methyl *p*-hydroxybenzimidate hydrochloride (0.308 g, 1.65 mmol) and **5** (0.5 g, 0.33 mmol) were placed in dry, ethanol-free chloroform (15 mL). Upon the addition of diisopropylethylamine (1 mL), the reaction mixture turned clear. The reaction was kept at 23 °C overnight. Then, chloroform−water (40 mL/40 mL) was added to the mixture, and the oil layer was washed with water (40 mL) again. The organic layer was evaporated and purified by HPFC (10−70% methanol in chloroform). Yield: 332 mg, 62.2% wrt **5**. TLC: $R_f = 0.63$ in chloroform−methanol (4:1). ^{1}H NMR ($CDCl_3$), δ 1.44 (s, 54H); 1.46 (s, 27H); 1.53−1.78 (m, 24H); 3.16−3.30 (m, 12H); 3.45 (m, 16H); 6.59 (m, 2H); 7.42 (m, 2H); 8.01 (br, 2H). MALDI-MS calcd for $C_{83}H_{144}N_9O_{22}^+$ $[M + H]^+$ 1619.05, found 1619.02.

*Compound **16***. This compound was synthesized according to the same method as **9** but using **15** as the substrate. Yield: 93% wrt **15**. ^{1}H NMR (MeOH-d_4), δ 1.55−1.89 (m, 24H); 3.24 (m, 12H); 3.50 (m, 16H); 6.97 (m, 2H); 7.65 (m, 2H). MALDI-MS calcd for $C_{47}H_{72}N_9O_{22}^+$ $[M + H]^+$ 1114.48, found 1114.42.

*Compound **17***. 3,6,9-Trioxaundecanoic diacid (110 mg, 0.495 mmol) was azeotropically dried with toluene and then dissolved in dry, ethanol-free chloroform (20 mL). To this solution were added NHS (125.3 mg, 1.09 mmol), DMAP (50 mg), and DCC (224.3 mg, 1.09 mmol). The reaction was kept at 23 °C for 1 h, then **5** (1.63 g, 1.09 mmol) with additional dicyclohexylcarbodiimide (224.3 mg, 1.09 mmol) in dry ethanol-free chloroform (15 mL) was added to the reaction mixture. The reaction was left at 23 °C overnight. The precipitate was filtered off, and the filtrate was evaporated at reduced pressure. The crude product was purified by HPFC (0−5% methanol in chloroform). Yield: 0.97 g, 61.5% wrt 3,6,9-trioxaundecanoic diacid. ^{1}H NMR ($CDCl_3$), δ 1.44 (s, 54H); 1.46 (s, 27H); 1.52−1.88 (m, 48H); 3.24 (m, 24H); 3.45 (m, 32H); 3.70 (m, 8H); 3.98 (m, 4H).

*Compound **18***. This compound was synthesized according to the same method as **9** but using **17** as the substrate. Yield: 95% wrt **17**. ^{1}H NMR (MeOH-d_4), δ 1.49−1.80 (m, 48H); 3.24 (m, 24H); 3.45−3.71 (m, 40H); 4.00 (m, 4H). MALDI-MS calcd for $C_{88}H_{142}N_{16}NaO_{47}^+$ $[M + Na]^+$ 2197.91, found 2197.96.

Cloning, Expression, and Purification of His-yCD. The yeast cytosine deaminase gene was amplified by a polymerase chain reaction using Pfu Ultra DNA polymerase (Stratagene, La Jolla, CA), pORF-fcy::fur plasmid (InvivoGen, San Diego, CA) as a template, a 5′ primer designed to include NdeI restriction site and a 6x-histidine tag followed by a thrombin cleavage site sequence (5′-CTCGT**CATATG**CATCATCACCACCATCACCTGGTGCCACGCGGTAGTGTCACAGGAGGCATGGC-3′), and a 3′ primer including XhoI restriction site and a stop codon (5′-GCTCGT**CTCGAG**TTACTCCCCAATGTCCTCAAAC-3′). The amplified gene and pET41 bacterial expression vector (Novagen; San Diego, CA) were digested with NdeI and XhoI restriction enzymes (New England Biolabs; Beverly, MA) and ligated together using T4 ligase (New England Biolabs; Beverly, MA). The ligated plasmid, pET41-HY, was transformed into DH5α *E. coli* cells (Invitrogen; Carlsbad, CA). The DNA sequence of purified pET41-HY plasmid was verified (SeqWrite DNA Technology Services; Houston, TX).

Expression and purification of His-yCD from *E. coli* were accomplished following published protocols (*20*, *21*). To express His6-yCD, purified pET41-HY plasmid was transformed into BL21-Codon Plus (DE3)-RIPL *E. coli* cells (Stratagene; La Jolla, CA). For a large-scale expression, the cells were grown in 1 L of LB culture medium containing 30 μg/mL kanamycin and 50 μg/mL chloramphenicol at 35 °C until the $OD_{600\ nm}$ reached 0.6−0.8, and the protein expression was induced by adding 0.5 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) supplemented with 0.5 mM zinc acetate. The protein was expressed overnight at 23 °C with constant shaking at 200 rpm.

To purify His-yCD, the IPTG-induced cells were harvested by centrifugation at 6000 × *g* at 4 °C for 30 min. The cell pellet was resuspended in 20 mL of the lysis buffer containing 300 mM NaCl, 20 mM Tris-Cl, 40 mM imidazole, 0.2% Triton X-100, and 0.5 mM PMSF protease inhibitor. After one freeze−thaw cycle, the cells were lysed by lysozyme and sonication treatments on ice−water bath. The cell lysate was further treated with DNase I and RNase A, and it was centrifuged at 10 000 × *g* for 45 min at 4 °C. 1 mM DTT was added to the supernatant fraction and filtered through a 0.4 μm membrane. The filtered supernatant fraction was applied to HisTrap FF affinity column (Amersham Biosciences; Piscataway, NJ) pre-equilibrated with 300 mM NaCl, 20 mM Tris-Cl, pH 8.0, 40 mM imidazole at the flow rate of 1 mL/min. Then, the column was washed with a 15-column volume of the equilibration buffer, and the bound protein was eluted with the elution buffer containing 300 mM NaCl, 20 mM Tris-Cl, pH 8.0, and 500 mM imidazole. The eluates were pooled together and applied to HiPrep Sephacryl S-100HR 16/60 size exclusion column (Amersham Biosciences) equilibrated with 50 mM NaCl and 25 mM Tris-Cl, pH 8.0, at 4 °C. The column was operated at the flow rate of 0.5 mL/min, and 2 mL was collected for each fraction. $OD_{280\ nm}$ was

measured to obtain the fractions containing His6-yCD. On average, 30 mg of highly pure His6-yCD was obtained from a liter of culture using this method. The purity of His6-yCD was confirmed by SDS-PAGE analysis (see Supporting Information).

Surface Plasmon Resonance (SPR). The binding affinity of tri-NTA and His-tagged proteins was determined by SPR using an upgraded Biacore 1000 instrument (Piscataway, NJ). His6-yCD was freshly prepared as mentioned above, and the molecular weight of the dimer in the solution is ca. 36 KDa. HIP1R is a homolog of the Huntington protein HIP1, an adaptor protein for membrane transport. His6-tagged HIP1R is a generous gift from Jeremy Wilbur (University of California, San Francisco, Department of Biochemistry and Biophysics). His6-tagged HIP1R forms dimer in the solution with a molecular weight of 22 KDa. Tris-HCl buffer (50 mM NaCl, 20 mM Tris-HCl, 0.005% Tween 80, pH 8.0) served as the instrument running buffer and was used in the preparation and dilution of all samples. The streptavidin-coated SA sensor chip is from Biacore (Piscataway, NJ). The chip was pre-rinsed with 1 M NaCl, followed by 50 mM NaOH, then primed with Tris-HCl buffer, and coated with tri-NTA by flowing 100 nM biotin-PEO3-tri-NTA at 20 μL/min for 1 min to capture a 50 RU response. Various concentrations of the His-tagged HIP1R protein were injected to flow over the tri-NTA surface, according to an automated program cycle of the following sequence: (1) activation of tri-NTA with Ni(II), (2) protein injection, (3) Ni(II) removal with 0.3 M EDTA, and (4) rinse with 0.25% SDS for baseline regeneration. For the reference control, the same program cycle was used, except that no Ni(II) was provided in the first step. Both sample and control measurements were run in duplicate. The crude data were processed with the manufacturer-supplied *Biaevaluation 3.2 RC1* software, and the kinetic parameters were obtained by fitting the experimental curves with 1:1 Langmuir binding model.

Load of His6-Tagged yCD on Liposomes. Liposomes were prepared by sonication and extrusion as described by Szoka et al. (*22*). Briefly, a solution of given lipids was added to a depyrogenated borosilicate glass tube and evaporated under reduced pressure at room temperature to form a lipid film. The tube was placed under high vacuum overnight to remove residual solvent. Films were hydrated in 1 mL HEPES buffer (20 mM HEPES, 140 mM NaCl, pH 8.0) with intermittent vortex. Tubes containing the lipid suspension were then filled with argon, sealed, and sonicated at 23 °C for 5 min. The resultant liposomes were extruded 11 times through a 100 nm polycarbonate membrane (Nucleopore; Pleasanton, CA) with a hand-held extruder (Avestin; Ontario, Canada). The tri-NTA containing formulation (DOD−tri-NTA/POPC/Chol, 5:57:38, molar ratio) was used to bind to His-tagged yCD, and the POPG formulation (POPG/POPC/Chol, 22.5:46.5:31, molar ratio) with a similar negative charge density to the tri-NTA formulation was used as a negative control. To load the NTA head groups with Ni(II), liposomes were incubated with 5 mM $NiCl_2$ at 4 °C for 15 min with stirring. Excess Ni(II) was removed by immediately passing the liposomes down a 1 × 20 cm Sepharose 4B column under gravity flow. In some experiments, a tri-NTA-containing formulation without Ni(II) was also used as a negative control. The final phospholipid concentration was determined by the method of Bartlett (*23*). Liposome size and ζ potential were measured using a Zetasizer 3000 (Malvern, U.K.).

The ability of NTA liposomes to bind His-tagged yCD was assessed. Liposomes containing 1 μmol total lipids were incubated with 180 μg His6-yCD in 0.49 mL HEPES buffer at 4 °C for 1 h with magnetic stirring. For tri-NTA-containing lipids, this yielded a 10:1 molar ratio of DOD−tri-NTA/His6-yCD. After 1 h incubation, samples were immediately passed down a 1 × 20 cm Sepharose 4B column under gravity flow. Liposomes eluted in the void volume. The absorbance of eluted fractions at 220 nm was measured with a NanoDrop spectrophotometer (NanoDrop; Wilmington, DE). For liposome-containing fractions, phospholipid concentration was determined by the method of Bartlett. Protein concentration was determined by the CBQCA assay (Molecular Probes; Eugene, OR).

Enzyme Activity Assay. Cytosine deaminase assay was performed using the methods described by Senter et al. (*24*). Briefly, a stock solution of 50 mM 5-fluorocytosine (5-FC) was prepared in 1 × PBS. Then, 5 mM 5-FC and His6-yCD liposomes in 1 × PBS were incubated together at 37 °C. An aliquot (20 μL) of the reaction mixture was removed at given time point, and quenched by 0.1 N HCl in 1 × PBS (980 μL). The amount of 5-fluorouracil (5-FU) formed in the reaction was determined by measuring the UV absorbance at 255 and 290 nm.

Fluorescent Labeling of His-yCD. Fluorescein−tri-NTA was incubated with excessive $NiCl_2$ for 15 min at 23 °C in the dark and chromatographed on a Sephacryl S-100 HR column (1 × 20 cm) to remove the excessive Ni(II). Then, the Ni(II)-loaded fluorescein−tri-NTA was incubated with His6-yCD at a given molar ratio. The mixture was separated on a Sephacryl S-100 HR column (1 × 20 cm). Fractions were monitored at both 220 nm (protein) and 492 nm (fluorescein). When fluorescein−tri-NTA was in excess, the fractions of the first peak were pooled and analyzed by absorbance at 280 nm (protein) and 492 nm (fluorescein). All solutions were prepared in 20 mM HEPES, 150 mM NaCl, pH 8.0 buffer.

Fluorescence Spectra. The fluorescence spectra were recorded on a Spex Fluorolog fluorometer (Edison, NJ) with 1.25 mm excitation and emission slits. Fluorescein−tri-NTA was dissolved in pH 7.4 PBS and diluted to 7.5 μM for the measurement of absorption (E_m: 518 nm) and emission (E_x: 492 nm) spectra. Then, the stock solution was mixed with 3 mol equiv of $NiCl_2$ and diluted to 7.5 μM for the fluorescence spectra measurement. For fluorescein-labeled His-yCD, the concentration of fluorescein was determined by absorbance (492 nm) first, then the emission spectra of both protein and fluorescein−tri-NTA were measured at the same concentration.

RESULTS

Synthesis of NH_2-tri-NTA(*t*-Bu)$_3$. The synthetic steps for building NH_2-tri-NTA(*t*-Bu)$_3$ are shown in Scheme 1. In the initial step, H-Lys(Z)-OtBu.HCl was converted to **1** by introducing two more *tert*-butyl acetate groups on the α-nitrogen. Selective removal of the protective groups from **1** led to the first generation of NTA dendrons with either an amino group (**2**) or three carboxylic groups (**3**). The coupling of **2** and **3** afforded the fully protected dendrimer **4**. The key intermediate (**5**) was obtained after the removal of Cbz group by catalytic transfer hydrogenation.

Synthesis of Biotin−tri-NTA As shown in Scheme 2, the reaction of activated biotin with excessive 4,7,10-trioxatridecane diamine gave **6** in a moderate yield. Then, the carboxylic group was introduced through the amino group by reaction with succinic anhydride. Compound **8** was obtained by the coupling of **7** and **5**. The removal of *tert*-butyl groups from **8** led to biotin−tri-NTA (**9**) in a good yield.

Synthesis of DOD−tri-NTA. The synthetic strategy (Scheme 3) is similar to the synthesis of **9.** First, dioctadecylamine was transformed to the acid derivative (**10**) using succinic anhydride. Then, **10** was activated,and coupled to **5**, affording **11**. Finally, *tert*-butyl groups were cleaved from **11**, and DOD−tri-NTA (**12**) was obtained in good overall yield.

Synthesis of Fluorescein−tri-NTA. The synthesis of **14** is straightforward (Scheme 4). The direct reaction of commercially available fluorescein−PEG2000-NHS and **5** led to **13** in 25% yield after the removal of unreacted PEG by HPFC. The removal

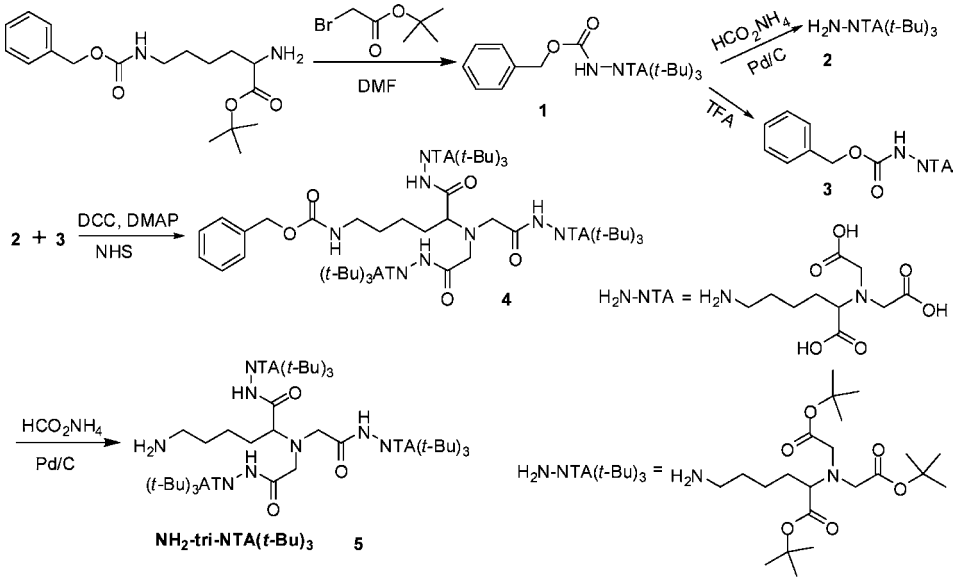
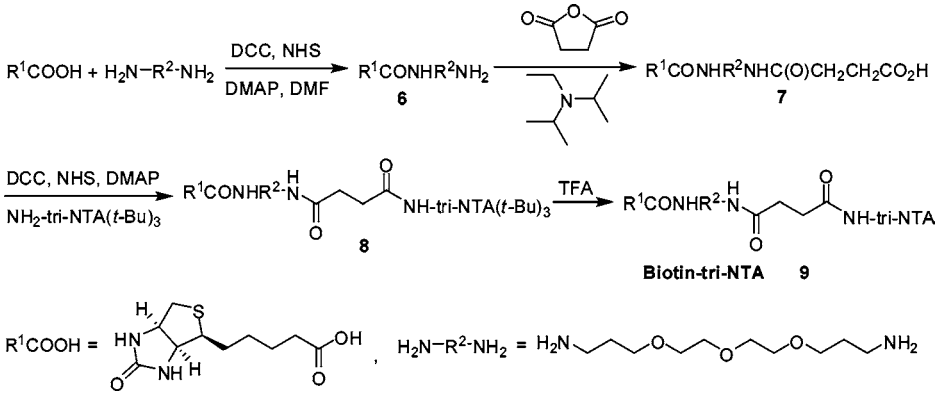
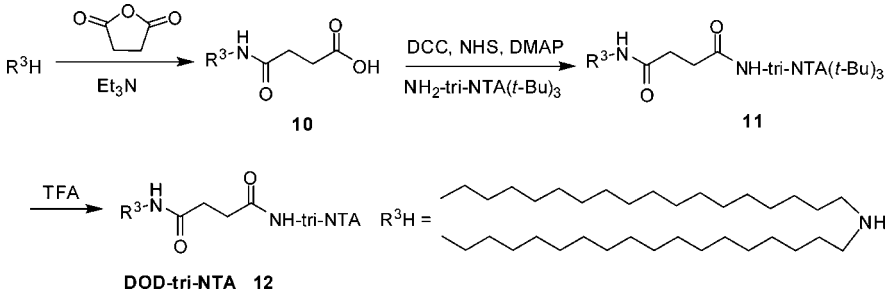


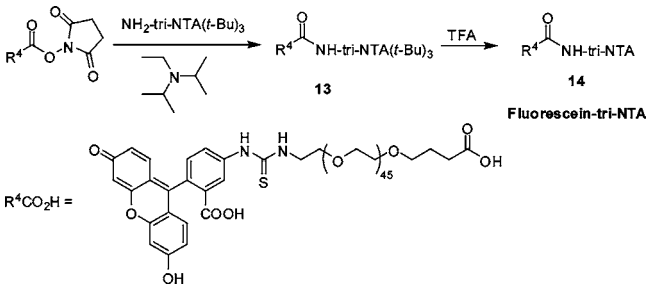
Scheme 2. Synthesis of Biotin−tri-NTA



Scheme 3. Synthesis of DOD−tri-NTA



Scheme 4. Synthesis of Fluorescein−tri-NTA



of *tert*-butyl group from **13** gave the desired product fluorescein−tri-NTA (**14**).

Synthesis of 16. As shown in Scheme 5, the reaction of NH_2-tri-NTA(*t*-Bu)$_3$ with excessive methyl *p*-hydroxybenzimidate afforded **15** in 62.2% yield. Compound **16** was obtained in high yield after the treatment of **15** with TFA.

Synthesis of 18. This molecule was synthesized following a similar method to **9** (Scheme 6). Trioxaundecanoic diacid was first activated with NHS using DCC and DMAP. Then, the activated ester was treated with slightly excessive **5**, affording **17** in moderate yield. The cleavage of *tert*-butyl groups with TFA gave the final product **18** in high yield.

Binding Constants. We synthesized biotin−tri-NTA as a bridging reagent to allow the use of standard streptavidin Biacore chip to anchor His6-containing protein and peptide to the chip. These proteins could then be used as receptors for probing protein−ligand interactions. In order to minimize surface crowding (*25*), we coated the SA chip with a very low density (50 response units, about 0.005 ng/mm) of biotin−tri-NTA. Signal from nonspecific interactions of His-tagged protein with

K_a (1/Ms)	8.65×10^4	1.66×10^5	2.16×10^5	1.89×10^5	4.04×10^5
K_d (1/s)	2.88×10^{-3}	3.43×10^{-3}	3.92×10^{-3}	4.32×10^{-3}	2.17×10^{-3}
K_D (M)	3.33×10^{-8}	2.06×10^{-8}	1.81×10^{-8}	2.28×10^{-8}	5.37×10^{-9}
χ^2 [a]	0.609	0.226	1.42	3.03	0.232

[a] The χ^2 value represents the sum of squared differences between the experimental data and the fit data at each point. It was used to evaluate the quality of fit between the experimental data and the binding model.

