Preparation of Mono-PEGylated-Lysozyme Conjugates. With fast stirring, the activated PEG linker powder (compound **11**), at a reaction molar ratio of 1.75:1 (PEG:lysozyme), was added to a lysozyme solution of 5 mg/mL in 50 mM phosphate buffer, pH 7.6. After 60 min at 25 °C, the reaction mixture was diluted 5-fold with 20 mM sodium phosphate, pH 5.1, to a conductivity lower than 2 mS, and mono-PEGylated PEG-lysozyme was purified on a cation exchange column (Poros, HS) using a solvent system of 20 mM sodium phosphate at pH 5.1 and a NaCl gradient. The peak of mono PEG-lysozyme was collected, dialyzed against 140 mM NaCl, and concentrated using an ultrafree centrifugal filter device with a 10 kDa NMWL membrane (Millipore Corp., Bedford, MA). The compositions of mono PEG-lysozyme crude conjugate preparations (compound **12**) were also determined from the peak areas of the chromatograms from HS chromatography. The overall yields of with different PEG linkers are 12kDa SC-PEG-lysozyme (83% conjugation yield with 100% mono-PEG-lysozyme), 12 kDa PEG-BCN3-lysozyme (73% conjugation yield; 74% mono-PEG-lysozyme and 26% di-PEG-lysozyme), and 20 kDa PEG-BCN3-lysozyme (74% conjugation yield; 65% mono-PEG-lysozyme and 35% di-PEG-lysozyme).

Preparation of Multi-PEGylated-Lysozyme Conjugates. With fast stirring, the activated PEG linker powder (compound **11**) at a reaction molar ratio of 20:1 (PEG:lysozyme) was added to a lysozyme solution of 5 mg/mL in 0.1 M phosphate buffer, pH 7.6. After 60 min at 25 °C, the reaction was stopped by adding a 5-fold volume of 140 mM NaCl, 20 mM sodium phosphate, pH 6.0, filtered through a 0.2 μm membrane, and separated on a Hiload Superdex 200 column which was equilibrated with 20 mM sodium phosphate, pH 6.0, 140 mM

NaCl. The fractions of the desired peak were pooled, dialyzed against 140 mM NaCl, and concentrated using an ultrafree centrifugal filter device with a 30 kDa NMWL membrane (Millipore Corp., Bedford, MA). The final conjugate contained 3−4 PEG attachments per lysozyme molecule for 20 kDa PEG-BCN3-lysozyme conjugates and 4−5 PEG attachments for 12 kDa PEG-BCN3-lysozyme conjugates, as estimated on SDS−PAGE and SEC analysis. The overall yields of all the multi-PEGylated lysozyme conjugates using either 12 kDa SC-PEG, 12 kDa PEG-BCN3, or 20 kDa PEG-BCN3 linker were about 85%.

rPEGylation of IFN-β-1b. IFN-β-1b (0.28 mg/mL; 50 mL) in 50 mM HEPES, 0.1% zwittergent 3−14, pH 7.8, was conjugated with either of two rU-PEG-BCN3 polymers with PEG mass of 24 kDa and 40 kDa, respectively. A 30-fold molar excess of the PEG-BCN3 activated polymer was added slowly into the IFN-β-1b solution over a period of 1 min with stirring and continued at 25 °C for 2 h. The reaction was quenched by lowering the pH to 3−4 with dilute acetic acid and then diluted with water to lower the conductivity to 1 mS. Poros 50 HS (8 mL column volume) was equilibrated with buffer containing 20 mM sodium acetate, pH 4.75. The dilute reaction mixture was loaded onto the equilibrated column at 7 mL/min. The column was chased to baseline and washed with five column volumes of equilibration buffer to remove zwittergent and unreacted PEGs. The bound PEGylated IFN-β-1b conjugate was eluted from the column using a linear gradient of elution buffer (1 M NaCl in equilibration buffer) of 200 mL over 40 min at a 5 mL/min flow rate and peak fractions were collected based on SDS−PAGE analysis of fractions. The fractions were dialyzed using a 25 kDa-MW-cutoff membrane against 5% mannitol, 3 mM acetic acid, pH 3.7 at 4 °C overnight with two changes of buffer. The PEGylated IFN-β-1b conjugate solution was concentrated using a 10 kDa Amicon filtration system and sterile filtered to a final concentration of 0.2−0.5 mg protein/mL. The number of PEG attachments per protein was determined independently by SDS−PAGE and gel filtration.

PEGylation of IFN-β-1b with SC or SPA Linkers. IFN-β-1b (0.8 mg/mL; 5 mL) in 100 mM sodium phosphate, 0.05% Zwittergent 3−14, 2 mM EDTA, pH 7.8, was conjugated with activated PEG polymers with PEG mass of 12 kDa or 20 kDa. PEG-SC or PEG-SPA compounds were dissolved in 0.1 mM acetic acid. With fast stirring without generating foam, the PEG solution was added at 0.5−1.0 g/min to a final 10-fold molar excess over protein. The reaction was conducted at 25 °C for 60 min, quenched by adding glycine to a final molar ratio of 50:1 (glycine:PEG) and filtered through a 0.2 μm membrane before the column purification.

Purification of PEG-IFN-β-1b. The PEGylation reaction (5 mL; 0.8 mg protein/mL) was purified by Superdex 200 High Load chromatography with a 10 mM sodium phosphate, pH 7.3, 0.05% Zwittergent running buffer at a flow rate of 2 mL/min. In the second step, 8 mL of peak fractions were loaded onto an HS-50 column with 10 mM sodium phosphate, pH 7.3, 5% mannitol running buffer. The PEG-IFN-β-1b was eluted with 1 M NaCl in equilibration buffer at 2 mL/min and 2 mL/fraction over a period of 40 min. Fractions identified on SDS−PAGE were combined and the pH of the sample was immediately adjusted to 3.7 with HAc. It was then dialyzed using a 30 kDa-MW-cutoff membrane against 5% mannitol, 3 mM HAc, pH 3.7 at 4 °C for 12 h. The fractions were diafiltered on Amicon membranes to a final concentration of 0.5−1 mg/mL in 3 mM HAc, pH 3.7, 5% mannitol.

Determination of Release of Lysozyme from PEG-Lysozyme Conjugates. Under the conjugation reaction conditions for these experimental procedures, lysozyme enzymatic activity was virtually eliminated after the attachment with only one PEG strand. The release of the lysozyme from the conjugate was determined by regeneration of the lysozyme activity under various release conditions and confirmed on SDS polyacrylamide gel electrophoresis. For most experiments, lysozyme conjugates (0.5 mg/mL) were incubated in 0.1 M borate buffer, pH 9.2, 37 °C for 16 h. The activity was compared with the activity of native lysozyme stored in 140 mM NaCl at 4°C.

Analytical Characterization of Lysozyme, IFN-β-1b, and PEG-Protein Conjugates. Protein concentrations were determined by measuring the UV absorbance at 280 nm, using a determined IFN-β-1b extinction coefficient of 1.5 mL/mg/cm. The concentration was also confirmed by the bicinchoninic acid assay (BCA), obtained as a Micro BCA Protein Assay Reagent kit from Pierce Biotechnology using lysozyme or BSA as standards. Mass values of IFN-β-1b and lysozyme were determined by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) (Bruker Daltronics OmniFlex NT) using an internal standard with a similar molecular weight. Apparent molecular weights (Stoke radius) of the compounds were estimated using Superdex 200 HR 10/30 gel filtration column chromatography (Amersham Bio-Sciences) in 100 mM sodium phosphate, pH 6.8, at 24 °C with BioRad (Hercules, CA) molecular weight standards or PEG−protein molecular mass standards (Enzon).

Capillary Electrophoresis (CE). CE was performed on a P/ACE MDQ capillary electrophoresis system (Beckman, Fullerton, CA) equipped with a fused silica capillary (inner diameter 75 μm; 50 cm effective length, 57 cm total length). The parameters of PDA were set at 214, 220, and 280 nm and separation was conducted at +30 kV. The sample running buffer was composed of 25 mM sodium phosphate, pH 2.7, 0.1 mg/mL PEG. The capillary temperature was maintained at 23 °C by the thermostated coolant from Beckman. Between each run, the capillary was regenerated with 1 N HCl (5 min), H_2O (2 min), 0.1 N NaOH (10 min), H_2O (2 min), and then 25 mM sodium phosphate, pH 2.7, 0.1 mg/mL PEG (20 min) at 20 psi.

Antiviral Assays of IFN-β-1b. Specific antiviral activity from the cytopathic effect of IFN-β-1b was assayed by published methods (*24*) using Vero cells and EMCV virus, which were cultivated as recommended by the ATCC supplier. Vero cells were distributed on 96-microtiter plates (20000 cells/well) in 0.05 mL of culture medium. Serial dilutions of 0.05 mL of the IFN-β samples were incubated at 37 °C, 5% CO_2, for 24 h. EMCV (200 pfu/20 μL) were added to each well at 25 °C for 30 min; then incubated at 37 °C for 24 h. After the addition of 20 μL of 10 mg/mL 3-(4,5-dimethyl-2-thiazoyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT; Promega, Madison, WI) dye solution to each well, incubation was continued for 4 h, 100 μL of stop solution (1.2 N HCl in 2-propanol) was added to each well, and the plate was read at 570 nm in a 96-well plate reader (Molecular Devices, Sunnyvale, CA) to determine EC_{50} values, as analyzed with Softmax Pro software. Native IFN-β-1b, PEGylated IFN-β-1b, and released PEG-IFN-β-1b were analyzed in triplicate on each plate. Conversion of antiviral activity units to protein mass was attained using the specific activity of the parent compounds (native IFN-β-1b or PEG-IFN-β-1b).

Pharmacokinetic Analysis of PEG-IFN-β-1b. C57BL/6 mice (7−8 week, female) were supplied by Sprague Dawley Harlan (Madison, WI). Mice (5/group) were injected subcutaneously intrascapular, with 100 μL per mouse (0.2 mg/kg) of IFN-β-1b, or its PEGylated conjugates. Following sedation with 0.09% avertin, sampling of blood was undertaken into vials containing EDTA. At 2, 15, 30, and 60 min, the mice were bled 100 μL, and at 4, 24, 48, 72, and 96 h, the mice were terminally bled by cardiac puncture. The plasma was collected following centrifugation of the blood at 5000 rpm at 4 °C for

[a] Linkers are either permanent (SC; SPA), linear releasable (BCN3), or branched releasable (rU-BCN3). [b] P, permanent linkage; R, releasable linkage. [c] Mass of PEG polymer strand used in linear or branched configuration. [d] Number of attachments of PEG linker on protein. [e] Number of PEG attachments measured by EA, enzymatic activity; CE, capillary electrophoresis; PAGE, reducing SDS−PAGE; BA, antiviral bioactivity; SEC, size exclusion chromatography; MS, MALDI-TOF mass spectrometry.

5 min and immediately frozen on dry ice. The concentrations of the compounds were analyzed by both antiviral activity and by ELISA. The data were modeled using WinNonlin software (WinNonlin Pharsight, Mountain View, CA) to determine pharmacokinetic parameters.

RESULTS AND DISCUSSION

Design of the BCN3 Linker and Nomenclature. Releasable PEGylation was investigated using designed BCN3 linkers with either one PEG per linker (linear design) or two PEGs per linker (branched design). In this investigation, we have modified and further examined the previous branched (rU-PEG; releasable umbrella PEG) design (*20*) and, most significantly, designed new linear bicin linkers, which are more easily synthesized and less complex in the chemical pathway of protein release (Scheme 5). The linear PEG BCN3 linkers were investigated with PEG polymers of different molecular weights, and with differing numbers of PEG attachments, in conjugates with model proteins, lysozyme, and IFN-β-1b. Our present investigation focuses on the performance of both types of PEG BCN3 linkers, i.e., linear PEG BCN3 and rU-PEG BCN3. In this nomenclature, compounds designated "linear PEG-BCN3" employ one polymer per linker, whereas compounds designated "rU-PEG-BCN3" contain two polymers per linker. The terms "mono-PEGylated" and "multi-PEGylated" identify bioconjugates consisting of either one, or multiple, PEG attachment sites per protein, respectively. All protein conjugate compounds are identified by number in Table 1.

Due to difficulties in purification of the rU-PEG BCN3 polymer (separating the two stranded PEG from the single stranded PEG), there are detectable amounts of linear PEG BCN3 in the final rU-PEG-BCN3 compound. As a result, in the protein conjugation mixture, there was a minor impurity of linear PEG-BCN3-protein and the impurity profile would become more complex when multisite PEGylation was employed. On the other hand, we expected that if a linear PEG-BCN3 linker were used as the only activated PEG species, the protein conjugation mixture would be much more homogeneous. As shown in the Scheme 5, the acetyl group of compound **12** is predicted to quickly release in vivo to produce compound **12a**. The cleavage of PEG from the conjugate is the rate-determining step and can be controlled by using different linker side-chains between the PEG and the bicin moiety. After the intermediate **12b** is formed, it will quickly fold into the "double" assisting conformation and the coordination of two hydroxyl groups facilitates the breakdown of the amide bond to release intact protein. When a different acid than **3** is used in the synthesis, linear PEG BCN linkers with different hydrolysis rates may also be constructed. The current study focused on the application of the specific BCN3 linker design (compounds **1** and **11**) for controlled release of protein from PEG conjugates.

Preparation of Linear PEG-BCN3-Lysozyme. Mono-PEGylated linear 12 kDa or 20 kDa PEG-BCN3-lysozyme compounds (**18**, **21**) were prepared and purified by cation exchange chromatography to separate di- or multi-PEGylated conjugates. The PEG-BCN3-lysozyme conjugates were analyzed by SDS−PAGE and size exclusion chromatography. A representative 4−20% SDS−PAGE analysis of a purified linear 12 kDa PEG-BCN3-lysozyme conjugate is shown in Figure 1A.

Table 2. Lysozyme Activity (%) after 16 h Release in Vitro from Linear PEG-BCN3-Lysozyme Conjugates

		mono-PEGylated-lysozyme			multi-PEGylated-lysozyme

control (140 mM NaCl in H_2O)	100	2.3	34.0	54.7	2.3	0.9	3.4
hydrolysis (0.1 M borate, pH 9.2)	93.8	9.6	97.4	101.6	2.3	95.8	99.7

Reversibility of Linear PEG-BCN3-Lysozyme Linkage. Linear PEG-BCN3-lysozyme conjugates (0.5 mg/mL) were incubated in 0.1 M borate buffer, pH 9.2, 37 °C for 16 h. An aliquot was withdrawn and lysozyme activity was analyzed. The activity was compared with the activity of native or PEGylated lysozyme stored in 140 mM NaCl at 4 °C. The results indicate that lysozyme activity of linear PEG-BCN3-lysozyme was fully recoverable after the 16 h high-pH incubation in vitro. When lysozyme was permanently PEGylated with one or more SC-PEG polymers, the lysozyme activity from such conjugates was not restored during the entire incubation period. The analysis of enzyme activity of BCN3-PEG conjugates following protein release at high-pH in vitro is shown in Table 2.

Lysozyme has seven amine groups: six ϵ-amine groups of lysine and one α-amine of the N-terminal amino acid. When lysozyme was treated with maleic anhydride at 1:1.5 molar ratio, thereby mimicking the PEGylation stoichiometry, the activity of lysozyme was reduced by 60% (data not shown), demonstrating that attachment of a small molecule such as maleic anhydride to an amine group of lysozyme could also inhibit enzyme activity. The full recovery of lysozyme activity in the linear PEG-BCN3-lysozyme conjugates implies a complete release of lysozyme from both the PEG and the linker under the conditions described.

Capillary Electrophoresis Analysis of Protein Release from BCN3-PEG. The complete release of lysozyme was also confirmed by CE analysis. The linear 12 kDa PEG BCN3-lysozyme conjugate (**18**) was incubated in 5 mM sodium borate buffer, pH 9.5, 37 °C for 24 h, after which one-tenth sample volume of 250 mM sodium phosphate, 1 mg/mL 12 kDa PEG was added. CE was conducted as described in Experimental Procedures. The electropherograms of lysozyme and linear 12 kDa PEG-BCN3-lysozyme (**18**) before and after hydrolysis are shown in Figure 2. Linear 12 kDa PEG-BCN3-lysozyme, after lysozyme release, exhibited an identical electropherogram compared to native lysozyme ($t = 6.65-6.82$) indicating a full release of lysozyme from both PEG and PEG linker. The PEG conjugate migrated as a broad peak ($t = 22.55$) with a detected trace of native lysozyme. The 24 kDa rU-PEG-BCN3-lysozyme (**23**) also demonstrated complete release of enzyme under identical in vitro release conditions when analyzed by SDS−PAGE (Figure 1B).

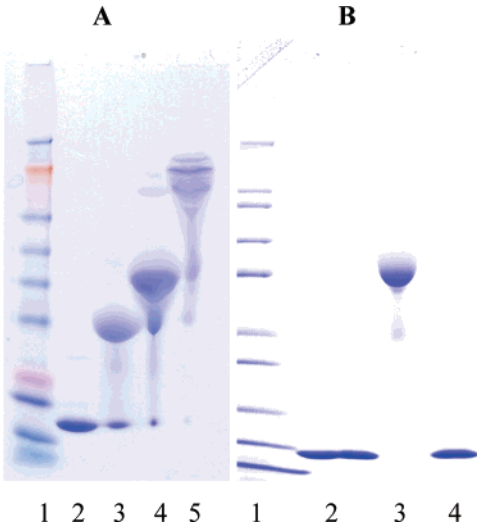

Figure 1. SDS−PAGE analysis of BCN3 PEGylated lysozyme formulations. Coomassie blue stained proteins and conjugates were analyzed by 4−20% SDS−PAGE. (A) Lane 1: molecular weight standards (250, 148, 98, 64, 50, 36, 22, 16, 6, and 4 kDa); Lane 2: native lysozyme; Lane 3: mono-PEGylated linear 12 kDa PEG-BCN3-lysozyme (**18**); Lane 4: di-PEGylated linear 12 kDa PEG-BCN3-lysozyme (**20**); Lane 5: multi-PEGylated linear 12 kDa PEG-BCN3-lysozyme (**19**). (B) Lane 1: molecular weight standards (200, 116, 97, 66, 55, 36, 31, 22, 14, 6, and 4 kDa); Lane 2: native lysozyme; Lane 3: 24 kDa rU-PEG-BCN3-lysozyme (**23**) before release at high pH; Lane 4: 24 kDa rU-PEG-BCN3-rU-lysozyme (**23**) after release at high pH.

Table 3. Hydrolysis Rate of PEG-NHS at pH 7.8, 23 °C

NHS linker	PEG, kDa	k (min^{-1})	$t_{1/2}$ (min)
SC (**8**)	12	0.0325 ± 0.0080	22.24 ± 5.64
linear BCN3 (**11**)	5	0.0470 ± 0.0005	14.76 ± 0.02
linear BCN3 (**11**)	12	0.0406 ± 0.0004	17.09 ± 0.17
linear BCN3 (**11**)	30	0.0553 ± 0.0013	12.54 ± 0.29
BCN3-rU (**1**)	24	0.0423 ± 0.0003	16.38 ± 0.12

Hydrolysis of PEG-BCN3 Linker and Reaction with Glycine. We investigated the intrinsic aqueous stability of the activated linear PEG-BCN3 polymer as its NHS ester to determine its suitability as a functional reagent. The hydrolysis rates were investigated for SC-PEG (**8**), linear PEG-BCN3 (**11**), and rU-PEG-BCN3 (**1**) linkers by determination of NHS elimination by UV spectroscopy. The results demonstrated that the hydrolysis rate of linear PEG-BCN3 was faster than SC and similar to rU-PEG-BCN3 (Table 3). Since both linear PEG-BCN3 and rU-PEG-BCN3 contain the same linking moiety but a different number of PEG chains, similar hydrolysis rates were expected. The reaction with glycine at an equal molar ratio of all the linkers was faster than the buffer hydrolysis rate. Based

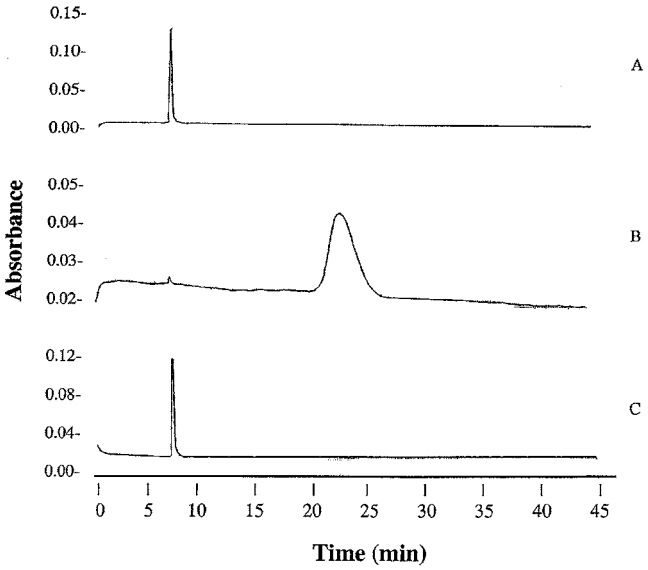

Figure 2. CE electropherograms of lysozyme and linear 12 kDa PEG-BCN3-lysozyme (**18**) before and after lysozyme release. (A) Native lysozyme. (B) Linear 12 kDa PEG-BCN3-lysozyme before release at high pH. (C) Linear 12 kDa PEG-BCN3-lysozyme (**18**) after release at high pH.

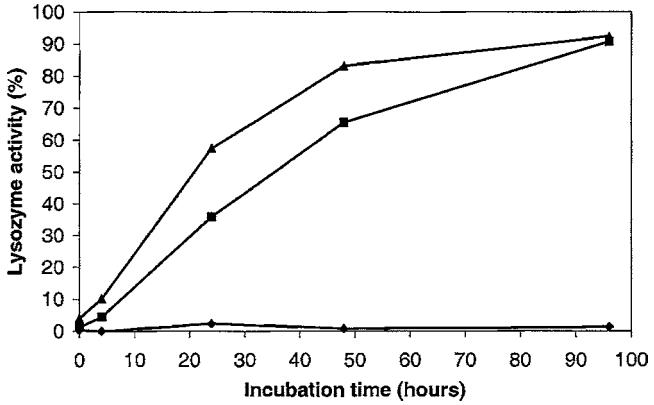

Figure 3. Release profile in vitro of lysozyme from multi-PEGylated linear BCN3-lysozyme conjugates incubated in rat plasma. Enzymatic activity (% recovered) of linear 12 kDa PEG-BCN3 (**19**) (■) and linear 20 kDa PEG-BCN3 (**22**) (▲) conjugates are compared with the linear 12 kDa PEG-SC permanent linker derivative (**17**) (◆).

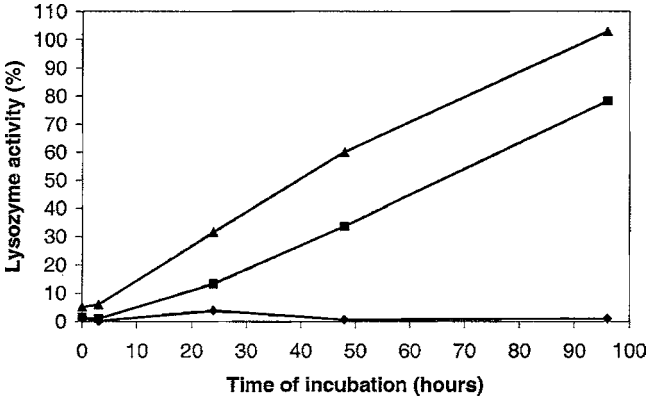

Figure 4. Release profile in vitro of lysozyme from multi-PEGylated linear BCN3-lysozyme conjugates incubated in PBS, pH 7.4. Enzymatic activity (% recovered) of linear BCN3-12k (**19**) (■) and linear BCN3-20k (**22**) (▲) conjugates are compared with the SC-12k permanent linker derivative (**17**) (◆).

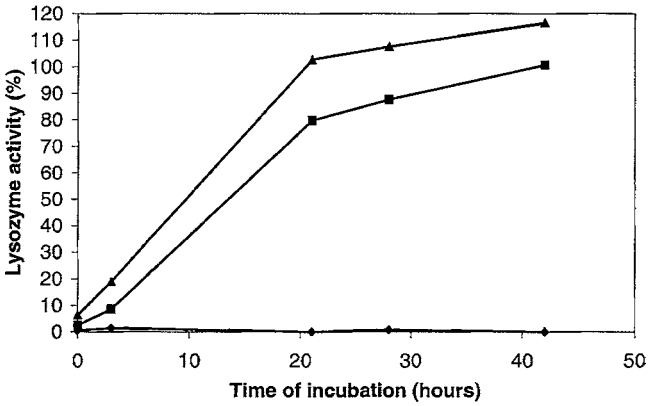

Figure 5. Release profile in vitro of lysozyme from multi-PEGylated linear BCN3-lysozyme conjugates incubated at pH 8.5. Enzymatic activity (% recovered) of linear 12 kDa PEG-BCN3 (**19**) (■) and linear 20 kDa PEG-BCN3 (**22**) (▲) conjugates are compared with the linear 12 kDa PEG-SC permanent linker derivative (**17**) (◆).

on first-order kinetics for the initial rate, the reaction rate with glycine was about 2−3-fold faster than that of buffer hydrolysis rates (data not shown). These studies demonstrate that the BCN3 compounds display the necessary stability to be used as practical reagents.

Release Rate of Lysozyme from Multi-PEGylated Linear BCN3 Conjugates in Rat Plasma. Multi-PEGylated-lysozyme conjugates (0.15 mg/mL) were incubated in rat plasma at 37 °C under nitrogen. At the times indicated in Figure 3, an aliquot was withdrawn, acidified with 0.2 M sodium phosphate, pH 5.0 to pH 6.5, and stored at −20 °C until enzyme analysis. The half-lives of protein release were estimated from the graph of incubation time versus activity as described in Experimental Procedures. The purified multi-PEGylated lysozyme conjugates have three to four PEG strands per lysozyme for linear 20 kDa PEG-BCN3 compounds (**22**), and four to five PEG polymer strands per lysozyme for the linear 12 kDa PEG-BCN3 compounds (**19**). As shown in Figure 3, a slightly higher release rate from multi-PEGylated lysozyme for the linear 20 kDa PEG-BCN3-lysozyme (total PEG mass ∼ 70 kDa) was observed compared to the linear 12 kDa PEG-BCN3-lysozyme (total PEG mass ∼ 55 kDa) of 21 h vs 35 h, respectively. This phenomenon might correspond to the higher number of PEG linker attachments, and greater steric hindrance, in the latter compound. No detectable protein release was observed for the permanently PEGylated lysozyme conjugate using SC-PEG (**17**). The similar release profiles of PEG-BCN3-lysozyme conjugates of differing mass suggest that the release rates are primarily dependent on characteristics of the PEG linker, rather than PEG size.

Influence of pH on Release Rate of Lysozyme from Linear PEG-BCN3-Lysozyme Conjugates. Multi-PEGylated linear PEG-BCN3-lysozyme (0.15 mg/mL) was incubated in phosphate buffered saline (PBS), pH 7.4, 37 °C, or in 50 mM Tris, pH 8.5, 37 °C, under nitrogen. At the times indicated in Figure 4 and Figure 5, respectively, an aliquot was withdrawn, acidified with 0.2 M sodium phosphate, pH 5.0 to pH 6.5, and stored at −20 °C until enzyme analysis. The half-lives of protein release were estimated from the graph of time of incubation versus activity. A control experiment demonstrated that native lysozyme retained full activity after a two-day incubation in 50 mM Tris, pH 8.5, at 37 °C. Compared to the release rate in rat plasma and PBS (pH 7.4−7.6), the faster release rate at pH 8.5 suggests a simple hydrolytic reaction enabling the release of lysozyme from the PEG-lysozyme conjugates. Both multi-PEGylated 12 kDa PEG-BCN3-lysozyme (**19**) (t = 18 h) and multi-PEGylated 20 kDa PEG-BCN3-lysozyme (**22**) (t = 12 h) showed similar release profiles in Figure 5, while the permanent conjugate made from SC-PEG exhibited no detectable release after the 5 day incubation. The relatively higher release rates in plasma compared to PBS could be influenced by a slight pH difference in plasma (pH 7.6 versus 7.4) or involve additional unidentified nucleophiles in plasma. We do not have evidence of enzyme involvement in the release of lysozyme from the conjugates in rat plasma, although the participation of hydrolytic enzymes in this pathway is possible.

Comparison of rU-PEG-BCN3-Lysozyme and Linear PEG-BCN3-Lysozyme Conjugates. Table 4 summarizes the properties of the rU and linear BCN3 designs and illustrates the benefits of both categories of linkers. The mono-PEGylated conjugates and multi-PEGylated conjugates display release parameters that span a range of hours to days, as would be required for therapeutic applications. The stability of linear PEG-BCN3-lysozyme conjugates (0.3 mg/mL) in PBS, pH 7.4, at different temperatures such as 4 °C, 25 °C, and 37 °C were monitored by analyzing lysozyme activity. The results demonstrated that the stability of linear PEG-BCN3-lysozyme conjugates was temperature dependent, with diminished stability at elevated temperatures. No detectable protein release was observed in multi-PEGylated BCN3-PEG-lysozyme compounds at 4 °C after the five-day incubation.

The release of lysozyme from linear PEG-BCN3-lysozyme conjugates corresponds to the second strand of PEG release from rU-PEG-BCN3-lysozyme conjugates. From our prior results (*20*), it was predicted from considerations of steric hindrance that the second strand PEG liberation from rU-PEG-BCN3-lysozyme would be much faster than the first strand release.

Table 4. Comparison of Release Rates of Branched and Linear BCN3-Lysozyme PEG Conjugates[a]

conjugate	PBS, 37 °C	PBS, 25 °C	PBS, 4 °C	plasma, 37 °C	pH 8.5, 37 °C
		Mono-PEGylated Compounds			
linear 12kDa BCN3-lysozyme (**18**)	4	75	>120	5	N.D.[b]
linear 20kDa BCN3-lysozyme (**21**)	7	37	>120	4	N.D.

multi PEG-lysozyme (12 kDa SC-PEG) (**17**)	N.R.	N.R.	N.R.	N.R.	N.R.

[a] Half-life of protein release (h). [b] N.D. indicates the release was too rapid to determine half-life. [c] SC-PEG forms permanent carbamate linkage. [d] N.R. indicates no release after 96-h incubation.

Table 5. Pharmacokinetic Parameters of IFN-β-1b and PEG-IFN-β-1b Compounds in Mice[a]

compound[b]	route	dose (mg/kg)	AUC (h/ng/mL)	AUC (h/U/mL)	K_HL $t_{1/2}$ (h)	T_{max} (h)	C_{max} (ng/mL)
IFN-β-1b	sc	0.2	226	6780	1.29	1.38	21
BCN3-24k (**25**)	sc	0.2	11248	89984	1.87	4.31	961
BCN3-40k (**26**)	sc	0.2	74792	149584	5.07	9.27	2967
SPA-20k (**27**)	sc	0.2	32610	195660	8.93	12.9	930

[a] sc, subcutaneous; AUC, area under the curve; K_HL, biological half-life; T_{max}, time of maximal concentration; C_{max}, maximal concentration. [b] BCN3-rU-24k-PEG compound has three conjugated 24 kDa U-PEGs per IFN-β-1b; BCN3-rU-40k-PEG compound has two conjugated 40 kDa U-PEGs per IFN-β-1b; SPA-20k-PEG compound has two conjugated linear 20 kDa PEGs per IFN-β-1b.

The results in Table 4 demonstrate that mono-PEGylated linear PEG-BCN3-lysozyme conjugates **18** and **21** ($t = 4$ h when PEG mw is 12 kDa; $t = 7$ h when PEG mw is 20 kDa) indeed showed a statistically significant faster release rate of native lysozyme than that of **23**, the mono-PEGylated 24 kDa rU-PEG-BCN3-lysozyme ($t = 33$ h). We propose that steric hindrance in the rU-PEG design contributes to the slower releasing rates.

The results also show that the release rates of native lysozyme from the multi-PEGylated compounds are slower than from the mono-PEGylated compounds. Possibly, the influence of additional neighboring polymers on the protein surface, with respect to steric effects, is already near maximal at a PEG number of about three polymer strands per protein. There are two to three attachments of U-PEG per lysozyme for 24 kDa rU-PEG-BCN3-lysozyme (**24**), four to five PEG for linear 12 kDa PEG-BCN3-lysozyme (**19**), and three to four PEG for linear 20 kDa PEG-BCN3-lysozyme (**22**).

PEGylation of IFN-β-1b Using rU-PEG-BCN3 Linker. To extend our characterization of the utility of releasable rU-PEG-BCN designs in vivo, we investigated multi-PEGylated derivatives of human IFN-β-1b. Two bioconjugates, 24 kDa rU-PEG-BCN3-IFN-β-1b (**25**) (three U-PEG attachments per protein) and 40 kDa rU-PEG-BCN3-IFN-β-1b (**26**) (two U-PEG attachments per protein), were prepared with a one-step HS cation exchange chromatography as described in Experimental Procedures. We chose these particular experimental compounds for initial examination because they exhibit a comparable total PEG mass (72 kDa and 80 kDa). The compositions of the conjugates were confirmed by molecular mass determinations on SEC, SDS−PAGE, and MALDI-TOF. The increased mass of the di-PEGylated 40 kDa rU-PEG-BCN3 bioconjugate (~108 kDa) and the triple-PEGylated 24 kDa U-PEG bioconjugate (~91 kDa), when compared to the native IFN-β-1b protein (19876 Da), resulted in a marked increase in Stokes radius and apparent molecular size (>1000 kDa) for both bioconjugates due to the hydrophilicity and flexibility of the PEG polymers. The PEGylated IFN-β-1b compounds were stable when stored for a week at 4 °C as described in Experimental Procedures; an additional positive attribute for these multi-PEGylated proteins may prove to be an amelioration of the propensity of IFN-β toward self-aggregation.

Bioassays which measured antiviral activity of IFN-β-1b in cell culture demonstrated the expected specific activity of native IFN-β-1b (30 MIU/mg), and a diminished specific activity for the 40 kDa rU-PEG-BCN3-IFN-β-1b (compound **26**; 2 MIU/mg) and the 24 kDa rU-PEG-BCN3-IFN-β-1b (compound **25**; 8 MIU/mg) compounds. However, it is expected that protein release occurs during the cell incubation in the bioassay for the releasable compounds. Therefore, each analyzed sample was measured with internal controls for both the unmodified and permanently or releasably PEGylated protein. Since the PEG strands are continuously releasing in both in vitro and in vivo environments, it is not possible to obtain a complete image of these molecules without the use of radioisotope tracers and/or real time mass spectrometric analysis. In the current pilot investigation, an initial comparative analysis was performed with inclusion of a permanently PEGylated analogue. We observed that an IFN-β-1b permanently conjugated with three attachments of 20 kDa PEG or two attachments of 40 kDa demonstrated virtually undetectable bioactivity with in vitro assays (data not shown). Therefore, as the closest comparative, yet, active molecule, we prepared a conjugate of IFN-β-1b with two 20 kDa PEG polymers, randomly attached via an SPA linker (compound **27**; 6 MIU/mg). This conjugate also demonstrated similar characteristics to a conjugate with a single permanent 40 kDa branched PEG (data not shown).

Pharmacokinetics of IFN-β-1b and PEG-BCN3-IFN-β-1b in Mice. Pharmacokinetic (PK) parameters of the IFN-β-1b, PEG-SPA conjugate, and the PEG-BCN3 conjugates were determined following subcutaneous administration in mice of 0.2 mg/kg of protein (Table 5). Plasma samples in EDTA were stored in dry ice before analysis. The antiviral bioactivity assay was employed for measurement of active compounds in the collected plasma samples, as described in Experimental Procedures. Protein quantities of IFN-β-1b in these samples were derived from the determined specific activity of the parent bioconjugates. An ELISA assay which measured total compound concentrations was also developed for analysis of the PK parameters. While these immunoassay and bioactivity data were in agreement in ranking the PK profiles for the bioconjugates, the sensitivity of the ELISA format did not permit detection of the non-PEGylated IFN-β-1b in the PK analysis due to its rapid elimination (data not shown). Subcutaneous administration of the 24 kDa rU-PEG-BCN3-IFN-β-1b (**25**) and 40 kDa rU-PEG-BCN3-IFN-β-1b (**26**) compounds resulted in a 50-fold and 330-fold increase, respectively, in area under the curve (AUC; h·

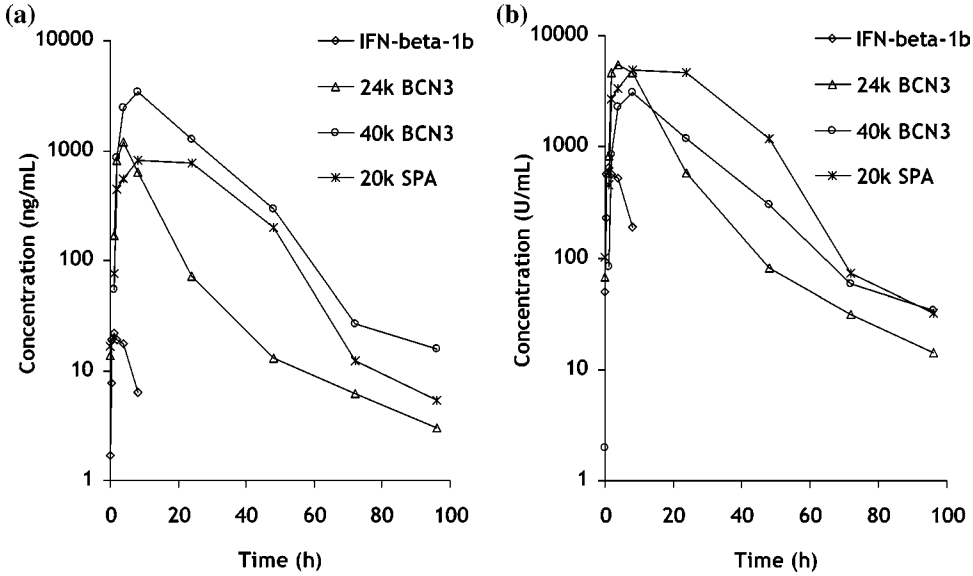

Figure 6. Pharmacokinetics of IFN-β-1b and BCN3 multi-PEGylated IFN-β-1b in mice. Subcutaneous administration of 0.2 mg of IFN-β-1b protein/kg for IFN-beta-1b (◇), 24 kDa rU-PEG-BCN3 multi-PEGylated IFN-β-1b (**25**) (△), 40 kDa rU-PEG-BCN3 multi-PEGylated IFN-β-1b (**26**) (○); and 20 kDa linear PEG-SPA multi-PEGylated IFN-β-1b (**27**) (×); mean of three mice per group. (A) The PK profiles are shown with ng protein/mL. (B) The PK profiles are shown with U/mL. The IFN-β-1b conjugates have either two (40 kDa rU-PEG-BCN3); two (20 kDa linear PEG-SPA); or three (24 kDa rU-PEG-BCN3) attached polymers per IFN-β-1b.

ng/mL) for each protein conjugate compared with native interferon (Figure 6A). As shown in Figure 6B, the extensions of AUC for the BCN3 derivatives relative to native protein or the permanent conjugate, when determined in units of antiviral activity by bioassay, are less pronounced due to the diminished in vitro activity of the releasable conjugates.

The expansive prolongation of pharmacological exposure for BCN3 bioconjugates addresses a limitation of native interferons as therapeutics due to their rapid systemic elimination, and the observed systemic exposure of the BCN3 released IFN-β activity over a period of hours to days is within a therapeutically useful range. While the investigated conjugates were chosen to exhibit an intermediate degree of PEGylation (two to three attachments per interferon), one can expect that purified conjugates containing BCN3 attachments ranging from only one, up to twelve amine-directed sites per interferon, could be similarly produced and that the controlled release of the native interferon could be designed to span an even larger pharmacokinetic profile. As shown in Table 5, a markedly increased maximal concentration and total exposure may be achieved with the BCN3 bioconjugates, and this correlates with a diminished clearance of both PEG-BCN3-IFN-β-1b compounds compared to unmodified IFN-β-1b. Although the pharmacological profile of the optimal permanent PEG conjugate showed similar benefits, the data support further investigation of rPEGylated interferons that examine the key in vivo performance parameters corresponding to efficacy or pharmacodynamic biomarkers. Indeed, we expect that therapeutics utilizing releasable PEG polymers can only be fully understood by monitoring in vivo biological effects.

CONCLUSIONS

We describe the synthesis and in vitro and ex vivo performance of a new releasable linker, i.e., the linear PEG-BCN3 linker, designed for the controlled release of proteins and other macromolecules from their PEG conjugates. The design of the linear PEG-BCN3 linker was accomplished by selective esterification of the hydroxyl group of bis-*N*-2-hydroxyethylglycinamide derivative followed by a temporary capping of the second hydroxyl group with the acetyl function, which can be quickly removed by in vivo hydrolysis. The conjugation of the linear PEG-BCN3 linker with proteins proceeded similarly to the branched rU-PEG-BCN3 linker in both the mono-PEGylation and multi-PEGylation approaches. The rate of protein release from the linear PEG conjugates in general was faster than with the rU-PEG counterparts. This phenomenon could be due to reduced hindrance of the linear PEG conjugates toward esterase or nonenzymatic hydrolysis of the PEG conjugates. Steric hindrance within the linker structure has frequently played an important role in the release kinetics of proteins from their PEG conjugates.

The PEG-BCN3 linker displays suitable characteristics for applications in formulation of therapeutic proteins. Our results support the performance of both types of PEG-BCN3 linkers in regeneration of physically and functionally equivalent native proteins from their PEG-conjugates in a therapeutically relevant period of hours to days. Although attachment of permanent PEG polymers will continue to offer benefits to clinical protein candidates, it will be instructive to determine whether those protein therapeutics which exhibit significant activity losses following conjugation might demonstrate superior effects with releasable PEGylation. The ability to apply PEGylation in a controlled release fashion opens new opportunities to capture the inherit benefits of PEGylation. New clinical uses and routes of administration may be facilitated by the tailored pharmacokinetics employing releasable PEG linkers that can gradually deliver the sequestered authentic drug compounds. The two model compounds in our investigations illustrate these possibilities. Enzyme therapeutics, such as lysozyme, may be inactivated by permanent PEGylation due to the requirement for extended substrate interactions with an expansive and intricate active site cleft. Unlike many conventional PEG modified cytokines and growth factors, rPEGylated interferons may reacquire full bioactivity in vivo following programmed release. Since an interferon's biodistribution, potency, bioavailability, immunogenicity, antigenicity, and other pharmacological properties may be improved by diverse formulation approaches, it will be particularly interesting to further explore the in vivo consequences of rPEGylated interferon compounds. The benefits in avoidance of early systemic clearance mechanisms and the designed deposition of released native protein therapeutics offer a new avenue to the application of PEGylation science.

ACKNOWLEDGMENT

We thank Sam Liu and Magda Mendez for preparation of IFN-β-1b. We are grateful to Mary Mehlig and Cliff Longley for performance of animal studies and pharmacokinetic data analysis. We also thank Jack Lipman for a critical review of the manuscript and Carol Aitken for clerical assistance.

Orientation and Affinity of HIV-1 Tat Fragments in Tat−TAR Complex Determined by Fluorescence Resonance Energy Transfer

Hong Cao,[§] Natarajan Tamilarasu,[§,†] and Tariq M. Rana*

Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, Massachusetts 01605. Received September 15, 2005; Revised Manuscript Received January 2, 2006

The human immunodeficiency virus (HIV-1) encodes a transcriptional activator protein, Tat, which is expressed early in the viral life cycle and is essential for viral gene expression, replication, and pathogenesis. Tat interacts with the transactivation responsive region (TAR) RNA, a 59-base stem-loop structure located at the 5′-end of all HIV mRNAs. Tat-derived peptides that contain the basic arginine-rich region of Tat are able to form in vitro complexes with TAR RNA, and these peptides provide a well-characterized system for understanding the mechanism of RNA−protein recognition. It is not known how RNA-binding Tat peptides are folded or docked in the Tat−TAR complex, and to what extent structural reorganization occurs upon TAR binding. To address these questions, we developed a fluorescence resonance energy transfer (FRET) system to analyze the interactions between TAR RNA and a Tat protein fragment (aa 38−72) uniquely labeled with donor and acceptor dye molecules, respectively. Using this FRET assay, we determined the binding affinity of Tat (47−58) and Tat (38−72) for TAR RNA under physiological conditions. We also delineated the distance between the N- and C-terminus of Tat (38−72) and the distance between the two termini and the 5′ end of TAR when Tat (38−72) is bound to TAR. Our results suggest that the N- and C-termini of Tat (38−72) are close to each other when the peptide is folded and that the peptide does not go through a large structural change upon TAR binding.

INTRODUCTION

RNA-protein interactions are vital for many regulatory processes, including gene regulation during which proteins specifically interact with binding sites found within RNA transcripts. Human immunodeficiency virus (HIV-1) encodes transcriptional activator protein, Tat, which binds RNA to regulate transcription. Tat is expressed early in the viral life cycle and is essential for viral gene expression, replication, and pathogenesis (reviewed in refs 1−3). Tat enhances the processivity of RNA polymerase II (RNA Pol II) elongation complexes that initiate transcription in the HIV-1 long terminal repeat (LTR) region. To accomplish this, Tat binds the TAR (*trans*-activation responsive) RNA element, a 59-base stem-loop structure located at the 5′ end of all nascent HIV-1 transcripts (*4*). This Tat−TAR interaction results in the recruitment of positive transcription elongation factors that increase the processivity of RNA Pol II.

TAR RNA was originally localized to nucleotides +1 to +80 within the viral long terminal repeat (LTR). Subsequent deletion studies have established that the region from +19 to +42 incorporates the minimal domain that is both necessary and sufficient for Tat responsiveness in vivo (reviewed in ref 4). TAR RNA contains a six-nucleotide loop and a three-nucleotide pyrimidine bulge which separates two helical stem regions (Figure 1). Due to difficulties in Tat purification, small Tat peptides that specifically bind TAR RNA with high affinity have been used in Tat−TAR studies (*5*−*12*). Since Tat-derived peptides containing the basic arginine-rich region of Tat (aa 48−57) are able to form in vitro complexes with TAR RNA (*5*−*12*), these peptides provide a well-characterized system for understanding principles of RNA−protein recognition.

Although Tat peptide−TAR-binding affinities have been well studied by electrophoretic mobility shift assays (*5*−*8*, *12*−*16*), there is little known about Tat peptide−TAR affinities in solution under physiological conditions. RNA molecules can fold into extensive structures containing regions of double-stranded duplexes, hairpins, internal loops, bulged bases, and pseudoknotted structures (*17*). Due to the complexity of RNA structure, the rules governing sequence-specific RNA−protein recognition are not well understood, which makes it difficult to design ligands for sequence-specific RNA recognition. Recent structural and biochemical studies have provided insight into TAR RNA folding in the absence and presence of various ligands and Tat peptides (reviewed in ref 4). NMR studies showed that TAR RNA undergoes structural changes upon L-argininamide and Tat peptide binding (*13*, *18*, *19*). However, it is not known how RNA-binding Tat peptides are folded or docked in the Tat−TAR complex, and to what extent structural reorganization occurs upon TAR binding.

To dissect the Tat−TAR interaction under physiological conditions, we used a fluorescence resonance energy transfer (FRET) assay to determine RNA−peptide binding affinities and the peptide orientation in RNA−protein complexes. We found that the N- and C-termini of Tat (38−72) are close to each other when the peptide is folded and that the peptide does not go through a large structural change upon TAR binding. These findings suggest that the architecture of TAR RNA bulge is the key element that defines intramolecular interactions and structural reorganization essential for Tat peptide−TAR interactions.

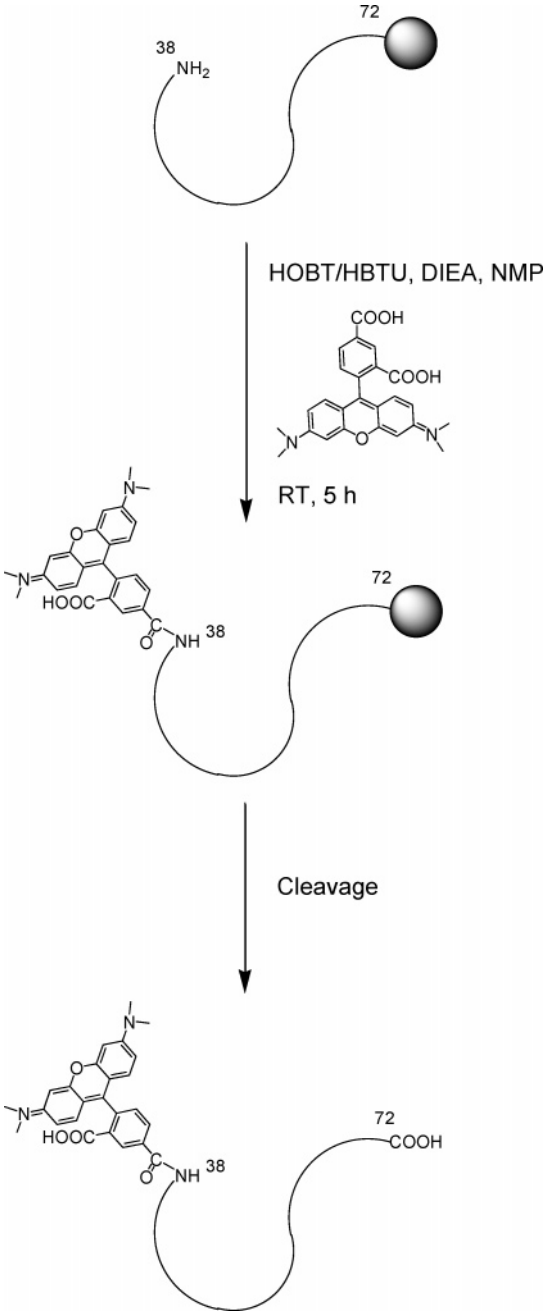
Figure 1. (A) Secondary structure of TAR RNA used in this study. TAR RNA spans the minimal sequences that are required for Tat responsiveness in vivo and for in vitro binding of Tat-derived peptides (*25*). TAR RNA (1 μmole) was chemically synthesized on a CPG 500 support. After deprotection, RNA was purified and characterized as described previously (*26*). (B) Sequence of Tat (38−72) peptide and four dye-labeled Tat peptides indicating the positions of modification. Tat-derived peptides were synthesized by using FastMoc chemistry on an automated 431 ABI peptide synthesizer. Rhodamine or fluorescein attachment at the amino terminal position was accomplished on the solid support using carboxyl derivatives of the dyes and peptide coupling reagent (Schemes I, II, and III). For carboxyl terminal labeling, a Cys residue was added at position 73, which was postsynthetically modified with tetramethylrhodamine-5-iodoacetamide. All dye-Tat conjugates were purified by reverse phase HPLC and characterized by mass spectrometry. The relative dissociation constants for dye-peptides were determined and compared with those of wild-type peptide as described previously (*8*, *27*). Tat peptide modifications did not significantly alter the structure of Tat (38−72), preserving the TAR-binding affinities of the peptide (data not shown).

MATERIALS AND METHODS

Synthesis of Tat (38−72). Tat-derived peptide (amino acids 38−72) was synthesized on HMP[1] resin (Novabiochem) (0.1 mmol) on an Applied Biosystems 431A peptide synthesizer using standard FastMoc protocols. Cleavage and deprotection of the peptide were carried out in reagent K. After cleavage and deprotection, the peptide was purified by HPLC on a Zorbax SB-C8 reverse phase column. The mass of the peptide was confirmed by MALDI mass spectrometry. Calculated mass for tat (38−72), 4083.70 [M + H]; found 4083.55.

Synthesis of N-Terminal-rhodamine Tat (38−72) on Solid Support. An amount of 1.0 μmol of the HMP resin containing the peptide N^{α}-free Tat (38−72) was coupled with 5-carboxy tetramethyl rhodamine (4.3 mg) using HBTU/HOBT (0.45 M in DMF, 22.0 μL) and DIEA (4.0 μL) in NMP (500 μL) for 5 h at room temperature (Scheme 1). All Fmoc-amino acids, piperidine, 4-(dimethylamino)pyridine, dichloromethane, *N*,*N*-dimethylforamide, 1-hydroxybenzotriazole (HOBT), 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), diisopropylethylamine (DIEA), and HMP-linked polystyrene resin were obtained from Bachem, CA. Trifluoroacetic acid, 1,2-ethanedithiol, phenol, and thioanisole were from

Scheme 1. Synthesis of N-Terminal-rhodamine Tat(38−72)



Sigma. Cleavage and deprotection of the peptide was carried out in 2 mL of Reagent K for 6 h at room temperature. Reagent K contained 1.75 mL of TFA, 100 μL of thioanisole, 100 μL of water, and 50 μL of ethanedithiol. The resin was thoroughly washed with NMP followed by dichloromethane and dried. After cleavage and deprotection, the peptide was purified by HPLC on a Zorbax SB-C8 reverse phase column. The mass of the peptide was confirmed by MALDI mass spectrometry. Calculated mass for N-terminal-rhodamine tat (38−72), 4496.16 [M + H]; found 4493.14.

Synthesis of Tat (38−72) Cys-73. Tat-derived peptide (amino acids 38−72) Cys-73 was synthesized on SASRIN resin (BACHEM) (0.1 mmol) on an Applied Biosystems 431A peptide synthesizer using standard FastMoc protocols. Cleavage and deprotection of the peptide were carried out in reagent K. After cleavage and deprotection the peptide was purified by HPLC on a Zorbax SB-C8 reverse phase column. The mass of the peptide was confirmed by MALDI mass spectrometry.

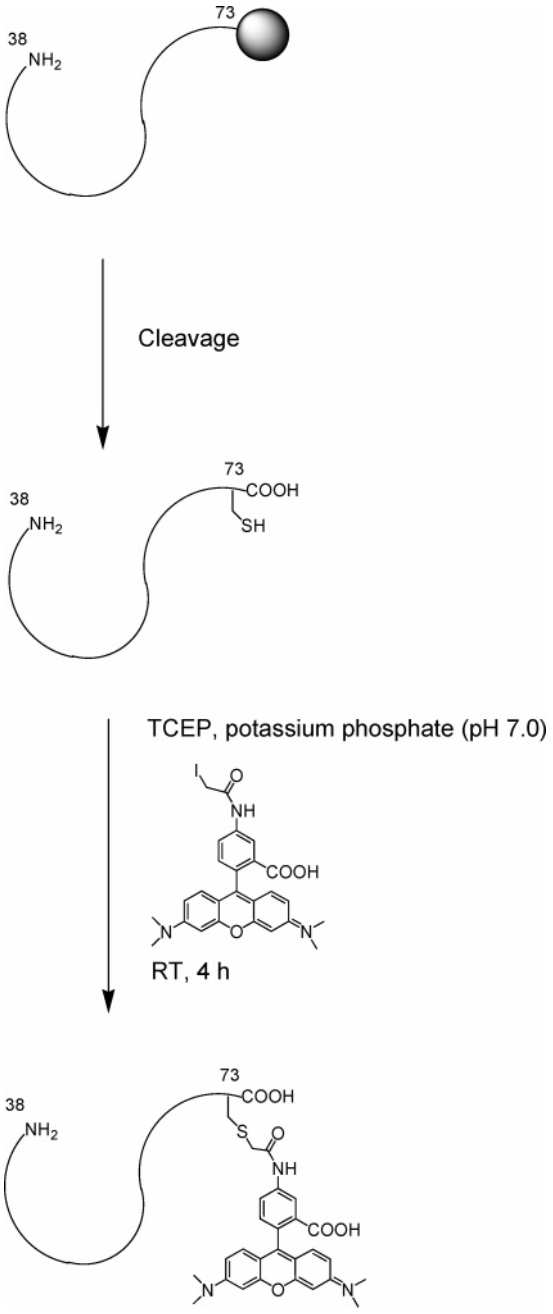
Scheme 2. Synthesis of C-Terminal-rhodamine Tat(38−72) Cys-73



Calculated mass for tat (38−72) Cys-73, 4186.83 [M + H]; found 4185.20.

Synthesis of C-Terminal-rhodamine Tat (38−72) Cys-73. Tat (38−72) Cys-73 (1.0 mM, 500 μL) in potassium phosphate buffer (pH 7.0) containing TCEP (20.0 mM, 50.0 μL) was added to a freshly prepared solution of tetramethylrhoadamine-5-iodoacetamide·2HI (15.0 mM, 100 μL) in DMSO (Scheme 2). The reaction was incubated at room temperature for 4 h and purified by gel filtration (Sephadex G-25, eluent 0.1% TFA/water) followed by reverse phase HPLC (Zorbax SB-C8 reverse phase column). Calculated mass for C-terminal-rhodamine Tat (38−72) Cys-73, 4629.00 [M + H]; found 4631.54.

Synthesis of N-Terminal-fluorescein Tat (38−72) Cys-73. An amount of 2.0 μmol of the resin containing N^{α}-free Tat (38−72) Cys-73 was coupled with 5-carboxyfluorescein (7.5 mg) using HBTU/HOBT (0.45 M in DMF, 44.0 μL) and DIEA (8.0 μL) in NMP (500 μL) for 3 h at room temperature. The resin was thoroughly washed with NMP followed by dichloromethane and dried. Cleavage and deprotection of the peptide were carried out in reagent K (1.0 mL, 5 h, room temperature). After cleavage and deprotection, the peptide was purified by HPLC on a Zorbax SB-C8 reverse phase column. The mass of the peptide was confirmed by MALDI mass spectrometry. Calculated mass for N-terminal-fluorescein Tat (38−72) Cys-73, 4544.9 [M + H]; found 4548.4.

Synthesis of N-Terminal-fluorescein C-Terminal-rhodamine Tat (38−72) Cys-73. N-Terminal-fluorescein Tat (38−72) Cys-73 peptide (38.0 μM, 146.0 μL) in potassium phosphate buffer (pH 7.0) containing TCEP (20.0 mM, 20.0 μL) was added to a freshly prepared solution of tetramethylrhoadamine-5-iodoacetamide·2HI (2.2 mM, 50.0 μL) in DMSO. The reaction was incubated at room temperature for 4 h and purified by gel filtration followed by reverse phase HPLC (Zorbax SB-C8 reverse phase column). Calculated mass for N-terminal-fluorescein C-terminal-rhodamine Tat (38−72) Cys-73, 4987.06 [M + H]; found 4986.46.

Preparation of Dye-Labeled-TAR RNA. RNAs were prepared by chemical and enzymatic methods. Modified TAR RNA was synthesized on an Applied Biosystems Model 392 DNA/RNA synthesizer using 2-cyanoethyl phosphoramite chemistry (Figure 1). All monomers of 2-cyanoethyl phosphoramite were obtained from Glen Research (Sterling, VA). Cleavage and deprotection of dye-labeled RNA was carried out in methanolic ammonia (1 mL) for 16 h at room temperature. After cleavage from the resin, the methanolic supernatant was transferred to an Eppendorff tube and dried under a stream of nitrogen. The green pellet was desilylated in 50% triethylamine trihydrofluoride in dimethyl sulfoxide (0.5 mL) for 16 h at room temperature. The crude red dye-labeled RNA was precipitated by adding 2-propanol (1 mL) at −78 °C for 1 h. The desired RNA was purified on 20% acrylamide−8 M urea denaturing gels.

Measurement of FRET and RNA−Protein Binding Affinities. Fluorescence resonance energy transfer (FRET) from fluorescein to rhodamine was measured on a PTI (Photon Technology International) fluorescence spectrophotometer. The fluorescein-labeled TAR RNA (Fl-TAR) was excited at 490 nm. The emission spectrum was recorded from 500 to 650 nm for each scan. The slits were set 4 nm for both excitation and emission lights. All experiments were carried out in Tris-HCl buffer, pH 7.4, at room temperature.

The initial concentration of Fl-TAR was 10 nM for all experiments. Each addition of rhodamine-labeled Tat (Rh-Tat or Tat-Rh) to the Fl-TAR was followed by a 2 min equilibration before the fluorescence spectrum was recorded. The stock concentration of Rh-Tat (or Tat-Rh) for titration was 2 μM (determined at 555 nm using a molar extinction coefficient (ϵ) of 9.5×10^4 M^{-1} cm^{-1}). The fluorescence intensities were subtracted from background of buffer.

The energy transfer efficiency (E) from donor to acceptor was calculated from the decrease of donor fluorescence intensity at 514 nm according to eq 1.

$$E = \left(1 - \frac{I_{DA}}{I_D}\right) \quad (1)$$

where I_{DA} and I_D are the donor fluorescence intensities in the presence and absence of an acceptor, respectively. The distance (R) between donor and acceptor was calculated according to eq 2.

$$R = R_0(E^{-1} - 1)^{1/6} \quad (2)$$

where $R_0 = 47.6$ Å for the fluorescein−rhodamine pair (*21*). The dissociation constant (K_D) of Tat and TAR RNA complex

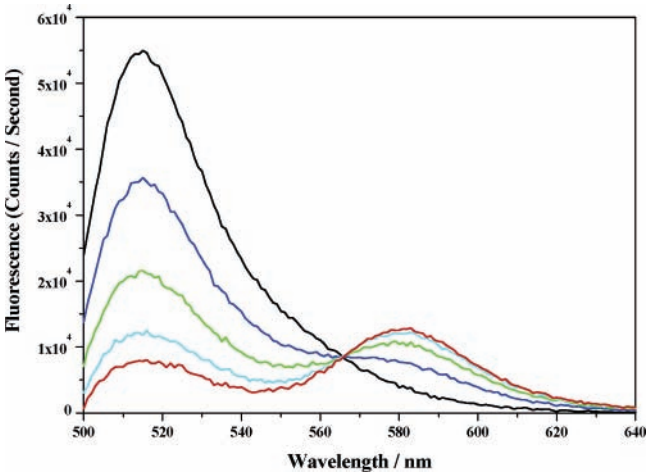


Figure 2. Fluorescence spectra of 10 nM Fl-TAR with (1) 0 nM (black), (2) 3.33 nM (blue), (3) 6.64 nM (green), (4) 9.95 nM (cyan), and (5) 13.25 nM (red) of Rh-Tat(47−58) after excitation at 490 nm.

was determined by using Grafit program (Erithcus software Ltd, version 5) to fit the experimental data. The equation for the fitting was as follows.

$$y = \frac{-(K_D + x + \mathrm{Cap}) + \sqrt{(K_D + x + \mathrm{Cap})^2 - 4x\mathrm{Cap}}}{2} \quad (3)$$

where y is the relative fluorescence intensity of the donor and x is the total ligand (Tat) concentration that is used. Cap is moles of bound ligand.

RESULTS AND DISCUSSION

Determination of Tat (47−58)−TAR RNA Binding Affinity Using FRET. To determine the binding affinities of Tat fragments with TAR RNA under physiological conditions, we developed a fluorescence resonance energy transfer (FRET) system containing TAR RNA and a Tat protein fragment uniquely labeled with donor and acceptor dye molecules, respectively (Figure 1). FRET, in which a fluorescent donor molecule transfers energy via a nonradiative dipole−dipole interaction to an acceptor molecule (which is usually also a fluorescent molecule) is a standard spectroscopic technique for measuring distances in the 10−70 Å range (*20*). The donor's lifetime and quantum yield are reduced upon energy transfer, and the acceptor fluorescence is increased, or sensitized. Quantification of the efficiency of energy transfer allows determination of the distance between the two fluorophores.

The TAR RNA binding region corresponds to amino acids 48−57 of Tat, which has six arginines and two lysines and preferentially binds to the bulge region of TAR. To quantitatively determine Tat−TAR binding affinity using FRET, fluorescein-labeled TAR RNA (Fl-TAR) and rhodamine-labeled Tat (47−58) (Rh-Tat (47−58)) were chemically synthesized as described in Materials and Methods and shown in Figure 1. Gel-shift experiments using equimolar amounts of Tat peptides (modified or unmodified) caused similar mobility shifts in radiolabeled TAR RNA, indicating that neither modification affected the functional properties of Tat or TAR (ref *21*; data not shown). Fluorescein and rhodamine were used because they are a well-characterized fluorescence energy transfer pair with high fluorescence quantum yields and the fluorescein emission and rhodamine absorption spectra overlap significantly.

We measured the fluorescence spectra of F-TAR in the absence and presence of the Rh-Tat (47−58) by exciting at 490 nm (Figure 2). The spectrum of Fl-TAR alone was characterized

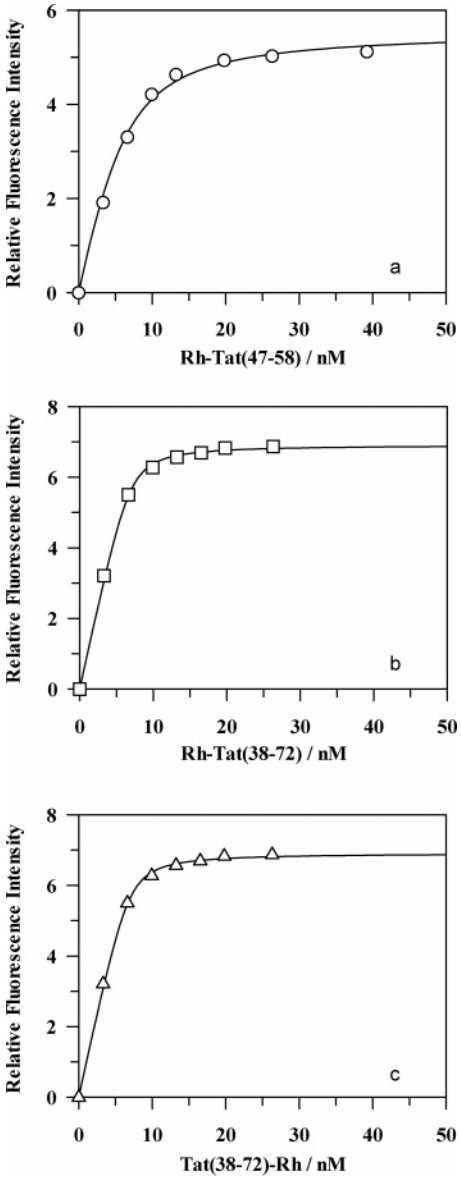

Figure 3. Relative fluorescence intensity (514 nm) of 10 nM Fl-TAR as a function of the concentrations of (a) Rh-Tat (47−58); (b) Rh-Tat (38−72); (c) Tat (38−72)-Rh. The solid lines represent the best fitting of the data by nonlinear regression to eq 3.

by an emission maximum at 514 nm, precisely the wavelength position expected for fluorescein; no emission was recorded at 575 nm. Addition of unlabeled Tat (47−58) caused no change in the intensity of emission (data not shown). Addition of Rh-Tat (47−58), however, resulted in a significant decrease in the intensity of the fluorescein emission at 514 nm and a small increase in rhodamine emission at 575 nm. As predicted, Rh-Tat (47−58) binding to Fl-TAR decreased the distance between the two dyes to within range of Förster distance (R_0) (*20*), which allowed for energy transfer from fluorescein to rhodamine. It is unlikely that the fluorescence intensity of fluorescein was quenched by intramolecular collisions since quenching was only observed in the presence of Rh-Tat (47−58) and not unlabeled Tat (47−58) and because the concentrations for both samples were very low (low nanomolar range).

Figure 3a is a typical titration curve for the binding of Rh-Tat (47−58) to Fl-TAR. While the addition of Rh-Tat (47−58) resulted in a rapid increase in the relative fluorescence intensity, which is the difference between the donor only intensity and the donor intensity in the presence of the acceptor, the same amount of buffer solution did not have any effect on

Table 1. Binding Dissociation Constant, Energy Transfer Efficiency, and Distance between Two Dyes upon Tat and TAR RNA Binding

Tat	K_D (nM)	E (%)	R (Å)
Rh-Tat(47−58)	2.1 ± 0.2	94.4 ± 0.4	29.7
Rh-Tat(38−72)	1.0 ± 0.1	91.2 ± 0.5	32.2
Tat(38−72)C-Rh	0.31 ± 0.04	89.5 ± 0.4	33.3

the fluorescence intensity of Fl-TAR. These results indicated that the enhanced relative fluorescence intensity was a result of specific binding. The data of relative fluorescence intensity as a function of Rh-Tat (47−58) concentration was fitted to eq 3 and a dissociation constant K_D of 2.1 ± 0.2 nM was obtained (Table 1). This K_D value confirmed the formation of a high affinity Tat−TAR complex. We had previously measured a K_D of 0.78 ± 0.05 μM for the formation of the Tat−TAR complex using direct and competition electrophoretic mobility assays (*18*). Since a higher concentration of labeled Tat or TAR is required to detect a gel shift, the K_D value is always underestimated when calculated from gel shift assays. Our fluorescence-based assays were more sensitive than gel shift assays and were performed in an environment that more closely resembles physiological conditions. Therefore, these results demonstrate that we have established a quantitative FRET method to determine RNA−protein binding affinities under physiological conditions.

According to eq 1, energy transfer efficiency (E) can be measured experimentally by calculating the ratio of Fl-TAR intensity in the absence and presence of Rh-Tat (47−58). An efficiency of 94% was obtained from this experiment. Furthermore, a distance of 30 Å between the two dyes was calculated from eq 2 (Table 1). This calculated distance is based on the assumption that both the donor and acceptor have high rotational mobility (*27*) and is supported by the low anisotropy values in our system. The anisotropy are 0.08 and 0.09 for Fl-TAR and Rh-Tat(47−58), respectively. Since the error of energy transfer efficiency is ∼0.4%, this error should not significantly affect the estimated distance between the donor and acceptor.

Binding Affinity of Tat (38−72) to TAR RNA. To address whether additional amino acids from other region outside the basic region of Tat increase its RNA binding affinity, we used FRET to measure the binding affinity of TAR for Tat (38−72), which is composed of core, basic, and glutamine-rich functional regions of Tat. Rhodamine was used to label the N-terminus and C-terminus of Tat (38−72) (Rh-Tat (38−72) and Tat (38−72)-Rh, respectively). The change in fluorescence intensity upon Fl-TAR binding to Rh-Tat (38−72) and Tat (38−72)-Rh are presented in Figure 3b and 3c. A K_D of 1.0 ± 0.1 nM and 0.31 ± 0.04 nM was obtained for Rh-Tat (38−72) and for Tat (38−72)-Rh, respectively (Table 1).

Several control experiments support these findings and demonstrate the specificity of Tat−TAR interactions. First, unmodified Tat (38−72) had no effect on the emission spectrum of Fl-TAR. Second, in the presence of a Tat peptide that does not contain TAR-interacting sequences, quenching of Fl-TAR RNA was not observed. FRET was also not observed when Fl-TAR was incubated with free rhodamine dye. Finally, wild type unlabeled TAR RNA successfully competed with the labeled TAR RNA bound to Tat (38−72) (data not shown), indicating that Fl-TAR RNA and Tat (38−72)-Rh exhibit FRET because they specifically interact. Further by measuring anisotropy changes in Fl-TAR using unlabeled peptides, we obtained K_D values for Tat−TAR that were identical to the values shown in Table 1 (unpublished results).

When comparing the binding affinity of the three different rhodamine-labeled Tat fragments, the TAR−Tat binding affinity ordered from highest to lowest is Tat (38−72)-Rh > Rh-Tat (38−72) > Rh-Tat (48−57). The higher binding affinity of Tat (38−72) as compared to Tat (48−57) is consistent with previous studies that showed that the core region plays an important role in Tat function (*7*, *11*, *12*). Amino acids from the core region make additional contacts with TAR RNA and stabilize the structure of the TAR−Tat complex to enhance the affinity and specificity of Tat for TAR.

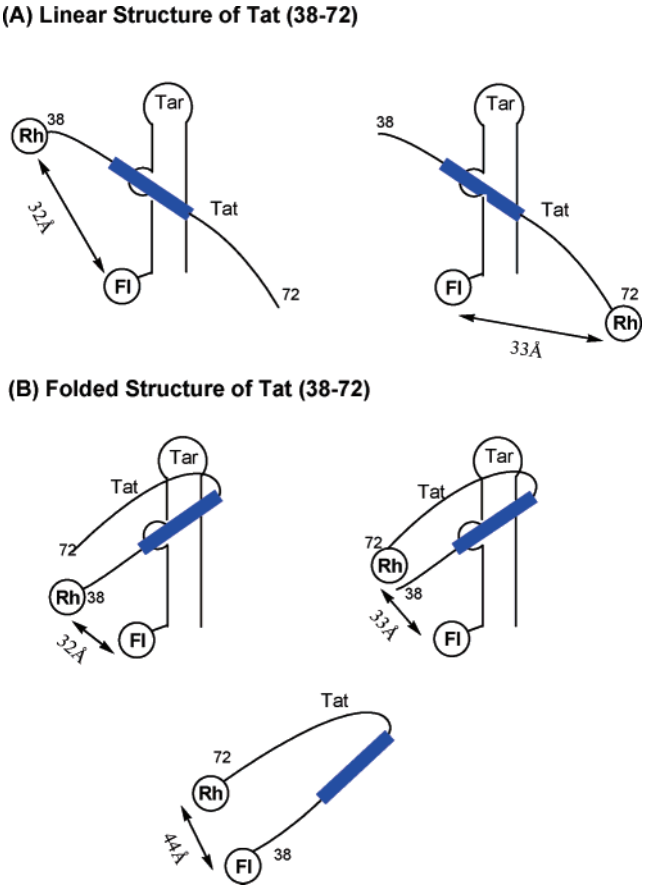

Figure 4. Models for Tat−TAR interactions: (A) linear structure of Tat (38−72), and (B) folded structure of Tat (38−72). RNA-binding region of Tat is highlighted in blue. See text for details.

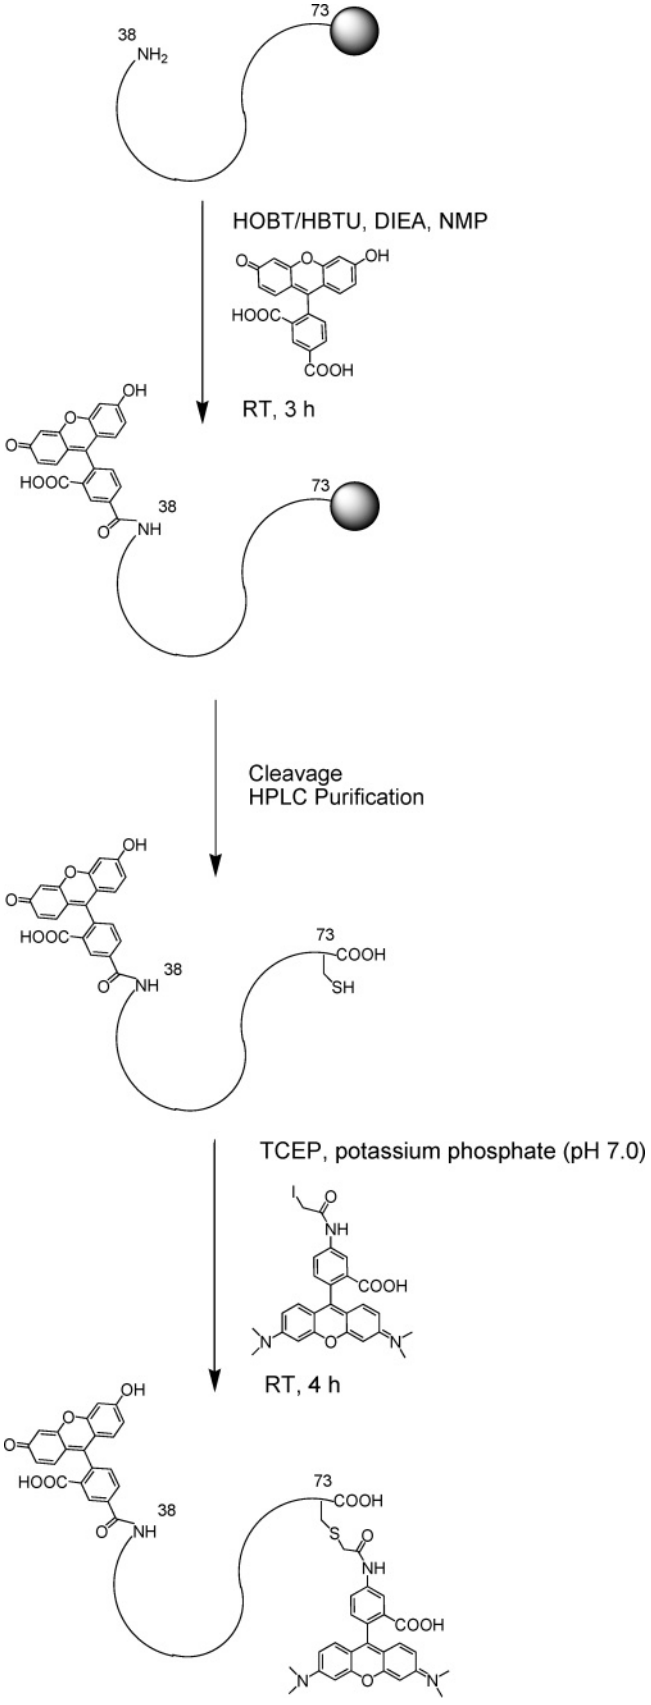
It is worth noting that the K_D value of TAR−Tat (38−72)-Rh is 3-fold greater than TAR−Rh-Tat (38−72). The only difference between the two Tat conjugates is the position of the rhodamine label. The rhodamine moiety of Tat (38−72)-Rh is relatively far from the basic binding region of Tat (15 aa) and should not influence the binding affinity significantly. However, the N-terminal rhodamine of Rh-Tat (38−72) was conjugated to Tat residue 38, which is near the RNA binding region (within 10 aa) and associated with the core region that significantly contributes to binding. Rhodamine is 12.1 Å (end-to-end distance, according to the structure at a minimum energy), which is equivalent to two amino acid residues (for example, 6.6 Å for lysine and 5.8 Å for arginine). Therefore, it is possible that the relatively bigger rhodamine molecule at the N-terminus of Tat (38−72) weakened hydrogen bonding or diminished van der Waals interaction normally formed between TAR RNA and the core or basic region of Tat (38−72), accounting for the lower binding affinity we observed.

Tat (38−72) Binds TAR in a Folded Conformation. We next used our FRET system and Tat (38−72) labeled with rhodamine at different terminals to determine the conformation of rhodamine-labeled Tat (38−72) when it is bound to RNA. FRET allowed us to estimate the distance between fluorescein and rhodamine when rhodamine-labeled Tat (38−72) was bound to Fl-TAR RNA, which were 32 Å Rh-Tat (38−72) and 33 Å

Scheme 3. Synthesis of N-Terminal-fluorescein and C-Terminal-rhodamine Tat(38−72) Cys-73



for Tat (38−72)-Rh, respectively (Table 1). Although the binding affinities for Rh-Tat (38−72) and Tat (38−72)-Rh are quite different, the distance between the fluorophores was about the same. To begin to establish the conformation of Tat (38−72) associated with RNA, we first visualized the conformation of Tat (38−72) when bound to RNA if Tat (38−72) had a linear structure (see Figure 4a). In this scenario, the basic region of Tat binds TAR RNA, resulting in the farthest possible distance between its N- and C-termini, but in relation to the fluorescein label at the 5′-end of TAR, the distance between either terminus and fluorescein is the same. On the other hand, if we assume the amino acid sequence of Tat is flexible and amenable to folding (see Figure 4 b), the C-terminus of Tat (38−72) would fold toward the N-terminus bringing them close in proximity. However, in this folded conformation, the distance from either termini to the fluorescein label would still be about the same as when they were farthest apart.

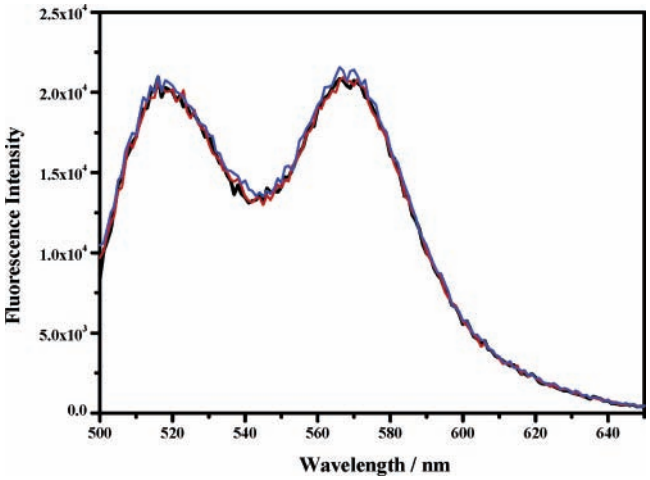


Figure 5. Fluorescence spectra of 10 nM Fl-Tat (38−72)-Rh with 0 nM (black line); 3.33 nM (red line); 558 nM (blue line) wild-type unlabeled TAR RNA after excitation at 490 nm.

To distinguish whether either of our models is correct, we labeled Tat (38−72) with fluorescein on its N-terminus and rhodamine on its C-terminus (Figure 1 and Scheme 3; (Fl-Tat (38−72)-Rh)). Under the same experimental conditions used to measure FRET above, the fluorescence emission spectrum of Fl-Tat (38−72)-Rh after excitation at 490 nm was recorded. The spectrum of Fl-Tat (38−72)-Rh (10 nM) shows two emission bands at 514 and 575 nm (Figure 5), which belong to fluorescein and rhodamine, respectively. To measure FRET, we compared the rhodamine emission detected after direct excitation to the rhodamine emission detected after excitation via fluorescein. The emission of Tat (38−72)-Rh at 575 nm seen after excitation at 490 nm was 50% of the intensity of Fl-Tat (38−72)-Rh at 575 nm. This difference reflected the intramolecular energy transfer from fluorescein to rhodamine in Fl-Tat (38−72)-Rh.

We next synthesized fluorescein-labeled Tat (47−58) (Fl-Tat (47−58)) (Figure 1B) to determine the efficiency of intramolecular energy transfer for Fl-Tat (38−72)-Rh. The fluorescence intensity of Fl-Tat (47−58) (10 nM) at 514 nm after excitation at 490 nm was about 3-fold greater than Fl-Tat (38−72)-Rh under exactly the same conditions. From this measurement, we were able to calculate an intramolecular energy transfer efficiency, E, of 60% for Fl-Tat(38−72)-Rh. The distance R between the N-terminal fluorescein and C-terminal rhodamine of Fl-Tat (38−72)-Rh is 44 Å (Figure 4b). These results suggest that Tat (38−72) has a folded structure and is not in a linear conformation because FRET can only be observed if the two termini are close enough in proximity for energy transfer. According to Förster theory, when R is greater than R_0, the energy transfer efficiency decreases steeply since E is inversely proportional to the sixth power of R. The Förster distance depends on the donor−acceptor dye pair which was

fluorescein−rhodamine in our experiments. If Tat (38−72) was linear, the distance between the two termini should be much longer than R_0 and would not allow for the energy transfer we observed for Fl-Tat (38−72)-Rh. Titration of Fl-Tat (38−72)-Rh with up to ∼560 nM of wild-type TAR RNA did not alter the emission spectra observed with Fl-Tat (38−72)-Rh alone (Figure 5), suggesting that the distance between the N- and C-terminus is maintained before and after RNA binding. This observation indicates that Tat (38−72) was in a folded conformation regardless of whether it was bound to TAR RNA. This finding is consistent with the structure of the bovine immunodeficiency virus (BIV) Tat−TAR complex determined previously by NMR (*22*, *23*). These studies showed that the RNA-binding region of Tat adopts a β-turn conformation rather than a linear conformation. Computer modeling of HIV-1 Tat−TAR complexes (*24*) also suggested that HIV-1 Tat(46−58) forms a hairpin loop when complexed with TAR that is strikingly similar to the hairpin formed by the structure of BIV Tat protein.

Combining all of the distances derived from our FRET analysis, we can visualize the distance between the two termini of Tat (38−72) and the distance from each terminal end to the 5′-end of TAR RNA. These results suggested the possible orientation of Tat peptide in the Tat−TAR complex where the amino and carboxyl termini of Tat (38−72) are close to each other but they are arranged in three-dimensional space at equal distance from the 5′-end of TAR RNA (Figure 4). Collectively, this study demonstrates that the N- and C-termini of Tat (38−72) are in close proximity to each other when the peptide is folded and that the peptide does not go through a large structural change upon TAR binding.

Received September 16, 2005; Revised Manuscript Received February 6, 2006

We describe a process for covalently linking proteins to glass microscope slides and microbeads in a manner that optimizes the reactivity of the immobilized proteins and that is suitable for high-throughput microarray and flow cytometry analysis. The method involves the diazo coupling of proteins onto activated self-assembled monolayers formed from *p*-aminophenyl trimethoxysilane. Proteins immobilized by this method maintained bioactivity and produced enhanced levels of protein−protein interaction, low background fluorescence, and high selectivity. The binding of immobilized proteins to their specific binding partner was analyzed quantitatively and successfully correlated with solution concentrations. Diazotized surfaces bound more efficiently to proteins containing a hexahistidine tag than those without a his-tag. Moreover, significantly higher reactivity of the immobilized his-tagged proteins was observed on diazotized surfaces than on amine-terminated surfaces. Results suggest that his-tagged proteins are immobilized by reaction of the his-tag with the diazotized surface, thus offering the possibility for preferential orientation of covalently bound proteins.

INTRODUCTION

Understanding of the functions, modification and regulation of proteins will continue to improve our knowledge of complex biological systems (*1*−*4*). Because each biological system can include thousands of different proteins, the ability to simultaneously analyze proteins by a cost-effective and reproducible methodology has become extremely attractive (*5*). Protein arrays that provide high-throughput, quantitative measurement of receptor−ligand complexation are finding applications broadly in proteomics (*6*, *7*), drug development (*8*, *9*), and diagnostics (*10*, *11*). Two popular array formats, planar substrates used in high-throughput microarray technology (*12*−*15*), and microparticle-based assays that can be used for high-throughput flow cytometry (*16*−*18*), have been developed for these applications. Both type of arrays are fabricated by immobilizing receptor proteins onto a solid substrate. The reactivity of the receptor proteins, which can directly affect the sensitivity and specificity of the array, is largely dependent on the immobilization chemistry (*1*, *19*).

There are several substrates commonly used in the fabrication of protein arrays. These include aldehyde-containing silane surfaces (i.e. SuperAldehyde substrate from TeleChem, International Inc.) that react with primary amines on the proteins, amine-terminated surfaces (i.e. GAPS-coated slides from Corning) that carry a positive charge at a neutral pH and will form ionic bonds with negatively charged amino acid residues, Ni-coated surfaces that will specifically bind proteins engineered with histidine tags (*4*, *6*, *20*), BSA-*N*-hydroxysuccinimide modified substrates (*3*, *12*), and glyoxylyl-modified surfaces (*13*). A detailed comparison of several methods for protein immobilization is found in Seong's work (*21*). However, because proteins have a heterogeneous structure, and are very likely to denature or lose activity after immobilization, the search for a suitable solid support for protein arrays remains active (*1*, *22*). The optimization of the orientation and stability of immobilized receptor proteins, which will likely affect binding efficiency and specificity of the immobilized proteins, is one of the issues that remains to be addressed.

We describe a chemical process for covalently linking proteins onto ordinary microscope slides and glass microbeads in a manner that preserves their activity. We have previously used diazo coupling chemistry to covalently immobilize nucleic acids to activated self-assembled monolayers (SAMs)[1] formed from *p*-aminophenyl trimethoxysilane (ATMS) in the manufacture of DNA microarrays(*23*). Our goal in this study is to extend the application of this method to covalently couple proteins to glass substrata. Although the application of diazo coupling reaction for biomolecular immobilization can be traced back to the late 1970s when Stark et al. coupled single-standed DNA on diazotized Whatman paper (*23*), and has been extended to coupling proteins with cellulose (to be used in affinity chromatography) (*24*) as well as polymer supports (*25*), in-depth, quantitative analysis of immobilized proteins over glass substrata has not been performed. To this end, we have characterized the binding efficiency of the substrata and the binding specificity and reactivity of the immobilized proteins. Moreover, because randomly oriented proteins may exhibit severely reduced reactivity, the possibility of directed orientation of the immobilized proteins on the surfaces is also studied. To achieve preferential orientation, hexahistidine-tagged (his-tagged) proteins were used because (a) histidine is one of two common

amino acids that can be covalently coupled with diazotized surfaces (*25*, *26*), (b) the attachment of a hexahistidine tag is commonly used in the production of recombinant proteins, and (c) currently there are many commercially available his-tagged proteins (*27*−*29*). Our data suggest that the process described results in preferential reaction of the his-tags on proteins with surface diazonium groups, thus enabling covalent immobilization of oriented protein layers.

EXPERIMENTAL PROCEDURES

Materials. *p*-Aminophenyl trimethoxysilane (ATMS) (90%; Gelest Inc., PA), sodium nitrite (Sigma, St. Louis, MO), sodium acetate (Sigma), ethanol (EtOH, absolute; Aaper Alcohols and Chemical Company, KY), glycine (Aldrich, WI), 20× SSC (0.3M sodium citrate/3M sodium chloride, Sigma), and SDS (sodium dodecyl sulfate, Sigma) were used as obtained. Glass beads (4.9 μm diameter) were obtained from Duke Scientific Corp. (Palo Alto, CA). Hexahistidine-tagged wild-type green fluorescent protein (His_6GFP, $\lambda_{ex} \approx 395$ nm) and HisProbe horseradish peroxidase (HisProbe-HRP) were obtained from Pierce Biotechnology Inc. (Rockford, IL) and used without further purification. FITC-conjugated, affinity-purified anti-horseradish peroxidase (FITC-antiHRP) was obtained from Jackson ImmunoResearch Laboratories, Inc. (West Grove, PA). M1 anti-FLAG antibody and FITC-FLAG (FITC-DYKDDDDK) were obtained from Sigma. Unless otherwise indicated, all antibodies are monoclonal to ensure high binding specificity. All other biological reagents were obtained from Molecular Probes Inc. (Eugene, OR) and used without further purification unless specified. Protein solutions were made in Tris buffer (100 mM Tris, 150 mM NaCl, pH 7.4 to 8.0, all from Sigma) or Tris-BSA buffer (Tris buffer containing 0.1% bovine serum albumin (BSA), pH 7.5).

Cleaning of Substrata. The covalent attachment of organosilanes to glass surfaces is partially dependent on the number of hydroxyl groups exposed on the substrate (*30*). There are several commonly used methods for cleaning silica substrata, including washes with acid or base solutions (e.g. concentrated HCl (*31*), NH_4OH/H_2O_2(*32*), piranha(*31*, *33*−*36*)), and UV/ozone treatment (*37*−*39*). Eight different chemical cleaning methods for glass were compared by Cras et al. (*30*), who found that 30 min incubation in 1:1 MeOH:HCl followed by an additional 30 min incubation in concentrated H_2SO_4 yielded the highest concentration of surface OH groups after treatment and provided the best surface for subsequent silanization without the requirement of heating or other extreme procedures. This method was chosen as our treatment procedure.

Formation of Silane Layers. After the cleaning procedure, glass slides were rinsed with deionized water (dH_2O) and EtOH, dried in a stream of N_2, and immersed into 3 mM ATMS in toluene for 3 h. ATMS-functionalized glass slides were then rinsed exhaustively in EtOH and dH_2O, dried in a stream of N_2, and stored in an airtight container at 4 °C until further use. After the cleaning procedure, glass beads were rinsed with dH_2O and EtOH, centrifuged briefly at 135 000*g* to remove the rinse solutions, and then incubated with 3mM ATMS in toluene for 3 h with mild vortexing. ATMS-coated glass beads were then washed with EtOH and dH_2O, recentrifuged, and used within 24 h.

Diazotization of ATMS-Functionalized Surfaces. Before reacting with biomolecules, ATMS-coated surfaces were converted to the diazobenzyl form by treatment with a solution containing 40 mL of water, 80 mL of 400 mM HCl, and 3.2 mL of freshly prepared solution of $NaNO_2$ (200 mM) for 30 min at 4 °C (*40*). The diazotized surfaces were then washed three times, each for 3 min, with ice-cold sodium acetate buffer (50 mM, pH 4.7) followed by washing with ice-cold deionized water and then EtOH two times each (5 min washes). The diazotized glass slides were air-dried and gently blotted with Kimwipes (Kimberly-Clark, GA) and kept at 4 °C. Diazotized glass beads were also maintained at 4 °C after discarding the wash solution. Diazotized glass slides or glass beads were used immediately for protein immobilization. Uibel and Harris have carried out quantitative studies of this diazo coupling reaction on porous silica gel, and concluded that a surface coverage of 0.36 μmol/m^2 of amine group resulted in approximately 80% diazotization (*41*−*44*). We estimate a surface coverage of $\approx 2 \times 10^7$ amines per 4.9 μm diameter bead prior to diazotization (*43*, *44*). Assuming an 80% rate of diazotization, we expect at least 1×10^7 diazonium salts per bead to be formed.

Formation of Protein Microarrays. Aliquots (10 μL) of different types and concentrations of sample proteins were loaded into a 96-well microtiter plate prior to each set of experiments. These proteins were transferred onto the diazotized microscope slides using a microarrayer (Packard Bioscience, Meriden CT) at room temperature and > 40% humidity. This array-printing process was computer driven, and took ~ 15min/slide when employing four printing pins. Printed slides were then transferred from the microarrayer to a humid chamber and incubated for 1−4 h at room temperature before use. Printed glass slides were blocked with 1% BSA in Tris (pH 7.5) for 1−2 h and incubated with up to 1 μM solution of complementary antigens or antibodies under a glass coverslip in a humid chamber at room temperature for 2 h, followed by sequential washes in 1 × SSC + 0.1% SDS, 0.1 × SSC + 0.1% SDS, 0.1 × SSC, and dH_2O.

Protein-Bearing Microbeads. Suspensions containing ~100 000 ATMS-functionalized glass microbeads in 400 μL aliquots of pH 8.0 Tris buffer were reacted with nM to 3 μM protein (streptavidin, M1 anti-FLAG antibody, or His_6GFP) for 1 h at room temperature under mild vortexing. The samples were then rinsed with deionized water and resuspended in Tris buffer. The respective site densities of streptavidin, M1 anti-FLAG antibody, and His_6GFP were analyzed on the basis of their binding to fluorescent ligands. It is worth noting that the wild-type His_6GFP obtained from Pierce has an excitation wavelength maximum of 395 nm, which is not suitable for routine flow cytometric detection. Thus a fluorescently labeled anti-GFP was employed to detect the presence of His_6GFP. The experimental procedures used have been described elsewhere (*45*). The binding characteristics of protein-coated beads to fluorescein biotin (streptavidin beads), FITC-FLAG peptides (M1 beads), and Alexa488-antiGFP were generally determined by incubation of 40 000 protein-coated beads in 400 μL of fluorescently labeled ligand solutions (10^{-9} to 10^{-6} M) for 1−2 h, unless otherwise specified. Protein-bearing beads were exposed to 1% BSA in Tris buffer for 1 h before ligand incubation in order to reduce nonspecific binding. Measurements of fluorescence associated with samples blocked with large excesses of nonfluorescent ligands (>5-fold) before exposure to fluorescently labeled ligands were preformed in parallel to estimate nonspecific binding. We determined the amount of specific binding by subtracting signals of blocked samples from unblocked samples and then quantified the fluorescence intensity (488 nm excitation) by comparison to calibrated fluorescent beads (*45*, *46*). For diazotized substrates, nonspecific binding was less then 30% of total binding in all experiments.

Data Collection and Analysis. Protein microarrays were visualized with a confocal laser scanner, GenePix 4000B from Axon Instruments, Inc., and data were processed using the associated image-processing software (GenePix 3.0) (*40*). The surface density of immobilized proteins on beads was determined by centrifugation assays and flow cytometry (*45*, *46*). The flow cytometric analysis used a Becton-Dickinson FACScan

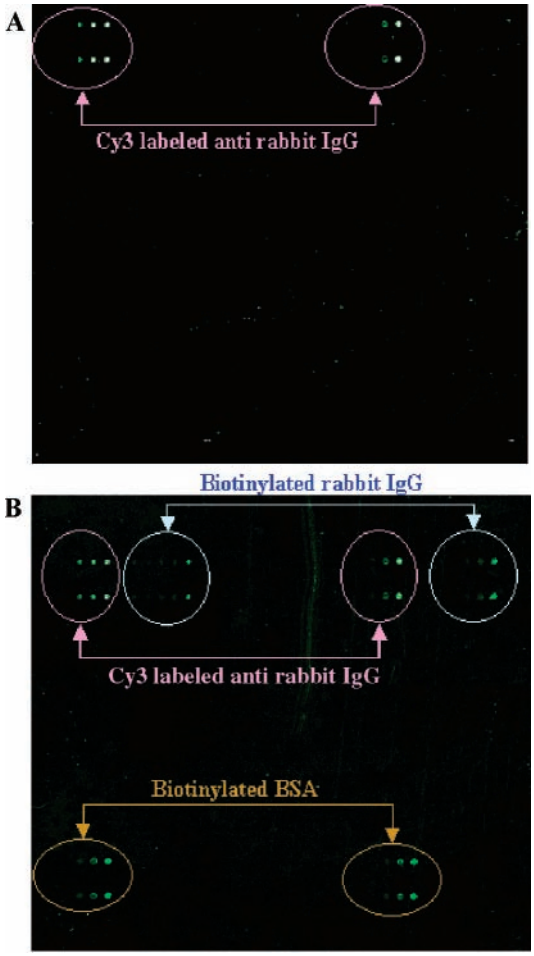

Figure 1. A protein microarray formed on an ATMS/diazotized glass slide. Spot sizes are about 100 μm in diameter. A. Scanned image before FITC-streptavidin incubation. Different proteins were arrayed onto the slide in duplicates of five different concentrations: Cy3-labeled anti mIgG (0.06, 0.6, 6, 60, 600 pM), biotinylated rIgG (0.06, 0.6, 6, 60, 600 pM), and biotinylated BSA (0.3, 3, 30, 300, 3000 pM). B. Scanned image of the same protein microarray after incubation with FITC-streptavidin.

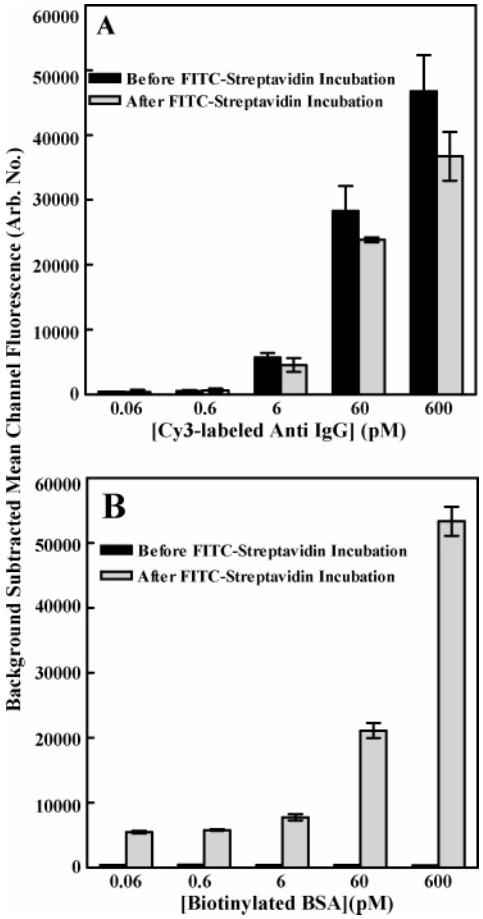

Figure 2. Quantitative intensity analysis of protein microarrays imaged in Figure 1 before and after incubation with FITC-streptavidin. A. Intensity of Cy3-labeled anti mIgG spots (λ_{em} = 530 nm). flow cytometer (Sunnyvale, CA) interfaced to a Power PC Macintosh running CellQuest software package. The FACScan is equipped with a 15 mW air-cooled argon ion laser. It has been shown elsewhere (*46*) that the mean of the histogram is the quantity relevant to binding capacity. The average fluorescence of a single bead is converted to the number of fluorophores per bead on the basis of flow cytometric calibration beads (*46*). Data were subsequently analyzed using Microsoft Excel or GraphPad Prism software (GraphPad Software, Inc. San Diego, CA).

RESULTS AND DISCUSSION

Protein Microarrays. In a previous report, we demonstrated that the ATMS-based diazo coupling method can produce reusable DNA microarrays that provide uniform DNA spots with high spot intensity (*40*). These microarrays have been used to successfully quantify differential gene expression in different RNA libraries (Dolan P. L., Nelson M. A., unpublished data). Similar experimental procedures were used as a starting point for the fabrication of protein microarrays. Scanned images and quantitative analyses of protein microarrays are presented in Figure 1 and Figures 2 and 3, respectively.

Figure 1 shows the scanned images of a typical protein microarray before (Figure 1A) and after 2 h incubation of 1 μM FITC-labeled streptavidin in Tris−BSA (Figure 1B). Three different proteins, including a fluorescently labeled "control protein", Cy3-anti mouse IgG (Cy3-anti mIgG), and two biotinylated proteins, biotinylated BSA and biotinylated rabbit IgG (rIgG), that bind specifically to FITC-labeled streptavidin, were arrayed on diazotized glass microscope slides at five different concentrations, each in duplicates. The scanned images in Figure 1 show that (1) signals representing the control protein, i.e., Cy3-anti mIgG, appear clearly on both images with similar spot intensity, (2) signals from biotinylated areas are visible only after the incubation in FITC-labeled streptavidin, and (3) the signal intensity of all three types of proteins reflect protein concentration in the spotted samples. Results of spot intensity analysis are shown in Figure 2.

Figure 2A shows the background-subtracted mean spot intensity of Cy3-anti mIgG before and after incubation with FITC-streptavidin. Although some signal decrease is observed (likely due to photobleaching occurring during scanning), neither the mean spot intensity nor the proportional relationship between different concentrations of the immobilized control protein is significantly influenced by the incubation of FITC-streptavidin. In contrast, spot intensities of biotinylated BSA shown in Figure 2B increase dramatically after incubation with FITC-streptavidin, which binds specifically with the biotinylated protein. The spot intensity after FITC-streptavidin incubation reflects the concentration of biotinylated BSA in the spotted samples. Similar results were obtained on the spots of biotinylated rIgG (data not shown). These observations indicate the possibility of applying the diazo coupling method to produce protein microarrays for quantitative analysis.

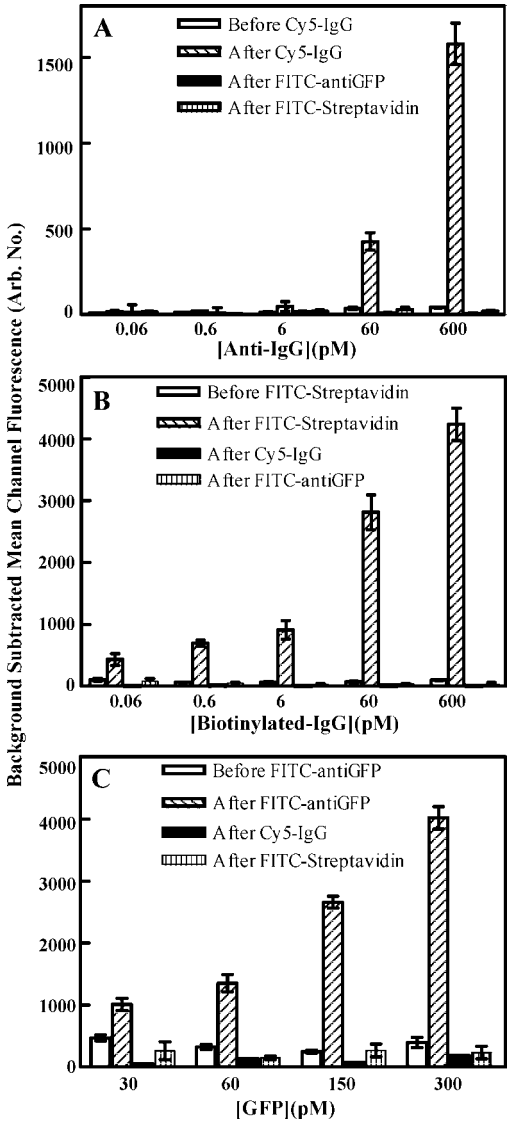

Figure 3. Responses of different proteins arrayed on diazotized surface to their specific binding partner. The microarrays were prepared by spotting the proteins at the concentrations indicated. Intensity of anti-mIgG spots (A), biotinylated rIgG spots (B), and His_6GFP spots (C) before and after the incubation of 1 μM Cy5-mIgG, FITC-streptavidin, or FITC-antiGFP.

An important criterion for the success of covalent protein immobilization strategies is the preservation of bioactivity of immobilized proteins, i.e., their ability to recognize specific binding partners. We demonstrated binding specificity of proteins immobilized on diazotized substrates by first forming microarrays consisted of five different concentrations of three different types of proteins, an antibody (anti-mIgG), an antigen (GFP), and a conjugated protein (biotinylated rIgG). The printed slides were then incubated with Cy5-labeled mIgG, FITC-labeled antiGFP, or FITC-labeled streptavidin at room temperature for 1 h, to compare the reactivity of the arrayed proteins. Intensity analysis results in Figure 3 show all three immobilized proteins bound specifically to their binding partners, and the signal intensities are proportional to the protein concentration in spotted samples. These observations indicate that protein microarrays formed on the ATMS-based diazonium surfaces maintain relatively high binding specificity, and that it is also possible to obtain quantitative data using this protein immobilization method.

Protein-Bearing Micro Particle Assays. Among the 20 common amino acids, only four contain an aromatic ring, and

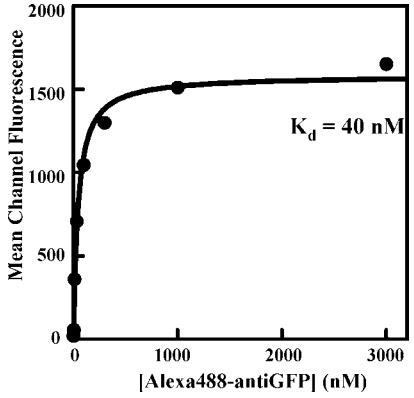

Figure 4. Equilibrium binding curve of Alexa488-antiGFP binding to His_6GFP. Samples for binding curve analysis were prepared by incubating diazotized beads in 400 μL of 200 nM His_6GFP for 1 h at room temperature under mild vortexing, and then the beads were reacted with nM to μM range of Alexa488-antiGFP for 1 h.

of these, only histidine and tyrosine readily bind covalently to diazonium salts (*25*, *26*). Our expectation is that the rapid reaction between the diazonium group and tyrosine or histidine residues in proteins is the basis for the immobilization described here. Polyhistidine tags that consist of five or six contiguous histidine residues, attached to either the N or the C terminus of the protein and exposed at protein surfaces, are widely employed in the purification of recombinant proteins (*28*, *47*). Therefore, we compared the reactivity of diazotized surfaces with proteins bearing and lacking histidine tags.

We investigated the binding of His_6GFP, streptavidin, and M1 anti-FLAG antibody to diazotized glass microbeads (4.9 μm in diameter) and performed quantitative analysis by flow cytometry. We used fluorescein biotin to measure the surface concentration of streptavidin (MW $\sim$ 66 kDa; $K_d = 10^{-13}$ M (*46*, *48*)), FITC-FLAG to detect M1 anti-FLAG antibody (MW $\sim$ 150 kDa; $K_d \sim 8$ nM (*45*)), and Alexa488-antiGFP to detect His_6GFP (MW $\sim$ 27 kDa). High concentrations of fluorescently labeled ligands (at least 10 times higher than K_d) were used in order to ensure characterization of the amount of proteins bound to the diazotized surface at saturation. To determine the affinity of Alexa488-antiGFP to His_6GFP bound to the diazotized bead surface, a binding curve (Figure 4) was measured. A one-site binding hyperbola was used to analyze the experimental data in Prism software, and the best-fit values gave the equilibrium dissociation constant, K_d, after background subtraction, as $\sim$40 nM (Figure 4). On the basis of this result, 400 nM antiGFP (i.e., $10 \times K_d$ of the antiGFP/GFP reaction) was chosen for the characterization of the reaction of His_6GFP with the diazo beads, while 100 nM of FITC-FLAG and 200 nM of fluorescein biotin were chosen to characterize the reaction of M1 and streptavidin, respectively, with the diazotized beads.

Figure 5 compares the binding efficiency of His_6GFP (Figure 5A), streptavidin, and M1 anti-FLAG antibody (Figure 5B). These data indicate that each of the tested proteins was immobilized to the diazotized surface consistently, and that the diazotized surface showed especially high binding of the his-tagged protein. To ascertain whether this is due to high binding reactivity of diazotized surfaces for his-tagged proteins or to the size of the immobilized proteins, the maximum possible protein coverage over diazotized microbead surfaces was estimated. As described in the Experimental Procedures, approximately 1×10^7 active sites/bead are expected after diazotization; however, the degree of protein binding may also depend on characteristics of the protein molecule, e.g., tertiary structures. GFP is an 11-stranded β-barrel threaded by an α-helix running through the axis of the cylinder (*49*). These cylinders have a diameter of about 30 Å and a length of 40 Å (*50*). The

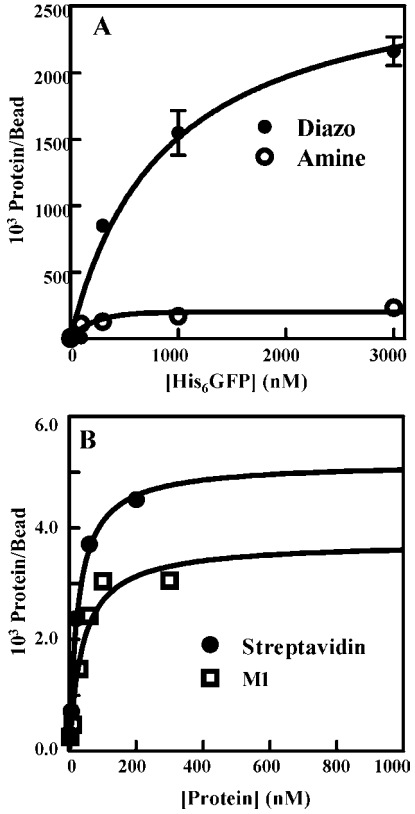

Figure 5. Comparison of diazo coupling reaction for proteins with and without histidine tag. A. Comparison of binding efficiency of His_6GFP with diazotized and amine terminated surface. B. Binding efficiency of proteins without a histidine tag (streptavidin, and M1 anti-FLAG antibody) with diazotized surfaces.

minimum surface coverage for a single GFP molecule is thus ~780 Å^2. Because the surface area of a 4.9 μm diameter bead is ~7.5 × 10^9 Å^2, the maximum number of His_6GFP molecules that can be attached to a 4.9 μm bead is ~1 × 10^7. On the basis of a similar estimation, there should be a maximum of about 4 million streptavidin molecules [dimension ~ 40 Å × 50 Å × 50 Å] (*51*, *52*) and 0.4 million M1 molecules [~15 nm in diameter] that can be packed onto a single 4.9 μm bead.

Results in Figure 5 show that when incubated in 300 nM protein solution, approximately 900 000 His_6GFP molecules per bead were detected, while less than 5000 protein/bead (or less than 0.5% of the bound His_6GFP) were detected for both non-his-tagged proteins (streptavidin and M1 anti-FLAG antibody). Moreover, as illustrated in the Figure, detectable His_6GFP molecules/bead increased to approximately 2.2 million (when the His_6GFP concentration in solution was 3 μM), which is about 20% of the estimated maximum His_6GFP binding sites/bead. Geometrically, the maximum number of His_6GFP that can pack on a single glass bead should only be about twice that of streptavidin and twenty times more than that of M1 anti-FLAG antibody. Thus, these results indicate that the his-tagged proteins are substantially more reactive with the diazotized surface than non-his-tagged proteins.

