Synthesis of Very Short Chain Lysophosphatidyloligodeoxynucleotides†

Rosa Chillemi, Danilo Aleo, Giuseppe Granata, and Sebastiano Sciuto*

Dipartimento di Scienze Chimiche, Università di Catania, viale A. Doria 6, 95125, Catania, Italy. Received December 28, 2005; Revised Manuscript Received May 19, 2006

Very short chain 5′-*O*-lysophosphatidyloligonucleotides [5′-*O*-(1-*O*-palmitoyl-*sn*-glycero-3-phosphoryl)oligodeoxynucleotides, (5′-LyPOdNs)] were synthesized following a two-step chemoenzymatic synthesis. 5′-*O*-(*sn*-Glycero-3-phosphoryl)oligodeoxynucleotides (5′-GPOdNs) were first prepared by simply using a phosphoramidite of [(4*S*)-2,2-dimethyl-1,3-dioxolan-4-yl]methanol (**1**) in a further coupling step after the solid-phase elongation of each desired oligodeoxynucleotide. Next, the regioselective palmitoylation at the C-1 hydroxyl of the glycerol moiety of 5′-GPOdNs was achieved by a lipase-catalyzed transacylation with trifluoroethyl palmitate in organic solvent. Despite of the molecular bulkiness of 5′-GPOdNs, 2-, 3-, and 4-mer 5′-LyPOdNs were prepared by this procedure. Although in very low yield, 5- and 6-mer 5′-LyPOdNs were also obtained by this way.

INTRODUCTION

In the continuous searching for antiviral drugs with different structures and unique mechanisms of action, other than those conferred by conventional nucleoside analogues (*1*), a number of small oligonucleotides and oligonucleotide analogues have been shown to be of great pharmacological interest. Some natural dinucleotides and dinucleotide analogues have been discovered as inhibitors of HIV integrase (*2*), while short oligonucleotide analogues have been reported as novel inhibitors of RNA-dependent RNA polymerase of HCV (*3*). More recently, some di- and trinucleotide analogues have been identified as potent inhibitors of HBV replication (*4*). So, the use of very short chain oligonucleotide analogues as inhibitor molecules to target viral replication represents a promising novel approach to antiviral interference. However, one of the recurring problems encountered for in vivo application of oligonucleotides is the low permeability of cell membranes to these large polyionic molecules (*5*, *6*). Nevertheless, the transport of these molecules into cells has been shown to be facilitate by linking them to lipophilic carriers (*7*, *8*); so, pharmacologically active oligonucleotides bearing a terminal biodegradable lipophilic group attached through a phosphoester bond could be useful pro-drugs with improved cellular uptake.

In this regard, the phosphatidyl group seems to be one of the most suitable lipophilic groups, on account of its widespread occurrence in the molecular structure of many lipid constituents of cell membranes. But, to our knowledge, neither this group nor the structurally related lysophosphatidyl one have been utilized as the lipophilic moiety of lipo-oligonucleotides.

This is probably due to an actual difficulty encountered in a direct chemical attachment of these groups to oligonucleotides elongated on the solid phase by standard phosphoramidite chemistry procedures; such a way, in fact, suffers from the lability of the carboester bond in these groups under the strongly basic conditions routinely used to remove classical amino protecting groups of nucleotides.

In our previous work (*9*, *10*) we developed a general synthetic preparation of 5′(3′ or 2′)-*O*-lysophosphatidyl conjugates of deoxyribo- and ribonucleosides as well. Following a two-step chemoenzymatic strategy, mono[(2*R*)-2,3-dihydroxypropyl] esters of the pertinent 5′(3′ or 2′)-mononucleotides (glycerophosphorylnucleosides, GPNs) were first prepared by opportunely applying the phosphoramidite chemistry on solid phase or in solution. In a subsequent step, selective acylation at 1-OH of the glycerol moiety of GPNs was achieved by a lipase-catalyzed (Lipozyme) transacylation with activated fatty acid esters in organic solvent. By this procedure, lysophosphatidyl derivatives of pharmacologically active nucleoside analogues were also prepared, which showed a clearly enhanced ability to penetrate model lipid monolayers over that of free nucleoside counterparts (*10*).

So, in light of these findings and aiming to overcome the above drawbacks, we considered the possibility of preparing lysophosphatidyl conjugates of short chain oligodeoxynucleotides by exploiting once again the chemoenzymatic strategy previously followed for the preparation of lysophosphatidylnucleosides. This work reports usefulness and limits of such a procedure for the preparation of this kind of lipoconjugates.

EXPERIMENTAL PROCEDURES

General Methods. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Unity Inova spectrometer at 500 and 125.7 MHz, respectively. The chemical shifts are reported as δ (ppm) referenced to the following: (a) TMS as internal standard for the experiments in $CDCl_3$, C_6D_6, and CD_3OD; (b) the resonance of the residual HOD ($\delta = 4.82$ ppm) for ^{1}H experiments in D_2O; (c) the signal of appropriately added CD_3OD ($\delta = 49.0$ ppm) for ^{13}C experiments in D_2O. Unequivocal assignments of ^{1}H and ^{13}C resonances were supported by 1D (spin decouplings, NOEDS, DEPT, or APT) and 2D (^{1}H−^{1}H COSY, HSQC, ROESY) experiments. FAB-MS spectra were recorded with a Fisons ZAB 2SE spectrometer with glycerol as matrix (unless otherwise specified). ESI-MS spectra were recorded with a Finnigan LCQ Deca instrument. MALDI-MS spectra were recorded with a Voyager-DE PRO time-of-flight (Applied Biosystems) using 3-hydroxypicolinic acid as matrix. The solid-phase oligonucleotide syntheses were carried out on the Cyclone Plus 8400 DNA synthesizer. Aminopropyl-CPG (500 Å pore size) was purchased from CPG Inc. PLC were performed on silica gel (40−63 μm, Merck). HPLC was performed on a Hewlett-Packard 1050 chromatograph equipped with UV detector set at 260 nm, using LiChrospher-100 ODS (5 μm; 4 × 250

mm) and Zorbax SB-C18 (5 μm; 9.4 × 250 mm) columns for analytical and semipreparative runs, respectively. Modified oligodeoxynucleotides dissolved in water were spectroscopically quantified (A_{260}) by attributing to them the extinction coefficient values reported elsewhere (*11*). Commercially purchased solvents and reagents were all of reagent quality. Diethyl ether, petroleum ether, CH_2Cl_2, triethylamine, and *t*BuOH were freshly dried and stored under argon as previously reported (*9*). Trifluoroethyl palmitate (TFEP) was synthesized by standard procedure, using trifluoroethanol and palmitic anhydride in pyridine and DMAP as catalyst; its purity was checked on the basis of its chromatographic and spectroscopic properties. Lipases from *Rhizomucor miehei* (immobilized, Lipozyme), *Rhizomucor miehei* (not immobilized), *Candida antarctica*, *Candida cylindracea*, *Pseudomonas cepacea*, *Pseudomonas fluorescens*, hog pancreas, and *Rhizopus niveus* were purchased from Fluka. Before use all the enzymes were allowed to stand in dried *t*BuOH for 45 min.

2-Cyanoethyl [(4*R*)-2,2-Dimethyl-1,3-dioxolan-4-yl]methyl Diisopropylamidophosphite (1). The synthesis and the purification of compound **1** were performed by using a previously reported procedure (*9*). Its purity was checked on the basis of its chromatographic and spectroscopic properties.

General Procedure for the Synthesis of 5′-GPOdNs (2−8). Compounds **2**−**8** were synthesized according to solid-phase cyanoethyl phosphoramidite chemistry by using a DNA synthesizer (15 μmol scale) with two or more coupling cycles between the appropriate 3′-CPG-linked protected nucleoside [5′-*O*-(4,4′-dimethoxytrityl)-*N*^{6}-benzoyl-2′-deoxyadenosine or 5′-*O*-(4,4′-dimethoxytrityl)-2′-deoxythymidine] and 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite of 5′-*O*-(4,4′-dimethoxytrityl)-*N*^{6}-benzoyl-2′-deoxyadenosine, 5′-*O*-(4,4′-dimethoxytrityl)-*N*^{2}-isobutyryl-2′-deoxyguanosine, or 5′-*O*-(4,4′-dimethoxytrityl)-2′-deoxythymidine, ending each synthetic run by a coupling cycle with the phosphoramidite **1**. After detachment of the condensation product from the CPG column by treatment with concd ammonia at room temperature for 1 h, the ammonia solution was kept at 55 °C for 6 h and then taken to dryness in vacuo. The residue was dissolved in 30% aqueous AcOH and allowed to stand at room temperature for 5 h. The mixture was then taken to dryness in vacuo and the totally deprotected product was purified by semipreparative RP-HPLC, eluting with a gradient of CH_3CN in 0.1 M triethylammonium acetate (TEAA; pH 7.0) from 4 to 15% in 40 min, at a flow rate of 3.5 mL min^{-1}.

The above mild acid treatment had been set up in our previous work (*9*, *10*) to remove the isopropylidene ketal protecting group from the glycerol moiety of various glycerophosphorylnucleosides. The removal of this protecting group is commonly accomplished by using 80% AcOH at room-temperature overnight, but depurination may occur under these conditions. For this reason, benzylidene acetals have been proposed by Edupuganti et al. (*12*) as alternative protecting groups for vic-diols which may be removed by 80% AcOH at room temperature for 1 h, without significant depurination.

To this regard, the purine rich 5′-GPd(GpA) was in parallel checked for its stability in 80% AcOH at room temperature for 1 h, and in 30% AcOH at room temperature for 5 h. HPLC analysis of the reaction mixtures obtained after the two different acidic treatments gave quite similar results in both the cases, thus indicating that removal of isopropylidene ketal protecting group by the mild acidic treatment we used did not produce significant depurination of 5′-GPOdNs.

5′-GPd(ApA) (2). (74% isolated yield). ^{1}H NMR (D_2O): δ 2.55 and 2.58 (partially overlapped multiplets, 2 H altogether, 2″-H A2 and 2′-H A1 respectively), 2.73 (ddd, $J_{2'',2'} = -14.3$, $J_{2'',1'} = 5.8$, $J_{2'',3'} = 1.5$ Hz, 1 H, 2″-H A1), 2.79 (ddd, $J_{2',2''} = -13.8$, $J_{2',1'} = 7.3$, $J_{2',3'} = 6.7$ Hz, 1 H, 2′-H A2), 3.47 (dd, $J_{1a,1b} = -11.6$, $J_{1a,2} = 6.0$ Hz, 1 H, 1a-H of glycerol), 3.56 (dd, $J_{1b,1a} = -11.6$, $J_{1b,2} = 4.0$ Hz, 1 H, 1b-H of glycerol), 3.68 (m, 1 H, 3a-H of glycerol), 3.77−3.82 (overlapped multiplets, 2 H, 2-H and 3b-H of glycerol), 3.98 (ddd, $J_{5',5''} = -11.5$, $J_{5',4'} = 2.8$, $J_{5',P} = 4.7$ Hz, 1 H, 5′-H A1), 4.06 (ddd, $J_{5'',5'} = -11.5$, $J_{5'',4'} = 3.6$, $J_{5'',P} = 4.5$ Hz, 1 H, 5″-H A1), 4.20 (ddd, $J_{5'',5'} = -11.5$, $J_{5'',4'} = 2.8$, $J_{5'',P} = 3.0$ Hz, 1 H, 5"-H A2), 4.26 (ddd partially overlapping with next signal, $J_{5',5''} = -11.5$, $J_{5',4'} = 2.0$, $J_{5',P} = 3.8$ Hz, 1 H, 5′-H A2), 4.29 (m partially overlapping with previous signal, 1 H, 4′-H A2), 4.39 (dddd, $J_{4',5'} = 2.8$, $J_{4',5''} = 3.6$, $J_{4',3'} = 2.0$, $J_{4',P} = 2.1$ Hz, 1 H, 4′-H A1), 4.99 (dddd, $J_{3',2'} = 5.6$, $J_{3',2''} = 1.5$, $J_{3',4'} = 2.0$, $J_{3',P} = 4.3$ Hz, 1 H, 3′-H A1), 6.19 (dd, $J_{1',2'} = 8.8$, $J_{1',2''} = 5.8$ Hz, 1 H, 1′-H A1), 6.33 (dd, $J_{1',2'} = 7.3$, $J_{1',2''} = 6.7$ Hz, 1 H, 1′-H A2), 7.98 (s, 1 H, 2-H A1), 8.11 (s, 1 H, 2-H A2), 8.24 (s, 1 H, 8-H A1), 8.37 (s, 1 H, 8-H A2) ppm. The 3′-H A2 resonance is obscured by the residual HOD signal. ^{13}C NMR (D_2O): δ 39.9 (C-2′ A1), 41.8 (C-2′ A2), 64.7 (C-1 of glycerol), 67.3 (d, $J_{COP} = 4.6$ Hz, C-5′ A2), 67.9 (d, $J_{COP} = 5.4$ Hz, C-5′ A1), 69.1 (d, $J_{COP} = 6.0$ Hz, C-3 of glycerol), 72.7 (C-3′ A2), 73.4 (d, $J_{CCOP} = 8.4$ Hz, C-2 of glycerol), 79.5 (d, $J_{COP} = 5.4$ Hz, C-3′ A1), 85.4 (C-1′ A2), 86.3 (C-1′ A1), 87.8 (t, $J_{CCOP} = 9.8$ Hz, C-4′ A1), 87.9 (d, $J_{CCOP} = 9.9$ Hz, C-4′ A2), 120.4 and 121.0 (C-5 A1 and A2), 142.6 (C-8 A2), 142.7 (C-8 A1), 150.8 and 150.9 (C-4 A1 and A2), 153.8 (C-2 A1 and A2), 156.7 and 156.9 (C-6 A1 and A2) ppm. HRFAB-MS(−) calcd for $C_{23}H_{31}N_{10}O_{13}P_2$ $(M - H)^-$ 717.1547, found 717.1539.

(72% isolated yield). ^{1}H NMR (D_2O): δ 1.75 (d, $J = 1.1$ Hz, 3 H, CH_3 T3), 2.27 (dt partially overlapping with next signal, $J_{2',2''} = -14.1$, $J_{2',1'} = 6.9$, $J_{2',3'} = 6.9$ Hz, 1 H, 2′-H T3), 2.31 (ddd partially obscured by previous signal, $J_{2'',2'} = -14.1$, $J_{2'',1'} = 6.9$, $J_{2'',3'} = 4.5$ Hz, 1 H, 2″-H T3), 2.64 (ddd, $J_{2',2''} = -14.0$, $J_{2',1'} = 9.2$, $J_{2',3'} = 5.3$ Hz, 1 H, 2′-H A1), 2.77−2.83 (overlapped multiplets, 3 H, 2′-H and 2″-H A2, 2″-H A1), 3.47 (dd, $J_{1a,1b} = -11.7$, $J_{1a,2} = 6.1$ Hz, 1 H, 1a-H of glycerol), 3.56 (dd, $J_{1b,1a} = -11.7$, $J_{1b,2} = 4.2$ Hz, 1 H, 1b-H of glycerol), 3.69 (m, 1 H, 3a-H of glycerol), 3.78−3.83 (overlapped multiplets, 2 H, 2-H and 3b-H of glycerol), 3.99 (ddd, $J_{5',5''} = -11.5$, $J_{5',4'} = 2.6$, $J_{5',P} = 4.8$ Hz, 1 H, 5′-H A1), 4.08 (ddd, $J_{5'',5'} = -11.5$, $J_{5'',4'} = 3.6$, $J_{5'',P} = 4.4$ Hz, 1 H, 5"-H A1), 4.12−4.16 (partially overlapped multiplets, 2 H, 5″-H and 4′-H T3), 4.22−4.30 (partially overlapped multiplets, 3 H, 5′-H and 5″-H A2, 5′-H T3), 4.42 (m, 1 H, 4′-H A1), 4.49 (m, 1 H, 4′-H A2), 4.59 (ddd, $J_{3',2'} = 6.9$, $J_{3',2''} = 4.5$, $J_{3',4'} = 4.1$ Hz, 1 H, 3′-H T3), 5.02 (m, 1 H, 3′-H A1), 5.08 (m, 1 H, 3′-H A2), 6.14 (t, $J = 6.9$ Hz, 1 H, 1′-H T3), 6.19 (dd, $J_{1',2'} = 9.2$, $J_{1',2''} = 5.7$ Hz, 1 H, 1′-H A1), 6.29 (dd, $J_{1',2'} = 8.0$, $J_{1',2''} = 6.3$ Hz, 1 H, 1′-H A2), 7.46 (q, $J = 1.1$ Hz, 1 H, 6-H T3), 7.98 (s, 1 H, 2-H A), 8.09 (s, 1 H, 2-H A), 8.26 (s, 1 H, 8-H A1), 8.41 (s, 1 H, 8-H A2) ppm. ^{13}C NMR (D_2O): δ 14.4 (CH_3 T3), 39.9 (C-2′ A1), 40.6 (C-2′ A2), 41.6 (C-2′ T3), 64.9 (C-1 of glycerol), 67.3 (d, $J_{COP} = 4.6$ Hz, C-5′ T3), 67.7 (d, $J_{COP} = 4.6$ Hz, C-5′ A2), 68.2 (d, $J_{COP} = 4.2$ Hz, C-5′ A1), 69.2 (d, $J_{COP} = 5.0$ Hz, C-3 of glycerol), 72.5 (C-3′ T3), 73.5 (d, $J_{CCOP} = 7.6$ Hz, C-2 of glycerol), 78.2 (d, $J_{COP} = 4.6$ Hz, C-3′ A2), 79.9 (d, $J_{COP} = 5.0$ Hz, C-3′ A1), 85.3 (C-1′ A2), 86.3 (C-1′ A1), 87.0 (C-1′ T3), 87.3 (t, $J_{CCOP} = 9.2$ Hz, C-4′ A2), 87.4 (d, $J_{CCOP} = 8.8$ Hz, C-4′ T3), 88.0 (t, $J_{CCOP} = 8.9$ Hz, C-4′ A1), 114.1 (C-5 T3), 120.7 and 121.2 (C-5 A1 and A2), 139.6 (C-6 T3), 142.3 (C-8 A2), 142.5 (C-8 A1), 150.9 and 151.2 (C-4 A), 153.9 (C-2 T3), 154.7 and 154.9 (C-2 A1 and A2), 157.4 and 157.7 (C-6 A1 and A2), 168.5 (C-4 T3) ppm. HRFAB-MS(−) calcd for $C_{33}H_{44}N_{12}O_{20}P_3$ $(M - H)^-$ 1021.2008, found 1021.2020.

5′-GPd(ApApApT) (4). (68% isolated yield). HRFAB-MS(−) calcd for $C_{43}H_{56}N_{17}O_{25}P_4$ $(M - H)^-$ 1334.2584, found 1334.2561.

5′-GPd(ApApApApT) (5). (65% isolated yield). MALDI-MS(−) calcd for $C_{53}H_{68}N_{22}O_{30}P_5$ $(M - H)^-$ 1647.32, found 1648.10 $(M - H)^-$, 1669.93 $(M - 2\,H + Na)^-$.

5′-GPd(ApTpApTpTpA) (6). (64% isolated yield). MALDI-MS(−) calcd for $C_{63}H_{82}N_{21}O_{39}P_6$ $(M - H)^-$ 1942.35, found 1942.74 $(M - H)^-$, 1964.63 $(M - 2\,H + Na)^-$.

5′-GPd(GpA) (7). (73% isolated yield). HRFAB-MS(−) calcd for $C_{23}H_{31}N_{10}O_{14}P_2$ $(M - H)^-$ 733.1496, found 733.1490.

5′-GPd(TpA) (8). (76% isolated yield). HRFAB-MS(−) calcd for $C_{23}H_{32}N_7O_{15}P_2$ $(M - H)^-$ 708.1432, found 708.1428.

Synthesis of 3′-GPd(ApA) (19). *Synthesis of 1-O-Benzoyl-3-O-(4,4′-dimethoxytrityl)-sn-glycerol (**16**).* To a solution of [(*R*)-2,2-dimethyl-1,3-dioxolan-4-yl]methanol (49 μL, 0.39 mmol) in anhydrous pyridine (800 μL) was added benzoyl chloride (45 μL, 0.39 mmol), and the stirred mixture was kept at room temperature for 1 h. Then, more benzoyl chloride (45 μL, 0.39 mmol) was added, and the mixture was allowed to react at 55 °C for 4 h. The reaction mixture was dissolved in EtOAc (15 mL) and the solution washed with H_2O (3 × 10 mL). The organic layer was dried (Na_2SO_4) and taken to dryness in vacuo. The residual oil was taken up in 50% aqueous AcOH (10 mL) and the mixture stirred at room temperature for 5 h. After evaporation of the solvents in vacuo, the residue was chromatographed on silica gel eluting with petroleum ether/EtOAc/*i*PrOH (70:20:10), and fractions containing pure 1-*O*-benzoyl-*sn*-glycerol were taken to dryness. The residue (0.29 mmol) was dissolved in anhydrous pyridine (2 mL) and the stirred solution added with 4,4′-dimethoxytrityl chloride (0.35 mmol). The reaction mixture was kept at room temperature for 3 h, quenched with CH_3OH (1 mL), and taken to dryness in vacuo. The residue was dissolved in CH_2Cl_2 (15 mL) and the solution washed with H_2O (3 × 10 mL), dried on Na_2SO_4 and evaporated in vacuo. The product was purified by PLC on silica gel (preeluted with anhydrous triethylamine) eluting with petroleum ether/*n*BuOH/triethylamine (97:3:1). Pure compound **16** (119 mg, 61% overall yield) was then obtained and analyzed for its spectroscopic (NMR) properties.

*Synthesis of Succinic Acid [(2S)-1-O-Benzoyl-3-O-(4,4′-dimethoxytrityl)trihydroxypropyl] Hemiester (**17**).* To a stirred solution of **16** (100 mg, 0.20 mmol) in anhydrous pyridine (2 mL) containing DMAP (18 mg, 0.15 mmol) was added succinic anhydride (26 mg, 0.26 mmol). The reaction mixture was left at 60 °C for 18 h and then added to CH_2Cl_2 (15 mL) and washed with H_2O (3 × 10 mL). The organic layer was dried on Na_2SO_4 and evaporated in vacuo. The residue was chromatographed on silica gel, preeluted with anhydrous triethylamine, eluting with EtOAc/CH_3OH/triethylamine (80:20:1), giving pure compound **17** (103 mg, 87% yield). Selected NMR data referring to the succinyl group: ^{1}H NMR ($CDCl_3$): δ 2.57 (t, $J = 6.5$ Hz, 2 H, C*H*$_2$COOH), 2.64 (t, $J = 6.5$ Hz, 2 H, C*H*$_2$COOR) ppm. ^{13}C NMR ($CDCl_3$): δ 30.8 (*CH*$_2$COOH), 31.1 (*CH*$_2$-COOR), 173.0 (COOR), 177.0 (COOH) ppm. FABMS(−) (3-nitrobenzyl alcohol as matrix): *m/z* 597 $(M - H)^-$.

Coupling of Succinic Acid [(2S)-1-O-Benzoyl-3-O-(4,4′-dimethoxytrityl)trihydroxypropyl] Hemiester to CPG Support. To carry out the title coupling, a procedure commonly used in solid-phase peptide synthesis (*13*) was adapted as follows. To a solution of compound **17** (84 mg, 0.14 mmol) and *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU, 49 mg, 0.13 mmol) in DMF (1.5 mL) was added diisopropylethylamine (DIEA, 24 μL, 0.14 mmol), and the mixture was shaken for 5 min. After more DIEA (24 μL, 0.14 mmol) was added, the solution was poured onto the aminopropyl-CPG support (0.65 g, capacity: 85.3 μmol g^{-1}). The slurry was kept for 1 h with occasional swirling, and then the solution was filtered off and the CPG was washed with DMF (3 × 5 mL) and CH_3CN (3 × 5 mL). The functionalized CPG was suspended in anhydrous THF (4 mL) and added to capping solutions (Cap A: 10% acetic anhydride in THF, 2.2 mL; Cap B: 10% 1-methylimidazole in THF/pyridine 8:1, 2.2 mL). The mixture was shaken for 2.5 h, and then the CPG was filtered, washed successively with THF (5 × 5 mL), CH_2Cl_2 (5 × 5 mL), and diethyl ether (5 × 5 mL), and finally dried in vacuo. A total yield of 0.63 g of functionalized CPG (**18**) was obtained with a capacity of 81.0 μmol g^{-1}, as estimated on the basis of DMT group determination.

3′-GPd(ApA) (19). The prepared solid phase **18** (3 × 15 μmol scale columns) was then utilized to accomplish on a DNA synthesizer two coupling cycles with the 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite of 5′-*O*-(4,4′-dimethoxytrityl)-N^6-benzoyl-2′-deoxyadenosine. After detachment of the condensation product from the CPG column by treatment with concd ammonia at room temperature for 1 h, the ammonia solution was kept at 55 °C for 6 h and then taken to dryness in vacuo. The totally deprotected product was purified by semipreparative HPLC as above-described for 5′-GPOdNs (76% isolated yield). ^{1}H NMR (D_2O): δ 2.25 (ddd, $J_{2',2''} = -13.7$, $J_{2',1'} = 9.1$, $J_{2',3'} = 5.6$ Hz, 1 H, 2′-H A1), 2.57 (dd, $J_{2'',2'} = -13.7$, $J_{2'',1'} = 5.6$, $J_{2'',3'} = 0$ Hz, 1 H, 2′′-H A1), 2.75 (ddd, $J_{2'',2'} = -14.0$, $J_{2'',1'} = 6.1$, $J_{2'',3'} = 3.2$ Hz, 1 H, 2′′-H A2), 2.94 (ddd, $J_{2',2''} = -14.0$, $J_{2',1'} = 8.1$, $J_{2',3'} = 6.5$ Hz, 1 H, 2′-H A2), 3.67 (dd, $J_{1a,1b} = -11.8$, $J_{1a,2} = 5.9$ Hz, 1 H, 1a-H of glycerol), 3.75 (dd, $J_{1b,1a} = -11.8$, $J_{1b,2} = 4.2$ Hz, 1 H, 1b-H of glycerol), 3.78 (d, $J_{5',4'} = 3.3$ Hz, 2 H, 5′-H A1), 3.93−4.05 (partially overlapped multiplets, 3 H, 2-H and 3-H of glycerol), 4.23 (m, 2 H, 5′-H A2), 4.29 (dt, $J_{4',3'} = 1.1$, $J_{4',5'} = 3.3$ Hz, 1 H, 4′-H A1), 4.51 (m, 1 H, 4′-H A2), 4.87 (ddd, $J_{3',2'} = 5.6$, $J_{3',4'} = 1.1$, $J_{3',P} = 4.5$, $J_{3',2''} = 0$ Hz, 1 H, 3′-H A1), 5.13 (dddd, $J_{3',2'} = 6.5$, $J_{3',2''} = 3.2$, $J_{3',4'} = 3.1$, $J_{3',P} = 6.0$ Hz, 1 H, 3′-H A2), 6.17 (dd, $J_{1',2'} = 9.1$, $J_{1',2''} = 5.6$ Hz, 1 H, 1′-H A1), 6.38 (dd, $J_{1',2'} = 8.1$, $J_{1',2''} = 6.1$ Hz, 1 H, 1′-H A2), 7.99 (s, 1 H, 2-H A1), 8.08 (s, 1 H, 8-H A1), 8.14 (s, 1 H, 2-H A2), 8.43 (s, 1 H, 8-H A2) ppm. ^{13}C NMR (D_2O): δ 39.9 (C-2′ A1), 40.8 (C-2′ A2), 64.6 (C-5′ A1), 65.0 (C-1 of glycerol), 67.5 (C-5′ A2), 69.3 (C-3 of glycerol), 73.6 (C-2 of glycerol), 77.7 (C-3′ A2), 79.7 (C-3′ A-1), 85.5 (C-1′ A2), 87.4 (C-4′ A2), 87.8 (C-1′ A1), 89.7 (C-4′ A1), 120.7 and 121.8 (C-5), 142.5 (C-8 A2), 143.2 (C-8 A1), 150.5 and 151.3 (C-4), 154.6 (C-2 A2), 154.8 (C-2 A1), 157.3 and 157.9 (C-6) ppm. General Procedure for the Enzymatic Synthesis of 5′(3′)-O-(1-*O*-Palmitoyl-sn-glycero-3-phosphoryl)oligodeoxynucleotides 9−15 and 20 [5′(3′)-LyPOdNs]. The enzymatic synthesis and the purification of the title compounds were accomplished following the optimized experimental conditions reported in our previous work (*10*). Each 5′-GPOdN (25 μmol) was first converted into the relevant TBA salt by passing it through a column of Dowex-50 W (TBA^+ form). The aqueous eluate was taken to dryness in vacuo, and the residue was allowed to stand under reduced pressure over P_2O_5 overnight. The residue was then dissolved in dried *t*BuOH (40 mL), and the solution added with TFEP (1.0 mmol) and Lipozyme (220 mg). The suspension was shaken at 240 rpm at 38 °C. Each reaction course was followed by HPLC monitoring of the rising amount of the relevant 5′(3′)-LyPOdN, prolonging the reaction time until it was of practical convenience. HPLC analyses were carried out using a linear gradient of CH_3CN in 0.1 M TEAA (pH 7) from 0 to 70% in 30 min at a flow rate of 1.0 mL min^{-1}. The enzyme was then filtered off and the solvent evaporated in vacuo. The residue was taken up and partitioned in a heptane/CH_3OH (3:1) mixture, and the CH_3OH layer was concentrated in vacuo.

The residue containing the acylated product was then purified by semipreparative HPLC eluting with a linear gradient of CH_3CN in 0.1 M TEAA (pH 7) from 0 to 70% in 30 min and a flow rate of 3.5 mL min^{-1}. Fractions containing the desired compound were pooled, evaporated in vacuo to remove CH_3CN and then freeze-dried. A minimum amount of each of compounds **9**, **10**, and **20** was dissolved in CH_3OH and passed through a column of Dowex-50 W (NH_4^+ form), while the remainder was passed through a column of Dowex-50 W (Na^+ form) to optimize the relevant MS and NMR analyses, respectively. The freeze-dried residues of compounds **11**−**15**, dissolved in CH_3OH, were passed through a micro-column of Dowex-50 W (NH_4^+ form) and then analyzed by MS.

5′-LyPd(ApA) (9). 10.4 μmol (reaction time 52 days, 41.4% isolated yield from **2**). ^{1}H NMR (CD_3OD): δ 0.90 (t, J = 7.0 Hz, 3 H, CH_3 of palmitoyl), 1.25 and 1.28 (br. singlets, 24 H altogether, from γ- to ξ-CH_2 of palmitoyl), 1.54 (m, 2 H, β-CH_2 of palmitoyl), 2.27 (t, J = 7.5 Hz, 2 H, α-CH_2 of palmitoyl), 2.45 (ddd, $J_{2'',2'} = -13.4$, $J_{2'',1'} = 6.2$, $J_{2'',3'} = 2.8$ Hz, 1 H, 2′′-H A2), 2.73 (ddd, $J_{2'',2'} = -13.7$, $J_{2'',1'} = 5.5$, $J_{2'',3'} = 1.4$ Hz, 1 H, 2′′-H A1), 2.80 (ddd, $J_{2',2''} = -13.4$, $J_{2',1'} = 8.0$, $J_{2',3'} = 5.9$ Hz, 1 H, 2′-H A2), 2.86 (ddd, $J_{2',2''} = -13.7$, $J_{2',1'} = 8.7$, $J_{2',3'} = 5.2$ Hz, 1 H, 2′-H A1), 3.89 (m, 2 H, 3-H_2 of glycerol), 3.95 (m, 1 H, 2-H of glycerol), 4.05−4.15 (partially overlapped multiplets, 6 H, 1-H_2 of glycerol, 5′-H_2 A1 and A2; on the basis of the 1a-H/2-H and 1b-H/2-H cross-peaks showed in the COSY spectrum it was possible to assign the resonances of 1a-H and 1b-H of glycerol at δ = 4.07 and 4.14, respectively), 4.18 (m, 1 H, 4′-H A2), 4.39 (m, 1 H, 4′-H A1), 4.72 (ddd, $J_{3',2'} = 5.9$, $J_{3',2''} = 2.8$, $J_{3',4'} = 2.5$ Hz, 1 H, 3′-H A2), 5.06 (m, 1 H, 3′-H A1), 6.49 (overlapped multiplets, 2 H, 1′-H A1 and A2), 8.16 and 8.17 (singlets, 2 H altogether, 2-H A1 and A2), 8.47 (s, 1 H, 8-H A1), 8.52 (s, 1 H, 8-H A2) ppm. ^{13}C NMR (CD_3OD): δ 14.4 (CH_3 of palmitoyl), 23.7 (ξ-CH_2 of palmitoyl), 26.0 (β-CH_2 of palmitoyl), 30.2, 30.4, 30.5, 30.6, 30.8 (from γ- to μ-CH_2 of palmitoyl), 33.1 (ν-CH_2 of palmitoyl), 34.9 (α-CH_2 of palmitoyl), 40.1 and 40.2 (C-2′ A1 and A2), 66.0 (d, J_{COP} = 4.6 Hz, C-5′ A1), 66.2 (C-1 of glycerol), 66.5 (d, J_{COP} = 6.6 Hz, C-5′ A2), 67.7 (d, J_{COP} = 5.0 Hz, C-3 of glycerol), 69.6 (d, J_{CCOP} = 7.2 Hz, C-2 of glycerol), 72.8 (C-3′ A2), 77.6 (d, J_{COP} = 4.8 Hz, C-3′ A1), 85.2 and 85.4 (C-1′ A1 and A2), 86.6 (br. dd, C-4′ A1), 87.5 (d, J_{CCOP} = 8.5 Hz, C-4′ A2), 141.4 (C-8 A2), 142.5 (C-8 A1), 150.2 (C-4 A1 and A2), 153.5 (C-2 A1 and A2), 157.2 and 157.4 (C-6 A1 and A2), 175.4 (COO) ppm; C-5 not detectable. RESULTS AND DISCUSSION

Bearing in mind that mono[(2*R*)-2,3-dihydroxypropyl] esters of 5′-nucleotides (5′-GPNs) had been prepared from a phosphoramidite of [(4*S*)-2,2-dimethyl-1,3-dioxolan-4-yl]methanol (**1**) and the appropriately protected CPG-anchored nucleosides (*9*), we hypothesized that, in a similar way, a glycerophosphoryl residue could be joined to whichever oligodeoxynucleotide by simply using phosphoramidite **1** in a last coupling step after the solid-phase elongation of that given oligodeoxynucleotide. After detaching from CPG and removing of all protective groups, 5′-*O*-glycerophosphoryloligodeoxynucleotide (5′-GPOdN) would subsequently be acylated by Lipozyme (or other lipases) in organic solvent in the presence of suitable acyl donors. This idea was of course based on the assumption that substrates as large as 5′-GPOdNs could be recognized by the enzyme.

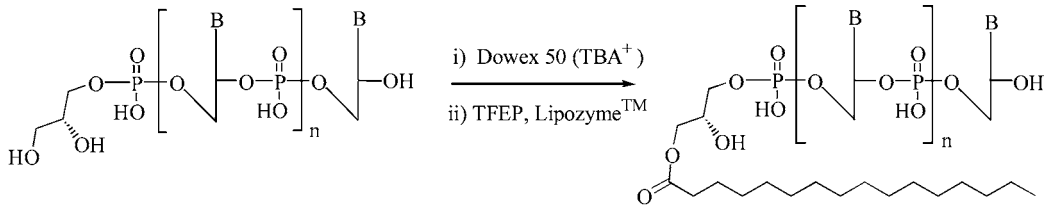
Synthesis of the Oligomeric Substrates. In accordance with the planned way, various 5′-GPOdNs were synthesized by automated DNA synthesizer, following the path reported in Scheme 1. First, adenine and thymine nucleotides only were employed to build up the 5′-GPOdNs, these being selected as a model of purine and pyrimidine nucleotide, respectively. While the nucleotide sequence of each oligomer was chosen regardless of any specific sense, all of them contained the adenine nucleotide at the 5′-end involved in the formation of the phosphodiester bond with the glycerol moiety. Thus, that molecular side of 5′-GPOdNs which would undergo enzyme recognition showed in any case a common structural motif. Taking into account that bulky substrates are not easily accommodated inside the active site of most enzymes, 5′-GPOdNs no longer than 6-mer were prepared as starting material.

After purification by HPLC, the synthesized 5′-GPOdNs (**2**−**6**) were characterized on the basis of their spectroscopic (NMR and HRMS) properties. The correct sequence of each of them was ascertained by ROESY or NOEDS experiments.

Later on, to give additional evidence of the method generality, 5′-GPd(GpA) (**7**) and 5′-GPd(TpA) (**8**) were also synthesized by the same route and successively underwent enzymatic acylation.

Enzymatic Acylation of 5′-GPOdNs. Enzymatic acylation of each 5′-GPOdN [as tetrabutylammonium (TBA) salt] was then carried out by use of *Rhizomucor miehei* lipase (immobilized, Lipozyme) in *tert*-butyl alcohol and in the presence of trifluoroethyl palmitate (TFEP), following the same experimental procedure previously reported for the acylation of glycerophosphoryl derivatives of nucleoside analogues (Scheme 2) (*10*).

Scheme 2. Synthesis of 5′-Glycerophosphoryloligodeoxynucleotides



2 - 8 **9 - 15**

B = Adenine, Guanine, Thymine

	n	5'-LyPOdN
9	1	5'-LyPd(ApA)
10	2	5'-LyPd(ApApT)
11	3	5'-LyPd(ApApApT)
12	4	5'-LyPd(ApApApApT)
13	5	5'-LyPd(ApTpApTpTpA)
14	1	5'-LyPd(GpA)
15	1	5'-LyPd(TpA)

At the end of the synthetic run, HPLC analyses of the crude reaction mixtures in each case revealed the presence of only one acylation product which was next isolated by semipreparative HPLC and characterized on the basis of its spectroscopic features. It is worth noting that, when parallel experiments were carried out under the same experimental conditions but in the absence of the enzyme, no acylation took place.

The NMR spectral data obtained for compounds **9** and **10** are reported in detail in Experimental Procedures. Unequivocal assignments of ^{1}H and ^{13}C resonances were supported by 1D (spin decouplings, NOEDS, DEPT or APT) and 2D ($^{1}H-^{1}H$ COSY, HSQC, ROESY) experiments, and by the analysis of $^{13}C-^{31}P$ coupling constants.

The NMR spectra showed the presence in both compounds of one palmitoyl residue and indicated its location. In particular, in the ^{13}C NMR spectra of **9** and **10** the C-1 and C-2 resonances of the glycerol moiety, compared with those of the pertinent 5′-GPOdNs, were downfield ($\Delta\delta = 1.4 \pm 0.1$ ppm) and upfield ($\Delta\delta = -3.7 \pm 0.1$ ppm) shifted, respectively. On account of the α and β effect of acylation, these data indicated that both the relevant 5′-GPOdNs **2** and **3** had undergone regioselective acylation at the primary hydroxyl group of their glycerol residue. In accordance, in the ^{1}H NMR spectra of **9** and **10**, 1-H_2 resonances of the glycerol residue were downfield ($\Delta\delta = 0.59 \pm 0.02$ ppm) shifted, in comparison with the relevant ones in the spectra of **2** and **3**. From these results, the structures of 5′-*O*-(1-*O*-palmitoyl-*sn*-glycero-3-phosphoryl)d(ApA) [5′-LyPd-(ApA)] and 5′-*O*-(1-*O*-palmitoyl-*sn*-glycero-3-phosphoryl)d-(ApApT) [5′-LyPd(ApApT)] were assigned to **9** and **10**, respectively. ESI-MS(−) spectra of these two 5′-*O*-lysophosphatidyloligodeoxynucleotides were in agreement with the proposed structures as well (see Experimental Procedures).

Once the structural features of the previous two acylated products had been outlined, the identification of 5′-LyPd-(ApApApT) (**11**), 5′-LyPd(ApApApApT) (**12**) and 5′-LyPd-(ApTpApTpTpA) (**13**), 5′-LyPd(GpA) (**14**) and 5′-LyPd(TpA) (**15**), was achieved by MS analysis only. On the other hand, this way was unavoidable for compound **13,** whose available amount was so small to make difficult NMR spectroscopic analysis.

ESI-MS(−) spectrum of **11** showed diagnostically important peaks at *m*/*z* 1572.8 $(M - H)^-$ and 786.2 $(M - 2H)^{2-}$. MALDI-MS(−) spectra of **12** and **13** gave peaks of diagnostic value at *m*/*z* 1885.58 $(M - H)^-$ and 1908.14 $(M - 2H + Na)^-$ for compound **12,** and at *m*/*z* 2180.96 $(M - H)^-$ and 2202.37 $(M - 2H + Na)^-$ for compound **13**. FAB-MS(−) spectra of **14** and **15** gave the relevant $(M - H)^-$ peaks at *m*/*z* 971.38 and 946.37.

Table 1. Lipase-Catalyzed Palmitoylation of Glycerophosphoryloligodeoxynucleotides

substrate	product	conversion[a] (%)
5′-GPdA	5′-LyPdA	98.0
5′-GPd(ApA)	9	31.3
5′-GPd(ApApT)	10	7.8
5′-GPd(ApApApT)	11	4.6
5′-GPd(ApApApApT)	12	1.7
5′-GPd(ApTpApTpTpA)	13	0.95
5′-GPd(GpA)	14	31.2
5′-GPd(TpA)	15	32.1
3′-GPd(ApA)	20	32.5

[a] After 26 days incubation in the experimental conditions reported under Experimental Procedures for the synthesis of 5′(3′)-LyPOdNs.

Table 1 reports the conversion values obtained after 26 days enzymatic palmitoylation of seven 5′-GPOdNs, in comparison with that found, under the same experimental conditions, for the palmitoylation of the mononucleotide 5′-GPdA.

These values were derived from HPLC analyses of single crude reaction mixtures at the fixed incubation time, assuming that the new formed 5′-LyPOdN had the same molar extinction coefficient of the relevant 5′-GPOdN.

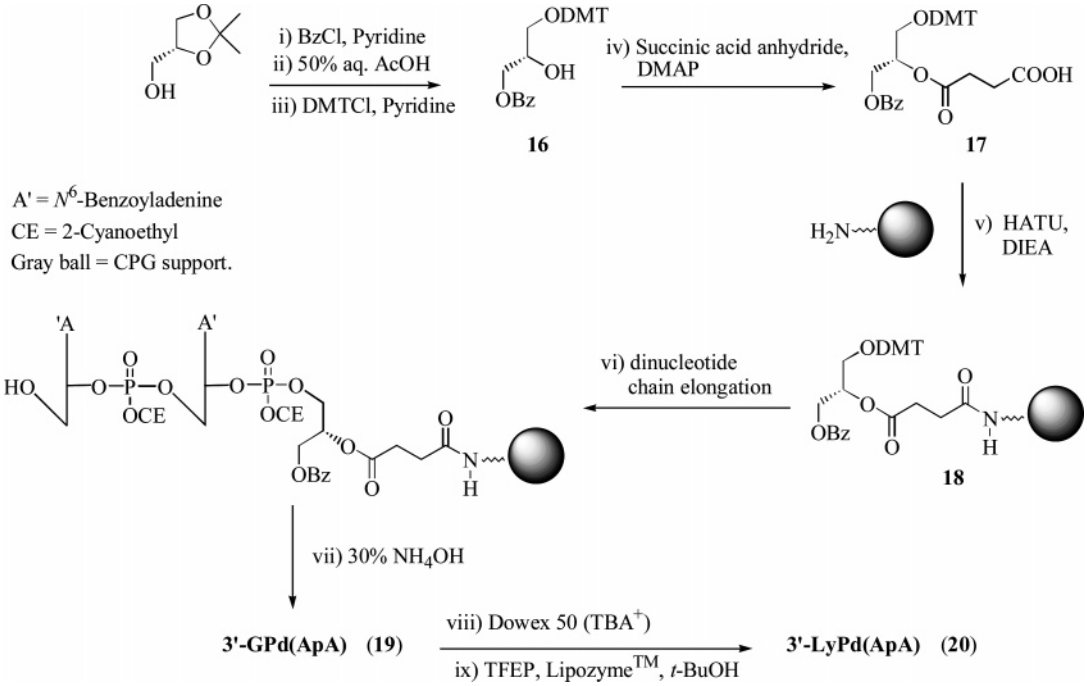
The results, as a whole, indicated that in each case the enzymatic step had actually yielded the desired LyPOdN, but showed also that the ability of Lipozyme to acylate 5′-GPOdNs had been dramatically affected by the molecular size of the utilized substrate. Suffice it to observe that the conversion value for enzymatic acylation of the dinucleotide 5′-GPd(ApA) was near one-third of that found for 5′-GPdA.

Aiming to understand if the position of the glycerol residue on the sugar moiety of GPOdNs could anyhow influence the enzymatic acylation behavior, 3′-GPd(ApA) (**19**) was synthesized, to subject it to subsequent palmitoylation by Lipozyme, in comparison with the relevant 5′-GPOdN (**2**).

To this purpose, the synthesis of **19** was achieved by carrying out two successive coupling steps of appropriately protected adenosine 3′-*O*-phosphoramidite, on a solid support consisting of a protected glycerol residue anchored to aminoalchil-CPG (**18**, Scheme 3).

Such a solid phase was prepared by coupling the succinic acid hemiester of a suitably protected glycerol (**17**) to aminoalchil-CPG, by applying the efficient HATU-DIEA in situ activation protocol commonly used (*13*) in solid-phase peptide

Scheme 3. Synthesis of 3′-Glycerophosphoryl- and 3′-Lysophosphatidyld(ApA)



synthesis. The primary alcoholic function of glycerol, involved in the subsequent formation of phosphodiester bond, was protected with the dimethoxytrityl group, which was removed following the first deblocking step of the solid-phase elongation of the dinucleotide.

Next treatment of **19** with Lipozyme and TFEP afforded the expected 3′-LyPd(ApA) (**20**), with a conversion value near to that observed following enzymatic palmitoylation of the 5′-counterpart (see Table 1), thus indicating that the position of the glycerol unit on the sugar moiety does not play a crucial role in determining the extent of the enzymatic acylation of GPOdNs.

It should be noted that oligonucleotides containing 3′-(*RS*)-glycerol moiety were previously synthesized by other authors *(14)* by a different route. Then, the synthesis of 3′-*O*-[(2*RS*)-glycerophosphoryl]d(ApA) followed by enantioselective enzymatic acylation of the *R*-isomer would be an elegant way to prepare 3′-LyPd(ApA) with the natural *R* configuration at the chiral center of the glycerol moiety. However, a preliminary attempt to enzymatically palmitoylate the test compound 3′-*O*-[(2*RS*)-glycerophosphoryl]dA gave a near equimolar mixture of two diastereomeric 3′-LyPdA. So, as Lypozyme does not show the desired selectivity, the synthetic run reported in Scheme 3 appears to be more appropriate.

To evaluate the possibility that lipases different from Lipozyme could be used to acylate 5′-GPOdNs, the enzymes reported in Table 2 were tested, in parallel experiments, for their ability to palmitoylate 5′-GPd(ApApApApT) (**5**).

Apart from Lipozyme, the tested lipases were nonimmobilized enzymes and a constant (total enzyme activity)/(substrate amount) ratio (E/S) was used in all the experiments. The parallel reference experiment with Lipozyme (*Rhizomucor miehei* lipase, immobilized on an ion-exchange resin) was carried out following the same experimental conditions previously set up for the preparation of LyPOdNs (see Experimental Procedures). Under these conditions, the E/S ratio was near 100 times lower than that fixed for the remaining part of experiments. Indeed, considering that the specific activity of Lipozyme was 2 or 3 orders of magnitude lower than that of the nonimmobilized enzymes, a considerable amount of this enzyme should have been used to reach the fixed E/S ratio. We abandoned this approach to avoid an undesired marked absorption of the substrate on the polymeric support of the enzyme.

Table 2. Acylation of 5′-GPd(ApApApApT) by Various Lipases

lipase source	specific enzyme activity (U/mg)	enzyme amount (mg)	conversion[a] (%)
Candida antarctica	3	10	0.5
Candida cylindracea	2	15	-
Pseudomonas cepacea	50	0.7	-
Pseudomonas fluorescens	40	0.8	1.5
hog pancreas	30	1	-
Rhizopus niveus	1.5	20	-
Rhizomucor miehei	1	30	-
Rhizomucor miehei immobilized, Lipozyme	3×10^{-2}	11	1.7

[a] Determined by HPLC, after 26 days incubation of single aliquots of 5′-GPd(ApApApApT) (TBA^+ form, 1.25 μmol) in the presence of TFEP (50 μmol) and the selected enzyme, in dried *t*BuOH (2 mL).

The above experiments showed that only lipases from *Pseudomonas fluorescens* and *Candida antarctica* were capable of acylating the pentameric substrate. The former giving better results than the latter, but both working at a lower extent than Lipozyme. Of course, the different behavior of the tested lipases with respect to Lipozyme comes out more stressed when considering that the latter worked with an activity/substrate ratio much lower than that fixed for the other enzymes.

From these results it was evident that the attempt to use some enzymes different from Lipozyme did not allow an effective improvement of the enzymatic step. Nevertheless, since a check of Lipozyme activity before and after a single reaction cycle did not show any significant variation, in those cases in which conversion values of the enzymatic step were low, it was possible to increase the target compound yield by properly recycling the enzyme and the unreacted substrate.

CONCLUSIONS

In this report the chemoenzymatic synthesis of lysophosphatidyl conjugates of short chain oligonucleotides, ranging from 2- to 4-mer, has been described. The same synthetic strategy has allowed us to obtain also, but in very small yield, lysophosphatidyl derivatives of 5- and 6-mer oligonucleotides.

It is worthy of note that, in the chemical step of the reported synthesis, the desired GPOdN is prepared making use of the phosphoramidite chemistry protocol commonly employed on DNA synthesizers. This, when required, would allow easy preparation of glycerophosphoryl derivatives of those oligonucleotide analogues cited in the literature for their antiviral properties. These could subsequently undergo enzymatic palmitoylation to give the relevant LyPOdN analogues.

Also, the newly synthesized LyPOdNs could be useful building blocks for the preparation of lipoconjugates of higher-mer oligonucleotides, possibly by chemical ligation. In fact, considering that all the LyPOdNs we prepared are water-soluble compounds, their template-directed chemical ligation (*15*, *16*) to selected 5′-P-oligonucleotide donors appears to be an interesting route for the preparation of lysophosphatidyl antisense oligonucleotides. Further work is in progress in this regard.

The exceptionally high affinity of biotin toward avidin and streptavidin is at the basis of (strept)avidin−biotin biotechnology, which has numerous applications in life sciences. Recent biotin developments for in vivo and in vitro acylation of selective targeted protein and intein-mediated site specific protein biotinylation require the free biotin carboxyl function to covalently bind with the targeted protein. However, recently this carboxylic function has been used to substitute biotin with numerous ligands and flags. In the present work, we propose the N-1′ labeling possibilities of biotin, keeping the valeric chain free. We describe liquid and solid-phase syntheses of functionalized biotin N-1′ derivatives. Although the N-1′ modification involves a two-log decrease in affinity, in vitro these molecules kept their high avidin affinity (around 10^{-12} M) and the in vivo acylation ability of new biotin derivatives.

INTRODUCTION

Biotin has been extensively used in the life sciences for many years, and renewed interest in this molecule has recurred with recent biological developments (*1*−*4*). In numerous applications, the carboxyl function of biotin has been chemically linked to the desired oligonucleotide, peptide, or fluorochrome, etc., and complexed with avidin and streptavidin for recognition. However, not all of these biotins modified on the carboxyl function at the end of its valeric chain allow covalent linkage with peptides. The initial challenge of the present work was to obtain a labeled biotin that could target a fusion between the desired protein with either the biotin carboxy carrier protein (BCCP) or the biotin linker peptide (BLP). However, nearly all of the chemical modifications of labeled biotin have involved this carboxyl function, which results in molecules that are not usable for our purposes. There are few reports of chemical modifications of commercial biotin on the N-1′ position (*5*, *6*). Using these studies as a reference, we developed derivatives of biotin that have been modified at N-1′ and bear active functions at the extremity of the N-1′ arm while keeping the carboxyl function at the end of its valeric chain free. A series of syntheses were first conducted in solution, using classical reaction procedures (Scheme 1). The last methyl deprotection of biotin appeared to be the rate-limiting step of the synthesis; moreover, in numerous cases this deprotection was not able to give the desired final product. To ensure good recovery, facile synthesis, and gentle deprotection of the product, in a second series of experiments biotin was linked to a solid phase (Scheme 2) to generate the bifunctional biotin derivatives.

Because lipid−protein interactions are of great interest for our group (*7*, *8*) the ligands chosen to make biotin derivatives were *cis*-9-octadecanoic acid (oleic acid), geranyl geraniol, and estradiol. Their in vitro affinities for avidin were evaluated and then the ability of the radioactive conjugated molecule oleic acid−biotin to penetrate into *Escherichia coli* and to link BCCP, and the fusion protein $LexA_{DB}$-BCCP, were assessed.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemical and biochemical reagents were purchased either from Sigma-Aldrich or Prolabo except for (9,10(n)-^{3}H) oleic acid (10 Ci/mmol), which was purchased from ICN. All reactions using nonaqueous solvents were carried out under a dry argon atmosphere. The progress of the reactions was monitored by analytical thin-layer chromatography on silica gel Merck 60F254. The TLC visualization was done by iodine, ninhydrin, or ammonium-cerium(IV) nitrate. Flash chromatography was performed on a Merck Kieselgel 60 device (230−400 mesh). Preparative TLC was carried out on silica gel Merck 60F254. Radioactive compounds were revealed by a Berthold ^{3}H radioactivity detector. ^{1}H NMR spectra were recorded on a Brucker AC-200 at 200 MHz or on a Brucker AC-400 at 400 MHz, and ^{13}C NMR spectra were recorded on a Brucker AC-200 at 50 MHz or on a Brucker AC-400 at 100 MHz, using tetramethylsilane as an internal standard. DCI and FAB mass spectra were obtained on a Nermag R10-10 machine. High-resolution FAB mass spectra were obtained by the Mass Spectrometry Service, CESAMO, Bordeaux. Elemental analyses were performed on a Carlo Erba 1106. The radioactivity in the solutions was counted with a Packard 2000CA scintillation counter in ReadySafe scintillation liquid (Beckman). A protein assay was done with a Biorad kit, using bovine serum albumin (BSA) as a standard. For bacterial culture, Luria broth (LB) was purchased from Gibco-BRL. Luminescence enhancement of the nitrocellulose filters (Protran BA83 0.25 mM; Schleicher & Schuell) was accomplished with an ECL kit (Amersham). Autoradiography was performed on Kodak XLS films developed on an Amersham Hyperprocessor.

[a] Reaction conditions: (a) HCl (3 M), acetone, reflux; (b) 2-chlorotrityl chloride resin, DIEA, and DMF at RT; (c) geranylgeranyl-*N*-acetyl cysteine plus HOAt, DIC, tributylphosphine, THF anhydrous at RT; (d) acetic acid, trifluoroethanol, CH_2Cl_2 at RT.

Chemicals. D-Biotin Methyl Ester (2). A mixture of D-biotin (**1**) (2.44 g, 10 mmol) and hydrochloric Amberlite resin (IR120, 2.6 g) in anhydrous methanol (75 mL) was heated to reflux for 7 h. The resin was filtered and washed with methanol. The combined organic solutions were concentrated under reduced pressure to obtain D-biotin methyl ester **2** as a white solid (2.05 g, 7.95 mmol, 79.5%). $R_f = 0.41$ (MeOH:$CHCl_3$ 5:95). ^{1}H NMR (200 MHz, DMSO, 25 °C, TMS) $\delta = 6.37$ (d, *J* (H, H) = 13.8 Hz, 2H; >NH), 4.31 (m, 1H; >CH−NH-), 4.14 (m, 1H; >CH−NH-), 3.59 (s, 3H; $COOCH_3$), 3.12 (m, 1H; >CH−S-), 2.63 (dd, *J* (H, H) = 5.0 Hz, 12.4 Hz, 1H; $-CH_2-$S), 2.58 (d, *J* (H, H) = 12.4 Hz, 1H; $-CH_2-$S), 2.30 (t, *J* (H, H) = 7.3 Hz, 2H; $-CH_2-COOCH_3$), 1.7−1.4 (m, 6H; -$(CH_2)_3-CH_2-COOCH_3$); ^{13}C NMR (50 MHz, DMSO, 25 °C) $\delta = 173.22$ ($-COOCH_3$), 162.66 (−HN−CO−NH-), 60.96 (>CH−NH-), 59.11 (>CH−NH-), 55.26 (>CH−S-), 51.11 ($-COOCH_3$), 39.43 ($-CH_2-$S-, $-CH_2-COOCH_3$), 33.01, 27.91, 24.40 (-$(CH_2)_3-CH_2-COOCH_3$).

***N*-1′-(4-Chloro-1-butoxycarbonyl)-D-biotin Methyl Ester (3).** A solution of (258 mg, 1 mmol) and 4-chlorobutyl chloroformate (2.46 mL, 18 mmol) in anhydrous chloroform (5 mL) was heated to reflux for 4 days. The chloroform was evaporated under reduced pressure, and the solution was diluted in a large volume of petroleum ether at 4 °C. The resulting precipitate was filtered and purified by flash chromatography (methanol:dichloromethane, 3: 97) to yield **3** as a yellow solid (351 mg, 0.895 mmol, 89.5%). $R_f = 0.33$ (MeOH:CH_2Cl_2 3:97). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) δ = 6.7 (s, 1H; >NH), 4.7 (m, 1H; >CH−N<), 4.24 (m, 3H; >CH−NH-, $-CH_2-O-CO-$), 3.63 (s, 3H; $-COOCH_3$), 3.57 (t, *J* (H, H) = 2.4 Hz, 2H; $-CH_2-$Cl), 3.3 (m, 1H; >CH−S-), 3.03 (m, 2H; $-CH_2-$S-), 2.31 (t, *J* (H, H) = 7.3 Hz, 2H; $-CH_2-COOCH_3$), 1.8−1.4 (m, 10H; -$(CH_2)_3-CH_2-COOCH_3$, Cl−CH_2-$(CH_2)_2-CH_2-O-CO-$); ^{13}C NMR (50 MHz, $CDCl_3$, 25 °C) $\delta = 173.98$ ($-COOCH_3$), 155.93 (>N−CO−NH-), 151.75 (−O−CO−N<), 65.77 ($-CH_2-O-CO-$), 62.75 (>CH−N<), 57.80 (>CH−NH-), 55.26 (>CH−S-), 51.11 ($-COOCH_3$), 44.52 ($-CH_2-$Cl), 38.74 ($-CH_2-$S-), 33.57 ($-CH_2-COOCH_3$), 29.14, 28.29, 28.05, 26.10, 24.63 (-$(CH_2)_3-CH_2-COOCH_3$, Cl−CH_2-$(CH_2)_2-CH_2-O-CO-$); MS (DCI/NH_3, CH_2Cl_2): *m*/*z*: 393 [$M^+ - H$]; 410 [$M^+ - NH_4$]; $C_{16}H_{25}ClN_2O_5S$ (392.9): calculated C 48.91, H 6.41, N 7.13, O 20.36; found C 48.97, H 6.46, N 7.12, O 20.36.

***N*-1′-(4-Azido-1-butoxycarbonyl)-D-biotin Methyl Ester (4).** A solution of (392 mg, 1 mmol), sodium iodide (17 mg, 0.1 mmol), and sodium azide (325 mg, 5 mmol) in acetone:

water (4:1; 10 mL) was heated to reflux for 4 days. The acetone was evaporated under reduced pressure, and the resulting aqueous solution extracted three times with dichloromethane. The organic phase was dried (Na_2SO_4) and concentrated under reduced pressure. Purification by flash chromatography (methanol:dichloromethane, 4:96) yielded a yellow solid (379 mg, 0.95 mmol, 95%). R_f = 0.33 (MeOH:CH_2Cl_2 3:97). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) δ = 7.26 (s, 1H; >NH), 4.80 (m, 1H; >CH−N<), 4.24 (m, 3H; >CH−NH-, $-CH_2-O-CO$-), 3.63 (s, 3H; $-COOCH_3$), 3.32 (t, *J* (H, H) = 6.4 Hz, 2H; $-CH_2-N_3$), 3.32 (m, 1H; >CH−S-), 3.02 (m, 2H; $-CH_2-S$-), 2.31 (t, *J* (H, H) = 7.3 Hz, 2H; $-CH_2-COOCH_3$), 1.8−1.4 (m, 10H; -$(CH_2)_3-CH_2-COOCH_3$, $N_3-CH_2-(CH_2)_2-CH_2-O-CO$-); ^{13}C NMR (50 MHz, CD_3OD, 25 °C) δ = 175.81 ($-COOCH_3$), 157.96 (>N−CO−NH-), 153.10 ($-O-CO-N<$), 66.98 ($-CH_2-O-CO$-), 64.20 (>CH−N<), 59.36 (>CH−NH-), 56.67 (>CH−S-), 52.21 ($-COOCH_3$), 52.14 ($-CH_2-N_3$), 39.71 ($-CH_2-S$-), 34.63 ($-CH_2-COOCH_3$), 27.14, 29.76, 29.45, 26.65, 25.95 (-$(CH_2)_3-CH_2-COOCH_3$, $N_3-CH_2-(CH_2)_2-CH_2-O-CO$-); MS (DCI/$NH_3$, CH_2Cl_2) *m*/*z* 400 [M^+ − H], 417 [M^+ − NH_4]; $C_{16}H_{25}N_5O_5S$ (399.5): calculated C 48.11, H 6.31, N 17.53, O 20.03; found C 48.03, H 6.49, N, 17.29, O 20.02.

Anhydrous dimethylformamide (920 μL) was added, and the mixture was stirred at room temperature for 5 days. The dimethylformamide was evaporated under reduced pressure, and the residue was dissolved in dichloromethane (100 μL). The solution was purified by two successive preparative TLC runs (methanol 5%, dichloromethane 95%), to yield **^{3}H6** (34.8 μCi). The identity of the compound was checked by comigration with **6** on TLC. R_f = 0.55 (MeOH:CH_2Cl_2 8:92, ^{3}H radioactivity detection).

***N*-1′-(4-(9,10(n)-^{3}H)-Oleylamido-1-butoxycarbonyl)-D-biotin (^{3}H7).** Acidic hydrolysis. We assumed that the tritiated product had the same specific activity as the initial tritiated oleic acid (10 Ci/mmol).

Solid-Phase Synthesis. *N*-1′-(4-Azido-1-butoxycarbonyl)-D-biotin (4b). To a solution of **4** (399 mg, 1 mmol) dissolved in acetone (4 mL) was added 2 mL of HCl (3 M), and the solution was stirred for 7 h at reflux. The acetone was evaporated off and the resulting powder dissolved and purified by a preparative TLC run (MeOH:CH_2Cl_2, 5:95); 270 mg of pure product was obtained (recovery = 70%). R_f = 0.39 (MeOH: CH_2Cl_2, 5: 95). ^{1}H NMR (200 MHz, CD_3OD, 25 °C, TMS) δ = 4.90 (m, 1H; >CH−N<), 4.25 (m, 3H; >CH−NH-, $-CH_2-$O−CO-), 3.36(t, *J* (H−H) = 7.3 Hz, 2H; $-CH_2-$COOH), 3.36 (m, 1H; >CH−S-), 3.05 (m, 2H; $-CH_2-$S-), 2.32 (t, J (H, H) =7.3 Hz, 2H; $-CH_2-$COOH), 1.72−1.47 (m, 10H; -$(CH2)_3-$ CH_2-COOH, $N_3-CH_2-(CH_2)_2-CH_2-$O−CO-).

Anchorage of 4b on Styrene-DVB Resin (S-DVB). A solution of **4b** (1.2 equiv/ S-DVB) in 2.5 mL of DMF was added, with diisopropylethylamine (DIEA) (4 equiv/**4b**), to S-DVP (261 mg: 0.261 mmol, in 2 mL of CH_2Cl_2), and the mixture was stirred for 18 h. The polymer was then filtered and washed three times with a solution of CH_2Cl_2:MeOH:DIEA (17:2:1) and then twice with 2.5 mL of DMF and twice with 2.5 mL of CH_2Cl_2. The polymer was then dried overnight under vacuum in the presence of P_2O_5.

Coupling of Geranyl-geranyl *N*-Acetylcysteine to *N*-1′-(4-Azido-1-butoxycarbonyl)-D-biotin−S-DVB (N3−S-DVB). N3−S-DVB (62.1 mg, 0.56 mmol/g) was incubated in anhydrous CH_2Cl_2 for 15 min and then washed three times with 1 mL of anhydrous THF and filtered before being evaporated to dryness. The carboxyl function of geranyl-geranyl *N*-acetylcysteine (4 equiv/N3−S-DVB) was activated at 0 °C in the presence of 1-hydroxy-7azabenzotriazole (HOAt) (4 equiv/N3−S-DVB) in anhydrous THF (1 mL); 4 equiv of diisopropylcarbodiimine (DIC) was added, and the mixture was stirred at 0 °C for 30 min. At that time, the mixture was added to N3−S-DVB, 3 equiv/N3−S-DVB of tributylphosphine was added, and the mixture was stirred at room temperature for 18 h. The polymer was washed with DMF and with 3 × 1 mL of CH_2Cl_2 and then dried under vacuum in the presence of P_2O_5.

***N*-1′-(4-(Geranyl-geranyl-*N*-acetylcysteine)-1-butoxycarbonyl)-D-biotin (8).** Acidic cleavage of the polymer was performed in CH_2Cl_2 by addition of acetic acid and trifluoroethanol (6:2:2) stirred at room temperature for 7 h. The polymer was filtered and washed three times with 1 mL of the cleavage solution. The flow through was mixed with 80 mL of hexane and evaporated. TLC purification yielded a yellow oil with a 54% recovery MM = 777.092 g·mol^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS) δ = 4.65 (m, 1H; >CH−N<), 4.23 (m, 3H; >CH−NH-, $-CH_2-$O−CO-), 3.15 (m, 1H; >CH−S-), 2.95 (m, 4H; $-CH_2-$S-, $-CH_2-$NH), 2.16 (t, *J* (H, H) = 7.4 Hz, 2H; $-CH_2-$COOH), 1.70−1.55 (m, 10H; -$(CH_2)_3-CH_2-$ $COOCH_3$, $-NH-CH_2-(CH_2)_2-CH_2-$O−CO-), 3.03 (m, 1H; >CH−NH−$COOCH_3$), 1.98 (s, 3H; $-CH_3-$CO−NH-), 2.80 (m, 2H; >CH−CH_2-CO-), 3.15 (d, 2H; >CH−CH_2-S-), 5.10 (m, 4H; >CH−C-), 1.59 (s, 15H; CH_3-C<), 2.05 (m, 12H; >C−$(CH_2)_2-$CH<); ^{13}C NMR (400 MHz, $CDCl_3$, 25 °C) δ = 171.541 (−COOH), 174.157 (>N−CO−NH-), 170.256 (CH3−CO−NH-), 169.590 (−NH−CO−CH<), 139.568, 135.456, 134.257, 132.894 (>C<), 151.236 (−O−CO−N<), 119.568 (>CH−C<), 67.125 ($-CH_2-$O−CO-), 53.546 (>CH−N<), 51.699 (>CH−NH-), 52.527 (>CH−S-), 52.807 (−$COOCH_3$), 39.624 ($-CH_2-$NH), 38.709 ($-CH_2-$S-), 35.535 ($-CH_2-$ $COOCH_3$), 20−40 (-$(CH_2)_3-CH_2-COOCH_3$, NH_2-CH_2- $(CH_2)_2-CH_2-$O−CO-, >C−$(CH_2)_2-$CH<, >C−CH_2-S-, >C− CH_2-S−CH_2-), 10−25 (CH_3-C<, CH_3-CO−NH-); MS (DCI/NH_3) *m*/*z* 777 [M^+ − H].

Biochemicals. *Strains*. The bacterial strains used were *E. coli* DH5α for subcloning and SU 202 (9) for lexA-BCCP expression study.

Plasmids. All the biological tools were described previously by Dmitrova et al. (*9*). pMS604 and pDP804 were generous gifts of Schnarr group (Strasbourg, France) and were used for *E. coli* studies. pMS604-$LexA_{DB}$-BCCP was constructed by insertion of the BCCP gene, generated from PCR fragments of *E. coli* genomic DNA, into BstEII-XhoI restriction sites of pMS604 (*9*). The oligonucleotides used for PCR were 5′AAA-CGGGTGACCGCGCGCGATATTCGTAAGATTAAAAA-AC3′ and 3′GACCAGCAGT AGCTCATTGAGCTCTAGAAG AAA 5′.

Fluorescence in Vitro Binding Studies to Avidin. Avidin (Sigma; A9275) was coated on C8 White Maxisorp Fluoro-NUNC plates (NUNC; 437591) at 5 μg/mL at RT for 18 h. The plates were then washed and saturated with PBS in the presence of 0.5% BSA and stored at 4 °C for less than 1 week before use. Fluorescent biotin, 50 nM (biotin-4-fluorescein; Sigma B-9431), was loaded into the plates in the presence or absence of increasing concentrations of various N1′ biotin derivatives (10^{-8}−10^{-4} M). After 3 h incubation at RT, the plates were washed three times with PBS, and the remaining fluorescence was determined with a fluorometer (Wallac; Flite Fluorometer at excitation 485 nm and emission 535 nm).

In Vivo Binding of the Oleic Acid−Biotin Molecule to BCCP. Transformed bacteria were grown overnight at 37 °C in LB (3 mL) that contained tetracyclin (50 μg/mL). The solution was diluted to $OD_{600\ nm}$ = 0.05 and grown at 37 °C in the same culture medium until $OD_{600\ nm}$ = 0.4 (start of exponential growth). Synthesis of the $LexA_{DLA}$-BCCP fusion protein was then induced by the addition of 1 mM IPTG until the OD reached approximately 0.8 (end of exponential growth). At the same time as IPTG, 0.1 nM of [^{3}H]-oleic acid−biotin (10 Ci/mmol) was added.

Extraction of Proteins. *E. coli*. The bacterial solution (10 mL) ($OD_{600\ nm}$ = 0.7 to 1) was centrifuged for 10 min at 4000*g*. The supernatant was eliminated, and the bacterial pellet was washed twice with PBS (1 mL each). The pellet was then resuspended in Tris-HCl buffer (pH 7.8), 2% SDS, and 0.1 M DTT (100 μL). The solution was incubated for 10 min at 100 °C and then sonicated four times for 30 s each. The solution was centrifuged (16000*g*) at 4 °C for 15 min. The supernatant contained the extracted proteins.

Electrophoresis and Immunodetection. The proteins were separated on a 12.5% acrylamide/bisacrylamide gel, and 100 μg amounts of proteins were run on the gel. The proteins were transferred onto a nitrocellulose filter, and immunodetection was achieved using the monoclonal anti-biotin antibody. Visualization was enabled by an enhanced chemiluminescence kit (Amersham).

Radioactivity Distribution in the Cells. The nitrocellulose filter lanes corresponding to the [^{3}H]-oleic acid−biotin conditions (Figure 2) were cut into 4-mm strips. The radioactivity present on each strip was quantified with a scintillation counter Packard 2000CA in ReadySafe scintillation liquid (Beckman).

RESULTS

Synthesis of N1′-Biotin Derivatives (Scheme 1). Our objective was to modify biotin on its N-1′ end with an arm that would facilitate subsequent coupling of a large variety of molecules.The different steps of the synthesis are shown in Scheme 1. Protection of the carboxyl group of biotin was carried out by the usual methods (*6*). From the biotin methyl ester (**2**), the N-1′ modification was adapted to our purposes: 4-chlorobutyl chloroformate was condensed on N-1′, to give *N*-1′-(4-chloro-1-butoxycarbonyl)-D-biotin methyl ester (**3**) with a yield close to 90%. The drastic reaction conditions (4 days at reflux with 18 equiv of 4-chlorobutyl chloroformate) are required because of the lack of reactivity of the N-1′ function of biotin.

Formation of an azido group from the chlorides (**3**) was carried out with sodium azide in the presence of potassium iodide. This step was performed by maintaining in reflux a solution of **3** and sodium azide in DMF. *N*-1′-(4-Azido-1-butoxycarbonyl)-D-biotin methyl ester (**4**) was obtained with a yield of 90%. This azide can be kept in the dark and −20 °C for several months without any degradation.

Catalytic hydrogenation of **4** was carried out in ethanol, in the presence of Pd/C. After 4 h under a H_2 atmosphere, the solution was filtered and the Pd/C washed with ethanol. The filtrate was concentrated under reduce pressure to afford **5** as yellow oil (yield = 75%).

Coupling of Oleic Acid to Biotin. As we have reported elsewhere (*7*), oleic acid could be involved in the mechanism of action of antiestrogen; it has been implicated in various diseases, and a commercially radioactive form is available. Oleic acid was therefore chosen to improve our biological system. The coupling reaction was achieved using a classical method of carboxylic acid activation using the BOP reagent (benzotriazolyl-*N*-oxytris(dimethylamino)phosphonium hexafluorophosphate). *N*-1′-(4-Oleylamido-1-butoxycarbonyl)-D-biotin methyl ester (**6**) was then obtained with a yield of 54%.

The final step of the synthesis consisted of the deprotection of the methyl ester of **6** (R = Me), to regenerate the free carboxyl group of biotin (R = OH). This involved acid hydrolysis, in which a solution of **6** and H_2SO_4 in acetonitrile/water was heated for 48 h, to produce *N*-1′-(4-oleylamido-1-butoxycarbonyl)-D-biotin (oleic acid−biotin **7**) with a yield of 47%. It should be noted that basic hydrolysis of **6** was not considered because of the degradation of the carbamate group that would result. The same procedure was done with tritiated oleic acid; however, our tools were not suited to working with very small quantities of product, and losses were high, leading to a final recovery of around 1%.

Although this methodology worked with oleic acid, it did not work in numerous other syntheses namely estradiol and geranyl-geraniol. It appeared that the difficulty in acheiving the last methyl deprotection was a limiting step.

Solid-Phase Synthesis (Scheme 2). To circumvent these problems, methylbiotin was hydrolyzed with 3 M HCl at the N-1′-(4-azido-1-butoxycarbonyl)-D-biotin methyl ester (**4**) step. Then, the biotin carboxyl group (1.2eq/Sresin) was linked to a styrene-DVB resin (2-chlorotrityl chloride resin) in methyldichloride in the presence of diisopropylethylamine (4 eq). After 18 h of shaking, 70% of the **4b** was bound to the resin.

Coupling of Geranyl-geranyl-*N*-acetylcysteine to Biotin. Geranyl-geranyl-*N*-acetylcysteine was synthesized as described elsewhere (*8*). A modified Staudinger (*10*) reaction allowed, in the presence of 1-hydroxy-7-azabenzotriazole plus diisopropylcarbodiimine and tributylphosphine, a direct linkage of the carboxyl function of cysteine, giving an amide link between biotin and the geranyl-geranyl-*N*-acetylcysteine. *N*-1′-(4-(Geranyl-geranyl-*N*-acetylcysteine)-1-butoxycarbonyl)-D-biotin (**8**) was then obtained after cleavage from the resin in acetic acid, trifluorethanol, and methylene dichloride; the global recovery was 54%.

The solid-phase synthesis strategy allowed the obtention of *N*-1′-(4-(17β-estradiol-6-one 6-(*O*-amidomethyloxime))-1-butoxycarbonyl)-D-biotin which, in our hands, could not be obtained with other methodologies (data not shown).

Avidin Affinities. The affinities of N-1′ biotin derivatives were determined by competition with fluorescent biotin on coated avidin plates. If biotin appeared, as shown in Figure 1, the most efficient ligand to compete with fluorescent biotin on avidin binding, N-1′-(4-azido-1-butoxycarbonyl)-D-biotin (N3-biotin), competes with fluorescent biotin at a 1.5-log difference with regard to biotin. *N*-1′-(4-Oleylamido-1-butoxycarbonyl)-D-biotin (oleic-biotin, **7**) and *N*-1′-(4-(Geranyl-geranyl-*N*-acetyl cystein)-1-butoxycarbonyl)-D-biotin (GG-biotin, **8**) displaced fluorescent biotin with a 2-log difference with regard to biotin. Although a strong loss of affinity for avidin is induced by the N-1′ modification of biotin, and assuming that biotin's avidin affinity is around 10^{-14} M, the newly synthesized derivatives would keep sufficient affinities (around 10^{-12} M) to be recognized by avidin. The same results were obtained with streptavidin (data not shown).

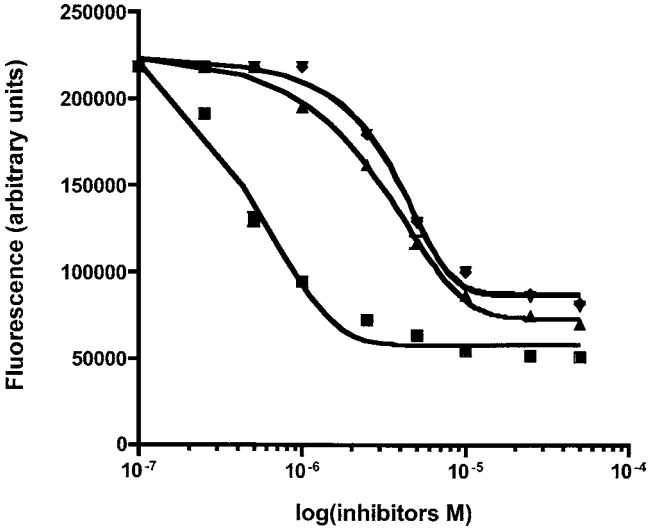

Figure 1. Relative binding affinity to avidin. Competition of biotin derivatives with fluorescent biotin (FB) on avidin-coated 96-well plate. Fluorescent binding saturation was obtained with FB = 0.2 μM. Competition was performed with a constant concentration of 50 nM of FB (100% relative fluorescence) in the presence of increasing concentrations of biotin (■), N3-B (▲), oleic-B (◆), GG-B (▼).

Study of BCCP Labeling by Oleic Acid−Biotin Molecules. Oleic Acid−Biotin and [^{3}H]-Oleic Acid−Biotin Were Used for the Studies of Binding to BCCP in *E. coli*. The system of in vivo detection of small molecule−protein interactions which used the LexA-based genetic system for monitoring protein−protein interaction has been described by Dmitrova (*9*). The gene coding $LexA_{DB}$-BCCP was under the control of an IPTG (isopropyl D-thiogalactopyranoside)-inducible promoter, allowing its overexpression with a theoretical 26-kDa molecular mass, whereas endogenous BCCP is a 16.7-kDa protein. The construction was used to check the ability of the biotin derivatives to penetrate and to bind in vivo to the $LexA_{DB}$-BCCP fused protein.

The proteins were extracted from the cells, and the results of immunoelectrophoresis with an anti-biotin antibody revealed, as expected, two biotinylated proteins (Figure 2, left, lanes 1 and 2). The first, present both with and without IPTG, exhibited a molecular mass of about 22 kDa. This corresponds to endogenous BCCP, which has been reported to possess atypical migration properties on SDS−PAGE: although its gene codes a 16.7-kDa protein, it behaves like a 22.5-kDa protein (*11*). The second protein detected with the anti-biotin antibody, which was weakly visible without treatment with IPTG, was clearly detected after treatment with IPTG and had an apparent molecular mass of 31 kDa. It was identified as the fusion protein $LexA_{DB}$-BCCP. Given that this protein exhibits the same atypical migration properties as BCCP, the chimeric protein $LexA_{DB}$-BCCP is biotinylated in vivo. Moreover, the mutated (−35 lys/gly) $LexA_{DB}$-BCCP protein, which was unable to link biotin, was not revealed by anti-biotin antibody (data not shown). The presence of a weak band at the $LexA_{DB}$-BCCP position, without induction with IPTG, is probably due to a slight leak of promoter. The addition of the oleic acid−biotin derivative to the culture medium gave an unchanged Western blot pattern

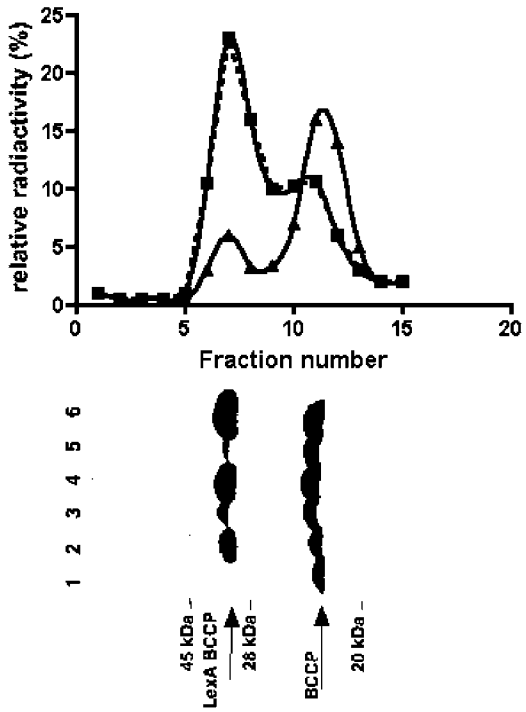

Figure 2. Western blots and radioactivity pattern in *E. coli*. Transformed bacteria were grown in selective medium (containing tetracyclin 50 μg/mL). When their concentrations reached OD = 0.4, they were divided in two parts, one grown in the initial conditions (lanes 1, 3, and 5) and the second submitted to IPTG 1 mM (lanes 2, 4, and 6) until OD = 0.8. Proteins were extracted and submitted to immunoelectrophoresis. Western blots used anti-biotin antibody: culture medium did not contain (lanes 1, 3, and 5) or did contain IPTG (lanes 2, 4, and 6). Oleic-biotin (10 μM) was added in lanes 3 and 4, and [^{3}H]-oleic-biotin (0.1 nM) was added in lanes 5 and 6. After Western blots, lanes 5 and 6 of the nitrocellulose filter were cut into 4-mm strips and counted for tritium activity. The percentage of radioactivity measured for each strip of nitrocellulose versus total radioactivity present in the lane is shown in Figure 2B, lane 5 (solid line) and lane 6 (dotted line).

(Figure 2, left, lane 3 in the absence and lane 4 in the presence of IPTG). When we incubated cells overexpressing $LexA_{DB}$-BCCP with [^{3}H]-oleic acid−biotin, two bands corresponding to endogenous BCCP and $LexA_{DB}$-BCCP were revealed by the anti-biotin antibody (Figure 2, left, lanes 5 and 6), and they fixed the radioactivity (Figure 2, Right). This observation indicates that the compound is able to penetrate *E. coli* and to be covalently linked to BCCP and chimeric lexA-BCCP.

CONCLUSION

Although the avidin−biotin interaction has numerous life-science applications, in recent years, various reports have increased its sphere of operations in cell biology. However, these new biotechnologies need the carboxyl function of biotin to be free, impairing the use of commercially available labeled biotin derivatives. The aim of the present work was, first, to synthesize a labeled biotin that would be able to be used in the new developments of the (strept)avidin−biotin interaction (*1*−*3*), keeping the carboxyl function of biotin free. We have described the synthesis of biotin N-1′ derivatives that allow the coupling of most molecules of interest. Compound **4**, a derivative of biotin bearing an azide group, is stable for several months at −20 °C. It was linked to a styrene-DVB polymer, allowing, with a modified Staudinger reaction, the solid-phase coupling of numerous molecules such as geranyl-geranyl-*N*-acetylcysteine. Estradiol and fluorescein have also been successfully linked (data not shown). Although these derivatives have lost a 2-log affinity for (strept)avidin, they are still able to be used in biotin−avidin life-science applications. We show that, when linked to the N-1′ of biotin, lipids such as oleic acid or geranyl-geranyl-*N*-acetylcysteine can be carried into bacteria; moreover, they are able to covalently bind BCCP chimeras in vivo. This work is the first step toward the use of bifunctional biotin as a small molecule able to tag protein or to control gene expression.

ACKNOWLEDGMENT

Synthesis of Immunoisolation Barriers That Provide Localized Immunosuppression for Encapsulated Pancreatic Islets

Charles Y. Cheung and Kristi S. Anseth*

Department of Chemical and Biological Engineering and the Howard Hughes Medical Institute, University of Colorado, Campus Box 424, Boulder, Colorado 80309-0424. Received January 31, 2006; Revised Manuscript Received April 14, 2006

Pancreatic islet encapsulation into synthetic, passive material matrixes can provide protection for transplanted islets from destruction via cell-contacted mediated interactions with autoreactive immune cells for treatment of Type I diabetes mellitus. However, one of the fundamental deficiencies with current encapsulation technology is that passive material barriers cannot protect islets from exposure to cytokines and other small, diffusible cytotoxic molecules produced by activated immune cells, subsequently leading to β-cell destruction. Preparation of material matrixes that can actively provide localized immunosuppression of autoreactive immune cells may prolong the viability, and hence function, of encapsulated islet grafts. We have demonstrated the ability to conjugate apoptosis-inducing anti-Fas monoclonal antibodies (MAbs) to the surfaces of poly(ethylene glycol)-modified hydrogels, providing a surface that actively attempts to locally down-regulate the autoimmune response by destroying autoreactive T cells against pancreatic islet cells. We have conjugated anti-Fas MAbs to a high degree to the surface of these hydrogels, with retention of anti-Fas recognition of the Fas antigen as shown by ELISA testing. Apoptosis induction of Fas-sensitive Jurkat T cells was enhanced in the presence of anti-Fas conjugated hydrogels. In addition, this apoptosis induction was specific to anti-Fas MAbs, with no apoptosis induction with control antibodies or with Fas-insensitive T cells. These experiments promote the concept that surface-conjugated hydrogel constructs can provide localized immunosuppression for encapsulated grafted tissue.

INTRODUCTION

Pancreatic islet transplantation represents an attractive treatment option for Type I diabetes mellitus but requires lifelong systemic immunosuppressive therapies to be successful. Encapsulation of islets within a cell impermeant polymer matrix provides a passive physical barrier that allows for small molecule diffusion through the barrier but prevents T-cell infiltration and cell contact-mediated destruction of grafted islets. Most of the current research has focused on forming polyionic complexes using sodium alginate mixed with different polycationic compounds to form polymeric barriers for immunoisolation of islets (*1*). The first and most extensively investigated microencapsulation system of individual islets was with a polyelectrolyte complex of alginate and polylysine (*2*). Over the past 20 years, this system has been continually optimized and has seen limited success in a number of animal models. Islets encapsulated in alginate matrixes have survived in vivo for a significant duration of time while maintaining euglycemia, up to 6 months (*3*), but biocompatibility issues with these types of matrixes still persist, especially with the choice of polycation used to form these membrane barriers (*4*).

Poly(ethylene glycol) (PEG) represents an alternative biomaterial that holds potential promise for encapsulation of pancreatic islets. PEG is a biocompatible polymer that has gained FDA approved when incorporated into different drug formulations (*5*). Cruise et al. microencapsulated islets by photopolymerizing PEG diacrylate (PEGDA) to form their passive membrane barriers (*6*). Islets encapsulated in PEGDA were able to maintain normoglycemia in streptozotocin-induced mice for up to 4 months (*7*). Investigations into the biocompatibility of PEG has shown that in vitro PEG itself does not activate immune cells, such as splenetic lymphocytes and macrophages; however, PEG cannot actively protect islets from cytotoxic molecules produced by preactivated immune cells (*8*). This example illustrates one of the fundamental deficiencies with current encapsulation technology, that cytokines and other effector molecules produced by immune cells can still diffuse through these passive barrier matrixes to inactivate or destroy transplanted β-cells within these islets (*9*−*11*).

Encapsulation of grafted islets with passive materials may prevent destruction of β-cells initiated by cell−cell contact with autoreactive T cells; however, such passive barriers cannot protect islets from exposure to cytokines and other effector molecules, such as IL-1, produced by activated immune cells that can subsequently lead to β-cell destruction (*9, 12*). Preparing encapsulation matrixes that can actively suppress the autoimmune response will therefore be beneficial in prolonging the survivability and function of islet grafts. One method of activating these polymeric barriers is to conjugate monoclonal antibodies to the surface of these hydrogel constructs that can actively induce destruction of T cells, thereby providing localized immunosuppression for transplanted tissue grafts.

EXPERIMENTAL PROCEDURES

Preparation and Characterization of Mouse Anti-Human IgG Conjugated Hydrogels. Poly(ethylene glycol diacrylate) (PEGDA, MW = 4600 g/mol) was polymerized with *N*-hydroxysuccinimide-PEG-acrylate (NPA, MW = 3400 g/mol) by UV-initiated photopolymerization to form PEGDA-*co*-NPA hydrogels with PEGDA-to-NPA ratios ranging from 95/5 to 50/50 (wt) using a 0.05% (wt) UV photoinitiator, 1-[4-(2-hydroxyethoxy)phenyl]-2-hydroxy-2-methyl-1-propan-1-one (I2959, Ciba Geigy, Newport, DE). Hydrogel constituents were dissolved in 0.15 M sodium phosphate buffer, pH 6.5, and hydrogels were prepared by photopolymerization for 15 min at 365 nm. Mouse anti-human IgG (MAH IgG, Fitzgerald Industries International, Concord, MA) was then conjugated to these

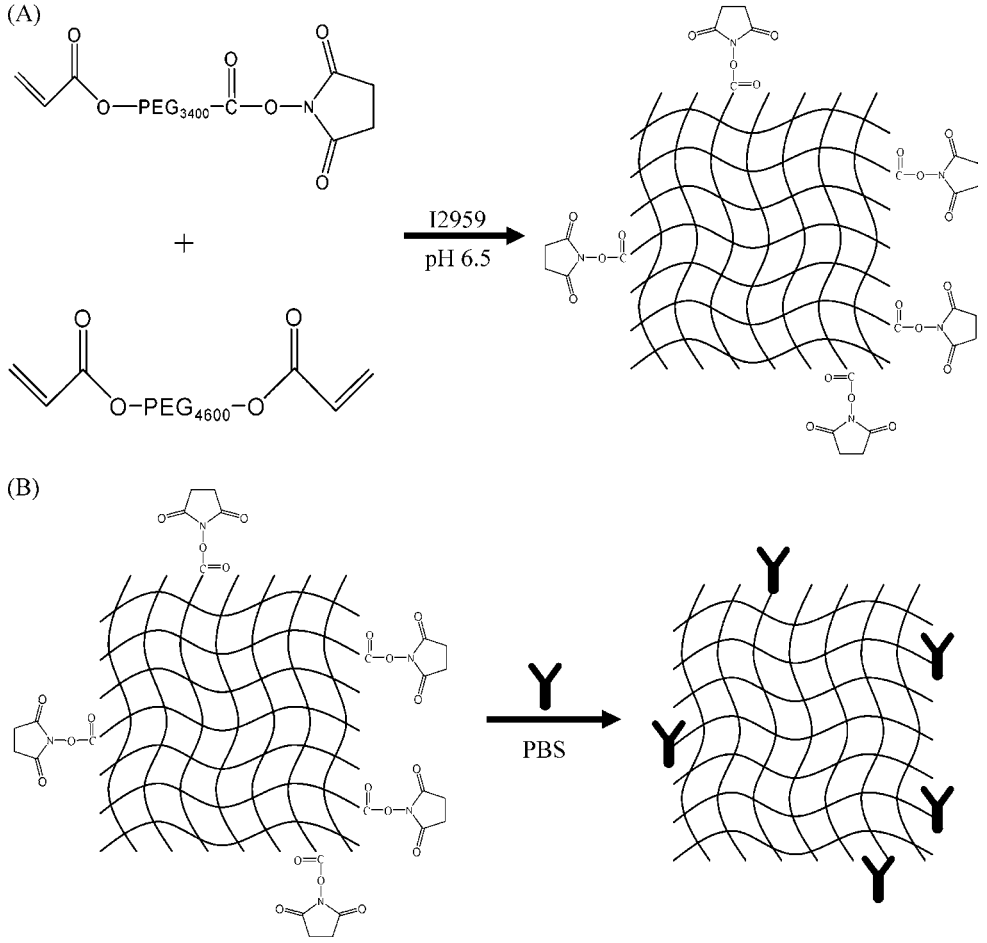

Figure 1. (A) Schematic representation of photopolymerization of PEG_{4600} diacrylate and NPA, forming hydrogel networks with pendant NHS moieties on the hydrogel surface, and (B) conjugation of MAH IgG MAbs to the surface of these hydrogels.

hydrogels at concentrations ranging from 0.05 to 1 mg/mL for 1 h in PBS. Hydrogels were then incubated with 50 mM glycine in PBS to quench the reactivity of any unreacted NHS groups remaining in the gels.

The level of MAH IgG conjugated to the surface of the hydrogels was assessed by a modified indirect ELISA using goat anti-mouse horseradish peroxidase (GAM HRP) (Jackson Immunoresearch, West Grove, PA) to detect surface-conjugated MAH IgG. A modified sandwich ELISA was prepared to determine the extent to which MAH IgG retained the ability to recognize its antigen, human IgG, after conjugation. 75/25 or 50/50 PEGDA-*co*-NPA hydrogels conjugated with MAH IgG were exposed to human IgG at concentrations ranging from 0 to 50ng/mL, followed by incubation with goat anti-human HRP. Hydrogels in both assays were incubated with Ultra-TMB (Pierce Biotechnology, Rockford, IL), and quantitative absorbance measurements were taken at 450 nm.

Immunostaining and Cryosectioning of Hydrogels. 75/25 PEGDA-*co*-NPA hydrogels were polymerized and conjugated with 0−0.5 mg/mL MAH IgG, as described in the previous section. Hydrogels were then soaked in Cryo-Gel (Instrumedics, Hackensack, NJ), snap-frozen in liquid N_2, and sectioned into 50 μm sections with a Leica CM 1850 cryostat (Leica, Bannockburn, IL) and placed onto glass slides. The sections were then soaked three times in PBS for 5 min and blocked with 1% BSA in PBS for 1 h. After an additional PBS wash, the sections were then immunostained with Alexa 488-conjugated goat anti-mouse $F(ab')^2$ antibody fragments for 1 h. The sections were washed three times with PBS and then mounted with Biomeda Gel/Mount (Biomeda, Foster City, CA) supplemented with 1,4-diazabicyclo[2.2.2]octane and coverslipped. Fluorescence images were taken with a Zeiss Axioplan 2 confocal microscope (Zeiss, Thornwood, NY).

Preparation and Characterization of Anti-Fas MAb Conjugated Hydrogels. PEGDA-*co*-NPA hydrogels were prepared at 100/0 to 50/50 PEGDA/NPA ratios as described in the previous section. These hydrogels were then conjugated with 0−0.25 mg/mL of anti-Fas MAbs (DX2 clone, R&D Systems, Minneapolis, MN) using the same reaction conditions as described previously for MAH IgG. Following conjugation to DX2 antibodies, 50 mM glycine methyl ester (Sigma-Aldrich, St. Louis, MO) was then added to the gels to quench any unreacted NHS groups within the gels. Both modified indirect and sandwich ELISAs were performed as described previously. The degree of DX2 conjugation was assessed by indirect ELISAs using goat anti-mouse HRP. Sandwich ELISAs to verify DX2 recognition and binding of recombinant human Fas (Peprotech, Rocky Hill, NJ) was performed utilizing goat anti-Fas PAb (R&D Systems) for the sandwich antibody and donkey anti-goat HRP for secondary detection (Jackson Immunoresearch).

Apoptosis Assessment by Annexin V Assay. Jurkat T cell lymphoma cells were a kind gift from Dr. Peter Mariner (Department of Chemistry & Biochemistry, University of Colorado). Jurkat cells were cultured with RPMI 1640 supplemented with 100 units/mL penicillin/streptomycin and fungizone and 10% fetal bovine serum (FBS). For apoptosis induction experiments, 75/25 PEGDA/NPA hydrogels were polymerized in 96-well TCPS under aseptic conditions. These gels were soaked in sterile-PBS for 5 min and then conjugated to 0.25 mg/mL MAH IgG, or 0.25 mg/mL DX2 anti-Fas MAbs in PBS. After washing and blocking remaining reactive sites on hydro-

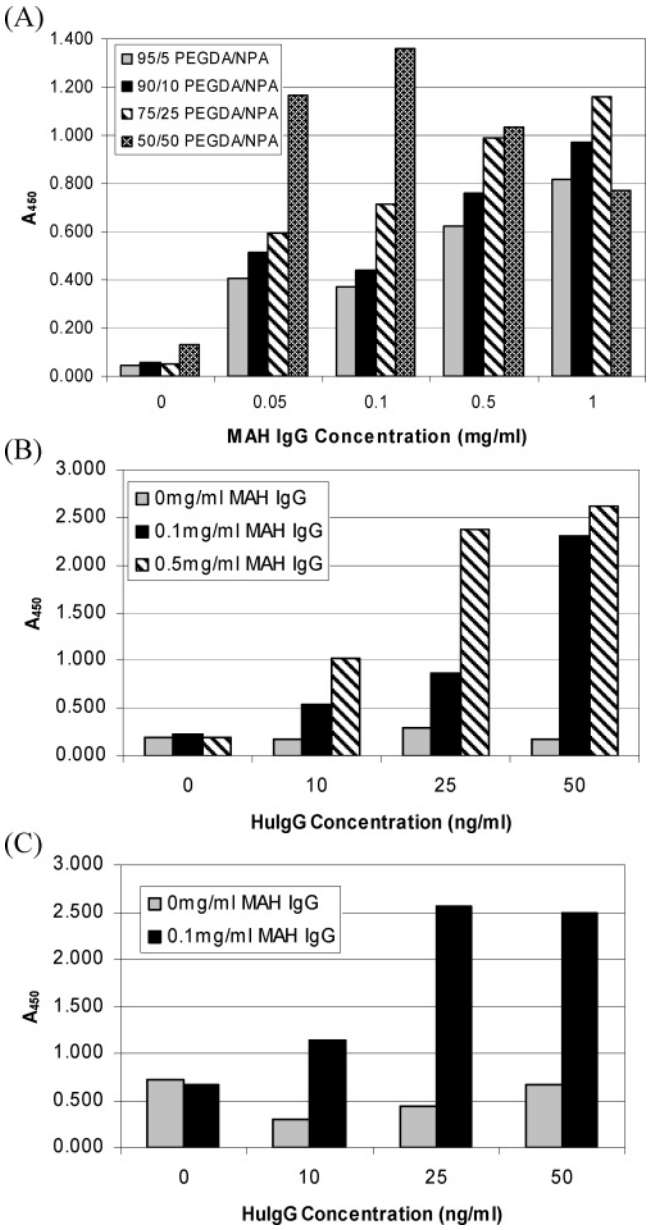

Figure 2. (A) Indirect ELISA for detection of MAH IgG conjugated to PEGDA-*co*-NPA hydrogels. PEGDA-*co*-NPA hydrogels were photopolymerized at 100/0, 90/10, 75/25, and 50/50 (wt) ratios of PEGDA to NPA. Hydrogels were conjugated to MAH IgG at concentrations ranging from 0 to 1 mg/mL antibody. MAH IgG conjugated to the surface of hydrogels was detected using GAM HRP. Sandwich ELISAs were formed for (B) 75/25 and (C) 50/50 PEGDA-*co*-NPA hydrogels conjugated with MAH IgG. Hydrogels were conjugated with 0−0.5 mg/mL MAH IgG and then exposed to Human IgG antigen. Sandwiches were completed using goat anti-human HRP.

gels using 50 mM glycine methyl ester, 5000 or 10000 Jurkat cells were added to the gels and the cells were allowed to incubate suspended atop these hydrogels for 2 days at 37 °C. Jurkat cells were then removed and placed into fresh wells following the incubation period. The Annexin Apoptosis Assay (Invitrogen, Carlsbad, CA) was then used to determine the extent of apoptosis. Cells were stained with annexin V-FITC conjugate and then counterstained with propidium iodide (PI), which allows for the differentiation between necrotic and apoptotic cells. The cells were resuspended in RPMI without phenol red and supplemented with 10% FBS, and images were taken with a Nikon Eclipse TE300 fluorescent microscope (Nikon, Lewisville, TX). The fraction of apoptotic and necrotic cells within each condition tested was quantitated by counting cells within four random fields of view. Approximately 150−400 cells were counted per field of view.

Additional apoptosis studies compared the ability of DX2-conjugated hydrogels to induce apoptosis within Fas-sensitive (Jurkat) and Fas-insensitive (I9.2) T cell lines. 75/25 PEGDA/NPA hydrogels were conjugated with either no DX2 or 0.25 mg/mL DX2 in the same manner as stated above. 10000 cells/well of either Jurkat cells or I9.2 cells (ATCC, Manassas, VA), a caspase-8 mutant Jurkat cell line that is Fas-insensitive, were then added to these hydrogels. Annexin V-FITC binding studies were then performed following 2 days incubation. Quantitation of the fraction of apoptotic cells with all samples was calculated using the same techniques as described above.

RESULTS

PEGDA-*co*-NPA hydrogels were photopolymerized prior to conjugation to MAH IgG (Figure 1A). NHS moieties were utilized to react to amine groups in the antibodies (Figure 1B). Preliminary results showed that a high level of MAH IgG was conjugated to the surface of prepolymerized PEGDA-*co*-NPA hydrogels. Indirect ELISA assays showed higher levels of MAH IgG conjugated to these hydrogels upon both increasing MAH IgG solution concentration (0−1 mg/mL) and fraction of NPA (5−50 mol %) comprising the hydrogels (Figure 2A). The highest degree of conjugation was observed with 50/50 PEGDA-*co*-NPA gels; however, these gels were less mechanically robust due to the lower quantity of cross-linking PEGDA monomer present within these gels. In addition, minimal color formation was evident when 100/0 PEGDA/NPA control gels were reacted with MAH IgG antibodies, indicating that the presence of antibody was due to conjugation to NPA groups and not due to physical adsorption of the antibodies to the hydrogel matrix (data not shown). Sandwich ELISA assays performed on 75/25 and 50/50 PEGDA-*co*-NPA hydrogels showed that conjugated MAH IgG retained the ability to recognize human IgG antigen, with greater detection sensitivity with gels that contain higher quantities of conjugated MAH IgG (Figure 2B, 75/25 gels). High nonspecific background absorbance was observed with 50/50 gels in the absence of human IgG (Figure 2C, 50/50 gels). Detection levels for human IgG become saturated at 25ng/mL with both gel compositions. These ELISA results indicate that monoclonal antibodies can be conjugated to a high degree to preformed PEGDA-*co*-NPA hydrogels without significantly compromising the abilities of the antibodies to recognize their antigens.

Cryosectioning and immunostaining of MAH-conjugated hydrogels showed that MAH IgG conjugation was limited to the hydrogel surface, as indicated by the lack of fluorescence observed within the interior of the gels (Figure 3). No fluorescence was observed with hydrogels not exposed to MAH (Figure 3A). In addition, a thicker band of fluorescence on the hydrogel surfaces was evident with higher concentrations of MAH used for conjugation, which may be indicative of greater degrees of surface conjugation (Figure 3B,C).

Conjugation of DX2 anti-Fas MAbs to PEGDA-*co*-NPA hydrogels was performed using the methodology and conditions developed for MAH IgG discussed in the above section. Indirect and sandwich ELISAs were performed with PEGDA-*co*-NPA hydrogels prepared at varying ratios (100:0 to 50:50 PEGDA:NPA). These assays show similar trends for detection of protein conjugation and antigen recognition by DX2, respectively, as seen with ELISAs with model MAH IgG antibodies (Figure 4). A higher degree of DX2 conjugation was observed with higher concentrations of antibody added for conjugation (Figure 4A). However, minimal differences in conjugation efficiency were observed with gels polymerized with different concentrations of NPA, which is in contrast to MAH IgG results. Greater

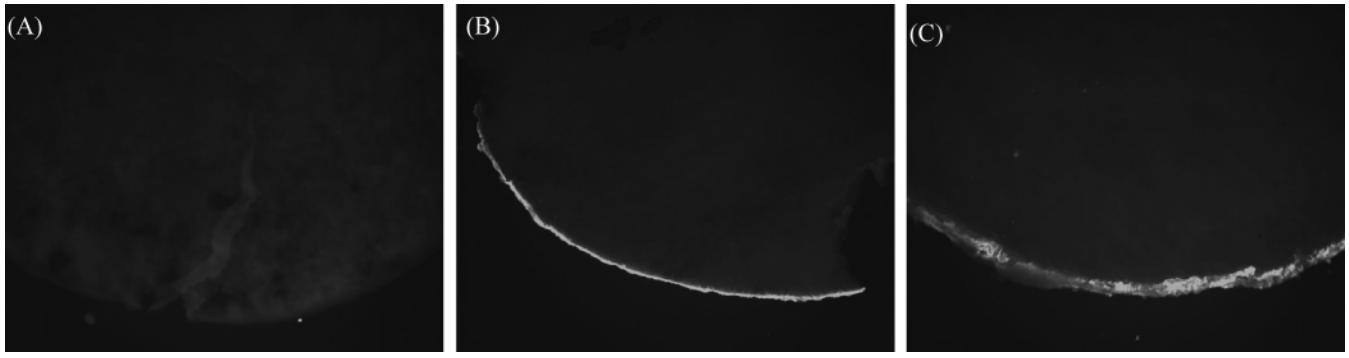

Figure 3. Immunological staining of MAH IgG-conjugated PEG-*co*-NPA hydrogel cryosections. Hydrogels were conjugated with (A) 0 mg/mL, (B) 0.1 mg/mL, and (C) 0.5 mg/mL MAH IgG. Conjugated hydrogels were then frozen and cryosectioned at 50 μm thickness. Section were then stained with goat anti-mouse (H+L) $F(ab')_2$ Alexa 488 conjugate. Images were taken at 4× (objective) magnification. Fluorescently stained sections were then observed by fluorescence microscopy.

sensitivity of rFas detection was evident with higher concentrations of DX2 conjugated to both 75/25 and 50/50 PEGDA/NPA hydrogels; however, significant background was evident with 50/50 hydrogels, most likely due to rFas entrapment within these gels (due to greater pore sizes) (Figure 4B,C).

The ability of DX2-conjugated hydrogels to induce apoptosis within Jurkat cells, a model T cell line, was assessed by monitoring Annexin V binding. Annexin V binds to phosphatidylserine, which is usually located on the inner leaflet of the phospholipids bilayer of the cell membrane, but becomes translocated to the outer leaflet in dying cells. Binding of Annexin-FITC conjugates to apoptotic Jurkat cells can be visualized by fluorescence microscopy. Counterstaining of cells with propidium iodide can differentiate between apoptotic and necrotic cells, as PI can diffuse into and bind with the DNA only within necrotic cells. In our experiments, relatively few cells (less than 1%) were observed to be necrotic throughout all conditions tested, and therefore only apoptosis results are shown and discussed.

Experiments were performed to compare the ability of DX2-conjugated hydrogels to induce apoptosis within Jurkat cells compared to control hydrogels. Control hydrogels were either unconjugated or were conjugated with MAH IgG control antibodies that are not apoptosis-inducing. Fluorescence images screening for Annexin V fluorescence showed that while similar fractions of cells appear to induce apoptosis in the presence of both control hydrogel formulations, a significant increase in apoptotic cells was observed with hydrogels conjugated with DX2 (Compare fluorescence images from Figure 5A and 5B with 5C). These cell images were also used for quantitation of the fraction of apoptotic cells within each condition tested. Quantitative results confirm that an enhancement in apoptosis induction was observed with Jurkat cells exposed to DX2-conjugated gels. Only 5−7.5% of Jurkat cells were apoptotic in the presence of control gels, whereas approximately 20% of Jurkats appeared apoptotic with DX2-conjugated gels (Figure 6). Statistical analysis by student's *t*-test showed that all *p*-values were lower than 0.05, indicating statistical significance of the data. Other tests were performed to test the specificity of apoptosis induction by DX2 antibodies. I9.2 Fas-insensitive T cells were exposed to DX2-conjugated hydrogels to determine whether apoptosis induction occurred due to the specific action of the Fas/anti-Fas interaction or whether apoptosis induction was a nonspecific occurrence. Results from this study show that no enhancement in apoptosis was observed with I9.2 cells exposed to 0.25 mg/mL DX2 over levels induces with control gels lacking conjugated antibodies, whereas higher levels of apoptosis were observed within Jurkat cells as expected (Figure 7).

DISCUSSION

Passive encapsulation technology has made great strides in providing protection for islets against cell−cell-mediated immunity by presenting a physical barrier between islet cells and activated $CD4^+$ and $CD8^+$ T cells. However, inflammatory cytokines produced by these activated cells, such as TNFα, IL-1, and IFNγ, can elicit a toxic response within islets, leading to β-cell destruction (*13*). PEG represents a functionally versatile inert polymer material that can be modified to attach biological moieties to actively promote and assist the long-term survival of islet grafts by down-regulating the immune response around encapsulated tissue. In addition, PEGylation has improved the serum half-life and stability of proteins. The studies discussed in this work describe the application of PEGylated antibodies into hydrogel network for the treatment of autoimmune diabetes, assessing the potency of antibodies conjugated to hydrogel surfaces to act in a therapeutic manner. Investigators have previously incorporated polymerizable antibodies and antibody fragments into hydrogels by free radical polymerization, but with the sole purpose for the diagnostic detection of antigens and biosensor applications (*14*, *15*).

Studies have shown that conjugation of apoptosis-inducing anti-Fas IgG MAbs to PEGDA hydrogels provides a matrix that can actively work to suppress T cell mediated immunity. Fas is a 45kD is a cell surface protein belonging to the TNF receptor family of proteins that can induce apoptosis when engaged with Fas Ligand (FasL). Fas-mediated apoptosis is normally involved in clonal deletion of autoreactive T cells by negative selection (*16*). The Fas pathway is also responsible for the elimination of activated T cells following the completion of the immune response to infection. Many tissues and cell lines weakly express Fas, but Fas is highly expressed in activated, mature lymphocytes, making lymphocytes highly susceptible to Fas-mediated apoptosis (*17*, *18*). FasL is the natural homotrimeric protein binding ligand for Fas, binding to three Fas receptor molecules to induce apoptosis (*18*). FasL expression is induced upon activation of cytotoxic T lymphocytes, which can then destroy Fas-expressing activated lymphocytes (*17*). Fas activation requires FasL multimerization or cross-linking of Fas receptors to initiate the signal transduction cascade for apoptosis (*19*). Binding of MAbs to Fas receptors can also induce apoptosis. The multimeric nature of Anti-Fas IgM antibodies effectively induce apoptosis by allowing for multiple cooperative binding events to cross-link several Fas receptors simultaneously on cell surfaces (*20*, *21*). Monomeric IgG subclass anti-Fas antibodies do not induce apoptosis as effectively as the IgM subclass due to their inability to simultaneously cross-linking multiple Fas receptors in the absence of exogenously added cross-linking molecules (*22*). DX2 is an anti-Fas monoclonal antibody (IgG1

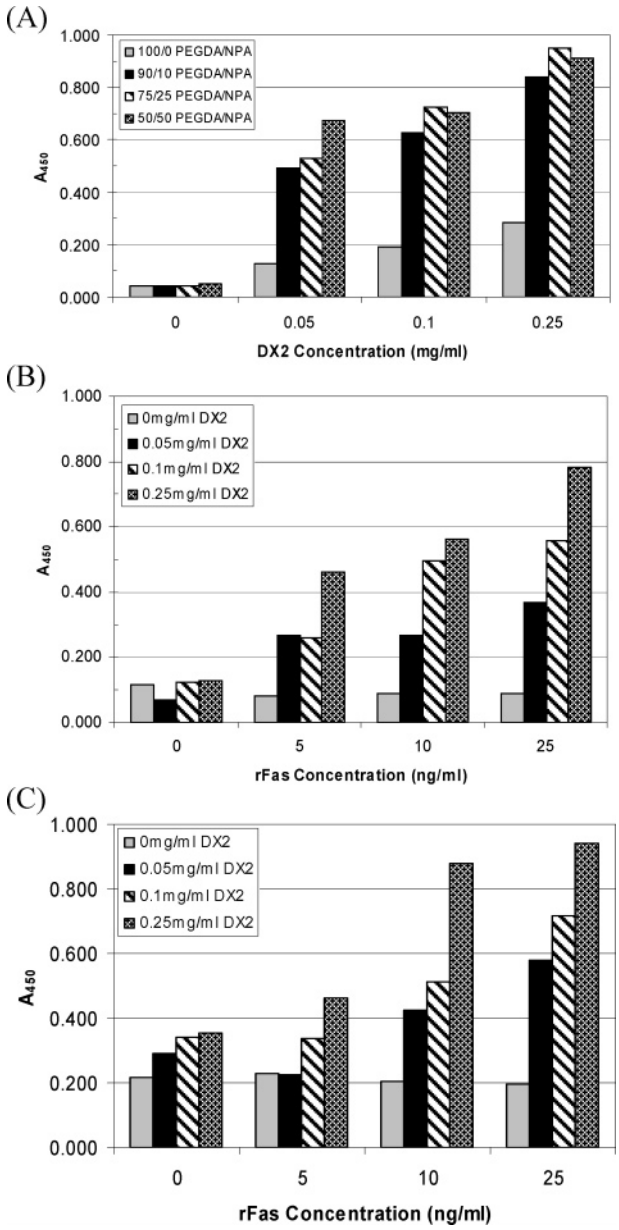

Figure 4. (A) Indirect ELISA for detection of DX2 anti-Fas MAb conjugated to PEGDA-*co*-NPA hydrogels. PEGDA-*co*-NPA hydrogels were photopolymerized at 100/0, 90/10, 75/25, and 50/50 (wt) ratios of PEGDA to NPA. Hydrogels were conjugated to DX2 at concentrations ranging from 0 to 0.25 mg/mL antibody. DX2 conjugated to the surface of hydrogels was detected using GAM HRP. Sandwich ELISAs were formed for (B) 75/25 and (C) 50/50 PEGDA-*co*-NPA hydrogels conjugated with DX2. Hydrogels were conjugated with 0−0.25 mg/mL DX2 and then exposed to rFas antigen. Sandwiches were completed using goat anti-Fas PAb, followed by detection with donkey anti-goat HRP secondary antibodies.

subclone) that can induce apoptosis in human T cells lines in solution upon antibody cross-linking (*21, 23*).

Antibody immobilization can induce cellular activation more effectively than soluble antibodies due to the ability to provide high local concentrations of antibodies for binding and receptor clustering that leads to enhanced transcriptional signal strength of activation signals or secondary messengers (*24*). Immobilization of anti-CD3 antibodies on solid surfaces has been shown to both enhance stimulation and activation of T cells and induce anergy within T cells in the presence and absence of co-stimulatory factors, respectively (*21, 24−26*). Surface immobilization techniques were modified in our studies to account for the future presence of live islets to be encapsulated within

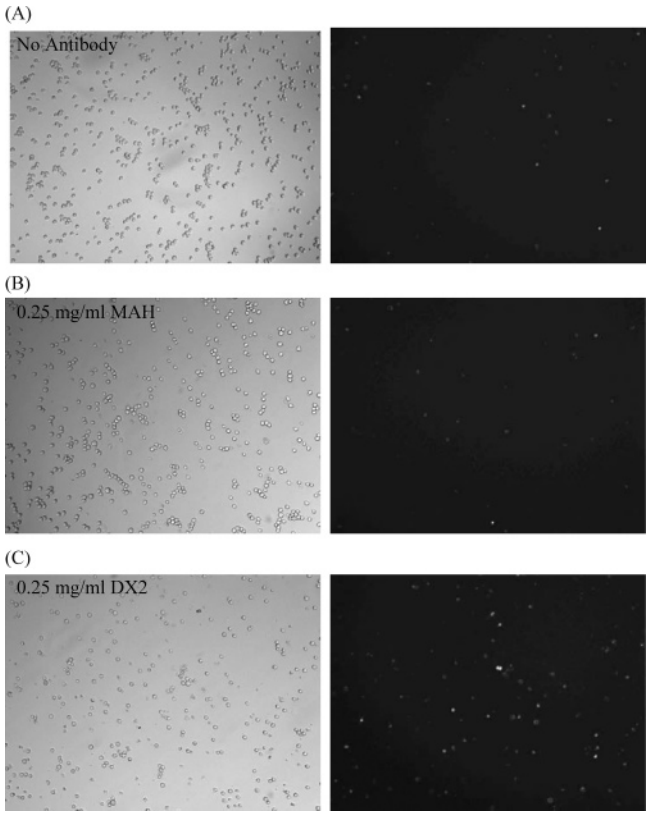

Figure 5. Brightfield and fluorescent images of Jurkat T cells exposed to hydrogels conjugated with various antibodies. Jurkat T cells were cultured for 2 days in 96-well tissue culture plates in the presence of PEG-*co*-NPA hydrogels conjugated with (A) no antibody, (B) 0.25 mg/mL MAH IgG control MAb, or (C) 0.25 mg/mL DX2 anti-Fas MAb. Following the culture period, Jurkat cells were removed from wells containing hydrogels and then assayed for the presence of phosphatidylserine using annexin V-FITC conjugates. Images were taken at 10× (objective) magnification. Brightfield images show Jurkat cell density for each condition tested, whereas green fluorescence observed in fluorescent images (shown in grayscale) are indicative of annexin V-FITC conjugation to phosphatidylserine, which is indicative of apoptotic cells.

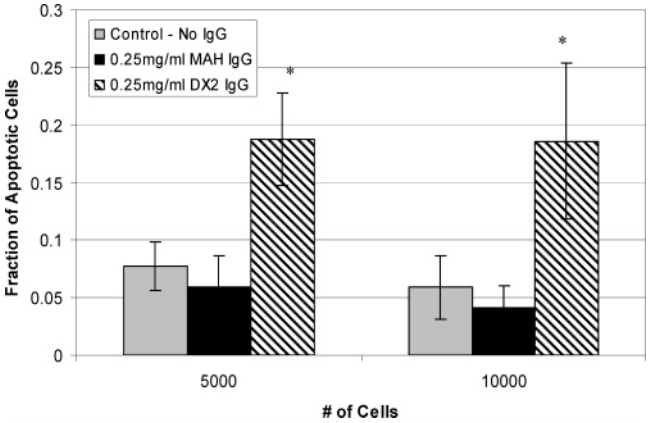

Figure 6. Quantitative evaluation of annexin V binding to Jurkat cells. The fraction of apoptotic cells was calculated by counting both apoptotic and total cell numbers from four random fields of view. Data were generated from both 5000 and 10000 Jurkat cells exposed to hydrogels prepared at the various experimental conditions described in Figure 4. * denotes $p \leq 0.04$ when results are compared to controls lacking conjugated antibody.

our hydrogel devices, which precluded the use of organic solvents for surface conjugation. Therefore, aqueous conjugation conditions at physiological salt concentrations were required. Copolymerization of PEGDA with NPA allowed for incorpora-

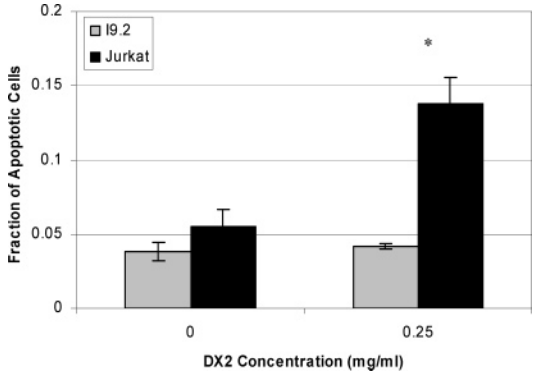

Figure 7. Quantitative evaluation of annexin V binding to both Fas-insensitive I9.2 and Fas-sensitive Jurkat T cells. 10000 I9.2 or Jurkat cells were exposed to hydrogels conjugated with either no antibody or 0.25 mg/mL DX2 anti-Fas MAb. * denotes $p \leq 0.001$ when results are compared to controls for the same cell line exposed to hydrogels lacking conjugated antibody.

tion of aqueous-reactive NHS groups prevalent both within the hydrogel as well as on the surface of hydrogels. Initial studies with MAH IgG model antibodies confirmed the ability to conjugate antibodies to the surfaces of NHS-reactive hydrogels, as well as demonstrated the ability of these antibodies to retain antigen recognition after conjugation. Surface conjugation was verified by cryosectioning and immunostaining of MAH IgG-conjugated hydrogels. These studies with MAH IgG also provided framework conditions to conjugate DX2 anti-Fas MAb to hydrogel surfaces at varying surface densities. Preliminary data indicated that DX2 antibodies adsorbed onto TCPS surfaces induced higher levels of Jurkat cell apoptosis compared to DX2 antibodies added in solution, suggesting that higher localized concentrations of DX2 promoted apoptosis induction (data not shown). In accordance with these results, immobilization of DX2 antibodies onto the surface of PEGDA-*co*-NPA hydrogels also enhanced apoptosis of Jurkat cells over passive, unconjugated hydrogel controls. These studies also showed that apoptosis induction was a unique quality observed solely with DX2 antibodies and demonstrated the specificity of apoptosis induction with DX2, as only Fas-sensitive cells underwent apoptosis in the presence of DX2.

The results presented in this study demonstrate the utility of surface conjugation of immunosuppressive moieties into encapsulation matrixes to down-regulate the immune response to transplanted tissues. Although the degree of T cell apoptosis with current systems may not be high enough to fully down-regulate immune responses to grafted tissue, this work demonstrates the potential that activation of passive barrier holds, whereby biological processes may be altered by the addition of biological moieties, favoring enhanced survival and function of encapsulated grafted tissue. Modifications to improve current systems, such as developing systems with higher degrees of grafting/clustering of immunosuppressive proteins on hydrogel surfaces, may lead to adequate and sustainable immunosuppression and allow for long-term graft survival. Research into active barrier systems will hopefully change traditional views and begin addressing the different shortcomings associated with current encapsulation systems pursued for treating diabetes mellitus.

The purpose of this study was to design, synthesize, and initially characterize a representative set of novel constructs for large-molecular radiographic/computed tomography (CT) contrast agents, intended for a primarily intravascular distribution. A new assembly of well-known and biocompatible components consists of paired, symmetrical dendritic polylysines initiated from both ends of a poly(ethylene glycol) (PEG) core, yielding an array of multiple free amino groups to which were conjugated highly soluble and stable triiodophthalamide ("triiodo") moieties. An array of six dendritic contrast agents was synthesized originally, using three different PEG cores (3, 6, 12 kDa) with t-Boc lysine-generated dendrimer "amplifiers" (from three to five generations) containing 16 to 64 amino groups for conjugation with reactive triiodo moieties. A clinically used, nonionic, small molecular CT contrast agent, iobitridol, was derivatized via a hydroxyl protection/deprotection strategy, introducing a new carboxyl group available for conjugation to the lysine amino groups of dendrimers. Final products were purified by size exclusion chromatography and characterized by NMR, UV, HPLC, and elemental analysis. Preliminary evaluations were conducted for physicochemical characterization and in vivo CT contrast enhancement in a rat model. All six iodinated PEG-core dendrimer conjugates were synthesized in good yields, with a high degree of size monodispersity, large apparent molecular weight, favored physicochemical properties. A representative compound, PEG12000-carbamate-Gen4-IOB conjugate, 27% (w%) rich in iodine, demonstrated a desirable strong and persistent intravascular enhancement with a monoexponential blood half-life of approximately 35 min assayed by dynamic CT imaging and also showed high water solubility (>550 mg/mL at 25 °C), large apparent molecular size (comparable to a 143-kDa protein), high hydrophilicity (butanol−water partition coefficient 0.015), and stability to autoclaving conditions. This study showed the synthetic feasibility, desired basic characteristics, and potential utility for CT contrast enhancement achieved with a new type of iodinated, large-molecular PEG-core dendritic construct. Further development of this class of macromolecular contrast agents will be required to define the optimal formulation, pharmacology, safety profile, and the full range of diagnostic applications including tumor microvascular quantitative characterization by CT imaging.

INTRODUCTION

New water-soluble radio-dense iodinated pharmaceuticals administered intravenously in conjunction with diagnostic X-ray and computed tomography (CT) have the potential to improve the quality, nature, and yield of resulting diagnostic information. So-called iodinated "contrast media" were first considered in the same year as Wilhelm Roentgen's discovery of the X-ray and have evolved over the past century to the current state of well tolerated and highly efficacious drugs used in the vast majority of patient CT examinations. Without exception, the CT contrast media currently given parenterally, either intravenously or intra-arterially, belong to a class of relatively small molecular compounds, less than 2000 Da, which quickly equilibrate between the intravascular and extracellular fluid compartments of the body. However, another class of compounds, namely macromolecular contrast media (MMCM), has been described, both for CT and magnetic resonance imaging (MRI) tomography, as being potentially better suited for quantitative characterization of tissues and blood vessels and certain types of pathologic abnormalities as found in cancer, ischemic injury, and altered states of angiogenesis (*1*−*4*). These MMCM, sometimes referred to as "blood pool" contrast media, have in common a prolonged intravascular half-life, an initial volume of distribution approximating the plasma volume, and molecular weights generally greater than 30 kDa.

Properties considered desirable for candidate macromolecular CT contrast media, in addition to an intravascular distribution, include relatively high content of iodine or other radiodense atoms, high stability, near or complete monodispersity, low osmolality, high water solubility, limited viscosity, high in vivo tolerance, and complete elimination from the body.

Toward these goals, a new group of iodinated MMCM, intended for use as blood pool CT contrast enhancing agents, has been designed, synthesized, and preliminarily tested. This class of agents consists of paired, symmetrical dendritic polylysines in a cascade arrangement initiated from both ends of a poly(ethylene glycol) (PEG) core, yielding an array of multiple (16 to 64) free amino groups for conjugation with tri-iodinated ring intermediates. Six of these tri-iodo PEG dendrimer conjugates with varying sizes of the PEG core (3, 6, and 12 kDa) and varying dendritic generations (3, 4, and 5) were synthesized as examples of the class and compared for physicochemical properties. One selected compound was further

evaluated by in vivo CT imaging in an experimental animal subject for angiographic contrast enhancement.

EXPERIMENTAL PROCEDURES

Materials and Apparatus. Poly(ethylene glycol) (PEG) 6000 (M_n 6470, M_w 6517, polydispersity index 1.01, measured by MALDI-TOF mass spectroscopy) was purchased from Fluka. PEG12000 (M_n 12163, M_w 12650, polydispersity index 1.04 according to the manufacturer's data) was purchased from Polymer Labs. These PEGs were dried by azeotropical distillation with anhydrous benzene. Poly(ethylene glycol) bisamine 3400 (M_n 3290, M_w 3321, polydispersity index 1.01) was purchased from Shearwater Polymers Inc., N^2,N^6-di-*tert*-butyloxycarbonyl-L-lysine dicyclohexylamine salt (N^2,N^6-di-t-Boc-L-Lys·DCHA) was from Advanced ChemTech, dicyclohexyl carbodiimide (DCC), *N*-hydroxysuccinimide (HONSu), *p*-nitrophenyl chloroformate, *N*,*N*-dimethylaminopyridine (DMAP), diisopropylethylamine (DIPEA), trifluoroacetic acid (TFA), *N*,*N*-dimethylformamide (DMF, dried with 4−8 mesh 4 Å molecular sieves), 1,3,5-trinitrobenzenesulfonic acid (TNBS), and other reagents were purchased from Aldrich, Sigma, or Fischer Scientific. All these reagents are of analytical grade or superior. Conventional iodinated contrast agents Iohexol, Iobitridol, and Iodixanol were commercially available, and Iobitridol solution was lyophilized to give a white powder of 99.9% purity (by reversed phase HPLC).

H-1 and C-13 NMR spectra were recorded on a Varian 400 NMR spectrometer. Analytical SE-HPLC was performed on a Superdex 200 10/300 GL column (10 mm × 300 mm) using a Rainin HPXL solvent delivery system and a Rainin pressure module (Rainin Instrument Inc., Emeryville, CA) with a Knauer diode array UV detector and a Shimadzu RID-6A as the refractive index detector. A solution of 0.1% TFA and 0.3 M Na_2SO_4 (pH 2.7) was used as the mobile phase at 0.80 mL/min and 23 °C for purity test of PEG-core dendritic polylysines (UV detection at 210 nm), while a solution of 0.05 M phosphate and 0.15 M NaCl (pH 7.0) was used as the mobile phase at 0.80 mL/min and 23 °C for the purity test of iodinated contrast agents (245 nm). Preparative size exclusion chromatography (SEC) was run on a Sephadex G-100 (or G-75) column (5 cm I. D. × 50 cm) with UV detection. TLC with detection by UV or iodine vapor, or a ninhydrin spray test, was conducted on precoated Merck TLC plates with silica gel G25 UV_{254} (5 × 20 cm, 250 μm). UV spectra were recorded on a Shimadzu UV-260 spectrophotometer. ESI mass spectra were recorded on a Perkin-Elmer SCIEXAPI300 LC/MS mass spectrometer. MALDI-TOF mass spectra were obtained on a Perkin-Elmer Voyger DESTR mass spectrometer. Melting points were determined on an electrothermal melting point apparatus (uncorrected). Dialysis was carried out using the regenerated cellulose Spectra/Por tubing (cutoff M_w 3500 Da).

The CT experiment was performed at 80 kVp and 130 mA on an eight-slice clinical GE LightSpeed QX/I CT Scanner (GE Medical Systems, Milwaukee, WI). One seven-week-old healthy Sprague Dawley rat (180 g, female, Charles River Laboratories, Wilmington, MA) was used for CT imaging.

Activation of N^2,N^6-Di-*tert*-butyloxycarbonyl-L-lysine. *Preparation of Free N^2,N^6-Di-t-Boc-L-lysine*. According to a standard procedure, dicyclohexylamine (DCHA) was removed from N^2,N^6-di-t-Boc-L-Lys·DCHA by thoroughly washing its CH_2Cl_2 solution with 0.5 M citrate buffer (pH 3.5). Yield 92%. TLC: R_f = 0.70 ($CHCl_3$:CH_3OH: HAc = 90:8:2). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 1.22−1.28 (t, 4H, CH_2CH_2), 1.44 (s, 18H, *tert*-butyl), 1.68 (m, 2H, C*H*$_2$CH), 3.10 (t, 2H, CH_2N), 4.21 (t, 1H, NCHCO), 4.90 (br, 1H, N^6-H), 5.42 (d, 1H, N^2-H, J = 7.2 Hz), 10.39 (br, 1H, COOH).

Carboxy Activation of N^2,N^6-Di-t-Boc-L-lysine. DCC (2.06 g, 10 mmol) was dissolved in 10 mL of CH_2Cl_2 and cooled to −15 °C. With stirring, to this cold solution was dropwise added a solution of N^2,N^6-di-t-Boc-L-Lys (3.47 g, 10 mmol) in CH_2Cl_2 (20 mL). The reaction temperature was kept below −10 °C. Several minutes later, the reaction mixture turned turbid and then was continued to stir for 3−4 min. The resulting solution containing DCC-activated di-t-Boc-lysine should be used immediately in the subsequent coupling reaction with the amines.

For comparison, two types of active esters of di-t-Boc-lysine, namely 4-nitrophenyl ester or *N*-hydoxysuccinimide ester, were also prepared by the reaction of this t-Boc amino acid with 4-nitrophenol (or *N*-hydroxysuccinimide) and DCC in an equivalent mole ratio in anhydrous chloroform.

Synthesis of PEG-Core Dendrimers (with PEG6000 as an example). *Preparation of PEG6000 Bis(4-nitrophenyl carbonate (**5a**).* Dried PEG6000 (M_n 6470, 4.0 g, 0.62 mmol) was dissolved in anhydrous CH_2Cl_2 (15 mL) and dry pyridine (15 mL) and then cooled to 0 °C. To it was added 1.0 g of 4-nitrophenyl chloroformate (4.96 mmol) and 80 mg of DMAP. At 0 °C this mixture was stirred for 8 h. The reaction mixture was evaporated and precipitated by 80 mL of ether. After standing 0.5 h, the syrupy precipitate solidified and was filtered and washed by ether. The crude product was dissolved in 1−2 mL of CH_2Cl_2 and precipitated in 40 mL of anhydrous ether; this procedure was repeated twice. A white powder (**5a**, 4.06 g) was finally obtained (97% yield). ^1H NMR ($CDCl_3$), δ 3.61 (s, CH_2CH_2O), 7.3 (d, aromatic H), 8.2 (d, aromatic H). In ^{13}C NMR ($CDCl_3$), δ 155.2 (OCO_2). UV spectrophotometry at 400 nm showed, after complete hydrolysis of this carbonate at pH 12, each mole of the carbonate contained 2.05 mol of 4-nitrophenyl group.

α,ω-Bis(N-t-Boc-ethylcarbamoyl)-PEG6000. A solution of **5a** (2.58 g, 0.38 mmol) in 15 mL of $CHCl_3$ was added dropwise to a solution of 1-*N*-*t*-Boc-ethylenediamine (493 mg, 3.08 mmol, prepared according to the literature method) (*5*) and DIPEA (0.6 g, 4.64 mmol) in 10 mL of $CHCl_3$ at 0 °C. This reaction continued for 24 h at room temperature. The resulting mixture was evaporated and precipitated by 50 mL of ether and purified by three cycles of dissolution-precipitation using $CHCl_3$ and ether. A slightly yellow powder **6** (2.50 g) was obtained in a yield of 97%. ^1H NMR ($CDCl_3$), δ 1.41 (s, *tert*-butyl), 2.92, 3.13 (2 m, CH_2N), 3.62 (s, CH_2CH_2O).

PEG6000 Bisamine. Boc-protected biscarbamate **6** (3.02 g, 0.446 mmol) obtained above was dissolved in 8 mL of CH_2Cl_2 and cooled to 0 °C, to which was added 8 mL of TFA. This mixture was stirred at 0 °C for 30 min and room temperature for another 2 h. Evaporation of the solution under 60 °C gave an oil after adding 50 mL of anhydrous ether. Dissolution/precipitation of the crude product was performed twice with CH_2Cl_2/ether. The precipitate solidified while standing at room temperature for several hours, further purified by dialysis (cutoff M_w 3500 Da), and then lyophilized to give 2.93 g of a white powder (yield 97.5%). ^1H NMR ($CDCl_3$), δ 1.42 (s, *tert*-butyl), 2.90, 3.11 (2 m, NCH_2), 3.61 (s, CH_2CH_2O). This PEG bisamine was thus used as an initiator core molecule for subsequent dendrimer synthesis. PEG6000 bisamine can be also regarded as "PEG6000-carbamate-Gen0.0" dendrimer, while "Gen" stands for "generation" and "carbamate" is the chemical linkage between the PEG core and lysine dendrimer component.

Dendrimer Propagation (two-step cycle to reach a higher generation). *Typical Coupling Step (PEG6000-Gen0.5 preparation).* Immediately after the DCC-activated di-t-Boc-lysine was formed as described above, a cooled solution of PEG6000 bisamine (2.07 g, 0.608 mmol NH_2) and DIPEA (0.39 g, 3 mmol) in 10 mL of CH_2Cl_2 was added with stirring at −5 °C. This coupling reaction (COOH/NH_2 mole ratio = 4.0) was

continued at −5 °C for 0.5 h and room temperature for 20 h. A white precipitate was filtered and washed by CH_2Cl_2, and the combined filtrate was evaporated under reduced pressure to give a thick syrup. After the dissolution of the syrup in 3 mL of CH_2Cl_2, 120 mL of anhydrous ether was added. Standing 0.5 h, a white precipitate separated and gradually solidified. This procedure was repeated twice so as to remove DIPEA and excess di-t-Boc-lysine from the crude product. The compound was washed profusely by ether and dried in a vacuum. A white, loose solid was afforded in a yield of 87% (1.93 g). Ninhydrin test: negative.

Typical Deprotection Step (PEG6000-Gen1.0 preparation). PEG6000-Gen0.5 (1.8 g, 0.247 mmol) was dissolved in 15 mL of CH_2Cl_2 and cooled to 0−5 °C. With stirring, 15 mL of TFA was added slowly while the reaction temperature was kept below 20 °C. After the TFA addition, the reaction was continued at room temperature for 2−3 h. An anhydrous $MgSO_4$ drying tube was connected to the reaction flask since gaseous byproducts such as CO_2 and isobutene were emitted in this deprotection. After the reaction went to completion, the mixture was evaporated under reduced pressure below 40 °C, giving a slightly yellow syrup. Anhydrous ether was added. After standing 1−2 h at room temperature, the syrup solidified. The dissolution/precipitation procedure was repeated twice. A white precipitate was collected, washed with ether, and dried in a vacuum to give 1.78 g of a white powder (yield 98%, positive for ninhydrin test).

Following procedures from Gen1.0 through Gen5.0 are similar. Yields of coupling steps ranged from 85 to 92%, while the yields of deprotection steps varied from 90 to 98%. Every reaction was monitored by ninhydrin test. Of important note, one repeated coupling was conducted in the preparation of Gen4 and Gen5 dendrimers to guarantee a complete capping of those amino groups. Preparative SEC (Sephadex-75 gel, mobile phase 0.1 M trifluoroacetate buffer with pH 3.0, flow rate 14 $mL\cdot min^{-1}\cdot cm^{-2}$) and subsequent dialysis were employed for purification of these full-generation dendrimers (**8a** through **11b**). NMR, MALDI-TOF MS, and UV (for amino quantification using TNBS method) (*6*) were used for characterization of main intermediates and undecorated dendrimers (data shown in Table 1).

For t-Boc-protected half-generation dendrimers including Gen0.5, Gen1.5, Gen2.5, Gen3.5, and Gen4.5, ^1H NMR spectra ($CDCl_3$) were given: δ 1.3−1.6 (br, $(CH_2)_3$ in lysine), 1.42 (s, *tert*-butyl), 3.1(br, NCH_2), 3.61 (s, CH_2CH_2O), 4.2 (br, NCH-CO). For deprotected full-generation dendrimers including Gen1.0, Gen 2.0, Gen3.0, Gen4.0, and Gen5.0 (TFA salts), ^1H NMR spectra (D_2O): δ 1.3−1.8 (br, $(CH_2)_3$ in lysine), 2.9−3.2 (br, NCH_2), 3.62 (s, CH_2CH_2O), 4.1−4.3 (d, br, NCHCO). The integration ratio of characteristic peaks (PEG and CH_2-CH_2CH_2 in lysine) obtained in ^1H NMR confirmed that the t-Boc-protected and deprotected dendrimers had the expected structure. Six synthesized dendrimers for subsequent decoration include PEG6000-carbamate-Gen3.0 (**1a**), PEG12000-carbamate-Gen3.0 (**1b**), PEG6000-carbamate-Gen4.0 (**2a**), PEG12000-carbamate-Gen4.0 (**2b**), PEG3400-amide-Gen4.0 (**3a**), and PEG3400-amide-Gen5.0 (**3b-I**).

For two representative dendrimers, ^{13}C NMR data were given. For PEG3400-carbamate-Gen5.0: δ (ppm) 22.7, 26.5, 28.0, 30.9 ($CH_2CH_2CH_2CH$), 39.4 (CH_2N), 53.4, 54.6 (CH), 69.7 (PEG), 112.2, 115.1, 118.0, 120.9 (CF_3), 162.7, 163.1 (CF_3COO^-), 174.7, 179.0 (N^6-CO and N^2-CO); for PEG6000-carbamate-Gen4.0, δ (ppm) 25.7, 26.5, 28.1 ($CH_2CH_2CH_2$), 39.1, 39.5 (CH_2N), 53.2, 53.8 (CH), 69.7 (PEG), 112.2, 115.0, 117.9, 120.7 (CF_3), 162.5, 163.0 (CF_3COO^-), 174.4, 178.7 (N^6-CO and N^2-CO in dendritic lysine).

Quantification of Periphery Amino Groups in the "PEG Amplifiers". The NH_2 analysis was conducted according to a typical TNBS method (*6*). To 1 mL of a standard solution (a series of L-lysine mono hydrochloride solution with known concentration, 20−100 μg/mL) or 1 mL of a dendrimer sample solution (0.2−1.5 mg/mL) were added 1.0 mL of 4% sodium bicarbonate solution (pH 8.5) and 1.0 mL of 0.1% freshly prepared TNBS solution. The reaction was continued at 40 °C for 4 h, and 1.0 mL of 10% sodium dodecylsulfonate (SDS) solution and then 0.5 mL of 1 N HCl were added, consecutively. Against a blank control solution the absorbance at 335 nm of standard or sample solutions were recorded. Amino concentration in solutions and hence amino contents in dendrimers were determined (results shown in Table 1). For **9a**, **11a**, and **11b**, their trinitrophenyl conjugates obtained above were redissolved in 1,4-dioxane for UV quantification at 415 nm.

Synthesis of an Amino-Reactive "Triiodo" Derivative. *Hydroxyl Protection of Iobitridol by Ketalization (compound **13** synthesis). Method A.* A powder of Iobitridol **12** (16.70 g, 20 mmol) was added in 50 mL of DMF. With stirring, 10.4 g of 2,2′-dimethoxylpropane (DMP, 100 mmol) and 100 mg of *p*-toluenesulfonic acid monohydrate were then added. The resulting solution was brought up to 90 °C and stirred at this temperature for 1 h in which the acetalization reaction was shown complete by TLC ($CHCl_3/CH_3OH$ 15:1, material R_f = 0, product R_f = 0.64, 0.50, isomers). DMF and excess DMP were removed by vacuum distillation. A crude product was obtained as a yellow syrup. Further purification was conducted by silica gel chromatography using $CHCl_3$ and then $CHCl_3/CH_3OH$ 8:1 as the eluting solvent, 18.7 g of slightly yellow crystalline **13** was obtained (yield 98%). M.p. 88−90 °C. ESI-MS: m/z = 956.0 $(M + H)^+$, 978.0 $(M + Na)^+$, 898.0 $(M - CH_3COCH_3 + H)^+$ for $C_{29}H_{40}O_9I_3N_3$. ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 1.35, 1.40, 1.46 (3s, 18H, 3 isopropylidene groups), 2.96, 2.97 (2 s, 6H, 2 N-CH_3), 3.22 (m, 1H, CHC═O), 3.36, 4.03 (2 br, 4 H, 1:1, $CH(CH_2O)_2$), 3.85, 4.17 (2m, 4H, 1:1, 2 NCH_2), 4.25, 4.29 (2 m, 4 H, 1:1, 2 OCH_2CHO), 4.53 (m, 2 H, 2 OCH_2CHO), 8.52, 9.45 (2 br, 1 H, 0.45:0.55, PhNHC═O). ^{13}C NMR (75 MHz, $CDCl_3$): δ (ppm) 21.0, 25.7, 27.2, 31.7, 36.7, 37.9, 38.2, 41.9, 42.2, 50.3, 61.0, 61.3, 67.2, 67.8, 68.0, 74.2, 74.5, 98.3, 98.8, 109.6, 143.6, 149.0, 162.8, 169.9, 170.6.

Method B. A powder of Iobitridol **12** (2.64 g, 3.16 mmol) was suspended in 60 mL of dry acetone. With vigorous stirring, 3 g of freshly fused zinc chloride (finely ground) was added, the resulting mixture was allowed to react for 24 h at room temperature. During this period, Iobitridol was converted to a new derivative, which was monitored by TLC ($CHCl_3/CH_3OH$

= 15:1). Sodium carbonate (5 g) in 25 mL of water was added to the reaction mixture. Vigorous stirring was continued for 1−2 h to completely precipitate the zinc catalyst. After filtering the white precipitate, the filtrate was evaporated to remove acetone. The residue was neutralized to pH 7 and extracted with 3 × 25 mL of $CHCl_3$, the organic phase was then dried overnight (anhydrous $MgSO_4$) and evaporated. Following chromatographic purification was similar to Method A above. Slightly yellow product **13** was obtained in a yield of 83% (2.56 g).

*Subsequent N-Alkylation by Ethyl Bromoacetate (compound **14** synthesis).* Sodium methoxide solution was freshly prepared from sodium and methanol, with a concentration of 1.90 M titrated by potassium hydrogen phthalate. This $NaOCH_3/CH_3OH$ solution (8.27 mL, 15.72 mmol) was added to a 150-mL anhydrous THF solution of **13** (10.00 g, 10.47 mmol). Upon addition, the clear yellow solution turned orange. Ten minutes after $NaOCH_3$ addition, ethyl bromoacetate (2.85 g, 15.70 mmol) was added. White precipitate appeared in minutes, and the reaction mixture was stirred at room temperature for 1 h as shown to be complete by TLC ($CHCl_3/CH_3OH$ 15:1). In this procedure, compound **13** (R_f = 0.64 and 0.50) was completely converted into **14** (R_f = 0.96 and 0.85, isomers), and the color of solution turned back to yellow. After filtration, the tetrahydrofuran solution was washed to neutral by water and dried over anhydrous $MgSO_4$. The solution was evaporated to give a yellow oil as crude product. Purification was conducted by silica gel chromatography, eluting first with $CHCl_3$ to remove excess ethyl bromoacetate, and then with $CHCl_3/CH_3OH$ (10:1, v/v) to give the pure product **14** as slightly yellow crystals. The yield was 95% (10.30 g). M.p. 112−4 °C. ESI-MS: m/z = 1042.0 $(M + H)^+$, 1064.0 $(M + Na)^+$, 983.9 $(M - CH_3COCH_3 + H)^+$ for $C_{33}H_{46}O_{11}I_3N_3$. ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 1.28 (t, J = 5.2 Hz, 3 H, CH_2CH_3), 1.35, 1.40, 1.46 (3s, 18H, three isopropylidene groups), 2.63 (m, 2 H, CH_2CH_3), 2.95, 3.03 (2 s, 6H, 2 N−CH_3), 3.25 (m, 1 H, CHC=O), 3.36 (m, 2 H, O=CCHCH_2O), 3.83 (m, 2 H, CH_3NCH_2), 3.98−4.42 (m, 10 H, NCH_2C=O, CH_3NCH_2, O=CCHCH_2O and 2 OCH_2CHO), 4.54 (m, 2 H, 2 OCH_2CHO). ^{13}C NMR (75 MHz, $CDCl_3$): δ (ppm) 19.5, 20.3, 25.6, 27.2, 28.7, 31.5, 35.4, 36.9, 37.8, 41.6, 50.3, 62.0, 62.4, 67.8, 74.3, 74.6, 98.3, 98.7, 109.6, 150.5, 151.4, 162.9, 168.5, 170.0, 170.6.

*Hydrolysis of Ethyl Ester (compound **15** synthesis).* A 2 N NaOH solution (18 mL) was added slowly to a 20-mL solution of ester **14** (10.50 g, 10.09 mmol). After the addition, the reaction was continued for 2.5 h at room temperature. The solution was neutralized to pH 7 and evaporated to remove most methanol under 40 °C. The residue was dissolved in 80 mL of water, and the solution pH was adjusted to 3.5 by 2 N HCl at which time an abundant white precipitate appeared. Saturated NaCl solution (80 mL) was added, and then 3 × 100 mL of chloroform was used to extract the carboxylic acid. The extracts were dried over anhydrous $MgSO_4$ overnight and evaporated to give 9.37 g of yellowish crystalline **15** (yield 91.7%). TLC ($CHCl_3/CH_3OH$ 15:1): R_f = 0.33 and 0.20 (isomers). M.p. 118−120 °C. ESI-MS: m/z = 1014.0 $(M + H)^+$, 1036.0 $(M + Na)^+$ and 956.0 $(M - CH_3COCH_3 + H)^+$ for $C_{31}H_{42}O_{11}I_3N_3$. ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 1.34, 1.40, 1.46 (3s, 18H, 3 isopropylidene groups), 2.95, 3.03 (2 m, 6H, 2 N−CH_3), 3.21 (m, 1H, CHC=O), 3.35 (m, 2 H, O=CCHCH_2O), 3.82 (m, 2 H, CH_3NCH_2), 4.02 (s, 2 H, NCH_2C=O), 4.1−4.4 (m, 8 H, CH_3NCH_2, O=CCHCH_2O and 2 OCH_2CHO), 4.52 (m, 2 H, 2 OCH_2CHO). ^{13}C NMR (75 MHz, $CDCl_3$): δ (ppm) 18.9, 19.4, 25.7, 27.2, 28.4, 28.9, 31.1, 37.1, 37.6, 41.2, 50.4, 62.2, 62.5, 67.8, 74.4, 74.6, 98.3, 98.6, 109.7, 150.8, 151.3, 162.9, 168.2, 170.2, 170.9.

*Preparation of N-Hydroxysuccinimde Ester (compound **16** synthesis).* Carboxylic acid **15** (9.12 g, 9.0 mmol) and *N*-hydroxysuccinimide (1.04 g, 9.0 mmol) were dissolved in 40 mL of chloroform. After cooling to −5−0 °C, dicyclohexylcarbodiimide (1.85 g, 9.0 mmol) in 5 mL of chloroform was added. The reaction continued for 0.5 h at 0 °C and r.t. for 24 h. The white precipitate was filtered, and the filtrate was evaporated to give 9.89 g of active ester **16** (99%). TLC ($CHCl_3/CH_3OH$ 15:1): R_f = 0.93 and 0.80 (isomers). M.p. 116−118 °C. ESI-MS: m/z = 1111.0 $(M + H)^+$, 1133.0 $(M + Na)^+$ and 1053.0 $(M - CH_3COCH_3 + H)^+$ for $C_{35}H_{45}O_{13}I_3N_4$. ^{1}H NMR (400 MHz, $CDCl_3$), δ (ppm) 1.35, 1.40, 1.47 (3 s, 18H, three isopropylidene groups), 2.84 (m, 4 H, CH_2CH_2), 2.98, 3.04 (2 m, 6 H, 2 N-CH_3), 3.21 (m, 1 H, CHC=O), 3.37 (m, 2H, O=CCHCH_2O), 3.83 (m, 2 H, CH_3NCH_2), 3.90−4.45 (m, 10 H, NCH_2C=O, CH_3NCH_2, O=CCHCH_2O and 2 OCH_2CHO), 4.53 (m, 2 H, 2 × OCH_2CHO). ^{13}C NMR (75 MHz, $CDCl_3$): δ (ppm) 18.1, 23.9, 24.2, 24.9, 25.1, 26.6, 28.4, 29.0, 34.1, 40.9, 41.0, 47.2, 49.8, 53.8, 61.7, 67.2, 73.9, 97.7, 109.2, 110.0, 148.1, 150.4, 162.2, 168.1, 168.3, 168.5, 169.8, 172.2.

Synthesis of Dendritic Iodinated Contrast Agents. A general procedure is described here with PEG6000-carbamate-Gen4-triiodo as an example.

PEG6000-carbamate-Gen4.0 dendrimer **9a** (0.76 g, 1.72 mmol NH_2 groups) and DIPEA (0.66 g, 5.13 mmol) were dissolved in 20 mL of DMF. Active ester **16** (8.59 g, 7.74 mmol) was added in two portions 24 h apart (2/3 was added initially and 1/3 added later). The reaction lasted for 96 h at room temperature at which time the reaction was shown to be complete by a negative ninhydrin test. A small amount of 2-aminoethanol (6 mmol) was added to destroy the excess unreacted ester. The solvent was removed by distillation in a vacuum, and the residue obtained was dissolved in 10 mL of chloroform and precipitated by 180 mL of anhydrous ether. A yellowish solid was obtained and subsequently treated by 40 mL of 60% (v/v) aqueous TFA at room temperature for 6 h. After the deprotection, the solution pH was brought to 7 by 2 N NaOH and then dialyzed against 2 × 2 L of deionized water (cutoff M_w of 3500 Da). The dialysate was concentrated and then purified by SEC on a Sephadex G-100 column (mobile phase 0.05 M phosphate and 0.15 M NaCl, pH 7.0, flow rate 12 mL·min^{-1}·cm^{-2}). Chromatographically pure macromolecular fractions were combined, dialyzed (to remove buffer salts), and lyophilized to give a white material, PEG6000-carbamate-Gen4.0-IOB, namely **2a** (1.84 g, 90% yield, "IOB" stands for Iobitridol moiety). UV (λ_{max}, water): 245 nm. Iodine analysis by UV: 31.88%. Elemental analysis measured for I, C, H, and N. ^{1}H NMR (400 MHz, D_2O): δ (ppm) 1.20−1.80 (m, $CH_2CH_2CH_2CH$), 2.39 (br, NCH_2), 3.02, 3.16 (2 s, 2 N-CH_3), 3.2−3.6 (m, CH_2 and CH groups of IOB), 3.62 (s, PEG), 4.0−4.4 (br, other CH groups of IOB, NCHCO of lysine residue). ^{13}C NMR (75 MHz, D_2O): δ (ppm) 22.9, 25.7, 28.2, 31.0, 37.9, 39.4, 43.6, 47.7, 48.0, 50.6, 52.3, 54.4, 59.9, 60.6, 63.6, 64.2, 69.3, 69.8,71.0, 71.8, 90.7, 98.0, 99.6, 148.2, 150.4, 168.9, 171.6, 172.0, 174.2, 175.1. SE-HPLC: retention time 18.41 min.

Similarly, other conjugates including PEG6000-carbamate-Gen3-IOB (**1a**), PEG12000-carbamate-Gen3-IOB (**1b**), PEG-12000-carbamate-Gen4-IOB (**2b**), PEG3400-amide-Gen4-IOB (**3a**), and PEG3400-amide-Gen5-IOB (**3b-I**) were synthesized and purified. Of note, the feeding [IOB]/[NH_2] ratio was 3, 4.5, and 6, respectively, for Gen3, Gen4, and Gen5 dendrimers. The conjugation reaction time was 72, 96, and 120 h for Gen3, Gen4, and Gen5 dendrimers, respectively. Their structures were similarly characterized by ^{1}H (and ^{13}C) NMR. Synthetic yields, iodine analysis, and SE-HPLC results were also given. (Table 2).

Table 2. Synthetic Yields and Structure Characterization of Dendritic Iodinated Contrast Agents

code	yield (%)[a]	iodine % (w/w) measured by UV (or microanalysis)	no. of IOB[b] measured (theoretical)	molecular weight (M_n)[c]	polydispersity (M_w/M_n)[d]	retention time (min) in SE-HPLC
1a	82	26.67 (26.31)	15.2 (16)	21700	1.012	19.30
1b	90	21.67 (nd)	15.5 (16)	27500	1.014	17.52
2a	78	31.88 (31.24)	30.3 (32)	36800	1.010	18.41

3b-I	84	32.14 (31.86)	39.4 (64)	46700	1.023	19.07
3b-II	86	35.64 (nd)	57.5 (64)	66400	1.017	18.35

[a] Yield based on the PEG dendrimer. [b] Measured by ^{1}H NMR (IOB stands for iobitridol). [c] Calculated by microanalysis data (iodine %). [d] Determined by size exclusion HPLC.

UV Quantification of the "Triiodo" Group in Iodinated Dendrimers. A series of dilute Iobitridol (IOB) solutions in distilled water, with known concentrations ranging from 1.0 to 50 μg /mL, was prepared. Their absorption at 245 nm was measured; thus, the standard absorbance versus concentration curve was set up. Data points for this curve followed Beer's law in the range of 0−30 μg IOB/mL ($r = 0.9995$). UV absorption data of dilute sample solutions (**1a** to **3b**) at 245 nm were measured, yielding the IOB contents; hence, iodine percentages were obtained for these iodinated dendrimers (Table 2).

Measurement of Apparent Molecular Weight and Size Distribution by SE-HPLC. Analytical SE-HPLC, performed on a Superdex 200 10/300 GL column (10 mm × 300 mm, Amersham Biosciences, Uppsala, Sweden), was utilized for molecular weight/size characterization of synthesized polymers in this work (see conditions in Apparatus). A molecular weight calibration curve was set up based on the SE-HPLC measurements of five protein standards (cytochrome C, carbonic anhydrase, bovine serum albumin, alcohol dehydrogenase, and amylase) with a molecular weight range of 13 to 200 kDa. Size distribution of each iodinated dendrimer, represented by the polydispersity index (PDI), was calculated by the equation: PDI $= M_w/M_n = (\Sigma N_i M_i^2/\Sigma N_i M_i)/(\Sigma N_i M_i/\Sigma N_i)$, M_w and M_n are weight- and number-average molecular weights, respectively, while N_i and M_i stand for the molecular number and molecular weight respectively of the i-th fraction of a polymer sample.

Basic Physicochemical Characterization. A specific amount of a test iodinated dendrimer containing 300 mg iodine was added to 2 mL of distilled water and allowed to stand overnight with gentle stirring, to observe if the test conjugate was completely dissolved at this concentration (150 mg iodine/mL). The unit, mg iodine/mL, was then converted to "mg contrast agent /mL" since the iodine% was known for each compound.

Through the flask-shaking method, the butanol−water partition equilibrium of each iodinated contrast agent was measured. Tris buffer (50 mM, pH 7.4) and 1-butanol were chosen as two immiscible solvents. The contrast agent was dissolved in Tris buffer at a concentration of 10 μg iodine/mL. Eight milliliters of a contrast agent solution was mixed with 8 mL of butanol and shook for 0.5 h in a separation funnel (30 mL). After centrifugation, the water phase was separated and its IOB concentration was determined by UV spectrophotometry at 245 nm. The partition coefficient thus was calculated by $(C_0 - C)/C$, where C_0 and C represent the IOB concentration of the contrast agent prior to and after the partition in aqueous phase. In addition, Iobitridol and Iodixilan were tested as standard controls. For each contrast agent, this measurement was conducted in triplicate.

Osmolality of the solutions containing synthesized CT MMCM was measured using a conventional freezing point depression method on a wide range osmometer (Model 3W, Advanced Instruments, Needham Heights, MA), expressed with a unit of "mOsm/kg water". The osmometer was calibrated with standard NaCl solutions (100 and 900 mOsm/Kg water) before sample measurements. Viscosity of certain contrast agent solutions (Iohexol at 300 mgI/mL, **2b** at 75 mgI/mL) were measured by a standard Ubbelohde viscometer (capillary diameter 0.4 mm) in a water bath (37.0 ± 0.3 °C). Each sample was measured in triplicate.

Formulation of Contrast Agents. Prior to CT experiments, lyophilized macromolecular contrast agents were dissolved in distilled water in the presence of a trace amount of stabilizer, i.e. 0.40 mg of tris(hydroxymethyl)methylamine (*7*) per 100 mg of iodine, followed by sterile filtration twice with Acrodisk 25 mm syringe filters (membrane pore size 0.2 μm, Gelman Laboratory). They were finally formulated as 75 mg iodine/mL solutions with pH of 6.8−7.4.

The formulated contrast media were autoclaved for 30 min at 120 °C, followed by a series of tests including SE-HPLC, inorganic iodide detection, and free iodine detection, respectively, to see if any decomposition occurred in this procedure.

Preliminary CT Imaging in a Rat Model. The CT scan was performed using an eight-detector-row clinical CT scanner (Lightspeed QX/I, GE Healthcare, Milwaukee, WI). One anesthetized Sprague Dawley rat was placed supine in the CT scanner. Immediately before, and 2, 10, 22, 32 min after, tail-vein intravenous contrast injection (dose 450 mg iodine/kg body weight), CT images of the entire animal were acquired using the following imaging parameters: 80 kVp, 130 mA, 0.5 s/gantry rotation, 1.25 mm slice thickness, 2.5 mm/s table speed (pitch 0.625), and 10 cm field of view. Images were transferred to a picture archiving and communications workstation (Impax, AGFA, Mortsel, Belgium). Representative axial images at the level of liver were chosen for comparison of intravascular CT enhancement over the time.

RESULTS AND DISCUSSION

Concept and Molecular Design (Scheme 1). Poly(ethylene glycol) (PEG) was selected as the backbone of the iodinated blood pool contrast agents due to its unique properties. PEG's each repeating units CH_2CH_2O has the ability to bind several water molecules. Compared to other water-soluble polymers (either naturally occurring or synthetic) with the same molecular weight, PEG has an extremely simple chemical structure but with an extremely high exclusion volume in water. In aqueous solution, PEG physically repulses all other surrounding macromolecules and is well-known for its nonimmunogenicity and good biocompatibility. Attachment of PEG to biomacromolecules can dramatically increase their blood half-life while markedly reduce the immunogenicity. As early as in 1991, the first PEG−protein conjugate (Adagen) for intravenous use was approved by FDA. Extremely narrow size distribution is another advantage of PEG, which makes it possible to synthesize nearly monodisperse PEG conjugates. In addition, PEG has good solubility not only in water but also in organic solvents including methylene chloride, a useful characteristic in practical synthesis (*8*−*10*).

For CT contrast media development, radiopaque atoms (e.g. iodine, barium) are necessary due to their outstanding X-ray

attenuation ability under clinical CT conditions. Comparing various elements with relatively high atomic number (39−82) comprehensively in their radio-opacity effectiveness, biocompatibility, and synthetic availability, the iodine atom (atomic number 53) now still remains our first choice as the radiopaque atom. (*11*−*13*)

In the subsequent screening of iodinated building blocks, tolerability is considered as the criterion with the highest priority. Thus, abandoning the ionic or incompletely substituted triiodobenzene derivatives, we selected a type of nonionic, highly soluble and stable structure containing *N*,*N*′-bis(polyhydroxyalkyl)-5-(*N*-acylamino)-2,4,6-triiodo-1,3-phthalamide moiety for signal enhancement. Specifically, Iobitridol, a new nonionic clinically used contrast agent, was chosen as the initial ''triiodo'' building block in our syntheses.

PEG has only two termini available for derivatization; thus, an appropriate amplifying method needs to be adopted to produce sufficient reactive termini (such as NH_2 groups) for following chemical decoration.

To carry out this method, dendritic polylysines as "amplifiers" with the varying generations are introduced to two ends of PEG diol (or PEG bisamine) via carbamate (or amide) linkages (see Scheme 2). Different from commonly used pegylation strategies in syntheses of PEG-based macromolecular pharmaceuticals (*8*, *14*, *15*), in this design we use the PEG as a macro core to initiate the total synthesis of dendrimeric contrast agents, instead of conjugating PEG to either a synthetic or a naturally occurring macromolecule. Thus, both the number of conjugated PEG (only one here) and conjugation site could be exactly controlled.

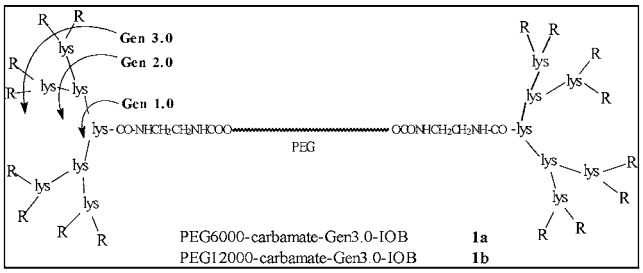
Rational derivatization of Iobitridol molecules and subsequent conjugation to PEG-core dendrimers were originally designed (see Schemes 3 and 4). The overall molecular size and terminal group number may be precisely controlled by adjusting PEG size and number of generation during the synthesis. On the basis of PEG-core dendrimer structure, we synthesized and preliminarily characterized six macromolecular iodinated contrast agents for CT imaging in this study.

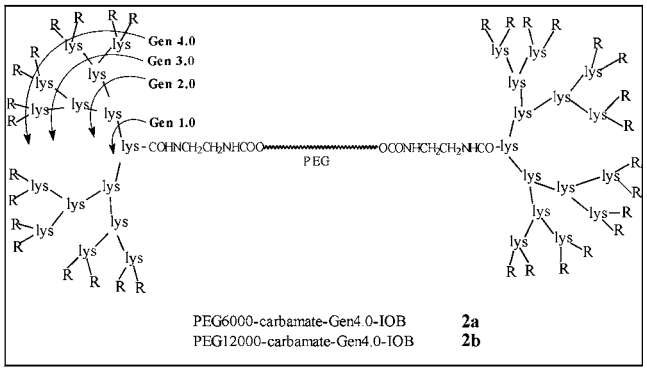
Synthesis and Chemical Characterization of PEG-Core Dendritic Polylysines. To synthesize the dendritic polylysine part, t-Boc chemistry was chosen due to the substantially lower cost of the monomer di-t-Boc-L-lysine compared with di-Fmoc-L-lysine. PEG3400 bisamine was used directly as the core molecule due to the high reactivity of terminal NH_2 groups. PEG6000 and PEG12000 bisamines were not commercially available and were thus prepared from their corresponding PEG diols. PEG diol was first converted to its bis(4-nitrophenyl) biscarbonate, subsequently reacted with 1-*N*-t-Boc-ethylenediamine, and then deprotected by TFA, yielding PEG bisamines containing stable linkages (NHCOO) in the backbone.

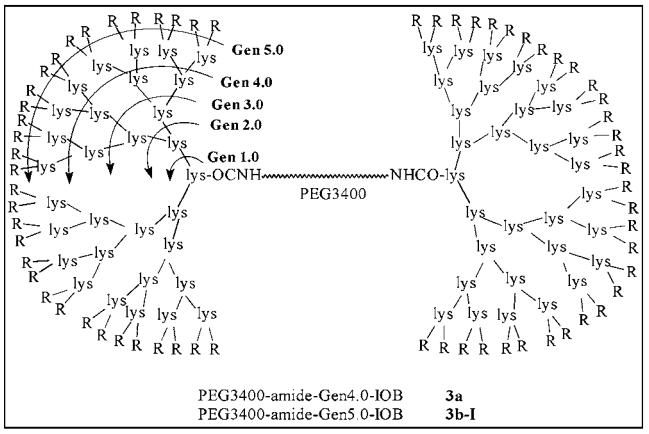
The synthesis of each dendrimeric generation includes two steps: the coupling step and the deprotection step. Coupling reaction between an amino-terminated lower generation dendrimer Gen *n* ($n = 0, 1, 2, 3$ ...) and excess COOH-activated di-t-Boc-lysine gives a t-Boc-protected dendrimer, defined as Gen ($n + 0.5$), namely the half generation. To prevent the formation of a defected structure, such as missing lysine sequences or coexistence of different generations, we must ensure that every coupling step is complete, or else the defective structure would arise and exponentially accumulate with the increase of generation. To address this extremely important issue, several factors including reactant feeding ratio, reaction time, and reaction solvent need to be considered carefully.

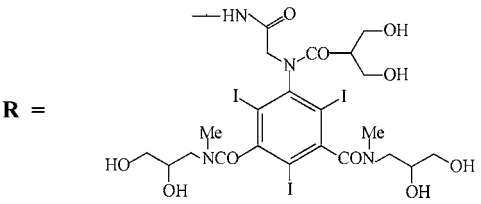
The equivalent ratio of activated di-t-Boc-lysine to the dendrimer amino group, namely the [COOH]/[NH_2] ratio, needs to be at least 3, and up to 6 in our synthesis. The ratio of <3 may lead to incomplete capping of NH_2, but the ratio of >6 did not give further benefits in the reaction completeness. For

Scheme 1. Synthesized PEG-Core Dendrimer Conjugates with Multiple Triiodophthalamide Moieties as Macromolecular Contrast Agents for Computed Tomography (CT)[a]









[a] Note: As a typical example, the abbreviation "PEG6000-carbamate-Gen4-IOB" stands for a macromolecular conjugate of generation-4 (Gen4) dendritic polylysine initiated with a PEG3400 core via carbamate linkages, having iobitridol (IOB) moieties as terminal decorating groups.

lower generations (<Gen3), the feeding ratio [COOH]/[NH_2] is chosen to be between 3 and 4, while for relatively higher generations (≥ Gen3), the feeding ratio is chosen to be between 4 and 6. The coupling reaction needs 24−48 h to the completion for lower-generation (<Gen3) dendrimers, and 48−120 h for higher generations. The obvious incompletion is detectable by ninhydrin test. Double coupling with t-Boc lysine is recommended to minimize the defects of synthesized dendrimer especially of those with Gen3 or higher.

The reaction solvent needs to be carefully chosen, too. In the preparation of dendrimers of ≥3 generations, after the failure of methylene chloride, chloroform, CH_3CN, tetrahydrofuran, and

1,4-dioxane, DMF was eventually chosen as the reaction solvent to well dissolve both reactants and products. For the deprotection step, CH_2Cl_2/TFA (1:1) was always used as the reaction medium without problems. In the synthesis of PEG3400-amide-Gen4, three activated species of di-t-Boc lysine, including DCC-activated t-Boc lysine, 4-nitrophenyl ester, and *N*-hydoxysuccinimide ester, were employed for the coupling reaction, respectively. Each approach yielded the similar dendrimer eventually under similar conditions. The first approach was generally used for dendrimer synthesis in this work.

The PEG-core polylysine dendrimers were nicely purified by preparative SEC on a Sephadex G-75 column. Dendrimer

fractions could be readily detected by UV or a ninhydrin test. Small molecular byproducts, such as lysine or its oligomers, were completely removed.

MALDI-TOF mass spectra gave expected results of their molecular weights (Figure 1). Characteristically, the regular mass interval of 44 (CH_2CH_2O unit) between adjacent MALDI peaks demonstrated the existence of PEG, while we could not find a typical mass interval of 128 (lysine residue) which indicated the absence of defected polylysine dendrons with a missing lysine sequence (see Figure 1). The PDI values derived from these spectra were highly close to 1.00, less than 1.05, and even less than the PDI values of their precursor PEGs, proving that these synthesized dendrimers have a high degree of size homogeneity. $^1H/^{13}C$ NMR spectra confirmed the expected structure of the synthesized new dendrimers. (Figures 4a and 5a, Table 1) Interestingly, in the ^1H NMR spectra of PEG12000-carbamate-Gen4 as an example, two well-resolved peaks (1.38, 1.70 ppm) were found in the range of 1.2−1.8 ppm characteristic for a lysine trimethylene group, and also two smaller peaks (2.95, 3.15 ppm) found in the range of 2.9−3.2 ppm for another CH_2 adjacent to α-C. This implied that all dendritic lysine residues were likely divided into one exterior population with unconjugated NH_2 termini, and another interior population. This was supported by the fact that after conjugation with IOB groups, only one broad peak containing three poorly resolved subpeaks was found in 1.2−1.8 ppm region, corresponding to three adjacent methylene groups.

In a recent work a Gen-3.5 dendritic polylysine with 16 hydrophobic t-Boc termini and one ester-bonded monomethoxy PEG tail (only 5 kDa PEG tested) was synthesized for testing as a surfactant (*16*). In another work an ABA triblock copolymer with a PEG core (3.4 kDa) and generation-4 dendritic polylysines at each end was synthesized via Fmoc chemistry for the use as a nonviral plasmid DNA vector (*17*). By contrast,

our synthesis of PEG-core polylysine dendrimers featured larger PEGs (up to 12 kDa), higher generation (up to 5), comprehensive structure characterization (SE-HPLC besides MALDI-MS and NMR), relatively inexpensive t-Boc chemistry, and subsequent chemical decoration by triiodophthalamides.

"Triiodo" Derivatives Synthesis and Characterization. In the development of clinically approved iodinated contrast media, tolerability has been an extremely important issue. Nonionic contrast media were proven better tolerated than their ionic counterparts due to their lower osmotic pressure, close to that of plasma (*18*−*20*). A recent study showed that a nonionic iodinated contrast agent with molecular weight of 13 kDa was highly tolerated with an acute toxicity dose of >8900 mg iodine/kg in rodents (*21*). In our work, a nonionic, well-tolerated clinically approved contrast agent Iobitridol was thus selected as the precursor "triiodo" molecule for subsequent derivatization. Of additional note, by choosing this approach, a lengthy and time-consuming de novo synthetic route generally starting from triiodination of 5-amino-1,3-phthalic acid could be avoided and be replaced by a substantially shorter and more economical synthetic route. Iobitridol was preferably chosen due to its higher hydroxyl number compared with Iopamidol and Ioxilan (six vs five OH), also due to its possession of only one remained modifiable CONH group compared with Iohexol, allowing a possible regioselective derivatization.

Somewhat similar to monosaccharides, Iobitridol has six hydroxyl groups including two 1,3-diol and one 1,2-diol

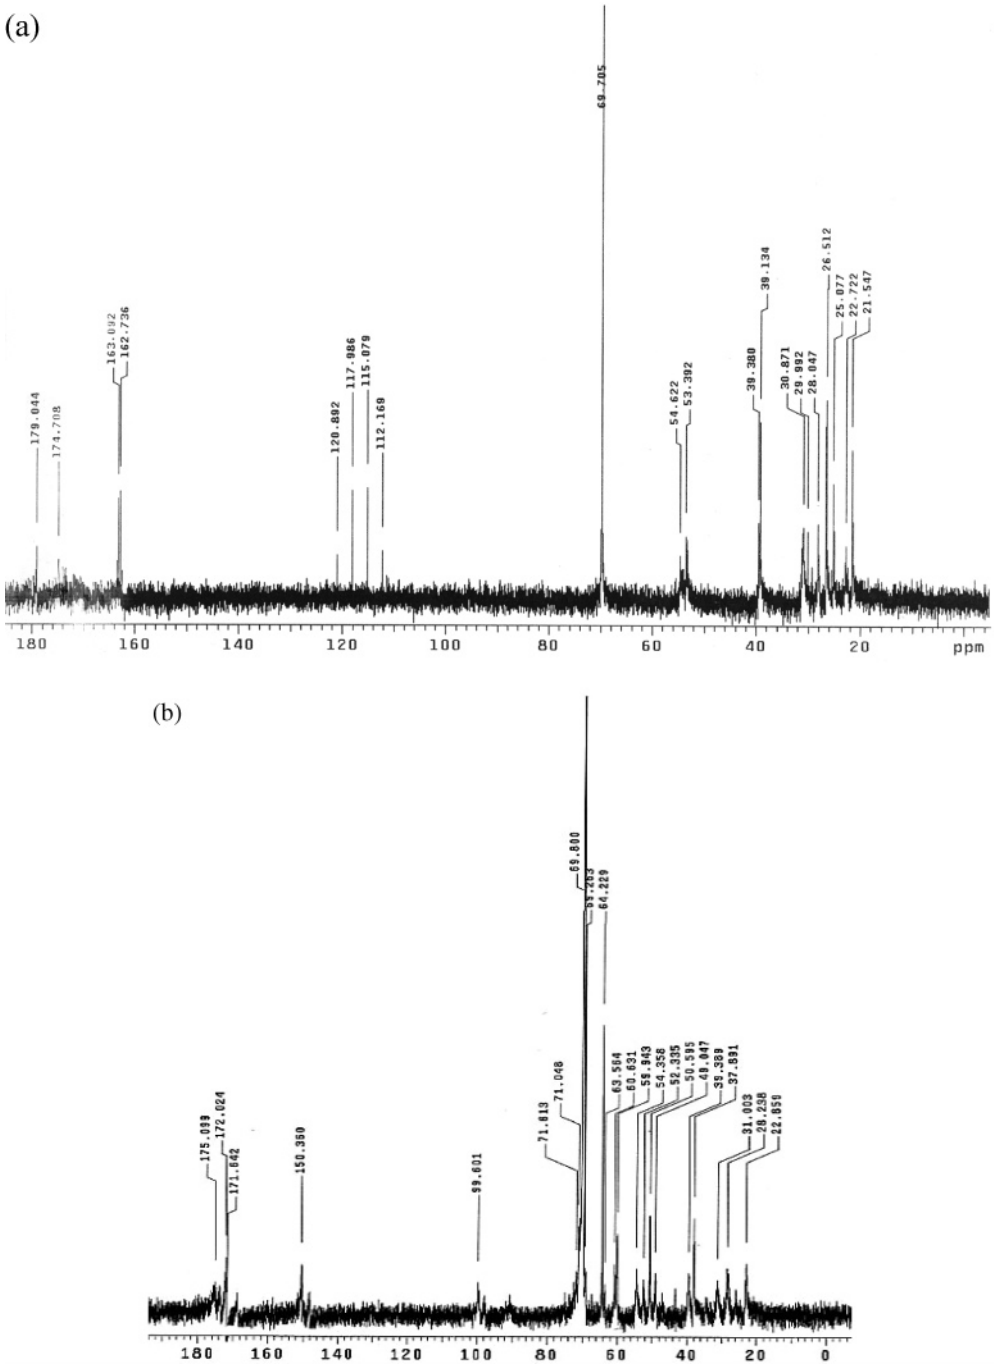

Figure 4. ^{13}C NMR spectra of PEG3400-amide-Gen5 dendrimer **11b** (a, TFA salt) and PEG6000-carbamate-Gen3-IOB conjugate **1a** (b) in D_2O.

structure. It is natural to think of using ketal chemistry to block all hydroxyl groups, leaving the only CONH group exposed for selective modification. Two ketalization approaches, the acetone/$ZnCl_2$ method and the 2,2-dimethoxypropane/*p*-toluenesulfonic acid (DMP/TsOH) method, were compared. The conventional $ZnCl_2$ method requires the use of a large amount of fused zinc chloride (irritant!), a $CHCl_3$ extraction step, and a relatively long time (24 h) since the reaction proceeds in a heterogeneous phase. By contrast, the less common DMP/TsOH method gave a facile and clean ketalization in DMF with a trace amount of TsOH as the catalyst and was also fast (1 h reaction in homogeneous phase) in a superior and near quantitative yield (98% vs 83% after chromatography). Silica gel chromatography was used to remove a minor unknown byproduct ($R_f = 0.90$). The DMP/TsOH ketalization was found complete at 90 °C with a mole ratio of [DMP]/[IOB] = 5. It was found that either a reduction of [DMP]/[IOB] ratio to 3 or a temperature decline to 25 °C led to an incomplete ketalization, yielding an Iobitridol di-isopropylidenyl byproduct identified by ^1H NMR. This byproduct has a lower $R_f = 0.20$ and 0.14, compared to the desired product ($R_f = 0.64$, 0.50). Both compounds showed two highly close spots in TLC essentially due to the well-known aromatic amide isomerism (*22*).

A subsequent amide N-alkylation of **13** is a key step to introduce a spacer between a "triiodo" group and a dendrimer. Various halides were tested as the electrophiles. First, $ClCH_2$-$CH_2OCH_2CO_2Me$ as a flexible spacer molecule was synthesized according to the literature (*23*) and reacted with **13** in the presence of anhydrous K_2CO_3 in DMF, which however did not give a significant amount of alkylation product (yield < 5%) at various temperatures up to 120 °C for a reaction time up to 24 h. Further, TLC showed no significant change even after

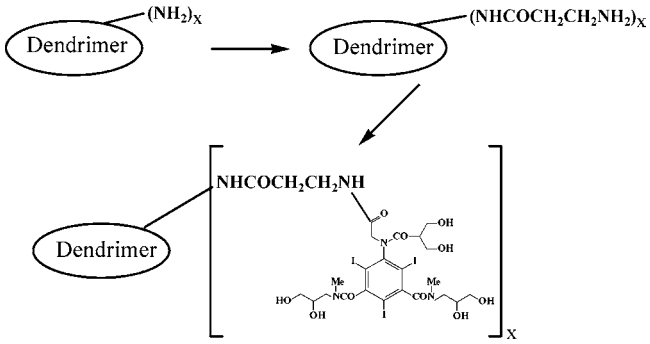
addition of potassium iodide as a catalyst. Alternatively, $ICH_2CH_2OCH_2CO_2Me$ was prepared (*24*) and used for the alkylation with **13** under similar conditions. TLC showed that no reaction virtually occurred. The likely reasons for these failed N-alkylations are that, on one hand, the chloride $ClCH_2CH_2OCH_2CO_2Me$ is not electrophilic enough toward the anion of **13**, and on the other hand, the iodine atom in $ICH_2CH_2OCH_2CO_2Me$ is too bulky and may exert a high steric hindrance effect on the alkylation. Their bromide analogue might be a suitable electrophile here. However, $BrCH_2CH_2OCH_2CO_2Me$ could not be prepared easily by refluxing its chloride analogue with NaBr or KBr. This bromide could be prepared by the reflux of 4-dioxan-2-one with HBr/methanol solution via a ring-opening transesterification, but the method was momentarily abandoned since the highly reactive cyclic ester is difficult to obtain. Alternatively, another simple bromide, $BrCH_2CO_2Et$, was used instead, even though it is not a long spacer molecule, but its N-alkylation with the anion of **13** was proven straightforward and highly efficient. Additionally, $BrCH_2CH_2CO_2Et$ was also tried as an electrophile in the alkylation of **13**, but it was proven unsuccessful probably because a severe β-elimination of the bromide happened under basic conditions, yielding the unwanted ethyl acrylate.

In the N-alkylation using ethyl bromoacetate, other condition variables including the solvent, base, temperature and reaction time were also investigated. Certainly, DMF can be used since it can dissolve both reactants and products. Other aprotic polar solvents with lower boiling points are also tried. For example, acetone/1,4-dioxane (1:1, v/v) or tetrahydrofuran alone worked fairly well. Tetrahydrofuran is preferred due to its easy removal and chemical inertness. The base used in this alkylation is $NaOCH_3$ in methanol. Use of anhydrous K_2CO_3 in DMF as a reaction system also worked well for this alkylation. $NaOCH_3$ method was carried out in the homogeneous phase at room temperature while the K_2CO_3 method conducted in the heterogeneous phase required a higher reaction temperature ($\geq$60 °C). Reaction time is much less for the $NaOCH_3$ method (0.5−1 h) compared to the K_2CO_3 method (16−20 h). Of note, an initial addition of 50% excess of both sodium methoxide and the bromide was helpful for the full conversion of **13**.

The ester **14** obtained above was hydrolyzed in 2.5 h in 1 N NaOH solution (1:1 methanol/water). As expected, the isopropylidene ketal groups were stable at this condition. Subsequent acidification of the hydrolysis product in pH 3.5 citrate buffer produced acid **15** which could be extracted by chloroform. In chloroform the acid **15** was then converted to its *N*-hydroxysuccinimidyl ester which, instead of 4-nitrophenyl ester, is chosen due to its higher reactivity toward the amine.

"Triiodo" derivatives **13**−**16** were characterized by TLC, ESI mass spectra, and ^1H and ^{13}C NMR. As examples, the mass spectra of compound **14** and **16** were given in Figure 2. For each, the molecular ion $(M + H)^+$ peak is the base peak; other characteristic peaks include the $(M + Na)^+$ peak, and the $(M - CH_3COCH_3 + H)^+$ peak, which corresponds to a likely 1,2-epoxy structure produced in ESI process. In ^1H NMR spectra of all these derivatives (see examples in Figure 3), several singlet peaks at 1.3−1.5 ppm indicated the presence of isopropylidene groups (18 H). Peaks at 1.28 and 2.63 ppm belong to the ethyl group in **14**. The peak at ~1.28 ppm disappeared after the hydrolysis of **14**. For compound **16**, the succinimidyl group was indicated by the existence of a peak at ~2.86 ppm (4 H). From **13** through **16**, ^{13}C NMR spectra showed small but consistent changes (position of peaks, number of peaks) with their structure variation in two regions, 20−50 ppm (aliphatic C) and 160−175 nm (carbonyl) (see details in Experimental Section). TLC showed that R_f values were significantly affected by the side chain attached to the aromatic amino N atom. Compared to ketal **13** (0.64, 0.50), esters **14** (0.96, 0.85) and **16** (0.93, 0.80) gave higher R_f values while acid **15** (0.33, 0.20) had a lower R_f value, which agrees well with the polarity change of this N-alkylated side chain. All these "triiodo" derivatives gave two close spots in TLC because isomers exist in each of them owing to restricted rotation along the aromatic amide bond, which is a well-known phenomenon for iodinated CT contrast media (*25*).

Scheme 5. Insertion of a β-Alanine Spacer, between Dendrimer NH_2 and the Triiodo Group, Resulted in Higher Efficiency of Triiodo Conjugation for a Generation-5 Dendrimer (e.g., use of PEG3400-amide-Gen5 dendrimer to synthesize iodinated conjugate 3b-II)



Synthesis and Chemical Characterization of Dendritic Contrast Agents. In the triiodo conjugation step, we added the active ester **16** to the dendrimer solution in two portions with a 24-h interval, which worked better than single addition since a higher degree of IOB-substitution was obtained (in the case of **1a**, 99% vs 92%). The feeding equivalent ratio of [IOB]/[NH_2] has to be sufficient. In the case of PEG6000-Gen4 dendrimer, when this ratio increased from 3 to 4.5, the percentage of amino substitution increased from 87% to nearly 100%. The 72-h coupling reaction was required for Gen3 dendrimer synthesis, while 96-h and 120-h were needed for preparation of Gen4 and Gen5 dendrimers due to increasing steric hindrance effect.

For dendrimers with generation-4 or less, single coupling often gave a high substitution degree close to 100% under specific conditions, while in some other batches incomplete coupling was still found (substitution degree lower than 92%). In the latter cases, a second coupling was recommended and proven useful to minimize the defects of decorated dendrimers to less than 5%. However, Gen5 dendrimer has such high steric hindrance that unsatisfactory amino-substitution degrees (40% and 63%) were obtained after a single coupling, and even a second coupling with IOB (see **3b-I** in Table 2). Thus a spacer arm β-alanyl group was covalently attached to each amino terminus of PEG3400-amide-Gen5 by reacting with the *N*-hydroxysuccinimide ester of t-Boc alanine. After t-Boc deprotection, the resulting β-alanyl-terminated Gen5 dendrimer was subsequently conjugated with the "triiodo" active ester **16** for a single coupling under standard conditions, yielding an iodinated Gen5-dendrimer **3b-II** with a remarkedly higher degree of amino substitution (91.4%) (see Scheme 5 and Table 2).

DMF, a good solvent for both the dendrimers and their iodinated conjugates, was selected as the conjugation reaction medium. Room temperature was adopted and recommended because higher temperatures (>50 °C) caused formation of minor byproducts with higher molecular weights, likely due to intermolecular cross-linking of unreacted lysine chains.

In contrast agent synthesis, the final step, namely the hydroxyl deprotection, was completed in 60% (v%) aqueous TFA solution at room temperature. Other acids such as 2 N HCl in 1:1 methanol/water also worked well.

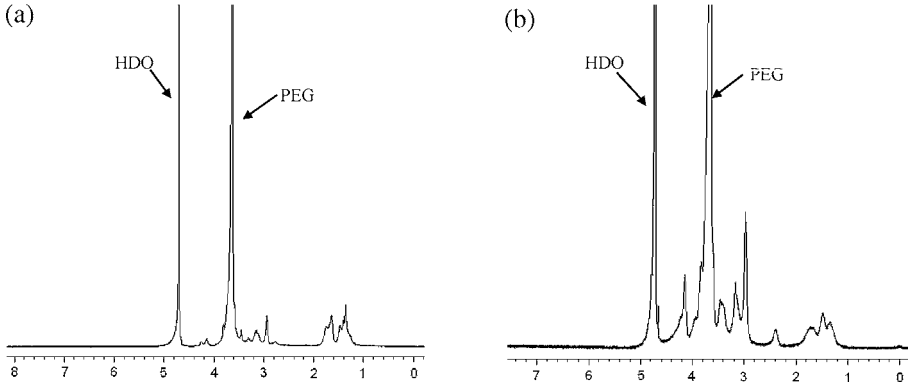


Figure 5. ^{1}H NMR spectra of PEG12000-carbamate-Gen4 **9b** (a, TFA salt) and PEG12000-carbamate-Gen4-IOB **2b** (b) in D_2O.

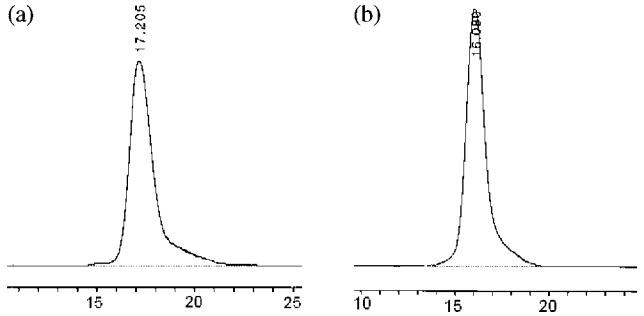

Figure 6. SE-HPLC traces of PEG12000-carbamate-Gen4 polyamine **9b** (a, TFA salt) and PEG12000-carbamate-Gen4-IOB conjugate **2b** (b) on a Superdex 200 column, with flow rate of 0.8 mL/min and each run time of 30 min. Other HPLC conditions: (a) mobile phase 0.1% trifluoroacetic acid and 0.3 M Na_2SO_4 (pH 2.7), UV detection at 210 nm; (b) 0.05 M phosphate and 0.15 M NaCl (pH 7.0), 245 nm.

All synthesized iodinated dendrimers were first dialyzed and then purified by a Sephadex G-100 column eluted with phosphate buffer at pH 7. An alternative mobile phase includes 0.1 M ammonium acetate (pH 7). Excess small molecular iodinated derivatives and seldom found large-molecular cross-linked byproducts were removed efficiently and completely. Analytical SE-HPLC (Figure 6) showed that PEG12000-carbamate-Gen4-IOB gave considerably narrow and symmetric peaks in size exclusion chromatography, indicating a high degree of monodispersity in molecular size. Iodine quantitative analysis (both by UV and elemental analysis), ^{1}H/^{13}C NMR, and UV confirmed that synthesized contrast agents have the expected structure. Both PEG (3.62 ppm in ^{1}H NMR, ~69.7 ppm in ^{13}C NMR) and the iobitridol derivative (NCH_3 at 3.0−3.2 ppm, in ^{1}H NMR, aromatic C in regions of 90−100 ppm and 145−150 ppm in ^{13}C NMR, λ_{max} 245 nm in UV) were present in the final products (Figures 4b and 5b). Due to overlapping of the PEG peak (3.62 ppm) with most IOB side chain peaks (3.2−4.5 ppm), the degree of dendrimer amino substitution could not be determined using the PEG peak. However, the ratio of IOB/lysine can be obtained by comparing the integrals of lysine trimethylene group (1.2−1.8 ppm) and characteristic NCH_3 groups (3.0−3.2 ppm) in IOB. Thus, the degree of dendrimer amino substitution can be calculated; for example, the conjugation degree was 96% in the case of PEG12000-carbamate-Gen4 dendrimer (Table 2). Iodine percentages (w%) measured by UV or elemental analysis agree with these NMR-measured amino substitution results. These data were used to calculate the actual molecular weights of iodinated dendrimer products (Table 2).

To directly measure the absolute molecular weights, MALDI-TOF mass spectrometry of these iodinated dendrimers were tried but failed under varying conditions (different ratios of matrix/sample, different spectrometers in different MS labs). Additionally, two derivatives of PEG12000-carbamate-Gen4-IOB, including its ketal precursor (i.e. the intermediate compound prior to hydroxyl deprotection) and its fully acetylated derivative, were isolated or prepared and then underwent MALDI mass spectral analysis; unfortunately there still were no peaks observed because their protonated ions could not fly under test conditions. Compared with our successful MALDI analyses of the undecorated PEG-core dendrimers, this unexpected difficulty must be due to the existence of a large number of heavy iodine atoms in their structure.

Preliminary Data of Physicochemical Characteristics of Iodinated PEG-Core Dendrimers. The ideal macromolecular CT contrast agent could be defined as being (a) highly efficient in X-ray attenuation, (b) primarily intravascular in distribution, (c) well-tolerated and nonimmunogenic, (d) monodisperse or near-monodisperse in size, (e) eliminated completely in a timely manner, and (f) with certain desired physicochemical properties including high water solubility, low osmolality, limited viscosity, and good stability to autoclave conditions.

The new structures described in this work virtually demonstrated most of these desired features, at least all of those tested in this preliminary study (Table 3). Apparent molecular weight based on protein standards ranged from 35 kDa (PEG3400-amide-Gen4-IOB) to 143 kDa (PEG12000-carbamate-Gen4-IOB) with a high degree of molecular monodispersity (Table 2, polydispersity index $M_w/M_n < 1.04$ for all six compounds), and the ratios between apparent and actual molecular weights were as large as 3.4, indicating that the choice of PEG as the macromolecular backbone substantially increased the molecular hydrodynamic size. The largest one of this series, PEG12000-carbamate-Gen4-IOB, had a CT-assayed blood half-life ($t_{1/2}$) of approximately 35 min (monoexponential kinetics) and an estimated volume of distribution (V_d) of 13%, intermediate between the accepted normal intravascular volume (~5%) and the normal extracellular fluid volume (~25% of the body weight), as reported somewhere else (*11*). Of note, both blood $t_{1/2}$ and V_d might be underestimated due to relatively short time course (~30 min) at dynamic CT. The same compound was tested by SE-HPLC prior to and after heat sterilization, showing identical HPLC traces, and neither inorganic iodide nor iodine was detected in autoclaved solutions. This contrast agent was proven to be highly stable to autoclaving conditions for 30 min at 120 °C. The six synthesized iodinated dendrimers were effective for producing strong X-ray attenuation due to generally high iodine contents (21−36%, w/w). (Table 2).

Water solubility for each of the four compounds tested for this characteristic was >440 mg/mL. These new compounds also showed high levels of hydrophilicity. Butanol−water partition coefficients of the four test compounds were between 0.015 and 0.064, similar to or more hydrophilic than clinically used CT contrast media (Iobitridol, 0.070; Iodixanol, 0.046;

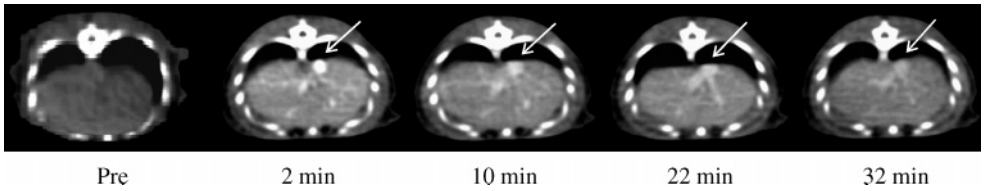

Figure 7. Serial axial CT images of a normal Sprague−Dawley rat at the level of liver prior to, 2, 10, 22, and 32 min after intravenous injection of PEG12000-carbamate-Gen4-IOB as a CT contrast agent at a dose of 450 mg iodine/Kg body weight. Note the strong and persistent enhancement of the inferior vena cava (see the arrows) and other vessels (hepatic veins) within the liver.

Iohexol, 0.055), likely due to the presence of the PEG core. Of note, taking advantage of the so-called "hydrophilic sphere stabilization" effect (*26*), Iobitridol molecules were carefully derivatized, chemically activated, and conjugated to the dendrimer with such a strategy that did not sacrifice any of its six hydroxyl groups upon conjugation. This strategy enabled all attached IOB moieties to remain highly soluble and hydrophilic after conjugation. Our initial attempts to conjugate Ioxilan to the same dendrimers via exploitation of one of its five hydroxyl groups yielded poorly water-soluble iodinated dendrimers, indicating that it is mandatory to keep a sufficient number of hydroxyl groups surrounding the hydrophobic triiodobenzene core so as to retain the required hydrophilicity and solubility of attached "triiodo" moieties (*11*).

The optimal concentration chosen for intravenous use will depend not only on water solubility but also on the viscosity and osmolality of the contrast agent. The viscosity of PEG12000-carbamate-Gen4-IOB was measured to be 11.4 cP (75 mg I/mL, 37 °C), a value considered acceptable for a macromolecular formulation, but higher than viscosity values obtained for conventional small molecular (<2 kDa) contrast agents (6.1 cP for 300 mgI/mL Iohexol; 6.5 cP for 270 mg I/mL Iodixilan) at the same temperature. Osmolality of four tested formulations at 75 mgI/mL concentation ranged from 230 to 310 mOsm/kg water, comparable or superior to certain clinically used formulations (684 mOsm/Kg for Iohexol at 300 mgI/mL, 295 mOsm/Kg for Iodixanol at 270 mgI/mL).

The presence of PEG cores makes the PEG-core dendrimers appear larger than their actual molecular weights, with only one exception of **3b-II** (one with the smallest PEG and highest triiodo content). The apparent molecular weights measured by SE-HPLC at physiological pH were consistent with our prediction: the bigger the PEG core, the larger the apparent molecular weight (or hydrodynamic size) for same-generation iodinated dendrimers, i.e. **3a** < **2a** < **2b**. Also the measured hydrophilicity did increase with the same order when the size of PEG increases. Interestingly, properties of PEG12000-based dendrimers are basically different from those based on PEG6000 and PEG3400; so are Gen4 and Gen5 dendrimers compared with Gen3 dendrimers. Looking at different generations, Gen3, Gen4, and Gen5 dendrimers gave the iodine percentage as high as 27%, 33%, and 36%, respectively; in general, generation-4 seemed the best generation choice for this type of dendrimers.

The PEG-core iodinated dendrimers described in this study are distinctly different from agents now available for clinical use in CT imaging. Iodinated contrast agents currently used and approved are quite similar to each other in design and characteristics. All are small-molecular ones, less than 2 kDa, and all distribute throughout the extracellular fluid (ECF) space, not primarily the intravascular compartment. These ECF agents can be divided into monomeric (e.g., Iohexol, Iopamidol, Iobitridol) or dimeric species (e.g., Iotrolan, Iodixilan). Dissociating "ionic" agents containing carboxylates have generally fallen from favor and are now rarely used clinically. Compared to ECF agents, the macromolecular CT contrast agents for intravascular distribution have been less explored with the exception of emulsion-type contrast agents, represented by perfluorooctyl bromide (PFOB) (*27*). PFOB has been extensively evaluated in preclinical and clinical CT studies, but for unclear reasons its development has been discontinued.

Other efforts to develop water-soluble macromolecular contrast agents (>30 kDa) for CT enhancement have not advanced to the point of warranting clinical trials. Previously reported macromolecular formulations include iodinated hydroxyethyl starch (*28*), carboxymethyl dextran derivatives with triiodobenzoic acid (*29*), and vinyl copolymers from acrylamide and hydrophilic "triiodo" monomer (*30*). Different designs revealed different shortcomings: some were highly heterogeneous in molecular size. For others, radioopacity was low, and some were too viscose, not sufficiently stable, or poorly tolerated. Of note, there were other efforts reported to achieve pegylated long-circulating vesicles including Iopromide-encapsulated liposome (*31*), iodinated triglyceride emulsion (*32*), and iodinated micelles (*33*).

Experimental CT Imaging. As shown in Figure 7, the intravascular CT enhancement in the normal rat through 32 min postinjection of PEG12000-Gen4-IOB (450 mg I/kg dose) was considerably intensive and persistent. Although not shown, it is well-known that for CT imaging obtained after administration of conventional small-molecular contrast media there is exhaustion of the vascular enhancement in less than 5 min. The iodinated PEG-core dendrimers by virtue of their large size remain much longer in the blood pool. The details of the considerable advantages of prolonged intravascular enhancement in CT go beyond the scope of this chemistry-focused report.

For the in vivo CT image enhancement available with iodinated PEG-core dendrimers, only one compound was evaluated in this study as an example. Further characterization studies of this new class of CT contrast agents including pharmacology, metabolism, and the safety profile are ongoing.

CONCLUSION

To summarize, a new design for macromolecular contrast enhancing agents with potential applications in angiographic and dynamic CT imaging has been developed by the synthesis and preliminary testing of six representative compounds. The basic construct consists of a poly(ethylene glycol) core with two dendritic polylysine amplifiers (dendrons) at both PEG termini, to which amplifiers are conjugated multiple "triiodo" moieties. Basically, the desirable characteristics for such a macromolecular contrast agent could be approximated by one or more of these PEG-core dendrimer conjugates. Demonstrated favorable characteristics include prolonged intravascular enhancement in an animal model, adjustable and large apparent molecular weights (35 to 143 kDa), near monodispersity in size, high X-ray attenuation, high water-solubility and hydrophilicity, low osmolality, and good chemical stability. This new class of iodinated dendrimers has good potential in angiography and, more importantly, in quantitative microvascular characterization of a wide variety of diseases and abnormalities including cancer, ischemic injury, inflammation, and altered states of angiogenesis.

ACKNOWLEDGMENT

This work was supported in part by NIH grants CA103850 and CA82923 and by Lucile-Packard Foundation. MALDI-TOF MS and ESI-MS measurements were conducted by the UCSF Mass Spectrometry Facility (Director Dr. A. L. Burlingame) supported by NIH NCRR RR01614. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Varian 400 NMR spectrometer in the NMR Lab, School of Pharmacy at UCSF. Drs. Karl Turetschek and Vincenzo Lucidi are thanked for their generous gifts of Iobitridol. Mr. Jason Kipke, Ms. Christina Hampton, and Ms. Jessica Pfannenstiel are acknowledged for their great assistance in the CT scans.

Gene Transfer with Poly-Melittin Peptides

Chang-Po Chen, Ji-seon Kim, Erin Steenblock, Dijie Liu, and Kevin G. Rice*

Division of Medicinal and Natural Products Chemistry, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242.
Received February 3, 2006; Revised Manuscript Received May 15, 2006

The 26 amino acid hemolytic melittin peptide was converted into a gene transfer peptide that binds to DNA and polymerized through disulfide bond formation. Melittin analogues were synthesized by the addition of one to four Lys repeats at either the C- or the N-subterminal end along with terminal Cys residues. Melittin analogues were able to bind and polymerize on plasmids resulting in the formation of DNA condensates. In the absence of DNA, melittin analogues retained their red blood cell hemolytic potency but were inactive when bound to plasmid DNA. The in vitro gene transfer efficiency mediated by poly-melittin analogues was equivalent to PEI in HepG2 cells. Attempts to truncate portions of either of the two melittin α-helices resulted in concurrent loss of hemolytic potency and gene transfer efficiency. The results demonstrate the ability to transform melittin into a gene transfer peptide by transiently masking its membrane lytic activity by the addition of Lys and Cys residues to promote DNA binding and polymerization.

INTRODUCTION

Nonviral gene delivery systems depend on endosomal lysis to allow DNA to enter the cytosol (*1*−*3*). Two main strategies have emerged to achieve endosomal lysis. The first relies upon endosomal lytic peptides that respond to a lowering of the pH, leading to fusion with the endosomal membrane and lysis (*3*−*7*). The most widely used fusogenic peptides used to enhance gene delivery include the hemolytic peptide (HA2), GALA, and melittin. The second strategy to achieve endosomal lysis relies upon the use of endosomal buffering agents that resist changes in pH leading to osmotic lysis. This is the reported mechanism by which chloroquine, PEI, and polyhistidine achieve enhanced gene delivery (*8*−*10*).

Naturally occurring melittin from bee venom is a 26 amino acid peptide composed of two α-helices joined by an interrupting proline (*11*−*13*). A number of prior studies have examined melittin and its analogues to elucidate the amino acid sequences that are essential to its potent hemolytic and antimicrobial activity (*14*−*16*). Likewise, one prior study examined the hemolytic activity of dimeric melittin formed by disulfide bond formation between terminal Cys residues (*17*). Unlike HA2, which is primarily hemolytic at pH 4 but not 7, the hemolytic activity of melittin is not pH dependent. Consequently, because melittin remains hemolytic at pH 7, its utility for enhancing gene delivery necessitates masking to avoid unintended cell lysis.

Despite this potential limitation, melittin has been examined as an in vitro gene transfer agent to increase endosomal escape of DNA (*3*, *5*, *18*, *19*). Several groups have incorporated a Cys containing melittin into either a lipid or a PEI resulting in a significant improvement in the gene transfer efficiency while simultaneously diminishing melittin's toxicity (*3*, *5*, *19*). An alternate strategy involved masking the hemolytic activity of melittin by reversible derivatization of Lys residues (*18*).

We previously reported that the gene transfer efficiency of short polylysine peptides can be dramatically increased by installing terminal Cys residues resulting in peptide polymerization (*20*, *21*). The multiplication of cationic residues in sulfhydryl polymerized peptides relative to a monomeric peptide results in much greater DNA binding affinity. Likewise, sulfhydryl polymerized peptides are postulated to undergo intracellular reduction to trigger the release of DNA (*22*).

In the present study, we have transformed melittin into a sulfhydryl polymerized peptide and investigated its in vitro gene transfer activity. One of the goals of this study was to investigate how structural modifications in the melittin sequence influence its hemolysis of red blood cells and gene transfer efficiency. The results establish a relationship between melittin hemolytic activity and gene transfer efficiency and provide a means to transiently mask the membrane lytic activity of melittin to enhance gene transfer.

EXPERIMENTAL PROCEDURES

Substituted Wang resin for peptide synthesis, N-terminal Fmoc protected amino acids, 9-hydroxybenzotriazole, diisopropylcarbodiimide, and diisopropylethylamine were obtained from Advanced ChemTech (Lexington, KY). *N*,*N*-Dimethylformamide, trifluoroacetic acid (TFA), acetic anhydride, acetonitrile, and piperidine were purchased from Fisher Scientific (Pittsburgh, PA). Tris(2-carboxyethyl)-phosphine hydrochloride (TCEP) and thiazole orange were obtained from Sigma Chemical Co. (St. Louis, MO). Polyethylene amine (PEI) of 25 KDa was purchased from Aldrich (Milwaukee, WI). D-Luciferin and luciferase from *Photinus pyralis* (EC 1.13.12.7) were obtained from Roche Applied Science (Indianapolis, IN). HepG2, CHO, and COS-7 cells were acquired from the American Type Culture Collection (Manassas, VA). Inactivated qualified fetal bovine serum (FBS) was from Life Technologies, Inc. (Carlsbad, CA). BCA reagent was purchased from Pierce (Rockford, IL).

Peptide synthesis was carried out on an Apex 396 Advanced ChemTech solid-phase peptide synthesizer. Peptidepurification was performed using a semipreparative (10 μm) C_{18} RP-HPLC column from Vydac (Hesperia, CA). Preparative HPLC was performed using a computer-interfaced HPLC and fraction collector from ISCO (Lincoln, NE). Electrospray ionization mass spectrometry (ESI-MS) was performed using an Agilent 1100 Ion Trap LC-MS system.

Synthesis and Characterization of Melittin Analogues. Melittin and its analogues were synthesized using standard Fmoc procedures with 9-hydroxybenzotriazole and diisopropylcarbodiimide double couplings on a 30 μmol scale. Peptides were cleaved from the resin, and side chain protecting groups were removed by reaction with TFA/ethane dithiol/water (95:2.5:2.5 v/v/v) for 3 h. Cleaved peptides were precipitated with cold ether. The precipitate was washed twice with cold ether and dissolved in 0.1% TFA for purification. Peptides were purified to homogeneity on RP-HPLC by injecting 2 μmol onto a Vydac C_{18} semipreparative column (2 × 25 cm) eluted at 10 mL/min with 0.1 v/v % TFA and a gradient of acetonitrile of 20−55 v/v % over 30 min while monitoring tryptophan absorbance at 280 nm. The major peak was collected and pooled from multiple runs, concentrated by rotary evaporation, lyophilized, and stored dry at −20 °C. Purified peptides were reconstituted in 0.1 v/v % TFA (degassed with argon) and quantified by tryptophan absorbance ($\epsilon_{280} = 5600\ M^{-1}\ cm^{-1}$) to determine the isolated yield, which was typically 10−25%.

Purified peptides were characterized by LC-MS by injecting 1 nmol onto a Vydac C_{18} analytical column (0.47 × 25 cm) eluted at 0.7 mL/min with 0.1 v/v % TFA and an acetonitrile gradient of 5−65 v/v % over 30 min. The mass spectral data were obtained in the positive mode.

Circular Dichroism (CD) Spectrometry Melittin Analogues. CD spectra were recorded on a JASCO-J-715 spectra polarimeter in 1 cm path length cells under nitrogen at 25 °C. The spectra were recorded between 200 and 240 nm at a peptide concentration of 10 μM in either 10 mM Na_2HPO_4 pH 7.4 or 40 v/v % TFE (trifluoroethanol) in 10 mM Na_2HPO_4 pH 7.4. The percentage of α-helix structure was calculated as follows: α-helix (%) = $([\theta]_{222} - [\theta]^0_{222})/[\theta]^{100}_{222}$, where $[\theta]_{222}$ is the experimentally observed absolute mean residue ellipticity at 222 nm. Values for $[\theta]^0_{222}$ and $[\theta]^{100}_{222}$, corresponding to 0 and 100% helix content at 222 nm, were estimated to be −2000 and −28 400 deg cm^2/dmol, respectively (*16*). The absolute mean residue ellipticity at 222 nm was calculated using the formula $[\theta]_{222} = 100\ (\theta)/(lcN)$, where (θ) is the observed ellipticity in degrees, l is the optical path length in centimeters, c is the molar concentration of the peptide, and N is the number of residues in the peptide.

RBC Hemolysis by Melittin Analogues. Whole blood samples were obtained from male ICR mice by heart puncture with heparinized 22G needles and collected in conical tubes containing 10 mL of 0.15 M PBS (pH 7.4) prewarmed to 37 °C. The erythrocytes were immediately separated from plasma by centrifugation at 2000 rpm for 2 min, washed three times with 10 mL of PBS, and then diluted to 1.5 × 10^8 cells/mL.

Peptide stock solutions of 15 μM were prepared and serially diluted in a total volume of 100 μL in a MultiScreenHTS BV 96 well plate. Erythrocytes (50 μL, 7.5 × 10^6 cells) were added to the peptide and incubated at 37 °C for 1 h followed by filtration on a Multiscreen vacuum manifold (Millipore Corporation, Billerica, MA). The filtrate was measured for Abs_{415nm} on a plate reader, and the percent hemolysis was calculated relative to complete hemolysis caused by replacing PBS with water. Peptide DNA condensates (5 μg of DNA, 1 nmol of peptide in 100 μL of PBS) were also assayed for hemolysis as described previously.

Formulation of Melittin DNA Condensates. Peptide DNA condensates were prepared by combining 50 μg of DNA in 500 μL of Hepes-buffered mannitol (HBM) (0.27 M mannitol, 5 mM Hepes, pH 7.5) with 5−75 nmol of peptide in 500 μL of HBM while vortexing to create DNA condensates possessing a calculated charge ratio (NH_4^+/PO_{4-}) ranging from 0.1 to 2.4. Peptide DNA condensates were incubated for 1 h at room temperature to allow peptide polymerization.

The particle size of each peptide DNA condensate was determined by quasi-elastic light scattering at a scatter angle of 90° on a Brookhaven ZetaPlus particle sizer. Condensates were analyzed at a DNA concentration of 50 μg/mL in HBM at a stoichiometry of 0.3−0.8 nmol of peptide/μg of DNA corresponding to a charge ratio of approximately 1.5:1 for each. The mean diameter was computed from the diffusion coefficient using a unimodal cumulate analysis supplied by the manufacturer.

Stability of Poly-Melittin DNA Condensates. DNA condensates (50 μL of 50 μg/mL) were formed at 0.9 nmol peptide per μg of pCMVL and incubated at RT for 30 min and then combined with 0−50 μL of 4 M sodium chloride and normalized to 100 μL with HBM to achieve a final sodium chloride concentration of 0, 0.2, 0.4, 0.8, 1.0, and 2.0 M. Each sample was sonicated for 30 s with a 100 W Microson XL-2000 ultrasonic probe homogenizer (Kontes, Vineland, NJ) with a vibrational amplitude of 6 to fragment uncondensed DNA (*23*). DNA condensates were digested with 2.5 μg of proteinase K for 18 h at 37 °C and then electrophoresed on a 1% agarose gel and visualized by ethidium bromide staining.

In Vitro Gene Transfer Using Poly-Melittin DNA Condensates. HepG2 cells (5 × 10^5) were plated on 6 × 35 mm wells and grown to ca. 50% confluency. Transfections were performed in MEM (2 mL/35 mm well) supplemented with 2% FBS, sodium pyruvate (1 mM), and penicillin/streptomycin (100 U and 100 μg/mL). Melittin analogues were combined with pCMVL in HBM to form condensates at a 1.5:1 (N:P) charge ratio. Peptide−DNA condensates (10 μg of DNA in 0.2 mL of HBM) were added dropwise to wells in triplicate. After 6 h incubation at 37 °C, the transfection media were replaced with 10% FBS supplemented culture media.

After 24 h, cells were washed twice with 2 mL of ice-cold phosphate-buffered saline (Ca^{2+}- and Mg^{2+}-free) and then treated with 0.5 mL of lysis buffer (25 mM Tris chloride, pH 7.8, 1 mM EDTA, 8 mM magnesium chloride, 1% Triton X-100) for 10 min at 4 °C. The cell lysates were scraped, transferred to 1.5 mL microcentrifuge tubes, and centrifuged for 7 min at 13 000*g* at 4 °C to pellet cell debris. Luciferase relative light units were measured by a Lumat LB 9501 (Berthold Systems, Germany) with 10 s integration after automatic injection of 100 μL of 0.5 mM D-luciferin. The relative light units were converted to fmol using a standard curve generated by adding a known amount of luciferase to 35 mm wells containing 50% confluent HepG2 cells. The resulting standard curve had an average slope of 8.4 × 10^4 relative light units/fmol of enzyme. Protein concentrations were measured by a BCA assay using bovine serum albumin as a standard (*24*). The amount of luciferase recovered in each sample was normalized to milligrams of protein and reported as the mean and standard deviation obtained from triplicate transfections.

PEI pCMVL complexes were prepared by mixing 50 μg of DNA in 500 μL of HBM with 60 μg of PEI in 500 μL of HBM while vortexing to create DNA complexes possessing a charge ratio (NH_4^+/PO_4^-) of 9:1. HepG2 cells were transfected with 10 μg of PEI-DNA condensates as described previously. COS-7 and CHO cells (1 × 10^5) were plated on 6 × 35 mm wells and grown to ca. 50% confluency and then transfected as described previously.

The toxicity of melittin analogues was evaluated by MTT assay (*25*). Briefly, HepG2, COS-7, and CHO cells were plated on 6 × 35 mm wells at 3 × 10^5 cells/well and grown to 40−70% confluency. The culture media were replaced with 2 mL of fresh MEM supplemented with 2% FBS and 3 μM melittin analogues. After 6 h of incubation, the media was replaced with fresh culture media and grown for an additional 18 h. The media was replaced with 2 mL of fresh media and 500 μL of 0.5%

[a] Calculated and observed mass. [b] RBC hemolytic activity at pH 7.4 and 4.5. [c] Salt concentration above which the peptide dissociates from DNA determined by gel electrophoresis as illustrated in Figure 2. [d] Mean particle size of peptide DNA condensates as determined by QELS. [e] Mean zeta potential determined in 5 mM Hepes, pH 7.4.

(w/v) 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) in PBS solution and then incubated for 2 h to let formazan crystals form. The crystals were dissolved by adding 2 mL of dimethyl sulfoxide (DMSO) and then measured spectrophotometrically at 595 nm on a microplate reader (Bio-Rad, Bethesda, MD). The percent viability was determined relative to untreated cells.

RESULTS

Melittin is a well-characterized α-helical membrane disrupting peptide derived from bee venom. Its utility in enhancing PEI mediated gene transfer has been previously established (*3*, *19*). To investigate its potential utility for gene transfer, the hemolytic activity of melittin has been transiently masked by reversible N-acetylation (*18*). On the basis of these results, we proposed the transient masking of melittin's hemolytic activity by controlling its reversible binding to plasmid DNA. This would potentially mask the hemolytic activity of melittin until released intracellularly following disulfide bond reduction.

Natural melittin possesses six positively charged amino groups that are insufficient to mediate strong binding to DNA to form stable condensates. Therefore, we prepared a series of melittin analogues supplemented with additional Lys residues to endow it with the ability to bind and condense plasmid DNA. To facilitate DNA binding, one to four Lys residues were added to the N-terminus or C-terminus of melittin (Table 1). In addition, each melittin analogue was equipped with N- and C-terminal Cys residues to encourage melittin disulfide polymerization on DNA. We anticipated that polymeric melittin should possess a higher DNA binding affinity due to the larger number of amines per molecule.

The hemolytic activity of melittin analogues was evaluated using mouse blood cells as a primary screen. Dose−response curves revealed that natural melittin (M0) possessed an HL_{50} (hemolytic activity of 50%) of approximately 1.5 μM at pH 7.4 (Figure 1), whereas M0 was 4-fold less active at pH 4.5. Importantly, the combination of M0 and DNA resulted in hemolytic activity at pH 7.4 that was indistinguishable from M0 alone (Figure 1), suggesting that M0 failed to bind to DNA.

Comparison of the results of M0 with a melittin peptide endowed with C- and N-terminal Cys residues (M1) established an $HL_{50} = 3$ μM at pH 7.4 and 1 μM at pH 4.5. In contrast to M0, there was nearly a complete loss of hemolytic activity in the presence of DNA up to 5 μM peptide, followed by a recovery of activity at higher concentrations of peptide (Figure 1). This result suggested that M1 was able to weakly bind and polymerize on DNA, resulting in its lack of hemolytic activity below 5 μM.

To enhance the ability of melittin to bind DNA, analogues were prepared by adding additional Lys residues to the N-terminal side of the peptide, considering that the endogenous KRKR sequence in melittin would likely be sufficient to promote DNA binding near the C-terminal and encourage disulfide bond formation with a neighboring peptide. The addition of one to four N-terminal Lys residues (Table 1, M2−M5) resulted in up to a 5-fold decrease in hemolytic activity relative to M0 but simultaneously afforded increased DNA binding affinity as determined by gel electrophoresis as described next.

Melittin analogues were also prepared with two to four Lys residues added to both the N- and the C-subterminal end of melittin, along with terminal Cys residues. Comparison of the hemolytic activity for melittin analogues possessing two, three, or four N- and C-subterminal Lys residues (M6, M7, and M8) established that each was slightly less potent than M0 (Table 1).

Comparison of the hemolytic activity of peptides M0−M8 at pH 4.5 revealed that only M0 and M1 possessed significant activity at low pH, whereas M2−M8 were inactive. Interestingly, M1, which possessed terminal Cys residues, was more potent in hemolysis at pH 4.5 as compared to native melittin (M0) (Table 1).

The hemolytic activity of M2−M8 at pH 7.4 was masked when the peptides were combined with DNA as illustrated for M6 (Figure 1). This result can be rationalized by considering the binding properties of M0−M8 with DNA using a gel based assay as illustrated in Figure 2 (*20*, *21*). Agarose gel electrophoresis revealed peptide protection of the DNA from sonication until a critical salt concentration, at which the peptide dissociates and DNA is fragmented. The results established that M0 dissociates from DNA between 0 and 0.2 M sodium chloride (Figure 2A, lane 2), whereas M6 binds and polymerizes on DNA, resulting in condensates that are stable up to 0.4 M sodium chloride (Figure 2B, lane 6). A similar result was

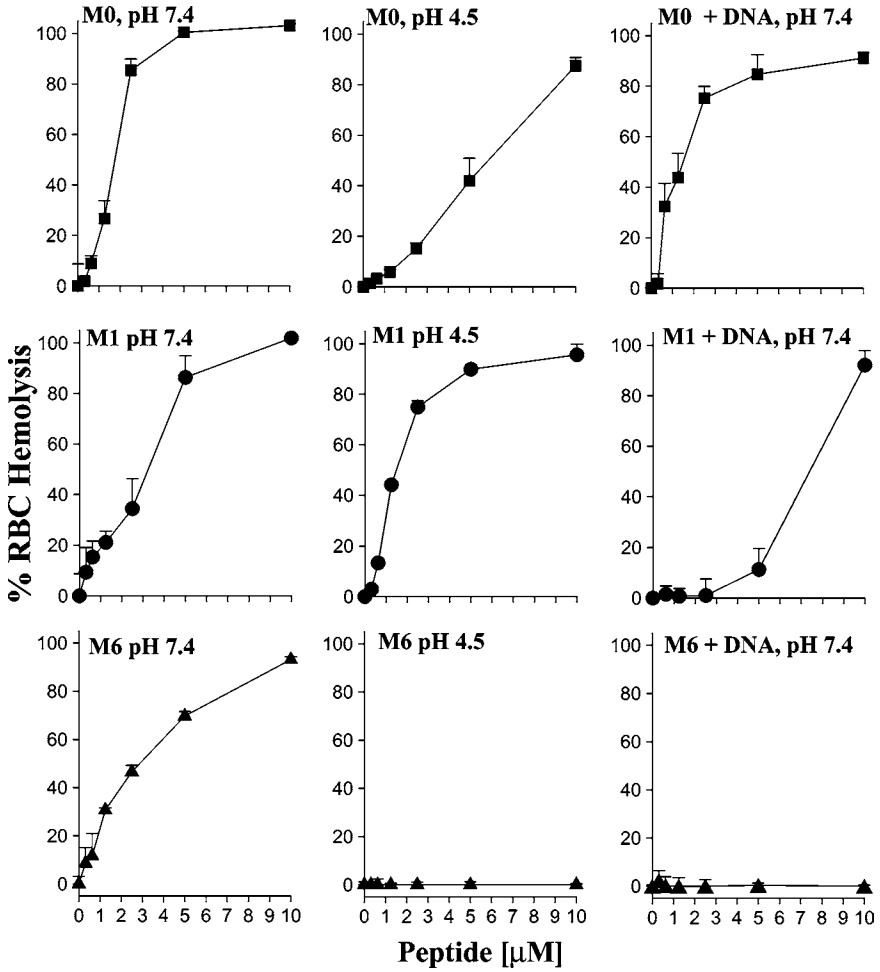

Figure 1. Hemolysis activity of melittin analogues and melittin DNA condensates. The RBC hemolytic activity of melittin (M0) and melittin analogues (M1 and M6) are compared at pH 7.4 and 4.5 and when bound to DNA at pH 7.4. The results illustrated in the left panels indicate that M0 is able to lyse RBCs with HL_{50} of 1.5 μM at pH 7.4, as compared to M1 and M6 with HL_{50} of 3.0 and 2.5 μM. At pH 4.5 (middle panels), M0 is less potent (HL_{50} of 6 μM), whereas M1 has an HL_{50} of 1 μM and M6 is inactive. When combined with plasmid DNA at pH 7.4 (right panels), M0 retains its hemolytic activity, M1 is reduced to HL_{50} of 8 μM, and M6 is completely inactivated.

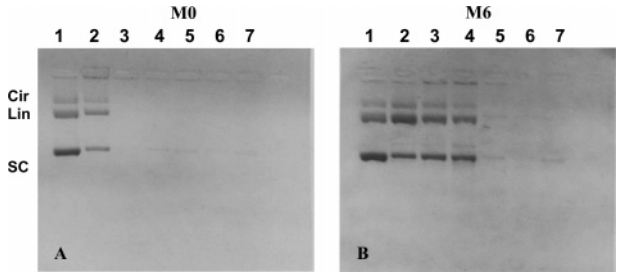

Figure 2. Stability of melittin DNA condensates. The stability of melittin DNA condensates was analyzed by gel electrophoresis following 30 s sonication in the presence of increasing concentrations of sodium chloride. Lanes 1−7 represent DNA standard (1) and peptide−DNA in 0 (2), 0.2 (3), 0.4 (4), 0.8 (5), 1.0 (6), and 2.0 M (7) sodium chloride, respectively. In panel A, M0 was only able to protect DNA during sonication at 0 M sodium chloride (lane 2) but not at 0.2 M (lane 3), whereas in panel B, M6 was able to polymerize on DNA and stabilized condensates up to 0.4 M sodium chloride (lane 4).

observed for peptides M2−M8, all of which demonstrated the ability to bind and polymerize on DNA and thereby protect it from sonication in 0.4 M sodium chloride or higher (Table 1). These data establish that melittin analogues with four or more additional Lys and terminal Cys residues bind and polymerize on DNA, thereby masking their hemolytic activity.

A second series of shorter melittin analogues was prepared in an attempt to truncate either the C- or the N-terminal α-helix while retaining hemolytic activity. To evaluate which of the two α-helices was most active, analogues were prepared that eliminated either two, four, six, eight, or 10 amino acids from the N-terminal α-helix of M8. The hemolytic potency of M9 and M10 established that most of the activity could be retained after deletion of four residues but that further deletion of six, eight, or 10 N-terminal melittin residues (M 11, M12, and M13) abolished hemolytic activity (Table 1).

A melittin analogue (M14) possessing a full-length N-terminal α-helix sequence with a deletion of six amino acids from the C-terminal α-helix retained modest hemolytic activity (Table 1). However, deletion of seven, eight, nine, or 10 amino acids from the C-terminal α-helix (M15, M16, M17, and M18) resulted in complete loss of hemolytic activity (Table 1). In addition, the hemolytic activity of melittin analogues was not influenced by the addition of 1 mM DTT, suggesting that the monomeric peptides were the primary form active in hemolysis.

The conformation of melittin peptides was examined by CD spectroscopy acquired in 10 mM sodium phosphate, pH 7.4, containing 40% TFE in an attempt to mimic a membrane environment (*16*). Representative hemolytic peptides M0, M6, and M14 each produced coincident CD spectra calculated to be 80% α-helical (Figure 3). In contrast, M11, which was devoid of hemolytic activity, produced a CD spectrum consistent with a random coil (Figure 3). These results are representative of the data obtained in each of the peptides in the series.

The particle size of each poly-melittin DNA condensate was evaluated using quasi-elastic light scattering at a constant charge

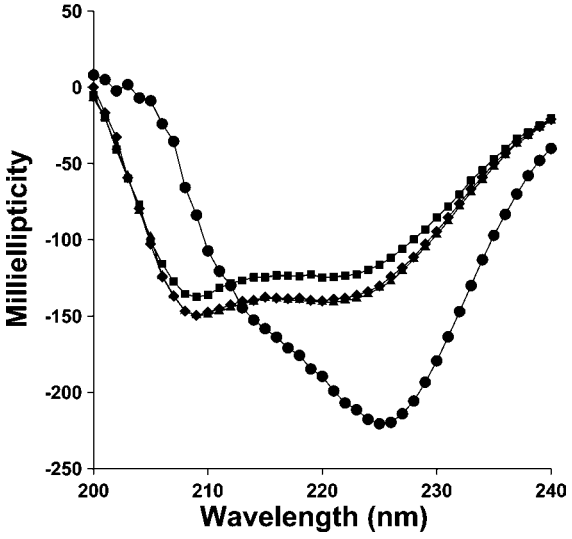

Figure 3. Circular dichroism of melittin analogues. The CD spectra of M0 (▲), M6 (◆), M11 (●), and M14 (■) acquired in 40% trifluoroethanol (v/v) in 10 mM pH 7.4 phosphate buffer at 25 °C are compared. The results establish that M11 was unable to form an α-helix, thereby accounting for its lack of hemolytic activity and gene transfer efficiency.

ratio of 1.5:1 (N:P). M0−M7 formed large DNA condensates >1 μm in mean diameter (Table 1). Alternatively, M8−M18 condensed DNA to form smaller condensates of a mean diameter of approximately 200−300 nm.

Poly-melittin DNA condensates were evaluated for their in vitro transfection activity in HepG2, COS-7, and CHO cells using PEI and $CWK_{17}C$ (*20*) to bracket the level of gene expression with (PEI) and without ($CWK_{17}C$) endosomal escape. In all three cell lines, M0 DNA failed to produce measurable luciferase expression, which was due to its cellular toxicity as demonstrated by MTT assay. In contrast, M1 mediated equivalent gene expression as $CWK_{17}C$ in CHO and COS 7 and was 10-fold more efficient in mediating gene expression in HepG2 (Figure 4). The cellular toxicity of M0 DNA (<20% cell viability) by MTT assay, in comparison to that determined for M1−M18 DNA (>70% cell viability), supports the hypothesis that DNA binding transiently masks the membrane lytic activity of melittin analogues.

Comparison of the relative luciferase gene expression mediated by M1−M8 in all three cell lines established a general trend in which melittin analogues were either equivalent or 10-fold more potent than $CWK_{17}C$. Within the series, M3 and M6 demonstrated the most potent activity in HepG2 cells, which was equivalent to the gene transfer mediated by PEI (Figure 4).

Comparison of the gene transfer efficiency of M1−M8 with deletion peptides M9−M13 established a loss of activity for M9−M13 in all three cell lines that was coincident with the loss of hemolytic potency (Figure 4). The partial recovery of gene transfer activity for M14 was coincident with its ability to produce hemolysis (Figure 4 and Table 1). Likewise, the decreased gene transfer activity for deletion peptides M15−M18 was coincident with the lack of hemolytic activity for these truncated melittin peptides (Figure 4 and Table 1).

DISCUSSION

One of the rate-limiting steps in gene delivery is the efficient escape of DNA from targeting lysosomes. To facilitate this process, fusogenic peptides have been incorporated into gene delivery carriers in an attempt to mimic the process used by viruses. A recent example emphasizes an important directionality

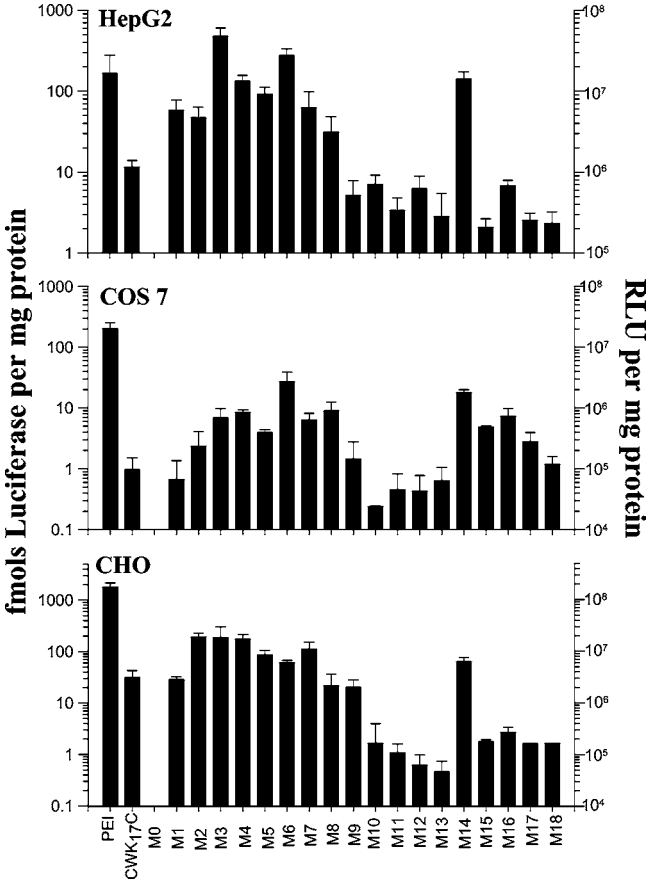

Figure 4. In vitro gene transfer of melittin analogue DNA condensates. Transfections were performed with a peptide DNA charge ratio of 1.5:1. The luciferase reporter gene expression was measured in HepG2 (A), COS-7 (B), and CHO (C) cells at 24 h. PEI and $CWK_{17}C$ mediated gene delivery were used as positive controls. The results represent the mean and standard deviation for three independent transfections.

in linking melittin into a gene delivery system. In this study, it was found that linking melittin to PEI through its C-terminus improves its activity relative to linking through the N-terminus (*19*).