Table 2: Liposome Diameter and ζ Potential

	POPG[a]	NTA[b]	NTA + Ni[c]	NTA−yCD[d]
diameter (nm)	104.3 ± 0.8	91.5 ± 1.5	139.6 ± 4.6	105.6 ± 2.9
ζ potential (mV)	−29.6 ± 12.7	−37.2 ± 12.3	−24.2 ± 4.6	−24.6 ± 8.4

[a] POPG liposomes: POPG/POPC/Chol, 22.5:46.5:31. [b] Tri-NTA liposomes: DOD−tri-NTA/POPC/Chol, 5:57:38. [c] Ni(II) loaded tri-NTA liposomes. [d] Tri-NTA liposomes with His6-yCD engrafted on the surface.

the prepared tri-NTA surface was removed by subtracting the response on the control surface (inactivated tri-NTA). After appropriate processing of the raw data (e.g., alignment, zeroing, and reference subtraction), the tri-NTA/His-tagged protein interaction data were fitted to a simple 1:1 Langmuir model. The kinetic parameters of the interaction at various concentrations are listed in Table 1. The χ^2 value represents the sum of squared differences between the experimental data and the fit data at each point. The χ^2 value and residual plots (not shown) indicated a satisfactory fit between the experimental data and the binding model. For His-tagged HIP1R, the computed equilibrium dissociate constant (K_D) was around 20 nM (18−33 nM). The K_D of tri-NTA/His-tagged yCD (5.4 nM) is similar to that of HIP1R, albeit slightly lower. A difference may be expected due to varying accessibility of His6 tags in their different protein structure contexts.

His6-yCD-NTA Liposomes. DOD−tri-NTA was readily incorporated into the liposome bilayer. The particle diameters and ζ potentials of all the liposomes are summarized in Table 2. The presence of DOD−tri-NTA in the liposome formulation led to a negative surface charge on the liposomes at pH 8.0. The incorporation of Ni(II) into the NTA−lipid resulted in a less-negative surface charge and larger particle diameter. The diameter change of Ni(II)-loaded liposomes may be attributed to partial aggregation due to the reduced surface charge and possible cross-linking through the relatively weak NTA-Ni(II)-NTA interaction (*26*). When His6-yCD was incubated with Ni(II)-NTA-containing liposomes for 1 h and the preparation applied to the size exclusion column, His6-yCD was associated with liposome peak (first peak), and the free protein peak was not detectable (Figure 1). Enzymatically active yCD was detected in the liposome fractions. His6-yCD on the liposome surface caused the particle diameter to drop to around 105 nm

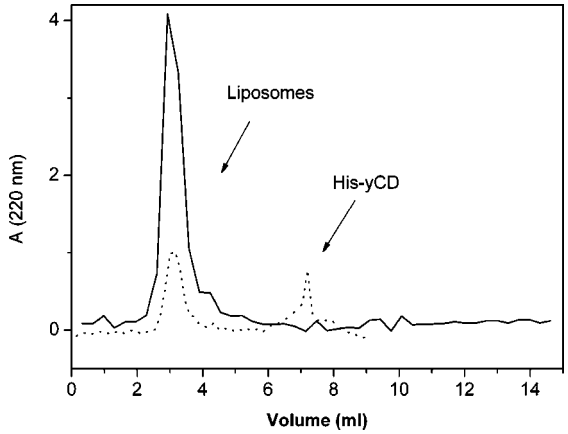

Figure 1. Incorporation of His6-yCD on the surface of tri-NTA liposome. The absorbance was monitored at 220 nm. Solid line: chromatogram of Ni(II) loaded tri-NTA liposome (excess) + His6-yCD. Dotted line: chromatogram of POPG liposome (excess) + His6-yCD. First peak: liposomes. Second peak: His6-yCD.

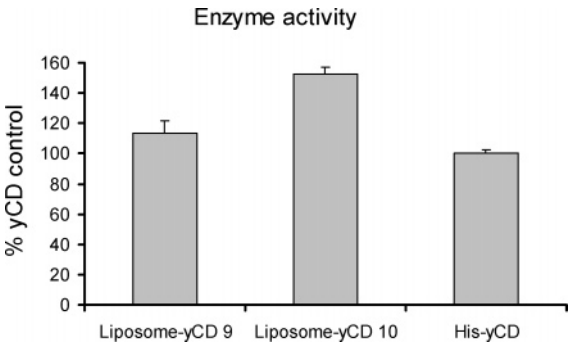

Figure 2. Relative enzyme activity of liposomal yCD. The enzyme activity was normalized with respect to the activity of yCD control. Liposome-yCD 9 and 10 are the major fractions of yCD bound on liposomes collected from size exclusion column.

and had no significant influence on the surface charge. When His6-yCD was incubated with POPG control liposomes for 1 h and passed down a Sepharose 4B column, two separate chromatographic peaks were evident. No protein was detected in the liposome peak (first peak), and enzymatically active protein was found in the second peak. Similar results were also obtained in experiments using tri-NTA liposomes without Ni(II) as an additional negative control. Liposome-associated protein was only detected on the Ni(II)-loaded tri-NTA liposomes (Supporting Information Figure S2).

Enzyme Activity of Liposomal yCD. The activity of liposomal yCD to convert 5-FC to 5-FU was measured, calculated as the rate of production of 5-FU (mM/min) per milligram of protein, and normalized with respect to the activity of free His6-yCD (Figure 2). Two liposomal yCD fractions showed a similar order of activity as that of free yCD. The slight increase in activity of liposome-associated yCD may be due to the interference of the liposome lipid on the protein concentration measurement rather than a surface-induced increase in enzyme activity.

Fluorescent Labeling of His6-yCD. We sought to confirm that fluorescein−tri-NTA could be used to noncovalently label His6-containing proteins. The absorption and emission spectra

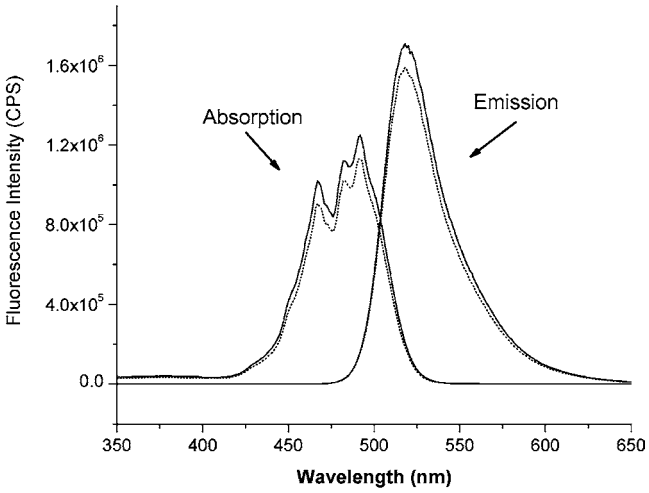

Figure 3. Fluorescence spectra of fluorescein−tri-NTA. Solid line: without Ni(II). Dotted line: Ni(II) loaded. Spectra were recorded at same concentration of fluorescein.

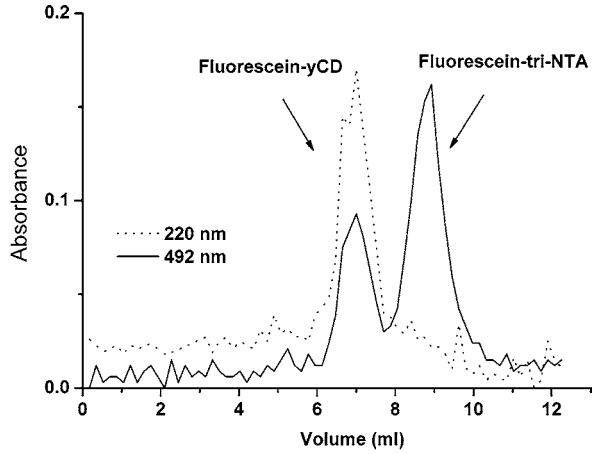

Figure 4. Fluorescent labeling of His6-yCD. His6-yCD was mixed with excessive Ni(II) loaded fluorescein−tri-NTA, then passed down a Sephacryl S-100 HR column. Absorbance of fractions was monitored at both 220 nm (protein) and 492 nm (fluorescein). First peak: fluorescein−NTA-yCD conjugate. Second peak: free fluorescein−tri-NTA.

of fluorescein−tri-NTA were measured with or without Ni(II) (Figure 3). The incorporation of Ni(II) resulted in slight decrease of both absorption and emission intensity. When His6-yCD was incubated with excess fluorescein−tri-NTA-Ni(II), two distinct peaks were obtained from the column (Figure 4). The first peak was detectable at both 220 nm (protein) and 492 nm (fluorescein). The second peak was only detectable at 492 nm, corresponding to excess fluorescein−tri-NTA-Ni(II). When excess His6-yCD was used, there was no free fluorescein−tri-NTA, and only the first peak (His6-yCD bound fluorescein) was detectable (data not shown). The absorbance analysis of the purified fluorescein−yCD conjugate showed a 1:1 (fluorescein/His6) composition. Thus, His6-yCD was quantitatively labeled with fluorescein−tri-NTA-Ni(II), and stable 1:1 conjugate was obtained after column separation. No significant fluorescence quenching was observed on the fluorescein−NTA-yCD conjugate (spectra not shown).

DISCUSSION

A number of groups have documented the great potential of multivalent NTAs in the handling of His-tagged molecules (*5*, *15*). The broad application of this type of noncovalent interaction will depend upon the ease of synthesis of the multivalent NTA and the ability to prepare a variety of multivalent NTA conjugates in high yield. Our strategy is to build NH_2-tri-NTA-(t-Bu)$_3$ as the key intermediate first and introduce specific functionality into the conjugate later. This strategy provided a general way to construct a variety of tri-NTA molecules. The presence of *tert*-butyl ester group provided NH_2-tri-NTA(t-Bu)$_3$ good organic solvent solubility and less polarity, which made the synthesis and purification of the tri-NTA conjugates much easier compared with the synthesis of tri-NTA conjugates containing multiple unprotected carboxylic groups (*5*). Furthermore, the lysine-based dendritic structure branched each mono-NTA unit seven atoms apart, which might allow a more flexible binding of NTA to His-tag that favors the formation of a stable complex.

Biotin−tri-NTA was designed and synthesized for the modification of streptavidin sensor chips so that the interaction between tri-NTA and His-tagged molecules can be measured by SPR. The inclusion of a short polyethylene oxide spacer provided good solubility and flexibility. This bifunctional adaptor can be used in many other applications where a conversion between streptavidin/biotin interaction and tri-NTA/His-tag interaction is desired. The PEO spacer could be adjusted to fit the application. Although both HIP1R and yCD form dimers in the solution and have the potential to cross-link with tri-NTA, the kinetic data showed good fits with the simple 1:1 Langmuir binding model. We avoided the potential complexity of an avidity effect due to the binding of two subunits of the His-tagged protein by the experimental conditions used here: low surface capacity, relatively high flow rate, and low concentration of analyte.

An advantage of the tri-NTA chip is that it can retain strong affinity at very low surface capacity due to the low equilibrium dissociation constant. Similar affinity can be achieved in a mono-NTA chip only at a high surface density (*12*). At high surface densities, analysis of the binding efficiency is complicated due to mass transport, surface crowding, and possible avidity effect (*25*).

Due to the low equilibrium dissociation rate, tri-NTA is a promising tool for the noncovalent modification of His-tagged proteins. Fluorescent labeling is a powerful technique for the study of biomacromolecules. We have shown that fluorescein−tri-NTA forms a stable complex with His6-yCD without significant fluorescent quenching. The coordination of Ni(II) with NTA dramatically quenches the fluorescence of NTA-associated fluorophore and the effect is distance-dependent (*17*). The PEG2000 spacer between fluorescein and tri-NTA shielded not only the influence of Ni(II) on fluorescein but also the influence of protein on fluorescence. The removal of excessive Ni(II) can be easily achieved by size exclusion chromatography in the presence of PEG2000 spacer. Thus, fluorescein−tri-NTA is an ideal molecule for the noncovalent yet reversible labeling of His-tagged proteins and a good example for making other similar fluorophores.

There is also a demand for an efficient yet mild method to radiolabel proteins without damaging the protein activity. In the traditional method, the radiolabeling chemistry is done directly on the protein, and there is always a risk of activity loss. Since His-tag technology has been widely adopted in the engineering of recombinant proteins, the use of radioactive tri-NTA as a noncovalent way of labeling protein could be a good choice. We have designed and synthesized compound **16** as a potential tool for this purpose. The beauty of this method is we can always iodinate **16** first (*27*), then conjugate it with His-tagged protein, avoiding the direct exposure of protein to the harsh iodination conditions. The use of **16** for radiolabeling His-tagged proteins is under investigation, and we will publish it elsewhere later.

To enable the noncovalent cross-linking of two different proteins to the same carrier, we have synthesized **18** as a bifunctional tri-NTA with a short polyethylene oxide spacer. This molecule could be used to form fusion proteins by attaching different His-tagged proteins at each end. It provides a shortcut to creating fusion proteins that are difficult to engineer or manufacture by the traditional recombinant methods.

Mono-NTA lipids have been used to attach His-tagged proteins to monolayers (*4*, *28*) and also liposomes (*29*). However, the affinity of the proteins to a mono-NTA lipid was not high enough to keep the protein from dissociating from the liposomal surface during separation of liposome-bound protein from nonattached protein (*29*). The introduction of tri-NTA lipid has solved the problem (*5*, *16*). The synthesis of DOD−tri-NTA introduced here is efficient. Although van Broekhoven and coworkers clearly recognized the importance of multivalent binding to attach a protein to a liposome, they did not reveal the synthesis of NTA_3−DTDA in detail (*15*, *16*). The Tampe group has discussed the synthesis of mono-NTA−lipid conjugates and the multi-NTA−fluorophore conjugates, but has not yet published the use of multivalent NTA to attach proteins to the liposome surface. As a proof of the concept, we synthesized DOD−tri-NTA and used it as an adaptor to attach His6-yCD to the liposome surface, and demonstrated complete retention of enzyme activity. Multiple proteins could be attached to the same liposome surface. Using the tri-NTA liposome as a surface to attach different proteins permits one to use a single liposome to explore the effect of a wide range of ratios of multiple proteins without having to do chemistry for each combination. As others have noted (*5*, *16*), this provides a toolbox to create combinatory arrays of proteins and other molecules such as PEG. His-tagged targeting molecules could be incorporated on the liposome surface by the same method.

We have demonstrated a practical method to synthesize the lysine-based dendron NH_2-tri-NTA(*t*-Bu)$_3$ and its derivatives. The applications of multivalent NTAs have been anticipated by others (*5*), but we provide a facile chemical synthesis to accelerate their use in biotechnology applications and drug delivery.

Preparation and Biological Characterization of Isomeric ^{188}Re(V) Oxocomplexes with Tetradentate S_4 Ligands Derived from *meso*-Dimercaptosuccinic Acid for Labeling of Biomolecules

Sepp Seifert,* Tobias Heinrich, Christian Jentschel, Christian Smuda, Ralf Bergmann, and Hans-Juergen Pietzsch

Forschungszentrum Rossendorf, Institut für Radiopharmazie, PF 510 119, D-01314 Dresden, Germany. Received July 27, 2006; Revised Manuscript Received September 15, 2006

A new type of tetradentate S_4 ligand has been synthesized by bridging two molecules of *meso*-2,3-dimercaptosuccinic acid for stable binding and easy conjugation of rhenium-188 to tumor targeting structures. The stereoisomeric tetrathiolato S_4 ligands form very robust anionic five-coordinated oxorhenium(V) and oxotechnetium(V) complexes. Two routes for the preparation of the ^{188}Re(V) oxocomplexes with $(iBu)_2N(O)C-C(SH)C(SH)C(O)NH(CH_2)_3NH(CH_2)_3NHC(O)C(SH)C(SH)C(O)N(iBu)_2$ (ligand **1**) and its hydrophilic crown ether derivative (ligand **2**) were tested and optimized. Several isomers were separated by HPLC from the preparation solutions and characterized *in vitro* and *in vivo*. The identity of the species obtained was determined by comparison with the HPLC profiles of reference $^{185/187}$Re analogues and $^{99/99m}$Tc complexes which were characterized by ESI-MS. All of them were absolutely stable in rat and human plasma solutions. Challenge experiments with cysteine corroborated the high inertness of the isomers toward ligand exchange reactions. Various *in vivo* samples, taken off at different times from blood, intestine, and urine of rats, confirmed the high *in vivo* stability of the $^{188}Re-S_4$ complexes. Biodistribution studies using male Wistar rats were performed and exhibited a high uptake and fast clearance from the liver of the more lipophilic cis and trans isomers of complex **I** (log $P_{o/w}$ between 1.5 and 1.7), whereas the isomers of the hydrophilic complex **II** (log $P_{o/w}$ about -1.75) were rapidly excreted *via* the renal and the hepatobiliary pathway. The low level of activity in the stomach confirms good *in vivo* stability. Thus, these new $^{188}Re-S_4$ complexes fulfill the requirements for a stable and high specific activity labeling of biomolecules with rhenium-188.

INTRODUCTION

Rhenium-188 ($E_{\beta max} = 2.1$ MeV, $t_{1/2} = 16.9$ h) is an attractive radionuclide for developing therapeutic radiopharmaceuticals due to its favorable nuclide properties and its daily availability from commercial $^{188}W/^{188}Re$ generators in high specific activity (*1*−*3*). Besides the therapeutic usefulness of ^{188}Re, the emission of the 155 keV gamma photon is an additional advantage since the biodistribution of ^{188}Re-labeled agents can be evaluated *in vivo* with a gamma camera. A further advantage of using rhenium-188 as a therapeutic radionuclide is the chemical analogy with technetium-99m, which is the most widely used radioisotope in gamma camera imaging. Both radionuclides are obtained as sodium permetalates by elution of the generator with 0.9% saline. Because $Na^{188}ReO_4$ constitutes the starting material for the preparation of ^{188}Re radiopharmaceuticals, any synthetic procedure must comprise an appropriate reduction step required to change the metal oxidation state from +7 to lower values and to allow the formation of complexes between the metal and some selected ligand. To improve the potencies of rhenium-188, tumor-specific substances must be developed to accumulate the radioactive compound in the tumor and to spare healthy tissue from radiation. This can be achieved by linking a radionuclide-bearing chelate to a target-seeking biomolecule. Various chelate systems coordinating the metal at different oxidation states are currently under investigation for stable labeling of biomolecules according to the bifunctional approach (*4*−*8*). At oxidation state +5, ligands of the "N_2S_2" or "N_3S" type (e.g., *9*−*11*) are used. They bind rhenium rapidly to form stable pentacoordinate complexes with oxorhenium(V). Unfortunately, chelate complexes of ^{188}Re often degrade much more rapidly than the ^{99m}Tc analogues, which are limiting the further development of rhenium-based therapeutic agents.

To overcome this stability problem, we developed a tetradentate S_4 ligand system derived from *meso*-dimercaptosuccinic acid (DMSA), which forms very robust oxorhenium(V) complexes (*12*). Two isomers have been fully characterized both in solid and solution states and found to adopt the expected square-pyramidal coordination geometry. The equatorial plane is formed by four thiolate sulfur atoms, whereas the oxygen occupies the apical position. The orientation of the metal oxo group is exo in relation to the carbamido groups in both isomers (Figure 1).

In the present study, we describe preparation routes for the lipophilic complex **I** (no carrier added and carrier added ^{99m}Tc−S_4 **I** and carrier-free $^{188}Re-S_4$ **I**) and the hydrophilic $^{188}Re-S_4$ complex **II** (Figure 2).

While the preparation of the ^{99m}Tc(V) oxocomplex succeeded in one step in alkaline solution with propylene glycol as an ancillary ligand (*13*), attempts to prepare the corresponding ^{188}Re complex by direct reduction of perrhenate, according to the preparation of $[^{188}ReO(DMSA)_2]^-$ (*14*), failed. However, the preparation was successful using conditions described by Bolzati et al. (*15*). This procedure differs from that commonly applied to the reduction of pertechnetate or perrhenate by the presence of two additional reagents (oxalate ions as ancillary ligand and γ-cyclodextrin as host molecule). Beside this improved preparation method, we also tested an indirect preparation route. Recently, we have reported the preparation of ^{188}Re(V) oxocomplexes by a combined reoxidation/ligand exchange reaction starting from ^{188}Re(III)−EDTA (*16*). The formation of the precursor complex and the subsequent preparation of the desired ^{188}Re(V) complexes may be performed under mild conditions

and consequently allows the labeling of sensitive biomolecules coupled to bidentate or tetradentate chelators.

Beside various preparation methods, we report on the *in vitro* and *in vivo* behavior of the two ^{188}Re−S_4 complexes **I** and **II** and their isolated isomers.

EXPERIMENTAL PROCEDURES

Materials and Methods. All solvents and commercially available substances were of reagent grade and used without further purification. The tetradentate S_4 ligand **1** has been synthesized by bridging two molecules of *N*,*N*′-diisobutyl-2,3-dimercaptosuccinamide with *N*-(3-aminopropyl)propane-1,3-diamine (*12*). Ligand **2** was prepared in an analogous way, starting from 4-nitrophenyl 2,2-dimethyl-5-(1,4,7,10,13-pentaoxa-16-azacyclooctadecan-16-ylcarbonyl)-1,3-dithiolane-4-carboxylate. $Na^{99m}TcO_4$ was obtained from a ^{99}Mo/^{99m}Tc generator (Mallinckrodt, Petten, The Netherlands), and $Na^{188}ReO_4$ was eluted from a ^{188}W/^{188}Re generator (Oak Ridge National Laboratories, Oak Ridge, TN). Thin-layer chromatography (TLC) and high performance liquid chromatography (HPLC) analyses were performed for controlling the identity, the radiochemical purity, and the stability of the preparations. For controlling the ^{188}Re−EDTA preparations by TLC, silica gel strips (Kieselgel 60, Merck) were used and developed with mobile phases of acetone and water. RP-18 strips and mixtures of acetonitrile and water (80/20 to 20/80) were used as mobile phases for analyzing the final ^{188}Re−S_4 complex preparations. The strips were scanned with a TLC radioanalyzer (Rita, raytest Isotopenmessgeräte GmbH, Straubenhardt, Germany). HPLC analyses were performed on a Perkin-Elmer device consisting of a Turbo LC System with a quaternary pump (Series 200 LC Pump), a Programmable Absorbance Detector Model 785A (Perkin-Elmer Instruments GmbH, Rodgau-Jügesheim, Germany), and a homemade γ-ray detector (well-type NaI(Tl) crystal). HPLC analyses were carried out with a Zorbax 300SB-C18 column (5 μm, 250 × 4.6 mm, Agilent) using a gradient eluant of acetonitrile (A) with 0.1% TFA/water (B) with 0.1% TFA, linear gradient elution (**I**): 0−20 min 40 to 50% A, 5 min 50 to 90% A, 10 min 90% A; linear gradient elution (**II**): 0−5 min 0 to 20% A, 30 min 20 to 25% A, 5 min 25 to 100% A, 10 min 100% A; flow rate 1 mL/min. The effluent from the column was monitored by UV absorbance at 254 nm for Re reference complexes or γ-ray detection for the ^{99m}Tc and ^{188}Re complexes. The separation of the isomers was performed with a semipreparative Zorbax 300SB-C18 column (5 μm, 250 × 9.4 mm, Agilent) using the same linear gradient elution and a flow rate of 4 mL/min. For separation of the $^{99/99m}$Tc complexes the HPLC system started with 50% of A from 0 to 20 min followed by a linear gradient 50% A/50% B to 100% B from 20 to 25 min. The gradient remained at 100% B for 6 min before switching back to 50% A. Mass spectrometric analyses were carried out on a Micromass Tandem Quadrupole Mass Spectrometer (Quattro LC) operating in the MS mode. Mass spectral data were recorded at the negative and positive ESI mode using a cone voltage between 20 and 150 V. About 0.01 mg of the sample dissolved in 1.0 mL methanol/water (50/50) was infused at a flow rate of 5 μL/min.