The identification of an immobilization chemistry that can preserve the reactivity of the bound proteins has always been a challenge for high-throughput protein analysis (*21*, *53*). Reactivity of the surface bound proteins can be a function of the structure, orientation, and packing of the protein. We compared the reactivity of his-tagged proteins for activated diazotized surfaces with their reactivity to unactivated primary amine-terminated surfaces. Figure 5A presents the amount of reactive His_6GFP bound to diazotized and unactivated SAMs formed from ATMS as detected by the binding of Alexa488-antiGFP.

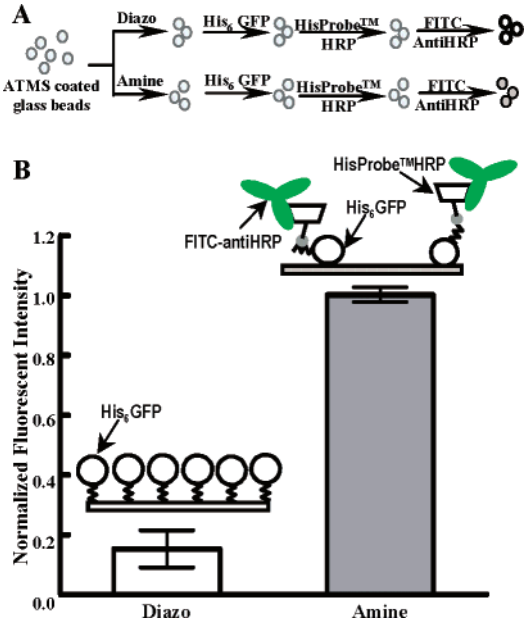

Figure 6. A. Experimental design for studying the reactivity of his-tagged protein immobilized on diazotized surfaces. B. Results of experiments in part A detected by flow cytometry. Diazo: represents response of immobilized His_6GFP on diazotized beads coupled to HisProbe-HRP detected by FITC-antiHRP. Amine: response of immobilized His_6GFP on primary amine-terminated beads coupled to HisProbe HRP detected by FITC-antiHRP. Inserts schematically depict possible protein orientations on each surface.

The amount of reactive his-tagged protein measured on the diazotized surface is considerably higher than that observed on the amine surface, reaching a maximum of 1000% higher at a solution concentration of 3 μM of His_6GFP. Similar experiments with proteins without a his-tag did not show any significant difference between diazotized surfaces and amine-terminated surfaces. These observations indicate that when compared to amine surfaces, the diazo-coupling method can result in much higher levels of adsorbed his-tagged proteins.

Because the ligand binding site(s) over a protein surface is generally asymmetric, the geometric orientation of the immobilized protein may determine whether it retains its binding activity (*22*, *54*). Figure 5A indicates that the coupling reaction of His_6GFP with diazotized beads yields a much greater surface density of the reporter Alexa488-antiGFP antibodies than the primary amine (i.e. unactivated ATMS) surfaces. The reporter antibody (Alexa488-antiGFP) can be considered as an indirect measure of surface His_6GFP coverage. However, it is not possible to definitively distinguish whether the higher surface coverage of the reporter antibody at diazotized surface is due to improved coupling efficiency to His_6GFP molecules, or to proper orientation of GFP that allows optimum antibody capture, or both. To assess whether the results shown in Figure 5 were related to the geometric orientation of the immobilized his-tagged proteins, we further investigated the diazo coupling method as a means of covalent immobilization of oriented proteins on surfaces. An assay specifically targeting surface-accessible his tags using HisProbe-HRP was employed to explore this issue.

HisProbe-HRP is a Ni^{2+} activated HRP derivative, that can be used to detect surface-exposed his-tags (http://www.piercenet.com/). Figure 6A shows a typical experimental scheme that was followed. The results are shown in Figure 6B. The results indicate that a higher amount of HisProbe-HRP is bound to GFP treated primary amine surfaces than to GFP-treated diazotized SAMs. Because HisProbe-HRP is only able to bind to surface-exposed histidine residues, this indicates that

few his-tags are available for binding on the GFP-treated diazotized SAMs. Taken together with the data presented in Figure 5A, these results suggest that high levels of His_6GFP were bound to the diazotized SAMs, and that a large percentage of the immobilized His_6GFP was bound in an oriented fashion on these surfaces (see inserts of Figure 6B). These proteins were likely coupled to the diazotized surfaces via a covalent linkage to the his-tags. The results further suggest that amine-terminated surfaces do not react as efficiently with his-tagged proteins as diazotized surfaces, and that they may react nonspecifically with other negatively charged amino acid residues scattered on the protein surface, as discussed previously (*21*), to result in a nonpreferential orientation of the adsorbed His_6GFP molecules.

SUMMARY

A diazo coupling method was used to covalently immobilize proteins onto solid substrates. When compared with commonly used microarray supports, e.g., amine-terminated surfaces, the diazotized surfaces provide low background fluorescence and high signal/noise ratio. Proteins containing a hexahistidine tag exhibited over 10× higher reactivity compared to non-his-tagged proteins. Results indicate that immobilized his-tagged proteins are likely coupled to diazotized surfaces through the histidine tag, which allows for preferential orientation of the immobilized proteins and thereby can be used to optimize the reactivity of the protein to interact with specific binding partners. Because of the wide availability of his-tagged proteins, the described surface immobilization described herein may be useful in the fabrication of protein arrays and protein-coated microbeads for high throughput analyses.

Selection of Streptavidin Binders from a DNA-Encoded Chemical Library

Christoph E. Dumelin,§ Jörg Scheuermann,§ Samu Melkko, and Dario Neri*

Institute of Pharmaceutical Sciences, Department of Chemistry and Applied Biosciences, ETH Zürich, Wolfgang-Pauli-Strasse 10, CH-8093 Zurich, Switzerland. Received September 21, 2005; Revised Manuscript Received January 26, 2006

DNA-encoded libraries of small organic molecules facilitate the construction of large, encoded self-assembling chemical libraries for the identification of high-affinity binders to protein targets. We have constructed a library of 477 chemical compounds, coupled to 48mer-oligonucleotides, each containing a unique six-base sequence serving as "bar-code" for the identification of the chemical moiety. The functionality of the library was confirmed by selection and amplification of both high- and low-affinity binding molecules specific to streptavidin.

INTRODUCTION

The isolation of molecules capable of high-affinity and specific binding to a biological target is a central problem in chemistry, biology, and pharmaceutical sciences. The construction of libraries of compounds which carry a unique DNA sequence as a "bar-code" for each library member promises to facilitate the identification of binding molecules and to speed-up and miniaturize screening procedures. In principle, very large libraries of compounds can be panned with the target protein of interest immobilized on a suitable support, followed by the identification of the preferentially enriched compounds by procedures which may involve PCR[1] amplification of the DNA codes, sequencing, and/or hybridization to a DNA microarray (*1*−*4*).

Our group has recently developed a novel technology for the construction of large encoded self-assembling chemical (ESAC) libraries (*4*). The self-assembly of DNA oligonucleotides carrying individual chemical compounds at their extremity enables the facile generation of large chemical libraries from smaller sublibraries. Chemical groups which display a synergistic chelate binding mode to the target protein of interest can be identified from an ESAC library. The corresponding bidentate ligands can display a binding affinity which is dramatically higher compared to the individual chemical moieties (*4*).

Encouraged by the first ESAC affinity-maturation selections for binders to human serum albumin and bovine carbonic anhydrase (*4*), we have now constructed a large library containing 477 compounds [with molecular weights ranging between 100 and 500 Da], covalently coupled to a primary amino group at the 5′ extremity of 477 individual oligonucleotides of general structure 5′-$NH_2(CH_2)_6PO_4$-GGA GCT TCT GAA TTC TGT GTG CTG XXX XXX CGA GTC CCA TGG CGC AGC-3′ (where XXX XXX denotes different unique combinations of six bases for the individual compounds, with three/six bases being G or C). The performance of this large library in the selection, read-out, and identification procedure was analyzed in a screening against streptavidin. Thereby one high- and two low-affinity binding molecules to streptavidin were identified.

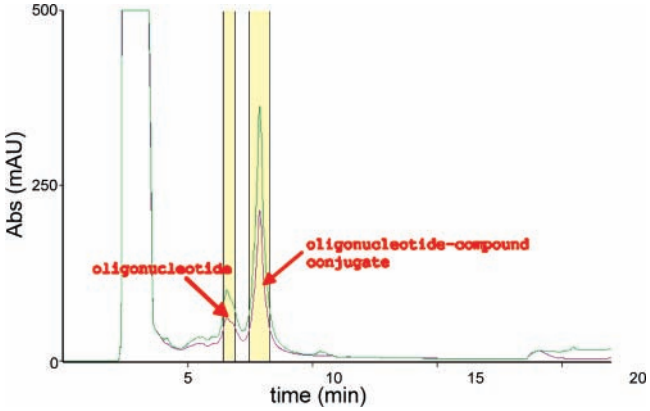

Figure 1. HPLC purification of the oligonucleotide−compound conjugate **337**. The green chromatogram indicates the absorption at 260 nm, the purple chromatogram at 280 nm. The peaks highlighted in yellow indicate the collected fractions.

EXPERIMENTAL PROCEDURES

Preparation of Oligonucleotide−Compound Conjugates. The coupling of compounds to DNA was accomplished by formation of either an amide or a thiourea. The oligonucleotide carrying a primary amino group (IBA) was coupled to carboxylic acids, acyl chlorides, cyclic anhydrides, or isothiocyanates. Some of the carboxylic acids further contained an Fmoc-protected amino group. Scheme 1 shows the different classes of compounds present in the library and the resulting oligonucleotide−compound conjugates. For acyl chlorides, 200 μL of a 25 μM solution of oligonucleotide in 100 mM $NaHCO_3$, pH 9, was added to 200 μL of a 4 mM solution of acyl chloride in MeCN. In the case of isothiocyanates, 100 μL of a 50 μM solution of oligonucleotide in 100 mM $KHPO_4$, pH 7.1, was added to 200 μL of a 2.6 mM solution of isothiocyanate in DMSO. For cyclic anhydrides, 100 μL of a 50 μM solution of oligonucleotide in 100 mM $KHPO_4$, pH 7.1, was added to 200 μL of a 2.6 mM solution of anhydride in DMSO. To activate the carboxylic acids, 22 μL of a solution containing 45 mM EDC and 180 mM sulfo-NHS in 15% H_2O/85% DMSO was added to 230 μL of a 5.5 mM solution of the carboxylic acid in DMSO. After 30 min at 30 °C, 60 μL of a solution of 83 μM oligonucleotide in 420 mM TEA/HCl, pH 10, was added. All reactions were

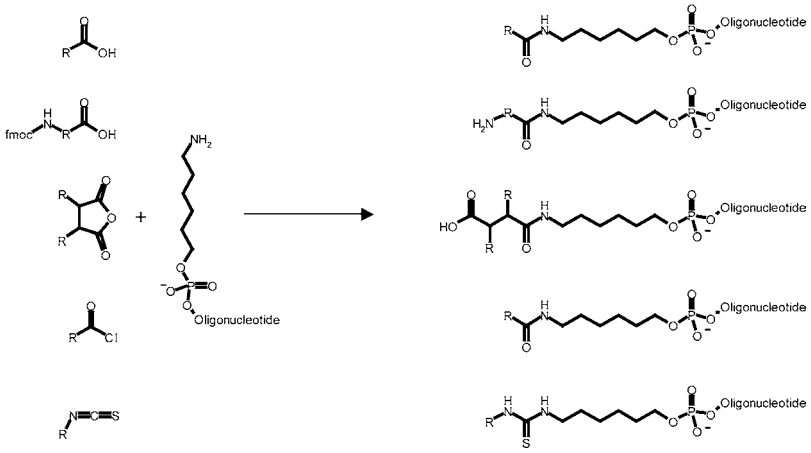
Scheme 1. Functional Groups Used for the Coupling of Different Compound Classes to Amino-Tagged 48mer Oligonucleotides



stirred for 12 h at 30 °C. The reactions were quenched by adding 20 μL of 500 mM Tris/HCl, pH 8, and stirred for an additional 1 h at 30 °C. In the case of Fmoc-protected compounds, the quenching and removal of the Fmoc group was performed by addition of 5 μL of 1 M Tris and 5 μL of triethylamine and stirring for 1 h at 30 °C.

Purification of Oligonucleotide−Compound Conjugates. Prior to HPLC purification, 400 μL of 100 mM TEAA, pH 7, was added to the reaction mixture. In the case of the Fmoc samples, 20 μL of 1 M HCl was additionally added. Purifications were performed by HPLC on an XTerra Prep RP_{18} column (5 μM, 10 × 150 mm) using a linear gradient from 10 to 40% MeCN in 100mM TEAA. The HPLC purification chromatogram of the oligonucleotide−compound conjugate **337** is given as an example in Figure 1. Fractions absorbing at 260 nm were collected, and those with an absorption ratio 260 nm/280 nm of 1.8:1 were dried under vacuum.

LC-ESI-MS. The desired samples were redissolved in 100 μL of H_2O. An amount of 5 μL was analyzed by LC-ESI-MS on an XTerra RP_{18} column (5 μM, 4.6 × 20 mm) using a linear gradient from 0 to 50% MeOH over 1 min in 400 mM HFIP/5 mM TEA. The mass spectrum was measured from 900 to 2000 *m*/*z* by a Waters Quattro Micro instrument. The mass spectra of oligonucleotide **337** before and after conjugation are given as an example in Figure 2. The samples containing the oligonucleotide−compound conjugates of the expected size were pooled and precipitated by adding 10% v/v of 3 M NaAc, pH 4.7, and 250% v/v of EtOH. The pellets were collected by centrifugation and washed by addition of ice cold 85% EtOH, followed by drying under vacuum. The oligonucleotide−compound conjugates were then redissolved in 100 μL of H_2O, and the OD_{260} was determined by a ND-1000 (Nanodrop).

Screening Procedure. All library members were pooled to a final total oligonucleotide−compound conjugate concentration of 900 nM (1.8 nM for each individual oligonucleotide−compound conjugate). The library was dimerized by heterodu-

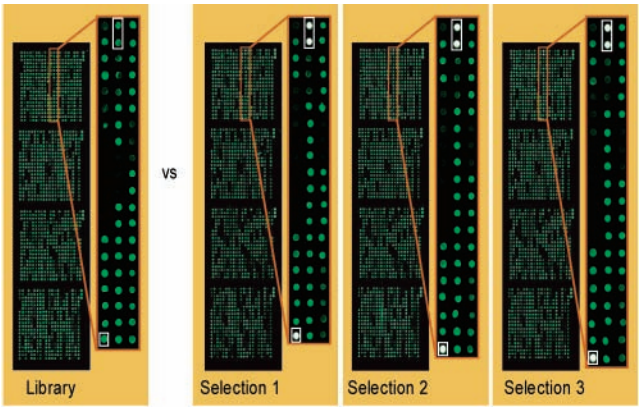


Figure 3. Microarray readout of the PCR amplification of the library before selection and after selection (in triplicate). The inset highlights the enhancement of the signal from compound **337** (spotted in triplicate).

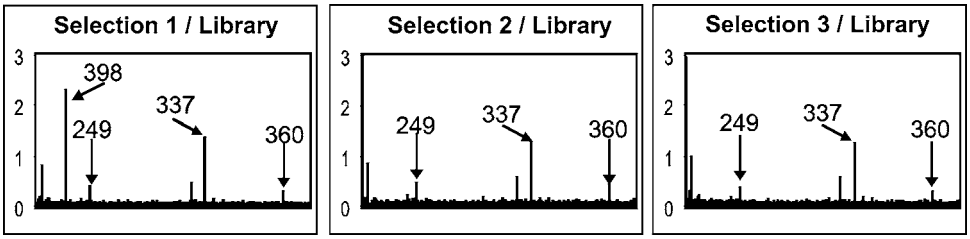

Figure 4. Ratios of the fluorescence signal after and before the selections. The signals of compounds **249**, **337**, and **360** are highlighted. Compounds are sorted on the *x*-axis according to increasing signal intensities on the library slide. Approximately 20 compounds in the left part of the graph show larger signal variability due to their low fluorescence signal. The enrichment of **398** is an artifact.

plex formation with an unmodified pairing oligonucleotide at a concentration of 100 nM. The resulting DNA duplex was diluted 1:10 in PBS, and 100 μL was added to 50 μL of streptavidin-sepharose slurry (GE Healthcare) preincubated with PBS, 0.3 mg/mL herring sperm DNA. After incubation for 1 h at 25 °C, the mixture was transferred to a SpinX column (Corning Incorporated), the supernatant removed, and the resin washed 3× with 300 μL of 1 mM $MgCl_2$, 0.1% Tween 20 in PBS. The resin was resuspended in 100 μL of H_2O.

Identification of Binding Molecules. The codes of the oligonucleotide−compound conjugates were amplified before and after selection by PCR (50 μL, 25 cycles of 1 min at 94 °C, 1 min at 55 °C, 40 s at 72 °C) of either 5 μL of the resuspended resin or 5 μL of 100 fM DNA duplex library using primers AB_fo_short (GGA GCT TCT GAA TTC TGT GTG CTG) and Elib2_ba (GCT GCG CCA TGG GAC TCG). The product was purified and subsequently linearly amplified by PCR (see above) using 5′-Cy3-labeled Elib2_ba as primer. The product was precipitated in EtOH as described above and redissolved in 120 μL of hybridization buffer (4 × SSC, 50 mM HEPES, 0.2% SDS, pH 7) and incubated with microarray glass slides (displaying 19mers with the structure 5′-TGTGCT-GXXXXXXCGAGTC-3′ in triplicate) in a Tecan HS 400 hybridization instrument for 4 h at 44 °C followed by successive washing steps with 2 × SSC/0.2% (w/v) SDS, 0.2 × SSC/0.2% (w/v) SDS, and 0.2 × SSC. After hybridization, microarrays were analyzed by using a Genepix professional 4200A scanner (λ_{ex} = 532 nm, 100% laser power, photomultiplier 300). Spot intensities were quantified and evaluated using Genespotter (v2.4.3). After background subtraction, the mean value was used as spot signal intensity (average of three spots).

Affinity Measurements. The enriched compounds **249**, **337**, and **360** were coupled to bovine serum albumin following the same procedure as for the oligonucleotides, except that the protein was added as 750 μL of a solution of 6.7 μM bovine serum albumin in 33 mM TEA/HCl, pH 10. After purification on a PD-10 column (GE Healthcare), 20 μL of the eluted protein (2.7 μM) was injected onto a streptavidin-coated BIAcore chip.

Fluorescein isothiocyanate was conjugated to ethylenediamine in DMSO. The fluorescein−ethylenediamine conjugate was coupled to compounds **249** and **360** following the same procedure as for oligonucleotides. Fluorescein−compound conjugates (500 nM) and fluorescein as negative control were incubated with increasing amounts of streptavidin in PBS, 5% DMSO, for 1 h at 25 °C. The biotin competition was performed by incubating 500 nM fluorescein−compound conjugates with 200 μM streptavidin either with or without 250 μM biotin in PBS, 5% DMSO, for 1 h. The fluorescence polarization was determined by excitation at 485 nm and measurement at 535 nm (TECAN Polarion).

The oligonucleotide−compound conjugate **337** was hybridized to a pairing 24mer carrying a Cy3 label at the 3′ end. The resulting duplex (13 nM) was incubated with increasing concentrations of streptavidin in 150 mM Tris/HCl, 10 mM $MgCl_2$, pH 8.9, for 1 h and analyzed on a 20% TBE polyacrylamide gel.

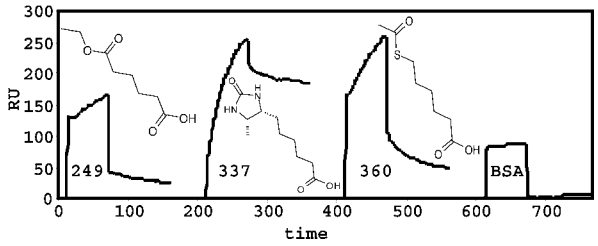

Figure 5. BIAcore measurements of **249**, **337**, and **360** coupled to BSA and BSA alone on streptavidin chips together with the structures of the binding compounds.

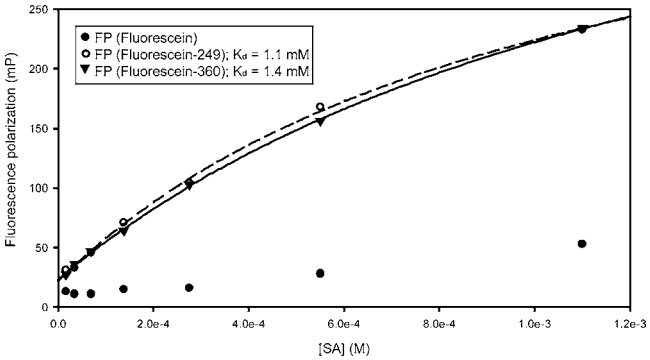

Figure 6. Fluorescence polarization of fluorescein and of fluorescein conjugated to either compound **249** or **360** titrated with increasing amounts of streptavidin. The fitting for the fluorescein−compound **249** conjugate (dashed line) and the fluorescein−compound **360** conjugate (solid line) is indicated.

Isothermal titration calorimetry measurements were performed using a VP-ITC instrument (Microcal). Streptavidin (1 μM) in PBS was titrated with a 10 μM solution of compound **337** in PBS at 30 °C (after an initial dummy injection of 1 μL, 29 injections of 10 μL each were performed). The resulting titration curves were then processed and fitted with the Origin 7 software (Microcal).

Quantitative Model Selection Experiments. A 24mer oligonucleotide with a complementary sequence to the hybridization domain of the library oligonucleotides was radioactively labeled at the 5′ terminus using γ^{33}P-ATP (GE Healthcare) and T4 polynucleotide kinase (USB). In three separate tubes the radiolabeled oligonucleotide was hybridized either with the oligonucleotide−compound conjugate **337**, the oligonucleotide-compound conjugate **360**, or an unconjugated oligonucleotide as negative control at an oligonucleotide concentration of 100 nM each. Aliquots of these oligonucleotide duplex pairs were incubated with streptavidin-sepharose slurry (with different coating densities of streptavidin) or with unconjugated sepharose in PBS. After 2 h of incubation, repeated rounds of washing were performed with PBS, and the remaining beads as well as aliquots of the input, flow-through, and all washing fractions were subjected to ^{33}P radioactivity counting with a Beckman LS 6500 scintillation counter. Streptavidin was conjugated to sepharose beads as follows: Different concentrations of strepta-

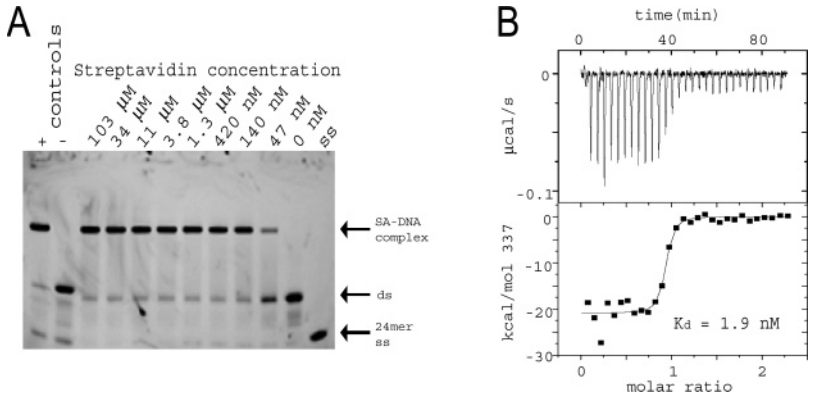

Figure 7. (A) Affinity of the oligonucleotide−compound conjugate **337** paired with a 24mer carrying no modification measured in an electromobility shift assay. (B) Isothermal titration calorimetry profile of compound **337**.

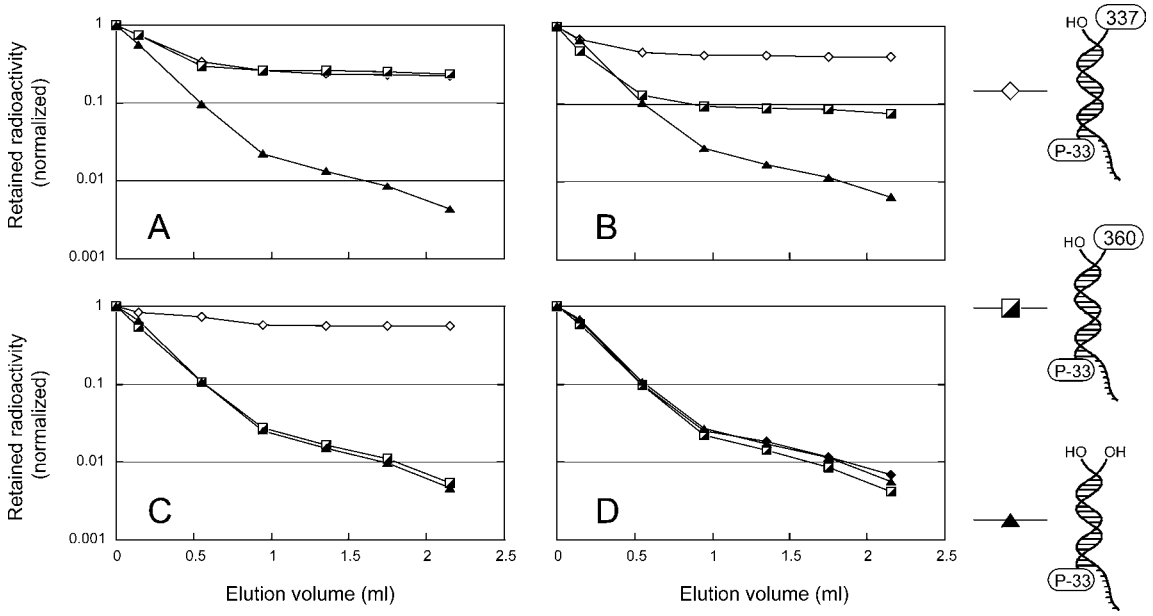

Figure 8. Recovery profiles of the oligonucleotide−compound conjugates **337** and **360** and an unconjugated control oligonucleotide hybridized with ^{33}P-labeled oligonucleotide in selection experiments to streptavidin. Experiments were performed with sepharose beads conjugated to streptavidin at 1 mg/mL (A), 0.2 mg/mL (B), and 8 μg/mL (C) and with unconjugated sepharose (D). The remaining radioactivity was normalized to the input value and plotted as function of the elution volume by adding up the fractions of radioactivity measured in the different washing steps in the selection procedure.

vidin (end concentration 1 mg/mL, 0.2 mg/mL, 8 μg/mL) (Biospa) were incubated overnight at 4 °C with 150 mg of CNBr-sepharose beads (GE Healthcare) in a total volume of 900 μL in coupling buffer (0.1 mM $NaCO_3$, 0.5 mM NaCl, pH 9). Excess reactive groups on the beads were quenched using 100 mM Tris/HCl, pH 8.9, and the beads were washed repeatedly with alternating buffers (0.1 M sodium acetate, 0.5 M NaCl, pH 4, and 0.1 M Tris/HCl, 0.5 M NaCl, pH 8) using SpinX columns (Corning Incorporated).

RESULTS

To test the functionality of the library and the reliability of the selection and read-out procedure, we hybridized an equimolar mixture of the 477 oligonucleotide derivatives with a single 24-mer oligonucleotide, complementary to the conserved DNA sequence at the 5′ extremity of the library members. The resulting library of compounds was biopanned onto streptavidin-sepharose in three independent selection procedures. The library was PCR-amplified before and after selection with a fluorescently labeled oligonucleotide primer, thus allowing a microarray read-out of the codes of those compounds which had been preferentially enriched during the selections (*4*). Figure 3 shows a fluorescence imaging of the microarray decoding of the 477 member library before and after the three independent streptavidin selections. Each library compound was represented by one oligonucleotide, spotted in triplicate onto the microarray. Some compounds (see insets) appear to be preferentially enriched as a result of the biopanning. Figure 4 shows a plot of the ratios of the fluorescence intensities before and after selection. In all three panning procedures, compound **337** among others appears to be preferentially enriched compared to the background of nonbinding compounds. Interestingly, compound **337** turned out to be D-desthiobiotin, a known binder to streptavidin (*5*, *6*).

The binding of **337** to streptavidin could be confirmed by real-time interaction analysis on a BIAcore instrument, following conjugation of **337** to bovine serum albumin (BSA). The binding of compounds **249** (adipic acid monoethyl ester) and **360** (6-acetylthiohexanoic acid) could also be verified by BIAcore analysis using multivalent conjugates to BSA (Figure 5).

For the precise determination of the binding affinities of compounds **249** and **360** in solution, these molecules were conjugated to fluorescein. Fitting of the increase in fluorescence polarization of the fluorescein−compound conjugates when titrating with streptavidin gave rise to binding constants of K_d = 1.1 mM for the **249** conjugate and K_d = 1.4 mM for the **360**

conjugate (Figure 6). Adding biotin as competitor diminished the fluorescence polarization induced by the streptavidin binding indicating that both compounds bind to the same pocket (data not shown).

A band-shift analysis of the **337**−oligonucleotide conjugate exhibited an apparent dissociation constant for streptavidin of $K_d = 47$ nM (Figure 7A). Isothermal titration of streptavidin with the carboxylic acid of **337** gave rise to a $K_d = 1.9$ nM (Figure 7B).

To determine whether the selection procedure allowed for distinction of high- and low affinity binding molecules the recovery of ^{33}P-labeled oligonucleotide−compound conjugates of **337** and **360** throughout a panning experiment under different conditions was monitored. This revealed that the recovery of **360** rapidly decreased when reducing the amount of streptavidin present on the beads whereas the recovery of **337** was not affected (Figure 8).

DISCUSSION

The results presented in this study show that binders with dissociation constants ranging from nanomolar to millimolar for a target antigen can rapidly be identified out of a large DNA-encoded library, containing 477 compounds. Varying the surface density of target protein in the panning experiment enables the discrimination between high- and low-affinity binding molecules. The decoding procedure, featuring an asymmetric PCR amplification and microarray hybridization, appears to be a convenient methodology for identifying compounds which are preferentially enriched. Furthermore, the oligonucleotide derivatives (corresponding to the individual library members) are immediately available for the confirmation of binding specificity and for the determination of the affinity constant of the compounds to the respective target protein.

The availability of the large DNA-encoded chemical library promises to be particularly useful for the rapid affinity maturation of low affinity binders (mM to μM) to a number of different proteins, by the formation of suitable bidentate derivatives (*4*), or for the de novo identification of synergistic binding pairs from two ESAC sublibraries. ESAC libraries can be synthesized with a stringent quality control of each individual library member and can be used at subnanomolar concentrations in selection experiments, thus allowing thousands of selections using different antigens and/or different experimental conditions.

ACKNOWLEDGMENT

The authors acknowledge a financial contribution from the ETH Zürich (CLE' INIT), the Bundesamt für Bildung und Wissenschaft (BBW) for the EU Project STROMA, and from Philogen. C.E.D. is the recipient of a bursary from the Roche Research Foundation. The experimental support of Dr. Jens Sobek and Dr. Ralph Schlapbach (Functional Genomics Center Zurich) for microarray decoding and of Ms. Madalina Jaggi for the quality controls of the library is gratefully acknowledged.

A structured chemical platform based on chitosan, an amine-rich polysaccharide, is presented as an alternative chemistry to functionalize solid support (in this case, glass slides) for grafting biomolecules. This approach has been adopted for generating arrays using amino-modified oligonucleotides with two different lengths (25-mer and 70-mer) for different purposes. Results using these chitosan-activated surfaces indicate high oligonucleotide loading capacity, good availability to hybridization against targets, and effectiveness in enzyme-mediated single nucleotide polymorphism (SNP) detection procedures by DNA polymerase and DNA ligase enzymes with low background. Universal arrays have been prepared and extensively used with excellent results in different applications. The chitosan-treated surfaces were also evaluated for their performance in a gene expression experiment.

INTRODUCTION

Chemical binding of biomolecules to solid surfaces is a key step in a very large set of applications. Among many others, the generation of arrays of biomolecules is a relevant field where proper chemical platforms are needed. Microarrays consisting of oligonucleotides, polynucleotides, peptide nucleic acids, peptides, proteins, and other molecules are becoming a valuable tool in modern molecular biology (*1*), opening a way for large-scale screening of mutations and studies of gene polymorphisms, gene expression analysis, and functional biology. The most relevant example of the application of arrays is their use for massive DNA analyses in parallel using oligonucleotides or polynucleotides as molecular probes. Oligonucleotide microarrays can be mass produced by photolithographic techniques in situ (*2*), but many users prefer homemade microarrays prepared by the spotting of modified oligonucleotides (*3*). This widely adopted option requires direct attachment of presynthesized oligonucleotides to an activated surface. This approach permits a very quick set up of new microarrays and their upgrading, incorporating new genetic information.

A key step in this approach is the preparation of surfaces modified with appropriate functional groups allowing for the attachment of oligonucleotides to the solid support. Many different approaches have been proposed including those compatible with 5′-thiolated oligonucleotides (*4*), although in general amino-modified oligonucleotides are preferred. Gel pads have been proposed (*5*) as well as the use of branched linkers (*6*). Similarly, chemically preactivated microscope slides have been commercially proposed offering 3D reactive structures (*7*).

We started exploring the potentials and pitfalls of a structured approach to the preparation of coated surfaces aimed especially at the microarray preparation. This approach requires proper functionalization of the glass surface with silanes chosen according to the functional moiety to be reacted, the scaffold creation using a polymer (either natural or synthetic), and finally the activation of the resulting surface using proper moieties. We presented our results using poly-L-lysine and acrylamide/acrylic acid copolymer as scaffolds for oligonucleotide microarray preparation (*8*). These two polymers are well-known in the field and have been already used. Here we present our results using chitosan, an amine-rich polysaccharide derived by partial deacetylation of chitin (*9*). Its deprotonated amino groups can react with a variety of electrophiles. As a result, various chemistries can be exploited to cross-link chitosan and to graft substituents onto this polymer (*10*−*14*).

We prepared three chemical supports using chitosan with three different molecular weights (120 kDa, 400 kDa, 650 kDa), each of these with or without KCl. In all these cases, the polymer is covalently bound to glass slides activated with 3-glycidoxypropyltrimethoxysilane (GOPS) as a scaffold for generating arrays. Polymer-coated slides have been activated with 1,4-phenylene diisothiocyanate (PDITC) for generating arrays with presynthesized oligonucleotides bearing amino groups.

Results obtained using this coupling platform show simple preparation of the surface, high oligonucleotide loading capacity, good binding efficiency, remarkably uniform performance over the entire surface, and no particular care required for their storage. We also demonstrate that the attachment of amino-modified oligonucleotides consistently yields arrays of readily accessible probes with different lengths (25-mer and 70-mer) to hybridization. Mutation detection by enzyme (ligase or polymerase)-mediated approaches has been successfully performed with low background. In combination with a universal array prepared using this platform, a PCR-ligation detection reaction approach was used for the single nucleotide polymorphism (SNP) detection in different fields with excellent specific-

ity and high sensitivity. Finally, a large microarray for the detection of RNA expression levels has been prepared.

EXPERIMENTAL PROCEDURES

All chemicals and solvents were purchased from Sigma-Aldrich (Milan, Italy) and, unless otherwise stated, used without further purification. Precleaned nonderivatized microscope slides (25 × 75 × 1 mm) were used (Sigma-Aldrich). Oligonucleotides were purchased from Thermo Hybaid (Ulm, Germany). They were HPLC purified and checked by MALDI-MS.

Cleaning and Silanization of Microscope Slides. Glass slides were cleaned by soaking in 1 M NaOH for 2 h on a shaker followed by rinsing with distilled water, immersed in 1 N HCl solution overnight on a shaker, and then rinsed again in distilled water. Slides were immersed in 96% ethanol for 10 min and then washed three times with distilled water. Slides were immersed in acetone for 10 min, removed, and dried. Then they were treated with 1% (v/v) GOPS (3-glycidoxypropylsilane) in 95% ethanol for 1 h. Excess silane was removed by dipping the slides in 95% ethanol for 1 min. Finally they were dried at 150 °C for 20 min.

Polymeric Coating Synthesis and Surface Activation. The polymer solution was prepared by dissolving 10 g of chitosan (120, 400, or 650 kDa) in a liter of HCl 50 mM. Each different polymer solution was prepared with or without KCl (0.5 M) in order to have six different coatings. The solutions were heated at 70 °C, stirred for 1 h, and then filtered. Treated slides were left in a water solution containing 10% PBS and 10% polymer (0.1% w/v) for 1 h on a shaker. The slides were washed five times with distilled water, centrifuged at 800 rpm for 3 min. and dried for 10 min at 45 °C.

The slides were then activated by immersion into a 0.2% solution of 1,4-phenylene diisothiocyanate in 90% *N*,*N*-dimethylformamide and 10% pyridine. The activation reaction was carried out at room temperature for 2 h. After being washed with methanol and acetone (2 min each), the activated slides were dried and stored, until used, in a dark closed box under vacuum.

Oligonucleotide Immobilization. Amino-modified oligonucleotides were diluted in printing buffer (150 mM sodium phosphate, pH 8.5) and spotted onto the treated slides. The spotting was performed using a contact system (MicroGrid II Compact, Biorobotics, UK).

The covalent attachment to activated supports and the deactivation process were performed according to the following protocol: (a) The printed slides were placed in a saturated NaCl humidification chamber. (b) After overnight incubation at RT, the deactivation step was carried out by treatment with a solution consisting of 50 mM ethanolamine, 0.1 M Tris (pH 9), and 0.1% SDS at 50 °C for 15 min. (c) After being rinsed twice with distilled water, the modified surfaces were immersed into a 4X SSC/0.1% SDS solution (prewarmed to 50 °C) for 15 min on a shaker. (d) Finally, printed surfaces were washed twice with distilled water and spun at 800 rpm for 3 min.

We chose to use two different deposition schemes to test the loading and the binding capacity of our surfaces.

(a) Coupling Efficiency (loading capacity). The loading capacity of the six chemically modified surfaces was tested by spotting at 10 different final concentrations (0.1−50 μM) of two oligonucleotides with two different lengths (25-mer and 70-mer) (Table 1a) bearing a 5′-amino modification and a 3′-Cy3 fluorescent label. Each slide contains eight identical subarrays in a 2 × 4 conformation: the spots are arranged in a 16 × 13 matrix. Each concentration was replicated four times (*15*).

(b) Binding Capacity. The activated surfaces were tested in hybridization experiments. These were performed using two 5′-Cy5-labeled oligonucleotides with a sequence complementary to the 25-mer and 70-mer covalently attached amino-modified oligonucleotides (Table 1a), respectively.

The two different oligonucleotides were spotted at a final concentration of 50 μM in a 150 mM sodium phosphate buffer (ph 8.5) onto the six different surfaces, using the attachment protocol described above. The deposition scheme has the usual structure of eight identical subarrays in a 2 × 4 conformation. Each oligonucleotide was replicated 64 times in each subarray.

An amount of 65 μL of hybridization solution consisting of the Cy5-labeled oligonucleotides (0.1−1 μM), 5X SSC, 0.1% SDS, and 0.1 mg/mL denatured salmon sperm DNA was used to perform hybridization in a homemade multiple sample chamber (eight-well chamber), using Press-To-Seal silicone isolators (Schleicher & Schuell, Germany). The hybridization solution was heated in a boiling water bath for 2 min and then cooled in ice before the application onto the array. Hybridization experiments were carried out at 65 °C for 1.5 h. After incubation, slides underwent four washing steps at 65 °C by using 1X SSC/0.1% SDS for 15 min in a oven. Finally, hybridized oligo-arrays were spun at 800 rpm for 3 min.

Ligation Detection Reaction and a Universal Array Format. We chose to use chitosan with medium molecular weight to prepare universal arrays. Solutions of 5′-amino-modified oligonucleotides with a 5′-polyA tail, called zip-codes, were transferred into a 384-well microtiter plate in a volume of 30 μL and spotted at a final concentration of 50 μM in 150 mM sodium phosphate buffer (pH 8.5) onto the surface using the attachment protocol described above.

The oligonucleotides were applied onto the slides by contact printing using the MicroGrid II Compact arrayer. Each microscope slide contains eight identical subarrays, represented as a universal array whose layout (*15*) consisted of zip-codes

printed in quadruplicate distributed within the printing area; two zip-codes, namely 63 and 66, were associated to a ligation control and a hybridization control, respectively (*15*); as a negative control (blank), printing buffer was used. Each universal array was a subarray consisting of 208 spots of 13 rows × 16 columns.

As described in detail in Consolandi et al. (*15*), two discriminating probes (allele-specific probes designed to have their 3′-position placed just over the polymorphic site) labeled with two distinct fluorocromes (cyanine 3 and cyanine 5) and a common probe were selected for each SNP. Common probes were designed with a complementary zip-code sequence affixed to their 3′-end to unify the kinetics of the hybridization. Each zip-code sequence has a unique specific array location. The LDR mixture contained 81 oligonucleotides (27 common probes and 54 discriminating oligos), designed to identify 27 polymorphic sites in the HLA-A gene. As target, we used a heterozygous sample (A*0201/030101). The LDR mixture was cycled for 30 rounds of 94 °C for 30 s and 65 °C for 4 min in a thermal cycler (GeneAmp, PCR System 9700, Applied Biosystem, Foster City, CA) and then diluted to prepare the hybridization mixture. The mixture, after heating to 94 °C for 2 min and chilling on ice, was applied onto the subarray under a homemade multiple sample chamber (eight-well chamber), using Press-To-Seal silicone isolators (Schleicher & Schuell, Germany). Hybridization was carried out in the dark at 65 °C for 1.5 h, in a temperature-controlled system (Shack′n′Stack, Hybaid, England). After removal of the chamber, the slide was washed for 15 min in a prewarmed (65 °C) solution of 1X SSC/0.1% SDS with gentle shaking (Shack'n'Stack, Hybaid, England). Finally, the slide was spun at 800 rpm for 3 min.

Solid-Phase Minisequencing Reaction Using a Synthetic Template. In the minisequencing technique (*16*), a primer extension reaction is performed, starting from a specifc primer that is designed to anneal directly adjacent to the mutation site, by the incorporation of a single fluorescent dideoxynucleotide (ddNTP) which is complementary to the variant base in the template. Each ddNTP is labeled with a different fluorophore with distinct spectral emission, thus allowing the identification of the incorporated base.

The minisequencing reaction was performed onto an oligo-array, prepared by spotting of four oligonucleotides designed on the *Actinomyces* 16S ribosomal RNA sequence, according to Busti et al. (*17*). Three oligonucleotides (1450-1 ATTINO1, 1450-1 ATTINO2, 1450-1 ATTINO3) were designed in order to anneal directly adjacent to three consecutive bases while another oligonucleotide represents the negative control (1336 PSEUDO) (Table 1b). Each oligonucleotide was spotted 10 times in a row. We used a synthetic template as a sample at 1 μM final concentration and a labeled-ddNTPs mix (Tamra-ddCTP, Cy5-ddUTP, R110-ddGTP, TexasRed-ddATP) at 0.1 μM final concentration. The reaction buffer consisted of 26 mM Tris-HCl pH 9.5, 6.5 mM $MgCl_2$, and 0.2% Triton X-100 buffer with 0.25 U/μL Dynazime DNA polymerase (Finnzymes OY, Helsinki, Finland). The mixture, after heating to 94 °C for 2 min and chilling on ice, was applied onto the array under the homemade multiple sample chamber described above. The reaction was carried out in the dark at 55 °C for 1 h, in a temperature-controlled system (Shack'n'Stack, Hybaid, UK). After removal of the chamber, the slide was washed for 5 min in MilliQ-filtered water with gentle shaking (Shack'n'Stack, Hybaid, England). Finally, the slide was spun at 800 rpm for 3 min.

Detection of RNA Expression Levels. Finally, the performance of the chitosan treated surface was evaluated in a gene expression experiment. A set of 5376 probes, comprising 4998 peach genes (Operon Technologies, Alameda, CA), 188 randomly generated controls, 30 human spike-in controls, 15 hybridization controls, and 145 Blanks negative controls, were deposited by a MicroGrid II Compact arrayer, equipped with 4 Apogent Discoveries Microspot 10K pins. Oligonucleotides were resuspended in 384-well plates in a sodium phosphate buffer, to reach a final concentration of 15 pmol/μL oligonucleotide in each well. All probes were 5′-amino-modified 70-mers. Each probe was spotted in duplicate.

Slides were processed according to the protocol described in the Oligonucleotide Immobilization section. We evaluated the quality of the slides by using both a 9-mer complementary oligonucleotide and two aliquots of peach RNA, labeled with two different fluorochromes in a self-to-self-experiment.

The 9-mer hybridization solution was prepared as follows: 7.5 pmol/mL 5′-Cy3-labeled 9-mer, 5X SSC, 0.1% SDS, and 0.1 mg/mL salmon sperm DNA. The hybridization was performed at 16 °C for 8 h in a GenTac HybStation (Genomic Solutions, Perkin-Elmer Life Sciences, Boston, MA); then the slides were washed with a 2X SSC, 0.1% SDS solution for 5 min at 16 °C.

Target cDNAs, labeled with Cy3 and Cy5, were independently generated according to the SuperScript Indirect cDNA Labeling System (Invitrogen, Life Technologies, Paislay, UK). A 20 μg amount of RNA was used in each reaction. The resultant cDNA targets labeled with Cy3 and Cy5 were then purified using a PCR purification kit (Invitrogen, Life Technologies, Paislay, UK), as described by the manufacturer, and mixed together just before hybridization.

The hybridization solution for the self-to self-experiment was the same as that used in the experiment with the 9-mer oligonucleotide. Hybridization was performed in the hybridization station for 8 h at 42 °C. The slides were washed with a preheated solution that contained 2X SSC, 0.1% SDS for 5 min at 42 °C and then with SSC 0.2% for 5 min.

Signal Detection. Fluorescent signals were acquired at 5 μm resolution using a ScanArray 4000 laser scanning system (Perkin-Elmer Life Sciences, Boston, MA). The Green laser was used for CY3 dye (λ_{ex} 543 nm/λ_{em} 570 nm), Tamra dye (λ_{ex} 552 nm/λ_{em} 575 nm), the Red laser for CY5 dye (λ_{ex} 633 nm/λ_{em} 670 nm), the Yellow laser for Texas Red (λ_{ex} 593 nm/λ_{em} 612 nm), and finally the Blue laser for Rhodamine 110 (R110) (λ_{ex} 505 nm/λ_{em} 530 nm). Both the laser and photomultiplier tube (PMT) power were set in order to have no saturated signals in any case.

Data Analysis. To quantitate the fluorescent intensity of spots, we used the QuantArray Quantitative Microarray Analysis software (Perkin-Elmer Life Sciences, Boston, MA). The quantitation method we chose was the "fixed circle" method. Spot intensities were calculated using the mean intensity option. Data analysis of each experiment was performed by the following calculations: local background was subtracted from the intensity of each spot; fluorescent intensities (IF) of the replicates spots were averaged and the coefficient of variation was calculated.

RESULTS AND DISCUSSION

Since the advent of microarray technology, several chemistries have been proposed for oligonucleotide attachment to glass surfaces (*16*, *18*). We have tested many of the simplest strategies to attach amino-modified oligonucleotides. Our experience indicates that such chemistries are not suited for oligonucleotide microarray preparation aimed at polymorphism or mutation detection. More complex strategies have been proposed, including those that incorporate polyfunctional linkers such as polyacrylamide gel pads (*5*), branched chains (*3*), and poly(acrylic acid-*co*-acrylamide) copolymers generated in situ (*18*). Such approaches overcome some difficulties arising from poor

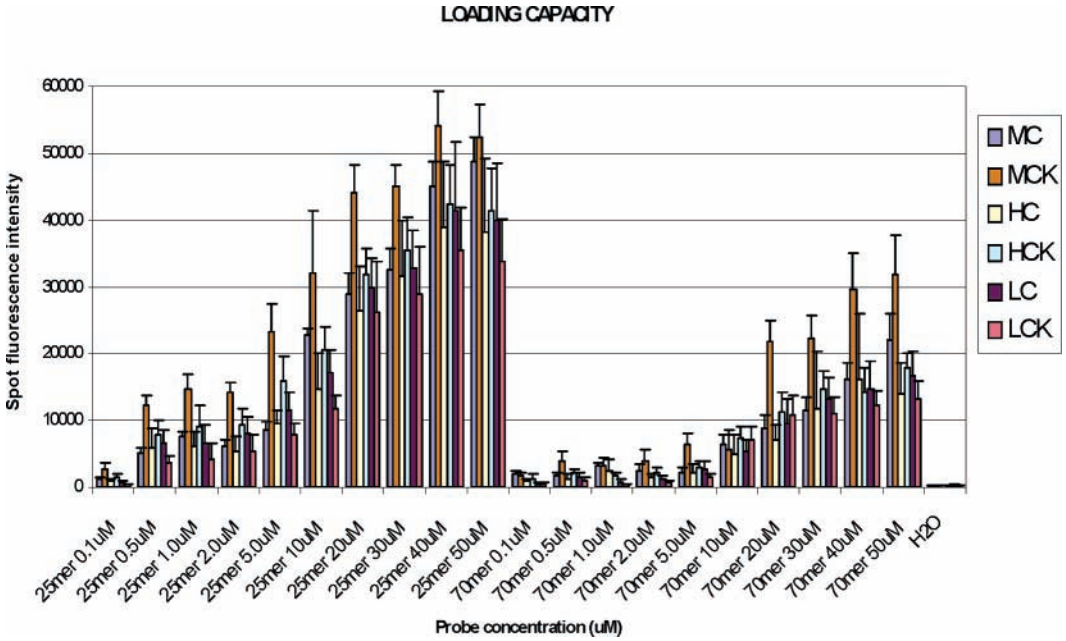

Figure 1. Array loading capacity. GOPS-chitosan-modified surfaces were spotted by using increasing concentrations from 0.1 to 50 μM of two oligonucleotides with two different lengths (25-mer and 70-mer) bearing a 5′-amino modification and a 3′-Cy3 fluorescent label. The graph shows the relationship between the oligonucleotide concentration and the surface-loading capacity measured as spot fluorescence intensity for the six modified surfaces (MC = medium chitosan, MCK = medium chitosan plus KCl, HC = high chitosan, HCK = high chitosan plus KCl, LC = low chitosan, LCK = Low chitosan plus KCl. Low corresponds to 120 kDa as molecular weight, medium corresponds to 400 kDa, and high corresponds to 650 kDa).

loading capacity of the (two-dimensional) glass surface, thanks to the three-dimensional structure of the swollen polymers. Following such an approach, we recently started experimenting with a three stage-process for preparing such surfaces involving (a) the functionalization of the glass surface, (b) attachment of a natural or synthetic polymer creating the scaffold, and (c) proper polymer scaffold activation against moieties to be targeted on the probes. Following our preliminary studies (*8*) using poly-L-lysine and acrylamide/acrylic acid copolymer, we selected chitosan, a polycation, to create a chemical platform suitable for biomolecules attachment to solid surfaces.

Our approach involves the creation of a polymeric layer covalently bound to the surface and activated with phenyldiisothiocyanate (PDITC). This allows the attachment of amine-bearing molecules. We analyzed the performance of these chemical platforms in order to characterize their behavior and ascertain their potential in oligonucleotide microarray preparation. All the sequences of the oligonucleotides used in the applications are reported in Table 1 (parts a and b).

Efficiency and Specificity of Oligonucleotide Covalent Attachment: Array-Loading Capacity. The chitosan-modified surfaces were analyzed before oligonucleotide spotting by laser scanning at 543 nm (suitable for cyanine 3 dye excitation) and at 633 nm (suitable for cyanine dye excitation) to determine their overall fluorescent background, which was found in all cases to be very low at both wavelengths (data not shown).

For DNA microarray fabrication, a pin contact arrayer was used. We tested a contact pin spotter (MicroGrid II Compact, Biorobotics, UK), demonstrating the mechanical stability of the polymeric coatings we propose (data not shown).

We employed 5′-amino, 3′-Cy3-modified 25-mer and 70-mer oligonucleotides to investigate the influence of the six different coating solutions on the surface-loading capacity. To explore this issue, we analyzed our six derivatized surfaces by spotting the doubly modified oligonucleotides at different concentrations (ranging from 0.1 μM to 50 μM in 10 different concentrations) arranged in a 16 $\times$ 13 matrix. The corresponding signals were quantitated using QuantArray Quantitative Microarray Analysis software. Sixty-four spots (two slides, eight subarray, four replicates) for each concentration were used to calculate mean and standard deviation.

The results, shown in Figure 1, illustrate the relationship between the oligonucleotide concentration and the surface-loading capacity measured as spot fluorescence intensity collected at 543 nm for the six modified surfaces. The loading capacity increases with increasing of the concentration of the spotted oligonucleotides in the both cases (25−70-mer). The 25-mer oligonucleotide shows a loading capacity higher than that of the 70-mer one. The surface prepared using the medium molecular weight chitosan with KCl shows the best spot fluorescence intensity (Figure 1), but the use of the same polymer without KCl gives a support with the best CV range (5% < CV < 17%), thus becoming the most reliable surface. The worst spot fluorescence intensity and the worst CV range are found for the surface prepared using the low molecular weight chitosan with KCl.

Efficiency of Hybridization to Immobilized Oligonucleotides. A set of experiments was performed to evaluate the fluorescence signal produced in an oligo-oligo hybridization model experiment by determining the relationship between the loaded oligonucleotide concentration and the hybridization efficiency. This test is of great importance, as the major concern in oligonucleotide arrays preparation is the accessibility of the probe for hybridization, as well as the specificity obtained in the interaction. DNA microarrays described above were hybridized with two Cy5-labeled oligonucleotides complementary to the 25-mer and 70-mer spotted sequences using a range of oligonucleotide concentration from 0.1 to 1 μM. Figure 2a,b depicts the relationship between the loaded oligonucleotide concentration and the hybridization signal intensity for the both oligonucleotides.

As shown in Figure 1, the loading capacity and availability to hybridization are good (Figure 2a,b). Above a probe concentration threshold, loading and availability remain nearly constant (tested at either 1 or 10 μM template concentration). This can be explained assuming that these chemistries yield

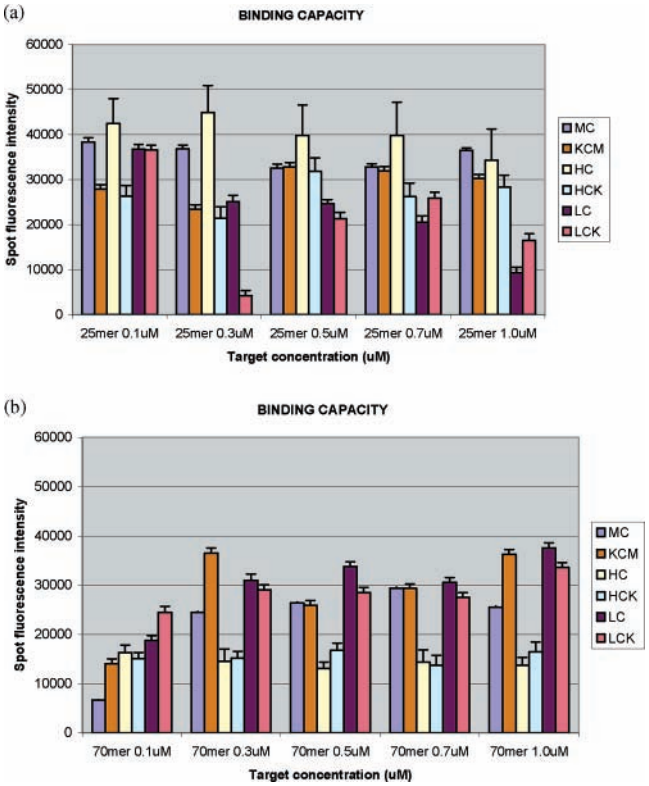

Figure 2. Binding capacity. Printed slides with 10 different concentrations of covalently attached oligonucleotides were hybridized with five different concentrations (0.1−1 μM) of Cy5-labeled oligonucleotide complementary to the spotted ones. The graph depicts the relationship between the loaded oligonucleotide concentration and the hybridization signal intensity for the both oligonucleotides (a, b). (MC = medium chitosan, MCK = medium chitosan plus KCl, HC = high chitosan, HCK = high chitosan plus KCl, LC = low chitosan, LCK = low chitosan plus KCl. Low corresponds to 120 kDa as molecular weight, medium corresponds to 400 kDa, and high corresponds to 650 kDa).

surfaces with fairly well-spaced reactive groups that avoid excessive crowding of probes that could negatively affect the microarray performance.

Applications. *Efficiency of Ligation Detection Reaction Combined to a Universal Array.* To explore the potential of the new surfaces, a ligation detection reaction (LDR) combined to a Universal Array (UA) platform has been optimized to analyze single nucleotide polymorphisms distributed within exons 2 and 3 of the HLA-A gene. The assay involves the amplification by PCR of the HLA-A genomic region (1900 bp), a multiplex LDR carried out to type twenty-seven HLA polymorphic sites followed by the capture of ligated products through hybridization onto a universal array. According to Consolandi et al. (*15*), a polymorphic site is typed by using two discriminating oligonucleotides labeled at their 5′-end with two fluorophores. Figure 3 shows the scanner analysis of the ligation detection reaction/universal array experiments obtained using a heterozygous sample (A*0201/030101). HLA genotyping by PCR/LDR/UA is in perfect agreement with typing obtained by direct sequencing. Our results clearly demonstrate that our treated surfaces are suitable to support hybridization reactions of complex targets, showing good specificity and efficiency. Good spot quality facilitates the subsequent evaluation of array data and has immediate effects on the reliability of the results.

Enzymatic Reaction: Efficiency of Minisequencing Reaction onto the Surface. Our slides were also tested for their performance as supports for in-situ enzymatic reactions. In respect to the experiment described above, in which the enzymatic reaction was performed in liquid phase, we carried out the minisequencing reaction directly on the surface. The concept of the minisequencing assay is to anneal a detection primer to the nucleic acid sequence immediately 3′ of the nucleotide position to be analyzed and to extend this primer with a single labeled dideoxynucleotide using a DNA polymerase.

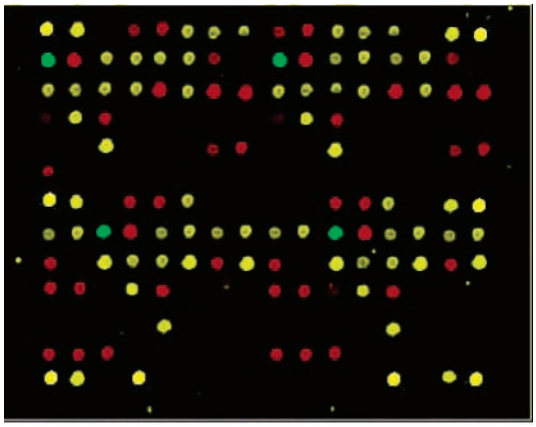

Figure 3. Scanner analysis of ligation detection reaction/universal array experiment. Fluorescent laser scanning of a heterozygous (A*0201/030101) sample analysis by using PCR/LDR/UA approach. This composite image is realized by overimposing Cy3 fluorescent signals (green palette) and Cy5 fluorescent signals (red palette). Yellow spots are the combination of Cy3 and Cy5 dyes.

To test this enzymatic procedure, we chose the *Actinomyces* 16S ribosomal RNA gene as reference sequence to design our synthetic template (see Experimental Procedures section) and probes (Table 1, part b). Three out of the four oligonucleotides (1450-1 ATTINO1, 1450-1 ATTINO2, 1450-1 ATTINO3) were designed in order to anneal directly adjacent to the targeted site. The 1336 PSEUDO oligonucleotide represent a negative control. The oligo-array contains the four oligonucleotides, acting as primers in the minisequencing reaction, each spotted 10 times in a row. During the reaction, the DNA polymerase carried out the incorporation of the fluorescent dideoxynucleotide (ddNTP), which is complementary to the targeted base in the template DNA. The extended probes, covalently bound to the solid support, can be detected thanks to the incorporation of fluorescent dyes. Figure 4 shows the fluorescent signals obtained using the four filters for the detection of the fluorescent signal due to the incorporation of the ddNTPs labeled with Tamra, Cy5, Rhodamine110, and Texas Red dyes. As expected, a fluorescent signal of the proper wavelength is detected identifying the targeted base on the template. No signal is detected from the negative control. This result suggests that our surfaces allow primer extension in-situ.

Detection of RNA Expression Levels. In the 9-mer hybridization, 99.1% of the 4998 "discovery" genes was present with at least one replicate per array. The randomly generated sequences and the spike-in controls were all present with at least one replicate per slide, whereas 98.5% of the hybridization controls performed as expected; at the same time 93.5% of the blank spots were not found by the quantitation software.

In the self-to-self-hybridization, instead, we found that 3238 "discovery" probes (65%) were found as present by the quantitation software. The background subtracted intensities for the two channels were then drawn as a scatter plot against each other, to represent levels of up or down regulation. As the samples were aliquots of the same starting RNA, we expected no change or a very little number of transcripts to be differentially expressed. Given a threshold of 2-fold change as the limit of differential expression, only 131 out of the 3238 "discovery" genes were obtained. This means that about 96% of the transcripts were not recognized as differentially expressed. Pearson's correlation coefficient between the two channels was

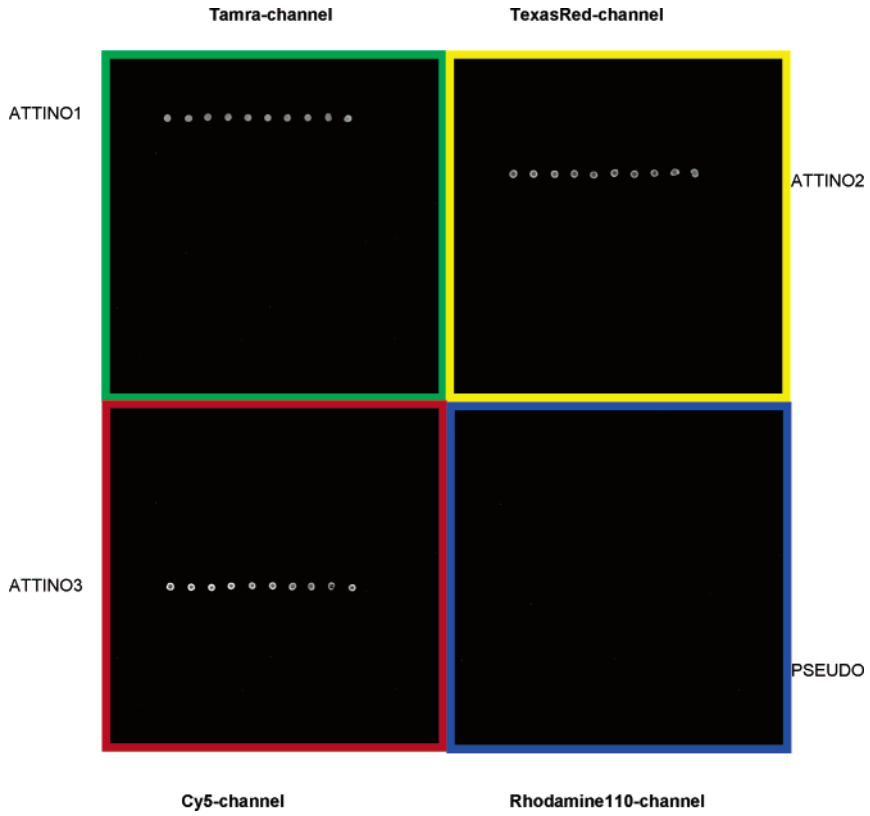

Figure 4. Scanner analysis of the minisequencing experiment. An oligo-array, prepared by spotting of four oligonucleotides (Table 1b) designed on the Actynomices 16S rRNA sequence, is scanned by using the four filters for the detection of the fluorescent signal due to the incorporation of the ddNTPs labeled with Tamra, Cy5, Rhodamine110, and Texas Red dyes. The green frame includes the fluorescent image scanned by Tamra filter, showing a C extension for 1450-1 ATTINO1 as expected. The yellow frame includes the image scanned by Texas Red filter, showing an A extension for 1450-1 ATTINO2 as expected. The red frame includes the image scanned by using Cy5 filter, showing a T extension for 1450-1 ATTINO3 as expected. No extension is detected in the blue frame (Rhodamine 110 filter). The fluorescent signals are visible only for the three oligonucleotides specific for the 16S rRNA sequence. In the fourth case (1336 PSEUDO sequence not specific for the template used), no signal is detected.

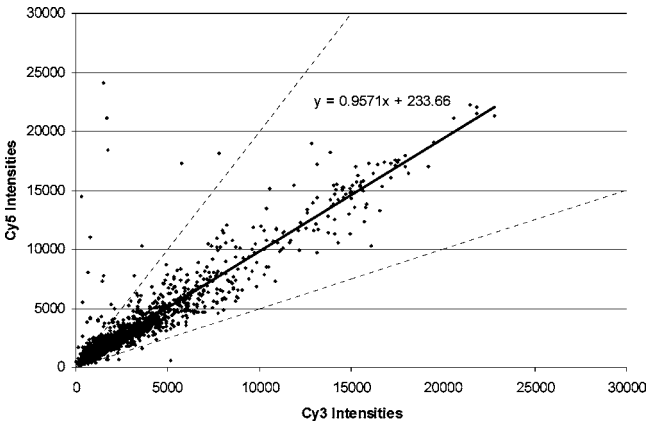

Figure 5. Scatter plot of intensities in the gene expression self-to-self-experiment. Values for each channel are plotted one against each other in black dots. The solid line is the linear regression curve, whose equation is also reported on the plot. The dotted lines represent the 2-fold change thresholds for differential expression.

0.937, indicating a very high reproducibility of the sample preparation procedure, whereas the slope of the linear regression curve was found to be 0.957, indicating that the two fluorophores were well balanced and there was no need for normalization or correction of the data (Figure 5).

We have reported here a robust chemical method for covalent immobilization of amino-modified oligonucleotides with two different lengths (25-mer and 70-mer) on glass surfaces based on polymeric coating. The DNA microarrays we prepared show good performance in terms of coupling specificity, and loading and binding capacity. As demonstrated by the discrimination of SNPs, oligonucleotides attached to our surfaces reveal highly specific hybridization properties and the accessibility to polymerase for enzyme-mediated reactions. Also labeled cDNAs react with the oligonucleotide probes attached to the functionalized surfaces, indicating an excellent availability to hybridization.

Received October 10, 2005; Revised Manuscript Received January 8, 2006

The unique properties of fullerenes have raised the interest of using them for biomedical applications. Within this framework, the interactions of fullerenes with proteins have been an exciting research target, yet little is known about how native proteins can bind fullerenes, and what is the nature of these interactions. Moreover, though some proteins have been shown to interact with fullerenes, up to date, no crystal structure of such complexes was obtained. Here we report docking studies aimed at examining the interactions of fullerene in two forms (C_{60} nonsubstituted fullerene and carboxyfullerene) with four proteins that are known to bind fullerene derivatives: HIV protease, fullerene-specific antibody, human serum albumin, and bovine serum albumin. Our work provides docking models with detailed binding pockets information, which closely match available experimental data. We further compare the predicted binding sites using a novel multiple binding site alignment method. A high similarity between the physicochemical properties and surface geometry was found for fullerene's binding sites of HIV protease and the human and bovine serum albumins.

INTRODUCTION

Since the discovery of fullerenes (*1*, *2*), these molecules and their derivatives (*3*) have been extensively explored for biomedical applications. Examples of fullerene bioactivity includes antibacterial activity (*3*), neuroprotection (*4*, *5*), DNA cleavage (*6*), apoptosis (*7*), ion channel inhibition (*8*), and amyloid formation inhibition (*9*). Enzyme inhibition by fullerene-based compounds was found for nitric oxide synthases (*10*) and glutathione reductase (*11*). Antiviral activity of fullerenes was demonstrated in the inhibition of the HIV protease, initially by modeling and subsequently by in vitro studies (*12*−*15*). Namely, the prediction that fullerene derivatives can potentially fit into the catalytic cavity of HIV protease was supported by binding and inhibition experiments. Interactions of fullerenes with some other proteins were also documented, including a fullerene-specific antibody (*16*, *17*), human serum albumin (HSA), and bovine serum albumin (BSA) (*18*−*20*). However, in all cases, the reported information provides only partial data regarding structures of these fullerene−protein complexes. We have recently reported the preparation, characterization, and a docking model of a stable complex of HSA with a C3-isomer of carboxyfullerene (CF) (*18*). The agreement of the docking predictions with the experimental results has encouraged us to generate docking models of fullerenes with additional proteins. Characterizing protein binding sites of fullerenes is an important step toward better understanding of mechanisms by which various enzymes and receptors are interacting with fullerenes.

Here, using leading computational tools for protein structure analysis, we first provide docking models for the interactions of C_{60} nonsubstituted fullerene (NS-C_{60}) and CF with four selected proteins: HSA, BSA, HIV protease, and the fullerene-specific antibody. Our models, obtained using the PatchDock algorithm (*21*−*23*), are consistent with previously reported experimental results and hence are highly reliable. The predicted binding sites were further compared using a novel method for multiple binding site alignment, MultiBind (*24*, *25*), which revealed a significant similarity between fullerene's binding sites of HSA, BSA, and HIV-protease.

METHODS

Protein Structures. For docking studies we used the following structures: (i) HSA. We used the structure of free HSA (PDB: 1ao6, (*26*)). (ii) BSA. Using the Swiss-model server (*27*), the HSA structure was used as a template in order to build a structural model for the BSA protein. The pairwise sequence alignment has only one gap over all the 578 residues of the BSA sequence, with 75% identity and 87% similarity shared between the human and bovine sequences (Figure 1). Thus, our model for BSA is reliable and is likely to resemble the native three-dimensional structure. (iii) HIV-protease. We used the structure of PDB: 1aid (*28*). (iv) Fullerene specific antibody. We used the structure of PDB: 1emt (*16*).

Docking. Docking models were obtained using the PatchDock algorithm (*21*). PatchDock takes as input two molecules and computes three-dimensional transformations of one of the molecules with respect to the other with the goal of maximizing surface shape complementarity while minimizing the number of steric clashes. Complexes may be of the types: protein−protein, protein−small molecule, antibody−antigen, or protein−nucleic acid. The program was tested and shown to successfully predict protein interactions for many examples (*21*, *22*, *29*, *30*). Given two molecules, PatchDock first divides their surfaces into patches according to the surface shape (concave, convex, or flat).

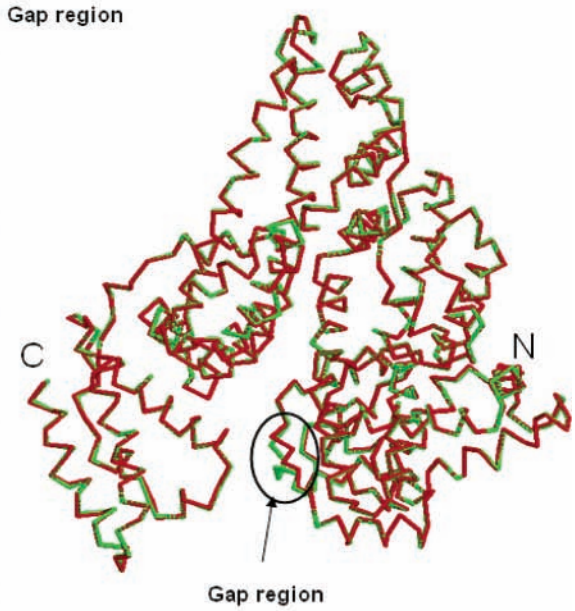

Figure 1. Sequence and structure alignment of human and bovine serum albumins. Left: sequence alignment. In the middle line of each three lines, identical residues are detailed; "+" stands for similar residues. Right: Structure alignment of HSA (PDB: 1ao6) with the model for BSA, built using the Swiss-model server (*27*). Structure alignment was performed using the C-α match program (http://bioinfo3d.cs.tau.ac.il). The gap region is marked in both alignments. Bovine serum albumin has one less amino acid residue, lacking a corresponding residue to Val112, using PDB: 1ao6 (HSA) numbering.

Then, it applies the Geometric Hashing algorithm to match concave patches with convex patches and flat patches with flat patches and generates a set of candidate transformations. Each candidate transformation is further evaluated by a set of scoring functions that estimate both the shape complementarity and the atomic desolvation energy (*31*) of the obtained complex. Finally, redundant solutions are discarded by the application of an RMSD (root-mean-square deviation) clustering. PatchDock is highly efficient, since it utilizes advanced data structures and spatial pattern detection techniques which are based on matching of local patches. The local shape information is then extended and integrated to achieve global solutions. The algorithm implicitly addresses surface flexibility by allowing minor penetrations.

Binding Sites Alignment. The alignment of the predicted binding sites of the modeled complexes was performed using the MultiBind algorithm (*24*, *25*). MultiBind considers protein binding sites represented by a set of three-dimensional points with assigned physicochemical and geometrical properties important for protein−ligand interactions. It performs multiple alignment of binding sites and allows recognition of the structurally conserved physicochemical and geometrical patterns that may be responsible for the binding and biological effect. The goal of MultiBind is to find a set of transformations that will superimpose the binding sites in a manner that will maximize the physicochemical score of the matched properties. Five physicochemical properties are considered: hydrophobic aliphatic, aromatic, hydrogen bond donors, hydrogen bond acceptors, and mixed donor/acceptors. The scoring function compares the similarity of the attributes, which are more important for the specific property. The molecules representation is based on the model of Schmitt et al. (*32*). According to this model, each amino acid is represented by a set of three-dimensional points in space, denoted as pseudocenters. Each pseudocenter represents one of the five considered properties. The pseudocenters are extracted from the side-chains, as well as from the protein backbone. For example, the side chain of arginine is represented by three donors (nitrogen atoms) and an aliphatic pseudocenter (located at the center of mass of its three carbons), while the side-chain of phenylalanine is represented by an aromatic pseudocenter, located at the center of its ring.

The MultiBind algorithm has three major computational steps. The first one is a generation of three-dimensional transformations that would align the binding sites. The second step is a search for a combination of three-dimensional transformations that would give the highest scoring common three-dimensional pattern of physicochemical properties. The final step is a computation of matching between points under multiple transformations. The MultiBind algorithm was applied to some well studied biological examples such as estradiol, ATP/ANP, and transition state analogues binding sites, providing results which agree with the available biological data (*24*, *25*).

Evaluation of Common Binding Patterns. To calculate the frequency of random occurrence of structural patterns recognized by MultiBind, we searched their occurrence on the complete surfaces of proteins in the nonredundant PDB representation by the ASTRAL dataset (*33*, *34*) (release 1.65, less than 40% sequence identity). The searched structural pattern was represented by the pseudocenters of the first molecule (in the alignment input order). Each pattern that was recognized on the surface of some protein was scored by the above-described physicochemical scoring function of MultiBind. The frequency of occurrence was calculated as the ratio between the number of times that a pattern with a score higher than a reference score was observed, relative to the total number of searched proteins.

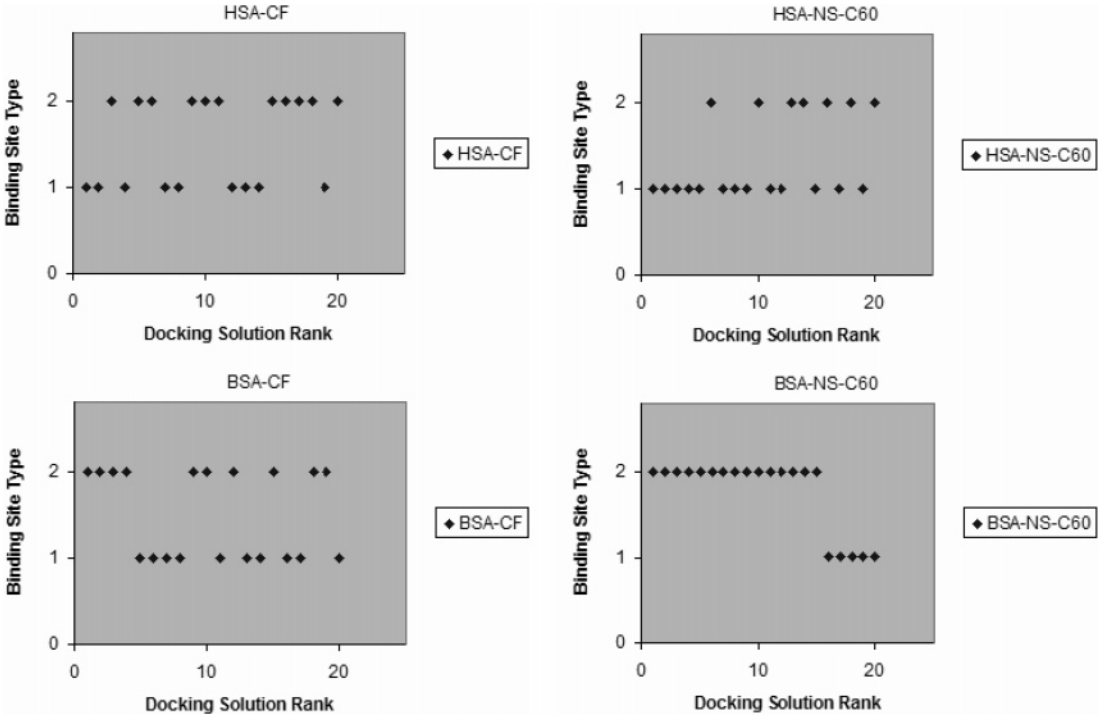

Figure 2. Distribution of the two fullerene binding sites on HSA and BSA among the top 20 ranking solutions. *X* axis: Rank of docking solution, from 0 to 20. The ranking of docking solutions is determined by their score, which optimizes geometric complementarity. *Y* axis: Type of binding site on human or bovine serum albumin. Note, that this axis has no numerical value and numbers 1 and 2 stand for the different binding sites (Figures 3 and 4 for type 1 and type 2 binding sites, respectively). The upper and lower graphs depict the distribution of HSA and BSA binding sites, respectively. The left and right graphs depict the sites distribution for carboxy- and nonsubstituted fullerene, respectively. For example, the top two ranked docking solutions for the binding of HSA to carboxyfullerene (up, left) are on the binding site type 1.

The reference score is defined to be the score of the outlier, i.e., lowest score of the most different binding site that participated in the pattern construction with MultiBind. The obtained ratio represents the estimation of the chances for a random occurrence of the recognized pattern. Using the score of the outlier as a reference score provides the highest possible ratio and the worst case estimation of the most frequent pattern.

RESULTS AND DISCUSSION

1. Docking Models of Nonsubstituted C_{60} Fullerene and Carboxyfullerene with Four Proteins. We docked nonsubstituted C_{60} fullerene (NS-C_{60}) and carboxyfullerene (CF) to four biomolecules: human serum albumin (HSA), bovine serum albumin (BSA), HIV protease (HIVP), and a fullerene-specific antibody. For three of the examined proteins, previously published data exists regarding fullerene binding sites: HIVP (*12*, *15*, *35*), fullerene-specific antibody (*16*, *17*), and HSA (*18*). PatchDock successfully detected surface pockets that are in agreement with previously suggested binding sites. In all the reported docking models, no a priori information was used as an input for the PatchDock algorithm, i.e., the surface pockets on the receptor molecules were detected fully automatically. Being able to reconstruct known fullerene binding sites makes PatchDock a reliable tool for prediction of fullerene binding sites in other proteins.

Docking of Fullerenes to HSA and BSA. The binding of HSA and BSA to fullerenes was observed experimentally (*18*−*20*). The location of CF binding site in HSA was suggested to be adjacent to the Trp214 residue, based on time-resolved FRET measurements (*18*). The results of our docking studies suggest that both proteins are capable of fullerene binding by two distinctive binding sites, located on the opposite faces of the albumin molecules and for clarity termed binding sites "type 1" and "type 2". For each of these proteins and for both ligands (NS-C_{60} and CF), the 20 top scored docking solutions were found to be distributed over these two sites (Figure 2). In HSA, the type 1 binding site docking solution positions the fullerene molecule in a short distance from Trp214 residue (Figure 3). In general, this binding pocket was found to be almost identical for both albumins and for HSA can be marked by Trp214, His288, and His440 residues (the complete list of residues in radius of 6 Å from the fullerene ligand is detailed in the Supporting Information). The type 2 binding site places the fullerene ligand in a pocket on the opposite face of the albumin molecules (Figure 4). In HSA, this binding pocket can be marked by residues Lys190, Glu425, and Arg428 (the complete list of residues in radius of 6 Å from the fullerene ligand is detailed in the Supporting Information). Figure 2 presents the distribution of the type 1 and type 2 binding sites among the top 20 docking solutions. As can be seen in the figure, although both type 1 and type 2 binding sites appear in the top 20 ranking docking solutions for HSA and BSA, HSA protein displayed preferential binding of fullerene toward type 1 site, while the BSA protein displayed preferential binding toward type 2 site (Figure 2). The correlation between binding preferences and clustering of docking solutions was recently discussed (*36*). We estimate that these differences can be mostly attributed to the fact that type 2 binding site of BSA lacks an amino acid corresponding to the Val112 residue, which is present in type 2 binding site of HSA. This difference appears to make the type 2 site of BSA more compatible and less sterically crowded for accommodation of fullerene, in comparison to the similar site in HSA.

Comparison between Binding of Fullerenes and Other Known HSA Ligands. The Protein Data Bank (*37*) currently holds 22 complexes of HSA with 14 different ligands, uniquely located at multiple various binding sites. Although, due to the substantial differences in ligands shapes, fullerene binding sites of types 1 and 2 are not identical to pockets of other known serum albumin ligands, these sites share many common amino

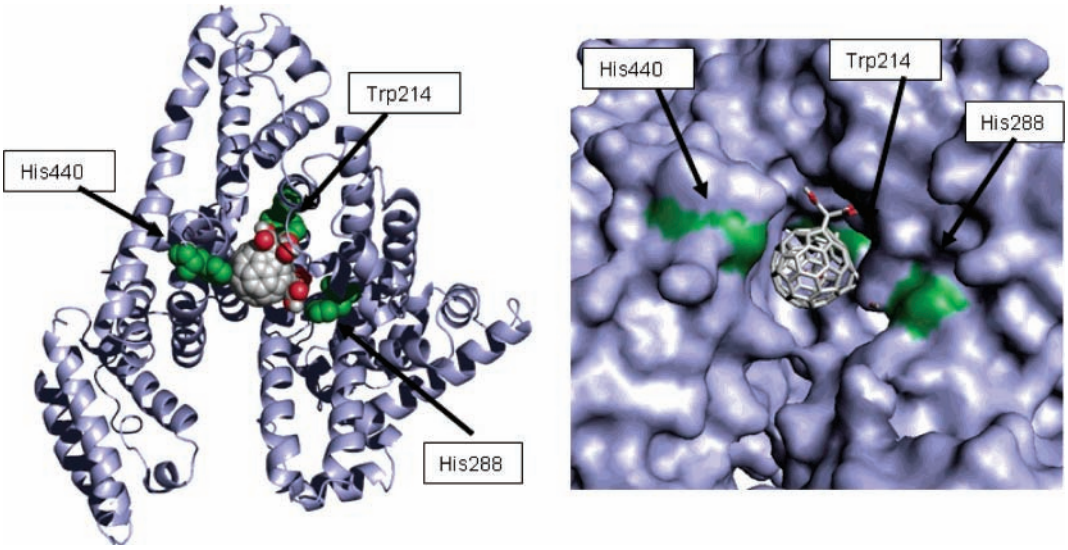

Figure 3. Predicted binding site (type 1) for carboxyfullerene on human serum albumin. Left: carboxyfullerene is represented in a spacefill model. HSA is represented in cartoon, except for His288, Trp214, and His440 which are represented in spacefill and colored green. Right: Fullerene is represented in sticks. HSA is represented by its surface and colored light blue except for His288, Trp214, and His440 which are colored green. This Figure, as well as Figures 4, 5, and 6 were prepared using PyMOL (*44*).

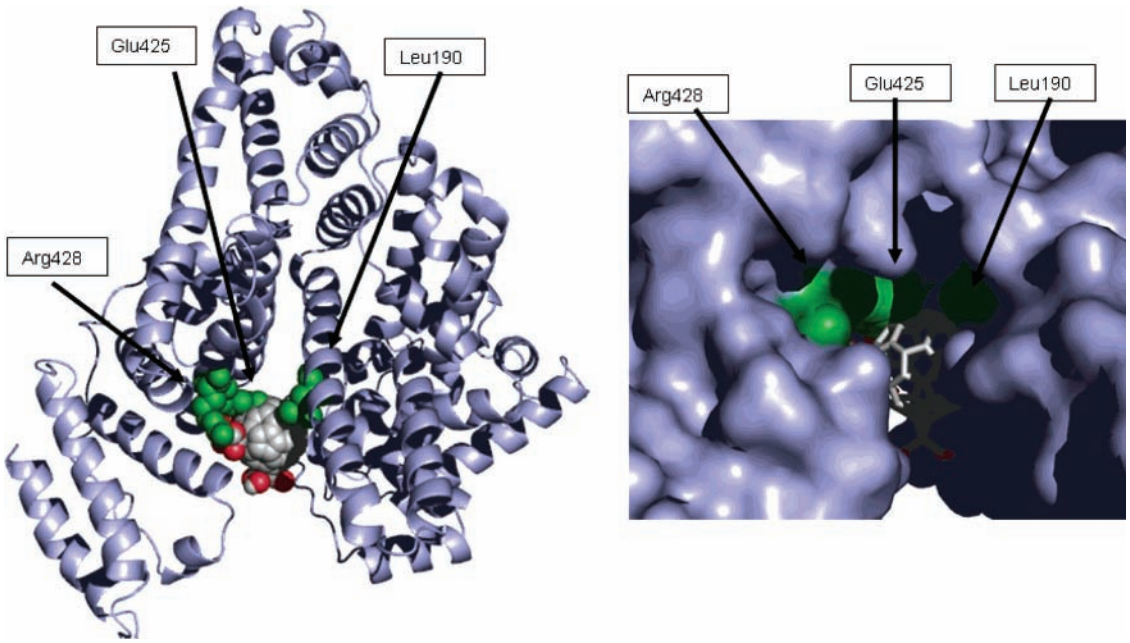

Figure 4. Predicted binding site (type 2) for carboxyfullerene on bovine serum albumin. Leu190, Glu425 and Arg428 are marked. Coloring and representation are the same as in Figure 3.

acid residues with other reported binding pockets of HSA. For example, the predicted type 1 binding site of fullerene consists of residues that participate in binding of the following ligands: tribenzoic acid (PDB: 1bke); 2-bromo-2-chloro-1,1,1-trifluoroethane (PDB: 1e7c); decanoic acid (PDB: 1e7e); lauric acid (PDB: 1e7f); myristic acid (PDB: 1e7g, 1hk4, 1hk5, 1o9x); palmitic acid (PDB: 1e7h); stearic acid (PDB: 1e7i); oleic acid (PDB: 1gni); arachidonic acid (PDB: 1gnj); *R*-wafarin (PDB: 1h9z); *S*-wafarin (PDB: 1HSA-2); 3,5,3′,5′-tetraiodo-L-thyronine (PDB: 1hk1, 1hk2, 1hk3); citric acid (PDB: 1tf0). The predicted type 2 binding site of fullerene consists of residues that participate in binding of the following ligands: tribenzoic acid (PDB: 1bke); myristic acid (PDB: 1bke, 1e7c, 1e7g, 1h9z, 1HSA-2, 1hk4,1hk5); 2-bromo-2-chloro-1,1,1-trifluoroethane (PDB: 1e7c); decanoic acid (PDB: 1e7e); lauric acid (PDB: 1e7f); palmitic acid (PDB: 1e7h); stearic acid (PDB: 1e7i); oleic acid (PDB: 1gni); arachidonic acid (PDB: 1gnj); 3,5,3′,5′-tetraiodo-L-thyronine (PDB: 1hk4, 1hk5); Fe-containing protoporphyrin IX (PDB: 1o9x, 1n5u).

Figure 1 in the Supporting Information displays side-by-side the docking model of HSA-CF complex aligned with the structure of the HSA complex with citric and decanoic acids (PDB: 1tf0, (*38*)). Coloring the fullerene's type 1 site residues on both the HSA-CF docking model and on the crystal structure of HSA complex with citric acid clearly demonstrates the similar residues that participate in the binding of both ligands.

Docking of Fullerenes to HIV Protease. The binding of fullerene to HIV protease (HIVP) was first demonstrated by Friedman and co-workers (*12*, *15*). Docking of fullerene to HIVP (PDB: 1aid, (*28*)), by using PatchDock, suggests the same binding pocket for NS-C_{60} and CF ligands (Figure 5). This cylindrically shaped, symmetric binding pocket can be marked by residues Asp25, Asp25′, Ile50, and Ile50′ (i.e. residues 25 and 50 on chains A and B; the complete list of residues is

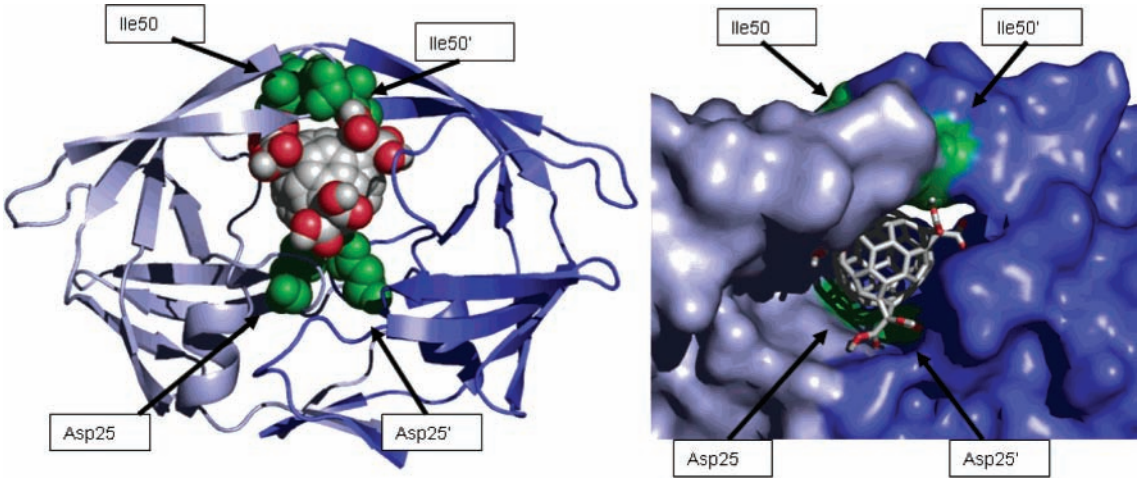

Figure 5. Predicted binding site for carboxyfullerene on HIV protease. Residues Asp25, Asp25′, Ile50, and Ile50′ are marked. Coloring and representation are the same as in Figure 3.

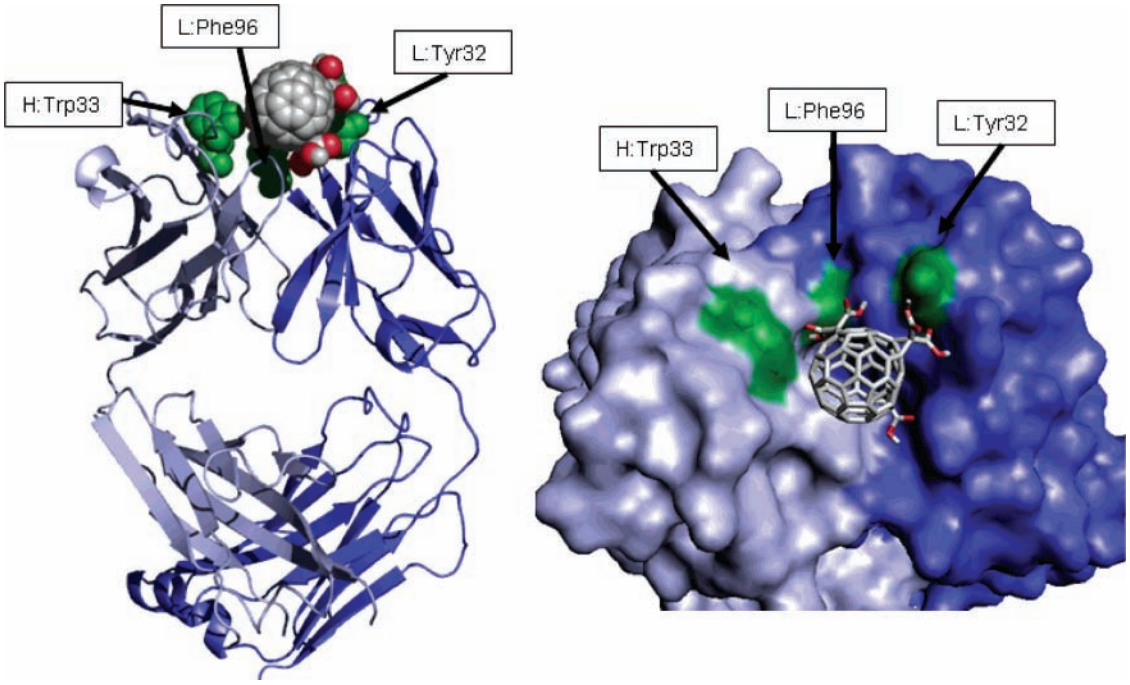

Figure 6. Predicted binding site for carboxyfullerene on a fullerene specific antibody. L chain residues Tyr32 and Phe96, as well as chain H residue Trp33 are marked. Coloring and representation are the same as in Figure 3.

detailed in the Supporting Information), which were reported to participate in various ligands binding and, in particular, in fullerene binding by HIVP (*39*).

Docking of Fullerene to a Fullerene-Specific Antibody. Erlanger and co-workers have prepared a monoclonal fullerene-specific antibody and determined its structure by X-ray crystallography (*16*, *17*). The suggested fullerene binding site was further subjected to molecular dynamics calculations (*40*), supporting the involvement of chain L residues Asn34, Leu46, Tyr49, Gln89, Tyr91, and Phe96, along with chain H residues Trp33, Trp47, Arg50, Tyr52, Ala97, and Ala101. In this work, by using the PatchDock algorithm with a set of parameters designed for antibody−antigen interactions prediction, we found the same pocket as the most likely site for fullerene binding by this antibody molecule (PDB: 1emt, (*16*)). Figure 6 displays the predicted binding site for fullerene on the fullerene-specific antibody. This binding pocket can be marked by chain L residues Tyr32 and Phe96, as well as chain H residue Trp33 (the complete list of residues is detailed in the Supporting Information).

2. Binding Sites Alignment and Analysis. After obtaining the docking models, our goal was to compare between the predicted binding sites and recognize the common features that may be related to the binding of fullerenes. Thus, we analyzed the similarities between the fullerene binding sites of HSA type 1, HSA type 2, HIVP, and the fullerene-specific antibody. The predicted binding sites of BSA were excluded from the multiple binding sites alignments, mainly due to these sites close resemblance to the corresponding HSA type 1 and type 2 sites. In addition, besides the inherent deviation of a docking model from the bound complex, additional deviations could exist due to the structure model building of BSA.

The four compared binding sites have different overall sequences and tertiary structures. Specifically, the sequence identity between the HIVP and HSA proteins is only 8% and between HSA and the fullerene-specific antibody is 15%. Obviously, HSA, HIVP, and the fullerene-specific antibody are also structurally nonrelated. Due to the above-mentioned differences, the proteins in our study cannot be aligned by standard alignment methods, that assume similarity of either sequence

Table 1. Details of the Common Pattern Calculated between the Three Most Similar Fullerene Binding Sites

HSA, type 2			HSA, type 1			HIV-protease

422	Thr	mixed donor−acceptor	448	Cys	acceptor	25 (B)	Asp	acceptor
425	Glu	acceptor	451	Asp	acceptor	25 (A)	Asp	acceptor

[a] The common features detected by Multibind contain either Pii (aromatic) interactions, hydrogen bond donor or acceptor, or mixed donor−acceptor (can use as both). [b] The chain ID is in parentheses.

or backbone patterns (*41*−*43*). Thus, to compare between the predicted binding sites of the modeled complexes, we used a recently developed method, MultiBind (*24*, *25*), which performs a multiple structure alignment between protein binding sites, in the absence of overall sequence, fold, or binding partner similarity. The MultiBind method recognizes the common spatial arrangements of physicochemical properties shared by the compared binding sites. This method is suitable for the comparison of the diverse studied proteins due to the utilized physicochemical representation of the protein molecules, where each amino acid is represented by a set of three-dimensional points in space, denoted as pseudocenters (see Methods for details (*32*)). Additionally, MultiBind does not consider the location of the binding partners, and therefore it is most appropriate for comparison of docking models, which provide only an approximate representation of the bound complex.

Here, we describe the patterns of pseudocenters which were recognized as shared by the compared binding sites. The predicted binding sites of the modeled protein−fullerene complexes were compared with both NS-C_{60} and CF ligands. We analyzed the results of the alignments between a set of all four binding sites in addition to its different subsets (two and three binding sites). Then, we evaluated the quality and the significance of the resulted patterns recognized by MultiBind by calculating their frequency of occurrence on the surfaces of complete proteins in the nonredundant PDB representation by the ASTRAL dataset (*33*, *34*). The ratio of the number of observed patterns, relative to the size of the searched dataset, provides an estimation regarding the probability of observing such a pattern by chance, on a randomly selected protein. The lower the frequency of occurrence, the more significant and rare is the pattern. Additional details regarding the exact calculations are provided in Methods.

Multiple Alignments between Four Binding Sites (HSA type 1, HSA type 2, HIVP, and the fullerene-specific antibody). Multiple alignment between the four predicted binding sites of NS-C_{60} recognized a pattern of seven physicochemical properties. The pattern contained one aromatic property, one hydrogen bond donor, and five hydrogen bond acceptors. Although the NS-C_{60} ligands were not taken into account during any of MultiBind computational steps, transformations calculated by MultiBind for the binding sites superimpose the NS-C_{60} molecules to similar locations in space, supporting the correctness of the alignment. However, when the recognized pattern was searched in the proteins of the ASTRAL dataset, it was found in 36% of the cases. This suggests that the detected pattern is not likely to be specific enough to distinguish between proteins that can bind NS-C_{60} and those that cannot.

The application of MultiBind to the four predicted binding sites of CF recognized a pattern of six physicochemical properties. The pattern consisted of three aromatic pseudocenters and three hydrogen bond acceptors. Two properties, one acceptor and one aromatic, were created by backbone atoms in all of the compared binding sites. The frequency of occurrence of this pattern in the ASTRAL dataset was 37%, which is also too high to be statistically significant.

Multiple Alignments between Three Binding Sites. The alignment between all four binding sites has shown that the binding site of the fullerene-specific antibody was the most different from all the rest, since it received the lowest score in the alignment. The inclusion of the antibody in the multiple alignment significantly reduced the size, the score, and the statistical significance of the common pattern. Therefore, in the alignments below, we removed this binding site from the aligned ensemble and compared only between the three binding sites of HSA type 1, HSA type 2, and HIVP. It must be noted that since the sequence and the fold of HIVP is very different from those of HSA, these three binding sites cannot be compared by standard sequence and structural alignment methods. The binding sites of HSA type 1 and HSA type 2 are also very different. They are located at opposite faces of HSA and are created by different noncontiguous sequences of HSA.

Three NS-C_{60} Binding Sites. Comparison between the three predicted binding sites of NS-C_{60} revealed an interesting pattern of 10 common physicochemical properties. Table 1 presents the details of the recognized pattern. Figure 7 presents the spatial arrangement of the recognized features and the superimposition between the proteins and the fullerene ligands, according to the transformations suggested by MultiBind. The recognized pattern contained three aromatic properties, two donors, and five hydrogen acceptors. The frequency of occurrence of this pattern was 1%, which shows its relative rarity.

Three CF Binding Sites. Interestingly, the pattern recognized by the alignment of the three CF binding sites was almost the same as the pattern recognized by the alignment of the three NS-C_{60} binding sites. This pattern contained 10 features with exactly the same properties. The contribution of the backbone and side-chain atoms has also remained the same. The slight differences in the exact alignment correspondence details may be explained by the different boundaries of the binding sites and by the approximation algorithms of the MultiBind method (see Methods). In general, we can summarize that the same binding pattern was recognized for the predicted binding sites of both NS-C_{60} and CF.

Pairwise Alignments. To evaluate the similarity between the compared binding sites, we also performed all-against-all pairwise surface alignments (Table 2). Naturally, the patterns detected between pairs of binding sites contained more features than the patterns common to larger sets (three or four binding sites). The frequency of occurrence of the recognized pairwise patterns in the ASTRAL dataset was very low and ranged from 0 to 1.4%. The size of the pairwise patterns ranged from 11 to 20 (mean = 17) properties for the predicted NS-C_{60} binding

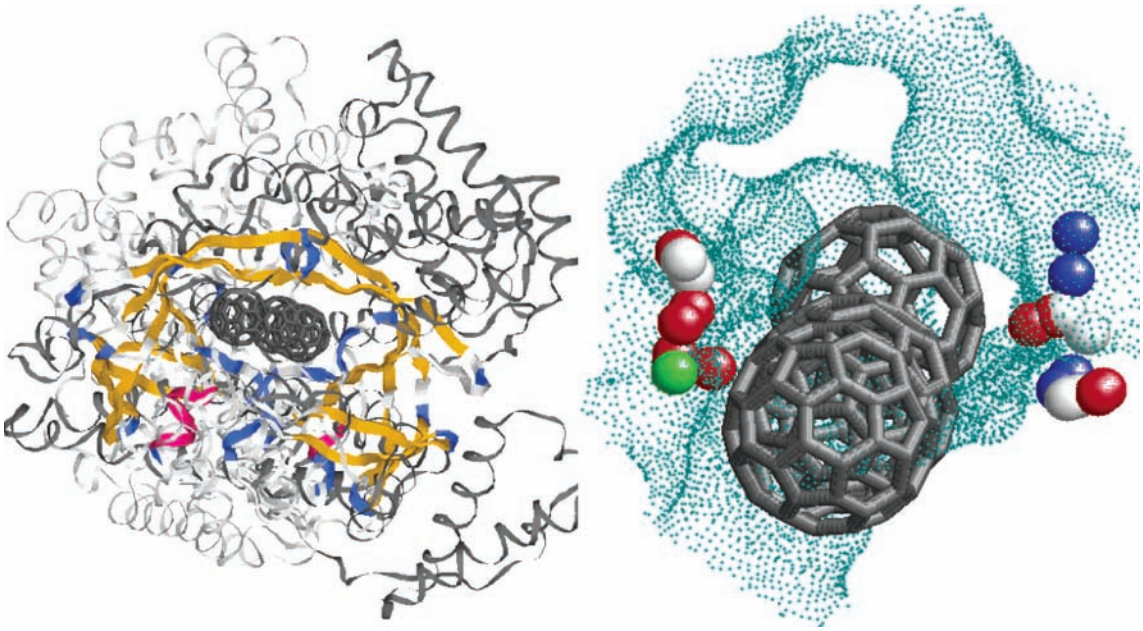

Figure 7. Surface alignment between the predicted binding sites of human serum albumin (types 1 and 2) and HIV protease. Left: the structures of human serum albumin (HSA) and HIV protease (HIVP) are represented by cartoons. HSA- type 1 is colored gray, HSA- type 2 is colored light gray and HIVP is colored according to secondary structure (β-strands are colored yellow and α-helices are colored pink). Fullerenes are represented as sticks and colored gray. The ligand molecules are presented for verification purpose only and are not a part of the input to MultiBind. Right: close-up on the aligned binding sites. Matched pseudocenters are represented by balls. Hydrogen bond donors are blue, acceptors are red, donors/acceptors are green, and aromatic is white. The surface of human serum albumin (type 2 binding site) is represented in dots and colored cyan. The figure was prepared using RasMol.

Table 2. Summary of Pairwise Alignments of Fullerene Binding Sites

compared proteins[a]	no. detected features	score	solution rank
Ligand: Nonsubstituted [C_{60}] Fullerene			
HSA-1, HSA-2	20	521.1	1
HIVP, HSA-2	19	489	1
HSA-1, HIVP	19	426.4	1
HSA-2, C_{60}Ab	16	337.0	1
HSA-1, C_{60}Ab	17	291.9	1
HIVP, C_{60}Ab	11	238.4	1
Ligand: Carboxyfullerene			
HIVP, HSA-2	21	454.3	1
HSA-1, HSA-2	20	446.7	1
HSA-1, HIVP	19	442.7	1
HSA-2, C_{60}Ab	15	318.4	1
HSA-1, C_{60}Ab	12	291.1	1
HIVP, C_{60}Ab	14	255.8	1

[a] HSA-1 = human serum albumin, type 1. HSA-2 = human serum albumin, type 2. HIVP = HIV protease. C_{60}Ab = fullerene specific antibody (*16, 17*). The columns containing the number of detected features, the score, and the solution rank are the output of the MultiBind algorithm.

sites and from 14 to 21 (mean = 18) for the CF binding sites. In both cases the alignments that involved the fullerene-specific antibody recognized smaller patterns, with lower score and with higher frequency of random occurrence than in the rest of the cases. Figure 2 in the Supporting Information presents the similarity relationships between the compared binding sites, according to the score of MultiBind, plotted using the statistical toolbox of the Matlab program. The two binding sites that were recognized to be most similar to each other are those of HSA type 1 and HSA type 2. As can be seen in this figure, the binding site of the fullerene-specific antibody was indeed the most different from all the rest.

Summary and Discussion of the Alignment Results. We have observed that patterns common to all the four binding sites are not specific enough and are not likely to represent the features essential for the binding of fullerenes. This can be explained by several factors. First, as shown by the pairwise comparisons, the binding site of the fullerene-specific antibody is very different from all the rest. Second, in all of the cases the binding sites were actually extracted from unbound complexes (i.e. the molecules are given in their structures that were determined separately). Both the docking and the alignment algorithms are rigid and address protein flexibility only implicitly through a set of thresholds that allow certain variability in locations. In practice, both the side-chains and the protein backbone can undergo conformational changes upon ligand binding. The alignment results suggest that either the fullerene binding sites are different on different proteins, or that the fullerene binding sites undergo more significant conformational changes.

A more interesting and significant pattern of shared physicochemical properties was recognized between the three binding sites of HSA type 1, HSA type 2, and HIVP. From the computational standpoint, the high similarity of the patterns recognized for the binding sites of NS-C_{60} and CF is encouraging and shows consistency of the docking and alignment methods. However, from the biological standpoint, we would have expected these patterns to be different. Specifically, NS-C_{60} is a hydrophobic ligand and we would expect the pattern that characterizes its binding to be more hydrophobic. On the other hand, the CF ligand has chargeable groups, and we would expect its binding pattern to be less hydrophobic. The same pattern obtained for NS-C_{60} and CF cases could be explained by the fact that we have used the same unbound protein structures to construct the docking models with both ligands.

The observation that most of the properties that constitute the recognized pattern are contributed by backbone atoms suggests the differences in side-chain orientations and conformations. In reality the side-chains of the considered binding sites may rearrange and undergo conformational changes to accommodate each of the considered ligands in a slightly different manner. However, only solving the structures with these ligands will provide an exact answer to this puzzle.

CONCLUSIONS

Here we have employed a computational approach in order to address the subject of fullerene interactions with proteins. We suggested docking models consistent with available experimental data for the interactions of fullerenes with four proteins. We further compared between the surface spatial and physicochemical properties of the suggested binding sites. A similarity was found between the (human and bovine) serum albumins and the HIV-protease binding sites, while the binding site of the fullerene-specific antibody was found to be different from the others.

ACKNOWLEDGMENT

We would like to thank Dina Schneidman-Duhovny for software support and critical reading of this manuscript. We would like to thank Maxim Shatsky for useful suggestions. This work was supported by the Israel Science Foundation.

Supporting Information Available: Detailed lists of amino acids that are within 6 Å distance from the docked ligand for each of the predicted binding sites. Two figures that depict (i) the similarity of the predicted binding site of carboxy-fullerene on HSA to binding sites of other known ligands, demonstrated for the case of citric acid (Figure S1) and (ii) similarity relationships between the four predicted binding sites of HSA-type 1, HSA-type 2, HIVP and a fullerene-specific antibody (Figure S2). Detailed below are the lists of residues that comprise the detected binding sites that are within 6Å distance from the docked ligand.

Residues participating in the NS-C_{60} pocket of type 1 on HSA are: Ala191, Ser192, Lys195, Gln196, Leu198, Lys199, Trp214, Arg218, Arg222, Ala291, Glu292, Val293, Val343, Lys436, Cys437, Pro447, Cys448, Ala449, Asp451, Tyr452, Leu453 and Val455.

Residues participating in the CF pocket of type 1 HSA are: Glu153, Glu188, Ala191, Ser192, Ala194, Lys195, Gln196, Leu198, Lys199, Trp214, Arg218, Gln221, Arg222, His288, Cys289, Ile290, Ala291, Glu292, Val293, Glu294, Asn295, Pro339, Val343, Lys436, Cys437, His440, Lys444, Pro447, Cys448, Ala449, Asp451, Tyr452 and Val455.

Residues participating in the NS-C_{60} pocket of type 2 on HSA are: Asp108, Asn109, Pro110, Asn111, Leu112, Pro113, Arg114, Leu115, Glu141, Arg145, His146, Arg186, Lys190, Pro421, Glu425, Gln459 and Leu463.

Residues participating in the CF pocket of type 2 on HSA are: Asp108, Asn109, Pro110, Asn111, Leu112, Pro113, Arg114, Leu115, Val116, Glu141, Ile142, Arg145, His146, Pro147, Arg186, Lys190, Ser193, Ala194, Pro421, Thr422, Val424, Glu425, Val426, Arg428, Asn429, Lys432, Gln459, Leu463, Lys519, Glu520 and Ile523.

Residues participating in the HIV binding site for NS-C_{60} (Chain A:) Leu23, Asp25, Gly27, Ala28, Asp29, Asp30, Val32, Ile47, Gly48, Gly49, Ile50, Thr80, Pro81, Val82, Ile84, (Chain B:) Arg8, Leu23, Asp25, Gly27, Ala28, Gly48, Gly49, Ile50, Thr80, Pro81, Val82 and Ile84.

Residues participating in the HIV binding site for CF (chain A:) Arg8, Leu23, Asp25, Gly27, Ala28, Asp29, Asp30, Val32, Ile47, Gly48, Gly49, Ile50, Ile54, Pro79, Thr80, Pro81, Val82, Asn83, Ile84.

(Chain B:) Leu23, Asp25, Thr26, Gly27, Ala28, Asp29, Ile47, Gly48, Gly49, Ile50, Gly51, Gly52, Phe53, Ile54, Pro81, Val82 and Ile84.

Residues participating in the fullerene specific antibody binding site for NS-C_{60} (chain L) Tyr32, Asn34, Tyr49, Tyr50, Tyr91, And Phe96; (chain H)Ser32, Trp33, Arg50, Thr98, Ser99, Ser100 and Ala104.

Residues participating in the fullerene specific antibody binding site for CF (chain L) Ser30, Asn31, Tyr32, Leu33, Asn34, Tyr36, Leu46, Tyr49, Tyr50, Ser53, Arg55, Gln89, Tyr91, Ser92, Arg93, Leu94 and Phe96; (chain H) Ser31, Ser32, Trp33, Asn35, Arg50, Thr98, Ser99, Ser100 and Ala104.

FIGURE CAPTIONS FOR SUPPORTING INFORMATION

Supplementary Figure 1. Predicted binding site for carboxy-fullererene on HSA occupying the known binding site for cytric acid. In all the four sub-figures, predicted binding site residues are colored green. Left: NS-C_{60} in its predicted binding site on free HSA (PDB: 1ao6). Right: the crystal structure of HSA complexed with cytric acid and decanoic acid (PDB: 1tf0). The lower figures provide a closer look on the surface of the binding sites.