In the present study, we attempted to evolve melittin into a sulfhydryl polymerized peptide, considering that its potent membrane lytic properties could potentially be transient while bound to DNA. We further considered that a sulfhydryl polymerized melittin analogue could potentially be adapted for in vivo use by incorporating it into a nonviral gene delivery system through copolymerization with Cys containing peptides (*26*). One potential difficulty in using melittin for this purpose would be its cytotoxicity, since unlike HA2, it is highly hemolytic at pH 7.

In order for a peptide to be active in nonviral gene delivery, it must bind and condense DNA, usually through cationic interactions. Although melittin has six cationic residues, we have previously shown that polycations of a minimum of 13−18 are usually necessary to fully condense DNA and mediate gene transfer in vitro (*27*). Fewer cationic groups result in DNA condensates that are large (>1 μm) and dissociate at physiological salt concentrations (0.15 M) (*23*). The results of the gel electrophoresis assay (Figure 3) demonstrate this effect for M0 binding to DNA to form large condensates that dissociate between 0 and 0.2 M sodium chloride. Dissociation at this salt concentration would release M0 from ionic binding to DNA and explains why M0 DNA results in red blood cell lysis (Figure 1). These results also explain the lack of gene transfer activity and the cytotoxicity observed by M0 DNA in three cell lines (Figure 4).

It was possible to decrease the cellular toxicity of M0 by the addition of C- and N-terminal Cys residues resulting in M1. This modification leads to the improved salt stability of M1 DNA condensates (Table 1), indicating that the peptide is able to polymerize on DNA. Polymeric M1 displays weaker hemolysis activity when bound to DNA and an increase in gene transfer potency. The further addition of one to four Lys residues on the N-terminal side of melittin (M2−M5) or two to three Lys residues on both the C- and the N-terminal (M6 and M7) did not increase polymerization as measured by gel electrophoresis (Table 1). DNA condensates prepared with M1−M7 were large (>1 μm) and possessed a relatively low zeta potential (+5 mV). The large particle size was most likely the result of particle coalescences initiated through interaction of hydrophobic domains on melittin peptides. Nonetheless, M1−M7 possessed significant hemolytic activity, and M3 proved to be one of the most potent gene transfer peptides in the series. The addition of four Lys residues to the C- and N-subterminal to form M8 led to a more complete polymerization on DNA as revealed by dissociation above 0.8 M sodium chloride (Table 1). Despite a decrease in particle size for M8 DNA to approximately 0.3 μm (Table 1), the gene transfer efficiency was not increased (Figure 4).

Attempts to truncate a portion of either the N- or the C-terminal α-helix revealed a relationship between hemolytic activity and gene transfer activity. Only M14, in which KRKR QQ was deleted and replaced with a tetra Lys and terminal Cys, was able to mediate gene transfer activity comparable to full-length melittin analogues. This was likely because the QQ was unnecessary, and the KRKR substituted for KKKK.

The results of this study demonstrate the conversion of a hemolytic peptide into a DNA condensing peptide. We hypothesize that melittin analogues function by depolymerizing in the reducing environment inside the cell, resulting in the release of DNA. The neutralization of hemolytic activity when melittin analogues bind and polymerize on DNA appears to protect cells from cytotoxicity and facilitate gene transfer. This strategy should be useful to evolve many different fusogenic peptides into sulfhydryl polymerized peptides to positively influence nonviral gene delivery.

A Mixed-Phase Immunoassay Based on Simultaneous Binding of Fluorescently Tagged and PNA-Conjugated Peptide Epitopes on Antibodies: Quantification on PNA-Coated Microparticles

Kaisa Ketomäki* and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received February 7, 2006; Revised Manuscript Received June 9, 2006

A mixed-phase immunoassay based on simultaneous binding of an antibody to its fluorescently tagged peptide epitope and a PNA conjugate of the same peptide has been developed. As a fluorescent marker, a europium(III) chelate allowing time-resolved measurement from a single particle has been employed. The ternary complex formed in solution is immobilized by Watson−Crick base-pairing to a microparticle bearing a PNA sequence complementary to that present in the complex. The concentration of the antibody in the sample may then be determined by a single particle measurement. Accordingly, different antibodies may in principle be addressed by sequence-specific hybridization to different categorized microparticles.

INTRODUCTION

High density peptide microarrays have received increasing interest as a highly potent analytical construct for high-throughput screening of peptide−protein interactions (*1*−*4*). Such arrays, obtained by parallel light-directed assembly of peptide chains on a glass surface (*4*−*9*) or by covalent immobilization of prefabricated peptides to an appropriately activated support (*1*, *10*−*16*), have been applied to detection of antibodies from biological samples (*1*, *14*, *15*), epitope screening of antibodies (*8*), determination of enzyme activitities (*1*, *11*, *12*, *16*−*19*), and studies on adhesion of cells to peptides (*1*, *20*). While the efficiency of high density microarrays in high-throughput screening undoubtedly is unbeatable, their superiority in assays where accurate quantification of a limited number of antibodies plays a key role is not as self-evident. For the latter purpose, categorized microparticles as a solid phase and lanthanide chelates as photoluminescent labels offer a competitive alternative (*21*). The applicability of this methodology to both immunoassays (*22*−*24*) and oligonucleotide hybridization (*25*−*29*) has been previously established. Lanthanide chelates as markers allow application of a time-resolved mode in the measurement of the fluorescence emission, and hence the prompt background fluorescence may be effectively eliminated. Of even greater importance is that these markers do not suffer from concentration quenching, owing to large difference between the wavelength of excitation and emission. For this reason, the linear dynamic range of emission is over 6 orders of magnitude. On using a microfluorometer equipped with a microscope, the fluorescence emission can be measured from a single microparticle in a reproducible manner. This allows a multiplexed assay based on a suspension array of categorized microparticles (*30*). We now report on a novel assay format for quantification of antibodies, the principle of which is depicted in Scheme 1. Antibody **A** is allowed to form in solution a ternary complex **D** with its fluorescently tagged epitopic peptide **B** and a PNA-conjugate **C** of the same peptide. This ternary complex may then be immobilized by hybridization to a microparticle coated with a PNA[1] sequence complementary to that in conjugate **C** and the intensity of the fluorescence emission is determined by time-resolved fluorometry. A related approach has previously been applied to conversion of an oligonucleotide microarray to spatially addressable arrays of small molecules and used for functional proteomic profiling (*31*). The advantage of the assay described in Scheme 1 is that covalent labeling of the antibodies is avoided. In case a large number of samples are analyzed, the same prefabricated peptide conjugates may be used for quantification of each sample. The present study is aimed at demonstrating the feasibility of such an approach. Three cardiac antibodies, generally used for detection of peptides as markers for cardiac diseases, are now employed as analysts (**A**) and their epitopic peptides as fluorescently tagged (**B**) and PNA conjugates (**C**) for detection and capture probes, respectively.

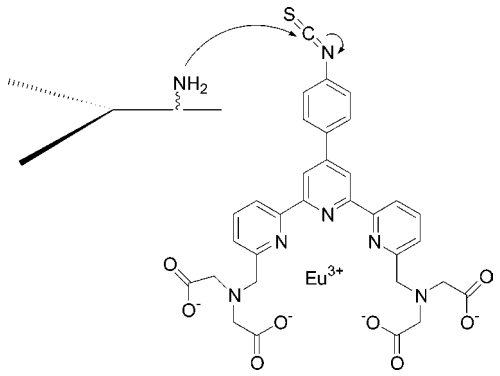
[a] The sequences are given from the amino terminus (left) to the carboxamide terminus (right). [b] ⟨Eu⟩ stands for the photoluminescent europium(III) chelate attached to the mercapto group of the C-terminal cysteine residue. For the structure, see Scheme 4. [c] PNA stands for the sequence H-AGTGATCTAC-Cys-NH_2, given from the amino terminus (left) to the carboxamide terminus (right). For the structure, see Scheme 5. [d] By ESI-TOF mass spectrometry. [e] For **1**−**3** and **7**−**10**, buffer A: 0.1% TFA/H_2O, buffer B: 0.1% TFA/MeCN; linear gradient 0−70% B in 30 min; ThermoHypersil HyPURITY C-18 column (4.6 mm × 150 mm, 5 μm). For **4**−**6**: buffer A: 20 mmol L^{-1} TEAA; buffer B: 20 mmol L^{-1} TEAA + 65% MeCN; linear gradient 5−100% B in 30 min; ThermoHypersil C-18 column (4.6 mm × 250 mm, 5 μm).

were conducted by HOBt/DIC activation in NMP. The crude products were purified by RP HPLC on a ThermoHypersil HyPURITY C-18 column (4.6 mm × 150 mm, 5 μm). A linear gradient from 0.1% TFA in water to 0.1% TFA in 70% aq MeCN in 30 min was applied. The peptides were characterized by ESI-TOF mass spectrometry. Table 1 lists the sequences, observed and calculated molecular masses, and the HPLC retention times for the peptides (**1**−**3**, **10**) prepared.

Preparation of Peptide- and PNA-Coated Microparticles. The beads employed as a solid-phase in the mixed-phase assays were uniformly sized (59 μm) polymer particles of SINTEF (Norway). They were made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethylacrylate (60%) and were functionalized with primary amino groups (1 mmol g^{-1}). The particles were modified for attachment of peptides or PNA probes by acylating the amino groups with sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC; Pierce) (step 1 in Scheme 2). This was achieved by incubating the particles with a 5-fold molar excess of sulfo-SMCC in DMF at room-temperature overnight. After repeated washings, the unreacted amino functions were capped with Ac_2O in pyridine using NMI as a catalyst. Peptides **1**−**3** and **10** (20 nmol), containing an C-terminal Cys residue, were incubated with the maleimido-functionalized particles (2 mg) in water at room-temperature overnight (step 2 Scheme 2). After repeated washings, the unreacted maleimido groups were capped with hexanethiol in 1,4-dioxane (45 min) and the particles were washed. The PNA probe, H-GTAGATCACT-Cys-NH_2 (MedProbe, Norway), was immobilized similarly through the C-terminal cysteine residue.

Antibody Labeling. Monoclonal mouse anti-cardiac troponin I (anti-cTnI) clone 19C7, monoclonal mouse anti-NT-proBNP clone 29D12 and monoclonal mouse anti-NT-proBNP clone 15-C4 (products of HyTest, Finland) were labeled with {2,2′,2″,2‴-{[4′-(4‴-isothiocyanatophenyl)-2,2′:6,2″-terpyridine-6,6″-diyl]bis(methylenenitrilo)}tetrakis(acetato)}europium(III) (*32*) (Scheme 3). For this purpose, the antibody was incubated with

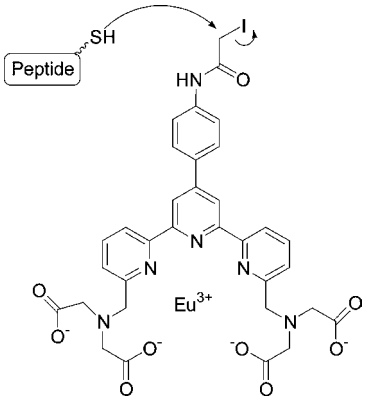
Scheme 3



a 30-fold molar excess of the chelate in a 50 mmol L^{-1} HCO_3^-/CO_3^{2-}-buffer (pH 9.8) at room-temperature overnight (in dark). The labeled antibody was purified from the excess of the chelate by gel filtration on a Superdex75 column (Pharmacia Biotech). A Tris-HCl buffer (50 mmol L^{-1}, pH 7.5) containing NaCl (0.39 mol L^{-1}) and NaN_3 (7.7 mmol L^{-1}) was used as an eluent. The labeling degree of the antibody varied from 2.1 to 4.4 Eu^{3+} ions per antibody molecule, when assayed according to the DELFIA protocol (*33*) against a Eu^{3+} calibration solution.

Peptide Labeling. The antibody specific peptides (**1**−**3**) were labeled to the C-terminal Cys residue with {2,2′,2″,2‴-{[4′-(4‴-iodoacetamido)-2,2′:6,2″-terpyridine-6,6″-diyl]bis(methylenenitrilo)}tetrakis(acetato)}europium(III). The peptide was incubated with a 3.5-fold molar excess of the chelate in a 50 mmol L^{-1} HCO_3^-/CO_3^{2-}-buffer (pH 8.5) at room-temperature overnight in dark (Scheme 4). The crude product was purified on an RP HPLC ThermoHypersil C-18 column (4.6 mm × 250 mm) eluting with a TEAA buffer: buffer A 20 mmol L^{-1} aq TEAA, buffer B 20 mmol L^{-1} aq TEAA containing 65% MeCN (*v*/*v*), a linear gradient from 5% to 100% B in 30 min. The conjugates obtained (**4**−**6**) were characterized by ESI-TOF mass

Scheme 4



spectrometry. The observed and calculated molecular masses and the HPLC retention times are given in Table 1.

Preparation of Peptide−PNA Conjugates. A PNA probe complementary to that immobilized in particles, i.e. H-AGT-GATCTAC−Cys-NH_2 (MedProbe, Norway), was converted to a maleimido conjugate with 1,8-bis(maleimido)triethyleneglycol ($BM[PEO]_3$, Pierce) (Scheme 5). 15 nmol (40 μg) of PNA and 1.6 μmol (0.5 mg) of $BM[PEO]_3$ were incubated in 10 mmol L^{-1} phosphate-buffer (pH 6.7) at 37 °C for 2 h. The conjugate was purified on a RP HPLC ThermoHypersil HyPURITY C-18 column (4.6 mm × 150 mm, 5 μm) eluting with 0.1% TFA: buffer A 0.1% aq TFA, buffer B 0.1% TFA in MeCN, linear gradient from 0 to 70% B (*v*/*v*) in 30 min. The purified PNA−maleimido conjugate was incubated with the peptide (67 nmol; 0.1 mg) in 10 mmol L^{-1} phosphate buffer (pH 6.7) at 37 °C for 2 h. The PNA−peptide conjugate obtained was purified as described above for the PNA-maleimido conjugate. The identity of the conjugates (**7**−**9**) was verified by ESI-TOF mass spectrometry. The mass spectrometric and chromatographic data is given in Table 1.

Assays with Peptide-Coated Particles. Immunoassays with peptide-coated particles were carried out in Tris-HCl-buffer (50 mmol L^{-1}, pH 7.5) containing 0.5 mol L^{-1} NaCl and 0.01% Tween 20. Labeled antibody was shaken with 50 particles (Rotamix, 15 rpm) in 50 μL of the buffer room-temperature overnight and washed with a DELFIA-wash buffer (8 × 200 μL). A single particle was subjected to a time-resolved fluorescence measurement (*21*). The time-resolved channel was adjusted to count the emission over a time window of 300 μs after a delay of 600 μs from the beginning of the excitation pulse and 1000 excitations were integrated in one measurement. Each measurement was repeated with 10 particles to eliminate the influence of random variation. The measurements with a mixture of an unlabeled antibody and fluorescently labeled peptide (**4**−**6**) were carried out similarly.

Assays with Peptide−PNA Conjugates. Immunoassays with PNA−peptide conjugates (**7**−**9**) were carried out in Tris-HCl-buffer (10 mmol L^{-1}, pH 7.5) containing 0.01% Tween 20, the total volume being 10 μL. The PNA−peptide conjugate, unlabeled monoclonal antibody, and fluorescently labeled peptide (**4**−**6**) were shaken (Rotamix, 15 rpm) at room-temperature overnight. Fifty particles coated with a PNA probe complementary to the sequence of the PNA−peptide conjugate were added, and the shaking was continued overnight. The particles were washed with Tris-HCl-buffer (10 mmol L^{-1}, pH 7.5, 4 × 200 μL) and subjected to a single particle time-resolved fluorescence measurement described above.

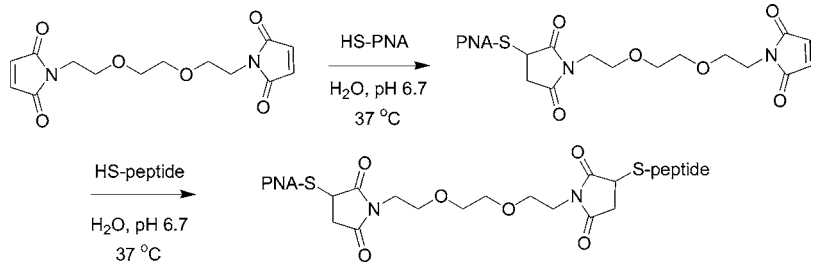
RESULTS AND DISCUSSION

PNA− and Peptide-Coated Microparticles. To construct a mixed-phase assay setup depicted in Scheme 1, PNA-coated microparticles were prepared. Uniformly sized (59 μm) amino-functionalized (1 mmol g^{-1}) porous particles that were made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethylacrylate (60%) and had an average pore size of 50 nm and a surface area of 92 m^2 g^{-1} were used for the purpose. The amino groups were acylated with sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate, as depicted in Scheme 2, and the unreacted amino groups were carefully capped by acetylation. A mercapto-functionalized PNA bearing a C-terminal cysteine residue, H-GTAGATCACT-Cys-NH_2, was then immobilized to the particles by allowing the mercapto function to react with the support-bound maleimido groups. The remaining maleimido groups were capped with hexanethiol. Particles bearing antibody-specific peptides instead of PNA probes were prepared for comparative purposes. They were obtained as the PNA-coated particles using Cys-derivatized epitopic peptides (**1**−**3**).

Binding of Antibodies to Particle-Bound Peptides. To verify that peptides **1**−**3** exhibited sufficiently high affinity to the respective antibodies, viz. monoclonal mouse anti-cardiac troponin I clone 19C7, monoclonal mouse anti-NT-proBNP clone 29D12 and monoclonal mouse anti-NT-proBNP clone 15C4 (HyTest, Finland), the binding of photoluminescently labeled antibodies (Scheme 3) to the support-bound peptides was quantified. The peptide-coated particles were incubated with the labeled antibodies at different concentrations falling in the range 0.05−3 μg mL^{-1}, and the intensity of the fluorescence emission was measured directly from a single particle. Unspecific binding of anti-cardiac troponin I was determined with the aid of particles bearing a sequence H-CTHQDIDFLIEE-IERLGQDL-NH_2 (**10**). The specific signal was at least 100-fold compared to the unspecific one. The unspecific binding of anti-NT-proBNP clones 29D12 and 15C4, when determined with H−RGHRKMVLYTLC−NH_2 and H-GSPGSASDLEC−NH_2, respectively, was considerably higher, ≤10% of the specific signal. As seen from Figures 1−3, the fluorescence intensity measured from a single particle was with each peptide−antibody pair proportional to the concentration of the antibody in solution.

Binding of Peptide−Antibody Complexes to Particle-Bound Peptides. The next experiments were aimed at clarifying whether a complex of an unlabeled antibody and a labeled epitopic peptide could be captured by the same epitopic peptide covalently immobilized to a microparticle. In other words, could unlabeled antibodies be quantified by a mixed-phase assay by using their epitopic peptide both as a fluorescent label and as a catcher probe.

Scheme 5



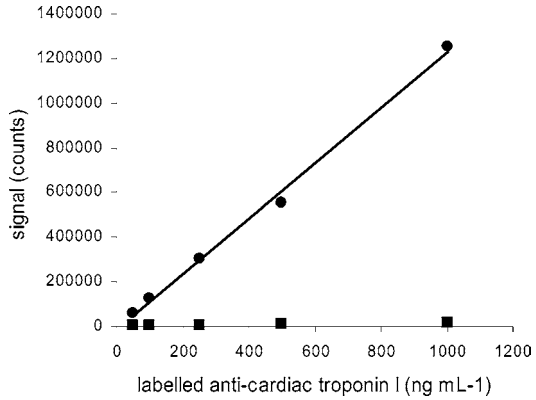


Figure 1. Binding of fluorescently labeled anti-cardiac troponin I antibody (clone 19C7) to microparticles coated with its epitopic peptide **1** (●): intensity of the fluorescence emission of a single particle plotted against the concentration of the antibody in solution ($R^2 = 0.996$). The loading of peptide **1** on particles was ≤ 2 μmol g^{-1}. Unspecific binding (■) was determined on particles coated with peptide **10**.

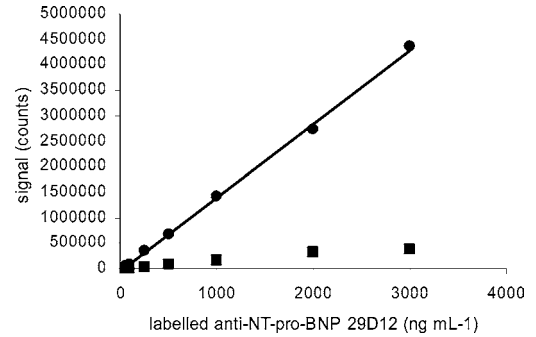

Figure 2. Binding of fluorescently labeled anti-NT-proBNP antibody (clone 29D12) to microparticles coated with its epitopic peptide **2** (●): intensity of the fluorescence emission of a single particle plotted against the concentration of the antibody in solution ($R^2 = 0.999$). The loading of peptide **2** on particles was ≤ 10 μmol g^{-1}. Unspecific binding (■) was determined on particles coated with peptide **3**.

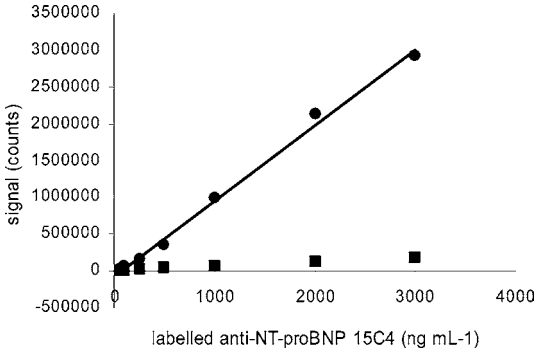

Figure 3. Binding of fluorescently labeled anti-NT-proBNP antibody (clone 15D4) to microparticles coated with its epitopic peptide **3** (●): intensity of the fluorescence emission of a single particle plotted against the concentration of the antibody in solution ($R^2 = 0.994$). The loading of peptide **3** on particles was ≤ 10 μmol g^{-1}. Unspecific binding (■) was determined on particles coated with peptide **2**.

The assay was first performed in two steps. Anti-cardiac troponin I antibody was first incubated (24 h) with the particles coated with peptide **1**. The particles were washed and then incubated (24 h) with the labeled peptide (**4**). When the concentration of the antibody was varied from 1 to 10 μg mL^{-1} and the concentration of labeled peptide was kept constant, the intensity of the fluorescence emission was proportional to the antibody concentration. Figure 4 shows the results obtained when the concentration of the labeled peptide was 22 nmol L^{-1}. The experiments were then repeated by adding all three components, viz. the antibody, labeled peptide and peptide-coated particles, at the same time and incubating them for 24 h. The results obtained were virtually identical with those obtained on using the stepwise addition format described above (Figure 4). The unspecific binding was measured by carrying out the assay as described above but in the absence of the antibody.

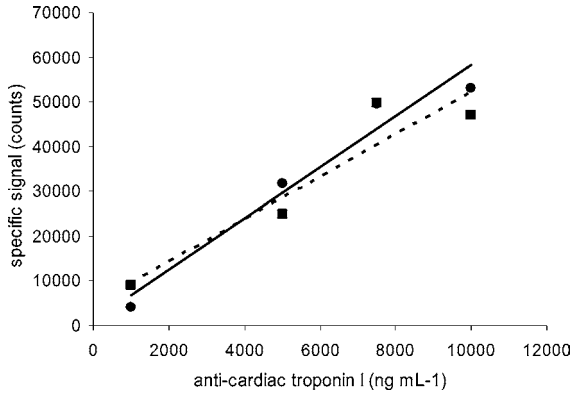

Figure 4. Binding of a complex of anti-cardiac troponin I antibody (clone 19C7) and its fluorescently tagged epitopic peptide (**4**) to microparticles coated with the same peptide (**1**): intensity of the fluorescence emission of a single particle plotted against the concentration of the antibody in solution. The loading of peptide **1** on particles was ≤ 10 μmol g^{-1}. Notation: binding of the antibody and the fluorescently tagged peptide in a stepwise manner (●, $R^2 = 0.88$), binding of the antibody and the fluorescently tagged peptide in a single step (■, $R^2 = 0.95$). The concentration of the fluorescently tagged peptide (**4**) was 22 nmol L^{-1}. At this concentration, the unspecific signal obtained in the absence of the antibody was 17000 counts on applying a stepwise mode and 18000 counts on applying a single step mode for the quantification.

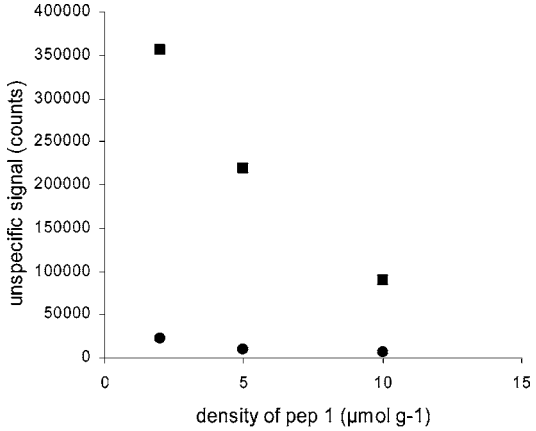

Figure 5. Unspecific binding of fluorescently tagged peptide **4** to microparticles coated with the same peptide (**1**): signal vs loading of peptide **1** on microparticles at two concentrations of the labeled peptide (**4**): 22 nmol L^{-1} (●) and 658 nmol L^{-1} (■).

To optimize the assay conditions, the effects of the peptide-loading on the particles and the concentration of labeled peptide on the signal intensity were studied. The concentration of labeled peptide (**4**) was varied from 22 nmol L^{-1} to 8.8 μmol L^{-1}. The signal intensities expectedly increased with the increasing concentration of **4**, but at the same time the proportion of unspecific binding was continuously increased, reducing the reproducibility of measurements (Figure 5). This was especially the case when a single-step format was applied, i.e. when all the components were added at the same time. For this reason, a relatively low concentration of labeled peptide (44 nmol L^{-1}) turned out to be optimal for detection. Particles having three different loadings of peptide **1**, viz. 2, 5, and 10 μmol g^{-1}, were then tested as a solid phase for detection of anti-cardiac Troponin

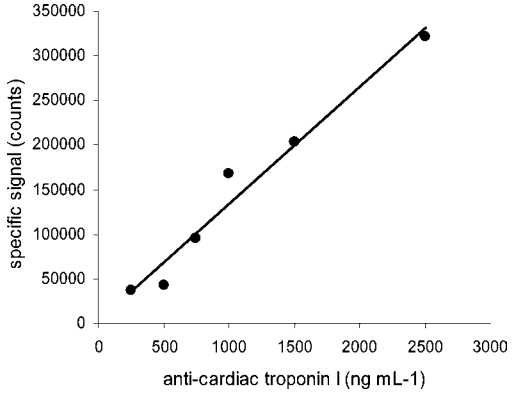

Figure 6. Binding of a ternary complex of anti-cardiac troponin I antibody (clone 19C7), its fluorescently tagged epitopic peptide (**4**), and a PNA conjugate (**7**) of the same peptide to microparticles coated with a PNA sequence complementary to that in conjugate **7**: intensity of the fluorescence emission of a single particle plotted against the concentration of the antibody in solution ($R^2 = 0.96$). The loading of PNA ≤ 10 μmol g^{-1}. The concentrations of peptide-conjugates **4** and **7** were 32 nmol L^{-1} and 1.67 nmol L^{-1}, respectively. At these concentrations, the unspecific signal obtained in the absence of the antibody was 21000 counts.

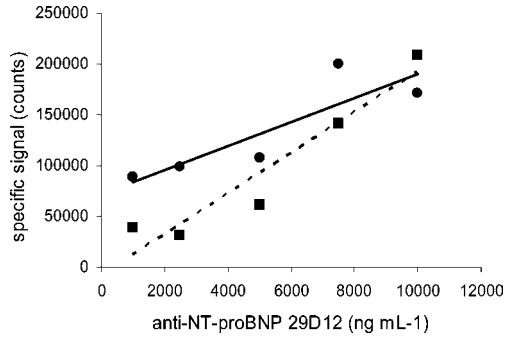

Figure 7. Binding of a ternary complex of anti-NT-proBNP antibody (clone 29D12), its fluorescently tagged epitopic peptide (**5**) and a PNA conjugate (**8**) of the same peptide to microparticles coated with a PNA sequence complementary to that in conjugate **8**: intensity of the fluorescence emission of a single particle plotted against the concentration of the antibody in solution. Notation: measurement in the absence (●, 0.74) and in the presence (■, 0.91) of anti-cardiac troponin I antibody (1000 ng mL^{-1}). The concentrations of peptide-conjugates **5** and **8** were 0.82 μmol L^{-1} and 0.53 nmol L^{-1}, respectively. At these concentrations, the unspecific signal obtained in the absence of both anti-NT-proBNP and anti-cardiac troponin I was 20000 counts and that obtained in the absence of anti-NT-proBNP but in the presence of anti-cardiac troponin I 19900 counts.

I. Interestingly, the signal intensity exhibited inverse dependence on the peptide-loading. Evidently, the antibody tends to bind to two solid-supported peptides when the peptide-loading is sufficiently high. In other words, the labeled peptide is not any more able to compete with the support-bound peptides. Unfortunately, low peptide-loading also increased the proportion of unspecific binding of the labeled peptide.

Binding of Ternary Complexes of Antibody, Labeled Peptide, and Peptide−PNA Conjugate to PNA-Coated Particles. Encouraged by the preliminary experiments described above, implementation of the assay format depicted in Scheme 1 was tried. In other words, a fluorescently tagged epitopic peptide and a PNA conjugate of the same peptide compete for the antibody, and the ternary complexes consisting of the antibody, labeled peptide, and PNA−peptide conjugate is immobilized by Watson−Crick base-pairing to a particle bearing a complementary PNA sequence. On using categorized microparticles, each antibody present in a multiplexed assay may, hence, in principle be immobilized to a different PNA-coated

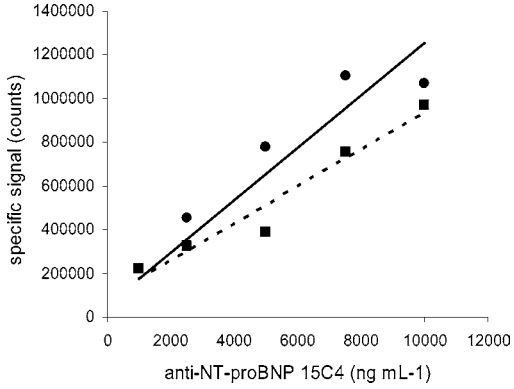

Figure 8. Binding of a ternary complex of anti-NT-proBNP antibody (clone 15C4), its fluorescently tagged epitopic peptide (**6**) and a PNA conjugate (**9**) of the same peptide to microparticles coated with a PNA sequence complementary to that in conjugate **9**: intensity of the fluorescence emission of a single particle plotted against the concentration of the antibody in solution. Notation: measurement in the absence (●, 0.86) and in the presence (■, 0.95) of anti-cardiac troponin I antibody (1000 ng mL^{-1}). The concentrations of peptide-conjugates **6** and **9** were 0.66 μmol L^{-1} and 0.48 nmol L^{-1}, respectively. At these concentrations, the unspecific signal obtained in the absence of both anti-NT-proBNP and anti-cardiac troponin I was 236000 counts and that obtained in the absence of anti-NT-proBNP but in the presence of anti-cardiac troponin I 227000.

microparticle or a PNA chip could be used for spatially addressable detection.

For this purpose, the epitopic peptides **1**−**3** were converted to their PNA conjugates **7**−**9** as follows. A Cys-derivatized PNA 10-mer, H-AGTGATCTAC-Cys-NH_2, was first reacted with 1,8-bis(maleimido)triethyleneglycol to obtain a maleimido-conjugate, with which the Cys-containing peptides were then allowed to react (Scheme 5). The PNA−peptide conjugates obtained were used in a mixed-phase immunoassay together with microparticles bearing a PNA sequence, H-GTAGATCACT-Cys-NH_2, attached to the particle through the cysteine residue. The PNA−peptide conjugate (**7**−**9**), the fluorescently tagged peptide component (**4**−**6**) of the conjugate, and the antibody were incubated overnight to form the desired ternary complex (**D** in Scheme 1). PNA-coated microparticles were then added, and another overnight incubation was performed to collect the ternary complex on the particles. Individual particles were finally subjected to measurement of fluorescence emission by time-resolved fluorometry.

Measurements were carried out at various concentrations of the PNA−peptide conjugate (0.48−166 nmol L^{-1}) and labeled peptide (22 nmol L^{-1} − 2.2 μmol L^{-1}). The optimal concentration for detection of the three antibodies studied varied somewhat from one antibody to another. With anti-cardiac troponin I, the best results were obtained on using a low concentration of the PNA−peptide conjugate **7** (1.67 nmol L^{-1}) and approximately a 1 order of magnitude higher concentration of the labeled peptide **4** (32 nmol L^{-1}). As seen from Figure 6, the assay showed a good linear dependence of the fluorometric signal intensity on the concentration of the antibody. The two other antibodies could only be detected by using the labeled peptides in larger excess compared to the PNA−peptide conjugates (**5** 0.82 μmol L^{-1}, **6** 0.66 μmol L^{-1} vs **8** 0.53 nmol L^{-1}, **9** 0.48 nmol L^{-1}). For this reason, the unspecific binding varied from 10 to 40% of the observed signal, making the plots of signal intensity vs antibody concentration rather scattered, as seen from Figures 7 and 8. The presence of another antibody does not seem to disturb the detection. As seen from Figures 7 and 8, addition of anti-cardiac troponin I antibody to give a concentration of 1000 ng mL^{-1} only moderately reduced the observed signals.

In summary, the assay depicted in Scheme 1 appears to be a viable method for quantification of a limited number of antibodies from a single sample. The applicability of the method is, however, limited by the fact that the relative affinities of the fluorescently labeled epitopic peptide and the PNA conjugate of the same peptide for the antibody appear to differ from one antibody to another. Accordingly, approximate information on the variation of the relative binding affinities is desirable for proper planning of the assay conditions. It is also worth noting that PNA rather than oligonucleotides should be used as a catcher probe. The reason is that the negatively charged sugar−phosphate backbone of oligonucleotides tends to bind electrostatically positively charged peptides. The sensitivity of detection is somewhat lower than the detection of covalently labeled antibodies, but labeling of the antibody is avoided.

ACKNOWLEDGMENT

Financial aid from the Technology Development Agency of Finland is gratefully acknowledged. The authors wish to thank Dr. Harri Hakala for performing the ESI-MS analyses. HyTest Ltd is acknowledged for providing antibodies for experiments.

This report describes the evaluation of biodistribution properties of three radiotracers, [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)] (SQ168 = [2-[[[5-[carboonyl]-2-pyridinyl]-hydrazono]methyl]benzenesulfonic acid]-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}; EDDA = ethylenediamine-*N*,*N*′-diacetic acid; PDA = 2,5-pyridinedicarboxylic acid; TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate), and their potential to image the glioma integrin $\alpha_v\beta_3$ expression in BALB/c nude mice bearing the U87MG human glioma xenografts. It was found that all three radiotracers were able to localize in glioma tumors with a relatively high tumor uptake and long tumor retention time by binding to the integrin $\alpha_v\beta_3$ expressed on both tumor cells and endothelial cells of tumor neovasculature. It seems that the coligand has minimal effect on integrin $\alpha_v\beta_3$ targeting capability of the ^{99m}Tc-labeled RGDfK dimer, but it has a significant impact on their biodistribution properties. For example, the complex [^{99m}Tc(SQ168)(tricine)(TPPTS)] has the lowest liver uptake and the highest metabolic stability in normal BALB/c nude mice. Results from SPECT imaging studies show that the glioma tumors can be clearly visualized with all three radiotracers at 4 h postinjection. Among the three radiotracers evaluated in this study, [^{99m}Tc(SQ168)(tricine)(TPPTS)] has the best imaging quality and is a promising candidate for more preclinical evaluations in the future.

INTRODUCTION

Gliomas or tumors derived from glial cells of the central nerve system are the most frequent primary intracranial neoplasma in adults. Malignant gliomas are the second leading cause of cancer death in children under age 15 and also in young adults up to age 34 (*1*, *2*). With a high proliferation rate, marked neovascularization, and extensive local invasion of tumor cells into the normal brain parenchyma, gliomas are resistant to conventional treatment, such as surgery, chemotherapy, and radiation therapy. The median survival of aggressively treated patients with glioblastoma is about 12 months (*3*). Therefore, early detection of brain tumors such as glioma is highly desirable so that various therapeutic regimens can be given before the primary tumors become widely spread. Since gliomas are extremely invasive with a high level of integrin $\alpha_v\beta_3$ overexpression (*4*−*6*), which also correlates with metastatic disease human neuroblastomas (*7*), it would be of great clinical benefit to develop a radiotracer that can be used not only to noninvasively visualize and quantify integrin $\alpha_v\beta_3$ expression but also to select patients under consideration for anti-integrin treatment and monitor treatment efficacy in integrin $\alpha_v\beta_3$-positive patients.

For the last several years, many high affinity integrin $\alpha_v\beta_3$ antagonists (RGD-containing cyclic peptides and nonpeptide RGD mimetics) have been proposed as targeting biomolecules to carry the diagnostic "probes" into the integrin $\alpha_v\beta_3$-positive tumors (*8*−*13*). Several molecular probes have been developed for magnetic resonance imaging (*14*), ultrasound (*15*), optical imaging (*16*), positron emission tomography (PET) (*17*−*23*), and single-photon emission computed tomography (SPECT) imaging (*24*−*28*). Although most of "molecular" probes containing a monomeric RGD-tripeptide sequence are able to target tumors by binding to the integrin $\alpha_v\beta_3$ overexpressed on tumor cells and endothelial cells of the tumor neovasculature, they suffer from several shortcomings, such as low tumor uptake, which limit their application as tumor imaging agents in clinics.

We and others have been using cyclic RGD peptide dimers, such as E[c(RGDfK)]$_2$, for development of the integrin $\alpha_v\beta_3$-targeted diagnostic (^{64}Cu, ^{99m}Tc, and ^{111}In) radiotracers (*29*−*35*). Recently, we reported evaluation of complexes [^{99m}Tc(SQ168)(tricine)(L)] (Figure 1: SQ168 = [2-[[[5-[carboonyl]-2-pyridinyl]hydrazono]methyl]benzenesulfonic acid]-Glu(cyclo{Lys-Arg-Gly-Asp-D-Phe})-cyclo{Lys-Arg-Gly-Asp-D-Phe}; L = ISONIC (isonicotinic acid), TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate), and PDA (2,5-pyridinedicarboxylic acid)) as radiotracers for imaging the integrin $\alpha_v\beta_3$ expression in nude mice bearing the MDA-MB-435 human breast cancer xenografts (*29*, *31*). It was found that coligands have minimal effect on tumor targeting capability, but it has a significant impact on excretion kinetics of the ^{99m}Tc-labeled cyclic RGDfK dimer. Results from the blocking experiment suggest that the tumor localization of the ^{99m}Tc-labeled cyclic RGDfK dimer is indeed integrin $\alpha_v\beta_3$-mediated (*31*).

As continuation of our interest in the integrin $\alpha_v\beta_3$-targeted radiotracers for imaging solid tumors of different origin, we have evaluated the biodistribution characteristics of ternary ligand complexes [^{99m}Tc(SQ168)(tricine)(PDA)] and [^{99m}Tc(SQ168)(tricine)(TPPTS)] in the female BALB/c nude mice bearing the U87MG human glioma xenografts. The main objective is to assess their potential as SPECT radiotracers for imaging the integrin $\alpha_v\beta_3$-expression in gliomas. For comparison

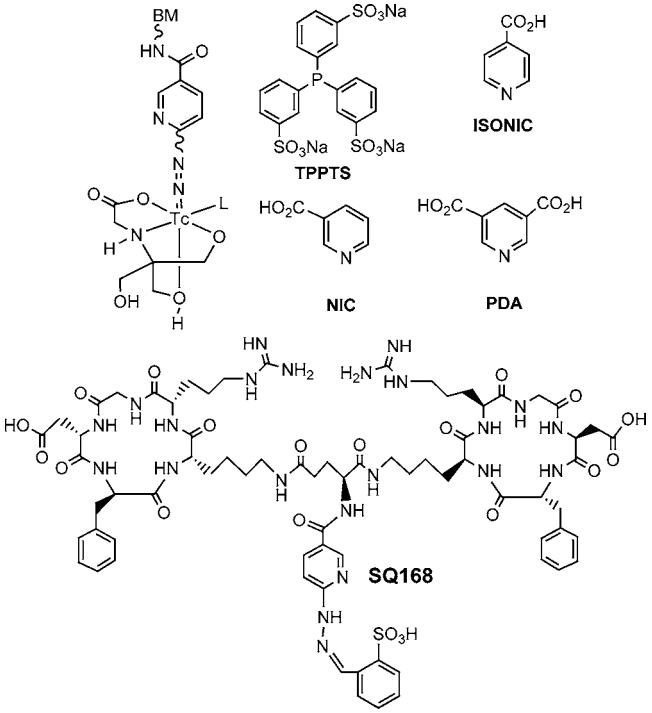

Figure 1. Structures of the HYNIC-conjugated cyclic RGDfK dimer (SQ168), coligands, and their ternary ligand complexes [^{99m}Tc(SQ168)-(tricine)(L)] (SQ168 = HYNIC-E[c(RGDfK)]$_2$; L = TPPTS, ISONIC, NIC, and PDA).

purposes, we also evaluated the complex [^{99m}Tc(SQ168)-(EDDA)] (EDDA = ethylenediamine-*N*,*N*′-diacetic acid) in the same tumor animal model. EDDA has been used as a coligand for preparation of ^{99m}Tc-labeled somatostatin analogues, which are under investigation as new radiotracers for imaging somatostatin receptor-positive tumors in humans (*36*−*38*).

EXPERIMENTAL SECTION

Materials and Methods. All chemicals were purchased from Aldrich Chemical Co., unless specified. Synthesis of SQ168 (HYNIC-E[c(RGDfK)]$_2$) was described in our previous communication (*31*). Na^{99m}TcO$_4$ was obtained from a commercial ^{99}Mo/^{99m}Tc generator (Beijing Atom High Tech Co., Ltd.). The radio-HPLC method used a HP Hewlett Packard Series 1100 HPLC system equipped with Radioflow Detector LB509 and Agilent Zorbax SB-C18 column (4.6 mm × 250 mm, 5 μm). The flow rate was 1.0 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM NaOAc buffer, pH = 5.0) and 10% solvent B (acetonitrile) at 0−2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min, then to 10% solvent B at 25 min.

Synthesis of [^{99m}Tc(SQ168)(EDDA)]. To a clean vial were added 100 μL of SQ168 solution (100 μg/mL in H_2O), 100 μL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), 20 μL of $SnCl_2$ solution (3.0 mg/mL in 0.1 N HCl), and 100 μL of Na^{99m}TcO$_4$ solution (∼10 mCi). The reaction mixture was kept at room temperature for 10 min. To the solution was added 200 μL of EDDA (30 mg/mL in 1 M NaOH, pH 7.0). The mixture was heated at 100 °C for 30 min. After radiolabeling, a sample of the resulting solution was analyzed by radio-HPLC.

Synthesis of [^{99m}Tc(SQ168)(tricine)(L)] (L = PDA and TPPTS). To a clean vial were added 100 μL of SQ168 solution (100 μg/mL in H_2O), 100 μL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), 20 μL of $SnCl_2$ solution (3.0 mg/mL in 0.1 N HCl), and 100 μL of Na^{99m}TcO$_4$ (∼10 mCi). The reaction mixture was kept at room temperature for 10 min. To the solution above was added 120 μL of TPPTS or PDA solution (50 mg/mL in 25 mM succinate buffer, pH 5.0), and the mixture was heated at 100 °C for 30 min. After radiolabeling, a sample of the resulting solution was analyzed by radio-HPLC.

Doses Preparation for Animal Studies. All three ^{99m}Tc radiotracers were purified using Sep-Pak C-18 cartridge (Waters, Milford MA) before animal studies. The Sep-Pak C-18 cartridge was activated with 10 mL of ethanol followed by washing with 10 mL of water. The radiotracer was passed through a Sep-Pak C-18 cartridge to filter out the [^{99m}Tc]-colloid. The Sep-Pak C-18 cartridge was then washed with 10 mL of saline to remove unlabeled SQ168 and excess coligand. The ^{99m}Tc radiotracer was eluted with 0.4 mL of 80% ethanol. Doses for animal studies were prepared by dissolving the purified radiotracer in saline to give a concentration of 150 μCi/mL for biodistribution studies, 4.0 mCi/mL for metabolism, and 2.0 mCi/mL for imaging studies. For the blocking experiment, E[c(RGDfK)]$_2$ was used as the blocking agent. Doses were prepared by dissolving E[c(RGDfK)]$_2$ in saline to give a final concentration of 3.0 mg/mL. Each tumor-bearing mouse was injected with 0.1 mL of E[c(RGDfK)]$_2$ solution, which corresponds to a dose of 15 mg/kg.

Animal Studies. Both biodistribution and imaging studies were performed by Dr. Wang's group at the Peking University Medical Isotopes Research Center, according to the literature (*21*, *23*, *39*). All animal experiments were performed in accordance with guidelines of Peking University Health Science Center Animal Care and Use Committee.

Tumor-Bearing Mice. The human U87MG glioma tumor cells from Professor Jingde Zhu (Shanghai Cancer Research Institute) were maintained at 37 °C and 5% CO_2 in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum (FBS). Female BALB/c nude mice (4−5 weeks of age) were purchased from Department of Animal Experiment, Peking University Health Science Center. The U87MG cells (5×10^6) were implanted subcutaneously into the right upper flanks of mice. When tumors reached ∼0.8 cm in mean diameter, the tumor-bearing mice were used to biodistribution and imaging studies.

Biodistribution. Sixteen tumor-bearing mice were randomly divided into four groups, each of which had four animals. Animals were anesthetized with an intraperitoneal injection of sodium pentobarbital at a dose of 45.0 mg/kg. The ^{99m}Tc radiotracer (∼15 μCi in 0.1 mL saline) was administered intravenously to each tumor-bearing mouse. Animals were sacrificed by cervical dislocation at 0.5, 1, 2, and 4 h postinjection. Blood, heart, liver, spleen, kidney, stomach, intestine, muscle, and tumor were harvested, weighed, and measured for radioactivity in a γ-counter (Wallac 1470−002, Perkin-Elmer, Finland). The organ uptake was calculated as a percentage of the injected dose per gram of wet tissue mass (%ID/g). For the blocking experiment, each animal was administered with 300 μg of E[c(RGDfK)]$_2$ (0.1 mL in saline) 30 min prior to the injection of [^{99m}Tc(SQ168)(tricine)(PDA)]. At 1 h postinjection, all four animals were sacrificed for biodistribution using the same procedure above. The results were compared to those obtained in animals without the injection of E[c(RGDfK)]$_2$.

Metabolism. The metabolic stability of ^{99m}Tc radiotracers was evaluated in normal BALB/c nude mice. Animals were anesthetized with intraperitoneal injection of sodium pentobarbital (45.0 mg/kg). Each mouse was administered with the radiotracer at a dose of 800 μCi in 0.2 mL saline via intravenous injection. The mice were sacrificed by cervical dislocation at 2 h postinjection, and livers were removed and homogenized. The homogenate was extracted with 500 μL of 50% acetonitrile aqueous solution. The extract was centrifuged at 1500 rpm for

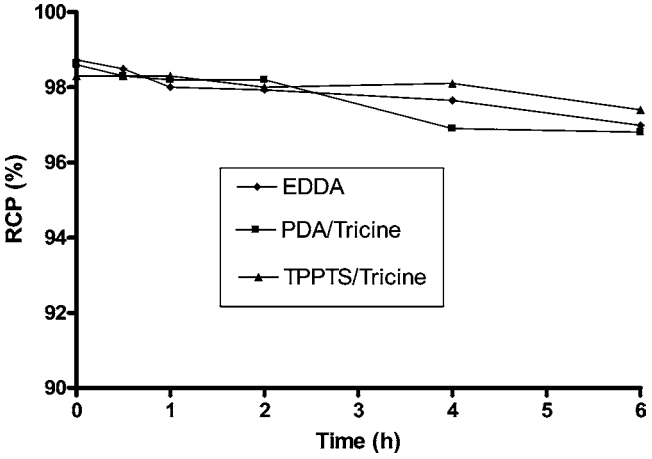

Figure 2. Solution stability data for [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc-(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)] in the presence of cysteine (1.0 mg/mL).

15 min, and the supernatant was filtered through a 0.22 μ Millex-LG syringe driven filter unit. The filtrate was analyzed by radio-HPLC. Urine samples were collected at 2 h postinjection and were mixed with equal volume of acetonitrile. The mixtures were centrifuged at 1500 rpm for 15 min. The supernatants were collected and filtered through a 0.22 μ Millex-LG syringe driven filter unit. The filtrates were analyzed by radio-HPLC.

SPECT Imaging. SPECT imaging was performed on nine tumor-bearing mice (three groups). Animals were anesthetized with an intraperitoneal injection of sodium pentobarbital at a dose of 45.0 mg/kg. Each animal was administered with 400 μCi of the ^{99m}Tc radiotracer in 0.2 mL of saline. Animals were placed supine on a two-head γ-camera (SIEMENS, E. CAM) equipped with a parallel-hole, low-energy, and high-resolution collimator. Anterior images were acquired 4 h postinjection and stored digitally in a 128 $\times$ 128 matrix. The acquisition count limits were set at 1000 K. After completion of imaging, animals were sacrificed by cervical dislocation.

Statistical Analysis. The biodistribution data and T/B ratios are reported as an average plus the standard variation. Comparison between two different radiotracers was also made using the one-way ANOVA test. The level of significance was set at $p = 0.05$.

RESULTS

Radiochemistry. Complexes [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc-(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)] were prepared using a two-step radiolabeling procedure. First, HYNIC-E[c(RGDfK)]$_2$ (SQ168) was allowed to react with Na^{99m}TcO$_4$ in the presence of excess tricine and stannous chloride to form the [^{99m}Tc(SQ168)(tricine)$_n$] intermediate, which underwent ligand exchange with EDDA to give the complex [^{99m}Tc(SQ168)(EDDA)], or reacted with PDA or TPPTS to form ternary ligand complexes [^{99m}Tc(SQ168)-(tricine)(L)] (L = PDA and TPPTS). The radiochemistry purity (RCP) for all three ^{99m}Tc radiotracers was >95% after purification with the Sep-Pak C-18 cartridge before animal studies.

Solution Stability. The solution stability of complexes [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)] was monitored by radio-HPLC after addition of cysteine. Figure 2 shows their solution stability data. It is quite clear that all three radiotracers remain stable over 6 h in the presence of cysteine (1.0 mg/mL).

Biodistribution. Biodistribution studies were performed using female BALB/c nude mice bearing the U87MG human glioma xenografts. This animal model has been used to evaluate radiolabeled RGD peptides as potential radiotracers for imaging gliomas (*21*, *23*, *39*). The selected biodistribution data for [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)] with/without the presence of excess E[c(RGDfK)]$_2$ are summarized in Figure 3. Figure 4 illustrates their tumor-to-background (T/B) ratios in several selected organs. Figure 5 shows the direct comparison of their organ uptake at 0.5, 1, 2, and 4 h postinjection and excretion kinetics from the blood, liver, and kidneys.

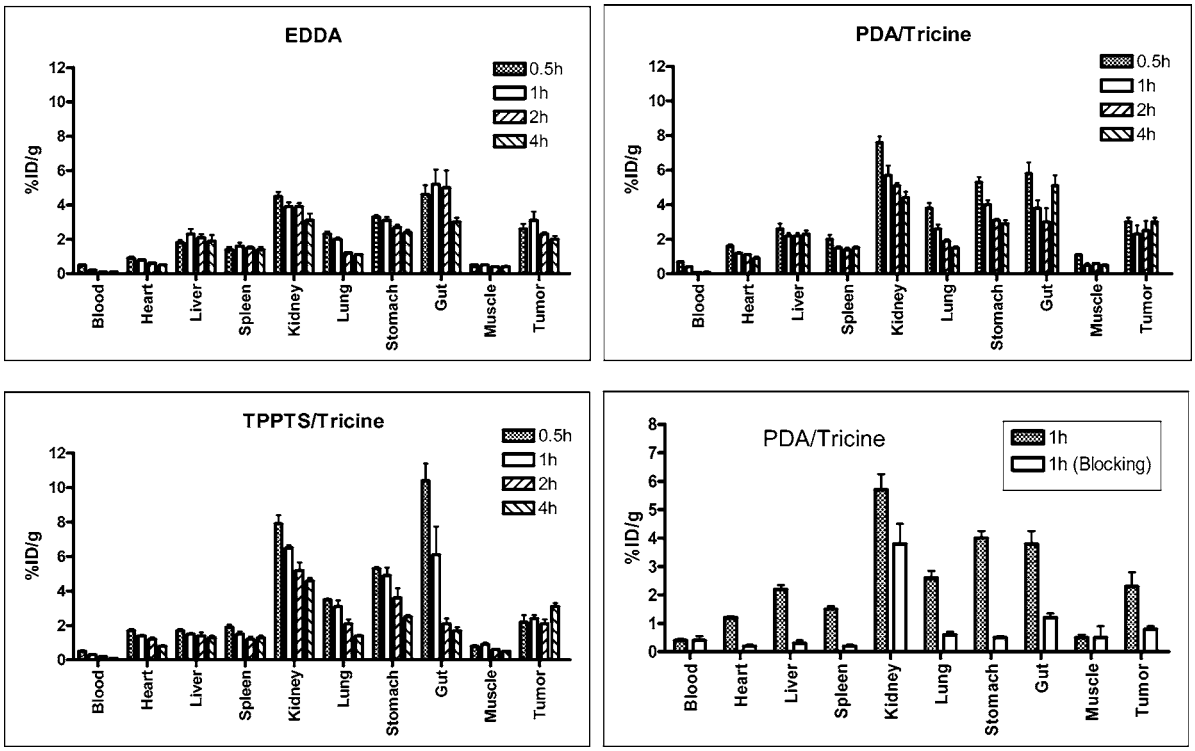

Figure 3. Comparison of the organ uptake (%ID/g) between [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)-(TPPTS)] in BALB/c nude mice bearing the U87MG human glioma xenografts. Each data point represents an average of biodistribution data in four animals.

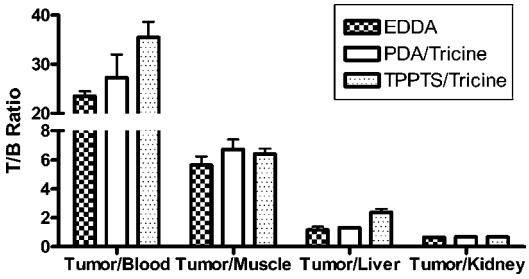

Figure 4. Tumor/background ratios for [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)] in BALB/c nude mice bearing the U87MG human glioma xenografts at 4 h postinjection.

In general, all three complexes, [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)-(TPPTS)], displayed a rapid clearance from the blood via renal and hepatobiliary routes. Their blood clearance curves were almost identical (Figure 5), suggesting that coligands have little impact on their protein binding. Their tumor uptake remained relatively unchanged over 2 h within the experimental error (Figure 5). However, the tumor uptake of [^{99m}Tc(SQ168)-(tricine)(PDA)] (3.01 ± 0.47%ID/g) and [^{99m}Tc(SQ168)(tricine)-(TPPTS)] (3.10±0.35%ID/g) was significantly ($p < 0.01$) higher than that of [^{99m}Tc(SQ168)(EDDA)] (1.99 ± 0.44%ID/g) at 4 h postinjection. The kidney uptake of [^{99m}Tc(SQ168)(tricine)-(PDA)] and [^{99m}Tc(SQ168)(tricine)(TPPTS)] was higher than that of [^{99m}Tc(SQ168)(EDDA)]. The liver uptake of [^{99m}Tc-(SQ168)(tricine)(TPPTS)] was lower than that of [^{99m}Tc-(SQ168)(EDDA)] and [^{99m}Tc(SQ168)(tricine)(PDA)] at >1 h postinjection (Figure 5). As a result, it has the best tumor-to-liver ratio (2.39 ± 0.46) at 4 h postinjection (Figure 4).

The blocking experiment was performed by preinjecting or coinjecting a known receptor ligand to demonstrate the tumor-specificity of target-specific radiotracers. In this study, we used E[c(RGDfK)]$_2$ (15 mg/kg or 300 μg/mouse), the IC_{50} of which was 32.1 ± 2.1 nM against ^{125}I-echistatin binding to integrin $\alpha_v\beta_3$ on U87MG tumor cells (*39*), as the blocking agent. Figure 3 shows the comparison of uptake (%ID/g) for [^{99m}Tc(SQ168))-(tricine)(PDA)] at 1 h postinjection with/without E[c(RGDfK)]$_2$. Obviously, excess E[c(RGDfK)]$_2$ resulted in a significant reduction in the uptake of [^{99m}Tc(SQ168))(tricine)(PDA)] in the tumor, lungs, liver, spleen, stomach, and guts. The kidney uptake was also inhibited (to a lesser degree) by excess E[c(RGDfK)]$_2$ (Figure 3). Similar results were obtained for [^{99m}Tc(SQ168)-(tricine)(TPPTS)] and ^{111}In-DOTA-E[c(RGDfK)]$_2$ in the BALB/c mice bearing ovarian carcinoma (*33*−*35*) and for [^{99m}Tc-(SQ168)(tricine)(ISONIC)] and ^{64}Cu-DOTA-E[c(RGDfK)]$_2$ in the nude mice bearing the MDA-MB-435 human breast cancer xenografts (*31*, *32*). However, there is no significant difference in the blood activity with/without excess E[c(RGDfK)]$_2$ (Figure 3).

Imaging Studies. We performed imaging studies on all three radiotracers in the BALB/c nude mice bearing the U87MG human glioma xenografts. Figure 6 illustrates representative SPECT images of tumor-bearing mice administered with ∼400 μCi of [^{99m}Tc(SQ168)(EDDA)] (left), [^{99m}Tc(SQ168)(tricine)-(TPPTS)] (middle), and [^{99m}Tc(SQ168)(tricine)(PDA)] (right). In general, tumors in all three SPECT images are clearly visualized at 4 h postinjection. The complex [^{99m}Tc(SQ168)-(tricine)(TPPTS)] has the least activity accumulation in the abdominal region while [^{99m}Tc(SQ168)(EDDA)] has relatively low kidney uptake (Figure 6), which is completely consistent with the ex vivo biodistribution data at the same time point (Figure 3). Among three radiotracers evaluated in this study, [^{99m}Tc(SQ168)(tricine)(TPPTS)] has the best imaging quality at 4 h postinjection due to its rapid clearance from liver and lungs in BALB/c nude mice bearing the U87 human glioma xenografts.

Metabolic Properties. We performed metabolism studies on all three radiotracers using normal BALB/c nude mice. Since they are excreted from both renal and hepatobiliary routes, we analyzed the samples from both liver and urine to determine if these radiotracers retain their chemical integrity at 2 h postinjection. Figure 7 illustrates the radio-HPLC chromatograms of [^{99m}Tc(SQ168)(tricine)(PDA)] (left) and [^{99m}Tc(SQ168)(tricine)-(TPPTS)] (right) in the kit matrix before injection (A), in the liver (B), and in the urine (C). It is quite clear that [^{99m}Tc-(SQ168)(tricine)(TPPTS)] retained its integrity while [^{99m}Tc-(SQ168)(tricine)(PDA)] showed a certain degree of metabolism (10−15%) in both urine and liver samples at 2 h postinjection.

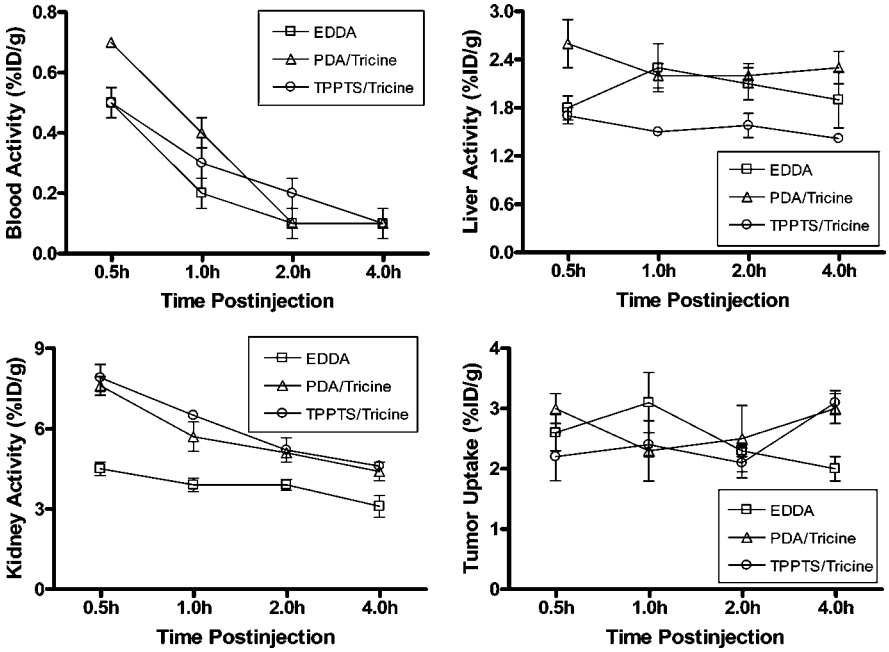

Figure 5. Direct comparison of excretion kinetics between [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)-(TPPTS)] in BALB/c nude mice bearing the U87MG human glioma xenografts.

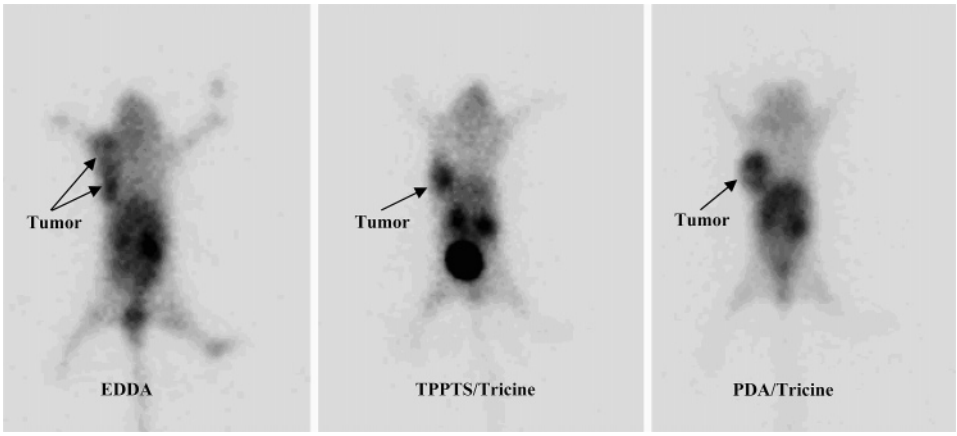

Figure 6. SPECT images of BALB/c nude mice bearing the U87MG human glioma xenografts administered with ~400 μCi of [^{99m}Tc(SQ168)-(EDDA)] (left), [^{99m}Tc(SQ168)(tricine)(TPPTS)] (middle) and [^{99m}Tc(SQ168)(tricine)(PDA)] (right) at 4 h postinjection. Arrows indicate the location of glioma tumors.

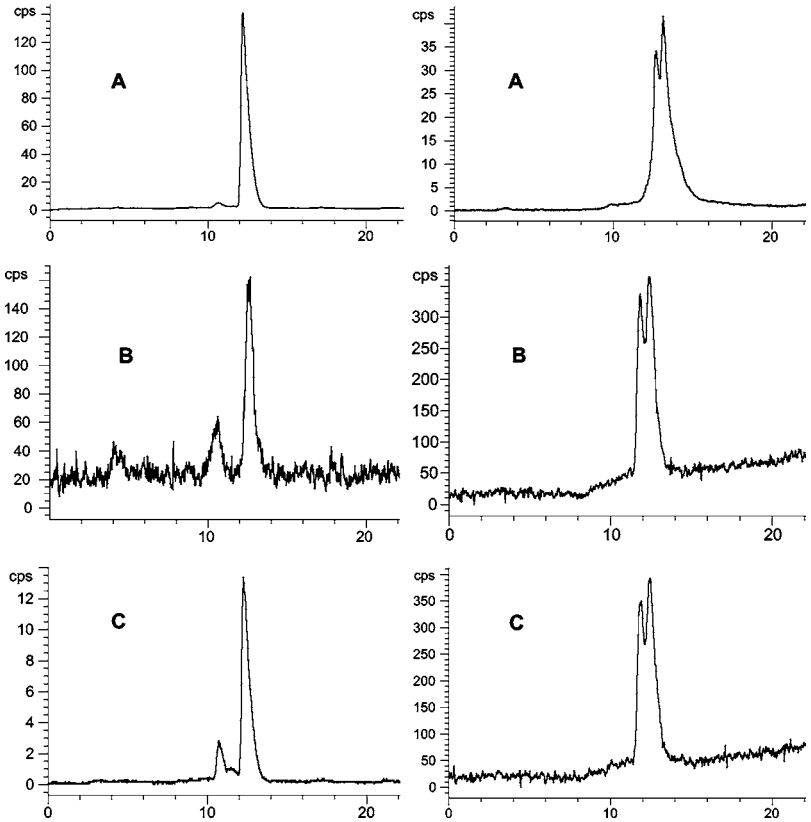

Figure 7. Radio-HPLC chromatograms of [^{99m}Tc(SQ168)(tricine)(PDA)] (left) and [^{99m}Tc(SQ168)(tricine)(TPPTS)] (right) in the kit matrix before injection (A), in the liver (B), and in the urine (C) at 2 h postinjection.

The metabolic patterns of [^{99m}Tc(SQ168)(EDDA)] are very similar to those of [^{99m}Tc(SQ168)(tricine)(PDA)] (Figure SI).

DISCUSSION

It is well established that the integrin $\alpha_v\beta_3$ overexpressed on the neovasculature of many solid tumors, including neuroblastomas, glioblastomas, melanomas, lung carcinomas, and breast, prostate, and bladder cancers (*6*, *40*−*50*). The integrin $\alpha_v\beta_3$ expression level also correlates well with tumor progression in melanoma, glioma, and ovarian and breast cancers (*7*, *40*−*47*). For the past decade, many cyclic RGD peptides and nonpeptide RGD mimetics have been labeled with different radioisotopes to develop the angiogenesis-targeting radiotracers for both diagnosis (^{125}I, ^{99m}Tc, ^{111}In, ^{18}F, and ^{64}Cu) and tumor-specific radiotherapy (^{90}Y and ^{177}Lu) (*17*−*35*). Since integrin $\alpha_v\beta_3$ is overexpressed on the surface of the "activated" endothelial cells of tumor neovasculature, the integrin $\alpha_v\beta_3$-targeted radiotracers would be specific for rapidly growing and metastatic tumors.

In general, the radiolabeled RGD peptide radiotracer of clinical importance should have high affinity and specificity for integrin $\alpha_v\beta_3$. In the last several years, we and others have been using the "multivalency" concept to improve $\alpha_v\beta_3$ binding affinity and the tumor targeting of the radiolabeled RGD peptides (*11*, *13*, *29*−*35*, *51*−*55*). It is found that the use of a multimeric cyclic RGD peptide could significantly increase the affinity of radiotracers for integrin $\alpha_v\beta_3$ through either simultaneous receptor binding or reduction of dissociation from the integrin $\alpha_v\beta_3$ binding sites. For example, the integrin $\alpha_v\beta_3$ binding affinity of E[c(RGDfK)]$_2$ (a cyclic RGDfK dimer) is 10-fold higher than that of its monomeric analogue c(RGDfK) (*33*). In athymic female BALB/c nude mice with subcutaneous OVCAR-3 ovarian cancer xenografts, the ^{99m}Tc-labeled RGDfK

dimer had significantly higher tumor retention than its monomeric counterpart (*33*). Similar results were also obtained with ^{64}Cu- and ^{90}Y-labeled cyclic RGD dimer conjugates: DOTA-E[c(RGDfK)]$_2$ and DOTA-E[c(RGDyK)]$_2$ (*27*, *32*, *34*, *35*).

For the radiolabeled RGD peptide radiotracer to be clinically useful, it is necessary to demonstrate its capability to image the integrin $\alpha_v\beta_3$ expression in animal models bearing solid tumors of different origin. Janssen and co-workers evaluated the biodistribution characteristics of [^{99m}Tc(SQ168)(tricine)(TPPTS)] in BALB/c nude mice with subcutaneous OVCAR-3 ovarian cancer xenografts (*33*). Recently, we reported the evaluation of [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, ISONIC, and PDA) in nude mice bearing the MDA-MB-435 human breast cancer xenografts (*31*). In this study, we use the BALB/c nude mice bearing the U87MG human glioma xenografts to examine biodistribution properties of three radiotracers, [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)], and their capability to image the glioma integrin $\alpha_v\beta_3$ expression. On the basis of biodistribution data, it is clear that all three radiotracers are able to localize in glioma tumors with moderately high tumor uptake (>2% ID/g over 4 h study period) and long tumor retention time. Results from the blocking experiment suggest that their tumor localization is integrin $\alpha_v\beta_3$-mediated. SPECT imaging studies have demonstrated that the glioma tumors can be clearly visualized with all three radiotracers at 4 h postinjection. On the basis of their clearance patterns from blood, muscle, liver, and lungs, it seems that [^{99m}Tc(SQ168)(tricine)(TPPTS)] has the best imaging quality (Figure 6).

Several approaches have been used to modify pharmacokinetics of the radiolabeled cyclic RGD peptides. For example, a sugar moiety has been used to improve the hepatobiliary clearance of ^{18}F-labeled cyclic RGD peptides (*17*−*19*). The poly(ethylene glycol) linking groups are also useful for improving both tumor uptake and liver clearance of radiolabeled cyclic RGD peptides (*23*, *24*, *27*, *52*−*54*). A number of coligands have been used to modify biological properties of the ^{99m}Tc-labeled HYNIC-biomolecule conjugates (*29*, *31*, *36*−*38*, *56*−*60*). For example, it was found that the coligands had significant impact on biodistribution properties of complexes [^{99m}Tc(fMLFK−HYNIC)(L)$_2$] (L = glucoheptonate, mannitol, glucamine, and tricine) (*57*). [^{99m}Tc(HYNIC-TOC)(tricine)$_2$] (TOC = Tyr^3-octreotide) was found to have higher protein binding than [^{99m}Tc(HYNIC-TOC)(EDDA)] and [^{99m}Tc(HYNIC-TOC)(tricine)(NA)] (*58*, 59). It was reported that the best coligand combinations are tricine/NIC and tricine/ISONIC for the ^{99m}Tc-lablled HYNIC−CCK8 (CCK8 = cholecystokinin peptides) conjugates (*60*). In our previous study, we also found that [^{99m}Tc(SQ168)(tricine)(PDA)] had lower liver uptake in the athymic nude mice bearing the MDA-MB-435 human breast cancer xenografts over 2 h study period, and better tumor/liver ratios than [^{99m}Tc(SQ168)(tricine)(TPPTS)] at >60 min postinjection (*31*). In this study, [^{99m}Tc(SQ168)(tricine)(TPPTS)] was found to have the lowest liver uptake (Figure 5) and the best imaging quality (Figure 6) in BALB/c nude mice bearing U87MG human glioma xenografts. It also has the highest metabolic stability (Figure 7) in normal BALB/c nude mice. We believe that this discrepancy is most likely caused by the animal species. Therefore, caution must be taken when comparing biodistribution and excretion characteristics of radiotracers in different animals.

The choice of coligand for routine preparation of complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, NIC, ISONIC, and PDA) depends on several factors. For example, the radiotracer must demonstrate its capability to image the tumor integrin $\alpha_v\beta_3$ expression in various animal models. It must be excreted via the renal route to minimize the unwanted radioactivity accumulation in the abdominal region. It should have a high metabolic stability. In addition, a kit formulation is needed for routine preparation of the radiotracer. From the formulation development point of view, TPPTS has the obvious advantage over ISONIC and PDA since it is a strong reducing agent, and stannous chloride is not needed for successful preparation of [^{99m}Tc(SQ168)(tricine)(TPPTS)]. A non-$SnCl_2$ formulation has been developed for routine ^{99m}Tc-labeling of the HYNIC-conjugated cyclic RGD peptides (*61*). Since TPPTS is able to "extract" the oxygen from [^{99m}Tc]pertechnetate, there is virtually no [^{99m}Tc]colloid formation if the non-$SnCl_2$ formulation is used for ^{99m}Tc-labeling.

On the basis of the results from this and our previous studies, it is concluded that coligands in ternary ligand ^{99m}Tc complexes [^{99m}Tc(SQ168)(tricine)(L)] (L = TPPTS, NIC, ISONIC, and PDA) have minimal effect on their tumor-targeting capability. The coligand effect on excretion kinetics and metabolic fate of the radiotracer is not completely consistent in two animal species. Therefore, their biodistribution patterns and metabolic stability must be verified in larger rodents or mammals, which are more indicative of those in humans.

CONCLUSION

The key finding of this study is that all three radiotracers, [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)], are able to localize in glioma tumors via integrin $\alpha_v\beta_3$-binding. The coligand has minimal effect on the integrin $\alpha_v\beta_3$-targeting capability of radiotracers, but it has a significant impact on their biodistribution properties. Results from the SPECT imaging studies show that glioma tumors can be clearly visualized with all three radiotracers at 4 h postinjection. On the basis of their clearance patterns from blood, muscle, liver, and lungs, it seems that [^{99m}Tc(SQ168)(tricine)(TPPTS)] has the best imaging quality and is a promising candidate for more preclinical evaluations in the future.

ACKNOWLEDGMENT

Authors would thank Professor Jingde Zhu, Shanghai Cancer Research Institute, for providing the U87MG human glioma cells. This work is supported, in part, by Peking University Health Science Center (F.W.) and research grants: Z00004105040311 (F.W.) from Beijing Science and Technology Program and BCTR0503947 (S.L.) from Susan G. Komen Breast Cancer Foundation.

Supporting Information Available: Biodistribution data (%ID/g) for [^{99m}Tc(SQ168)(EDDA)], [^{99m}Tc(SQ168)(tricine)(PDA)], and [^{99m}Tc(SQ168)(tricine)(TPPTS)] are listed in Tables S1−S3. Figure SI shows the radio-HPLC chromatograms of [^{99m}Tc(SQ168)(EDDA)] in kit matrix, urine, and feces at 2 h postinjection. These materials are available free of charge at http://pubs.acs.org.

Methacrylamide Polymers with Hydrolysis-Sensitive Cationic Side Groups as Degradable Gene Carriers

Jordy Luten, Niels Akeroyd, Arjen Funhoff, Martin C. Lok, Herre Talsma, and Wim E. Hennink*

Department of Pharmaceutics, Utrecht Institute for Pharmaceutical Sciences (UIPS), Faculty of Pharmaceutical Sciences, Utrecht University, P.O. Box 80.082, 3508 TB Utrecht, The Netherlands. Received March 17, 2006; Revised Manuscript Received June 8, 2006

Water-soluble polymers with hydrolyzable cationic side groups (structure of the monomers are shown in Figure 1) were synthesized and evaluated as DNA delivery systems. The polymers, except for pHPMA−NHEM, were able to condense plasmid DNA into positively charged nanosized particles. The rate of hydrolysis at 37 °C and pH 7.4 of the side groups differed widely; the fastest rate of hydrolysis was observed for HPMA−DEAE (half-life of 2 h), while HPMA−DMAPr had the lowest rate of hydrolysis (half-life of 70 h). In line with this, pHPMA−DEAE-based polyplexes showed the fastest destabilization of the polyplexes at 37 °C and pH 7.4. Polyplexes based on pHPMA−DEAE, pHPMA−DMAE, and pHPMA−MPPM showed release of intact DNA within 24, 48, and 48 h, respectively, after incubation at 37 °C and pH 7.4. PHPMA−DEAE and pHPMA−MPPM based polyplexes showed the highest transfection activity (almost twice as active as pEI). Importantly, the pHPMA−DEAE, pHPMA−MPPM, and pHPMA−BDMPAP polyplexes preserved their transfection activity in the presence of serum proteins. All polymers investigated showed a substantial lower in vitro cytotoxicity than pEI. In conclusion, pHPMA-based polyplexes are an attractive class of biodegradable vectors for nonviral gene delivery.

INTRODUCTION

Gene therapy aims to treat various forms of diseases with a genetic origin including cystic fibrosis, different forms of cancer, and cardiovascular disorders (*1*−*3*). For the treatment of patients using gene therapy protocols, safe and efficient DNA delivery vehicles are needed. The gene delivery vehicles under investigation at present can be divided into viral and nonviral systems. The majority of gene therapy protocols clinically used in the past decade employs viral delivery systems, such as retroviruses, adenoviruses, and adeno-associated viruses (*4*). However, severe drawbacks are associated with the use of viral vectors, like the induction of an immune response against the viral proteins, possible recombination with wild-type viruses, limitations in the size of inserted DNA, and difficult large-scale pharmaceutical grade production (*5*, *6*).

As an alternative for the viral vectors, cationic lipids and polymers have been developed as nonviral carrier systems. Examples of frequently studied cationic gene delivery polymers are polyethylenimine (pEI), poly(2-dimethylaminoethyl methacrylate) (pDMAEMA), and poly-L-lysine (pLL) (*7*−*10*). However, these polymers either are nonbiodegradable (pEI and pDMAEMA) or show low transfection activity (pLL). Therefore, in recent years, biodegradable polycations are designed as DNA delivery vehicles. The potential advantage of biodegradable carriers is their reduced toxicity. Moreover, the degradation of the polymer can be used as a tool to release the plasmid DNA into the cytosol. It has been reported that biodegradable polymers, like poly[α-(4-aminobutyl)-L-glycolic acid] (pAGA), poly(2-aminoethylpropylene phosphate), and more recently polyphosphazenes and poly(ester amine)s, mediate gene transfection (*11*−*16*). Generally speaking, these polymers indeed have a lower toxicity than their nondegradable counterparts. However, the degradation of these polymers depends on the degradation of the polymer backbone and is rather slow (from days to months). Since the cellular uptake and endosomal escape of polyplexes take place within hours (*17*), the design of polymers with more rapid degradation kinetics is a logical step. Pack et al. (*18*) reported on degradable pEI derivatives, which had half-lives between 4 and 30 h. However, the degradation rate of the polymers was the same under conditions mimicking cytoplasmic and endosomal conditions. Recently, Funhoff et al. (*19*) reported on a novel polymer, poly(carbonic acid 2-dimethylamino-ethyl ester 1-methyl-2-(2-methacryloylamino)-ethyl ester) (pHPMA−DMAE), that has degradable cationic side groups with a half-life of around 10 h at pH 7.4 at 37 °C. Moreover, this polymer is rather stable at pH 5, therefore protecting the plasmid DNA in the endosomal compartment of the cell against DNAase induced degradation. A limitation of pHPMA−DMAE is that it only shows significant transfection in the absence of serum.

The aim of this study is to investigate whether a polymer with hydrolysis-sensitive cationic side groups could be developed that shows significant transfection in the presence of serum. It has been reported that structural variations in gene delivery polymers can have a significant impact on their transfection efficacy (*9*, *20*, *21*). Therefore, polymers with structures related to that of pHPMA−DMAE were synthesized and characterized. The corresponding polyplexes were studied for their destabilization behavior and evaluated in vitro for their transfection activities and cytotoxicity properties.

MATERIALS AND METHODS

Materials. The following materials were used as received: D,L-1-amino-2-propanol 99+%,1-methyl-2-piperidine methanol (MPPM), *N*-(2-hydroxyethyl)morpholine (NHEM), *N*,*N*-diethylaminoethanol (DEAE), 1,1′-carbonyldiimidazole (CDI) (all purchased from Acros, Geel, Belgium), *N*,*N*-dimethylaminoethanol (DMAE), 1-[bis[3-(dimethylamino)propyl]amino]-2-propanol (BDMPAP), and *N*,*N*-dimethylaminopropanol (DMAPr) (all purchased from Aldrich, Zwijndrecht, The Netherlands). Hydroquinone monomethyl ether and poly(L-aspartic acid),

Table 1. Overview of Results of the Synthesis and Polymerization of the Monomers, the Molecular Mass of the Synthesized Polymers, and pK_a Values of the Monomers and Polymers

monomer	amount of alcohol (mL)[a]	yield of monomer over two steps	pK_a monomer in NaCl[b]	M_w of polymer (kDa)	M_n of polymer (kDa)	average pK_a of polymer in NaCl[b]	yield of polymer
HPMA−DMAE	2.50	2.70 g (42%)	9.9	100	50	9.5	600 mg (72%)
HPMA−DEAE	3.50	2.86 g (40%)	9.8	40	20	8.7	605 mg (66%)
HPMA−DMAPr	3.00	3.75 g (55%)	8.1	60	15	7.1	655 mg (75%)
HPMA−MPPM	3.50	3.73 g (50%)	9.7	25	10	9.3	649 mg (68%)
HPMA−BDMPAP	7.00	3.11 g (30%)	5.8, 8.1, 8.9	70	25	7.0	796 mg (60%)
HPMA−NHEM	3.00	3.90 g (52%)	9.3	90	40	9.1	673 mg (70%)

[a] 25 mmol of alcohol used in the first step of the monomer synthesis. [b] $\mu = 0.15$ M.

p(Asp) (p5387), were purchased from Sigma (Zwijndrecht, The Netherlands). Methacryloyl chloride (97%, Fluka, Zwijndrecht, The Netherlands) was freshly distilled before use. The plasmid pCMVLacZ, containing a bacterial LacZ gene preceded by a nuclear localization signal under control of a CMV promoter, was purchased from Sanvertech (Heerhugowaard, The Netherlands). INF-7, a 24 amino acid containing peptide with fusogenic activity derived from the influenza virus, was synthesized via standard Fmoc solid-phase synthesis (*22*). Poly((dimethylamino)ethyl methacrylate) (pDMAEMA, $M_n = 92$ kg/mol) was synthesized via radical polymerization (*23*), and PEI (branched, 25 kDa) was purchased from Sigma. *N*-(2-Hydroxypropyl)-methacrylamide (HPMA) was synthesized according to Oupicky et al. (*24*).

Monomer Synthesis. A dry round-bottom flask was filled with 1,1′-carbonyldiimidazole (CDI) (6.84 g, 45.0 mmol) and 40 mL of dichloromethane. The different alcohols (25.0 mmol) (Table 1) were added dropwise over a period of 15 min to the suspension of CDI in dichloromethane. During the addition of the alcohol a clear solution was obtained, which was stirred for 2 h at room temperature. Next, the reaction mixture was washed with water (70 mL), dried over $MgSO_4$, and filtered, and the solvent was removed under reduced pressure, yielding the corresponding carbamates as colorless oils. The ^{1}H NMR data of the carbamates are given below.

DMAE−CI: ^{1}H NMR ($CDCl_3$, δ in ppm) 8.12 (s, 1H, NC*H*N), 7.40 (s, 1H, NCHCHN), 7.04 (s, 1H, NCHC*H*N), 4,48 (t, 2H, OCH_2), 2,68 (t, 2H, CH_2N), 2.29 (s 6H, N(CH_3)$_2$).

DEAE−CI: ^{1}H NMR ($CDCl_3$, δ in ppm) 8.14 (s, 1H, NC*H*N), 7.43 (s, 1H, NCHCHN), 7.06 (s, 1H, NCHC*H*N), 4.48 (t, 2H, OCH_2), 2.82 (t, 2H, CH_2N), 2.62 (dq, 4H, N(CH_2)$_2$), 1.04 (dt, 6H, N(CH_2CH_3)$_2$).

MPPM−CI: ^{1}H NMR ($CDCl_3$, δ in ppm) 8.13 (s, 1H, NC*H*N), 7.41 (s, 1H, NCHCHN), 7.04 (s, 1H, NCHC*H*N), 4.48 (t, 2H, OCH_2), 2.80 (m, 1H, OCH$_2$C*H*N), 2.37 (s, 3H, CH_3N), 2.23 (m, 2H, CH_2-ring), 1.65 (m, 6H, CH_2-ring).

DMAPr−CI: ^{1}H NMR ($CDCl_3$, δ in ppm) 8.14 (s, 1H, NC*H*N), 7.42 (s, 1H, NCHCHN), 7.08 (s, 1H, NCHC*H*N), 4.49 (t, 2H, OCH_2), 2.45 (t, 2H, CH_2N), 2.29 (s 6H, N(CH_3)$_2$), 2.01 (quintet, 2H, (CH_2CH_2CH$_2$).

BDMPAP−CI: ^{1}H NMR ($CDCl_3$, δ in ppm) 8.13 (s, 1H, NC*H*N), 7.43 (s, 1H, NCHCHN), 7.06 (s, 1H, NCHC*H*N), 5.21 (m, 1H, OC*H*CH$_3$), 2.71 (bs, 2H, OCH(CH$_3$)CH_2N), 2.52 (m 4H, CH_2N((CH$_2$)$_3$N(CH$_3$)$_2$)$_2$), 2.43 (m, 4H, CH_2CH_2CH_2N-(CH$_3$)$_2$)$_2$), 2.24 (bs 12H, N((CH$_2$)$_3$N(CH_3)$_2$)$_2$), 1.57 (m, 4H, CH$_2$N(CH_2CH_2CH_2N(CH$_3$)$_2$)$_2$), 1.37 (d, 3H, OCHCH_3).

NHEM−CI: ^{1}H NMR ($CDCl_3$, δ in ppm) 8.15 (s, 1H, NC*H*N), 7.44 (s, 1H, NCHCHN), 7.09 (s, 1H, NCHC*H*N), 4.58 (t, 2H, OCH_2), 3.74 (bs, 4H, (CH_2)$_2$O), 2.81 (t, 2H, CH_2N), 260 (bs, 4H, N(CH_2)$_2$).

In the next step the carbamate was dissolved in toluene (10 mL) and *p*-methoxyphenol (10 mg) was added as an inhibitor to prevent premature polymerization. HPMA (1.1 equiv) in toluene (10 mL) was added. The reaction mixture was stirred overnight at 80 °C, and subsequently the solvent was removed under reduced pressure. The product was purified using silica flash column chromatography (eluent 1 (EtOAc) used to remove the inhibitor ($R_f = 0.9$) and free HPMA ($R_f = 0.4$), followed by eluent 2 (MeOH/CH_2Cl_2 (1/9 v/v) used to elute the product from the column). The ^{1}H NMR data of the monomers are given below.

HPMA−DMAE: ^{1}H NMR ($CDCl_3$, δ in ppm) 6.40 (bs, 1H, CON*H*CH$_2$), 5.73 (s 1H, H_2C═C), 5.34 (s 1H, H_2C═C), 4.86 (m, 1H, CH$_2$C*H*(CH$_3$)O), 4.20 (m, 2H, s OCH_2CH$_2$), 3.60 (m, 2H, CH_2CH(CH$_3$)O), 2.74 (t, 2H, OCH$_2$CH_2N), 2.40 (s, 6H, N(CH_3)$_2$), 1.97 (s, 3H, CH_2═CCH_3), 1.30 (d, 3H, CH_2CH-(CH_3)O).

HPMA−DEAE: ^{1}H NMR ($CDCl_3$, δ in ppm) 6.60 (bs, 1H, CON*H*CH$_2$), 5.73 (s 1H, H_2C═C), 5.34 (s 1H, H_2C═C), 4.86 (m, 1H, CH$_2$C*H*(CH$_3$)O), 4.30 (m, 2H, s OCH_2CH$_2$), 3.60 (m, 2H, CH_2CH(CH$_3$)O), 2.92 (t, 2H, OCH$_2$CH_2N), 2.78 (q, 2H, N(CH_2)$_2$), 2.57 (q, 2H, N(CH_2)$_2$), 1.97 (s, 3H, CH_2═CCH_3), 1.27 (d, 3H, CH_2CH(CH_3)O), 1.18 (t, 3H, N(CH_2CH_3)$_2$), 1.04 (t, 3H, N(CH_2CH_3)$_2$).

HPMA−MPPM: ^{1}H NMR ($CDCl_3$, δ in ppm) 6.40 (bs, 1H, CON*H*CH$_2$), 5.70 (s 1H, H_2C═C), 5.34 (s 1H, H_2C═C), 4.86 (m, 1H, CH$_2$C*H*(CH$_3$)O), 4.20 (m, 2H, s OCH_2CH$_2$), 3.60 (m, 2H, CH_2CH(CH$_3$)O), 2.86 (m, 1H, OCH$_2$C*H*N), 2.40 (s, 3H, NCH_3), 2.20 (m, 2H, CH_2-ring), 1.96 (s, 3H, CH_2═CCH_3), 1.60 (m, 6H, CH_2-ring) 1.30 (d, 3H, CH_2CH(CH_3)O).

HPMA−DMAPr: ^{1}H NMR ($CDCl_3$, δ in ppm) 6.50 (bs, 1H, CON*H*CH$_2$), 5.70 (s 1H, H_2C═C), 5.36 (s 1H, H_2C═C), 4.88 (m, 1H, CH$_2$C*H*(CH$_3$)O), 4.10 (m, 2H, s OCH_2CH$_2$), 3.60 (m, 2H, CH_2CH(CH$_3$)O), 2.48 (t, 2H, OCH$_2$CH$_2$CH_2N), 2.35 (s, 6H, N(CH_3)$_2$), 1.97 (s, 3H, CH_2═CCH_3), 1.80 (m, 2H, (CH_2CH_2-CH$_2$), 1.27 (d, 3H, CH_2CH(CH_3)O).

HPMA−BDMPAP: ^{1}H NMR ($CDCl_3$, δ in ppm) 6.60 (bs, 1H, CON*H*CH$_2$), 5.73 (s 1H, H_2C═C), 5.47 (s 1H, H_2C═C), 4.85 (m, 3H, CH$_2$C*H*(CH$_3$)O, OC*H*CH$_3$), 3.60 (m, 2H, NCH_2-CH(CH$_3$)O), 2.50 (m, 10H, CH_2N((CH$_2$)$_3$N(CH$_3$)$_2$)$_2$, CH$_2$N(CH_2-CH$_2$CH_2N(CH$_3$)$_2$)$_2$), 2.25 (m, 12H, N((CH$_2$)$_3$N(CH_3)$_2$)$_2$), 1.95 (s, 3H, CH_2═CCH_3), 1.65 (m, 4H, CH$_2$N(CH_2CH_2CH_2N-(CH$_3$)$_2$)$_2$), 1.26 (m, 6H, CH$_2$CH(CH_3)O, OCHCH_3).

HPMA−NHEM: ^{1}H NMR ($CDCl_3$, δ in ppm) 6.80 (bs, 1H, CON*H*CH$_2$), 5.58 (s 1H, H_2C═C), 5.23 (s 1H, H_2C═C), 4.80 (m, 1H, CH$_2$C*H*(CH$_3$)O), 4.14 (m, 2H, CH_2CH$_2$), 3.74 (bs, 4H, (CH_2)$_2$O), 3.60 (m, 2H, CH_2CH(CH$_3$)O), 2.81 (m, 2H, CH_2N), 260 (bs, 4H, N(CH_2)$_2$), 1.95 (s, 3H, CH_2═CCH_3), 1.27 (d, 3H, CH$_2$CH(CH_3)O).

Polymer Synthesis. The different monomers (3.2 mmol) were dissolved in dry dioxane (total volume of 2 mL) in a glass vial. Then 2,2′-azo-bis(isobutyronitrile) (AIBN) (1.2 mg, M/I = 400 (mol/mol) was added and the vial was capped, degassed, and extensively flushed with nitrogen. The reaction mixture was heated to 70 °C and stirred at this temperature for 16 h. Next, the reaction mixture was diluted with 20 mM ammonium acetate buffer, pH 5, and dialyzed with a Spectra/Por membrane MWCO 3500 (SPECTRUM, Breda, The Netherlands) against the same buffer for 3 days. After dialysis the solution was freeze-dried, and the polymer was obtained as a white fluffy material.

pK_a Measurements. The pK_a values of monomers and polymers were determined by titration with a Mettler Toledo DL21 titrator (Mettler Toledo, Tiel, The Netherlands). The compounds were dissolved in 0.9 w/v % NaCl solutions (concentration of 0.2−0.3 w/v %), acidified with 0.1 M HCl, and titrated with 0.25 M NaOH.

Hydrolysis of the Monomers. The different monomers (100 mg) were dissolved in 100 mM 4-(2-hydroxyethyl)-1-piperazine-ethanesulfonic acid (HEPES), adjusted to 150 mM with NaCl, pH 7.4, or in 100 mM sodium acetate, adjusted to 150 mM with NaCl, pH 5.0. The solutions were incubated at 37 °C, and samples were withdrawn at regular time intervals and immediately measured using RP-HPLC. The RP-HPLC system consisted of a Waters pump model 515 (Waters Associates, Milford, MA), Spark Marathon Basic+ injector (Spark, Emmen, The Netherlands), and a LKB 2151 UV detector (LKB, Roosendaal, The Netherlands) set at 210 nm. The columns used were a Merck LiChrosphere 100 (Merck, Darmstadt, Germany) RP-18 column (5 μm, 125 mm × 4 mm i.d.) and a RP-18 guard column (4 mm × 4 mm). The mobile phase consisted of a water−acetonitrile 95/5 (w/w) solution completed with 10 mM triethylamine and brought to pH 2 with TFA. The flow rate was 1 mL/min; the injection volume was 20 μL.

GPC Measurements. Weight average molecular weight (M_w) and number average molecular weight (M_n) of the synthesized polymers were determined by gel permeation chromatography (GPC), performed with three thermostated (35 °C) columns in series (Shodex OHpak SB-G and two SB-806M HQ, Showa Denko, Kawasaki, Japan) on a Waters HPLC system consisting of a controller (type 600), autosampler (type 717plus), tunable absorbance detector (type 486), and a differential refractometer (type 410) (Waters, Milford MA). Data were analyzed with Empower Pro software (Waters, Milford MA). The eluent was an aqueous solution of 0.3 m NaAc, pH 4.4, at a flow rate of 0.5 mL/min (*25*). The columns were calibrated with PEG standards (Fluka).

Size and Charge Measurements of the Polyplexes. The *Z*-average diameter of the polymer/plasmid DNA complexes were measured by dynamic light scattering (DLS) using a Malvern ALV CGS-3 system equipped with an argon-ion laser (488 nm, 10.4 mW) (uniphase). The ALV correlator software in combination with DTS(Nano) and ALVFilereader software was used. The instrument was calibrated with 100 nm poly(styrene) particles dispersed in water. In a typical experiment, 200 μL of HEPES buffer (5.0 mM, pH 7.4, adjusted to 150 mM with NaCl), containing 15 μg of plasmid DNA, was added to 800 μL of HEPES buffer (5.0 mM, pH 7.4, adjusted to 150 mM with NaCl) with various amounts of polymer. The resulting solution was vortexed for 5 s, and after 30 min of incubation time at room temperature the size of the polyplexes was determined using DLS at 25 °C.

The ζ-potential of the polyplexes was measured at 25 °C using a Zetasizer 2000 unit (Malvern) equipped with a DTS5001 cell. The instrument was calibrated using a poly(styrene) dispersion with a known ζ-potential. In a typical experiment, 200 μL of HEPES buffer (5.0 mM, pH 7.4), containing 15 μg of plasmid DNA was added to 800 μL of HEPES buffer (5.0 mM, pH 7.4) with various amounts of polymer. The resulting solution was vortexed for 5 s, and after 30 min of incubation time at room temperature the surface charge properties of the polyplexes was determined.

Polyplex Destabilization Studied with DLS. Polyplexes of the polymers and plasmid DNA were made at a polymer/DNA (w/w) ratio of 12 (corresponding to a N/P ratio of 14 and in the case of pHPMA−BDMPAP to a ratio of 28), either in 10 mM HEPES, pH 7.4, or in 10 mM acetate buffer, pH 5, ionic strength adjusted to 150 mM with NaCl. The size of the polyplexes at 37 °C was monitored in time using DLS.

Polyplex Destabilization Studied with Agarose Gel Electrophoresis. Polyplexes were made by mixing 10 μL of plasmid solution, 200 μg/mL, with 40 μL of polymer solution, 200 μg/mL, corresponding to a polymer/DNA (w/w) ratio of 12, and incubated for 30 min at room temperature. The buffers used were 10 mM HEPES, pH 7.4, and 10 mM sodium acetate, pH 5; ionic strength was adjusted to 150 mM with NaCl. The polyplex dispersions were subsequently incubated at 37 °C for 0, 2, 4, 7, 24, or 48 h. After the mixture was cooled to room temperature, 10 μL of the corresponding buffer and 3 μL of sample buffer (0.4% w/v bromophenol blue, 10 mM EDTA, 50% v/v glycerol in water) were added to 20 μL of each polyplex dispersion. An amount of 30 μL of these solutions was applied onto a 0.7% agarose gel containing 0.5 μg/mL ethidium bromide, and the gels were run at 100 V (*26*).

Transfection Studies. Transfection studies were done in COS-7 cells as described previously using pCMVLacZ as reporter gene (*23*). In brief, 96-well plates were seeded with cells at a density of 3×10^4 cm^{-2} 24 h before transfection. Polyplexes were prepared as follows: 150 μL of polymer solution (various concentrations) was added to 50 μL of plasmid solution (50 μg/mL), and after incubation for 30 min at room temperature, 50 μL of either buffer or INF-7 solution (150 μg/mL) was added, and the polyplexes were incubated for another 15 min before addition to the cells. After the cells were rinsed with HBS, 100 μL of polyplex dispersion and 100 μL of culture medium (with or without 10% serum) were incubated with the cells for 1 h. After removal of the polyplex dispersion, fresh culture medium was added, and the cells were incubated for another 48 h. All transfection experiments were performed in two identical series in separate 96-well plates. One series was tested for reporter gene expression (β- galactosidase) by ONPG colorimetric assay. The other series was used to determine the number of viable cells using an XTT colorimetric assay. Transfection efficiencies were normalized to that of pDMAEMA polyplexes (polymer/DNA ratio of 3/1) in the presence of serum. For comparison, the transfection activity of polyplexes of PEI (branched, 25 kDa) in the presence of 5% serum was also measured.

Fluorescence Measurements. The binding of the cationic polymers to DNA was examined by the fluorescence quenching of ethidium bromide (*27*). Ethidium bromide was added at a 1:10 molar ratio to DNA phosphates in 20 mM HBS (20 mM HEPES buffer (pH 7.4) containing 150 mM NaCl). Polyplexes were formed at different polymer/DNA ratios by vortexing solutions of known concentration of DNA/ethidium bromide and polymer in 20 mM HBS (final concentration of DNA, 2.5 μg/mL), followed by incubation at room temperature for 30 min. The fluorescence was measured using a Spex Fluorolog III spectrofluorimeter (Spex, Edison). The excitation and emission wavelengths were 520 and 600 nm, respectively. The excitation and emission slit widths were set at 1.26 and 4.52 nm, respectively. The relative fluorescence (F_r) values were calculated as

$$F_r = \frac{F_{obs} - F_e}{F_0 - F_e}$$

where F_{obs} is the measured fluorescence, F_e is the fluorescence of ethidium bromide in the absence of DNA, and F_0 is the initial fluorescence of DNA/ethidium bromide in the absence of a cationic polymer. Dissociation of polyplexes was studied by measuring the fluorescence 30 min after addition of p(Asp) (final concentration is 100 μg/mL) (*26*).

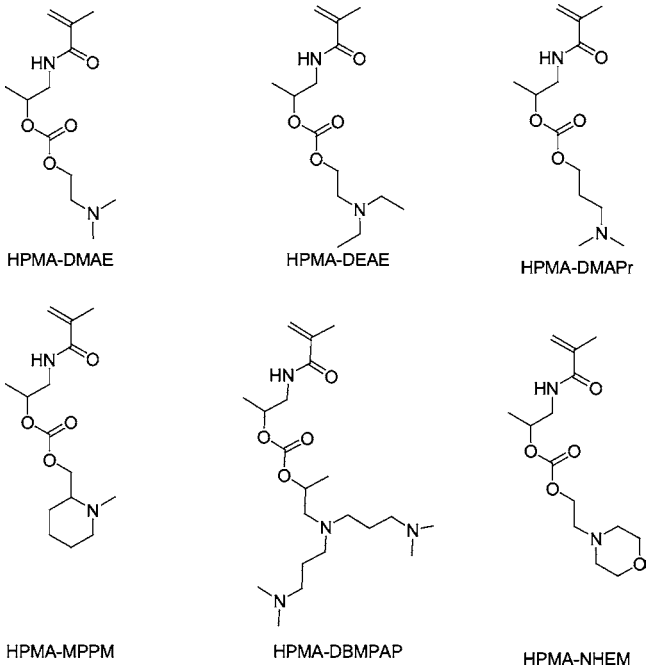

Figure 1. Chemical structures of the synthesized monomers.

RESULTS AND DISCUSSION

Synthesis and Characterization of the Different Monomers and Polymers. The synthesis of the monomers was performed in two steps. In the first step, the amino alcohols DMAE, DEAE, DMAPr, MPPM, BDMPAP, and NHEM were activated with 1,1′-carbonyldiimidazole. The corresponding carbamates were obtained in a good yield (70−90%) and good purity (>97% by NMR). Funhoff et al. (*19*) reported the synthesis of HPMA−DMAE with 5 days of reaction time at room temperature for the second step. However, this method was not successful for some of the monomers, e.g., HPMA−BDMPAP and HPMA−NHEM. Therefore, the second reaction (coupling of HPMA and CI-activated alcohol) was done in toluene overnight at 80 °C instead of in dichloromethane at room temperature for 5 days. Under these conditions all monomers were successfully synthesized (Figure 1, Table 1).

Radical polymerization of the monomers was performed in freshly distilled dioxane using AIBN as initiator, and the resulting polymers were obtained in good yields (60−75%). The weight-average molecular weight (M_w) and the number-average molecular weight (M_n) of the polymers are given in Table 1. The M_w of the polymers was between 25 and 100 kDa, and the M_n of the polymers was between 10 and 50 kDa. Furthermore, Table 1 shows the pK_a values of the monomers and the average pK_a values of the polymers (which is defined as the pH at which 50% of the amine groups of the polymers is protonated). Since the pK_a of PHPMA−DBMPAP and pHPMA−DMAPr is around 7.0, these polymers, in contrast to the other synthesized polymers (pK_a values ranging from 8.7 to 9.5), have higher buffer capacities in the endosomal vesicles.

Hydrolysis of the Monomers. The hydrolysis kinetics of the monomers at 37 °C were studied with RP-HPLC. The k_{obs} for the hydrolysis of the monomer was calculated by plotting the natural logarithm of the peak areas of the monomer divided by the peak area at time zero of the monomer versus the time using a linear fit. Table 2 gives the results. By far the fastest hydrolysis is observed for HPMA−DEAE (half-life 2 h). HPMA−DMAE and HPMA−MPPM are more stable with a half-life of around 10 h. As expected, the half-live of HPMA−BDMPAP is much longer (40 h) because the carbonate function originates from two secondary alcohols instead of one as in the case of the other monomers. The long half-lives of HPMA−DMAPr (79 h) and HPMA−NHEM (40 h) are not fully understood at this moment and needs further investigation.

Table 2. Monomer Hydrolysis at 37 °C and pH 7.4

monomer	k_{obs} (h^{-1})	$t_{1/2}$ (h)
HPMA−DMAE	$6.2 \times 10^{-2} \pm 5.6 \times 10^{-4}$	11 ± 0.1
HPMA−DEAE	$3.0 \times 10^{-1} \pm 2.1 \times 10^{-2}$	2.3 ± 0.2
HPMA−DMAPr	$8.8 \times 10^{-3} \pm 1.4 \times 10^{-4}$	79 ± 1.2
HPMA−MPPM	$7.0 \times 10^{-2} \pm 9.1 \times 10^{-4}$	10 ± 0.1
HPMA−NHEM	$2.4 \times 10^{-2} \pm 9.2 \times 10^{-5}$	29 ± 0.1
HPMA−BDMPAP	$1.6 \times 10^{-2} \pm 1.4 \times 10^{-4}$	43 ± 0.4

Table 3. Particle Size (Diameter) and ζ-Potential of the Polyplexes at a Polymer/DNA Ratio of 12 (w/w) in HBS Buffer (5.0 mM, pH 7.4, Adjusted to 150 mM with NaCl) and in HEPES Buffer (5.0 mM, pH 7.4), Respectively

polymer	*Z*-average (nm)	ζ-potential (mV)
PHPMA−DMAE	169 ± 3	30 ± 2
PHPMA−DEAE	200 ± 2	35 ± 2
PHPMA−DMAPr	142 ± 3	25 ± 4
PHPMA−MPPM	117 ± 2	20 ± 2
PHPMA−BDMPAP	136 ± 3	35 ± 3
PHPMA−NHEM	aggregates	-17 ± 1

Particle Size and ζ-Potential Measurements. pHPMA−DMAE, pHPMA−DEAE, pHPMA−MPPM, pHPMA−DMAPr, and pHPMA−BDMPAP were capable of condensing DNA into positively charged nanoparticles at N/P ratios greater than 4 (size between 120 and 150 nm). In buffer with physiological ionic strength (5 mM hepes, 150 mM NaCl) the size of the polyplexes slightly increased (120−200 nm, Table 3). Independent of the ionic strength, DNA/polymer aggregates were observed at lower N/P ratios of <4. The ζ-potentials of these polyplexes were all between 20 and 30 mV (Table 3). Although ^{1}H NMR showed no degradation of the polymer, pHPMA−NHEM was unable to condense DNA; the addition of pHPMA−NHEM to plasmid DNA resulted in the formation of large aggregates.

Polyplex Destabilization Studied with DLS. The (in)stability of the polyplexes was investigated by dynamic light scattering at 37 °C at both pH 7.4 and pH 5.0 (parts A and B of Figure 2, respectively). At pH 5.0 the size of the polyplexes remained constant for at least 16 h. The polyplexes based on pHPMA−DMAE, pHPMA−MPPM, and pHPMA−DEAE increased in size at pH 7.4 and 37 °C (Figure 2A) in time. This can be explained by hydrolysis of the side chains. Because of this hydrolysis, the charge density of the polymer decreased, leading to a decreased binding and condensing capacity of the polymer which results in swelling and aggregation of the polyplexes. The results are consistent with those of the monomer hydrolysis. HPMA−DEAE, the monomer with shortest hydrolysis half-life at pH 7.4, gave the fastest polyplex destabilization (Figure 2A). The monomers with long hydrolysis half-lives, e.g., pHPMA−BDMPAP and pHPMA−DMAPr, lead to polyplexes that were stable at pH 7.4 for more than 16 h. Beyond 13 h and at pH 7.4, complex aggregation and precipitation made accurate DLS measurements impossible for pHPMA−DMAE and pHPMA−MPPM based polyplexes.

Polyplex Destabilization Studied with Agarose Gel Electrophoresis. To investigate whether plasmid DNA can be released from the polyplexes by side chain hydrolysis of the polymers, polyplexes were incubated at 37 °C at pH 7.4 up to 48 h (Figure 3A). This figure shows that after 7 h of incubation and independent of the polyplex formulation all the plasmid DNA remained in the starting slots, indicating that the polymers are still complexed with DNA. After 24 h, pHPMA−DEAE showed release of intact DNA. After 48 h, pHPMA−DMAE and pHPMA−MPPM also showed release of DNA. PHPMA−BDMPAP and pHPMA−DMAPr showed no release of DNA

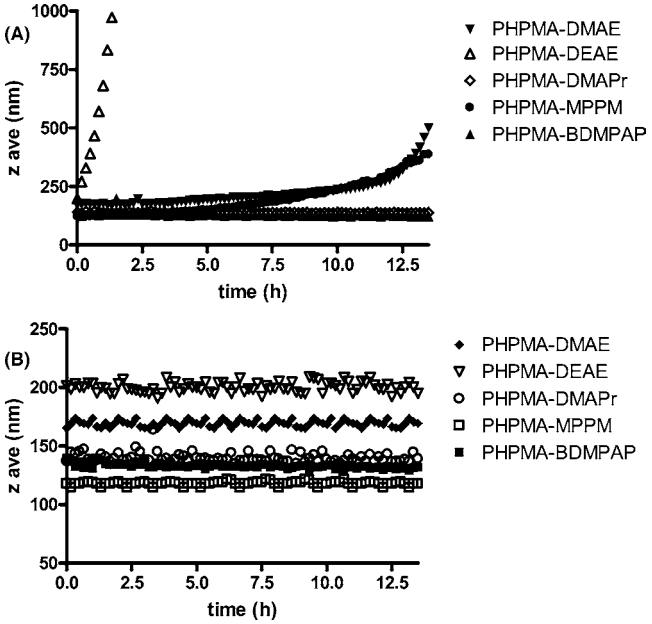

Figure 2. (A) Destabilization of polyplexes studied with DLS at 37 °C, adjusted to 150 mM with NaCl at pH 7.4. The polymer/DNA ratio is 12 (w/w). (B) Destabilization of polyplexes studied with DLS at 37 °C, adjusted to 150 mM with NaCl at pH 5.0. The polymer/DNA ratio is 12 (w/w).

in the time frame studied. As a control, polyplexes were incubated at 37 °C at pH 5.0 up to 48 h (Figure 3B). Under these conditions no release of DNA was observed from the polyplexes. The results obtained in the agarose gel study are in line with the results obtained with the destabilization of the polyplexes as studied with DLS. The polymer with the fastest destabilization at pH 7.4 and 37 °C, pHPMA−DEAE, also shows the fastest release of DNA (Figure 3). PHPMA−DMAE and pHPMA−MPPM both show similar release of plasmid DNA and also have similar destabilization curves and hydrolysis rates. Polyplexes of the polymers with long half-lives, e.g., pHPMA−BDMPAP and pHPMA−DMAPr, did not release plasmid DNA within the time frame studied. The results further suggest that partial degraded polymers are still capable of complexing DNA because the hydrolysis rate of the polymer is much faster than the DNA release.

Fluorescence Measurements. The binding of the polymers to plasmid DNA was studied using ethidium bromide fluorescence measurements (Table 4). This table shows that all the polymers quenched the plasmid DNA/ethidium bromide fluorescence except for pHPMA−NHEM. This result is in line with the DLS data where we also found that pHPMA−NHEM did not complex the DNA. PDMAEMA and pLL showed more quenching than the HPMA polymers, indicating a stronger binding of former mentioned polymers to the plasmid DNA. Of the different HPMA polymers, pHPMA−DMAE, pHPMA−DMAPr, and pHPMA−BDMPAP showed the strongest quenching, suggesting the strongest binding of the polymer to the plasmid DNA. The addition of p(Asp) to the polyplexes caused little effect on the DNA/ethidium bromide fluorescence intensity of pHPMA−DEAE and pHPMA−MPPM. In contrast, for the other polymers p(Asp) caused a substantial increase in the DNA/ethidium bromide fluorescence intensity. This indicates that the polyplexes based on pHPMA−DEAE and pHPMA−MPPM are more resistant toward destabilization by anionic macromolecules than the polyplexes based on the other polymers.

Transfection Activity and Cell viability Studies. The in vitro transfection properties of the polyplexes were studied with the COS-7 cell line (Figures 4 and 5). As a representative example, Figure 4 shows the transfection activity of pHPMA−

MPPM based polyplexes in the presence and the absence of INF-7 peptide. Without the addition of the endosomal membrane disrupting INF-7 peptide to the polyplex dispersion, low transfection activity was observed. However, when INF-7 peptide was added to the polyplex dispersion, high levels of transfection were observed, as reported previously for pHPMA−DMAE (*19*). The low transfection activity of the polyplexes in the absence of INF indicates that the polyplexes are unable to destabilize endosomal vesicles. PHPMA−BDMPAP, despite its buffering capacity, also needed the addition of INF-7 peptide to escape from the endosome. This has been observed previously by Funhoff et al. (*28*) for pDAMA polymers and leads to further indications that the proton sponge hypothesis (*29*) is not generally valid.

Figure 5 shows the transfection activity and cytotoxicity of the different polyplexes in the presence of INF-7 peptide and in the presence and the absence of serum. PHPMA−DMAPr

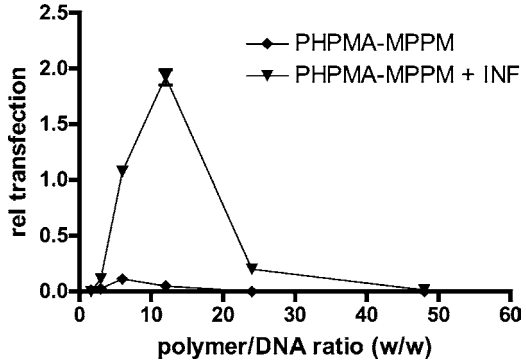

Figure 4. Transfection activity of pHPMA−MPPM based polyplexes with and without INF-7 peptide and in the presence of serum. Values are relative to pDMAEMA/plasmid DNA 3:1 (w/w). β-Galactosidase activity was determined using OPNG as substrate (*27*).

based polyplexes, like pHPMA−DMAE based polyplexes, only show efficient gene expression in the absence of serum. PHPMA−DEAE and pHPMA−MPPM polyplexes were twice as active as pHPMA−DMAE polyplexes in the absence of serum. PHPMA−DEAE, pHPMA−MPPM, and pHPMA−BDMPAP based polyplexes showed similar transfection levels in the presence and absence of serum and suggest that these polyplexes, in contrast to pHPMA−DMAE based polyplexes (*19*), are stable toward serum. The presence of serum proteins can lead to a decrease in transfection activity due to destabilization and/or aggregation of the polyplexes (*19*, *30*, *31*). The pHPMA−DEAE and pHPMA−MPPM polyplexes were also twice as active as the well-known transfectants pDMAEMA and pEI in the presence of serum proteins (Figure 5A).

The IC_{50} (defined as the concentration resulting in 50% inhibitory activity (cell death)) for the pHPMA-based polyplexes was between 12 and 96 μg/mL in the presence of serum (Figure 5A), whereas the IC_{50} for the polyplexes with nondegradable polymers, like pDMAEMA and pEI, was around 5 μg/mL (*14*, *32*). The toxicity of the polyplexes was lower in the presence of serum than in the absence of serum (Figure 5B). The serum proteins likely mask cationic surfaces of the polyplexes, thereby reducing the toxicity (*14*). The maximum transfection efficiency of the different polyplexes was observed at 50−80% cell viability as described before for other polymeric carrier systems (*14*, *22*).

Potentially limiting barriers to efficient gene transfer include endocytosis, escape from endosome into the cytoplasm, cytoplasmic mobility, transport across the nuclear membrane, and release of the plasmid DNA (*33*, *34*). Successful polymeric transfectants have to overcome all these different barriers in the different stages of transfection pathway. The polymer with the highest overall transfection activity is the polymer with the best average over all these barriers. Therefore, polymers with

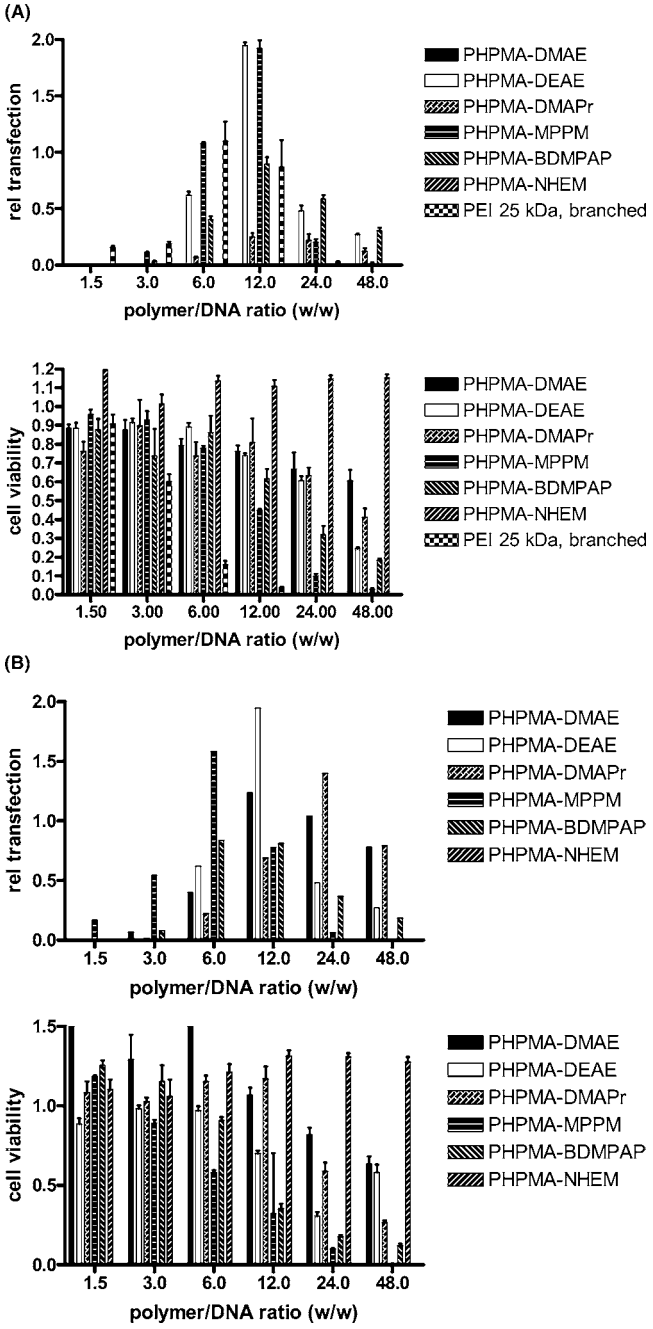

Figure 5. (A) Transfection activity and cell viability of the polyplexes in the presence of serum (5%) and in the presence of INF-7 peptide. Values are relative to pDMAEMA/plasmid DNA 3:1 (w/w). β-Galactosidase activity was determined using OPNG as substrate (*26*). The transfection activity and cell viability of 25 kDa branched pEI-based polyplexes in the presence of serum (5%) are also shown. (B) Transfection activity and cell viability of the polyplexes in the absence of serum and in the presence of INF-7 peptide. Values are relative to pDMAEMA/plasmid DNA 3:1 (w/w). β-Galactosidase activity was determined using OPNG as substrate (*26*).

different physical properties such as pHPMA−DMAE, pHPMA−BDMPAP, and pHPMA−DMAPr can have similar transfection properties, and polymers with similar physical properties can have different transfection properties. For example, pHPMA−DMAE and pHPMA−MPPM have similar pK_a values, similar half-lives, and similar polyplex destabilization characteristics; however, their transfection and cell viability properties differed widely, indicating that a small structural change of the side group can have a drastic effect on the transfection activity. This has also been observed for other structurally related polymers (*35*, *36*).

CONCLUSION

We have synthesized a series of new gene delivery polymers with hydrolyzable cationic side groups. It was shown that polyplexes based on these polymers were stable at pH 5.0. Some of these polymers showed release of intact DNA within 24 h (pHPMA−DEAE) or 48 h (pHPMA−DMAE and pHPMA−MPPM) after incubation at 37 °C and pH 7.4. Polyplexes based on these polymers showed a lower cytotoxicity than well-known polymeric transfectants such as pEI and pDMAEMA. The transfection activities of PHPMA−DEAE, pHPMA−MPPM, and pHPMA−BDMPAP were also serum-independent. The transfection activities of PHPMA−DEAE and pHPMA−MPPM are even superior to the transfection activity of pEI. Future work will focus on in vivo application of the new polymers.

N^{ϵ}-(3-[*I]Iodobenzoyl)-Lys^5-N^{α}-maleimido-Gly^1-GEEEK ([*I]IB-Mal-D-GEEEK): A Radioiodinated Prosthetic Group Containing Negatively Charged D-Glutamates for Labeling Internalizing Monoclonal Antibodies

Novel methods are needed for the radiohalogenation of cell-internalizing proteins and peptides because rapid loss of label occurs after lysosomal processing when these molecules are labeled using conventional radioiodination methodologies. We have developed a radiolabeled prosthetic group that contains multiple negatively charged D-amino acids to facilitate trapping of the radioactivity in the cell after proteolysis of the labeled protein. N^{ϵ}-(3-[^{125}I]iodobenzoyl)-Lys^5-N^{α}-maleimido-Gly^1-GEEEK ([^{125}I]IB-Mal-D-GEEEK) was synthesized via iododestannylation in 90.3 ± 3.9% radiochemical yields. This radioiodinated agent was conjugated to iminothiolane-treated L8A4, an anti-epidermal growth factor receptor variant III (EGFRvIII) specific monoclonal antibody (mAb) in 54.3 ± 17.7% conjugation yields. In vitro assays with the EGFRvIII-expressing U87MGΔEGFR glioma cell line demonstrated that the internalized radioactivity for the [^{125}I]IB-Mal-D-GEEEK-L8A4 conjugate increased from 14.1% at 1 h to 44.7% at 24 h and was about 15-fold higher than that of directly radioiodinated L8A4 at 24 h. A commensurately increased tumor uptake in vivo in athymic mice bearing subcutaneous U87MGΔEGFR xenografts (52.6 ± 14.3% injected dose per gram versus 17.4 ± 3.5% ID/g at 72 h) also was observed. These results suggest that [^{125}I]IB-Mal-D-GEEEK is a promising reagent for the radioiodination of internalizing mAbs.

INTRODUCTION

Targeted radionuclide therapy is an attractive alternative cancer treatment to conventional external beam radiation, particularly when the molecule being targeted is truly tumor specific. An example of such a target is the epidermal growth factor receptor variant III (EGFRvIII), a mutant receptor found on glioma, and breast, lung, and ovarian carcinomas, and characterized by a deletion in the extracellular domain of EGFR (*1*). EGFRvIII-specific monoclonal antibodies (mAbs) have been generated and, as is generally the case with anti-receptor mAbs, undergo rapid internalization and extensive lysosomal degradation after cell surface receptor binding (*2*).

Internalization is a necessary prelude for cytotoxic potency with immunotoxins (*3*). On the other hand, internalization creates a serious problem for radioimmunotherapy because of the rapid loss of radioactivity after tumor cell processing of mAbs radioiodinated by the direct electrophilic route (*4*, *5*). This has provided motivation for the development of "residualizing" labeling methods which seek to overcome the rapid egress of radioiodine from tumor by labeling the mAb via a labeled prosthetic group that will remain trapped inside the cell after mAb degradation (*6*−*9*). The approach taken by our group for labeling internalizing mAbs has been to exploit the limited diffusion of charged species across cell and lysosomal membranes. We have evaluated a series of aromatic acylation agents bearing positively (*4*, 10) or negatively charged (*11*) substituents for this purpose. Indeed, in preclinical studies, substantially higher retention of radioiodine in tumor cells and human tumor xenografts have been achieved for anti-EGFRvIII mAbs radioiodinated using such templates compared to the same mAbs radioiodinated by the direct method (*12*−*14*).

In an extension of this general strategy, the anti-EGFRvIII mAb L8A4 was radioiodinated using D-N^{α}-Ac-KRYRR, a peptide containing three arginines to impart positive charge and composed of D-amino acids to inhibit proteolysis (*15*). The procedure involved three steps: peptide radioiodination, reaction with the bifunctional agent sSMCC, and finally, conjugation to mAb derivatized by reaction with iminothiolane. Tumor retentions of radioiodine, both in cells and xenografts, for L8A4 mAb labeled by this method compared favorably with those observed using other labeling approaches; however, kidney uptake was also higher, presumably due to the cationic nature of the D-amino acid peptide. In addition, the procedure involves radioiodination of the D-tyrosine, rendering the labeled mAb susceptible, albeit to a lesser degree (*16*), to in vivo deiodination. Furthermore, extension of this method for use with the heavier halogen ^{211}At, of interest for α-particle radioimmunotherapy (*17*), would be problematic because introduction of ^{211}At onto tyrosine residues has not been successful (*18*, *19*).

The objective of the current study was to refine our D-amino acid peptide prosthetic group strategy by developing a labeling reagent with the following properties: (1) simpler chemistry, (2) potential applicability for both radioiodination and astatination, (3) structural dissimilarity to thyroid hormones, and (4) D-peptide sequence with net negative charge. To accomplish this, a pentapeptide consisting of a maleimidoglycine, three D-glutamines, and a D-lysine was synthesized, and the lysine ϵ-amino group was derivatized with a 3-(tri-*n*-butylstannyl)benzoyl moiety. Herein we present the results of synthesis of this precursor and its radioiodination to N^{ϵ}-(3-[*I]iodobenzoyl)-Lys^5-N^{α}-maleimido-Gly^1-GEEEK ([*I]IB-Mal-D-GEEEK) and evaluation of the potential utility of this reagent for labeling the anti-EGFRvIII mAb L8A4.

EXPERIMENTAL SECTION

General. All chemicals were purchased from Sigma-Aldrich unless otherwise noted. Sodium [^{125}I]iodide and sodium [^{131}I]iodide with specific activities of 2200 Ci/mmol and 1200 Ci/mmol, respectively, were obtained from Perkin-Elmer Life and Analytical Sciences (Boston, MA). Fmoc-D-Lys(Boc) attached to Wang resin and Fmoc-D-Glu-(O-*t*Bu) were obtained from Novabiochem (West Chester, PA). *N*-Succinimidyl 3-iodobenzoate (SIB) and *N*-succinimidyl 3-(tri-*n*-butyl)stannylbenzoate (STB) were prepared as reported (*20*). D-Amino acid peptides N^{α}-Ac-KRYRR and KEYEE were obtained from Peptide Technologies Corp. (Gaithersburg, MD) and LSU Health Sciences Center Core Laboratories (New Orleans, LA), respectively.

Solid-phase peptide synthesis was carried out on a Perkin-Elmer Applied Biosystems (Foster City, CA) Model 433A automated peptide synthesizer employing their Fast-Moc chemistry with HBTU activation of carboxyl groups. FAB mass spectra were obtained on a JEOL SX-102 high-resolution mass spectrometer. Two HPLC systems were used. For radiochemistry, a Beckman System Gold HPLC equipped with a Model 126 programmable solvent module, a Model 166 NM variable wavelength detector, a Model 170 radioisotope detector, and a Beckman System Gold remote interface module SS420X was employed; data were acquired in this system using 32 Karat software. For nonradioactive and preparative work, a Waters Model Delta 600 semiprep system with a Model 600 controller and a Model 2487 dual wavelength absorbance detector was used; data were acquired using Millenium software. A Waters XTerra C18 HPLC column (4.6 × 250 mm, 5 μm), which was eluted at a flow rate of 1 mL/min was used for analytical chromatography and a Waters XTerra C18 column (19 × 150 mm, 7 μm), which was eluted at 10 mL/min was used for semipreparative chromatography. In some cases, a YMC-basic column (S-5 micron, 4.6 × 250 mm; YMC Inc., Wilmington, NC) was used. For size-exclusion HPLC, a 7.5 × 600-mm TSK gel G3000 SW 113 (10 μm) gel filtration column (Tosohaas; Montgomeryville, PA) was used. The following different HPLC solvents and gradient conditions were employed: (I) XTerra analytical column; A = 0.1% TFA/Water, B = 0.1% TFA/CH_3CN; 90:10 (A/B) for 10 min and then to 10:90 over next 10 min; (II) XTerra analytical column; A = 0.1% HOAc in water, B = 0.1% HOAc in CH_3CN; 96:4 (A/B) for 10 min and then to 0:100 over 30 min; (III) Semipreparative column; same solvents and gradient as in II; (IV) XTerra analytical column; same solvents as in II; 96:4 (A/B) for 10 min and then to 0:100 over 15 min and held at this composition for additional 15 min; (V) semipreparative column; same solvents and gradient as in IV; (VI) XTerra analytical column; same solvents as in IV; 96:4 (A/B) for 10 min, then to 0:100 over 5 min and held at this composition for additional 15 min; (VII) YMC column was eluted at a flow rate of 1 mL/min; same solvents as in I; 99:1 (A/B) for 1 min, to 35:65 in 25 min; and (VIII) Size-exclusion column; phosphate-buffered slaine (PBS) at 1 mL/min.

Cells, mAb, and Culture Conditions. Murine IgG1 L8A4 is a mAb which reacts specifically with the 145 kDa deletion mutant EGFRvIII molecule found on multiple human malignancies including gliomas and breast carcinomas (*21*). The EGFRvIII-expressing cell line used for these studies was U87MGΔEGFR which was established from U87 MG human glioma cell line by transfection with EGFRvIII cDNA (*22*). In cell culture, this line expresses an average of $4-13 \times 10^5$ EGFRvIII molecules per cell (*12*). Cells were grown in Zinc Option media (Life Technologies, Inc., Grand Island, NY) containing 10% fetal calf serum and Geneticin sulfate (600 mg/mL).

Synthesis. *Mal-D-GEEEK.* Maleimido glycine (maleimido acetic acid) was synthesized following a literature procedure (*23*). Three D-glutamic acids (*O-t*Bu) and the above glycine derivative were sequentially attached to D-lysine (Boc) supported on Wang resin (0.1 mmol) using the automated synthesizer. Cleavage from the resin and simultaneous removal of side-chain protecting groups were achieved by treatment with 100:95:2.5:2.5 (v/v/v/v/) DCM:TFA:water:triisopropylsilane. The resin was filtered, and the peptide was precipitated from the concentrated filtrate with diethyl ether to yield 40 mg (60%) of N^{α}-maleimido-Gly^1-GEEEK (Mal-D-GEEEK). HPLC conditions I: t_R = 5.4 min. MS (*m*/*z*) Calcd. for: $C_{27}H_{38}N_6O_{14}$ 670.6. Found: 671.1 (MH^+); 693.1 $(M + Na)^+$.

*N^{ϵ}-(3-Iodobenzoyl)-Lys^5-N^{α}-maleimido-Gly^1-GEEEK (IB-Mal-D-GEEEK) (**5**).* This compound was synthesized for use as an HPLC standard. A solution of Mal-GEEEK (1.2 mg; 1.8 μmol) in 30 μL DMF was added to a solution of SIB (7.2 mg; 21 μmol) in 70 μL of 1% (v/v) triethylamine in DMF over a period of 15 min, and the homogeneous mixture was stirred at room-temperature overnight. The peptide was precipitated with excess ether, pelleted, washed twice with ether, and purified by preparative HPLC using conditions III to obtain **5** (yield not determined). HPLC conditions II: t_R = 26.8 min. MS (*m*/*z*) Calcd. for: $C_{34}H_{41}IN_6O_{15}$ 900.6. Found: 901.1 (MH^+).

*N^{ϵ}-(3-(Tri-n-butyl)benzoyl)-Lys^5-N^{α}-maleimido-Gly^1-GEEEK (TB-Mal-D-GEEEK) (**6**).* A solution of Mal-D-GEEEK (8 mg; 12 μmol) in 75 μL DMF was added over a period of 15 min to a solution of STB (24.4 mg; 48.75 μmol) in 125 μL of 1% triethylamine in DMF. The homogeneous mixture was stirred at room-temperature overnight, and the peptide was isolated as above and purified using HPLC conditions V to get 3 mg (23%). HPLC conditions IV: t_R = 30.2 min. MS (*m*/*z*) Calcd. for: $C_{46}H_{68}N_6O_{15}Sn$ 1063.8. Found: cluster peaks around 1087.4 $(M + Na)^+$; 1109.3 $(M + 2Na - H)^+$; 1131.3 $(M + 3Na - 2H)^+$; 1153.3 $(M + 4Na - 3H)^+$.

Radiochemistry. *N^{ϵ}-(3-[^{125}I]Iodobenzoyl)-Lys^5-N^{α}-maleimido-Gly^1-GEEEK ([^{125}I]IB-Mal-D-GEEEK) (**5a**).* Acetic acid (20 μL) was added to a vial containing [^{125}I]sodium iodide (0.5 mCi in 1 μL 0.1 N NaOH) followed by **6** (25 μg; 1 μg /μL AcOH) and NCS (0.4 mg/20μL AcOH). The mixture was incubated for 5 min, and the labeled peptide was isolated by reversed-phase HPLC (conditions VI; t_R = 19.7 min). The HPLC fractions containing the product was pooled and evaporated to dryness using an argon stream.

D-N^{α}-Ac−KR[^{125}I]YRR and D-*KE[^{131}I]YEE.* These peptides were prepared by electrophilic substitution of their tyrosine residues using the Iodogen method. For this, peptide in PBS (480 μg/160 μL and 400 μg/200 μL, respectively, for the positively and negatively charged peptides), was added to $^1/_2$-dram vials coated with Iodogen (10 μg) and containing 558 μCi of ^{125}I and 457 μCi of ^{131}I, respectively. The mixtures were incubated at room temperature for 40 min, and the labeled peptides were isolated by reversed-phase HPLC using conditions VII. The retention times for D-N^{α}-Ac-KR[^{125}I]YRR and D-KE[^{131}I]YEE were 10.3 and 7.5 min, respectively. The pooled HPLC fractions containing the peptide were concentrated by solid-phase extraction using a Sep-pak plus tC18 cartridge (Waters, Milford, MA). After the HPLC fractions were loaded on the cartridge, it was washed sequentially with 5 mL each of water and 5 mM hexanesulfonic acid. The peptides were eluted with 1% HOAc in methanol (4 × 1 mL). The solvents were evaporated with a stream of argon, and the residual radioactivity was reconstituted in PBS prior to use in the animal experiment.

mAb Labeling. *Direct.* A solution of mAb L8A4 (250 μg; 2.5 mg/mL) in phosphate buffer, pH 7.4, was added to a $^1/_2$-dram vial coated with Iodogen (10 μg) followed by a solution

of [^{131}I]sodium iodide (0.5 mCi) in PBS (40 μL). The mixture was incubated for 10 min with occasional shaking, and the labeled mAb was isolated by gel filtration on a PD-10 column (GE Healthcare, Piscataway, NJ) eluted with PBS.

*[^{125}I]IB-Mal-*D*-GEEEK.* L8A4 was dialyzed overnight against PBS, pH 7.4, containing 1 mM EDTA. The above solution of L8A4 (95 μL; 2.6 mg/mL) was treated with a solution of 2-iminothiolane in 1 mM EDTA in PBS (1.5 mL; 2 mg/mL), and the mixture was incubated for 90 min at room temperature. The thiol-derivatized mAb was isolated using a Microspin G-25 column (GE Healthcare, Piscataway, NJ) and added to [^{125}I]IB-Mal-D-GEEEK (0.4 mCi). The mixture was incubated at room temperature for 70 min with occasional mixing. Iodoacetamide (10 μL; 100 mg/mL PBS/EDTA) was added to quench the reaction. After a further incubation for 10 min, the labeled mAb was purified on a PD-10 column eluted with PBS.

Characterization of Labeled mAbs. Protein-associated radioactivity was determined by coprecipitating the labeled mAbs with BSA in a paired-label format with cold methanol. The fraction of radioiodine activity with a retention time corresponding to IgG was measured by size-exclusion HPLC (conditions VIII). The immunoreactive fraction of the labeled mAbs was determined in a paired-label format using magnetic beads coated with EGFRvIII and analyzed according to the Lindmo method as described before (*11*).

Internalization Assay. The retention of radioiodine activity inside the cell and on the cell surface for the L8A4 labeled by the two methods was determined as a function of time. The in vitro assay was performed in a paired-label format using the EGFRvIII-expressing U87MGΔEGFR cell line following previously described procedures (*10*). Briefly, cells at a density of 5 $\times$ 10^5 cells per well were incubated with 1 μCi (0.5−1.0 μg of each mAb) of the labeled mAbs for 1 h at 4 °C. The cells were washed and brought to 37 °C and then processed in triplicate at 0, 1, 2, 4, 8−10, 16, and 24 h as follows: The cell culture supernatant was withdrawn, and surface-bound radioactivity was removed by washing the cells with pH 2 Zinc Option medium. Finally, the cells were solubilized in 0.5 mL of 0.5 N NaOH to determine internalized radioactivity. The cell culture supernatants, acid washes (cell surface-bound), and the cell lysates (internalized) were counted and the results expressed as the percentage of radioactivity initially bound to the cells after the 1 h incubation at 4 °C. The experiment was performed twice.

Biodistribution Measurements. Animal studies were performed under the guidelines established by the Duke University Institutional Animal Care and Use Committee. In these experiments, labeled compounds were injected intravenously via the tail vein, and groups of five animals were evaluated at each time point. Mice were killed by an overdose of halothane and dissected, and tissues of interest were harvested. Blood samples were obtained by retro-orbital bleeding. Tissues were blot-dried, weighed, and counted along with input standards for both ^{125}I and ^{131}I using a dual-channel automated gamma counter that applied corrections for radioactive decay and crossover. Results were expressed as the percent of injected dose per gram of tissue (% ID/g). The difference in the tissue radioactivity levels of the two compounds administered in each experiment was analyzed for statistical significance with a paired *t*-test using the Microsoft Excel program, with $p < 0.05$ considered to represent a significant difference.

D-N$^\alpha$-Ac−KR[^{125}I]YRR versus D-KE[^{131}I]YEE. The experiment was performed to evaluate the effect of charge (three negatively charged glutamates versus three positively charged arginine residues) on the tissue distribution of D-amino acid pentapeptides. Normal mice weighing approximately 25 g were obtained from Charles River Laboratories International Inc. (Wilmington, MA). Animals were injected with 5 μCi of each peptide, and groups of five mice were killed at 0.5, 1, 2, and 4 h postinjection.

Paired-Label Biodistribution of L8A4 Labeled with [^{125}I]IB-Mal-D-GEEEK and with ^{131}I Using Iodogen. BALB/c *nu*/*nu* mice were obtained from a closed breeding colony at the Duke University Cancer Center Isolation Facility. Xenografts were established from the U87MGΔEGFR cell line (*22*). On the basis of the flow cytometry data, disaggregated U87MGΔEGFR xenografts express a mean of 2.5 $\times$ 10^5 EGFRvIII receptors per cell (*12*). The xenografts were generated by injecting the mice subcutaneously in the flank with 50 μL of U87MGΔEGFR tumor homogenate through a 16-gauge needle. Biodistribution measurements were initiated when the xenograft volume reached 200−400 mm^3. Mice were injected with 5 μCi (18.5 μg) and 1.5 μCi (1.6 μg) of ^{125}I- and ^{131}I-labeled L8A4, respectively. Necropsy was performed at 12, 24, 48, 72, and 144 h postinjection.

RESULTS AND DISCUSSSION

Receptor-mediated internalization of radioligands generally results in their translocation to lysosomes where they are subject to degradation by proteases. A consequence of these processes for mAbs labeled by direct methods is the rapid loss of radioiodine from the cell in the form of mono-iodotyrosine (*4*). Because D-amino acids are poor substrates for endogenous proteases, prosthetic groups containing a D-peptide core are a "natural" choice for labeling internalizing mAbs. In this way, different modifications can be made at multiple positions along the peptide with the expectation that the molecule will remain intact in vivo.

A series of D-peptides bearing one or two diethylenetriaminepentaacetic acid (DTPA) substituents have been evaluated for use in labeling internalizing mAbs (*8*, *24*). The rationale for this particular approach is based on the fact that when radiometals are administered as DTPA−mAb conjugates, they are retained inside cells in the form of radiometal-DTPA-lysine. All D-peptide−DTPA reagents provided similar advantages in tumor retention of radioiodine activity for an internalizing mAb compared with directly labeled mAb. In contrast, considerable differences in normal tissue retention were observed, with less accumulation achieved when the hydrophilicity of the peptide was maximized by appending two DTPA moieties.

We have been pursuing an alternative strategy in which the characteristics of the D-amino acid peptide itself are modulated in order to achieve trapping of the radionuclide inside the cell after mAb internalization. The feasibility of this approach was demonstrated in studies utilizing D-N$^\alpha$-Ac-KRYRR (*15*), a peptide with three positively charged arginine residues included in the sequence in order to inhibit egress of labeled catabolites across lysosome and cell membranes. Considerably higher tumor levels were observed for an internalizing mAb labeled with ^{125}I-labeled D-N$^\alpha$-Ac-KRYRR compared with ^{131}I-labeled L-N$^\alpha$-Ac-KRYRR, confirming the role of D-amino acids in achieving these favorable results. One of the motivations for the current study was to determine whether similar results could be obtained with other D-amino acid peptides, in this case, bearing three negatively charged glutamic acids.

In our D-N$^\alpha$-Ac-KRYRR-based conjugation labeling method (*15*), the radiolabeled peptide was conjugated first to iminothiolane-treated mAb via a bifunctional reagent containing a maleimido moiety. To avoid this extra step, we have included a maleimido-glycine at the N-terminus of the peptide. This was built-in during the solid-phase synthesis of the peptide (Scheme 1). The stability of maleimido moiety to coupling and cleavage conditions (peptide synthesis) was evaluated by thin-layer chromatography, and the maleimido glycine was shown to be inert under these conditions (data not shown). Other investigators

also have synthesized peptides with built-in maelimido functionalities (*25*). The molecular weights observed for the backbone peptide, as well as the SIB- and STB-derivatized peptides, were consistent with the theoretically calculated values.

The tin precursor was radioiodinated to [^{125}I]IB-Mal-D-GEEEK (Scheme 2) in 90.3 ± 3.9% radiochemical yield and in more than 99% radiochemical purity. [^{125}I]IB-Mal-D-GEEEK was coupled to thiolated mAb L8A4 in conjugation efficiencies of 54.3 ± 17.7%. Conjugation efficiencies were similar to those observed previously for D-*N*$^{\alpha}$-Ac-KRYRR to this same mAb (*15*) and comparable to those reported by Stein et al. (*24*) for D-peptides with one maleimido functionality. Although these investigators were able to increase coupling yield by inclusion of a second maleimido group, we chose not to pursue this tactic because of the potential for forming multimeric mAb species.

Coprecipitation of the labeled protein with BSA using methanol indicated that 94 ± 6% of the radioactivity was protein-associated. This was corroborated by size-exclusion HPLC of the preparation, which showed a single radioactivity peak eluting with a retention time corresponding to monomeric IgG with minimal aggregation of the protein (data not shown). The immunoreactive fraction as determined by the Lindmo method was 83 ± 2% compared to 70% obtained for L8A4 labeled with Iodogen.

The primary hypothesis of this work is that incorporation of multiple negatively charged amino acids in the D-peptide prosthetic group for mAb radiohalogenation would provide labeled catabolites that will be trapped inside cells after mAb internalization. The labeled reagent that was developed, [*I]IB-Mal-D-GEEEK, has three glutamic acid residues with carboxylate side chains (p*K* 4.25) that should be predominantly anionic at lysosomal pH. To determine whether labeling the anti-EGFRvIII mAb L8A4 with [*I]IB-Mal-D-GEEEK increased cellular retention of radioactivity compared with direct iodination, a paired-label internalization experiment was performed in vitro using the U87MGΔEGFR cell line. As shown in Figure 1A, the percent of initially bound radioactivity that internalized increased with time throughout the 24 h observation period for L8A4 labeled with [^{125}I]IB-Mal-D-GEEEK; on the other hand, not only was this amount considerably lower for L8A4 labeled by the direct method but intracellular activity decreased with the time. For example, internalized radioactivity for L8A4 labeled with [^{125}I]IB-Mal-D-GEEEK at 24 h (44.7 ± 3.1%) was about 15-fold higher than that from directly labeled L8A4 (3.0 ± 0.3%). The surface-bound radioactivity (Figure 1B) was higher for L8A4 labeled with [^{125}I]IB-Mal-D-GEEEK at each time point compared to the directly labeled mAb. As a result, the total cell-associated radioactivity was substantially higher for the mAb labeled using this novel method. The radioactivity pattern seen in cell culture supernatants (Figure 1C) was complementary to the above.

The degree of enhancement in cell-associated radioactivity obtained with [*I]IB-Mal-D-GEEEK at 24 h was even more favorable than that obtained with D-*N*$^{\alpha}$-Ac-KRYRR (5-fold; same mAb and cell line) (*15*). The tumor delivery advantage obtained using the IB-Mal-GEEEK template also is higher than that obtained with other residualizing labels (*10, 11*). Although comparison to other mAbs and cell lines must be done with caution, it is worth noting that the increase in intracellular and total cell associated radioactivity seen with [*I]IB-Mal-D-GEEEK was substantially higher than that reported for other D-amino acid peptide prosthetic groups (*24*). In addition, [*I]IB-Mal-D-GEEEK was the only reagent that resulted in an increase in intracellular activity with time. The reason for these differences is not known at this time. We speculate that a probable factor is the fact that the site of [*I]IB-Mal-D-GEEEK radioiodination is less susceptible to deiodination, with the result that a greater fraction of the label is still associated with the mAb at later time points.

A drawback of the KRYRR method, which provided one of the motivations for the current study, was that the use of this reagent for labeling L8A4 increased renal uptake considerably

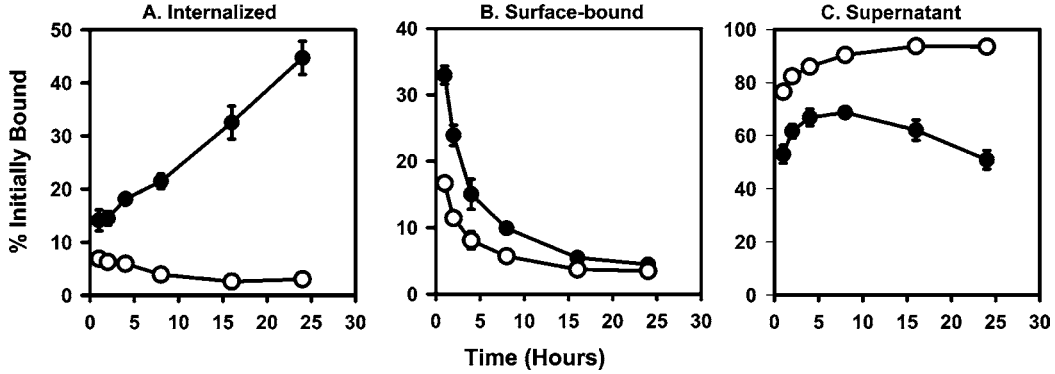

Figure 1. Paired-label internalization by U87MGΔEGFR cells of L8A4 directly radioiodinated with ^{131}I using Iodogen (open circles) and that labeled with [^{125}I]IB-Mal-GEEEK (filled circles). Cells were allowed to take the tracers by incubating them together for 1 h at 4 °C. Medium containing unbound radioactivity was removed, and the cells were supplemented with fresh medium, brought up to 37 °C and processed as described under Experimental Section.

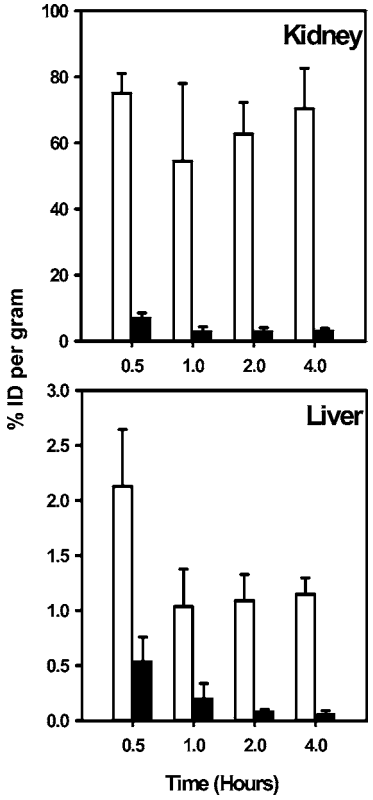

Figure 2. Paired-label uptake of D-N^{α}-Ac-KR[^{125}I]YRR (open bars) and D-KE[^{131}I]YEE (closed bars) in kidneys and liver of normal mice.

(*15*). It is well-known that positively charged molecules are retained to a greater degree by the kidneys because they are more likely to undergo tubular absorption due to the negative charge of the luminal membranes of kidney (*26*). In fact, lysine is often pre-administered to obviate the high renal accumulation of several radiopharmaceuticals (*27*). On the basis of this, we hypothesized that utilization of a peptide with multiple D-glutamates instead of D-lysines should allow enhancement of tumor retention of radioactivity without increasing uptake in kidneys.

To determine whether a decrease in kidney uptake, and possibly other normal organ accumulation, could be achieved by substitution of negatively charged for positively charged amino acids, a tissue distribution experiment was performed in normal mice comparing the organ uptake of radioactivity from D-N^{α}-Ac-KR[^{125}I]YRR and D-KE[^{131}I]YEE. The latter peptide was derived by substituting D-glutamates for D-lysines in D-N^{α}-Ac-KRYRR; in addition, the N-terminus was not acetylated.

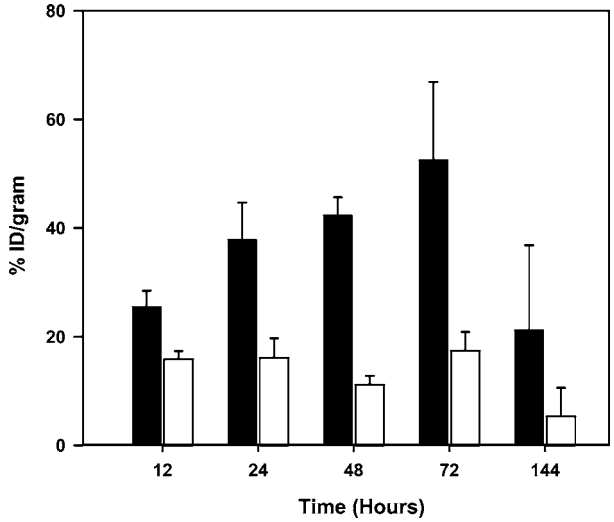

Figure 3. Paired-label tumor uptake of L8A4 directly radioiodinated with ^{131}I using Iodogen (open bars) and that labeled with [^{125}I]IB-Mal-GEEEK (filled bars) in athymic mice bearing U87MGΔEGFR xenografts.

As shown in Figure 2, over a period of 4 h, the uptake of radioactivity in kidneys from D-KE[^{131}I]YEE was more than 10-fold lower than that from the coadministered D-N^{α}-Ac-KR[^{125}I]YRR ($p < 0.01$). Accumulation of radioiodine in the liver with D-KE[^{131}I]YEE also was at least four times less than observed for co-administered D-N^{α}-Ac-KR[^{125}I]YRR ($p < 0.01$). The substantial reduction in the renal uptake is consistent with the net negative charge of the KEYEE construct. In addition to negative charge, the lower lipophilicity of KEYEE might have been a contributory factor to lowering liver uptake. One would expect the cationic peptide to be more lipophilic due to capping of its N-terminus with an acetyl group, and indeed, under identical conditions, it had a retention time of 10.3 min in reversed-phase HPLC compared with 7.5 min for KEYEE. On the basis of these results, we embarked on the design and evaluation of IB-Mal-GEEEK as a reagent for labeling internalizing mAbs.

The biodistribution of L8A4 labeled with [^{125}I]IB-Mal-GEEEK and mAb labeled with ^{131}I using Iodogen method were compared in a paired-label format in athymic mice bearing subcutaneous U87MGΔEGFR human glioma xenografts. In concert with the in vitro internalization data, the tumor uptake in vivo of [^{125}I]IB-Mal-GEEEK-labeled L8A4 was substantially higher ($p < 0.05$ except at 144 h) than that of the directly labeled mAb (Figure 3). The tumor uptake of [^{125}I]IB-Mal-GEEEK-labeled L8A4 increased with time, reaching a maximum of 52.6 ± 14.3% ID/g at 72 h. A 1.6, 2.3, 3.8, 3.0, and 4.0-fold higher

[a] Mean ± S.D ($n = 5$; for 144 h, $n = 4$) of %ID/gram. [b] The difference in uptake between the two methods not statistically significant ($p > 0.05$).

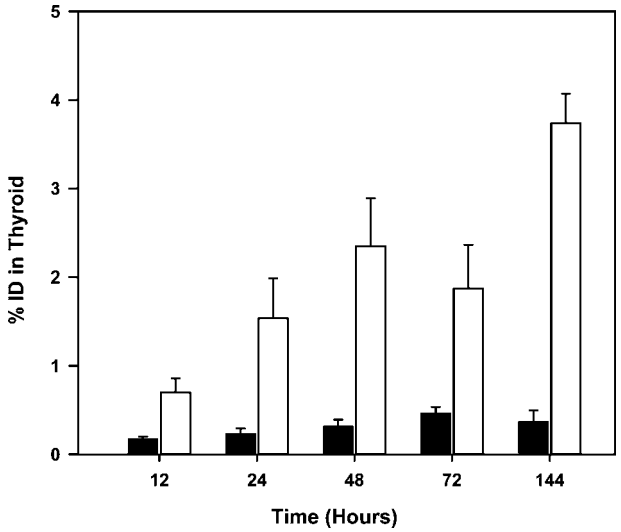

Figure 4. Uptake of radioiodine activity in mouse thyroid after administration of L8A4 labeled with ^{125}I using [^{125}I]IB-Mal-GEEEK (filled bars) and with ^{131}I using the Iodogen method (open bars).

tumor uptake was observed for mAb labeled with [^{125}I]IB-Mal-GEEEK compared with that labeled using Iodogen at 12, 24, 48, 72, and 144 h, respectively. The tumor delivery advantage using [^{125}I]IB-Mal-GEEEK was about the same as observed previously with D-N^{α}-Ac-KR[^{125}I]YRR; however, the maximum tumor uptake was seen at 3 days rather than 1 day after injection (*15*). This suggests that [*I]IB-Mal-GEEEK may be a useful radiohalogenation method for increasing the tumor radiation dose achievable in radioimmunotherapy with internalizing mAbs such as L8A4 labeled with 8.1-day half-life ^{131}I.

Thyroid uptake is frequently used as an indicator of degree of in vivo deiodination of radioiodinated compounds. In Figure 4, the thyroid accumulation of ^{125}I and ^{131}I activity following injection of [^{125}I]IB-Mal-GEEEK-labeled L8A4 and L8A4 labeled with ^{131}I using Iodogen are compared. The % ID recovered from the thyroid for L8A4 labeled with [^{125}I]IB-Mal-GEEEK ranged from 0.18 ± 0.02% at 12 h to 0.47 ± 0.07% at 72 h and were 4- to 10-fold lower than that seen for mAb labeled using Iodogen, but not significantly different from those observed for L8A4 labeled with D-N^{α}-Ac-KR[^{125}I]YRR (*15*). Thus, labeling on an iodobenzoyl moiety offered no advantage compared with a D-tyrosine site in minimizing the deiodination in vivo of this internalizing mAb.

These results are consistent with the stability of D-tyrosine toward deiodination (*16*) but also may reflect other factors as well. Thyroid accumulation of a mAb that does not undergo internalization, 81C6, labeled by coupling to SIB was about an order of magnitude lower than that seen in the current study (*28*). Interestingly, the thyroid uptake observed after injection of this mAb labeled with using *N*-succinimidyl iodobenzoates bearing positively (*10*) or negatively (*11*) charged polar substituents was somewhat lower than that seen with the two D-amino acid peptide reagents. In addition differences related to the processing of the two mAbs and the nature of the linkage between the prosthetic group and the mAb also may play a role.

The tissue distribution of radioiodine labels in other normal tissues was similar for L8A4 mAb labeled by the two methods with two notable exceptions (Table 1). Uptake of ^{131}I was higher at all time points in the stomach, another tissue known to take up free iodide avidly, and this is consistent with the observed higher thyroid uptake of ^{131}I. Contrary to the expectations, however, the accumulation of radioactivity in the kidneys for L8A4 labeled with [^{125}I]IB-Mal-GEEEK was about 2- to 3-fold higher than that for directly labeled mAb. In fact, the renal uptake of [^{125}I]IB-Mal-GEEEK-labeled L8A4 was similar to that seen for the same mAb labeled with the cationic D-peptide reagent (*15*), suggesting that changing the net charge of the D-peptide from positive to negative was not an effective strategy for reducing kidney uptake of intact mAbs labeled using this type of prosthetic group. On the other hand, the uptake in liver for L8A4 labeled with [^{125}I]IB-Mal-GEEEK was quite similar to that for coadministered mAb labeled using Iodogen and about 3-fold lower compared to L8A4 labeled with D-N^{α}-Ac-KR[^{125}I]YRR (*15*). Increased kidney and liver retention of radioiodine has been observed, compared with direct labeling,

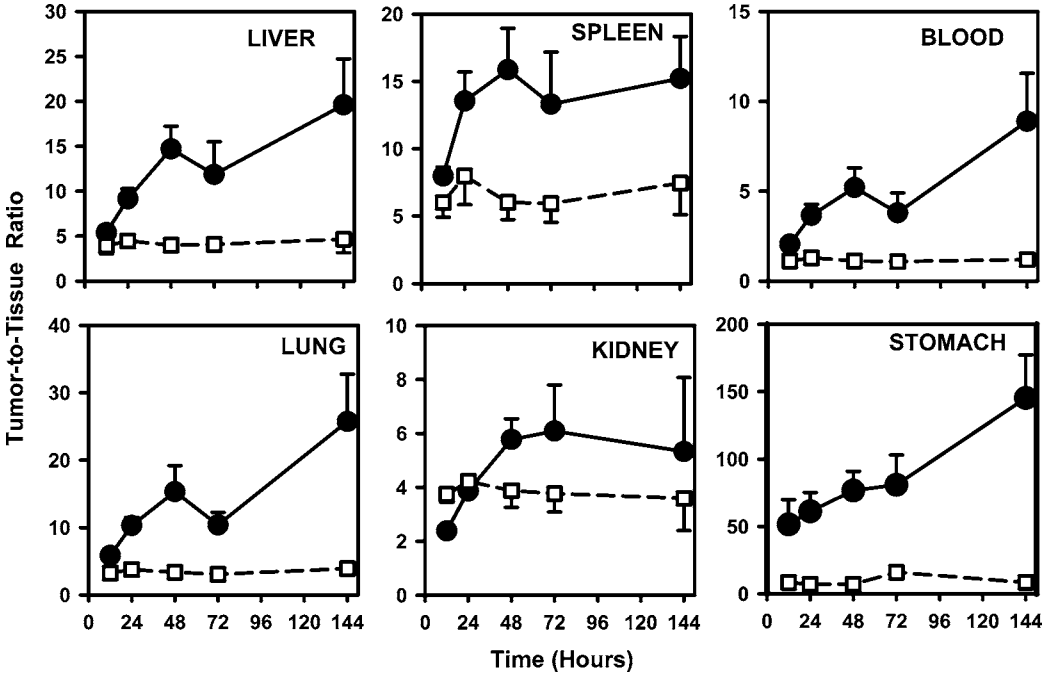

Figure 5. Tumor-to-normal tissue ratios of ^{125}I (filled circles) and ^{131}I (open circles) in athymic mice after paired injection of L8A4 labeled with [^{125}I]IB-Mal-GEEEK and with ^{131}I using the Iodogen method.

for mAb RS7 after labeling with six different D-peptide labeling reagents, with the effect most prominent for the IMP−R2 peptide bearing four tyrosine residues, a DTPA, and two maleimido moieties (*24*). Taken together, these results suggest that decreasing the hydrophobicity of the D-peptide results in decreased liver accumulation; however, it is difficult to ascertain the best strategy for minimizing renal accumulation with this class of radiohalogenation agents.

Tumor:normal tissue ratios for L8A4 labeled with [^{125}I]IB-Mal-GEEEK and with ^{131}I using Iodogen are shown in Figure 5. Except for the kidney at some time points, significantly higher tumor:normal tissue ratios were observed for the D-peptide conjugate. With the exception of the kidney, selectivity of radioiodine increased with time as did the selectivity advantage for mAb labeled using the D-peptide reagent. At 6 days after injection, tumor:normal tissue ratios for L8A4 labeled with [^{125}I]IB-Mal-GEEEK reached 5.3 ± 2.7, 8.9 ± 2.7, 15.2 ± 3.1, 19.6 ± 5.1, 25.7 ± 7.0, and 145 ± 32 in kidney, blood, spleen, liver, lung and stomach, respectively. These values were 1.5- to 17-fold higher than those for coadministered L8A4 labeled using Iodogen and reported previously for this mAb labeled with D-N^{α}-Ac-KR[^{125}I]YRR (*15*).

In summary, a new prosthetic group, [*I]IB-Mal-GEEEK, consisting of three D-glutamates, a D-lysine carrying an [*I]iodobenzoyl moiety, and a maleimide function was synthesized from a tin precursor and conjugated to an internalizing anti-EGFRvIII mAb with preservation of immunoreactivity. Compared with mAb labeled using Iodogen, labeling L8A4 using [*I]IB-Mal-GEEEK enhanced intracellular retention of radioiodine in EGFRvIII-expressing tumor cells in vitro and in tumor xenografts and resulted in significantly higher tumor:normal organ uptake ratios. We conclude that [*I]IB-Mal-GEEEK is a promising reagent for the radioiodination of mAbs that undergo internalization. Further work is in progress to evaluate the potential of this approach for labeling mAbs with the α-emitter astatine-211.

TECHNICAL NOTES

Thermostability of Native and Pegylated *Myceliophthora thermophila* Laccase in Aqueous and Mixed Solvents

J. I. López-Cruz,[†] G. Viniegra-González,*[,†] and A. Hernández-Arana[‡]

Laboratorio de Biología Molecular y Enzimología de Hongos Filamentosos, Departamento de Biotecnología, and Laboratorio de Biofisicoquímica, Departamento de Química, Universidad Autónoma Metropolitana Iztapalapa, CP. 09340, Avenida San Rafael Atlixco, 186, México D.F. . Received December 5, 2005; Revised Manuscript Received April 17, 2006

A commercial preparation of laccase (EC 1.10.3.2), cloned from *Myceliophthora thermophila* and expressed in *Aspergillus oryzae* (MtL), was purified and modified by conjugation with poly(ethylene glycol) ($M_r = 5000$) and is labeled PEG−MtL. Native enzyme was found to have a molecular mass of 80 kDa, as determined by gel filtration, and 110 kDa, by SDS−PAGE. The oxidative dimerization of 2,6-dimethoxyphenol (DMP) to produce the corresponding dibenzoquinone was catalyzed by MtL in a manner comparable to that for a diffusion-controlled reaction ($k_{cat}/K_M \cong 10^8$ M^{-1} s^{-1} and $E_a \cong 18$ kJ M^{-1}). PEG−MtL was found, by TNBS titration, to have blocked 54% of lysine groups; its hydrodynamic and charge properties were different from those of MtL. Catalytic efficiency (k_{cat}/K_M) of PEG−MtL was similar to that of MtL with DMP as substrate; however, k_{cat}/K_M was 2-fold reduced for the reaction in which 2′,2-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) is oxidized to form a radical cation. E_a values were similar in both enzyme preparations when assayed in buffered solutions. Far-UV CD spectra were similar for MtL and PEG−MtL and consistent with a protein rich in β-sheet structure with negligible content of α-helices. A blue shift of near-UV CD spectrum for PEG−MtL as compared to MtL was consistent with the decreased polarity of the tyrosyl side chains upon PEG conjugation. Also the blue band of the copper active site was shifted from $\lambda \sim 610$ nm (MtL) to $\lambda \sim 575$ nm (PEG−MtL). Scanning microcalorimetry showed small denaturation enthalpies (6.3 and 7.5 J g^{-1} for MtL and PEG−MtL, respectively), indicating the high stability of the β-sheet folding pattern of laccases. However, PEG−MtL proved to be more stable, its half-denaturation temperature being 2 °C higher than that of MtL. In 30% alcohol, pegylated laccase showed slower enzyme-activity decay rates than the unmodified enzyme; this behavior was caused by a decrease in the activation entropy of the denaturation reaction. Results can be explained by entropic stabilization by PEG conjugation because of the restricted motion of some surface amino acid side chains, which results in a more stable active site.

INTRODUCTION

Laccase is an enzyme (*p*-diphenol: dioxygen oxido-reductase, EC 1.10.3.2) that catalyzes the oxidation of a large variety of phenolic and polyaromatic compounds (*1*). It has been proposed as a potential bleaching agent of cellulose pulp and organic dyes (*2*, *3*) and also as a catalyst for the oxidation of polluting polycyclic aromatic hydrocarbons (*4*, 5). This enzyme has four copper atoms in its active site that reduce O_2 to water using an appropriate electron donor as substrate (*6*, *7*). One of those copper atoms (T_1) absorbs light near 620 nm due to a highly covalent bond between cysteine and Cu (*8*, *9*). Another copper (T_2) does not show strong absorption of light, and two other copper atoms (T_3) are coupled through a hydroxide and shuttle electrons from substrate to the trinuclear T_2/T_3 cluster (*11*, *12*).

Among the future applications of laccase, the oxidation of dibenzothiophene derivatives in diesel fuel has been mentioned (*13*, *14*), but the rates of oxidation of this compound were found too slow, perhaps because the substrate is sparsely soluble in water and the enzyme is inactivated by the presence of organic solvents (*13*). García-Arellano et al. (*15*) showed that the conjugation of cytochrome *c* with poly(ethylene glycol) (PEG) improved the thermal stability of the catalytic site. Furthermore, Vandertol-Varnier et al. (*16*) showed that laccase from *Coriolopsis gallica* conjugated with PEG had a higher catalytic activity on syringaldazine than the native enzyme.

In this work the thermal stability of laccase from *Myceliophthora thermophila* (*17*) conjugated with PEG was studied in relation to the presence of alcohols of different polarity using spectropolarimetric, calorimetric, and enzymological techniques as compared with the native preparation. The hypothesis of this work was that the thermal stability of PEG−laccase would be better than that of native laccase.

EXPERIMENTAL PROCEDURES

Chemicals. The enzyme MtL was obtained from the company Novo Nordisk, in the form of a commercial preparation called Deni Lite IIs. Bovine serum albumin (BSA), cyanuric chloride-activated monomethoxy poly(ethylene glycol) ($M_r = 5$ kDa), 2′,2-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), 2,6-dimethoxyphenol (DMP), and trinitrobenzenesulfonic acid (TNBS) were from Sigma (St. Louis, MO).

Extraction and Purification of Laccase. Fifty grams of Deni Lite IIs was suspended in 200 mL of 50 mM potassium

phosphate buffer, pH 6.0, and shaken for 24 h at 4 °C. Solids were removed by centrifugation at 10 000 rpm for 30 min. The supernatant was concentrated nearly 40-fold and dialyzed against the phosphate buffer using an ultrafiltration stirred system (Millipore) with a 10 kDa cutoff cellulose membrane pressurized at 5.95 bar with N_2, on ice. The concentrate was applied to an anion exchange Q-Sepharose column (Hi-Prep 16/10 QFF, Bio-Rad, 120 mg HSA/mL gel) preequilibrated with two column volumes of 50 mM Tris-HCl, pH 7.3, and eluted with a linear gradient from 0.0 to 0.5 M NaCl in the Tris-HCl buffer. Fractions with laccase activity were pooled and concentrated, dialyzed, and stored at −5 °C in phosphate buffer. This preparation was labeled as MtL (native enzyme). To determine the molecular weight of the enzyme a sample was dialyzed against 0.5 mM acetate buffer solution (pH 5.0) and applied to a Superdex 200 HR 10/30 column (Amersham Pharmacia); protein was eluted with buffer containing 0.5 M NaCl (0.5 mL min^{-1}).

Determination of Enzymatic Activity. Laccase activity was routinely assayed by measuring the rate of ABTS oxidation at room temperature. The reaction mixture contained 1.0 mL of 5 mM ABTS dissolved in 50 mM potassium phosphate buffer (pH 6.0) and 100 μL of appropriately diluted enzyme. ABTS oxidation was followed by an increase of absorbance at 420 nm ($\epsilon_{420} = 36\,000\ M^{-1}\ cm^{-1}$). One unit of activity was defined as the amount of laccase that oxidized 1 μmol of substrate per minute. In assays carried out at other pH values, reaction solutions were buffered with citrate (pH 3.0 and 4.0), acetate (pH 5.0), and phosphate (pH 6.0, 7.0, and 8.0) solutions at 50 mM. For determination of catalytic constants, ABTS solutions were prepared in the phosphate buffer (pH 6.0) at concentrations varying from 0.01 to 5.0 mM. When DMP was the substrate, it was dissolved in a mixture of 10% propanol in the same buffer to a final concentration from 0.01 to 0.50 mM. Oxidation of DMP was followed by the absorption increment at 469 nm ($\epsilon_{469} = 49\,600\ M^{-1}\ cm^{-1}$).

Protein Concentration. The protein was assayed by the Bradford method (*18*) using the Bio-Rad protein reagent with bovine serum albumin as standard.

Chemical Modification of Laccase. Chemical modification of the exposed lysine amino groups of laccase was carried out with 50-fold excess of monomethoxy poly(ethylene glycol) activated with cyanuric chloride (Sigma) in 40 mM borate buffer, pH 10.0. The reaction was allowed to proceed for 2.5 h at 25 °C (*16*). The resulting solution was dialyzed and concentrated 20-fold with 50 mM phosphate buffer, pH 6.0, by using the same procedure as for the native enzyme. This preparation was labeled as PEG−MtL.

Determination of Modified Amino Groups. The degree of protein modification was estimated by titration of the residual free amino groups using the reagent TNBS in order to obtain the corresponding trinitrophenyl derivatives, according to the Habeeb method (*19*). The reaction was carried out at pH 8.5. Absorbance was measured at 335 nm against the appropriate blank. The molar extinction coefficient was taken to be $\epsilon_{335} = (1.09 \pm 0.01) \times 10^4\ M^{-1}\ cm^{-1}$.

Gel Electrophoresis. Polyacrylamide gel electrophoresis with sodium dodecyl sulfate (SDS−PAGE) was performed in a Mini-Protean II Cell (Bio-Rad), using a 10.0% gel containing 0.1% SDS according to the methodology of Laemmli (*20*). Protein bands were revealed with Coomassie Blue G-250 or the silver staining kit (Amersham Biosciences, Uppsala, Sweden). The samples were compared to high-range molecular weight markers of Sigma (St. Louis, MO). Other experiments were carried out using a 10.0% polyacrylamide gel, without SDS and mercaptoethanol.

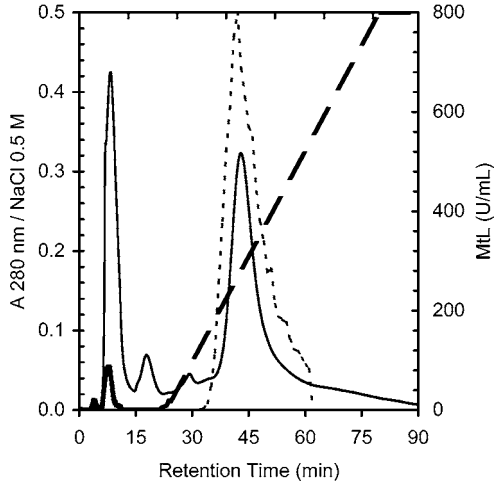

Figure 1. Purification of commercial laccase by ion-exchange chromatography. Six milliliters of mediator-free Deni Lite IIs solution was applied to a Q-Sepharose column and eluted with a NaCl gradient (0−0.50 M). —, absorbance at 280 nm; - - -, laccase activity; − − −, concentration of NaCl in the eluent.

Stability Assays. The stabilities of MtL and PEG−MtL preparations were compared by measuring the decay of enzyme activities (assayed by ABTS oxidation at room temperature) when incubated at various temperatures (40−80 °C) in the presence of 0, 10.0, or 30.0% (v/v) of methanol, ethanol, propanol, or acetonitrile. Decay rate constants, k_i, were estimated by fitting the first-order equation, $A = A_o \exp(-k_i t)$, to the experimental data.

Circular Dichroism (CD) Measurements. CD measurements were performed in a Jasco J-715 spectropolarimeter (Jasco Inc, Easton, MD) equipped with a PTC-348WI Peltier-type cell holder for temperature control. MtL or PEG−MtL samples (0.2 mg mL^{-1}) were dissolved in 50 mM phosphate buffer (pH 6.0) and placed in a 0.10 cm cell. CD scans were run at 25 °C in the range from 190 to 250 nm. For the aromatic absorption region (above 250 nm) protein concentration was increased to 1.0 mg mL^{-1} and a 1.00 cm cell was used.

Differential Scanning Calorimetry (DSC). Calorimetric endotherms were obtained with a Microcal MC2 differential scanning calorimeter (MicroCal Inc, Northampton, MA). Measurements were carried out with a degassed enzyme solution (2.0 mg mL^{-1}, prepared in 5 mM citrate buffer, pH 5.0) in the sample cell. The reference cell was filled with the buffer alone. Both cells were pressurized to nearly 2.0 atm with N_2 gas and heated from 25 to 109 °C at a rate of 1.0 °C min^{-1}. The adiabatic jacket was kept at a partial vacuum of 0.0106 atm. Buffer (blank) tracings were recorded under the same conditions. The Origin software package (MicroCal) was used for data analysis including baseline subtraction and the calculation of specific enthalpies (ΔH_{cal}).

RESULTS AND DISCUSSION

Purification and Catalytic Properties of *M. thermophyla* Laccase (MtL). The reddish color of Deni Lite IIs, which is due to the presence of the redox mediator 10-phenotyazinpropionic acid (*21*), was completely eliminated by extensive dialysis through a 10 kDa cellulose membrane. This operation produced an apparent decrease of approximately 10.0% in the total laccase activity of the material. The elution profile from the ion-exchange column (Figure 1) showed four peaks with absorbance at 280 nm, but all the laccase activity was contained in the peak that eluted last; fractions with enzyme activity were pooled and further submitted to PAGE, where a single major protein band was observed (Figure 2).

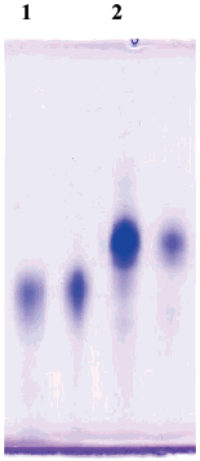

Figure 2. Native PAGE of *M. thermophila* laccase (MtL) and its PEG derivative at pH 6.8. Lane 1, MtL; lane 2, PEG−MtL. The anode is on top.

Table 1. Catalytic Constants for MtL and PEG−MtL[a]

	MtL			PEG_{5000}-MtL		
substrate	k_{cat} (s^{-1})	K_M (μM)	k_{cat}/K_M ($s^{-1}\,M^{-1}$)	k_{cat} (s^{-1})	K_M (μM)	k_{cat}/K_M ($s^{-1}\,M^{-1}$)
ABTS	6.01×10^2	49.5	1.21×10^7	3.76×10^2	71.2	5.29×10^6
DMP	3.48×10^2	5.02	6.93×10^7	8.73×10^2	9.06	9.63×10^7

[a] Michaelis−Menten constants (k_{cat}, K_M) were determined from activity assays in 50 mM phosphate buffer (pH 6.0) at 25 °C.

After ion-exchange chromatography the specific activity was 29 U mg^{-1}, approximately twice the value shown by the original, mediator-free Deni Lite IIs; the yield was about 60%, based on the amount of protein recovered. All further studies were performed with the enzyme obtained from the Q-Sepharose column. The molecular mass of MtL, as determined by SDS−PAGE (data not shown), was 110 kDa, whereas gel filtration chromatography gave a M_r of 80 kDa. Such a difference in M_r determinations probably arises from differences in the glycosylated nature of MtL (*17*), because it is well-known that the presence of covalently attached carbohydrates often results in incorrect M_r values when using SDS or gel filtration techniques (*15*). It should be mentioned that the protein moiety of this enzyme has a mass of 61 781 kDa, according to its amino acid sequence (*22*). The isoelectric point of the laccase was 3.8, in agreement with previous determinations (*17*).

MtL displayed good activity toward ABTS in the 3.0−7.0 pH range; however, the enzyme was more stable between pH 6.0 and 8.0. Determination of kinetic constants was carried out at pH 6.0. With either ABTS or DMP as substrate, MtL showed typical Michaelis−Menten kinetics (results not shown). The values obtained for k_{cat} and K_M (Table 1) indicate that the catalytic efficiency (k_{cat}/K_M) of the enzyme is comparable to that of diffusion-controlled enzyme reactions (i.e., about 1×10^8 M^{-1} s^{-1}; *23*) when the substrate is the relatively small DMP molecule. With ABTS as substrate, the value found for k_{cat}/K_M is about 5-fold smaller, but still close to that for diffusion-controlled reactions, and 2 orders of magnitude larger than the value reported by Li et al (*3*).

The apparent activation energy, E_a, for the MtL-catalyzed oxidation of ABTS was determined from activity assays in the 25−70 °C temperature range; at temperatures higher than 70 °C, thermal denaturation of the enzyme led to notable loss of activity (Figure 3). From the Arrhenius plot on the low-temperature arm of Figure 3, E_a was determined as 18.0 kJ mol^{-1}, in agreement with the low value observed for diffusion-controlled reactions, which have E_as between 10 and 30 kJ mol^{-1} (*23*).

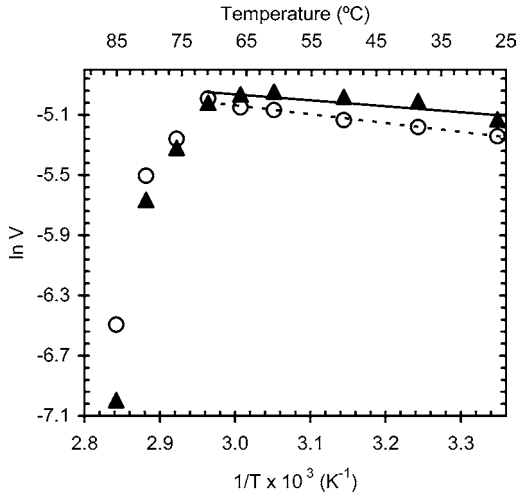

Figure 3. Arrhenius plots for the ABTS-oxidation reaction (pH 6.0) with MtL (▲) and PEG−MtL (○) as catalysts.

Catalytic Properties of Chemically Modified MtL. Under the conditions described in the Experimental Procedures, chemical modification of MtL resulted in a protein material with 54% of its amino groups linked to PEG chains. As a consequence of the reduction in the number of free amino groups, the enzyme derivative (PEG−MtL) showed a smaller electrophoretic mobility toward the cathode than the unmodified laccase (Figure 2). Similarly, attachment of PEG chains notably affected the hydrodynamic properties of MtL, leading to a large reduction of its elution volume in the gel filtration column; the apparent M_r of PEG−MtL determined by this method was larger than 300 kDa, although the expected increase in molecular mass, as computed from the number of modified amino groups, amounts to only 40 kDa.

Determination of the catalytic constants for PEG−MtL gave the results listed in Table 1. It can be seen that the kinetic constants k_{cat} and K_M of the enzyme suffered only minor changes after chemical modification. This is an important result, because with other enzymes the use of cyanuryl chloride−PEG has led sometimes to substantial loss of enzymatic activity due to the low selectivity of this reagent as a protein modifier (*24*, *25*). In the case of MtL, PEG modification slightly affected the affinity of the enzyme (i.e., K_M increased less than 2-fold) for both of the substrates tested. In contrast, PEG−MtL showed a value of k_{cat} that was twice that for the unmodified laccase when DMP was the substrate; with ABTS as substrate, however, k_{cat} was about 2-fold reduced. As a result of these changes in the individual kinetic constants, the catalytic efficiency (k_{cat}/K_M) of the laccase, with the substrate DMP, was practically unaltered by chemical modification; with ABTS, on the contrary, k_{cat}/K_M was more than 2-fold diminished. These findings indicate that the presence of PEG chains on the macromolecular surface somewhat reduces the binding rate of the larger, more hydrophilic ABTS molecule but not that of the small hydrophobic DMP molecule. In other words, PEG modification apparently increased the relative selectivity of the enzyme toward two of its substrates. On the other hand, the apparent activation energy (E_a) for the oxidation of ABTS, whose value is also shown in Table 1, keeps the characteristic small magnitude of diffusion-controlled enzymatic reactions (see Figure 3).

Conformational Characteristics of the Laccase Forms. At 20 °C, the far-UV CD spectrum of MtL (Figure 4) shows a negative band around 216 nm and a positive one at 194−195 nm, both of which are typical of proteins rich in β-strands and with poor helix content (*26*). This observation was expected, given the high sequence identity between MtL and the laccase from *Melanocarpus albomyces* (*27*), whose secondary structure

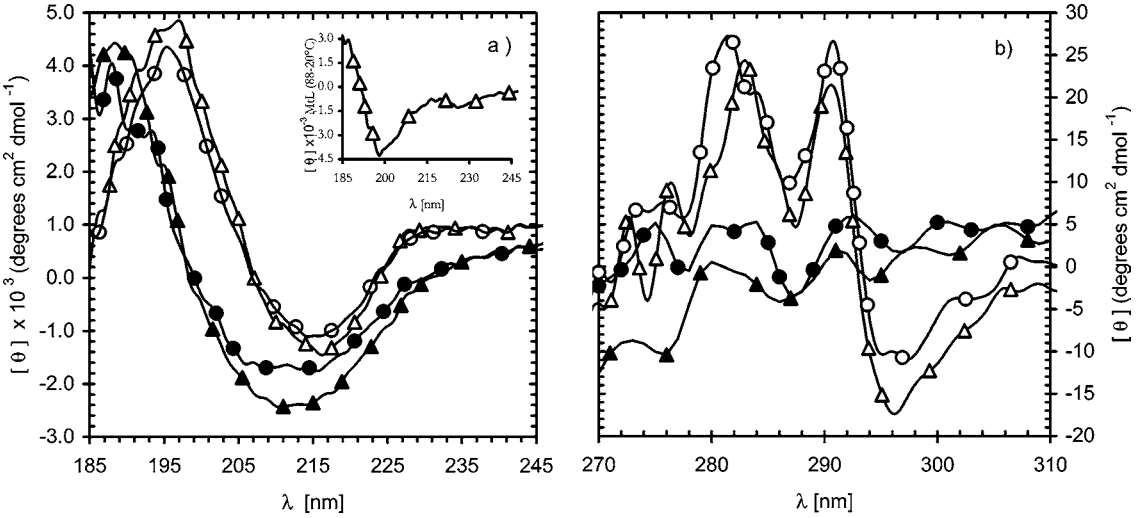

Figure 4. Circular dichroism (CD) spectra of MtL and PEG−MtL at low and high temperature (pH 6.0). Far- and near-UV regions are shown in the left and right panel, respectively. Spectra of MtL (triangles) and PEG−MtL (circles) were recorded at low temperature (25 °C; open symbols) and at high temperature (recorded at 88 °C, after thermal denaturation; closed symbols). Shown in the inset is the difference spectrum obtained by subtracting the low-temperature CD curve of MtL from that of the heat-denatured enzyme.

contains about 33% β-sheet and only 8% helices. As seen in Figure 4, the spectrum of PEG−MtL looks similar to that of its parent enzyme, indicating that chemical modification introduced no major structural changes in the secondary structure of the protein. On the other hand, in the near-UV spectra it is seen that the band envelope at 276−282 nm, a region where tyrosine residues display intense CD bands, is blue-shifted in the modified enzyme; this spectral shift might be caused by a less polar environment for the tyrosine side chains (*28*) in PEG−MtL owing to the presence of the hydrocarbon chains of PEG. Similar polarity changes seem to take place around the active site, as inferred from absorption spectra (results not shown): the absorption maximum in the visible region, characteristic of type 1 copper atoms present in laccase enzymes (*29*, *30*), was shifted from 610 to 575 nm as a result of chemical modification.

Thermal Denaturation. When MtL was heated to 88 °C until the enzyme activity was reduced to only 5% of the original value measured at room temperature, its far-UV CD bands were shifted toward shorter wavelengths (Figure 4). The spectrum of denatured MtL, however, differs from those observed in other heat-denatured proteins such as lysozyme and trypsin (*31*). Thus, although some structural changes occurred at high temperature, the laccase molecule likely possesses residual native secondary structure (*31*). That some protein segments became unstructured at high temperature is clearly discerned from the difference spectrum of heat-denatured versus native MtL, which shows the negative peak around 198−201 nm (inset to Figure 4) characteristic of irregular polypeptide structures (*28*). Heating had more drastic effects on the local environment of aromatic residues, as judged from the abatement of the near-UV bands (Figure 4). Regarding PEG−MtL, its thermal denaturation was accompanied by conformational changes resembling those observed with the unmodified enzyme, as judged by the CD spectra at high temperature.

Thermal scannings of MtL and its PEG derivative were carried out to determine the heat absorbed upon denaturation, as well as the changes in stability introduced by PEG modification. Both laccase preparations denatured irreversibly, with small denaturation enthalpies of only 6.3−7.5 g^{-1} (1.5−1.8 cal g^{-1}), but the modified enzyme proved to be more stable, its temperature of half-denaturation being approximately 2 °C higher than that of MtL (Figure 5). For comparative purposes, the scanning thermogram of hen's egg lysozyme, recorded in the same instrument, is also shown in Figure 5. The specific

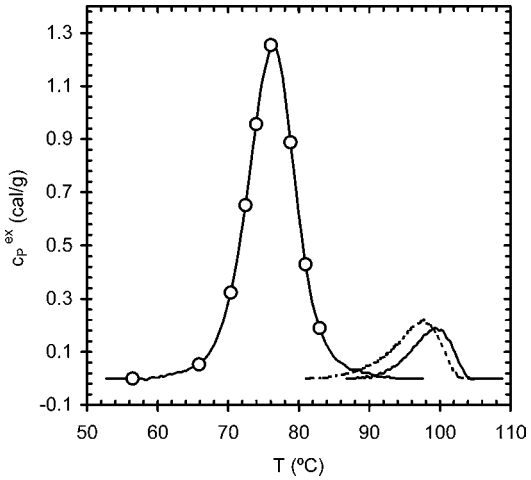

Figure 5. DSC profiles for the denaturation of the laccase enzymes at pH 5.0. Dashed line, MtL; solid line, PEG−MtL. For comparison, the scanning profile of hen's egg lysozyme, at pH 3.0, is also shown (−○−). Curves represent the excess heat capacity function, C_P^{ex}, obtained by subtracting buffer−buffer tracings and neglecting any change in heat capacity that takes place after denaturation. The area under a C_P^{ex} curve is the denaturation enthalpy. The protein concentration was ca. 2.0 mg mL^{-1}; the scanning rate was 1.0 °C min^{-1}.

heat of denaturation of this protein, which is representative of values found with other small proteins, was determined as 10.8 cal g^{-1}, in accord with previously reported determinations (*32*). It is clear then that thermal unfolding of the laccase enzymes is much less extensive than those of other typical proteins. This result is in keeping with the aforementioned characteristics of the CD spectra at high temperature and suggests that the β-structure scaffolding of the laccase family is notably resistant to high temperatures. Additional stability for the protein molecule may come from disulfide bonds; indeed, three of these bonds are known to be present in the structure of *M. albomyces* laccase (*27*), and the six Cys residues involved in those S−S bonds are all conserved in the sequence of MtL.

Inactivation of the Laccases in Mixed Solvents. The kinetics of inactivation of MtL and its PEG derivative in mixed aqueous−organic solvents was studied at several temperatures. The loss of enzyme activity followed first-order kinetics, with an apparent rate constant, k_i, that increased with the amount of organic cosolvent. We also made some measurements of the time course of ellipticity changes, at 202 nm, under the same

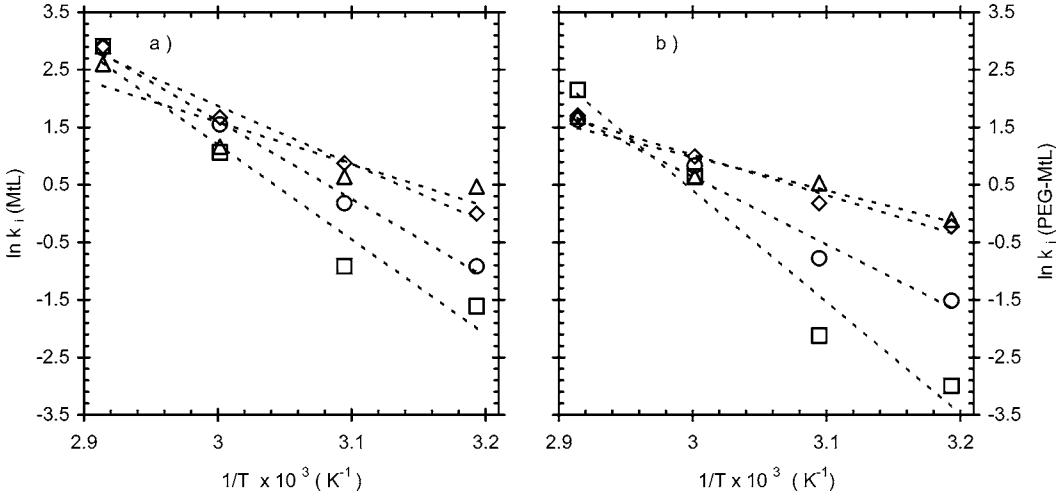

Figure 6. Arrhenius plots for denaturation of MtL (a) and PEG−MtL (b) in mixed solvents. Values of the rate constant (k_i) were determined by measuring the loss of laccase activity upon incubation in aqueous−organic solutions containing 30% v/v of the following organic solvents: methanol (□), ethanol (○), propanol (△), acetonitrile (◇). k_i is in min^{-1}.

Table 2. Activation Energies (E_a^i) and Preexponential Factors (A) for the Inactivation of MtL and PEG−MtL in Mixed Solvents[a]

	MtL		PEG−MtL	
solvent	E_a^i (kJ/mol)	ln A	E_a^i (kJ/mol)	ln A
methanol	33.0 ± 4.9	51.0	38.8 ± 5.6	59.0
ethanol	27.2 ± 1.4	42.7	23.6 ± 2.6	36.2
propanol	14.6 ± 4.6	23.6	11.7 ± 2.7	18.6
acetonitrile	20.2 ± 1.8	32.4	14.0 ± 1.5	22.2

[a] Values were determined from the linear fits shown in Figure 6. Solvents contained 30% (v/v) of the organic component in 50 mM phosphate buffer. [b] E_a^i and A represent the activation energy and the preexponential factor, respectively, in the Arrhenius equation (see the text).

solvent composition and temperature as those used to follow enzyme inactivation. Rate constants determined by both methods were nearly identical within experimental error, indicating that the loss of activity is accompanied by the appearance of disordered regions in the enzyme molecules. In solutions containing 30% of the organic component, the effect of temperature on k_i showed a clearly distinct trend depending on the nature of the cosolvent being present. Results obtained are plotted in Figure 6 according to the Arrhenius equation: $\ln k_i = \ln A - (E_a^i/R)(1/T)$. Values of the preexponential term (A) and the activation energy (E_a^i) for the inactivation reaction are given in Table 2. It is seen in Figure 6 that at temperatures below 70 °C the denaturing efficiency of linear alcohols increases with the length of the alkyl chain. The denaturing effect of *n*-alcohols is well-documented in the literature (*33*), where it has been attributed mainly to a decrease in the strength of "hydrophobic interactions" in water−alcohol solutions. The contribution of alcohols to protein denaturation has both enthalpic and entropic terms that compensate with each other in a rather complex way (*34*, *35*), depending on the concentration and type of the organic cosolvent. With 30% alcohol−water mixtures, Velicelebi and Sturtevant (*35*) found that the greater denaturing action of 1-propanol, with respect to ethanol and methanol, on hen lysozyme is due to a smaller enthalpy of denaturation. A similar situation is observed for the inactivation of both laccase forms: the activation energy suffers a large drop in *n*-propanol (Table 2) that results in the largest kinetic destabilization of the enzymes. When acetonitrile was the cosolvent, the temperature dependence of k_i was similar to that observed in the presence of *n*-propanol. In this case, however, it is difficult to rationalize the effect of the cosolvent on the basis of the hydrophobic effect alone. Other mechanisms, such as the influence of acetonitrile on hydrogen bonding and electrostatic interactions, may also play relevant roles.

It should be noted that, despite the similar inactivation behavior of both laccase samples in different solvents, the value of k_i for the modified enzyme was 2−3-fold smaller than that for the unmodified enzyme. An inspection of data in Table 2 shows that the extra stability of PEG−MtL can be attributed to its smaller activation entropy, because the A term is proportional to the entropy difference between the transition and native states of a reaction (*23*). This entropic stabilization may have its origin in the restricted motion of some amino acid groups on the protein surface due to the shell-like structure formed by coiled PEG chains (*36*).

CONCLUSIONS

Chemical modification of *M. thermophila* laccase (MtL) with PEG_{5000} yielded an enzyme derivative showing only minor changes in both secondary structure and enzyme activity, in comparison with the parent enzyme. Besides, pegylation led to a modest increase in the enzyme thermostability and to a decrease in the rate of inactivation in aqueous−organic solvents. To enhance these effects, an issue that would be of importance for the industrial applications of MtL, it would be interesting to carry out studies with bigger PEG molecules. Furthermore, it should be noticed that only eight out of the 16 lysine residues of MtL seemed to have been linked to PEG. A more extensive modification could be attempted by increasing the number of solvent-exposed lysines using directed mutagenesis of cloned and expressed versions of the corresponding gene.

ACKNOWLEDGMENT

This work was supported in part by CONACyT (convenio SEP-2003-CO2-44681). We thank the Novo Co., for providing the sample of Deni Lite IIs. Also Dr. Rafael Vazquez Duhalt (Instituto de Biotecnología, UNAM) helped us to do the pegylation reaction. L.-C.J.I. had a doctoral fellowship from Consejo Nacional de Ciencia y Tecnología (CONACYT).

Facile Functionalization of Lipid Bilayer Vesicles by Titania: The Use of Cerasome-Forming Lipids for Surface and Core Modification

Mineo Hashizume, Maki Yamada, Kiyofumi Katagiri,† Masahiko Tsuji, and Jun-ichi Kikuchi*

Graduate School of Materials Science, Nara Institute of Science and Technology, 8916-5 Takayama, Ikoma, Nara 630-0192, Japan. Received January 11, 2006; Revised Manuscript Received April 10, 2006

Two kinds of functionalization of a lipid bilayer vesicle by titania were achieved by utilizing a cerasome-forming lipid, which is the starting material to prepare a cerasome, a morphologically stable lipid bilayer vesicle having an atomic layer of siloxane networks on its surface. One system is the preparation of the titania-coated cerasomes by immobilizing nanaometer-sizes of titania onto the surface siloxane network of cerasomes. The other is the creation of an asymmetric lipid bilayer structure on the surface of the colloidal titania particles. The characteristics of these surface- and core-functionalized vesicles were investigated, and it was found that these conjugates showed photocatalytic activity as evaluated by photolysis experiments of the cationic dye methylene blue.

INTRODUCTION

Lipid bilayer vesicles prepared from natural and synthetic lipids are well-known biomembrane models and have been widely investigated for the last 40 years (*1*, *2*). There has been interest in the functionalization of vesicles not only for use in the reconstruction of biological systems but also in the creation of supramolecular systems (*3*, *4*). To add specific functions to a vesicle, incorporation of functional components, for example membrane proteins or glycosphingolipids, into the vesicle is a commonly used approach. Not only naturally occurring components but also synthetic and semisynthetic compounds are useful for this purpose. One method for the functionalization is the incorporation of synthetic lipids having specific hydrophilic headgroups, such as receptor molecules (*5*, *6*), antibodies and their subunits (*7*, *8*), poly(ethylene glycol)s (*9*), etc., into the lipid bilayer. Another method is the coating of polymers with anchoring parts that can be inserted into the lipid bilayer (*10*). The polymer coating is also simply achieved by covalent boning or electrostatic adsorption to the vesicle surface (*11*). These modifying compounds are usually biomimetic organic molecules. Although there are many examples of the preparation of inorganic nanocomposites templated by supramolecular assemblies (*12*, *13*), coating them on a vesicle surface has not been very widely investigated (*14*−*16*), probably due to the structural instability of vesicles when interacting with inorganic precursors compared to other assembled structures. Metal or semiconductor (metal oxide) materials having a size of several nanometers or less in at least one dimension, for example, ultrathin films, nanowires, and nanoparticles, have unique physicochemical properties expressed by the term "quantum size effect". The conjugates of these materials and biomolecules have recently been paid much more attention, especially in applications for sensing devices (*17*). Nanomaterials of metals and metal oxides can be expected to bring new functionality when they are coupled to the surface of the vesicles. However, there are few studies focusing on this point.

Recently, we have developed a novel vesicular system, named "cerasome", which is a lipid bilayer vesicle having an atomic layer of siloxane networks on its surface (*18*, *19*). The cerasomes are prepared from organoalkoxysilane lipids that have an organic dialkyl chain and an inorganic triethoxysilyl headgroup connected to each other in one molecule. The surface siloxane networks of the cerasome bring remarkably high morphological stability compared to that of conventional vesicles. For example, the cerasome can maintain its vesicular structure even in the presence of an excessive amount of a surfactant, whereas the reference vesicle is completely dissolved (*20*, *21*). Also the cerasome can be integrated onto a solid substrate to form a multicellular structure (*22*, *23*), which is triggered by electrostatic interaction. Under the same conditions, conventional vesicles collapse to form a supported bilayer on the substrate. Furthermore, the cerasome still possesses the features intrinsic to conventional vesicles, such as gel-to-liquid crystalline phase transition behavior.

Another advantage of the surface siloxane network of the cerasome is its high chemical reactivity. We have successfully functionalized the cerasome surface by introducing alkoxide compounds such as tetraethoxysilane (TEOS) or (3-aminopropyl)triethoxysilane (APS) during the preparative process of the cerasome (*24*). These alkoxides were incorporated into the siloxane network of the cerasome surface through the siloxane bonding. The resultant surface-modified cerasomes represented the surface characteristics coming from the added alkoxide compounds.

The other system that highlights the advantages of the cerasome is an asymmetric bilayer coating of monodispersed colloidal silica particles (*25*). The particles were first coated with a cerasome-forming lipid and then coated with a bilayer-forming lipid to form an asymmetric lipid bilayer structure, which is usually seen in nature and difficult to reconstitute by conventional techniques, on the particle surface.

In this study, on the basis of studies noted above, two systems for the functionalization of the cerasome by metal oxides were investigated (Figure 1). To show the possibility of these resultant conjugates as novel functional materials, we chose titania as the metal oxide component because it is known as a functional metal oxide which, for example, exhibits photocatalytic activity (*26*, *27*). One of the two systems investigated in this study is the surface coating of the cerasome by titania. The other is the asymmetric bilayer coating of colloidal titania particles. The

characteristics of these two kinds of conjugates were investigated and their photocatalytic activities were evaluated.

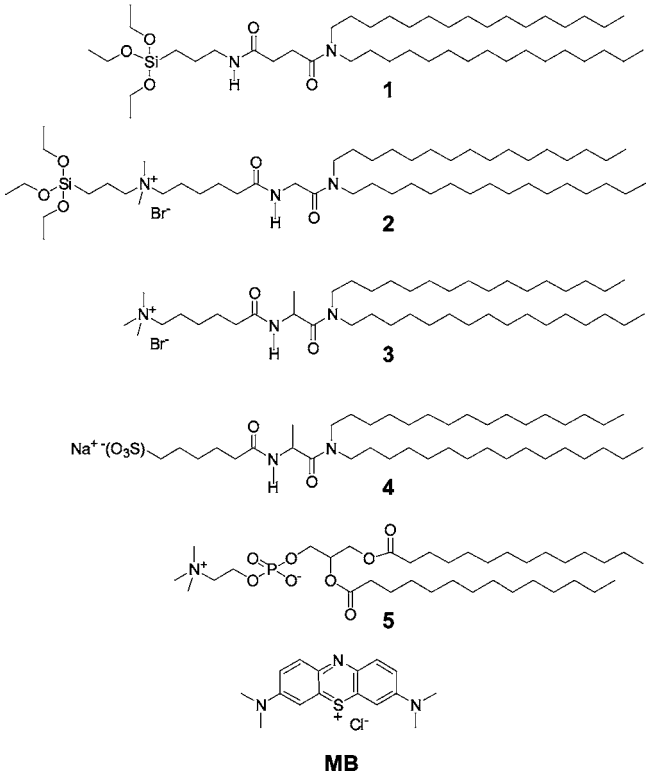
EXPERIMENTAL PROCEDURES

Materials. Unless otherwise stated, all reagents and chemicals were obtained commercially and used without further purification. Titanium tetrabutoxide ($Ti(O^nBu)_4$), hydroxypropylcellulose (HPC), and acetylacetone (AcAc) were purchased from Wako Pure Chemical Industries. Colloidal titania particles were prepared by the procedure described in ref 28, with the exception that the particles were not submitted to hydrothermal treatments. Methylene blue (MB) was purchased from Nacalai Tesque, Inc. Titania sol TKS-203 was kindly donated by Tayca Corporation, Japan. The cerasome-forming lipids, *N*-[*N*-(3-triethoxysilyl)propylsuccinamoyl]dihexadecylamine (**1**) and *N*,*N*-dihexadecyl-*N*$^{\alpha}$-[6-[(3-triethoxysilyl)propyldimethylammonio]hexanoyl]glycinamide bromide (**2**) (*18*, *22*), and bilayer-forming peptide lipids, *N*,*N*-dihexadecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]alaninamide bromide (**3**) (*29*), and sodium *N*,*N*-dihexadecyl-*N*$^{\alpha}$-(6-sulfohexanoyl)alaninamide (**4**) (*30*), were synthesized in our laboratory as described in previous reports. Dimyristoylphosphatidylcholine (DMPC; **5**) was obtained from Funakoshi Co., Ltd. These chemical structures are shown in Chart 1. Solvents used for the synthesis and coating were purified by distillation. Water used for the particle preparation and coating was distilled and deionized using an Autostill WS33 (Yamato Scientific) and Milli-Q Labo (Nihon Millipore), respectively.

Preparation of Titania-Coated Cerasomes. The surface coating of the cerasome by titania was performed by a similar procedure as that for the preparation of tetraethoxysilane (TEOS) or (3-aminopropyl)triethoxysilane (APS)-coated cerasomes (*24*). First, because of its high reactivity compared to that of ethoxysilane compounds, $Ti(O^nBu)_4$ was capped by 1 equiv of AcAc in ethanol, followed by the addition of deionized water. The mixture was stirred for 6 h to form a complex named $Ti(O^nBu)_3(AcAc)$. The ratio of ethanol:$Ti(O^nBu)_4$:AcAc:H_2O was 200:1:1:10. In the case of the lipid **1**, an ethanol sol of **1** with the ratio of **1**:ethanol:H_2O:HCl = 1:200:19:0.03 was stirred for 8 h using a vortex mixer. This ethanol sol was mixed with the $Ti(O^nBu)_3(AcAc)$ solution in the molar ratio of **1** and Ti to be 1:1, and further stirred for 30 min. The resultant sol was then injected into H_2O of appropriate pH. After the incubation of the solution at room temperature for more than 24 h, the AcAc group was finally photocleaved by xenon lamp irradiation without an optical filter, to obtain the titania-coated cerasome **1**. Lipid **2** was directly mixed with the $Ti(O^nBu)_3(AcAc)$ solution in the molar ratio of **2**:Ti to be 1:1. The mixture was stirred for 4 h and then injected into H_2O, followed by the photocleavage process.

Asymmetric Bilayer Coating on Colloidal Titania Particles. The procedure for the asymmetric bilayer coating on the surface of colloidal titania particles was basically same as that for coating on colloidal silica particles (*25*). The first (inner) layer was created from the lipid **1** by condensation of triethoxysilyl group of **1** with the surface hydroxyl group of titania in toluene while refluxing. The second (outer) layer was created from the lipids **3**−**5**. First a thin film of the lipid was prepared in the presence of the particle on the wall of a vial. After the addition of water, the film was detached and dispersed by a vortex mixer, followed by ultrasonication. The particles were collected by centrifugation and well washed with H_2O to remove excess lipids.

Chart 1. Chemical Structures of the Lipids and Methylene Blue (MB) Employed in This Study.



Characterization. The titania-coated cerasomes and the bilayer-coated colloidal titania particles were evaluated by the following conventional physical measurements. Hydrodynamic diameters of the cerasomes and titania particles were obtained by dynamic light scattering (DLS) measurements (DLS-6000HL, Otsuka Electronics). Scanning electron microscopy (SEM) was performed using a Hitachi S-5000 with an acceleration voltage of 25 kV, and the samples were coated by Pt. Transmission electron microscopy (TEM) was performed using a Hitachi H-7100 with an acceleration voltage of 100 kV. To see the distribution of titania components on cerasome surface, some of the samples were observed without using staining agents such

as uranyl acetate. Zeta-potential of the samples were obtained using an ELS-6000 (Otsuka Electronics) in an aqueous NaCl (10 mM). Inductively coupled plasma atomic emission spectroscopy (ICP-AES) was performed using an Optima 2000 DV Instruments (Perkin-Elmer). Standard Si and Ti solutions were used for calibration. X-ray diffraction (XRD) patterns of the titania-coated cerasomes and colloidal titania particles were obtained by a RINT-2200VL (Rigaku). The sample dispersions were cast on amorphous Si plates for measurements.

Photocatalysis Measurements. Photocatalytic activity of the titania-coated cerasomes and the bilayer-coated colloidal titania particles were evaluated as the photolysis of methylene blue (MB). The sample solution was irradiated by a xenon light source system (SX-UID500XAMQ, USHIO Inc, Japan). The light was passed through the UV-D35 filter to cut the light below 300 nm and over 600 nm. The power of the light was around 10 mW cm^{-2} at 400 nm. The titania-coated cerasome solution was mixed with the stock solution of MB. The final concentration of the lipid and MB were 0.1 mM and 0.01 mM, respectively. In the case of the bilayer-coated colloidal titania particles, the concentration of the particle was adjusted to 0.1 mM as Ti, and that of MB was adjusted to 0.01 mM. In the first 30 min the sample was placed in the dark and not irradiated, to observe the spontaneous degradation of MB. The sample was then irradiated and the photolysis of MB was monitored as the change of the UV−vis spectra. To obtain the rate constant (k) corresponding to a first-order reaction, the decomposition amount of MB by photolysis was obtained by subtracting the amount of spontaneous decomposition of MB from the total decrease of MB.

RESULTS AND DISCUSSION

Titania-Coated Cerasomes. Compared to the surface modification of the cerasome by TEOS or APS, titanium alkoxides have higher reactivity than ethoxysilyl compounds, so that we modified the procedure for the preparation of the titania-coated cerasome. $Ti(O^nBu)_4$ was partly capped with AcAc, and the vesicle was prepared by the ethanol sol injection method in the presence of $Ti(O^nBu)_3(AcAc)$ followed by the photocleavage of the AcAc group. The cleavage of AcAc group was confirmed by the spectral change of the solution, which showed a decrease of the peak corresponding to $\pi-\pi^*$ transition ($\lambda_{max} = 270$ nm). The optimal timing to mix the lipid and $Ti(O^nBu)_3(AcAc)$ was different between the cerasome-forming lipid **1** and **2**, which seems to reflect the difference in hydrolysis activity of the triethoxysilyl groups in each lipid (*19*). The hydrodynamic diameter of the titania-coated cerasome **1** was 144 nm both before and after the photoclevage of AcAc group, which indicated that the vesicular morphology was not affected by this irradiation. We previously reported that the diameter of the cerasome **1** without titania components prepared by the ethanol sol injection method was around 300 nm (*24*). The smaller diameter of the titania-coated cerasome might be due to the coupling of the titania component to the lipid headgroup. That is, the lipid having a larger headgroup tends to form a smaller vesicle based on the concept of the critical packing parameter (*31*). The formation of vesicular structure was also confirmed by the results of SEM measurements (Figure 2a). The nonstaining TEM images of the titania-coated cerasome **1** indicate that the titania components of titania-coated cerasome **1** had nanoparticle-like shapes and scattered on the bilayer surface (Figure 2b). This is different from the cases of other inorganic coating system reported by other groups, which form continuous inorganic layers on the vesicular surfaces (*14*−*16*). Such a difference is probably attributed to the difference in their preparative methods. In the current system, the ratio of lipid/Ti was 1 and Ti source was first mixed with the lipids in the ethanol sols before forming the vesicular structures in water, whereas inorganic sources were excess to the lipid and added after the vesicles were formed in other groups' systems. In our system, the lipid bilayer surface can be exposed to water even after the coupling of titania components. This is an additional useful functionality to titania-coated cerasomes. For example, ligand−receptor interactions on the vesicular surface can be achieved by incorporating other kinds of lipids having a ligand headgroup into the bilayer part of titania-coated cerasomes. The hydrodynamic diameter of the titania-coated cerasome **2** was 140 nm. There is no large difference in size before and after titania coating, because the existence of the quaternary ammonium group of lipid **2** makes the vesicular size of the cerasome **2** smaller compared to the case of the cerasome **1** (*19*). The SEM image of the titania-coated cerasome **2** shows similar morphology to that of the titania-coated cerasome **1** (Figure 2c).

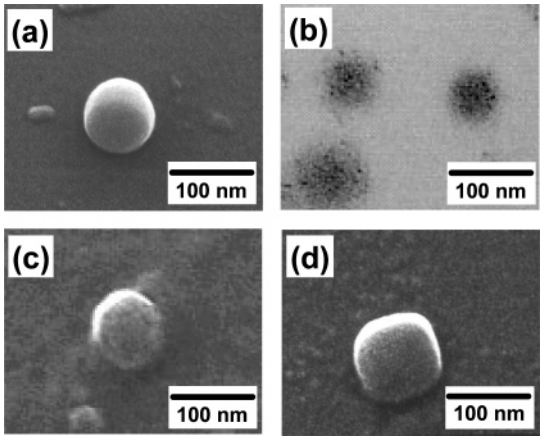


Figure 2. SEM (a) and TEM (b) images of the titania-coated cerasome **1**. (c) A SEM image of the titania-coated cerasome **2**. (d) A SEM image of the titania-coated cerasome **1** after the photolysis experiment.

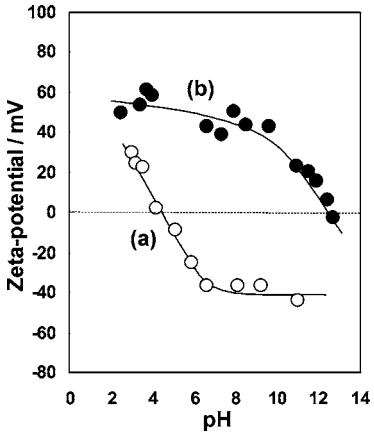

Figure 3. pH dependences of the zeta-potentials of the titania-coated cerasomes **1** (open circle) and the titania-coated cerasome **2** (closed circles).

Figure 3 shows pH dependences of zeta-potentials of the titania-coated cerasomes. The zeta-potential of the titania-coated cerasome **1** changed from +30 to −40 mV depending on the media pH, whereas that of cerasome **2** was positive in a wide pH range, which is largely due to its quaternary ammonium group. The isoelectric point (IEP) of the titania-coated cerasome **1** and the titania-coated cerasome **2** was obtained as 4.8 and 12.7, respectively. The IEP values of the cerasome **1** and the cerasome **2** are 4.3 and 11.5, and that of colloidal titania are 5−7 (*32*), respectively. So these results also support the maintenance of the surface nature of the cerasomes even after the titania coating. In addition, it was found that we can prepare both positively and negatively charged titania-coated cerasomes

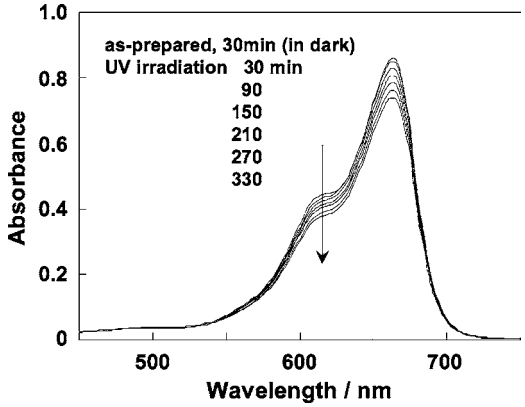

Figure 4. Time course of the UV−vis spectra of the MB solution in the presence of the titania-coated cerasome **1** upon the light irradiation.

in physiological pH at will. It is also possible to prepare the titania-coated cerasome having the desired IEP by mixing these two lipids at the proper ratio.

Asymmetric Bilayer-Coated Colloidal Titania Particles. The cerasome-forming lipid can covalently bond to a surface having hydroxyl groups. The formation of the first layer by the lipid **1** on the titania particle surface was confirmed by FT-IR spectroscopy as the appearance of the peak corresponding to the stretching vibrations of methylene part. Drastic decrease of dispersibility of the particle in water also strongly indicates the existence of the monolayer of lipid **1**. The following coating of the second layer by bilayer-forming lipids resulted in the recovery of the dispersibility of the particles in water. The hydrodynamic diameter and the zeta-potential in aqueous NaCl of the unmodified titania particle were 274 nm and −7.9 mV, respectively. Those parameters for asymmetric bilayer-coated particles for the lipid **3** (cationic), **4** (nonionic), and **5** (zwitterionic) as the second layer were (289 nm, 23.3 mV) for **3**, (284 nm, −38.0 mV) for **4**, and (288 nm, −0.2 mV) for **5**, respectively. The increases of hydrodynamic diameters for bilayer-coated particles were reasonable when thinking about the thickness of a lipid bilayer. TEM images of negatively stained samples showed the existence of such ultrathin organic layers (data not shown), similar to the case of colloidal silica particles (*25*). Also, zeta-potentials of the samples were well reflected in the nature of the coating lipids. These results showed that the asymmetric bilayer coating on the surface of the colloidal titania particles was successfully achieved.

Photocatalytic Activity. To show the usefulness of the titania-coated cerasomes, the photocatalytic activity of the titania-coated cerasome was evaluated by photolysis experiments of a commercial cationic dye, methylene blue (MB). The conditions for the light irradiations were adjusted to prevent self-decomposition of MB. The mixed solution of the titania-coated cerasomes with MB did not show decomposition of MB, which can be monitored by UV−vis spectroscopy, when placed in the dark. On the other hand, the light irradiation of the sample solution preceded decomposition of MB (Figure 4). This indicates that the decomposition of MB was the result of photolysis by the titania-coated cerasome. Figure 2d shows the SEM image of the titania-coated cerasome **1** after photolysis measurements, which confirms the maintenance of its vesicular morphology. The photocatalytic activity of the titania-coated cerasome was normalized as the rate constant assuming a first-order reaction, and the results were summarized in Table 1. Both of the titania-coated cerasomes prepared from the lipid **1** and **2** showed photocatalytic activity; however, there was a difference in the effect of the media pH. At pH 3, the rate constant was similar between **1** and **2**, whereas the value for **1** was larger than that of **2** at pH 8. The results seem to be due to the effect

Table 1. Rate Constants (k)[a] of the Photolysis of MB for the Titania-Coated Cerasomes[b]

catalyst	k/h^{-1} at pH 3	k/h^{-1} at pH 8
titania-coated cerasome **1**	0.022	0.056
titania-coated cerasome **2**	0.021	0.027

[a] The rate constant assuming a first-order reaction. [b] [Ti] = [lipid] = 0.1 mM, [MB] = 0.01 mM.

Table 2. Rate Constants (k)[a] of the Photolysis of MB for the Asymmetric Bilayer-Coated Colloidal Titania Particles[b]

catalyst	k/h^{-1}
unmodified colloidal titania	0.025
lipid **3** in the second layer	0.019
lipid **4** in the second layer	0.017
lipid **5** in the second layer	0.020

[a] The rate constant assuming a first-order reaction. [b] [Ti] = 0.1 mM, [MB] = 0.01 mM, at pH 3.

of the surface charge of the titania-coated cerasomes; both are positively charged at pH 3, and **1** is negative and **2** is still positive at pH 8 according to the results seen in Figure 3. At pH 8, positively charged MB should be more accessible to the titania-coated cerasome **1** than that prepared from **2**. These phenomena are welcomed for designing substrate-selective catalyst systems. However, the photocatalytic activities were relatively small compared with that of commercial anatase titania sol TKS-203 (0.19 h^{-1}), normalized as the same titania amount. The main difference is that the present titania-coated cerasome was not intended to make titania to form its specific crystal structure like anatase, which shows high catalytic activity. According to previous reports for the effect of photoirradiation on anatase formation by sol−gel processes (*33*, *34*), there is a possibility that the formation of anatase structure proceeds when the sample is irradiated by whole xenon light to cleave AcAc group. However, XRD patterns of the titania-coated cerasome **1** did not show significant peak patterns assignable to those of anatase, nor rutile and brookite, which indicates that the majority of the titania components on the cerasome surface were amorphous. In addition, not all of the titania components seemed to couple to the cerasome surface under current condition. When the titania-coated cerasome **1** was purified by conventional gel permeation chromatography and analyzed by ICP-AES, the ratio of Ti:Si was obtained as 1:2.7, which is ideally 1:1. The rest of the titania probably existed as sols similar to the photocleaved products of Ti(O^{n}Bu)$_3$(AcAc) which were prepared in the absence of the cerasome-forming lipid. The photocatalytic activity of such a sol was, however, significantly small (k = 0.0055 h^{-1}) compared to that of the titania-coated cerasomes. The pH dependence of the photocatalytic activity also strongly suggests that the activity mainly comes from the titania-coated cerasome. The procedure without purification is quite powerful for practical application, so we are currently improving the preparative condition to minimize the amount of titania components which do not couple to the cerasome surface.

Table 2 shows the rate constant of MB decomposition in the presence of the asymmetric bilayer-coated colloidal titania particles. These values were in the range of 10^{-2} h^{-1} as were those of the template titania colloidal particle and also the titania-coated cerasomes, and approximately ten-times smaller than that of TKS-203. The template colloidal titania particles were not calcinated or hydrothermally treated, because such treatment diminishes surface hydroxyl groups of the particles. The XRD patterns of the particles show that these particles were amorphous, which is in good agreement with the literature (*28*). Different from the case of the titania-coated cerasome, there was not good correlation between the surface charges of the asymmetric bilayer-coated colloidal titania particles and their photocatalytic activities in this case. Since photocatalytic

reactions have distance dependencies, the existence of a lipid bilayer between MB and the titania surface may largely affect the photocatalytic activity. In such cases, the difference in accessibility of the substrate to the particle surface may not appear significant to the photocatalytic activity. However, the important point of the results in Table 2 is that these colloidal titania particles covered by ultrathin organic layers still retain their photocatalytic activities. The bilayer structure on the titania surface could donate a molecular recognition site for substrate-specific catalysis, similar to the case for the monolayer-coated systems developed by Ohno et al. (*35*, *36*), which show substrate-selective photocatalytic reactions based on the interactions between the substrate and the organic layer.

The photocatalytic activities of both the titania-coated cerasomes and the bilayer-coated colloidal titania particles should be able to be improved. Hydrothermal treatment (*28*) of these conjugates is one of the possible techniques for this purpose since it can form the anatase structure of titania without burning out the organic components in the conjugates. In the case of titania-coated cerasomes, increase of the relative amount of titania in the conjugates is another considerable factor to increase the photocatalytic activity. We are continuing systematic investigations of these points to find out general rules for precise control of these conjugates' photocatalytic activities.

In summary, we showed that the surface and the core modifications of lipid bilayer vesicles by titania were successfully achieved by employing cerasome-forming lipids. The resultant conjugates have unique organic−inorganic hybrid structures and show photocatalytic activities owing to their titania components. One important advantage of these conjugates is that they can maintain and utilize the nature of the lipid bilayer surface even after the titania modification. Not only for the control of surface charges, the bilayer parts of these conjugates can be used for selective incorporation of hydrophobic substrates, realizing ligand−receptor interactions on membrane surfaces, immobilization of membrane proteins, etc. Such conjugates are expected to be useful as substrate-specific catalysts, sensing systems for events which occur on and in the membranes, carriers for drug delivery systems, scaffolds for artificial signal transduction systems (*4*, *37*, *38*) combining photochemical processes, etc. The current two methods are simple and applicable to various metal oxide species, which could open a new field of biomembrane models.

ACKNOWLEDGMENT

The authors greatly thank Mr. K. Hayashi (NAIST) for SEM and TEM observations and Prof. M. Tanihara and Dr. M. Kamitakahara (NAIST) for the use of ICA-AES apparatus and XRD analyses. Synthesis of a nucleosidic phosphoramidite building block which allows solid-phase introduction of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) to synthetic oligonucleotides using a standard oligonucleotide synthesizer is described.

INTRODUCTION

Because of its excellent metal chelating properties and high in vivo and in vitro stability, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) is widely used as an organic ligand in magnetic resonance imaging (MRI) and positron emission tomography (PET) (*1*−*3*). Indeed, Gd^{3+}-DOTA is one of the most commonly used clinical MRI contrast agents (*4*, *5*). Bioactive molecules labeled with DOTA, in turn, have found applications as target-specific radiopharmaceuticals (*6*).

In several applications, covalent conjugation of DOTA to bioactive molecules is required. Most commonly, isothiocyanato, *N*-hydroxysuccinimide, or maleimide derivatives of the chelates are used in the labeling of amino and mercapto functions of the target molecules (*7*). Because the labeling reaction is performed in the presence of an excess of an activated label, laborious purification procedures cannot be prevented. Especially, when attachment of several label molecules is needed, purification and characterization of the desired biomolecule conjugate may be extremely difficult. These problems can be avoided by performing the labeling reaction on solid phase. Indeed, derivatives of DOTA for the solid-phase oligopeptide derivatization using standard oligopeptide synthesizers have been reported (*8*, *9*). Surprisingly, no methods for the attachment of DOTA to synthetic oligonucleotides have been available: oligonucleotide labeling is still a multistep procedure including synthesis of an oligonucleotide bearing a tether with a nucleophilic ω-function followed by its reaction with an activated chelate derivative (*10*, *11*). Here is presented a simple method for the preparation of a nucleosidic DOTA derivative which allows solid-phase oligonucleotide conjugation.

EXPERIMENTAL PROCEDURES

General Methods. Adsorption column chromatography was performed on columns packed with silica gel 60 (Merck). Reagents for oligonucleotide syntheses were from Proligo. The oligonucleotides were assembled on an Applied Biosystems 3400 instrument using recommended protocols. All dry solvents were from Merck, and they were used as received. NMR spectra were recorded on a Brucker 250 spectrometer operating at 250.13 MHz for ^{1}H and on and on a JEOL LA 400 spectrometer operating at 161.9 MHz for ^{31}P. The signal of TMS was used as an internal (^{1}H) and H_3PO_4 as an external (^{31}P) reference. ESI-TOF mass spectra were recorded on an Applied Biosystems Mariner instrument.

1,4,7,10-Tetraazacyclododecane-4,7,10-tricarboxymethyl Methyl Ester 1-Carboxymethyl-benzyl Ester, 2. To a stirred mixture of 1,4,7,10-tetraazacyclododecane-1-carboxymethyl-benzyl ester, **1** (*8*) (0.45 g, 1.4 mmol), and potassium carbonate (0.79 g, 5.7 mmol) in anhydrous acetonitrile (8 mL) was added methyl bromoacetate (0.54 mL, 5.7 mmol; predissolved in 2 mL of MeCN) dropwise during 0.5 h. The reaction was allowed to proceed for additional 2 h before being filtered. The filtrate was concentrated in vacuo. Purification was performed on silica gel (eluent MeOH:CH_2Cl_2, 1:9, v/v). Yield was 0.45 g (60%). ^{1}H NMR ($CDCl_3$): δ 7.35 (5H, m); 5.20 (2H, s); 3.76 (6H, s); 3.74 (3H, s); 3.49−2.35 (24 H). ESI-TOF-MS for $C_{26}H_{41}N_4NaO_8^+$ $(M + Na)^+$: calcd, 559.27; found, 559.27.

1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic Acid Tris-methyl Ester, 3. Compound **2** (0.35 g, 0.64 mmol) was dissolved in methanol (50 mL). Pd/C (10%, 55 mg) was added, and the mixture was hydrogenated at atmospheric pressure overnight. The mixture was filtered through Celite and concentrated. It was used for the next step without further derivatization. ESI-TOF-MS for $C_{19}H_{34}N_4NaO_8^+$ $(M + Na)^+$: calcd, 469.23; found, 469.22.

2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl)-3-(6-aminohexyl)uridine, 4. 2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl)-3-(6-trifluoroacetamidohexyl)uridine (*12*) (1.41 g, 1.95 mmol) was suspended in the mixture of concentrated aqueous ammonia and methanol (100 mL; 1:1, v/v) and heated overnight at reflux. All volatiles were removed in vacuo. The residue was partitioned between water and dichloromethane. The organic layer was dried over Na_2SO_4 and concentrated. Yield was quantitative. ^{1}H NMR ($CDCl_3$): δ 7.75 (1H, d, *J* 8.3, H-6); 7.40−7.23 (9H, DMTr); 6.84 (4H, d, *J* 8.9, DMTr); 6.31 (1H, t, *J* 6.2, H-1′); 5.45 (1H, d, *J* 8.3, H-5); 4.53 (1H, m, H-3′); 4.00 (1H, m, H-4′); 3.89 (2H, m); 3.78 (6H, s, 2 · OMe); 3.49 (1H, dd, *J* 3.0 and 10.6, H-5′); 3.41 (1H, dd, *J* 3.3 and 10.6, H-5″); 2.64 (2H, t, *J* 6.5); 2.42 (1H, m, H-2″); 2.24 (1H, m, H-2′); 2.19 (3H, br); 1.62 (2H, p, *J* 6.4); 1.40 (2H, p, *J* 6.7); 1.34 (4H, m). ESI-TOF-MS for $C_{36}H_{44}N_3O_7^+$ $(M + H)^+$: calcd, 630.31; found, 630.34.

The DOTA Nucleoside, 5. Compound **3** (0.26 g, 0.58 mmol) and DIPEA (100 μL) were dissolved in dry DMF (9 mL). HATU (220 mg, 0.58 mmol) was added, and the mixture was stirred for 30 min at RT. Compound **4** (0.37 g, 0.58 mmol) was added, and the mixture was stirred for 4 h at RT and concentrated. The residue was dissolved in dichloromethane, washed twice with sat. $NaHCO_3$, and dried. Purification on silica gel (eluent, MeOH:CH_2Cl_2 1:9, v/v) gave 0.43 g (82%) of the title compound. ^{1}H NMR ($CDCl_3$) δ 7.75 (1H, d, *J* 8.3, H-6); 7.40−7.22 (9H, DMTr); 6.84 (4H, d, *J* 8.8); 6.47 (1H, br t, *J*

4.7, NH); 6.32 (1H, t, *J* 6.3, H-1′); 5.43 (1H, d, *J* 8.0, H-5); 4.59 (1H, m, H-3′); 4.05 (1H, m, H-4′); 3.89 (2H, m); 3.79 (6H, s, 2 · OMe); 3.74 (6H, s); 3.73 (3H, s); 3.42 (2H, d, *J* 2.9, H-5′ and H-5″); 3.20 (8H); 2.60 (16H); 2.46 (1H, m, H-2″); 2.27 (1H, m, H-2′); 1.70 (1H, br); 1.62 (2H, m); 1.50 (2H, m); 1.35 (4H, m). ESI-TOF-MS for $C_{55}H_{76}N_7O_{14}^+$ $(M + H)^+$: calcd, 1058.54; found, 1058.54.

Synthesis of the Phosphoramidite, 6. Predried compound **5** (0.30 g, 0.28 mmol) and 2-cyanoethyl *N,N,N*′,N′-tetraisopropylphosphordiamidite (1.5 equiv) were dissolved in dry acetonitrile. 1*H*-Tetrazole (1 equiv; 0.45 M in acetonitrile) was added, and the mixture was stirred for 30 min at room temperature before being poured into 5% $NaHCO_3$, extracted with dichloromethane, and dried over Na_2SO_4. Purification on silica gel (eluent: MeOH:CH_2Cl_2:TEA, 5:95:1, v/v/v) yielded the desired phosphoramidite. ^{31}P NMR ($CDCl_3$): δ 149.60 (0.5 P); 149.20 (0.5 P). ESI-TOF-MS for $C_{64}H_{93}N_9O_{15}P^+$ $(M + H)^+$: calcd, 1258.65; found, 1258.66.

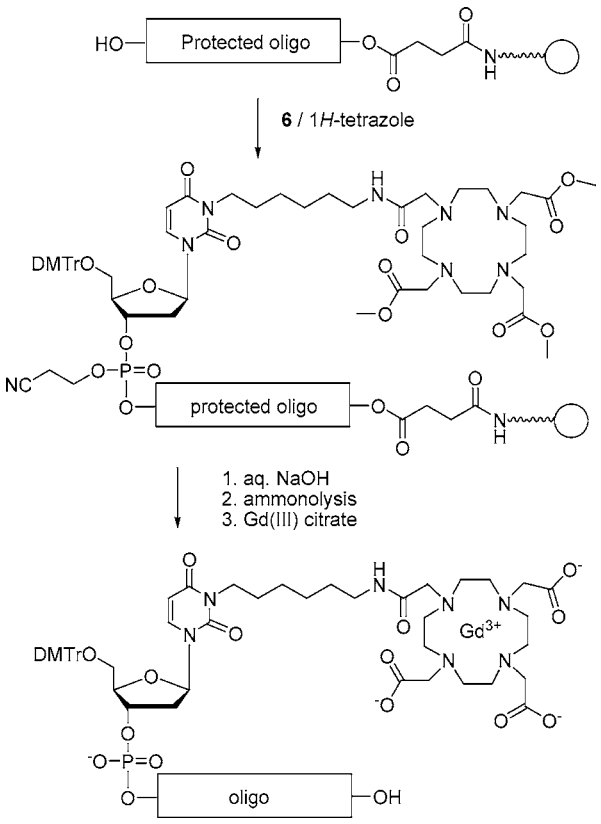
Synthesis and Purification of the Oligonucleotide Conjugate. A sequence 5′-TAATGTAGCCCCTGAA-3′ was assembled on 1.0 μmol scale using phosphoramidite chemistry and recommended protocols (DMTr-Off synthesis). The block **6** was coupled to its 5′-terminus (coupling time 10 min, concentration 0.2 M). As the chain assembly was completed, the oligonucleotide was deprotected and converted to the gadolinium(III) chelate as follows: (i) treatment with 0.1 M NaOH for 4 h at RT; (ii) concentration in vacuo in the presence of ammonium chloride; (iii) treatment with concentrated aqueous ammonia for 16 h at 55 °C; (iv) treatment with gadolinium(III) citrate (15 equiv per ligand) overnight at RT; (v) desalting by gel filtration (NAP 5); (vi) denaturing 20% PAGE; (vii) passive elution from the gel to aqueous solution (Na_2CO_3 buffer, pH 9.8); (viii) butanol concentration; (ix) desalting by gel filtration (NAP 5). Yield was 2.02 OD (ca 100 μg, 19%). ESI-TOF MS *m*/*z*: 566.55 $[M - 10H]^{10-}$, 629.96 $[M - 9H]^{9-}$, 708.71 $[M - 8H]^{8-}$, 810.22 $[M - 7H]^{7-}$, 945.28 $[M - 6H]^{6-}$, 1134.32 $[M - 5H]^{5-}$, 1418.64 $[M - 4H]^{4-}$. Reconstitution of the data gives M = 5674.05, which is in accordance with the proposed structure.