Synthesis of Nonradioactive Reference Rhenium Complexes I and II. To a solution of 1 equiv of tetrabutylammonium tetrachlorooxorhenate(V) in dry methanol was added slowly a solution of 1 equiv of the corresponding S_4 ligand **1** or **2** dissolved in dry methanol and stirred at room temperature under nitrogen. The crude product was purified and separated by preparative HPLC yielding single isomers. The cis and the trans isomer of **I** was already intensively described (*12*).

Two different isomers of complex **II** could be separated by preparative HPLC and characterized by ESI-MS.

HPLC: $t_R(\mathbf{II^1}) = 10.9$ min, $t_R(\mathbf{II^2}) = 11.5$ min (0−12 min, 20−30% A; 12−15 min, 30−40% A; 15−20 min, 40−90% A; 20−22 min, 90% A).

II^1 MS: pos. ESI: $[M + H]^+$, *m*/*z* 1151.2, $[M + Na]^+$, *m*/*z* 1173.3; neg. ESI: $[M - H]^-$, *m*/*z* 1148.4.

II^2 MS: pos. ESI: $[M + H]^+$, *m*/*z* 1151.0, $[M + Na]^+$, *m*/*z* 1172.8; neg. ESI: $[M - H]^-$, *m*/*z* 1148.2.

The mixture of isomers was characterized by NMR. ^{1}H NMR (CD_3OD)/399.95 MHz: δ = 1.64−1.85 (m, 4H, 2 CH_2CH_2-CH_2), 2.70−3.23 (m, 8H, $CH_2NH_2CH_2$, 2 CH_2NH), 3.51−3.82 (m, 48 H, 24 CH_2), 3.92−4.03 (m, 2H, 2 C*H*S), 4.66−4.72 (m, 2H, 2 C*H*S), the ammonium and amide protons were not detected.

Preparation of No-Carrier-Added and Carrier-Added ^{99m}Tc−S_4 Complex I. To 0.5 mg of the S_4 ligand **1** dissolved in 0.1 mL of methanol and 0.2 mL of propylene glycol were added 0.1 mL of pertechnetate eluate and 0.2 mL of 1 M NaOH. After addition of 0.5 mg of stannous chloride dissolved in 0.2 mL of methanol, the reaction solution was allowed to stand for 10 min at room temperature. Carrier-added preparations for ESI-MS analyses were performed with 20 μL of a 0.005 M $K^{99}TcO_4$ solution (0.1 μmol) which was added to the eluate. The isomers were separated by HPLC before mass analyses; MS: pos. ESI: $[M + H]^+$, *m*/*z* 794.4; neg. ESI: $[M - H]^-$, *m*/*z* 792.3.

Synthesis Procedure for the ^{188}Re Complexes. *^{188}Re−S_4 Complex I. Method 1*. Following the procedure developed by the Duatti group (*15*) for the preparation of ^{188}Re(V)−DMSA, which was optimized for the tetradentate S_4 ligand **1**, a mixture of 1.0 mL of perrhenate eluate (50−500 MBq) and 0.2 mL of ethanol, containing 5 mg of oxalic acid, 5 mg of γ-cyclodextrin, 5 mg of ascorbic acid, and 0.05−0.1 mg of S_4 ligand **1**, was reduced by adding 0.1−1.0 mg of stannous chloride dissolved in 0.1 mL of 0.1 N HCl. The reaction was completed by heating at 50 °C for 30 min. Radiochemical yield: 90−93% (HPLC and TLC, all isomers). For stability and biodistribution studies, the isomers were separated by semipreparative HPLC. After neutralization of the isomer fraction, the organic eluants were evaporated *in vacuo*, and the complexes were redissolved in saline and 20% of propylene glycol. Finally, the desired radioactive concentration was adjusted by dilution with saline. The identity of the species obtained was confirmed by comparison with the HPLC profiles of reference $^{185/187}$Re analogues.

^{188}Re-EDTA. A 2−3 mL volume of perrhenate eluate from a ^{188}W/^{188}Re generator (50−500 MBq/mL) were added together with 0.05 mL of 1 M HCl to a kit vial containing 5 mg of EDTA, 5 mg of mannitol, and 1.0 mg of $SnCl_2$ in freeze-dried form under nitrogen. After 20−30 min at room temperature, the complex formation was finished. Radiochemical yield: >95% (TLC).

Method 2. To 1.0 mL of the acidic ^{188}Re−EDTA solution, 0.25 mg of the S_4 ligand **1** dissolved in 0.5 mL of ethanol was added, and the reaction solution was heated at 50 °C for 30 min. Radiochemical yield: 65−75% (HPLC).

*^{188}Re−S_4 Complex **II**. Method 1*. Using 0.005−0.01 mg of the hydrophilic ligand **2**, the preparation of complex **II** may be performed in aqueous solution with the same amounts of ancillary ligands and reducing agent. The reaction is completed within 30 min at 50 °C. Radiochemical yield: 90−94% (HPLC and TLC, all isomers).

Both complexes can be prepared using a kit formulation, in which the ligand is stabilized in the form of a stannous complex. The kit vial contains 5 mg each of oxalic acid, γ-cyclodextrin, and ascorbic acid, 10−50 μg of the Sn−S_4 complex, and 1.0 mg of $SnCl_2$ in freeze-dried form and under nitrogen. For the reconstitution not more than 1.5 mL of [^{188}Re]perrhenate eluate must be added.

Method 2. To 1.0 mL of the acidic ^{188}Re−EDTA solution was added 0.25 mg of the S_4 ligand **2** dissolved in 0.5 mL of water, and the reaction solution was heated at 50 °C for 30 min. Yield: 60−70% (HPLC).

Determination of Partition Coefficients. Partition coefficients of the separated isomers of the ^{188}Re−S_4 complexes were determined by shake-flask method by mixing 0.5 mL of the complex solution (0.1 M phosphate buffer pH 7.4 with 20% propylene glycol) and 0.5 mL of octanol and shaking for 5 min. After centrifugation, aliquots of both phases were counted and the partition coefficient calculated. The measurement was repeated three times.

Stability Studies. For *in vitro* stability studies, 0.5 mL of 0.1 M phosphate buffer solution of pH 7.4 as well as rat and human plasma (diluted 1:1 with 0.1 M phosphate buffer) were incubated with each separated isomer of ^{188}Re−S_4 complexes **I** and **II** at 37 °C for 1, 2, 24, and 48 h. The reoxidation to perrhenate was determined by TLC. The pH-stability of the cis and trans isomer was determined in aqueous solutions containing 20% propylene glycol at pH 2, 7, and 9. The samples were analyzed by HPLC after 1, 4, 24, and 48 h. Ligand exchange (challenge) experiments were performed in 0.01 M solution of cysteine at 37 °C for 2 h and analyzed by HPLC. The *in vivo* stability of ^{188}Re−S_4 complexes was studied using rat arterial blood samples, kidneys, urine, and intestine samples at various time points (1−10 min, 1 h, 2 h) after injection of 30 MBq of ^{188}Re−S_4 complex. To precipitate the blood cells and proteins, 0.15 mL of ethanol was added to 0.10 mL of the supernatants obtained after centrifugation (11000*g*, 3 min) of the samples. After cooling at −60 °C for 5 min and repeated centrifugation, the supernatants were analyzed by HPLC and TLC.

Biodistribution Studies. The animal studies were carried out according to the relevant national regulations using male Wistar rats (5−6 weeks old). About 0.5 mL of the ^{188}Re complex solution (0.5 MBq) was injected into the tail vein under slight ether anesthesia. After the injection, the rats were sacrificed by heart puncture 5 and 60 min as well as 24 and 48 h postinjection (pi). Selected organs were isolated for weighing and counting. The activity concentration in the tissue of organs was calculated in terms of percentage of injected total activity (dose) per gram tissue (% ID/g) or injected dose per organ (% ID/organ).

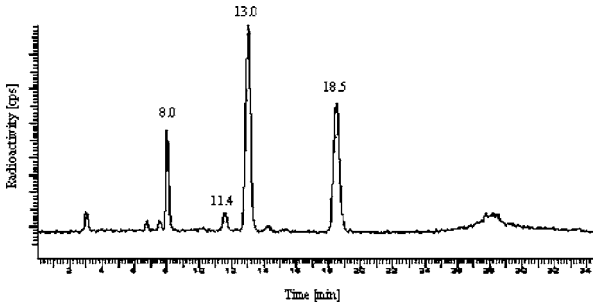

Figure 3. HPLC pattern of a $^{99/99m}$Tc−S_4 preparation used for separation of isomers; RP-18 column (Zorbax 300, 5 μm, 9.4 × 250 mm), acetonitrile/0.1% TFA (A)//water/0.1% TFA (B), (50/50) for 20 min, than in 5 min to 90% A, 6 min at 90% A; flow rate 4.0 mL/min.

RESULTS AND DISCUSSION

Synthesis and Characterization of ^{99m}Tc and ^{188}Re Complexes. The preparation of the ^{99m}Tc complex **I** succeeded in high yields in slightly alkaline solution. The reaction products were analyzed by HPLC and ESI-MS. For that reason, carrier-added preparations were performed which resulted in the same HPLC pattern as no-carrier-added preparations. Using optimized HPLC conditions, the following chromatogram was obtained (Figure 3). It shows a mixture of isomers which was eluted between 8 and 19 min. The main products were identified by comparison of their retention times with those of isolated cold rhenium isomers (not shown). They represent the exo-trans (13.0 min) and the exo-cis (18.5 min) isomers of the Tc−S_4 complex **I**. For the compounds which were eluted at 8.0 and 11.4 min, the same masses of m/z = 794.4 ($[M + H]^+$) and 792.3 ($[M-H]^-$) were found as for both exo isomers. It may be concluded that the corresponding endo isomers may also be formed under the special reaction conditions.

The preparation of the desired ^{188}Re−S_4 complexes was performed by two different reaction routes. According to method 1, the direct reduction of perrhenate in the acidic solution of the S_4 ligand and ancillary ligands, perrhenate was completely reduced within 30 min at 50 °C or 60 min at room temperature by 1.0 mg of stannous chloride. Using 1.0 mg of S_4 ligand **1**, more than 30% of an unknown ^{188}Re product was formed which was eluted in HPLC at about 31 min. The percentage of this impurity decreased when the ligand amount was reduced. Less than 10% was still formed using 0.05−0.01 mg of the S_4 ligand (Figure 4). Under these conditions, the reduction was completed after 60 min at 50 °C in a total volume of not more than 1.5 mL. Because of the high lipophilicity of the S_4 ligand **1** and the resulting ^{188}Re complex **I**, the preparation had to be carried out in aqueous/alcoholic solution.

As demonstrated for the corresponding ^{99m}Tc complex isomers, the exo-cis and exo-trans isomer of the ^{188}Re−S_4 complex **I** was determined by comparison of retention times with those of cold rhenium reference isomers.

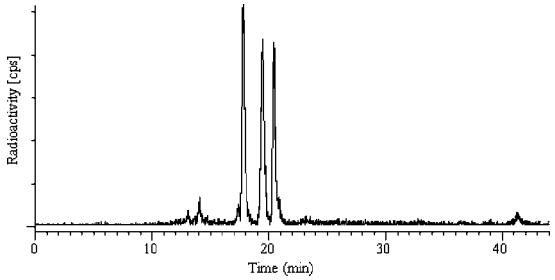

Figure 5. HPLC pattern of $^{188}Re-S_4$ complex **II** prepared according to method 1 with 0.01 mg of ligand 2 and 1.0 mg $SnCl_2$ by 30 min heating at 50 °C.

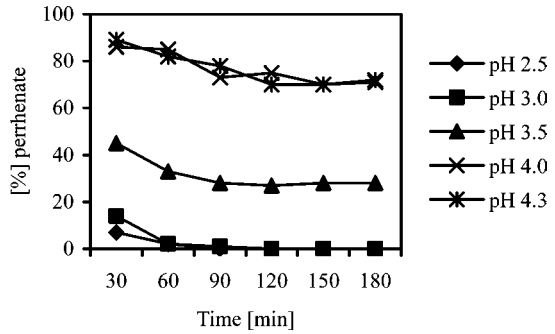

Figure 6. Decrease of perrhenate yield in the reaction solution as measure of formation of complex **II** in dependence on pH (50 °C, 1.0 mg $SnCl_2$).

Table 1. Logarithms of Partition Coefficients of $^{188}Re-S_4$ Complex Isomers between Octanol and 0.1 M Phosphate Buffer of pH 7.4 (mean ± SD, $n = 5$)

complex/isomer	log $P_{o/w}$, pH 7.4
I/trans	1.56 ± 0.03
I/cis	1.73 ± 0.04
II/1	−1.72 ± 0.05
II/2	−1.86 ± 0.04
II/3	−1.71 ± 0.03

The preparation of complex **I** according to method 2 resulted in lower yields of the $^{188}Re-S_4$ complex. In contrast to the preparation of $^{188}Re(V)$−DMSA, which was formed in neutral solution in yields of >95% using the same ^{188}Re−EDTA preparation as starting complex (*16*), the $^{188}Re-S_4$ complex requires acidic solution for the formation. The four isomers known from method 1 were also observed in method 2 preparations. The conformation of the two other isomers, which were eluted between the trans and the cis isomer, remains unknown, because they were only observed in solutions of very low concentrations of the radiometals. Probably, rhenium-188 and technetium-99m form complexes with the meso as well as the racemic bridged ligands. That would result in six isomers according to the following Scheme 1.

In contrast to the non-radioactive rhenium complex preparations, in which only the exo complexes were detected, the carrier-free ^{188}Re preparations seem to result in the formation of the exo and endo complexes, respectively. Three assumed isomers were separated by HPLC, when the $^{188}Re-S_4$ complex **II** with the crown ether S_4 ligand **2** was analyzed (Figure 5).

Two of the three peaks found in HPLC analyses of carrier-free preparations could be assigned to the two isomers which were separated by HPLC of cold reference rhenium complex **II** preparations. These isolated fractions $\mathbf{II^1}$ and $\mathbf{II^2}$ showed the same *m*/*z* values in positive and negative ESI-MS analyses. As already observed for complex **I**, more than two isomers were also detected in preparations of $^{188}Re-S_4$ complex **II**. In accordance with findings made for the optimum preparation of $^{188}Re-S_4$ **I**, diminishing of ligand quantity also resulted in higher

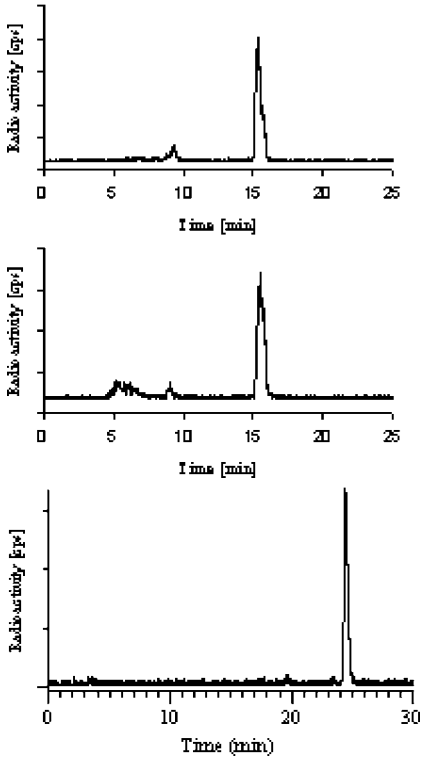

Figure 7. HPLC patterns of *in vivo* samples of the cis isomer of complex **I** (top: intestine, 2 h pi; middle: urine, 2 h pi), and isomer 2 of complex **II** (bottom: urine, 1 h pi).

yields of the desired complex isomers. While 15−20% of the lipophilic impurities ($t_R = 41$ min) were formed when the preparations were carried out with 0.5−0.1 mg of ligand **2**, only 3−5% was found in HPLC using the very low amounts of 0.02−0.005 mg of ligand **2** for preparation.

On the basis of these results, a kit formulation for the preparation of the $^{188}Re-S_4$ complexes was developed. The low amounts of the sensitive tetrathiolate ligands could be stabilized as stannous complexes. Between 10 μg (complex **II**) and 50 μg (complex **I**) of the $Sn-S_4$ complex was found to be sufficient for optimum labeling yields of 90−94%.

Surprisingly, it is possible to clearly diminish the amount of the reducing agent $SnCl_2$. For a complete reduction of 100−1000 MBq of [^{188}Re]perrhenate, 0.1 mg or even 0.05 mg of $SnCl_2$ per vial was sufficient. The complex formation succeeded quickly and completely in an acidic solution of pH 1.5−2.0. However, the reduction of perrhenate was delayed when the pH of the reaction solution was increased (Figure 6). Despite

the high excess of 1.0 mg of $SnCl_2$, no complete reduction was reached within several hours, when the pH of the solution was higher than 3.

These results, which were observed for both preparations, could be improved using the kit formulation mentioned above. Under the special conditions and an additional portion of 15 mg of oxalic acid a complete reduction of perrhenate within 3 h was still possible at pH 3.5.

For further characterization of the $^{188}Re-S_4$ complex **I** its cis and trans isomers were separated by HPLC. Using optimized HPLC conditions, the trans isomer was earlier eluted than the cis isomer. The observed difference in retention time was confirmed by octanol/water distribution studies at pH 7.4 performed with both isomers. As shown in Table 1, the cis isomer is more lipophilic. As expected, complex **II** exhibits a strong hydrophilic behavior caused by the crown ether groups of ligand **2**. A successful separation of the isomers was only possible using a very smooth gradient for HPLC analysis. In accordance, nearly similar octanol/water distribution data were determined for the three isomers of complex **II**.

***In Vitro* Stability of $^{188}Re-S_4$ Complexes.** The stability of the ^{188}Re complexes toward reoxidation to perrhenate was investigated with the isolated isomers in phosphate buffer solution of pH 7.4, in rat plasma, and in human plasma at 37 °C for 48 h. Only minor reoxidation (<3%) of the metal center to $^{188}ReO_4^-$ could be observed in phosphate buffer solution during this time. Moreover, the isomers were absolutely stable in rat and human plasma solutions. Both isomers of complex **I** were also stable against isomerization at pH 2, 7, and 9. The challenge experiments with cysteine corroborated the high stability of the cis and trans isomers. They were completely inert toward ligand exchange in the cysteine solution. The isomers of complex **II** were stable in acidic and neutral solutions. At pH values higher than 8 they were converted to unknown products which were eluted in HPLC between 12 and 15 min. These products were also observed as impurities in low yields in the reaction solution (Figure 5).

***In Vivo* Stability and Biodistribution.** Samples of rat plasma, urine, kidneys, and contents of intestine were analyzed by HPLC and TLC 1 and 2 h postinjection of the isomers. Neither perrhenate nor other metabolites were observed in plasma samples of complexes **I** and **II**. However, some metabolites were detected in the intestine and the urine samples of the cis and the trans isomers of complex **I** (Figure 7a and 7b). In both samples a more lipophilic product was observed which was eluted at about 9.5 min. Additionally, perrhenate

and other hydrophilic products were found in the urine samples. Between 60 and 70% of the total injected dose of complex **I** was found in the intestine 2 h postinjection. Considering the predominant hepatobiliary excretion pathway of complex **I**, it can be concluded that only a very low part of the administered ^{188}Re complex is reoxidized *in vivo*. There are no differences concerning the *in vivo* stability between the cis and the trans isomers. That applies to the isomers of complex **II** too. Because of their high hydrophilicity they were excreted *via* the renal and the hepatobiliary pathway. Therefore, urine samples were analyzed by HPLC (Figure 7c). No perrhenate was detected in the urine samples. That demonstrates again the high *in vivo* stability of the ^{188}Re−S_4 complexes.