Supplementary Figure 2. Similarity relationships between the four binding sites of HSA-type 1, HSA-type 2, HIVP and a fullerene-specific antibody. The dendrogram was constructed according to the score of MultiBind plotted using the statistical toolbox of Matlab. The similarity relationships are the same for both non-substituted fullerene and carboxyfullerene binding sites.

Synthesis of Thiol-Reactive, Long-Wavelength Fluorescent Phenoxazine Derivatives for Biosensor Applications

Douglas B. Sherman, J. Bruce Pitner, Arounaguiry Ambroise, and K. Joseph Thomas*

BD Technologies, 21 Davis Drive, Research Triangle Park, North Carolina 27709. Received October 24, 2005; Revised Manuscript Received January 10, 2006

Two environmentally sensitive, long-wavelength fluorescent phenoxazine derivatives, INR and IANR, were synthesized with linkers for conjugation to the thiol group of cysteine in binding proteins. The linkers were designed based on the attachment sites at two different positions on the phenoxazine, which were chosen in order to study the orientation of the dye with respect to the binding protein. Conjugation of the dyes to the S337C maltose binding protein (MBP) mutant provided conjugates of these dyes that are capable of detecting maltose with different sensitivities. The dye INR gave a 3-fold (+200%) change in fluorescence intensity upon maltose binding when conjugated to S337C MBP with a binding constant (K_d) of 435 μM. The fluorescence change for IANR was only 20% and the K_d was 1.4 mM. Conformational analysis of the dyes by molecular modeling suggested that the linker in IANR imparted greater conformational freedom to the dye, resulting in little change in environment between the open and the closed-form conformations. The linker in INR, on the other hand, showed restricted motion, which placed the dye in different environments in the open and closed forms of the protein. Thus, design and placement of the linker play a critical role in the performance of these dyes as environmentally sensitive probes.

INTRODUCTION

Long-wavelength fluorescent dyes that are thiol-reactive and environmentally sensitive can play an important role in biosensor chemistry (*1*, *2*). Particularly, when dealing with biological interferences during the in vivo measurement of metabolites such as glucose or lactate, dyes that fluoresce above 600 nm are preferred since tissue and serum fluorescence are minimal, and background scattering is limited to its lowest value in the long-wavelength window (*3*, *4*). This allows the measurement of fluorescence signal from a sensor dye with greater accuracy, and therefore the long-wavelength region is superior to visible spectral regions for fluorescence-based diagnostic applications. Although there are several dyes known to emit in the long-wavelength region (*5*−*7*), to our knowledge none are commercially available that are both environmentally sensitive and have a linker for specific conjugation to an engineered cysteine on a binding protein.

Binding proteins offer an alternative approach for sensing a variety of analytes such as maltose, glucose, lactate, and other metabolites (*8*−*11*). In contrast to enzymatic sensors, fluorophore-labeled binding proteins require no cofactors and produce no enzymatic byproducts, a source of potential biosensor degradation during longer implant times. Binding proteins can be specific to molecules of biological interest and can reversibly bind these ligands, properties that are desirable for constructing continuous biosensors. The most important property of these receptors is they all share a substantial conformational change upon ligand binding, typically a hinge-type motion centered around the ligand binding site that brings two protein domains toward each other. To take advantage of these receptor properties, the binding protein must be coupled to a reporter moiety that can reliably provide a quantitative signal corresponding to the concentration of the desired ligand.

A reliable approach for protein biosensor design is to place an environmentally sensitive fluorescent dye near the binding pocket (*12*). The fluorescence properties of such dyes can be correlated to changes in microenvironment associated with the binding of analytes to protein. Keeping this in mind, we have developed two long-wavelength fluorescent dyes suitable for bioconjugation that possess significant sensitivity to their microenvironment and emit in the 600−700 nm region. The two dyes are derivatives of Nile Red, a phenoxazine that is known to possess a very high environmental sensitivity. Various research groups have used Nile Red for probing the polarity of organic and micro-heterogeneous media. The absorption and emission maxima are in the range of 550 and 600 nm, respectively, with emission maxima shifting to as much as 650 nm when the dye interacts with the hydrophobic surface of tubulin, for example (*13*−*15*).

Although Nile Red derivatives have been reported that are amine-reactive (*16*−*18*), these would likely have little or no site-specificity when conjugated to proteins such as MBP that contain numerous lysines. A thiol-reactive moiety would provide site-specificity for protein attachment through a native or an engineered cysteine (*11*). The mutant S337C provides a cysteine location in MBP that has been previously shown to provide a significant signal with the environmentally sensitive visible fluorophore IANBD (*N*-[2-(iodoacetoxy)ethyl]-*N*-methylamino-7-nitrobenz-2-oxa-1,3-diazole) (*8*, *9*). One of our further objectives was to identify the optimal location on the phenoxazine dye for introducing a thiol-reactive linker. In the first design, the linker was placed on the dialkylamino group, and in the second, the linker was placed on the aromatic chromophore (Schemes 1 and 2). Herein we report the performance of these dyes for maltose detection on S337C MBP and examine the differences with respect to linker design and placement of the dyes.

EXPERIMENTAL PROCEDURES

Materials. The starting materials for the syntheses were either purchased from Sigma-Aldrich or from another commercial vendor as indicated. S337C MBP was produced by methods

described by Gilardi et al. (*8*). Absorption spectra were recorded on a Cary 50 Bio UV−Vis spectrophotometer, and fluorescence measurements were taken on a PTI QM-4/2003 SE spectrofluorimeter. The NMR spectra were obtained on either a Varian Mercury 400 MHz or on a Bruker (400 MHz) AMX 400 spectrometer. Mass spectra were recorded on a Finnigan-MAT 212 (FAB) or on a Sciex 150 Electrospray spectrometer.

Synthesis of INR (1). *Intermediate **1b***: *N*-Phenyl-*N*-methylethanolamine **1a** (50 mmol) was suspended in concentrated HCl (28 mL) and was cooled to 5 °C. To this solution was added dropwise a sodium nitrite solution (6.67 g in 10 mL water) over a period of 40 min. After the addition, the reaction was kept stirring for 2 h more. The product was then filtered, washed with 0.5 M HCl, and dried in vacuo to give the nitroso compound **1b** (yield 40%). ^{1}H NMR (D_2O) δ ppm: 3.59 (s, CH_3, 3H); 3.90 (t, CH_2, 2H); 4.05 (t, CH_2, 2H); 7.22−7.30 (m, aromatic, 2H); 7.50 (d, aromatic, 1H); 7.77 (d, aromatic, 1H). ^{13}C NMR (D_2O) δ ppm: 42.44, 57.92, 58.72, 120.29, 122.52, 125.93, 140.56, 149.93, 163.21. Mol wt calculated for $C_9H_{12}N_2O_2$ is 180 (M^+), found 181 (M + 1) (FAB).

*Intermediate **1d***: 1,3-Dihydroxynaphthalene **1c** (5 mmol) was suspended in ethanol (25 mL) and was brought to reflux while stirring. To the refluxing solution was added intermediate **1b** (5 mmol) in fractions over a period of 45 min. After the addition, the reaction mixture was maintained at reflux for 4 h more and then cooled. The solvent was evaporated, and the product dye **1d** was purified by flash column chromatography over silica gel using methanol and chloroform (1:9) as eluent (yield 50%). ^{1}H NMR ($CDCl_3$) δ ppm: 2.98 (s, 3H); 3.48 (t, 2H); 3.83 (t, 2H); 6.20 (s, 1H); 6.77 (d, 1H); 7.10 (d, 1H); 7.45 (s, 1H); 7.60−7.75 (m, 2H); 7.72 (m, 1H); 8.08 (m, 1H). ^{13}C NMR ($CDCl_3$) δ ppm: 39.2, 55.6, 60.3, 102.2, 110.2, 113.6, 124.7, 126.3, 126.6, 126.8, 130.6, 132.3, 133.7, 135.1, 145.8, 148.2, 152.4, 182.5, 183.8. Mol wt calculated for $C_{19}H_{16}N_2O_3$ is 320 (M^+), found 321 (M + 1) (FAB).

*Compound **1** (INR)*: The intermediate dye **1d** was dissolved in anhydrous acetonitrile (10 mL), and *p*-(dimethylamino)-pyridine (3 mg) was added, followed by iodoacetic anhydride (250 mg). The reaction was stirred for 2 h. The product **1** was separated by evaporation of the solvent and then purified by repeated precipitation from methylene chloride and hexane (yield 25%). ^{1}H NMR ($CDCl_3$) δ ppm: 3.14 (s, 3H); 3.66 (s, 2H); 3.74 (t, 2H); 4.38 (t, 2H); 6.40 (s, 1H, ArH); 6.54 (d, 1H, ArH); 6.72 (d, 1H, ArH); 7.64−7.75 (m, 3H, ArH); 8.29 (d, 1H, ArH); 8.65 (d, 1H, ArH). ^{13}C NMR ($CDCl_3$) δ ppm: −6.1, 39.6, 50.9, 63.0, 97.5, 106.4, 110.1, 124.1, 125.6, 126.0, 130.6, 131.2, 131.7, 131.98, 132.0, 141.5, 146.5, 151.8, 152.2, 169.0, 184.1. Exact Mass Calculated for $C_{21}H_{17}IN_2O_4$ is 489.0317, found 489.0317 (HRMS).

Synthesis of IANR (2). *Intermediate **2b***: 9-Diethylamino-2-hydroxy-5*H*-benz[*a*]phenoxazin-5-one **2a** (50 mg, 0.15 mmol), *N*-bromoethylphthalimide (50 mg, 0.20 mmol), and potassium carbonate (60 mg, 0.09 mmol) were combined in DMF (15 mL) under argon with stirring. The reaction proceeded at reflux for 4.5 h. Additional bromoethylphthalimide (25 mg) was added at 4.5 h and at 6.5 h (15 mg). The temperature was lowered to 115 °C, and the reaction proceeded overnight. DMF was removed in vacuo, and the residue was dried in vacuo. Column chromatography over silica gel (2% MeOH/CH_2Cl_2 as mobile phase) afforded the product **2b** in 85% yield. ^{1}H NMR ($CDCl_3$) δ ppm: 1.22 (t, 6H); 3.40 (q, 4H); 4.19 (t, 2H); 4.40 (t, 2H); 6.23 (s, 1H); 6.36 (d, 1H); 6.59 (dd, 1H); 7.09 (d, 1H); 7.52 (d, 1H); 7.70 (m, 2H); 7.84 (m, 2H); 7.96 (d, 1H); 8.13 (d, 1H). ^{13}C NMR ($CDCl_3$) δ ppm: 12.8, 37.5, 45.2, 65.3, 96.3, 105.2, 106.5, 109.8, 118.6, 123.5, 124.9, 126.0, 127.9, 131.3, 132.1, 134.2, 139.6, 146.8, 150.7, 152.2, 161.0, 162.8, 168.4, 183.3. Mol wt calculated for $C_{30}H_{25}N_3O_5$ is 507, found 508 (MH^+) (FAB-MS).

*Intermediate **2c***: Intermediate **2b** (30 mg, 0.06 mmol) was dissolved in anhydrous MeOH (8 mL) and was kept under an atmosphere of argon. Next, methylamine (2 M in MeOH, 4 mL, 8 mmol) was added. The reaction was allowed to proceed for 5 min at RT and 2.5 h at reflux. Flash chromatography was performed over silica gel using 10% MeOH/CH_2Cl_2 as the mobile phase to remove fast moving impurities and then with 30% MeOH/CH_2Cl_2 to elute the product **2c**. Solvent was removed on a rotary evaporator, and the residue was dried in vacuo (70% yield). ^{1}H NMR ($CDCl_3$) δ ppm: 1.25 (t, 6H); 3.17 (t, 2H); 3.45 (q, 4H); 4.20 (t, 2H); 6.27 (s, 1H); 6.43 (d, 1H); 6.63 (dd, 1H); 7.15 (m, 1H); 7.56 (d, 1H); 8.02 (m, 1H); 8.18 (d, 1H). ^{13}C NMR ($CDCl_3$) δ ppm: 12.8, 41.6, 45.3, 63.9, 96.4, 105.4, 106.6, 109.9, 118.4, 124.9, 125.9, 127.4, 128.0, 131.3, 134.3, 147.1, 151.0, 152.3, 161.7, 183.5. Mol wt calculated for $C_{22}H_{23}N_3O_3$ is 377, found 378 (MH^+) (FAB-MS).

*Compound **2** (IANR)*: Intermediate **2c** (11 mg, 0.03 mmol) was dissolved in CH_2Cl_2 (5 mL). Iodoacetic anhydride (21 mg, 0.06 mmol) was then added and allowed to react for 40 min. An additional 25 mL of CH_2Cl_2 was added, and the reaction mixture was transferred to a separation funnel. The organic phase was washed with 10% Na_2CO_3 (10 mL each) twice, dried over anhydrous $MgSO_4$, and filtered. After the solvent was removed on a rotary evaporator, the final product **2** was dried under vacuum and precipitated from CH_2Cl_2/hexane (yield 87%). ^{1}H NMR ($CDCl_3$) δ ppm: 1.17 (t, 6H); 3.35 (q, 4H); 3.69 (t, 2H); 3.78 (s, 2H); 4.14 (t, 2H); 6.12 (s, 1H); 6.27 (s, 1H); 6.48 (dd, 1H); 6.91 (d, 1H); 7.34 (d, 1H); 7.74 (s, 1H); 7.95 (s, 1H). ^{13}C NMR ($CDCl_3$) δ ppm: 12.9, 29.9, 40.1, 45.3, 66.9, 96.3, 105.2, 106.7, 109.8, 118.0, 124.9, 125.9, 127.8, 131.3, 134.1, 139.4, 147.0, 151.0, 152.2, 161.1, 168.1, 183.3. Exact mass calculated for $C_{24}H_{24}IN_3O_4$ is 546.0889, found 546.0889 (HRMS).

Quantum Yield Measurements. Relative fluorescence quantum yields were determined using optically dilute solutions with rhodamine 101 in ethanol (quantum yield 1.0) (*19*). Typically, the absorption was matched to 0.05 at the excitation wavelength

and adjustments were made for minor changes in absorption at the excitation wavelength in fluorescence quantum yield measurements. Spectroscopic grade solvents were used for fluorescence measurements.

Bioconjugation of INR and IANR to MBP. Dyes were conjugated to the binding proteins in the following manner. To S337C MBP (4 nmol) in PBS (200 μL) was added dithiothreitol (8 nmol), and the reaction proceeded for 30 min at room temperature. INR or IANR were prepared as stock solutions (approximately 1 mg in 100 μL DMSO). An aliquot containing 40 nmol of the dye was added to the protein solution and was stirred for 4 h at room temperature in the dark. The reaction mixture was then passed through a NAP-5 size exclusion column (Amersham-Pharmacia, Uppsula, Sweden), with the product eluting in the second (0.5 mL) fraction. The percent change in fluorescence intensity was measured on a PTI fluorimeter using 1 μM protein with either 0 or 100 mM maltose.

Determination of Binding Constants. A 0.1 μM solution of S337C MBP/dye conjugate was titrated on the fluorimeter against maltose concentrations from 0 to 100 mM. The binding constant (K_d) was calculated using relationships shown below that were derived from similar calculations by Pisarchik and Thompson (*20*).

$$F = F_{inf} + \frac{F_0 - F_{inf}}{1 + x/K_d}$$

where F is fluorescence, F_{inf} and F_0 are fluorescence at infinity and at the initial value, and K_d is the binding constant. The free concentration of maltose ($[Mal]_{free}$) is denoted by x and is determined by the relationship:

$$[Mal]_{free} = \frac{[Mal]_{tot} - [Prot]_{tot} - K_d + \sqrt{([Mal]_{tot} - [Prot]_{tot} - K_d)^2 + 4 \times [Mal]_{tot} \times K_d}}{2}$$

where $[Mal]_{tot}$ and $[Pro]_{tot}$ are total maltose and protein concentrations, respectively. If $[Mal]_{tot} \gg K_d$ and $[Mal]_{tot} \gg [Pro]_{tot}$, then the equations simplify to the following form:

$$F = F_0 + [(F_{const} \times x)/(1 + x/K_d)]$$

where $F_{const} = (F_{inf} - F_0)/K_d$.

Molecular Modeling. Models of INR and IANR were constructed in Sybyl (Tripos, St. Louis, MO). X-ray crystal structures of MBP in the open (1OMP.pdb) and closed (1ANF.pdb) forms were obtained from the Protein Data Bank (*21*). After residue S337 was modified to Cys, the dyes were attached to form the models of the bioconjugates. Genetic algorithm (GA) conformational searches were then performed using the method provided in Sybyl. For INR, the eight bonds between the Cys alpha-carbon and the dialkylamino nitrogen were defined as rotatable. In the IANR linker, the amide bond was fixed in the trans conformation, and the bond between the aryl oxygen and the aromatic ring was defined as rotatable, which also produced a total of eight rotatable bonds. Default settings in the GA search were employed, except the duplicate window was set to 10. The results of the search were up to 20 conformers within a 20 kcal/mol energy window.

RESULTS

Synthesis. Nile Red derivative INR (**1**) was synthesized according to Scheme 1. Briefly, intermediate **1b** was synthesized by reacting *N*-phenyl-*N*-methylethanolamine **1a** with sodium nitrite at 5 °C in the presence of concentrated HCl, and the resulting product was dried to give **1b**. The parent dye **1d** was prepared by the cyclization reaction of **1b** with 1,3-dihydroxynaphthalene (**1c**) at reflux in ethanol followed by purification. Reaction of **1d** with iodoacetic anhydride in the presence of (dimethylamino)pyridine afforded the thiol-reactive product INR (**1**).

The synthesis of derivative IANR (**2**) was carried out in three steps according to Scheme 2. Starting material 9-diethylamino-2-hydroxy-5*H*-benz[*a*]phenoxazin-5-one **2a** was reacted with *N*-bromoethylphthalimide in DMF in the presence of potassium carbonate to produce the intermediate **2b**. Intermediate **2c** was then prepared by the deprotection of the amine in **2b** with methylamine at refluxing temperatures in methanol. The final thiol-reactive compound IANR (**2**) was synthesized by reaction of the amine derivative **2c** with iodoacetic anhydride.

Absorption and Fluorescence Properties. The sensitivity of INR and IANR toward surrounding microenvironment was tested by studying their spectral properties in solvents of varying dielectric constants. Table 1 summarizes the absorption, emission, and quantum yield of these dyes in a range of polar and nonpolar solvents. The absorption and emission spectra of INR and IANR showed a bathochromic shift with increase in polarity of the medium. For example, the absorption maximum of INR shifted from 500 nm in toluene to 534 nm in methanol, and the fluorescence emission maximum shifted from 556 to 627 nm. IANR gave the same trends, although the absorption maximum shifted 27 nm from toluene to methanol versus 34 nm for INR. The shift in fluorescence maximum was 71 nm for INR and 64 nm for IANR. When conjugated to S337C MBP (not shown in Table 1), the absorption maxima of the dyes in PBS shifted to 580 nm for INR and 550 nm for IANR. Likewise, the fluorescence emission maxima shifted significantly to 640 nm for INR and 653 nm for IANR, placing the emission maxima in the desired long-wavelength range.

In a nonpolar solvent such as toluene, the quantum yield of fluorescence was found to be 1.0 for INR and 0.97 for IANR. High fluorescence quantum yields were also observed in solvents such as chloroform and methylene chloride. With increasing solvent polarity the quantum yield decreases significantly. For

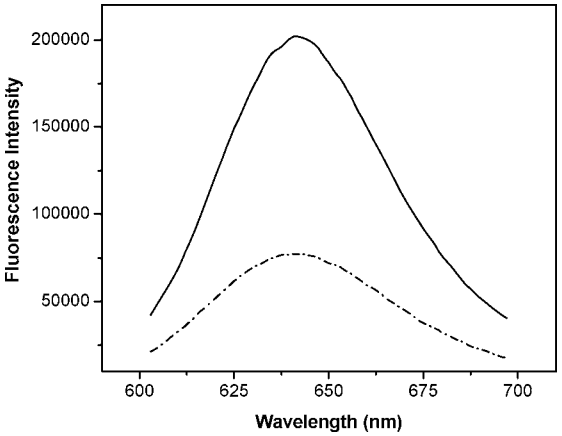

Figure 1. Fluorescence intensity change of S337C-INR MBP between 0 (dotted line) and 100 mM (solid line) maltose.

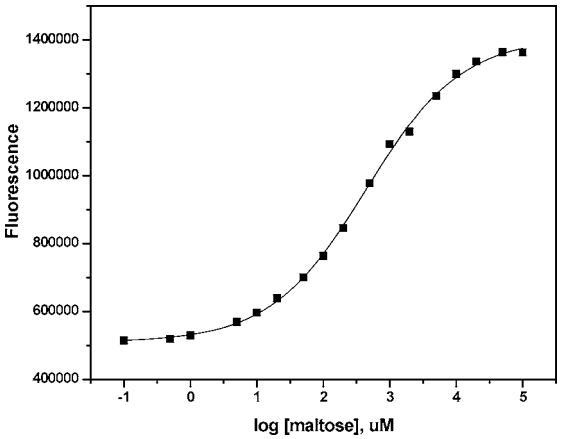

Figure 2. Plot for the determination of binding constant (K_d) for S337C-INR MBP conjugate.

example, in a moderately polar solvent such as acetonitrile, the quantum yield observed for INR was 0.53, and for IANR it was 0.59. In protic polar solvents the quantum yield was further reduced; in methanol the quantum yield for both INR and IANR was observed as 0.25. This is a 4-fold decrease in quantum yield as compared to toluene.

Bioconjugate Performance. Figure 1 shows the fluorescence spectrum of the conjugate S337C-INR MBP in PBS. Upon maltose binding by the protein, the fluorescence intensity underwent a 3-fold enhancement (+200%), whereas S337C-IANR MBP gave only a 20% change in fluorescence intensity. The binding curve for S337C-INR MBP is shown in Figure 2, and the binding constant (K_d) was calculated as described in Experimental Section. The K_d calculated for the S337C-INR MBP conjugate was 435 μM, and the K_d for S337C-IANR MBP was 1.4 mM. These values are higher than the K_d of 62 μM reported for S337C MBP conjugated with IANBD ester (*9*) and are 100 to 400 times higher than the K_d (3.5 μM) of wild-type MBP (*22*).

Molecular Modeling Analysis. Models of the dyes attached to S337C MBP in the open and closed form protein conformations were prepared, and GA conformational searches were performed as described in Experimental Procedures. Representative conformers are illustrated in Figure 3 for the open (left) and closed (right) forms of the protein. S337C-IANR MBP returned 20 conformers that formed five families in the open form as illustrated by representative structures in Figure 3a. All 20 conformers were within 5 kcal/mol of each other and were distributed in the cleft between the domains or near the surface of one of the domains. In the closed form, the conformational search of S337C-IANR MBP returned four families (Figure 3b). S337C-INR MBP, on the other hand, returned 20 conformers in the open form that were within 2 kcal/mol of each other and that formed a single family, as shown in Figure 3c. The search on S337C-INR MBP also returned a single family of 20 conformers (Figure 3d). Here the dye was parallel to the surface of the upper domain in the protein.

DISCUSSION

INR and IANR were synthesized in three steps as outlined in Schemes 1 and 2. Both dyes displayed absorption, emission, and quantum yield properties that demonstrated the environmental sensitivity required in order for these dyes to function as a reporter for binding protein-based reagentless biosensors. As the polarity of the solvent increased, INR and IANR displayed bathochromic shifts in absorption (up to 34 nm) and emission (up to 71 nm) wavelengths. Although both structures were based on the same chromophore, the absorption and emission maxima of INR were blue shifted compared to IANR in any given solvent. In the case of INR, placement of the linker at the dialkylamino group may be affecting the degree of charge transfer, which would in turn lead to a blue shift for INR with respect to IANR. The presence of the linker at the dialkylamino group may also be the reason that the molar extinction coefficient of INR (14 000 M^{-1} cm^{-1}) is lower than that of IANR (29 000 $M^{-1}cm^{-1}$).

Previous reports in the literature described similar trends for the parent dye Nile Red, which were explained as arising from a twisted intramolecular charge transfer (TICT) (*23*−*25*). TICT can occur upon excitation when an electron donor group in a molecule transfers an electron to an acceptor group in the molecule with a concomitant 90° rotation of the bond between the donor and acceptor (*26*−*28*). In Nile Red, the diethylamino group would serve as the donor, the ketone moiety would serve as the acceptor, and the single bond between the diethylamino group and the phenoxazine ring would rotate.

Later reports of experimental and theoretical calculations (*29*, *30*) on Nile Red suggested that the solvatochromic properties could be adequately explained based on the change in the dipole moment of the dye between the ground and excited state (*31*), which has been calculated to be in the range of 5.5 to 7.4D (*23*, *24*, *29*). Thus, the excited dye molecule could be better stabilized in a polar medium such as methanol or DMF as compared to a nonpolar medium such as toluene. This stabilization leads to lower free energy of the excited state, whereas the ground state remains relatively unaffected from nonpolar to polar medium. The decrease in the free energy of the excited state leads to the reduction in the separation between the S_0-S_1 state, and thereby a shift toward higher wavelength (bathochromic shift) is observed.

The quantum yield of both dyes showed a 4-fold decrease from toluene to methanol. The decrease in quantum yield of fluorescence between hydrophobic and polar solvent environments may also be explained based on changes in the dipole moment of the dyes. In nonpolar solvents, electrostatic interactions are limited with the solvent molecules, which would significantly arrest the nonradiative decay pathways. In toluene, all the nonradiative decay pathways for INR are eliminated, leading to an absolute quantum yield of fluorescence. However, in polar solvents such as methanol, strong electrostatic interactions exist between the dye and solvent molecules, leading to radiationless vibronic relaxations and thereby a significant decrease in fluorescence intensity.

INR and IANR displayed considerably different fluorescence responses when conjugated to S337C MBP for detection of maltose. The INR conjugate gave a +200% fluorescence change with a K_d of 435 μM, whereas IANR gave only a +20% fluorescence change with a K_d of 1.4 mM. These results

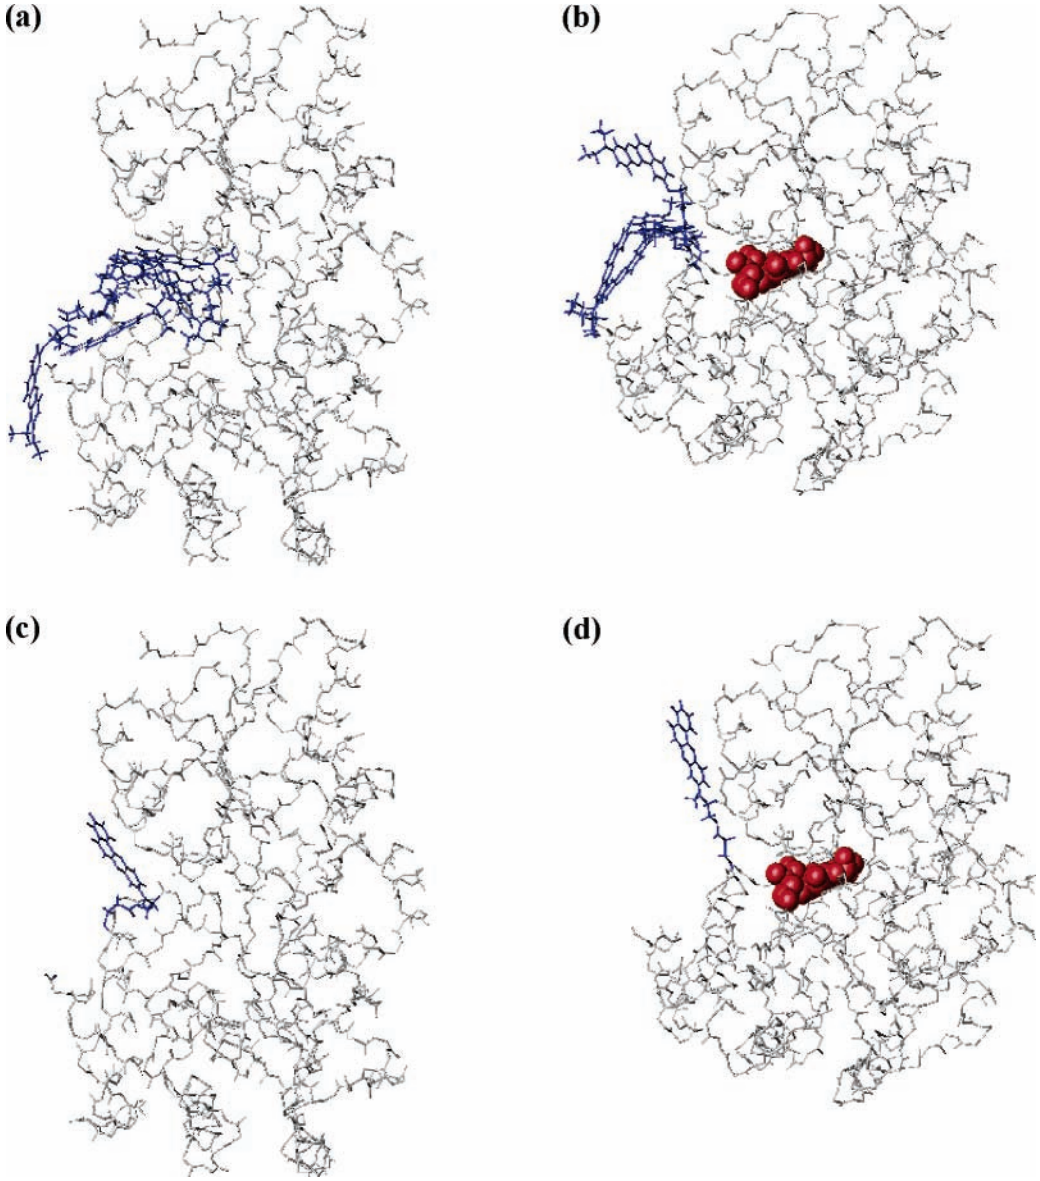

Figure 3. Results of genetic algorithm conformational searches for IANR (a and b) and INR (c and d) at S337C MBP in the open (left) and closed (right) conformations. Dye structures are in blue and maltose is in red.

suggested that the position and nature of the linker on the dye may have a profound effect on the sensor performance when these dyes are used to construct fluorescent sensors for maltose. Such behavior was previously reported for studies of phosphate binding protein (PBP), in which the coumarin dye *N*-[2-(1-maleimidyl)ethyl]-(diethylamino)coumarin-3-carboxamide (MDCC) gave a +405% fluorescence change when conjugated to mutant A197C of PBP (*32*). Replacement of the ethyl group between the coumarin carboxamide and the maleimide group with *n*-propyl (MPrCC) or a *p*-phenyl group (MPhCC) changed the binding activity to −4% and −22%, respectively. Retention of the ethyl group but replacement of the maleimide group with an iodoacetamide group resulted in no change in fluorescence (*33*). In the current study, the linker of INR contains a flexible ester compared to the more rigid amide in the linker of IANR. On the other hand, the INR linker is connected to the ring system of the dye through a dialkylamino group that donates electrons to the aromatic ring system as mentioned above, whereas the IANR linker is attached through an aryl ether bond that may allow greater freedom of rotation near the chromophore.

To evaluate the effect of the linker on dye orientation with respect to the S337 C MBP protein, molecular modeling studies were performed. The conformational analysis studies by molecular modeling suggested that IANR appeared to be much more flexible in the bound and unbound states than INR. The added flexibility in the linker may prevent IANR from experiencing a large change in environment between the bound and unbound states. INR, on the other hand, appeared locked into two conformations of distinctly different environments in the bound and unbound states, which would agree with the larger change in fluorescence that was observed for this dye, especially if the dye interacts more with polar residues on the surface of the protein in one conformation over the other (*34*). Furthermore, IANR was located more deeply and in parallel with the cleft between the two domains of the open form model than INR. It is possible that placement of the dye in this position may help to stabilize the open form of the protein relative to the closed form (*35*), which in turn would account for the weaker binding affinity for the IANR conjugate relative to the INR conjugate.

In conclusion, we have synthesized two long-wavelength fluorescent thiol-reactive derivatives of Nile red for biosensor applications. The thiol reactive pendants were placed at two different locations on the dye in order to understand the effect of linker position on the fluorescence response of the dyes, especially when conjugated to binding proteins. The high environmental sensitivity of these dyes was demonstrated by

measuring their spectral properties in solvents of varying dielectric constants. Bioconjugation of these dyes to maltose binding protein S337C MBP showed fluorescence changes of up to 200% upon binding of maltose for INR but only 20% for IANR. To a first approximation, the binding event places INR in an environment with relatively fewer interactions with the solvent water molecules, while IANR experiences less of an environmental change. Furthermore, we have observed that the attachment position of the linker to the dye and the flexibility of the linker play a key role in sensor performance, which was supported qualitatively by modeling studies. Placing the dye such that the charge transfer center would be closer to the protein surface may also explain the higher fluorescence performance for the biosensor. We believe that these dyes can be employed with binding proteins for other ligands, which can lead to the development of binding protein-based metabolite sensors that can be used with relatively low interference from the biological media when measured in vivo.

ACKNOWLEDGMENT

This work is supported in part by a grant from the Technologies for Metabolic Monitoring (TMM) program, contract number W81XWH-04-1-0076. The authors thank Dr. A. E. G. (Tony) Cass (Imperial College) for providing clones of S337C MBP as well as Colleen Nycz and David Wright of BD Technologies for assistance with protein production.

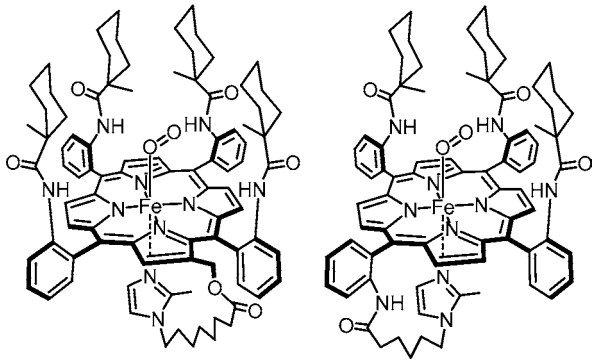
Received November 3, 2005; Revised Manuscript Received February 10, 2006

Artificial O_2-carrying hemoprotein composed of human serum albumin including tetrakis(*o*-amidophenyl)-porphinatoiron(II) (Fe4P or Fe3P) [HSA−FeXP] has been modified by maleimide- or succinimide-terminated poly(ethylene glycol) (PEG), and the formed PEG bioconjugates have been physicochemically characterized. 2-Iminothiolane (IMT) reacted with the amino groups of Lys to create active thiol groups, which bind to α-maleimide-*ω*-methoxy PEG [Mw: 2-kDa (PEG_{M2}), 5-kDa (PEG_{M5})]. On the other hand, α-succinimidyl-*ω*-methoxy PEG [Mw: 2-kDa (PEG_{S2}), 5-kDa (PEG_{S5})] directly binds to Lys residues. MALDI-TOF MS of the PEG-conjugated HSA−FeXP showed distinct molecular ion peaks, which provide an accurate number of the PEG chains. In the case of PEG_{MY}(HSA−FeXP), the spectroscopic assay of the thiol groups also provided the mean of the binding numbers of the polymers, and the degree of the modification was controlled by the ratio of [IMT]/[HSA]. The viscosity and colloid osmotic pressures of the 2-kDa PEG conjugates (phosphate-buffered saline solution, [HSA] = 5 g dL^{-1}) were almost the same as that of the nonmodified one, whereas the 5-kDa PEG binding increased the rheological parameters. The presence of flexible polymers on the HSA surface retarded the association reaction of O_2 to FeXP and stabilized the oxygenated complex. Furthermore, PEG_{MY}(HSA−FeXP) exhibited a long circulation lifetime of FeXP in rats (13−16 h). On the basis of these results, it can be concluded that the surface modification of HSA−FeXP by PEG has improved its comprehensive O_2-transporting ability. In particular the PEG_{MY}(HSA−FeXP) solution could be a promising material for entirely synthetic O_2-carrying plasma expander as a red cell substitute.

INTRODUCTION

Poly(ethylene glycol) (PEG) is commonly used for the surface modification of peptides, proteins, enzymes, and liposome to confer several potential beneficial effects: not only a longer plasma half-life and nonimmunogenicity but also a solubility in organic solvents and extreme thermostability (*1*−*4*). To develop an artificial O_2 carrier, substantial efforts have been directed to the preparation of PEG-conjugated hemoglobin (Hb) over the past decades (*5*−*8*), and the optimized PEG−Hbs are currently being tested in clinical trials. Human serum albumin (HSA) is a versatile protein, which is found in our blood plasma at a high concentration (4−5 g dL^{-1}) (*9*). We have reported that HSA including tetrakis(*o*-amidophenyl)porphinatoiron(II) (Fe3P or Fe4P, Chart 1) [HSA−FeXP] can reversibly bind and release O_2 under physiological condition (pH 7.4, 37 °C) in a fashion similar to Hb (*10*). The administration of this synthetic O_2 carrier into anesthetized rats has proved its safety and O_2-transporting efficacy (*11*). Nevertheless, there is only one defect in that the FeXP molecule easily dissociates from HSA when infused into animals. This is due to the fact that FeXP is noncovalently bound to the hydrophobic cavity of albumin with binding constants (*K*) of 10^4−10^6 (M^{-1}). Natural heme, namely protoporphinatoiron IX, is also incorporated into HSA and shows a 10^2−10^4-fold higher *K* compared to FeXP (*12*); however, it is released from HSA during blood circulation with a half-life of 2.5−3.6 h (*13*, *14*). Under these circumstances,

Chart 1. Structures of O_2-Adduct Complexes of Tetrakis-(*o*-amidophenyl)porphinatoiron(II)



we postulated that the surface modification of HSA−FeXP by PEG could help to prolong the circulation life of FeXP and thereby retain its O_2-transporting ability for a long period. Although HSA is a very common plasma protein, its PEG conjugation chemistry has not yet been studied in detail. It is known that a huge variety of drugs are incorporated into specific sites of HSA (*9*). The PEG modification should prevent the rapid release of these drugs from the HSA scaffold and contribute to raising their potential therapeutic efficacies.

In the present study, we have systematically prepared several PEG-conjugated HSA−FeXPs and characterized their physicochemical properties. The surface modification by PEG affects the viscosity and colloid osmotic pressure of the solution, O_2-binding behavior of the parent HSA−FeXP, and circulatory lifetime of FeXP. The PEG-conjugated HSA−FeXP could be

of extreme medical importance as a red cell substitute or O_2-therapeutic reagent.

EXPERIMENTAL PROCEDURES

Materials and Apparatus. All reagents were purchased from commercial sources as special grades and used without further purification. 2-Iminothiolane hydrochloride (IMT) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). α-[3-(3-Maleimido-1-oxopropyl)amino]propyl-ω-methoxy PEG [averaged Mw: 2333 (Sunbright ME-020MA, PEG_{M2}), averaged Mw: 5207 (Sunbright MEMAL-50H, PEG_{M5})] and α-succinimidyloxyglutaryl-ω-methoxy PEG [averaged Mw: 2325 (Sunbright MEGC-20HS, PEG_{S2}), averaged Mw: 5261 (Sunbright MEGC-50HS, PEG_{S5})] were purchased from NOF Corp. (Tokyo, Japan). 2-{8-(2-Methylimidazolyl-1-yl)-octanoyloxymethyl}-5,10,15,20-tetrakis{α,α,α,α-*o*-(1-methylcyclohexanamido)phenyl}porphinatoiron(III) chloride (Fe4P) and 5,10,15-tris{α,α,α-*o*-(1-methylcyclohexanamido)-phenyl}-20-mono-[β-*o*-{6-(2-methylimidazolyl) hexanamido}-phenyl]porphinatoiron(III) chloride (Fe3P) were synthesized using previously reported procedures (*10d,e*). Recombinant HSA was provided by the NIPRO Corp. (Osaka, Japan). The UV−vis absorption spectra were recorded using an Agilent 8453 UV−visible spectrophotometer fitted with an Agilent 89090A temperature control unit. The water was deionized using Millipore Elix and Simpli Lab-UV.

Preparation of PEG-Conjugated HSA−FeXP. The HSA−FeXP solutions ($X = 3$, 4, [HSA]: 5 g dL^{-1}, [FeXP]/[HSA]= 4 (mol/mol), pH 7.4) were prepared as described elsewhere (*10b,d*).

PEG_{MY}(HSA−FeXP): The modification of HSA−FeXP by α-maleimide-ω-methoxy PEG_{M2} was, for instance, carried out as follows. IMT (72 mg, 0.54 mmol) was slowly added to the HSA−FeXP solution (48 mL, [HSA]: 5 g dL^{-1}, [Fe4P] = 3 mM, pH 7.4) ([IMT]/[HSA] = 15/1, mol/mol) and gently stirred at room temperature in the dark. After 3 h, PEG_{M2} (1.44 g, [PEG_{M2}]/[HSA]:20/1, mol/mol) was added to the mixture, which was continually stirred for another 2 h. The resultant solution was ultrafiltered and washed by at least a 600 mL of phosphate-buffered saline (PBS) solution (pH 7.4) to remove any unreacted IMT and PEG_{M2} using the ADVANTEC UHP-76K holder with a Q0500 076E membrane (cutoff Mw: 50 kDa). The volume was finally condensed to 48 mL and sterilized by a DISMIC 0.45 μm filter, producing the PEG_{M2}(HSA−FeXP) solution. The FeXP concentration was determined by the assay of the iron ion by inductively coupled plasma (ICP) spectrometry using a Seiko Instruments SPS 7000A Spectrometer. The HSA concentration was calculated from the intensity of the circular dichroism spectrum at 208 nm, because the molar ellipticity of HSA (1.9×10^4 deg cm^2 $dmol^{-1}$) was unaltered after the PEG conjugation. Circular dichroism (CD) spectra were obtained using a JASCO J-725 spectropolarimeter. The concentration of the HSA sample was 0.15 μM in PBS, and quartz cuvettes with a 10-mm thickness were used for the measurements over the range of 195−250 nm. The PEG_{M2}(HSA−Fe3P) and PEG_{M5}-(HSA−Fe4P) solutions were also prepared by the same procedure. The product was sealed in a glass bottle under CO pressure and stored at 4 °C.

PEG_{SY}(HSA−Fe4P): The surface modification of HSA−Fe4P by α-succinimidyl-ω-methoxy PEG_{S2} was carried out as follows. PEG_{S2} (0.72 g, 0.36 mmol) was directly added to the HSA−Fe4P solution ([HSA]: 5 g dL^{-1}, [Fe4P] = 3 mM, pH 7.4) ([PEG_{S2}]/[HSA]:10/1, mol/mol), and the mixture was stirred at room temperature for 2 h. The resultant solution was ultrafiltered, condensed (48 mL), and sterilized as described above, producing the PEG_{S2}(HSA−Fe4P) solution. Using PEG_{S5} instead of PEG_{S2}, PEG_{S5}(HSA− Fe4P) was obtained. The Fe4P and HSA concentrations were determined by the same procedures for PEG_{MY}(HSA−FeXP).

Matrix-Associated Laser Desorption Ionization Time-of-Flight Mass Spectra (MALDI-TOF MS). The MALDI-TOF MS were obtained using a Shimadzu/Kratos AXIMA-CFR S/W Version 2, which was calibrated by BSA (Sigma A-0281) and HSA (Sigma A-3782). The specimens were prepared by mixing the aqueous sample solution (10 μM, 1 μL) and matrix (10 mg mL^{-1} sinapinic acid in 40% aqueous CH_3CN, 1 μL) on the measuring plate and air-drying.

Determination of Mean of PEG_{MY} Chains per Protein by Assay of Thiol Groups. The active thiol groups on the protein surface can be assayed by the disulfide exchange reaction with 2,2′-dithiopyridine (2,2′-DTP) to produce 2-thiopyridinone (2-TP) with an absorption at 343 nm (molar absorption coefficient (ϵ_{343}): 8.1×10^3 M^{-1} cm^{-1}) (*15*). Quantitative spectroscopic measurements conveniently provide the thiol concentration. The parent HSA−FeXP showed a small absorption band in this range, which should be subtracted from the spectrum after the disulfide exchange reaction. The difference in the thiol groups per HSA−FeXP before and after the PEG_{MY} modification corresponds to the mean of the PEG_{MY} chains on the protein surface.

Solution Properties. The viscosity and density of the PEG-conjugated HSA−FeXP solution (PBS, pH 7.4) were obtained using an Anton Paar DSC 300 capillary viscometer at 37 °C. The colloid osmotic pressures of the solutions (PBS, pH 7.4) were measured by a WESCOR 4420 Colloid Osmometer at 25 °C. A membrane filter with a 30 kDa cutoff was used.

O_2-Binding Parameters. O_2-binding to PEG-conjugated HSA−FeXP was expressed by eq 1,

$$\text{PEG(HSA}-\text{FeXP)} + \text{O}_2 \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} \text{PEG(HSA}-\text{FeXPO}_2\text{)} \quad (1)$$

where $K = k_{on}/k_{off}$. The O_2-binding affinity (gaseous pressure at half O_2 binding for FeXP, $P_{1/2} = 1/K$) was determined by spectral changes at various partial pressures of O_2/N_2 as previously reported (*10b,d*). The FeXP concentrations of 10−20 μM were normally used for the UV−vis absorption spectroscopy. The spectra were recorded within the range of 350−700 nm. The half-lifetime of the O_2-adduct complex was determined by the time dependence of the absorption intensity at 550 nm (O_2-adduct species). The association and dissociation rate constants for O_2 (k_{on}, k_{off}) were measured by a competitive rebinding technique using a Unisoku TSP-1000WK laser flash photolysis as reported in a previous paper (*16*).

Circulation Lifetime in Vivo. The animal investigations were carried out using twenty male Wistar rats (297 ± 29 g). All animal handling and care were in accordance with the NIH guidelines. The protocol details were approved by the Animal Care and Use Committee of Keio University. The PEG-conjugated HSA−FeXP solution (20% volume of the circulatory blood) was intravenously injected into rats from the tail vein (1 mL/min) under an inhalation anesthesia with diethyl ether ($n = 4$ each). Blood was taken from the tail vein at 3, 30 min, 1, 2, 4, 8, 16 h, 1, 2, 3 days (10 time points) after the infusion and then centrifuged to isolate the serum, which was colored brown by the presence of the sample. The animals were sacrificed after the experiments by hemorrhage. The FeXP concentration was measured by an iron ion assay using ICP spectrometry as described above.

RESULTS AND DISCUSSION

Synthesis of PEG-Conjugated HSA−FeXP. The HSA−FeXP molecules were conjugated with PEG having a terminal reactive chain-end, maleimide-PEG or succinimide-PEG, at

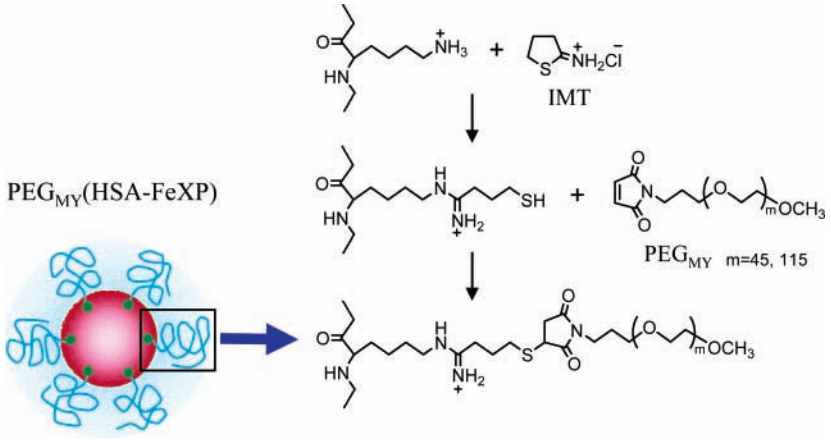

Figure 1. Two-step reaction schemes of IMT and maleimide-PEG (PEG$_{MY}$) with HSA−FeXP.

ambient temperature. Thiolation regent, IMT, quantitatively reacted with the amino groups of Lys to create active thiol groups, which bind to the α-maleimide-ω-methoxy PEG (PEG$_{M2}$ or PEG$_{M5}$) (Figure 1). The two-step reaction is reproducible and did not form any toxic side-product. On the other hand, the α-succinimidyl-ω-methoxy PEG (PEG$_{S2}$ or PEG$_{S5}$) directly binds to the amino groups of Lys. The gel permeation chromatogram (Sephacryl 200HR) of the well-washed PEG conjugate exhibited a single band, so that we did not need any further chromatographic purification.

The MALDI-TOF MS of PEG$_{M5}$(HSA−Fe4P), as prepared under the condition of [IMT]/[HSA−Fe4P] = 15/1 (mol/mol), showed five distinct ion peaks at 85, 90, 95, 101, and 106 kDa (Figure 2a). No unreacted HSA−FeXP was observed at all. The difference in each mass was 5.25 kDa, which implies that HSA−Fe4P is covalently bound to PEG$_{M5}$ and the individual peaks are attributed to PEG$_{M5}$(HSA−Fe4P) having a different number of PEG chains. Here, we have to be cautious whether these mass values involve a molecular weight of Fe4P, because our previous MALDI-TOF MS experiments of HSA−Fe4P demonstrated a single peak of HSA (Mw: 66.5 kDa); the incorporated Fe4P dissociated from the albumin during the ionization process (*10a*). In this study, we found that the mean of the surface PEG chains on HSA−FeXP is conveniently determined by a spectroscopic assay of the HSA scaffold and thiol groups. In general, the concentration of HSA is measured by the absorption at 280 nm or bromcresol green method (*17*), but they are probably obstructed by the surface modification. We then employed a CD measurement to determine the HSA concentration. The comparison of the CD spectra of HSA and PEG−HSA solutions revealed that the molecular ellipcity of albumin ($\epsilon_{208} = 1.9 \times 10^4$ deg cm^2 dmol^{-1}) is unaltered even after the PEG binding. Moreover, the presence of FeXP does not disturb the CD in the range of 190−250 nm. Therefore, the HSA concentration of PEG modified HSA−FeXP was quantitatively determined by its CD intensity at 208 nm. On the other hand, the active thiol groups on proteins are generally assayed by a disulfide exchange reaction with 2,2′-DTP (*15*). The combination of these two methodologies allows us to estimate the number of thiols on HSA−FeXP. The mean of the thiol groups was 6.7 per protein after the thiolation by IMT ([IMT]/[HSA−Fe4P] = 15 mol/mol) and decreased to 0.6 after the reaction with 20-fold excess moles of PEG$_{M5}$ (Table 1). These results suggested that the mean of 6.1 reactive thiols was conjugated with PEG$_{M5}$. The averaged molecular weight of this PEG$_{M5}$(HSA−FeXP) calculated from the intensity of the MS peak was 95 kDa. If one subtracts the total mass of the six PEG$_{M5}$ chains (5 kDa × 6 = 30 kDa) from 95 kDa, the difference of 65 kDa equals that

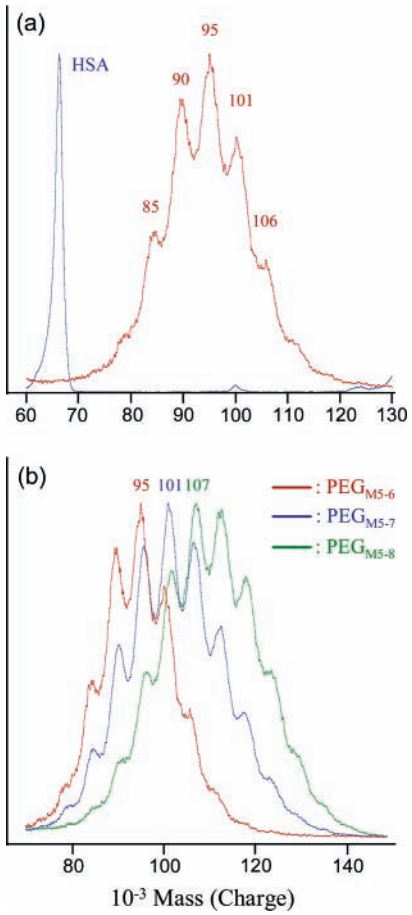

Figure 2. MALDI-TOF MS of (a) HSA and PEG$_{M5-6}$(HSA−Fe4P) and (b) PEG$_{M5}$(HSA−Fe4P) prepared in different [IMT]/[HSA−Fe4P] ratios of 15 (red), 20 (blue), and 30 (green) (mol/mol).

of HSA without Fe4P. Therefore, we concluded that all the mass ion peaks observed in the MALDI-TOF MS did not include the molecular weight of FeXP.

The number of the meleimide-PEG$_{M5}$ chains on HSA−Fe4P were modulated by the mixing ratio of [IMT]/[HSA−Fe4P] (mol/mol). The maximum peak of PEG$_{M5}$(HSA−Fe4P) in the MALDI-TOF MS significantly shifted to the higher molecular region (95 → 101 → 107 kDa) by increasing the IMT (Figure 2b). It is quite remarkable that the distributions of the entire spectral pattern were always identical. The averaged binding number of the PEG$_{M5}$ chains per HSA estimated from the intensity of the mass peak was consistent with the number determined from the assay of the thiol groups (Table 1).

Table 1. The Mean of Thiol Groups per HSA−Fe4P Molecule and Binding Number of the PEG Chains

PEG	[IMT]/[HSA−Fe4P] mol/mol	thiol groups per HSA after IMT addition (A)	thiol groups per HSA after PEG binding (B)	decreased thiol groups (B − A)[a]	averaged PEG number from MS
PEG_{M2}	10	5.6	0.5	5.1	4.6

[a] This number corresponds to the binding numbers of PEG_{MY} on the protein surface.

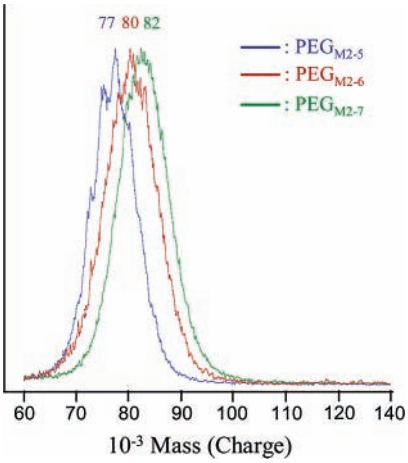

Figure 3. MALDI-TOF MS of PEG_{M2}(HSA−Fe4P) prepared in different [IMT]/[HSA−Fe4P] ratios of 10 (blue), 15 (red), and 20 (green) (mol/mol).

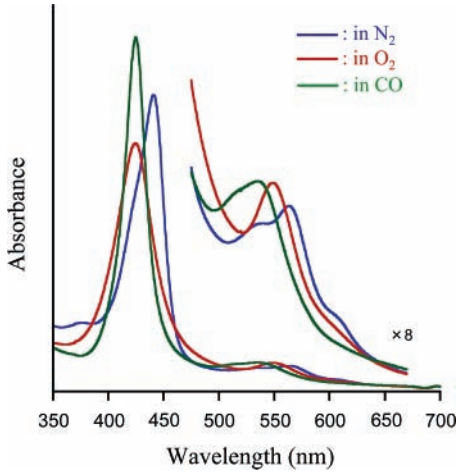

Figure 4. UV-vis absorption spectral change of PEG_{M2-6}(HSA−Fe4P) in PBS solution (pH 7.4).

Table 2. Solution Properties of PEG-Conjugated HSA−FeXP Solutions at 37 °C (pH 7.4, [FeXP] = 3 mM)

PEG	density (g/cm^3)	viscosity (cP)	COP (mmHg)
PEG_{M2-5}(HSA−Fe4P)	1.01	1.08	22
PEG_{M2-6}(HSA−Fe4P)	1.01	1.14	27
PEG_{M2-7}(HSA−Fe4P)	1.01	1.17	28
PEG_{M2-6}(HSA−Fe3P)	1.01	1.14	26
PEG_{M5-6}(HSA−Fe4P)	1.01	2.34	65
PEG_{S2-6}(HSA−Fe4P)	1.01	1.14	22
PEG_{S5-6}(HSA−Fe4P)	1.01	2.30	45
HSA−Fe4P	1.01	1.05	21
HSA	1.01	1.00	21

On the contrary, PEG_{M2}(HSA−Fe4P) demonstrated only one broad peak, because the difference in each mass is relatively close compared to the PEG_{M5} conjugate. The peak maxima of PEG_{M2}(HSA−Fe4P) also shifted to the higher region, dependent on the [IMT]/[HSA−Fe4P] ratio (Figure 3, Table 1).

The succinimide-PEG modified HSA−Fe4P showed the same MALDI-TOF MS patterns as PEG_{MY}(HSA−Fe4P) (data not shown). The number of 5-kDa PEG_{S5} chains per protein increased from 4 → 5 → 6 by elevating the ratio of [PEG_{S5}]/[HSA−Fe4P] (mol/mol): 10 → 20 → 30, respectively. However, the introduced 2-kDa PEG_{S2} number was always 6 in the range of [PEG_{S2}]/[HSA−Fe4P] 10−20. The stoichiometry of the PEG_{S2} binding could not be controlled. This is probably due to the hydrolysis of the succinimidyl end group in aqueous media. The concentration assays of [HSA] by CD and [FeXP] by ICP measurements showed that the initial FeXP/HSA ratio, 4/1 (mol/mol), were constant after the PEG conjugation.

Solution Properties. The viscosity and colloid osmotic pressure (COP) of the 2-kDa PEG-conjugates, PEG_{M2}(HSA−FeXP) and PEG_{S2}(HSA−Fe4P) (PBS solution, [HSA] = 5 g dL^{-1}, pH 7.4), were almost the same as those of the nonmodified HSA−FeXP independent of the number of the PEG chains (Table 2). In contrast, the 5-kDa PEG-conjugate solutions, PEG_{M5}(HSA−FeXP) and PEG_{S5}(HSA−Fe4P), showed a high viscosity (2.30−2.34, at a shear rate of 230 s^{-1}) and hyperoncotic property (45−65 mmHg) in comparison to those of HSA−Fe4P and HSA. From the viewpoint of the design of a blood alternative, it has to achieve a COP similar to that of human blood. However, to increase the effectiveness as a plasma expander, the COP should be higher than the physiological level (*18*). Similar approaches have been utilized for hypertonic saline−dextran formulations.

On the other hand, maintenance of the viscosity has recently been proposed as an important mechanism to preserve shear forces in the microcirculation which prevents loss of the functional capillary density (*19*). The latest PEG-Hb product has been designed to approach that of human whole blood (*7*). Anyway, the COP and viscosity of our PEG-conjugated HSA−FeXP can be adjustable to some extent based on the length of the PEG chains (2-kDa, 5-kDa) on the molecular surface.

O_2-Binding Properties. The UV−vis absorption spectrum of the PEG_{M2}(HSA−Fe4P) solution under an N_2 atmosphere showed λ_{max} at 441, 537, 563 nm (Figure 4), which indicates the formation of the ferrous five-N-coordinate high-spin complex of Fe4P with an intramolecular coordinated 2-methylimidazolyl-group (*10b,c, 20*). The other amino acid residue of HSA did not bind to the sixth-coordinate position of the central ferrous ion. Upon flowing O_2 gas through this solution, the spectral pattern shifted to that of the well-defined O_2-adduct complex of the tetrakis(phenyl)porphinatoiron(II) derivatives (λ_{max}: 424, 550 nm) (*10b,c, 20*). This oxygenation was reversibly observed, dependent on the O_2-partial pressure. After exposure of this solution to CO, PEG_{M2}(HSA−Fe4P) produced a very stable CO-adduct complex (λ_{max}: 425, 535 nm). The all maleimide- and succinimide-PEG-conjugated HSA−FeXP solutions showed similar UV−vis absorption spectra under N_2, O_2, and CO atmospheres. These spectral changes were completely the same as that observed in the nonmodified HSA−Fe4P.

Table 3. O_2-Binding Parameters of PEG-Conjugated HSA−FeXP Solution at 25 °C (pH 7.4)

system	k_{on} ($\mu M^{-1} s^{-1}$) fast	k_{on} slow	k_{off} (ms^{-1}) fast	k_{off} slow	$P_{1/2}$ (Torr)	$\tau_{1/2}$ (h) at 37 °C
PEG_{M2-5}(HSA−Fe4P)	11	5.8	0.16	0.08	38 (11)	13

The time course of the absorption decay after laser flash photolysis determined the association rate constants of the O_2binding to the PEG-conjugated HSA−FeXP (k_{on}). We have previously reported that the O_2-binding reaction to HSA−FeXP was significantly affected by the microenvironment around FeXP in the protein (e.g., steric hindrance of the amino acid residue and difference in polarity) (*10c*−*e*). As a result, the binding process of O_2 was observed as the sum of the two single-exponentials, giving fast and slow association rate constants [k_{on}-(fast) and k_{on}(slow)]. This unique property of HSA−FeXP has been unaltered after the surface modification by PEG, and all kinetics accompanying the O_2 recombinations consisted of two phases (Table 3). Interestingly, their k_{on}(fast) values were 1.9−3.3-fold lower than those of the corresponding HSA−FeXP, independent of the molecular weight (2-kDa or 5-kDa) and the linkage structure of the PEG. The differences observed in the slow phase were smaller. It may be considered that the presence of flexible polymers on the protein surface retarded the diffusion of the O_2 molecule.

The O_2-binding affinities ($P_{1/2} = K(O_2)^{-1}$) of the PEG-modified HSA−FeXP series were determined by measuring the UV−vis absorption spectral changes by O_2/N_2 titration (Table 3). All the PEG conjugates showed almost the same $P_{1/2}$ values relative to that of the original HSA−FeXP, indicating that the O_2-binding equilibria were not influenced by the presence of PEGs. In contrast, the surface modification by PEG delayed the proton-driven oxidation of the $FeXPO_2$ species and prolonged the half-lifetime of the O_2-adduct complex [$\tau_{1/2}(O_2)$]. The PEG_{M5-6}(HSA−Fe4P)O_2 complex showed the longest $\tau_{1/2}(O_2)$ of 16 h at 37 °C, which is greater than those of HSA−Fe4P and natural hemoprotein, myoglobin ($\tau_{1/2}(O_2)$: 12 h at pH 7, 35 °C) (*21*). Basic polymer PEG conjugation might change the local proton concentration of the HSA interior compared to the outer aqueous solution. Actually, it was shown that the surface PEG modification of hemoproteins has modulated the redox behavior of the active heme site (*1*, *2*, *22*).

Circulation Lifetime in Bloodstream of Rats. The circulation persistence of FeXP in the bloodstream after the administration of PEG_{MY-6}(HSA−FeXP) or PEG_{SY-6}(HSA−Fe4P) solution in rats is shown in Figure 5. The concentration decays of the PEG_{MY}(HSA−FeXP) series showed single exponentials, and the half-lifetimes ($\tau_{1/2}$) were 12.9−15.8 h, independent of the molecular weight of the polymers and FeXP structures. These values are much longer than those of the corresponding nonmodified HSA−FeXP (0.6−3.2 h) (*23*). The surface modification by PEG significantly prevented the rapid clearance of the incorporated FeXP and contributed to increasing the O_2-transporting efficacy.

On the contrary, the PEG_{SY}(HSA−Fe4P) series showed biphasic kinetics and a $\tau_{1/2}$ value of 1.5−2.1 h. We have postulated two reasons for this short circulation lifetime. The first reason is the charges of the Lys residues. The maleimide-PEG connects to Lys through the ring-opened IMT, which maintains the positive charge of Lys; therefore, PEG_{MY}(HSA−FeXP) could preserve the total electrostatic potential of albumin. In contrast, the succinimide-PEG directly binds to the amino group of Lys to form the amide bond, thereby reducing the positive charge and alters the surface electrostatic potential. This changing of the molecular charge may influence the rapid clearance of the incorporated FeXP.

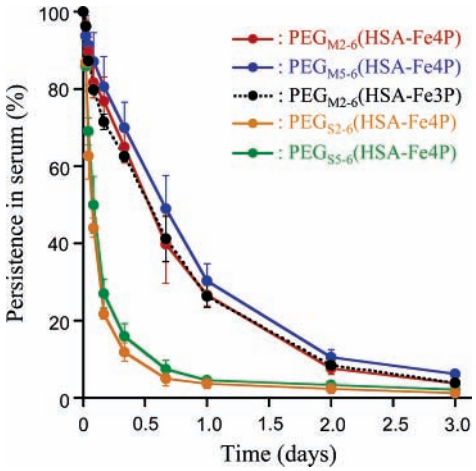

Figure 5. Persistence of FeXP in serum after administration of PEG-conjugated HSA−FeXP into Wistar rats. All values are mean ± SD (n = 4).

The second probability is the binding sites of the PEG chains. As shown in Table 1, the difference in the thiol number per protein before and after the reaction with maleimide-PEG was 0.5−1.1. This means that the binding position of PEG_{MY} is governed by the reaction place of IMT, which is small enough to statistically attach 59 Lys in HSA. Thus, the molecular surface of HSA−FeXP is uniformly covered by PEG_{MY}. On the other hand, the attaching sites of succinimide-PEG are presumably heterogeneous, because PEG_{SY} could only bind the accessible amino group of Lys due to the bulkiness of the long polymer. The incorporated Fe4P molecules might be more easily released from the PEG_{SY}-modified HSA in the circulatory system.

CONCLUSIONS

The surface modification of the albumin-based synthetic hemoprotein, HSA−FeXP, by PEG (Mw 2-kDa or 5-kDa) has improved its comprehensive O_2-transporting ability. The PEG conjugation decreased the O_2-association rate constant but retarded the irreversible oxidation of the central ferrous ion, thereby increasing the stability of the O_2-adduct complex. The 5-kDa PEG conjugation increased the viscosity and COP; however, the 2-kDa PEG conjugation did not change these rheological parameters. The linkage form of the PEG chain dramatically affects the circulation persistence of FeXP. In particular, the maleimide-PEG_{MY} conjugates showed a 6−8-fold longer lifetime compared to the succinimide-PEG_{SY} analogues. This is not dependent on the molecular weight of the polymer chains. In summary, the PEG_{MY}(HSA−FeXP) solution is the most promising candidate as an entirely synthetic O_2-carrying plasma expander for a red cell substitute.

Furthermore, we have recently found that water evaporation of the PEG_{MY}(HSA−FeXP) solution produced a red-colored thin film. Its UV−vis absorption spectrum reversibly changed from the deoxy state under an N_2 atmosphere to the oxy state by exposure to O_2 gas. This PEG_{MY}(HSA−FeXP) film was redissolved in nonaqeuous organic solvents, ethanol, chloroform, etc., and the reversible O_2 binding was again observed. The detailed study of the oxygenations of PEG_{MY}(HSA−FeXP) in a cast film and organic solvent are now underway.

ACKNOWLEDGMENT

This work was partially supported by a Grant-in-Aid for Scientific Research (No. 16350093) from JSPS, a Grant-in-Aid for Exploratory Research (No. 16655049) from MEXT Japan, and Health Science Research Grants (Regulatory Science) from MHLW Japan. Prof. Koichi Kobayashi, Dr. Hirohisa Horinouchi (Keio University), and Mr. Hisashi Yamamoto (NIPRO Corp.) are greatly appreciated for their cooperation with the animal experiments.

Epidermal Growth Factor-Conjugated Poly(ethylene glycol)-*block*-Poly(*δ*-valerolactone) Copolymer Micelles for Targeted Delivery of Chemotherapeutics

Faquan Zeng,[†] Helen Lee,[†] and Christine Allen*[,†,‡]

Departments of Pharmaceutical Sciences and Chemistry, University of Toronto, 19 Russell St., Toronto, Ontario, Canada M5S 2S2. Received December 8, 2005

Epidermal growth factor (EGF)-conjugated copolymer micelles were prepared from a mixture of diblock copolymers of methoxy poly(ethylene glycol)-*block*-poly(*δ*-valerolactone) (MePEG-*b*-PVL) and EGF-PEG-*b*-PVL for targeted delivery to EGF receptor (EGFR)-overexpressing cancers. The block copolymers and functionalized block copolymers were synthesized using PEG as the macroinitiator and HCl−diethyl ether as the catalyst. The MePEG-*b*-PVL and the carboxyl-terminated PEG-*b*-PVL (HOOC-PEG-*b*-PVL) copolymers were found to have molecular weights of 5940 and 5900, respectively, as determined by gel permeation chromatography (GPC) analyses. The HOOC-PEG-*b*-PVL copolymers were then activated by *N*-hydroxysuccinimide and subsequently reacted with EGF to form the EGF-PEG-*b*-PVL copolymers. The efficiency for the conjugation of EGF to the copolymer was found to be 60.9%. A hydrophobic fluorescent probe, CM-DiI, was loaded into both the nontargeted MePEG-*b*-PVL micelles and the targeted EGF-conjugated PEG-*b*-PVL micelles. The effective mean diameters of the CMDiI-loaded nontargeted and the CMDiI-loaded targeted micelles were found to be 32 ± 1 nm and 45 ± 2 nm, respectively, as determined by dynamic light scattering (DLS). The zeta potentials for the nontargeted micelles (no CM-DiI-loaded), CM-DiI-loaded nontargeted micelles, and CM-DiI-loaded targeted micelles were found to be −6.5, −8.7, and − 13.5 mV, respectively. Evaluation of the in vitro release of CM-DiI from the MePEG-*b*-PVL micelles in phosphate buffer saline (0.01 M, pH = 7.4) containing 10% (v/v) fetal bovine serum at 37 °C revealed that approximately 20% of the probe was released within the first 2 h. Confocal laser scanning microscopy (CLSM) analysis revealed that the targeted micelles containing CM-DiI accumulated intracellularly in EGFR-overexpressing MDA-MB-468 breast cancer cells following a 2 h incubation period, while no detectable cell uptake was observed for the nontargeted micelles. Results obtained from the confocal images were confirmed in an independent study by measuring the intracellular CM-DiI fluorescence in cell lysate. In addition, the presence of free EGF was found to decrease the extent of uptake of the targeted micelles. Nuclear staining of the cells with Hoechst 33258 indicated that the targeted micelles mainly localized in the perinuclear region and some of the micelles were localized in the nucleus. These results demonstrate that the EGF-conjugated copolymer micelles developed in this study have potential as vehicles for targeting hydrophobic drugs to EGFR-overexpressing cancers.

INTRODUCTION

In recent years, active targeting of colloidal drug carriers has gained increasing interest in the field of drug delivery. The enhanced therapeutic efficacy of anticancer drugs delivered in conventional colloidal carriers has mainly been attributed to increased tumor accumulation due to the enhanced permeation and retention (EPR) effect, also known as passive targeting. Active targeting of a delivery system should result in higher intracellular drug concentrations and therefore a further improvement in drug safety and efficacy. Indeed, the cell-type specificity introduced by these actively targeted drug carriers through ligand-conjugation has been shown to result in enhanced therapeutic efficacy and reduced systemic toxicity in several studies (*1*−*5*).

To date, active targeting of drug delivery vehicles as a strategy to improve tumor therapy has been most extensively pursued with long circulating liposomes (*5*−*7*). A wide variety of moieties, such as monoclonal antibodies (mAbs) (*2*, *5*, *7*−*9*) and growth factors (*6*, *10*, *11*), have been conjugated to the liposome surface as a means to achieve active targeting. Ishida et al. reported both increased in vitro cytotoxicity and in vivo therapeutic efficacy for doxorubicin formulated in mAb-conjugated liposomes that target CD19, an antigen expressed on B-lymphoma cells (*9*). Other examples of targeted systems include the anti-HER2-liposomes (*2*) and the F(ab′)$_2$/GAH-liposomes (*5*) for treatment of breast and gastrointestinal cancers, respectively. A few actively targeted liposome formulations are entering and have already entered clinical trial development (*7*, *12*). Therefore, much success has been realized with active targeting of liposome-based systems; however, this technology is most suitable for delivery of hydrophilic drugs or molecules that are susceptible to active loading techniques (*13*).

The hydrophobic nature of many anticancer drugs has directed researchers toward the design and development of other delivery strategies including polymeric nanoparticles (*14*, *15*), lipid micelles (*4*, *16*, *17*), and block copolymer micelles (*18*, *19*). Amphiphilic diblock copolymers with PEG as the hydrophilic block and a poly(ester) (*18*, *20*−*22*), poly(amino acid) (*23*−*26*), or poly(ether) (*27*−*29*) as the hydrophobic block have been explored extensively for applications in drug delivery. In an aqueous medium, these copolymers self-assemble to form micelles that consist of a hydrophobic core surrounded by a hydrophilic shell. The hydrophobic core may serve as a nanoreservoir for loading hydrophobic drugs, while the hydrophilic shell provides a protective coating between the core and

the external medium. Drug formulations based on block copolymer micelles have entered clinical trial development, and others have shown promise in preclinical evaluation (*30*−*32*).

To this point, few studies have focused on the preparation and characterization of actively targeted systems formed from micelles. One of the earliest reports on active targeting of a micelle system was put forth by Kabanov's group and included α_2-glycoprotein-conjugated Pluronic micelles. The α_2-glycoprotein-micelles were shown to have increased brain tissue localization and decreased clearance by the lung, when compared to nontargeted micelles (*33*, *34*). Recently, Yoo and Park also prepared folate-conjugated PEG-*b*-poly(lactide-*co*-glycolide) micelles loaded with doxorubicin for active targeting to folate receptor-overexpressing cancers such as epidermal carcinoma. Their experimental results revealed that both the in vitro IC_{50} and the in vivo tumor volume were reduced when treating the folate receptor-overexpressing cancers with doxorubicin formulated in these micelles (*3*). Also, Torchilin's group has demonstrated that lipid immuno-micelles, with the monoclonal antibody 2C5 attached to the surface, actively target Lewis lung tumors in nude mice (*4*, *35*).

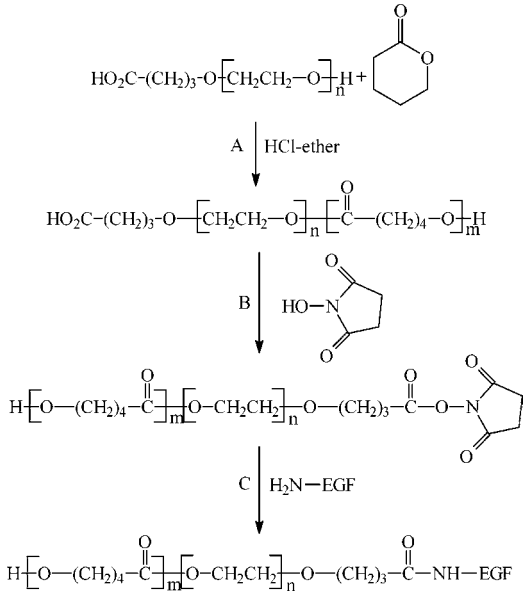
At present, our group is focused on developing a diblock copolymer micelle system conjugated with epidermal growth factor (EGF) for active targeting to EGF receptor (EGFR)-overexpressing cancers. It is established that the EGF receptor is overexpressed in various human cancers such as lung, prostate, and breast (*36*). Therefore, several cancer treatments are being developed with the aim of targeting EGFR (*2*, *11*, *37*). For example, the radiopharmaceutical ^{111}In-DTPA-hEGF for treatment of EGFR-overexpressing breast cancer developed by Reilly's group is now in phase I clinical trial development (*38*, *39*). Several EGF-conjugated liposome-based formulations have also been designed (*6*, *10*, *11*, *40*). For example, Gedda's group has investigated the use of an EGF-conjugated liposome to overcome problems such as the low degree of specificity and the insufficient intracellular agent concentrations that are typically associated with boron capture neutron therapy (*6*, *10*, *11*). However, to date the utilization of EGF as a targeting moiety for a block copolymer micelle system has not been reported.

In an attempt to design and develop a novel, cancer cell specific delivery system we have synthesized a new telechelic diblock copolymer, carboxyl-terminated poly(ethylene glycol)-*b*-poly(δ-valerolactone) (HOOC-PEG-*b*-PVL) and conjugated EGF to the PEG terminus of the copolymer. GPC and ^{1}H NMR were used to confirm that the macroinitiator was consumed and the copolymer molecular weight and composition were as predicted. The successful conjugation of EGF to the copolymer was verified using an established in vitro assay. The critical micelle concentration (CMC) of the MePEG-*b*-PVL copolymer was measured using a traditional fluorescence-based method. The CellTracker fluorescent probe, CM-DiI, was physically entrapped within both the nontargeted and targeted micelles. CM-DiI-loaded nontargeted MePEG-*b*-PVL micelles and CM-DiI-loaded targeted EGF-conjugated micelles were prepared and characterized in terms of size, size distribution, and zeta potential. Cellular uptake of the nontargeted and targeted CM-DiI-loaded micelles was evaluated quantitatively using a fluorescence-based method and also monitored using confocal laser scanning microscopy (CLSM) in EGFR-overexpressing MDA-MB-468 breast cancer cells. Overall, these studies demonstrate the cell-type specific active targeting of nanosized copolymer micelles to EGFR-overexpressing breast cancer cells via receptor−ligand mediated internalization.

EXPERIMENTAL SECTION

Materials. MePEG (M_n= 2 000, M_w/M_n= 1.06 as determined by SEC) from Sigma-Aldrich and α-carboxyl-ω-hydroxyl-terminated PEG from Polymer Source Inc. (M_n = 2 000, M_w/M_n = 1.16) were dried twice by azeodistillation of toluene. Hydrogen chloride (1 M in diethyl ether, HCl−ether), 1,6-diphenyl-1,3,5-hexatriene (DPH), *N*-hydroxysuccinimide (NHS), and dicyclohexylcarbodiimide (DCC) were purchased from Sigma-Aldrich (Oakville, Ontario). Fluorescent probes including CellTracker CM-DiI, fluorescein phalloidin, and Hoechst 33258 were purchased from Molecular Probes Inc. (Eugene, OR). Toluene and δ-valerolactone (VL) were dried under calcium hydride and distilled prior to use. Other solvents such as hexane, ethyl ether, chloroform, acetone, and *N*,*N*-dimethylformamide were used as received.

Scheme 1. Scheme for Synthesis of HOOC-PEG-*b*-PVL, NHS-Activated PEG-*b*-PVL, and EGF−PEG-*b*-PVL Copolymers



Synthesis of MePEG-*b*-PVL. The block copolymer was synthesized using a metal-free cationic method (*41*). A typical procedure was carried out as follows: In a flame dried flask, 5 g of monomethoxy-terminated poly(ethylene glycol) (2.5 mmol, M_n = 2 000, M_w/M_n = 1.06) was added and dried twice by toluene azeodistillation. An amount of 50 mL of dichloromethane (dried by calcium hydride) and 5 g of VL (50 mmol, dried and distilled over calcium hydride) were then added to the flask. 7.5 mL (1 M, 7.5 mmol) of the catalyst, hydrogen chloride in ether, was added to the mixture at 0 °C, and the reaction was maintained for 3 h at this temperature. The reaction was terminated by the addition of 0.5 mL of triethylamine, and the reaction mixture was then filtered. The copolymer was collected by precipitation in ether. The molecular weight of the PVL block was calculated from ^{1}H NMR and the known molecular weight of the MePEG precursor. ^{1}H NMR assignments were: 3.60 ppm for the MePEG unit (4H, b, OCH_2CH_2), signals for the PVL block appeared at 1.68 ppm (4H, m, $COCH_2CH_2CH_2CH_2O$), 2.35 ppm (2H, m, $COCH_2CH_2CH_2$-CH_2O), and 4.08 ppm (2H, m, $COCH_2CH_2CH_2CH_2O$).

Synthesis of α-Carboxy-ω-hydroxy-Terminated PEG-*b*-PVL (HOOC−PEG-*b*-PVL). Carboxyl-terminated PEG-*b*-PVL was synthesized using a similar method as that outlined for the synthesis of MePEG-*b*-PVL. The synthetic scheme is shown in Scheme 1A, and the detailed assignment for the ^{1}H NMR spectrum has been provided in the Results section.

Synthesis of NHS Activated PEG-*b*-PVL (NHS−PEG-*b*-PVL). To a round-bottom flask equipped with a magnetic stir bar and a rubber septum, attached to a nitrogen line and a bubbler, 0.5 g of α-carboxy-ω-hydroxy-terminated-PEG-*b*-PVL (0.128 mmol), 0.0396 g of *N*,*N*′-dicyclohexylcarbodiimide (1.5×

excess, 0.192 mmol), 0.0221 g of *N*-hydroxysuccinimide (1.5× excess, 0.192 mmol), and 5 mL of dichloromethane were added. The reaction was maintained for 24 h at room temperature. The reaction mixture was then filtered, concentrated under reduced pressure, and precipitated in cold diethyl ether. The yield was found to be 0.38 g (i.e. 76%).

Synthesis of EGF-Conjugated PEG-*b*-PVL (EGF−PEG-*b*-PVL). 5 mg of NHS-PEG-*b*-PVL ($M_{n,NMR}$ = 4569, M_w/M_n=1.32) was added to a solution of 100 μg of EGF in 0.6 mL PBS (pH = 7.4, equiv. 166 μg/mL). Following 4 h, an additional 5 mg of NHS-PEG-*b*-PVL was added to the reaction mixture. The reaction was then maintained for 24 h at room temperature. Following this period the reaction mixture was dialyzed against water using cellulose ester membrane with a molecular weight cut-off of 8000 (Spectrum Laboratories Inc.; Rancho Dominguez, CA) for 48 h in order to remove the uncoupled EGF (*42*). The EGF-conjugation efficiency was measured using the Micro BCA Protein Assay (Pierce Inc.; Rockford, IL) (*42*).

Characterization of Block Copolymers. ^{1}H NMR spectra were obtained on a Gemini 200 spectrometer (200 MHz for ^{1}H) in $CDCl_3$ solvent. Chemical shifts were reported in ppm with $CHCl_3$ as the internal standard. GPC measurements were carried out at room temperature using a Waters 590 liquid chromatography system equipped with three Waters Styragel HR 4E columns and a 410 differential refractometer detector. THF with 1% triethylamine was used as the solvent at a flow rate of 1.0 mL/min at 40 °C. Narrow polystyrene standards (Polysciences Inc.; Warrington, PA) were used to generate a calibration curve. The data obtained were recorded and manipulated using the Windows-based Millenium 2.0 software package (Waters Inc.; Milford, MA).

Measurement of Critical Micelle Concentration. The CMC of the MePEG-*b*-PVL copolymer was determined using an established fluorescence-based method (*43*). The copolymer studied had a total molecular weight of 4040 g/mol and block lengths of 2000-*b*-2020 (i.e. *x*-*b*-*y*, where *x* denotes the molecular weight of MePEG and *y* the molecular weight for PVL) as determined by ^{1}H NMR. In short, a specific aliquot of MePEG-*b*-PVL dissolved in chloroform was added to glass vials such that the concentration of copolymer ranged from 0.1 to 200 mg/L. An aliquot of a DPH stock solution was then added to each vial such that the concentration of DPH was maintained at 1 mg/L in each solution. The solutions were vigorously stirred for 4 h and then thoroughly dried under nitrogen. The dried vials were heated to 60 °C, and 1 mL of double distilled water was added into each vial. The solutions were equilibrated with stirring overnight at room temperature, and the fluorescence emission was measured at 430 nm (λ_{ex} = 350 nm) using a Spectra GeminiXS dual-scanning microplate spectrofluorometer (Molecular devices; Sunnyvale, CA).

Preparation of CM-DiI-Loaded Copolymer Micelles. 10 μg of CM-DiI and 5 mg of MePEG-*b*-PVL were codissolved in DMF. After stirring for 4 h, the DMF was removed under nitrogen. The dried CM-DiI-copolymer film was then heated to 60 °C and hydrated with 1 mL of PBS (0.01 M, pH = 7.4). For preparation of the targeted micelles, 0.25 mg of the EGF-PEG-*b*-PVL copolymer dissolved in filtered deionized water was added to the preformed nontargeted MePEG-*b*-PVL micelles. The mixture was stirred at 60 °C for 1 h and then overnight at room temperature (*10*).

Size and Size Distribution of Micelles (+/− EGF). The hydrodynamic diameters of micelles were determined by dynamic light scattering (DLS) at an angle of 90° and a temperature of 25 °C (90Plus Particle Size Analyzer; Brookhaven Instruments Corporation; Holtsville, NY). The sample solutions were diluted in distilled water and filtered prior to analysis (0.22 μm Millipore filter). The copolymer concentrations of the analyzed sample solutions were approximately 1 mg/mL. BIC Particle Sizing software was employed to determine the effective mean diameters of the targeted and nontargeted copolymer micelles (+/− EGF) using cumulant analysis. The software also determines the size distribution by multimodal size distribution analysis in which the data are fitted using the non-negatively constrained least squares (NNLS) algorithm.

Zeta Potential of Micelles. The zeta potentials of nontargeted, CM-DiI-loaded nontargeted and CMDiI-loaded targeted micelles were measured using a Zetasizer 3000HSA (Malvern Instruments). Micelle solutions were prepared as described above and were diluted 40 times in double-distilled water. The zeta potential measurements were analyzed using the Photon Correlation Spectroscopy software (version 1.6.1).

In Vitro Release of CM-DiI-Loaded MePEG-*b*-PVL Micelles. The release kinetics of the CM-DiI-loaded micelles was investigated using the dialysis method (*44*). Briefly, a micelle solution was placed in Spectra/Por 7 dialysis membrane with a molecular weight cut-off of 10 000 and dialyzed against an excess amount of PBS containing 10% (v/v) fetal bovine serum (FBS) at 37 °C. A 50 μL aliquot of the micelle sample was removed from the dialysis membrane at designated time points. A calibration curve for CM-DiI was obtained (i.e. linear range from 0.01 to 1.00 μg/mL), and the fluorescence intensity of the collected samples was measured (Fluoro Max-3, Jobin Yvon Inc.).

Cell Culture. EGFR-overexpressing breast cancer cells (MDA-MB-468) were kindly donated by Dr. R. M. Reilly (University of Toronto). The MDA-MB-468 cells were maintained in Dulbecco's Modified Eagle Medium (DMEM). The DMEM was supplemented with 10% (v/v) heat-inactivated FBS and 1% (v/v) penicillin−streptomycin (100 U/mL penicillin G and 100 μg/mL streptomycin). Cells were allowed to grow in a monolayer in a tissue culture flask incubated at 37 °C in 5% CO_2 atmosphere and 90% relative humidity.

Quantitative Evaluation of Cell Uptake. MDA-MB-468 cells were seeded onto 24-well plates at a density of 80 000 cells/well and then incubated for 24 h prior to treatment. As a negative control, cells were incubated with only DMEM. Targeted micelles (+ EGF) or nontargeted MePEG-*b*-PVL micelles (− EGF) were diluted in prewarmed DMEM to achieve a final CM-DiI concentration of 4 μM. For positive controls, free CM-DiI in sterile DMSO was diluted to a final CM-DiI concentration of 4 μM or 0.88 μM (i.e. equivalent to the 22% of the total CM-DiI loaded that is anticipated to be released from micelles during the 2 h incubation; refer to Results section). The cells were incubated with the treatments for 2 h at 37 °C. For competitive binding, the cells were preincubated with 1.7 μg/well of free EGF for 30 min at 37 °C prior to the addition of targeted micelles. The cells were washed with warm PBS three times to remove unbound micelles or free CM-DiI and trypsinized for fluorescence and cell viability measurements. To quantify CM-DiI fluorescence the cells were lysed with lysis buffer (2% Triton X-100 in PBS) and the fluorescence intensity was measured at λ_{ex} = 553 nm and λ_{em} = 570 nm (Fluoro Max-3, Jobin Yvon Inc.). Cell uptake was expressed as relative fluorescence normalized to the number of cells in each well as determined using the MTT assay described below.

Cell Fixation for Confocal Microscopy. MDA-MB-468 cells were seeded onto two-well Lab-Tek II Chamber Slide System (Nalge Nunc International; Naperville, IL) at a cell density of 300 000 cells/well. The cells were then incubated for 24 h to allow for adhesion prior to the cell uptake studies. The cells were treated with CM-DiI-loaded nontargeted or targeted micelles as described above. Following the incubation period the cells were washed with warm PBS three times in order to remove the unbound micelles. For fixation of the cells, 3.7%

Table 1. Summary of the Characteristics of the Block Copolymers

sample	$M_{n,GPC}$	$M_{n,PEG}$	$M_{n,PVL}$[a]	M_w/M_n	CMC (mg/L)
MePEG-*b*-PVL	5940	2000	2020	113	23.3
HOOC-PEG-*b*-PVL	5900	2000	1890	1.32	n.d.

[a] Molecular weight determined by ^{1}H NMR. $M_{n,PEG} + M_{n,PVL} = M_{n,NMR}$.

formaldehyde (Sigma-Aldrich; Oakville, Ontario) in PBS was added and the cells were incubated at room temperature for 10 min. The cells were then once again washed with warm PBS three times. Finally, the chambers were removed; the specimen was mounted with ProLong Gold anti-fade reagent (Molecular Probes Inc.; Eugene, OR) and a coverglass was added for confocal microscopy imaging.

Cytoplasmic and Nuclear Staining. Following cell fixation with 3.7% formaldehyde, 0.1% Triton X-100 (Sigma-Aldrich; Oakville, Ontario) in PBS was added and the cells were incubated at room temperature for 5 min for membrane permeabilization. The cells were then washed three times with warm PBS and incubated with fluorescein phalloidin in PBS (165 nM) at room temperature for 20 min to allow for cytoplasmic staining. Prior to proceeding to nuclear staining, the cells were washed with warm PBS three times to remove excess fluorescein phalloidin. An aliquot of Hoechst 33258 in water (5 μg/mL) was then added, and the cells were incubated for 5 min at room temperature. Excess Hoechst solution was removed by washing the cells with warm PBS three times, and the slides were then processed for mounting.

Confocal Laser Scanning Microscopy. Confocal fluorescence imaging was performed on an inverted microscope (Zeiss LSM510 META NLO) that is equipped with both confocal and two-photon scanning systems. CM-DiI (λ_{ex} = 553 nm; λ_{em} = 570 nm) and fluorescein phalloidin (λ_{ex} = 496 nm; λ_{em} = 516 nm) were excited by HeNe (543 nm) and argon (488 nm) lasers, respectively. Hoechst 33258 (λ_{ex} = 350 nm; λ_{em} = 452 nm) was excited by the tunable two-photon Chameleon laser at 750 nm. All images were acquired with a C-Apo 63×/1.4 oil lens. During the acquisition of all images, microscope settings including detector gain, amplification offset, amplification gain, and laser power were kept constant in order to allow for a comparison of the cell uptake of targeted and nontargeted micelles.

Cell Proliferation Studies. MDA-MB-468 cells were seeded onto 96-well plates at a density of 5000 cells/well and were incubated for 24 h prior to treatment. Free EGF, nontargeted micelles (MePEG-*b*-PVL) and targeted micelles (EGF-PEG-*b*-PVL) were diluted in DMEM such that the EGF and copolymer concentrations were identical to those employed during treatment with the targeted micelles. The cells were treated in triplicate and were incubated for 48 h prior to the assessment of cell viability. Cell viability was determined using the MTT assay as outlined in detail elsewhere (*45*). Briefly, 10 μL of 5 mg/mL of thiazolyl blue tetrazolium bromide solution was added to each well. Following a 4 h incubation period, the cells were lysed and cell viability was measured by optical absorbance at 570 nm using a SpectraMax plus microplate reader (Molecular Devices, Sunnyvale, CA). Cell viability was expressed relative to that of untreated cells which was assumed to have 100% viability.

RESULTS

Synthesis and Characterization of MePEG-*b*-PVL Copolymers. As shown in Table 1, the molecular weight of the MePEG-*b*-PVL copolymer was found to be 4020 and 5940 as determined by ^{1}H NMR and GPC analysis, respectively. The discrepancy between the values obtained for the molecular weight of the copolymer from ^{1}H NMR and GPC analyses may be attributed to the difference between the hydrodynamic volumes of the block copolymers and the polystyrene standards. The polydispersity of the copolymer was found to be M_w/M_n = 1.13 as determined by GPC analysis. The CMC of the MePEG-*b*-PVL copolymer (Table 1, Sample MePEG-*b*-PVL) was found to be 23.3 mg/L as determined by a fluorescence-based method using DPH as the probe.

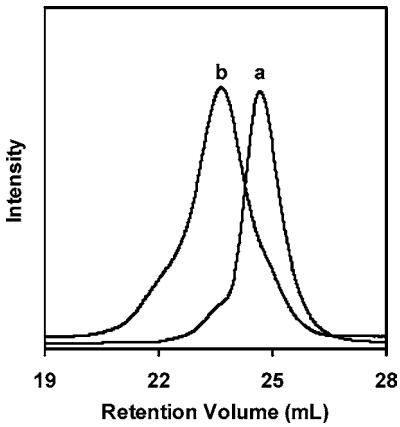


Figure 1. GPC traces for: (a) HOOC-PEG, M_n = 2000, M_w/M_n = 1.16; (b) HOOC-PEG-*b*-PVL, $M_{n,GPC}$ = 5900, M_w/M_n = 1.32 from crude product (Table 1, sample HOOC-PEG-*b*-PVL).

Synthesis and Characterization of the Carboxyl-Terminated PEG-*b*-PVL Copolymers (HOOC-PEG-*b*-PVL). Scheme 1A outlines the method employed for the synthesis of HOOC-PEG-*b*-PVL. The α-carboxyl-ω-hydroxyl PEG (HOOC-PEG) was selected as the macroinitiator and hydrogen chloride as the catalyst. The heterofunctional PEG was found to be able to initiate VL polymerization in dichloromethane at 0 °C and resulted in a copolymer having the predicted molecular weight and a slightly broad molecular weight distribution (M_w/M_n = 1.32) as revealed by GPC analysis. Figure 1 compares the GPC chromatograms of the HOOC-PEG macroinitiator (M_n = 2000, M_w/M_n = 1.16) and the HOOC-PEG-*b*-PVL diblock copolymer from the crude product. The GPC trace demonstrates that the peak corresponding to the macroinitiator is shifted to a higher molecular weight, which indicates the successful synthesis of the telechelic copolymer (HOOC-PEG-*b*-PVL). Figure 2a includes the ^{1}H NMR spectrum and the complete peak assignments for the diblock HOOC-PEG-*b*-PVL copolymer. ^{1}H NMR assignments are as follows: the signal *c* at 3.60 ppm corresponds to MePEG (4H, b, O*CH*$_2$CH$_2$), signals for PVL appeared at 1.68 ppm (4H, m, COCH$_2$*CH*$_2$CH$_2$CH$_2$O), 2.35 ppm (2H, m, CO*CH*$_2$CH$_2$CH$_2$CH$_2$O), and 4.08 ppm (2H, m, COCH$_2$CH$_2$-CH$_2$*CH*$_2$O). The molecular weight of the PVL block was calculated from the overall composition obtained from ^{1}H NMR (Figure 2a) and the known molecular weight of the HOOC-PEG macroinitiator.

Synthesis and Characterization of NHS-Activated PEG-*b*-PVL and EGF Conjugated PEG-*b*-PVL. In the second step, the carboxyl-terminated block copolymer was activated by reaction with NHS as shown in Scheme 1B. The chemical structure was confirmed by ^{1}H NMR (Figure 2b), and the coupling efficiency was found to be 92%. This further confirmed the successful synthesis of the carboxyl-functionalized block copolymer with functionality above 90%. The signal *c* at 2.82 ppm (4H, b, CO*CH*$_2$CH$_2$CO) was assigned to the protons of the NHS unit, which indicates the addition of NHS to the PEG terminus. The other assignments for the ^{1}H NMR spectrum are as follows: signal *a* at 1.67 ppm (4H, b, COCH$_2$*CH*$_2$CH$_2$CH$_2$O), signal *b* at 2.36 ppm (2H, b, CO*CH*$_2$CH$_2$CH$_2$CH$_2$O), signal *d* at 3.64 ppm (4H, b, O*CH*$_2$CH$_2$O), and signal *e* at 4.08 ppm (2H, b, COCH$_2$CH$_2$CH$_2$*CH*$_2$O).

Finally, the NHS-activated block copolymer was reacted with EGF in PBS (pH = 7.4) (Scheme 1, Step C). The uncoupled

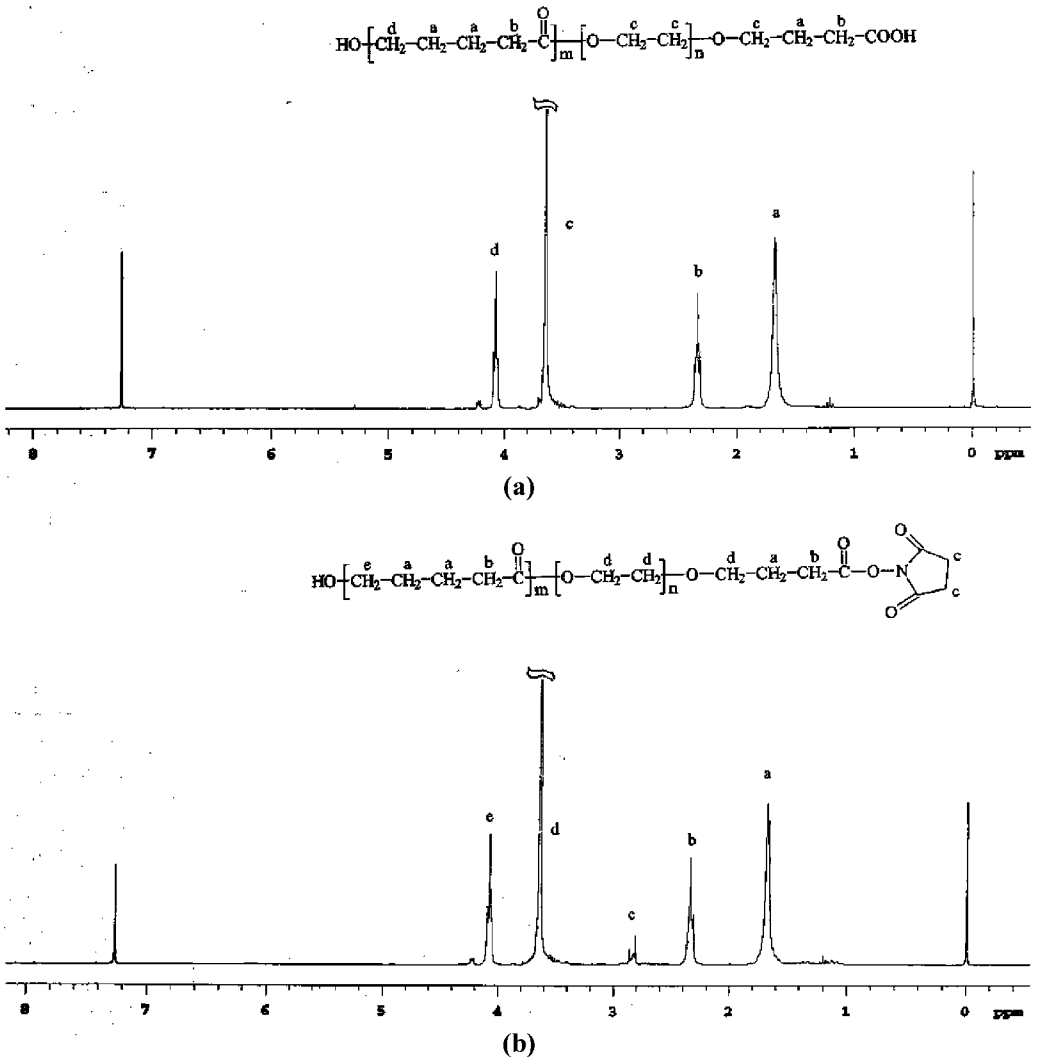

Figure 2. ^{1}H NMR spectra of HOOC-PEG-*b*-PVL and NHS-PEG-*b*-PVL copolymers: (a) HOOC-PEG-*b*-PVL, $M_{n,GPC} = 5900$, $M_w/M_n = 1.32$ (Table 1, sample HOOC-PEG-*b*-PVL); (b) NHS-PEG-*b*-PVL copolymer.

EGF was removed by dialysis, and the final product was recovered by lyophilization. The amount of EGF conjugated to the copolymer was quantified using the Micro BCA assay. It was found that 101.7 μg of EGF was conjugated per 10 mg of copolymer, which corresponds to a conjugation efficiency of 60.9%.

Size, Size Distribution, and Zeta Potential of Copolymer Micelles (+/− EGF). The effective mean diameters of the CM-DiI-loaded nontargeted MePEG-*b*-PVL micelles (− EGF) and targeted micelles (+ EGF) were found to be approximately 32 ± 1 nm and 45 ± 2 nm, respectively. Both micelle solutions (+/− EGF) were found to have a monomodal size distribution. The zeta potentials for the nontargeted MePEG-*b*-PVL micelles (no CM-DiI), the CMDiI-loaded nontargeted micelles and the CM-DiI-loaded targeted micelles were found to be − 6.5, − 8.7, and − 13.5 mV, respectively.

In Vitro Release of CM-DiI-Loaded MePEG-*b*-PVL Micelles. An evaluation of in vitro release was carried out in 0.01 M PBS (pH = 7.4) containing 10% fetal bovine serum (FBS) at 37 °C in order to mimic the conditions employed for the cell uptake studies. Figure 3 includes the 24-h release profile for CM-DiI from the MePEG-*b*-PVL micelles. Approximately 20% of the CM-DiI was released within the first 2 h of incubation, and 90% of the total probe was released over the entire 24 h incubation period.

Cell Uptake of Targeted Micelles (+ EGF) and Nontargeted Micelles (− EGF). Figure 4 illustrates the uptake profile

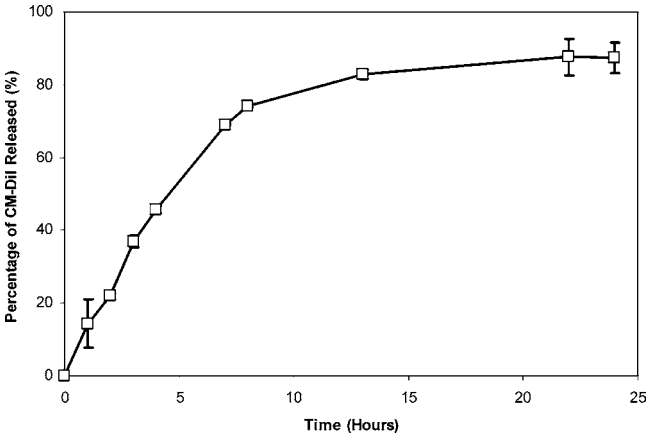

Figure 3. In vitro release of CM-DiI from MePEG-*b*-PVL micelles in PBS (0.01 M, pH = 7.4) at 37 °C.

of CM-DiI-loaded micelles in MDA-MB-468 cells as determined by fluorescence measurements. Untreated cells were found to have minimal autofluorescence, and the fluorescence was negligible when compared to treated cells. The amount of CM-DiI fluorescence detected in cells that were treated with targeted micelles (+ EGF) greatly exceeded that of cells treated with nontargeted micelles (- EGF). Similar results were observed with confocal microscopy. Figure 5a and 5d are fluorescence

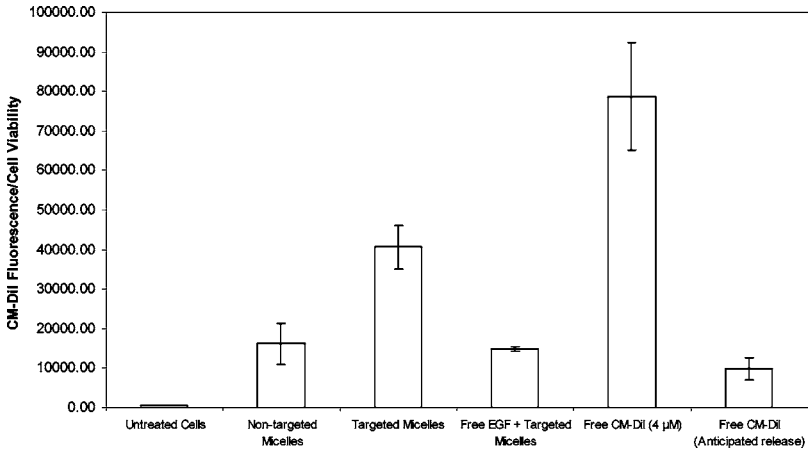

Figure 4. CM-DiI fluorescence of cell lysate measured from cells treated with cell culture medium (untreated group as negative control), CM-DiI-loaded nontargeted micelles, CM-DiI-loaded targeted micelles, free EGF with CM-DiI-loaded targeted micelles, 4 μM of free CM-DiI (equivalent to 100% loading in micelles as positive control), and 0.88 μM of free CM-DiI (fraction of anticipated release from micelles). Cell uptake was expressed in terms of the relative fluorescence intensity normalized to cell viability for each well.

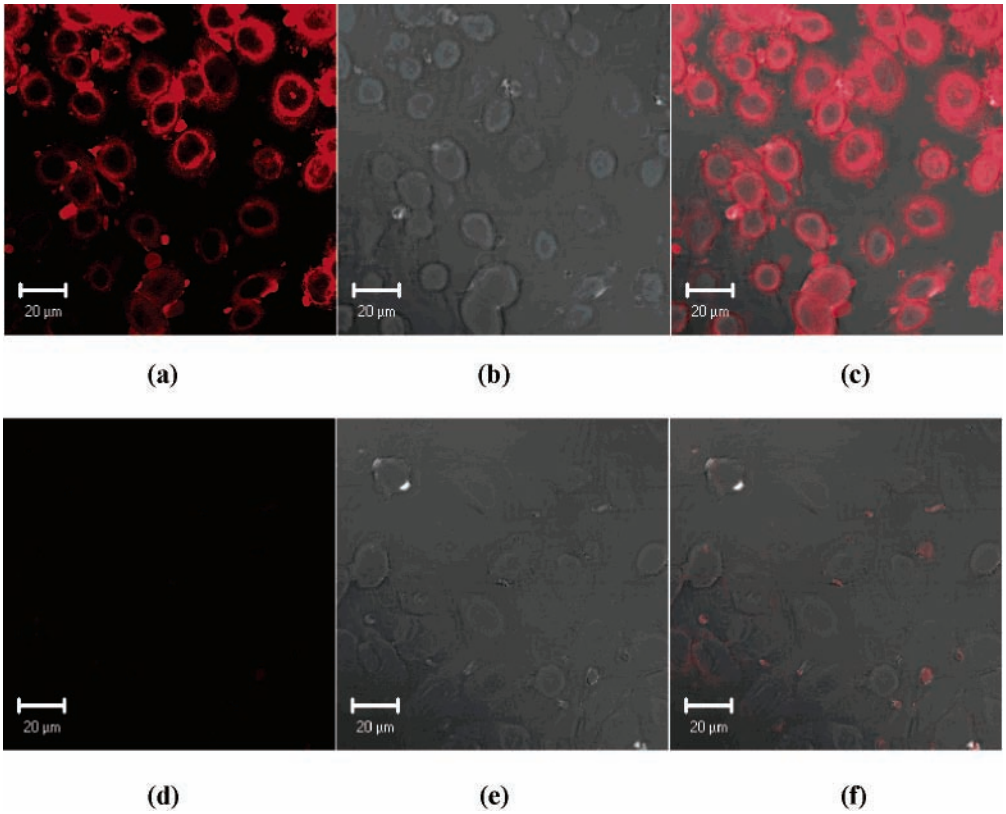

Figure 5. Images of EGFR-overexpressing (i.e. MDA-MB-468) cells that have been incubated with targeted PEG-*b*-PVL micelles (+ EGF) (a−c) or nontargeted MePEG-*b*-PVL micelles (− EGF) (d−f) for 2 h at 37 °C. Panels a and d include confocal images visualized using the fluorescence channel for CM-DiI. Panels b and e include the light microscopy images visualized using transmitted light (b is the same field as in a, e is the same field as in d). Panel c is a superimposition of panels a and b, while panel f is a superimposition of panels d and e. All microscope settings were held constant for imaging.

confocal images of cells that have been incubated with targeted micelles (+ EGF) and nontargeted micelles (− EGF), respectively. For the incubation of the cells with the nontargeted micelles, there appeared to be no accumulation of CM-DiI following the 2-h incubation period. In comparison, significant accumulation of CM-DiI was observed when the MDA-MB-468 cells were incubated with the targeted micelles. In addition, the results included in Figure 4 also demonstrate that preincubation of the cells with free EGF decreased the uptake of the targeted micelles due to competitive binding. These results suggest that the targeted micelles with EGF conjugated to the surface are selectively internalized into the EGFR-overexpressing MDA-MB-468 cells. Figure 5c includes an overlay of the confocal (Figure 5a) and transmitted light images (Figure 5b) and reveals that the CM-DiI fluorescence is concentrated around the nucleus with lower intensity fluorescence distributed throughout the cytoplasm. Furthermore, as shown in Figures 5a and 5c, there seems to be a small degree of nuclear localization of CM-DiI in the cells.

Localization of Targeted Micelles (+ EGF). Cytoplasmic (i.e. with fluorescein phalloidin) and nuclear staining (i.e. with Hoechst 33258) were performed in order to further investigate

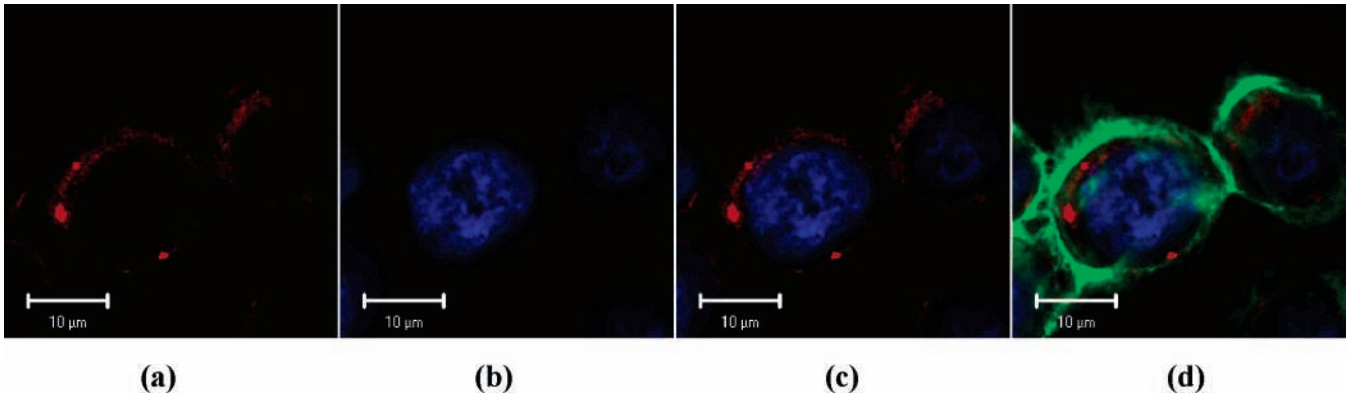

Figure 6. Confocal microscopy images of EGF-conjugated (targeted) micelles (red signal) in two representative cells. The cells were permeabilized with Triton X-100 and stained with both fluorescein phalloidin (green signal) and Hoechst 33258 (blue signal). (a) Visualized using the fluorescence channel for CM-DiI (targeted micelles). (b) Visualized using the fluorescence channel for Hoechst 33258 (i.e. nuclear stain). (c) A superimposition of panels a and b. (d) Same as panel c with additional superimposition of the image obtained using the fluorescence channel for fluorescein phalloidin (i.e. cytoplasmic stain).