RESULTS AND DISCUSSION

Synthesis of the nucleosidic phosphoramidite building block is shown in Scheme 1. Accordingly, treatment of 1,4,7,10-tetraazacyclododecane-1-carboxymethyl-benzyl ester (*8*), **1**, with bromomethyl acetate yielded the tetraester, **2**. Removal of the benzyl group by hydrogenolysis gave the corresponding carboxylic acid derivative, **3**. Reaction of **3** with the nucleoside **4**, in the presence of HATU [*O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate] and DIPEA (*N,N*-diisopropylethylamine) gave the nucleoside derivative, **5**. Finally, conventional phosphitylation yielded the phosphoramidite **6**.

To demonstrate the applicability of the phosphoramidite **6** for the preparation of oligonucleotide conjugates, an oligonucleotide was synthesized using standard instrument-assisted chemistry. The block **6** was coupled to the 5′-terminus of the coding sequence using 10 min coupling time and 0.2 M concentration. No differences in coupling efficiency between **6** and commercial nucleoside analogues were detected as judged on DMTr-cation assay. Upon completion of the syntheses, the conjugate was deprotected (*13*) and converted to the corresponding gadolinium(III) chelate by treatment with gadolinium(III) citrate (Scheme 2). It is worth noting that a prolonged reaction time (overnight at RT) and an excess of gadolinium(III) citrate was required to ensure complete chelate formation. According to gel electrophoresis, the crude oligomer containing the tethered DOTA survived completely the reaction conditions required for deprotection and chelate formation. The desired oligonucleotide conjugate (over 95% of the crude reaction mixture) was easily isolated from the gel and characterized by mass spectrometry. The observed molecular weight was in accordance with the proposed structure.

Scheme 2



The major advantages of the present method are as follows: (i) The block can be introduced to the biomolecule structure with a standard oligonucleotide synthesizer in high efficiency using normal procedures. (ii) The position of the label in the oligonucleotide chain is not restricted. (iii) The method allows multilabeling. This is very advantageous in applications where high detection sensitivity is required. (iv) Since the metal is introduced after the chain assembly is completed, the molecule synthesized can be used in various applications simply by changing the metal. (v) Because of the synthetic strategy, the oligonucleotide conjugate is always free from unconjugated chelate. This is extremely important for in vivo applications.

In summary, a simple method for the preparation of a DOTA-based oligonucleotide labeling reactant is demonstrated. As shown here, the building block is suitable for site specific introduction of MRI contrast agents to oligonucleotides. Naturally, for PET and SPECT applications, the metal should be introduced just prior to analysis. Since the formation of the chelate is rather slow, the complexation can be accelerated using microwaves (*10*). It is worth noting that the labels attached at the N3 position of uracil residues naturally weaken hydrogen bonds in the duplex. Thus, these labels should be used only up- or downstream of the coding sequence.

HER2 Specific Tumor Targeting with Dendrimer Conjugated Anti-HER2 mAb

Rameshwer Shukla, Thommey P. Thomas, Jennifer L. Peters, Ankur M. Desai, Jolanta Kukowska-Latallo, Anil K. Patri, Alina Kotlyar, and James R. Baker, Jr.*

Michigan Nanotechnology Institute for Medicine and Biological Sciences, Department of Internal Medicine, Division of Allergy, University of Michigan, 9220 MSRB III, Box 0648, Ann Arbor, Michigan 48109. Received December 6, 2005; Revised Manuscript Received July 12, 2006

In the present study, we report the synthesis and human growth factor receptor-2 (HER2) specific tumor targeting properties of a dendrimer conjugated to anti-HER2 mAb (monoclonal antibody) conjugate. The polyamidoamine (PAMAM) dendrimer generation five (G5) was labeled with alexaFluor 488 and conjugated to anti-HER2 mAb. The binding and internalization of the antibody-conjugated dendrimer to HER2-expressing cells was evaluated by flow cytometry and confocal microscopy. Uniquely, the conjugate demonstrated cellular uptake and internalization in HER2-expressing cells as compared to free antibody. The time course of internalization and blocking experiments with free antibody suggest that the rapid and efficient cellular internalization of the dendrimer−antibody conjugate was achieved without alterations in specificity of targeting. Animal studies demonstrated that the conjugate targets HER2-expressing tumors.

INTRODUCTION

Tumor-targeted drug delivery can enhance the effectiveness of chemotherapeutics while decreasing the systemic toxicity of these drugs. The use of monoclonal antibodies (mAbs) with specificity toward tumor markers is a well-established immunological strategy in cancer therapy. Monoclonal antibodies against various antigens have been used to deliver chemotherapeutic drugs (*1*, *2*), potent plant and bacterial toxins (*3*), and radionuclides (*4*) to tumors. The carrier capacity of antibodies can be increased significantly by attaching drug reservoirs such as nanoparticles, liposomes, and polymers. This approach potentially allows the delivery of a higher payload of drugs in a cell-specific manner.

Human epidermal growth factor receptor-2 (HER2) is one of the most promising targets in immunotherapy. The expression of the HER2 protein has been observed in a variety of tumors, in particular, breast and ovarian cancers (*5*), and has been associated with poor clinical outcomes (*6*). The overexpression of HER2 receptors in tumor cells provides an opportunity for development of HER2-targeted drug delivery systems. In addition, the presence of an extracellular domain makes the HER2 receptor an ideal target for receptor-mediated drug delivery in tumors. Monoclonal antibodies directed against HER2 offer a potential strategy for HER2-targeted delivery. Trastuzumab (Herceptin), a recombinant humanized monoclonal anti-HER2 antibody which has been approved for clinical use is reported to bind the HER2 receptor (*7*) with nanomolar affinity (*8*, *9*) and inhibits the growth of HER2-expressing breast cancer cells (*10*, *11*). The main objective of the present study was to investigate the utility of anti-HER2 mAb−PAMAM dendrimer conjugates as targeted drug delivery vectors. Antibody−dendrimer conjugates have been utilized in targeting prostate-specific membrane antigen (PSMA) (*12*) and CD14 antigen (*13*), delivery of boron (*14*), and tumor imaging applications (*15*). There has been growing interest in the synthesis of anti-HER2 mAb conjugates for gene delivery (*16*), tumor targeting (*17*), and imaging applications (*18*).

PAMAM dendrimers are biocompatible (*19*), nonimmunogenic (*20*), and water soluble and have been attached to many biological molecules such as proteins, synthetic drugs, and small molecules (*21*, *22*). In this study, we synthesized anti-HER2−mAb−dendrimer conjugate and studied its binding and internalization in HER2-overexpressing tumor cells. The specific targeting was clearly demonstrated in cell lines overexpressing HER2 by flow cytometry analysis. In addition, preincubation of HER2-overexpressing cells with free antibody prevented binding and uptake of antibody-conjugated dendrimers. This observation suggested that binding of the conjugate is mediated by HER2 on the surface of the analyzed cells. The cellular uptake of the conjugate as well as cellular distribution pattern was studied by confocal laser scanning microscopy. The antibody conjugated to dendrimer was shown to internalize in the cells faster and more efficiently than the antibody alone.

EXPERIMENTAL PROCEDURES

General. G5−PAMAM dendrimer was prepared at the Michigan Nanotechnology Institute for Medicine and Biological sciences, University of Michigan, and analyzed extensively by ^{1}H and ^{13}C NMR, matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry, high-performance liquid chromatography (HPLC), gel-permeation chromatography (GPC), and polyacrylamide gel electrophoresis (PAGE). The molecular weight of synthesized dendrimer was found to be 26 530 g/mol by GPC, and the average number of primary amino groups was estimated to be 108 by potentiometric titration (*23*). The heterobifunctional cross-linkers sulfosuccinimidyl 3-(2-pyridyldithio)propionate (sulfo-LC-SPDP) and sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC) were obtained from Pierce (Rockford, IL). Prepacked Sephadex G-25 PD-10 columns were purchased from Amersham Pharmacia Biotech (Piscataway, NJ) and equilibrated with degassed eluting buffer before sample introduction.

Synthesis of G5−Ac, 1. G5 amine dendrimer (0.265 g, 0.0099 mmol) and triethyl amine (0.088 g, 0.8635 mmol) were dissolved in 30 mL anhydrous MeOH and allowed to stir for 30 min. To this solution, acetic anhydride (0.076 g, 0.744 mmol) in anhydrous MeOH (15 mL) was added dropwise while stirring. The reaction mixture was allowed to stir overnight at room temperature. After evaporation of the solvent, the residue was dissolved in H_2O and dialyzed in 10 000 MWCO regenerated cellulose dialysis bags initially against PBS buffer followed by water. The partially acetylated dendrimer was lyophilized to give a colorless powder (0.270 g, 91.2%). The average number of acetyl groups (*80*) was determined on the basis of a ^{1}H NMR calibration curve drawn by plotting a ratio of acetyl protons and the sum of all methylene protons vs degree of actetylation (*24*).

Synthesis of G5−Ac−SPDP, 2. To a solution of G5−Ac, **1**, (0.042 g, 0.0014 mmol) in PBS buffer (pH 7.4, 10 mL), Sulfo-LC-SPDP (0.0052 g, 0.0098 mmol) dissolved in 2 mL PBS buffer was added dropwise, and the reaction mixture was allowed to stir for 3 h. The unreacted reagents and byproducts were separated by ultrafiltration using a 10K MWCO Pelicon device washing initially with PBS and then with DI water. The conjugate was lyophilized to give 0.036 g, 85.7% of conjugate as a white powder. The compound was characterized by HPLC and ^{1}H NMR spectroscopy. The number of SPDP linker was determined by pyridine-2-thione assay as described in the manufacturer's protocol. Briefly, conjugate **2** was dissolved in PBS/EDTA buffer (pH 7.4, 1 mg/mL), and the absorbance was recorded at 343 nm in comparison to a PBS−EDTA blank. To this solution, 10 μL of 15 mg/mL DTT was added and stirred for 15 min. After exactly 15 min, the absorbance at 343 nm of the reduced sample was recorded. The experiment was carried out in triplicate. On the basis of the change in absorbance, a molar ratio of 3.6 SPDP linkers per mole of dendrimer was calculated.

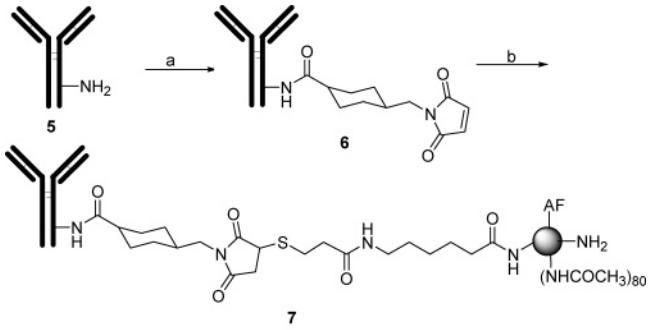
Scheme 2. Conjugation of Dendrimer Thiol with Anti-HER2 mAb



a) Sulfo-SMCC, PBS, rt, 2h b) **4**, PBS EDTA, rt, 2h, N-ethylmaleimide

Synthesis of G5−Ac−SPDP−AF, 3. AlexaFluor-NHS ester (0.003 g, 0.0046 mmol) dissolved in DMSO was added to a solution of dendrimer disulfide conjugate, **2** (0.030 g, 0.00096 mmol) in PBS buffer (pH 7.4) while stirring. The solution was allowed to stir for 18 h at room temperature. Concentration of the reaction mixture by membrane filtration and further purification on a G-25 Sephadex column gave the dendrimer conjugate, which was further purified by membrane filtration and lyophilized to give an orange powder (0.027 g, 90.0%). The purified conjugate was characterized by ^{1}H NMR and UV−vis spectroscopy and HPLC.

Synthesis of G5−AF−HN, 7. The disulfide bond on dendrimer conjugate **3** was reduced with 10 mM DTT solution in degassed PBS−EDTA buffer (pH 7.4) at room temperature (RT) under nitrogen to provide dendrimer−thiol, **4**. This conjugate was purified by gel filtration eluting with PBS−EDTA buffer (pH 7.4) under nitrogen on a PD-10 column to remove excess reagents and byproducts and was used immediately for antibody conjugation. A thiol-reactive maleimide group was introduced in anti-HER2 mAb, **5** (0.002 g, 0.00013 mmol), by reacting with sulfo-SMCC (0.0006 g, 0.00136 mmol) at room temperature for 2 h to give modified antibody **6**. The excess reagent was removed by gel filtration on a Sephadex G-25 column. Conjugate **6** was then concentrated on a microcon YM100 and immediately reacted with dendrimer thiolate (0.004 g, 0.00013 mmol) for 2 h at room temperature in PBS−EDTA buffer. After 2 h, *N*-ethylmaleimide (0.003 g, 0.024 mmol) was added to the

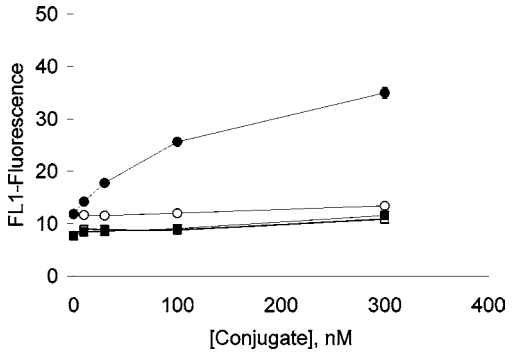


Figure 1. In vitro binding of the control conjugate G5−AF (open symbols) and the targeted conjugate G5−AF−HN (filled symbols) in control MCA207 cells (square symbols) and HER2-expressing (circle symbols) MCA207 cells. The cells were exposed to different concentrations of the conjugates for 1 h at 37 °C, rinsed, and the fluorescence measured by flow cytometry. Shown is the mean ± SE of three cell samples from an experiment. Similar results were obtained in an independent experiment.

reaction mixture. The final conjugate (G5−Ac−AF−HN, **7**) was purified by ultrafiltration (MWCO 100 000). The dendrimer−antibody conjugate was analyzed by HPLC, PAGE, and UV−vis spectroscopy.

Cell Culture and in Vitro Microscopy Experiments. MCA 207 control and −HER2 cells were a generous gift from Dr. Kevin McDonagh (University of Kentucky). SK-BR-3 cells were obtained from American Type Tissue Collection (Manasass, VA) and were grown as a monolayer at 37 °C and 5% CO_2 in McCoy's 5A medium supplemented with 15% fetal bovine serum, penicillin (100 units/mL), and streptomycin (100 μg/mL). The standard fluorescence of the dendrimer solutions was quantified using a Beckman spectrofluorimeter. For flow cytometric analysis of the uptake of the targeted polymer, cells were trypsinized and suspended in PBS containing 0.1% bovine serum albumin (PBSB) and analyzed using a Becton Dickinson FACScan analyzer. The FL1 fluorescence of 10 000 cells was measured, and the mean fluorescence of gated viable cells was quantified. For confocal experiments, cells were seeded at a density of 5×10^5 cells/plate on glass-bottom culture dishes (Mattek, Ashland, MA) 2 days prior to the experiment. Before each experiment, cells were washed three times in Dubelco's phosphate buffered saline (pH = 7.4) and incubated with 30 nM G5−HN−AF 488 or HN−AF 488 for 60 min at 37 °C except where noted. Preincubation experiments were carried with 3 μM HER2−mAb solution. For quenching experiments, anti-Alexa 488 (Molecular Probes, Eugene, OR) 600 nM was applied. The cells were fixed with 2% *p*-formaldehyde for 15 min at room temperature, washed, and mounted with a coverslip using Prolong Gold (Molecular Probes, Eugene, OR). In some cases, Prolong gold with DAPI was used to counterstain the nuclei of the cells. Cells were imaged on an Olympus FluoView

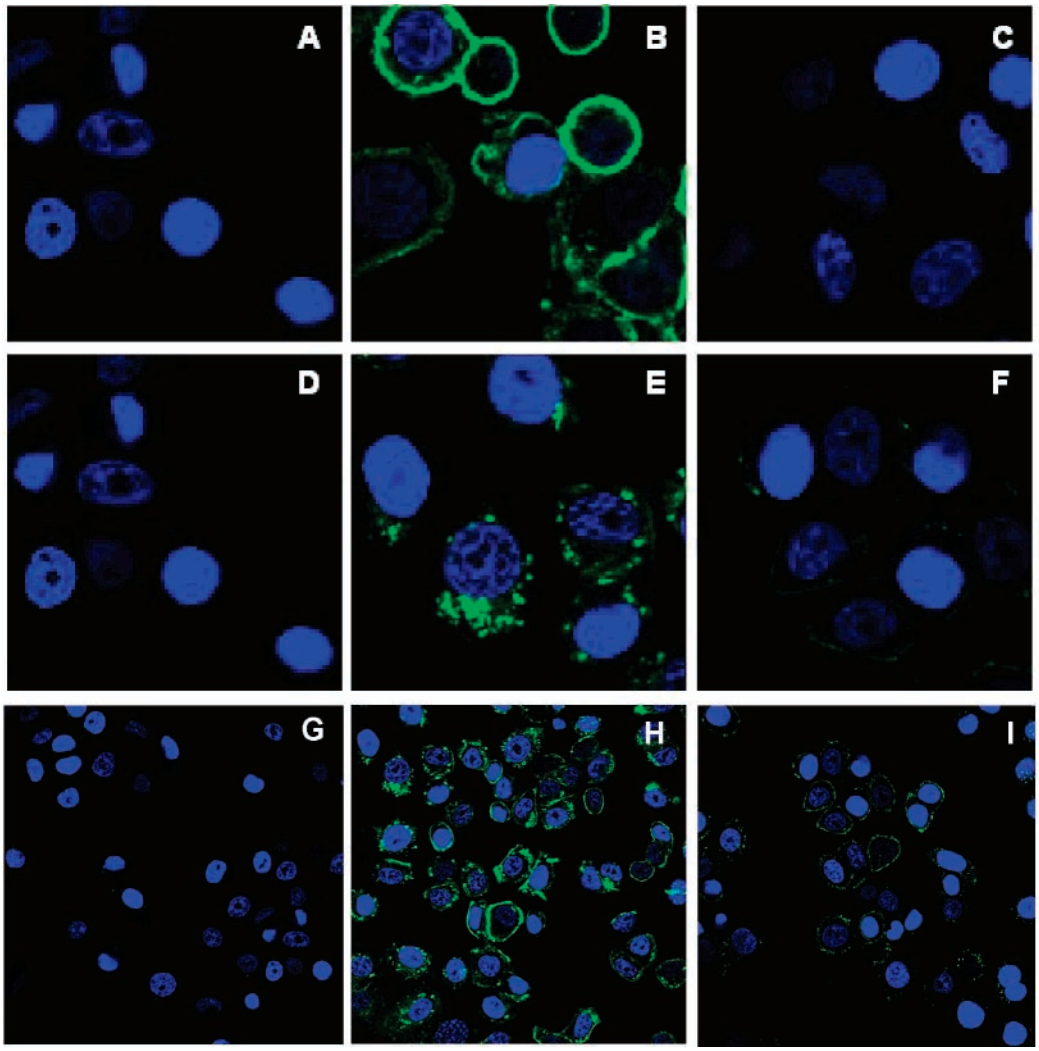

Figure 2. The blocking of HN−AF (A−C) and G5−HN−AF (D−F) by free anti-HER2 mAb in SKBR-3 cells. (A,D) Unstained cells. (B,E) Cells stained with 30 nM compound. (C,F) Cells blocked with 3 μM free anti-HER2 mAb before the addition of 30 nM compound. Panels G, H, and I show the lower-magnification images of D, E, and F, respectively.

The same field of view is shown before (A) and 10 min after (B) the addition of 600 nM anti-Alexa. (C,D) The same experiment using G5−HN−AF. (E,F) Lower-magnification images of C and D, respectively.

500 laser scanning confocal microscope with a 60×, 1.4 NA objective and pinhole settings resulting in an optical section thickness of 0.5 μm.

Animal Model. MCA207 control and −HER2 xenograft tumors were developed in 7-week-old female SCID mice by subcutaneous inoculation of 50 000 cells in the left and right flank areas. The cells were rinsed and injected as a 0.1 mL suspension using sterile PBS. Mice were housed under sterile conditions, and the tumors were allowed to reach 0.7−0.8 cm in diameter before analysis. A solution of 2.4 nmol of the conjugate in 0.1 mL of PBS or a control solution of PBS alone was administered through the tail vein. Fifteen hours later, at the end of the study, the mice were anesthetized with isoflurane, and the tumors were excised and frozen in Optimum Cutting Temperature solution (Sakura Finetechnical, Tokyo, Japan) by immersing in methylbutane/dry ice, as we have described before (*25*). The tumors were subsequently sectioned on a cryostat into 10 μm sections which were thawed, rinsed three times with DPBS, and fixed in 2% *p*-formaldehyde for 15 min at 4 °C. The sections were then rinsed and mounted with coverslips using Prolong gold with DAPI. Images were taken on an Olympus FluoView 500 laser scanning confocal microscope using a 20×, 0.7 NA objective and an optical section thickness of 1.0 μm, unless otherwise indicated.

RESULTS

Conjugate Synthesis and Characterization. The dendrimer terminal group modification was done as shown in Scheme 1. In order to improve targeting efficacy and reduce the nonspecific interactions, amine-terminated G5 dendrimers were partially surface modified with acetic anhydride (75 mol equiv) in the presence of triethylamine as base. The surface modification leaves some unreacted amines on the surface while considerably reducing the nonspecific binding to cells. The partially acetylated G5 dendrimer (G5−Ac, **1**) was purified by repeated dialysis initially using pH 7.4 PBS and subsequently using water. The purity of compound **1** and the extent of acetylation were measured and monitored by ^{1}H NMR, which shows a distinct signal for the terminal $NHCOCH_3$ protons of the dendrimer at δ1.85. ^{13}C NMR spectrum also showed a new peak at δ174.4 for the carbonyl carbon of the acetyl group. The degree of acetylation was measured by comparing the ratio of $NHCOCH_3$ protons with the sum of all methylene protons in the dendrimer to a calibration curve as described previously (*24*). In order to introduce a disulfide group on the dendrimer, heterobifunctional cross-linking agent sulfo-SPDP was conjugated to the partially acetylated dendrimer (G5−Ac, **1**) to provide a protected thiol in the form of a disulfide (G5−Ac−SPDP, **2**) as described previously (*13*). The extent of disulfide modification was monitored by UV spectroscopy, using the pyridine-2-thione assay as described in the manufacturer's protocol. Briefly, DTT was added to a measured quantity of dendrimer, and absorbance of the released 2-thiopyridine at 343 nm was recorded. On the basis of this measurement, an average of three disulfide groups per dendrimer in **2** were calculated, which is in agreement with values obtained by ^{1}H NMR by comparing the integral values of the heteroaromatic signals of the pyridine and the aliphatic signals of the dendrimer.

Compound **2** was reacted with alexaFluor NHS ester (5 molar excess) to give alexaFluor-labeled conjugate **3**. The ^{1}H NMR spectrum of the conjugate shows overlapping signals in the aromatic region for both the alexaFluor and the pyridine ring from the disulfide linker apart from the expected aliphatic signals for the dendrimer. The number of dye molecules was calculated to be ∼3 based on UV−vis spectroscopy. The reduction of disulfide bonds on dendrimer conjugate **3** was carried out using dithiothreatol, DTT, in PBS−EDTA buffer. The resultant dendrimer thiol, **4**, was carefully purified under an inert atmosphere in degassed PBS−EDTA buffer.

A thiol-reactive maleimide group was introduced on the antibody, **5**, with water-soluble sulfo-SMCC using standard protocols (*13*), and the resultant conjugate, **6**, was purified by gel filtration. To minimize the free antibody, a tenfold molar excess of dendrimer conjugate was used in the antibody−dendrimer coupling reaction; the unreacted thiols were quenched with *N*-ethylmaleimide to minimize the dimer formation due to cross-linking of dendrimer to antibodies. Free unreacted dendrimer was removed by filtration with a 100K MWCO microcon. The resultant conjugate, **7** (Scheme 2), was analyzed using PAGE, which shows a band above the antibody band that confirms the conjugation and an absence of a band for the free dendrimer. The fluorescence of the conjugates gives indirect proof of conjugation, as the fluorescent label was attached to the dendrimer.

In Vitro Targeting Studies. The cellular uptake of dendrimer−anti-HER2−mAb conjugates was measured in MCA207 control and MCA207−HER2 cells by flow cytometry (*25*). As shown in Figure 1, the conjugate G5−AF−HN bound the HER2-expressing cells but not MCA 207 control cells that do not express the receptor. The receptor specificity of the conjugates was further tested in SKBR-3 cells, which have been shown to express the HER2 receptor by confocal microscopy (*17*). SKBR-3 cells stained with HN−AF or G5−AF−HN (30 nM) were washed and fixed with *p*-formaldehyde; the nuclei were counterstained with DAPI. It is evident from the appear-

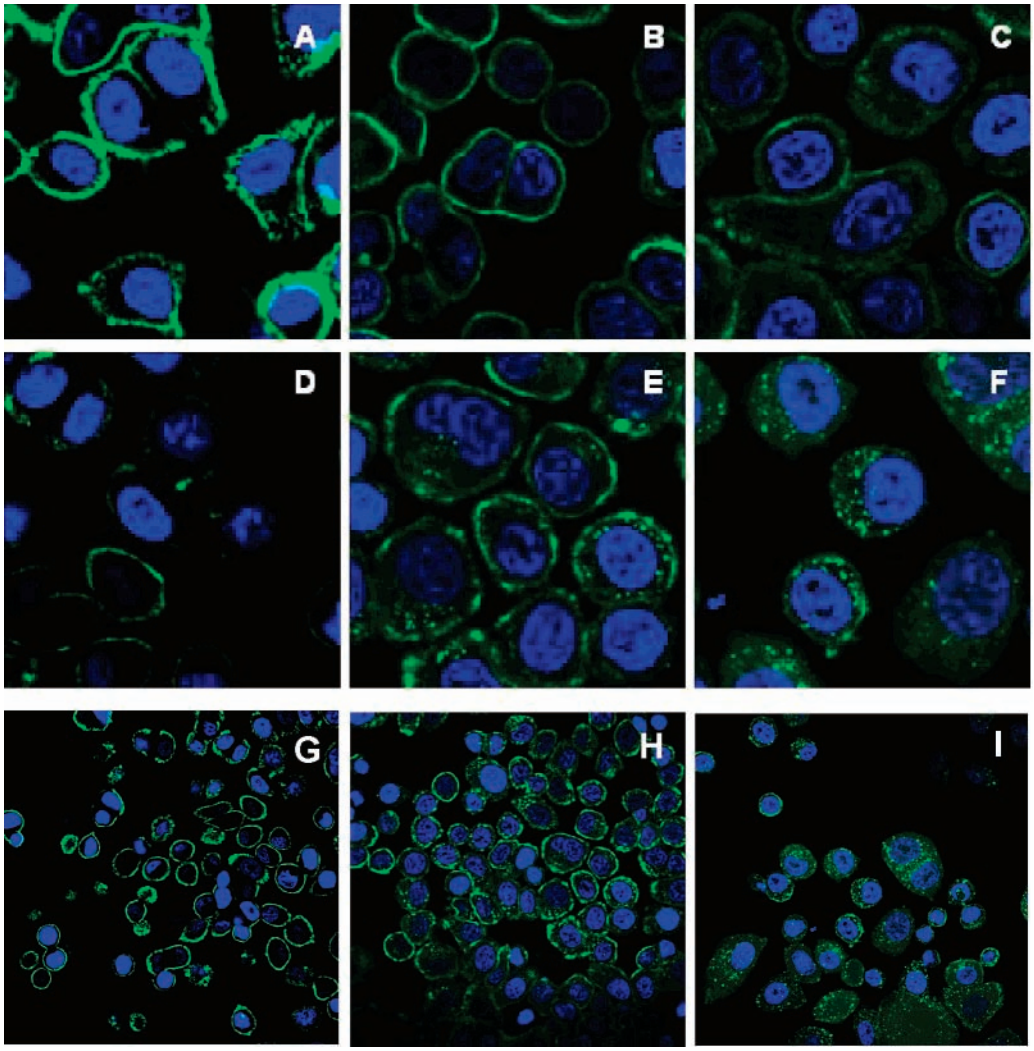

Figure 4. The time course of the internalization of HN−AF (A−C) and G5−HN−AF (D−F) in SKBR-3 cells. Cells were stained with 30 nM compound according to the following conditions: (A,D) 30 min at 4 °C; (B,E) 1 h at 37 °C; (C,F) 6 h at 37 °C; (G,H,I) lower-magnification images of D, E, and F, respectively.

ance of fluorescence in Figure 2B,E that conjugate **7** binds to the cell surface receptors and internalizes, whereas HN−AF reveals a different pattern with a higher signal on the cell surface and more uniform distribution of staining, suggesting a different internalization pattern. The images of cells stained only with DAPI (A,D) did not show autofluorescence within the instrumental parameters used. As shown in Figure 2C,F, pretreatment of cells with a 100-fold excess of free anti-HER2−mAb completely blocked fluorescence. The flow cytometry and confocal microscopic analysis suggest that anti-HER2−mAb dendrimer conjugate not only binds the cell surface HER2 receptor but is also internalized in the cells overexpressing the HER2 receptor.

In Vitro Internalization. AlexaFluor 488 serves as a hapten that is recognized by specific rabbit, anti-Alexa 488 antibodies. Upon binding, anti-Alexa 488 effectively quenches the fluorescence of AlexaFluor 488. Since anti-Alexa 488 does not cross cellular membranes, it quenches the fluorescence of surface-bound AlexaFluor-labeled conjugates, leaving aside the conjugates internalized within cells. Therefore, the decrease in fluorescence upon binding of anti-Alexa 488 to cells pretreated with HN−AF 488 or G5−AF−HN provides a useful index of the degree of internalization of these compounds. Figure 3A shows cells that were incubated with HN−AF for 1 h at 37 °C. In Figure 3B, after the addition of anti-Alexa 488, nearly all of the fluorescence was quenched, confirming that this compound is mainly surface-bound. In contrast, when the same experiment is performed with G5−AF−HN, a much smaller decrease in fluorescence is observed, indicating that antibody−dendrimer conjugate is largely internalized.

Comparison of the time course of the internalization of HN−AF and G5−AF−HN in SKBR-3 cells reveals that the antibody−dendrimer conjugate was rapidly internalized in HER2-expressing cells in comparison with antibody alone. As shown in Figure 4A,D, after 30 min at 4 °C, both conjugates were mainly localized in the cellular membrane. After 1 h incubation at 37 °C (panels B and E), HN−AF was still present in the plasma membrane, whereas a significant internalization was observed in the cells incubated with G5−AF−HN. After 6 h incubation at 37 °C (panels C and F), G5−AF−HN internalization was significantly higher as compared to HN−AF.

In Vivo Studies. Tumors were developed in SCID mice by subcutaneous injection of the control and HER2-expressing MCA 207 cells, on left and right flank areas of the mice. The tumor uptake of G5−AF−HN or its vehicle was tested by injecting the conjugates into the bloodstream from the tail vein. As shown in Figure 5, the conjugate showed an increased binding to HER2-expressing tumor when compared with control tumor, whereas both PBS and control compound (G5−AF) did not show any preferential binding by flow cytometry.

We also analyzed the in vivo binding by confocal microscopy. Internalized fluorescence due to uptake of the conjugate can be clearly seen in HER2-expressing tumor cells (Figure 6A), whereas no fluorescence was observed in any of the control

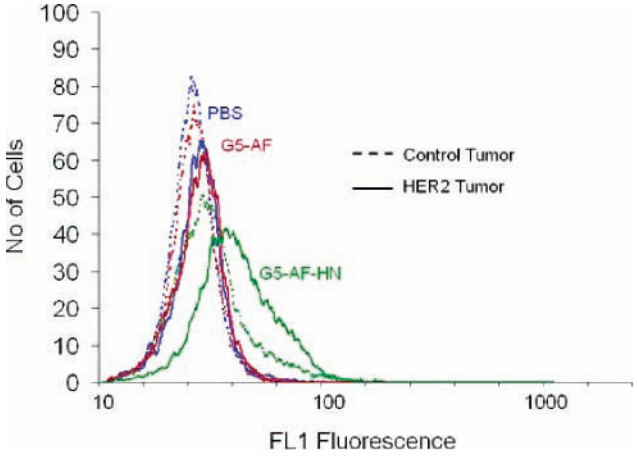

Figure 5. Binding of G5−AF−HN in MCA 207 control and HER2-expressing mice xenograft tumors in vivo. Tumors were developed in SCID mice by subcutaneous injection of the two cell lines on left and right flank areas, respectively, of the mice. When the tumors were about 0.7 cm in diameter, 2.4 nmols G5−AF−HN or its vehicle were injected intravenously. The tumors were isolated after 15 h, and the cells were separated by collagenase digestion and analyzed by flow cytometry.

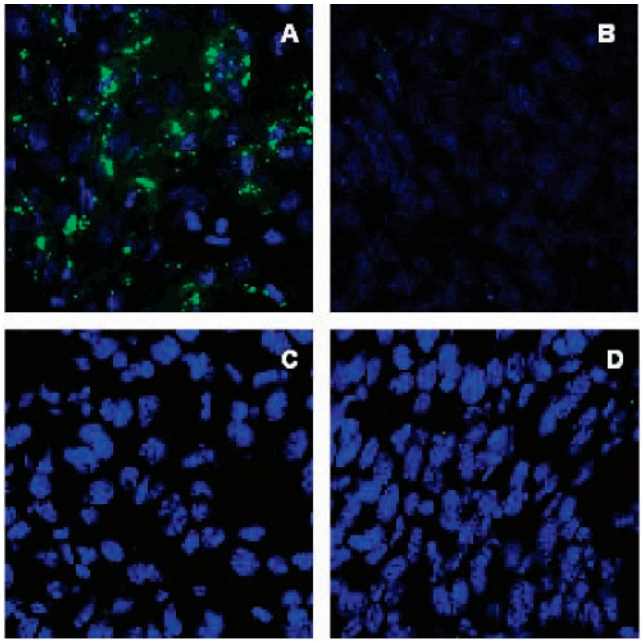

Figure 6. Images of tumor sections. (A,B) HER2+ (A) and HER2− (B) tumors from an animal injected with G5−HN−AF. (C,D) HER2+ tumors from an animal injected with PBS (C) or G5−AF (D).

cells, including an HER2-negative tumor from the same animal (B) and HER2-positive tumors in animals where PBS (C) or the control conjugate G5−AF (D) was given.

DISCUSSION

The major disadvantage of most antitumor drugs is their high toxicity, which leads to toxic side effects. Targeted cancer therapy aims to reduce or eliminate side effects by specifically delivering a cytotoxic pharmaceutical agent to tumor cells. Successful drug targeting can also result in a lower dosage required to obtain a therapeutic response, thus improving antitumor effects and again limiting systemic toxicity. Antibodies themselves can be used as drug carrier systems, but attaching drugs to an immunoglobulin may result in the loss of binding efficacy and decrease the solubility of the immunoconjugates. These problems can be overcome by attaching a water-soluble drug reservoir to the antibodies. The G5−PAMAM dendrimer is stable and nonimmunogenic and contains, on average, 110−128 primary amines on the surface. This provides an ample number of reactive sites for the construction of complex drug delivery systems by attaching multiple chemical moieties, such as radiopharmaceuticals, drugs, dyes, and contrast agents (*26*). The overexpression of HER2 protein in a high percentage of epithelial tumors and substantially greater expression of HER2 protein on cancerous cells will permit the selective targeting of malignant cells using anti-HER2−mAb. Therefore, in the present study, we synthesized a conjugate of HER2−mAb with PAMAM dendrimer as the drug carrier. Amine-terminated PAMAM dendrimers are reported to bind to the cells in a nonspecific manner owing to the positive charge on the surface and were also shown to be comparatively more toxic than charge neutral surfaces. The amine-terminated G5 dendrimer was partially surface modified with acetic anhydride in presence of triethylamine as base. The partial modification of the surface also improves the aqueous solubility and minimizes aggregate formation. The partially acetylated dendrimer was reacted with a heterobifunctional linker, sulfo-LC-SPDP to provide a 2-pyridylthiol group on the surface, which upon reduction with DTT gives a reactive thiol group. For detection of conjugates by flow cytometry or confocal microscopy, a detectable fluorescent probe is needed. We used AlexaFluor 488 (AF) as the fluorescent label, because it is significantly brighter than fluorescein conjugates (*27*) and is also much more photostable. The reduction of the 2-pyridylthiol group and conjugation to anti-HER2−mAb which was modified with maleimide linker gave the final dendrimer−mAB conjugate. The remaining thiol groups were capped with *N*-ethylmaleimide to prevent cross-linking. The HPLC analysis of the final conjugate shows a homogeneous peak, which indicates that under the present reaction conditions there was minimal cross-linking, possibly because of the steric hindrance posed by the relatively larger size of the antibody.

The dendrimer−anti-HER2−mAb bound HER2-expressing MCA 207 to the cell in a dose-dependent manner as shown by flow cytometery. As flow cytometry cannot distinguish between conjugate uptake and cell surface binding, confocal laser scanning microscopy was used to evaluate the cellular uptake of the synthesized dendrimer conjugate. By confocal microscopic analysis, it was shown that the dendrimer−HER2−mAb conjugate not only bound to the outer surface of the HER2-expressing cells but was also internalized. The conjugate uptake was further confirmed by quenching experiments carried out using anti-Alexa 488. The anti-Alexa is a noninternalizing antibody that interacts with surface-bound AlexaFluor and quenches its fluorescence. This experiment indicates that dendrimer−HER2−mAb conjugate was predominantly internalized into HER2-expressing tumor cells. A time course study of internalization demonstrated that the antibody-conjugated dendrimer internalized in the HER2-expressing cells more efficiently and rapidly. The in vivo experiments indicate that this conjugate may be capable of targeting imaging agents and/or chemotherapeutics to HER2-overexpressing tumors. In conclusion, we have synthesized anti-HER2−dendrimer conjugate that efficiently binds to HER2-overexpressing cells. From flow cytometery and confocal microscopic analysis, it was demonstrated that the anti-HER2−mAb−dendrimer conjugates not only bound the HER2-overexpressing cells but was also internalized in the cells. Preincubation experiments with unlabeled antibody, a lack of binding and uptake in control cells, and insignificant binding of control antibody−dendrimer conjugates all suggest that the conjugates internalize in HER2-overexpressing cells. The time course of internalization reveals a faster and more efficient internalization of the conjugate than anti-HER2 antibody alone. In vivo experiments indicate that

this conjugate may be capable of targeting imaging agents and/or chemotherapeutics to HER2-overexpressing tumors.

Amino-Terminal Dimerization of Peptides on the Solid Support. Synthesis and Biological Activity of the Immunosuppressive HLA−DR Fragments Linked by Poly(ethylene glycol)s

Monika Biernat,[†] Piotr Stefanowicz,[†] Michał Zimecki,[‡] and Zbigniew Szewczuk*,[†]

Faculty of Chemistry, University of Wrocław, Wrocław, Poland, and Institute of Immunology and Experimental Therapy, PAN, Wrocław, Poland. Received December 22, 2005; Revised Manuscript Received July 27, 2006

The nonapeptide fragment of the HLA−DR molecule, located in the exposed loop of the β chain (164−172) and having the sequence VPRSGEVYT, suppresses the immune response. On the basis of the three-dimensional structure of the HLA−DR superdimer, we designed new dimeric analogs in which the VPRSGEVYT peptides are linked through their N-termini by poly(ethylene glycol) linkers of different lengths and are able to mimic the dimeric nature of the immunosuppressive fragments of HLA class II molecules. The analogs were synthesized using standard solid-phase peptide synthesis protocols. The dimerization was achieved by cross-linking the N-terminal positions of the peptides, attached to an MBHA resin, with α,ω-bis(acetic acid) poly(ethylene glycol), activated by esterification with pentafluorophenol. Our results demonstrate that the amino-terminal dimerization of the peptide results in enhanced immunosuppressive activity and that the potency of the conjugates depends on the length of the poly(ethylene glycol) linker. MS/MS analysis of the obtained dimeric peptides is also presented.

INTRODUCTION

MHC[1] class II molecules present antigenic peptides to helper T cells and thereby alert the immune system to infectious attack (reviewed by Pieters (*1*), Hiltbold and Roche (*2*)). MHC class II molecules are heterodimers with a molecular mass of 60 kDa consisting of noncovalently associated polymorphic α and β subunits. The class II molecules are highly polymorphic proteins. The presence of several isotypes (DP, DQ, and DR) of human MHC (HLA) class II molecules further increases their diversity.

Our previous studies showed that fragments located in the β164−172 loop of HLA−DQ suppress the humoral and cellular immune responses (*3, 4*) and inhibit some integrins (*5*). The fragments contain the RGD sequence, known to be important in several proteins in mediating cell adhesion interactions. The sequence is located in an exposed loop of the HLA−DQ molecule and may therefore be involved in interactions with other proteins. The immunosuppressive region is situated in close spatial proximity to the site identified as interacting with the T-cell coreceptor CD4 (*6*). The pentateptide fragment of the loop, Arg-Gly-Asp-Val-Tyr-NH_2, is the shortest immunosuppressive sequence found, although its potency is relatively low (*7*). The corresponding fragments of HLA−DP and HLA−DR show immunological properties similar to the HLA−DQ fragment (*8*). Particularly, the nonapeptide fragment of HLA−DR (Val-Pro-Arg-Ser-Gly-Glu-Val-Tyr-Thr) is a strong suppressor of the immune response, although the fragment does not contain the RGD sequence. We also designed and synthesized constrained (by cyclization) analogs of the fragment to mimic the immunosuppressive loop of HLA class II molecules and found that some of the investigated peptides suppress immune responses more strongly than their linear counterparts (*9, 10*). On the basis of our results, we suggested that the loop may serve as a functional epitope on the HLA class II surface for intermolecular binding and that a possible mechanism of biological action of the synthesized peptides is connected with specific interference with the adhesion of HLA class II molecules to their coreceptors, e.g., some specific integrins and/or the T-cell coreceptor CD4 (*11*). Recently, we pointed out some topological correspondence between the β-164−172 loop of HLA−DQ and the 50−59 loop of ubiquitin, suggesting that the proteins may interact with similar proteins, although the ubiquitin fragment contains the retro-RGD sequence. We showed that the linear and cyclic fragments of ubiquitin, designed to mimic the loop, may significantly inhibit both humoral and cellular immune responses (*12*). The low toxicity of such compounds compared with classic suppressors such as cyclosporine A (CsA) may lead to potential application of the peptides in therapy. A combined use of these peptides with conventional immunosuppressors may have even better therapeutic perspectives.

The three-dimensional structure of the HLA class II molecule has been determined by X-ray crystallography (*13*). The crystal structure shows that the $\alpha\beta$ heterodimer can itself dimerize to form a four-chain $(\alpha\beta)_2$ superdimer of 120 kDa. There is also evidence for the existence of the 120 kDa $(\alpha\beta)_2$ complex of the class II molecules in animal B cells (*14*). It has been suggested that MHC class II molecules may interact with the T-cell receptor (TCR) and $CD4^+$ as an $(\alpha\beta)_2$ superdimer, potentially ensuring more stable and stimulatory interactions than can be provided by the simple $\alpha\beta$ heterodimer alone (*15, 16*). Evidence has also been presented that the formation or rearrangement of a T-cell receptor dimer is necessary and sufficient for initiation of T-cell signaling (*17*). Self-association of the CD4 coreceptor may also affect T-cell activation (*18*). Therefore, substances that are able to modulate the receptors'

dimerization may control such a process and are potential immunomodulators. Dimeric ligands are known candidates for mediating dimerization of these types of receptors (*19, 20*). It was previously found (*21*) that peptides that consist of two tandemly repeated epitopes joined by a flexible linker have an increased affinity for class II molecules and are more potent in inducing proliferation of T-cell clones than monomeric epitopes. These results support a role of the MHC class II dimer of heterodimers in amplifying the proliferative response of T cells to antigen by dint of the superdimers having a higher affinity for CD4 than the nominal class II $\alpha\beta$ heterodimers. Recently, we synthesized a series of dimeric analogs of the immunosuppressive fragments of HLA class II molecules. The dimeric analogs consist of two VPRSGEVYT sequences joined through their C-termini by oligoglycine spacers of different length connected to the lysine residue $(VPRSGEVYTG_n)_2K\text{-}NH_2$ ($n = 4$, 5, and 6). Our results demonstrate that the immunosuppressive activities of the resulting dimeric analogs are significantly higher than those of their monomeric counterparts and their potencies depend on the length of their linker (*22*). However, employment of the oligoglycine sequences in the dimers significantly decreased their solubility in aqueous media. This problem might be solved by replacing the linker by a more soluble one, for example, poly(ethylene glycol).

Conjugation of poly(ethylene glycol) with bioactive proteins or peptides (PEGylation) increases their solubility in physiological fluids as well as their plasma half-life and resistance to proteolytic cleavage (*23*). In addition, the conjugate's immunogenicity may also be decreased (*24, 25*). It has also been shown that the length of the PEG chains that are attached to the protein affects the protein's biological activities (*26*).

In this paper, we report the synthesis of dimeric peptides linked through their N-termini by poly(ethylene glycol) spacers of different length. On the basis of the three-dimensional structure of the HLA−DR superdimer, we designed new dimeric analogs able to mimic the dimeric nature of the immunosuppressive fragments of HLA class II molecules by which the VPRSGEVYT peptides were linked with a commercially available mixture of α,ω-bis(acetic acid) poly(ethylene glycol) (PEG−diacid) activated by esterification with pentafluorophenol. The dimeric peptides (peptides **1** and **2**), in which the sequences VPRSGEVYT were linked with polyether linkers of defined length, were also obtained. The synthesized dimers were analyzed by ESI-MS/MS spectrometry, and their immunomodulatory properties were also tested.

MATERIALS AND METHODS

Peptide Synthesis. *Materials.* The derivatives of amino acids for peptide synthesis and the coupling reagent (TBTU) were purchased from NovaBiochem. The side-chain-protecting groups for Fmoc−amino acids were *t*-butyl for Thr, Tyr, Glu, and Ser, and Pmc for Arg. The MBHA-Rink amide resin (0.55 mmol/g) was purchased from NovaBiochem. Poly(ethylene glycol) 600 diacid and poly(ethylene glycol) 250 diacid α,ω-bis(acetic acid) poly(ethylene glycol) were purchased from Aldrich. The poly(ethylene glycol) 250 diacid used for the synthesis of dimeric peptide **2** contains α,ω-bis(acetic acid) tri(ethylene glycol) as a main component. The homogeneous α,ω-bis(propionic acid) dodecae(ethylene glycol) used for the synthesis of dimeric peptide **1** was purchased from Iris Biotech GmbH (Germany). The solvents for peptide synthesis were obtained from Riedel de Haën (DMF) and J.T. Baker (methanol).

Preparation of Peptides. Peptides were prepared by manual solid-phase techniques using the standard Fmoc synthesis procedure. The first amino acid attached to the MBHA-Rink amide resin was Thr(Bu^t). Fmoc-protecting groups were removed in the presence of 25% piperidine in dimethylformamide (DMF). Single coupling by TBTU was performed in DMF followed by acetylation with acetic anhydride at the end of each cycle.

Preparation of Pentafluorophenol−PEG Diesters (PEG-Pfp_2). The poly(ethylene glycol) 600 diacid (90 mg, 0.15 mmol (according to the average molecular weight)) and pentafluorophenol (55 mg, 0.3 mmol) components were dissolved in 20 mL of ethyl acetate at 0 °C, and DCC (62 mg, 0.3 mmol) was added. The reaction mixture was stirred for 1.5 h at 0 °C. Dicyclohexylurea was filtered off, and the filtrate was evaporated in vacuo. The resulting PEG-Pfp_2 product was used for the following synthesis without further purification. Syntheses of the pentafluorophenol diesters of the individual PEG−diacids (α,ω-bis(propionic acid) dodecae(ethylene glycol) and α,ω-bis(acetic acid) tri(ethylene glycol)) were carried out with an identical procedure.

Dimerization. The peptide on the resin was linked by forming an amide bond between the N-terminal amino acid residues and PEG-Pfp_2 in DMF at room temperature in the presence of 1-hydroxybenzotriazol. The peptidyl resin (120 mg, 0.7 mmol) was mixed in DMF in the reaction vessel. The PEG diester (34 mg, 0.35 mmol) and HOBT (50 mg, 1.75 mmol) were added to the reaction mixture in five equal portions (one portion per day). The peptide was cleaved from the resin using Reagent K (TFA/thioanisole/water/phenol/TIS 33:2:2:2:1, v/v) at room temperature for 4 h and extracted with trifluoroacetic acid, followed by precipitation with cold diethyl ether.

Purification and Characterization of the Product. The crude product was characterized by HPLC on a 5-μm C-18 column (ODS 4.6 mm × 250 mm). Solvent systems were S1, 0.1% aqueous trifluoroacetic acid (TFA); S2, 80% acetonitrile + 0.1% TFA, linear gradient from 0−100% of S2 for 60 min, flow rate 1.0 mL/min, determined at 220 nm. The main heterogeneous reaction product was further purified and fractionated to three approximately equal fractions by preparative reversed-phase HPLC on a Vydac C-18 column (22 mm × 250 mm) using the solvent systems S1, 0.1% aqueous TFA; S2, 40% acetonitrile + 0.1% TFA, linear gradient from 50−100% of S2 for 60 min, flow rate 7.0 mL/min, determined at 220 nm. The fractions were collected, transformed into acetate forms, and lyophilized. The homogenic peptides **1** and **2** were purified by the same method. Their purity was over 98% measured by reversed-phase HPLC analyses. The obtained products possessed the correct amino acid composition (measured on a DIONEX-AAA Direct System). Their molecular weights were checked on a Finnigan MAT TSQ 700 mass spectrometer equipped with a Finnigan electrospray ionization source and Q-TOF instrument (Micromass, Manchester, U.K.). The identity of peptides **1** and **2** was confirmed using a micrOTOF-Q (Bruker, Germany) electrospray mass spectrometer on the basis of high-resolution mass measurement.

Structural Analysis. *MS/MS Spectra.* Mass spectrometric measurements were performed on a quadruple time-of-flight instrument (Q-TOF Micromass, Manchester, U.K.) equipped with an electrospray source. Spectra were recorded using aqueous solutions of acetonitrile (50%) and formic acid (1%) at a peptide concentration of typically 5 μM (according to the average molecular weight). The potential between the spray needle and the orifice was set to 2.5 kV, and the cone voltage was 35 V. In MS/MS mode, the quadrupole was used to select the precursor ions, which were fragmented in the hexapole collision cell, generating product ions that were subsequently mass analyzed by the orthogonal reflectron TOF mass analyzer. For CID MS/MS measurements, the voltage over the hexapole collision cell varied from 25 to 70 V, and argon was used as the collision gas at a pressure of 11 kPa. MS/MS data were processed by a maximum entropy data enhancement program,

[a] The results are presented as a mean from four determinations $\pm$ standard error. [b] Control - 0.9% NaCl solution. [c] Results for nonapeptide VPRSGEVYT were published previously (*8*).

MaxEnt 3 (Micromass, U.K.), to deconvolute spectra where peaks in a variety of charge states are present. The simplified spectra, consisting of mono-isotopic peaks in only a single charge state are presented.

Immunological Tests. *Animals.* Twelve-week-old female BALB/c mice were used for the experiments. The mice were kept at the Animal Facility of the Institute of Immunology and Experimental Therapy, Wroclaw, and fed commercial granulated food and water ad libitum.

Reagents. Sheep red blood cells (SRBCs) were provided by the Wroclaw Agriculture Academy. The SRBCs were kept in Alsever's solution until use.

Priming of Mice with Antigen. Mice were sensitized with 0.2 mL of a 1% SRBC suspension in 0.09% NaCl intraperitoneally (i.p.). Four days later, the spleens were used for generating the secondary immune response in vitro.

Determination of the Antibody-Forming Cell (AFC) Numbers in the Cell Culture. The spleens were isolated aseptically and pressed through a plastic screen into Hank's medium. The cells were then centrifuged and treated for 5 min at room temperature with 0.83% ammonium chloride to lyze erythrocytes. Subsequently, the cells were washed twice with Hank's medium and passed through cotton wool columns to remove cell debris. Finally, the splenocytes were resuspended in culture medium (RPMI 1640, supplemented with 10% fetal calf serum, glutamine, sodium pyruvate, 2-mercaptoethanol, and antibiotics) and distributed to 24-well culture plates (5×10^6/well). The cell cultures were immunized with 50 μL of 0.001% SRBC, and the peptides were added at the dose range of 1−100 μg/mL. To control cultures, 0.1 mL of the culture medium was added. After 4 days of incubation in a cell culture incubator, the AFC numbers were determined using the Mishell and Dutton assay (*27*). The results are presented as mean AFC numbers from 4 wells, calculated per 1 million viable splenocytes plus/minus standard error (SE). The Student's *t*-test was applied in evaluating the data. The results are presented as mean AFC numbers from quadriplicate wells (determinations) plus/minus SE. The results are regarded as significant when $p < 0.05$. To make comparison of the data easier, we included the percentage values of the inhibition of the immune responses. The values were calculated according to the equation

$$\%\ \text{of immunosuppression} = 100\left(1 - \frac{\text{experimental value}}{\text{control}}\right)$$

The values are shown in brackets in the case of statistically nonsignificant (NS) results. The results of the immunological tests are summarized in Table 1.

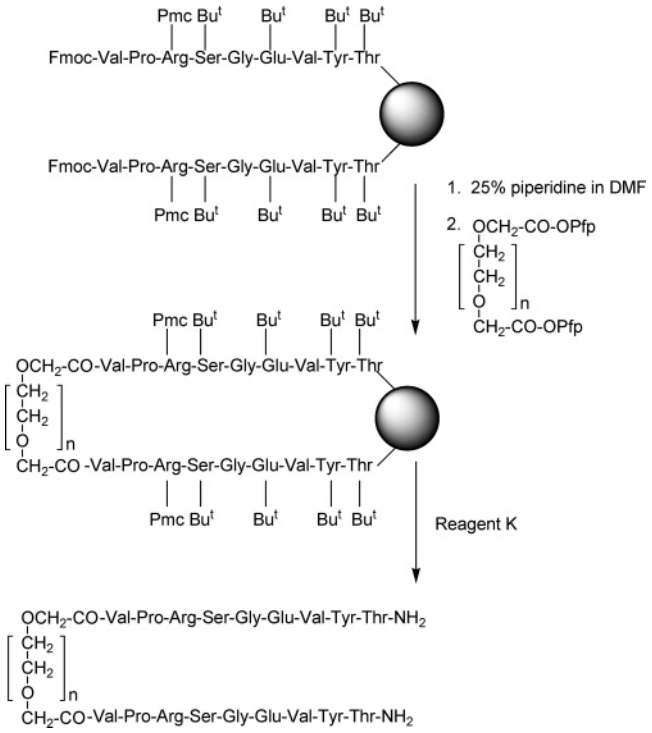
RESULTS

Peptide Synthesis. We synthesized a series of dimeric compounds consisting of two VPRSGEVYT sequences linked through their N-termini by flexible PEG spacers of different length. The dimerization was achieved directly on a solid support by cross-linking the N-terminal amino groups of the peptides attached to an MBHA resin with α,ω-bis(acetic acid) poly(ethylene glycol) activated by esterification with pentafluorophenol (PEG-Pfp_2) (Scheme 1). Previously, a similar reagent was successfully used for peptide cyclization via connecting lysine side chains by the PEG linker (*28*). The progress of the reaction was monitored by HPLC and ESI-MS. The synthesis parameters (resin loading, coupling reagent, temperature, incubation time, number of portions of PEG-Pfp_2 added to the reaction mixture) were optimized to obtain the best yield of the dimers. The optimized parameters are given in the experimental part. Our experiments showed that shortening the incubation time or adding a greater excess of PEG-Pfp_2 at once gave significant amounts of monomeric PEGylated peptide. The solubility of the obtained dimers in water was very good (more than 10 mg in 1 mL).

The presented data show that under the described experimental conditions the peptide dimer was formed with a relatively high yield. The HPLC profile and ESI-MS spectrum of the crude peptide dimer are shown in Figures 1 and 2, respectively. The ESI-MS spectrum of the synthetic dimeric peptide PEG−(VPRSGEVYT-NH_2)$_2$ revealed a very characteristic pattern, typical of heterogeneous polymeric material (*29*). There were two groups of peaks in the spectrum. The first group, at lower *m*/*z* values, corresponded to $[MH_3]^{+3}$ ions, while the second, at higher *m*/*z* values, corresponded to $[MH_2]^{+2}$ ions (confirmed by the pattern of isotopic peaks). $[MH]^{+1}$ ions were not observed, probably because each dimeric molecule contained two cationic arginine residues. Experimental *m*/*z* values are in excellent agreement with *m*/*z* calculated theoretically on the basis of the formulas of the synthesized compounds. The maximal abundance corresponds to the linker containing ten ethylene ether units.

The analysis of the HPLC profile (Figure 1) showed the same number of molecular species observed in the ESI-MS spectrum.

Scheme 1. Cross-linking of N-terminal Position of the Immunosuppressive Nonapeptide Fragment of HLA−DR Molecules, Attached to an MBHA Resin, with Poly(ethylene glycol)bis(carboxymethyl)ether Activated by Esterification with Pentafluorophenol



The distribution of the molecular masses of the PEG−diacids used in the synthesis (Figure 3) and in the obtained dimers (Figure 4A) was evaluated on the basis of ESI-MS spectra. The most populated PEG−diacid contained twelve ethylene ether units, which corresponded to $[MNa]^+$ 685.9 (the value corresponds well to the average value of molecular weight provided by manufacturer (655) and estimated acidimetrically by us (647)), while in the peptide dimer, the most populated linker contained ten ethylene ether units ($[MH_2]^{2+}$ 1276.4).

To answer the question whether this synthesis approach is of general value, we additionally performed the synthesis of other model peptide dimers. Dimerization of hexapeptide RGDVYT-NH_2, containing the RGD sequence, produced essentially the same results. Surprisingly, even the application of a significantly shorter, commercially available PEG−diacid with a molecular weight of 250 (purchased from Aldrich) as well as other non-poly(ethylene glycol) diacids (including glutaric, adipic, suberic, and sebacic acids) gave similarly satisfactory results (not shown in the experimental part).

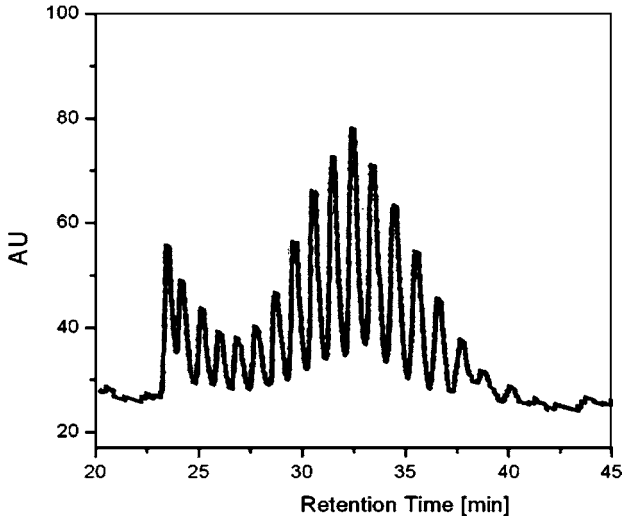


Figure 1. HPLC profile of the crude product of the solid-phase dimerization of VPRSGEVYT-NH_2 peptide.

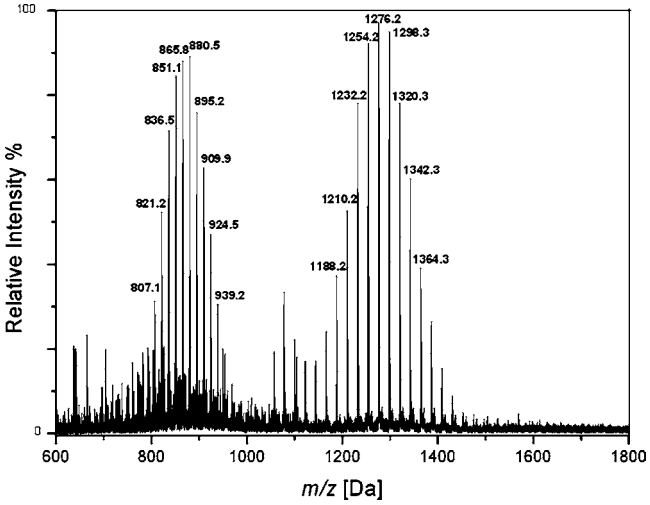

Figure 2. ESI-MS spectrum of the crude product of the solid-phase dimerization of VPRSGEVYT-NH_2.

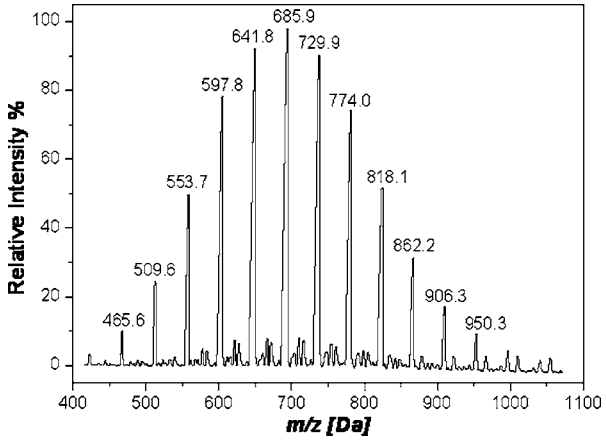

Figure 3. ESI-MS spectrum of PEG−diacid (average molecular mass approximately 600 Da) used in the syntheses of dimers. Spectrum obtained by cationization with a 10^{-4} M solution of NaCl in methanol. The most populated PEG−diacid contains 12 ethylene ether units, which corresponds to $[MNa]^+$ 685.9.

A partial separation of the dimers according to linker length by analytical HPLC encouraged us to attempt fractionation of the dimeric peptides on the preparative scale. We did not obtain homogeneous samples of defined linker length; however, fractions separated in preparative HPLC showed a relatively narrow distribution of molecular masses (Figure 4). Fraction A, which contained a set of dimeric peptides with the linker consisting of 35 or fewer atoms in their backbone chain, and fraction C, mostly populated by molecules with longer linkers (41−50 atoms), were tested for their immunological properties. Fraction C contained only a small amount (less than 20%) of shorter linker molecules. The structures of the fractionated peptides were further confirmed by amino acid analysis and mass spectrometry.

Although we were able to separate and purify small amounts of the individual PEG dimer peptides on reverse-phase HPLC, this separation is impractical because only very small amounts of purified material were obtained, too little to perform the biological test. On the other hand, the inhomogeneity of the synthesized peptide library with PEG linkers might be beneficial.

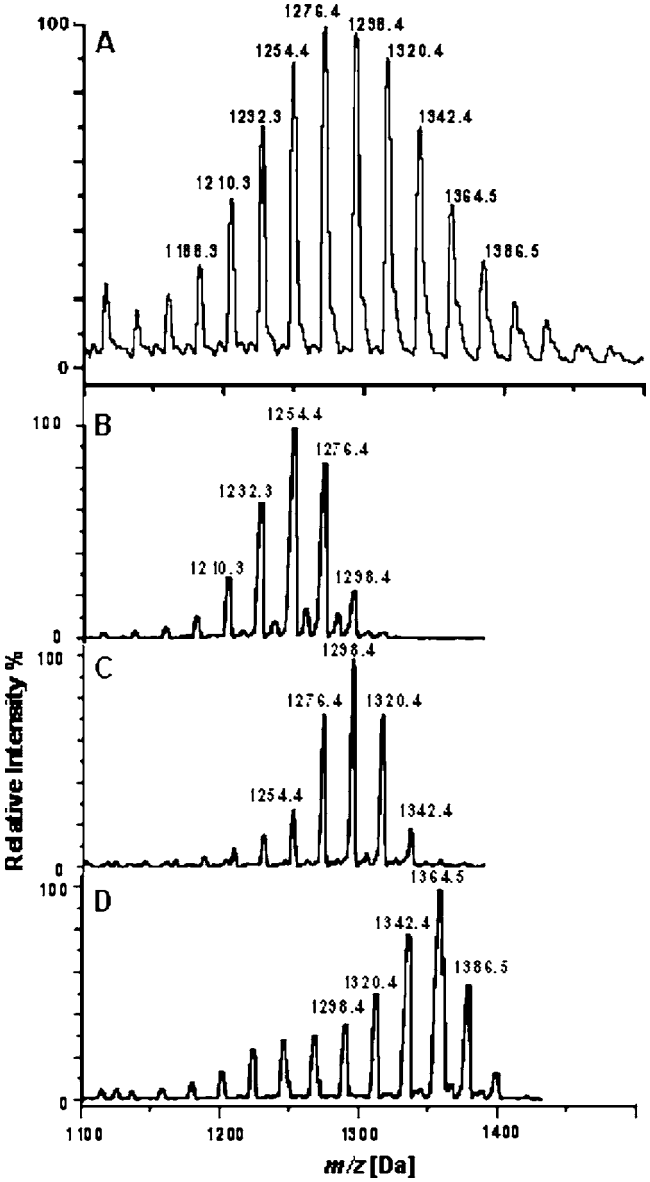

Figure 4. ESI-MS spectra (measured on Finnigan TSQ 700) of PEG−$(VPRSGEVYT\text{-}NH_2)_2$ conjugate. Presented are the double-charged set of peaks only. (A) Crude product of reaction dimerization. (B) Fraction A with the highest *m/z* peak of 1254.4, corresponding to a linker length of 32 atoms. (C) Fraction B mostly populated by molecules with a 38-atom linker (*m/z* 1298.4). (D) Fraction C, containing dimeric peptides mostly populated by molecules with linkers containing 41−50 atoms (*m/z* 1320.4−1386.5).

Such a peptide library is more likely to span two receptor molecules when the distance and orientation between them are not certain.

We also attempted to obtain peptide dimers linked by a polyether bridge of defined length. We synthesized two new compounds (peptides **1** and **2**) starting from commercially available α,ω-bis(propionic acid) dodecae(ethylene glycol) and PEG−diacid 250 (composed mainly of α,ω-bis(acetic acid) tri-(ethylene glycol)), respectively. The synthesis protocols were essentially identical to the dimerization procedure described above (Scheme 1). The reaction products were easily purified by the HPLC method, and their identities were confirmed by high-resolution mass spectrometry. The high yields of the synthesis of these dimers suggest that the method we proposed is appropriate for the synthesis of both individual PEG−peptides and their libraries with various linker lengths.

ESI-MS/MS Studies of Peptide Dimers Linked by PEG−Diacid. The MS/MS experiments were performed on $[MH_2]^{+2}$ ions of the dimeric peptides PEG−$(VPRSGEVYT\text{-}NH_2)_2$ and PEG−$(RGDVYT\text{-}NH_2)_2$. The representative MS/MS spectrum of the parent ion 1276 ($[MH_2]^{2+}$) for PEG−$(VPRSGEVYT\text{-}NH_2)_2$ is given in Figure 5. The analysis of the spectrum showed mainly a, b, and y ion types, according to the Roepstorf and Fohlmann nomenclature (*30*). Series b ions, ranging from b_1 to b_7, were accompanied by corresponding ions of type a. Ions belonging to the y series (y_2, y_3, y_4, y_7, y_8, and y_9) did not contain a PEG linker and therefore were located at lower *m/z*. The fragments of PEG linker were not found in the fragmentation spectrum. Similarly, fragmentation of PEG−$(RGDVYT\text{-}NH_2)_2$ (2+ ion) revealed a series of b ions, ranging from b_1 to b_5 (Figure 6). Ions of the b type were accompanied by ions of type a. The abundance of type y ions was low, with only the fragment y_2 being well-pronounced. In contrast to the dimeric peptide PEG−$(VPRSGEVYT\text{-}NH_2)_2$, internal fragments were relatively abundant, and the series (b_3b_3) and (b_3b_4) were observed. This particular type of internal fragment ions was observed only in dimeric peptides connected by the N-termini or side chains. Fragmentation of the PEG linker was not observed in PEG−$(RGDVYT\text{-}NH_2)_2$ either. Comparison of the fragmentations of molecules differing by the length of the linker did not reveal any essential differences.

Biological Properties. The effects of the peptides on humoral, secondary immune response to SRBC were tested in vitro. The results (Table 1) show that the peptides added to the cultures of SRBC-primed splenocytes suppressed the number of AFCs in the cell cultures in different ways. Fraction A exhibited a strong inhibitory effect at the concentration of 10 μg/mL; however, its inhibitory action at the 100 μg/mL dose was much smaller. On the other hand, Fraction C clearly exhibited a dose-dependent inhibition of the immune response. Similar dose-dependent immunosuppressive effects were observed for the homogenic dimeric peptides **1** and **2**.

DISCUSSION

Receptor dimerization is an essential part of cellular signal transduction. Molecules that induce or stabilize the association of receptor macromolecules hold tremendous promise as biological effectors. Ligands having two pharmacophores connected by a spacer (bivalent ligands) have a potential for bridging vicinal receptors. Such a bridging should be manifested by a modulation of biological responses (*31*). Indeed, homodimeric analogs of biologically active peptides with a specific spacer length have been reported to possess enhanced agonistic or antagonistic potencies compared with their monomeric counterparts (*32*−*38*). The increase in potency of these analogs may also be due to the high local concentration of the free pharmacophore in the vicinity of the proximal recognition site when the dimeric peptide ligand is bound in a monovalent mode.

The relatively easy synthesis of new dimeric analogs of biologically active peptides has attracted a great deal of attention. The rotationally symmetric homodimeric peptide analogs can be synthesized by covalent linkage through either side chains (for example, by disulfide bridge) or the N- or C-termini of the two-monomer backbone. So far, direct synthesis of dimeric peptides in the solid phase utilized simultaneous synthesis of two identical peptide chains on lysine (or other diamino acid) attached to the resin (*22*). This method allowed the formation of antiparallel dimeric peptides where monomer residues were covalently linked through their C-termini, whereas dimeric constructs linked through their N-termini were synthesized utilizing tedious methods "in solution" only.

The idea of dimerization of the molecules directly on a solid support has been described as a tool for the synthesis of natural

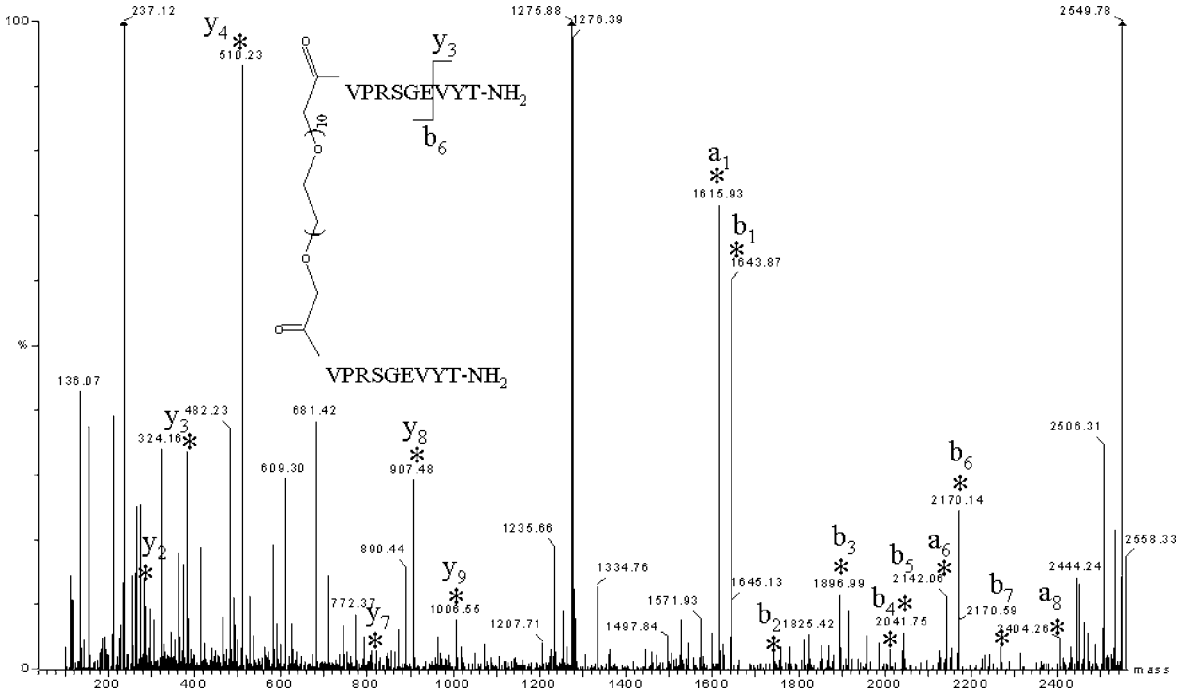

Figure 5. Fragmentation spectrum of $[MH_2]^{2+}$ ion of dimeric peptide PEG−(VPRSGEVYT-NH_2)$_2$. The parent ion is at *m*/*z* 1276. Spectrum was deconvoluted using the Maxent program.

product-like molecules (*39, 40*). Peptide dimerizations on solid support were observed previously as a side reaction during peptide cyclization on a resin (*41, 42*) and by linkage through lysine side chains (*43*). To the best of our knowledge, this paper describes the first cross-linking reaction between two N-terminal amino groups of peptide chains attached to a resin to produce the desired products. Our results suggest that this method is general and may be applied to various peptide sequences. The basic restriction of this method is that only symmetrical dimers containing two identical sequences can be obtained. The dimers can be synthesized rapidly in a relatively small number of synthesis steps, because the strategy of synthesis is convergent.

The bivalent analog of the immunosuppressive fragment of the HLA−DR molecule (VPRSGEVYT) should consist of two monomers covalently linked by a spacer with sufficient length to be able to position them in the same manner as in the HLA−DR superdimers. We began the design by examining the three-dimensional structure of the superdimers (*13*) (Figure 7A). The distance between the N-terminal groups of Val$^{\beta 164}$ is significantly shorter (37 Å) than that of the carbonyl groups of C-terminal Thr$^{\beta 172}$ (47 Å) in the nonapeptide immunosuppressive fragment, suggesting that the amino-terminal dimerization may be more efficient than that obtained by C-terminal linkage. The molecular modeling study (results not shown) suggested

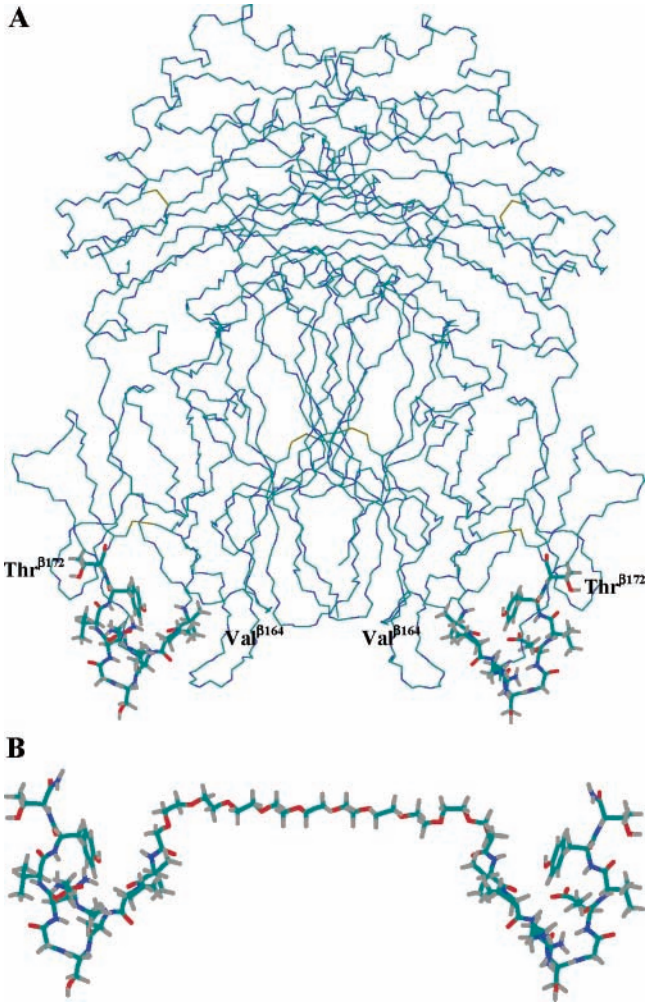

Figure 7. (A) View of the superdimer of human class II histocompatibility antigen HLA−DR1. The β164−172 loops with the immunosuppressive sequences (VPRSGEVYT) are boldface. (B) The β164−172 loops connected with a 35-atom linker to span the distance between the carbonyl groups of Val$^{\beta164}$. The linker structure is stretched and may produce distortions on the peptide fragments if oriented as in the superdimer structure. Therefore, the linker should be longer than the 35-atom one.

that a linker consisting of 35 atoms in the main chain may be too short to span the N-terminal groups of Val$^{\beta164}$ without distortions (Figure 7B).

It was previously shown that the linker length may dramatically affect the biological potencies of bivalent bioligands (*44*). We synthesized a library of dimeric analogs containing linkers of various lengths using a commercially available mixture of PEG−diacids. The distribution of the molecular masses in the mixture can be calculated from the spectrum in Figure 4. A comparison of the spectra presented in Figures 4A and 3 suggests that the dimerization yield does not depend dramatically on the length of the linker.

Although we were unable to separate a practical amount of each dimer molecule with a particular linker length, we succeeded in fractionating the library according to the molecules' ability to span the gap between the N-terminal groups of Val$^{\beta164}$ residues in the crystal structure (Figure 7A). Fraction A comprises mostly molecules with a linker not longer than the 35-atom one. The linkers may be too short to locate the suppressors in the same position as in the crystal structure. In contrast to this, fraction C contains dimeric peptides mostly populated by molecules with linkers of sufficient length. The structures of the fractionated peptides were further confirmed by amino acid analysis and mass spectrometry.

The heterogeneous peptides obtained by our method are difficult to characterize by the routine methods used to confirm the structures of organic compounds. Therefore, tandem mass spectrometry must be the method of choice. Direct ESI measurement provides information concerning the distribution of the linker length. This information may also be applied to verify the purity of the obtained set of compounds. MS/MS experiments were performed to confirm the primary structures of the obtained dimeric analogs. Mass spectrometry fragmentation of conjugates composed of dimeric peptide sequences N-terminally linked with PEG−dicarboxylic acid has not been reported in the literature. However, MS/MS analysis of peptides containing a PEG amino acid was described by Catalina et al. (*45*). The authors established that fragmentation of these conjugates produced not only ions of the b, y, and d types and the internal ions (y_nb_m) (y_nb_m) but also fragmentation of the PEG amino acid. The dimeric compounds described in this paper produced a set of ions generated in collision-induced dissociation belonging to the b and a series. Some ions of the y series and internal ions (b_nb_m) were also observed. However, we did not observe any fragmentation of the PEG linker, which suggests that the PEG−diacid linker does not decompose as easily as the amino acid PEG one or that its fragmentation pathway is different. As can be expected, introducing the PEG bridge shifted the series of b and a peaks toward a higher *m/z*, which facilitated the MS/MS analysis. The information provided by the fragmentation spectra is sufficient to confirm the sequences unambiguously.

With the potential therapeutic value of the studied peptides taken into consideration, it seems that application of the dimeric peptides may be beneficial in preventing rejection of allotransplants, since it significantly suppressed, at a low dose, the magnitude of the secondary immune response, which is dependent on the presence of memory T cells. Other studies showed that memory T cells are resistant to apoptosis during chemotherapy (*46*), so our finding that the peptide**s** are effective in the suppression of immunological memory suggests that this new approach to preventing allogeneic organ rejection by the immune system is plausible to implement.

The enhancement of the immunosuppressive activity of our dimeric analogs could be explained by a microaggregation of the receptors at the cell surface induced by the dimeric antagonists, which would prevent access of the agonist to the receptors. Nevertheless, the increased affinity of dimeric analogs of the ligands may also be independent of receptor density (*47*). Their potencies may be attributed to a higher concentration of pharmacophores in the proximity of their recognition sites by a simple statistical advantage. Bivalent ligands are known to produce thermodynamically more favorable binding interactions with their receptors than monovalent ones (*48*). Our results are in agreement with those reported previously by Cochran et al. (*49*). The authors studied the influence of intermolecular orientation within the activating T-cell receptor dimer on T-cell activation. Dimers of class II MHC proteins coupled in a variety of orientations and topologies were able to activate $CD4^+$ T cells, although the triggering was affected by the intermolecular distance between the MHC molecules. Interestingly (Table 1), the A mixture was less suppressive at higher (100 μg/mL) concentration. However, lack of a direct dose-dependent effect of a given immunosuppressive compound is not a rare phenomenon in immunological processes. We observed a similar phenomenon in our previous investigation with one of the dimeric, immunosuppressive peptides (peptide **4**), which was less suppressive of both the humoral and cellular immune response (*22*). A much smaller suppressive activity at very high doses, in contrast to cyclosporine A, was also observed for cyclolinopeptide A, a natural nonapeptide from linseed oil (*50*).

Methotrexate (MTX) could serve as another example of a lack of correlation between dose and cytotoxic effect. In the model of mitogen-activated human peripheral blood mononuclear cells (*51*), MTX caused a progressive decrease in viable cell counts in the concentration range 0.1−10 μM, whereas at low (0.01 μM) and high (100 μM) concentrations, MTX inhibited cell proliferation but induced only a moderate loss of viable cells. The reason for these observations remains largely unexplained, although even such a basic immunological phenomenon as specific antigen tolerance occurs at very low or high, but not at moderate, doses of antigen (*52*).

In summary, we presented a new and straightforward procedure for the direct amino-terminal dimerization of peptides on a solid support by a poly(ethylene glycol) spacer which is compatible with solid-phase peptide synthesis protocols. The amino-terminal dimerization of the nonapeptide fragment of HLA−DR results in enhanced immunosuppressive properties. The dimerization may also serve as a new derivatization method to facilitate MS/MS peptide analysis by shifting the series of b and a peaks toward higher *m/z*.

ACKNOWLEDGMENT

This work was supported by the Ministry of Scientific Research and Information Technology grant no. 3 T09A 082 27. We thank Professor Michał Dadlez for the use of his Micromass Q-TOF mass spectrometer and Dr. Andreas Jakob from Bruker Daltonik GmbH for the high-resolution mass analysis. We also thank Ms. Marzena Cydzik for technical assistance. This work is part of a doctoral thesis (M.B.).

Oligosaccharides are increasingly being recognized as important partners in receptor−ligand binding and cellular signaling. Surface plasmon resonance (SPR) is a very powerful tool for the real-time study of the specific interactions between biological molecules. We report here an advanced method for the immobilization of oligosaccharides in clustered structures for SPR and their application to the analysis of heparin−protein interactions. Reductive amination reactions and linker molecules were designed and optimized. Using mono-, tri-, or tetravalent linker compounds, we incorporated synthetic structurally defined disaccharide units of heparin and immobilized them as ligands for SPR. Their binding to an important hemostatic protein, von Willebrand factor (vWf), and its known heparin-binding domain was quantitatively analyzed. These multivalent ligand conjugates exhibited reproducible binding behavior, with consistency of the surface conditions of the SPR chip. This novel technique for oligosaccharide immobilization in SPR studies is accurate, specific, and easily applicable to both synthetic and naturally derived oligosaccharides.

INTRODUCTION

Oligosaccharides of two to ten sugar moieties are responsible for many important biological functions (*1*). Both the specific structural attributes of the minimum oligosaccharide unit and the spacing and distribution of these key binding units determine the ultimate biological function of heparins and heparin-like glycosaminoglycans (*2*). Often, the minimal oligosaccharide unit with a structurally specific interaction may be as small as a di- or trisaccharide (*3*, *4*). However, for full biological activity, these key binding units must often be presented in repeating units or clusters, appropriately spaced to interact with the heparin-binding sites of the cognate protein. Two major problems arise in the study of these structure−function relations. First, it is not easy to obtain large quantities of a homogeneous, structurally defined oligosaccharide. They cannot be expressed recombinantly, like proteins, and therefore, long and tedious chemical processes are necessary to synthesize or derive them from natural sources. The second problem is that an individual oligosaccharide motif may have low affinity but in biological systems they are often presented in clustered or repeating forms, which contribute significantly to their potency and affinity. We hypothesized that a chip or an array technology, in which structurally defined key oligosaccharide binding units are two-dimensionally immobilized on a surface, would be an effective method to solve these problems and could be used as a high-throughput screening method.

A number of investigators have tackled the challenges of oligosaccharide immobilization. Techniques for self-assembled monolayers have been described by Horan et al. (*5*), Mrksich and co-workers (*6*, *7*), and others. However, no method has so far been devised that both is procedurally simple and does not significantly modify or potentially interfere with the biological activity of the oligosaccharide. Most of these techniques require significant chemical modifications of the glycans, potentially obscuring the interpretation of structure−function relations. For example, conventional methods have involved chemical modifications at the 1-position of the carbohydrate, such as amination or allylation (*8*, *9*). But these approaches invariably put functional sulfate or phosphate groups at risk. Finally, currently established methods do not afford the opportunity to control the clustering or multimerization of oligosaccharide functional domains. To this end, we pursued novel immobilization strategies for oligosaccharides, which would be technically simpler and less destructive, making them useful to a wider group of investigators. For detection, we chose surface plasmon resonance (SPR) technology, which permits the real-time analysis of molecular binding using microgram quantities of analyzing materials, without further labeling (*10*−*14*). It can measure the binding affinity and on (association) and off (dissociation) rates and is useful for high-throughput screening of new drug targets.

In previous work, we had shown that a specific disaccharide unit in heparin, *O*-(2-deoxy-2-sulfamido-6-*O*-sulfo-α-D-glucopyranosyl)-(1−4)-2-*O*-sulfo-α-L-idopyranosyluronic acid (abbreviated as GlcNS6S-IdoA2S), was a key unit responsible for heparin binding to human platelets (*15*) and von Willebrand factor (vWf) (*16*). We also found that the clustering of these disaccharides significantly enhanced the interaction (*17*, *18*). To systematically investigate heparin's binding interactions, we

have developed a novel method for the immobilization of sulfated oligosaccharide onto a gold-coated SPR chip to prepare a "sugar chip" and devised an analytical system that can be applied to the binding interactions of a variety of structurally defined oligosaccharides in clustered structures that mimic nature.

In this paper, mono-, tri-, and tetravalent types of linker compounds containing one, three, or four aromatic amines and thioctic acid moieties were designed. The ligand moiety, a GlcNS6S-IdoA2S unit, was conjugated with these novel linker compounds to prepare a ligand conjugate using an optimized reductive amination reaction. The ligand conjugates were immobilized on a gold SPR sensor chip through an improved gold−sulfur (Au−S) permanent bond. By this approach, we were able to accurately measure the specific interactions of the GlcNS6S-IdoA2S structure in heparin with native human vWf protein and with the recombinant fragment of its A1 domain. To compare our method with conventional immobilization techniques, the GlcNS6S-IdoA2S unit was conjugated with a hydrophobic aromatic amine by a similar reductive amination reaction and immobilized through hydrophobic interactions with a hydrophobic 1-octanethiol-coated chip surface.

The goal of this current work was to refine the methods for immobilizing clustered oligosaccharides using these new techniques, to measure their uniformity and distribution on the SPR chip, and to measure the relative impact of ligand clustering on the binding of well-known heparin-binding proteins. Our long-term goal is to provide a simple, versatile, and reproducible method for studying glycosaminoglycan−protein interactions, which can be implemented by a wide range of investigators beyond the specialized laboratories that pioneered these approaches.

EXPERIMENTAL PROCEDURES

General Procedure. All reactions in organic media were carried out with freshly distilled solvents or with commercially available extra grade solvents purchased from Kanto Chem. Co. (Tokyo, Japan), Nacalai Tesque (Kyoto, Japan), or Wako Chem. Co. (Osaka, Japan). Silica gel column chromatography was performed using silica gel 60 (no. 9386, Merck & Co. Inc., Whitehouse Station, NJ). Spectral data were obtained as follows. Electrospray ionization time-of-flight mass (ESI-TOF/MS) spectra were obtained by Mariner (Applied Biosystems, Framingham, MA). ^{1}H NMR measurements were performed with JEOL (Tokyo, Japan) Lambda-500, GSX-400, and ECA-600. The chemical shifts are expressed in δ-values using tetramethylsilane (δ 0) or HDO (δ 4.65) as an internal standard.

SPR Experiments. SPR experiments were perfomed with SPR-670 (Nippon Laser and Electric Lab., Nagoya, Japan) under the recommended manufacture's guideline with a slight modification. Sensor chips used for SPR experiments were prepared as follows. The gold-coated chip was purchased from Nippon Laser and Electronics Lab. For ligand conjugates containing the thioctic acid moiety, the gold-coated chip was soaked in a 100 μM solution (methanol/water = 1/1, v/v) of the appropriate ligand conjugate at room temperature for 2 h or overnight, followed by subsequent washing with methanol/water containing 0.05% Tween-20, phosphate-buffered saline (PBS) at pH 7.4 containing 0.05% Tween-20, and PBS (pH 7.4). All washings were done with microwave irradiation for 5−30 min. The solvent for the binding experiment was PBS at pH 7.4 and run at a flow rate of 15 μL/min at 25 °C.

For ligand conjugates containing an octyl group, the gold chip was first soaked in 1 mM methanol solution of octanethiol at room temperature overnight, followed by washing with methanol, methanol/water (1/1, v/v), and PBS (pH 7.4) containing 10% 2-propanol. The octanethiol immobilized chip (self-assembled monolayer (SAM) chip) was set in the SPR-670; then the solution of ligand conjugate containing the octyl group in PBS (pH 7.4) containing 10% 2-propanol was loaded and run at a flow rate of 15 μL/min at 25 °C. The ligand conjugate became immobilized through a hydrophobic interaction between the SAM on the chip and the octyl group of the conjugate. This was monitored by SPR-670. The subsequent saccharide−protein binding experiments were done using PBS (pH 7.4) containing 10% 2-propanol. Bovine serum albumin (BSA) was employed as the control, nonspecific protein of study. It is ubiquitous in biological systems and is known to have low nonspecific interactions with sulfated polysaccharides.

Synthesis of Compounds. Details of compound syntheses can be found in Supporting Information.

RESULTS

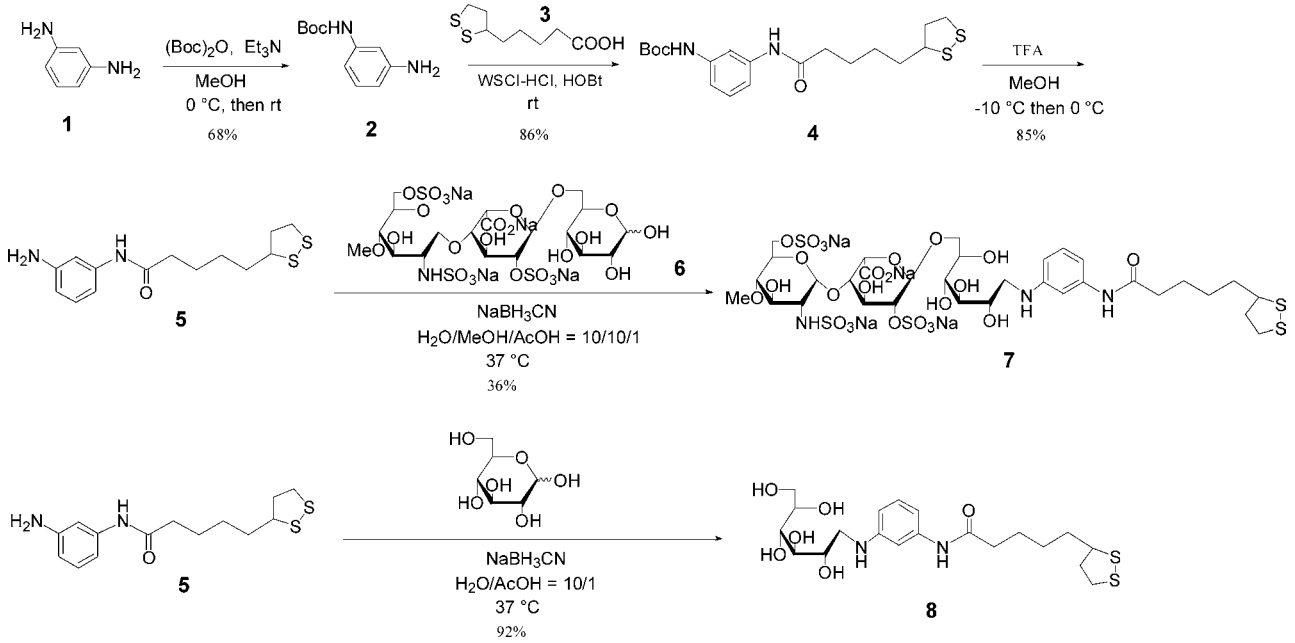
Preparation of Oligosaccharide-Linker Conjugates (Abbreviated as "Ligand Conjugates"). Mono-, tri-, and tetravalent linker molecules and ligand conjugates were prepared as illustrated in Schemes 1−5. The linker compounds possessed one, three, or four incorporating points, and the ligand conjugates were composed of the linker attached to a structurally defined, biologically active sulfated disaccharide unit (GlcNS6S-IdoA2S) or D-glucose as a control. All the structures of the compounds were confirmed by ESI-TOF/MS and NMR.

Monovalent Linkers and Ligand Conjugates (Schemes 1 and 2). The reaction of *m*-phenylenediamine **1** with di-*t*-butyl dicarbonate in methanol solution yielded 3-(*t*-butoxycarbonylamino)phenylamine **2**. The compound **2** was then reacted with thioctic acid **3** in dichloromethane to give the thioctamide derivative **4**, followed by treatment with trifluoroacetic acid to yield the linker compound **5**. A reductive amination reaction with a sulfated trisaccharide **6** (synthesized as previously reported (*18*)) was employed to incorporate the disaccharide unit into a novel ligand conjugate **7** (Mono-GlcNS6S-IdoA2S-Glc). By a similar reductive amination reaction using D-glucose, a control ligand conjugate **8** (Mono-Glc) was also prepared.

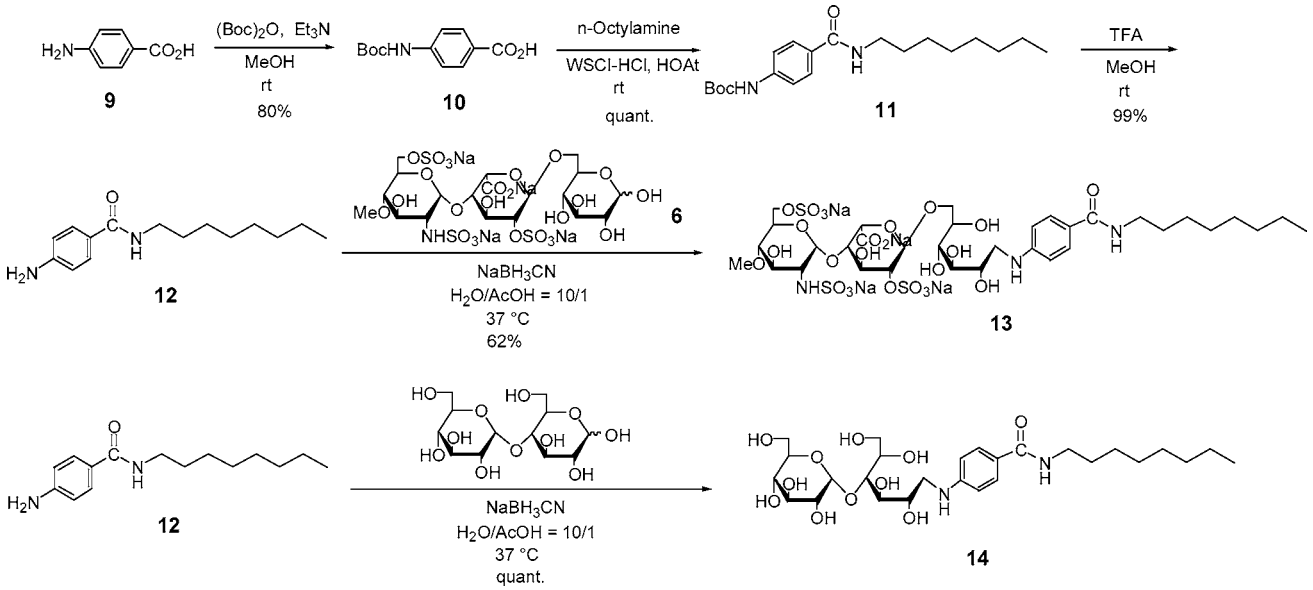
For the hydrophobic immobilization strategy (Scheme 2), a hydrophobized ligand conjugate **13** containing the GlcNS6S-IdoA2S unit was prepared. The reaction of 4-aminobenzoic acid **9** with di-*t*-butyl dicarbonate in methanol solution yielded 4-(*t*-butoxycarbonylamino)benzoic acid **10**. Further reaction with *n*-octylamine in dichloromethane gave benzamide **11**, which was then treated with trifluoroacetic acid to yield the hydrophobic linker *N*-octyl-4-aminobenzamide **12**. The linker **12** was coupled with the trisaccharide **6** using a reductive amination reaction to give the hydrophobized compound **13** (Hydro-mono-GlcNS6S-IdoA2S-Glc). A similar reductive amination was performed with D-maltose to give D-glucopyranoside-containing ligand conjugate **14** (Hydro-mono-Glc-Glc), which was used for the control experiments.

Trivalent Linker and Ligand Conjugate (Scheme 3). For the trivalent type linker compound **24**, the Michael addition reaction followed by reduction with Raney nickel was applied to nitromethane **15** to give tribranching amine **18** according to Weis and Newkome (*19*) with a slight modification. The production of a side product, di-*t*-butyl 4-[(2-*t*-butoxycarbonyl)ethyl]-4-aminoheptanedicarboxylate, was less than 5% in this case. To the amine moiety **18**, a *Z*-glycine unit was incorporated, which served as a spacer between the branching part and the further incorporating thioctic acid moiety. The coupling reductive amination reaction was performed as above with a slight modification, in which dimethylacetoamide was used to dissolve the tribranched linker compound **24** instead of methanol. The reaction was monitored with thin-layer chromatography (TLC) and ESI-TOF/MS. After confirmation of the formation of the Shiff base, the ratio of the mixed solvent was changed to promote a more efficient reduction reaction. We found that it

Scheme 1. Synthesis of Monovalent Linker and Ligand Conjugates



Scheme 2. Synthesis of Hydrophobized Monovalent Linker and Ligand

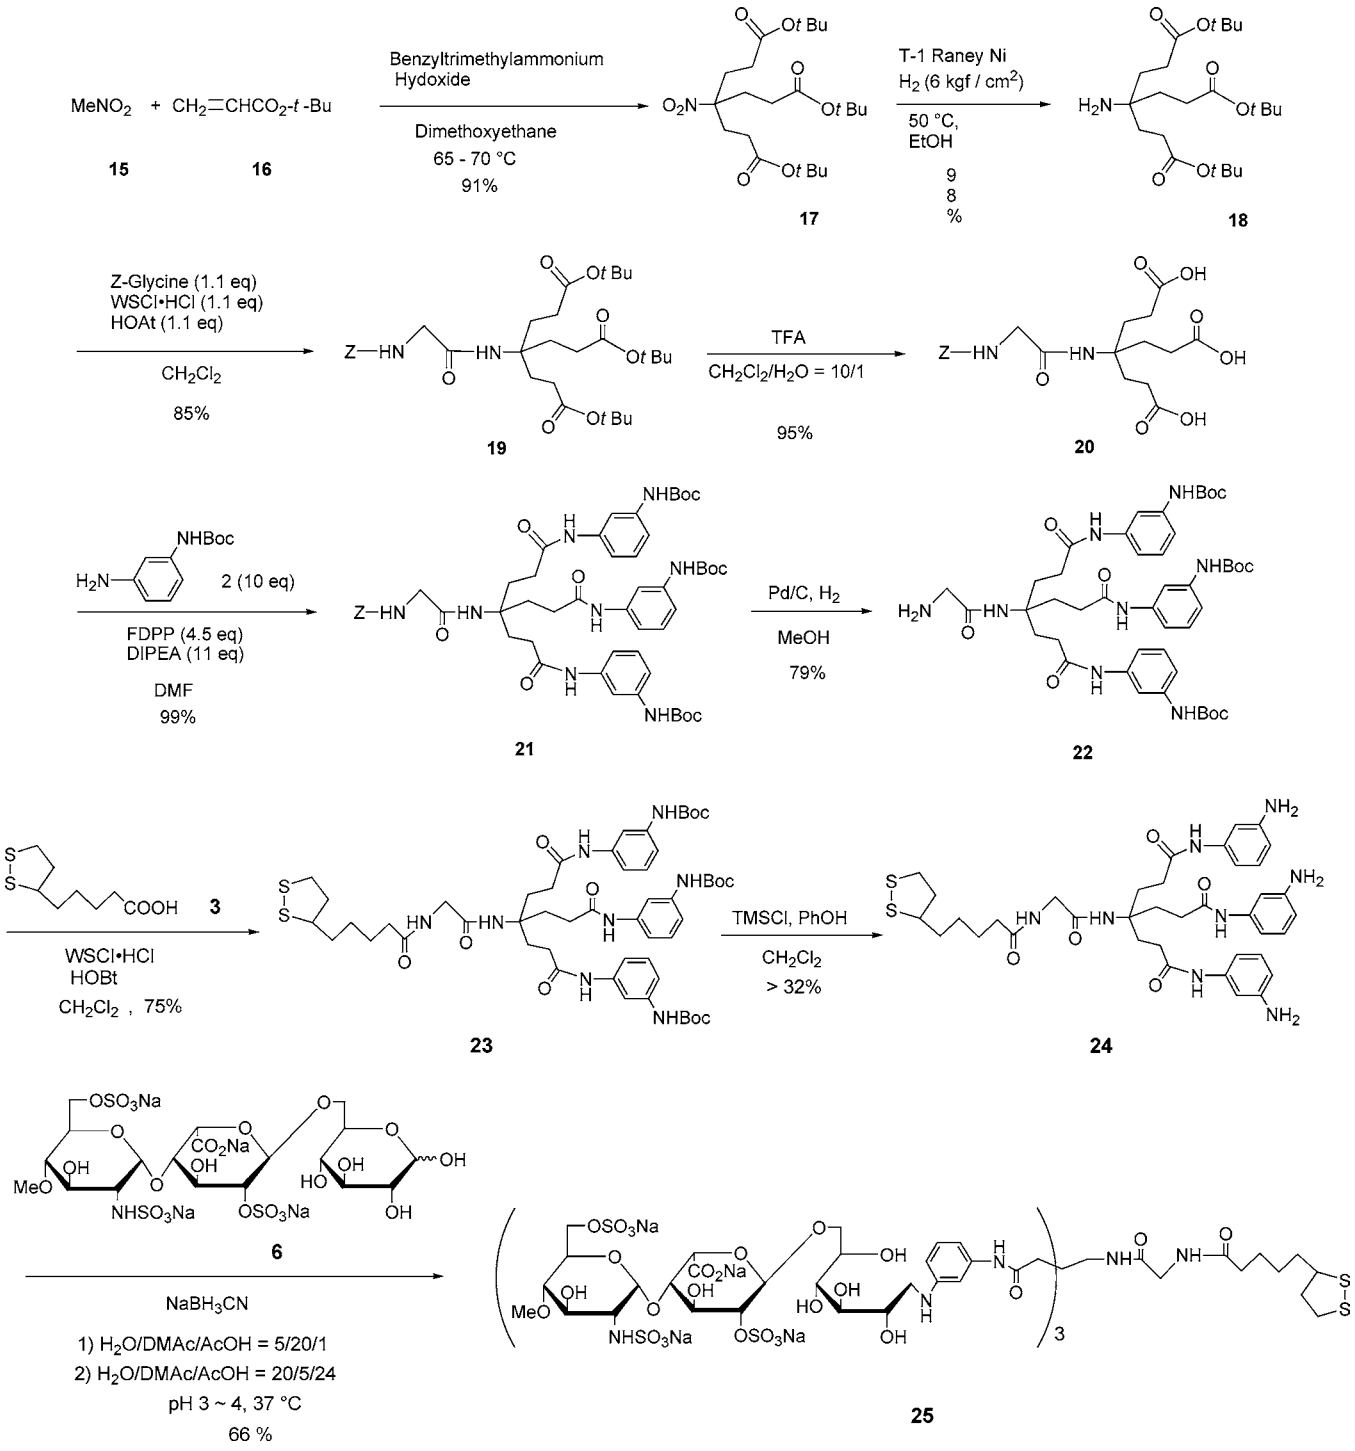


was important to maintain the pH of the solvent between 3 and 4 to increase the conversion of the reaction. A 5-fold ratio of sulfated trisaccharide **6** to the linker **24** was necessary to incorporate all three of the aromatic amine moieties in **24** to produce **25** (Tri-GlcNS6S-IdoA2S-Glc). The lower than expected yield (66%) was due to losses during purification.

Tetravalent Linker and Ligand Conjugate (Scheme 4). The tetravalent linker compound **34** was prepared according to Ashton et al. (*20*) with modifications. In brief, two units of aminobenzoic acid moieties were incorporated into the two primary amines in diethylenetriamine with a relatively good yield by precisely controlling their molar ratio. For the spacer between the thioctic acid moiety and the branching part, *Z*-glycine was incorporated to give compound **30**. The condensation of **27** and **31** needed a stronger condensation reagent, pentafluorophenyl diphenylphosphinate (FDDP), to give the tetravalent linker unit containing four units of aromatic amine derivative **35**. The incorporation of sulfated disaccharide units to yield **35** was performed by similar reaction conditions as applied to **24**. A 5-fold ratio of sulfated trisaccharide **6** to the linker **35** was also necessary to incorporate all four of the aromatic amine moieties in **35** to produce **36** (Tetra-GlcNS6S-IdoA2S-Glc-short). Diminished yield (40%) was again due to losses during purification.

Tetravalent Linker and Ligand Conjugate with Longer Spacer Arm (Scheme 5). In order to create an immobilized oligosaccharide cluster with a longer leash, or spacer arm, we created tetravalent linker **48** and ligand conjugate **49** by modifying **35** and **36**, respectively (Scheme 5). An oligo(ethylene glycol) unit was incorporated between the branched part and the thioctic acid moiety. The oligo(ethylene glycol) unit was derivatized according to Houseman and Mrksich (*6*) to afford the *O*-toluenesulfonyl compound **40**. By the S_N2 reaction with sodium azide, an azide unit was incorporated. After hydrolysis, we obtained **42**, which was then used for the spacer unit instead of *Z*-glycine in the preparation of **30**. The azide moiety was converted to amine by mild reduction, and the thioctic acid moiety was condensed to the amino group, followed by deblocking of the aromatic amine by trifluroacetic acid to yield the tetravalent linker **48** containing an oligo(ethylene glycol)

Scheme 3. Synthesis of Trivalent Linker and Ligand Conjugate

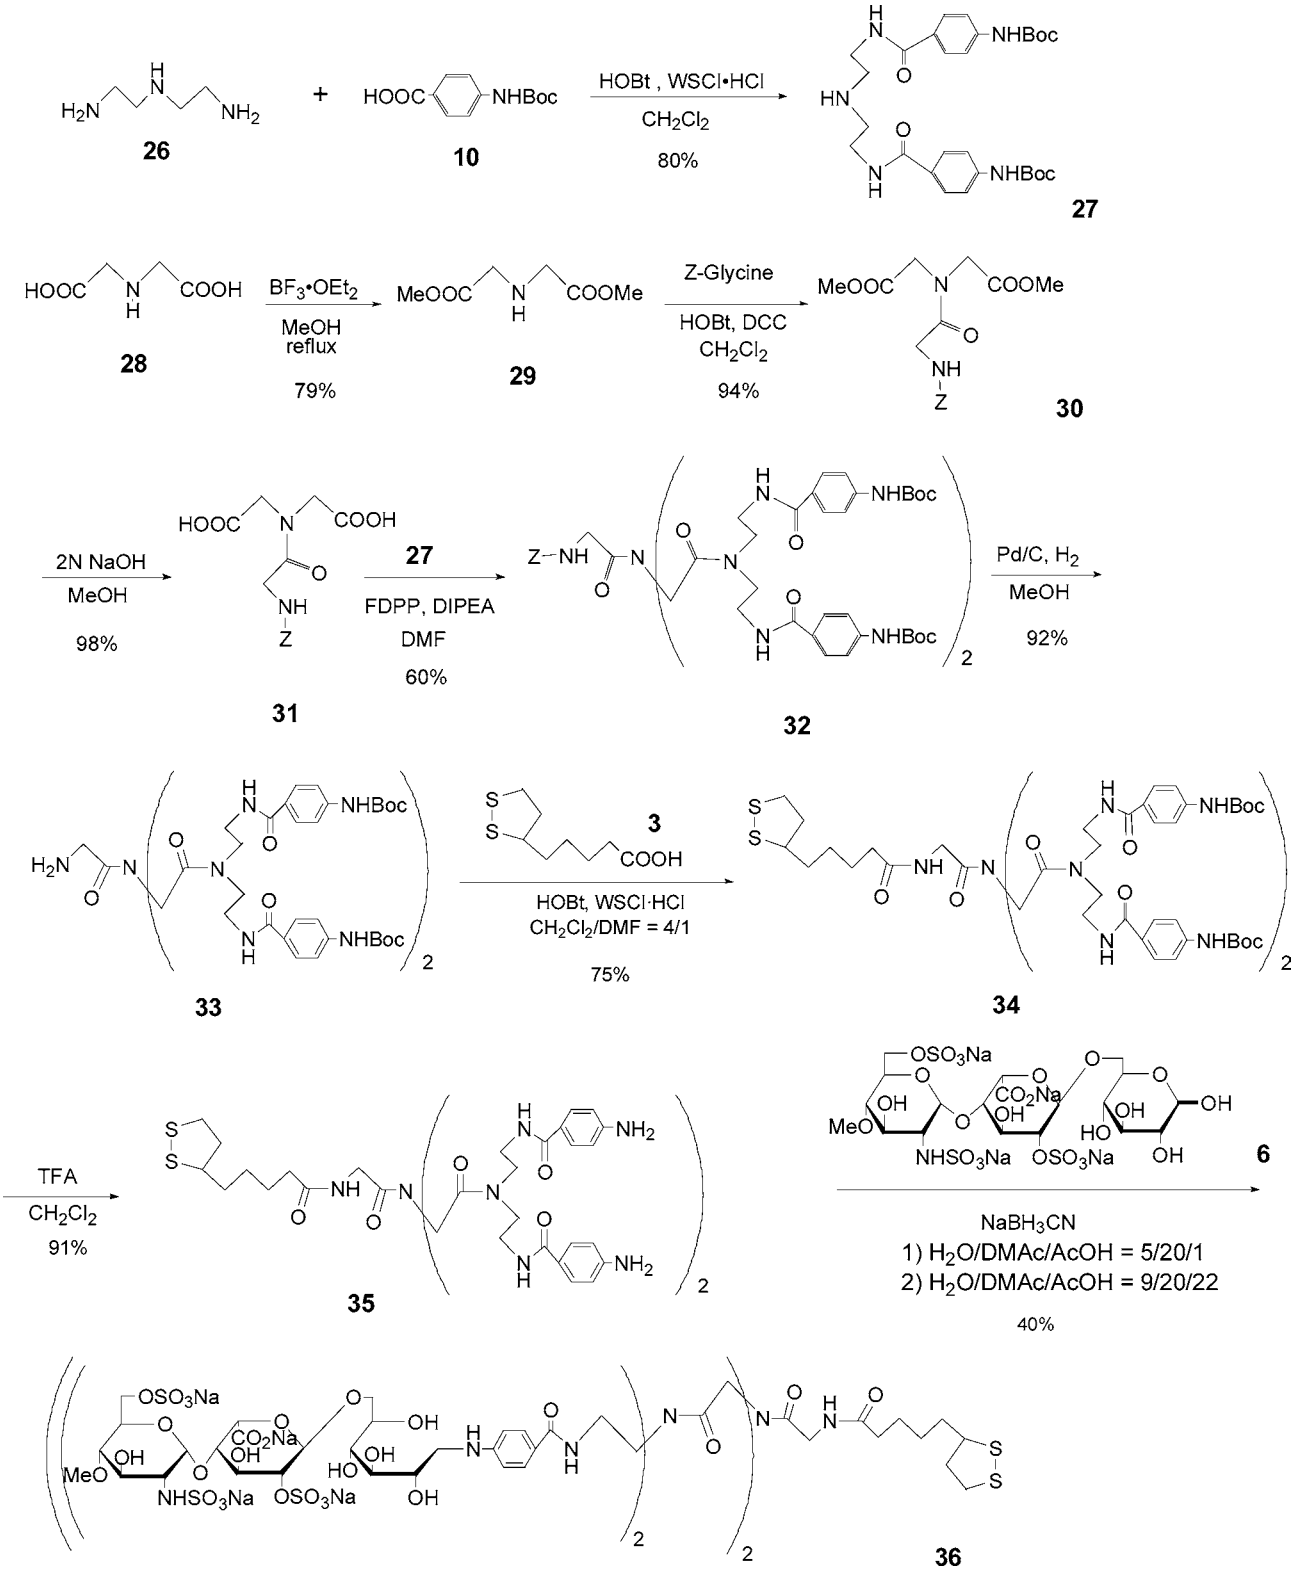


unit. The incorporation of sulfated disaccharide units into **48** was performed by the same reaction as applied to **25**. A 7-fold ratio of sulfated trisaccharide **6** to the linker **48** was necessary to incorporate the four aromatic amine moieties in **48** to prepare **49** (Tetra-GlcNS6S-IdoA2S-Glc-long). Yield (22%) was again diminished primarily due to purification. All the structures of the compounds were confirmed by ESI-TOF/MS and ^{1}H NMR.

Comparison of Immobilization Methods. The monovalent ligand conjugates **7** (Mono-GlcNS6S-IdoA2S-Glc) and **8** (Mono-Glc) were first immobilized on the gold chip by soaking the chip in the 100 μM 50% aqueous methanol solution of the ligand conjugate for 2 h or overnight at room temperature with gentle agitation. It was predicted that the ligand conjugates would be immobilized on the gold-coated chip through direct Au−S bonding. With use of an SPR670 apparatus (Nippon Laser and Electronics Lab, Nagoya, Japan), a binding interaction to the ligand moiety on the chip was confirmed when 2 μM of the synthetic peptide KDRKRSELRRIASQVK (a discrete heparin-binding domain of human vWf (*21*), abbreviated as vWf-peptide) was injected over the surface of the chip in the apparatus (Figure 1a). Because minimal binding was observed with 1.5 μM of BSA, it was not even necessary to subtract a nonspecific binding value.

When the control Mono-Glc was immobilized using the same method, no significant increase in resonance units was observed even though a high concentration of synthetic vWf-peptide was used (Figure 1b). In contrast, a typically positive binding saturation curve was seen with the Mono-GlcNS6S-IdoA2S-

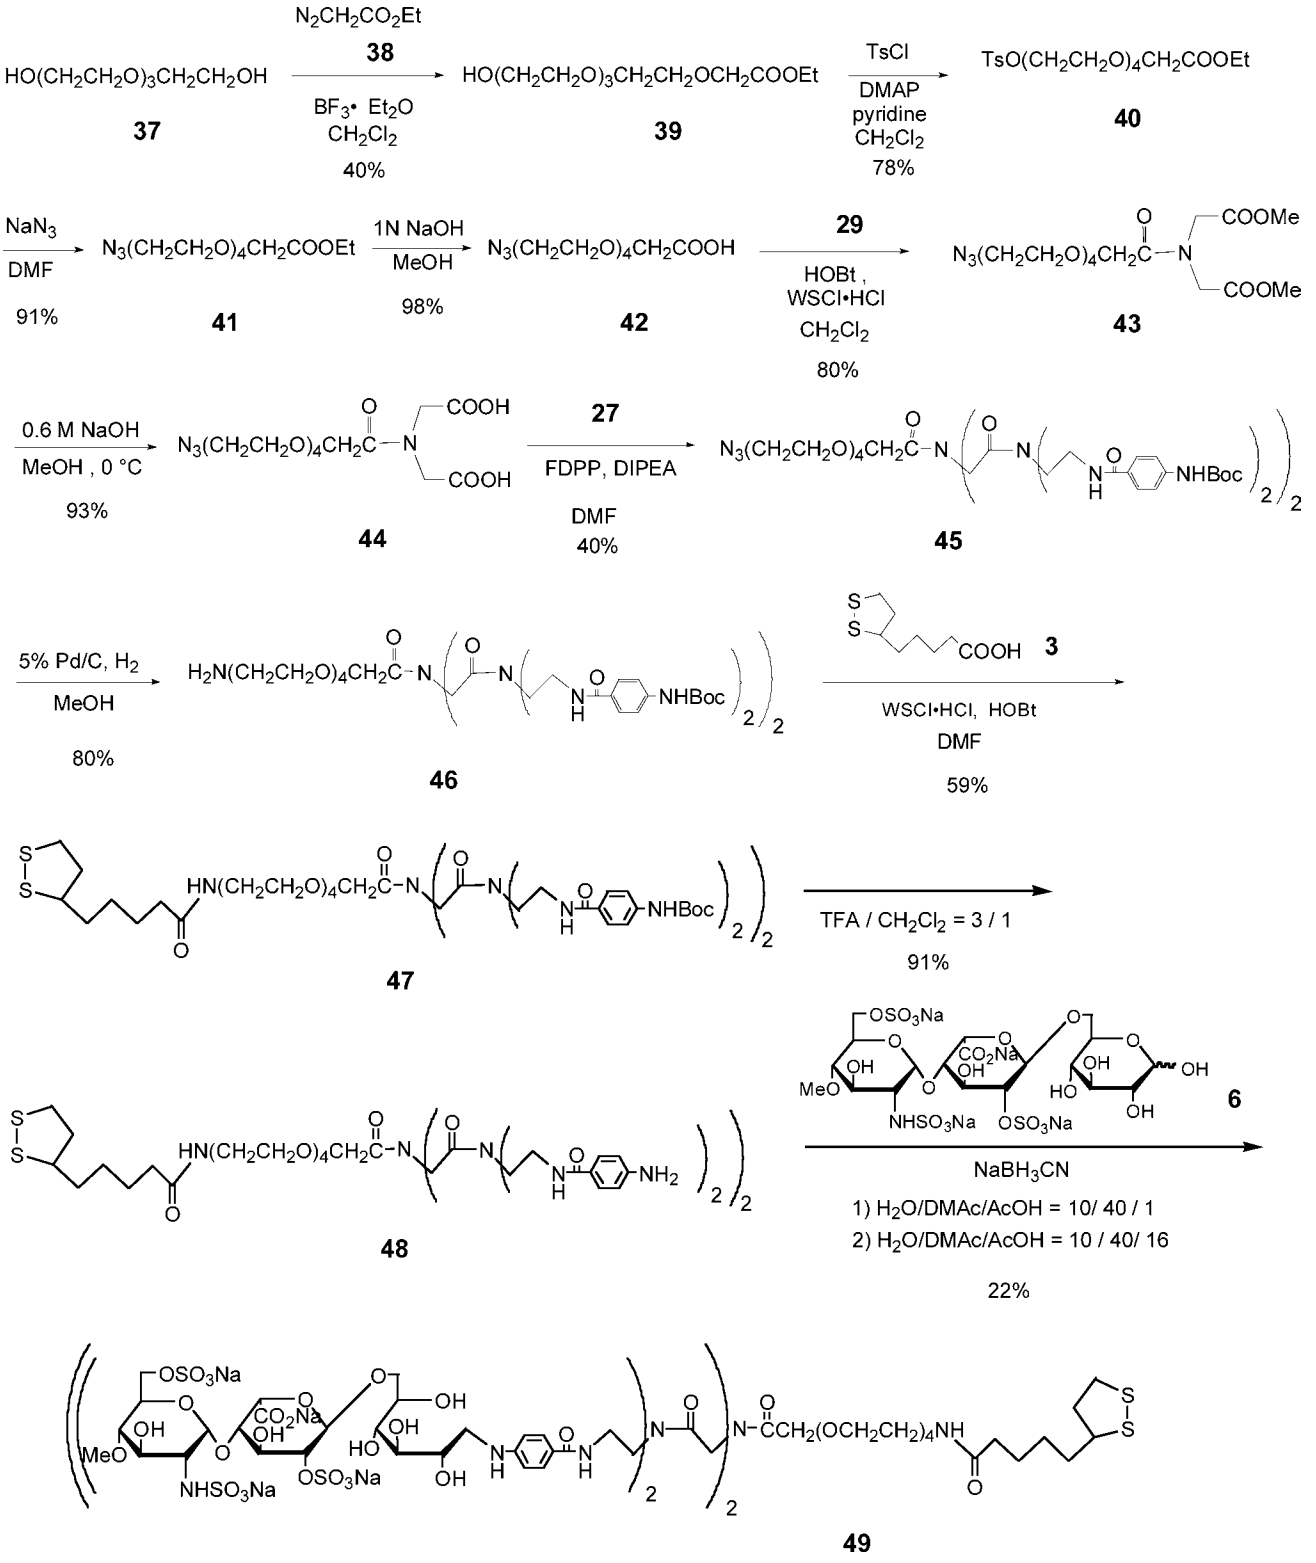
Scheme 4. Synthesis of Tetravalent Linker Containing Short Spacer Arm and Ligand Conjugate



Glc immobilized chip. The K_D, dissociation constant, was estimated to be 220 nM, very close to that reported previously (370 ± 100 nM) for unfractionated heparin and vWf using a conventional radioligand binding assay (*21*).

This direct, covalent immobilization method was then compared to a conventional hydrophobic method of immobilization. A self-assembled monolayer (SAM) of octanethiol was first prepared on the chip as previously reported (*10*, *11*). The SAM chip was set in the SPR670 apparatus and a solution of **13** or **14** was loaded on the chip in phosphate-buffered saline. The total amount of **13** or **14** that was immobilized on the sensor chip is indicated by the differences in resonance units (ΔRU^1) at equilibrium shown in Figure 2a. Then, the binding of synthetic vWf-peptide was evaluated. Figure 2b shows that the vWf-peptide bound to both the sulfated oligosaccharide SAM chip (using **13**, Hydro-mono-GlcNS6S-IdoA2S-Glc) and the control SAM chip (using **14,** Hydro-mono-Glc-Glc). These nonspecific interactions were confirmed when BSA was tested on the same SAM sensor chip; strong binding of BSA to both chips was observed (data not shown).

Scheme 5. Synthesis of Tetravalent Linker Containing Long Spacer Arm and Ligand Conjugate



Evaluation of Immobilization of the Ligand Conjugates via the Covalent Attachment Method. The tri- and tetravalent ligand conjugates containing the sulfated disaccharide units were immobilized on gold chips as described above, and nonspecific binding to 1.5 μM BSA was measured. Experience showed that the chips prepared in this manner were quite stable, retaining full binding potency when stored dry at room temperature for 6 months (data not shown). Figure 3 shows that chips immobilized with conjugates **25** (Tri-GlcNS6S-IdoA2S-Glc) and **49** (Tetra-GlcNS6S-IdoA2S-Glc-long) showed very little nonspecific binding, just as was observed in Figure 1a with the Mono-GlcNS6S-IdoA2S-Glc (conjugate **7**). The tetravalent conjugate with the short linker arm (conjugate **36**) exhibited high nonspecific binding (Figure 3) that is typical of a BSA interaction with a bare, unmodified gold chip. Hence, we concluded that conjugate **36** did not achieve optimal immobilization to the gold chip. Its more flexible linkage chemistry, combined with a short spacer arm, may have obscured the accessibility of the S−S portion of the linker for effective immobilization. In subsequent experiments, trivalent

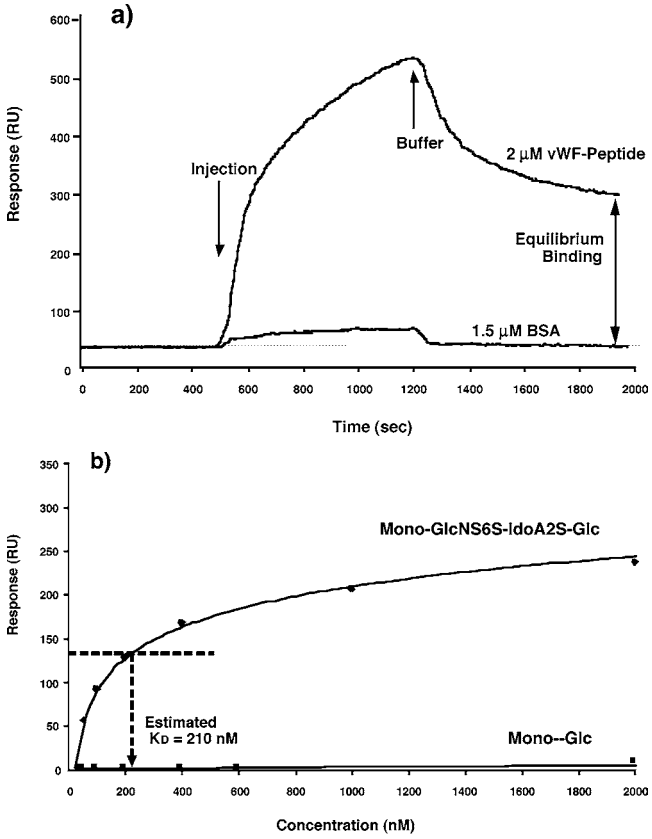


Figure 1. (a) Binding of vWf-peptide and BSA to Mono-GlcNS6S-IdoA2S-Glc (ligand conjugate **7**) on the chip was observed (flow rate = 5 μL/min, temp = 25 °C, pH 7.4, PBS); (b) the equilibrium binding data were used to generate a saturation curve for vWf-peptide binding to Mono-GlcNS6S-IdoA2S-Glc and to the control ligand conjugate **8** (Mono-Glc).

ligand conjugate **25** (Tri-GlcNS6S-IdoA2S-Glc) and ligand conjugate **49** (Tetra-GlcNS6S-IdoA2S-Glc-long) were used in addition to Mono-GlcNS6S-IdoA2S-Glc (compound **7**).

Density and Homogeneity of Immobilization. We wished to determine how the density of immobilization of different conjugates on the chip would influence binding activity. Accordingly, different percentages of biologically active ligand conjugates were individually diluted with the control glucose monovalent conjugate **8** (Mono-Glc) and immobilized as above. The relative concentration of the immobilized sulfated disaccharide was determined by attenuated total reflection (ATR) FT-IR spectra with IRPrestige-21 equipped with MIRacle (Shimdzu Co., Kyoto, Japan). Figure 4a shows parts of the ATR-FT-IR spectra for the region of sulfate groups (1200 and 1303 cm^{-1}) on the gold surface, where Mono-GlcNS6S-IdoA2S-Glc was immobilized over a range of relative densities. The intensity of absorbance increased as the chip was coated with an increasing percentage of Mono-GlcNS6S-IdoA2S-Glc in the ligand conjugate mixture. The absorbance between 1200 and 1303 cm^{-1} was integrated and plotted against the relative concentration of ligand conjugate including the sulfated disaccharide units. As shown in Figure 4b−d, there were linear relationships between the integral of absorbance for sulfate groups on the chip and the relative concentration of the active ligand conjugate in the mixture, suggesting that the sulfated disaccharide units were homogeneously immobilized on the gold surface. In other words, the relative density of ligand oligosaccharides on the chip surface can be controlled by admixing the Mono-Glc ligand conjugate, since the efficiency of S−Au bonding does not appear to be altered between Mono-GlcNS6S-IdoA2S-Glc and Mono-Glc.

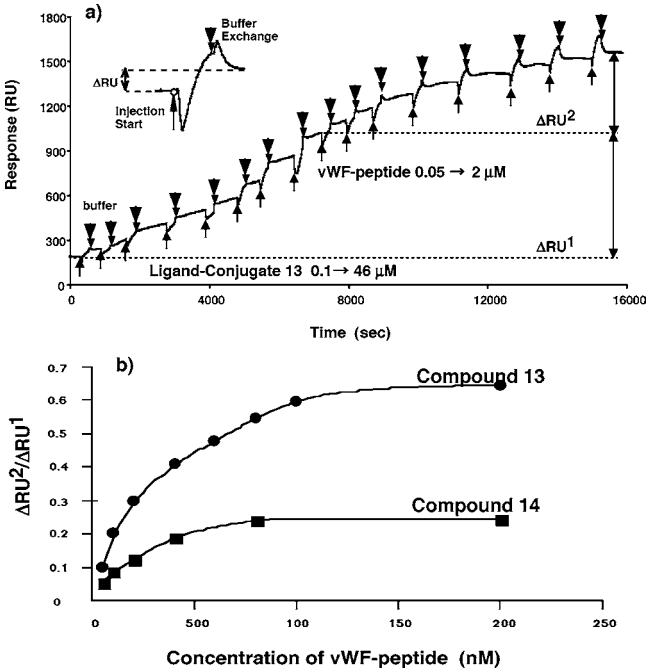

Figure 2. (a) Immobilization of ligand conjugate **13** (Hydro-mono-GlcNS6S-IdoA2S-Glc) containing GlcNS6S-IdoA2S on the SAM chip and the binding of vWf-peptide were observed (flow rate = 15 μL/min, temp = 25 °C, pH 7.4, PBS containing 10% 2-propanol); (b) the equilibrium binding data were used to generate saturation curves for the binding of vWf-peptide to the ligand conjugate **13** and to the control **14** (Hydro-mono-Glc-Glc).

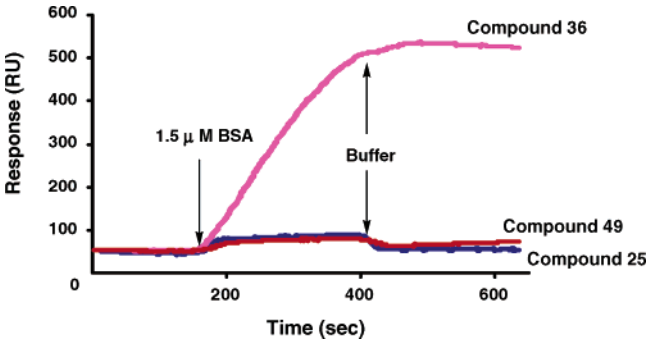

Figure 3. Binding of BSA to the sulfated disaccharide, GlcNS6S-IdoA2S, immobilized chips by ligand conjugates **25** (Tri-GlcNS6S-IdoA2S-Glc), **36** (Tetra-GlcNS6S-IdoA2S-Glc-short), and **49** (Tetra-GlcNS6S-IdoA2S-Glc-long). The immobilization and SPR experiment were done as described in the Experimental Procedures.

Measurement of Binding Affinities for Model Heparin-Binding Proteins. To evaluate the influence of oligosaccharide immobilization density on protein binding, 2 μM vWf-peptide was injected over chips immobilized with different percentages of Mono-GlcNS6S-IdoA2S-Glc to Mono-Glc immobilized chip (Figure 5). The binding affinity decreased as the relative density of the surface-immobilized sulfated disaccharide units diminished. When the biologically active disaccharide comprised less than 40% of the immobilized ligand, binding was minimal.

We also studied the binding of the recombinant human vWf-A1 domain (rhvWf-A1) (*22*). This protein contains the same heparin-binding domain studied in Figure 5 (vWf-peptide) but also includes a secondary or cooperative heparin binding site (*23*). The three ligand conjugates, Mono-GlcNS6S-IdoA2S-Glc, Tri-GlcNS6S-IdoA2S-Glc, and Tetra-GlcNS6S-IdoA2S-Glc-long, were immobilized at 100% and 50% density (mixed 1:1 with Mono-Glc). Table 1 compares the effects of clustering (valency) and immobilization density on the binding parameters

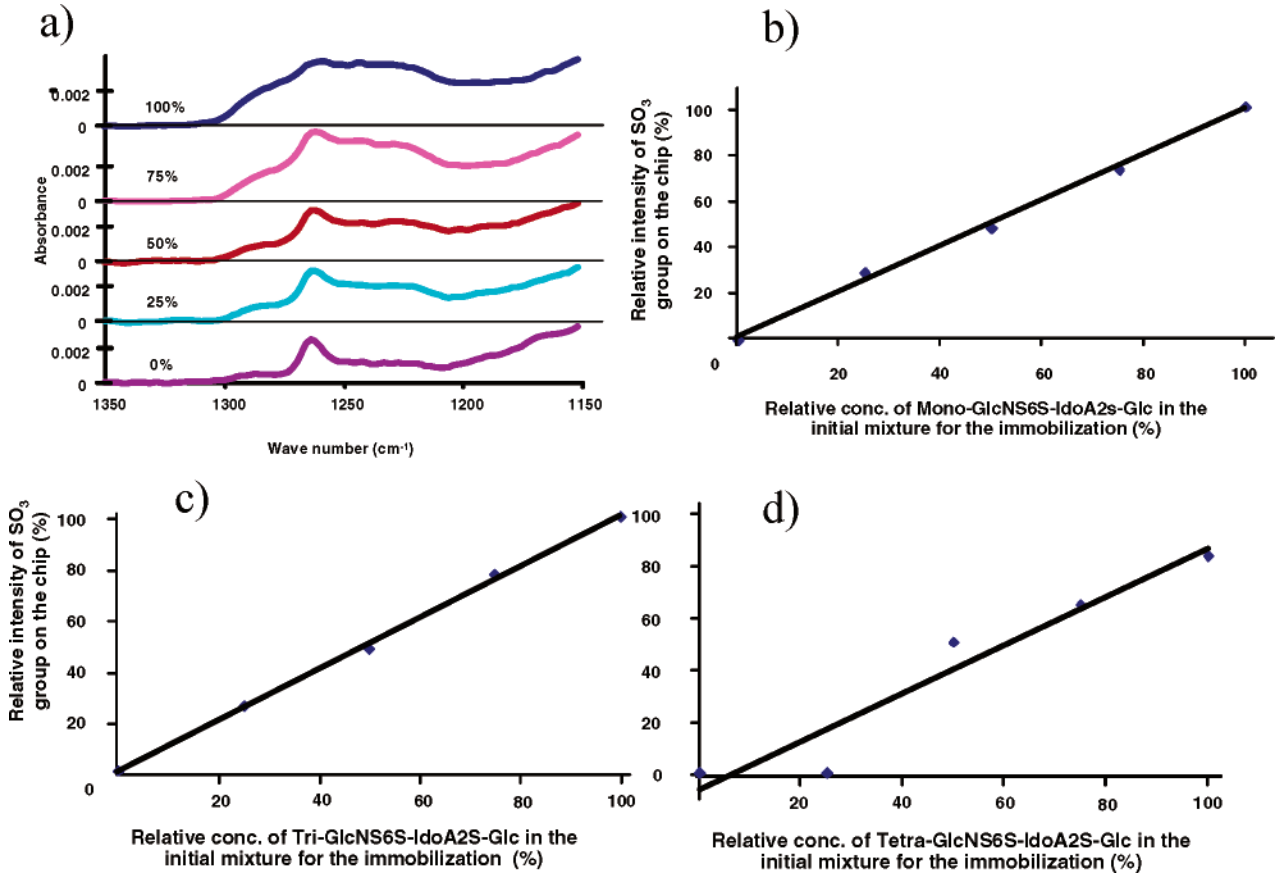

Figure 4. (a) ATR-FT-IR spectra of Mono-GlcNS6S-IdoA2S-Glc immobilized chip. The immobilization was done by adding Mono-GlcNS6S-IdoA2S-Glc to the control ligand conjugate (Mono-Glc) with changing concentration (0 to 100%). Intensity of ATR-FT-IR was plotted against the initial concentration of (b) Mono-GlcNS6S-IdoA2S-Glc ($R^2 = 0.9984$), (c) Tri-GlcNS6S-IdoA2S-Glc (compound **25**; $R^2 = 0.9993$), and (d) Tetra-GlcNS6S-IdoA2S-Glc-long (compound **49**; $R^2 = 0.9610$) in the ligand conjugate mixture.

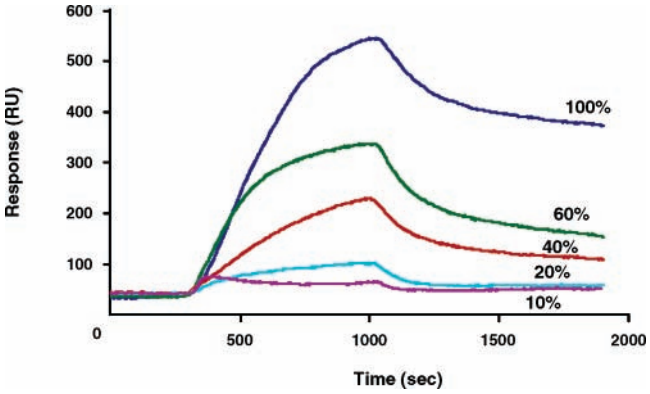

Figure 5. SPR sensorgram of vWf-peptide binding. Chips were immobilized with increasing proportions of Mono-GlcNS6S-IdoA2S-Glc, with the total concentration ([Mono-GlcNS6S-IdoA2S-Glc] + [Mono-Glc]) fixed at 100 μM. vWf-peptide was 2 μM.

(calculated from kinetic data using the analytical software of the SPR670).

The increased clustering of oligosaccharides provided by the tri- and tetravalent conjugates uniformly yielded lower dissociation constants K_D and lower dissociation rates k_d. The monovalent conjugate had an ~2.5−3-fold higher K_D and k_d. A 50% decrease in the density of immobilization hardly changed the binding parameters of the tri- and tetravalent ligand conjugates, while the same decrease in density of the monovalent ligand raised the K_D by 1.5-fold and doubled the k_d.

We then measured oligosaccharide binding of an even more complex version of this heparin-binding protein, the whole human vWf protein. A single vWf monomer protein is 270 kDa

Table 1. Binding of rhvWf-A1: Clustering Effect of Sulfated Oligosaccharide on the Chip

ligand conjugates	ratio	K_D [a] (μM)	k_a [b] ($M^{-1}\,s^{-1} \times 10^3$)	k_d [c] ($s^{-1} \times 10^{-3}$)
Mono-GlcNS6S-IdoA2S-Glc	100/0	2.60	8.38	21.9
Mono-GlcNS6S-IdoA2S-Glc/Mono-Glc	50/50	3.79	14.6	55.2

molecular mass, but it forms large multimers reaching several million daltons, displaying multiple heparin-binding sites. Experiments were performed using mono-, tri-, and tetravalent (long) ligand conjugates immobilized at 100% and 20% relative concentrations. Table 2 summarizes the estimated binding constants derived from the data illustrated in Figure 6a−c. The estimated K_D values were all very similar and did not depend

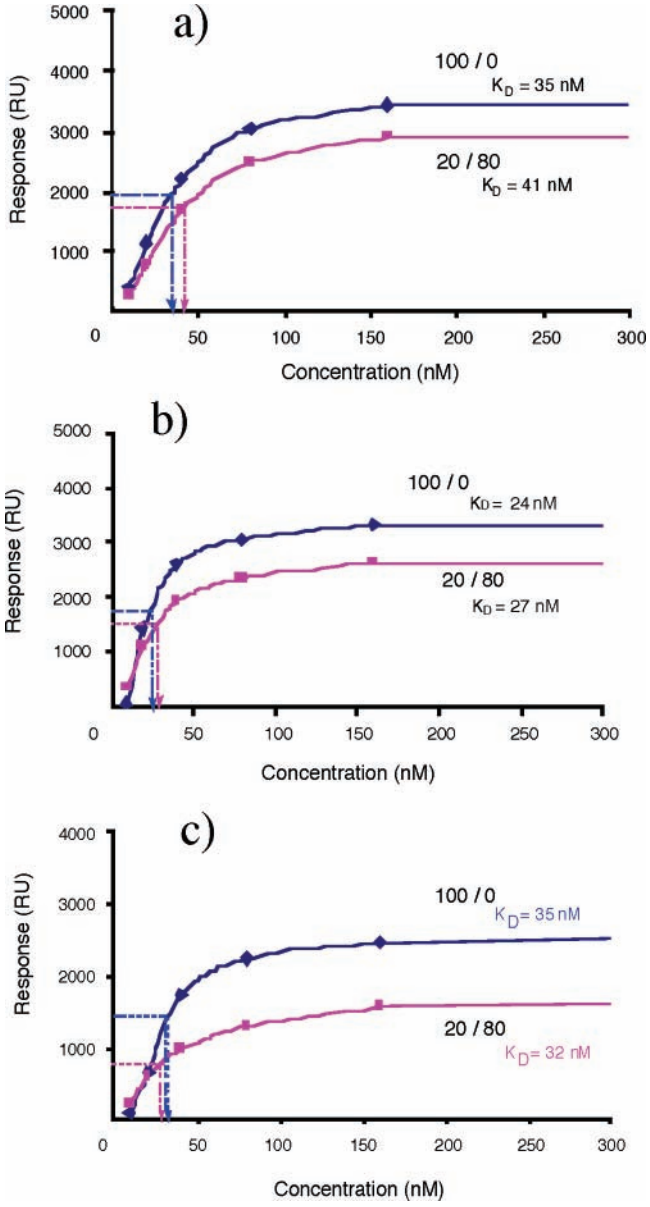

Figure 6. Equilibrium binding of whole hvWf protein to chips immobilized with Mono-GlcNS6S-IdoA2S-Glc/Mono-Glc (a), Tri-GlcNS6S-IdoA2S-Glc/Mono-Glc (b), and Tetra-GlcNS6S-IdoA2S-Glc-long/Mono-Glc (c). The ratios of Mono-GlcNS6S-IdoA2S-Glc, Tri-GlcNS6S-IdoA2S-Glc, or Tetra-GlcNS6S-IdoA2S-Glc-long/Mono-Glc were 100/0 and 20/80.

on the relative density of the immobilization of the ligand conjugates nor the multivalency of the ligand conjugate.

Finally, we studied the binding affinity for a completely different heparin-binding protein, human basic fibroblast growth factor (bFGF). Here we performed competitive binding studies with immobilized Tri-GlcNS6S-IdoA2S-Glc (compound **25**) and bFGF (200 nM) in solution phase admixed with increasing concentrations of unfractionated pharmaceutical grade heparin (Nacalai Tesque, from porcine intestine, average MW = 15000). Figure 7a shows that with increasing concentrations of soluble heparin, the binding of 200 nM of bFGF decreased. Figure 7b shows the estimated IC_{50} of heparin to be 50−100 nM, which is close to the reported K_D of bFGF for heparan sulfate proteoglycan (*24*).

DISCUSSION

The first goal of this work was to devise and refine a simpler and nondestructive strategy for immobilizing structurally defined

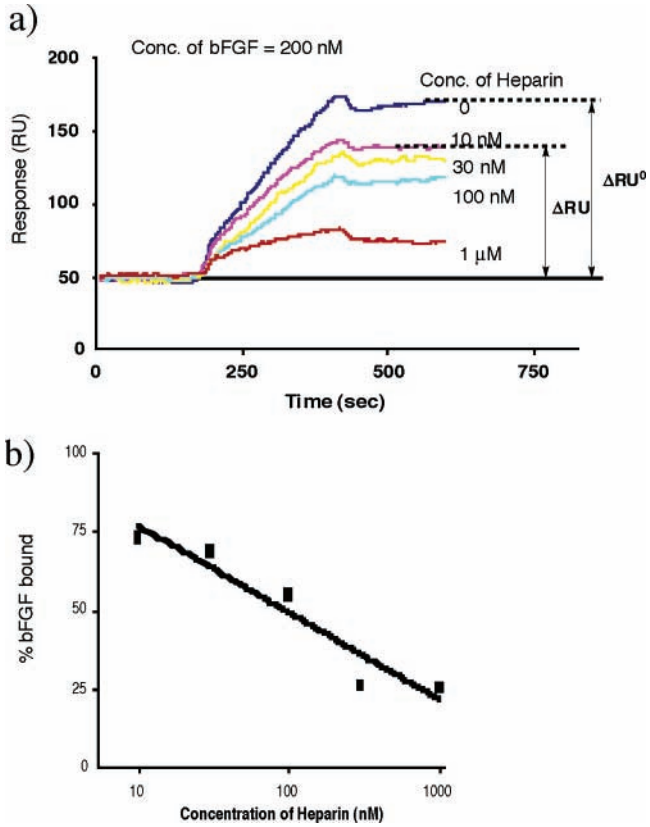

Figure 7. (a) SPR sensorgram of competitive heparin binding to bFGF. Mixtures of bFGF (200 nM) with or without soluble commercial heparin (Nacalai Tesque, from porcine intestine, average MW = 15000) were run on the chip of Tri-GlcNS6S-IdoA2S-Glc. (b) Relationship between the concentration of heparin and ΔRU at equilibrium.

oligosaccharides on a chip for SPR. When ligand immobilization methods were compared, the direct, covalent immobilization to the gold surface via Au−S bonds yielded minimal nonspecific binding interactions, as examplified by the negligible binding of BSA, and minimal protein binding to the control glucose ligand. In contrast, BSA bound to the self-assembled monolayer of octanethiol through nonspecific hydrophobic interactions, and the vWf-peptide bound with some measurable affinity even to the negative control glucose ligand.

We also sought to develop a linkage method that was simple, nondestructive, and applicable to a wider range of naturally occurring oligosaccharides. The reductive amination coupling to linker compounds containing aromatic amines offered more precise, quantitative control over the linkage process, especially when compared with techniques of mass immobilization using the lysine groups of albumin or other proteins. The reductive amination reaction is certainly a well-established method. It is typically used for the labeling of oligosaccharides, such as in the pyridyl amination reaction. In that case, excess amounts of pyridylamine are used, and the labeled compounds have been used primarily for the analysis of the structure of oligosaccharides. With use of this known pyridyl amination reaction, ligand conjugates for the immobilization of oligosaccharides onto the gold surface cannot be obtained.

Other methods have used the amino groups in a carrier protein, like bovine serum albumin, to form multivalent ligand oligosaccharides with dramatic increases in binding affinity. We previously examined the reductive amination strategy in detail and found the optimized conditions (*25*). In brief, the reaction should be done at around pH 4 to get a high yield. Therefore, regular alkyl amines gave lower yields because of the protonation of the amino group. If the pH is increased to over seven to have more free amino groups, the simple reduction at the

reducing end of oligosaccharide predominated. Thus, we found that aromatic amines had the optimal properties. Using those linker compounds described here, many other oligo- and polysaccharides including sialic containing ones, unfractionated high molecular weight heparin, low molecular weight heparins (LMWHs) prepared by several different methods, or amyloses, were also successfully conjugated. Those results will be reported soon.

Gold−sulfur immobilization schemes have also been used by Ratner et al. (*26*) and Horan et al. (*5*), but the regular thiol-containing compounds they used for self-assembling monolayers can form both S−S and S−H bonds, depending on the concentration. Therefore, purification of these oligosaccharide−thiol conjugates may be challenging, with low yields. Our current approach using a linker compound containing a thioctic acid with intramolecular S−S bonds avoids these significant challenges in purification during the synthesis. The advantages of using thioctic acid have been recognized in our patent (*27*) and in a recent publication (*28*).

The second purpose was to precisely quantify the nanostructural contributions of clustering, or valency, on the affinity of oligosaccharide ligands for increasingly complex heparin-binding proteins by varying spacer-arm length, immobilization density, and valency. Here, the distinction should be made between the minimal oligosaccharide binding unit and the minimal functional oligosaccharide necessary for biological activity. Often, a di- or trisaccharide of specific structure can be identified as the key binding unit (as we have done previously (*17*)). However, an isolated disaccharide often has low affinity and biological activity for the target protein. When multiple copies of this minimal binding unit are spaced appropriately (either within a single heparin chain or by adjacent chains), then the ligand protein may engage in higher affinity equilibrium binding that results in biological effects. Thus, overall the tri- or tetravalent compounds had higher affinities than the monovalent type, and the affinity was less dependent on their relative density on the surface of the SPR gold chip (Table 1). That is, when multivalency was incorporated as an intrinsic property of the ligand, variations in the density of immobilization had significantly less effect on the observed affinities. In contrast, the affinities of the monovalent ligand conjugates dropped dramatically when their relative density fell to 50%. Even though the changes shown in Table 1 were small, we observed a larger increase of K_D (lower affinity) of rhvWf-A1 when the relative density was decreased to 20% (data not shown). A larger k_d rate constant (Table 1) was observed compared to 100% density, suggesting that the observed binding of rhvWf-A1 occurred via equilibrium binding. These results support the concept that oligosaccharide ligand valency and density are important determinants for protein affinity. In biological systems, the key minimal oligosaccharide structure may either be spaced appropriately as a repeating unit within the same polymer chain or be displayed by clusters of neighboring polymers.

In addition to intrinsic ligand valency and density, it was interesting to find that a third factor also influenced equilibrium binding, the complexity of the heparin-binding protein. In the case of the simplest monovalent disaccharide ligand conjugate, its binding to a single, linear heparin-binding domain peptide (vWf-peptide) was highly dependent on the density of immobilized ligand (Figure 5). The monovalent ligand's interaction with a more complex heparin-binding protein (rhvWf-A1 containing major and minor heparin-binding domains) was still dependent on immobilization density, but slightly less so (Table 1). Finally, the monovalent ligand's interaction with the native multimeric vWf protein (containing multiple heparin-binding sites) showed the least dependency on immobilization density (Table 2). The binding of multivalent oligosaccharide ligands to increasingly complex heparin-binding proteins was much less sensitive to immobilization density. The trivalent and tetravalent constructs with the long spacer arm exhibited no significant change in K_D with reduced density.

Microarrays of synthetic heparin oligosaccharides have been reported very recently (*29*). But from these "sugar chips", the influence of the heparin-binding protein lends insights into the nature of protein−glycosaminoglycan binding mechanisms. It suggests that as the protein presents a multiplicity of heparin-binding sites, the interactions with the sulfated disaccharide units change from static multipoint binding to kinetic equilibrium binding. Neither ligand clustering nor density seemed to play as important a role in binding native multimeric hvWf, most likely because of the many widely spaced ligand binding sites presented by the protein itself. These results point to one unexpected advantage of this current technology: by altering the relative density and valency of the ligand on the surface, one can easily distinguish between single-site and multisite binding interactions between proteins and oligosaccharides. Thus, the heparin-binding properties of an unknown protein can be deduced.

Another utility of this approach is illustrated by the competitive binding assay using the trivalent ligand conjugate and human bFGF. We measured similar competition curves by soluble heparin against the monovalent or tetravalent ligand conjugates (data not shown). This technique can be easily applied, for example, to the screening of inhibitors or competitors of growth factors.

In previous work, we have found that the surface of the commercial gold-coated chip, at nanometer scale, is not perfectly flat. It varies in vertical elevation by as much as 10 nm up and down (detected by atomic force microscopy (AFM), data not shown). Thus, it was not surprising that the immobilization of ligands less than 2 nm in size might be affected by surface conditions, producing less consistent two-dimensional clustering of ligand on the surface. However, in the tri- or tetravalent type ligand conjugates, the biologically active oligosaccharides were dispersed within 2−3 nm, making a nanometer-sized cluster, which is independent of the surface irregularities of the gold-coated chip. Up to a point, a clustering-type effect can be achieved by immobilizing monovalent ligands at a higher density, but the nanostructural properties of the surface may interfere with the consistency and reproducibility of this effect. One explanation may be that the multivalent linkers are less affected by these surface conditions and thus show comparable affinities at lower density. Among them, the trivalent type may have some advantages. The trivalent linker contains an sp^3 carbon at the branching point. This branching makes a rigid structure and therefore gives an open space for the thioctic acid moiety (intramolecular S−S part) to immobilize the ligand conjugate to the gold surface. In contrast, the tetravalent type linker's branching parts are flexible enough to allow the large oligosaccharides to move apart and potentially mask the thioctic acid moiety. The ligand conjugate **36** (short spacer, tetravalent) was not able to be effectively immobilized. When a longer spacer arm was inserted (four units of ethylene glycol between the branching part and the thioctic acid moiety), compound **49** could then be successfully immobilized.

CONCLUSION

We have studied the binding of mono- and multivalent oligosaccharide ligands to increasingly complex heparin-binding protein structures. We have devised relatively simple and novel nondestructive methods of conjugation and immobilization that are applicable to a wide range of synthetic or naturally occurring oligosaccharides. The data show that clustering of the biologically active oligosaccharides enhances their affinity for simple

heparin-binding motifs and reduces the impact of surface irregularities or variations in the density of immobilization. For more complex heparin-binding proteins, the density of immobilization and the degree of ligand valency play less of a role. This relative dependence on density can thus be used as one rapid method to characterize the nature of the glycosaminoglycan−protein interaction.

Several technical advantages are conferred by these approaches. The reductive amination technique using an aromatic amino moiety offers a simpler, more quantitatively precise method of conjugation than that reported by Feizi and Chai (*30*). It is suitable for any oligosaccharide with a reducing end and does not require significant modification of their functional sulfate groups. The sulfur−gold immobilization using a thioctic acid moiety permits tighter control of the sulfur reactions, and easier purification of the conjugate. With tri- or tetravalent linkers, the oligosaccharides can easily be incorporated as a clustered form that mimics nature. These novel applications of SPR offer the potential to elucidate a range of fundamental structure−function relations of oligosaccharide−protein interactions at the molecular level and hold promise as a novel approach to rapid throughput screening of new bioactive molecules.

ACKNOWLEDGMENT

We wish to thank Mr. Y. Murakami (Shimazu Co., Kyoto Customer Support Center) for his great support for the measurement of ATR-FT-IR. This work was supported in parts by grants from Japan Science and Technology Agency (YS), the National Institutes of Health (Grants RO1HL39903 and HL079182 to M.S.) and the Department of Veterans Affairs Research Service (to M.S.).

Received March 20, 2006; Revised Manuscript Received July 4, 2006

Oligodeoxynucleotides containing unmethylated CpG sequences (CpG DNAs) are known as an immune adjuvant. CpG DNAs coupled with a particular antigen enabling both CpG DNA and antigen delivery to the same antigen-presenting cell have been shown to be more effective. Based on our previous finding that β-(1→3)-D-glucan schizophyllan (SPG) can be used as a CpG DNA carrier, here we present the synthesis of an antigen-conjugated SPG and the characterization of the conjugate. Ovalbumin (OVA, 43 kDa) was used as a model antigen, and two OVA were conjugated to one SPG molecule (M_w = 150 000), denoted by OVA−SPG. Circular dichroism and gel electrophoresis showed that OVA−SPG could form a complex with a $(dA)_{40}$-tailed CpG DNA at the 3′ end (1668-$(dA)_{40}$). When OVA−SPG was added to macrophages (J774.A1), the amount of the ingested OVA−SPG was increased compared with that of OVA itself, suggesting that Dectin-1 (proinflammatory nonopsonic receptor for β-glucans) is involved to ingest OVA−SPG. Furthermore, the complex of the conjugate and DNA was co-localized in the same vesicles, implying that OVA (antigen) and CpG DNA (adjuvant) were ingested into the cell at the same time. This paper shows that OVA−SPG can be used as a CpG DNA carrier to induce antigen-specific immune responses.

INTRODUCTION

Antigen-presenting cells (APCs), particularly dendritic cells, macrophages, and B-cells, play a crucial role in initiating immune responses. Generally, the immune responses are outcomes of the following events: foreign proteins are engulfed by APCs with phagocytosis and the fragments of the protein are presented on the surface of APCs as a major histocompatibility complex (MHC). Naïve T cells bind MHC through T cell receptors, eventually, to induce differentiation of T cells into two cell subsets: T helper 1 (Th1) and T helper 2 (Th2) cells, depending on what cytokines are induced.

Oligodeoxynucleotides containing unmethylated CpG sequences (CpG DNAs) are known as an immune adjuvant to effectively induce Th1 response (*1*−*4*). After CpG DNAs are engulfed by APCs, they are recognized by toll-like receptor 9 (TLR-9) in phagosome-like vesicles to produce cytokines (*5*, *6*). Among pro-inflammatory cytokines induced by CpG DNAs, interleukin (IL)-12 facilitates development of Th1 cells, and thus Th1 cells produce interferon γ (IFN-γ), which can suppress the differentiation of Th2 cells (*7*). Consequently, CpG DNAs can decrease Th2-mediated IgE production, which is a major cause of allergy if excessively secreted. Taking advantage of this response of CpG DNAs, they can be used as an antiallergy adjuvant. Especially, when phagocytosis-mediated antigen presentation is coupled with TLR-9-triggered events in the same cell, the resultant cytokines and co-stimulatory molecules should develop antigen-specific Th1 immunity. Therefore, to effectively induce this type of immunity, it is essentially important that CpG DNA and antigen are co-delivered to the same APC. The importance of the co-delivery has been proved by several groups using alum (*8*), cationic liposome (*9*), or bifunctional cross-linker (*10*, *11*). However, there are some drawbacks in those methods. The most serious one is that CpG DNA is quickly degraded by nuclease under biological conditions. To protect CpG DNA, the terminal nucleotides are converted to phosphorothioate (*12*); however, phosphorothioate creates cytotoxicity and undesirable side effects (*13*, *14*). Furthermore, cytotoxicity of cationic liposomes sometimes leads to serious side effects (*15*−*17*).

We found that a natural polysaccharide called schizophyllan (SPG)[1] forms a complex with single-stranded homo-polynucleotides (*18*). SPG is composed of a β-(1→3)-D-glucan main chain, and one β-(1→6)-D-glycosyl side chain links to the main chain every three glucose residues (Figure 1) (*19*). The complex can protect the bound DNA against nuclease-mediated hydrolysis or nonspecific binding to serum proteins. We have showed that these characteristics make it possible to use native phos-

phodiester DNAs for antisense therapy (*20*−*22*). Furthermore, SPG was selectively distributed in reticuloendothelial tissues such as liver, spleen lymph node, and bone marrow (*23*). On the basis of these findings, we have applied the SPG/DNA complex to a CpG DNA carrier. When the complex was added to macrophages or spleen cells, the secretion of IL-12 was enhanced over that with the naked dose. Moreover, when CpG DNA was complexed with SPG and intraperitoneally injected into mouse, the maximum secretion of IFN-γ was found to be twice as large as that invoked by the naked doses, and the secretion period was prolonged dramatically (*24*, *25*). These excellent performances should be ascribed to both the stability of the SPG composite and the reticuloendothelial localization of SPG itself. In this paper, we synthesized an antigen-conjugated SPG and examined the performance of the conjugate as a CpG DNA carrier using circular dichroism (CD), fluorescence activated cell sorting (FACS) analysis, and confocal laser scanning microscopy (CLSM).

EXPERIMENTAL PROCEDURES

Materials. Mitsui Sugar Co., Ltd. (Japan) kindly supplied the SPG sample. The weight-average molecular weight (M_w) and the number of repeating units were found to be 1.5×10^5 and 231, respectively. Ovalbumin (OVA, a model antigen) was purchased from Sigma-Aldrich. As a CpG DNA, we adopted the sequence of 5′-TCC ATG ACG TTC CTG ATG-3′. To combine these sequences with SPG, we attached a $(dA)_{40}$ tail at the 3′ end (*26*). Hereinafter, we denote this phosphodiester 5′-TCC ATG ACG TTC CTG ATG-$(dA)_{40}$-3′ as 1668-$(dA)_{40}$. For CD and CLSM, we used $(dA)_{40}$ and rhodamine X-labeled $(dA)_{40}$ (ROX-$(dA)_{40}$), respectively. All DNA samples were synthesized at Hokkaido System Science (Hokkaido, Japan) and purified with high-pressure liquid chromatography. The lengths of the synthesized DNAs were confirmed with denatured PAGE. The fetal bovine serum (FBS), and penicillin/streptomycin were purchased from Gibco/BRL. Dulbecco's modified Eagle's medium (DMEM) was obtained from Nissui Pharmaceutical Co., Ltd.

Preparation of OVA-Conjugated SPG. We already established a method to introduce functional groups only to the side chain of SPG (*26*, *27*). SPG (100 mg) was dissolved in water, sodium periodate (27 mg) was added to the solution, and the solution was stirred at 5 °C for 2 days to obtain an oxidized SPG bearing aldehyde groups. The oxidized SPG (1.25 mg/mL), OVA (2.5 mg/mL), and sodium cyanoborohydride (100 mg) were dissolved into 0.1 M sodium bicarbonate, and the mixture was stirred at room temperature for 14 h. The OVA-conjugated SPG (OVA−SPG) was purified by gel filtration (Sephacryl S200, Amersham), and the purity was examined with SDS−PAGE. The amount of OVA introduced to SPG was determined with a protein quantification kit (DOJINDO).

Analysis of Gel Electrophoresis. OVA−SPG (or unmodified SPG) was dissolved in 97% DMSO and 3% H_2O. The OVA−SPG solution (final concentration 0.67 mg/mL) was added to 1668-$(dA)_{40}$ (final concentration 0.01 mg/mL) in a 30 mM Tris-HCl (pH = 7.0) buffer containing 0.15 M NaCl. The mixture was incubated at 5 °C for 2 days, and the formation of the complex was examined with agarose gel (2%) electrophoresis. The bands were visualized with GelStar (Amersham).

Measurement of CD Spectra. OVA−SPG (or unmodified SPG) was dissolved in 97% DMSO and 3% H_2O. The OVA−SPG solution (final concentration 0.67 mg/mL) was added to $(dA)_{40}$ (final concentration 0.175 mg/mL) in a 30 mM Tris-HCl (pH = 7.0) buffer containing 0.15 M NaCl. The mixture was incubated at 5 °C for 2 days. CD was measured at 5 °C on a JASCO J-720WI spectrometer with a 1 mm cell.

Cell Culture. Murine macrophage-like cells (J774.A1) were obtained from the American Type Culture Collection (ATCC, Rockville, MD). The J774.A1 cells were maintained in DMEM supplemented with 10% FBS, containing a 1 wt % penicillin/streptomycin mixture. The cell incubation was always carried out at 37 °C in fully humidified air containing 5 wt % CO_2.

Fluorescence Activated Cell Sorting (FACS) Analysis and Confocal Laser Scanning Microscopy (CLSM). FITC-labeled OVA−SPG was prepared for FACS and CLSM. FITC (72 μL of a 5 mg/mL solution) was added to 1 mL of OVA−SPG (4.4 mg/mL) in 0.1 M sodium bicarbonate (pH = 9.0), and the mixture was stirred at 4 °C for 15 h. The mixture was purified with dialysis and gel filtration. FITC-labeled OVA was prepared by the same method. The amounts of OVA and FITC were determined with a protein quantification kit and the UV absorbance of FITC, respectively. The FITC/protein (F/P) molar ratios were 1.5 and 1.6 for F−OVA−SPG and F−OVA, respectively.

For FACS, J774.A1 cells were plated in a 48-well dish (2×10^6 cells/mL; 200 μL/well) and allowed to attach to the wells at 37 °C for 24 h. The cells were washed twice with DMEM without FBS, and then 25 μg/mL (200 μL) OVA in F−OVA−SPG or F−OVA was added to the cells. The cells were incubated at 37 °C for 2 h, washed twice with PBS, harvested with a scraper, and fixed with 5% HCHO at 4 °C for 20 min. The number of the cells that had FITC was counted with an EPICS XL (BECKMAN COULTER). For CLSM, J774.A1 cells were plated in a glass-bottom dish (ϕ = 12 mm) and allowed to attach to the dish at 37 °C for 24 h. The cells were washed twice with DMEM without FBS, and 200 μL of F−OVA−SPG/ROX-$(dA)_{40}$ complex or F−OVA was added to the cells at the concentration of 25 μg/mL OVA in F−OVA−SPG or F−OVA and 37.5 μg/mL ROX-$(dA)_{40}$ in the complex. The cells were incubated at 37 °C for 2 h and washed twice with PBS and fixed with 5% HCHO containing 4′,6-diamidino-2-phenylindole (DAPI) at 4 °C for 20 min. The cells were observed with a Nikon fluorescence microscope (ECLIPS TE2000-U) with a Radiance2100 BioRad confocal scan unit attached.

RESULTS AND DISCUSSION

Preparation of OVA-Conjugated SPG. OVA−SPG was synthesized as described in the Experimental Procedures section. Figure 2A shows the gel filtration chromatograms of a crude OVA−SPG (before purification, including a large amount of unconjugated OVA) and OVA itself. OVA has a large peak around 40−45 mL, and the crude OVA−SPG peak is overlaid with that of OVA. It can be seen that OVA−SPG conjugate was eluted at 25−30 mL as a shoulder. We carefully collected the shoulder ranging 25−28 mL. Figure 2B compares SDS−PAGE patterns for OVA−SPG before and after the purification, as well as free OVA. Before the purification, two bands were observed (lane 4), corresponding the migrated and unmigrated bands to free OVA and OVA−SPG, respectively. After the purification, there was no appreciable band of free OVA,

Figure 2. (A) Gel filtration chromatograms of OVA−SPG and OVA. The shoulder ranging 25−28 mL was collected. (B) Analysis of OVA−SPG by 8% SDS−PAGE: lane 1, a molecular weight marker; lane 2, OVA only; lane 3, SPG only; lane 4, the crude sample examined in the gel filtration; lane 5, the purified sample obtained from the shoulder.

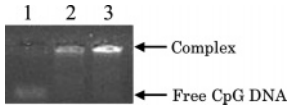

Figure 3. Confirmation of complex formation between OVA−SPG and 1668-$(dA)_{40}$ by 2% agarose gel electrophoresis stained with GelStar: lane 1, 1668-$(dA)_{40}$ only; lane 2, mixture of unmodified SPG and 1668-$(dA)_{40}$; lane 3, mixture of OVA−SPG and 1668-$(dA)_{40}$; [unmodified SPG] = 0.42 mg/mL, [OVA−SPG] = 0.67 mg/mL, and [1668-$(dA)_{40}$] = 0.01 mg/mL.

indicating that the purification removed all free OVA. We determined that 0.4 mg of OVA per 1 mg of OVA−SPG was introduced, meaning that two OVA (43 kDa) molecules were attached to one SPG (M_w = 150 000) molecule.

DNA Binding Ability of OVA-SPG. Figure 3 shows agarose gel electrophoresis when 1668-$(dA)_{40}$ only, SPG/1668-$(dA)_{40}$, and OVA−SPG/1668-$(dA)_{40}$ were applied. The 1668-$(dA)_{40}$ migrated into the gel. On the other hand, the complexed 1668-$(dA)_{40}$ with unmodified SPG stayed at the well and never moved to show a retarded band, which is evidence of the complex formation (lane 2) (*28*). The retarded band at the well was observed in lane 3 in the same way as in lane 2, indicating that OVA−SPG formed a complex with 1668-$(dA)_{40}$. To confirm the complexation, CD spectra were measured (Figure 4A). In this case, for convenience, we used $(dA)_{40}$ instead of 1668-$(dA)_{40}$. OVA−SPG itself and SPG itself were not CD-active, showing no spectrum at 240−320 nm. When OVA−SPG was added to $(dA)_{40}$, a negative band at 250 nm disappeared, and a new negative band at 275 nm appeared. The band at 280 nm in $(dA)_{40}$ itself seemed to red-shift and increase in intensity upon complexation with OVA−SPG. These spectral changes completely agree with those of the SPG/$(dA)_{40}$ complex (*29*),

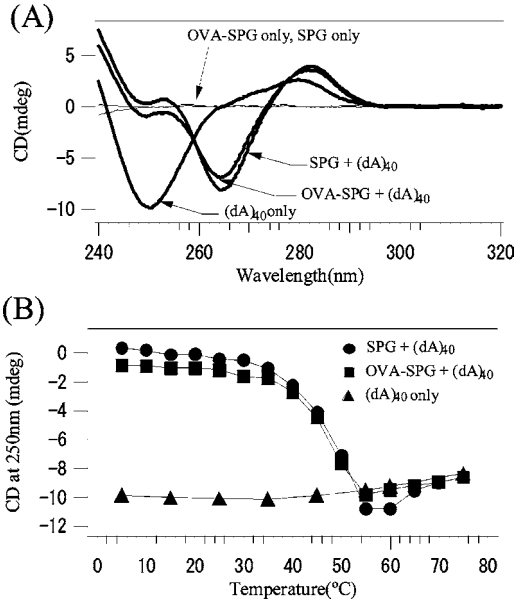

Figure 4. (A) Comparison of CD spectra for the mixture of OVA−SPG + $(dA)_{40}$, unmodified SPG + $(dA)_{40}$, SPG only, OVA−SPG only, and $(dA)_{40}$ only measured at 5 °C in 30 mM Tris-HCl (pH = 7.0) containing 0.15 M NaCl and 8.3% DMSO. (B) Temperature dependence of the CD intensity at 250 nm of the complexes and $(dA)_{40}$ only. [unmodified SPG] = 0.42 mg/mL, [OVA−SPG] = 0.67 mg/mL, and [$(dA)_{40}$] = 0.175 mg/mL.

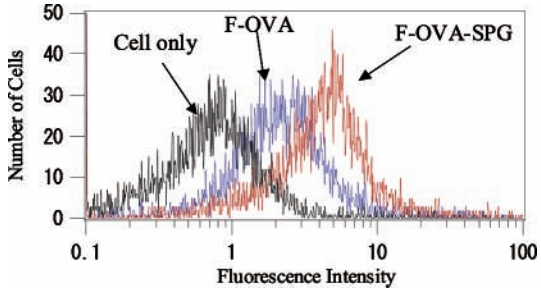

Figure 5. FACS profiles of F−OVA or F−OVA−SPG-treated macrophage-like cells (J774.A1). OVA (25 μg/mL) in F−OVA or F−OVA−SPG was added to the cells in DMEM without FBS at 37 °C for 2 h. Black line, blue line, and red line indicate untreated cells, F−OVA-treated cells, and F−OVA−SPG-treated cells, respectively.

indicating that the attachment of two OVA molecules to SPG does not interfere in the complexation ability at all.

Figure 4B plots the CD intensity at 250 nm of OVA−SPG/$(dA)_{40}$ complex against temperature, compared with SPG/$(dA)_{40}$ and $(dA)_{40}$. Owing to the presence of the complexes, 250 nm CD intensities for OVA−SPG/$(dA)_{40}$ and SPG/$(dA)_{40}$ are larger than that of $(dA)_{40}$ at low temperatures. They merge into that of $(dA)_{40}$ above 55 °C, indicating that the dissociation of the complex takes place at this temperature. The melting (or dissociation) curves are almost the same between the two complexes. These results indicate that OVA−SPG can form a thermally stable complex with DNA in the same manner as SPG/DNA complexes. The morphological (*30*) and fundamental thermodynamic properties (*18*, *28*) of SPG/nucleic acid complexes have been well studied, and the similarity in CD spectrum between SPG/DNA and OVA−SPG/DNA complexes implies that the basic properties of the complex are not changed after conjugation of OVA.

Ingestion and Distribution of OVA−SPG and Complexed DNA. Figure 5 compares the FACS profiles between F−OVA and F−OVA−SPG when these were added to J774.A1. The number of cells that had ingested FITC was increased when F−OVA−SPG was added, compared with F−OVA. This result

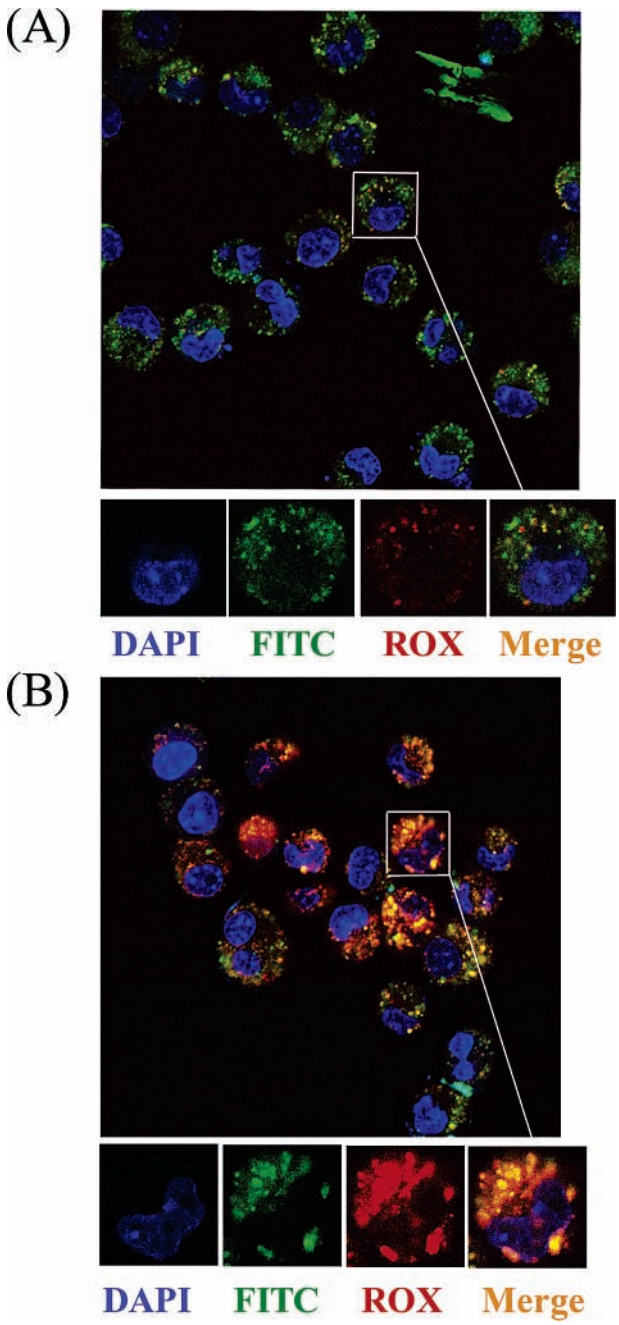

Figure 6. Intracellular localization of (A) a mixture of unmodified SPG/ROX-$(dA)_{40}$ and F−OVA and (B) the complex made from F−OVA−SPG and ROX-$(dA)_{40}$ in J774.A1 cells. The blue, green, and red colors correspond to DAPI (nucleus), FITC (OVA), and ROX (DNA), respectively. The yellow color is the outcome of the merge between FITC and ROX, which is only observed for the complex.

indicates that the presence of SPG enhanced the cellular ingestion. It has been reported that β-1,3-glucans, especially for zymosan and other cell-wall glucans, are recognized by a receptor called Dectin-1 (*31*) and are internalized by phagocytosis (*32*). Increased uptake of OVA−SPG might be ascribed to the receptor-mediated uptake for SPG.

By use of CLSM, we examined the intracellular distribution for the OVA−SPG/ROX-$(dA)_{40}$ complex compared with a mixture of F−OVA and SPG/ROX-$(dA)_{40}$. Figure 6A shows the CLSM image when a mixture of F−OVA and the unmodified SPG/ROX-$(dA)_{40}$ complex were added to the J774.A1 cells, where F−OVA and the SPG/ROX-$(dA)_{40}$ complex do not form a complex. The image A shows that F−OVA and ROX-$(dA)_{40}$ are distributed heterogeneously within the cytosol. However, most of F−OVA and ROX-$(dA)_{40}$ seem not to localize at the same vesicles, indicating that both objects were ingested independently. Figure 6B is the CLSM image when the F−OVA−SPG/ROX-$(dA)_{40}$ complex was added. F−OVA−SPG and ROX-$(dA)_{40}$ are distributed heterogeneously within cytosol in the same manner as Figure 6A. In contrast to the previous image, most images are yellow, indicating that a large number of F−OVA−SPG and ROX-$(dA)_{40}$ are colocalized in the same vesicles. In addition, there seemed to be a quantitative difference in the ingested CpG DNA between photos A and B in Figure 6. OVA−SPG induces more uptake of CpG DNA than SPG itself. Presumably, an unknown uptake mechanism for OVA as an antigen might be responsible for this increment.

The present results imply that OVA (antigen) and CpG DNA (adjuvant) were ingested at the same time and delivered to the same vesicles when CpG DNA and OVA−SPG were complexed. Therefore, we can speculate that the present complex can antigen-specifically induce a TLR-9-dependent Th1 immune response.

CONCLUSIONS

An OVA-conjugated SPG was synthesized, and the characterization of the conjugate was carried out. Composition analysis showed that two OVA molecules are attached to one SPG molecule, and agarose gel electrophoresis and CD proved that the conjugate can form a complex with 1668-$(dA)_{40}$. When the FITC-labeled conjugate was added to J774.A1 cells, the number of cells that had ingested FITC was increased compared with OVA itself, suggesting that the cells ingested the conjugate by SPG/Dectin-1 recognition. CLSM showed that the ingested OVA and DNA were in the same vesicles. We believe that antigen-conjugated SPG is applicable as a carrier to induce an antigen-specific and TLR-9-dependent Th1 immune response.

Received March 26, 2006; Revised Manuscript Received June 16, 2006

Liposomes have been a main focus of tumor-selective boron delivery strategies in boron neutron capture therapy (BNCT), a binary method for the treatment of cancer that is based on the nuclear reaction between boron atoms and low-energy thermal neutrons. Three novel carboranyl cholesterol derivatives were prepared as lipid bilayer components for the construction of nontargeted and receptor-targeted boronated liposomes for BNCT. A major structural feature of these novel boronated cholesterol mimics is the replacement of the B and the C ring of cholesterol with a carborane cluster. Computational analyses indicated that all three boronated compounds have structural features and physicochemical properties that are very similar to those of cholesterol. One of the synthesized boronated cholesterol mimics was stably incorporated into non-, folate receptor (FR)-, and vascular endothelial growth factor receptor-2 (VEGFR-2)-targeted liposomes. No major differences were found in appearance, size distribution, and lamellarity between conventional dipalmitoylphosphatidylcholine (DPPC)/cholesterol liposomes, nontargeted, and FR-targeted liposomal formulations of this carboranyl cholesterol derivative. FR-targeted boronated liposomes were taken up extensively in FR overexpressing KB cells in vitro, and the uptake was effectively blocked in the presence of free folate. In contrast, a boronated cholesterol mimic incorporated into nontargeted liposomes showed significantly lower cellular uptake. There was no apparent in vitro cytotoxicity in FR overexpressing KB cells and VEGFR-2 overexpressing 293/KDR cells when these were incubated with boronated FR- and (VEGFR-2)-targeted liposomes, respectively, although the former accumulated extensively in KB cells and the latter effectively interacted with VEGFR-2 by causing autophosphorylation and protecting 293/KDR cells from SLT (Shiga-like toxin)−VEGF cytotoxicity.

INTRODUCTION

Boron neutron capture therapy (BNCT) is a binary method for the treatment of cancer (*1*), which is based on the nuclear reaction between boron atoms and low-energy thermal neutrons. Naturally occurring elemental boron has two stable isotopes, namely, boron-10 (^{10}B) and boron-11 (^{11}B). The abundant isotope is ^{11}B (around 80%); however, the most distinguishing property of ^{10}B is its high neutron capture cross section for thermal (slow) neutrons. Hence, the reaction of a neutron with ^{10}B yields two charged particles, a ^{4}He nucleus and a ^{7}Li nucleus, each of which are able to kill tumor cells due to their high linear energy transfer. For successful BNCT, a minimum of 20−30 μg of nonradioactive ^{10}B per gram of tumor tissue is required. Another key requirement for the success of BNCT is the selective delivery of high amounts of boronated compounds to tumor cells, while at the same time, the boron concentration in the cells of surrounding normal tissue should be kept low to minimize the damage to normal tissue.

Liposomes have been a main focus of tumor selective boron delivery strategies in BNCT since research activities in this area were initiated by Hawthorne (*2*) and Yanagie (*3*) in the early 1990s. Design strategies for boron-containing liposomes for BNCT centered on both nontargeted (*4*, *5*), and tumor-targeted formulations. The latter included liposomes conjugated to transferrin (*6*), the epidermal growth factor (EGF) (*7*), antibodies (*8*), α (v)-integrin specific arginine−glycine−aspartate (RGD) peptides (*9*), and folic acid (*10*, *11*). Most liposomes designed for BNCT contained hydrophilic low molecular weight boron agents, which presumably localized in the aqueous core of the liposomes during preparation. These boron agents include sodium borocaptate (BSH) (*12*, *13*) and boronophenylalanine (BPA) (*14*), both of which have been used in clinical BNCT (*1*), negatively charged boron clusters with or without simple substitution patterns (*2*, *15*), as well as carborane cage-substituted polyamines (*11*), acridines (*7*, *8*), porphyrins (*16*), carbohydrates (*17*), and nucleosides (*18*).

Phospholipids are common lipid bilayer components of liposomes and have proven to be effective anchors for boron entities in the form of dual- (*19*, *20*) or single- (*10*, *21*) chain *nido*-carboranyl phospholipid mimics. Cholesterol is another major component of the mammalian cell membrane and most liposomal formulations. It is transported in the blood stream by low-density lipoprotein (LDL). Owing to its natural carrier capability and receptor-targeting specificity, LDL has been

extensively studied as a drug carrier (*22*). Therefore, the development of boron-containing compounds that mimic physiological cholesterol and cholesterol esters is potentially an effective approach for boron delivery to cancer cells via both liposomes and LDL, and thus, extensive efforts in BNCT drug development have focused on such structures (*23*−*30*).

To the best of our knowledge, all synthetic approaches directed toward boron-containing cholesterol derivatives have focused on the attachment of carboranyl moieties to the hydroxyl group of cholesterol via ether or ester linkages. In the present manuscript, we report a novel strategy for the design and synthesis of carboranyl cholesterol mimics. This design strategy is based on a groundbreaking concept developed by Endo et al. for the synthesis of a carboranyl analogues of estradiol (*31*, *32*). Analogous to Endo's carboranyl estradiols, both the B and the C ring of cholesterol were replaced with a carborane cluster in the boronated cholesterol mimics described in this paper (Figure 1). The design and synthesis of these structures, their incorporation into liposomes, and the evaluation of the capacity of these liposomes for efficient boron delivery are the subjects of this paper. Both the folate receptor (FR) (*33*, *34*) and the vascular endothelial growth factor receptor-2 (VEGFR-2) (*35*, *36*) have been identified as important molecular targets for cancer therapy in recent years. The capacity of the designed boronated liposomes for incorporation of receptor-targeting ligands such as folate and VEGF (vascular endothelial growth factor) and the results of in vitro uptake and cytotoxicity studies with the resulting constructs are discussed.

EXPERIMENTAL PROCEDURES

General Chemical Procedures. Proton and carbon-13 NMR spectra were obtained on Bruker (250 MHz or 400 MHz) NMR instruments at The Ohio State University College of Pharmacy. Chemical shifts are reported in parts per million (ppm) from an internal tetramethylsilane standard. The coupling constants are reported in hertz (Hz). High resolution electron impact mass spectrometry (HR-EIMS) was carried out with a Kratos MS-25 instrument with typical ionization conditions of 70 eV electron impact ionization at the Department of Chemistry of The Ohio State University by Dr. Christopher M. Hadad and Ms. Susan Hatcher. Compound visualization on silica gel 60 F_{254} precoated TLC plates (0.25 mm layer thickness) (Merck, Darmstadt, Germany) was attained by UV light. Carborane-containing compounds were selectively visualized by spraying a solution of 0.06% $PdCl_2$/1% aqueous HCl on TLC plates and subsequent heating to ∼120 °C, which caused the slow formation (15−45 s) of gray spots due to the reduction of Pd^{2+} to Pd^0. Reagent-grade solvents were used for column chromatography using silica gel 60, particle size 0.040−0.063 mm (Merck, New Jersey). Standard chemicals were purchased from various vendors. *Para*- and *meta*-carborane were purchased from Katchem, Prague, Czech Republic. All chemicals were used as purchased without further purification. Anhydrous benzene, anhydrous dichloromethane, and anhydrous tetrahydrofurane (THF) were purchased from VWR Scientific Products. THF was additionally dried over sodium metal before use. All chemical syntheses were carried out under argon atmosphere to maintain inert reaction condition unless mentioned otherwise.

1-(4-Methoxyphenyl)-7-(6-methylheptyl)-1,7-dicarba-*closo*-dodecaborane (2). To a solution of 1-(4-methoxyphenyl)-1,7-dicarba-*closo*-dodecaborane (*31*) (**1**) (125 mg, 0.5 mmol) in THF (20 mL) at 0 °C was added *n*-BuLi (2.5 M in hexane, 0.2 mL, 0.51 mmol). The mixture was first stirred at 0 °C for 45 min and then for 1 h at room temperature. Toluene-4-sulfonic acid 6-methylheptyl ester (*37*) (142 mg, 0.5 mmol) in 5 mL THF was added and the resulting mixture stirred for 12 h at room temperature, poured into ice−water (50 mL), extracted with ether (3 × 50 mL), washed with brine, and dried over $MgSO_4$. The solvent was evaporated under vacuum, and the residue was purified by silica gel flash column chromatography using hexanes/ethylacetate (9:1) as the eluent (TLC R_f: 0.5) to give **2** in 61% yield. ^{1}H NMR ($CDCl_3$): δ 0.83−0.85 (d, 6H, J = 6.5 Hz) 1.15−1.38 (m, 9H, CH_2), 2.16 (2H, t, J = 6 Hz), 3.75 (s, 3H), 6.64−6.67 (2H, d, J = 8.6 Hz), 7.51−7.55 (2H, d, J = 8.6 Hz). ^{13}C NMR ($CDCl_3$): δ 19.59, 23.01, 27.40, 28.31, 29.86, 30.12, 30.45, 37.59, 39.20, 54.89, 55.72, 72.23, 113.89, 128.19, 129.39, 160.14. HR-EIMS calcd for $C_{17}H_{34}B_{10}O$ (M^+): 362.3607. Found 362.3585.

1-(4-Methoxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane, an intermediate in the synthesis of compound **II**, was obtained by adapting the procedure described for compound **2** using 1-(4-methoxyphenyl)-1,12-dicarba-*closo*-dodecaborane (*31*) as the starting material. Purification by silica gel flash chromatography using hexanes/ethylacetate (9:1) as the eluent (TLC R_f: 0.5) gave 1-(4-methoxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane in 52% yield. ^{1}H NMR ($CDCl_3$): δ 0.82−0.84 (d, 6H, J = 6.6 Hz) 1.20−1.39 (m, 9H, CH_2), 2.15 (t, 2H, J = 6.5 Hz), 3.75 (s, 3H), 6.75−6.72 (d, 2H, J = 7.5 Hz), 7.32−7.29 (d, 2H, J = 7.5 Hz). ^{13}C NMR ($CDCl_3$): δ 23.01, 27.40, 28.31, 29.86, 30.12, 30.45, 37.60, 39.20, 55.72, 72.25, 113.64, 113.90, 116.75, 128.58, 129.39, 129.73, 138.59, 159.95. HR-EIMS calcd for $C_{17}H_{34}B_{10}O$ (M^+): 362.3607. Found: 362.3585.

1-(3-Methoxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane, an intermediate in the synthesis of compound **III**, was obtained by adapting the procedure described for compound **2** using 1-(3-methoxyphenyl)-1,12-dicarba-*closo*-dodecaborane (*31*) as the starting material. Purification by silica gel flash chromatography using hexanes/ethylacetate (9:1) as the eluent (TLC R_f: 0.5) gave the 1-(3-methoxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane in 55% yield. ^{1}H NMR ($CDCl_3$): δ 0.82−0.84 (d, 6H, J = 6.6 Hz) 1.11−1.39 (9H, m, CH_2), 1.97 (t, 2H, J = 8.3 Hz), 3.64 (3H, s), 6.71−6.75 (dd, 2H, J = 10 Hz), 7.29 (s, 1H), 7.32−7.31(d, 1H, J = 2.2 Hz). ^{13}C NMR ($CDCl_3$): δ 24.3, 28.10, 29.20, 30.02, 31.03, 32.24, 40.12, 50.10, 115.20, 113.89, 128.20, 129.25, 129.39,

160.15. HR-EIMS calcd for $C_{17}H_{34}B_{10}O$ (M^+): 362.3607. Found: 362.3585.

1-(4-Hydroxyphenyl)-7-(6-methylheptyl)-1,7-dicarba-*closo*-dodecaborane (I). To a solution of 1-(4-methoxyphenyl)-7-(6-methylheptyl)-1,7-dicarba-*closo*-dodecaborane (**2**) (90.5 mg, 0.25 mmol) in CH_2Cl_2 (5 mL) was added dropwise a 1 M solution of BBr_3 in CH_2Cl_2 (0.48 mL) at −78 °C. The mixture was stirred at room temperature for 2 h, then poured into ice water and extracted with CH_2Cl_2. The organic layer was washed with brine, dried over Na_2SO_4, and concentrated under vacuum. Purification by silica gel flash chromatography (hexanes/ethylacetate 8:2; R_f: 0.4) gave **I** in 56% yield. ^{1}H NMR ($CDCl_3$): δ 0.87−0.85 (d, 6H, J = 7.9 Hz), 1.10−1.64 (m, 9H, CH_2), 1.98 (t, 2H, J = 8.2 Hz), 6.68−6.70 (d, 2H, J = 8.6 Hz), 7.78−7.80 (d, 2H, J = 8.0 Hz). ^{13}C NMR ($CDCl_3$): δ 23.01, 27.40, 28.316, 29.86, 30.12, 30.45, 37.59, 39.20, 81.12, 86.41, 115.38, 128.50, 129.65, 156.181. HR-EIMS calcd for $C_{16}H_{32}B_{10}O$ (M^+): 348.3450. Found: 348.3453.

1-(4-Hydroxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane (II) was obtained by adapting the procedure described for compound **I** using 1-(4-methoxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane as the starting material. Purification by silica gel flash chromatography (hexanes/ethylacetate 8:2; R_f: 0.4) gave **II** in 50% yield. ^{1}H NMR ($CDCl_3$): δ 0.82−0.85 (d, 6H, J = 6.5 Hz), 1.09−1.36 (m, 9H, CH_2), 1.97 (2H, t, J = 8.0 Hz), 6.65−6.68 (d, 2H, J = 8.7 Hz), 7.24−7.28 (d, 2H, J = 8.7 Hz), ^{13}C NMR: δ 23.01, 26.37, 27.40, 28.31, 28.62, 29.86, 30.12, 30.54, 32.34, 34.09, 66.64 72.26, 128.29, 128.50, 129.65, 156.17. HR-EIMS calcd for $C_{16}H_{32}B_{10}O$ (M^+): 348.3450. Found: 348.3454.

1-(3-Hydroxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane (III) was obtained by adapting the procedure described for compound **I** using 1-(3-methoxyphenyl)-12-(6-methylheptyl)-1,12-dicarba-*closo*-dodecaborane as the starting material. Purification by silica gel flash chromatography (hexanes/ethylacetate 8:2; R_f: 0.4) gave **III** in 46% yield. ^{1}H NMR ($CDCl_3$): δ 0.82−0.84 (d, 6H, J = 6.6 Hz) 1.11−1.39 (m, 9H, CH_2), 1.99 (t, 2H, J = 8.3 Hz), 6.70−6.74 (dd, 2H, J = 10 Hz), 7.29 (s, 1H), 7.30−7.31 (d, 1H, J = 2.2 Hz). ^{13}C NMR ($CDCl_3$): δ 22.59, 26.97, 27.90, 29.45, 30.03, 37.20, 38.80, 68.54, 77.87, 114.98, 129.24, 134.07, 135.21, 145.10, 165.02. HR-EIMS calcd for $C_{16}H_{32}B_{10}O$ (M^+): 348.3450. Found: 348.3453.

RMS Fit of Cholesterol with Compounds I−III (Figure 2). *Hyperchem 7.51* (Hypercube, Inc., Gainsville, FL) was used on a Dell Inspiron 4100 to produce the rms fit of cholesterol with the carboranyl cholesterol mimics **I−III**. Carboranyl cholesterols **I−III** were energy-minimized with the HyperMMplus module, using the Polak−Ribiere conjugate gradient method and an energy gradient of 0.03 kcal mol^{-1} Å^{-1}. The minimized structures of **I−III** were then used for the rms fit with the energy-minimized structure of cholesterol. Appropriate side-chain carbons were used to obtain the optimal fit.

Polar and Apolar Surface Areas (PSAs/APSAs) of Cholesterol and Compounds I−III (Table 1). Parameters for minimized structures, generated as described in the previous section, were transferred to the *VEGA ZZ 2.0.4* software package (*38*) for the calculation of PSAs and APSAs. Analogous to previous theoretical studies involving carborane-containing compounds (*39*, *40*), boron atom types in the carborane clusters of compounds **I−III** were replaced with carbon atom types using *Hyperchem 7.51* before data transfer to *VEGA ZZ 2.0.4*.

Calculated LogP Values of Cholesterol and Compounds I−III (Table 1). LogP calculations were carried out using the *ChemDraw 7.0.1* version (CambridgeSoft Corporation, Cambridge, MA). This software package does not allow LogP calculations with compounds containing hexavalent boron and/or carbon atoms, as they can be found in the carborane cluster. Therefore, the carborane clusters in compounds **I−III** (Figure 1) were replaced with adamantane, because both cage structures are comparable in lipophilicity and dimensions (*41*). In order to mimic para and meta substitution patterns in compounds **I−III**, the 1,4(6,10)-position and 1,3(5,7)-position of the adamantane moiety were substituted appropriately. For validation, experimental LogP values of a series of twelve previously described carboranyl compounds (*42*) and the calculated LogP values of their virtual adamantane counterparts were fitted on a straight line to obtain the R^2 value. The obtained R^2 value of 0.92 indicated that the approximation of using adamantane instead of the carborane moiety for the theoretical calculation of the LogP values of carboranyl compounds with *ChemDraw* is acceptable.

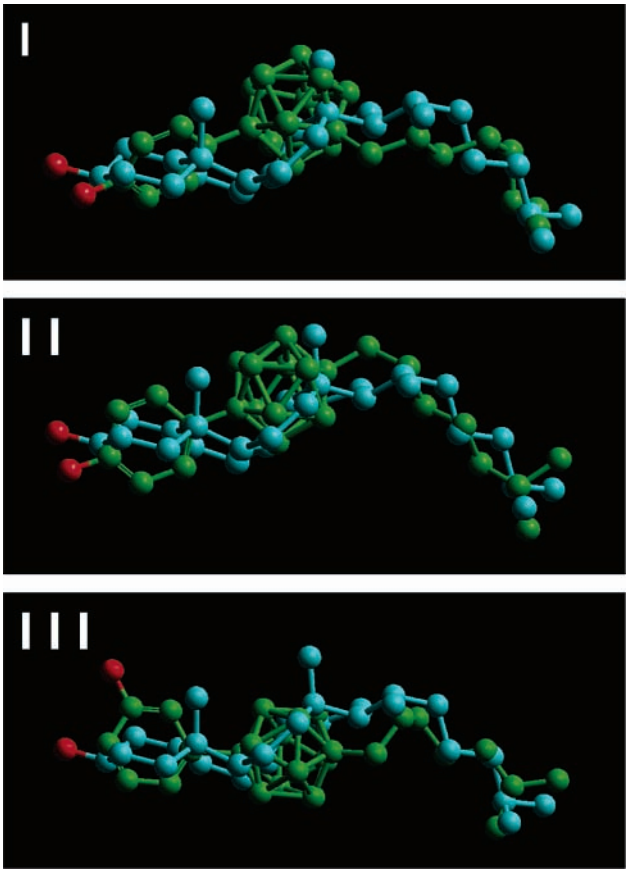

Figure 2. RMS fit of cholesterol with compounds **I−III**. Hydrogen atoms were omitted for the clarity. Cholesterol is shown in cyan and compounds **I−III** in green. For better orientation, oxygen atoms of all molecules are shown in red.

[a] See Experimental Procedures ("Calculated LogP Values of Cholesterol and Compounds I-III" and "Polar and Apolar Surface Areas (PSAs/APSAs) of Cholesterol and Compounds I-III") for detailed descriptions. [b] Cholesterol [experimental LogP: 7.445 (http://redpoll.pharmacy.ualberta.ca/drugbank)].

Materials for Biological Studies. Dipalmitoylphosphatidylcholine (DPPC) was purchased from Genzyme (Boston, MA). Monomethoxypolyethylene glycol(2000)−distearoylphosphati-

dylethanolamine (mPEG−DSPE) was purchased from Lipoid (Newark, NJ). Distearoylphosphatidylethanolamine−polyethylene glycol(2000)−maleimide (DSPE−PEG(2000)−maleimide) was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Cholesterol, calcein, and Sepharose CL-4B were purchased from Sigma (St. Louis, MO). Folate−polyethylene glycol-(2000)−cholesterol (folate−PEG−cholesterol) was synthesized as described previously (*43*). Spectra/Por DispoDialyzer dialysis tubes (1 mL, molecular weight cutoff [MWCO] 10 000) were purchased from Spectrum Lab (Rancho Dominguez, CA). Tissue culture media RPMI 1640 without folic acid, fetal bovine serum (FBS), and antibiotics were purchased from Life Technologies (Rockville, MD). The KB HeLa variant cell line (ATCC # CCL-17) was gift from Dr. Philip Low, Purdue University (West Lafayette, IN). The 293/KDR cell line, expressing 2.5×10^6 VEGFR-2/cell, has been described in detail previously by us (*44*). Nitric acid (trace metal quality) was purchased from Fisher Scientific (Pittsburgh, PA) and 18.2 MΩ−cm water was obtained from a Milli-Q laboratory purification unit (Millipore, Billerica, MA). Other materials and vendors are listed in the following: Mouse antihuman VEGF monoclonal antibody (Pharmingen, San Diego, CA); Anti-mouse IgG: horseradish peroxidase (HRP) conjugate (GE Healthcare, Piscataway, NJ), Enhanced Chemiluminescent (ECL) Plus kit (GE Healthcare, Piscataway, NJ), Anti-phosphotyrosine RC20 antibody conjugated to horseradish peroxidase (BD Transduction Labs, San Diego, CA), SLT (Shiga-like toxin)−VEGF (SibTech, Newington, CT), CellTiter 96 AQ_{ueous} One Solution Cell Proliferation Assay kit (Promega, Madison, WI).

Preparation of Liposomes. Nontargeted liposomes, control liposomes, and FR-targeted liposomes were prepared using the thin-layer evaporation method (*45*). The particle size was reduced by ultrasonication and extrusion. The compositions for each liposomal formulation were as follows: Nontargeted liposome (DPPC/compound **I**/mPEG−DSPE, 55:40:5 mol %), control liposome (DPPC/cholesterol, 55:45 mol %), and FR-targeted liposome (DPPC/compound **I**/mPEG−DSPE/folate−PEG−cholesterol, 55:40:4.5:0.5 mol %). Lipids were first dissolved in chloroform, dried to a thin film in a round-bottom flask under nitrogen, and then further dried using vacuum for 4 h. The dried lipid was then resuspended using 10 mM calcein solution and pulse-sonicated for 5 min. The resulting liposomal suspension was passed through a 100 nm polycarbonate membrane for five cycles using a high-pressure extruder (Northern Lipid, Vancouver, British Columbia, Cannada). A 10 mL Sepharose CL-4B column equilibrated with pH 7.4 phosphate buffered saline (PBS) was applied to separate the liposomal portions from low molecular weight components. Elutions were collected in 1 mL quantities and subjected to the determination of boron concentrations by inductively coupled plasma atomic emission spectroscopy (ICP-AES) as described in a following section on boron measurements.

(VEGFR-2)-targeted liposomes were prepared as follows: Cys-tagged single-chain VEGF (scVEGF) was constructed and expressed, as described previously (*46*). Briefly, two 3−112 aa long fragments of human $VEGF_{121}$ were fused head-to-tail and expressed with a N-terminal Cys-tag, a novel cysteine-containing 15-aa peptide tag for site-specific modification of recombinant proteins (*47*). scVEGF was site-specifically lipidated with DSPE−PEG(2000)−maleimide and incorporated into liposomes as follows: scVEGF was incubated with DSPE−PEG(2000)−maleimide at a molar protein to lipid ratio of 1:10 at ambient temperature for 2 h, then mixed with an equal volume of the nontargeted liposomal formulation of compound **I** described above and incubated at 37 °C for 16 h. Non-incorporated scVEGF was removed by chromatography on Sepharose CL-4B. Purified VEGF/liposomes were analyzed by Western blotting using mouse antihuman VEGF monoclonal antibody diluted 1:2000 followed by anti-mouse IgG−HRP conjugate diluted 1:10 000. The anti-VEGF antibody was visualized on the blots by the ECL Plus kit.

In Vitro Release Analysis of Liposomes. The in vitro release profiles of nontargeted liposomes, control liposomes, and FR-targeted liposomes were measured by both calcein release and determination of boron concentrations via ICP-AES. Briefly, 1 mL of Sepharose CL-4B column-purified liposome samples were added to 1 mL dialysis tubes (MWCO 10 000) and incubated in 500 mL PBS at 37 °C. Constant magnetic stirring (100 rpm) was applied to the dialysis beaker. At 24, 48, 72, and 96 h, 1 mL samples were taken from the beaker, and the released calcein was measured using a Perkin-Elmer spectrofluorometer (Wellesley, MA) with excitation and emission at 485 and 520 nm, respectively. Excitation and emission slits were set to 5 nm. The boron concentrations of liposomal suspensions before and after the dialysis were also measured by ICP-AES. The percentage of retention was calculated on the basis of normalization using the original concentration before dialysis.

Boron Uptake Study of Liposomes in FR-Positive KB Cells. KB cells were cultured as a monolayer in folate-free Roswell Park Memorial Institute (RPMI) 1640 media supplemented with penicillin, streptomycin, and 10% FBS in a humidified atmosphere containing 5% CO_2 at 37 °C. After reaching confluence, KB cells were collected with trypsin/ethylenediaminetetraacetic acid (EDTA), washed with PBS, and suspended in folate-free RPMI media at a density of 2×10^7 cells/mL. Boronated FR-targeted or nontargeted liposomes (40 μg/mL boron) were added to the media, and cells were incubated under CO_2 atmosphere at 37 °C for 2 h. Subsequently, cells were centrifuged at 400 g for 10 min, and the media was removed. Cells were washed twice with cold PBS by resuspension and centrifugation at 400 g. Cell pellets were then collected, and boron concentrations were determined by direct current plasma-atomic emission spectroscopy (DCP-AES) (*48*). All treatments and measurements were triplicated.

Functional Activity of (VEGFR-2)-Targeted Liposomal Formulations of Compound I. The functional activity of VEGF inserted into nontargeted liposomal formulations of compound **I** (see Preparation of Liposomes section) was evaluated in tissue culture using 293/KDR cells expressing 2.5×10^6 VEGFR-2/cell. Two functional assays, VEGFR-2 tyrosine autophosphorylation and protection of 293/KDR cells from VEGFR-2 mediated toxicity of the SLT−VEGF chimeric toxin, were carried out as described previously by us (*49*). Briefly, for VEGFR-2 autophosphorylation, 7.5×10^4 293/KDR cells were plated into 24-well plates. After 6 h, complete medium (Dulbecco's Modified Eagle Medium [DMEM]/10% FBS) was replaced with starvation medium (DMEM/0.5% FBS) and the cells were incubated for 16 h at 37 °C in 5% CO_2. Subsequently, the starvation medium was replaced with serum-free DMEM containing 0.5 mM sodium vanadate for 20 min at 37 °C; the cells were incubated with VEGF-2 or (VEGFR-2)-targeted liposomes for 10 min at 37 °C, lysed, and analyzed by Western blotting using anti-phosphotyrosine RC20 antibody conjugated to horseradish peroxidase. For the SLT−VEGF protection assay, 10^3 293/KDR cells were plated on 96-well plates. Varying amounts of (VEGF-2)-targeted liposomes were mixed with SLT−VEGF in complete medium (DMEM/10% FBS) and added to cells in triplicate wells to a final SLT−VEGF concentration of 1 nM. Cells were quantitated after 96 h incubation using a CellTiter 96 AQ_{ueous} One Solution Cell Proliferation Assay kit.

Transmission Electron Microscope (TEM) and Photon Correlation Spectroscopy (PCS) Analysis. The consistencies of nontargeted liposomes, control liposomes, and FR-targeted

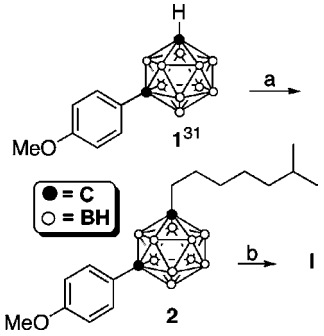
liposomes constructed with compound **I** were investigated with TEM after negative staining with uranyl acetate (UA) as described previously (*50*). Briefly, the liposomal samples were placed onto 100-mesh grids. After 3 min, excess solution was wiped off with filter paper, and the grid was immersed in 2% UA. The UA solution was removed after 1 min, and the grids were washed twice with 200 μL of distilled water. The grids were then imaged on a Philips CM 12 transmission electron microscope (Campus Microscopy and Imaging Facility, OSU, Columbus, OH). Photos were taken at 55 000-fold magnification from the suspended liposomal particles. The mean particle diameter and distribution were measured by PCS on a NICOMP particle sizer model 370 (Santa Barbara, CA), and the normalized Gaussian-distributed volume-weighted particle size was collected after 3 runs.

Boron Determinations. Boron concentrations of samples obtained from boron uptake studies with KB cells were obtained by DCP-AES, as described previously (*48*). Boron concentrations for all other samples were obtained by ICP-AES with a Varian VISTA AX ICP spectrometer system. The Varian argon-purged echelle spectrometer, which has a bandpass of $\leq$10 pm at wavelengths below 260 nm, enabled intensity measurements free of spectral interferences for the four neutral-atom boron lines used in this study: 208.889 nm, 208.956 nm, 249.678 nm, and 249.772 nm. All relative intensities for boron spectral lines were based on background-corrected peak heights. A charge-coupled device (CCD) detector, maintained at -34 °C by a Peltier cooler, generated all spectrum-based electronic signals processed by the spectrometer system. The central axial region of a 1.3 kW, 40 MHz ICP was aligned optically with the axis of the acceptance angle of the Echelle spectrometer. Sample solutions were injected into the high-temperature plasma as aerosols produced by a perfluoroalkoxy (PFA) nebulizer. The aerosols first passed through a 50 mL Polycon cyclone spray chamber from which fine aerosol particles were swept by an argon stream through a polytetrafluoroethylene (PTFE) tube and alumina injector tube into the plasma. In the plasma, free atoms and ions were produced and excited to emit quantized radiation. Calibration was achieved with one blank and four accurately diluted aliquots of a single-element standard solution. The boron concentration in the original standard was certified traceable to the National Institute of Standards and Technology (NIST) by the supplier, Inorganic Ventures (Lakewood, NJ). All dilutions, including those for samples, were accomplished in polyethylene tubes on a mass basis enabled by an analytical balance capable of measurements to 0.1 mg. The diluent was 0.5 M nitric acid in 18.2 M$\Omega-$cm water. Samples (1 mL) were diluted by factors that ranged from 3 to 15 to provide the 3 mL solution volume needed for nebulization into the ICP. Calibration functions were second-degree polynomial least-square regression fits with correlation coefficients greater than 0.995. Concentration values obtained by this approach generally are within 10% of actual concentrations. Certified reference materials were not available for further corroboration of accuracy.

RESULTS AND DISCUSSION

Design of Carboranyl Cholesterol Mimics. As already discussed in the Introduction, the design strategy for carboranyl cholesterol mimics described in this paper is based on the a replacement of the B and C rings of cholesterol with highly lipophilic *meta*- and *para*-carborane clusters (*31*, *32*). The dimensions of these clusters are approximately 50% larger than the space occupied by the three-dimensional sweep of a phenyl group (*51*). Figure 1 shows the structural resemblance of cholesterol and the carboranyl cholesterols mimics **I**−**III**. In order to further validate our design strategy, we calculated apolar and polar surface areas (APSAs, PSAs) as well as the LogP values of all compounds shown in Figure 1 prior to embarking on the synthesis of compounds **I**−**III**. Using *HyperChem 7.51* software, we also produced an overlay of energy-minimized structures of compounds **I**−**III** with that of cholesterol. The data are summarized in Figure 2 and Table 1. In particular, the structures of compounds **I** and **II** showed very good structural overlap with the structure of cholesterol, and APSAs, PSAs, and LogP values of all compounds were similar.

Scheme 1. Representative Synthesis of Carboranyl Cholesterol Mimics Using Compound I as the Example[a]



[a] Key: a, *n*-BuLi/toluene-4-sulfonic acid 6-methylheptyl ester/benzene/room temperature; b, BBr_3/CH_2Cl_2, room temperature.

Synthesis of Carboranyl Cholesterol Mimics. Encouraged by our computational studies, we carried out the syntheses of compounds **I**−**III** as shown in Scheme 1 by the example of compound **I**. Starting material for the synthesis of compound **I** was 1-(4-methoxyphenyl)-1,7-dicarba-*closo*-dodecaborane (Scheme 1, compound **1**), which was previously described by Endo et al. (*31*). For the syntheses of compounds **II** and **III**, 1-(4-methoxyphenyl)- (*31*) and 1-(3-methoxyphenyl)-substituted *para*-carborane (*31*), respectively, were used as starting materials. Compound **1** was reacted with toluene-4-sulfonic acid 6-methylheptyl ester (*37*) to afford compound **2**. The yields for compound **2** and its derivatives used in the syntheses of **II** and **III** ranged from 52% to 61%. The methoxy group in **2** was removed using boron tribromide in dichoromethane to afford target compound **I**. Target compounds **II** and **III** were obtained in a similar fashion, and yields for all three target compounds ranged from 46% to 56%. All intermediates and target compounds were purified effectively by silica gel column chromatography and characterized by ^{1}H NMR, ^{13}C NMR, and HR-EIMS. An important criterion for the synthesis of compounds **I**−**III** was practicability. All target compounds were synthesized from readily available starting materials. However, structural resemblance of carboranyl cholesterol mimics with cholesterol probably could be further improved by substituting the A ring of cholesterol with nonaromatic ring systems instead of using the phenyl group (*52*), methyl substitution at boron atoms of the carborane clusters (*53*), and insertion of a 2,6-dimethylheptane (*54*) rather than a 6-methylheptane side chain. However, such a structure would require multiple laborious reaction steps. It should be noted that, due to the high lipophilicity of all carboranyl compounds described in this paper, standard ESI-MS (electrospray ionization mass spectrometry) was unsuccessful, and EIMS had to be used.

Incorporation of Carboranyl Cholesterol Mimics into Liposomes. Compounds **I**−**III** were formulated into nontargeted liposomes using the thin-layer evaporation method (*10*), and the particle sizes and lamellarities were further defined using ultrasonication followed by extrusion. We characterized the incorporation efficiency using size-exclusion chromatography. Liposomal and free compound fractions were separated at different elution volumes, and the boron concentrations were measured by ICP-AES. The results, shown in Figure 3, indicated

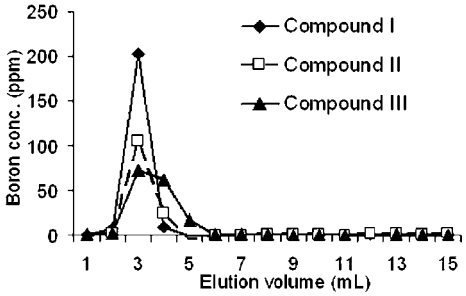


Figure 3. Incorporation of compounds **I**−**III** into liposomes. The preparation for the liposomes are described in Experimental Procedures (composition = DPPC/compound **I**−**III**/PEG−DSPE, 55:40:5 mol %). Encapsulation of boron compounds was determined by eluting 0.5 mL liposomal samples through a 10 mL Sepharose CL-4B column with pH 7.4 PBS. Fractions were collected for determination of boron concentrations by ICP-AES. The encapsulation efficiencies were 99.7% for compound **I**, 94.3% for compound **II**, and 96.8% for compound **III**.

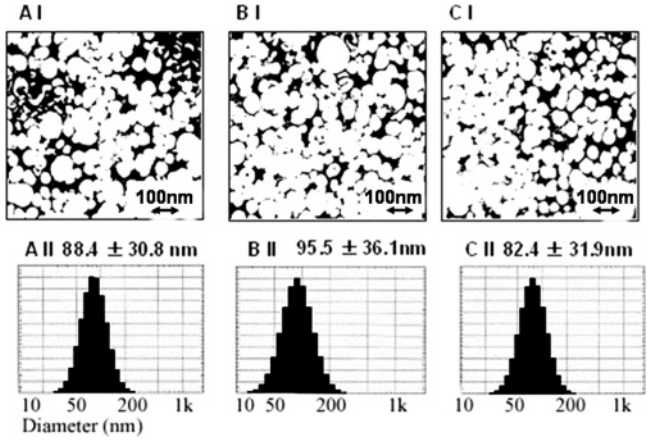

Figure 4. Characterization of size distribution and lamellarity of liposomal formulations of compound **I**. (A) nontargeted boronated liposome; (B) non-boronated control liposome (DPPC/cholesterol); (C) FR-targeted boronated liposome. (I) Morphology of the liposomes visualized by transmission electronic microscopy (TEM). Negative staining was applied to observe the particle size and lamellarity of liposomes. Formation of small unilamellar vesicle (SUV) was confirmed for all three formulations of compound **I**. (II) Particle sizes measured by photon correlation method. Numbers shown are the mean particle size ± standard deviation (volume-weighted) of the individual samples.

that all three compounds had >90% incorporation efficiency (**I** = 99.7%, **II** = 94.3%, and **III** = 96.8%). For all liposomal formulations prepared subsequently from compound **I** for in vitro release and cell uptake studies, >90% incorporation efficiency was confirmed with the same method (data not shown). Samples for in vitro release and cell uptake studies were all purified using the Sepharose CL-4B column to eliminate free compound. Compound **I** was selected for all further studies because of its good structural overlap with cholesterol (Figure 2) and its high incorporation efficiency.

Size and Lamellarity Characterization of Liposomal Formulations of Compound I. For liposomal delivery of BNCT agents, as well as other anticancer therapeutics, the size distribution and lamellarity of liposomes are of great importance for parameters such as stability, drug release profile, in vivo half-life, and tissue distribution. Small, homogeneous, and unilamellar particles are preferred for optimal delivery to malignant tissues, as they are able to escape reticular endothelial system (RES) uptake (*55*). We applied TEM and PCS for the analysis of the physical properties of conventional, nontargeted, and FR-targeted liposomes. After negative staining, both FR-targeted and nontargeted liposomal formulation of compound **I** were inspected with TEM (Figure 4AI,CI) for particle size distribution and lamellarity observation. As a control, conventional liposomes (DPPC/cholesterol [55:45 mol %]) were also constructed under identical conditions and analyzed accordingly (Figure 4BI). Since the TEM method does not allow the particle size quantification, the same samples were also analyzed for mean particle size and distribution using a laser particle sizer in parallel (Figure 4AII,CII). Data presented in Figure 4 demonstrate that homogeneous small unilamellar vesicles (SUVs) were formed by using compound **I** both for nontargeted and FR-targeted liposomal formulations. The mean particle sizes for all three formulations ranged from 82.4 to 95.5 nm with size distributions around 30−40 nm. No major differences were found in appearance, size distribution, and lamellarity between conventional DPPC/cholesterol liposomes, nontargeted, and FR-targeted liposomal formulations of compound **I**.

In Vitro Release of Liposomal Formulations of Compound I. The performance of boron-containing liposomes in vivo is highly affected by the stability of incorporation of the boron entities. Therefore, a standard in vitro release experiment (*56*) was conducted using PBS as the media at 37 °C, and the stability of incorporation of compound **I** in both FR-targeted and nontargeted liposomal formulation was evaluated. Control liposomes were constructed with cholesterol instead of compound **I**, and thus, calcein, a green fluorescent dye, was encapsulated into the liposomal hydrophilic compartment of all liposomal formulations to analyze stability via fluorescence measurements of calcein release. Samples were taken at different time points beginning at 0.5 h after the initiation of incubation, and calcein release was measured by absorbance (Figure 5A). Boron concentrations of samples obtained at 0 and 96 h were determined by ICP-AES (Figure 5B). Overall, both data sets indicate that a 45% molar ratio of compound **I** was stably incorporated into the vesicles and that the release of calcein followed a pattern similar to that of conventional DPPC−cholesterol liposomes. For both the nontargeted and FR-targeted formulation, the calcein release was less than 30% at 24 h, which was not significantly different from the control liposome. At later time points, however, the targeted formulation appeared to release calcein, and presumably also boron, at an increased rate. This could be due to insufficient anchoring of folate−PEG−cholesterol to the lipid bilayer or even the degradation of this receptor-targeting ligand. We have made similar observations previously in studies using doxorubicin as the incorporated compound (X.B. Zhao, unpublished results). Nevertheless, nontargeted liposomal formulations showed a release profile comparable to that of the control liposomes, with more than 50% calcein and boron remaining unreleased at 96 h. The release rate of FR-targeted liposomes at least until 48 h should be sufficient for selective receptor-mediated boron delivery to tumor cells for BNCT.

In Vitro Uptake of FR-Targeted Liposomal Formulations of Compound I. We determined the in vitro delivery of compound **I** to KB cells, an established FR-expressing cell line (*57*), in the form of nontargeted liposomal formulations as well as in FR-targeted liposomal formulations in the presence and absence of free 5 mM free folate. No significant cytotoxicity was noted during the 4 h incubation time based on a microscopic inspection of the cells. Cellular uptake of the liposomes was determined by measuring cell-associated boron concentrations with DCP-AES (*48*). The obtained data are summarized in Figure 6. The nontargeted liposomal formulation of compound **I** appeared to bind in a nonspecific way to KB cells (30 μg boron/g cells), which have a very low background level of boron (<1 μg boron/g cells; data not shown) in cell culture environment. Specific targeting to FR was demonstrated by increased boron levels for FR-targeted liposomal formulation of compound

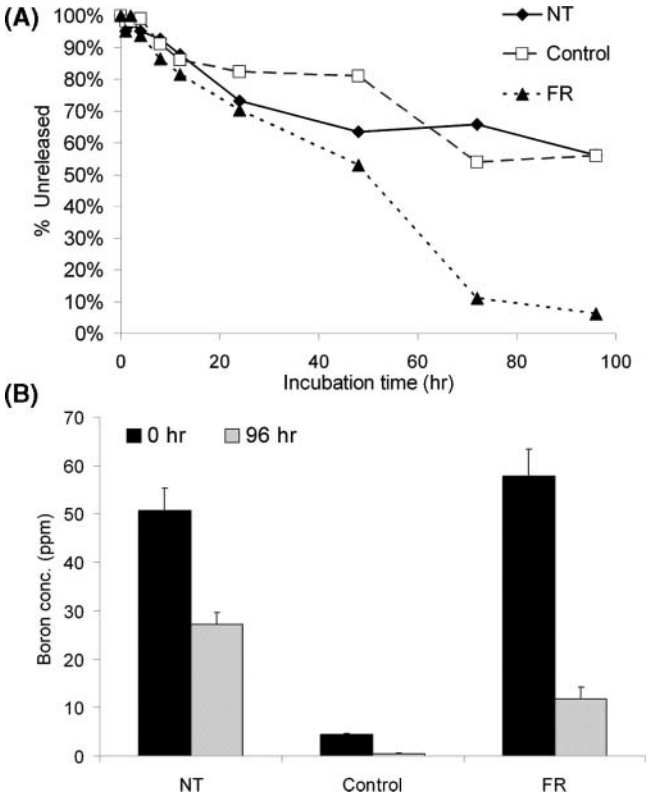

Figure 5. In vitro release profile of liposomal formulations of compound **I** in pH 7.4 PBS at 37 °C. (A) Compound **I** was formulated into liposomes with different compositions as described in Experimental Procedures. In parallel, DPPC/cholesterol control liposomes without boron components were prepared using the same protocol. All liposomal formulations contain a 10 mM solution of calcein. The percentage of calcein release was determined by fluorescence and absorbance measurements. (B) Boron concentrations of the liposomal suspensions were measured at 0 and 96 h by ICP-AES. NT: boronated liposomes (nontargeted). Control: control liposomes (no boron). FR: FR-targeted boronated liposomes. Error bars shown in Figure 5B are based on standard deviations calculated from three measurements.

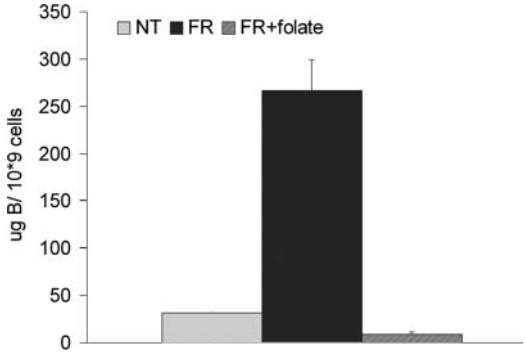

Figure 6. Cellular uptake of liposomal formulations of compound **I**. NT: Nontargeted boronated liposomes. FR: FR-targeted boronated liposomes. FR + folate: FR-targeted boron-containing liposomes were coincubated with 5 mM free folate. 2×10^7 cells in 1 mL media were incubated with liposomes containing 40 μg/mL boron. Each data point represents the mean of boron amount in the cell lysates normalized to 1×10^9 cells (equivalent to 1 g tissue). Error bars stand for standard deviations of the normalized boron amount in triplicates.

I (267 μg/g cells). FR specificity was further demonstrated by the reduction of the boron concentration of FR-targeted boronated liposomes that were incubated with KB cells in the presence of 5 mM free folate (9 μg/g cells). All three liposomal formulations were colabeled with calcein, and specific binding was also confirmed by the increased fluorescence intensity in KB cells treated with FR-targeted boronated

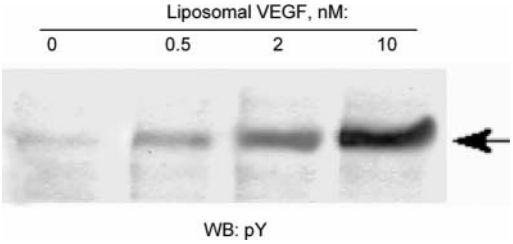

Figure 7. (VEGFR-2)-targeted liposomes induce VEGFR-2 autophosphorylation in a dose-dependent manner. 293/KDR cells were stimulated with the indicated concentrations of liposomal scVEGF, and tyrosine phosphorylation of VEGFR-2 was determined by Western blotting with an anti-phosphotyrosine RC20−HRP conjugate. The arrow indicates the position of VEGFR-2.

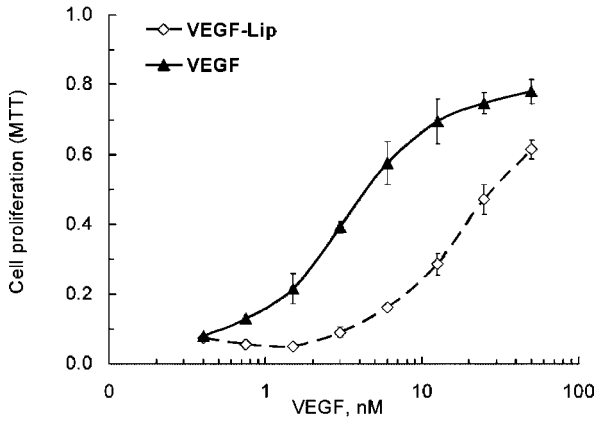

Figure 8. Boronated (VEGFR-2)-targeted liposomes protect VEGFR-2 expressing 293/KDR cells from SLT−VEGF-induced cell death. 293/KDR cells were exposed to boronated (VEGFR-2)-targeted liposomes (VEGF-Lip) or scVEGF (VEGF) that was serially diluted in a complete culture medium containing 1 nM SLT−VEGF.

liposomes, as demonstrated by fluorescence microscopy (data not shown).

(VEGFR-2)-Targeted Liposomal Formulations of Compound I. The purpose of these studies was to establish that liposomal formulations of compound **I** are also effective in targeting cell receptors other than FR. For this purpose, nontargeted liposomal formulations of compound **I** were decorated with a novel single-chain VEGF (scVEGF) that comprises two 3−112-aa-long fragments of human $VEGF_{121}$ fused head-to-tail (*46*) and expressed with a N-terminal 15-aa Cys tag, a novel cysteine-containing peptide tag for site-specific modification of recombinant proteins (*47*). Cys-tagged scVEGF was site-specifically lipidated with DSPE−PEG(2000)−maleimide at the molar lipid/protein ratio 10:1, and the reaction mixture was added to a nontargeted liposomal formulations of compound **I** for a so-called postinsertion of lipidated scVEGF into the liposomal membrane, as described in Experimental Procedures.

After purification on Sepharose CL-4B, the concentration of scVEGF in the liposomal formulations of compound **I** was determined by Western blot analysis, and the functional activities of the VEGF moiety were tested in two different tissue culture assays. In a short-term (10 min) assay, we tested the ability to induce VEGFR-2 tyrosine autophosphorylation in 293/KDR cells (*44*, *47*, *49*), and in a long-term (72−96 h) assay, we tested the ability to protect 293/KDR cells from VEGFR-2 mediated toxicity of the chimeric toxin SLT−VEGF, comprising a catalytic subunit of Shiga-like toxin and $VEGF_{121}$ (*47*, *49*). As shown in Figures 7 and 8, liposomal (VEGFR-2)-targeted formulations of compound **I** effectively activated VEGFR-2 autophosphorylationin 293/KDR in a nanomolar range typical for these cells (*44*) and protected 293/KDR cells from SLT−

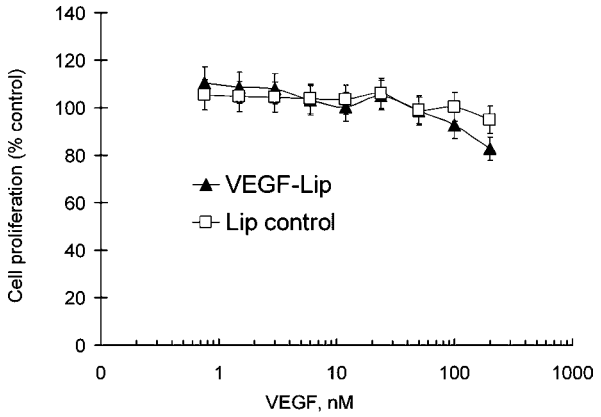

Figure 9. (VEGFR-2)-targeted boronated liposomes are not toxic to VEGFR-2 expressing cells. 293/KDR cells were exposed to indicated amounts of (VEGFR-2)-targeted boronated liposome (VEGF-Lip) or volume equivalents of nontargeted boronated liposomal formulation of compound **I** (Lip control).

VEGF cytotoxicity, although not to the same extent as parental scVEGF. When taken together, these data indicate that boronated (VEGFR-2)-targeted liposomes are indeed effective in targeting VEGFR-2 expressing cells. Furthermore, the data suggest that these liposomes most likely will be internalized via VEGFR-2-mediated endocytosis, as has been demonstrated by us for (VEGFR-2)-targeted liposomes loaded with doxorubicin (*58*).

The cytotoxicity of the (VEGFR-2)-targeted liposomal formulation of compound **I** was evaluated in 293/KDR cells. The cells were plated at low density (1000 cells/well) and allowed to grow for 96 h in the presence of different amounts of either (VEGFR-2)-targeted or nontargeted liposomal formulations of **I**. The obtained results (Figure 9) indicate that neither liposomal formulation affected significantly the growth of 293/KDR cells. Given the recently reported rapid receptor-mediated internalization of VEGF-targeted therapeutic liposomes by 293/KDR cells (*59*), one can expect that these cells also internalize the (VEGFR-2)-targeted liposomal formulations of **I** and that the internalized liposomes are not toxic in the absence of neutron irradiation.

SUMMARY AND CONCLUSIONS

Three carboranyl cholesterol derivatives were synthesized and analyzed applying novel molecular design concepts. All three compounds have structural features and physicochemical properties that are very similar to those of cholesterol. One of the synthesized boronated cholesterol mimics (compound **I**) was stably incorporated into non-, FR-, and (VEGFR-2)-targeted liposomes. No major differences were found in appearance, size distribution, and lamellarity between conventional DPPC/cholesterol liposomes, nontargeted, and FR-targeted liposomal formulations of compound **I**. The calcein release properties of conventional DPPC/cholesterol liposomes and nontargeted boronated liposomes were comparable and were reflected by the boron release rate of the latter. The calcein and boron release rates of FR-targeted boronated liposomes were higher than those of nontargeted boronated liposomes, but the overall stability of the latter was acceptable for the purpose of tumor-selective boron delivery for BNCT. There was no apparent in vitro cytotoxicity to FR overexpressing KB cells and VEGF overexpressing 293/KDR cells when these were incubated with boronated FR- and (VEGFR-2)-targeted liposomal formulations, respectively, although the former accumulated extensively in KB cells, and the latter effectively interacted with VEGFR-2 by causing autophosphorylation and protecting 293/KDR cells from SLT−VEGF cytotoxicity. These results convincingly demonstrate that the novel carboranyl cholesterol mimics are excellent lipid bilayer components for the construction of nontargeted and receptor-targeted boronated liposomes for BNCT of cancer.