Biodistribution studies in male Wistar rats were performed with the cis and trans isomers of complex **I** and the three isomers of complex **II** to investigate their organ uptake and excretion pathways. Generally, a fast clearance of radioactivity within 1 h from significant organs and the blood was observed. As shown in Table 2, the lipophilic isomers of complex **I** were preferentially excreted *via* the hepatobiliary pathway. Meanwhile, no increase of radioactivity was found in the stomach indicating high *in vivo* stability of the cis and trans isomers, respectively. In contrast to complex **I**, the hydrophilic isomers of complex **II** were excreted *via* the kidneys as well as the hepatobiliary pathway. The concentration of the isomers 2 and 3 in the kidneys was around three times higher than that of isomer 1. Correspondingly, the concentration of isomer 1 in the liver was higher than the concentration of isomers 2 and 3. All three isomers exhibited a remarkable high in vivo stability. The observed differences in the elimination behavior could hence be due to varying affinities to plasma proteins, the transport to the elimination organs, or other parts of the biological system. This has to be further investigated.

CONCLUSIONS

Two routes for carrier-free preparations of a new type of ^{188}Re−S_4 complexes were studied and the reaction conditions were optimized. A kit formulation was developed which contains only microgram amounts of the S_4 ligand stabilized in the form of a stannous complex. The ^{188}Re−S_4 complexes were found to be stable toward reoxidation and ligand exchange *in vitro* and *in vivo*. Their charge and lipophilicity may be controlled by various possibilities to introduce functional groups. The bridging amine group of the ligand framework makes available a reactive position for coupling biomolecules to the chelate. Summarizing, it can be concluded that the new ^{188}Re−S_4 complexes offer the possibility of stable and high specific activity labeling of biomolecules for therapeutic application.

Paramagnetic beads have considerable potential as identification tags in biological analysis. For example, magnetic sensor-based arrays using the magnetic field generated by paramagnetic beads to test hybridization between interacting molecules have attracted widespread interest in recent years. However, application of paramagnetic beads as identification tags is still limited, since they do not permit differentiation between samples for multiplex analysis. Here, we report the application of a novel encoding of paramagnetic beads with peptide sequences. This strategy allows DNA samples labeled with peptide-encoded paramagnetic beads to be identified by the selective enzymatic cleavage of each peptide cross-linker.

INTRODUCTION

Paramagnetic beads have been extensively used for the preparation, separation, transportation, and detection of biological molecules such as DNA, due to their efficiency, simplicity, and low cost (*1*−*4*). More recently, paramagnetic particles have also been used as labels for target DNA in microarray applications, where, in the presence of an external magnetic field, the field from the paramagnetic bead labels can be detected using an array of integrated magnetic sensors (e.g., giant magnetoresistance (GMR) sensors), thereby enabling the detection of DNA hybridization (*5*−*8*). However, the range of applications that can utilize paramagnetic beads has been limited due to the difficulty of distinguishing between different particles based on magnetic properties, and hence, they do not permit differentiation between samples for multiplexed analysis (e.g., parallel analysis of a test and control sample in a single reaction as is done using different fluorophores for gene expression analysis). Therefore, methods are required that enable paramagnetic bead based assays to be multiplexed. In this report, paramagnetic beads have been encoded using different peptide sequences, which are each cleavable by a specific enzyme. This novel approach based on an enzymatic cleavage methodology enables differentiation between beads (and hence samples). Using this approach, we have labeled oligonucleotides with different peptide-encoded paramagnetic beads. Subsequent identification of each oligonucleotide was possible through selective enzymatic cleavage of peptide cross-linkers from the paramagnetic beads.

EXPERIMENTAL PROCEDURES

Chemicals and Oligonucleotides. EDC (1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide), sulfo-NHS (sulfo-*N*-hydroxysuccinimide), PDITC (4-phenylenediisothiocyanate), 3-aminopropyltrimethoxysilane, proteinase K, and organic solvents were purchased from Sigma Chemical Co. (Poole, U.K.). Oligonucleotides were obtained from MWG Biotech (Ebersberg, Germany). Chymotrypsin was purchased from Calbiochem (La Jolla, CA).

Target DNA Labeling with Peptide-Tagged Paramagnetic Beads. Preparation of peptide-tagged paramagnetic beads to was done as follows: 1 μm paramagnetic beads (Roche; Roche Diagnostics Ltd., Sussex, U.K.) coated with streptavidin were washed in twice their volume of PBS (phosphate-buffered saline) buffer giving a final concentration of 5 mg/mL. A magnetic separator was used to remove the beads from solution. Then, 2 pmol of a biotin-terminated oligonucleotide (sequences used were GGGG (peptide G) and GGFG (peptide F); Bachem UK Ltd., Merseyside, U.K.) were added for every 1 μL of bead solution, and the mixture was allowed to react for 2 h at room temperature while rotating at a speed of 30 rpm. Following the conjugation of the peptide to the beads, the free carboxylic end of the peptide was activated by means of EDC chemistry as follows: 20 pmol EDC and 20 pmol sulfo-NHS were added into the bead solution for every picamole of peptide, and the resulting mixture was shaken for 3 h at room temperature. Subsequently, labeling of target DNA with peptide-tagged paramagnetic beads was done as follows: a 1:50 dilution of the solution containing the activated peptide-tagged beads was prepared in 0.15 M borate buffer pH 8.5, and 4 μM of target DNA were added into it and the mixture allowed to react for 3 h at room temperature while rotating at a speed of 30 rpm.

Specificity Studies of Oligonucleotide Attachment onto the Peptide-Tagged Bead Surface. Studies were done using oligonucleotide F. Fluorescence intensity was compared between blank solutions containing beads, peptide-encoded tagged beads (peptide G), and samples containing oligonucleotide F modified with cy3 and labeled with peptide-tagged paramagnetic beads (peptide/oligonucleotide ratios 1:1, 1:2.5, 1:5, and 1:10). Fluorescence intensity was measured at 560 nm (excitation at 510 nm) with a FlexStation II instrument (Molecular Devices, Wokingham, U.K.) at room temperature.

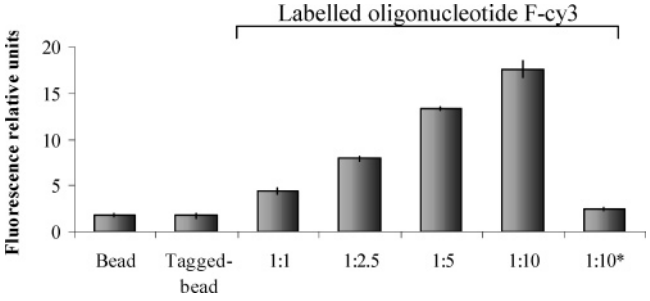

Figure 1. Specific binding of a 20mer oligonucleotide to peptide-encoded beads. Fluorescence studies demonstrated specific binding of oligonucleotide F-cy3 (5′-GTGACTTCCCCTAAATATAA-3′; modifications: 5′ amino-modifier C12 and 3′ Cy3) to paramagnetic beads encoded with peptide G. A peptide/oligonucleotide ratio of 1:10 rendered the maximum coupling yield with no indication of nonspecific binding (coupling in sample 1:10* was performed without EDC and supho-NHS). The data shown represent mean ± SD (standard deviation) of three independent experiments.

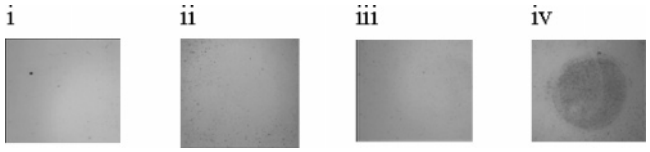

Figure 2. Hybridization and control experiments with peptide-encoded paramagnetic beads. Oligonucleotides G and F were labeled with peptide-encoded beads (G). Substrate contained the oligonucleotide comp-F, which is complementary to oligonucleotide F but not to G. Examples where (i) substrate has no oligonucleotide on it, (ii) beads have no oligonucleotide but the substrate does, (iii) the substrate and the peptide-encoded beads have noncomplementary oligonucleotide sequences (comp-F and G, respectively), and (iv) the substrate and the peptide-encoded beads have complementary oligonucleotide sequences (comp-F and F, respectively). Figures are representative of an experiment performed in triplicate. Images were acquired using a Zeiss Axioskop II Plus epi-fluorescence microscope equipped with an Optronics DEI-750 CCD camera and appropriate filter sets.

Surface Functionalization. Deposition and covalent immobilization of synthetic DNA probes onto the array surface involved substrate cleaning and deposition of a silane anchor layer, followed by the addition of a PDITC homobifunctional linker molecule, to facilitate the covalent binding of the oligonucleotides (see Scheme 2). Substrates were cleaned by sonication in trichlorethylene (10 min), immersion in acetone at 50 °C (10 min), sonication in isopropyl alcohol (10 min), followed by drying in N_2. For deposition of the anchor layer, 3-aminopropyltrimethoxysilane (3% v/v) was reacted with the free hydroxyl groups on the surface by sonication in ambient temperature using a in a 95:5 methanol/water solution, then sequentially rinsed in methanol and water and dried in N_2. Following this, substrates were cured at 120 °C (15 min). Covalent attachment of the amino-terminated oligonucleotide probes was mediated by activation of the amino silanated substrates with a PDITC homobifunctional crosslinker. For this, the amino silanated substrates were immersed in a 40 mL solution of 1 mM PDITC in 10% v/v anhydrous pyridine/dimethylformamide (DMF, 2 h), followed by thorough sequential rinsing with DMF and dichloroethane, and then drying in N_2.

Oligonucleotide Probe Patterning and Immobilization over Functionalized Substrate. Deposition of unlabeled amino modified oligonucleotide comp-F was performed using a Staedtler technical drawing pin to print 0.5 mL of a 4 μM oligonucleotide solution in 1% *N*,*N*-diisopropylethylamine Tris-HCl buffer. Substrates were then placed in a humid atmosphere at 37 °C overnight. After immobilization, substrates were washed in a 0.1% SDS solution at 60 °C (10 min) and dried in N_2. Following this, substrates were immersed in 0.1% milk PBS buffer for 2 h to deactivate any remaining unreacted surface-bound isothiocyanate groups to prevent nonspecific binding of target DNA or beads during hybridization. Finally, substrates were rinsed thoroughly in water and dried in N_2.

DNA Hybridization. A solution comprising 5 mg/mL of paramagnetic bead-labeled target DNA suspended in 20 μL hybridization buffer (3× SSPE) was introduced onto the array surface. Hybridization was carried out at room temperature for 3 h. Substrate surface was then rinsed with deionized water to remove nonspecifically bound beads, so that only beads immobilized by selective hybridization of target DNA to complementary probes remained.

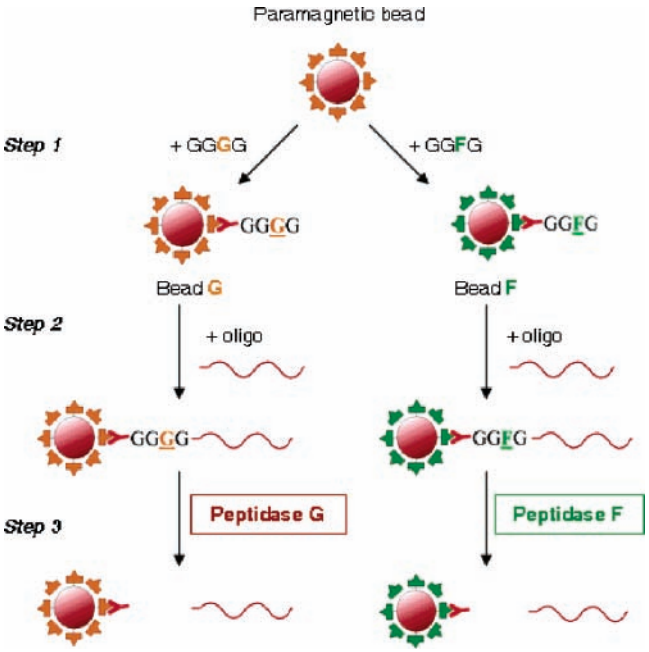
Enzyme Studies. Cleavage and Removal of Beads. Release of the beads attached to oligonucleotide F through peptide F was done using chymotrypsin, which specifically cleaves the sequence containing phenylalanine while leaving the sequence containing glycine intact (beads tagged with the peptide G remain attached to oligonucleotide F). A solution containing 200 ng of chymotrypsin was prepared in 100 M Tris 10 mM $CaCl_2$ buffer (pH 7.8). Then, 20 μL of the enzyme solution was added onto the chip surface and incubated for 3 h at 37 °C. Following this, the substrate surface was rinsed with deionized water to remove cleaved beads, so that only beads attached to oligonucleotide F through peptide G remained. Selective release of beads attached through peptide F was then visualized by fluorescence imaging. Subsequently, beads attached to oligonucleotide F through peptide G were released using the peptidase proteinase K. For this purpose, a saturated solution of proteinase K was prepared in 100 M Tris 10 mM $CaCl_2$ buffer (pH 7.8). Then, 20 μL of the enzyme solution were added onto the substrate surface and incubated for 3 h at 37 °C. Subsequently, the surface was rinsed with deionized water to remove the remaining beads. Selective release of beads attached through peptide G was then visualized by fluorescence imaging. Images were acquired using an Axioskop II Plus epi-fluorescence microscope equipped with an optronics DEI-750 CCD camera and appropriate filter sets. Imagines were analyzed using *Image Pro Express* software (Media Cybernetics).

RESULTS AND DISCUSSION

Paramagnetic beads were encoded by coating them with one of two different peptide sequences: G or F (Scheme 1, step 1). Each peptide comprised a 4 amino acid sequence with the amino end modified with a biotin molecule (Table 1). In this manner, attachment of the peptides to the surface of streptavidin-coated paramagnetic beads was done by means of a biotin−streptavidin conjugation. In a second step, oligonucleotides were labeled with the peptide-encoded beads. This step comprised the attachment of the oligonucleotide containing a 5′-amino group (Table 1) to the free carboxylic end of the specific amino acid sequence of the peptide-encoded bead using carbodiimide chemistry in a buffered solution (Table 2). In this manner, the peptide remained as a cross-linker between the bead and the target DNA sequence (Scheme 1, step 2). To control the number of DNA oligonucleotide molecules per peptide-encoded bead and to minimize nonspecific attachment onto the bead surface, we optimized the peptide/oligonucleotide ratio in the coupling reaction to 1:10. Figure 1 illustrates how a 1:10 peptide/oligonucleotide ratio yielded the maximum fluorescence intensity from all the proportions assayed. Lack of fluorescence in a sample, in which the coupling reaction of oligonucleotide F modified with cy3 onto the beads had been done without EDC and sulfo-NHS, confirmed specific attachment of the oligonucleotide onto the bead surface. Peptide/oligonucleotide ratios higher than 1:10 rendered nonspecific attachment of the oligonucleotide onto the bead surface (data not shown).

Specific hybridization of target DNA labeled with peptide-encoded paramagnetic beads to the complementary DNA

Scheme 1. Scheme of the Strategy for Labeling and Differencing DNA Oligonucleotide Target Sequences with Peptide-encoded Paramagnetic Beads[a]



[a] The first step comprises encoding paramagnetic beads with different peptide sequences (G or F in the example). In a subsequent step, DNA oligonucleotide targets are labeled with peptide-encoded paramagnetic beads. In this manner, the peptide sequence remains as a cross-linker between the bead and the target oligonucleotide. Then, each target DNA oligonucleotide can be selectively recognized by cleavage of the peptide sequence with a specific peptidase (peptidase F will cleave peptide F but not G). This strategy allows multiplexed analysis in paramagnetic bead based assays.

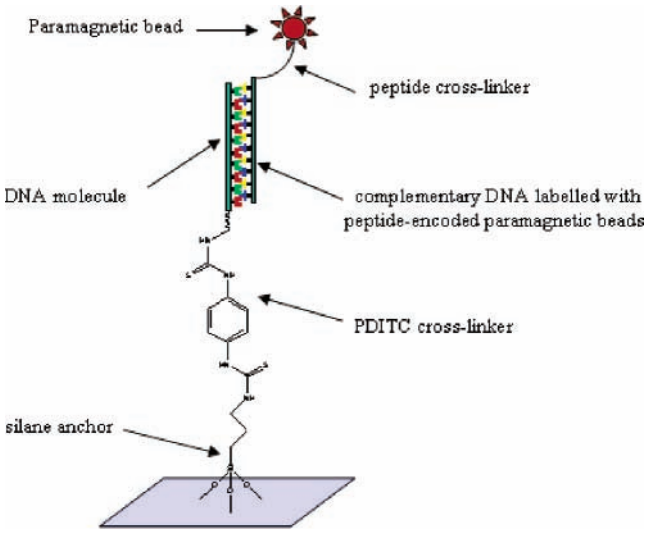
sequence attached onto an array surface was investigated. Surface functionalization and oligonucleotide patterning and immobilization over the substrate were carried out as previously described (*9*) (see Scheme 2). Control studies were performed to investigate nonspecific interaction onto the substrates of target DNA labeled with peptide-encoded beads. Furthermore, hybridization conditions were optimized to achieve specific hybridization of target oligonucleotide (F) to complementary sequences (oligonucleotide comp-F). A concentration of beads of 5 mg/mL produced the best results. We found higher concentrations of beads to produce nonspecific binding onto the substrate and lower concentrations to render poor density of bead spots. Under the optimized conditions, assays were carried out in which either the substrate (Figure 2i) or the beads (Figure 2ii) did not bear DNA. Control experiments demonstrated that nonspecific binding was minimal. As illustrated in Figure 2, bead spots were only distinctly observed when the oligonucleotide attached to the bead was complementary to the one on the substrate (noncomplementary oligonucleotide G, Figure 2iii; complementary oligonucleotide F, Figure 2iv).

Scheme 2. Scheme of the Surface Functionalization, Oligonucleotide Immobilization, and Hybridization of Complementary Probe Labeled with Peptide-Encoded Paramagnetic Beads



The peptidase chymotrypsin selectively hydrolyzes peptide sequences at bonds involving the carboxyl group of aromatic L-amino acids such as phenylalanine (F). Therefore, we chose chymotrypsin as the peptidase for releasing paramagnetic beads tagged with peptide F. Since chymotrypsin does not cleave nonaromatic L-amino acids such as glycine (G), paramagnetic beads encoded with the peptide G should remain unaffected after chymotrypsin treatment. Then, for releasing of beads cross-linked with peptide G, we chose the general peptidase proteinase K. Studies to evaluate the enzymatic activity of chymotrypsin and proteinase K were performed on glass slides, in which for simplification oligonucleotide probes labeled with peptide-encoded fluorescent tags were immobilized. Under these conditions, concentration of enzyme, reaction time, and temperature were optimized to achieve maximum activity and selectivity toward each peptide sequence (Figure 3). Subsequently, selective cleavage of peptide-encoded paramagnetic beads from target oligonucleotides by a specific peptidase was investigated. Oligonucleotide F encoded with either beads G or F was hybridized to oligonucleotide comp-F attached onto the substrate surface. In a first step, substrates were treated with chymotrypsin, which only removed beads encoded with peptide F (Figure 4a). Under these conditions, beads encoded with peptide G remained unaltered on the substrate surface. Subsequent treatment with proteinase K cleaved the beads encoded with peptide G. Neither treatment with chymotrypsin nor treatment with proteinase K affected the density of beads on the control spot (beads with no peptide linker). Therefore, our results demonstrate that the enzymatic cleavage approach allows the selective removal of the beads from the substrate surface.

CONCLUSIONS

This report proposes a strategy for encoding paramagnetic beads by labeling them with different peptide sequences. It has been demonstrated that samples labeled with encoded paramagnetic beads can be subsequently identified by the selective enzymatic cleavage of each peptide cross-linker. Using this approach, we have been able to differentiate between beads

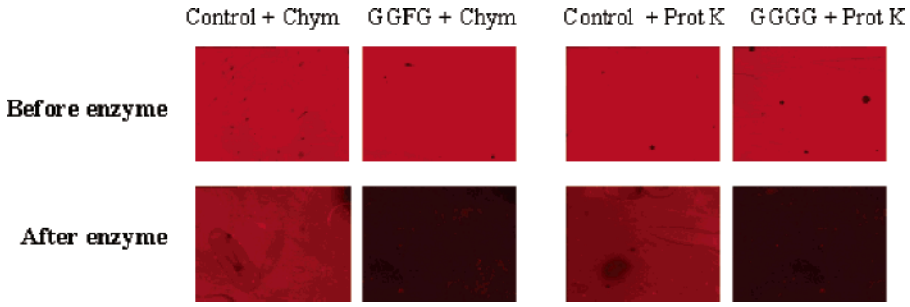


Figure 3. Selective cleavage of fluorophores from glass surface. Oligonucleotide F labeled with peptide-tagged fluorophores (fluorophore is streptavidin, Alexa Fluor; Bio Sciences, Ltd., Dun Laoghaire, Ireland) was immobilized onto a glass surface as described in the Experimental Procedures section. Conditions were optimized for selective recognition and hydrolysis of peptide F and peptide G by chymotrypsin and proteinase K, respectively. Both chymotrypsin and proteinase K successfully removed the fluorophores encoded with peptide F and G, respectively, from the glass surface resulting in a significant decrease of fluorescence, while only a slight lost of fluorescence was observed in controls (fluorophores without the peptide). Images were acquired using a Zeiss Axioskop II Plus epi-fluorescence microscope equipped with an Optronics DEI-750 CCD camera and appropriate filter sets.