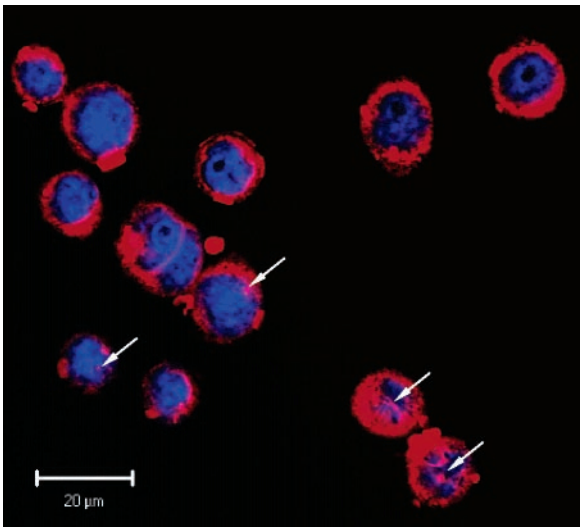

Figure 7. Confocal microscopy images of EGF-conjugated (targeted) micelles (red signal). The cells were nuclear stained (blue signal) with Hoechst 33258 without cell membrane permeabilization with Triton X-100. The white arrows indicate colocalization of the targeted micelles in the nucleus.

whether the EGFR-targeted micelles were indeed localizing at the nucleus. Figure 6 includes a series of images of two representative cells that had been incubated with EGFR-targeted micelles for 2 h prior to cytoplasmic (green signal in Figure 6d) and nuclear staining (blue signal in Figure 6b−d). Figure 6c provides a clear indication that the CM-DiI is mainly distributed in the perinuclear region. However, the CM-DiI intensity was much lower than that obtained in Figure 5a although the microscope settings were held constant. It was therefore hypothesized that some of the CM-DiI was washed away due to the addition of Triton X-100 which had been used to permeabilize the cell membrane. Permeabilization of the cell membrane is necessary for cytoplasmic staining with fluorescein phalloidin.

To confirm that the decrease in fluorescence intensity that was observed in Figure 6 could be attributed to membrane permeabilization during sample preparation, the cells were fixed and stained with Hoechst 33258 without incubating with Triton X-100. As illustrated in Figure 7, the intracellular signal for CM-DiI in cells that had not been incubated with Triton X-100 was much more intense than that in Figure 6 and similar to that in Figure 5a (i.e. cells not incubated with Triton X-100). Furthermore, once again the CM-DiI was found to be localized mostly in the perinuclear region with a small amount scattered throughout the cytoplasm. Also, some nuclear localization of CM-DiI was detected as indicated with white arrows in Figure 7.

Cell Proliferation Studies. EGF is an endogenous molecule that stimulates growth of cells (*46*, *47*). As a targeting moiety for drug carriers to treat EGFR-overexpressed cancers, EGF must not stimulate growth of tumor cells. The viability of MDA-MB-468 cells following treatment with free EGF, nontargeted micelles (MePEG-*b*-PVL) and targeted micelles (EGF-PEG-*b*-PVL) was found to be 55 ± 7%, 81 ± 7%, and 56 ± 6%, respectively. Therefore, the EGF-conjugated copolymers exert similar cell growth inhibition as that of free EGF at the same EGF concentration. This agrees with the results reported by Chen et al. which demonstrated that EGF inhibits cell growth at high concentrations (IC50 ∼ 500 pM in MDA-MB-468 cells) (*48*).

DISCUSSION

EGF, also known as urogastrone, is one of the proteins in the EGF family that exhibits binding affinity toward the EGF family of cell surface tyrosine kinase receptors (*36*). EGF is a 53-amino acid peptide with a molecular weight of 6 kDa and is generated by proteolytic cleavage of precursor proteins such as Neu and tissue plasminogen activator (*49*). Like other proteins, the binding affinity of EGF to its receptor is extremely sensitive to its conformation (*49*). To preserve the conformation of EGF, which is necessary for active targeting, the EGF-copolymer coupling reaction was carried out in the absence of any organic solvents.

The block copolymerization of VL was conducted following a reported procedure using MePEG as the macroinitiator and HCl as the catalyst in dichloromethane (*41*). The HOOC-PEG-*b*-PVL copolymer was then synthesized which allows the carboxyl terminus to serve as the EGF-conjugation site. To our knowledge, there has been no previous report of the synthesis of HOOC-PEG-*b*-PVL. To allow for coupling of EGF to the carboxyl terminus of HOOC-PEG-*b*-PVL, the copolymers were activated with NHS. The NHS-PEG-*b*-PVL copolymer was conjugated via an amide bond to the N-terminal end of EGF. This amide linkage is similar to that used by Lee et al. for conjugation of PEG to EGF and was found to be stable in the circulation in vivo (*42*). Many other studies have also reported on the conjugation of ligands, such as folate and transferrin, to PEG through an amide bond (*50*−*52*). The N-terminal conjugation site on EGF is located at a distance from the amino acid residues that are known to be responsible for binding to EGFR. Previous studies had demonstrated that the binding affinity of EGF for EGFR is not affected by conjugation of molecules to

this specific site on the peptide (*42*, *53*). The efficiency for coupling EGF to the PEG-*b*-PVL copolymer was found to be approximately 60%. This value appears reasonable when compared to that reported by other groups for the coupling of moieties to materials. For example, Kullberg et al. reported that the efficiency for conjugating EGF to maleimide-PEG-DSPE was 30% (*10*). Also recently, Mamot et al. reported that the efficiency for coupling C225-Fab′ to Mal-PEG-DSPE was 30−50% and that for coupling scFv C10 to Mal-PEG-DSPE was 50−80% (*8*).

The CMC of the copolymer was measured in order to evaluate the thermodynamic stability of the MePEG-*b*-PVL micelles. The CMC for the MePEG-*b*-PVL (i.e. 2000-*b*-2020) copolymer was found to be 23.3 mg/L which is slightly higher than that reported for a MePEG-*b*-poly(ϵ-caprolactone) copolymer of similar molecular weight (*54*). The lower CMC for the PCL-based copolymer is due to the more hydrophobic nature of poly(ϵ-caprolactone) when compared to PVL (*20*). Nevertheless, the CMC value obtained for MePEG-*b*-PVL is well below the typical range of concentrations of copolymer that would be anticipated following intraveneous administration of a drug formulated in block copolymer micelles (*30*). In this way, the MePEG-*b*-PVL micelles would be expected to be thermodynamically stable as drug carriers in vivo (*54*).

As mentioned previously, to achieve effective active targeting with EGF-conjugated micelles, the denaturation of the protein has to be avoided in order to preserve the conformation of the EGF binding domain. Therefore, the transfer method was employed to prepare the targeted CM-DiI-loaded micelles. For this method, the EGF-conjugated copolymers were added to the preformed MePEG-*b*-PVL micelles containing CM-DiI and allowed to incubate in order for the EGF-conjugated copolymer to become incorporated into the micelles. The transfer method has been established and commonly used in the preparation of other targeted delivery systems such as liposomes (*6*, *8*, *10*, *40*). For example, Kullberg et al. found that the optimal conditions for the insertion of EGF-conjugated lipids into preformed liposomes (i.e. DSPC/Chol/DSPE-PEG 60/35/5 mol %) is a 1-h incubuation at 60 °C. In their studies, it was also demonstrated that a 24-h incubation of EGF at 60 °C does not result in a significant loss in biological activity for the peptide and only causes a slight decrease in the EGF-substrate binding affinity (*10*). The incubation at an elevated temperature was required in order to increase the fluidity of the lipid bilayer as a means to promote lipid exchange and insertion. The MePEG-*b*-PVL copolymers employed in this study have a melting temperature (T_m) of approximately 46 °C as revealed by differential scanning calorimetry analysis (data not shown). Therefore, the EGF-PEG-*b*-PVL copolymers and the preformed micelles were incubated at a temperature above the T_m of the copolymer (i.e. 60 °C) in order to increase the fluidity of the micelle and maximize the efficiency of copolymer insertion. To ensure complete transfer of the conjugated copolymer, the micelle solution was left to equilibrate with constant stirring overnight at room temperature. It was estimated that once the micelle solution had come to equilibrium each micelle would include approximately five EGF molecules on its surface, assuming that the micelle has an aggregation number (i.e. number of copolymer molecules per micelle) of 250.

The incorporation of EGF-PEG-*b*-PVL copolymers into the MePEG-*b*-PVL micelles was further confirmed by the sizing results. DLS measurements indicated that the targeted micelles with EGF molecules at the surface have a slightly larger effective mean diameter (i.e. $D = 45$ nm) than the nontargeted micelles (i.e. $D = 32$ nm). Knowing that the molecular weight of EGF is approximately 6 kDa, it may be estimated that EGF has a hydrodynamic diameter of approximately 4 nm according to the Stokes−Einstein equation (*53*). Therefore, if it is assumed that the EGF molecules are equally distributed on the surface of the micelles, then the presence of EGF would be predicted to increase the size of the MePEG-*b*-PVL micelles by approximately 8 nm. In this way, the diameter of the targeted micelles would be expected to be 40 nm; which is in rough agreement with the measured value for the size of the micelles (i.e. $D = 45$ nm). Moreover, the in vitro studies in the EGFR-overexpressing cells, MDA-MB-468, clearly demonstrate an increase in cellular internalization of the targeted micelles, in comparison to the nontargeted micelles, which also confirms the successful transfer of the EGF-conjugated copolymer to the micelles. Although the insertion of the EGF-conjugated copolymer increased the effective diameter of the micelles by 13 nm, the diameter of the particles is still in the appropriate size range for consideration for in vivo applications. Particles with diameters of 200 nm or more are known to be cleared rapidly by the cells of the reticuloendothelial system and extravasation of particles of this size into tumor vasculature has been shown to be impeded (*4*, *55*).

The CM-DiI-loaded nontargeted and targeted micelles were found to have a slightly negative surface charge with zeta potentials of −8.7 and −13.5 mV, respectively. Comparison of the zeta potentials for the blank nontargeted micelles (i.e. −6.5 mV) and the CM-DiI-loaded nontargeted micelles (i.e. −8.7 mV) revealed that the incorporation of the fluorescent probe had a negligible effect on micelle surface charge. The slightly more negative surface charge for the targeted micelles may be due to the presence of negatively charged carboxyl end groups on PEG-*b*-PVL copolymers that did not react with EGF. This slight difference between the surface charge for the nontargeted and targeted micelles is unlikely to give rise to any significant difference between the potential for the nontargeted and targeted micelles to engage in cell interactions or undergo cellular uptake. Indeed, the negative surface charge for the micelles may result in electrostatic repulsions between the micelles and cells owing to the net negative charge of the cell surface (*56*, *57*).

The in vitro release of the fluorescent probe, CM-DiI, from the micelles was evaluated in order to confirm that it could be effectively used to follow the in vitro fate of the micelles over the 2-h incubation period. As shown in Figure 3, the in vitro release profile for the probe from the micelles is biphasic with a burst release phase for the first 8 h of the incubation period followed by a sustained release phase over the remainder of the 24 h period. The burst release phase of the profile may be attributed to the pool of drug that resides at the core−shell interface, as well as possible protein−probe interaction (release medium contains 10% FBS), while the drug that is solubilized in the hydrophobic core results in the sustained release phase. A similar biphasic profile was also obtained for the release of CM-DiI from PCL-*b*-PEO micelles as reported by Lim Soo et al. (*58*). Importantly, only 20% of the total probe loaded into the micelles is released over the initial 2-h incubation period (i.e. the period employed for the cell uptake studies). In this way, it is shown that the majority of the probe remains within the MePEG-*b*-PVL micelles over the incubation period employed for the in vitro cell studies. Figure 5d includes a confocal image of cells incubated with the nontargeted micelles, and as shown there is no measurable intracellular fluorescence. In this way, the free CM-DiI (i.e. fraction released from the nontargeted micelles) does not result in a detectable fluorescence signal within the cells. This has also been confirmed by quantification of the level of CM-DiI fluorescence in cells following incubation with this particular concentration of free CM-DiI (i.e. equivalent to the anticipated fraction released from the micelles within 2 h). The cells incubated with this concentration of CM-DiI were

found to have less fluorescence than cells incubated with the nontargeted micelles (Figure 4). Furthermore, the decrease in the extent of uptake of the EGF-conjugated micelles in the presence of excess free EGF suggests that the internalization of the targeted micelles was mediated via the EGF receptors. Therefore, the stronger fluorescence for CM-DiI that is observed in Figures 5a, 6, and 7 may be attributed to the specific cell uptake of the targeted micelles via EGF receptor−ligand-mediated internalization.

It has been reported that upon binding of EGF to the binding domain of cell surface EGFR, dimerization and clustering of the EGF-EGFR complex occurs rapidly at the cell surface. The EGF-EGFR complexes are then reported to be internalized into the cell (*59*, *60*). This receptor−ligand-mediated internalization has been shown to effectively allow for delivery of radiopharmaceuticals and liposome encapsulated agents into EGFR-overexpressing cells (*6*, *38*). Furthermore, Mamot et al. have developed liposomes conjugated with the monoclonal antibody fragment C225 for active targeting to EGFR-overexpressing MDA-MB-468 cells. The cell uptake profile obtained by Mamot et al. was similar to that obtained in these studies in that no cell uptake was observed for the nontargeted liposomes following a 2-h incubation with the MDA-MB-468 cells, while significant cytoplasmic accumulation of the C255-immunoliposomes was observed following the same incubation period (*8*). Several other studies have obtained similar cell uptake profiles for targeted and nontargeted delivery systems as reported elsewhere (*4*, *17*, *42*, *61*).

A few groups have demonstrated that the cell surface EGFR is able to translocate into the nucleus via a specific endocytotic pathway following stimulation of the cells with EGF (*38*, *62*, *63*). Torrisi et al. demonstrated that following saturated EGF binding, the cell surface EGFR redistributed into the cytoplasm and then the perinuclear region following 10 and 30 min incubation at 37 °C, respectively (*63*). A similar distribution for the fluorescence, which is attributed to the targeted micelles containing CM-DiI, is observed in Figures 6 and 7 where the signal is mostly localized in the perinuclear region following the 2-h incubation period. This observation further supports that the targeted micelles are internalized through a specific endocytotic pathway that is mediated by the binding of the EGF-conjugated micelles to cell surface EGFR on the MDA-MB-468 cells. Also, Wang et al. demonstrated that 16% of the ^{111}In-DTPA-HAS-hEGF radiopharmaceutical incubated with MDA-MB-468 cells was imported into the nucleus as measured by subcellular fractionation studies (*38*). In the present study, a small portion of the targeted micelles containing CM-DiI was also observed in the nucleus of the cells as shown in Figures 5c and 7. The nuclear localization of EGFR may be of particular significance when delivery is required for therapeutic agents whose site of action is intranuclear. Therefore, the EGFR-targeted delivery system developed in this study may not only serve to increase the overall intracellular accumulation of an encapsulated agent but may also facilitate the delivery of agents to the perinuclear or nuclear regions of the cell.

CONCLUSION

The carboxyl-terminated diblock copolymer of PEG-*b*-PVL was synthesized using a metal-free cationic polymerization method. EGF was then successfully conjugated to the PEG-*b*-PVL copolymer as a targeting moiety for the nanosized micelles. Targeted micelles prepared from the EGF-conjugated PEG-*b*-PVL copolymers were found to be internalized by the EGFR-overexpressing MDA-MB-468 breast cancer cells via receptor−ligand mediated endocytosis. By contrast there was no intracellular accumulation of the nontargeted MePEG-*b*-PVL micelles (− EGF) into cells over the period of time examined. Interestingly, the EGF-conjugated copolymer micelles were found to localize in the perinuclear region as well as the nucleus. These results suggest that the EGF-conjugated copolymer micelles developed in this study may serve as vehicles for targeting hydrophobic anticancer agents to EGFR-overexpressing cells.

ACKNOWLEDGMENT

C. Allen is grateful to Rx&D and Canadian Institutes of Health Research (CIHR) for a career award. The authors would also like to thank Dr. R. M. Reilly for kindly donating the MDA-MB-468 breast cancer cells, Dr. J. P. Uetrecht for use of the fluorescence microplate reader, Dr. Y. L. Cheng for use of the Particle Size Analyzer, and Mike Dunne for experimental assistance.

CC49 is a clinically validated antibody with specificity for TAG-72, a carbohydrate epitope that is overexpressed and exposed on the cell surface in a large fraction of solid malignancies. We constructed a single-chain fragment (scFv) based on CC49 and fused it to β-lactamase (BLA). Following optimization of the scFv domain by combinatorial consensus mutagenesis (CCM) for increased expression and stability, we characterized the protein variant for binding, in vivo pharmacokinetics (PK), and antitumor efficacy. The fusion protein TAB2.5 possessed a similar binding specificity relative to the parent antibody CC49. TAB2.5 also showed prolonged retention ($T_{1/2}$ = 36.9 h) in tumor-bearing mice with tumor/plasma ratios of up to 1000. Preliminary evaluation of TAB2.5, in combination with a novel prodrug, GC-Mel, resulted in significant efficacy in a colorectal xenograft tumor model and supports the utility of the protein as an agent for tumor-selective prodrug activation.

INTRODUCTION

Most chemotherapeutic drugs act against rapidly proliferating cells, which gives them limited selectivity for tumor tissues. Consequently, the effectiveness of these drugs is limited by their narrow therapeutic indices. In contrast, antibodies directed against tumor-specific antigens can bind to tumor tissues with high selectivity, which makes them suitable tools for the tumor-targeted delivery of drugs or radionuclides (*1*−*3*). One antibody-based approach for drug delivery is the direct conjugation of active drug molecules to a tumor-specific antibody (*4*). To be effective, this approach requires that the conjugate reach the great majority of tumor cells. However, penetration of antibodies into solid tumor tissue can be hindered by diffusion, thus limiting the efficacy of antibody−drug conjugates in the treatment of solid malignancies. An alterative method of using antibodies for tumor drug delivery is antibody-directed tumor prodrug therapy (ADEPT) (*5*−*7*). ADEPT is a two-step approach to cancer therapy. The first step involves the administration of an antibody−enzyme conjugate or fusion protein that specifically binds to tumor tissue. Subsequently, a small molecule prodrug is injected that is enzymatically activated at the tumor site by the tumor-bound fusion protein. As a result, small amounts of fusion protein at the tumor site can liberate large quantities of drug that can then further diffuse through tumor tissue. The abilities to deliver large quantities of drug, to achieve deep tissue penetration and to attain very high tumor/plasma ratios of drug exposure make ADEPT a very attractive strategy for the treatment of solid malignancies.

Recently, we described the construction of a fusion protein between β-lactamase (BLA) and a single-chain fragment (scFv) based on antibody CC49 (*8*). The fusion protein was optimized for high-level soluble production in *Escherichia coli* and good protease stability using combinatorial consensus mutagenesis. The resulting fusion protein, TAB2.5, should combine the proven tumor specificity of antibody CC49 (*9*) with the high catalytic activity of β-lactamase (BLA). CC49 is a second-generation murine antibody with specificity for the carbohydrate epitope TAG-72 (*9*). This epitope is highly expressed in the majority of solid malignancies (*10*, *11*), while its expression in normal tissues is relatively low (*12*). CC49 has been tested in various formats in clinical studies where significant tumor binding was observed (*13*−*15*). Single-chain fragments based on CC49 have been described in the past but they showed a relatively low level of expression and a tendency to form aggregates (*16*−*18*). BLA is a very versatile enzyme in its use for ADEPT. It has been shown that BLA can activate prodrugs derived from a variety of common cancer drugs such as vinblastin (*19*), paclitaxel (*20*, *21*), doxorubicin (*22*), and melphalan (*23*). Recently, we described the construction of a BLA variant with reduced immunogenicity (*24*) that should further enhance the therapeutic utility of this enzyme.

This report demonstrates that the engineered fusion protein TAB2.5 has a specificity that closely mimics the specificity of its parent antibody CC49. TAB2.5 shows very good tumor retention in mice bearing LS174T human colorectal tumor cells. In addition, very high tumor/plasma ratios of BLA activities were observed. Furthermore, we describe the synthesis of a novel prodrug, GC-Mel, that has good solubility and releases melphalan after BLA cleavage. Initial evidence of efficacy of the fusion protein TAB2.5 in combination with GC-Mel is reported.

EXPERIMENTAL PROCEDURES

Synthesis of Glutaryl Cephalosporin Bis-diphenylmethyl Ester (4). NaOH (20%, 13 mL, 80 mmol, 2.2 equiv) was added to a suspension of 7-aminocephalosporanic acid (7-ACA) **3** in water (75 mL) giving a dark brown solution. The deacetylation was complete in 30 min as measured by HPLC (0.05% aqueous formic acid−MeCN gradient). Glutaric anhydride (4.7 g, 40 mmol, 1.1 equiv) was added all at once as a solid, and the contents were stirred for 1.5 h. The reaction was diluted with THF (250 mL) and adjusted to pH 4 with concentrated HCl. Freshly prepared diphenyldiazomethane (*25*) in THF was added via a pipet while being monitored by HPLC (5 mM aqueous

phosphate (pH 7)−MeCN gradient). More diphenyldiazomethane was added as the purple color faded from the reaction mixture. Loss of the starting material occurred after about 1−2 h. However, formation of the second diphenylmethyl (DPM) ester was somewhat sluggish. HCl (1 M) was added to maintain a pH of 4.0−4.5 in the reaction mixture. After 30 h, the reaction was transferred to a separatory funnel and extracted with EtOAc (1 × 800 mL, 1 × 250 mL). The combined organics were dried, filtered, and evaporated to form an oil with a white precipitate (benzophenone azine). Addition of EtOAc and cooling caused further precipitation. After filtration, the filtrate was concentrated, taken up in DMSO, and purified by reversed-phase HPLC (C_{18} column, water−MeCN gradient). The fractions were analyzed by TLC (100% EtOAc) or HPLC. All fractions containing the product were pooled and concentrated to a yellow solid that was stored at 0 °C. The overall yield for the product was 7.31 g (30%). R_f 0.45 (100% EtOAc); ES-MS *m*/*z* 699 $[M + Na]^+$; UV λ_{max} 220, 260 nm. ^{1}H NMR (DMSO-d_6) δ 8.88 (1 H, d, J = 8.0 Hz, 7-NH), 7.23−7.52 (20 H, m, Ar−H), 6.88 (1 H, s, benzhydryl-CH), 6.77 (1 H, s, benzhydryl-CH), 5.68 (1 H, dd, $J_{NH,7}$ = 8.0 Hz, $J_{6,7}$ = 4.4 Hz, H-7), 5.16 (1 H, bt, J = 5.2 Hz, OH), 5.10 (1 H, d, $J_{6,7}$ = 4.8 Hz, H-6), 4.15−4.23 (1 H, m, CH_2OH), 3.62 (1 H, d, $J_{A,B}$ = 18 Hz, H-2_A), 3.54 (1 H, d, $J_{A,B}$ = 18 Hz, H-2_B), 2.46 (2 H, t, J = 7.6 Hz, glutaryl-CH_2), 2.23 (2 H, t, J = 7.6 Hz, glutaryl-CH_2), 1.79 (2 H, p, J = 7.2 Hz, glutaryl-CH_2).

Synthesis of Activated Glutaryl Cephalosporin (5). The cephalosporin intermediate **4** (3.9 g, 5.76 mmol) was dissolved in methylene chloride (50 mL) followed by the sequential addition of 1,2,2,2-tetrachloroethylchloroformate (0.90 mL, 5.76 mmol) and pyridine (0.52 mL, 6.34 mmol, 1.1 equiv). Reaction was complete in 1 h as measured by HPLC. Following completion of the reaction, ice (100 g) and 1 M HCl (10 mL) were added, and the contents were stirred for 2 min. The mixture was transferred to a separatory funnel that contained 100 mL of CH_2Cl_2, and the layers were separated. The organic layer was further washed with water and brine. Drying of the organic phase with $MgSO_4$, followed by filtration and partial solvent removal in vacuo down to about 100 mL, led to the formation of a yellow solution that was used in the next step without further purification. R_f 0.72 (1:1 hexanes−EtOAc); UV λ_{max} 260 nm.

The above mixture was cooled to 0 °C and treated with excess MCPBA (1.81 g, 8.02 mmol, 1.4 equiv). Reaction was completed in 20 min as measured by HPLC. $NaHSO_3$ (10%, 15 mL) followed by 0.1 N $NaHCO_3$ (100 mL) was added, and the contents were transferred to a separatory funnel containing chloroform (ca. 50 mL). The aqueous layer was discarded, and the organic phase was further washed with 0.1 N $NaHCO_3$, water, and brine. The organic layer was dried and filtered, and the solvent was removed to give a tan foam. The product was used in the next step without further purification. Overall yield of the product was 4.75 g (91% overall). R_f 0.30 (1:1 hexanes−EtOAc); ES-MS *m*/*z* 923.00 $[M + Na]^+$; UV λ_{max} 260 nm. ^{1}H NMR ($CDCl_3$) δ 7.27−7.48 (20 H, m, Ar-H), 6.95 (1 H, s, benzhydryl-CH), 6.89 (1 H, s, benzhydryl-CH), 6.64 (1 H, s, CHCl), 6.60 (1 H, d, J = 10.0 Hz, 7-NH), 6.13 (1 H, dd, $J_{NH,7}$ = 10.0 Hz, $J_{6,7}$ = 4.8 Hz, H-7), 5.64 (1 H, dd, $J_{A,B}$ = 14 Hz, $J_{CH,A}$ = 5.6 Hz, H-2_A), 4.91 (1 H, dd, $J_{A,B}$ = 14 Hz, $J_{CH,A}$ = 5.6 Hz, H-2_B), 4.46−4.50 (1 H, m, H-6), 3.80 (1 H, d, $J_{A,B}$ = 18.8 Hz, $CH_{2A}OCOO$), 3.22 (1 H, d, $J_{A,B}$ = 19.6 Hz, CH_{2B}-OCOO), 2.52 (2 H, t, J = 7.6 Hz, glutaryl-CH_2), 2.31 (2 H, t, J = 6.8 Hz, glutaryl-CH_2), 2.02 (2 H, p, J = 7.2 Hz, glutaryl-CH_2).

Synthesis of Glutaryl C-Mel (1) (Figure 1A,B). A solution of melphalan (0.31 g, 0.97 mmol) in a mixture of 0.5 N $NaHCO_3$ (5.1 mL, 2.53 mmol, 2.6 equiv), water (5 mL), and THF (10 mL) was added to a solution of activated cephalosporin **5** in THF (25 mL). The solution was stirred at ambient temperature for 30 min, and the reaction was found to be complete by HPLC analysis. Ice (ca. 10 g) and 1 N HCl (5 mL) were added to this mixture, and it was extracted with EtOAc (2 × 30 mL). The combined organic phases were washed with brine and dried. Filtration, followed by solvent removal, led to the formation of a yellow film that was dissolved in CH_2Cl_2 (100 mL) and treated with anisole (5 mL) and TFA (5 mL) for 1 h. Concentration of the reaction led to a dark oil that was precipitated with ether (ca. 150 mL). The product was filtered to give a tan solid that was further purified by reverse-phase HPLC (C_{18} column, 0.1% aqueous TFA−MeCN gradient). The desired fractions were pooled, frozen, and lyophilized to give a fluffy off-white powder. A total of 0.36 g (54%) of product was obtained. ES-MS *m*/*z* 690.93 $[M + H]^+$; UV λ_{max} 260, 300 nm. ^{1}H NMR (DMSO-d_6) δ 8.22 (1 H, d, $J_{NH,7}$ = 8.0 Hz, mel-NH), 7.65 (1 H, d, J = 8.0 Hz, 7-NH), 7.06 (2 H, d, J = 8.8 Hz, mel-Ar−CH ×2), 6.63 (2 H, d, J = 8.8 Hz, mel-Ar−CH ×2), 5.75 (1 H, dd, $J_{NH,7}$ = 8.0 Hz, $J_{6,7}$ = 4.8 Hz, H-7), 5.04 (1 H, d, $J_{A,B}$ = 13.6 Hz, $CH_{2A}OCONH$), 4.81 (1 H, d, $J_{6,7}$ = 3.6 Hz, H-6), 4.54 (1 H, d, $J_{A,B}$ = 13.2 Hz, $CH_{2B}OCONH$), 3.99−4.07 (1 H, m, mel-CH), 3.30−3.75 (10 H, m, H-2_A, H-2_B, NCH_2CH_2Cl ×2), 2.85−2.92 (1 H, m, mel-CH_{2A}), 2.64−2.73 (1 H, m, mel-CH_{2B}), 2.17−2.32 (4 H, m, glutaryl-CH_2 ×2) 1.70 (2 H, p, J = 7.2 Hz, glutaryl-CH_2).

Production and purification of TAB2.5. The production and purification of TAB2.5 is described elsewhere. In brief, *E. coli* cells carrying the production plasmid were cultured for 48 h at 30 °C. Cells were harvested by centrifugation and lysed, and soluble TAB2.5 was purified by affinity chromatography on phenylboronic acid agarose (Sigma, St. Louis, MI). Monomeric TAB2.5 was isolated by size-exclusion chromatography on Superdex 75 (Amersham, Piscataway, NJ) as shown in Figure 2. Peaks were assigned by electrospray mass spectrometry. The purified protein retained its monomeric state even after several months of storage at 4 °C or at −80 °C. As an additional step, material used for in vivo studies was passed through a 10 mL detoxi-gel column (Pierce, Rockford, IL) for endotoxin removal to achieve less than 5 EU/mg protein endotoxin level.

In Vivo Tumor Model Efficacy Studies. Female athymic nude mice (Charles River, approximately 21 g body weight, 4−6 weeks of age) were allowed to acclimate to the Genencor animal facility for at least 4 days prior to treatment. All animal-related procedures were in compliance with the Animal Welfare Act Regulations (9CFR 3). The LS174T cell line was obtained from ATCC (Manassas, VA). The cells were maintained in RPMI 1640 (Mediatech, Herdon, VA) supplemented with 15% (v/v) fetal bovine serum (Hyclone, Logan, UT), 0.5% (v/v) penicillin (10 000 IU), and streptomycin sulfate (10 mg/mL) and incubated in a 5% CO_2/95% humidity atmosphere at 37 °C. The adherent cells were dissociated and passaged as per supplier's instructions. For tumor implantations, the cells were harvested in log phase, washed once with PBS, and resuspended in Ham's F12 culture media (Mediatech, Herdon, VA) at a density of 4 × 10^7 cells/mL. The tumor cells were injected subcutaneously in 100 μL of fluid consisting of 50 μL of Ham's F12 containing 2 × 10^6 cells and 50 μL of Matrigel (BD Biosciences, San Diego, CA). Every 3−4 days, body weights were recorded, and the tumors were measured on two axes with calipers. Tumor volumes were calculated according to the following formula: tumor volume = long axis × (short axis)^2 × 0.4. TAB2.5 was diluted in a sterile saline solution, where necessary, for injection. The prodrug was reconstituted in 8% PEG 400, 2% dimethyl acetamide, 5% captisol (Cydex, Lenexa, KS), and 0.1 M NaCl containing 2.75 equiv of Tris buffer to neutralize its acidic groups.

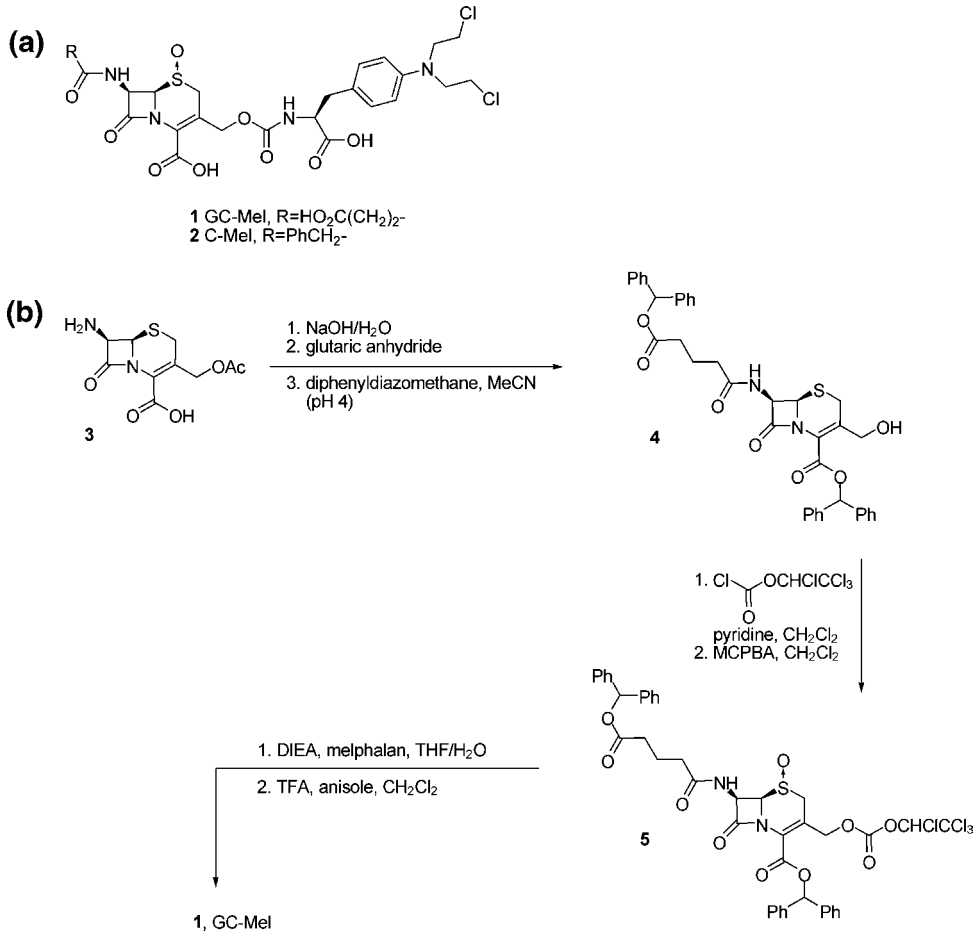

Figure 1. (A) Structure of GC-Mel, **1**, and C-Mel, **2**, and (B) schematic representation of the synthesis of GC-Mel, **1**, and the intermediates formed in the synthesis.

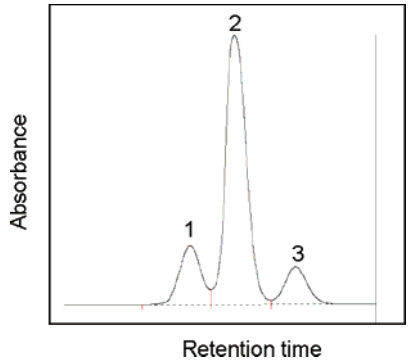

Figure 2. Size-exclusion chromatography of TAB2.5. Peak 1 (57.7min), dimer of TAB2.5; peak 2 (65.8 min), monomer fraction of TAB2.5; peak 3 (77.0 min), free BLA.

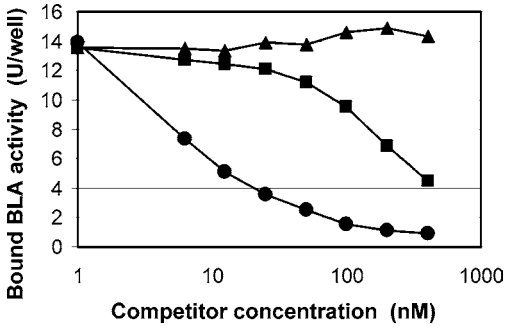

Figure 3. Target binding of TAB2.5 is effectively competed by CC49 or BSM. TAB2.5 binding to plate bound tumor lysate was measured in the presence of CC49 (●), BSM (■), or BSA (▲) as a negative control.

Binding of TAB2.5 to Tumor Lysate. LS174T xenograft tumor samples were homogenized in T-PER lysis solution (Pierce Inc., Rockford, IL) containing a protease inhibitor cocktail (Halt, Pierce, Rockford, IL) on ice. Insoluble material was removed by centrifugation, and the protein concentration of supernatant was measured using the BCA assay (Pierce, Rockford, IL). A microtiter plate was coated with 50 μL of 200 μg/mL LS174T tumor lysate in PBS by drying overnight at 4 °C. The plate was blocked with 300 μL/well of 2.5% BSA in PBS for 1 h at room temperature. A solution of 90 nM TAB2.5 was mixed with increasing concentrations of competitor CC49, bovine submaxillary mucin (BSM, Sigma, St. Louis, MO), or BSA in equal volume, and 100 μL of the mixture was added into each tumor lysate-coated well. The plate was incubated at room temperature for 2 h and washed four times with PBS−Tes (PBST) buffer, and bound BLA activity was measured by adding 100 μL of nitrocefin (Oxoid, Lenexa, AZ) in PBS containing 0.125% octylglucopyranoside.

Histochemistry. Formalin-fixed sections (colon tumor microarrays (Accumax, Isu Abixis Co., LTD, Seoul, South Korea) and LS174T solid tumor xenograft) were deparaffinized, rehydrated, and subjected to a heat-based antigen retrieval procedure (30 min incubation in a 1 mM EDTA, pH 8.0, solution at 90 °C). Sections were then rinsed with TBS and incubated in peroxidase blocking solution (DAKO, Carpinteria, CA), followed by a solution of 1% normal goat serum. Samples were then incubated with TAB2.5 or CC49 at 2.0 and 0.2 mg/mL, respectively, for 30 min in PBS containing 1% normal goat serum. TAB2.5-containing sections were then incubated with a rabbit polyclonal anti-BLA antibody for 30 min, while CC49-

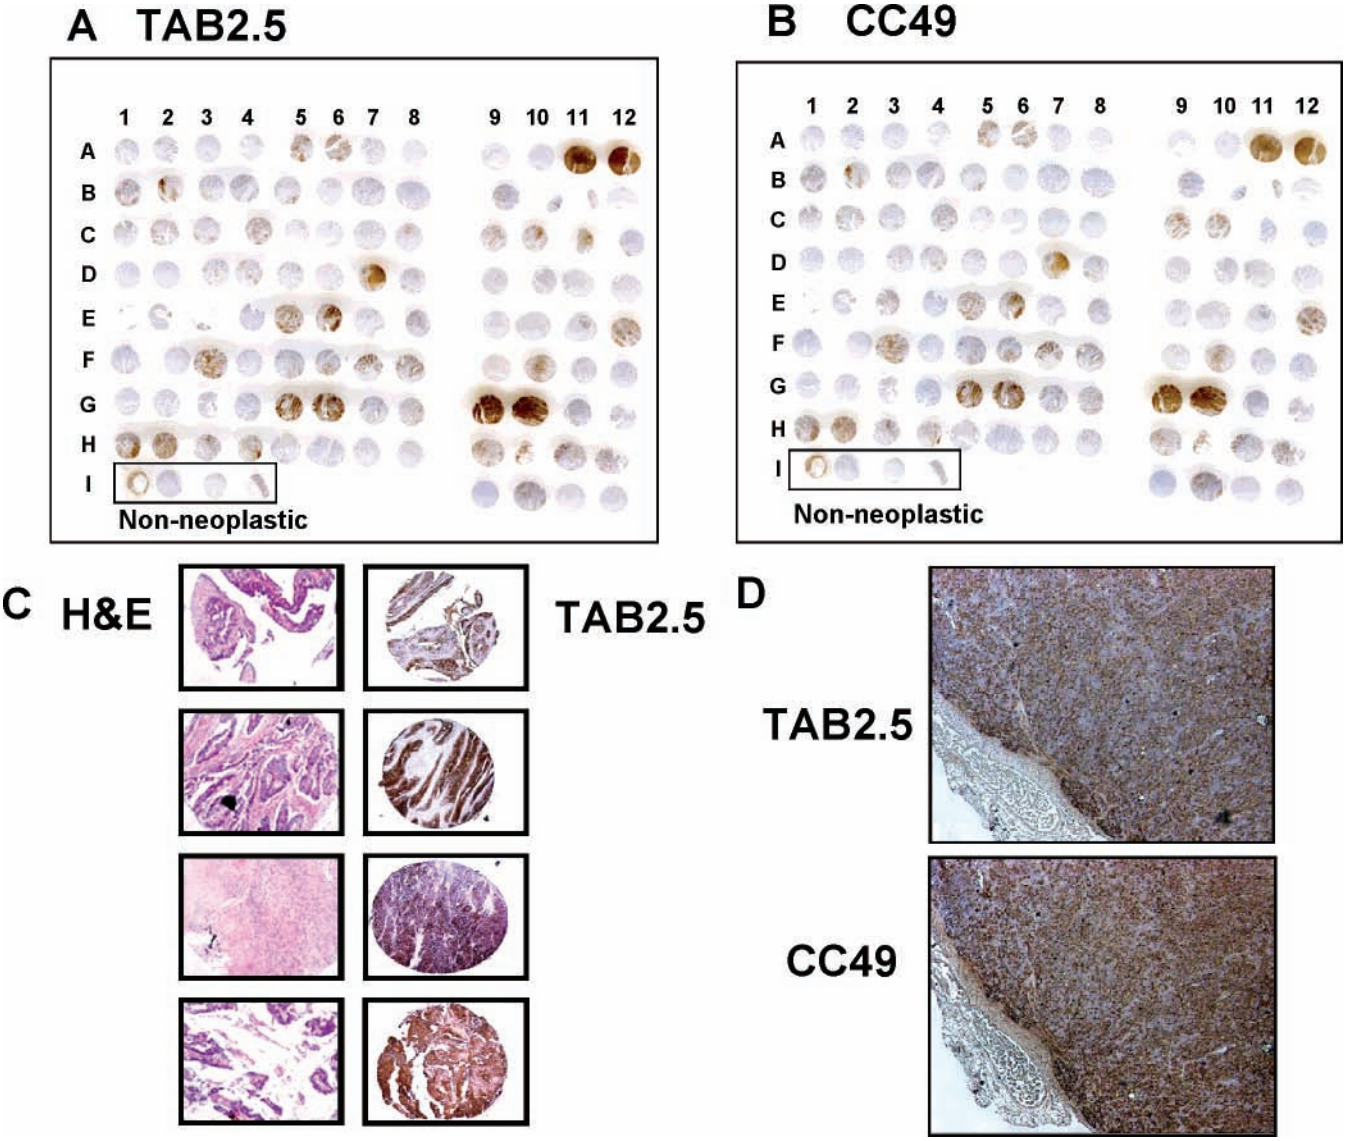

Figure 4. Immunohistochemical localization of TAG-72 in sections from human colorectal and LS174T xenograft tumors. Microarrays containing duplicate sections from 50 primary colorectal tumors and two nonneoplastic tissue samples were stained with TAB2.5 (A) or CC49 (B). In panel C, sections A6, G5, A11, and G9 (from panel A) are shown enlarged and stained with hematoxylin and eosin (H&E). In panel D, LS174T tumors were grown in vivo in athymic nude mice for 2 weeks prior to isolation and fixation.

containing sections were incubated with goat anti-mouse−HRP (DAKO, Mouse Envision+ System-HRP). The sections that were treated with TAB2.5 were rinsed and incubated with anti-rabbit−HRP antibody (DAKO, Rabbit Envision+ System-HRP) for 30 min. Finally, the TAB2.5- and the CC49-treated sections were rinsed and incubated with peroxidase substrate (DAB, DAKO) for color development and counterstained with hematoxylin.

In Vivo Pharmacokinetics and Tumor Retention. The pharmacokinetic studies were conducted with athymic animals bearing 100−200 mm^3 LS174T subcutaneous tumors. The animals were injected intravenously with 100 μL of TAB2.5 (1 or 5 mg/kg) or MUB3.4 (5 mg/kg) (a control construct with specificity for MUC1) diluted in PBS. Blood samples were drawn via tail vein bleeds at 0.033, 0.083, 0.25, 0.5, 1, 2, 4, 8, 12, 24, 48, 72, and 96 h. Solid tumors were collected, frozen, and maintained at −80 °C until use. Two milliliters of ice-cooled lysis buffer (PBS with 15 μg/mL Aprotinin) was added per gram of wet tissue that was weighed semifrozen, and the tissue was homogenized with a Polytron PT1200 homogenizer (Polytron Kinematica, Switzerland). Homogenate (75 μL) was combined with an equal volume of B-Per (Pierce) and shaken vigorously for 10 min at room temperature. Samples were then centrifuged for 10 min at 4 °C. The resulting supernatants (20 μL) were collected and assayed for BLA activity. Blood samples (0.6 mL) were collected in EDTA anticoagulant, placed on ice, and centrifuged at 5 °C within 30 min to harvest plasma. The resulting plasma samples were transferred into polypropylene tubes and stored at −70 ± 10 °C until analysis. BLA concentrations in plasma and tissue samples were measured using a capture assay as follows. Microtiter high binding capacity plates (Costar Co., Cambridge, U.K.) were coated with 5 μg/mL chicken polyclonal anti-BLA antibody (ProSci Inc., Poway, CA) in PBS and then blocked with casein blocker buffer (Pierce, Rockford, IL) at room temperature (RT) for 2 h. Plasma samples (20 μL) or negative controls were added to each well, followed by the addition of 80 μL/well of casein blocker buffer, and incubated for 2 h at RT. Samples were diluted as needed using negative control plasma or tissue lysate as reference. The plates were then washed, and 200 μL/well of nitrocefin substrate solution (100 μg/mL) in PBS containing 0.125% of *n*-octyl-β-D-glucopyranoside (Sigma, St. Louis, MO) was added to each well. The plates were read as a kinetic assay at 490 nm for 15 min at 25 °C. The limit of detection under these conditions was

5 ng/mL. The calculated concentration of TAB2.5 was determined by linear regression using a standard curve within the linear range of the concentration−response curve.

RESULTS

Synthesis of the Prodrug GC-Mel. Previous studies using prodrugs of doxorubicin and phenylenediamine mustard have demonstrated that anionic side chains of the 7-amino group of the cephem core decrease in vitro prodrug cytotoxic activity (*22*, *23*). The prodrugs are also more soluble, easier to formulate, and less toxic in vivo. In this study, we applied similar modifications to C-Mel (*2*), which was previously shown to be a highly active molecule when administered in animals that were pretreated with a scFv−BLA fusion protein (*23*). A more water-soluble form of **2** was expected to be less toxic and easier to administer (Figure 1A).

The synthesis of GC-Mel (*1*) is shown in Figure 1B. Briefly, 7-aminocephalosporanic acid (*3*) was converted to **4** in three steps involving saponification, acetylation with glutaric anhydride, and esterifications with diphenyldiazomethane. The resulting alcohol (intermediate **4**) was converted to the activated carbonate, followed by sulfide oxidation to give the key intermediate **5**. Melphalan was then added, followed by deprotection of the esters with trifluoroacetic acid, to provide GC-Mel, **1**. The aqueous solubility of GC-Mel was four times greater than that of C-Mel (data not shown).

Binding Properties of TAB2.5. Recently, we described the construction of a fusion protein between BLA and a scFv fragment based on antibody CC49. The fusion protein was optimized for high-level soluble production in *E. coli* and good protease stability using combinatorial consensus mutagenesis (*8*). Monomeric TAB2.5 was isolated as described in the Experimental Procedures (Figure 2). The binding specificity of TAB2.5 was validated in competition assays as shown in Figure 3. The data demonstrate that parent antibody CC49 or soluble target BSM effectively compete the binding of TAB2.5 to tumor lysate indicating that TAB2.5 and CC49 bind to the same epitope.

To further establish the relative equivalency of TAB2.5 and CC49 in terms of antigen detection, the binding to TAG-72 in primary colorectal tumor biopsies was determined by immunohistochemistry (Figure 4A,B). The molecules were compared at concentrations that resulted in comparable staining intensities. Very similar staining patterns were observed for TAB2.5 and CC49, which is evidence for the very similar binding specificity of both molecules. Consistent with previous reports, the expression of TAG-72 was heterogeneous within the tumor sections, although, in most cases the antigen was dispersed throughout the entire section. The majority of the sections that were strongly immunopositive were graded G2 or G3. Selected tumor sections at higher magnification are shown in Figure 4C, along with a corresponding section from the same tumor stained with hematoxylin and eosin. The colorectal cell line LS174T has previously been observed to express TAG-72 in vitro as well as in vivo (*26*). The presence of TAG-72 in LS174T tumors after 2 weeks of growth in vivo was confirmed using CC49 antibody and TAB2.5 fusion protein as shown in Figure 4D. Consistent with the expression pattern observed in the primary tumor tissue, the distribution of TAG-72 was heterogeneous in LS174T tumors, although the protein did appear dispersed throughout the tumor mass. No binding of TAB2.5 was observed for a variety of normal tissues (thyroid, lung, liver, ovary, uterus, stomach; data not shown).

In Vivo Pharmacokinetic Characteristics of TAB2.5. The plasma and tumor pharmacokinetics of TAB2.5 and MUB3.4, a nonbinding BLA fusion protein control, were compared in LS174T tumor-bearing animals (Figure 5A,B, respectively). The

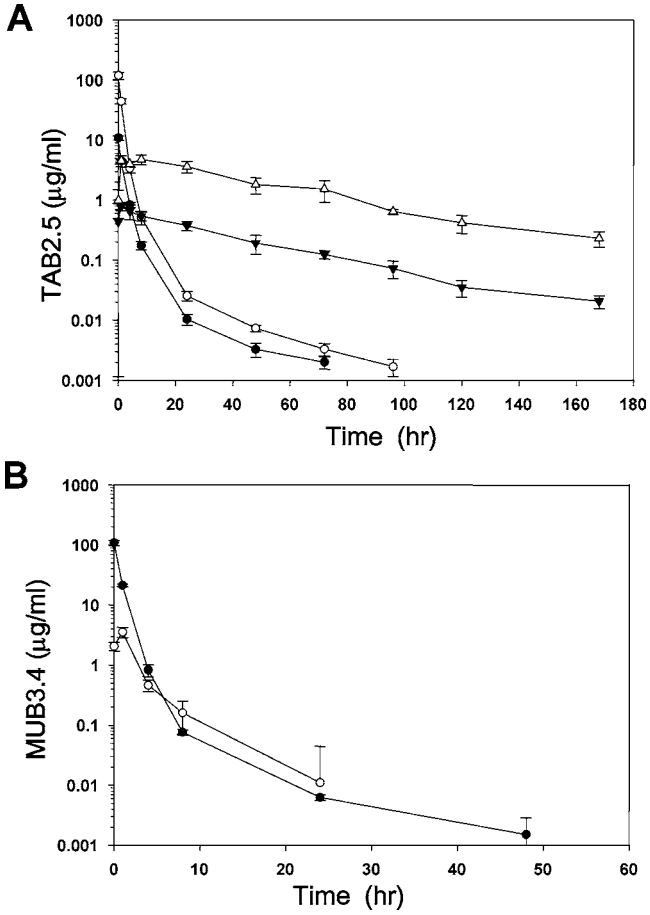

Figure 5. Pharmacokinetics of TAB2.5 and MUB3.4 in nude mice bearing human colorectal LS174T xenografts. The animals were administered TAB2.5 (A) iv at 1 (plasma, ●; tumor, ▼) and 5 mg/kg (plasma, ○; tumor, △) and MUB3.4 (B) at 5 mg/kg (plasma, ●; tumor, ○). Plasma and tumor samples ($n = 3$ per time point) were collected at various times up to 170 h. The concentrations of TAB2.5 and MUB3.4 were determined by comparing the level of BLA activity in the samples to the level of enzymatic activity in purified preparations.

pharmacokinetic data were analyzed using a compartmental model. The plasma distribution of both fusion proteins was multiphasic with the volume of distribution being comparable to the plasma volume. TAB2.5 when dosed iv at 1 or 5 mg/kg had an $\alpha T_{1/2}$ and a $\beta T_{1/2}$ in plasma of 1.3 and 1.0 and 20.0 and 18.4 h, respectively. While in the tumors, the $T_{1/2}$ at the two doses was 36.9 and 49.5 h, respectively. The total body clearance was 0.017 and 0.011 mL/min at 1 and 5 mg/kg, respectively. In contrast, when dosed iv at 1 mg/kg, MUB3.4 had an $\alpha T_{1/2}$ and a $\beta T_{1/2}$ in plasma of 0.56 and 7.3 h, respectively. While in the tumors, the $T_{1/2}$ for MUB3.4 was 5.0 h. The ratio of the $T_{1/2}$ values for the tumor elimination of TAB2.5 versus MUB3.4 was 5.0 demonstrating that TAB2.5 is specifically retained in the LS174T tumors for a substantial period of time, thus potentially allowing for sufficient systemic clearance to occur to provide for selective tumor targeting with the prodrug.

Efficacy of TAB2.5 during ADEPT Treatment. The efficacy of TAB2.5 was studied in combination with the prodrug GC-Mel. TAB2.5 was administered to female athymic nude mice on day 9 when tumor size reached 150−200 mm^3. Following an interval of 72 h to allow for the systemic clearance of unbound TAB2.5, the prodrug GC-Mel was administered at doses of 75, 150, 300, or 450 mg/kg. The subcutaneous tumors in the vehicle-treated control group grew rapidly, and the growth curves did not plateau over the course of the experiment (Figure 6A). Furthermore, no spontaneous tumor regression was noted in this tumor model. By day 19, the tumor volume in the control

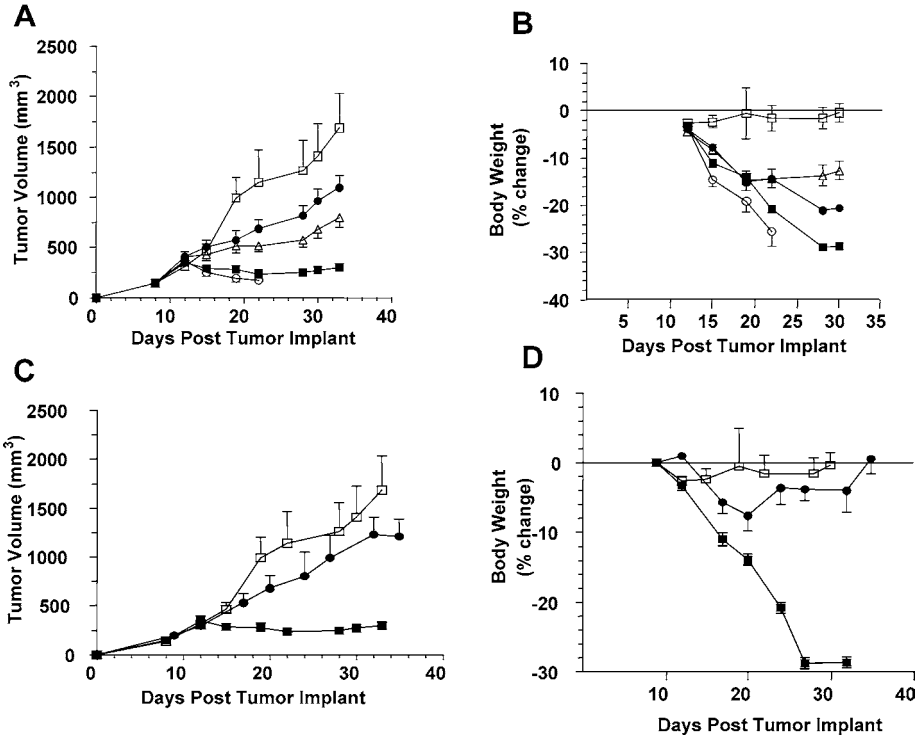

Figure 6. Antitumor activity of TAB2.5 and GC-Mel in nude mice bearing LS174T xenografts. In panel A, 8 days postinjection of the LS174T cells, the tumors were measured, and the animals were randomized into various control and treatment groups ($n = 10$/group). Seventy-two hours after the injection of TAB2.5 (1 mg/kg), the animals were administered control vehicle (□) or GC-Mel at 75 (●), 150 (△), 300 (■), and 450 mg/kg (○). Tumor growth was monitored every 3−4 days. Panel B shows the effect of the various treatments on body weight. The animals were weighed every 3−4 days, and the change in the body weight is expressed as a percentage of the animal's starting weight. Panel C shows tumor volumes from animals administered vehicle (control, □), GC-Mel (300 mg/kg, ●), or TAB2.5 (1 mg/kg) and then after 72 h GC-Mel (300 mg/kg, ■). Panel D shows body weights from the animals in the groups described in panel C.

group had increased by 7-fold to 990 ± 210 mm^3 and subsequently by 12-fold to 1700 ± 340 mm^3 by the end of the experiment on day 33. In contrast, a dose-dependent inhibition in tumor growth was observed in the groups that received GC-Mel. Doses of 75 and 150 mg/kg slowed the growth of the tumors, so by day 33 the average tumor volumes in these two treatment groups were 1100 ± 120 and 790 ± 96 mm^3 ($p = 0.033$, compared to control group), respectively. Treatment with 300 mg/kg GC-Mel resulted in a slow reduction in the volume of the tumors that reached a nadir by day 22. By day 33, no significant regrowth of the tumors was noted, and the average volume of tumors in the group was 300 ± 40 mm^3 ($p = 0.0018$, compared to control group).

As a measure of peripheral toxicity, the body weight of the animals was monitored regularly following treatment. All of the animals in the groups receiving GC-Mel lost a significant amount of body weight as shown in Figure 6B. By day 19, the groups that received the prodrug at a dose of 75, 150, or 300 mg/kg had lost 15.1%, 14.8%, and 14.0% of their starting body weight, respectively. The body weights of all animals in these groups were stabilized eventually by day 28. However, by the end of the experiment, they had not started to gain weight. The group that were dosed with 450 mg/kg GC-Mel lost more than 30% of their body weight by day 22 and had to be sacrificed.

To confirm that the release of free melphalan that was affecting tumor growth was associated with the β-lactamase activity retained in the tumor, GC-Mel was administered at the 300 mg/kg dose level to LS174T tumored animals in the absence of TAB2.5. GC-Mel alone or the melphalan formed from the spontaneous breakdown of GC-Mel had a minimal effect on the growth of the LS174T tumors (Figure 6C). On day 20, the average volume of the tumors in the group that received 300 mg/kg GC-Mel was not significantly different from the volume of the tumors in the control group. In regards to the peripheral toxicity, the 300 mg/kg treated group lost body weight with the nadir being reached within 1 week of the dosing of the animals (Figure 6D). In contrast to the response observed following the administration of the combination of TAB2.5 and GC-Mel, the extent of the weight reduction was less and the rate of recovery was faster. Thus, this data suggests that a portion of the peripheral toxicity observed following the administration of TAB2.5 and GC-Mel was due to the spontaneous release of melphalan, as well as to the free melphalan (0.3%) present in the prodrug preparation and in part to the leak back of melphalan from the tumor following the enzymatic cleavage by the β-lactamase.

To evaluate the sensitivity of the LS174T model to chemotherapy, we examined the efficacy of systemically delivered agents melphalan (single dose, iv), irinotecan (3 weekly doses, iv), and doxorubicin (3 weekly doses, ip). All three drugs led to only minor delays in tumor outgrowth as shown in Figure 7, even at concentrations that caused significant weight loss of the animals.

DISCUSSION

Several ADEPT systems have shown promising in vivo efficacy in a number of tumor models (*6*). There is clear evidence that ADEPT can deliver commonly used cancer drugs reaching high concentrations and targeting the tumor tissue with high selectivity. TAG-72 is a particularly attractive target because it is overexpressed in a large fraction of solid malignancies (*10*, *27*, *28*). Its expression in normal adult tissues is very low and is limited to a few immunoprivileged areas (*12*). CC49 is the best-characterized antibody against TAG-72. CC49 was tested in multiple clinical studies where it showed very high tumor selectivity (*13*, *14*, *29*). In addition, an ^{123}I-labeled scFv based on CC49 has been visualized in primary tumors and

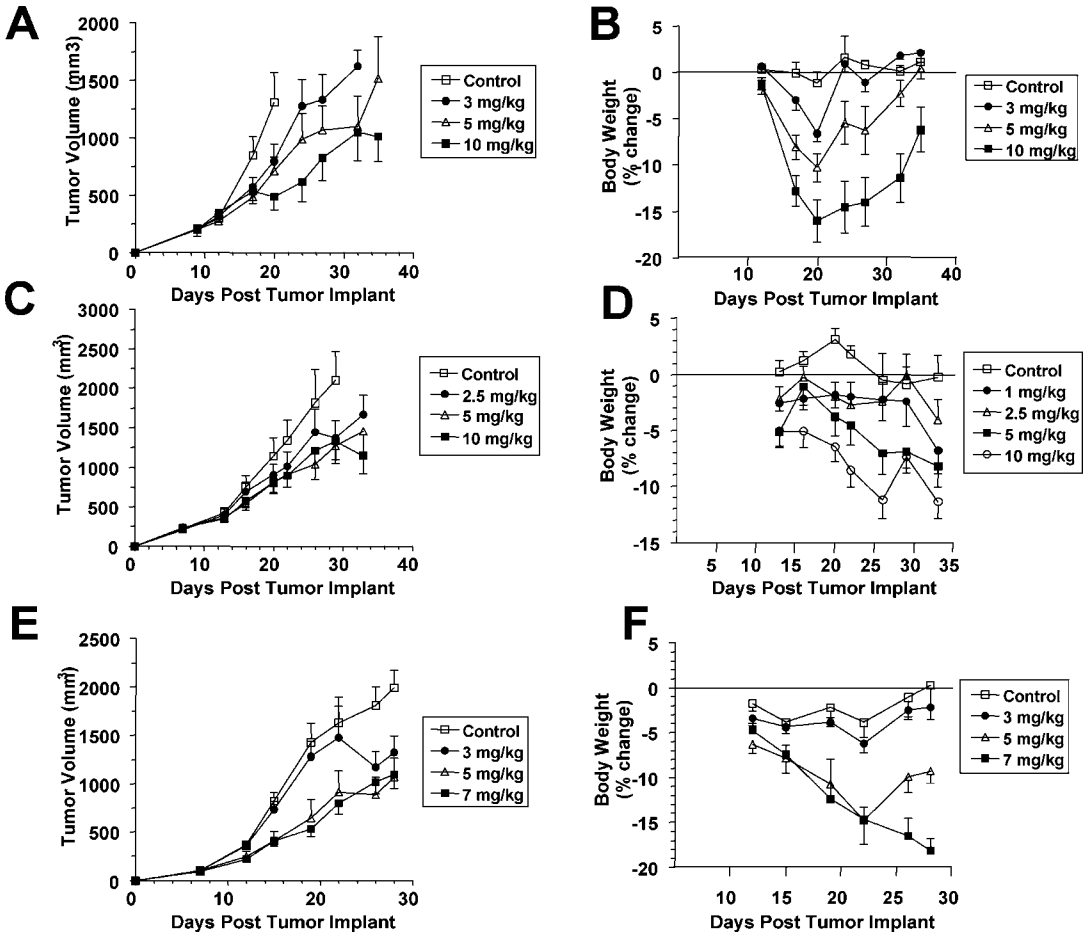

Figure 7. Antitumor activity of melphalan (A, B), irinotecan (C, D), and doxorubicin (E, F) in nude mice bearing LS174T xenografts. Animals were dosed iv with melphalan ($n = 10$/group) once on day 12, and the effect of the drug on tumor growth (A) and body weight (B) was monitored every 3−4 days. Animals were dosed iv with irinotecan ($n = 10$/group) weekly for 3 weeks, and the effect of the drug on tumor growth (C) and body weight (D) was monitored every 3−4 days. Animals were dosed ip ($n = 10$/group) weekly with doxorubicin for 3 weeks, and the effect of the drug on tumor growth (E) and body weight (F) was monitored every 3−4 days.

metastases of five colorectal cancer patients (*30*). Given the clinical validation of CC49, it was of critical importance that the fusion protein TAB2.5 retains the exact specificity of its parent antibody. Figure 3 shows that CC49 and TAB2.5 compete for the same epitope, and Figure 4 demonstrates that both proteins have extremely similar specificity. Thus, none of the mutations that were introduced to improve expression and stability of TAB2.5 appear to have impacted its target binding specificity.

TAB2.5 is very stable and shows excellent tumor retention in vivo as shown in Figure 5. Significant BLA activity can still be detected in tumor tissue approximately 1 week postinjection. If one considers tumor growth during the experiment, then the majority of the BLA activity that was bound in the tumor during the first 2 h after injection could still be found in the tumor after 1 week. This opens the opportunity to administer multiple prodrug injections after a single administration of TAB2.5. However, the growth of LS174T tumors is too aggressive to explore this option, and slower growing tumors will need to be studied.

Another important feature of TAB2.5 is its rapid clearance from the circulation. This is important for ADEPT treatment, because systemic BLA activity would lead to nonspecific prodrug activation. Previously described antibody−enzyme conjugates based on dimeric carboxypeptidase G2 showed slower plasma elimination and clearing antibodies (*31*) or mannosylation (*32*) had to be utilized to remove excess conjugate from the circulation. In contrast, the long tumor retention of TAB2.5 in combination with its rapid plasma elimination resulted in very high tumor/normal ratios of up to 1000 without any additional means of fusion protein clearance. Careful dose optimization will be required to translate this large tumor/plasma ratio of TAB2.5 into a large tumor/plasma ratio of drug exposure during ADEPT.

The novel prodrug GC-Mel was prepared to increase the solubility of C-Mel, which was previously reported to be very efficacious in ADEPT (*23*). Melphalan is an attractive choice for ADEPT due to its steep dose response (*33*), which makes it useful as an agent for high dose chemotherapy (*34*). Melphalan is an amino acid analogue that is actively transported into tumor cells (*35*, *36*). Thus, tumor cells actively take up free melphalan once it has been cleaved from the cephalosporin portion by BLA. This should help in reducing leakage of free active drug from tumor tissue during ADEPT.

The data in Figure 6 provide evidence for the efficacy of TAB2.5 in ADEPT, although the current dosing regimen led to significant toxicity. It is important to note that the LS174T model is extremely difficult to treat. Minimal efficacy was observed for systemic melphalan and doxorubicin, as well as irinotecan, which is the standard of care for colorectal cancer patients. The level of chemoresistance observed in the LS174T model described here is in agreement with literature reports, where irinotecan was found to have low activity (*37*). The further evaluation of TAB2.5 may require a tumor model with a slower in vivo growth profile, which would better reflect the growth rate in patients. Such a model will allow evaluation of longer intervals between the administration of TAB2.5 and GC-Mel to reduce systemic toxicity and allow administration of multiple

prodrug doses per protein dose. The careful optimization of dosing parameters such as dose of fusion protein and prodrug, as well as time interval between administrations of each component, should allow a further reduction of systemic toxicity while maintaining efficacy. The extremely favorable pharmacokinetic (PK) properties of TAB2.5 in tumor-bearing mice suggest that there is a wide window between tumor and systemic levels of BLA that can be exploited for ADEPT.

Based on the results from the PK studies, a 72 h time interval between the administration of TAB2.5 (1 mg/kg) and the prodrug was selected for the initial in vivo efficacy study. Using these conditions, a potent dose-dependent inhibition of the growth of the LS174T tumors was observed with the response appearing to saturate at 300 mg/kg. Treatment with 75 mg/kg of the prodrug resulted in a nearly equivalent response to that observed following the systemic administration of 10 mg/kg of melphalan. However, dosing with 300 or 450 mg/kg induced a pronounced loss of weight that did not show signs of recovery during the course of the experiment. Experiments conducted with the prodrug alone demonstrated that a portion of the weight loss was due to the spontaneous release of melphalan following the iv administration. However, the extent of the weight loss was much greater and no recovery was apparent in the animals that received the combination of TAB2.5 and GC-Mel suggesting that there may have been some "leak back" of melphalan from the tumor or a low-level of residual systemic TAB2.5. Regardless, using a lower initial dose of TAB2.5 or a longer time interval between the administration of the TAB2.5 and GC-Mel should allow reduction of the extent of the peripheral toxicity. Indeed this concept has been demonstrated to work with another targeting agent (Chen et al., manuscript in preparation). The advantage of using the ADEPT approach is clearly demonstrated when the extent of the inhibition of tumor growth achieved with TAB2.5 and GC-Mel, Figure 6, is compared to that observed with other chemotherapeutic agents that are currently being used in the clinic for treating colorectal cancer, for example, irinotecan, Figure 7. The latter uniformly produced only a weak cytostatic effect and a comparable amount of weight loss in the LS174T xenograft model.

In summary, we have described a novel fusion protein, TAB2.5, based on antibody CC49 that closely mimics the clinically validated specificity of CC49 and can be used in ADEPT. The prodrug GC-Mel shows good solubility and liberates melphalan upon exposure to TAB2.5. Further dose optimization will be required to fully evaluate the potential of both compounds for ADEPT. The clinical application of TAB2.5 will benefit from the removal of T cell epitopes from BLA that has been described recently (*24*).

Received December 20, 2005

A general procedure is presented for the preparation of a new class of nitrido asymmetrical Tc-99m complexes containing two different bidentate ligands bound to the same $[Tc(N)]^{2+}$ core that could be used to design either essential or target specific imaging agents. This procedure is based on the chemical properties of a new monosubstituted $[Tc(N)(R_2PS)Cl(PPh_3)]$ species composed of a Tc≡N multiple bond and an ancillary phosphine thiol ligand (R_2PSH). This intermediate readily reacts with bidentate mononegative ligands (S^Y) containing soft π-donor coordinating atoms to give neutral pentacoordinate asymmetrical complexes of the type $[Tc(N)(R_2PS)(S^Y)]$. The ability of several bidentate ligands containing different combination of heteroatoms (S, N, O) to form complexes with the $[Tc(N)(R_2PS)]^+$ building block was investigated. It was found that mononegative dithiocarbamate (DTC) or cysteine carboxyl derivate ligands promptly react with the monosubstituted species to form the final mixed compound in high yield. Preliminary biodistribution data in rats of some representative $[Tc(N)(R_2PS)(DTC)]$ compounds revealed an interesting initial brain uptake (in the range 0.20 ± 0.01% ID/g and 0.91 ± 0.06% ID/g), indicating their ability to cross in and out of the intact BBB. In these complexes the dithiocarbamate, or more generally the bidentate ligand (S^Y), can be designed to carry a functional group or a bioactive molecule, which could be involved in a trapping mechanism to increase brain retention for longer time intervals. These results could be conveniently utilized to devise a new procedure for the production of a novel class of brain perfusion and/or brain receptor imaging agents.

INTRODUCTION

Over the past few years, several ^{99m}Tc-based radiopharmaceuticals have been approved by the FDA for determining organ functions or assessing disease status by imaging methods. Despite this, the development of new ^{99m}Tc-based brain perfusion or brain receptor imaging agents, which can play an important role in the diagnosis of various cerebrovascular, neurological, and neuropsychiatric disorders, remains a subject of great interest in the radiopharmaceutical field.

At present, Tc-99m-based radiopharmaceuticals used in the clinic for the assessment of brain perfusion are [^{99m}Tc]-HMPAO and [^{99m}Tc]-ECD, whereas [^{99m}Tc]-TRODAT-1 represents the first successful reported example of a Tc-based tracer for brain receptor imaging. Since these radiopharmaceuticals are far from ideal, the efforts to find more efficient Tc-99m brain perfusion and new CNS receptor imaging agents continue.

Generally, these agents must possess certain basic characteristics in order to cross the intact blood−brain barrier (BBB). They must be stable in vitro and in vivo, neutral in charge, lipophilic in character (Log *P* octanol/water in the range 1.0−2.5), and a molecular weight lower than 600 Da. Moreover, after crossing the BBB, a potential Tc-99m perfusion imaging agent must be retained in the tissue for a sufficient amount of time to allow SPECT imaging, via a trapping mechanism which typically involves enzymatic or chemical conversion into a more hydrophilic compound that prevents the agent from recrossing the BBB in the opposite direction. In addition, a potential Tc-99m receptor imaging agent must have the appropriate molecular shape to fit correctly with the target receptor site (IC_{50} value <10 nM) in order to localize selectively and specifically into the target receptor (*1*−*3*).

Recently a new strategy called 'metal-fragment' approach has been proposed to design receptor-specific Tc-99m tracers. This method is based on the reactivity of certain types of substitution labile technetium complexes toward ligands having a specific set of coordinating atoms (*4*). In these complexes some coordination positions are occupied by a chelating ligand (i.e. PXP hetero-diphosphine in $[Tc(N)(PXP)]^{2+}$ moieties) or by a set of ligands (i.e. CO groups in the $[Tc(CO)_3]^+$ moiety) which are strongly bound to the metal center defining a stable molecular building block. The remaining coordination positions are saturated by labile ligands (i.e. Cl, H_2O) that can selectively be replaced by other ligands carrying specific sets of coordinating atoms. Hence, the reaction between the precursor complex and the incoming ligand proves to be highly selective and produces a stable final hetero-complex in high yield. In this context, a target specific agent could be prepared as an asymmetrical complex containing two different coordinating systems, one which stabilizes the metal ion and the other designed to carry the bioactive molecule (*5*−*9*).

Recently we have reported a class of asymmetrical nitrido complexes characterized by the presence of two polidentate ligands bound to the same $[Tc(N)]^{2+}$ core. These mixed-ligand compounds are prepared by reacting the $[Tc(N)Cl_2(PNP)]$ precursor (where PNP is a diphosphine with a tertiary amine

incorporated in the chain) with bidentate ligands carrying π-donors as coordinating atoms (*10, 11*). The application of this approach has led to the production of a new class of cationic *pseudo*-octahedral compounds $[^{99m}Tc(N)(DTC)(PNP)]^+$ (DTC is a dithiocarbamate ligand), showing high myocardial uptake which are currently under investigation as potential myocardial imaging agent (*12*−*14*).

The use of the same $[Tc(N)(PNP)]^{2+}$ molecular fragment, where PNP was the bis(dimethylphosphinoethyl)methylamine (PNP4) in conjunction with dinegative mercaptoacetate $[O^-,S^-]$ or dithiol $[S^-,S^-]$ ligands (H_2L), generates a neutral [Tc(N)-(L)(PNP4)] species designed, in principle, for brain imaging (*15*). Despite the correct physicochemical properties of these agents (neutral charge, lipophilicity, and molecular weight), biodistribution data showed negligible brain uptake. This adverse behavior may be attributed either to in vivo structural alterations of the neutral native complex (e.g. protonation of the PNP amine function) into charged or polar adducts incapable of crossing the BBB or to the more crowded *pseudo*-octahedral arrangement of these complexes (*16*, *17*) compared with the pentacoordinated structures exhibited by [^{99m}Tc]-HMPAO and [^{99m}Tc]-ECD brain agents.

On the basis of these considerations, we proposed decreasing the complex coordination number by removing the tertiary amino nitrogen from the diphosphine framework. However, diphosphine ligands (P^P) incorporating only methylene units in the bridging chain did not promote the formation of mixed [Tc(N)(S^S)(P^P)] complexes when reacted with dithiol ligands (*18*). On the other hands, an identical P_2S_2 donor set, but with a different connection between P and S atoms, gave another series of stable, neutral pentacoordinated complexes of the type $[Tc(N)(R_2PS)_2]$, where R_2PS is a phosphino-thiol ligand (*19*). Biodistribution studies of this class of complexes have shown transient myocardial uptakes (*20*). One tracer of this series, incorporating the 2-dimethylphosphino propanethiolate ligand, has shown the additional ability to penetrate the intact BBB.

According to these preliminary results, we decided to further investigate the biological behavior of a further number of disubstituted $[Tc(N)(R_2PS)_2]$ complexes containing alkyl phosphino-thiolate ligands as potential brain perfusion imaging agents. In addition, aiming at the introduction of a bioactive molecule into a nitrido Tc-complex, we have devised a general procedure for the preparation of a new class of pentacoordinate neutral species of the type [Tc(N)(P^S)(S^Y)] where P^S is an ancillary ligand which stabilizes the $[Tc(N)]^{2+}$ core and S^Y is a bifunctional chelating agent (BFCa).

The opportunity of designing mixed ligand complexes of the type [^{99m}Tc(N)(P^S)(S^Y)] has been made possible by recent studies carried out at macroscopic level with the long-lived Tc-99g (*21*). The use of encumbering substituents at the P donor in phosphino thiol ligands led to the isolation of the monosubstituted compound $[^{99g}Tc(N)(R_2PS)Cl(PPh_3)]$ (R = cyclohexyl). This intermediate reacted with bidentate mononegative ligands (S^Y) to produce quantitatively neutral pentacoordinate asymmetrical complexes of the type $[Tc(N)(R_2PS)(S^Y)]$ (*22*).

In this study we report the synthesis and characterization of pentacoordinate $[^{99m}Tc(N)(R_2PS)_2]$ complexes and of a new class of pentacoordinate $[^{99m}Tc(N)(R_2PS)(S^Y)]$ mixed complexes. Alkylphosphino thiols and HS^Y ligands utilized in the studies are outlined in Figures 1 and 2. In vitro stability and tranchelation toward an excess of GSH and Cys of all synthesized symmetrical and asymmetrical compounds were evaluated. Tissue distribution data in rats of all $[^{99m}Tc(N)(R_2PS)_2]$ complexes and of some representative $[Tc(N)(R_2PS)(S^S)]$ compounds are also studied.

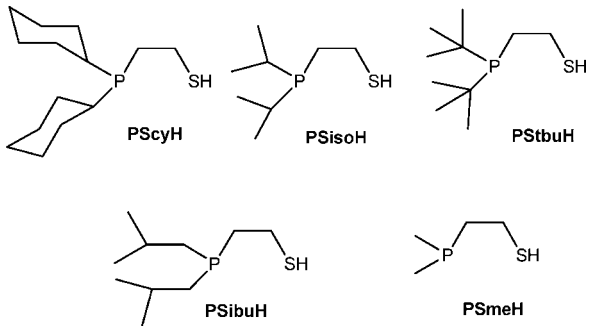

Figure 1. Phosphino thiol ligands (R_2PSH) utilized in this study.

EXPERIMENTAL SECTION

Materials. All chemicals and reagents were purchased from Aldrich Chemicals. The solvents were reagent grade and used without further purification. Due to the tendency of the phosphino-thiol ligand to oxidize, all the solvents were previously degassed to remove dissolved dioxygen traces and reactions were carried out under an inert atmosphere of dry dinitrogen. Technetium-99m as $Na^{99m}TcO_4$ was eluted from a $^{99}Mo/^{99m}Tc$ generator provided by Nicomed Amersham-Sorin (Saluggia, Italy). Disubstituted $[^{99g/99m}Tc(N)(PScy)_2]$ and monosubstituted $[^{99g}Tc(N)(PScy)Cl(PPh_3)]$ compounds were prepared as previously described (*19*−*21*). The phosphine thiol ligands used in these studies were purchased from Argus Chemicals (Prato, Italy). Dithiocarbazate (Dtcz) dithiocarbamate (DTC4), dithiophosphinate (PSS1, 2), dithiocarboxylate (DTCOX1, 2) ligands, as sodium salts, were synthesized according to the literature method (*23*−*26*). Dithiocarbammate (DTC1, 2, 3), cysteamine (SN), L-cysteine ethyl ester (SN-Cys), and the remaining bidentate ligands, tertiary phosphine (PPh_3, triphenylphosphine; TPPS (tris(3-sulfonatophenyl)phosphine)) and SDH (succinic dihydrazide), were purchased from Sigma Aldrich (Milan, Italy). PCN [tris(2-cyanoethyl)phosphine] and $P(CH_2OH)_3$ [tris(hydroxymethyl)phophine] were purchased from Sterm Chemicals, Inc. (Bischheim, France). Hydroxypropyl-beta-cyclodextrin (β-HPC) was purchased from Acros (Morris Plains, NJ). Sep-Pak RP-C18 and Oasis HLB extraction cartridges were purchased from Waters Corporation (Milford, MA).

Analysis. Radiochemical purity (RCP) and stability of the radioactive compounds were evaluated by thin-layer chromatography (TLC) carried out on SiO_2 F_{254S} or C18 F_{254S} (Merck) and high performance liquid chromatography (HPLC). Radioactivity on TLC plates were detected and measured using a Cyclone Instrument equipped with phosphorus imaging screen and OptiQuant image analysis software (Packard, Meridian, CT). HPLC was performed on a Beckman System Gold Instrument equipped with a programmable solvent system Model 126, a scanning detector Model 166 and a radioisotope detector Model B-FC-3200 Bioscan.

The chromatographic conditions used in TLC and HPLC analyses, together with the RCYs (radiochemical yields) and the chromatography results, are reported in Table 1.

To determine the chemical nature of the Tc-99m complexes, comparison by HPLC with the well characterized Tc-99g analogues was pursued applying parallel photometric and radiometric detection. Thus, after co-injection of appropriate Tc-99m/Tc-99g couples, identical retention times were observed (Figure 3).

Synthesis of Disubstituted Symmetrical ^{99m}Tc Complexes: $[^{99m}Tc(N)(R_2PS)_2]$ (R= CH_3, $CH(CH_3)_2$, $CH_2CH(CH_3)_2$, $C(CH_3)_3$). *Method 1:* 0.25 mL of saline containing $^{99m}TcO_4^-$ (activity ranging from 1.0 Mbq to 1.0 Gbq) was added to a vial containing 1 mg of Dtcz, or alternatively 5 mg of SDH,

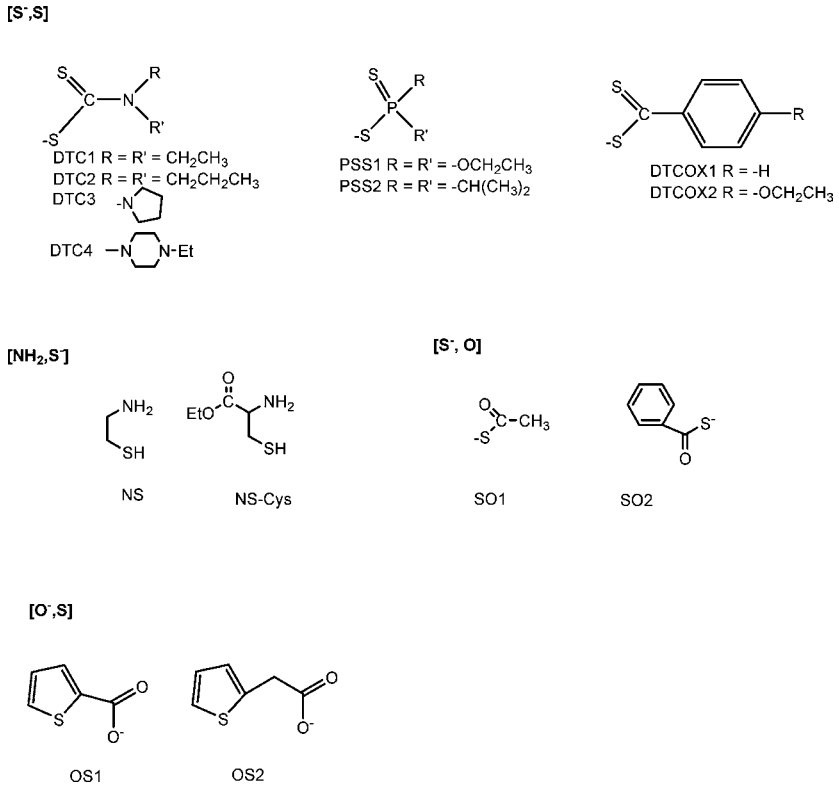

Figure 2. Bifunctional ligands (S^Y) utilized in this study.

0.1 mg of $SnCl_2$ suspended in 0.1 mL of saline, and 1.0 mL of EtOH. The resulting solution was kept at room temperature for 30 min, at which point 0.2 mL of an alcoholic solution containing 0.25−1 mg of the selected phosphino-thiol ligand followed by 0.1 mL of HCO_3^-/CO_3^{--} buffer (0.5 M) was added. The resulting solution was heated at 100 °C for 30 min.

Method 2: 0.25 mL of saline containing $[^{99m}TcO_4]^-$ (activity ranging from 1.0 Mbq to 1.0 Gbq) was added to a vial containing 5 mg of SDH, 3 mg of PPh_3, 0.1 mL of HCl (1 M), and 1.5 mL of EtOH. The resulting solution was heated at 100 °C for 15 min. After cooling, 0.2 mL of an alcoholic solution containing 0.25−1 mg of the selected R_2PSH ligand was added. Then, the pH was raised to 8 by adding 0.250 mL of HCO_3^-/CO_3^{--} buffer (0.5 M) and the resulting solution was incubated at room temperature for 1 h. RCP for the complexes, evaluated by TLC and HPLC, was reported in Table 1.

Method 3: 0.25 mL of saline containing $^{99m}TcO_4^-$ (activity ranging from 1.0 Mbq to 1.0 Gbq) was added to a vial containing 1 mg of Dtcz, 0.1 mL of HCl (1 M), 1.5 mL of EtOH, and 2 mg of the appropriate phosphino-thiol ligand. The resulting solution was heated at 100 °C for 15 min.

Purifications. The final disubstituted $[^{99m}Tc(N)(R_2PS)_2]$ compounds were purified from cold ligands, by Sep-Pak RP-C18. The preparation was diluted with water (8 mL) and loaded onto the cartridge previously activated with 95% ethanol (5 mL) and water (5 mL). The cartridge was rinsed with water (20 mL) followed by EtOH 30% (1 mL). $[^{99m}Tc(N)(PSme)_2]$ was eluted using 1 mL of EtOH 60% (1 × 0.25 mL, 1 × 0.75 mL). The other $[^{99m}Tc(N)(R_2PS)_2]$ complexes were eluted using 1 mL of EtOH 100% (1 × 0.25 mL, 1 × 0.75 mL). In all cases, the activity was collected in the second fraction.

$[^{99m}Tc(N)(S^Y)_2]$ (S^Y = DTC, PSS, DTCOX, etc.). The disubstituted symmetrical complexes were synthesized following the literature procedure (*24*−*26*).

Synthesis of Asymmetrical ^{99m}Tc Complexes: $[^{99m}Tc(N)(R_2PS)Cl(PPh_3)]$ (R= CH_3, $CH(CH_3)_2$, $CH_2CH(CH_3)_2$, C_6H_{11}, $C(CH_3)_3$). *Method a:* 0.25 mL of saline containing $^{99m}TcO_4^-$ (activity ranging from 1.0 Mbq to 1.0 Gbq) was added to a vial containing 5 mg of SDH, 3 mg of PPh_3, 0.1 mL of HCl (1 M), and 1.5 mL of EtOH. The resulting solution was heated at 100 °C for 15 min. After cooling, 0.2 mL of an alcoholic solution containing $\sim 10^{-4}$ mmol (0.025−0.050 mg) of the selected phosphino-thiol ligand was added. The resulting solution was incubated at room temperature for 1 h.

TLC and HPLC analysis revealed a mixture of different products. In all cases, when the reactions were carried out at 100 °C or at RT but in basic media, a conversion of the intermediate compounds into the corresponding disubstituted symmetrical complexes was observed.

Method b: 0.25 mL of saline containing $^{99m}TcO_4^-$ (activity ranging from 1.0 Mbq to 1.0 Gbq) was added to a vial containing 5 mg of SDH, 3 mg of PPh_3, 0.1 mL of HCl (1 M), 1.5 of EtOH, and 0.2 mL of an alcoholic solution containing $\sim 10^{-4}$ mmol of phosphino-thiol ligand. The resulting solution was heated at 50 °C for 15 min. The mixture revealed the same chromatographic profiles as those obtained by method a.

$[^{99m}Tc(N)(R_2PS)(S^Y)]$. This preparation implies the preliminary formation of the precursor complex $[^{99m}Tc(N)(R_2PS)Cl(PPh_3)]$ followed by its conversion into the final asymmetrical compound by reaction with 0.2 mL of water solution containing 1−0.025 mg of the appropriate bidentate ligand (S^Y), at room temperature. RCY, which evaluated by TLC and HPLC chromatography, was reported in Table 1 for each compound. TLC and HPLC characterizations of $[^{99m}Tc(N)(R_2PS)(NS\text{-}Cys)]$ showed the presence of two separate radioactive spots, which resulted from the formation of two distinct isomeric forms of the complex.

Purifications. The final mixed compounds were purified by HPLC. The desired fraction was diluted with water (8 mL) and loaded onto a Sep-Pak RP-C18 previously activated with 95% ethanol (5 mL) and water (5 mL). The cartridge was rinsed with water, and the Tc-99m species was eluted using 1 mL of EtOH (1 × 0.40 mL, 1 × 0.60 mL). The second fraction containing all the activity was diluted with saline to obtain an aqueous

solution with 20% of EtOH and utilized for in vitro and in vivo studies or, alternatively, with a physiological solution containing 0.5 mg/mL of β-HPC.

Stability Studies. *In Vitro Stability*. The in vitro stability of the complexes was evaluated by monitoring the radiochemical purity (RCP) at different time points using the following procedures. In a propylene test tube 50 μL of HPLC purified Tc-99m complex were added to (a) 950 μL of saline, (b) 450 μL of phosphate buffer (0.10 M, pH 7.4), and (c) 950 μL of β-HPC saline solution (0.1−0.5 mg/mL). The resulting mixture was incubated at 37 °C for 24 h. RCP was determined by TLC and HPLC chromatography at 15 min, 1, 3, and 24 h.

Serum Stability. In a propylene test tube 100 μL of HPLC purified Tc-99m complex was added to 900 μL of rat serum and incubated at 37 °C. At 15 min, 1 and 3 h aliquots (200 μL) of the solution were withdrawn, diluted with 800 μL of

phosphate buffer (0.2 M, pH 7.4), and loaded onto an OASIS HLB extraction cartridge previously conditioned with MeOH (1 mL) and equilibrated with water (1 mL). The cartridge was rinsed with MeOH 5% (3 mL), and 90% of the starting activity was eluted with 1 mL of MeOH. Aliquots (100 μL) of this fraction were analyzed by HPLC chromatography.

Glutathione (GSH) and Cysteine Challenge. An aliquot (50 μL) of a freshly prepared aqueous solution of GSH (10 mM) or, alternatively, of L-cysteine (10 mM, 1 mM) was added to a propylene test tube, containing phosphate buffer (250 μL, 0.2 M, pH 7.4), water (100 μL), and Tc-99m complex (100 μL). The mixture was vortexed and incubated at 37 °C for 24 h. A control reaction adding an equal volume of water instead of GSH or cysteine solution was conducted in parallel. At 15, 30 min, 1, 3, and 24 h aliquots of the reaction mixture were analyzed by TLC and HPLC chromatography.

Determination of Log k'_0 Values. Log k'_0 values of complexes were determined by HPLC as described elsewhere (*13*) and compared with the Log k'_0 values of the commercially available cerebral agent [^{99m}Tc]-ECD, obtained under the same chromatographic conditions. The results are reported in Table 1. It has been previously shown that the Log k'_0 values are highly correlated with their Log *P* values as an expression of the lipophilic character molecules.

Log k'_0 is obtained from Log k', where k' is the capacity factor measuring the partitioning of the compound between a nonpolar stationary phase and a polar mobile phase. The Log k' values were determined here using methanol and phosphate buffer (0.02 M, pH 7.4) at various compositions. An analysis of the relationship between Log k' and mobile phase composition gave extrapolated Log k' values at 0% organic solvent composition (Log K'_0) as a measure of the activity partitioning between the hydrophobic stationary phase and water. The Log k'_0 values were extrapolated from the linear part of the curve Log $k' = a + bC$, where C is the methanol concentration and Log k'= Log-$(t_r - t_0)/t_0$.

The elution time (t_0) for an unretained component was considered to be equal to the elution time for $Na^{99g}TcO_4$. For each compound, retention data were measured by using a minimum of four different methanol concentrations in the mobile phase. Each measurement was replicated at least three times.

Animal Studies. Biodistribution was carried out in rats. Before injection, Tc-99m complexes were purified using the procedure outlined above. After purification, the activity recovered was further diluted with a saline solution containing β-HPC 0.1 mg/mL to obtain a final solution that was 2% in ethanol content. Female Sprague−Dawley rats weighing 180−200 g were anesthetized with an intraperitoneal injection of a mixture of Zoletil (40 mg kg^{-1}) and Xilazine (2 mg kg^{-1}). A jugular vein was surgically exposed and 100 μL (300−370 kBq) of the solution containing the radioactive complex were injected. The animals ($n = 3$) were sacrificed by cervical dislocation at different times postinjection. The blood was withdrawn from the heart with a syringe immediately after sacrifice and quantified. Organs were excised, rinsed in saline, weighed and the activity counted in a NaI well counter. Results were expressed as percentage of injected dose per gram (%ID/g).

RESULTS

Synthesis of Disubstituted [^{99m}Tc(N)(R_2PS)$_2$] Compounds. Neutral disubstituted [^{99m}Tc(N)(R_2PS)$_2$] nitrido compounds were prepared, in high yield (>90%), through a two-step procedure (methods 1, 2). The first step involved the preliminary conversion of the starting [$^{99m}TcO_4$]$^-$ into a mixture of prereduced species containing the [Tc(N)]$^{2+}$ multiple bound. The second step, which took place in basic media, required the addition of 0.25−1 mg of the bidentate phosphino-thiol ligand (R_2PSH).

Scheme 1

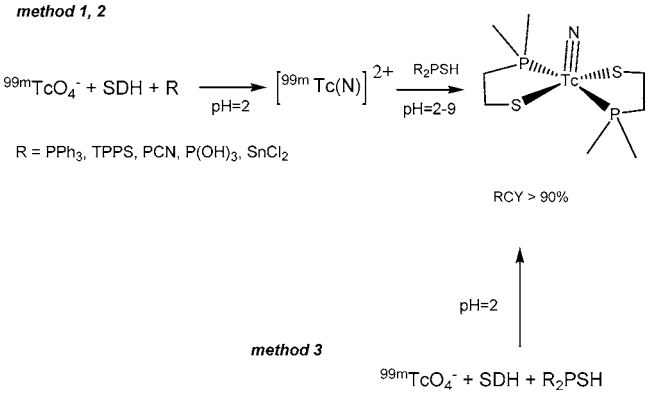

Table 2. Variation of % RCY in Formation of [^{99m}Tc(N)(R_2PS)$_2$] Complexes, at Different Times, as Function of pH, Temperature, and Amount of R_2PSH Ligand

			[Tc(N)(PScy)$_2$] (% RCY)

0.050	9	RT	73.0	78.0	91.0
0.050	7	RT	60.4	78.5	87.2
0.050	5	RT	57.3	69.0	85.8
0.050	2	RT	−	−	−
0.050	2	100	40.5	57.9	85.0
1	2	RT	85.0	65.1	94.9
			[Tc(N)(PSiso)$_2$] (% RCY)		
PSisoH (mg)	pH	temp (°C)	15 min	30 min	60 min
0.025	9	RT	73.0	75.0	71.0
0.025	7	RT	86.4	88.5	87.2
0.025	5	RT	84.2	87.2	87.4
0.025	2	RT	−	−	−
0.025	2	100	40.5	57.9	85.0
1	9	RT	78.1	80.1	78.9
1	2	RT	95.0	95.1	94.9

The reaction was carried out using different procedures depending on the reducing agents, the source of nitride (N^{3-}), and the pH employed (Scheme 1).

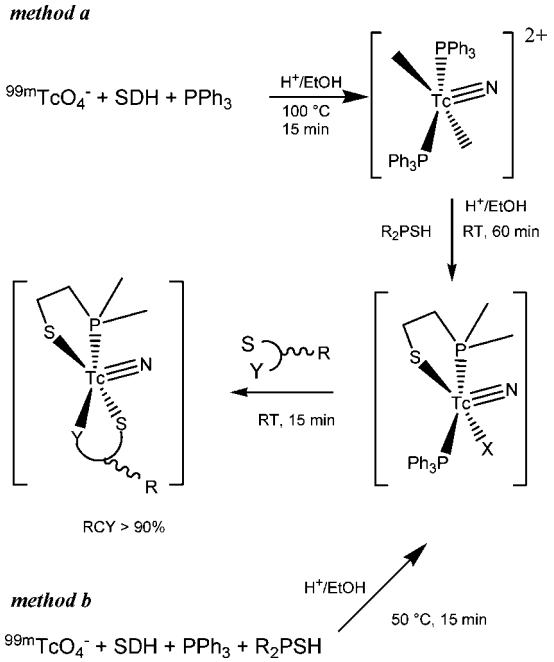
Coordination of R_2PSH was achieved at basic pH after 15 min at 100 °C. Lower temperatures (50 °C) required prolonged reaction times. Acidic media caused the reaction to be incomplete; in particular when SDH and PPh_3 were used to produce the intermediate nitrido compounds, different species were obtained (vide infra). Following this latter procedure, the influence of pH, temperature, and concentration of R_2PSH on the RCY formation of [^{99m}Tc(N)(R_2PS)$_2$] (R = C_6H_{11} and CH-$(CH_3)_2$) was monitored at different times. The results are illustrated in Table 2.

Alternatively, due to the intrinsic reducing power of the phosphino-thiol ligands, disubstituted symmetrical compounds may be obtained directly with a one-step procedure (method 3) using these ligands as reducing and coordinating agents. In this case an increased amount of R_2PSH (ca. 1−2 mg) was required to guarantee a radiochemical yield >85%. However, this reduction−substitution procedure gave low yield of formation (<70%) when applied to PS*me*H or PS*tbu*H ligands.

Synthesis of Monosubstituted Intermediate [^{99m}Tc(N)-(R_2PS)Cl(PPh_3)] Compounds. The monosubstituted compounds [^{99m}Tc(N)(R_2PS)(PPh_3)]$^+$ were prepared through a two step procedure, as reported in Scheme 2.

The first step involved the reduction of pertechnetate with PPh_3, in acidic media at 100 °C and in the presence of a donor of nitride (N^{3-}) (SDH). A mixture of labile PPh_3-containing intermediate nitrido complexes was obtained. In the second step the monosubstituted asymmetrical compounds [^{99m}Tc(N)(R_2PS)-

Scheme 2



$(PPh_3)]^+$ (R = C_6H_{11}, $CH(CH_3)_2$, and $CH_2CH(CH_3)_2$) were generated, at room temperature, through a ligand exchange reaction by adding a specific amount (10^{-4} mmol) of the selected bidentate phosphino-thiol. Proton concentration was found to be critical in obtaining a quantitative conversion of the mixture of intermediate nitrido complexes into the $[^{99m}Tc(N)(R_2PS)(PPh_3)]^+$ species (Table 2). In fact, as previously described, when the preparation was carried out in basic media, the yield of $[^{99m}Tc(N)(R_2PS)(PPh_3)]^+$ was endangered due to the formation of the corresponding symmetric disubstituted complexes $[^{99m}Tc(N)(R_2PS)_2]$.

Alternatively, the monosubstituted compounds could be obtained in 15 min at 50 °C through a one-step procedure by adding pertechnetate to a vial containing SDH and PPh_3 at low pH (pH = 2) and 10^{-4} mmol of R_2PSH.

A systematic study was performed under the optimized pH and R_2PSH concentrations in order to evaluate the role of the PPh_3 in the formation of monosubstituted complexes compared to the use of other tertiary phosphines. The results indicated that PPh_3 (used as both reducing and coordinating agent) gave better yields compared to other tertiary phosphines (PCN, TPPS, $P(CH_2OH)_3$) or compared to the classical reducing agent tin chloride. These alternative phosphines were selected considering their solubility in hydro-alcoholic solution and their electronic and steric properties.

For all alternative phosphines, the HPLC analysis revealed the formation of $[^{99m}Tc(N)(R_2PS)_2]$ as main products, further underlying the key role of PPh_3 in controlling $[^{99m}Tc(N)(PS)(PPh_3)]^+$ formation and stabilization. The molecular structure of this monosubstituted complex has been schematically drawn in Scheme 2. It is composed of a terminal Tc≡N multiple bond coordinated to a phosphino-thiol ligand (R_2PS) through the neutral phosphorus and deprotonated sulfur thiol atoms and a tertiary phosphine PPh_3. The residual position, in the square pyramid arrangement, is available for the coordination of monodentate ligands such as Cl^-, OH^-, and H_2O (X), present in physiological solution. This hypothesis was confirmed by the comparison of the HPLC profiles of various $[^{99m}Tc(N)X(R_2PS)(PPh_3)]^{+/0}$ (R= C_6H_{11}, $CH(CH_3)_2$, and $CH_2CH(CH_3)_2$) complexes with those of the corresponding $[^{99g}Tc(N)Cl(R_2PS)(PPh_3)]$ compounds prepared with the long-lived isotope Tc-99g (Figure 3b) which showed a mixture of different compounds. One of them was characterized as the neutral $[^{99m}Tc(N)Cl(R_2PS)(PPh_3)]$ species (RCY < 30%). At macroscopic level, these $[^{99g}Tc(N)Cl(R_2PS)(PPh_3)]$ intermediate complexes were prepared by reacting the precursor $[^{99g}Tc(N)Cl_2(PPh_3)_2]$ with the R_2PSH ligand in dichloromethane solution and were characterized by elemental analysis and spectroscopic methods (*22*). In addition, the synthesis and the chemical structure of the $[^{99g}Tc(N)Cl[(C_6H_{11})_2PS](PPh_3)]$ prototype complex has been previously reported (*21*). The X-ray analysis showed a square pyramidal geometry with the nitrido at the apex and the remaining coordinating atoms (P, S, P, Cl) at the base of the pyramid.

At nanomolar level, despite the unfeasibility in identifying the remaining species, the mixture containing the monosubstituted complexes was easily and quantitatively converted into the corresponding final mixed compounds $[^{99m}Tc(N)(R_2PS)(S\text{^}Y)]$ by reaction with the appropriate bidentate S^Y ligand (see below). This behavior suggests that the mixture of intermediate compounds possesses the same $[^{99m}Tc(N)(R_2PS)]^+$ moiety.

Attempts to prepare similar monosubstituted $[^{99m}Tc(N)X(R_2PS)(PPh_3)]^{+/0}$ compounds using PS*me*H and PS*tbu*H failed. The less sterically hindered PS*me*H ligand led only to the formation of the stable disubstituted symmetrical compound $[^{99m}Tc(N)(PSme)_2]$. Meanwhile, the bulkiest PS*tbu*H yielded unstable species which rapidly converted in to the disubstituted $[^{99m}Tc(N)(S\text{^}Y)_2]$ complexes after addition of the bidentate S^Y ligand. This behavior can be attributed to the ligand bulkiness which decreases its binding ability, owing to the increased congestion around the binding face of the P atom. This fact indicates that a careful choice of the bulkiness is necessary to control the formation of $[^{99m}Tc(N)X(R_2PS)(PPh_3)]^{+/0}$.

Synthesis of Asymmetrical $[^{99m}Tc(N)(R_2PS)(S\text{^}Y)]$ Compounds. The preparation of asymmetric $[^{99m}Tc(N)(R_2PS)(S\text{^}Y)]$ was carried out following the procedure reported in Scheme 2. Table 1 summarizes the chromatographic properties and the RCY values obtained for the corresponding hetero-complexes. RCY data showed the ability of S^Y ligands, containing different combinations of heteroatom (S, N, O), to form the final complexes. The results indicated that [S^-,S] ligands such as dithiocarbamate, dithiophosphinate, and dithiocarboxylate exhibited a high selectivity in displacing the monodentate ligands (X^- and PPh_3) from the $[^{99m}Tc(N)X(R_2PS)(PPh_3)]^{+/0}$ intermediate compound. A quick and quantitative conversion into neutral asymmetrical nitrido species occurred within 15 min at room temperature by using a small amount (1−0.025 mg) of the bidentate [S^-, S] ligand.

Analogously, encouraging preliminary results were found using monoanionic bidentate ligands having [S^-, NH_2] as coordinating pairs such as cysteamine (SN) or L-cysteine ethyl ester (SN-Cys). Also in these cases, neutral species of the type $[^{99m}Tc(N)(R_2PS)(S\text{^}NH_2)]$ were isolated after 15 min at 60 °C, by adding 1 mg of the bidentate [S^-, NH_2] ligand to the intermediate species. The $[^{99m}Tc(N)(R_2PS)(SN\text{-}Cys)]$ complex was formed as a mixture of two isomeric forms (60/40 ratio) due to the relative syn or anti orientation of the pendant lateral group with respect to the Tc≡N multiple bond. On the contrary, no reactivity toward the $[^{99m}Tc(N)X(R_2PS)(PPh_3)]^{+/0}$ species was observed for bidentate ligands carrying [O^-, S] or [S^-, O] pair of coordinating atoms. The chemical identity of ^{99m}Tc-complexes was determined by HPLC comparison of their chromatographic properties with those of the corresponding Tc-99g complexes (see Table 1 and Figure 3c).

The Log k_0' values of some representative compounds as measure of the relative lipophilicity of the complexes were calculated by reverse phase HPLC using various mixtures of methanol/phosphate buffer (pH 7.4) as eluant and compared with

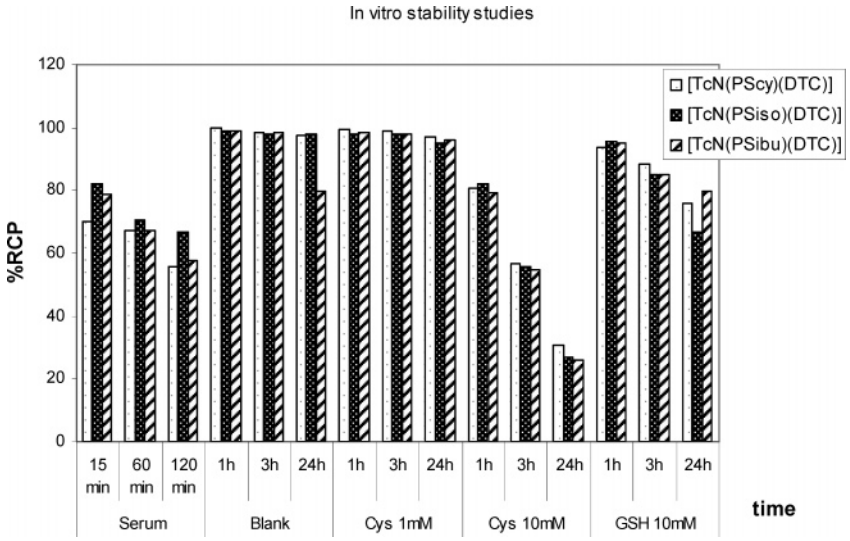


Figure 4. In vitro stability studies of some representative [^{99m}Tc(N)(DTC)(R_2PS)] asymmetrical compounds.

Log k_0' of the commercially available perfusion agent [^{99m}Tc]-ECD measured under the same experimental conditions.

Stability Studies. Neutral disubstituted symmetrical compounds [^{99m}Tc(N)(R_2PS)$_2$] were found stable under all investigated conditions. Neutral asymmetrical [^{99m}Tc(N)(R_2PS)(S^Y)] compounds were stable for 24 h, after HPLC purification, in ethanol solution or in aqueous solution containing 15% EtOH. Transformation of mixed complexes into more hydrophilic compounds was observed after dilution with saline or phosphate buffer (0.02 M, pH 7.4), to obtain a final solution containing 5% EtOH. The corresponding RCP evaluated by TLC and HPLC chromatography was reduced to 50% at 1 h. In these latter conditions a remarkable increase of the stability (RCP 90% after 24 h) in aqueous solution was achieved by adding a small amount of β-HPC (0.5 mg/mL) to the complex solution.

In Vitro Stability Studies with Serum and Challenge with Glutathione or Cysteine. The stability of all complexes in serum and toward transchelation with GSH and cysteine were investigated. The complexes were found stable after serum incubation at 37 °C for 2 h. More specifically, after 15 min of incubation about 5−15% of the starting activity was associated to the plasma proteins, while the remaining activity matched the initial product. After 2 h the activity associated to the proteins was generally increased to 20%, and the HPLC profile revealed the presence of traces of some more hydrophilic compounds near the initial complex.

No significant changes in RCPs of the [^{99m}Tc(N)(R_2PS)$_2$] complexes were observed in challenge experiments, after 24 h of incubation at 37 °C with cysteine and GSH, whereas a slight difference in stability was observed for [^{99m}Tc(N)(R_2PS)(S^Y)] complexes. The results are showed in Figure 4.

No considerable change of RCP was observed after incubation at 37 °C with an excess of GSH. However a more hydrophilic compound was observed after incubation with an excess of Cys (10 mM) as consequence of a tranchelation reaction between the S^Y ligands and Cys. Nevertheless, studies carried out with 1 mM of Cys showed a reduction of the transchelation rate of the complexes which therefore return to stability.

Biodistribution Studies. Biodistribution studies of neutral symmetrical and asymmetrical disubstituted compounds were evaluated in female Sprague−Dawley rats. The experiments were carried out in compliance with the international laws for the conducting of animal experimentation. Purification of the radiolabeled compound before injection was necessary in order to remove excess of cold ligands and any radiochemical impurity formed during the labeling procedure. The radiochemical purity and stability of the purified compounds were verified with HPLC prior to in vivo administration, as well as during the utilized period, to guarantee >90% purity of the injected radiolabeled compounds. Tissue distribution data of neutral disubstituted symmetrical compounds [^{99m}Tc(N)(R_2PS)$_2$] are summarized in Table 3.

Our results show that the substituents at the phosphorus atom of the R_2PSH ligand influence the biodistribution pattern. Notable differences were observed in blood, liver, and kidney accumulations and especially in the brain uptake. For all these compounds a rapid blood clearance is generally observed. The high liver uptake suggests that the hepatobiliary system is the major route of excretion of the administered agents.

In detail, the [^{99m}Tc(N)(PS*iso*)$_2$] complex revealed the highest brain uptake (1.28 ± 0.02% ID/g) at 2 min postinjection (p.i.), with a significant brain-to-blood ratio (B/bl = 4), though, the initial high brain uptake was followed by a rapid wash-out and at 20 min p.i. the brain activity dropped to 0.20 ± 0.02% ID/g. The more lipophilic [^{99m}Tc(N)(PS*tbu*)$_2$] complex showed initial brain uptake (0.71 ± 0.02% ID/g; 2 min p.i.), but a slower brain elimination (0.23 ± 0.06% ID/g; 60 min p.i.), indicating that by increasing the lipophilicity of the complex it is possible to reduce the wash-out from the brain tissue.

Biodistribution of some representative neutral [^{99m}Tc(N)(R_2PS)(S^S)] mixed compounds are summarized as % of dose/g in Table 4. The data show that, at 2 min p.i., all the investigated compounds were distributed throughout the body with a similar pattern, independently from the nature of the two bidentate ligands. The complexes exhibited a rapid blood clearance and, despite their high lipophilicity, the radioactivity was eliminated through the liver and intestines as well as the kidneys and the urine.

A significant initial high extraction by the myocardial tissue was observedfor all [^{99m}Tc(N)(R_2PS)(S^S)] compounds (in the range 5.48 ± 0.09%ID/g; 2.48 ± 0.35% ID/g) followed by a rapid wash-out (0.55 ± 0.09% ID/g; 0.29 ± 0.01% ID/g).

All investigated complexes show a transient but significant initial brain uptake at 2 min p.i. with the activity in the range 0.20 ± 0.01% ID/g and 0.91 ± 0.06% ID/g. A brain-to-blood ratio > 1 was observed at 2 and 10 min p.i., demonstrating that these compounds quickly diffuse across the BBB, probably through passive diffusion due to their lipophilicity.

DISCUSSION

A systematic investigation on the reactivity of bidentate phosphino-thiol ligands (R_2PSH where R = alkyl groups) toward

nitrido-^{99m}Tc precursors led to the preparation of pentacoordinate symmetrical [^{99m}Tc(N)(R_2PS)$_2$] and asymmetrical [^{99m}Tc(N)-(R_2PS)(S^Y)] complexes. [^{99m}Tc(N)(R_2PS)$_2$] complexes were prepared following the methods reported in Scheme 1. The best labeling procedure involved ligand-exchange reactions performed in basic media (methods 1, 2) using a very low amount of phosphino-thiol ($\sim 10^{-4}$ mmol). The basic pH was essential in guaranteeing the quantitative formation of the disubstituted products, indicating that the coordination of the R_2PSH ligand probably occurred through the initial nucleophilic attachment of the deprotonated thiol sulfur to the metal center. Lower radiochemical yields were obtained using the R_2PSH ligand as both a reducing and coordinating agent (one-step procedure, method 3), because of the concomitant formation of the corresponding Tc(III) compounds [^{99m}Tc(R_2PS)$_3$] (*20*).