Cholesterol-Linked Fluorescent Molecular Beacons with Enhanced Cell Permeability

Young Jun Seo,[†] Hyun Seok Jeong,[†] Eun-Kyoung Bang,[†] Gil Tae Hwang,[†] Jong Ha Jung,[‡] Sung Key Jang,[‡] and Byeang Hyean Kim*,[†]

National Research Laboratory, Department of Chemistry, and Department of Life Science, Division of Molecular and Life Sciences, Pohang University of Science and Technology, San 31 Hyoja Dong, Pohang 790-784, Korea. Received March 29, 2006; Revised Manuscript Received July 29, 2006

We appended pyrene units covalently onto adenosine (forming A^P units) and then incorporated them into oligonucleotides such that they were positioned in complementary locations in opposite strands in the middle positions of hairpin stems. System **1** (A^PA^P) behaves as an effective molecular beacon (MB) that changes color from green to blue upon duplex formation. In addition, we attached a cholesterol unit to a free terminus of one of these hairpins; this approach enhanced the cellular delivery of the modified MB relative to those encountered when using conventional transfection methods. These structurally simple cholesterol-based MB systems, which can be synthesized very efficiently, have good potential for opening up new and exciting opportunities in the field of in vivo biosensors.

INTRODUCTION

The detection of the molecular dynamics of DNA and RNA in living cells is becoming one of the most rapidly growing areas of research among all of the comprehensive investigations into the genomic information provided by nature (*1*). Such studies are aimed at providing information regarding the biological functions of DNA and RNA, the roles they play in disease, and their uses as (or interactions with) novel types of drugs. Fluorescence biosensors are powerful tools for probing the structures and interactions of biomolecules, but a strong demand exists for increasingly more advanced biomolecular recognition probes (*2*). We are interested in preparing chemically modified fluorescence biosensors, especially those exploiting $\pi-\pi$ stacking interactions, that can also be used to investigate nucleic acid interactions and structures (*3*−*5*). One of the most useful aromatic planar dyes is pyrene, and its fluorescence has been utilized widely for detecting the DNA and RNA structures (*6*−*8*).

Among the most useful probe systems for detecting molecular dynamics are the molecular beacons (MBs) (*9*−*11*). Unfortunately, these systems are somewhat limited for use as oligonucleotide probes in vivo, because they are difficult to transfect into cells due to their polar anionic backbones and bulky structures. Even though there is much demand for materials that enhance the transfection efficiencies of materials suitable for studying the dynamics of mRNA and DNA, the only means possible at present are the use of transfection agent, microinjection and electroporation techniques. General transfection techniques, such as those employing liposomes or dendrimers, often result in false positive signals and significantly increase the aggregation signal in the endosomes (*12*−*14*); microinjection (*15*) and electroporation (*16*) are invasive and may cause severe damage to cells.

To overcome these difficulties, we have developed novel cholesterol-linked MBs. The cholesterol unit positioned at the 5′ terminus of the hairpin MB allows these systems to enter into living cells efficiently without the need for any other transfection agent. Although there have been many research reports published in this area (*17*−*22*), to the best of our knowledge there are no papers describing cholesterol-containing MBs whose signal formation occurs through aromatic stacking within the stem of a hairpin. In this paper, we report such a system and demonstrate how it can be utilized effectively in vivo.

EXPERIMENTAL PROCEDURES

Synthesis of Cholesterol Monomer Cholesterol-3-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite. Chloro-(2-cyanoethoxy)-*N*,*N*-diisopropylaminophosphine (225 mg, 0.95 mmol) was added to a solution of cholesterol (261 mg, 0.67 mmol) and 4-methylmorpholine (223 mg, 2.20 mmol) in CH_2Cl_2 (7 mL). After stirring the reaction mixture at room temperature for 5 min, the solution was washed with 5% aqueous $NaHCO_3$. The organic layer was dried (Na_2SO_4) and concentrated under reduced pressure. Purification by flash chromatography (ethylacetate/hexane 1:7) provided the product as a white solid (277 mg, 70%). ^{1}H NMR (300 MHz, $CDCl_3$) δ = 5.31 (m, 1H), 3.77 (m, 2H), 3.58 (m, 3H), 2.60 (t, J = 6.3 Hz, 2H), 2.34 (m, 2H), 2.00−1.79 (m, 6H), 1.65−1.05 (m, 32H), 0.98 (s, 6H), 0.89 (d, J = 6.3 Hz, 6H), 0.84 (d, J = 6.5 Hz, 6H), 0.65 (s, 3H); ^{13}C NMR (75.5 MHz, $CDCl_3$) δ = 140.8, 140.6, 121.8, 121.7, 117.6, 74.1, 74.1, 73.9, 73.8, 58.4, 58.2, 56.8, 56.2, 50.1, 43.1, 42.9, 42.3, 39.8, 39.6, 36.2, 35.8, 31.9, 28.3, 28.0, 24.8, 24.7, 24.5, 24.4, 24.3, 23.9, 22.9, 22.6, 21.1, 19.4, 18.8, 11.9; ^{31}P NMR (121 MHz, $CDCl_3$) δ = 148.3, 148.2; IR (neat) υ = 3749.8, 3734.4, 2964.7, 2962.3, 2902.5, 2867.4, 2252.8, 1465.0, 1457.6, 1363.7, 798.8, 731.1, 1183.0, 1060.1, 1031.4, 975.4, 798.8, 731.1 cm^{-1}; HRMS (FAB) calcd for $C_{36}H_{63}N_2O_2P$ 586.4627 $[M + Na]^+$; found 609.4525.

Synthesis of Oligonucleotides. The phosphoramidite A^P and cholesterol were introduced as building blocks to produce fluorescent oligodeoxynucleotides (ODNs) on a controlled-pore glass (CPG) solid support by using the phosphoramidite approach and an automated DNA synthesizer (Perceptive Biosystems 8909 Expedite Nucleic Acid Synthesis System). For comparison, the unmodified ODNs were also prepared. The synthesized oligonucleotides were cleaved from the solid support upon treatment with 30% aqueous NH_4OH (1.0 mL) for 10 h

at 55 °C. The crude products from the automated ODN synthesis were lyophilized and diluted with distilled water (1 mL). The ODNs were purified by HPLC (Merck LichoCART C18 column; 10 × 250 mm; 10 μm; pore size: 100 Å). The HPLC mobile phase was held isocratically for 10 min with 5% acetonitrile/0.1 M triethylammonium acetate (TEAA) (pH 7.0) at a flow rate of 2.5 mL/min. The gradient was then increased linearly over 10 min from 5% to 50% acetonitrile/0.1 M TEAA at the same flow rate. The fractions containing the purified ODN were cooled and lyophilized. 80% aqueous AcOH was added to the ODN. After 30 min at ambient temperature, the AcOH was evaporated under reduced pressure. The residue was diluted with water (1 mL), and this solution was then purified by HPLC using the same conditions as those described above. The ODNs were analyzed by HPLC (Hewlett−Packard, ODS Hypersil; 4.6 × 200 mm; 5 m; 79916OD-574) using almost the same eluent system. For characterization, matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometric data of the fluorescent ODNs were collected using a PE Biosystems Voyager System 4095 instrument operated in the positive-ion mode and a 1:1 mixture of 3-hydroxypicolinic acid (0.35 M) and ammonium citrate (0.1 M) as the matrix; the accelerating voltage was 25 kV.

Steady-State Fluorescence Measurements. Steady-state fluorescence (FL) spectra were recorded using an MD-5020 PTI model microscope photometer operating at a bandwidth of 15 nm and quartz cuvettes (0.5 × 2 cm) having a light pass length of 1 cm. The cell holder was thermostatted with circulating water that was controlled using a PolyScience digital temperature controller 9110. An excitation wavelength of 386 nm was used; all excitation and emission slits were set to 1 nm. All hybridizations and fluorescence experiments were performed in 1 mM $MgCl_2$/100 mM Tris−HCl buffer (pH 8) containing a one-to-one ratio of complementary ODNs at a duplex concentration of 1.5 μM.

Cell Culture and Transfection. Monolayers of human hepatoma cell line Huh7 were grown in Dulbecco's Modified Eagle's Medium (DMEM; Gibco-BRL), 10% FBS (Hyclone), penicillin, and streptomycin. For fluorescence microscopy imaging, the coverslips were washed with HCl and rinsed with distilled water. 0.5% gelatin-coated coverslips were placed in 6-well dishes; culture cells were grown directly on the coverslips, with up to 80% confluence. Each ODN was diluted in serum-free DMEM to a final concentration of 40 nM. The cells were washed with phosphate-buffered saline (PBS); serum-free media containing each ODN (2 mL) were added to the cells grown on the coverslips. The lipofectamine 2000 reagent (Invitrogen) was used to compare the transfection efficiencies of the different delivery methods. Transfection assays were performed according to the manufacturer's instructions.

Image Acquisition and Processing. After incubation with an MB for the indicated time, the cells were washed three times with PBS and then fixed with 3.5% (w/v) paraformaldehyde (Sigma) at room temperature (RT) for 12 min. After being washed three times with PBS, the coverslips were placed on a glass slide and then sealed with transparent nail polish. The fluorescence images were captured using a cooled charge-coupled device camera and a Zeiss Axioplan microscope (Jena, Germany). Data were processed using *Adobe Photoshop* software (Mountain View, CA).

Cellular Uptake of the Cholesterol-Bearing MB. The amount of ODN present within the transfected cells was quantified using a SPECTRAmax GEMINI microplate spectrofluorometer (Molecular Device). Huh7 cells were seeded onto 48-well culture dishes before transfection. 40 nM ODN solutions in serum-free DMEM were used in the transfection analyses. Cell extracts were collected after lysis of the cells (the cell lysis had been performed through the addition of lysis buffer). The fluorescence intensity was recorded with the excitation wavelength set at 386 nm and the emission wavelengths set at 450 and 510 nm. Concurrently, the total cell mass was determined using the BCA method (Pierce, Rockford, IL).

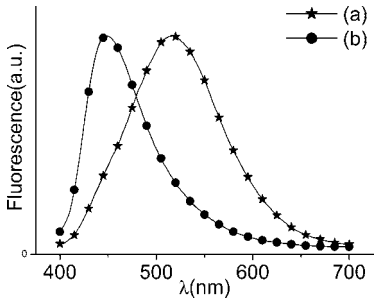

Figure 3. Fluorescence spectra of (a) ODN **3** (λ_{max} = 509 nm) and (b) the perfectly matched duplex **3·5** (445 nm). The conditions were the same as those described in Figure 2.

RESULTS AND DISCUSSION

Design of Functional Oligonucleotides. We synthesized pyrene-modified nucleoside building blocks through Sonogashira coupling of pyrene units to the 8-position of a 2′-deoxyadenosine base (i.e., to form 8-(1-ethynylpyrenyl)-2′-deoxyadenosine; A^{P}) (*23*). The quantum yields of A^{P} are very high: 81% and 89% in $CHCl_3$ and MeOH (*23*), respectively. We incorporated A^{P} into oligodeoxynucleotides (ODNs) by using the phosphoramidite method and the aid of a DNA synthesizer. We constructed modified single-stranded ODN **1** in which the two fluorophores were positioned in opposite strands of the stem of each hairpin. We also synthesized a perfectly matched sequence **2** for hybridizing to the loop regions of ODN **1**. We synthesized a cholesterol-bearing MB system (ODN **3**) that is complementary to ODN **5**. We also synthesized the corresponding unmodified ODN **4** to compare the transfection properties between two systems (Figure 1).

Cholesterol-Bearing MB. *In Vitro Fluorescence Changes.* Figure 2 displays the fluorescence spectra of A^{P}A^{P}. Interestingly, **1** (existing in its hairpin state) emits a strongly red-shifted band

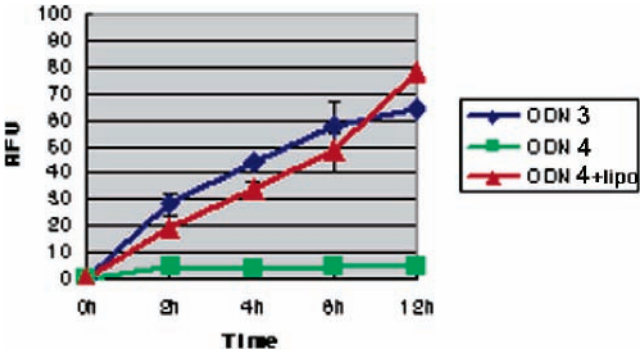

Figure 4. Time-dependent cellular uptake of ODNs **3** and **4** in the absence and presence of lipofectamine ("lipo"). The fluorescence intensities were recorded with the excitation wavelength set at 386 nm and the emission wavelengths set at 510 nm. Concurrently, the total cell mass was determined using the BCA method (Pierce, Rockford, IL).

(λ_{max} = 521 nm; Figure 2a); in comparison, the value of λ_{max} of the duplex **1·2** is 450 nm (Figure 2b).

On the basis of the results presented above, we prepared a cholesterol-bearing ODN incorporating a cholesterol unit at the 5′ end of the hairpin; because the 5′ and 3′ termini of ODN **1** are unsubstituted, it is very easy to use an ODN synthesizer to modify them with functional molecules. Thus, we synthesized a cholesterol-bearing MB system (ODN **3**) that is complementary to the ODN **5**. We also synthesized the corresponding unmodified ODN **4** to compare the two systems' transfection properties. Figure 3 displays the change in the appearance of the fluorescence spectrum of ODN **3** after the addition of its target sequence, ODN **5**. The spectra suggest that, even though we had attached a cholesterol moiety at the 5′ end of the MB, the photophysical signals of the MB system remained unaffected. We believe that the strongly red-shifted band at 509 nm must arise from stacking interactions between the two pyrene units of A^P. In our fluorescence experiments. specific origin of this red-shifted band comes from an exiplex or merely that of a dimer of the two pyrene units. Fluorescence wavelengths are very close to that of a typical pyrene excimer (*24*), suggesting that the excited complex of each fluorophore was formed in the hairpin state.

In Vivo Fluorometry. Our cholesterol-bearing MBs can enter into living cells efficiently without the need for any transfection agent (Figure 4). The transfection efficiency of the MB conjugated with cholesterol (ODN **3**, blue curve) during the first 12 h in Huh7 cells was much higher than that of the unmodified MB (ODN **4**, green curve); we observed essentially no signal for the latter, even after 12 h. For the sake of comparison, the unmodified ODN **4** was transfected with a commercial transfection reagent, lipofectamine ("ODN **4** + lipo," red curve). The fluorescence obtained when using the transfection reagent (lipofectamine) was similar to that of the cholesterol-linked MB.

In Vivo Fluorescence Microscopy. We performed a fluorescence microscopy experiment to observe the transfection pattern of the cholesterol-bearing MB in Huh7 cells. Figure 5 displays

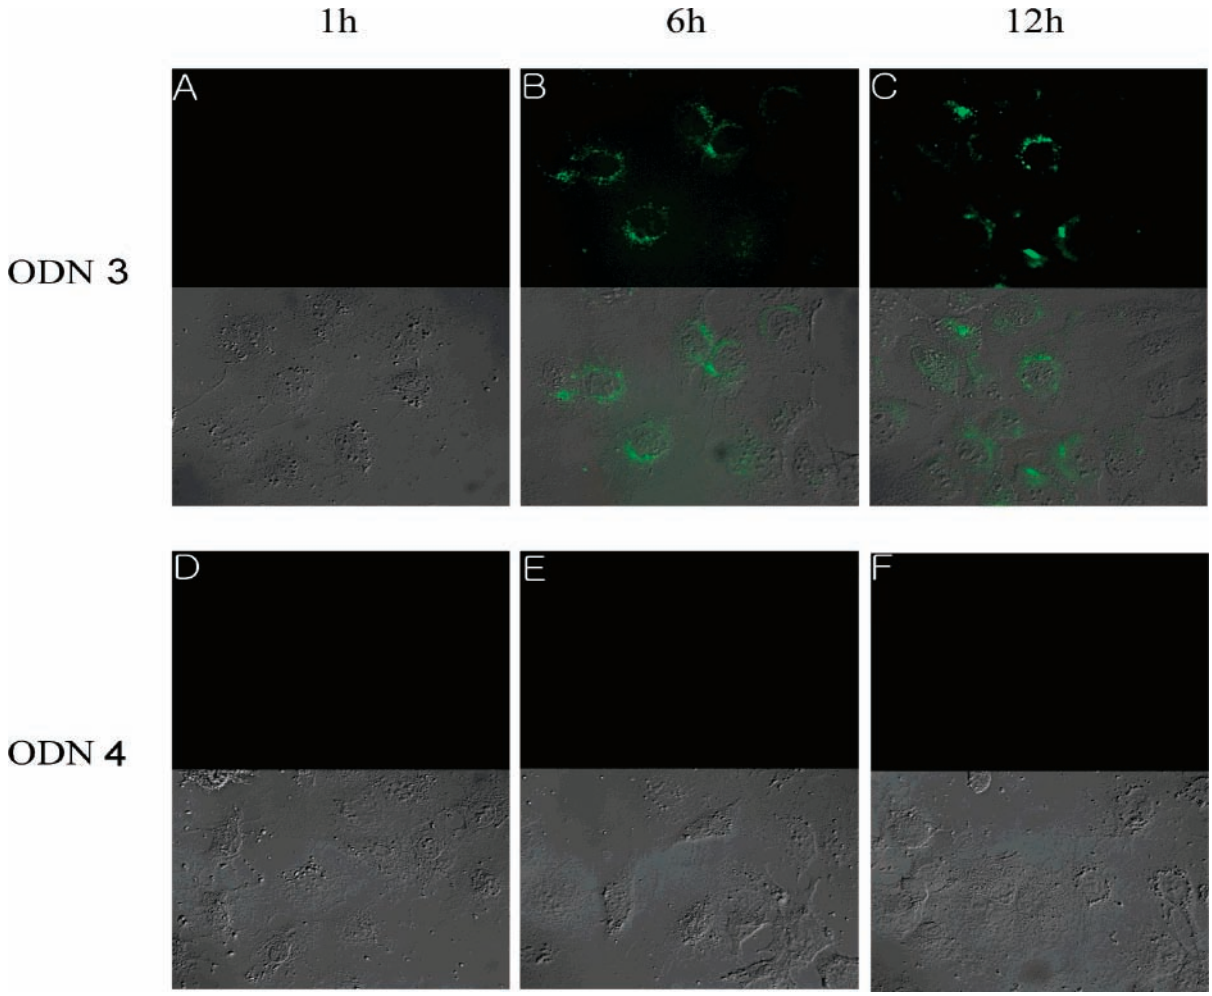

Figure 5. Cellular delivery of MBs in Huh7 cells. (A−C) Fluorescence signals of cholesterol-conjugated ODN **3** transfected into Huh7 cells at different times (p.t.). Fluorescence signals of ODN **3** were not observed at 1 h p.t., but were detected in the cytoplasm around the nucleus at 6 and 12 h p.t. (D−F) Fluorescence of the unmodified ODN **4** after the indicated times (p.t.). The upper panels present the fluorescence signals of the MBs; the lower panels represent a combination of the images in the upper panels and the phase-contrast images of the cells.

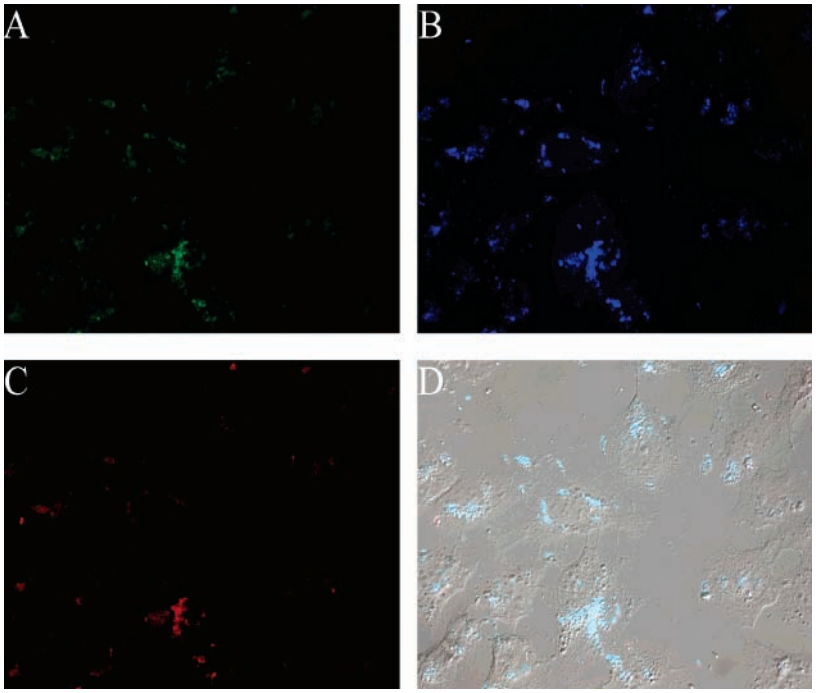

Figure 6. Cellular delivery of ODN **4** when using the lipofectamine reagent. (A−C) Fluorescence signals in Huh7 cells after transfection of the unmodified MB with lipofectamine for 12 h. Each emission filter accepted a different range of wavelengths: (A) 410−490 nm; (B) 508−523 nm; (C) >570 nm. (D) The three separate images from A−C (coded blue, green, and red, respectively) merged into a single image.

the cellular transfection property as imaged directly in vivo. Consistent with our fluorometry experiments, these images clearly demonstrate that the cellular transfection of the ODN **3** (bearing the cholesterol unit) is far better than that of ODN **4** (without cholesterol) and that obtained by using the conventional transfection agent (Figure 6). Indeed, in the case of ODN **4**, we observed no signal, as expected, whereas ODN **3** displayed extremely strong signals in the cytoplasm. To demonstrate whether the ODN **3** reached the cytoplasm of cells, double-fluorescence staining experiments were carried out with Lysotracker (see Supporting Information). In the presence of the transfection reagent (lipofectamin), ODN **4** displayed different characteristics than did the cholesterol-linked ODN **3**. Specially, the fluorescence signals obtained by using lipofectamin were concentrated in random "bright spots" in both the cytoplasm and the nucleus, indicating the aggregation pattern (Figure 6). We observed a similar trend after we transfected other oligonucleotides with lipofectamin in Huh7 cells (data not shown). However, we did not observe any cross-signal or nonspecific aggregated bright spots (compare Figure 5 to Figure 6) in our MB system. Therefore, our MB system is more efficient than one using the transfection agent. We are now investigating the ability of using such MB systems to fluorescently detect the dynamic pathway of hepatitis C virus in living cells.

CONCLUSION

Systems **1** (A^PA^P) individually exhibit aromatic stacking between the opposing pyrene units in the stems of their hairpins; their spectra display the characteristics of π-stacked pyrene units. Systems **1** (A^PA^P) can be used as effective MBs that change color from green to blue upon duplex formation. These novel types of MBs are relatively simple to synthesize, and their termini remain free for the introduction of other useful functionalities. We introduced a cholesterol unit into one terminus of an MB and demonstrated clearly that the cellular delivery of this modified MB was enhanced significantly relative to those obtained by using the corresponding unmodified MB or by using conventional transfection agent-based methods. Cholesterol-based transfection has the potential to avoid the endocentric pathway and, therefore, to reduce the number of false positive signals arising from nuclease degradation. The cholesterol-bearing, pyrene-π-stacking-based MB system represents a new type of MB whose high cellular uptake efficiency makes such probes unique and novel; we believe that this one holds great promise for studying the dynamics of biomolecular systems in living cells and that its use will open up other new and exciting opportunities for applications in vivo.

DNA Binding to Protein−Gold Nanocrystal Conjugates

Michelle K. Calabretta,[§,*] Kathleen S. Matthews,[†] and Vicki L. Colvin[§]

Department of Chemistry and Department of Biochemistry and Cell Biology, Rice University, 6100 Main Street, Houston, Texas 77005. Received April 9, 2006; Revised Manuscript Received June 1, 2006

The *E. coli* DNA binding protein *lac* repressor (LacI) and a derivative with a designed thiol (T334C) were developed as gold nanocrystal conjugates to assess the effects of conjugation on DNA binding function. The designed derivative was engineered with a solvent-accessible thiol to promote oriented conjugation, avoiding obstruction of the DNA-binding domain by the nanocrystal. Analytical ultracentrifugation (AU) and electrophoretic mobility shift assays (EMSA) were used to evaluate the ability of conjugated repressors to bind the natural operator DNA sequence O^1. The results show that LacI does not retain significant DNA binding function when conjugated to gold nanocrystals, presumably because the basic DNA-binding domain is the site for nonspecific conjugation. T334C, with the potential for both directed and nonspecific conjugation, shows enhanced interaction with O^1 when conjugated. Interestingly, the order of component addition is a key factor in producing functional *lac* repressor conjugates.

INTRODUCTION

DNA recognition proteins have recently been the subject of interest in nanoscience (*1*−*5*). Yun and co-workers (2002) tested the ability of DNA binding proteins to interact with DNA oligonucleotides tethered on both ends to small (1.4 nm) gold nanocrystals. Interparticle distances obtained from TEM demonstrate that EcoRI can cause topological changes, such as bending, in conjugated DNA. This type of manipulation generates the potential for design of nanoarchitectures for electronics and sensors (*5*). Protein−DNA complexes have also been used as functional scaffolds for the fabrication of nanoelectronics. For example, Keren and co-workers used the structural and functional properties of the RecA nucleoprotein filament to produce gold nanowires with branched architectures and other structural characteristics (*1*). Another nanoarchitecture, using protruding biotinylated thymine loops on DNA oligonucleotides, produced uniformly spaced streptavidin-coated gold nanocrystals. The researchers propose that regularly spaced arrays of gold nanocrystals could interconnect nanoelectric components and aid in the development of logical nanoelectronic devices (*2*).

The *lac* repressor (LacI), an *E. coli* DNA binding protein, is attractive for use as a structural and functional nano building block because of the large amount of genetic and biochemical information available for this protein (for review see ref 6). LacI is structurally well characterized, with several crystallographic and solution structures available. This protein binds two types of ligand: DNA (operator) and small sugar molecules (inducer). The binding of an inducer sugar reduces the ability of LacI to bind DNA, effectively making LacI a logic switch, where "on" is the high DNA affinity state and "off" is in the presence of inducer when DNA affinity is low. One approach to the assembly of nanoelectronic components onto DNA nanostructures could utilize the specificity of DNA binding proteins, like LacI, for their DNA substrates. For example, DNA sequences created with natural operator sequence O^1 at regular intervals could be mixed with LacI-bound gold nanocrystals, resulting in uniformly spaced gold nanocrystal architectures. This type of application requires oriented protein conjugation and would be sensitive to the ability of the conjugated repressor to interact with DNA, which is in turn modulated by inducer binding.

There is substantial evidence that nonspecific protein−gold nanocrystal interactions are largely electrostatic, occurring through basic surface residues and the negatively charged nanocrystal surface (*7*, *8*). The DNA-binding domain is logically the most probable region for gold nanocrystal conjugation to LacI because it is highly basic, having a theoretical pI ∼9.3, and lacks well-defined structure in the absence of operator DNA, providing easy accessibility (*9*). If the DNA-binding domain is the site of interaction, then LacI−gold nanocrystal conjugates would be sterically prevented from binding operator DNA. The purpose for creating T344C, with its solvent accessible cysteines, was to provide a means for thiol-directed conjugation to gold through the C-terminal region of LacI, thereby precluding nanocrystal interference with the DNA-binding domain. Here, we assess the operator DNA binding affinity of LacI and T334C gold nanocrystal conjugates. This work develops the understanding of how conjugation can be manipulated to optimize the function of protein-nanocrystal materials.

EXPERIMENTAL PROCEDURES

Materials. All materials were purchased from Sigma unless specified otherwise.

Protein Mutation, Purification, and Conjugation. The T334C mutation was produced on plasmid pLS1 (*10*) with the QuikChange PCR site-directed mutagenesis kit (Stratagene) using the provided protocol. Mutant plasmids were transformed into supercompetent GC5 cells (Gene Choice) for growth and purification. Mutant plasmids were sequenced (SeqWright) to verify that no other mutations were present. Purification of wild type LacI was carried out as described previously (*11*−*14*). Briefly, expression occurred in *E. coli* strain BLIM (Novagen), which was cured of the LacI episome (*15*). After centrifugation, cell culture pellets were resuspended and lysed, and the lysis supernatant was precipitated in 37% ammonium sulfate. The resuspended precipitate was dialyzed overnight and loaded onto phosphocellulose. LacI was eluted with a gradient of 0.12−0.3 M potassium phosphate buffer, pH 7.5. The concentration of LacI-containing fractions was determined by absorbance at 280 nm (extinction coefficient = 1.6 mL mg^{-1} cm^{-1}). The T334C

mutant was purified similarly to wild type protein, with the following exceptions: Protease inhibitor tabs (Roche) were added to inhibit degradation of the protein. Dialysis time of the resuspended ammonium sulfate pellet is reduced to three 20-min steps. All buffers contained 10 mM DTT to prevent aggregation via the solvent-exposed cysteine residues. Last, T334C was eluted stepwise (0.12 M KP to 0.3 M KP) instead of with a gradient to minimize time of purification. Proteins were stored at −20 °C for up to 6 months with 10 mM DTT.

Conjugates were formed as follows: The LacI potassium phosphate storage buffer was exchanged for conjugation buffer (50 mM Tris, pH 9.2, 5% (w/v) glucose) by centrifugation in Amicon Ultra-15 (MWCO 30000) centrifugal filters (Millipore). LacI or T334C (250 μL) was diluted into 15 mL of conjugation buffer and centrifuged at 2500*g* for 15 min. The process was repeated twice more to ensure complete exchange. A gold nanocrystal suspension, prepared by citrate reduction and characterized as described previously (*14*), was added to specified repressor concentrations diluted in conjugation buffer so that the final concentration of gold nanocrystal was one-fourth the initial concentration. This dilution factor was necessary to decrease the nanocrystal absorbance in the UV−visible region to below 1 absorbance unit and sufficiently dilutes the nanocrystals so that concentration-dependent nonideality in sedimentation is minimized. Samples were allowed to conjugate for approximately 30 min at room temperature unless specified otherwise.

[^{35}S]-Methionine-labeled LacI and T334C were generated as described previously (*14*) with the TNT T7 Quick for PCR DNA transcription/translation kit (Promega). Briefly, the LacI gene (with and without the T334C mutation) under the T7 promoter was cloned into pGEM-T (Promega). Following translation, unincorporated [^{35}S]-methionine (ICON Isotopes) was removed with protein desalting spin columns (Pierce). [^{35}S]-repressors were further purified on a small phosphocellulose column and diluted with unlabeled repressor to determine protein concentration (μg/μL) by absorbance at 280 nm. The amount of radioactive isotope in counts per minute (cpm) was measured for an aliquot of the repressor mixture to produce a specific activity (cpm/g) for the sample. For [^{35}S]-repressor−gold nanocrystal conjugates, free protein was removed by centrifugation at 14000 rpm for 30 min in a desktop centrifuge. The conjugated repressor concentration was determined based on the amount of radioactive isotope present using the specific activity of the initial protein sample.

Operator DNA Radiolabeling. Operator affinities of conjugated proteins were measured with double-stranded natural operator O^1 (5′-TGTTGTGTGGAATTGTGAGCGGATAACAATTTCACACAGG-3′). Complementary strands (BioSource) were hybridized in annealing buffer (8 mM Tris-HCl, pH 7.5, 4 mM $MgCl_2$, 10 mM NaCl) and labeled with [^{32}P] by polynucleotide kinase (NEB) and γ-[^{32}P]-ATP (MP Biomedicals) in a final volume of 15 μL. The labeling reaction was terminated with 2 μL of 0.5 M EDTA and diluted to 50 μL with Tris-EDTA, pH 8. Labeled operator was purified from unincorporated γ-[^{32}P]-ATP on NICK columns (Amersham Biosciences) and eluted with Tris-EDTA, pH 8.0. DNA was aliquoted and stored at −20 °C for up to 1 month.

Analytical Ultracentrifugation (AU). AU data were collected using the vendor's software on a Beckman XL-A analytical ultracentrifuge. Sedimentation velocity experiments were performed at 20 °C at 3100 rpm. A total of 80 scans were taken at 10 scans per hour for each sample. Raw data were processed with the enhanced van Holde−Weischet and second moment utilities in Ultrascan version 7.2 (*16*).

NaCl Flocculation Assays. Conjugates, prepared as described above, were mixed with NaCl to a final concentration of 1%. Flocculation proceeded for 10 min before recording the UV−visible spectra (200−800 nm) on a Varian Cary 50 UV−visible spectrophotometer. A minimum of three spectra for each protein concentration were recorded.

Electrophoretic Mobility Shift Assay (EMSA). Nondenaturing 4% polyacrylamide (37.5:1 acrylamide:bisacrylamide) gels containing 2% glycerol were preelectrophoresed in 0.5× TBE (0.045 M Tris-borate, pH 8.0, 1.0 mM EDTA) at 100 V, constant current, for 1 h prior to loading the samples. Conjugate-[^{32}P]-O^1 interactions were measured in conjugation buffer at pH 8 (50 mM Tris-HCl, pH 8, 5% glucose w/v), with BSA added to a final concentration of 1 mg/mL just prior to loading to aid in entry of the sample into the gel. Samples were loaded onto gels at 250 V until separation of loading dye occurred. The voltage was reduced to 150 V, and gels were run for approximately 1.5 h or until the loading dye reached a distance of 6 cm into the gel. Gels were dried with a vacuum gel dryer and exposed overnight to a Fuji phosphorimaging plate. Binding data were visualized and quantified with MultiGauge software (Fuji).

RESULTS

The DNA recognition capability of LacI requires contact between operator DNA (^{1}O) and the charged binding domain of LacI. Negatively charged gold nanocrystals could in principle interact with this important region and render the protein inactive. With that possibility in mind, we developed a mutant of LacI, T334C, to direct nanocrystal attachment to another region of the protein. This system contains a solvent-exposed cysteine residue in the C-terminus, on the opposite end of the protein from the N-terminal DNA-binding domain. Figure 1 shows the crystal structure of tetrameric LacI and the position of the basic DNA-binding domain and threonine 334 on each monomer. The cysteine mutation provides potential for site-directed conjugation via a gold−sulfur bond, and its location would orient the DNA-binding domain away from the nanocrystal. Additionally, nanocrystal attachment to the cysteines of T334C would require a stronger, more stable gold−sulfur bond than the nonspecific and reversible electrostatic interactions expected for binding between gold nanocrystals and the native LacI repressor (*17*).

Central to any comparison of function between nanoparticle-bound and free proteins is accurate evaluation of the stoichiometry of the nanobionconjugates; in particular, it is important that nanobioconjugates are produced with saturation coverage of proteins and that free protein is removed from the suspensions. Here, these issues were addressed for gold nanocrystal−repressor conjugates using three methods: NaCl-induced flocculation, [^{35}S]-repressor association, and analytical ultracentrifugation. Taken together these techniques provide both a measure of the success of conjugation strategies, and also a determination of the stoichometry of the resulting complexes. The results from all methods are summarized in Table 1.

In NaCl-induced flocculation assays, gold nanocrystals become aggregated because of the reduced electrostatic repulsion at higher ionic strengths. This aggregation is signaled by a pronounced shift in the peak position of their absorbance. If nanocrystals are bound to proteins, the aggregation is modified significantly and can in fact be avoided when nanocrystals are fully coated by proteins. Thus, an examination of the gold nanocrystal−repressor solutions as a function of [gold nanocrystal]/[repressor] ratio provides a verification of the successful conjugation of LacI and T334C to nanocrystals. Figure 2 shows that ∼12 LacI repressors are needed to prevent flocculation, whereas a smaller number of repressors produce the same outcome for T334C (Table 1). These data suggest that reversible electrostatic interactions are important in the conjugation of gold nanocrystals to the native LacI repressor. Compared to a stronger

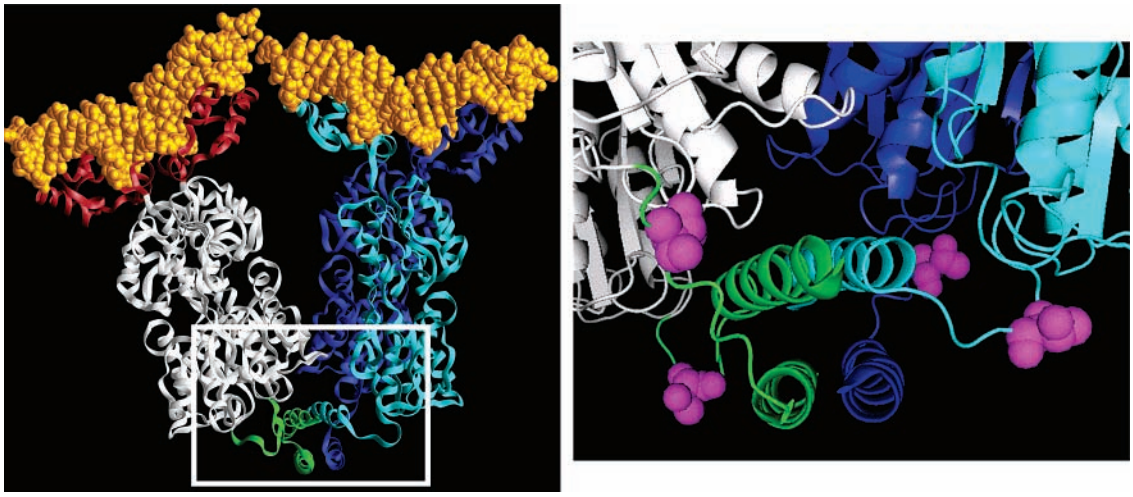

Figure 1. Crystal structure of LacI and placement of the T334C mutation. LacI is a dimer of dimers. In the right dimer, one monomer of LacI is shown in light blue and the other in dark blue. In the left dimer, the DNA-binding domain is colored red, the core domain (that binds sugar inducer) of the protein white, and the tetramerization domain in green. Operator DNA is shown as the yellow space-filled molecule. The white box indicates the region for enlargement to show the position of threonine 334. Threonine 334, shown in magenta in the enlargement, was chosen for cysteine mutation because it is solvent accessible and should orient the protein so that neither the DNA-binding domain nor the inducer sugar pocket are obstructed when the protein is bound to gold nanocrystals. Figure generated from pdb files 1LBG and 1LBI (*9*).

Table 1. Repressor−Gold Nanocrystal Ratios (13.2 nm Gold Nanocrystals)[a]

	repressors per nanocrystal		
protein	NaCl flocculation	[^{35}S]-labeling	AU S_{max}
LacI	~12	7.1 ± 0.7	10.8 ± 0.7
T334C	~8	9.6 ± 0.2	10.4 ± 1.0.

[a] For comparison, a theoretical prediction of 11 repressors per nanocrystal is based on the average diameter of the gold core from TEM data and dimensions from the LacI crystal structure 1LBI (*9*).

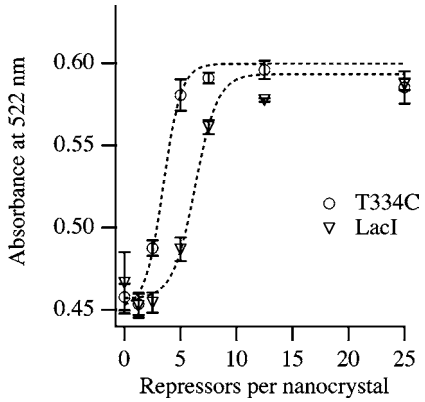

Figure 2. NaCl-induced flocculation of repressor conjugates. The absorbance of the gold nanocrystal plasmon peak was measured after NaCl was added to samples with a range of repressor concentrations. T334C (circles) prevents flocculation at lower concentration than LacI (triangles). Lines are shown for guidance only. Data are from three separate experiments.

gold−sulfur bond such as that engineered in T334C, native LacI repressors would require higher protein concentrations for stabilization.

The relative amount of gold nanocrystal and protein in these conjugates can also be found using radiolabeled [^{35}S]-repressor conjugates (Table 1). Here, [^{35}S]-repressors were conjugated to gold nanocrystals using our standard methods, and free protein was separated from conjugates by multiple rounds of centrifugation. The results show that LacI−gold nanocrystal conjugates have on average three fewer proteins per nanocrystal than conjugates produced using T334C mutants, a result that contradicts the trend found in the NaCl flocculation assay. In this analysis, bionanoconjugates were separated from proteins using a strong centrifugal force (14000 rpm for 30 min) to rapidly pellet the sample; subsequent washes, and recovery, could result in the removal of weakly bound LacI repressor proteins from gold nanocrystal surfaces and subsequently lower [protein]/[nanocrystal] ratios. This effect would be less substantial for T334C−gold nanocrystal conjugates since conjugation in that case relies on the stronger gold−sulfur bond.

Bioconjugate structure can also be evaluated by shifts in the *S* value obtained from AU sedimentation velocity experiments (*14*). Sedimentation velocity, unlike repeated centrifugation and separation of pellet and supernatant, occurs at much lower centrifugal forces and in equilibrium (i.e., the components are not separated during the measurement). Therefore, the [gold nanocrystal]/[protein] values calculated using this technique should reflect both those protein molecules that are weakly and strongly bound to the nanocrystal surfaces. The ratios for both LacI and T334C proteins are ~10 repressors per nanocrystal. This result is consistent with the fact that, despite the mutation, LacI and T334C have the same physical dimensions. Given the average diameter of the gold nanocrystals used in these experiments (13.2 ± 1.5 nm) and the approximate dimensions of an unliganded LacI tetramer (7.8 × 7.9 × 7.7 nm) (*9*), we estimate 11 repressors as the maximum number that the surface of a gold nanocrystal could accommodate, in good agreement with our ratios as measured both by flocculation assays and in ultracentrifugation (Figure 3).

Of great interest in this work is how the conjugation process affects protein function, in this case the binding of operator DNA. To examine this, we used analytical ultracentrifugation to measure the sedimentation characteristics of conjugates mixed with operator DNA. When conjugated repressors interact with operator DNA, substantial changes in the hydrodynamic properties should be signaled by a change in the *S* values measured by AU. Figure 4 compares the *S* values of repressor conjugates with O^1 and an inducer sugar, IPTG. We first considered the properties of the native LacI conjugates. When the LacI conjugate is formed before O^1 is added, the nanocrystals have *S* values comparable to the LacI conjugate without O^1 (Figure 4A). This result suggests that O^1 is not binding to the conjugated LacI, as predicted if the nanocrystals are blocking the DNA recognition domain. We confirmed this by reversing the order of addition, and generated LacI-O^1 complexes that were then exposed to gold nanocrystals. These samples have higher *S*

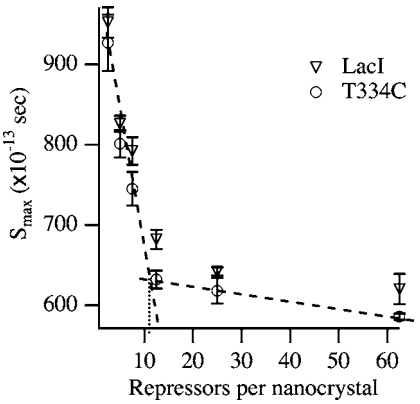

Figure 3. Repressor−gold nanocrystal stoichiometries using S_{max} as an observable. The stoichiometric ratio corresponds to the point where the line fit at lower protein concentrations intersects the line extending the saturation plateau. For simplicity only the lines for LacI are shown. Both LacI (triangles) and T334C (circles) have similar ratios of ~10 repressors per nanocrystal (D = 13.2 nm) at the stoichiometric breakpoint. Data are from three separate experiments.

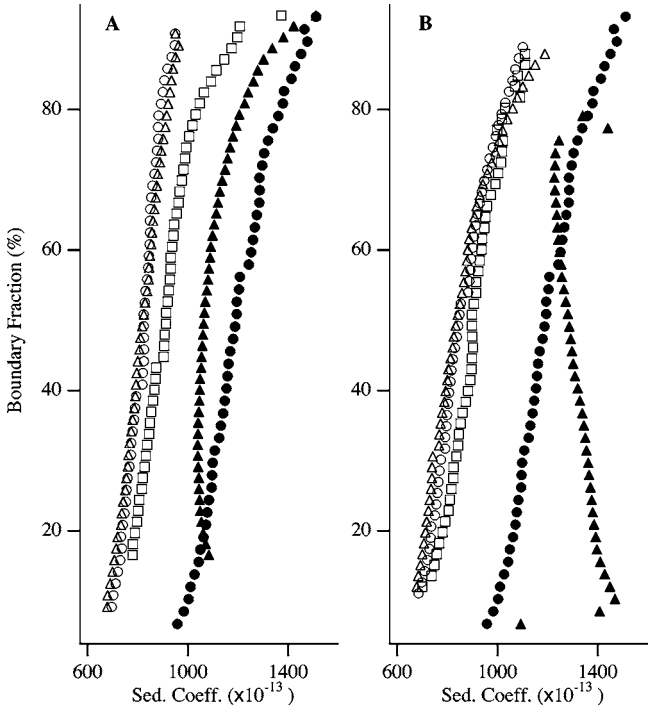

Figure 4. Comparison of S for repressor conjugates with O^1 and inducer IPTG. Integral plots from raw data analyzed in the Enhanced van Holde−Weischet utility in Ultrascan are shown. A, Samples containing LacI and B, samples containing T334C. ●, Gold nanocrystals (4 nM). △, Repressor (30 nM) gold nanocrystal (4 nM) conjugate. ○, Gold nanocrystal conjugated first, then operator (90 nM). ▲, Operator complexed first, then gold nanocrystals. □, Operator complexed first, then gold nanocrystals, then 1 mM IPTG. Data from three separate T334C-operator first experiments displayed a negative slope, indicative of strong repulsive interactions.

values comparable to gold nanocrystals alone, indicating no substantial conjugation occurs (Table 2). These data suggest that LacI interacts with either O^1 or gold nanocrystals, but does not significantly interact with both at the same time. In other words, the gold nanocrystals and operator DNA compete for the same binding site on the native LacI repressor.

The behavior of the mutant T334C repressor conjugates with operator DNA is quite different than that found for native LacI (Figure 4B). When the T334C conjugate is formed prior to O^1 addition, there is a small but significant increase in S (Table 2, $p < 0.2$). This change is larger than that for LacI under similar

Table 2. Average *S* Values of Repressor Conjugates with O^1 and IPTG

protein	AuNC	AuNC, then O^1	O^1, then AuNC	O^1, AuNC, then IPTG
LacI	838 ± 9	855 ± 21	1169 ± 19	947 ± 45
T334C	889 ± 10	906 ± 17	1242 ± 69[a]	952 ± 56
no protein	1114 ± 19	1147 ± 11		1107 ± 137

[a] This value is not accurate due to the strong concentration-dependent nonideality in this sample (see Figure 4).

conditions. What remains uncertain is whether this change arises from conjugate-operator binding, or is the result of reduced nanocrystal coverage when T334C associates with O^1 instead of nonspecifically with the nanocrystal. Interestingly, when the T334C-O^1 complex is formed prior to conjugation, the data are poorly behaved in the van Holde−Weischet analysis and yield an S value distribution with a negative slope, indicative of repulsive interactions in the sample (Figure 4B). Second moment analysis of the data sets in Ultrascan reveal that there is a large concentration-dependent nonideality in these samples (not shown). One possible explanation for the concentration-dependent nonideality is that gold nanocrystals with a primary layer of T334C attached through the engineered cysteine and a secondary layer of O^1 bound to T334C have an exceptionally large hydrodynamic radius. If correct, these conjugates would also possess a strong negative charge on the surface. DNA and large particles like viral capsids are well-known for concentration-dependent nonideality, especially in the low salt conditions found in these experiments. The proposed O^1-T334C−gold nanocrystal complex thus contains all of the elements that cause concentration-dependent nonideality in other systems. Interestingly, when IPTG is added to the T334C O^1-first conjugates, the anomalous behavior is alleviated and the slope of the distribution becomes positive like the other samples. This result indirectly demonstrates that the nonideality is due to T334C-O^1 interactions, although confirmation of the assembly of the O^1-T334C−gold nanocrystal complex cannot be unambiguously deduced from the sedimentation velocity experiments.

Although analytical ultracentrifugation indicates distinctive differences between how T334C and native LacI repressor conjugates recognize DNA, another method is required to confirm the relative ability of each system to interact with operator DNA. Electrophoretic mobility shift assays (EMSA) are readily adapted to this conjugate system. Indeed, agarose gel electrophoresis has been used previously to separate (*18*, *19*), characterize the structure (*20*, *21*), and quantify the binding (*22*) of gold nanocrystal−DNA conjugates. The assembly of albumin and antibody−quantum dot conjugates has also been assessed with polyacrylamide gel electrophoresis (*23*, *24*). Here we use the EMSA to provide information about the operator DNA−repressor complexes.

An EMSA gel of repressor conjugates with [^{32}P]-O^1 is shown in Figure 5. The first four lanes establish the necessary controls. The faster migrating band present in the operator only control is attributed to single stranded DNA (lane 3). When O^1 is bound to unconjugated repressor, the free O^1 band is shifted due to a reduction in electrophoretic mobility (lanes 1 and 2), whereas gold nanocrystals alone do not cause a shift, establishing that there is no significant interaction between the operator and the nanocrystals (lane 4).

When the repressor−operator complex is formed before gold nanocrystals are added, native LacI retains significant O^1 binding affinity as an unconjugated protein, demonstrated by the band with similar mobility to the LacI-operator control (lanes 5−7). Here, the presence of operator appears to compete with conjugate formation, as observed in the AU experiments. Additional bands in these samples as compared to the control lanes are also apparent. First, the supershifted band (lowest mobility

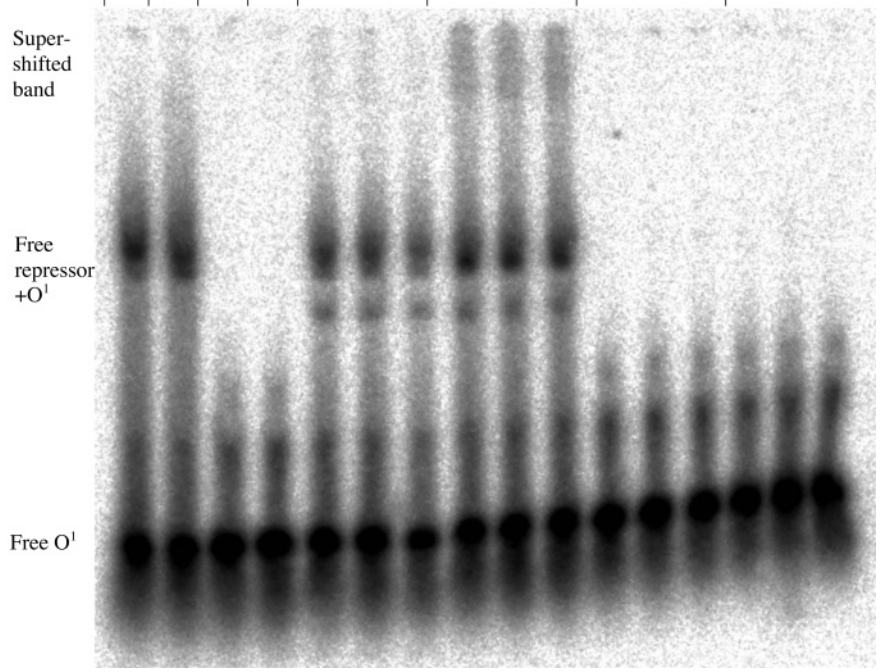

Figure 5. EMSA of 30 nM repressor conjugates with operator DNA O^1. [^{32}P]-O^1 (90 nM) is shown with 30 nM LacI (L) or T334C (T) and 4 nM gold nanocrystals. This protein concentration was chosen because it is slightly below the stoichiometric concentration for repressor−gold nanocrystal conjugation, so all of the protein should be conjugated in the gold nanocrystal-first conditions. The order of reaction components was varied and is denoted 1 or 2. Three predominant bands were observed corresponding to free O^1, unconjugated repressor−O^1 complex, and a super-shifted band representing O^1 bound to conjugate. Lanes 1−3, no nanocrystal added; 4, O^1 and nanocrystal; 5−7, LacI, O^1 added first; 8−10, T334C, O^1 first; 11−13, LacI, nanocrystal first; 14−16, T334C, nanocrystal first.

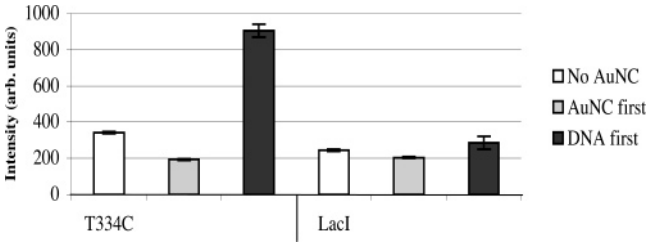

Figure 6. Quantification of the intensities of the supershifted bands in the EMSA. Intensities are measured in the region of the gel corresponding to the supershifted band. All areas used were identical, and data from three separate experiments were averaged. The T334C-O^1 first sample is the only one with significant intensity over background, demonstrating that T334C can interact with both O^1 and gold nanocrystal.

band), which we assign to O^1 bound to gold nanocrystal−protein conjugates (O^1•AuNC•protein) is more significant in the T334C sample (lanes 8−10) than for the native repressor, as predicted from the previous experiments. Visual inspection of the gel shows that, in addition to radiolabeled O^1, this region contains gold nanocrystal-based pink color (data not shown). Quantification of the [^{32}P]-O^1 signal from this band in Figure 6 shows that the T334C super-shifted band is ∼3−4-fold more intense than the analogous LacI band, corresponding to enhanced DNA binding capacity of the T334C conjugate. This difference presumably arises from the ability of O^1-bound T334C to orient conjugation through the engineered cysteine sulfhydryl. The other observed band in lanes 5−10 not present in the control lanes is faster migrating and weaker in intensity than the unconjugated repressor-operator band; this band is assigned to two operators binding to a single tetramer. As expected, no difference in the intensity of this band is observed between LacI and T334C.

In contrast, when LacI or T334C are conjugated to gold nanocrystals prior to the addition of O^1, signals are not observed at the positions corresponding to unconjugated repressor-O^1 complex nor the gold-nanocrystal-conjugated repressor-O^1 complex (lanes 11−16). At these repressor concentrations, little free protein appears to be present to form the unconjugated repressor-O^1 complex, and assembly of O^1-repressor−gold nanocrystal is precluded, presumably by gold nanocrystal binding blocking the basic DNA-binding domain. Note that conjugation prior to O^1 addition interferes with both LacI and T334C binding, suggesting that oriented binding by T334C does not preclude interaction of the basic N-terminal DNA binding domain with gold nanocrystals in the absence of operator DNA sequences.

Similar to AU, the EMSA data demonstrate that the order of addition of reactants is critical for the maintenance of DNA binding function, presumably due to an electrostatic interaction with the DNA-binding domain despite the strong nature of the possible T334C gold−sulfur bond. However, with addition of DNA first, T334C is able to conjugate to the gold nanocrystals through the engineered cysteine and retain significant interaction with O^1 as a conjugate.

DISCUSSION

We developed a LacI mutant designed with a solvent-exposed cysteine residue to facilitate directed conjugation through a gold−sulfur bond, alleviating the functionally deleterious consequences of nonspecific conjugation through the DNA-binding domain. This mutant, T334C, prevents NaCl-induced

flocculation at lower concentrations than native LacI. This observation suggests that LacI conjugates through a weaker, reversible electrostatic interaction, making it less efficient at preventing flocculation compared to T334C, which has the ability to conjugate through a gold−sulfur bond. Furthermore, more radiolabeled repressor is present in the T334C conjugate than the LacI conjugate after removal of free repressor via repeated centrifugation, indicating again that T334C has a stronger, more robust interaction with gold nanocrystals than LacI. Precise ratios of protein to nanocrystal were obtained under equilibrium conditions by the sedimentation velocity of conjugates. With this equilibrium technique, both LacI and T334C exhibit ratios of approximately 10 repressors per nanocrystal, in good agreement with calculations based on the nanocrystal and repressor dimensions.

Analytical ultracentrifugation and EMSA allow characterization of the interaction of conjugated LacI and T334C with the operator DNA sequence O^1. LacI conjugates do not interact strongly with O^1 in either assay. In contrast, T334C conjugates associate with O^1 depending on the order in which the operator-T334C−nanocrystal complex is formed. These data establish that T334C is capable of oriented conjugation to maintain DNA binding function, whereas LacI appears to conjugate primarily through its basic DNA-binding domain, thereby blocking the interaction with O^1 when conjugated. Nonspecific electrostatic protein−gold nanocrystal interactions, while easy to implement, may result in a loss of function for proteins with basic functional regions. If the biological function of the final hybrid material is to be maintained, the possibility of nonspecific interactions between functional regions and the nanostructure must be considered. We have shown that these complications can be avoided at least in part by directing conjugation using thiols placed in regions of the biomolecule that direct orientation to minimize inhibition of function.

ACKNOWLEDGMENT

The authors thank Jennifer Jamison for preparation of the gold nanocrystals used in this work and Joshua Falkner for TEM characterization of the nanocrystals. Endothelial cells are an important cell type to both cardiovascular disease and cancer, as they play critical roles in vascular function and angiogenesis. However, effective and safe gene delivery to primary endothelial cells in the presence of serum proteins is known to be particularly challenging. A library of biodegradable poly(β-amino esters) was synthesized for use as potential vectors. Promising vectors were optimized for high efficacy and low cytotoxicity to human umbilical vein endothelial cells (HUVECs) in serum. Vector parameters including polymer type, polymer weight, and DNA loading were varied, and biophysical properties including particle size, ζ potential, and particle stability over time were studied. While many of the poly(β-amino ester) vectors have similar biophysical properties in the presence of buffer, their biophysical properties changed differentially in the presence of serum proteins, and the properties of these serum-interacting particles correlated to transfection efficacy. Leading poly(β-amino ester) vectors were found to transfect HUVECs in the presence of serum significantly higher ($47 \pm 9\%$ positive, $n = 10$) than the best commercially available transfection reagents including jetPEI ($p < 0.001$) and Lipofectamine 2000 ($p < 0.01$). These results demonstrate the potential of a new class of biomaterials, poly(β-amino esters), for effective human endothelial cell gene therapy.

INTRODUCTION

Cardiovascular disease and cancer are the leading causes of death in the United States. Gene therapy has the potential to treat many cardiovascular conditions including peripheral arterial disease, restenosis, and myocardial ischemia, as gene delivery enables long-term expression of target genes useful for treatments such as therapeutic angiogenesis and inhibition of cell proliferation (*1*−*3*). Endothelial cells are a significant cell target in cardiovascular disease, as they control vascular function. Endothelial cells are also an important cell type for cancer treatments that target against vasculogenesis and angiogenesis (*4*, *5*). In these experiments, we use human umbilical vein endothelial cells (HUVECs) as a model primary cell system to test the efficacy of gene delivery vectors. This is a challenge, as primary endothelial cells have higher intrinsic resistance to gene delivery than other cell lines (*6*).

There are two main approaches to gene delivery: viral and nonviral. The primary advantages of viral delivery are efficient infection of cells and long-term gene expression (*7*, *8*). However, problems with viral vectors as compared to nonviral vectors include limited cargo capacity, resistance to repeated infection, production and quality control issues, and safety (*7*, *9*). Specific safety concerns include acute toxicity, cellular immune response, and oncogenicity due to insertional mutagenesis (*7*). Nonviral vectors are attractive for gene delivery, as they do not have these viral vector limitations.

To improve stability and uptake of DNA, numerous biomaterials have been used to create synthetic gene delivery vectors. The main biomaterials that have been studied include cationic polymers, cationic lipids, liposomes, chitosans, inorganic nanoparticles, and dendrimers (*8*−*10*). Though these biomaterials improve transfection in comparison to naked DNA, they still have relatively low transfection efficacy, and many of these materials are cytotoxic.

Recently, a large library of 2350 structurally unique poly(β-amino esters) was developed using high-throughput combinatorial chemistry (*11*). Poly(β-amino esters) are promising for nonviral gene delivery due to their (1) ability to condense DNA into nanoparticles, (2) ability to buffer the endosome, (3) ability to promote endosomal escape, (4) low cytotoxicity compared to other cationic polymers, (5) biodegradability via hydrolytic cleavage of ester groups, and (6) large potential for structural diversity (*12*−*16*).

Previously, we have shown that top-performing poly(β-amino ester) vectors have particle sizes smaller than 150 nm, positive ζ potentials, polymer weight to DNA weight ratios greater than or equal to 40, molecular weights above 10 000, amine-terminated chains, and other structural similarities (*11*, *13*, *17*, *18*). However, all of these assays and measurements were conducted in serum-free conditions, and the role of serum interactions on biophysical properties and transfection efficacy of poly(β-amino ester) vectors has not previously been studied. Important particle properties such as size, ζ potential, and particle stability are dependent on the local aqueous environment, and gene delivery particles demonstrated to have certain biophysical characteristics in a buffer may not have the same characteristics in the presence of serum or in vivo (*19*, *20*).

Here, we demonstrate that poly(β-amino esters) as a class, and C32 in particular, transfect human primary endothelial cells better than several top commercially available reagents. Analysis of the biophysical properties of poly(β-amino ester)/DNA complexes as a function of media and over time provide insight into serum stability and efficacy of these complexes.

EXPERIMENTAL PROCEDURES

EGM-2 media supplemented with SingleQuot Kits (Cambrex). HUVEC cells were used by passage five and in accordance with the manufacturer's instructions. Cells were grown at 37 °C in a humid 5% CO_2 atmosphere.

Polymer Synthesis. Monomers were purchased from Aldrich (Milwaukee, WI), TCI (Portland, OR), Pfaltz and Bauer (Waterbury, CT), Matrix Scientific (Columbia, SC), Scientific Polymer (Ontario, NY), and Dajac Monomer−Polymer (Feasterville, PA). Optimal amine/diacrylate stoichiometric ratios for each polymer were determined from previous work (*13*). To synthesize each polymer, 400 mg of amino monomer was weighed into a 1-mL sample vial with a Teflon-lined screw cap. Next, the appropriate amount of diacrylate was added to the vial, and a small Teflon-coated stir bar was then put in each vial. Polymers were then synthesized on a multiposition magnetic stir-plate residing in an oven at either 95 °C (solvent-free) or 60 °C (with 2 mL DMSO added). High-temperature synthesis was performed for approximately 12 h, and low-temperature synthesis was performed for 2 days. After completion of reaction, all vials were removed from the oven and stored at 4 °C. All polymers were analyzed by gel-permeation chromatography (GPC) as previously discussed (*13*).

Polymeric Vectors. The nonviral vectors are formed through electrostatic interactions between poly(β-amino esters) and plasmid DNA. Depending on transfection experiments, plasmid DNA encoding either pEGFP-enhanced green fluorescent protein (ElimBiopharmaceuticals, South San Francisco, CA) or pCMV-Luc firefly luciferase (ElimBiopharmaceuticals, South San Francisco, CA) was used. By varying the amount of DNA used in preparation, the amount of DNA loading per cellular well was varied. At a fixed DNA basis, by varying the weight of polymer, the charge ratio (N/P) of polymer nitrogen (N) to DNA phosphate (P) was varied. To ease handling, polymer stock solutions (100 mg/mL) were prepared in DMSO solvent prior to use. Working dilutions of each polymer were prepared in 25 mM sodium acetate buffer (pH 5). For 96-well plate experiments, 25 μL of the diluted polymer was added to 25 μL of DNA and mixed well. The mixtures were then incubated at room temperature for 10 min to allow for complex formation. For 24-well experiments and for biophysical characterization experiments, the same steps were followed, but all volumes were scaled up appropriately.

Biophysical Characterization. Particle size and ζ potential measurements were measured by using a ZetaPALS dynamic light scattering detector (Brookhaven Instruments Corp., Holtsville, NY, 15-mW laser, incident beam 676 nm). Samples were prepared for biophysical characterization in the same manner and at the same concentrations as they were for transfections, but the media/polymer/DNA solution was scaled up to a final volume of 1.6 mL. Generally, particles were first sized in 25 mM NaAc buffer while initial polymer/DNA complexation occurred and then added to 12% serum EGM-2 media and sized dynamically in time for up to 8 days. Particle stability was determined by changes to particle size over time. Polymer/DNA ratios shown are those determined to have the highest transfection efficacy unless otherwise stated. Correlation functions were collected at a scattering angle of 90°, and particle sizes were calculated using the MAS option of BICTs particle-sizing software (version 2.30) using the viscosity and refractive index of water at 25 °C. Particle sizes are expressed as effective diameters assuming a log-normal distribution. Average electrophoretic mobilities were measured at 25 °C using BIC PALS ζ potential analysis software, and ζ potentials were calculated using the Smoluchowsky model for aqueous suspensions.

Luciferase Transfections. Nonviral vector transfections were performed on HUVECs with and without the presence of serum. HUVECs were seeded (15 000 cells/well) into each well of an opaque white 96-well plate (Corning-Costar, Kennebunk, ME) 24 h prior to transfection to allow for growth to confluence. Vectors were constructed as previously mentioned, and then, 30 L of each polymer/DNA solution was added to either 200 μL of Opti-MEM with sodium bicarbonate (Invitrogen), EGM-2 media (2% serum), or FBS supplemented EGM-2 media (12% serum) in 96-well polystyrene plates. The growth medium was removed from the cells using a 12-channel aspirating wand (V&P Scientific, San Diego, CA) after which 150 μL of the media/polymer/DNA solution was immediately added. Complexes were incubated with the cells for 1−4 h and then removed using the 12-channel wand and replaced with 100 μL of warm EGM-2 media. Final DNA loading was 0.3 or 0.6 μg per well depending on the experiment. Cells were then allowed to grow for 48 h and then analyzed for luciferase expression. Control experiments were also performed with PEI (MW 25 000; Sigma−Aldrich), jetPEI (Qbiogene, Irvine, CA), jetPEI−HUVEC (Bridge Bioscience Corporation, Portsmouth, NH), and Lipofectamine 2000 (Invitrogen). PEI transfections were performed as described above using a polymer/DNA weight ratio of 1/1. Jet PEI, jetPEI−HUVEC, and Lipofectamine 2000 transfections were performed as described by their vendors. The same quantity of DNA per well and incubation time was used with the control vectors as with the poly(β-amino ester) vectors. Luciferase expression was analyzed using Bright-Glo assay kits (Promega, Madison, WI). Briefly, 100 μL of Bright-Glo solution was added to each well of the 96-well plate containing cell medium and cells. Luminescence was measured using a Mithras luminometer (Berthold, Oak Ridge, TN).

GFP Transfections. GFP transfections paralleled the luciferase transfections except that all volumes were scaled up fivefold and the experiments were conducted in clear 24-well plates (Becton Dickinson, Franklin Lakes, NJ) with 3 ug GFP DNA per well. Cells were seeded at 75 000 per well, 24 h prior to transfection, and cells were transfected with 750 μL of media/polymer/DNA solution. Cells were aspirated prior to transfection using a 6-channel aspirating wand (V&P Scientific, San Diego, CA). After a 1−4 h incubation, the nonviral vector solution was aspirated off and replaced with 500 μL of warm EGM-2 media. After 48 h, transfected and untransfected control cells were washed, removed from the 24-well plates by trypsinization, microcentrifuged, and resuspended in 1 mL of FACS running buffer (98% PBS/2% FBS/1:200 propidium iodide solution (Invitrogen)) for FACS analysis.

Flow Cytometry. GFP expression was measured using fluorescence activated cell sorting (FACS) on a FACSCalibur (Becton Dickinson, San Jose, CA). Propidium iodide staining was used to exclude dead cells from the analysis, and 20 000 live cells per sample were acquired. Two-dimensional gating was used to separate increased autofluorescence signal from increased GFP signal to more accurately count positively expressing cells. Gating and analysis was performed using *FlowJo 6.3* software (TreeStar, Ashland, OR).

Cell Viability Measurements. To measure cytotoxicity and cell viability, cellular metabolic activity was measured using the Cell Titer 96 Aqueous One Solution assay kit (Promega, Madison, WI). Metabolic activity was measured using optical absorbance on a Victor3 Multilabel plate counter (Perkin-Elmer Life Sciences, Boston, MA). Measurements of treated cells were converted to percent viability by comparison to untreated controls.

Statistics. Statistical calculations were carried out using *GraphPad Prism 4.0* for Windows. Results are reported as mean ± standard deviation. For comparison of gene delivery vectors, statistical significance was obtained by using unpaired, two-tailed, Student's *t*-tests with 99% confidence.

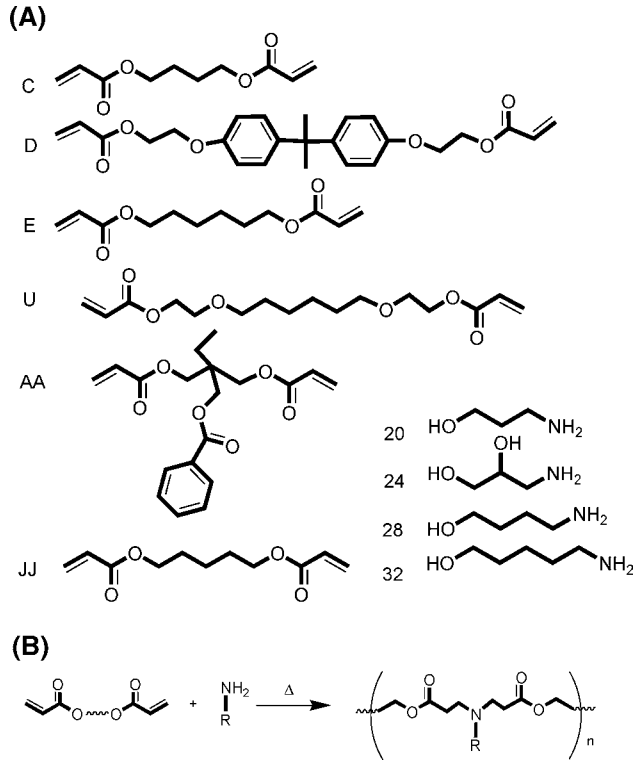

Figure 1. (A) Diacrylate esters and amine monomers. (B) Synthesis of poly(*β*-amino esters).

RESULTS AND DISCUSSION

Polymer Synthesis and Gene Delivery Vector Formulation. Poly(*β*-amino esters) are synthesized by the conjugate addition of amine monomers to acrylate esters. The acrylate and amine monomers used in this experiment and their synthesis scheme can be seen in Figure 1. High-throughput screening and synthesis of a large library of over 2000 poly(*β*-amino esters) was conducted (*11*). The top 486 polymers were then resynthesized on a larger scale at a range of molecular weights (*13*). On the basis of transfection efficacy to COS-7 cells in serum-free conditions, 11 of the best-performing polymers were then selected for further analysis and optimization for transfection to human primary cells in the presence of serum.

Cationic polymeric gene delivery vectors were formed in sodium acetate buffer solution. It was determined that particles quickly self-assemble and that a 10-min complexation time is optimal for transfection efficacy. Adding poly(*β*-amino esters) to DNA was found to create vectors that were significantly more effective than those vectors formed by adding DNA to the polymers. These results parallel earlier results found with PEI (*21*) and suggest that this mixing order may be a general rule for all cationic polymers used to condense DNA.

Biophysical Characterization. Previously, nanoparticle size and *ζ* potential of poly(*β*-amino ester) vectors in PBS buffer were reported. For the top-performing vectors, particle sizes were smaller than 150 nm and *ζ* potentials were positive (*13*). We hypothesized that these biophysical properties change during actual transfections when the complexes are added either to serum-free OptiMem or cell culture media with differential levels of serum. As it has been reported that nonviral vector formulations have low efficacy in the presence of serum (*19, 20*), we wanted to determine how media and serum might change the biophysical properties of these vectors and if serum proteins inhibited poly(*β*-amino ester) vector transfection.

Figure 2 shows the effect of media type on poly(*β*-amino ester) vector particle size and stability over time. In this figure, gene delivery particles are prepared at the same concentrations as they are for typical in vitro bioassays. This figure demonstrates that C32/DNA particles delivered in OptiMem are significantly larger than those delivered in cell culture media with serum. This figure also demonstrates that in OptiMem, these particles are unstable and the biophysical properties of the particles change over time. This is important, as during transfection, the population of functional gene delivery nanoparticles can be dynamically changing in time. In contrast, serum proteins are shown to differentially reduce particle size and instability, presumably, from negative electrostatic repulsions.

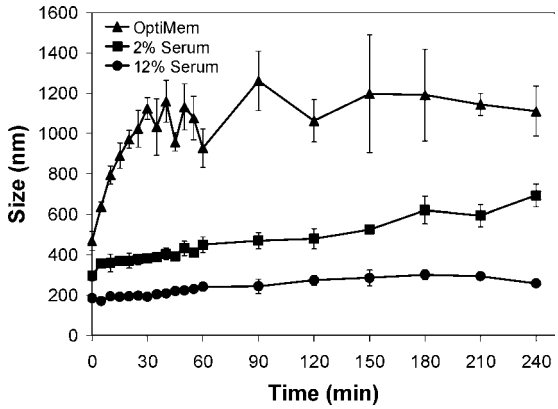

Figure 2. C32/DNA (50 w/w) particle size and stability is dependent on media type and serum concentration and can change dynamically in time. Error bars are the standard deviations of triplicate samples.

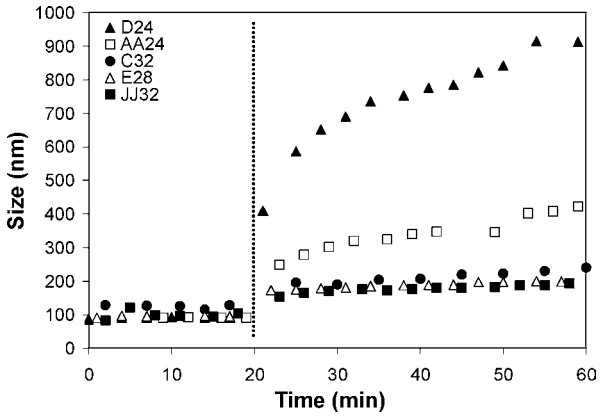

Figure 3. Particle size and stability is dependent on polymer type. All particles have a similar <150-nm size in NaAc buffer but grow disparately in size when added to 12% serum-containing media (indicated by the vertical line). Size in serum-containing media correlated to transfection efficacy.

The size of a polymeric gene delivery complex is known to dramatically affect transfection efficacy (*13, 19, 22*). However, there is some controversy in the literature about what size is optimal for delivery. Some researchers have found that, for in vitro experiments, large aggregated particles transfect better than small particles (*19, 23, 24*). This is believed to be from a sedimentation effect of large particles. Interestingly, the reverse has also been reported (*13, 22*). In either case, for an in vivo application, larger particles could cause problems due to physical size exclusions in capillaries and tissues. Small particles that are stable in serum are typically preferred.

Figure 3 demonstrates that the choice of aqueous solution used during bioassays can result in dramatic differences in the biophysical characteristics of closely related biomaterials. In this figure, poly(*β*-amino ester) vectors are first sized in sodium acetate buffer and then sized in high-serum-containing media. Whereas all vectors condensed DNA into small nanoparticles below 150 nm while in buffer, particle size dramatically changed

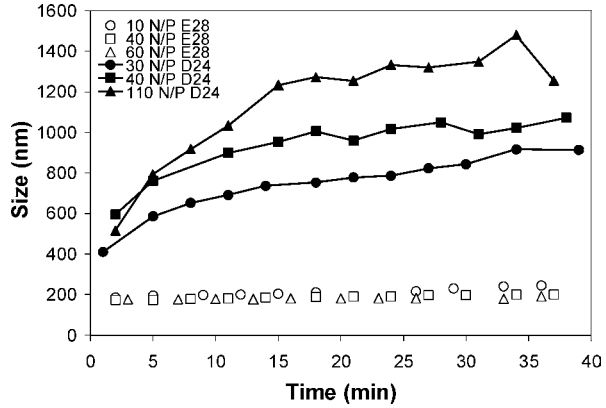

Figure 4. Particle size and stability in 12% serum is dependent on polymer type and the N/P (and w/w) ratios of polymer to DNA. E28/DNA particles show stability over a range of N/P ratios, whereas D24/DNA complexes grow increasingly larger based on their N/P ratio. E28/DNA particles were found to transfect well, whereas D24/DNA particles were found to transfect poorly.

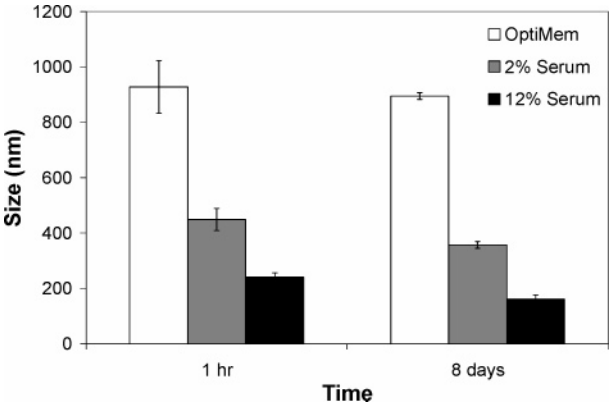

Figure 5. C32/DNA (50 w/w) particles are stable over a long time period while in various media conditions. Error bars are the standard deviations of triplicate samples.

when these particles were sized in serum. Some vectors such as C32, JJ32, and E28 formed small, stable particles in the 200-nm range, whereas other vectors such as D24 aggregated in serum to large particles in the 1-μm range. The biophysical characteristics of a gene delivery vector in a high-serum environment are likely one important indicator in predicting effectiveness for in vivo cardiovascular gene delivery.

Figure 4 shows how particle size depends on poly(β-amino ester) to DNA N/P ratio (and weight ratio) for top-performing and poor-performing vectors in the poly(β-amino ester) library. This figure shows that E28, a representative top-performing vector, forms uniformly sized small nanoparticles over a range of weight ratios, whereas a poor-performing vector, such as D24, forms large, aggregating particles that are differentially sized according to N/P ratio.

Figure 5 shows the long-term stability of C32/DNA gene delivery vectors. C32/DNA vectors were found to stay stable for at least 8 days in OptiMem, 2% low-serum enhanced media, and 12% high-serum enhanced media. For all the poly(β-amino ester) vectors tested, particles that aggregated tended to do so within the first hour of formation and then remained relatively stable for subsequent time points. Nonaggregating particles were stable for all time points tested. Particle stability is advantageous for effective delivery by circulating nanoparticles, consistent transfections, and for storage.

Table 1 shows the optimized polymer weight ratios (w/w), nitrogen to phosphate charge ratios (N/P), and biophysical parameters for the poly(β-amino ester) vectors in 12% serum-containing media. This table demonstrates that, for efficient transfection of HUVECs in serum, a higher w/w ratio and N/P ratio were generally required as compared to our previous work in COS-7 cells without the presence of serum (*13*). As previously mentioned, gene delivery particle sizes in PBS were all sub-150 nm, but in serum varied greatly from 200 nm to 1 μm. ζ potential was found to go from positive in PBS to negative in serum. This is likely due to negatively charged serum proteins adsorbing to the positively charged nanoparticles and coating them to have an overall net negative surface charge. Among the different types of polymers, ζ potential was found to vary depending on polymer type from nearly neutral to strongly negative. Interestingly, the difference in ζ potential and size between similar vectors in serum seems to correlate to single atom changes to their constitutive monomers. For example, at the same fixed N/P ratio of 60, JJ32 vectors have nearly neutral ζ potential and small size (−6 mV and 193 nm), JJ28, which has one less carbon on its amine monomer, forms larger, more negatively charged vectors (−14 mV and 226 nm), and JJ20, which is missing yet another carbon on its amine monomer forms vectors still more negative in charge and larger in size (−22 mV and 251 nm). JJ32, with the longest amine monomer chain and forming the most neutral and smallest JJ-based particle overall, transfected best in serum, followed next by JJ28, and last JJ20. This analysis highlights the use of a large polymeric library in elucidating structure/function relationships.

Luciferase Transfections. Transfection experiments are commonly performed in vitro on immortal cancerous cell lines under serum-free conditions. Immortal cancerous cell lines are frequently chosen, as they are easier to propagate and manipulate than primary cells, and are often easier to transfect. Primary endothelial cells in particular have been shown to have an intrinsic resistance to the uptake of exogenous genes compared to other cell lines (*6*). Serum-free conditions are routinely employed to prevent unwanted electrostatic interactions between positively charged nanoparticles and negatively charged serum proteins. Though these conditions are known to maximize in vitro transfection, they do not closely correspond to the conditions likely to be found in vivo.

Poly(β-amino ester)/DNA vector transfections to confluent HUVECs in 12% serum containing media were initially found to be relatively poor when using particle formulations optimized for serum-free media conditions. The differences in transfection performance among several poly(β-amino ester)/DNA vectors in different media conditions as a function of polymer type, polymer to DNA w/w ratio, and DNA loading can be seen in Figure 6A,B. In this figure, optimal transfection of HUVECs in high-serum-containing media occurs at much higher w/w ratios (and higher N/P ratios) than in non-serum-containing media (polymers C32 and AA24). Other polymers like C28 are unable to transfect well in serum-containing media at any weight ratio tested even though they are quite efficacious in non-serum-containing media. In non-serum conditions, peak transfection is relatively insensitive to DNA loading (200 ng vs 600 ng per well), whereas the higher DNA loading is needed for effective transfection in serum-containing media.

These results highlight the differences in polymer vector design depending on the application conditions. Given the previous biophysical characterization results, it appears that particle size, stability, and surface charge changes are likely factors that are in part responsible for these differences in efficacy.

GFP Transfections. While high-throughput screening gives a measurement of the total gene expression per microtiter plate well, this is an aggregate measurement without any information on individual cells. To learn the transfection efficacy to

individual cells, we used fluorescent activated cell sorting (FACS) and enhanced green fluorescent protein (GFP) DNA.

FACS data was interpreted by using a two-dimensional density plot that compares the ratio of GFP channel fluorescence (*x*-axis) to yellow channel autofluorescence (*y*-axis). This method was chosen as it separates changes in autofluorescence from changes in actual GFP signal and divides the cells into two distinct populations, thereby reducing the overcounting of falsely positive cells. For example, Figure 7B shows the two-dimensional density plot of a C32/DNA transfection as 60% positive, whereas Figure 7C, which shows a one-dimensional histogram of the same experiment, would count the cells to be 76% positive. All FACS results of poly(β-amino ester) vectors and control vectors were calculated using this more conservative two-dimensional analysis.

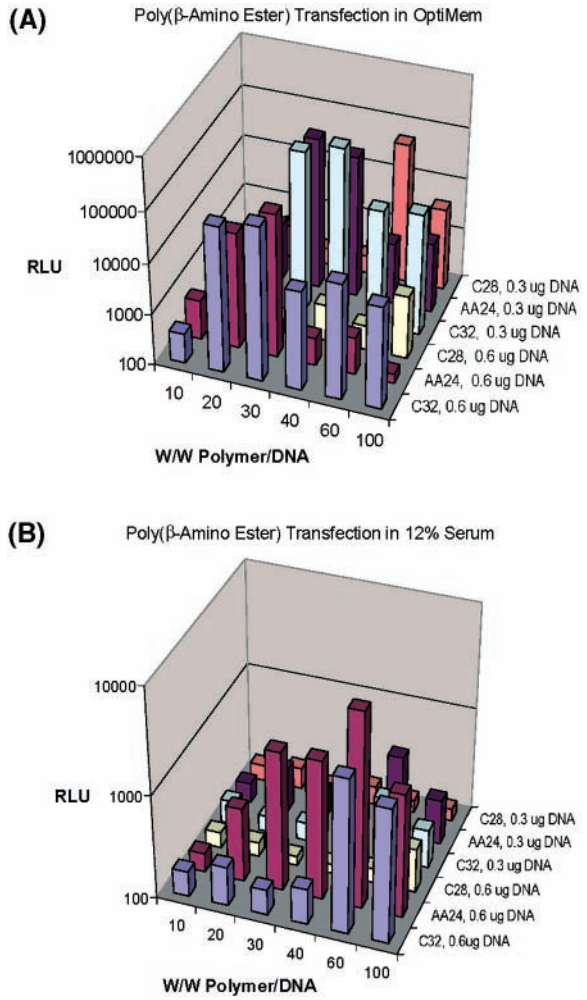

Figure 6. High-throughput screening of vectors. Optimal transfection is dependent on DNA loading, polymer weight ratio (N/P ratio), type of polymer, and presence of serum.

The best previously known transfecting polymers from the poly(β-amino ester) library (*13*) were reoptimized for transfecting HUVECs in high serum levels, and the results are shown in Figure 8. This figure demonstrates that high transfection to COS-7 cells in the absence of serum is not a guarantee of efficacy to primary human endothelial cells in serum. However, Figure 8 also demonstrates that several poly(β-amino ester) vectors were indeed found to transfect HUVECs at high levels, particularly polymers C32, JJ32, and E28.

Interestingly, the best-performing polymers all share a nearly identical structure, and single molecular differences in the polymers' structure were found to correlate to transfection efficacy. For example, polymers formed with C, JJ, and E differ by only the length of their acrylate monomer carbon chain (4, 5, and 6 carbons, respectively). Similarly, polymers formed with 20, 28, and 32 differ by only the length of their amine monomer carbon chain (3, 4, and 5 carbons, respectively). Yet, these small changes to molecular structure lead to dramatic differences in transfection efficacy. For example, increasing the length of the number of carbons in the constituent amine monomer was found to correlate to increased transfection efficacy. Polymers formed with the same acrylate monomer but different-length amine monomers transfected differentially according to length: 32 (5 carbons) > 28 (4 carbons) > 24 (3 carbons + hydroxyl group) > 20 (3 carbons). It has been reported that amine groups on a polymer are functionally responsible for the ability of a gene delivery vector to bind and unpack DNA (*25*) and to buffer the endosome to promote osmotic swelling and rupture (*26*). We hypothesize that that the seemingly small changes to constituent amine monomer length may play a role in at least one of these gene delivery bottlenecks. This analysis highlights the utility of a combinatorial library approach to designing a nonviral gene delivery vector, as similarly structured but functionally different vectors can be obtained and analyzed.

The ranked order of efficacy of these polymers shows similarities and differences between the two cell systems tested. Table 1 shows relative effectiveness of poly(β-amino ester) vector transfections to HUVECs in high-serum media versus transfections to COS-7 cells in OptiMem based on our previous work (*13*). Generally, higher w/w ratios of polymer to DNA (and correspondingly higher N/P ratios) were needed for effective delivery in high-serum-containing media. Polymer C32 was reinforced as the lead poly(β-amino ester) vector, but interestingly, other vectors performed differentially between these two cells types. C28 and U28 were previously found to be in the top 5 transfecting vectors of the whole class, but were found to transfect HUVECs in serum rather poorly. In contrast, JJ32 and E28, which were previously seen as mediocre vectors, were found to transfect HUVECs in serum with high efficacy. These findings demonstrate that a vector able to transfect well

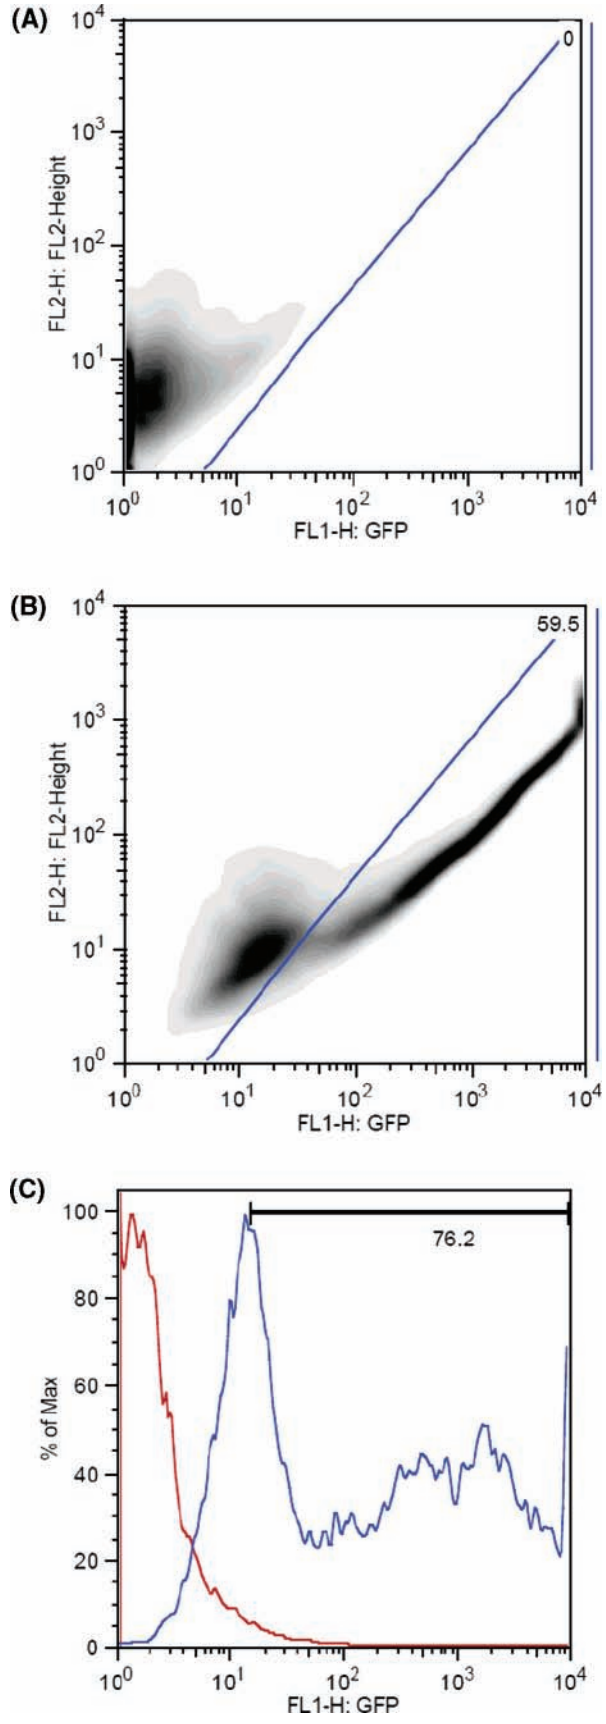

Figure 7. (A) FACS density plot and gating for negative control (0% positive) and comparison to (B) C32/DNA vector transfection (59.5% positive). Ratio of GFP fluorescence (*x*-axis) to background fluorescence (*y*-axis) was used to accurately gate positive cells. (C) The same FACS data shown in a one-dimensional histogram plot. C32/DNA transfected cells (76.2% positive) include some falsely positive cells that are excluded during the two-dimensional analysis used in part B.

in serum-free conditions may not necessarily transfect human primary cells well in high-serum conditions.

High transfection in serum-free OptiMem with poly(β-amino ester) vectors may be due in part to large particle size and positive surface charge, both promoting physical interaction of the gene delivery complexes with cells through sedimentation and attractive electrostatic forces respectively. However, in serum-containing media, ζ potential of these particles is neutral to negative, and particle size changes according to weight ratio and polymer material properties as previously indicated in the biophysical characterization section. Thus, serum interactions are potentially responsible for poorer transfection by reducing particle uptake. This hypothesis was furthered by experiments that varied particle incubation time and found that, in OptiMem or serum-free media, a 1 h incubation is sufficient for high expression, whereas in serum-containing media, a 4 h incubation is necessary (but not sufficient) to achieve high expression.

Biophysical properties of the particles in serum were found to correlate to HUVEC transfection in serum, whereas biophysical properties in buffer were unable to give the same predictive information. For example, as mentioned above, all poly(β-amino ester) vectors tested were able to condense DNA into small nanoparticles below 150 nm while in buffer, but some vectors such as C32, JJ32, and E28 formed small, stable particles while in high-serum containing media, whereas other vectors such as D24, aggregated in serum to form large particles in the micron range. C32, JJ32, and E28 were found to be the highest transfecting vectors for HUVECs in serum, whereas D24 and other aggregating polymers were found to transfect much more poorly. The top five performing polymeric vectors in serum formed particles in the 193−236-nm range, whereas the bottom performing polymers tended to form particles larger than 250 nm in the presence of high-serum-containing media. Thus, the formation of small, stable gene delivery particles in serum was found to be predictive for high efficacy in serum-containing media, and the formation of large and/or aggregating particles in serum was found to correlate to poor efficacy. On the other hand, particle size of these polymers in buffer was found not to be predictive of transfection performance in serum.

As compared to other top commercially available nonviral transfection vectors, poly(β-amino ester) vectors as a class, and C32, in particular, were found to be very efficacious. Figure 9 compares the best-performing poly(β-amino ester), C32, to other commonly used nonviral vectors. Polymeric vector C32 averages 47 ± 9% positively transfected HUVECs, which is statistically significant versus the control vectors 25K PEI (2 ± 1%, $p < 0.001$), jetPEI (11 ± 2%, $p < 0.001$), jetPEI−HUVEC (6 ± 5%, $p < 0.001$), and Lipofectamine 2000 (29 ± 1%, $p < 0.01$).

Other researchers have recently shown that tetraglucose-grafted L-PEI (jetPEI−HUVEC) is a top-performing nonviral transfection agent for transfection of HUVECs as compared

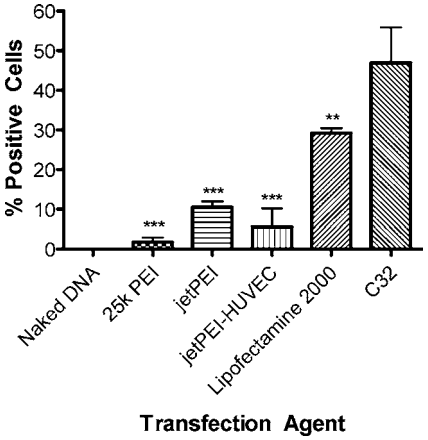

Figure 9. Comparison of vectors for HUVEC transfection in 12% serum-containing media. Each vector is shown at its optimal formulation. Error bars are standard deviations ($n \geq 4$). As compared to C32, (**) and (***) indicate statistical significance of $p < 0.01$ and $p < 0.001$ respectively.

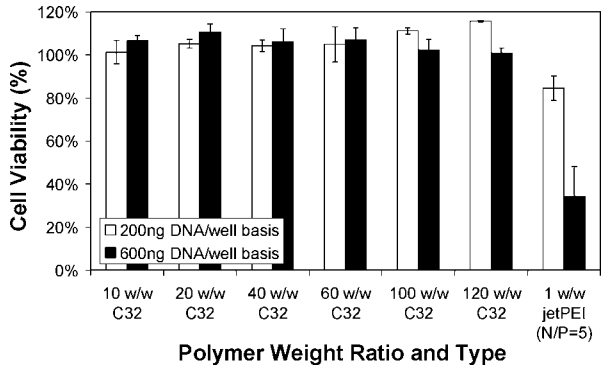

Figure 10. Poly(β-amino ester) C32 is non-cytotoxic to HUVECs in contrast to the premiere commercially available polymeric vector jetPEI. Error bars are the standard deviations of quadruplicate samples.

to other commercially available reagents (*27*). To our knowledge, C32 and other poly(β-amino ester) vectors can transfect HUVECs significantly higher than any reported nonviral vector system. It is important to note that this high transfection took place under conditions generally seen as difficult for in vitro transfection but important for an in vivo cardiovascular application: fully confluent primary cells in the presence of a high concentration of serum proteins. The percentage of HUVECs positively transfected by C32 approach those achieved with viral systems. Recently, 70% in vitro transfection of HUVECs was reported by using an engineered vesicular stomatis virus G-protein (VSV-G)-pseudotyped lentiviral vector and a nuclear localizing signal (NLS)-tagged lacZ gene (*28*). Improvements to C32 to allow for cellular targeting and nuclear targeting are hypothesized to further narrow this gap between viral and nonviral vectors.

Cell Viability. We have previously shown that poly(β-amino ester) vectors are biodegradable and generally non-cytotoxic (*16, 18*). In this study, C32 was non-cytotoxic to HUVECs. Figure 10 shows the cell viability of HUVECS transfected with C32 gene delivery particles as compared to non-transfected controls. Over a range of polymer to DNA w/w ratios and DNA loadings, C32/DNA vectors were determined to be non-cytotoxic. In comparison, jetPEI particles are found to be cytotoxic, particularly at high concentrations of gene delivery particles and higher DNA loading. It is also interesting to note that the C32/DNA particles are non-cytotoxic at polymer concentrations as high as ~500 ug/mL (600 ng DNA, 120 w/w C32) over 2 orders of magnitude more concentrated than when jetPEI shows cytotoxicity, indicating the relative safety of poly(β-amino esters). Of note, C32 has been shown to have good in vivo biocompatibility (*12*), in contrast to certain viral systems (*29*).

CONCLUSIONS

We have demonstrated that poly(β-amino esters) as a class, and C32 specifically, transfect human primary endothelial cells better than several leading commercially available reagents. We have determined that these particles have high efficacy, are stable in the presence of serum proteins, and are non-cytotoxic. It was also demonstrated that analyzing biophysical properties of poly(β-amino ester)/DNA complexes including size, stability, and ζ potential in the proper media conditions and dynamically over time provides good correlation to transfection efficacy and can pick up phenomena missed when biophysical particle properties are only tested in buffer. We optimized vector parameters including DNA loading and polymer-to-DNA weight ratio and determined efficacy with and without serum-containing media. As biodegradable polymers have certain safety advantages over viruses, poly(β-amino ester) gene delivery vectors may prove useful in various clinical applications.

Preparation of Bioactive and Surface Functional Oligomannosyl Neoglycoprotein Using Extracellular pH-Sensitive Glycosylation of Mutant Lysozyme Having N-Linked Signal Sequence in Yeast

Soichiro Nakamura,*,† Masanori Ban,# and Akio Kato#

Department of Biosciences and Biotechnology, Shinshu University, Nagano 399-4598, Japan, and Department of Biochemistry, Yamaguchi University, Yamaguchi 753, Japan. Received April 19, 2006; Revised Manuscript Received July 21, 2006

Bioactive oligomannosyl lysozyme with improved surface functionalities was successfully prepared by using an extracellular pH-sensitive glycosylation system for heterogeneous protein in yeast cell. A recombinant *Saccharomyces cerevisiae* carrying a mutant lysozyme gene encoding the signal sequence of an N-linked glycosylation site at position 49 was cultivated in various pH conditions to investigate the effects of extracellular pH on the glycosylation patterns and the expression of the protein. A large polymannose ($Man_{310}GlcNAc_2$) chain-linked lysozyme was predominantly expressed accompanied by small amounts of a core-type oligomannose chain ($Man_{14}GlcNAc_2$)-linked lysozyme in the yeast medium where the extracellular pH was kept at 3.5 or above, while an oligomannose chain lysozyme was preferentially expressed in the yeast medium where the pH was less than 3. The lytic activities of the oligomannosyl and the polymannosyl lysozymes were found to be 70.4 and 5.1%, respectively, of the wild-type lysozyme when *Micrococcus lysodeikticus* cells were used as the substrate. The enzymatic activity of the oligomannosyl lysozyme was totally conserved for the glycolysis assay with a soluble substrate, glycol chitin, whereas that of the polymannosyl lysozyme was not. After heating the sample up to 95 °C at pH 7.0 where no visible protein coagulation was observed, thermostability of the enzymatic activity of the oligomannosyl lysozyme was drastically improved with more than 60% of residual lytic activity. Emulsifying properties of the protein also were highly improved by the oligomannosylation, in which the emulsifying activity was 3.2 times higher than that of the wild-type protein. Corresponding to the increase of the surface functionalities, the surface tension of the oligomannosyl protein exhibited a significantly ($p < 0.05$) lower value compared to that of the wild-type. By using the lower pH medium at 3.0, it was revealed that a substantial amount (0.31 mg/L) of the oligomannosyl lysozyme was successfully obtained in the culture medium. Therefore, the extracellular pH-sensitive glycosylation system can be used to obtain bioactive and surface functional neoglycoproteins.

INTRODUCTION

Yeasts are considered cost-effective host organisms for producing high titers of recombinant heterologous proteins (*1*). The yeast *Saccharomyces cerevisiae* has been expected to be a promising candidate to produce therapeutic human glycoproteins (*2*). Yeasts and mammalian cells share the features of asparagine-linked (N-linked) oligosaccharide processing in the endoplasmic reticulum (ER), including the attachment of the common dolichol-linked precursor oligosaccharide (Dol-PP-$GlcNAc_2$-Man_9-Glc_3) and subsequent truncation to $GlcNAc_2$-Man_8. However, the oligosaccharide processed in the ER is subsequently modified in the Golgi apparatus in different glycosylation systems when comparing mammalian cells and yeasts. In *S. cerevisiae*, the core oligosaccharide is elongated in the Golgi cisternae through stepwise addition of mannose residues catalyzed by several mannosyltransferases, leading to highly branched outer chains consisting of 50−150 mannose residues (*3*, *4*). Although the yeast expression system can be used to increase the stability during heating or protease attack, hyperglycosylation in *S. cerevisiae* is a problem for therapeutic glycoprotein production. Indeed, the large molecular size of N-glycosylated lysozyme with a few hundred mannose residues was expressed in the yeast carrying the mutant lysozyme expression plasmid (*5*). The unusual polymerization of mannose outer chains in mutant lysozyme may be due to the time interval during which the protein molecule is present in Golgi cisternae. There is little information on the effects of culture condition on the expression and glycosylation patterns of heterologous proteins in yeast cells, while much work has been accomplished on the production of human therapeutics requiring glycosylation using mammalian cells (*6*−*14*). Mammalian expression studies revealed that culture pH, ammonia concentration, temperature, and carbon source influenced the glycosylation level and yield of recombinant glycoproteins (*13*−*16*). The existence of extracellular ammonia has been shown to decrease the amount of glycosylation and degree of sialylation in the mammalian expression system, indicating that this is due to local intracellular pH alterations as a result of importing ammonia into the cell (*13*, *15*, *16*). An extracellular ammonia concentration of 10−15 mM can increase the trans-Golgi pH to 7.0−7.2, while β-1,4-galactosyltransferase has been identified as having optimum activity at pH 6.5 (*15*). The shift in culture pH can alter the enzymatic activity of the transferase involved in protein processing, resulting in changes in glycosylation of the protein (*14*). It has been postulated that the extracellular pH of yeast transformants indirectly affects glycosylation during processing. In the present study, we assumed that the glycosylation pattern of mutant lysozyme could be affected by the culture condition, especially by the culture pH.

Although it has been anticipated that the attachment of carbohydrate chains to protein brings about its stability and surface functionalities, polyglycosylation appears to be inappropriate to use for the production of biologically active proteins

because of the steric hindrance of excessively long chains. The lytic activity of lysozyme was drastically diminished by the polyglycosylation with dextran through Maillard-type glycosylation (*17*), while the conjugation with small carbohydrate molecules such as glucose or lactose caused insoluble aggregates with poor surface properties (*18*). Accordingly, if a conjugation with oligosaccharide were to be applied, then a desirable active neoglycoprotein with improved surface functionalities could be created. The objective of this study was to synthesize bioactive and surface functional oligomannosyl lysozyme using an extracellular pH-sensitive glycosylation system of heterogeneous protein in yeast cells.

EXPERIMENTAL PROCEDURES

Materials. The yeast expression plasmid pYG-100 was supplied from Dr. K. Matsubara, Osaka University. The recombinant plasmid pKK-1, which contains a full-length hen egg-white lysozyme cDNA (*19*), was from Dr. I. Kumagai, University of Tokyo. T4 DNA ligase, alkaline phosphatase, and restriction enzymes were purchased from Takara Shuzo (Kyoto). The 7-DEAZA sequence kit for sequencing and the kit for blunting were also purchased from Takara Shuzo. The oligonucleotide-directed in vitro mutagenesis system (version 2) for site-directed mutagenesis and [α-^{32}P] dCTP (800 Ci/mmol) were purchased from Amersham Pharmacia Biotech. CM-Toyopearl 650M resin was from Tosoh (Tokyo). Concanavalin A-Sepharose and α-methylmannoside were from Amersham Pharmacia Biotech and Wako Pure Chemical Industries Ltd. (Tokyo), respectively. Sephadex G-50 was from Amersham Pharmacia Biotech. *Micrococcus lysodeikticus* dried cells and ethylene glycol chitin for lysozyme assay were from Sigma and Nacalai Tesque Inc. (Kyoto), respectively. Endo-β-*N*-acetylglucosaminidase (endo-H) was from Genzyme. All other chemicals were of analytical grade for biochemical use.

Construction of Yeast Expression Plasmid Carrying a Mutation of the Lysozyme Gene. A mutant lysozyme cDNA was constructed to introduce the potential asparagine-linked (N-linked) glycosylation sites (Asn-Ser-Thr) on the molecular surface at position 49, as described before (*5*). The conversion of Gly^{49} codon to Asn was carried out by site-specific mutagenesis using the bacteriophage vector M13mp19. The *Eco*RI/*Hind*III fragment of pKK-1 plasmid was subcloned into the *Eco*RI/*Hind*III site of the bacteriophage vector M13mp19. The mutant hen egg-white lysozyme cDNA was constructed in the M13mp19 vector by the Amersham oligonucleotide-directed mutagenesis system (version 2). A mutagenic oligonucleotide primer, 5′-AACACCGATAACAGTACCGA-3′, which was synthesized by the phosphoamidate method using a Pharmacia DNA synthesizer, was used to convert the Gly^{49} (GGG) codon to Asn (AAC). The presence of the mutation was confirmed by dideoxy DNA sequencing analysis (*20*). For construction of the vector, the mutant lysozyme cDNA was inserted into *Sal*I site of a yeast expression plasmid pYG-100, as previously described (*19*, *21*).

Yeast Transformation and Cultivation. The expression vector carrying a mutant lysozyme gene was introduced into *S. cerevisiae* AH22 (*MAT*a, *Leu*2, *His*4, Cir$^{\pm}$) according to the lithium acetate procedure (*22*). Leu^{+} transformants were screened by subculturing in the modified Burkholder minimum medium (*23*) plates supplemented with histidine (20 μg/mL) at 30 °C. After cultivation, well-growing colonies were then replica-cultivated in the yeast medium on a small scale (5 mL), and the overexpression subclones with the highest levels of lysozyme activity were screened and propagated from single colonies. The overexpression colonies were directly subcultured on a large scale (6 L) at 30 °C in the yeast minimum medium, in which ammonium sulfate or L-asparagine was used as a nitrogen source. Extracellular pH of the culture was controlled at the given pHs by addition of 1 N sodium hydroxide solution. Duplicate 10 mL samples were removed for monitoring pH and measuring turbidity of the culture mediums. The culture pH for all experiments was controlled within $\pm$0.1 pH units.

Isolation and Purification of the Mutant Lysozyme from Yeast Culture Medium. The supernatant of yeast culture medium was directly applied to a CM-Toyopearl 650M opened column (1.8 $\times$ 5 cm) equilibrated with 50 mM Tris-HCl buffer (pH 7.5), and the column was washed with the same buffer until the washing solution was free from proteins. The adsorbed lysozyme was eluted with 0.5 M NaCl in 50 mM Tris-HCl buffer (pH 7.5). The protein solution was diluted with deionized water at least five times and again applied to the regenerated CM-Toyopearl 650M column. The eluted lysozyme was collected and then lyophilized to measure the secretion amount and to analyze SDS−polyacrylamide gel electrophoresis. For the chemical analysis and assay of enzymatic activity, further purification was carried out using the gel filtration on a Sephadex G-50 equilibrated and eluted with 50 mM Tris-HCl buffer, pH 7.5. The protein content in each fraction was detected by measuring the absorbance at 280 nm, and the carbohydrate content was determined by measuring the absorbance at 490 nm after color development with the phenol−sulfuric acid reaction. All fractions containing glycoprotein were collected and concentrated using a regenerated cation-exchange column. The glycoprotein samples were further applied to a concanavalin A-Sepharose column (0.9 $\times$ 3 cm), which was prewashed with 10 bed volumes of 20 mM Tris-HCl buffer (pH 7.5) containing 0.5 M NaCl and then washed with the same buffer until the washing solution was free from proteins. The adsorbed glycoprotein was subsequently eluted with 100 mM α-methylmannoside in the 20 mM Tris-HCl buffer containing 0.5 M NaCl. The glycoprotein solution was diluted with deionized water at least five times and again applied to the regenerated CM-Toyopearl 650M opened column (1.8 $\times$ 2 cm).

SDS−Polyacrylamide Gel Electrophoresis. SDS−polyacrylamide gel electrophoresis (SDS−PAGE) was conducted according to the method of Laemmli (*24*) using a 15% (w/v) acrylamide separating gel and a 5% (w/v) stacking gel containing 1% (w/v) SDS. Samples were heated at 100 °C for 5 min in Tris-glycine buffer (pH 8.8) containing 1% SDS and 1% (v/v) 2-mercaptoethanol. Electrophoresis was carried out at a constant current of 10 mA for 5 h using an electrophoretic buffer of Tris-glycine containing 0.1% (w/v) SDS. After electrophoresis, the gels were stained for protein and carbohydrate with 0.025% (w/v) Coomassie Brilliant Blue R-250 solution and 0.5% (w/v) periodic acid-Fuchsin solution (*25*), respectively.

Endo-H Treatment. The digestion of the glycosylated lysozymes with endo-H was carried out according to the slightly modified method of Tarentino and Maley (*26*). The glycosylated lysozymes (0.1 mg/mL) were boiled in 50 mM sodium citrate buffer (pH 5.5) containing 1% (w/v) SDS and 200 μg/mL of phenylmethylsulfonyl fluoride for 5 min. After cooling, samples were supplemented with an equal volume of either 0.02 unit of endo-H in 50 mM sodium citrate buffer (pH 5.5) or the same buffer without the enzyme and were subsequently incubated at 37 °C for 20 h. After incubation, the samples were analyzed by SDS−PAGE.

Analysis of the N-Linked Oligosaccharide Length of Mutant Lysozyme. The total sugar content of the glycosylated lysozymes was estimated using the phenol−sulfuric acid reaction employing mannose as a standard. HPLC analysis serves as a method of identification of the hexose liberated from glycosylated lysozymes by hydrolysis with 2 N HCl at 100 °C for 3 h in a sealed glass ample. The hydrolysates were dried, dissolved in water, and chromatographed on an Asahipak NH2P-

50 column (Asahi Chemical, Tokyo) in 75% acetonitrile using the Hitachi HPLC system equipped with an RI detector. For the analysis of hexosamine, the hydrolysates with 3 N HCl at 100 °C for 4 h were dried and then analyzed using an amino acid analyzer (Tosoh, HLC 805).

Enzymatic Assay. Lysozyme activity was measured by a lysis and glycolysis assays using *M. lysodeikticus* cells and ethylene glycol chitin as substrates, respectively. Bacteriolytic activity of lysozyme was assayed by the method of Parry et al. (*27*) with a slight modification. The suspensions of *M. lysodeikticus* cells ($OD_{450} = 0.7$) were prepared in 100 mM acetic acid-sodium acetate buffer at pH 6.0. After its absorbance at 280 nm was first adjusted to 0.050, the assay lysozyme solution (0.1 mL) was added to 2.4 mL of the cell suspension in sodium acetate buffer (pH 6.0). The initial decrease in the absorbance at 450 nm of the mixture caused by lysis of *M. lysodeikticus* cells was measured at 20 °C for 1 min with a Hitachi U-2000 spectrophotometer. Hydrolytic activity with glycolysis was measured by following the reducing procedure (*28*). 0.5 mL of the lysozyme solution in 10 mM acetate buffer (pH 4.5) was added into a 1.0 mL of 0.05% (w/v) solution of ethylene glycol chitin. The mixture was incubated at 40 °C for 30 min. After the reaction, 2.0 mL of the color reagent (made by dissolving 0.5 g of potassium ferricyanide in 1 L of 0.5 M sodium carbonate) was added, and the mixture was immediately boiled for 15 min to estimate the reducing power resulting from hydrolysis of ethylene glycol chitin.

Emulsifying Properties and Surface Tension. Emulsifying activity and emulsion stability were estimated according to the modified method of Pearce and Kinsella (*29*). An emulsion was prepared by homogenizing the mixture of 1.0 mL of corn oil and 3.0 mL of a 0.1% (w/v) protein solution in a Polytron homogenizer PT 10-35 (Kinematica Co., Switzerland) at 12 000 rpm for 1 min at 20 °C. A total of 100 μL of emulsion was taken from the bottom of the test tube after the sample stood for 0, 1, 2, 3, 5 and 10 min and was diluted with 5.0 mL of 0.1% (w/v) SDS solution. The absorbance of the diluted emulsion was then measured at 500 nm. The relative emulsifying activity was represented as the absorbance at 500 nm measured immediately after emulsion formation (0 min). The emulsion stability was estimated by measuring the half-life of the turbidity detected immediately after the emulsion had formed. Surface tension was measured by an interfacial tensiometer (Kyowa Kagaku Co., Tokyo), a duNouy tensiometer, which is essentially a torsion balance with platinum ring (2 cm diameter) suspended from the beam. The platinum ring was put into 2 mL of a 0.05% (w/v) protein solution, and then the force required to release the ring from the surface was measured using the apparatus. The exhibitions of the steady surface tension required 5 min after preparation of the interface. Therefore, the measurement was carried out at 5 min intervals.

Thermal Denaturation. The apparent heat stability was estimated by measuring the developed turbidity when 0.1% (w/v) protein concentration of native and glycosylated lysozymes were heated to 95 °C from 30 °C at a heating rate of 1 °C/min in 1/15 M sodium phosphate buffer (pH7.0). After a given temperature, the heated sample was immediately replaced into a cuvette and the turbidity was measured at 500 nm. The residual lytic activity of the heated samples was determined by using *M. lysodeikticus* cells as substrate.

RESULTS

Effect of Extracellular pH on the Glycosylation and Secretion of Mutant Lysozyme. Ammonium sulfate as a nitrogen source is not used for the yeast minimum medium because the pH of the medium is lowered by the increases in sulfate during the growth of yeast. However, the nitrogen source was very useful for investigating the effect of pH on the glycosylation and expression of the heterologous lysozyme. When ammonium sulfate was used as a nitrogen source, the extracellular pH during yeast growth was reduced to 2.0, as shown in Figure 1A, whereas the pH in a culture of *S. cerevisiae* AH22 was kept at 4.6−4.7 in the yeast minimum medium in which L-asparagine was used as a nitrogen source. Although the growth of yeast was slightly suppressed in the medium containing ammonium sulfate, compared to that in the medium containing L-asparagine, almost the same order (10^8 cells/mL) of cell growth was kept in the stationary phase despite the extreme lowering of the extracellular pH. To investigate the effect of the extracellular pH on the expression of mutant lysozyme, the pH regulation of yeast culture was carried out as follows. After the cultivation of the recombinant yeast in the medium of ammonium sulfate for 4 days at 30 °C, the pH of the medium was raised to 4.0 by addition of 1 N NaOH and then kept to the same pH for another 4 days. As shown in Figure 1B, the secreted amount of lysozyme was greatly increased with the recovery of pH to 4.0. The SDS−polyacrylamide gel electrophoretic patterns of mutant lysozyme at each culture stage are shown in Figure 2. After incubation in the culture medium

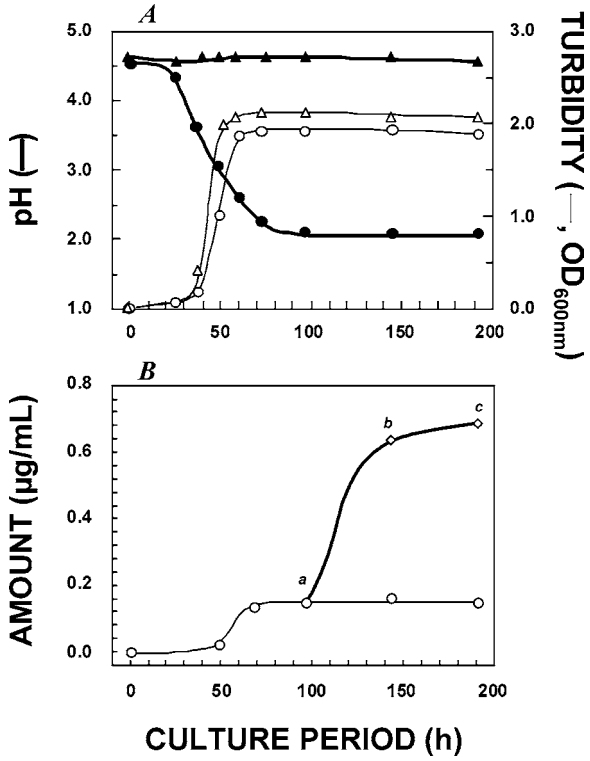

Figure 1. Effects of extracellular pH on expression of mutant lysozyme in the recombinant yeast *S. cerevisiae* AH22. (A) pH profiles and growth curves when the recombinant yeast cells carrying mutant lysozyme gene were cultured at 30 °C for 8 days in Burkholder's yeast minimum medium with L-asparagine (△, ▲) or ammonium sulfate (○, ●) as sole nitrogen sources. The solid and open symbols indicate pH and the turbidity of culture, respectively. Duplicate 10 mL samples were removed and used for monitoring pH and turbidity of the culture mediums. (B) Time course of secretion amount of the mutant lysozyme. The yeast cells were grown in Burkholder's yeast minimum medium with ammonium sulfate as a sole nitrogen source at 30 °C for 4 days (at final pH 2.0) and then incubated continuously at 30 °C for 4 days in the pH-controlled medium at pH 4.0 by the addition of NaOH. The secretion amounts of the mutant lysozyme at pH 2.0 (○) and pH 4.0 (◇) were determined by measuring the dry weight of the mutant proteins purified by two steps of cation-exchange chromatography with CM-Toyopearl from the cultivation medium. The small letters a, b, and c in the panel indicate the position and the secreted amount of mutant lysozymes obtained 0, 2, and 4 days after raising the pH to 4.0, respectively.

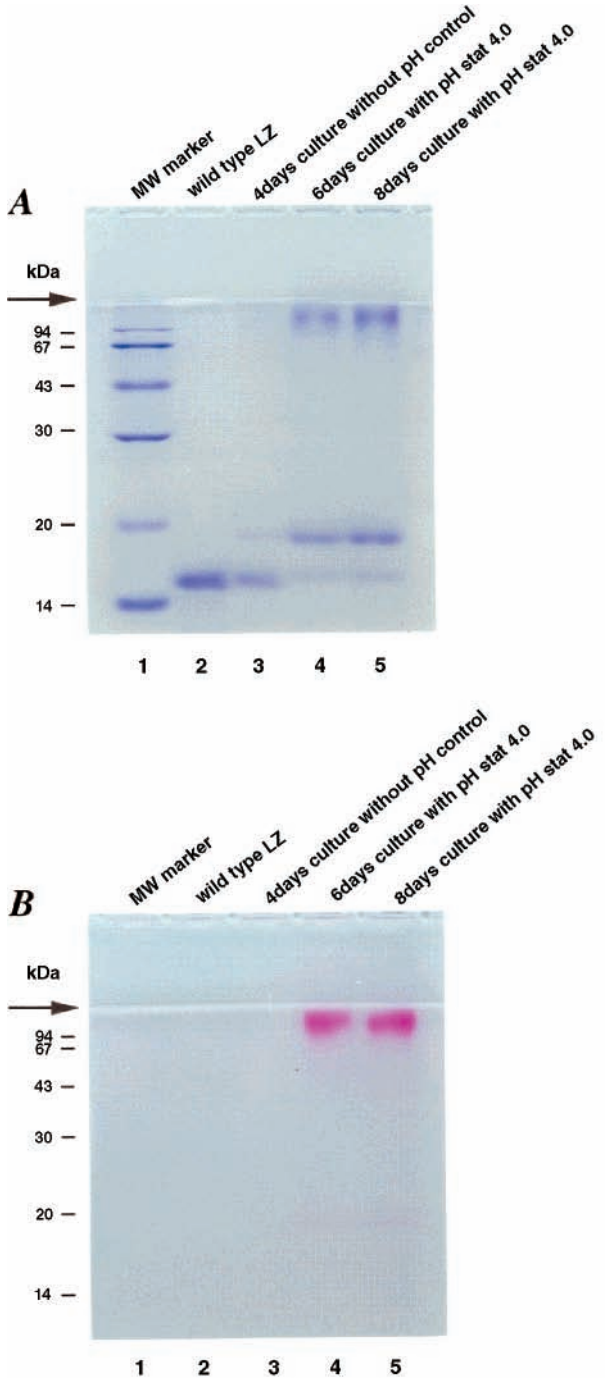

Figure 2. Changes in the SDS−polyacrylamide gel electrophoretic patterns of mutant lysozymes secreted from the recombinant yeast *S. cerevisiae* AH22 in the pH-controlled condition. The yeast cells were cultured in the yeast minimum medium with ammonium sulfate as a sole nitrogen source at 30 °C for 4 days and then incubated continuously at 30 °C for 4 days in the controlled medium at pH 4.0. The secreted lysozyme in the culture supernatant after 4 (lane 3), 6 (lane 4), and 8 days (lane 5) of incubation were purified by cation-exchange chromatography with CM-Toyopearl and subjected directly to SDS−PAGE. Electrophoresis was carried out at a constant current of 10 mA for 5 h in an electrophoresis of Tris-glycine buffer (pH 8.8) containing 0.1% SDS. The gels were stained for proteins and carbohydrates with Coomassie Brilliant Blue (A) and periodic acid-Fuchsin (B), respectively. Arrows indicate the position of the boundary between the stacking (upper) and separating (lower) gels. Lane 1, molecular weight markers (94 000, phosphorylase *b*; 67 000, bovine serum albumin; 43 000, ovalbumin; 30 000, carbonic anhydrase; 20 100, trypsin inhibitor; 14 300, α-lactalbumin); lane 2, wild-type lysozyme; lane 3, 4-day culture product shown in Figure 1B, a; lane 4, 6-day culture product shown in Figure 1B, b; lane 5, 8-day culture product shown in Figure 1B, c.

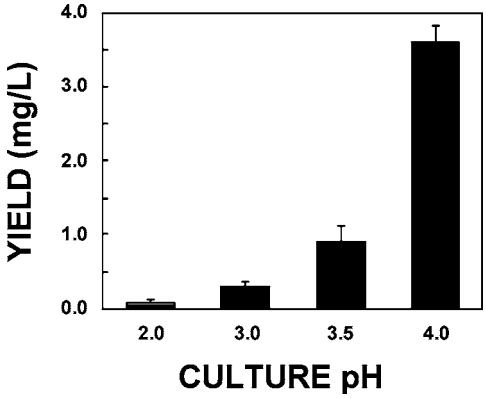

Figure 3. Effect of extracellular pH on the expression rates of mutant lysozyme. The yeast cells were cultured in the yeast minimum medium with ammonium sulfate as a sole nitrogen source at 30 °C for 4 days. To maintain pH conditions at 4.0, 3.5, and 3.0, 1 N NaOH was added in constantly maintaining by pH controller. The final pH became 2.0 without pH control. The secreted lysozymes were purified by cation-exchange chromatography with CM-Toyopearl, and the concentration was determined based on the absorbance at 280 nm. Represented values are means of three independent experiments, and the bars indicate the standard deviation.

for 4 days at 30 °C (pH 2.0), most lysozymes were not glycosylated, but a small amount of oligomannosyl protein was observed (Figure 2, lane 3). The subsequent incubation at pH 4.0 resulted in dramatic increases in the expression of polymannosyl and oligomannosyl lysozymes (Figure 2, lanes 4 and 5), although cell growth was not observed during incubation at pH 4.0. This result suggests that the glycosylation of the mutant lysozyme in yeast was regulated by the extracellular pH.

To confirm the above result, the effects of the extracellular pH in the yeast culture medium on the glycosylation of the mutant lysozyme were further examined. In the medium containing ammonium sulfate as a nitrogen source, the extracellular pHs were constantly adjusted to 4.0, 3.5, and 3.0 using 1 N NaOH, and yeast cell growth was monitored by the measurement of the culture turbidity. The cell growth increased in proportion to the incubation time at each pH and attained stationary phase after a 60 h incubation. No significant differences in the cellular growth were observed at each pH. On the other hand, remarkable increases in the secretion amounts of the lysozyme were observed with the increase in extracellular pH (Figure 3). The secretion amounts from the cultured yeast cells incubated at pH 2.0, 3.0, 3.5, and 4.0 were 0.10, 0.31, 0.91, and 3.6 mg/L of medium, respectively. When the extracellular pH was maintained at 4.0, the yield of the mutant lysozyme was 36% of that in the medium (pH 4.6−4.7) using L-asparagine as a nitrogen source (*5*). Figure 4 shows the SDS−PAGE patterns of the secreted lysozymes in the supernatant of the pH-controlled media at 4.0, 3.5, and 3.0. Polymannosyl lysozyme was secreted in proportion to increases in extracellular pH. It is interesting that pH regulation of the yeast medium greatly affected the glycosylation patterns of the mutant lysozyme. The first step in glycosylation (oligomannosylation) of the mutant lysozyme was greatly suppressed at pH 2.0 (lane 3), although protein synthesis proceeded normally. On the other hand, the mutant lysozyme was predominantly oligomannosylated at pH 3.0 (lane 4) and mostly polymannosylated at pH 3.5 (lane 5) or above (lane 6). These observations suggest that the glycosylation of proteins in yeast is affected by the extracellular pH. These data indicate that a substantial amount (0.31 mg/L) of the oligomannosyl lysozyme could be obtained in the culture medium by using the lower pH medium, i.e., at 3.0.

The glycosylated lysozymes were treated with endo-H which cleaves the high mannose-type asparagine-linked oligosaccharide

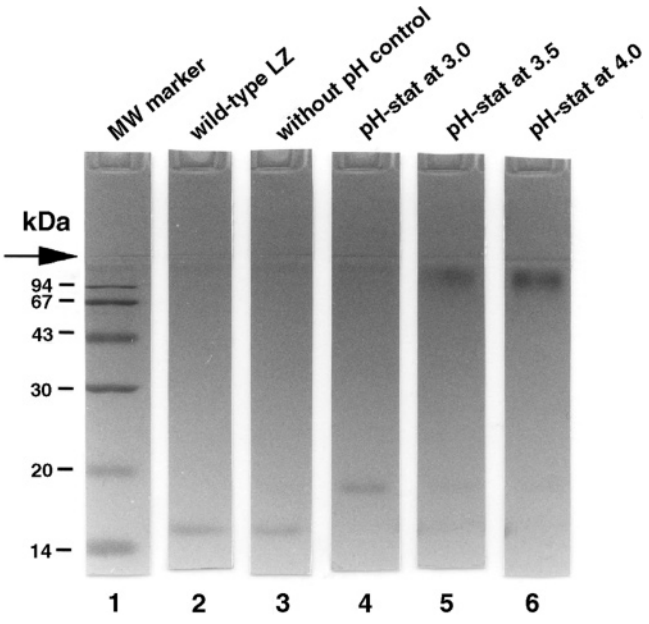

Figure 4. Electrophoretic patterns of mutant lysozymes secreted from the recombinant yeast *S. cerevisiae* AH22 cultured at various pH. The secreted lysozymes in the various pH-controlled conditions were purified by cation-exchange chromatography with CM-Toyopearl and treated with endo-H as described in Experimental Procedures and then subjected to SDS−PAGE. The gels were stained with Coomassie Brilliant Blue. Arrow indicates the position of the boundary between the stacking (upper) and separating (lower) gels. Lane 1, molecular weight markers; lane 2, wild-type lysozyme; lane 3, product obtained from the medium without pH control (final pH 2.0); lane 4, product obtained from the medium controlled at pH 3.0; lane 5, product obtained from the medium controlled at pH 3.5; lane 6, product obtained from the medium controlled at pH 4.0.

(*30*). Oligomannosyl and polymannosyl lysozyme were completely digested by endo-H, suggesting that these glycosyl lysozymes are a type of N-linked glycosylation (data not shown). The cell growth of the yeast may affect the glycosylation pattern of mutant lysozyme. To elucidate this point, the glycosylation pattern of the mutant lysozyme in various growth stages was investigated. The polymannosylation occurred in the early or mid-log phase, and no differences in the polymannosylation of mutant lysozymes were observed in each growth stage. On the other hand, as shown in Figures 2 and 4, the polymannosylation in extremely acidic medium (less than pH 3.0) did not occur in the stationary phase where the yeast growth was almost the same as that in normal medium. These results suggest that the polymannosylation was affected only by extracellular pH, independent of the yeast cell growth. The extracellular pH may affect the sorting and secretion of the foreign lysozyme in yeast cells. The polymannosyl lysozyme may remain in the cytosol or cell membrane at extremely low pH. Therefore, the presence of polymannosyl lysozyme in the yeast cell membrane and the cytosol was investigated. No polymannosyl lysozyme was observed in the cytosol or cell membrane at pH 2.0, although considerable amounts of glycosylated lysozymes were obtained at pH 4.0 or 4.6. Except for the presence of mutant lysozymes, there are no differences in the SDS−PAGE patterns of membrane proteins under various medium conditions (data not shown). Thus, it was confirmed that the glycosylated lysozyme did not remain in the yeast cell membrane or cytosol at low pH 2.0.

Chemical and Enzymatic Analysis of Glycosylated Lysozymes. The chemical composition analysis revealed that the polysaccharide chain of the polymannosyl lysozyme consisted of 310 mol of mannose and 2 mol of *N*-acetylglucosamine, while that of oligomannosyl one consisted of 14 and 2 mol, respectively (Table 1). The composition indicates that poly- and oligomannosyl lysozymes carry $Man_{310}GlcNA_2$-linked and $Man_{14}GlcNAc_2$-linked forms, respectively. This result corresponds to an increase in apparent molecular mass in SDS−PAGE (Figure 2). The carbohydrate composition of oligomannosyl lysozyme secreted at acidic pH 3.0 is almost the same as that of the core type N-linked oligosaccharide, $Man_8GlcNAc_2$, while the length of the polymannosyl chains secreted at pH 4.0 was almost the same as that secreted in normal medium (*5*). These results suggest that the acidic extracellular pH 3.0 did not affect the processing in the ER membrane but affected the subsequent elongation of the outer chains in the Golgi cisternae. Thus, it was confirmed that the lysozyme glycosylated with N-linked oligosaccharide and polysaccharide chains were separately secreted in the recombinant yeast and controlled by the extracellular pH. A similar dependency of the glycosylation of the mutant lysozyme on the extracellular pH was also observed in the medium in which asparagine was used as a nitrogen source.

Table 1. Carbohydrate Analysis of Glycosylated Lysozymes

	contents (mol/mol lysozyme) of	
lysozyme	*N*-acetylglucosamine[a]	mannose[b]
polymannosyl[c]	2	310 ± 7.5
oligomannosyl[d]	2	14 ± 0.4

[a] Determined with an amino acid analyzer using the hydrolysates with 3 N HCl at 100 °C for 4 h. [b] Determined by HPLC analysis using an NH2P-50 column and by the phenol−sulfuric acid method. Each value is the means ± standard deviation of three replications. [c] Obtained from the medium at pH 4.0. [d] Obtained from the medium at pH 3.0.

Table 2. Enzymatic Activity of Oligomannosyl and Polymannosyl Lysozymes

	enzymatic activity (%)[a] determined by	
types of protein	*M. lysodeikticus*[b]	glycol chitin[c]
wild-type lysozyme	100	100
oligomannosyl lysozyme	70.4 ± 2.7	100 ± 1.5
polymannosyl lysozyme	5.1 ± 2.8	88.7 ± 3.1

[a] Enzymatic activity was represented as the percentages of wild-type lysozyme. Each value is the means ± SD of independent experiences performed in triplicate. [b] The lytic activity was measured in 0.1 M acetate buffer (pH 6.0) with *M. lysodeikticus* as substrate. [c] The glycosis activity was measured in 0.01 M acetate buffer (pH 4.5) with glycol chitin as substrate.

The lysozyme activities were measured by lysis and glycolysis assays for oligomannosyl lysozyme and polymannosyl lysozyme secreted in the medium at pH3.0. The enzymatic activities of oligomannosyl and polymannosyl lysozymes were, respectively, 70.1 and 5.1% of the wild-type protein when *M. lysodeikticus* cells were used as substrate; therefore, long-chain glycosylation may be unsuitable for producing biologically active proteins (Table 2). These lysozyme activities were recovered by treating with endo-H. On the other hand, when glycol chitin was used as the substrate, the enzymatic activity of the oligomannosyl lysozyme was almost the same as that of unglycosylated (wild-type) lysozyme, while that of the polymannosyl lysozyme was 88.7% (Table 2). These results indicate that mature oligomannosyl lysozyme was correctly processed during the secretion in the recombinant yeast at lower pH (3.0), suggesting the inhibition of oligomannosylation was not caused by the structural changes in protein structure under the acidic condition. The biological activity of lysozyme was not appreciably deteriorated by oligomannosylation in the yeast expression system. The inhibitory activity was highly conserved in the oligomannosylated lysozyme, whereas it was significantly decreased in the fully polymannosylated lysozyme. This result indicates that the long polymannosyl chain may interfere with

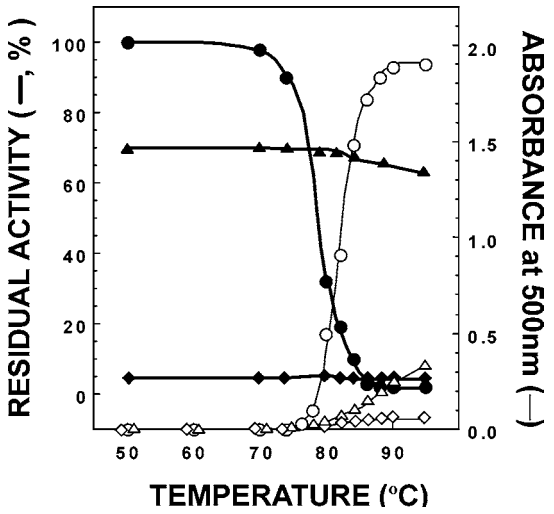

Figure 5. Thermal stability of oligomannosyl lysozyme. The thermal stability was determined by measuring the turbidity and residual activity. Samples were heated to 95 °C from 30 °C at a rate of 1 °C/min in 1/15 M sodium phosphate buffer, pH 7.0. After a given temperature, the heated sample was immediately replaced into a cuvette, and the residual activity was determined based on the lytic activity using *M. lysodeikticus* as substrate (solid symbols). The turbidity of the sample solution was measured at the absorbance of 500 nm (open symbols). Data shown are from a representative experiment repeated three times with similar results. ●○, wild-type lysozyme; ▲△, oligomannosyl lysozyme; ◇◆, polymannosyl lysozyme.

effective interaction between enzymatic pockets of the protein moiety and the substrate.

Heat Stability of Recombinant Lysozymes. Figure 5 shows the heat stability of oligomannosyl lysozyme, which was assessed by monitoring its thermal denaturation when a 0.1% protein solution was heated to 95 °C at a rate of 1 °C/min. As a result, the heating assay revealed that polymannosylation greatly improved the heat stability of the protein to an extent that no coagulation was observed. Under the same conditions, unglycosylated protein had coagulated. Almost the same phenomenon was observed in the heating system coexisting with oligomannosyl lysozyme. During heating, the protein molecules are partially unfolded, resulting in aggregation due to the heat-induced disruption of a delicate balance of various noncovalent interactions. This process was reversible in the glycosylated cystatins because of the inhibition of aggregation by poly and oligomannosyl chains through interaction of unfolded proteins, whereas that of wild-type lysozyme was irreversible. In addition, as shown in Figure 5, considerably high residual lytic activity of lysozyme toward *M. lysodeikticus* cells was kept in the oligomannosyl lysozyme after heating to 95 °C. After heating of the sample to 95 °C, the lytic activity of the polymannosyl lysozyme was 4.5% that of the native wild-type lysozyme, whereas that of oligomannosyl lysozyme was 63.3%. Thus, we have succeeded in obtaining a bioactive and stable lysozyme with an oligomannose chain. The oligomannosyl lysozyme was used for further investigation.

Improved Surface Functionalities of Oligomannosyl Lysozyme. The emulsifying properties of the oligomannosyl lysozyme constructed by genetic modification were measured under various solution systems (Figure 6). The turbidity of emulsion is plotted as the ordinate, and standing time after emulsion formation is plotted as the abscissa. The value of the ordinate at zero time is relative emulsifying activity, and the half-life of initial turbidity reflects the stability of the emulsion. Better emulsifying properties were observed in the emulsion of the oligomannosyl lysozyme. Emulsifying activity was 3.2 times higher than that of wild-type lysozyme in the neutral pH system (Figure 6A). The emulsifying properties of the oligo-

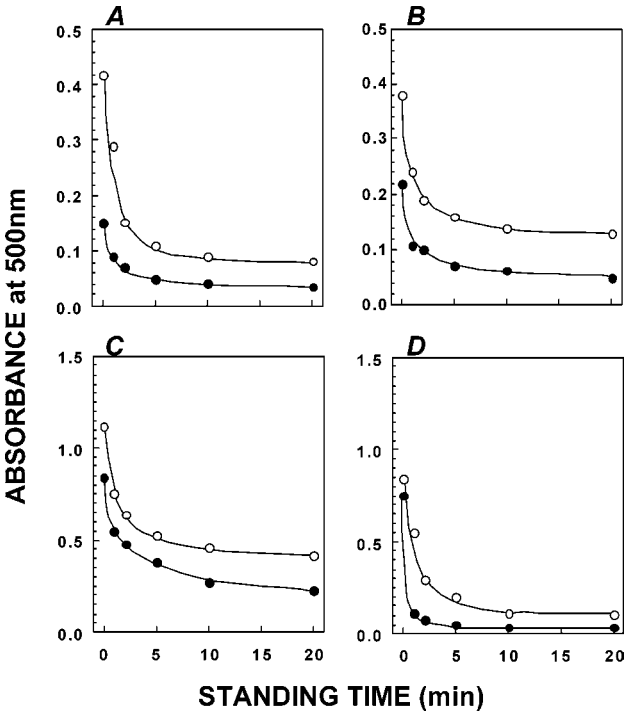

Figure 6. Emulsifying properties of oligomannosyl lysozyme under a neutral pH (1/15 M sodium phosphate buffer, pH 7.0) condition (A), an acidic pH (1/15 M sodium citrate buffer, pH 3.0) condition (B), a high-salt concentration (1/15 M sodium phosphate buffer, pH 7.0, containing 0.2 M NaCl) condition (C), and in a heating (at 65 °C for 30 min in the above neutral pH solution) condition (D). Representative data are obtained from three independent experiments with similar results. ○, oligomannosyl lysozyme; ●, wild-type lysozyme.

mannosyl lysozyme were still excellent in the high-salt condition containing 0.2 M NaCl compared to those of wild-type. The emulsifying activity and the emulsion stability of the oligomannosyl lysozyme were respectively 1.8- and 3.1-fold higher in the wild-type lysozyme (Figure 6B). The emulsifying properties of lysozymes were substantially improved in the acidic (1/15 M acetate buffer, pH 3.0) system. In particular, further improvement was demonstrated in the oligomannosyl lysozyme (Figure 6C). The emulsifying activity of the oligomannosyl lysozyme was increased 1.1 times that of the native form by preheating to 95 °C from 30 °C at a rate to 1 °C/min in the neutral pH system (Figure 6D). As shown in Figure 5, the oligomannosyl lysozyme was heat-stable, and no coagulate was observed during heat treatment at 95 °C. The resulting unfolded form of the oligomannosyl lysozyme was kept by the attached oligomannosyl outer chains without coagulation of the protein portion. The amphiphilic balance between the protein and the carbohydrate chain may play an important role for better emulsifying properties of glycoproteins. It is assumed that the hydrophobic residues of the protein moiety partially denaturated during emulsion formation at the oil−water interface may be anchored to the surface of oil droplets in emulsion, where the hydrophilic residues of the extended branched oligomannosyl chains oriented to water may cover oil droplets to inhibit the coalescence of oil droplets, resulting in higher emulsion formation. Indeed, the emulsifying properties of the oligomannosyl lysozyme were deteriorated compared to those of wild-type lysozyme after deglycosylation with endo-H (data not shown). The measurement of surface tension supplied us reasonable data to elucidate the mechanisms of the improved surface functional properties of the oligomannosyl lysozyme. As shown in Table 3, the surface tension of a 0.05% protein concentration of lysozyme solution was significantly ($p < 0.05$) reduced by the oligomannosylation compared to that of wild-

Table 3. Surface Tension of Oligomannosyl and Polymannosyl Lysozymes[a]

types of protein	surface tension (dynes/cm)
wild-type lysozyme	71.5 ± 1.7^{a}
oligomannosyl lysozyme	65.5 ± 1.5^{b}
polymannosyl lysozyme	60.1 ± 1.3^{c}

[a] The surface tension was determined in room temperature (20 °C) where the value of distilled water without any protein was 75.6 ± 0.9. Values are the means ± SD of ten times replications, and values with different letters are significantly different ($P < 0.05$).

type lysozyme. The oligomannosylation allows lysozyme to convert to a surface-active protein without a fatalloss of the biological activity.

DISCUSSION

We have shown that the polymannosyl lysozyme was preferentially secreted in the medium when the mutant lysozyme gene encoding the N-linked signal sequence at the position 49 was expressed in the yeast *S. cerevisiae* AH22 (*5*). The length of the mannose chain was found to be widely distributed from 200 to 350 residues per mole of protein, as reported in the previous paper (*5*). The length of the mannose residues of the polymannosyl lysozyme was above twice that of the general mannoproteins in yeast. This observation suggests that extensive glycosylation of the outer chain occurs in the secretion system of the heterogeneous lysozyme in yeast, probably due to its specific structural factors. In the yeast *S. cerevisiae* cells, the polymannose chain can be elongated by a highly branched outer chain that has an α-1,6-linked backbone attached to numerous side chains with one to two α-1,2-mannoses and terminal residues in an α-1,3 linkage (*31*). In addition, the mannose outer chains are extended by the different elongation specific α-1,6-mannosyltransferases (*31*). The chain length of the carbohydrate is reported to be strain specific for glycoproteins in yeast (*32*). The presence of various sizes of mannose outer chains in the yeast seems to be dependent on the characteristic of the protein structure, the degree of phosphorylation of the side chains, and the action of mannosyl transferase, etc. In addition, the size of the outer chains may also be determined by the time interval in which the corresponding proteins are present in the Golgi cisternae. Therefore, the unusual polymannosylation of lysozyme may arise from the activation of these factors to secrete harmful heterogeneous protein into the exterior of the yeast cell. However, the secretion amounts of the polymannosyl lysozyme were greatly dependent on the conditions used in the yeast culture as described in this paper. The results in Figure 1 demonstrate that the glycosylation and expression of the recombinant N-glycosylated lysozyme are reversibly recovered by raising the extracellular pH after the suppression of the glycosylation at pH 2.0. When the cultured medium pH was raised from 2.0 (extremely acidic condition) to 4.0, the yeast cells began to produce significant quantities of oligomannosyl or polymannosyl lysozyme, indicating that the recovery of the culture environment to normal pH caused the activation of the glycosylation events in the ER membrane and Golgi cisternae. This suggests that the glycosylation of protein in the ER membrane is inhibited, and further modification in the Golgi apparatus is suppressed by pH stress (the extremely low pH). No polymannosyl lysozyme was secreted; only a core-type oligomannosyl protein was secreted in a yeast culture medium at pH 3.0.

A core-type oligosaccharide ($Man_{14}GlcNAc_2$) is formed in the initial steps in the elongation pathway in the Golgi. The selective secretion of core-type oligomannosyl lysozyme at pH 3.0 is important for elucidating the mechanism of the polymannosylation of lysozyme. The possible explanations are due to inhibition of the subsequent elongation events of enzymes, alteration of the steric accessibility in the core oligosaccharide, and/or shortened period of time in the Golgi in the low pH (3.0) condition. The internal pH in yeast cells may be lowered to less than 6.0 when the extracellular pH is less than 3.0, although it is well-known that yeasts are able to maintain their internal pH between 6 and 7.5 when the extracellular pH varies from 3.5 to 9.0 (*33*). The decrease in the internal pH of yeast cells may affect the various events in the elongation of mannose outer chains in the Golgi cisternae. It is most likely that the enzymes involved in the elongation of polymannosyl residues may be inhibited at an extremely low pH. The results obtained in this study also suggest that the glycosylated lysozymes could be subjected to the transport and sorting mechanisms, which regulate their direction into regulated or constitutive secretion pathways even at an extracellular pH of less than 3.0. Defects in the polymerization of the outer chains lead to a clumped morphology, reduced viability, and distortion of the yeast cell wall (*34*), although a functional explanation is not possible at the moment. The secretion of polymannosyl lysozyme was observed at the normal extracellular pH but not at lower pH. However, the membrane proteins were secreted at lower pH as well as at the normal pH. It seems that the elongation of the outer chains in the heterologous lysozymes is sensitive to pH stress and is uniquely inhibited in the yeast culture at the low pH. Hence, the heterologous lysozyme gene could be used as a reporter in studies of the intracellular traffic of proteins through the ER and Golgi apparatus. It was also revealed that the processing of the N-linked glycosylation of heterologous proteins in yeast is greatly affected by the extracellular pH.

In this paper, we demonstrated that oligomannosylation in yeast using lower extracellular pH is able to carry an excellent emulsifying properties to lysozyme without serious loss of biological activity. The mechanism was supported by the measurement of surface tension of the oligoglycosyl lysozyme solution. It has been confirmed that the reduction of surface tension of protein solution induces excellent surfactant activity (*35*). The excellent emulsifying properties of the oligoglycosyl lysozyme were not reduced even in a high-salt solution system (1/15 M phosphate buffer, pH 7.4, containing 0.2 M NaCl) nor in an acidic (1/15 M sodium citrate buffer, pH 3.0) system and in a heating (at 65 °C for 30 min in the above neutral pH solution) system. Since high-salt, acidic pH, and heating conditions are commonly used in industrial applications, the oligomannosyl lysozyme constructed by the genetic modification could be a suitable ingredient for food agents. The oligomannosyl lysozyme revealed much better emulsifying properties, especially emulsion stability, than those of the wild-type protein, suggesting the special role of the carbohydrate chain in emulsion stability. It is well-known that amphiphilic proteins such as casein, serum albumin, and β-lactoglobulin show good emulsifying properties (*36*). By the natural attachment of the carbohydrate chain, the amphiphilicity of the protein increased in the oligomannosyl lysozyme. The enzymatic activity of lysozyme was highly conserved in the oligomannosylation in the yeast expression system; therefore, the novel oligomannosyl lysozyme with improved emulsifying properties suggests the direction of the design of new functional proteins. There is accumulating evidence that the N-linked oligosaccharide serves to improve the folding and function of bioactive proteins including *Erthrina corallodendron* lectin, soybean agglutinin, RNase B, protein aquaporin 2, and so on (*37*). We previously demonstrated that anti-rotavirus activity of human cystatin C was substantially enhanced by site-directed oligomannosylation using the yeast expression system. The highly efficient action of oligomannosyl cystatin was interpreted as a binding effect of the oligomannosyl chain to rotavirus (*38*). With the improved

surface functionalities by oligomannosylation, proteins are capable of acquiring extended biological activities. The characteristics can be exploited for various health benefits, for example, in pharmaceuticals, nutraceuticals, and food ingredients. Thus, the present study will be further appreciated from many fields.

Transcription Inhibition Using Oligonucleotide-Modified Gold Nanoparticles

Chiamaka Agbasi-Porter, Jessica Ryman-Rasmussen,† Stefan Franzen,* and Daniel Feldheim*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695. Received April 21, 2006; Revised Manuscript Received June 16, 2006

The capture of T7 RNA polymerase using double-stranded promoter DNA on the surface of gold nanoparticles has been demonstrated. The competitive binding and inhibition of T7 RNA polymerase due to specific interactions on the nanoparticle surface represents a transcription factor decoy approach in a model system. The efficiency of inhibition was determined for various nanoparticle sizes, surface coverage, and linker length for double-stranded promoter DNA on gold nanoparticles. The experiments provide a basis for determining the accessibility of binding sites on nanoparticle surfaces for applications involving cell targeting or the use of nanoparticles as binding agents in solution.

INTRODUCTION

Methods for interrupting genetic transcription and translation have become invaluable in studying the molecular biology of cells and have shown promise as in vivo therapeutic reagents (*1*−*10*). Several strategies are available to manipulate gene expression at the DNA or RNA stages. By introducing whole genes into cells, gene therapy (*2*) works at the DNA level, effectively replacing aberrant mRNA with mRNA that codes for functional protein. In contrast, antisense oligonucleotides hybridize to mRNA to alter gene splicing or prevent translation (*11*−*14*). Yet another strategy for manipulating gene expression is to prevent transcription altogether by interfering with transcription factors (*15*−*18*). This can be accomplished by introducing a competitive binding agent into the cell, for example a DNA duplex sequence that mimics a transcription factor binding site on the gene of interest. The DNA duplex acts as a "decoy", competitively binding to a transcription factor so that it is not available to perform its normal role in DNA transcription.

A critical limitation in the implementation of nearly all oligonucleotide therapeutic strategies remains the translocation of the active agent across cell and nuclear membranes. Oligonucleotides do not readily diffuse across cell membranes, and many transport vectors have been studied to aid in their cellular uptake. Nanoparticles with multiple targeting peptides have been observed to transit to both the cytoplasm and the nucleus of HepG2 and HeLa cell lines (*19*, *20*). These observations of intracellular internalization of gold nanoparticles (5 nm to 20 nm in diameter) modified with cell and nuclear targeting peptides provides the impetus to study nucleotide interactions on nanoparticle surfaces. The present study focuses on the interaction of the dsDNA promoter sequence for T7 RNA polymerase (RNAP) attached to gold nanoparticles with RNAP in solution. We show that the promoter-modified particles can effectively compete with a template DNA sequence for RNAP. This study also addresses the ability of gold particles in the 5−15 nm size range to interact with a large protein.

EXPERIMENTAL PROCEDURES

Reagents. Citrate-coated gold nanoparticles (10 and 15 nm) were purchased from Ted Pella. NAP-10 columns were purchased from Pharmacia Biotech. In vitro transcription assay kit and RNAP were obtained from Promega. Freeze & Squeeze gel extraction kit, 40% Acrylamide/Bis solution 19:1, TEMED, and ammonium persulfate were purchased from Bio-Rad. Dithiothreitol (DTT) was obtained from Pierce Chem.

The oligonucleotide sequences used in this study are listed in Table 1. Oligonucleotides were purchased from MWG Biotech Inc or IDT. The bold sections of the oligonucleotide sequence indicate the promoter region for RNAP binding. The control strand was a sequence that lacks the promoter region for RNA polymerase.

Preparation of Decoy Oligonucleotide−Gold Conjugates. Thiolated oligonucleotides were received as disulfides. The disulfide was cleaved using a 100 mM solution of dithiothreotol (DTT) in 0.1 M sodium phosphate, pH 8.3 buffer. The reaction was allowed to proceed for 30 min at room temperature, after which the oligonucleotide was desalted and separated from DTT on a NAP-10 column. The purified solution of the DNA was quantified using the absorbance at 260 nm and the extinction coefficient for each specific sequence.

Decoy oligonucleotide−Au conjugates were prepared as described in the literature with few modifications (*21*). Briefly, 20 μL or 7 μL of a 200 μM solution of the oligonucleotide were added to 500 μL of 10 nm diameter or 15 nm diameter colloidal gold solution, respectively. The final concentrations of decoy oligonucleotide and gold particles were 8 μM and 9.5 nM for 10 nm diameter particles, and 3 μM and 2.3 nM for 15 nm diameter particles, respectively. The samples were placed in a water bath at 37 °C for 4 h, after which the solution was diluted with 0.1 M NaCl/10 mM Na phosphate pH 7 to a total volume of 800 μL. The samples were incubated in the solution for at least 16 h at 37 °C. Following this, samples were centrifuged at 14 000*g* for 30 min and rinsed with 500 μL of 0.1 M NaCl/10 mM Na phosphate. After this procedure was repeated three times, the samples were resuspended in 0.3 M NaCl/10 mM Na phosphate to a final volume of 200 μL.

Mixed monolayers of decoy oligonucleotide/mercaptohexanol (MCH) were prepared by simultaneous addition of decoy oligonucleotide and MCH to gold nanoparticles. This was accomplished by adding 60 μL of 200 μM oligonucleotide solution, and 2.5 μL or 1 μL of 500 μM MCH to 2.5 mL of 10

nm diameter or 5 mL of 15 nm diameter gold nanoparticles, respectively, and allowing the reaction to proceed for 8 h. The reaction mixture was subsequently diluted with 0.1 M NaCl/10 mM Na phosphate pH 7 to a total volume of 4 mL and 9.5 mL for 10 and 15 nm gold nanoparticles, respectively. The samples were incubated in the solution for at least 16 h. The resulting nanoparticles were centrifuged three times at 14 000*g* for 30 min and washed with 500 μL of 0.1 M NaCl/10 mM Na phosphate between centrifugations. The samples were resuspended in 0.3 M NaCl/10 mM Na phosphate to a final volume of 1.5 mL.

To quantify surface-bound oligonucleotides, the nanoparticles were oxidatively etched with 0.1 M KCN. The freed oligonucleotides in solution were then quantified using OliGreen ssDNA Quantitation Kit (Molecular Probes) according to manufacturer's directions. The fluorescence was analyzed by a BioTek FL-600 plate reader.

To determine the number of oligonucleotides hybridized per nanoparticle, fluorophore-labeled oligonucleotides, which were complementary to the surface-bound oligonucleotides, were allowed to hybridize to the gold nanoparticles. Oligonucleotide−gold conjugates were prepared as described above and resuspended into a final volume of 300 μL of 0.1 M NaCl/10 mM sodium phosphate at pH 7.0. 20 μL of 100 μM fluorophore-labeled complement was added to the decoy oligonucleotide−gold conjugates. The samples were heated to 35 °C for 1 h and then allowed to anneal while cooling to room-temperature overnight in a water bath. After hybridization, the conjugates were centrifuged three times at 14 000 rpm for 30 min, washing with 200 μL of 0.3 M NaCl/10 mM sodium phosphate pH 7 buffer between centrifugations. Conjugates were resuspended into a final volume of 200 μL. The fluorophore-labeled oligonucleotides were denatured by addition of NaOH (final concentrated ∼50 mM, pH 11). After 2 h, the conjugates were centrifuged again at 14 000 rpm for 30 min. The pH of the supernatant was adjusted to 9 with 1.0 M HCl, and the fluorescence was analyzed by a BioTek FL-600 plate reader.

Transcription Assay. A competitive in vitro runoff transcription assay was performed utilizing a modification of the manufacturer's (Promega) instructions. Five micrograms (194 pmol) of the T7 DNA template was mixed with 80 units of RNAP, 33.3 mM nucleotide triphosphates (NTPs), and increasing concentrations of 10 and 15 nm decoy modified gold nanoparticles in a final reaction volume of 100 μL. The reaction was allowed to proceed for 16 h at 37 °C. The reaction mixture was spun at 14 000*g* for 30 min to pellet the gold nanoparticles, and 10 μL of the supernatants was run on a native 6% polyacrylamide gel in glycine-HCl buffer at 100 V for 90 min. The mRNA product was revealed by staining the gel with 0.45 μg/mL ethidium bromide. mRNA bands were excised, and the RNA was extracted with the Freeze & Squeeze Gel Extraction kit (Bio-Rad) according to instructions. The mRNA content of the excised bands was quantified by measuring the absorbance at 260 nm in a Hewlett-Packard 8453 Chemstation photodiode array spectrophotometer. All transcriptions were done in triplicate.

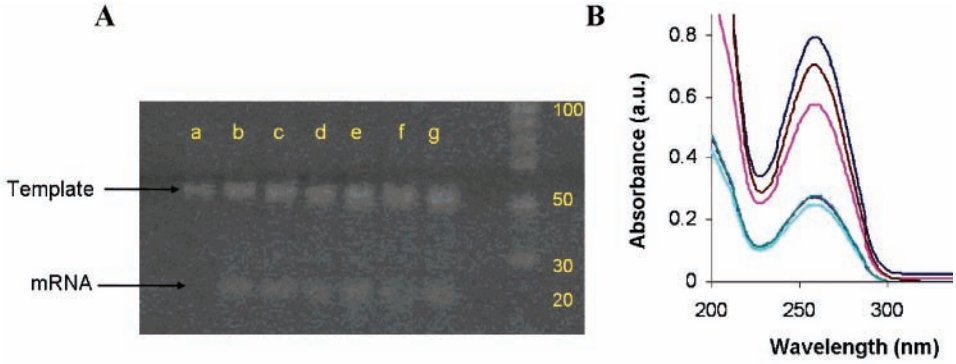

Figure 1. (A) 6% PAGE gel of transcripts after transcription assay. Lanes a) DNA template, b) no gold nanoparticles, c−g) 0.80 nM, 2.3 nM, 7.8 nM, and 11 nM, respectively, of 10 nm gold nanoparticles at 39 decoys/particle. (B) UV−visible spectra of mRNA following gel purification. Spectra correspond to material extracted from lanes b to g going from highest to lowest absorbance peak.

RESULTS

The effects of decoy surface density on RNAP binding were first studied by assembling mixed monolayers of the hexanethiol-terminated ssDNA decoy sequence (HS-$(CH_2)_6$-Decoy) and mercaptohexanol (MCH) on gold nanoparticles and then hybridizing the complement to form the fully double-stranded decoy sequence. Within the mole fractions studied (solution oligonucleotide mole fractions of 0.9, 0.75, and pure DNA), it was found that lowering the surface density of ssDNA increased the yield of duplex formation on the particle surface for both 10 and 15 nm diameter gold nanoparticles (Tables 2−4). A maximum of 50 ± 7 and 130 ± 3 duplexes per particle was found for 10 and 15 nm diameter particles, respectively, using a mole fraction of 0.75. Smaller mole fractions of DNA were investigated; however, particle aggregation was observed during preparation.

A transcription competition assay was used to compare in vitro inhibition of transcription by gold nanoparticles carrying the T7 transcription factor decoy as a function of particle diameter and number of dsDNA transcription factor decoys per particle. In a typical assay, the dsDNA template was incubated in solution with increasing concentrations of 10 or 15 nm diameter decoy-capped gold nanoparticles in the presence of NTPs and RNAP. After the transcription reaction was completed, the reaction mixture was centrifuged to separate the nanoparticles from the template and mRNA transcript (supernatants). The supernatants were eluted on a 6% PAGE gel, and the transcript bands were removed and purified by freeze and squeeze extraction. Figure 1A shows a representative PAGE gel. Lane a in Figure 1A is a sample containing only the dsDNA template, while lane b contains the template that had been transcribed with T7 polymerase in the absence of nanoparticles carrying the decoy. Lanes c−g are samples in which the transcription was performed in the presence of increasing concentrations of 10 nm diameter gold nanoparticles modified with 39 ± 6 decoy oligocnucleotides per particle. The top band in each lane corresponds to the dsDNA template, and the second band contains mRNA transcript. To quantify the amount of mRNA produced in each transcription, the second band from each lane was excised, and the mRNA was purified and analyzed by UV−visible spectroscopy.

The spectra presented in Figure 1B show that the T7 promoter-modified nanoparticles inhibited transcription of the template DNA. At the highest nanoparticle concentration, transcription was inhibited by approximately 80%. To determine if the inhibition of mRNA observed during the transcription assay was due to the oligonucleotide-capped gold nanoparticle decoy, controls were performed in which unmodified nanoparticles and nanoparticles modified with duplex DNA lacking the T7 promoter region were added to the transcription assay.

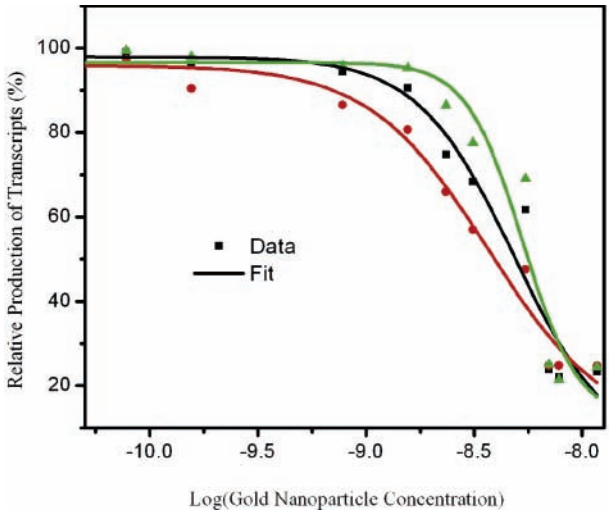

Figure 2. Dose−response curves used in the determination of IC_{50} values for decoy- modified 10 nm gold nanoparticles. The curves are (black) 1.2×10^{13} decoy/cm^2, (green) 1.5×10^{13} decoy/cm^2, (red) 1.6×10^{13} dsDNA decoy was bound to particles via a hexanethiol linker.

Transcription of the template was not inhibited in either experiment. This suggests that the oligonucleotide-capped gold nanoparticle decoy does play a specific role in the down regulation of RNA transcription by RNAP. It was then of interest to quantitatively assess transcription inhibition by nanoparticles of different sizes and decoy coverages.

To make quantitative comparisons between different nanoparticle decoys, the IC_{50} was determined. The IC_{50}, or 50% inhibition concentration values, were determined by plotting relative production of mRNA vs log nanoparticle concentration (dose−response curves, Figure 2). The dose−response curves showed, for a given particle size, only a modest change in IC_{50} as a function of decoy density (Table 5). The lowest density particles displayed an approximately 50% greater inhibition than the particles that were fully covered with the T7 promoter sequence. A much more important parameter appears to be particle size. Increasing particle size from 10 to 15 nm in diameter decreased IC_{50} by a factor of roughly 5 (Table 5). This is not solely a surface area effect since the surface area of 15 nm diameter particles is only a factor of 2 larger than that of 10 nm particles.

Another potential method for minimizing the effects of sterics on T7 polymerase binding to decoy-modified nanoparticles is to add a longer spacer between the promoter sequence and the particle surface. Three spacers were chosen to test this hypothesis, HS-$(CH_2)_6$-Adenine$_6$-Decoy (C_6-A_6), HS-$(CH_2)_6$-[OCH_2-CH_2O]$_3$-Decoy (C_6-EG_3), and HS-$(CH_2)_6$-[OCH_2CH_2O]$_6$-Decoy

(C_6-EG_6). Again, it was found that lowering the surface density of ssDNA increased the yield of duplex formation on the particle surface (Tables 3 and 4). A maximum of 77 ± 4 and 155 ± 2 duplexes per particle were found for 10 and 15 nm diameter particles, respectively, for the C_6-EG_3 linker at a mole fraction of 0.75. Surprisingly, the longer chain, C_6-EG_6, yielded less total hybridized dsDNA per particle than the shorter linkers, and a lower or comparable percentage of hybridized DNA than all but the C_6 linker. A comparison of IC_{50} values between linkers at constant particle size and mole fraction revealed a slight decrease in IC_{50} with increasing linker length in all but two cases. It is noteworthy that despite the relatively low coverage of dsDNA for particles modified with C_6-EG_6 (Table 3), IC_{50} values were lowest for this linker (Table 5).

DISCUSSION

The present study addresses the effects of steric crowding on the ability of proteins to recognize DNA-modified gold nanoparticles. One advantage of using gold nanoparticles in biological assays is that cooperative effects may enhance the binding of target molecules with biomolecules attached to the particles surface. This has been shown to improve internalization efficiencies of nanoparticles into cells (*19*−*22*) and greatly improve DNA hybridization assays (*23*, *24*). Indeed, dsDNA has been reported to be more stable when hybridized on the surface of a gold nanoparticle, yielding binding constants that are enhanced by two orders-of-magnitude compared to the identical sequences hybridized in solution (*25*). However, when a larger biomolecule such as T7 polymerase interacts with a dsDNA promoter sequence attached to a gold nanoparticle, one might expect that steric hindrance could negate any advantage afforded by the high density of DNA decoy strands on the nanoparticle. Thus, our main objective was to assess the role of steric interactions in a nanoparticle-based transcription factor decoy approach.

The role of oligonucleotides conjugated to nanoparticle surfaces in promoting nanoparticle interactions with proteins and complementary oligonucleotides has been probed in the present experiments using both differing surface concentrations of oligonucleotides and tether lengths. The congestion at the surface of a colloidal gold particle could affect the binding of proteins and the ability of DNA or RNA to hybridize. Such congestion will have functional consequences for cell targeting experiments. For this reason it is of interest to understand whether nanoparticles prepared with a high concentration of surface-bound species are able to interact with biological macromolecules.

The yield of DNA hybridization for three different surface concentrations of ssDNA was considered first. The surface concentration of ssDNA was diluted by mercaptohexanol (MCH), a passivating molecule that competes effectively with thiol-labeled ssDNA molecules for the gold surface. The importance of dilution in permitting sufficient freedom of the surface-attached ssDNA chains for hybridization was clearly demonstrated on both 10 and 15 nm particles. The implication from Tables 2−4 is that the hybridization increases as the surface density of oligonucleotides decreases. Similar observations have been made on gold nanoparticles, where hybridization efficiencies approaching 98% were also reported (*21*), and on planar gold surfaces where the maximum hybridization efficiency was observed for approximately 40% coverage by ssDNA (*26*). We would expect that the maximum hybridization yield would occur when the ssDNA chains are behaving as free nonentangled Gaussian chains. For Gaussian chain behavior the average diameter of the ssDNA would be $d = L\sqrt{N}$, where L is the distance between each successive monomer and N is the number of monomers. For ssDNA there are six single bonds separating each base (C5′-O−P−O−C3′−C4′−C5′). For the 21-mer sequence with a C_6 spacer (six carbon spacer) used in the transcription factor decoy experiments there are $N = 6 \times 22 = 132$ bonds (including the spacer) with an average bond length of $L = 1.55$ Å, we can estimate the Gaussian chain length to be $d = 1.8$ nm. We assume that the projection of the Gaussian chain length d on the surface gives the radius of gyration $r = d \cos \theta$. This simple model neglects the radius of curvature of the gold nanoparticle surface. Given this value, the area swept out by a tethered rotating ssDNA on the surface is approximately $\pi d^2 \cos \theta^2 = 4.2$ nm^2, if the projection angle θ on the surface is 50° as shown in Figure 3. The surface area of 10 and 15 nm nanoparticles are 314 nm^2 and 707 nm^2, respectively. Dividing the total surface area by the surface projection per free rotating ssDNA monomer gives an estimated maximum surface coverage of 74 and 168 ssDNA for 10 and 15 nm gold particles, respectively. If we assume that the requirement for efficient hybridization is that the ssDNA chains are free to rotate so that they can adopt a full range of conformations, and then maximum dsDNA coverage should correspond approximately to these values. These numbers compare reasonably well to the maximum values of 75 and 150 given in Table 2. If the ssDNA concentration is higher, then there is entanglement and restriction of motion leading to reduced hybridization yield.

The effect of spacer length can be to increase the freedom of the chains; however, this effect competes with an increase in the radius of gyration on the surface. The C_6-EG_3 and C_6-EG_6 chains have an increase of 9 and 18 bonds, respectively, compared to C_6. These linkers increase the Gaussian chain length by approximately 0.5 nm per EG_3 unit (i.e. 0.5 nm for EG_3 and 1.0 nm for EG_6). The longer chain and higher radius of gyration

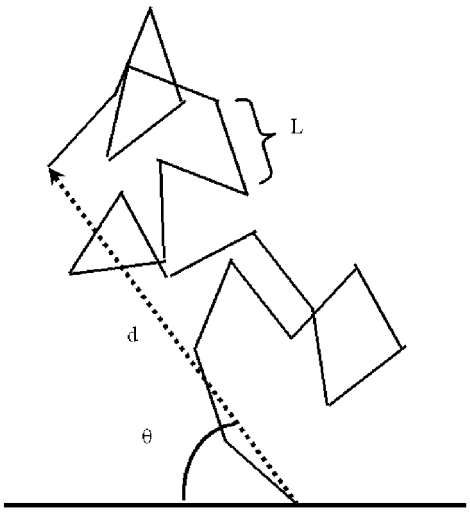

Figure 3. Illustration of the Gaussian chain length model for surface-attached oligonucleotides. The bond length is *L*. The angle of vector *d* with respect to the surface is θ.

tends to decrease the surface coverage at which maximum free rotation occurs (if the angle remains the same). For example, this model predicts that the coverage will decrease from 75 (C_6) to 67 (C_6-EG_6) for 10 nm particles and from 168 (C_6) to 151 (C_6-EG_6) for 15 nm particles due to the longer Gaussian chain length. To quantitatively explain the coverages given in Table 2 using the tethered Gaussian chain in Figure 3. Specifically, if the angle θ increases to 55° for the C_6-EG_3 linker, the predicted optimal surface coverage is 90 and 200 ssDNAs on 10 and 15 nm gold nanoparticles, respectively, which is in reasonable agreement with the data in Tables 2-4.

The binding of RNAP to the transcription factor decoy on the surface was probed by determining the IC_{50} value for inhibition of transcription in solution. The ability of RNAP to bind to dsDNA on nanoparticles with high surface densities is clearly hindered when compared to the binding to the same sequence in solution. The IC_{50} value for transcription inhibition using free decoy was found to be 1.1 pM. However, given its molar mass of 98 kDa, the fact that RNAP binds to decoy modified nanoparticles to the extent observed in this study indicates that there is a some free volume in these bioconjugates. Despite the lower surface coverage measured for decoys bound to nanoparticles through the C_6-EG_6 linker, this linker provided the optimum chain length for transcription inhibition. The results presented here thus serve to illustrate the importance of sterics in the design of nanoparticle bioconjugates for protein recognition. Short linkers or densely packed ssDNA monolayers can hinder both dsDNA formation and protein binding. The coverage of dsDNA, on the other hand, is actually highest for the C_6-EG_3 linker and decreases slightly for the longer the C_6-EG_6 linker. This effect may be due to greater entanglement of the complementary ssDNA strand if the nanoparticle-surface-bound ssDNA strand has many degrees of freedom.

One result from the current work appears to be that there is a confinement effect that hinders surface binding on small nanoparticles. We can use the transcription factor decoy assay to compare the functional binding of RNAP to oligonucleotides in solution and on nanoparticle surfaces. The binding of RNAP to oligonucleotides free in solution is ~2.5 orders-of-magnitude more favorable than binding to the same oligonucleotide on a 15 nm nanoparticle. The binding of RNAP to a tethered oligonucleotide (as represented by the IC_{50} value) is a factor of 5 stronger on a 15 nm nanoparticle than on a 10 nm nanoparticle that has the same coverage in terms of oligonucleotides/cm^2. This result is somewhat surprising since the radius of curvature is larger for the small particle, and this may be interpreted as providing greater access to the surface-attached promoter sequence for RNAP. This effect is counterbalanced by the avidity of the larger nanoparticle. On a per nanoparticle basis, a 15 nm particle has roughly twice the number of binding sites per particle.

CONCLUSIONS

The availability of surface-attached ssDNA and dsDNA on the surface of nanoparticles for binding has been probed both in terms of surface density and chain length of the linker between the oligonucleotide and the gold surface. The key results are that the optimum surface coverage for ssDNA requires a mole fraction of 0.25 for a relatively short surface passivation molecule such as MCH, and that the optimum chain length for both DNA hybridization and RNAP binding includes an EG_3 spacer adding nine bonds to the linker and greater conformational freedom of ether (CH_2OCH_2) bonding compared to aliphatic ($CH_2CH_2CH_2$) bonding. However, the enhancement of DNA hybridization promoted by the EG_3 spacer is a modest effect overall of ~10% on 15 nm particles and at most 60% on 10 nm particles. The inhibition of transcription has been demonstrated and while the binding of T7 to a surface-attached promoter sequence is clearly reduced significantly compared to a free oligonucleotide, the ability of nanoparticles to interact with DNA-binding proteins has been quantitatively demonstrated.

Oligonucleotide Microarrays: Immobilization of Phosphorylated Oligonucleotides on Epoxylated Surface

S. Mahajan, P. Kumar, and K. C. Gupta*

Nucleic Acids Research Laboratory, Institute of Genomics and Integrative Biology, Mall Road, Delhi University Campus, Delhi-110 007, India. Received April 24, 2006; Revised Manuscript Received July 19, 2006

A facile and efficient method for direct immobilization of phosphorylated oligonucleotides on an epoxy-activated glass surface is described. The new immobilization strategy has been analyzed for its performance in DNA microarray under both microwave and thermal conditions. It reflects high immobilization efficiency (~23%), and signal-to-noise ratio (~98) and resulted in high hybridization efficiency (~36%) in comparison to those obtained with standard methods, viz., NTMTA (~9.76%) and epoxide−amine (~9.82%). The probes immobilized through the new strategy were found to be heat-stable, since the performance of microarray decreased by only ~7% after subjecting it to 20 PCR-like heat cycles, suggesting that the chemistry could be used in integrated PCR/microarray devices. The immobilization of probes following the proposed chemistry resulted in spots of superior quality in terms of spot morphology, spot homogeneity, and signal reproducibility. The constructed microarrays have been successfully used for the discrimination of nucleotide mismatches. In conclusion, these features make the new immobilization strategy ideal for facile, efficient, and cost-effective manufacturing of DNA microarrays.

INTRODUCTION

DNA microarrays have rapidly evolved to become one of the essential tools to study expression or mutation of thousands of genes simultaneously (*1*−*4*). DNA microarrays are mostly based on hybridization of targets with double-stranded PCR amplicons or single-stranded oligonucleotides (probes) immobilized on a polymer surface (biochip), followed by detection via an imaging or a scanning process. These biochips are replacing labor-intensive and reagent-consuming conventional gel-based methods. Basically, oligonucleotide microarrays can be fabricated in two different ways, viz., (i) by *in situ* synthesis following conventional and photolithographic techniques (*5*−*8*) and (ii) by deposition method, i.e., immobilization of presynthesized oligonucleotides on selected polymer surfaces (*9*−*16*). The deposition method, where prefabricated oligonucleotides are immobilized either covalently or noncovalently onto various solid surfaces (organic or inorganic), offers flexibility insofar as a variety of ligands can be fixed after purification (*17*−*24*). In this approach, reactive groups are generated on the chip surface, which can form covalent bonds with the reactive functionalities available in presynthesized oligonucleotide sequence in the presence of an activator or condensing agent (*25*−*28*). The methodology allows the attachment of probes in a regioselective manner with a good surface coverage as well as retention of the full activity of probes.

In the present report, we describe a novel approach to synthesize oligonucleotide arrays that employs immobilization of 3′-phosphorylated oligonucleotides onto epoxy-functionalized glass microslides (Scheme 1) under microwave irradiation, where the reaction completes in just 10 min with remarkably high immobilization efficiency (~23% at 0.2 μM probe concentration). The uniqueness of the proposed strategy lies in opening of the epoxy ring anchored on the polymer support by the phosphate group of the 3′-phosphate oligomers, which can be synthesized simply by employing a commercially available aminoalkylated polymer support (universal support) instead of conventional nucleoside-loaded polymer supports and hence eliminates the use of engineered polymer supports. Even the larger fragments of DNA as well as PCR amplicons can be immobilized after incorporating phosphate groups by enzymatic phosphorylation.

EXPERIMENTAL PROCEDURES

Glass Silanization. The glass slides (75 × 22 mm^2) were first cleaned according to published protocol (*29*). The silanization was accomplished using GOPTS (2%, v/v) in toluene (75 mL) for 4−5 h at 50 °C (*30*). After washing and drying, the slides were stored under an inert atmosphere.

Oligonucleotide Synthesis and Purification. Oligonucleotides were synthesized at 0.2 μmol scale on a Pharmacia Gene Assembler Plus (see Supporting Information) using the standard phosphoramidite approach following the manufacturer's protocol (Gene Assembler Plus Manual, Uppsala, Sweden, 1988) (*31*).

Determination of Optimal pH Required for Immobilization of Phosphorylated Oligomers on Epoxy-Activated Glass Surface. In order to study the effect of pH on immobilization of phosphorylated oligonucleotides on epoxylated glass slide, the attachment of the probe was carried out at different pHs (6−12). Briefly, a labeled oligomer, viz., TET-d (TCT TGT ACG TCC GTC AAC GT)-OPO_3^{2-} (3 μM) dissolved in reaction buffer (*N*-methylimidazole (0.1 M) containing 10% dimethylsulfoxide (DMSO) (v/v)) of different pHs 6, 8, 10, and 12, was spotted by a pipetteman (0.5 μL) on a functionalized glass microslide and incubated in a humid chamber for 12 h, followed by capping of the residual epoxy functionalities with a capping buffer (0.1 M Tris containing 50 mM ethanolamine, pH 9.0) for 15 min at 50 °C. The slide was then subjected to washings with 1× SSC buffer (4 × 50 mL), pH 7.0, for 20 min and Milli Q water (2 × 50 mL), followed by drying under vacuum. Finally, the slide was scanned under a laser scanner.

Immobilization Kinetics. The result obtained from the model experiment was used to study the immobilization kinetics of phosphorylated oligonucleotide onto the epoxy-functionalized glass surface under microwaves (see Supporting Information).

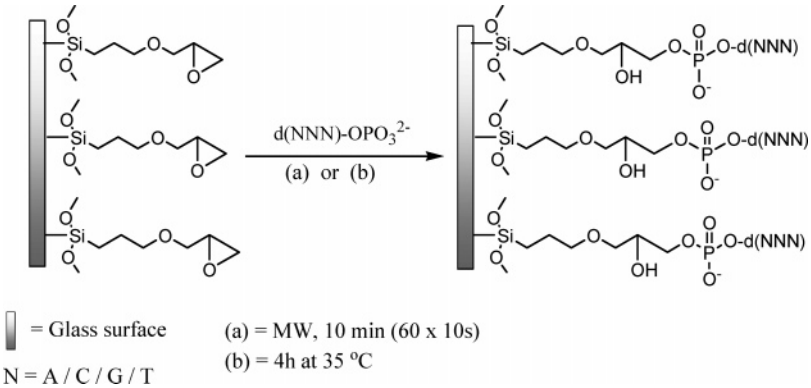
Scheme 1. Strategy for the Immobilization of Phosphorylated Oligonucleotides on Epoxy-Functionalized Glass Surface.



In order to determine the optimal time required for immobilization of 3′-phosphorylated oligonucleotide, TET-d (TCT TGT ACG TCC GTC AAC GT)-OPO_3^{2-} was diluted in reaction buffer (pH 10) to concentrations of 5, 10, and 20 μM and spotted onto epoxy-functionalized glass microslides in duplicates and subjected to microwave (MW) irradiation (with no exposure longer than 10 s in a humid chamber) in a MW oven operating at 800 W. Slides were withdrawn at regular time intervals (2, 4, 6, 8, 10, and 12 min) and subjected to capping and washings as described above. After drying under vacuum, the spots were visualized under a laser scanner and quantified.

Spotting and DNA Immobilization. In order to look into the effect of oligonucleotide concentration to achieve highest density of oligonucleotide attachment on the surface, the kinetics of the probe immobilization at various concentrations under microwave irradiation was investigated. The reactions were carried out by spotting a labeled probe, TET-d (TCT TGT ACG TCC GTC AAC GT)-OPO_3^{2-}, in a dilution series ranging from 0.2 to 40 μM concentrations for 10 min (60 $\times$ 10 s) under microwaves (as mentioned above). After treatment with capping buffer and usual washings, the slide was visualized under a laser scanner and quantified.

PCR Heat Cycling. To evaluate the thermal stability of the linkage formed by probe immobilization, a microarray was prepared by immobilizing labeled 3′-phosphorylated oligonucleotide TET-d (TCT TGT ACG TCC GTC AAC GT)-OPO_3^{2-} (5 μM) under microwave irradiation for 10 min. The constructed microarray was subjected to PCR-like conditions for 0, 5, 10, 15, and 20 cycles in 2$\times$ SSC buffer (pH 7). PCR parameters were as follows: 94 °C for 30 s (denaturing step), 54 °C for 30 s (annealing step), and 72 °C for 30 s (extension step). After thermocycling, the slide was washed, dried, and visualized under a laser scanner.

Similarly, the pH stability of the projected chemistry was evaluated by subjecting the constructed microarray to washings (4 $\times$ 15 min) with buffers of different pHs, ranging from 7 to 9.

Specificity of Immobilization Chemistry. In order to investigate the specificity of the system, four oligonucleotides, viz., d (ACG GTA ACA GGA AAA AGA AG)-OPO_3^{2-}, d (ACG GTA ACA GGA AAA AGC AG)-OPO_3^{2-}, d (ACG GTA ACA CGA AAA AGC AG)-OPO_3^{2-}, and d (TTT TTT TTT TTT TTT TTT TT)-OPO_3^{2-} (5 μM) having zero, one, and two mismatches and noncomplementary probe, were spotted on an epoxylated glass slide (under microwave irradiation) followed by capping and usual washings. Subsequently, the spots on the microslide were hybridized with a complementary labeled TET-d (CTT CTT TTT CCT GTT ACC GT) and kept at 45 °C for 1 h and then at room temperature for 12 h. After washings with hybridization buffer, 2$\times$ SSC buffer (pH 7) (5 $\times$ 5 min), the microslide was subjected to laser scanning followed by quantification.

For each experimental condition tested on the microarrays, the experiment was repeated 2−3 times. The immobilization and hybridization data presented are the average of these repetitions, and the error bars represent the percentage error ($\pm$2−4%) observed on this average. In order to determine the immobilization and hybridization efficiencies, a calibration curve was constructed using a labeled oligomer (see Supporting Information).

RESULTS AND DISCUSSION

Oligonucleotide probes bearing a 3′-phosphate group bind covalently to the epoxy-functionalized glass slide under the influence of microwaves (MW), a nonconventional energy source, which has significantly reduced the chemical reaction time from hours to minutes with increased yields (immobilization efficiency) and improved reproducibility (*32*−*34*). Though a large number of articles describe rate enhancement of reactions by microwaves, in contrast to thermal/photochemical reactions, the use of microwaves to construct oligonucleotide arrays has largely remained unexplored. We have constructed oligonucleotide arrays following the proposed chemistry and evaluated them for parameters like thermal stability, specificity, sensitivity for detection of targets, and reproducibility of attachment chemistry. The proposed strategy has been compared with the standard methods, viz., NTMTA and epoxide−amine, to highlight its advantages over them.

With the aim to determine the optimal time required to complete the reaction between 3′-phosphorylated oligomers and the epoxy-functionalized glass surface, a model experiment was designed for which a compound, 2-(4,4-dimethoxytrityloxy)-ethyl phosphate {$DMTrO(CH_2)_2OPO_3^{2-}$}, was synthesized and reacted with the epoxy-functionalized control pore glass (CPG 500 Å) under microwaves and thermal condition (see Supporting Information). The results with the model compound indicate that the reaction between phosphate and epoxy group essentially completes in 10 min under microwaves, while it takes ~4 h at 35 °C under thermal conditions.

The optimal pH required for effective immobilization of phosphorylated oligonucleotides on the epoxy-activated glass surface was determined by spotting a labeled probe (at 3.0 μM) at different pHs. The results show that maximum immobilization was achieved at pH 10.0 (Figures 1A,B); therefore, immobilization of modified probes was carried out at pH 10.0 for the rest of the experiments. Similarly, optimal time required for the immobilization process under microwaves was evaluated by constructing a microarray as mentioned in the Experimental Procedures. The results confirmed that attachment density reaches a maximum between 8 and 10 min under microwaves (Figure 2A). The immobilization of probes reaches saturation level above 20 μM as shown by the fluorescence intensity of

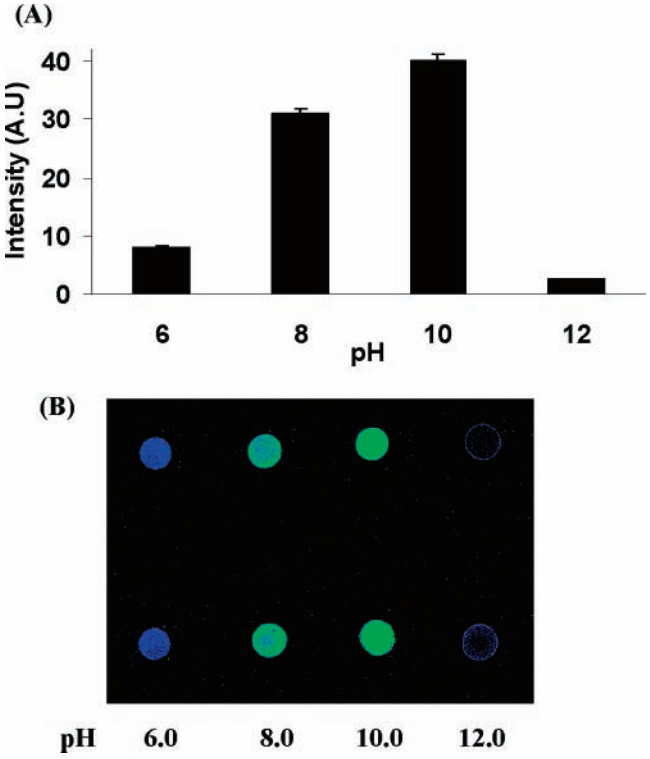


Figure 1. (A) A graph representing influence of pH on immobilization reaction of phosphorylated probe with epoxy-activated surface. (B) Fluorescence map obtained by immobilization of 5′-labeled, 3′-phosphorylated probe, TET-d (TCT TGT ACG TCC GTC AAC GT)-OPO_3^{2-}, at different pHs (6−12). Slide was scanned at 75% of laser power and 70% of photomultiplier gain.

the spots (Figure 2B). The pictorial image showing the detection limit of 0.2 μM achieved with a 20-mer oligonucleotide is shown in Figure 3.

The extent of involvement of internucleotidic phosphodiester groups and amines of heterocyclic bases to the immobilization reaction was determined by taking 5′-labeled nonphosphorylated oligomer and 4,5,6,7-tetrachlorofluorescein (TET dye) as controls of the experiment. The 5′-labeled-3′-phosphorylated, 5′-labeled nonphosphorylated oligonucleotides, and 4,5,6,7-tetrachlorofluorescein were spotted at 0.5 μM concentration on the same slide and exposed to microwaves for 10 min followed by usual washings (Figure 4A). Fluorescence intensity of spots of the nonphosphorylated oligonucleotide was found to be ∼12% of the probe with the 3′-phosphate modification, whereas no signal was observed at the place where only TET dye was spotted, implying selective binding of the terminal phosphate to the epoxy-activated surface (Figure 4B). The low but noticeable amount of immobilization of unmodified oligonucleotide could have arisen from weaker binding of phosphodiester groups of the probe to the surface. This was significantly reduced by treating the slides with capping buffer.

The thermal stability of the constructed microarray was evaluated by subjecting it to 0, 5, 10, 15, and 20 cycles of PCR-like conditions. The fluorescent signal of the heat-treated microarrays was found to decrease by only ∼3% after 10 cycles and ∼7% after 20 cycles. The fluorescent signals of heat-treated and untreated microarrays (Figure 5A) show that the oligonucleotides immobilized on an epoxy−glass slide following the proposed strategy are sufficiently stable to be used in biological research.

In an analogous way, the vulnerability of the constructed microarray toward different pHs was evaluated. The quantification results revealed that fluorescence intensity decreases by ∼4.5% at pH 8, whereas it became slightly unstable with ∼15.3% of reduction at pH 9.0 as compared to the intensity obtained at pH 7 (Figure 5B).

The dynamics of microarray hybridization was demonstrated by performing the kinetics of the hybridization reaction for different target oligonucleotide concentrations. The results depict that, in the initial stage of increasing target concentration, the hybridization signal increases and then reaches a steady state between 40 and 80 μM (Figure 6A). The kinetics of hybridization efficiency (defined as the percent of covalently attached oligonucleotides that participated in duplex formation) for different probe concentration were realized by plotting the hybridization efficiency for different amounts of immobilized probes. The hybridization efficiency reaches a maximum (∼36%) for an optimal immobilized probe concentration of 5 μM; above this concentration, the efficiency did not increase even if the concentration of immobilized probes was increased (Figure 6B). This could be explained on the basis that overloading the surface with probes might cause a crowding effect that could lower the accessibility of the surface-bound probes. In addition, the efficiency of hybridization depends on many factors like the number of accessible epoxy groups to the 3′-phosphorylated oligonucleotides on the surface, the attachment efficiency of oligonucleotides to the epoxy-functionalized surface, and the efficiency in the reaction of hybrid formation between immobilized and target oligonucleotide concentration.

However, by using a more sensitive label in the target oligonucleotide, viz., Cy 3, immobilized probes can be recognized even at low concentration (1 nM) of the target (see Supporting Information).

In order to demonstrate the specificity of the system, four oligonucleotides were immobilized onto an epoxy-functionalized glass microslide, each at 5 μM concentration. After treatment with capping buffer, the microslide was subjected to a hybrid-

ization step with a labeled oligomer (complementary to zero mismatch sequence). Fluorescence was only detected at spots exposed to the appropriate complement. Figure 7A clearly shows the base mismatches; the perfectly matched sequence gave the maximum intensity (lane 1), while spots having one (lane 2) and two (lane 3) mismatches showed fluorescence intensity in decreasing order. No measurable nonspecific hybridization signal from the noncomplementary control (lane 4) was detected, demonstrating that nonspecific hybridization did not occur. The signal-to-noise ratio was, on an average, >98 as calculated from the signals obtained from complementary hybridized spots and noncomplementary hybridized spots. The quantitative result of the scanned image is depicted in Figure 7B. The applicability of the projected strategy to recognize the target even at low concentration of spotted probe solution (0.2−1 μM) was determined by performing the hybridization experiment (see Supporting Information).

The proposed strategy for oligonucleotide microarray preparation was compared with the two existing standard methods, viz., NTMTA (*20*) and epoxide−amine (*21*). For comparison purposes, an equal concentration of the appropriate oligonucleotide (each at 5 μM) was used. However, different reaction times, as reported therein, were employed in all three methods. After immobilization, the slides were subjected to usual washings and drying. The spots were then scanned under a laser scanner for quantification, and the immobilization efficiencies for each method were calculated using the calibration curve (see Supporting Information). Similarly, to confirm the superiority of the proposed strategy, hybridization experiments were also performed at the same spotting concentration (5 μM), and the results obtained were quantified. The immobilization and hybridization efficiencies of the proposed method (∼10% and 36%) were found to be significantly higher than the method employing NTMTA reagent (∼4.5% and 9.76%) and epoxide−

amine immobilization chemistry (~4.62% and 9.82%), as shown in Figures 8A,B.

The effect of time of washing on fluorescence intensity for the above-discussed three approaches was also evaluated. Briefly, the microslides obtained after performing hybridization assay for the three methods, viz., the proposed, NTMTA, and epoxide−amine, were subjected to 5, 10, and 20 cycles of washing with 2× SSC buffer, pH 7 (each cycle of 5 min duration). The quantification results (Figure 9) reveal that the fluorescence intensities decrease by ~1.28% and 1.75% (proposed method), ~1.22% and 1.62% (NTMTA), and ~0.81% and 2.42% (epoxide−amine method) after 10 and 20 cycles, respectively.

CONCLUSIONS

We have demonstrated a new, efficient, and fast method for fabrication of oligonucleotide arrays under microwaves. The technique relies on modification of oligonucleotide at the 3′-end with a free phosphate group, an easy modification that can be performed by using commercially available aminoalkylated support, followed by reaction with epoxy-activated surface. The utility of the method is demonstrated by probing the chemical and thermal stability as well as the reproducibility of the constructed microarray. The highlighting feature of the proposed strategy is that DNA sequences as well as PCR amplicons can

also be immobilized on an epoxylated glass surface after enzymatic phosphorylation. We hope that the projected attachment chemistry involved in this effort will enable a nonchemist, the actual user, to construct oligonucleotide microarrays for routine applications.

Trastuzumab−Polyethylenimine−Polyethylene Glycol Conjugates for Targeting Her2-Expressing Tumors

Oliver Germershaus,[†] Thomas Merdan,[†] Udo Bakowsky,[†] Martin Behe,[‡] and Thomas Kissel*[,†]

Department of Pharmaceutics and Biopharmacy, Philipps University Marburg, Ketzerbach 63, 35032 Marburg, Germany and Department of Nuclear Medicine, Philipps University Marburg, Baldingerstrasse, 35043 Marburg, Germany. Received April 27, 2006; Revised Manuscript Received July 20, 2006

In this study, we describe the synthesis and characterization of a conjugate consisting of poly(ethylene glycol 2000 Da)$_{10}$-*graft*-poly(ethylene imine 25 kDa) (PEG−PEI) covalently coupled to Trastuzumab (Herceptin) via *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP) for specific gene delivery to Her2-expressing cell lines. The efficiency of DNA condensation was studied using an ethidium bromide exclusion assay and demonstrated negligible differences compared to PEG−PEI. Conjugate complex sizes were determined by dynamic light scattering to be in the range 130−180 nm. ζ potentials at different N/P ratios were close to neutral. Flow cytometry and confocal microscopy revealed efficient binding and uptake of Trastuzumab−PEI−PEG complexes using Her2-positive SK-BR-3 cells. In contrast, binding and uptake into Her2-negative OVCAR-3 cells was negligible. In good correlation with these findings, reporter gene expression using targeted complexes in SK-BR-3 cells was up to sevenfold higher than that of unmodified PEG−PEI complexes. With the use OVCAR-3 cells, no significant difference in expression efficiencies could be observed between conjugate and PEG−PEI complexes. Inhibition experiments with free Trastuzumab showed a significant decrease in reporter gene expression using SK-BR-3 cells but no decrease using OVCAR-3 cells, strongly supporting a specific Her2-receptor-mediated uptake mechanism. Our results suggest that Trastuzumab−PEI−PEG might be a promising new bioconjugate for targeted gene transfer to Her2-positive tumor cells in vivo.

INTRODUCTION

An ideal vector system for gene delivery under in vivo conditions needs to meet certain requirements: it should *efficiently* deliver genes to *specific target tissues* with *minimal toxicity* and *immunogenicity*.

Viral vectors are still the most efficient gene delivery systems, but some serious drawbacks such as immune and/or toxic reactions, oncogeniticity, and potential virus recombination limit their application (*1*, *2*).

Therefore, nonviral vectors may become a promising alternative. Among a multitude of nonviral vectors, poly(ethylene imine) (PEI) gained specific attraction, since it facilitates endosomal release and mediates efficient transfection without the use of endosomolytic reagents by the so-called proton-sponge effect (*3*−*5*). A major disadvantage of PEI−DNA polyplexes is their positive surface charge, leading to undesired interactions with nontargeted cells, blood components, or vessel endothelia (*6*, *7*). These interactions not only decrease polyplex blood half-life by fast opsonization and entrapment in fine capillaries, but they also decrease tumor specificity by accumulation of polyplexes in liver, lung, and spleen. Furthermore, biocompatibility and toxicity are major problems strongly related to these polyplex characteristics. Therefore, an important goal in developing polycation-based nonviral vectors is the design of polyplexes with decreased tendencies toward aggregation and unspecific adhesion under in vivo conditions.

To improve the aforementioned characteristics, our group (*7*, *8*) and others (*9*, *10*) have synthesized different poly(ethylene glycol)-grafted PEIs (PEG−PEI) and studied the biophysical and biological properties of the resulting complexes with DNA. Great emphasis was put on defining structure−function relationships between PEI chain length, the degree of substitution, and the MW of PEG chains for optimal complexation and shielding capacities. This research resulted in PEG-*graft*-bPEI copolymers, which showed good transfection results combined with low cytotoxicity (*7*). Furthermore, some of the resulting polyplexes showed encouraging results in pharmacokinetic studies in mice (*8*). Nevertheless, polymer composition, DNA dose, and experimental design strongly influence the outcome of such pharmacokinetic studies as shown by Merdan and co-workers (*11*), and more detailed studies will be needed.

Especially for tumor gene therapy, vectors are desired that show a high specificity for tumor cells while leaving normal cells unaffected. This would offer the possibility of applying high doses of gene constructs with minimal side effects. Several studies described specific ligand-mediated gene transfer using nonviral vectors, e.g., by transferrin (*12*, *13*), folate (*14*, *15*), or saccharides (*9*, *16*, *17*), or by antibodies or antibody fragments such as anti-CD3 (*13*, *18*), anti-PECAM (*19*), anti-OA3 (*20*), anti-GAD (*21*), or anti-PSMA antibodies (*22*). The coupling of antibodies is an advantageous strategy for targeted delivery due to their versatility, the highly specific binding to target cells, and, if an appropriate target was chosen, subsequent uptake by receptor-mediated endocytosis.

Trastuzumab, a monoclonal antibody directed against the Her2 epitope, offers the possibility of specific targeting of various cancers, such as breast, lung, ovarian, and prostate cancers (*23*−*26*). In normal tissues, Her2 is only expressed in low levels and only in certain epithelial cell types (*27*). Upon ligand binding, it is fully internalized, which is mimicked by Trastuzumab (*28*). Anti-Her2 antibodies were already successfully used for targeted drug delivery employing immunolipo-

somes (*29*) or immunoconjugates with different chemo- or radiotherapeutics (*26, 30*−*32*), in virus-like particles for gene delivery (*33*), and, most recently, as targeting moieties coupled to linear (*34*) and branched PEI (*35*).

In these studies, Trastuzumab was coupled with different linkers to unmodified PEI and revealed varying specificity and efficiency depending on the linker chemistry used, the degree of substitution, and the N/P ratio. One major drawback in both studies was the use of unmodified linear or branched PEI with the aforementioned disadvantages.

Our aim in this study was the design of a Her2-targeted nonviral vector potentially applicable for in vivo gene therapy. As described above, unmodified branched as well as linear PEIs are not suitable due to their tendency toward aggregation, unspecificity, and toxicity. We therefore used PEG-grafted branched PEI and modified this copolymer with Trastuzumab, using SPDP as a linker. Complexes were characterized by photon correlation spectroscopy (PCS), laser doppler anemometry (LDA), ethidium bromide exclusion, and atomic force microscopy (AFM). We studied Her2 expression levels of SK-BR-3 and OVCAR-3 cells using flow cytometry and correlated the findings to the binding, uptake, and reporter gene expression of targeted and nontargeted complexes in vitro. Results were verified by competitive inhibition with free Trastuzumab, underlining the receptor-dependent manner of uptake and gene expression.

EXPERIMENTAL PROCEDURES

Chemicals and Plasmid. Branched PEI 25 kDa (Polymin, 99% water free) was a kind gift of BASF AG, Ludwigshafen, Germany. Salmon testes DNA and *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP) were purchased from Sigma-Aldrich, Taufkirchen, Germany. Luciferase plasmid (pCMV-Luc) was purchased from the Plasmid Factory, Bielefeld, Germany. Trastuzumab (Herceptin) was purchased from Roche, Basel, Switzerland. All other chemicals were obtained from Merck, Darmstadt, Germany, if not otherwise indicated.

Cell Culture. SK-BR-3 and OVCAR-3 cells were purchased from ATCC, Teddington, U.K., and maintained in RPMI 1640 (PAA Laboratories, Cölbe, Germany) supplemented with 10% and 20% fetal calf serum (Cytogen, Sinn, Germany), respectively, in humidified atmosphere with 5% CO_2 at 37 °C.

Synthesis of PEG−PEI and Trastuzumab−PEG−PEI Conjugates. Poly(ethylene glycol 2000 Da)$_{10}$-*graft*-poly(ethylene imine 25 kDa) (abbreviated as PEG−PEI) was synthesized and characterized as described previously (*7*). For the synthesis of conjugates, 5 mg of PEG−PEI (equivalent to 2.8 mg of PEI) was dissolved in 1 mL reaction buffer (150 mM sodium chloride; 20 mM 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid (HEPES); pH 7.5). 20 μL of a 10 mM solution of SPDP in 100% ethanol was added while stirring and allowed to react for 60 min at room temperature. Purification of the product was performed by gel filtration on a PD-10 column (Amersham Pharmacia Biotech, Freiburg, Germany) in reaction buffer. SPDP-activated PEG−PEI was reduced using 13 μmol dithiothreitol (DTT) in 500 μL reaction buffer for 1 h at 37 °C.

Twenty milligrams Trastuzumab in reaction buffer were allowed to react with 24 μL of SPDP solution (10 mM in pure ethanol) under stirring at room temperature and were purified according to the procedure described above. SPDP-activated Trastuzumab was added to PEG−PEI−thiopropionate and allowed to react for 24 h at room temperature. Purification of the conjugate was performed by a modified ion exchange chromatography method described by Kircheis et al. (*18*). Briefly, the solvent of the reaction solution was exchanged with 150 mM NaCl and 10 mM HEPES pH 7.4 (buffer A), and the solution was applied on two serial HiTrap SP Sepharose HP columns (1 mL column volume, flow rate 1 mL/min, ÄKTAprime System, Amersham Pharmacia Biotech, Freiburg, Germany). After elution of unbound antibody with buffer A, the solvent was changed to 3 M NaCl and 10 mM HEPES pH 7.4 (buffer B) stepwise, and the conjugate was eluted. The solvent was changed to 150 mM NaCl solution pH 7.4 in a further gel filtration step, and PEI was quantified by copper complexation (*36*). The amount of antibody was determined by UV spectrometry with background correction using a solution of PEG−PEI of equal concentration with Warburg's formula

$$c\ (\mathrm{mg/mL}) = 1.55 \times (A_{280} - A_{320}) - 0.76 \times (A_{260} - A_{320})$$

where c is protein concentration in milligrams per milliliter calculated with the absorbance at the wavelengths indicated.

Preparation of Polyplexes. Luciferase plasmid and the appropriate amount of polymer were prepared in equal volumes of 150 mM NaCl, pH 7.4. Complexes were formed by adding pCMV−Luc solution to polymer solution followed by intensive mixing. Complexes were allowed to incubate at room temperature for 10 min before use.

Ethidium Bromide Exclusion Assay. DNA condensation was measured by quenching of ethidium bromide as described earlier (*37*). Briefly, 8 μg of salmon testes DNA dissolved in 79 μL water and 50 μL of 60 mM Tris buffer pH 7.4 were added to each well of a 96-well plate. Water was added to give a final volume of 300 μL per well. Subsequently, appropriate volumes of 0.05 mg/mL polymer solutions were added to produce N/P ratios between 0.2 and 4. After a 10 min incubation, 20 μL of a 0.1 mg/mL ethidium bromide solution were added. Solutions were mixed intensively, and fluorescence was measured using a fluorescence plate reader (LS 50 B, Perkin-Elmer, Rodgau-Jügesheim, Germany) at 518 nm excitation and 605 nm emission wavelengths. Results are given as the mean of triplicate measurements plus or minus standard deviation and as relative fluorescence values, where 100 is the fluorescence of DNA without polycation and 0 is the remaining fluorescence of non-intercalating ethidium bromide.

Photon Correlation Spectroscopy and ζ Potential Measurements. Hydrodynamic diameters and ζ potentials were determined in a 150 mM NaCl solution employing a Zetasizer 3000 HS (Malvern Instruments, Herrenberg, Germany; 10 mW HeNe laser, 633 nm) as described previously (*17*). In the PCS measurements, scattered light was detected at a 90° angle through a 400 μm pinhole at a temperature of 25 °C. The viscosity (0.88 mPa s) and refractive index (1.33) of distilled water at 25 °C were used for data analysis. The accuracy of size measurements was routinely checked using reference polymer particles (Nanosphere Size Standards; 50, 100, and 200 nm; Duke Scientific Corp., Palo Alto, CA). Data were analyzed using the CONTIN algorithm. Determination of the ζ potential of complexes was carried out using the standard electrophoresis cell of the Zetasizer 3000 HS at position 17.0 at 25 °C. Sampling time was set to automatic. 4 μg of luciferase plasmid in 200 μL 150 mM NaCl, pH 7.4, was complexed with the appropriate amount of polymer in the same volume. The accuracy of the instrument was checked with ζ potential transfer standard (Malvern Instruments, Herrenberg, Germany). Values given are the mean of five measurements of the same sample plus or minus the standard deviation.

Atomic Force Microscopy. Size and surface morphology of polyplexes was analyzed by atomic force microscopy. Complexes of pCMV−Luc and PEG−PEI or conjugate were prepared as described above immediately after synthesis at an N/P ratio of 3.5. Silicon chips were used as sample support. The chips were incubated with complex suspension for 10 min before drying in a stream of dry nitrogen gas. Samples were

investigated within 2 h of preparation. Microscopy was performed on a vibration- and acoustic-damped Nanoscope IV Bioscope (Veeco Instruments, Santa Barbara, CA). Commercial pyramidal Si3N4 tips (NCH-W, Veeco Instruments, Santa Barbara, CA) on an I-type cantilever with a length of 125 μm, a resonance frequency of about 220 kHz, and a nominal force constant of 36 N/m were used. All measurements were performed in tapping mode to avoid damage to the sample surface. The scan speed was proportional to the scan size. The scan frequency was between 0.5 and 1.5 Hz. Heights and phase images were recorded simultaneously.

Flow Cytometry. For flow cytometry experiments, cells were seeded in 6-well plates at a density of 400 000 cells per well and grown for 24 h. For Her2 expression experiments, cells were detached with trypsin and washed twice with 500 mL PBS at 4 °C, and cell density was adjusted to 600 000 cells/mL. Cell suspensions were mixed with Trastuzumab solution to give concentrations of 500 μg/mL and 1000 μg/mL Trastuzumab, respectively, and incubated for 15 min at 4 °C. After three washings with cold PBS, cells were incubated with 5 μg/mL FITC−goat antihuman antibody (Sigma-Aldrich, Steinheim, Germany) at 4 °C for 15 min. After three washings with cold PBS, cells were suspended in 1 mL FACS Flow (BD Biosciences, San Jose, CA) containing 4% paraformaldehyde and stored on ice until analysis.

For polyplex binding experiments, pCMV−Luc was labeled with YOYO-1 (Molecular Probes, Eugene, OR) as described elsewhere (*38*). Cells were incubated for 15 min at 4 °C with polyplexes prepared with 10 μg of YOYO-1-labeled pCMV−Luc and the appropriate amount of either PEG−PEI−Trastuzumab or PEG−PEI to obtain an N/P ratio of 3.5. Cells were subsequently washed three times with ice cold PBS, suspended in 1 mL FACS Flow containing 4% paraformaldehyde, and stored on ice until analysis.

Flow cytometry was performed using a FACScan (BD Biosciences, San Jose, CA) equipped with a 488 nm argon-ion laser. The emission filter setting was 530/30 bandpass (FL1). First, forward and sideward scatter sensitivity was adjusted so that all signals were within detection limits. The amplification of fluorescence signals was set to mean fluorescence values of approximately 0.5×10^1 for untreated cells, and settings were kept constant throughout the measurement. 10 000 events were measured in each sample. Viable cells were gated according to untreated cell samples, and only cells within this gate were subjected to further analysis. Data thus obtained were then normalized to the untreated cells. *CellQuest 3.3* software (BD Biosciences, San Jose, CA) was used for data acquisition. Data analysis was performed with *FCS Express V3* (De Novo Software, Thornhill, Canada).

Confocal Laser Scanning Microscopy. Cells were incubated with either conjugate or PEG−PEI complexes prepared with 1.66 μg YOYO-1-labeled DNA (see flow cytometry) and the appropriate amount of polymer to obtain N/P 3.5 for 20 min at 4 °C and for 2 h at 37 °C, respectively. Afterward, cells were washed three times with PBS, fixed with 4% paraformaldehyde in PBS for 20 min, and subsequently incubated for 20 min with DAPI solution (0.18 μg/mL in PBS) at room temperature. Cells were washed again three times, embedded with FluorSave Reagent (Calbiochem, San Diego, CA), and kept on ice until analysis.

A Zeiss Axiovert 100 M microscope coupled to a Zeiss LSM 510 scanning device (Zeiss, Oberkochen, Germany) was used for confocal microscopy. For excitation of YOYO-1 fluorescence, an argon laser with an excitation wavelength of 488 nm was used. Fluorescence emission was detected using a 505 nm long-pass filter. Transmission images were obtained in the same scan. In a second scan, DAPI was detected using a Coherent Enterprise II 653 laser (Coherent, Inc., Santa Clara, CA) with an excitation wavelength of 351 nm and a 385−470 nm bandpass emission filter.

Transfection Experiments. Complexes for transfection experiments were prepared using 4 μg of luciferase plasmid per well in 100 μL 150 mM NaCl pH 7.4 and the appropriate amount of polymer in 100 μL of the same solution. Transfection experiments were carried out using PEI, PEG−PEI, and conjugated PEG−PEI at N/P ratios of 2.5, 3.5, 7, and 10. SK-BR-3 and OVCAR-3 cells were seeded in 12-well plates at a density of 80 000 cells per well. After 24 h of growth, medium was removed, and complexes were added to 1.5 mL fresh medium. For inhibition experiments, 1, 10, or 100 μg/mL of free Trastuzumab was added to fresh media 20 min before addition of the complexes. Medium was changed again after 4 h, and the cells were incubated for an additional 44 h.

Luciferase gene expression was quantified using a commercial kit (Promega, Mannheim, Germany) and photon counting on a luminometer (Sirius, Berthold, Pforzheim, Germany). Results were measured in relative light units per second (RLU/s) and afterward converted to nanograms of luciferase using a standard curve of recombinant luciferase (Promega, Mannheim, Germany). Protein concentration was determined using a modified BCA assay (Perbio Science, Bonn, Germany) with bovine serum albumin as a standard (*39*). All experiments were performed in triplicate, and results are expressed as nanograms of luciferase per milligrams of protein.

Statistical Analysis. Statistical significance of differences was evaluated by either two-tailed unpaired Student's *t*-test or one-way ANOVA with Dunnett's post test. The level of significance is indicated with a single asterisk if $p \leq 0.05$, two asterisks if $p \leq 0.01$, and three asterisks if $p \leq 0.001$.

RESULTS

Synthesis of PEG−PEI and PEG−PEI−Trastuzumab. Synthesis resulted in a copolymer consisting of 10 PEG chains of 2 kDa grafted onto a chain of branched PEI with a molecular weight of 25 kDa. Copolymer composition was determined by ^{1}H NMR and FT-IR spectroscopy (*7*).

Purification of PEG−PEI−Trastuzumab by ion exchange chromatography displayed one peak of free unconjugated antibody at low ionic strength conditions. When low-ionic buffer A was stepwise substituted with high-ionic buffer B, a second peak was found containing the conjugate. The elution volumes of free antibody and PEG−PEI−Trastuzumab were comparable to those of a blend of Trastuzumab and PEG−PEI. Under the chosen experimental conditions, the SPDP linker strategy led to conjugation of Trastuzumab to PEG−PEI with a PEI to antibody ratio of 1:0.2. Variations of Trastuzumab and PEG−PEI amounts as well as SPDP concentrations and reaction times did not increase the conjugation degree.

Ethidium Bromide Exclusion Assay. To probe whether DNA condensation properties were altered by antibody conjugation, we performed an ethidium bromide exclusion assay.

Free ethidium bromide shows only weak fluorescence, but its fluorescence is strongly increased when it intercalates into DNA. Condensation of DNA by PEI and other cationic polymers decreases fluorescence by inhibiting this intercalation.

The ethidium bromide exclusion assay with PEG−PEI−Trastuzumab showed only minor differences in shape and position of the curve compared to unmodified PEG−PEI (Figure 1), suggesting no inhibitory effect of antibody-modification to DNA condensation capacity. We assume that PEI and some PEG chains form a core, which is responsible for efficient complexation of DNA, while most of the hydrophilic PEG chains as well as coupled antibody form a shell structure. This accounts for efficient shielding and presentation of the targeting moiety

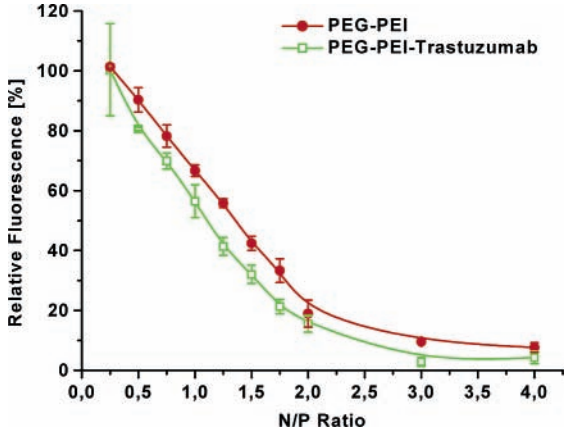

Figure 1. Ethidium bromide exclusion assay comparing unmodified PEG−PEI and PEG−PEI−Trastuzumab. Only minor differences in complexation efficiency were found after conjugation of Trastuzumab.

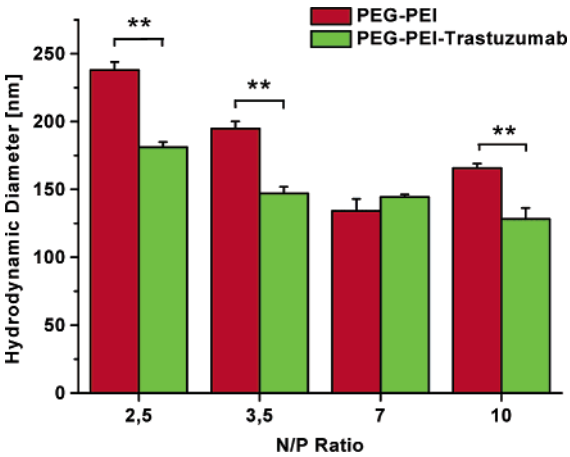

Figure 2. Comparison of hydrodynamic diameters of complexes of PEG−PEI and PEG−PEI−Trastuzumab at different N/P ratios. The PEG−PEI−Trastuzumab complexes are significantly smaller (except N/P 7) than the unmodified PEG−PEI complexes.

combined with effective complexation of DNA. These findings are in line with results obtained with Fab′−PEI−PEG conjugates (*20*). N/P ratios higher than 4 were not investigated, since DNA condensation was almost complete at this point.

Hydrodynamic Diameter and ζ Potential. Hydrodynamic diameters of PEG−PEI−Trastuzumab and PEG−PEI complexes were determined at different N/P ratios using photon correlation spectroscopy (Figure 2). The hydrodynamic diameter decreased with increasing N/P ratio for both targeted and nontargeted complexes. Complex sizes were 237.8 ± 6.1 nm or 181.0 ± 3.8 nm at N/P 2.5 and 165.7 ± 3.2 nm or 128.1 ± 8.2 nm at N/P 10 for PEG−PEI and PEG−PEI−Trastuzumab complexes, respectively. Conjugate complex sizes were significantly smaller than those of PEG−PEI complexes (except at an N/P ratio of 7). Complex sizes of 200 nm and less are favorable for endocytosis (*40*), the proposed route of cell entry for PEI/pDNA complexes (*41, 42*). Therefore, all complexes at N/P 3.5 and higher may be taken up via endocytosis.

ζ potential measurements revealed nearly neutral complex charges for PEG−PEI−Trastuzumab (maximum of +5 mV at N/P 3.5) and for PEG−PEI (maximum of +5 mV at N/P 3.5 and 10) complexes (Figure 3), which are in good correlation with earlier observations with this type of PEG−PEI copolymer (*7, 8, 20*).

Atomic Force Microscopy. Complexes were imaged using atomic force microscopy with the aim of visualizing fine structural differences in PEG−PEI−Trastuzumab vs PEG−PEI complexes. The extraordinarily high resolution of atomic force

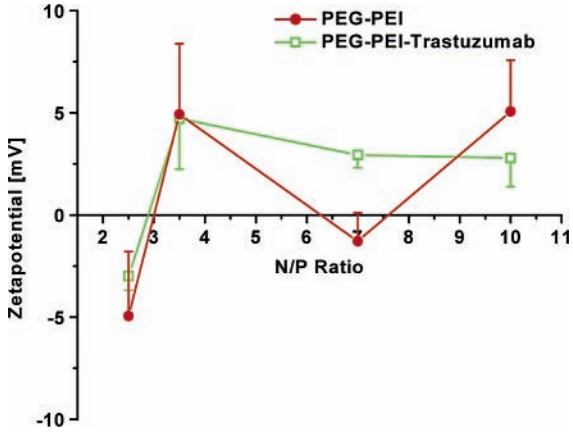

Figure 3. ζ potential values of PEG−PEI and PEG−PEI−Trastuzumab complexes at different N/P ratios. Slightly negative ζ potential values at N/P 2.5 are due to inefficient complexation of DNA. Overall ζ potential range is −5 to +5 mV, indicating nearly neutral surface charges for all complexes at each N/P ratio tested.

microscopy enables the visualization of structures down to the level of antibodies or even DNA strands. In these experiments, an N/P ratio of 3.5 was chosen to represent characteristics of complexes used for flow cytometry, confocal microscopy, and transfection studies.

PEG−PEI/pDNA complexes depicted in Figure 4A were of spherical shape with smooth surfaces and nearly homogeneous but with fairly soft material characteristics. Mean particles sizes were determined to be 152.2 ± 5.8 nm. The decrease in particle sizes compared to PCS measurements can be explained by sample preparation: Samples were measured in a semidry state in the case of AFM measurements and dispersed in sodium chloride solution in the case of PCS measurements.

In contrast, complexes of PEG−PEI−Trastuzumab were significantly smaller (Figure 4B). The mean diameter was determined to be 85.2 ± 4.2 nm. Again, complex size was significantly decreased compared to PCS measurements due to different experimental conditions. The complex surface was not as smooth as and even softer than that of PEG−PEI complexes. A small fraction of particles with sizes of about 10−20 nm was seen on and in the proximity of the complexes in the case of PEG−PEI−Trastuzumab (see arrows in 4B). The mean diameter of these particles was determined to be 18.6 nm. In a second experiment, the size of free Trastuzumab antibodies was determined under the same experimental conditions to be between 10 and 20 nm (Figure 4C). A recently published study by Thomson supports our results on sizes of IgG molecules (*43*). In this study, measurements of IgG molecules under comparable experimental conditions revealed diameters of approximately 9 nm for molecules in the "angled" position and approximately 20 nm for the "flat" orientation. We therefore conclude that the small particles found exclusively in PEG−PEI−Trastuzumab samples represent successfully coupled Trastuzumab antibodies. Hence, the presentation of targeting moieties on the complex surface can be directly verified by this method.

Flow Cytometry. Cell membrane adhesion of complexes at 4 °C was tested using flow cytometry. These data were then correlated to the binding of pure Trastuzumab to the corresponding cell line. For complex adhesion experiments, plasmid DNA was labeled using the intercalating dye YOYO-1. Unconjugated and Trastuzumab-conjugated PEG−PEI was then used to prepare complexes with labeled DNA at an N/P ratio of 3.5. After incubation at 4 °C, cell-associated fluorescence was quantified.

In the case of Trastuzumab binding studies, Trastuzumab was incubated with the cells and subsequently labeled using a

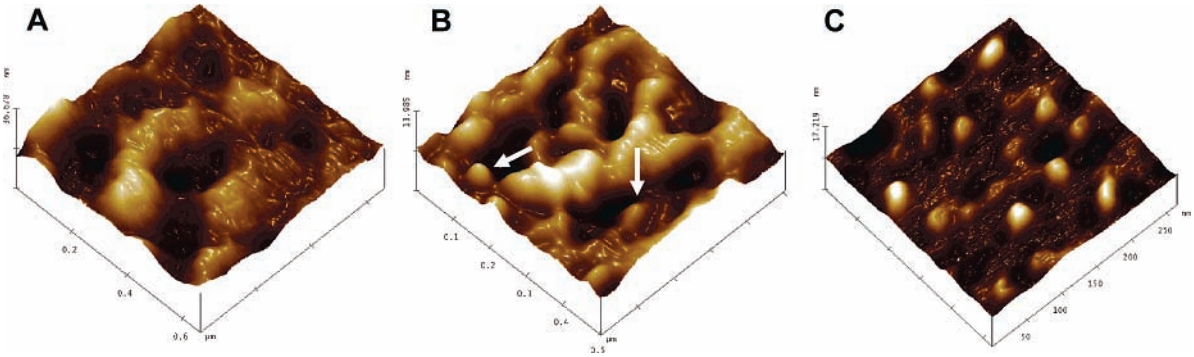

Figure 4. Atomic force micrographs of PEG−PEI/pDNA (A) and PEG−PEI−Trastuzumab/pDNA complexes (B) at N/P 3.5. Free antibody was visualized under the same experimental conditions (C). Arrows in B depict coupled Trastuzumab antibodies.

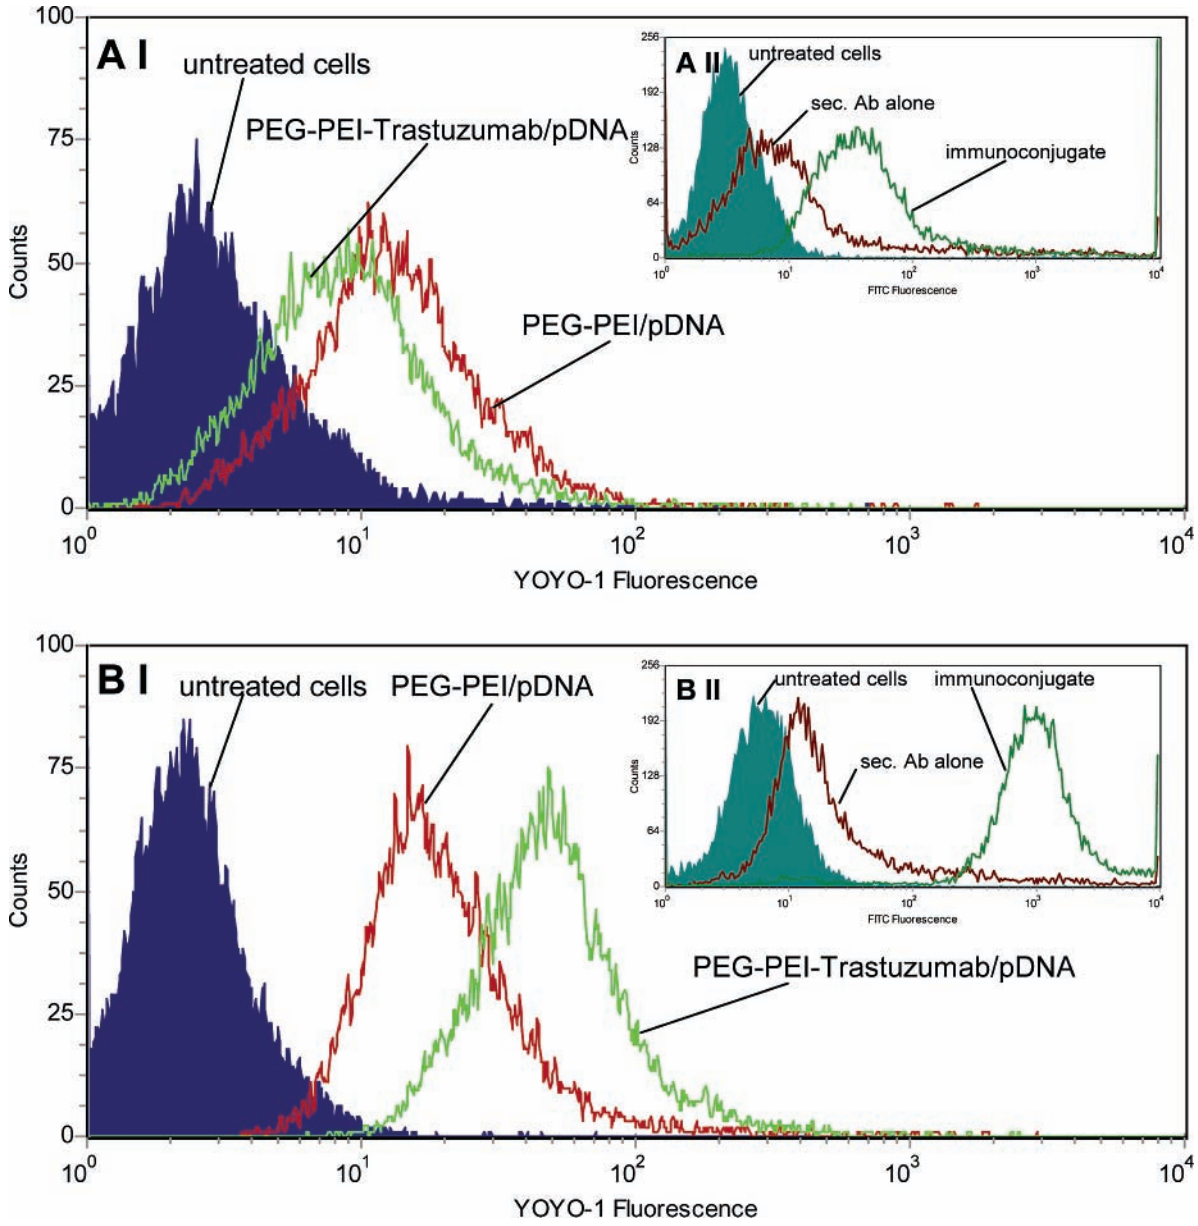

Figure 5. Flow cytometry using OVCAR-3 (A) and SK-BR-3 (B) cells. Cell surface adhesion of targeted and nontargeted PEG−PEI/YOYO-1-pDNA complexes at 4 °C were compared in OVCAR-3 and SK-BR-3 cells (A I and B I). These data can be correlated to Her2 expression levels in these cell lines tested by incubation with Trastuzumab at 4 °C and subsequent labeling with FITC−antihuman antibody (A II and B II).

secondary FITC−antihuman antibody. Cell-associated FITC fluorescence was then measured by flow cytometry as well.

OVCAR-3 cells were used as a negative control. Her2 expression was found to be very low using the immunoconjugate of Trastuzumab and FITC−antihuman antibody (Figure 5A II). When the immunoconjugate was used, the mean fluorescence increased only 4.7-fold compared to unspecific binding of FITC secondary antibody alone. With increasing amounts of Trastuzumab, the mean fluorescence showed no further increase, indicating saturation of receptors at the lowest concentration

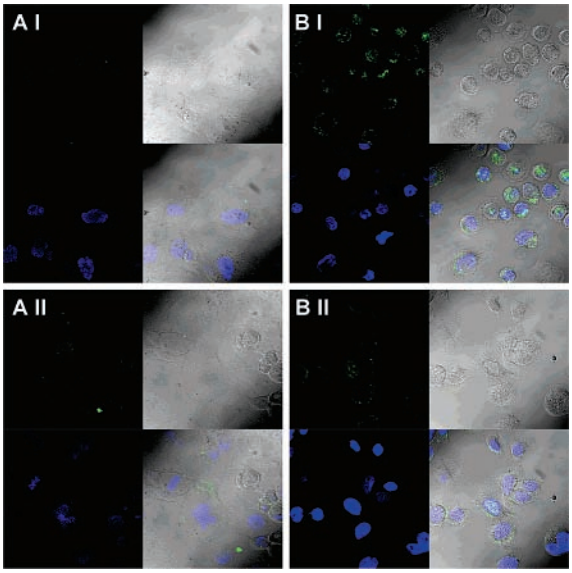

Figure 6. Confocal microscopy images of OVCAR-3 (A) and SK-BR-3 (B) cells. Cells were incubated with PEG−PEI−Trastuzumab/YOYO-1-pDNA (I) or PEG−PEI/YOYO-1-pDNA (II) complexes for 2 h at 37 °C. Upper left: YOYO-1 fluorescence (complexes). Upper right: phase contrast transmitted light image. Lower left: DAPI fluorescence (cell nuclei). Lower right: merge of all channels.

used (data not shown). These findings are consistent with low receptor expression levels in OVCAR-3 cells determined by Western blotting (*44*).

SK-BR-3 cells are reported to overexpress the Her2 antigen (*45*). Fluorescence increased 36-fold using 0.5 mg/mL Trastuzumab subsequently labeled with FITC secondary antibody compared to FITC labeled secondary antibody alone (Figure 5B II). A twofold increase of Trastuzumab concentration resulted in a 1.6-fold increase of relative fluorescence, indicating that, in the case of the lower Trastuzumab concentration, a certain number of Her2 receptors were still unsaturated (data not shown).

Unconjugated complexes showed moderate binding to OVCAR-3 cells with a mean fluorescence intensity of 13.28. By using PEG−PEI−Trastuzumab/pDNA complexes, cell adhesion decreased remarkably. The mean fluorescence value was only 8.82 in this case (Figure 5A I).

Unspecific binding of unconjugated PEG−PEI to Her2-positive SK-BR-3 cells produced a mean fluorescence intensity of 20.25. In contrast, cell-associated fluorescence increased 2.4-fold using PEG−PEI−Trastuzumab (mean fluorescence 49.58, Figure 5B I).

Confocal Laser Scanning Microscopy. Uptake of the complexes was studied by confocal microscopy. SK-BR-3 and OVCAR-3 cells were incubated for 20 min or 2 h at 37 °C with complexes composed of either unconjugated or Trastuzumab-conjugated PEG−PEI and YOYO-1-labeled plasmid DNA.

After incubating for 20 min, binding to the cell membrane occurred in both cell lines for unconjugated PEG−PEI, while a specific binding was observed only with SK-BR-3 cells if PEG−PEI−Trastuzumab was used (Data not shown).

A similar phenomenon was found when polyplexes were incubated with the cells for 2 h at 37 °C. Comparable cell uptake occurred within this time frame for both OVCAR-3 and SK-BR-3 cells using PEG−PEI/pDNA complexes (Figure 6A II and B II). With PEG−PEI−Trastuzumab/pDNA, only very little intracellular fluorescence was found for OVCAR-3 cells (Figure 6A I). In contrast, PEG−PEI−Trastuzumab complexes were readily taken up into SK-BR-3 cells (Figure 6B I).

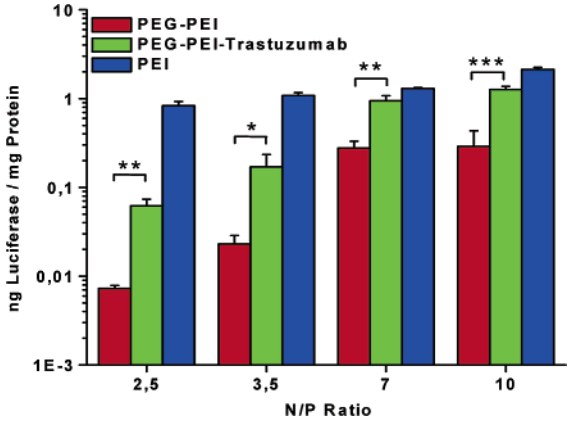

Figure 7. Transfection results using PEG−PEI/pDNA vs PEG−PEI−Trastuzumab/pDNA complexes at different N/P ratios with SK-BR-3 cells. With increasing N/P ratio, transfection efficiency of unconjugated and Trastuzumab-conjugated PEG−PEI complexes increases while differences between transfection efficiency of both complexes decrease. Transfection efficiencies of unmodified PEI 25 kDa are shown for comparison.