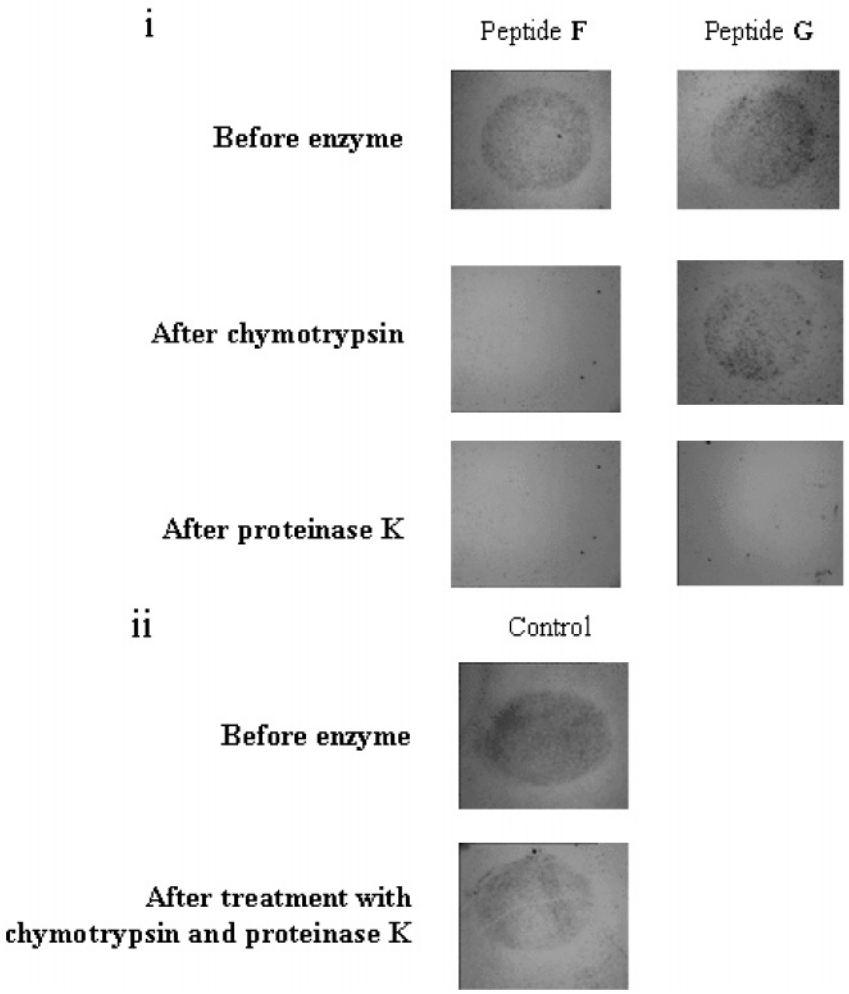

Figure 4. Demonstration of selective enzymatic cleavage of peptide-encoded paramagnetic beads, where oligonucleotide comp-F was immobilized onto the substrate surface by means of covalent chemistry. (i) Hybridization with Oligonucleotide F labeled with peptide-encoded paramagnetic beads (i.e., Bead F or Bead G) was then performed. In a first step, release of the beads encoded with Peptide F was done using chymotrypsin where beads tagged with Peptide G and control beads (beads with no peptide cross-linker) remained intact. Subsequently, beads encoded with Peptide G were released using the generic enzyme, Proteinase K. In this manner, selective enzymatic cleavage of the peptide linkers enabled differentiation between beads, and thereby enabled differentiation between the attached oligonucleotides. Figures are representative of an experiment done in triplicate. (ii) Controls were done with Oligonucleotide F labeled with paramagnetic beads with no peptide cross-linker. Images were acquired using a Zeiss Axioskop II Plus epi-fluorescence microscope equipped with an Optronics DEI-750 CCD camera and appropriate filter sets

encoding different target DNA oligonucleotides. Interestingly, this strategy is not restricted to encoding of paramagnetic beads, but it can also be used to label supports of any nature (for example, nanocrystals, gold nanoparticles, glass beads). While some micro- and nanoparticles are distinguishable on the basis of different colors (or if fluorescent, on the basis of different excitation and emission spectra), the sensitivity achievable with sensor systems necessary to enable color imaging is typically

much less than that achievable with equivalent monochrome technology. Therefore, the present methodology can be employed to increase the multiplicity in any kind of biological assay. Moreover, in addition to the possibility of simultaneous analysis of multiple samples, this approach allows modulation of the bead characteristics by introducing a large number of distinguishable sequences. Brust and co-workers have already reported that functionalized peptide binding to nanoparticle permits introducing multiple functionalities onto gold nanoparticles (*10*). We contemplate that properties related to hydrophobicity and charge of the encoded beads could also be modulated in a controlled manner by modifying the nature and the number of the nonrelevant amino acids comprising the peptide sequence. Undoubtedly, this would have an impact on the hybridization efficiency. This approach could also be adapted to create dynamic substrates, in which the surface properties could be selectively modified in a spatial manner, by patterning of different molecules that would be tethered to the substrate by different peptide sequences, and by subsequent selective cleavage of molecules in an ordered manner.

Synthesis of Fluorescent Analogs of α-Conotoxin MII

Vijay A. Vishwanath[†] and J. Michael McIntosh*[,‡]

Interdepartmental Program in Neuroscience and Departments of Psychiatry and Biology, University of Utah, Salt Lake City, Utah 84112. Received June 9, 2006; Revised Manuscript Received August 23, 2006

α-Conotoxins (α-CTxs) are small peptides that are competitive inhibitors of nicotinic acetylcholine receptors (nAChRs) and have been used to study the kinetics of nAChRs. α-CTx MII, from the venom of *Conus magus*, has been shown to potently block both rat α3β2 and rat chimeric α6/α3β2β3 cloned nAChRs expressed in *Xenopus* oocytes. Tetramethylrhodamine (TMR), Bodipy FL, Alexa Fluor 488, and terbium chelates (TbCh) are fluorescent molecules that can be reacted with the N-terminus of the conopeptide to produce fluorescent conjugates. TMR and Bodipy FL were individually conjugated to α-CTx MII using different succinimidyl ester amine labeling reactions resulting in the formation of carboxamide conjugates. Alexa Fluor 488 succinimidyl ester conjugation reaction yielded low amounts of conjugate. TbCh was also individually reacted with the N-terminus of MII using the isothiocyanate conjugation reaction resulting in the formation of a thiourea conjugate. The conjugates were purified using reverse-phase high-pressure liquid chromatography (RP-HPLC) and their masses verified by matrix-assisted laser desorption-ionization with time-of-flight mass spectroscopy (MALDI-TOF MS). When tested on target nAChRs expressed in *Xenopus* oocytes, TMR−MII, Bodipy FL−MII, and TbCh−MII potently blocked the response to acetylcholine with slow off-rate kinetics. These fluorescent conjugates can be used to localize specific subtypes of neuronal nAChRs or ligand-binding sites within receptors in various tissue preparations; additionally, they may also be used to study conformational changes in receptors using fluorescence or lanthanide-based resonance energy transfer.

INTRODUCTION

The venom of *Conus* (cone snail) contains diverse pharmacologically active peptides (*1*). Conotoxins are disulfide-rich peptide toxins that act at ligand-gated ion channels and voltage-gated ion channels. α-Conotoxins (α-CTxs) are small peptides that competitively inhibit nicotinic acetylcholine receptors (nAChRs) and have been used extensively to study and differentiate specific subtypes of nAChRs. Some α-CTxs also bind with different affinities to the individual acetylcholine-binding sites on nAChRs. α-CTxs are thus ligands of choice to study localization, differentiation, and kinetics of specific subtypes of nAChRs (*2*−*5*). α-CTxs may act on either muscle or neuronal nAChRs (*2*−*5*). Most α-CTxs generally have four cysteines, with disulfide connectivities between the first and third cysteines and between the second and fourth cysteines. On the basis of the number of residues in between successive cysteine residues in a two-loop framework, the α-CTxs that act on neuronal nAChRs are further classified into α4/7, α4/3, or α4/4 framework peptides (*5*). α-CTx MII, isolated from the venom of *Conus magus*, is a peptide that has sixteen amino acid residues, with four residues in the first loop and seven residues in the second loop, making it a prototypical α4/7 framework peptide (*6*). The peptide sequence and characteristic disulfide linkage of α-CTx MII are shown in Figure 1. α-CTx MII specifically blocks α3- and α6-containing cloned nAChRs expressed in *X. laevis* oocytes (*6*−*9*). ^{125}I-α-CTx MII has been used to label α3- and α6-containing nAChRs in autoradiography assays (*10*, *11*). Striatal α6-containing nAChRs have been implicated in Parkinson's disease (*12*, *13*). Fluorescent analogs of α-CTx MII would thus provide a novel tool to explore the functional neuroanatomy of α3- and α6-containing nAChRs in the central nervous system.

Fluorophores are functional fluorescent groups that absorb energy of a specific wavelength and emit the energy at a different specific wavelength. Fluorescence labeling, when used in conjunction with a sensitive imaging device (such as a confocal microscope) provides a direct method to visualize molecular interactions with high precision and resolution. An external energy source (like a laser) excites photons, and a photon's energy can be absorbed by a fluorophore creating an excited, unstable electronic singlet state, following which the excited molecules drop to the lowest vibrational energy level within the electronic excited state and then to the ground state. When a fluorophore molecule falls from the excited state to the ground state, the energy of the emitted photon is often emitted at a characteristic wavelength (*14*). A fluorophore can be chemically attached to a nonfluorescent molecule like a peptide (*15*) to produce novel fluorescent conjugate molecules (Scheme 1). Tetramethylrhodamine (TMR) (*16*), Bodipy FL (*17*), Alexa Fluor 488 (*18*), and terbium chelates (TbChs) (*19*) are fluorescent molecules (available as succinimidyl ester, sulfosuccinimidyl ester, carboxylic acid−succinimidyl ester, and isothiocyanate, respectively) that can be reacted with the N-terminus of the conopeptide to produce fluorescent conjugates (Figure 1). Herein, we report the successful synthesis and purification of three different fluorescent analogs of α-CTx MII, namely, TMR−MII, Bodipy FL−MII, and TbCh−MII. The use of conjugation reaction to synthesize fluorescent analogs of conotoxins is particularly appealing because the bond between the fluorophore and peptide is stable to routine storage conditions. The masses of these fluorescent analogs were measured and verified. They were then tested on *X. laevis* oocytes that heterologously expressed rat α6/α3β2β3 nAChRs.

Three-dimensional structure of α-CTx MII with fluorophore being conjugated to the free α-amine of the N-terminus of α-CTx MII.

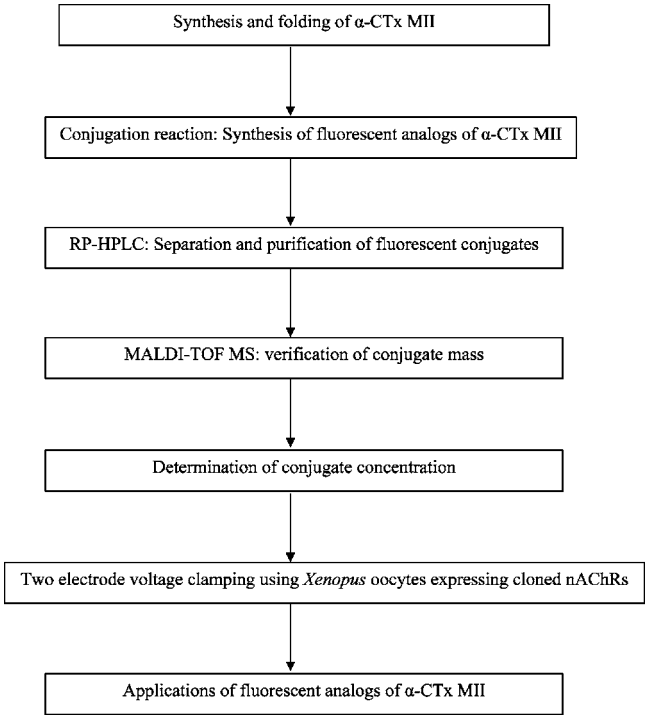
EXPERIMENTAL PROCEDURES

Materials. TMR, Bodipy FL, and Alexa Fluor 488 (catalog nos. C2211, D6140, and A20000, respectively) were obtained from Molecular Probes, Inc. (Eugene, OR). TbChs (catalog no. P3055) was obtained from PanVera LLC (Madison, WI).

Synthesis and Folding of α-CTx MII. α-CTx MII was synthesized as described earlier (*6*). Briefly, the synthesis was done on an amide resin using Fmoc (*N*-(9-fluorenyl)methoxycarbonyl) chemistry and standard side protection, except on cysteine residues, that were protected in pairs with *S*-trityl on the first and third cysteine residues and *S*-acetamidomethyl on the second and fourth cysteine residues. Following removal from the resin and precipitation, the peptides were folded using a two-step oxidation process using potassium ferricyanide and iodine.

Conjugation Reaction. The dye and the conopeptide were mixed in fixed ratios in the presence of an alkaline buffer, like

Scheme 1. Experimental Design: Synthesis of Fluorescent Analogs of α-CTx MII.



sodium bicarbonate or sodium borate, to enable the conjugation process. The following measures helped in obtaining a higher labeling yield:

(i) The reaction had 3 to 4 molar excesses of dye per toxin peptide.

(ii) The pH of the reaction was kept alkaline (pH range 7.0−8.5).

(iii) The reaction was carried out at room temperature for 1 h and stored overnight at 4 °C.

Acylating reagents are susceptible to degradation in the presence of water molecules, with the rate increasing as the pH increases. Since most of the buffers do contain water molecules, the three measures listed above help in reducing the degradation of the reactants (*14*). The photosensitive dye was protected from UV light throughout the experiments (*15*). There was minimal light exposure during the conjugation reaction and the purification of the conjugated peptides.

RP-HPLC. Analytical reverse-phase high-pressure liquid chromatography (RP-HPLC) with a diode array detector was used to separate the conjugated products from the unconjugated reactants. The analysis and separation of the conjugated products was done on an analytical RP-HPLC using buffers A (0.1% trifluoroacetic acid) and B (0.092% trifluoroacetic acid, 60% acetonitrile) on a Vydac C18 column. The samples tested included the unconjugated parent peptide, unconjugated dye, and the conjugation reaction mixture. The buffer gradients used to purify TMR−MII, Bodipy FL−MII, Alexa Fluor−MII, and TbCh−MII were 25% to 60% B60 in 35 min, 2% to 95% B60 in 40 min, 2% to 70% B60 in 60 min, and 0% to 80% B60 in 40 min, respectively, at a flow rate of 1 mL/min.

The eluents corresponding to the various peaks in the chromatogram were collected, quantitated, and lyophilized. The absorbance of the eluent peak corresponding to the conjugate at 220 nm (A_{220}) and 280 nm (A_{280}) and the emission maximum of the fluorophore (A_{EM}) were measured. Following purification of TbCh−MII using RP-HPLC, the terbium center of the chelate was reconstituted by adding 1.1 equiv of $TbCl_3$ to the purified conjugate.

Mass Spectrometry. The conjugation process was verified by measuring the mass of the conjugates using matrix-assisted laser desorption-ionization with time-of-flight mass spectroscopy (MALDI-TOF MS).

Oocyte Expression and Electrophysiology. When injected with appropriate β nAChR subunits, rat α6 nAChR subunits do not express successfully in *X. laevis* oocytes (*7*, *9*), but they can be functionally expressed as a chimeric receptor with amino acids 1 to 237 of rat α6 nAChR subunit protein linked to amino acids 233 to 499 of the rat α3 nAChR subunit protein (*7*). cRNA was transcribed in vitro, injected in *X. laevis* oocytes, and electrophysiological recording using two-electrode voltage-clamp configuration (model OC-725B; Warner Instrument, Hamden, CT) was done as described previously (*7*). Briefly, 5 ng cRNA of each subunit was injected into stage V *X. laevis* oocytes and incubated at 18 °C. After 3 days, the oocytes were voltage-clamped at −70 mV in a 30 μL cylindrical Sylgard recording chamber perfused with ND96A buffer (96.0 mM NaCl, 2.0 mM KCl, 1.8 mM $CaCl_2$, 1.0 mM $MgCl_2$, 1 μM atropine, and 5 mM HEPES, pH 7.1−7.5) and pulsed with acetylcholine (ACh) every minute. The fluorescent analogs were applied for 5 min in a static bath, followed by monitoring of responses to ACh pulses. Nonspecific adsorption of peptide was reduced by including 0.1 mg/mL bovine serum albumin in buffer and toxin solutions.

RESULTS AND DISCUSSION

Fluorophores. The use of fluorophores to label ligand peptide molecules produces a novel ligand analog that can functionally help in understanding and visualizing receptor−ligand interactions (*14*). TMR, Bodipy FL, and Alexa Fluor 488 are organic fluorophores; TMR has an absorbance maximum of 555 nm and emission maximum of 580 nm, Bodipy FL has an absorbance maximum of 505 nm and emission maximum of 513 nm, and Alexa Fluor 488 has an absorbance maximum of 494 nm and emission maximum of 519 nm. TbChs (a kind of lanthanide chelates) are good alternatives to conventional organic fluorophores because of their distinct structural and spectral characteristics. Structurally, the amine-reactive TbChs used to label peptides are made up of a diethylene triamine pentaacetate (DTPA) chelate with a carbostyril 124 (CS124) antenna and an isothiocyanate functional group. The CS124-DTPA-based terbium chelates have an absorbance maximum of 340 nm, and the emission spectrum has four distinct peaks at 490, 546, 585, and 620 nm. The reaction between the TbCh isothiocyanate and the peptide N-terminus free α-amine results in the formation of a thiourea conjugate.

Conjugation Reaction. α-CTx MII is a prototypical α4/7 α-conotoxin that is composed of 16 amino acid residues. Other important structural characteristics of α-CTx MII are (a) the C-terminal α-carboxyl group of α-CTx MII is amidated, (b) the backbone structure conformation of α-CTx MII is determined by the disulfide bonds, and (c) there are no lysines in the α-CTx MII peptide sequence (*6*). Amine-reactive fluorescent moieties are ideal functional groups that can be conjugated to the N-termini of small peptides. Most commercially available amine-reactive fluorophore moieties are acylating reagents that form carboxamides, thioureas, or sulfonamides upon reaction with amines (*15*). Amine reactive moieties generally react with (a) the free α-amine at the N-terminus or (b) lysine's ϵ-amino group in a peptide. The free α-amine at the peptide N-terminus usually has a pK_a of ∼7 making it selective to modification at near-neutral pH. If the peptide contains lysine in its sequence, the ϵ-amino group of lysine will also be labeled at pH of 8.5 to 9.5 (*14*). Succinimidyl and sulfosuccinimidyl esters of dyes are commonly used in conjugation reactions to label peptides, because they form carboxamide products containing stable

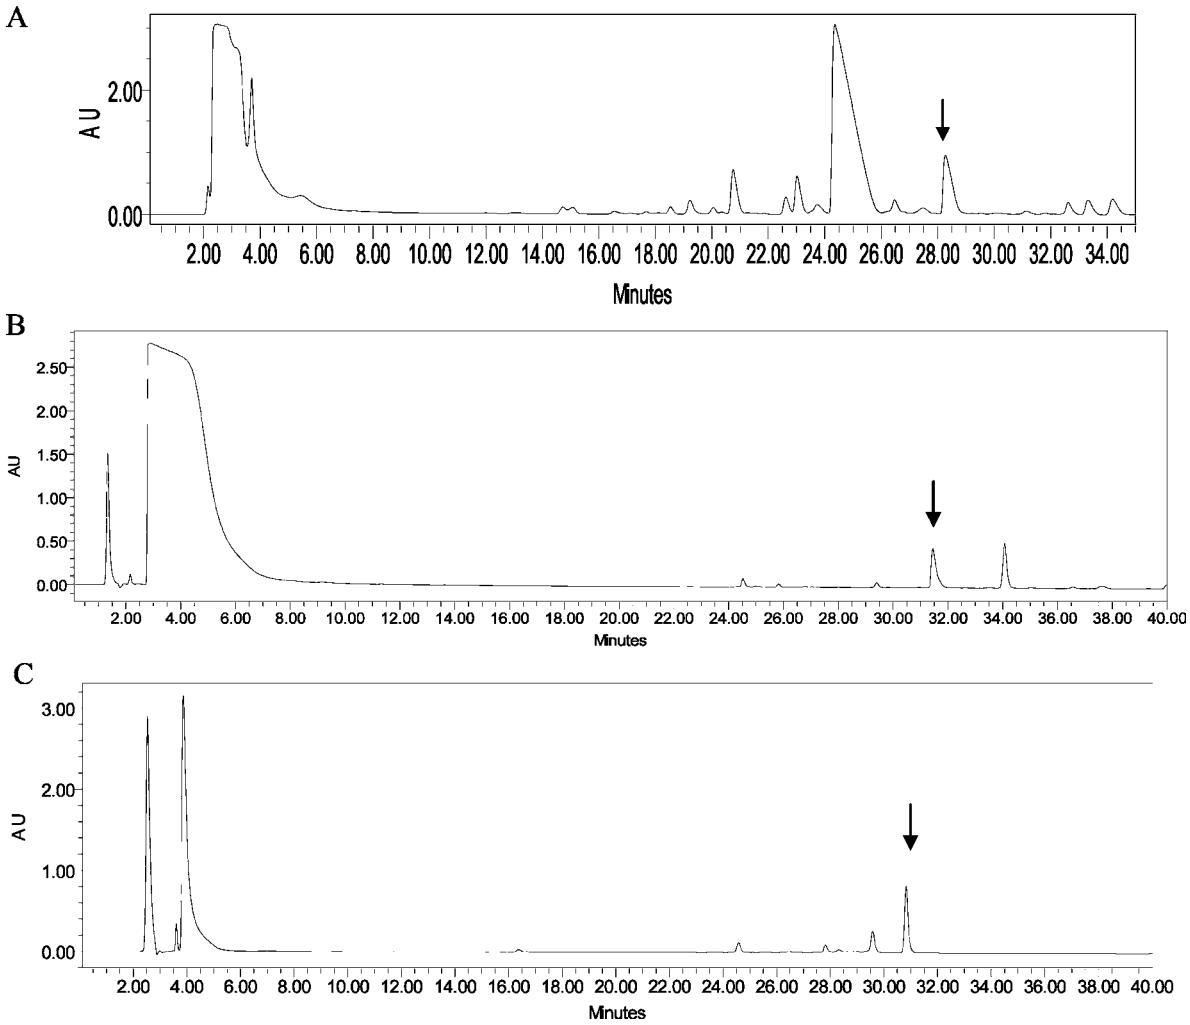


Figure 2. Analysis of the TMR (A), Bodipy FL (B), and TbCh (C) conjugation reaction samples at wavelength 220 nm. Black arrows indicate respective conjugates in each HPLC chromatogram.

amide bonds between the dye molecules and the peptides. An alternative labeling strategy involves the use of thiol reactive fluorescent moieties, which would be unsuitable for labeling α-CTxs because of the characteristic disulfide connectivities between the cysteines.