The chemical identity of [^{99m}Tc(N)(R_2PS)$_2$] complexes was established by HPLC comparison with the corresponding compounds prepared at macroscopic level with the long-lived isotope Tc-99g (Figure 3a). The remarkable in vitro stability of the disubstituted compounds is determined by the combination of two π-acceptor (P) and two π-donor (S^-) atoms around the $[Tc(N)]^{2+}$ core which confer high thermodynamic stability and kinetic inertness.

Biological evaluation of these agents showed encouraging results. The [^{99m}Tc(N)(PS*iso*)$_2$] compound showed the best brain uptake of the series with a significant brain-to-blood ratio (B/bl = 4) at 2 min p.i. (Table 3). However, the initial high brain uptake was followed by a rapid wash-out, and at 20 min p.i. brain activity dropped to 1/6 of its initial value. Data collected for the more lipophilic [^{99m}Tc(N)(PS*tbu*)$_2$] species revealed that

it was possible to modulate the kinetic of the wash-out, increasing the permanence of the complex in the tissue.

These results suggested that the diffusion across the BBB was a reversible process for this class of complexes, and that these compounds moved freely in and out of the brain. This behavior could be attributed to the absence of an efficient trapping mechanism that prevents the complex from crossing the BBB in the opposite direction. In connection, while the lipophilicity of $[Tc(N)(R_2PS)_2]$ symmetrical compounds can be modified by varying the substituents on the phosphorus donor or on the R_2PSH backbone, the introduction of pendant groups that could be involved in trapping mechanisms required instead quite complicated and difficult synthesis.

Considering the recent demonstration that other disubstituted complexes of the type $[^{99m}Tc(N)(S\text{^}Y)_2]$, where S^Y is a dithiocarbamate (DTC) or a dithiophosphinate (PSS) ligand, showed an appreciable accumulation in the cerebral tissue (*25*, *27*, *28*), we decided to design a new class of CNS agents which combined the biological properties of $[^{99m}Tc(N)(S\text{^}Y)_2]$ and $[^{99m}Tc(N)(R_2PS)_2]$ compounds through the preparation of mixed pentacoordinate species of the type $[^{99m}Tc(N)(R_2PS)(S\text{^}Y)]$. In these complexes the co-ligand S^Y offered the possibility of being modified with an appropriate functional group designed for trapping mechanism in order to increase the brain retention for longer time intervals.

The possibility of introducing only one R_2PSH ligand onto a $[Tc(N)]^{2+}$ group was accomplished with bulky aliphatic substituents to the phosphine phosphorus under particular reaction conditions. In fact, the existence of a monosubstituted phosphino thiolato complex $[^{99g}Tc(N)Cl(R_2PS)(PPh_3)]$ has already been demonstrated at macroscopic level using the encumbering 2-(dicyclohexylphosphino)ethanethiol (PS*cy*H) ligand (*21*). The subsequent replacement of the monodentate chloride and PPh_3 ligands with a mononegative chelate (S^Y) such as dithiocarbamate (DTC) permitted the preparation of neutral disubstituted asymmetrical complexes of the type $[^{99g}Tc(N)(R_2PS)(DTC)]$. They represent prototypes of a new class of complexes characterized by the presence of the $[Tc(N)(R_2PS)]^+$ building block (*22*).

Identical asymmetrical monosubstituted $[^{99m}Tc(N)Cl(R_2PS)(PPh_3)]$ and disubstituted $[^{99m}Tc(N)(R_2PS)(DTC)]$ species were efficiently prepared at tracer level, following the procedures indicated in Scheme 2. The acidic medium was essential in obtaining the monosubstituted compounds. In fact, high proton concentration prevented the thiol group of the R_2PSH ligand from being deprotonated, thus reducing its affinity toward the metal center. On the contrary, as described above, basic conditions favored the substitution of chlorine and PPh_3 ligands giving the substitution inert $[^{99m}Tc(N)(R_2PS)_2]$ symmetrical complexes.

In addition, the use of PPh_3 was also found to be a key factor in the redox synthesis and in the stabilization of the monosubstituted compounds. In particular in the one step procedure (method b), the complex was obtained though a redox-exchange reaction, by adding pertechnetate to a vial containing SDH, PPh_3 and the R_2PSH, in the presence of H^+. Despite the recognized ability of the phosphino thiol ligands to work both as reducing and coordinating agents, the small amount ($\sim 10^{-4}$ mmol) of R_2PSH used in this preparation was not enough to guarantee reduction of the pertechnetate. Thus, reduction was performed by PPh_3 that simultaneously acts with R_2PSH as coordinating agent to form $[^{99m}Tc(N)Cl(R_2PS)(PPh_3)]$ compounds.

Addition of the appropriate bidentate mononegative ligand (S^Y) to the reaction vial containing the monosubstituted species (15 min, at room temperature) gave the final neutral $[^{99m}Tc(N)(R_2PS)(S\text{^}Y)]$ complexes in high yield. These results suggest that the monosubstituted $[Tc(N)Cl(R_2PS)(PPh_3)]$ complex represents the key intermediate for the synthesis of this new class of mixed technetium species.

In general, the intermediate complex prefers to react with S^Y ligands having 'soft' σ-,π-donor combinations such as $[S^-, S]$ or $[S^-, NH_2]$ pairs, whereas ligands containing at least one 'hard' σ-donor atom, such as $[O^-, S]$ or $[S^-, O]$ combinations, do not react at all. The ability to form the $[^{99m}Tc(N)(R_2PS)(S\text{^}Y)]$ species ($R = CH(CH_3)_2$), expressed as % of RCY, is as follows:

$$DTC[94\%] > PSS[90\%] > DTCOX[88\%] > SN[85\%] \geq SN\text{-}Cys[83\%]$$

In vitro stability studies demonstrated that these mixed agents were stable for hours in aqueous solution in the presence of β-HPC and inert toward tranchelation in the presence of GSH (10 mM) or cysteine (1 mM). This indicates that the combination of π-acceptor and π-donor coordinating atoms is responsible for the stability and kinetic inertness of the resulting mixed complexes in this case as well. No significant interaction with the serum protein was observed.

In vivo biodistribution data of some representative $[^{99m}Tc(N)(R_2PS)(S\text{^}Y)]$ compounds displayed a similar pattern, comparable to those exhibited by the symmetrical $[^{99m}Tc(N)(PSiso)_2]$ complex. All investigated compounds showed a transient brain uptake and encouraging B/bl ratio >1, indicating that this class of mixed complexes retains the ability to freely cross the intact BBB. The initial brain uptake of these tracers was apparently driven by their lipophilic character as we have already demonstrated for the disubstituted compounds. Data collected for the complexes having a Log k_0' value around 4.4 ($[^{99m}Tc(N)(PSibu)(DTC3)]$ and $[^{99m}Tc(N)(PSiso)(PSS2)]$) revealed that the kinetic of the wash-out from the brain tissue was decreased.

Prolonged brain retention must still be achieved, but the possibility of introducing specific groups onto the S^Y ligand in mixed complexes allows for the designing of updated agents which may be subject to the trapping mechanism inside the cerebral tissue. Studies aimed toward this goal are currently in progress (*29*).

CONCLUSIONS

This study devises a general procedure for the preparation of a new class of nitrido asymmetrical Tc-99m complexes containing two different bidentate ligands bound to the same $[Tc(N)]^{2+}$ core, which could be used to design either essential or target specific imaging agents.

This procedure is based on the chemical property of a new monosubstituted $[Tc(N)Cl(R_2PS)(PPh_3)]$ species which represents the key intermediate for the development of a new class of neutral pentacoordinate asymmetrical nitrido compounds of the type $[Tc(N)(R_2PS)(S\text{^}Y)]$, characterized by the presence of a Tc≡N terminal group, an *ancillary* P^S ligand and a bidentate mononegative co-ligand (S^Y), such as a dithiocarbamate. In these complexes the phosphino-thiol ligand stabilizes the metal oxidation state, whereas the S^Y chelate, designed to carry a functional group or a bioactive molecule, completes the metal coordination sphere.

The molecular weight of the $[Tc(N)(R_2PS)]^+$ building block (about 300 Da) allows the molecular weight of the final compound to be maintained within the limit required to cross the BBB. Moreover, the bidentate ligand S^Y may be used to carry additional functional groups which are useful for the trapping mechanism such as 'pH shift', enzymatic degradation mechanism, and receptor specific interactions, to increase brain retention for longer time intervals.

The flexibility of this system due to the possibility of changing the substituents at the P atoms and/or the bidentate ligand may

be utilized to design a wide range of Tc≡N mixed compounds and to modulate their biological properties. The discovery that the amino acid cysteine exhibited encouraging coordinating properties toward the $[Tc(N)(R_2PS)]^+$ intermediate suggests the use of this chelating system for incorporating a short peptide in a Tc-99m asymmetrical complex.

ACKNOWLEDGMENT

The authors are grateful to Mr. Mariano Schiavon for his assistance in the animal studies.

Surface-Assisted Delivery of Fluorescent Groups to hGST A1-1 and a Lysine Mutant

Johan Viljanen, Lotta Tegler, Jenny Larsson, and Kerstin S. Broo*

IFM, Department of Organic Chemistry, Linköping University S-581 83 Linköping, Sweden. Received September 13, 2005

Human glutathione transferase (hGST) A1-1 and a lysine mutant (A216K) can both be rapidly and site-specifically acylated on Y9 and K216, respectively, using a range of thiolesters of glutathione (GS-thiolesters) as modifying reagents. The present investigation was aimed at developing a method with which to deliver a fluorescent acyl group from a solid support under conditions compatible with standard protein purification schemes. A number of fluorescent GS-thiolesters with modified peptide backbones were therefore prepared and tested for reactivity toward hGST A1-1 and the A216K mutant. Substitutions at the α-NH_2 part of the glutathione backbone were not tolerated by the proteins. However, two fluorescent reagents that carry a biotin moiety at the C-terminal part of glutathione were found through MALDI-MS experiments to react in solution with Y9 of the wild-type protein and one reagent with K216 of A216K. The reaction can take place in the presence of glutathione and even in a crude *E. coli* lysate of cells expressing A216K. Delivery of the fluorescent group to Y9 or K216 was possible using NeutrAvidin (NA) beads that had been preincubated with biotinylated reagent. Alternatively, excess reagent can be removed by a brief incubation with NA beads. We have thus now developed a system for protein labeling with easy removal of excess and used up low-molecular weight reagent. This strategy can conceivably be utilized in future protein purification and labeling experiments.

INTRODUCTION

Following the completion of the HUGO project (*1*, *2*), proteomic research has become an even more expansive field (*3*). There is thus a considerable need for tools that can aid in expression, purification, and analysis of old and new proteins. A popular method is to express a protein linked to a dependable fusion-protein partner (*4*, *5*). In our protein reengineering efforts, we have focused on extending the repertoire of protein scaffolds by chemical modification to introduce an artificial group (*6*−*8*). This new methodology could conceivably be exploited in protein fusion and protein purification applications.

We use the glutathione transferases (GSTs, EC 2.5.1.18)[1,2] as scaffolds, and on the basis of the results from our previous studies (*6*−*8*), we have focused on human glutathione transferase (hGST) A1-1 (Figure 1), which is easy to express in a high yield, displays a high stability, is easy to purify, and is relatively tolerant to mutations. A number of crystal structures of the GSTs have been published, and there is thus an extensive knowledge of structure−activity relationships (*9*). The GSTs are detoxication enzymes (phase II) that catalyze the nucleophilic addition of the thiol of glutathione (GSH, Scheme 1) to a wide range of hydrophobic electrophilic molecules (*10*−*13*). The proteins form homo- or heterodimers (*12*, *14*) and the fold of the N-terminal part of the proteins where GSH binds (G-site) is very similar throughout the classes (*10*, *15*). The differences between the isoenzymes are mostly situated in the promiscuous hydrophobic binding sites (H-sites) that provide a broad and overlapping substrate specificity (*16*). In the alpha class the catalytic function is dependent on a conserved tyrosine residue in the G-site that aids in the ionization of GSH to form the more reactive thiolate ion (*10*). The modular features of the GSTs are close to ideal from a protein engineering aspect with specific binding of GSH in the G-site combined with an

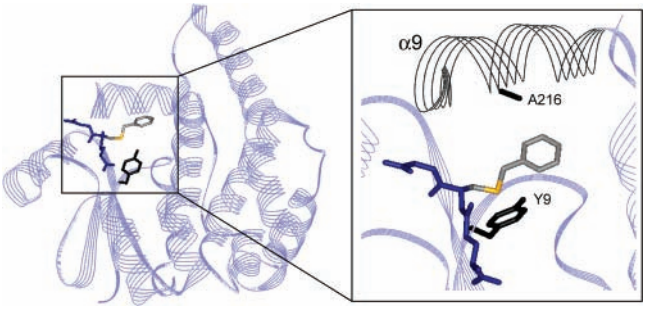

Figure 1. A close-up of the crystal structure (1GUH) of wt hGST A1-1 in a complex with *S*-benzylglutathione (*15*). The targeted positions (Y9 and A216) are shown in "stick" representation, and the flexible helix 9 (α9) is also indicated in the figure. The protein is dimeric but shown here as a monomer for reasons of clarity of presentation.

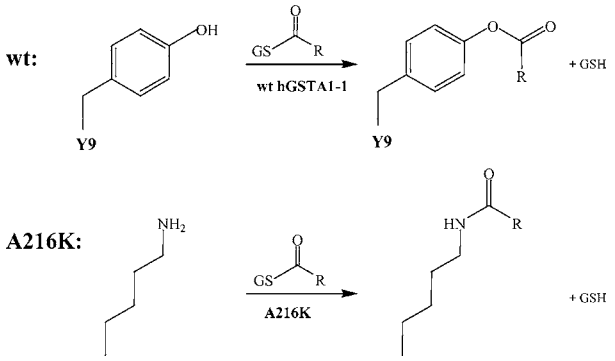
Scheme 2



adjacent, promiscuous H-site. This, together with the robustness of the proteins, singles out the GSTs as exceptional candidates for chemical reengineering purposes.

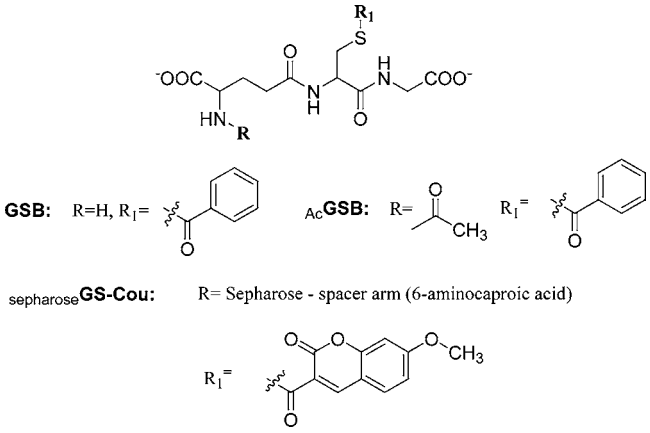
Previously, we reported that hGST A1-1 (Figure 1) can be site-specifically acylated on a single tyrosine residue (Y9) using thiolesters of glutathione (GS-thiolesters, Scheme 2) (*6*). Out of a total of 20 GS-thiolesters tested, 15 are accepted by hGST A1-1 (*7*), and this is thus a very versatile reaction. We then produced a mutant (A216K) of hGST A1-1 that can be rapidly and site-specifically modified at the introduced lysine residue to form a stable amide linkage with a range of acyl groups (Scheme 2) (*8*). The reaction can take place in the presence of GSH and even in a crude *E. coli* lysate. The acylation reaction is very versatile, fast, and site-directed toward one residue in the protein (Y9 or K216) with minimal side reactions. This is due to the glutathione-based backbone of the reagents that orient the thiolester functionality in close proximity to the reactive residues while the adjacent, promiscuous H-site accepts a large variety of acyl groups. Using an appropriate GS-thiolester reagent, we can thus chemically reengineer folded protein scaffolds with the goal of obtaining new function.

To create an even more user-friendly acylating reagent, we wanted to investigate the possibility of surface-assisted delivery of the acyl group to the folded protein scaffold. If the acyl group could be delivered from a solid support or if a solid support could be used to mop up excess reagent, the need for purification of the protein conjugate from excess reagent after labeling would be removed. Because of the physiological importance of the GSTs, alot of work has been put into investigating the substrate requirements, both for GSH (*17*−*19*) and also for the electrophile (*16*). It has been found that even though the binding of GSH by the GSTs is quite specific, some changes of the peptide are accepted (*18*). Alterations of the unusual γ-Glu part of the tripeptide are generally not accepted whereas the GSTs seem to be tolerant to some changes at the C-terminal glycyl-moiety (*18, 19*). However, since neither the A216K mutant nor our particular type of reaction has been studied in this respect, we decided to synthesize a series of fluorescent GS-thiolesters where the GSH moiety was altered either at the α-NH_2 group (Scheme 3) or at the glycine residue (GSC-thiolesters, Scheme 4).

MATERIALS AND METHODS

All chemicals and reagents used were of the highest purity available. The tripeptides were synthesized using solid-phase Fmoc-chemistry, and protected amino acids were purchased from Novabiochem (Darmstadt, Germany) or Bachem Holding AG (Weil am Rhein, Germany). The fluorescent acyl groups were purchased from Sigma-Aldrich, Inc. (St. Louis, MO) or Molecular Probes, Inc. (Eugene, OR). NHS-activated Sepharose was purchased from Amersham Biosciences (Uppsala, Sweden) and EZ-LinkPEO-Iodoacetyl Biotin and Immobilized NeutrAvidin (NA) gel were purchased from Pierce Biotechnology, Inc.

Scheme 3



(Rockford, IL). All solid-phase syntheses were carried out in a VacMaster (International Sorbent Technology). The HPLC experiments were carried out using a Kromasil C_8-column (4.6 mm × 250 mm, Supelco inc.) or a Grace Vydac Everest C18 column (4.6 mm × 150 mm) attached to a Varian system with a ProStar 230 Delivery System, a ProStar 330 Photodiode Array Detector, controlled by the Varian LC Software. All mass spectra were recorded using a MALDI-TOF MS (Voyager System 4212, Applied Biosystems) with detection in the positive mode. The UV measurements were performed using a Varian Cay 100 Scan UV-visible spectrophotometer and the results analyzed with the CaryWin UV software.

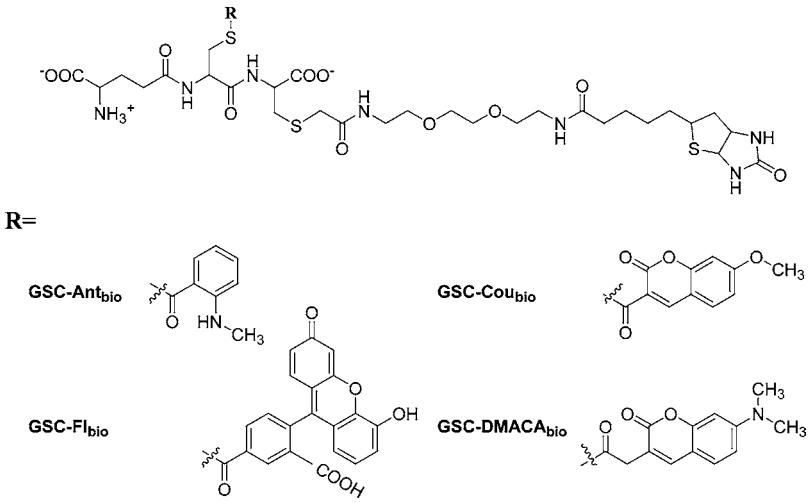
Attachment of GS-Cou to NHS-Activated Sepharose and Incubation with hGST A1-1. The tripeptide GS-Cou was attached to NHS-activated Sepharose (Amersham Biosciences) in accordance with the protocol supplied by the manufacturer. The substitution level was 16−23 μmol/mL drained gel, and the thiolester was added in a 3.5 times excess over activated groups. The reaction was performed at 25 °C for 3 h. Unreacted NHS groups on the gel were then blocked, and the gel was washed again in accordance with the protocol to remove excess GS-Cou. The derivatized gel fluoresced under a UV lamp (λ = 337 nm). The gel was stored in buffer (0.1 M NaPi, pH 7) at +4 °C until used in the experiments.

The wt protein hGST A1-1 was added to the $_{\text{sepharose}}$GS-Cou gel with the immobilized thiolester in a ratio of protein:thiolester of 1:20 assuming a 100% yield in the derivatization reaction. The mixture was allowed to incubate at 25 °C for 5 h, and the protein was then eluted with a quick spin in a tabletop centrifuge. The eluted protein was digested with *Staphylococcus aureus* V-8 Protease (see below), and the peptide fragments were analyzed with MALDI-MS.

Synthesis of $_{\text{Ac}}$GSB. To synthesize $_{\text{Ac}}$GSB, GSB (2 mM) was incubated with 20 equivalents of sulfosuccinimidyl-acetate in 0.1 M NaP_i, pH 7.0 at r.t. After 30 min another 20 equivalents of sulfosuccinimidyl acetate was added to the reaction mixture. The reaction was followed by analytical reversed phase HPLC using a GraceVydac, Everest C-18 column (4.6 × 150 mm) with a shallow gradient of ACN:H_2O from 20 to 90% ACN. The identity of the product was confirmed with MALDI-MS (Voyager System 4212, Applied Biosystems) using an α-cyano-4-hydroxycinnamic acid matrix with detection in the positive mode. The acetylated product was purified by reversed phase HPLC.

Synthesis of γ-Glu-Cys-Cys (GSC). The tripeptide γ-Glu-Cys-Cys was synthesized using Fmoc-chemistry, starting from Fmoc-Cys(t-Bu-thio)-Wang-resin (0.5 g, 0.51 mmol/g). The two thiol groups in the peptide were orthogonally protected with the Mmt- and t-Bu-thio group to enable selective deprotection. Deprotection of the Fmoc groups was carried out using 20%

Scheme 4



piperidine in DMF. Couplings of Fmoc-Cys(Mmt)-OH and subsequently Boc-Glu-OtBu were performed in DMF using amino acid:HOBt:TBTU:DIPEA (3:5:5:6), with coupling times of 1−2 h. The deprotection and coupling steps were monitored by Kaiser tests (*20*), to estimate the amount of free amino groups. After completed synthesis, the polymer was washed thoroughly with DMF and DCM and dried under vacuum.

Synthesis of C-Terminally Biotinylated GSC-thiolesters. The tripeptides were synthesized in parallel, each on a 0.025 mmol scale, starting with 56 mg of protected γ-Glu-Cys-Cys -polymer for each tripeptide. The t-Bu-thio group was removed using β-mercaptoethanol:DMF (1:1) overnight. The coupling of EZ-LinkPEO-iodoacetyl biotin was performed in DMF with 6 equivalents of DIPEA. The Mmt group was removed with DCM:TFA:TIS (97:1:2) 3 × 6 mL with shaking for 2 min. The couplings of the different acyl groups were performed in DMF using a cocktail of acid:DIPCIDI:HOBt:DIPEA (2:3:3:6) with addition of a catalytic amount of 4-pyrrolidinopyridine. After 1 h, the solutions were removed, an additional batch of coupling-cocktail was added, and the couplings then proceeded overnight.

For each peptide, total deprotection and simultaneous cleavage from the solid support was achieved with TFA:H_2O (97.5:2.5), with occasional shaking for 2 h. The mixtures were filtered into preweighed centrifuge tubes, and the polymers were washed with small amounts of TFA. The volumes were then reduced to less than 0.5 mL, and the peptides were precipitated with cold diethyl ether. The peptide precipitates were collected by centrifugation and washed twice with diethyl ether, dried, dissolved in 0.1% TFA, and lyophilized. If a peptide was hard to dissolve in water, ACN was added before lyophilization. The peptides were purified using reversed phase HPLC on a C8-column or a C18-column with a gradient of ACN:H_2O from 20 to 90% ACN. The identities of the products were confirmed with MALDI-TOF MS using a α-cyano-4-hydroxycinnamic acid matrix with detection in the positive mode. The measured masses of the GSC-thiolesters were in good agreement with the calculated masses.

Site-Directed Mutagenesis, Protein Expression, and Purification. The mutant A216K was prepared by site-directed mutagenesis using the Quik-Change kit (Stratagene) as described elsewhere (*8*). The purity was confirmed by SDS−PAGE, and the concentration was determined spectrophotometrically using $\epsilon_{280} = 24\,700\ M^{-1}\cdot cm^{-1}$ (*21*). The fluorescence spectra of hGST A1-1 and A216K (1 μM each in 100 mM NaPi, pH 7.0) were collected using a Hitachi f-4500 fluorescence spectrophotometer, with excitation at 280 nm and emission scanning between 310 and 380 nm as described elsewhere (*8*).

The activities of the GSTs (*8*) were tested with a standard assay (*22*) containing 1 mM each of 1-chloro-2,4-dinitrobenzene (CDNB) and GSH (pH 6.5 in 0.1 M NaP_i at 30 °C). The proteins were stored in NaP_i buffered solutions containing NaCl and 10% glycerol at −80 °C or −20 °C until used in the experiments.

Modification Reactions in Solution. A typical modification was performed in the following way: 0.54 μL of protein (0.372 mM stock solution) was diluted with 15.5 μL of buffer (0.1 M NaP_i, pH 7.0), and the reaction was initiated by adding 4 μL of reagent (0.5 mM stock solution). The reaction was allowed to proceed at 25°C from 1 min up to 24 h. To control the temperature, the incubations were performed in an Eppendorf Master cycler gradient.

Modification Reactions in an *E. coli* Lysate. A lysate was prepared from *Escherichia coli* BL21(DE3) cells (Novagen) containing the vector pET-21a(+) with the A216K gene inserted (*8*). The cells were grown in 20 mL of 2 x YT medium to an OD_{600} of 0.6, induced with IPTG, and incubated at 37 °C for 3.5 h. The cells were harvested by centrifugation and resuspended in 250 μL of 0.1 M NaPi, pH 7, and lysed by freezing at −80 °C and thawing four times. The modification reactions were carried out by adding GS-thiolester (100 μM) to 2.5 μL of the cell lysate and the mixtures were then incubated for 5 h at 25 °C. The lysate itself was also analyzed by MALDI-MS to identify lysate-specific peaks. In the lysate experiments, all mixtures were acidified using 0.1% TFA and citrate was added (see below) prior to MALDI-MS analyses.

Proteolytic Digestion and MALDI-MS Analysis of Modified GSTs. The digestions were performed in the following way: 5 μL of modification mixture was diluted with 15 μL of buffer (75 mM NH_4OAc, pH 4), and the reaction was started by addition of 1 μL of *Staphylococcus aureus* V-8 Protease (1 μg/μL stock solution in 75 mM NH_4OAc, pH 4) from Pierce Biotechnology, Inc.. The mixture was then incubated at 25 °C for 2 h. A control reaction was also performed for each protein, containing unmodified protein, buffer, and protease. Cleaving with this protease results in fragments that contain K216 (K_{216}-RKIFRF) and Y9 (AEKPKLHY$_9$FNARGRME, one missed cleavage).

After proteolysis, an equal amount of 0.1% TFA (eg., 20 μL to 20 μL reaction mixture) was added to the digestion mixture to quench and acidify the sample. Following incubation, 0.5 μL of the reaction mixture was mixed with 0.5 μL of saturated α-cyano-4-hydroxycinnamic acid matrix, and 0.5 μL of citrate (10 mg/mL) was also added to quench salts from the buffers. The samples were then analyzed by MALDI-TOF MS (Voyager 4212, Applied Biosystems) with detection in the positive mode.

The Rate of the Reaction between A216K and GSC-Cou$_{bio}$. A216K (10 μM) was incubated with 100 μM GSC-Cou$_{bio}$ in 0.1 M NaPi buffer, pH 7, at 25 °C, and samples were withdrawn at various time points starting at $t = 0$ min. The samples were immediately quenched with 0.1% TFA and stored at −20 °C until digestion at pH 4 and analysis using MALDI-MS. The data were analyzed by dividing the *m*/*z* peak resulting from the modified fragment containing K216 by that of the respective (unmodified + modified) fragment.

Modification Reactions Using Premodified NA Gel. Loading of the tripeptides on to the NA gel (Pierce Biotechnology, binding capacity ≥20 μg biotin/mL gel) was performed in buffer (0.1 M NaPi, pH 7) with the tripeptide in two times excess over the available biotin-binding sites. After a brief incubation, the gel was washed with 5× the double volume of the gel with buffer and stored in buffer at 4 °C until used in the experiments.

The modification reactions with premodified gel were typically performed with 50 μL of premodified NA gel (containing approximately 4.1 nmol tripeptide) and 100 μL of hGST A1-1 in buffer (0.1 M NaPi, pH 7), with hGST A1-1 concentration ranging from 1 to 25 μM. The reaction was allowed to proceed at 25 °C for up to 5 h with occasional gentle mixing. Alternatively, the temperature was lowered to 4 °C after 5 h and the protein eluted the following day. The labeled protein was eluted with 100 μL of buffer and the sample diluted to 200 μL before fluorescence measurements.

Modification Reactions Using NA Gel as Scavenger. After completed modification in solution, 1.5 equiv of NA beads (binding capacity ≥ 20 μg biotin/ mL gel) was added to the reaction mixture. The gel had been preequilibrated with 0.1 M NaP$_i$, pH 7.1, containing 0.15 M NaCl in VacMaster (International Sorbent Technology) tubes. After incubation with the gel (from 10 min up to 1 h), the labeled protein was eluted from the gel by a brief spin in a tabletop centrifuge.

Fluorescence Measurements of Labeled Proteins. In the experiments where the acyl group was delivered from the solid support, the fluorescence measurements were performed using a Hitachi F-4500 fluorescence spectrophotometer. The coumarin-labeled proteins were analyzed with excitation at 350 nm, and emission spectra were collected between 370 and 600 nm with a slit width of 5/5 nm. All measurements were performed in 0.1 M NaPi, pH 7.

In the experiments where the gel was used as a scavenger, the fluorescence spectra were recorded with an ISA spex FluoroMax-2apparatus (Jobin Yvon, Longjumeau, France). All spectra were recorded in 0.1 M NaPi, pH 7, with excitation at 360 nm using 2-nm excitation and emission slits, at 20 °C in a 1-cm quartz cuvette.

HPLC Analysis of Labeled A216K. A216K (10 μM) was incubated with GSC-Cou$_{bio}$ (100 μM) in 0.1 M NaPi buffer (total volume 500 μL), pH 7, at 25 °C for 5 h. After completed modification (verified by MALDI-MS) 25 μL were removed and injected on a C18 column using a gradient from 100% buffer A (buffer A: 10% ACN, 90% H_2O, 0.1% TFA; buffer B: 90% ACN, 10% H_2O, 0.1% TFA) to 30% buffer A over 30 min. The rest of the modification mixture was then incubated with NA-gel for 1 h and A216-Cou was eluted with N_2(g). In this experiment, the dilution factor resulting from the gel treatment was estimated to be roughly 3 and 75 μL of the eluate was therefore injected on the HPLC column using the same gradient.

Determination of the Yield from the Gel Treatment. GSC-Cou$_{bio}$ (200 μM) was incubated with A216K (20 μM) in 0.1 M NaPi buffer, pH 7, for 5 h at 25 °C. The extent of the reaction was confirmed to be >99% by MALDI-MS. The reaction mixture was then spilt into three different samples, and the fractions were treated in parallel with NA gel in the same manner as described above. The volumes of the eluted samples were carefully estimated with automatic pipets. The protein concentration in each sample was determined by UV measurements at 280 nm, and the fluorescence spectra were then recorded after diluting 100 μL of eluate with 400 μL of buffer (0.1 M NaP$_i$, pH 7.0).

Table 1. Modification Reactions with α-NH$_2$-Substituted GS-thiolesters

GS-thiolester	hGST A1−1[a]	A216K[b]
GSB	yes[c]	yes[d]
$_{Ac}$GSB	no	no

[a] Yes and no corresponds to modified or not modified Y9 fragment. [b] Yes and no corresponds to modified or not modified K216 fragment. [c] From reference 6. [d] From reference 8.

The A216K Concentration in Unknown Samples. The concentration studies were performed in the following way: 100 μM GSC-Cou$_{bio}$ was incubated with A216K (1 and 10 μM) in 0.1 M NaPi buffer, pH 7. Two separate modification mixtures were also prepared with A216K concentrations unknown to the person performing the subsequent steps. These two samples contained 100 μM GSC-Cou$_{bio}$ and A216K (5 and 9 μM) in buffer. All samples were incubated at 25 °C for 5 h. The samples were then treated with NA gel, and the protein mixtures were eluted by a quick spin in a tabletop centrifuge. The dilution factors from the gel treatment were estimated by careful use of calibrated automatic pipets. The samples were then diluted and the fluorescence spectra recorded as described above.

Addition of GSH to A216K-Cou. GSC-Cou$_{bio}$ (100 μM) was incubated with A216K (10 μM) in 0.1 M NaPi buffer, pH 7, for 5 h at 25 °C. The extent of the reaction was confirmed to be >95% by MALDI-MS. After incubation and elution by centrifugation, the concentration of A216K in the eluted sample was found to be 4.2 μM using the absorbance at 280 nm and $\epsilon_{280} = 24\ 700\ M^{-1}\cdot cm^{-1}$ (*21*). The absorbance of the coumarin probe was negligible at this wavelength. The sample was split in two fractions and the samples diluted with NaPi buffer, pH 7, to final concentrations of 0.84 and 0.25 μM, respectively. The fluorescence spectra of the A216K-Cou samples were then recorded using $\lambda_{exc} = 280$ nm and $\lambda_{exc} = 360$ nm, respectively. Increasing amounts of GSH (1, 10, 50, 100, and 500 equiv) were then added to the cuvettes using a stock solution of 3 mM in 0.1 M NaPi buffer.

RESULTS

Modification Reactions Using GS-thiolesters and GSC-thiolesters. The outcome of adding the GS-thiolesters and GSC-thiolesters to hGST A1-1 and A216K was investigated by MALDI-MS. Each reagent (100 μM) was incubated with protein (10 μM) at 25 °C for 5 h. The samples were then analyzed by MALDI-MS following proteolytic digestion. To simplify subsequent analyses we used *S. aureus* V-8 protease since it cleaves after glutamic acid residues (and aspartic acid depending on reaction conditions) and is thus unaffected by a potential lysine modification. In general, if a residue becomes covalently modified, the mass of the fragment containing this residue will increase with the mass of the corresponding acid minus the mass of water (Scheme 2). For control purposes, the proteins were also digested after incubation in buffer without addition of any reagent.

Both the A216K mutant and the wt protein were unaffected by the addition of the α-NH$_2$ acetylated GSB analogue $_{Ac}$GSB (Table 1). We also tried to acylate the wt protein by incubating hGST A1-1 with sepharose-linked GS-Cou (Scheme 3) but could not detect any modified protein in the eluate after proteolytic digestion and MALDI-MS analysis. This negative result was also backed up by the lack of fluorescence of the eluted protein.

Table 2. Modification Reactions with GSC-thiolesters

	hGST A1−1[a]		A216K[b]	
acyl group	GS-thiolester	GSC-thiolester$_{bio}$	GS-thiolester	GSC-thiolester$_{bio}$
Ant	yes[c]	yes	no	no
Cou (GS-4[d])	yes[c]	yes	yes[d]	yes
Fl	yes[c]	no	no[d]	no
DMACA	n.m.[e]	no	n.m.[e]	no

[a] Yes and no corresponds to modified or not modified Y9 fragment. [b] Yes and no corresponds to modified or not modified K216 fragment. [c] From reference 7. [d] From reference 8. [e] n.m. = not measured.

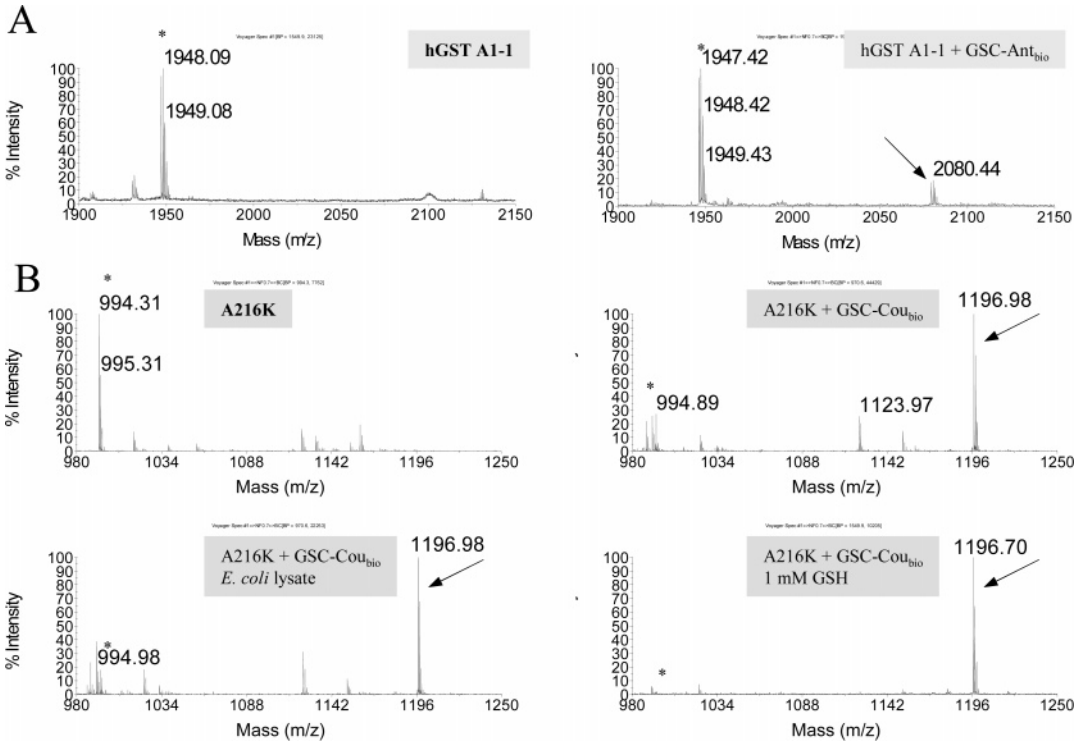


Figure 2. MALDI-MS spectra of proteolytic (*S. aureus* V-8) peptide fragments from (A) hGST A1-1 and hGST A1-1 (10 μM) incubated with GSC-Ant$_{bio}$ (100 μM) for 5 h and; (B) A216K and A216K (10 μM) incubated with GSC-Cou$_{bio}$ (100 μM) for 5 h in buffer, in buffer with 1 mM GSH, and in an *E. coli* lysate of cells expressing A216K. The *m*/*z* interval containing the Y9 (A1-1) or K216 (A216K) fragment is shown in the figure. Parent fragments are indicated with asterisks and modified fragments are highlighted with arrows.

However, the wt protein could be modified at the Y9 residue with two of the C-terminally altered GSC-thiolesters (Scheme 4) and the A216K mutant reacted with one of the GSC-reagents (Table 2 and Figure 2). A positive classification corresponds to more than 10% modified fragment relative to the parent fragment (unmodified fragment). This threshold was set because MALDI-MS is not a quantitative technique and also because the reaction conditions are not optimized for each individual reagent and protein combination (*7*).

The Rate of the Reaction between A216K and GSC-Cou$_{bio}$. The rate of the reaction between A216K and GSC-Cou$_{bio}$ was estimated from semiquantitative MALDI-MS experiments. The reagent (100 μM) was added to A216K (10 μM in 0.1 M NaPi, pH 7), time points were withdrawn, and the samples were quenched with 0.1% TFA. To enhance the resolution compared to whole-protein analysis, the mixtures were subjected to proteolytic digestion before MALDI-MS analysis. The resulting peptide fragments were analyzed, and the ratio (modified K216 fragment/(modified K216 fragment + unmodified K216 fragment)) was plotted vs time (Figure 3). About 85% of the K216 fragment is modified after 1 h (Figure 3).

Modification Reactions in the Presence of GSH and in an *E. coli* Lysate. The reagent GSC-Cou$_{bio}$ (100 μM) was added to lysed BL-21 (DE3) cells expressing A216K and to a buffer (0.1 M NaPi, pH 7) containing A216K (10 μM) and GSH (1 mM), and both mixtures were incubated at 25 °C for 5 h. We found (Figure 2) that GSC-Cou$_{bio}$ was able to modify K216 in lysed *E. coli* cells directly after expression. The modification reaction could also be carried out in a buffer containing GSH (Figure 2).

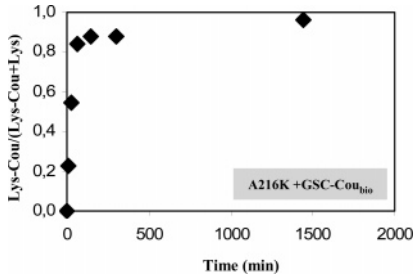

Figure 3. Semiquantitative analysis of the reaction between A216K (10 μM) and GSC-Cou$_{bio}$ (100 μM) obtained from MALDI-MS experiments. Samples were withdrawn at the indicated time points, quenched with 0.1% TFA and treated with protease (*S. aureus* V-8). The ratio of modified K216 fragment divided by the total amount of fragment (K216 + modified K216 fragment) is plotted vs time.

Modification Reactions Using Premodified NA Beads. To test the ability of delivery of coumarin to hGST A1-1 and A216K from a solid support, GSC-Cou$_{bio}$ was preincubated with NA gel in buffer (0.1 M NaPi, pH 7). After a brief incubation, the gel was washed with buffer. The beads fluoresced under a UV lamp (λ = 337 nm) (Figure 4A). As a control, the gel was

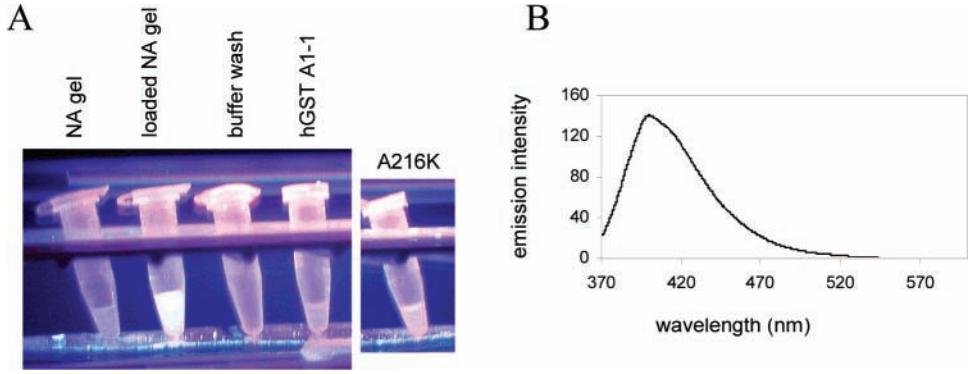

Figure 4. An illustration of the experiments with premodified (GSC-Cou_{bio}) NA gel. (A) A photography (under UV lamp, $\lambda = 337$ nm) showing the NA gel, the NA gel after incubation with GSC-Cou_{bio}, buffer washes, and the eluted hGST A1-1 after a 5 h incubation with the derivatized gel. The cut out shows eluted A216K after a similar treatment. (B) Fluorescence measurements ($\lambda_{exc} = 350$ nm) of eluted labeled hGST A1-1 in buffer at pH 7.

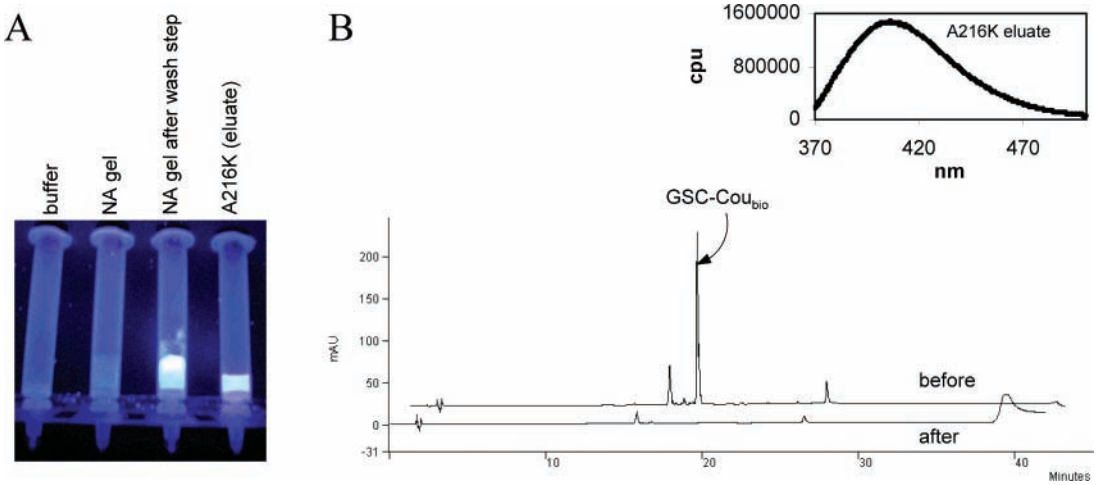

Figure 5. An illustration of the experiments where NA gel was used as a scavenger. (A) A photography (under UV lamp, λ=337 nm) showing A216K (10 μM) that had been preincubated with GSC-Cou_{bio} (100 μM) for 5 h. The mixture was then incubated with NA gel and the labeled protein finally removed from the gel by centrifugation. (B) HPLC chromatograms ($\lambda = 355$ nm) from the labeling mixture before and after the scavenging step. The inset shows the fluorescence spectrum ($\lambda_{exc} = 360$ nm) of the labeled A216K after elution.

washed with buffer prior to adding the protein solution, and no leaking from the gel could be observed (Figure 4A).

The NA gel (approximately 4.1 nmol GSC-thiolester) was then incubated with hGST A1-1 or A216K in buffer with protein concentration ranging from 1 to 25 μM. The reactions were allowed to proceed at 25 °C for 5 h with occasional gentle mixing. The protein solutions were then eluted from the gel by centrifugation in a tabletop centrifuge (Figure 4A) and the samples subjected to fluorescence measurements after dilution. The protein-containing samples did show the typical coumarin fluorescence (Figure 4B, Supporting Information).

Using NA Beads as Scavenger after Labeling. The NA gel was also used as a scavenger to remove excess and used up reagent. In a pilot experiment GSC-Cou_{bio} (100 μM) and A216K (10 μM) were incubated in a buffered solution (0.1 M NaPi, pH 7) at 25 °C for 5 h, and we used MALDI-MS to verify that the reaction had gone to completion. The mixture was then applied to NA beads that had been preequilibrated in buffer. The gel was added in excess (1.5 equiv) over the amount of biotin in solution to mop up used up and surplus GSC-Cou_{bio}. The labeling mixture was incubated for 45 min with the beads, and the protein solution was then separated from the gel by a brief spin in a tabletop centrifuge (Figure 5). The eluate was then analyzed by reversed phase HPLC to check the efficiency of the scavenging step. We found that the treatment with the gel had quantitatively removed residual reagent (Figure 5B). A fluorescence spectrum of A216-Cou was recorded (Figure 5B, inset), and it displayed the typical coumarin spectrum.

To test the yield and repeatability of the gel-treatment step, GSC-Cou_{bio} (200 μM) was incubated with A216K (20 μM) for 5 h at 25 °C. The extent of the reaction was confirmed to be >99% by MALDI-MS. The mixture was then spilt into three different samples (100 μL each), and the resulting fractions treated separately with NA gel. The volumes of the eluted samples were 165, 157, and 190 μL. From UV measurements (*21*) (280 nm) we found that the protein concentrations in these samples were 3.9, 4.2, and 3.6 μM, respectively. The samples thus contained $6.6 \pm 0.2 \times 10^{-10}$ mol which corresponds to a 3% difference in the different samples after gel treatment.

Measurement of A216K Concentration Using GSC-Cou_{bio} and NA Beads. A diagnostic test of the ability to measure the A216K concentration in a sample was carried out by incubating GSC-Cou_{bio} (100 μM) with two known (1 and 10 μM) and two unknown (5 and 9 μM but unknown to the person performing the subsequent steps) concentrations of A216K. All samples were incubated at 25 °C for 5 h and treated with NA gel, and the protein solutions were eluted by a quick spin in a tabletop centrifuge. The fluorescence spectra were then recorded (Figure 6), and using the intensities at 407 nm from the samples with known concentrations of A216K, the concentrations of labeled A216K in the unknown samples were calculated to be 4.8 and 9.1 μM with the dilution factors taken into account.

Addition of GSH to A216K-Cou. To test the ability of labeled A216K to bind GSH, GSC-Cou_{bio} (100 μM) was incubated with A216K (10 μM) for 5 h at 25 °C, conditions that result in >95% labeling. Excess probe was then removed

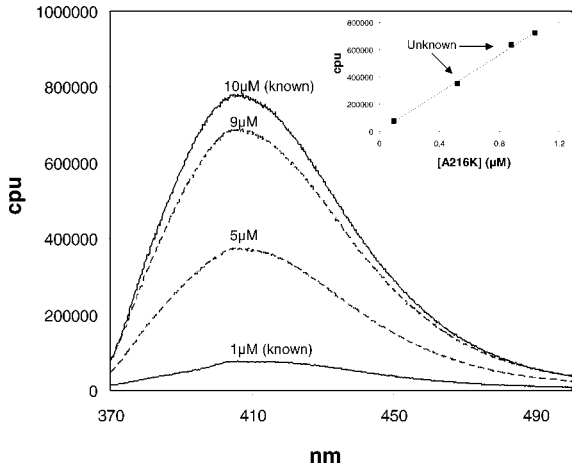

Figure 6. Fluorescence spectra (λ_{exc} = 360 nm) resulting from incubating two known (1 and 10 μM) and two unknown (5 and 9 μM, dotted lines) concentrations of A216K with GSC-Cou_{bio} (100 μM) for 5 h with subsequent treatment with NA beads. The inset shows the intensity of the signal at 407 nm plotted vs concentration of protein. The two unknown samples are highlighted with arrows.

by NA gel treatment. The fluorescence spectra of A216K-Cou with (1, 10, 50, 100, and 500 equiv) and without GSH were then recorded using λ_{exc} = 280 nm (excitation of W21) and also λ_{exc} = 360 nm (direct excitation of the coumarin probe). We found that adding GSH to the labeled protein quenched the fluorescence of A216-Cou (Figure 7). This was true both for direct excitation of the coumarin probe and also in the case of FRET from W21 to the coumarin probe.

DISCUSSION

The versatility, speed, and site-selectivity of the covalent modification reaction between Y9 of hGST A1-1 and K216 of the A216K mutant and numerous GS-thiolesters (*6*−*8*) encouraged us to try to construct an even more user-friendly labeling reagent with a handle that could be used to mop up excess reagent. Since it is difficult to predict which reagent (if any) that would work we prepared a minilibrary of four GS-thiolesters with biotinylated GSH moieties in the hope that at least one would be a reagent in the labeling reaction. Biotin was chosen because of the multitude of commercially available, protein-friendly products that utilize the highly specific and extraordinarily strong biotin−streptavidin interaction ($K_a = 10^{15}$ M^{-1}) (*23*). If successful, we would thus not be confined to a single system. The thiol-reactive biotin derivative that we used is commercially available, is water-soluble, and has an extended arm to allow for optimal interactions with the biotin-binding pocket of streptavidin and its analogues. Since the biotin tag is situated in the leaving group (i.e. the GSH moiety), this allows for both potential delivery of the acyl group from a streptavidin-covered surface to the protein and also for the use of a streptavidin-containing surface to mop up residual reagent in a fashion akin to the use of polymer-bound scavengers in organic synthesis. In addition, we also synthesized α−NH_2-modified reagents since such alterations have been shown to increase the stability of GSH analogues in a physiological environment (*24*, *25*). This was done despite indications that such modifications would not be tolerated (*26*).

Substitutions at the Glycine Position Are Tolerated but Not α-NH_2 Substitutions. We have previously found that the α-NH_2 group of GS-thiolesters can be reacted with NHS-esters leaving the thiolester linkage intact (*27*). This finding was utilized in the manufacturing of the α-NH_2-derivatized substances. Unsurprisingly, sepharose-linked GS-Cou (Scheme 3) was not able to modify hGST A1-1. To rule out any specific deleterious interactions with the linker or the sepharose gel, control experiments were performed where the α-NH_2 group was simply acylated. The well characterized reagent GSB was used in these experiments since it has been highly successful as a labeling reagent for both hGST A1-1 and A216K. The proteins however also rejected the resulting reagent $_{Ac}$GSB, and we could thus conclude that alterations of this part of the GSH backbone are not a viable route to user-friendly labeling reagents.

We were however pleased to observe that two of the biotinylated GSC-thiolesters based on the peptide γ-Glu-Cys-Cys were successful in labeling hGST A1-1 (Table 2). One of these (GSC-Cou_{bio}) was also a reagent for the A216K mutant. Our results are in agreement with previously published data that suggest that using C-terminally modified GSH analogues are to some extent accepted by GSTs in the natural detoxication reaction (*18*). Our results also suggest that other C-terminally altered GS-thiolester analogues might be accepted by the proteins. It is not surprising that the A216K mutant is more selective than the wt protein since this is in accordance with our previous studies using a 20-membered GS-thiolester library (*8*). We have thus now produced a fluorescent reagent, GSC-Cou_{bio}, with a biotin handle that can modify either Y9 (wt hGST A1-1) or K216 (A216K). Two types of residues are thus targeted, and this increases the flexibility of the system in a potential protein fusion scheme since, if desired, the ester bond formed with the wt protein can be quickly and gently broken simply by addition of GSH (*7*) whereas the amide bond formed with K216 in the mutant is very robust.

A Fast Labeling Reaction of A216K Using GSC-Cou_{bio}. In our previous studies (*8*) we found that the reaction between A216K and GS-4 (i.e. GS-Cou, Scheme 3, Table 2) is fast since it takes approximately 10 min for the reaction to reach 50% completion. Interestingly, the modification of the GSH moiety actually seems to add positive binding interactions since the reaction between A216K and GSC-Cou_{bio} appears to be even faster. This is highly gratifying considering the advantages resulting from the added biotin functionality.

K216 Can Be Modified in a Cell Lysate Using GSC-Cou_{bio}. We have been able to modify both Y9 (*6*) and K216 (*8*) in protein-doped *E. coli* lysates before using GS-thiolesters with the normal GSH backbone. Gratifyingly, using GSC-Cou_{bio} we were able to modify K216 in an *E. coli* lysate of cells expressing A216K. This is ideal in a potential application with A216K as a fusion partner since a combination of GSC-Cou_{bio} and streptavidin-based products should create a clean signal from A216K-Cou. This system could then be used for optimization of protein expression in an easy format. The product in the reaction between A216K and GSC-Cou_{bio} is a stable amide linkage, and the conjugate can thus be handled "roughly" without bothering about the stability. A diagnostic of this is also the inertness toward GSH in the labeling mixture.

Direct Labeling with GSC-Cou_{bio} Using NA Gel. It was indeed possible to deliver the acyl group from a solid support. This significantly simplifies the handling of the labeling reaction. However, it is not easy to control the extent of the reaction in this format. In a potential application such as measurement of fusion protein concentration one would want to be sure that the reaction has gone to completion, and it is laborious and time-consuming to remove samples for MALDI-MS analysis during incubation. We therefore turned to the use of the gel as a scavenger instead.

Excess GSC-Cou_{bio} Can Be Removed Using NA Gel as Scavenger. It is common for example in solid-phase peptide synthesis to use scavengers to quench reactive species when the peptide is cleaved from the solid support. These scavengers are also commercially available attached to a solid support to

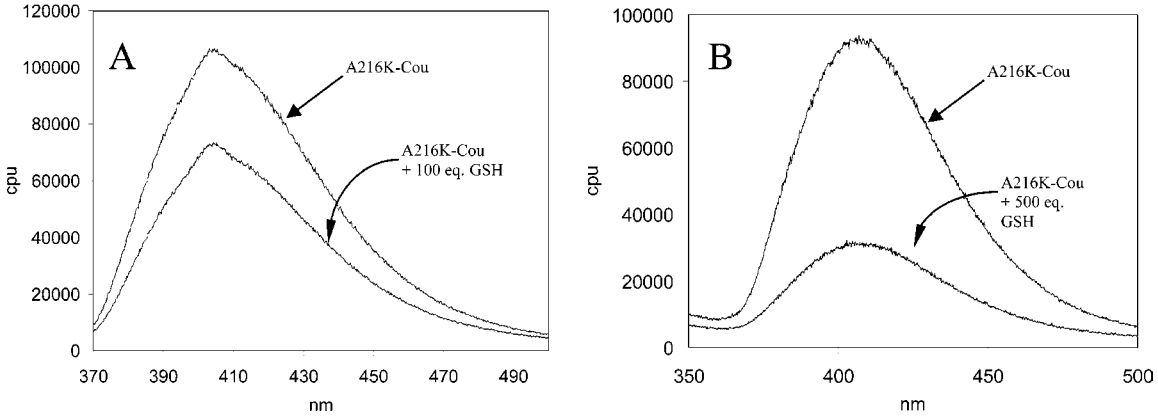

Figure 7. Fluorescence spectra resulting from adding (A) GSH (100 equiv) to A216K-Cou (250 nM) with excitation at 360 nm (e.g. the coumarin probe) and (B) GSH (500 equiv) to A216K-Cou (800 nM) with excitation at 280 nm (e.g. W21). The emission signal in Figure 7B is thus a result of FRET from W21 to the coumarin probe.

facilitate the workup of the soluble product. With this in mind, we performed the labeling reaction in solution so that we could verify that the reaction had gone to completion and then used the gel as a scavenger. Gratifyingly, from HPLC experiments we found that this step completely removed excess and used up reagent. This is a significant improvement in the handling of the labeling reaction since it is no longer necessary to purify the labeled protein with extended dialysis or size exclusion chromatography. We also found that the yield from the NA step was repeatable within 3%, a satisfactory result considering that the handling of the gel has not been optimized. These results in combination with the finding that A216K can be derivatized directly after expression further add to the value of the reaction. Using our setup with centrifugation as elution method, there is however a (repeatable) loss of protein during the gel treatment on the order of 50%. From SDS−PAGE experiments, it appears as if the protein adheres both to the beads and the filter (Supporting Information). Since the loss is repeatable and none of the steps have yet been optimized with respect to handling of protein mixtures and yield, we do not believe that this will be a problem.

The Concentration of A216K Can Be Determined Using GSC-Cou$_{bio}$ and NA Beads. Since the HPLC experiments (Figure 5B) show that the reagent is quantitatively removed, the fluorescence intensity at 407 nm is a result of the concentration of A216K-Cou in the sample. This inspired us to perform an experiment with known (as calibration) and unknown amounts of A216K, and we found that the concentration of A216K in a sample can be determined using a combination of GSC-Cou$_{bio}$ and NA beads. The calculated amounts of A216K in the unknown samples were within 5% of the actual concentrations. Since the handling of the steps has not been optimized, we find a 5% variation to be satisfactory. On the basis of the intensities of the fluorescence signals, we estimate that we can measure protein concentrations at least in the upper nanomolar range.

Both A216K and A216K-Cou Can Bind GSH. When a protein is expressed in the fusion format, it is frequently done to facilitate expression and purification. With this in mind, a fusion protein partner should be able to bind an affinity gel. From measuring the kinetics of the mutant A216K, we know that it catalyzes the conjugation reaction between GSH and CDNB with about 30% of wt hGST A1-1 activity (*8*). To catalyze the reaction A216K must bind GSH, hence it should be possible to find an affinity gel that binds A216K and fusion protein constructs thereof.

By adding GSH to A216K-Cou, we also know that the labeled protein binds GSH since the coumarin-fluorescence was quenched upon addition of GSH. To further verify that GSH binds in the G-site, even though the probe could occupy some of the available space, we also measured the effect of adding GSH by exciting W21 (λ_{exc} = 280 nm), a well-known reporter of events taking place in the active site of hGST A1-1 (*28*). The transferred fluorescence from W21 to the coumarin probe was also quenched upon addition of GSH in agreement with binding of GSH in the G-site. Thus, A216K, both in its unlabeled and labeled form, binds GSH. This is of course very useful in a protein fusion scheme since a partner could potentially be purified using commercially available glutathione-based protein purification products.

CONCLUSIONS

We have designed protein-labeling reagents that attach a fluorescent probe in a site-specific manner. The reaction is quantitative, fast, creates a stable amide bond and can be performed directly in an *E. coli* lysate after expression. The reagents have a biotin handle to mop up excess reagent. The lysine mutant A216K is expressed in a high yield, is easy to purify, and binds GSH both labeled and in its free form. A216K can easily be perceived as a fusion protein partner that in combination with this new type of reagent could be quite useful in protein expression and labeling systems.

Micelles as Intermediates in the Preparation of Protein−Liposome Conjugates

Jennifer Takasaki and Steven M. Ansell*

Inex Pharmaceuticals Corporation, 100-8900 Glenlyon Parkway, Burnaby, BC, V5J 5J8, Canada. Received February 24, 2005; Revised Manuscript Received November 21, 2005

A method for preparing protein−liposome conjugates based on micelles as intermediates was developed. Ovalbumin was thiolated with 2-IT and conjugated to the surface of micelles composed of a maleimide-derivatized active lipid and a micelle-forming lipid. These micelles were then incubated with liposomes, allowing the micelle components to exchange into the liposome bilayers. Using this technique we were able to demonstrate that it was possible to saturate the surface of the micelle with protein and use this property to control the level of conjugation. Titration of these protein−micelle conjugates into liposome solutions resulted in reproducible batches of protein−liposome conjugates. Chemical cross-linking could be observed in some cases; however, this was controllable through selection of reagent concentrations. The effects of parameters such as thiolation levels, micelle lipid composition, active lipid structure, micelle-forming lipid structure, and micelle/liposome/protein ratios were examined. The method represents a general approach to the preparation of well defined and reproducible protein−liposome-based drug formulations.

INTRODUCTION

The attachment of proteins to the surface of liposomes in order to alter their in vivo behavior is an area of continuing interest. These proteins might serve a wide range of functions, with the most common application being use as targeting vectors (*1*) for liposomal drug delivery systems. More currently, interest is increasing in the use of liposome surface-bound proteins and peptides as antigens in immunological applications (*2*−*4*).

Traditionally proteins have been conjugated to liposomes using maleimide−sulfhydryl coupling chemistry (*5*). Typically the protein is thiolated using a heterobifunctional cross-linker and subsequently coupled to the surface of liposomes containing a maleimide lipid as one of the lipid components. In most reports the reagent SPDP[1] has been used as the cross-linker. More recently a few reports using 2-IT have appeared (*6*, *7*).

Early work in the field involved coupling proteins directly onto the surface of the liposome. Many problems were experienced with this approach due to cross-linking reactions between protein−liposome conjugates and additional liposomes, leading to aggregation (*8*). Since size is an important parameter in determining the clearance behavior in vivo (*9*), these liposome−protein conjugates often suffered from poor pharmacokinetics in vivo. Many years ago we resolved this problem by incorporating small amounts of PEG−lipids in the liposome formulations to act as steric barriers to inhibit the cross-linking reaction (*10*). However, including these "steric barrier" molecules in the bilayer also reduced the overall conjugation efficiency of the protein to the bilayer surface.

This problem was partially resolved by using maleimide lipids (or other reactive lipids) in which the reactive function and the lipid anchor were separated by a PEG chain (*11*). The steric inhibition of the conjugation step seen in our early work was partially abolished when the reactive function was placed outside of the steric barrier created by the PEG−lipids in the formulation. Recently work done in Allen's laboratory has demonstrated that maleimide- or hydrazide-PEG−lipids in pure or mixed micelles could be reacted with thiolated or oxidized proteins, respectively. The products from those reactions could then be exchanged into bilayers when they were mixed with conventional liposomes (*12*).

We believe that the critical aspect of these recent publications is not that the protein is conjugated to the terminus of a PEG−lipid, but rather the fact that the process is based on a micelle intermediate. By performing the actual conjugation reaction remote from the liposome surface we can potentially obtain a system that has a high degree of reproducibility. In fact it may not be necessary to have the PEG tether present at all, if the reaction is done under the appropriate conditions.

With this hypothesis in mind we set out to explore the range of utility of micelle-based conjugation methods and to characterize the parameters that might affect the outcome of those reactions. We determined that micelle-based reactions can be performed on a wide range of micelle compositions, and in fact that large steric barrier molecules are unnecessary and frequently undesirable components in the formulation. The conditions that lead to aggregation were characterized, allowing us to develop formulations with minimal aggregation without resorting to the use of additional steric barrier molecules. Application of this micelle-based technology led to the development of reproducible, simple, and scaleable methods for preparing liposome−protein conjugates.

There are two general methods which can be used for preparing liposomes with proteins attached to their surfaces. Ultimately the protein is conjugated to a lipid anchor, and this

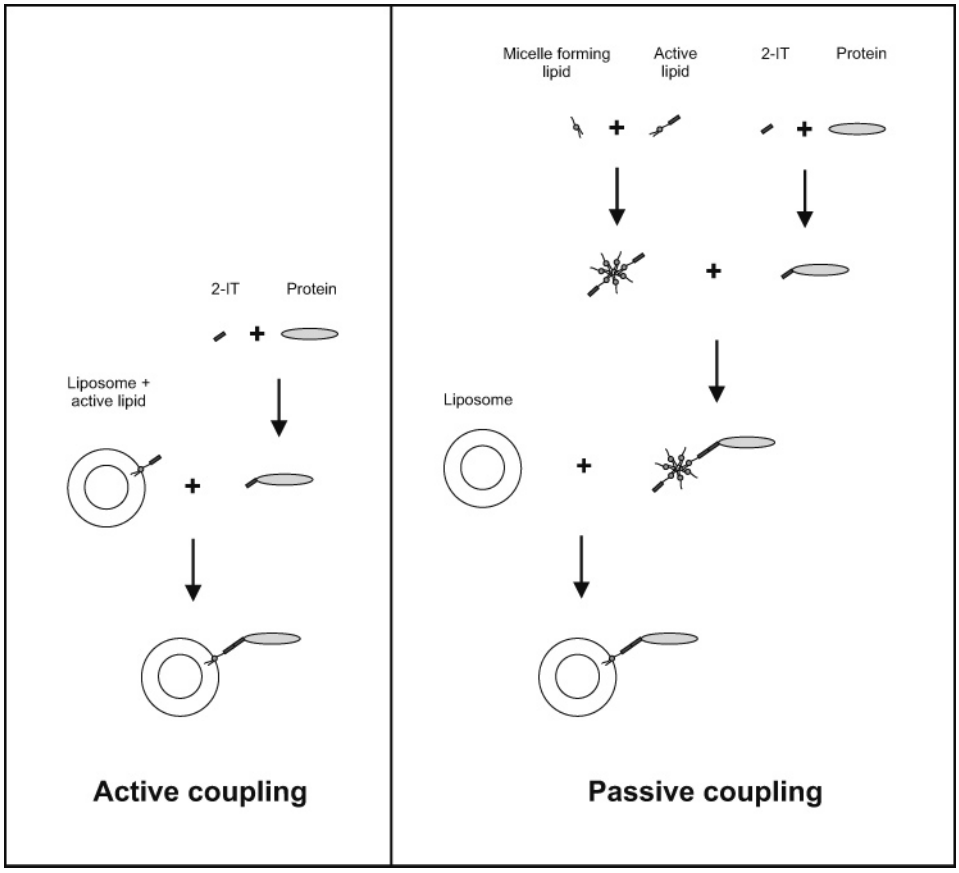

Figure 1. Examples of protocols involving active and passive coupling techniques. In this work active coupling refers to methods in which the lipid−protein conjugation reaction occurs at the liposome surface, and passive coupling refers to methods in which the lipid−protein conjugation reaction occurs remote from the liposome surface.

can be done either at the surface of a preformed liposome with the appropriate active lipid already present, or it can be done remotely and then introduced to the liposome at a later point, using a variety of methods. We are using the terms "active" and "passive" coupling in this work when referring to the two types of conjugate formation. Examples of these two types of coupling procedures are presented in Figure 1.

"Active coupling" applies to procedures where the chemical linkage occurs at the liposome surface. There are a number of ways to produce a liposome with an active lipid incorporated in the membrane structure. For example, liposomes could be prepared directly where the active lipid is one of the component lipids (*8*). Alternatively, liposomes could be prepared without the active lipid present. The active lipid may then be exchanged into the outer leaflet of the bilayer from micelles. Both methods would result in liposomes with reactive functions on their surfaces, available for conjugation with a suitably derivatized protein. The former method is the one generally used in the literature for the preparation of protein−liposome conjugates.

"Passive coupling" applies to procedures where the protein is conjugated to the lipid anchor away from the liposome surface. Generally in such reactions a micelle serves as the platform for performing the conjugation reaction since lipids and proteins are usually not soluble in the same solvents. Once formed, the protein−lipid conjugate could then be incorporated into the bilayer during liposome formation, either by cohydration of dried lipid/conjugate, or by detergent dialysis. Alternatively, the micelles on which the conjugates were formed could be exchanged into preformed liposomes (*12*). We have used the latter method as our starting point for this work.

EXPERIMENTAL PROCEDURES

Materials. DSPE was obtained from Genzyme Pharmaceuticals, Cambridge, MA. DSPE-MPB was obtained from Northern lipids Inc, Vancouver, Canada. 2-IT was obtained from Sigma-Aldrich.

Synthesis of 11-Azido-3,6,9-trioxaundecanol 1. A solution of tetraethylene glycol (1.2 kg) and methanesulfonyl chloride (400 mL) in benzene (2 L) was cooled in an ice bath. Triethylamine (716 mL) was slowly added with stirring. The reaction mixture was stirred at room temperature for 2 h and filtered and the solvent removed on a rotovap. The oil was diluted with water (100 mL). Saturated sodium bicarbonate solution was then added until the solution tested neutral using pH paper. The mixture was diluted with ethanol (1.6 L). Sodium azide (270 g) was then slowly added as a slurry in water (500 mL). The reaction mixture was heated to 60 °C with stirring for 2 h. Water (5 L) was added to the reaction mixture, and the resultant solution was washed with diethyl ether. The aqueous fraction was then extracted with dichloromethane (3 passes, 500 mL). The combined organic fraction was washed with water (250 mL), which in turn was extracted with methylene chloride (250 mL). The combined methylene chloride fractions were dried over anhydrous magnesium sulfate and filtered, and the solvent was removed on a rotovap, yielding ∼400 g of **1**.

Synthesis of 14-Azido-3,6,9,12-tetraoxatetradecanoic Acid 2. Finely powdered potassium bromoacetate was prepared by neutralizing a solution of bromoacetic acid in water with potassium hydroxide and lyophilizing the resultant solution. A portion of this product (270 g) was added to a solution of **1** (252 g) in toluene (750 mL) in a water-jacketed reactor. The suspension was vigorously stirred with a mechanical stirrer at 45 °C, and four portions of sodium hydroxide pellets (4 × 40

g) were added at 15 min intervals. The reaction was allowed to proceed for an hour and then quenched by the addition of water (500 mL). The two phases were allowed to separate and the aqueous phase run off. The toluene phase was washed with 5% sodium hydroxide. The two aqueous phases were combined and washed with methylene chloride. The resultant aqueous phase was acidified to ~pH 3−4, and extracted with methylene chloride. The organic fraction was dried over magnesium sulfate and filtered and the solvent removed on a rotovap, yielding crude **2** as a pale yellow oil (~120 g).

Synthesis of Ethyl *N*-(*N*′-BOC-14′-amino-3′,6′,9′,12′-tetraoxatetradecanoyl))-14-amino-3,6,9,12-tetraoxatetradecanoate 4. Ethyl *N*-(14′-amino-3′,6′,8′,12′-tetraoxatetradecanoyl)-14-amino-3,6,9,12-tetraoxatetradecanoate **3** was prepared as previously described (*13*). A solution of **3** (30 g) in methylene chloride (100 mL) was treated with di-*tert*-butyl dicarbonate (13.2 g) and triethylamine (8.5 mL) at room temperature for 1 h. The solution was washed with dilute hydrochloric acid, dried over anhydrous magnesium sulfate,and filtered and the solvent removed on a rotovap. Yields ~30 g of **4** as a colorless oil.

Synthesis of *N*-(*N*′-(*N*″-(*tert*-Butoxycarbonyl)-14″-amino-3″,6″,9″,12″-tetraoxatetradecanoyl)-14′-amino-3′,6′,9′,12′-tetraoxatetradecanoyl)-1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine 5. A solution of **4** (5 g) in aqueous sodium carbonate (4.5 g in 100 mL) was warmed at 60 °C for 30 min with stirring. The solution was washed with methylene chloride, acidified to ~pH 3 with hydrochlorics acid, and extracted with methylene chloride. The organic phase was dried over magnesium sulfate and filtered and the solvent removed. The residue was dissolved in alcohol free chloroform (50 mL). *N*-Hydroxysuccinimide (1.65 g) was added, followed by a solution of dicyclohexylcarbodiimide (2.90 g) in alcohol free chloroform (50 mL). The solution was stirred at room temperature for 20 min and then filtered. 1,2-Distearoyl-*sn*-glycero-phosphethanolamine (DSPE, 4.5 g) was added, and the solution was heated in a water bath at 60 °C until the DSPE had dissolved. Triethylamine (3 mL) was added and the solution stirred at room temperature for 1 h. The solution was filtered, diluted with water, and extracted with methylene chloride. The organic phase was washed with dilute hydrochloric acid and dried over anhydrous magnesium sulfate and the solvent removed on a rotovap. The product was purified using a preparative HPLC, yielding **5** as a colorless solid (7.6 g).

Synthesis of *N*-(*N*′-(*N*″-(3‴-Maleimidopropionoyl)-14″-amino-3″,6″,9″,12″-tetraoxatetradecanoyl)-14′-amino-3′,6′,9′,12′-tetraoxatetradecanoyl)-1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine. 6. Trifluoroacetic acid (4 mL) was added to solid **5** (2.75 g) and stirred at room temperature for 30 min. The excess trifluoroacetic acid was removed on a rotovap and the residue dissolved in distilled water (50 mL), neutralized with aqueous sodium hydroxide, and extracted with methylene chloride. The organic fractions were dried over anhydrous magnesium sulfate and filtered and the solvent removed. 3-Maleimidopropanoic acid (0.41 g) was dissolved in chloroform (20 mL) and treated with NHS (0.42 g) and DCC (0.71 g). The solution was stirred at room temperature for 20 min and filtered. The filtrate was added to a solution of the previously obtained crude product in chloroform (30 mL). Triethylamine (2 mL) was added and the solution stirred at room temperature for 1 h. The solution was filtered, diluted with water, and extracted with methylene chloride. The organic fractions were washed with dilute hydrochloric acid, dried over anhydrous magnesium sulfate, and filtered, and the solvent was removed. The residue was purified by HPLC, taken up in benzene, and lyophilized, yielding **6** (1.7 g) as an off white powder. The product appeared as a single spot on TLC analysis and showed no evidence of primary amines when stained with a flouresc-amine/acetone solution and viewed under UV light.

Preparation of Liposomes. Lipid mixtures composed of POPC/chol (55:45) were dissolved in chloroform. On larger scales the solvent was removed in a round-bottomed flask on a rotovap at 50 °C. In small scale preparations the solvent was removed by blowing nitrogen into the sample tube while warming the solution in a water bath. The resulting thin film was dried on a lyophilizer and rehydrated in HBS, for a final lipid concentration of 25 mM. The lipid solution was then passed 10 times through 2 × 100 nm stacked filters using an extrusion device (Northern Lipids Inc., Vancouver, Canada) at 45 °C.

Preparation of Micelle−Ovalbumin Conjugates. Ovalbumin was dissolved in HBS at a concentration of 30 mg/mL. An aliquot of from a freshly prepared stock solution of 2-IT in HBS (prepared at a concentration such that the total volume added to the albumin did not exceed 5%) corresponding to 1−5 equiv (depending on the particular experiment) was added to the ovalbumin solution and the mixture stirred at room temperature for 0.5 h.

Lipid mixtures were prepared by combining an active lipid (DSPE-MPB or DSPE-ATTA2-MPA) and a micelle-forming lipid (DSPE-ATTA4, OGP, or CHAPS). The lipid was dissolved in 1 part of ethanol, with warming if required, and diluted sequentially with 1 part of HBS, with vortexing and warming, until a total of 9 parts HBS had been added. The total volume should was such that the final concentration of lipid was approximately 10 mM. Any residual solid materials were removed by filtration through 0.22 micron filters.

An aliquot of freshly prepared thiolated ovalbumin was added to freshly prepared maleimide-micelles in the appropriate ratio. In most cases this corresponded to 3000 g protein/mol micelle lipid. The micelle−protein mixture was allowed to stir at room temperature overnight. It was then either used immediately without additional purification, or stored at 5 °C for use at a later date.

Incubation of Protein−Micelles with Liposomes. Liposomes were mixed with ovalbumin−micelle conjugates in proportions appropriate for the particular experiment. Typically the standard preparation used a 1:19 micelle/liposome lipid ratio, corresponding to an initial protein/final lipid ratio of 150 g/mol when using the typical 3000 g protein/mol micelle lipid reagent. The liposome−micelle mixtures were incubated in a water bath at 60 °C for 30 min and then passed down a Sepharose CL-4B column (0.8 mL of sample/25 mL bed volume) using HBS as the running buffer.

Assays. Lipid was assayed by determining the phosphate content as previously described (*14*). The protein content of the final liposome−protein conjugates was determined using a modified micro-BCA assay as previously described (*14*), with negative controls being performed where possible to correct for background interference. Protein/lipid ratios in this work are expressed either as g protein/mol micelle-forming lipid, or as g protein/mol final lipid. The first quantity relates to the ratio of protein to lipid present in the initial micelles, while the second quantity refers to the ratio of protein to the total lipid present in the final liposomes. Particle size was measured using a Nicomp 380 submicron particle sizer.

RESULTS

The basic design of the process is outlined in Figure 1. The passive conjugation method can be divided into three parts, which can be performed separately. These are (1) preparation of the liposomes, (2) preparation of micelle−protein conjugates, and (3) incubation of the liposomes with the micelle−protein conjugates. This contrasts with the active conjugation method also outlined in Figure 1, where the liposome preparation and

protein derivatization need to be done more or less simultaneously due to the chemical instability of some of the reagents used. The more flexible time constraints associated with the passive conjugation method make it a more attractive choice from the perspective of scalability. This was an important consideration if this technology is to be used in commercial products which are generally prepared in very large quantities.

It needs to be kept in mind however that while the "passive conjugation" terminology is being applied to the entire process, the actual conjugation is taking place in the micelle step, whereas the final assembly of the system is mediated through purely physical exchange processes. The apparent coupling efficiency on the micelle surface is implied by the level of protein on the surface of the final liposome composition. It is necessary for the micelles to equilibrate with the liposomes for that to be true. Generally a 1 h incubation is sufficient to equilibrate most systems, but in some cases, for example in liposomes with high levels of securely anchored steric barrier molecules, longer incubation times may be required to equilibrate the system.

Presence of Ethanol and Detergents in the Final Formulation. Since the presence of ethanol and/or detergents in the final formulation might affect the integrity of various components during the assembly or after assembly of the final liposome system, it is necessary to ensure that the levels of these materials remain with acceptable limits. Many proteins will denature in the presence of organic solvent. Typically we limit the ethanol content of any solution that proteins might be dissolved in to 5%. In this protocol we mix equal volumes of a thiolated protein solution with a micelle solution. The micelle solution was generally prepared by diluting an ethanolic solution of lipid in buffer. To limit the final ethanol concentration to 5% we needed to prepare the micelles using 1 part of ethanolic lipid solution to 9 parts of buffer solution. The final lipid concentration of the protein−micelle solution was 5 mM. The final ethanol content in the liposome solution can be controlled using the initial liposome concentration. Typically liposomes are prepare with lipid concentrations in the range 10−50 mM. The reference formulation protocol used a 1:19 micelle/liposome lipid ratio, i.e. 10 mM and 50 mM liposome solutions would be treated with 2/19ths and 10/19ths the volume of protein−micelles. This would result in final ethanol concentrations of ∼0.5−1.7%. It might be necessary to use lower initial liposome concentrations if this level of ethanol is a problem in any particular system.

The stereotypical micelle formulation in this work was composed of an active lipid and a micelle-forming lipid in a 1:4 ratio and were added to liposomes in a 1:19 lipid ratio. This means that the final active lipid content of the protein−liposome system is 1%, and the final micelle lipid content is 4%. These values are well within the range used in typical "targeted" or "steric barrier" liposome formulations. These ratios were chosen to ensure that this was the case.

Thiolation of the Protein. One of the most commonly used methods of preparing protein conjugates involves the use of the maleimide−sulfhydryl coupling reaction. Usually the protein is derivatized with a heterobifunctional cross-linker based either on a maleimide or protected sulfhydryl. This is then reacted with a substrate bearing the complementary reactive function. Most of the literature dealing with liposome−protein conjugation reactions involves modifying the protein with SPDP, deprotecting the sulfhydryl with DTT, and then reacting the product with liposomes containing lipids bearing a maleimide function.

Initially we used this chemistry when preparing our micelle−protein conjugates. The use of SPDP presents a number of problems however. The cross-linker generally reacts with the protein in high yield, but the need to deprotect the sulfhydryl with DTT is a major issue, particularly when trying to scale-up the reaction. The DTT treatment is time sensitive, since it may damage intramolecular disulfide bonds in the protein as well as performing the deprotection of the introduced sulfhydryl group. While this can be controlled to some extent by performing the reaction at lower pH, the reaction needs to be stopped relatively quickly (∼15 min) to prevent significant damage to the disulfide bonds. The reaction is stopped by passing the reaction mixture down a gel column to remove the DTT and exchange the buffer back to pH 7. These constraints make the method unsuitable for large scale preparations. Another disadvantage with the method is that if the DTT is not completely separated from the protein, it may be present in sufficient quantities to quench the reaction with the activated liposomes.

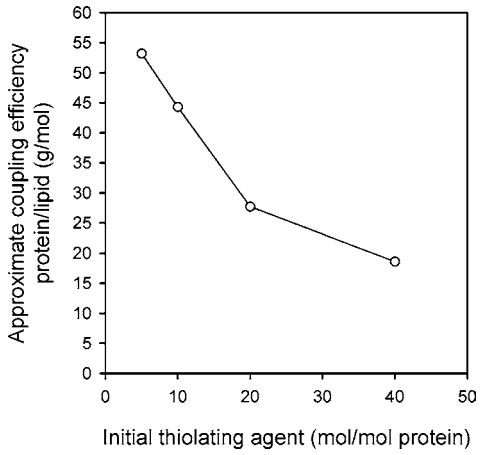

Figure 2. The effect of increasing the 2-iminothilone/protein ratio on the coupling efficiency. Ovalbumin was thiolated using 5−40 equiv of 2-iminothiolane. The resultant thiolated protein solution was used without workup and incubated with DSPE-ATTA2-MPA/DSPE-ATTA4 (1:4 ratio) micelles at 3000 g protein/mol micelle lipid. The protein−micelle conjugates were exchanged into POPC/chol (55:45) liposomes at a 1:19 mol/mol ratio by incubation at 60 °C for 1 h. The liposomes were recovered by passing the solution down a sepharose CL-4B column. Final amounts of protein coupled are represented as g protein/mol total lipid.

A less commonly used thiolating agent is 2-IT. The advantage of using 2-IT is that it is a cyclic reagent that exposes the sulfhydryl group when it reacts with amino functions on proteins. This means that it is not necessary to exchange the buffers or use a specific deprotection reagent, and in principle it may not be necessary to remove excess 2-IT before use of the thiolated protein. 2-IT has been used previously to conjugate proteins to liposomes (*6*, *7*). In those studies it was used in a 20-fold excess, with unreacted reagent being removed by gel filtration before the conjugation of the thiolated protein with liposomes.

Since we were interested in minimizing the amount of processing required during the process, we wanted to determine if 2-IT could be used in the passive conjugation protocol without an intermediate gel filtration step to remove unreacted 2-IT. An experiment was conducted where 2-IT was titrated into an ovalbumin solution, and the resultant thiolated product conjugated to DSPE-ATTA2-MPA/DSPE-ATTA4 micelles. The conjugation efficiency was determined by incubation of the ovalbumin−micelles with POPC/chol liposomes at an initial protein/final lipid ratio of 150 g/mol. Unconjugated protein and micelles were removed by gel filtration though sepharose CL-4B and the recovered liposome fraction analyzed for lipid and protein content. The results are presented in Figure 2.

Interestingly it was found that as the ratio of 2-IT relative to ovalbumin increased, the apparent coupling efficiency decreased. This behavior is likely due to the omission of the gel filtration step for removal of unreacted 2-IT prior to incubation with the maleimide micelles. Hydrolysis of the excess 2-IT in solution probably resulted in quenching of some of the maleimide

functionality, inhibiting the slower protein−micelle conjugation reaction. The best conjugation efficiency was seen at about 5 equiv of 2-IT. Following this experiment we used 5 equiv of 2-IT as our baseline in further optimization studies.

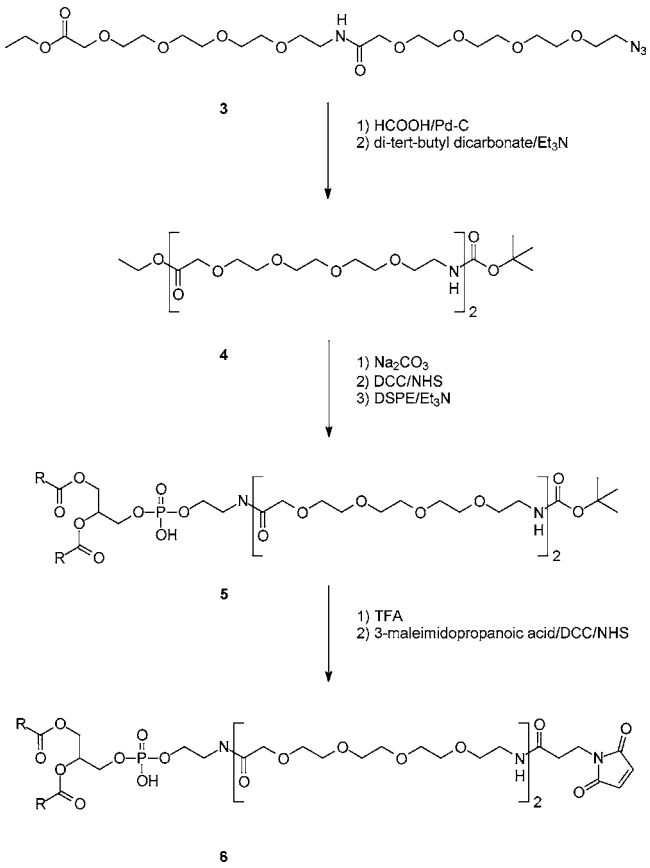
Synthesis of Lipids Used. Most of the original protein−liposome conjugation studies reported in the literature used simple lipids derivativatized with a cross-linker to introduce the reactive function. One of the most commonly used lipids is DSPE-MPB. After the development of PEG−lipids as steric barrier molecules in liposomes, some researchers began conjugating proteins to the ends of PEG−lipids in an attempt to get systems with good conjugation efficiencies and favorable pharmacokinetic properties. Maleimide-capped PEG−lipids were good candidates for the first application of micelle-based conjugation techniques in the preparation of liposome−protein conjugates.

We were interested in investigating the relationship between the size of the tether in the active lipid and the size of the hydrophilic domain in the micelle-forming lipid in terms of their effects on coupling efficiency. PEG lipids are not ideal for this since they are polymers composed of a wide range of molecular sizes. We have recently developed PEG like molecules based on repeating units of 14-amino-3,6,9,12-tetraoxatetradecanoic acid (ATTA) (*13*). These ATTA derivatives are suitable for investigating the effects of the relative headgroup size of the active and micelle-forming lipids on the conjugation efficiency since they can be tailored to exact sizes.

The synthesis of the ATTA monomer was performed using a modified version of a literature procedure (*15*). 11-Azido-3,6,9-trioxundecanol **1** was prepared by partially mesylating tetra(ethylene glycol), treating the product with sodium azide and recovering the product through a series of selective extraction procedures. Crude **1** was then treated with a suspension of finely powdered potassium bromoacetate and sodium hydroxide pellets in toluene. The literature method used DMF as the solvent; however, we found this to be unsuitable due to decomposition of the solvent under the reaction conditions, which caused considerable problems. The most effective results were obtained with lyophilized potassium bromoacetate. Other methods of preparing the potassium bromoacetate yielded granular forms of the salt, which were found to be relatively ineffective in the reaction. Synthesis of ATTA2 and ATTA4 were performed as previously described (*13*).

The primary active lipid used in this work was DSPE-ATTA2-MPA. This was prepared by reducing the azido group of ATTA2 to the amine **3** and protecting the amino function using a BOC group to form **4**. The carboxyl group was then deprotected by basic hydrolysis to form the acid **5**. This was conjugated to DSPE using DCC/NHS chemistry. The BOC protecting group was removed with TFA and the amino function derivatized with MPA using DCC/NHS chemistry. The product **6** was purified by HPLC. Excessive workup of the product should be avoided since this results in hydrolysis and other side reactions with the maleimide group, reducing yields and complicating purification. The storage conditions for the product were important. Over time an unknown material insoluble in organic solvents and water began to form. We believe that this material is a polymer stemming from ring opening of nearby maleimide functions by maleamic acid contaminants. Maleamic acids are much less reactive than maleimides, and excessive presence of those compounds can lead to an apparent loss of activity of the active lipid. Material stored as a lyophilized powder was generally sufficiently stable to be used for up to 4−5 months with noticeable loss of coupling activity. New batches were prepared every 4−6 months. However, material stored as gums formed by evaporating solutions directly using rotovaps usually became unusable within weeks. It is important

Scheme 1. The Synthesis of DSPE-ATTA2-MPA



that active lipids be stored in a cool dry location once lyophilized and, if significantly below room temperature, be allowed to equilibrate to room temperature to prevent water from condensing on the product. An outline of the synthesis is shown in Scheme 1.

It is not practical to synthesize a fresh batch of active lipids prior to each micelle formulation experiment. Consequently any polymerized material formed in the active lipid stocks on storage were removed from the micelles by filtration through 0.22 micron filters. The presence of the impurity can be observed through the appearance of a "haze" in the lipid ethanol and in micelle solution after dilution with buffer. It is necessary to remove this material since it potentially could interfere in size determination measurements. The problem becomes increasingly pronounced as the sample ages. Properly stored reagents were typically effective with minimal insolubles for 4−5 months after synthesis. Material much older than that tended to generate significant amounts of insoluble materials and showed noticeably lower conjugation efficiencies. Whenever using maleimide-based active lipids in formulations of this sort, it is advisable to perform small test runs periodically to ensure that the lipid activity is at an acceptable level.

A number of micelle-forming lipids were used in this work. Some of them were commercially obtained but a number of them were based on our ATTAn templates and synthesized in house. These included DSPE-ATTAn, where $n = 1$, 2, and 4. The synthesis of these lipids was performed as described previously (*16*).

Effect of Micelle Lipid Structure. The use of micelle-mediated passive coupling techniques have been reported in a number of publications (*6*, *7*). All of these reports use lipid-PEG−maleimide conjugates as the active lipids and PEG−lipids as micelle-forming lipids.

There are a number of good reasons for diluting the active lipid with a micelle-forming lipid, even if the active lipid forms

micelles in isolation. First, the active lipid is typically a relatively high cost component in formulations. It is highly unlikely that a large molecule such as a protein can be coupled to every maleimide on pure micelles; therefore, much of the active lipid in those cases is wasted. In principle it should be possible to dilute the active lipid out with another lower cost micelle-forming lipid. Second, it should be remembered that maleimide functions are active molecules, which might cause issues in pharmaceutical applications if they are present in high levels.

The previously reported work had used DSPE-PEG-2000 as the micelle-forming lipid, and DSPE-PEG-2000-maleimide as the active lipid, in a 4:1 ratio. In that particular case the active group is presented approximately at the surface of the PEG shroud above the micelle; consequently, there should be little inhibition of reaction with proteins. Such systems are expected to exhibit at least some degree of cross-linking since both the micelles and the thiolated protein are multivalent species. Traditionally when doing similar reactions at liposome surfaces, PEG lipids are included to inhibit these cross-linking reactions, based on the principle that, at some ideal concentration range, the PEG is dense enough to inhibit the approach of a liposome−protein conjugate but not the protein by itself. Since both approaches were being presented as "improvements" over previous technology, we asked the question: what effect does the relative size of the hydrophilic domain of the two lipids present have on coupling efficiency using the micelle based passive conjugation method?

To answer this question we designed an experiment where we used micelles composed of a 1:4 ratio of DSPE-ATTA2-MPA:micelle-forming lipid, where the micelle-forming lipid was one of the following: DSPE-ATTA1, DSPE-ATTA2, DSPE-ATTA4, MePEGS-2000-DSPE, and MePEGS-5000-DSPE. The ATTA1, ATTA2, and ATTA4 correspond approximately to PEG 250, 500, and 1000 in size. A micelle-forming lipid was required in this case since the active lipid used, DSPE-ATTA2-MPA, did not form a micellar solution by itself. DSPE-ATTA1 was found not to be an effective micelle-forming lipid and was dropped from the study. The four remaining lipid compositions were hydrated by first dissolving the lipids in ethanol and then diluting the solution with nine parts of buffer, such that the final lipid concentration was 10 mM.

Previously reported studies on the phase behavior of pure mono methoxy PEG−lipids have shown that MePEG-350-DSPE forms bilayer phases on hydration, whereas the MePEG-750, MePEG-2000, and MePEG-5000 analogues form micellar phases (*17*). It is likely that DSPE-ATTA1 forms a bilayer phase, while DPSE-ATTA4 forms a micelle phase. It is not immediately clear what form DSPE-ATTA2 adopts, but when fully hydrated it forms a clear solution suggesting that it forms micelles.

The MePEGS-5000-DSPE system hydrated very readily, with the other systems showing some signs of nonhydrated material as the size of the micelle-forming lipid headgroup decreased. In the case of the DSPE-ATTA2 system the solution exhibited thermotropic behavior, forming a gel at room temperature which reverted to micellar form on being heated in a 60 °C water bath. The micelles thus formed were incubated with previously thiolated ovalbumin at a protein/micelle lipid ratio of 3000 g/mol. The reaction was allowed to proceed overnight at room temperature. Interestingly, once reacted with the thiolated protein, the DSPE-ATTA2 micelles no longer exhibited the thermotropic behavior previously seen.

Each sample was then divided into two parts. One-half was mixed directly with liposomes in a 1:19 ratio and incubated at 60 °C for 30 min. The solution was then run down a sepharose CL-4B column to remove any excess protein or micelles from the sample. The second half of the micelle/protein solutions were filtered through 0.22 micron filters and then treated in the same way as the first half. Protein content was assessed using a modified BCA assay (*10*) and lipid content with a molybdate assay (*10*). The samples were also sized with a Nicomp 380 particle sizer. The results of the experiment are shown in Figure 3.

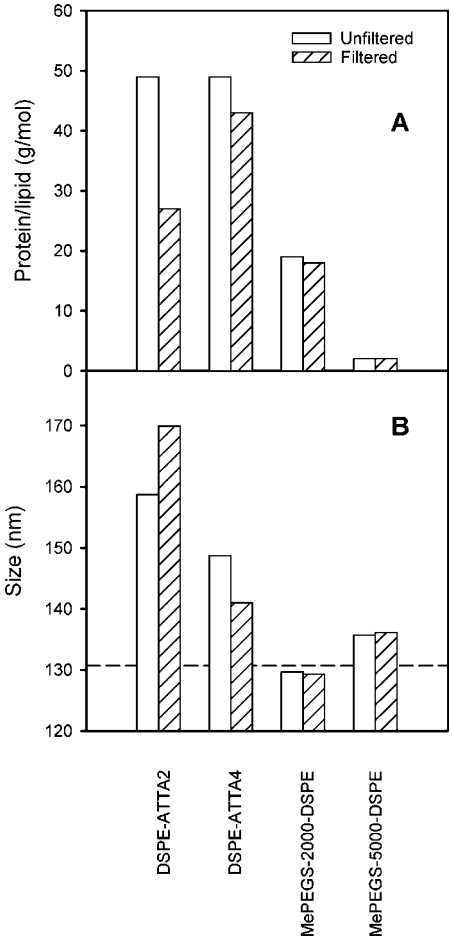


Figure 3. The effect of the micelle-forming lipid headgroup size on coupling efficiency in passive coupling protocols. Ovalbumin was thiolated with 5 equiv of 2-IT and incubated with DSPE-ATTA2-MPA/micelle-forming lipid (1:4) micelles in a 3000 g/mol ratio. The micelle-forming lipids used were as denoted on the figure. The protein−micelle conjugates were incubated with POPC/chol (55:45) liposomes in a 1:19 mol/mol ratio. Panel A: Final bound protein/lipid ratio (g/mol) where the protein−micelle conjugates were filtered before incubation with the liposomes (crossed bars), or added directly to the liposomes without pretreatment (open bars). Panel B: Size increases of liposomes after incubation with the protein−micelle conjugates. The dotted line represents the original size of the liposomes.

The first observation made was that filtering the micelle−protein conjugates prior to incubation with the liposomes had little effect on coupling efficiency except for the DSPE-ATTA2 systems, which showed a marked drop. There was a slight increase in turbidity as the micelle-forming lipid headgroup decreased in size, which was removed by the filtration step. This suggested that cross-linking increased as the headgroup size decreased, which is not a surprising finding. Similar trends were observed with the particle sizing data for the final liposome constructs.

Aggregation of the liposomes is indirectly linked to cross-linking in the micelle solutions since it is mediated by proteins that have two or more lipid anchors attached at distal ends. Thus, when one lipid anchor inserts into the liposome membrane, the distal anchor is available to insert into another liposome, inducing aggregation. Multiple distal derivatization of the protein

occurs when a protein conjugated to one micelle surface is able to access and react with another micelle surface. Clearly, increasing the size of the micelle-forming lipid inhibits this cross-linking as evidenced by the particle sizing data. However, increasing headgroup size also inhibits the conjugation reaction, resulting in decreasing conjugation efficiencies. PEG5000 essentially stopped the reaction, suggesting that the maleimide group was inaccessible. Significant inhibition is also seen with PEG2000. ATTA2 and ATTA4 have similar conjugation efficiencies, capping at approximately 50 g/mol, which, as we will show later, corresponds to the saturation of the micelle surface.

The apparent coupling efficiency for the filtered DSPE-ATTA2 micelles is lower than the unfiltered sample due to the removal of aggregated micelle−protein constructs. This in turn is reflected in the sizing data where the protein−liposomes generated from the filtered sample are larger than those from the unfiltered sample. This apparent contradiction is likely due to the removal of the most severely aggregated liposomes during the gel filtration step, resulting in a selective recovery of smaller liposomes.

The trend of decreased coupling efficiency as the extent of the steric barrier coverage of the surface of the micelle increases is similar to the behavior seen when conjugating protein to PEGylated liposomes using active coupling methods (*18*). In that experiment protein is conjugated to the surface of liposomes containing varying amounts of PEG2000 lipids in the membrane. As the level of PEG2000 increases, the conjugation efficiency drops off to a background level at ∼6 mol %. At this point the protein can no longer access the surface due to steric inhibition.

The results of these experiments demonstrate that a wide range of micelle compositions are possible provided that the micelle-forming lipid headgroup does not become so large that it prevents access of the protein to the maleimide group. The primary issues to consider in developing optimal reaction/formulation conditions are aggregation and reaction efficiency.

Zero Length Micelle-Forming Lipids. The fact that the passive coupling protocol worked with the DSPE-ATTA2 system posed new questions: How small is it possible for the micelle-forming lipid to be and still comprise a working formulation? How small is it possible for the active lipid to be and still comprise a working formulation? To answer these questions we designed an experiment where we used either DSPE-MPB or DSPE-ATTA2-MPA as the active lipids, and DSPE-ATTA4, OGP, and CHAPS as the micelle-forming lipids, six systems in all. The DSPE-ATTA2-MPA/DSPE-ATTA4 system was used as a reference point. Thiolated protein corresponding to a range of initial protein/final lipid ratios (based on final lipid, after mixture of the protein−micelles to the liposomes) from 50 to 500 g/mol was added to sets of micelle samples from each formulation group (since the final micelle/liposome lipid ratio is 1:19, this corresponded to protein/micelle lipid ratios of 1000−10000 g/mol micelle lipid). The protein−micelles (42 in all) were added to liposome samples and treated as described earlier. Lipid, protein, and size analyses were performed for each system. The results for the DSPE-ATTA2-MPA/OGP system data set are presented in Figure 4. Results for the other five systems can be seen in the Supporting Information.

We used the usual hydration method for preparing the micelles. This involved dissolving the lipid in ethanol and diluting the resultant solution in 9 parts buffer, such that the final concentration was ∼10 mM. This worked well in most cases, except for the CHAPS systems. CHAPS formed a gel-like solid in ethanol but formed micelles readily enough when the buffer was added. All systems formed micelles during the hydration process. Two systems showed thermotropic gel

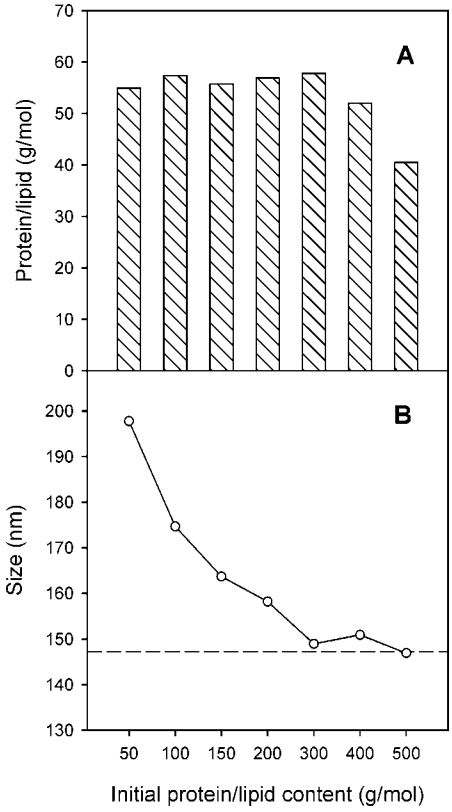

Figure 4. The effect of increased protein/micelle lipid ratio. Micelles were composed of DSPE-ATTA2-MPA/OGP (1:4). Ovalbumin was thiolated with 2-IT in a 1:5 ratio and incubated with micelles at various protein/lipid ratios. The initial protein/lipid content is expressed as g ovalbumin/mol total lipid for convenience, the initial protein/micelle lipid (g/mol) ratio is 20× the number shown. Liposomes were based on POPC/chol (55:45), and were treated with protein−micelles in a 1:19 micelle/liposome lipid ratio. Panel A: Protein bound to liposomes as a function of the initial protein content. Panel B: Final liposome size as a function of the initial protein content. The dashed line represents the size of the precursor liposomes.

formation behavior, namely the DSPE-MPB formulation with OGP and CHAPS. Gel formation was heaviest in the latter case. However, both systems could be redissolved into a micellar solution on warming in a 60 °C water bath. It is likely that this behavior is due to transient hydrophobic interactions between the maleimide groups in the absence of some sort of steric barrier molecule on the micelle surface.

Addition of thiolated ovalbumin in various ratios resulted in abolition of the thermotropic behavior mentioned above. The reaction was allowed to proceed overnight at room temperature. The systems containing CHAPS at 50 g/mol (initial protein/final total lipid) showed heavy aggregation, with light aggregation at 100 g/mol (initial protein/final total lipid). No aggregation was observed at higher ratios. Light aggregation was also seen in the DSPE-MPB/OGP system at 50 g/mol (initial protein/final total lipid). Slight turbidity was seen in a number of other formulations at 50 g/mol (initial protein/final total lipid) but could be dispersed on heating. The heavy aggregation observed in some of the systems was likely caused by cross-linking between the micelles, resulting in proteins which have been derivatized with hydrophobic anchors on distal ends of the molecule. Such molecules are undesirable when associated with liposome surfaces due to their ability to cause cross-linking and aggregation of the liposomes. The enhanced aggregation observed in the CHAPS systems at lower initial protein/lipid ratios is probably due to ionic interactions between the CHAPS and protein. At higher initial protein concentrations this effect is no longer seen, most likely as a result of conjugated protein

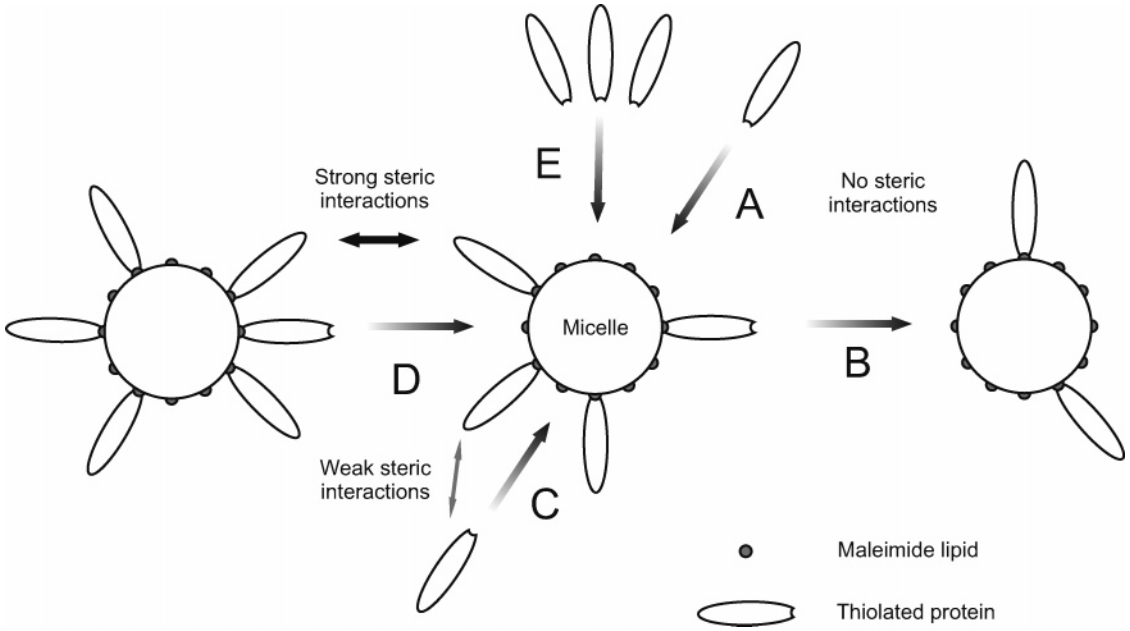

Figure 5. Mechanism for the inhibition of aggregation. A. Single macro-molecules can access unprotected surfaces readily. B. Surfaces without sufficient density of protein can undergo cross-linking reactions. C. Single macromolecules can access protected surfaces. D. Modified surfaces cannot access other modified surfaces readily, inhibiting cross-linking. E. Increasing concentration of free protein relative to other surfaces increases the rate of reaction of single protein conjugation

acting as a steric barrier molecule on the liposome surface, inhibiting further cross-linking reactions.

Figure 4 (and the related Supporting Information) show several interesting trends. In many cases the coupling efficiency increases to somewhere between 50 and 60 g/mol (initial protein/final total lipid) and then plateaus out. At high ratios it begins to decline. This would suggest that the micelle surfaces are being saturated at some point between 50 and 60 g/mol (initial protein/final total lipid), and that attempting to achieve higher ratios would reduce coupling efficiency. The particle sizing data (Figure 4 panel B) showed a steady decline in aggregation levels until around 200−300 g/mol (initial protein/final total lipid). We chose 150 g/mol (initial protein/final total lipid) as the standard initial protein/final lipid ratio, since it saturated the micelle surface at reasonable coupling efficiencies with relatively minor size increases due to aggregation. The apparent decline in coupling efficiency seen at high initial protein/final lipid ratios is probably due to the advent of maleimide quenching by excess hydrolyzed 2-IT which is still present in the thiolated protein solution.

Another interesting observation was that the saturation level of the DSPE-MPB micelles appeared to be somewhat lower than the DSPE-ATTA2-MPA systems (Supporting Information). This is not surprising since the area available for protein coverage is determined by the radius of the maleimide functionality, which is somewhat larger in the case of DSPE-ATTA2-MPA than DSPE-MPB. A smaller radius means less reactive surface area and hence a lower saturation level.

These results suggest a general model for preparing protein−micelle conjugates. Both the micelles and the proteins are multifunction entities. Micelles have a great many copies of maleimide on their surface, while the ovalbumin has on average up to five sulfhydryl groups. This means that once a thiolated protein has reacted with the surface of a micelle, it may still be available for reaction to another micelle. Once a protein is conjugated to a micelle however, the probability of it reacting with another micelle is smaller than the free protein alone due to steric hindrance.

As the surface concentration increases, the protein starts to act as a steric barrier molecule in its own right and eventually stops aggregation reactions. In situations where the initial free protein/micelle ratio is large, the rapid coating of the micelles prevents further aggregation reactions. Alternatively, where the initial free protein/micelle ratio is smaller, aggregation can still occur (Figure 5). This suggests that the degree of aggregation in a particular system can be controlled simply by adjusting the initial protein/lipid ratio. There is a limit to how far this can be taken though, since coupling efficiency is likely to be an issue with many proteins, particularly those in limited supply. For most of our work we selected 150 g/mol (initial protein/final total lipid) as our baseline standard, since aggregation was reasonable and coupling efficiency acceptable (∼35%).

If this mechanism is correct, we can predict that changing other parameters should also have effects on coupling efficiency and aggregation. These include the active lipid content of the micelles, initial 2-IT concentration, and the initial protein/final lipid ratio.

Effects of Changes to the Active Lipid Content. If the proposed mechanism is correct, we would expect that alterations to the active lipid content should affect the coupling efficiency. A micelle surface concentration of 1000 g/mol (initial protein/micelle lipid) corresponds to 0.022 mol protein/mol lipid. This implies that there is one protein for every 45−50 lipid molecules in the micelle. Our baseline formulation used a micelle composition of active lipid/micelle-forming lipid in a 1:4 ratio; in other words there is one protein for every 9−10 active lipid molecules. That would imply that the surface is being saturated, rather than the reactive functions on the surface, since this appears to be the upper limit of conjugation in these systems.

We designed an experiment in which the active lipid content in the micelles was changed, but the total amount of micellar lipid relative to liposome lipid was held constant. Thiolated protein was incubated with various samples of micellar lipid in a 3000 g/mol ratio (or 150 g initial protein/mol final lipid) and then treated with POPC/chol liposomes in a 1:19 lipid ratio. The results are shown in Figure 6. As expected reducing the amount of active lipid in the micelles resulted in reduced aggregation. However, coupling efficiency is also adversely affected, falling off as the active lipid content drops.

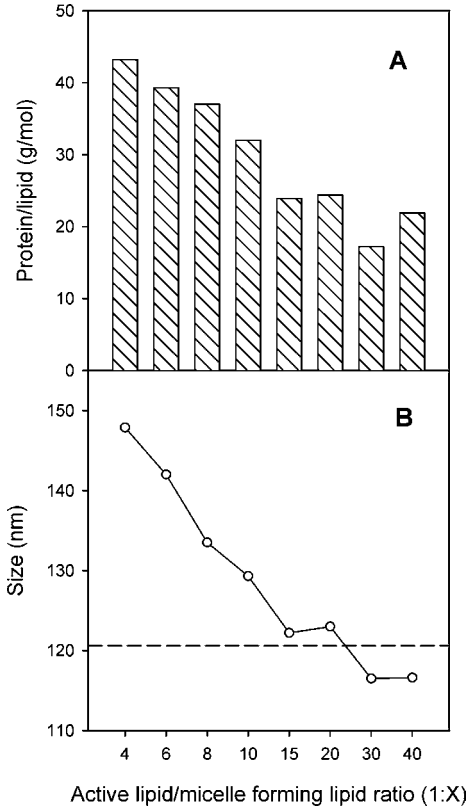

Figure 6. The effect of reducing the active lipid content while keeping the micelle/liposome lipid ratio constant. Micelles were composed of DSPE-ATTA2-MPA/OGP (1:X). Ovalbumin was thiolated with 2-IT in a 1:5 ratio and incubated with micelles at 3000 g protein/mol micelle lipid. Liposomes were based on POPC/chol (55:45), and were treated with protein−micelles in a 1:19 micelle/liposome lipid ratio, for an initial protein/total lipid content of 150 g/mol. Panel A: Final bound protein content as a function of active lipid content in the micelles. Panel B: Final liposome size. The dashed line represents the size of the precursor liposomes.