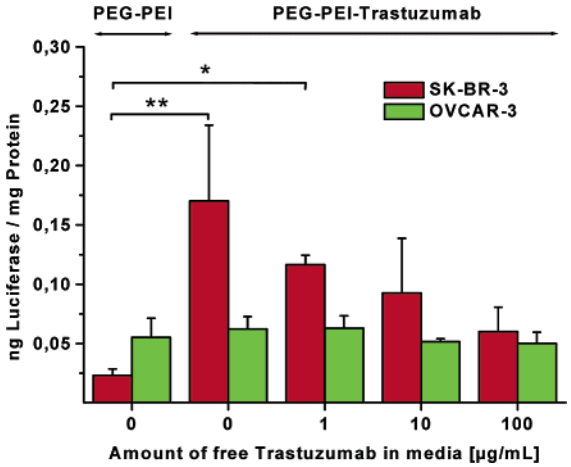

Figure 8. Reporter gene expression using PEG−PEI/pDNA vs PEG−PEI−Trastuzumab/pDNA complexes at N/P 3.5 in SK-BR-3 and OVCAR-3 cells. In the presence of free Trastuzumab in culture media, transfection efficiency is significantly decreased using SK-BR-3 cells but not in the case of OVCAR-3 cells.

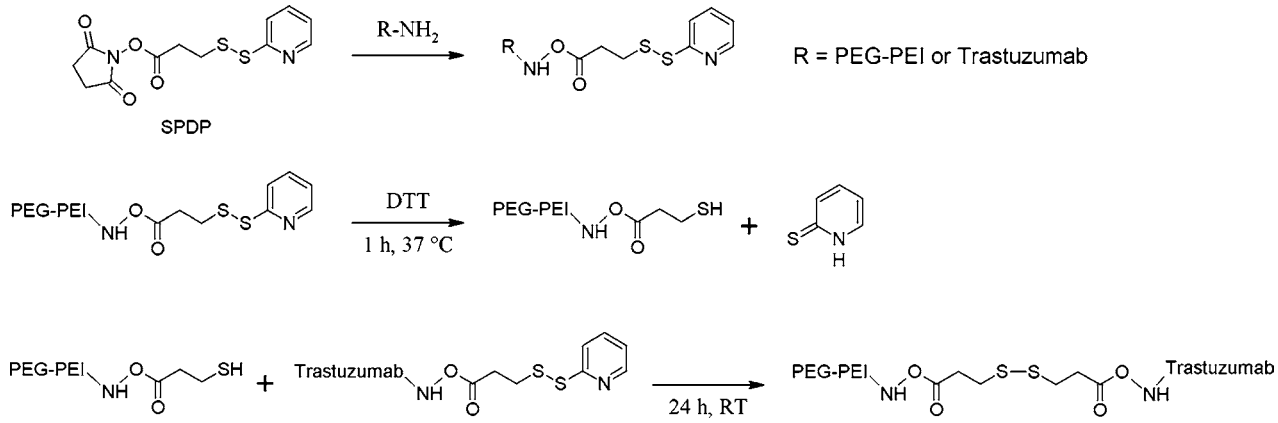
Transfection Experiments. The aim of these experiments was to correlate receptor expression levels, binding, and internalization properties with transfection efficiency in vitro and to verify the receptor-dependent manner of uptake by competitive inhibition with free Trastuzumab in culture media. As a control, pure plasmid DNA was used for transfection in both cell lines. Luciferase expression levels were not significantly different from untreated cells in this case. Unmodified PEI 25 kDa, an efficient transfection reagent under in vitro conditions, was used as a positive control in these experiments. As anticipated, complexes of unmodified PEI 25 kDa and pDNA at a N/P ratio of 3.5 showed comparably high transfection efficiencies of 1.1 and 7.0 ng luciferase per milligram of protein in SK-BR-3 and OVCAR-3 cells, respectively. However, unmodified PEI is not suitable for in vivo gene delivery due to the earlier mentioned disadvantages and serves as a point of reference.

Transfection efficiencies in SK-BR-3 were determined at four different N/P ratios (Figure 7), showing decreasing differences between conjugate and unmodified PEG−PEI with increasing N/P ratio. The overall transfection efficiency increased for both polymers with increasing N/P ratio. For transfection experiments, an N/P ratio of 3.5 was favorable due to the ap-

Scheme 1. Synthesis of PEG−PEI−Trastuzumab Conjugate



proximately neutral complex charges and appropriate complex sizes for both polymers at this point.

With OVCAR-3 cells, no significant increase in transfection efficiency could be detected with Trastuzumab conjugate compared to unmodified PEG−PEI, and no significant inhibition with free Trastuzumab was possible (Figure 8), which is in excellent agreement with the flow cytometry and confocal microscopy results.

Transfection experiments using SK-BR-3 showed up to sevenfold higher luciferase expression with Trastuzumab−PEG−PEI compared to PEG−PEI at N/P 3.5. Reporter gene expression was in this case significantly inhibited by increasing Trastuzumab concentrations. At 10 and 100 μg/mL Trastuzumab, transfection efficiencies decreased to values that were not significantly different from those of the nontargeted complexes (Figure 8).

DISCUSSION

The aim of this study was a detailed physicochemical and biological in vitro characterization of an antibody-targeted, surface-shielded, PEI-based nonviral vector system for potential in vivo application. Previous investigations with PEGylated PEIs showed efficient complexation of plasmid DNA combined with suitable complex sizes and a neutral ζ potential (*7*). If these copolymers are modified with targeting moieties such as antibodies, nonspecific interactions are minimized and transfection efficiencies in target cells are increased due to specific recognition and subsequent uptake of complexes (*46*). Therefore, PEG−PEIs are favorable for targeted gene delivery in vivo.

Recently, Chiu et al. (*34*) studied conjugates of Trastuzumab with linear PEI (22 kDa). Linear PEI is known to show a high selectivity for the lung if administered systemically (*6*, *47*). From this point of view, linear PEI is not the ideal vector system for targeted gene therapy of distant tumors in vivo. Chiu et al. used the homo-bifunctional linker dithio-bis(succinimidyl propionate) (DSP) to prepare Trastuzumab-conjugated PEI. It was reported that DSP can be used as a cross-linking reagent for branched PEI under comparable conditions (*48*). Even by using linear PEI and thereby reducing the amount of reactive amine groups per PEI molecule, intra- and intermolecular cross-linking of PEI cannot be completely ruled out. This may result in an ill-defined complex composition which would not be comparable to linear PEI itself and may lead to significantly altered physicochemical and biological complex properties. Furthermore, the reaction mixture was purified by dialysis, which does not allow separation of conjugate and free antibody. Therefore, in all probability, a mixture of L-PEI−Trastuzumab conjugate and free antibody was used by Chiu et al.

Strehblow et al. synthesized conjugates of Trastuzumab and PEI (branched, 25 kDa) using different linker chemistries (*35*). Conjugation of Trastuzumab to PEI via the hetero-bifunctional linker *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP) resulted in nonspecific gene expression. The authors suspected that this is due to the blocking of critical amino groups either by the linker or by PEI itself. When Trastuzumab was coupled to PEI by sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) or 3-(2-(2-(vinylsulfonyl)ethylthio)-ethyl)quinazoline-2,4(1*H*,3*H*)-dione (IBFB 110001), an effective and specific transfection was reported.

In contrast to the results of Strehblow et al., Kircheis et al. reported successful conjugation of an anti-CD3 antibody to PEI (800 kDa) via SPDP. By using this conjugate, transfection efficiency in CD3-positive Jurkat cells was increased 30-fold, whereas CD3-negative K562 cells showed no increase in transfection efficiency (*18*).

In our study, Trastuzumab was successfully coupled to PEG−PEI via SPDP, enabling specific conjugation without the risk of changing polymer properties by cross-linking. Trastuzumab and PEG−PEI were both activated with SPDP and were then coupled to form PEG−PEI−S−S−Trastuzumab (see Scheme 1).

Apart from a chemically defined polymer composition, our system offers several additional advantages over the Trastuzumab−PEI derivatives mentioned above. Tendency toward aggregation, toxicity, and electrostatic interaction with nontargeted cells are decreased, while biocompatibility is increased due to pegylation. On the other hand, endosomal escape and intracellular trafficking of complexes is improved due to potential intracellular cleavability of the disulfide bond between the targeting moiety and the polymer (*48*).

With this conjugation technique, every fifth PEI chain was modified with one Trastuzumab antibody. In contrast, Kircheis et al. report a coupling ratio of about 1:2.8 (PEI/Ab) with PEI 800 kDa (*18*). Coupling efficiencies comparable to PEG−PEI−Trastuzumab conjugates were obtained in a previous study in our laboratory, where conjugation of OV-TL 16 Fab′ to PEG−PEI via SPDP resulted in a PEI/Fab′ ratio of 1:0.5 (*20*).

Since 31% of the amino groups of PEI are primary amines (*49*), there is an upper limit for modification with PEG or antibody depending on the molecular weight of PEI, which accounts for reduced degree of antibody modification in our case. Attachment of PEG chains also increases steric hindrance, so that substitution is also hampered by this effect. Due to the decreased molecular weight of OV-TL 16 Fab′ (approximately 50 kDa) compared to Trastuzumab (approximately 150 kDa), reduced steric hindrance may explain the slightly higher conjugation degree in the former case.

Physicochemical properties of the complexes were not significantly influenced by the coupling of Trastuzumab. Complexation efficiencies as well as ζ potential values of the PEG−

PEI−Trastuzumab complexes were comparable to PEG−PEI complexes at all N/P ratios tested. Neutral surface charge of complexes is a main prerequisite for in vivo applicability. Opsonization, aggregation, and nonspecific interactions with blood components, vessel endothelia, and nontargeted cells will be minimized with neutral complexes; therefore, systemic circulation will be prolonged (*8*, *12*, *50*, *51*).

For both PEG−PEI and PEG−PEI−Trastuzumab complexes, the size decreases with increasing N/P ratio due to enhanced complexation of DNA, which was shown by the ethidium bromide exclusion experiments. Measurements of hydrodynamic diameters revealed significantly decreased complex sizes of Trastuzumab conjugate compared to unconjugated complexes (except at N/P ratio 7). This effect may be explained by an increased hydrophilicity of targeted complexes and a decreased interaction between particles due to additional steric shielding by coupled antibody. However, the proposed route of cell entry for these complexes is mainly by clathrin-mediated endocytosis, and uptake efficiency may not be significantly affected by particle size as long as complex diameters are within the range 100−200 nm (*41*, *42*).

Detailed analysis of complex shape and surface hardness was performed by atomic force microscopy. AFM measurements of complexes composed of PEI, PEG−PEI, or PEG−PEI conjugates and plasmid DNA or oligonucleotides were previously published by several authors (*7*, *20*, *52*, *53*). In all cases, complexes of more or less spherical shape with smooth surfaces were observed. These findings were confirmed for PEG−PEI and PEG−PEI−Trastuzumab complexes in our study. Visualization of coupled antibodies was to the best of our knowledge not previously reported for this type of bioconjugate. Small particles found only in the case of Trastuzumab−PEI−PEG complexes were identified as coupled antibodies by comparing the size and shape of particles to a control sample with pure antibody. A comparable approach was reported by Anabousi et al., who visualized the surface modification of liposomes with transferrin molecules by AFM (*54*). Due to the more rigid and defined shape of liposomes compared to polyplexes, targeting moieties could be visualized more easily in this case. Surface-bound water, softness of complexes, and possible interactions of antibodies with the polymer impaired a detailed visualization of antibody subdomains as reported in (*43*, *55*). However, AFM measurements verify the presentation of Trastuzumab on the complex surface, which is essential for targeted transfection.

In the next step, specific binding of Trastuzumab−PEI−PEG conjugates was proven by flow cytometry. Receptor expression levels could be directly correlated to the binding of targeted and nontargeted complexes. Even the effect of additional steric shielding by coupled Trastuzumab and therefore decreased binding compared to unmodified complexes was shown in the case of Her2-negative cells. These results are perfectly in line with previously performed flow cytometry experiments with OV-TL 16 Fab′−PEI−PEG conjugates (*20*). Furthermore, confocal laser scanning microscopy showed that the internalization of targeted complexes occurs exclusively in Her2-positive cells. In contrast, uptake of unconjugated complexes was negligible in both Her2-negative and Her2-positive cell lines.

Finally, transfection efficiencies in Her2-positive SK-BR-3 were determined at four different N/P ratios, showing overall increases in transfection efficiencies and decreasing differences between targeted and nontargeted PEG−PEI complexes with increasing N/P ratio. To explain these observations, we assume that the conjugate binds to the cell 1) via nonspecific interaction of cationic PEI with the cell surface and 2) via specific receptor-mediated interaction. With increasing N/P ratio, the effect of charge-mediated binding more and more outweighs the effect of specific binding via antibody−receptor interactions. A comparable effect was observed in different studies in the literature. Conjugation of PEI with anti-PECAM antibody led to efficient transfection of mouse lung endothelial cells, especially at lower N/P ratios (*19*). Targeting of HepG2 cells with galactosylated PEI complexes only showed improved transfection efficiencies for N/P ratios of 3 or lower (*16*, *17*). In contrast, no significant difference was found in transfection efficiencies of targeted and nontargeted complexes in Her2-negative cells. Ultimately, inhibition with increasing amounts of free Trastuzumab verified receptor-dependent uptake, which matches previous results obtained with different antibodies and antibody fragments (*18*, *20*, *21*, *34*, *38*).

Physicochemical and biological properties found in this study give rise to the assumption that this system may be applicable for in vivo use. In the next step, the balance between PEG and Trastuzumab substitution will be optimized to further enhance the targeting effect. Pharmacokinetic, organ distribution, and toxicity studies will then be performed to proceed toward the goal of targeted transfection of tumor tissues in vivo.

CONCLUSION

We have developed a targeted gene delivery system for highly specific in vitro transfection of Her2-positive cell lines, which may potentially be applicable for targeted transfection of tumor cells in vivo.

Polyplex surface charge was efficiently shielded by modification with PEG and targeting moieties, while efficient pDNA complexation was maintained. Hydrodynamic diameters of polyplexes are suitable for possible extravasation and efficient endocytosis. Trastuzumab was shown to be presented on the complex surface by AFM, and accessibility of antigen-binding domains was verified by flow cytometry and confocal microscopy experiments. Confocal microscopy was also used to demonstrate specific and efficient cellular uptake of targeted complexes. Finally, transfection experiments showed efficient and specific reporter gene expression in Her2-positive cells using targeted complexes. By inhibition with free Trastuzumab, Her2-receptor dependency of reporter gene expression was verified.

ACKNOWLEDGMENT

We are grateful to Eva Mohr and Nicole Bamberger (Department of Pharmaceutics and Biopharmacy) for their excellent support in cell culture experiments and Dr. Cornelia Brendel (FACS laboratory, Department of Hematology, Oncology and Immunology, University Hospital Marburg) for the generous use of equipment and facilities. We thank Erik Rytting for helpful discussions.

Received April 27, 2006; Revised Manuscript Received July 6, 2006

Nonviral gene delivery is limited to a large extent by the cationic nature of most of the chemical vector. We have shown that lipopolythioureas interact with DNA. However, lipopolythioureas were not very efficient at transfecting cells, probably due to reduced interaction between the noncationic synthetic lipid and the cell membrane. Here, we report that liposomes made from a new thiourea lipid, DPPC, and a lipid bearing an RGD ligand allowed very efficient entry of the lipopolythioureas into integrin $\alpha_v\beta_3$ expressing cells. In addition, we show that a stable interaction between DNA and lipopolythiourea could be obtain with two thiourea groups. Moreover, the addition of a hydrophilic terminus improves the formulation of these new DNA binding agents.

INTRODUCTION

Gene therapy considers the use of nucleic acid as a drug to treat or cure acquired or innate diseases. In most cases, the genetic material must be packed in a delivery system to be protected from nucleases and to cross physiological barriers and/or cell membranes (*1*). During the past years, efforts have been undertaken to develop physical (*2*), viral (*3, 4*), or synthetic DNA delivery processes (*5, 6*). Because of the polyanionic nature of DNA and the overall negative charge of cell membranes, nonviral vectors are mostly cationic. They have been proven to efficiently transfect cells in culture. However, most of them are ineffective for in vivo DNA delivery, due to interaction with serum, opsonins, or other physiological components (*7*). To improve synthetic vector efficiency, several attempts have been made to mask (*8*) or suppress cationic charges (*9, 10*).

Thiourea derivatives have been intensively investigated in the area of molecular recognition due to their strong hydrogen-bonding activity (*11*). Moreover, bis-thiourea moieties selectively bind to dihydrogenphosphate via multitopic hydrogen bonding, giving stronger complexes with $H_2PO_4^-$ than any synthetic neutral receptor known so far (*12*).

On the basis of these data, which suggested that stable lipoplexes could be made from the interaction between thiourea and nucleic acid, we reported that *N*-(2-{3-[2-(2-{3-[2-(3-methylthioureido)ethyl]thioureido}ethylamino)ethyl]thioureido}ethyl)-*N*′,*N*′-ditetradecylsuccinamide (DTTU, Figure 1) formulated with DPPC were able to interact with DNA and formed nanometric particles (*13*). This new lipopolythiourea lipid (LPT) was composed of a hydrophobic anchor connected to a linear trithiourea. Lipopolythiourea lipoplexes made from DTTU exhibited a longer circulation time in the blood than cationic lipid RPR209120 (*14*) taken as a reference compound. However, this particular lipopolythiourea was difficult to formulate as liposome because of its highly hydrophobic nature and presented very poor transfecting properties. These primary results clearly indicated that the LPT physicochemical properties and perhaps their interaction with cell membranes have to be improved.

A recent study using density functional theory (DFT) calculation (*15*) predicts that DTTU binds to DNA by six hydrogen bonds with a major contribution of thioureas **II** and **III** that form four of the six bonds (Figure 1). This interaction induces a conformational change with the three thiourea groups, normally in trans from one another in the bare molecule, which moves into the cis position. From these predictions, it could be expected that a headgroup containing two thioureas will lead to a stable complex with nucleic acid. On the other hand, it has been reported that a T-shaped branched structure improved the transfecting properties of cationic polyamine (*16*). Moreover, such a structure will probably avoid the constraints due to the cis conformation of DTTU.

So, we designed new noncationic lipids with a T-shaped bis-thiourea headgroup. We introduced also hydroxyl and diol termini, which have been proven to have a positive effect on transfection efficiency (*17*). Finally, we chose two different linkers composed of a benzyl group or a 3-motives-PEG to connect the hydrophobic anchor to the headgroup. These new lipopolythioureas (LPT) have been synthesized and evaluated in terms of DNA compaction and transfection efficiency. As a final point, we investigated RGD-mediated internalization of endothelial cells expressing integrin $\alpha_V\beta_3$.

MATERIALS AND METHODS

All solvents were purchased from Carlo Erba-SDS (Peypin France). Dichloromethane was distilled from P_2O_5. DMF was dried over 3 Å molecular sieves and pyridine over KOH. All chemicals were purchased from Sigma-Aldrich-Fluka or Lancaster. Tosyl chloride (petroleum ether) and cholesteryl chloroformate (acetone) were recrystallized, and diglycolic anhydride was dehydrated (P_2O_5) prior to use. Other solvents and products were used without further purification. Reactions were monitored by thin-layer chromatography using Merck precoated 60 F254 silica gel plates. Column chromatography was performed over SDS (Peypin France) 35−70 m silicagel according to the method of Still, Khan, and Mitra (*18*) or using small-column flash chromatography (SFC) according to the following procedure. A plastic syringe was filled with silicagel (product/silicagel 1/5) and connected to vacuum (12 mmHg). The column was

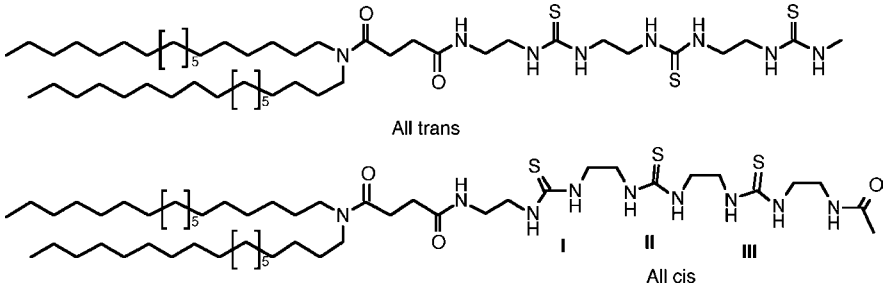

Figure 1. Structures of the linear trithiourea DTTU.

equilibrated with heptane, then the sample dissolved in a minimum of dichloromethane was added to the top. The column was eluted by ten fractions of a heptane/ethyl acetate mixture. The volume was equal to the silicagel volume. For each fraction, the amount of ethyl acetate was increased (10% (v/v) to 100% ethyl acetate in heptane). Inverse-phase solid-phase extraction (SPE) was performed on a Supelco Superclean C8 cartridge using water/acetonitrile/methanol mixture. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker Advance DRX-300 spectrometer at 300.13 MHz for ^{1}H and 75.47 MHz for ^{13}C. NMR spectra were processed using XwinNmr (Bruker) or SwaN-MR (*19*). Mass spectra were carried out on a Shimazu 2010A LC-MS on ESI mode. High-resolution mass spectra and elemental analysis were carried out by the "Service Central de Micro-analyse du CNRS" Vernaison France. Dipalmytoylphosphatidylcholine (DPPC) and phosphatidylethanolamine lissamine rhodamine were purchased from Aventi Polar Lipids (Alabaster, Alabama).

Synthesis of Lipopolythioureas. *2,3-Dihydroxy-1,4-di-para-toluenesulfonyloxy butane (2).* A dichloromethane solution (60 mL) of tosyl chloride (15.6 g, 82 mmol) was added dropwise for 5 h to a cooled (−20 °C) pyridine solution (16.6 mL, 0.21 mole) of D,L-threitol (5.0 g, 41 mmol). The reaction mixture was stirred overnight at 0 °C, then the solvent was evaporated. 1 N HCl (100 mL) was added to the residual oil that was extracted six times with dichloromethane. The combined organic layers were washed with brine, dried ($MgSO_4$), and then evaporated under reduced pressure. The residual oil was purified by chromatography (heptane/ethyl acetate 6:4) to yield 9.1 g of **2** as a white solid (52%). mp 83 °C. ^{1}H NMR ($CDCl_3$) δ (ppm) 2.44 (s, 6H, CH_3), 2.95 (m, 2H, OH), 3.88 (m, 2H, CHOH), 4.05 (d, 4H, J = 5 Hz, CH_2O), 7.35 (d, 4H, J = 8.1 Hz, H_{arom}), 7.88 (d, 4H, J = 8.1 Hz, H_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 21.80 (s, CH_3), 68.62 (s, CHOH), 71.05 (s, CH_2O), 128.96 (s, CH_{arom}), 130.21 (CH_{arom}), 132.68 (s, C_{arom}), 145.81 (s, C_{arom}). MS (ESI, *m/z*) 431 $(M + H)^+$, HPLC purity 96% by ELSD. Anal. Calcd for $C_{18}H_{22}O_8S_2$ C, 50.22; H, 5.15; N, 14.90. Found: C, 50.21; H, 5.35; N, 14.64.

4-[4,5-Bis-(toluene-4-sulfonyloxymethyl)-1,3-dioxolan-2-yl]-benzoic Acid Methyl Ester (4). A solution of diol **2** (1.07 g, 2.5 mmol), *para*-toluene sulfonic acid monohydrate (48 mg, 0.25 mmol), and 4-dimethoxymethylbenzoic acid methyl ester **3** (0.58 g, 2.75 mmol) in dry benzene (30 mL) was heated under reflux with a Dean−Stark trap during 5 h. Then, pyridine was added (0.5 mL), and the reaction mixture was concentrated under reduced pressure. The resulting solid was purified by flash chromatography (heptane/ethyl acetate/CH_2Cl_2 4:1:1, then 4:4:1) to afford 1.1 g of dioxolane **4** as a white solid (75%). mp 130° C. ^{1}H NMR ($CDCl_3$) δ (ppm) 2.45 (s, 6H, CH_3), 3.96 (s, 3H, OCH_3), 4.14 (m, 2H, CHO), 4.22 (m, 4H, CH_2O), 5.82 (s, 1H, CHO_2), 7.28−7.37 (m, 6H, H_{arom}), 7.71−7.77 (m, 4H, H_{arom}), 7.97 (d, 2H, J = 7.5 Hz, H_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 21.80 (s, CH_3), 52.36 (s, OCH_3), 68.51 (d, CH_2O), 75.68 (d, CHO), 103.98 (s, CHO_2), 126.59 (s, CH_{arom}), 128.10 (s, CH_{arom}), 129.74 (s, CH_{arom}), 130.17 (s, CH_{arom}), 131.23 (s, C_{arom}),132.14 (s, C_{arom}), 141.12 (s, C_{arom}), 145.61 (s, C_{arom}), 166.71 (s, C═O). MS (ESI) *m/z* 577 $(M + H)^+$, HPLC purity 100% by ELSD. Anal. Calcd for $C_{27}H_{28}O_{10}S_2$: C, 56.24; H, 4.89; S, 11.12. Found: C, 55.65; H, 5.01; S, 11.44.

4-(4,5-Bis-azidomethyl-1,3-dioxolan-2-yl)benzoic Acid Methyl Ester (5). A solution of ditosyl **4** (1.48 g, 2.5 mmol) and sodium azide (0.97 g, 15.0 mmol) in DMF (25 mL) was heated overnight under reflux. The reaction mixture was evaporated under reduced pressure, then the residual solution was coevaporated several times with toluene. The resulting oil was treated with brine (30 mL) and extracted with ethyl acetate (3 × 20 mL). The combined organic extracts were dried ($MgSO_4$) and evaporated under reduced pressure to yield a yellow oil (0.75 g, 94%) that was used without further purification. ^{1}H NMR ($CDCl_3$) δ (ppm) 3.49 and 3.60 (m, 4H, CH_2), 3.90 (s, 3H, OCH_3), 4.20 (m, 2H, CHO), 6.03 (s, 1H, CHO_2), 7.57 (d, 2H, J = 8.1 Hz, H_{arom}), 8.06 (d, 2H, J = 8.1 Hz, H_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 51.88 (s, CH_2), 52.24 (s, CH_3), 77.54 and 78.36 (2s, CHO), 103.58 (s, CHO_2), 126.56 (s, CH_{arom}), 129.83 (s, CH_{arom}), 131.32 (s, C_{arom}), 141.57 (s, C_{arom}), 166.72 (s, C═O). MS (ESI, *m/z*) 378 $(M + H)^+$, HPLC purity 82% by ELSD.

4-(4,5-Bis-azidomethyl-1,3-dioxolan-2-yl)benzoic Acid (6). Ester **5** was treated with a solution of sodium hydroxide (0.64 g, 16.0 mmol) in a mixture of $H_2O/CH_3OH/THF$ (1:1:1 v/v/v, 45 mL). When all the starting material had disappeared, iced 2 N HCl was added to reach pH 3. Then, the reaction mixture was extracted with ethyl acetate (3 × 20 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and evaporated under reduced pressure to give a yellow oil (0.75 g, 94%) that was used without further purification. ^{1}H NMR ($CDCl_3$) δ (ppm) 3.44−3.67 (m, 4H, CH_2), 4.23 (m, 2H, CHO), 6.07 (s, 1H, CHO_2), 7.61 (d, 2H, J = 8.1 Hz, H_{arom}), 8.15 (d, 2H, J = 8.1 Hz, H_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 51.80 (s, CH_2), 77.54 and 78.36 (s, CHO), 103.48 (s, CHO_2), 126.71 (s, CH_{arom}), 130.50 (s, CH_{arom}), 131.31 (s, C_{arom}), 142.39 (s, C_{arom}), 171.85 (s, C═O). MS (ESI, *m/z*) 302 $(M + HCOO)^-$. HPLC purity 98% by ELSD.

4-(4,5-Bis-azidomethyl-1,3-dioxolan-2-yl)-N,N-ditetradecyl-benzamide (7). *N*-methylmorpholin (0.20 mL, 1.8 mmol) was added to a THF solution (30 mL) of **6** (0.54 g, 1.8 mmol) cooled to −40 °C. Then, a THF solution (3 mL) of isobutyl chloroformate (0.23 mL, 1.8 mmol) was added slowly. The reaction mixture was stirred for 1 h at −40 °C, then a THF solution (5 mL) of ditetradecylamine (0.68 g, 1.8 mmol) and *N*-methylmorpholin (0.20 mL, 1.8 mmol) was added slowly. The resulting mixture was stirred vigorously for 20 h at RT. Then, ethyl acetate (150 mL) and water (150 mL) were added. The water layer was extracted twice with ethyl acetate; then, the combined organic layers were successively washed twice with 1 N HCl, twice with a saturated solution of $NaHCO_3$, twice with brine, and then dried ($MgSO_4$). The solvent was removed under reduced pressure, then the resulting oil was purified by chromatography (heptane/ethyl acetate 1:4, then 3:7) to yield **7** as a clear oil (0.55 g, 46%). ^{1}H NMR ($CDCl_3$) δ (ppm) 0.87 (t,

6H, $J = 6.9$ Hz, CH_3), 1.21−1.46 (m, 44H, $-CH_2-$), 1.63 (m, 4H, CH_2), 3.14 (t, 2H, $J = 7.2$ Hz, CH_2N), 3.38−3.63 (m, 6H, CH_2N, CH_2N_3), 4.20 (m, 2H, CHO), 6.01 (s, 1H, CHO_2), 7.37 (d, 2H, $J = 7.1$ Hz, CH_{arom}), 7.52 (d, 2H, $J = 7.1$ Hz, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.20 (s, CH_3), 22.78 (s, $-CH_2-$), 27.17 (s, $-CH_2-$), 28.77 (s, $-CH_2-$), 29.73 (m, $-CH_2-$), 32.01 (s, $-CH_2-$), 44.76 and 49.04 (2s, CH_2N), 51.85 (s, CH_2N_3), 77.80 (d, CHO), 103.82 (s, CHO_2), 126.69 (s, CH_{arom}), 137.57 (s, C_{arom}), 138.76 (s, C_{arom}), 171.09 (s, C═O). MS (ESI, *m/z*) 697 $(M + H)^+$, HPLC purity 99% by ELSD.

*4-(4,5-Bis-aminomethyl-1,3-dioxolan-2-yl)-N,N-ditetradecylbenzamide (**8**).* A 25 mL round-bottom flask equipped with a magnetic stirring bar was filled successively with diazide **7** (0.35 g, 0.5 mmol), ethanol (10 mL), Pd/C (50 mg), and hydrogen. The suspension was stirred for 19 h at RT, then the mixture was filtered through celite to yield after evaporation the diamine **8** (0.31 g, 96%), which was used without further purification. ^1H NMR ($CDCl_3$) δ (ppm) 0.84 (t, 6H, $J = 6.9$ Hz, CH_3), 1.04−1.46 (m, 44H, $-CH_2-$), 1.56 (m, 4H, $-CH_2-$), 2.99−3.40 (m, 8H, CH_2N, CH_2NH_2), 4.24 (m, 2H, CHO), 5.97 (s, 1H, CHO_2), 6.40 (m, 4H, NH_2), 7.28 (d, 2H, $J = 7.1$ Hz, CH_{arom}), 7.55 (d, 2H, $J = 7.1$ Hz, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.12 (s, CH_3), 22.71 (s, $-CH_2-$), 27.25 (s, $-CH_2-$), 28.82 (s, $-CH_2-$), 29.73 (m, $-CH_2-$), 31.97 (s, $-CH_2-$), 41.73 (d, CH_2NH_2), 45.02 and 49.24 (2s, CH_2-N), 78.15 (d, CHO), 102.87 (s, CHO_2), 126.51 (s, CH_{arom}), 127.31 (s, CH_{arom}), 138.16 (s, C_{arom}), 171.29 (s, C═O). MS (ESI, *m/z*) 645 $(M + H)^+$. HPLC purity 92% by ELSD.

*4-(4,5-Bis-isothiocyanatomethyl-1,3-dioxolan-2-yl)-N,N-ditetradecylbenzamide (**9**).* Diisopropylethylamine (0.26 mL, 1.5 mmol) and carbon disulfide (0.12 mL, 2 mmol) were successively added to a solution of diamine **8** (0.32 g, 0.5 mmol) in dichloromethane (5 mL). The solution was stirred for 90 min, then a solution of tosyl chloride (0.19 g, 1 mmol) in dichloromethane was added dropwise. The mixture was stirred for 20 h at room temperature, diluted with dichloromethane, and washed three times with brine. The organic solution was dried ($MgSO_4$) and evaporated under vacuum. The crude was purified by chromatography (heptane/ethyl acetate 8:2, 7:3, and 6:4) to yield **9** as a colorless oil (0.24 g, 66%). ^1H NMR ($CDCl_3$) δ (ppm) 0.84 (t, 6H, $J = 6.9$ Hz, CH_3), 1.04−1.30 (m, 44H, $-CH_2-$), 1.46 (m, 4H, $-CH_2-$), 3.15 and 3.46 (m, 4H, CH_2N), 3.80 and 3.90 (m, 4H, CH_2NCS), 4.28 (m, 2H, CHO), 6.06 (s, 1H, CHO_2), 7.39 (d, 2H, $J = 6.5$ Hz, CH_{arom}), 7.53 (d, 2H, $J = 6.5$ Hz, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.07 (s, CH_3), 22.71 (s, $-CH_2-$), 27.17 (s, $-CH_2-$), 29.04 (s, $-CH_2-$), 29.73 (m, $-CH_2-$), 31.93 (s, $-CH_2-$), 44.97 and 49.19 (s, $-CH_2N$), 46.59 (CH_2NCS), 77.1 (d, CHO), 104.40 (s, CHO_2), 126.74 (s, CH_{arom}), 132.02 (s, C═S), 138.58 (s, C_{arom}), 138.83 (s, C_{arom}), 171.17 (s, C═O). IR (NaCl): σ (cm^{-1}) 1086 (ν_{C-O-C}), 1465 (δ_{CH_2}), 1629 ($\nu_{C=O}$), 2048 ($\nu_{N=C=S}$), 2842 ($\nu_{=C-H_2}$), 2934 (ν_{CH_2}), 3196 ($\nu_{=C-H_{arom}}$).

*4-{4,5-Bis-[3-(2-hydroxyethyl)thioureidomethyl]-1,3-dioxolan-2-yl}-N,N-ditetradecylbenzamide (**10**).* Ethanolamine (0.026 mL, 0.4 mmol) was added to a solution of diisothiocyanate **9** (62 mg, 0.09 mmol) in THF (1 mL), then the mixture was stirred for 22 h at room temperature. The solution was concentrated under reduced pressure. The resulting oil was purified by SPE (C-8 100% acetonitrile to 100% methanol) to afford the dithiourea **10** (29.8 mg, 39%) as a colorless oil. ^1H NMR ($CDCl_3$) δ (ppm) 0.87 (m, 6H, CH_3), 1.25 (m, 44H, $-CH_2-$), 1.62 (m, 4H, $-CH_2-$), 3.14 (m, 2H, $-CH_2NCO$), 3.44−3.78 (m, 14H, $-CH_2NCO$, CH_2NCS, CH_2OH), 4.16 (m, 2H, CHO), 5.94 (s, 1H, CHO_2), 7.25 (m, 4H, NH), 7.33 (m, 2H, CH_{arom}), 7.52 (m, 2H, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.09 (s, CH_3), 22.71 (s, $-CH_2-$), 27.22 (s, $-CH_2-$), 28.83 (s, $-CH_2-$), 29.73 (m, $-CH_2-$), 31.97 (s, $-CH_2-$), 45.30 (s, CH_2NCS), 45.80 (s, CH_2NCS), 46.97 and 49.45 (s, CH_2NCO), 61.42 (s, CH_2OH), 78.23 (d, CHO), 102.83 (s, CHO_2), 126.48 (s, CH_{arom}), 127.05 (s, CH_{arom}) 138.14 (s, C_{arom}), 138.80 (s, C_{arom}), 171.71 (s, C═O), 183.35 (s, C═S).

*N,N-ditetradecyl-4-(4,5-bis-azidomethyl-1,3-dioxolan-2-yl)-benzamide (**11**).* 3-Amino-1,2-propanediol (22 mg, 0.24 mmol) was added to a solution of **9** (41 mg, 0.056 mmol) in dry DMF. The solution was stirred at RT for 20 h then concentrated to dryness. The crude was dissolved in ethyl acetate and washed three times with brine. The organic layer was dried ($MgSO_4$) and evaporated to dryness. Purification as for **10** gave **11** as a colorless oil (20 mg, 38%). ^1H NMR ($CDCl_3$) δ (ppm) 0.88 (m, 6H, CH_3), 1.27 (m, 44H, $-CH_2-$), 1.65 (m, 4H, $-CH_2-$), 3.16 (m, 2H, $-CH_2NCO$), 3.35−3.48 (m, 6H, $-CH_2NCO$, CH_2-NCS), 3.47−3.68 (m, 8H, CH_2NCS, CH_2OH), 3.97 (m, 2H, CHOH), 4.16 (m, 2H, CHO), 5.97 (s, 1H, CHO_2), 7.35 (m, 2H, CH_{arom}), 7.55 (m, 2H, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 13.96 (s, CH_3), 22.64 (s, $-CH_2-$), 27.11 (s, $-CH_2-$), 28.78 (s, $-CH_2-$), 29.73 (m, $-CH_2-$), 31.91 (s, $-CH_2-$), 45.27 (s, $-CH_2NCS$), 45.83 (s, $-CH_2NCS$), 46.91 and 49.44 (s, $-CH_2NCO$), 63.65 (s, CH_2OH), 70.99 (s, CHOH), 78.33 (d, CHO), 102.88 (s, CHO_2), 126.42 (s, CH_{arom}), 126.86 (s, CH_{arom}), 138.02 (s, C_{arom}), 138.72 (s, C_{arom}), 171.87 (s, C═O), 183.49 (s, C═S). ES-HRMS Calcd. for $C_{48}H_{87}N_5O_7NaS_2$: 932.5945. Found: 932.5965.

*2-(2-{2-[2-(2,2-Diethoxyethoxy)ethoxy]ethoxy}ethoxy)-tetrahydropyran (**13**).* Sodium hydride (1.7 g, 43 mmol) was added portionwise to an iced cooled solution of **12** (previously dried by codistillation with THF) in THF (50 mL). The suspension was stirred for 30 min, then bromoacetaldehyde diethylacetal (2.3 mL, 17 mmol) was added dropwise. The mixture was stirred for 3 h at RT, then heated overnight at 60 °C. The reaction mixture was cooled with an ice bath, then the reaction was stopped by the addition of water (2 mL). Most of the solvent was removed by evaporation under reduced pressure, then water and dichloromethane were added. The water layer was extracted three times with dichloromethane, then the combined organic layer was washed with brine, dried ($MgSO_4$), and concentrated under reduced pressure. The residual oil was purified by chromatography (heptane/ethyl acetate 1:1) to afford **13** (3 g, 100%), which was used without further purification. ^1H NMR ($CDCl_3$) δ (ppm) 1.11 (t, 6H, $J = 6.9$ Hz, CH_3), 1.41−1.72 (m, 6H, $-CH_2-$ring), 3.43 (m, 4H, OCH_2-CH_3), 3.48 (m, 2H, CH_2O-ring), 3.53−3.59 (m, 12H, $-CH_2O-$), 3.75 (m, 2H, CH_2-CH), 4.53 (m, 2H, CHO_2). ^{13}C NMR ($CDCl_3$) δ (ppm) 15.32 (s, CH_3), 19.45 (s, CH_2-ring), 25.46 (s, CH_2-ring), 30.58 (s, CH_2-ring), 62.21 ($-CH_2O-$), 66.64 (CH_2O-ring), 70.62 (s, $-CH_2O-$), 70.91 (s, $-CH_2O-$), 71.95 (s, $-CH_2O-$), 98.86 (s, CHO_2), 101.22 (s, CHO_2). MS (ESI, *m/z*) 373 $(M + H)^+$. Anal. Calcd for $C_{17}H_{34}O_7$: C, 58.26; H, 97.8; Found: C, 57.79; H, 9.90.

*2-{2-[2-(4,5-Bis-(toluene-4-sulfonyloxymethyl)-[1,3]-dioxolan-2-ylmethoxy)ethoxy]ethoxy}ethanol (**14**).* Ditosyl **2** (0.28 g, 0.65 mmol) and *para*-toluenesulfonic acid (0.022 g, 0.13 mmol) was added to a solution of **13** (0.23 g, 0.65 mmol) in benzene (10 mL), then the solution was heated to reflux for 22 h. Pyridine (0.1 mL) was added at RT, then the solvent was removed under reduced pressure, and the residual oil was purified to yield a mixture of the acetals protected by THP (0.14 g, 31%) or with free hydroxyl terminus **14** (0.096 g, 24%). After dissolution of the THP-protected compound in methanol (2 mL), *para*-toluenesulfonic acid was added to the solution, and the reaction mixture was stirred for 6 h, then poured in an Erlenmeyer flask filled with solid potassium carbonate. The solution was filtered, and the filtrate was concentrated under reduced pressure. The residual oil was dissolved in dichloromethane and washed three times with a saturated $NaHCO_3$ solution and brine successively.

Then, the solvent was removed under reduced pressure to afford the alcohol **14**. The total yield for the reaction was 52% (65 mg). ^{1}H NMR ($CDCl_3$) δ (ppm) 2.46 (s, 6H, CH_3), 2.85 (m, 1H, OH), 3.47 (d, 2H, $J = 4.6$ Hz, CH_2O), 3.60−3.65 (m, 10H, $-CH_2O-$), 3.71 (m, 2H, $-CH_2OH$), 4.07−4.13 (m, 6H, CHO, CH_2OS), 5.11 (t, 1H, $J = 3.3$ Hz, CHO_2), 7.36 (d, 2H, $J = 8.1$ Hz, CH_{arom}), 7.78 (d, 2H, $J = 8.1$ Hz, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 21.67 (s, CH_3), 61.84 (s, CH_2OH), 66.33 (d, CH_2OS), 70.56 (s, $-CH_2O-$), 70.69 (s, $-CH_2O-$), 71.26 (s, $-CH_2O-$), 71.88 (s, $-CH_2O-$), 72.54 (s, $-CH_2O-$), 75.67 (s, CHO), 104.16 (s, CHO_2), 128.05 (s, CH_{arom}), 130.06 (s, CH_{arom}), 132.71 (s, C_{arom}), 145.28 (s, C_{arom}). MS (ESI, *m/z*) 605 $(M + H)^+$.

*{2-[2-(4,5-Bis(toluene-4-sulfonyloxymethyl)-[1,3]-dioxolan-2-ylmethoxy)ethoxy]ethoxy}acetic acid (**15**).* Alcohol **14** (0.145 g, 0.24 mmol) was dissolved in acetone (2.5 mL). A solution of $NaHCO_3$ (15% in water, 0.75 mL) was added, and the reaction mixture was cooled to 0 °C. Then, sodium bromide (5 mg, 0.05 mmol), TEMPO (4 mg, 0.024 mmol), and trichloroisocyanuric acid (0.11 g, 0.48 mmol) were successively added. The reaction mixture was stirred vigorously for 14 h, and isopropanol (0.14 mL) was added to stop the reaction. After filtration, the solvent was evaporated under reduced pressure to yield a solid that was dissolved in a saturated solution of Na_2CO_3. The solution was extracted three times with ethyl acetate, dried ($MgSO_4$), and evaporated under reduced pressure to give the acid **15** as a yellow oil (0.106 g, 71%). ^{1}H NMR ($CDCl_3$) δ (ppm) 2.40 (s, 6H, CH_3), 3.41 (d, 2H, $J = 4.6$ Hz, $-CH_2O-$), 3.57−3.68 (m, 8H, $-CH_2O-$), 4.05 (m, 6H, CHO, CH_2OS), 4.10 (s, 2H, CH_2CO), 5.05 (t, 1H, $J = 3.3$ Hz, CHO_2), 7.31 (d, 2H, $J = 8.1$ Hz, CH_{arom}), 7.72 (d, 2H, $J = 8.1$ Hz, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 21.65 (s, CH_3), 61.42 (d, CH_2OS), 70.35 (s, $-CH_2O-$), 70.50 (s, $-CH_2O-$), 71.08 (s, $-CH_2O-$), 71.67 (s, $-CH_2O-$), 75.61 (m, CHO, CH_2CO), 104.01 (s, CHO_2), 128.00 (s, CH_{arom}), 132.37 (s, CH_{arom}), 133.87 (s, C_{arom}), 145.28 (s, C_{arom}), 173.01 (s, C═O). MS (ESI, *m/z*) 619 $(M + H)^+$.

*2-{2-[2-(4,5-Bis(toluene-4-sulfonyloxymethyl)-[1,3]-dioxolan-2-ylmethoxy)ethoxy]ethoxy}-N,N-ditetradecylacetamide (**16**).* *N*-methylmorpholin (0.21 μL, 0.19 mmol) was added to a THF solution (4 mL) of **15** (0.54 g, 1.8 mmol) cooled to −40 °C. Then, a THF solution (0.5 mL) of isobutyl chloroformate (0.24 μL, 0.19 mmol) was added slowly. The reaction mixture was stirred for 1 h at −40 °C, then a THF solution (0.5 mL) of ditetradecylamine (0.07 g, 0.17 mmol) and *N*-methylmorpholin (0.21 μL, 0.19 mmol) was added slowly. The resulting mixture was stirred vigorously at RT for 20 h. Then, ethyl acetate (10 mL) and water (10 mL) were added. The water layer was extracted twice with ethyl acetate, then the combined organic solutions were successively washed twice with 1 N HCl, twice with a saturated solution of $NaHCO_3$, twice with brine, and then dried ($MgSO_4$). The solvent was removed under reduced pressure, then the resulting oil was purified by SFC to yield **16** as a clear oil (0.072 g, 42%). ^{1}H NMR ($CDCl_3$) δ (ppm) 0.86 (t, 6H, $J = 6.6$ Hz, $-CH_3$), 1.20−1.32 (m, 44H, $-CH_2-$), 1.49 (m, 4H, $-CH_2-$), 2.44 (s, 6H, CH_3), 3.15 and 3.26 (t, 4H, $J = 7.5$ Hz, $-CH_2N$), 3.42 (d, 2H, $J = 4.6$ Hz, $-CH_2O$), 3.58−3.68 (m, 8H, $-CH_2O-$), 4.01−4.09 (m, 6H, CHO, CH_2OS), 4.16 (s, 2H, CH_2CO), 5.07 (t, 1H, $J = 3.6$ Hz, CHO_2), 7.35 (d, $J = 8.1$ Hz, CH_{arom}), 7.75 (d, $J = 8.1$ Hz, CH_{arom}). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.14 (s, $-CH_3$), 21.69 (s, CH_3), 22.72 (s, $-CH_2-$), 27.11 (s, $-CH_2-$), 29.03 (s, $-CH_2-$), 29.69 (m, $-CH_2-$), 31.97 (s, $-CH_2-$), 45.86 and 47.03 (s, $-CH_2N$), 68.25 (d, s, CH_2OS), 70.07 (s, $-CH_2O-$), 70.58 (m, $-CH_2O-$), 71.27 (s, $-CH_2O-$), 71.88 (s, $-CH_2O-$), 75.60 (s, CHO), 104.16 (s, CHO_2), 128.06 (s, CH_{arom}), 130.09 (s, CH_{arom}), 133.66 (s, C_{arom}), 145.31 (s, C_{arom}), 168.69 (s, C═O). MS (ESI, *m/z*) 1011 $(M + H)^+$.

*2-{2-[2-(4,5-Bis-azidomethyl-[1,3]-dioxolan-2-ylmethoxy)-ethoxy]ethoxy}-N,N-ditetradecylacetamide (**17**).* A solution of ditosyl **16** (0.36 g, 0.36 mmol) and sodium azide (0.23 g, 3.60 mmol) in DMF (10 mL) was heated overnight under reflux. The reaction mixture was evaporated under reduced pressure, then the residual solution was coevaporated several times with toluene. The resulting oil was treated with brine (30 mL) and extracted with ethyl acetate (3 × 20 mL). The combined organic extracts were dried ($MgSO_4$) and evaporated under reduced pressure to yield a yellow oil (0.28 g, 100%) that was used without further purification. ^{1}H NMR ($CDCl_3$) δ (ppm) 0.86 (t, 6H, $J = 6.6$ Hz, CH_3), 1.20−1.32 (m, 44H, $-CH_2-$), 1.52 (m, 4H, $-CH_2-$), 3.16 and 3.27 (t, 4H, $J = 7.5$ Hz, $-CH_2N$), 3.38−3.55 (m, 4H, CH_2N_3), 3.61 (d, 2H, $J = 4.6$ Hz, $-CH_2O$), 3.68 (m, 8H, $-CH_2O-$), 4.05 (m, 2H, CHO), 4.17 (s, 2H, $-CH_2CO$), 5.26 (t,1H, $J = 3.6$ Hz, CHO_2). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.05 (s, CH_3), 22.65 (s, $-CH_2-$), 26.90 (s, $-CH_2-$), 28.07 (s, $-CH_2-$), 29.69 (m, $-CH_2-$), 31.90 (s, $-CH_2-$), 45.79 and 46.99 (2s, $-CH_2N$), 49.96 (s, $-CH_2N_3$), 70.13 (s, $-CH_2O-$), 70.56 (m, $-CH_2O-$), 71.24 (s, $-CH_2O-$), 72.07 (s, $-CH_2O-$), 77.12 (d, CHO), 103.66 (s, CHO_2), 162.49 (s, C═O).

*2-{2-[2-(4,5-Bis-aminomethyl-[1,3]-dioxolan-2-ylmethoxy)-ethoxy]ethoxy}-N,N-ditetradecylacetamide (**18**).* A 25 mL round-bottom flask equipped with a magnetic stirring bar was filled successively with diazide **17** (0.30 g, 0.4 mmol), ethanol (10 mL), Pd/C (50 mg), and hydrogen. The suspension was stirred for 19 h at RT, then the mixture was filtered through celite to yield after evaporation the diamine **18** (0.304 g, 100%), which was used without further purification. ^{1}H NMR ($CDCl_3$) δ (ppm) 0.80 (t, 6H, $J = 6.6$ Hz, CH_3), 1.20−1.32 (m, 44H, $-CH_2-$), 1.45 (m, 4H, $-CH_2-$), 2.50 (m, 4H, NH), 2.78−2.93 (m, 4H, CH_2NH_2), 3.09 and 3.20 (t, 4H, $J = 7.5$ Hz, $-CH_2N$), 3.53 (d, 2H, $J = 4.6$ Hz, $-CH_2O$), 3.59−3.63 (m, 8H, $-CH_2O-$), 4.09 (m, 2H, CHO), 4.12 (s, 2H, CH_2CO), 5.14 (t, 1H, $J = 3.6$ Hz, CHO_2). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.11 (s, CH_3), 22.69 (s, $-CH_2-$), 27.05 (s, $-CH_2-$), 28.06 (s, $-CH_2-$), 29.69 (m, $-CH_2-$), 31.93 (s, $-CH_2-$), 43.66 (s, CH_2NH_2), 45.87 and 46.98 (s, $-CH_2N$), 69.88 (s, $-CH_2O-$), 70.55 (m, $-CH_2O-$), 71.17 (s, CH_2CO), 72.44 (s, $-CH_2O-$), 80.50 (d, CHO), 102.33 (s, CHO_2), 168.69 (s, C═O).

*2-{2-[2-(4,5-Bis-isothiocyanatomethyl-[1,3]-dioxolan-2-ylmethoxy)ethoxy]ethoxy}-N,N-ditetradecylacetamide (**19**).* Diisopropylethylamine (0.18 mL, 1 mmol) and carbon disulfide (0.084 mL, 1.4 mmol) were successively added to a solution of diamine **18** (0.26 g, 0.35 mmol) in dichloromethane (5 mL). The solution was stirred for 90 min, then a solution of tosyl chloride (0.13 g, 0.7 mmol) in dichloromethane (3 mL) was added dropwise. The mixture was stirred for 20 h, then evaporated under reduced pressure. The crude was purified by SFC to yield **19** as a colorless oil (0.096 g, 35%). ^{1}H NMR ($CDCl_3$) δ (ppm) 0.87 (t, 6H, $J = 6.6$ Hz, CH_3), 1.22−1.29 (m, 44H, $-CH_2-$), 1.51 (m, 4H, $-CH_2-$), 3.13 and 3.28 (t, 4H, $J = 7.5$ Hz, $-CH_2N$), 3.62 (d, 2H, $J = 4.3$ Hz, $-CH_2O-$), 3.65−3.73 (m, 8H, $-CH_2O-$), 3.79−3.84 (m, 4H, $-CH_2NCS$), 4.16 (m, 2H, CHO), 4.18 (s, 2H, −CH2CO−), 5.34 (t, 1H, $J = 3.6$ Hz, CHO_2). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.14 (s, CH_3), 22.70 (s, $-CH_2-$), 27.07 (s, $-CH_2-$), 28.96 (s, $-CH_2-$), 29.67 (m, $-CH_2-$), 31.93 (s, $-CH_2-$), 45.87 and 46.44 (s, $-CH_2N$), 46.94 (s, $-CH_2NCS$), 69.88 (s, $-CH_2O-$), 70.51 (m, $-CH_2O-$), 71.32 (s, CH_2CO), 71.83 (s, $-CH_2O-$), 77.03 (d, CHO), 104.43 (s, CHO_2), 132.03 (s, C═S), 168.54 (C═O). MS (ESI, *m/z*) 785 $(M + H)^+$.

acetamide (20). 3-Amino-1,2-propanediol (0.008 g, 0.092 mmol) in DMF (0.1 mL) was added to a solution of **19** (41 mg, 0.056 mmol) in dry DMF (0.2 mL). The solution was stirred at RT for 20 h, then concentrated to dryness. The crude was dissolved in ethyl acetate and washed three times with brine. The organic layer was dried ($MgSO_4$) and evaporated to dryness. SFC purification yield **20** as a colorless oil (0.016 g, 72%). ^{1}H NMR ($CDCl_3$) δ (ppm) 0.88 (t, 6H, J = 6.6 Hz, CH_3), 1.22−1.29 (m, 44H, $-CH_2-$), 1.52 (m, 4H, $-CH_2-$), 3.11 and 3.28 (t, 4H, J = 7.5 Hz, $-CH_2N$), 3.50−3.75 (m, 22H, $-CH_2O-$, $-CH_2NCS$, CH_2OH), 4.13−4.34 (m, 6H, $-CH_2CO$, CHO, CHOH), 5.25 (t, 1H, J = 3.6 Hz, CHO_2). ^{13}C NMR ($CDCl_3$) δ (ppm) 14.13 (s, CH_3), 22.72 (s, $-CH_2-$), 27.16 (s, $-CH_2-$), 28.94 (s, $-CH_2-$), 29.67 (m, $-CH_2-$), 31.98 (s, $-CH_2-$), 45.44 (s, $-CH_2NCS$), 46.48 and 47.14 (s, $-CH_2NCO$), 63.74 (s, CH_2OH), 68.98 (s, CHOH), 69.84 (s, $-CH_2O-$), 70.28 (m, $-CH_2O-$), 70.59 (s, $-CH_2CO$), 71.39 (s, $-CH_2O-$), 78.35 (d, CHO), 101.93 (s, CHO_2), 169.06 (s, C═O), 183.55 (s, C═S). ES-HRMS Calcd for $C_{48}H_{95}N_5O_{10}NaS_2$: 988.6418. Found: 988.6389.

Lipopolythiourea Formulation. ARTUtetraol (2.27 mg, 2.5 μmol) and DPPC (3.66 mg, 5.0 μmol) were dissolved in a chloroform/acetone/ethanol mixture (1/5/4 v/v/v, 500 μL). This mixture was then added dropwise to 5 mL of stirred H_2O and vigorously stirred overnight. Most of the solvents were removed under vacuum to obtain a fairly concentrated suspension of liposomes (concentration of ARTUdiol = 8.5 mM). Similar procedures were used for the other LPT.

Complex Size. The complex diameter was determined by dynamic light scattering on a Zetasizer Nano Series Malvern. 10 μL of ARTUdiol/DPPC 1/2 (C = 8.5 mM) was added to 800 μL of H_2O; mean value of three runs is given (1 min equilibration, 3 min run).

Preparation of the Complexes LPT/DPPC/DNA. Plasmid DNA (pVax2luc) (100 μL, 0.02 g/L in H_2O) was added dropwise with constant vortexing to various amounts of ARTUdiol/DPPC 1/2 particles (for a ratio value of thiourea function over DNA phosphate of 20: 100 μL, 1.2 mM) at RT. The samples were left to incubate at RT overnight before size measurements, which were performed on a Zetasizer Nano Series Malvern.

Agarose Gel Electrophoresis. Samples were prepared as described above (20 μL), and 5 μL of bromophenol blue was added. The mixtures were loaded into 0.8% agarose gel in TBE buffer (1 M Tris, 0.9 M boric acid, 0.01 M EDTA) at 80 V/cm. DNA was revealed with ethidium bromide and visualized under UV light.

Luciferase Measurement. The NIH3T3, mice fibroblasts cells, were grown in DMEM medium, supplemented with 10% fetal bovine serum, 1% antibiotics (penicillin and streptomycin), and 1% glutamine. HUVEC cells, primocultures of human unbilical vein endothelial cels, were grown into endothelial cell growth medium kit (Promo Cell) medium. One day before transfection, the cells were treated with trypsin, deposed into 24-well plates (3T3, 50 000 cells/well; HUVEC, 70 000 cells/well) and incubated 24 h at 37 °C. A volume of 200 μL of LPT/DNA (corresponding to 0.5 μg DNA) complexes was loaded on each well, and the plates are incubated at 37 °C for 48 h. Then, the cells were washed twice with PBS and lysed with 200 μL of a passive lysis buffer (Promega) containing SDS (2.5%) and TRIS (50 mM) at pH 7.5. After 15 min, the cells were centrifuged for 5 min at 12 000 rpm. 10 μL of supernatant and 10 μL iodoacetamide were deposited onto a 96-well plate, which was incubated at 37 °C for 1 h. Protein quantification was performed with the BCA protein assay kit (Pierce) and reported to the BSA taken as a reference curve. Luciferase activity was quantified using a commercial kit Luciferase assay system (Promega). On 10 μL of the lysed cells, 50 μL of the luciferin substrate was injected via an injector, and the absorbance was read immediately at 563 nm on a Wallac Victor2 1420 Multilabel Counter (Perkin-Elmer).

RGD-Mediated Lipopolythiourea Liposomes Delivery to HUVEC and NIH3T3 Fibroblast Cells. One day before transfection, HUVEC or NIH3T3 cells were deposed into 12-well plates with glass lamellae (3T3, 70 000 cells/well; HUVEC, 150 000 cells/well) and incubated at 37 °C for 24 h in MEM

Scheme 2. Table 1. Size (nm) of LPT/Colipid Particles Measured in H_2O on a Malvern Instrument Zetasizer NanoSeries

formulation	ARTUdiol	ARTUtetraol	PEG_3TUtetraol
LPT/DPPC (1:1)	no particles	79 ± 20	no particles
LPT/DPPC (1:2)	107 ± 26	122 ± 28	142 ± 49
LPT/Chol-PEG_{45} (10:1)	264	130	ND

medium. Lipopolythiourea/DNA complexes (200 μL, 0.5 μg DNA) were loaded in each well. After 7 h at 37 °C, the wells were washed twice with PBS, and 500 μL of PFA (3% in PBS) was added. The plates were left 30 min in the dark at RT before being washed twice with PBS. DAPI (0.05 μg in 500 μL PBS) was then added. The plates were left 30 min in the dark, washed with PBS, and treated with mowiol. Fluorescence was observed on a ZEISS Axiophot noninversed microscope.

RESULTS

Synthesis. Three myristyl compounds were chosen as models to evaluate the impact of LPT structural modifications to DNA compaction and to transfection efficacy. First, the synthesis of compounds **10** and **11**, bearing an aromatic linker, is described in Scheme 1.

Considering the structure of **10** and **11,** we chose to investigate a strategy starting from the readily available D,L-threitol (**1**). Tosylation of **1** with two tosyl chloride equivalents proceeded selectively (6:1) to give **2** in 52% yield with the tritosyl derivative as a minor product (8%) (*20*). Attempts to increase the selectivity using the more bulky trisyl chloride provided no improvement (*21*). Transacetalation with methyl 4-(dihydroxymethyl)cyclohexa-1,3-diene-1-carboxylate **3** (*22*) in the presence of a catalytic amount of APTS and using a Dean−Stark trap afforded the five-membered-ring acetal **4** in 75% yield (*23*). Azidation of **4** afforded the diazide **5** (94%), then saponification of the methyl ester gave the carboxylic acid **6** (97%).

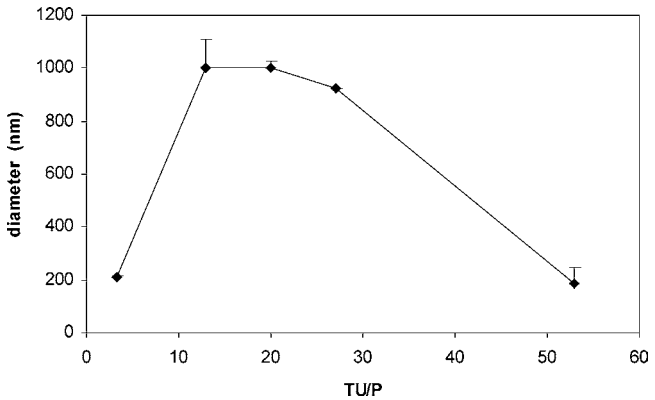

Figure 2. Diameter of particles PEG_3TUtetraol/DPPC (1:2) with increasing amounts of DNA measured in H_2O on a Malvern Instrument Zetasizer NanoSeries (ratio TU/P = mol thiourea functions/mol DNA phosphate groups).

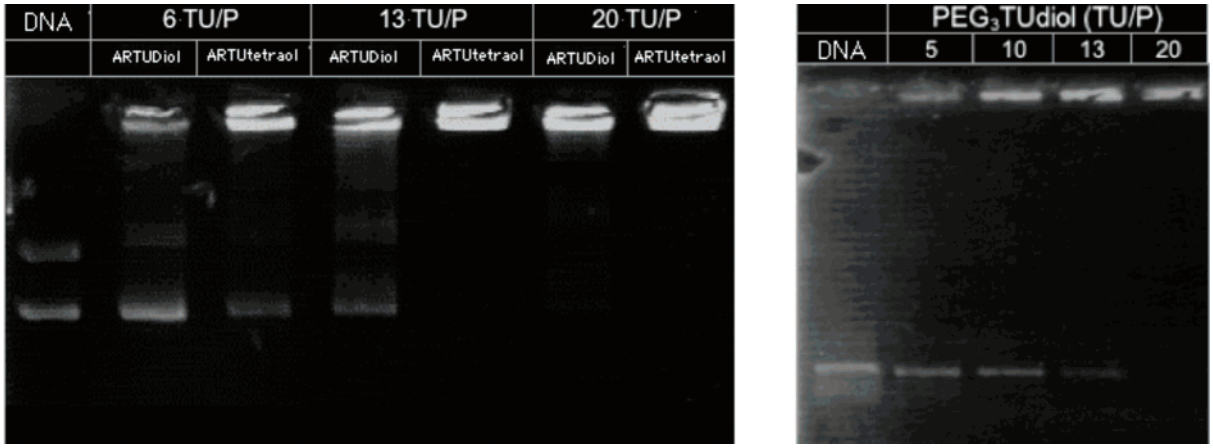

Figure 3. Migration of the ARTUdiol/DPPC(1:2)/DNA and ARTUtetraol/DPPC(1:2)/DNA complexes (left) and PEG_3TUtetraol/DPPC(1:2)/DNA complexes (right) on a 0.8% agarose gel in TBE (1×). DNA was revealed with ethidium bromide and visualized under UV light.

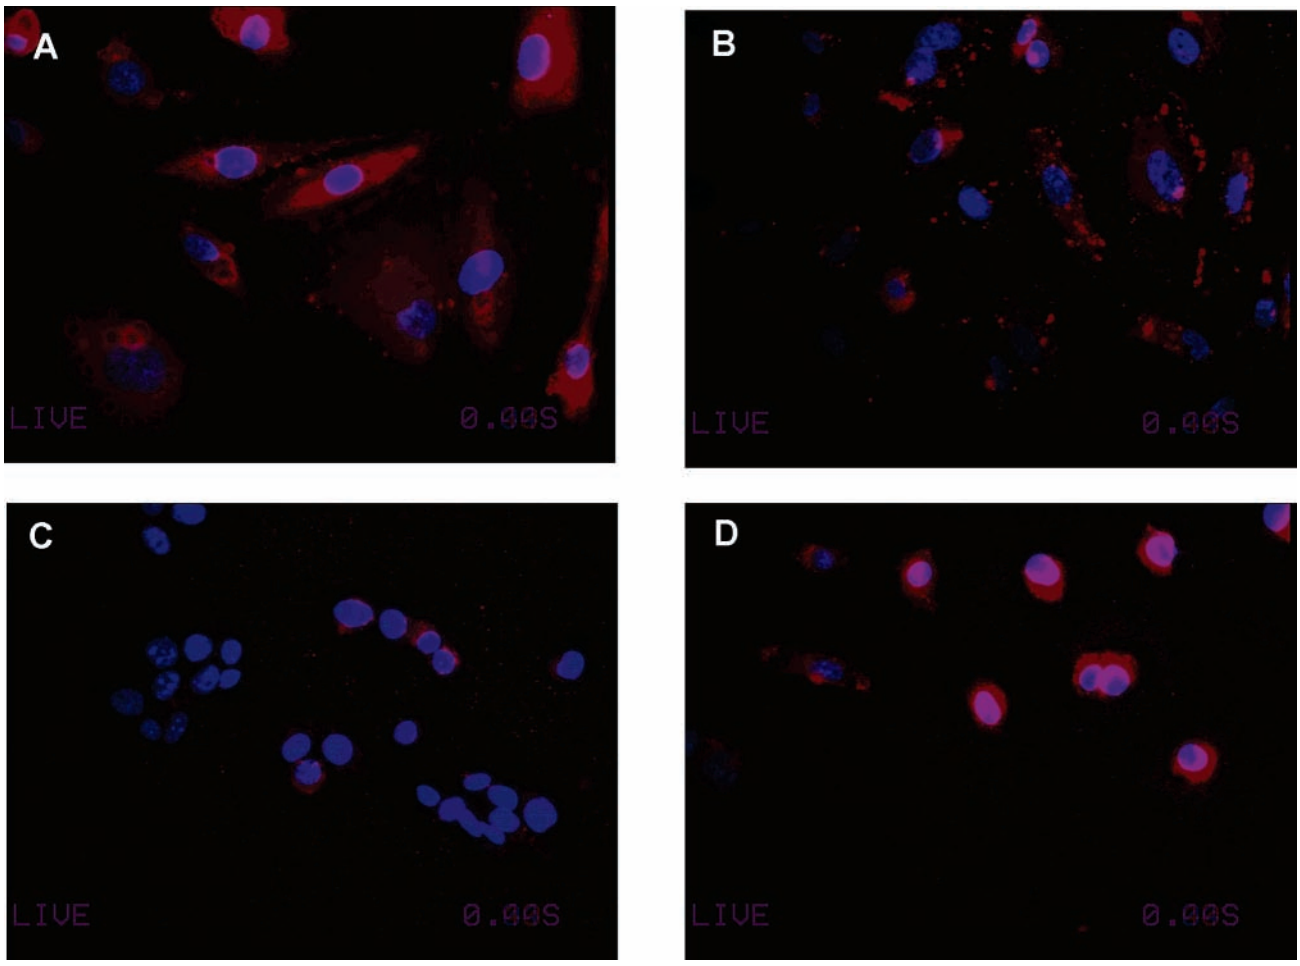

Figure 4. Fluorescence microscopy of ARTUtetraol particles. ARTUtetraol/DPPC/ $CholPEG_{45}$/DOPE−Rhodamine (10:10:0.20:0.1) ± Chol−PEG_{75}−RGD−4C (0.2) complexes were incubated for 7 h on HUVEC cells (A and B) in the absence (A) or presence (B) of RGD ligand, and on NIH3T3 cells (C and D) in the absence (C) or presence (D) of RGD ligand. Nuclei are stained with DAPI .

Subjecting **6** to amidation with ditetracedylamine using a mixed-anhydride procedure (*24*) provided good access to compound **7**. Catalytic reduction of the diazide **7** effected the conversion to the diamine **8** in high yield. The bis-isothiocyanate **9** was obtained in good yield by the reaction of **8** with CS_2 in the presence of tosyl chloride (*25*). The desired lipopolythioureas **10** and **11** were ultimately prepared by condensation of **9** with ethanolamine and 3-aminopropane-1,2-diol, respectively.

The synthesis of the lipopolythiourea bearing a short PEG linker is described in Scheme 2. It started with the synthesis of 2-{2-[2-(tetrahydropyranyl-2-yloxy)ethoxy]ethoxy}ethanol (**12**) as described in the literature (*26*).

Then, substitution of the hydroxyl terminus with bromoacetaldehyde diethyl acetal (*27*) led to the diethoxy acetal **13** that was converted to the 1,3-dioxolane **14** through treatment with diol **2** in the presence of APTS. Oxidation of **14** was performed using TEMPO and trichloroisocyanuric acid (*28*). The resulting acid **15** was treated with isobutyl chloroformate and ditetradecylamine to afford the amide **16**. Substitution of the tosyl group of **16** with sodium azide followed by palladium

reduction of the azido group gave the diamine **18** quantitatively. Elaboration of the diisothiocyanate **19** from the diamine **18** proved to be difficult and led to a modest 35% yield. Addition of 3-amino-1,2-propanediol to **19** completed the synthesis of the lipopolythiourea **20**.

Formulation Study. Compounds **10** (ARTUdiol) and **11** (ARTUtetraol) bear the same aromatic linker and differ only by the number of hydroxyl groups attached to the thiourea functionalities. Compound **20** is similar to compound **11** (PEG_3TUtetraol) considering the thiourea part, but differs by its linker. In terms of the hydrophilic/hydrophobic balance, we expected ARTUdiol < ARTUtetraol < PEG_3tetraol.

The ability of these 3 LPTs to form micellar or liposomal particles was evaluated. Similarly to the previously studied linear LPT (*13*), we chose DPPC or PEG_{45} lipid as co-lipids because of the hydrophobic behavior of the LPT. Several formulations were evaluated (Table 1). ARTUdiol/DPPC (1:2), ARTUtetraol/DPPC (1:1 and 1:2), ARTUdiol/Chol−PEG_{45} (10:1), ARTUtetraol/Chol−PEG_{45} (10:1), and PEG_3TUtetraol/DPPC (1:2) led to small particles whose diameters ranged from 100 to 250 nm, depending on the co-lipid. It is noteworthy that only ARTUtetraol could be formulated with 1 equiv of DPPC. Comparison among the aromatic lipids indicated that a tetraol terminus eased the formulation, since ARTUtetraol required a lower amount of DPPC than ARTUdiol, with the tetraol moiety probably increasing the hydrophilicity. Comparison of the two tetraol lipids showed that the lipid bearing an aromatic linker had a better capacity to form particles, possibly due to aromatic $\pi-\pi$ stacking within the lipid bilayer (*29*).

Interaction of LPT/DPPC with DNA. The capacity of LPT/DPPC (1:2) particles to associate to plasmid DNA was then studied. Setting a fixed DNA amount, we added on the DNA solution an increasing amount of lipids. After one night of incubation, we measured the size of the complexes by dynamic light scattering. The results are reported for PEG_3TUtetraol (Figure 2), but similar data have been obtained for ARTUdiol and ARTUtetraol. In the presence of DNA, we observed a size increase from 200 nm to the micrometer range, proving an interaction between lipopolythiourea particles and plasmid DNA. Adding an excess of lipids (30 equiv thiourea functions/DNA phosphate groups) let the system return to a colloidal stability.

Gel retardation experiments of LPT/DPPC/DNA complexes were performed to evaluate DNA association to particles ARTUdiol/DPPC (1:2), ARTUtetraol/DPPC (1:2), and PEGTUtetraol/DPPC (1:2). Partial retardation was observed above 6 thiourea functions/DNA phosphate groups (TU/P), and complete retardation was observed for ratios of 13 TU/P for ARTUtetraol and 20 TU/P for ARTUdiol and PEG_3TUtetraol (Figure 3). In our previous study (*13*), complete retardation was obtained for a ratio equal to 20 thiourea functions/DNA phosphate groups (TU/P). Thus, we observed that, using branched lipids bearing only two thiourea functions, we could obtain an interaction with DNA at lower or identical ratio TU/P, as compared to the DTTU lipid bearing three linear functions. These data indicated that a stable interaction between LPT and DNA could be established with only two thiourea groups.

Transfection Activity and RGD-Mediated Delivery into Endothelial Cells. DNA transfection mediated by ARTUdiol, ARTUtetraol, and PEGTUtetraol led to disappointing results, since no significative luciferase activity could be measured on the treated B16 cell. This lack of transfection activity may be explained by the noncationic nature of the LPT, causing poor contact with cell membranes. To improve these interactions, RGD-mediated internalization of endothelial cells expressing integrin $\alpha_V\beta_3$ was investigated. Thus, we added a PEG_{75}−lipid bearing a RGD peptide (*14*) to the formulation, and a rhodamine-labeled lipid/DNA complex were prepared. Their intracellular fate was investigated using fluorescence microscopy. These experiments were carried out on two cell types: human umbilical vein endothelial cells (HUVEC), which express integrin $\alpha_V\beta_3$, and NIH3T3 fibroblasts, taken as a negative control. Only the results with ARTUtetraol are shown in Figure 4. In the absence of Chol−PEG−RGD, we only observed extracellular binding of lipoplexes to the cell membrane. Such a result has also been reported for PEGylated lipoplexes (*30*). However, in its presence, we clearly saw intracellular punctuations, which indicated particle internalization. In opposition, no internalization was observed in NIH3T3 cell fibroblasts, although the extracellular binding to cell membranes seemed to be stronger with the RGD group. Thus, addition of Chol−PEG−RGD allowed a specific uptake of the LPT/DNA complexes into the cells. These results are in agreement with the specific capture previously reported on RGD-functionalized spherulites (*31*). However, this has been found to lead to neither HUVEC nor NIH3T3 transfection. This might result from a lack of DNA release from the LPT/DNA complex, possibly due to the PEG−lipid, that was shown to stabilize lipoplexes and reduce transfection efficiency (*32*).

CONCLUSION

These results present new lipopolythioureas able to associate DNA. Adding a diol or a tetraol terminus to the thiourea part improved the hydrophilicity and eased the DNA formulation. Use of Chol−PEG−RGD allowed observation of a specific internalization of the complexes in HUVEC cells as shown earlier with other particle types, such as spherulite. On the other hand, these particles were unable to transfect DNA, an effect which might be related to the presence of a PEG moiety in the formulation, thus inducing a shielding effect, which has been shown to affect transfection. Work is in progress to obtain more hydrophilic thiourea compounds and to study the internalization using an RGD derivative without any PEG moiety.

Polyplexes between siRNA and poly(ethylene imine) (PEI) derivatives are promising nonviral carriers for siRNA. The polyplex stability is of critical importance for efficient siRNA delivery to the cytoplasm. Here, we investigate the effect of PEGylation at a constant ratio (∼50%) on the biophysical properties of the polyplexes. Particle size, ζ potential, and stability against heparin as well as RNase digestion and reporter gene knockdown under in vitro conditions of different siRNA polyplexes were characterized. Stability and size of siRNA polyplexes were clearly influenced by PEI−PEG structure, and high degrees of substitution such as PEI(25k)-*g*-PEG(550)$_{30}$ resulted in large (300−400 nm), diffuse complexes (AFM) which showed condensation behavior only at high N/P ratios. All other polyplexes and the PEI control showed similar sizes (150 nm) and compact structures in AFM, with complete condensation reached at N/P ratio of 3. Stability of siRNA polyplexes against heparin displacement and RNase digestion could be modified by PEGylation. Protection against RNase digestion was highest for PEI(25k)-*g*-PEG(5k)$_4$ and PEI(25k)-*g*-PEG(20k)$_1$, while siRNA/PEI provided insufficient protection. In knockdown experiments using NIH/3T3 fibroblasts stably expressing *β*-galactosidase, it was shown that PEG chain length had a significant influence on biological activity of siRNA. Polyplexes with siRNA containing PEI(25k)-*g*-PEG(5k)$_4$ and PEI-(25k)-*g*-PEG(20k)$_1$ yielded similar efficiencies of ca. 70% knockdown as lipofectamine controls. Confocal microscopy demonstrated enhanced cellular uptake of siRNA into cytosol by polyplexes formation with PEI copolymers. In conclusion, both the chain length and graft density of PEG were found to strongly influence siRNA condensation and stability and hence affect the knockdown efficiency of PEI−PEG/siRNA polyplexes.

INTRODUCTION

RNA interference (RNAi) using small interfering RNA (siRNA, a double-stranded RNA with 21−23 bp) has recently emerged as a powerful tool for silencing target genes and holds great possibility for therapeutic application (*1*). The first clinical data on RNAi have been published recently (*2*). However, to achieve efficient gene knockdown under in vivo conditions, siRNA degradation in the physiological milieu, poor cellular uptake, and inefficient translocation into the cytoplasm need to be improved. Macromolecules like siRNA are typically internalized by endocytosis followed by lysosomal fusion causing siRNA degradation. Endosomal escape is a prerequisite for efficient delivery of intact siRNA to the cytosol, its site of biological action (*3*). Moreover, the polyanionic nature of siRNA impairs diffusion through cell membranes and cellular uptake. Therefore, delivery systems for siRNA are of particular importance to exploit their therapeutic potential (*4*). A promising approach could be siRNA delivery through complexation of siRNA using biodegradable and biocompatible polycations (*5*).

Poly(ethylene imine) (PEI) is well-known as an efficient nonviral nucleic acid vector demonstrating high transfection rates under in vitro and in vivo conditions (*6*). PEI forms polyplexes with anionic nucleotides by electrostatic interactions. The strong buffer capacity, designated as the proton sponge hypothesis, could be responsible for the fact that PEI-based delivery systems do not require endosome disruptive agents for lysosomal escape (*7*). Once released from endosomes, the siRNA may enter the cytosol, where it associates with its complementary siRNA strand and, depending on its complementarity, results in either targeting cleavage of the mRNA or translational arrest. However, intact PEI/plasmid complexes were found in the cell nucleus (*8*, *9*), implying that PEI/siRNA polyplexes might be too stable to be released in the cytosol and will be transported into the nucleus, as in the case of plasmid/PEI complexes (*8*); therefore, no knockdown will be observed. To guarantee the biological activity of siRNA, this point needs to be clarified, and stability of the PEI/siRNA polyplexes needs to be further modified. The polyplexes should be sufficiently stable during the endocytosis process to ensure sufficient intracellular uptake of siRNA, but thereafter, siRNA should be released into the cytosol. While it was noticed that a significant decrease in transfection activity for the PEI−PEG/DNA polyplexes was found (*10*, *11*), it is reasonable to assume that PEGylation might be able to destabilize PEI/siRNA polyplexes, leading to increased siRNA release in the cytoplasm and therefore efficient knockdown. This hypothesis was investigated in this study.

Recently, application of linear PEI or low molecular PEI as an siRNA delivery vector has been reported (*12*−*15*). In agreement with our hypothesis, linear PEI was efficient for delivering nucleic acids to cells but did not lead to siRNA activity within the applied dose of <0.5 pmol (*12*). Direct intratumor injection of a siRNA-encoding plasmid complexed

[a] The black part of the structure represents the branched PEI 25 kDa, and the blue part represents the nonionic linear PEG segments.

with linear PEI efficiently reduced the vascularization of treated tumors but was not able to reduce tumor growth (*13*). The low activity of siRNA might be attributed to insufficient release in the cytosol.

PEGylated PEI was synthesized in our group to decrease the cytotoxicity of branched PEI and was extensively studied as vectors for DNA delivery (*16*). Moreover, strong evidence was provided that PEGylated PEI could be adapted to function as an effective carrier for cellular delivery of small oligonucleotides. Recent reports have characterized the properties and transfection capacity of PEGylated PEI25k complexed with oligonucleotides (*17*, *18*). Similarly, branched PEI-*graft*-poly(ethylene glycol) has been recently reported as a carrier of siRNA with different targeting ligands, and the results are promising (*19*−*21*).

Regarding PEGylation, both PEG chain length and graft density clearly affect pharmacokinetic properties of polyplexes containing nucleic acids, although in vivo results are discussed controversially. While some authors suggest that low graft densities with high molecular weight PEG are more effective in reducing protein adsorption than the higher surface density of low molecular weight polymers (*22*), others found that density of PEG grafting on the surface of polyplexes had a more pronounced effect on protein adsorption than PEG chain length on steric repulsion and van der Waals attraction (*23*). For DNA polyplexes, a sufficiently high graft density with PEG molecules seems to be necessary to prevent opsonization and avoid rapid clearance from the blood stream (*17*). However, little information is available regarding the influence of PEG chain length on the physicochemical and biological properties of nucleic nanoparticles (*17*).

Therefore, the objective of this study was to evaluate the stability of PEI and PEI−PEG polyplexes with siRNA using biophysical methods and to elucidate the influence of PEG chain length and graft density. Our hypothesis was tested with a panel of PEI−PEGs having similar composition (50% PEG content) but vastly different structures. Here, PEI(25k)-*g*-PEG copolymers with PEGylation degree in the range 40−60% and different PEG chain lengths (550, 2k, 5k, 20k, respectively) were selected and compared with that of the homopolymer PEI(25k). This selection is based on the fact that the molecular weights of linear PEGs used in biomedical applications usually range between a few hundred to 20 000 Da. The relationship between polymer structure and stability of the polyplexes was investigated. Furthermore, the knockdown efficiency of the selected polyplexes was studied in cell culture to find the correlation between in vitro stability and biological effect. Uptake and distribution of the polyplexes in cells were visualized by confocal laser scanning microscopy. Due to the different properties of siRNA compared to DNA (*24*), this study should provide a basis for the design of siRNA delivery systems.

MATERIALS AND METHODS

Materials. Branched poly(ethylene imine), PEI, with a molecular weight of 25 kDa was purchased from Sigma-Aldrich (Seelze, Germany). The poly(ethylene imine)-*graft*-poly(ethylene glycol) (PEI−PEG) with a PEG content of approximately 50% (w/w) was synthesized as previously described (*16*) by grafting linear PEG of 550 Da and 2, 5, and 20 kDa, respectively, onto branched PEI 25 kDa. Polymers were stored as sterile filtered, aqueous stock solutions (5 mg/mL) at pH 7.4. These graft copolymers were designated using the following nomenclature: PEI(25k)-*g*-PEG(x)$_n$. The number in brackets (25k or x, where x = 550, 2k, 5k, or 20k) represents the MW of PEI or PEG block in daltons, and the index n is the average number of PEG blocks per PEI molecule. This number was calculated on the basis of ^{1}H NMR spectra as described previously (*16*). The schematic structure and properties of the copolymers investigated in this paper are shown in Table 1. siGL3 (luciferase GL3 Duplex) was purchased from Dharmacon (Lafayette, CO) and used for physicochemical studies. The sequence is as follows: 5′-CUU ACG CUG AGU ACU UCG A dTdT/ dTdT GAA UGC GAC UCA UGA AGC U-5′. For the knockdown experiment in cell culture, an anti β-Gal siRNA duplex was purchased from Dharmacon with the following sequence: 5′-CUA CAC AAA UCA GCG AUU U UU /UU GAU GUG UUU AGU CGC UAA A P-5′. Cyanine 3 (Cy3)-labeled siRNA was from Dharmacon (Lafayette, CO). RNase A for the RNase digestion study was purchased from Roche Diagnostics GmbH, Mannheim, Germany. All other materials were obtained in analytical quality.

Preparation and Characterization of Polymer/siRNA Polyplexes. All polyplexes consisting of siRNA and PEI derivatives were prepared in isotonic glucose solution at pH 7 unless otherwise mentioned. The polymer/siRNA ratio was expressed as the nitrogen/phosphate (N/P) ratio, where N represents moles of amine on PEI and P represents moles of phosphate on siRNA. On the basis of the N/P ratio, the appropriate amount of polymer was added to the siRNA solution, mixed by vigorous pipetting, and incubated for 10 min at room temperature.

The hydrodynamic diameter of freshly prepared polyplexes was measured using a Zetasizer Nano ZS from Malvern Instruments (Herrenberg, Germany) equipped with a 10 mW HeNe laser at a wavelength of 633 nm. Measurements were

performed at 25 °C and analyzed in CONTIN mode. The instrument was checked periodically with nanospheres size standards (polymer microspheres in water, 199 nm ± 6 nm) from Duke Scientific (Palo Alto, CA). For data analysis, the viscosity and refractive index of water at 25 °C (0.89 mPa·s and 1.333, respectively) were used. The measurements were performed in triplicate. The ζ potentials (surface charge) of freshly prepared polyplexes were determined using the standard capillary electrophoresis cell of Zetasizer Nano ZS from Malvern Instrument at 25 °C. Measurements were performed in glucose 5%, pH 7.4. Average values were calculated with the data of 10 runs with standard deviation.

Atomic Force Microscopy (AFM). The polyplexes were prepared as described above and diluted in milliQ water. AFM images were obtained on a NanoWizard (JPK instruments, Berlin, Germany). The microscope was vibration-damped. Commercial pyramidal tips (Micromash, Estonia) on an I-tape cantilever with a length of about 230 μm, a resonance frequency of about 160 kHz, and a nominal force constant of 40 N/m were used. All measurements were performed in intermittent-contact mode at a scan speed of approximately 1 Hz to avoid damage of the sample surface. The acquired pictures had a resolution of 512 × 512 pixels. Polyplexes were directly transferred onto a prewashed silicon chip by dipping the chip into the polyplex solution for 10 min, rinsing it with MilliQ water, and allowing it to dry in air.

SiRNA Condensation. To study siRNA condensation as a function of N/P ratio, polyacrylamide gel (20%) electrophoresis (PAGE) retardation assays were performed (*18*). Briefly, polyplexes preparation was carried out in 5% glucose solution at pH 7.0. Increasing amounts of PEI were added to 6 pmol siRNA to reach final N/P ratios of 0.5, 0.7, 1, 1.5, 2, 3, and 5 for PEI 25k and 2, 3, 5, 7, 10, 15, and 20 for other copolymers. The resulting polyplexes were incubated for 10 min prior to loading to the gel. Then, the gel electrophoresis was run in TBE buffer pH 8 at a constant current of 15 mA. To visualize siRNA, the gel was immersed in 0.0017% ethidium bromide solution for 5 min. Thereafter, fluorescence of intercalated ethidium bromide was detected using a transilluminator (BioDoc Analyze, Biometra, Goettingen, Germany).

Polyanion Competition Assay. The relative stability of polyplexes was tested by measuring siRNA release from polyplexes in the presence of a competing polyanion heparin (*25*). All polyplexes were formed at N/P of 10. Polyplex solutions were incubated in the presence of 0.01, 0.02, 0.03, 0.04, 0.05, 0.1, and 0.15 IU of heparin/μg siRNA, respectively. These solutions were mixed well and incubated for 10 min before being applied to a 20% PAGE. In each gel, free siRNA was applied as a reference. Gels were run for 2 h at 15 mA and then scanned using a Biometra gel analyzing system. The experiments were performed in triplicate.

RNase Digestion. Stability of siRNA polyplexes against RNase digestion was investigated according to a method described previously (*26*) with little modification. The protection effect of different siRNA/PEI derivative polyplexes against series RNase digestion was investigated. Briefly, polyplexes were prepared at N/P of 10 in glucose 5%. Aliquots of 12.5 μL polyplexes corresponding to 0.17 μg of siRNA were incubated with 0.05, 0.10, 0.20, 0.50, 0.70, 1.0, and 1.2 mIU of RNase in phosphate buffer at pH 7.0 for 30 min at 37 °C. Afterward, samples were incubated for a further 30 min at 70 °C to inactivate RNase and divided into two equal fractions. The first fraction was used for determination of integrity of the polyplexes and the second fraction with 2 μL of a heparin solution containing 1000 IU per mL to release of the amount of siRNA remaining intact. Resulting mixtures were applied to a 20% PAGE gel, and electrophoresis was carried out at 15 mA for 2 h. A positive control containing free siRNA was tested under the same conditions. The resulting gel was imaged on a Biometra transilluminator. The intensity of the "free siRNA" band was quantified by densitometry using the software program *Scion Image 4.0.2. beta* (Scion Corporation, Frederick, MD). At a given RNase concentration, the percentage of siRNA dissociated from the polyplexes was obtained by normalizing against the siRNA band measured from a sample containing siRNA only on the same gel. All experiments were performed in triplicate.

Knockdown Experiments in NIH 3T3 Fibroblasts under in Vitro Conditions. The knockdown experiment was performed as described in the literature (*27*). Briefly, 24 h before transfection, NIH/3T3 cells stably expressing β-galactosidase (Orbigen, San Diego, CA) were seeded in 24-well plates at a density of 3×10^4 per well in 500 μL Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS) at 37 °C and 5% CO_2 (v/v). Cells were at 50−80% confluence before experiment. siRNA polyplexes with different polymers were prepared at N/P of 10 and incubated for 10 min at room temperature. The total volume of the polyplexes was 100 μL, and the polyplexes were added to the cells in 400 μL DMEM/10% FBS (50 pmol siRNA per well). For lipofectamine 2000, the method was similar except that the lipofectamine 2000/siRNA ratio was 2:1. After 4 h incubation, the medium was changed, and cells were further incubated for 20 h. Thereafter, the cells were washed with PBS and then were lysed with 100 μL of lysis buffer (Galacto-Star System, Applied Biosystems, Bedford, MA). Protein concentration was measured by using the BCA assay kit. β-Galactosidase activity was measured with a luminometer. Relative light units were converted to picograms of β-galactosidase by using β-galactosidase as a standard. The experiments were performed in triplicate.

Preparation of FITC-Labeled Copolymer. Copolymer PEI(25k)-*g*-PEG(5k)$_4$ was labeled with fluorescein isothiocyanate (FITC) for cellular trafficking studies. Briefly, 10 mg PEI(25k)-*g*-PEG(5k)$_4$ was dissolved in 2 mL of 0.1 M sodium hydrogen carbonate (pH 8.2). FITC (1 mg in 200 μL water-free DMSO) was added to the solution dropwise under stirring, and the mixture was stirred at room temperature for 4 h under light exclusion. Purification was performed on a PD-10 column (Amersham Pharmacia Biotech, Freiburg, Germany).

Confocal Laser Scanning Microscopy (CLSM). Confocal laser scanning microscopy was utilized to visualize the internalization of siRNA polyplexes. NIH/3T3 cells stably expressing β-galactosidase were seeded at a density of 12 000 cells per well in 8-well chamber slides (LabTek, Nunc, Wiesbaden, Germany). After 24 h, medium was removed and polyplexes containing FITC-labeled PEI(25k)-*g*-PEG(5k)$_4$, and Cyanine 3 labeled siRNA, free Cyanine 3 labeled siRNA, and free FITC-labeled polymer were added in fresh media. After 2 h incubation, cells were washed three times with phosphate buffered saline (PBS). Fixation of cells was done by incubation with 4% paraformaldehyde solution in PBS pH 7.4 at room temperature for 30 min and counterstaining with DAPI (4,6-diamidino-2-phenylindole, 0.2 μg/mL) for 20 min, both under light exclusion. Cells were embedded in FluorSave Reagent (Calbiochem, San Diego, CA). A Zeiss Axiovert 100 M microscope coupled to a Zeiss LSM 510 scanning device (Zeiss, Oberkochen, Germany) was used for confocal microscopy. For excitation of Cy3 fluorescence, a helium−neon laser with an excitation wavelength of 543 nm was used. Fluorescence emission was detected using a 560−615 nm band-pass filter. In a second scan, FITC was detected using an argon laser with an excitation wavelength of 488 nm and a 505−550 nm band-pass emission filter. Simultaneously, transmitted light images were obtained in this scan. In a third scan, DAPI was excited at 364 nm using an Enterprise

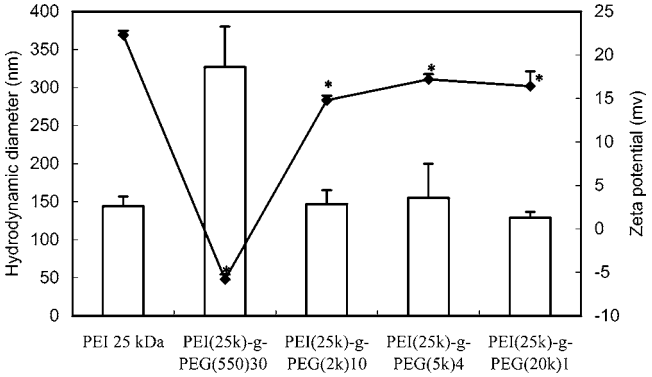

Figure 1. Physicochemical properties of PEI−PEG/siRNA (siGL3) polyplexes in 5% glucose at N/P ratio of 10. (◆) ζ potential; (bar) particle size. *$P < 0.05$.

II 653 laser (Coherent Inc., Santa Clara, CA), and fluorescence was detected using a 385−470 nm band-pass filter.

Statistics. The results are reported as mean ± standard deviation (SD) of at least three experiments. Significance between the mean values was calculated using one-way ANOVA analysis (*Origin 7.0 SRO*, Northampton, MA). Probability values $P < 0.05$ were considered to be significant.

RESULTS AND DISCUSSION

With PEG weight ratio (∼50%) kept constant, branched PEI 25 kDa was grafted with PEG 0.55k, 2k, 5k, and 20k, respectively, and the influence of PEG chain length on the stability and biological activity of the resulting siRNA polyplexes was studied. We hypothesized that PEGylation might modify the stability of the polyplexes and therefore affect the knockdown efficiency of siRNA by increasing the proportion of siRNA released in the cytoplasm avoiding uptake into the nucleus.

Characterization of the Polyplexes. The hydrodynamic diameters of PEI−PEG/siGL3 polyplexes were determined at nitrogen-to-phosphate (N/P) ratio of 10. In preliminary experiments with the copolymer PEI(25k)-*g*-PEG$(2k)_{10}$, it was shown that polyplex sizes decreased with increasing N/P ratios from 5 to 10 and remained constant up to N/P of 50. Therefore, N/P of 10 was adopted for size measurements. Properties of PEI−PEG/siGL3 polyplexes in 5% glucose are shown in Figure 1. The influence of PEG chain length could be seen in the way that the copolymer with fewer PEG blocks formed smaller polyplexes than copolymers with more PEG blocks. The homopolymer PEI exhibited a particle size of 144 nm. In contrast, copolymer PEI(25k)-*g*-PEG$(550)_{30}$ formed large polyplexes of 300−400 nm even at N/P ratio of 20, probably due to a decreased condensation efficiency of this highly grafted derivative, as indicated in the siRNA retardation assay. The copolymers with PEG chains 2k and 5k formed polyplexes of appropriately 150 nm, and slightly decreased particles size was found with copolymer PEI(25k)-*g*-PEG$(20k)_1$, with particles size around 130 nm.

The enhanced siRNA complexation might be attributed to the special copolymer structure. With only one PEG block on average, this is a diblock-like copolymer, and there might be a PEI domain and a PEG domain clearly separated from each other. Thus, the siRNA seems to interact with the PEI domain without interference from PEG. However, no statistical difference was found among the particle sizes of polyplexes prepared with copolymers of PEG chains 2k, 5k, and 20k. A similar trend was reported for NF-kB decoy and DNA PEI−PEG complexes (*17*, *28*). Moreover, the stability of the polyplexes was investigated for 20 min. It is very important to note that all the siRNA/copolymer polyplexes remained stable after 20 min incubation (data not shown). In comparison, the size of PEI(25k)/siRNA polyplexes increased approximately 35%. This can be explained by the steric shielding effect of PEG, thereby abolishing aggregation. This effect has been demonstrated for PEGylated PEIs in other studies (*28*). In addition, PEG might additionally participate in the siRNA condensation process in a synergistic manner (*29*). In contrast, particle size of PEI-*g*-PEG/oligonucleotides was reported to be less than 100 nm in 150 mM sodium chloride (*18*), and this was attributed to differing sequences of the nucleic acid and different media used in this study. To clarify this point, hydrodynamic diameters of PEI−PEG/siGL3 polyplexes were also investigated in 150 mM sodium chloride solution. Aggregation appeared immediately after preparation of polyplexes with particle sizes between 500 and 1000 nm. These data confirm that properties of the polyplexes were siRNA sequence- and medium-dependent. Similarly, particle size of β-Gal siRNA polyplexes of 400−900 nm was reported recently, which was measured in 20 mM HEPES buffer after incubating in OptiMEM medium for 30 min (*30*).

Interactions between polymer/siRNA polyplexes and cell surfaces are dependent upon the charge of the particles. The surface charges of PEI−PEG/siRNA polyplexes are described in Figure 1. PEI 25 kDa polyplexes revealed high positive surface charge of +22.3 mV. All copolymers showed a significantly reduced ζ potential compared to PEI. Full shielding was observed with copolymer PEI(25k)-*g*-PEG$(550)_{30}$. No statistically significant difference was found for the copolymers with PEG$(2k)_{10}$, PEG$(5k)_4$, and PEG$(20k)_1$, implying that at least part of the PEG blocks of the copolymers orientate toward the surface while PEI and siRNA are located in the inner part of the polyplexes. Therefore, it is reasonable to conclude that the PEG protective effect is caused by a combination of PEG chain length and density; a threshold PEG length is needed for higher efficiency.

Atomic Force Microscopy. Atomic force microscopy (AFM) was used to study the morphology of polymer/siRNA polyplexes and compared with that of free siRNA, as shown in Figure 2. Polyplexes were imaged at an N/P ratio of 10 except PEI−PEG(550) (N/P 20). As anticipated, a double-stranded structure was found for free siRNA duplex (Figure 2a). After complexation with the polymers, the double-stranded structure disappeared, and all the polyplexes were spherical or subspherical with smooth surfaces (Figure 2). The homopolymer PEI 25 kDa showed images of compact homogeneously distributed polyplexes, with some large particles. PEGylation affected the properties of the polyplexes considerably. Particle aggregation was quite serious in the case of PEI−PEG(550) (Figure 2c), and this is in agreement with the results from dynamic light scattering (DLS) measurement. The phenomenon of aggregation decreased with increasing PEG chain length to 2k and 5k (Figure 2d,e). For the PEI−PEG(20k) polyplexes, the majority of the particles was separated from each other (Figure 2f), suggesting that these polyplexes were better stabilized against agglomeration. This is in agreement with the decreased particle size measurement. Similarly, it was also reported that PEG chain length was a main determinant of polyplex aggregation (*31*).

SiRNA Condensation. To quantify siRNA condensation as a function of N/P ratio, we utilized the ability of PEI to quench siRNA/ethidium bromide fluorescence by immersing the gel in ethidium bromide solution for 5 min before imaging. If siRNA is condensed by cationic polymers, ethidium bromide can no longer intercalate, and fluorescence intensity decreases measurably. First of all, with PEI(25k)-*g*-PEG$(2k)_{10}$ copolymer taken as an example, the effect of ionic strength in the medium on the electrostatic interaction between polymer and siRNA was investigated. Complete siRNA condensation was found at N/P ratio of 5 in 150 mM NaCl solution, compared to N/P ratio of

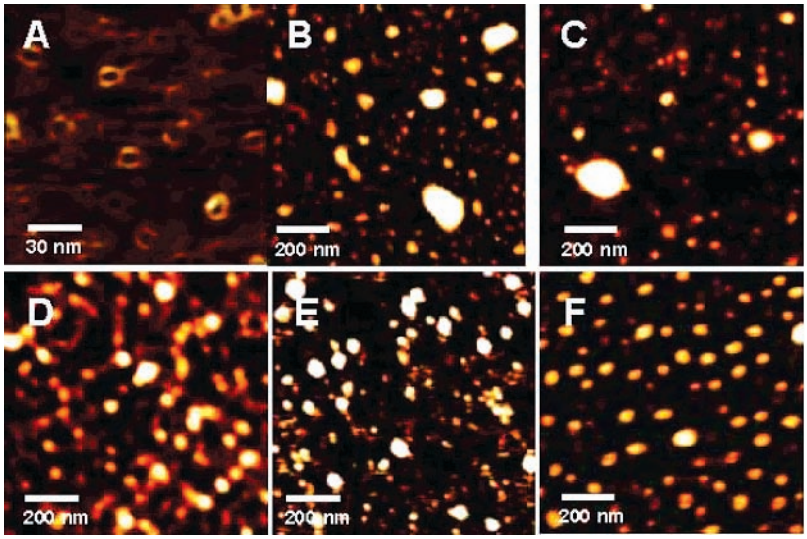

Figure 2. AFM images of different siRNA polyplexes. (a) free siRNA, (b) PEI 25kDa, (c) PEI(25k)-*g*-PEG(550)$_{30}$, (d) PEI(25k)-*g*-PEG(2k)$_{10}$, (e) PEI(25k)-*g*-PEG(5k)$_4$, (f) PEI(25k)-*g*-PEG(20k)$_1$.

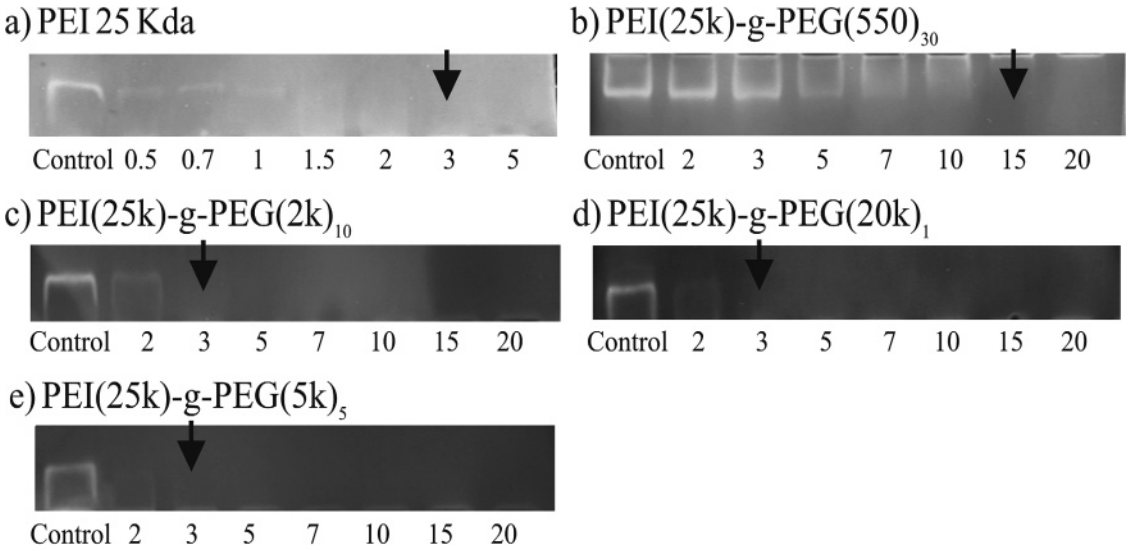

Figure 3. siRNA condensation of PEI and PEI−PEG by increasing the N/P ratio measured by polyacrylamide gel electrophoresis. Lane 1, N/P 0 (siRNA only as control); completed siRNA condensation ratio was indicated by arrows.

3 in 5% glucose solution, indicating that higher N/P is essential for complete siRNA complexation at higher ionic strength. Therefore, 5% glucose was used to prepare the polyplexes in the following studies.

As shown in Figure 3, unmodified PEI condenses siRNA even at N/P ratio as low as 0.5, and complete condensation was found at N/P ratio of 3, suggesting that all negatively charged siRNA phosphate residues are saturated with PEI. Similarly, it was reported that at N/P ratios of >2.5 plasmid DNA was fully retarded in agarose gel electrophoresis with PEI (*32*). When PEI was grafted with short PEG blocks as in the case of copolymer PEI(25k)-*g*-PEG(550)$_{30}$, the complexation was hindered slightly at N/P of 5.0 but complete condensation was realized at N/P ratio 15, probably due to the decreased charge density of the copolymer at a relatively high PEG density. In contrast, with the same copolymer, only slight hindrance for DNA complexation was found (*28*), emphasizing different properties between DNA and siRNA (*24*). No difference was found for copolymers PEI(25k)-*g*-PEG(2k)$_{10}$, PEI(25k)-*g*-PEG-(5k)$_5$, and PEI(25k)-*g*-PEG(20k)$_1$, and complete retardation of siRNA was achieved at N/P of 3, which is comparable to homopolymer PEI 25k, the same trend found in the size measurement. This implies that at similar PEG content PEG chain length plays a critical role for nucleic acid condensation. Anyway, no difference was found at PEG 2k, 5k, and 20k. In contrast, slightly increased DNA condensation was reported with increasing PEG MW from 550 to 20 kDa in the same copolymer (*28*).

Heparin Displacement. In this study, except for copolymer PEI(25k)-*g*-PEG(550)$_{30}$ (N/P 20), all the other polyplexes were prepared at N/P of 10, at which complete siRNA condensation was demonstrated in previous studies. The stability of different polymer/siRNA polyplexes against heparin displacement is shown in Figure 4. PEI/siRNA polyplexes were the most stable, and dissociation occurred at heparin 0.31 IU/μg siRNA; complete dissociation was found at heparin 0.42 IU/μg siRNA, suggesting a strong interaction of PEI with siRNA. In contrast, the stability of the polyplexes decreased after PEGylation. This observation is in agreement with our hypothesis and can probably be explained by the weakened interaction of siRNA with polymer as a result of decreased charge density. Interestingly, the protection efficiency increased with increasing PEG chain length at similar PEG content. PEI(25k)-*g*-PEG(550)$_{30}$/siRNA polyplexes were extremely unstable, and 81% siRNA dissociation was observed even at heparin of 0.10 IU/μg siRNA, which created doubt as to its capacity to bring a sufficient

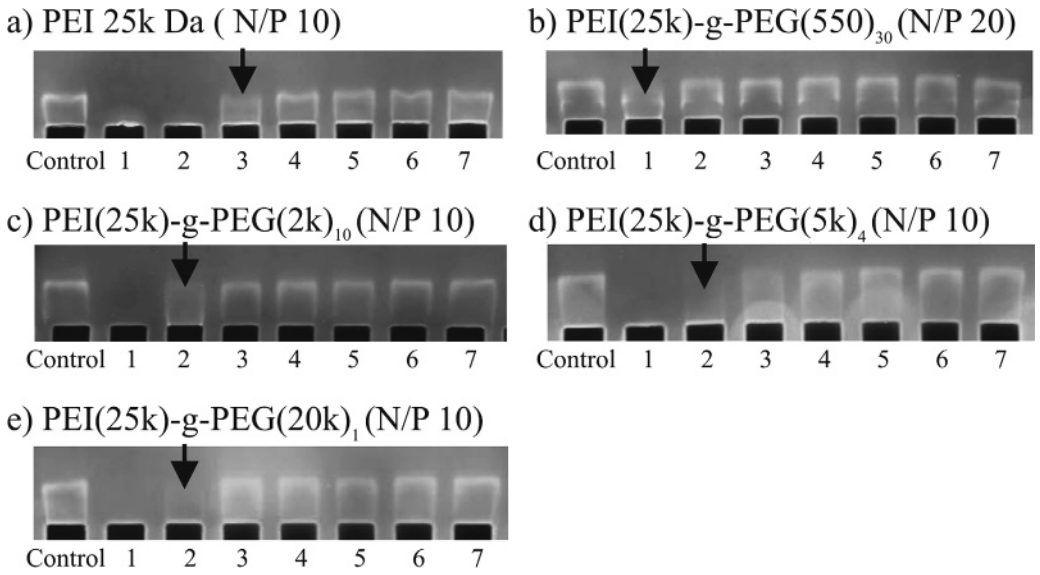

Figure 4. siRNA polyplexes stability against heparin displacement. Control: free siRNA. Lanes 1−7: heparin 0.10, 0.21, 0.31, 0.42, 0.52, 1.04, 1.57 IU/μg siRNA, respectively.

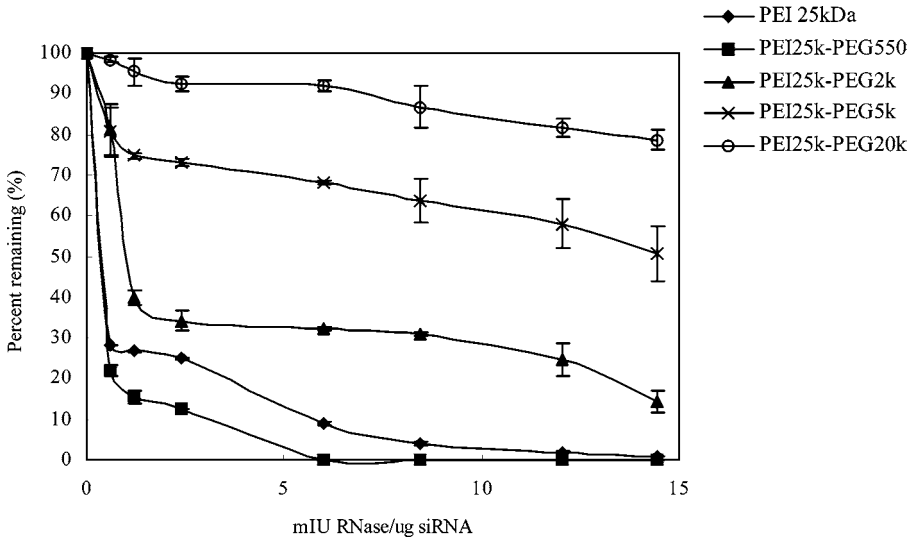

Figure 5. Incubation of PEI and PEG−PEI/siRNA polyplexes with RNase A at an N/P ratio of 10 over 0.5 h. The percentage recovery of intact siRNA is shown in reference to the intact amount of noncomplexed control siRNA.

amount of siRNA into cells. In contrast, for copolymers PEI(25k)-*g*-PEG(2k)$_{10}$, PEI(25k)-*g*-PEG(5k)$_4$, and PEI(25k)-*g*-PEG(20k)$_1$, dissociation of polyplexes occurred at heparin of 0.21 IU/μg siRNA, and 24%, 6.8%, and 5.9% of siRNA was released, respectively, indicating that PEG chain length instead of surface density played a critical role in protection of the polyplexes, and a better steric effect was found at PEG chain length of >2k. With the same copolymer PEI(25k)-*g*-PEG(2k)$_{10}$, previous study demonstrated that DNA polyplexes started to dissociate at heparin of 0.2 IU/μg DNA (*25*), which is comparable to our results. However, PEI(25k)/DNA polyplexes were less stable against heparin displacement (*25*) compared to PEG(25k)/siRNA polyplexes (0.2 IU/μg DNA vs 0.3 IU/μg DNA). This can probably be explained by the smaller MW of siRNA, which can be compacted more efficiently by the polymer. No statistically significant difference was found for the polyplexes prepared with the copolymer containing PEG 5k and 20k (P > 0.05), implying that PEG 5k might be sufficient for effective PEGylation.

Stability against RNase Digestion. The enzymatic degradation of siRNA is accompanied by a rapid decline in biological activity and therapeutic efficiency. The ability of the gene carrier to protect siRNA against enzymatic degradation by RNase, which is located in the cytoplasm, can be demonstrated by RNase digestion studies. First of all, stability of free siRNA against RNase was studied. It was found that free siRNA was degraded completely even at RNase of 0.01 mIU (0.12 mIU/μg). Thereafter, the protection effect of different PEI copolymer/siRNA polyplexes against RNase digestion was investigated. The PEG shell was expected to play an important role not only in sterically stabilizing the structure of the complex, but also in protecting the siRNA vector from being attacked by nucleases (*33*). The quantification of the siRNA displaced from the polyplexes is shown in Figure 5. At RNase of 6.0 mIU/μg siRNA, almost all the siRNA was degraded in PEI−PEG(550)/siRNA polyplexes, whereas 9% was left in PEI(25k)/siRNA polyplexes despite the strong interaction as indicated in the heparin displacement assay. In contrast, by sterically shielding the siRNA domains susceptible to proteolytic attack, the PEG layer can decrease the amount of siRNA degraded, and the effect is PEG chain-length-dependent. It showed that 32%, 68%, and 92% of siRNA was protected from degradation in PEI(25k)-*g*-PEG(2k)$_{10}$, PEI(25k)-*g*-PEG(5k)$_4$, and PEI(25k)-*g*-PEG(20k)$_1$ polyplexes, respectively. The super protection effect of PEG 5k and PEG 20k against RNase digestion suggest their promising application in vivo. The increased stability of the polyplexes

Table 2. Particle Size of Polymer/β-Gal siRNA Polyplexes in Different Media

		5% glucose		0.9% NaCl	
polymer	N/P	size	PI	size	PI
PEI 25 kDa	10	482 ± 28	0.38 ± 0.02	144 ± 12.2	0.078 ± 0.029
PEI(25k)-*g*-PEG(550)$_{30}$	20	1320 ± 4.6	0.28 ± 0.31	434 ± 55.5	0.524 ± 0.045
PEI(25k)-*g*-PEG(2k)$_{10}$	10	650 ± 65	0.46 ± 0.01	102 ± 4.96	0.273 ± 0.049
PEI(25k)-*g*-PEG(5k)$_4$	10	642 ± 24	0.47 ± 0.01	118 ± 24.1	0.320 ± 0.108
PEI(25k)-*g*-PEG(20k)$_1$	10	490 ± 85	0.45 ± 0.06	109 ± 3.86	0.270 ± 0.010

and enhanced enzymatic resistance support the hypothetical core−shell structure of these self-assembling polyplexes; that is, the siRNA is trapped within a cationic core surrounded by a hydrophilic PEG shell. The strength of the PEG shell is its chain length dependency. It is well-known that, in aqueous solutions, PEG is a highly hydrated polymer and has a high degree of segmental flexibility. It is thought to be capable of influencing the structure of several molecular layers of water, leading to its pronounced conformational entropy and large exclusion volume (*34*). The influence of molecular weight, surface density, and conformation of PEG affect dramatically the enzyme adsorption pattern. The brush conformation is presented as the highest steric protection against protein adsorption due to the steric hindrance of heavily hydrated chains of PEG molecules and their flexibility in terms of free rotation of individual polymer units around interunit linkage (*35*). The polymer chain flexibility correlates with its ability to squeeze nonlinked water molecules out of the molecular dynamic "cloud" formed over the surface (*36*). When PEG chains are short, like PEG 550, flexibility is insufficient, structured water can be "squeezed out" due to entropic instability, and RNase can adsorb on the surface of the polyplex, leading to siRNA degradation. As the molecular weight of a PEG molecule rises, the cloud temperature, which is the temperature at which the polymer separates from the water solution, also increases, suggesting an increased amount of structured water and, therefore, increased stability with increasing PEG molecular weight (*37*). As shown in our results, flexibility and high hydration of long chains like PEG 5000 and 20 000 Da allow the repulsion of RNase to a higher extent despite its low density. Similarly, computer simulations suggest that a relatively small number of molecules of a hydrophilic flexible polymer are sufficient to decrease the number of direct collisions of colloid surface with opsonizing proteins by creating a dense protective conformational cloud over the liposome surface (*38*). Oily core nanoparticles made of PLA or PEG−PLA were studied for complement consumption, and the testing of longer PEG chains (20 kDa) showed them to be more effective, even at lower surface density (*39*).

In addition, integrity of the siRNA polyplexes in the presence of RNase was investigated. No dissociation of polyplexes was found for siRNA polyplexes with PEI homopolymer and the copolymers with PEG chain lengths 2k, 5k, and 20k at N/P ratio of 10 even when the RNase amount was as high as 6 mIU/μg siRNA. In contrast, even at N/P ratio of 20, PEI(25k)-*g*-PEG(550)$_{30}$ could not inhibit siRNA release from the polyplexes even when the RNase amount was as low as 0.6 mIU/g (data not shown), implying that PEG 550 is too short to protect siRNA efficiently. Moreover, most of the PEG-modified proteins currently approved for human use by the FDA rely on PEG with MW 5000 Da or higher (*40*, *41*).

Knockdown Experiment in Cell Culture. On the basis of the in vitro properties of different polyplexes, the knockdown efficiency of siRNA polyplexes with the following copolymers, PEI(25k)-*g*-PEG(2k)$_{10}$, PEI(25k)-*g*-PEG(5k)$_4$, and PEI(25k)-*g*-PEG(20k)$_1$, were studied in cell culture and compared with that of the homopolymer PEI(25k)−siRNA polyplexes. The polyplexes were prepared in 150 mM sodium chloride solution based on the particle size data in Table 2. Lipofectamine 2000 was used as a positive control (*27*). The biological results are shown in Figure 6. All the polymers investigated could down-regulate gene expression significantly compared to the control ($P < 0.05$). Since it was reported that no difference between the use of small siRNA particles (50−100 nm) and large aggregates (200−600 nm) for gene knockdown was observed (*24*), it is reasonable to assume that the knockdown difference caused by particle size difference of the polyplexes was marginal. It was noticed that the knockdown efficiency increased with increasing PEG chain length up to PEG MW 5 k. Beyond this point, further increasing PEG MW to 20k led to no apparent change in knockdown efficiency, a similar trend observed in RNase digestion assay. The low knockdown efficiency of PEI can probably be explained by the fact that the high siRNA condensation of PEI might prevent siRNA release in the cytosol, in agreement with its high stability against heparin displacement. In contrast, for PEI−PEG polyplexes, heparin can reach siRNA in the condensed form even at quite a low concentration, implying that siRNA complexed with PEI−PEG was accessible to the targeting mRNA, in line with the enhanced knockdown efficiency. Therefore, in agreement with our hypothesis, PEGylation of PEI appears to enhance siRNA release in the cytoplasm, leading to enhanced biological activity. On the other hand, it should be mentioned that several important factors are likely to be synergistically involved in the pronounced siRNA activity of PEI−PEG(>2kDa) polyplexes, such as the improvement of the stability against enzymatic degradation, minimal interaction with serum proteins, and the effective transport of free siRNA from endosome into cytoplasm.

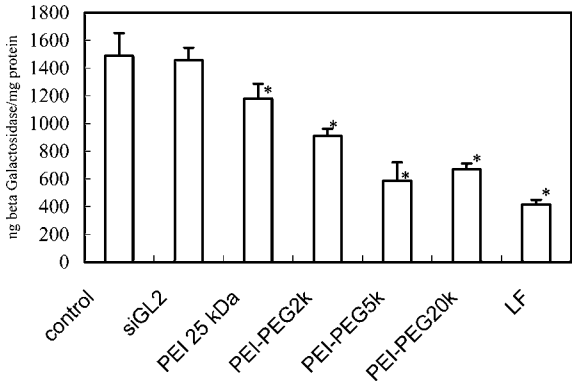

Figure 6. Biological activity of different polymer/siRNA polyplexes in NIH/3T3 fibroblasts stably expressing β-galactosidase. All polyplexes were prepared at N/P of 10. *$P < 0.05$.

Interestingly, an extremely good correlation between RNase digestion and knockdown efficiency data in cell culture was established. Figure 7 exemplifies the logarithmic relationship between stability of the polyplexes at RNase of 6 mIU and knockdown efficiency. The insert shows a linear correlation when remaining siRNA was less than 70%. It implies that RNase digestion stability could be employed as a potential tool to predict the biological activity of siRNA delivery systems.

In addition, our RNase digestion and cell culture data did indicate that stability and biological activity of siRNA polyplexes was significantly improved for the copolymer with PEG chain length of >5 kDa. This information provides further

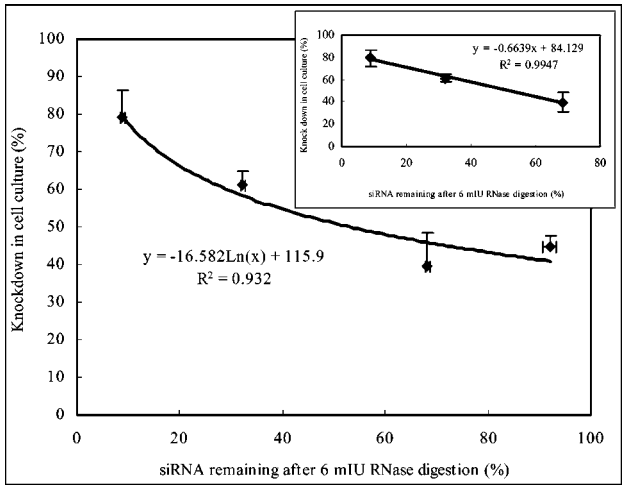

Figure 7. Correlation between RNase digestion stability and biological activity in cell culture. Insert shows a linear correlation when remaining siRNA was less than 70%.

rationale for using PEG with MW of >5 kDa in the FDA-approved protein products.

Subcellular Localization of the siRNA Polyplexes. On the basis of the results from cell culture, copolymer PEI(25k)-*g*-PEG(5k)$_4$ was selected for cellular trafficking of siRNA polyplexes. Confocal microscopy was employed to provide direct evidence for localization of polyplexes. To investigate the uptake and intracellular localization of the polyplexes, both siRNA and the copolymer were fluorescently labeled. With regard to free siRNA, rarely any red fluorescence was observed (Figure 8B). In contrast, a significantly higher internalization of siRNA was found for the copolymer/siRNA polyplexes (Figure 8A). As shown in Figure 8A, a large amount of yellow color, resulting from the colocalization of green and red, was distributed within the cytoplasm in a punctuated pattern, in small, round vesicles localized in the perinuclear area, implying that at least part of the polyplexes are being taken up by endocytosis without dissociation. The red spots in the image (Figure 8A(e)) indicated intracellular siRNA release in the cytosol after 2 h incubation. No fluorescence signal was found in the nuclear area, in this special image areas in white represent colocalization of green and red, as shown in Figure 8A(f). It shows that the polyplexes were mainly distributed in the cytosol, its site of action, instead of entering the nucleus. This is in agreement with our hypothesis. Distribution of polymer in the cells was investigated as well. Figure 8C showed that the polymer itself was dispersed throughout the cytoplasm, being taken up by the cells in an unspecific manner. This point has been mentioned in the former studies (*42*).

CONCLUSIONS

With the PEG ratio in the copolymer kept constant (~50%), influence of the polymer structure on the stability and biophysical properties of the polyplexes was studied. Interestingly, the stability and size of siRNA polyplexes were clearly influenced by PEI−PEG structure, and high degrees of substitution such as PEI(25k)-*g*-PEG(550)$_{30}$ resulted in large (300−400 nm), diffuse complexes (AFM) which showed condensation behavior only at N/P ratio of 15. All other polyplexes and the PEI control showed similar sizes (150 nm) and compact structures in AFM. Complete condensation was reached at N/P ratio of 3. Displacement of siRNA from polyplexes using heparin and stability against RNase digestion confirmed this observation. Surprisingly, protection against RNase digestion was highest for PEI(25k)-*g*-PEG(5k)$_4$ and PEI(25k)-*g*-PEG(20k)$_1$, while siRNA/PEI provided insufficient protection. In knockdown experiments

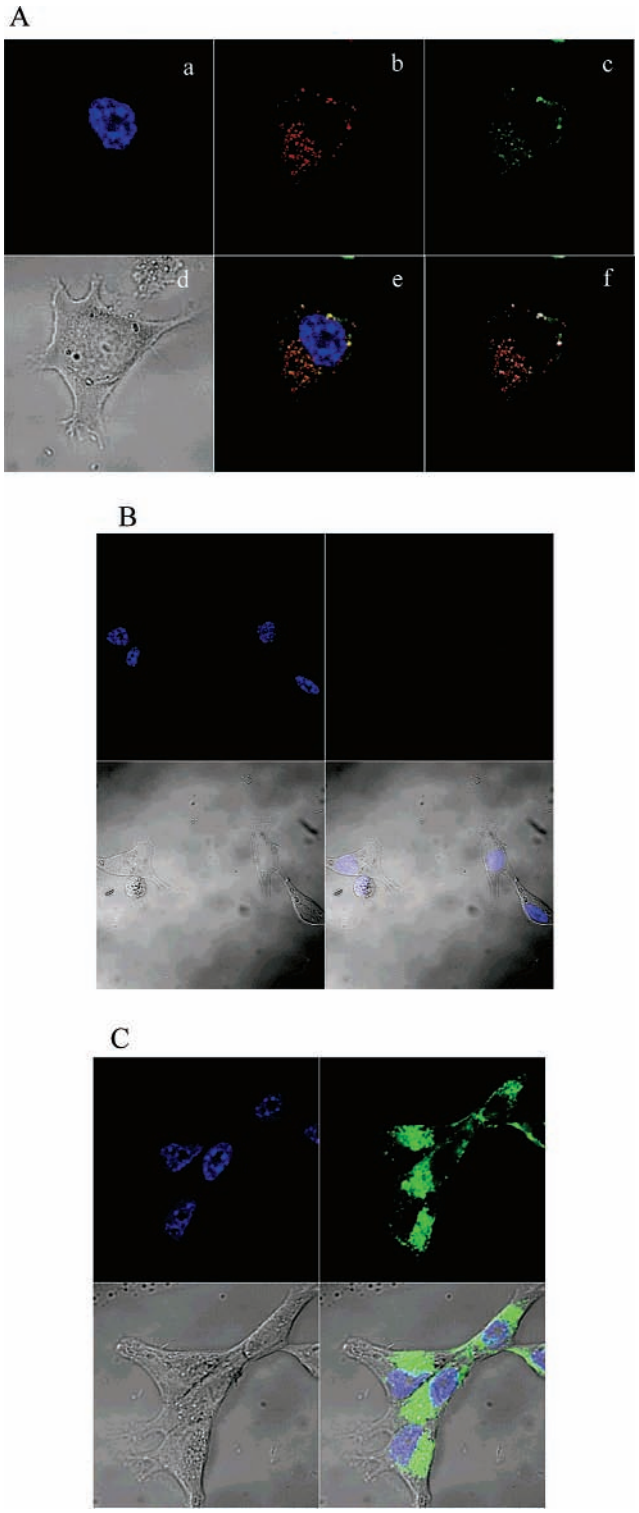

Figure 8. Confocal micrograph images of NIH/3T3 cells incubated with polyplexes, copolymer, and siRNA. Copolymer PEI(25k)-*g*-PEG(5k)$_4$ was labeled with FITC; siRNA was labeled with Cyanine 3. (A) Incubated with PEI(25k)-*g*-PEG(5k)$_4$ copolymer/siRNA polyplexes: (a) blue filter, (b) red filter, (c) green filter, (d) cell morphology, (e) overlay of a−c, and (f) overlay of b and c, indicating that the polyplexes were distributed in the cytosol instead of entering nucleus. Areas in white represent colocalization. (B) Incubated with free siRNA. (C) Incubated with free PEI(25k)-*g*-PEG(5k)$_4$ copolymer.

using NIH/3T3 fibroblasts stably expressing β-galactosidase, it was shown that PEG chain length had a significant influence on biological activity of siRNA. Polyplexes with siRNA containing PEI(25k)-*g*-PEG(5k)$_4$ and PEI(25k)-*g*-PEG(20k)$_1$ yielded similar efficiencies of ca. 70% knockdown as lipo-

fectamine controls. In conclusion, in agreement with our hypothesis, PEGylation can modify the stability of PEI/siRNA polyplexes. Release of siRNA in the cytosol depends on polyplex stability and protection against RNase digestion. A good correlation between RNase stability and knockdown efficiency in cell culture was found for the polyplexes studied. The in vivo behavior of the polyplexes is ongoing. Further optimizations are promising to develop biodegradable PEI−PEG as siRNA carriers.

Received May 30, 2006; Revised Manuscript Received July 27, 2006

Synthesis of a new fluorescent rhodamine derivative, dye **1**, is reported. This probe is different from other rhodamines insofar as it has several (four) carboxylic acid functionalities to promote water solubility and facilitate conjugation to proteins. It also has an aryl bromide functionality that could, in principle, be used to further functionalize the system for specialized applications. Dye **1** was conjugated to a model protein called ACBP (acyl-CoA binding protein). The properties of this conjugate were tested to establish that the label does not significantly perturb the binding function of the protein to its natural ligand in vitro and to confirm that its secondary structure was not significantly perturbed (circular dichroism). Experiments were performed to test if the labeled protein could be imported into *living* COS-7 cells (using the Chariot-peptide delivery system) and, if so, to observe, via fluorescence microscopy, which of the labeled protein was able to migrate to the nucleus, as expected for ACBP in cells. In the event, all these postulates were confirmed.

INTRODUCTION

Intracellular imaging (*1*) requires a selection of water-soluble, fluorescent dyes that absorb and emit at wavelengths longer than those commonly associated with autofluorescence in cells (*2*), i.e., above around 550 nm. Some rhodamine dyes with these characteristics are commercially available, but specialized situations call for "tailor-made" probes that can be modified with other functionalities via organic transformations. Preparation and manipulation of water-soluble fluorescent dyes is challenging, because separation of gram amounts of material tends to be more difficult for polar, water-soluble materials relative to others that are soluble, and chromatographically separable, using organic solvents. Furthermore, even recrystallization of highly colored, fluorescent dyes is experimentally difficult, simply because it is difficult to see when crystals are forming.

Our collaborative project on intracellular imaging of proteins involved in nuclear localization called for a special type of rhodamine dye. Specifically, the probe should (i) be water soluble; (ii) absorb and fluoresce above 550 nm; (iii) have functional groups that allow attachment to proteins; (iv) have another functional group that would allow attachment of other organic fragments to the dye via organometallic reactions involving conditions that would not perturb other functional groups in the dye; and (v) be synthetically accessible. Rhodamine derivative **1** was conceived on the basis of these considerations (Figure 1; "rosamine" is informal nomenclature introduced by Molecular Probes to denote rhodamine without a carboxylic acid on the peripheral benzene ring). This probe has four carboxylic acid groups to promote water solubility (at least above pH levels of approximately 4.5) and to provide points of attachment to proteins. Use of carboxylic acids means that most of the synthetic steps could be performed on tetraesters, and these compounds tend to be hydrophobic and more easily chromatographed on a gram scale. Finally, the aryl bromide functionality was included in the design to allow fusion of other entities to the fluorescent dye via palladium-catalyzed reactions (e.g., Suzuki (*3*) and Sonogashira (*4*) couplings). Our particular need was to attach other dye fragments to this site, to form "through-bond energy transfer cassettes" (*5*, *6*). That particular goal is beyond the scope of this paper, but what is important here is simply the concept that this functional group could be used to attach other groups to create dual-purpose probes. We propose that the second site could be modified to include useful entities such as EPR spin-labels, chelating groups to facilitate MRI imaging, or radioactive reporter functionalities.

reagents were dried prior to use. Diethyl ether and dichloromethane were deoxygenated by purging with N_2 and then dried by passing through activated alumina. Tetrahydrofuran and toluene were distilled from sodium and hexanes from calcium hydride. DMF was distilled from CaH_2 under reduced pressure. K_2CO_3 was used as received from EMD ACS grade. 3-Aminophenol and acrylic acid from Across Organics were used as received, and 4-bromobenzaldehyde, *N*-hydroxysuccinimide, and DIC (diisopropylcarbodiimide) were purchased from Aldrich. Buffer ingredients and solutions for liquid chromatography, gel electrophoresis, and cell culture were purchased from Gibco BRL (Invitrogen, Carlsbad, CA) and Sigma-Aldrich (St. Louis, MO). Bio-Gel P-4 for gel filtration chromatography was from Bio-Rad (Hercules, CA).

Instruments. Analytical thin layer chromatography (TLC) was performed on EM Reagents 0.25 mm silica gel 60-F plates. Visualization was accomplished with UV light. Chromatography on silica gel was performed using a forced flow of the indicated solvent system on EM Reagents Silica Gel 60 (230−400 mesh). ^{1}H NMR spectra were recorded (VXR-300 and Inova 500 MHz spectrometer) at room temperature, and chemical shifts are reported in parts per million (ppm) from the solvent resonance ($CDCl_3$ 7.26 ppm, CD_2Cl_2 5.30 ppm, DMSO-d_6 2.49 ppm, D_2O 4.80 ppm). Data are reported as follows: chemical shift, multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, br = broad, m = multiplet), coupling constants, and number of protons. Proton decoupled ^{13}C NMR spectra were also recorded (VXR and Inova spectrometers) at room temperature. Chemical shifts are reported in parts per million from tetramethylsilane resonance ($CDCl_3$ 77.36 ppm). MS were measured (Thermofinnigan LC-Q Deca spectrometer) under ESI, MALDI, or APCI conditions. IR spectra were recorded on a Bruker (Tensor 27), UV on an HP (Diode Array Spectrophotometer), and fluorescence spectra were recorded on a Fluorolog spectrometer.

Preparation of the Diester 2. A solution of 3-aminophenol (1.00 mol, 109 g) in acrylic acid (3.00 mol, 185 mL) and water (93 mL) was heated to 70 °C. After stirring for 3 h, the reaction mixture was cooled, ethanol (180 mL) was added and the solution kept at 5° C. After 12 h, precipitate appeared and was filtered, washed with ethanol (50 mL), and dried under vacuum to afford the intermediate diacid as a solid (200 g, 80%). Mp = 153−154 °C (lit (*7*) 149−150 °C); ^{1}H NMR (300 MHz, acetone−d_6) δ 7.02−6.98 (m, 1H), 6.28−6.24 (m, 2H), 6.19−6.17 (m, 1H), 3.65 (t, 4H, J = 4.5 Hz), 2.60 (t, 4H, J = 4.5 Hz); ^{13}C NMR (75 MHz, acetone−d_6) δ 172.6, 158.6, 148.6, 130.0, 104.0, 104.2, 99.6, 46.8, 31.7; MS (ESI) calcd for $C_{12}H_{15}NO_5$ 253.0950, found 253.0400.

A solution of the diacid prepared above (39.5 mmol, 10.0 g) in methanol (500 mL) and HCl (10 M, 1 mL) was refluxed for 12 h, then cooled to room temperature, and MeOH evaporated under reduced pressure. The residue was dissolved in EtOAc (100 mL), and the organic layer was washed with water (5 × 20 mL). The organic layer was evaporated under reduced pressure to yield **2** (*8*) as a yellow semisolid (7.0 g, 63%). R_f = 0.7 (50% EtOAc/hexane). ^{1}H NMR (300 MHz, CD_3OD) δ 7.05−6.95 (m, 1H), 6.25−6.15 (m, 3H), 3.65 (s, 6H), 3.60 (t, 4H, J = 7.2 Hz), 2.58 (t, 4H, J = 7.2 Hz); ^{13}C NMR (75 MHz, CD_3OD) δ 173.3, 158.36, 148.5, 130.1, 104.6, 104.2, 99.9, 51.1, 46.9, 32.1; MS (ESI) calcd for $C_{14}H_{19}NO_5$ 281.1263, found 281.3614.

Bromorosamine Tetraacid 1. 4-Bromobenzaldehyde (3.6 mmol, 0.66 g) was added to a solution of dimethyl ester **2** (7.2 mmol, 2.0 g) in ether (5 mL). After stirring for 15 min, the ether was evaporated. The neat mixture was subjected to microwave irradiation (300 W, 150−155 °C, 20 min). Chloranil (4.1 mmol, 1.0 g) in 1:1 (CH_2Cl_2/MeOH) (10 mL) was then added, and the reaction was stirred for 1 h. The solvents were removed, and residue was chromatographed (SiO_2; 20% MeOH/CH_2Cl_2) to afford **3** (0.5 g) in 20% yield (80−85% purity) as a sticky solid. R_f = 0.30 (10% MeOH/CH_2Cl_2); ^{1}H NMR (500 MHz, CD_3OD/$CDCl_3$) δ 7.89 (d, 2H, J = 8.5 Hz), 7.49 (d, 2H, J = 9.5 Hz), 7.46 (d, 2H, J = 8.5 Hz), 7.21 (dd, 2H, J = 2.5 Hz, 2.5 Hz), 7.13 (d, 2H, J = 2.5 Hz), 4.03 (t, 8H, J = 7.0 Hz), 3.72 (s, 12H), 2.81 (t, 8H, J = 7.5 Hz); MS (ESI) calcd for $C_{35}H_{38}BrN_2O_9^+$ 709.1755, found 709.1904, 711.1924.

Solid K_2CO_3 (1.4 mmol, 193 mg) was added to a solution of compound **3** (0.07 mmol, 50 mg) in 1:1:1 (H_2O/MeOH/THF) (10 mL). After stirring for 12 h at 40 °C, the MeOH and THF were removed, and the aqueous layer was extracted with EtOAc (3 × 50 mL). The aqueous layer was further acidified with conc HCl to attain pH = 2−3, then extracted with 1:2 (^{i}PrOH/CH_2Cl_2) and concentrated to afford crude compound **1** (30 mg). Crude compound **1** (30 mg) was dissolved in 1:1 (CH_3CN/H_2O) (30 mL) and subjected to reverse-phase preparative HPLC (C18, 5:95 (CH_3CN/H_2O), t_R = 12.0 min) to afford pure compound **1** (10 mg) in 22% yield as a solid: R_f = 0.10 (10% MeOH/CH_2Cl_2); ^{1}H NMR (500 MHz, CD_3OD/$CDCl_3$) δ 7.84 (d, 2H, J = 10 Hz), 7.48 (d, 2H, J = 10 Hz), 7.35 (d, 2H, J = 10 Hz), 7.12 (dd, 2H, J = 2.5 Hz, 2.0 Hz), 7.02 (d, 2H, J = 5.0 Hz), 4.00 (t, 8H, J = 5.0 Hz), 2.75 (t, 8H, J = 5.0 Hz); ^{13}C NMR (125 MHz, CD_3OD/$CDCl_3$) δ 173.1, 158.4, 158.0, 156.3, 132.6, 132.3, 131.2, 130.6, 125.5, 115.2, 114.1, 97.5, 77.8, 32.1; IR (neat) ν (cm^{-1}) 1644; MS (ESI) calcd for $C_{31}H_{30}BrN_2O_9^+$ 653.1129, found 653.1062, 655.1052.

Activation of Bromorosamine 4. *N*-Hydroxysuccinimide (0.003 mmol, 0.36 mg) and DIC (0.004 mmol, 0.47 mg) were added to a solution of **1** (0.003 mmol, 2.0 mg) in dry DMF (0.5 mL) under N_2. After stirring for 24 h at 25 °C, the solvent was removed, and the residue was dried under high vacuum. This sample, without purification, was used to label the protein.

Labeling of Recombinant Mouse Acyl-CoA Binding Protein (ACBP). A recombinant mouse ACBP as described before (*9*) was tagged with five histidine (His) residues at its C-terminus, expressed in *E. coli*, and purified by affinity chromatography on Ni-CAM-Sepharose. Newly synthesized water-soluble rhodamine-based dye **1** was coupled to ACBP by using multiple dye-to-protein molar ratios, and the optimal ratios were 5:1 and 10:1, so that in the end a molecule of protein would be labeled with 0.5−5 dye molecules. Typically, 50 nmoles of ACBP were incubated with 250−500 nmoles of rhodamine derivative **1** in PBS, pH 8.5. Incubation of protein with dye was allowed at room temperature for 1 h, in the dark with gentle stirring. ACBP/dye reaction mixtures were then centrifuged at 13 000 rpm for 20 s in an Eppendorf centrifuge 5415 D to remove possible large particles and aggregates resulting from the coupling reaction. The supernatant containing soluble dye-labeled protein and unbound dye was collected and loaded onto a 20 mL Bio-Gel P-4 (fine, 45−90 μm, wet gel particles) column which had been equilibrated in PBS, pH 7.4, in order to separate the colored protein from unbound dye. The column separated two bands: the first one contained labeled ACBP, while the slower band consisted of unbound dye; this separation was confirmed by reading protein absorbance at 280 nm in all collected fractions. The dye-labeled ACBP was characterized in terms of protein and dye concentrations, as well as dye-to-protein molar ratio. Protein concentration was determined by Bio-Rad protein assay as recommended by the manufacturer. The molecular size of ACBP protein after labeling with **1** was checked by SDS-PAGE in 14% polyacrylamide electrophoresis gel following a Bio-Rad procedure based on Laemmli's method (*10*).

Absorbance and Fluorescence Spectroscopy of Rhodamine-Dye-labeled ACBP. The absorbance properties of rhodamine dye after coupling to ACBP protein were measured by using a Carry 100 Scan UV−visible spectrophotometer from Varian (website at www.varianinc.com), while its fluorescence emission spectra were recorded with a PC1 photon-counting fluorometer from ISS (ISS, Inc., Urbana, IL).

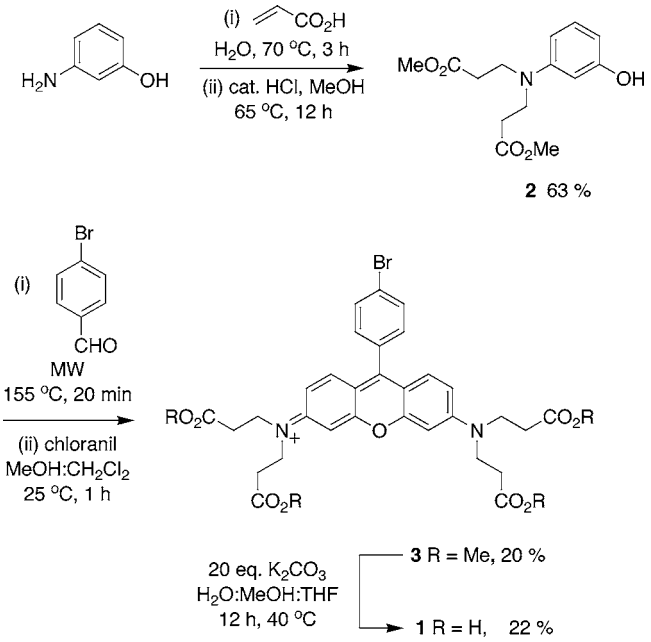
Fluorescence Binding Assays. *cis*-Parinaroyl-CoA, a long acyl-CoA with an 18-carbon chain and 4 conjugated double bonds, that emits with a maximum at 410 nm when it is excited at 320 nm, was used for titration of 0.02−0.2 μM unlabeled and dye-labeled ACBP, as described before (*9, 11*). Increasing concentrations of *cis*-parinaroyl-CoA from 2.5 to 500 nM were added to a constant amount of ACBP, and fluorescence emission spectra were recorded at each titration point from 350 to 500 nm, with excitation of *cis*-parinaroyl-CoA at 320 nm. Controls for unbound ligand (identical concentrations of *cis*-parinaroyl-CoA but in the absence of protein) and for protein-interfering emission were measured and subtracted. The maximum fluorescence intensities from recorded spectra were then plotted against total concentration of *cis*-parinaroyl-CoA at each titration point. Further analysis of these binding curves by nonlinear regression and fitting to ligand binding to one site equations was performed with *Sigma Plot 8.0* software, and the values of K_d, i.e., dissociation constant, and B_{max}, i.e., maximum binding fluorescence intensity, were then obtained.

Circular Dichroism (CD) Analysis of ACBP Before and After Labeling with Dye 1. Far-UV CD spectra of unlabeled and **1**-ACBP at a concentration of 4 μM in 20 mM potassium phosphate buffer, pH 7.4, were recorded by the use of a J-710 spectropolarimeter (Jasco, Baltimore, MD). Measurements were done in a 1 mm cuvette, and spectra were recorded from 260 to 190 nm at 50 nm/min with a time constant of 1 s and a bandwidth of 2 nm. For each CD profile, an average of 10 scans was obtained. Percentages of secondary structures in ACBP when unlabeled or **1**-labeled were calculated from CD spectra by using the *CD-PRO* software (*12*).

Cell Culture and Delivery of Dye-1 Labeled ACBP into Cells for Intracellular Imaging. COS-7 cells were purchased from the American Type Culture Collection (ATCC, Manassas, VA) and grown in DMEM with 10% fetal bovine serum (FBS), in 2-well chamber glasses (LabTek from VWR, Suwanee, GA) at 37 °C and 5% CO_2. A sample of **1**-ACBP was delivered to cells grown to about 80% confluence, according to a modified procedure recommended by Active Motif (Carlsbad, CA) for the use of Chariot transfection reagent. Briefly, dye-labeled ACBP from 500 ng to 2 μg were preincubated with Chariot (from Active Motif, Carlsbad, CA) in protein-to-peptide ratio of 1:20 (w/w) for 30 min at room temperature and then added to COS-7 cells in the presence of serum-free DMEM. After 30 min incubation, the protein−Chariot mixes were washed off cells with PBS, and cells were incubated with 10% FBS/DMEM at 37 °C, 5% CO_2 for 2 h before confocal microscopy. Cell nuclei were counterstained by adding 1 μg/mL Hoechst 33342 nuclear marker solution (from Molecular Probes, Eugene, OR) about 30 min before confocal microscopy observation.

Intracellular Imaging of Labeled ACBP By Laser Scanning Confocal Microscopy (LSCM). An MRC1024 confocal imaging system (from Bio-Rad) consisting of an Axiovert 135 microscope (Zeiss, New York) equipped with three independent low-noise photomultiplier tube channels was used for LSCM. The excitation light (λ = 488 and 568 nm) from a 15 mW krypton−argon laser was delivered to sample through a 63× Zeiss Plan-Fluor oil immersion objective, numerical aperture 1.45. Emission filters 540/30 (allowing emission light of 520−530 nm wavelengths) and HQ598/40 (allowing emission light of 580−660 nm wavelengths) were employed to detect fluorescence images in the green (PMT2) and red (PMT1) channels, respectively. Hoechst 33342 nuclear marker was excited at 408 nm by using a solid-state laser (from Power Technology, Little Rock, AR) and detected in the green channel with a 540/30 emission filter in PMT2. Colocalization analysis was achieved by using the *LaserSharp* v 3.0 software from Bio-Rad, and colocalization coefficients were calculated as described (*13*). Additional processing of images was performed by using MetaMorph Image Analysis from Advanced Scientific Imaging (Meraux, LA).

Scheme 1. Synthesis of Dye 1



Electronic Spectra. Figure 3 shows the UV and fluorescence spectra of dye **1** in PBS at pH 7.4. For this solution, the molar extinction coefficient, ϵ, was measured to be 91 000 and $\lambda_{max\ abs}$ = 556 nm. It fluoresced at 579 nm with a quantum yield of 0.76. Fluorescence quantum yield measurements were measured on a photon counting spectrofluorometer PC1 SSI instrument equipped with an R928P photomultiplier tube which is sensitive up to ~850−900 nm. The slit width was 0.5 nm for both excitation and emission. Relative quantum efficiencies of fluorescence of dye **1** were obtained by comparing the areas under the corrected emission spectrum of the test sample in PBS buffer (pH = 7.4) with that of a solution of rhodamine B, which has a quantum efficiency of 0.97 according to the literature (*14*). DI water for the PBS buffer and a 10 mm quartz cuvette were used. Dilute solutions ($0.01 < A < 0.05$) were used to minimize reabsorption effects. The excitation wavelength was 556 nm for both compound **1** and the reference.

Quantum yields were determined using eq 1 (*15*)

$$\Phi_X = \Phi_{st}(I_X/I_{st})(A_{st}/A_X)(\eta_X^2/\eta_{st}^2) \quad (1)$$

where Φ_{st} is the reported quantum yield of the standard, I is the integrated emission spectra, A is the absorbance at the excitation wavelength, and η is the refractive index of the solvent used (η = 1 if same solvent). The X subscript denotes unknown, and "st" denotes standard.

RESULTS

Synthesis. Scheme 1 summarizes the synthesis of compound **1**. Double Michael addition of acrylic acid to 3-aminophenol

via a literature procedure (*7*) gave the diacid as a precipitate. This material, without purification, was esterified to give the diester **2** which could be isolated on a multigram scale via extraction with ethyl acetate. The next step in the synthesis was to condense the phenol **2** with an aldehyde to give the rosamine framework. Such syntheses usually feature protic acid media (*16*); however, we found that the reaction proceeds without solvent or added catalysts. We were unable to identify reaction conditions for this condensation that featured heating under conventional conditions. However, in a microwave reactor specifically designed for holding reactions at a set temperature (Discover, CEM Corporation), the reaction was found to proceed with good conversion in only 20 min. Chloranil was added to oxidize the initial condensation product to the rosamine tetraester **3**, which was then isolated by column chromatography. This tetraester was then hydrolyzed to the desired product **1**. Crude samples of the rosamine **1** with quite good purity could be isolated via an acid−base extraction procedure. Pure material was isolated via preparative RP-HPLC to give a 22% yield of the product. Selected data for compounds **1** and **3** are shown in Figure 2. The dye is highly soluble in aqueous buffer at pH 7.4.

Electronic spectra of compound **1** showed several desirable characteristics. The dye absorbs strongly at 556 nm and emits with a high quantum yield at 579 nm in aqueous buffer. Variation of the concentration of the dye in the buffer showed that the emission maxima wavelength did not shift; this indicates that the dye is not aggregated in this media (Figure 3).

Monoactivation of tetraacid **1** to give the reactive ester **4** was performed by employing DIC and *N*-hydroxysuccinimide in DMF (Scheme 2). Compound **4** was used, without purification, to tag with an illustrative protein, as described below. The unimolecular binding of dye **1** to protein is confirmed by MALDI-TOF (Figure 3).

Spectral Properties of Dye 1 After Conjugation to the Illustrative Protein: Acyl-CoA Binding Protein (ACBP). ACBP was chosen to test the possibility of using the newly synthesized water-soluble rhodamine derivative for intracellular imaging by laser scanning confocal microscopy. A recombinant mouse ACBP was purified and conjugated to dye **1** as described under Experimental Procedures. Tests to ensure that the basic physical and functional properties of fluorescent dyes were maintained after conjugation to the protein included absorbance and fluorescence spectra on the labeled protein and compared with dye **1**. Figure 4 shows the absorbance spectra of **1**−ACBP and the dye only, in PBS pH 7.4. The wavelength corresponding to maximum absorbance for the conjugate was slightly shifted from 553 nm for the dye only, to 560 nm for **1**−ACBP conjugate. The fluorescence emission spectra of **1** either free in PBS or conjugated to ACBP protein demonstrated that the maximum fluorescence wavelength exhibited a small red shift from 574 nm for free dye **1** to 583 nm for ACBP-coupled dye **1** when excitation was at 568 nm.

Physical and Functional Properties of Acyl-CoA Binding Protein (ACBP) After Conjugation to Dye 1. The structural and functional properties of the protein were also tested after conjugation to dye **1**. Thus, SDS-polyacrylamide gel electrophoresis, fluorescence binding assays, and circular dichroism were performed on the **1**−ACBP product and compared to unlabeled ACBP.

An SDS-PAGE test demonstrated that the molecular size of **1**−ACBP was very similar to that of ACBP (not shown). The small increase in molecular weight of ACBP after labeling was due to the additional weight of dye molecules that had been covalently attached to the protein by conjugation. Most importantly, the SDS-PAGE assay demonstrated that no intermolecular cross-linking occurred as a negative side effect during protein−

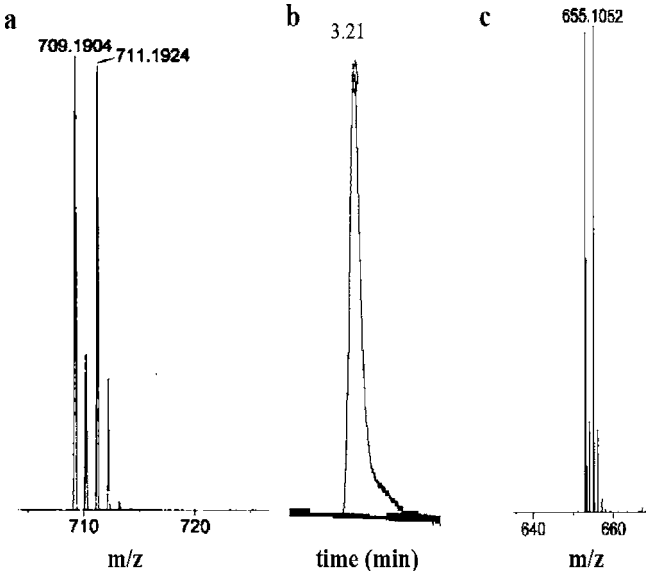


Figure 2. Data for **1** and **3**. (a) Electrospray MS showing molecular ion peak for **3**; (b) analytical RP-HPLC (C18, 5% CH_3CN in H_2O and 0.1% TFA, $t_R = 3.21$ min) for **1**; (c) electrospray MS showing molecular ion peak for **1**.

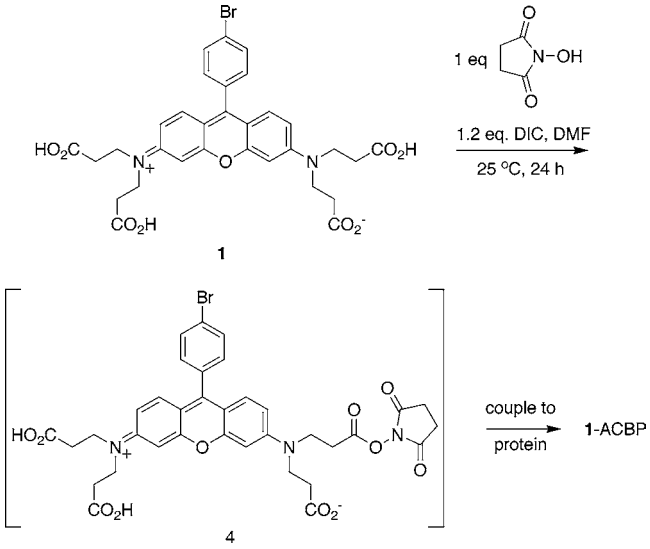
Scheme 2. Monoactivation of Dye 1



dye reaction. This result was possible by purposely activating dye **1** once to contain a single reactive group available for conjugation to amino groups on the surface of ACBP protein.

One of the most important functions of ACBP is to bind medium- and long-chain fatty acyl-CoA thioesters with high affinity (i.e., low-range nanomolar dissociation constant, K_d). To check if this property was maintained after labeling, the recombinant ACBP was assayed by titration with a fluorescent ligand, namely, *cis*-parinaroyl-CoA up to saturation of binding, as described under Experimental Procedures. The binding curves as shown in Figure 5a,b were obtained by plotting fluorescence intensities versus total concentration of ligand (*cis*-parinaroyl-CoA) at each titration point, followed by nonlinear regression analysis and calculation of K_d and B_{max} (maximum fluorescence intensity at binding saturation). The labeled **1**−ACBP exhibited *cis*-parinaroyl-CoA binding to saturation, just as the unlabeled ACBP did, with a K_d of 6.3 ± 2.7 nM; this was a slightly higher affinity for *cis*-parinaroyl-CoA than unlabeled ACBP (K_d of 11.3 ± 2.8 nM).

Circular dichroism (CD) spectra in the far UV were recorded to get more information about the structural and conformational

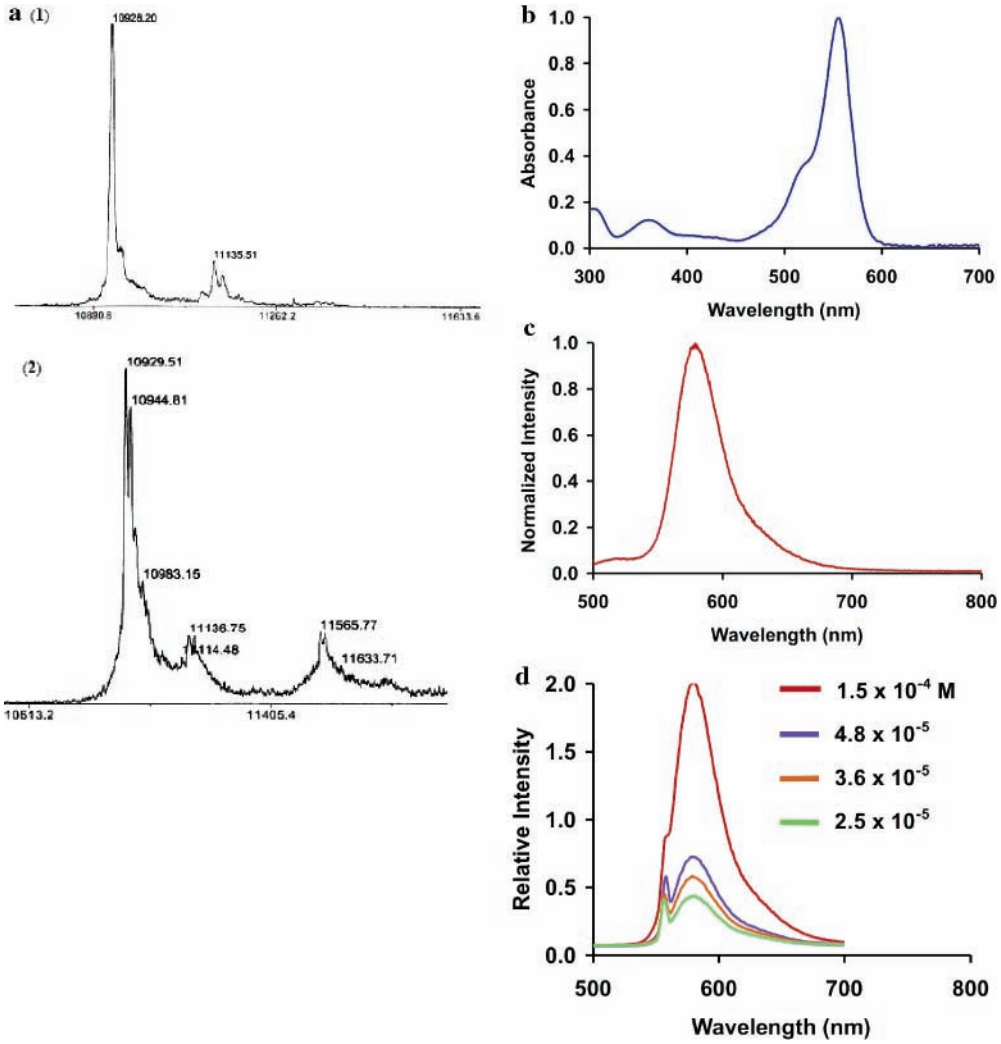


Figure 3. Mass spectra of free and labeled His−ACBP−**1** and electronic spectra of **1** in PBS buffer (pH = 7.4). (a) (1) MALDI-TOF of free His−ACBP [$M^+ + X.K^+/Na^+$(10 928.20)]; (2) MALDI-TOF for His−ACBP−**1** [$MH^+ + X.K^+/Na^+$ (11 565.77) (before conjugate purification)]; (b) normalized UV spectrum at concentration 10^{-4} M, ϵ 91 000, $\lambda_{max\ abs}$ = 556 nm; (c) fluorescence spectrum at 10^{-5} M, $\lambda_{max\ emis}$ = 579 nm, using 556 nm excitation wavelength; (d) the fluorescence emission wavelength of compound **1** does not vary with concentration.

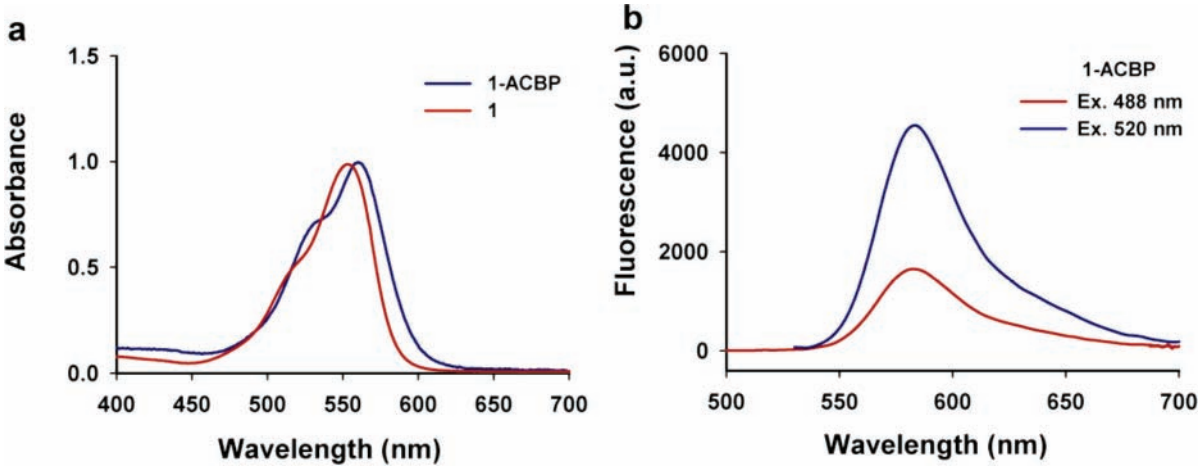

Figure 4. Absorbance and fluorescence spectra of free and **1**−ACBP-bound in PBS at pH 7.4. (a) UV−vis spectra of free dye is shown in red line and that of ACBP-bound dye in black line; (b) emission spectra of **1**−ACBP.

changes caused by dye **1** on ACBP. Figure 5c shows the CD spectra of ACBP and **1**−ACBP. The two spectra are similar, suggesting that only small changes in the secondary structure of ACBP were introduced by coupling it to dye **1**.

Intracellular Imaging of 1−ACBP. COS-7 cells were incubated with **1**−ACBP that had been labeled with dye **1** in the presence of the Chariot system (*17*) to test whether the labeled protein could be imported into cells in this way. If free **1**−ACBP is internalized in the cells, and functions in the same way as the unlabeled protein, then some of it should localize in the nucleus (*18*). The cell nuclei were counterstained with Hoechst 33342 dye to test for this. Figure 6a shows fluorescence

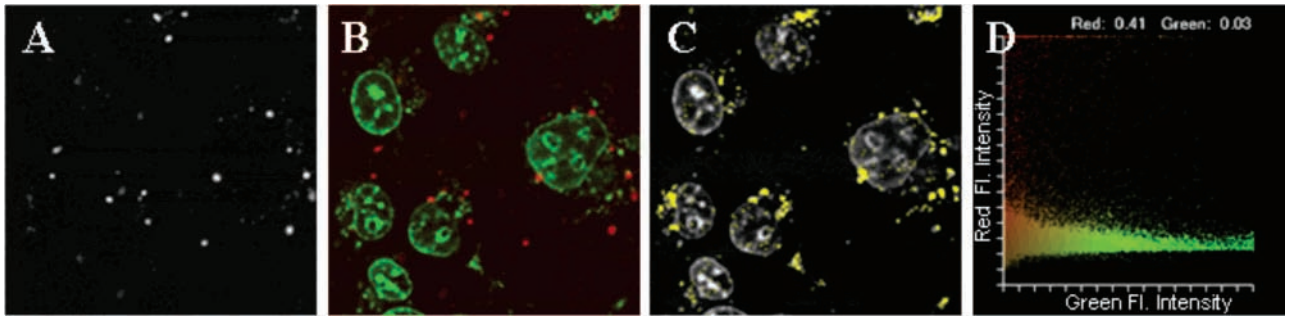

Figure 6. Intracellular imaging of **1**−ACBP labeled COS-7 cells by confocal microscopy. (A) **1**−ACBP with excitation at 568 nm, and emission filter HQ 598/40; (B) overlay of **1**−ACBP image (red) with nuclei image (green, given by the nuclear marker Hoechst 33342 that emits at 530 nm with excitation at 408 nm); (C) colocalized pixels (yellow) from **1**−ACBP and the nuclear marker; and (D) fluorograph indicating the extent of colocalization.

images of **1**−ACBP in cells (detected in the red channel, with an emission filter at 598 nm, excitation at 568 nm). In Figure 6b, fluorescence signals from **1**−ACBP (in red) and Hoechst-stained nuclei (in green) are shown to demonstrate the distribution of ACBP molecules inside cells relative to nuclei. Most of the fluorescently labeled ACBP molecules appeared in the cytoplasm, around nuclei, but a fraction of the **1**−ACBP molecules were observed inside nuclei. This demonstrates that the Chariot-mediated import of **1**−ACBP was successful and that some of the labeled protein is gravitating to the region of the cell (the nucleus) that is expected from its postulated function (*18*). Yellow pixels in Figure 6c represent the colocalization of **1**−ACBP with the nuclear marker. The fluorogram in Figure 6d shows a more quantitative colocalization analysis for the relative distribution and fluorescence intensities of the two signals (green and red).

DISCUSSION

This paper reports the synthesis of a new water-soluble dye, **1**. This compound has four carboxylic acid groups to increase water solubility and to facilitate coupling to proteins. It can be selectively coupled to just one protein molecule without significant cross-linking to a second one. In the particular case of the protein ACBP, the data presented here show that conjugation of this model probe does not significantly perturb the secondary structure or the natural binding function of the protein in vitro. Moreover, **1**−ACBP can be imported into *living* cells using the novel Chariot−peptide carrier system wherein it accumulates, at least partially, in the nucleus as expected.

Though the work presented here does not actually demonstrate this, it is clear that organometallic coupling reactions could be used to add different molecular entities to the aryl bromide functionality of compound **1**. If this were done, a variety of "bifunctional" labels might be prepared. They too might be imported into living cells via the Chariot system, then studied in vivo.

ACKNOWLEDGMENT

We thank Mr. Jiney Jose for developing a procedure to prepare compound **2**, CEM for support with the Discover unit

used in this research, and the TAMU/LBMS-Applications Laboratory directed by Dr. Shane Tichy for assistance with mass spectrometry. Support for this work was provided by The NIH (GM72041) and by The Robert A. Welch Foundation A-1121.

Synthesis and Biological Evaluation of EC140: A Novel Folate-Targeted Vinca Alkaloid Conjugate

Christopher P. Leamon,* Joseph A. Reddy, Iontcho R. Vlahov, Paul J. Kleindl, Marilynn Vetzel, and Elaine Westrick

Endocyte, Inc., 3000 Kent Ave., West Lafayette, Indiana 47906. Received May 31, 2006; Revised Manuscript Received August 1, 2006

A novel folate conjugate of desacetylvinblastine monohydrazide (DAVLBH), herein referred to as EC140, was designed and evaluated for biological activity against folate receptor (FR)-positive cells and tumors. EC140 was produced by coupling a peptidic analogue of the vitamin folic acid to DAVLBH via an acylhydrazone bond. This water-soluble conjugate was found to retain high affinity for FR-positive cells, and it produced specific, dose-responsive activity in vitro. Initial in vivo tests confirmed EC140's activity in both syngeneic and xenograft models. Hence, enduring complete responses were observed in animals bearing established, subcutaneous tumors prior to therapy using regimens that produced minor toxicity. In contrast, treatment with the unconjugated DAVLBH drug produced nominal efficacy when dosed at its MTD. Overall, EC140's performance *i*n vitro and in vivo warrants further preclinical study before this novel targeted chemotherapeutic is considered for clinical investigation.

INTRODUCTION

Chemotherapy is the principal method of treatment for patients with metastatic or disseminated cancers, and common regimens are designed to administer a drug in an intermittent fashion (e.g., once every 3 to 6 weeks) at its maximum tolerated dose (MTD) followed by a recovery period. Such regimens have been used for over 50 years, but very few agents produce adequate clinical improvements when administered this way. One cause for disappointing outcomes is that this method of treatment is plagued by toxicity resulting from the indiscriminate uptake of these poisons into proliferating cells of both normal and neoplastic tissue. Yet, because tumor tissue recovers from chemotherapy so much faster than normal tissue, tumor elimination is rare following infrequent drug administration.

Theoretically, the toxicity of a chemotherapeutic drug should be decreased or eliminated if the pharmacophore were specifically targeted to the cancer cells. This alternative approach has certainly been exemplified recently by the apparent clinical successes of tumor-targeted/tumor-specific agents like Herceptin and Gleevec (*1*). However, alternative methods for targeting drugs to cancer cells are also being explored. One such technique is to exploit the receptor-mediated uptake pathway for folic acid.

The vitamin folic acid is a ligand capable of targeting covalently attached bioactive agents quite specifically to folate receptor (FR)-positive cells (*2*). The FR, which is a tumor-associated protein, can actively internalize bound folates via endocytosis (*2*, *3*). It has been detected at very high levels in >90% of ovarian and other gynecological cancers, as well as at high to moderate levels in kidney, brain, lung, and breast carcinomas (*4*−*14*). The concept of "folate-drug targeting" has been effectively exemplified using payloads as diverse as small radiopharmaceutical agents to large DNA-containing formulations (see ref 15 for a comprehensive overview of this technology). Importantly, there are a few examples of folate-targeted chemotherapy applications; however, most of these investigations were limited to in vitro evaluations (*16*).

We recently published on the synthesis and in vitro/in vivo activity of a novel folate−mitomycin C conjugate, called EC72 (*17*, *18*). This agent was shown to produce targeted activity against FR cells and tumor xenografts; however, EC72 had difficultly eradicating established subcutaneous (s.c.) tumors as a stand-alone agent (*18*). Our laboratory's latest efforts, however, have led to the creation of a folate−vinca alkaloid conjugate. This novel FR-targetable chemotherapeutic, named EC140, was constructed using acyl hydrazone coupling technology to afford molecular separation of the vinca alkaloid from folate once this conjugate enters the acidic endosomes of FR-positive cancer cells. As reported below, EC140 was found to produce encouraging therapeutic activity in multiple FR-positive, established tumor models.

EXPERIMENTAL PROCEDURES

Materials. Pteroic acid (Pte) and N^{10}-trifluoroacetylpteroic acid were prepared according to Vlahov et al. (*19*). Peptide synthesis reagents were purchased from NovaBiochem (La Jolla, CA) and Bachem (San Carlos, CA). Folate-free RPMI media (FFRPMI) and PBS were obtained from Gibco, Grand Island, NY. *N*-(4-Acetylphenyl)maleimide was purchased from Avocado Research Chemicals (Ward Hill, MA). ^{3}H-thymidine was purchased from Moravek Biochemicals, Brea, CA. Vinblastine sulfate and all other common reagents were purchased from Sigma (St. Louis. MO).

Synthesis, Purification, and Analytical Characterization of EC140. The folate-containing spacer unit Pte-γGlu-Asp-Arg-Asp−Asp-Cys-OH[1] (herein referred to as EC119) was synthesized using standard fluorenylmethyloxycarbonyl-based solid-phase peptide synthesis (Fmoc SPPS) on a Wang resin polymeric support. It was purified by preparative HPLC (Waters NovaPak C_{18} 19 × 300 mm) with 10 mM NH_4OAc, pH 5 (solvent A) and acetonitrile (solvent B) using a gradient consisting of 1% B to 20% B over 40 min at a flow rate of 15 mL/min. The structure of EC119 was confirmed by ^{1}H NMR (300 MHz, D_2O): δ 8.68 (s, 1H, FA H-7), 7.57 (d, 2H, J =

8.4 Hz, FA H-12 and 16), 6.67 (d, 2H, $J = 9$ Hz, FA H-13 and 15), 4.40−4.75 (series of m, 5H), 4.35 (m, 2H), 4.16 (m, 1H), 3.02 (m, 2H), 2.55−2.95 (series of m, 8H), 2.42 (m, 2H), 2.00−2.30 (m, 2H), 1.55−1.90 (m, 2H), 1.48 (m, 2H) ppm); and ESI-MS ($(M + H)^+ = 1046$) analysis.

DAVLBH was prepared from commercially available vinblastine (VLB) following a literature procedure (*20*). The hydrazide was purified by preparative HPLC (Waters NovaPak C_{18} 19 × 300 mm) with 0.1% trifluoroacetic acid, pH 2.0 (solvent A) and acetonitrile (solvent B) using a gradient consisting of 5% B to 80% B over 30 min at a flow rate of 15 mL/min. Treatment of a tetrahydrofuran solution (350 μL) of this acylhydrazide (26 mg, 33 mol) with an equimolar amount of *N*-(4-acetylphenyl)maleimide (8.4 mg) for 1.5 h at room temperature resulted in the desired vinblastenyl hydrazone **B**. The tetrahydrofuran was removed in vacuo, and the pale white residue was used for the following reaction without any further manipulations.

The free acid form of EC119 (34 mg, 33 μmol) was dissolved in DMSO (150 μL) and treated under argon with an excess of triethylamine (75 μL, 538 μmol) and then reacted at room temperature for 2 h with the Michael acceptor **B** (dissolved in 300 μL DMSO and added with the help of microsyringe). The formation of the conjugate, EC140, was monitored by analytical HPLC (Waters NovaPak C_{18} 3.9 × 150 mm). This product was purified by preparative HPLC (Waters NovaPak C_{18} 19 × 300 mm) with 1 mM phosphate buffer, pH 7.0 (solvent A) and acetonitrile (solvent B) using a gradient consisting of 10% B to 50% B over 30 min at a flow rate of 15 mL/min. Acetonitrile was removed from the collected fractions in vacuo and the residue subjected to freeze-drying to give 62 mg (91% yield) of EC140 (Na form) as a yellow amorphous solid containing 15 mg phosphate salts (derived from the buffer used in the prep HPLC). LC-MS [ESI: $(M + H)^+ = 2013$; $(M - H)^+ = 2011$)] and ^{1}H NMR signals were in agreement with the expected structure. Selected ^{1}H NMR data for EC140 (D_2O, 300 MHz): δ 8.47 (s, 1H, FA H-7), 7.62−7.6 (m, 2H, VLB H-11′ and VLB H-14′), 7.50−7.35 (m, 3H, FA H-12 and H-16 and VLB H14′), 7.25 (m, 1H, VLB H-13′), 7.05−6.95 (m, 5H, VLB H-12′ and 4H from the linker), 6.51 (d, 2H, FA H-13 and 15), 6.4 (s, 2H, VLB H-14 and 17), 5.65 (m, 1H, VLB H-7), 5.5 (m, 1H, VLB H-6), 4.05(m,1H, VLB H-8′), 3.90 (s, 3H, $-CO_2CH_3$), 3.69 (s, 3H, VLB C_{16} $-OCH_3$), 2.8 (s, 3H, VLB N$-CH_3$), 1.35 (br s, 1H, VLB H-3′), 1.15 (m, 1H, VLB H-2′), 0.9 (t, 3H, $J = 7$ Hz, VLB H-21′), 0.55 (t, 3H, $J = 6.9$ Hz, VLB H-21) ppm.

The release of the free desacetylvinblastine monohydrazide moiety from EC140 was also studied by dissolving 1 mg of EC140 in isotonic buffer, pH 5.0, at 37 °C. The HPLC profile (UV detection at 280 nm) showed complete cleavage of the hydrazone bond with concomitant release of the *N*-succinimidyl acetophenone derivative of EC119 within 16 h ($t_{1/2} \approx 5.5$ h). The free DAVLBH unit was not observed as the result of its low solubility in this aqueous buffer; however, its formation was confirmed by LC-MS. The stability of the conjugate was also investigated as a 20 μM solution in PBS buffer, pH 7.4, at 37 °C. In this case, the $t_{1/2}$ of EC140 was ∼22 h.

Cell Culture. The cell lines used for these studies (KB, M109, and 4T1) have been previously described (*18*). Cells were grown continuously as a monolayer using folate-free RPMI medium (FFRPMI) containing 10% heat-inactivated fetal calf serum (HIFCS) at 37 °C in a 5% CO_2/95% air-humidified atmosphere with no antibiotics. The HIFCS contained its normal complement of endogenous folates which enabled the cells to sustain growth in this more physiologically relevant medium (*2*). All cell experiments were performed using FFRPMI containing 10% HIFCS (FFRPMI/HIFCS) as the growth medium.

Relative Affinity Assay. The relative affinity of EC140 was determined according to the method described by Westerhoff et al. (*21*) with slight modification. Briefly, FR-positive KB cells were seeded in 24-well Falcon plates and allowed to form adherent monolayers (∼80% confluent) overnight in FFRPMI/HIFCS. Spent incubation media was replaced with FFRPMI supplemented with 10% HIFCS and containing 100 nM of ^{3}H-folic acid in the absence and presence of increasing concentrations of unlabeled folic acid or EC140. Cells were incubated for 1 h at 37 °C and then rinsed three times with 0.5 mL of PBS. Five hundred microliters of 1% sodium dodecylsulfate in PBS were added to each well; after 5 min, cell lysates were collected, transferred to individual vials containing 5 mL of scintillation cocktail, and then counted for radioactivity. Cells exposed to only the ^{3}H-folic acid in FFRPMI (no competitor) were designated as negative controls, whereas cells exposed to the ^{3}H-folic acid plus 1 mM unlabeled folic acid served as positive controls; disintegrations per minute (DPMs) measured in the latter samples (representing nonspecific binding of label) were subtracted from the DPM values from all samples. Notably, relative affinities were defined as the inverse molar ratio of compound required to displace 50% of ^{3}H-folic acid bound to FR on KB cells, and the relative affinity of folic acid for the FR was set to 1.

Dose-Dependent Activity. Cells were heavily seeded in 24-well Falcon plates and allowed to form nearly confluent monolayers overnight in FFRPMI/HIFCS. Thirty minutes prior to the addition of EC140, spent medium was aspirated from all wells and replaced with fresh FFRPMI. Note, designated wells received media containing 100 μM folic acid, and cells within the latter wells were used to determine the targeting specificity, since cytotoxic activity produced in the presence of excess folic acid (enables competition for FR binding) would signify the portion of the total activity that was unrelated to FR-specific delivery. Following one rinse with 1 mL of fresh FFRPMI/HIFCS, each well received 1 mL of media containing increasing concentrations of test article (four wells per sample). EC140-treated cells were pulsed for 1 h at 37 °C, rinsed four times with 0.5 mL of media, and then chased in 1 mL of fresh media up to 70 h. VLB- and DAVLBH-treated cells were incubated continuously for 46 h at 37 °C. Spent media was aspirated from all wells and replaced with fresh media containing 5 μCi/mL ^{3}H-thymidine. Following a further 2 h 37 °C incubation, cells were washed three times with 0.5 mL of PBS and then treated with 0.5 mL of ice-cold 5% trichloroacetic acid per well. After 15 min, the trichloroacetic acid was aspirated and the cells solubilized by the addition of 0.5 mL of 0.25 N sodium hydroxide for 15 min. Four hundred and fifty microliters of each solubilized sample were transferred to scintillation vials containing 3 mL of Ecolume scintillation cocktail and then counted in a liquid scintillation counter. Final tabulated results were expressed as the percentage of ^{3}H-thymidine incorporation relative to untreated controls.

Tumor Models and Therapy. Four- to seven-week-old mice (*Balb*/*c* or *nu*/*nu* strains) were purchased from Harlan Sprague Dawley, Inc. (Indianapolis, IN). Since normal rodent chow contains a high concentration of folic acid (6 mg/kg chow), mice used in these studies were maintained on the folate-free diet (Harlan diet #TD00434) for 1 week before tumor implantation to achieve serum folate concentrations close to the range of normal human serum (*22*). For tumor cell inoculation, 1×10^6 M109 cells, 2×10^5 4T1 cells, or 1×10^6 KB cells in 100 μL were injected in the subcutis of the dorsal medial area. Tumors were measured in two perpendicular directions every 2−3 days using a caliper and their volumes calculated as $0.5 \times L \times W^2$, where L = measurement of longest axis in millimeters and W = measurement of axis perpendicular to L in millimeters. Dosing

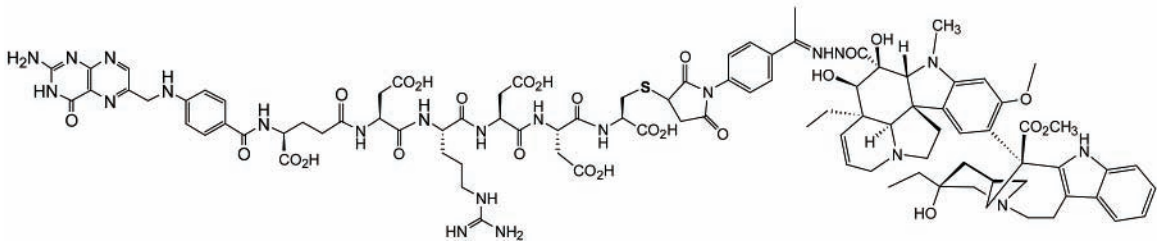

Figure 1. Modular design of folate−drug conjugates. Part A. A folate−drug conjugate consists of four basic modules: (1) a pteroate ligand, (2) a hydrophilic spacer, (3) a biologically cleavable bond, and (4) a potent drug moiety. Part B. Structure of EC140.

solutions for EC140 were prepared in PBS and administered through the lateral tail vein of the mice. Importantly, dosing was typically initiated when the s.c. tumors were between 50−100 mm^3 in volume.

Drug toxicity was assessed by collecting blood via cardiac puncture and submitting the serum for independent analysis of blood urea nitrogen (BUN), creatinine, AST-SGOT, and ALT-SGPT at Ani-Lytics, Inc. (Gaithersburg, MD). In addition, histopathologic evaluation of formalin-fixed heart, lungs, liver, spleen, kidney, intestine, skeletal muscle, and bone (tibia/fibula) were done at Animal Reference Pathology Laboratories (ARUP; Salt Lake City, Utah).

RESULTS

Folate-Targeted Chemotherapy. As shown in Figure 1A, a folate−drug conjugate consists of four basic modules: (1) a pteroate ligand such as Pte, (2) a hydrophilic spacer, (3) a biologically cleavable bond, and (4) a potent drug moiety. EC140 specifically consists of the vitamin folic acid covalently extended by the peptide Asp-Arg-Asp-Asp-Cys, which, in turn, is coupled to DAVLBH via an acylhydrazone linker (Figure 1B).

The mechanism of folate-targeted drug delivery has been previously described (*16*). Briefly, cells expressing the FR protein can bind folate−drug conjugates very tightly and endocytose them into acidic compartments. For EC140, it has been found that separation of the folate−peptide and DAVLBH moieties can occur within these vesicular structures; thus, it is possible that the released drug molecules are permitted to diffuse across these compartmentalized membranes to exert activity against microtubules (i.e., the biological target for vinca alkaloids).

EC140 Synthesis. The synthesis of EC140 is schematically shown in Scheme 1. A thiol containing folate−peptide spacer, EC119, was coupled in near-quantitative yield to DAVLBH to produce EC140. It was purified by preparative reverse-phase HPLC and stored as a lyophilized powder. The structure of EC140 was confirmed by ^{1}H NMR spectroscopy and electrospray ionization mass spectroscopy.

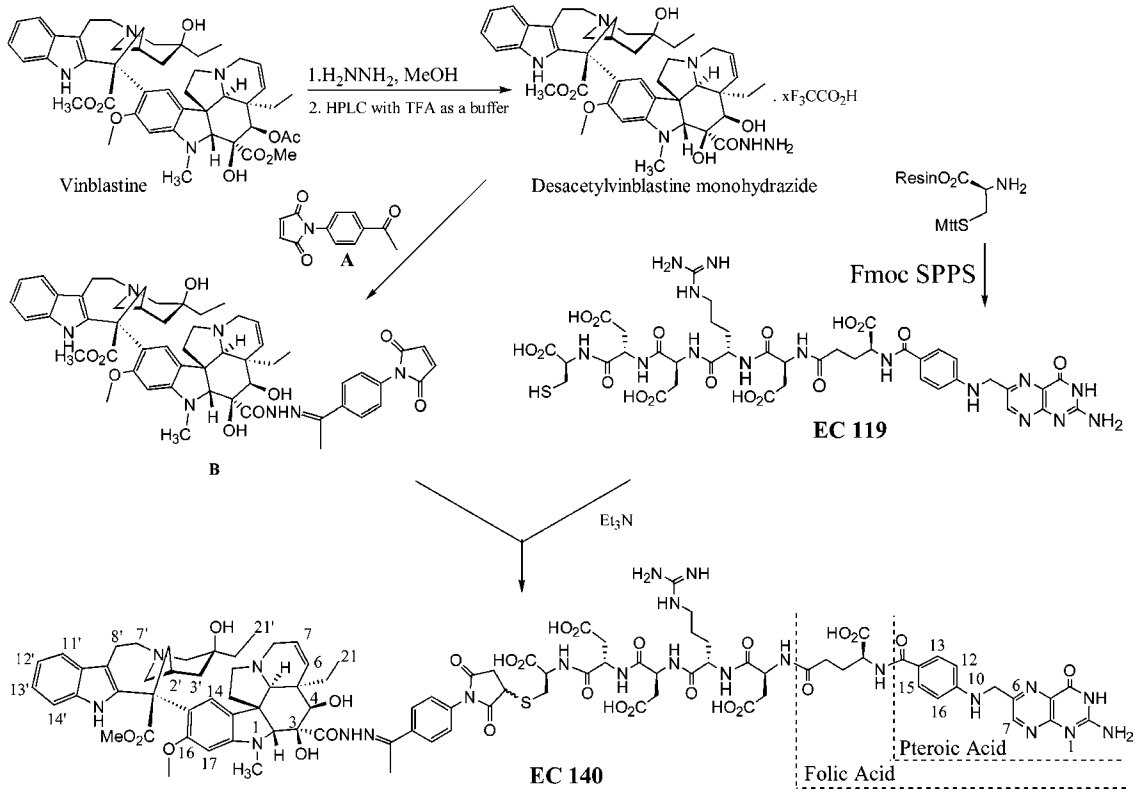
Drug release studies were performed in pH 5.0 buffer, since the milieu within a cancer cell's endosome (i.e., the compartment that EC140 will enter following endocytosis) is believed to be ∼pH 5 (*23*). Under these conditions, the hydrazone bond within EC140 was found to be labile, with an estimated $t_{1/2}$ of ∼5.5 h. In contrast, the $t_{1/2}$ of EC140 was found to be ∼22 h at pH 7.4.

Relative Affinity Assay. EC140 was first evaluated biologically using an in vitro relative affinity assay that measures a ligand's ability to directly compete with folic acid for binding to cell surface FRs. Importantly, a relative affinity value of 1.0 implies that the test article ligand has an affinity equal to that of folic acid for the FR. Likewise, values lower than unity reflect weaker affinity, and values higher than unity reflect stronger affinity.

Monolayer KB cells were incubated with 100 nM ^{3}H-folic acid in the presence of increasing concentrations of non-radioactive folic acid or EC140. Following a 1 h incubation at 37 °C, cells were rinsed free of unbound material and counted for residual cell-associated radioactivity. The quantity of bound radioactivity was plotted against the concentration of unlabeled ligand, and the IC_{50} value (concentration of ligand required to block 50% of ^{3}H-folic acid binding) was estimated. As shown in Figure 2, EC140 was experimentally determined to have an affinity of 0.35 relative to that of folic acid for human FRs. Thus, chemical modification of folate with the DAVLBH drug motif only minimally altered the vitamin's intrinsic affinity for the FR.

Dose-Dependent Activity. DAVLBH was chosen as the drug moiety for EC140 because it contains a modifiable hydrazide

Scheme 1. Synthetic Route for EC140.



functional group to which we could attach our folate−spacer group. DAVLBH is a potent vinca alkaloid analog (*24*), and as shown in Figure 3, this agent displays high, dose-dependent activity against FR-positive KB cells. In fact, the IC_{50} of DAVLBH was determined to be nearly equivalent to the IC_{50} of VLB.

The activity of EC140 was also evaluated to determine its dose responsive properties. As shown in Figure 4, the activity of EC140 was found to be concentration dependent with an IC_{50} of ∼11 nM when cells were pulsed for only a 1 h period at 37 °C. The activity of EC140 was also effectively blocked in the presence of excess free folic acid, indicating that the observed activity was folate-mediated. The latter result is significant, for it suggests that normal tissues that express little to no FR may not be affected by EC140 (see discussion).

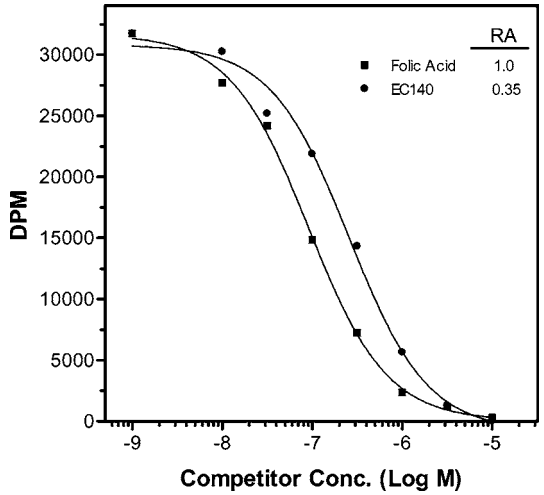


Figure 2. Relative folate receptor binding affinity of EC140. KB cells were incubated for 1 h at 37 °C with 100 nM ^{3}H-folic acid in the presence and absence of increasing competitor concentrations. (■) folic acid; (●) EC140. Error bars represent 1 standard deviation ($n = 3$). RA, relative affinity.

In Vivo Activity. *a. Syngeneic Model.* The activity of EC140 was next evaluated in vivo. Eleven days after receiving a subcutaneous (s.c.) inoculation of syngeneic, FR-positive M109 tumor cells, animals received i.v. injections of 10 μmol/kg EC140 given on days 11, 13, 15, and 18. As shown in Figure 5, tumors in the untreated animals reached ∼1000 mm^3 by day 29. In contrast, animals briefly treated with EC140 experienced a significant response; thus, tumors in 3 of 5 animals disappeared and did not recur during the study period, while the remaining 2 of the 5 animals in that cohort had a partial response (2.7 log cell kill, LCK; 175% *T/C*). Importantly, maximum weight loss during this therapy ranged from 3% to 16%, and no other gross toxicities or abnormalities were observed.

b. Activity against the KB Xenograft Model. The encouraging activity results obtained from our pilot in vivo study prompted us to test EC140 against a human tumor xenograft. Here, EC140 was evaluated against established s.c. KB tumor-bearing animals using a variety of different dose levels and schedules. Furthermore, the performance of EC140 was also compared to that of

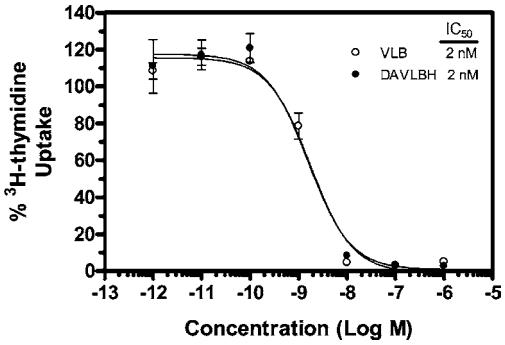

Figure 3. Activity of DAVLBH and VLB against KB cells. Adherent KB cells were incubated for 46 h at 37 °C with increasing concentrations of test article. Cells were then incubated for 2 h with ^{3}H-thymidine and then counted for radiolabel incorporation into newly synthesized DNA, as described in the Experimental Procedures. (●) DAVLBH; (○) VLB. Data represent the average ± 1 SD ($n = 4$).

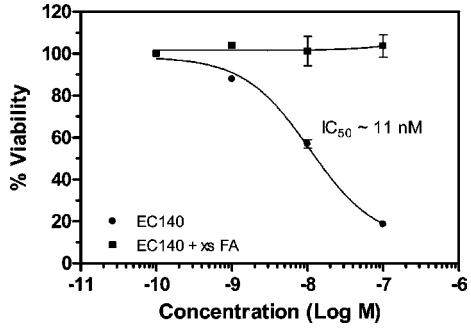

Figure 4. EC140 dose response. KB cells were pulsed for 1 h with increasing concentrations of EC140 in the presence or absence of 0.1 mM folic acid (as a competitor). Following a 70 h chase in fresh media, cells were incubated with ^{3}H-thymidine for 2 h and then counted for radiolabel incorporation into newly synthesized DNA, as described in the Experimental Procedures. (●), EC140; (■), EC140 plus 0.1 mM folic acid. Data represent the average ± 1 SD (n = 4).

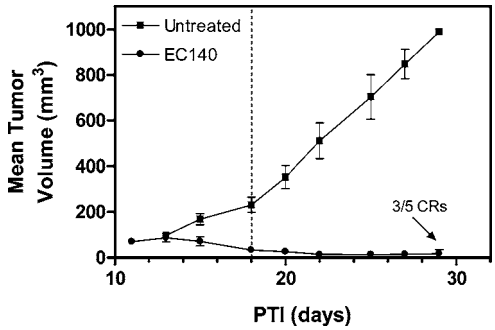

Figure 5. Antitumor activity of EC140 in a syngeneic model. 1 × 10^6 M109 cells were inoculated s.c. into each *Balb/c* mouse. Eleven days later, animals were treated intravenously with (●) 10 μmol/kg of EC140 on days 11, 13, 15, and 18. A control cohort (■) was not treated. Tumor volume was assessed every 2 to 3 days. The dotted vertical line represents the day of final dosing. Data represent the average ± 1 SD (n = 5 animals per cohort).

the free drug, DAVLBH, administered to *nu*/*nu* mice at its MTD. As shown in Table 1, EC140 therapy was found to be dose-dependent, and all animals in each cohort seemingly responded to this therapy. Dose levels of ≥5 μmol/kg consistently produced CRs in many of the treated mice. In fact, we observed 5 of 5 CRs in the cohort that received 10 μmol/kg of EC140 following a brief BIW, 2 week regimen. Interestingly, animals treated with DAVLBH at its MTD (TIW, 2 week schedule) did respond, but only partial responses were observed (i.e., no CRs). Taken together, EC140 has proven to be active against both murine and human FR-positive tumor models, and its overall response appears to be greater than the free DAVLBH drug when dosed at its MTD.

c. Activity against an FR-Negative Tumor Model. To gain insight on in vivo specificity, EC140 was next evaluated for activity against the recognized FR-negative 4T1 tumor model

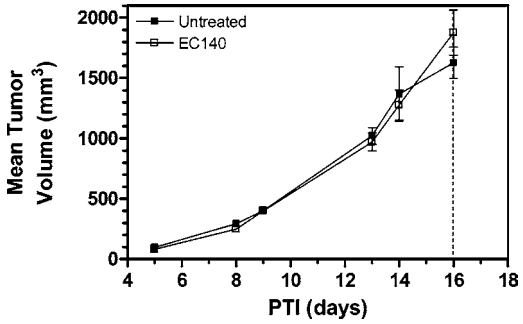

Figure 6. Antitumor activity of EC140 in a FR-negative model. 2 × 10^5 FR-negative 4T1 cells were inoculated s.c. into each *Balb/c* mouse. Five days later, animals were treated intravenously with (□) 3 μmol/kg of EC140 on days 11, 13, 15, 18, 20, and 22. A control cohort (■) was not treated. Tumor volume was assessed every 2 to 3 days. The dotted vertical line represents the day of final dosing. Data represent the average ± 1 SD (n = 5 animals per cohort).

(*14*, *17*, *18*). Thus, animals bearing established s.c. 4T1 tumors were treated intravenously TIW for two consecutive weeks with 3 μmol/kg EC140. Note, the 3 μmol/kg dose level was chosen for this study because (i) it is near the single-dose, receptor-saturable level (*25*), and (ii) as little as 1 μmol/kg doses were previously found to be active against an FR-positive tumor (see Table 1). As shown in Figure 6, 4T1 tumors grew at the same rate in both the untreated and EC140-treated animals. Taken together with the aforementioned data, these results suggest that EC140 activity could be specific for FR-expressing cells.

d. Toxicity. Aside from minimal to manageable weight loss during EC140 therapy, no other obvious gross toxicities or abnormal behavior were observed. If an EC140-treated animal were euthanized, it was principally due to the tumors reaching 1500 mm^3. However, preliminary toxicity assessments were made using the KB tumor-bearing *nu*/*nu* animals that completely responded to EC140 therapy. Thus, collected sera were analyzed for lasting adverse effects on kidney and liver function. When possible, hematology and tissue pathology assessments were also conducted. The following toxicity data correlates with the cohort information supplied in Table 1.

For mice treated with the 5 μmol/kg, TIW, 2 week regimen (a total dose of 30 μmol/kg; maximum weight loss of 5%), 3 of 5 were tumor-free 12 days after dosing began, and they remained tumor-free for 24 days thereafter (i.e., at the end of the study). At that time, animals were sacrificed, and biological samples were analyzed. In sera, AST-SGOT, BUN, creatinine, and total protein were all found to be within normal levels; however, ALT-SGPT levels were found to be lower (range: 17−22 U/L) than reference values (24−140 U/L). Tissue pathology indicated that heart, lung, spleen, bone, kidney, muscle, intestine, and brain of treated mice were all normal; occasional degeneration was, however, observed in some livers.

All 5 of the mice treated with the 10 μmol/kg, BIW, 2 week regimen (a total dose of 40 μmol/kg; maximum weight loss of

Table 1. Activity of EC140 and Free DAVLBH against FR-positive Human KB Tumor Xenografts[a]

16%), were tumor-free 12 days after dosing began, and they remained tumor-free for 24 days thereafter (end of study). At that time, animals were sacrificed, and biological samples were analyzed. In sera, creatinine and total protein were found to be within normal levels. AST-SGOT levels were occasionally found to be higher (range: 142−820 U/L) than reference values (72−288 U/L). ALT-SGPT levels (10−181 U/L) were also sometimes out of the reference range (24−140 U/L). BUN levels were found to be occasionally higher (range 14−37 mg/dL) than reference values (9−28 mg/dL). Whole blood analysis was essentially normal with the exception of an occasional high red blood cell count of $(8.1-10.3) \times 10^6/\mu$L (reference range: $(6.4-9.4) \times 10^6$/L), higher segmented neutrophil count of $(3.17-3.92) \times 10^3/\mu$L (reference range: $(0.13-2.57) \times 10^3/\mu$L) and a detectable basophil count of 10−20 cells/μL (basophils are normally not detectable). Tissue pathology indicated that liver, lung, spleen, bone, kidney,[2] muscle, intestine, and brain of treated *nu*/*nu* mice were all normal. Occasional to mild degeneration was observed in the hearts of some treated mice; however, such observations were also noted in untreated animals; therefore, heart toxicity was not considered to be EC140-related.

DISCUSSION

The objectives of this investigation were to design and test a novel folate−vinca alkaloid conjugate for activity against FR-positive cells and tumors. One drug candidate, named EC140, was created whereby a peptide derivative of the vitamin folic acid was coupled to DAVLBH via an acyl hydrazone linker. Notably, the inclusion of the acyl hydrazone bond is believed to be important for efficient release of the DAVLBH moiety within the acid endosomal milieu (*26*).

EC140 was found to retain high affinity for FR-positive cells, and it produced dose responsive activity in vitro against FR-positive cells via an endocytic mechanism. EC140 also proved to be active against syngeneic and xenograft in vivo models, and possible curative activity resulted with minimal to moderate toxicity. EC140 was also shown to be more effective and less toxic than its free drug counterpart (DAVLBH) when dosed at MTD.

Despite the ability of EC140 to cause complete regression of established s.c. tumors, animals periodically experienced weight loss; furthermore, this effect was not surprisingly found to be more pronounced with increasing dose. Whether the weight loss resulted from gastrointestinal toxicity could not be verified, because tissue samples were only analyzed by a pathologist after a modest recovery period (24 days post final dose). Regardless, future studies will be aimed at understanding whether acute toxicity of EC140 manifests during and/or immediately following therapy. Interestingly, we have confirmed that murine liver does not express the FR (*14*). Thus, if gastrointestinal toxicity is confirmed, it should prompt further studies to understand the full mechanism of EC140 clearance. Regardless, pharmacokinetic studies are warranted to better understand the disposition of EC140 and to also determine the extent of release of the DAVLBH moiety, because it is possible that the toxicities observed in mice treated with high EC140 dose levels were actually manifested by the release of free drug.

Importantly, EC140 represents a folate-targeted chemotherapeutic that can produce potent activity against established s.c. tumors. In recent publications, we demonstrated activity of a folate−mitomycin C conjugate (called EC72) against similar tumors; however, the extent of the maximal activity of EC72 is lower than that of EC140. For example, EC72 was found to be active as a single agent primarily when the tumors were young (i.e., not well-established), whereas the therapeutic benefit was reduced when EC72 was administered to animals bearing s.c. tumors of ≥ 30 mm^3 (i.e., 7 days post-inoculation) (*18*). In contrast, EC140 was found to cause complete tumor responses, even in animals originally bearing up to 100 mm^3 xenografts at the onset of therapy (vide supra). Interestingly, both agents are similar in that neither produced significant kidney toxicity despite the fact that murine kidney expresses very high levels of the FR (*14*). However, as previously stated in Reddy et al. (2005), these observations do support the hypothesis that the FRs in the kidney proximal tubules function primarily to shuttle scavenged folates (or small folate−drug conjugates) back into systemic circulation rather than to consume them for localized biological functions (*18*, *27*, *28*).

Additional animal studies with EC140 are planned to better understand the effects of dose level and dose schedule. We also plan to study the effects of tumor growth rate and FR content (i.e., different tumor models) on the overall observed antitumor response manifested by EC140 therapy. We feel that it is equally important to study the effect of replacing the acyl hydrazone bond with a biologically cleavable disulfide linker (*16*) or perhaps even a biologically cleavable peptide linker, such as that utilized successfully in various antibody−drug conjugates (*29*, *30*). Interestingly, the latter approach would most likely require the exploitation of an endosome-resident peptidase, since folate conjugates are known to largely avoid the more degradative lysosomal compartments during intracellular trafficking (*2*, *31*). Clearly, structure−activity studies for folate−vinca alkaloid conjugates are warranted to maximize the efficacy of this novel therapeutic approach.

[2] Normal kidney expresses high levels of the FR; see discussion.

Poly(amido ethylenimine) polymers, a new type of peptidomimetic polymer, containing multiple disulfide bonds (SS-PAEIs) designed to degrade after delivery of plasmid DNA (pDNA) into the cell were synthesized and investigated as new carriers for triggered intracellular gene delivery. More specifically, three SS-PAEIs were synthesized from Michael addition reactions between cystamine bisacrylamide (CBA) and three different ethylene amine monomers, i.e., ethylenediamine (EDA), diethylenetriamine (DETA), or triethylenetetramine (TETA). Complete addition reactions were confirmed by ^{1}H NMR. The molecular weight, buffer capacity, and relative degree of branching for each SS-PAEI was determined by gel permeation chromatography (GPC), acid−base titration, and liquid chromatography−mass spectroscopy (LC-MS), respectively. Physicochemical characteristics of polymer/pDNA complexes (polyplexes) were analyzed by gel electrophoresis, particle size, and ζ-potential measurements. All three SS-PAEIs effectively complex pDNA to form nanoparticles with diameters less than 200 nm and positive surface charges of ~32 mV. The in vitro gene transfer properties of SS-PAEIs were evaluated using mouse embryonic fibroblast cell (NIH3T3), primary bovine aortic endothelial cell (BAEC), and rat aortic smooth muscle cell (A7R5) lines. Interestingly, polyplexes based on all three SS-PAEIs exhibited remarkably high levels of reporter gene expression with nearly 20× higher transfection efficiency than polyethylenimine 25k. The high transfection efficiency was maintained in the presence of 10% serum in the transfection medium. Furthermore, confocal microscopy experiments using labeled pDNA indicated that polyplexes of SS-PAEI displayed greater intracellular distribution of pDNA as compared to PEI, most likely due to environmentally triggered release. Therefore, SS-PAEIs are a new class of transfection agents that facilitate high gene expression while maintaining a low level of toxicity.

1. INTRODUCTION

Nucleic acid-based therapeutics for the treatment of genetic and acquired diseases has developed rapidly over the past decade as a direct result of the advances in molecular biology and biotechnology. Such progress has enabled the use of plasmid DNA (pDNA), antisense oligonucleotides, ribozymes, peptide nucleic acids, and silencing RNAs for gene therapy (*1*). Viral carriers in gene therapy has shown promising results; however, issues with potential immunogenicity and host chromosomal integration still remain (*2*, *3*). Nonviral carrier approaches are seen as the answer to the safety concerns introduced by viral vectors in addition to being relatively simple to prepare and having an unlimited cargo space (*4*).

Discovery and use of potent but nontoxic carriers is the key to unlocking the potential of nonviral gene delivery. Carriers such as polyethylenimine (PEI) (*5*, *6*), poly(L-lysine) (PLL) (*7*, *8*), cationic lipids (*9*), and polyamidoamine starburst dendrimers (PAMAM) (*10*) have all produced moderate gene expression but have also, to varied degrees, induced carrier associated toxicity to in vitro and/or in vivo (*11*, *12*).

Poly(amidoamine)s (PAAs) are water-soluble, peptidomimetic polymers obtained by polyaddition of primary or secondary aliphatic amines to bisacrylamide monomers (*13*). Their water-soluble nature makes PAAs ideal candidates in various drug delivery applications in pharmaceutics. Examples of these applications include tissue engineering, nucleic acid delivery, attachment of proteins and hydrophobic drugs, incorporation of stealth characteristics such as PEG to avoid uptake by the reticuloendothelial system, and passive targeting to tumors (*14*−*16*). Reinke and co-workers showed by synthesizing a new group of PAA-derived gene carrier, known as poly(glycoamidoamine)s, that significant gene expression could be achieved in different types of mammalian cells (*17*, *18*).

Davis and co-workers have shown that cellular toxicity increases as the molecular weight increases for cationic polymers such as PAAs (*19*). The use of reducible polymer systems provides a way to maintain polymer stability and achieve efficient gene expression in vivo while limiting effects of toxicity. The difference in redox potential (100-fold) between the oxidizing extracellular space and the reducing intracellular space makes disulfide bonds unique in cellular biology and may be utilized in therapeutic delivery systems (*20*). Reduction of PLL and polyrotaxane polymer-based nonviral systems containing disulfide bonds is thought to facilitate uncoupling of polymer/pDNA complexes to further increase gene expression (*21*−*23*). Moreover, recent studies of Lin et al. on various

substituted linear poly(amidoamine)s as nonviral gene delivery systems, using COS-7 cells, have shown that the introduction of disulfide linkages in the polymer chains results in significantly increased transfection efficiency and cell viability (*24*). In this way, reduced polymer carriers may avoid issues of long-term toxicity and organ accumulation that have hampered in vivo applications of nondegradable, high molecular weight carriers.

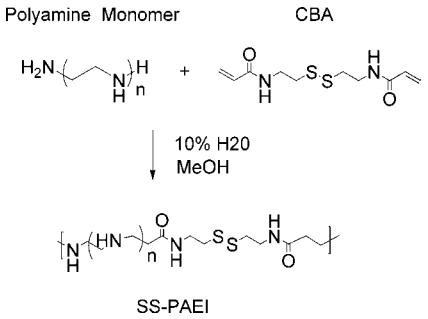
In this paper, we report a new form of PAA, disulfide-containing poly(amido ethylenimine)s (SS-PAEIs), as potential carriers for gene delivery. We hypothesize that the combination of polyamines with multiple reducible disulfide bonds through amide bond formation will (1) introduce a new kind of nonviral carrier containing minimal toxicity while utilizing the effective nonviral characteristics of PEI-based systems such as pDNA condensation and buffer capacity, (2) produce polymers that form small, stable nanoparticles in an aqueous environment when combined with pDNA, and (3) protect against nucleic acid degradation until successfully triggered delivery in the intracellular cytoplasmic compartment by glutathione reduction. Polymers were synthesized from Michael addition reactions of different amine donors to a reducible cystamine bisacrylamide linker. Polymers were characterized by ^{1}H NMR, GPC, and acid−base titration and LC-MS measurements. Further characterization was done using reduction/protection of free sulfhydryls to look at the relative degree of branching for each polymer. Complex formation with pDNA was studied via gel electrophoresis and dynamic light scattering. In vitro transfection activity and cellular toxicity of SS-PAEIs complexed with pDNA was evaluated using mouse embryonic fibroblasts (NIH3T3), primary bovine aortic endothelial cells (BAEC), and/or rat aortic smooth muscle cells (A7R5). Finally, confocal miscroscopy was used to look at the intracellular distribution of labeled pDNA.

2. MATERIALS AND METHODS

2.1. Materials. Triethylenetetramine (TETA), diethylenetriamine (DETA), ethylenediamine (EDA), and hyperbranched polyethylenimine (bPEI, M_w = 25 000) were purchased from Aldrich (St. Louis, MO). Linear polyethylenimine (LPEI, M_w = 25 000) and cystamine bisacrylamide (CBA) were purchased from Polysciences, Inc. (Warrington, PA). The plasmid pCMV−Luc was made by insertion of luciferase cDNA into a pCI (Promega, Madison, WI) plasmid driven by the CMV promoter and was purified using standard Maxiprep (Invitrogen, Carlsbad, CA) protocols. Dubelcco's Modified Eagle's Medium (DMEM), penicillin−streptomycin, trypsin-like enzyme (TrypLE Express), and Dubelcco's phosphate buffered saline were purchased from Gibco BRL (Carlsbad, CA). Fetal bovine serum (FBS) was purchased from Hyclone Laboratories (Logan, UT). Other commercially available reagents were used as received.

2.2. Polymer Synthesis. Reducible PAA polymers were synthesized by a Michael's-type addition (Scheme 1) polymerization between ethylene amine monomer (TETA, DETA, or EDA) and CBA. Polymerizations were conducted in brown flasks using 10% aqueous MeOH as a solvent at 50 °C for a period of 18 h to 2 days under an argon atmosphere. In a typical experiment, a brown reaction vessel equipped with a stir bar was charged with TETA (449 mg, 3.07 mmol), solvent (2.8 mL), and CBA (0.8 g, 3.07 mmol). The vessel was closed and placed in an oil bath set at 50 °C. The polymerization was allowed to proceed until stirring of the magnetic bar became difficult due to the high viscosity of the reaction mixture (16 h). Excess TETA (~50 mg) in MeOH was then added to consume any remaining acrylamide functional groups and allowed to stir for an additional 2 h. Polymer product was isolated by ultrafiltration (MWCO 1000) by first diluting the reaction mixture with ultrapure deionized water (ddH_2O) to 10 mL and adjusting to pH 5. Purification was allowed to go overnight at 4 Barr followed by concentration and freeze-drying. Conditions for polymerizations using EDA and DETA with CBA were conducted in an identical fashion with the exception that the duration of the polymerization step prior to addition of excess amine was 18 h for DETA and 2 days for EDA. Composition of each polymer product was established by ^{1}H NMR (300 MHz, D_2O); poly(EDA/CBA) δ 2.48 (COCH_2CH$_2$NH, 4H), 2.72 (NHCH$_2$CH_2S-S, 4H), 3.01 (COCH$_2$CH_2NHCH_2-CH_2NH, 8H), 3.40 (NHCH_2CH$_2$S-S, 4H); poly(DETA/CBA) δ 2.61 (COCH_2CH$_2$NH, 4H), 2.72 (NHCH$_2$CH_2S-S, 4H), 2.84−3.21 (COCH2CH_2NHCH_2CH_2, 12H), 3.41 (NHCH_2CH$_2$S-S, 4H); poly(TETA/CBA) δ 2.61 (COCH_2CH$_2$NH, 4H), 2.72 (NHCH$_2$CH_2S-S, 4H), 2.90−3.21 (COCH2CH_2NHCH_2CH_2, 16H), 3.41 (NHCH_2CH$_2$S-S, 4H).

Scheme 1. Synthesis of SS-PAEIs[a]



[a] Amino groups reacting with cystamine bisacrylamide (CBA) where the *n* values of 1, 2, and 3 represent the initial ethylene amine monomers of ethylenediamine (EDA), diethylenetriamine (DETA), and triethylenetetramine (TETA).

2.3. Polymer Characterization. *2.3.1. Gel Permeation Chromatography (GPC).* GPC experiments were conducted as previously reported (*25*). A Waters (Milford, MA) 2695 Alliance liquid chromatography system was used to perform the size exclusion chromatography (SEC) experiments. The instrument contained a built-in auto-injector and a Waters 2414 refractive index detector. A set of two PL aquagel−OH 30 columns (8 mm, 300 × 7.5 mm, Polymer Labs) were thermostated at 30 °C. The eluent was sodium acetate buffer (0.3 M NaAc, pH 4.4) with 30% (v/v) methanol. The eluent was filtered through a 0.2 μm HPLC filter (Nylon, Alltech) and degassed prior to use by simultaneous application of ultrasound and vacuum. The flow rate was 0.5 mL/min. The calibration curve was prepared with poly(ethylene glycol) (PEG) standards. The data collection and data analysis were done with Waters *Empower* software.

2.3.2. Acid−Base Titration. The buffering capacity of the SS-PAEIs between pH 10 and 3 was followed as previously described (*26*). Briefly, 6 mg of polymer was dissolved in 30 mL of 0.1 M NaCl (0.2 mg/mL polymer). Polymer solutions were titrated to an initial pH 10 with NaOH followed by subsequent additions of 0.1 M HCl.

2.3.3. Degree of Branching. Relative degree of branching was determined by reduction and protection of disulfide bonds followed by LC-MS analysis. Polymers were dissolved (2 mg/mL) in sodium phosphate buffer (20 mM, pH 7.2). Complete reduction of each disulfide bond was done in the presence of tris(2-carboxyethyl)phosphine (TCEP, 15 mM) stirring at room temperature in a sealed tube for 1 h. Protection of free sulfhydryls was immediately done by adding at least a twofold molar excess of *N*-ethylmaleimide (NEM) and stirring for 2 h at room temperature. The resulting fragments were subjected to positive-ion ESI LC-MS/MS analysis on a Finnigan LCQ Deca ion trap mass spectrometer (Thermo Finnigan, San Jose, CA) equipped with a Picoview Nanospray source. Chromatographic separation was accomplished using an HPLC system consisting of an Eksigent NanoLC-1D binary pump with a self-

packed column (100 um × 100 mm, 3 m particle size; Waters Atlantis dC18). A gradient of 5% acetonitrile (ACN), 95% water (solvent A), and 80% ACN and (solvent B) was operated at 400 nL/min, at 5% B for the first 3 min, followed by a linear increase to 50% B in 50 min, a linear increase to 80% B in 1 min, maintenance at 80% B for 14 min, and finally maintainence at 85% B for 5 min. Spectra were acquired in automated triple-play mode for recording of full-scan MS, zoom scan, and MS/MS data. The scan range for MS mode was set at *m*/*z* 300−1500.

2.4. Characterization of Polymer/pDNA Complexes. *2.4.1. Gel Retardation Assay.* Polymer/pDNA complexes were prepared at varying weight ratios (w/w) ranging from 0.75:1 to 48:1 in a buffered solution (20 mM HEPES, pH 7.4, 5% glucose) with or without 2.5 mM DTT. Polyplexes were incubated at room temperature for 30 min, then loaded (1 μg pDNA/well) onto a 1% agarose gel stained with ethidium bromide (EtBr, 5 μg/mL) at 96 V for 30 min in TAE (40 mM Tris-acetate, 1 mM EDTA) buffer.

2.4.2. DNase Protection Assay. The serum protection assay used was modified from a previously reported method (*27*). Each group contained 3 μg pCMV-Luc (in 30 μL) complexed with 29 μL of polymer at 6:1 w/w in 1 RQ1 DNase I buffer (Promega). After 30 min incubation at room temperature, 1 μL RQ1 RNase-free DNase I (10 mU/μL) was added, and each sample was incubated at 37 °C, taking 10 μL aliquots at 0, 30, 60, 90, and 120 min time points. At each time point, aliquots were added to 8 μL stop buffer (250 mM NaCl, 25 mM EDTA, 2% SDS) and incubated on ice for the remaining duration of the experiment. Samples were incubated overnight at 60 °C to completely dissociate polymer/pDNA complexes. Samples were then loaded onto a 1% agarose gel stained with EtBr and subjected to electrophoresis as explained above.

2.4.3. Light Scattering and ζ-Potential Measurements. The particle diameters and ζ-potentials of each polymer complexed with pDNA in HEPES buffer (20 mM, pH 7.4, 5% glucose) at 25 °C was determined using a Zetasizer 2000 instrument equipped with a DTS5001 cell and dynamic light scattering (DLS) on a Malvern 4700 system. The polymer/pDNA complexes were prepared by adding polymer with a desired concentration in 800 μL HEPES (14.1−900 μg/mL) to a buffered solution (200 μL) of pDNA (75 μg/mL) resulting in polymer/pDNA ratios ranging from 0.75:1 to 48:1 w/w. Complexes were vortexed, then allowed to incubate for 30 min at room temperature prior to analysis.

2.5. In Vitro Transfection and Cellular Toxicity. *2.5.1. Reporter Gene Expression.* In vitro characterization of the SS-PAEIs was carried out on mouse embryonic fibroblasts (NIH3T3, ATCC), primary bovine aortic endothelial (BAEC, Cambrex), and murine aortic smooth muscle (A7R5, ATCC) cell lines between passages 3 and 9 using a pCMV-Luc reporter plasmid. Cells were cultured according to specifications recommended by the provider in DMEM containing 10% FBS and 1% antibiotics (penicillin−streptomycin, 10 000 U/mL) at 37 °C in a humidified atmosphere containing 5% CO_2. Cells were plated in 6-well plates at 2.0×10^5, 2.5×10^5, and 1.2×10^5 cells/well for NIH3T3, BAEC, and A7R5 cells, respectively. Polyplexes were prepared using polymer/pDNA ratios ranging from 3:1 to 24:1 w/w in a buffered solution (20 mM HEPES, pH 7.4, 5% glucose) at a total pDNA concentration of 50 μg/mL. Cells were cultured in 2 mL media containing 10% serum until ∼70% confluency was reached, at which time cells were washed with 1 × PBS. Media with or without serum was then added, followed by addition of polymer/pDNA complexes, and the cells were allowed to incubate for 4 h. Media was replaced with fresh media containing serum, and cells were allowed to incubate further for a total of 48 h. Cells were washed with 1 × PBS and treated with cell culture lysis buffer (Promega). Luciferase quantification was performed using a luciferase assay system (Promega) on a Luminometer from Dynex Technologies, Inc. (Chantilly, VA). The amount of protein in the cell lysate was determined using a standard curve of bovine serum albumin (Sigma) and a BCA protein assay kit (Pierce).

2.5.2. Cell Viability Assay. For viability assays, BAEC cells were plated in 24-well plates at 4×10^4 cells/well, and transfections were carried out when cellular confluency reached ∼70%. Polyplexes were prepared using different polymer/pDNA ratios from 0.75:1 to 24:1 w/w in buffered solution as mentioned above. Briefly, media was replaced with fresh serum-free media followed by addition of complexes (0.5 μg pDNA/well). Media was again replaced with fresh serum (10% v/v) containing media after 4 h, and cells were left to incubate for a total of 24 h before analyzing cell viability using an MTT assay (Sigma). Cellular toxicity was determined relative to untreated cells. Experiments were performed in duplicate.

2.5.3. Confocal Microscopy Studies. Confocal microscopy was used to study pDNA release from polyplexes of poly(EDA/CBA). Fluorescently labeled pCMV-Luc using ethidium monoazide bromide (EMA, Invitrogen) was prepared as previously described (*28*). NIH3T3 cells were plated on 35 mm glass-bottom plates (MatTek Corp, Ashland, MA) at 2.5×10^5 cells/plate 24 h prior to and were ∼85% confluent at the time of transfections. Polymer/EMA−pDNA complexes were prepared at a polymer/pDNA ratio of 6:1 and added in a similar manner to those steps mentioned above using 2 μg EMA−pDNA/well. At specific time points, cells were washed with 1 × PBS and incubated with 1% *para*-formaldehyde at 4 °C until image analysis. Images were taken using a FluoView FV-300 Olympus microscope (Hauppauge, NY). As a control, bPEI/EMA−pDNA complexes at 0.75:1 and free EMA−pDNA were used.

3. RESULTS AND DISCUSSION

3.1. Synthesis and Characterization of Disulfide-Containing Poly(amido ethylenimine) (SS-PAEI). SS-PAEIs were synthesized by Michael addition reactions between three different amine monomers, i.e., ethylenediamine (EDA), diethylenetriamine (DETA), or triethylenetetramine (TETA) with cystamine bisacrylamide (CBA) (Scheme 1).

Polymerizations were carried out in 10% (v/v) aqueous MeOH at 50 °C under argon. In each case, during the course of the reaction, an increase of viscosity was observed. Reactions were terminated with 10% excess corresponding amine monomer prior to gelation. The ^{1}H NMR (D_2O) of the purified products showed that the characteristic acrylamide peaks between δ 5.8 and 6.5 were no longer present (data not shown), suggesting a complete consumption of the acrylamide functional group. The molecular weights of the SS-PAEIs were determined by gel permeation chromatography (GPC). As shown in Table 1, these polymers have M_w values in the range $(2.0-5.0) \times 10^3$. Commercial 25k branched and linear PEIs, as external controls, were also analyzed, producing values of 9.5 and 13.1 $\times 10^3$, respectively. This clearly indicates that the M_w values are underestimated. It should be noted that these SS-PAEIs have a rather low polydispersity ($M_w/M_n = 1.26-1.47$).

The buffering capacity of gene carriers is an important factor, since it may have direct impact on their ability to effectively condense, protect, and deliver pDNA into the cell for expression (*26*). The buffering capacity of SS-PAEIs was determined by acid−base titration in 0.1 M NaCl. Buffering capacity is defined as the percentage of amine groups becoming protonated from pH 7.4 to 5.1 as previously described (*29*). The results in Table 1 revealed that these polymers exhibit a higher buffering capacity as compared to LPEI and bPEI 25k controls (poly-

Table 1. Synthesis and characteristics of SS-PAEIs

polymer	reaction time	M_n[a] (kDa)	M_w[a] (kDa)	M_w/M_n[a]	titration[b] (μmol HCl)	% protonated nitrogens	degree of branching[c]
poly(EDA/CBA)	48 h	1.6	2.0	1.26	8.2	21.9	0.37
poly(DETA/CBA)	18 h	3.3	4.8	1.47	5.0	10.1	0.72

[b] Titration values determined by the volume of 0.1 M HCl required to shift pH from 7.4 to 5.1 in 0.1 M aqueous NaCl after adding 6 mg of polymer. [c] Relative degree of branching determined by reduction of disulfide bonds with TCEP, then protection of free sulfhydryls with NEM followed by LC-MS analysis.

(DETA/CBA) < LPEI < bPEI, < poly(TETA/CBA), poly(EDA/CBA)).

It has been reported that polymerization generally occurs predominantly through primary amines with a low degree of branching found through secondary amines (*17*). It was realized that, under the conditions set for SS-PAEI polymer synthesis, branching could occur depending on the relative reactivity of amines in each polyamine monomer. To test the relative degree of branching for each SS-PAEI polymer, each disulfide bond was cleaved using a thiol-free reducing agent, TCEP, followed by the formation of a stable thioether bond using NEM. Reduced fragments were then analyzed by liquid chromatography−mass spectroscopy (LC-MS). For example, poly(EDA/CBA) was completely reduced, then protected using conditions as described above (Figure 1). An LC-MS spectrum within the range *m*/*z* 400−1500 showed two distinct ions with $m/z = 573.3$ and 829.4 representing both a linear and a single-branched population of fragments. The relative degree of branching (DB) was determined by the following general equation:

$$\mathrm{DB} = \frac{\mathrm{BSeg}}{\mathrm{BSeg} + \mathrm{LSeg}} \quad (1)$$

where BSeg is the total number of branched segments and LSeg is the total number of linear segments. It should be noted that, for poly(EDA/CBA), there should also be an ion peak at *m*/*z* 316.24 representing the terminal fragments of the polymer. Analyzing the LC-MS spectrum within the range *m*/*z* 300−1500 produced such a peak at intensity ~10. We decided not to include the terminal fragments in the calculations for each polymer due to the minor contributions made and since we were mainly interested in comparison of the linear and branched portions in each polymer. On the basis of relative intensities for all three SS-PAEIs in this semiquantitative analysis, it was estimated that the degree of branching was the least for poly(EDA/CBA) followed by poly(TETA/CBA) and poly(DETA/CBA) as reported in Table 1.

3.2. Characterization of Polymer/pDNA Complexes. The ability of these SS-PAEIs to condense pDNA was investigated by particle size and ζ-potential measurements (Figure 2). Dynamic light scattering (DLS) studies using different polymer/pDNA (w/w) ratios showed that small particle sizes with diameters less than 200 nm are obtained when polymer/pDNA ratios are at or above 1.5:1 for poly(TETA/CBA), 3:1 for poly(DETA/CBA), and 6:1 for poly(EDA/CBA).

The ζ-potential profile showed a similar trend as the w/w ratio increased, but at and above 6:1 w/w, all three polymers exhibited a charge of +32 mV. These values were slightly lower than that obtained for bPEI 25k at and above 0.75:1 w/w (+36 mV). When poly(TETA/CBA) was complexed with pDNA in solution containing 2.5 mM DTT, there was no apparent shift in ζ-potential at any of the weight ratios, indicating the inability of the reduced polymer to actively interact with the pDNA by affecting its overall surface charge potential in solution. The lack of such interactions may suggest that pDNA would be fully

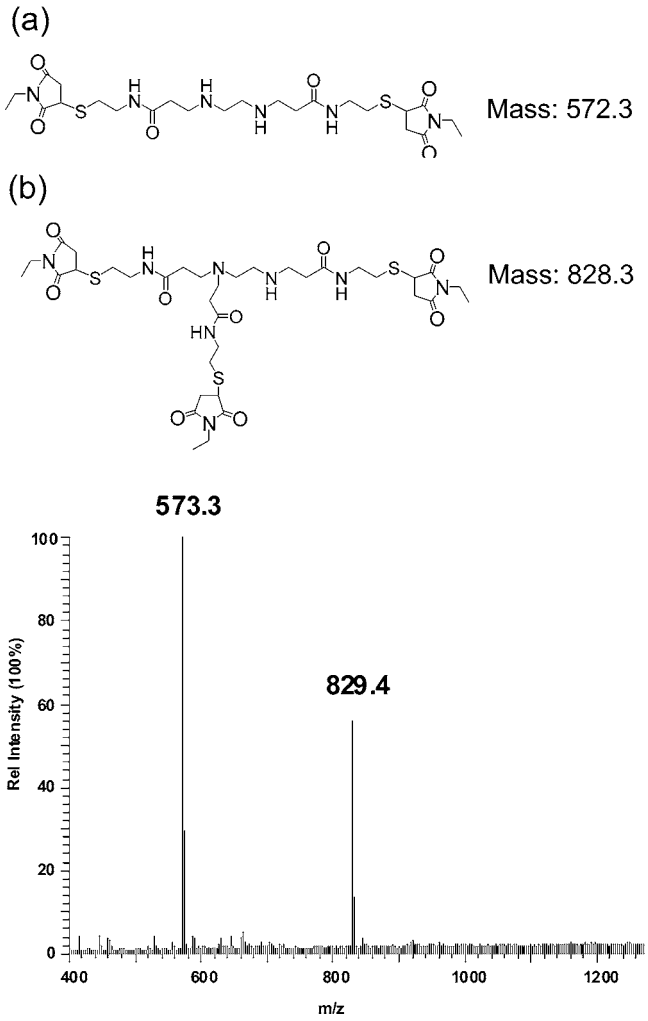

Figure 1. LC-MS spectrum of the reduced products for poly(EDA/CBA).

dissociated in the cytoplasm upon complete reduction of the SS-PAEI polymer/pDNA complexes.

Results from physicochemical characterizations were further verified by agarose gel electrophoresis stained with EtBr. Figure 3 shows gel electrophoresis results for poly(EDA/CBA). Poly(EDA/CBA) was capable of effectively condensing pDNA at w/w 0.75:1 and excluding EtBr intercalation with pDNA at and above 6:1 w/w. Poly(TETA/CBA) formed condensed, EtBr-excluding complexes sooner (1.5 w/w), followed by poly(DETA/CBA) at 3:1 w/w in agreement with DLS results (Figure 2a).

Polyplex formation can be better understood when the w/w ratios of each corresponding polymer/pDNA polyplex are converted into nitrogen/phosphate (N/P) ratios, where positively charged nitrogen atoms on the polymer backbone interact electrostatically with negatively charged phosphate residues on

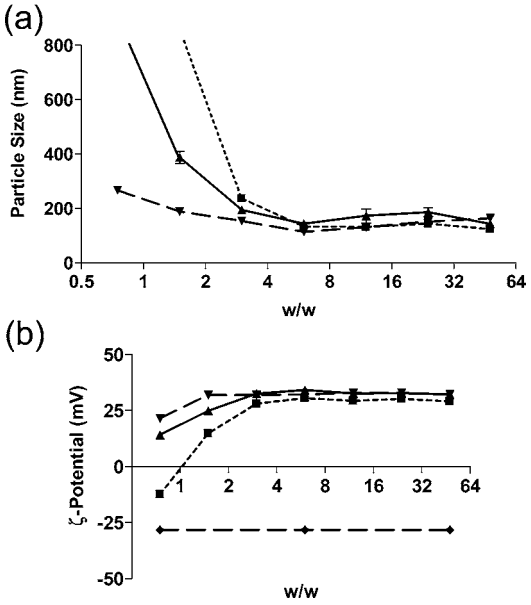

Figure 2. Physicochemical characterizations of polymer/pDNA complexes where (a) particle size and (b) ζ-potential ($n = 5 \pm$ SEM) are measured at varying w/w ratios with and without the presence of 2.5 mM DTT ($n = 3 \pm$ SEM). (■) poly(EDA/CBA); (▲) poly(DETA/CBA); (▼) poly(TETA/CBA); and (◆) poly(TETA/CBA) in the presence of 2.5 mM DTT.