Since there are no lysines in the peptide sequence of α-CTx MII, only the N-terminus free α-amine reacts with the succinimidyl esters of TMR and Alexa Fluor 488, the sulfosuccinimidyl ester of Bodipy FL or the isothiocyanate group of TbCh to form fluorescent α-CTx MII analogs. The amount of conjugate yield from the conjugation reaction, using only a few nanomoles of peptide, depends on (i) reaction buffer pH, (ii) reaction temperature, (iii) duration of reaction, and (iv) dye-to-peptide molar ratio (*15*). All of the above factors were altered to determine optimal conditions for each conjugation reaction.

Purification and Quantification of the Fluorescent Conjugates. Analysis of the RP-HPLC chromatogram indicated four distinct peaks, two of which corresponded to the unreacted dyes, one of which corresponded to the unreacted toxin, and the other peak corresponding to the fluorescent conjugate. The peak areas for the conjugates provide estimates of the efficiency of the labeling reaction. When calculating the concentration of the fluorescent conjugates, the contribution of the dye to the absorbance of the conjugate (A_{280}) was corrected using published values of correction factors and extinction coefficients for each of the fluorophores. The conjugate yield was 28−40% of the parent peptide added in the reaction. The TMR−MII conjugation reaction was the most efficient with the conjugate yield close to 40% under optimal conditions. The Bodipy FL−MII conjugate was easier to purify because the unconjugated reactants showed distinct peaks on the RP-HPLC chromatogram and could be more discernibly differentiated on the basis of their absorbance analysis (Figure 2). Alexa Fluor 488 conjugation reaction produced a very low conjugate yield that could not be further improved by altering the reaction conditions (see Supporting Information). The other fluorescent analogs were purified and tested on cloned nAChRs expressed in *X. laevis* oocytes.

Verification of Masses of Fluorescent Conjugates. Since α-CTx MII has a mass of 1710.6 Da (*6*) and the molecular masses of TMR, Bodipy FL, and TbCh are 527.53, 491.2, and 909.14 Da (*16*, *17*, *19*), respectively, the fluorescent conjugates must have masses approximately in the range 1900−2500 Da (equal to the sum of the mass of a single molecule of each fluorophore and the molecular mass of α-CTx MII minus the mass of the byproduct, if present, after accounting for the new bonds being formed during the conjugation reaction). The monoisotopic masses of TMR−MII, Bodipy FL−MII, and TbCh−MII were observed to be 2122.52 (calculated 2122.79), 1984.86 (calculated 1984.75), and 2465.17 (calculated 2464.86), respectively.

Activity of the Fluorescent Conjugates. The lyophilized eluent fractions that were confirmed by MALDI-TOF MS to be fluorescent α-CTx MII conjugates were then tested on rat α6/α3β2β3 nAChRs expressed in *X. laevis* oocytes using two-electrode voltage clamping. All fluorescent analogs of α-CTX MII blocked rat α6/α3β2β3 nAChRs with slow off-rate kinetics

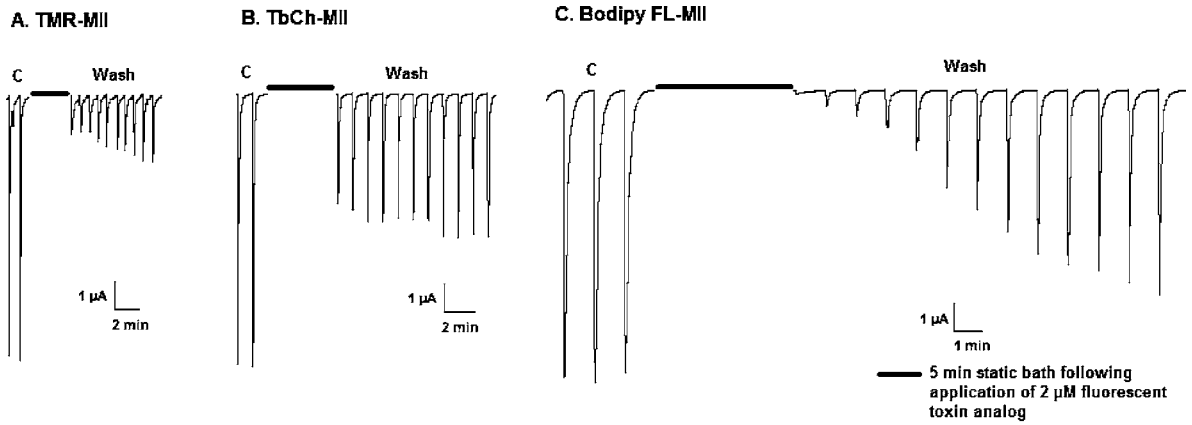

Figure 3. Kinetics of toxin block. 2 μM fluorescent analogs of α-CTx MII were applied to *X. laevis* oocytes expressing rat α6/α3β2β3 nAChRs. TMR-MII (A), TbCh-MII (B), and Bodipy FL-MII (C) at 2 μM were bath-applied for 5 min, and the toxin unblock kinetics were monitored by applying 1 s pulses of ACh every minute. C, control pulses.

similar to that of α-CTx MII (Figure 3). 2 μM of Bodipy FL−MII was found to be more potent on rat α6/α3β2β3 nAChRs than the same concentration of TMR−MII or TbCh−MII. TMR−MII was further investigated by testing its potency on α3β2 nAChRs expressed in *X. laevis* oocytes (see Supporting Information). When compared to the parent peptide, the fluorescent analogs of α-CTx MII exhibited ∼45−60-fold decrease in affinity toward the target receptors. The fluorescent analogs of α-CTx MII have not exhibited dissociation following long storage times (n = 60 days).

Limitations. There are certain limitations in the above-described synthesis of fluorescent conjugates of α-CTxs. The conjugation reaction is an efficient method of labeling the N-termini of α-CTxs that have no lysines in their peptide sequences. In the presence of lysine(s) in the peptide sequence of an α-CTx, the lysine can be selectively labeled by increasing the pH of the conjugation reaction buffer. Alternatively, selective deprotection of the lysine residue after fluorophore conjugation could be utilized. If lysine is not critical to toxin activity, a mutant version of the toxin (where the lysines have been substituted by alanines) may be used for labeling. The other limitation in the function of these conjugates is the ∼45−60-fold loss in affinity toward the target receptors, which might be overcome by the insertion of a spacer between the fluorophore and the peptide.

CONCLUSION

We have synthesized three different fluorescent analogs of α-CTx MII after optimizing the conditions for each conjugation reaction. These fluorescent analogs have the expected masses and retain activity against target receptors with off-rates comparable to that of the parent peptide. They can be used to localize target neuronal nAChRs including α3β2 and α6* nAChRs in the central nervous system.

There may be other applications of these fluorescent α-CTx MII analogs. Both Bodipy FL−MII and TMR−MII are organic fluorophore-conjugated molecules with the emission spectrum of Bodipy FL overlapping the absorbance spectrum of TMR, making them a probable donor−acceptor pair for fluorescence resonance energy transfer (FRET). FRET has been used to quantify distances in the range 1−10 nm between two fluorophore molecules and study conformational changes following interaction between receptors and ligands (*20*). TbCh−MII is a conjugate that holds the terbium ion in the chelate and acts as a donor to conventional organic fluorophores like TMR in lanthanide-based resonance energy transfer (LRET) (*21*). LRET is a modification of the FRET technique that has the advantages of reducing problems of background luminescence and accurately measuring larger distance ranges (>10 nm). LRET has been used to study conformational changes in *Shaker* potassium channels (*22*), interactions of proteins dystrophin and actin in muscle cells (*23*), and conformational changes following DNA−protein interactions (*24*).

Fluorescent analogs of α-CTx MII have been used in preliminary studies to localize α6-containing receptors in specific anatomical regions of mouse brain using confocal microscopy (*25*, *26*). Other α-conotoxins could also be fluorescently labeled to increase the number of fluorescent ligand probes for specific subtypes of nAChRs. Thus, fluorescent analogs of α-conotoxins represent a novel class of functional tools that may aid in our understanding of receptor localization and in the study of receptor conformational changes, kinetics, and neuroanatomy.

ACKNOWLEDGMENT

This work was supported by NIH grant MH53631 (to J.M.M). MALDI-MS was performed by W. Low and R. Kaiser of the Salk Institute. The authors thank Dr. Doju Yoshikami for technical advice and Dr. Layla Azam for RNA used in *X. laevis* oocyte injections.

Supporting Information Available: Additional information about (a) synthesis of Alexa Fluor 488−MII and (b) testing of TMR−MII on *X. laevis* oocytes expressing α3β2 nAChRs. This material is available free of charge via the Internet at http://pubs.acs.org.

NOTE ADDED AFTER ASAP PUBLICATION

This manuscript published ASAP on October 21, 2006 with a missing character in the sequence of the peptide in Figure 1. The correct version was posted on October 31, 2006.

Received May 29, 2006; Revised Manuscript Received July 28, 2006

Tagged biologically active molecules represent powerful pharmacological tools to study and characterize ligand−receptor interactions. However, the labeling of such molecules is not trivial, especially when poorly soluble tags have to be incorporated. The classical method of coupling usually necessitates a tedious final purification step to remove the excess of reagents and to isolate tagged molecules. To overcome this limitation, Cu(I)-catalyzed 1,3-dipolar cycloaddition, referred to as "click" chemistry, was evaluated as a tool to facilitate the access to labeled molecules. In order to validate the approach, we focused our attention on the incorporation of a fluorophore (Lissamine Rhodamine B), a nonfluorescent dye (Patent Blue VF), or biotin into a muscarinic antagonist scaffold derived from pirenzepine. The reaction performed in acetonitrile/water, in the presence of $CuSO_4$ and Cu wire, allowed us to obtain three novel pirenzepine derivatives with high purity and in good yield. No coupling reagents were needed, and the quasi-stoichiometric conditions of the reaction enabled the straightforward isolation of the final product by simple precipitation and its use in bioassays. The affinity of the compounds for the human M1 muscarinic receptor fused to EGFP was checked under classical radioligand and FRET binding conditions. The three pirenzepine constructs display a nanomolar affinity for the M1 receptor. In addition, both dye-labeled derivatives behave as potent acceptors of energy from excited EGFP with a very high quenching efficiency.

INTRODUCTION

Biomolecules bearing a biotin tag or dye labels represent useful pharmacological tools for studying receptors (*1*). Biotinylated compounds, together with their streptavidin partner, can be used in a wide variety of bioanalytical applications, such as affinity chromatography, affinity cytochemistry, and immunoassays (*2*), and also as biosensors for drug development (*3*) or for receptor purification (*4*). Fluorescent drug molecules allow the visualization of their receptor target at the single-cell level (*5*, *6*). More generally, these molecules are used as tracers in binding assays where they represent a safe and versatile alternative to radioligands, thus eliminating issues related to handling and disposal of radioactive materials (*7*). Recently, Ilien et al. reported on the synthesis of a series of fluorescent derivatives of the muscarinic M1 antagonist pirenzepine and on their binding properties at an enhanced green fluorescent protein (EGFP)−human M1 receptor chimera, examined through fluorescence resonance energy transfer (FRET) (*8*, *9*). Among these ligands, Lissamine Rhodamine B-labeled pirenzepine **1a** (Figure 1) displayed both a nanomolar affinity and the highest FRET efficiency. In a subsequent article, these authors provided evidence that pirenzepine derivatives labeled with a nonfluorescent dye, such as Patent Blue VF in compound **1b,** were useful tools to improve the reliability of FRET-based binding assays when performed at high probe concentrations (*10*).

Several methods are currently available to label biomolecules such as peptides or small organic molecules (*11*). However, most of these methods suffer from several limitations: (1) Activated tags are generally provided in small quantities suitable for biochemical applications, but amounts typically required for synthetic organic chemistry are prohibitively expensive. (2) To ensure good solubility of both partners, the coupling step has to be carried out in high boiling point solvents such as DMF or DMSO. This renders the final workup, i.e., the isolation of the labeled molecule, more difficult. (3) Excess of one of the partners is generally used to drive the reaction to completion. This makes final purification more tedious, as the excess of both reagents and coupling agents have to be removed. (4) Last but not least, the labeling is not chemoselective and other nucleophile groups have to be protected before performing the

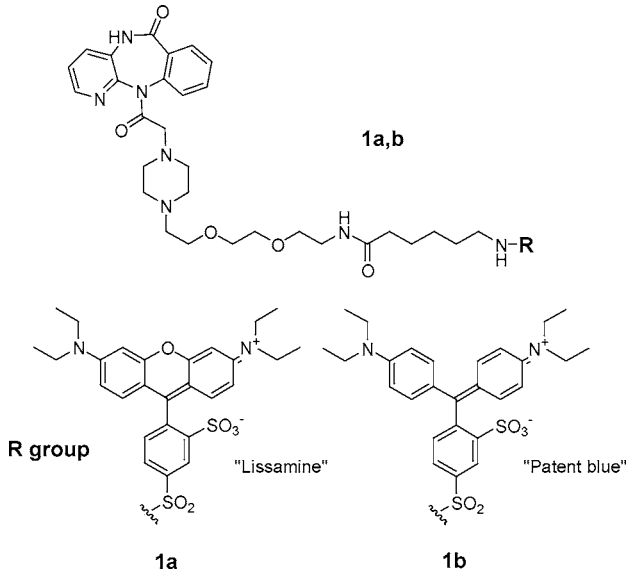

Figure 1. Chemical structures of fluorescent (Lissamine Rhodamine B-labeled; **1a**) and nonfluorescent (Patent Blue VF-labeled; **1b**) pirenzepine derivatives as described in refs 9 and 10.

coupling reaction. Therefore, the numerous difficulties associated with the preparation of such molecules prompted us to develop a novel method to ensure rapid, low-cost, and chemoselective labeling of biomolecules.

Herein, we describe a simple and efficient method, referred to as "click" chemistry, to label a small ligand with various tags (such as biotin, Lissamine Rhodamine B, or Patent Blue VF) using Cu(I)-catalyzed 1,3-dipolar cycloadditions. After optimization on a model reaction, the method was successfully applied to the synthesis of three novel pirenzepine (an M1 selective muscarinic antagonist) derivatives **14a**−**c**, with high yield and purity. An important issue was the impact of the triazole link on the biological activity of these ligands. Therefore, their binding properties at the muscarinic M1 receptor were examined through classical [^{3}H]-NMS competition experiments and through FRET-based saturation assays using the EGFP-(Δ17)hM1 chimera (*8*). Affinity parameters (K_i and K_d values) were determined and compared to those previously reported for the parent molecules **1a** and **1b**. Maximal amplitudes for EGFP fluorescence extinction, achieved at saturating concentrations of **14a** and **14b**, allowed the estimation of the efficiency of the energy transfer process promoted by their interaction with the receptor.

EXPERIMENTAL PROCEDURES

General. All chemicals were obtained from commercial suppliers and used without further purification. Lissamine Rhodamine B sulfonyl chloride and D(+)biotin were purchased from Acros and Avocado, respectively. 6-(Boc-amino)caproic acid *N*-succinimidyl ester **6** and 11-azido-3,6,9-trioxaundecan-1-amine were from Fluka and benzotriazole-1-yl-oxy-tris-(pyrrolidino)phosphonium hexafluorophosphate (PyBOP) was supplied from Novabiochem. Compounds **9** and **13** were prepared as previously described in the literature (*9*, *10*). Silica gel 60F 254 plates for thin-layer chromatography (TLC) were purchased from Merck. Column chromatographic separations were carried out by flash chromatography using silica gel (Merck) with a particle size of 0.040−0.063 mm. ^{1}H NMR spectra were recorded at 200 or 300 MHz on a Bruker Advance spectrometer. Chemicals shifts are given in parts per million and coupling constants (*J*) in hertz. Analytical RP-HPLC separations were performed on a C18 Symmetry Shield column (4.6 × 150 mm) using a linear gradient of eluent B in eluent A (0−100% B in 30 min, flow rate 1 mL.min^{-1}, detection at 220 and 254 nm) and a linear gradient of eluent D in eluent C (0−100% D in 60 min, flow rate 0.8 mL.min^{-1}, detection at 220 and 254 nm). The following buffers were used: (eluent A) water containing 0.1% TFA; (eluent B) acetonitrile containing 0.1% TFA; (eluent C) water containing 0.1% HFBA; (eluent D) MeOH containing 0.1% HFBA. ESI-TOF (electrospray ionization time-of-flight) spectra were recorded on a Perseptive Biosystem Mariner 5155 spectrometer. The *m*/*z* range 200−2100 was scanned using an ion-spray voltage of 4500 V. The nozzle was ranged between 30 and 60 V.

***N*-(2-{2-[2-(2-Azidoethoxy)-ethoxy]-ethoxy}-ethyl)-4-nitrobenzamide 2.** 11-azido-3,6,9-trioxaundecan-1-amine (200 μL, 1 mmol) was dissolved in CH_2Cl_2 and Et_3N (210 μL, 1.5 mmol). 4-Nitrobenzoyl chloride (226 mg, 1.2 mmol) dissolved in CH_2Cl_2 was added to the solution. The resulting mixture was stirred for 4 h at room temperature. The crude reaction was then diluted with CH_2Cl_2 and washed with 10% citric acid solution and brine. The organic layer was dried over Na_2SO_4, filtered, and concentrated under reduced pressure. Compound **2** was isolated by column chromatography (CH_2Cl_2/CH_3OH 98/2) to afford a yellow oil (281 mg, 77%); R_f = 0.35 (CH_2Cl_2/MeOH 98/2); ^{1}H NMR ($CDCl_3$, 300 MHz) δ 8.28 (d, *J* = 8.4 Hz, 2H), 7.98 (d, *J* = 7.1 Hz, 2H), 3.95−3.35 (m, 14H), 3.35 (t, 4.8 Hz, 2H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 165.7, 149.8, 140.5, 128.6, 123.9, 70.9, 70.7, 70.5, 70.2, 69.8, 50.9, 40.3; ES-MS MW calcd 368.14 *m*/*z*, found 390.17 [M + Na]$^+$; RP-HPLC purity >90%.

2 (and 4)-[6-(diethylamino)-3-(diethyliminio)-3*H*-xanthen-9-yl]-5 (or 3)-({[6-oxo-6-(prop-2-ynylamino)hexyl]amino}-sulfonyl)benzenesulfonate 3. To a solution of 6-(Boc-amino)-caproic acid *N*-succinimidyl ester (200 mg, 0.61 mmol) in a CH_2Cl_2/DMF (1/2) mixture were added propargylamine (62 μL, 0.91 mmol) and Et_3N (94 μL, 0.66 mmol). The resulting solution was stirred at room temperature overnight and then diluted with CH_2Cl_2 and washed with 10% citric acid solution, 10% aqueous Na_2CO_3, and brine. The organic layer was dried over Na_2SO_4, filtered, and concentrated under reduced pressure to give a white powder which was further purified through a short column of silica gel (CH_2Cl_2/CH_3OH 97/3) to afford compound **7** in 76% yield (125 mg). R_f = 0.38 (CH_2Cl_2/MeOH 97/3); ES-MS MW calcd 268.4, *m*/*z* found 291.2 [M + Na]$^+$. Compound **7** (100 mg, 0.37 mmol) was treated with a CH_2Cl_2/TFA (1/1) mixture for 20 min at room temperature. Following TFA removal under reduced pressure, the resulting deprotected compound **8** (yellow oil) was dissolved in CH_2Cl_2/DMF (5/1) mixture containing Et_3N (250 μL) and cooled at 0 °C. Lissamine Rhodamine B sulfonyl chloride (165 mg, 0.28 mmol) was added in portions over 20 min. The solution was allowed to warm up to room temperature and stirred overnight. The crude mixture was concentrated under reduced pressure. Compounds **3a** (para isomer) and **3b** (ortho isomer) were isolated by flash chromatography with a step gradient from 5% to 10% MeOH in CH_2Cl_2 and obtained as a red dark solid: **3a** (89 mg, 44%,); R_f = 0.37 (CH_2Cl_2/MeOH 93/7); ^{1}H NMR ($CDCl_3$/CD_3OD 9/1, 300 MHz) δ 8.57 (d, *J* = 1.8 Hz, 1H), 7.94 (dd, *J* = 1.8 and 8.1 Hz, 1H), 7.18 (d, *J* = 8.1 Hz, 1H), 7.04 (d, *J* = 9.6 Hz, 2H), 6.75 (dd, *J* = 2.1 and 9.6 Hz, 2H), 6.63 (d, *J* = 2.1 Hz, 2H), 3.80 (d, *J* = 2.5 Hz, 2H), 3.25 (bs, 1H), 2.95 (t, *J* = 6.6 Hz, 2H), 2.10−2.08 (m, 3H), 1.51−1.38 (m, 4H), 1.31−1.14 (m, 14H); ^{13}C NMR ($CDCl_3$/CD_3OD 9/1, 75 MHz) δ 175.7, 159.4, 158.5, 157.1, 147.8, 144.3, 135.2, 134.2, 132.0, 129.4, 128.2, 115.6, 115.2, 97.3, 72.4, 47.8, 47.4, 44.4, 37.1, 31.1, 30.6, 30.1, 27.4, 26.6, 13.9, 10.0; MW calcd 708.88, *m*/*z* found 731.36 [M + Na]$^+$; RP-HPLC purity >95%. **3b** (53 mg, 27%); R_f = 0.30 (CH_2Cl_2/MeOH 93/7); δ 8.44 (d, *J* = 1.7 Hz, 1H), 8.13 (dd, *J* = 1.7 and 7.8 Hz, 1H), 7.19 (d, *J* = 7.8 Hz, 1H), 7.01 (d, *J* = 9.4 Hz, 2H), 6.77 (dd, *J* = 2.4 and 9.4 Hz, 2H), 6.65 (d, *J* = 2.5 Hz, 2H), 3.82 (d, *J* = 2.5 Hz, 2H), 3.23 (bs, 1H), 3.03 (q, *J* = 7.5 Hz, 8H), 2.75 (t, *J* = 6.6 Hz, 2H), 2.11 (t, *J* = 2.5 Hz, 2H), 2.10−2.05 (m, 2H), 1.42−0.75 (m, 18H); ^{13}C NMR ($CDCl_3$/CD_3OD 9/1, 75 MHz) δ 175.7, 159.4, 157.3, 154.4, 150.7, 134.1, 133.5, 131.4, 127.6, 119.6, 115.6, 110.0, 99.0, 97.7, 72.7, 47.9, 47.6, 44.5, 37.2, 31.2, 30.2, 29.5, 27.5, 26.4, 14.0, 10.1; ES-MS MW calcd 708.88, *m*/*z* found 731.33 [M + Na]$^+$; RP-HPLC purity >95%.