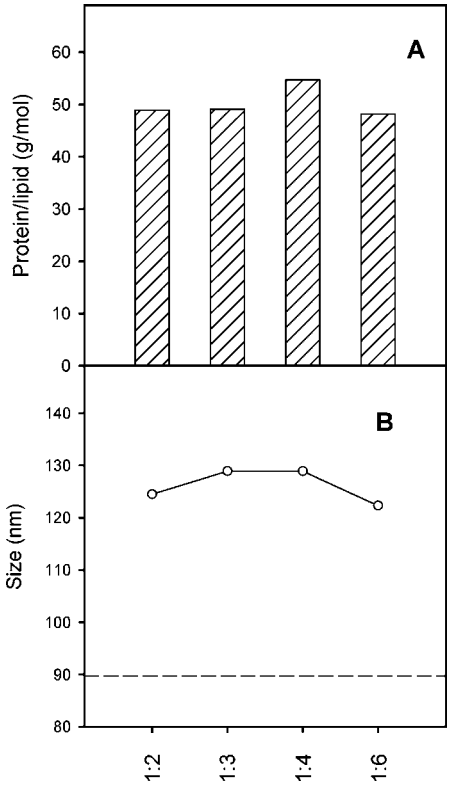

Figure 7. The effect of reducing the micelle lipid content while keeping the active lipid/liposome lipid at 1%. Micelles were composed of DSPE-ATTA2-MPA/OGP (1:X). Ovalbumin was thiolated with 2-IT in a 1:5 ratio and incubated with micelles at 15000 g protein/mol active lipid. Liposomes were based on POPC/chol (55:45) and treated with micelles such that the initial protein/total lipid content was 150 g/mol. Panel A: Final bound protein content. Panel B: Final liposome size. The dashed line represents the size of the precursor liposomes.

A second experiment was done in which the active lipid/micelle-forming lipid ratio was changed, but with the total amount of micelles added to the liposomes normalized against the active lipid. The final active lipid content was 1%. The results are presented in Figure 7. We had expected that the amount of conjugated protein would increase as the amount of micelle-forming lipid increased, since this should have resulted in more micelles with a corresponding increase in the reaction surface. In fact there were relatively small changes in the conjugation efficiency, with no clear change in particle size. This would imply that either the surface area of the micelles was remaining approximately constant, or that the reaction efficiency on the surface was decreasing as the micelle number increased. The most probable explanation is that both the micelle number and the reactive radius in the context of this experiment are being determined largely by the active lipid. The results suggest that the protocol is relatively insensitive to changes in the micelle lipid composition, at least within the data range covered by the experiment.

Effects of 2-IT Ratio on Aggregation. An alternative method for reducing cross linking reactions is to reduce or minimize the number of additional sulfhydryl groups in the thiolated protein. To investigate the effect of the number of cross-linking groups we titrated in 2-IT corresponding to 1−5 equiv per protein, with 5 equiv being our baseline system. The experiment was performed at two initial protein/final lipid ratios, namely 50 and 200 g/mol (initial protein/final total lipid). The results of the experiment are presented in Figure 8. As expected, decreasing the amount of cross-linker used decreased the level of aggregation. Surprisingly, however, reducing the amount of cross-linker used did not dramatically affect coupling efficiency, although a slight drop-off could usually be seen at the lowest cross-linker content, even in the 50 g/mol (initial protein/final total lipid) system.

Reducing the Initial Protein Content below the Saturation Level. Since the micelle surface was apparently becoming saturated at a protein/micelle lipid ratio of ∼1000 g/mol, we ran an experiment in which the initial protein content was titrated into micelles below the saturation level. The results are presented in Figure 9 (P/L is represented as initial protein/final lipid). The apparent coupling efficiency in this particular experiment is 60−70% for all the data points, except for the final one at 100 g/mol where it has fallen off to 45%. This would indicate that the surface of the micelle is saturated at approximately 1000 g/mol (protein/micelle lipid), which is consistent with the result previously obtained. The limit to the apparent coupling efficiency at 60−70% in this experiment suggests that at least some of the protein is not thiolated, or is thiolated in areas of the protein that are not available for reaction. Modest changes to the sizes of the liposomes were observed after incubation with the protein−micelle conjugates, suggesting that the liposomes were more prone to cross-linking reactions as the protein content decreased. Again, this is to be expected if protein bound on the surface of the micelles acted as a steric barrier, since reducing the protein on the surface should increase the probability of a successful cross-link reaction.

Titration of Protein−Micelles into Liposomes. A solution of protein−micelles with an initial protein/micelle lipid ratio of 3000 g/mol was prepared and titrated into liposomes (Figure 10). At this concentration, coupling efficiency is typically 30−

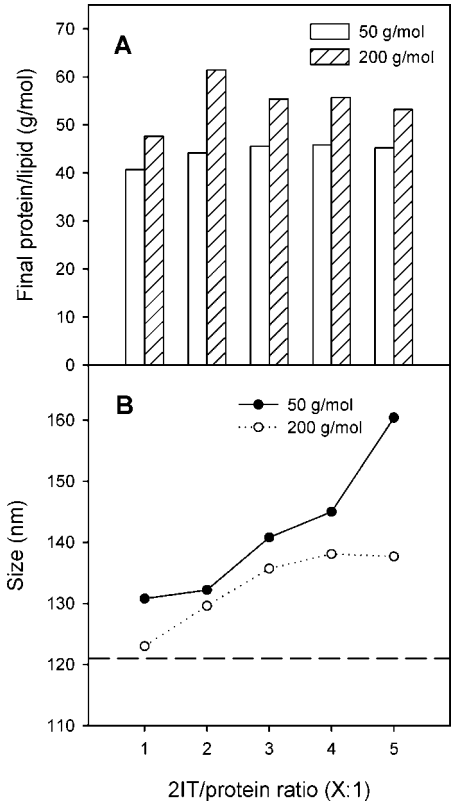

Figure 8. The effect of the 2-IT/ovalbumin ratio. Micelles were composed of DSPE-ATTA2-MPA/OGP (1:4). Ovalbumin was incubated with 1−5 equiv of 2-IT and incubated with micelles at 1000 g/mol or 4000 g/mol. Liposomes were based on POPC/chol (55:45) and incubated with micelles in a 19:1 lipid ratio, so that the initial protein/total lipid content was either 50 or 200 g/mol. Panel A: Final bound protein content as a function of the initial 2-IT/ovalbumin ratio. Panel B: Final liposome size. The dashed line represents the size of the precursor liposomes.

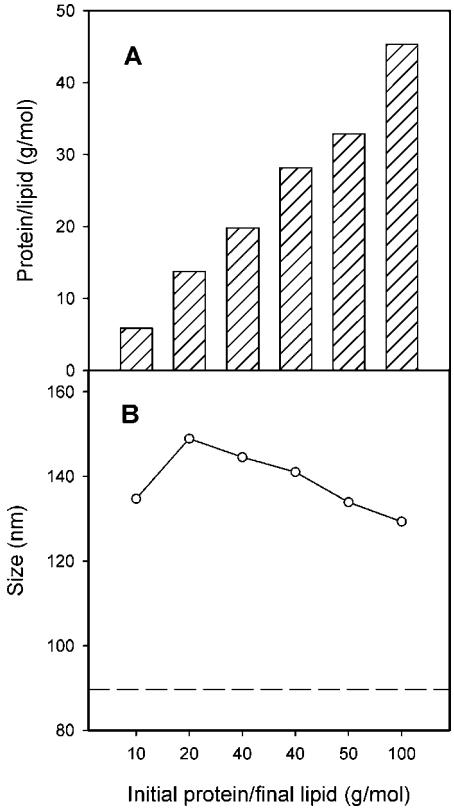

Figure 9. The effect of low initial protein/lipid ratios. Ovalbumin was incubated with 5 equiv of 2-IT and added to micelles composed of DSPE-ATTA2-MPA/OGP (1:4) at protein/micelle lipid ratios of 200−2000 g/mol. Liposomes based on POPC/chol (55:45) were incubated with micelles in a 19:1 lipid ratio, for initial protein/total lipid ratios of 10−100 g/mol. Panel A: Final bound protein content as a function of initial protein added. Panel B: Final liposome size. The dashed line represents the size of the precursor liposomes.

40%. The protein content associated with the final liposome formulations increased in proportion to the amount added. This value tended to fall off at very high levels of added micelles. Figure 10 shows a slight fall off in association efficiency at 300 g/mol (initial protein/final total lipid); however, at this point the ratio of liposome/micelle lipid is 10:1. At these levels the detergent itself may start to affect the system in significant ways. We have titrated the micelles into liposomes to much higher levels (see Supporting Information) and start to see a marked decline in association efficiency, together with a fall in the levels of liposome aggregation at very high micelle contents. Those results suggest that the liposome surfaces might be becoming saturated at those levels, but it is difficult to draw conclusions since at those detergent levels, the surfactants must be playing a role.

The levels of aggregation observed in Figure 10 is approximately the same for all the systems studied. This is not surprising since the cross-linking reaction occurs during the micelle−protein incubation, and the same micelle−protein solution was used to prepare all of the final liposome formulations. The systems should show equivalent levels of aggregation provided that the surface of the liposomes was not saturated.

Reproducibility of the Conjugation Process. One of the primary problems when using active coupling protocols for preparing protein−liposome conjugates is controlling parameters such as conjugation efficiency. This problem is exacerbated in some cases by the presence of steric barrier molecules on the surface of some liposome formulations, since even small changes in the concentration of these molecules can have significant effects on the accessibility of the liposome surface to the reactive face of the protein. In principle the passive conjugation process should result in far more reproducible formulations since the amount of protein−lipid conjugates formed can be regulated by saturation of the micelle surface. The protein micelles can then be titrated into liposomes at specific concentrations, allowing the user to accurately tailor the particular composition of a protein−liposome formulation.

To test this idea we designed an experiment in which three separate sets of protein solutions were thiolated using the same 2-IT stock solution. The three thiolate protein solutions were then incubated with three separately prepared maleimide-containing micelle solutions. Aliquots of these three solutions were then treated with POPC/chol liposomes as usual. The final micelle−liposome incubation was repeated 4 days later using the same protein−micelle and liposome solutions. After final workup and analysis, the results plotted and presented in Figure 11. The experiment served to demonstrate that relatively reproducible results can be obtained if a standard protocol is followed.

DISCUSSION

The primary focus of our laboratory is the development of liposome-based drug delivery systems that are practical candidates for commercialization as pharmaceutical products. Two areas of interest to us have long been the development of a functional “targeted” formulation and artificial vaccines. In both cases, to develop viable products based on these concepts we have considered it important that we have techniques for conjugating proteins of interest to these systems that are both robust and reproducible.

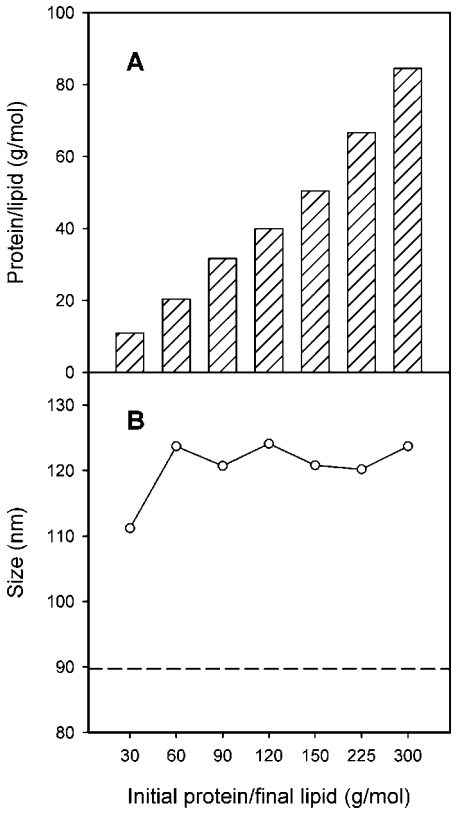

Figure 10. Titration of ovalbumin/micelles conjugates into POPC/chol (55:45) liposomes. Ovalbumin was incubated with 5 equiv of 2-IT and added to micelles composed of DSPE-ATTA2-MPA/OGP (1:4) in a 3000 g protein/mol micelle lipid ratio. Aliquots of ovalbumin/micelles were added to liposomes such that the initial protein/total lipid ratio was as indicated in the figure. Panel A: Final bound protein content as a function of the initial protein/lipid ratio. Panel B: Final liposome size. The dashed line represents the size of the precursor liposomes.

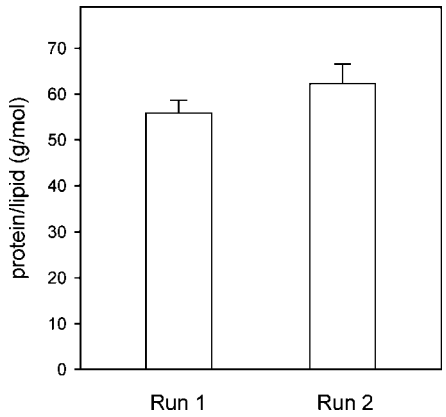

Figure 11. Reproducibility of the passive coupling procedure. Three separate ovalbumin solutions were treated with 2-IT in a 1:5 ratio. Aliquots of the thiolated ovalbumin were added independently to three separately prepared micelle solutions (DSPE-ATTA2-MPA/DSPE-ATTA4; 1:4) at 3000 g protein/mol micelle lipid. Aliquots of the three micelle−ovalbumin conjugate solutions were added to POPC/chol liposomes (55:45; a single stock solution was used) at an initial protein/total lipid ratio of 150 g/mol. After a few days of storage the micelle−ovalbumin/liposome incubations were repeated a second time using the same liposome and micelles stock solutions.

Drugs encapsulated in liposomes largely assume the pharmacokinetic characteristics of the liposomes themselves, with the primary variable being the leakage rate of the drug in vivo. This creates limitations in the utility of these systems however, since liposomes distribute in vivo in specific ways. It has long been an objective of many groups in the field to alter this distribution through the attachment of targeting functions on the surface of liposomes, such that they would accumulate in a specific tissue or a specific cell type. Much of this work has focused on the use of proteins such as antibodies to achieve this goal.

Many problems have been experienced in these studies however. It is often difficult to determine if a "targeted" liposome has truly reached the target in vivo, since in many cases access to the target requires extravasation to take place first. Extravasation then becomes the rate-limiting step, making it difficult to distinguish between actual targeting and non specific association. In addition, many of the proteins used in these studies have natural effector functions, or are recognized as foreign by the immune system when attached to liposomes.

One of the issues faced when comparing different studies or experiments is that very often the levels of conjugated protein vary considerably. This is partly the result of the intrinsic variability in conducting multistep reactions on proteins and partly due to aggregation reactions and/or steric inhibition of reactions on liposome surfaces due to the presence of steric barrier molecules. The development of the work discussed in this paper was motivated to address these issues and provide a conjugation system that was both reproducible and technically simple.

The other area of interest to us in this field was the synthesis of artificial vaccines. While working on the development of liposome-encapsulated oligonucleotides (*19*) we discovered that these formulations had powerful immunostimulatory effects (*20*). We also made the serendipitous discovery that a subset of these formulations which included nonexchangeable PEG−lipids as part of the lipid composition showed dramatic increases in liposome clearance rates on repeat administrations. This was later shown to be due to an induced immune response to the PEG (*21*), a molecule which is normally thought of as nonimmunogenic. Following this discovery we were able to show that greatly enhanced immune responses to protein was achieved when they were conjugated to the surface of these oligonucleotide−liposome particles.[2]

Originally we conjugated proteins to these particles using active coupling methods. It was difficult to get reproducible results with these methods however, necessitating the development of more controllable methods of conjugation. Although the nature of the particle is very different from those used in drug targeting applications, the fundamental issues involved in performing a protein−particle conjugation are much the same. The same techniques should be applicable to both applications. This need led to the development of the general technique described in this paper.

Active conjugation methods tend to suffer from a number of serious drawbacks. The most important of these are reaction control, aggregation, and conjugation efficiency. When conjugating a protein to the surface of a liposome, both entities have multiple sites of possible reaction. In the absence of any sort of controlling mechanism, this leads to cross-linking of liposomes and the formation of liposome aggregates. These aggregates are rapidly cleared in vivo and are considered pharmaceutically undesirable. The formation of the aggregates can be suppressed by including steric barrier molecules in the formulation or by controlling the relative concentrations of the reactants. However, these methods lead to the suppression of the reaction through either steric inhibition or by competition

[2] Yuan, Z. N., Brodsky, I., Ansell S. M., Klinuk, S.K, and Semple, S. C. (2004) Systemic and mucosal immune responses induced by liposomes with surface-coupled antigen and high levels of encapsulated immunostimulatory oligonucleotides. Unpublished data.

from hydrolysis reactions. This manifests itself through generally low and variable coupling efficiencies.

The basic problem with active conjugation is that we are performing two processes simultaneously, namely: (a) associating the protein with the liposome; and (b) forming a lipid−protein conjugate. Since a number of variables affect this process, we end up with a system that is intrinsically difficult to control. The simplest and most obvious solution to the problem is to separate the procedure into two steps, and this is what we do with the passive conjugation method. The lipid protein−conjugate is formed externally from the liposome, after which it is exchanged into the liposome bilayer.

In this particular case we are using a micelle as a substitute surface to perform the reaction on. As can be seen from the data in Figure 4, once you reach a certain point it is no longer possible to increase the amount of protein associated with the micelles since the surface has been saturated with protein. This property allows us to prepare a reagent in which the amount of lipid−protein conjugate available for association with the liposomes is determined primarily by the micelle surface area. This can then be titrated into a preformed liposome solution and incubated under appropriate conditions until the protein−lipid conjugates exchanges into the liposome bilayer. The method allows us to make protein−liposome conjugates with a precision not previously possible.

Reports in the literature have used similar techniques to prepare protein−liposome conjugates (*6*, *7*). In those cases the active lipid used was a phospholipid−PEG−maleimide derivative. Placing the reactive function on the end of a PEG chain effectively dramatically increases the micellar radius of reaction, meaning that considerably more protein is required to saturate the micelle surface. Since saturation of the micelle surface is advantageous for reproducible results, the active lipids we have used here (DSPE-MPB and DSPE-ATTA2-MPA) should be more effective than PEG-based analogues.

The issue of aggregation of the final protein−liposome conjugates is not immediately solved by the approach described here since the micelles can still undergo cross-linking reactions in much the same way liposomes do. However, there are methods for controlling this process. With active coupling protocols this would be achieved by including a steric barrier lipid in the liposome composition. This results in systems where the reaction at a liposome surface with a free protein is more likely than with the much larger protein−liposome conjugate, because of interactions between the steric barrier lipids in the respective liposomes. The same principle applies for micelles, except that in this case the conjugated protein acts as the steric barrier molecule. As the initial protein content increases above the amount needed for saturation, the faster rate of reaction for the free protein would result in increased inhibition of the slower cross-linking reaction and consequent reduction in cross-linking. This is reflected indirectly in the sizing data for the final liposome conjugate.

This means that aggregation can be minimized by increasing the initial protein−lipid ratio. The price paid is a lower coupling efficiency. This might be acceptable if the protein is inexpensive or readily available, but in many cases this may not be true and consequently the cost aspect may a factor to consider when designing the specifics of the process used. An alternative approach to the problem is to reduce the probability of cross-linking occurring by reducing the amount of one of the reactive functions. This can be done by reducing the active lipid content in the micelles, or by reducing the level of thiolation in the protein. As can be seen in Figures 6 and 8, both of these approaches work, albeit with lowered coupling efficiency in some cases. The process works by making the cross-linking reaction less likely than the primary conjugation reaction.

In conclusion we have demonstrated that micelle-based passive coupling techniques are highly effective for the preparation of well defined protein−liposome techniques, and that a wide range of micelle-forming and active lipids can be used for this purpose. The ideal system to use would be one in which a relatively large excess of initial protein was used. The active lipid chosen should have a relatively nonexchangeable lipid anchor, such as DSPE, and preferably have a short tether between the lipid anchor and the maleimide function. A micelle-forming lipid should be present to dilute out some of the reactive lipid and to facilitate micelle formation where necessary. A range of micelle-forming lipids are suitable; however, the hydrophilic headgroup should not be so large that it inhibits the reaction through steric interactions. The application of these techniques to the preparation of protein−lipid-antisense complexes will be described in a later work.

Figure S.6. Titration of protein-micelles into liposomes. Ovalbumin was coupled to DSPE-ATTA2-MPA/OGP (1:4) micelles in a 3000 g protein/mol micelle lipid ratio. Aliquots of these micelles were added to POPC/cholesterol (55:45) liposomes, such that the % of active lipid relative to the liposome lipid was as shown above. Sample processing and workup protocols were conducted as described generally in the manuscript methods section. Protein, lipid and particle sizing assays were conducted as described in the manuscript. Each % active lipid added corresponds to 5% total micelle lipid, ie between 5 and 50% micelle lipid is added to the liposomes.

S.7. Comments regarding the assays used and reproducibility

The passive method has a relatively high level of reproducibility provided that experimental conditions are kept constant and provided that analytical methods are accurate. However, there are potential sources of variability in terms of the numbers that are generated in different experiments. Much of this stems from the assay that is used to determine protein content. Basically it involves a chemical colorimetric assay using a standard curve performed with reagents from Pierce's BCA assay kit. The standard curve itself is generated using a set of BSA standards. These standards are prepared by first diluting 50 µl of a kit stock solution with 950 µl of buffer to prepare a working stock solution. Aliquots ranging from 25 to 200 µl are then taken from this stock to prepare the standard curve samples. Any pipetting errors in this series of dilutions will result in deviations from the true concentration, both in terms of the slope of the standard curve and scatter of the data points making up the curve. The actual samples were analyzed in triplicate, for both the protein assay and the phosphate assay. Consequently, while data within a particular experiment is reasonable consistent, data between experiments may show some variability.

In addition to issues involving uncertainty with the slope of standard curve, the lipids used to produce liposomes can generate varying levels of background interference independent of the presence of protein. Usually this interference is small relative to the assay numbers with normal liposomes (typically 1-3 g/mol), but it can be fairly large in some cases with SALP lipids (up to around 5-6 g/mol). The reported number can deviated from the true value somewhat depending on whether or not results are corrected for background. The background and the associated uncertainty places constraints on the sensitivity of the BCA assay as well as the accuracy.

The BCA assay is far from ideal, but under the circumstances it was the most reliable method available to us. We attempted using flourescamine based assays, but found that the standard curve varied considerably depending on what exactly was used to produce it. Standard curves were generated using ovalbumin, albumin and thiolated ovalbumin, and yielded different results in each case for test samples, apparently all inaccurate based on comparisons with values determined using extinction coefficients. The BCA assay on the other hand, generated concentration results consistent with that obtained using extinction coefficients irrespective of which standard curve was used. Florescamine should be more sensitive in principle, but it was limited by the lack of material suitable for generating an appropriate standard curve.

Probably the best assay method to use would be one based on labeled protein, but that was not available for this work.

A second factor affecting the absolute results was the slow degradation of maleimide reagents on storage. Over a period of months the materials start to form insoluble products that we believe are polymers formed from intermolecular trans-acylation reactions initiated by maleamic acid impurities present in the samples. This results in polymeric materials which are unreactive and cause formulation issues, collectively

reducing conjugation efficiency. If properly stored, materials would perform consistently for 4-5 months, after which degradation of performance (in the form of coupling efficiency) would start to become apparent. Normally we would synthesize fresh reagents before this happened, but some data sets were generated with older material, and consequently absolute coupling efficiencies in those cases are lower than normal.

However, since general conclusions drawn from this work were made within data sets, and not between data sets, we believe that these discrepancies do not impact the overall message. Comparing data between sets is probably of dubious validity, but within data sets it is reasonably consistent. For example, in figure 6 the coupling efficiency is somewhat lower than what we would normally expect, but the message that the micelles can be titrated proportionally into SALP in a concentration dependant manner is still valid.

Methods for the Preparation of Protein−Oligonucleotide−Lipid Constructs

Inex Pharmaceuticals Corporation, 100-8900 Glenlyon Parkway, Burnaby, BC, V5J 5J8, Canada. Received February 24, 2005; Revised Manuscript Received November 21, 2005

A mixture of ionizable cationic lipids, steric barrier lipids, and colipids is used to encapsulate oligonucleotide DNA in lipidic particles called SALP. This material is under development as an adjuvant for vaccines. Previously we have shown that coupling the antigen directly to the surface of SALP can lead to enhanced immunological responses in vivo. Two different methods for preparing ovalbumin−SALP were assessed in this work. Originally the conjugates were prepared by treating SALP containing a maleimide-derivatized lipid with thiolated ovalbumin, a method we refer to as active coupling. This reaction was found to be difficult to control and generally resulted in low coupling efficiencies. The issues relating to this approach were characterized. We have recently developed alternative techniques based on first coupling ovalbumin to a micelle and then incubating the resultant product with SALP, methods we refer to as passive coupling. We have shown that this method allows accurate control of the levels of protein associated SALP and does not suffer from surface saturation effects seen with the active coupling method that places maximum limits on the amount of protein that can be coupled to the SALP surface. The products from the passive coupling protocol are shown to have activity comparable to those derived from the active coupling protocol in investigations of in vivo immune responses.

INTRODUCTION

As part of a program for the development of drug delivery systems, an efficient means of formulating oligonucleotides in lipidic particles (*1*, *2*) has been developed. These particles were formed through a self-assembly process after addition of an ethanolic solution of lipids to a solution of the oligonucleotide in a citrate buffer at pH ∼4.0. The lipids used included cholesterol, a bilayer-forming phospholipid (typically DSPC or POPC), a protonatable amino lipid, and a steric barrier lipid. Addition of the lipid solution to the buffer resulted in protonation of the amino lipid and formation of bilayer structures. The anionic oligonucleotide associates with these charged bilayer structures as they assemble, resulting in the formation of lipidic particles entrapping the oligonucleotide. The steric barrier lipid, typically a PEG−lipid, acts to moderate the rate of particle formation, regulating growth and inhibiting aggregation of particles. After the initial dilution, the preparation is extruded through a high-pressure filtration device and the external buffer replaced with one at pH ∼7.0 (usually HBS). At this pH the amino lipids are neutral. The final product is a lipidic particle that is stable in solution, with physical and pharmacokinetic properties much like liposomes of similar size. We refer to these particles as SALP (stabilized antisense lipid particles).[1]

During the biological characterization of SALP, a number of interesting observations were made. First, during early studies aimed at the investigation of the role played by the steric barrier molecule's relative exchangeability on pharmacokinetic behavior, we noted that certain formulations would be rapidly cleared in vivo when administered on a repeat dose schedule (*3*). This effect was only observed with formulations with (a) PEG-lipids that did not exchange rapidly out of the bilayer on administration in vivo and (b) more than a certain level of encapsulated oligonucleotide. Further studies demonstrated that the clearance behavior was due to an immune response to PEG, and that this immune response was induced by the encapsulated oligonucleotide.

Other studies with these oligonucleotide−lipid particles demonstrated that they were capable of potent enhancement of the immune stimulation associated with the CpG motif in oligonucleotides (*4*). This sequence had been shown to cause activation of macrophages, dendritic cells and B-cells, and release of various cytokines (*5*).

These observations led us to investigate the use of SALP as adjuvants for vaccines. Initially we mixed the SALP with an antigen and found that coupling the antigen directly to the surface of the particle resulted in an enhanced biological response.[2] These initial formulations were prepared using the classical protein-liposome coupling technique (*6*), namely derivatizing the protein with SPDP and coupling the resultant product (after deprotection) to SALP which had a maleimide lipid included in its composition.

From a production point of view, the process of coupling a thiolated protein to the surface of a liposome or lipid particle is fraught with difficulty. Coupling efficiency tends to be variable

and aggregation is a frequent problem (*7*). To study and characterize the in vivo effects of these particles we required systems that were reproducible and controllable; consequently, we required more robust methods of preparing these materials.

A number of groups in recent years have attempted to solve many of the original problems associated with conjugating proteins directly to liposome surfaces by moving the point of attachment from the liposome surface to the end of PEG tethers (*16, 17*). In theory this should allow efficient conjugation while still allowing a formulation to have a PEG coating on the surface. However, by moving the reactive radius outside the steric barrier domain many of the advantages of such barriers in terms of aggregation control are potentially lost. In addition to this problem there are a number of other reasons why these systems are unsuitable for use in our particles. First, if a PEG based active lipid is used with an active coupling protocol, most of the active lipid would not conjugate to a protein and would still be present as free PEG attached to the surface. Since these compounds have relatively nonexchangeable anchors by design they would remain associated with the particle in vivo sufficiently long to generate an immune response in their own right. This would limit the use of the particle as a generic platform for vaccines since the application of one formulation in a patient would generate an immune response to the platform and would presumable render any other formulations useless in that patient.

A second potential negative of the PEG tether approach relates to the exchangeability of the lipid−protein molecule once attached to the surface. The association-dissociation of a lipid−macromolecule from a bilayer surface is determined in part by the increase in freedom of motion of the macromolecule. PEG generally has considerable freedom of motion in solution, whereas most proteins and oligosaccharides are relatively rigid. Consequently, the exchange rates of PEG−lipids are much more sensitive to constraints on their freedom of motion than most biological macromolecules. Introducing a PEG tether between a macromolecule and a lipid anchor is expected to adversely affect the retention of the macromolecule in vivo, and this effect should become worse as the length of the tether increases.

Finally, we were concerned with the chemical stability of the maleimide functions used in the active lipids during processing. These compounds are susceptible to hydrolysis, forming ring-opened maleamic acids which are fairly unreactive in the coupling reaction. This is not normally a major concern when preparing research quantities of various formulations since they can be prepared fast enough, but will be an issue for large scale preparations where processing times are usually significantly longer than lab scale.

We have recently characterized general methods for an alternative method of preparing similar constructs, wherein the protein is coupled to a micelle, and the micelle lipids exchanged into liposome bilayers.[3] These methods were found to be reproducible and controllable. In this work we describe the adaptation of these micelle-based methods to the production of protein−SALP particles, demonstrate the advantages of the new method, and show that constructs prepared by the micelle method are at least as efficacious as those prepared by traditional methods.

EXPERIMENTAL PROCEDURES

Materials. Ovalbumin (grade V), cholesterol, and OGP were obtained from Sigma. MePEGS-2000-DMG (*14*) and DSPE-ATTA2-MPA[3] were synthesized in our laboratories as described elsewhere. DPSC was obtained from Northern Lipids Inc., Vancouver. SIINFEKL peptide was synthesized on contract by Commonwealth Biotechnologies Inc., Richmond, VA. The oligonucleotides used were synthesized on contract by Trilink Biotech, San Diego, CA. CD8-FITC and TCR-cychrome were obtained from BDPharMingen, San Diego. Phycoerythrin-coupled H-2Kb-SIINFEKL tetramers were synthesized on contract by Beckman Coulter Immunomics, San Diego, CA.

Synthesis of DODMA. DODMA was synthesized using an adaptation of a previously described method (*15*). Briefly, a solution of 3-(dimethylamino)-1,2-propanediol in benzene was treated with an excess of potassium hydride with stirring for 1 h under argon. Oleyl bromide (1.5 equiv) was then added and the solution refluxed for 3 h. After workup, the product was isolated from the crude reaction mixture by column chromatography.

Preparation of SALP. Solutions containing 26 μmol of lipid in 0.4 mL of ethanol and 4 mg of oligonucleotide in 0.6 mL of citrate buffer were warmed to 60 °C. The ethanol solution was then slowly added to the buffer while vortexing. The resultant suspension was passed 10 times through 2 × 100 nm filters using a pressurized extruding device. The SALP was then passed down a Sepharose CL-4B column in HBS to remove external oligonucleotide and to exchange the buffer. The quantities used were adjusted in proportion when larger amounts of material were required.

Preparation of Micelle−Ovalbumin Conjugates. Ovalbumin was dissolved in HBS at a concentration of 30 mg/mL. An aliquot of from a stock solution of 2-iminothiolane in HBS corresponding to 1−5 equiv (depending on the particular experiment) was added to the ovalbumin solution and the mixture stirred at room temperature for 0.5 h. The solution was used without further purification.

Lipid composed of the DSPE-ATTA2-MPA and a micelle-forming lipid (DSPE-ATTAn, where $n = 2$, 4, 8, or OGP) were weighed and combined. The lipid was dissolved in 1 part of ethanol, with warming if required, and diluted sequentially with 1 part of HBS, with vortexing and warming, until a total of 9 parts HBS had been added. The total volume should was such that the final concentration of lipid was approximately 10 mM. Any residual solid materials were removed by filtration through 0.22 micron filters.

An aliquot of freshly prepared thiolated ovalbumin was added to freshly prepared maleimide−micelles in the appropriate ratio. In most cases this corresponded to 3000 g protein/mol micelle lipid. The micelle−protein mixture was allowed to stir at room temperature overnight. It was then either used immediately without additional purification or stored at 5 °C for use at a later date.

Incubation of Protein−Micelles with SALP. SALP was mixed with ovalbumin−micelle conjugates in proportions appropriate for the particular experiment. Typically the standard preparation used a 1:19 micelle/SALP lipid ratio, corresponding to an initial protein/total lipid ratio of 150 g/mol. The SALP−micelle mixtures were incubated in a water bath at 60 °C for 30 min and then passed down a Sepharose CL-4B column (0.8 mL of sample/25 mL bed volume) using HBS as the running buffer.

Assays. Lipid was assayed by determining the phosphate content as previously described (*8*). Samples containing oligonucleotide were analyzed for lipid content after processing as follows. An aliquot of the formulation (usually 100−250 μL) was diluted with 750 μL CHCl3/MeOH (1:2 vol/vol) in a 13 × 100 mm tube and vortexed for 1−2 min. A few drops of additional methanol were added if the solution was still turbid. Water (250 μL) and CHCl3 (250 μL) were then added and the solution vortexed for 1−2 min. The sample was then centrifuged at 3000 rpm for 10 min. The upper phase was carefully removed. An aliquot of water/methanol (1:1: 300 μL) was then added

[3] Takasaki, J., and Ansell, S. M. (2005) Micelles as intermediates in the preparation of protein-liposome conjugates. Unpublished data.

and the solution vortexed for 1−2 min. The solution was centrifuged at 300 rpm for 5 min and the upper layer carefully removed. The organic fraction was washed with water/methanol a further two times in the same manner. The organic fraction was first dried down under a nitrogen stream and then under vacuum. The lipid assay was then carried out as previously described.

The protein content of the final liposome−protein conjugates was determined using a modified micro-BCA assay as previously described (*8*), with negative controls being performed where possible to check for background interference. Particle size, where determined, was measured using a Nicomp 380 submicron particle sizer.

Oligonucleotide content was determined by diluting a 20 μL sample with 250 μL of distilled water, 1200 μL of methanol, and 500 μL of chloroform and determining absorbance at 260 nm relative to a similarly treated sample of HBS buffer. The oligonucleotide concentration was calculated using the equation $[\text{oligo (mg/mL)}] = 3.41 \times A_{260}$

Immunization Protocols. 6- to 8-week-old female C57BL6 (H-2b) and BalbC (H-2d) mice were purchased from Harlan (Indianapolis, IN). All animal studies were completed using protocols that were approved by the institution's animal care committee, and the methods used are consistent with the current guidelines of the Canadian Council of Animal Care. Mice (C57BL6 for cellular response and BalbC for humoral response; five animals in each test group) were immunized by injection sc with 100 μL of HBS alone or containing either 66 μg of ovalbumin, 66 of μg ovalbumin mixed with 100 μg of free 6295PS, 66 μg of ovalbumin mixed with 100 μg of 6295PS encapsulated in SALP, 73 μg of ovalbumin passively coupled to SALP containing 100 μg of 6295PS or 60 μg of ovalbumin actively coupled to SALP containing 100 μg of 6295PS.

Mice received injections on day 0 and 7 for investigation of immunological cellular responses. Spleens were harvested 7 days after the last immunization and a cell suspension was generated for the tetramer assay.

Mice received injections on day 0 and 14 for investigation of the humoral response. Blood was recovered by cardiac puncture after 42 days, placed in EDTA tubes, and centrifuged (4 °C, 2000 rpm, 10 min) to obtain plasma. The pooled plasma was examined for antibody induction by ELISA.

Tetramer Assay. Specific CD8 T cells raised against the SIINFEKL epitope were assessed using a modified tetramer assay (*9*) as described by the manufacturer (Beckman-Coulter, Immunomics, San Diego, CA). Briefly, this consisted of incubation of 2×10^6 spleen cells with 1 μL of phycoerythrin-coupled H-2K^b-SIINFEKL-tetramers for 1 h at room temperature. Samples were then labeled with anti-mouse CD8-FITC and TCR-Cychrome (BD PharMingen, San Diego, CA) for 20 min at 4 °C. After two washes with PBS 2% FBS, samples were analyzed using FACSort and CellQuest software (Beckton-Dickinson).

Humoral Immunogenicity Studies. Ovalbumin-specific mouse IgG was detected and quantified by end-point dilution ELISA assay on samples of plasma pooled together from individual animals. Briefly, a solid phase of ovalbumin (100 μL of 10 μg/mL per well, overnight at 4 °C) was used to capture ovalbumin specific antibody from plasma samples serially diluted with 2% BSA−PBS. The antibody was then detected by treatment with horseradish peroxidase-conjugated rabbit anti-mouse IgG (1:3000 in PBS−BSA-2%; 100 μL/well), followed by incubation with TMB liquid substrate system (200 μL/well, 30 min at room temperature, light protected). The reaction was stopped by addition of 100 μL/well of 0.5 M sulfuric acid and the absorbance measured at 450 nm on an Elisa plate reader. End point dilution titers were defined as the highest dilution of ovalbumin specific antibodies detected in plasma that resulted in absorbance value (OD_{450}) two times greater than that of naive animal, with a cut off value of 0.1.

RESULTS

We have drawn a distinction between coupling protocols where the conjugation reaction takes place at the liposome surface (active coupling) or at some point remote from the liposome surface (passive coupling).[3] The traditional method of producing protein−liposome conjugates is an active coupling process in which a protein is first thiolated and then incubated with liposomes containing maleimide-derivatized lipids.

Our first preparations of protein−SALP constructs were made using an active coupling protocol. The model antigen used in these studies was ovalbumin. The thiolation of the ovalbumin in the initial studies was performed using the reagent SPDP in HBS at pH 7.4. Once the protein had been derivatized, the protecting group had to be removed using DTT at pH 4.4. The external buffer was then replaced with HBS at pH 7.4 in preparation for the conjugation reaction. This process involves a large number of steps, and in later work the thiolation process was greatly simplified by using the reagent 2-iminothiolane (2-IT).[3]

The original SALP formulation had been developed with 10 mol % of the steric barrier lipid MePEGS-2000-Mcer as part of the lipid composition. The high levels of steric barrier lipids in these formulations presented a problem, since it is known that PEG−lipids in the bilayer inhibit the liposome−protein reactions required for preparing the construct. Most earlier work in the field of liposome−protein constructs had relied on zero length cross-linker active lipids, such as DSPE-MPB (*6*). In our work we have used an alternative lipid, DSPE-ATTA2-MPA. DSPE-ATTA2-MPA has a maleimide cap which is less susceptible to hydrolysis than that in DSPE-MPB and a cross-linker roughly equivalent to a 500 MW PEG in size. This lipid was chosen since aliphatic maleimides are supposedly more stable in aqueous solution than aromatic versions and since the small tether should provide greater accessibility of the reactive function on the bilayer surface.

Effect of PEG−Lipids on SALP Stability and Coupling Efficiency. Earlier work showed that the presence of PEG−lipids on a liposome surface inhibits the lipid−protein reaction, causing saturation of the surface to occur at lower concentrations. This effect results in a steady fall off in conjugation efficiency as the surface concentration of PEG rises, bottoming out at roughly 6 mol % PEG (*18*). However, significant amounts of PEG are required in SALP formulations to stabilize the construct during formation and prevent aggregation. Since these two requirements are mutually exclusive, we needed to determine what the minimum amount of PEG for a stable formulation of SALP actually was. A formulation experiment was conducted in which SALP was prepared with varying amounts of PEG−lipid in the composition. The stability of the final product was assessed by doing particle sizing and seeing which samples showed evidence of aggregation (Figure 1). All samples showed roughly equivalent encapsulation efficiencies (50−70%), suggesting that particle formation was equivalent in all cases. However, particle sizes were uniform until the PEG concentration dropped to ∼2 mol %, at which point the particle size started to increase. The conclusion was that the minimum required PEG concentration in a SALP formulation was ∼2%.

Previous work had shown that the range of PEG concentration that allowed effective conjugation in liposomes was 0−5 mol %. The cross-linker we were using in the current studies (DSPE-ATTA2-MPA) was rather larger than the cross-linker used in the earlier work, so it was not immediately obvious to what extent the SALP PEG−lipid would inhibit the coupling reaction.

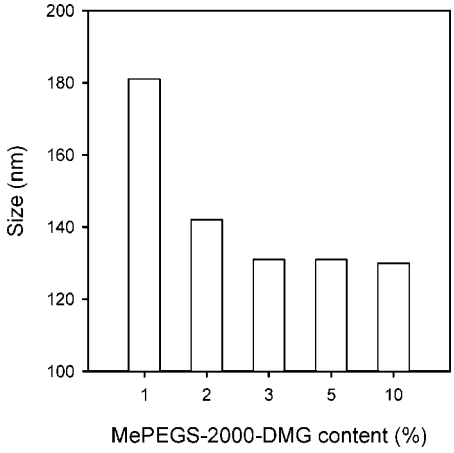

Figure 1. The effect of steric barrier lipid concentration on the stability of SALP particles. SALP composed of DSPC/chol/DODAP/MePEGS-2000-DMG ((25 + *n*):45:20:(10 − *n*); where *n* = 0, 5, 7, 8, and 9) was prepared with 6295 oligonucleotide encapsulated at an initial oligo/lipid ratio of 0.15 g/mol. Encapsulation efficiencies ranged from 50 to 70%. Physical stability is assessed by the size of the product as determined using a Nicomp.

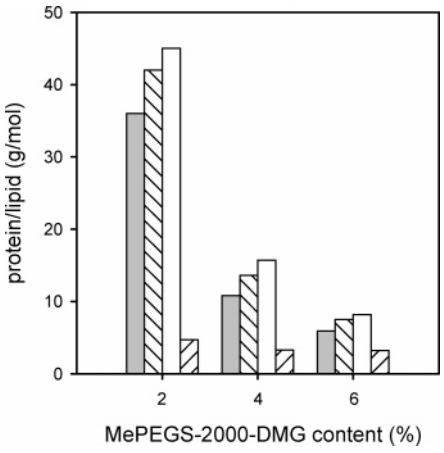

Figure 2. The effect of steric barrier molecules on coupling efficiencies when conjugating ovalbumin to SALP using the active conjugation method. Ovalbumin derivatized with 5 equiv of SPDP was treated with SALP composed of DSPC/chol/DODAP/MePEGS-2000-DMG/DSPE-ATTA2-MPA ((34 − *n*):45:20:*n*:1; *n* = 2, 4, 6%). Initial protein/lipid ratios were 100 g/mol (solid bars), 200 g/mol (hatched left bars) and 400 g/mol (open bars). A negative control, where SALP (*n* = 2) was incubated with underivatized ovalbumin, was included (hatched right bars).

We designed an experiment to determine what the effect of the SALP PEG concentration on coupling efficiency was. Ovalbumin was thiolated with 5 equiv of SPDP and conjugated to SALP containing 2, 4 or 6 mol % MePEGS-2000-DMG. Protein aliquots corresponding to an initial protein/lipid ratio of 100, 200, and 400 g/mol were incubated with samples of each SALP formulation, respectively. In addition, a negative control was performed for each SALP formulation, where the SALP was incubated with nonthiolated ovalbumin at 100 g/mol and worked up as usual. The results can be seen in Figure 2. Clearly the coupling efficiency drops off dramatically as the SALP PEG concentration increases. Increasing the initial protein/lipid ratio has only a small effect on the overall amount of protein coupled to the SALP surface, presumably since the surface is approaching saturation under these conditions. The response seen in the negative controls is due to background interference in the protein assay used.

The implication of the experiments presented in Figures 1 and 2 is that for active coupling protocols the competing requirements that the levels of PEG in SALP be high enough to inhibit aggregation but low enough to allow reasonable coupling efficiencies means that in general anyone using these sorts of coupling protocols has a very narrow range of PEG concentration to work with. Small uncertainties in the PEG concentration might have dramatic effects on the coupling efficiency. In addition, the surface saturation effect caused by the presence of the steric barrier molecules during coupling means that the amount of protein that can be conjugated to the surface is relatively small. These limitations mean that the active coupling protocol is unattractive from a production point of view.

Effect of PEG−Lipids and Micelle-Forming Lipids on the Passive Conjugation Protocol. In a companion report we have described the characterization of a passive coupling technique in which the protein is first coupled to the surface of a micelle and then exchanged into liposome bilayers.[3] This method has a number of advantages over active coupling when applied to SALP. First, since the coupling reaction is performed at the micelle surface, the presence of PEG−lipids in SALP will not interfere. It should be possible to obtain a range of reproducible levels of protein at the SALP surface since the protein−lipid conjugates can be titrated into the liposomes. The lack of interference from the SALP PEG−lipids would also mean that in principle it should be possible to obtain much higher levels of protein on the SALP surface, if required. The second advantage of the passive conjugation method is that it separates the SALP formulation step from the protein−lipid coupling step. When using the active conjugation method it is necessary to have both the SALP preparation and the protein thiolation process occurring simultaneously because of the potential for competing side reactions to quench the reactive functionality of the reagent. This presents potential logistical problems when scaling the process up since larger scale processes tend to take longer periods of time. With the passive conjugation method the two components can be prepared independently and combined at the appropriate time.

We conducted a study looking at the effects of various micelle-forming lipids and different PEG−lipid levels in SALP when using the passive conjugation method. SALP was prepared with 2, 4, and 10% PEG−lipid as part of the composition. The 2% formulation represented the lower limit for physical stability as determined in Figure 1. The 10% formulation represented the "classical" SALP particle, whereas the 4% one was our guess at the "ideal" SALP formulation for passive conjugation methods. A POPC/chol liposome formulation was also included in the data set to serve as a control. Micelles were prepared using DSPE-ATTA2-MPA as the active lipid in a 1:4 ratio with the micelle-forming lipid. The micelle-forming lipids used in this study were DSPE-ATTA2, DSPE-ATTA4 and DSPE-ATTA8. The results are shown in Figure 3.

DSPE-ATTA4 was found to be the best micelle-forming colipid in the group studied for Figure 3, similar to earlier work with POPC/chol liposomes.[3] DSPE-ATTA2 generally gave somewhat lower coupling efficiencies; however, this is likely due to the tendency of DSPE-ATTA2-MPA/DSPE-ATTA2 micelles to show some thermotropic behavior at room temperature. The much larger DSPE-ATTA8 resulted in sharply lower coupling efficiencies. This is comparable to the results we had seen earlier with MePEGS-2000-DSPE liposomes and is likely a result of steric inhibition of the micelle−protein reaction. The SALP formulations generally resulted in slightly lower final protein/lipid ratios than regular control liposomes. The reason for this is not clear, but it might be related to the fact that SALP frequently forms multilamellar structures, which would result in a lower particle protein/lipid ratio. The most interesting aspect of this experiment was the observation that the PEG level in the SALP did not appear to affect the final protein/lipid ratio. This is sharp contrast to the active coupling method, where 10

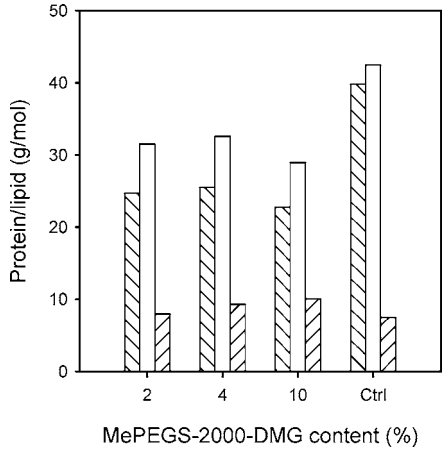

Figure 3. The effect of steric barrier molecules on coupling efficiencies when conjugating ovalbumin to SALP using the passive conjugation method. Ovalbumin was thiolated with 5 equiv of SPDP and conjugated to DSPE-ATTA2-MPA/DSPE-ATTAn (1:4) micelles in a 3000 g/mol protein/lipid ratio. DSPE-ATTAn used were as follows: $n = 2$, hatched left bars; $n = 4$, open bars; and $n = 8$, hatched right bars. Micelles were incubated with DSPC/chol/DODAP/MePEGS-2000-DMG ((25 + n):45:20:(10 − n); $n = 0, 6, 8$) SALP or POPC/chol (55:45) liposomes ("Ctrl" in the figure) at 150 g/mol protein/lipid. The SALP was prepared using 6295 PS oligonucleotide at a 0.15 oligo/lipid ratio.

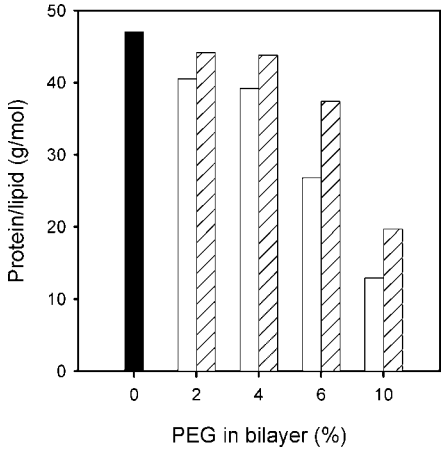

Figure 4. The effect of the exchangeability of PEG−lipids in liposomes on the passive coupling protocol. Ovalbumin was thiolated with 5 equiv of 2-IT and conjugated to DSPE-ATTA2-MPA/OGP (1:4) micelles in a 3000 g/mol protein/lipid ratio. Micelles were incubated with POPC/chol/PEG-lipid (55 − n:45:n; $n = 0, 2, 4, 6, 10$) liposomes at 150 g/mol protein/lipid. PEG-lipids used included MePEGS-2000-DSPE (open bars) and MePEGS-2000-DMG (hatched right bars). The solid bar is the 0% PEG-lipid sample.

mol % of PEG would effectively shut down the conjugation reaction.

This raised an interesting question, since we knew that PEG was capable of preventing surface conjugation reactions by inhibiting access of the protein to the reactive surface. The most reasonable explanation of the difference was that once coupled to a lipid anchor, the protein−lipid conjugate would behave like any other steric barrier molecule and would compete for a place on the liposome surface with the PEG−lipids already there. Given enough time an equilibrium should be reached based on the thermodynamic states of the molecules at the surface or in solution. If this is true, then less exchangeable PEG−lipids should still inhibit exchange of the protein−lipid conjugates from micelles, while exchangeable analogues are competed off. To determine if this is the case we set up an experiment where protein−micelles were incubated with POPC/chol liposomes with varying amounts of MePEGS-2000-DSPE (non exchangeable) or MePEGS-2000-DMG (exchangeable). The results are shown in Figure 4.

In this experiment PEG−lipids start to inhibit association of the protein−lipid conjugates with the liposomes when levels exceed 4 mol %. The effect is more pronounced with the nonexchangeable PEG−lipid but takes place with both species. Presumably SALP formulations, which contain MePEGS-2000-DMG, do not anchor the PEG−lipid as well as a POPC/chol liposome since no such drop-off is observed at high PEG−lipid concentrations. It is likely however, that the effect may still take place in SALP formulations to a greater or lesser extent based depending on the conditions of the final formulation step. With that in mind it is advisable to use a 4 mol % PEG SALP formulation.

Comparison between the Active and Passive Coupling Protocols. An additional experiment was performed to characterize the surface saturation effect when using the active coupling protocol. SALP containing 2 mol % MePEGS-2000-DSPE and 1 mol % DSPE-ATTA2-MPA was coupled to ovalbumin which had been thiolated with 2 or 5 equiv of 2-IT. Each data set was repeated with initial protein/lipid ratios ranging from 50 to 300 g/mol. The same two thiolated ovalbumin solutions were used to prepare ovalbumin−micelle reagents, which in turn were used to prepare protein−SALP conjugates under our standard passive conjugation conditions.

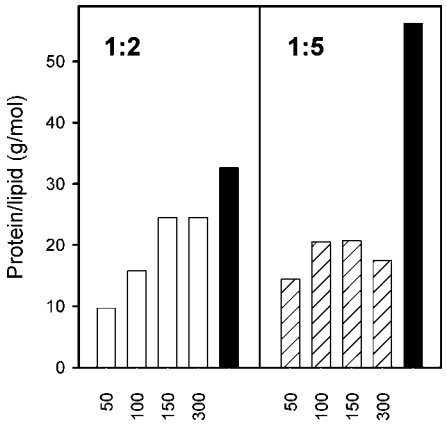

Figure 5. Comparison of active and passive coupling protocols. Ovalbumin was thiolated with 2 or 5 equiv of 2-IT. Thiolated ovalbumin (2 equiv of 2-IT: open bars; 5 equiv of 2-IT: hatched right bars) was coupled to DSPC/chol/DODMA/MePEGS-2000-DMG/DSPE-ATTA2-MPA (32:45:20:2:1) SALP at initial protein/lipid ratios of 50, 100, 150 and 300 g/mol. The same two thiolated ovalbumin solutions were coupled to DSPE-ATTA2-MPA/OGP (1:4) micelles in a 3000 g/mol protein/micelle lipid ratio. These micelles were incubated with DSPC/chol/DODMA/MePEGS-2000-DMG (31:45:20:4) SALP at 150 g/mol protein/final lipid, with the final results shown as the solid bars. All SALP was prepared with 6295 PS oligonucleotide at 0.15 g/mol oligo/lipid.

The results are shown in Figure 5. It is clear that saturation of the surface is occurring at relatively low levels, since increasing the initial thiolated protein concentration has minimal effects on the final surface protein concentration. In addition the maximum surface concentration is quite low. In contrast the passive conjugation samples showed much higher levels of bound protein.

The passive conjugation efficiency is largely regulated by saturation of the micelle surface. This means that it is possible to prepare relatively uniform samples if an excess of initial protein is used. Since the SALP PEG concentration does not inhibit association of the protein−lipid with the SALP surface (unlike the reaction inhibition seen with active coupling protocols), it should be possible to accurately titrate a specific amount of protein into a SALP formulation. We conducted an experiment where an ovalbumin−micelle reagent was prepared and then titrated into a SALP formulation. The results are shown

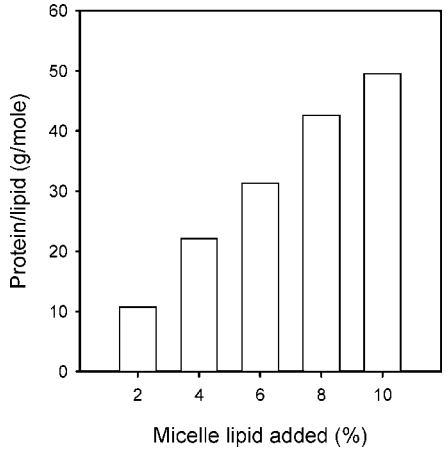

Figure 6. Titration of ovalbumin−micelles into SALP. Ovalbumin was thiolated with 5 equiv of 2-IT and coupled to DSPE-ATTA2-MPA/OGP (1:4) micelles at 3000 g/mol protein/lipid. Portions of this ovalbumin−micelle solution corresponding to 2, 4, 6, 8 and 10% of the SALP lipids were added to DSPC/chol/DODMA/MePEGS-2000-DMG (31:45:20:4) SALP prepared using 6295 PS oligonucleotide at 0.15 g/mol oligo/lipid.

in Figure 6. As expected, the final protein−lipid ratio shows a uniform rate of increase in the surface protein levels in proportion to the amount of the reagent added to the SALP. The implication of this experiment is that not only is it possible to prepare SALP with relatively high levels of protein on the surface, it is also feasible to prepare samples with predetermined levels. This aspect is very important if the mechanism of in vivo action is to be properly characterized.

Stability and Reproducibility during Formulation. Analysis of the oligonucleotide content of the samples in Figure 6 before and after incorporation with the micelles indicated that the treatment did not cause loss of entrapped oligonucleotide. However, since the micelles are detergents, it is likely that at some point sufficient detergent will be present to disrupt the integrity of the SALP particles. We have not determined what this point actually is, at best we can say that treatment with up to 10 mol % micelles will not disrupt the SALP. It may be possible to go significantly higher than this, provided that excess micelle-forming lipid is removed through some means, such as by dialysis.

As a final demonstration of the utility of the method we performed a reproducibility study using the passive coupling protocol. Three sets of protein−micelles were prepared independently and incubated with samples taken from a single batch of SALP (Figure 7). After workup the products were assayed for size, protein/lipid ratio, and oligonucleotide/lipid ratio. The three samples were reassayed after one week of storage at 5 °C. The purpose of the experiment was to demonstrate that material prepared according to standard conditions would yield consistent results. This turned out to be the case in terms of levels of bound protein. The specific conditions used for the coupling generally result in limited aggregation. This aggregation is caused by proteins on the bilayer surface that have been derivatized by more than one lipid anchor. If one of the three batches included protein which was derivatized to a greater or lesser degree than the other batches, it would be reflected in a change in size even though the levels of bound protein were the same. The size differences between the three data sets was minimal, indicating that the protein in all three data sets was largely in the same state. Storage of the samples for a week did not appear to adversely affect the integrity of the constructs. These results suggest that the method potentially has a high degree of reproducibility and result in relatively stabile constructs.

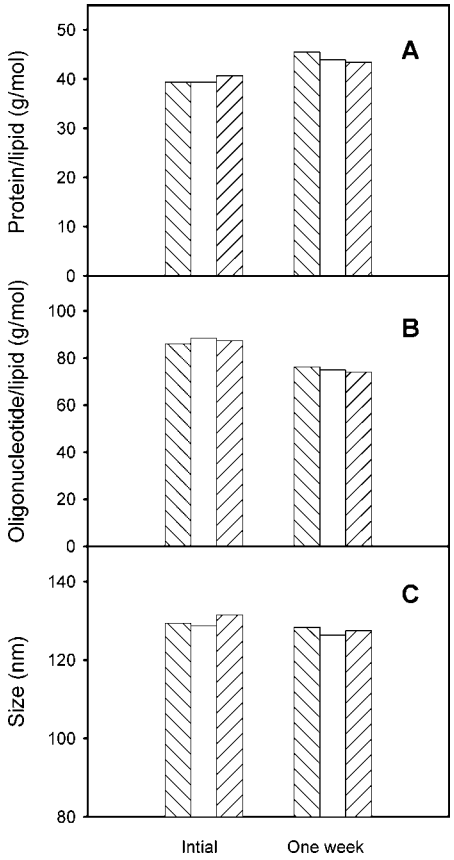

Figure 7. Reproducibility of the passive coupling protocol when preparing protein−SALP conjugates. Three separate ovalbumin solutions were thiolated with 5 equiv of 2-IT and coupled to three individual DSPE-ATTA2-MPA/OGP (1:4) micelle solutions at 3000 g/mol protein/lipid. These three sets of solutions were incubated at 150 g/mol protein/lipid with samples of a single DSPC/chol/DODMA/MePEGS-2000-DMG (31:45:20:4) SALP batch prepared using 6295 PS oligonucleotide at 0.15 g/mol oligo/lipid. The samples were analyzed at the time of production and again after one week of storage at 5 °C.

The effects of the structure of the oligonucleotide was also studied. SALP was prepared using the following oligonucleotides: 6295 PS (5′-TAACGTTAGGGGCAT-3′; phosphothioate chemistry); 6295 PO (5′-TAACGTTAGGGGCAT-3′; phosphodiester chemistry); 5001 PS (5′-AACGTT-3′; phosphothioate chemistry); and 2006 PS (5′-TCGTCGTTTTGTCGTTTTCT-CGTT-3′; phosphothioate chemistry). The structure of an oligonucleotide plays a role in the encapsulation efficiency, and a wide range was observed in this case (75%, 47%, 13%, and 27%, respectively). All four SALP formulations were treated with the same protein−micelle reagent (initial protein/lipid ration of 150 g/mol) as usual. All four formulations showed similar levels of conjugated protein, with minimal size changes compared to the original SALP controls. The results demonstrate that the coupling process produces similar products irrespective of the structure of the oligonucleotide used.

In Vivo Immunological Behavior. In a companion report[2] we have shown that coupling an antigen to the surface of SALP results in enhanced humoral responses in vivo compared to a sample where the antigen and SALP were mixed but not coupled. The material used in that study was conjugated using the active coupling protocol. While it is reasonable to presume that the antigen−SALP conjugate prepared by the passive conjugation protocol would be equivalent, we needed to demonstrate that this was indeed the case. An experiment was conducted to compare the basic in vivo cellular and humoral responses to treatment with ovalbumin−SALP prepared by the two methods.

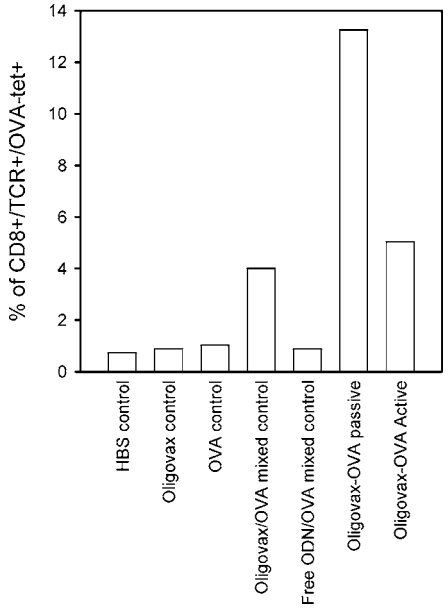

Figure 8. Assessment of cellular response induced against OVA antigen delivered coupled with SALP-6295 PS either with active or passive protocol. Mice were immunized sc at day 0 and 7 (see Materials and Methods) with either HBS, OVA protein (66 μg), OVA (66 μg) mixed with free 6295PS (100 μg), OVA (66 μg) mixed with 6295PS (100 μg) encapsulated in SALP, OVA (73 μg) passively coupled to SALP containing 6295PS (100 μg), or OVA (60 μg) actively coupled to SALP containing 6295PS (100 μg). Seven days after the last injection spleens were assessed for CD8 T cell induced against SIINFEKL epitope using the tetramers assay. *Y*-axis report % of CD8+/TCR+/OVA-tet+ among gated lymphocytes.

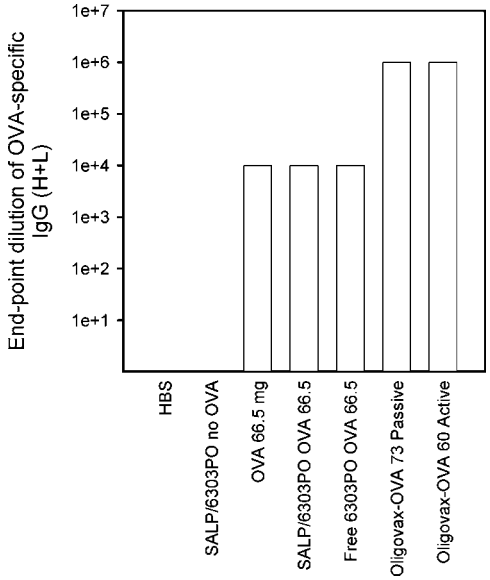

Figure 9. The effect of coupling on humoral immunonogenicity. Plasma obtained six weeks upon SC prime-boost immunization with ovalbumin mixed (66 μg), actively (73 μg), or passively coupled (60 μg) with 100 μg of free or SALP encapsulated 6295PS ODN. IgG levels measured by end-point dilutions ELISA. Data points represent the Mean value from group of four animals.

C57BL6 mice were injected with various controls and ovalbumin-6295 SALP conjugates prepared by the active and passive techniques on days 0 and 7. The spleens were recovered after a further 7 days and the level of CD8 T cells specific for an epitope derived from ovalbumin (SIINFEKL) determined by flow cytometry. The results are shown in Figure 8. As expected, the negative controls (HBS, SALP, and ovalbumin individually) show similar background levels of response. Mixing free oligonucleotide with ovalbumin did not cause proliferation of specific T cells, whereas oligonucleotide encapsulated in SALP and mixed with ovalbumin did. A similar response was seen with ovalbumin−SALP conjugates prepared using the active conjugation method. A much stronger response was observed when the ovalbumin−SALP sample prepared by the passive conjugation protocol was tested. The reason for the difference is not clear at this point. All the samples were normalized to the oligonucleotide content on administration, and consequently protein and lipid content may not be entirely comparable. We plan to do more detailed studies with these systems to determine which formulation parameters affect efficacy and will report that data when it becomes available. In the meantime, however, for the purposes of this work we can state that the passive coupled conjugate is at least as effective as the active coupled material in the stimulation of SIINFEKL reactive T-cell proliferation.

In a second in vivo experiment samples and controls were injected into BalbC mice to investigate humoral responses to the formulations. The treatment was repeated after two weeks and the blood from the animals recovered after a further four weeks. Plasma was recovered from the pooled blood and the level of ovalbumin specific IgG determined using a serial dilution ELISA assay. The results are shown in Figure 9. The negative controls (HBS and SALP) produced no response, as expected. Positive controls (ovalbumin, SALP + ovalbumin, and oligonucleotide + ovalbumin) generated similar responses. The two ovalbumin−SALP conjugates (prepared by the active and passive conjugation methods, respectively) produced responses 2 orders of magnitude greater than the positive controls. This demonstrated the increased efficacy associated with coupled systems as opposed to mixed analogues. More importantly, it shows that the products derived from the two methods are more or less equivalent in terms of inducing a humoral response.

DISCUSSION

Active coupling protocols have been widely used to produce protein−liposome conjugates. While these methods are relatively straightforward to use on lab scales, they suffer from a number of problems. These range from the lack of fine control over the reaction to logistical problems on scale-up. More recent work (*10, 11*) has shown that passive coupling protocols may greatly simplify the logistics of scaling a preparation up. Using these ideas as a lead we have demonstrated that, with proper selection of materials and appropriate experiment design, it is possible to prepare protein−liposome conjugates with a relatively high degree of precision using passive coupling protocols. In addition, the passive coupling protocols greatly simplify many of the workup processes involved in the production of the final conjugate.

SALP type formulations are particularly troublesome to deal with when using the active coupling protocol since the formulation requires relatively large amounts of PEG lipid in order to stabilize the particle. This has two effects, namely that it is very difficult to reproduce a specific level of coupled protein, and the surface becomes saturated at relatively low levels. The passive coupling technique solves many of these problems since it separates the process of forming the protein−lipid conjugate from the process of forming the protein−particle conjugate.

The initial coupling event in the passive conjugation process occurs at the surface of a micelle, which acts as a surrogate for the SALP surface. Since the micelle has a much smaller surface area than the final SALP particle, it is possible to saturate this surface with protein and then use the resultant protein−micelles as a reagent for preparing the final protein−SALP conjugate. By saturating the micelle surface we are effectively placing an upper limit on the amount of protein that can in principle

associate with the micelles, and this fact allows us to produce micelles with reproducible protein/lipid ratios.

A second advantage of using micelles in this manner is that once formed, the protein−lipid conjugate in the micelle essentially becomes yet another steric barrier lipid when exposed to SALP and consequently can compete for spots on the surface of the SALP with the endogenous PEG−lipids. Once there it would be subject to the same thermodynamic influences that determine exchange rates, namely the enthalpy component derived from association of the lipid anchor with bilayer lipids (drives association with the bilayer) and the entropy factor associated with an increase in freedom of motion of the macromolecule on dissociation into free solution (drives disassociation from the bilayer). The PEG−lipids used in SALP are based on an uncharged dimyristoyl lipid anchor (DMG) and as such dissociate from the bilayer very readily (*12*, *13*). The protein−lipid conjugates, on the other hand, use DSPE as a lipid anchor. DSPE is known to provide a much stronger association with the bilayer than DMG. In addition, even though proteins are much larger than the PEG molecules used as steric barrier molecules, they are relatively rigid in free solution and consequently do not have the same entropy contributions that PEG−lipids do. The result of this is that these DSPE−protein conjugates should compete out the PEG−DMG on the SALP surface, producing much higher levels of protein on the surface than would be possible using active conjugation methods.

The effect of constraining freedom of motion of macromolecules on liposome surfaces has been shown in work carried out a number of years ago by Silvius (*12*). He studied interbilayer exchange rates using fluorescent labeled PEG lipids which made up 0.5 mol % of the donor membranes. In that work it was noted that including 4% of unlabeled PEG−lipid significantly increased the off rate of the fluorescent label, thereby providing strong evidence for the effect of steric interactions between individual PEG molecules. Silvius also showed that rigid macromolecule−lipids, such as the protein transferrin and dextrans in the size range 10−70 kDa, had much lower off rates than PEG analogues (2 kDa and 5 kDa) even though they are considerably larger in size. Also, while the off rate for PEG lipids showed a clear relationship to polymer size, rigid polymers such as dextran did not. The data presented by Silvius is consistent with the arguments made in this work.

By being able to control both the amount of protein associated with the micelles, and the amount of the protein−micelles titrated into SALP, we were able to demonstrate that it was possible to produce a series of protein−SALP samples with accurate protein/lipid ratios. In doing so we have opened the door for future studies investigating the role that the relative amounts of protein/lipid/oligonucleotide play in in vivo efficacy. From a production point of view this technology allows us to produce sophisticated formulations with an unparalleled degree of accuracy. The separation of the SALP formation, protein−lipid conjugate formation, and protein−SALP formulation into three distinct and independent steps greatly improves the logistics of scale-up.

Finally, we have shown that the in vivo efficacy of the product produced by the passive coupling protocol is at least as good as that of the material produced by the active coupling process.

S.1. Comments regarding the assays used and reproducibility

The passive method has a relatively high level of reproducibility provided that experimental conditions are kept constant and provided that analytical methods are accurate. However, there are potential sources of variability in terms of the numbers that are generated in different experiments. Much of this stems from the assay that is used to determine protein content. Basically it involves a chemical colorimetric assay using a standard curve performed with reagents from Pierce's BCA assay kit. The standard curve itself is generated using a set of BSA standards. These standards are prepared by first diluting 50 µl of a kit stock solution with 950 µl of buffer to prepare a working stock solution. Aliquots ranging from 25 to 200 µl are then taken from this stock to prepare the standard curve samples. Any pipetting errors in this series of dilutions will result in deviations from the true concentration, both in terms of the slope of the standard curve and scatter of the data points making up the curve. The actual samples were analyzed in triplicate, for both the protein assay and the phosphate assay. Consequently, while data within a particular experiment is reasonable consistent, data between experiments may show some variability.

In addition to issues involving uncertainty with the slope of standard curve, the lipids used to produce liposomes can generate varying levels of background interference independent of the presence of protein. Usually this interference is small relative to the assay numbers with normal liposomes (typically 1-3 g/mol), but it can be fairly large in some cases with SALP lipids (up to around 5-6 g/mol). The reported number can deviated from the true value somewhat depending on whether or not results are corrected for background. The background and the associated uncertainty places constraints on the sensitivity of the BCA assay as well as the accuracy.

The BCA assay is far from ideal, but under the circumstances it was the most reliable method available to us. We attempted using flourescamine based assays, but found that the standard curve varied considerably depending on what exactly was used to produce it. Standard curves were generated using ovalbumin, albumin and thiolated ovalbumin, and yielded different results in each case for test samples, apparently all inaccurate based on comparisons with values determined using extinction coefficients. The BCA assay on the other hand, generated concentration results consistent with that obtained using extinction coefficients irrespective of which standard curve was used. Florescamine should be more sensitive in principle, but it was limited by the lack of material suitable for generating an appropriate standard curve.

Probably the best assay method to use would be one based on labeled protein, but that was not available for this work.

A second factor affecting the absolute results was the slow degradation of maleimide reagents on storage. Over a period of months the materials start to form insoluble

products that we believe are polymers formed from intermolecular trans-acylation reactions initiated by maleamic acid impurities present in the samples. This results in polymeric materials which are unreactive and cause formulation issues, collectively reducing conjugation efficiency. If properly stored, materials would perform consistently for 4-5 months, after which degradation of performance (in the form of coupling efficiency) would start to become apparent. Normally we would synthesize fresh reagents before this happened, but some data sets were generated with older material, and consequently absolute coupling efficiencies in those cases are lower than normal.

However, since general conclusions drawn from this work were made within data sets, and not between data sets, we believe that these discrepancies do not impact the overall message. Comparing data between sets is probably of dubious validity, but within data sets it is reasonably consistent. For example, in figure 6 the coupling efficiency is somewhat lower than what we would normally expect, but the message that the micelles can be titrated proportionally into SALP in a concentration dependant manner is still valid.

Development of Saxitoxin-Conjugated Affinity Gels

Ryuichi Watanabe, Ritsumi Samusawa-Saito, and Yasukatsu Oshima*

Laboratory of Bioorganic Chemistry, Graduate School of Life Sciences, Tohoku University, Sendai 981-8555, Japan.
Received December 21, 2004; Revised Manuscript Received January 25, 2006

Saxitoxin (STX) and its analogues accumulated in bivalves cause food poisoning through the blockade of sodium channels in the nervous system. In the current studies, STX-conjugated agarose gels as affinity chromatography reagents were prepared for investigation of the fate of the toxins in natural environments and in the human body. A carboxyl moiety was introduced through positions C11 and C13 to leave the most characteristic part of the molecule intact. Two types of synthesized derivatives, 11-(2-carboxyethylthio)saxitoxin and 13-*O*-hemisuccinyldecarbamoylsaxitoxin, were successfully conjugated to Sepharose 4B in high yield. Affinity gels containing 500 nmol of STX or decarbamoylsaxitoxin per milliliter of gel were accomplished by masking the residual amino groups by acetylation. Finally, the STX-conjugated affinity gel was effective for concentrating STX-binding proteins from pufferfish and bullfrog plasma.

INTRODUCTION

The human health syndrome known as paralytic shellfish poisoning is caused by the consumption of shellfish containing high levels of saxitoxin (STX) and its numerous analogues (Chart 1). The STXs are originally produced by certain dinoflagellates, such as *Alexandrium* spp. (e.g., *A. catenella, A. tamarense,* and *A. minutum*), *Pyrodinium bahamense* var. *compressa*, and *Gymnodinium catenatum* (*1*−*5*). Also, some freshwater cyanobacteria (*Aphanizomenon flos-aquae*, *Anabaena circinalis* and *Lyngbya wollei*) are known to produce these toxins (*6*−*9*).

Filter feeding mollusks accumulate these toxins when they feed on these microalgae. The toxins are subsequently introduced into aquatic food chains. The toxicity levels and persistence of toxins in bivalves vary greatly according to the species of mollusk and the physiological conditions (*10*). Actual mechanisms of accumulation and depuration of toxins by bivalves have not been clarified, but circumstantial evidence strongly suggests that macromolecules play a role in the transportation or bioaccumulation of highly ionized toxins in marine animals.

STXs comprise three classes of tetrahydropurine derivatives: carbamate, *N*-sulfocarbamoyl, and decarbamoyl toxins (Chart 1). The toxicity of the STXs is attributed to the reversible blockage of voltage-gated sodium channels on excitable cells. The STXs bind to site 1 on the channels, blocking channel opening and thereby interfering with neurotransmission at neuronal synapses and skeletal muscle (*11*). All the STX analogues bind to the same receptor site, although affinities differ greatly. On the basis of structure−activity studies of STXs, 7,8,9-guanidino and geminal diols at C12 are most important for receptor binding. The carbamoyl side chain also contributes to binding, and introduction of a N-sulfonate results in low binding affinity, probably due to ionic interaction with the channel protein. Furthermore, N1-hydroxy and 11-hydroxysulfate moieties of both stereochemistries have little effect on the binding affinity (*12*, *13*).

In addition to sodium channel proteins and artificially induced antibodies (*14*−*16*), some other macromolecules have an affinity for STX. Toxin-transforming enzymes have been found in dinoflagellates (*17*) and mollusks (*18*−*20*). In addition, saxiphilin, a soluble circulatory protein related to transferrin and found in vertebrates and arthropods, binds to STX (*21*). However, the function of the protein in the organisms has not been clarified. During studies on the mechanism of tetrodotoxin accumulation by pufferfish, Yamashita et al. (*22*) found a STX-tetrodotoxin binding protein (PSTBP) in *Fugu pardalis* plasma that has a higher affinity for STX than tetrodotoxin.

A radioisotope assay with tritium-labeled STX has been the most sensitive and commonly used method for isolating and characterizing STX-binding proteins; however, this reagent is not commercially available, partly due to the designation of STX as a schedule one chemical by the United Nations Chemical Weapon Convention. Other methods developed for the analysis of toxins in shellfish have not always been effective for research on the above macromolecules, mainly due to their lack of sensitivity. Therefore, development of new research tools is essential for advancing the understanding of STX binding macromolecules and their role in determining the fate of the toxins in animals and controlling toxin kinetics in humans (*23*, *24*).

In this paper, we describe the development of STX-conjugated affinity gels for tracking and purifying macromolecules that interact with the STXs. The binding sites available after conjugation were carefully chosen to leave the most characteristic part of the molecule intact and thereby maintain its affinity for the sodium channel. Two types of affinity gels were prepared and tested with biological materials known to contain STX-binding proteins.

EXPERIMENTAL PROCEDURES

Chemicals and Organisms. Gonyautoxins 2 and 3 (GTX2/3), and C1/C2 were prepared as mixture of epimers from a mass culture of the freshwater cyanobacteria *Anabaena circinalis* TA04 strain (CSIRO, Hobart, Australia) (*25*). STX was purified from the spiny oyster *Spobylus butreli* collected in the Palau Islands (*3*). EAH-Sepharose 4B was purchased from Amersham Pharmacia Biotech (Uppsala, Sweden). Centrifugal filter devices, Ultrafree-MC (30 000 Da cutoff) and Ultrafree-CL (30 000 Da cutoff), were obtained from Amicon (Bedford, USA). The Micro-BCA protein assay kit was from Pierce (Rockford, USA). 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride

(EDC) and 2-(*N*-morpholino)-ethanesulfonic acid (MES) were from Dojindo Lab (Kumamoto, Japan). All other reagents used were analytical grade and purchased from Wako Pure Chemicals (Osaka, Japan) unless otherwise stated.

The Neuro 2A cell line (American Type Culture Collection, Manassas, USA) for the neuroblastoma cell assay was obtained from Dainippon Pharmaceuticals (Tokyo, Japan). Plasma from the pufferfish *F. pardalis* and purified STX-binding protein (PSTBP) were gifts from Professor Mari Yotsu-Yamashita of Tohoku University, Japan. Bullfrogs, *Rana catesbeiana*, were collected in Miyagi Prefecture, Japan, in August 2001.

HPLC Analysis of the Toxins and Derivatives. Saxitoxins were analyzed by postcolumn fluorescent derivative high-performance liquid chromatography (FD-HPLC) as reported previously (*26*). Detection of the STX derivatives, 11-(2-carboxylethylthio)-saxitoxin (CET-STX) and 13-*O*-hemisuccinyl-decarbamoylsaxitoxin (HS-dcSTX), was performed with a slightly modified mobile phase (1 mM sodium 1-heptane-sulfonate in 35 mM ammonium phosphate, pH 3.5) and postcolumn oxidizing reagent (0.6% of hydrogen peroxide in 50 mM potassium phosphate buffer [KPB], pH 9.0) on a Mightysil RP-8 GP column (150 × 4.6 mm; Kanto Chemicals, Tokyo, Japan).

Spectral Analysis. Electrospray ionization mass spectra were recorded in positive ion mode with a TSQ 700 mass spectrometer (Finnigan Mat, San Jose, USA) using 10% methanol at a flow rate of 0.1 mL/min. High resolution-fast atom bombardment (HR-FAB) mass spectra were measured with a JEOL JMS-700 spectrometer in positive ion mode using glycerol as a matrix. NMR spectra were measured with an INOVA 600 spectrometer (Varian, Palo Alto, USA) at 20 °C, and chemical shifts are given on a δ (ppm) scale with 2.06 ppm of CHD_2COOD as an internal standard.

Preparation of Carboxyl STX Derivatives. Preparation of CET-STX was carried out using the reaction described by Sato et al. (*27*). Lyophilized GTX 2/3 (47 μmol) was dissolved in 5 mL of 50 mM KPB (pH 7.4) containing 500 mM 3-mercapto-propionic acid. The mixture was stirred at 70 °C for 1 h, and the reaction was terminated with 1.0 M acetic acid. The reaction mixture was applied to a Bio Gel P-2 (Bio-Rad, Hercules, USA) column using 50 mM acetic acid as a mobile phase. Fractions containing CET-STX were further purified with Hitachi gel 3011-C (Hitachi, Tokyo, Japan) using 0.8 M acetic acid as a mobile phase.

Preparation of HS-dcSTX was performed using C1/C2 as starting material as follows. Lyophilized C1/C2 (36 μmol) was dissolved in 5 mL of 100 mM KPB (pH 7.0) and stirred at 75 °C for 50 min. Decarbamoylgonyautoxin 2 and 3 (dcGTX2/3) formed by the reaction were separated from unreacted C1/C2 using a Bio Gel P-2 (Bio-Rad) column with 50 mM acetic acid as a mobile phase. Lyophilized dcGTX2/3 (17 μmol) was dissolved in 5 mL of a 1:1 mixture of β-mercaptoethanol and 100 mM KPB (pH 6.0) and then heated at 60 °C for 1 h. The resulting dcSTX was purified using a Bio Gel P-2 (Bio-Rad) column with 50 mM acetic acid as a mobile phase. Lyophilized dcSTX (4 μmol) was dissolved in 5 mL of saturated sodium bicarbonate solution and mixed with 200 mg (2 mmol) of succinic anhydride. The solution was stirred at ambient temperature for 24 h, and the reaction was terminated with acetic acid. HS-dcSTX was purified by column chromatography using a Bio-Rex 70 (Bio-Rad) column with stepwise elution of 0.05 and 0.8 M acetic acid, followed by a Hitachi gel 3011-C (Hitachi) column with isocratic elution of 0.8 M acetic acid.

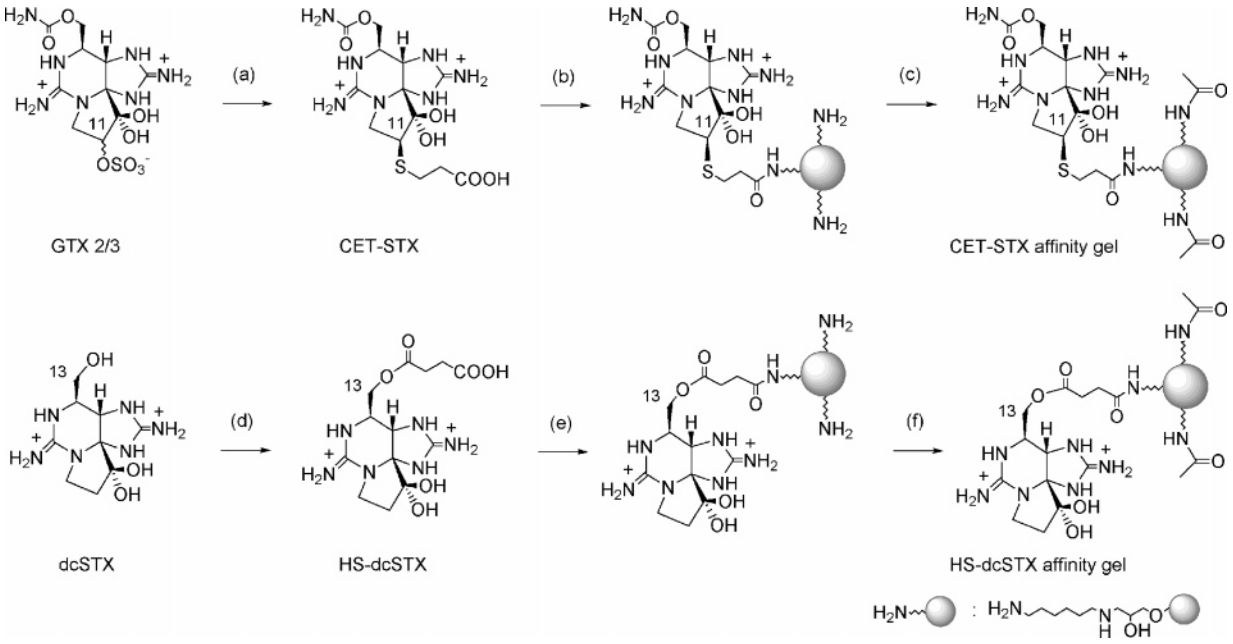
Coupling of STX Derivatives to EAH-Sepharose 4B Gel. Prior to use, EAH-Sepharose 4B was washed with 100 vol of distilled water and 100 vol of 50 mM MES buffer, pH 6.5. To 1 mL of EAH-Sepharose 4B suspended in 50 mM MES buffer (pH 6.5) in a 4-mL vial, 800 μL of 0.83 mM CET-STX and 700 μL of 678 mM EDC in the same buffer were added. The suspension was mixed gently on a revolution mixer (Asahi Techno Glass, Tokyo, Japan) at room temperature for 24 h. Next, the gel was washed sequentially with 6 vol of 50 mM MES buffer (pH 6.5), 6 vol of 0.1 M acetic acid containing 0.5 M NaCl, and 6 vol of distilled water. The gel was then suspended in an equal volume of 0.5 M acetate buffer, pH 7.4. Unreacted amino moieties on the gel were masked by acetylation with acetic anhydride on ice for 30 min. The gel was washed with 6 vol of distilled water, resuspended with 50 mM MES buffer (pH 6.5), and stored at 4 °C.

To 1 mL of EAH-Sepharose 4B in a 4-mL vial, 450 μL of 3 mM HS-dcSTX, 700 μL of 678 mM EDC, and 350 μL of 87 mM *N*-hydroxysuccinimide (NHS) were added. The suspension was rotated with revolution mixer (Asahi Techno Glass, Tokyo, Japan) at 4 °C for 24 h. The resulting dcSTX-affinity gel was washed and acetylated as described above.

Neuroblastoma Cell Bioassay of STX Derivatives. The sodium channel binding activity of intermediate derivatives (CET-STX and HS-dcSTX) was measured by the method of Manger et al. (*28*). Serial dilutions of the standard STX or the derivatives were made with complete medium containing 500 μM ouabain (Sigma, St. Louis, USA) and 20 μM veratridine (Sigma). To each well on a 96-well microplate, 100 μL of the diluted toxins and 100 μL of 5×10^5 cells/mL were added. After the plate was incubated for 20 h under 5% CO_2 at 37 °C, 50 μL of medium containing 0.74 mM 2,3-bis[2-methoxy-4-nitro-5-sulfonyl]-2H-tetrazolium-5-carboxanilide (Sigma) and 9 nM phenazine methosulfate (Sigma) was added. Cell viability was calculated by measuring the absorbance at 490 nm after 4 h incubation with an IMMUNO-MINI NJ-2300 microplate reader (Nalge Nunc International, Rochester, USA). The tests were performed in triplicate.

Measurement of Gel-Immobilized STX and dcSTX. To evaluate the amount of STX bound to the CET-STX gel, 50 μL of the gel was boiled for 10 min in 500 μL of 1 M 2-mercaptoethanol in 50 mM KPB, pH 7.0. STX released by this reaction was assessed by direct injection into FD-HPLC. The amount of dcSTX bound to the HS-dcSTX gel was determined by boiling 50 μL of gel in 500 μL of 1 M HCl for 10 min. The dcSTX released from the gel was then determined by FD-HPLC.

Scheme 1. Preparation of Saxitoxin-Conjugated Affinity Gels[a]



[a] (a) MPA/KPB, pH 7.0, 70 °C, 60 min, (b) EAH-Sepharose 4B, EDC/MES, pH 6.5, room temperature, 24 h, (c) $(CH_3CO)_2O$/acetate buffer, pH 7.4, on ice, 30 min, (d) succinic anhydride/saturated $NaHCO_3$ aqueous, room temperature, 60 min, (e) EAH-Sepharose 4B, EDC, NHS/MES, pH 6.5, 4 °C, 24 h, (f) $(CH_3CO)_2O$/acetate buffer, pH 7.4, on ice, 30 min. GTX: gonyautoxin; CET-STX: 11-(2-carboxyethylthio)saxitoxin; HS-dcSTX: 13-*O*-hemisuccinyldecarbamoylsaxitoxin.

Stability of the STX-Conjugated Affinity Gels. One milliliter of STX-conjugated affinity gels was suspended in one of the following buffers and kept at 4 °C in the dark: 50 mM acetate buffer, pH 4.5; 50 mM succinate buffer, pH 5.5; 50 mM MES buffer, pH 6.5; or 50 mM HEPES buffer, pH 7.5. An aliquot of each suspension was taken out at various times and used to assess the amount of bound toxin as described above.

Preparation of Plasma from Pufferfish and Bullfrog. The plasma protein fraction from the pufferfish *F. pardalis* was obtained according to the method of Yotsu-Yamashita et al. (*22*). Tetrodotoxin was removed from the plasma by washing it several times with 50 mM acetate buffer (pH 5.0) using an Ultrafree-CL (30 000 Da cutoff) with centrifugation at 4500*g* at 4 °C for 30 min. Finally, plasma proteins were dissolved in 50 mM Tris-HCl buffer, pH 7.4. Bullfrog plasma was prepared according to the modified method of Li et al. (*29*). Bullfrogs were anesthetized with diethyl ether. Blood was taken from the systemic arch into a heparinized syringe and was centrifuged for 5 min at 1500*g* at 4 °C. The plasma was stored at −80 °C until use.

Chromatography on the STX-Conjugated Affinity Gels. A 1.5-mL sample of each type of STX-conjugated affinity gel was equilibrated with 50 mM Tris-HCl buffer (pH 7.4) and packed in a plastic column (40 × 7 mm). Pufferfish and bullfrog plasma protein solutions were applied to the column and eluted with 50 mM Tris-HCl (pH 7.4) containing different concentrations of NaCl and finally with 50 mM acetate buffer (pH 5.0) at a flow rate of 0.2 mL/min. The elution was monitored with a diode array detector (Shimadzu, Tokyo, Japan), and 0.5 mL of each fraction was collected. The acetylated gel as control was also performed with the same chromatographic procedure.

Protein Assay and Electrophoresis of the Fractions. Aliquots of fractions were concentrated with Ultrafree-MC (30 000 Da) at 4500*g* at 4 °C for 10 min. Retained proteins were washed with 100 μL of 10 mM Tris-HCl buffer (pH 7.4) and then dissolved in 30 μL of the same buffer. The amount of protein in the concentrated mixture was determined using a Micro BCA Protein Assay kit (Pierce) with bovine serum albumin as the standard. SDS−PAGE was performed on a 7.5% polyacrylamide gel according to the method of Laemmli (*30*). Gels were stained with Coomassie brilliant blue R-250.

Measurement of STX Binding Activity in the Fractions. Aliquots (5 to 100 μL) of each fraction were concentrated with Ultrafree-MC as above. The residue remaining was dissolved in 30 μL of 10 mM Tris-HCl buffer (pH 7.4) containing 330 pmol of STX and then kept on ice for 10 min. After ultrafiltration, the amount of STX in the filtrate was quantified by FD-HPLC. The amount of STX bound to proteins was calculated by subtracting the amount in the filtrate from the control without proteins.

RESULTS

Preparation of Carboxyl Derivatives of STX and their Na Channel-Binding Activities. STX-conjugated affinity gels were prepared according to the strategy shown in Scheme 1. For the first step of reactions, GTX2/3 was reacted with 3-mercaptopropionic acid to introduce carboxylic moiety into the toxin by the unique substitution reaction (*27*). Using 47 μmol of a GTX2/3 mixture, we obtained 19 μmol of CET-STX in 40% yield. A molecular formula of $C_{13}H_{22}O_6N_7S$ was obtained by HR-FAB MS ($[M + H]^+$ 404.1355; $\Delta = +0.3$ mmu). Figure 1 shows the ^{1}H NMR spectra taken in both D_2O and D_2O/H_2O (1:1) containing 4% CD_3COOD, with assigned HMBC and NOESY correlations. Methylene protons at δ 2.94 to 3.06 and 2.74 indicated the replacement of the hydroxysulfate of GTX2/3 with a carboxyethylthio moiety. The HMBC correlation from H-1′ to C-11 indicated that the position of substitution was at C-11. H-11 was not observed in D_2O by complete exchange to deuterium in solvent through keto−enol equilibration, but observed as triplet at δ 3.65 in D_2O/H_2O. The coupling constant was 9.3 Hz, close to that of ($^3J_{10\alpha,11}$ 8−9 Hz) of GTX3, which has a 11β-hydroxysulfate (*31*), indicating that the substituent was in a β-configuration. The long-range correlation signal between H-10α (δ 4.15) and H-11 in the NOESY experiment also supported this stereochemical assignment.

As another way to introduce carboxyl moiety into STX skeleton, dcSTX was succinylated. HS-dcSTX was obtained in

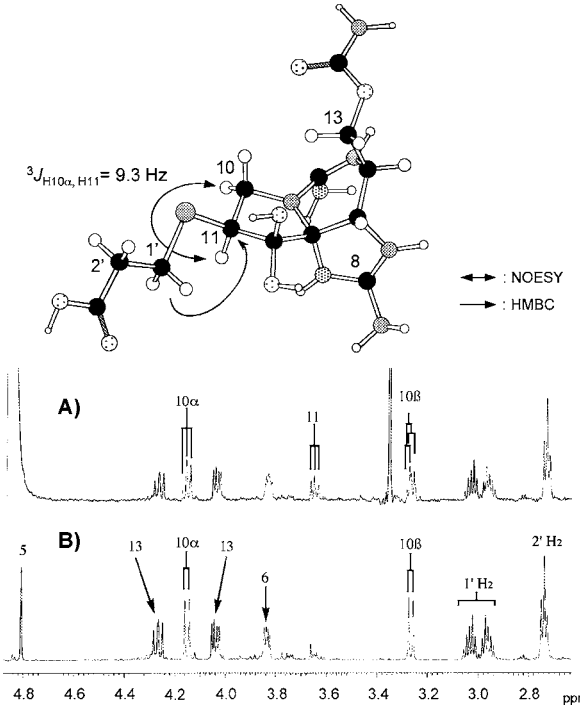


Figure 1. ^{1}H NMR spectra and structure of 11-(2-carboxyethylthio)-saxitoxin. These spectra were measured in 4% CD_3COOD/D_2O:H_2O (1:1) (A) and 4% CD_3COOD/D_2O (B) at 600 MHz. In the structure, observed HMBC and NOESY correlations are shown only around C11.

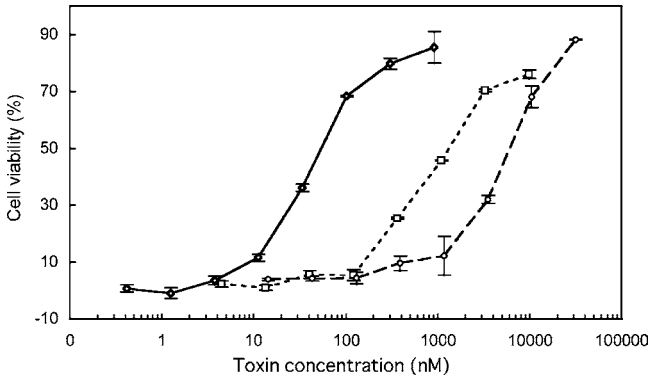

Figure 2. Dose−response curve of neuroblastoma assay. ◇: STX, □: CET-STX, ○: HS-dcSTX.

a yield of 53%. A molecular formula of $C_{13}H_{21}O_6N_6$ ([M + H]$^+$ 357.1524; Δ = +0.2 mmu) was confirmed by HR-FAB mass spectroscopy, and the following signals were observed in^{1}H NMR (4% CD_3COOD/D_2O, 600 MHz): δ (ppm), 4.77 (1H, s, H-5), 4.40 (1H, dd, J = 11.7, 9.4 Hz, H-13), 4.11 (1H, dd, J = 11.7, 5.4 Hz, H-13), 3.87 (1H, dd, J = 9.4, 5.4 Hz, H-6), 3.80 (1H, d, J = 9.9 Hz, H-10α), 3.58 (1H, d, J = 9.9 Hz, H-10β), and 2.70 (4H, m, succinate). The parameters were identical to those reported for this compound by Koehn et al. (*32*), with a 0.5 ppm difference due to the use of different standards.

Figure 2 shows dose−response curves of CET-STX and HS-dcSTX together with the control STX in the Neuro 2A cell bioassay. The Hill coefficients calculated from the curves were identical for the three compounds (1.23), suggesting that the action of two derivatives on the cell were similar to that of STX. The EC_{50} values of STX, CET-STX, and HS-dcSTX were 40, 888, and 6530 nM, respectively.

Preparation of STX-Conjugated Affinity Gels and Their Stability. After several preliminary experiments with different reaction conditions, CET-STX and HS-dcSTX were effectively

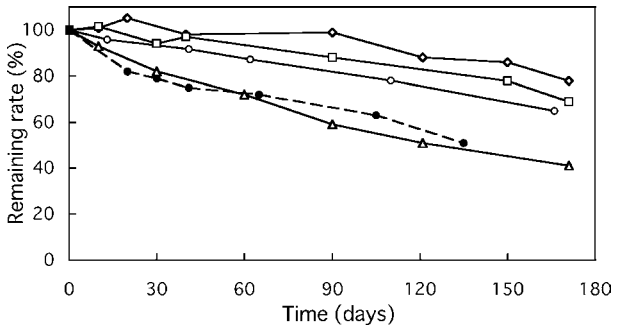

Figure 3. Stability of CET-STX affinity gel. The remaining STX on a CET-STX affinity gel was plotted as % of 0 day. The gel was stored at 4 °C in the following buffers: pH 4.5 (◇): 50 mM acetate buffer, pH 5.5 (□): 50 mM succinate buffer, pH 6.5 (○): 50 mM MES buffer, pH 7.5 (△): 50 mM HEPES buffer was plotted against time after preparation. CET-STX was stored at 4 °C in 50 mM MES buffer at pH6.5 (●).

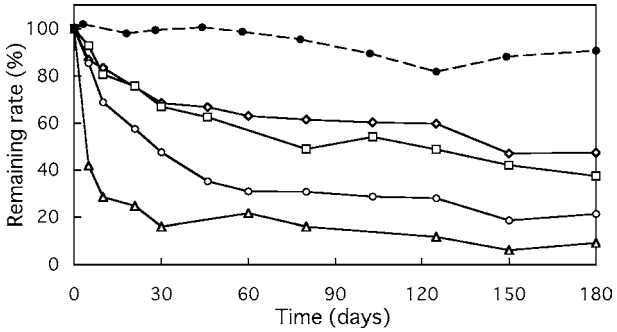

Figure 4. Stability of the HS-dcSTX affinity gel. The remaining dcSTX on the HS-dcSTX affinity gel was plotted as % of 0 day. Symbols for buffers are the same as in Figure 3.

bound to EAH-Sepharose 4B. Use of MES buffer and 0.6−0.7 μmol of CET-STX per 1 mL of gel were found to be optimal, resulting in a 90% yield of reaction. During acetylation step for masking amino residues, a small portion of STX was released from the gel, but 90% remained intact. The amount of STX bound to 1 mL of the final product (CET-STX affinity gel) was estimated to be 500 nmol, which is equivalent to coupling of 4−7% of the amino groups on the gel based on the reported value of 7−12 μmol of amino groups/mL in EAH-Sepharose 4B.

Addition of NHS was essential for the coupling of HS-dcSTX to EAH-Sepharose 4B, and the derivative was quantitatively introduced into the gel. However, more dcSTX was released by acetylation than in the case of CET-STX. The concentration of dcSTX bound to the final gel (HS-dcSTX affinity gel) was 510 nmol/mL gel, which is equivalent to 4−7% of the amino groups in the gel.

Masking of amino residues by acetylation reduced the ionic binding of proteins as demonstrated by testing with bovine serum albumin. In this case, acetylation reduced nonspecific protein binding by 99% (data not shown).

The stability of the affinity gels during storage was tested at various pHs. CET-STX gels gradually lost their toxin moieties during storage at 4 °C in a pH-dependent manner. The gels were more stable at lower pH, and more than 80% of toxins were retained at pH 4.5 after 6 months (Figure 3). HS-dcSTX gels were less stable, and approximately 50% of the toxin was lost after 6 months, even at pH 4.5 (Figure 4).

Chromatography of Pufferfish and Bullfrog Plasma on the STX-Conjugated Affinity Gels. To evaluate the binding activities of the STX-conjugated gels, pufferfish and bullfrog plasma preparations, which are known to contain STX-binding proteins, were subjected to chromatography on the columns.

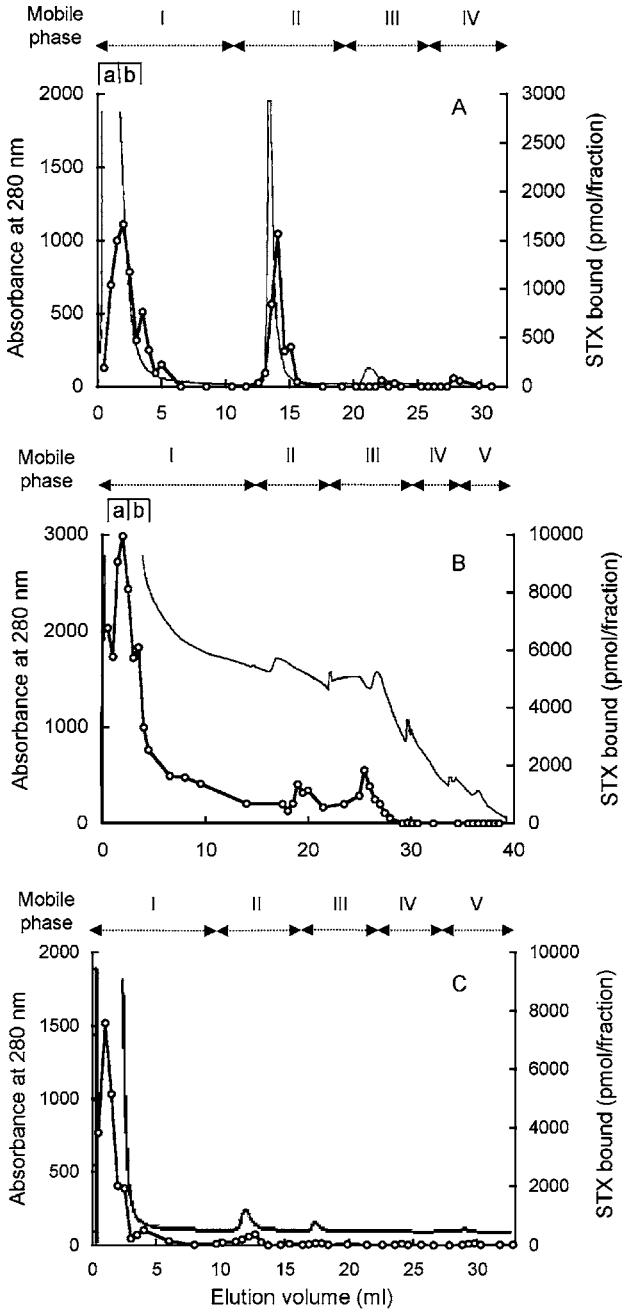

Figure 5. Chromatograms of pufferfish or bullfrog plasma on STX-conjugated affinity gels. The elution of protein and STX binding activity was monitored by the absorbance at 280 nm and the amount of STX bound to protein (○), respectively. (A) Pufferfish plasma on CET-STX affinity gel eluted with I: 50 mM Tris-HCl buffer (pH 7.4), II: 50 mM Tris-HCl buffer (pH 7.4) containing 500 mM NaCl, III: 50 mM Tris-HCl buffer (pH 7.4) containing 1 M NaCl, IV: 50 mM acetate buffer (pH 5.0) as mobile phases at a flow rate of 0.2 mL/min. (B) Bullfrog plasma on the CET-STX affinity gel eluted with I: 50 mM Tris-HCl buffer (pH 7.4), II: 50 mM Tris-HCl buffer (pH 7.4) containing 50 mM NaCl, III: 50 mM Tris-HCl buffer (pH 7.4) containing 500 mM NaCl, IV: 50 mM Tris-HCl buffer (pH 7.4) containing 1 M NaCl, V: 50 mM acetate buffer (pH 5.0) as mobile phases at a flow rate of 0.2 mL/min. (C) Bullfrog plasma on HS-dcSTX affinity gel. Eluting condition is the same as B.

Figure 5 shows chromatograms of pufferfish plasma (panel A) and bullfrog plasma (panel B) on CET-STX affinity gel and bullfrog plasma on a HS-dcSTX affinity gel column (panel C). SDS−PAGE of the corresponding fractions from A and B are shown in Figure 6. Distribution of STX-binding activity and specific activities of each fraction are summarized in Table 1. Several fractions, especially in flow-through fraction, showed

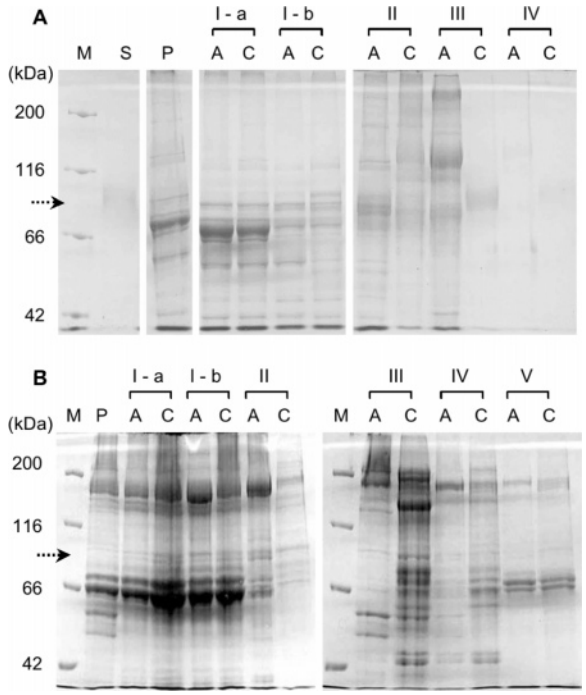

Figure 6. SDS−PAGE of fractions from CET-STX affinity column chromatography. (A) Pufferfish plasma. M: marker, S: standard PSTBP, P: pufferfish plasma, A: acetylated gel as control, C: CET-STX affinity gel, I−IV: fractions in Figure 5A. (B) Bullfrog plasma. M: marker, P: bullfrog plasma, A: acetylated gel as control, C: CET-STX affinity gel I−V: fractions in Figure 5B. Each arrow indicates the bands corresponding to PSTBP (A) and the reported molecular weight of saxiphilin (B) (90.8 kDa), respectively.

higher STX-binding activity than the estimated activity (approximately 440 pmol for pufferfish plasma and 150 pmol for bullfrog plasma). This finding implies the activity includes nonspecific binding activity.

When 400 μL (12−14 mg of protein) of pufferfish plasma was chromatographed on the CET-STX gel (Figure 5A), or the acetylated gel as control, a large proportion of the STX-binding activity (65% of the total recovered) was found in the unbound fraction (I), and 30% was eluted with buffer containing 0.5 M NaCl (II). Although only 5% of the STX-binding activity was detected in the affinity gel, the 1 M NaCl fraction (III) showed a specific activity of 7 nmol/mg of protein. This 40-fold increase in specific activity was similar to the original report of PSTBP purification with 4 steps (*22*), although a different method was used for the evaluation of binding activity in the previous study. Like the PSTBP standard, this purified fraction shows a single broad band at around 90 kDa on SDS−PAGE (Figure 6A). In contrast, this band was not detected in the lane of the acetylated gel. From SDS−PAGE, PSTBP was selectively concentrated on fraction III by the CET-STX affinity gel.

Bullfrog plasma (400 μL, containing 25−30 mg protein) was also applied to the CET-STX affinity gel column (Figure 5B) or the acetylated gel. Most of the STX-binding activity (84%) was found in the unbound fraction (I), and 7 and 9%, respectively, were found in the 0.05 and 0.5 M NaCl fractions (II and III). The latter two fractions showed specific activities of 12 and 17 nmol/mg of protein, respectively, corresponding to 109- and 159-fold purifications of the activity in the original plasma preparations. Fractions II and III in the affinity gel showed several bands on SDS−PAGE including a 91-kDa band corresponding to the reported molecular weight of saxiphilin in bullfrog (*29*) (Figure 6B). These bands other than saxiphilin were also detected in the control, suggesting that these are nonspecific binding to this affinity gel.

Table 1. Saxitoxin Binding Activities in Each Fraction from CET-STX Affinity Chromatography

pufferfish plasma				bullfrog plasma			
fraction no.	NaCl (M) in buffer[a]	activity[b] (%)	specific activity (nmol/mg of protein)	fraction no.	NaCl (M) in buffer*	activity[b] (%)	specific activity (nmol/mg of protein)
original			0.14	original			0.11
I	0.00	65.0	0.82	I	0.00	84.1	2.22
II	0.50	29.0	2.11	II	0.05	6.9	11.69
III	1.00	5.3	6.98	III	0.50	9.0	17.04
IV		0.7	5.31	IV	1.00	0.0	0.34
				V		0.0	0.00

[a] In 50 mM Tris HCl buffer, pH 7.4. Eluting buffer of fraction IV for pufferfish plasma and fraction V for bullfrog plasma was 50 mM acetate buffer, pH 5.0. [b] Percent of total recovered STX binding activity (pmol).

HS-dcSTX affinity gel was tested only for bullfrog plasma due to unavailability of pufferfish plasma. The gels did not show any interaction with saxiphilin in bullfrog, which accounted for almost all the activity in the first fraction (Figure 5C).

DISCUSSION

The first step in our strategy for the preparation of STX-conjugated affinity gels was the introduction of carboxylic acids at positions C-11 or C-13 of STX, leaving two guanidine groups and the *gem*-diols at C-12 intact (Scheme 1). Using the methods described here, CET-STX could be prepared in sufficient yields for the first time. Preparation of HS-dcSTX has been reported previously (*32*), but our reaction in sodium bicarbonate solution gave a much higher yield. Both derivatives were shown to maintain Na channel-binding activity, although we observed a 1 order of magnitude reduction for CET-STX and 2 orders of magnitude reduction for HS-dcSTX. A low affinity of HS-dcSTX for the Na channel-binding site might be due to an ionic repulsion between the carboxylic acid and the receptor site, similar to that between the channel and the N-sulfocarbamoyl group of the toxin (*33*). This repulsion is expected to be reduced by the formation of an amido bond with the EAH-Sepharose 4B gel.

CET-STX obtained was exclusively composed of 11-β epimer, despite the use of a 11-hydroxysulfate epimeric mixture (GTX2/3) as the starting material. A similar result was reported for glutathione derivatives of GTX1/4 (*27*). This might be a reflection of the highly favored energetic stability of the β- rather than the α-configuration because a keto−enol equilibration can be observed by substitution of 11-α H with solvent deuterium.

For the second step, the derivatives were effectively coupled to an agarose gel with amino groups under aqueous conditions. The reaction yields were as high as 90%, and two derivatives could be introduced into affinity gels at a concentration of 500 nmol/mL of gel. The STX skeleton was separated from agarose by 15 bonds (Scheme 1). The length was expected to be enough as a spacer.