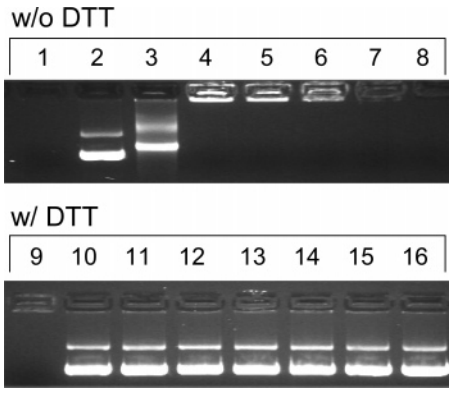

Figure 3. Gel electrophoresis of poly(EDA/CBA) complexed with pDNA at different polymer/plasmid ratios. Lanes 1 and 9, bPEI 25k at 0.75:1 w/w; lanes 2 and 10, free pDNA; lanes 3−8, poly(EDA/CBA) complexed with polymer/DNA ratios (w/w) of 0.25, 0.75, 1.5, 3, 6, and 12; and lanes 11−16, same conditions as lanes 3−8 except for the final concentration of 2.5 mM DTT. Polymers poly(DETA/CBA) and poly(TETA/CBA) were subjected to the same conditions producing complete condensation of pDNA and exclusion of EtBr at and above 6:1 w/w (data not shown).

pDNA to form compact structures as described previously (*30*). Weighted ratios used for SS-PAEIs at 6:1 convert into 12:1, 16:1, and 19:1 N/P ratios for poly(EDA/CBA), poly(DETA/CBA), and poly(TETA/CBA), respectively, where 0.75:1 w/w is 5:1 N/P for bPEI. The higher nitrogen content for poly(TETA/CBA) explains why pDNA condensation occurs sooner in contrast to poly(DETA/CBA) and poly(EDA/CBA).

When complexes were incubated with 2.5 mM DTT, unlike the bPEI control, all SS-PAEIs were unable to condense pDNA, producing results similar to those for the free pDNA control. Again, this complements results shown in Figure 2b where completely reduced SS-PAEI polymers are unable to interact with pDNA. The control polymer, bPEI, is not affected by DTT content and therefore sustains complete complexation of pDNA in both conditions. It is therefore likely that, upon reduction in the cytoplasm, SS-PAEIs will completely release pDNA, allowing for an increase in DNA uptake and gene expression

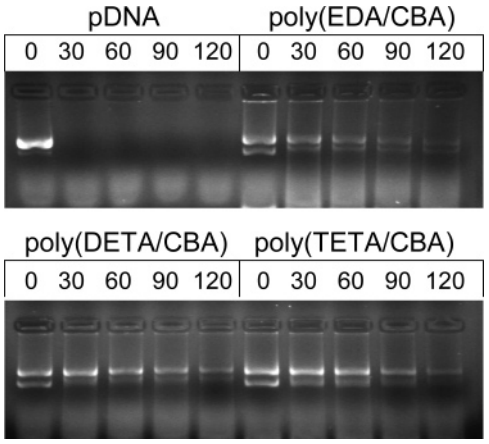

Figure 4. DNase I protection assay. SS-PAEI/pDNA complexes were prepared at 6:1 w/w and tested for their ability to protect pDNA against degradation. 10 μL aliquots containing 0.5 μg pDNA was taken at each time point (0, 30, 60, 90, 120 min).

inside the nucleus. Such mechanisms have already been proposed in the literature (*31*−*34*). It has been suggested that one limitation of bPEI 25k mediated nucleic acid delivery is the inability to completely release pDNA inside the cell, which would limit the accessibility of transcription machinery in the nucleus and therefore limit gene expression (*35*).

Last, to determine how effective these polymers are at protecting pDNA from DNase degradation, a DNase assay was conducted (Figure 4). All three polymers showed effective protection against DNase degradation up to 2 h incubation without any apparent difference between each polymer/pDNA complex analyzed. Under the same conditions, free pDNA was readily degraded by 15 min (data not shown).

3.3. In Vitro Transfection and Toxicity. Transfection experiments were conducted using SS-PAEIs at different polymer/pDNA ratios ranging from 0.75 to 24:1 on three different cell lines in the absence of serum. Optimized bPEI was used as a positive control showing the greatest gene expression while maintaining at least 80% cell viability. Figure 5 shows that poly(EDA/CBA) gives a significantly higher level of gene expression than the bPEI in all three cell lines. Specifically, poly(EDA/CBA) showed nearly a 20-fold increase in expression compared to bPEI in BAECs at 24:1 w/w. Other polymers showed an overall lower reporter expression compared to poly(EDA/CBA) where poly(DETA/CBA) appeared to decrease as w/w ratios increased, suggesting polymer carrier induced cellular toxicity. Poly(TETA/CBA), however, showed a w/w ratio dependence on gene expression producing luciferase higher than other polymer carriers in A7R5 cells only at 6:1 and 12:1 w/w. These results are especially interesting, since they show that SS-PAEIs produce significant gene expression not only in cells generally hard to transfect (NIH3T3), but also in a primary endothelial cell line (BAEC) and aortic smooth muscle cells (A7R5).

Kataoka and co-workers showed, after effective intracellular delivery of disulfide crosslinked complexes, that complete reduction leads to a substantial decrease in polymer/pDNA association and therefore higher gene expression (*21*). Gene expression results mediated by SS-PAEIs are supportive of these results. Of the three polymers, poly(EDA/CBA) has the lowest charge density of amines and therefore the lowest attraction to pDNA when reduced in the intracellular compartment but produces an overall higher gene expression.

Relative cellular viability was evaluated on the basis of an MTT assay against cells not receiving any formulated pDNA treatment on BAEC cells. Reduced toxicity was seen for SS-PAEIs compared to bPEI. The overall profile in Figure 6 showed

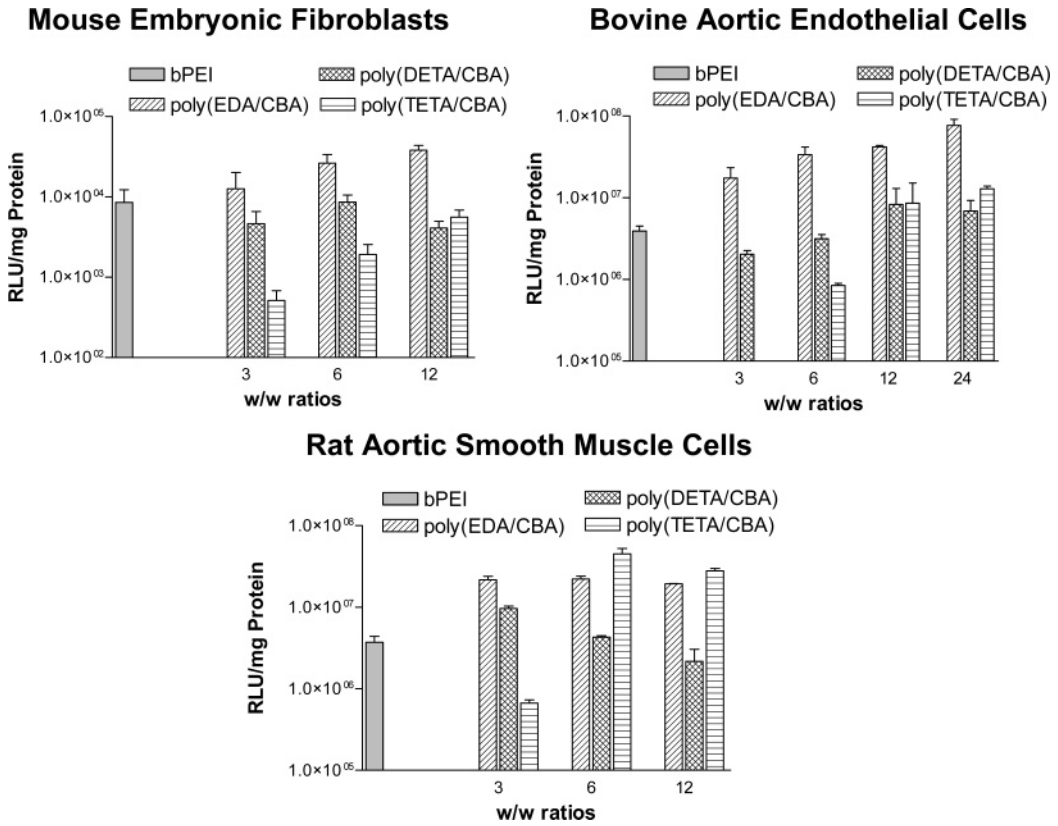

Figure 5. Transfection efficiencies for SS-PAEI/pDNA complexes in three different cell lines compared to a bPEI control at 0.75:1 w/w (2 μg pDNA/well). Results are expressed as the amount of reporter luciferase expressed normalized by the amount of protein in each well ($n = 3 \pm$ SEM).

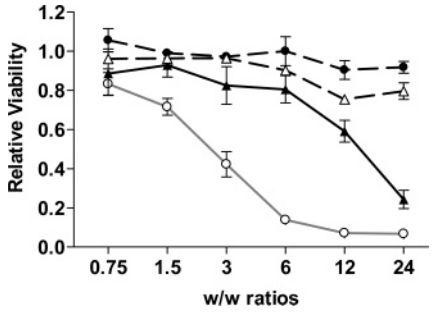

Figure 6. SS-PAEI/pDNA complex toxicity compared to a bPEI control: (Δ) poly(EDA/CBA), (▲) poly(DETA/CBA), (●) poly(TETA/CBA), and (○) bPEI. Relative cellular viability was determined using a MTT assay where results were compared to an untreated control ($n = 4 \pm$ SEM).

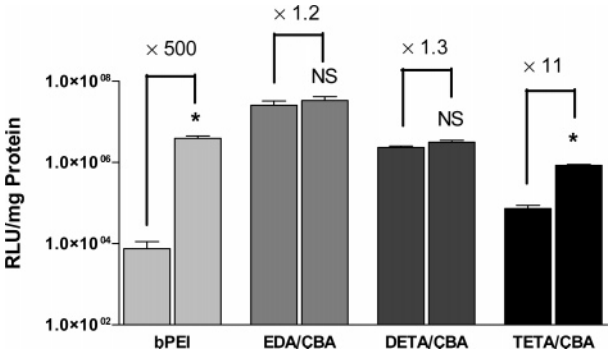

Figure 7. Effect of serum on SS-PAEI transfections. BAEC cells were used to look at the difference in gene expression with serum (left column) and without serum (right column) when polymers were complexed with pCMV-Luc reporter plasmid at 6:1 w/w and 0.75:1 for bPEI. Similar results were obtained at higher w/w ratios for SS-PAEIs (data not shown). Statistical significance was determined by a Student's *t*-test where $n = 3 \pm$ SEM, $^*p < 0.05$; NS—not significant.

an unexpected trend where poly(TETA/CBA) complexed with pDNA was less toxic than poly(EDA/CBA) followed by poly(DETA/CBA) and bPEI. Both poly(EDA/CBA) and poly(TETA/CBA) show a relative cellular viability of ≥80% at all polymer/pDNA ratios where poly(DETA/CBA) and bPEI produced similar viability up to 6:1 and 0.75:1, respectively. Higher toxicity would help explain the decrease in gene expression for poly(DETA/CBA) in Figure 5 using increasing w/w ratios on all three cell lines. In vitro results for this polymer may also directly correlate with the higher degree of branching and lower buffering capacity (Table 1) compared to the other SS-PAEIs where poly(EDA/CBA) produced the lowest degree of branching but the highest buffering capacity and overall gene expression.

Furthermore, transfections were conducted in the presence of 10% serum on BAEC cells in order to see the effect serum has on the gene expression of the SS-PAEI polymer/pDNA complexes. Interestingly, polyplexes containing reducible PAEIs did not show a large difference in gene expression between groups with and without serum, which contrasts significantly with the bPEI control, where there was a calculated 500× difference between gene expression in serum versus non-serum-containing groups (Figure 7). This might be explained by the difference in charge density of the overall polymer/pDNA complexes where a more densely charged colloid is likely to interact with serum proteins, leading to aggregation and therefore decreasing transfection efficiency (*12*).

Intracellular release of pDNA from polymer-labeled pDNA complexes was studied using confocal microscopy on NIH3T3 cells. Figure 8 shows the difference in intracellular distribution after 6 h as a result of delivery by poly(EDA/CBA) or bPEI. As a control, 2 μg free EMA−pDNA showed significantly less fluorescence after 90 min (data not shown). Cells receiving poly(EDA/CBA)/EMA−pDNA or bPEI/EMA−pDNA complexes

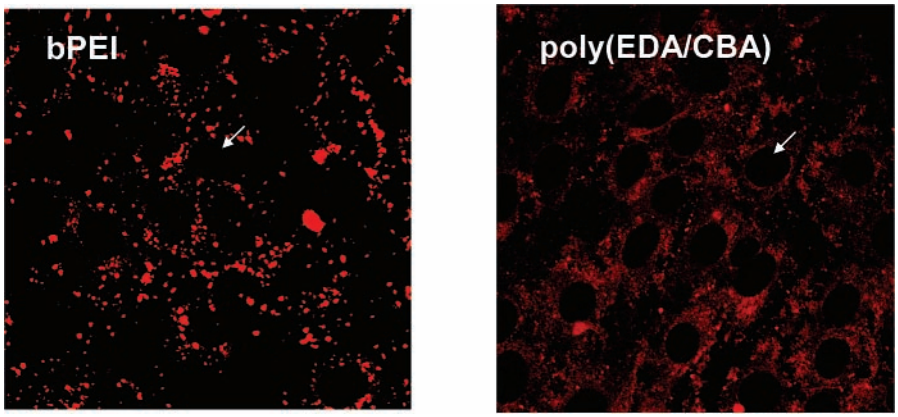

Figure 8. Confocal microscopy. Images show the difference in distribution of EMA-labeled pDNA on NIH 3T3 cells using poly(EDA/CBA) (6:1 w/w) and bPEI (0.75:1 w/w). Results show the distribution 6 h after transfection of polymer/EMA−pDNA complexes. Arrows point out the nucleus in each image. As a negative control, carrier free EMA−pDNA produced considerably less fluorescence after 90 min (data not shown).

did not produce any significant difference in intracellular images after 90 min incubation (data not shown). Both groups displayed a globular morphology suggesting that the complexes were still intact inside the cell (data not shown). Images taken after 6 h, however, show a distinct difference between the two polymer carriers. Delivery using poly(EDA/CBA) shows a more dispersed fluorescence inside the cell, suggesting that the polymer has been reduced, therefore releases the EMA−pDNA, where bPEI-mediated delivery still shows a globular fluorescence similar to both polymers after 90 min. This would suggest that both bPEI- and poly(EDA/CBA)-mediated delivery occur through similar pathways where both are endocytosed and subsequently released from the endosome by the "proton sponge effect" (*5*). Upon endosomal release, poly(EDA/CBA) polymer is reduced, therefore releases pDNA in the cytoplasm. A similar mechanism was proposed by Gosselin et al. using reversibly crosslinked low molecular weight PEI (*33*).

It was suggested previously that the reduction of disulfide-containing polymer/pDNA complexes in the intracellular compartment by glutathione reduces the cationic affinity to bind pDNA and therefore leads to enhanced gene expression (*33*, *34*). At the same time, Read et al. showed that increasing intracellular levels of GSH decreased gene expression of reducible gene carriers where a PEI control was not significantly affected (*36*). This suggests a time dependence of pDNA release inside the cell in order to obtain effective expression. Early reduction in the endo-lysosomal compartment could occur, as a result of higher glutathione levels inside the cell, that would lead to deprotection and early degradation of pDNA before it can be released into the cytoplasm.

Physicochemical characterization of our reducible PAEIs using ζ-potential and gel electrophoresis helps to confirm the effect that a completely reduced polymer has on pDNA. Results on confocal microscopy showed more dispersed pDNA using reducible poly(EDA/CBA) when compared to the bPEI control. A complete reduction of poly(EDA/CBA) in vitro is indicative of the dispersed fluorescence and would suggest a reason that higher gene expression is produced in cultured cells as shown in Figure 5.

4. CONCLUSIONS

We have shown that reducible SS-PAEIs are indeed a new class of peptidomimetic nonviral gene carrier designed for triggered intracellular nucleic acid delivery. Polymerization using Michael addition was used to produce three reducible poly(amido ethylenimine)s containing low polydispersity. These polymers were stable in aqueous solution allowing for possible facile vector modification. Polymers were further characterized with pDNA forming polyplexes exhibiting the ability to form stable nanoparticles and pDNA protection against degradation. SS-PAEIs also mediated significant gene expression in cell culture without showing inhibition by the presence of serum proteins. In the future, different forms of nucleic acid delivery will be evaluated in order to more fully characterize the potential of these polymers in established in vitro and in vivo models.

Hemoglobin Vesicles Containing Methemoglobin and L-Tyrosine to Suppress Methemoglobin Formation in Vitro and in Vivo

Tomoyasu Atoji,[†] Motonari Aihara,[†] Hiromi Sakai,[‡] Eishun Tsuchida,[‡] and Shinji Takeoka*[,†]

Department of Applied Chemistry, Graduate School of Science and Engineering, and Advanced Research Institute for Science and Engineering, Waseda University, Tokyo, 169-8555, Japan. Received December 8, 2005; Revised Manuscript Received July 20, 2006

Hemoglobin (Hb) vesicles have been developed as cellular-type Hb-based O_2 carriers in which a purified and concentrated Hb solution is encapsulated with a phospholipid bilayer membrane. Ferrous Hb molecules within an Hb vesicle were converted to ferric metHb by reacting with reactive oxygen species such as hydrogen peroxide (H_2O_2) generated in the living body or during the autoxidation of oxyHb in the Hb vesicle, and this leads to the loss of O_2 binding ability. The prevention of metHb formation by H_2O_2 in the Hb vesicle is required to prolong the in vivo O_2 carrying ability. We found that a mixed solution of metHb and L-tyrosine (L-Tyr) showed an effective H_2O_2 elimination ability by utilizing the reverse peroxidase activity of metHb with L-Tyr as an electron donor. The time taken for the conversion of half of oxyHb to metHb (T_{50}) was 420 min for the Hb vesicles containing 4 g/dL (620 μM) metHb and 8.5 mM L-Tyr ((metHb/L-Tyr) Hb vesicles), whereas the time of conversion for the conventional Hb vesicles was 25 min by stepwise injection of H_2O_2 (310 μM) in 10 min intervals. Furthermore, in the (metHb/L-Tyr) Hb vesicles, the metHb percentage did not reach 50% even after 48 h under a pO_2 of 40 Torr at 37 °C, whereas T_{50} of the conventional Hb vesicles was 13 h under the same conditions. Moreover, the T_{50} values of the conventional Hb vesicles and the (metHb/L-Tyr) Hb vesicles were 14 and 44 h, respectively, after injection into rats (20 mL/kg), confirming the remarkable inhibitory effect of metHb formation in vivo in the (metHb/L-Tyr) Hb vesicles.

INTRODUCTION

Hemoglobin (Hb)-based O_2 carriers (HBOCs) as red blood cell substitutes have been developed for clinical application in recent years (*1*−*3*). Their safety and usefulness have been demonstrated by many researchers in various fields such as physiology, toxicology, and biochemistry (*4*−*6*). The demand for HBOCs has been increasing year by year due to limitations of donated blood, such as infectious agents, shortage, and storage issues.

HBOCs are generally classified into two types: One is the acellular type, which comprises directly modified Hb molecules such as cross-linked Hb (*7*), polymerized Hb (*8*), and polymer-conjugated Hb (*9*). Some of the acellular-type HBOCs have advanced to phase III clinical trials (*10, 11*). Another kind is the cellular-type Hb systems such as Hb vesicles (*12*) or liposome-encapsulated Hb (*13*), in which Hb molecules are encapsulated with a phospholipid bilayer membrane. Although they are not yet in clinical trials, they have been shown to have excellent O_2 carrying ability and good safety profiles in vivo (*10, 14*−*18*).

Ferrous Hb (Hb(Fe^{2+})) molecules of HBOCs gradually lose their O_2 binding ability, because they react with reactive oxygen species (ROS) such as hydrogen peroxide (H_2O_2) (*19, 20*) or nitrogen monoxide (NO*) (*21*) to become nonfunctional ferric Hb (Hb(Fe^{3+}), metHb), in addition to the autoxidation of oxyHb molecules themselves. In humans, the concentration of metHb molecules in the red blood cells is usually kept below 1% by reduction systems such as NADH-cytochrome b_5, NADPH-flavin, glutathione, and ascorbic acid. Furthermore, ROS are eliminated by several mechanisms such as superoxide dismutase (SOD), catalase, and peroxidase that help to prevent the metHb formation (*23*, *24*). In contrast, metHb generated in the Hb vesicle are not reduced to the ferrous state due to the absence of the reduction systems, because constitutive enzymes and reductants necessary for metHb reduction are removed during the Hb purification process (*25*). The half-life of oxyHb of the Hb vesicles was 14 h in vivo, and more than 90% of oxyHb was converted to metHb within 48 h in the case of 20 vol % top loading to rats (*20*). In human plasma, the concentration of H_2O_2 is reported to be 4−5 μM (*26*) and to elevate to as much as 100−600 μM under inflammatory (*27*) or ischemia-reperfusion conditions (*28*). Therefore, Hb vesicles are required to have an H_2O_2 elimination system for effective prolongation of their O_2 carrying ability. We previously reported that H_2O_2 generated in the living body was the main reason for metHb formation of the Hb vesicles, and the O_2 carrying ability of the Hb vesicles in which catalase was coencapsulated was vastly prolonged in vivo by elimination of H_2O_2 (*20*). Regarding the catalase-coencapsulated vesicles, it is somewhat difficult to obtain a sufficient amount of human catalase from human donated blood. Furthermore, the catalase activity is gradually lost due to denaturation during storage at 25 °C.

Horseradish peroxidase (HRP), which also eliminates H_2O_2 in its enzymatic reaction, is converted to a ferrylHb radical Hb(Fe^{4+}═O*) state after reaction with H_2O_2, and the radical state is returned to the ferric state by acceptance of two electrons from substrates such as *p*-hydroxyphenylacetic acid (HPA) (*29, 30*). This is a well-known reaction in an H_2O_2 assay method. L-Tyrosine (L-Tyr) dimer or polymer can also be synthesized by an HRP-catalyzed oxidation (*31, 32*). We considered from the above mechanism that if metHb, which has ferric heme like HRP does, could also function as an H_2O_2 elimination enzyme in the presence of L-Tyr as a substrate, then metHb can easily

be prepared from purified Hb for the preparation of vesicles. Moreover, L-Tyr itself is an amino acid with high stability and good cost performance. In this study, we prepared Hb vesicles coencapsulating metHb and L-Tyr, thereby incorporating the metHb elimination system into the Hb vesicles themselves. We then evaluated the effect of this coencapsulation on the suppression of metHb formation. Furthermore, we evaluated the safety of the vesicles in vivo.

EXPERIMENTAL PROCEDURES

Purification of Hb from Red Blood Cells (*19, 33*). Hb was purified from outdated human red blood cells provided by the Japanese Red Cross. The red blood cells were washed three times with saline by centrifugation (2000*g*, 10 min) and concentrated by the removal of the supernatant. They were hemolyzed by the addition of an equal volume of water for injection, and then the stroma were removed by ultrafiltration (cutoff M_w 1000 kDa, Biomax-1000V, Millipore Co., Ltd., Bedford). The ligand exchange from O_2 to CO was carried out for the stroma-free Hb solution by CO gas flowing over the stirred solution. The proteins other than HbCO were denatured by heat treatment at 60 °C for 12 h and removed as precipitates. The HbCO solution was fractionated using ultrafiltration filters with a cutoff molecular weight between 1000 kDa and 8 kDa (Biomax-8V, Millipore), followed by concentration with an 8 kDa ultrafilter.

Reaction of Hb Samples with H_2O_2. HbCO was decarbonylated to HbO_2 by the irradiation of visible light to a liquid film of the Hb solution under O_2 atmosphere; potassium ferricyanide was added to the oxyHb solution to convert the oxyHb to metHb (*34*). The conversion of oxyHb to metHb was 99.9% as measured by the modified Evelyn−Malloy method (*35*). After the mixed solution was stirred at 25 °C for 2 h, the potassium ferricyanide was removed from the resulting metHb solution by gel filtration chromatography on Sephadex G-25 (Pharmacia AB, Uppsala). Deferoxamine mesylate (1.6 mM; DFO, Sigma, St. Louis) and L-Tyr (0 or 1 mM; free base, ICN Biomedicals, Inc., Aurora) were added to the oxyHb or metHb solutions, and these solutions were used as Hb samples. Hb samples ([heme] = 20 μM) were reacted with 200 μM H_2O_2 ([heme]/[H_2O_2] = 1/10 molar ratio) in phosphate buffered saline (PBS, pH 7.4 at 37 °C), and the reaction was monitored by the repetitive scanning of a visible region from 300 to 700 nm at 2 min interval by using a UV−vis spectrometer (V-570, Jasco, Tokyo).

For the measurement of H_2O_2 concentrations, samples were reacted with H_2O_2 under the same conditions and were periodically sampled, and the concentration of H_2O_2 was determined spectrofluorometrically by measuring the amount of 6,6′-dihydroxy-[1,1′-biophenyl]-3,3′-diacetic acid (DBDA; Ex, 317 nm; Em, 405 nm), generated by the HRP-catalyzed reaction of HPA with H_2O_2. The final concentrations of HRP and HPA were 4 μM and 6 mM, respectively, and the DBDA concentration was calculated after separating the Hb samples by centrifugal filtration (cutoff 5 kDa, Ultrafree-MC, Millipore, Bedford) (*19, 29*).

Preparation of the Hb Vesicles Containing metHb and L-Tyr ((metHb/L-Tyr) Hb Vesicles) (*36*). MetHb was prepared by the reaction of HbCO (10 g/dL) with an excess amount of potassium ferricyanide. The unreacted potassium ferricyanide and ferrocyanide were removed by ultrafiltration (cutoff M_w 50 kDa, ADVANTEC, Tokyo) until the concentration of potassium ferricyanide was less than 1 μM by monitoring the absorbance with the UV−vis spectrometer. The metHb solution was concentrated to 40 g/dL using a 50 kDa cutoff filter as noted above. HbCO solutions containing 5 or 10 mol % metHb were prepared by mixing the concentrated metHb solution with a 40 g/dL HbCO solution. Pyridoxal 5′-phosphate (PLP, Sigma, St. Louis, MO) was added to the Hb solution as an allosteric effector at a 2.5 equimolar ratio of PLP to HbCO. The L-Tyr solution prepared previously was added to 0.2 N NaOH, and the resulting solution was added to the HbCO/metHb solution. The final concentrations of Hb and L-Tyr in the HbCO/metHb solution were adjusted to 40 g/dL and 1.0 and 8.5 mM, respectively. To prepare the Hb vesicles, powders of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylchorine (DPPC), cholesterol, 1,5-bis-*O*-hexadecyl-*N*-succinyl-L-glutaminate (DHSG) (Nippon Fine Chemical Co., Osaka), and 1,2-distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-PEG_{5000} (PEG-DSPE, NOF Co., Tokyo) were mixed at a molar ratio of 5:5:1:0.033 and added to the HbCO/metHb solution, and the mixture was stirred at 25 °C for 12 h. The resulting dispersion of the multilamellar vesicles was subsequently extruded through the nitrocellulose membrane filters with a pore size of 0.22 μm (Fuji Film Co., Tokyo) to prepare the Hb vesicles with an average diameter of 261 ± 30 nm. After the separation of unencapsulated Hb by ultracentrifugation (10000*g*, 60 min), the precipitate of the Hb vesicles was redispersed into saline in order to adjust the Hb concentration of the Hb vesicle dispersion to 10 g/dL. HbCO within the vesicles was decarbonized and oxygenated to HbO_2 by irradiation of visible light onto a liquid film under O_2 atmosphere.

Stepwise Injection of H_2O_2 to a Dispersion of (metHb/L-Tyr) Hb Vesicles. A dispersion of (metHb/L-Tyr) Hb vesicles in PBS (pH 7.4) coencapsulating metHb and L-Tyr (metHb/L-Tyr = 2 g/dL:1 mM, 4 g/dL:1 mM, or 4 g/dL:8.5 mM) was incubated with stirring, and H_2O_2 (310 μM, Ultra Pure Grade, Kanto Chemical Co., Tokyo) was injected in stepwise fashion into the solutions at 10 min intervals. Just before each injection, 20 μL of the dispersion of the (metHb/L-Tyr) Hb vesicles was sampled out, and 20 μL of a catalase solution (50 000 unit) was immediately added for the elimination of the remaining H_2O_2. The percentage of metHb in the (metHb/L-Tyr) Hb vesicles was periodically calculated by the ratio of absorbance at 405 nm (metHb) and 430 nm (deoxyHb) in the Soret band using a UV−vis spectrometer without destruction of the Hb vesicles.

Autoxidation of (metHb/L-Tyr) Hb Vesicles. A dispersion of (metHb/L-Tyr) Hb vesicles was incubated and shaken (120 times/min) under pO_2 of 40 Torr at 37 °C. The percentage of metHb in the vesicles was periodically measured with a UV−vis spectrometer.

Measurement of metHb Formation in the Hb Vesicles in Vivo. Wistar rats (body weight: 240−260 g) were anesthetized with diethyl ether, and a preparation of (metHb/L-Tyr) Hb vesicles containing 4 g/dL of metHb and 8.5 mM of L-Tyr was injected into the tail vein (20 mL/kg, n = 6). Blood was withdrawn from the tail vein and centrifuged (12000*g*, 5 min) to collect the vesicle fraction in the supernatant. The percentage of metHb within the vesicles was measured with a UV−vis spectrometer. The number of blood cells was measured with a blood cell counter (Sysmex, KX-21, Kobe).

RESULTS AND DISCUSSION

Reaction of the L-Tyr Containing metHb Solution with H_2O_2. We added H_2O_2 to the metHb solution (5 μM) with or without 1 mM L-Tyr. Figure 1 shows the changes of the H_2O_2 concentration in the metHb solutions with and without L-Tyr. The initial elimination rates of H_2O_2 in the metHb solutions were calculated on the basis of a pseudo-first-order rate law. The elimination rates with and without L-Tyr at 37 °C were 3.0×10^3 and 3.2×10^4 M^{-1} s^{-1}, respectively. The apparent rate constant of the metHb solution containing L-Tyr was about 10 times larger than that with the metHb solution alone, and this

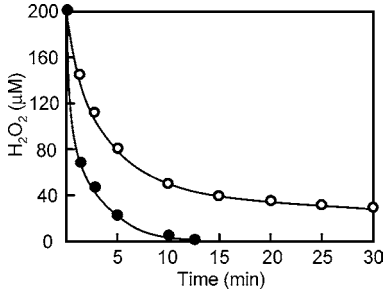

Figure 1. Time course of H_2O_2 elimination by (○) metHb (5 μM) (●) metHb (5 μM) + L-Tyr (1 mM) during the reaction with 200 μM of H_2O_2 at 37 °C.

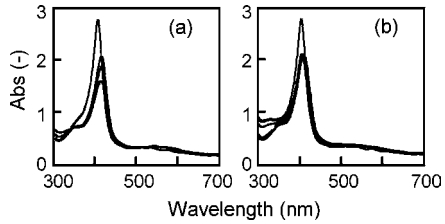

Figure 2. UV−vis spectral changes of (a) a metHb (5 μM) solution and (b) a metHb (5 μM) solution containing L-Tyr (1 mM) during the reaction with 200 μM H_2O_2 ([heme]:[H_2O_2] = = 1/10) at 37 °C. The scanning was performed at 4 min intervals, immediately after the addition of H_2O_2 solution to each Hb solution.

value was estimated to be approximately equal to the 150 units of catalase. Moreover, around 40 μM H_2O_2 remained after a 30 min reaction of 200 μM H_2O_2 in the metHb solution alone, whereas H_2O_2 was completely eliminated within 15 min in the metHb solution containing L-Tyr.

The UV−vis spectral changes during the reaction of H_2O_2 in the metHb solution (5 μM) and the metHb solution containing L-Tyr (1 mM) are shown in Figure 2a and b, respectively. In the case of metHb alone, there was a shift in the spectrum of metHb, namely, the Soret band of metHb (405 nm) was shifted to 417 nm, and the typical metHb peak at 630 nm was completely abolished, which indicated a change to a different form of metHb. There was a time-dependent decrease in peak intensities, indicating the degradation of this intermediate form of Hb during the reaction of H_2O_2. We speculated that this intermediate form of Hb was ferrylHb radical. It has been reported that the ferrylHb radical is formed by the reaction of metHb with H_2O_2 (*37*). Furthermore, the stoichiometry of metHb (5 μM) and the reacted H_2O_2 (200 μM) suggests that the metHb worked as an enzyme such as catalase, although the stability of the enzyme was low and it was degraded. Because the Fenton reaction can be prevented by the addition of DFO, which is a chelator of Fe^{3+}, this enzymatic H_2O_2 elimination was considered to be a pseudo-catalase-like reaction of metHb. Conversely, the metHb solution with L-Tyr showed a fast spectral change and then stayed constant during the reaction, as shown in Figure 2b. Also, the small spectral shift of the metHb solution with L-Tyr suggested that the metHb reacted with H_2O_2 was converted to the ferrylHb radical. The ratio of metHb to ferrylHb should be constant during reaction with H_2O_2. Comparing with the reaction mechanism of peroxidase, where the ferric state is converted to the ferrylHb radical state by the reaction of H_2O_2 to produce H_2O, and then the ferryl radical state is recovered to the ferric state by one-electron oxidation of two substrate molecules to generate another molecule of H_2O, we could compare, in this case, the peroxidase and the substrate to metHb and L-Tyr, respectively. More precisely, we could describe the enzymatic reaction as reverse peroxidation, and the substrate as H_2O_2 where L-Tyr works as an electron donor. Furthermore, we detected L-Tyr dimer (L-Tyr-L-Tyr (diTyr)), which was

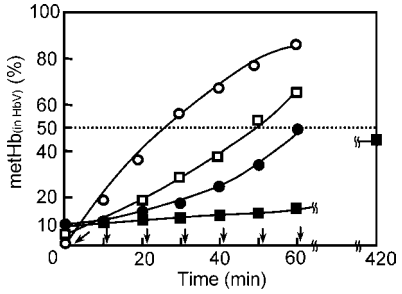

Figure 3. Time course of metHb formation in Hb vesicles at 37 °C during the stepwise addition of H_2O_2 (310 μM) to 5 g/dL Hb vesicle dispersions coencapsulating (●) 4 g/dL metHb and 1 mM L-Tyr, (□) 2 g/dL metHb and 1 mM L-Tyr, (■) 4 g/dL metHb and 8.5 mM L-Tyr, and (○) no metHb and L-Tyr.

produced from the coupling of the two L-Tyr radicals in their ortho position. Such a stable reaction of the unstable ferrylHb radical to metHb by L-Tyr would help the stable elimination reaction of H_2O_2. Therefore, we aimed to construct this system in the Hb vesicles.

H_2O_2 Stepwise Addition to the (metHb/L-Tyr) Hb Vesicles. Figure 3 shows the time course of metHb formation in the conventional Hb vesicles or the (metHb/L-Tyr) Hb vesicles by stepwise injection of H_2O_2 (310 μM) in 10 min intervals. H_2O_2 (310 M) injection to a 5 g/dL conventional Hb vesicle dispersion ([heme] = 3.1 mM) showed an elevation in the metHb percentage with increasing injections of H_2O_2, and the percentage of metHb reached 85% after 60 min (6 injections). However, the (metHb/L-Tyr) Hb vesicles (metHb/L-Tyr = 2 g/dL:1 mM, 4 g/dL:1 mM) showed a significant suppression of metHb formation in the vesicles. The metHb percentages of these Hb vesicles were 67% and 50% after 60 min (6 injections), respectively. Furthermore, by increasing the amount of L-Tyr to 8.5 mM (metHb: 4 g/dL), metHb formation was dramatically suppressed; the percentages were 17% and 45% after 60 and 420 min, respectively (6 and 42 injections, respectively).

From these results, it was confirmed that the formation of metHb from oxyHb by reaction with H_2O_2 was suppressed by the H_2O_2 elimination system of metHb and L-Tyr. Moreover, the persistence of the metHb suppression effect depends on the amount of metHb as an enzyme and L-Tyr as a substrate. The solubility of L-Tyr in pure water is 1.2 mM; however, we succeeded in preparation of an Hb solution containing 8.5 mM L-Tyr by using an alkali solution (NaOH) and the interaction of L-Tyr with highly concentrated Hb molecule (40 g/dL). We succeeded in the construction of Hb vesicles having an H_2O_2 elimination system using Hb only as protein or enzyme.

Autoxidation of the (metHb/L-Tyr) Hb Vesicles. Besides the formation of metHb by H_2O_2, oxyHb is automatically oxidized to metHb, initiated by one-electron reduction of a coordinated dioxygen molecule to generate superoxide anion radical (O_2^{-}*). MetHb formation in vesicles by such autoxidation was measured under the condition of the pO_2 of 40 Torr at 37 °C, because at this pO_2 value, the rate of metHb formation is maximal (*38*). In the conventional Hb vesicles, the percentage of metHb periodically increased by autoxidation of oxyHb in the vesicles. The T_{50} was 13 h, and the metHb percentage reached 90% after 24 h incubation (Figure 4). On the other hand, the metHb formation of the Hb vesicles containing 4 g/dL metHb and 1 mM L-Tyr was effectively suppressed; the T_{50} was 24 h. Furthermore, in the Hb vesicles containing 4 g/dL metHb and 8.5 mM L-Tyr, the percentage of metHb formed was 20% and 43% after 24 and 48 h, respectively, and did not reach 50% when the measurement ended (48 h).

Autoxidation of oxyHb is also an important factor of metHb formation. The autoxidation rate of oxyHb depends on many factors such as the O_2 affinity, P_{50}, the pO_2, temperature, and

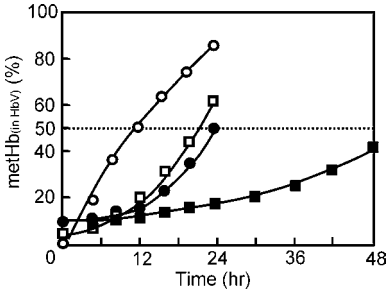

Figure 4. Time course of metHb formation in Hb vesicles under pO_2 of 40 Torr at 37 °C during autoxidation of 5 g/dL Hb vesicle dispersion coencapsulating (●) 4 g/dL metHb and 1 mM L-Tyr, (□) 2 g/dL metHb and 1 mM L-Tyr, (■) 4 g/dL metHb and 8.5 mM L-Tyr, and (○) no metHb and L-Tyr.

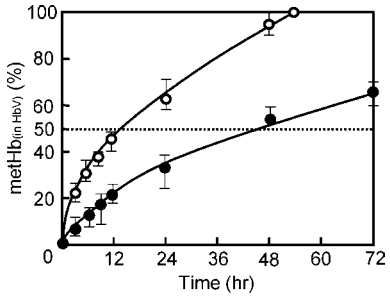

Figure 5. Time course of metHb formation in Hb vesicles injected into Wistar rats (20 mL/kg). Hb vesicles were encapsulating (●) 4 g/dL metHb and 8.5 mM L-Tyr, and (○) no metHb and L-Tyr.

pH. OxyHb molecules in the Hb vesicles are also influenced by these same factors, though the rates could be different from that of the oxyHb solution. The half-life of oxyHb to metHb (T_{50}) in the conventional Hb vesicles (P_{50} = 33 Torr) at 37 °C was about 12 h, shorter than that of the oxyHb solution (T_{50} = 24 h, PBS, pH 7.4). The autoxidation rate of the Hb vesicles containing metHb and L-Tyr was also effectively reduced in a similar way to that observed in the above experiment of H_2O_2 stepwise addition. The reason could be that the autoxidation of oxyHb is additionally influenced by H_2O_2. A superoxide anion radical (O_2^{-}*) generated by the oxyHb autoxidation is spontaneously converted to H_2O_2 in the presence of H^+. This H_2O_2 attacks the other oxyHb molecules. Therefore, the elimination of the H_2O_2 would result in the suppression of the autoxidation rate of oxyHb in the Hb vesicles.

Measurement of metHb Formation in (metHb/L-Tyr) Hb Vesicles in Vivo. Figure 5 shows the percentage of generated metHb after the intravenous injection (20 mL/kg) of the conventional Hb vesicles or the (metHb/L-Tyr) Hb vesicles into the tail vein of Wistar rats (n = 6). The metHb percentages of the conventional Hb vesicles and the (metHb/L-Tyr) Hb vesicles after 4 h were 22% and 18%, respectively, and the T_{50} values were 14 and 44 h, respectively. Furthermore, the Wistar rats were all alive for 72 h after the measurement, at which time they were sacrificed, indicating the safety of this system in vivo. These results confirmed the suppressive effect of metHb formation in vivo using the (metHb/L-Tyr) Hb vesicles.

In a previous study, we coencapsulated catalase to eliminate H_2O_2 generated in vivo, thus suppressing the formation of metHb within Hb vesicles, and we confirmed the suppression of metHb formation (*20*). The T_{50} of the catalase-coencapsulated Hb vesicles was 37 h with a catalase concentration of 4.2×10^4 unit/mL (0.5 g/dL catalase as a protein concentration). We estimated that the concentration of catalase was the amount at the saturation point of T_{50} prolongation, because the same T_{50} was obtained when 5.6×10^4 unit/mL catalase was used for coencapsulation. In comparison with these results, the (metHb/L-Tyr) system was more effective in the suppression of metHb formation by elimination of H_2O_2. It is thought that catalase activity is gradually lost at 37 °C in vivo (*20*), whereas the activity of the (metHb/L-Tyr) system should be very stable at 37 °C, and the amount of L-Tyr (8.5 mM within the Hb vesicle) was sufficient to eliminate H_2O_2 in the Hb vesicles. From these results, the increase of the metHb percentage of the (metHb/L-Tyr) Hb vesicles is likely due to the autoxidation of Hb, which is impossible to suppress in this system.

ACKNOWLEDGMENT

The authors thank Dr. K. Ohta at Oxygenix Co., Ltd., for technical advice about in vivo measurement of (metHb/L-Tyr) Hb vesicles. Endothelial cells play an important role in inflammatory disorders, as they control the recruitment of leukocytes into inflamed tissue and the formation of new blood vessels. Activation of p38MAP kinase results in the production of proinflammatory cytokines and the expression of adhesion molecules. P38MAP kinase inhibitors are therefore considered important candidates for the treatment of inflammatory disorders. In the present study, we propose a novel strategy to counteract these processes by delivery of the p38MAP kinase inhibitor SB202190 into angiogenic endothelial cells. A drug-targeting conjugate was developed by conjugation of SB202190 to human serum albumin (HSA) using a novel platinum-based linker. Specificity for angiogenic endothelial cells was introduced by conjugation of cyclic RGD-peptides via bifunctional polyethylene glycol linkers. The final products contained an average of nine SB202190 and six RGDPEG groups per albumin. The platinum-based linker displayed high stability in buffers and culture medium, but released SB202190 slowly upon competition with sulfur-containing ligands like glutathione. RGDPEG−SB−HSA bound to α_{v3}-integrin expressing endothelial cells (human umbilical cord vein endothelial cells) with low nanomolar affinity and was subsequently internalized. When HUVEC were treated with TNF to induce inflammatory events, pretreatment with RGDPEG−SB−HSA partially inhibited proinflammatory gene expression (IL-8, E-selectin; 30% inhibition) and secretion of cytokines (IL-8, 34% inhibition). We conclude that the developed RGDPEG−SB−HSA conjugates provide a novel means to counteract inflammation disorders such as rheumatoid arthritis.

INTRODUCTION

In chronic inflammatory diseases, endothelial cells are a key player in induction and progression of the disease. Proinflammatory proteins like TNFα and IL-1β induce signaling via p38MAP kinase and NFκB to activate endothelial cells (*1*). The activated endothelial cell excrete cytokines and chemokines (IL-8, IL-6), which in concert with cellular adhesion molecules (P-selectin, E-selectin, VCAM, ICAM) promote leukocyte recruitment and infiltration, and mediate vascular remodeling (*2*, *3*). Signal transduction inhibitors have been developed to interfere with these processes (*4*−*6*), and especially, inhibitors of the p38MAP kinase are considered promising candidates for treatment of chronic inflammation (*7*, *8*). Despite promising results in preclinical inflammation models, most of the p38MAP kinase inhibitors have failed in phase II clinical studies due to unacceptable side effects. Local delivery of the inhibitor to endothelial cells may overcome this problem. Previously, we developed RGD-equipped conjugates that bind to $\alpha_v\beta_3$-integrin and are internalized by endothelial cells (*9*−*11*).

In the present paper, we investigate how activation of endothelial cells can be inhibited by a drug delivery approach, in which the p38MAP kinase inhibitor SB202190 is delivered to angiogenic endothelium. For the purpose of intracellular delivery of SB202190, we designed a macromolecular conjugate of drug, carrier backbone, and homing device (Figure 1). In the past, we succesfully applied the carrier protein human serum albumin (HSA) for drug delivery to the liver (*12*). HSA functions as a natural polymer featuring long circulation times, high biocompatibility, and excellent biodegradability that can be readily modified with drugs and targeting ligands. A novel type of platinum-based linker chemistry was applied to conjugate SB202190 to HSA. This linker, which has been named universal linkage system (ULS), binds SB202190 via a coordination linkage at the pyridyl nitrogen of SB202190 (Figure 2), and another coordination bond is formed with methionine or histidine

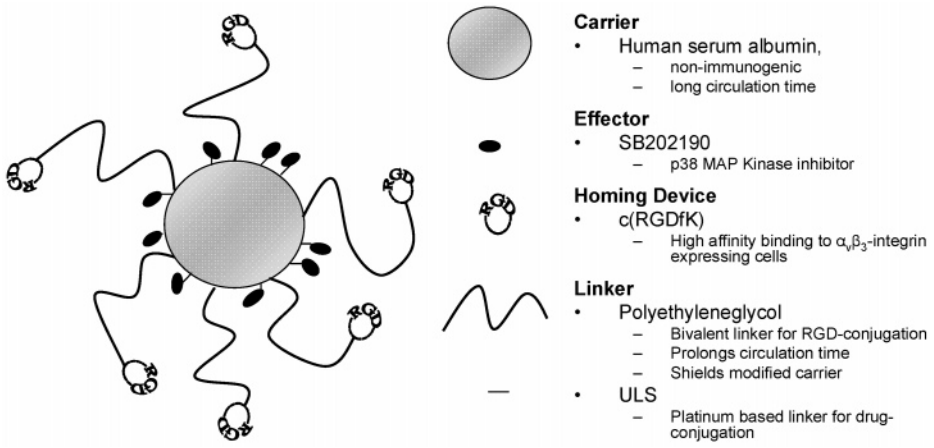

Figure 1. Schematic presentation of drug-targeting construct.

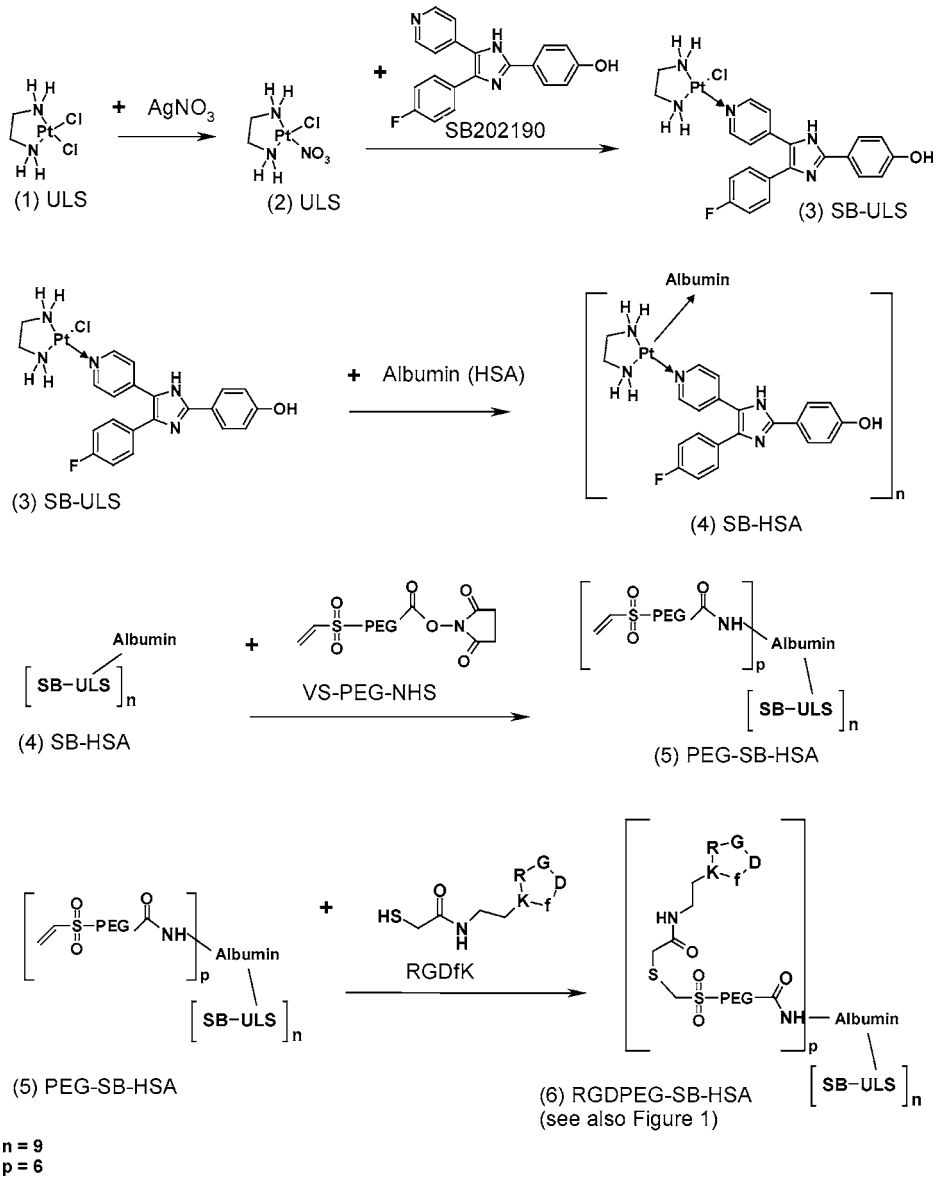

Figure 2. Reaction scheme for synthesis of RGDPEG−SB−HSA.

residues of the carrier (*13*). The stability and release properties of SB−ULS−HSA are reported in this study.

To infer specificity for angiogenic endothelial cells, we attached RGD-peptide targeting ligands to SB−HSA via bivalent 3.5 kDa PEG linkers. These PEG linkers will shield the modifications in the albumin, and thereby will prevent nonspecific uptake, prolong circulation times, and even might lead to passive retention in the leaky vasculature in inflamed tissue (*14*). The appended targeting ligand, cyclic RGDfK pentapeptide, is known to bind with high affinity and specificity to $\alpha_v\beta_3$-integrin, which is expressed in high amounts on angiogenic endothelium (*15*, *16*). Excessive angiogenesis is part of the pathology of

chronic inflammatory disease like rheumatoid arthritis or Crohn's disease. Expression of $\alpha_v\beta_3$-integrin is minimal on resting endothelial cells and highly limited in other healthy tissue. Significant amounts of $\alpha_v\beta_3$-integrin have only been found in osteoclasts (*17*). The restricted expression profile of endothelial cells makes it an ideal target for drug delivery purposes. Moreover, the endothelium is in direct contact with the systemic circulation, which renders these target cells easily accessible for macromolecules and particulate delivery systems. Vascular targeting strategies are therefore an exciting option for therapeutic intervention in chronic inflammation (*18*).

We now report on the synthesis and characterization of the RGDPEG−SB−HSA conjugate. The targeting potential of the product was evaluated on human umbilical cord vein endothelial cells (HUVEC), and pharmacological effects of the delivered drug were studied by its effects on the expression of TNFα-induced gene expression and cytokine secretion.

MATERIALS AND METHODS

Synthesis and Purification of RGDPEG−SB−HSA Conjugate. *Synthesis of SB−ULS. Cis*-[Pt(ethylenediamine)nitrate-chloride] (referred to as ULS, KREATECH Biotechnology, Amsterdam, The Netherlands) was synthesized by reacting *cis*-[Pt(ethylenediamine)dichloride] in *N*,*N*′-dimethylformamide (5 mg/mL) with 1 molar equiv of $AgNO_3$ (51 mM in *N*,*N*′-dimethylformamide (DMF)). Precipitated silver chloride was removed by centrifugation. SB202190 ((4-(fluorophenyl)-2-(4-hydroxyphenyl)-5-(4-pyridyl)-1*H*-imidazole, obtained from L.C. Laboratories, Woburn, MA) was dissolved in DMF at a concentration of 10 mg/mL. Then, 440 μL of the ULS solution (5.18 μmol) was added to 180 μL of the SB202190 solution (5.43 μmol). The resulting solution was heated at 37 °C for 3 h, and the reaction was followed by analytical HPLC using a Luna2 C18 column that was maintained at 40 °C. The mobile phase consisted of a binary solvent system of triethylammonium acetate (100 mM pH 5.0)/acetonitrile 90:10 (solvent A) and triethylammonium acetate (100 mM pH 5.0)/acetonitrile 70:30 (solvent B). The column was eluted at a flow rate of 1.1 mL/min. Compounds were eluted at a stepwise gradient (0% B from 0−4 min; 0−46% B from 4−17 min; 46−100% B from 17−19 min; 100% B from 19−25 min; 100−0% B from 25−27 min; 0% B from 27−34 min). SB202190 eluted at 14.7 min (33.6% B) and SB−ULS eluted earlier (21.8% B). After the reaction was completed, the mixture was evaporated to dryness under reduced pressure, affording a pale yellow solid (yield 92%). SB202190−ULS was analyzed by HPLC ^{1}H NMR and electronspray mass spectrometry.

^{1}H NMR of free SB202190 (CD_3OD): δ_H 6.88 (d, $J = 8.74$ Hz, 2H, $F(CHCH)_2$), 7.17 (m, 2H, $N(CHCH)_2$), 7.50 (m, 4H, $(CHCH)_2OH$), 7.82 (d, $J = 8.68$ Hz, 2H, $F(CHCH)_2$), 8.41 (m, 2H, $N(CHCH)_2$) ppm.

^{1}H NMR of SB202190−ULS (CD_3OD): δ_H 2.59 (m, 4H, $H_2N(CH_2)_2NH_2$), 5.58 (s, 2H, NH_2), 5.91 (s, 2H, NH_2), 6.89 (d, $J = 8.75$ Hz, 2H, $F(CHCH)_2$), 7.22 (m, 2H, $N(CHCH)_2$), 7.53 (m, 4H, $(CHCH)_2OH$), 7.82 (d, $J = 8.73$ Hz, 2H, $F(CHCH)_2$), 8.52 (m, 2H, $N(CHCH)_2$) ppm.

Mass spectrometry of SB202190−ULS (ESI^+): Theoretical mass *m*/*z* of SB−ULS: 620.97 [M]. Detected masses *m*/*z*: 622 $[M + H]^+$, 585 $[M - Cl^- - H^+]^+$.

Starting material of ULS was consumed completely, and formation of a new compound was observed by HPLC analysis. This new peak was SB−ULS as confirmed by LC-MS. SB−ULS was used without further purification in the next reaction step.

Synthesis of SB−ULS−HSA. HSA (22 mg, 325 nmol) was dissolved in 1 mL of 20 mM tricine−NaOH/$NaNO_3$ buffer pH 8.5. SB202190−ULS (3250 nmol) was added in tenfold molar excess, and the mixture was reacted for 24 h at 37 °C, after which nonreacted SB−ULS was removed by dialysis against PBS at 4° C using Slide-A-Lyzer dialysis cassettes (MWCO 10 000 Da, Pierce). The product was sterilized by filtration via a 0.2 μm filter and stored at −20 °C. Conjugation of SB−ULS to the protein was verified by UV analysis at 364 nm. SB−ULS−HSA displayed a specific absorbance at this wavelength ($\epsilon = 13\,955\ M^{-1}\ cm^{-1}$), not found in HSA. SB−ULS−HSA was furthermore characterized for protein content, drug content, and platinum linker content as described below.

Synthesis of RGDPEG−SB−HSA. In the final reaction step, SB−ULS−HSA was modified with PEG and RGD−peptide. SB−ULS−HSA (147 nmol) dissolved in PBS was incubated with a 50-fold molar excess of vinylsulfone−polyethylene glycol−*N*-hydroxysuccinimide ester (VNS−PEG−NHS; Nektar, Alabama; 3.5 kDa, 20 mg/mL in water, 7.39 μmol), which was added dropwise. The mixture was protected from light with aluminum foil and incubated for 1 h at room temperature while gently shaking on a spiramix. Meanwhile, the RGD-peptide c(RGDf(ϵ-*S*-acetylthioacetyl)K) (Ansynth Service, Roosendaal, The Netherlands) was dissolved at 10 mg/mL in a 1:4 acetonitrile/water mixture. The peptide (8.085 μmol) was added dropwise to the reaction mixture in a 55-fold molar excess, after which hydroxylamine was added to a final concentration of 50 mM. Reactions were carried out overnight at room temperature while protecting from light. Remaining VNS groups were quenched by addition of cysteine (8.085 μmol; equivalent to the amount of RGD-peptide), after which the product was dialyzed against PBS, and finally purified by size exclusion chromatography (SEC) on a Superdex200 column on an Äkta System (GE Healthcare, Uppsala, Sweden) using PBS at 0.5 mL/min as the mobile phase. Eluting peaks were monitored simultaneously at 214, 280, and 364 nm. The final products RGDPEG−SB−HSA and RADPEG−SB−HSA were stored at −20 °C. The control conjugate RADPEG−SB−HSA was prepared according to the same protocol with a c(RADf(ϵ-*S*-acetylthioacetyl)K) peptide.

Characterization of RGDPEG−SB−HSA. Protein content was evaluated using BCA protein assay kit (Pierce). Free drug and conjugated drug content were analyzed by isocratic HPLC using a Waters system (Massachusetts) with a C18 μBondapak column and a UV detector operating at 254 nm. SB202190 was eluted with a mixture of water/acetonitrile/trifluoroacetic acid 20/80/0.1 at 1 mL/min. The absence of free SB202190 and SB−ULS in the drug-targeting preparation was determined by analysis of PBS diluted samples (retention times: SB202190, 8.7 min; SB-ULS, 11 min). The amount of SB202190 conjugated to the carrier was determined after release of the drug by overnight incubation with 0.5 M KSCN in PBS at 80 °C. The cooled samples were injected into the HPLC without further sample pretreatment or stored at −20 °C for later HPLC analysis.

The ULS-linker content was evaluated by inductive coupled plasma atomic emission spectroscopy (ICP-AES) at the specific wavelengths of platinum (214.424 and 265.945 nm) on a VISTA AX CCD Simultaneous ICP-AES (Varian, Palo Alto, CA). Standard solutions were made with cisplatin, and yttrium was used as internal standard (360.074 nm).

Intermediate and final products were subjected to analytical SEC to reveal increases in size, purity, and grade of aggregation.

SDS-PAGE (12% ready gels in a mini-Protean II system; Bio-Rad, Veenendaal, The Netherlands) followed by Western blot detection with an in-house-prepared anti-RGD antiserum was performed to detect the presence of RGD-peptide conjugated to the PEGylated albumins (*9*). Duplicate gels were either stained for protein (Coomassie Brilliant Blue staining) or blotted on a PVDF membrane (Roche, Mannheim, Germany). The

membrane was blocked with bovine serum albumin (BSA) and subsequently incubated with rabbit anti-RGD antiserum. The signal was amplified with a polyclonal goat anti-rabbit IgG conjugated with horseradish peroxidase (GARPO, DAKO). Peroxidase was visualized by incubation with 3-amino-9-ethylcarbazole (AEC, Sigma).

The grade of PEGylation was accurately determined by MALDI-TOF analysis using a Voyager-DE PRO workstation (Applied Biosystems). HSA, SB−HSA, and RGDPEG−SB−HSA were dissolved at a concentration of 1 mg/mL in 50:50:0.1 methanol/water/acetic acid. A 1 μL aliquot was mixed with 1 μL of matrix (20 mg/mL sinapinic acid in 60:40:0.1 water/acetonitrile/trifluoroacetic acid), transferred onto a stainless steel sample holder, and dried before being introduced into the mass spectrometer. Mass spectra were obtained by averaging the signals from 100 laser shots. Spectra were calibrated using BSA as a control. MALDI-TOF analysis of BSA provided, among others, signals of single-charged monomeric BSA and of the single-charged dimer of BSA. Our products displayed masses that were inbetween these two calibration peaks. The number of RGDPEG groups bound per albumin was calculated from the averaged masses of the products.

Stability and Drug Release Properties of the SB−ULS Linkage. Appropriately diluted aliquots of SB−ULS−HSA (40 μM) were incubated for 24 h at 37 °C with different matrices to investigate the stability of the conjugate and its drug-releasing properties. Studied matrices were PBS (pH 7.4), 0.1 M sodium acetate buffer (pH 5.0), PBS or acetate buffer spiked with either 5 mM glutathione (GSH) or with 5 mM dithiothreitol (DTT), and endothelial cell (EC) medium containing 20% FCS. Complete release of SB202190 was effected by overnight incubation with 500 mM KSCN at 80 °C. 35 μL of the resulting solutions and standard solutions were treated with 100 μL of acetonitrile (3:1 v/v), vortexed, and centrifuged for 10 min to precipitate proteins. The clear supernatant was subjected to isocratic HPLC analysis as described above.

Cells. HUVEC were obtained from the UMCG Endothelial Cell Facility (*19*). Primary isolates were cultured in 1% gelatin-coated tissue culture flasks or culture wells (Corning, Costar, The Netherlands) at 37 °C under 5% CO_2/95% air. The culture medium, hereafter referred to as EC medium, consisted of RPMI 1640 (BioWittaker, Verviers, Belgium) supplemented with 20% heat-inactivated fetal calf serum (Integro, Zaandam, The Netherlands), 2 mM L-glutamine (Invitrogen, Breda, The Netherlands), 5 U/mL heparin (Leo Pharmaceutical Products, Weesp, The Netherlands), 100 U/mL penicillin (Yamanouchi Pharma, Leiderdorp, The Netherlands), 100 g/mL streptomycin (Radiumfarma-Fisiopharma, Italy), and 50 μg/mL endothelial cell growth factor supplement extracted from bovine brain. After attaining confluence, cells were detached from the surface by trypsin/EDTA (0.5/0.2 mg/mL in PBS) treatment and split into 1:3 ratio. Cells were used up to passage four.

Binding and Uptake of RGDPEG−SB−HSA to HUVEC. Binding affinity of RGDPEG−SB−HSA for target cells was determined by competitive binding studies with ^{125}I-labeled echistatin as $\alpha_v\beta_3$-integrin specific radioligand (*20*). Echistatin was radiolabeled using the chloramine T method (*21*). On the day of the experiment, ^{125}I-echistatin was purified using a PD-10 column (GE Healthcare). Confluent monolayers of HUVEC in 24-well plates (Costar) were incubated with 100 000 cpm ^{125}I-echistatin in the presence of serial dilutions of RGDPEG−SB−HSA in binding buffer (50 mM Tris−HCl, pH 7.4, 150 mM NaCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mM $MnCl_2$, and 1% BSA) at 4 °C for 4 h (*10*). Subsequently, the supernatant was harvested, and cells were washed three times with binding buffer and lysed with 1 M NaOH. Radioactivity was counted in a Packard RIASTAR multiwell gamma counter (GMI, Minnesota). Data were analyzed by nonlinear regression using the GraphPad Prism program (GraphPad Software).

To determine the specificity of RGDPEG−SB−HSA binding and its uptake by target cells, HUVEC were incubated with ^{89}Zr-radiolabeled RGDPEG−SB−HSA. For radiolabeling, 3.73 nmol RGDPEG−SB−HSA was mixed with 18.6 nmol of the chelator TFP−*N*-succinyldesferal−Fe(III) (desferal) (*22*) in 0.1 M $NaHCO_3$, pH 8.5. After an incubation period of 30 min, the reaction mixture was purified on a Hitrap desalting column (GE Healthcare). The conjugation of desferal to the product was confirmed by measurement of its UV absorbance at 430 nm. Fe(III) was replaced with radioactive ^{89}Zr (supplied by Cyclotron BV, Amsterdam) as described (*22*), but the incorporation of zirconium was performed at pH 6.8 and the product was purified using a centricon column (Millipore, Billerica, MA). Radiochemical purity was 96% as determined by trichloroacetic acid precipitation, and specific activity was 740 000 cpm/μg. Specificity of binding was studied by incubating confluent HUVEC layers (24 well plates) with 70 000 cpm ^{89}Zr−RGDPEG−SB−HSA in the presence of an excess of different competitors at 4 °C for 4 h, while uptake was studied by incubating the cells with 70 000 cpm ^{89}Zr−RGDPEG−SB−HSA at 37 °C for 4 h and 8 h. Supernatant and cell-associated radioactivity was harvested as described above, and radioactivity was counted on a 1282 COMPUGAMMA CS (Perkin-Elmer, Boston, MA).

Effect of RGDPEG−SB−HSA on Cell Viability. Platinum-related toxicity of RGDPEG−SB−HSA and ULS-containing intermediate products was evaluated by incubating HUVEC cells for 3 days with EC medium spiked with RGDPEG−SB−HSA (100 μg/mL), SB−ULS (100 μM), ULS (100 μM), or cisplatin (100 μM). The effect on cell proliferation and viability was detected by MTS assay (Promega) according to the manufacturer's protocol.

Effect of RGDPEG−SB−HSA on Inflammatory Events. Effect of targeted SB202190 on transcription and translation of inflammatory genes and proteins was evaluated using quantitative real time PCR (rtPCR) and enzyme-linked immunosorbent assay (ELISA) as described (*23*). In short, confluent monolayers of HUVEC in 12-well plates were incubated with EC medium spiked with RGDPEG−SB−HSA conjugate, RAD-containing control conjugate, free drug, RGDPEG−HSA without drug or an equivalent volume of PBS. After 24 h, the cells were activated by the addition of 5 ng TNFα. After an additional 24 h, medium was harvested, and cells were lysed for RNA isolation (Absolutely RNA Microprep Kit, Stratagene, CA). The amount of isolated RNA was quantified by NanoDrop according to the manufacturer's protocol. Equal amounts of RNA were translated to cDNA by SuperScript III First-Strand Synthesis System (Invitrogen). cDNA was diluted to 10 ng/μL concentration after RT reaction. Exons overlapping primers and Minor Groove Binder (MGB) probes used for RT-PCR were purchased as Assay-on-Demand from Applied Biosystems (Niewekerk a/d IJssel, The Netherlands). Expression levels of human IL-8, E-selectin, and GAPDH were evaluated by RT-PCR on an ABI Prism 7900HT sequence detection system (Applied Biosystems).

Harvested HUVEC supernatants were analyzed for IL-8 production by ELISA using a MoAb.anti-IL-8 (R&D Systems, Minneapolis, MN). The signal was amplified by a biotinylated secondary antibody (polyclonal swine anti-human IL-8; R&D) followed by streptavidin-E+ (CLB, Amsterdam, The Netherlands). Color development was performed using tetramethylbenzidine (Roth, Karlsruhe, Germany) as substrate for the peroxidase.

Statistical Analysis. Statistical analysis was performed using Student's two-tailed *t*-test, assuming equal variances. Difference were considered to be significant when $p < 0.05$ unless otherwise stated.

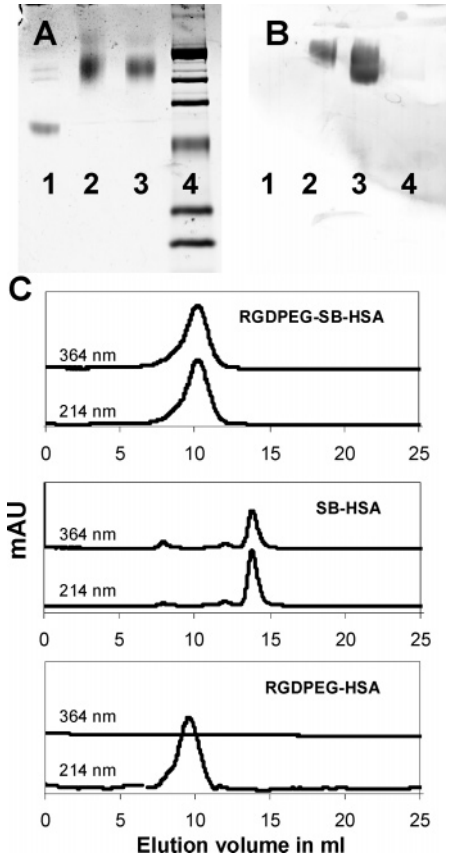

Figure 3. Characterization of RGDPEG−SB−HSA demonstrated successful introduction of SB202190, PEG, and RGD peptide. SDS-PAGE stained for protein with CBB (A) and Western blot with anti RGD antibody (B) of the same gel give proof of RGD-conjugation. The gel shows SB−HSA (1), RGDPEG−SB−HSA (2), RGDPEG−HSA (3), and molecular size marker (4). Size exclusion chromatography (C) demonstrated an increase in size of RGDPEG−SB−HSA compared to SB−HSA detected at 214 nm (bottom line of each graph) due to introduced PEG. SB−ULS absorbed also at 364 nm (upper line of each graph), which is indicative of conjugated SB202190. This peak was detected for RGDPEG−SB−HSA and SB−HSA but not for RGD-PEG−HSA.

RESULTS

Preparation and Characterization of RGDPEG−SB−HSA. We applied a novel type of drug linker to couple SB202190 to our albumin carrier (Figure 2). The ULS linker provided a rapid and straightforward alternative to conventional linkers for conjugation of SB202190. The synthesis of SB−ULS−HSA proceeded at an overall yield of 80% over the combined synthesis steps. In contrast, we also studied the conjugation of SB202190 via ester or carbamate linkages at the hydroxyl group of the drug, which eventually led to products at low yield and undesired fast drug release rates in serum (Prakash et al., submitted).

The first synthesis step between SB202190 and the linker yielded the desired 1:1 SB−ULS species as confirmed by mass spectrometry analysis. ^{1}H NMR studies indicated that binding of SB202190 took place via coordination of the N-donor of the pyridine ring, because only the protons of the pyridyl ring were shifted with the more prominent shift for the protons closest to the nitrogen (8.41 ppm to 8.52 ppm). Additionally, peak splitting was observed for these protons typical for an extra paramagnetic group like platinum. Conjugation of SB−ULS to HSA was confirmed by several techniques. First, the absorbance of SB−ULS at 364 nm was detectable in the SB−HSA product peak, while unmodified albumin had no UV absorption at this wavelength. Monitoring of the 364 nm absorbance also confirmed that SB−ULS remained attached to the carrier during subsequent PEGylation and purification procedures (Figure 3). Second, the drug load of SB−HSA was determined by release of the drug and subsequent HPLC detection (Table 1), and the number of ULS groups attached to the protein was determined by ICP-AES Pt analysis. Both analyses yielded similar numbers of conjugated SB/HSA and ULS/HSA, illustrating that SB202190 was bound to HSA via ULS. Free SB or SB−ULS levels in the conjugate were below the detection limit of the HPLC method (>0.3%).

The SB−HSA product was modified with RGD peptides via a 3.5 kDa PEG linker. Successful PEGylation and purity of the product was shown by size exclusion chromatography (SEC, Figure 3). SEC also revealed the absence of aggregates. Final proof of binding of the RGD peptide to the distal end of the PEG-linker was given by SDS-PAGE and Western blot with an anti-RGD antibody (Figure 3). The molecular weight (MW) of the products was determined by MALDI-TOF analysis, and differences in MW were used to calculate the number of RGDPEG bound per albumin (Table 1). On average, SB−ULS−HSA was modified with 6.3 RGDPEG/HSA, while 7.1 RGD-PEG/HSA were bound to parental HSA.

SB202190 is Released via Competition with Sulfur Donors. We studied the stability and release properties of the novel SB−ULS−HSA conjugate in different conditions. All incubations were performed at 37 °C for 24 h (Figure 4). Only minimal drug release was observed in buffers or culture medium containing 20% serum, indicating the high stability of the SB202190−ULS linkage. However, addition of thiols like GSH and DTT accelerated the release of the drug. Complete release of the drug could be effected by incubating the conjugate at 80° C with a large excess of the thiocyanate (data not shown). Since thiols are preferred ligands for platinum, competitive displacement seems a likely release mechanism. These results are in good agreement with prior studies in our group with other drug−ULS−albumin (*24*). Changing the pH from 7.4 (cytosolic) to pH 5.0 (lysosomal) gave a reduction in drug release by DTT, while GSH-induced release was not affected.

RGDPEG−SB−HSA Binds via $\alpha_v\beta_3$-Integrin to Target Cells and Is Internalized. Binding constants of RGDPEG−SB−HSA for target cells have been evaluated in competition experiments with the known $\alpha_v\beta_3$-integrin ligand ^{125}I-echistatin as shown in Figure 5A. The RGDPEG−SB−HSA conjugate demonstrated a higher affinity for $\alpha_v\beta_3$-integrin (IC_{50} = 71.4 nM; Table 2) compared to the single peptide (IC_{50} = 383 nM), but a lower affinity than RGDPEG−HSA (IC_{50} = 11.7 nM), which had been equipped with a higher amount of RGD groups.

Table 1. Characterization of Drug Targeting Conjugates (n.a., not applicable; n.d. not determined; −, negative; +, positive)

	number of SB bound per HSA[a]	number of ULS bound per HSA[a]	number of RGDPEG bound per HSA[b]	MW in kDa[b]	Western blot for RGD[b]
SB−HSA	9.1	7.8	n.a.	69.2	−
RGDPEG−SB−HSA	9.6	8.0	6.3	95.2	+

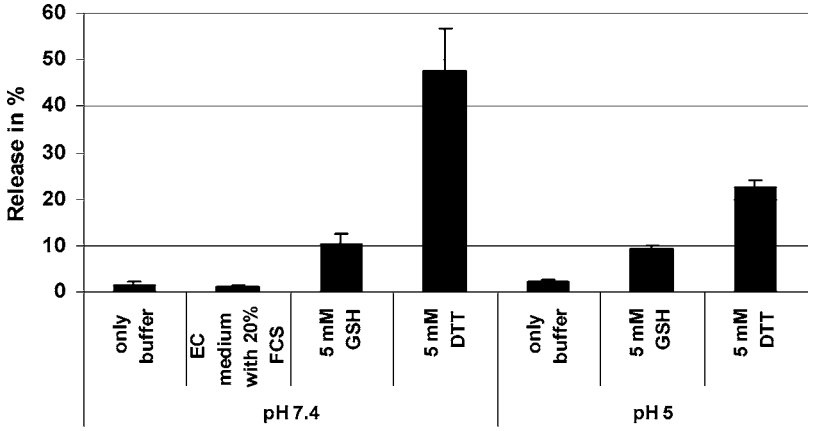

Figure 4. Release of SB202190. SB−ULS−HSA was incubated for 24 h at 37 °C with 5 mM GSH or DTT at pH 5 in acetic acid buffer or at pH 7.4 in PBS and in endothelial cell medium with 20% FCS. Released drug was determined by HPLC.

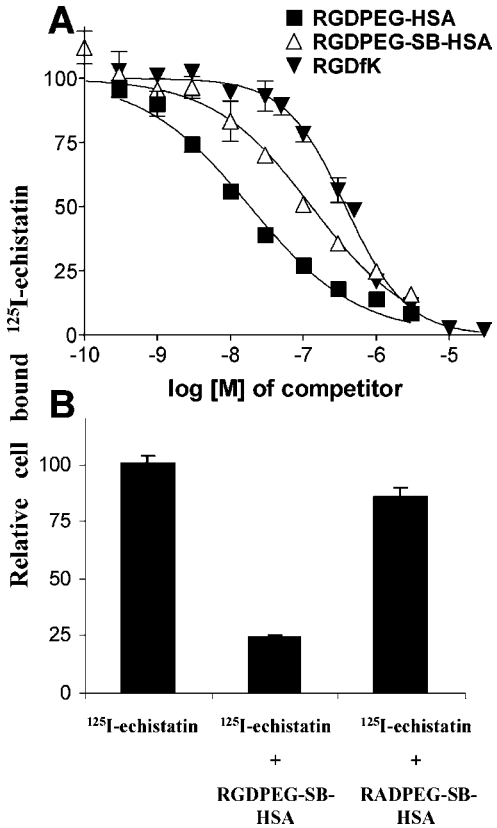

Figure 5. Binding properties of RGDPEG−SB−HSA. (A) shows competitive displacement of ^{125}I-echistatin with RGDPEG−HSA (squares), RGDPEG−SB−HSA (open triangles), and RGDfK (closed triangles). (B) demonstrates displacement of ^{125}I-echistatin by RGD-PEG−SB−HSA but not by control conjugate RADPEG−SB−HSA, both at 1 μM.

Table 2. IC_{50} of Binding to $\alpha_v\beta_3$-Integrin and the Fold Increase in Affinity Compared to the Single Peptide

	IC_{50} in nM	fold increase in affinity
RADfK	>10 000	−
RADPEG−SB−HSA	>3000	−
RGDfK	383	1
RGDPEG−SB−HSA	71.4	5.4
RGDPEG−HSA	11.7	33

RADPEG−SB−HSA could not displace ^{125}I-echistatin at any of the concentrations tested (Figure 5B).

We also studied binding and uptake of ^{89}Zr−RGDPEG−SB−HSA by endothelial cells. ^{89}Zr, captured by the chelator desferal, is highly stable, and its hydrophilicity will entrap it inside cells after degradation of the carrier (*25*, *26*). Since this will prevent redistribution of the radiolabel, Zr−desferal is an ideal label for uptake studies. We attached an average of 1.7 desferal groups/HSA, which were subsequently loaded with ^{89}Zr. Such a relatively minor modification will not affect the binding of RGDPEG−SB−HSA to target cells, as was also demonstrated by comparing the binding of ^{125}I and ^{89}Zr-labeled RGDPEG−SB−HSA (data not shown). Furthermore, the extended nature of the RGDPEG ligand will prevent steric interactions between radiotracer and RGD groups.

^{89}Zr−RGDPEG−SB−HSA was incubated at 4 °C and 37 °C with HUVEC. ^{89}Zr−RGDPEG−SB−HSA binding to $\alpha_v\beta_3$-expression HUVEC could only be blocked by excess of RGD peptide but not by excess of SB−HSA (Figure 6A). This proved that binding was solely mediated by the introduced RGD peptide. Cell-associated activity was increased when incubation were carried out at 37 °C and could be further increased with prolonged incubation times (Figure 6B). This indicated active uptake of RGDPEG−SB−HSA into endothelial cells.

RGDPEG−SB−HSA Is Not Toxic to Endothelial Cells. RGDPEG−SB−HSA, SB−ULS, and free ULS tested at 100 μM did not influence the proliferation and viability of HUVEC (Figure 7). In the same concentration, cisplatin eradicated all cells, suggesting that both monofunctional ULS derivatives as well as bifunctional ULS mononitratemonochloride are not toxic, whereas cisplatin (bifunctional) is.

Effect of RGDPEG−SB−HSA on Activated HUVEC. The anti-inflammatory effects of the conjugate were investigated in TNF-activated HUVEC. TNFα induced a 20-fold upregulation in gene expression of hIL-8 and 200-fold upregulation of hE-selectin (Figure 8). Free SB202190 inhibited this upregulation up to 50%, which is in agreement with previous studies (*23*). RGDPEG−SB−HSA was tested at 21 μg/mL and 70 μg/mL, which corresponds to a drug concentration of 3 μM and 10 μM, respectively. Significant down-regulation of the studied genes was observed in all conditions, except for hE-selectin when cells were incubated with a low concentration of RGDPEG−SB−HSA. Expression of both genes was reduced for approximately 30% compared to the TNF-activated control cells ($p < 0.01$). RGDPEG−HSA, i.e., carrier without drug, and nontargeted conjugate RADPEG−SB−HSA demonstrated no inhibitory effect. RGDPEG−HSA showed even a slight upregulation of the tested genes, especially when given in the higher dose.

Similar inhibitory effects of the delivered drug were observed when IL-8 secretion in the culture medium was analyzed (Figure 9). RGDPEG−SB−HSA at both concentrations reduced the IL-8 secretion by 18% and 34% as compared to untreated cells

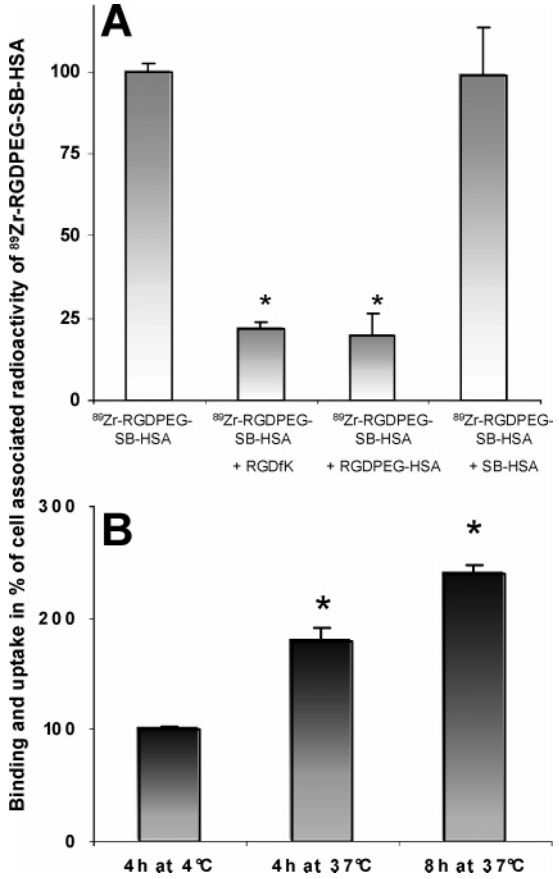

Figure 6. RGDPEG−SB−HSA binds via the introduced RGD moiety to target cells and is internalized. (A) ^{89}Zr−RGDPEG−SB−HSA was incubated with a confluent HUVEC monolayer. The addition of high excess of different competitors (RGDfK, 20 μM; RGDPEG−HSA, 1 μM; SB−HSA, 1 μM) demonstrated that RGDPEG−SB−HSA only bound via the RGD-peptide. (B) HUVEC were incubated with ^{89}Zr−RGDPEG−SB−HSA at 4 and 37 °C for 4 and 8 h to determine uptake of the drug-targeting conjugate. *$p < 0.01$ compared to no competitor in (A) and to 4 °C in (B).

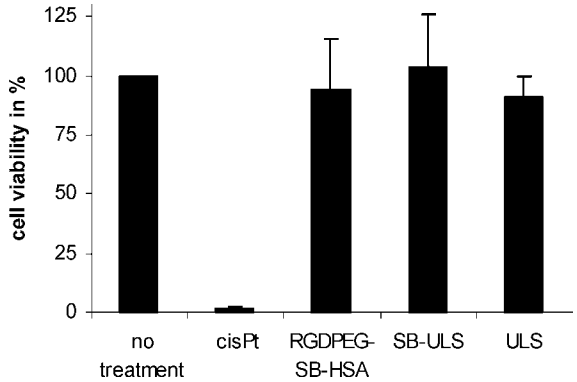

Figure 7. RGDPEG−SB−HSA and ULS containing conjugates displayed no toxicity for endothelial cells. RGDPEG−SB−HSA (100μg/mL), SB−ULS, ULS, or cisplatin (all at 100 μM) were added to EC medium and incubated for 3 days. Cell viability was assessed in comparison to nontreated control cells (=100% viability) using MTS assay.

($p < 0.01$). Control conjugates did not decrease levels of IL-8 in the medium.

DISCUSSION

In the present study, we developed an endothelial-directed conjugate for cell-specific intracellular delivery of SB202190, a potent p38MAPK inhibitor (Figure 1). We applied a novel

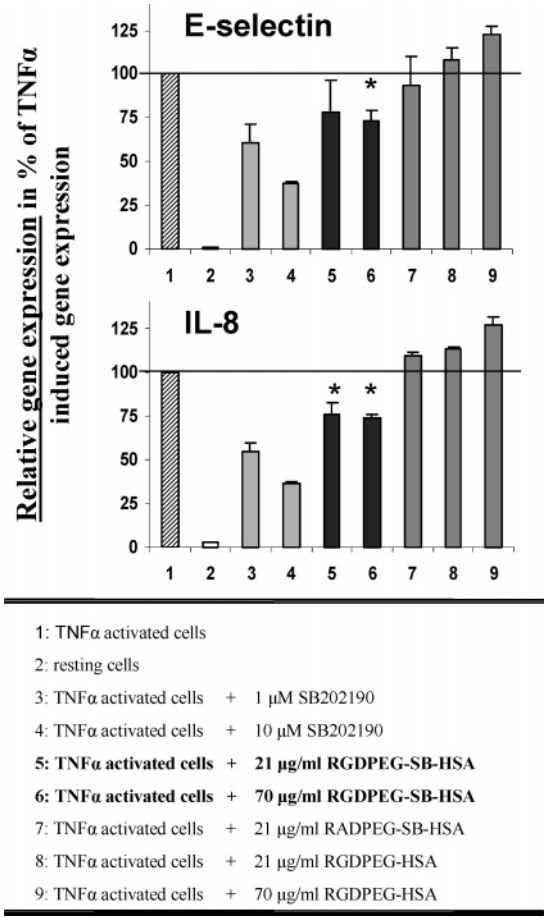

Figure 8. RGDPEG−SB−HSA delivered active SB202190 into target cells. HUVEC were preincubated with drug, drug-targeting conjugate, and control conjugates for and 24 h, after which TNFα was added. RNA was harvested after an additional 24 h of incubation. Gene expression levels of hE-selectin and hIL-8 as determined by qRT-PCR are shown. Light gray bars represent free drug, black bars represent drug-targeting conjugate, and dark gray bars represent different control conjugates. 21 μg/mL of RGDPEG−SB−HSA equals 3 μM SB202190 and 70 μg/mL equals 10 μM drug. $p < 0.01$ compared to respective control conjugates and to TNFα-treated control.

type of platinum linker for coupling of SB202190 to albumin, which provided a straightforward and robust coupling method (Figure 2). The conjugation of ULS with SB202190 took place by formation of a coordinative bond between the nitrogen of the pyridine and the Pt atom. Since aromatic nitrogens are present in many drug structures, our approach is applicable to many other drugs besides SB202190. We have recently reported on a similar linkage approach for the delivery of pentoxifyllin to hepatic stellate cells (*24*), and several other conjugates are under investigation.

We assume that the drug−ULS adduct binds to HSA by coordination to sulfur-containing residues, mostly methionine, but also with histidine residues as demonstrated earlier for other Pt(II) compounds (*27*, *28*). Our hypothesis that SB−ULS preferably binds to sulfur groups in the carrier is supported by the finding that pentoxifyllin−ULS/albumin conjugation ratios increased when HSA was first modified with a thiocarbonyl-containing targeting ligand (*24*). Similarly, elevated drug−ULS/carrier ratios were found when the kidney-selective carrier lysozyme was modified with extra methionine groups (J. Prakash et al., submitted). HSA contains only six methionine residues, which are not exposed at the protein surface. The hydrophobic character of SB−ULS will allow its binding to methionines in the core of HSA. As the number of SB−ULS per HSA exceeded

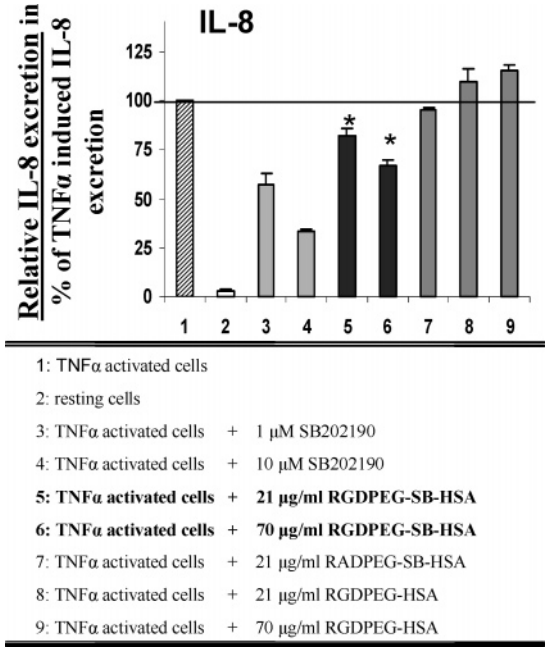

Figure 9. RGDPEG−SB−HSA treatment reduced the excretion of IL-8. HUVEC were preincubated with drug, drug-targeting conjugate, and control conjugates, and 24 h later, TNF was added. Medium was harvested after an additional 24 h of incubation. Relative levels of hIL-8 as determined by ELISA are depicted in the graph. Light gray bars represent free drug, black bars represent drug-targeting conjugate, and dark gray bars represent different control conjugates. 21 μg/mL of RGDPEG−SB−HSA equals 3 μM SB202190 and 70 μg/mL equals 10 μM SB202190. $p < 0.01$ compared to respective control conjugates and to TNFα-treated control.

the number of available methionines, it seems likely that SB−ULS is also bound to histidine or cysteine residues.

We assume that SB202190 needs to be released from the linker to exert therapeutic effects, since the pyridyl ring of SB202190 to which ULS is bound is also interacting with the ATP pocket of the p38 MAP kinase. Release of SB202190 was triggered by competition with sulfur ligands like glutathione at intracellular concentration. We have found the same release mechanism for other drug−ULS conjugates (Prakash et al., submitted) (*24*).

Conjugation of PEG and RGD peptide to SB−HSA resulted in a macromolecular conjugate that was characterized by several techniques. MALDI-TOF analysis illustrated that further modification of SB−HSA is not hampered by already bound SB202190−ULS. This was expected, given that ULS binds best to methionine residues, but also to cysteine and histidine residues, while the PEG linker reacted with amino groups of, e.g., lysine residues. The kind of RGD peptide (c(RGDfK)) used in this study binds specifically and with a high affinity to $\alpha_v\beta_3$-integrin due to the special constrained conformation. We now show that these properties are transferred to SB−HSA upon conjugation of RGD peptides. The 5.4-fold improvement in binding affinity as compared to the single peptide indicates multivalent binding of the conjugate. This is in line with earlier observations of Kok et al. (*9*) and is also relevant for receptor-mediated uptake of the conjugate, since multivalency is known to facilitate internalization and routing to lysosomes (*11*, *29*).

Platinum is an intrinsic component of ULS, and this prompted us to evaluate potential toxicity of the drug-targeting conjugate, and of ULS in particular. It is generally accepted that cisplatin toxicity involves cross-linking of DNA (*30*). The availability of a reactive ligand site at the platinum atom is essential for the toxicity of platinum(II) compounds. However, the platinum atom in RGDPEG−SB−HSA is fully coordinated, which prevents its binding with endogenous compounds. ULS can therefore only react with DNA after release of the drug or carrier. In view of the slow drug release from the construct, we expect only a slow formation of reactive platinum species in the target cells that will readily detoxified, as described for cisplatin and other platinum compounds (*31*, *32*). The absence of toxicity on HUVEC viability of ULS-containing compounds was clearly demonstrated even at high concentrations (Figure 7). Likely, glutathione adducts will be the major metabolite. We concluded that drug−ULS conjugates have no apparent toxicity despite their similarity to cisplatin. The same conclusion has been drawn for other ULS-containing drug-targeting conjugates that have been developed in our lab for the targeting to hepatic stellate cells (*24*) or kidney tubular cells (Prakash et al., submitted).

RGDPEG−SB−HSA partially inhibited the TNFα-induced activation of HUVEC, both at gene expression levels and when considering the secretion of proinflammatory cytokines (Figures 8 and 9). Since premature drug release in endothelial cell medium can be excluded on the basis of the drug release studies, we concluded that SB202190 was released after internalization of RGDPEG−SB−HSA. Although RGDPEG−SB−HSA demonstrated the anticipated effects, the observed inhibitions were lower than those of free SB202190. Several considerations may explain these differences. First, the different uptake mechanisms of conjugate and free drug will affect intracellular drug levels. The passive diffusion of a small molecule drug will be faster than the active uptake process and subsequent lysosomal degradation of a high molecular weight drug-targeting conjugate. Typically, inhibiting drugs are preincubated with the cells for about 1 h. Since such a short period would allow only limited uptake of the conjugate, we have preincubated the cells for 24 h with the compounds. Apparently, this had not resulted in extensive accumulation of active drug in the cells. Another explanation may be that intracellularly released SB202190 diffused out of the target cells. Such a redistribution of the compound by diffusion or active transport might limit the applicability of such conjugates in vivo. It therefore seems interesting to study the intracellular drug levels of free and conjugate-bound drug. This, however, proved to be impossible with the available HPLC techniques, as these have a relatively low sensitivity. Alternatively, one might prevent redistribution by delivering charged or hydrophilic drug molecules.

When considering the in vivo applicability of our approach, several studies support our strategy. The feasibility of RGD-mediated targeting for chronic inflammatory disorders has been demonstrated by RGD-peptide imaging agents that specifically accumulate in chronically inflamed tissue but not in acutely inflamed tissue (*33*, *34*). Furthermore, Gerlag et al. have treated mice suffering from collagen-induced arthritis with an RGD-targeted proapoptotic peptide (*35*). Their approach induced apoptosis of synovial blood vessels and significantly decreased clinical arthritis. We, however, aimed for the development of a therapeutic agent that can block inflammatory signaling pathways without compromising the viability of the vasculature. We furthermore expect improved pharmacokinetics of our macromolecular product as compared to smaller peptides or free SB202190. Free SB202190 is rapidly cleared from the circulation with a $t_{1/2}\alpha$ of 4.3 min in rats and has no affinity for inflamed tissue (*36*). In contrast, RGDPEG−SB−HSA can accumulate in inflamed endothelium in analogy to the RGD-peptide-based imaging agents. The long PEG linker will shield the modified albumin to prevent unspecific uptake and can increase the circulation time (*37*). Passive retention of the PEGylated drug carrier might also occur due to enhanced permeability of endothelium in inflamed tissues (*14*). In principle, RGDPEG−SB−HSA will be administered intravenously rather than by local injection in the joints. Since the

endothelium is in direct contact with the systemic circulation, these target cells can be reached from within the circulation. Thus, painful injections into inflamed joints would not be necessary.

In conclusion, we have prepared a novel drug-targeting conjugate in which we linked the drug via platinum coordination chemistry to the carrier. This RGDPEG−SB−HSA bound with high affinity and specificity to $\alpha_v\beta_3$-integrin and was subsequently internalized. The delivered drug was furthermore capable of interfering in inflammatory signaling cascades. These results show the potential of MAPkinase inhibitor delivery as a new strategy to counteract chronic inflammatory disorders.

ACKNOWLEDGMENT

J. H. Pol from the Department of Nuclear Medicine is kindly acknowledged for radiolabeling of echistatin, H. E. Moorlag from the Endothelial Cell Facility UMCG for skillful isolation and culturing of HUVEC, B. Doornbos-van der Meer for assistance with ELISA, and J. Ijmker for platinum detection using ICP-AES. We also acknowledge Prof. G. A. M. S. van Dongen and Ir. L. R. Perk of the VUmc for providing the desferal labeling technology. Our colleagues from KREATECH are acknowledged for critical review of the manuscript. This work was made possible by grants from Marie Curie (HPMI-CT-2002-00218), SenterNovem (TSGE1083), and Hungarian Scientific Research Fund OTKA (T-049478).

A series of ferrocenyl conjugates to fatty acids have been designed and synthesized to establish the key properties required for use in biomolecular binding studies. Amperometric detection of the ferrocene conjugates was sought in the region of 0.3 V (vs Ag/AgCl) for use in protein/blood solutions. Different linkers and solubilizing moieties were incorporated to produce a conjugate with optimal electrochemical properties. In electrochemical studies, the linker directly attached to the ferrocene was found to affect significantly the $E_{1/2}$ value and the stability of the ferrocenium cation. Ester-linked ferrocene conjugates had $E_{1/2}$ ranging from +400 to +410 mV, while amide-linked compounds ranged from +350 to +370 mV and the amines +260 to +270 mV. Folding of long-chain substituents around the ferrocene, also significantly affected by the choice of linker, was inferred as a secondary effect that increased $E_{1/2}$. The stability of the ferrocenium cation decreased systematically as $E_{1/2}$ increased. Disubstituted ferrocene ester and amide conjugates, with oxidation potentials of +640 and +570 mV, respectively, showed only a barely discernible reduction wave in cyclic voltammetry at 50 mV/s. Electrochemical measurements identified two lead compounds with the common structural characteristics of an amide and carbamate linker (compounds **17** and **21**) with a C_{11} fatty acid chain attached. It is envisaged that such molecules can be used to mimic and study the biomolecular binding interaction between fatty acids and molecules such as human serum albumin.

INTRODUCTION

Molecular interactions in biological systems have been studied using many different techniques such as surface plasmon resonance and fluorescence-based methodologies. There are, however, few reports in the literature utilizing electrochemical labels to study such interactions, with the exception of antibody−antigen interactions, where historically ferrocene-labeled molecules have been used. Metalloimmunoassays were first described in the 1970s when ferrocene was used to label steroid antigens with detection using flameless atomic absorption spectroscopy (*1*). Subsequently, an immunoassay incorporating a ferrocene electrochemical label was reported using a ferrocene−morphine conjugate whose electrochemistry was perturbed on binding to an antibody, resulting in a homogeneous competitive assay not requiring the separation of a free and antibody-bound label (*2*). Since then, a range of carbonylmetalloimmunoassays (CMIA) have been developed using metal−carbonyl-labeled molecules, in particular, incorporating ferrocene, which has been used as an electrochemical tracer and signaling molecule (*3*). The range of ferrocene derivatives available, ease of conjugation to a range of functionalities, reversible electrochemistry, and ability to synthetically tailor redox properties for a particular application makes it ideally placed for use in electrochemical sensing systems. More recent applications include the utilization of ferrocene as an oligonucleotide label in DNA probes (*4*−*6*) and as an electrochemical sensor for the detection of proteins (*7*). Ferrocene immunoassays with reduced glucose oxidase incorporating enzyme amplification (*8*), an amperometric immunoassay for lidocaine (*9*), and a homogeneous ferrocene−theophylline conjugate electrochemical assay (*10*) have also been reported.

Our aim was to demonstrate the utility of ferrocene for the study of biomolecular interactions and its potential in such applications. Interactions between fatty acids and their naturally occurring ligands have been intensively studied and thus provide a well-characterized system in which to study rationally designed synthetic electrochemical probe molecules; to our knowledge, no such probes have been reported in the literature. Fatty acid−human serum albumin (HSA) binding interactions are particularly important due to the effect on the transport of therapeutic drugs, for example, the reduced capacity of HSA to bind warfarin in the presence of bound fatty acids (*11*). Therefore, the synthesis of a series of ferrocene-labeled fatty acids would be a suitable model system for study but could also provide a greater understanding of the interactions between fatty acids and HSA. Conventionally such fatty acid ligand interactions have been studied by a number of techniques. Bhattacharya et al. have studied complexes of medium- and long-chain fatty acids and HSA using X-ray crystallography, identifying medium- and long-chain fatty acid binding sites (*12*). X-ray crystallography has also been used to study the complex of intestinal fatty acid binding protein and palmitate (*13*). Acrylodan-modified HSA has been used to study, using fluorescent techniques, the effect of oleic acid binding to the microenvironment around residue cysteine-34 in HSA (*14*). The binding characteristics of the fluorescently labeled fatty acid probe 11-(dansylamino)undecanoic acid with HSA (*15*) and a *Fascilo*

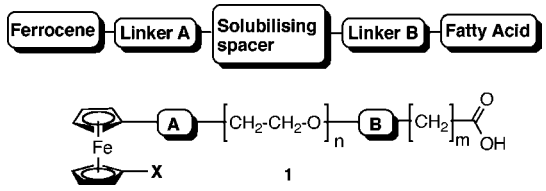

Figure 1. Ferrocene multifunctional conjugates.

hepatica fatty acid binding protein have also been studied (*16*). In addition, acrylodan-modified intestinal FABP (ADIFAB) has been used to investigate the binding of a range of fatty acids, allowing measurement of K_d values by fluorescent measurement (*17*). However, such measurements can only normally be performed in protein solution or plasma, while electrochemical measurements can potentially be performed in whole blood.

In the present study, we have designed and synthesized a range of electrochemically labeled molecules to establish the key properties required for use in binding studies in the presence of serum, such as $E_{1/2}$, reversibility, and aqueous compound solubility. The final component in the molecular design was the introduction of a moiety for recognition or binding purposes. In our studies, we conjugated a fatty acid as the specific biorecognition for potential applications in fatty acid binding studies. However, alternative functionalities can be introduced depending on the molecular interaction being investigated.

The molecular conjugates were designed as shown in Figure 1, incorporating ferrocene as the electrochemical detection method and a solubilizing spacer group together with the binding moiety, in these studies a fatty acid. Poly(ethylene glycol) (PEG)-modified ferrocenes have previously been reported incorporating long polymeric PEG units and have exhibited enhanced aqueous solubilities for use in homogeneous redox membrane biosensors (*18*, *19*). Commercially available PEG spacers were therefore incorporated as solubilizing moieties. However, short, defined PEG units were used to ensure that the spacer group did not interfere with any binding or recognition properties. Also, two linkers, **A** and **B**, were introduced to enable the rapid synthesis of a range of analogues that could be modified to alter molecular properties and stabilities. The ferrocene conjugate selected (**1**) is shown in Figure 1 with linkers **A** and **B**, PEG repeat unit *n*, the option of a second functionality on ferrocene (**X**), and fatty acid pendant group containing a methylene chain of length *m*.

EXPERIMENTAL PROCEDURES

Materials. Unless otherwise noted, solvents and reagents were reagent grade from commercial suppliers and used without further purification. THF was dried by distillation from a sodium/benzophenone suspension under a dry N_2 atmosphere. CH_2Cl_2 was dried by distillation from CaH_2 under a dry N_2 atmosphere. All moisture-sensitive reactions were performed under a nitrogen atmosphere using oven-dried glassware. Reactions were monitored by TLC on Kieselgel 60 F_{254} plates with detection by UV or permanganate, ninhydrin (for ureas), and phosphomolybdic acid stains. Flash column chromatography was carried out using silica gel (particle size 40−63 μm). Melting points are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded in $CDCl_3$ at the field indicated. 1-*t*Butyloxycarbonyl-1,8-diamino-3,6-dioxaoctane **7** (*20*), methyl 16-hydroxyhexadecanoate (*21*), and methyl 11-aminoundecanoate (*22*) were prepared as previously reported.

Ferrocenoyl-8-hydroxy-3,6-dioxaoctanoate (3). The reaction was carried out under anhydrous conditions. To a solution of tri(ethylene glycol) (3.26 g, 21.7 mmol) in CH_2Cl_2 (50 mL) was added a solution of ferrocenecarboxylic acid **2** (0.500 g, 2.17 mmol) in CH_2Cl_2 (10 mL). After 15 min, DCC (0.525 g, 2.30 mmol) and DMAP (0.03 g, 0.02 mmol) were added. The solution was stirred at room temperature for 18 h, then the solution was concentrated and purified by flash silica chromatography (EtOAc/hexane, 1:1) to afford **3** (0.55 g, 70%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 3.40 (br s, 1H, OH), 3.55 (t, J = 4.5 Hz, 2H), 3.58 (m, 6H), 3.72 (t, J = 4.8 Hz, 2H), 4.14 (s, 5H, C_5H_5), 4.28 (m, 2H, C_5H_2), 4.32 (m, 2H, CO_2CH_2), 4.75 (m, 2H, C_5H_2); ^{13}C NMR (75 MHz; $CDCl_3$) 61.8, 63.1, 69.5, 69.8, 70.2, 70.4, 70.7, 70.8, 71.4, 72.6, 171.7 (C═O); *m*/*z* HRMS calculated for $C_{17}H_{22}O_5FeNa$ $(MNa)^+$ 385.07089, found (ES+) 385.07110.

Ferrocenoyl-(8-ethanoate)-3,6-dioxaoctanoate (4). The reaction was carried out under anhydrous conditions. To compound **2** (100 mg, 0.27 mmol) in CH_2Cl_2 (5 mL) was added pyridine (0.25 mL) and DMAP (3 mg, 0.03 mmol). The solution was cooled to 0 °C and acetic anhydride (0.032 mL, 0.66 mmol) added dropwise. After 30 min, the solution was warmed to room temperature (rt) and stirred for 2 h. The solvents were evaporated and the resulting oil purified by flash silica chromatography (EtOAc/hexane, 7:3) to afford compound **4** (88 mg, 80%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 2.03 (s, 3H, $COCH_3$), 3.69 (m, 6H), 3.76 (t, J = 4.8 Hz, 2H), 4.17 (s, 5H, C_5H_5), 4.18 (m, 2H), 4.34 (m, 2H), 4.36 (m, 2H, C_5H_2), 4.79 (m, 2H, C_5H_2); ^{13}C NMR (75 MHz; $CDCl_3$) 20.8 ($COCH_3$), 63.1, 63.5, 69.1, 69.4, 69.7, 70.1, 70.5, 70.9, 71.2, 170.8 (C═O), 171.5 (C═O); *m*/*z* HRMS calculated for $C_{19}H_{25}O_6Fe$ $(MH)^+$ 404.09168, found (CI+) 404.09263.

***N*-(5-Hydroxy-3-oxapentanyl)ferrocenoylamide (5).** The reaction was carried out under anhydrous conditions. Ferrocene carboxylic acid **2** (3.00 g, 13.0 mmol) and HOBt (1.94 g, 14.3 mmol) were dissolved in CH_2Cl_2 (200 mL), and the reaction was stirred at rt for 10 min. EDCI (2.85 g, 13.0 mmol) and triethylamine (3.60 mL, 26.0 mmol) were then added, and after 30 min, 2-(2-aminoethoxy)ethanol (1.37 g, 13.0 mmoles) was added and the solution stirred at rt for 4 h. The solution was concentrated and purified by flash silica chromatography (gradient: 100% EtOAc to 15% methanol in EtOAc) to afford the title compound (3.47 g, 84%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 2.90 (br, 1H, OH), 3.44 (td, J = 5.2 and 5.2 Hz, 2H), 3.51 (m, 4H), 3.64 (t, J = 4.5 Hz, 2H), 4.07 (s, 5H, C_5H_5), 4.17 (m, 2H, C_5H_2), 4.63 (m, 2H, C_5H_2), 6.58 (br s, 1H, NH); ^{13}C NMR (75 MHz; $CDCl_3$) 39.2 (CH_2N), 61.3, 68.0, 69.4, 69.9−70.0 (signals superimposed), 72.2, 170.6 (C═O); *m*/*z* HRMS calculated for $C_{15}H_{19}NO_3FeNa$ $(MNa)^+$ 340.06066, found (ES+) 340.06126.

***N*-(8-Amino-3,6-dioxaoctanyl)ferrocenoylamide (8).** The reaction was carried out under anhydrous conditions. DCC (88 mg, 0.43 mmol) was added to compound **7** (95 mg, 0.39 mmol) and ferrocene carboxylic acid (80 mg, 0.35 mmol) in CH_2Cl_2 (20 mL), and the reaction was stirred for 18 h at rt. The solvent was evaporated in vacuo and the resulting oil purified by flash silica chromatography (100% EtOAc) to afford the Boc-protected intermediate (82 mg, 46%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.36 (s, 9H, 3 × CH_3), 3.24 (td, J = 5.2 and 5.1 Hz, 2H), 3.47 (m, 4H), 3.51 (m, 6H), 4.11 (s, 5H, C_5H_5), 4.24 (m, 2H, C_5H_2), 4.62 (m, 2H, C_5H_2), 4.98 (br s, 1H, NH), 6.24 (br s, 1H, NH); ^{13}C NMR (75 MHz; $CDCl_3$) 28.4 (Boc-*C*H_3), 39.3 (CH_2N), 40.3 (CH_2N), 68.2, 69.8, 70.2−70.4 (signals superimposed), 79.3 (Boc-*C*), 156.0 (C═O Boc), 170.4 (C═O amide).

The protected amine (82 mg, 0.18 mmol) was dissolved in a mixture of CH_2Cl_2/TFA (4 mL/4 mL), and the solution was stirred at rt for 2 h. The solvents were evaporated and the resulting oil purified by flash silica chromatography (CH_2Cl_2/MeOH/NEt_3; 85/10/5) to afford **8** (45 mg, 70%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$/CD_3OD) 3.09 (m, 2H), 3.28 (td, J = 5.3 and 5.3 Hz, 2H), 3.43 (m, 8H), 3.95 (s, 5H, C_5H_5),

4.14 (m, 2H, C_5H_2), 4.56 (m, 2H, C_5H_2), 6.70 (br s, 1H, NH); ^{13}C NMR (75 MHz; $CDCl_3$) 39.5 (CH_2N), 39.8 (CH_2N), 68.4, 69.9, 70.1−70.9 (signals superimposed), 75.5, 172.5 (C═O); *m/z* HRMS calculated for $C_{17}H_{25}N_2O_3Fe$ $(MH)^+$ 361.12091, found (ES+) 361.12111; *m/z* (ES+) 383 (MNa^+, 41%), 361 (MH^+, 100).

Ferrocenylmethylamine *N*-(5-hydroxy-3-oxapentanyl) (10). The reaction was carried out under anhydrous conditions. Ferrocene carboxaldehyde **9** (150 mg, 0.70 mmol) and 2-(2-aminoethoxy)ethanol (147 mg, 1.40 mmol) in toluene (30 mL) were heated at reflux for 18 h. After cooling to rt, sodium borohydride (79.8 mg, 2.10 mmol) was added, and the reaction was stirred at rt for 6 h. Water (5 mL) was added, the solvent removed in vacuo, and the residue suspended in CH_2Cl_2. The organic phase was washed with water (10 mL), dried (sodium sulfate), and evaporated. The residue was purified by flash silica chromatography (gradient: 100% EtOAc to 20% methanol in EtOAc) to give **10** (74 mg, 35%) as a dark orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 2.83 (t, J = 5.3 Hz, 2H, CH_2CH_2N), 3.53 (s, 2H, CH_2-ferrocenyl), 3.57−3.64 (m, 4H), 3.70 (t, J = 4.4 Hz, 2H), 4.10 (m, 2H, C_5H_2), 4.12 (s, 5H, C_5H_5), 4.18 (m, 2H, C_5H_2); ^{13}C NMR (75 MHz; $CDCl_3$) 48.9 (C-1), 61.9 (C-5), 67.9, 68.4, 68.5, 70.1, 72.4, 86.3; *m/z* (ES+) 326 (MNa^+, 91%), 304 (MH^+, 100).

Ferrocenylmethylamine *N*-methyl-*N*-(5-hydroxy-3-oxapentanyl) (11). The reaction was carried out under anhydrous conditions. To a solution of **10** (70 mg, 0.23 mmol) in CH_3CN (30 mL) was added formaldehyde (37%, 38 μL, 0.46 mmol). After stirring for 10 min, sodium borohydride (26 mg, 0.69 mmol) was added in portions, and the mixture was stirred for 5 h. Water (5 mL) was added, the solvent removed in vacuo, and the residue was suspended in CH_2Cl_2. The organic layer was washed with water (10 mL), dried (sodium sulfate), and evaporated, and the residue was purified by flash silica chromatography (gradient: 100% EtOAc to 20% methanol in EtOAc) to give **11** (26 mg, 35%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 2.21 (s, 3H, Me), 2.55 (t, J = 5.6 Hz, 2H, CH_2CH_2N), 3.47 (s, 2H, CH_2-ferrocenyl), 3.58 (m, 4H), 3.68 (t, J = 4.5 Hz, 2H), 4.11 (m, 7H, C_5H_5, C_5H_2), 4.18 (m, 2H, C_5H_2); ^{13}C NMR (75 MHz; $CDCl_3$) 41.2 (NMe), 55.6, 57.2, 62.0, 67.8, 68.3, 68.5, 70.4, 72.6; *m/z* (ES+) 340 (MNa^+, 100%), 318 (MH^+, 18).

1,1′-Ferrocenoyl-(8-ethoxy-3,6-dioxaoctanoate) (13). The reaction was carried out under anhydrous conditions. DCC (1.19 mmol, 245 mg) and DMAP (5 mg), were added to a solution of 1,1′-ferrocenedicarboxylic acid **12** (0.54 mmol, 150 mg) and tri(ethylene glycol) monoethyl ether (2.16 mmol, 385 mg) in CH_2Cl_2 (30 mL). The reaction was stirred at rt for 18 h. After filtration, the filtrate was concentrated in vacuo, dissolved in Et_2O, and urea was removed by filtration. The solvent was removed under reduced pressure and the residue purified by flash silica chromatography (EtOAc/hexane: 60/40) to give **13** (96 mg, 30%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.22 (t, J = 6.9 Hz, 6H, 2 × CH_3), 3.54 (q, J = 6.9 Hz, 4H, 2 × CH_2CH_3), 3.55−3.70 (m, 16H), 3.79 (m, 4H), 4.38 (m, 4H, CH_2OCO), 4.42 (m, 4H, 2 × C_5H_2), 4.86 (m, 4H, 2 × C_5H_2); ^{13}C NMR (75 MHz; $CDCl_3$) 15.2 (CH_3), 63.5, 66.7, 69.4, 69.9, 70.7, 70.8, 71.7, 72.6, 73.1, 170.4, 212.1 (C═O); *m/z* (ES+) 617 (MNa^+, 100%), 433 (28).

***N*-(5-Hydroxy-3-oxapentanyl)-1,1′-ferrocenoylamide (14).** The reaction was carried out under anhydrous conditions. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide (2.20 mmol, 420 mg) (which had been previously neutralized with 2.20 mmol Et_3N) and HOBt (2.20 mmol, 295 mg) were added to a solution of 1,1′-ferrocenedicarboxylic acid **12** (0.54 mmol, 150 mg) in CH_2Cl_2 (20 mL), and the mixture was stirred for 30 min. A solution of aminoethoxyethanol (2.16 mmol, 227 mg) in CH_2Cl_2 (5 mL) was then added and the reaction stirred for 18 h at rt. The organic phase was washed with water (5 mL), dried (sodium sulfate), and the solvent removed under reduced pressure. The residue was purified by flash silica chromatography (gradient: 100% hexane to 100% EtOAc, then CH_2Cl_2/MeOH 95/5) to give **14** (107 mg, 50%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 3.62−3.75 (m, 16H), 4.35 (m, 4H, 2 × C_5H_2), 4.57 (m, 4H, 2 × C_5H_2), 7.32 (br, 2H, N*H*); ^{13}C NMR (75 MHz; $CDCl_3$) 39.8, 61.6, 69.9, 70.9, 71.3, 72.5, 78.0, 170.9, 212.0 (C═O); *m/z* (ES+) 471 (MNa^+, 100%), 449 (MH^+, 25).

11-(Ferrocenoyl-3,6-dioxaoctanyloxycarbonylamino)-undecanoic acid (15). The reaction was carried out under anhydrous conditions. To compound **3** (680 mg, 1.87 mmol) in acetonitrile (20 mL) at 0 °C was added *N*,*N*-disuccinimidyl carbonate (574 mg, 2.24 mmol). The solution was stirred at 0 °C for 30 min and at rt for 18 h. The solvent was then evaporated and the resulting oil purified by flash silica chromatography (hexane/EtOAc, 1:4) to afford the succinimidyl carbonate activated **3** (254 mg, 27%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 2.83 (s, 4H, CH_2 succinimidyl), 3.69 (m, 4H), 3.78 (m, 4H), 4.22 (s, 5H, C_5H_5), 4.40 (m, 4H), 4.45 (m, 2H), 4.82 (s, 2H, C_5H_2); ^{13}C NMR (75 MHz; $CDCl_3$) 25.4 (CH_2-succinimidyl), 63.2, 68.4, 69.5, 69.8, 70.1, 70.6−70.9 (signals superimposed), 71.3, 152.3, 162.4, 168.9 (C═O ester); *m/z* (ES+) 526 (MNa^+, 46%), 429 (100).

To 11-aminoundecanoic acid (12 mg, 0.06 mmol) in THF/H_2O (0.5 mL/1 mL) was added the succinimidyl carbonate activated **3** (15 mg, 0.03 mmol) in THF (0.5 mL). The reaction was stirred at rt for 18 h, then the solvents were evaporated under reduced pressure. The remaining oil was purified by flash silica chromatography (MeOH/CH_2Cl_2, 5/95) in to afford **15** (13 mg, 74%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.27 (m, 12H), 1.46 (quint, J = 6.8 Hz, 2H), 1.62 (quint, 2H, J = 6.8 Hz), 2.33 (t, J = 7.2 Hz, 2H, CH_2CO_2H), 3.13 (dt, J = 6.6 and 6.6 Hz, 2H, CH_2N), 3.68 (m, 6H), 3.79 (t, J = 4.8 Hz, 2H), 4.19 (m, 2H), 4.20 (s, 5H, C_5H_5), 4.38 (m, 2H, C_5H_2), 4.39 (m, 2H), 4.79 (m, 2H, C_5H_2), 4.81 (br, 1H, NH); ^{13}C NMR (75 MHz; $CDCl_3$/CD_3OD) 24.8, 26.6, 28.9, 29.1−29.7 (signals superimposed), 34.2, 40.8, 63.7, 68.1, 69.3−70.6 (signals superimposed), 75.4, 156.8 (C═O carbamate), 171.7, 177.9; *m/z* HRMS calculated for $C_{29}H_{43}NO_8FeNa$ $(MNa)^+$ 612.22303, found (ES+) 612.22331.

16-(Ferrocenoyl-3,6-dioxaoctanoyl)hexadecanoic acid (16). The reaction was carried out under anhydrous conditions. DCC (89 mg, 0.435 mmol) was added to a stirred solution of hexadecanedioic acid (230 mg, 0.829 mmol) in CH_2Cl_2 (20 mL), and the reaction was stirred at rt for 2 h. To this was added **3** (150 mg, 0.414 mmol), and DMAP (50 mg, 0.041 mol), and the reaction was stirred at rt overnight. Insoluble urea was filtered from the reaction and washed with CH_2Cl_2 (10 mL), and the combined organic extracts were removed under reduced pressure, leaving a brown viscous oil. The remaining oil was purified by flash silica chromatography (100% EtOAc) to afford the title compound (20 mg, 4%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.25 (m, 20H), 1.59 (m, 4H), 2.27 (m, 4H), 3.68 (m, 6H), 3.77 (t, J = 4.8 Hz, 2H), 4.22 (m, 7H), 4.38 (m, 4H), 4.81 (m, 2H, C_5H_2); ^{13}C NMR (75 MHz; $CDCl_3$) 24.7, 29.2, 29.3, 29.5, 29.6, 29.8, 30.0−30.1 (signals superimposed), 34.2, 34.6, 63.2, 63.3, 69.3, 69.5, 69.8, 70.2, 70.5−70.6 (signals superimposed), 71.4, 170.5, 172.2, 174.2; *m/z* HRMS calculated for $C_{33}H_{50}O_8FeNa$ $(MNa)^+$ 653.27473, found (ES+) 653.27595.

11-(Ferrocenoylamide-3-oxapentanyloxycarbonylamino)-undecanoic acid (17). The reaction was carried out under anhydrous conditions. Compound **5** (50 mg, 0.16 mmol) was dissolved in acetonitrile (10 mL), and triethylamine (45 μL, 0.32 mmol) was added. The solution was cooled to 0 °C, and *N*,*N*-disuccinimidyl carbonate (49 mg, 0.19 mmol) was added. The

solution was stirred at 0 °C for 30 min and at rt for 18 h. The solvent was then evaporated in vacuo and the resulting oil purified by flash silica chromatography (20% hexane in EtOAc) to afford the activated intermediate (64 mg, 87%) as an oil. ^{1}H NMR (300 MHz; $CDCl_3$) 2.76 (s, 4H, succinimide), 3.49 (m, 2H, C*H*$_2$NH), 3.62−3.74 (m, 4H), 4.11 (s, 5H, C_5H_5), 4.16 (m, 2H, C_5H_2), 4.45 (m, 2H, CH_2OCO), 4.68 (m, 2H, C_5H_2), 6.35 (br s, 1H, NH); ^{13}C NMR ($CDCl_3$; 75 MHz) 25.5, 39.4 (CH_2N), 68.1, 68.2, 69.7, 69.8, 69.9, 70.2, 70.5, 151.6 (C═O), 168.8 (C═O), 172.5 (C═O amide); *m*/*z* (ES+) 481 (MNa^+, 100%), 439 (48).

The intermediate (50 mg, 0.11mmol) was dissolved in DMF (0.7 mL), and triethylamine (18 μL, 0.13 mmol) was added. To this was added 11-aminoundecanoic acid (22 mg, 0.11 mmol) dissolved in a mixture of water/DMF (1.1 mL/0.4 mL). The reaction was stirred at rt for 18 h, and the solvents then evaporated in vacuo. The resulting oil was purified by flash silica chromatography (5% methanol in CH_2Cl_2) to afford **17** (54 mg, 90%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.23 (m, 12H), 1.41 (m, 2H), 1.59 (m, 2H), 2.32 (t, J = 7.5 Hz, 2H, C*H*$_2$CO$_2$H), 3.10 (dt, J = 4.8 and 4.6 Hz, 2H, $(CH_2)_9$C*H*$_2$-NH), 3.56−3.66 (m, 6H), 4.18 (s, 5H, C_5H_5), 4.21 (m, 2H, CH_2O), 4.31 (m, 2H, C_5H_2), 4.72 (m, 2H, C_5H_2), 4.90 (br, 1H, NH carbamate), 6.47 (br, 1H, NH amide); ^{13}C NMR (75 MHz; $CDCl_3$) 24.7, 26.6, 28.9, 29.0 (2 signals), 29.1, 29.2, 29.6, 34.0, 39.4, 41.0, 63.6, 68.2, 69.6, 69.7, 69.9, 70.5, 75.5, 156.4 (C═O carbamate), 171.2 (C═O amide), 177.9 (C═O acid); *m*/*z* HRMS calculated for $C_{27}H_{40}N_2O_6Fe$ M^+ 544.22356, found (FAB+) 544.22408.

2-(8-Hydroxy-3,6-dioxaoctanyl)isoindole-1,3-dione (19). The reaction was carried out under anhydrous conditions. 1-Chloro-3,6-dioxaoctan-1-ol **18** (5.00 g, 29.7 mmol) and potassium phthalimide (7.14 g, 28.6 mmol) were dissolved in DMF (20 mL) and heated at 40 °C for 4 h. The mixture was extracted with water and CH_2Cl_2. The organic phase was dried (magnesium sulfate) and evaporated to afford **19** (5.76 g, 70%) as a yellow oil, which was used without further purification. ^{1}H NMR (300 MHz; $CDCl_3$) 3.57 (m, 4H), 3.62 (m, 6H), 3.71 (m, 2H), 7.77 (m, 4H, H-phthalimide); ^{13}C NMR ($CDCl_3$; 75 MHz) 37.1, 62.3 (C-8), 68.9, 71.2, 71.5, 73.7, 124.2, 133.0, 135.4, 169.7 (C═O); *m*/*z* HRMS calculated for $C_{14}H_{17}NO_5Na$ $(MNa)^+$ 302.09989, found (ES+) 302.09998.

11-(8-[1,3-Dioxo-1,3-dihydroisoindol-2-yl]-3,6-dioxaoctanyloxycarbonylamino)undecanoic acid methyl ester (20). The reaction was carried out under anhydrous conditions. Compound **19** (1.00 g, 3.57 mmol) in acetonitrile (35 mL) was cooled to 0 °C, and *N*,*N*-disuccinimidyl carbonate (1.48 g, 4.28 mmol) was added. The solution was stirred at 0 °C for 30 min and at rt for 18 h. The solvent was evaporated in vacuo and the resulting oil purified by flash silica chromatography (20% hexane in EtOAc) to afford NHS activated **19** (910 mg, 61%) as a white solid. ^{1}H NMR (300 MHz; $CDCl_3$) 2.80 (s, 4H, H succinimidyl), 3.59 (m, 4H), 3.67 (m, 4H), 3.85 (t, J = 5.6 Hz, 2H), 4.32 (m, 2H), 7.67 (m, 2H, H-phthalimide), 7.80 (m, 2H, H-phthalimide); ^{13}C NMR ($CDCl_3$; 75 MHz) 25.3 (CH_2 succinimidyl), 37.0 (CH_2N), 67.6, 68.0, 69.8, 70.4, 71.1, 122.9, 132.5, 133.6 (C aromatic), 151.4 (C═O carbonate), 167.9 (C═O succinimidyl), 168.8 (C═O phthalimide); *m*/*z* (ES+) 443 (MNa^+, 18%).

The subsequent reaction was carried out under anhydrous conditions. 11-Aminoundecanoic acid methyl ester (285 mg, 1.32 mmol) was added to the NHS activated intermediate (556 mg, 1.32 mmol) in CH_2Cl_2 (30 mL), and the reaction was stirred at rt for 18 h. The solvent was evaporated and the resulting oil purified by flash silica chromatography (6:4 hexane/EtOAc) to afford **20** (228 mg, 34%). ^{1}H NMR (300 MHz; $CDCl_3$) 1.24 (m, 12H), 1.45 (m, 2H), 1.58 (m, 2H), 2.27 (t, J = 7.5 Hz, 2H, C*H*$_2$CO$_2$Me), 3.12 (q, J = 6.7 Hz, 2H, CH_2N), 3.59 (m, 6H), 3.63 (s, 3H, O-Me), 3.71 (t, J = 5.3 Hz, 2H), 3.87 (t, J = 6.0 Hz, 2H), 4.08 (m, 2H), 7.69 (m, 2H, H-phthalimide), 7.70 (m, 2H, H-phthalimide); ^{13}C NMR ($CDCl_3$; 75 MHz) 24.8, 25.4, 26.5, 26.6, 29.0−29.6 (signals superimposed), 33.8, 36.7, 37.1, 39.4, 40.8, 51.2 (O-Me), 63.4, 67.7, 69.4, 69.8, 70.4, 123.0 (CH-Ar), 131.8, 133.7 (CH-Ar), 156.2 (C═O carbamate), 168.0 (C═O phthalimide), 174.0 (C═O ester); *m*/*z* (ES+) 543 (MNa^+, 40%).

11-(Ferrocenoylamide-3,6-dioxaoctanyloxycarbonylamino)-undecanoic acid (21). A solution of **20** (228 mg, 0.44 mmol) and hydrazine hydrate (110 mg, 2.2 mmol) in ethanol (3 mL) was heated at reflux for 2 h. The solvent was evaporated and the resulting product dissolved in CH_2Cl_2. The precipitate was removed by filtration and the solvent evaporated to afford the amine intermediate as an oil (167 mg, 93%), which was used without further purification. ^{1}H NMR (300 MHz; $CDCl_3$) 1.26 (m, 12H), 1.38 (m, 2H), 1.54 (m, 2H), 2.27 (t, J = 7.5 Hz, 2H, C*H*$_2$CO$_2$Me), 3.12 (q, J = 5.5 Hz, 2H, CH_2N), 3.53 (m, 6H), 3.61 (s, 3H, OMe), 3.66 (t, J = 5.6 Hz, 2H), 3.83 (t, J = 5.6 Hz, 2H), 4.05 (m, 2H); ^{13}C NMR ($CDCl_3$; 75 MHz) 25.8, 26.9, 29.1−29.9 (signals superimposed), 31.2, 34.1, 38.1, 41.0, 51.5 (OMe), 63.7, 67.9, 69.6, 69.9, 70.5, 156.4 (C═O carbamate), 174.2 (C═O ester); *m*/*z* HRMS calculated for $C_{19}H_{39}N_2O_6$ $(MH)^+$ 391.28026, found (ES+) 391.28031.

The subsequent reaction was carried out under anhydrous conditions. To the amine intermediate (167 mg, 0.41 mmol) and ferrocenecarboxylic acid **2** (190 mg, 0.82 mmol) in CH_2Cl_2 (20 mL) was added EDCI (85 mg, 0.43 mmol), and the reaction was stirred for 18 h at rt. The solvent was evaporated and the resulting oil purified by flash silica chromatography (20% hexane in EtOAc) to afford the ferrocene-coupled methyl ester (35 mg, 15%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.25 (m, 12H), 1.39 (m, 2H), 1.49 (m, 2H), 2.28 (t, J = 7.5 Hz, 2H, C*H*$_2$CO$_2$Me), 3.14 (q, J = 5.5 Hz, 2H, CH_2N), 3.61 (m, 6H), 3.63 (s, 3H, O-Me), 3.68 (m, 2H), 3.75 (m, 2H), 4.06 (s, 5H, C_5H_5), 4.14 (m, 2H), 4.22 (m, 2H, C_5H_2), 4.61 (m, 2H, C_5H_2), 4.80 (br s, 1H, NH), 6.44 (br s, 1H, NH); ^{13}C NMR ($CDCl_3$; 75 MHz) 24.8, 26.9, 29.2−29.9 (signals superimposed), 30.2, 34.1, 38.1, 40.9, 51.53 (OMe), 63.7, 68.1, 69.7, 67.9, 69.6−70.5, 156.4 (C═O carbamate), 171.4 (C═O amide), 174.2 (C═O ester).

The ester (35 mg, 0.06 mmol) was dissolved in dioxane (3 mL), and to the solution was added lithium hydroxide (5 mg, 0.12 mmol) in water (2 mL). The reaction was stirred at rt for 3 h, and the dioxane removed in vacuo. The crude product was dissolved in CH_2Cl_2 (20 mL), the aqueous layer neutralized, and the organic layer was separated, dried ($MgSO_4$), and concentrated. The resulting oil was purified by flash silica chromatography (100% ethyl acetate to 5% MeOH in EtOAc) to afford **21** (20 mg, 60%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.29 (m, 12H), 1.41 (m, 2H), 1.54 (m, 2H), 2.22 (t, J = 7.5 Hz, 2H, CH_2CO_2H), 3.15 (q, J = 5.5 Hz, 2H, CH_2N), 3.64 (m, 6H), 3.69 (m, 2H), 3.77 (m, 2H), 4.09 (s, 5H, C_5H_5), 4.16 (m, 2H), 4.28 (m, 2H, C_5H_2), 4.64 (m, 2H, C_5H_2), 4.85 (br s, 1H, NH), 6.45 (br s, 1H, NH); ^{13}C NMR ($CDCl_3$; 75 MHz) 24.8, 26.9, 29.1−29.9 (signals superimposed), 30.3, 34.1, 39.1, 41.9, 64.4, 68.1, 69.8−70.2 (signals superimposed), 70.6, 156.9 (C═O carbamate), 171.9 (C═O amide), 174.2 (C═O acid); *m*/*z* HRMS calculated for $C_{29}H_{44}N_2O_7Fe$ M^+ 588.24977, found (CI+) 588.25104.

16-(2,5-Dioxopyrrolidin-1-yloxycarbonyloxy)hexadecanoic acid methyl ester (23). The reaction was carried out under anhydrous conditions. To methyl 16-hydroxyhexadecanoate (450 mg, 1.60 mmol) and triethylamine (0.240 mL) and acetonitrile (30 mL) at 0 °C was added *N*,*N*-disuccinimidyl carbonate (487 mg, 1.88 mmol). The reaction was stirred at 0 °C for 30 min and at rt for 18 h. The solvent was evaporated and the resulting

oil purified by flash silica chromatography (20% hexane in EtOAc) to afford **23** (590 mg, 85%) as an oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.19 (m, 22H), 1.71 (m, 2H), 1.68 (m, 2H), 2.23 (t, $J = 7.5$ Hz, 2H, CH_2CO$_2$Me), 2.77 (s, 4H, CH_2 succinimidyl), 3.59 (s, 3H, OMe), 4.25 (t, $J = 6.7$ Hz, 2H, CH_2O); ^{13}C NMR (75 MHz; $CDCl_3$) 25.4, 25.7, 26.2, 29.5, 29.6−30.1 (signals superimposed), 30.3, 34.0, 34.5, 51.5 (OMe), 68.4, 151.7, 168.4, 175.3 (C═O ester).

16-[8-(2-tert-Butoxycarbonylamino)-3,6-dioxaoctanylaminocarbamoyloxy]hexadecanoic acid methyl ester (24). The reaction was carried out under anhydrous conditions. Compound **7** (415 mg, 1.68 mmol) was added to **23** (590 mg, 1.4 mmol) in CH_2Cl_2 (30 mL), and the reaction was stirred at rt for 18 h. The solvent was evaporated and the resulting oil purified by flash silica chromatography (6:4, hexane/EtOAc) to afford **24** (311 mg, 42%). ^{1}H NMR (300 MHz; $CDCl_3$) 1.25 (m, 22H), 1.35 (m, 9H, CH_3-Boc), 1.58 (m, 4H), 2.26 (t, $J = 7.5$ Hz, 2H, CH_2CO$_2$Me), 3.28 (m, 2H), 3.33 (m, 2H), 3.57 (m, 8H), 3.62 (s, 3H, O-Me), 4.00 (m, 2H); ^{13}C NMR ($CDCl_3$, 75 MHz) 24.5, 25.5, 28.0, 28.7−29.2 (signals superimposed) 33.6, 40.0, 40.4, 51.0 (OMe), 64.4, 70.1 (signals superimposed), 78.6, 155.6 (C═O carbamate), 156.4 (C═O carbamate), 173.7 (C═O ester); *m*/*z* (ES+) 460 ([MH − Boc]$^+$, 100%).

16-(Ferrocenylamide-3,6-dioxactanylaminocarbamoyloxy-)hexadecanoic acid (25). The protected amine **24** (310 mg, 0.58 mmol) in a mixture of CH_2Cl_2/TFA (3 mL/3 mL) was stirred at rt for 2 h. The solvents were removed in vacuo, and the resulting oil was evaporated several times with methanol and CH_2Cl_2 to give the amine (250 mg, 99%) as a yellow oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.27 (m, 22H), 1.59 (m, 4H), 2.35 (t, $J = 7.5$ Hz, 2H, CH_2CO$_2$Me), 3.21−3.39 (m, 4H), 3.59 (m, 2H), 3.64 (m, 7H), 3.67 (m, 2H), 4.03 (m, 2H); ^{13}C NMR ($CDCl_3$, 75 MHz) 25.1, 25.8, 28.4 , 28.9−29.5 (signals superimposed), 31.7, 34.2, 34.5, 40.1, 51.9 (OMe), 65.3, 66.1, 69.7−69.7 (signals superimposed), 157.8 (C═O carbamate), 174.5 (C═O ester); *m*/*z* (ES+) 461 (MH$^+$, 100%), 449 (95).

The reaction was carried out under anhydrous conditions. To the amine intermediate (250 mg, 0.54 mmol) and triethylamine (0.113 mL) in CH_2Cl_2 (10 mL) was added ferrocenecarboxylic acid **2** (186 mg, 0.81 mmol) and DCC (165 mg, 0.81 mmol), and the reaction was stirred for 18 h. After removal of the solvents in vacuo, the resulting oil was purified by flash silica chromatography (100% EtOAc) to afford the ferrocenyl methyl ester intermediate (167 mg, 46%). ^{1}H NMR (300 MHz; $CDCl_3$) 1.20 (m, 22H), 1.53 (m, 4H), 2.32 (t, $J = 7.5$ Hz, 2H), 3.33 (m, 2H), 3.63 (m, 10H), 3.65 (s, 3H, OMe), 3.99 (m, 2H), 4.13 (s, 5H, C_5H_5), 4.26 (m, 2H, C_5H_2), 4.65 (m, 2H, C_5H_2), 5.24 (br s, 1H, NH), 6.13 (br s, 1H, NH); ^{13}C NMR ($CDCl_3$, 75 MHz) 24.9, 25.8, 29.0−29.6 (signals superimposed), 34.1, 39.3, 40.7, 51.9 (OMe), 65.1, 68.2, 69.7−70.3 (signals superimposed), 76.1, 156.9 (C═O carbamate), 170.3 (C═O amide), 174.3 (C═O ester).

The ferrocene conjugate (167 mg, 0.25 mmol) was dissolved in dioxane (3 mL), and sodium hydroxide (15 mg, 0.38 mmol) in water (2 mL) was added. The reaction was stirred at rt for 3 h, the dioxane was removed in vacuo, and then CH_2Cl_2 (10 mL) was added. The aqueous layer was neutralized and the organic layer separated, dried ($MgSO_4$), and concentrated. The resulting oil was purified by flash silica chromatography (100% EtOAc to 5% MeOH in EtOAc) to afford **25** (50 mg, 32%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.23 (m, 22H), 1.55 (m, 4H), 2.22 (t, $J = 7.5$ Hz, 2H, CH_2CO_2H), 3.37 (m, 2H), 3.51−3.65 (m, 10H), 4.01 (m, 2H), 4.17 (s, 5H, C_5H_5), 4.29 (m, 2H, C_5H_2), 4.67 (m, 2H, C_5H_2), 5.31 (br s, 1H, NH), 6.23 (br s, 1H, NH); ^{13}C NMR ($CDCl_3$, 75 MHz) 24.9, 25.9, 29.1−29.6 (signals superimposed), 34.1, 39.3, 40.8, 65.1, 68.2, 69.7−70.3 (signals superimposed), 71.5, 156.9 (C═O carbamate), 170.4 (C═O amide), 177.3 (C═O acid); *m*/*z* HRMS calculated for $C_{34}H_{54}N_2O_7FeNa$ (MNa)$^+$ 681.31727, found (ES+) 681.31763.

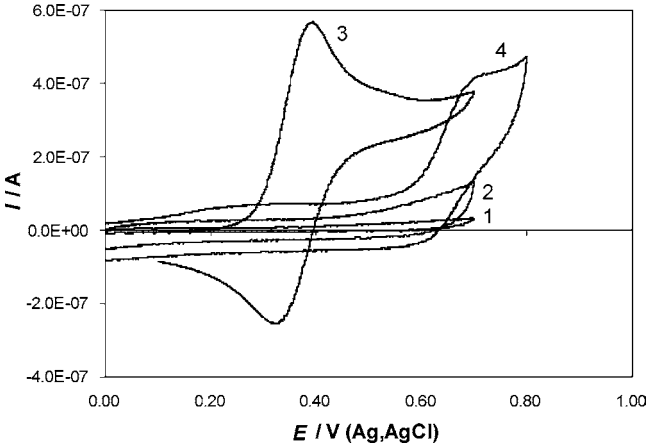

Figure 2. Cyclic voltammetry of substituted ferrocenes (~100 μM in PBS). Curves 1,2, background, illustrating the variability between different screen-printed carbon electrodes; 3, compound **17**; 4, compound **13**.

Electrochemical Methods. All measurements were performed with screen-printed electrodes consisting of carbon working (area 0.03 cm^2) and counter electrodes and a silver/silver chloride reference electrode. All electrochemical measurements were performed with an Autolab General Purpose Electrochemical System (Eco Chemie B.V. Netherlands).

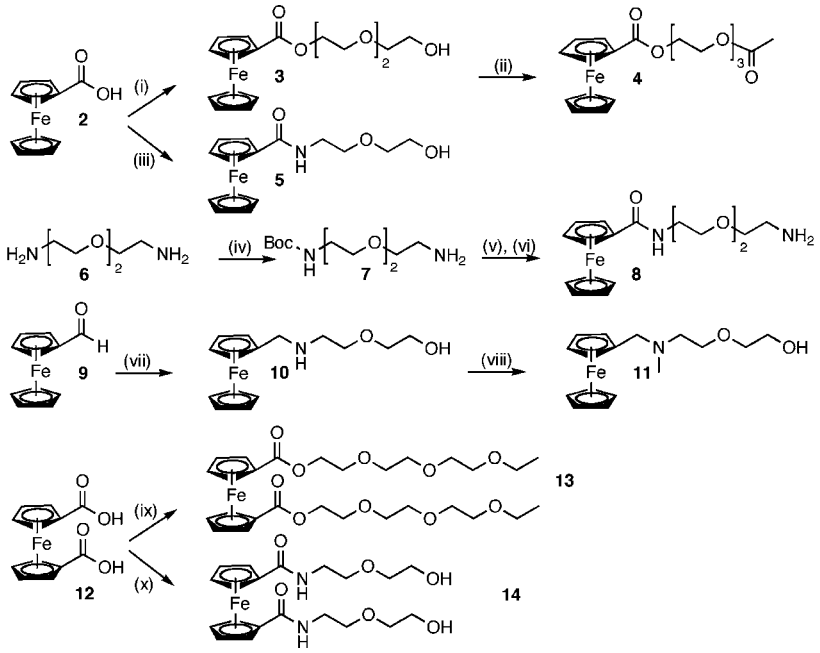
All signal molecule stock solutions (approximately 100 μM) were dissolved in methanol due to poor solubility at high concentrations in phosphate-buffered saline (PBS: 0.137 M NaCl, 0.0027 M KCl, 0.01 M phosphate buffer pH 7.4). Subsequent dilutions were made with PBS, and the final concentration of methanol was never more than 5% v/v, which was found to have no effect on experiments. All solutions were filtered using a 0.2 μm cutoff filter.

20 μL of solution was applied to the sample/working area of the electrode ensuring complete coverage of the working, counter, and reference electrodes. All samples were premixed before being applied to the electrode, and a new electrode was used for each measurement. Cyclic voltammetry measurements were made immediately. The potential ramp was digitally generated and therefore in the form of a staircase, with a small step height. Cyclic voltammogram scan parameters were as follows: pretreatment of 0 V potential for 5 s, start potential 0 V, second vertex potential 0.7 V, step potential 0.00198 V, and scan rate 0.05 V/s. All potentials are quoted with respect to Ag/AgCl in PBS. Carbon electrodes prepared by screen printing have a small inherent variability associated with some porosity of the electrodes, that gives rise to a variable background and has some effect upon peak shape in cyclic voltammetry. Typical variability of background caused by electrode variability is illustrated in Figure 2.

RESULTS

The nature of linker **A** was initially explored with a range of spacers (together with either no group or a small group at position **B**), since this was likely to significantly affect the electrochemical properties of the ferrocene due to their close proximity and potential shielding properties. Three types of linker were synthesized: ester, amide, and amine. The synthesis of ferrocenyl esters has been reported using DCC as a coupling reagent, which was found to be effective unless the alcohol had poor solubility when rearrangement of the *O*-acyl urea occurred (*23*, *24*). This was not the case with tri(ethylene glycol), which readily reacted with ferrocenecarboxylic acid **2**, DCC, and

Scheme 1. Synthesis of Ferrocene Conjugates with Different Linkers at A[a]



[a] (i) Tri(ethylene glycol), DCC, DMAP, CH_2Cl_2, 70%; (ii) $(CH_3CO)_2O$, pyridine, DMAP, 80%; (iii) 2-(2-aminoethoxy)ethanol, EDCI, HOBt, CH_2Cl_2, Et_3N, 84%; (iv) Boc_2O, CH_2Cl_2, 30%; (v) **2**, EDCI, HOBt, CH_2Cl_2, Et_3N, 46%; (vi) TFA, CH_2Cl_2, 70%; (vii) 2-(2-aminoethoxy)ethanol, $NaBH_4$, 35%; (viii) CH_2O, $NaBH_4$, 35%; (ix) tri(ethylene glycol), DCC, DMAP, CH_2Cl_2, 30%; (x) 2-(2-aminoethoxy)ethanol, EDCI, HOBt, CH_2Cl_2, Et_3N, 50%.

DMAP to give the ester **3** in 70% yield (Scheme 1). As a control, the ferrocene alcohol **3** was converted into the corresponding acetate **4**, to assess electrochemical properties compared to other analogues.

For the synthesis of the ferrocene amide, commercially available 2-(2-aminoethoxy)ethanol was reacted with ferrocenecarboxylic acid **2** and *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDCI), that has been used in ferrocenecarboxamide synthesis (*24*), together with HOBt to give **5** in 84% isolated yield. The synthesis of a second amide linker with an alternative spacer possessing a terminal amine group was also investigated. The monoprotection of *N*,*N*′-bis-(2-hydroxylethyl)ethylenediamine **6** was achieved using Boc anhydride to give **7** (*20*), which was coupled to ferrocenecarboxylic acid **2** again using EDCI (Scheme 1) in 46% yield. Removal of the Boc group using 50% TFA in CH_2Cl_2 generated **8** in 70% yield.

To synthesize amine-linked conjugates, ferrocenecarboxaldehyde **9** was used. This was coupled to 2-(2-aminoethoxy)-ethanol to afford the corresponding imine, which was then reduced in situ using sodium borohydride to the amine **10**. The amine **10** was also methylated to give the tertiary amine **11**, since this derivative could potentially be used in further coupling reactions to avoid a competing reaction at the nitrogen center. 1,1′-Ferrocenedicarboxylic acid **12** (**X** = CO_2H, Figure 1) was used to prepare disubstituted ferrocenes to assess the effect of difunctionalization on the electrochemical properties: the diester **13** from tri(ethylene glycol), and DCC and DMAP, and diamide **14** from 2-(2-aminoethoxy)ethanol, EDCI, and HOBt (Scheme 1).

From the initial electrochemical data (see below), the ester-linked compound **3**, amides **5** and **8**, and amine **11** were the most suitable ferrocenyl scaffolds. However, as the amine was generated in generally low yields, only the ester and amides were carried through for further structural elaboration. The nature of the solubilizing spacer together with the linker **B** were then explored to assess the influence of the spacer and second linker on electrochemical properties. Depending on the types of spacer and linker incorporated, three different functionalized acids were attached, either 11-aminoundecanoic acid, hexadecanedioic acid, or 16-hydroxyhexadecanoic acid.

Initially, a carbamate linkage was synthesized using the ferrocenyl ester with a PEG-3 spacer. Accordingly, alcohol **3** was activated using *N*,*N*′-disuccinimidyl carbonate (DSC) to give the corresponding *N*-hydroxysuccinimidyl ester which was converted into **15** via coupling with 11-aminoundecanoic acid in THF/H_2O in 74% isolated yield (Scheme 2).

The diester-linked analogue **16** was also prepared from **3** and hexadecanedioic acid using DCC and DMAP in low yield, due to isolation problems and side-product formation; however, sufficient material was prepared for electrochemical analysis. The synthesis of an amide analogue of **15** to establish any benefits of a longer PEG spacer was carried out using an identical method. Compound **5** was activated as the *N*-hydroxysuccinimidyl ester, which was isolated and coupled with 11-aminoundecanoic acid to afford **17** in 78% yield over the two steps.

To evaluate the potential benefits of a longer PEG spacer, compound **21** (an analogue of **17**) was also prepared. Synthesis of the spacer with a terminal amine and alcohol was required, and accordingly, 2-[2-(2-chloroethoxy)ethoxy]ethanol **18** was reacted with potassium phthalimide to give **19** in 70% yield. The hydroxyl group was then activated as before using DSC, and the isolated intermediate was coupled with methyl 11-aminoundecanoate to generate **20**. Removal of the phthalimide group was achieved by treatment with hydrazine in 93% yield, and ferrocenecarboxylic acid **2** was attached to the resulting free amino group using EDCI. Finally, hydrolysis of the methyl ester afforded compound **21**.

Finally, an analogue of **21** with the carbamate reversed was synthesized. To do this, initially methyl 16-hydroxyhexadecanoate **22** was activated and isolated as the *N*-hydroxysuccinimidyl ester **23** in 85% yield. The activated alcohol was coupled with the mono-Boc-protected diamine, **7**, to give compound **24**. The Boc group was removed in quantitative yield using TFA and the resulting amine coupled to ferrocenecarboxylic acid **2**, using DCC and triethylamine. Finally, hydrolysis of the methyl ester revealed the reverse carbamate analogue **25** (Scheme 2).

[a] Electrochemical data were obtained in PBS on printed carbon electrodes with scan rate 50 mV/s. $E_{1/2}$ was taken as the mean of the peak potentials for anodic and cathodic peaks or as the half-wave potential where there was no cathodic peak (compound **13**). The peak current ratio was determined by the extrapolation method illustrated in ref 29. nd: not determined. [b] Shoulder at $E_{1/2} = 250$ mV.

The properties of the ferrocene conjugates were then studied using cyclic voltammetry. In blood samples, electrochemical measurements are complicated due to the presence of several electrochemically active compounds including uric acid, glycine, ascorbic acid, and urea (*25*). These compounds have an oxidation potential of approximately +350 to +550 mV (vs Ag/AgCl reference). The various components of the blood including proteins such as HSA produce a significant electrochemical background signal at approximately +550 mV. For use in binding studies, compounds with reversible voltammograms and an $E_{1/2}$ of approximately +350 mV are preferred to limit the interference from such an electrochemical background.

The range of electrochemical behavior observed is given in Table 1 and illustrated in Figure 2. For some compounds (the esters and the disubstituted compounds), a second process appearing as a shoulder at lower $E_{a,p}$ was occasionally observed. The probable explanation, since the appearance of the effect correlated with the time between synthesis and electrochemical measurement (up to several weeks in some cases) is that it was due to ferrocene carboxylic acid formed by hydrolysis of the compound. For comparison, the cyclic voltammetry curve for ferrocenecarboxylic acid (FcCOOH) has a half-wave potential $E_{1/2}$ of approximately +300 mV (vs Ag/AgCl) (*26*). A one-electron reversible electrochemical process would have peak to half-peak and anodic peak to cathodic peak potential differences ($E_{p,a} - E_{p,a/2}$ and $E_{p,a} - E_{p,c}$) of approximately 60 mV, in the absence of effects due to ohmic drop between working and reference electrodes, and would have the peak current ratio $I_{p,a}/I_{p,c} = 1$. The compounds all essentially satisfied

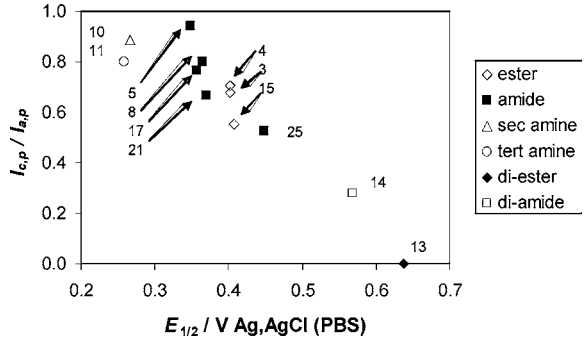

Figure 3. Variation with half-wave potential, $E_{1/2}$, of ratio of cathodic to anodic peak current in cyclic voltammetry, $I_{c,p}/I_{a,p}$ The points are labeled with the compound number.

the criteria for the peak potential differences, but not for the peak current ratio. A satisfactory interpretation is that the oxidized product of the anodic reaction (ferrocenium) decomposes to an electroinactive species at a rate dependent upon the substituents. There was a systematic trend with the nature of linker **A** and the length of the substituent chain, shown in Figure 3: as $E_{1/2}$ increased, indicating relative destabilization of the ferrocenium cation, the decomposition rate of ferrocenium, measured by $I_{p,c}/I_{p,a}$, also increased.

DISCUSSION

Since the carboxylate anion can stabilize ferrocenium more than an amide group, conversion of ferrocene carboxylic acid to an amide or ester should cause a shift to a higher redox potential, as observed. The shift in $E_{1/2}$ caused by substitution onto the ferrocene correlates with the expected relative ability of the substituent groups to disperse the charge on the ferrocenium cation: amine > amide > ester > diamide > diester. The amide **8**, possessing a slightly longer PEG unit than the amide conjugate **5** and a terminal amine group, had a similar $E_{1/2}$ value, indicating that further substitution should not affect the electrochemical properties significantly. Indeed, previous studies on ferrocenoyl peptides have indicated that the electrochemical behavior was relatively insensitive to the amino acid R group (*27*). However, there was a discernible effect in each group of compounds of the length of the alkyl chain—the longer the chain, the lower the ratio $I_{c,p}/I_{a,p}$ and, to a degree perhaps dependent on the nature of the second linker, the greater $E_{1/2}$.

These results indicated that when the ferrocenyl esters were linked through either a carbamate or an ester to a fatty moiety, $E_{1/2}$ increased such that compounds **15** and **16** were unsuitable for application in an electrochemistry in protein solutions, plasma, and blood. In contrast, ferrocenyl amides linked to a fatty moiety through a carbamate unit, compounds **17** and **21**, showed $E_{1/2}$ values close to that observed without the linked fatty acid chain. Interestingly, however, the reverse carbamate **25** had significantly increased $E_{1/2}$, possibly due to hydrogen-bonding effects and folding of the molecule. The best properties were displayed by compounds **17** and **21**, but **17** was more synthetically accessible. This was therefore selected as our model compound for further synthetic and electrochemical studies.

In summary, two structural characteristics can be identified that determine the reversibility and half-wave potential for oxidation. The first is stabilization of ferrocenium (Fc^+) by electron donation from ring substituents. Thus, the lowest $E_{1/2}$ is found for ferrocene carboxylic acid (stabilization of Fc^+ by carboxylate attached directly to the ring) and for amines **10** and **11** where the nitrogen is separated from the ring by a methylene group: ferrocene methanol has a similar $E_{1/2}$ value (*28*). If the carboxylic acid is derivatized as the corresponding amide or ester, then $E_{1/2}$ increases, with the amide being more effective at stabilizing Fc^+ than the ester. The disubstituted ferrocenes are most likely distorted: this was supported by the ^{13}C NMR spectroscopic data with the two carbonyl signals separated by more than 30 ppm. The second effect relates to the way in which long-chain substituents can potentially fold around the ferrocene (*5*, *6*). The effect seems to be determined by the length of the chain and functional group at the linker. Thus, we have identified that, to enable electrochemical measurements to be made in protein solutions, plasma, and blood, an amide at linker **A**, carbamate at linker **B**, short PEG unit, and fatty acid moiety are required for use in biomolecular binding studies, to mimic fatty acid binding. Applications of the model compound **17** and analogues as an electrochemical probe of biochemical interaction will be described in a future paper (*30*).

Isermann Department of Chemical and Biological Engineering, Rensselaer Polytechnic Institute, Troy, New York 12180, and Department of Laboratory Medicine and Pathobiology, University of Toronto, 1 King's College Circle, Toronto, Ontario M5S1A8, Canada. Received February 21, 2006; Revised Manuscript Received June 18, 2006

We report the synthesis of biodegradable polyvalent inhibitors of anthrax toxin based on poly-L-glutamic acid (PLGA). These biocompatible polyvalent inhibitors are at least 4 orders of magnitude more potent than the corresponding monovalent peptides in vitro and are comparable in potency to polyacrylamide-based inhibitors of anthrax toxin assembly. We have elucidated the influence of peptide density on inhibitory potency and demonstrated that these inhibitory potencies are limited by kinetics, with even higher activities seen when the inhibitors are preincubated with the heptameric receptor-binding subunit of anthrax toxin prior to exposure to cells. These polyvalent inhibitors are also effective at neutralizing anthrax toxin in vivo and represent attractive leads for designing biocompatible anthrax therapeutics.

INTRODUCTION

Polyvalency refers to the simultaneous attachment of multiple ligands to multiple complementary receptors (*1*, *2*). Nature uses polyvalency in a variety of biological contexts, including interactions between bacterial toxins and cell surface receptors (*1*, *3*−*6*). Polyvalent interactions can collectively be much stronger than the corresponding monovalent interactions, and several groups have successfully used this concept to enhance the potency of synthetic ligands (*1*, *2*, *7*−*15*). Linear polymers present an attractive scaffold for the polyvalent display of ligands, because they are easily synthesized and their structure and the composition of ligands can be modulated (*7*, *8*, *11*, *16*−*18*). Poly-L-glutamic acid (PLGA) represents a particularly attractive scaffold for designing polymeric therapeutics because of its high water solubility, biodegradability, and low toxicity (*19*−*21*). Consequently, researchers have conjugated PLGA with drugs such as camptothecin, paclitaxel, doxorubicin or antibodies for drug delivery (*21*−*26*), with DNA for gene delivery (*27*−*29*), and with other ligands for synthesizing inhibitors of the influenza virus (*20*, *30*, *31*).

We report the design of potent polyvalent inhibitors of anthrax toxin based on PLGA. Anthrax toxin—responsible for the major symptoms and death in anthrax—is composed of three proteins: two enzymes, lethal factor (LF) and edema factor (EF), and a cell-binding protein, protective antigen (PA). PA is cleaved into a 63 kDa fragment that forms heptamers, $[PA_{63}]_7$, on the surface of target cells and translocates LF and/or EF into the cytosol wherein they exhibit their toxic effects (*3*). The biocompatible inhibitors reported in this work prevent the binding of LF to $[PA_{63}]_7$ and neutralize anthrax toxin both in vitro and in vivo.

EXPERIMENTAL PROCEDURES

Materials and Methods. Poly-L-glutamic acid sodium salt (M_w = 7.5, 17.6, 41.4 kDa) and 1-hydroxybenzotriazole (HOBt), was purchased from Sigma (St. Louis, MO). 1-[3-(Dimethylamino)propyl]-3-ethylcarbodiimide (EDC) was purchased from Acros Chemicals (Somerville, NJ). Solvents were purchased from Acros Chemicals (Somerville, NJ) and were anhydrous unless stated otherwise. Peptide Ac-HTSTYWWLDGAPK-Am was purchased from Genemed Synthesis, Inc. (South San Francisco, CA). Spectra/Por4 (MWCO = 12 000−14 000) dialysis membranes were purchased from Spectrum Laboratories (Rancho Dominguez, CA). ^{1}H and ^{13}C NMR spectra were recorded on a Varian 500 MHz spectrometer. Chemical shifts are reported in parts per million (ppm) relative to trimethylsilane (TMS) for the ^{1}H NMR spectra and relative to DMSO-d_6 at 39.5 ppm for the ^{13}C spectra. Gel permeation chromatography (GPC) was carried out using a ViscoGEL column (GMPWXL, Mixed Bed, dimensions: 7.8 mm × 30 cm) using phosphate-buffered saline as the eluent (pH 7.5, 20 mM NaH_2PO_4, 130 mM NaCl, flow rate = 1 mL/min, dn/dc = 0.190 mL/g). Molecular weight was estimated using a light scattering instrument (Viscotek 270 Trisec Dual Detector; OmniSEC software, λ = 670 nm). Infrared measurements were made on an FT-IR spectrophotometer (Biorad FTS-3000 MX). CD spectra were recorded on a J-715 instrument (Jasco, Easton, MD) (Xe lamp, cell length 0.2 mm) using the Spectra Manager software.

Synthesis of Activated PLGA. EDC (140 mg, 0.662 mmol) and a solution of HOBt (111 mg, 0.728 mmol) in *N*,*N*-dimethylformamide (DMF) (1 mL) were added to a solution of PLGA sodium salt (50 mg, 0.331 mmol) in water (1 mL) at room temperature (*31*). The reaction mixture was stirred at room temperature for 1 h. The resulting precipitate was washed with water and dried under vacuum. The residue was dissolved in DMF (2 mL) along with HOBt (111 mg), and a solution of EDC (280 mg) in water (1 mL) was added. The reaction mixture was stirred at room temperature for 1 h. The resultant precipitate was washed with water, followed by 2-propanol and dried under vacuum to give activated PLGA (60% yield, complete conversion of carboxylic acid groups to activated esters). ^{1}H NMR (DMSO-d_6): δ 1.6−2.0 (br, 2H), 2.0−2.4 (br, 2H), 3.8−4.3 (br, 1H), 7.2−8.4 (br, m, 4H). ^{13}C NMR (DMSO-d_6): δ 27.2, 30.2, 52.0, 109.9, 119.1, 124.4, 126.8, 127.9. IR (KBr): 3295, 3073, 1717, 1655, 1549, 1388, 1297, 1263, 1105, 777, 742 cm^{-1}. Elemental analysis was carried out after reaction of the activated PLGA with aqueous ammonium hydroxide. Calcd. (%) for 0.7-($C_5H_7NO_3$)·0.3($C_5H_8N_2O_2$)·1H_2O: C, 40.89; H, 6.34; N, 12.41; O, 40.31. Found: C, 39.60; H, 5.84; N, 12.68; O, 38.46.

Synthesis of Polyvalent Inhibitors of Anthrax Toxin. Activated PLGA was dissolved in DMF (5 mg/mL, 30 mM of repeat unit). Peptide, Ac-HTSTYWWLDGAPK-Am, dissolved in DMF, was then added to the polymer solution followed by triethylamine (twofold excess based on repeat unit). The mixture was allowed to react overnight at room temperature, following which the unreacted active ester groups in the polymer backbone were quenched using ammonium hydroxide (fivefold excess based on repeat unit). The polymer was dialyzed extensively using MilliQ water for 2 days and lyophilized to yield a white powder. ^{1}H NMR (DMSO-d_6): δ 0.6−0.86 (br), 0.88−1.06 (br), 1.1−1.4 (br), 1.4−1.6 (br), 1.6−2.0 (br), 2.0−2.3 (br), 2.7−3.0 (br), 3.8−3.95 (br), 3.95−4.2 (br), 4.2−4.4 (br), 4.4−4.6 (br), 6.4−6.6 (br), 6.7−6.8 (br), 6.8−7.2 (br), 7.2−7.4 (br), 7.4−7.6 (br), 7.6−8.4 (br).

Estimation of Molecular Weight. Polymers obtained by hydrolysis of activated PLGA with 0.1 N NaOH were characterized using aqueous GPC with a ViscoGEL column (GMPWXL, Mix Bed, dimensions: 7.8 mm × 30 cm) using phosphate-buffered saline as the eluent. The molecular weight was estimated using a laser light scattering instrument (Viscotek 270 Trisec Dual Detector; OmniSEC 4.0 software, λ = 670 nm) inline with the column. A decrease in molecular weight was observed after activation, as reported earlier by Paterson and Leach (*32*); the polydispersity of the polymers was ca. 1.3. The average number of peptides per polymer chain was calculated using the number average molecular weight (M_n) and the peptide density (estimated by ^{1}H NMR spectroscopy), accounting for the error due to the polydispersity of the polymer and the error in estimating the peptide density by NMR spectroscopy.

Circular Dichroism Measurements. Circular dichroism (CD) measurements were carried out at room temperature (23 °C) on a JASCO J-715 spectropolarimeter. The spectra were scanned in a quartz optical cell with a path length of 0.2 mm. All spectra were recorded in 0.2 nm wavelength increments with a 4 s response and a bandwidth of 1 nm and at a scanning speed of 100 nm/min. For observing the secondary structure of the polymers, the samples were dissolved in 20 mM sodium phosphate buffer (pH 7.5), and the spectra were scanned from 180 to 250 nm. Each spectrum is the average of five scans with a full scale sensitivity of 100 mdeg. All spectra were corrected for background.

Cytotoxicity Assay. RAW264.7 cells were grown in RPMI medium supplemented with 5% fetal calf serum (Hyclone). The cells were plated on a 96-well plate and either left untreated or treated with PA (10^{-9} M), LF (3×10^{-10} M), and various concentrations of the inhibitors and incubated for 4 h at 37 °C in 5% CO_2. For the preincubation experiments, $[PA_{63}]_7$ (3×10^{-9} M) was incubated with various concentrations of inhibitors for 0, 1, or 2 h, before adding LF (10^{-9} M) and incubating the mixture with cells for 4 h at 37 °C in 5% CO_2. Cell viability was assessed by adding 20 μL of a mixture of MTS (3-(4, 5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium) and phenazine methosulfate (PMS) to each well and incubating for 1 h, according to manufacturer's instructions (Promega). The amount of soluble formazan product generated from the reduction of MTS by living cells was determined by measuring the absorbance at 490 nm. The IC_{50} of each inhibitor was determined using the software program *Prism* (GraphPad Software).

Rat Intoxication. Purified PA (40 μg) and LF (8 μg) diluted in PBS were mixed with PBS, the monovalent peptide (300 nmol) in PBS, or the polyvalent inhibitor (300 nmol on a per-peptide basis) in PBS. Fisher 344 rats (Charles River Laboratories) were injected intravenously in the tail vein. The rats were injected with the different mixtures, and the appearance of symptoms of intoxication was monitored. When the symptoms were obvious, the rats were euthanized to avoid unnecessary distress.

(B) Influence of peptide density on the potency of polyvalent inhibitors with different molecular weights M_w = 4.5 kDa (●), 12 kDa (■), and 29 kDa (□); average number of repeat units ca. 27, 70, 170, respectively.

RESULTS AND DISCUSSION

Synthesis and Characterization of PLGA-Based Polyvalent Inhibitors. To synthesize a PLGA-based polyvalent inhibitor, we activated the carboxylic acid groups of PLGA using 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide (EDC) and 1-hydroxybenzotriazole (HOBt) (see Experimental Procedures). The activated polymer was allowed to react with the peptide Ac-HTSTYWWLDGAPK-Am, a peptide that binds $[PA_{63}]_7$ and inhibits the binding of LF (*7*). The remaining active ester groups were quenched by a reaction with aqueous ammonium hydroxide (Scheme 1). We also synthesized unfunctionalized (control) polymers by reacting the activated polymers with aqueous ammonium hydroxide. Elemental analysis suggested that the polymer backbone of the control polymer was composed of a mixture of glutamine and glutamic acid units (3:7). This polymer had an aqueous solubility in excess of 30 mg/mL.

In Vitro Activity of Polyvalent Inhibitors. To test the ability of the PLGA-based polyvalent inhibitors to neutralize anthrax toxin in vitro, we incubated RAW264.7 cells with a mixture of PA and LF in the presence or absence of inhibitors. While the monovalent peptide had no activity at concentrations as high as 250 μM (data not shown), the polyvalent inhibitor could inhibit toxin activity with a half-maximal inhibitory concentration (IC_{50}) of 20 nM on a per-peptide basis (Figure 1A). Polyvalency therefore enabled an enhancement in the potency of the peptide by over 4 orders of magnitude. Unfunctionalized polymers showed no appreciable activity (Figure 1A). Furthermore, the potency of the inhibitor based on the biocompatible

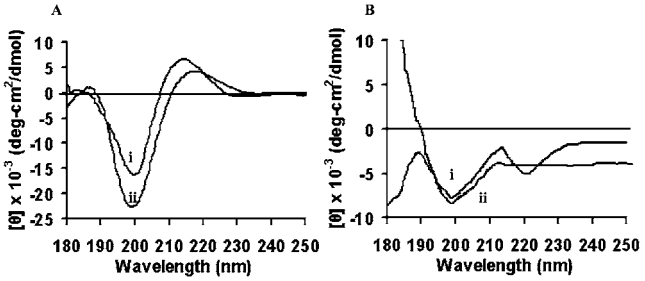

Figure 2. (A) CD spectrum of (i) ammonia hydrolyzed activated PLGA, (ii) NBS-treated PLGA-based polyvalent inhibitor. (B) CD spectrum of (i) monovalent peptide, (ii) NBS-treated monovalent peptide. [θ] is the mean residue molar ellipticity.

polymer, PLGA, was comparable to that of a previously reported inhibitor based on a polyacrylamide backbone (IC_{50} = 50 nM) (Figure 1A) (*33*).

Influence of Peptide Density on the Potency of the Polyvalent Inhibitors. To elucidate the influence of peptide density on inhibitory potency, we synthesized a series of polyvalent molecules based on PLGA backbones of three different molecular weights, with peptide densities varying between 0% and 18%. For each backbone, we observed an initial sharp increase in potency (decrease in IC_{50}) with increasing peptide density, followed by a transition to a plateau, where the potency is independent of peptide density (Figure 1B). While the polydispersity of the backbone prevents a precise estimation of the number of peptide units per chain near the transition, the number was small (less than ten) for each backbone and was also close to the number of peptide-binding sites on the heptameric target (seven).

Characterization of PLGA-Based Polyvalent Inhibitors by Circular Dichroism Spectroscopy. To further characterize these polyvalent molecules, we used circular dichroism (CD) spectroscopy. Characterization by CD spectroscopy revealed that the unfunctionalized (control) polymer obtained by the reaction of activated PLGA with aqueous ammonium hydroxide exists in an unordered (random coil) structure as seen from the strong negative band near 200 nm (Figure 2A) (*34*). A similar spectrum was previously reported for PLGA (*35*, *36*). The CD spectrum of the monovalent peptide shows two minima, one near 222 nm, which is characteristic of tryptophans (*37*), and the other near 200 nm (Figure 2B). In order to resolve the spectrum, we treated the monovalent peptide and the PLGA-based polyvalent inhibitor with *N*-bromosuccinimide (NBS), which is known to oxidize the indole of tryptophan to oxindole, resulting in the disappearance of the peak near 222 nm (*38*). The resulting spectra show that the monovalent peptide and the polyvalent inhibitor exist as unordered (random coil) structures (Figure 2A,B). The CD spectrum of the NBS-treated peptide is similar near 200 nm to that of the unmodified peptide, indicating that there is no significant change in the secondary structure of the peptide on modification.

Influence of Kinetics on the Potency of the Polyvalent Inhibitors. We hypothesized that the enhancement in potency obtained through polyvalency might be limited by kinetics, since equilibrium between the polyvalent inhibitor and $[PA_{63}]_7$ might not be reached before the toxin is endocytosed. To determine if kinetics limit the potency of the polyvalent inhibitor, we preincubated the inhibitor with $[PA_{63}]_7$ for different amounts of time before adding LF and exposing cells to this mixture. If kinetics play a role in influencing the potency of the inhibitor, then one would expect the IC_{50} to decrease with increasing preincubation time. We observed an order of magnitude decrease in the IC_{50} of the inhibitors following preincubation with $[PA_{63}]_7$ for 2 h (Figure 3), confirming that the enhancement in inhibitory potency is limited by kinetics.

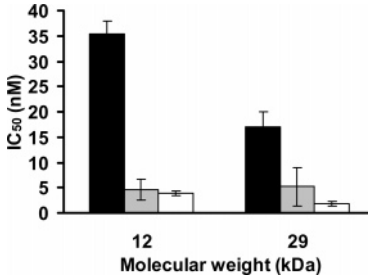

Figure 3. Preincubation of $[PA_{63}]_7$ with a polyvalent inhibitor decreases the measured IC_{50}. $[PA_{63}]_7$ was incubated with various concentrations of two different molecular weight inhibitors for 0 h (■), 1 h (grey shaded column), and 2 h (□). Following the preincubation period, the inhibitor−$[PA_{63}]_7$ mixtures were tested in cytotoxicity assays.

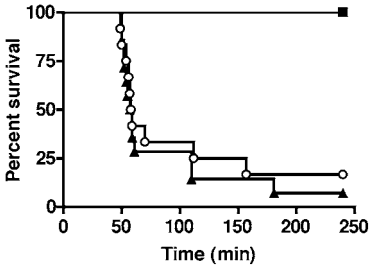

Figure 4. PLGA-based inhibitor protects rats from lethal toxin challenge. Rats were injected with lethal toxin alone (▲, n = 14), lethal toxin plus Ac-HTSTYWWLDGAPK-Am peptide (○, n = 12), or lethal toxin plus PLGA-based inhibitor (■, n = 7). The log-rank test indicates a statistically significant difference between the group that received lethal toxin alone and the group that received the toxin plus the PLGA-based inhibitor (P = 0.0002), but no significant difference between the group that received lethal toxin alone and the group that received the toxin along with peptide (P = 0.54).

In Vivo Activity of PLGA-Based Polyvalent Inhibitors. Biocompatible and biodegradable polymer scaffolds are particularly suitable for the synthesis of anthrax toxin inhibitors that can be used in vivo. We therefore tested the ability of PLGA-based inhibitors to neutralize anthrax toxin in Fischer rats. Although the inhibitor was coinjected with the toxin, neutralization could occur only in vivo, since the inhibitor binds to $[PA_{63}]_7$ and not to PA. As seen in Figure 4, 13 of 14 rats injected with toxin alone (40 μg of PA and 8 μg of LF) became moribund, while none of the rats that received the polyvalent inhibitor along with the toxin became moribund. The log-rank test indicates that the difference between these two groups is statistically significant (P = 0.0002). In contrast, the log-rank test does not indicate a significant difference between the group that received lethal toxin alone and the group that received the toxin along with the monovalent peptide (P = 0.54; see Figure 4).

CONCLUSION

In summary, we have designed inhibitors of anthrax toxin that are more than 4 orders of magnitude more potent than the corresponding monovalent inhibitors. This study shows that even a small number of pendant ligands, which is close to the number of binding sites on the target, may be sufficient to synthesize a potent polyvalent inhibitor. The enhancements in potency obtained from polyvalent systems may not be governed solely by thermodynamics, as is often assumed, but also by the kinetics of binding, suggesting that the intrinsic enhancements in affinity may be even greater than the already impressive numbers reported. These PLGA-based inhibitors are comparable in potency to the best polyvalent inhibitors of anthrax toxin assembly, and the biocompatibility of their scaffolds makes them attractive for in vivo use.

ACKNOWLEDGMENT

This research was supported by NIH grant U01 AI056546. We thank the Biochemistry Core Facility at the Wadsworth Center for use of the circular dichroism and chromatography instrumentation.

Synthesis and Characterization of AP5346, a Novel Polymer-Linked Diaminocyclohexyl Platinum Chemotherapeutic Agent

Paul Sood,* K. Bruce Thurmond, II, Jeremy E. Jacob, Lynda K. Waller, George O. Silva, Donald R. Stewart, and David P. Nowotnik

Access Pharmaceuticals, Inc., 2600 Stemmons Freeway, Suite 176, Dallas, Texas 75207. Received March 1, 2006; Revised Manuscript Received June 28, 2006

Syntheses of the novel polymer-bound platinum-based chemotherapeutic agent poly(HPMA)-GGG-Ama=Pt=(1*R*,2*R*)-DACH, AP5346, and its precursors are reported. The method utilized in preclinical development of AP5346 is described herein. Additionally, an improved synthesis, which has shown that ion exchange resins can be removed, significantly less platinum can be used when the reaction mixture is pH-stated, and the synthesis can be performed at a higher concentration, is reported. These combined improvements result in a more cost-effective, scaleable procedure. Various methods of analysis of the drug substance are also discussed. Specifically, ^{1}H NMR spectroscopy is used for identity and can also distinguish small molecule impurities to below 0.1%. ^{195}Pt NMR determines the coordination environment of the platinum and also identity and purity in relation to platinum chelation of the construct. Size exclusion chromatography is used to establish the molecular weight of AP5346 while ICP-AES determines platinum content and platinum release rates in phosphate-buffered saline. The cumulative results of this work have yielded an efficient syntheses of a polymer-based chemotherapeutic agent with subsequent detailed characterization methods.

INTRODUCTION

Since the serendipitous discovery of the anticancer properties of cisplatin by Rosenberg (*1*), platinum-containing drugs have been extensively used in the treatment of solid tumors (*2*). When administered with other agents, cisplatin has exhibited remarkable activity against refractive disease states. In combination chemotherapy with paclitaxel survival rates of patients with advanced ovarian cancer are significantly improved, while co-administering the drug with vinblastine and bleomycin is extremely effective against testicular cancer (*3*). This effectiveness has resulted in cisplatin now being one of the three most utilized chemotherapeutics in the world. However, clinical use of cisplatin has been limited by the severe side effects which accompany its use, the most prominent being nephrotoxicity, neurotoxicity, nausea, and vomiting (*4*−*7*). Additionally, intrinsic or acquired tumor resistance is a major issue.

Such limitations, coupled with a narrow therapeutic index and poor solubility, have been the driving force behind a sustained research effort into the discovery of novel platinum agents or novel formulations and delivery methods of existing platinum agents. The resulting compounds would preferably have better toxicity profiles, improved efficacies, and a broader spectrum of activity. Many new platinum molecules have undergone preclinical and clinical testing; however, only carboplatin and oxaliplatin (Figure 1) have been approved worldwide for routine use in the clinic. Additionally, nedaplatin has been approved for use against ovarian and cervical cancers in Japan (*8*). The *cis*-NH_3 ligands in cisplatin are also present in both carboplatin and nedaplatin, whereas the two chlorides have been replaced by the more stable cyclobutanedicarboxylate and glycolate ligands, respectively. In oxaliplatin the *cis*-NH_3 groups have been replaced by a diaminocyclohexyl (DACH) chelate ligand and the chlorides by an oxalato chelate. The influence of structure on the activity and toxicity of Pt anti-cancer drugs has been comprehensively described by Hambley (*9*). Carboplatin has been shown to less toxic than cisplatin and therefore can be administered at much higher doses (*10*) with the dose-limiting toxicity being myelosuppression (*11*). Oxaliplatin is active in colorectal cancer and has supplanted carboplatin and cisplatin as the largest selling platinum therapeutic. Despite its success, the most frequently encountered dose-limiting toxicity of this agent is acute onset neurotoxicity which is observed in approximately 90% of patients, while 10−15% of patients suffer from cumulative sensory neuropathy (*12*).

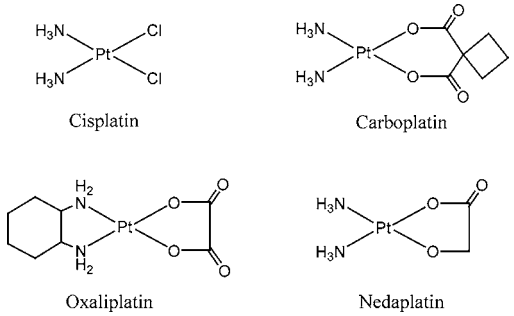

Figure 1. Structures of cisplatin, carboplatin, oxaliplatin, and nedaplatin.

In order to improve the therapeutic index of platinum agents, Access Pharmaceuticals has used a rational drug design approach, based on the principles of polymer drug delivery, to develop a polymer-linked DACH-platinum chemotherapeutic, AP5346. The biodistribution of soluble macromolecules is governed extensively by their ability to penetrate endothelial layers. As growing tumors establish their own blood supply, they develop pathological neovasculature whose blood vessels are frequently hyperpermeable to circulating macromolecules and small particulates. In addition to this enhanced permeability, tumor tissue often has limited lymphatic and/or capillary drainage, so the macromolecules can be trapped and concentrated in tumors (extensively reviewed in ref 13). If a chemotherapeutic agent is coupled to a suitable polymer or other

macromolecular carrier *via* a biodegradable linker, then such carriers have the potential of increasing the concentration of the chemotherapeutic agent within the tumor tissue. As a result of these characteristics, concentrations of polymer−drug conjugates in tumor tissue can reach levels some 10−100 times higher than that produced by administration of the free drug (*14*). This effect has been termed the "enhanced permeability and retention" (EPR) effect (*15*). In addition, the intrinsic cytotoxicity of the native drug is often substantially diminished when the drug is chemically linked to the polymer. This also reduces the systemic toxicity of the polymer−drug conjugate relative to the native drug.

The concept of linking a platinum agent to the water-soluble, biocompatible copolymer, *N*-(2-hydroxypropyl)methacrylamide (HPMA), was initially developed at the School of Pharmacy, University of London (*16*). The first HPMA-based chemotherapeutic drug conjugate to enter clinical trials was an HPMA−doxorubicin conjugate named PK1 (*17*). An analogue of PK1, named PK2, is also under clinical evaluation (*18*). Additional poly(HPMA)-based drug (camptothecin and paclitaxel) conjugates have also been investigated (*19, 20*). Generally for HPMA polymer platinum constructs, conjugates are synthesized by copolymerization of HPMA monomer with another monomer unit containing an oligopeptide side chain. The latter moiety contains an activated group such as a paranitrophenoxy unit, which can be substituted with a chelating ligand. This terminus to the oligopeptide is then further reacted with a platinum reagent to form the polymer−platinum construct (*21*). In other synthetic methodologies, cyclic polyphosphazene is polymerized to form a linear polyphosphazene backbone unit to which a linker-glutamate chelator moiety is then attached (*22*). This is subsequently reacted with a platinum agent to form the drug−polymer entity. A review of current polymer−platinum drug syntheses was described by Siegmann-Louda and Carraher (*23*).

The polymer-linked DACH−platinum agent AP5346 is a further example of an HPMA-based polymer therapeutic which was designed to deliver more platinum-containing drug to the tumor than can be achieved by conventional small molecule platinum agents. It consists of a hydrophilic polymer backbone linked by a tripeptide to a chelated platinum (II) species. The structure is denoted as poly(HPMA)-GGG-Ama═Pt═1*R*,2*R*-DACH, where HPMA denotes the polymer backbone, GGG denotes the tripeptide glycyl-glycyl-glycine, and the Ama═Pt═1*R*,2*R*-DACH denotes the *N*,*O*-amidomalonate═Pt-(1*R*,2*R*)-diaminoclyclohexane chelate. Preclinical data for AP5346 shows that it repeatedly exhibits superior tumor growth inhibition in numerous cell lines than oxaliplatin (*24*, *25*). This paper describes the AP5346 manufacturing procedure and characterization methods developed prior to the initiation of clinical trials, and details of an improved synthetic procedure.

EXPERIMENTAL PROCEDURES

Materials. Commercial reagents and solvents were purchased from the following sources: Pyridine (Fisher), ethanol (absolute, Aaper Alcohol), ethyl acetate (HPLC grade, Fisher), diethyl ether (ACS, Fisher), acetone (HPLC grade, Fisher), AIBN (Aldrich, recrystallized from dichloromethane), triethylamine (Aldrich), Bio-Rex MSZ 501 D resin (Bio-Rad), $DACHPt(NO_3)_2$ (Strem).

Instrumentation. NMR spectra were recorded on a Bruker AVANCE300 multinuclear NMR spectrometer resonating at 300.131 MHz for ^1H and 64.354 MHz for ^{195}Pt. A Bruker Variable Temperature unit held samples at a constant temperature of 300 K. ^1H NMR samples were prepared by dissolving 20 ± 5 mg of material in 0.7 mL of D_2O and then filtering the sample into a 5 mm NMR tube. ^1H resonances were referenced to TMSP at 0 ppm. ^{195}Pt NMR samples were prepared by dissolving 100 ± 5 mg of AP5346 in 0.7 mL of 93/7 H_2O/D_2O and filtering the sample into a 5 mm NMR tube. ^{195}Pt resonances were externally referenced to Na_2PtCl_6 at 0 ppm. Spectra were obtained using a broadband observe 5 mm probe with *z*-axis gradient capability. ^1H spectra were acquired using the standard Bruker pulse program *zg30* with 16 scans in 25 K data points over a 3.592 kHz spectral width (3.5 s acquisition time). For ^{195}Pt NMR experiments the 90° pulse width was calculated from the 360° pulse width using the Na_2PtCl_6 sample with the transmitter on resonance. The transmitter power was set to give a 90° pulse of ca. 10 μs. For samples of AP5346 the transmitter offset (o1p) was placed midway between the N,O- and N,N-chelates at −2550 ppm. The Bruker pulse program *zgmultiscan* was modified to execute a very short delay time (set at d1 = 2 ms) followed by a hard 90° pulse. The experiment was run in increments of 20 000 scans (ns = 20 000) over a 130 kHz sweep width (9 ms acquisition time). A loop counter parameter l3 = 100 was incorporated such that the initial iteration of 20 000 scans was repeated 90 times to give an accumulated number of 2 000 000 scans (the FIDs from each iteration were automatically combined and Fourier transformed to produce the frequency domain spectrum). The FIDs of AP5346 samples were processed to determine what peaks were present and the percent of the N,O-chelate relative to the total area of all integrated peaks. To these ends the following steps were taken with the exponential line broadening set at 150 Hz. The line broadening was selected prior to Fourier transform of the FID and may be increased or decreased appropriately to obtain the best resolved spectrum. First, the FID was left-shifted, Fourier transformed, and phased. This step was repeated until the baseline was flat. Second, a polynomial baseline correction was applied to the spectrum. Finally, the integral values were set such that the total of the integrated peaks was 100 which produced a convenient percent ratio of chelates. ^1H and ^{195}Pt NMR were used to determine both identity and purity of AP5346. For identity, the former indicates the presence of HPMA and MA-Gly-Gly-Gly-derived subunits while the latter shows the chelation environment of the platinum complexes and the chelate ratio. ^1H NMR was used to determine the percent of impurities with fixed or nonexchangeable hydrogen atoms such as ethanol and isopropyl alcohol. ^{195}Pt NMR was used to verify purity in that no less than 90% of the integrated peaks correspond to the amido-malonato-N,O-chelate.

A Viscotek TriSec Model 302 gel permeation chromatography (GPC) instrument was used to determine molecular weight distribution as reported by the M_w, M_n, and polydispersity index (PDI) of AP5346. The system consists of an HPLC pump with an autosampler, a refractive index detector, and a column oven set at 40 °C. Three PL Aquagel-OH mixed bed columns (one 70 × 7.5 mm guard column and two 300 × 7.5 mm analytical columns with 8 μm particles) were used. The mobile phase consists of 35/65 $MeOH/H_2O$ with 10 mM $LiClO_4$ and was pumped at 1.0 mL/min. The columns were calibrated with PEO/PEG standards (∼1.5 to 205 kD) and results fit to a fourth order polynomial of $\log(M_p)$ vs RT^{-1}. The sample was dissolved in mobile phase to give a ∼1 mg/mL solution of which 100 μL was injected. The standards and sample were run in triplicate. The reported values for M_w, M_n, and PDI represent the average of the three determinations.

Inductively coupled plasma-atomic emission spectroscopy (ICP-AES) was used for the determination of platinum in two identity analyses and one purity analysis. The identity tests were the determination of %Pt in AP5346 and the %Pt released from the polymer system at 3 and 24 h in PBS at 38 °C. The purity test was the determination of the %free Pt in pure water at ambient temperature. While release of low molecular weight platinum species within the tumor extracellular fluid or the

malignant cell itself is probably required for anticancer activity, the pharmaceutical constraints of a drug product mandate that the platinum complex remains bound to the polymer prior to administration and that release of platinum from AP5346 be minimal while in systemic circulation. The release of platinum species from the polymer carrier of AP5346 is of interest for both pharmaceutical and physiological reasons. From a pharmaceutical perspective, the release of platinum from AP5346 is a fundamental chemical characteristic, and it is a requirement of a pharmaceutical product that this property remain within a narrow range for all batches of the manufactured product.

The %Pt was determined by accurately weighing 15 ± 0.1 mg of AP5346 into each of three 20 mL scintillation vials. An accurately weighed quantity of 20 g of 3% HNO_3 was added to each vial and the mixture was vortexed to give a homogeneous sample. Platinum standards at 0, 30, and 60 ppm were prepared from a dilution of a 1000 ppm certified Pt standard in 3% HNO_3. The emission at 214.42 nm of the samples and standards were detected. From these standards a calibration curve was generated from which the amount of platinum in the sample was calculated. The results from the three samples were averaged and reported as the %Pt.

The %Pt released at 3 and 24 h from a PBS solution at 38 °C was determined by weighing 42 ± 0.1 mg of AP5346 into a 50 mL Corning centrifuge tube. Sufficient PBS solution (Sigma Chemicals: 120 mM NaCl, 2.7 mM KCl, 10 mM sodium phosphate salts, pH ~7.4) was added to make a ~2 mg/mL solution, and the mixture was vortexed to homogeneity. The solution was placed in an oven at 38 °C. After 3 h a 2.5 mL aliquot was transferred to each of three prewashed Centricon YM-3 (Millipore Corporation, 3 kDa NMWCO) ultracentrifugation devices. The charged devices were spun down at 38 °C and 4100 rpm for 90 min. After 24 h at 38 °C three additional prewashed Centricon YM-3 devices were similarly charged and centrifuged. A sample for the total Pt content is prepared by diluting 200 μL of the stock solution with 4 mL of the HNO_3/PBS solution. The six filtrates were transferred into 7 mL scintillation vials containing 4.0 mL of a 3% HNO_3/PBS solution from which a calibration curve was generated. The Pt concentration of the stock solution and the 3 and 24 h samples were determined from the emission at 214.42 nm. The %Pt released at 3 and 24 h is calculated from the ratio of the Pt content in the filtrates relative to the stock solution. The average of the three samples at each timepoint was reported.

The %free Pt of AP5346 was determined in pure water at ambient temperature. The method used was similar to that described above for 3 and 24 h release rates in PBS except the stock solution was allowed to stand for 1 h before being centrifuged. In this case, however, the calibration curve is generated using 0, 5, and 10 ppm Pt standards. The free Pt was a combination of (i) unbound small molecule Pt species, (ii) small molecule Pt species released from the polymer, and (iii) Pt attached to lower molecular weight polymer chains which have breached the membrane.

The sodium, chloride and phosphate (as phosphorus) contents were determined by elemental analysis by Desert Analytics, Tucson, AZ. These values represent the extent to which salts used in the synthesis have been removed. The sodium analysis also provides details regarding the purity of AP5346, which is a sodium salt and should contain one sodium per amidomalonato-bound platinum. This equates to a theoretical %Na of around 1%.

Tangential Flow Filtration (TFF). AP5346 was purified by an ultrafiltration technique called tangential flow filtration (TFF). This technique, where the filtered solution is pumped tangentially to the membrane, utilizes the large difference in molecular weights for the separation between AP5346 and any small molecules or ions. The TFF membranes retain large molecules and allow the small molecule or salt impurities to pass through. The retained solution is called the retentate, and the filtered solution is called the permeate or filtrate. Water for injection (WFI) quality water is used to make up the water that appears in the permeate. When seven or more volumes of permeate relative to the initial retentate volume have been collected, the concentration of small impurities have been reduced to <0.1% of their initial concentration. Because the AP5346 material is within the same size range as endotoxins, only WFI quality water was used in the preparation and in the TFF purification steps.

Initial AP5346 General Synthesis. The preclinical procedure for the synthesis of AP5346 is depicted in Figure 2. In the first step the "ONp polymer" was synthesized from two monomers using a known literature method (*26*). This material was then converted to the aminomalonate-containing polymer (the "Ame-polymer"), hydrolyzed, and platinated with subsequent purification to produce AP5346.

ONp-Polymer Synthesis. An oven-dried 10 L media bottle containing a magnetic stir bar, a three-port cap, a Teflon sparging tube, and under an $Ar_{(g)}$ flow was charged with acetone (4.7 L), MA-GG-ONp (75.2 g, 0.23 mol, 1 equiv), and HPMA (369.4 g, 2.6 mol, 11 equiv). Ar was sparged through the vigorously stirring mixture to remove oxygen for 90 min. A solution of AIBN (25.6 g, 0.16 mol, 0.7 equiv) in acetone (0.2 L) was added to the reaction mixture. Sparging with Ar was continued for an additional 90 min. The bottle was sealed from the Ar flow and heated at 50 °C for 48 h (no stirring).

After 48 h a white precipitate had formed on the bottom of the bottle and it was collected *via* centrifugation. The polymer precipitate was washed with acetone (3 × 250 mL) and diethyl ether (3 × 250 mL) and centrifuged after each wash. The supernatant was decanted and discarded each time. The polymer was dried *in vacuo* to afford 336 g of white product (76% yield).

Conversion From ONp- to Ame-Polymer. An oven-dried 10 L media bottle containing a magnetic stir bar, a septum cap, and under an Ar flow was charged with pyridine (3 L), glycylamidomalonate trifluoroacetic acid salt (TFA-Gly-Ame) (147.3 g, 0.43 mol, 2.8 equiv), and triethylamine (64.5 g, 0.64 mol, 4.1 equiv). Once a homogeneous solution was achieved, poly(HPMA)-GG-ONp (298 g, 0.15 mol, 1 equiv) was added slowly while maintaining vigorous stirring. After 2.5 h, a sample was analyzed *via* HPLC to determine the concentration of free and total *p*-nitrophenol. Once the analysis indicated 100% free, the reaction mixture was heated for an additional 2 h at 40 °C to ensure completion.

The polymer was precipitated by adding ethyl acetate/diethyl ether (6/1) (7 × total volume) to the vigorously stirring polymer solution. The precipitated polymer was collected *via* centrifugation, washed with Et_2O (2 × 250 mL), and centrifuged after each wash. The supernatant was decanted and discarded each time. The polymer was dried *in vacuo*.

A 10 L media bottle was charged with ethanol (2 L), and with vigorous stirring the polymer was added slowly. Once the polymer was in solution, the stirring was stopped, and prewashed (with ethanol) Bio-Rex MSZ 501D Resin (1 kg) was added. After 2.5 h the resin was removed *via* filtration and thoroughly washed with ethanol. All washings and filtrate were combined. The polymer was precipitated by adding ethyl acetate/diethyl ether (10/1) (6 × total volume) to the vigorously stirring polymer solution. The precipitated polymer was collected *via* centrifugation, washed with Et_2O (3 × 250 mL), and centrifuged after each wash. The supernatant was decanted and discarded each time. The polymer was dried *in vacuo* to afford 291 g (93% yield) of pure Ame-polymer.

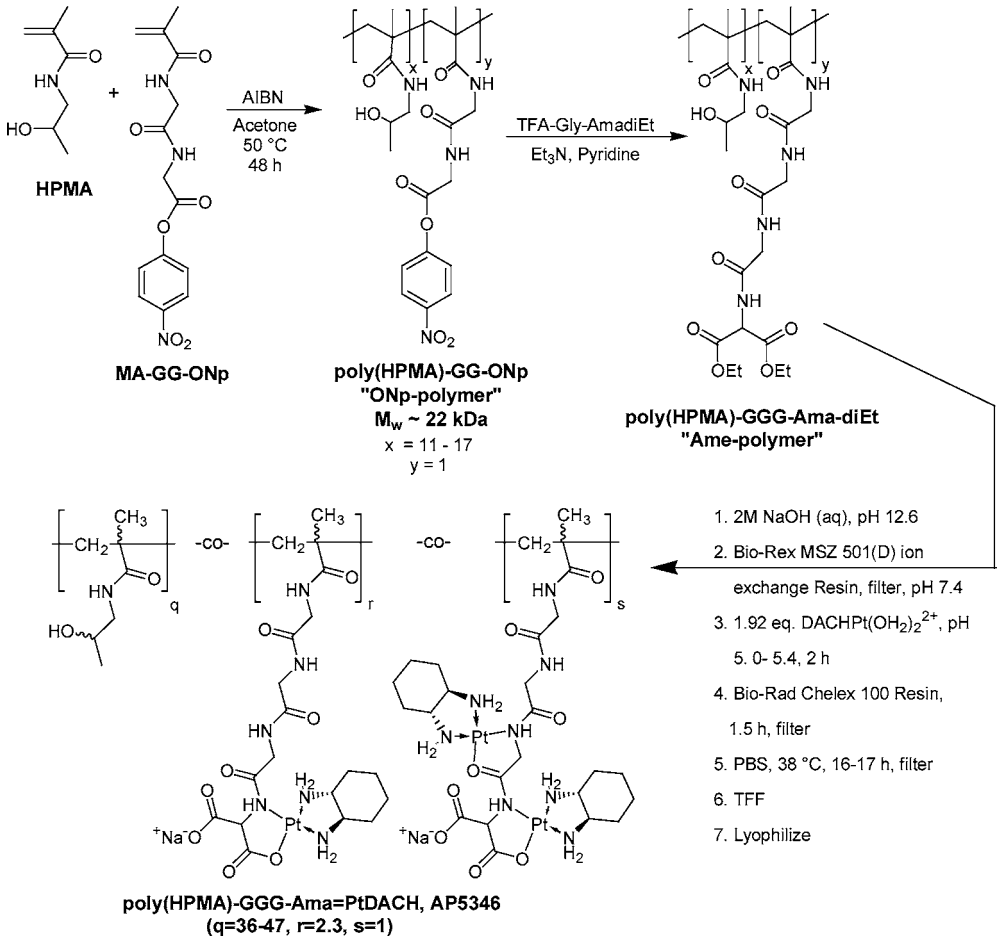

Figure 2. Initial synthesis of AP5346.

Conversion from Ame-Polymer to AP5346 (initial method). A 100 mL media bottle containing a stir bar was charged with $DACHPtCl_2$ (2.16 g, 5.69 mmol), $AgNO_3$ (1.88 g, 11.13 mmol), and 40 mL water. 5% HNO_3 was added until pH < 2 was reached, the vessel wrapped in foil, and the mixture was stirred in a 70 C water bath for 15 h. It was then cooled in an ice−water bath (0 to 5 °C) and the precipitate removed by filtration through a 0.22 μm GP Express PLUS PES Membrane Steritop device. The filtrate containing $DACHPt(OH_2)_2$ was then analyzed by ICP: 24736 mg Pt/L (99.6%).

A 100 mL media bottle containing a stir bar was charged with poly(HPMA)-GGG-Ame (5.00 g, 2.65 mmol Ame) and Milli-Q water (37 mL). The pH was raised to 12.6 by the addition of 2 M NaOH (3.4 mL) and the solution stirred for 30 min. Ion-exchange resin (5.00 g) was added and the mixture filtered when pH dropped below 7. The filtrate was adjusted to pH 7.4 using 2 M NaOH, and $DACHPt(OH_2)_2$ (40.1 mL, 5.08 mmol of a 24,736 mg Pt/L solution) was added. The reaction mixture was readjusted to pH 5.4 and stirred at 5.0−5.4 for 2 h, and then Chelex resin (3.0923 g) added with stirring for 90 min. The resin was filtered off and the resulting solution diluted to 133 mL (3.75 wt. %). It was then made 110 mM in chloride and 80 mmol in phosphate by addition of NaCl (0.8550 g, 14.63 mmol), $NaH_2PO_4 \cdot H_2O$ (0.2936 g, 2.1276 mmol), and $Na_2HPO_4 \cdot 7\ H_2O$ (2.2818 g, 8.5119 mmol). After dissolution of the salts, pH was 7.25. This was adjusted to 7.4 using 2 M NaOH, and the solution warmed to 38 °C and then placed in a 38 °C oven for 17 h. The mixture was filtered to remove a small amount of yellow precipitate, and the filtrate was purified by tangential flow filtration (7 permeate volumes collected). Lyophilization yielded the product as a tan solid (4.3451 g, 78%).

Improved Method of AP5346 Synthesis. The improved synthesis of AP5346 is depicted in Figure 3. A detailed breakdown of the process is shown although abbreviated structures have been used (the carbonyl of the third glycyl unit is included). The final AP5346 is structurally identical to that in Figure 2. The same Ame-polymer precursor is used; however, the formation of $DACHPt(OH_2)_2$ and AP5346 are somewhat different.

Conversion from Ame-Polymer to AP5346 (improved method). A 50 mL media bottle containing a stir bar was wrapped in foil and charged with $DACHPt(NO_3)_2$ (1.3965 g, 3.2231 mmol) and water (13 mL). 5% HNO_3 (100 μL) was added, the vessel capped, and the mixture stirred in a 70 °C water bath for 1 h. The platinating solution was cooled to room-temperature prior to use.

A 100 mL media bottle containing a stir bar was charged with Ame-polymer (5.00 g, 2.5330 mmol Ame) and water (28.3 mL). Upon dissolution of the polymer, 2 M NaOH (3.10 mL, 6.2 mmol) was added to the stirred polymer solution and the pH rose to 12.6 where it was maintained for 30 min. The solution was then taken to pH 7.4 by the slow addition of 5% HNO_3 (~3 mL) and then filtered through a 0.22 μm GP Express PLUS PES Membrane Steritop device. The platinating solution was then added with vigorous stirring. The pH dropped to 4.8 and was raised to 5.2 using 2 M NaOH. The solution was then stirred for 2 h with the pH held constant using a Mettler DL25 autotitrator loaded with 500 mM NaOH. The pH was adjusted to 7.4 using 2 M NaOH and placed in a 38 °C water bath and pH held constant at 7.4 for 17 h with stirring. The clear, pale yellow solution was filtered through a Steritop device and purified by TFF (five permeates collected). It was made 200

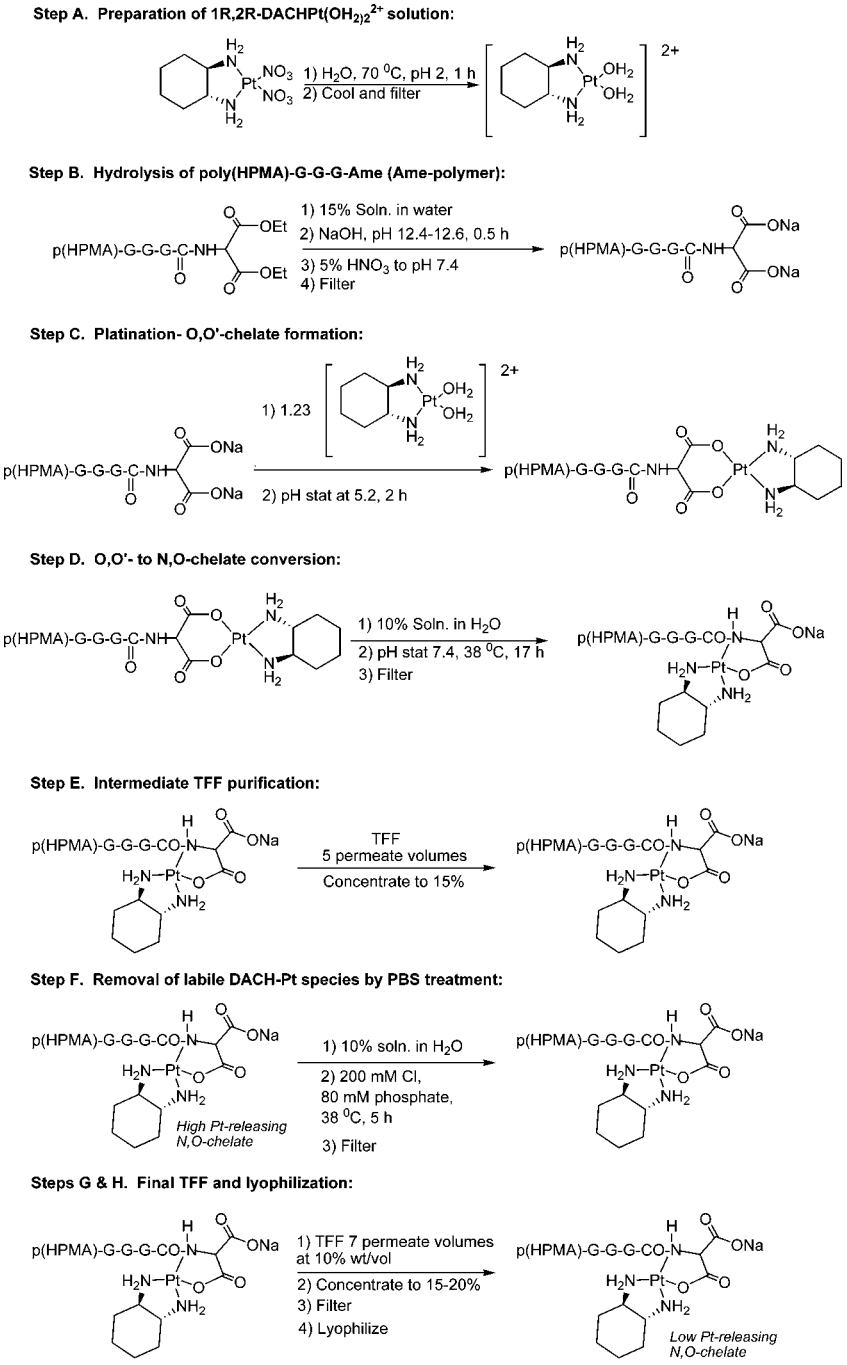

Figure 3. Improved synthesis of AP5346.

mM in chloride and 80 mM in phosphate by addition of NaCl (0.5844 g, 10.00 mmol), $NaH_2PO_4 \cdot H_2O$ (0.1104 g, 0.8000 mmol), and $Na_2HPO_4 \cdot 7H_2O$ (0.78 g, 3.2000 mmol). The solution was diluted to 50 mL (10.00 wt. %) and stirred. After dissolution of the salts, the pH was 7.1. The pH was raised to 7.4 and the solution filtered and quickly heated to 38 °C. The vessel was then placed in a 38 °C water bath for 4.5 h with no stirring. The clear solution was filtered through a Steritop device, purified by TFF (seven permeates collected), and lyophilized to yield a tan solid (4.3920 g, 75%).

RESULTS AND DISCUSSION

The initial preparation of AP5346 from its Ame-polymer precursor is a four-part process with subsequent purification and lyophilization steps. While no intermediates are isolated, two *in situ* purifications are performed. The platinating solution of the dinitrato salt of $DACHPt(OH_2)_2^{2+}$ is prepared by heating a stirring mixture of $DACHPtCl_2$ and $AgNO_3$ with a trace of nitric acid. The nitric acid and heating steps are performed to prevent any μ-hydroxo Pt species forming. Slightly less than 2 equiv of $AgNO_3$ are used otherwise the filtered solution becomes cloudy with slow forming AgCl.

Saponification of the Ame-polymer at pH 12.6 was found by ^1H NMR to proceed very quickly (complete within a few minutes). To remove any non-polymer-bound ions that would allow nonproductive electrostatic interactions with the platinating species, the solution was neutralized using mixed bed ion-exchange resin.

The saponified polymer solution was combined with the platinating solution at pH 7.4. This pH was chosen to give a combined reaction mixture with a pH of approximately 5. This pH control was important because at high pH levels the diaqua

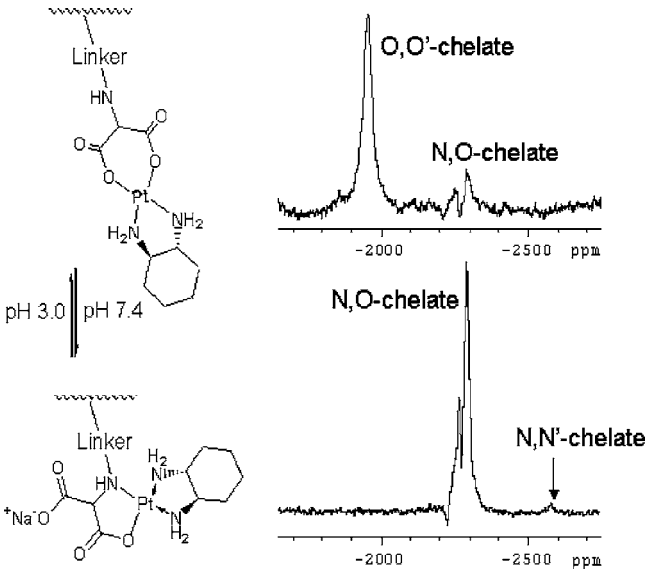

Figure 4. ^{195}Pt NMR of the conversion of O,O′-chelate to AP5346 N,O-chelate by the initial method.

platinum species (pK_{a1} = 5.4, pK_{a2} = 7.2 at 27 °C) (*27*) becomes significantly deprotonated, yielding the less reactive mono- or unreactive dihydroxo species. The pH was kept above 3 to ensure that no decarboxylation (pH < 2) takes place. A pH near 5 was preferred so that a high proportion of the amidomalonate groups are doubly deprotonated (pK_a values of approximately 2.8 and 5.6) (*28*). Thus, at a pH of approximately 5.0−5.4, the predominate Pt species will be the reactive DACHPt$(OH_2)_2^{2+}$, decarboxylation is avoided, and the amidomalonate is at least singly deprotonated with a substantial fraction of the doubly deprotonated species. These factors are all seen to facilitate the desired chelate formation and inhibit undesired or unproductive side reactions. The solution of the saponified polymer was treated with almost 2 equiv of the platinating solution. Several stoichiometries were tested and this value was chosen as it resulted in materials with the most desirable biological activity. A reaction time of 2 h was found to be ample for formation of the predominately O,O′-chelate solution.

Before proceeding to the O,O′- to N,O-chelate conversion step, the reaction mixture was treated with a metal chelating ion-exchange resin (Chelex Resin, biotech grade). Since the O,O′- to N,O− chelate conversion was performed in 110 mM NaCl and since remaining DACHPt$(OH_2)_2^{2+}$ converts to the poorly soluble DACHPtCl_2 at this concentration, the Chelex resin was used to scavenge any remaining free platinum species. This resin does not allow the polymer platinum conjugate to penetrate because it has a nominal molecular weight cutoff (NMWCO) of 1 kDa. Treatment for 90 min was sufficient to remove any such Pt species as confirmed by ICP analysis.

The filtered solution of mostly O,O′-chelate (approximately 85% O,O′-, 15% N,O-) was converted *in situ* to the N,O-species, as described, in PBS at pH 7.4 and 38 °C. These salts were chosen for their general biocompatibility. The chloride concentration is close to physiological, and it is expected and desired that any labile platinum species under such concentrations would be lost in the chelate conversion. The phosphate quantity was chosen not only to give well buffered solutions but also to account for the fact that some may also react with any free Pt species (*29*). A ^{195}Pt NMR depiction of the chelate conversion is shown in Figure 4.

While O,O′- to N,O-chelate conversion is essentially 100% at pH 7.4, it is interesting to note that the O,O′-chelate can be re-formed by treatment of the AP5346 N,O-chelate solution at pH 3 at 38 °C. After 3 h under these conditions a mixture of 85% O,O′-, 15% N,O- can be obtained. Furthermore, when the mixture of mainly O,O′- and some N,O-chelate (prior to PBS treatment for conversion to N,O-species) is treated *in situ* at pH 3 (38 °C, 3 h), the platinum converts almost entirely back to the O,O-form. Greater than 98% O,O-chelate was achieved. Increasing the reaction time did not increase the percentage of O,O′. Sohn and co-workers have recently reported on the difficulty in isolation of isomerically pure amino dicarboxylate Pt (II) complexes (*30*). They were however able to isolate a pure O,O′-chelate by utilizing N-substituted small molecule glutamates, where formation of the N,O- species was blocked. These structures were confirmed by ^{195}Pt NMR spectroscopy. In further work, the same authors report O,O′-chelates of glycyl-L-glutamate bound to polyphosphazene polymer backbones (*22*). No ^{195}Pt NMR data of these materials were obtained. The O,O′-structures were assigned based upon the fact that the glycyl-L-glutamates are also N-substituted, and as such, rearrangement to form the N,O-chelate would also be blocked in these systems. Other workers report O,O′-isomers of linear, aliphatic polyamide carriers, also with an N-substituted site adjacent to the suggested chelate structure (*31*). Again, no ^{195}Pt NMR data was obtained, and the O,O′-structure assigned based upon ^{1}H NMR spectra. The reported polymer-based O,O′-chelate structures are shown in Figure 5.

However, we have previously shown (*32*) by ^{195}Pt NMR that in polymer systems containing linkers which incorporate N-substituted moieties, the formation of the N,O-chelate is easily achieved. These studies were performed on a cisplatin type analog of AP5346, containing a GFLG-amidomalonato linker-chelate system. In fact, this N,O-isomer is preferred at higher pHs, while the pure O,O′ chelate could only be formed in two ways; by taking a solution of the N,O-species to low pH, or by forming the initial O,O′-/N,O-chelate mixture after platination and treating this in situ at pH 3.0 − 3.5 for 1 h, to form 100% O,O′-chelate. Results of the pH studies starting from 100% N,O-chelate are shown in Table 1.

Taking this data into account it is very likely that the reported O,O′-structures of Sohn (*22*) and Neuse (*31*), neither of which were confirmed by ^{195}Pt NMR, do in fact contain significant quantities of N,O-chelates, as strict pH control must be employed to isolate pure samples of either isomer. The N,O-materials are the thermodynamic products of such reactions, and the smaller ring sizes compared to the larger ring sizes of their respective O,O-analogues (kinetic products) makes their formation more favorable. The free amine tethered to the backbone in the structure reported by Neuse is also very likely to bind platinum.

As the O,O′-chelate form is more labile than the N,O-chelate, conversion back to the O,O-chelate is the reason for the increased rate of platinum release observed as pH is lowered. This characteristic enables safe transit of the conjugate in its N,O form during systemic circulation, with the low pH environment of the tumor activating increasing platinum release from the macromolecular carrier.

Purification of the AP5346 crude product was performed by TFF using a polyethersulfone (PES) membrane with a 5 kDa NMWCO. A TFF-based purification was chosen rather than preparative SEC because it is linearly scalable from mg to multi-kilogram amounts. Concentration of the purified solution to 10% w/v followed by lyophilization produces a cake of the drug substance. Less concentrated solutions produced a material which was difficult to handle due to static.

For the future synthesis of AP5346 drug substance, a more cost-effective and scaleable process were sought for both polymer manufacture and platination. Both mixed bed and Chelex ion exchange resins are expensive and elimination of these resins would be advantageous. An improvement of the reaction yields in terms of weight and/or platinum was important

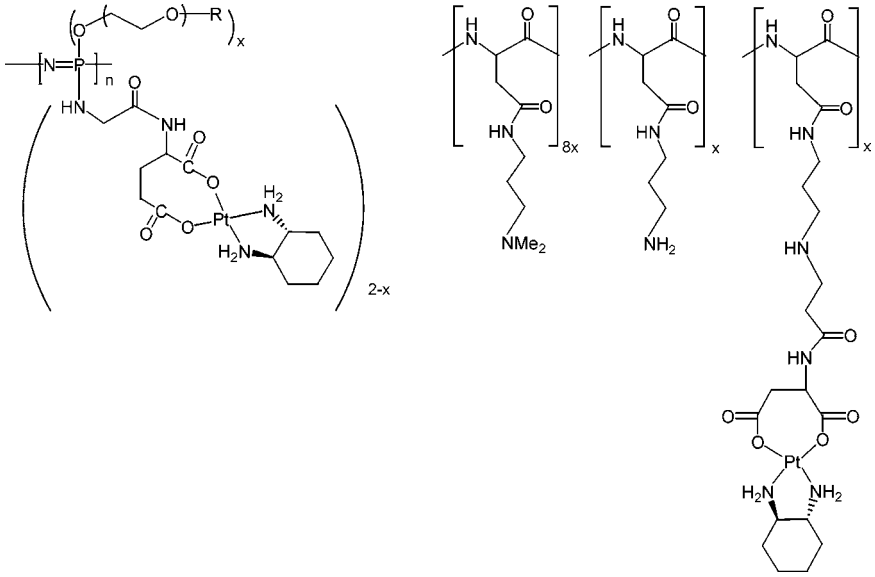

Figure 5. Reported polymer-based O,O′-chelate structures.

Table 1. Effects of pH on the p(HPMA)-GFLG-Ama═Pt(NH$_3$)$_2$ Chelate

	starting from 100% N,O-chelate p(HPMA)-GFLG-Ama═Pt(NH$_3$)$_2$							
	pH 3.0−3.5		pH 4.0−4.5		pH 5.0−5.5		pH 6.0−6.5	
time	O,O-	N,O-	O,O-	N,O-	O,O-	N,O-	O,O-	N,O-
1 h	98	2	45	55	6	94	0	100
5 h	100	0	56	44	15	85	0	100
20 h	100	0	68	32	19	81	0	100

because of the high cost of platinum. Last, a more concentrated process to allow for larger scale-up was considered to be necessary.

The formation of the DACHPt(OH$_2$)$_2^{2+}$ platinating solution for the improved synthesis was achieved by heating DACHPt-(NO$_3$)$_2$ in low pH water for 1 h. The diaqua species readily forms, and there was no need for overnight heating, filtration, and in-process testing for platinum concentration by ICP as there was in the initial method. Additionally, significantly less platinum was used (approximately 40% reduction), while obtaining the same quantities of platinum in the final product. The saponified polymer solution was prepared in the same way in both processes; however, neutralization was performed using 5% HNO$_3$ in place of the more expensive mixed bed ion-exchange resin. Upon combination of these solutions the pH was held constant at 5.2 for 2 h using an autotitrator loaded with NaOH. In this process, however, the resulting (mainly) O,O′-chelate solution was converted to the N,O-chelate by merely increasing the pH to 7.4 and heating at 38 °C for 17 h. In the initial synthesis, where a large excess of platinum was used, the same process was performed by overnight heating in PBS. The high chloride concentration prevented a significant quantity of platinum from binding to the polymer. In contrast, the lack of PBS in the improved chelate conversion process resulted in the reduction of the amount of platinum used, such that all or most of the platinum which was added binds to the polymer. Therefore there was no need for the addition of Chelex resin for removal of excess free platinum. Isolation and analysis of the N,O-chelate at this stage of the synthesis shows that by ^{1}H and ^{195}Pt NMR, this N,O-chelate is identical to the final AP5346 product. However, 3 and 24 h platinum release rates, determined by ICP, were outside the specifications. This shows that NMR spectroscopy of polymer platinum conjugates alone cannot be used to ensure reproducibility of the pharmaceutical product. Consequently this solution was purified by TFF, followed by short treatment with PBS (200 mM Cl$^-$, 80 mM PO$_4^{3-}$) at 38 °C for 4.5 h, and then subjected to a second TFF. It is believed that the short PBS treatment causes rearrangement and/or removal of small concentrations of highly labile Pt species to produce the lower Pt releasing species. The resulting solution was lyophilized to produce an AP5346 product which was identical to the initial material.

Table 2. Identity and Purity Specifications for AP5346 Drug Substance

analysis	result
Identity Specification	
^{1}H NMR spectroscopy	conforms to reference spectrum
^{195}Pt NMR spectroscopy	not less than two peaks in the range −2200 to −2350 ppm, with the main peak appearing at −2290 ± 10 ppm, and the next most distinct peak appearing at −2260 ± 10 ppm
% Pt (wt/wt)	determine and report
% water	NMT 14%
% Pt (dry weight)	10.5 ± 2.2%
% Pt Released at 3 h	NMT 1.5%
% Pt Released at 24 h	NMT 4.5%
M_w (by SEC)	25 kDa ± 8 kDa
M_n (by SEC)	17 kDa ± 6 kDa
SEC peak shape	monomodal distribution
Purity Specification	
^{1}H NMR spectroscopy	
for ethanol	NMT 1.0% ethanol
for other protonated impurities	NMT 1.0% total other impurities
^{195}Pt NMR spectroscopy	the integral of peaks in the range −2000 to −2350 ppm is not less than 90% of total
% small Pt species	NMT 0.8%
% Na	determine and report
% Cl	NMT 0.2%
% P	NMT 0.2%

In order for a batch of AP5346 to be deemed appropriate for clinical use it must conform to a set of carefully chosen specifications. The identity and purity specifications for AP5346 drug substance are listed in Table 2.

Despite the differences in the syntheses, the initial and improved methods produce AP5346 drug substance with very comparable data, all of which conforms to the specifications in Table 1. A large number of batches of AP5346 have been prepared to date, and it was found that the analytical results for these batches of drug substance usually appear within a relatively

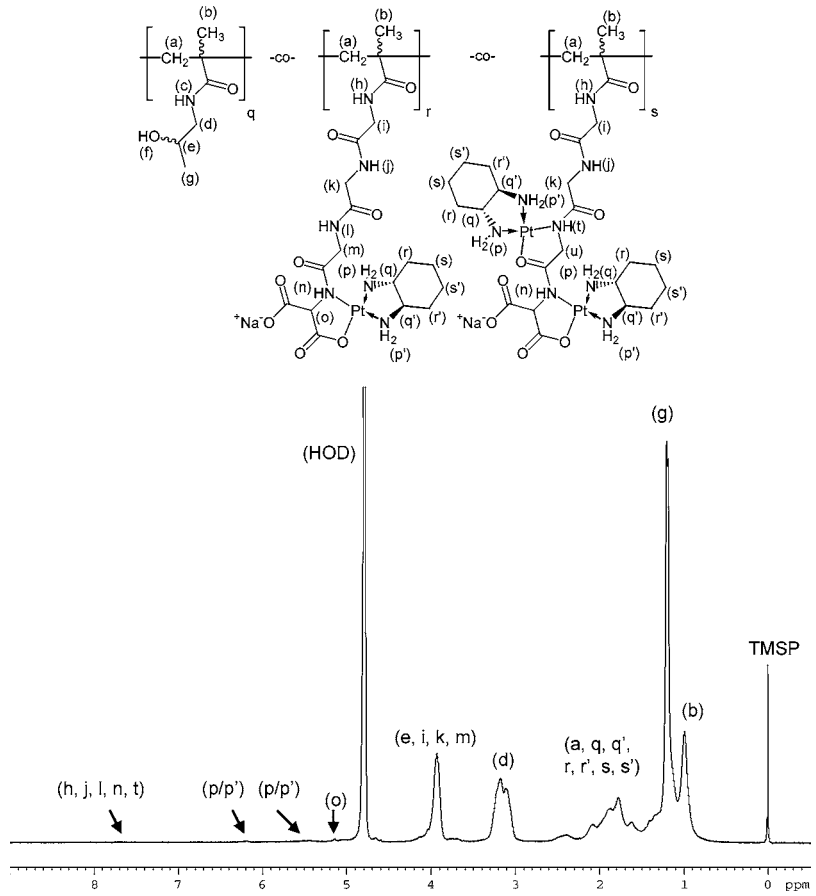

Figure 6. ^{1}H NMR spectrum and assignments of AP5346 in D_2O.

Table 3. ^{1}H NMR Chemicals Shifts, Assignments, and Peak Appearance for AP5346 in D_2O

chemical shift in D_2O (ppm)	assignment	peak appearance and number of hydrogens
0.99	(b)	br s, 3H
1.19−1.20	(g)	d, 3H
1.51−2.67	(a, q, q′, r, r′, s, s′)	br unresolved envelope, 14H
2.75−3.50	(d)	2 br peaks, 2H
3.64−4.30	(e, i, k, m)	unresolved envelope, 7H
4.78	HOD peak	sharp s
5.15	(o)	s, mostly exchanged out, 1H
5.35	(p, p′)	br peak, mostly exchanged out, 2H
6.10	(p, p′)	br peak, mostly exchanged out, 2H
7.30−8.30	(h, j, l, n, t)	br peak, mostly exchanged out, 2H

narrow range inside those specifications. The platinum release rates at 3 and 24 h are normally in the range of 1.00−1.30 and 3.00−3.80, respectively. Molecular weight analyses typically afford weight average molecular weights (M_w) and number average molecular weights (M_n) of 23 ± 3 and 14 ± 2 kDa, respectively. The % small Pt species (free platinum) is usually found to be less than 0.3%. Percent Pt is dependent on the amount of chelators present in any starting sample of Ame polymer but falls comfortably within the specification range. Elemental analyses for Cl and P only ever show trace amounts of these elements, which are significantly below the specification limit. The product is isolated by lyophilzation, and water content is determined by Karl Fischer titration.

Both methods of AP5346 syntheses produce materials which are identical by ^{1}H NMR spectroscopy. A representative spectrum of material from the improved synthesis is shown in Figure 6, and peak assignments for identity purposes are listed in Table 3.

It is known that small molecule impurities in a polymer therapeutic can be effectively quantified by ^{1}H NMR (*33*). This is possible because for most spin 1/2 nuclei in small, rapidly tumbling molecules, T_1 (longtitudinal relaxation time) and T_2 (transverse relaxation time) have the same value. The faster motion leads to slower relaxation and narrower line widths. Conversely for a polymer system such as AP5346, which tumbles more slowly in solution, T_2 is often very much shorter than T_1, leading to broad linewidths. This means that very low quantities of small molecule impurities in an AP5346 sample will have sufficiently large signal-to-noise ratio to readily allow their observation by ^{1}H NMR. Such impurities can be detected to below 0.1%.

Chemical shifts in ^{195}Pt NMR spectroscopy are very sensitive to the nature of the coordinating donor atoms. Assignments in ^{195}Pt spectra of AP5346 were made based on the literature precedents of Gibson (*34*) and Margerum (*35*). As shown in Figure 4, the main signal is the N,O-chelate at ∼ −2290 ppm. A small and controllable amount of the N,N′-chelate appears at ∼ −2600 ppm. ^{195}Pt NMR spectra of the initial and improved AP5346 syntheses are identical.

In Figure 2 it is shown that some PtDACH has bound to a glycine residue on the linker which connects the amidomalonato chelate to the polymer backbone. If one considers a sample of the Ame-polymer precursor, a known quantity of amidomalonato chelating groups must be present. This quantity corresponds to a theoretical platinum content, assuming that each group chelates one PtDACH moiety. The platinum contents in materials from both initial and improved syntheses were found to be approximately 1.2 times the theoretical value of platinum saturated amidomalonato chelators. It has been shown (*36*) using ^{15}N enriched glycyl linker groups that this "extra" platinum is located on the terminal glycine group as depicted in Figure 2. This work also seemingly suggests that the amidomalonato H atom and the terminal glycyl do not deprotonate on formation of the N,O-chelate. Deprotonation of amides upon coordination

to platinum has been studied previously (*37*). A detailed study of the AP5346 construct and related polymer-linker-chelate structures by ^{15}N PENDANT NMR, with ^{15}N enriched linkers and platinum bound ammines is in progress.

CONCLUSIONS

The syntheses of poly(HPMA)-GGG-Ama═Pt═1*R*,2*R*-DACH (AP5346) by the initial and improved routes, and the methods of analysis of the drug substances are described. It is shown that these substances can be characterized spectroscopically and furthermore that the material derived from an improved synthesis is identical to the initial material.

ACKNOWLEDGMENT

We thank Dr. N. Rao Ummaneni and Dan Nguyen of Access Pharmaceuticals, Inc., for their syntheses of the monomers used for the production of the Ame-polymer precursor to AP5346.

HIV-1 Tat Peptide Immunoconjugates Differentially Sensitize Breast Cancer Cells to Selected Antiproliferative Agents That Induce the Cyclin-Dependent Kinase Inhibitor p21$^{WAF-1/CIP-1}$

Meiduo Hu,[†,§] Judy Wang,[†] Paul Chen,[†] and Raymond M. Reilly*[,†,‡,§]

Division of Nuclear Medicine, University Health Network, Toronto, Department of Medical Imaging, University of Toronto, Toronto, and Department of Pharmaceutical Sciences, University of Toronto, Toronto, ON, Canada. Received March 3, 2006; Revised Manuscript Received July 6, 2006

In this study, we evaluated the ability of anti-p21 antibodies conjugated to 17-mer peptides [GRKKRRQRRRP-PQGYGC] harboring the membrane-translocating and nuclear import sequences [underlined] of HIV-1 tat protein to inhibit the cyclin-dependent kinase inhibitor, p21$^{WAF-1/Cip-1}$ (p21) and differentially sensitize MDA-MB-468 and MCF-7 human breast cancer (BC) cells to the antiproliferative effects of treatments that induce or do not induce p21. BC cells were treated with increasing concentrations of epidermal growth factor (EGF; 0.5−10 nM), the topoisomerase I inhibitor, camptothecin (CPT; 0.1−4 μM), or increasing doses of γ-radiation (2−20 Gy). Western blot was used to evaluate p21 expression. The effect of treatment on cell cycle distribution was studied. Growth inhibition was measured by the WST-1 assay. Expression of p21 was increased in MDA-MB-468 cells treated with EGF or CPT but not by γ-irradiation. MCF-7 cells exhibited p21 upregulation following exposure to CPT and γ-radiation but not EGF. EGF caused cell cycle arrest in G_1 phase for MDA-MB-468 cells. CPT caused G_1-phase arrest in MDA-MB-468 cells and prolonged S phase in MCF-7 cells. γ-Radiation caused an increase in cells in G_2/M phase for MDA-MB-468 and MCF-7. MDA-MB-468 cells were growth-inhibited by EGF, CPT, and γ-radiation. MCF-7 cells were growth-stimulated by EGF and inhibited by CPT and γ-radiation. Combining EGF with tat-anti-p21 immunoconjugates (ICs) amplified the growth-inhibitory effect on MDA-MB-468 cells 1.2-fold to 2.3-fold, but had no effect on the growth stimulation of MCF-7 cells by EGF. Tat-anti-p21 ICs sensitized MCF-7 cells 1.4-fold to γ-radiation but had no effect on the growth of γ-irradiated MDA-MB-468 cells. Tat-anti-p21 ICs sensitized both MDA-MB-468 and MCF-7 cells 1.7-fold to CPT. We conclude that tat-anti-p21 ICs are promising sensitizers for cytotoxic cancer therapies and that their sensitization is dependent on treatment-related p21 expression. This general approach could potentially be extended to other growth-regulatory molecules that are associated with tumor growth and progression.

INTRODUCTION

The cyclin-dependent kinase inhibitor, p21$^{WAF-1/CIP-1}$ (p21) protects cells from potentially lethal DNA damage by arresting cell cycle progression to facilitate DNA repair (*1*, *2*). p21 binds and inactivates CDK-4/Cyclin-D and CDK-2/Cyclin-E complexes, blocking G_1/S-phase cell cycle transition (*3*). CDK-2/Cyclin-A complexes required for transition through G_2/M phase are also inhibited by p21 (*4*). Furthermore, p21 has an anti-apoptotic function mediated through its phosphorylation by Akt (*5*, *6*). p21 may also promote apoptosis under certain conditions (*4*, *7*). It has been suggested that the cell cycle arrest function of p21 exists in cells with an intact p21-dependent checkpoint (*7*), whereas cells in which this checkpoint is defective may undergo p21-mediated apoptosis due to unfaithful repair of DNA damage (*5*, *8*, *9*). Many cancer therapeutics (e.g., chemotherapy and γ-radiation) cause reproductive cell death by inflicting DNA damage (*7*). Strategies to interfere with the DNA-protective function of p21 could amplify the cytotoxicity of these agents. Several approaches have been explored to attenuate p21 function in cells (*6*). Many of these have relied on antisense oligodeoxynucleotides (ODNs) to interfere with the translation of p21 mRNA into functional protein. In one study, 21-mer antisense ODNs complementary to p21 mRNA promoted apoptosis in serum-starved T47D or MCF-7 human breast cancer (BC) cells (*5*). In another report, 20-mer antisense ODNs directed against p21 mRNA converted growth arrest to apoptosis in γ-irradiated HCT 116 human colon cancer cells (*9*). These strategies are limited, however, by the well-known delivery barriers faced by DNA-based therapeutics (*10*). Furthermore, there is post-transcriptional regulation of p21 which may uncouple the expression of p21 mRNA and protein, thus potentially diminishing the effectiveness of any antisense ODN strategy (*11*).

In this study, we describe for the first time an alternative approach for inhibiting the function of p21 in cancer cells that employs anti-p21 antibodies conjugated to 17-mer synthetic peptides derived from HIV-1 virus transactivator of transcription (tat) protein. These peptides (GRKKRRQRRRPPQGYGC) harbor the polyarginines required for cell membrane penetration and the nuclear-localizing sequence (underlined) of the full-length tat protein. The construction of these tat-anti-p21 immunoconjugates (ICs) was recently reported (*12*, *13*). Tat-anti-p21 ICs penetrated MDA-MB-468 BC cells and were imported into the nucleus, where they functionally attenuated the ability of p21 to promote G_1/S-phase arrest caused by exposure of these cells to epidermal growth factor (EGF) (*13*). Nuclear translocation was important because the ability of p21 to mediate cell cycle arrest has been found to be associated mainly with its nuclear distribution (*14*).