2-{[4-(diethylamino)phenyl][4-(diethyliminio)cyclohexa-2,5-dien-1-ylidene] methyl}-5- ({[6-oxo-6-(prop-2-ynylamino)-hexyl]amino}sulfonyl)benzenesulfonate 4. A solution of aqueous lithium hydroxide hydrate 1 N (89 μL, 89.7 μmol) was added at room temperature to methyl 6-(4-[(4-diethylamino-phenyl)(4-diethylimino-2,5-cyclohexadien-1ylidene)methyl]-3-sulfo-1-phenylsulfonamido)hexanoate **9** (20 mg, 29.7 μmol) dissolved in dioxane. The mixture was stirred overnight at room temperature or 10 min at 80 °C using microwave irradiation. Dioxane was removed under reduced pressure, and water was added. The mixture was washed with CH_2Cl_2, acidified with a 1 M $KHSO_4$ solution, and extracted with CH_2Cl_2. Organic layers were combined and concentrated under pressure to give acid **10** which was used as crude material in the next step.

Crude acid **10** was dissolved in DMF with propargylamine (3 μL, 38.6 μmol). PyBOP (16 mg, 29.7 μmoles) was added, followed by DIEA (16 μL, 89.1 μmol). The resulting mixture was stirred at room temperature overnight. DMF solvent was removed under reduced pressure, and the crude material was purified by column chromatography (CH_2Cl_2/MeOH 95/5) to afford compound **4** as a blue powder (17.3 mg, 83%). R_f = 0.35 (CH_2Cl_2/MeOH 95/5); ^{1}H NMR ($CDCl_3$/CD_3OD 9:1, 300 MHz) δ 8.54 (d, *J* = 1.5 Hz, 1H), 7.88 (dd, *J* = 1.5 and 7.7 Hz, 1H), 7.33 (d, *J* = 9.5 Hz, 4H), 7.12 (d, *J* = 7.8 Hz, 1H), 6.72 (d, *J* = 9.5 Hz, 4H), 4.21 (d, *J* = 3.4 Hz, 1H), 3.84 (brd, *J* = 2.5 Hz, 2H), 3.58−3.48 (m, 8H), 2.98 (t, *J* = 6.5 Hz, 2H), 2.14−2.07 (m, 3H), 1.53−1.18 (m, 18H); ^{13}C NMR ($CDCl_3$/CD_3OD 9:1, 75 MHz) 174.1, 155.4, 147.0, 142.8, 140.9, 132.0, 131.2, 129.0, 128.4, 127.9, 127.4, 127.1, 126.8, 113.4, 46.1, 45.1, 43.0, 35.8, 29.8, 28.8, 26.0, 25.2, 12.8. ES-MS MW calcd 694.9, *m*/*z* found 717.4 $[M + Na]^+$; RP-HPLC purity >95%.

5-[(4*R*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]-*N*-prop-2-ynylpentanamide 5. D(+)biotin (50 mg, 205 μmol) was dissolved in DMF in presence of DIEA (107 μL, 615 μmol). Propargylamine (28 μL, 410 μmol) was added, followed by PyBOP (106 mg, 205 μmol). After overnight stirring at room temperature, DMF solvent was removed under reduced pressure. The crude material was then purified by column chromatography on silica gel (CH_2Cl_2/MeOH 9/1) to get compound **5** as a white powder (35 mg, 60%). R_f = 0.24 (CH_2Cl_2/MeOH 9/1); ^{1}H NMR (CD_3OD, 200 MHz) δ 4.56−4.52 (m, 1H), 4.37−4.31 (m, 1H), 3.99 (d, *J* = 2.5 Hz, 2H), 3.32−3.22 (m, 1H), 2.97 (dd, *J* = 6.0 Hz, 12.0 Hz, 1H), 2.74 (d, *J* = 11.4 Hz, 1H), 2.61 (t, *J* = 2.5 Hz, 1H), 2.26 (*t*, *J* = 7.2 Hz, 2H), 1.84−1.40 (m, 6H); ^{13}C NMR (CD_3OD, 75 MHz) δ 176.4, 166.9, 81.5, 72.9, 64.2, 62.4, 57.8, 41.8, 37.3, 30.5, 30.3, 30.2, 27.5; ES-MS MW calcd 281.38, *m*/*z* found 304.15 $[M + Na]^+$.

General Procedure for the Preparation of Triazoles: **Synthesis of Compound 12.** Azido **2** (4.1 mg, 11.2 μmol) and alkyne **3a** (9.6 mg, 13.5 μmol) were dissolved in 9/1 acetonitrile/water mixture (600 μL) in presence of $CuSO_4$ (solution 26.7 μM, 40 μL, 1.11 μmol) and Cu wire (68 mg). The solution was stirred overnight at 30 °C, the solvent removed, and the crude material purified by column chromatography (CH_2Cl_2/MeOH 9/1). Compound **12** (9.0 mg, 75%) was obtained as a red solid. R_f = 0.28 (CH_2Cl_2/MeOH 9/1); ^{1}H NMR ($CDCl_3$/CD_3OD 9:1, 200 MHz) δ 8.62 (s, 1H), 8.13 (d, *J* = 8.5 Hz, 2H), 7.95 (m, 3H), 7.20 (d, *J* = 7.8 Hz, 1H), 7.07 (d, *J* = 9.3 Hz, 2H), 6.75 (d, *J* = 9.3 Hz, 2H), 6.59 (d, *J* = 1.9 Hz, 2H), 4.39−4.33 (m, 4H), 3.75 (t, *J* = 4.6 Hz, 2H), 3.60−3.33 (m, 18H), 2.95 (t, *J* = 4.6 Hz, 2H), 2.77 (bs, 1H), 2.35−1.93 (m, 4H), 1.6−1.0 (m, 18H); ^{13}C NMR (CD_3OD, 50 MHz) δ 158.1, 155.8, 133.8, 133.0, 130.5, 128.9, 128.0, 127.0, 123.8, 114.3, 114.0, 95.9, 70.6, 70.3, 69.7, 46.2, 43.1, 40.2, 12.7; ES-MS MW calcd 1075.4, *m*/*z* found 1076.6 $[M + H]^+$, 1098.6 $[M + Na]^+$; RP-HPLC purity >95%.

Compound 14a. The same procedure as that described above for compound **12** was used starting from azido **13** (4.7 mg, 9.5 μmol) and alkyne **3a** (8.0 mg, 11.3 μmol). After 4 h at 30 °C, triazole **14a** (8.9 mg, 78%) was isolated by column chromatography on silica gel (CH_2Cl_2/MeOH 9:1/NH_4OH 1% in water) as a red solid. R_f = 0.21; RP-HPLC purity >95%; HRMS calcd for $C_{60}H_{75}N_{12}O_{11}S_2$ 1203.5114, found 1203.5156.

Compound 14b (5.0 mg, 70%, blue solid) was obtained by reacting azido **13** (3 mg, 6.0 μmol) and alkyne **4** (5.3 mg, 7.5 μmol) at 30 °C for 4 h and subsequent purification by column chromatography (CH_2Cl_2/MeOH 9:1/NH_4OH 1% in water). R_f = 0.27; RP-HPLC purity >95%; HRMS calcd for $C_{60}H_{77}N_{12}O_{10}S_2$ 1189.5322, found 1189.5298.

Compound 14c (5.9 mg, 92%, white solid) was obtained by reacting azido **13** (4.2 mg, 8.5 μmol) and alkyne **5** (3.0 mg, 10.6 μmol) following the same experimental conditions as for **14b**. R_f = 0.15 (CH_2Cl_2/MeOH 9:1/NH_4OH 1% in water); RP-HPLC purity >95%; HRMS calcd for $C_{37}H_{50}N_{11}O_6S$ 776.3661, found 776.3631.

Construction and Expression of the Chimeric hM1 Receptor. The human M1 muscarinic receptor with a truncated N-terminus fused to EGFP, referred to as EGFP-(Δ17)hM1, was obtained and stably expressed in HEK 293 cells as previously reported (*8*).

[^{3}H]-NMS Binding Assays. Competition experiments were performed using intact EGFP-(Δ17)hM1 expressing cells (60 000 cells) suspended in 1 mL HEPES/BSA buffer (10 mM HEPES, 137.5 mM NaCl, 1.25 mM $MgCl_2$, 1.25 mM $CaCl_2$, 6 mM KCl, and 10 mM glucose, pH 7.4; supplemented with 1 mg.mL^{-1} bovine serum albumin). Incubation proceeded at 20 °C for 22 h in the presence of 100−150 pM [^{3}H]-NMS ([^{3}H]-*N*-methylscopolamine) of various concentrations of compounds to be tested or of 4 μM atropine for nonspecific binding measurement. K_i values of competitors were calculated from IC_{50} values, using the Cheng and Prusoff relationship (*12*) and taking a K_d value of 90 pM for the radioligand.

Spectroscopy. UV−visible absorbance spectroscopy was performed with a Cary 1E (Varian) spectrophotometer. Absorption spectra for compounds, diluted in MeOH, were recorded in the 450−750 nm wavelength range. Fluorescence measurements were made using a SPEX Fluorolog 2 (Jobin Yvon Horiba) spectrofluorimeter equipped with a 450 W Xe lamp. Data were stored using the DM3000 software provided with the spectrofluorimeter.

FRET-Based Binding Measurements. EGFP-(Δ17)hM1 cells (1 × 10^6 cells), suspended in 1 mL HEPES/BSA buffer, were incubated with increasing concentrations of fluorescent ligand, in the absence or presence of 10 μM atropine to assess the specificity of the signal. Equilibrium was allowed to proceed for 22 h at 20 °C. Thereafter, the incubation medium was transferred to a 1 mL thermostated (21 °C) quartz cuvette with magnetic stirring and recorded for fluorescence intensity at 510 nm (excitation set at 470 nm). Occupancy curves were generated by plotting amplitudes for fluorescence extinction as a function of ligand concentration as previously described (*10*). K_d values and maximal FRET amplitudes were from data fitting to the empirical Hill equation derived for saturation. Efficiency of fluorescence energy transfer (*E*) was defined as the fractional decrease in specific EGFP fluorescence due to ligand binding as previously reported (*8*).

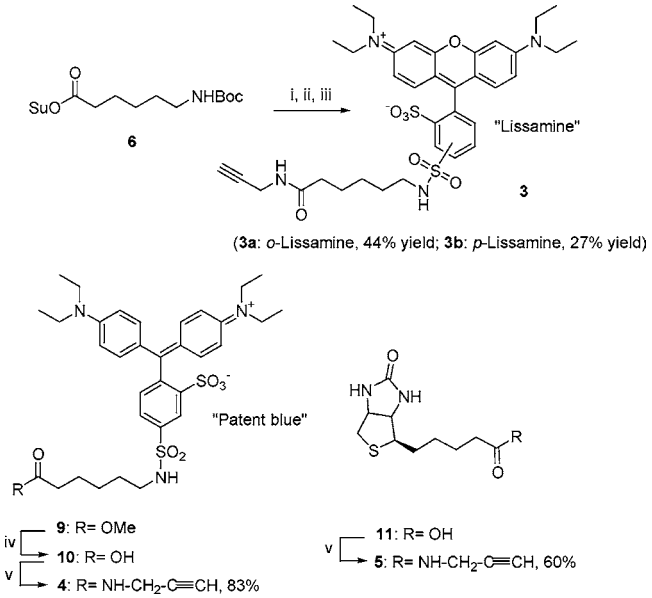
RESULTS AND DISCUSSION

Chemistry. The generation of (1,2,3)-triazoles through 1,3-dipolar cycloadditions of alkynes to azides, which belongs to a group of reactions referred to as "click chemistry" (*13*), proceeds at room temperature in the presence of copper(I) as a catalyst (*14*). Among various applications, this reaction has enabled the selective modification of virus particles (*15*), nucleic acids (*16*), and proteins (*17*) in biological environments.

In the first part of the study, the potential of this method for the labeling of bioactive molecules was examined using the azido model **2** and alkynes derived from Lissamine Rhodamine B **3**, Patent Blue VF **4**, and biotin **5** (Scheme 1).

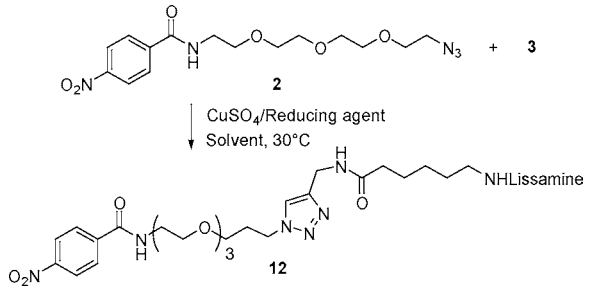
Alkyne **3** was obtained in three steps starting from commercially available 6-(Boc-amino)caproic acid *N*-succinimidyl ester **6**. Substitution of ester with propargylamine gave access to alkyne **7** that was subsequently deprotected in the presence of TFA. Resulting amine **8** was reacted with Lissamine Rhodamine B sulfonyl chloride (commercially available as a mixture of ortho and para isomers) in CH_2Cl_2/DMF mixture in the presence of Et_3N and 4-dimethylaminopyridine (DMAP) to afford **3** as a mixture of ortho **3a** and para **3b** isomers (1:1.6

Scheme 1. Routes for Preparation of Alkyne Derivatives 3−5[a]



[a] Legend: (i) propargylamine, CH_2Cl_2/DMF, Et_3N, rt, 16 h; (ii) TFA/CH_2Cl_2 (1:1), rt, 20 min; (iii) Lissamine sulfonyl chloride, CH_2Cl_2/DMF (5:1), Et_3N/DMAP, 0 °C, 15 min then rt, overnight; (iv) LiOH, dioxane/H_2O, 40 °C, 16 h or microwave irradiation (80 °C, 10 min); (v) propargylamine, PyBOP, DIEA, DMF, rt, overnight.

Scheme 2. Model Reaction to Optimize Cu(I)-Catalyzed 1,3-Dipolar Cycloaddition



ratio, respectively, as shown by ^{1}H NMR and RP-HPLC analysis (*18*)). Column chromatography on silica gel allowed the separation of both isomers **3a** and **3b** obtained in a 44% and 27% overall yield, respectively.

Alkyne **4** was prepared starting from Patent Blue VF methyl ester **9** (*10*). In an attempt to obtain **4** in one step, aminolysis of **9** with an excess of propargylamine was tried and found to be inefficient, regardless of the solvent, the temperature, and the presence or absence of a catalytic amount of cyanide anion (*19*). Compound **4** was finally obtained in two steps. Ester **9** was first hydrolyzed in the presence of LiOH in a dioxane/water mixture at 40 °C overnight, leading quantitatively to acid **10**. Interestingly, hydrolysis was dramatically accelerated by using microwave irradiation (80 °C, 10 min). Crude acid **10** was then coupled with propargylamine following PyBOP in situ activation to provide **4** in 83% overall yield.

Finally, alkyne derived from biotine **5** was obtained by coupling propargylamine with D(+)biotin using PyBOP activation in DMF at 40 °C in 60% yield after purification on silica gel (Scheme 1).

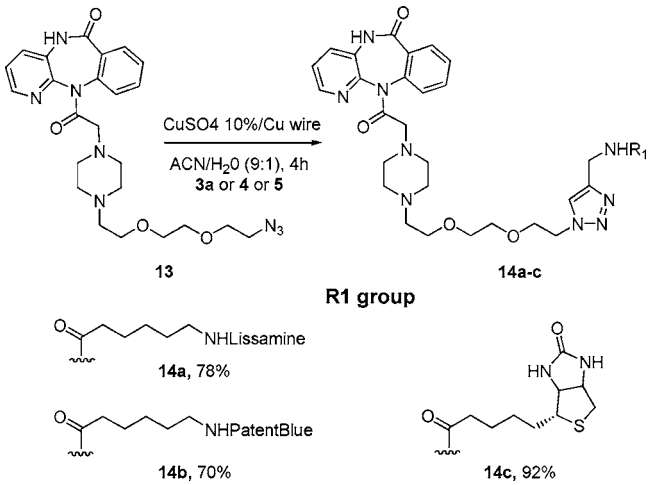
With alkynes **3**−**5** in hand, "click" reaction efficacy was evaluated with the model azido **2** and the alkyne derived from Lissamine **3**. The reaction was conducted in the presence of $CuSO_4$ and of a reducing agent to generate Cu(I) species in polar solvents at 30 °C (Scheme 2). The influence of key parameters such as the nature of the reducing agent and the solvent on the formation of the triazole derivative **12** was carefully investigated. RP-HPLC yields were determined following overnight stirring at 30 °C (Table 1).

Table 1. Optimization of the Synthesis of Triazole 12.

entry	solvent	reducing agent	RP-HPLC yield of **12**[a] (%)
1	EtOH/$H_2$0 (1:1)	TCEP	0
2	EtOH/$H_2$0 (1:1)	ascorbic acid	30
3	EtOH/$H_2$0 (1:1)	Cu wire	38
4	EtOH/$H_2$0 (9:1)	Cu wire	68
5	MeOH/$H_2$0 (9:1)	Cu wire	59
6	tBuOH/$H_2$0 (9:1)	Cu wire	65
7	ACN/$H_2$0 (9:1)	Cu wire	90
8	ACN/$H_2$0 (1:1)	Cu wire	74

[a] Yields were approximated by RP-HPLC and calculated using the ratio of surface area of reactant species to surface area of product species (see experimental procedures for RP-HPLC conditions).

Scheme 3. Novel Pirenzepine Derivatives Obtained Using "Click" Chemistry



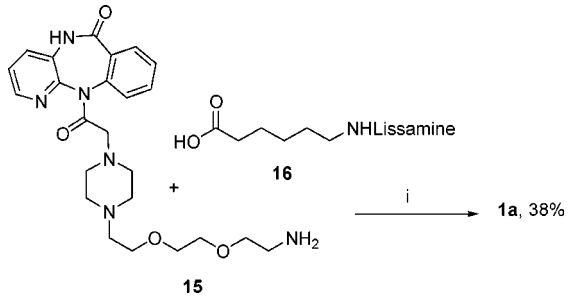
In our hands, the classical experimental conditions described in the literature (*14*), i.e., EtOH/H_2O (1:1) mixture in the presence of tris(carboxyethyl)phosphine (TCEP), failed (entry 1). Replacement of phosphine by ascorbic acid or Cu wire allowed an improvement of RP-HPLC yields from 30% to 38% (entries 2 and 3). The nature of the solvent and the ratio of water were found to be crucial for the reaction (entries 4−8), with the best result (90%) being obtained by using an acetronitrile (ACN)/water (9:1) mixture (entry 7). Using these conditions, compound **12** was isolated in 75% overall yield.

The scope and limitations of the method were further investigated by considering the incorporation of Lissamine Rhodamine B, but also of Patent Blue and of sparsely soluble biotin onto pirenzepine (Scheme 3). The azido pirenzepine derivative **13** was synthesized as previously described (*9*). 1,3-Dipolar cycloaddition was performed in the presence of 1.2 equiv of alkyne **3a** (para isomer), 0.1 equiv of $CuSO_4$, and Cu wire in an acetonitrile/water (9:1) mixture. Completion of the reaction was observed after only 4 h stirring at 30 °C. Thus, compound **14a** was isolated by column chromatography in 78% yield.

Similar results were obtained with alkynes derived from Patent Blue VF leading to the corresponding labeled pirenzepine **14b** in 70% isolated yield. Finally, the "click" reaction of alkyne **13** with azido-derived biotin **5** was found to be particularly clean and rapid, since conjugate **14c** was isolated in 92% yield following 4 h at 30 °C.

It is noteworthy that, owing to the excellent purity of the crude mixture, labeled compounds could be used directly for

Scheme 4. Synthesis of Fluorescent Labeled Pirenzepine 1a[a]



[a] Legend: (i) PyBOP, DIEA, DMF, 30 °C, 4 h.