A preliminary test using known STX binding proteins showed that the affinity gels would be useful for the purification of active proteins. A high degree of purification could be achieved in the NaCl-eluted fraction. In fact, especially for the CET-STX gel, nearly pure PSTBP was obtained in just one chromatographic step. A large proportion of activity in the first unbound fraction might be the result of nonspecific binding with native STX, since this affinity gel possessed enough binding capability to interact with the active proteins (approximately 440 pmol in pufferfish and 150 pmol in bullfrog) present in plasma preparations.

Several proteins were observed by SDS−PAGE in the 0.5 and 1.0 M NaCl fractions (Figure 6A). These proteins were also detected in the acetylated gel, suggesting that the affinity gel interacted with proteins other than the active protein, mainly due to the masked moiety of the gel. Such nonspecific binding would be inevitable and however could be reduced by treating crude extract with ammonium sulfate, dialysis, or column chromatography, or by using the affinity gel conjugated to more toxins. Therefore, those steps will improve the interaction between active proteins and toxins without being disturbed by nonspecific binding. Further, the comparison of the elution profile between the affinity gel and the acetylated gel is effective and necessary to find unidentified active proteins. Experiments are also necessary to clarify whether these were actual STX-binding proteins or were merely bound by nonspecific hydrophobic or ionic binding to the unmasked amino groups remaining on the gels.

the HS-dcSTX affinity gel showed no interaction with saxiphilin, probably because it was hindered by the introduced side chain. It was also expected from the reported binding characteristic of saxiphilin, which showed much lower affinity to GTX5 (N-sulfonate derivative) than did STX or dcSTX (*34*). However, it is important to have affinity gels with different toxin structures because unidentified STX-binding proteins might have diverse modes of interaction with the toxin.

The high reaction yields for introducing carboxyl-conjugated STX derivatives in the gels are noteworthy because the reaction can be utilized to prepare STX-conjugated proteins. In the past, direct coupling using formaldehyde (*35*) was widely used for the preparation of antigens or toxin-linked enzymes for the development of an enzyme-linked immunosorbent assay for STX groups. However, the established protocol using formaldehyde has fundamental problems due to the uncertain binding between toxins and proteins and to the large consumption of toxins. Therefore, this coupling reaction of carboxyl-conjugated STX derivatives may solve these problems.

We established the preparation of two types of toxin-conjugated affinity gels in short steps and in high yields under aqueous conditions. They are expected to be a new research tool to elucidate the mechanism of transportation or bioaccumulation in marine organisms. Screening of toxin-binding proteins in bivalve mollusk using these affinity gels is underway.

ACKNOWLEDGMENT

We are grateful to Professor Mari Yotsu-Yamashita, Graduate School of Agricultural Science, Tohoku University, for providing pufferfish plasma and PSTBP. We also thank Dr Susan Blackburn, CSIRO Hobart, Australia, for permitting us to use the *Anabaena circinalis* culture strain. This study was supported by a Grant-in-Aid from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

A novel uridine-based nucleo-lipid, DOTAU (*N*-[5′-(2′,3′-dioleoyl)uridine]-*N*′,*N*′,*N*′-trimethylammonium tosylate) was prepared by using a convenient four-step synthetic pathway. From the preliminary physicochemical studies (quasielastic light scattering and light microscopy), this amphiphilic structure forms supramolecular organizations in aqueous solution. In addition, in the presence of nucleic acids, transmission electronic microscopy experiments (TEM) and small angle X-ray scattering (SAXS) reveal the formation of multilamellar structures similar to lipoplexes (cationic liposome−DNA complexes) with cationic lipids. The formation of a complex was confirmed by fluorescence spectroscopic assays involving ethidium bromide. Transfection assays of mammalian cell lines (HeLa and MCF-7) indicate that DOTAU can transfect efficiently an expression vector (pEGFP) encoding GFP. Proliferation assays realized on these cell lines show that DOTAU does not inhibit cell proliferation and is less toxic than the commercial Lipofectamine 2000.

INTRODUCTION

The transport of nucleic acids through a cell membrane for subsequent transcription is fundamental for the delivery of therapeutic genes (*1*−*3*). Viruses are efficient vectors for transportation of DNA, but there are risks associated with their clinical application (*4*). Consequently, there is significant basic and clinical interest in nonviral vectors, and a large variety of synthetic gene-delivery systems have been investigated including cationic lipids, dendritic macromolecules, and linear polymers (*5*−*12*).

New cationic lipids have been synthesized and evaluated for plasmid DNA delivery (*13*) since the discovery of *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA)[1] as a cationic transfecting agent (*5*, *14*). In general, cationic lipids are attractive materials for this application because (1) of their reduced cytotoxicity compared to viral vectors, (2) of their well-defined structure (compared to linear polymers), (3) tuneable chemical structure, and (4) ease of synthesis. Four primary motivations for this research are to improve the transfection activity or modulate the level of gene expression, reduce the cytotoxicity, broaden the scope of the nucleic acid payload, and expand the repertoire of chemical structures under investigation. Consequently, numerous structural features have been altered on the basic cationic lipid structure, leading to compositions such as DOTAP (*N*-[1-(2,3-dioleoyloxy)propyl]-*N*′,*N*′,*N*′-trimethylammonium chloride) which are now commercially available and under clinical evaluation (Figure 1) (*15*). Among the chemical variants/alterations of the lipid structure explored, the incorporation of natural moieties such as cholesterol, oleic acids, and amino acids or multicationic charges have been investigated. Currently, all the synthetic vectors used relay on either electrostatic interactions or electrostatic and hydrophobic interactions for DNA binding and supramolecular assembly formation required for gene delivery. We are interested in molecular interactions such as hydrogen bonding and $\pi-\pi$ stacking to further modulate the interactions between DNA and the synthetic vector. Within this framework, hybrid molecules bearing both nucleic acid units and amphiphilic moieties would be the simplest prototype. To the best of our knowledge, there are no previous examples of synthetic gene carriers derived from cationic nucleoside-based lipids. Herein, we describe a promising nucleic acid vector based on a cationic amphiphilic uridine. We report the synthesis, physicochemical studies, cytotoxicity, and in vitro transfection results of this new nucleoside-based lipid (DOTAU, Figure 1).

MATERIALS AND METHODS

General Experiments and Analytical Conditions. Unless noted otherwise, all starting materials were obtained from Aldrich and were used without further purification, and the solvents were redistilled over calcium chloride, calcium hydride, potassium hydroxide, or sodium according to the solvent used.

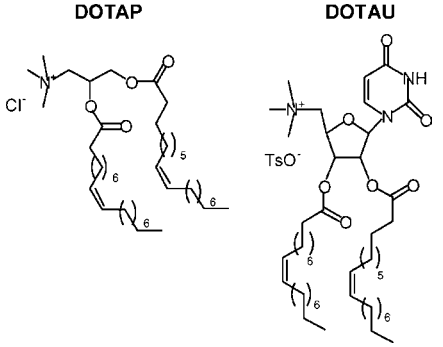

Figure 1. Chemical structures of DOTAP (*N*-[1-(2,3-dioleoyloxy)-propyl]-*N*′,*N*′,*N*′-trimethylammonium chloride) and DOTAU (*N*-[5′-(2′,3′-dioleoyl)uridine]-*N*′,*N*′,*N*′-trimethylammonium tosylate).

All compounds were characterized using standard analytical and spectroscopic techniques such as ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy (apparatus Bruker Avance DPX-300, ^{1}H at 300.13 MHz, ^{13}C at 75.46 MHz, and ^{31}P at 121.49 MHz) and mass spectrometry (Instrument JEOL SX 102, NBA matrix). The NMR chemical shifts are reported in ppm relative to tetramethylsilane for ^{1}H and ^{13}C. The ^{1}H NMR coupling constants, *J*, are reported in Hz. TEM microscopy experiments were performed on a Philips CM 10 (negative staining with ammonium molybdate 1% in water, Cu/Pd carbon coated grids). A Wyatt QELS system was used to obtain the Rh. Silica gel 60 (particle size: 40−60 μm) was employed for flash chromatography. Thin layer chromatograms were performed with aluminum plates coated with silica gel 60 F_{254} (Merck). Varian silica gel reverse phase C18 Mega BE-C18, 2GM 12 mL, and Sephadex LH-20 (25−100 μm) were used for quantitative chromatography. ^{13}C chemical shifts were determined by HMQC.

2′,3′-*O*-Isopropylideneuridine, 1. To a stirring solution of uridine (1.5 g, 6.14 mmol) in dry acetone (135 mL) was added a catalytic amount of H_2SO_4 dropwise, at room temperature. After being stirred for 2 h, the solution became clear and was quenched with $BaCO_3$ until neutralization. The heterogeneous mixture was filtered on a Celite pad, and the filtrate was evaporated under reduced pressure. The crude product was immediately purified by flash column chromatography (CH_2Cl_2/MeOH: 90/10) to give **1** (1.24 g, 71%) as a white solid. mp = 161 °C. ^{1}H NMR (D_3CCOCD_3): δ 7.84 (1H, d, J = 8.06 Hz), 5.92 (1H, d, J = 2.69 Hz), 5.62 (1H, d, J = 8.06 Hz), 4.92 (2H, 2 × dd, J = 2.76 Hz, 6.3 Hz and J = 3.24 Hz, 6.3 Hz), 4.19 (q, 1H, J = 3.47 Hz), 3.78 (2H, t, J = 3.70 Hz), 1.54 (3H, s), 1.34 (1H, s). ^{13}C (D_3CCOCD_3): δ 163.64, 152.00, 142.71, 114.28, 102.67, 93.04, 87.63, 85.14, 81.59, 62.74, 29.55 FAB MS *m*/*z*: 285 (M + 1), 307(M + 23).

2′,3′-*O*-Isopropylidene-5′-*O*-tosyluridine, 2. 2′,3′-*O*-Isopropylideneuridine **1** (1.2 g, 4.22 mmol) was dissolved in dry pyridine (15 mL), and the solution was cooled to 0 °C. Tosyl chloride (2.4 g, 12.67 mmol) was added in small portions. After the addition, the solution which was allowed to warm to room temperature, was stirred overnight, and was quenched with methanol. The resulting mixture was stirred for 30 min, diluted with CH_2Cl_2, and successively washed with brine, aqueous $NaHCO_3$ 5% w/v, and brine. The organic layer was dried on Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by flash column chromatography (cyclohexane/EtOAc: 50/50) to give **2** (1.32 g, 71%) as a white solid. mp = 67 °C. ^{1}H NMR ($CDCl_3$): δ 9.48 (1H, s), 7.75 (2H, d, J = 8.29 Hz), 7.32 (2H, d, J = 7.98 Hz), 7.23 (1H, d, J = 8.13 Hz), 5.71 (1H, d, J = 8.06 Hz), 5.63 (1H, d, J = 2.05 Hz), 4.93 (1H, dd, J = 2.05 Hz, 6.40 Hz), 4.78 (1H, dd, J = 3.63 Hz, 6.40 Hz), 4.32 (1H, m), 4.27 (2H, m), 2.43 (3H, s), 1.53 (3H, s), 1.32 (3H, s). ^{13}C ($CDCl_3$): δ 163.41, 150.10, 145.42, 142.41, 132.59, 130.03, 128.09, 114.79, 102.83, 94.96, 85.16, 84.45, 80.94, 69.45, 27.15, 23.31, 21.81 FAB-MS *m*/*z* 439 (M + 1).

2′,3′-Dioleyl-5′-*O*-tosyluridine, 3. At 0 °C, 2′,3′-*O*-isopropylidene-5′-*O*-tosyluridine **2** (200 mg, 0.46 mmol) was dissolved in 3.5 mL of an aqueous trifluoroacetic acid/H_2O (6/1) solution and stirred for 1 h at 0°C. The solvents were coevaporated with methanol under reduced pressure, and the residue was dried in vacuo. The crude product was dissolved in 10 mL of CH_2Cl_2, and the solution was cooled to 0 °C. Dicyclohexylcarbodiimide (388 mg, 1.88 mmol), (dimethylamino)pyridine (230 mg, 1.88 mmol), and oleic acid (531 mg, 1.88 mmol) were added, and the mixture was stirred at room temperature overnight. DCU was then filtered through a Celite pad, and the filtrate was successively washed with aqueous 2 N HCl and aqueous saturated $NaHCO_3$ solutions. The organic layer was dried on Na_2SO_4, filtered, and evaporated under reduced pressure. The crude product was purified by flash column chromatography (cyclohexane/EtOAc: 90/10 to 70/30) to give **3** (349 mg, 82%) as an oil which solidify upon standing. ^{1}H NMR (DMSO-d_6): δ 7.80 (2H, d, J = 8.37 Hz), 7.62 (1H, d, J = 8.21 Hz), 7.48 (2H, d, J = 8.06 Hz), 5.83 (1H, d, J = 5.05 Hz), 5.70 (1H, d, J = 8.06 Hz), 5.21−5.49 (6H, m), 4.17−4.40 (3H, m), 2.24−2.30 (4H, m), 1.88−2.00 (8H, m), 1.17−1.39 (44H, m), 0.80−0.87 (6H, m) ^{13}C NMR (DMSO-d_6): 171.48, 162.84, 150.098, 145.06, 141.45, 131.83, 130.00, 129.38, 129.37, 127.62, 102.26, 88.16, 78.63, 71.42, 69.03, 33.626, 31.22, 29.02, 28.80, 28.64, 28.58, 28.44, 28.39, 28.3, 26.5, 24.16, 22.02, 21.01, 13.79 FAB MS *m*/*z*: 927 (M + 1), 949 (M + 23).

Tosylate Salt of 2′,3′-Dioleyl-5′-(trimethylammonio)uridine, 4. Anhydrous trimethylamine (1 mL) was transferred to a pressure tube cooled at −50 °C via a syringe. Next, anhydrous acetonitrile (2 mL) and a solution of **3** (200 mg, 0.46 mmol) in dry THF (2 mL) were added. The tube was sealed and heated in an oil bath at 50 °C during 48 h and then cooled to −20 °C and opened. The solvents were evaporated under reduced pressure to give **4** (229 mg, quantitative) as a white solid. ^{1}H NMR (DMSO-d_6): δ 8.06 (1H,d, J = 8.13 Hz), 7.69 (2H, d, J = 8.06 Hz), 7.32 (2H, d, J = 7.90 Hz), 6.09 (1H, d, J = 4.27 Hz), 5.92 (1H, d, J = 9.80 Hz), 5.60−5.67 (1H, m), 5.52 (6H, m), 4.00 (2H, broad s), 3.34 (9H, s), 2.29−2.34 (4H, m), 1.91−2.02 (8H, m), 1.13−1.35 (44H, m), 0.82−0.86 (6H, m). ^{13}C NMR (DMSO-d_6): δ 172.00, 162.93, 150.10, 145.71, 142.35, 137.44, 129.38, 127.92, 125.40, 102.30, 89.13, 74.73, 70.89, 70.41, 66.53, 52.99, 33.25, 31.21, 28.20−29.20, 26.49, 24.20, 22.01, 20.01, 14.00 FAB MS *m*/*z*: 815 (M cation). (**4**+H_2O) Anal. Cal. C, 65.77; H, 9.33; N, 4.18. Found Cal. C, 65.22; H, 9.51; N, 4.61.

Materials. pEGFP-N3 (Clontech) plasmid was amplified in *E. coli* and purified with endotoxin free plasmid preparation kit (Qiagen). Calf thymus DNA (CAS regist. no. 91080-16-9) and ethidium bromide (EB) were obtained from Sigma. EB was weighed, and a stock solution (0.6 mg/mL) was prepared in distilled water and filtered (0.22 μm) water. The buffer solutions were also prepared in distilled and filtered (0.22 μm) water, and the buffers were pH adjusted to 7.4 with 0.1 N NaOH. A stock solution (1 mL) of calf thymus DNA (1 mg/mL) for the fluorescence exclusion assay and for TEM and SAXS studies was dissolved in Tris buffer: 20 mM Tris, 100 mM NaCl, 10 μM EDTA, pH 7.4.

Exclusion Assay. Five micrograms (5 μL of 1 mg/mL solution) of DNA and a varying amount of lipid (dependent on the lipid/DNA ratio required) were diluted to 1000 μL with buffer (Tris buffer: 20 mM Tris, 100 mM NaCl, 10 μM EDTA, pH 7.4). The solutions were mixed on a benchtop vortex and incubated for 60 min at room temperature. Each solution was then diluted to 3 mL with buffer. Immediately prior to the

analysis, 3 μL of an ethidium bromide (EB) solution (0.6 mg/mL, 1.3 mM) was added, the sample was mixed on a benchtop vortex, and the fluorescence was measured (λ_{exc} = 546 nm, λ_{em} = 600 nm; 1 cm path length glass cuvette, slit width 3 nm). The fluorescence was expressed as the percentage of the maximum fluorescence signal when EB was bound to the DNA in the absence of lipid. All assays were run in triplicate.

Transmission Electronic Microscopy. Samples containing lipoplexes were obtained from the mixture of 3 mg/mL of extruded (50 nm) liposome and 1.25 mg/mL DNA solutions (Tris buffer: 20 mM Tris, 100 mM NaCl, 10 μM EDTA, pH = 7.4). Before TEM imaging, the mixture was incubated for 5 h at 4 °C. TEM microscopy experiments were realized on a Philips CM 10 (negative staining with ammonium molybdate 1% in water, Cu/Pd carbon coated grids).

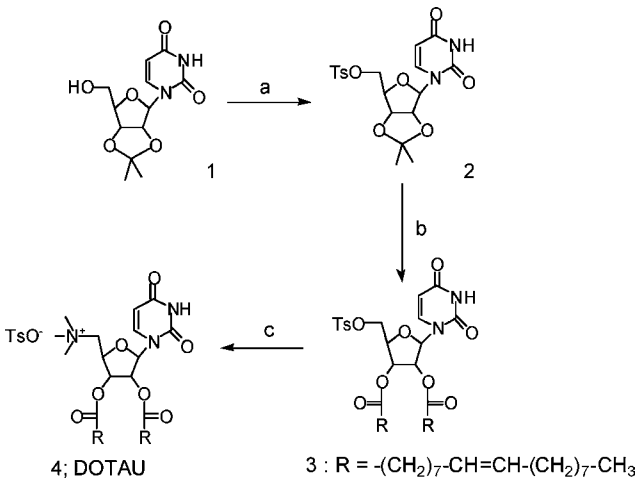
X-ray Diffraction. A typical procedure for lipoplex formation with DOTAU and CT-DNA in a Tris buffer (20 mM Tris, 100 mM NaCl, 10 μM EDTA, pH = 7.4) is described. The samples were prepared from 10 mg/mL of extruded (50 nm) liposome solutions (33 μL) and 10 mg/mL DNA solution (20 μL), in 53 μL of buffer. The mixture was incubated for 5 h at 4 °C and then centrifuged in an eppendorf tube. The supernatant was removed, and the pellet was suspended in 50 μL of buffer. Lipoplexes were studied by placing a small amount of this suspension in a sealed quartz capillary (diameter 1 mm) and then placing the capillary in a sample holder. SAXS measurements were conducted at the University of Montpellier II, Laboratoire GDPC, on a diffraction system equipped with a two-dimensional position-sensitive area detector. The sample-to-detector distance was 30 cm, source: "Rigaku" copper rotating anode working at 40 kV, 100 mA, monochromator confocal Max Flux Osmic optic. Diffraction patterns were obtained using an image plate 2D detector. The low angle reflections were in accordance with Bragg's law $2d \sin \theta = h\lambda$, where λ is the wavelength (1.54 Å), d is the repeat period, h is the number of the diffraction order, and θ is the Bragg angle.

Cell Culture and Transfection. The human epitheloid carcinoma Hela cells and the human breast adenocarcinoma MCF-7 cells were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS). Cells were grown on plastic tissue dishes at 37 °C in a 5% CO_2 containing atmosphere. One day before transfection, cells were seeded in 24-well plates (1×10^5 cells/well), to reach 70−90% confluency at the time of the transfection. Just prior to transfection, the complete medium was replaced by serum-free DMEM (350 μL/well). DOTAU and DOTAP solutions at 1 mg/mL in water or Lipofectamine 2000 (Invitrogen) were mixed with DNA (2.5 μg/well) in serum-free medium. Various liposome/DNA ratios were tested. The lipoplexes were formed at room temperature during 20 min and then loaded on cells which were incubated at 37 °C. At 4 h posttransfection, 350 μL of DMEM supplemented with 20% FBS was added to the cells. Cells were analyzed 48 h after transfection.

Flow Cytometry. The transfection efficiency was defined by the expression of the green fluorescent protein (GFP). After transfection, cells were detached from the plastic dish with trypsin/EDTA and then resuspended in PBS. Then single-cell suspensions were analyzed by flow cytometry using a fluorescence-activated cell sorter (FACS) Becton-Dickinson model BD-LSR II device and the FlowJo software.

Proliferation Assay. Proliferation in cell population was defined using the 5-bromo-2′-deoxyuridine (BrdU) labeling and detection kit III (Roche) accordingly to the manufacturer recommendations. Briefly, after 48 h of incubation with the liposomes, the cells cultured in 96-well plates were incubated during 3 h with BrdU, fixed with ethanol, and incubated with an anti-BrdU monoclonal antibody labeled with peroxidase. Upon addition of its substrate, the peroxidase catalyzes a colored reaction which was quantified by the measure of the absorbance at 405 nm.

Scheme 1. Synthetic Route to DOTAU[a]



[a] Conditions: (a) TsCl, pyridine, 14 h, rt, 71%; (b) TFA/H_2O, 1 h, 0 °C then oleic acid, DCC, DMAP, CH_2Cl_2, 14 h, rt, 82%; (c) NMe_3.HCl, THF, CH_3CN, 48 h, quant.

RESULTS AND DISCUSSION

Lipid−DNA interactions control many of the steps in the path to efficient gene transfection. There are two primary mechanisms for a lipid to interact with DNA. The lipid can possess one or more cationic charges that interact with the negatively charged phosphate backbone of DNA, as is typical. Alternatively, the lipid possesses a functional group for nonionic interactions with DNA (e.g., Watson−Crick/Hoogsteen hydrogen-bonding and base $\pi-\pi$ stacking) to form a lipid/DNA supramolecular assembly (*17*). Both of these interaction features can be combined in one molecular structure to affect the binding between DNA and the lipid. Thus, we prepared a new lipid possessing a DNA unit (e.g., nucleobase), a cationic ammonium group, and hydrophobic oleyl chains connected by an ester linkage to the ribose hydroxyls. The amphiphilic polar head bears a cationic charge to ensure formation of a stable DNA complex. The cationic charge is required, since our previous studies on a noncationic derivative of **4**, which possesses a phosphocholine group, does not strongly bind DNA (*18*). This is not entirely unexpected, given that the binding constant for a single U−U base−base interaction in a non-hydrogen bonding organic solvent (e.g., $CHCl_3$), is estimated to be less than 10^2 M^{-1} and orders of magnitude weaker than known cationic lipids such as DOTAP binding to DNA in water (*19*). Lipid **4** also possesses a hydrophobic section, which entails two oleyl chains. These chains were selected since previous studies have shown that this chain length and unsaturation was the most efficient for gene transfer in the cationic lipid family (*20*). Herein, we report the synthesis of 2′,3′-dioleyl-5′-(trimethylammonio)-uridine (DOTAU), the lipoplex formed between DNA and DOTAU, cytotoxicity, and successful in vitro gene delivery.

Synthesis. A nucleoside-based cationic lipid derived from uridine was synthesized as shown in Scheme 1. After preparation of the uridine acetonide **1** in acidic conditions, this intermediate was treated with tosyl chloride in pyridine to afford the 5′-tosylate nucleoside derivative, **2**. Hydrolysis of the acetonide protecting group followed by a coupling reaction with oleic acid using the standard reagent DCC to the 2′ and 3′ secondary alcohols of **2** afforded the intermediate **3**. Next, **3** was transferred to a pressure tube and treated for 2 days with trimethylamine in acetonitrile to give the final lipid product, **4**. Importantly,

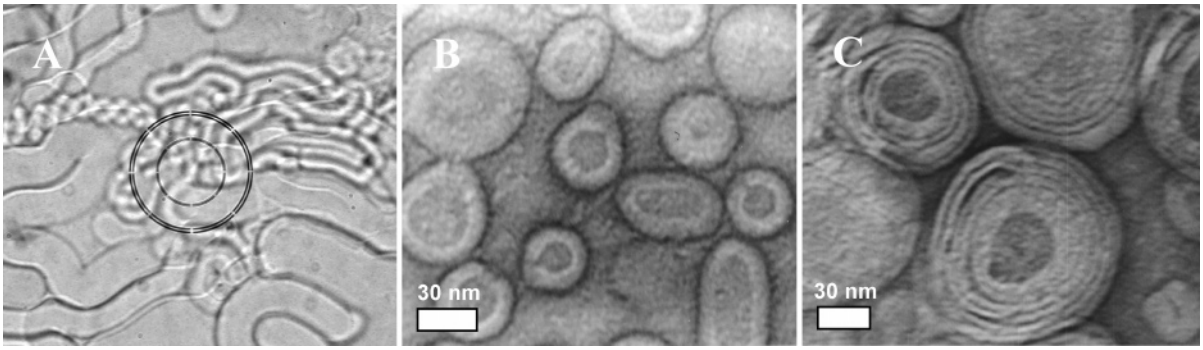


Figure 2. (A) Light micrograph of DOTAU "worm-like" structures upon hydration (internal circle is 14 μm, method A). (B) TEM images of SUV obtained after extrusion of DOTAU through a 50 nm filter. (C) TEM micrograph of DOTAU lipoplexes resulting from the incubation of CT-DNA.

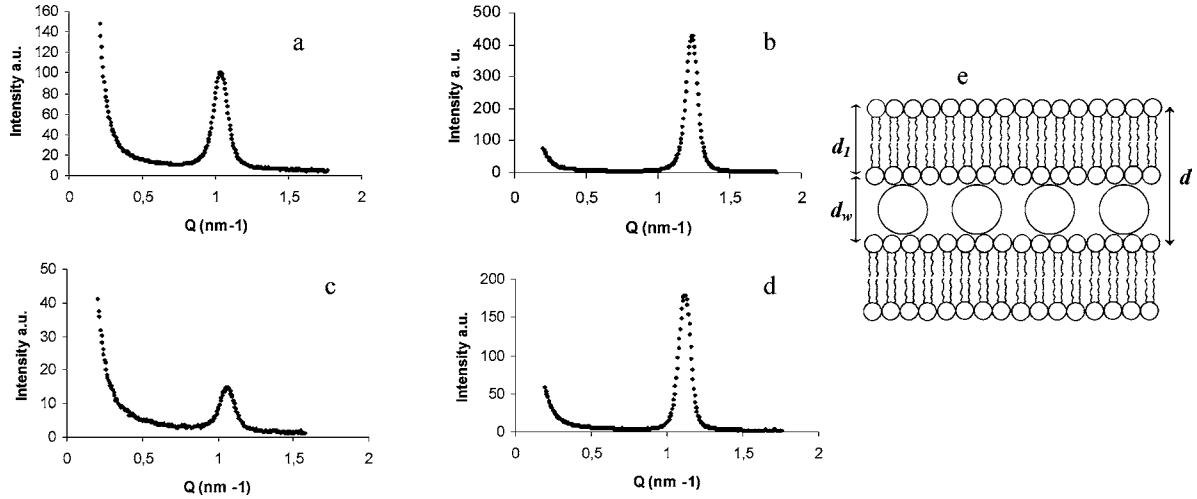

Figure 3. SAXS profiles of (a) CT-DNA/DOTAU, (b) poly A/DOTAU, (c) CT-DNA/DOTAP, and (d) poly A/DOTAP complexes showing Bragg peaks at Q (0.1041 Å^{-1}), Q (0.1241 Å^{-1}), Q (0.1061 Å^{-1}), and Q (0.1131 Å^{-1}), and corresponding lamellar repeat distances d of 6.0 nm, 5.0, 5.9, and 5.6 nm, respectively. SAXS measurements realized on samples containing only DOTAU in the absence of nucleic acids (data not shown) give a repeat period of 4.6 $\pm$ 0.2 nm. (e) Schematic drawing of a CL-DNA complex in the L_α^C phase, displaying a condensed multilamellar structure with DNA rods intercalated between lipid bilayers. The key length scales are the bilayer spacing d and the interaxial DNA spacing dDNA.

the synthetic strategy developed allows easy access in four steps to only one stereoisomer of the lipid.

Supramolecular Assembly Studies. The supramolecular structures formed by **4** in aqueous solution with and without DNA were studied by light and transmission electronic microscopy (TEM). Lipid **4** was observed to self-assemble at room temperature into liposome-like structures in aqueous solutions. Under these conditions, at room temperature, the oleyl chains are in a "fluid" state. This result is consistent with that reported previously for phosphocholine uridine derivatives (*18*). Interestingly, the presence of both a nucleobase and a cationic charge on the molecular structure does not prohibit the formation of lamellar phases. Depending on the procedure used, different sizes of liposomes ranging from 60 nm to 15 μm can be prepared. Light microscopy and TEM experiments were initially performed on samples without DNA. Solid lipid material can be hydrated directly on a glass slide (method A). Under this experimental setup, hydration was followed visually under a microscope and vesicular organization and/or multilamellar systems were observed. A light micrograph of supramolecular organizations forming on a hydrated thin film of DOTAU is shown in Figure 2. Another typical procedure (method B) to form self-assembled structures involves extrusion. In this procedure, 3 mg of the lipid was first dissolved in 1 mL of buffer (Tris buffer: 20 mM Tris, 100 mM NaCl, 10 μM EDTA, pH 7.4). After 20 min of agitation at room temperature, the liposomes were extruded through a polycarbonate filter (50 nm) 10 times at 21 °C to obtain small unilamellar vesicles (SUV). Particle sizing using a QELS showed supramolecular organizations of approximately 60 nm. The presence of this SUV population was confirmed by TEM experiments (see Figure 2b). TEM experiments were also performed on samples prepared with DNA. For this experiment, a SUV population of the lipid was prepared as described above, and then these vesicles were incubated for 5 h in the presence of calf thymus DNA (CT-DNA). TEM micrographs of the DNA−lipid supramolecular assemblies exhibited a typical multilamellar structure called a lipoplex as shown in Figure 2c. The apparent size of the bilayer was estimated to be roughly 6−7 nm, suggesting that the DNA macromolecules are entrapped within the organized structures.

SAXS Studies. To further characterize the molecular organization within the DNA supramolecular assemblies, small-angle X-ray scattering (SAXS) experiments were performed with lipid **4** in the presence of either calf thymus double stranded or polyadenylic acid single strand DNA. For lamellar lipoplexes, the repeat distance of the lipid−DNA multilayer d is related to the membrane thickness d_1 and solvent thickness containing DNA in the intermembrane space d_w via the expression: $d = d_w + d_1$ (Figure 3e). Data collected from several SAXS experiments at room temperature show that CT-DNA/lipid complexes arrange into L_α^C lamellar phases. For reference, supramolecular assemblies of DOTAP/CT-DNA and DOTAU/CT-DNA at 20 °C possess lamellar repeat periods d of 5.9 $\pm$ 0.2 nm and 6.0 $\pm$ 0.2 nm, respectively (Figure 3c and 3a). A priori, since DOTAU possesses a larger polar head volume than DOTAP, such a result indicates that the uracil moiety of DOTAU does not increase the d_w distance. It can be postulated that the uracil is closely associated to the DNA double helix.

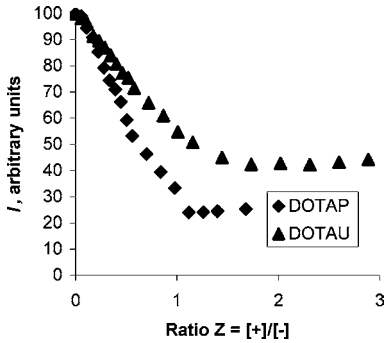

Figure 4. EB exclusion assays with DOTAP and DOTAU in the presence of CT-DNA (fluorescence intensity versus charge ratio).

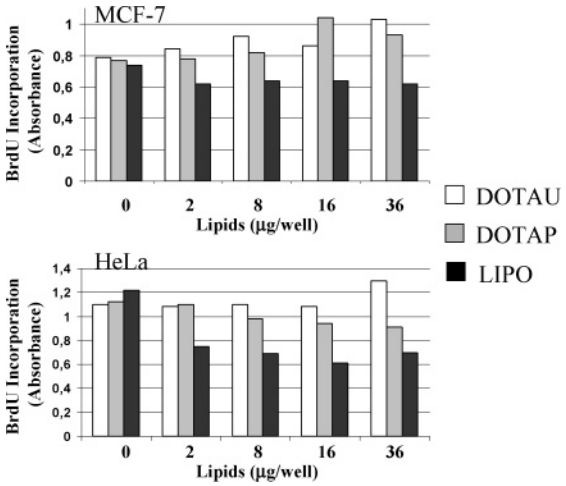

Figure 5. Effects of nucleoside lipids on cell proliferation. MCF-7 (top) and HeLa cells (bottom) were incubated with various quantities of lipids then BrdU was added to the cells.

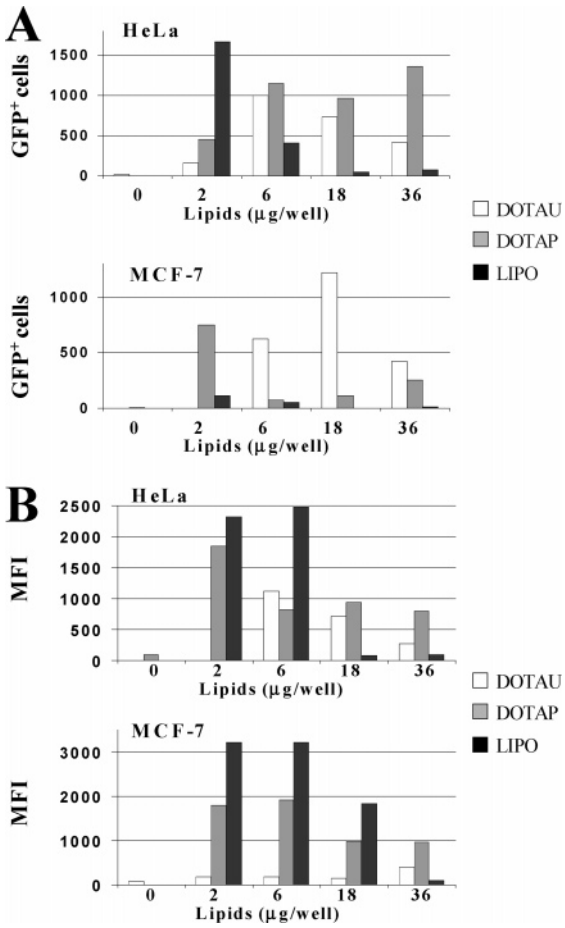

Figure 6. Transfection efficiency of nucleoside lipids. The pEGFP vector (2.5 μg) was transiently transfected into HeLa (top histograms) or MCF-7 cells (bottom histograms) using various quantities of lipotransfectant. After transfection, cells were analyzed by FACS. In part A, the number of GFP positive cells is reported. The MFI of GFP positive cells is reported in part B.

As expected, the distance *d* decreases when a poly A single strand is added to the liposome solutions, indicating more compact structures, which are likely due to smaller d_w distances. Interestingly, the DOTAU/poly A lipoplexes exhibit a repeat period of $d = 5.0 \pm 0.2$ nm (Figure 3b), which is 0.6 nm smaller than DOTAU/poly A lipoplexes ($d = 5.6 \pm 0.2$ nm) (Figure 3d). In that case, the smaller *d* value observed may be attributed to tighter association involving the uracil base of DOTAU and adenine of the poly A single strand. The infrared spectrum of the DOTAU/poly A lipoplex in the KBr pellet shows a carbonyl stretch at 1712 cm^{-1} for the C_2═O uracil-associated stretching vibration and both C═N and C═C ring vibrations characteristic of adenine upon duplexation in RNA (*21*), confirming U−A hydrogen bonding in the DOTAU/poly A complex.

Ethidium Bromide Exclusion Assays. The formation of the DNA−lipid complexes was also studied using an ethidium bromide (EB) exclusion assay (*22*). The binding affinity of the nucleoside-based lipid to CT-DNA was investigated by the fluorescence titration of EB with a premixed solution of DNA and various concentrations of lipid **4**. In the presence of DNA, the fluorescence emission of EB is enhanced relative to that in water as a result of EB intercalation between the DNA base pairs (*23*). The subsequent addition of lipids to the DNA-EB solution results in lipid binding to DNA and displacement of EB from the DNA helix to water, which yields a decrease in fluorescence intensity. As expected, the fluorescence intensity decreases rapidly for DOTAU and DOTAP (Figure 4). The binding curves for DOTAP and DOTAU indicate that 1:1 and 1:1.5 charge complexes are formed, respectively, between DNA and the lipids. The residual fluorescence intensity of 45% measured for DOTAU above a charge ratio of 1.5 indicates that certain portions of DNA are still exposed to EB (*24*). In the same conditions, DOTAP induces a residual fluorescence intensity of 20%. These results would suggest that DOTAU exhibits a lesser ability to condense DNA compare to DOTAP.

Cell Proliferation. The effect on mammalian cell lines proliferation of the nucleoside lipids was compared to a commercially available transfectant, Lipofectamine 2000 (LIPO). As shown in Figure 5, the incorporation of BrdU into HeLa or MCF-7 DNA is not affected by DOTAU or DOTAP, as the absorbance does not decrease in the presence of these cationic lipids. In contrast, in both cell types, the incorporation of BrdU decreases in the presence of Lipofectamine 2000. The effect is much stronger in HeLa cells than in MCF-7 cells as the absorbance is respectively reduced by 50% and 15% in the presence of Lipofectamine 2000. These proliferation assays show that the nucleoside lipids do not inhibit cell proliferation and appear to be less toxic than the commercial Lipofectamine 2000.

Transfection. To investigate the efficiency of DOTAU to transfer DNA into cells, we performed transient transfection assay of mammalian cell lines (HeLa and MCF-7). The transfected DNA is an expression vector (pEGFP) encoding GFP which fluorescence can be detected by FACS. Various quantities of cationic lipids were mixed with 2.5 μg of pEGFP, and then lipoplexes were incubated with HeLa or MCF-7 cells. Single-cell suspensions were analyzed by FACS. The GFP negative and positive gates were defined using the control experiment

carried out in absence of lipoplex. In each experiment 5000 cells were sorted, the results are shown in Figure 6 and in Supporting Information Figure 1. DOTAU is efficient for transfection at a concentration of 6 μg/well. At a concentration of 36 μg/well, approximately 400 cells are GFP positive. With DOTAP, 2 μg/well is the best concentration to transfect MCF-7 cells. Higher quantities are necessary to transfect 20% of Hela cells; however, an equivalent transfection efficiency is obtained with concentrations of 6, 18, and 36 μg/well. In comparison, the commercial Lipofectamine 2000 is efficient only at 2 μg/well, while higher quantities induce a strong decrease of transfection efficiency. Therefore, it appears that the nucleoside lipid is efficient in a wider range of concentration compared to Lipofectamine 2000; likely this feature might be linked to the low cell toxicity of these products. It must be underlined that ongoing transfection studies on nucleolipid analogues have shown similar results with high transfection efficiency only at high charge ratios. The mean fluorescence intensities (MFI) defined for GFP positive cells reveal that the level of GFP expression with a higher MFI value correlated with a high GFP expression. Surprisingly, transfection carried out with DOTAU is characterized by low MFI values (around 1000 for Hela cells and 400 for MCF-7). DOTAP and Lipofectamine 2000 lead respectively to medium MFI values (around 1900) and high MFI values (around 3000) (Figure 6). This study reveals that cells transfected using DOTAU express GFP at a low level. For the moment we can only speculate about the basis of this observation. One possibility is that DOTAU/DNA lipoplex might contain less DNA molecules than the lipoplex formed with DOTAP or Lipofectamine 2000. Another possibility is that the vectors do not reach the nuclei where DNA is transcribed because DOTAU/DNA lipoplex might dissociate in the cytoplasm instead of the nuclei. Only at higher nucleolipid concentrations compared to Lipofectamine 2000 can we observe increased transfection efficiencies. Further studies are in progress to confirm these hypotheses.

CONCLUSION

The results obtained by SAXS, TEM studies, ethidium bromide exclusion assays, and FTIR clearly indicate that the cationic nucleolipid DOTAU interacts with both DNA double helix and polyadenylic acid single strand. Transfection assays of mammalian cell lines (HeLa and MCF-7) reveal that DOTAU can efficiently transfect a high number of cells with a low level of gene expression by cells (compare to DOTAP and Lipofectamine). This aspect could be of interest in the case of gene overexpression; the possibility of this novel nucleolipid to tune gene expression could be exploited when transfection of toxic proteins is needed, for example. The proliferation assays realized on the same cell lines show that the nucleoside lipid DOTAU does not inhibit cell proliferation and is less toxic than the commercial Lipofectamine 2000. In summary, the data reported here suggest that the presence of a nucleoside moiety on the cationic lipid has an impact on the lipoplex efficiency and cell toxicity. The results collected for this biocompatible lipid suggest its potential use as a transfection reagent for mammalian cells and in vitro applications for gene therapy. Further cell biology experiments, such as cellular uptake studies and intracellular trafficking experiments aimed at understanding subcellular localizations of the nucleolipid/DNA complexes, are planned to gain better mechanistic insights into the origin of the contrasting transfection profiles of these novel nucleolipids.

A Novel Ternary Ligand System Useful for Preparation of Cationic ^{99m}Tc-Diazenido Complexes and ^{99m}Tc-Labeling of Small Biomolecules

Young-Seung Kim, Zhengjie He, Wen-Yuan Hsieh, and Shuang Liu*

Department of Industrial and Physical Pharmaceuticals, Division of Nuclear Pharmacy, Purdue University, 575 Stadium Drive, West Lafayette, Indiana 147907-205. Received September 7, 2005; Revised Manuscript Received December 5, 2005

This report describes a novel ternary ligand system composed of a phenylhydrazine, a crown ether-containing dithiocarbamate (DTC), and a PNP-type bisphosphine (PNP). The combination of three different ligands with ^{99m}Tc results in cationic ^{99m}Tc-diazenido complexes, $[^{99m}Tc(NNAr)(DTC)(PNP)]^+$, with potential radiopharmaceuticals for heart imaging. Synthesis of cationic ^{99m}Tc-diazenido complexes can be accomplished in two steps. For example, the reaction of phenylhydrazine with $^{99m}TcO_4^-$ at 100 °C in the presence of excess stannous chloride and 1,2-diaminopropane-*N*,*N*,*N*′,*N*′-tetraacetic acid (PDTA) results in the $[^{99m}Tc(NNPh)(PDTA)_n]$ intermediate, which then reacts with sodium *N*-(dithiocarbamato)-2-aminomethyl-15-Crown-5 (L4) and *N*,*N*-bis[2-(bis(3-ethoxypropyl)phosphino)ethyl]ethoxyethylamine (PNP6) at 100 °C for 15 min to give the complex, $[^{99m}Tc(NNPh)(L4)(PNP6)]^+$ in high yield (>90%). Cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ are stable for ≥6 h. Their composition was determined to be 1:1:1:1 for Tc:NNPh:DTC:PNP using the mixed-ligand experiments on the tracer (^{99m}Tc) level and was further confirmed by the ESI-MS spectral data of a model compound $[Re(NNPh)(L4)(L6)]^+$. It was found that both DTCs and bisphosphines have a significant impact on the lipophilicity of their cationic ^{99m}Tc-diazenido complexes. Results from a ^{99m}Tc-labeling efficiency experiment showed that 4-hydrazinobenzoic acid (HYBA) might be useful as a bifunctional coupling agent for ^{99m}Tc-labeling of small biomolecules. However, the ^{99m}Tc-labeling efficiency of HYBA is much lower than that of 6-hydrazinonicotinic acid (HYNIC) with tricine and trisodium triphenylphosphine-3,3′,3″-trisulfonate (TPPTS) as coligands.

INTRODUCTION

Abrams and co-workers first reported the use of arylhydrazines, including 4-hydrazinobenzoic acid (HYBA) and 6-hydrazinonicotinic acid (HYNIC), as bifunctional coupling agents (BFCs) for ^{99m}Tc-labeling of polyclonal IgG (*1*, *2*). Since then, HYNIC has been used for the ^{99m}Tc-labeling of antibodies (*3*, *4*), chemotactic peptides (*5*−*8*), somatostatin analogues (*9*−*14*), antisense oligonucleotides (*15*, *16*), folate receptor ligands (*17*), and polypeptides (*18*, *19*). The advantage of HYNIC is its high labeling efficiency (*20*, *21*). Since HYNIC occupies only one coordination site, coligands are needed to complete the Tc coordination sphere (Figure 1). The use of coligands, such as glucoheptonate and tricine, allows easy modification of hydrophilicity and pharmacokinetics of ^{99m}Tc-labeled biomolecules. The use of HYNIC for ^{99m}Tc-labeling of small biomolecules has recently been reviewed (*22*−*26*).

For the last several years, we have been using a ternary ligand system (Figure 1: HYNIC, tricine, and TPPTS) for the ^{99m}Tc-labeling of chemotactic peptides (*27*, *28*) and LTB_4 receptor antagonists (*29*−*31*), integrin $\alpha_v\beta_3$ antagonists (*32*), and GPIIb/IIIa receptor antagonists (*33*−*37*) in attempt to develop new target-specific radiopharmaceuticals. It was found that this ternary ligand system forms very stable ^{99m}Tc complexes $[^{99m}Tc(HYNIC-BM)(tricine)(TPPTS)]$ (BM = biomolecule) with high specific activity (>20000 mCi/μmol). Through a series of mixed ligand experiments, the composition of these ternary ligand ^{99m}Tc complexes was determined to be 1:1:1:1 for Tc:HYNIC−BM:tricine:TPPTS and has been confirmed by LC-MS at both the tracer (^{99m}Tc) and macroscopic (^{99}Tc) levels (*38*, *39*). Like phosphines, pyridine analogues (Figure 1) were also used as coligands for ^{99m}Tc-labeling of biomolecules (*40*−*42*). Unlike phosphines, pyridine analogues are much smaller and more amendable for further derivatization. Despite the

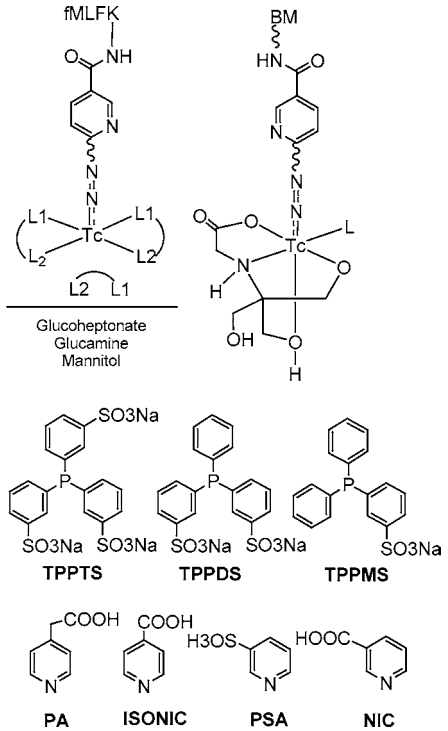

Figure 1. Binary and ternary ligand ^{99m}Tc complexes of HYNIC-conjugated biomolecules (HYNIC−BM). The combination of HYNIC, tricine, and a phosphine or pyridine analogue results in a versatile ternary ligand system that forms ternary ligand ^{99m}Tc complexes $[^{99m}Tc(HYNIC-BM)(tricine)(TPPTS)]$ (BM = biomolecule) with extremely high solution stability.

success of HYNIC, very little has been reported on the use of HYBA as a BFC for the ^{99m}Tc-labeling of small biomolecules, and the cationic ^{99m}Tc(III)-diazenido complexes as radiotracers for scintigraphic imaging.

It is well-documented that arylhydrazines form highly stable Tc(III)-hydrazino and Tc(III)-diazenido complexes (*43*−*53*). To understand the coordination chemistry of HYNIC with Tc, a number of heteroatom-containing arylhydrazines, such as 2-hydrazinopyridine (HYPY), have been used as model compounds for preparation of their Tc(III) and Re(III) complexes with various coligands (*54*−*62*). It was found that the binding modality and number of HYPY ligands in Tc(III)/Re(III) complexes depend on the nature and availability of coligands. Like HYPY, phenylhydrazine analogues also bind strongly to Tc(III) to form the Tc(III)-diazenido core. Cationic complexes $[^{99}Tc(NNPh\text{-}R)(PP)_2Cl]^+$ (R = H, CH_3, Cl, and NO_2; PP = bisphosphine) have been reported (*45*−*47*). However, it is not clear if they are able to maintain their cationic character in biological system since the chloride ligand may become dissociated to form the dicationic species $[^{99m}Tc(NNPh\text{-}R)(PP)_2]^{2+}$ at the tracer (^{99m}Tc) level.

Recently, we found that the combination of phenylhydrazine with a crown ether-containing dithiocarbamate (DTC) and a PNP bisphosphine (PNP) and resulted in a novel ternary ligand system that forms stable cationic complexes, $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ (Figure 2: DTC = L1−L5; PNP = PNP5, PNP6, and L6), in high yield. The ether-containing bisphosphines and crown ether-containing DTCs are used for three purposes: (1) to stabilize the ^{99m}Tc-diazenido core, (2) to control the cationic character of the ^{99m}Tc-diazenido complexes, and (3) to balance their lipophilicity so that the heart uptake and target-to-background (T/B) ratios can be optimized systematically. We are interested in HYBA for its potential as a BFC for the ^{99m}Tc-labeling of small biomolecules, and cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ for their potential as new radiopharmaceuticals in myocardial perfusion imaging.

In this report, we present the use of this ternary ligand system for preparation cationic ^{99m}Tc-diazenido complexes and for the ^{99m}Tc-labeling of HYBA. The main objective of this study is: (1) to explore radiolabeling conditions for preparation of cationic ^{99m}Tc-diazenido complexes, (2) to study the impact of both DTC and bisphosphine coligands on the lipophilicity of cationic ^{99m}Tc-diazenido complexes, and (3) to demonstrate the utility of HYBA as a BFC for the ^{99m}Tc-labeling of small biomolecules. This study represents the first to use the crown ether-containing DTCs for modifying the lipophilicity of cationic ^{99m}Tc radiotracers. Results from biodistribution and imaging studies on cationic ^{99m}Tc-diazenido complexes in rats will be reported in a separate communication elsewhere (*63*).

EXPERIMENTAL SECTION

Instruments and Methods. Chemicals and reagents were purchased from Sigma/Aldrich (St. Louis). NMR (^{1}H and ^{13}C) spectral data were recorded on a 300 MHz Bruker spectrometer, and chemical shifts are reported as δ in ppm relative to TMS. ^{31}P NMR spectra were recorded on a 300 MHz Bruker spectrometer using 85% phosphoric acid as the external reference. Mass spectral data were collected on a Finnigan LCQ mass spectrometer, School of Pharmacy, Purdue University. Elemental analysis was performed by Dr. H. Daniel Lee using a Perkin-Elmer Series III analyzer, Department of Chemistry, Purdue University. *N*,*N*-Bis(ethoxyethyl)dithiocarbamate (DBODC) was prepared according to the literature method (*64*−*66*).

Radio-HPLC Method 1 used a LabAlliance semi-prep HPLC system with a β-Ram IN-US detector, and a Zorbax C_8 column (4.6 mm × 150 mm, 100 Å pore size). The flow rate was 1 mL/min. The mobile phase was isocratic with 30% solvent A (25 mM NH_4OAc buffer, pH = 6.8) and 70% solvent B (methanol) at 0−5 min, followed by a gradient from 70% solvent B at 5 min to and 90% solvent B at 20 min. Radio-HPLC Method 2 was almost identical to method 1 except the mobile phase was isocratic with 30% solvent A (25 mM NH_4OAc buffer, pH = 6.8) and 70% solvent B (methanol) at 0−10 min, followed by a slow gradient from 70% solvent B at 10 min to and 90% solvent B at 20 min. The radio-HPLC Method 3 was slightly different from Method 1, and used an isocratic mobile phase with 50% solvent A (25 mM NH_4OAc buffer, pH = 6.8) and 50% solvent B (methanol) at 0−5 min, followed by a gradient from 50% solvent B at 5 min to and 90% solvent B at 20 min.

General Procedure for Synthesis of the Crown Ether-Containing DTCs. To an ice-cold solution of aminomethyl

crown ether or aza-crown ether (2.0 mmol) and sodium hydroxide (0.08 g, 2.0 mmol) in 6 mL of ethanol was added dropwise carbon disulfide (0.30 g, 2.0 mmol). The mixture was stirred at 0−5 °C for 2−3 h, during which a white precipitate was formed. To the reaction mixture was added 40 mL of diethyl ether with vigorous stirring. The supernatant was decanted and discarded. The white precipitate was washed twice with diethyl ether (2 × 10 mL) and dried under vacuum overnight to give the final product.

Sodium *N*-(Dithiocarbamato)-1-aza-12-crown-4 (L1): The yield was 92%. ^{1}H NMR (D_2O): 4.22 (t, 4H, J = 5.1 Hz), 3.83 (t, 4H, J = 5.1 Hz), and 3.59 (m, 8H). ^{13}C NMR (D_2O, DMSO-d_6 as internal reference): 212.7 (C═S), 71.8, 71.2, 70.8, and 56.8 (crown ether ring carbons). Anal. (Calcd) for $C_9H_{16}NO_3S_2Na$: C, 39.52 (39.54); H, 6.11 (5.90); N, 4.81 (5.12).

Sodium *N*-(Dithiocarbamato)-1-aza-15-crown-5 (L2): The yield was 67%. ^{1}H NMR (D_2O): 4.13 (t, 4H, J = 5.7 Hz), 3.77 (t, 4H, J = 5.7 Hz), and 3.56 (m, 12H). ^{13}C NMR (D_2O, DMSO-d_6 as internal reference): 212.8 (C═S), 71.4, 71.2, 70.8, 69.8, and 57.7 (crown ether ring carbons). Anal. (Calcd) for $C_{11}H_{20}NO_4S_2Na$: C, 41.58 (41.62); H, 6.48 (6.35); N, 4.44 (4.41).

Sodium *N*-(Dithiocarbamato)-1-aza-18-crown-6 (L3): The yield was 84%. ^{1}H NMR (D_2O): 4.19 (t, 4H, J = 6.0 Hz), 3.70 (t, 4H, J = 6.0 Hz), and 3.52 (m, 16H). ^{13}C NMR (D_2O, DMSO-d_6 as internal reference): 205.7 (C═S), 71.9, 70.9 (m), 69.5, 56.7 (crown ether ring carbons). Anal. (Calcd) for $C_{13}H_{24}NO_5S_2Na$: C, 43.12 (43.20); H, 6.92 (6.69); N, 3.77 (3.88).

Sodium *N*-(Dithiocarbamato)-2-aminomethyl-15-crown-5 (L4): The yield was 99%. ^{1}H NMR (D_2O): 3.80−3.72 (m, 2H), 3.64−3.45 (m, 17H), and 3.41 (m, 2H). ^{13}C NMR (D_2O, DMSO-d_6 as internal reference): 214.0 (C═S), 78.1, 72.0, 71.1, 71.0, 70.8, 70.7, 70.6, 70.5, 70.4, 70.3 (crown ether carbons), and 49.4 (CH_2N). Anal. (Calcd) for $C_{12}H_{22}NO_5S_2Na$: C, 41.22 (41.48); H, 6.53 (6.38); N, 3.82 (4.03).

Sodium *N*-(Dithiocarbamato)-2-aminomethyl-18-crown-6 (L5): The yield was 95%. ^{1}H NMR (D_2O): 3.78 (m, 2H), 3.66−3.40 (m, 21H), and 3.37 (m, 2H). ^{13}C NMR (D_2O, DMSO-d_6 as internal reference): δ 197.0 (C═S), 78.5, 72.0, 71.5, 71.0, 70.9, 70.8 (m), 70.2, 70.0 (crown ether carbons), and 47.7 (CH_2N). Anal. (Calcd) for $C_{14}H_{26}NO_6S_2Na$: C, 41.22 (41.25); H, 6.51 (6.43); N, 3.19 (3.44).

General Procedure for Preparation of Bisphosphines (PNP5, PNP6, and L6). N-Substituted Bis(2-Diethoxyphosphorylethyl)amine (1). A mixture of the primary amine (2.0 mmol) and excess diethyl vinylphosphonate (4.4−6.0 mmol) in 10 mL of ethanol was refluxed for 7−12 days. The solvent and excess vinylphosphonate were evaporated under reduced pressure, and the crude product was purified by column chromatography using silica gel as the solid phase and a mixture of CH_2Cl_2−methanol (20:1 = v:v) as the mobile phase.

***N*-Methoxyethyl-*N*,*N*-Bis(2-Diethoxyphosphorylethyl)amine (1a):** The yield was 77%. ^{1}H NMR ($CDCl_3$): 4.09 (m, OCH_2CH_3, 8H), 3.44 (t, J = 5.7 Hz, CH_3OCH_2, 2H), 3.33 (s, CH_3OCH_2, 3H), 2.82 (dt, J = 7.7, 8. Hz, NCH_2CH_2P, 4H), 2.64 (t, J = 5.7 Hz, OCH_2CH_2, 2H), 1.92 (m, NCH_2CH_2P, 4H), 1.32 (t, J = 7.0 Hz, OCH_2CH_3, 12H). ^{13}C NMR ($CDCl_3$): 70.7, 61.4 (d, J = 6.2 Hz), 58.8, 52.2, 46.9, 23.1 (d, J = 136.4 Hz), 16.3 (d, J = 5.8 Hz). ^{31}P NMR ($CDCl_3$): 28.6 ppm.

***N*-Ethoxyethyl-*N*,*N*-Bis(2-Diethoxyphosphorylethyl)amine (1b).** The yield was 74%. ^{1}H NMR ($CDCl_3$): 4.08 (m, OCH_2CH_3, 8H), 3.49 (t, J = 5.7 Hz, $CH_3CH_2OCH_2$, 2H), 3.47 (q, J = 7.0 Hz, $CH_3CH_2OCH_2$, 2H), 2.81 (dt, J = 7.7, 8.1 Hz, NCH_2CH_2P, 4H), 2.64 (t, J = 5.7 Hz, OCH_2CH_2, 2H), 1.93 (m, NCH_2CH_2P, 4H), 1.32 (t, J = 7.0 Hz, OCH_2CH_3, 12H), 1.18(t, J = 7.0 Hz, $CH_3CH_2OCH_2$, 3H). ^{13}C NMR ($CDCl_3$): 68.7, 66.4, 61.4 (d, J = 6.2 Hz), 52.3, 47.1, 23.3 (d, J = 136.3 Hz), 16.4 (d, J = 5.8 Hz), 15.1. ^{31}P NMR ($CDCl_3$): 28.7 ppm.

N-Substituted Bis(2-Phosphinoethyl)amine (2). *All manipulations were carried out under nitrogen atmosphere using standard Schlenk line.* A solution of the bisphosphonate **1** (2.0 mmol) in 5 mL of anhydrous THF was added dropwise into a stirred suspension of lithium aluminum hydride (8.0 mmol) in 5 mL of anhydrous THF. After the initial exothermal reaction subsided, the reaction mixture was heated under reflux for 16 h. The reaction mixture was cooled to room temperature, and 20 mL of ether was added into it. The excess lithium aluminum hydride was hydrolyzed by cautious addition of 3% sodium hydroxide solution (2−3 mL). The ethereal layer was separated from the precipitate via cannula transfer. Another 20 mL of ether was used to wash the precipitate. The combined ether layers were dried over anhydrous sodium sulfate, then filtered, and evaporated to afford the desired product **2** as colorless liquid. This crude product was used in next step reaction without further purification and characterization.

N-Substituted *N*,*N*-Bis[2-(Bis(3-Ethoxypropyl)phosphino)-ethyl]amine (PNP5, PNP6, and L6). Bisphosphine **2** (1.0 mmol), allylethyl or allylmethyl ether (9.0 mmol), and VAZO 67 (1,1′-azobis-(cyclohexanecarbonitrile), 0.2 mmol) were dissolved in 5 mL of ethanol, and the resulting mixture was heated to reflux for 20 h. Volatiles were removed under vacuum, and the residue was mixed thoroughly with 3 mL of 6 M hydrochloric acid. The resulting mixture was extracted twice with diethyl ether (2 × 10 mL), and the ethereal layer was discarded via cannula transfer. The pH of the aqueous layer was adjusted >12 using 20% (w/w) sodium hydroxide solution. The aqueous layer was extracted three times with ether (3 × 10 mL). The combined ether layers were dried over anhydrous sodium sulfate, filtered, and then acidified with 4 M hydrogen chloride in dioxane until there was no more white precipitate. The supernant solution was separated from the precipitate and discarded. The precipitate was washed with diethyl ether (2 × 10 mL) and dried under vacuum to afford the desired product (PNP5, PNP6, and L6) as a colorless viscous oil. Since all bisphosphines are extremely air-sensitive under basic conditions, they were isolated as the hydrochloride salts, and stored under inert atmosphere all the time.

***N*-Ethoxyethyl-*N*,*N*-bis[2-(bis(3-methoxypropyl)phosphino)ethyl]amine (PNP5).** The yield was 84%. ^{1}H NMR ($CDCl_3$): 4.10−3.20 (m, $CH_3CH_2OCH_2CH_2N$, NCH_2CH_2P, CH_2OCH_3, 22H), 3.35(s, $PCH_2CH_2CH_2OCH_3$, 12H), 2.63 (m, $PCH_2CH_2CH_2$, 8H), 1.99 (m, $PCH_2CH_2CH_2$, 8H), 1.18(t, J = 7.0 Hz, $CH_3CH_2OCH_2CH_2N$, 3H). ^{31}P NMR ($CDCl_3$): 10.4 ppm. ESI-M: m/z = 497 ($[M + H]^+$).

***N*-Ethoxyethyl-*N*,*N*-bis[2-(bis(3-ethoxypropyl)phosphino)-ethyl]amine (PNP6).** The yield was 74%. ^{1}H NMR ($CDCl_3$): 4.10−3.20 (m, $CH_3CH_2OCH_2CH_2N$, NCH_2CH_2P, $CH_2OCH_2CH_3$, 30H), 2.62 (m, $PCH_2CH_2CH_2$, 8H), 2.05 (m, $PCH_2CH_2CH_2$, 8H), 1.20 (t, J = 6.9 Hz, OCH_2CH_3, 12H), 1.18 (t, J = 7.0 Hz, $CH_3CH_2OCH_2CH_2N$, 3H). ^{31}P NMR ($CDCl_3$): 11.5 ppm. ESI-M: m/z = 553 ($[M + H]^+$).

***N*-Methoxyethyl-*N*,*N*-bis[2-(bis(3-ethoxypropyl)phosphino)ethyl]amine (L6):** The yield was 68%. ^{1}H NMR ($CDCl_3$): 4.00−3.20 (m, OCH_2CH_2N, NCH_2CH_2P, $CH_2OCH_2CH_3$, 28H), 3.38 (s, CH_3O, 3H), 2.72 (m, $PCH_2CH_2CH_2$, 8H), 2.01 (m, $PCH_2CH_2CH_2$, 8H), 1.20 (t, J = 7.0 Hz, OCH_2CH_3, 12H). ^{31}P NMR ($CDCl_3$): 12.0 ppm. ESI-MS: m/z = 539 ($[M + H]^+$).

General Procedure for Preparation of ^{99m}Tc-Diazenido Complexes. To a 5 mL vial was added 1.0 mL of 0.5 M NH_4-OAc buffer containing PDTA (5 mg/mL) and arylhydrazine (1 mg/mL), followed by addition of 0.5 mL $Na^{99m}TcO_4$ solution (~20 mCi) in saline, and 20 μL $SnCl_2$ solution (1 mg/mL) in 1.0 N HCl. The reaction mixture was heated at 100 °C for 10 min to form the ^{99m}Tc-diazenido intermediate. To the reaction mixture above was added 0.5 mL of the solution containing

the DTC chelator (2 mg) and bisphosphine (2 mg). The vial was heated at 100 °C for another 10−15 min. After cooling to room temperature, a sample of the resulting solution was analyzed by ITLC and radio-HPLC. In all cases, the ^{99m}Tc-colloid formation was minimal.

Determination of Log *P* Values of Cationic ^{99m}Tc-Diazenido Complexes. The Log *P* values of cationic ^{99m}Tc-diazenido complexes were determined using the following procedure: the cationic ^{99m}Tc-diazenido complex was prepared and purified by HPLC. HPLC mobile phases were evaporated under reduced pressure and the residue was dissolved in a mixture of equal volume (3 mL:3 mL) *n*-octanol and 25 mM phosphate buffer (pH = 7.4). After vertex for at least 20 min, samples (in triplets) from *n*-octanol and aqueous layers were counted in a gamma counter (Beckman Gama 8000). The *P* values was calculated using the following equation: P = (activity concentration in *n*-octanol)/(activity concentration in aqueous layer). For comparison, we also determined the log *P* values of ^{99m}Tc-Sestamibi and ^{99m}TcN-DBODC5.

Solution Stability of Cationic ^{99m}Tc-Diazenido Complexes. For the solution stability in kit matrix, cationic ^{99m}Tc-diazenido complexes were prepared and were analyzed by radio-HPLC at 0, 1, 2, 3, and 6 h post-labeling. For the stability in diluted solutions, the cationic ^{99m}Tc-diazenido complex was prepared, and the resulting solution was diluted to 10−20 μCi/mL. Samples of the dilute solution were analyzed by radio-HPLC at 0, 1, 2, 3, and 6 h. For the cysteine challenging experiment, the cationic ^{99m}Tc-diazenido complex was prepared, and the reaction mixture was mixed with an equal volume of a cysteine solution (1 mg/mL). Samples of the resulting solution were analyzed by radio-HPLC at 0, 1, 2, 3, and 6 h.

Composition Studies of Cationic ^{99m}Tc-Diazenido Complexes. Number of DTCs. To a 5 mL vial was added 1.0 mL of 0.5 M NH_4OAc buffer containing PDTA (5 mg/mL) and phenylhydrazine (1 mg/mL), 0.5 mL of $Na^{99m}TcO_4$ solution (∼10 mCi), and 20 μL $SnCl_2$ solution (1 mg/mL) in 1.0 N HCl. The mixture was heated at 100 °C for 10 min. To the mixture above was added DBODC (2 mg), L4 (2 mg), L5 (2 mg), and PNP5 (2 mg) in 0.5 mL of 50% ethanol. The vial was heated at 100 °C for 15 min. After cooling to room temperature, a sample of the resulting solution was analyzed by radio-HPLC.

Number of Bisphosphines. To a 5 mL vial was added 1.0 mL of 0.5 M NH_4OAc buffer containing PDTA (5 mg/mL) and phenylhydrazine (1 mg/mL), 0.5 mL of $Na^{99m}TcO_4$ solution (∼10 mCi), and 20 μL $SnCl_2$ solution (1 mg/mL) in 1.0 N HCl. The mixture was heated at 100 °C for 10 min. To the mixture above was added L4 (2 mg), PNP5 (2 mg), and PNP6 (2 mg) in 0.5 mL of 50% ethanol. The vial was heated at 100 °C for another 15 min. After cooling, a sample of the resulting solution was analyzed by radio-HPLC.

^{99m}Tc-Labeling Efficiency of HYBA. To a 5 mL vial was added 1.0 mL of 0.5 M NH_4OAc buffer containing PDTA (5 mg/mL) and HYBA (1−100 μg/mL), followed by addition of 0.5 mL $Na^{99m}TcO_4$ solution (∼10 mCi) in saline, and 20 μL $SnCl_2$ solution (1 mg/mL) in 1.0 N HCl. The mixture was heated at 100 °C for 10 min. To the mixture were added L4 (2 mg) and PNP6 (2 mg) in 0.5 mL of saline. The vial was heated at 100 °C for 15 min. After cooling to room temperature, a sample of the resulting mixture was analyzed by radio-HPLC.

Preparation of [Re(NNPh)(L4)(L6)]$^{+}$. $[ReCl_2(NNPh)(PPh_3)_2(CH_3CN)]$ was prepared directly from $[^nNBu_4][ReO_4]$ according to the literature method (*67*). To a 10 mL vial were added $[ReCl_2(NNPh)(PPh_3)_2(CH_3CN)]$ (18.5 mg, 0.02 mmol), 2.0 mL of chloroform, 1.0 mL of 0.5 M NH_4OAc buffer (pH = 5.0), and 2 mL of ethanol solution containing L6 (25 mg, 0.046 mmol). The reaction mixture was heated at 100 °C for 10 min to form the $[ReCl_2(NNPh)(L6)]$ intermediate. To the reaction mixture above was added 0.5 mL of the 0.5 M NH_4OAc buffer solution containing L4 (20 mg, 0.062 mmol). The vial was heated at 100 °C for another 10−15 min. After removal of volatiles, the residue was dissolved in 6 mL of methanol and water mixture (70:30 = v:v). The resulting solution was subjected to HPLC purification. The HPLC method used a LabAlliance semi-prep HPLC system equipped with a LabAlliance UV/visible detector (model 500, λ = 254 nm) and a Zorbax C_{18} semi-prep column (9.4 mm × 250 mm, 300 Å pore size). The flow rate was 2.5 mL/min. The mobile phase was isocratic with 30% solvent A (water) and 70% solvent B (methanol) at 0 − 5 min, followed by a gradient from 70% solvent B at 5 min to and 90% solvent B at 20 min. The fraction at ∼15 min due to the cationic complex $[Re(NNPh)(L4)(L6)]^+$ was collected. The combined fractions were combined and lyophilized to give a brown oil. The HPLC concordance experiment was performed by co-injecting HPLC-purified $[Re(NNPh)(L4)(L6)]^+$ and $[^{99m}Tc(NNPh)(L4)(L6)]^+$.

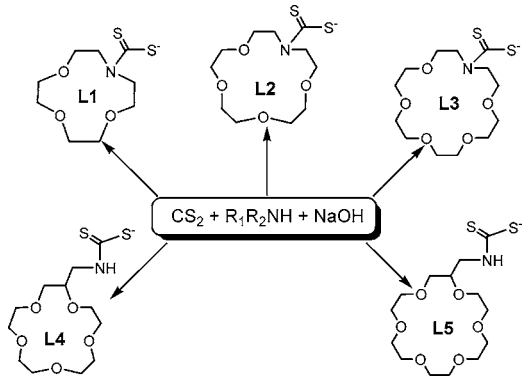
RESULTS AND DISCUSSION

^{99m}Tc-Diazenido Complex Design. It is well-documented that arylhydrazines form highly stable Tc(III)-diazenido complexes when appropriate coligands are used (*43*−*53*). Since aryldiazenido is monodentate, triphenylphosphine (Ph_3P), *N*,*N*′-bis(salicylidene)ethane (salen), *N*,*N*-dimethyldithiocarbamate (DMDC), and 1,2-bis(diphenylphosphino)ethane (DPPE) have been used as coligands to stabilize the Tc(III)-diazenido core. For example, the complex $[^{99m}Tc(NNPh)(DPPE)_2Cl]^+$ has a slight distorted octahedral coordination geometry with the PhNN and chloride occupying the *trans*-axial sites, and the P-donors from two DPPTE coligands occupying four equatorial sites. $[^{99m}Tc(NNC_6H_4)(salen)(Ph_3P)]^+$ also has a distorted octahedral coordination geometry with salen and Ph_3P as coligands (*48*). In the complex $[^{99}Tc(NNC_6H_4Cl)(DMDC)_2(Ph_3P)]$, PhNN and Ph_3P are monodentate, and two DMDC chelators occupy the other four remaining coordination sites of technetium (*46*).

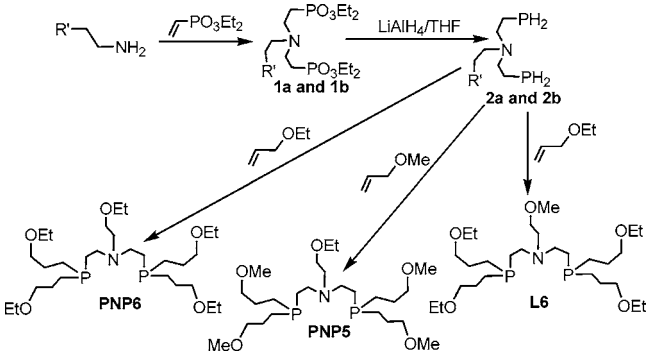
Recently, Duatti's group reported a series of cationic ^{99m}Tc-nitrido complexes with ether-containing DTC and PNP-type bisphosphine coligands (*64*−*66*). It was found that the cationic complex $[ReN(DEDC)(PNP2)]^+$ (DEDC = *N*,*N*-diethyldithiocarbamate; PNP2 = bis[(2-diphenylphosphino)ethyl]methoxyethylamine) had a distorted octahedral coordination geometry with the amine-N atom weakly bonded to the Tc (*64*, *66*). The combination of DTC and bisphosphine coligands is critical in maintaining the cationic character of Tc-nitrido complexes. On the basis of these findings, we propose that the combination use of phenylhydrazine, a bisphosphine, and a DTC might result in a ternary ligand system that forms cationic complexes, $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ (Figure 2: DTC = L1−L5; and PNP = PNP5, PNP6, and L6), with potential as radiopharmaceuticals for heart imaging. This new ternary ligand system may also be useful for the ^{99m}Tc-labeling of small biomolecules.

Choice of DTCs and Bisphosphines. During the development of ^{99m}Tc-Sestamibi, it was discovered that ether groups in isonitriles greatly improved biodistribution properties of the radiotracer (*68*−*72*). Studies on the Q-series of cationic ^{99m}Tc complexes also show that ether groups from the phosphine coligands improve excretion kinetics of radiotracers (*73*−*75*). The results from biodistribution studies showed that ether groups from DTC and bisphosphine coligands play a significant role in heart uptake and excretion kinetics of cationic ^{99m}Tc-nitrido complexes (*76*−*78*). For example, ^{99m}Tc-N-DBODC5 (Figure 1) is rapidly extracted by the rat myocardium and is retained in the heart for a long time. The liver activity is almost completely eliminated into intestine at 60 min postinjection. The heart/liver ratio was higher than that of ^{99m}Tc-Sestamibi and ^{99m}Tc-Tetrofosmin (*76*, *77*). In contrast, ^{99m}TcN-DBODC6 has a lower

Scheme 1. Synthesis of Crowned DTCs (L1−L5)



Scheme 2. Synthesis of the Bisphosphines (PNP5, PNP6, and L6)



heart uptake and much lower target-to-background (T/B) ratios than ^{99m}TcN-DBODC5 due to its high lipophilicity (*76, 77*), even though they share the same bidentate DBODC chelator. These results clearly show that it is possible to design cationic ^{99m}Tc radiotracers with a high heart uptake and fast liver clearance by *balancing* their lipophilicity with the ether- or crown ether-containing groups. That is why in this study we use the ether-containing bisphosphines (PNP5, PNP6, and L6) and the crown ether-containing DTCs (L1−L5) as coligands to prepare cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ (DTC = L1−L5; PNP = PNP5, PNP6, and L6).

Synthesis of L1 − L5. The crown containing DTCs (L1−L5) were synthesized according to Scheme 1. Aza-crown ethers (1-aza-12-crown-4, 1-aza-15-crown-5, 1-aza-18-crown-6) and aminomethyl-crown ethers (2-aminomethyl-15-crown-5 and 2-aminomethyl-18-crown-6) are commercially available from Aldrich/Sigma. The aza-crown or aminomethyl-crown ether reacts with carbon disulfide in the presence of sodium hydroxide to give the corresponding DTC as its sodium salt in high yield (80−90%). L1−L5 were purified by recrystallization from a mixture of ethanol and diethyl ether and were characterized by NMR (^{1}H and ^{13}C) and elemental analysis.

Synthesis of PNP5, PNP6, and L6. PNP5, PNP6, and L6 were prepared according to the literature method (*64, 66*) using 2-methoxyethylamine and 2-ethoxyethylamine as starting materials (Scheme 2). The primary amine reacted with excess diethyl vinylphosphonate to produce the bisphosphonate intermediate $ROCH_2CH_2N(CH_2CH_2PO_3Et_2)_2$ (**1a**: R = Me, and **1b**: R = Et), which was then reduced with $LAlH_4$ in anhydrous THF to afford the bisphosphine intermediate $ROCH_2CH_2N(CH_2CH_2PH_2)_2$ (**2a**: R = Me, and **2b**: R = Et). The reaction of **2** with excess allylmethyl or allylethyl ether in the presence of a radical initiator, such as VAZO 67, produced PNP5, or PNP6 and L6. Since they are very air-sensitive under basic conditions, all PNP-type bisphosphines (PNP5, PNP6, and L6) were isolated as hydrochloride salts, and should be stored under inert atmosphere at all times. PNP5, PNP6, and L6 were characterized by NMR (^{1}H and ^{31}P) and ESI-MS.

Synthesis and Characterization of Cationic ^{99m}Tc-Diazenido Complexes. Cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ (DTC = L1−L5; PNP = PNP5, PNP6, and L6) were prepared according to Scheme 3. First, $^{99m}TcO_4^-$ reacted with phenylhydrazine in the presence of excess stannous chloride and PDTA to give the $[^{99m}Tc(NNPh)(PDTA)]^-$ intermediate, which reacted with a DTC and a PNP to form the cationic complex $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ (DTC = L1−L5; PNP = PNP5, PNP6, and L6), which were analyzed using reversed HPLC method. The HPLC retention times are listed in Table 1. Figure 3 shows a typical HPLC chromatograms for cationic complexes $[^{99m}Tc(NNPh)(L2)(PNP6)]^+$ and $[^{99m}Tc(NNPh)(L4)(PNP6)]^+$. The RCP was 80−90% with one or two small peaks (5−12%) as the main radioimpurities (Figure 3) for the synthesized cationic ^{99m}Tc-diazenido complexes. The amount of radioimpurities is largely dependent upon the quality of the bisphosphine while changing the DTC has little impact on the amount of these radioimpurities. Therefore, it is reasonable to believe that the radioimpurities are caused by the partial oxidation of the bisphosphine during preparation.

We tried to use HYPY to replace phenylhydrazine for preparation of cationic complexes $[^{99m}Tc(HYPY)(L4)(L)]^+$ (L = PNP5, PNP6, and L6) and found that the resulting mixture often contains several ^{99m}Tc-containing species (Figure SI) most likely due to the fact that HYPY itself is a bidentate chelator and may compete with bisphosphines as coligands for ^{99m}Tc-bonding. In addition, HYPY has several bonding modalities with the Tc(III) and Re(III) (*61, 62*).

PDTA is a transferring ligand to stabilize the $[^{99m}Tc(NNPh)(PDTA)]^-$ intermediate. The PDTA concentration in each vial can be varied from 2 to 10 mg/vial. Lower PDTA level (<1.0 mg/vial) often results in a significant amount of ^{99m}Tc-colloid. PDTA can be replaced by other polyaminocarboxylates, such as ethylenediamine-*N*,*N*-diacetic acid (EDDA), ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA), and *N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′-triacetic acid (HEDTA). However, replacing PDTA with tricine always results in formation of several ^{99m}Tc-containing species in the reaction mixture (Figure SII).

The new ternary ligand system is composed of three different ligands (phenylhydrazine, DTC, and a PNP bisphosphine), all of which can influence the yield and purity of their cationic ^{99m}Tc-diazenido complexes. For example, the DTC and bisphosphine levels in each vial can be varied from 0.5 to 5.0 mg/vial. In all cases, cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ (DTC = L1−L5; PNP = PNP5, PNP6, and L6) can be prepared in high yield (RCP = 80−90%). Lower DTC and bisphosphine levels (<0.1 mg/vial) often result in incomplete reaction with the $[^{99m}Tc(NNPh)(PDTA)]^-$ intermediate. The level of phenylhydrazine can be varied in the range of 0.5−2.0 mg using PDTA as the transferring ligand. Lower phenylhydrazine concentration will results in a significant amount of more hydrophilic radioimpurities as demonstrated by the radiolabeling efficiency experiments.

The ^{99m}Tc-Labeling Efficiency of HYBA. For HYBA to be useful as a BFC, it must show a high ^{99m}Tc-labeling efficiency. In this study, we used PDTA (5 mg/vial) as the transferring ligand. The concentration of DTC and bisphosphine coligands was 2.0 mg/vial. It was found that the RCP for $[^{99m}Tc(HYBA)(L4)(PNP6)]$ was still >90% when the HYBA concentration is 100 μg/vial (6.85×10^{-7} mole, FW = 146) for 10 mCi of $^{99m}TcO_4^-$ ($\sim 7 \times 10^{-11}$ mole of ^{99m}Tc and ^{99}Tc for 24 h generator). The HYBA/Tc ratio is about 10000:1 under the radiolabeling conditions used in this study. This specific activity (~15 Ci/mmol) is much lower than that obtained with

Scheme 3. Synthesis of Cationic Complexes [^{99m}Tc(NNPh)(DTC)(PNP)]$^+$ (DTC = L1−L5; PNP = PNP5, PNP6, and L6)

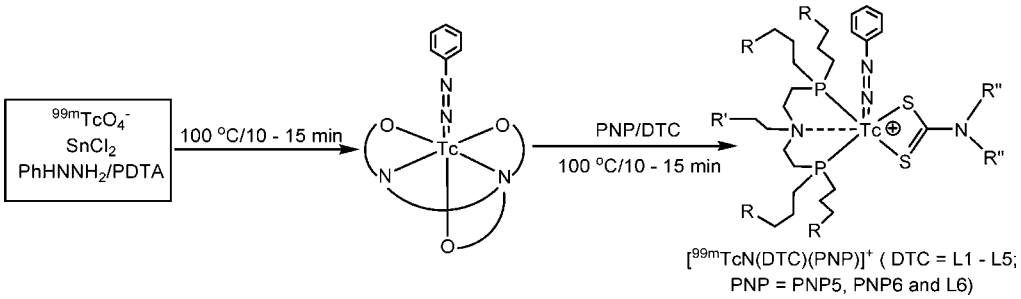


Table 1. The RCP Data and Radio-HPLC Retention Times of Cationic ^{99m}Tc-Nitrido Complexes

compound	radiochem purity (%)	HPLC retention time (min)[a]	log *P* value
^{99m}Tc−Sestamibi	>98	16.5	1.29 ± 0.15

[a] The HPLC retention times were obtained using Method 1.

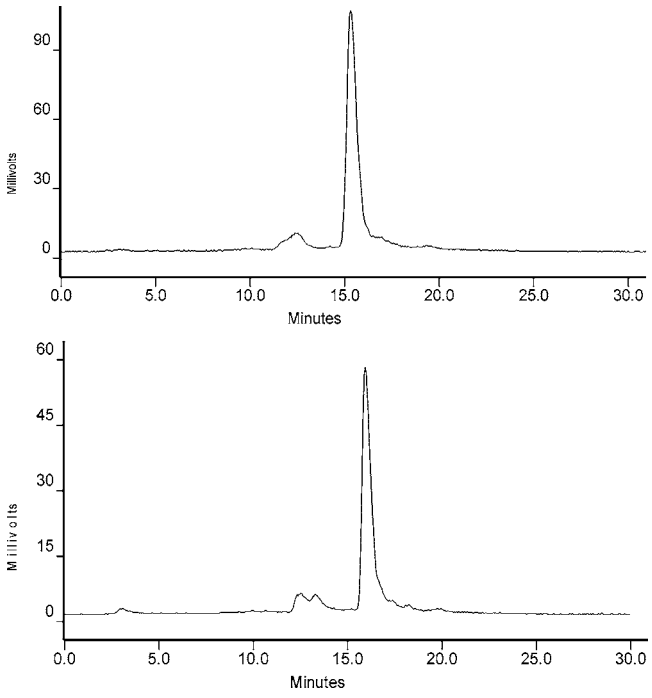

Figure 3. Typical radio-HPLC chromatograms (Method 1) for cationic complexes [^{99m}Tc(NNPh)(L2)(PNP6)]$^+$ and [^{99m}Tc(NNPh)(L4)(PNP6)]$^+$. Small radioimpurity peaks at ~12.5 min are most likely caused by the partial oxidation of the bisphosphine during preparation.

HYNIC with the BFC, tricine, and TPPTS as coligands (*34*, *40*). The low ^{99m}Tc-labeling efficiency of HYBA may also be caused by the use of PDTA as the transferring ligand that forms the [^{99m}Tc(NNPh)(PDTA)]$^-$ intermediate with low reactivity toward ligand exchange (*1*, *2*, *34*, *40*). It is important to note that HYBA is just a BFC without the attached biomolecule, and the radiolabeling conditions have not been optimized yet. Our future research will focus on improvement of ^{99m}Tc-labeling efficiency of this novel ternary ligand system (HYBA-BM, DTC, and bisphosphine) by varying radiolabeling conditions (pH, buffering agents, transferring ligand, and reaction time or temperature), as well as the component levels.

Stability of Cationic ^{99m}Tc-Diazenido Complexes. High solution stability is a requirement for a useful cationic ^{99m}Tc radiotracer. In this experiment, we studied the solution stability of cationic complexes [^{99m}Tc(NNPh)(L4)(PNP)]$^+$ (PNP = PNP5, PNP6, and L6). It was found that they all remain stable for more than 6 h both in the kit matrix and after HPLC purification. The cysteine challenge experiment was also performed for cationic complexes [^{99m}Tc(NNPh)(L4)(PNP)]$^+$ (PNP = PNP5, PNP6, and L6). They are all relatively stable (>6 h) in the presence of cysteine (1.0 mg/mL) at ambient temperature. These results are consistent with their extremely high in vivo metabolic stability in rats (Figure SIII).

Log *P* Values of Cationic ^{99m}Tc-Diazenido Complexes. In addition to the charge, lipophilicity plays a significant role in the heart uptake of cationic ^{99m}Tc radiotracers. Therefore, we determined the partition coefficient constants by measuring the distribution of the HPLC purified cationic ^{99m}Tc-diazenido complexes in a mixture of equal volume *n*-octanol and 25 mM phosphate buffer (pH = 7.4). HPLC purification was needed to minimize possible interference from other radioimpurities. The log *P* values are summarized in Table 1. As the number of the ether linkage increases, the lipophilicity of cationic ^{99m}Tc-diazenido complexes decreases (lower log *P* value), indicating that the crown ether groups have a significant impact on the lipophilicity of cationic ^{99m}Tc-diazenido complexes. Like the crown ether-containing DTCs, bisphosphine coligands also have a significant impact on the lipophilicity of their cationic ^{99m}Tc-diazenido complexes. For example, cationic complexes [^{99m}Tc(NNPh)(DTC)(PNP6)]$^+$ (DTC = L1−L5) are much more lipophilic than [^{99m}Tc(NNPh)(DTC)(PNP5)]$^+$ (DTC = L1−L5) due to the presence of four ethoxypropyl groups in PNP6 instead of four methoxypropyl groups in PNP5. It is very interesting to note that substituents on the aromatic benzene ring have little impact on the lipophilicity of their cationic ^{99m}Tc-diazenido complexes, which explains why we had difficulties in determining the number of phenyldiazenido ligands in cationic ^{99m}Tc-diazenido complexes.

Examination of the heart uptake mechanism of ^{99m}Tc-Sestamibi indicates that the cationic charge and lipophilicity are important for its accumulation and retention in myocardium (*68*−*72*). If the ^{99m}Tc radiotracer is too lipophilic (log *P* >1.5), it often shows a high protein binding and slow liver clearance. If the ^{99m}Tc radiotracer is too hydrophilic (log *P* <0), it tends to have a low heart uptake and fast heart washout. In both cases, the heart/liver ratio is low due to either high liver uptake or fast myocardial washout (*74*, *75*). In this study, we use crown ether-containing DTCs and ether-containing bisphosphines to

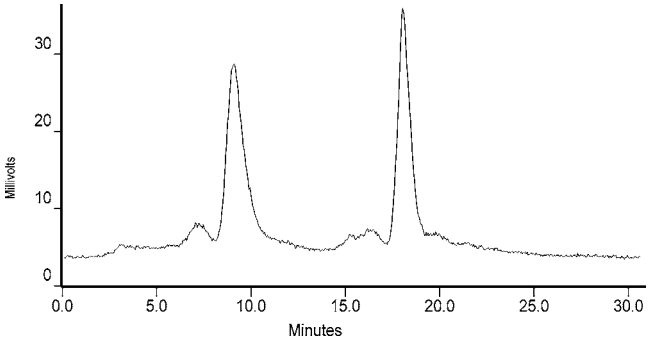

Figure 4. A typical radio-HPLC chromatogram (Method 2) of the reaction mixture containing cationic complexes $[^{99m}Tc(NNPh)(L4)(PNP5)]^+$ and $[^{99m}Tc(NNPh)(DBODC)(PNP5)]^+$.

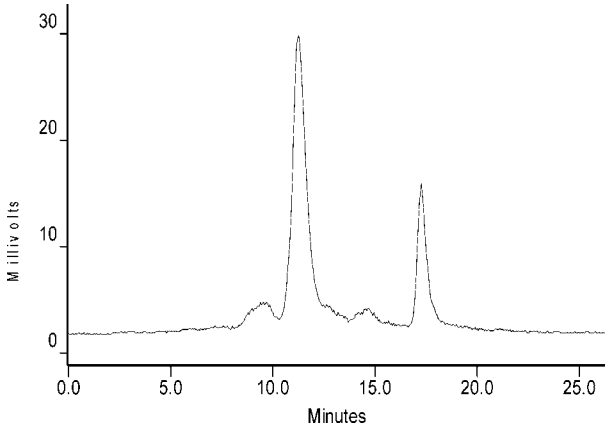

Figure 5. Radio-HPLC chromatogram (Method 1) of the reaction mixture containing cationic complexes $[^{99m}Tc(NNPh)(L4)(PNP5)]^+$ (left) and $[^{99m}Tc(NNPh)(L4)(PNP6)]^+$.

balance the lipophilicity of cationic ^{99m}Tc-diazenido complexes so that their heart uptake and excretion kinetics can be optimized in a systematic fashion. We are interested cationic ^{99m}Tc-diazenido complexes with the log *P* values similar to that of ^{99m}TcN-DBODC5, which was reported to have the best heart-to-liver ratio (*76*−*78*). On the basis of log *P* values (Table 1), we believe that $[^{99m}Tc(NNPh)(L4)(L6)]^+$ might show a heart uptake and heart/liver ratio equivalent to those of ^{99m}TcN-DBODC5 due to their almost identical log *P* values (1.10 ± 0.07 for $[^{99m}Tc(NNPh)(L4)(L6)]^+$ and 1.09 ± 0.10 for ^{99m}TcN-DBODC5). Recent results (Figure SIV) from imaging and biodistribution studies support this hypothesis.

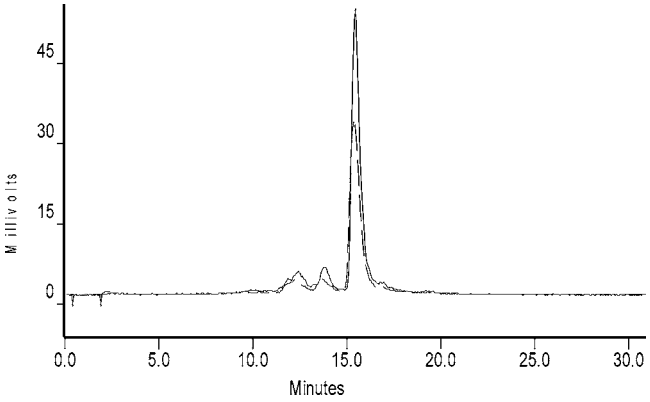

Figure 6. Typical radio-HPLC chromatograms (Method 1) for cationic complexes $[^{99m}Tc(NNPh)(L2)(L6)]^+$ (solid line) and $[^{99m}Tc(NNPh\text{-}2,5\text{-}Me_2)(L4)(L6)]^+$ (dashed line). Small radioimpurity peaks at ∼12.5 min are most likely caused by the partial oxidation of the bisphosphine during preparation.

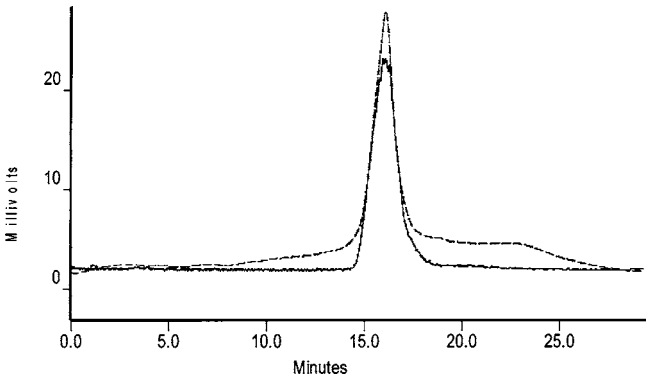

Figure 7. The HPLC concordance (Method 1) for the HPLC-purified $[Re(NNPh)(L4)(L6)]^+$ (dashed line) and $[^{99m}Tc(NNPh)(L4)(L6)]^+$ (solid line).

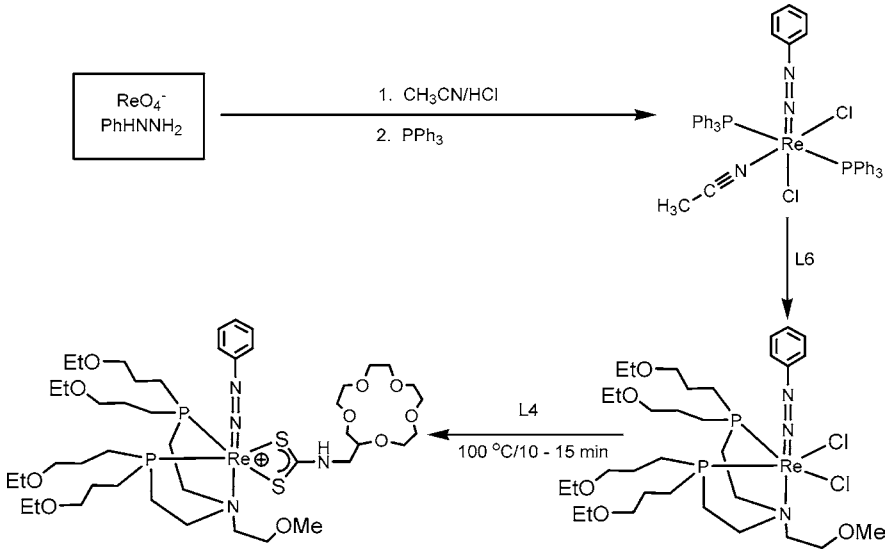
Composition Studies of Cationic ^{99m}Tc-Diazenido Complexes. The mixed-ligand experiment was performed to determine the composition of cationic ^{99m}Tc-diazenido complexes according to the procedure described in our previous report (*40*). In the first experiment, we used PNP5 as the bisphosphine coligand, L4 and DBODC as the competing chelators. After radiolabeling, the reaction mixture was analyzed by radio-HPLC. If only one DTC is bonded to the Tc, the HPLC chromatogram should show two peaks: one from $[^{99m}Tc(NNPh)(L4)(PNP5)]^+$ and the other from $[^{99m}Tc(NNPh)(DBODC)(PNP5)]^+$. If there

Scheme 4. Synthesis of $[Re(NNPh)(L4)(L6)]^+$



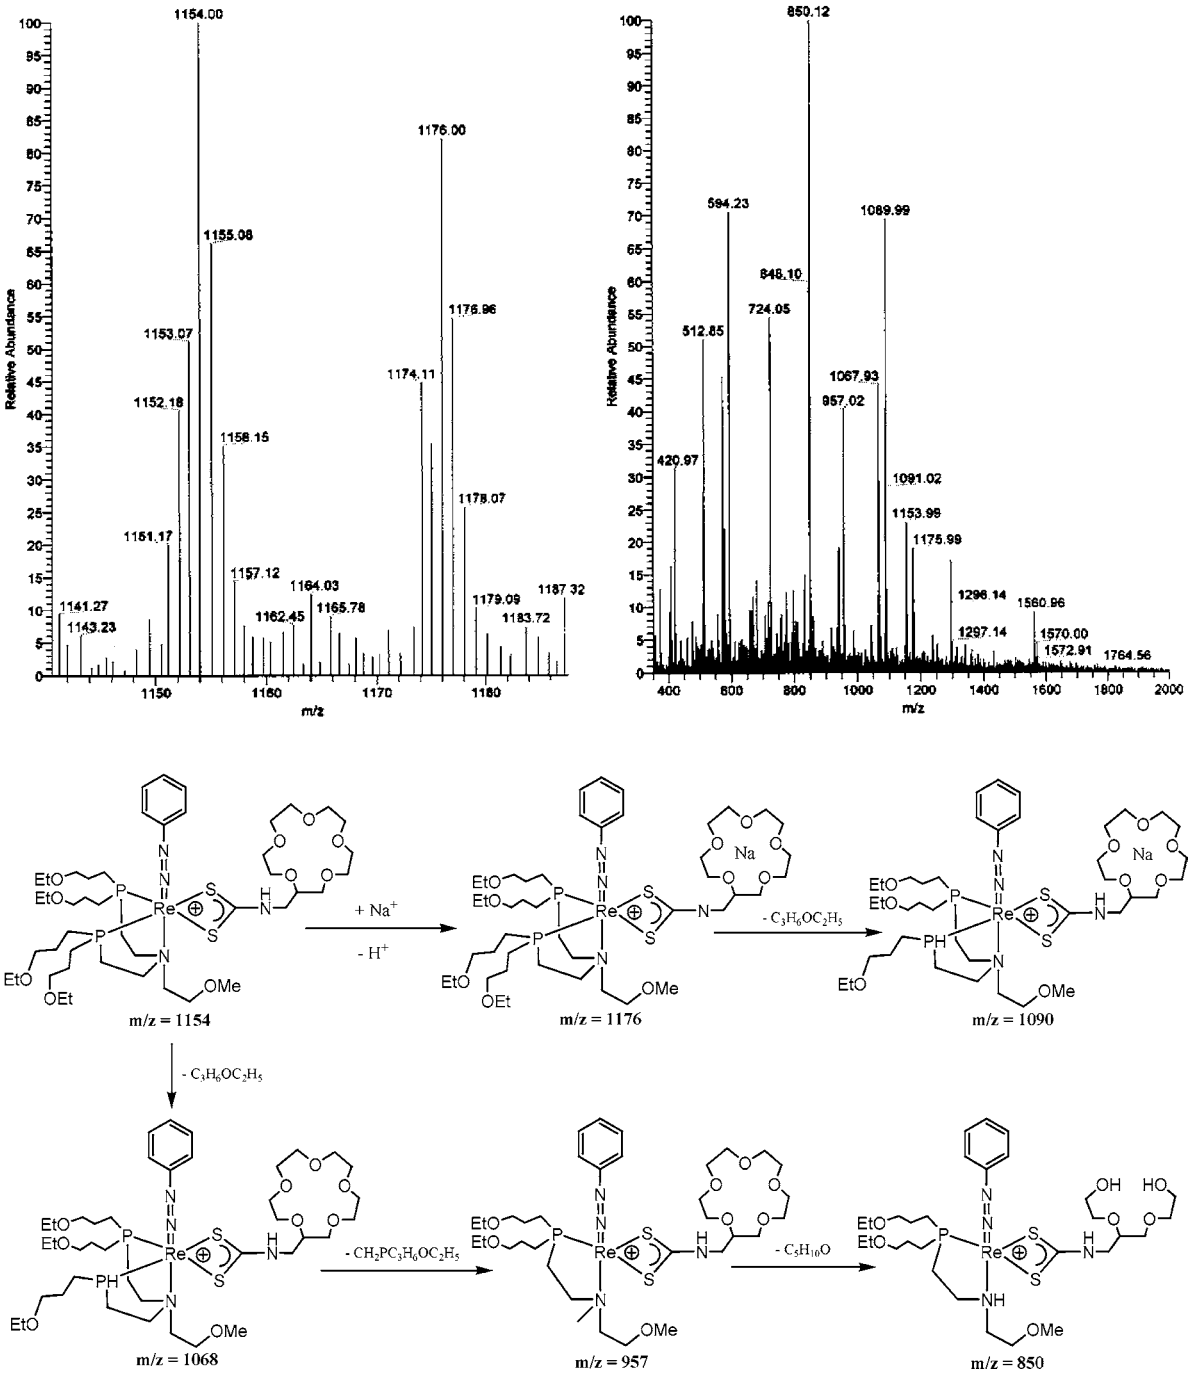


Figure 8. ESI mass spectrum (top) and the proposed fragmentation pattern (bottom) for the cationic complex $[Re(NNPh)(L4)(L6)]^+$.

were two DTC chelators bonded to the Tc, a third peak from the mixed-ligand complex, $[^{99m}Tc(NNPh)(L4)(DBODC)(PNP5)]^+$. The presence of only two radiometric peaks in the HPLC chromatogram (Figure 4) clearly shows that there is only one DTC in cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$.

The number of bisphosphine ligands in $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ was determined in a similar fashion using L4 as the DTC chelator, and PNP5 and PNP6 as competing coligands. Figure 5 shows the typical radio-HPLC chromatogram of the resulting reaction mixture. The peaks at 11.5 min is due to the cationic complex $[^{99m}Tc(NNPh)(L4)(PNP5)]^+$, and the peak at 17.5 min is from the cationic complex $[^{99m}Tc(NNPh)(L4)(PNP6)]^+$. This clearly demonstrates that there is only one bisphosphine coligand in cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$.

We made many attempts to determine the number of phenyldiazenido ligands in cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ using phenylhydrazine, 4-methoxyphenylhydrazine, 4-chlorophenylhydrazine, 4-methylphenylhydrazine, and 2,5-dimethylphenylhydrazine as competing ligands. Regardless of the DTC and bisphosphine coligands, cationic complexes $[^{99m}Tc(NNPh\text{-}R)(DTC)(PNP)]^+$ (R = H, Cl, OCH_3, and 2,5-Me_2) all showed very similar HPLC retention times. For example, cationic complexes $[^{99m}Tc(NNPh)(L4)(PNP6)]^+$ and $[^{99m}Tc(NNPh\text{-}2,5\text{-}Me_2)(L4)(PNP6)]^+$ have almost identical HPLC retention time (Figure 6). Thus, it is impossible to separate them using chromatographic conditions described in this study.

On the basis of the results from three mixed-ligand experiments and their similarity to cationic ^{99m}Tc-nitrido complexes, we believe that the cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ most likely have a distorted coordination geometry with one monodentate phenyldiazenido ligand, one bidentate DTC, and one bisphosphine coligand.

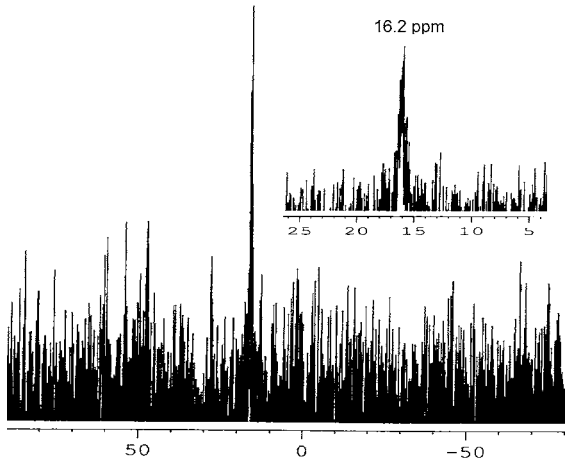

Figure 9. The ^{31}P NMR spectrum of $[Re(NNPh)(L4)(L6)]^+$.

Synthesis of $[Re(NNPh)(L4)(L6)]^+$. To further confirm the findings in the mixed ligand experiments, we decided to prepare $[Re(NNPh)(L4)(L6)]^+$ as a model compound for the cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$. Attempts to synthesize $[Re(NNPh)(L4)(L6)]^+$ from the direct reaction of $[^nNBu_4][ReO_4]$ using the procedure for $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ were not successful due to difficulty in the reduction of Re(VII) to Re(III), which reflects the significant difference in the redox chemistry of Re and Tc. Thus, we used $[ReCl_2(NNPh)(PPh_3)_2(CH_3CN)]$ as the starting material, and the substitution reaction was carried out in a mixture of chloroform, ethanol, and 0.5 N ammonium acetate buffer (pH = 5.0) according to Scheme 4. The acetonitrile and two PPh_3 ligands in $[ReCl_2(NNPh)(PPh_3)_2(CH_3CN)]$ were first replaced by L6 to give the intermediate complex $[ReCl_2(NNPh)(L6)]$, which was then reacted with L4 to give the cationic complex $[Re(NNPh)(L4)(L6)]^+$ in very low yield (<20% by UV/vis at λ = 254 nm), which is in sharp contrast to the high radiochemical purity (>95%) of the cationic complex $[^{99m}Tc(NNPh)(L4)(L6)]^+$ at the tracer level. After HPLC purification, only 1−2 mg of [Re(NNPh)(L4)(L6)]Cl was obtained for the HPLC concordance experiment, and spectroscopic characterization (ESI-MS, ^{1}H and ^{32}P NMR).

HPLC Concordance Experiment. We performed the HPLC concordance experiment using the HPLC-purified $[Re(NNPh)(L4)(L6)]^+$ and $[^{99m}Tc(NNPh)(L4)(L6)]^+$. Figure 7 shows the HPLC concordance of cationic complexes $[Re(NNPh)(L4)(L6)]^+$ (dashed line) and $[^{99m}Tc(NNPh)(L4)(L6)]^+$ (solid line). It is quite clear that they share the same composition due to their identical HPLC retention times.

Spectroscopic Characterization of $[Re(NNPh)(L4)(L6)]^+$. The ES-MS spectrum (Figure 8) shows the expected molecular ion at m/z = 1154 for $[Re(NNPh)(L4)(L6)]^+$ and 1176 for $[M + Na]^+$. On the basis of fragmentation patterns reported for cationic Re(V)-nitrido complexes, $[ReN(DTC)(PNP)]^+$ (*64*, *66*), we were able to identify several molecular fragments (Figure 8). The ^{31}P NMR spectrum (Figure 9) of $[Re(NNPh)(L4)(L6)]^+$ clearly shows a singlet at ∼16 ppm, which is almost identical to that (16.3 ppm) of the complex [Re(NPh)(O,O-cat)(PNMeP)]Cl (O,O-cat = catechol; PNMeP = bis[(2-diphenylphosphino)ethyl]methylamine) in the same solvent (*79*). The ESI-MS and NMR spectral data are completely consistent with our conclusion that the cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ contain one phenyldiazenido ligand, one bidentate DTC, and one bisphosphine coligand. More detailed structural and spectroscopic characterization of cationic Re(III)-diazenido complexes is still in progress.

CONCLUSIONS

This report describes the discovery of a new ternary ligand system for the ^{99m}Tc-labeling of small biomolecules and for preparation of cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ with potential as radiopharmaceuticals for heart imaging. The cationic ^{99m}Tc-diazenido complexes can be prepared in two steps with high yield and have very high solution stability. Their composition was determined to be 1:1:1:1 for Tc:NNPh:DTC:PNP through the mixed-ligand experiments on the tracer (^{99m}Tc) level and was further confirmed by the ESI-MS and NMR spectral data of a model compound $[Re(NNPh)(L4)(L6)]^+$.

Apparently, this new ternary ligand system offers several advantages. The cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ have high solution stability. Since no post-labeling chromatographic purification is needed for cationic Tc-diazenido complexes, the new ternary ligand system is amendable for the development of a kit formulation. All cationic complexes $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$ show only one radiometric peak in their HPLC chromatograms due to the "symmetric" nature of the Tc chelate. Their hydrophilicity can be modified by the choice of DTC and bisphosphine coligands. The toxicity of the crown ether-containing DTCs and phenylhydrazine should be minimal since they are used in small amount (<1 mg/25 mCi or 13 μg/kg if injected into a 75 kg patient).

It is important to note that LD_{50} values of crown ethers does not apply to the crown ether-containing DTCs because the N-functionalization will change their toxicity significantly. It is also important to emphasize that the formulation for preparing cationic ^{99m}Tc-diazenido complexes has not been optimized. Once a promising agent is identified, efforts will be made to optimize the formulation so that each components in the kit matrix can be minimized while maintaining the high RCP for the selected cationic complex $[^{99m}Tc(NNPh)(DTC)(PNP)]^+$.

Supporting Materials for the Manuscript Entitled

"A Novel Ternary Ligand System Useful for Preparation of Cationic ^{99m}Tc-Diazenido Complexes and ^{99m}Tc-Labeling of Small Biomolecules" by Young-Seung Kim, Zhengjie He, Wen-Yuan Hsieh, and Shuang Liu*

Figure SI. Typical radio-HPLC chromatogram (**Method 3**) of the reaction mixture containing the cationic complex $[^{99m}Tc(HYPY)(L4)(L6)]^+$. The large difference in retention times of two main peaks suggests that they might be two different compounds with completely different compositions.

Figure SII. Typical radio-HPLC chromatogram (**Method 1**) of the reaction mixture containing the cationic complex $[^{99m}Tc(NNPh)(L4)(L6)]^+$ prepared using PDTA (top) or tricine (bottom) as transferring ligands. The large difference in retention times of two main peaks suggests that they might not be the same compound and have different compositions.

Figure SIII. Radio-HPLC chromatograms of the cationic complex $[^{99m}Tc(NNPh)(L6)(L4)]^+$ in the kit matrix before injection (A), in the urine at 30 min postinjection (B), in the urine at 120 min postinjection (C), and in feces at 120 min postinjection (D). Each rat was administered with about 600 μCi of $[^{99m}Tc(NNPh)(L6)(L4)]^+$. Based on these results, it is quite clearly that the cationic ^{99m}Tc-diazenido complexes would have very high *in vivo* stability with little metabolism in rats under anesthesia.

Figure SIV. Planar images (no decay correction) of the Sprague-Dawley rats administered with ~600 μCi of $[^{99m}Tc(NNPh)(L4)(L6)]^+$ (left) and ^{99m}TcN-DBODC5 (right). Both rats were placed side-by-side so that they are compared in a direct fashion. Arrows indicate the location of the heart, liver and salivary gland (as determined by ex-vivo gamma counting).

Figure SV. ^{1}H NMR of the cationic complex $[Re(NNPh)(L4)(L6)]^+$.

Received August 1, 2005; Revised Manuscript Received February 1, 2006

The radiolanthanides ^{149}Pm, ^{166}Ho, and ^{177}Lu have decay characteristics suitable for radioimmunotherapy (RIT) of cancer. *N*-Hydroxysulfosuccinimidyl DOTA (DOTA-OSSu) and methoxy-DOTA (MeO-DOTA) were conjugated to the anti-TAG-72 monoclonal antibody CC49 for radiolabeling with ^{149}Pm, ^{166}Ho, and ^{177}Lu. While both DOTA conjugates could be labeled to high specific activity with ^{177}Lu, MeO-DOTA afforded superior conjugate stability, radiolabeling, and radiochemical purity. Pilot biodistributions in nude mice bearing LS174T human colon carcinoma xenografts demonstrated that MeO-DOTA afforded higher tumor uptake and lower kidney retention of ^{177}Lu than DOTA-OSSu. The in vitro stability of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 was evaluated using serum and hydroxyapatite assays. Serum stability of radiolanthanide-labeled MeO-DOTA−CC49 followed a trend based on the coordination energies of the radiometals, with ^{177}Lu showing the highest stability after 96 to 168 h at 37 °C. In contrast, MeO-DOTA−CC49 labeled with all three radiolanthanides was >92% stable to hydroxyapatite challenge for 168 h at 37 °C. Comprehensive biodistributions of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 were obtained in LS174T-bearing nude mice. Maximum tumor uptakes were 100.0% ID/g for ^{149}Pm at 96 h, 69.5% ID/g for ^{166}Ho at 96 h, and 132.4% ID/g for ^{177}Lu at 168 h. Normal organ uptakes were generally low, except in the liver, spleen, and kidney at early time points. By 96 to 168 h postinjection, nontarget organ uptake decreased to approximately 7% ID/g (kidney), 12% ID/g (spleen), and 20% ID/g (liver) for each radiolanthanide. When labeled with ^{149}Pm, ^{166}Ho, and ^{177}Lu, MeO-DOTA−CC49 has potential for RIT of colorectal cancer and other carcinomas.