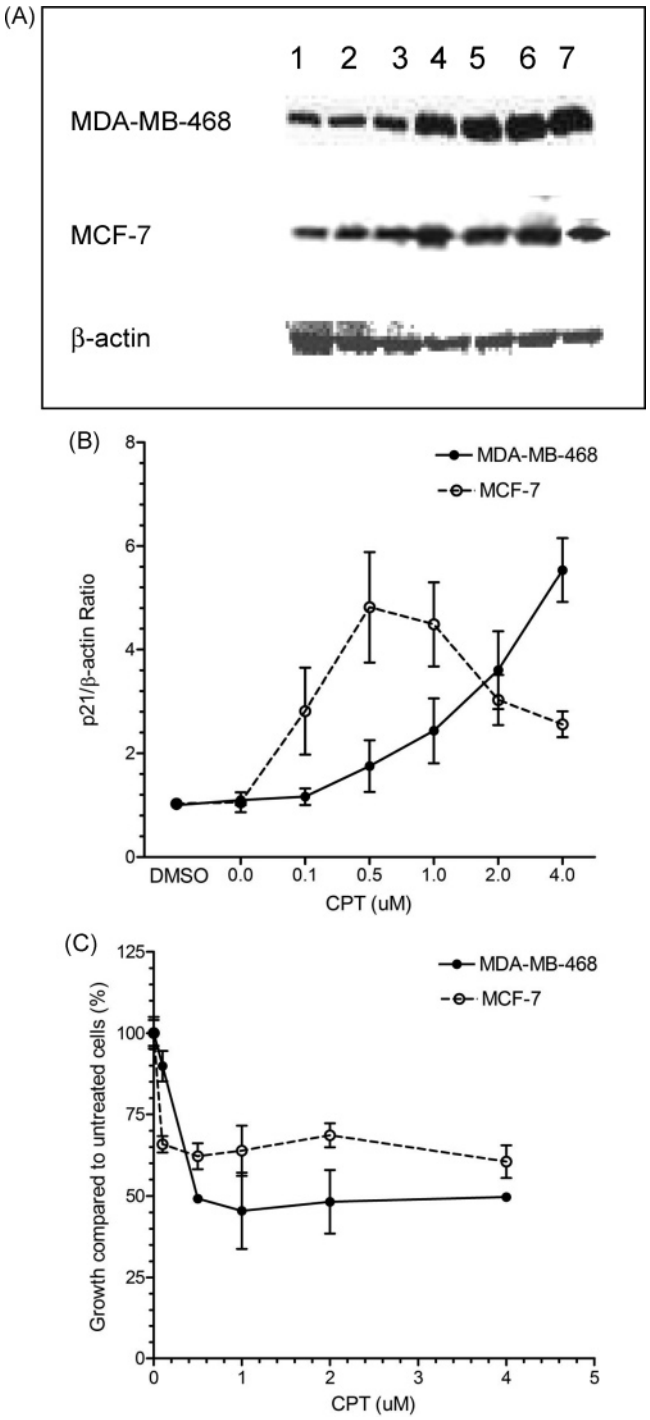

Figure 1. (A) Effect of exposure of MDA-MB-468 or MCF-7 human breast cancer cells for 24 h to increasing concentrations of camptothecin (CPT) on the expression of p21. Lane 1, DMSO-treated cells; Lanes 2−7 are cells treated with 0.0, 0.1, 0.5, 1, 2, or 4 μM of CPT, respectively. (B) The p21/β-actin ratio in the cells was evaluated by Western blot. (C) Effect of CPT exposure of MDA-MB-468 or MCF-7 cells on cell growth measured colorimetrically using the WST-1 assay. Cell growth of treated cells at 24 h was expressed as a percentage relative to that of untreated cells. Data shown are the mean ± sem of three replicate determinations.

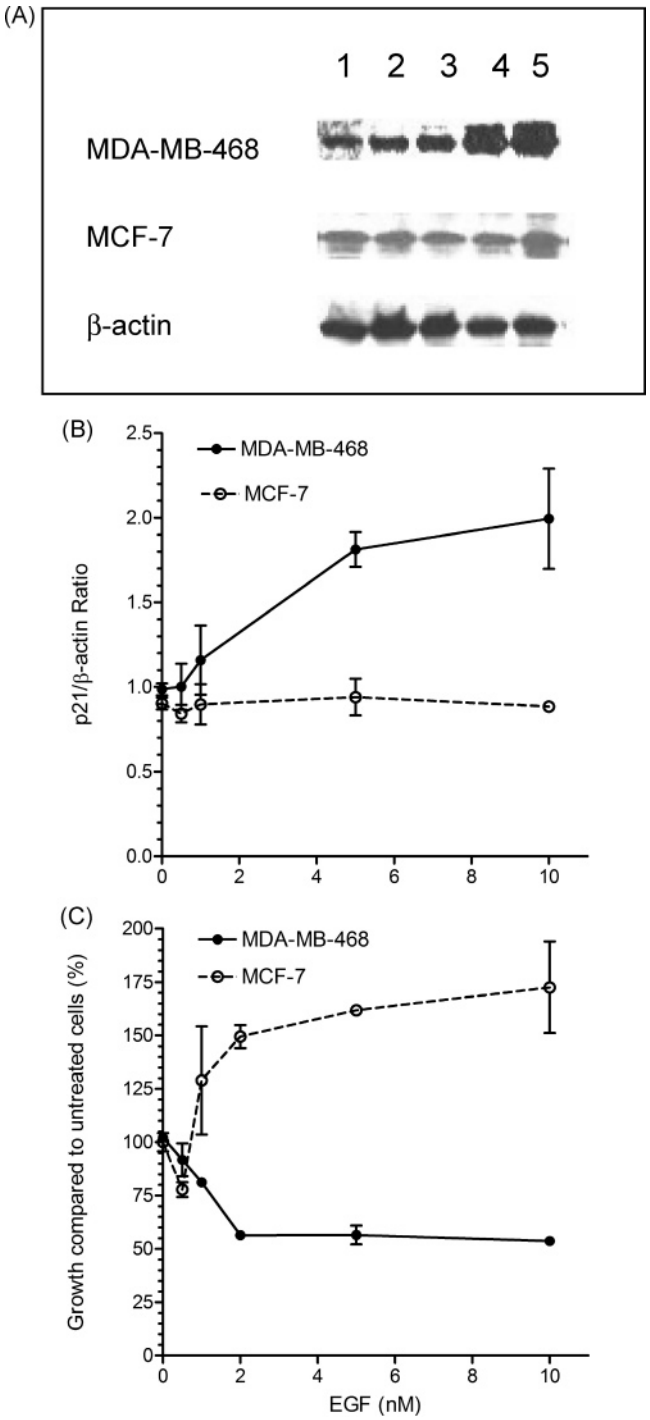

Figure 2. (A) Effect of exposure of MDA-MB-468 or MCF-7 human breast cancer cells for 24 h to increasing concentrations of EGF on the expression of p21. Lanes 1−5 are cells treated with 0.0, 0.5, 1, 5, or 10 nM of EGF, respectively. (B) The p21/β-actin ratio in the cells was evaluated by Western blot. (C) Effect of EGF exposure of MDA-MB-468 or MCF-7 cells on cell growth measured colorimetrically using the WST-1 assay. Cell growth of treated cells at 24 h was expressed as a percentage relative to that of untreated cells. Data shown are the mean ± sem of three replicate determinations.

For the current studies, two human BC cells that broadly represent two clinically relevent BC phenotypes were chosen. MDA-MB-468 cells have a mutated p53 gene (*15*), are estrogen-receptor (ER) negative, and display overexpression of EGF receptors (EGFR; $1-2 \times 10^6$ receptors/cell) (*16*). MCF-7 cells have wild-type p53, are ER-positive, and display a 100-fold lower level of EGFR on their surface (*15*). To determine if tat-anti-p21 ICs could differentially sensitize these BC cells to the growth-inhibitory effects of agents that induce p21, we selected EGF, camptothecin (CPT), and γ-radiation as treatments for these studies. Although EGF is a mitogenic peptide growth factor for MCF-7 cells, it paradoxically has growth-inhibitory effects on MDA-MB-468 cells that are mediated by its induction of p21 causing cell cycle arrest in the G_1/S phase (*16*, *17*). Camptothecin (CPT) is a topoisomerase I inhibitor in the same

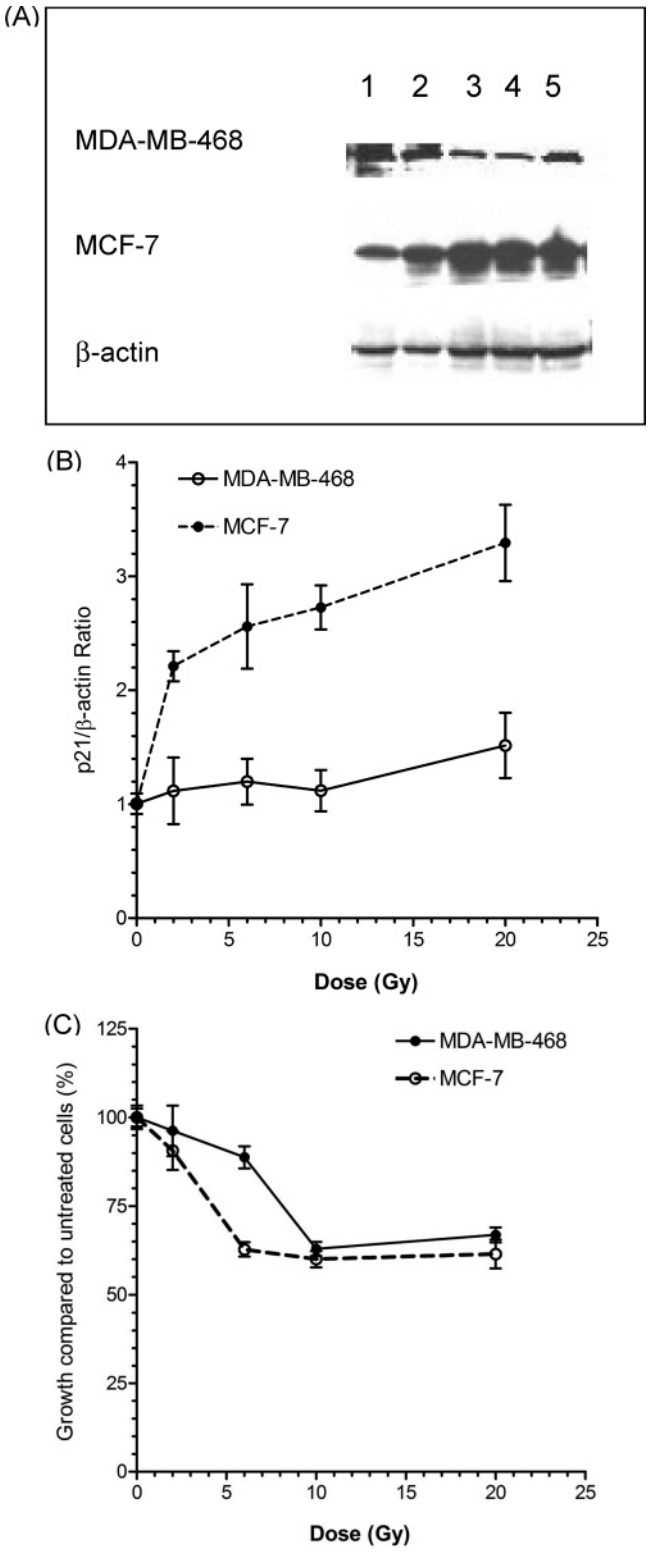

Figure 3. (A) Effect of exposure of MDA-MB-468 or MCF-7 human breast cancer cells to increasing doses of γ-radiation on the expression of p21. Lanes 1−5 are cells treated with 0, 2, 6, 10, and 20 Gy, respectively. (B) The p21/β-actin ratio in the cells was evaluated by Western blot. (C) Effect of γ-irradiation of MDA-MB-468 or MCF-7 cells on cell growth measured colorimetrically using the WST-1 assay. Cell growth of treated cells at 8 h was expressed as a percentage relative to that of untreated cells. Data shown are the mean ± sem of three replicate determinations.

class as the chemotherapeutic agents, ironotecan and topotecan. CPT has been reported to induce p21 in MDA-MB-468 and in MCF-7 cells (*15*). γ-Radiation is a standard treatment for locoregional control of BC; its effects on p21 expression are dependent on wild-type p53 expression by cells (*18*). Our objectives were (i) to fully characterize the effects of treatment of MDA-MB-468 and MCF-7 cells on p21 expression; (ii) to study the effects of p21 induction on cell cycle distribution; and (iii) to correlate p21 induction with the sensitization observed following coexposure to tat-anti-p21 ICs.

EXPERIMENTAL PROCEDURES

Breast Cancer Cells. MDA-MB-468 and MCF-7 human BC cells were obtained from the American Type Culture Collection (ATCC, Manassas, VA) and were cultured in Dulbecco's minimal essential medium (DMEM, Ontario Cancer Institute, Toronto, ON) supplemented with 10% fetal calf serum (FCS, Sigma Chemical Co., St. Louis, MO), containing 100 units/mL penicillin, 100 μg/mL streptomycin, 4 mM glutamine, and 400 μM sodium pyruvate, at 37 °C in an atmosphere of 5% of carbon dioxide (CO_2).

Treatment of Breast Cancer Cells. MDA-MB-468 and MCF-7 BC cells were seeded into 60-mm culture dishes (Nolge Nunc Internationa, Roskilde, Denmark) at a density of 6×10^5 cells per dish and cultured overnight. The cells were then treated with increasing concentrations of CPT (Sigma-Aldrich, St. Louis, MO) (0.1−4 μM) or EGF (Upstate Biotechnology, Lake Placid, NY) (0.5−20 nM). CPT was initially dissolved in dimethylsulfoxide (DMSO) at a concentration of 4 mM and stored at −20 °C. CPT was diluted in DMEM to the desired concentration immediately before use. The final concentration of DMSO in the cell culture was <0.1% (v/v), which has been shown to be nontoxic to cells (*19*). Treated and control untreated cells were harvested at 24 h after treatment by scraping them into 1 mL of 150 mM sodium chloride (AstraZeneca Canada, Inc., Mississauga, ON) and centrifuging at 350*g* for 5 min. Cells were treated with γ-radiation (2−20 Gy) delivered over 2−22 min, depending on the dose required, by a cell irradiator (model GC40-E, MDS-Nordion, Kanata, ON). These cells were harvested at 8 h postirradiation. Cell pellets were lysed in 50 μL E7 buffer consisting of 0.1% sodium dodecylsulfonate (SDS, Bio-Rad Laboratories, Hercules, CA), 1% sodium deoxycholate (Sigma), and 1% Triton X-100 (Bio-Rad Laboratories) in 10 mM Tris-HCL (Sigma)/150 mM sodium chloride (Sigma) pH 7.4 containing proteinase inhibitor (Roche, Montreal, PQ). Protein concentrations were estimated using the Bio-Rad Protein Assay kit (Bio-Rad Laboratories).

Dose-Dependent Induction of p21 Expression. Cell lysates were analyzed by Western Blot to evaluate the dose-dependent induction of p21 expression. Briefly, sodium dodecylsulfonate polyacrylamide gel electrophoresis (SDS-PAGE) was performed under reducing conditions on 10 μL (10 μg) of cell lysates on a 4−20% Tris HCL gradient Ready-Gel (BioRad, Mississauga, ON). Electrophoresed proteins were transferred to a nitrocellulose membrane (Trans-Blot, BioRad) using 25 mM Tris, 192 mM glycine, pH 8.3 buffer. The membranes were blocked overnight with 5% skimmed milk (Nestle Canada, Inc., North York, ON) or 5% bovine serum albumin (BSA) in Tris-buffered saline (TBS: 150 mM sodium chloride, 20 mM Tris-HCL, and 0.1% Tween-20, pH 7.6), rinsed with TBS, and probed at 37 °C for 45 min with 1 μg/mL of mouse anti-p21 antibodies (Oncogene Research, Cedarlane Laboratories, Mississauga, ON) or 1 μg/mL of goat polyclonal anti-β-actin antibodies (Santa Cruz Biotechnology, Santa Cruz, CA). The membranes were rinsed with TBS, then incubated at 37 °C for 45 min with a 1:1500 dilution of goat anti-mouse IgG-horseradish peroxidase (HRP) secondary antibodies (Sigma) in the case of the p21 blots or rabbit anti-goat IgG-HRP antibodies (Sigma) in the case of β-actin blots. Reactive bands were detected using the ECL enhanced chemiluminescence kit (NEN Life Science Products,

Table 1. Effect of Treatments on Cell Cycle Distribution of MDA-MB-468 and MCF-7 Cells[a]

	MDA-MB-468					MCF-7				
	untreated	DMSO[b]	CPT[c] (1 μM)	EGF[d] (10 nM)	γ-radiation (20 Gy)	untreated	DMSO	CPT (1 μM)	EGF (10 nM)	γ-radiation (20 Gy)

[a] At 24 h after treatment, cell cycle distribution was determined by flow cytometry by staining with propidium iodide. [b] DMSO: dimethylsulfoxide. [c] CPT: camptothecin. [d] EGF: epidermal growth factor.

Boston, MA) and visualized by exposure to Kodak BioMax film (Kodak, Rochester, NY). The intensities of p21 and β-actin bands were quantified by gel densitometry (LabWorks Analysis software, UVP, Inc., Upland, CA).

Effects of p21 Expression on Cell Cycle Distribution. The effect of p21 expression on cell cycle distribution was determined by flow cytometry. At 24 h after exposure to CPT or EGF and 8 h after γ-radiation, MDA-MB-468 or MCF-7 cells were recovered by trypsinization and rinsed with 150 mM sodium chloride/10 mM sodium phosphate pH 7.6 (PBS), then fixed in 70% ethanol (Sigma) overnight. Fixed samples were rinsed with PBS, resuspended, and stained with 10 μg/mL propidium iodide (PI) (Sigma) and 200 units of RNAse A (Sigma) in PBS. Stained samples were analyzed on a FACScan flow cytometer (BD Bioscience, Sat Jose, CA). The percentage of cells in G_1, S, and G_2/M phase were quantified using the *Modfit* software program (Verity Software House, Topsham, ME).

WST Cell Proliferation Assay. Eight thousand cells treated with CPT, EGF, or γ-radiation were cultured in wells of 96-well plates. At 8 or 24 h after treatment, 1/10 (v/v) of WST-1 (Roche) was added into each well. Two hours after incubation, the plates were read at a wavelength of 450 nm (690 nm as the reference wavelength) using an ELISA plate reader (EL_X 800, Bio-Tek Instruments, Inc., Winooski, VT). Absorbance in the wells containing treated cells was expressed as a percentage of control wells containing untreated cells. Triplicate measurements were performed at each concentration of CPT, EGF, or dose of γ-radiation.

Treatment Sensitization Effects of Tat-anti-p21 ICs. BC cells were exposed to 1 μM CPT or 10 nM EGF for 24 h in DMEM containing 10% FCS for CPT or serum-free DMEM for EGF followed by incubation with 5 μM tat-anti-p21 ICs, 5 μM unmodified anti-p21 antibodies, or normal saline (control) for 4 h. We previously found that internalization of these tat-anti-p21 ICs labeled with ^{123}I by MDA-MB-468 cells was saturable above 5−8 μM and nuclear uptake was saturable above 5 μM (*12*). Similar studies were performed for MDA-MB-468 or MCF-7 cells exposed to 10 Gy of γ-radiation. Following γ-irradiation, BC cells were cultured for 8 h in DMEM containing 10% FCS, then incubated for 4 h with 5 μM tat-anti-p21 ICs, 5 μM unmodified anti-p21 antibodies, or normal saline (control). The cellular uptake and nuclear importation of tat-anti-p21 ICs, unmodified anti-p21 antibodies, or tat peptides labeled with ^{123}I (5 μM) in MDA-MB-468 and MCF-7 cells were measured as previously reported (*12, 13*).

Statistical Analyses. Data were expressed as mean ± sem. Statistical comparisons were made by Student's *t*-test and one-way ANOVA, and post-testing was performed using Bonferroni Multiple Comparisons Test using *Prism* v. 3.02 software (GraphPad Software, Inc., San Diego, CA). Statistical significance was defined as $p < 0.05$.

RESULTS

Dose-Dependent Induction of p21 Expression. Western blot showed that the p21/β-actin ratio in MDA-MB-468 cell lysates increased in direct proportion to CPT exposure (0.1−4 μM) (Figure 1). The maximum p21/β-actin ratio (5.54 ± 0.62) occurred at a concentration of 4 μM of CPT and was significantly higher than that in cells exposed to DMSO-containing buffer without CPT (1.10 ± 0.09) or untreated cells (0.99 ± 0.02). Treatment of MCF-7 cells with CPT for 24 h also increased p21 levels (Figure 1). The maximum p21/β-actin ratio (5.29 ± 0.14) occurred at 0.5−1 μM CPT and was significantly higher than for MCF-7 cells treated with DMSO-containing buffer without CPT (1.06 ± 0.19) or for untreated cells (1.03 ± 0.01). The p21/β-actin ratio decreased in MCF-7 cells above CPT concentrations of 1 μM (Figure 1). Treatment of MDA-MB-468 cells with EGF for 24 h caused a concentration-dependent increase in p21 expression (Figure 2). The maximum p21/β-actin ratio was observed at 5 nM EGF (1.8 ± 0.1) to 10 nM EGF (2.0 ± 0.3) and was significantly higher than for untreated cells (1.0 ± 0.1; $p < 0.05$). In contrast, there was no effect of EGF on p21 expression in MCF-7 cells (Figure 2). The p21/β-actin ratio in MCF-7 cells exposed to 5 nM EGF (0.84 ± 0.12) or 10 nM EGF (0.79 ± 0.10) was not significantly different than for untreated cells (0.90 ± 0.04; $p > 0.05$). Exposure of BC cells to γ-radiation increased p21 expression up to threefold in MCF-7 cells, but there was no significant change in p21 expression in γ-irradiated MDA-MB-468 cells (Figure 3).

Effects of p21 Expression on Cell Cycle Distribution. Induction of p21 by CPT caused an increase in the proportion of MDA-MB-468 cells in G_0/G_1 phase and a decrease in the proportion of cells in G_2/M phase compared to cells exposed to DMSO-containing buffer without CPT or untreated cells (Table 1). Induction of p21 by CPT in MCF-7 cells decreased the proportion of cells in G_0/G_1 phase and increased the fraction of cells in S phase, possibly due to G_2/M-phase transition block. Induction of p21 by EGF in MDA-MB-468 cells caused an increase in the fraction of MDA-MB-468 cells in G_0/G_1 phase compared to untreated cells (Table 1). The proportion of MDA-MB-468 cells in G_0/G_1 phase increased from 54% to 72% following exposure to 10 nM EGF, whereas there was no change in the G_0/G_1-phase fraction for EGF-exposed MCF-7 cells. Exposure of BC cells to 20 Gy of γ-radiation caused a twofold increase in MDA-MB-468 cells in G_2/M phase (40.0% versus 20.5%; Table 1), whereas exposure of MCF-7 cells caused a five-to-sixfold increase in the G_2/M-phase fraction (60.5% versus 10.8%).

WST Cell Proliferation Assay. Treatment of BC cells with CPT (up to 4 μM) caused a 1.6-fold to 2-fold decrease in the growth of MDA-MB-468 cells over 24 h, whereas a 1.6-fold decreased growth rate of MCF-7 cells was observed (Figure 1). These results were comparable to those previously reported for BC cells exposed to CPT (*15, 20*). Treatment with EGF (0 to 10 nM) caused a 2-fold decrease in the growth of MDA-MB-468 cells over 24 h, whereas a 2-fold increased growth of MCF-7 cells was observed (Figure 2). Despite the lack of p21 induction in MDA-MB-468 cells, these cells were nevertheless growth-inhibited by γ-radiation (Figure 3), although they were less sensitive than MCF-7 cells, particularly at lower doses (<10 Gy). For example, the growth of MDA-MB-468 cells relative to unexposed cells follow-

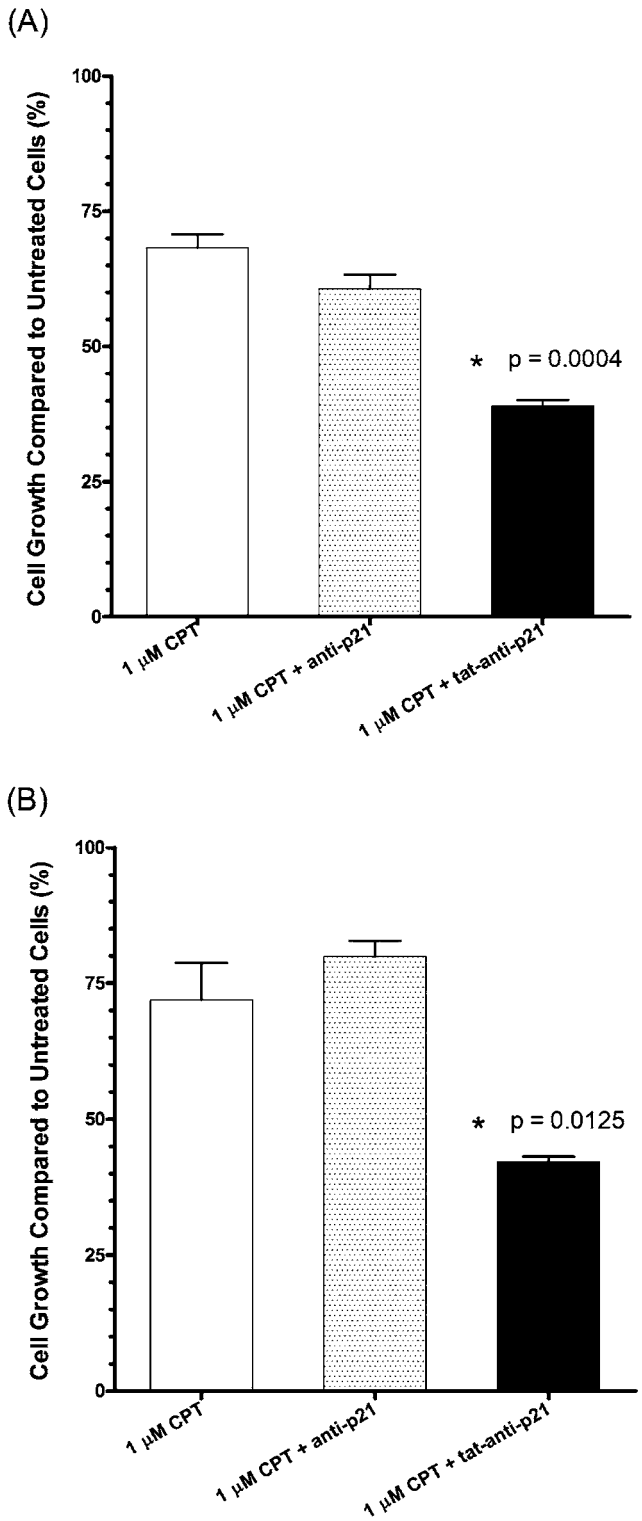

Figure 4. (A) Effect of exposure of MDA-MB-468 human breast cancer cells for 24 h to 1 μM CPT or 1 μM CPT followed by incubation with 5 μM anti-p21 antibodies or 5 μM tat-anti-p21 ICs on cell growth over 4 h measured colorimetrically using the WST-1 assay. (B) Effect of exposure of MCF-7 human breast cancer cells to 1 μM CPT followed by incubation with 5 μM anti-p21 antibodies or 5 μM tat-anti-p21 ICs or on cell growth. Cell growth is expressed as a percentage relative to that of untreated cells. Data shown are the mean ± sem of three replicate determinations. Statistical significance is indicated by the asterisk and *p*-value.

ing treatment with 6 Gy of γ-radiation was 88.7 ± 3.1% compared to 62.7 ± 2.0% for MCF-7 cells ($p = 0.002$). These results were consistent with the growth inhibitory effects of γ-radiation on MDA-MB-468 (*21*) and MCF-7 cells (*21, 22*).

Table 2. Effect of Incubation Time with EGF on Sensitization of Growth Inhibition by Tat-anti-p21 Immunoconjugates (ICs)[a]

	incubation time		
	24 h	48 h	72 h
10 nM EGF	72.5 ± 1.8%	40.1 ± 0.2%	16.5 ± 1.6%
10 nM EGF + anti-p21 antibodies	70.4 ± 0.1%	39.9 ± 4.1%	16.5 ± 0.8%
10 nM EGF + tat-anti-p21 ICs	60.9 ± 0.4%[b]	21.1 ± 1.8%[b]	7.1 ± 0.7%[b]
sensitization effect[c] (fold)	1.2-fold	1.9-fold	2.3-fold

[a] Cells were treated with 10 nM EGF for 24, 48, or 72 h, then exposed/not exposed to tat-anti-p21 ICs or unmodified anti-p21 antibodies for 4 h. Cell growth was measured colorimetrically using the WST-1 assay. Values shown are the percentage growth relative to control untreated cells (mean ± sem; $n = 3$). [b] Significantly different ($p < 0.05$) from cells treated with 10 nM EGF alone or 10 nM EGF + tat-anti-p21 antibodies. [c] Sensitization effect (fold) was calculated by dividing the growth of cells treated with 10 nM EGF + tat-anti-p21 ICs by that for cells treated with 10 nM EGF alone.

Treatment Sensitization Effects of Tat-anti-p21 ICs. The growth of MDA-MB-468 cells exposed to 1 μM CPT followed by tat-anti-p21 ICs relative to untreated cells was 39.0 ± 1.1% compared to 68.2 ± 2.5% for cells treated with CPT alone ($p = 0.0004$; Figure 4). The growth of MDA-MB-468 cells treated with 1 μM CPT and unmodified anti-p21 antibodies was 64.6 ± 2.6% relative to untreated cells. Tat-anti-p21 ICs also caused significant sensitization of MCF-7 cells to the effects of 1 μM CPT (42.1 ± 0.9% vs 71.9 ± 6.8%, respectively; $p = 0.0125$; Figure 4). Cotreatment with unmodified anti-p21 antibodies did not alter the growth inhibitory effects of CPT in MCF-7 cells (71.9 ± 6.8% vs 79.9 ± 2.9%; $p > 0.05$).

The growth of MDA-MB-468 cells exposed to EGF and tat-anti-p21 ICs relative to untreated cells was 60.9 ± 0.4% compared to 72.5 ± 1.8% for cells treated with EGF alone ($p = 0.003$; Figure 5). Although the sensitization factor was relatively low (1.2-fold), it increased with longer times of incubation with EGF. The sensitization factor increased to 1.9-fold at 48 h to 2.3-fold at 72 h of incubation with 10 nM EGF (Table 2.). There was no significant effect of tat-anti-p21 ICs on the growth of EGF-exposed MCF-7 cells relative to untreated cells (154.8 ± 4.6% vs 153.0 ± 2.4%, respectively; $p = 0.739$; Figure 5). In each case, EGF stimulated the growth of MCF-7 cells, irrespective of their exposure to tat-anti-p21 ICs. Cotreatment with unmodified anti-p21 antibodies did not change the growth of BC cells exposed to EGF: 70.4 ± 0.04% and 146.5 ± 3.8% compared to untreated cells for MDA-MB-468 and MCF-7, respectively.

Growth of MDA-MB-468 cells exposed to γ-radiation and tat-anti-p21 ICs relative to untreated cells was 73.6 ± 4.0% compared to 68.2 ± 1.9% for cells exposed to γ-radiation alone ($p = 0.291$; Figure 6). In contrast, the growth of MCF-7 cells was diminished significantly from 71.0 ± 1.3% for cells treated with γ-radiation alone to 51.4 ± 4.6% for cells treated with γ-radiation combined with tat-anti-p21 ICs relative to untreated cells ($p = 0.0154$; Figure 6). Cotreatment with unmodified anti-p21 antibodies did not significantly change the growth of BC cells exposed to γ-radiation: 74.2 ± 1.4% and 72.3 ± 1.4%, respectively; $p > 0.05$. There were no significant differences in cellular uptake or nuclear uptake of tat-anti-p21 ICs labeled with ^{123}I in MDA-MB-468 or MCF-7 cells (Table 3). The uptake of ^{123}I-tat-anti-p21 ICs by MDA-MB-468 cells was 27.9 ± 4.3% compared to 22.4 ± 1.3% for MCF-7 cells ($p > 0.05$). Nuclear importation of

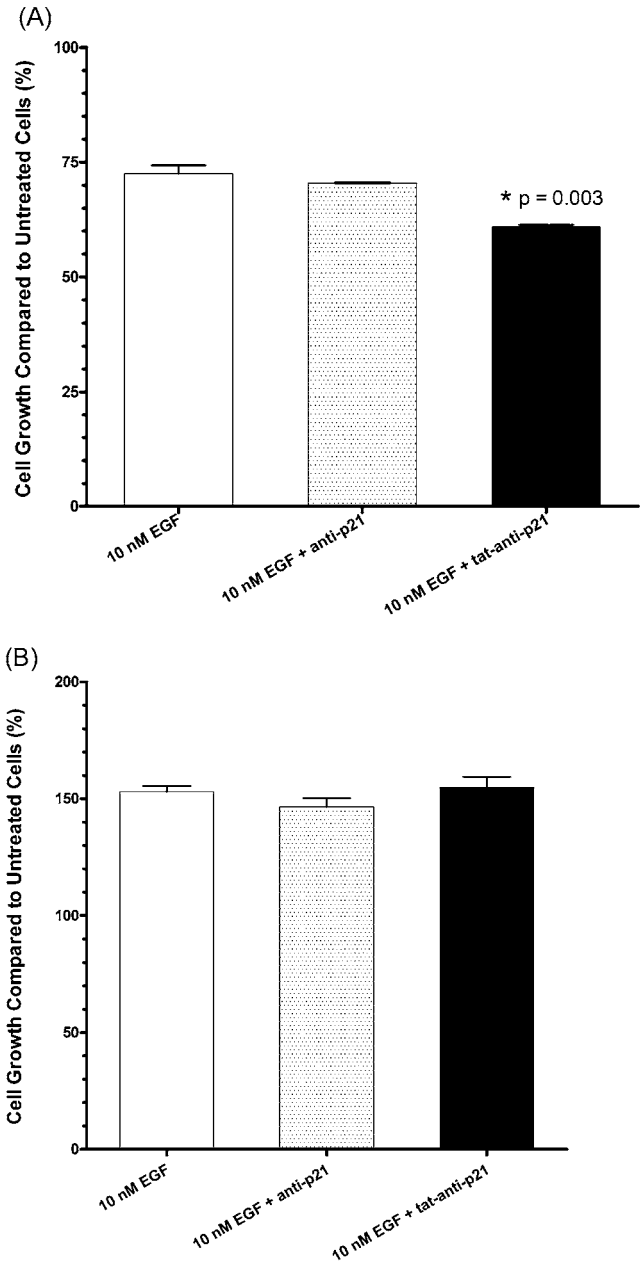

Figure 5. (A) Effect of exposure of MDA-MB-468 human breast cancer cells for 24 h to 10 nM EGF or 10 nM EGF followed by incubation with 5 μM anti-p21 antibodies or 5 μM tat-anti-p21 ICs on cell growth over 4 h measured colorimetrically using the WST-1 assay. (B) Effect of exposure of MCF-7 human breast cancer cells to 10 nM EGF followed by incubation with 5 μM anti-p21 antibodies or 5 μM tat-anti-p21 ICs or on cell growth. Cell growth is expressed as a percentage relative to that of untreated cells. Data shown are the mean $\pm$ sem of three replicate determinations. Statistical significance is indicated by the asterisk and *p*-value.

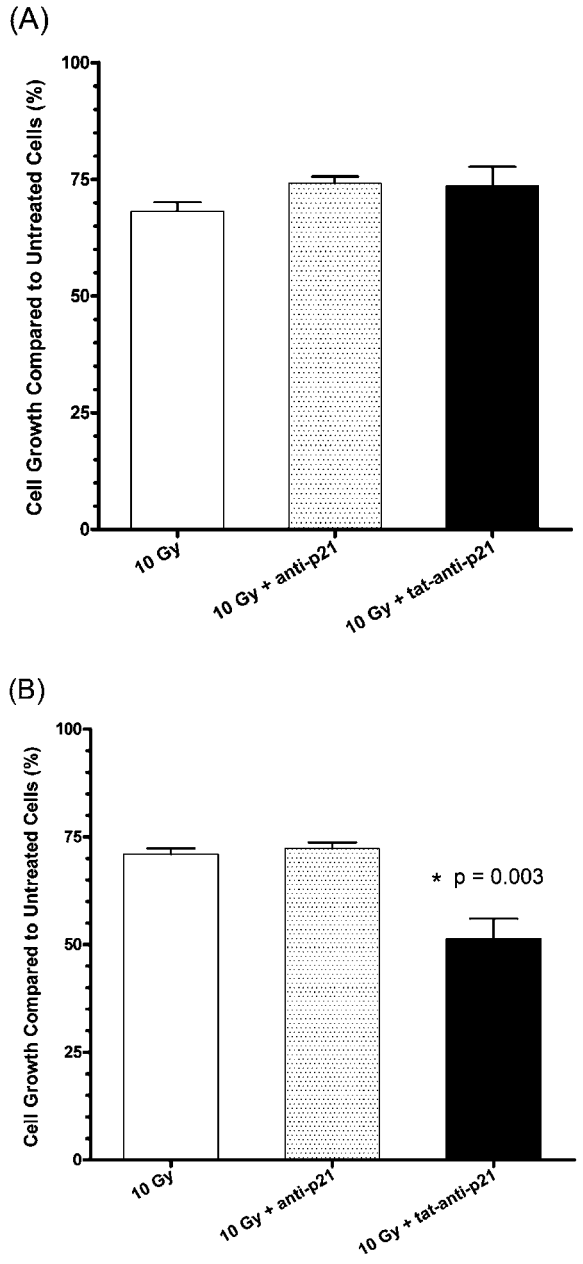

Figure 6. (A) Effect of exposure of MDA-MB-468 human breast cancer cells to 10 Gy of γ-radiation followed by incubation with 5 μM anti-p21 antibodies or 5 μM tat-anti-p21 ICs on cell growth over 4 h measured colorimetrically using the WST-1 assay. (B) Effect of exposure of MCF-7 human breast cancer cells to 10 Gy of γ-radiation, then incubation with 5 μM anti-p21 antibodies or 5 μM tat-anti-p21 ICs on cell growth. Cell growth is expressed as a percentage relative to that of untreated cells. Data shown are the mean $\pm$ sem of three replicate determinations. Statistical significance is indicated by the asterisk and *p*-value.

^{123}I-tat-anti-p21 ICs was 68.4 $\pm$ 9.3% in MDA-MB-468 and 71.6 $\pm$ 2.3% in MCF-7 cells, respectively. Accumulation of ^{123}I-labeled tat-anti-p21 ICs in cells or nuclei was similar to that of ^{123}I-tat peptides (Table 3). However, cell penetration and nuclear uptake of unmodified ^{123}I-anti-p21 antibodies were threefold and tenfold lower than those of ^{123}I-tat-anti-p21 ICs (Table 3).

DISCUSSION

In this study, we investigated for the first time the ability of tat-anti-p21 ICs to differentially sensitize BC cells to the growth-inhibitory effects of EGF, CPT, or γ-radiation. Tat peptides have been found useful for insertion of many different types of proteins and biomolecules into cells (*23*, *24*). In particular, tat peptides have been employed to insert p53 (*25*) as well as the cyclin-dependent kinase inhibitors, $p27^{Kip1}$ (*26*) or $p16^{INK4a}$ (*27*) into cells in order to restore normal growth regulatory function. The results of this study now extend these findings to the application of tat peptides for insertion of antibodies into cancer cells that have the ability to interfere with cell-protective mechanisms that limit the effectiveness of cytotoxic therapies. The construction and characterization of tat-IgG ICs were described in earlier reports by our group (*12*, *13*). In one of these studies (*13*), we showed that tat-anti-p21 ICs penetrated MDA-MB-468 cells and were translocated to the nucleus, where

Table 3. Cell Penetration and Nuclear Uptake of ^{123}I-Labeled Tat-anti-p21 Immunoconjugates (ICs), Anti-p21 Antibodies, or Tat Peptides by MDA-MB-468 or MCF-7 Cells

	MDA-MB-468 cells			MCF-7 cells		
	^{123}I-tat-anti-p21 ICs	^{123}I-anti-p21 antibodies	^{123}I-tat peptides	^{123}I-tat-anti-p21 ICs	^{123}I-anti-p21 antibodies	^{123}I-tat peptides
cell penetration	27.9 ± 4.3%[a]	9.7 ± 2.9%	26.9 ± 4.2%	22.3 ± 1.3%	7.9 ± 0.7%	19.1 ± 2.6%
nuclear uptake	59.7 ± 8.6%[b]	5.2 ± 0.3%	63.0 ± 7.3%	70.2 ± 7.4%	4.6 ± 1.0%	66.4 ± 5.7%

[a] Percentage (mean ± sem; $n = 3$) of radioactivity internalized into breast cancer cells after incubation for 4 h at 37 °C with ^{123}I-labeled tat-anti-p21 ICs, unmodified anti-p21 antibodies or tat peptides. [b] Percentage (mean ± sem; $n = 3$) of internalized radioactivity that was associated with cell nucleus. There were no significant differences in cell penetration or nuclear uptake of ^{123}I-tat-anti-p21 ICs by MDA-MB-468 or MCF-7 cells.

they attenuated the ability of p21 to mediate G_1-S-phase arrest in EGF-exposed cells. MDA-MB-468 cells exposed to 8 μM tat-anti-p21 ICs had a significantly decreased proportion of cells in G_1 phase compared to EGF-treated cells (46.1 ± 0.7% vs 81.9 ± 0.7%, respectively; $p < 0.001$); in fact, the proportion of cells in G_1 phase approached that of untreated MDA-MB-468 cells (25.8 ± 0.2%).

The sensitization by tat-anti-p21 ICs of BC cells to the growth-inhibitory effects of EGF, CPT, or γ-radiation were directly correlated with induction of p21 expression by these treatments. MDA-MB-468 cells were growth-inhibited by EGF, which was associated with higher levels of p21 and an increased proportion of cells in G_0/G_1 phase (Table 1). The antiproliferative effects of EGF were enhanced 1.2-fold to 2.3-fold by tat-anti-p21 ICs, depending on the incubation time of the cells with EGF (24 to 72 h; Table 2). Induction of p21 in MDA-MB-468 cells by EGF is mediated by a p53-independent mechanism, since these cells harbor a p53 mutation (*15*). In contrast, MCF-7 cells were growth-stimulated by EGF and did not exhibit increased p21 induction or a change in their cell cycle distribution. Cotreatment of MCF-7 cells with tat-anti-p21 ICs and EGF had no significant effect on their growth. Similar but complementary results were found for MDA-MB-468 and MCF-7 cells treated with γ-radiation. In this case, γ-irradiation increased p21 expression in MCF-7 cells (which have wild-type p53) (*15*) but not in p53-mutant MDA-MB-468 cells. Both MDA-MB-468 and MCF-7 cells showed an increase in the proportion of cells G_2/M phase and were growth-inhibited by γ-radiation. However, only in MCF-7 cells in which p21 was induced did tat-anti-p21 ICs provide a 1.4-fold significant sensitization of the growth-inhibitory effects of γ-radiation. Finally, exposure to CPT increased p21 levels in both MDA-MB-468 and MCF-7 cells, causing G_0/G_1-phase arrest in the case of MDA-MB-468 cells and an increase in the S-phase fraction for MCF-7 cells (possibly due to G_2/M-phase block). In this example, tat-anti-p21 ICs sensitized MDA-MB-468 and MCF-7 cells equivalently 1.7-fold. This differential sensitization to treatments that induce p21 by tat-anti-p21 ICs was not due to differences in cellular penetration or nuclear localization between MDA-MB-468 or MCF-7 cells, since these were virtually identical (Table 3). Unmodified anti-p21 antibodies did not sensitize BC cells to the growth-inhibitory effects of EGF, CPT, or γ-radiation (Figures 4−6). Moreover, in an earlier study, we demonstrated that nonspecific tat-mouse IgG ICs had no significant effect on G_1/S-phase arrest caused by exposure of MDA-MB-468 cells to EGF. The proportion of EGF-treated MDA-MB-468 cells in G_1 phase was 82.1 ± 0.7% and 81.9 ± 0.7% with/without cotreatment with tat-mouse IgG, respectively ($p > 0.05$). These results clearly showed that tat peptides were required for delivery of anti-p21 ICs to the nucleus of BC cells and that these ICs sensitize the cells to the growth-inhibitory effects of agents that induce p21 expression.

Our findings suggest that combining tat-anti-p21 ICs with cytotoxic agents is a promising area of research which may improve the effectiveness of anti-cancer therapy. The magnitude of sensitization observed for BC cells in this study ranged from 1.2-fold in the case of EGF (but increased to 2.3-fold with a 72 h incubation period) to 1.4-fold for CPT and 1.7-fold for γ-radiation. The ultimate clinical usefulness of this level of sensitization cannot be determined at this stage, but these orders of magnitude are similar to those previously reported for other well-known sensitizers. For example, in one study (*28*), the IC_{50} for γ-irradiation of colon cancer cells was 2.27 Gy, but this was reduced to 1.61 Gy following incubation with the radiosensitizer, 5-FU. This represents a 1.4-fold sensitization. A serious challenge in cancer treatment is the development of chemotherapy-resistant strains as a consequence of inadequate sterilization of tumor cells (*29*). Therefore, enhancement of cytotoxic potency using tat-anti-p21 ICs as illustrated in this study could potentially lessen the risk of treatment failure. Moreover, the approach could potentially be extended to functional inhibition of other key cell cycle regulatory proteins (e.g., p53, $p27^{Kip-1}$), inhibitors of apoptosis (e.g., bcl-2) or transcription factors (e.g., myc) that have been implicated in the progression of cancer (*30*−*32*). It is feasible to deliver these tat-anti-p21 ICs in vivo to human tumors. Recently, we showed that ^{123}I-labeled tat-anti-p21 ICs injected i.v. (tail vein) in athymic mice implanted s.c. with MDA-MB-468 xenografts localized preferentially in tumors that were injected intratumorally with EGF to induce p21 compared to control tumors that received saline injections (3.1 ± 0.4% i.d./g vs 1.8 ± 0.2% i.d./g, respectively; $p < 0.05$) (*13*). We have confirmed that these and other tat-immunoglobulin ICs labeled with ^{123}I penetrated cells in tumors (and normal tissues) and were imported into the nucleus of cells in vivo. Therefore, in summary, we believe that tat-anti-p21 ICs are promising as potential sensitizers for the treatment of tumors with those agents that induce p21 expression.

CONCLUSIONS

We conclude that tat-anti-p21 ICs sensitized BC cells to the antiproliferative agents of EGF, CPT, or γ-radiation and that this sensitization was dependent on the differential ability of these agents to induce p21 expression in the cells. Due to the central role of p21 in causing cell cycle arrest and/or promoting apoptosis in cells exposed to DNA-damaging agents, tat-anti-p21 ICs offer the potential to amplify the antiproliferative effects of cytotoxic therapy on cancer cells. This approach, if successful, could ultimately lessen the risk of treatment failure and the development of resistant tumor strains and could be extended to inhibit other cell growth regulatory molecules.

Alloimmunization to donor blood group antigens remains a significant problem in transfusion medicine. A proposed method to overcome donor−recipient blood group incompatibility is to mask the blood group antigens by the covalent attachment of poly(ethylene glycol) (PEG) to the red blood cell (RBC) membrane. Despite much work in the development of PEG-coating of RBCs, there is a paucity of data on the optimization of the PEG-coating technique; it is the aim of this study to determine the optimum conditions for PEG coating using a cyanuric chloride reactive derivative of methoxy-PEG as a model polymer. Activated PEG of molecular mass 5 kDa was covalently attached to human RBCs under various reaction conditions. Inhibition of binding of a blood-type specific antiserum (anti-D) was employed to evaluate the effect of the PEG-coating, quantified by hemocytometry and flow-cytometry. RBC morphology was examined by light and scanning electron microscopy. Statistical analysis of experimental design together with microscopy results showed that the optimum PEGylation conditions are pH = 8.7, temperature = 14 °C, and reaction time = 30 min. An optimum concentration of reactive PEG could not be determined. At high polymer concentrations (>25 mg/mL) a predominance of type III echinocytes was observed, and as a result, a concentration of 15 mg/mL is the highest recommended concentration for a linear PEG of molecular mass 5 kDa.

INTRODUCTION

The immunological response to transplanted allogeneic tissue and cells has been a significant barrier in both organ transplantation and blood transfusion. The most common example of allogeneic cell exposure is the use of red blood cells (RBCs) in transfusion. The cell surface serves as an important biological interface and biochemical barrier. The extreme complexity of proteins, carbohydrates, and lipids comprising the cell surface serves as the primary loci for tissue rejection. For blood banking, following Landsteiner's discovery of the ABO blood group antigens on RBCs a century ago (*1*), the major cause of this immune reaction had been identified. Blood samples from donor and recipient were each tested and classified into one of the four phenotypes, O, A, B, or AB, which allowed the donor and recipient phenotypes to be matched. Since this initial discovery, there are currently over 200 different known antigens (*2*). In most transfusions, ABO and D (Rhesus) blood typing is sufficient to identify appropriate donors. More often, problems are encountered in individuals who receive multiple transfusions, such as patients with sickle cell anemia and thalassemia. In such patients, alloimmunization against minor RBC antigens can make it nearly impossible to identify appropriate blood donors (*3*−*5*).

More than 20 years ago, Abuchowski et al. developed a technique to modify proteins by the covalent attachment of poly(ethylene glycol) (PEG). They showed that PEG-modified bovine albumin was less immunogenic than its unmodified counterpart (*6*, *7*).

The covalent attachment of PEG is now commonly used to modify a variety of proteins, enzymes, drugs, and artificial surfaces (*8*−*12*). Despite these applications, RBCs have only recently been considered for use as substrate for PEG modification. An overview of PEG-coating of RBCs by Fisher (*13*) summarizes the development of the field, and Lublin (*14*) reviewed the potential for PEG-coated RBCs as a component for the future creation of a safe, "universal" blood. The PEG-coating of RBCs provides a protective shell around the RBC that potentially excludes large molecules, such as antibodies, but does not appear to inhibit the passage of small molecules, such as glucose and oxygen (*13*).

Several reactive derivatives of methoxy-PEG (mPEG) have been used to covalently attach mPEG to the surface of RBCs (*15*−*18*). All of these reactive derivatives preferentially target epsilon amino acids (almost exclusively lysine residues) on the extracellular surface of the plasma membrane (*13*, *19*). All cells can be readily modified using cyanuric chloride activated PEG with only slight variations in pH, temperature, and time. Cyanuric chloride's strengths as a coupling agent include the malleability of its chemistry, the efficacy in membrane protein modification, and the chemical stability of the modified proteins (*20*).

Despite the development of this technology to PEG-coat RBCs, optimization of the reaction conditions has not been thoroughly investigated. In this study, RBCs were coated with a reactive cyanuric chloride mPEG derivative of 5 kDa

molecular mass. The effects of process variables (polymer concentration, temperature, time, and pH) were investigated. Full factorial design and Taguchi analysis were employed to identify the optimum reaction conditions for PEGylation of RBCs. To assess the effectiveness of the PEG-coating, inhibition of agglutination by blood-type specific antisera was measured, using a hemocytometer to count the remaining single RBCs. In addition, the hemocytometery data were confirmed by flow cytometric analysis of fluorescein-labeled anti-D binding to PEG-coated RBCs. Finally, the morphology of PEG-RBCs was studied by light microscopy and scanning electron microscopy (SEM).

EXPERIMENTAL PROCEDURES

Reagents. Methoxy-poly(ethylene glycol) of 5 kDa molecular mass, triethanolamine (TEA), and fluorescein isothiocyanate (FITC) were purchased from Sigma (St. Louis, MO). Cyanuric chloride (2,4,6-trichloro-1,3,5-triazine), benzene, anhydrous sodium carbonate, D-glucose, sodium chloride, and potassium chloride were obtained from Merck-Schuchardt (Darmstadt, Germany). Cyclohexane was purchased from Roth (Karlsruhe, Germany). Packed Rh-positive RBCs were obtained from Iranian Blood Transfusion Organization. Anti-D was purchased from CinnaGen Inc. (Tehran, Iran).

Polymer Derivatization. Derivatization of 5 kDa mPEG with cyanuric chloride was performed using a modification of the method described by Abuchowski et al. (*6*). Briefly, 5 g of vacuum-dried mPEG (overnight at 80 °C) was dissolved in 40 mL of hot anhydrous benzene, cooled to 15 °C, and then slowly added to a solution of cyanuric chloride in benzene (5-fold molar excess). One gram of anhydrous sodium carbonate was then added. The mixture was stirred for 48 h at 15 °C under an atmosphere of dry nitrogen, and then the sodium carbonate was removed by vacuum filtration. The PEG derivative was precipitated with anhydrous cyclohexane, collected by vacuum filtration, and then resuspended in benzene. This process was repeated five times to remove any unreacted cyanuric chloride (*21*). The product was then dried under vacuum, using a freeze dryer system (Zirbus Technology, Vaco 5), and stored at −70 °C, under vacuum, until use (*22*).

Coating of Red Blood Cells with mPEG. Packed Rh-positive RBCs were resuspended to a 10% hematocrit in TEA buffer (30 mM TEA, 110 mM NaCl, 4 mM KCl, 5 mM D-glucose). A fresh cold stock solution of the derivatized polymer was prepared in 0.9% NaCl, containing 1 mM HCl, and appropriate volumes were immediately added to the RBC suspensions to yield a final polymer concentration of 5−45 mg/mL; an equivalent volume of buffer was added to the control samples. This acidic solution retards hydrolysis of the reactive PEG derivative prior to exposure to the RBCs; since only small volumes of the stock solution were added, the final pH of the suspensions remained unaltered. The samples were incubated with gentle mixing under various conditions (pH, temperature, time, and polymer concentration, defined in subsequent sections). After two washes with isotonic phosphate buffer solution (PBS, pH = 7.4) at 200 g for 10 min, packed RBCs were prepared for evaluation of the polymer coating (*23*).

RBC Agglutination by Anti-D. Inhibition of anti-D mediated agglutination was employed to assess the effectiveness of the polymer coating. Four hundred microliters of a control or PEGylated RBC (Rh-positive) suspension (6% hematocrit in isotonic saline) (*24*) was mixed with a solution of anti-D in PBS with a known concentration (ratio of anti-D: PBS = 1:3) and were incubated with a gentle mixing at room temperature for 30 min. The RBC s were then centrifuged at 200*g* for 1 min. One microliter of the pellet was re-suspended in 1 mL of PBS (0.1% hct), and then using a dye exclusion test with trypan blue (viable cells remained uncolored, dead cells showed blue color) and light microscopic system (Nikon, E200), nonagglutinated viable free cells were counted using a hemocytometer (Improved Neubauer Ruling). The Improved Neubauer Ruling is a 3 by 3 mm (9 mm^2) grid, subdivided into nine secondary squares, each 1 by 1 mm (1 mm^2). The smallest squares in the center of the grid have an area of 1/400 mm^2 and are arranged in groups of 16. Single free erythrocytes in five of the 25 sections of 16 small squares of the hemocytometer (four corner sections and the center square) were counted, which is equal to the number of free erythrocytes in 0.02 μL of suspension. For determination of free cells per 1 mL of RBCs at 100% hct, the number of counted free cells per 0.02 μL at 0.1% hct was multiplied by 5×10^7. The higher the number of free cells, the greater the effectiveness of RBC PEGylation.

Table 1. Selected Experimental Variables with Corresponding Values at Two Levels for Full Factorial Design

variable	low level (1)	high level (2)
A: temperature of reaction (°C)	4	25
B: time of reaction (min)	30	60
C: mPEG concentration (mg/mL)	5	45
D: pH of TEA buffer	8	9.5

Flow Cytometry. Labeling of anti-D with FITC was achieved by following the procedure described by Coligan et al. (*25*). Fluorescein-labeled anti-D was added to a dilute suspension of RBCs in PBS. The ratio of fluorescein-labeled anti-D to RBCs, obtained by titration, was high to prevent agglutination (60 μL of 0.1% hematocrit in PBS, added to 200 μL of fluorescein-labeled anti-D solution with a protein concentration of 0.16 mg/mL). The samples were incubated for 30 min at room temperature in the dark with gentle mixing, centrifuged, and washed twice with PBS at 500*g* for 2 min. The labeled cells were then resuspended in 1 mL of PBS. The fluorescence intensity of FITC-anti-D labeled PEG-cells was measured using a FACSTAR PLUS flow cytometer (Becton Dickinson, San Jose, CA). Ten thousand cells were counted for each sample (*23*). The fluorescence intensity of FITC-anti-D labeled cells was recorded for each sample and expressed as a ratio to the intensity of FITC-anti-D labeled control (uncoated) cells. The lower this ratio, the greater the effectiveness of RBC PEGylation.

Microscopy. The morphology of PEG-RBCs and control (uncoated) RBCs at physiological pH was studied by SEM (XL 30, Philips, Netherlands). The procedure described by Kayden and Bessis (*26*) to prepare RBCs for SEM was followed. Additionally, RBCs were suspended in compatible plasma and the RBC morphology examined by light microscopy at 40 × magnification.

Design of Experiments. Statistically designed experiments are highly efficient in that they give a fixed amount of information with much less effort than the classical one-variable-at-a-time approach, and many of them give additional information about interactions between variables. Factorial and fractional-factorial experiments are the most powerful (statistical) techniques in research, and well chosen fractional-factorials are particularly economical in assessing multivariable systems (*27*).

Full Factorial at Two Levels. The first step (using the Yates Table) was to identify which variables have the largest effects on the PEGylation reaction. Selection of these factors was based on previous studies in literature for RBC PEGylation. The evaluated variables were temperature and time of PEGylation reaction, polymer concentration, and pH of TEA buffer (Table 1).

Taguchi Design. We have employed Taguchi statistical technique to study the impact of multiple variables on single outputs (prevention of agglutination and antibody binding). In this technique, the results of the experiments are analyzed to achieve one or more of the following three objectives: (1) To

[a] Treatment combination: The low level of any variable is denoted by l, and the high level of any variable is denoted by its lower-case letter. [b] Each value is the average number of free cells, per 1 mL suspension, for each test with two replicates. [c] $SS_x = (f^2_x)/N$, which f_x is the amount in the final column of Yates analysis corresponding to x (not presented here) and N is the total number of treatment combinations with their replications (*32*), $MS_x = SS_x/ø_x$, which $ø_x$ is the degree of freedom corresponding to x, TSS $= \Sigma y^2_i - (\Sigma y_i)^2/N = 36311.75 \times 10^{14}$, y_i is the result, RSS $=$ TSS $- \Sigma SS_x$ $= 1338 \times 10^{14}$, error degree of freedom ($ø$) $= 16$, residual error variance $=$ RSS/$ø$ $= 83.60 \times 10^{14}$, *F*-value $= MS_x$/(residual error variance), *F*-critical ($ø_1 = 1$, $ø_2 = 16$) $= 8.575$ (obtained from standard table).

establish the best or the optimum condition for a product or a process. (2) To estimate the contribution of individual factors. (3) To estimate the response under the optimum conditions.

The optimum condition is identified by studying the main effects of each of the factors. The process involves minor arithmetic manipulation of the numerical results. The main effects indicate the general trend of the influence of the factors.

If a systematic, sequential approach to experimental design is adopted, it is usually sufficient to restrict the design to two-level experiments. Sometimes, however, it is advantageous to work at three levels or more. The usual reason for employing either of these techniques is that a maximum or minimum is being approached. This design estimates the nonlinear (quadratic) effects (*28*).

To obtain the optimum condition for PEGylation of RBCs, an L_{27} array of Taguchi (*28*) for three variables at three levels was designed. The variables and their corresponding values are presented in Table 2. This design was also employed to compare the hemocytometry results with the flow cytometry data. All experiments with RBCs were performed in duplicate unless stated otherwise.

RESULTS

The results and statistical analysis for full factorial design (using Yates Table) at two levels are presented in Table 3. All the responses are presented as the number of viable free cells per 1 mL of packed cells. An increase in the number of free cells for PEGylated versus control (uncoated) RBCs shows that the PEG-RBCs were protected against agglutination. By comparison the obtained *F*-values with a critical $F_{(1,16)}$ value of 8.575 (obtained from the *F*-Table) (*27*), it is apparent that three variables (temperature, polymer concentration, and pH) and their interactions have *F*-values greater than critical *F*. Hence they were selected as important factors for PEGylation of RBCs. The effect of reaction time was less important. In fact after 30 min, the reaction was complete and any further increase in incubation time did not have a significant effect on the responses. As a result, the reaction time was fixed at 30 min to study the effect of other variables on the extent of PEGylation.

[a] Each value is the average number of free cells, per 1 mL suspension for each test with two replicates. [b] Each value is the average mean fluorescence intensity ratio of FITC labeled anti-D cells of PEG-RBCs versus control (uncoated) RBCs, for each test with two replicates.

The obtained results, using an L_{27} array of Taguchi, with both data from cell counting and flow cytometry methods are presented in Table 4. The main effects of the experimental variables on the number of free single RBCs and also the mean fluorescence intensity ratio of FITC-anti-D labeled cells of PEG-RBCs versus control (uncoated) RBCs, as two indicators of the extent of PEGylation, are shown in Figures 1 and 2, respectively. These figures show the effect of one variable, when the others vary. Each point in each curve presents an average of the obtained responses from 9 duplicate experiments (18 experiments). These figures show that the optimum temperature and pH of reaction medium are 14 °C and pH $=$ 8.7, respectively. But the optimum polymer concentration, obtained by cell counting and flow cytometry methods, was 25 and 45 mg/mL, respectively.

The morphology of control (uncoated) and PEG-coated RBCs (5, 10, 15, 25, and 45 mg/mL of activated mPEG) that were prepared under optimum conditions (30 min, 14 °C and pH $=$ 8.7) and then returned to a physiological pH with PBS (pH $=$ 7.4) are presented in Figure 3 (images from SEM). RBC morphology was classified according to Bessis (*29*). At 5 mg/mL, type I echinocytes were observed with a few cells of echinocyte type II or III. At 10 mg/mL, type II echinocytes predominate with some cells of type I still observable. At 15 mg/mL, an equal amount of type II and III echinocytes were observed, and at 25 and 45 mg/mL only type III echinocytes existed. Light microscopic examination of RBCs suspended in compatible plasma confirmed the SEM observations.

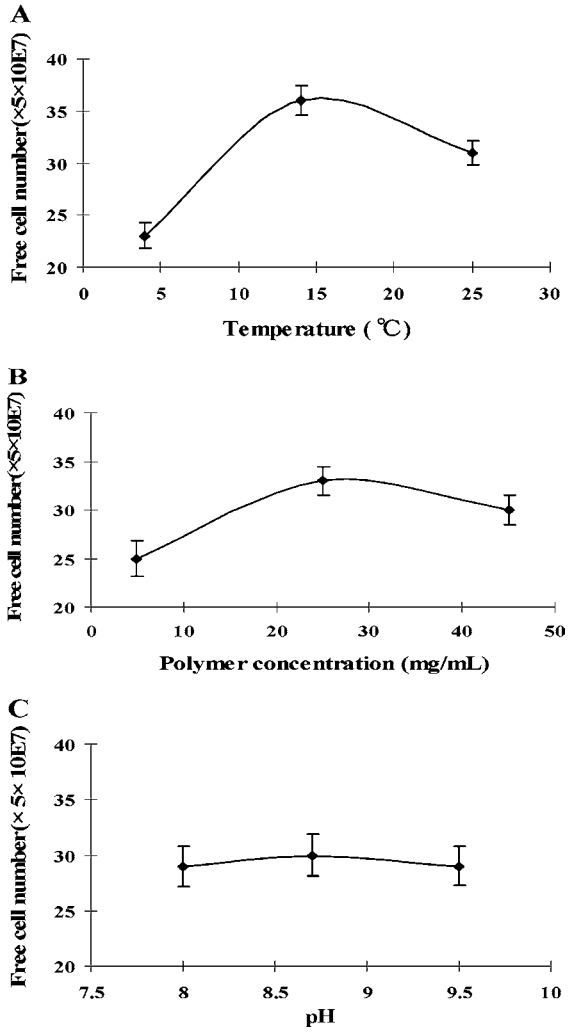

Figure 1. The effect of different factors on free cell (nonagglutinated cell) number. Shown are the effect of (A) temperature of reaction, (B) polymer concentration, and (C) pH of TEA buffer.

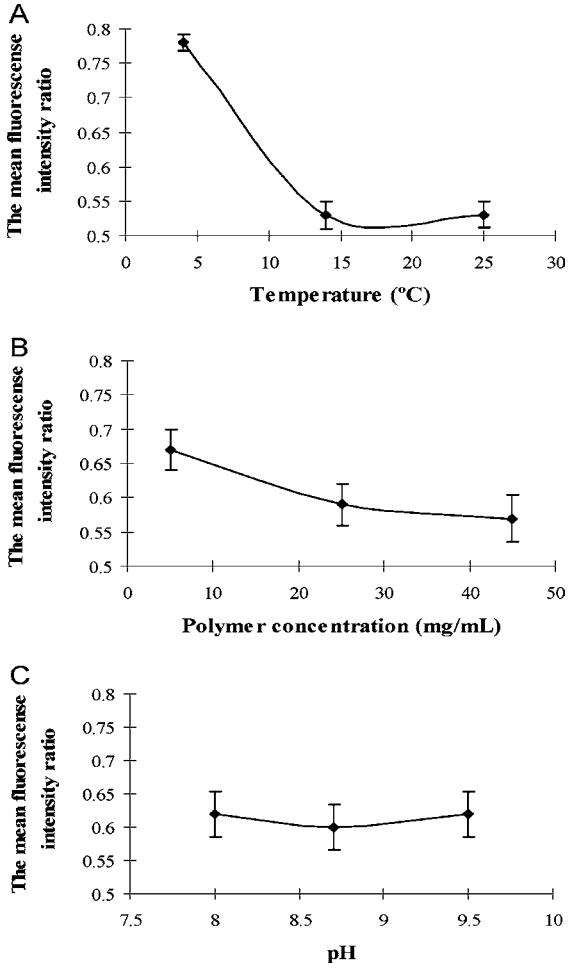

Figure 2. The effect of different factors on the mean fluorescence intensity ratio of PEG-RBCs versus control (uncoated) RBCs incubated with FITC labeled anti-D. Shown are the effect of (A) temperature of reaction, (B) polymer concentration, and (C) pH of TEA buffer.

DISCUSSION

The selection of the levels of factors for optimization were based on the range given in the literature. Jackson et al. (*30*) showed that pH = 9.2 is effective for coupling a cyanuric chloride activated mPEG to a protein. Other researchers used an elevated pH (pH = 8−9.2) for coupling an activated PEG with RBCs (*23*, *31*, *32*). The range of 30−60 min and 4−25 °C for the time and temperature of RBC PEGylation, respectively, have also been used.

Fisher (*13*) in his review noted that at polymer concentrations below 1 mM (5 mg/mL), the 5 kDa-activated mPEG is not very effective for masking antigens. Higher concentrations up to 50 mg/mL (10 mM) have also been used (*16*, *32*), but some abnormality in the morphology of RBCs was reported. Light microscopic examination of linear mPEG 5 kDa-coated RBCs in autologous plasma showed marked echinocytosis above a mPEG concentration of 2 mM (*33*) and poor *in vivo* survival of mPEG 5 kDa-coated RBCs has been observed by others in the mouse model at a concentration of 0.6mM and above (*31*). More effective antigen masking and maintenance of discocytic morphology was achieved with reactive derivatives of branched PEGs (*33*).

SEM and light microscopy results from our work presented here show that a polymer concentration of 15 mg/mL is the highest recommended level for PEGylation using a linear PEG of molecular mass 5 kDa. Above this concentration only type III echinocytes existed. RBCs of echinocyte type I and II may circulate in the host body, but cells of echinocyte type III would not circulate, because such cells are not deformable and hence would tend to get trapped in the microcirculation (*34*). Therefore the optimum concentration, 25 mg/mL, obtained by the cell counting method, and 45 mg/mL, obtained by the flow cytometry method, cannot be selected as optimum concentrations due to the loss of discocytic morphology.

The observation of increasing echinocytosis with increasing reactive PEG concentration is solely related to the presence of PEG on the cell surface, and not exposure to high pH, as all control cells showed normal discocytic morphology after returning to a physiological pH. For the purposes of the work undertaken here, it was reasonable to select a linear PEG of molecular mass 5 kDa, as this is the most commonly used PEG derivative. It is possible that PEGs of larger molecular mass or of different geometry may sustain discocytic RBC morphology, while being effective antigen masking agents (*33*), but investigation into these variables was beyond the scope of the current study.

During the incubation period at elevated pH, virtually no lysis (<1%) was observed in either the control or mPEG-modified RBCs. Indeed even mPEG concentration of up to 45 mg/mL yielded no significant lysis during RBC derivatization. Scott et al. showed that high polymer concentrations (>30 mg/mL) resulted in significant lysis after 24 h of incubation at 37 °C (but not at lower temperatures and times) (*32*).

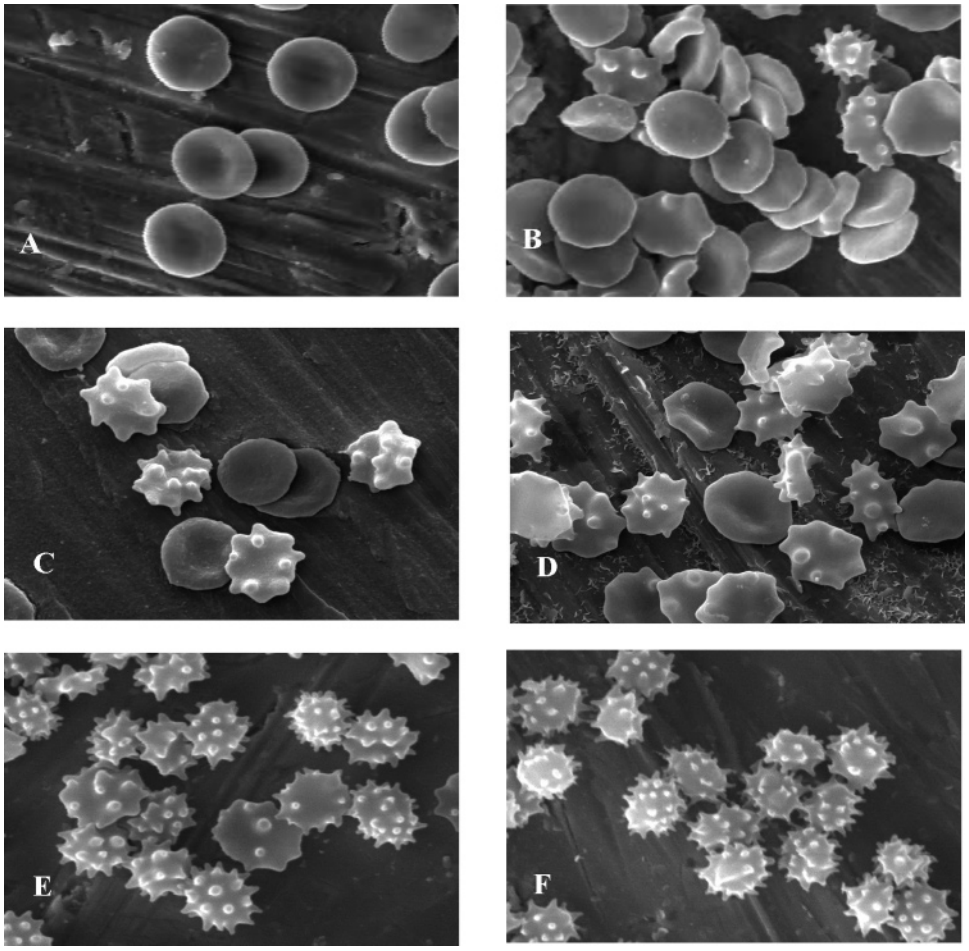

Figure 3. The morphology of mPEG-derivatized RBCs (3000×). The reactive mPEG 5kDa incubation concentrations are (A) 0 mg/mL control (uncoated), (B) 5 mg/mL, (C) 10 mg/mL, (D) 15 mg/mL (E) 25 mg/mL, and (F) 45 mg/mL.

The optimum temperature and pH of reaction medium, obtained by Taguchi design, are 14 °C and pH = 8.7. At 4 °C the rate of reaction is low, and more time is required for completion of the reaction. At temperatures higher than 20 °C, the activated polymer may show a less active form (*30*) that suggests a moderate temperature is more favorable. As mentioned earlier, a pH >7.0 is required for reaction of the PEG derivative with primary amine residues.

It can be seen that the optimum conditions at which the number of free cells was maximum, and the fluorescence intensity ratio of FITC-anti-D bound cells of the PEG-RBCs versus control (uncoated) RBCs was at a minimum, as shown in Table 4, are very similar to those deduced from Figures 1 and 2. It shows that agglutination between RBCs decreased and the corresponding number of free cells increased with increasing PEG concentration. Also as a result of RBC coating by mPEG, attachment of FITC labeled-anti-D to RBCs decreased and the corresponding ratio of mean fluorescence intensity of the PEG-RBCs versus control (uncoated) RBCs was decreased. It is worth mentioning that inhibition of agglutination does not necessarily indicate that antibody binding was inhibited relative to uncoated cells and may merely reflect the physical prevention of Igs bridging between cells. However, inhibition of agglutination does facilitate a way to quantify the PEG-coating of RBCs and is sufficient to determine the optimum conditions for PEGylating. Direct measurement of inhibition of anti-D binding to PEG-RBCs by flow cytometric analysis, using a FITC-labeled anti-D, demonstrates that the polymer coating does prevent antibody binding.

Cyanuric chloride-activated mPEG-5 kDa was covalently attached to human RBCs, and the optimum (best) conditions for this reaction were determined by different methods of experimental design. The optimum pH of TEA buffer, temperature, and reaction time were pH = 8.7, 14 °C, and 30 min, respectively. An optimum polymer concentration could not be determined by the methods employed here; however, a maximum concentration of 15 mg/mL, as the best condition, is recommended for a cyanuric chloride derivative of mPEG 5 kDa due to the observation of increasing echinocytosis with increasing concentration. Finally, concerning the good agreement between the results from hemocytometry and flow cytometry analyses, it can be concluded that the cell counting method is a simple and suitable technique to assess RBC PEGylation.

ACKNOWLEDGMENT

This work was supported by grants from the Ministry of Science, Research and Technology, and Tehran University of Medical Sciences. The authors also wish to thank Iranian Blood Transfusion Organization for providing the packed Rh-positive RBCs.

The integrin receptor $\alpha_v\beta_3$ is overexpressed on the endothelial cells of growing tumors and on some tumor cells themselves. Radiolabeled $\alpha_v\beta_3$ antagonists have demonstrated potential application as tumor imaging agents and as radiotherapeutic agents. This report describes the total synthesis of eight new HYNIC and DOTA conjugates of receptor $\alpha_v\beta_3$ antagonists belonging to the quinolin-4-one class of peptidomimetics, and their radiolabeling with ^{99m}Tc (for HYNIC) and ^{111}In (for DOTA). Tethering of the radionuclide−chelator complexes was achieved at two different sites on the quinolin-4-one molecule. All such derivatives maintained high affinity for receptor $\alpha_v\beta_3$ and high selectivity versus receptors $\alpha_{IIb}\beta_3$, $\alpha_v\beta_5$, $\alpha_5\beta_1$. Biodistribution of the radiolabeled compounds was evaluated in the c-neu Oncomouse mammary adenocarcinoma model. DOTA conjugate ^{111}In-**TA138** presented the best biodistribution profile. Tumor uptake at 2 h postinjection was 9.39% of injected dose/g of tissue (%ID/g). Activity levels in selected organs was as follows: blood, 0.54% ID/g; liver, 1.94% ID/g; kidney, 2.33% ID/g; lung, 2.74% ID/g; bone, 1.56% ID/g. A complete biodistribution analysis of ^{111}In-**TA138** and the other radiolabeled compounds of this study are presented and discussed. A scintigraphic imaging study with ^{111}In-**TA138** showed a clear delineation of the tumors and rapid clearance of activity from nontarget tissues.

INTRODUCTION

Integrins are a large family of transmembrane heterodimeric glycoprotein cell surface receptors formed by associations between α and β subunits. Integrins are important facilitators of cell−cell and cell−matrix interactions and are also involved in cell signaling events (*1*). The central role that integrins play in facilitating migration and adhesion of cells on the extracellular matrix have made integrins an important area of study in cancer metastasis and angiogenesis research (*2*−*4*). The integrin $\alpha_v\beta_3$, or vitronectin receptor, recognizes several extracellular proteins through the Arg-Gly-Asp (RGD) sequence, including vitronectin, fibronectin, fibrinogen, laminin, thrombospondin, collagen, von Willebrand factor, osteopontin, and bone sialoprotein I. This receptor is generally expressed at low levels on epithelial cells and on mature endothelial cells but is highly upregulated on the neovasculature found in tumors and in wound repair (*5*−*7*). This differential expression has made the vitronectin receptor a promising target in antiangiogenic research (*8*). For example, antagonists of integrin $\alpha_v\beta_3$ have been demonstrated to inhibit tumor angiogenesis and disrupt metastasis in a number of models (*9*−*13*). However, recent work has shown that knockout mice lacking β_3 integrins, rather than showing the expected inhibition of tumor growth, produce larger and more highly vascularized tumors (*14*). Clearly, the exact mechanism by which vitronectin receptor antagonists inhibit angiogenesis is not fully understood. In addition to expression on neovasculature, there is an upregulation in the expression of integrin $\alpha_v\beta_3$ on certain tumor cells present in clinical tissue specimens, including tumors of the kidney, breast, and prostrate, melanoma, and squamous carcinoma (*15*−*18*).

These literature reports suggest that integrin $\alpha_v\beta_3$ can be exploited as a target for selective localization of diagnostic and therapeutic radiopharmaceuticals in the vicinity of malignant tumors. The technical feasibility of imaging tumors by targeting integrin $\alpha_v\beta_3$ was first demonstrated using radiolabeled cyclic RGD peptide $\alpha_v\beta_3$ antagonists. Haubner and co-workers have described the selective tumor uptake of cyclic RGD peptides labeled with ^{125}I for SPECT imaging, and ^{18}F for PET imaging in melanoma-bearing and osteosarcoma-bearing mice (*19*, *20*). van Hagen and co-workers have described the internalization of an ^{111}In-labeled peptide in isolated human cancers, and tumor uptake in a rat tumor model in vivo (*21*). At BMS Medical Imaging we have shown that in the c-neu Oncomouse model, cyclic RGD peptide dimers give superior tumor uptake and retention compared to the cyclic monomeric peptides (*22*). This dimer effect has been confirmed by the groups of Oyen and Boerman at the University Medical Center Nijmegen using BALB/c mice growing OVCAR-3 xenografts (*23*). The use of radiolabeled peptides to image tumor angiogenesis has recently been reviewed (*24*).

While many radiolabeled peptides have demonstrated potential as tumor imaging agents, none have been able to combine the high tumor uptake and retention, and low uptake in nontarget tissues, required of a radiotherapeutic agent. We reasoned that peptidomimetics having high affinity and selectivity for integrin $\alpha_v\beta_3$ offered the best opportunity to deliver diagnostically and therapeutically useful quantities of radionuclides to tumors while minimizing dose to nontarget organs. Antagonists to integrin $\alpha_v\beta_3$ have potential applications in the control of pathological angiogenesis, and a wide variety of structurally novel $\alpha_v\beta_3$

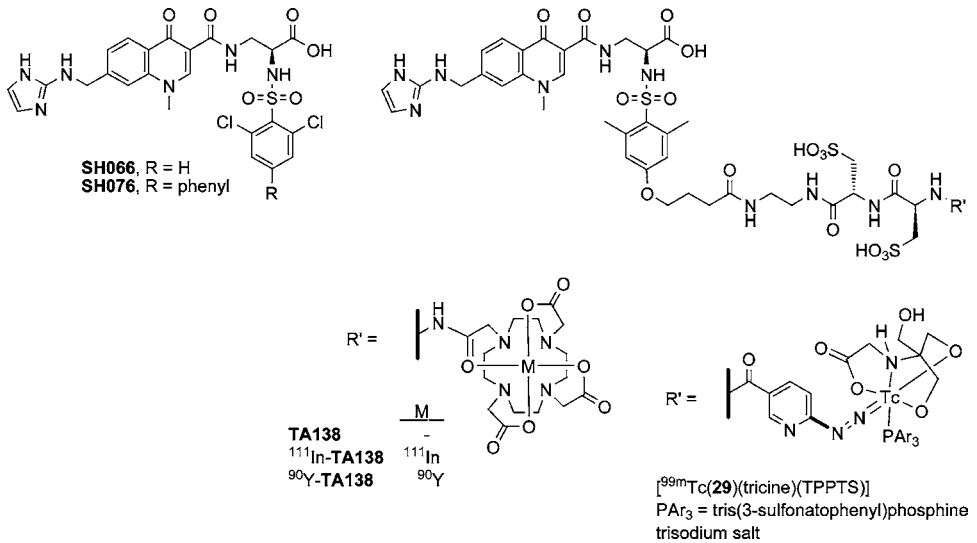

Figure 1. Structures of lead quinolin-4-one vitronectin receptor antagonist **SH066**, DOTA derivatives **TA138**, ^{111}In-**TA138**, and ^{90}Y-**TA138**, and HYNIC derivative [^{99m}Tc(**29**)(tricine))(tris{3-sulfonatophenyl}phosphine trisodium salt)].

peptidomimetic antagonists have been reported in recent years (*8*, *13*, *25*−29). The disubstituted quinolin-4-one system (e.g., **SH066**, Figure 1) developed by DuPont Pharmaceuticals was of particular interest to us. This series uses a quinolin-4-one central ring system to constrain the conformation and to serve as a scaffold on which to attach basic and acid groups that mimic the guanidine and carboxylate groups of the RGD sequence. The most active members of this series use 2-aminoimidazole and 2,3-diaminopropionate (DAP) arylsulfonamides as guanidine and carboxylate mimics, respectively. The structure−activity-relationship (SAR) for this series indicated excellent affinity for integrin $\alpha_v\beta_3$ and good selectivity versus integrin $\alpha_{IIb}\beta_3$ (*30*). The para position of the arylsulfonamide group is very tolerant of substitution and is also readily accessible synthetically, making it ideally suited as a site at which to tether a radionuclide−chelator complex. We also viewed the quinolin-4-one ring nitrogen as a potential site of derivatization. This combination of synthetic accessibility and favorable receptor selectivity made the quinolin-4-one system the ideal platform for our studies. In a preliminary publication we described the biodistribution and imaging properties of ^{111}In-**TA138**, a DOTA-conjugated quinolin-4-one integrin $\alpha_v\beta_3$ antagonists (Figure 1) (*31*). In the c-neu Oncomouse model, ^{111}In-**TA138** shows tumor uptake higher than any of the peptides reported above, while maintaining relatively low uptake in critical nontarget organs such as kidneys and bone marrow. Furthermore, in the same model, we have demonstrated a therapeutic effect using ^{90}Y-**TA138** (Figure 1) (*31*). More recently, the targeting biomolecule portion of **TA138** has been used to direct paramagnetic nanoparticles to angiogenic sites for magnetic resonance imaging (*32*, *33*). The potential applications of these molecules have also been broadened to include imaging of vascular remodeling following myocardial infarction (*34*, *35*). Herein we report the complete details of the synthesis of **TA138** and eight analogues, along with receptor affinity and biodistribution data of the radiolabeled analogues. The structural parameters investigated include attachment of tethers at two different sites on the parent quinolin-4-one structure, the use of two different radionuclide chelators (DOTA and HYNIC as shown in Figure 1), the use of two different imaging radionuclides (^{111}In and ^{99m}Tc), and the use of different pharmacokinetic modifiers (PKMs).

EXPERIMENTAL SECTION

General Experimental. All reactions were performed under a dry nitrogen atmosphere. All chemicals and solvents (reagent grade) were used as supplied from the vendors cited without further purification, unless otherwise noted. 3-((*tert*-butoxy)-carbonylamino)propyl bromide and 4,7,10-trioxa-1,13-tridecanediamine were purchased from Fluka. *tert*-Butyloxycarbonyl (Boc) amino acids and other starting amino acids were obtained from Bachem Inc., Bachem Biosciences Inc. (Philadelphia, PA), or Advanced ChemTech (Louisville, KY). 2-(1*H*-Benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) and benzotriazol-1-yl-oxy-tris-pyrrolidinophosphonium hexafluorophosphate (PyBOP) were purchased from Advanced ChemTech. *N*-Methylmorpholine (NMM), *m*-cresol, trimethylacetyl chloride, 1,2,4-triazole, stannous chloride dihydrate, biphenyl-4,4′-disulfonyl chloride, and tris(3-sulfonatophenyl)-phosphine trisodium salt (TPPTS) were purchased from Aldrich Chemical Co. Tricine was obtained from Research Organics, Inc. Technetium-99m-pertechnetate ($^{99m}TcO_4^-$) was obtained from a DuPont Pharma ^{99}Mo/^{99m}Tc Technelite generator. ^{111}Indium chloride (Indichlor) was obtained from Amersham Medi-Physics, Inc. ^{177}Lutetium chloride was obtained from the University of Missouri Research Reactor (MURR). Ethyl acetate, chloroform ($CHCl_3$), methanol (MeOH), acetonitrile (ACN), dichloromethane (DCM), ethyl ether, acetone, and hydrochloric acid (HCl) were obtained from Baker. Anhydrous dimethylformamide (DMF), acetonitrile (ACN), pyridine, triethylamine (TEA), and diisopropylethylamine (DIEA) were obtained from Aldrich in SureSeal bottles. Absolute ethanol was obtained from Quantum Chemical Corp. Merck silica gel, grade 9385, 230−400 mesh, 60 Å, was used for flash chromatography. DOTA(O*t*-Bu)$_3$OH was obtained from Macrocyclics, Dallas, TX. Other reagents were obtained from Lancaster Synthesis, Inc., Aldrich Chemical Co, or Fluka Chemical Corp.

^{1}H NMR spectra were recorded on a Bruker Avance DRX (600 MHz) spectrometer. Chemical shifts are reported in ppm from tetramethylsilane with the residual solvent resonance resulting from incomplete deuteration as the internal standard ($CDCl_3$: δ 7.25 ppm, ACN-d_3: δ 1.95 ppm, DMSO-d_6: δ 2.50 ppm). Data are reported as follows: chemical shift, multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, quin = quintet, b = broad, m = multiplet), coupling constants, and integration. ^{13}C NMR spectra were recorded on a Bruker Avance DRX (150 MHz) with complete proton decoupling. Chemical shifts are reported in ppm from tetramethylsilane with the solvent as the internal reference ($CDCl_3$: δ 77.0 ppm, ACN-d_3: δ 118.1 ppm, DMSO-d_6: δ 39.5 ppm). Low-resolution mass spectrometry was performed on an Agilent Technologies 1100 Series LC/MS ESI-

MS. High-resolution mass spectrometry was performed on a Ionspec Ultima FTMS; ESI-MS (positive mode). Melting points were determined using a Thomas-Hoover melting point apparatus and are uncorrected.

Benzyl 3-(2-(2-(3-Aminopropoxy)ethoxy)ethoxy)propylcarbamate (2). A solution of 4,7,10-trioxa-1,13-tridecanediamine (**1**) (158 mL, 0.72 mol), TEA (16.7 mL, 0.12 mol), and MeOH (300 mL) in peroxide-free THF (1000 mL) was placed in a 3 L three-neck flask fitted with a mechanical stirrer, thermometer, and addition funnel with nitrogen line. The addition funnel was charged with a solution of benzyl chloroformate (17.1 mL, 0.12 mol) in peroxide-free THF (1000 mL). The contents of the flask were cooled below 5 °C. The contents of the addition funnel were added to the flask with rapid stirring over 4 h while keeping the temperature below 5 °C. The solution was stirred an additional 30 min and concentrated to give a thick syrup. This syrup was taken up in saturated NaCl (1800 mL) and 10% Na_2CO_3 (200 mL) and extracted with ether (3 × 1.0 L). The combined ether extracts were washed with saturated NaCl (500 mL), dried ($MgSO_4$), and concentrated to give a pale yellow oil (36.74 g). Flash chromatography on a 7 × 29 cm silica gel column (DCM:MeOH:TEA, 20:15:0.5) gave **2** as a colorless syrup (19.14 g, 45%). ^{1}H NMR ($CDCl_3$): 7.33−7.25 (m, 5H), 5.59 (s, 1H), 5.06 (s, 2H), 3.62−3.45 (m, 12H), 3.32−3.25 (m, 2H), 2.74 (t, J = 6.7 Hz, 2H), 1.75 (quin, J = 6.0 Hz, 2H), 1.67 (quin, J = 6.4 Hz, 2H), 1.33 (s, 2H). MS (ESI): *m*/*z* 355.4 (M + H); HRMS: Calcd for $C_{18}H_{31}N_2O_5$ (M + H): 355.2233; Found: 355.2222.

(*S*)-Methyl 3-(*tert*-Butoxycarbonylamino)-2-(4′-(*N*-(3-oxo-1-phenyl-2,8,11,14-tetraoxa-4-azaheptadecan-17-yl)sulfamoyl)-biphenyl-4-ylsulfonamido)propanoate (3). Biphenyl-4,4′-disulfonyl chloride (2.64 g, 7.5 mmol, freshly recrystallized from $CHCl_3$) and DCM (200 mL) were placed in a 500 mL three-neck flask fitted with a thermometer, addition funnel, and nitrogen line. The addition funnel was charged with a solution of compound **2** (1.77 g, 5.0 mmol) and DIEA (0.87 mL, 5.0 mmol) in DCM (40 mL). The contents of the flask were cooled below 5 °C. The contents of the addition funnel were added to the flask with rapid stirring over 3 h while keeping the temperature of the flask below 5 °C. The addition funnel was charged with a solution of *N*-β-Boc-L-α,β-diaminopropionic acid methyl ester hydrochloride (2.55 g, 10 mmol) and DIEA (3.8 mL, 22 mmol) in DCM (25 mL). This solution was added to the flask with stirring at 5 °C over 15 min and stirred at ambient temperature for an additional 20 h. The reaction solution was washed consecutively with 0.1 N HCl (100 mL) and water (2 × 100 mL), dried ($MgSO_4$), and concentrated to give a viscous oil (5.79 g). Flash chromatography on a 5 × 21 cm silica gel column (85:15 EtOAc:hexanes, followed by 100% EtOAc) gave a colorless amorphous solid. Recrystallization from toluene (85 mL) gave the title compound as a colorless solid (2.52 g, 59%). MP: 104.5−106.5 °C; ^{1}H NMR ($CDCl_3$): δ 8.00−7.90 (m, 4H), 7.72−7.64 (m, 4H), 7.46−7.24 (m, 5H), 5.96−5.88 (m, 1H), 5.86−5.73 (m, 1H), 5.41 (s, 1H), 5.16−5.00 (m, 3H), 4.15−4.02 (m, 1H), 3.68−3.39 (m, 17H), 3.34−3.22 (m, 2H), 3.13−3.03 (m, 2H), 1.80−1.62 (m, 4H), 1.39 (s, 9H); ^{13}C NMR ($CDCl_3$): δ 170.2, 156.5, 156.1, 143.9, 143.0, 140.4, 139.4, 136.7, 128.4, 128.1, 128.0, 127.9, 127.9, 127.8, 127.3, 80.1, 70.6, 70.5, 70.2, 70.1, 70.0, 69.6, 66.5, 56.1, 52.9, 43.2, 42.4, 39.3, 29.4, 28.5, 28.2. MS (ESI): *m*/*z* 868.3 (M + NH_4); HRMS: Calcd for $C_{39}H_{55}N_4O_{13}S_2$ (M + H): 851.3207; Found: 851.3226.

(*S*)-Methyl 3-(1-Methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)-2-(4′-(*N*-(3-oxo-1-phenyl-2,8,11,14-tetraoxa-4-azaheptadecan-17-yl)sulfamoyl)biphenyl-4-ylsulfonamido)propanoate (6). Compound **3** (748 mg, 0.88 mmol) was dissolved in 25:75 TFA:DCM (15 mL) and allowed to stand at ambient temperature for 15 min. The TFA was removed under vacuum, and the resulting amber oil was taken up in 50:50 ACN:water (50 mL) and treated portion wise with Bio-Rad AG 3-X4 resin, free amine form, to raise the pH from 2 to 6. The resin was removed by filtration and the filtrate was lyophilized to amine **4** as a sticky pale yellow foam.

In a separate flask, 1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxylic acid (**5**) (*36*) (432 mg, 0.80 mmol), TEA (0.33 mL), and HBTU (364 mg, 0.96 mmol) were dissolved in anhydrous DMF (25 mL). The resulting solution was stirred at ambient temperature for 10 min and combined with a solution of compound **4** in anhydrous DMF (15 mL). The DMF was removed under vacuum after 18 h to give a viscous yellow oil. This oil was taken up in EtOAc (175 mL), washed consecutively with water (25 mL), saturated $NaHCO_3$ (50 mL), and saturated NaCl (25 mL), dried ($MgSO_4$), and concentrated to give a viscous yellow oil. Purification by flash chromatography on a 7 × 25 cm silica gel column using a $CHCl_3$:EtOAc:MeOH step gradient (47:47:6, 46:46:8, 60:30:10) gave compound **6** as a pale yellow solid (510 mg, 50%). MP: 136−140 °C. MS (ESI): *m*/*z* 1273.4 (M + H); HRMS: Calcd for $C_{68}H_{73}N_8O_{13}S_2$ (M + H): 1273.4738; Found: 1273.4730.

(*S*)-3-(1-Methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)-methyl)-1,4-dihydroquinoline-3-carboxamido)-2-(4′-(*N*-(3-oxo-1-phenyl-2,8,11,14-tetraoxa-4-azaheptadecan-17-yl)-sulfamoyl)biphenyl-4-ylsulfonamido)propanoic Acid (7). Compound **6** (295 mg, 0.232 mmol) was dissolved in a mixture of peroxide-free THF (12 mL), water (1.8 mL), and 3 N LiOH (1.2 mL) and stirred at ambient temperature for 30 min. The THF was removed under vacuum, and the resulting mixture was dissolved in $CHCl_3$ (75 mL) and water (50 mL). The aqueous layer was adjusted to pH 3 with 0.5 N HCl, and the layers were thoroughly mixed. The aqueous layer was extracted with additional $CHCl_3$ (2 × 25 mL). The combined $CHCl_3$ extracts were washed with saturated NaCl (50 mL), dried ($MgSO_4$), and concentrated to give the title compound as a pale yellow solid (291 mg, 100%). MS (ESI): *m*/*z* 1259.3 (M + H); HRMS: Calcd for $C_{67}H_{71}N_8O_{13}S_2$ (M + H): 1259.4582; Found: 1259.4610.

(*S*)-3-(7-((1*H*-Imidazol-2-ylamino)methyl)-1-methyl-4-oxo-1,4-dihydroquinoline-3-carboxamido)-2-(4′-(*N*-(3-(2-(2-(3-aminopropoxy)ethoxy)ethoxy)propyl)sulfamoyl)biphenyl-4-ylsulfonamido)propanoic Acid (8). Compound **7** (279 mg, 0.222 mmol) was dissolved in degassed TFA (30 mL) and treated with Et_3SiH (0.424 mL, 2.66 mmol). The solution was heated at 70 °C for 1 h and concentrated to a viscous oil. This oil was dissolved in water (20 mL) and washed with ether (2 × 20 mL). The combined ether washings were back-extracted with water (10 mL). The combined water extracts were diluted with an equal volume of ACN and treated with Bio-Rad AG 3-X4 resin, free amine form, to raise the pH from 4 to 6. The resin was removed by filtration and the filtrate was lyophilized to give the title compound as a colorless solid (220 mg). MS (ESI): *m*/*z* 883.4 (M + H), 442.5 (M + 2H); HRMS: Calcd for $C_{40}H_{51}N_8O_{11}S_2$ (M + H): 833.3118; Found: 833.3118.

(*S,E*)-3-(7-((1*H*-Imidazol-2-ylamino)methyl)-1-methyl-4-oxo-1,4-dihydroquinoline-3-carboxamido)-2-(4′-(*N*-(1-oxo-1-(6-(2-(2-sulfobenzylidene)hydrazinyl)pyridin-3-yl)-6,9,12-trioxa-2-azapentadecan-15-yl)sulfamoyl)biphenyl-4-ylsulfonamido)propanoic Acid Trifluoroacetic Acid Salt (10). A solution of compound **8** (15 mg, 0.0135 mmol), TEA (0.007 mL), and sodium (*E*)-2-((2-(5-carboxypyridin-2-yl)hydrazono)-methyl)benzenesulfonate (*37*) (**9**) (9.0 mg, 0.0204 mmol) in anhydrous DMF (2.5 mL) was allowed to stand at ambient temperature for 22 h. The DMF was removed under vacuum and the glassy solid was dissolved in 20% ACN and purified

by preparative HPLC on a Vydac C-18 column (22 × 250 mm) using 0.1% TFA in water for 5 min followed by a 2.52%/min gradient of 0−63% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 21.2 min was collected and lyophilized to give **10** as a colorless powder (3.5 mg, 20%). MS (ESI): *m*/*z* 1186.7 (M + H); HRMS: Calcd for $C_{53}H_{60}N_{11}O_{15}S_3$ (M + H): 1186.3432; Found: 1186.3410.

(*S*)-*tert*-Butyl 2,2′,2″-(10-(16-(4′-(*N*-(3-(7-((1*H*-imidazol-2-ylamino)methyl)-1-methyl-4-oxo-1,4-dihydroquinoline-3-carboxamido)-1-methoxy-1-oxopropan-2-yl)sulfamoyl)biphenyl-4-ylsulfonamido)-2-oxo-7,10,13-trioxa-3-azahexadecyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetate Tris(trifluoroacetic Acid) Salt (11). A solution of compound **6** (68 mg, 0.0534 mmol) and Et_3SiH (0.051 mL, 0.32 mmol) in degassed TFA (5.0 mL) was stirred at 70 °C for 1 h and concentrated to dryness. The resulting amber oil was dissolved in anhydrous DMF (2 mL) and treated with TEA until basic to pH paper. A solution of DOTA(O*t*-Bu)$_3$OH (46 mg, 0.080 mmol) in anhydrous DMF (1.0 mL) was added, followed by HBTU (24 mg, 0.064 mmol), and the solution was stirred at ambient temperature for 3 h. The DMF was removed under vacuum, and the residue was dissolved in 50% ACN and purified by preparative HPLC on a Vydac C-18 column (22 × 250 mm) using a 2.1%/min gradient of 0−63% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 23.8 min was collected and lyophilized to give compound **11** as a colorless powder (16 mg, 17%). MS (ESI): *m*/*z* 1451.7 (M + H); HRMS: Calcd for $C_{69}H_{103}N_{12}O_{18}S_2$ (M + H): 1451.6954; Found: 1451.698.

(*S*)-2,2′,2″-(10-(16-(4′-(*N*-(2-(7-((1*H*-imidazol-2-ylamino)-methyl)-1-methyl-4-oxo-1,4-dihydroquinoline-3-carboxamido)-1-carboxyethyl)sulfamoyl)biphenyl-4-ylsulfonamido)-2-oxo-7,10,13-trioxa-3-azahexadecyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic Acid Bis(trifluoroacetic Acid) Salt (12). Compound **11** (16 mg, 0.00893 mmol) was dissolved in a mixture of peroxide-free THF (1.0 mL), water (0.115 mL), and 3 N LiOH (0.075 mL) and stirred at ambient temperature for 24 h. The reaction was concentrated to give an oily solid. This solid was dissolved in 50% ACN and purified by preparative HPLC on a Vydac C-18 column (22 × 250 mm) using a 2.52%/min gradient of 0−63% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 24.0 min was collected and lyophilized to give a colorless powder (6.0 mg). This solid was dissolved in degassed TFA (2.0 mL) and Et_3SiH (0.050 mL), stirred at 70 °C for 4.5 h, and concentrated to dryness. The resulting oil was dissolved in 25% ACN and purified by preparative HPLC on a Vydac C-18 column (22 × 250 mm) using a 1.5%/min gradient of 0−45% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 19.0 min was collected and lyophilized to give the bis-TFA salt of **12** as a colorless powder (2.0 mg, 15%). MS (ESI): *m*/*z* 1269.5 (M + H), 635.5 (M + 2H), 424.3 (M + 3H); HRMS: Calcd for $C_{56}H_{77}N_{12}O_{18}S_2$ (M + H): 1269.4920; Found: 1269.4950.

Ethyl 4-(3,5-Dimethylphenoxy)butanoate (13). Sodium metal (17.12 g, 0.744 mol) was added to anhydrous EtOH (350 mL) and stirred until dissolved. 3,5-Dimethylphenol was added, and the solution was stirred 15 min at ambient temperature. Ethyl 4-bromobutyrate (58.7 mL, 0.41 mol) was added, and the solution was stirred at ambient temperature for 28 h. The EtOH was removed under vacuum, and the oily solid was partitioned between water (1 L) and EtOAc (500 mL). The aqueous layer was extracted with additional EtOAc (500 mL). The combined EtOAc extracts were washed consecutively with saturated $NaHCO_3$ (300 mL) and saturated NaCl (300 mL), dried ($MgSO_4$), and concentrated to give an amber liquid. This liquid was vacuum fractionally distilled through a 15 cm Vigreux column. The main fraction was collected from 91 to 117 °C/6 mmHg (lit. (*38*) BP 141 °C/2 mmHg) to give compound **13** as a colorless liquid (77.77 g, 89%). ^{1}H NMR ($CDCl_3$): δ 6.59 (s, 1H), 6.52 (s, 2H), 4.16 (q, J = 7.16 Hz, 2H), 3.98 (t, J = 6.14 Hz, 2H), 2.49 (t, J = 7.34 Hz, 2H), 2.28 (s, 6H), 2.11−2.07 (m, 2H), 1.26 (t, J = 7.16 Hz, 3H). Anal. Calcd for $C_{14}H_{20}O_3$: C,71.16; H, 8.53; Found: C,71.35; H, 8.59.

4-(3,5-Dimethylphenoxy)butanoic Acid (14). Compound **13** (75.52 g, 0.320 mol) and KOH pellets (38.5 g, 0.584 mol) were dissolved in absolute EtOH (1.5 L) and heated at reflux for 3 h. The solution was concentrated to a colorless solid, which was taken up in water (2.0 L) and washed with ether (2 × 750 mL). The aqueous layer was adjusted to pH 1 with concd HCl (55 mL), and the resulting oily precipitate was extracted into EtOAc (2 × 500 mL). The combined EtOAc extracts were washed consecutively with water (300 mL) and saturated NaCl, dried ($MgSO_4$), and concentrated to give a colorless solid (64.13 g). Recrystallization from hexanes (500 mL) gave compound **14** as a colorless solid (59.51 g, 89%). MP: 66−68.5 °C (lit. (*38*) MP 69−70 °C); ^{1}H NMR ($CDCl_3$): δ 11.70 (bs, 1H), 6.59 (s, 1H), 6.52 (s, 2H), 3.99 (t, J = 6.06 Hz, 2H), 2.57 (t, J = 7.29 Hz, 2H), 2.28 (s, 6H), 2.12−2.08 (m, 2H). Anal. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74; Found: C, 69.23; H, 7.40.

4-(4-(Chlorosulfonyl)-3,5-dimethylphenoxy)butanoic Acid (15). A solution of compound **14** (20.8 g, 0.100 mol) in $CHCl_3$ (100 mL) was cooled to 0 °C and treated with chlorosulfonic acid (36 mL, 0.54 mol) dropwise and with rapid stirring while keeping the temperature of the reaction at 0 °C. The resulting gelatinous mixture was stirred an additional 10 min and poured onto an ice/water mixture (600 mL). The resulting solid precipitate was collected by filtration, washed with water (3 × 75 mL), and dried under vacuum to give **15** as a colorless solid (12.52 g, 41%). MP: 114−115 °C (with dec); ^{1}H NMR ($CDCl_3$): δ 13.84 (bs, 1H), 6.50 (s, 2H), 3.91 (t, J = 6.48 Hz, 2H), 2.48 (s, 6H), 2.32 (t, J = 7.32 Hz, 2H), 1.89−1.84 (m, 2H). IR (KBr cm^{-1}): 1705 (s), 1370 (s), 1175 (s). MS (ESI): *m*/*z* 305.1 (M − H).

(*S*)-4-(4-(*N*-(3-(*tert*-Butoxycarbonylamino)-1-methoxy-1-oxopropan-2-yl)sulfamoyl)-3,5-dimethylphenoxy)butanoic Acid (16). A solution of (*S*)-methyl 2-amino-3-(*tert*-butoxycarbonylamino)propanoate hydrochloride (568 mg, 2.10 mmol) and DIEA (0.73 mL, 4.2 mmol) in DCM (5 mL) was cooled to 0 °C and treated with a suspension of compound **15** (656 mg, 2.10 mmol) in DCM (20 mL) in small portions over a 15 min period. The reaction was stirred at ambient temperature for 18 h. The reaction was diluted with DCM (100 mL) and washed with water (3 × 75 mL). The organic phase was dried ($MgSO_4$), and concentrated to give crude product (698 mg), which was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.96%/min gradient of 18−58.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product fraction eluting at 23.8 min was collected, adjusted to pH 3 using 1 N NaOH, partially concentrated to remove ACN, and extracted with DCM (2 × 100 mL). The DCM extracts were dried ($MgSO_4$) and concentrated to give compound **16** as a colorless solid (297 mg, 29%). ^{1}H NMR ($CDCl_3$): δ 6.61 (s, 2H), 5.66 (d, J = 7.2 Hz, 1H), 4.90 (s, 1H), 4.03 (bs, 2H), 3.86 (bs, 1H), 3.59 (s, 3H), 3.49 (bs, 2H), 2.62 (s, 6H), 2.58−2.51 (m, 2H), 2.18−2.07 (m, 2H), 1.41 (s, 9H). MS (ESI): *m*/*z* 489.4 (M + H); HRMS: Calcd for $C_{21}H_{33}N_2O_9S$ (M + Na): 511.1726, Found: 511.1747. Anal. Calcd for $C_{21}H_{32}N_2O_9S$: C, 51.62; H, 6.61; N, 5.74; Found: C, 51.47; H, 6.27; N, 5.48.

(*S*)-Methyl 2-(4-(4-(2-(Benzyloxycarbonylamino)ethylamino)-4-oxobutoxy)-2,6-dimethylphenylsulfonamido)-3-(*tert*-butoxycarbonylamino)propanoate (17). A solution of compound **16** (369 mg, 0.756 mmol), DIEA (0.52 mL, 3.0 mmol), and HBTU (315 mg, 0.832 mmol) in anhydrous

DMF (14 mL) was stirred at ambient temperature for 5 min, treated with benzyl *N*-(2-aminoethyl)carbamate hydrochloride (192 mg, 0.832 mmol), and stirred an additional 1 h. The DMF was removed under vacuum, and the oily residue was taken up in EtOAc (150 mL), washed consecutively with 0.1 N HCl (40 mL), water (40 mL), and saturated NaCl (40 mL), dried ($MgSO_4$), and concentrated to give a colorless viscous oil. Flash chromatography on a 3 × 16 cm silica gel column (EtOAc) gave the title compound as a colorless viscous oil (450 mg, 89.6%). ^{1}H NMR ($CDCl_3$): δ 7.34−7.27 (m, 5H), 6.58 (s, 2H), 6.31 (bs, 1H), 5.86 (bs, 1H), 5.36 (bs, 1H), 5.14−5.03 (m, 3H), 3.96 (t, J = 6.0 Hz, 2H), 3.88−3.83 (m, 1H), 3.56 (s, 3H), 3.47−3.25 (m, 6H), 2.59 (s, 6H), 2.31 (t, J = 6.9 Hz, 2H), 2.05 (p, J = 6.6 Hz, 2H), 1.39 (s, 9H); ^{13}C NMR ($CDCl_3$): δ 172.9, 170.5, 160.6, 157.3, 155.9, 141.8, 136.3, 128.5, 128.2, 128.0, 116.6, 79.9, 66.9, 55.5, 52.8, 43.1, 40.9, 40.3, 32.4, 28.2, 24.9, 23.3. MS (ESI): *m*/*z* 687.3 (M + Na), 665.4 (M + H); HRMS: Calcd for $C_{31}H_{45}N_4O_{10}S$ (M + H): 665.2856; Found: 665.2883.

(*S*)-Methyl 2-(4-(4-(2-(Benzyloxycarbonylamino)ethylamino)-4-oxobutoxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoate (19). Compound **17** (420 mg, 0.632 mmol) was dissolved in 25:75 DCM:TFA (20 mL) and allowed to stand at ambient temperature for 10 min. The solution was concentrated, and the resulting viscous oil was dissolved in 50% ACN and lyophilized to give compound **18** as a colorless solid (437 mg, 102%). MS (ESI): *m*/*z* 565.3 (M + H). In a separate flask a solution of 1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxylic acid (702 mg, 1.30 mmol), DIEA (0.678 mL, 3.90 mmol), and HBTU (542 mg, 1.43 mmol) in anhydrous DMF (60 mL) was stirred at ambient temperature for 10 min and treated with compound **18** (881 mg, 1.30 mmol). After 75 min the DMF was removed under vacuum and the resulting oil was purified by HPLC on a Vydac C-18 column (50 × 250 mm) using a 1.24%/min gradient of 18−67.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. A peak eluting at 18.9 min was lyophilized to give unreacted 1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxylic acid (308 mg). The main product peak eluting at 23.7 min was lyophilized to give compound **19** as a colorless solid (890 mg, 63.0%). ^{1}H NMR (1:1 CD_3CN:D_2O): δ 8.50 (s, 1H), 8.18 (d, J = 8.3 Hz, 1H), 7.70 (s, 1H), 7.51−7.25 (m, 15H), 7.25−7.12 (m, 5H), 6.97 (s, 1H), 6.58 (d, J = 2.3 Hz, 1H), 6.34 (s, 2H), 6.32 (d, J = 8.5 Hz, 1H), 5.09 (s, 2H), 4.65 (s, 2H), 4.29−4.23 (m, 1H), 3.88 (s, 3H), 3.80−3.50 (m, 7H), 3.41−3.28 (m, 4H), 2.61 (s, 6H), 2.26−2.11 (m, 2H), 1.92−1.76 (m, 2H). MS (ESI): *m*/*z* 1087.4 (M + H); 845.3 (M + H − Tr); HRMS: Calcd for $C_{60}H_{63}N_8O_{10}S$ (M + H): 1087.4388; Found: 1087.440.

(*S*)-2-(4-(4-(2-Aminoethylamino)-4-oxobutoxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic Acid (21). A solution of compound **19** (468 mg, 0.431 mmol) in MeOH (100 mL) was hydrogenolyzed over 10% Pd/C (95 mg) at 60 psi for 1 h. The catalyst was removed by filtration through Celite, and the filtrate was concentrated to give compound **20** as a pale amber oil (405 mg, 98.7%). MS (ESI): *m*/*z* 953.3 (M + H), 711.3 (M + H − trityl). A mixture of **20** (956 mg, 1.004 mmol), peroxide-free THF (35 mL), water (5.3 mL), and 3 N LiOH (3.53 mL, 10.6 mmol) was stirred at ambient temperature for 1 h, and adjusted to pH 5−6 using 1 N HCl (10 mL). The THF was removed under vacuum causing a gummy yellow solid to precipitate. The water layer was removed by decantation, and the solid was washed with water (15 mL). The solid was dried under vacuum to give compound **21** as a dry yellow solid (324 mg, 80%). ^{1}H NMR (DMSO-d_6): δ 10.03 (t, J = 5.7 Hz, 1H), 8.70 (s, 1H), 8.16 (t, J = 5.7 Hz, 1H), 8.06 (d, J = 8.4 Hz, 1H), 7.42−7.30 (m, 11H), 7.17−7.10 (m, 6H), 6.75 (d, J = 8.4 Hz, 1H), 6.58 (s, 2H), 6.51 (d, J = 1.8 Hz, 1H), 6.30 (d, J = 1.8 Hz, 1H), 4.35 (d, J = 6.4 Hz, 2H), 4.04 (t, J = 6.0 Hz, 1H), 3.86 (s, 3H), 3.87−3.49 (m 6H), 3.26−3.12 (m, 2H), 2,60 (t, J = 6.4 Hz, 2H), 2.54 (s, 6H), 2.17 (t, J = 6.5 Hz, 2H), 1.86 (t, J = 6.5 Hz, 2H); ^{13}C NMR (DMSO-d_6): δ 175.0, 171.8, 171.4, 164.2, 159.7, 149.5, 148.4, 145.9, 141.4, 140.8, 139.6, 129.4, 128.1, 127.7, 125.6, 123.8, 122.7, 116.5, 116.1, 115.0, 110.5, 73.1, 67.0, 66.6, 46.6, 45.8, 40.9, 38.2, 36.1, 31.6, 25.1, 24.4, 22.9. MS (ESI): *m*/*z* 939.3 (M + H, 40); 697.3 (M + H − Trt, 100); HRMS: Calcd for $C_{51}H_{55}N_8O_8S$ (M + H): 939.3864; Found: 939.3845.

(*S*)-2-(4-((*R*)-2,2-Dimethyl-4,7,12-trioxo-6-(sulfomethyl)-3-oxa-5,8,11-triazapentadecan-15-yloxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic Acid (22). A solution of Boc-L-cysteic acid (175 mg, 0.60 mmol), DIEA (0.208 mL, 1.20 mmol), and PyBOP (250 mg, 0.480 mmol) in anhydrous DMF (5.0 mL) was stirred at ambient temperature for 17 min, and added to a solution of compound **21** (375 mg, 0.400 mmol) and DIEA (0.070 mL, 0.400 mmol) in anhydrous DMF (4.0 mL). The resulting solution was stirred at ambient temperature for 45 min and concentrated under vacuum to give an amber oil. This oil was purified by HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.29%/min gradient of 31.5−43.2% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 22.0 min was lyophilized to give compound **22** as a colorless solid (430 mg, 90%). MS (ESI): *m*/*z* 1190.3 (M + H), 948.3 (M + H − Trt); HRMS: Calcd for $C_{59}H_{68}N_9O_{14}S_2$ (M + H): 1190.4327; Found: 1190.431.

(*S*)-2-(4-(4-(2-((*R*)-2-Amino-3-sulfopropanamido)ethylamino)-4-oxobutoxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic Acid (23). A solution of compound **35** (430 mg, 0.362 mmol) in 50:50 TFA:DCM (15 mL) was allowed to react at ambient temperature for 10 min and concentrated under vacuum. The resulting amber oil was taken up in 50% ACN (50 mL) and lyophilized to give **23** as a pale yellow solid (398 mg, 100%). ^{1}H NMR (MeOH- d_4): δ 8.49 (s, 1H), 8.19 (d, J = 8.4 Hz, 1H), 7.60 (s, 1H), 7.51−7.45 (m, 9H), 7.37−7.30 (m, 6H), 7.08 (d, J = 2.7 Hz, 1H), 6.81 (d, J = 2.7 Hz, 1H), 6.58 (d, J = 8.4 Hz, 1H), 6.23 (s, 2H), 4.68 (d, J = 4.9 Hz, 2H), 4.38−4.35 (m, 1H), 4.26−4.22 (m, 1H), 3.98 (s, 3H), 3.94−3.89 (m, 1H), 3.65−3.60 (m, 1H), 3.47−3.37 (m, 4H), 3.29−3.24 (m, 1H), 3.23−3.18 (m, 3H), 3.13−3.08 (m, 2H), 2.58 (s, 6H), 1.90−1.86 (m, 2H); ^{13}C NMR (MeOH-d_4): δ 177.4, 175.6, 173.6, 168.6, 167.2, 161.3, 150.0, 147.9, 143.7, 142.8, 141.5, 140.7, 131.3, 131.0, 130.0, 128.1, 127.8, 124.6, 119.5, 117.3, 116.8, 113.6, 111.5, 77.9, 68.1, 56.1, 51.9, 51.8, 47.7, 47.4, 42.5, 42.2, 40.7, 39.5, 33.5, 27.4, 26.4, 23.8. Sodium (*E*)-2-((2-(5-Carboxypyridin-2-yl)hydrazono)methyl)benzenesulfonate (28). A suspension of 6-hydrazinonicotinic acid (*39*) (0.994 g, 6.5 mmol) and sodium 2-formylbenzenesulfonate (1.84 g, 8.84 mmol) in DMF was stirred at ambient temperature for 3 h. The resulting homogeneous solution was concentrated and the residue was triturated with MeOH (3 × 25 mL) to give the title compound as a colorless solid (1.40 g, 63%). MS (ESI): *m*/*z* 344.3 (M + Na, 27), 322.2 (M + H, 100); HRMS: Calcd for $C_{13}H_{12}N_3O_5S$ (M + H): 322.0498; Found: 322.0511.

(*S*)-3-(7-((1*H*-Imidazol-2-ylamino)methyl)-1-methyl-4-oxo-1,4-dihydroquinoline-3-carboxamido)-2-(2,6-dimethyl-4-((3*R*,6*R*)-1,4,7,12-tetraoxo-1-(6-((*E*)-2-(2-sulfobenzylidene)hydrazinyl)pyridin-3-yl)-3,6-bis(sulfomethyl)-2,5,8,11-tetraazapentadecan-15-yloxy)phenylsulfonamido)propanoic Acid (29). A solution of sodium (*E*)-2-((2-(5-carboxypyridin-2-yl)hydrazono)methyl)benzenesulfonate (17.2 mg, 0.050 mmol), PyBOP (19.5 mg, 0.0375 mmol), and DIEA (26 μL, 0.150 mmol) in anhydrous DMF (1.0 mL) was stirred at ambient temperature for 30 min and added to a solution of **27** (25 mg, 0.025 mmol) and DIEA (26 μL, 0.150 mmol) in anhydrous DMF (1.5 mL). The solution was stirred at ambient temperature for 4 h and concentrated under reduced pressure. The resulting residue was purified by HPLC on a Higgins Clipeus C-18 column (20 × 250 mm) using a 0.56%/min gradient of 4.5−27% ACN containing 0.1% formic acid at a flow rate of 15 mL/min. The main product peak eluting at 27.5 min was lyophilized. The resulting solid was repurified by HPLC on the same column using a 0.45%/min gradient of 4.5−22% ACN containing 10 mmol NH_4OAc, pH 7 at a flow rate of 15 mL/min. The main product peak eluting at 28.0 min was lyophilized to give **29** as a colorless fluffy solid (10.4 mg, 32.0%). MS (ESI): *m*/*z* 1302.2 (M + H, 44), 651.7 (2M + H, 100); HRMS: Calcd for $C_{51}H_{60}N_{13}O_{20}S_4$ (M + H): 1302.2960; Found: 1302.2951.

(*R*)-3-(Bis(allyloxy)phosphoryl)-2-(*tert*-butoxycarbonylamino)propanoic Acid (30). A solution of *N*-(*tert*-butoxycarbonyl)-L-serine β-lactone (*40*) (198 mg, 1.06 mmol) in diallyl-(trimethylsilyl)phosphite (*41*) (1.98 g, 8.46 mmol) was heated at 70 °C for 50 h. Excess phosphite was removed under high vacuum with heating. The resulting oil was dissolved in EtOAc (20 mL), washed with water (20 mL), dried (Na_2SO_4), and concentrated to give 190 mg of crude product. Purification by flash chromatography on a 2.0 × 13.5 cm silica gel column using a DCM:MeOH:HOAc (95:5:1) mobile phase gave **30** as a pale yellow oil (71 mg, 19%). ^{1}H NMR ($CDCl_3$): δ 5.98−5.88 (m, 2H), 5.75 (bs, 1H), 5.41−5.33 (m, 2H), 5.26 (d, J = 10.4 Hz, 2H), 2.56−2.43 (m, 2H), 1.44 (s, 9H); ^{13}C NMR ($CDCl_3$): δ 176.1, 155.3, 132.4, 118.6, 80.2, 66.9, 49.1, 28.3, 20.6; ^{31}P NMR ($CDCl_3$): δ 28.6. MS (ESI): *m*/*z* 350.4 (M + H).

(*S*)-2-(4-((*R*)-6-((diallyloxyphosphoryl)methyl)-2,2-dimethyl-4,7,12-trioxo-3-oxa-5,8,11-triazapentadecan-15-yloxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic Acid (31). A solution of compound **30** (75.0 mg, 0.215 mmol), DIEA (0.100 mL, 0.861 mmol), and HBTU (68.0 mg, 0.179 mmol) in anhydrous DMF (4.0 mL) was stirred at ambient temperature for 20 min and added to a solution of compound **21** (134 mg, 0.143 mmol) and DIEA

(0.050 mL, 0.287 mmol) in anhydrous DMF (4.0 mL). The resulting solution was stirred at ambient temperature for 60 min and concentrated to a viscous yellow oil. The product was purified by HPLC on a Higgins C-18 column (20 × 250 mm) using a 0.30%/min gradient of 36−54% ACN containing 0.1% TFA at a flow rate of 15 mL/min. The main product peak eluting at 36.9 min was lyophilized to give compound **31** as a colorless solid (130 mg, 72%). MS (ESI): *m*/*z* 1270.4 (M + H, 100), 1028.3 (M + H − Trt, 55).

(*S*)-2-(4-((6*R*,9*R*)-6,9-Bis((diallyloxyphosphoryl)methyl)-2,2-dimethyl-4,7,10,15-tetraoxo-3-oxa-5,8,11,14-tetraazaoctadecan-18-yloxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic Acid (33). A solution of compound **31** (151 mg, 0.117 mmol) in 50:50 TFA:DCM (10.0 mL) was allowed to react at ambient temperature for 10 min and concentrated under vacuum to give amine **32** as an amber oil. This oil was dissolved in anhydrous DMF (3 mL) and made basic (pH 10) with DIEA. In a separate flask, a solution of compound **30** (65.0 mg, 0.186 mmol), DIEA (0.100 mL, 0.861 mmol), and HBTU (56.0 mg, 0.148 mmol) in anhydrous DMF (4.0 mL) was stirred at ambient temperature for 20 min and added to the above solution of compound **32**. The resulting solution was stirred at ambient temperature for 60 min and concentrated to a viscous yellow oil. The product was purified by HPLC on a Dynamax C-18 column (41 × 250 mm) using a 0.45%/min gradient of 36−54% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 32.7 min was lyophilized to give compound **33** as a colorless solid (121 mg, 69%). ^{1}H NMR ($CDCl_3$): δ 10.4 (s, 1H), 8.51 (s, 1H), 8.06 (s, 1H), 7.96 (s, 1H), 7.80 (s, 1H), 7.62 (s, 1H), 7.48−7.30 (m, 9H), 7.22−7.04 (m, 6H), 6.94 (s, 1H), 6.54−6.23 (m, 4H), 5.88 (s, 1H), 5.95−5.62 (m, 4H), 5.38−5.28 (m, 4H), 5.27−5.21 (m, 4H), 4.90 (s, 1H), 4.73−4.59 (m, 4H), 4.59−4.19 (m, 8H), 4.37−4.28 (m, 1H), 4.03 (s, 1H), 3.88−3.64 (m, 7H), 3.38−3.23 (m, 4H), 2.60 (s, 6H), 2.57−2.20 (m, 6H), 1.94 (s, 2H), 1.42 (s, 9H). MS (ESI): *m*/*z* 1501.5 (M + H, 100), 1259.4 (M + H − Trt, 45), 1159.2 (M + H − Trt-Boc, 8); HRMS: Calcd for $C_{74}H_{91}N_{10}O_{18}P_2S$ (M + H): 1501.5631; Found: 1501.570.

(*S*)-2-(2,6-Dimethyl-4-((4*R*,7*R*)-2,5,8,13-tetraoxo-4,7-bis((diallyloxyphosphoryl)methyl)-1-(4,7,10-tris(2-*tert*-butoxy-2-oxoethyl)-1,4,7,10-tetraazacyclododecan-1-yl)-3,6,9,12-tetraazahexadecan-16-yloxy)phenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic Acid Bis(Trifluoroacetic Acid) Salt (35). A solution of compound **33** (88.3 mg, 0.0588 mmol) in 50:50 TFA:DCM (10.0 mL) was allowed to react at ambient temperature for 15 min and concentrated under vacuum to give amine **34** as a viscous yellow oil. This oil was dissolved in anhydrous DMF (2.0 mL) and made basic (pH 10) with DIEA. In a separate flask, a solution of DOTA(O*t*-Bu)$_3$OH (50.5 mg, 0.0883 mmol), DIEA (0.008 mL), and HBTU (26.8 mg, 0.0707 mmol) in anhydrous DMF (2.0 mL) was stirred at ambient temperature for 15 min and added to a solution of amine **34**. HPLC analysis at 60 min indicated a slow rate of reaction. Additional DOTA(O*t*-Bu)$_3$OH (30.0 mg, 0.0524 mmol) was preactivated in a separate flask by combining it with DIEA (0.005 mL) and HBTU (15.0 mg, 0.0396 mmol) in DMF (1.5 mL) at ambient temperature for 15 min. The preactivated DOTA ester was added to the main reaction solution. After an additional 60 min, the solution was concentrated to give a viscous amber oil. The product was purified by HPLC on a Dynamax C-18 column (41 × 250 mm) using a 0.90%/min gradient of 36−63% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product, eluting as a broad peak from 21 to 25 min was lyophilized to give compound **35** as a colorless solid (37 mg, 29%). MS (ESI): *m*/*z* 1714.1 (M + H − Trt, 8), 978.9 (M + 2H, 13), 857.7 (M + 2H − Trt, 100); HRMS: Calcd for $C_{97}H_{133}N_{14}O_{23}P_2S$ (M + H): 1955.8786; Found: 1955.887.

2,2′,2″-(10-((4*R*,7*R*)-16-(4-(*N*-((*S*)-2-(7-((1*H*-Imidazol-2-ylamino)methyl)-1-methyl-4-oxo-1,4-dihydroquinoline-3-carboxamido)-1-carboxyethyl)sulfamoyl)-3,5-dimethylphenoxy)-2,5,8,13-tetraoxo-4,7-bis(phosphonomethyl)-3,6,9,12-tetraazahexadecyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic Acid (36). A solution of compound **35** (35.6 mg, 0.0163 mmol) in anhydrous THF (4.0 mL) was treated with morpholine (0.025 mL, 0.273 mmol) and tetrakis(triphenylphosphine)palladium ($(\phi_3P)_4Pd$) (4.6 mg, 0.004 mmol), and the reaction was stirred at ambient temperature. After 1.5 h, additional morpholine (25 μL) and catalyst (4.6 mg) were added, and the mixture was stirred an additional 4.5 h. The mixture was filtered through Celite, and the filtrate was concentrated to give the crude intermediate bis-phosphonic acid as a dark amber oil (68.2 mg). MS (ESI): *m*/*z* 1792.2 (M + H, 10), 1554.0 (M + H − Trt, 22), 777.7 (M + 2H, 100). A solution of the crude intermediate(66.7 mg, 0.037 mmol) in 97:3 TFA:Et_3SiH (5.0 mL) was heated at 70 °C for 1 h. The mixture was filtered through Celite, and the filtrate was concentrated to give a dark amber oil. The product was purified by HPLC on a Higgins Clipeus C-18 column (21 × 250 mm) using a 0.45%/min gradient of 4.5−22.5% ACN containing 0.1% TFA at a flow rate of 15 mL/min. The main product, eluting at 33 min was lyophilized to give the title compound as a colorless solid (4.5 mg, 20%). MS (ESI): *m*/*z* 1385.8 (M + H, 18), 693.5 (M + 2H, 100); HRMS: Calcd for $C_{54}H_{78}N_{14}O_{23}P_2S$ (M + H): 1385.4560; Found: 1385.465.

Ethyl 7-Bromo-1-(3-(*tert*-butoxycarbonylamino)propyl)-4-oxo-1,4-dihydroquinoline-3-carboxylate (38). A mixture of ethyl 7-bromo-4-oxo-1,4-dihydroquinoline-3-carboxylate (**37**) (*36*) (6.28 g, 0.0212 mol), 3-((*tert*-butoxy)carbonylamino)propyl bromide (30.3 g, 0.127 mol), and anhydrous K_2CO_3 (12.5 g, 0.904 mol) in anhydrous DMF (200 mL) was stirred at 60 °C for 4 h and then at ambient temperature for 72 h. The DMF was removed under vacuum, and the resulting oily solid was dissolved in EtOAc (500 mL). The EtOAc solution was washed consecutively with water (500 mL), saturated $NaHCO_3$ (500 mL), and saturated NaCl (500 mL), dried ($MgSO_4$), and concentrated to give a red oil. This oil was taken up in EtOAc (250 mL) and cooled, causing a solid precipitate to form. This precipitate was collected by filtration, washed with cold EtOAc, and dried to give **38** as a colorless solid (6.25 g, 65%). MP: 140−142 °C; ^{1}H NMR ($CDCl_3$): δ 8.49 (s, 1H), 8.39 (d, J = 8.6 Hz, 1H), 7.58 (s, 1H), 7.53 (d, J = 8.6 Hz, 1H), 4.72 (bs, 1H), 4.39 (q, J = 7.1 Hz, 2H), 4.20 (t, J = 7.6 Hz, 2H), 3.28−3.24 (m, 2H), 2.10−2.06 (m, 2H), 1.46 (s, 9H), 1.40 (t, J = 7.1 Hz, 3H). MS (ESI): *m*/*z* 455.2. (M + H); HRMS: Calcd for $C_{20}H_{26}BrN_2O_5$ (M + H): 453.1025; Found: 453.1028.

Ethyl 1-(3-(*tert*-Butoxycarbonylamino)propyl)-4-oxo-7-vinyl-1,4-dihydroquinoline-3-carboxylate (39). A solution of **38** (2.98 g, 6.60 mmol) in toluene (50 mL) at 100 °C was treated with $(\phi_3P)_4Pd$ (152 mg, 0.132 mmol). After 5 min the mixture was treated with tributyl(vinyl)tin (1.93 mL, 6.60 mmol) and stirred 4.5 h at 100 °C and 18 h at ambient temperature. Additional tributyl(vinyl)tin (0.386 mL) and $(\phi_3P)_4Pd$ (152 mg) were added, and the mixture was heated at 100 °C for an additional 17 h. The toluene was removed under vacuum, and the solid residue was triturated with ether to give **39** as a pale green solid (1.67 g, 63%). MP: 133−135 °C; ^{1}H NMR ($CDCl_3$): δ 8.52 (d, J = 8.4 Hz, 1H), 8.51 (s, 1H), 7.55 (d, J = 8.4 Hz, 1H), 7.38 (s, 1H), 6.88−6.82 (m, 1H), 5.97 (d, J = 17.4 Hz, 1H), 5.51 (d, J = 10.8 Hz, 1H), 4.75 (bs, 1H), 4.42 (q, J = 7.2 Hz, 2H), 4.27 (t, J = 7.8 Hz, 2H), 3.6−3.25 (m, 2H), 2.16−2.11 (m, 2H), 1.49 (s, 9H), 1.45 (t, J = 7.2 Hz,

3H). MS (ESI): *m*/*z* 401.3 (M + H); HRMS: Calcd for $C_{22}H_{29}N_2O_5$ (M + H): 401.2076; Found: 401.2075.

Ethyl 1-(3-(*tert*-Butoxycarbonylamino)propyl)-7-formyl-4-oxo-1,4-dihydroquinoline-3-carboxylate (40). A solution of **2** (1.50 g, 3.75 mmol) in dioxane (119 mL) and water (39 mL) was treated with a solution of OsO_4 (19.6 mg, 0.077 mmol) in dioxane (0.600 mL) and stirred at ambient temperature for 5 min. Sodium periodate (2.40 g, 11.2 mmol) was added, and the solution was stirred at ambient temperature for 2 h. The solvents were removed under vacuum, and the residue was taken up in DCM (500 mL). The DCM solution was washed consecutively with water (500 mL) and saturated NaCl (500 mL), dried ($MgSO_4$), and concentrated to give **40** as an orange oily solid (1.52 g, 100%). ^{1}H NMR ($CDCl_3$): δ 10.17 (s, 1H), 8.68 (d, J = 8.2 Hz, 1H), 8.64 (s, 1H), 8.01 (s, 1H), 7.88 (d, J = 8.2 Hz, 1H), 4.82 (bs, 1H), 4.41−4.35 (m, 4H), 3.28 (s, 2H), 2.15−2.07 (m, 2H), 1.45 (s, 9H), 1.41 (t, J = 7.1 Hz, 3H). MS (ESI): *m*/*z* 403.3 (M + H); HRMS: Calcd for $C_{21}H_{27}N_2O_6$ (M + H): 403.1870; Found: 403.1875.

Ethyl 1-(3-(*tert*-Butoxycarbonylamino)propyl)-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxylate (41). A solution of **40** (544 mg, 1.35 mmol) and 2-amino-1-(triphenylmethyl)imidazole (*42*) (456 mg, 1.35 mmol) in toluene (60 mL) was heated at reflux for 5 h with azeotropic removal of water. The solution was cooled, treated with $Na(OAc)_3BH$ (1.14 g, 5.38 mmol), and stirred at ambient temperature for 18 h. The mixture was diluted with EtOAc (400 mL), washed consecutively with water (500 mL) and saturated NaCl (500 mL), dried ($MgSO_4$), and concentrated to give an orange solid. This solid was dissolved in 50% ACN and purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.60%/min gradient of 18−52% ACN containing 0.1% TFA at a flow rate of 49 mL/min. The main product peak eluting at 30.8 min was collected and lyophilized to give **41** as a pale yellow solid (407 mg, 60%). MS (ESI): *m*/*z* 712.4 (M + H); HRMS: Calcd for $C_{43}H_{46}N_5O_5$ (M + H): 712.3499; Found: 712.3485.

1-(3-(*tert*-Butoxycarbonylamino)propyl)-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxylic Acid (42). A mixture of **41** (997 mg, 1.40 mmol), water (7.3 mL), 3 N LiOH (3.5 mL), and THF (50 mL) was stirred at ambient temperature for 3 h. The THF was removed under vacuum, and the resulting mixture was dissolved in $CHCl_3$ (500 mL) and water (100 mL). The aqueous layer was adjusted to pH 3 with 1.0 N HCl, and the layers were thoroughly mixed. The organic layer was washed consecutively with water (500 mL) and saturated NaCl (500 mL), dried ($MgSO_4$), and concentrated to give **42** as a pale yellow solid (998 mg). MP: 153−160 °C; ^{1}H NMR ($CDCl_3$): δ 14.83 (s, 1H), 8.76 (s, 1H), 8.68 (s, 1H), 8.24 (d, J = 6 Hz, 1H), 7.49−7.35 (m, 9H), 7.12−7.10 (m, 6H), 6.82 (s, 1H), 6.52 (s, 1H), 6.24 (d, J = 6 Hz, 1H), 5.75 (bs, 1H), 4.87−4.83 (m, 2H), 4.77 (bs, 1H), 4.51 (t, J = 9 Hz, 2H), 3.38 (s, 2H), 2.23 (s, 2H), 1.42 (s, 9H). MS (ESI): *m*/*z* 684.3 (M + H); HRMS: Calcd for $C_{41}H_{42}N_5O_5$ (M + H): 684.3186; Found: 684.3181.

(*S*)-Methyl 3-(1-(3-(*tert*-Butoxycarbonylamino)propyl)-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)-2-(2,4,6-trimethylphenylsulfonamido)propanoate (44). A solution of **42** (300 mg, 0.437 mmol), TEA (0.243 mL, 1.75 mmol), and HBTU (230 mg, 0.606 mmol) in anhydrous DMF (4 mL) was stirred at ambient temperature for 5 min. A solution of methyl (2S)-3-amino-2-(((2,4,6-trimethylphenyl)sulfonyl)amino)propanoate hydrochloride (**43**) (*36*) (184 mg, 0.637 mmol) in anhydrous DMF (3 mL) was added, and the solution was stirred at ambient temperature for 2 h. The solution was diluted with EtOAc (200 mL) and washed consecutively with water (2 × 50 mL), saturated $NaHCO_3$ (50 mL), and saturated NaCl (50 mL), dried ($MgSO_4$), and concentrated to give a viscous amber oil. Purification by flash chromatography on a 2.5 × 24 cm silica gel column using a EtOAc:MeOH step gradient (98:2, 95:5, 75:25) gave **44** as a pale yellow oil (330 mg, 78%). MS (ESI): *m*/*z* 966.6 (M + H); HRMS: Calcd for $C_{54}H_{60}N_7O_8S$ (M + H): 966.4224; Found: 966.4224.

(*S*)-3-(7-((1*H*-Imidazol-2-ylamino)methyl)-1-(3-aminopropyl)-4-oxo-1,4-dihydroquinoline-3-carboxamido)-2-(2,4,6-trimethylphenylsulfonamido)propanoic Acid Bis(trifluoroacetic Acid) Salt (46). A solution of **44** (51 mg, 0.052 mmol), water (0.27 mL), and 3 N LiOH (0.13 mL) in MeOH (2.0 mL) was allowed to stand at ambient temperature for 3.5 h and concentrated under vacuum. The resulting solid was dissolved in water (10 mL) and adjusted to pH 3 with 1.0 N HCl. The aqueous mixture was extracted with DCM (2 × 30 mL). The combined DCM extracts were washed with saturated NaCl (30 mL), dried ($MgSO_4$), and concentrated to give intermediate carboxylic acid **45** as a colorless solid (72 mg). MS (ESI): *m*/*z* 952.5 (M + H); HRMS: Calcd for $C_{53}H_{58}N_7O_8S$ (M + H): 952.4067; Found: 952.4056.

A solution of **45** and Et_3SiH (0.042 mL, 0.26 mmol) in degassed TFA (2 mL) was heated at 70 °C for 2.5 h and concentrated to give an amber oil. This oil was dissolved in water (25 mL) and washed with ether (2 × 15 mL). The combined ether washings were back-extracted with water (15 mL). The combined aqueous extracts were lyophilized to give **46** as a colorless powder (34 mg, 78%). MS (ESI): *m*/*z* 610.4 (M + H); HRMS: Calcd for $C_{29}H_{36}N_7O_6S$ (M + H): 610.2448; Found: 610.2462.

(*S*,*E*)-3-(7-((1*H*-Imidazol-2-ylamino)methyl)-4-oxo-1-(3-(6-(2-(2-sulfobenzylidene)hydrazinyl)nicotinamido)propyl)-1,4-dihydroquinoline-3-carboxamido)-2-(2,4,6-trimethylphenylsulfonamido)propanoic Acid Trifluoroacetic Acid Salt (47). A solution of **46** (13.7 mg, 0.0163 mmol), TEA (0.015 mL, 0.108 mmol), and sodium (*E*)-2-((2-(5-carboxypyridin-2-yl)-hydrazono)methyl)benzenesulfonate (*37*) (**9**) (8.2 mg, 0.0186 mmol) in anhydrous DMF (2.0 mL) was allowed to stand at ambient temperature for 24 h. The DMF was removed under reduced pressure and the resulting amber oil was dissolved in 50% ACN and purified by preparative HPLC on a Vydac C-18 column (22 × 250 mm) using 0.1% TFA in water for 5 min followed by a 2.52%/min gradient of 0−63% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 21.4 min was collected and lyophilized to give **47** as a colorless powder (12.5 mg, 74.7%). MS (ESI): *m*/*z* 913.3 (M + H); HRMS: Calcd for $C_{42}H_{45}N_{10}O_{10}S_2$ (M + H): 913.2761; Found: 913.2751.

(*S*)-Methyl 3-(1-(2,2-Dimethyl-4,20,23-trioxo-3,9,12,15-tetraoxa-5,19,24-triazaheptacosan-27-yl)-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)-2-(2,4,6-trimethylphenylsulfonamido)propanoate (49). A solution of **44** (46.1 mg, 0.477 mmol) in 50:50 TFA:DCM (2.0 mL) was stirred for 15 min at ambient temperature and concentrated to give a yellow oil. This oil was dissolved in anhydrous DMF (1.0 mL) and made basic with TEA. In a separate flask, *N*-Boc-*N*′-succinimidyl-4,7,10-trioxatridecane-1,13-diamine (**48**) (*43*) (26.1 mg, 0.062 mmol), TEA (0.014 mL, 0.099 mmol), and HBTU (27.7 mg, 0.074 mmol) were dissolved in anhydrous DMF (1.0 mL). The resulting solution was allowed to react for 5 min and combined with the DMF solution from the TFA deprotection reaction. The combined solutions were allowed to stand at ambient temperature for 20 min and concentrated under vacuum. The resulting oil was dissolved in 50% ACN and purified by preparative HPLC on a Vydac C-18 column (22 × 250 mm) using a 1.8%/min gradient of 18−72% ACN containing 0.1% TFA at a flow rate of 20

mL/min. The main product peak eluting at 26.8 min was collected and lyophilized to give **49** as a colorless powder (44.5 mg, 68%). MS (ESI): *m*/*z* 1268.6 (M + H); HRMS: Calcd for $C_{68}H_{86}N_9O_{13}S$ (M + H): 1268.6065; Found: 1268.6070.

(*S*,*E*)-3-(7-((1*H*-Imidazol-2-ylamino)methyl)-4-oxo-1-(1,17,20-trioxo-1-(6-(2-(2-sulfobenzylidene)hydrazinyl)pyridin-3-yl)-6,9,12-trioxa-2,16,21-triazatetracosan-24-yl)-1,4-dihydroquinoline-3-carboxamido)-2-(2,4,6-trimethylphenylsulfonamido)propanoic Acid Trifluoroacetic Acid Salt (52). A solution of **49** (31.1 mg, 0.0227 mmol), 3 N LiOH (0.091 mL), and water (0.117 mL) in MeOH (1.30 mL) was stirred at ambient temperature for 8.5 h. The MeOH was removed under vacuum, and the aqueous mixture was diluted with water (30 mL) and adjusted to pH 4 with 1.0 N HCl. The resulting aqueous mixture was extracted with DCM (2 × 50 mL). The combined DCM extracts were washed with saturated NaCl (50 mL), dried ($MgSO_4$), and concentrated to give carboxylic acid **50** as a colorless solid (24.6 mg, 86%). Compound **50** (24.6 mg, 0.0194 mmol) was taken up in TFA (2.0 mL) and Et_3SiH (0.016 mL, 0.097 mmol) and heated at 70 °C for 3 h. Concentration give a yellow solid, which was dissolved in water (50 mL) and washed with ether (2 × 25 mL). The aqueous layer was lyophilized to give free amine **51** as a pale yellow solid (20.7 mg, 93%). MS: *m*/*e* 912.5 (M + H). A solution of **51** (15.5 mg, 0.0136 mmol), TEA (10 μL, 0.0746 mmol), and succinimide ester **9** (8.0 mg, 0.0182 mmol) in anhydrous DMF (2.0 mL) was allowed to stand at ambient temperature for 24 h. The DMF was removed under vacuum and the resulting yellow oil was dissolved in 50% ACN and purified by preparative HPLC on a Vydac C-18 column (22 × 250 mm) using 0.1% TFA in water for 5 min followed by a 2.5%/min gradient of 0−63% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 21.7 min was collected and lyophilized to give **52** as a colorless powder (7.2 mg, 40%). MS (ESI): *m*/*z* 1215.5 (M + H); HRMS: Calcd for $C_{56}H_{71}N_{12}O_{15}S_2$ (M + H): 1215.4603; Found: 1215.4580.

(*S*)-2,2′,2″-(10-(2-(3-(7-((1*H*-Imidazol-2-ylamino)methyl)-3-(2-carboxy-2-(2,4,6-trimethylphenylsulfonamido)ethylcarbamoyl)-4-oxoquinolin-1(4*H*)-yl)propylamino)-2-oxoethyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic Acid Trifluoroacetic Acid Salt (54). A solution of DOTA(O*t*-Bu)$_3$OH (89 mg, 0.0974 mmol), DIEA (0.103 mL, 0.607 mmol), and HBTU (28.0 mg, 0.0735 mmol) in anhydrous DMF (1.0 mL) was stirred at ambient temperature for 15 min and treated with a solution of compound **46** (30.0 mg, 0.0358 mmol) in anhydrous DMF (1.0 mL). The DMF was removed under vacuum after 3 h, and the residue was purified by HPLC on a Vydac C-18 column (22 × 250 mm) using a 1.1%/min gradient of 18−72% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 17.5 min was lyophilized to give DOTA conjugate **53** as a colorless solid (48.0 mg, 65.0%). MS (ESI): *m*/*z* 1164.7 (M + H). A solution of **53** (48.0 mg, 0.0375 mmol) in 95:5 TFA:Et_3SiH (2.1 mL) was stirred at 50 °C for 2 h. The solution was concentrated under vacuum and the oily residue was purified by HPLC on a Vydac C-18 column (22 × 250 mm) using a 1.2%/min gradient of 0−36% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 18.6 min was lyophilized to give **54** as a colorless solid (25.7 mg, 58.7%). MS (ESI): *m*/*z* 996.5 (M + H); HRMS: Calcd for $C_{45}H_{62}N_{11}O_{13}S$ (M + H): 996.4249; Found: 996.4278.

(*R*)-1-(3-(7-((1*H*-Imidazol-2-ylamino)methyl)-3-((*S*)-2-carboxy-2-(2,4,6-trimethylphenylsulfonamido)ethylcarbamoyl)-4-oxoquinolin-1(4*H*)-yl)propylamino)-1-oxo-3-sulfopropan-2-aminium Trifluoroacetate (55). A solution of compound **46** (105 mg, 0.125 mmol), the *N*-hydroxysuccinimide ester of Boc-L-cysteic acid (*44*) (146 mg, 0.467 mmol), and DIEA (0.120 mL, 0.69 mmol) in anhydrous DMF (1.5 mL) was stirred at ambient temperature for 24 h. The DMF was removed under vacuum and the resulting solid residue was purified by HPLC on a Vydac C-18 column (22 × 250 mm) using a 0.68%/min gradient of 9−36% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 30.3 min was lyophilized to give Boc-cysteic acid conjugate **54** as a colorless solid (73.0 mg, 67.9%). MS (ESI): *m*/*z* 861.3 (M + H). A solution of **54** (70.0 mg, 0.0814 mmol) in 2:1 DCM:TFA (1.5 mL) was allowed to react at ambient temperature for 30 min. The solution was concentrated under vacuum and the amber oil was dissolved in 50% ACN (25 mL) and lyophilized to give **55** as a colorless solid (70.8 mg, 99.5%). MS (ESI): *m*/*z* 761.2 (M + H); HRMS: Calcd for $C_{32}H_{41}N_8O_{10}S_2$ (M + H): 761.2387; Found: 761.2393.

A solution of DOTA(O*t*-Bu)$_3$OH (20.8 mg, 0.0228 mmol), DIEA (0.006 mL, 0.034 mmol), and HBTU (6.5 mg, 0.0171 mmol) in anhydrous DMF (0.5 mL) was stirred at ambient temperature for 5 min and treated with a solution of compound **55** (10.0 mg, 0.0114 mmol) and DIEA (6 μL, 0.034 mmol) in anhydrous DMF (0.5 mL). Stirring was continued at ambient temperature for 24 h, and the reaction was diluted with water (3.0 mL), treated with concentrated ammonium hydroxide (3 μL), and stirred an additional 10 min. The solution was adjusted to pH 3 using 0.1 N HCl (6.0 mL) and diluted further with 10% ACN (5.5 mL). This solution was purified directly by HPLC on a Vydac C-18 column (22 × 250 mm) using a 0.68%/min gradient of 9−36% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 36.0 min was lyophilized to give DOTA conjugate **56** as a colorless solid (12.0 mg, 68.3%). MS (ESI): *m*/*z* 1315.6 (M + H). A solution of conjugate **56** (12.0 mg, 0.00778 mmol) in 95:5 TFA:Et_3SiH (1.0 mL) was stirred at ambient temperature for 18 h. The solution was concentrated under vacuum, and the oily residue was purified by HPLC on a Vydac C-18 column (22 × 250 mm) using a 1.2%/min gradient of 0−36% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 21.1 min was lyophilized to give **57** as a colorless solid (8.1 mg, 76%). MS (ESI): *m*/*z* 1147.3 (M + H); HRMS: Calcd for $C_{48}H_{67}N_{12}O_{17}S_2$ (M + H): 1147.4189; Found: 1147.418.

$\alpha_v\beta_3$-ELISA (Biotin-Vn) Adhesion Assay. Polystyrene ELISA plates (Costar #3590) were coated with a solution of human $\alpha_v\beta_3$ receptor (Chemicon) (500 ng/mL) in binding buffer (50 mM tris, 100 mM NaCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, pH 7.4) using 100 uL per well for 1 h at ambient temperature. The plates were rinsed three times with wash buffer (binding buffer with 0.05% Tween 20 and 1% BSA). Nonspecific binding was blocked by the addition of blocking buffer (150 uL per well) for 1 h at ambient temperatures. Human vitronectin (Chemicon) was biotinylated with sulfo-biotin-NHS (Pierce Chemical Co.) by a previously reported procedure (*45*). Solutions of the test agents were prepared using 10 nM biotinylated-n vitronectin. Test solutions (100 μL) were transferred to the ELISA plate, and the plate was incubated for 30 min at ambient temperature. Following the incubation, solution was removed from the wells, and the wells were rinsed three times with 150 uL of wash buffer. Following the washing, a solution (100 μL) of goat anti-biotin antibody alkaline phosphatase conjugate (Sigma, #A-7064) was added to each well and incubated for 1 h at ambient temperature. Solutions were removed, and the wells were rinsed with wash buffer (3 × 150 μL). A phosphatase substrate solution

was prepared by dissolving a phosphatase substrate tablet (Sigma) in 90:10 H_2O:diethanolamine. Phosphatase substrate solution (100 μL) was added to each well, and the plate was incubated for 30 min at ambient temperature. Absorbance was read on a spectrophotometer (μQuant Microplate Spectrophotometer, Bio-Tek Instruments Inc, Winooski, Vermont) at 410 nm. Nonspecific binding was subtracted from each data point, percent inhibition was calculated for each concentration of test agent, and IC_{50} values were derived.

General Procedure for ^{99m}Tc−Radiolabeling of HYNIC Conjugates. A vial containing the HYNIC conjugate (20 μg), tricine (1.0 mg), TPPTS (7.0 mg), and mannitol (20 mg) was sealed with a Teflon-coated serum stopper and aluminum crimp. A syringe was used to add a 0.9% saline solution (0.5 mL) containing 50 mCi of $^{99m}TcO_4^-$. The vial was placed in a boiling water bath for 10 min and allowed to cool to room temperature. Radiochemical purity was checked by a combination of instant thin-layer chromatography (ITLC) on silica gel strips (Gelman Sciences, Inc., Ann Arbor, MI) developed in a mobile phase of MeOH:acetone:saline, and RP-HPLC with a C18 column (Zorbax Rx-C18, 5 μm particle size, 80 Å pore size, 4.6 × 250 mm) on an Agilent 1100 HPLC system equipped with an in-line radio detector, using a 0.5%/min gradient of 10−20% ACN containing 25 mM ammonium acetate, pH 7.2, at a flow rate of 1.0 mL/min. The radiochemical purity was determined by the area percent of the product peak in the radio-HPLC method minus the area percent of insoluble ^{99m}Tc-colloid determined by the TLC method. Any compounds having a radiolabeling efficiency <95% were purified by RP-HPLC using the above column and mobile phase conditions. Gradients were modified as necessary to give the required separation. The desired product fractions were concentrated on a rotary evaporator, and the product was reconstituted in 0.9% saline for the animal studies. All complexes used in the biodistribution studies had an RCP >95%.

General Procedure for ^{111}In-Radiolabeling of DOTA Conjugates. The procedure for preparation of ^{111}In-DOTA complexes has been described in detail elsewhere (*26*, *46*). Briefly, the DOTA conjugate (200 μg), sodium gentisate (1.5 mg), and 0.5 M ammonium acetate, pH 6.0 (3.0 mL), were added to a 10 cm^3 glass vial, and the vial was sealed with a Teflon-coated serum stopper and aluminum crimp. The solution was degassed by vacuum pump for 1 min. A solution of 4.0−5.0 mCi $^{111}InCl_3$ in 0.05 N HCl (10−20 μL) was added to the vial, and the reaction solution was heated at 100 °C for 5 min and analyzed by HPLC and ITLC as described above. Purification, if required, was by the above procedure. All complexes used in the biodistribution studies had an RCP >95%.

^{177}Lu-36. The title compound was prepared in 98% RCP using a procedure developed for the preparation of ^{177}Lu-**TA138** (*47*).

In Vivo Biodistribution Study. c-neu Oncomouse Model. The mice used in this program were obtained from an in-house breeding program. Mice were used when tumors were 5−20 mm in size, as determined with digital caliper. Animals were anesthetized intramuscularly with 0.1 mL of ketamine/acepromazine (1.8 mL saline, 1.0 mL ketamine, and 0.2 mL acepromazine) prior to dosing and tissue sampling. Groups of mice (n = 3/group) were injected via the tail vein with either ^{111}In-DOTA conjugate (2 mCi/Kg in 0.1 mL) or [^{99m}Tc(HYNIC conjugate)(TPPTS)(tricine)] (2 mCi/kg in 0.1 mL). Mice were euthanized and dissected at 2 h pi. Selected tissues were removed, weighed, and counted on an LKB gamma counter. Raw radioactivity data was corrected for background and tested for quantitation limits according to the literature method.[48] Results are expressed as the percentage injected dose per gram of tissue (%ID/g). Since the c-neu Oncomouse spontaneously develops tumors in the mammary glands, most mice had more than one tumor. Each tumor was sampled and counted separately, and radioactive uptake for the tumors was then averaged to obtain an overall representation of tumor uptake. Biodistribution data are shown in Table 2, and tumor/organ ratios are shown in Table 3.

RESULTS

Synthesis of tethers on the DAP sulfonamide. Radionuclide−chelator complexes were tethered to the DAP arylsulfonamide moiety using two synthetic strategies. The first of these strategies employed a short diamino-PEG tether linked to DAP via the 4,4′-biphenyl moiety, as shown in Scheme 1 for the synthesis of **10**. 4,7,10-Trioxa-1,13-tridecanediamine (**1**) was converted to mono-Cbz derivative **2** in 45% yield using benzyl chloroformate in THF. Tethered DAP arylsulfonamide **3** was prepared from **2** in a single vessel, two-step condensation procedure in which freshly recrystallized biphenyl-4,4′-disulfonyl chloride was condensed first with **2**, and then with (*S*)-methyl 2-amino-3-(*tert*-butoxycarbonylamino)propanoate hydrochloride. Flash chromatography and recrystallization, followed by treatment with TFA to remove the Boc group gave a 59% overall yield of **4**. Conjugation with quinolin-4-one carboxylic acid **5**, prepared by the procedure of Wityak et al. (*36*), gave a 50% yield of **6**. All protecting groups were removed in a two step sequence of ester saponification using LiOH in THF, followed by treatment with TFA:Et_3SiH at 70 °C to give **8**. Conjugation with HYNIC succinimide ester **9** gave the TFA salt of **10** in 20% yield after reverse phase HPLC purification.

Compound **12**, the DOTA analogue of **10**, was prepared from compound **6** by the procedure depicted in Scheme 2. Treatment of **6** with TFA:Et_3SiH, followed by an HBTU-mediated conjugation to DOTA tri-*tert*-butyl ester gave **11** in 17% purified yield. Final deprotection consisted of ester saponification using aqueous LiOH in THF, followed by treatment with TFA:Et_3-SiH. The final purified yield of **12** was 15%, calculated as the bis-TFA salt.

The second strategy used to tether radionuclide−chelator complexes to DAP arylsulfonamides is shown in Scheme 3 for the synthesis of DOTA conjugate **TA138**. 4-(3,5-Dimethylphenoxy)butyric acid (**14**) was prepared in 79% yield from 3,5-dimethylphenol by alkylation with ethyl 4-bromobutyrate, followed by ester saponification using KOH in EtOH. Chlorosulfonation followed by conjugation of the resulting sulfonyl chloride to (*S*)-methyl 2-amino-3-(*tert*-butoxycarbonylamino)-propanoate afforded DAP arylsulfonamide **16** in 12% yield. The carboxylic acid of **16** was conjugated to benzyl *N*-(2-aminoethyl)carbamate using HBTU to give a 90% yield of **17**. Removal of the Boc protecting group using TFA and conjugation of the resulting amine to quinolin-4-one carboxylic acid **5** afforded a 57% yield of **19**. Hydrogenolysis over Pd/C removed the Cbz protecting group, and ester saponification using LiOH gave **21** in 79% yield. Two Boc-Csa(Na)-OH pharmacokinetic modifiers were added in stepwise fashion by preactivation with PyBOP to give **24** in 74% yield. Cleavage of the Boc protecting group from **24** was followed by refunctionalization of the resulting amine with preactivated DOTA tri-*tert*-butyl ester. Global deprotection using TFA:Et_3SiH gave **TA138** in 72% yield.

The HYNIC analogue of **TA138** was prepared as shown in Scheme 4. Treatment of compound **24** with 97:3 TFA:Et_3SiH removed the trityl and Boc protecting groups to give **27** in 73% yield. Conjugation of **27** with sodium (*E*)-2-((2-(5-carboxypyridin-2-yl)hydrazono)methyl)benzenesulfonate (**28**) gave **29** in 32% yield.

The cysteic acid pharmacokinetic modifiers of **TA138** were replaced with 3-phosphonoalanine as described in Scheme 5 to

Scheme 1. Synthesis of HYNIC Conjugate 10[a]

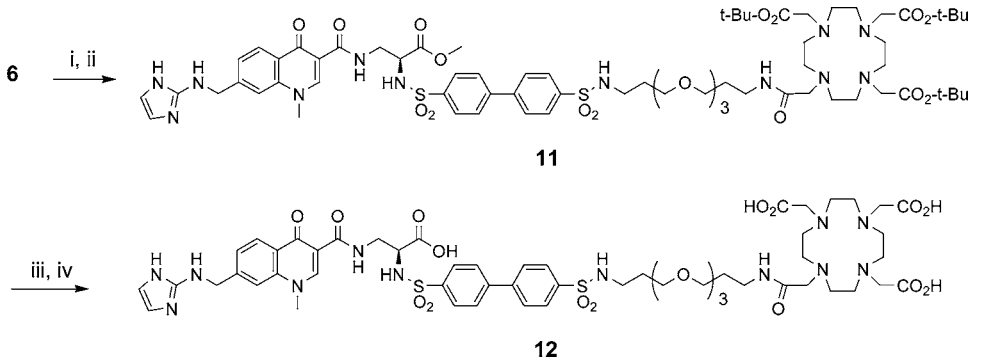
Scheme 2. Synthesis of DOTA Conjugate 12[a]

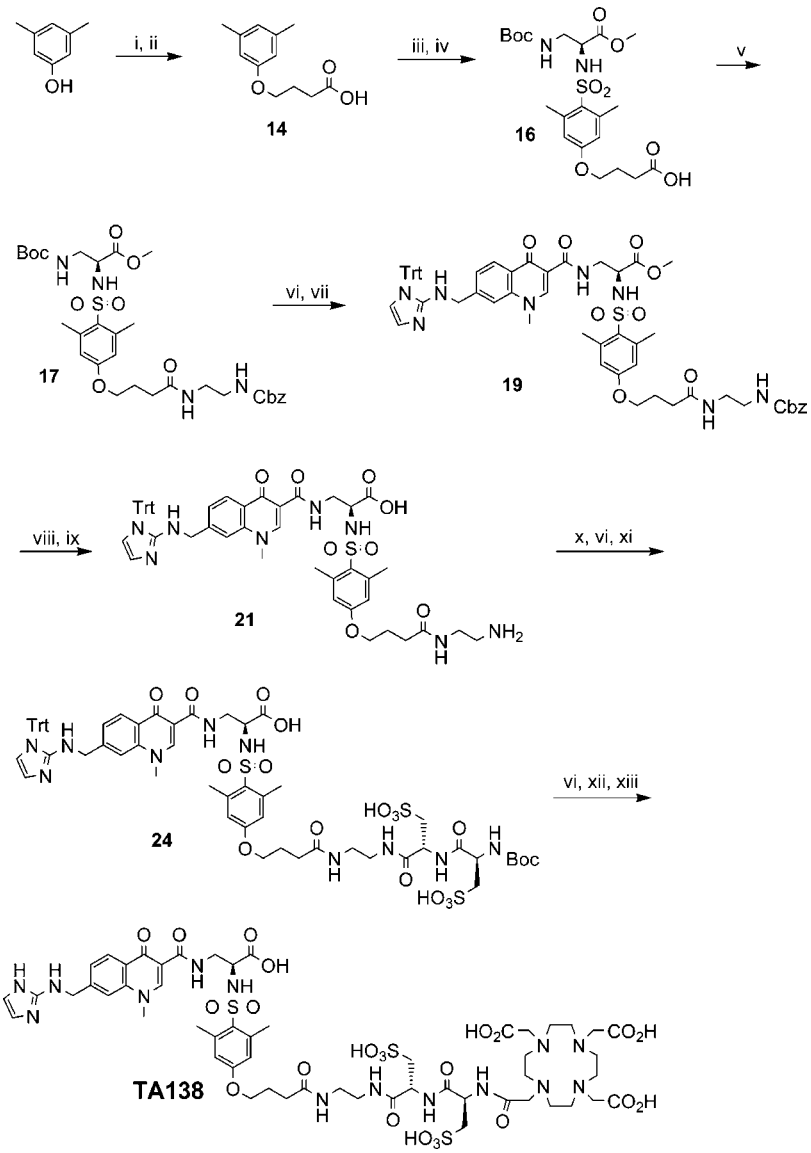


[a] Reagents: i) TFA, Et_3SiH, 70 °C; ii) DOTA(O*t*-Bu)$_3$−OH, HBTU, TEA, DMF, 17%; iii) 3 N LiOH, THF; iv) TFA, Et_3SiH, 70 °C, 15%.

give **36**. Orthogonally protected amino acid **30** was prepared from *N*-(*tert*-butoxycarbonyl)-L-serine β-lactone and diallyl-(trimethylsilyl)phosphite by a procedure analogous to that published by Lohse and Felber (*41*). Two of these phosphonic acid PKMs were added in stepwise fashion in 50% overall yield using the procedures described for **TA138** to give compound **33**. Boc protecting group cleavage was followed by conjugation to DOTA tri-*tert*-butyl ester. Final global deprotection was accomplished in two steps using $(\phi_3P)_4Pd$ and morpholine, followed by treatment with TFA:Et_3SiH. Overall yield of **36** for these final four steps was 5.8%.

Synthesis of Tethers on the Quinolin-4-one Ring Nitrogen. The quinolin-4-one ring nitrogen was alkylated with an aminopropyl tether as shown for HYNIC conjugate **47** in Scheme 6. Ethyl 7-bromo-4-oxo-1,4-dihydroquinoline-3-carboxylate (**37**) was alkylated using K_2CO_3 and a 6-fold excess of 3-((*tert*-butoxy)carbonylamino)propyl bromide in DMF at 60 °C. A liquid−liquid partitioning of the reaction mixture and crystallization from EtOAc gave compound **38** in 65% yield. Vinylation of **38** using tributyl(vinyl)tin and $(\phi_3P)_4Pd$ gave a 63% yield of compound **39**. Oxidation of the vinyl group using sodium periodate and a catalytic amount of osmium tetroxide,

Scheme 3. Synthesis of DOTA Conjugate TA138[a]



[a] Reagents: i) NaOEt, ethyl 4-bromobutyrate, EtOH, 89%; ii) KOH, EtOH, 89%; iii) chlorosulfonic acid, $CHCl_3$, 41%; iv) (*S*)-methyl 2-amino-3-(*tert*-butoxycarbonylamino)propanoate, DCM, 29%; v) benzyl *N*-(2-aminoethyl)carbamate, HBTU, DIEA, DMF, 90%; vi) TFA, DCM; vii) **5**, HBTU, DIEA, DMF, 63%; viii) H_2, 10% Pd/C, MeOH, 99%; ix) 3 N LiOH, THF, 80%; x) Boc-Csa(Na)-OH, PyBOP, DIEA, DMF; xi) Boc-Csa(Na)-OH, PyBOP, DIEA, DMF, 74%; xii) DOTA(O*t*-Bu)$_3$-OH, PyBOP, DIEA, DMF, 76%; xiii) TFA, Et_3SiH, 70 °C, 95%.

followed by reductive amination using 2-amino-1-(triphenylmethyl)imidazole and $Na(OAc)_3BH$, and saponification using LiOH gave a 60% purified yield of **42**. Conjugation of **42** with DAP arylsulfonamide **43** gave compound **44** in 78% purified yield. All protecting groups were removed in a two-step sequence consisting of ester saponification using LiOH in MeOH, followed by treatment with TFA:Et_3SiH to give a 90% yield of **46** as the bis-TFA salt. Conjugation with HYNIC succinimide ester **9** gave the TFA salt of **47** in 75% yield after reverse phase HPLC purification.

N-Boc-*N*′-succinimidyl-4,7,10-trioxatridecane-1,13-diamine (**48**), previously described by Trester-Zedlitz et al. (*43*), was used to extend the aminopropyl tether of **47**, as shown in Scheme 7. The aminopropyl tether of quinolin-4-one **44** was unmasked using TFA, and the resulting amine was conjugated to **48** using HBTU to give **49** in 68% yield. Ester saponification using LiOH, cleavage of the Boc and trityl protecting groups with TFA:Et_3-SiH, and conjugation with HYNIC succinimide ester **9** gave **52** in 32% yield.

Two DOTA analogues of **47** were prepared according to the procedures in Scheme 8. Conjugation of quinolin-4-one **46** with preactivated DOTA tri-*tert*-butyl ester, followed by protecting group cleavage gave the bis-TFA salt of **54** in 59% yield. Conjugation of quinolin-4-one **46** with the *N*-hydroxysuccinimide ester of Boc-L-cysteic acid, followed by TFA deprotection conditions, gave amine **55** in 68% yield. Conjugation of **55** with preactivated DOTA tri-*tert*-butyl ester, followed by protecting group cleavage gave the TFA salt of **57** in 52% yield.

Receptor Binding Assays. Affinity assays toward four integrin receptors were used to measure the potency and selectivity of the chelator conjugates described here. Our principle receptor $\alpha_v\beta_3$ assay was an ELISA (biotin-Vn) adhesion assay as described in the Experimental Section. The 293β_3-fibrinogen ($\alpha_v\beta_3$-mediated) adhesion assay, and the platelet aggregation $\alpha_{IIb}\beta_3$ assay have been described in detail by Wityak et al. (*42*). The human SKBR3 cell-vitronectin ($\alpha_v\beta_5$-mediated) adhesion assay and the human lymphocyte (Jurkat)-fibronectin ($\alpha_5\beta_1$-mediated) adhesion assay have been described in detail by Harris et al. (*26*). The affinity data in Table 1 shows that all compounds measured have high affinity toward receptor $\alpha_v\beta_3$, with IC_{50} values <5 nM in an ELISA assay. They also show excellent selectivity versus receptors $\alpha_{IIb}\beta_3$, $\alpha_v\beta_5$, and

$\alpha_5\beta_1$. Affinity and selectivity are nearly identical to parent compound **SH066** and nonradioactive complex ^{89}Y-**TA138**.

Radiolabeling. HYNIC conjugates **10**, **47**, and **52** formed stable ternary complexes with ^{99m}Tc using tricine and TPPTS as coligands, and they were isolated in >95% radiochemical purity (RCP). However, HYNIC conjugate **29** gave very poor radiochemical yields under the same conditions, and we were unable to purify it to a sufficiently high level to carry it into the biodistribution studies. The DOTA conjugates were our primary focus in this program, and no effort was made to optimize the labeling procedure for **29**. DOTA conjugates **12**, **TA138**, and **57** formed stable complexes with ^{111}In and these complexes were isolated in >95% RCP. The nonradioactive complex ^{89}Y-**TA138** was prepared in high yield and purity as previously reported (*47*). DOTA conjugate **36** failed to form a stable complex with ^{111}In. However, we were able to prepare the analogous ^{177}Lu-**36** complex in 98% RCP using a previously reported procedure (*47*), and this complex was used in the biodistribution studies described below.

In Vivo Biodistribution Study. The biodistribution properties of the compounds in this study were evaluated in the c-neu Oncomouse mammary adenocarcinoma model. The HYNIC conjugates were evaluated as ternary complexes with ^{99m}Tc using tricine and TPPTS as coligands (see, for example, the structure in Figure 1). For unknown reasons, HYNIC conjugate **29** gave an unusually low yield of the radiolabeled product, and we were unable to purify it sufficiently to carry out the biodistribution study. The DOTA conjugates were evaluated as

the ^{111}In complexes, except for **36**, which was evaluated at the ^{177}Lu complex. All compounds were administered at 2 mCi/Kg of body weight. Mice were euthanized and dissected at 2 h postinjection (pi), and activity in the organs and tumors was counted on a gamma counter. The data are presented in Table 2 and expressed as % of injected dose/gram of tissue (%ID/g). These data show that the agents are excreted primarily via the kidneys, with only ^{99m}Tc-**47** showing high bile activity (354% ID/g) and slightly elevated liver activity (7.10% ID/g). The relatively low blood activity indicates rapid blood clearance for all agents. Uptake was universally low in muscle, heart, eyes, spleen, bone, and stomach, and slightly elevated for most agents in colon and uterus. Tumor uptake was rapid for all agents and ranged from a low value of 2.95% ID/g for ^{111}In-**12** to a high of 11.8% ID/g for ^{111}In-**57**. Kidney uptake also covered a broad range of 2.33% ID/g for ^{11}In-**TA138** to 16.0% ID/g for ^{99m}Tc-

52. Lung activity was low for all agents except ^{99m}Tc-**52**, which, at 37.4% ID/g, was more than 9-fold higher than the next highest compound.

DISCUSSION

Chemistry. Our goal in this program was to develop radiopharmaceuticals capable of delivering useful quantities of imageable and therapeutic radionuclides to tumors. The choice of a radionuclide chelator was guided by our desire to use a single targeting platform for both imaging and radiotherapeutic applications. This led us to the macrocyclic chelator DOTA as our principle chelator. In this way a complex with an imageable isotope (e.g., ^{111}In) could be used to accurately predict the biodistribution of a complex with a nonimageable therapeutic isotope (e.g., ^{90}Y). This strategy has recently been confirmed in a bioequivalence study comparing ^{111}In and ^{90}Y complexes of receptor $\alpha_v\beta_3$ antagonist−DOTA conjugates (*46*). The radionuclide having the most useful nuclear properties for SPECT imaging is ^{99m}Tc, which, unfortunately, does not form stable complexes with DOTA. 6-Hydrazinylnicotinic acid (HYNIC) is one of the best chelators for ^{99m}Tc, forming stable complexes with a variety of coligands in aqueous solutions at very low ligand concentrations (*49*). We therefore also prepared a small number of HYNIC conjugates, and evaluated them as the ternary ^{99m}Tc complexes using tricine and TPPTS as coligands. Complexes in this report represented as ^{99m}Tc-**XX** are understood to be these ternary complexes. Second, DOTA and HYNIC complexes have very different structures (see Figure 1), suggesting the possibility that they may exhibit very different biodistribution and pharmacokinetic properties. The HYNIC conjugates were synthesized with the hydrazinyl group protected as a hydrazone of 2-formylbenzenesulfonic acid. We have previously shown that such hydrazones prevent reaction of HYNIC conjugates with trace quantities of aldehydes and ketones found in the research and manufacturing environment (*37*). The hydrazone protecting group is spontaneously hydrolyzed during the radiolabeling procedure. The sulfonic acid group is not essential to this protection strategy but serves to improve water solubility in the radiolabeling solution.

The use of an α-*N*-(arylsulfonyl)diaminopropanoic acid unit as a carboxylate mimetic is a common structural theme in vitronectin receptor antagonist research. The *N*-methylquinolin-4-one system reported by Wityak and co-workers (*30*, *36*) employs DAP phenylsulfonamide and DAP biphenylsulfonamide carboxylate mimetics as shown in Figure 1. The presence of the phenyl group at the 4-position of the phenylsulfonamide did not impart an increase in affinity for $\alpha_v\beta_3$ or any increased selectivity versus other integrins when compared to the phenylsulfonamides. However, it suggested to us that the 4-position would be an ideal site at which to place a radionuclide−chelator complex. In addition, the biphenyl system suggested a synthetically easy route into a tethered analogue of **SH066**. Using biphenyl-4,4′-disulfonyl chloride and PEG diamine **2**, we were able to assemble the tethered DAP arylsulfonamide in a single-

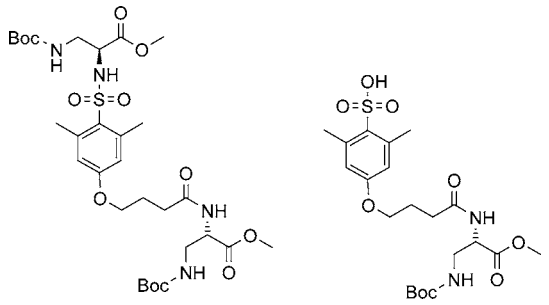
vessel, two-step condensation procedure, as shown in Scheme 1. With the proper molar ratios of reactants and careful control of addition, we were able to achieve a 59% purified yield of **4**, after removal of the Boc group. The condensation of **4** with quinolin-4-one carboxylic acid **5** used standard HBTU coupling conditions to give a 50% purified yield of **6**. All protecting groups were removed prior to conjugation with HYNIC. This strategy was guided by the concern that the hydrazone protecting group on HYNIC would react under the deprotection conditions. Reaction of fully deprotected tethered quinolin-4-one (**8**) with HYNIC succinimide ester **9** gave a 20% yield of **10** after purification. The reasons for the low yield are not fully understood, but it was observed by LC/MS that succinimide ester **9** reacts with **8** to give a transient *N*-acylimidazole byproduct.

The DOTA analogue of **10** was prepared by the procedures shown in Scheme 2. The trityl and Cbz protecting groups were removed from compound **6** using TFA/Et_3SiH, but the methyl ester was left intact for the conjugation reaction with DOTA tri-*tert*-butyl ester. Again, we saw evidence by LC/MS for the formation of *N*-acylimidazole byproducts during the conjugation reaction. In addition, the ester saponification was not as clean as we had come to expect with this system. The overall yield of DOTA conjugate **12** after final deprotection and purification was only 15%. The optimum deprotection/chelator conjugation strategy was realized with **TA138**, as described in Scheme 3.

While the DAP biarylsulfonamides described above offered a synthetically easy means of introducing a radionuclide complex, we felt that phenylsulfonamides such as **SH066** might provide improved biodistribution and pharmacokinetic properties because of their lower lipophilicity. In addition, we felt that our original use of a simple PEG tether as a pharmacokinetic modifier (PKM) provided only a small reduction in lipophilicity, and cysteic acid was selected as a second generation PKM. The high polarity of the sulfonic acid group offers a much larger PKM effect than PEG tethers, and because it is an unnatural amino acid it is less likely to undergo metabolic degradation. In addition, cysteic acid does not require side chain protection during conjugation reactions. This can increase solubility in the dipolar aprotic solvents typically used in amide bond forming reactions, as well as in the mobile phases used in reverse-phase HPLC.

3,5-Dimethylphenol was converted to carboxylic acid **14** in high yield by a combination of Williamson ether synthesis and ester saponification. Chlorosulfonation of **14** proceeded in high regioselectivity, and the small amount of unwanted isomer was removed by recrystallization from $CHCl_3$ to give a 41% yield of the desired chlorosulfonation product (**15**). This compound slowly decomposes, even when stored desiccated in the freezer, and should be used within a few days or weeks. Reaction of **15** with (*S*)-methyl 2-amino-3-(*tert*-butoxycarbonylamino)propanoate gave a 29% yield of DAP sulfonamide **16**. This reaction was very sensitive to reaction conditions, and considerable effort was expended investigating parameters such as reaction temperature, mode and rate of addition of reactants, and base used to neutralize the HCl byproduct. The principle side reaction observed was bis-conjugate **58** shown in Figure 2. Presumably this forms as a result of exchange of chloride between the sulfonyl and carboxyl groups. Curiously, we did not observe mono-conjugate **59**. Conversion of **16** to **19** proceeded in high yield. For the remaining conjugation and deprotection reactions, we elected to leave the trityl imidazole-protecting group in place but remove the methyl ester. This decision was based in part on our experiences with **10** and **12** but also on a preliminary experiment, not shown here, in which ester saponification was carried out after conjugation of the two cysteic acids and DOTA. This resulted in the formation of multiple, closely spaced, isomeric product peaks on LC/MS analysis. Presumably, these



58 **59**

Figure 2. Side product **58**, formed during the synthesis of DAP arylsulfonamide **16**.

isomers are the result of epimerization at the DAP and cysteic acid residues. The two cysteic acids were added to **21** in stepwise fashion by preactivation with PyBOP to give **24** in 74% overall yield. Conjugation to DOTA tri-*tert*-butyl ester proceeded in 76% yield, and final global deprotection and purification gave a 95% yield of **TA138**.

Intermediate **24** was fully deprotected, and the resulting amine was used to prepare the HYNIC analogue of **TA138** as shown in Scheme 4. An initial conjugation reaction with HYNIC succinimide ester **9**, not shown, gave no reaction. We hypothesized that this was due to electronic repulsion between the sulfonate side chains of the cysteic acid residues and the sulfonate group on the HYNIC hydrazone. Replacing succinimide ester **9** with the more reactive HOBt ester formed by preactivation with PyBOP produced a slow conjugation reaction and a 32% isolated yield of **29**.

3-Phosphonoalanine also appeared to have great potential as a PKM. Like cysteic acid it is highly hydrophilic and is an unnatural amino acid. Lohse and Felber have shown that 3-(bis-(allyloxy)phosphono)alanine can be incorporated into peptides using standard Fmoc solid-phase synthesis methodology (*41*). Incorporation of 3-phosphonoalanine by our existing synthetic strategies required the analogous Boc-protected amino acid (**30** in Scheme 5). An Arbuzov reaction between *N*-(*tert*-butoxycarbonyl)-L-serine β-lactone and diallyl(trimethylsilyl)phosphite gave **30** in 19% yield. Two of these PKMs were incorporated into intermediate **21** in 69% yield using chemistry completely analogous to that used to prepare **TA138**. Conjugation to DOTA tri-*tert*-butyl ester was accomplished in 29% yield, and the final two-step deprotection to remove the trityl, Boc, and allyl groups gave a 20% purified yield of **36**. To our knowledge this is the first example of a phosphonic acid being introduced into a radiopharmaceutical for the sole purpose of modifying pharmacokinetics.

The original SAR of the quinolin-4-one class of vitronectin receptor antagonists used the same *N*-methylquinolin-4-one template for all compounds in the series. Variation at the quinolin-4-one ring nitrogen was not examined. However, a comparison of the structure of **SH066** with other classes of integrin $\alpha_v\beta_3$ antagonists suggested that receptor $\alpha_v\beta_3$ would tolerate radionuclide-chelator complexes on the quinolin-4-one ring nitrogen. Synthetically, this was a less attractive option than use of the arylsulfonamide position because the tether is locked in very early in the synthesis, thus limiting the ability to quickly examine alternate tethers. But having two potential sites of derivatization was viewed as a distinct advantage of the quinolin-4-one class. We chose to use the relatively short aminopropyl tether shown in Scheme 6 as the basis for all compounds in this class. Further elaboration of this tether near the end of the synthesis would allow an examination of parameters such as tether length and lipophilicity while avoiding a lengthy resynthesis.

The aminopropyl tether was introduced by alkylation of **37** using K_2CO_3 and a 6-fold excess of 3-((*tert*-butoxy)carbonylamino)propyl bromide in DMF at 60 °C. The large excess of bromide was required to compensate for the γ-lactamization side-reaction. The remaining steps in the synthesis of **44** followed the procedures as described by Wityak and Tobin (*36*) for the synthesis of the *N*-methylquinolin-4-one system, and yields were good to excellent. Complete deprotection of **44**, followed by conjugation with HYNIC succinimide ester **9**, gave **47** in 75% yield. The effect of tether length was explored by the addition of a *N*-succinimidy-PEG spacer as shown in Scheme 7. The conjugation reactions with both the additional spacer and HYNIC succinimide ester **9** proceeded in moderate yields to give **52**. The syntheses of two DOTA conjugates tethered to the quinolin-4-one ring nitrogen are shown in Scheme 8. Conjugation of DOTA directly to the aminopropyl tether of intermediate **46** gave, after deprotection, **54**, the DOTA analogue of **47**. The effect of a cysteic acid PKM on pharmacokinetics was evaluated by conjugation of Boc-cysteic acid to **46**, followed by conjugation to DOTA to give compound **57**.

Receptor Affinity and Selectivity. The receptor binding properties of the compounds in this study were evaluated in a series of integrin receptor assays that included receptors $\alpha_v\beta_3$, $\alpha_{IIb}\beta_3$, $\alpha_v\beta_5$, and $\alpha_5\beta_1$. Receptor $\alpha_v\beta_3$ affinity was determined in an ELISA assay using isolated vitronectin receptors and in a whole-cell assay using human 293 cells engineered to overexpress the $\alpha_v\beta_3$ receptor. Relative selectivity of antagonism of the $\alpha_v\beta_3$ receptor versus the $\alpha_{IIb}\beta_3$ receptor was determined by comparing these data with the IC_{50} values obtained for inhibition of platelet aggregation in a human platelet-rich-plasma (PRP) assay. Similarly, selectivity versus receptor $\alpha_v\beta_5$ was obtained in a human SKBR3 cell-vitronectin adhesion assay, and selectivity versus receptor $\alpha_5\beta_1$ was obtained in a human lymphocyte (Jurkat cells)-fibronectin adhesion assay. Receptor affinity data for parent quinolin-4-one **SH066**, **TA138**, and ^{89}Y-**TA138** were previously reported (*31*). The data are reproduced in Table 1 to allow comparison with the eight new compounds. The data in Table 1 show that all compounds screened have high affinity for $\alpha_v\beta_3$ in the ELISA assay, with IC_{50} values of 0.4−3.0 nM. Parent quinolin-4-one **SH066** was evaluated in the 293β_3-fibrinogen assay, and by using **TA138** as a crossover point, one can see that tethering the chelators at either the arylsulfonamide or quinolin-4-one ring nitrogen had virtually no effect on $\alpha_v\beta_3$ affinity. This confirmed our original belief that both of these positions would be tolerant of modification and also confirmed that only a short tether is required to avoid steric and electronic interactions between the receptor and the radionuclide chelator. It is especially interesting that the highly charged cysteic acid PKM is well tolerated, despite the use of the relatively short *N*-(2-aminoethyl)-4-oxobutanamide spacer of **TA138** and the even shorter aminopropyl spacer of **57**. All compounds displayed good selectivity for $\alpha_v\beta_3$ versus the other integrin receptors in the panel, with selectivity ranging from a low of 333-fold (compound **10**, $\alpha_v\beta_5$) to a high of 20 375-fold (compound **57**, $\alpha_{IIb}\beta_3$). Receptor affinity of nonradioactive complex ^{89}Y-**TA138** is nearly identical to free ligand **TA138**.

In Vivo Biodistribution. The c-neu Oncomouse mammary adenocarcinoma model was the principle in vivo model used in this study. The c-neu Oncomouse is a spontaneous tumor-bearing mouse that carries an activated c-neu oncogene driven by a mouse mammary tumor virus (MMTV) promoter. Transgenic mice uniformly expressing the MMTV/c-neu gene develop mammary adenocarcinomas 4 to 8 months postpartum that involve the entire epithelium in each gland. The ideal biodistribution and pharmacokinetic profile for a radiopharmaceutical is one of rapid and high uptake in the target tissue, followed by rapid clearance from nontarget tissues, and renal excretion. Such

a profile minimizes radiation burden to the patient while minimizing background signal in imaging studies. All agents in this study showed rapid clearance from the general musculature, heart, eyes, spleen, bone, and stomach, and differences in total tracer uptake in these organs were small (Table 2). Blood clearance was generally fast for all agents with blood levels at 2 h PI in the range of 0.54% ID/g for ^{111}In-**TA138** to 4.46% ID/g for ^{111}In-**12**. Tumor uptake ranged from a low value of 2.95% ID/g for ^{111}In-**12** to a high of 11.8% ID/g for ^{111}In-**57**. Kidney uptake in the current study ranged from a low of 2.33% ID/g for ^{111}In-**TA138** to a high of 16.0% ID/g for ^{99m}Tc-**52**. Using tracer levels in tumor, blood, and kidney, we eliminated ^{99m}Tc-**52** (high kidney and blood), ^{111}In-**12** (high kidney and blood, low tumor), and ^{111}In-**54** (high kidney) from further consideration. The very high lung uptake of ^{99m}Tc-**52** (37.4% ID/g) was interesting and quite unexpected. Why the addition of the *N*-succinimidyl-PEG spacer to ^{99m}Tc-**47** should produce such a spike in lung uptake is unknown. The very high liver and bile uptake of ^{99m}Tc-**47** was sufficient to eliminate it from further consideration, while ^{99m}Tc-**10** was eliminated based on slightly higher liver and bile uptake, and tumor uptake lower than the remaining agents. The three remaining agents are all DOTA complexes, and they all have anionic PKMs (cysteic acid for ^{111}In-**TA138** and ^{111}In-**57**, and the phosphonic acid isostere of aspartic acid for ^{111}In-**36**). The failure of the radiolabeling of **29**, the HYNIC analogue of **TA138**, prevented us from assessing the relative contribution of the chelators and PKMs on biodistribution and pharmacokinetics. There is little question that the anionic PKMs in this study increase the hydrophilicity of these agents, and we believe they also contribute to lower kidney uptake. The average kidney uptake for these three agents (3.61% ID/g) is lower than the average for the entire group of DOTA complexes (5.35% ID/g) and also lower than the average of all agents in this study (6.21% ID/g). It has been reported that negatively charged molecules exhibit reduced renal uptake as a result of reduced nonspecific binding on the negatively charged membranes of renal tubular cells (*50*). The three remaining agents show excellent tumor uptake of 9.39% ID/g for ^{111}In-**TA138**, 11.8% ID/g for ^{111}In-**57**, and 11.5% ID/g for ^{111}In-**36**. While the absolute tumor uptake of ^{111}In-**TA138** is slightly lower than in the other two agents, ^{111}In-**TA138** is considered to be superior based on lower absolute uptake in kidneys, stomach, colon, and uterus and better tumor/organ ratios for these nontarget organs. See Table 3 for all tumor/organ ratios. The kidney uptake is especially important because this is considered to be the critical nontarget organ in therapeutic applications of these agents. The excellent biodistribution properties of ^{111}In-**TA138** are confirmed visually in the scintigraphic images shown in Figure 3. The images were acquired using a previously published procedure (*31*). Even relatively small tumors are clearly visible 2 h pi. The rapid clearance of background activity and the generally low level of activity in the GI track are also apparent in the images.

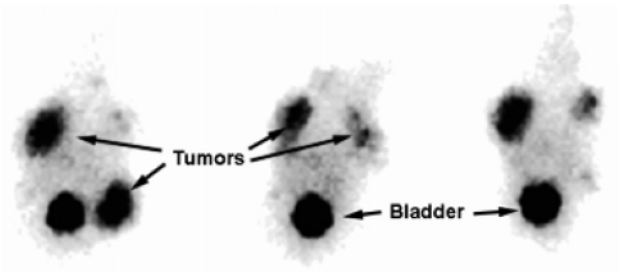

Figure 3. Representative scintigraphic images of ^{111}In-**TA138**, 2 mCi/Kg, c-neu Oncomouse mammary adenocarcinoma model, 2 h pi.

CONCLUSIONS

In the present work we have described synthetic methodology for tethering radionuclide−chelator complexes to two different positions on the quinolin-4-one class of receptor $\alpha_v\beta_3$ antagonists. A panel of integrin receptor affinity assays have shown that both of these positions, the para position of the DAP arylsulfonamide and the quinolin-4-one ring nitrogen, are very tolerant of derivatization, with no loss of receptor $\alpha_v\beta_3$ affinity and no loss of selectivity versus three other integrin receptors. Introduction of anionic, hydrophilic PKMs such as cysteic acid leads to a hydrophilic tracer with increased blood clearance and lower uptake in nontarget organs, without a reduction in tumor uptake. The complex ^{111}In-**TA138** is the superior imaging agent in this study, providing the best combination of tumor uptake and tumor/organ ratios. ^{111}In-**TA138** may be a valuable tool in patient selection, staging of disease, and the monitoring of therapy for solid tumors throughout the body.

Transferrin-Loaded *nido*-Carborane Liposomes: Tumor-Targeting Boron Delivery System for Neutron Capture Therapy

Yusuke Miyajima,[†] Hiroyuki Nakamura,*[,†] Yasuhiro Kuwata,[‡] Jong-Dae Lee,[†] Shinichiro Masunaga,[§] Koji Ono,[§] and Kazuo Maruyama*[,‡]

Department of Chemistry, Faculty of Science, Gakushuin University, Tokyo 171-8588, Department of Biopharmaceutics, School of Pharmaceutical Science, Teikyo University, Kanagawa 199-0195, and Research Reactor Institute, Kyoto University, Osaka 590-0494, Japan. Received March 13, 2006; Revised Manuscript Received July 8, 2006

The *nido*-carborane lipid **2** as a double-tailed boron lipid was synthesized from heptadecanol in five steps. The lipid **2** formed stable liposomes at 25% molar ratio toward DSPC with cholesterol. Transferrin was able to be introduced on the surface of boron liposomes (Tf(+)−PEG−CL liposomes) by the coupling of transferrin to the PEG−CO_2H moieties of Tf(−)−PEG−CL liposomes. The biodistribution of Tf(+)−PEG−CL liposomes, in which ^{125}I-tyraminyl inulins were encapsulated, showed that Tf(+)−PEG−CL liposomes accumulated in tumor tissues and stayed there for a sufficiently long time to increase tumor/blood concentration ratio, although Tf(−)−PEG−CL liposomes were gradually released from tumor tissues with time. A boron concentration of 22 ppm in tumor tissues was achieved by the injection of Tf(+)−PEG−CL liposomes at 7.2 mg/kg body weight boron in tumor-bearing mice. After neutron irradiation, the average survival rate of mice not treated with Tf(+)−PEG−CL liposomes was 21 days, whereas that of the treated mice was 31 days. Longer survival rates were observed in the mice treated with Tf(+)−PEG−CL liposomes; one of them even survived for 52 days after BNCT.

INTRODUCTION

Boron neutron capture therapy (BNCT) was first proposed as a binary approach to cancer treatment in 1936 (*1*). This therapy is based on the capture reaction of thermal neutrons using nonradioactive ^{10}B, which produces an α-particle and a lithium-7 nuclei ion with approximately 2.4 MeV. These high-linear-energy transfer particles dissipate their kinetic energy before traveling one cell diameter (5−9 μm) in biological tissues, ensuring their potential for precise cell killing (*2*−*4*). Their destructive effect is highly observed in boron-loaded tissues. Therefore, the successful treatment of cancer by BNCT demands the selective and marked accumulation of ^{10}B in malignant tumor tissues. The amount of ^{10}B required to obtain fatal tumor cell damage has been calculated to be more than 30 μg/g of tumor tissue, owing to the low contact probability between thermal neutrons and ^{10}B (*5*). Therefore, the marked accumulation and selective delivery of boron into tumor tissues are the most important requirements to achieve an effective BNCT of cancers. Although mercaptoundecahydrododecaborate (BSH) (*6*, *7*) and L-4-dihydroxyboronylphenylalanine (L-BPA) (*8*, *9*) have been utilized for BNCT, new boron-10 carriers that deliver an adequate concentration of ^{10}B atoms to tumors should be developed to achieve a potent and extensive cancer therapy (*10*). Recent promising approaches that meet this requirement entail the use of small boron molecules (*2*) and boron-conjugated biological complexes, such as monoclonal antibodies (*11*−*17*), epidermal growth factors (*18*−*21*), and carborane oligomers (*22*−*26*).

We have developed a new type of target-sensitive liposome-bearing polyethylene glycol (PEG), in which antibodies or specific ligands are coupled with PEG chains (*27*−*33*). PEG units have a heightened effect of a prolonged residence time in the circulation and escaping ability from reticulo-endothelial-system (RES) uptake (*34*, *35*), resulting in an enhanced vascular permeability in solid tumor tissues (*36*). Furthermore, transferrin (Tf)-loaded PEG liposomes are internalized into tumor cells by receptor-mediated endocytosis and taken up into endosome-like intracellular vesicles (*37*). This phenomenon is due to a higher Tf receptor concentration in tumor cells than that in normal cells (*38*−*40*). We have applied the selective delivery by and cell-entry mechanism of Tf−PEG liposomes in the boron delivery system for BNCT. In this system, boron compounds are encapsulated in liposomes and delivered to tumor tissues. Tf−PEG liposomes encapsulating BSH achieve sufficient therapeutic ^{10}B concentrations in solid tumor tissues in colon 26 tumor-bearing mice (e.g., 35.5 μg/g in tumor tissue) and inhibit tumor cell growth (*41*).

As an alternative boron delivery system, a system involving the accumulation of boron in the liposomal bilayer is highly potent, because drugs can be encapsulated into the vacant inner cell of a liposome. Therefore, boron and drugs may be simultaneously delivered to tumor tissues for BNCT and chemotherapy of cancer. Hawthorne and co-workers first introduced *nido*-carborane into the amphiphile **1** as a hydrophilic part (Figure 1) and examined liposomal boron delivery in mice using **1** and distearoylphosphatidylcholine (DSPC) (*42*, *43*). We designed the *nido*-carborane lipid **2** (CL), which has a double-tailed moiety conjugated with *nido*-carborane as a hydrophilic function, and communicated the successful synthesis of **2** (Scheme 1) and the stable vesicle formation determined by transmission electron microscopy analysis (*44*). Here, we developed of transferrin-loaded *nido*-carborane PEG liposomes (Tf(+)−PEG−CL liposomes) from **2** and found that Tf(+)−PEG−CL liposomes accumulate in tumor tissues for a prolonged time in tumor-bearing mice, thereby affecting the survival of such mice after neutron irradiation.

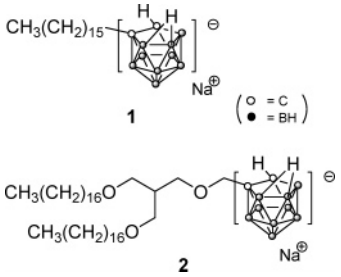

Figure 1. Structures of *nido*-carborane lipids.

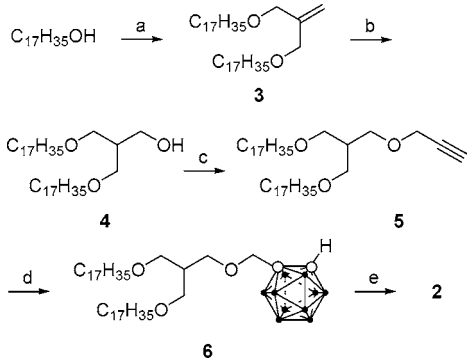
Scheme 1[a]



[a] Reagents: (a) (1) NaH, THF, (2) $CH_2{=}C(CH_2Cl)_2$, 93%; (b) (1) $BH_3{\cdot}Me_2S$, (2) H_2O_2, NaOH, 71%; (c) (1) NaH, THF, (2) propargyl bromide, 58%; (d) $B_{10}H_{14}$, CH_3CN, toluene, 80%; (e) NaOMe, MeOH, 57%.

MATERIALS AND METHODS

General. ^{1}H NMR and ^{13}C NMR spectra were measured on JEOL JNM-AL 300 (300 MHz) and VARIAN UNITY-INOVA 400 (400 MHz) spectrometers. Chemical shifts in the ^{1}H and ^{13}C NMR spectra were expressed in parts per million (ppm, δ units), and coupling constant was expressed in units of hertz (Hz). IR spectra were measured on a Shimadzu FTIR-8200A spectrometer. Analytical thin-layer chromatography (TLC) was performed on glass plates (Merck Kieselgel 60 F_{254}, layer thickness 0.2 mm). Column chromatography was performed on silica gel (Merck Kieselgel 70−230 mesh). All reactions were carried out under argon atmosphere using standard Schlenk techniques. Most chemicals and solvents were of analytical grade and used without further purification. Human iron-saturated transferrin (Holo-Tf) was purchased from Sigma. (St. Louis, MO). Distearoylphosphatidylcholine (DSPC) (COATSOME MC-8080), DSPE−PEG−OMe (DSPE-020C), and DSPE−PEG−O−$(CH_2)_5CO_2H$ (DSPE-034GC) were supplied by Nippon Oil and Fats (Tokyo, Japan). The average molecular weights of DSPE-020C and DSPE-034GC were 2136 and 3133, respectively, and their polydispersities were 1.03 and 1.04, respectively, as measured by gel permeation chromatography. ^{125}I-Tyraminyl inulin was synthesized as described previously (*30*, *31*).

3-Heptadecyloxy-2-heptadecyloxymethyl-1-propene (3). To a NaH (16.0 g, 0.34 mol) suspension in THF (100 mL) was added hexadecanol (26.9 g, 0.105 mol) in THF (100 mL) dropwise at 0 °C under Ar. The reaction temperature was increased to room temperature, and the reaction mixture was stirred for 4 h. The mixture was again cooled to 0 °C, and 2-chloromethyl-3-chloro-1-propene (5.5 mL, 47.6 mmol) was added dropwise. The reaction mixture was stirred at room temperature for 1 h and then refluxed for 89 h. The reaction was quenched with saturated aqueous NH_4Cl solution (50 mL), and the mixture was extracted with ether, washed with saturated aqueous NaCl solution, dried over anhydrous $MgSO_4$, and then concentrated. Purification by silica gel column chromatography (hexane/ethyl acetate = 50:1) gave **3** (25.1 g, 44.3 mmol, 93% yield) as a white solid: ^{1}H NMR ($CDCl_3$, 400 MHz) δ 5.14 (s, 2H), 3.94 (s, 4H), 3.38 (t, J = 6.8 Hz, 4H), 1.55 (m, 4H), 1.23 (brs, 56H), 0.86 (t, J = 7.2 Hz, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 143.3, 113.3, 71.5, 70.6, 31.9, 29.7, 29.7, 29.6, 29.5, 29.4, 26.2, 22.7, 14.1; IR (KBr) 2916, 2848, 2804, 2731, 1666, 1473, 1380, 1109, 1078, 1045, 1010 cm^{-1}; HRMS (ESI) m/z $(M + Na)^+$ calcd for $C_{38}H_{76}O_2Na$ 587.5743, found 587.5795.

3-Heptadecyloxy-2-heptadecyloxymethylpropane-1-ol (4). To a solution of **3** (18.1 g, 31.9 mmol) in THF (300 mL) was added $BH_3{\cdot}Me_2S$ (31.9 mmol) dropwise at 0 °C under Ar. The reaction temperature was increased to room temperature, and the reaction mixture was stirred for 6 h. The mixture was again cooled to 0 °C, and an aqueous NaOH solution (3 M, 100 mL) was added. The reaction mixture was stirred at 0 °C for 24 h, and then, H_2O_2 (30%, 100 mL) was added. After 12 h at room temperature with stirring, K_2CO_3 (5.0 g) was added, and the mixture was extracted with ether, washed with saturated aqueous NaCl solution, dried over anhydrous $MgSO_4$, and then concentrated. The residue was passed through a short column chromatograph on SiO_2 with hexane/ethyl acetate (30:1). Recrystallization from hexane gave **4** (13.3 g, 22.8 mmol, 71% yield) as a colorless crystal: ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.74 (t, J = 5.2 Hz, 2H), 3.50 (m, 4H), 3.38 (t, J = 5.2 Hz, 4H), 2.07 (quint, J = 5.6 Hz, 1H), 1.53 (t, J = 6.4 Hz, 4H), 1.23 (brs, 56H), 0.86 (t, J = 6.8 Hz, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 71.8, 71.2, 65.1, 41.4, 32.1, 29.9, 29.8, 29.7, 29.6, 26.3, 22.9, 14.3; IR (KBr) 3328, 2839, 2744, 1471, 1377, 1313, 1232, 1213, 1191, 1116, 1041 cm^{-1}; HRMS (ESI) m/z $(M + Na)^+$ calcd for $C_{38}H_{78}O_3Na$ 605.5848, found 605.5816.

3-Heptadecyloxy-2-heptadecyloxymethyl-1-propargyloxypropane (5). To a NaH (1.03 g, 25.7 mmol) suspension in THF (20 mL) was added **4** (3.0 g, 5.2 mmol) in THF (15 mL) dropwise at 0 °C under Ar. The temperature was increased to room temperature, and the reaction mixture was stirred for 3 h. The mixture was again cooled to 0 °C, and propargyl bromide (1.6 mL, 15.4 mmol) was added dropwise. The reaction mixture was stirred at room temperature for 20 h. The reaction was quenched with saturated aqueous NH_4Cl solution (20 mL), and the mixture was extracted with ether, washed with saturated aqueous NaCl solution, dried over anhydrous $MgSO_4$, and then concentrated. Purification by silica gel column chromatography (hexane/ethyl acetate = 30:1) gave **5** (1.87 g, 3.0 mmol, 58% yield) as a yellow solid: ^{1}H NMR ($CDCl_3$, 400 MHz) δ 4.41 (d, J = 2.4 Hz, 2H), 3.55 (d, J = 6.0 Hz, 2H), 3.43 (d, J = 6.4 Hz, 4H), 3.38 (t, J = 6.4 Hz, 4H), 2.39 (s, 1H), 2.14 (m, 1H), 1.52 (t, J = 6.8 Hz, 4H), 1.24 (brs, 56H), 0.87 (t, J = 6.8 Hz, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 74.2, 71.4, 69.2, 69.0, 58.6, 40.4, 32.1, 29.9, 29.8, 29.7, 29.6, 26.4, 22.9, 14.3; IR (KBr) 3249, 2912, 2848, 2798, 1508, 1473, 1458, 1359, 1087 cm^{-1}; HRMS (ESI) m/z $(M + Na)^+$ calcd for $C_{41}H_{80}O_3Na$ 643.6005, found 643.5989.

(3-Heptadecyloxy-2-heptadecyloxymethyl-1-propoxy)methyl-*o*-carborane (6). The mixture of **5** (0.61 g, 0.99 mmol), decaborane (0.15 g, 1.2 mmol), and acetonitrile (1.56 mL, 29.6 mmol) in toluene (20 mL) was stirred under reflux condition for 6 h. The solvent was removed under reduced pressure, and the residue was purified by silica gel column chromatography (hexane/ethyl acetate = 30:1) to give **6** (0.61 g, 0.83 mmol, 80% yield) as a white solid: ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.97 (brs, 1H), 3.51 (d, J = 5.6 Hz, 2H), 3.40−1.40 (m, 10H), 2.09 (quint, J = 6.0 Hz, 1H), 1.51 (t, J = 6.8 Hz, 4H), 1.24 (brs, 56H), 0.86 (t, J = 6.8 Hz, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 72.3, 71.6, 70.4, 68.9, 57.7, 40.4, 32.1, 29.9, 29.8, 29.7, 29.6, 26.4, 22.9, 14.3; IR (KBr) 2918, 2850, 2572, 1465, 1377, 1112, 1095, 1012 cm^{-1}; MS (MALDI) m/z $(M + Na)^+$ $C_{41}H_{90}O_3B_{10}Na$ 763.8.

(3-Heptadecyloxy-2-heptadecyloxymethyl-1-propoxy)methyl-*o*-*nido*-carborane sodium salt (2). The mixture of **6** (0.92 g, 1.25 mmol) and NaOMe (0.68 g, 12.5 mmol) in MeOH (15 mL) was stirred under reflux condition for 14 h. The reaction mixture was diluted with water (20 mL), extracted with ethyl acetate, washed with saturated aqueous NaCl solution, dried over anhydrous $MgSO_4$, and then concentrated. Purification by silica gel column chromatography (gradient from hexane/ethyl acetate = 30:1 to ethyl acetate only) gave **2** (0.56 g, 0.72 mmol, 57% yield) as a white solid: ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.77(d, J = 5.6 Hz, 2H), 3.52 (m, 6H), 3.40 (t, J = 6.4 Hz, 4H), 2.09 (m, 1H), 1.54 (m, 4H), 1.24 (brs, 56H), 0.87 (t, J = 6.8 Hz, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 41.05, 32.31, 29.93, 29.87, 29.57, 26.02, 22.90, 14.32; IR (KBr) 3419, 3251, 2850, 2520, 1714, 1614, 1456, 1373 cm^{-1}; MS (MALDI) m/z $(M + Na)^+$ $C_{41}H_{89}O_3B_9Na_2$ 774.8.

Preparation of Calcein Encapsulated CL and PEG−CL Liposomes. CL and PEG−CL liposomes were prepared from DSPC, CH, and CL (1:1:X = 0−1, molar ratio) or DSPC, CH, DSPE−PEG−OMe, and CL (1:1:0.12:X = 0−1, molar ratio) by the reverse-phase evaporation (REV) method (*44*). The representative procedure for the preparation of 25% CL containing the PEG−CL liposome is shown as follows: A mixture of DSPC (118 mg), CH (47 mg), DSPE−PEG−OMe (56 mg), and CL (29 mg) were dissolved in 2 mL of chloroform/diisopropylether mixture (1:1, v/v) in a round-bottom flask. An aqueous solution of calcein (100 mM, 2 mL) was added to the lipid solution to form an emulsion. The volume ratio of the aqueous phase to the organic phase was maintained at 1:2. The emulsion was sonicated for 1 min, and then, the organic solvent was removed under vacuum in a rotary evaporator at 37 °C while being broken down repeatedly to obtain a suspension of liposomes. The liposomes obtained were subjected to extrusion 10 times through a polycarbonate membrane of 100-nm pore size, using an extruder device (Lipex Biomembrane, Canada) thermostated at 60 °C. Purification was accomplished by ultracentrifuging at 200 000*g* for 20 min at 4 °C (Hitachi CS120, S100AT5 rotor), and the pellets obtained were resuspended in PBS buffer. Liposome size was measured with an electrophoretic light scattering spectrophotometer (ELS-700, Otsuka Electroics, Tokyo). The size distribution of CL (25−100%) containing the PEG−CL liposome was indicated in Figure 1 in the Supporting Information.

Stability of CL and PEG−CL Liposomes in Fetal Bovine Serum. The calcein-encapsulated CL and PEG−CL liposomes were added to a fetal bovine serum (FBS) (volume ratio of FBS/vesicle solution = 9:1), and the mixture was incubated at 37 °C with stirring. The fluorescence intensity of the FBS solution was measured at 0−24 h using an excitation wavelength of 490 nm with emission wavelength of 520 nm. The fluorescence intensity was also measured at each fraction after degradation of liposomes by the addition of a 5% aqueous solution of Triton X-100 to the FBS solution.

Conjugation of Transferrin on Surface of Tf(−)−PEG−CL Liposomes. Tf(−)−PEG−CL liposomes were prepared from DSPC, CH, DSPE−PEG−OMe, DSPE−PEG−O−$(CH_2)_5CO_2H$, and CL (molar ratio 1:1:0.11:0.021:0.25) according to the procedure described above. In the case of ^{125}I-tyraminyl inulin encapsulation, the Tf(−)−PEG−CL liposomes were prepared using an aqueous solution containing ^{125}I-tyraminyl inulin (500 μg lipid/200 μL), which was obtained according to the reported procedure (*46*). Tf(+)−PEG−CL liposomes were prepared by the coupling of transferrin to the PEG−CO_2H moieties of Tf(−)−PEG−CL liposomes as previously reported (*33*). Briefly, to 1 mL of Tf(−)−PEG−CL liposomes (5.8 μmol lipid) in 1.25 mL Mes buffer (10 mM Mes/150 mM NaCl, pH 5.5), 21 μmol of EDC and 28 μmol of S-NHS were added, and the mixture was incubated for 15 min at room temperature. The mixture was loaded into a Sephadex G25 column equilibrated with Mes buffer, and liposome fractions were collected. Transferrin (1 mg) in a NaCl solution (150 mM) with PBS (final 250 μL, pH 7.4) was then added to the liposome solution, and the mixture was incubated for 3 h at room temperature with gentle stirring. Purification was accomplished by ultracentrifugation at 200 000*g* for 20 min at 4 °C, and the pellets obtained were resuspended in 2 mL of PBS. Tf(+)−PEG−CL liposomes obtained were converted into the diferric form by treatment with $FeCl_3$−nitriloacetic acid solution (250 mM, 20 μL, pH 7.4). After the reaction, the suspension was purified by ultracentrifugation and resuspended in PBS.

Biodistribution of Tf(+)−PEG−CL and Tf(−)−PEG−CL Liposomes in Tumor-Bearing Mice. Biodistribution studies were performed using male BALB/c mice (6 weeks old, 16−18 g, Nihon SLC). Tumor-bearing mice were prepared by inoculating sc a suspension (5×10^6 cells) of colon 26 cells directly into their back. The mice were kept on regular mouse diet and water, and maintained under a standard light/dark cycle in an ambient atmosphere. These experiments were performed when the tumor was 7−9 mm in diameter. ^{125}I-Tyraminyl inulin solution was encapsulated in the liposomes, and 100 μL of liposomes was injected into the mice (3 per group) via the tail vein. At selected time intervals after administration, the mice were lightly anesthetized, bled via the retro-orbital sinus, sacrificed by cervical dislocation, and dissected. Their organs were excised, and their ^{125}I content was estimated by a liquid scintillation counter.

BNCT for Tumor-Bearing Mice Using Tf(+)−PEG−CL Liposomes. Tumor-bearing mice were prepared by inoculating sc a suspension (5×10^6 cells) of colon 26 cells directly into their left thigh. Tf(+)−PEG−CL liposomes, which were prepared from the ^{10}B-enriched *nido*-carborane lipid **2**, was injected into colon 26 tumor-bearing mice (18−22 g; 8 per group) via a tail vein at a dose of 7.2 mg ^{10}B/kg (720 ppm of ^{10}B concentration; 200 μL of liposome solution). Seventy-two hours after iv injection, 4 mice in each group were sacrified by cervical dislocation and dissected. Organs were excised, and a ^{10}B concentration in each organ was determined by prompt γ-ray spectroscopy. At the same time, the other 4 mice in each group were anesthetized with sodium pentobarbital solution and placed in an acrylic mouse holder (Iuchi, Tokyo), where their whole bodies except the tumor-implanted leg were shielded with acrylic resin. The mice were irradiated in the KUR atomic reactor for 37 min at a rate of 2×10^{12} neutrons/cm^2. The antitumor effect of BNCT was evaluated on the basis of the survival of the mice. All protocol were approved by the Institutional Animal Care and Use Committee in Kyoto University.

RESULTS AND DISCUSSION

Synthesis of Double-Tailed *nido*-Carborane Lipid 2. The synthetic route of *nido*-carborane lipid **2** is shown in Scheme 1. The reaction of 2 equiv of heptadecanol with 3-chloro-2-chloromethyl-1-propene using NaH as base gave the diether **3** in 93% yield, and the hydroboration of **3** gave the corresponding alcohol **4** in 71% yield. The alcohol **4** was converted into the propargyl ether **5** in 48% yield by the treatment with propargyl bromide, and the decaborane coupling of **5** was carried out in the presence of acetonitrile in toluene under reflux condition to give the corresponding *o*-carborane **6** in 80% yield. The degradation of the carborane cage by the treatment with sodium methoxide in methanol afforded the *nido*-carborane lipid **2** (CL) in 57% yield.

Stability of CL and PEG−CL Liposomes in FBS. PEG units conjugated on the surface of liposomes are important for a prolonged residence time in the circulation and escaping ability

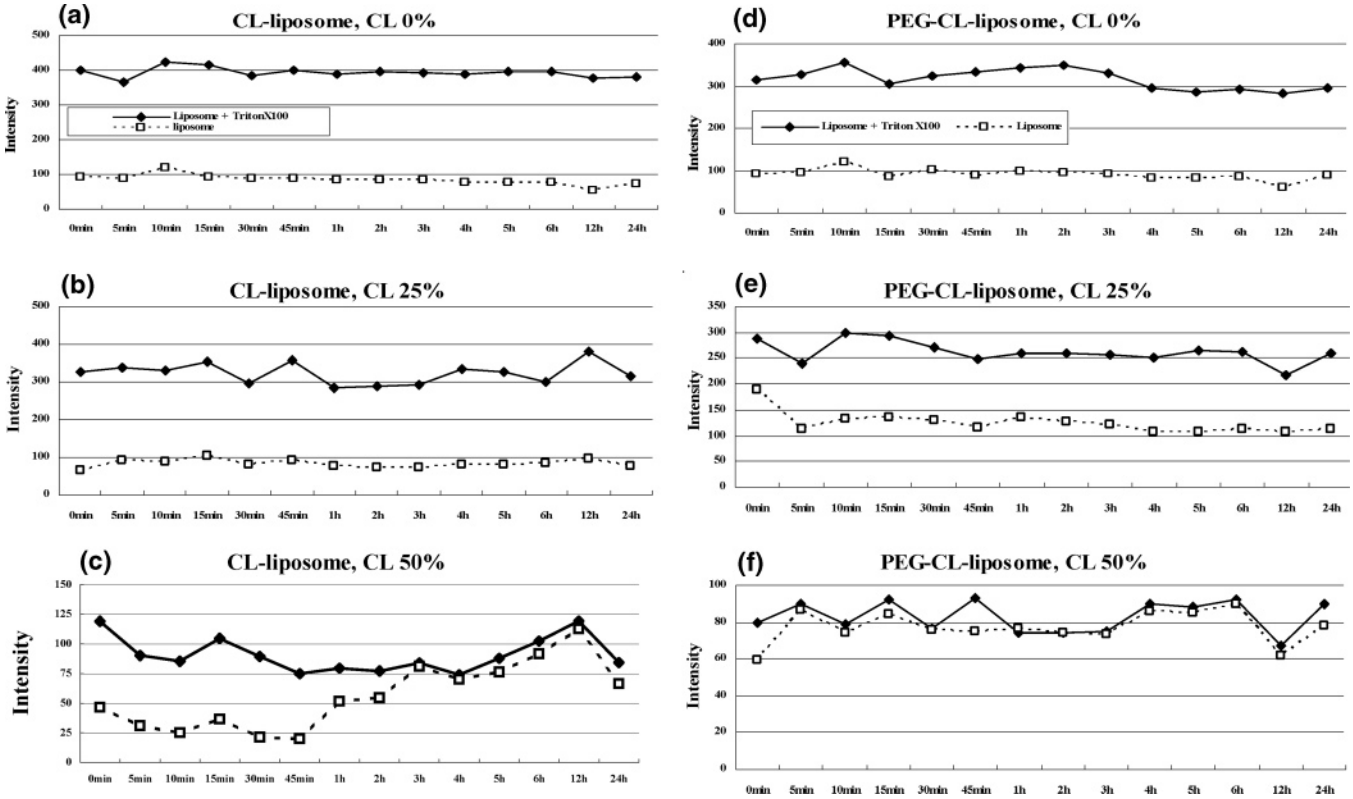


Figure 2. Fluorescence intensities of calcein-encapsulated CL and PEG−CL liposomes in fetal bovine serum (FBS). The white plots show the fluorescence intensity of the FBS solution, and the black plots show that of the solution after destruction of liposomes by the addition of Triton X-100. The difference in fluorescence intensity between the black and white plots indicates calcein release from liposomes.

from RES uptake, promoting the extravasation of the liposomes into the solid tumor tissue on liposomal drug delivery system. Therefore, we first investigated the stability of calcein-encapsulated CL and PEG unit-conjugated CL liposomes in FBS. To FBS was added a liposome solution (the volume ratio of FBS/liposome solution = 9:1) and incubated at 37 °C with stirring. The fluorescence of the FBS solutions was measured at 0−24 h. The results are shown in Figure 2. Fluorescence intensity is plotted on the vertical axis, and incubation time is plotted on the horizontal axis. The white plots show the fluorescence intensity of the FBS solution containing liposomes, and the black plots show that of the solution after destruction of liposomes by the addition of Triton X-100. In the case of liposomes with 0% and 25% CL (Figure 2a,b), no increase in the fluorescence intensity of the FBS solutions was observed within 24 h. However, the fluorescence intensity of the liposome with 50% CL increased after 1 h of incubation at 37 °C with stirring (Figure 2c). A similar tendency was observed in the case of the PEG liposomes, and the fluorescence intensity of the PEG liposomes with 50% CL increased even after 5 min of incubation (Figure 2d−f). These results indicate that the liposomes containing 25% of CL were stable in the FBS solution at 37 °C at least for 24 h and that liposomes with higher than 50% CL lead to an unstable liposomal formation. The increased rate of fluorescence intensity after the treatment with Triton X-100 may be associated with the amounts of calceins encapsulated in liposomes. Comparison of the increased rates of fluorescence intensity between PEG−CL liposome solutions and CL liposome solutions after treatment with Triton X-100 shows that the latter is relatively higher (Figure 2a−c vs d−f). This means that the PEG functional group would lower the capacity of calcein encapsulation in liposomes. Therefore, the higher CL content of the liposomes led not only to instability in liposome formation but also suppressed calcein encapsulation.

Biodistribution of Tf(−)−PEG−CL and Tf(+)−PEG−CL Liposomes in Tumor-Bearing Mice. Liposomes, in which ^{125}I-tyraminyl inulins were encapsulated, were injected intravenously into colon 26 tumor-bearing mice. At selected time intervals after administration, the mice were lightly anesthetized, bled via the retro-orbital sinus, killed by cervical dislocation, and dissected. Their organs were excised, and their ^{125}I content was estimated using a liquid scintillation counter. The time-dependent distributions of Tf(−)−PEG−CL and Tf(+)−PEG−CL liposomes in various tissues are shown in Figure 3. The rapid clearance of Tf(−)−PEG−CL and Tf(+)−PEG−CL liposomes was observed in the blood, lung, and kidney after 3 h of injection. In general, PEGylated liposomes possess a longer circulation time compared to nonstealth liposomes (*34, 35*). We examined the effect of CL on the circulation time of PEGylated liposomes and found that CL influenced a stealth property of the PEG−CL liposome (see Figure 4 in Supporting information). The enhanced accumulation of Tf(+)−PEG−CL liposomes in comparison with Tf(−)−PEG−CL liposome accumulation was observed in the spleen within 72 h. Tf(+)−PEG−CL liposomes accumulated in the liver and tumor gradually, whereas Tf(−)−PEG−CL liposomes were released from those organs 72 h after injection, although percentage doses of these liposomes were similar 24 h after injection. Surprisingly, more than 1.5% of the total dose injected accumulated in tumor tissues. This enhanced accumulation of Tf(+)−PEG−CL liposomes may reflect marked receptor-mediated endocytosis after binding to tumor cells (*37*). Since enhanced accumulation in tumor tissues and a high tumor/blood ratio were observed 72 h after the administration of Tf(+)−PEG−CL liposomes, we next investigated the ^{10}B distribution and BNCT effect in tumor-bearing mice.

^{10}B Concentration in Various Organs 72 h after Injection of Tf−PEG−CL Liposome. ^{10}B-enriched Tf(+)−PEG−CL liposomes were injected into tumor-bearing mice, in which colon

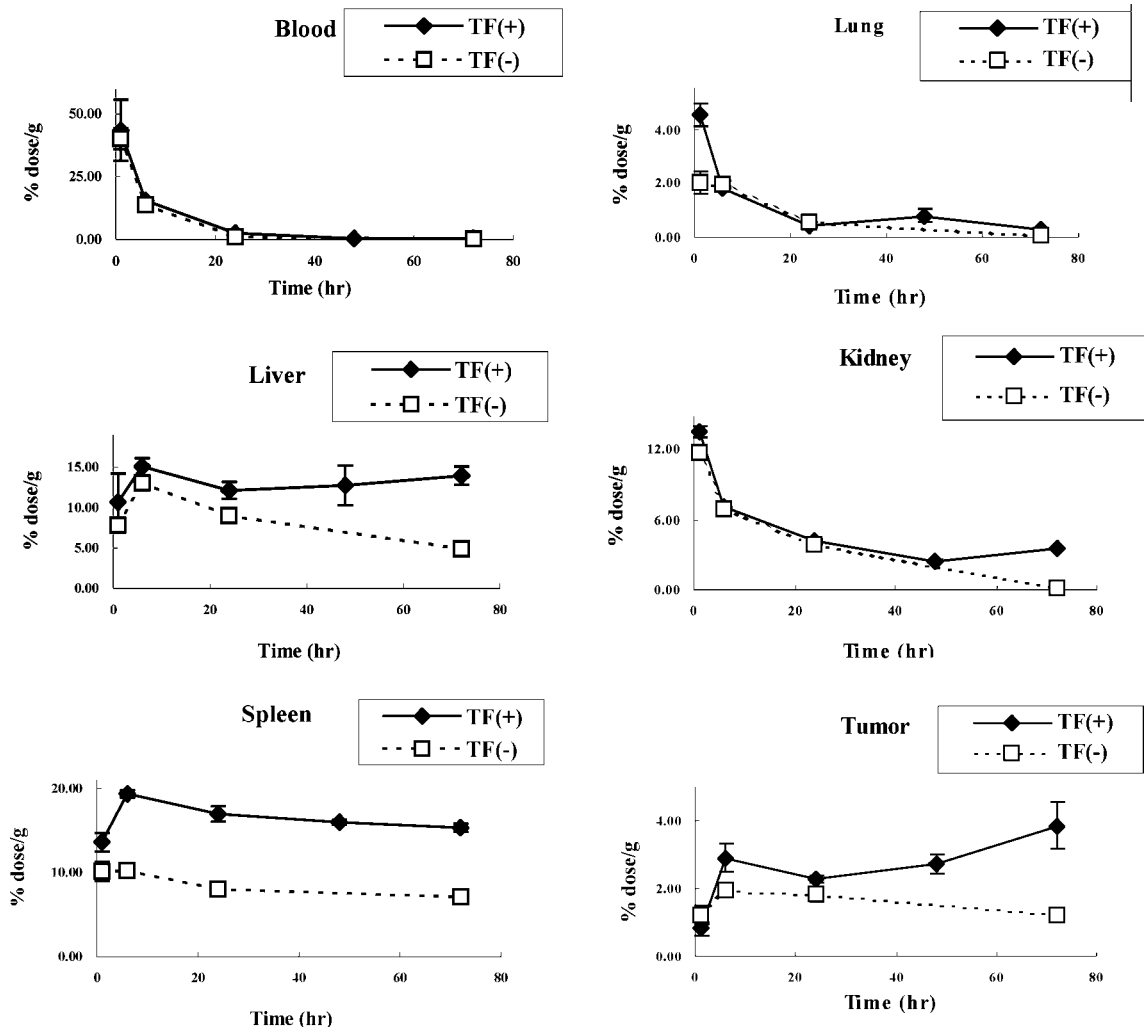

Figure 3. Time course of biodistribution of Tf(−)−PEG−CL liposome (TF(−)) and the Tf(+)−PEG−CL liposome (TF(+)). Liposomes encapsulating ^{125}I-tyraminyl inulin (500 g lipid/200 μL) were injected into male BALB/c mice (7 weeks old, weighing 20−25 g) via the tail vein. The distribution of liposomes was measured by determining the radioactivity of each tissue. The percent dose/per gram in each tissue is plotted on the vertical axis, and the time (h) after administration is plotted on the horizontal axis.

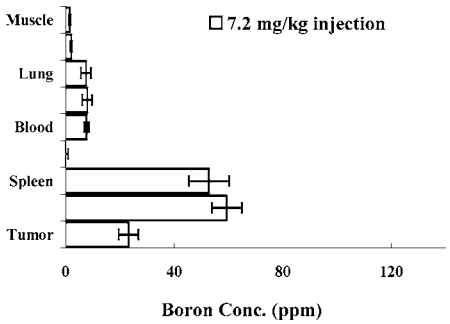

Figure 4. ^{10}B concentration in various tissues 72 h after injection of Tf(+)−PEG−CL liposomes into tumor-bearing mice. ^{10}B-enriched Tf(+)−PEG−CL liposomes were injected into tumor-bearing mice, in which colon 26 cells were transplanted into the left thigh, via the tail vein at a dose of 7.2 mg ^{10}B/kg (200 μL of liposome solution).

26 cells were transplanted into their left thigh, via the tail vein at a dose of 7.2 mg ^{10}B/kg (200 μL of a liposome solution). Seventy-two hours after administration, ^{10}B concentration in each organ was measured by prompt γ-ray spectroscopy. The results are shown in Figure 4. No boron accumulation was observed in the muscle, heart, and brain; however, the boron concentrations in the lung, kidney, and blood were approximately 10 ppm. Since no accumulation of Tf(+)−PEG−CL liposomes labeled with ^{125}I-tyraminyl inulin was observed, as shown in Figure 3, it is considered that the ^{10}B concentrations detected in such organs may be due to the accumulation of the *nido*-carborane lipid **2**, which was caused by the degradation of the parent liposomes. Enhanced accumulation of ^{10}B was observed in the spleen and liver, and this does not conflict with the result of the biodistribution of Tf(+)−PEG−CL liposomes as shown in Figure 3. A high level of ^{10}B concentration (22 ppm) in the tumor was observed in tumor tissues 72 h after the administration of Tf(+)−PEG−CL liposomes. Previously, we reported that BSH-encapsulated Tf(+)−PEG liposomes (*40*) accumulated in tumor tissues at 35.5 ppm ^{10}B concentration 72 h after administration of 35 mg/kg body weight ^{10}B. Therefore, ^{10}B delivery to tumor tissues by Tf(+)−PEG−CL liposomes would be more efficient in comparison with that by BSH-encapsulated Tf(+)−PEG liposomes. In both cases, the conjunction of transferrin to the surface of liposomes is essential for the enhanced and prolonged accumulation of ^{10}B in tumor tissues.

Survival of Tumor-Bearing Mice after BNCT. Besides the determination of ^{10}B concentration in various organs, the mice were anesthetized with sodium pentobarbital solution 72 h after the administration of Tf(+)−PEG−CL liposomes and placed in an acrylic mouse holder, where their whole bodies, except their tumor-implanted leg, were shielded with acrylic resin. Neutron irradiation was carried out for 37 min at a rate of 2×10^{12} neutrons/cm^2 in the KUR atomic reactor. The antitumor

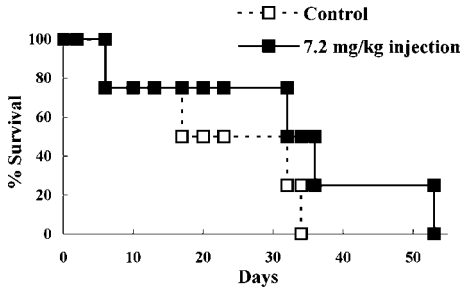

Figure 5. Survival curve of tumor-bearing mice after neutron irradiation for 37 min in KUR atomic reactor. The mice were injected with 7.2 mg ^{10}B/kg of the Tf(+)−PEG−CL liposome and incubated for 72 h before irradiation. Control indicates survival rates of tumor-bearing mice after neutron irradiation without administration of Tf(+)−PEG−CL liposomes.

effect of BNCT was evaluated on the basis of the survival of the mice, as shown in Figure 5. All the nontreated mice did not survive after 32 days of neutron irradiation, and their average survival rate was 21 days. Long survival rates were observed in the mice treated with Tf(+)−PEG−CL liposomes; one of them even survived for 52 days after neutron irradiation. The average survival rate of the treated mice was 31 days.

CONCLUSION

We succeeded in the synthesis of the double-tailed boron lipid **2**, which forms a stable liposome at 25% molar ratio toward DSPC with cholesterol. Transferrin was able to be conjugated to the surface of boron liposomes (Tf(+)−PEG−CL liposomes) by the coupling of transferrin to the PEG−CO_2H moieties of PEG(−)−CL liposomes. A biodistribution experiment on Tf(+)−PEG−CL liposomes, in which ^{125}I-tyraminyl inulins were encapsulated, showed that Tf(+)−PEG−CL liposomes accumulate in tumor tissues and stay there for a sufficiently long time to increase tumor/blood concentration ratio, although Tf(−)−PEG−CL liposomes were gradually released from tumor tissues with time. A ^{10}B concentration of 22 ppm was achieved by injection with Tf(+)−PEG−CL liposomes at 7.2 mg ^{10}B/kg in tumor-bearing mice. Although no complete cure of the tumor was observed after neutron irradiation, prolonged survivals of the mice were observed. The current boron delivery system uses the accumulation of boron in the liposomal bilayer instead of in the inner cell of liposomes. It is noted that the inner cells of a liposome are still vacant; therefore, it is envisioned that drugs can be encapsulated into the Tf(+)−PEG−CL liposome. In this system, boron and drugs can be simultaneously delivered to tumor tissues. The current investigation and liposomal delivery of the double-tailed boron lipid **2** possesses a dual-mode vehicle for BNCT and chemotherapy of cancer.

Supporting Information Available: Size distributions of PEG−CL liposomes, analysis of the conjugation of transferrin to liposomes, size distributions of Tf(−)−PEG−CL liposome and Tf(+)−PEG−CL liposome, and effect of CL on the circulation time and accumulation of PEG-conjugated liposomes in various tissues in mice. This work describes the use of 3-hydroxy-4-pyridinone ligands for binding the $[M(CO)_3]^+$ core (M = Re, Tc) in the context of preparing novel Tc(I) and Re(I) glucose conjugates. Five pyridinone ligands bearing pendent carbohydrate moieties, H**L**$^{1-5}$, were coordinated to the $[M(CO)_3]^+$ core on the macroscopic scale (M = Re) and on the tracer scale (M = ^{99m}Tc, ^{186}Re). On the macroscopic scale the complexes, Re**L**$^{1-5}(CO)_3(H_2O)$, were thoroughly characterized by mass spectrometry, IR spectroscopy, UV−visible spectroscopy, elemental analysis, and 1D/2D NMR spectroscopy. Characterization confirmed the bidentate coordination of the pyridinone and the pendent nature of the carbohydrate and suggests the presence of a water molecule in the sixth coordination site. In preliminary biological evaluation, both the ligands and complexes were assessed as potential substrates or inhibitors of hexokinase, but showed no activity. Labeling via the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ precursor gave the tracer species ^{99m}Tc**L**$^{1-5}(CO)_3(H_2O)$ in high radiochemical yields. Similar high radiochemical yields when labeling with ^{186}Re were facilitated by in situ preparation of the $[^{186}Re(CO)_3(H_2O)_3]^+$ species in the presence of H**L**$^{1-5}$ to give ^{186}Re**L**$^{1-5}(CO)_3(H_2O)$. Stability challenges, incubating ^{99m}Tc**L**$^{1-5}(CO)_3(H_2O)$ in the presence of excess cysteine and histidine, confirmed complex stability up to 24 h.