Table 2. Binding Properties of Compounds 14a−c at the Muscarinic M1 Receptor.

		fluorescence resonance energy transfer[b]		
compound	[^{3}H]NMS binding[a] K_i (nM)	K_d (nM)	amplitude (%)	efficiency E
pirenzepine	7.1			
1a	46	18.7	48	0.68
1b	189	30	37	0.52
14a[c]	30	20	55	0.78
14b	16.3	11	46	0.65
14c	49			

[a] K_i values are from competition experiments performed in duplicate using [^{3}H]-NMS as the radioligand. The K_i value reported for compound **1b** (tested against [^{3}H]-QNB) is from ref 10. [b] Values listed for compounds **1a** and **1b** are, respectively, from refs 9 and 10. Other values are from a typical experiment performed in duplicate. [c] Only the para isomer was considered.

biological evaluation without any additional purification. Cu wire is simply picked up from the solution with tweezers, the crude product is diluted in water, and the resulting precipitate washed to remove $CuSO_4$. The use of metal resin scavengers, such as Chelex resin (Bio-Rad), may be regarded as an alternative process to get rid of Cu^{2+} (*20*).

To highlight the efficiency of the "click" reaction versus traditional coupling, pirenzepine amine **15** obtained by reduction of azido **13** (*10*) was reacted with 1.2 equiv of acid **16** (*21*) following PyBOP in situ activation in DMF (Scheme 4). After 4 h at 30 °C, this control experiment resulted in a low conversion of starting materials involving a tedious final purification by RP-HPLC to isolate Lissamine-labeled pirenzepine **1** in modest 38% yield (vs 78% for "click" reaction).

This first part of the study highlighted the efficiency of the "click" process to easily access the novel pirenzepine-labeled derivatives **14a−c**. The reaction is rapid, insensitive to water, and almost quantitative regardless of the nature and the solubility of tags incorporated. Interestingly, the absence of coupling reagents and quasi-stoichiometric conditions, combined with the use of an acetonitrile/water mixture, allow the isolation of the final labeled products by simple precipitation.

The main issue of the second part of the work was to check whether the triazole moiety was compatible with high-affinity binding of the pirenzepine derivatives to the muscarinic M1 receptor, a G protein-coupled receptor belonging to the bioamine group whose binding domain is deeply buried in the receptor protein.

Pharmacological Study of Novel Pirenzepine Derivatives 14a−c. Ligand binding affinity at equilibrium was evaluated through competition (conventional [^{3}H]NMS assay) and saturation (FRET-based assay) experiments, using the EGFP-(Δ17)hM1 chimera (*8*).

Binding parameters are listed in Table 2 and may be compared to those determined for pirenzepine and for the two parent ligands **1a** and **1b**, under similar experimental conditions.

The three novel pirenzepine derivatives retain nanomolar affinities for [^{3}H]-NMS binding sites. The Lissamine Rhodamine B conjugate **14a** exhibits a K_i value similar to that of its parent molecule **1a**, while the Patent Blue derivative **14b** displays a significantly higher affinity than **1b** (which has been tested against [^{3}H]-QNB; (*10*)). The introduction of the small biotine substituent in **14c**, as compared to the more voluminous dyes in **14a** and **14b**, does not lead to appreciable affinity changes. Thus, neither the incorporation of a triazole ring within the spacer nor the exchange of a large chromophore for a smaller moiety are detrimental to high-affinity binding of the compounds to the hM1 receptor.

For all tested molecules, similar affinity rank order and parameter values were determined from competition-type ([^{3}H]-NMS binding) or from saturation-type (FRET) equilibrium experiments. A subtle but constant increase in affinity is however noted for the compounds when tested for their ability to behave as energy acceptors from excited EGFP. Such a feature has been already reported, and was even exacerbated, when [^{3}H]-QNB- and FRET-derived binding affinity constants for a series of dye derivatives of pirenzepine were compared (*9*, *10*). Most probably, these variations stem from differences in the physicochemical properties of the ligands.

A surprising finding was the apparent increase in maximal extinction amplitude afforded at saturating micromolar concentrations of **14a** and **14b**, as compared to **1a** and **1b**, respectively. These changes cannot be attributed to modifications in EGFP-(Δ17)hM1-expressing cell properties, as a control Bodipy-pirenzepine derivative (Bo(10)PZ), taken at 200 nM, provided here a maximal extinction amplitude of 44.8%, in perfect agreement with previous determinations (*8*, *9*). Moreover, the muscarinic specificity of the FRET signal achieved at high probe concentrations was verified by the full protective (competitive) effect of 10 μM atropine. As far as identical dyes (Lissamine Rhodamine B for **1a** and **14a**; Patent Blue for **1b** and **14b**) and identical EGFP-fused receptors (FRET donor) are concerned, it is tempting to suggest that an increase in maximal extinction amplitude reflects an increase in FRET efficiency. Indeed, the efficiency of fluorescence energy transfer (E) is defined as the fractional decrease in EGFP fluorescence due to ligand binding and is expressed by $E = 1 - F_{DA}/F_D$, where F_{DA} and F_D are the specific donor fluorescence emission values in the presence or the absence of saturating concentrations of ligand, respectively (*8*). According to the Förster equation, $R = R_0(1/E - 1)^{1/6}$ (*21*, *22*), with a Förster radius R_0 value set as a constant, an increase in FRET efficiency is clearly linked to a shortening of the actual distance R which separates the EGFP donor from the acceptor dye. It is thus possible that the triazole ring allows a reorientation of the ligand chromophore within the receptor and its projection toward an external domain, closer to EGFP. Though such a possibility deserves further investigations, similar distance shortenings (close to 3.5 Å) could be estimated when using triazole-containing probes instead of their more flexible original analogues.

An alternate explanation is to consider that, owing to the presence of the triazole ring within the spacer, the ligand chromophore would no longer adopt a random orientation of its absorption transition dipoles relative to those of donor emission. Such a possibility is difficult to verify and would affect the estimation of the Förster radius value, R_0, that specifies the theoretical distance separating a given donor−acceptor pair for 50% energy transfer efficiency. Altogether, these results indicate that the substitution of an amide bond to a small and rigid 1,4-triazole ring within the spacer connecting pirenzepine to the label is not deleterious for binding. Furthermore, this may be considered an interesting way to shorten the separation between FRET partners, i.e., between the donor (EGFP) and the acceptor

(dye moiety of the ligand), and to further increase the sensitivity in detecting the formation of ligand−receptor complexes.

CONCLUSION

In this paper, we describe a versatile and convenient method to facilitate the labeling of the small pirenzepine ligand with either a fluorescent probe, a nonfluorescent dye, or biotin. Cu(I)-catalyzed 1,3-dipolar cycloaddition, performed in partially aqueous media, is rapid, chemo- and regioselective, and leads to the formation of a stable triazole connection. The three new probes exhibit a nanomolar affinity for EGFP(Δ17)-hM1 receptors, indicating that the triazole link does not perturb binding to M1 receptors. It is also compatible with FRET-based binding assays. "Click" chemistry may thus be regarded as a convenient method to tag GPCR ligands with different probes useful for various applications. For instance, these three novel pharmacological tools will be involved in studies aimed at crystallizing muscarinic M1 receptor. Fluorescent and colored ligands will be used to detect and quantify correctly folded receptors. The biotinylated derivative will be used to prepare affinity chromatography columns necessary to the ultimate purification of functional M1 receptor.

A method for installing a distinguishable label onto cyclodextrins or cyclodextrin-containing polymers is reported. Cyclodextrins (CD) and cyclodextrin-containing polymers are exposed to labeled (^{2}H or ^{14}C) ethylene oxide (EO) vapor and the alcohol groups on the CD ring open the EO to give ether-linked labeled methylenes and a terminal alcohol. This method provides for the incorporation of an easily tracked and quantified label without the use of solvents or purification steps. The method can be generalized for use with materials that contain nucleophiles other than alcohols, e.g., amines.

INTRODUCTION

Cyclodextrin-containing compounds and materials are becoming more widespread in drug delivery applications due to commercial availability, ability to form inclusion complexes, biocompatibility, and other unique chemical properties that contribute to their ease of chemical functionalization (*1*). Cyclodextrins do not contain chromophores or fluorophores in the parent structure and thus create difficulties in monitoring by spectrophotometric methods. Herein, a robust and general method to incorporate labels (deuterium or ^{14}C) to cyclodextrin compounds simply and without solvents or purification is described that utilizes the reactivity of sugars with ethylene oxide vapor. This labeling method is also applicable to other sugar-containing molecules as well as any material bearing a reactive nucleophile group. The ability to incorporate radioactive isotopes such as ^{14}C provides for materials that can be used for pharmacokinetic and pharmacodynamic studies (tritium labels, for example, may be lost from material in vivo (*2*)). The addition of the EO to the CD does not change the total amount of alcohol groups and just inserts a two-methylene spacer onto the sugar. Thus, there is minimal differences in the physicochemical properties from the parent CD.

LeMaistre and Seymour (*3*) reported that the reaction of sucrose in aqueous sodium hydroxide solution with ethylene oxide occurred in high yield. However, there are no reports of the reaction of EO with CD. Here, we react individual CDs and CD-containing polymers with EO.

EXPERIMENTAL SECTION

General. Deuterated ethylene oxide was obtained as a gas from Sigma Aldrich. β-cyclodextrin was obtained from Wacker.

Labeling with Ethylene Oxide-d_4. β-Cyclodextrin (50 mg) was dried at 100 °C under vacuum for 12 h overnight in order to completely remove residual water (water reacts with ethylene oxide to form ethylene glycol if not removed). After drying, the solid β-cyclodextrin sample was then allowed to cool to RT. The lecture bottle with ethylene oxide-d_4 was then attached to the reaction flask, and gas was flowed over the material for 2 min at 17 psi. The reaction vessel was then placed under vacuum to remove unreacted ethylene oxide-d_4. The resulting white solid was then analyzed by ESI-MS to test for EO incorporation. Deuterium NMR experiments were performed also to confirm the presence of the EO incorporation.

Labeling with ^{14}C Ethylene Oxide. The cyclodextrin-containing polymer conjugate of camptothecin, IT-101 (*4*−*7*) (1.6 g), was reacted with 1 mmol ethylene oxide [1,2-^{14}C], 50 mCi/mmol, under anhydrous conditions. Ethylene oxide, [1,2-^{14}C] was generated from bromoethanol, [1,2-^{14}C] under basic conditions, dried, and vacuum transferred into a 50 mL glass pressure vessel containing IT-101. The resultant mixture, at approximately 0.5 atm, was allowed to incubate for 4 days. The excess ethylene oxide, [1,2-^{14}C] was removed by vacuum transfer, and no further workup was performed. The specific activity was measured by gravimetric assay to be 1.01 μCi/mg. Yield 1440 μCi, remaining a light yellow solid.

RESULTS AND DISCUSSION

The reaction of dried β-CD with ethylene oxide-d_4 (EO-d_4) was carried out with vapor EO (Figure 1). Ethylene oxide-d_4 has a mass of 48 and for each EO-d_4 that reacts with the β-CD a corresponding increase in mass should be detectable by ESI/MS.

The resulting solid product after exposure to EO-d_4 was analyzed by ESI/MS to observe the amount of labeling that has occurred. When the β-CD is not dried in advance, there is only a trace of EO incorporation (see Supporting Information), as residual water reacts with EO to give ethylene glycol. The same experiment was then carried out with β-CD that was dried at 100 °C for 24 h prior to use and then treated with EO-d_4 for 5 min. The resulting ESI/MS data are shown in Figure 2. It is clear that there are observable species in the mass spectrum that correspond to various levels of ethylene oxide incorporation into the β-CD. The parent peak at 1157.4 corresponds to [M + Na] for the parent β-CD. The corresponding peak for 1 addition of EO is at [M + Na] = 1205.4 and is clearly present. The corresponding peaks for 2, 3, 4, and 5 EO additions are also observed, as well as trace peaks corresponding to 6 and 7 additions at *m*/*z* of 1445 and 1493. The distribution of labeled products is also very clearly an exponentially decreasing trend

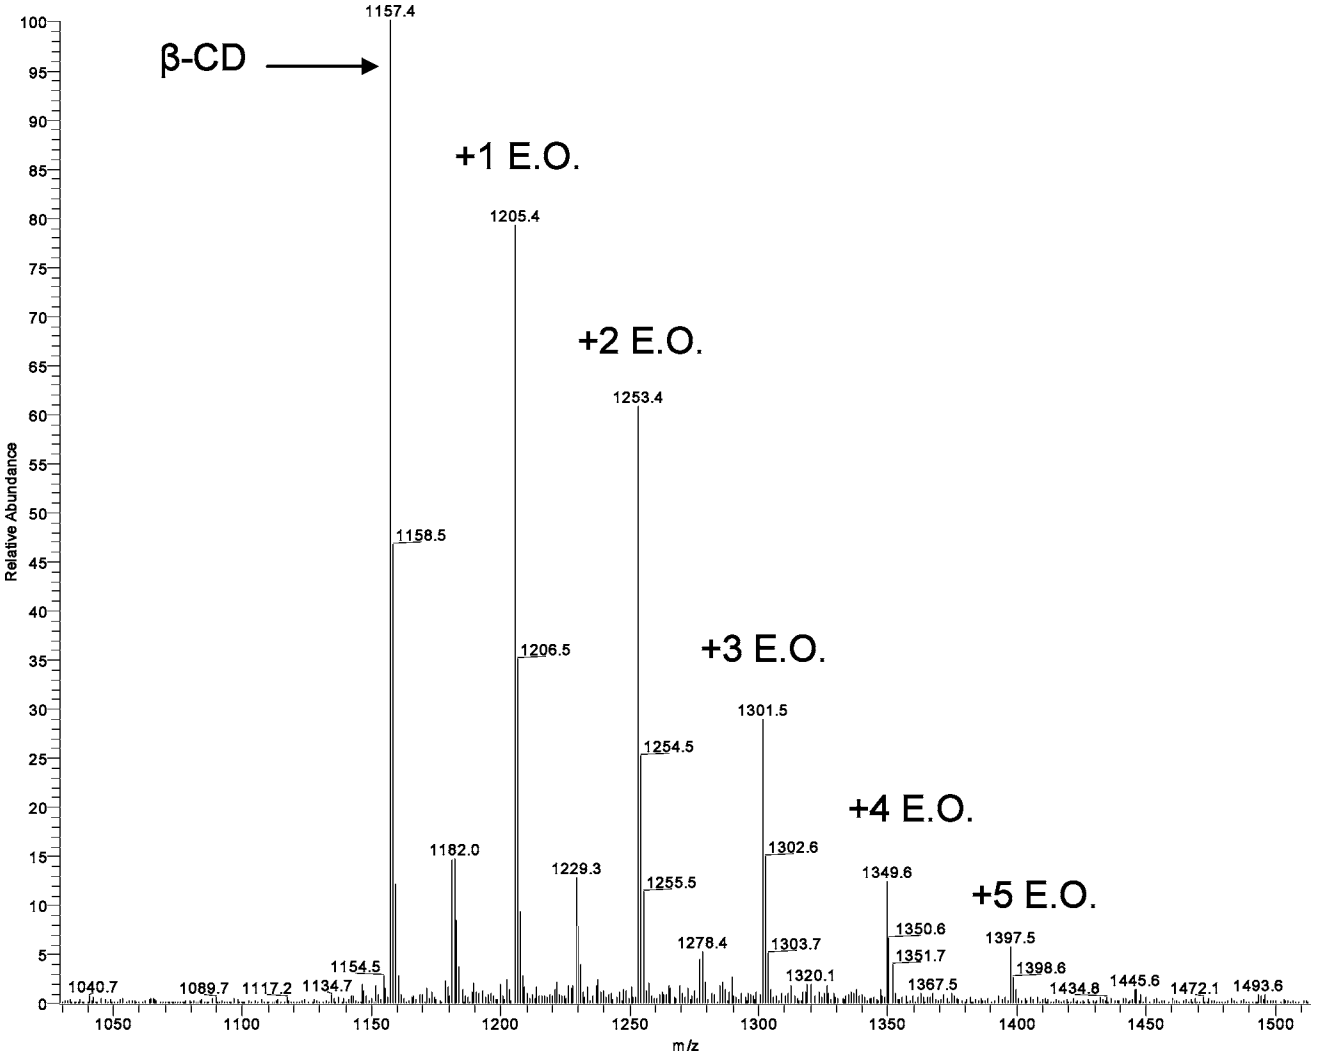

Figure 2. ESI/MS analysis of labeled β-CD.

as the *m*/*z* increases to values indicative of highly labeled species. By using shorter exposure time and lower reaction temperatures, less EO-d_4 is incorporated (see Supporting Information).

There is a need to incorporate radioactive labels into materials that can be used for in vivo studies. A major concern when labeling materials is whether or not the labeling significantly alters the material properties from those of the parent compound. Incorporation of EO into CDs does alter the properties of the labeled compound from those of the parent CD (unlike placing the label in the sugar itself). However, the consequences of the slight differences in properties may be significantly outweighed by the ease in the labeling methodology with EO; especially for CD-containing materials.

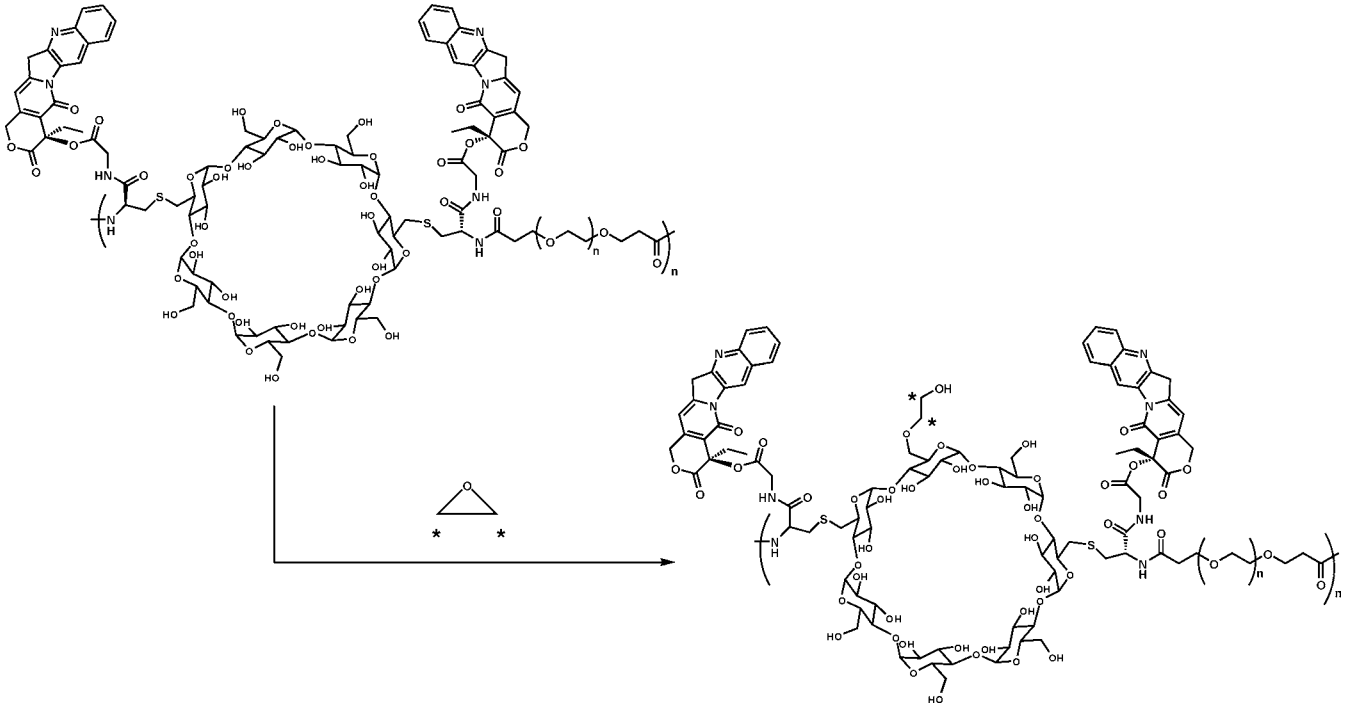

Figure 3. Schematic of radioactively labeled EO reaction with IT-101.

Radiolabeled ^{14}C ethylene oxide would be expected to react with β-CD in a manner similar to the EO-d_4. The radioactivity of the resulting material could be quantified to evaluate the level of incorporation of EO and provide for straightforward analysis if used in vivo. To illustrate the methodology on β-CD containing polymer, we used IT-101 (*4*−*7*), a linear, water soluble cyclodextrin-containing polymer that is conjugated with camptothecin (Figure 3) to react with ^{14}C ethylene oxide.

IT-101 was exposed to radiolabeled ^{14}C ethylene oxide, and the resulting material was analyzed for radioactivity to quantify the extent of labeling. Note that in this case the drying step was carried out at room temperature to prevent polymer−conjugate decomposition. This drying step is sufficient to show that no radioactively labeled ethylene glycol is formed (see Supporting Information). The labeled IT-101 contained 1.01 mCi/mg of radioactivity that corresponds to ca. 1.5 EO molecules added per polymer chain. The labeling was performed in the absence of solvents on the polymer conjugate, and when the "hot" IT-101 is dissolved in water it forms particles with average size of 43 nm (analysis was performed by The Southwest Research Institute). This size is consistent with published data of IT-101 that is not radiolabeled (*4*−*7*). These data suggest that substantial levels of radiolabel can be incorporated into IT-101 and its properties not significantly modified from the parent compound. Animal studies using radiolabeled IT-101 are in progress and will be reported at a later time.

In summary, a simple and efficient method for labeling cyclodextrin-containing materials without the use of solvents or purification is described through reaction with ethylene oxide, and this methodology is applicable to any materials bearing nucleophilic sites. When using radiolabeled ethylene oxide, an accurately quantifiable labeling method is achieved and it allows for the preparation of radiolabeled materials for in vivo studies.