INTRODUCTION

Because glucose is a major energy source for the body, especially for the heart and brain, the ability to monitor cell glucose metabolism has found utility in a myriad of areas of medicine (*1*). In the use of positron emission tomography, [^{18}F]-2-deoxy-2-fluoro-D-glucose (FDG) is the preeminent radiotracer used to image glucose metabolism (*2*) and is an important tool in cardiology (*3*) and neurology (*1*, *2*). As well, FDG is used in oncology as a tumor marker, due to the elevated level of glucose metabolism in many tumor types (*1*, *4*). Unfortunately, the radioisotope used in FDG, ^{18}F, is cyclotron-produced and has a short half-life ($t_{1/2}$ = 1.8 h), significantly limiting the availability of the radiotracer. Hence, there is much interest in developing FDG-like radiopharmaceuticals that are less expensive and more accessible. As well, no analogue of FDG that can be used in radiotherapy is currently available.

In developing a more accessible radiotracer, ^{99m}Tc is an optimal radioisotope to consider; ^{99m}Tc is already used in over 90% of nuclear medicine scans and is generator-produced, making it inexpensive and widely available (*5*). The physical properties of ^{99m}Tc ($t_{1/2}$ = 6.01 h, γ = 142.7 keV) are ideal for imaging with single photon emission computed tomography (SPECT), the infrastructure for which is already available in most major hospitals. In addition, the third row congener of Tc, Re, has relatively similar chemistry to that of Tc and has two particle-emitting radioisotopes of interest for therapy: ^{186}Re ($t_{1/2}$ = 3.68 d, β^- = 1.07 MeV, γ = 137 keV) and ^{188}Re ($t_{1/2}$ = 16.98 h, β^- = 2.12 MeV, γ = 155 keV). Clearly, the development of an FDG analogue which incorporates ^{99m}Tc could have a significant impact on health care cost and availability, while using the same methods to develop a Re-FDG analogue has potential for targeted radiotherapy. As well, the investigation of radiolabled carbohydrates in general has wider potential applications, such as imaging of tumor specific lectins or in investigating other biological processes where carbohydrates and carbohydrate conjugates play a central role.

Research to combine the accessibility and ideal nuclear properties of ^{99m}Tc with the biological properties and applications of FDG has led several groups to develop ^{99m}Tc glucose conjugates (*6*−*16*). The initial investigations of these radiometal carbohydrate conjugates suffered from poor characterization (*8*, *12*) or from undesirable bonding interactions between the carbohydrate and metal (*7*, *17*, *18*). More recently, well characterized ligands and complexes have been prepared, the ligands radiolabeled in high yields, and the complexes shown to be highly stable (*9*, *11*, *14*−*16*). Also, in vivo studies of a few of these compounds have shown promising biodistribution results and tumor uptake (*8*, *12*), although the mechanism of uptake does not appear to mimic that of FDG or glucose. Although nonradioactive Re compounds are commonly used as a surrogate for ^{99m}Tc on the macroscopic scale and as a standard for identifying the analogous ^{99m}Tc complexes, only two ^{186}Re glucose conjugates have been reported (*14*, *17*). Further research is needed to develop glucose conjugates of ^{99m}Tc, ^{186}Re, and ^{188}Re with high stability and optimal biological properties. In the development of ^{99m}Tc and $^{186/188}$Re glucose conjugates, the $[M(CO)_3]^+$ core is of interest due to its stability, small size, and well-studied chemistry (*19*−*27*). The $[M(CO)_3]^+$ core is kinetically inert due to the metal ion +1 oxidation state and low spin d^6 electron configuration, which is further stabilized by the facial and strongly back-bonding CO ligands. The compact core is advantageous in retaining biological activity when labeling small molecules such as glucose. Alberto and co-workers have pioneered the chemistry and radiochemistry

of this core and have developed a commercially available kit preparation of the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ species (*25*). The three aqua ligands, each trans to a CO ligand, are labilized for substitution by various chelates functionalized with the biomolecule of interest (*19*−*21*, *24*, *26*). The $[^{188}Re(CO)_3(H_2O)_3]^+$ analogue has also been described (*22*, *23*).

Different chelating derivatives have been studied with the $[M(CO)_3]^+$ core, to optimize stability, labeling, and the physical properties of the products. Both bidentate and tridentate ligands have been investigated with a broad range of hard and/or soft bases as binding groups, including amine (*20*, *21*, *26*, *28*−*33*), thiol/thioether (*28*, *30*, *31*, *34*, *35*), thiourea (*36*), carboxylate (*9*, *30*, *37*), imine (*38*, *39*), phosphine (*40*), carborane (*13*, *41*), and cyclopentadienyl (*42*−*45*) ligands. Most of these ligands can be efficiently labeled via the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ precursor and form highly stable complexes of varying charge and lipophilicity. Aromatic amines and borderline bases are considered among the best binding functionalities for this core (*21*, *33*) but do not neutralize the 1+ charge of the metal center.

A highly useful class of chelators that has not been studied with the $[M(CO)_3]^+$ system are the 3-hydroxy-4-pyrdinones, small, monanionic, bidentate O,O-chelators with a high affinity for a variety of metal ions. These chelators can be easily functionalized via the ring nitrogen. 3-Hydroxy-4-pyridinones have similar basicity to aromatic amines but can neutralize the charge of a 1+ metal center, such as Re(I) and Tc(I). Stable complexes with Re/Tc(V) (*46*) and (IV) (*47*) with 3-hydroxy-4-pyridinones have been reported. 3-Hydroxy-4-pyridnones have also been used to chelate a large number of other metals, both hard and soft acids, including V (*48*), Fe (*48*, *49*), Co (*50*), Cu (*51*, *52*), Mn (*53*), Zn (*54*), Pb (*54*), Rh (*55*), Ru (*55*, *56*), Ir (*55*), Al (*49*, *57*, *58*), Ga,(*49*, *57*−*60*), In (*57*, *59*), U (*61*), and Gd (*62*).

Recently we reported the synthesis of pyridinone bearing pendent glucose derivatives (Figure 1) and the neutral Ga and In tris complexes of these ligands as potential imaging agents (*59*). With the $[M(CO)_3]^+$ core, the pyridinone ligand is expected to form a stable neutral complex. When labeling a small neutral biomolecule such as glucose, a neutral complex may better retain the biological properties of the biomolecule compared to a cationic complex. In this work, we investigate the utility of the aforementioned pyridinone ligands bearing pendent glucose derivatives as chelates for the $[M(CO)_3]^+$ core. The resulting neutral complexes were fully characterized on the macroscopic scale, as well as prepared on the tracer level with both ^{99m}Tc and ^{186}Re. Preliminary evaluation of the complexes as potential radiopharmaceuticals is also reported.

EXPERIMENTAL SECTION

Materials. $[NEt_4]_2[Re(CO)_3Br_3]$ (*64*) $[Re(CO)_3(H_2O)_3]Br$ (*27*) and H**L**$^{1-5}$ (*59*, *63*) were prepared as reported in the literature. $Re(CO)_5Br$ was purchased from Strem Chemicals (Newburyport, MA). The Isolink boranocarbonate Kits were a gift from Mallinckrodt Inc. Saline solutions of $Na^{99m}TcO_4$ and $Na^{186}ReO_4$ were obtained from Vancouver Coastal Health-UBC Hospital and MDS Nordion Inc., respectively. All other chemicals were purchased from Sigma Aldrich and used without further purification. Water was deionized, purified (Barnstead D9802 and D9804 cartridges), and distilled with a Corning MP-1 Mega-Pure Still. All solvents were HPLC grade and purchased from Fisher. N_2 gas was acquired from Praxair. Thin layer chromatography (TLC) was performed using silica TLC plates with aluminum backing (Merck), and silica column chromatography was performed using silica from Silicycle (Quebec City, PQ). All NMR solvents were purchased from Cambridge Isotope Laboratories.

^1H NMR spectra were recorded on Bruker AV-300 or AV-400 instruments at 300.13, or 400.21 MHz, respectively. The NMR spectra were calibrated with the deuterated solvent used in each case, and $^1H-^1H$ COSY, $^1H-^{13}C$ HMQC, and HMBC HETCOR 2D NMR spectra were used to aid in the characterization of the compounds. Infrared spectra were recorded on an ATI Mattson Galaxy Series FTIR 5000 spectrophotometer as thin films on NaCl plates or as KBr discs. Mass spectra were obtained on either a Kratos Concept II H32Q instrument (Cs^+, LSIMS) or a Macromass LCT (electrospray, ES-MS). Elemental analysis was performed at the University of British Columbia Chemistry Department by Mr. M. Lakha (Carlo Erba analytical instrument). UV−visible spectra and hexokinase inhibition assays were run on a Hewlett-Packard model HP8453 diode array spectrophotometer, equipped with a kinetics software package. Purification by semipreparative HPLC was done on a Water Xterra RP C18 column (7 μm, 19 × 300 mm) using a Waters WE 600 HPLC system equipped with a 2478 dual wavelength absorbance UV detector and the Empower software package. Verification of radiolabeled products was done by HPLC analysis on a Phenomenex Hydro-Synergi C18 RP column using a Wellchrom Knauer K1001 system equipped with a K-2501 UV absorption detector, a Kapintek radiometric well counter, and Peak simple software.

Preparations of Re(L$^{1-5}$)(CO)$_3$(H$_2$O). Method A. A 1:1 stoichiometric mixture of $Re(CO)_5Br$ and H**L**$^{1-5}$ was dissolved in borate buffer (10−20 mL, 20 mM, pH 9), stirred, and heated at 75 °C for 30 min. The solvent was removed using a rotary evaporator to yield a white solid. The reaction was quantitative by ^1H NMR spectroscopy.

Method B. A 1:1 stoichiometric mixture of $[Et_4N]_2[Re(CO)_3Br_3]$ and H**L**$^{1-5}$ was dissolved in methanol (10−20 mL) and refluxed for 2 h. The solvent was removed using a rotary evaporator to yield a white solid.

Method C. A 1:1 stoichiometric mixture of $[Re(CO)_3(H_2O)_3]Br$ and H**L**$^{1-5}$ was dissolved in methanol (10−20 mL) and refluxed for 2 h. The solvent was removed using a rotary evaporator and pure product was obtained by recrystallization, column chromatography, or semipreparative HPLC.

Experimental for the Preparation of Re(L$^{1-5}$)(CO)$_3$(H$_2$O) by Method C. *fac*-(Aqua)tri(carbonyl)(1-{*N*-[*p*-benzyl β-D-glucopyranoside]ethanamide}-2-methyl-3-oxy-4(1*H*)-pyridinato)rhenium(I), (ReL^1(CO)$_3$(H$_2$O)). The title compound was prepared from H**L**^{1} (127 mg, 0.291 mmol) and $[Re(CO)_3(H_2O)_3]Br$ (119 mg, 0.294 mmol) in methanol (20 mL). The product was purified by semipreparative HPLC (30 mL/min gradient method 95% water 5% methanol to 100% methanol over 30 min) with the product collected between 11.5 and 12.5 min. Solvent was removed by rotary evaporation and the resulting white solid dried in vacuo overnight (90 mg, 44%). ^1H NMR ($CD_3OD:D_2O$ 1:1, 400 MHz): δ 2.48 (s, 3H, C13-CH_3), 3.35−3.57 (m, 4H, *H*2, *H*3, *H*4, *H*5), 3.72 (dd, 1H, *H*6a, $^3J_{5,6}$ = 5.63 Hz, $^2J_{6a,6b}$ = 12.2 Hz), 3.89 (d, 1H, *H*6b, J = 10.51 Hz), 4.98 (d, 1H, *H*1, $^3J_{1,2}$ = 7.22 Hz), 5.12 (s, 2H, *H*12), 6.68 (d, 1H, *H*16, $^3J_{16,17}$ = 6.55 Hz), 7.12 (d, 2H, *H*8, *H*8′, $^3J_{8,9}$ = 8.87 Hz), 7.46 (d, 2H, *H*9, *H*9′, $^3J_{8,9}$ = 9.05 Hz), 7.59 (d, 1H, *H*17, $^3J_{16,17}$ = 6.54 Hz). $^{13}C\{H\}$ NMR ($CD_3OD:D_2O$ 1:1, 75 MHz): δ 11.68 (C13-*C*H$_3$), 56.2 (*C*12), 60.69, (*C*6), 69.69 (*C*4), 73.21 (*C*2), 76.58 (*C*3), 76.99 (*C*5), 100.72 (*C*1), 109.15 (*C*16), 116.57 (*C*8, *C*8′). 120.49 (*C*9,*C*9), 132.56 (*C*10), 134.55 (*C*13), 135.09 (*C*17), 158.65 (*C*14), 164.34 (*C*11), 174.06 (*C*15), 199.28,

Solid-state Structure Determination for HL^5. Needle crystals of H**L**^{5} were grown by slow evaporation of a methanol solution, mounted on glass fibers and cooled to 173 K. Data sets were collected on a Bruker X8 APEX diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). Data were collected and integrated using the Bruker SAINT (*65*) software package and corrected for Lorentz and polarization effects as well as for absorption (SADABS) (*66*). The structure was solved by direct methods (SIR92) (*67*). Non-hydrogen atoms were refined anisotropically, while hydrogen atoms were added but not refined. Final refinement was completed using SHELXL-97 (*68*).

Measurement of Phosphorylation of HL$^{1-5}$ by Hexokinase. The ligands H**L**$^{1-5}$ were qualitatively tested as substrates for hexokinase. Each compound (10 L, 10^{-2} M) in 30 mM triethanolamine buffer (pH = 6) was added to 1 mL of the assay mixture, which contained 100 U/L hexokinase, 1 mM ATP, and 4 mM $MgCl_2$ all dissolved in 30 mM triethanolamine buffer (pH = 6). After incubating for 10 min or 24 h, the assay mixture was analyzed by analytical HPLC, using 30 mM KH_2PO_4 buffer as the solvent. The compound was determined to be a substrate of hexokinase if the HPLC chromatogram showed the disappearance of ATP (retention time 7.0 min) and the appearance of the ADP (retention time 9.8 min).

Inhibition of Hexokinase Glucose Phosphorylation by HL$^{1-5}$ and Re(L$^{1-5}$)(CO)$_3$(H$_2$O). The pro-ligands and their complexes were tested for their capacity to inhibit glucose phosphorylation by hexokinase. In a cuvette, 500 μL glucose (HK) assay kit (Sigma) was pipetted into a solution (750 μL) containing the pro-ligand or complex (final concentration 10^{-3}-10^{-4} M), and glucose, or just glucose alone (final concentration 10^{-4} M). The final total volume was 1250 μL. The solution was monitored by UV−visible spectroscopy at 340 nm every 30 s for 10 min to determine the reaction rate. The reaction rates with and without the pro-ligand or complex were compared to determine if each could inhibit the phosphorylation of glucose by hexokinase.

^{186}Re Radiolabelling. A sealed vial containing 3.5 mg of BH_3·NH_3 was purged with CO gas for 10 min. A solution containing 400 μL of 10^{-3} M solution of H**L**$^{1-5}$ in PBS, 100 μL of 100 MBq of $[^{186}ReO_4]^-$ in saline, and 4.5 μL of 85% H_3PO_4 was added to the vial. A syringe to compensate for any gas evolution was attached to the vial, and the vial was heated at 60 °C for 15 min. Radiochemical yield of ^{186}Re(**L**$^{1-5}$)(CO)$_3$(H$_2$O) was determined by HPLC using Re(**L**$^{1-5}$)(CO)$_3$(H$_2$O) as a standard.

RESULTS AND DISCUSSION

The 3-hydroxy-4-pyridinone moiety is a bifunctional chelate that deprotonates and binds as a monoanionic bidentate ligand, forming a stable 5-membered ring with the metal center. Simple functionalization of the nitrogen of the pyridinone ring gives a remarkable spectrum of ligand designs. In this work we examined the binding of five pyridinone based ligands bearing pendent carbohydrates (*59*). The glucose derivatives are tethered to the pyridinone binding moiety through the C1, C2, or C6 position with linkers of varying length. The solid-state structure of one of the ligands, H**L**^{5}, is reported, and confirms several salient points (Figure 2, Table 1). The structure diagram clearly shows the distance of the glucose derivative, in this case glucosamine, from the pyridinone moiety, suggesting that the carbohydrate will not interact with the metal center upon complexation. As well, the glucosamine moiety is in the common chair conformation. To retain biological activity, minimal hindrance or modification of the glucose derivative is ideal. As H**L**^{5} has one of the shortest tether lengths between the glucose and binding moieties, it can by hypothesized that none of the ligands used in this study will have direct metal-carbohydrate interaction. Although both anomers of the glucosamine are seen in the NMR spectra, (*59*) only one anomer is observed in the crystal lattice, due to preferential crystallization.

The Re**L**$^{1-5}$(CO)$_3$(H$_2$O) complexes were prepared in high yield by three different methods (Scheme 1). Preparation from Re(CO)$_5$Br required a basic buffer system and heating with the ligand, while preparation from $[NEt_4]_2[Re(CO)_3Br_3]$ and $[Re(CO)_3(H_2O)_3]Br$, which have labile Br^- and H_2O ligands respectively, only required heating. All methods were stoichiometric and quantitative as monitored by ^{1}H NMR spectroscopy. Preparation from $[Re(CO)_3(H_2O)_3]Br$ resulted in minimal side-products and was consequently the method of choice, as purification posed difficulties due to the polar nature of the complexes. In cases where recrystallization was not successful and solvent limitations excluded silica and alumina chromatography, semipreparative reverse phase HPLC was used. After purification, yields were between 30−65%.

All complexes were thoroughly characterized by the usual techniques. Electrospray mass spectrometry gave characteristic pairs of peaks with the correct isotopic pattern for Re (^{187}Re 62.6%, ^{185}Re 37.4%). In all cases the H_2O ligand proposed to occupy the sixth coordination site was not observed in the MS. The mass-to-charge ratios observed corresponded to $[M - H_2O + H]^+$ or $[M - H_2O + Na]^+$ for positive ES-MS, and $[M - H_2O - H]^-$ for negative ES-MS. Other peaks corresponding to the free ligand were observed, but are due to fragmentation, as no free ligand is observed in the NMR spectra of the crude or purified complexes. Elemental analysis confirmed the bulk composition of the complexes and included in every case the one water molecule proposed to occupy the sixth coordination site. Most complexes had more than just one water molecule associated with the solid product, common for carbohydrate containing compounds and also observed in the solid-state structure of H**L**^{5} (Figure 2). IR spectroscopy contained similar vibrational frequencies as the ligands, with additional peaks diagnostic of the carbonyl stretches. Three peaks for the carbonyl stretches are expected due to the low symmetry of each compound, one at 2025−2013 cm^{-1} and another at 1907−1883 cm^{-1}, with the broader latter peak attributable to two peaks overlapping.

Both ^{1}H and ^{13}C NMR spectroscopy confirmed the solution structures of the complexes of particular relevance, as radiolabeling is done exclusively in solution. The pendent nature of the carbohydrate groups after complexation was confirmed by the small shifts in carbohydrate-associated ^{1}H and ^{13}C NMR resonances, < 0.02 and 1 ppm, respectively (Figure 3). Large coordination-induced shifts (CIS) would be expected if any of the carbohydrate hydroxyl groups directly interacted with the metal ion. Shifts in the ^{1}H NMR spectra were observed for the pyridinone moiety, confirming binding. For all the complexes, the resonance associated with the hydrogen on the carbon atom adjacent to the binding ketone functionality shifted downfield 0.17−0.19 ppm (Figure 3). In the ^{13}C NMR spectra, the CISs were clearly observed for the carbon atoms bound to the coordinating oxygen atoms, as expected for bidentate chelation. For the ketone carbon, a downfield shift of 3.3−4.7 ppm confirms the dative bond, while the large downfield shift of 12−14.7 ppm for the adjacent hydroxyl carbon verifies the covalent metal oxygen bond. The three CO ligands were also observed in the ^{13}C NMR spectra, but the water molecule associated with the sixth coordination site was not observed in the ^{1}H NMR spectra, possibly due to exchange with the deuterated solvent (water and/or methanol).

Radiolabeling of H**L**$^{1-5}$ with ^{99m}Tc and ^{186}Re was simple, fast and high yielding. For ^{99m}Tc, the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ precursor was heated with excess ligand in PBS to give >95% yield for all ligands except H**L**^{2} (Table 2, Figure 4). The lower yield for H**L**^{2} is due to its lower water solubility. The Isolink

[a] HPLC run on Synergi 4 μm C-18 Hydro RP analytical column, isocratic 1 mL/min, solvent A: 0.1% w/w trifluoracetic acid in water, solvent B: methanol. [b] TLC run on silica plates, developing with 80% ethyl acetate and 20% methanol, analyzed with UV Lamp or RadioTLC. RT given is retention factor.

kits are found to be unsuitable for the preparation of the analogous ^{186}Re precursor, although alternative methods have been used to prepare $[^{188}Re(CO)_3(H_2O)_3]^+$ in good yields (80−90%) (*23*). Although Tc and Re have somewhat similar chemistry, Re is easier to oxidize, and thus reoxidation to perrhenate is facile, especially in basic media with extended heating. Preparing $[^{186}Re(CO)_3(H_2O)_3]^+$ as described in the literature (*14*, *17*) followed by incubation at a 75 °C for 10−30 min gave radiochemical yields <85%, with perrhenate as the major side product. To obtain the same high labeling yields for ^{186}Re as were achieved for ^{99m}Tc, several modifications were necessary. The best method was a one-pot preparation wherein the Re precursor is formed in the presence of the ligand, facilitating quick chelation of the precursor and shorter heating times to minimize reoxidation. The one-pot preparation is optimal for radiopharmaceutical synthesis and gave unprecedented radiochemical yields, for the $[^{186}Re(CO)_3^+]$ core, as high as 99% (Table 2, Figure 4). Again, H**L**^{2} labeled at lower yields due to low ligand solubility. For both ^{99m}Tc and ^{186}Re, the radiolabeled complexes were identified and radiochemical yields determined by either HPLC or TLC using the nonradioactive Re complexes for comparison. At tracer level concentrations of the radiolabeled complexes other characterization methods are precluded.

To assess the stability of the radiolabeled compounds, the ^{99m}Tc labeled species were challenged with an excess of cysteine or histidine, potential metal binding amino acids ubiquitous in vivo. All complexes were stable out to 24 h, suggesting that they would be appropriate for radiopharmaceutical applications

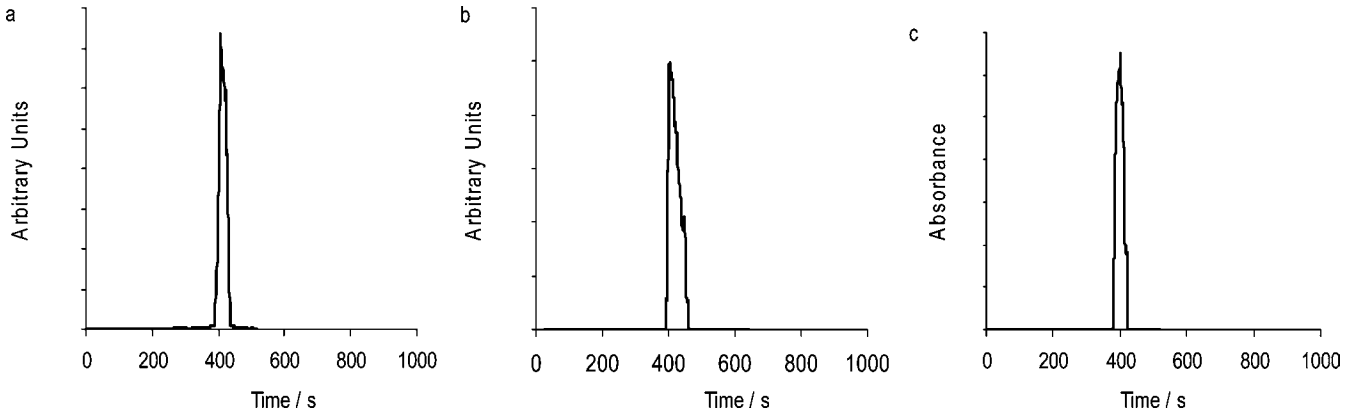

Figure 4. HPLC traces for labeling of H**L**^{5} (a) ^{186}Re(**L**^{5})$(CO)_3(H_2O)$ radiation trace, (b) ^{99m}Tc(**L**^{5})$(CO)_3(H_2O)$ radiation trace, (c) Re(**L**^{5})$(CO)_3(H_2O)$ UV trace.

Table 3. Percentage $^{99m}Tc(L^{1-5})(CO)_3(H_2O)$ Remaining Intact Determined by HPLC after 1, 4, and 24 h in 10^{-3} M Solution of Cysteine or Histidine at 37 °C

	cysteine			histidine		
ligand	1 h	4 h	24 h	1 h	4 h	24 h
H**L**^{1}	99 ± 7	99 ± 6	97 ± 3	95 ± 7	95 ± 3	71 ± 8
H**L**^{3}	99 ± 1	97 ± 2	79 ± 1	99 ± 3	97 ± 2	77 ± 6
H**L**^{4}	99 ± 1	99 ± 1	95 ± 5	99 ± 2	99 ± 4	75 ± 6
H**L**^{5}	99 ± 1	99 ± 1	81 ± 8	98 ± 1	96 ± 3	93 ± 5

(Table 3). At the 1 and 4 h time points, little decomposition was observed in all cases, with >95% of the complex remaining intact. At 24 h some decomposition was observed, mainly due to substitution of the amino acid for the ligand, but >70% of the complex was still intact regardless of which complex was challenged. High stability under these conditions has been reported for other $[^{99m}Tc(CO)_3]^+$ complexes of bidentate ligands, (*15*) but does not obviate the possibility of unfavorable binding of the complex to plasma proteins (*19*).

The optimal imaging properties of FDG partially stem from its unique interaction with hexokinase (HK), the first enzyme in glucose metabolism. FDG is a substrate for HK (*69*), which phosphorylates the sugar at the 6 position, but is not a substrate for the subsequent enzyme in the metabolism pathway. Instead, FDG becomes trapped in the cell and accumulates, resulting in higher resolution imaging than if FDG perfectly mimicked glucose (*1*). Hence, one of the potential targets for the Tc-glucose conjugates, reported herein, is the hexokinase enzyme. Each of the ligands and/or complexes was tested as potential substrates or inhibitors of HK. The free ligands were evaluated as substrates of HK, by monitoring the conversion of ATP to ADP in the presence of ligand and HK; none of ligands were substrates. To determine if other interaction between HK and the ligands could be observed, inhibition studies were completed by monitoring the affect of each ligand on the rate of glucose (the natural HK substrate) conversion. The rate was monitored using a secondary enzyme conversion which is coupled to the conversion of NAD^+ to NADH which can be quantitatively monitored by UV spectroscopy. At the concentrations tested, no inhibitory activity was observed. Other groups have noted inhibition activity of similar Re-carbohydrate complexes, even when no activity was observed for the ligand (*11*). Thus, the complexes Re**L**$^{1-5}(CO)_3(H_2O)$ were also tested for inhibition of HK, but no activity was observed at the concentration tested for the complexes either. At higher concentrations, absorptions of the ligand chromophore interfere with the assay, limiting accuracy at higher concentration for which the ligands or complexes may show activity. Further studies with other potential targets, such as glucose transporters, may show different results.

CONCLUSIONS

This work adds to the type of bifunctional chelates that have been studied with the popular $[M(CO)_3]^+$ core (M = Re, Tc) and broadens the scope of Tc-glucose conjugates. The complexes are well characterized and confirm the pendent nature of the carbohydrate, the bidentate chelation of the pyridinone, and the presence of a water molecule in the sixth coordination site. High yield labeling of the pyridinone-based ligands with both ^{99m}Tc and ^{186}Re was achieved. The one-vial, one-step labeling of ^{186}Re at such high yields is unprecedented and could be easily developed into a kit preparation. Only limited progress of Re labeling with the $[Re(CO)_3]^+$ core has been reported to date, especially with the ^{186}Re isotope, despite its radiotherapeutic potential. All ^{99m}Tc complexes proved to be reasonably stable up to 24 h when challenged with cysteine or histidine solutions, although further stability challenges in plasma and with the ^{186}Re complexes are needed to confirm that the complexes will be stable in vivo. Mixed ligand 2 + 1 complexes, where a second monodentate ligand is added, could be investigated to mask the sixth coordination site and increase the stability of the complexes. This second monodentate ligand would also allow systematic modification of the properties of the complex. Finally, the ligands and complexes were evaluated as potential substrates or inhibitors of the glucose metabolism enzyme hexokinase. Unfortunately, no substrate or inhibitory activity was observed at the concentrations tested. These compounds may still have potential as imaging and therapy agents, if they interact with glucose transporters (some of which are highly expressed in certain tumor types) or if they can accumulate in tumors via another pathway as observed for other promising Tc-glucose conjugates (*8*).

Chemical Conjugate TMV−Peptide Bivalent Fusion Vaccines Improve Cellular Immunity and Tumor Protection

Alison A. McCormick,* Tina A. Corbo, Sherri Wykoff-Clary, Kenneth E. Palmer, and Gregory P. Pogue

Large Scale Biology Corporation, 3333 Vacavalley Parkway, Suite 1000, Vacaville, California 95688. Received May 12, 2006; Revised Manuscript Received July 17, 2006

Chemical conjugation of CTL peptides to tobacco mosaic virus (TMV) has shown promise as a molecular adjuvant scaffold for augmentation of cellular immune responses to peptide vaccines. This study demonstrates the ease of generating complex multipeptide vaccine formulations using chemical conjugation to TMV for improved vaccine efficacy. We have tested a model foreign antigen target—the chicken ovalbumin-derived CTL peptide (Ova peptide), as well as mouse melanoma-associated CTL epitopes p15e and tyrosinase-related protein 2 (Trp2) peptides that are self-antigen targets. Ova peptide fusions to TMV, as bivalent formulations with peptides encoding additional T-help or cellular uptake via the integrin−receptor binding RGD peptide, showed improved vaccine potency evidenced by significantly enhanced numbers of antigen-reactive T cells measured by in vitro IFNγ cellular analysis. We measured the biologically relevant outcome of vaccination in protection of mice from EG.7-Ova tumor challenge, which was achieved with only two doses of vaccine (~600 ng peptide) given without adjuvant. The p15e peptide alone or Trp2 peptide alone, or as a bivalent formulation with T-help or RGD uptake epitopes, was unable to stimulate effective tumor protection. However, a vaccine with both CTL peptides fused together onto TMV generated significantly improved survival. Interestingly, different bivalent vaccine formulations were required to improve vaccine efficacy for Ova or melanoma tumor model systems.

INTRODUCTION

Peptides derived from cancer antigens have been used for more than a decade as cheap, safe, and easy-to-manufacture vaccines that stimulate target-specific immunogenicity (*1*−*6*). Peptide vaccines, typically given as single agents mixed with adjuvant, are taken up by antigen-presenting cells (APC) at the site of injection, and, by processes not well-understood, are cross presented on MHC class I to naive T cells (*7*, *8*). However, peptide vaccines have generally shown limited efficacy in a series of disappointing clinical trials. Although immune responses may be detectible in patients immunized with peptide-based vaccines (*9*−*12*), the functional activation of antigen-presenting cells, induction of antigen-specific $CD4^+$ and $CD8^+$ cells (*13*, *14*), is not sufficient to mediate subsequent tumor clearance or disease regression in the majority of treated patients (*13*, *15*, *16*). Much effort has been made to understand why peptide vaccines have limited efficacy, and new generations of peptide vaccine formulations are being tested with the hopes that they will overcome the limitations of previous peptide−adjuvant formulations.

The importance of the context of antigen presentation to achieve appropriate immune stimulation, especially for self-antigens and breaking tolerance, has led to a recent understanding that vaccines composed of peptides or whole protein antigens generally do not sufficiently stimulate APC activation (recently reviewed in (*17*)). Resulting T-cell responses are often only transient and subject to T-regulatory mechanisms that eliminate antigen-specific reactivity (*18*, *19*). There has been significant effort, therefore, to improve peptide antigen-specific responses by a number of different mechanisms that improve antigen delivery to APCs. First, by using a pathogen to deliver the antigen, by bacterial (*20*, *21*), yeast (*22*), viral vector, or virus-like particle delivery (*23*−*26*). These approaches take advantage of particulate antigen uptake and improved cellular targeting and activation of professional APCs, such as dendritic cells (DCs). Virus expression in mammalian cells and VLP manufacturing, however, are still production-limited processes (*27*). Direct DC pulsing has also proven successful but requires generation of patient-specific DC, which remains costly (*28*). Another method to improve immunogenicity is by association of poorly immunogenic antigens to toxins (*29*−*31*), cytokines (*32*), T-helper epitopes (*33*−*35*), or peptides that improve uptake by APCs (*36*). We have melded two approaches to improve peptide antigen efficacy, by chemically conjugating peptides to the surface of a virus to create a chimeric virus particle, as well as by formulating bivalent fusions with toxin-derived peptides, T-helper epitopes, or peptides that improve uptake.

We have explored the use of the tobacco mosaic virus as an ideal peptide antigen carrier, because it provides an easily manipulated scaffold of >2100 uniform coat proteins that are 17 KDa in size. TMV also contains a +strand RNA that only transcribes in plants, but which may still engage innate antiviral immunity and activate important signaling molecules like Toll-like receptor 7, and thereby stimulate immune activation (*37*−*39*). Many studies have shown that fusions of B-cell epitopes to TMV stimulate high levels of antibody titers, and more recently high levels of tumor-protective CTL responses (*40*). TMV is easily produced on the kilogram scale from infected plants, with low cost of goods, and has shown an excellent safety profile in preclinical tests because it is produced without animal or bacterial byproducts. Using TMV as a CTL peptide antigen carrier by chemical conjugation, we have improved vaccine efficacy by bivalent fusions with toxin-derived peptides, T-helper epitopes, or peptides that improve uptake. We report that, in two different murine tumor models, representing foreign (Ova) and self (melanoma) antigens, bivalent vaccine preparations stimulate significantly improved immune responses, as measured by interferon gamma (IFNγ) secreting cells and survival from lethal tumor challenge. Interestingly, different

formulations are required for Ova or melanoma-effective tumor protective immunity. Peptide antigen delivery on TMV, using less that 1 μg per dose, stimulates these protective immune responses in murine models indicating that this approach has promise for improving the efficacy of clinically relevant peptide vaccines without sacrificing safety.

MATERIALS AND METHODS

Vaccine Production. Chemical conjugation of peptides to TMV required the introduction of a surface-reactive lysine at the N-terminus. In these experiments, a well-characterized lysine-modified TMV (TMV-lys) was used (*30*; M_1 EPMK S_2-YS) that expresses a single reactive lysine (K) residue on the surface of the TMV virion (1295.10; (*41*)). The virus was expressed by transient infection of plants and purified as previously described (*40*−*42*). Purified 1295.10 TMV-lys virus was primed with a 20-fold molar excess of the heterobifunctional linker sulfo-LC-SPDP (hereafter SPDP; Pierce, Rockfold, IL) in PBS/0.05 M EDTA. After dialysis to remove free SPDP, Ova, melanoma p15e, or melamona Trp2 peptide (>95% pure; BioMer Technology, Concord, CA) was added at a 10-fold molar excess and reacted at room temperature overnight (sequences are listed in Table 1). Resulting vaccines, Ova, p15e, or Trp2, were subsequently dialyzed and analyzed by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectroscopy using a Voyager-DE STR Biospectrometry Workstation (Applied Biosystems, Foster City CA) (*40*, *41*). Mass calculations were based on the combined amino acid masses of peptide and TMV-SPDP, determined by *General Protein/Mass Analysis for Windows* software (GPMAW) version 5.0 (Lighthouse Data, Denmark). Differences between expected and observed masses were within MALDI-TOF error of measurement (0.05%; Table 1). Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) (10−20% Tris-Glycine; Invtrogen) and densitometry analysis (BioRad, Hercules, CA; *Quantity One* software) were used to confirm the extent of purity and >90% peptide conjugation efficiency.

Bivalent vaccine formulations were prepared by two methods. First, for most conjugations where peptide sizes were distinguishable by either SDS-PAGE or MALDI-TOF (TT, RGD, E7), 50/50 peptide mixtures were added directly to SPDP-activated TMV and evaluated for approximately 40−45% conjugation of each peptide. In some cases, peptide ratios were adjusted to balance conjugation ratios. For p15e bivalent formulation with Trp2 peptide, where peptide sizes are nearly identical, p15e peptide was added in limiting amounts to generate a TMV conjugate at 50% loading efficiency. Then, Trp2 peptide was added, and on the basis of the reduction of unconjugated TMV coat protein to ∼5%, Trp2 peptide conjugation at ∼45% was confirmed by SDS-PAGE (by the reduction in unconjugated TMV band) and by MALDI-TOF analyses (Table 1).

Vaccination. C57b/6 mice (Harlan Sprague Dawley, Indianapolis, IN) were housed at Antibodies, Inc. (Davis, CA), according to guidelines established in the *Care and Use of Animals*, and protocols were performed according to IACUC approval. Typically, 10 to 15 mice per group were given a 100−200 μL subcutaneuous (s.c.) injection of 10 or 15 μg protein with or without 25 μg of unmethylated CpG oligonucleotide (TCTCCCAGCGTGCGCCAT; (*43*)) having a stabilized phosphorothioate backbone (Oligo's Etc., Inc, Watsonville OR). Vaccines were typically administered at two-week intervals.

ELISpot Analysis of IFNγ T-Cell Secretion. Interferon-γ enzyme-linked immunospot (IFNγ ELISpot) analysis was carried out using an antibody kit, according to manufacturer's instructions (BD/Pharmingen) using membrane filter plates (Millipore, Bedford, MA), and as previously described in detail (*40*). Briefly, single cell suspensions of 2×10^5 spleen cells from each group were plated in 200 μL RPMI complete media with 10^{-5} M Ova SIINFEKL peptide, or 10^{-6} M Ova SIINFEKL peptide, or 10^{-5} M p15e (KSPWFTTL) or Trp2 (SVYDFFVWL) peptides, using a β-gal control (DAPIYTNV (*44*)) for all experiments. PMA/Ionomycin (2.5/250 ng/mL; Sigma, St. Louis, MO) treatment was used as a positive control. Cells were incubated for 22 h at 37 °C in a 5% CO_2 incubator, stained with an IFNγ−horseradish peroxidase (HRP) conjugate, and then developed for HRP reactivity according to the antibody manufacturer's instructions. IFNγ secreting cells were measured as positive spots (intensity, 7−255; size, 22−5000; gradient, 1−90) that were counted on an ELISpot reader (AID, Strasbourg, Germany), and normalized to 10^6 cells after background subtraction (irrelevant peptide stimulation, typically less than 10 spots per 10^6 cells).

Tumor Challenge. EG.7-Ova cells (ATTC, Manassas, VA (*45*)) were grown from a master cell bank for one week and maintained between 0.2 and 2×10^6 cells per milliliter in RPMI complete media. On the day of the tumor challenge, cells were washed three times in Hanks buffered saline solution (HBSS; Invtirogen/Gibco), counted (Vicell XR; Beckman Coulter, Fullerton, CA), and diluted to 2×10^6 cells/mL. 2×10^5 cells in 100 μL final volume (stored on ice until administration) were used to inoculate mice s.c. on the back. All mice showed a single subcutaneous bubble of fluid under the skin, without leakage. B16F1 cells (*46*) were grown in DMEM high glucose with 10% FCS, Glutamax, Pen/strep, Hepes, pyruvate, and nonessential amino acids (Invitrogen/Gibco). B16F1 cells were maintained for one week prior to challenge at ∼20−80% confluence, removed by Trypsin/EDTA treatment for 3 min at room temperature, washed extensively, counted, and resuspended at 5×10^5 cells/mL for delivery of 5×10^4 cells s.c. in 100 μL final volume.

Tumor appearance was monitored by eye for 8−10 days until visible signs of tumor formation were evident. Then, calipers were used to measure the longest and widest point until tumor size was in excess of 2.0 cm^2 or 1.5 cm^2, for Ova or B16 tumors, respectively, at which point animals were euthanized by CO_2 asphyxiation according to IACUC protocol. Tumor volume and survival curve comparison statistics were plotted in *GraphPad Prism 4.0* using Kaplan−Meier log rank analysis.

RESULTS

Chemical conjugate vaccines were prepared using Ova SIINFEKL peptide alone, or as bivalent vaccines combining Ova with T-helper epitopes HPV E7 (*47*, *48*)) or Tetanus toxoid

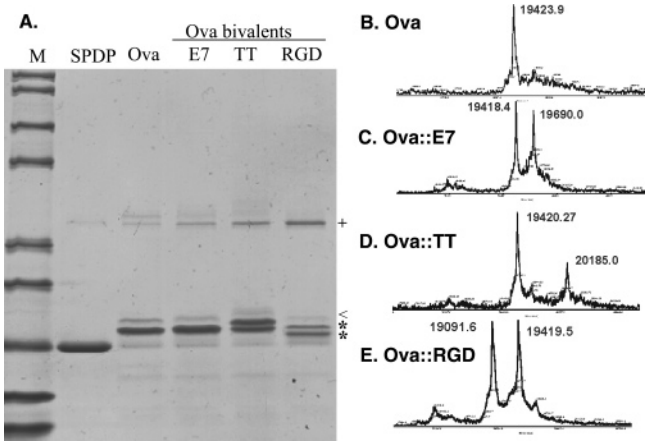

Figure 1. Qualification of TMV Ova conjugate vaccines. (A) SDS-PAGE analysis of SPDP conjugates of Ova peptides, and helper or uptake peptides, to TMV. Monovalent formulation (Ova) or bivalent formulations (::) with E7, tetanus (TT), or RGD uptake peptides are shown as final vaccine formulations, with approximately 45% Ova and 45% additional peptides in bivalent vaccines, compared to 90% conjugation of Ova alone. Single (*) and double (<) peptide additions to TMV are evident, as are TMV dimers (+). (B−E) Mass analysis by MALDI-TOF of each vaccine formulation confirms the presence of both peptides at the correct expected mass shift for monovalent or bivalent formulations, with a minimum of unconjugated free coat protein.

P2 (*49*−*51*)), or with an integrin RGD-binding domain, known to confer cellular uptake on macromolecules (*52*, *53*) and DC targeting of fiber knob modified adenovirus for improved cancer immunotherapy (*54*, *55*). Peptide sequence, mass, as well as expected and observed TMV conjugation mass for each vaccine are described in Table 1. As shown in Figure 1, vaccines were composed of TMV particles with >90% of the coat proteins conjugated with peptide and, to the extent possible, were composed of equal mixtures of Ova and additional epitopes. SDS-PAGE analysis indicates the degree of conjugation and relative percentage of Ova (Figure 1A). Ova peptide conjugation alone results in a clear size shift of TMV coat protein migration compared to TMV-SPDP alone under nonreducing conditions (*). Small amounts of Ova peptide dimers (<) and coat protein multimers (+) are also evident in less than 5% of conjugates. Ova bivalents with E7, though not clearly visible by SDS-PAGE, are evident in more definitive mass analysis (1C). Ova bivalents with tetanus toxoid (TT) and RGD peptides are clearly visible as larger and smaller shifts, respectively, based on peptide length differences (**). Mass analysis by MALDI-TOF (Figure 1B−E) confirms the presence of each correct full-length peptide fusion. The symbol (::) indicates the use of the reducible bond chemical linker to join both epitopes onto the same virus particle.

Vaccination of mice (10−20 μg TMV, normalized for the delivery of 600 ng Ova peptide per dose) was first carried out on a three-dose biweekly schedule with CpG adjuvant, and the results are shown in Figure 2. By IFNγ ELISPot analysis, Ova peptide stimulation of spleen cells from each vaccine group shows that all groups had high levels of activation, especially for a protein antigen (>500 IFN secreting cells, reported as spots per 10^6 spleen cells; Figure 2A) with a nearly 50% increase in the Ova::E7 group at >800 IFNγ spots per 10^6 cells and almost 400% more activated cells in the Ova::RGD bivalent group at

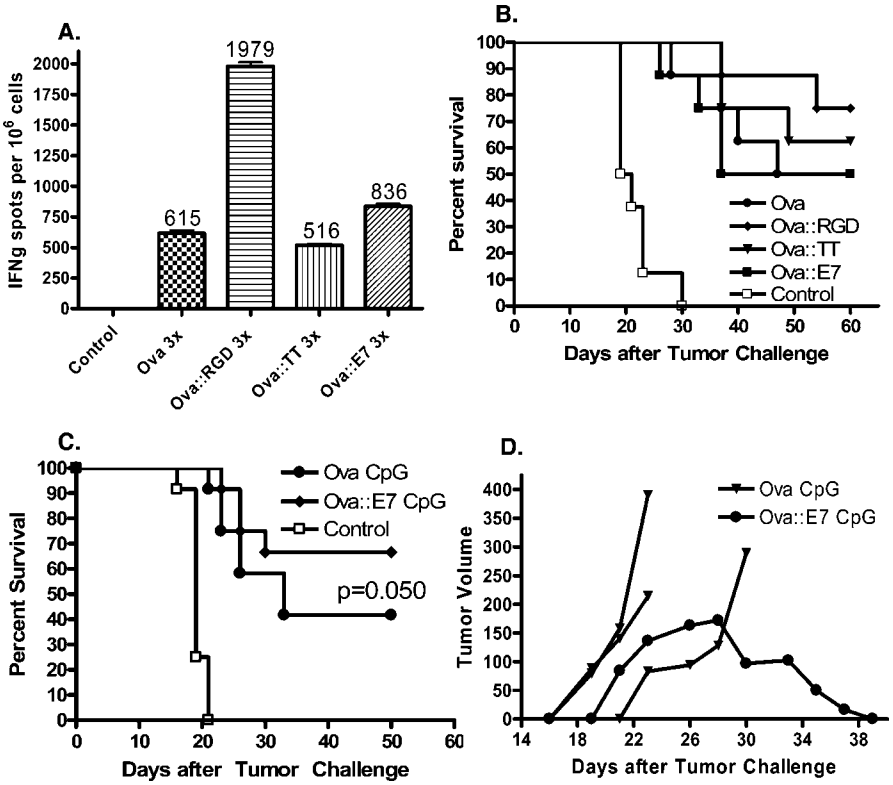

Figure 2. In vivo analysis of vaccine Ova TMV vaccine potency (with CpG DNA adjuvant) by IFNγ ELISpot and EG.7-Ova tumor challenge after three or two doses. (A) Nine days after 3 biweekly s.c. doses of 10 μg Ova TMV vaccines given with 25 μg CpG adjuvant, mice were sacrificed, and 2×10^5 single suspensions of spleen cells were tested on antibody-coated membranes for Ova-specific peptide reactivity (SIINFEKL; 10^{-6} M) after 22 h stimulation by IFNγ ELISpot. Error bars represent variation between 12-well replicates. (B) One day later, the remaining 10 animals were challenged with a lethal dose of 2×10^5 EG.7-Ova tumor cells given s.c., and the tumor area was monitored by the longest and widest caliper measurements after the onset of visible tumor. Mice were euthanized when the area exceeded 2.0 cm^2, and the time of death after tumor challenge recorded; long-term survivors were tumor-free. *GraphPad Prism 4.0* software was used to plot survival curves, and Kaplan−Meier analysis was used to determine significant difference (log-rank, $p = 0.05$). (C) EG.7-Ova survival results after two doses of the same vaccines, given with CpG adjuvant. Only Ova::E7 was statistically improved in comparison to the Ova monovalent control ($p = 0.05$); both groups were better than the control ($p < 0.0001$). (D) Tumor regression was observed in one Ova::E7 mouse, compared to Ova alone.

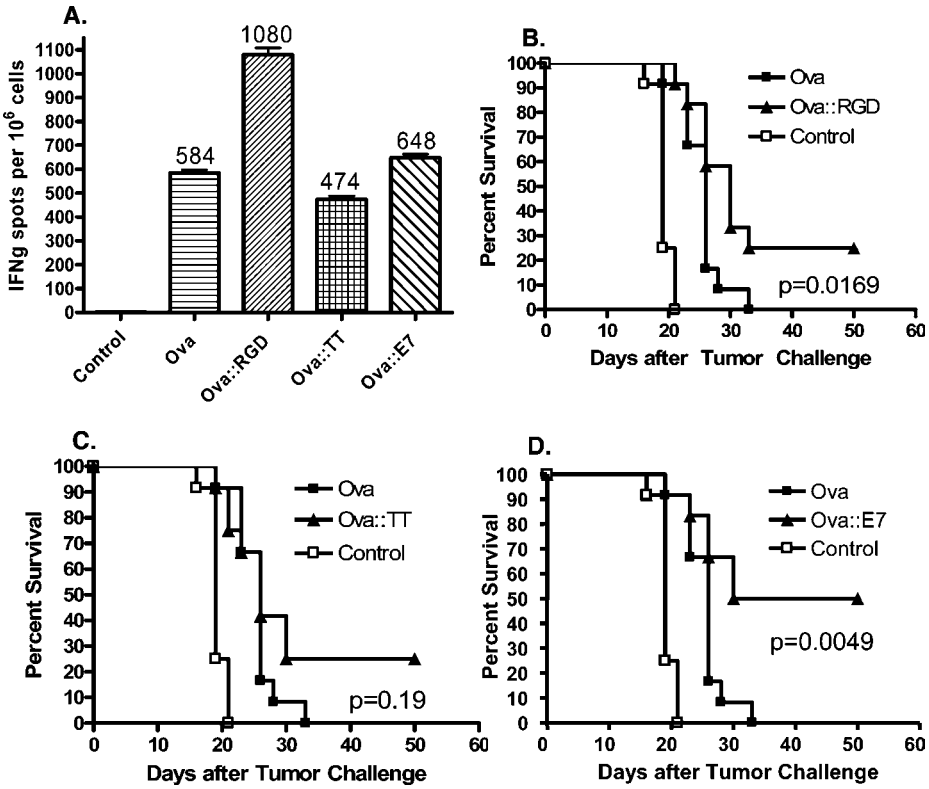

Figure 3. In vivo analysis of vaccine Ova TMV vaccine potency (no adjuvant) by IFNγ ELISpot and EG.7-Ova tumor challenge after two doses. (A) Nine days after two biweekly s.c. doses of 10 μg Ova TMV vaccines given without adjuvant, mice were sacrificed and tested for Ova-specific peptide reactivity (SIINFEL; 10^{-6} M) after 22 h stimulation by IFNγ ELISpot. (B−D) One day later, the remaining 12 animals were challenged with a lethal dose of 2×10^5 EG.7-Ova tumor cells given s.c., and the tumor area was monitored by the longest and widest caliper measurements after the onset of visible tumor and analyzed as in Figure 2. (B) Ova::RGD vaccine stimulated significantly improved survival compared to Ova TMV alone ($p = 0.0169$). (C) Ova::TT vaccine stimulated similar survival compared to Ova TMV alone ($p = 0.19$). (D) Ova::RGD vaccine stimulated significantly improved survival compared to Ova TMV alone ($p = 0.0049$).

nearly 2000 IFNγ spots per 10^6 cells. Ova::TT group had slightly lower numbers of activated cells. When the remaining mice in these groups were challenged with a lethal dose of Ovalbumin expressing EG.7-Ova tumor cells, all vaccine groups had significantly improved survival compared with the control ($p < 0.0001$; Figure 2B), with approximately 50−75% long-term survivors that were tumor-free. Previous experiments confirmed that animals immunized with TMV alone or TMV mixed with an equivalent dose of peptide (unlinked) showed similar survival kinetics compared with PBS controls (data not shown). Although Ova::RGD had the highest IFNγ activation in vitro and the highest percentage of survivors in vivo, this group was statistically similar to all other vaccine groups, including Ova−TMV given as a monovalent vaccine. Such data suggest an immune response threshold has been achieved after vaccination that protects the majority of mice from tumor lethality.

To discriminate between vaccine compositions, we administered only two immunizations normalized to deliver 600 ng of Ova peptide/dose, given with 25 μg CpG DNA adjuvant. All vaccine groups had high levels of IFN secretion by ELISpot analysis (data not shown), and all vaccine groups showed significantly improved tumor protection compared to the PBS control ($p > 0.0001$). Only one group, Ova::E7 CpG, showed improved survival compared with the monovalent Ova−TMV conjugate vaccine (Figure 2C; $p = 0.05$). Also of note, one animal in the Ova::E7 CpG group formed a visible tumor that regressed and was eliminated (Figure 2D), unlike tumors in mice vaccinated with the monovalent Ova−TMV. The figure shows tumor growth curves that are typically observed in three animals that received the Ova monovalent vaccine (triangles), in comparison with the single Ova:E7 vaccine recipient (closed circles), in which we observed clear regression of the tumor. In our experience, and on the basis of a lack of similar findings using the EG.7-Ova tumor model in the literature, peptide-vaccine-induced regression of an established tumor is unprecedented.

To further discriminate between vaccine potencies, we increased the stringency of the challenge. The same groups (as above) were vaccinated in parallel two times without CpG adjuvant. As shown in Figure 3A, in vitro analysis of cellular immunity by IFNγ ELISpot still demonstrated high levels of peptide-stimulated cells in all groups after only two immunizations, with greater than 500 IFNγ secreting (spot forming) cells per 10^6 splenocytes in the Ova−TMV group. Again, there were significantly higher numbers of activated cells in both the Ova::RGD and Ova::E7 groups compared with the monovalent vaccine, and fewer activated cells in the Ova::TT group. These results were remarkably similar to what we measured in an independent analysis after three doses with adjuvant (Figure 2A). A subsequent challenge by Ova expressing EG.7-Ova tumor cells indicates that all vaccine groups showed significantly improved tumor survival patterns in comparison with the control ($p < 0.0001$). However, two doses of the Ova−TMV monovalent conjugate vaccine only generated a significant delay in survival compared to the control, but no long-term survivors. The bivalent Ova::RGD vaccine group, with the highest level of IFNγ secreting cell numbers, performed better than Ova−TMV alone ($p = 0.0169$), with 25% long-term survivors. Ova::TT bivalent vaccine, that stimulated the lowest numbers of IFNγ secreting cells, performed no better than Ova−TMV 2× ($p = 0.19$) even though there were 25% long-term survivors. Ova::E7 outperformed Ova−TMV ($p = 0.0049$) with 50% long-term survivors. The responses of animals immunized with the Ova::RGD and Ova::E7 in the absence of adjuvant confirms the

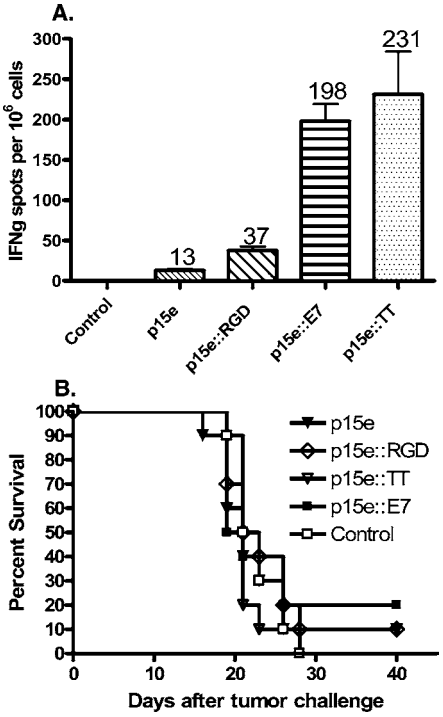

Figure 4. In vivo testing of p15e bivalent vaccine formulation efficacy by IFNγ ELISpot and by B16 tumor challenge. Three doses of 15 μg monovalent p15e vaccine, or peptide equivalent, was given on a biweekly schedule with 25 μg CpG adjuvant. (A) Nine days after the last vaccine, mice were sacrificed, and 2×10^5 single suspensions of spleen cells were tested on antibody-coated membranes for p15e specific peptide reactivity (KSPWFTTL; 10^{-5} M) after 22 h stimulation, by IFNγ ELISpot. (B) One day later, the remaining 10 animals were challenged with a lethal dose of 5×10^4 B16F1 melanoma tumor cells given s.c., and the tumor area was monitored by the longest and widest caliper measurements after the onset of visible tumor. Animals were euthanized when tumor area exceeded 1.5 cm_2; long-term survivors were tumor-free. Survival analysis was completed as in Figure 2.

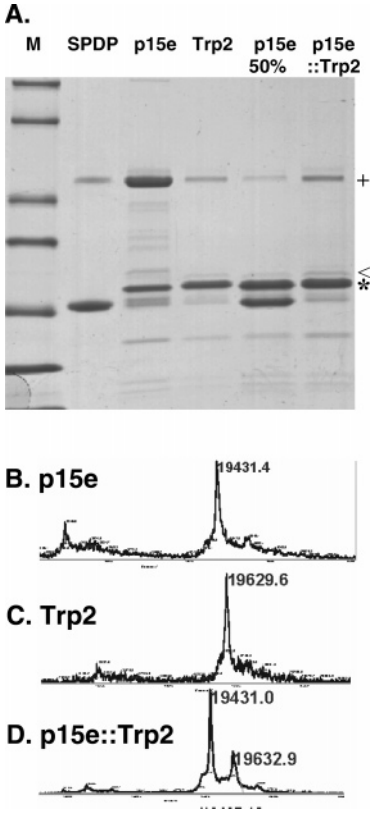

Figure 5. Qualification of TMV melanoma antigen conjugate vaccines. (A) SDS-PAGE analysis of SPDP conjugates of 15e or Trp2 peptides, and helper or uptake peptides, to TMV. Monovalent formulation (p15e or Trp2) or bivalent formulations (::) of p15e with Trp2 peptides combined are shown as final vaccine formulations, with approximately 45% p15e and 45% additional peptides in bivalent vaccines, compared to 90% conjugation of p15e or Trp2 alone. Single (*) and double (<) peptide additions to TMV are evident, as are TMV dimers (+). P15e and Trp2 peptides are of similar mass, so staged addition, first with p15e (50%) then with Trp2, was carried out. (B−D) Mass analysis by MALDI-TOF of each vaccine formulation confirms the presence of peptides fused to TMV with the correct expected mass shift for monovalent or bivalent formulations, with a minimum of unconjugated free coat protein. MALDI-TOF is qualitative, but not quantitative, for peptide addition.

improved efficacy associated with bivalent vaccine formulations when Ova peptide is presented on TMV.

In order to broaden the application of bivalent vaccine formulations, we also tested similar combinations of helper and uptake antigens in combination with a melanoma self-antigen peptide, p15e (*56*). Vaccines were formulated and qualified essentially as described for Ova bivalent vaccines, using SDS-PAGE and densitometry to gauge conjugation efficiency and MALDI-TOF mass analysis to confirm the presence of epitopes (data not shown). After three 15 μg biweekly s.c. vaccinations (~900 ng of peptide) with 25 μg CpG adjuvant, mouse splenocytes were tested for IFNγ secretion by ELISpot. Functionality of the immune response was measured by monitoring survival after challenging vaccinated animals with B16 melanoma tumor. Interestingly, for p15e bivalent vaccinations, p15e::RDG stimulated the lowest number of IFNγ secreting cells, while p15e::E7 and p15e::TT bivalents stimulated high levels of peptide-activated cell numbers after 22 h stimulation with 10^{-5} M p15e peptide (Figure 4A). After s.c. challenge with a lethal dose of B16F1 melanoma tumor cells, there were one or two tumor-free long-term survivors in all vaccine groups, but surprisingly, none of the p15e vaccine formulations provided improved protection compared to the control (Figure 4B).

In addition to testing bivalent formulations with helper or uptake peptides, we also tested the concept of delivering bivalent vaccines prepared from two different melanoma tumor-associated antigens, p15e and Trp 2 protein (*56*). Formulations of monovalent vaccines (p15e or Trp2 alone), mixtures of monovalent vaccines (p15e + Trp2), or bivalent conjugates (p15e::Trp2) were qualified as shown in Figure 5A. The majority of the species have one peptide addition (*), with a minor component of two peptide additions (<) or TMV coat multimers (+). TMV:p15e conjugates, as shown in some reactions, produce a higher proportion of coat multimers, possibly due to the presence of a second reactive lysine in the peptide. Because the p15e and Trp2 conjugation peptides were not sufficiently different in mass to resolve by SDS-PAGE (Figure 5B,C), staged conjugation, first with p15e, then with Trp2, was carried out to ensure approximately equal quantities of both peptides onto SPDP activated TMV, and the presence of the peptide was confirmed by MALDI-TOF (Table 1, Figure 5D).

Bivalent T-cell peptide vaccines were given s.c. three times with CpG adjuvant at 15 μg TMV dose, and mixed monovalent and bivalent conjugate vaccines were given at an equivalent p15e peptide dose each. After three immunizations, mice were tested for protection against tumor challenge in the B16F1 challenge model as described previously (Figure 4).

As shown in Figure 6A, monovalent formulations did not improve survival as compared with the negative control. This was the case, even though tumor dose did not yield fully penetrant lethality (one long-term survivor at 60 d post-challenge). As shown in Figure 6B, the mixture of two monovalent vaccines increased the number of tumor-free long-term survivors to 30% compared with the negative control, but

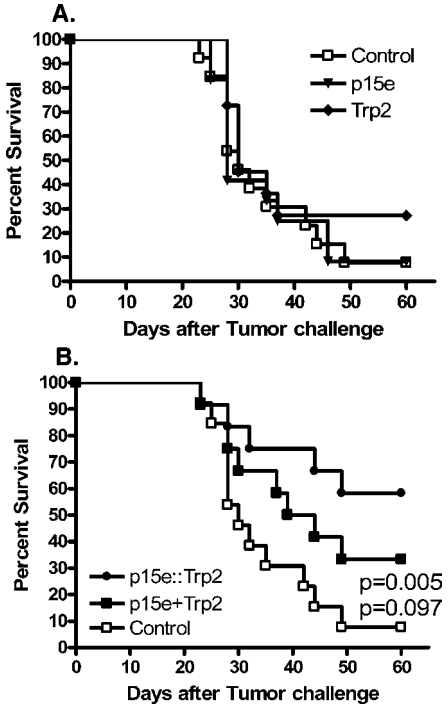

Figure 6. In vivo analysis of alternative TMV melanoma vaccine potency after B16 tumor challenge. After three 15 μg immunizations with 25*g* CpG adjuvant on a biweekly schedule, 12 mice were challenged with a lethal dose of 5×10^4 B16F1 tumor cells. After the appearance of visible tumor, the area was measured by calipers at the longest and widest points, and mice were sacrificed when the tumor area exceeded 1.5 cm^2; long-term survivors were tumor-free. With the time of death after tumor challenge recorded, *GraphPad Prism 4.0* software was used to plot survival curves, and Kaplan−Meier analysis was used to determine significant difference (log-rank, $p = 0.05$). Tumor penetrance was 91.6%, as 1 out of 12 challenged mice did not develop tumor. (A) Monovalent p15e and Trp2 vaccine formulations generated survival similar to the control. (B) Bivalent formulations of p15e with Trp2, either as mixed TMV vaccines (+) or as bivalent formulation on the same TMV (::), were tested. Both groups demonstrated long-term survivors, but only the bivalent formulation significantly improved survival compared to the control (**::** $p = 0.008$ compared to + $p = 0.097$).

this was not significantly different than the control ($p = 0.097$). In contrast, the p15e::Trp2 bivalent vaccine showed statistically improved survival ($p = 0.005$) compared with the control group, with 60% animals among the tumor-free long-term survivor group.

DISCUSSION

These data collectively demonstrate the ease of vaccine formulation and qualification (Figures 1 and 5), and the utility of combining helper, uptake, and additional T-cell targets onto a TMV virus scaffold, to improve Ovalbumin and melanoma specific vaccines. We feel that the flexible nature of the platform allows the rapid assembly of qualified target peptides into a format that has demonstrated active uptake in mammalian lymphocytes (*40*) and effective delivery of peptides in a context that stimulates effective cellular immunity at very low doses of antigen. In these studies, 600 ng of Ova peptide was delivered as a bivalent TMV vaccine with an equivalent dose of RGD, TT, or E7 peptides. In experiments where animals received three doses, given with CpG adjuvant, improvements in overall survival were evident for bivalent vaccine formulations, but none were significantly better than Ova−TMV alone (Figure 2A). When only two doses were given with adjuvant, only Ova::E7 demonstrated improved survival compared with the monovalent Ova vaccine coadministered with CpG adjuvant ($p = 0.05$; Figure 2B), and one animal in this group was actually able to reverse tumor growth after it was 1.5 cm $\times$ 1.1 cm in area (Figure 2C). In a previous study (*40*), we were able to show that after two immunizations on day one and day eight after tumor challenge, Ova−TMV vaccinated mice were protected in comparison to controls, so there is evidence in both experiments that TMV fusions may stimulate therapeutic efficacy. It will be interesting to test whether bivalent formulations can also improve vaccine potency in the presence of pre-existing tumor compared with Ova−TMV.

Using a different immunization approach to increase stringency, we also compared survival in bivalent vaccine groups given only two doses without adjuvant. We measured improved immunogenicity by increased levels of peptide-specific IFNγ secreting cells for Ova::RGD and Ova::E7 bivalent fusions (Figure 3A). These groups also had significantly improved protective immunity to the EG.7-Ova tumor challenge. Overall survival greater than 50% was measured for Ova::E7 vaccines given without adjuvant, which was similar to survival given with CpG DNA (compare Figure 3D Ova E7 to Figure 2A Ova 2x CpG).

These data indicate that TMV can be a very effective antigen delivery scaffold, and more importantly, we could replace adjuvant by formulating Ova conjugate vaccines with T-help or RGD uptake peptides. This is a 1000-fold improvement in efficacy compared to early studies with unconjugated Ova peptide, where 100 μmol doses of peptide were typically given in CFA/IFA adjuvant, in addition to 3 day CpG priming (*35*). It is also the first report, to our knowledge, of T-cell mediated immunogenicity and tumor protection from a synthetic peptide chemical conjugate vaccine given without adjuvant. Similar improvements have been demonstrated by ex-vivo pulsing of DC cells; however, we argue that, because we have previously demonstrated that TMV−antigen is efficiently taken up by DC and other important APCs, we hypothesize that the efficacy improvements we have shown are most likely due to improved in vivo DC uptake and activation, and the potential contribution of $CD4^+$ T help.

Although the helper and uptake peptides were chosen on the basis of their ability to augment immunogenicity in other vaccine applications, it is interesting to note that the ability of each peptide to augment immunogenicity in the context of self or foreign antigen fusions to TMV is quite distinct. E7, a heterologous helper epitope, and RGD, an uptake enhancer, both augment Ova::TMV vaccine immunogenicity, but not p15e self-antigen immunogenicity. It may be that because there is no pre-existing tolerance to Ova, modest improvements in vaccine potency are measurable by increased cellular activation and survival from tumor challenge but are insufficient to overcome immune tolerance.

In our second set of data, we tested similar bivalent TMV vaccine compositions using self-antigen peptides relevant to the murine B16 melanoma model. Although effective for the Ova model, we found in our first experiment that RGD, TT, and E7 bivalent vaccines with the T-cell antigen derived from p15e provided no survival advantage or long-term survival (Figure 4B) even though all p15e bivalent formulations increased the number of peptide-activated IFNγ secreting cells (Figure 4A). Although suggestive of immune induction, there was no strong correlation between IFNγ ELISpot data and tumor protection in either Ova or melanoma studies, indicating that there may be either a threshold of activated cells or a qualitative difference within activated cells, which correlates with survival. Further testing with other relevant ELISpot capture antigens, such as Granzyme B, may improve correlation strength.

Because data presented in Figure 5B did not show improved immunogenicity of p15e bivalent vaccine formulations, we also

created a bivalent vaccine composed of T-cell peptide antigens derived from two different overexpressed melanoma antigens, p15e and Trp2. Immune efficacy would be at least additive if both antigens stimulated cellular immunity independently, minimizing tumor escape from immune surveillance. Figure 6B demonstrates that two T-cell epitopes combined are indeed superior to single antigen fusions given alone, with the best formulation p15e::Trp2 providing 50% protection against tumor challenge. Interestingly, this group also had a single animal with melanoma antigen-specific autoimmunity, as measured by injection-site hair and skin depigmentation (data not shown), which was not evident in other groups in this experiment.

These results collectively demonstrate that TMV is an effective, easily qualified vaccine carrier for stimulating peptide-specific cellular immunity both for single and multipeptide fusions. Peptide vaccines are still being used actively in many recent oncology-related clinical trials (*57*−*65*) as well as in other health applications (*66*, *67*), primarily because these antigens are well-defined and have significant safety advantages. Additional studies have also used KLH conjugation for augmented T-help (*23*), but many obstacles exist in qualifying KLH−peptide conjugates, which has limited widespread clinical use. Our approach to chemically conjugating peptides directly to TMV (which in many animal studies has not induced any toxicity) may allow for stringent vaccine qualification, as well as greatly enhanced immune targeting and antigen delivery to antigen-presenting cells and improved potency, while still maintaining safety. Co-conjugation of additional stimulatory or T-helper epitopes or by generating multiepitope T-cell targets is also easily facilitated using these methods. That multiepitope melanoma vaccines have also recently been tested clinically (*10*, *68*, *69*) supports the further exploration of this type of multivalent vaccine formulation. We feel that TMV could provide superior antigen delivery of current clinically relevant peptides for future clinical use.

Gene Carriers Based on Hexanediol Diacrylate Linked Oligoethylenimine: Effect of Chemical Structure of Polymer on Biological Properties

Julia Kloeckner,[†] Stefano Bruzzano,[‡] Manfred Ogris,[†] and Ernst Wagner*[,†]

Department of Pharmacy, Center of Drug Research, Pharmaceutical Biology-Biotechnology, Ludwig Maximilian University, Butenandtstrasse 5-13, D-81377 Munich, Germany, and Fraunhofer Institute for Applied Polymer Research, Geiselbergstrasse 69, D-14476 Potsdam-Golm, Germany. Received May 23, 2006; Revised Manuscript Received July 28, 2006

Two biodegradable polycations based on hexanediol diacrylate linked oligoethylenimine (OEI) were synthesized by applying different reaction temperatures, 20 °C (LT-OEI-HD) and 60 °C (HT-OEI-HD). Their structural properties were analyzed by NMR, FTIR, and SEC/MALLS (size exclusion chromatography coupled with multiangle laser light scattering detection). Reaction temperature strongly influenced molecular weight and ester/amide ratio and thus resulted in polycations with different biological activities and degradation profiles. LT-OEI-HD was an ester-based polycation of 8.7 kDa which degraded rapidly at pH 7 and pH 9 respectively. HT-OEI-HD had a molecular weight of 26.6 kDa, was mainly based on amides, and degraded more slowly than LT-OEI-HD. Both polymers mediated gene transfer as efficiently as linear polyethylenimine of 22 kDa in two cell lines while being less toxic at their optimal conjugate/plasmid (C/P) ratios. LT-OEI-HD needed higher C/P ratios for gene delivery; however, it was significantly less toxic than HT-OEI-HD.

INTRODUCTION

Clinical application of nonviral gene delivery is still limited by poor gene transfer efficiency and side effects of available transfection agents. Since high transfection activity of commonly used nondegradable polycations usually comes along with a pronounced acute cytotoxicity (*1*, *2*) and an unknown risk of long-term effects after accumulation, there is an urgent need to develop biocompatible and biodegradable polycations with high gene transfer activity.

Currently, many research groups generate biodegradable polycations by cross-linking nontoxic low molecular weight monomers or oligomers with linkers containing labile bonds. Besides disulfide linkages (*3*, *4*), phosphoesters (*5*−*7*), phosphoramidates (*8*), phosphazenes (*9*), or imine linkages (*10*), all types of carbon ester bonds were utilized for the design of degradable polymers (*11*−*17*). In general, linear cationic polyester polymers are reported to degrade fast in aqueous solution (*11*); hence cross-linked poly(amino esters) have been generated to prolong degradation (*18*, *19*). The synthesis of mixed ester/amide polymers is another approach to obtain advantageous degradation profiles (*20*, *21*).

Recently we designed a library of degradable polycations based on oligomerized polyamines (*22*). Cell culture screening revealed polymerized derivatives of 800 Da oligoethylenimine (OEI800) as efficient gene carriers. Similar polymers were previously reported by Gosselin et al. (*3*) and Forrest et al. (*23*). One of the polymers, OEI-HD, i.e., OEI800 cross-linked with equimolar amounts of hexanediol diacrylate (HD), could compete with the "golden standard" linear polyethylenimine of 22 kDa (PEI22) in terms of gene delivery while being less toxic (*22*). Our synthesis of OEI-HD was performed at 60 °C for 4 days in order to obtain a high degree of polymerization. The reaction conditions promoted ester aminolysis and generated the polymer HT-OEI-HD which is predominantly based on amide bonds. Pack and co-workers (*23*) previously had generated a similar but ester-based polymer using different reaction conditions (45 °C for 6 h).

Herein we report an ester-based analogue LT-OEI-HD, synthesized at lower temperature (20 °C), and compare it with the original HT-OEI-HD. Both polymers were analyzed with regard to structural properties and their potential as gene carriers. Despite differences in molecular weight and ester content, the novel LT-OEI-HD has similar DNA binding efficiency as HT-OEI-HD. However, differences were noticed in terms of degradation kinetics, transfection activity, and toxicity. Importantly, when applied at optimum polymer/DNA ratio, the novel gene carrier mediated gene delivery as efficiently as PEI22 and HT-OEI-HD while being significantly less toxic.

MATERIALS AND METHODS

Chemicals and Reagents. Dimethylsulfoxide puriss. (DMSO) was obtained from Fluka (Fluka Chemie GmbH, Deisenhofen, Germany). Oligoethylenimine with an average molecular mass of 800 Da (OEI800), 1,6-hexanediol diacrylate, and branched PEI with an average molecular mass of 25 kDa (PEI25) were obtained from Sigma-Aldrich (Munich, Germany). Linear PEI with an average molecular mass of 22 kDa (PEI22) is available from Polyplus Transfections (Strasbourg, France). PEI22 was also synthesized by acid-catalyzed deprotection of poly(2-ethyl-2-oxazoline) (50 kDa, Aldrich) in analogous form as described in Brissault et al. (*24*). Gel-filtrated PEI was used as a 1 mg/mL stock solution neutralized with HCl. Plasmid pCMVLuc (*Photinus pyralis* luciferase under control of the CMV enhancer/promoter) as described in Plank et al. (*25*) was produced endotoxin-free by Elim Biopharmaceuticals (San Francisco, CA) or Aldevron (Fargo, ND).

Spectroscopy. ^{1}H NMR spectra were recorded at 500 MHz in d_3-MeOH on an Eclipse +500 spectrometer from JEOL, Tokyo, Japan. FTIR spectroscopy was conducted with a FT-IR Paragon 1000 spectrometer from Perkin-Elmer, Boston, MA, using KBr pellets.

Synthesis of High-Temperature Polymer HT-OEI-HD. OEI800 (1.93 mL; 400 mg/mL in DMSO) was mixed at

equimolar ratio with 0.73 mL of HD (300 mg/mL in DMSO) and reacted for 4 days at 60 °C with constant shaking. Prior to purification, polymer samples were diluted 1:4 with H_2O_{dd} and the pH was immediately adjusted to pH 6 (with concentrated aqueous HCl). The diluted unpurified polymer was dialyzed via a Spectra/Por membrane (molecular mass cutoff 3.5 kDa; Spectrum Medical Industries, Inc., California) for 48 h against 4 L of water at 4 °C. After 24 h, water was exchanged against 4 L of fresh water. Synthesis and purification resulted in 157 mg of lyophilized OEI-HD (yield 16%). According to NMR analysis (see below), the molar ratio of hexanediol residues to OEI was 0.5:1; within the hexanediol linker, the ratio of diester to monoester was 20:80.

^{1}H NMR (500 MHz, d_3-MeOH): $\delta = 4.1$ (m, COOCH_2 ester linker, 4^aH, diester, 2^bH, monoester), 3.53 (m, 2^bH, HOCH_2, monoester), 2.6−3.5 (br m, 80H, NCH_2, of OEI ethylenes and NCH_2CH_2COO linker) 1.66 (m, 4^aH, COOCH$_2$CH_2 diester, 2^bH, monoester), 1,52 (m, 2^bH, HOCH$_2$CH_2 monoester), 1.38 (m, 4^{a+b}H, −OCH$_2$CH$_2$CH_2 linker). Integrals: a+b (linker in total), 50% of OEI protons; a (diester), 10%; b (monoester), 40%. FTIR spectroscopy (KBr pellet) showed formation of amide bonds (1638 cm^{-1}) and a weak signal of remaining ester bonds (1718 cm^{-1}).

Synthesis of Low-Temperature Polymer LT-OEI-HD. Four milliliters of OEI800 stock (400 mg/mL in DMSO) was mixed at equimolar ratio with 1.51 mL of HD stock (300 mg/mL in DMSO) and reacted for 4 days at 20 °C with constant shaking. Purification was performed as described above and resulted in 224 mg of lyophilized LT-OEI-HD (yield 11%). According to NMR analysis (see below), the molar ratio of hexanediol residues to OEI was 1.25:1; within the hexanediol linker, the ratio of diester to monoester was 50:50.

LT-OEI-HD: ^{1}H NMR (500 MHz, d$_3$-MeOH) $\delta = 4.1$ (m, COOCH_2 ester linker, 4^aH, diester, 2^bH, monoester), 3.54 (m, 2^bH, HOCH_2, monoester), 2.6−3.5 (br m, 80H, NCH_2, of OEI ethylenes and NCH_2CH_2COO linker), 1.66 (m, 4^aH, COOCH$_2$CH_2 diester, 2^bH, monoester), 1.54 (m, 2^bH, HOCH$_2$CH_2 monoester), 1.40 (m, 4^{a+b}H, −OCH$_2$CH$_2$CH_2 linker). Integrals: a+b (linker in total), 125% of OEI protons; a (diester), 62%; b (monoester), 62%. FTIR spectroscopy (KBr pellet) clearly showed strong ester signals (1725 cm^{-1}).

Size Exclusion Chromatography with Multidetection. The samples were analyzed by size exclusion chromatography (SEC) (Degasser SCM 400, isocratic pump P1000 and auto sampler AS 1000 from Spectra Physics, Egelsbach, Germany; TSK columns (polyglycidyl(meth)acrylate gel) PWH-Guard (7.5 × 37 mm, 12 μm) + G-Oligo-PW0 (7.5 × 300 mm, 6 μm) up to 3×10^3 g/mol (PEG) by Toso Haas, Stuttgart, Germany) linked with a multidetection system (viscosimeter η/Δn-1003 from WGE Dr. Bures, Dallgow, Germany; multiangle laser light scattering (MALLS) detector Dawn DSP, 632.8 nm, cell type K5; 18 detectors from 22.5° up to 147° from Wyatt, Woldert, Germany; OPTILAB DSP interferometric refractometer, 632.8 nm, cell type P10 from Wyatt, Woldert, Germany; UV−vis detector UV 2000 by Spectra Physics, Egelsbach, Germany; software Astra 4.7 from Wyatt, Woldert, Germany). The accuracy and repeatability of the determined molar masses is about ±10 and ±3%, respectively. A mixture of 0.2 mol/L Na_2SO_4 and 1% (w/w) acetic acid in deionized water was used as eluent. The flow rate was 1.0 mL/min at 20 °C using a sample loop of 100 μL and sample concentrations of 1 to 4 g/L.

The refractive index increment of a branched polyethyleneimine standard was determined by the means of interferometric measurements (ScanRef; Polymer Standards Service, Mainz, 633 nm, 20 °C). For this purpose, polyethylenimine (molecular mass ∼ 50 000 Da, 37% aqueous solution from Aldrich) was ultrafiltrated (Minisette, Omega cutoff 10 kDa from Pall Gelman), freeze-dried, and afterward solved in the eluent. A value of dn/dc = 0.195 mL/g was found. Molar masses determined for HT-OEI-HD and LT-OEI-HD samples were compared to those of commercially available branched PEIs (Lupasol G100, 5000 Da, and G20, 1300 Da).

For use in some gene transfer studies, fractions of HT-OEI-HD were chromatographically separated as described above and samples F1 and F2 were concentrated via macroseparators (Omega 3k (PALL), 4000 rpm, 20 min). The procedure was accomplished 5 times, and resulting sample solutions were analyzed again by SEC.

Degradation of HT-OEI-HD and LT-OEI-HD. Degradation was studied with polymer stocks (5 mg/mL, pH 7) incubated for 5, 10, and 15 days at 37 °C in an Eppendorf Thermomixer (500 rpm). Solutions with a pH of 5 and 9 were prepared by adding the appropriate amount of HCl and NaOH, respectively. After incubation, the pH was adjusted to pH 7. Sample aliquots were analyzed by SEC on a Sephadex G25 (10/30) with 150 mM NaCl as eluent and a flow rate of 1 mL/min. Sample detection was carried out at 210, 220, and 240 nm, and degradation rates were calculated by integrating the AUC (area under the curve) of the main polymer peak.

Ethidium Bromide (EtBr) Exclusion Assay. Aliquots of OEI-HD, LT-OEI-HD, PEI22, or PEI25 were added sequentially to a DNA solution (20 μg/mL) in either HBG (Hepes buffered glucose; 20 mM Hepes pH 7.3 plus 5% w/v glucose) or HBS (Hepes buffered saline; 20 mM Hepes pH 7.3 plus 150 mM NaCl) containing 400 ng/mL EtBr, and the decrease of fluorescence was measured in a Varian Cary Eclipse fluorescence spectrophotometer (Varian, Mulgrave, Australia). EtBr/DNA fluorescence (λex 510 nm, λem 590 nm) was set to 100% prior to addition of polycation.

DNA Polyplex Formation. Plasmid DNA encoding luciferase was condensed with standard PEI or biodegradable polymers at various conjugate/plasmid (C/P) ratios (w/w). C/P = 1 presents a N/P ratio = 5.3 for HT-OEI-HD, N/P = 4.9 for LT-OEI-HD, and N/P = 7.6 for PEI. DNA/polycation polyplexes were prepared at a final DNA concentration of 20 μg/mL as described in ref *26*. Briefly, indicated amounts of plasmid DNA and polycation were each diluted in either HBS or HBG and rapidly mixed by pipetting. Polyplexes were allowed to stand for at least 20 min at RT before use.

Cell Culture. Cell culture media, antibiotics, and fetal calf serum (FCS) were purchased from Invitrogen GmbH (Karlsruhe, Germany). All cultured cells were grown at 37 °C in 5% CO_2 humidified atmosphere. Stock cultures were grown in the absence of antibiotics. B16F10 murine melanoma cells (kindly provided by I. J. Fidler, Texas Medical Center, Houston, TX) and murine neuroblastoma Neuro2A cells (ATCC CCI-131) were cultured in DMEM (1 g of glucose/L) supplemented with 10% FCS.

Luciferase Reporter Gene Expression. For standard transfection screenings cells were seeded in 96-well plates (TPP, Trasadingen, Switzerland) at a density of 10^4 cells (Neuro2A cells) or 5×10^3 cells (B16F10 cells) in 100 μL of culture medium per well. During transfection and for the following incubation before analysis, 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% FCS were present in the medium. Transfection complexes with indicated amounts of DNA (pCMVLuc) were added directly to the cells. Complex-containing medium was removed 4 h after transfection, 100 μL of fresh medium was added, and gene expression was measured after 24 h.

Cell lysis and measurement of luciferase was performed as described previously (*2*). Two nanograms of recombinant luciferase (Promega, Mannheim) corresponds to 10^7 light units.

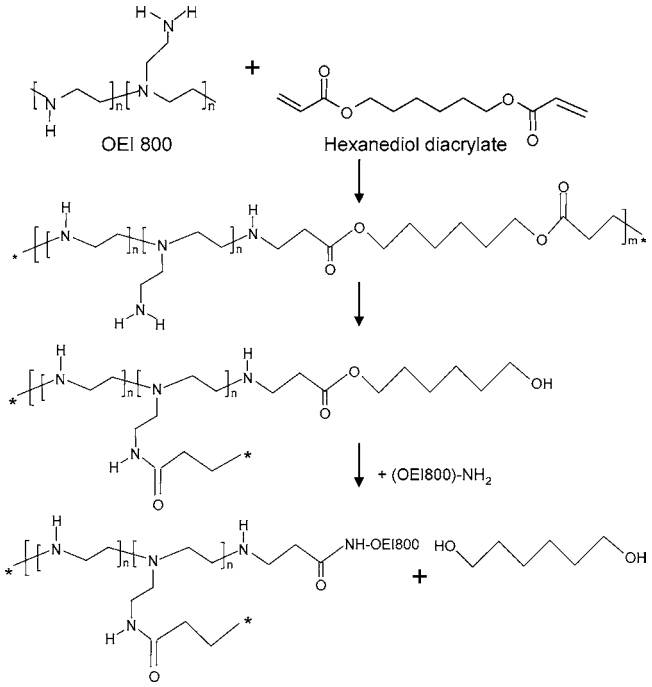

Figure 1. Synthesis of HT-OEI-HD and LT-OEI-HD. The HD (hexanediol diacrylate) linker reacts with primary and secondary amines of oligoethylenimine (OEI) to form amine bonds. At elevated temperature, amino groups of the OEI unit attack ester bonds, resulting in mixed ester/amide-based oligomers. With time, aminolysis of the esters releases the hexanediol moiety from the polymer, resulting in amide-linked derivatives of oligoethylenimine.

Metabolic Activity of Transfected Cells. Cells were grown (96-well plate) and treated with different amounts of DNA complexes as described in Luciferase Reporter Gene Expression. Metabolic activity of each well was determined by using a methylthiazoletetrazolium (MTT)/thiazolyl blue assay: To each well was added 10 μL of a 5 mg/mL solution of MTT in sterile PBS buffer (phosphate buffered saline; 150 mM NaCl buffered with 15 mM phosphate pH 7.4). Cells were incubated at 37 °C for 2 h, medium was removed, and the samples were frozen at −80 °C for at least 2 h. One hundred microliters of DMSO was added and samples were incubated at 37 °C for 30 min with constant shaking. Optical absorbance was measured at 590 nm (reference wavelength 630 nm) using a micro plate reader (Spectrafluor Plus, Tecan Austria GmbH, Grödig, Austria), and cell viability was expressed as a percent relative to untreated control cells.

RESULTS

Synthesis of OEI-HD Polymers. The 1,6-hexanediol diacrylate (HD) linker reacts with polyamines by Michael addition to either primary or secondary amines, generating ester-based polymers. In a following reaction, free amino groups may convert ester-containing polymers into amide derivatives by aminolysis of the esters **(**Figure 1). This side reaction depends on reaction temperature and the availability of supplementary free amines. In order to circumvent ester aminolysis and to generate mostly ester-containing polymers, a new OEI-HD derivative was synthesized at low temperature. The synthesis of LT-OEI-HD was carried out for 4 days at 20 °C instead of 60 °C (HT-OEI-HD). Polymers were purified by dialysis using a 3.5 kDa molecular mass cutoff membrane.

Polymer structures were analyzed by FTIR spectroscopy. LT-OEI-HD contained ester bonds (1725 cm^{-1}). In contrast, FTIR spectra of HT-OEI-HD showed only a weak signal of remaining ester bonds (1718 cm^{-1}) and the formation of amide bonds (1638 cm^{-1}). ^1H NMR confirmed the presence of ester bonds

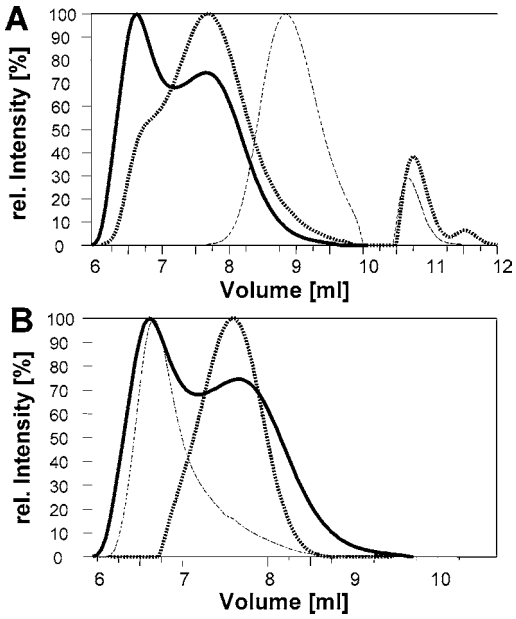

Figure 2. Fractionation and molar mass determination of polymers by SEC/MALLS. (A) SEC traces of the precursor OEI800 (dashed line) and its derivatives LT-OEI-HD (spotted line) and HT-OEI-HD-1 (solid line). Relative intensities of the refractive index detector signal are shown. Both derivatives show broad molar mass distributions, and higher molecular fractions eluting close to the column's exclusion limit (<6.7 mL) are not separated. (B) SEC traces of the standard HT-OEI-HD-1 (solid line) and its two fractions of higher (dashed line with spots) and lower (spotted line) molar masses.

in the product. Although FTIR spectra indicated extensive ester aminolysis in case of HT-OEI-HD, both polymers (HT-OEI-HD and LT-OEI-HD) clearly showed the protons belonging to methylene groups of the linker. The hexanediol chain of the HD linker was still present in both polymers, although the ratio between linker and OEI was very different. In the case of LT-OEI-HD, a molar ratio of linker to OEI of 1.25 was found, with 0.6 molar equiv of hexanediol linker preserved as diester. For the HT-OEI-HD polymer, a molar ratio of linker to OEI of 0.5 was found, with only 0.1 molar equiv of the hexanediol diester, as 80% of the linker was found converted into the monoester.

Molar Mass Determination and Polymer Fractionation. Polymer molar mass was analyzed by aqueous size exclusion chromatography (SEC) linked with a MALLS (multiangle laser light scattering) system, employing 0.2 M Na_2SO_4 + 1% HAc as eluent. Samples of different molar masses were successfully separated on a TSK-Gel Guard + G-Oligo-PW column (Figure 2). The elution profiles of HT-OEI-HD, LT-OEI-HD, and the precursor OEI800 are shown in Figure 2A. The ratio of RI (refractive index) and UV (254 nm) detection signals remained basically constant during the separation, demonstrating the same chemical composition of the polymer fractions. Absolute molar mass was determined with a MALLS detector and compared to commercially available low molecular weight PEIs **(**Table 1**)**. LT-OEI-HD had an average molar mass of 8.7 kDa, whereas HT-OEI-HD had a higher average molar mass of 26.6 kDa. The detected d*n*/d*c* of 0.21 mL/g correlated well with the d*n*/d*c* of the PEI reference (d*n*/d*c*(PEI) = 0.195 mL/g at 633 nm). Using the same SEC methodology, HT-OEI-HD was separated into two fractions F1 and F2, with average molar masses of 45.6 kDa and 9.5 kDa, respectively (Figure 2B and Table 1).

Polymer Toxicity and Degradation. Cytotoxic properties of a polycation usually correlate with the molecular weight. A decrease in molecular weight upon biological degradation should result in reduced toxicity of the polymer. Therefore, cytotoxicity of intact HT-OEI-HD and LT-OEI-HD was compared. In addition, cytotoxicity of the corresponding degradation products

Table 1. Molecular Mass Determination by SEC/MALLS[a]

	recovery (%)	Vp (mL)	Eta (mL/g)	Mp^{LS} (kDa)	Mw^{LS} (kDa)

fraction 1[b]		6.62		23.1	45.6
fraction 2[c]		7.61		4.7	9.5
LT-OEI-HD	90	7.71	11,5	4.6	8.7

[a] Vp: elution volume at peak maximum. Eta: bulk intrinsic viscosity. Mp: molar mass at peak maximum measured via static light scattering. Mw: mass average molar mass via static light scattering. [b] F1: fraction of higher molar mass. [c] F2: fraction of lower molar mass.

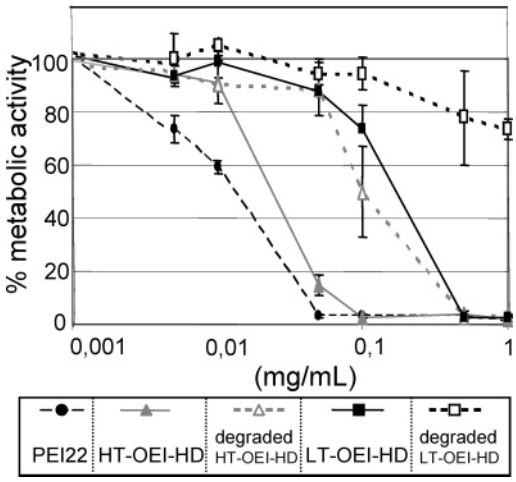

Figure 3. Cytotoxicity induced by OEI-HD polymers. HT-OEI-HD and LT-OEI-HD (5 mg/mL) were incubated at pH 9 for 5 days at 37 °C. B16F10 cells (5000 cells/well) were incubated with various concentrations of hydrolyzed and untreated polymer. After 4 h, polymer-containing medium was exchanged, and 24 h later, metabolic activity was determined by the MTT assay. Metabolic activity is presented as mean values of triplicates.

was determined. For this purpose, B16F10 cells were incubated with various amounts of free polymer for 4 h. After 24 h, the metabolic cell activity was determined by MTT assay and compared to untreated control cells. At a high polymer concentration of 50 μg/mL, PEI22 and HT-OEI-HD decreased metabolic activity down to 3% (PEI22) and 15% (HT-OEI-HD), whereas cells that were treated with the same amount of LT-OEI-HD retained 88% of their metabolic activity **(**Figure 3**)**.

For the degradation studies, both polymers were treated in aqueous solutions at pH 5, 7, and 9 at 37 °C for 5 to 15 days as described in Materials and Methods. The results of size exclusion chromatography (SEC) demonstrated that LT-OEI-HD was reduced to 68% ± 2% (pH 5), 51% ± 3% (pH 7), and 38% ± 3% (pH 9) of original polymer after 5 days of hydrolysis. As expected, HT-OEI-HD was less susceptible to hydrolysis since degradation could barely be observed after 5 days. Ten days of hydrolysis resulted in 94% ± 1% (pH 5), 77% ± 1% (pH 7), and 72% ± 2% (pH 9) of original polymer.

Interestingly, although the degradation of HT-OEI-HD was limited, it was sufficient to significantly reduce the toxicity (Figure 3) when the polymer was applied at lower doses (5−50 μg/mL). However, concentrations above 500 μg/mL strongly disturbed viability and resulted in 2−3% metabolic activity. After hydrolysis of LT-OEI-HD the degraded fragments exhibited negligible toxicity even at polymer concentrations up to 1000 μg/mL.

DNA Binding and Polyplex Formation. Next, the two OEI-HD polymers were evaluated for their ability to form DNA complexes. EtBr exclusion experiments demonstrated that DNA

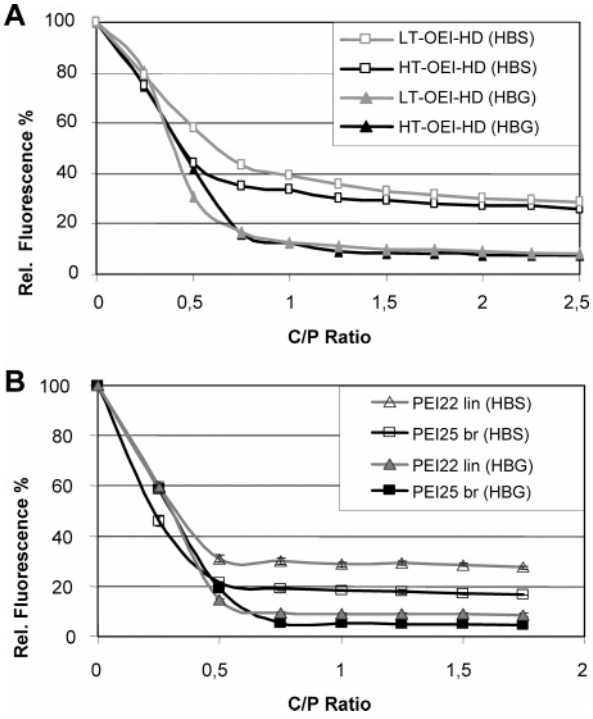

Figure 4. DNA binding and complex density of HT-OEI-HD and LT-OEI-HD. DNA complexes of HT-OEI-HD and LT-OEI-HD (A) or linear PEI22 and branched PEI25 (B) were formed in the presence of EtBr in either HBG or HBS, and inhibition of EtBr/DNA fluorescence was monitored as described in Materials and Methods. Measurements were performed in duplicate.

binding activity was not affected by differences of molecular weight or ester/amide content. Both polymers possessed similar DNA binding affinities (Figure 4A). In salt-free buffer (Hepes buffered glucose), the EtBr exclusion profiles were very similar to the profiles of linear PEI22 and branched PEI25 **(**Figure 4B**)**. In physiological salt-containing buffer (Hepes buffered sodium chloride), affinities of the OEI-HD polymers and PEI22 were comparable but slightly lower than for PEI25. Analogous trends of complexation and polyplex stability were observed using the agarose gel retardation assay. In the case of HT-OEI-HD as well as for LT-OEI-HD, DNA was completely retarded at C/P 1 (data not shown).

Reporter Gene Expression and Toxicity of HT-OEI-HD and LT-OEI-HD Polyplexes. Neuro2A cells were transfected with either HT-OEI-HD or LT-OEI-HD in order to investigate how structural differences will influence transfection efficiency and cytotoxicity of polyplexes. At C/P 2, HT-OEI-HD achieved maximal reporter gene expression **(**Figure 5A**)**, which decreased with increasing amount of polymer due to rising cytotoxicity **(**Figure 5B**)**. Although higher charge ratios (C/P 8) were needed for optimal gene delivery, LT-OEI-HD polyplexes were able to mediate gene transfer as efficiently as HT-OEI-HD without reducing the metabolic activity of transfected cells.

In order to verify these biological effects on a second cell line, different DNA concentrations were tested on B16F10 cells **(**Figure 5C**)**. According to previous experiments, HT-OEI-HD polyplexes prepared at C/P 2 were as efficient as PEI22. Polyplexes of LT-OEI-HD prepared at C/P 4 had efficiency similar to that of standard PEI polyplexes. With regard to toxicity, PEI22 and HT-OEI-HD exhibited pronounced toxicity even at low DNA concentrations, whereas LT-OEI-HD did not influence the metabolic activity of B16F10 cells at these concentrations **(**Figure 5D**)**. Generally, B16F10 cells were more sensitive than Neuro2A cells when treated with polyplexes. Metabolic activity determined 24 h after transfection was reduced by PEI22 to less than 20% of the nontransfected control

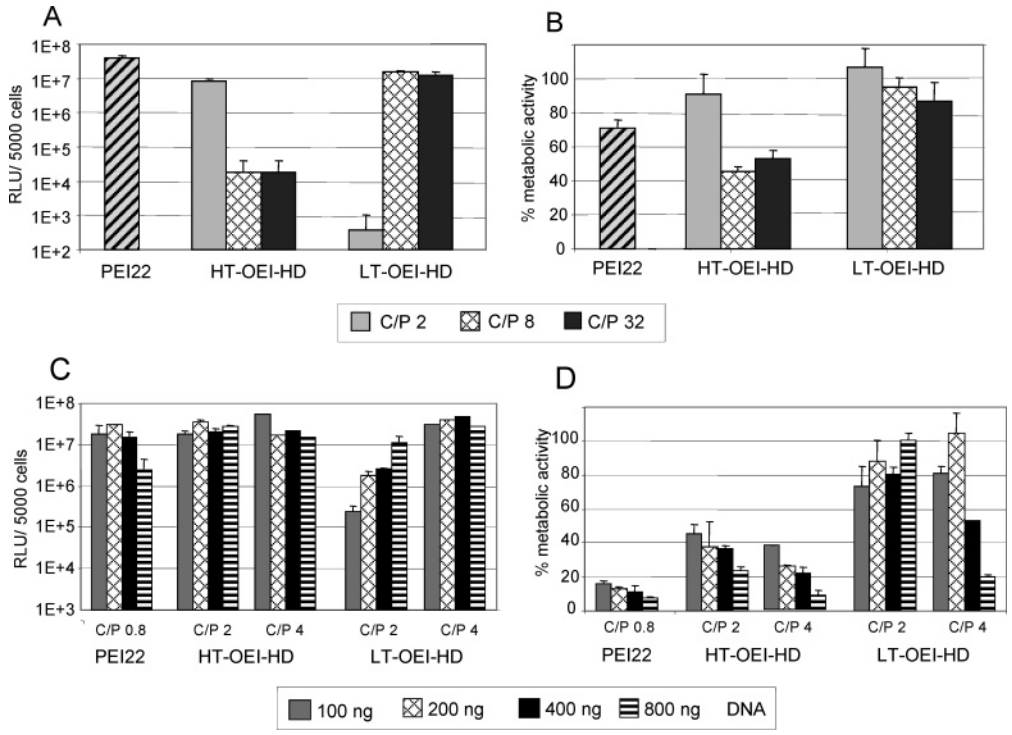

Figure 5. Reporter gene expression and toxicity after transfection with OEI-HD polymers. Neuro2a cells were transfected with polyplexes consisting of 200 ng (2 μg/mL DNA) of pCMVLuc complexed with HT-OEI-HD or LT-OEI-HD in HBS (A and B). B16F10 cells were transfected with 100−800 ng (1−8 μg/mL DNA) of pCMVLuc complexed with HT-OEI-HD or LT-OEI-HD at C/P 2 and 4 in HBS (C and D). Control PEI22 polyplexes were prepared at C/P 0.8 in HBS. Luciferase activity (A and C) and metabolic activity (MTT assay) (B and D) are presented as mean values + SD of triplicates.

cells **(**Figure 5D**)**. When cells were transfected with C/P 2 polyplexes containing 800 ng of DNA, HT-OEI-HD reduced metabolic activity down to 22% while cells transfected with LT-OEI-HD polyplexes maintained 100% of their metabolic activity. Cell viability was only affected by LT-OEI-HD when high doses of polymer and DNA were applied. Transfection with 400 ng of DNA and 1.6 μg of polymer (corresponding to C/P 4) resulted in 54% metabolic activity, which dropped to 20% at the maximal DNA dose.

Transfection Efficiency of Fractionated HT-OEI-HD. According to SEC analysis, HT-OEI-HD showed a broader molecular weight distribution with a higher average molecular mass of 26.6 kDa. To find out whether the larger or the smaller fraction is more efficient than the other, fractions F1 and F2 were collected and analyzed separately with regard to their gene transfer efficiency. B16F10 cells were transfected with HT-OEI-HD (nonpurified), fraction 1 (F1), fraction 2 (F2), and LT-OEI-HD **(**Figure 6A**)**. While standard OEI-HD reached maximal reporter gene expression at C/P 4, both F1 and F2 needed higher C/P ratios for efficient gene delivery. At C/P 8, F1 resulted in luciferase expression equivalent to that of PEI22 and HT-OEI-HD, whereas F2 was effective only at C/P 16. Neither of the purified fractions was more effective than the unpurified polymer. At the current stage the reasons for this remain unclear. It is also noteworthy that there was a difference between LT-OEI-HD and F2, although both polymers possessed similar molecular weight. LT-OEI-HD mediated efficient gene transfer at all analyzed C/P ratios and achieved maximal reporter gene expression at C/P 8 whereas F2 was characterized by poor transfection activity at low C/P ratios.

A clear correlation between molecular weight and toxicity was observed for all polymers **(**Figure 6B**)**. Cell viability decreased rapidly when cells were transfected with HT-OEI-HD or F1 polyplexes, while low molecular weight polymers (LT-OEI-HD and F2) were far less toxic.

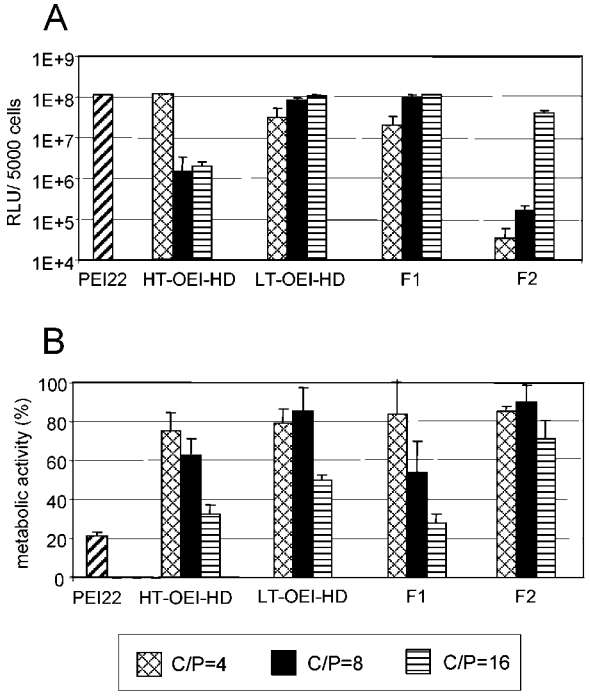

Figure 6. Reporter gene expression and toxicity of HT-OEI-HD after fractionation by SEC/MALLS. B16F10 cells were transfected with 200 ng (2 μg/mL DNA) of pCMVLuc complexed with HT-OEI-HD (nonpurified), LT-OEI-HD (8.7 kDa), HT-OEI-HD fraction 1 (53 kDa), and fraction 2 (8.1 kDa) at C/P 4 (gray bars), C/P 8 (patterned bars), and C/P 16 (black bars) in HBS. Control PEI 22 polyplexes were prepared at C/P 0.8. Luciferase activity (A) and metabolic activity (MTT assay) (B) are presented as mean values + SD of triplicates.

DISCUSSION

Previously we reported an OEI-HD polymer with high potential as a gene carrier (*22*). In contrast to a previously

published (*23*) analogous polymer, our synthesized polymer was predominantly based on amide bonds due to ester aminolysis as a result of a higher reaction temperature. Since structural properties impact both transfection activity and toxicity (*27*, *28*), we aimed to modify the synthesis protocol in order to generate faster degrading ester-based polymers (*23*) and compare them side-by-side with the amide-based polymers. Ideally, such OEI-HD ester derivatives should exhibit equivalent transfection efficiency while being less toxic.

The novel OEI-HD analogue, namely, LT-OEI-HD, was synthesized at 20 °C instead of 60 °C. According to FT-IR and NMR analysis, LT-OEI-HD largely had the predicted ester structure whereas HT-OEI-HD contained mainly amides with few esters left. Moreover, partial diester degradation was observed by the appearance of protons belonging to the methylene groups adjacent to hydroxyl groups; HT-OEI-HD lost 80% of hexanediol residue due to ester aminolysis. This demonstrates that high reaction temperature promoted inter- or intramolecular ester aminolysis.

In consideration of these structural differences, the ester-based LT-OEI-HD should be degraded under hydrolytic conditions, whereas the amide bonds of HT-OEI-HD should be more stable. Degradation studies at pH 5, 7, and 9 revealed that hydrolysis of both polymers were accelerated with increasing pH. Moreover, during the analyzed period of time (15 days), only slight alterations (∼30% degradation) were observed for HT-OEI-HD. This slow amide hydrolysis of HT-OEI-HD was in accordance with results previously reported by Kissel and his group. Their copolymer poly(ethylene-*co*-L-lactamide-*co*-succinamide) degraded via base-catalyzed hydrolytic cleavage of amide bonds over months (*20*).

Hydrolysis of LT-OEI-HD was confirmed by a rapid decrease of original polymer. After 5 days, more than 60% of LT-OEI-HD was cleaved into smaller fragments when incubated at pH 7 or pH 9. Incubation at pH 5 resulted in significantly slower degradation of LT-OEI-HD within the first 15 days. These data are in accordance with degradation profiles observed for hyperbranched poly(amino esters) (*17*). They explained rapid degradation at pH 7.4 and slow-going hydrolysis at pH 5.1 by the fact that at pH 7.4 a higher fraction of unprotonated amino groups in the polymer catalyzes the hydrolysis of ester groups.

Nevertheless, it was not yet clear whether these changes in polymer integrity would have any effect on cytotoxicity. To elucidate the impact of polymer degradation on toxicity, we analyzed metabolic activity of cells treated with either original or partially degraded polymer. In fact, moderate changes in molecular weight distribution that seemed unimportant with regard to SEC data had significant impact on the cytotoxicity of polymers. Even HT-OEI-HD-induced toxicity (which was very significant at high polymer concentrations) was strongly reduced after 5 days of hydrolysis. Degradation of the less toxic LT-OEI-HD resulted in nontoxic oligomer fragments. It should be noted that cytotoxicity induced by free polymers gives a worst case estimate for the interaction with cells and tissues (*27*, *29*). Toxicity of nonviral vectors usually decreases when polymers are complexed to DNA (*2*).

Apart from ester aminolysis, the chosen reaction conditions provoked a high degree of polymerization in the case of HT-OEI-HD, whereas LT-OEI-HD should have a significantly lower molecular weight. SEC/MALLS analysis of OEI-HD-based polymers confirmed the influence of reaction temperature on the degree of polymerization. As expected, the molecular weight of LT-OEI-HD was significantly lower than that of HT-OEI-HD. Synthesis at 20 °C (4 days) generated 8.7 kDa polymers, and a reaction temperature of 60 °C (4 days) resulted in polymers with a molecular mass of 26.6 kDa.

With regard to chemical structure, molecular weight, and degradation kinetics, we expected differences in polyplex stability, gene transfer activity, and cytotoxicity (*30*). Ester conversion into amide bonds reduces the number of potentially charge-bearing amines. On the other hand, high molecular weight and the presence of various secondary amines might provide enough positive charges for efficient DNA condensation.

While DNA-binding activity was similar for HT-OEI-HD and LT-OEI-HD, their biological activities showed significant differences. HT-OEI-HD mediated high transfection levels at low C/P ratios and was characterized by a rapid decrease in cell viability at high polymer concentrations. Furthermore, free HT-OEI-HD polymer induced erythrocyte aggregation; this can be easily explained by its higher molecular weight. In contrast, the lower molecular weight LT-OEI-HD did not interact with erythrocytes and was applied at high concentrations without inducing HT-OEI-HD-analogue toxicity. However, more polymer was needed for efficient gene transfer.

It is important to note that both polymers exceeded the "golden standard" PEI22 in terms of transfection efficiency/toxicity profile when applied at optimal doses.

Fractionation of HT-OEI-HD by SEC/MALLS resulted in a large fraction of 46 kDa and a small fraction of 9.5 kDa. The high molecular weight fraction was decisive for transfection activity as well as for cytotoxicity, and the low molecular weight fraction displayed low cytotoxicity similar to LT-OEI-HD, but far lower transfection activity.

In conclusion, we have shown the high impact of synthesis conditions on structural features of a polymer. Differences in molecular weight and degradability strongly influence gene transfer activity and cytotoxicity. Importantly, degradation of ester/amide-based OEI-HD polymers results in strongly reduced toxicity which is highly desirable with regard to long-term in vivo application. We demonstrated that both amide-based HT-OEI-HD and the ester-based LT-OEI-HD possess great potential as efficient gene carriers.

ACKNOWLEDGMENT

We thank Olga Brück for skillful assistance in preparing the manuscript and Wolfgang Rödl for helpful discussions. This work was in part funded by the Deutsche Forschungsgemeinschaft SFB 486 "Nanoman" and by the European Community FP6 network project "GIANT".

Synthesis and Characterization of Immunogens Based on Calix[4]arene-crown-6 for the Generation of Antibodies Directed Towards Cesium Ions

Samir Safi, Zouhair Asfari, Laurence Ehret-Sabatier, Maurice Leroy, and Agnès Hagège*

Laboratoire de Chimie Analytique et Minérale, UMR 7178 ULP/CNRS/IN2P3 (LC4), ECPM, 25 rue Becquerel, F-67087 Strasbourg Cedex, France. Received April 26, 2006; Revised Manuscript Received July 18, 2006

With the aim of generating antibodies directed towards cesium, a calix[4]arene-crown-6 in the 1,3-alternate conformation bearing an *N*-hydroxysuccinimide function was synthesized. The calixarene was coupled to bovine serum albumin using different calixarene/protein ratios, and cesium was loaded. Conjugates were characterized using trinitrobenzenesulfonic acid derivatization, matrix assisted laser desorption ionisation−mass spectrometry (MALDI-TOF-MS), and inductively coupled plasma-mass spectrometry (ICP-MS). Targeted lysines were determined after enzymatic cleavage followed by MALDI-TOF-MS, and a progressive targeting related to lysines accessibility was observed.

INTRODUCTION

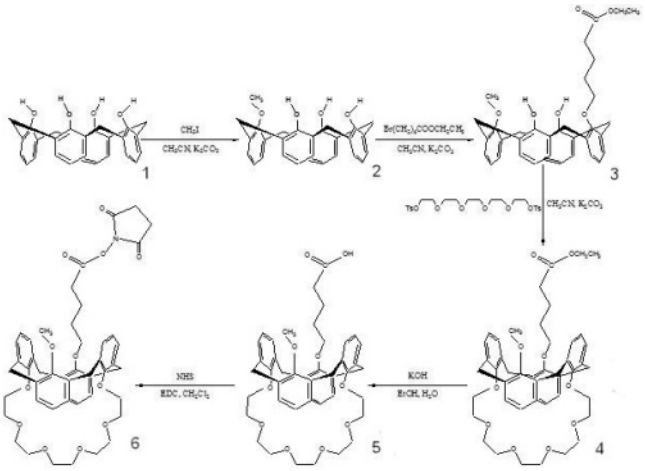
The ability to rapidly monitor metals in the environment and in bodily fluids is of fundamental importance. For that purpose, antibody-based sensors seem to provide an interesting solution for rapid, in situ assessment of metal contamination. The key point of an immunoanalysis is the design of the hapten. In the case of metal immunoanalysis, the hapten consists of a complex formed between the metal to be analyzed and a receptor which will be coupled later to a carrier protein. Antibodies directed toward metal chelates, such as EDTA or DTPA, have already been reported (*1*−*5*). However, the use of such chelating agents does not allow a clear differentiation between the various bound metals. Indeed, Blake et al. (*1*, *4*, *6*) reported the production of false positives with Hg(II) when using antibodies directed toward Cd(II). Moreover, strong interferences appeared in the presence of Mn(II) and In(III). The use of more selective ligands should permit circumvention of these selectivity limitations.

Calixcrowns represent an interesting class of compounds with a three-dimensional cavity that show unique complexing properties toward alkali, alkaline earth, and ammonium cations (*7*). Numerous calix[4]arenes-crown-6 have been synthesized, and their ability to selectively complex cesium has been reported (*8*−*10*).

The coupling of such hydrophobic molecules with proteins has been poorly documented. Bryant et al. (*11*) reported the synthesis of a noncovalent calix[4]arene−Gd^{III}−albumin complex. Reinhoudt et al. (*12*) realized the synthesis of immunogens based on ^{225}Ac−calix[4]arene complexes and showed that the low solubility of the calixarene in water did not allow an efficient coupling via an isothiocyanate function. It has been noted that the use of a calixarene bearing a masked thiol function leads to an albumin connected with five calixarenes.

We have reported in a previous work the synthesis of a series of calix[4]arenes -crown-5 and -crown-6 bearing COOH and OH groups for a potential use in alkali metal immunoanalysis (*13*). In this paper, we report the synthesis of both a calix[4]-arene-crown-6-based hapten with an activated NHS ester and its BSA conjugates. The characterization of the conjugates was accomplished by both spectrophotometric and mass spectrometric methods to determine the coupling ratios and by enzymatic digestion followed by MALDI-TOF-MS to localize the linked haptens. Cesium loading was performed and its incorporation rate was determined by ICP-MS.

Scheme 1



EXPERIMENTAL PROCEDURES

Materials and Methods. Melting points were determined with a Büchi 500 apparatus in a capillary sealed under nitrogen. ^{1}H NMR (300 MHz) spectra were recorded with a Bruker Avance spectrometer in the absence of an internal standard. FAB mass spectra were obtained with a VG Autospec and MALDI-TOF mass spectra with an Ultraflex (or a Reflex) instrument (Bruker). PlasmaQuad 3 ICP-MS (Thermo-Elemental) was used as an elemental detector for cesium quantification. Absorbance was measured on an HP8453E spectrophotometer. Microanalyses were performed at the Service de Microanalyse of the Institut de Chimie de Strasbourg. All reagents were purchased from Sigma at the highest purity available.

Hapten Synthesis. The synthetic pathway is illustrated in Scheme 1.

days. After cooling down to room temperature, the solvent was removed under reduced pressure. The residue was dissolved in CH_2Cl_2 and acidified with 1 N HCl. The organic phase was dried over Na_2SO_4, filtered, and then concentrated. After purification by chromatography (SiO_2, eluent: CH_2Cl_2), the calixarene derivative **1** (2.26 g) was recovered in a 43% yield as a white solid. Analytical data for compound **1**: Mp = 272 °C. ^{1}H NMR (300 MHz, $CDCl_3$): 9.70 (s, 1H, ArO*H*), 9.36 (s, 2H, ArO*H*), 7.27−7.01 (m, 8H, ArH_{meta}), 6.90 (t, 1H, J = 7.5 Hz, ArH_{para}), 6.70 (t, 3H, J = 7.5 Hz, ArH_{para}), 4.39 (d, 2H, J = 13.0 Hz, ArCH_2Ar), 4.29 (d, 2H, J = 13.0 Hz, ArCH_2Ar), 4.15 (s, 3H, OCH_3), 3.49 (d, 2H, J = 13.0 Hz, ArCH_2Ar), 3.48 (d, 2H, J = 13.0 Hz, ArCH_2Ar). Anal. Found: C, 79.38; H, 5.89. Calcd for $C_{29}H_{26}O_4$: C, 79.43; H, 5.97.

*1-(Ethyl-5-oxavalerate), 3-methoxy-calix[4]arene **2**.* Monomethoxy-calix[4]arene **1** (3.51 g, 8.0 mmol) and K_2CO_3 (0.57 g, 4.2 mmol) were dissolved in acetonitrile (200 mL) and stirred for 1 h at room temperature under a nitrogen atmosphere. Ethyl-5-bromovalerate (1.67 g, 8.0 mmol) was then added, and the mixture was refluxed for 5 days. The solvent was evaporated, and the residue obtained was solubilized in CH_2Cl_2, and K_2CO_3 was neutralized with 1 N HCl. The organic phase was dried over Na_2SO_4, filtered, and then concentrated. After purification by chromatography (SiO_2, eluent: CH_2Cl_2/acetone, 98/2), compound **2** (3.08 g) was recovered in a 68% yield as a white solid. Analytical data for compound **2**: Mp = 162−163 °C. ^{1}H NMR (300 MHz; $CDCl_3$): 7.76 (s, 2H, ArO*H*), 6.98 (d, 4H, J = 7.5 Hz, ArH_{meta}), 6.81 (d, 4H, J = 7.5 Hz, ArH_{meta}), 6.67−6.55 (m, 4H, ArH_{para}), 4.24 (d, 2H, J = 13.0 Hz, ArCH_2Ar), 4.21 (d, 2H, J = 13.0 Hz, ArCH_2Ar), 4.09 (q, 2H, J = 7.0 Hz, COOCH_2CH$_3$), 3.94 (t, 2H, J = 7.0 Hz, ArOCH_2), 3.91 (s, 3H, ArOCH_3), 3.31 (d, 2H, J = 13.0 Hz, ArCH_2Ar), 3.30 (d, 2H, J = 13.0 Hz, ArCH_2Ar), 2.44 (t, 2H, J = 7.0 Hz, CH_2COOCH$_2$CH$_3$), 1.99−1.97 (m, 4H, ArOCH$_2$CH_2CH_2), 1.20 (t, 3H, J = 7.0 Hz, COOCH$_2$CH_3). Anal. Found: C, 76.05; H, 6.86. Calcd for $C_{36}H_{38}O_6$: C, 76.30; H, 6.75.

*1-(Ethyl-5-oxavalerate), 3-methoxy-calix[4]arene-crown-6 **3**.* 1-(Ethyl-5-oxavalerate), 3-methoxy-calix[4]arene **2** (1.13 g, 2.0 mmol) and K_2CO_3 (2.76 g, 20.0 mmol) were dissolved in acetonitrile (300 mL) and stirred for 1 h at room temperature under a nitrogen atmosphere. Penta(ethylene glycol)ditosylate (1.15 g, 2.0 mmol) was then added, and the mixture was refluxed for 10 days. After evaporation of the solvent, the residue was solubilized in CH_2Cl_2, and K_2CO_3 was neutralized with 1 N HCl. The organic phase was dried over Na_2SO_4, filtered, and then concentrated. After purification by chromatography (SiO_2, eluent: CH_2Cl_2/acetone, 90/10), compound **3** (0.74 g) was recovered in a 48% yield as a yellow viscous liquid. Analytical data for compound **3**: ^{1}H NMR (300 MHz; $CDCl_3$): 7.39 (d, 2H, J = 7.5 Hz, ArH_{meta}), 7.10 (d, 2H, J = 7.5 Hz, ArH_{meta}), 6.95−6.92 (m, 4H, ArH_{meta}), 6.54−6.40 (m, 4H, ArH_{para}), 4.26 (d, 4H, J = 13.0 Hz, ArCH_2Ar), 4.23−4.18 (m, 2H, COOCH_2-CH$_3$), 3.95−3.85 (m, 2H, ArOCH_2), 3.79−3.35 (m, 20H, OCH_2CH_2O), 3.24 (s, 3H, ArOCH_3), 3.12 (d, 4H, J = 13.0 Hz, ArCH_2Ar), 2.45−2.41 (m, 2H, CH_2COOCH$_2$CH$_3$), 1.94−1.75 (m, 4H, ArOCH$_2$CH_2CH_2), 1.31 (t, 3H, J = 7.0 Hz, COOCH$_2$-CH_3). Anal. Found: C, 68.72; H, 7.49. Calcd for $C_{46}H_{56}O_{10}$·2H$_2$O: C, 68.63; H, 7.51.

*1-(5-Oxavaleric acid), 3-methoxy-calix[4]arene-crown-6 **4**.* 1-(Ethyl-5-oxavalerate), 3-methoxy-calix[4]arene-crown-6 **3** (0.31 g, 0.4 mmol) and KOH (1.00 g, 17.0 mmol) were dissolved in a mixture of EtOH/H_2O 50/50 (50 mL) and refluxed for 3 h. After evaporation of the solvents, the residue was dissolved in CH_2Cl_2 and acidified with 1 N HCl. The organic phase was dried over Na_2SO_4, filtered, and then concentrated. After purification by chromatography (SiO_2, CH_2Cl_2/acetone, 80/20), compound **4** (0.28 g) was recovered in a 96% yield as a white viscous liquid. Analytical data for compound **4**: ^{1}H NMR (300 MHz; $CDCl_3$): 7.34 (d, 2H, J = 7.5 Hz, ArH_{meta}), 7.05 (d, 2H, J = 7.5 Hz, ArH_{meta}), 6.90−6.85 (m, 4H, ArH_{meta}), 6.53−6.46 (m, 4H, ArH_{para}), 4.24 (d, 4H, J = 13.0 Hz, ArCH_2Ar), 4.03−3.93 (m, 2H, ArOCH_{2-}CH$_2$), 3.80−3.62 (m, 20H, OCH_2CH_2O), 3.20 (s, 3H, ArOCH_3), 3.08 (d, 4H, J = 13.0 Hz, ArCH_2Ar), 2.45 (t, 2H, J = 7.0 Hz, CH_2COOH), 1.89−1.67 (m, 4H, CH_2CH_2CH$_2$COOH). Anal. Found: C, 67.72; H, 7.63. Calcd for $C_{44}H_{52}O_{10}$·2H$_2$O: C, 68.02; H, 7.26.

*1-(N-succinimide-5-oxavalerate), 3-methoxy-calix[4]arene-crown-6 **5**.* 1-(5-Oxavaleric acid), 3-methoxy-calix[4]arene-crown-6 (0.59 g, 0.8 mmol), NHS (*N*-hydroxysuccinimide) (0.19 g, 1.6 mmol), and EDC [3-ethyl-3-(3-dimethylaminopropyl)-carbodiimide] (0.31 g, 1.6 mmol) were dissolved in CH_2Cl_2 (50 mL), and the mixture was stirred overnight at room temperature under a nitrogen atmosphere. After purification by chromatography (SiO_2, eluent: CH_2Cl_2/acetone, 90/10), the activated ester **5** (0.40 g) was recovered in a 60% yield as a white solid. Analytical data for compound **5**: Mp = 86−87 °C. ^{1}H NMR (300 MHz; $CDCl_3$): 7.28 (d, 2H, J = 7.5 Hz, ArH_{meta}), 6.99 (d, 2H, J = 7.5 Hz, ArH_{meta}), 6.87−6.78 (m, 4H, ArH_{meta}), 6.43−6.41 (m, 4H, ArH_{para}), 4.18 (d, 4H, J = 13.0 Hz, ArCH_2-Ar), 3.63 (s, 2H, ArOCH_2), 3.63−3.46 (m, 20H, OCH_2CH_2O), 3.14 (s, 3H, ArOCH_3), 3.02 (d, 4H, J = 13.0 Hz, ArCH_2Ar), 2.75 (broad s, 4H, NHS), 2.61 (t, 2H, J = 7.0 Hz, CH_2-COONHS), 1.85−1.79 (m, 4H, CH_2CH_2CH$_2$COONHS). Anal. Found: C, 68.70; H, 6.43. Calcd for $C_{48}H_{55}O_{12}N$: C, 68.80; H, 6.61. MS (FAB$^+$): m/z = 876.6 (MK$^+$), m/z = 855.6 (MNH$_4^+$).

Conjugation of Compound 5 and Characterization of the Immunogens. To 1 mL of a BSA solution (4 mg/ mL, Sigma 96%) in 25 mM sodium borate buffer at pH 9.2 were added 100 μL of DMF containing compound **5** at various concentrations. Final **5**/BSA ratios of 10:1, 30:1, and 50:1 (mol/mol) were used. The mixtures were vortexed and incubated overnight at 4 °C. These solutions were stored at 2 °C without purification.

Spectrophotometric Method. A modified version of Habeeb's TNBS (2,4,6-trinitrobenzenesulfonic acid) assay (*14*) was used. 20 μL aliquots of the crude mixtures were diluted 40 times in 0.1 M sodium borate buffer pH 9.2. Standard solutions of glycine (2−9 μg/mL) in 0.1 M sodium borate buffer were also prepared. To 1 mL of the conjugation mixture or the glycine standards were added 500 μL of a 0.01% TNBS in a 0.1 M sodium borate buffer, and incubation was performed at 42 °C for 2 h. 500 μL of 10% (w/w) SDS and 250 μL of 1 N HCl were then added, and the absorbance was measured at 335 nm.

Mass Spectrometric Method. After removing the low molecular weight compounds with size exclusion micro Bio-Spin 6 columns (Bio-rad) at 1000 g for 4 min, the extent of conjugation was determined by MALDI-TOF-MS. The matrix was prepared from a saturated solution of α-cyano-4-hydroxycinnamic acid in 50% acetonitrile and diluted twice in 0.1% TFA in 30% acetonitrile. The samples and the matrix solution were mixed in equal amounts (0.5 μL each) and added on the stainless steel probe. The samples were allowed to dry at room temperature. The data were acquired in the linear mode.

Enzymatic Digestion. SDS-PAGE of BSA and its conjugates (10:1, 30:1, 50:1) was performed according to Laemmli (*15*). Purified solutions (37.2 μg protein /mL) were diluted twice in Laemmli sample buffer (2X) and heated at 90 °C for 5 min. 10 μL of samples were loaded on minigels (10 × 8 cm 7% total acrylamide). Molecular markers covering a molecular weight range between 6.5 and 205 kDa were used for molecular mass estimation. Migration was performed at 150 V for 90 min. Coomassie blue R250 staining and destaining were done using the standard developing protocol supplied by the manufacturer. Protein bands corresponding to BSA were excised and washed

with 200 μL water, then dehydrated with 200 μL 25 mM NH_4HCO_3 in 50% acetonitrile, then with 100% acetonitrile. Gel pieces were rehydrated in 50 μL of dithiothreitol (25 mM in NH_4HCO_3 buffer), and proteins were reduced for 20 min at 56 °C. The residual liquid was removed, and 50 μL of freshly prepared iodoacetamide (55 mM in NH_4HCO_3 buffer) was added. Samples were incubated for 20 min at room temperature in the dark. The residual iodoacetamide was eliminated by washing and the samples dehydrated. Finally, gel pieces were rehydrated for 5 min at room temperature in 20 μL of either 12.5 ng/μL trypsin (Promega, Sequence Grade Modified) or 10 ng/μL of endoproteinase Glu-C (Sigma) in 25 mM NH_4HCO_3 and then overlaid with a minimum amount of 25 mM NH_4HCO_3 to keep them immersed during the digestion. The mixture was incubated overnight at 37 °C. Afterward, peptides were extracted by addition of 80 μL of 60% acetonitrile in 5% HCOOH and sonication for 10 min. The resulting peptide extracts were directly analyzed by MALDI-TOF-MS in reflector mode. The calibration was performed in internal mode using fragments from trypsin autolysis with monoisotopic $[M - H]^+$ at *m*/*z* 842.510 and 2211.105.

Cesium Binding. To 500 μL of BSA and conjugates solutions (4 mg protein/mL), various amounts of solid $CsNO_3$ (4−21 mg) were added. The solutions were mixed for 5 days at room temperature. 50 μL of each solution was then purified by micro Bio-Spin 6 columns (Bio-rad) at 1000 g for 4 min. Prior to ICP-MS analysis, the samples were diluted 200 times in ultrapure water. Nebulization of samples was performed by means of a concentric nebulizer (flow rate: 1 mL min^{-1}). ICP conditions were the following: nebulization gas flow rate 0.75 L min^{-1}, outer gas flow rate 13.5 L min^{-1}, auxiliary gas flow rate 1.8 L min^{-1}. Detection of cesium was performed at $m/z = 133$. Plasma power was set to 1350 W and detector voltage to −2700 V. Ion lens voltages were adjusted to maximize the signals of analytes.

RESULTS AND DISCUSSION

For the generation of antibodies directed against cesium, we synthesized immunogens via the covalent attachment of calix[4]arene-crown-6 haptens to a BSA molecule. For that purpose, we synthesized the first calixarene bearing an activated ester function. This approach ensures stable crosslinking and prevents the interprotein coupling during the conjugation process.

Conjugation of the Calixarene 5. The bioconjugates presented in this paper are based on a succinimide ester that is commonly used for reactive amine crosslinking, but the ester hydrolysis is a limiting factor. To bypass this problem, the pH must be controlled. Two buffers were tested for the coupling: a phosphate buffer (pH 7.5) and a borate buffer (pH 9.2). A higher pH was shown to favor the nucleophilic attack to the detriment of the ester hydrolysis, and pH 9.2 was thus used in further experiments. The conjugation reaction gave a stable coupling ratio as determined by the spectrophotometric method after 5 h. As calixarene **5** is not soluble in pure water, coupling conditions with BSA were also optimized by varying the DMF ratio (for the 50:1 mixture). As it was found that using more than 10% of DMF did not improve the conjugation, this final DMF ratio was adopted for the conjugate synthesis.

Characterization of the Conjugates. As the hapten density governs both quantity and affinity of the antibodies produced (*16*−*18*), it is of fundamental importance to characterize the different immunogens. Although the calixarene derivatives contain UV chromophores absorbing at 270 nm, the determination of the extent of conjugation using direct UV measurements was impossible. Indeed, the conjugation led to modifications of the amino acid environment which induces changes in the BSA spectrum. So, alternative methods, namely, mass spectrometry and free lysines titration, were used.

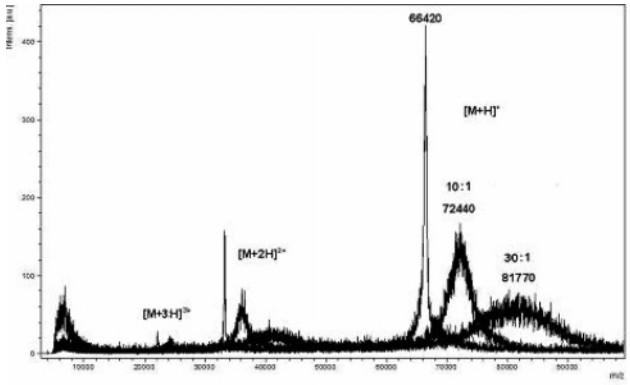

Figure 1. Mass spectra of BSA and conjugates. Values are indicated in *m*/*z*.

Table 1. Determination of Coupling Ratios Using MALDI-TOF and TNBS Methods

Calixarene **5**:BSA (mol/mol) ratio	average number of haptens[a] (mol/mol BSA)	
	MS analysis	TNBS analysis
10 :1	8 ± 2	8 ± 6
30 :1	19 ± 1	21 ± 1
50 :1		36 ± 2

[a] Standard deviations were determined from different conjugation experiments.

MALDI-MS techniques are considered an accurate tool for protein and peptide analysis (*19*, *20*). Figure 1 presents the mass spectra obtained for the BSA and its conjugates. The MALDI-TOF-MS analyses of conjugates showed that the molecular weights of the conjugates increased when increasing calixarene/BSA ratios. These mass shifts correspond to an increased coupling of calixarene moieties. The average number of coupled calixarenes was determined by calculating the mass shift between the peaks' maxima. A loss of resolution and less efficient ionization were also observed when the hapten density increases. Such behavior was previously observed by Bolbach et al. (*21*). The inability to detect the molecular ion of the conjugate when a calixarene-to-BSA ratio of 50:1 was used might be due to the high density of haptens.

The spectrophotometric method allows the determination of the available lysine residues. On the native BSA, the number of free lysines was found to be 57, while the BSA sequence actually contains 59 (*22*). The standard deviation was found to be less than 5%, except for low extents of conjugation for which this determination was found to be inaccurate.

Results obtained with both methods are given in Table 1. The results are in good agreement between TNBS and MALDI-TOF-MS methods. The coupling process was proven to be reproducible when comparing the results of various sets. As expected, the increase of calixarenes added to the BSA solution led to an increase in the hapten density, and 60% of the initial free lysines were modified.

Determination of the Targeted Lysines. Chappey et al. (*23*) found that the specificity of monoclonal antibodies depends on the structure of the hapten and on its coupling sites to the carrier protein. Attempts to localize calixarene coupling sites were then conducted by enzymatic digestion of BSA conjugates followed by MS analysis. Mass fingerprints were compared between BSA and the conjugates (10:1, 30:1, 50:1), and reduction in the intensity of peaks observed in the control sample and appearance of new peaks were examined as being indications of site modification. For the 10:1 conjugate (Figure 2), two peaks were strongly affected after conjugation with **5** (*m*/*z* 789.47, 1639.94). In parallel, appearance of peaks (*m*/*z* 1511.82, 2362.27) with observed masses corresponding to an attachment of one calix-

KVPQVSTPTLVEVSR	437−451	1639.94[a]	2362.27	722.36

[a] Peptides affected by the coupling found in the native mass spectrum.

arene moiety (calculated Δ*m*/*z* = 722.34) confirmed the modification of these peptides (Table 2). Interestingly, the detection of the modified peptide LVTDLTK (at *m*/*z* 1511.82) indicates that the functionalization of the lysine side chain does not fully preclude trypsin cleavage after this residue. In addition, four other peaks appeared after conjugation, which could correspond to modified BSA tryptic peptides (*m*/*z* 1231.64, 1238.67, 1917,94, 2262.17; Table 2). These peaks were not detected in the native BSA spectrum. Another digestion with endoproteinase Glu-C was performed. The disappearance in the 10:1 conjugate spectrum (not shown) of three peptides corresponding to sequences 254−267, 544−554, and 555−565 reinforced the results found after tryptic digestion (targeting of sequences 257−263, 545−548, 558−561). The results obtained from these two digestions led to the proposition of six targeted peptide regions after conjugation with calixarene **5**. When comparing these results to the protein 3D model (www.rcsb.org), it was found that only accessible surface lysines were affected by the coupling process.

By increasing the calixarene/BSA ratio to 30, all targeted lysines in the 10:1 conjugate remained modified. In addition, additional reductions in the intensity of peaks observed in the control sample and appearance of new peaks were observed. The same behavior was noticed when increasing this ratio from 30 to 50. We can thus assume that the coupling process follows a given order that could be related to the accessibility of the different lysines.

Cesium Binding. The quantity of cesium nitrate was varied from 4 to 21 mg in order to keep the Cs/calixarene **5** (mol/mol) ratio constant and equal to 100. The amount of bound cesium was determined using ICP-MS (Table 3). A control experiment indicates the presence of no more than 0.5 mol of Cs^+ per mole of native BSA. This was due to a partial retention capacity of the desalting column in the presence of a large excess of cesium. An increase of the incorporated cesium was noted with an increased coupling ratio. However, in all cases, around

Table 3. Determination of Cesium Binding to Different BSA Conjugates

coupling ratio (**5** : BSA)	average number of cesium[a,b] (mol/mol BSA)	percentage of loaded calixarenes[b]
10:1	1.70 ± 0.04	25.3 ± 0.6
30:1	4.4 ± 0.4	22 ± 2
50:1	6.7 ± 0.2	19.8 ± 0.6

[a] The blank value was subtracted. [b] The standard deviations were calculated from ICP/MS measurements performed in triplicate for each conjugate.

22% of the calixarene cavities were occupied by cesium. Increasing the cesium ratio (up to 1000) led to an increase to a maximum of 35%. This relatively low density of incorporated cesium may however not represent a limiting factor in antibodies production. Furthermore, the loading capacity was found to be reproducible when comparing results for various sets of 50:1 conjugate.

In conclusion, to get an optimum calixarene/BSA ratio for immunization, a series of conjugates was synthesized and characterized by mass spectrometry and free lysines titration. It was demonstrated that the proposed procedure allows the coupling of hydrophobic haptens in a reproducible way. Moreover, the coupling ratio can be simply tuned by varying the calixarene concentration. Some hapten coupling locations were also identified by accurate mass measurements. These data will be used to correlate both epitope density and hapten location to the immune response.

Cesium was proven to be complexed by such conjugates. However, further studies will be carried out in order to evaluate the stability of such immunogens in sera, particularly toward the potassium concentration, and immunization will also be performed.

ACKNOWLEDGMENT

This work was supported by a grant to S.S. from the French ministry of research and higher education. The authors would like to thank C. Vidaud (SBTN, CEA, and Marcoule, France) for helpful discussions, and the LSMBO (UMR 7178, Strasbourg) for MS facilities.

Directing Quadruplex-Stabilizing Drugs to the Telomere: Synthesis and Properties of Acridine−Oligonucleotide Conjugates

Joan Casals,[†] Laurent Debéthune,[†] Karine Alvarez,[†] Antonina Risitano,[‡] Keith R. Fox,*[,‡] Anna Grandas,[†] and Enrique Pedroso*[,†]

Departament de Química Orgànica, Facultat de Química, Universitat de Barcelona, Martí i Franquès 1-11, E-08028 Barcelona, Spain, and School of Biological Sciences, University of Southampton, Bassett Crescent East, Southampton SO16 7PX, U.K. Received July 3, 2006; Revised Manuscript Received August 10, 2006

Conjugates containing quadruplex-stabilizing acridines linked to oligonucleotides that are complementary to the G-rich human telomere sequence were synthesized. Acylation of 3,6-diaminoacridine followed by two Michael reactions provided derivatives suitable for conjugation, which were coupled to resin-linked amine-modified oligonucleotides by activating the carboxyl group with pentafluorophenyl 4-nitrobenzenesulfonate. After deprotection with aqueous ammonia at room temperature, conjugates incorporating different acridines, linkers, and oligonucleotide sequences were obtained. These were tested for their ability to stabilize intramolecular DNA quadruplexes that are based on the human telomeric repeat sequence $(GGGTTA)_n$.

INTRODUCTION

Telomerase is an enzyme that extends telomere sequences after DNA replication, and it is active in most cancer cells, but not in somatic cells. The enzyme is a ribonucleoprotein that uses an RNA template to elongate the telomeric single-stranded overhang, which has the sequence $(TTAGGG)_n$ in humans (*1*−*4*). It has been hypothesized that folding of this G-rich strand into an intramolecular quadruplex prevents interaction with the complementary RNA of telomerase and consequently interferes with the elongation of telomeres by telomerase in cancer cells (*5*−*11*).

Several classes of compounds, including anthraquinones, acridines, porphyrins, fluorenones, and other polycyclic aromatic molecules have been reported to bind to and stabilize DNA quadruplexes and possess telomerase-inhibiting properties (*12*−*18*). However, these aromatic molecules also behave as DNA intercalators and interact with double-stranded DNA as well as with G-quadruplexes. As a result, their potential use as anticancer drugs is limited by their cytotoxicity.

The parent aromatic compounds have been extensively modified to favor interaction with quadruplex rather than duplex structures (*19*−*23*). An alternative means of increasing the specificity might be to direct the aromatic drug to telomeric DNA by covalently attaching it to an oligonucleotide that is complementary to the G-rich telomere strand. This manuscript describes the preparation of a small library of such acridine−oligonucleotide conjugates and examines their interaction with intramolecular DNA quadruplexes.

EXPERIMENTAL PROCEDURES

3,6-Bis(acryloylamide)acridine, 1. A suspension of 2.5 g (10 mmol) of proflavine hydrochloride in acryloyl chloride (70 mL) was refluxed for 4 h. Then, the solid was filtered and washed with ether (4 × 25 mL). Purification of this solid by silica gel column chromatography eluting with acetone and increasing amounts of MeOH (0−30%) and TEA[1] (0−5%) afforded 2.3 g of 3,6-bis(acryloylamide)−acridine (80% yield). R_f (acetone/TEA 8:2) = 0.66. ^{1}H NMR (DMSO-d_6, 200 MHz) δ (ppm): 11.62 (s, 2H, NH), 9.50 (s, 1H, H-9), 8.88 (s, 2H, H-4,5), 8.28 (d, J = 9.2 Hz, 2H, H-1,8), 7.90 (d, J = 9.2 Hz, 2H, H-2,7), 6.70 (dd, J_{trans} = 17 Hz, J_{cis} = 10 Hz, 2H, COC**H$_A$**=CH$_B$H$_C$), 6.38 (dd, J_{trans} = 17 Hz, J_{gem} = 1 Hz, 2H, COCH$_A$=C**H$_B$**H$_C$), 5.90 (dd, J_{cis} = 10 Hz, J_{gem} = 1 Hz, 2H, COCH$_A$=CH$_B$**H$_C$**). ^{13}C-RMN (DMSO-d_6, 63 MHz) δ (ppm): 160.8 (NHCO), 146.6 (C-9), 137.6 (C-11,12), 132.4 (C-3,6), 128.7 (CH=), 126.3 (=CH$_2$), 124.8 (C-1,8), 119.7 (C-10,13), 117.3 (C-2,7), 111.6 (C-4,5). MALDI-TOF MS (positive mode, linear, DHB): m/z 318.72, $[M + H]^+$, calcd mass for $C_{19}H_{15}N_3O_2$ 317.34.

General Procedure for the Synthesis of Derivatives 2. To a stirred solution of **1** in EtOH (250 mL/g of **1**) was added dropwise a solution of the cyclic secondary amine (0.5 eq) in the same solvent (4 mL/mmol amine), and the mixture was reacted overnight (room temperature). The solvent was removed at reduced pressure, and the product was purified by silica gel column chromatography eluting with acetone and increasing amounts of MeOH (0−10%) and TEA (0−5%).

2a. 55% yield; R_f (DCM/MeOH 7:3) = 0.23. ^{1}H NMR (acetone-d_6, 200 MHz) δ (ppm): 11.20 (s, 1H, N**H**), 9.88 (s, 1H, N**H**), 8.76 (s, 1H, H-9), 8.67 (1H, H-4), 8.54 (s, 1H, H-5), 8.01 (d, J = 9 Hz, 2H, H-1,8), 7.78 (d, J = 9 Hz, 1H, H-2), 7.65 (d, J = 9 Hz, 1H, H-7), 6.47 (m, 2H, C**H$_A$**=C**H$_B$**H$_C$), 5.77

General Procedure for the Synthesis of Asymmetrically Substituted Acridines 3. 2 (250−300 mg) was reacted with a 2- to 3-fold molar excess of either L-proline or isonipecotic acid in MeOH (1 mL/10 mg of **2**, approximately) for 6 h at room temperature (rt). Removal of the solvent in vacuo was followed by chromatographic purification.

3a. Purification by silica gel column chromatography eluting with acetone and increasing amounts of MeOH (0−20%) and TEA (0−5%); 62% yield; anal HPLC (C8 column, gradient from 5% to 35% of B in 15 min, A = 0.045% TFA in H_2O, B = 0.036% of TFA in ACN): t_R = 9.2 min. ^{1}H NMR (CD_3OD, 200 MHz) δ (ppm): 8.55 (s, 1H, H-9), 8.29 (s, 1H, H-4), 8.26 (s, 1H, H-5), 7.9−7.7 (m, 2H, H-1,8), 7.7−7.5 (m, 2H, H-2,7), 4.32 (t, J = 4.4 Hz, 1H, NC**H**COOH), 4.08−3.80 (m, 2H, CH_2-$NCH(COOH)C\mathbf{H_2}$), 3.3−2.8 (m, 10H, CH_2N). ^{13}C NMR (CD_3-OD, 63 MHz) δ (ppm): 175.3 (COOH), 171.2 and 170.1 (NHCO), 150.2 (C-9), 141.1 (C-11,12), 140.2 (C-3,6), 129.7 (C-1,8), 123.0 (C-10,13), 120.7 (C-5,4), 114.5 (C-2,7), 68.2 (N**C**HCOOH), 54.4 ($COCH_2CH_2N\mathbf{C}H_2$), 54.0 ($N(\mathbf{C}H_2)_2$), 50.6 ($\mathbf{C}H_2NHCOOH$), 43.0 ($\mathbf{C}H_2N(CH_2)_2$), 34.2 ($CO\mathbf{C}H_2CH_2$-NHCOOH), 29.5 ($CO\mathbf{C}H_2CH_2N(CH_2)_2$), 25.6 (NCHCOO-H**C**$H_2$), 24.0 ($NCH_2\mathbf{C}H_2CH_2CHCOOH$), 23.9 ($N(CH_2\mathbf{C}H_2)_2$). MALDI-TOF MS (positive mode, linear, DHB): *m*/*z* 519.15 $[M + H]^+$, calcd mass for $C_{29}H_{35}N_5O_4$ 517.62.

3b. Purification by reversed-phase medium-pressure liquid cromatography on a C18-filled column, gradient from 0% to 35% of B (A = 0.1% TFA in H_2O, B = 0.1% TFA in ACN); 80% yield; anal HPLC (C8 column, gradient from 5% to 35% of B in 15 min, A = 0.045% TFA in H_2O, B = 0.0036% of TFA in ACN): t_R = 8.0 min. ^{1}H NMR (CD_3OD, 200 MHz) δ (ppm): 9.44 (s, 1H, H-9), 8.87 (m, 2H, H-4,5), 8.32 (d, J = 3.8 Hz, 1H, H-1), 8.27 (d, J = 3.8 Hz, 1H, H-8), 7.66−7.74 (m, 2H, H2−7), 4.33 (dd, J_1 = 9.4 Hz, J_2 = 6.2 Hz, 1H, NC**H**COOH), 3.6−3.94 (m, 10H, CH_2N), 3.07−3.15 (m, 4H, $COC\mathbf{H_2}CH_2N$), 2.48−2.67 (m, 2H, $NCH_2CH_2C\mathbf{H_2}CHCOOH$), 2.00−2.30 (m, 6H, $NCH_2C\mathbf{H_2}$). ^{13}C NMR (CD_3OD, 63 MHz) δ (ppm): 168.1 (COOH), 167.3 and 167.0 (NHCO), 143.9 (C-9), 143.6 (C-11,12), 139.9 (C-3,6), 128.8 (C-1,8), 119.9 (C-10,13), 118.6 (C-5,4), 102.0 (C-2,7), 65.9 (N**C**HCOOH), 52.8 ($COCH_2CH_2N\mathbf{C}H_2$), 52.0 ($N(\mathbf{C}H_2)_2$), 48.3 ($\mathbf{C}H_2N(CH_2)_2$), 47.8 ($\mathbf{C}H_2NHCOOH$), 30.2 ($CO\mathbf{C}H_2CH_2NHCOOH$), 30.0 ($CO\mathbf{C}H_2$-$CH_2N(CH_2)_2$), 26.0 ($NCHCOOH\mathbf{C}H_2$), 20.5 ($NCH_2\mathbf{C}H_2CH_2$-CHCOOH), 20.4 ($N(CH_2\mathbf{C}H_2)_2$). MALDI-TOF MS (positive mode, linear, DHB): *m*/*z* 504.49 $[M + H]^+$, calcd mass for $C_{28}H_{33}N_5O_4$ 503.59.

3c. Purification by reversed-phase medium-pressure liquid cromatography on a C18-filled column, gradient from 5% to 50% of B (A = 0.1% TFA in H_2O, B = 0.1% TFA in ACN); 94% yield; anal HPLC (C8 column, gradient from 5% to 35% of B in 15 min, A = 0.045% TFA in H_2O, B = 0.0036% of TFA in ACN): t_R = 9.1 min. ^{1}H NMR (CD_3OD, 200 MHz) δ (ppm): 9.48 (s, 1H, H-9), 8.62 (s, 2H, H-4,5), 8.37 (d, J = 9.3 Hz, 2H, H-1,8), 7.72 (dd, J_1 = 9.3 Hz, J_2 = 1.5 Hz, 2H, H-2,7), 3.75−3.85 (m, 8H, $N(C\mathbf{H_2}CH_2)_2$), 3.3−3.4 (m, 4H, $COCH_2C\mathbf{H_2}N$), 3.1−3.3 (m, 4H, $COC\mathbf{H_2}CH_2N$), 2.9 (m, 1H, C**H**COOH), 1.9−2.5 (m, 8H, $N(CH_2C\mathbf{H_2})_2$). ^{13}C NMR (D_2O, 63 MHz) δ (ppm): 176.5 (COOH), 169.6 and 169.4 (NHCO), 144.3 (C-9), 144.2 (C-11,12), 139.0 (C-3,6), 130.0 (C-1,8), 120.2 (C-10,13), 119.9 (C-5,4), 102.9 (C-2,7), 53.8 (**C**HCOOH), 51.7 ($N(\mathbf{C}H_2CH_2)_2$-CHCOOH), 51.3 ($N(\mathbf{C}H_2CH_2)_2$), 49.5 ($\mathbf{C}H_2N(CH_2CH_2)_2$-CHCOOH), 49.3 ($\mathbf{C}H_2N(CH_2CH_2)_2$), 37.5 ($CO\mathbf{C}H_2CH_2N$), 24.8 ($N(CH_2\mathbf{C}H_2)_2CHCOOH$), 22.0 ($N(CH_2\mathbf{C}H_2)_2$). MALDI-TOF MS (positive mode, linear, DHB): *m*/*z* 518.17 $[M + H]^+$, calcd mass for $C_{29}H_{35}N_5O_4$ 517.62.

3,6-Bis[3-N-(L-prolyl)propionamide]acridine, ***3d***. To a solution of 250 mg (0.78 mmol) of **1** in EtOH (200 mL) was added a solution of L-proline (907 mg, 10 equiv) in the minimal amount of MeOH, and the mixture was stirred for 24 h at rt. Removal of the solvent was followed by HPLC purification using a preparative C4 column (gradient from 10% to 40% of B in 1 h, A = 10 mM NH_4AcO, B = ACN). 46% yield; anal HPLC (C8 column, gradient from 10% to 35% of B in 20 min, A = 0.045% TFA in H_2O, B = 0.036% TFA in ACN): t_R = 11.9 min. ^{1}H NMR (CD_3OD, 200 MHz) δ (ppm): 8.73 (s, 1H, H-9), 8.33 (s, 2H, H-4,5), 7.95 (d, J = 9 Hz, 2H, H-1−8), 7.68 (dd, J_1 = 9 Hz, J_2 = 1.8 Hz, 2H, H-2,7), 4.10 (m, 2H, NC**H**COOH), 3.95−4.01 (m, 2H, $COCH_2CH_2NC\mathbf{H_2}$), 3.70 (t, J = 6 Hz, 4H, $COCH_2C\mathbf{H_2}N$), 3.27−3.34 (m, 2H, $COCH_2CH_2NC\mathbf{H_2}$), 3.09 (t, J = 6 Hz, 4H, $COC\mathbf{H_2}CH_2N$), 2.00−2.60 (m, 8H, $NCH_2C\mathbf{H_2}C\mathbf{H_2}$-CHCOOH). ^{13}C NMR ($CD_3OD$, 63 MHz) δ (ppm): 171.0 (COOH), 169.6 (NHCO), 150.0 (C-9), 140.9 (C-11,12), 135.8 (C-3,6), 129.7 (C-1,8), 123.0 (C-5,4), 120.7 (C-10,13), 114.6 (C-2,7), 69.0 (N**C**HCOOH), 54.8 ($COCH_2CH_2N\mathbf{C}H_2$), 50.8 ($COCH_2\mathbf{C}H_2N$), 33.4 ($CO\mathbf{C}H_2CH_2N$), 29.5 ($NCH(COOH)\mathbf{C}H_2$), 23.9 ($NCH_2\mathbf{C}H_2CH_2CHCOOH$). MALDI-TOF MS (positive mode, linear, DHB): *m*/*z* 549.76 $[M + H]^+$, calcd mass for $C_{29}H_{33}N_5O_6$ 547.60.

HO-[protected oligonucleotide]−Resin, 7. The amine-substituted polystyrene-1%-divinylbenzene support suitable for oligonucleotide synthesis (loading below 0.25 mmol/g) was obtained by partial acylation of the amine groups of *p*-methylbenzhydrylamine resin (0.70 mmol/g). This was achieved by reaction with 0.35 equiv of Fmoc-alanine and DCC in a DCM/DMF mixture (9:1) for 1 h at rt. The resin was then filtered and washed with DMF, DCM, and MeOH and dried overnight in a desiccator. An aliquot of Fmoc-Ala-resin was treated with 20% piperidine in DMF to remove the Fmoc group, and the amount of 9-fluorenylmethylpiperidine formed was quantified spectrophotometrically. The loading was 0.17 mmol/g, suitable for oligonucleotide synthesis. The resin was swelled in DCM/DMF, and the remaining free amines were capped by acetylation (reaction with Ac_2O for 10 min + 10 additional min after the addition of DIEA, 10 equiv of each reagent). The Fmoc group of the total of Fmoc-Ala-resin was removed by treatment with 20% piperidine/DMF (3 + 10 min, followed by DMF washings).

Nucleotide resins were synthesized by reacting 5′-*O*-DMT-T-succinate or 5′-*O*-DMT-dA^{Bz}-succinate (3 equiv, previously prepared by reaction between the DMT-protected nucleoside and succinic anhydride in pyridine) (*24*) with H-Ala-resin in

the presence of DCC (3 equiv) for 4 h at room temperature in a DCM/DMF mixture. The absence of unreacted amines was assessed by the ninhydrin test (*25*).

DMT-T-Succinate. R_f (DCM/MeOH 9:1) = 0.1. ^{1}H NMR ($CDCl_3$, 200 MHz) δ (ppm): 9.8 (s, 1H, N**H**), 7.59 (s, 1H, H-6), 6.6−7.4 (m, 14H, Ar-H), 6.38 (t, 1H, H-1′), 5.45 (m, 1H, H-3′), 4.18 (m, 1H, H-4′), 3.77 (s, 6H, Ar-OCH_3), 3.44 (m, 2H, H-5′/5″), 2.2−2.8 (m, 6H, OCO**CH_2**C**H_2**COOH, H-2′/2″), 1.36 (s, 3H, Ar-CH_3).

DMT-dA^{Bz}-Succinate. R_f (DCM/MeOH 9:1) = 0.1. ^{1}H NMR ($CDCl_3$, 200 MHz) δ (ppm): 8.68 (s, 1H, H-8), 8.15 (s, 1H, H-2), 6.98−7.4 (m, 14H, Ar-H), 6.40 (t, 1H, H-1′), 5.42 (m, 1H, H-3′), 4.22 (m, 1H, H-4′), 3.66 (s, 6H, Ar-OCH_3), 3.36 (m, 2H, H-5′/5″), 2.50−3.00 (m, 6H, OCO**CH_2**C**H_2**COOH, H-2′/2″).

Oligonucleotides were automatically assembled (DNA synthesizer: ABI 380B) on aliquots of H-Ala-resin at the 5-μmol scale, using phosphite triester procedures slightly modified for compatibility with polystyrene supports (*26*, *27*) and the 5′-*O*-DMT−3′-*O*-phosphoramide derivatives of dT, dA^{Bz}, and dC^{Ac}.

H_2N−Linker−Oligonucleotide−Resin, 8. The 5′ end of the resin-linked oligonucleotide was derivatized by reaction with the commercially available phosphoramidite derivatives of amine-protected linkers L_3 (see below), L_5, and L_6 (MMT−NH−linker−O(OCNE)$NiPr_2$; see structures in Scheme 3) using standard phosphite triester methodology. For the preparation of conjugate **4f**, linker L_{18} was first introduced by reaction of the corresponding oligonucleotide resin with commercially available DMT−[*O*-$(CH_2)_2$]$_6$−*O*-P(OCNE)$NiPr_2$, and this was followed by incorporation of the L_5-containing derivative. Assembly of the target linker−oligonucleotide was assessed, in all cases, by treating aliquots of the linker−oligonucleotide−resin with concentrated aqueous ammonia for 6 h at room temperature and analysis of the crude by MALDI-TOF MS (negative mode).

MMT−NH−CH_2-CH_2-CH_2-OH. 3-Aminepropan-1-ol (7 mL, 93 mmol) was reacted with MMT−Cl (2 g, 0.1 equiv) in anhydrous pyridine for 3 days (room temperature). The solvent was removed at reduced pressure, and the crude was dissolved in DCM and washed with a 10% aq citric acid solution and brine. Purification was accomplished by silica gel column chromatography, eluting with hexanes and increasing amounts of DCM (5−100%) in the presence of 2% TEA (58% yield). R_f (DCM/hexanes/TEA 79:19:2) = 0.4. ^{1}H NMR ($CDCl_3$, 200 MHz) δ (ppm): 6.77−7.44 (m, 14H, Ar-H), 3.88 (t, J = 5.2 Hz, 2H, C**H_2**OH), 3.78 (s, 1H, OH), 2.40 (t, J = 5.2 Hz, 2H, NHC**H_2**), 1.7 (m, J = 5.2 Hz, 2H, CH_2C**H_2**CH_2); anal HPLC t_R = 12.8 min (C18, gradient from 50% to 100% of B in 30 min; A, 10 mM NH_4OAc in H_2O; B, ACN).

MMT−NH−L_3−P(OCNE)$NiPr_2$. Phosphitylation of the free hydroxyl group of MMT−NH−CH_2-CH_2-CH_2-OH was accomplished by overnight reaction with P(OCNE)$(NiPr_2)_2$ (3 equiv) and tetrazole (0.7 equiv) in anhydrous ACN (room temperature). After removal of the solvent, the product was dissolved in DCM, washed with saturated aq $NaHCO_3$ and brine, dried and evaporated to dryness, and used without further purification (^{31}P NMR ($CDCl_3$, 120 MHz) δ 144.9 ppm); anal HPLC t_R = 28.6 min (C18, gradient from 50% to 100% of B in 30 min; A, 10 mM NH_4OAc pH = 7; B, ACN).

Synthesis of the Conjugates 4. 1,2,3,4,5-pentafluorophenyl 4-nitrobenzenesulfonate was prepared as previously described (*28*). The MMT−NH−linker−oligonucleotide−resin (5 μmol) was transferred from the automatic DNA synthesizer reactor into a 5-mL polypropylene syringe fitted with a polyethylene disc. The MMT group was removed by subsequent treatments with the standard detritylation solution (3% TCA/DCM) until no color corresponding to the monomethoxytrityl cation was observed, which was followed by washing with DCM.

A mixture of the carboxyl-derivatized acridine (**3**) to be coupled (5 equiv with respect to resin-bound amines), PFNB (5 equiv), DIEA (25 equiv), and a catalytic amount of HOBt was dissolved in 250 μL of a 0.8 M solution of LiCl in DMF/NMP, and, after 15 min for carboxyl group preactivation, it was added to the linker−oligonucleotide−resin. After 2.5 h at room temperature with stirring, the resin was filtered, washed (DMF, DCM, and MeOH) and dried, and treated with 2 mL of a 1:1 mixture of concentrated aqueous NH_3/dioxane for 6 h at room temperature. The filtrate and washings (H_2O, MeOH) were collected, and the acridine−oligonucleotide conjugate was purified by reversed-phase medium-pressure liquid chromatography (Vydac C18, 20 × 2 cm column, gradient from 0% to 100% of B, A = 10 mM NH_4AcO, B = [65% (10 mM NH_4AcO) + 35% (ACN/H_2O 1:1)], 600 mL of each solvent). Homogeneity of the collected fractions was assessed by reversed-phase HPLC analysis (C18, gradient from 5% to 35% of B in 15 min, A = 10 mM aq NH_4AcO, B = ACN/H_2O 1:1), and characterization was carried out by MALDI-TOF MS (negative mode, reflector, 2,4,6-trihydroxyacetophenone).

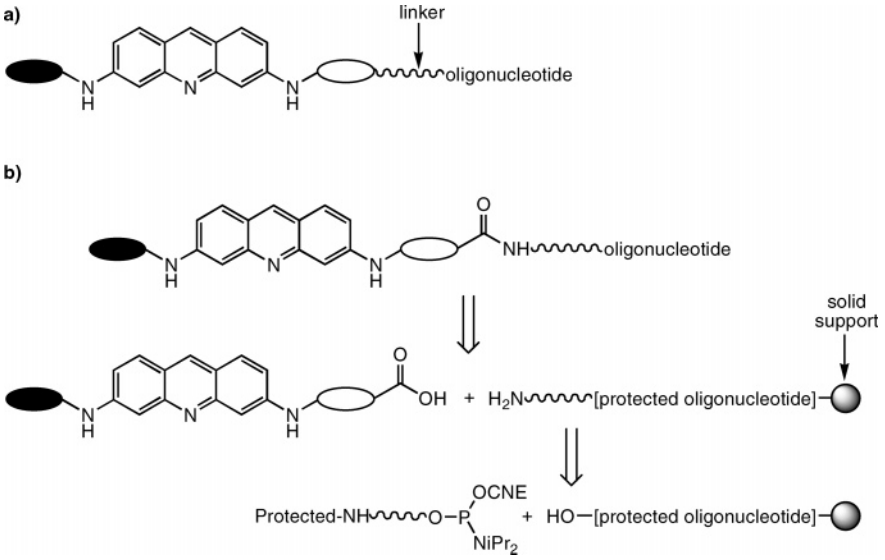
Fluorescence Melting Experiments. Fluorescence melting curves were determined using a Roche LightCycler as previously described (*29*−*31*) with excitation and detection wavelengths of 488 and 520 nm, respectively. The final concentration of the intramolecular quadruplex-forming oligonucleotide was 0.25 μM, in a total volume of 20 μL, dissolved in 50 mM potassium phosphate pH 7.4. Samples were first denatured by heating from 30 to 95 °C at a rate of 0.1 °C.s^{-1}. These were maintained at 95 °C for 5 min and annealed by cooling to 30 °C at 0.1 °C per second. The fluorescence was recorded during both the melting and annealing phases. Although the slowest heating rate for the LightCycler is 0.1 °C.s^{-1}, curves at lower rates of heating were obtained by raising the temperature in 1 °C increments, leaving the samples for 2 min between each temperature rise.

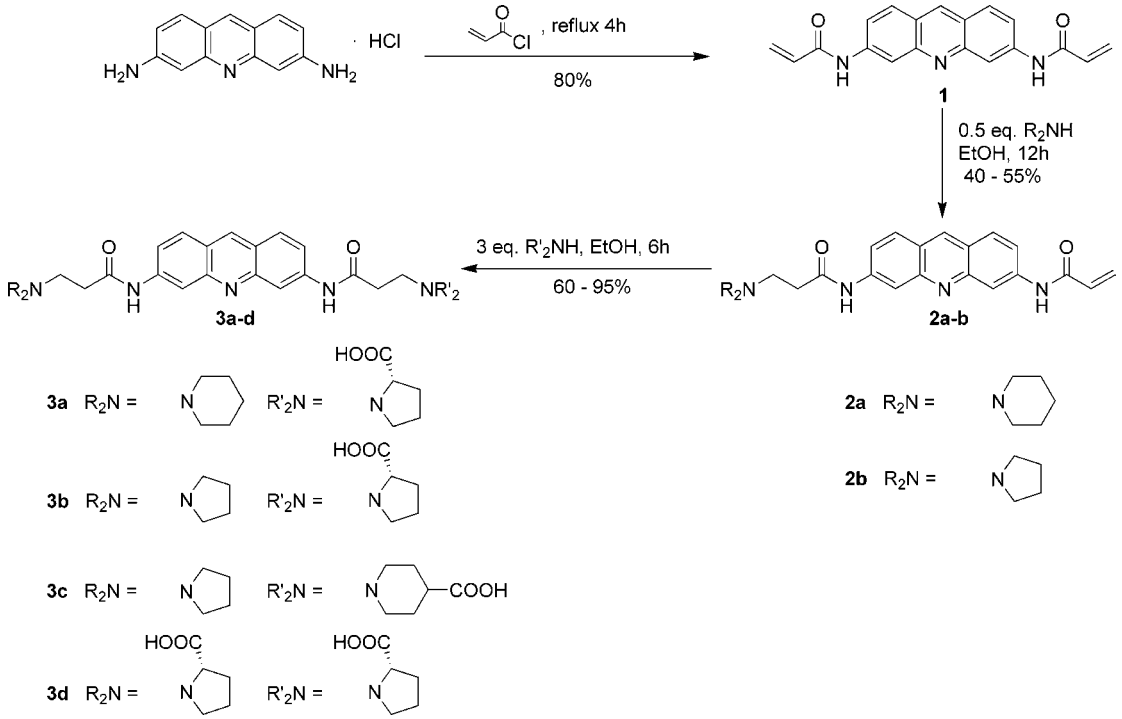
RESULTS AND DISCUSSION

Synthesis of the Acridine−Oligonucleotide Conjugates. Conjugates were designed so as to have the general structure shown in Scheme 1a. The aromatic moiety of the conjugates was expected to stabilize G-quadruplex structures and promote their formation, while the oligonucleotide chain was added to impart selectivity for the telomeric region. Acridines were chosen for the aromatic moiety of the conjugate since, when this work started, some of the most effective telomerase inhibitors reported were derivatives of 3,6-diaminoacridine (proflavin) with the two amines acylated with 3-(dialkylamine)-propionyl groups. The commercial availability and low price of proflavin also made it an advantageous starting material. We

Scheme 1. Schematic Representation of Acridine−Oligonucleotide Conjugates (a), and Retrosynthetic Analysis (b)



Scheme 2. Synthesis of the Asymmetrically Substituted Acridine Derivatives



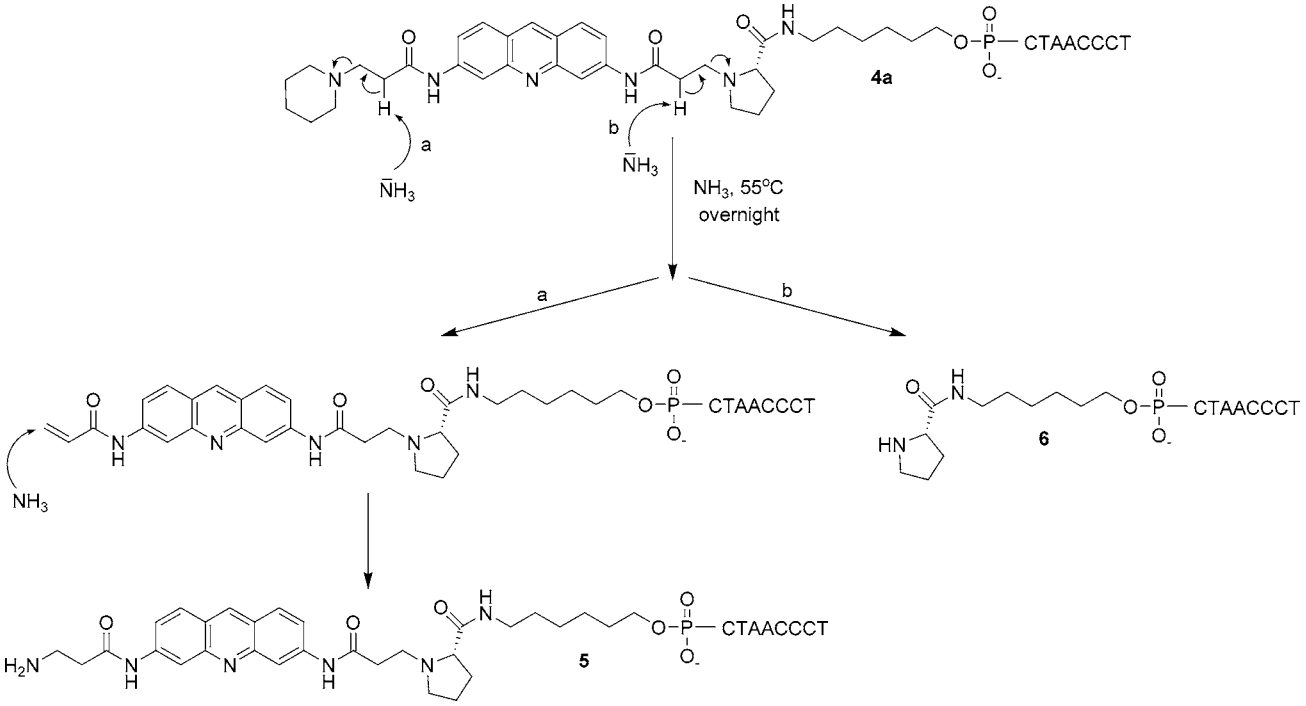
reasoned that it would be convenient to keep the same basic structure as that of the acridine derivatives that have been shown to be telomerase inhibitors (*14*). Although the two amines of proflavin have to be transformed into 3-(dialkylamino)propionamides, only one of these groups has to be derivatized to allow conjugation to the linker−oligonucleotide (Scheme 1b). Commercially available acridine phosphoramidite derivatives could not be used since their acridine rings are not suitably modified, while acridines that exhibit telomerase-inhibiting properties typically possess alkylamino side chains.

The conjugates were synthesized taking advantage of solid-phase procedures. Thus, the oligonucleotide was assembled, and its free end was modified with a suitable linker on a solid support, where the key conjugation was also carried out. An amide bond seemed a sensible choice to covalently link the two moieties. Amides are stable and can be obtained by exploiting a variety of reagents developed for peptide synthesis. In addition, amine groups are easy to add to oligonucleotide chains.

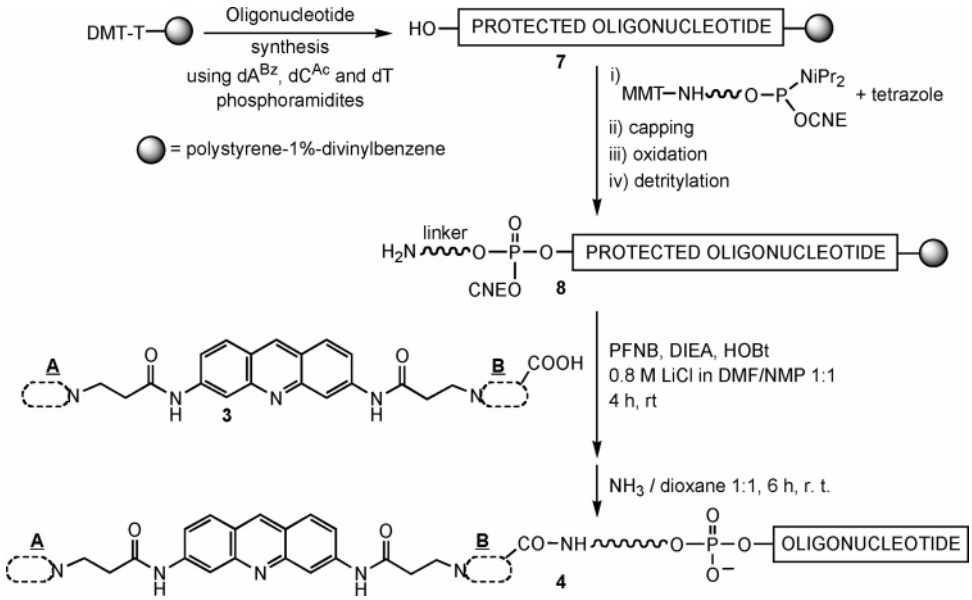
The synthesis of the asymmetrically substituted acridines was not straightforward. Attempts based on the selective protection of one of the amines of proflavin either failed or afforded the final product in very low yields. The acridines used in the conjugation reactions were synthesized from 3,6-diacryloylproflavin (**1**), which was prepared by reacting proflavin with an excess of acryloyl chloride (Scheme 2). The symmetry of the system was broken with the first Michael addition. Reaction of 3,6-diacryloylproflavine with piperidine or pyrrolidine afforded 3-(3-piperidinopropionyl)- or 3-(3-pyrrolidinopropionyl)-6-acryloylproflavin (**2a** or **2b**), respectively. The target carboxyl-derivatized acridines, **3**, were obtained after addition of proline or isonipecotic acid (isonipecotic = 4-piperidinecarboxylic) to **2**. Treatment of 3,6-diacryloylproflavin with an excess of proline afforded the symmetrical biscarboxylate **3d**.

Three oligonucleotide sequences were assembled using the standard phosphite triester methodology (phosphoramidite derivatives of dT, dA^{Bz}, and dC^{Bz}). Two were complementary to

Scheme 3. Side Reactions Taking Place at the Final Deprotection Step when the Ammonia Treatment Was Carried Out at 55 °C, Shown Here for Conjugate 4a



Scheme 4. Synthesis Scheme for the Preparation of the Conjugates



the single-stranded telomeric DNA (dCTAACCCT and dAACCCTAA) and the third, which contained the same bases randomized, was used as a control (dTCACTCAT). The 5′ end of resin-linked oligonucleotides was subsequently derivatized with an amine linker. The linker had to be long and flexible enough to allow the acridine to interact with the quadruplex structure and the oligonucleotide to hybridize with the single-stranded telomeric DNA. Linkers of different lengths containing either alkyl or ethylene glycol chains were used. The latter, more polar linkers were expected to facilitate the approach of the conjugate to the polyanionic DNA chains.

In the first conjugation experiments, the carboxyl group of the acridine derivative was activated using either *N*,*N*′-diisopropylcarbodiimide and 1-hydroxybenzotriazole, (benzotriazol-1-yloxy)trispyrrolidinophosphonium hexafluoroposphate (PyBOP) in the presence of DIEA, or (7-azabenzotriazol-1-yloxy)-trispyrrolidinophosphonium hexafluoroposphate (PyAOP) and DIEA. Although a large excess of acylating reagent was reacted with the H_2N−linker−oligonucleotide−CPG (2 h, rt), coupling yields were either 0% or below 10%.

Incorporation of the acridine moiety was controlled by treating an aliquot of conjugate−resin with concentrated aqueous ammonia and analyzing the crude by reversed-phase HPLC and MALDI-TOF MS. Detection of linker−oligonucleotide and/or acetyl−linker−oligonucleotide indicated that the coupling had not gone to completion. The origin of the acetyl−linker−oligonucleotide was not clear, but acetylation of amines has also been found to take place during the elongation of peptides on resin-linked oligonucleotides (*32*).

These experiments also showed that the deprotection conditions had to be fine-tuned. Since standard nucleobase protecting groups (A^{Bz}, C^{Bz}) had been used for oligonucleotide assembly,

Table 1.

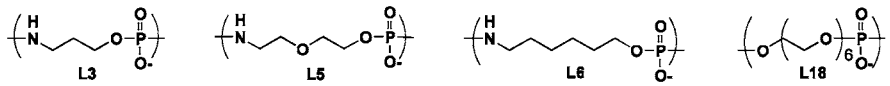
4i	Pyrrolidine	Proline	L5	5' AACCCTAA 3'



deprotection was carried out by overnight reaction with concentrated aqueous ammonia at 55 °C. Analysis of the crude product showed that the target conjugate (**4a**) was accompanied by a conjugate (**5**) in which the piperidine ring had been replaced by an amine group and proline−linker−oligonucleotide conjugate (**6**). **5** and **6** derive from the two possible reversed Michael reactions, with subsequent addition of ammonia to the acryloyl group in the case of **5** (Scheme 3).

Since we have previously obtained the best results in the synthesis of nucleopeptides and peptide−oligonucleotide conjugates using a polystyrene-1%-divinylbenzene copolymer rather than controlled pore glass (*33*, *34*), the linker−oligonucleotide moiety was resynthesized on a polystyrene matrix, and the PyAOP-mediated acylation reaction was repeated in the same conditions as on controlled pore glass. The yield of the conjugation step was slightly higher (17%) and somewhat better when *N*-[(dimethylamino)-1*H*-1,2,3-triazolo[4,5-*b*]pyridin-1-ylmethylene]-*N*-methylmethanaminium hexafluorophosphate *N*-oxide (HATU) was used to activate the carboxyl group (28% after 4 h). 1,2,3,4,5-Pentafluorophenyl 4-nitrobenzenesulfonate (*28*, *35*) was the reagent that finally allowed the conjugation reaction to attain acceptable yields (50−55%; for conditions, see below).

Finally, the target conjugates (**4**) were synthesized using the procedure outlined in Scheme 4. Oligonucleotides were assembled on an amine-derivatized polystyrene-1%-divinylbenzene support, replacing the phosphoramidite derivative of C^{Bz} by that of C^{Ac}. Linkers L_3, L_5, and L_6 (see structures in Table 1) were then introduced by coupling the corresponding monomethoxytritylamine phosphoramidite derivatives to the free 5′-hydroxyl group of the oligonucleotide (**7**), followed by capping and oxidation of the phosphite to phosphate. The longest linker, L_5-L_{18}, was introduced by subsequently coupling a hydroxyl-protected phosphoramidite (L_{18}) and an amine-protected phosphoramidite (L_5). The monomethoxytrityl amine-protecting group was removed using the same mild acid reagent commonly used to eliminate the DMT groups, and the carboxyl-derivatized acridine moiety was coupled to **8** by reaction with PFNB and DIEA (molar ratio with respect to polymer-bound amine groups 10:10:25), in the presence of catalytic amounts of HOBt. A 0.8 M solution of LiCl in a 1:1 mixture of *N*,*N*-dimethylformamide and *N*-methylpyrrolidone was used as the solvent, and the reaction was left to proceed for 4 h at room temperature. In spite of using these conditions, coupling yields remained below the expected value in some conjugation reactions.

Permanent protecting groups were removed by treatment of the conjugate resin with a 1:1 ammonia/dioxane mixture for 6 h at room temperature. In these conditions, the presence of impurities such as **5** and **6** was virtually nonexistant. Conjugates were purified by reversed-phase liquid chromatography and characterized by MALDI-TOF mass spectrometric analysis.

Interaction with Intramolecular Quadruplexes. We examined the interaction of these acridine−oligonucleotide conjugates with quadruplex-forming oligonucleotides that contain the human telomeric repeat sequences $(GGGTTA)_n$. These model oligonucleotides had to be designed to allow the formation of quadruplex structures as well as hybridization of the oligonucleotide portion of the conjugate. The quadruplex-forming sequence has to contain at least four GGG repeats, so the basic $(GGGTTA)_3GGG$ sequence was extended to offer a single-stranded arm suitable for duplex formation with the conjugates.

Information on quadruplex stabilization by the conjugates was obtained from thermal denaturation studies, in which an increase in the melting temperature of the quadruplex indicates a stabilizing effect. The thermal stability of the quadruplex was evaluated using a fluorescence-based method (*29*) which allows melting temperatures to be determined with high sensitivity using a small amount of material. In these experiments, the quadruplex-forming oligonucleotides are labeled at one end (5′) with a fluorophore (F, fluorescein) and at the other (3′) end with a quencher (Q, methyl red). When the quadruplex is folded, these groups are in close proximity, and the fluorescence is quenched. When the quadruplex melts, these groups become separated, and there is a large increase in fluorescence.

Conjugate−oligonucleotide interactions were studied using three different model oligonucleotides containing 5 or 6 GGG tracts: F-TGGGTTAGGGTTAGGGTTAGGGTTAGGG-Q (**OL-1**), F-TGGGTTAGGGTTAGGGTTAGGGTTAGGGTTAGGG-Q (**OL2**), and AGGGTTAGTTTT-Q-GGGTTAGGGTTAGGGT-TAGGG-Q (**OL3**), in which F and Q stand for the fluorophore and the quencher, respectively. **OL1** and **OL2** can adopt different structures, depending on which G tracts are part of the folded quadruplex and which are in the single-stranded overhang (Scheme 5). For **OL1**, only one of the structures

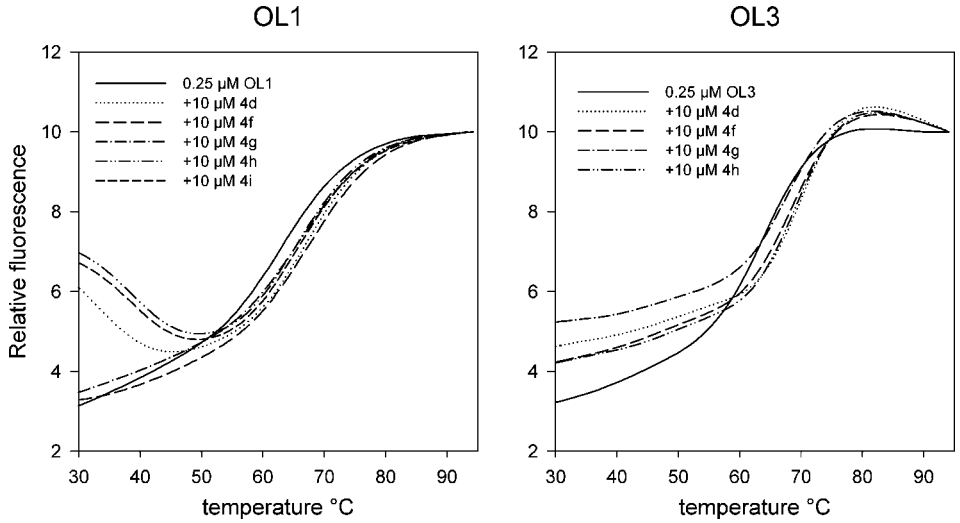


Figure 1. Fluorescence melting curves showing the effects of oligonucleotide−acridine conjugates (10 μM) on the melting of **OL1** (left-hand panel) and **OL3** (right-hand panel). The quadruplex concentration was 0.25 μM in each case, and the reactions were performed in 50 mM potassium phosphate pH 7.4. For **OL1**, the heating rate was 0.1 °C.s^{-1}; this was reduced to 0.5 °C.min^{-1} for **OL3**.

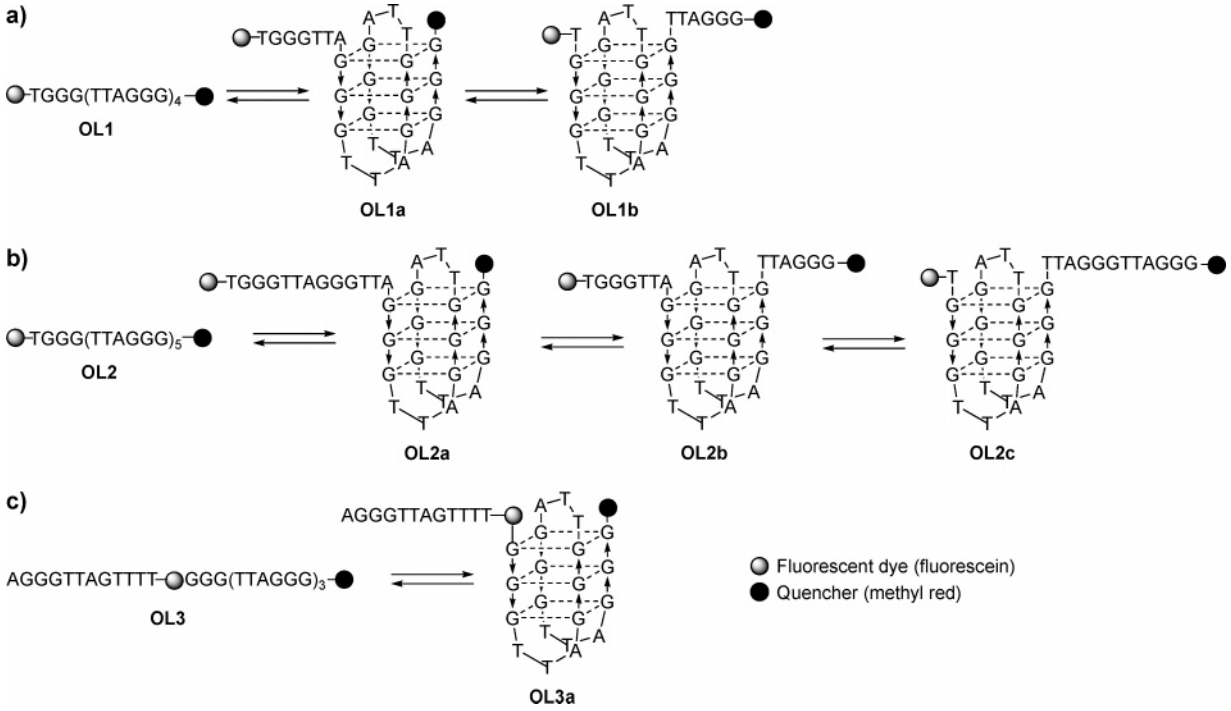
Scheme 5. Possible Structures for the Intramolecular Quadruplexes Adopted by (a) OL1, (b) OL2, and (c) OL3



(**OL1a**, Scheme 5a) will allow the oligonucleotide moiety of the conjugates to interact with the complementary telomeric sequence. Two of the conformations of **OL2 (OL2a** and **OL2b**, Scheme 5b) are appropriate for interaction with the acridine conjugates. **OL3** was designed so that only one quadruplex structure can be formed (Scheme 5c), where the "core" quadruplex system and the single-stranded telomeric sequence are more separated than in the other model oligonucleotides.

In these melting experiments, the quadruplex-forming oligonucleotide concentration was 0.25 μM, and the concentration of the conjugates ranged between 2 and 10 μM. Representative melting curves in the presence and absence of different conjugates are shown in Figure 1. The changes in the melting temperatures of the quadruplexes (ΔT_m) produced by the conjugates are summarized in Table 2.

Examination of the data in Table 2 shows that all the conjugates stabilize quadruplex structures, and the increases in melting temperature (T_m) depend on their concentration, as expected. Inspection of the melting profiles of oligonucleotide **OL1** (Figure 1) shows that, in some cases, the transition between the folded G-quadruplex and the single-stranded form is accompanied by another transition, with a reversed profile at lower temperatures. This curve corresponds to melting of the

Table 2.

duplex that is formed between the conjugated oligonucleotide and the single-stranded arm of **OL1**. Its reversed profile is explained by suggesting that hybridization shields the fluorophore and prevents energy transfer to the quencher. This curve was not observed when thermal denaturation experiments were carried out with **OL1** either alone, as expected, or in the presence of conjugates **4e**, **4f**, and **4g**. The oligonucleotide sequence in **4g** is not complementary to that of the telomere; this conjugate was synthesized as a control, and as expected, it does not display the reverse profile at low temperatures. Duplex formation does not occur with conjugates **4e** and **4f**. Since the main difference between these and the other conjugates is the length of the spacer linking the aromatic and oligonucleotide moieties of the conjugate, we surmise that duplex formation is hampered by the shortest and longest linkers. Linkers L5 and L6 (8 and 9 atoms long, respectively) thus seem to be the best for allowing duplex formation. Similar results were found with **OL2** with respect to duplex formation. In **OL3**, the relative position of the fluorophore and the quencher is different and is such that melting of the duplex is not observed.

Since the main purpose of this work was to add telomere-hybridizing properties to quadruplex-stabilizing molecules, these results confirm that our goal has been achieved. Our acridine−oligonucleotide conjugates can interact both with quadruplex structures and with the single-stranded telomeric sequence.

From a quantitative point of view, the quadruplex stabilization provided by the conjugates is not very high. Nevertheless, it has to be taken into consideration that **OL1** and **OL2** exist in equilibrium between three or four different structures (see Scheme 5). The T_m data therefore represent averages of the interaction with the different conformations, some of which cannot bind the conjugates. Only **OL3** adopts a single quadruplex structure, and the highest ΔT_ms were observed between this oligonucleotide and conjugates **4d** and **4h**. The complexes formed by the other conjugates and **OL3** displayed similar or slightly higher than those formed with **OL1**, which are higher than those formed with **OL2**. These results suggest that the apparent stabilization of the quadruplex by the acridine conjugate improves if the number of available conformations is lower.

CONCLUSIONS

We have developed a methodology for synthesizing a small library of acridine−oligonucleotide conjugates, making use of acylation and Michael reactions to modify the aromatic moiety, and of amide formation for the conjugation reaction. Conditions for the final deprotection of the conjugate were also established. The thermal denaturation experiments demonstrated that the acridine ring of the conjugates interacts with and stabilizes the quadruplex structures. The conjugated oligonucleotide hybridizes with the complementary single-stranded telomeric DNA to impart selectivity to the aromatic moiety. The best results were obtained with conjugate **4d**, in which the acridine ring is flanked by pyrrolidine and isonipecotic acid units and linked to oligonucleotide CTAACCCT by a bis(ethylene glycol) linker (L5).

TECHNICAL NOTES

Efficient Synthesis of an Aldehyde Functionalized Hyaluronic Acid and Its Application in the Preparation of Hyaluronan−Lipid Conjugates

Dipali Ruhela, Kareen Riviere, and Francis C. Szoka, Jr.*

Departments of Pharmaceutical Chemistry and Biopharmaceutical Sciences, School of Pharmacy, University of California at San Francisco, San Francisco, CA 94143-0446. Received March 22, 2006; Revised Manuscript Received June 26, 2006

An efficient method to synthesize hyaluronan oligosaccharide lipid conjugates is described. This strategy is based on the introduction of a double bond in the glucuronic acid of the hyaluronic acid (HA), by the biodegradation of HA with hyaluronate lyase, followed by the generation of a free aldehyde group at the nonreducing end of hyaluronic acid via ozonolysis and the subsequent reduction of the generated ozonide. The resulting aldehyde-functionalized HA is then coupled to dipalmitoyl phosphatidylethanolamine (DPPE) using reductive amination chemistry. This methodology can be extended to link molecules such as biotin, polymers, or proteins to HA for numerous applications in drug delivery and in the creation of biocompatible materials for tissue repair and engineering.

INTRODUCTION

Hyaluronic acid (HA) is a high molecular weight linear polysaccharide which is composed of a simple repeating disaccharide unit of D-glucuronic acid (GlcA) and *N*-acetyl-D-glucosamine (GlcNAc) linked through a β 1,3-glycosidic bond (Figure 1). The disaccharides are in turn linked to each other through a β 1,4-glycosidic bond. HA is found in the extracellular matrix and is the main ligand for CD44, a type 1 transmembrane glycoprotein that is overexpressed in many cancers.

HA has numerous applications in tissue repair and engineering and in gene and drug delivery. Cross-linked HA has been used as a biomaterial for cartilage repair (*1*). For gene delivery applications, HA−DNA microspheres and a DNA−HA matrix have been used for the controlled release of DNA and are adaptable for site specific targeting (*2*, *3*). Various HA conjugates have been tested for targeting drugs to CD44. HA−Taxol and HA−HPMA−Doxorubicin, both synthesized from high molecular weight HA, have been shown to have an increased uptake by tumor cells and therefore have a potential to target drugs selectively to tumors (*4*, *5*). Both high molecular (*6*, *7*) and low molecular (*8*) weight HA−lipid conjugates have been shown to successfully target liposomes to CD44 expressing cancers and to increase cell killing both in vitro and in vivo. However, certain liver receptors specifically recognize high molecular weight HA and rapidly clear it from the systemic circulation (*9*). In addition, high molecular weight HA may not be ideal since the frequency of attachment between HA and the conjugated drug is often unknown. Therefore, HA conjugates having small, defined oligosaccharides may avoid clearance by the liver while still preferentially target CD44-overexpressing tumor cells. Understanding the significance of oligomer length for receptor binding is important for furthering drug targeting studies using HA.

Several HA oligosaccharides, having different lengths and modified sequences, have been synthesized over the past decade (*10*), but there are no published studies of well-defined lipooligosaccharides. Reductive amination chemistry has been used to conjugate HA with lipids (*11*, *12*), polymers (*13*), and a fluorescent tag (*14*). In our ongoing efforts to synthesize lipooligosaccharides, we have designed a more efficient strategy for the synthesis of HA−lipid conjugates of defined length. In this paper, we summarize the results of a methodology, which is based on the generation of a free aldehyde group at the nonreducing end of hyaluronic acid (HA) via enzymatic digestion of high molecular weight HA using hyaluronate lyase, ozonolysis, and the subsequent reduction of the generated ozonide. The aldehyde is much more reactive than the hemiacetal so the resulting functionalized hyaluronic acid is easily coupled to DPPE through the aldehyde rather than via the reducing end using an equimolar concentration of the lipid.

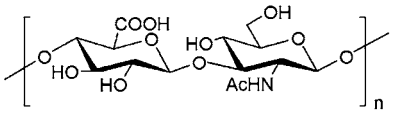

Figure 1. Disaccharide repeat unit of HA.

EXPERIMENTAL PROCEDURES

Enzymatic Digestion of HA. Sodium hyaluronate (Genzyme Biosurgery, Cambridge, MA) was dissolved in digest buffer (200 mM NaCl and 50 mM sodium acetate, adjusted to pH 6.0) at a concentration of 200 mg/40 mL, and stirred at room temperature for 1 day. To 40 mL of dissolved HA, 4000 U of hyaluronate lyase (*Streptomyces hyalurolyticus*, Sigma, St. Louis, MO) was added and allowed to incubate for 4 h at 37 °C. The enzyme was inactivated by immersing the flask in boiling water for 10 min, and the contents were lyophilized.

Size Exclusion Chromatography. The resulting white powder was dissolved in 1 mL of 0.05 M NH_4HCO_3 buffer, filtered through a 0.45 μm filter, and loaded via a sample injector onto a 50 mm × 100 cm Bio-Gel Column (Biorad P-30, medium grade, 300 g). The column was equilibrated in 0.05 M NH_4-

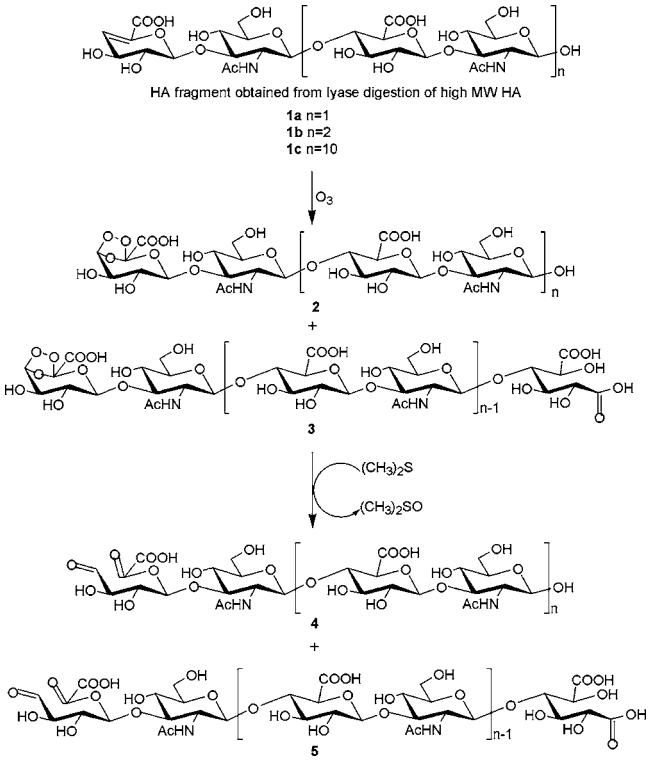
Scheme 1



HCO_3. The first 450 mL of eluate was not collected. Thereafter, fractions of 8 mL each were collected, and their absorbances were read at 232 nm. Fractions containing HA−oligomers were pooled as individual length oligomers, lyophilized, redissolved in H_2O, and lyophilized again to remove residual ammonium bicarbonate salt. The masses of the oligomers were confirmed by MALDI-TOF. The separation profile and the MALDI-TOF results are shown in the Supporting Information.

Ozonolysis/Reduction of the HA Oligomers (Scheme 1). The HA oligomer (**1**) was dissolved in a mixture of $(CH_3)_2SO$, H_2O and CH_3OH. The solution was cooled to −78 °C and ozone was bubbled into the solution via a sintered glass pipet until a pale blue color persisted. This treatment yielded ozonide (**2**) and ozonide (**3**). Oxygen was then bubbled through the solution to remove the excess ozone until the solution became colorless. After the addition of dimethyl sulfide, the solution was allowed to stir at room temperature for 2 h to reduce the ozonides to yield products **4** and **5**. This mixture was thoroughly dried and used immediately for coupling.

Synthesis of the Lipooligosaccharide (Scheme 2). The crude mixture of **4** and **5** was resuspended in a suitable combination of $(CH_3)_2SO$ and CH_3OH. To this, 1.05 equiv of DPPE (Avanti Polar Lipids, Alabaster, AL) in CH_3OH-$CHCl_3$ was added, and the mixture was stirred at 60 °C for 2 h. Thereafter, a 50-fold molar excess of freshly prepared reducing agent solution (1% w/v of $NaCNBH_3$ (Aldrich, St. Louis, MO) in $CHCl_3/CH_3OH$ (1:1 by volume) containing 0.1% CH_3COOH) was added in five portions in 1 h increments. The resulting yellow solution was then allowed to stir at 60 °C for 2 days to yield the HA_n−DPPE conjugate (**6**), which contains DPPE at the nonreducing end, and the HA_{n-1}−DPPE conjugate (**7**), which bears DPPE on the nonreducing residue and contains a lactone at the other end. The solvent was evaporated under vacuum. The residue was resuspended in a modest amount of water and repeatedly precipitated (three times) in acetone to remove excess $NaCNBH_3$. The resultant pellet was then resuspended in minimal $CHCl_3/CH_3OH/H_2O$ (65:25:4 by volume) and loaded onto a prepacked Biotage silica column. The column was first washed with $CHCl_3$, and then a gradient program of $CHCl_3/CH_3OH/H_2O$ was run to elute the two products separately. The purified conjugates were characterized by MALDI-TOF, as shown in Table 1.

The HA_4−DPPE conjugate was fully characterized by NMR using pyridine-d_5/DCl/CD_3OD/$CDCl_3$ in a volume ratio of 1:1:2:10 (*16*). ^1H NMR (400 MHz) with characteristic peaks: δ 5.2 (1H, H-1α), 4.39 (d, 2H, H-1′β, H-1″), 4.36 (d, 2H, H-1‴β, H-1′α), 4.32 − 4.11 (20H, sugar ring protons), 3.81−3.29 (12H, sugar ring protons), 2.25−1.29 (56H, methylene protons of DPPE), 2.01 (6H, $NHCOCH_3$), 1.56 (4H, $NHCH_2CH_2$), 0.87 (6H, terminal CH_3 of DPPE). The spectra for HA_4−DPPE and HA_6−DPPE are in the Supporting Information.

Synthesis of a Biotinylated Conjugate of 1c. As an extension to our study, we synthesized a biotinylated conjugate of HA using this strategy. For this purpose, compound **1c** was subjected to ozonolysis/reduction with $(CH_3)_2S$ as mentioned above. The product was then conjugated with biotinylated diaminopyridine (BAP) using $NaCNBH_3$. The crude product was loaded onto a column, packed with AG1X2 resin (formate form), and equilibrated with 10 mM ammonium acetate. The product was then eluted from the column with 250 mM ammonium acetate and analyzed for absorbance at 210 nm. The salt was removed by dialysis against water, and the product was lyophilized to afford a light yellowish powder. A portion of this product was then loaded onto a streptavidin−agarose column in parallel with a control experiment where free HA_{12} (**1c**) was loaded onto a separate column.

RESULTS AND DISCUSSION

Conventionally, HA derivatives are directly prepared from oligomers obtained by enzymatic digestion of high molecular weight HA with hyaluronidase. Alternatively, high molecular weight HA can be digested with hyaluronate lyase, an endo-hexosaminidase whose catalytic activity introduces an α,β unsaturated carboxylic acid moiety at the nonreducing end of the oligomers. We decided to exploit this unique double bond on HA for the synthesis of small, well-defined HA−lipid conjugates. The double bond can efficiently be cleaved and converted to an aldehyde functionality via ozonolysis and subsequent reductive workup. Previously, Weingarten and Thiem (*17*) have synthesized aldehyde functionalized carbohydrate derivatives by first introducing a functionality, containing a double bond, on the sugar which was then efficiently converted to a free aldehyde via ozonolyis. Coupling of amino acids with this aldehyde functionalized carbohydrate by reductive amination led to novel carbohydrate−amino acid conjugates. However, in our case, we can generate a double bond within the HA oligomer directly by digestion with hyaluronate lyase. Ozone-assisted cleavage of this double bond can then generate a free aldehyde functionality which can be easily coupled to proteins and phospholipid amino groups by reductive amination. To test our hypothesis, we carried out this sequence of reactions on small HA oligomers and characterized the products formed.

In order to obtain well defined, small HA oligomers, ranging from 4−12 sugar residues containing a double bond at the nonreducing end (having the structure β-D-4en-thrHexA-(1→3)-[β-D-GlcNAc-(1→4)-β-D-GlcA]$_n$-(1→3)-D-GlcNAc), we followed a published procedure by Price et al. (*15*). High molecular weight HA was digested with hyaluronate lyase to yield hyaluronan fragments ranging from 4 to 12 saccharides in length. The oligomers were separated on a size exclusion column and analyzed for their absorbance at 232 nm.

The tetrasaccharide and hexasaccharide thus obtained were subjected to ozonolysis/ reduction with $(CH3)_2S$. This treatment cleanly cleaved the terminal double bond and generated a free aldehyde functionality at the nonreducing end of the oligomer.

Scheme 2

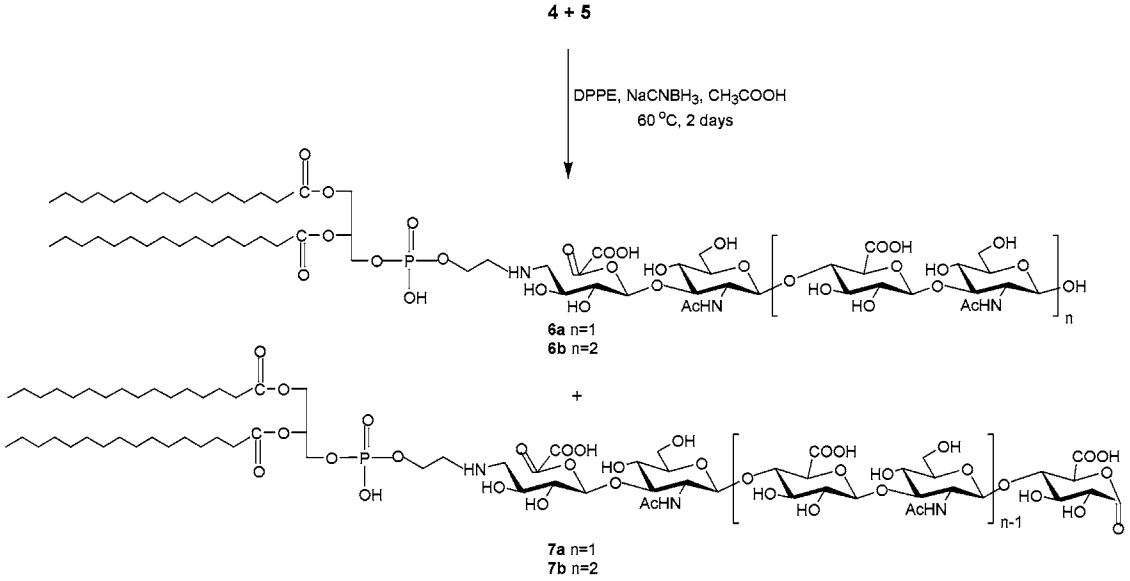


Table 1. MALDI-TOF MS (Positive Mode) Results for HA_n−DPPE Conjugates

starting compound	product	expected MW	observed MW
1a	**6a**	1464.3	1487.5 ($M + Na^+$)
	7a	1259.1	1260.3 ($M + H^+$)
1b	**6b**	1843.3	1866.3 ($M + Na^+$)
	7b	1638.1	1639.2 ($M + H^+$)

Ozonolysis of the oligomers (Scheme 1) yielded the corresponding ozonide (**2**) and ozonide (**3**) which resulted from the electrophilic attack of ozone on HA to liberate the anomeric carbon of the second sugar residue from the reducing end of the oligomer, via ozone catalyzed hydrolysis of the β 1,3-glycosidic bond. It has been previously reported that ozone can preferentially oxidize β-D-glycosidic linkages in unprotected carbohydrates and generate fragments of various repeat lengths (*18*, *19*). As illustrated in Scheme 1, controlled exposure of the carbohydrate to ozone yielded a mixture of even (compound **4**) and odd (compound **5**) numbered HA fragments, containing a free aldehyde functionality, from the same oligomer.

The resulting aldehyde functionalized HA oligomers were coupled to DPPE using reductive amination chemistry (Scheme 2) in a mixture of aprotic solvents ($CHCl_3$ and CH_3OH). The reaction with the HA_4 oligomer yielded the products **6a** and **7a**, and similarly the products **6b** and **7b** were obtained from HA_6. One-step purification of **6** and **7** by silica column chromatography afforded pure HA_n−DPPE and HA_{n-1}−DPPE conjugates. The products were analyzed by MALDI, and the correct masses for the even (**6a** and **6b**) and odd (**7a** and **7b**) lipooligosaccharides were obtained, as shown in Table 1.

HA_4−DPPE and HA_6−DPPE were also characterized by ^1H NMR. The NMR spectra showed characteristics peaks for both oligosaccharides and DPPE in the correct ratio. Furthermore, we observed the H-1α proton at δ 5.2 for HA_4−DPPE, which indicates that the anomeric proton at the reducing end of the tetrasaccharide is still intact. This confirms that DPPE is linked to HA via the nonreducing end. Due to line broadening and low resolution, we could not observe the peak for the anomeric proton in HA_6−DPPE. This line broadening is commonly encountered in the analysis of glycolipids, which have a tendency to self-associate in solution.

We also synthesized a biotinylated derivative of HA_{12} using this strategy. We purified the crude product by running the reaction mixture through an AG1X2 resin-packed column. We analyzed the fractions by reading their absorbance in the region of 210−250 nm. The product was then loaded onto a streptavidin−agarose column in parallel with a control experiment where free HA_{12} (**1c**) was loaded onto a separate column. Eluate from the control column showed absorbance in the region of 210−250 nm, which is characteristic of a sugar. In contrast, the eluate from the experimental column gave a baseline absorbance in this range, indicating that the conjugate qualitatively bound to the column via biotin−streptavidin interactions.

We have demonstrated a facile synthetic approach for preparing HA derivatives. This approach generates a free aldehyde on HA that can readily react with equimolar amounts of lipids containing an amino functionality. This route is more efficient in comparison to the conjugation at the reducing end of the sugar. In addition, we can synthesize a series of conjugates containing even and odd number sugar residues, which can have potential significance in certain applications where oligomer length is critical. Although this approach is quite efficient, it seems to be more suited for small length oligomers because of the difficulty in controlling the side reaction (the fragmentation of the larger oligosaccharides) that is caused by ozone-assisted hydrolysis of the glycoside bonds. The HA−lipid conjugates thus generated are currently being evaluated for their properties as targeting ligands and also as potential candidates to mask the surface of the liposomes and microspheres from nonspecific interactions with biological proteins and cells.

ACKNOWLEDGMENT

We wish to thank Dr. Paul Ortiz de Montellano for generously allowing us to use the ozonator in his laboratory, Joshua Park for synthesizing BAP, and Michael S. Cohen for assistance in performing the NMR analysis. We thank Dr. Joon Sig Choi for preliminary studies on hyaluronate lyase digestion of HA. We gratefully acknowledge the financial support from the National Institutes of Health (GM61851-01A1) and the Department of Defense (DAMD17-01-1-0192). Thanks are also extended to the UCSF Mass Spectrometry Facility (A. L. Burlingame, Director) supported by NIH NCRR RR01614.

An Intramolecular Cyclization Reaction Is Responsible for the in Vivo Inefficacy and Apparent pH Insensitive Hydrolysis Kinetics of Hydrazone Carboxylate Derivatives of Doxorubicin

Cameron C. Lee,[†] Andrew T. Cramer,[†] Francis C. Szoka, Jr.,[‡] and Jean M. J. Fréchet*[,†]

Department of Chemistry, University of California, Berkeley, California 94720-1460, and Department of Pharmaceutical Chemistry, University of California, San Francisco, California 94143-0446. Received May 5, 2006; Revised Manuscript Received June 23, 2006

Contradictory reports concerning the pH sensitive hydrolysis kinetics of certain hydrazone carboxylates of doxorubicin have appeared in this journal (Kaneko et al., *Bioconjugate Chem.* **1991**, *2*, 133. Padilla De Jesús et al., *Bioconjugate Chem.* **2002**, *13*, 453). Since the pH stability of the drug−carrier linkage in macromolecular prodrugs has a significant bearing on pharmacological efficacy, the hydrolysis kinetics of low molecular weight and polymeric doxorubicin hydrazone carboxylates were therefore reinvestigated. As observed previously, the conjugates readily release native doxorubicin at pH 5. Unexpectedly, in neutral buffer the hydrazone carboxylate conjugates do not release native doxorubicin, but instead rapidly release a doxorubicin derivative substituted at C-9 by 3,6-dihydro-1,3,4-oxadiazin-2-one with first-order kinetics ($t_{1/2}$ = 2.5 h). The proposed intramolecular cyclization reaction involving doxorubicin's C-14 hydroxyl and the carboxylate-substituted hydrazone rationalizes the seemingly anomalous hydrolysis kinetics seen for hydrazone carboxylate linked doxorubicin, and provides a possible explanation for the poor antitumor activity exhibited by polymer−doxorubicin conjugates utilizing this specific type of linkage.

INTRODUCTION

Drug delivery systems for the potent antineoplastic doxorubicin commonly rely on the use of a cleavable linkage between drug and carrier so that the drug may access the cell nucleus (*1*), although nuclear localization is not a prerequisite for cytotoxicity (*2*). For tumor-targeted drug delivery to be most effective the drug should only be released once the drug carrier has localized within the diseased tissue, and therefore premature release of the drug while circulating in the serum must be minimized. Linkages based on enzymatically labile peptides or acid-labile amides and hydrazones are the most commonly utilized means of covalent attachment between doxorubicin and a carrier (*3*, *4*).

Hydrazones, formed by condensation of the C-13 ketone of doxorubicin with a hydrazide, have been used for attaching the drug to antibodies (*5*, *6*) and polymers (*7*, *8*). Hydrazones are hydrolytically labile, with hydrolysis occurring at an accelerated rate at acidic pH. Acid-triggered prodrug conversion can be beneficial for tumor targeted drug delivery because (a) the extracellular environment of many tumors is mildly acidic (*9*) and (b) delivery of doxorubicin via an endocytic pathway, which can overcome multidrug resistance, involves trafficking via mildly acidic endosomes and lysosomes (*10*). Willner (*6*) and Ulbrich (*8*) have studied the influence of hydrazide structure on the rate of doxorubicin hydrazone hydrolysis in some depth. Curiously, Willner reported that the hydrolysis kinetics of the doxorubicin hydrazone **1** derived from hydrazine carboxylate **2** (Scheme 1) lacked pH sensitivity, with the rates of doxorubicin release at pH 4.5, 5.0, and 7.4 being essentially identical. Such behavior was not observed for hydrazones prepared from an acyl hydrazide, a semicarbazide, or a thiosemicarbazide; the authors offered no explanation for this apparent anomaly. We recently utilized a hydrazone carboxylate linkage very similar to **1** for the conjugation of doxorubicin to the end groups of a PEO−polyester dendrimer hybrid **3** (Scheme 2) (*11*, *12*). While we too found that the hydrazone carboxylate was hydrolyzed at acidic pH, in contrast to Willner's observation we reported that very little hydrolysis occurred under neutral conditions; at the time we failed to notice the discrepancy between our and Willner's results.

Our attempts at chemotherapy utilizing the doxorubicin-functionalized PEO−polyester dendrimer hybrids **3** and **4** (Scheme 2) in murine subcutaneous tumor models (B16F10 and C26) were largely unsuccessful in spite of substantial intratumoral concentrations of both polymer and drug (*13*, *14*, *15*). Unable to explain this lack of antitumor efficacy, we reexamined our system and the literature, and upon further review of the literature (especially Willner's report) we became suspicious of the hydrazone carboxylate linkage. Strengthening this suspicion was our observation that chemotherapy with PEO−dendrimer hybrid **5** (Scheme 2) provided a significantly enhanced tumor response relative to **4** (unpublished results). In polymer **5**, doxorubicin was attached via acyl hydrazone linkages, while in polymer **4**, doxorubicin was attached via hydrazone carboxylate linkages. We therefore investigated the hydrolysis kinetics of hydrazone carboxylate linked and acyl hydrazone linked doxorubicin from the polymers.

The release of drug from polymers **4** and **5** at 37 °C was monitored chromatographically. Polymers were dissolved in pH 5.0 and 7.4 buffers, and aliquots of the solutions were removed periodically for chromatographic analysis. The hydrolysis product of polymer **5** at pH 5.0 eluted at 14.2 min, coeluting with a doxorubicin hydrochloride standard. Under these conditions, the concentration of free doxorubicin in solution increased steadily with the half-maximum reached between 4 and 6 h. Only a small amount (<5%) of the same compound was released after 48 h at pH 7.4, consistent with previous reports (*6*, *7*, *8*). For polymer **4**, two unresolved peaks were observed in the

chromatogram during incubation at pH 5.0 (t_R = 14.2 min (major) and ~ 15 min (minor)), with the first peak coeluting with doxorubicin (Figure 1). The total peak area increased monotonically over time, reaching its half-maximum between 4 and 6 h. A single peak was observed upon incubation at pH 7.4, the elution time of which did not correspond to that of doxorubicin (t_R = 15.4). The area of this peak increased rapidly and reached its maximum value after 4 h, although the peak area decreased slowly over the next 48 h. We attribute the decrease in peak area to poor solubility of the released compound at pH 7.4, since we have also observed that doxorubicin hydrochloride is sparingly soluble in pH 7.4 phosphate buffers.

A quantity of the product eluting at 15.4 min suitable for characterization purposes was obtained by first synthesizing the hydrazone carboxylate **6**. As with **4**, conversion of compound **6** to the new product was >95% within 12 h upon incubation at 37 °C in a 100 mM NH_4OAc pH 7.0 buffer (the product remained soluble under these conditions). A plot of the area of **6** versus time determined chromatographically was best fit by a single inverse exponential function, indicating first-order reaction kinetics with a half-life of 2.5 h. The identity of the product was elucidated using mass spectrometry. The mass spectrum obtained was dominated by four major peaks at 584, 455, 437, and 419 *m*/*z*. We concluded that the highest mass peak was the singly protonated parent ion and was a doxorubicin

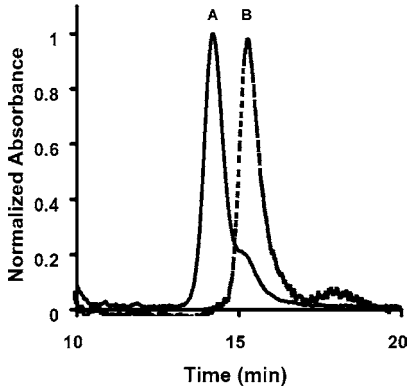

Figure 1. Normalized SEC chromatograms (λ_{abs} = 490 nm) for the products released from doxorubicin conjugate **4** after 24 h of incubation at 37 °C in aqueous solutions buffered at pH 5.0 (trace A) or pH 7.4 (trace B).

derivative, since the peaks at 455, 437, and 419 were 129, 147, and 165 *m*/*z* units below the parent ion, respectively, consistent with fragment ions resulting from the loss of daunosamine and two subsequent dehydrations. The parent ion is 40 mass units heavier than doxorubicin, and thus we have tentatively assigned its structure as a dihydrooxadiazinone cyclization product **7** resulting from intramolecular nucleophilic attack of the C-14 hydroxyl of doxorubicin on the carbonyl group of the hydrazone carboxylate linker (Scheme 3). Support for this type of reaction product is provided by a number of reports on the base-promoted cyclization of hydrazone carboxylates derived from α-hydroxy ketones (*16*, *17*, *18*).

Additional evidence for the dihydrooxadiazinone rearrangement product was provided by its ^{1}H NMR spectrum, which in most regards was identical to that of the starting material **6** but lacked the benzyl proton resonances and displayed a downfield shift of the C-14 methylene proton signal from 4.60 ppm in **6** (4.71 ppm in doxorubicin (*19*)) to 5.07 ppm in **7**, consistent with acylation of the C-14 hydroxyl. The absence of an upfield C-14 methylene proton resonance in the NMR spectrum of **7** indicates that the reaction was selective for the C-14 hydroxyl over the C-9 hydroxyl. This and the fact that the rearrangement occurs under such mild reaction conditions imply that the C-14 hydroxymethyl and carboxylate substituents of the imine are syn to each other in **4** and **6**, satisfying the geometrical requirements for nucleophilic attack by the C-14 hydroxyl (*16*, *18*). The cyclization selectivity seen for the primary hydroxyl of this α,α′-bishydroxyhydrazone is consistent with results reported by Kamernitskii et al. in their work with hydrazone derivatives of steroids with corticoid side chains (*17*). While the exclusive participation of the C-14 hydroxyl in this side reaction suggests that hydrazone carboxylate prodrugs of anthracyclines such as daunorubicin and idarubicin that lack C-14 hydroxyl groups would display normal hydrazone hydrolysis kinetics, rearrangement involving the C-9 hydroxyl to the spirocyclic dihydrooxadiazinone derivatives remains a possibility.

We contend that the dramatic difference in in vivo activity observed for the polymer−drug conjugates **4** and **5** can be explained by the relatively rapid loss of drug from **4** at physiological pH. If the drug is lost in transit before an effective dose of polymer−drug conjugate is delivered to the tumor, the targeting ability of the polymer is lost and the treatment rendered ineffective. While we have not explicitly determined the in vitro or in vivo activity of **7** alone, it is also possible that **7** is less potent than doxorubicin. However, even if **7** were an active chemotherapeutic, free doxorubicin (which is active in vitro against the tumor models utilized here) is not highly active against these tumor models in vivo without utilization of a carrier, and therefore, the rapidly released free **7** would likely be ineffective as well (*20*, *21*).

We believe that our previously published drug release results for polymer−drug conjugate **3** were affected by the analytical technique we had used (*12*). Our prior conclusions were based on data collected utilizing chromatographic conditions that may not be ideal for the analysis of doxorubicin. In the current study, we have used an acidic mobile phase for chromatography, which aids in the solubilization and elution of the hydrophobic and weakly basic drug doxorubicin; in contrast, our previous work made use of a neutral pH mobile phase. As doxorubicin is not as soluble in neutral phosphate buffers, it is possible that elution under neutral conditions could have led to strong retention or precipitation of doxorubicin within the column.

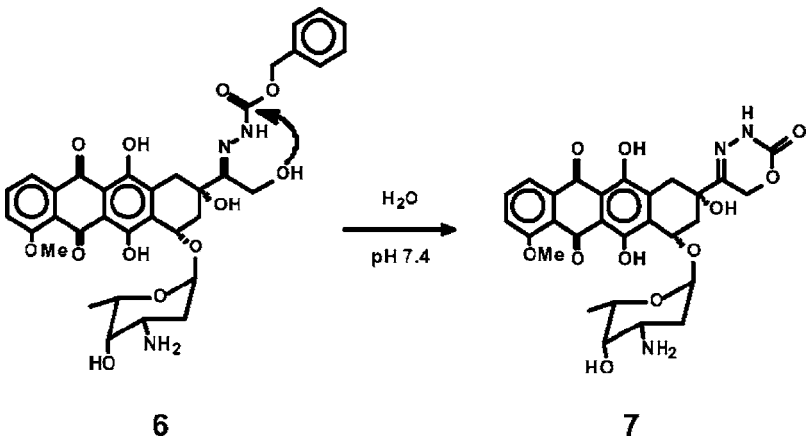
We also believe that Willner's previously published data for doxorubicin release from hydrazone carboxylate **1** at neutral pH may have been affected (*6*). While the release kinetics data may be accurate, the release rate reported at neutral pH probably represents the rate of release for the dihydrooxadiazinone cyclization product **7** derived from **1**, but not doxorubicin itself.

MATERIALS AND METHODS

Materials. Unless otherwise noted, reagents and solvents were obtained from commercial suppliers and used without further purification. Polymer **4** contained 9.25% doxorubicin by weight and was prepared as previously reported (*14*). Polymer **5** contained 9.94% doxorubicin by weight; its synthesis will be reported in a forthcoming publication.

Characterization. NMR spectra were recorded on a Bruker DRX 500 MHz instrument with MeOH as the internal standard (3.31 ppm). All chemical shifts are reported in parts per million.

Scheme 3. Intramolecular Cyclization of 6 to 7



Low- and high-resolution electrospray ionization mass spectrometry (ESI-MS) was performed at the UC Berkeley Mass Spectrometry Facility and Stanford University Mass Spectrometry Laboratory, respectively.

Chromatography: Drug Release from Polymers 4 and 5. Release of drug from polymers **4** and **5** at 37 °C was measured with an HPLC system composed of a Waters 2695 separations module (sample compartment maintained at 37.0 ± 3.0 °C), a Waters 996 photodiode array detector (λ = 490 nm), and a Shodex OHpak SB-804 HQ SEC column. An isocratic flow rate of 1.0 mL/min was used with a mobile phase composed of 70%/30%/0.05% water/acetonitrile/formic acid ($t_{R,DOX}$ = 14.2 min). Polymer−drug conjugates were dissolved at concentrations of 1.0 mg/mL in aqueous solutions buffered at pH 5.0 (50 mM acetate) and pH 7.4 (50 mM phosphate). Analysis commenced immediately after dissolution utilizing the above HPLC method with samples (25 μL) withdrawn periodically over a period of 48 h.

Chromatography: Drug Release from Compound 6. The conversion of **6** to **7** at 37 °C was measured with an HPLC system composed of a Waters 2695 separations module (sample compartment maintained at 37.0 ± 3.0 °C), a Waters 996 photodiode array detector (λ = 490 nm), and a Waters Symmetry C18 column (3.5 μm, 2.1 × 150 mm). The following HPLC method was employed at a flow rate of 0.3 mL/min ($t_{R,6}$ = 12.9 min, $t_{R,7}$ = 8.9 min): 0−5 min, linear gradient of 100:0.05 water:formic acid to 70:30:0.05 water:acetonitrile:formic acid; 5−15 min, held at 70:30:0.05 water:acetonitrile:formic acid; 15−18 min, linear gradient of 70:30:0.05 water:acetonitrile:formic acid to 100:0.05 water:formic acid. Hydrazone **6** was dissolved in distilled water (0.16 mg/mL) and diluted with an equal volume of 100 mM aqueous NH_4OAc (pH = 7.0). Analysis commenced immediately utilizing the above HPLC method with samples (25 μL) withdrawn periodically over a period of 16 h.

Benzyloxycarbonyl Hydrazone of Doxorubicin (6). Doxorubicin hydrochloride (5 mg, 9 μmol), trifluoroacetic acid (1 μL, 11 μmol), and an excess of benzyloxycarbonyl hydrazide trifluoroacetate (∼30 mg, ∼ 108 μmol) were combined in anhydrous methanol (0.5 mL) and stirred in the dark at rt overnight. The product was precipitated upon addition of diethyl ether, and the resulting red solid was isolated by gravity filtration and washed with more diethyl ether. The product was extracted from the filter paper with methanol and concentrated in vacuo to yield the product as a red solid (5 mg, 70%). ^{1}H NMR (500 MHz, CD_3OD, δ): 1.29 (d, J = 6.5 Hz, 3H), 1.88 (dd, J_1 = 4.0 Hz, J_2 = 12.7 Hz, 1H), 2.02 (dt, J_1 = 4.0 Hz, J_2 = 12.7 Hz, 1H), 2.37 (br m, 2H), 3.12 (br m, 2H), 3.55 (m, 1H), 3.64 (br s, 1H), 4.01 (s, 3H), 4.25 (m, 1H), 4.60 (AB, J = 15 Hz, 2H), 5.15 (br s, 1H), 5.21 (s, 2H), 5.45 (br s, 1H), 7.2−7.5 (m, 5H), 7.54 (d, J = 8.3 Hz, 1H), 7.81 (t, J = 8.3 Hz, 1H), 7.93 (d, J = 8.3 Hz, 1H). MS-ESI m/z (relative intensity): 692 (100%), 563 (24%), 545 (42%).

9-Dihydrooxadiazinone Doxorubicin (7). Hydrazone **6** was dissolved in distilled water (1.6 mg/mL), diluted with an equal volume of 100 mM aqueous NH_4OAc (pH = 7.0), and stirred in the dark at 37 °C for 24 h (at this concentration, some of the product precipitated from solution during the course of the reaction). The reaction mixture was then frozen and lyophilized. The red solid that remained was dissolved in a small amount of methanol, precipitated from diethyl ether, and isolated by centrifugation. ^{1}H NMR (500 MHz, CD_3OD, δ): 1.31 (d, J = 6.5 Hz, 3H), 1.87 (dd, J_1 = 3.8 Hz, J_2 = 12.6 Hz, 1H), 2.02 (dt, J_1 = 3.8 Hz, J_2 = 12.6 Hz, 1H), 2.30−2.45 (m, 2H), 3.10 (br s, 2H), 3.52 (m, 1H), 3.65 (br s, 1H), 4.02 (s, 3H), 4.24 (m, 1H), 5.07 (br s, 2H), 5.12 (br s, 1H), 5.47 (br s, 1H), 7.56 (d, J = 7.9 Hz, 1H), 7.83 (t, J = 7.9 Hz, 1H), 7.93 (d, J = 7.9 Hz, 1H). MS-ESI m/z (relative intensity): 584 (13%), 455 (6%), 437 (100%), 419 (21%). HRMS-ESI: $[M + H]^+$ calcd for $C_{28}H_{30}N_3O_{11}$ 584.1880, found 584.1869; $[M + Na]^+$ calcd for $C_{28}H_{29}N_3O_{11}Na$ 606.1700, found 606.1699.

PEG-Assisted DNA Solubilization in Organic Solvents for Preparing Cytosol Specifically Degradable PEG/DNA Nanogels

Hyejung Mok and Tae Gwan Park*

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon, 305-701, Korea. Received May 6, 2006; Revised Manuscript Received September 26, 2006

DNA was dissolved in selected organic solvents in the presence of poly(ethylene glycol) (PEG). Nanoscale PEG/DNA complex (∼100 nm) was produced in dimethylsulfoxide (DMSO) phase. Using a thiol-functionalized six-arm branched PEG for DNA solubilization, the PEG/DNA nanocomplex was cross-linked through the formation of disulfide linkages between the thiol groups, resulting in the production of stable PEG/DNA nanogels in aqueous solution. DNA release from the nanogels could be modulated by changing the concentration of an external reducing agent. The released plasmid DNA from the nanogels maintained intact structural integrity and exhibited appreciable gene transfection efficiency. The PEG/DNA nanogels could be potentially applied for gene therapy including DNA vaccination.

DNA is a highly charged macromolecule that is extremely difficult to solubilize in organic solvents. The direct solubilization of DNA in organic solvents is expected to broaden its therapeutic and diagnostic applications such as gene therapy and DNA-based sensing (*1, 2*). Cationic amphiphiles such as lipids, polymers, and surfactants have been commonly used to solubilize DNA in organic solvents by forming polyelectrolyte complex nanoparticles (*3*−*5*). Negatively charged DNA upon addition of positively charged amphiphile molecules is condensed by electrostatic interactions, and the resultant complex nanoparticles with hydrophobic ion-pairing could be solubilized to some extent in various organic solvents. DNA/cation complex nanoparticles formed in an aqueous solution have been widely used to transfer exogenous genes to cells via endocytosis (*6*−*12*). Use of chemically modified and synthesized cationic lipids and polymers as nonviral gene carriers still has serious cytotoxic problems in clinical applications, although they are much safer than their viral counterparts (*13*). In this communication, we demonstrate that nonionic and biocompatible poly(ethylene glycol) (PEG) can make DNA soluble in selected polar organic solvents by forming a nanoscale complex, probably resulting from hydrogen bonding between DNA and PEG. A thiol-functionalized multiarm PEG derivative was used to solubilize DNA in an organic solvent and to produce cross-linked PEG/DNA complex nanogels applicable for gene therapy. The resultant thiol-cross-linked PEG nanogels encapsulating plasmid DNA released DNA only in a reduced condition, such as an intracellular environment, by cleaving the S−S linkage.

To solubilize DNA in organic solvents, green fluorescent protein (GFP) plasmid DNA or salmon sperm DNA was desalted by ethanol precipitation (*14*). Varying amounts of PEG (Mw 3350) were mixed with 1 mg of salmon sperm DNA in deionized water and then freeze-dried. The lyophilized PEG/DNA mixture was dissolved in various organic solvents at a PEG/DNA weight ratio of 15. As shown in Figure 1a, it can be