INTRODUCTION

Radiolabeled monoclonal antibodies (mAbs) have shown great promise for cancer therapy. Recently, two commercial preparations of radiolabeled mAbs have been approved by the United States Food and Drug Administration for radioimmunotherapy (RIT)[1] of relapsed or refractory B-cell non-Hodgkin's lymphoma (*1*, 2). Targeted radiopharmaceuticals are well suited to the therapy of this disease, as tumors are well vascularized for the delivery of the mAbs, and lymphocytes are exquisitely sensitive to radiation injury. However, targeting of solid tumors with therapeutic radiopharmaceuticals has been far less effective in producing lasting remissions or tumor control. The slow plasma clearance properties of radiolabeled mAbs result in prolonged exposure of the bone marrow to ionizing radiation. This requires limiting the dose to the tumor to keep marrow exposure below 150 to 200 rad (1.5 to 2.0 Gy). Creation of stable fragments of mAbs has improved clearance kinetics but yielded decreased tumor antigen binding affinity and altered biodistributions, often with unacceptably high kidney doses (*3*).

An alternative strategy is to label mAbs with radionuclides having emission characteristics that are more effective for solid tumor therapy. The radiolanthanides ^{149}Pm, ^{166}Ho, and ^{177}Lu (Table 1) possess a range of half-lives and β^- energies for RIT applications. They also emit low abundance γ rays with energies suitable for tracking radiolabeled mAbs in vivo and estimating radiation dosimetry. Furthermore, these radiolanthanides can be

Table 1. Decay Characteristics and DOTA log K_{ML} Values for ^{149}Pm, ^{166}Ho, and ^{177}Lu

radiometal	$T_{1/2}$ (h)	β^- MeV (%)	γ keV (%)	log K_{ML} (M^{3+}-DOTA)
^{149}Pm	53.1	0.784 (9) 1.06 (90)	286 (3.1)	22.87
^{166}Ho	26.9	1.76 (47) 1.84 (52)	81 (5.4)	24.83
^{177}Lu	159.6	0.497 (90)	208 (11)	25.34

obtained readily from a nuclear reactor, by both direct neutron capture and indirect methods (*4*).

Bifunctional derivatives of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) have been used often to label mAbs with lanthanide radionuclides and other radiometals. We previously developed a facile, water-soluble method (*5*, *6*) for conjugating mAbs with *N*-hydroxysulfosuccinimidyl DOTA (DOTA-OSSu). Conjugates of several antibodies prepared with DOTA-OSSu have been labeled to high specific activity, high radiochemical purity, and high stability with ^{111}In and ^{90}Y (*5*−*7*), as well as ^{64}Cu (*8*−*10*). However, modified structures of DOTA, such as methoxy-DOTA (MeO-DOTA, Figure 1), may have improved binding kinetics and stability for radiolanthanides. Methoxy-DOTA has four amine and four carboxylic acid coordination sites available to bind the radionuclide, while the benzyl isothiocyanate moiety is available off one of the carboxylate arms for conjugation.

CC49 (*11*) is a second generation murine IgG_1 mAb that has been shown to react with the disaccharide sialyl Tn epitope on the extracellular antigen tumor-associated glycoprotein-72, or TAG-72. TAG-72 is expressed on ∼85% of human adenocarcinomas such as colon, breast, pancreatic, ovarian, prostate, non-small cell lung, and gastric cancers (*12*−*21*). Both ^{131}I- and ^{177}Lu-labeled CC49 have been evaluated for RIT in tumor-bearing mice (*22*, *23*) and patients (*24*−*29*). These studies demonstrated excellent tumor targeting and elimination of established tumors in rodent models.

The objective of the present studies was to obtain comparative biodistributions of CC49 labeled with ^{149}Pm, ^{166}Ho, and ^{177}Lu in nude mice bearing LS174T human colon carcinoma xenografts. CC49 conjugates were prepared using DOTA-OSSu and MeO-DOTA, and the stabilities and tumor-targeting properties of the radioimmunoconjugates were evaluated in vitro and in vivo. When labeled with ^{177}Lu, MeO-DOTA was superior to DOTA in terms of CC49 conjugate stability, radiolabeling, radiochemical purity, and biodistributions. The favorable and comparable biodistributions and tumor targeting properties exhibited by the three radiolanthanides allowed the current work to be extended to preclinical RIT studies with each radionuclide.

EXPERIMENTAL PROCEDURES

General. The radiolanthanides were obtained as $^{149}PmCl_3$, $^{166}HoCl_3$, and $^{177}LuCl_3$ in 0.05 M HCl from the University of Missouri Research Reactor (MURR, Columbia, MO). DOTA was purchased from Macrocyclics (Dallas, TX), and MeO-DOTA was provided by the Dow Chemical Company (Dowpharma, Freeport, TX). Chelex 100 (Analytical Grade, 100−200 mesh, sodium form) was purchased from Bio-Rad (Hercules, CA). All solutions were prepared using ultrapure water (18 MΩ-cm resistivity).

CC49 was produced from the hybridoma cell line provided by Dr. Jeffrey Schlom at the National Cancer Institute (Bethesda, MD). Hybridoma cells were grown in a CELLine CL 1000 bioreactor (Integra Biosciences AG, Chur, Switzerland) in serum-free medium (GIBCO Hybridoma-SFM, Invitrogen, Carlsbad, CA) with ORIGEN (Hybridoma Cloning Factor, IGEN International, Inc., Gaithersburg, MD) for 38 days, and

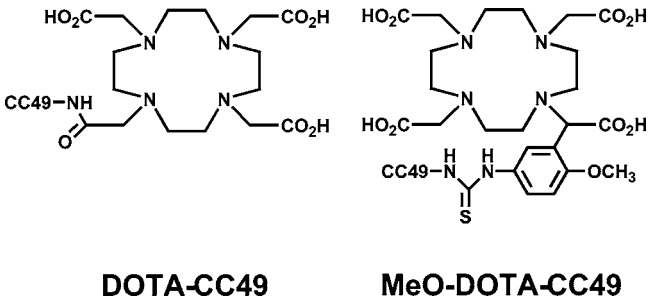

Figure 1. Structures of chelator−mAb conjugates DOTA−CC49 and MeO-DOTA−CC49.

supernatant from the cell side was harvested every 3−4 days. CC49 was purified from the supernatant by Protein G affinity chromatography, using a 10-mL UltraLink Immobilized Protein G column (Pierce, Rockford, IL). The column was washed with 0.1 M sodium acetate, pH 6.0, and eluted with 0.1 M glycine, pH 3.0, after which collected fractions were neutralized with 1 M Tris, pH 8.0. The pooled fractions containing purified mAb were dialyzed against of 1 L of 10 mM NaH_2PO_4/150 mM NaCl, pH 7.5, containing approximately 1 g of Chelex 100, for 72 h at 4 °C, with two buffer changes. This procedure afforded typical yields of 85 to 100 mg of CC49. CC49 concentration was measured by absorbance at 280 nm ($\epsilon = 1.5 \times 10^5$ M^{-1} cm^{-1}; A_{280} at 1 mg/mL = 1.4).

The purity of the radioimmunoconjugates was confirmed by gel filtration HPLC (GF−HPLC), using a Waters (Milford, MA) Delta 600 chromatograph equipped with a manual Rheodyne injector, a 2487 dual wavelength UV detector, a Packard 500TR Flow Scintillation Analyzer with a LQ flow cell for ^{149}Pm, ^{166}Ho, and ^{177}Lu, a Waters busSAT/IN analog-digital interface, and the Waters Millennium 32 software package. A Superose 12 HR 10/30 (Amersham Pharmacia, Torrance, CA) column (300 × 10 mm), an isocratic mobile phase of 100 mM NaH_2PO_4/0.05% NaN_3, pH 6.8, and a flow rate of 0.5 mL/min were used. Scintillation counting was performed on a Wallac 1480 Wizard 3″ automated gamma counter (PerkinElmer Life Sciences, Gaithersburg, MD).

Antibody Conjugation. An aliquot of 6.03 mg of CC49 was conjugated with the bifunctional chelating agent *N*-hydroxysulfosuccinimidyl DOTA (DOTA-OSSu) at a 20:1 molar ratio of DOTA-OSSu:mAb, as described previously (*5*). For methoxy-DOTA (MeO-DOTA) conjugation, a modification of the method of Sumerdon et al. (*30*) was used. Briefly, an aliquot of 6.03 mg of CC49 in 1 mL of 10 mM NaH_2PO_4/150 mM NaCl, pH 7.4, was dialyzed against 1 L of 0.1 M Na_2HPO_4, pH 7.5, containing approximately 1 g of Chelex 100, for 18 to 24 h at 4 °C, and then against 1 L of 0.1 M $NaHCO_3/Na_2HPO_4$, pH 8.5, containing approximately 1 g of Chelex 100, for 48 h at 4 °C, with one buffer change. CC49 was conjugated with MeO-DOTA at a MeO-DOTA:mAb molar ratio of 20:1. The reaction mixture was incubated for 3 h at 37 °C and then dialyzed against 0.25 M ammonium acetate, pH 7.0, containing approximately 1 g of Chelex 100, at 4 °C for 144 h, with five buffer changes. The DOTA−CC49 and MeO-DOTA−CC49 conjugate concentrations were measured by absorbance at 280 nm. The average number of chelates per antibody was determined using an ^{111}In isotopic dilution assay method, using a previously published procedure (*5*).

Radiolanthanide Labeling. Modifications of the methods previously described by Lewis et al. (*5*, *31*) were used to radiolabel DOTA−CC49 and MeO-DOTA−CC49. An initial radiolabeling ratio of 5 μCi/μg was used. In the ^{177}Lu labeling reaction, 59.6 μL of 1.0 M ammonium acetate, pH 4.5, was added to 2.0 mCi of $^{177}LuCl_3$ in 2.0 μL of 0.05 M HCl, followed by 400 μg of DOTA−CC49 or MeO-DOTA−CC49 in 65.6 μL

of 0.25 M ammonium acetate, pH 7.0. The reaction mixture was incubated at 43 °C for 1 h, and diethylenetriaminepentaacetic acid (DTPA), pH 6.0, was added to a final concentration of 1 mM. The reaction mixture was allowed to stand for 15 min at room temperature and then purified using a Bio-Spin 6 column (Bio-Rad) equilibrated with 10 mM Na_2HPO_4/150 mM NaCl, pH 7.5. Prior to purification, radiometal labeling efficiency and specific activity were determined by GF−HPLC. After spin column purification, the specific activity of the mAb was adjusted to 1 μCi/μg, by dilution with unmodified CC49. Radiochemical purity was then determined by GF−HPLC. For ^{166}Ho and ^{149}Pm labeling, similar conditions were used as for ^{177}Lu, except the ^{149}Pm solution contained 2.0 mCi in 6.0 μL of 0.05 M HCl.

Immunoreactivity Determination. A modification of a previously described method (*5*) was used. Briefly, a dilution of the purified radiolabeled CC49 conjugate, containing approximately 200 000 cpm of radioactivity, was mixed with a 20-fold molar excess of bovine submaxillary mucin type I-S (Sigma; St. Louis, MO) in 150 μL of 1% human serum albumin/10 mM NaH_2PO_4/150 mM NaCl, pH 7.4. A control sample was prepared in an identical manner, except that mucin type I-S was not added. The reaction mixtures were incubated at 37 °C for 15 min with continuous end-over-end mixing, after which aliquots of 100 μL were analyzed by GF-HPLC, as described above. Immunoreactivity was calculated as the percentage of the total radioactivity shifted to complexes with apparent molecular weights higher than that of the mAb.

Serum Stability Studies. An aliquot of 1 mCi of ^{177}Lu-DOTA−CC49 or ^{177}Lu-, ^{166}Ho-, or ^{149}Pm-MeO-DOTA−CC49 was added to 1 mL of mouse serum, clarified by centrifugation at 16 110*g* for 15 min and stabilized with 10 μL of 10% NaN_3. Serum samples were analyzed by GF−HPLC, as described above, after incubation at 37 °C for 1, 4, 24, 48, 96, and 168 h.

Hydroxyapatite Stability Studies. Hydroxyapatite stability studies were performed according to a previously published procedure (*32*). Reaction mixtures containing 300 μL of HA-Ultrogel (Sigma, 40% w/w aqueous ethanol suspension, particle size 60−180 μm), 100 μL of bovine serum albumin (BSA) to give a final concentration of 2.5%, 800 μL of 50 mM Tris with 0.01 M $CaCl_2$, and 10 to 20 μCi of radiolabeled MeO-DOTA−CC49 were incubated in 1.5-mL conical polypropylene tubes with continuous mixing at 37 °C. Each day for 7 days, one reaction mixture was separated into liquid and solid phases. The tubes were centrifuged in an Eppendorf 5415D centrifuge (Brinkmann Instruments, Westbury, NY) at 10 000 rpm for 1 min. The liquid phase was removed. The solid sample was washed with 1 mL of water and recentrifuged at 10 000 rpm for 1 min. The liquid wash was removed from the tube. The solid phase was dissolved in 1.3 N HNO_3. The liquid phase, wash, and solid phase were counted in a gamma counter. The percentage of radioactivity in the liquid phase of the sample was calculated by combining the liquid phase and wash and dividing by the total counts in the three parts (liquid, wash, and solid). The solid phase was calculated by taking the counts in the solid phase and dividing by the total counts.

Biodistribution Studies. All experiments were conducted in compliance with the guidelines established by the Animal Care and Use Committee of the University of Missouri−Columbia Animal Care Quality Assurance Office. Outbred female nu/nu mice (4 to 6 weeks of age) were implanted subcutaneously (sc) in the hind flank with 2×10^6 LS174T human colon cancer cells in 0.15 mL of Hank's Balanced Salt Solution. After 14 days, tumors had grown to 100−400 mg, with a mean weight of 175 mg. Mice were then injected intravenously (iv) via the tail vein with 60 μCi/60 μg of ^{177}Lu-DOTA−CC49 or ^{177}Lu-, ^{166}Ho-, or ^{149}Pm-MeO-DOTA−CC49.

Table 2. Serum Stability (mean ± SD)[a] of Radiolanthanide-Labeled MeO-DOTA−CC49 and ^{177}Lu-DOTA−CC49

	MeO-DOTA[b]			DOTA[b]
time (h)	^{149}Pm	^{166}Ho	^{177}Lu	^{177}Lu
0	99.2 ± 1.3	98.7 ± 0.9	99.2 ± 1.2	98.3 ± 2.9
1	99.0 ± 1.8	98.6 ± 1.1	99.6 ± 0.7	98.3 ± 2.9
4	98.1 ± 3.2	98.1 ± 1.4	100.0 ± 0.0	98.2 ± 3.1
24	97.4 ± 3.7	98.4 ± 1.4	98.1 ± 2.1	96.7 ± 3.2
48	96.7 ± 4.0	97.7 ± 1.4	99.3 ± 1.2	97.2 ± 3.6
96	93.7 ± 2.5	93.9 ± 0.7	96.5 ± 0.9	97.3 ± 4.0
168	91.6 ± 0.5	n.d.[c]	98.0 ± 2.4	94.3 ± 3.0

[a] The standard deviations (SD) represent variances of three separate experiments. [b] $n = 3$. [c] n.d. = not determined.

For ^{149}Pm- and ^{177}Lu-labeled CC49, biodistributions were obtained at 15 min, 1, 4, 24, 48, 96, and 168 h postinjection. For ^{166}Ho-MeO-DOTA−CC49, biodistributions were obtained at the same time points out to 96 h postinjection. Tissues harvested included blood, lung, liver, spleen, kidney, muscle, fat, heart, bone, uterus, ovaries, bladder, stomach, small intestine, large intestine, tumor, and carcass. Tissues were drained of blood, weighed, and counted in the gamma counter with a standard of the injected dose, such that decay-corrected uptakes were calculated as the percent injected dose per gram of tissue (% ID/g) and the percent injected dose per organ (% ID/organ).

Statistical Analysis. To compare biodistributions between ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49, one-way analysis of variance (ANOVA) using statistical software SPSS 12.0.1 (Chicago, IL) was performed. Differences at the 95% confidence level ($p < 0.05$) were considered significant.

RESULTS

Conjugation of DOTA and MeO-DOTA to CC49 and Radiolanthanide Labeling. The reactions of *N*-hydroxysulfosuccinimidyl-DOTA (DOTA-OSSu) and methoxy-DOTA (MeO-DOTA) with mAb CC49 are expected to produce amide and thiourea linkages, respectively, between chelators and the ϵ-amino group of lysine residues and/or the *N*-termini of polypeptide chains (Figure 1). Both bifunctional chelating agents were reacted with CC49 at a molar ratio of 20:1. The average number of chelates per antibody was 5.53 for DOTA−CC49, as determined by an ^{111}In isotopic dilution assay (*5*, *33*). In comparison, the average number of chelates per antibody for MeO-DOTA−CC49 was 2.51. Reaction with purified antigen and GF−HPLC analysis demonstrated that the immunoreactivity of the DOTA and MeO-DOTA conjugates of CC49 were 97%. The nonreactive fraction (3%) consisted of incompletely assembled mAb species, which were minor byproducts of hybridoma production.

The average labeling efficiency of DOTA−CC49 with ^{177}Lu was 70.8% at a ratio of 5 μCi/μg, and purification by gel filtration spin column chromatography afforded a radiochemical purity of 95% as determined by GF−HPLC. At a 5 μCi/μg ratio, the MeO-DOTA−CC49 conjugate gave average labeling yields of 76.8%, 63.5%, and 68.0%, respectively, with ^{149}Pm, ^{166}Ho, and ^{177}Lu. For each radiolanthanide, radiochemical purity of MeO-DOTA−CC49 was >98.0% after purification, as determined by GF−HPLC. Surprisingly, the radiolabeling efficiency of DOTA−CC49 dropped precipitously and reproducibly to near zero values within two months of storage at either 4 °C or −70 °C. In contrast, after more nine months at 4 °C the MeO-DOTA conjugate could be labeled with all three radiolanthanides with efficiencies up to 80% at 5 μCi/μg.

In Vitro Stability Studies. The stability of ^{177}Lu-DOTA−CC49 in mouse serum was 94.3 ± 4.0% after 168 h at 37 °C (Table 2), a value significantly lower ($p = 0.0067$) than that of

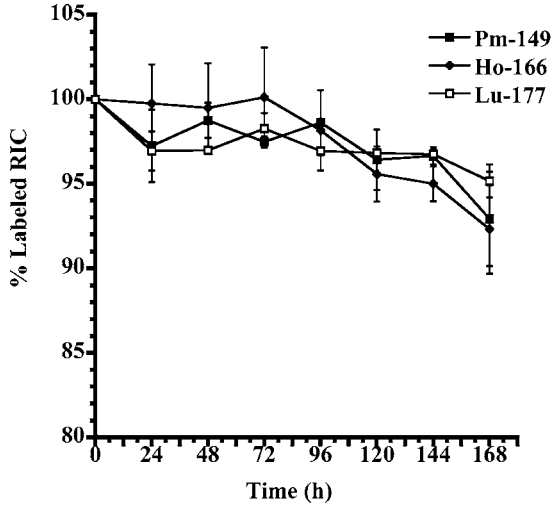

Figure 2. Percentages of ^{149}Pm, ^{166}Ho, and ^{177}Lu bound to MeO-DOTA−CC49 as a function of time of incubation with hydroxyapatite at 37 °C. Error bars represent standard deviations (SD) of three separate experiments.

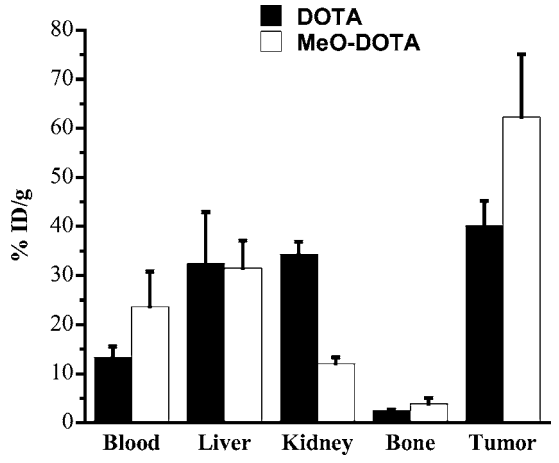

Figure 3. Comparison of ^{177}Lu-DOTA−CC49 and ^{177}Lu-MeO-DOTA−CC49 biodistributions ($n = 5$) in blood, liver, kidney, bone, and LS174T tumor at 24 h postinjection. Error bars represent standard deviations (SD).

^{177}Lu-MeO-DOTA−CC49 (98.0 ± 2.4%). In the case of the MeO-DOTA conjugate (Table 2), the serum stabilities at 96 h were statistically identical for ^{149}Pm (93.7 ± 2.5%) and ^{166}Ho (93.9 ± 0.7%), both lower than the corresponding value for ^{177}Lu (96.5 ± 0.9%). The ^{177}Lu-labeled MeO-DOTA conjugate was more stable than ^{149}Pm-MeO-DOTA−CC49 at 168 h ($p = 0.02$) and more stable than ^{166}Ho-MeO-DOTA−CC49 at 48 h ($p = 0.02$) and 96 h ($p = 0.03$). The radiolanthanides lost from DOTA−CC49 and MeO-DOTA−CC49 were invariably observed as low molecular weight species. Hydroxyapatite stability studies were also conducted, based on a previously published in vitro method for predicting the in vivo stability of radiolanthanide chelates (*32*). In the hydroxyapatite studies (Figure 2), the MeO-DOTA conjugate was 92.3 ± 2.6% stable with ^{166}Ho, 92.9 ± 2.8% stable with ^{149}Pm, and 95.2 ± 1.0% stable with ^{177}Lu for 168 h at 37 °C. The only statistically significant difference observed was between ^{177}Lu and ^{166}Ho at 168 h, which was marginal at $p = 0.048$.

Biodistribution Studies. Pilot ^{177}Lu biodistribution studies in nude mice bearing LS174T human colon carcinoma xenografts were conducted to compare CC49 conjugates of DOTA and MeO-DOTA. Uptakes in the major organs of interest at 24 h postinjection are shown in Figure 3. For ^{177}Lu-MeO-DOTA−CC49, substantially lower kidney uptake was observed, concomitant with considerably higher LS174T tumor uptake and slower blood clearance. With ^{177}Lu, the MeO-DOTA conjugate displayed superior conjugate and radiolabeling stability and more favorable biodistribution properties at 24 h postinjection. Therefore, MeO-DOTA−CC49 was selected for further in vivo evaluation using all three radiolanthanides.

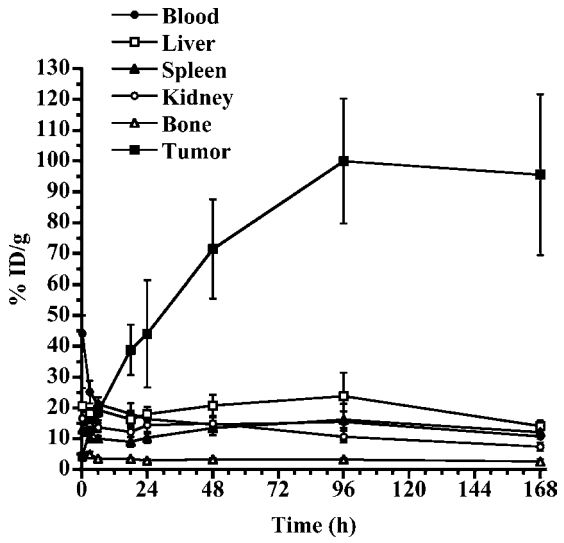

Figure 4. Biodistribution ($n = 5$) of ^{149}Pm-MeO-DOTA−CC49 in LS174T-bearing nude mice. Error bars represent standard deviations (SD).

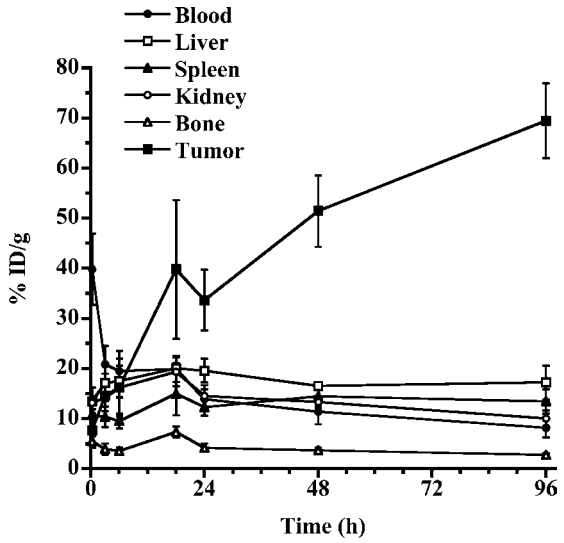

Figure 5. Biodistribution ($n = 5$) of ^{166}Ho-MeO-DOTA−CC49 in LS174T-bearing nude mice. Error bars represent standard deviations (SD).

Comprehensive biodistributions of ^{149}Pm- and ^{177}Lu-MeO-DOTA−CC49 were obtained in the LS174T mouse model at 15 min, 1, 4, 24, 48, 96, and 168 h postinjection. Biodistributions for ^{166}Ho-MeO-DOTA−CC49 were obtained at the same time points out to 96 h postinjection. The results obtained for ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 are given in Figures 4, 5, and 6, respectively. MeO-DOTA−CC49 exhibited extremely high tumor uptake for each of the radiolanthanides. The highest tumor uptake of ^{166}Ho-MeO-DOTA−CC49 was 69.5% ID/g at 96 h, which was significantly lower ($p < 0.05$) than the tumor uptake of ^{149}Pm- and ^{177}Lu-MeO-DOTA−CC49 (100.0% and 95.4%, respectively) at the same time point. Maximum tumor uptake of ^{177}Lu-MeO-DOTA−CC49, 132.4% ID/g, was observed at 168 h postinjection. This value was significantly higher than the maximum uptake observed for ^{166}Ho− ($p = 0.001$) and ^{149}Pm-MeO-DOTA−CC49 ($p = 0.001$).

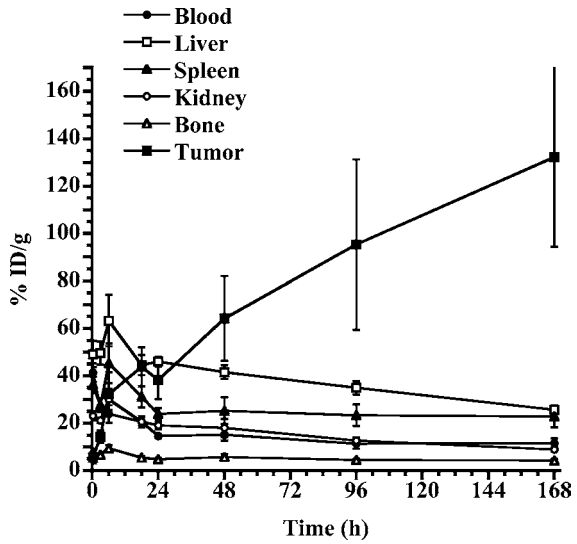

Figure 6. Biodistribution ($n = 5$) of ^{177}Lu-MeO-DOTA−CC49 in LS174T-bearing nude mice. Error bars represent standard deviations (SD).

Normal organ uptakes were generally below uniform distribution, except for initial uptakes of ^{177}Lu in the liver (63.3% ID/g), spleen (45.3% ID/g), and kidney (30.0%). Nontarget organ uptakes of ^{177}Lu decreased significantly ($p < 0.05$) with time to approximately 7% ID/g (kidney), 12% ID/g (spleen), and 20% ID/g (liver) at 96 to 168 h. Corresponding uptakes of ^{149}Pm and ^{166}Ho remained essentially constant at these values throughout the course of the studies. Blood levels of radiolanthanide-labeled MeO-DOTA−CC49 decreased significantly ($p < 0.05$) from approximately 21 to 27% ID/g at 3 h to 8 to 15% ID/g at 96 h. Bone uptakes of all three radiolanthanides decreased significantly ($p < 0.05$) from 4.89 to 7.66% ID/g at 15 min to 2.65 to 4.51% ID/g by 96 h. Small intestinal uptakes peaked at 1.33 to 2.52% ID/g at 6 h, and large intestinal uptakes reached maximum values of 1.33 to 2.48% ID/g by 6 h (data not shown).

Tumor-to-Blood Time−Activity Ratios of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49. The biodistributions of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 were used to generate tumor and blood time-activity curves for the three radioimmunoconjugates. Physical decay was included to calculate percent injected activity per gram of tissue (% IA/g). The ratio of areas under the curves (AUCs) was used to estimate the anticipated "therapeutic index" of each agent. For ^{149}Pm-MeO-DOTA−CC49, the tumor AUC was 4405% IA/g−h, and the blood AUC was 1177% IA/g−h, affording a tumor-to-blood ratio of 3.74. Using ^{166}Ho-MeO-DOTA−CC49, lower values were obtained, yielding a tumor AUC of 1329% IA/g−h, a blood AUC of 596% IA/g−h, and a tumor-to-blood ratio of 2.23. MeO-DOTA−CC49 labeled with ^{177}Lu gave the highest results, with a tumor AUC of 9166% IA/g−h, a blood AUC of 1778% IA/g−h, and a tumor-to-blood ratio of 5.15.

DISCUSSION

The present studies evaluated the anti-TAG-72 monoclonal antibody CC49 conjugated with two bifunctional chelating agents, DOTA-OSSu and MeO-DOTA, for labeling with lanthanide radionuclides. Over the past several years, numerous groups have developed a large number of C- and N-substituted analogues of DOTA for antibody conjugation. Using DOTA-OSSu, we have had success targeting mouse xenografts with a variety of mAbs and radiometals (*5*−*10*). Conversely, MeO-DOTA may have better binding and in vivo distribution properties for radiolanthanides. A recent study compared anti-TAG-72 mAb B72.3 conjugated to MeO-DOTA, an octadentate C-substituted DOTA derivative, and a heptadentate DOTA attached by conversion of one of the carboxylate groups to an amide linker (*34*). In non-tumor-bearing mice, ^{177}Lu-labeled MeO-DOTA-B72.3 showed the lowest lung and spleen uptake of the three conjugates, suggesting reduced formation of colloidal radiometal hydroxides in vivo. Bone uptake of ^{177}Lu-MeO-DOTA-B72.3 was lower than that of amide-linked DOTA and comparable to that of C-substituted DOTA, indicating high chelate stability. Blood clearance of ^{177}Lu-MeO-DOTA-B72.3 was also faster than that of the C-substituted conjugate. Another advantage of MeO-DOTA is that it is the product of a convergent synthesis, which is considerably more straightforward than those of many C-substituted DOTA analogues.

Several mAbs (cT84.66, cBR96, and NR-LU-10) have been conjugated with DOTA-OSSu to give immunoconjugates that labeled reproducibly to high specific activity and high stability with ^{111}In, ^{90}Y, and ^{64}Cu (*5*−*10*). One preparation of DOTA-cT84.66 (*5*) has afforded near quantitative labeling and immunoreactivity after more than nine years of storage at 4 °C (*8, 9*). In contrast, the DOTA−CC49 conjugate was not stable for extended storage at 4 °C, and after approximately two months, ^{177}Lu labeling gave consistently irreproducible results. This finding was unusual and suggested that the choice of mAb and bifunctional chelating agent may be important for developing stable and high specific activity radiolanthanide immunoconjugates for RIT applications. However, at present we have no logical explanation for the instability of DOTA−CC49 upon storage. Unlike the DOTA conjugate, MeO-DOTA−CC49 could be labeled with ^{149}Pm, ^{166}Ho, and ^{177}Lu stably and with reproducibly high specific activity, even after more than nine months of storage at 4 °C.

For initial comparisons of the in vivo properties of two ^{177}Lu chelate conjugates, pilot biodistributions in the major organs were obtained for ^{177}Lu-DOTA−CC49 and ^{177}Lu-MeO-DOTA−CC49 in LS174T-bearing nude mice at 24 h postinjection. When labeled with ^{177}Lu, MeO-DOTA−CC49 showed lower kidney uptake, slower blood clearance, and higher LS174T tumor uptake. For CC49, MeO-DOTA was a more robust bifunctional chelating agent for stable conjugation and reproducible, efficient labeling than DOTA. Therefore, MeO-DOTA−CC49 was chosen for further evaluation in vitro and in vivo using ^{149}Pm, ^{166}Ho, and ^{177}Lu.

To assess the in vitro stability of radiolanthanide-labeled CC49, studies were conducted in mouse serum and a hydroxyapatite model. In serum, the small degree of radiometal dissociation from the conjugate resulted only in lower molecular weight constituents in serum out to 96 to 168 h at 37 °C, consistent with other published reports evaluating ^{111}In-, ^{90}Y-, and ^{64}Cu-labeled mAbs (*5, 6, 8*−*10*). Relative to initial radiochemical purity, the serum stability of ^{177}Lu-DOTA−CC49 was statistically equivalent to ^{177}Lu-MeO-DOTA−CC49 over a 96-h period. Only at 168 h was the MeO-DOTA conjugate more stable than the DOTA conjugate when labeled with ^{177}Lu. Because of the lanthanide contraction, lutetium has the smallest radius and highest coordination energy of the three radiometals and is likely to be bound more tightly by the MeO-DOTA chelator. MeO-DOTA−CC49 was most stable in serum when labeled with ^{177}Lu, followed by ^{166}Ho and ^{149}Pm. However, radiolanthanides do not bind with high affinity to any major serum proteins. At longer time points in the serum stability studies, equilibria likely exist between the radiolanthanide chelate conjugates and the free radiometals. Over an extended period, the serum stability curves began to reach asymptotes for all three radioimmunoconjugates. This asymptotic behavior was characteristic of equilibrium conditions, under which thermodynamic stability of the radiolanthanide−mAb conjugates would be expected to prevail.

However, the in vivo stability of radiolanthanide-labeled CC49 is likely to depend on kinetic, rather than thermodynamic, properties. Therefore, a hydroxyapatite matrix (*32*) was used as an in vitro model to predict the relative in vivo stabilities of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49. Hydroxyapatite is a major constituent found in the extracellular matrix of bone. As calcium mimics, free lanthanides deposit and become fixed in bone, presumably by a hydroxyapatite-mediated mechanism. In contrast to the serum stability studies, hydroxyapatite binding showed that ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 were ≥92% stable for up to 168 h at 37 °C. The difference in stability of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-labeled CC49 in hydroxyapatite versus serum may reflect differences in kinetic versus thermodynamic stability, as measured respectively by the two assays. Dissociation of radiolanthanides from mAb conjugates in vivo will likely result in substantial accumulation in the skeleton. In the present studies, the high stabilities of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 to hydroxyapatite challenge paralleled the low bone uptakes of the three radiometals in LS174T-bearing nude mice. Bone uptakes were not statistically significant between the radiometals ($p > 0.05$), and by 96 h values for all three radiolanthanide immunoconjugates were <5% ID/g.

Given its high concentration in LS174T xenografts and the presence of multiple epitopes per molecule, TAG-72 represents a high capacity tumor target, and high specific activity of labeling CC49 is not necessary to achieve high tumor uptake. Empirically, a specific activity 1 μCi/μg, compared to approximately 4 μCi/μg, slightly improved the tumor uptake and normal tissue biodistribution of ^{177}Lu-MeO-DOTA−CC49 in the LS174T mouse model (data not shown). It is well-documented that TAG-72 is secreted into the blood of patients and correlates strongly with tumor antigen expression (*35*). In LS174T-bearing mice, TAG-72 could be shed into circulation, and the use of higher specific activity of CC49 may result in greater accumulation of immune complexes in the liver and spleen. It is possible that lowering the specific activity reduced the uptake in these organs and concomitantly increased tumor uptake. However, the slightly improved tumor uptake and reticuloendothelial clearance of lower specific activity ^{177}Lu-MeO-DOTA−CC49 was based on a limited number of pilot biodistributions and may not be statistically significant. Further studies of the relationship between the specific activity of radiolanthanide-labeled CC49 and its biodistribution properties are warranted.

Relative to the DOTA conjugate, an increased amount of ^{177}Lu from MeO-DOTA−CC49 was observed in the blood at 24 h. A possible explanation for this result is the decreased kidney uptake of ^{177}Lu from MeO-DOTA−CC49. However, the dose-limiting toxicity of conventional RIT is usually myelosuppression caused by slow blood clearance, raising the question as to whether the use of MeO-DOTA may augment this toxicity. Conversely, the higher kidney uptake of DOTA−CC49 might result in increased renal toxicity, although it is likely that bone marrow will remain the dose-limiting tissue. We have performed preliminary RIT studies of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 in LS174T-bearing nude mice (*36*). No overt signs of systemic toxicity were observed in any of these animals, and among six-month survivors, no microscopic evidence of liver, kidney, or spleen toxicity was found at necropsy. The results of these studies will be reported in greater detail in the future. However, the respective maximum tolerated doses of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 have not yet been determined. Dose escalation studies will be performed in order to identify the dose-limiting toxicities of these RIT agents, as well as ^{177}Lu-DOTA−CC49.

In vivo, free lanthanides also accumulate in the liver as a result of metabolic processing. Although relatively high liver uptake was observed for all three radiolanthanides, this phenomenon was more likely attributable to antibody metabolism and not chelate instability. Chelate instability would be expected to result in high bone uptake, which was not observed for ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49. Monoclonal antibody clearance and metabolism occurs predominantly through reticuloendothelial organs, primarily the liver and spleen. Antibodies are bound and internalized by asialoglycoprotein receptors in liver cells, resulting in concomitant radiometal retention in that organ for prolonged periods (*37*). In the present studies significantly higher liver uptake of ^{177}Lu-MeO-DOTA−CC49 was observed versus ^{166}Ho- ($p = 0.001$) and ^{149}Pm-MeO-DOTA−CC49 ($p = 0.001$). No significant difference in liver uptake was observed between ^{166}Ho- and ^{149}Pm-MeODOTA−CC49. Both ^{149}Pm- and ^{177}Lu-MeO-DOTA−CC49 exhibited a decrease in liver uptake with time, while ^{166}Ho-MeO-DOTA−CC49 showed an increase in liver accumulation with time. Regardless of this trend, ^{177}Lu-MeO-DOTA−CC49 had the highest liver uptake and retention of the three radiolanthanides. Spleen uptakes of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 were above uniform distribution and remained relatively constant over time for all three radiolanthanides. In addition to reticuloendothelial clearance of mAbs, positively charged metabolites of radiometal chelates bind to the negatively charged brush border of the renal proximal tubule, leading to kidney retention. Therefore, it was not surprising that MeO-DOTA−CC49 also displayed relatively high renal uptakes of ^{149}Pm, ^{166}Ho, and ^{177}Lu. However, radioactivity in the kidneys decreased appreciably over time for each radiolanthanide.

In the biodistribution studies, the major tissue of uptake for ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 was the tumor. The maximum tumor uptake of ^{177}Lu-MeO-DOTA−CC49 was 132.4% ID/g at 168 h. This result compares extremely favorably to the work of Schlom et al. (*23*), who observed an 81.1% ID/g uptake in subcutaneous LS174T xenografts in nude mice 168 h after injection of ^{177}Lu−PA-DOTA−CC49 (1 μCi/μg). However, direct comparisons between the work of Schlom et al. and the results reported here should be made with caution. PA-DOTA was conjugated to CC49 by a prelabeling strategy, in which essentially every conjugate was complexed with lutetium. In the present work, a postlabeling approach was used, such that at 1 μCi/μg, 1 of 24 MeO-DOTA−CC49 molecules was complexed with lutetium, one of three conjugates was complexed with holmium, and 1 of 395 conjugates was complexed with promethium, based on the respective specific activities of the radiolanthanides (*4*). Pre- and postlabeling strategies produce inherently different products that are likely to have different in vivo distribution properties. Furthermore, the average tumor weight in the experiments performed by Schlom *et* al. (*23*) was 30 mg, as opposed to 175 mg in the studies presented here. It is likely that larger tumors will exhibit lower antibody uptake, in % ID/g, than smaller tumors. For the larger tumors established in the present work, the uptake of ^{177}Lu-MeO-DOTA−CC49 was the highest of any radiopharmaceutical we have evaluated to date.

The maximum tumor uptake of MeO-DOTA−CC49 occurred in approximately two half-lives for ^{149}Pm, approximately four half-lives for ^{166}Ho, and approximately one half-life for ^{177}Lu. The time of maximum tumor uptake in conventional RIT relative to the half-life of the radionuclide could have a significant effect on therapeutic efficacy. As the half-life decreases, more radioactive decays will occur in the blood before the long-circulating mAb localizes to the tumor. As expected, the blood uptake of all three MeO-DOTA conjugates was initially high but slowly cleared to 8 to 12% ID/g by 96 to 168 h.

As a result, the tumor-to-blood AUC ratios, or anticipated "therapeutic indices," followed the trend ^{177}Lu > ^{149}Pm > ^{166}Ho. In subsequent RIT studies (*36*), it was determined that the most significant endpoint was time to progression to an LS174T tumor burden of 1 g. Using this endpoint, it was found that the therapeutic efficacy of ^{177}Lu-MeO-DOTA−CC49 was statistically superior to that of the ^{149}Pm conjugate, which in turn was statistically greater than that of the ^{166}Ho conjugate. These results suggest that, given the relatively long tumor targeting and clearance kinetics of intact radiolabeled antibodies, the physical half-life of the radionuclide should be well matched to the biological half-life of the targeting agent.

CONCLUSION

MeO-DOTA−CC49 labeled with the lanthanide radionuclides ^{149}Pm, ^{166}Ho, and ^{177}Lu showed extremely high tumor uptake and generally favorable biodistribution properties in nude mice bearing LS174T human colon carcinoma xenografts. The high tumor-specific targeting of each of these agents warrants further investigation for RIT of adenocarcinomas. However, the different physical half-lives and β^- particle energies of the radiolanthanides, as well as the different clearance properties of the radioimmunoconjugates, may have important effects on radiation dosimetry, toxicity, and therapeutic efficacy. The results of RIT studies of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 in the LS174T mouse model have been presented in preliminary form (*36*) and will be reported in more detail soon.

ACKNOWLEDGMENT

This research, under Award Number DAMD 17-02-1-0103, was supported by the Department of Defense Prostate Cancer Research Program, which is managed by the U.S. Army Medical Research and Materiel Command. This work was also funded by Grant URB-01-015 from the University of Missouri Research Board and a grant from the University of Missouri College of Veterinary Medicine Committee on Research. The authors would like to thank Dr. Jeffrey Schlom for providing the CC49 hybridoma cell line, as well as Dr. Christopher Johnson for assistance with statistical software SPSS 12.0.1. We also acknowledge the support of the U.S. Department of Veterans Affairs, for providing resources and the use of facilities at the Harry S. Truman Memorial Veterans' Hospital in Columbia, MO.

Supporting Information Available: Tables of mean percent injected dose per gram of tissue (% ID/g) with standard deviations (SD) of ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA−CC49 for all tissues and time points evaluated. Toward a Carbohydrate-Based HIV-1 Vaccine: Synthesis and Immunological Studies of Oligomannose-Containing Glycoconjugates

Jiahong Ni, Haijing Song, Yadong Wang, Nicholas M. Stamatos, and Lai-Xi Wang*

Institute of Human Virology, University of Maryland Biotechnology Institute, University of Maryland, Baltimore, Maryland 21201. Received September 20, 2005; Revised Manuscript Received January 19, 2006

Human antibody 2G12 is a broadly neutralizing antibody that exerts its anti-HIV activity by targeting a novel oligomannose cluster on HIV-1 gp120. It was previously demonstrated that synthetic oligomannose clusters could mimic the carbohydrate epitope of 2G12 and showed enhanced antigenicity (Wang L. X. et al. (2004) *Chem.* Biol. *11*, 127). This paper describes the synthesis of oligomannose-containing glycoconjugates that include either a carrier protein or a universal T-helper epitope peptide to provide an effective immunogen. It was shown that the synthetic neoglycoconjugates containing oligomannose clusters could be recognized by the human antibody 2G12. Rabbit immunization studies revealed that only a small fraction of antibodies raised by the glycoconjugates was directed to the carbohydrate antigens, with the majority of the IgG type antibodies being directed to the linkers in the conjugates. The anti-sera showed weak cross-reactivity to HIV-1 gp120.

INTRODUCTION

An effective protective vaccine against HIV-1 is believed to be the best hope to end the worldwide epidemic of HIV/AIDS. However, development of an effective HIV-1 vaccine has faced many challenges (*1*−*3*). To achieve maximal protection, both cellular immunity and humoral immunity are likely to be required for an effective HIV vaccine (*4*, *5*). While cytotoxic T lymphocyte (CTL) response is important to reduce HIV-1 infection by destroying the infected cells (*6*), CTL alone cannot prevent or eliminate HIV infection. On the other hand, passive immunization with some broadly neutralizing monoclonal antibodies such as 2F5, 2G12, and 4E10 has repeatedly demonstrated in animal models that these neutralizing antibodies can provide sterilizing immunity when present at sufficient concentrations (*7*−*9*). Therefore, eliciting broadly neutralizing antibodies remains a high priority in designing a preventive HIV vaccine. Unfortunately, attempts to create immunogens capable of eliciting broadly neutralizing antibodies have been largely unsuccessful (*4*, *10*, *11*). This situation urges the exploration of new vaccine approaches. Among the several broadly neutralizing antibodies so far identified from AIDS patients (*10*−*15*), the human monoclonal antibody 2G12 is of particular interest, as it targets a unique carbohydrate antigenic structure on HIV-1 gp120 (*15*). Recent biochemical and structural studies suggest that the epitope of 2G12 consists of a novel cluster of oligomannose residues on the "silence face" of the HIV-1 envelope glycoprotein gp120 (*16*−*19*).

Glycosylation with multiple high-mannose type N-glycans was found to be a common feature of the envelope glycoprotein gp120 of different HIV-1 strains so far analyzed (*20*−*23*). Such a high-density oligomannose clustering structure is rare for normal human glycoproteins. Thus a vaccine based on this unique antigenic structure may raise specific antibodies that would not be cross-reactive to normal human glycoproteins. Indeed, phase I clinical trials of the carbohydrate-specific antibody 2G12, together with another broadly neutralizing antibody 2F5, showed that 2G12 are safe and well tolerated in humans (*24*, *25*). The results suggest that targeting the oligomannose cluster on HIV-1 gp120 constitutes a feasible vaccine approach. As the first step toward this goal, several groups have performed 2G12-binding studies with structurally defined oligomannoses and/or related synthetic oligosaccharide clusters in order to define the antigenic structure (*26*−*30*). The binding studies indicated that the terminal Manα1,2Man unit was essential for 2G12 recognition but the Manα1,2Man unit alone was not sufficient for an effective binding to 2G12. In addition, it was shown that the full-size Man9 had the highest affinity to 2G12 among several natural high-mannose oligosaccharides, and the synthetic mannose tetrasaccharide corresponding to the D1 arm of Man9 showed comparable affinity to the antibody as that of the Man9 moiety (*26*). Using synthetic oligomannose clusters, we have further demonstrated that template-assembled oligomannose clusters are better mimics of the 2G12 epitope (*27*, *28*). For example, the galactose-based tetravalent Man9-cluster (Tetra-Man9) was 73-fold and 5000-fold more effective in binding to 2G12 than the monomeric $Man_9GlcNAc$ and Man_6-GlcNAc, respectively (*27*). These results suggest that the synthetic oligomannose cluster Tetra-Man9 may serve as a reasonable starting point for designing a carbohydrate-based HIV-1 vaccine. Since carbohydrate antigens alone are poorly immunogenic and are unable to raise T-cell dependent, IgG-type antibody responses, a conventional means to solve this problem is to conjugate the carbohydrate antigen to a strong T-helper epitope, e.g., a carrier protein, as exemplified by numerous studies on carbohydrate-based cancer vaccines (*31*). We describe in this paper the synthesis of conjugate vaccines in which Man9 and the oligomannose clusters are conjugated either to keyhole limpet hemocyanin (KLH) or to a universal T-helper epitope from tetanus toxoid (TT) (Figure 1). The glycoconjugates were used to immunize rabbits. The antigenicity and the immunogenicity of the synthetic glycoconjugates were investigated.

EXPERIMENTAL PROCEDURES

General Methods. ^1H NMR spectra were recorded on a 300 MHz machine with Me_4Si (δ 0) as the internal standard. The ESI-MS spectra were measured on a Micromass ZQ-4000 single

quadruple mass spectrometer. TLC was performed on glass plates coated with silica gel 60 F254 by visualizing the spots with UV light (254 nm) irradiation, 10% ethanolic sulfuric acid (for carbohydrates), ninhydrin spraying (for amines), and/or iodine coloration (for allyl groups). Flash column chromatography was performed on silica gel 60 (230−400 mesh). Photoaddition reaction was carried out in a quartz flask under N_2. Analytical HPLC was carried out with a Waters 626 HPLC instrument on a Waters Nova-Pak C18 column (3.9 × 150 mm) at 40 °C. The column was eluted with a linear gradient of MeCN−water containing 0.1% TFA at a flow rate of 1 mL/min with UV (214 nm) detection: Method A, 0−50% MeCN in 25 min; Method B, 0−90% MeCN in 25 min. Preparative HPLC was performed on a Waters 600 HPLC instrument equipped with a Waters C18 column (Symmetry 300, 19 × 300 mm). The column was eluted with a suitable gradient of MeCN−water containing 0.1% TFA at 12 mL/min.

2′-Azidoethyl 2,3,4,6-tetra-*O*-allyl-α-D-galactopyranoside (2). A solution of 2-azidoethyl α-D-galactopyranoside (**1**) (0.96 g, 3.85 mmol) in anhydrous DMF (5 mL) was added dropwise to a stirred suspension of sodium hydride (60% dispersion in mineral oil, 1.23 g, 30.80 mmol) in anhydrous DMF (30 mL). After being stirred for 30 min at room temperature, the reaction mixture was cooled to 0 °C, and then allyl bromide (3.70 g, 30.80 mmol) was added dropwise. The resulting mixture was stirred for 1 h at 0 °C and for 3 h at room temperature. After the mixture was cooled with an ice bath, the excess sodium hydride was quenched by the slow addition of methanol (5 mL). The volatile was evaporated to dryness, and then the residue was mixed with ethyl acetate (200 mL) and washed with brine (3 × 50 mL). The organic phase was dried over Na_2SO_4, filtered, and concentrated at a reduced pressure. The residue was purified by flash chromatography (hexane/EtOAc 80:20) to give compound **2** (1.39 g, 88%). R_f 0.46 (hexane/EtOAc 80:20); ^{1}H NMR (300 MHz, $CDCl_3$/TMS): δ 6.05−5.84 (m, 4 H, OCH_2CH═CH_2), 5.36−5.14 (m, 8 H, OCH_2CH═CH_2), 4.95 (d, 1 H, J = 3.2 Hz, H-1), 4.39 (dd, 1 H, J = 12.6, 5.5 Hz, $OCHHCH$═CH_2),), 4.26 (dd, 1 H, J = 12.6, 5.2 Hz, $OCHHCH$═CH_2), 4.22−4.06 (m, 4 H, OCH_2CH═CH_2), 4.04−3.98 (m, 2 H, OCH_2CH═CH_2), 3.96 (dd, 1 H, J = 6.6, 6.4 Hz, H-5),), 4.01−3.80 (m, 3 H, H-2, H-4 and $OCHHCH_2N_3$), 3.75 (dd, 1 H, J = 10.1, 2.8, H-3), 3.67 (ddd, 1 H, J = 10.8, 5.9, 3.9 Hz, $OCHHCH_2N_3$), 3.62−3.51 (m, 3 H, H-6, H-6′, and OCH_2CHHN_3), 3.38 (ddd, 1 H, J = 13.2, 5.6, 3.9 Hz, OCH_2CHHN_3); ESI-MS (*m*/*z*): 432.41 $(M + Na)^+$.

2′-(6-*tert*-Boc-Aminohexoic-amido)-ethyl 2,3,4,6-Tetra-*O*-allyl-α-D-galactopyranoside (3). To a stirred mixture of azide **2** (269.9 mg, 0.66 mmol) was added *N*-Boc-6-aminocaproic acid (191.6 mg, 0.83 mmol) in toluene (10 mL) *n*-Bu_3P (167.6 mg, 0.83 mmol) dropwise. After being stirred at room temperature for 3 h and then at 100 °C for 18 h, the resulting mixture was cooled to room temperature, and the solvent was evaporated at reduced pressure. The residue was purified by flash column chromatography (CH_2Cl_2/MeOH 95:5) to give compound **3** (180.9 mg. 46%), R_f 0.44 (CH_2Cl_2/MeOH, 95:5); ^{1}H NMR ($CDCl_3$/TMS): δ 6.63 (t, 1 H, J = 6.4 Hz, N*H*), 6.02−5.82 (m, 4 H, OCH_2CH═CH_2), 5.36−5.14 (m, 8 H, OCH_2CH═CH_2), 4.90 (d, 1 H, J = 3.2 Hz, H-1), 4.60 (t, 1 H, J = 6.2 Hz, N*H*Boc-*t*), 4.38 (dd, 1 H, J = 11.7, 5.8 Hz, $OCHHCH$═CH_2), 4.27 (dd, 1 H, J = 11.7, 5.8 Hz, $OCHHCH$═CH_2), 4.22−3.94 (m, 6 H, $OCHHCH$═CH_2), 3.90−3.78 (m, 3 H, H-2, H-4, $OCHHCH_2$-NH), 3.76−3.66 (m, 3 H, H-3, H-5, $OCHHCH_2NH$), 3.58 (d, 2 H, J = 6.2 Hz, H-6, H-6′), 3.52−3.38 (m, 2 H, OCH_2CH_2NH), 3.14−3.06 (m, 2 H, $(O)CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*), 2.15 (t, J = 7.1 Hz, 2 H, $(O)CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*), 1.72−1.55 (m, 2 H, $(O)CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*), 1.44 (s, 9 H, H−Boc-*t*), 1.43−1.30 (m, 2 H, $(O)CCH_2CH_2CH_2CH_2CH_2$-$NHBoc$-*t*), 0.94 (p, J = 6.7 Hz, 2 H, $(O)CCH_2CH_2CH_2CH_2$-CH_2NHBoc-*t*); ESI-MS (*m*/*z*): 619.32 $(M + Na)^+$, 597.27 $(M + H)^+$, 497.30 $(M - Boc + H)^+$.

2′-(6-*tert*-Boc-Aminohexoic-amido)-ethyl 2,3,4,6-Tetra-*O*-(6-amino-3-thiahexyl)-α-D-galactopyranoside (4). To a solution of compound **3** (173.0 mg, 0.29 mmol) and AIBN (20.0 mg) in methanol (15 mL) in a Quartz flask was added cysteamine hydrochloride (263.6 g, 2.32 mmol). After being degassed by bubbling N_2 into solution for 30 min, the resulting mixture was stirred and irradiated (UV, 254 nm) under N_2 for 24 h. The volatile was evaporated under reduced pressure, and the residue was purified by gel filtration on Sephadex G-15 column (2.5 × 75 cm) using water as eluent. Fractions containing the product were pooled and lyophilized to give compound **4** (859.5 mg, 82%). ^{1}H NMR (D_2O): δ 5.09 (d, 1 H, J = 3.4 Hz, H-1), 4.04−3.33 (m, 16 H, H-2, H-3, H-4, H-5, H-6, H-6′, $OCH_2CH_2CH_2S$, and OCH_2CH_2NH), 3.26−3.14 (m, 10 H, $SCH_2CH_2CH_2NH_2HCl$, and OCH_2CH_2NH), 3.04 (t, 2 H, J = 6.4 Hz, $(CH_2)_4CH_2NHBoc$-*t*), 2.90−2.82 (m, 8 H, SCH_2-$CH_2CH_2NH_2HCl$), 2.74−2.62 (m, 8 H, $OCH_2CH_2CH_2S$), 2.25 (t, J = 6.8 Hz, 2 H, $(O)CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*), 1.96−1.80 (m, 8 H, $OCH_2CH_2CH_2S$), 1.66−1.55 (m, 2 H, (O)-$CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*), 1.41 (s, 9 H, H−Boc-*t*), 1.38−1.26 (m, 2 H, $(O)CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*), 0.88 (p, J = 6.2 Hz, 2 H, $(O)CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*); ESI-MS (*m*/*z*): 927.44 $(M - 4HCl + Na)^+$, 905.53 $(M - 4HCl + H)^+$, 453.51 $(M - 4HCl + 2H)^{2+}$, 403.37 $(M - 4HCl - Boc + 2H)^{2+}$.

2′-(6-*tert*-Boc-Aminohexoic-amido)-ethyl 2,3,4,6-Tetra-*O*-(6-(6-maleimido-hexanamido)-3-thiahexyl)-α-D-galactopyranoside (5). To a stirred solution of *N*-succimidyl 6-maleimidohexanoic acid ester (50.2 mg, 162.90 μmol) in THF (3 mL) at 0−5 °C was added a solution of **4** (21.4 mg, 20.36 μmol) in 0.1 M aqueous solution of $NaHCO_3$ (1.0 mL). The resulting mixture was stirred for 1 h at 0−5 °C, then diluted with $CHCl_3$ (50 mL) and washed with brine (3 × 10 mL). The organic phase was dried over Na_2SO_4, filtered, and concentrated. The residue was purified by flash chromatography (CH_2Cl_2/MeOH 95:5) to give compound **5** (14.9 mg, 44%); R_f 0.57 (CH_2Cl_2/MeOH 90:10); ^{1}H NMR ($CDCl_3$/TMS): δ 6.70 (s, 8 H, C*H*═C*H*), 6.62 (t, 1 H, J = 6.4 Hz, N*H*), 6.36−6.16 (m, 4 H, N*H*), 4.89 (d, 1 H, J = 3.0 Hz, H-1), 4.80−4.68 (t, 1 H, J = 6.0 Hz, N*HBoc*-*t*), 3.94−3.84 (m, 2 H, $OCH_2CH_2CH_2$), 3.80−3.34 (m, 32 H, H-2, H-3, H-4, H-5, H-6, H-6′, $OCH_2CH_2CH_2S$, SCH_2CH_2NH, $(CH_2)_4CH_2N$, and OCH_2CH_2NH), 3.18−3.08 (m, 2 H, $(CH_2)_4CH_2$-NHBoc-*t*), 2.74−2.55 (m, 16 H, $OCH_2CH_2SCH_2CH_2NH$), 2.28−2.14 (m, 10 H, $(O)CCH_2CH_2CH_2CH_2CH_2$), 1.94−1.78

(m, 8 H, $OCH_2CH_2CH_2SCH_2CH_2N$), 1.74−1.54 (m, 20 H, $OCCH_2CH_2CH_2CH_2CH_2N$), 1.44 (s, 9 H, H−Boc-*t*), 1.40−1.24 (m, 10 H, $(O)CCH_2CH_2CH_2CH_2CH_2N$, $(O)CCH_2CH_2CH_2CH_2CH_2NHBoc$-*t*); ESI-MS (*m*/*z*): 1699.79 $(M + Na)^+$, 1677.73 $(M + H)^+$, 839.52 $(M + 2H)^{2+}$, 789.55 $(M - Boc + 2H)^{2+}$.

The Oligomannose Cluster Carrying a Boc-Protected Amino Group (6). To a solution of the SH-tagged oligomannose Man9GlcNAc2Asn-SH (18.0 mg, 8.69 μmol) (*27*) in a phosphate buffer (pH 6.6, 50 mM, 3.0 mL) and acetonitrile (3.0 mL) was added a solution of the scaffold **5** (1.83 mg, 1.09 μmol) in DMF (104 μL). The resulting mixture was shaken gently at room-temperature overnight. The mixture was lyophilized to dryness, and the ligation product was purified by preparative reverse-phase HPLC to yield the tetravalent oligomannose derivative **6** (10.9 mg, 68%): analytical HPLC (Method A), $t_R = 16.71$ min; ESI-MS: 2492.39 $(M + 4H)^{4+}$, 1994.05 $(M + 5H)^{5+}$, 1974.11 $(M - Boc + 5H)^{5+}$, 1961.41 $(M - Man + 5H)^{5+}$, 1941.74 $(M - Boc\text{-}Man + 5H)^{5+}$, 1929.31 $(M - 2Man + 5H)^{5+}$.

Oligomannose Cluster Carrying a Free Amino Group (7). A solution of the Boc-containing oligomannose cluster **6** (10.0 mg, 1.00 μmol) in a mixture of TFA, acetonitrile, and water (10/10/1, v/v, 2 mL) was shaken at room temperature for 2 h. The mixture was lyophilized to dryness, and the residue was purified by preparative HPLC to give the oligomannose cluster **7** (8.9 mg, 90%): Analytical HPLC (Method A), $t_R = 14.63$ min; ESI-MS (*m*/*z*): 2467.33 $(M + 4H)^{4+}$, 1973.97 $(M + 5H)^{5+}$, 1941.80 $(M - Man + 5H)^{5+}$, 1909.30 $(M - 2Man + 5H)^{5+}$.

Maleimido-Functionalized Oligomannose Cluster (8). Compound **7** (8.5 mg, 0.86 μmol) was dissolved in a mixed solvent of a phosphate buffer (pH 7.4, 50 mM) and acetonitrile (2/1, v/v, 1.5 mL). To the solution was added *N*-succimidyl 6-maleimidohexanoic ester (2.7 mg, 8.60 μmol) in acetonitrile (0.5 mL). The reaction mixture was stirred at room temperature for 2 h and then lyophilized to dryness. The residue was purified by preparative HPLC to yield the desired maleimido-functionalized oligomannose cluster (**8**) (5.9 mg, 68%): Analytical HPLC (Method A), $t_R = 16.36$ min; ESI-MS (*m*/*z*): 2516.45 $(M + 4H)^{4+}$, 2013.27 $(M + 5H)^{5+}$, 1980.75 $(M - Man + 5H)^{5+}$, 1948.22 $(M - 2Man + 5H)^{5+}$.

Biotinylated Oligomannose Cluster (9). Compound **7** (2.2 mg, 0.22 μmol) was dissolved in a mixed solvent of a phosphate buffer (pH 7.4, 50 mM) and acetonitrile (2/1, v/v, 1.0 mL). Then NHS-LS-biotin (5 equiv) was added, and the mixture was stirred at room temperature for 2 h. The mixture was lyophilized, and the residue was purified by preparative HPLC to give the M9Cluster-X-biotin (**9**) (1.88 mg, 84%): Analytical HPLC (Method A), $t_R = 15.81$ min; ESI-MS: 2552.52 $(M + 4H)^{4+}$, 2041.77 $(M + 5H)^{5+}$, 2009.205 $(M - Man + 5H)^{5+}$, 1977.50 $(M - 2Man + 5H)^{5+}$.

Oligomannose Cluster/T-Helper Peptide Conjugate (10). A mixture of the maleimido-M9Cluster (**8**) (2 mg, 0.2 μmol) and the cysteine-containing tetanus toxoid peptide (TT-peptide) CGQYIKANSKFIGITEL (*32*) (0.76 mg, 0.4 μmol) in a mixed solvent containing phosphate buffer (pH 6.6, 50 mM) and acetonitrile (1/1, 1 mL) was kept at room temperature for 2 h with gentle shaking. The reaction mixture was lyophilized to dryness. The residue was subject to preparative RP-HPLC to give the glycopeptide M9Cluster-Pep (**10**) (1.9 mg, 79%): Analytical HPLC (Method B), $t_R = 11.49$ min; ESI-MS: 2389.39 $(M + 5H)^{5+}$, 2357.21 $(M - Man + 5H)^{5+}$, 1991.38 $(M + 6H)^{6+}$, 1964.55 $(M - Man + 6H)^{6+}$, 1707.08 $(M + 7H)^{7+}$, 1684.01 $(M - Man + 7H)^{7+}$.

Oligomannose Cluster/KLH Conjugate (11). A mixture of thiolated KLH (10 mg), prepared according to the reported procedure (*33*), and the maleimido-M9Cluster 8 (2.2 mg) in a mixed solvent of phosphate buffer (pH 6.6, 50 mM) and acetonitrile (1/1, 3 mL) containing EDTA (5 mM) was incubated at room temperature for 4 h with gentle shaking. Then a solution of cysteine (0.1 M, 100 μL) in a phosphate buffer was added to quench any residual maleimide on KLH. The solution was lyophilized, and the conjugate M9Cluster-KLH (**11**) was isolated by gel filtration on a Sephadex G-15 column equilibrated and eluted with a phosphate buffer (10 mM, pH 7.2). The carbohydrate content was measured by anthrone assay, and the protein content was measured using BioRad dye reagent according to the manufacturer's instructions.

Man9/T-Helper Peptide Conjugate (13). A mixture of the maleimido-Man9 (*34*) (2.5 mg, 1.14 μmol) and the cysteine-containing tetanus toxoid peptide (TT-peptide) (5.4 mg, 2.8 μmol) in a mixed solvent containing phosphate buffer (pH 6.6, 50 mM) and acetonitrile (1/1, 1 mL) was kept at room temperature for 2 h with gentle shaking. The reaction mixture was lyophilized and the residue was subject to preparative RP-HPLC to give the glycopeptide Man9-Pep (**13**) (3.7 mg, 81%): Analytical HPLC (Method B), $t_R = 11.37$ min; ESI-MS: 1359.27 $(M + 3H)^{3+}$, 1305.27 $(M - Man{+}3H)^{3+}$, 1251.27 $(M - 2Man{+}3H)^{3+}$, 1019.73 $(M + 4H)^{4+}$, 979.24 $(M - Man{+}4H)^{4+}$, 938.62 $(M - 2Man{+}4H)^{4+}$.

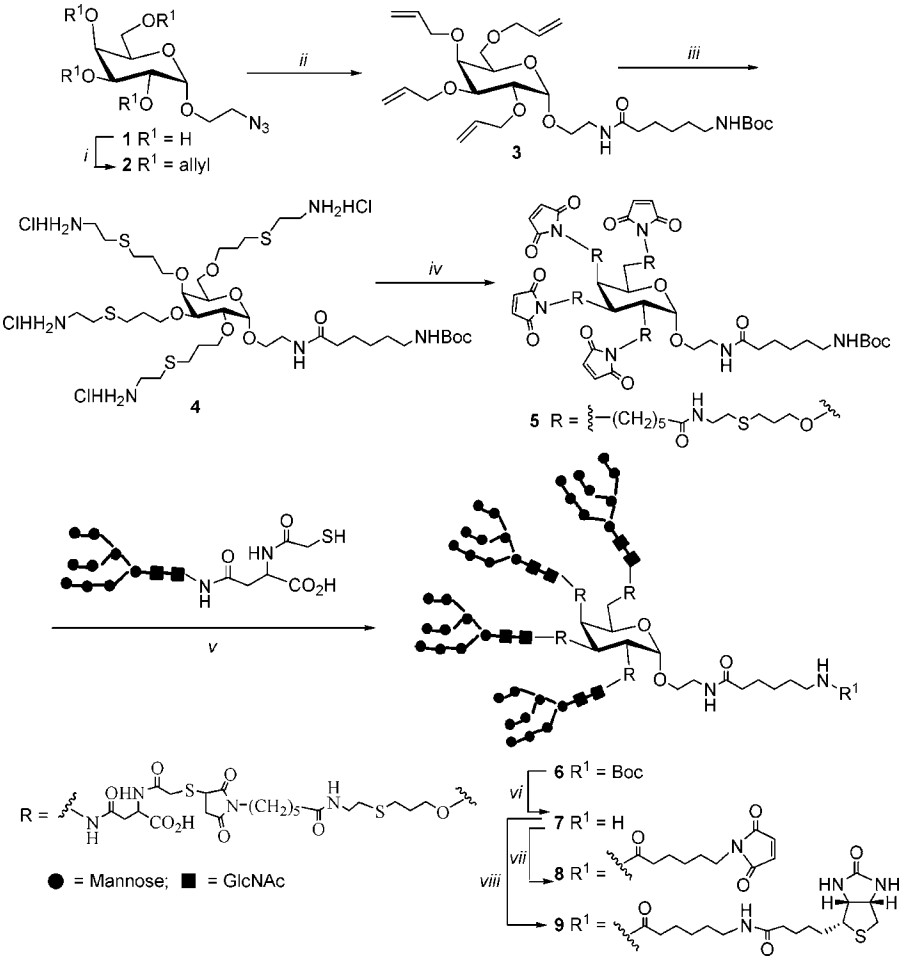
Man9/KLH Conjugate (14). A mixture of thiolated KLH (5 mg) and the maleimido-Man9 (1.5 mg) in a mixed solvent of phosphate buffer (pH 6.6, 50 mM) and acetonitrile (1/1, 2 mL) containing EDTA (5 mM) was incubated at room temperature for 4 h with gentle shaking. Then a solution of cysteine (0.1 M, 50 μL) in a phosphate buffer was added to quench any residual maleimide on KLH. The solution was lyophilized, and the conjugate Man9-KLH (**14**) was isolated by gel filtration on a Sephadex G-15 column equilibrated and eluted with a phosphate buffer (10 mM, pH 7.2). The carbohydrate content was measured by anthrone assay and the protein content was measured using BioRad dye reagent according to the manufacturer's instructions.

Biotinylated Man9 (15). A mixture of Man9GlcNAc2Asn (3 mg, 1.5 μmol) and NHS-LS-biotin (4.5 μmol) in a mixed solvent of phosphate buffer (pH 7.4, 50 mM) and acetonitrile (2/1, v/v, 1.0 mL) was stirred at room temperature for 3 h. The mixture was lyophilized and the residue was purified by preparative HPLC to give the Man9-X-biotin (**15**) (2.17 mg, 62%): Analytical HPLC (Method A), $t_R = 8.97$ min; ESI-MS: 2337.60 $(M + H)^+$, 1169.16 $(M + 2H)^{2+}$, 1088.40 $(M - Man + 2H)^{2+}$, 1007.12 $(M - 2Man + 2H)^{2+}$, 926.09 $(M - 3Man + 2H)^{2+}$, 845.12 $(M - 4Man + 2H)^{2+}$, 764.02 $(M - 5Man + 2H)^{2+}$.

Rabbit Immunizations. New Zealand white rabbits (two rabbits per group) were used for the immunization studies. One milligram of respective glycoconjugate in 500 μL of water was emulsified with 500 μL of complete Freunds' adjuvant (CFA). The emulsions were used for immunizing rabbits (two rabbits per group) subcutaneously. The rabbits were then boosted three times at days 14, 28, and 56, with each rabbit receiving at the intervals 0.5 mg of each glycoconjugate in 500 μL water emulsified with 500 μl of incomplete Freunds' adjuvant (IFA). The rabbits were bled 10 days after the last boosting and the sera were obtained for the assays.

Virus Neutralization Assay. The neutralizing activity of the sera was examined by the previously described method (*35*). Briefly, HIV-1_{IIIB} (100 $TCID_{50}$) was preincubated with serial dilutions of the rabbit anti-sera in RPMI 1640 containing 15% FCS for 45 min at 37 °C. Then 1.5×10^5 PHA-activated PBMCs were added, and the mixture were incubated for 24 h at 37 °C. The infected cells were washed five times with the complete medium to remove unabsorbed virus and residual antibody. Cells were resuspended in the complete medium containing IL-2 and were distributed into wells of a 96-well

Scheme 1. Synthesis of Maleimide- and Biotin-tagged Oligomannose Clusters[a]



[a] Reaction conditions: (i) allyl bromide, NaH, DMF, 88%; (ii) *N*−Boc-6-aminocaproic acid, Bu_3P, toluene, 46%; (iii) cysteamine hydrochloride, AIBN, MeOH, UV (254 nm), 82%; (iv) 6-maleimidohexanoic acid *N*-hydroxysuccinimide ester, THF, 0.1 M $NaHCO_3$, 44%; (v) phosphate buffer (pH 6.6, 50 mM)/MeCN (1:1, v/v), 68%; (vi) TFA/MeCN/H_2O (10:10:1, v/v), 90%; (vii) 6-maleimidohexanoic acid *N*-hydroxylsuccimide ester, phosphate buffer (pH 7.4, 50 mM)/MeCN (1:1, v/v), 68%; (viii) NHS-LC-biotin, phosphate buffer (pH 7.4)/MeCN, 84%.

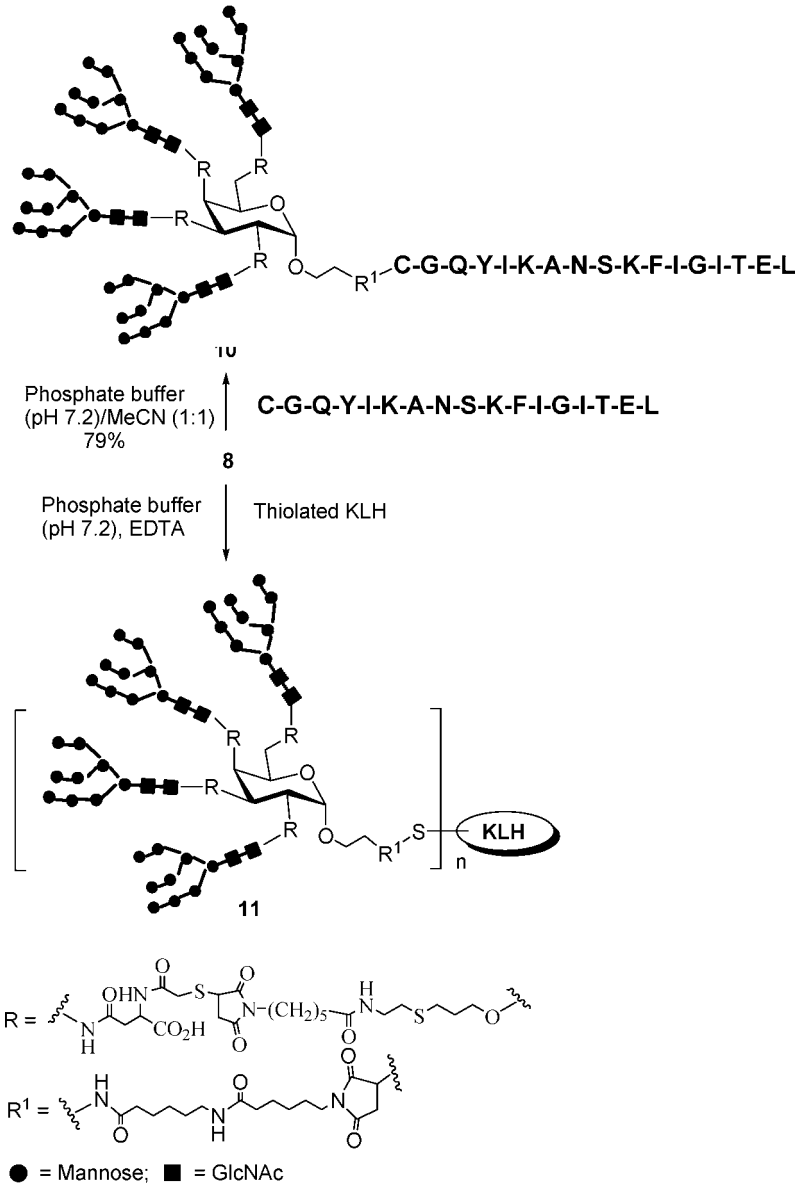
tissue plate. Aliquots were taken from the culture on day 4 and 6. Viral growth was determined by measuring HIV-1 p24 antigen released into the culture medium by ELISA. The extent of neutralization activity was determined by measuring and comparing the p24 antigens released from the cells that were infected by the virus in the presence and absence of the rabbit sera or antibody. Human antibody 2G12 was used as a positive control for the neutralizing activity.

Enzyme-Linked Immunosorbent Assay (ELISA). For biotinylated antigens (Man9-X-biotin, M9Cluster-x-biotin, G−X-biotin, and GCluster-X-biotin), the 96-well ELISA microtiter plates were first coated with 8 μg/mL Neutravidin (streptavidin) in PBS and incubated at 4°C overnight. After washings with PBS/0.5% Tween-20, nonspecific binding was blocked with 5% (w/v) BSA in PBS at room temperature for 1 h. Plates were washed, and then 5 μg/mL of the respective biotinylated antigen in 1% BSA was added. Plates were incubated at 37 °C for 1 h. The plates were again washed, and rabbit sera were added in a 1:2 or 1:3 serial dilution in 1% BSA/PBS. The plates were incubated at 37°C for 2 h and washed. To the plates was added a solution (100 μL) of 1:2000 diluted horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG (H & L) in 1% BSA/PBS. After incubation for 1 h at 37 °C, the plates were washed again and a solution of 3,3′,5,5′-tetramethylbenzidine (TMB) was added. Color was allowed to develop for 5 min, and the reaction was then quenched by adding a solution of 0.5 M H_2SO_4 to each well. The optical density was then measured at 450 nm. For testing the cross-reactivity of the sera to HIV-1 gp120, 10 μg/mL of HIV-1 (BAL) gp120 (produced in human H9 cell lines) was coated to the 96-well plates, and antibody titers were measured as described above. For testing the binding of the synthetic glycoconjugates with human antibody 2G12, the 96-well microtiter plates were incubated with 10 μg/mL of Man9-KLH and M9Cluster-KLH, and then the plates were titrated against a serial dilution of human antibody 2G12 (obtained from the NIH AIDS Research and Reference Reagent Program) starting at 10 μg/mL. After washings, the plates were incubated with a solution (100 μL) of 1:3000 diluted horseradish peroxidase (HRP)-conjugated goat anti-human IgG in 1% BSA/PBS. Color was developed and the OD_{450} was read.

RESULTS AND DISCUSSION

Synthesis. The construction of the glycoconjugate vaccines requires chemoselective conjugation of the galactose-based oligomannose cluster (Tetra-Man9) to a carrier protein or to a T-helper epitope peptide. For this purpose, the galactose scaffold was modified at the aglycon portion so that a suitable functional group could be selectively generated at later stage for ligation without influencing the integrity of the assembled oligomannose cluster. The synthesis started with the 2-azidoethyl α-D-galactoside (**1**), which was prepared by reaction of D-galactose with 2-chloroethanallyl alcohol under the catalysis of $BF_3{\cdot}Et_2O$ with subsequent displacement of the chloride with azide (*34*). Treatment of **1** with sodium hydride and allyl bromide in *N*,*N*-dimethylformamide gave the O-allylated 2-azidoethyl galacto-

Scheme 2. Synthesis of Oligomannose Cluster-Peptide/Protein Conjugates

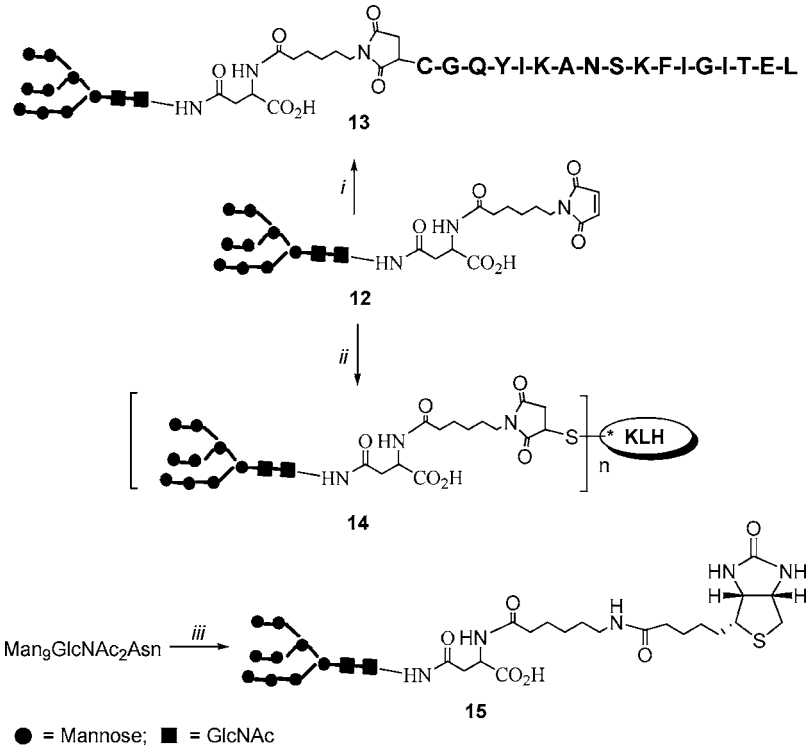


side **2**. Reaction of **2** with *N*-Boc-6-aminocarproic acid in the presence of tributylphosphine gave the derivative **3**. Introduction of four maleimido groups was achieved via a two-step conversion: the photoaddition of cysteamines to the allyl functional groups in **3** to give compound **4**, and subsequent elongation of the spacer by reaction of the free amino groups with the active ester of 6-maleimidohexanoic acid to provide the maleimido derivative **5** (Scheme 1). The ligation of the maleimido-functionalized scaffold with the SH-tagged Man9GlcNAc2Asn, which was prepared according to the literature (*27*), was performed in phosphate buffer (pH 6.6) containing MeCN to give the oligomannose cluster **6** in 68% yield, which was purified by HPLC and characterized by ESI-MS. The *N*-Boc group was selectively removed by treatment with TFA−MeCN−H_2O (10:10:1, v/v) to yield compound **7** that carries a free amino group. Treatment of **7** with 6-maleimidohexanoic acid *N*-hydroxylsuccinimide ester gave the maleimido-functionalized oligomannose cluster **8** in 68% yield. Selective biotinylation of **7** with active ester NHS-LC−biotin afforded the biotin-tagged oligomannose cluster (M9Cluster-X-biotin) (**9**) in 84% yield, which would be used as the coating antigen (Scheme 1).

The synthesis of the oligomannose cluster-containing glycoconjugates was achieved through the chemoselective ligation of the maleimido-functionalized oligomannose cluster (**8**) with the respective thiol-species under a mild aqueous condition. Briefly, chemoselective ligation between maleimide **8** and the T-helper peptide CGQYIKANSKFIGITEL from tetanus toxoid (aa830−844) (*32*) in a phosphate buffer (pH 6.6) containing MeCN gave the glycopeptide conjugate **10** (M9Cluster-Pep) in 79% yield, which was purified by HPLC and characterized by ESI-MS. On the other hand, treatment of **8** with thiolated KLH (*33*) in a phosphate buffer gave the KLH conjugate **11**, M9Cluster-KLH, which was isolated by gel filtration (Scheme 2). The corresponding Man9-containing glycopeptide conjugate **13**, Man9-Pep, was synthesized by chemoselective ligation between maleimido-functionalized Man9 (**12**) (*34*) and the TT-peptide (81% yield). Reaction of the maleimide-Man9 (**12**) with the thiolated KLH afforded the Man9-KLH conjugate **14** (Scheme 3). The carbohydrate contents of the KLH conjugates were determined by carbohydrate and protein assays. The synthetic M9Cluster-KLH (**11**) was determined to contain 15% carbohydrate, whereas the Man9-KLH (**13**) contained 19% carbohydrate. Finally, the coating antigen, Man9-X-biotin (**15**), was synthesized by treatment of Man9GlcNAc2Asn with NHS-LC-biotin (Scheme 3).

Binding of the Synthetic Glycoconjugates to Antibody 2G12. The 2G12 binding ability of the synthetic glycoconjugates

Scheme 3. Synthesis of Man9-KLH, Man9-Peptide, and Man9-Biotin Conjugates[a]



[a] Reaction conditions: (i) Cys-tagged T-helper peptide, phosphate buffer (pH 6.6)/MeCN (1:1, v/v), 81%; (ii) thiolated KLH, phosphate buffer (pH 7.2), EDTA; (iii) NHS-LC-biotin (Pierce), phosphate buffer (pH 7.4, 50 mM)/MeCN (1:1, v/v), 62%.

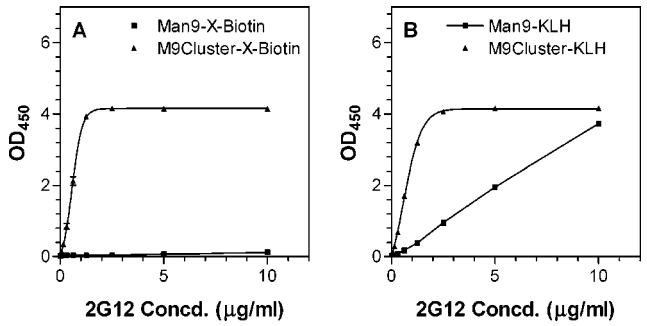


Figure 2. Binding of antibody 2G12 to synthetic glycoconjugates. A, binding to biotinylated Man9 and Man9 cluster; B, binding to KLH-conjugated Man9 and Man9 cluster.

was estimated by ELISAs. For the binding assays, the biotinylated coating antigens, M9Cluster-X-biotin (**9**) and Man9-X-biotin (**15**), were immobilized on streptavidin plates, whereas the KLH conjugates (**11**) and (**14**) were coated directly to the plastic microtiter plates. The plates were then titrated with serial dilutions of antibody 2G12 (Figure 2). As shown in Figure 2A, the Man9-cluster was readily recognized by antibody 2G12 at an apparent EC50 of ca. 0.8 μg/mL under the assay condition. However, the immobilized monomeric Man9 was unable to catch 2G12 in the solution when the concentration of 2G12 was below 10 μg/mL. The results are consistent with the previous observations that synthetic Man9-clusters are much better antigens than the monomeric Man9 oligomannose (*27*, *28*, *30*). Interestingly, the synthetic Man9-KLH conjugate, which contains 19% Man9 (by weight), was able to bind to 2G12 (EC50 at ca. 6 μg/mL) (Figure 2B), demonstrating certain clustering effect of the Man9 moieties within the conjugate. The 2G12-binding ability of M9Cluster-KLH is about the same as that of the M9Cluster-X-biotin under the same binding conditions (Figure 2, panels A and B). The results suggest that the mild chemoselective conjugation between the M9Cluster-maleimide and the thiolated KLH did not affect the structural integrity of the oligomannose cluster.

Immunization Studies. We next evaluated the immunogenicity of the synthetic glycoconjugates in rabbits. Pre-sera were taken before the immunization and the anti-sera were collected after four immunizations (priming and three boosts). The sera were first tested against the respective antigen-X-biotin as the coating antigen. The ELISA results were summarized in Table 1. It was found that the KLH conjugates raised higher IgG type antibody titers than the corresponding peptide conjugates. Particularly, the M9Cluster-KLH raised unusually high antibody titer (> 1:100 000). To examine the possibility that the antibodies might be raised against the linkers rather than the carbohydrate antigens, we prepared the corresponding biotin-tagged linkers (linker-X-biotin) by treatment of the biotin-tagged glycoconjugates with endo-β-*N*-acetyl-glucosaminidase from *Arthrobacter* (Endo-A). Endo-A is known to be able to remove the high-mannose type N-glycan (here, Man9GlcNAc) from gly-

Table 1. ELISA Antibody Titers against the Respective Coating Antigens[a]

	synthetic immunogens			
coating antigens	Man9-KLH	M9Cluster-KLH	Man9-Pep	M9Cluster-Pep
Man9-X-biotin	960	n.d.[b]	640	n.d.[b]
G-X-biotin	460	n.d.[b]	480	n.d.[b]
M9Cluster-X-biotin	n.d.[b]	163,840	n.d.[b]	2560
G-Cluster-X-biotin	n.d.[b]	81,920	n.d.[b]	1280

[a] The antibody titer was defined as the highest dilutions of the sera that yielded an absorbance (OD_{450}) of 0.2 in the ELISA. [b] Not determined.

Table 2. ELISA Antibody Titers against HIV-1 gp120[a]

	synthetic immunogens			
rabbit sera	Man9-KLH	M9Cluster-KLH	Man9-Pep	M9Cluster-Pep
pre-sera[b]	80	60	60	80
anti-sera	120	150	80	120

[a] The antibody titer was defined as the highest dilutions of the sera yielded an absorbance (OD_{450}) of 0.2 in the ELISA. [b] The pre-sera were the sera taken from each of the rabbit group before immunizations.

coconjugates by cleaving the N-glycans at the GlcNAcβ1,-4GlcNAc linkage (*36*, *37*). As monitored by HPLC coupled with ESI-MS analysis, we found that incubation of the Man9-X-biotin and the Man9Cluster-X-biotin with Endo-A could completely remove the Man9 portions from the conjugates, giving the corresponding GlcNAc-X-biotin (G-X-biotin) and GlcNAcCluster-X-biotin (G-cluster-X-biotin), respectively. When the G-X-biotin and G-Cluster-X-biotin were used as the coating antigens on a streptavidin plate, the ELISA assay revealed that the majority of the antibodies generated were in fact directed to the linkers, although a small fraction of the antibodies might be raised against the carbohydrate antigen (Table 1). The results suggest that the oligomannose (Man9) and the corresponding clustered oligomannose antigens were poorly immunogenic even when conjugated to KLH (a strong immune-stimulating carrier protein) or to the TT-peptide (a universal T-helper epitope). On the other hand, the fact that the majority of antibody responses were directed to the linkers strongly suggests that the choice of an appropriate linker in making the glycoconjugate vaccines is of primary importance for raising sufficient antibody responses against the weakly immunogenic carbohydrate antigen. Recently, an excellent study has also demonstrated that a maleimide-functionalized linker significantly suppressed the immunogenicity of a tumor-associated carbohydrate antigen in its KLH conjugate (*38*), resulting in low antibody titers specific for the carbohydrate antigen.

We also tested reactivity of the rabbit sera toward HIV-1 envelope glycoprotein gp120 (BAL gp120 expressed in human H9 cell lines) (Table 2). It was found that the rabbit pre-sera showed a significant background of cross-reactivity to the HIV-1 gp120. Nevertheless, the anti-sera clearly showed an enhanced reactivity to HIV-1 gp120 above the background of the pre-sera (Table 2), which might be contributed from the oligomannose-specific antibodies in the anti-sera. A preliminary HIV-neutralization assay indicated that, at 1:10 dilution, none of the rabbit anti-sera demonstrated HIV-1 neutralizing activities. The results implicated that either the glycoconjugates failed to raise any neutralizing antibodies under the immunization protocol or, if any, the neutralizing antibodies might be generated only at very low levels insufficient to show neutralizing activities.

CONCLUSION

The recent characterization of the neutralizing epitope of the broadly neutralizing antibody 2G12 as a novel oligomannose cluster on the envelope glycoprotein gp120 has implicated the possibility of developing a carbohydrate-based HIV-1 vaccine. The present work represents the first attempt to create such a vaccine by synthesizing oligomannose- and oligomannose cluster-containing glycoconjugates. The synthetic oligomannose cluster could be recognized by the human antibody 2G12 in binding studies. Preliminary immunization studies suggested that moderate carbohydrate-specific antibodies were raised by the glycoconjugate immunogens, but the majority of antibody responses were directed to the linkers. In addition, the anti-sera were weakly cross-reactive to HIV-1 gp120, but the carbohydrate-specific antibodies in the anti-sera generated by our current immunization protocol have not reached the level that could neutralize HIV-1 infection. The results implicated the poor immunogenicity of the carbohydrate antigens and, again, attested to the difficulties of raising neutralizing antibodies against HIV-1 in general. It is suggested that the next step should focus on enhancing the immunogenicity of the HIV-1 carbohydrate antigen, such as synthesizing more effective glycoconjugate immunogen (better linkers and more effective built-in adjuvant), optimizing the immunization protocols, and emphasizing fundamental studies on B cell immunology to break the immune tolerance on the HIV-1 carbohydrate antigens.

ACKNOWLEDGMENT

We thank Prof. Anthony L. DeVico, Prof. George K. Lewis, Dr. Shibo Jiang, and Dr. Robert Powell for helpful discussions during the work. The human antibody 2G12 was obtained from the National Institutes of Health (NIH)'s AIDS Research and Reference Reagent Program. The work was supported by the National Institutes of Health (NIH grant R21 AI054354).

Kinetics of Amine Modification of Proteins

George P. Smith[†]

Division of Biological Sciences, Tucker Hall, University of Missouri, Columbia, Missouri 65211-7400. Received October 14, 2005; Revised Manuscript Received December 23, 2005

A simple kinetic model for coupling small molecules such as biotin to proteins with amine-reactive reagents such as *N*-hydroxysuccinimide esters is developed. It predicts the reagent concentration required to modify a protein at a given concentration to a specified number of modified amines per molecule. By optimizing the model's three adjustable kinetic parameters, its predictions can be brought into close agreement with empirical data for modification of IgG, serum albumin, and other proteins over a wide range of protein and reagent concentrations. Data for modification of one protein can be used to approximate the results for modification of another protein with the same reagent under the same reaction conditions.

INTRODUCTION

A typical protein has numerous surface-exposed α- and ϵ-amino groups; in their unprotonated form they are strong nucleophiles that can be efficiently modified by a number of electrophilic reagents under mild, non-denaturing conditions to yield stable adducts. Although it sometimes happens that a few modifiable amino groups lie in or near functional sites—for example, the antigen-binding sites of an antibody—many more lie elsewhere on the surface of the molecule. Random modification of a few of these groups with small molecules is therefore unlikely to functionally inactivate more than a small fraction of the molecules. For these reasons, amine modification has become the most commonly used method of coupling small groups such as biotin or fluorescent dyes to proteins (reviewed in ref *1*). To exploit this simple coupling technology fully, it is necessary to control the level of amine modification. Increasing the number of coupled groups per protein molecule far beyond the required number unnecessarily incurs the risk of inactivating a significant fraction of the target proteins. The purpose of this paper is to help researchers achieve this goal by developing a simple mathematical model of modification kinetics.

It is obviously desirable that the reaction solution be as free as practicable of competing nucleophiles such as primary and secondary amines, but depletion of the reagent by hydrolysis is inevitable in aqueous solution, at a rate that depends on the particular reagent, pH, temperature, and buffer composition. In this regard, the protein itself must be considered a buffer component, quite apart from its modifiable amines. Protein-dependent hydrolysis would include futile modifications (e.g., of histidine) leading to unstable adducts that are rapidly hydrolyzed to regenerate the original nucleophile. In light of these considerations, hydrolysis will be divided into two additive components: a protein-independent component, the rate of which is independent of protein concentration; and a protein-dependent component, the rate of which is proportional to protein concentration, which is assumed to be effectively constant throughout the course of the reaction even though the content of modifiable amines diminishes.

Figure 1 shows a typical modification reaction, which will serve as an exemplar in this work: biotinylation with the *N*-hydroxysuccinimide (NHS) ester NHS−PEO_4−biotin. Nucleophilic attack on the activated carbonyl by a protein amino group displaces the NHS leaving group and couples the biotin-containing moiety to the protein through a stable amide bond. Competing with this modification reaction is hydrolysis, which releases the NHS leaving group and a nonreactive carboxyl.

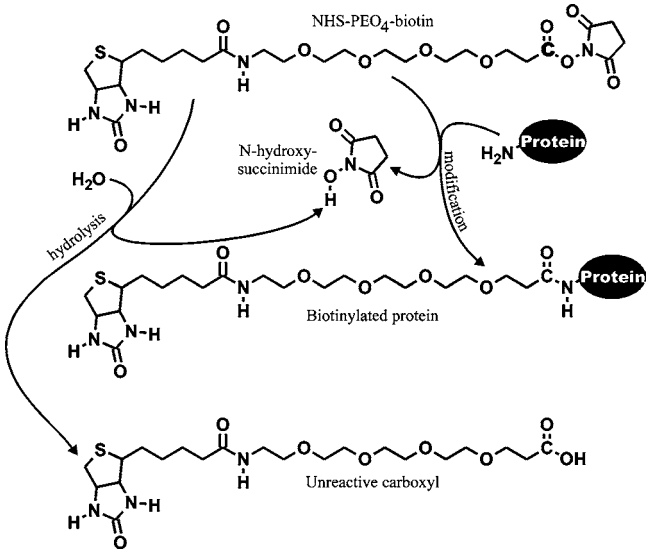

Figure 1. Modification of protein amines with the *N*-hydroxysuccinimide (NHS) ester, NHS−PEO_4−biotin. The electrophilic carbonyl carbon attacked by the nucleophile (protein amine or water) is printed in bold type.

Despite their name, amine-reactive reagents are not entirely selective for amines. In particular, free (non-disulfide-bonded) cysteine thiols in their unprotonated form are stronger nucleophiles and, if accessible on the protein surface, are readily modified by most amine-reactive reagents. The resulting thio adducts are generally much more susceptible than amine adducts to nucleophilic attack by neighboring nucleophiles on the protein itself or by nucleophilic solutes, but in the absence of such nucleophiles can be sufficiently stable in aqueous solution to be operationally indistinguishable from amine adducts. For the sake of simplicity in what follows the term "amine" will be used to refer to all stably modifiable nucleophiles, even though in some cases a few thiols or other nucleophilic groups might be included.

EXPERIMENTAL PROCEDURES

Biotinylation. Immunoglobulin G (IgG) was purified by protein G chromatography from human serum after prior solvent/detergent (SD) treatment essentially as described (*2*) and by protein A chromatography from rabbit serum with and without SD treatment. The IgGs were dialyzed against phosphate-buffered saline (PBS), pH 7.2 (0.15 M NaCl, 0.1 M NaH_2PO_4, pH adjusted to 7.2 with NaOH), and quantified spectrophotometrically, assuming an absorbance of 1.4 at 280 nm for a 1 mg/mL solution (*3*) and a molecular mass of 150 kDa. Bovine serum albumin (BSA; Sigma Chemical Co., St. Louis, MO; catalog no. A7906) was dissolved in water at a concentration of 726 μM, as determined spectrophotometrically assuming a molar extinction coefficient of 44 022 at 280 nm.

In each of 16 reactions, 1 mg of human IgG was reacted with various concentrations of NHS−PEO_4−biotin reagent in final volumes ranging from 100 μL to 7.1 mL. To accomplish this, the protein was diluted in PBS, pH 7.2, to a calculated volume slightly less than the final volume; a 2 mg (3.4 μmol) portion of the reagent (No-Weigh NHS−PEO_4−biotin; Pierce Chemical Co., Rockford, IL) was dissolved in 100 μL of dimethyl sulfoxide and diluted to the desired concentration in PBS, pH 7.2; working as rapidly as feasible, the diluted reagent was pipetted into the reaction vessels in sufficient volumes to give the desired final volumes and reagent concentrations; the vessels were vortexed immediately and incubated overnight (16−20 h) at room temperature. After the addition of PBS, pH 7.2, to the biotinylated IgG (Bio-IgG) samples as necessary to bring the total volume to 7.1 mL, they were concentrated to ∼50 μL by four concentration cycles on centrifugal ultrafiltration devices with a molecular mass cutoff of 30 kDa (Centricon; Millipore Corp., Bellerica, MA) and freed of uncoupled biotin by four cycles of dilution with 1.8 mL of TBS, pH 8 (0.15 M NaCl, 50 mM Tris-HCl, pH 8.0) and concentration to ∼50 μL on the same ultrafiltration devices. The final Bio-IgG retentates (in ∼50 μL) were diluted with 400 μL of TBS, pH 8, and quantified spectrophotometrically; the yield of Bio-IgG was ∼80% of the starting IgG. Reactions with rabbit IgG and BSA were carried out similarly.

Measuring Biotinylation Level. Most biotin assays rely on competition between the analyte (the biotin to be quantified) and another ligand for binding to avidin or streptavidin. Protein-coupled biotins, unlike free biotins, cannot react freely with all four biotin-binding sites on a tetrameric avidin or streptavidin molecule because of steric hindrance. Moreover, multivalent biotinylation can lead to formation of aggregates with uncertain effects on the results. These uncertainties can be reduced if the biotin analyte is released from the protein by acid hydrolysis or proteolytic digestion prior to quantitation (*1*, *4*, *5*). The biotinylation levels reported here were measured by inhibition ELISA after first digesting the biotinylated protein extensively with proteinase K and filtering the digest through a centrifugal ultrafiltration device with a molecular mass cutoff well below the size of intact proteinase K (molecular mass = 27 kDa).

In 2.2 mL microtubes, 2 μL of SDS/DTE (5% SDS, 10 mM dithioerythritol in TBS, pH 8) was mixed with 16 μL of TBS, pH 8, containing a known amount (∼30 μg) of biotinylated protein; after heating to 95−100 °C for 5 min, cooling to room temperature, and brief centrifugation to drive condensation to the bottom, 2 μL of 20 mg/mL proteinase K stock solution [a 1:1 v/v mixture of glycerol and 40 mg/mL proteinase K in 0.3 M NaCl, 0.1 M *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid), pH adjusted to 7.5 with NaOH; stored at −20 °C] was added (enzyme/substrate weight ratio = 1.3), and the tube was incubated at 50 °C for 30 min. After brief centrifugation, the digests were heated to 95−100 °C for 5 min, briefly centrifuged again, diluted with 1.8 mL of TBS, pH 7.5 (0.15 M NaCl, 50 mM Tris-HCl, pH 7.5), and filtered through a Centricon ultrafiltration device with a molecular mass cutoff of 10 kDa. A less extensive proteinase K digestion of biotinylated protein (enzyme/substrate weight ratio = 0.02; 37 °C for 24 h) is sufficient to release the bulk of the biotin in the form of free biotin and much of the remainder as small biotinylated peptide fragments (*5*). In accord with that finding, a pilot experiment in which fluoresceinated IgG and BSA were digested and filtered in the same way as our biotinylated proteins showed quantitative recovery of fluorescence in the filtrate and no detectable retention in the retentate (data not shown).

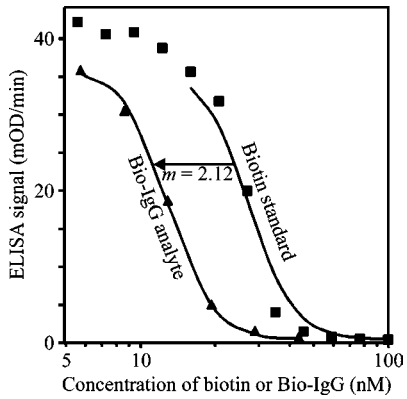

Figure 2. Biotin quantitation by inhibition ELISA. Analyte (filtered protein K-digested Bio-IgG) and biotin standard at known concentrations were tested for the ability to inhibit binding of an alkaline phosphatase conjugate of streptavidin (AP−SA) to biotinylated BSA immobilized on ELISA wells, as described in the text. All ELISA signals from a given ELISA dish were fitted to an empirical equation of the form $y = B + S/[1 + (mc/C)^N]$, where y = predicted ELISA signal (dependent variable), c = concentration of biotin or Bio-IgG inhibitor (independent variable), m = modification level (number of biotins per molecule; $m = 1$ for the biotin standard; m = a single positive number for all dilutions of a given Bio-IgG analyte), and B, S, C, and N are unknown "nuisance" parameters assumed to be constant for all 96 wells of a single ELISA dish. The modification level m for each Bio-IgG analyte and the four nuisance parameters were adjusted to minimize the root-mean-squared (RMS) deviation of the empirically measured ELISA signals from the theoretical ELISA signals predicted by the above equation. ELISA signals >35 mOD/min were excluded as being less accurate and informative than lower signals. On a semilogarithmic plot like the one shown, all curves of ELISA signal y as a function of inhibitor concentration c will have the same shape, but will be shifted to the left relative to the curve for the biotin standard ($m = 1$) by the increment $\log(m)$. The optimal value of m determined in this way for a given Bio-IgG sample was taken as the estimate of its biotinylation level. The modification levels for biotinylated proteins other than Bio-IgG were determined similarly.

Inhibition ELISA (detailed in the next paragraph) quantifies the ability of the analytes (filtered proteinase K digests) and of a free biotin standard to block binding of an alkaline phosphatase conjugate of streptavidin (AP−SA; Jackson ImmunoResearch Laboratories, West Grove, PA) to immobilized biotin in the wells of a 96-well ELISA dish. To minimize the effects of steric hindrance on the association rate, the AP−SA was preincubated with analyte or biotin for 30 min before being loaded into the biotin-coated wells.

The wells of the ELISA dish were first coated overnight at 4 °C with 200 μL of TBS, pH 7.5, containing nonbiotinylated BSA at 100 μg/mL and biotinylated BSA (Sigma; nominally 10 biotins/molecule) at 2 μg/mL. Meanwhile, using TBS/Tween (TBS, pH 7.5, supplemented with 0.5% v/v Tween 20) as diluent, serial dilutions of a free biotin standard at concentrations ranging from 1.95 to 100 nM and of the proteinase K filtrates equivalent to biotinylated protein concentrations ranging from 0.2 to 45 nM were set up. In the wells of a round-bottom 96-well dish (not the ELISA dish) were mixed 50 μL portions of the biotin and filtrate dilutions and 150 μL portions of a 200

- $da/dt = -k_m a r$
- $dr/dt = -k_m a r - (k_h + QP)r$

dividing the second equation by the first yields an easily solved differential equation relating r to a:
- $dr/da = 1 + [(k_h + QP)/k_m](1/a)$

eq 1 of the text is the solution to this equation when the reaction goes to completion ($r = 0$)

ng/mL dilution of AP−SA (also in TBS/Tween diluent); the dish was incubated for 30 min at room temperature. As that incubation was ending in the round-bottom dish, the ELISA dish was washed with a plate washer and 150 μL portions were pipetted from the wells of the round-bottom dish into the corresponding wells of the ELISA dish, which was incubated for 30 min at room temperature to allow AP−SA to bind the immobilized biotinylated BSA. The ELISA dish was washed extensively on a plate washer, and the wells were filled with 150 μL portions of substrate solution: a fresh mixture of 20 mL of 1 M diethanolamine, pH adjusted to 9.8 with HCl, 20 μL of 1 M $MgCl_2$, and 200 μL of 50 mg/mL *p*-nitrophenyl phosphate (stored at −20 °C). The difference between the optical density (OD) at 405 and that at 490 nm was read at 3 min intervals over a 57 min period on a kinetic plate reader at room temperature to obtain a slope (mOD/min) for each well (1 mOD corresponds to an OD of 1/1000), which was taken as the ELISA signal; for slopes up to at least 50 mOD/min, time dependence is linear, with correlation coefficients usually exceeding 0.995.

Figure 2 shows an example of an inhibition ELISA with the filtered proteinase K digest of a Bio-IgG sample. As can be seen in the graph, the equivalent Bio-IgG concentration required to reach a given level of inhibition was 2.12 times lower than the concentration of free biotin required to reach the same inhibition level; the modification level of this Bio-IgG sample is therefore estimated at 2.12 biotins/molecule. Duplicate measurements (on separate ELISA dishes) with all biotinylated protein samples gave closely similar numbers with few exceptions.

The inhibition data for the free biotin standard in Figure 2 deviate slightly but systematically from the theoretical curve, indicating that protein-derived biotins are not entirely equivalent kinetically to free biotins. A plausible explanation is that a few biotins remain coupled to small peptide fragments even after extensive proteinase K digestion, as noted above (*5*). Such peptide-coupled biotins may well bind streptavidin with somewhat altered kinetics compared to free biotin because of steric hindrance, thus accounting for the slight deviations in Figure 2. Still, there is no reason to believe such peptides are so abundant and so kinetically different from biotin as to lead to large errors in biotin content estimates. Complete acid hydrolysis has been advocated as a method for releasing all protein-coupled biotin in the form of free biotin (*5*); however, as measured by inhibition ELISA, that method yielded only 66% as much biotin from a Bio-IgG sample as did proteinase K digestion, possibly because some biotin was destroyed or altered in the acid (*6*). In any case, modest errors in biotin level (on the order of 33%, say) are seldom of practical importance and do not undermine the conclusions of this paper—especially if, as seems likely, they apply proportionally across all samples (see below under eq 2).

RESULTS AND DISCUSSION

Mathematical Model. If one makes the simplifying assumptions that all amines react independently and identically, depletion of the target amines and amine-reactive reagent from their respective initial concentrations is described by the differential equations in Table 1. At completion of the reaction those equations have the solution

$$R = \left[m - \frac{Q}{k_m}\ln\left(1 - \frac{m}{M}\right)\right]P - \frac{k_h}{k_m}\ln\left(1 - \frac{m}{M}\right) \qquad (1)$$

where M = total number of modifiable amines per protein molecule, m = average number of amines modified per protein molecule at completion of the reaction, R = reagent concentration, P = protein concentration, k_m = second-order modification rate constant, k_h = first-order protein-independent hydrolysis rate constant, and Q = second-order protein-dependent hydrolysis rate constant (derivation in Table 1).

According to eq 1, the reagent concentration R required to achieve a given modification level m is a linear function of the protein concentration P, with slope $[m - (Q/k_m)\ln(1 - m/M)]$ and intercept $-(k_h/k_m)\ln(1 - m/M)$ (both expressions are always positive, because the logarithm is negative). It is obvious from this expression that the ratio of reagent to protein, R/P, is not an adequate description of reaction conditions, contrary to common practice in protein chemistry. Indeed, in circumstances when the intercept term of eq 1 dominates, either because the protein concentration P is low or because protein-independent hydrolysis is relatively fast compared to modification, the reagent concentration required is independent of protein concentration. To fully describe the conditions of a modification reaction, therefore, both the reagent concentration R and the protein concentration P must be individually specified (along with buffer composition and pH, temperature, and time of reaction).

In most applications, the fraction of available amines modified m/M will be small (less than ~20%, say), in which circumstances $-\ln(1 - m/M) \approx m/M$ and eq 1 can be approximated by

$$R \approx \left[\left(1 + \frac{Q}{k_m M}\right)P + \frac{k_h}{k_m M}\right]m \quad \text{when } \frac{m}{M} \ll 1 \qquad (2)$$

In a typical modification reaction, therefore, the reagent concentration R required to achieve modification level m at fixed

protein concentration P will be nearly proportional to m. In these circumstances, proportional errors in measuring m lead only to the same proportional errors in R.

The mass-action law that underlies eq 1 is silent on the values of the three kinetic parameters Q/k_m, k_h/k_m, and M—or, when eq 2 applies, the two parameters Q/k_mM and k_h/k_mM. Those parameter values must be estimated empirically by adjusting their values to optimize the fit of eq 1 (or eq 2) to experimentally measured modification levels. It is vital that those experimental measurements span a wide range of protein concentrations, because modification at a single protein concentration is essentially governed by a single proportionality constant—the quantity in square brackets in eq 2—and cannot be used to constrain two or three separate parameters.

Biotinylation as an Example of Amine Modification. Conjugating biotin to proteins opens up a wealth of techniques that exploit the extremely rapid and stable binding of biotin to avidin and streptavidin (reviewed in refs *1* and *7*). For most of these purposes, a modification level of 2−3 biotins per molecule is fully sufficient and stands very little chance of interfering with the biological activity of most modified proteins. Biotinylation of human IgG with NHS−PEO_4−biotin (Figure 1) will serve as the chief example of amine modification in this paper.

Sixteen human IgG samples at concentrations ranging from 0.953 to 67.6 μM (from 143 μg/mL to 10.1 mg/mL) were biotinylated overnight at room temperature with NHS−PEO_4−biotin at various concentrations in PBS, pH 7.2, and freed of uncoupled biotin as described under Experimental Procedures. The biotin contents of the resulting biotinylated IgGs (Bio-IgGs) were quantified by proteinase K digestion and duplicate inhibition ELISA as described under Experimental Procedures. The measured biotinylation levels m were fitted to eq 1 by adjusting the kinetic parameters to optimize agreement with the data. A series of four biotinylation reactions with BSA were likewise fitted to eq 1, yielding an independent set of optimal parameter values. In Figure 3 those optimized IgG and BSA parameter values (reported in the caption) are used to plot the predicted reagent concentration R required to achieve various modification levels m as a function of protein concentration P (IgG in the upper part of the graph, BSA in the lower part); in a linear plot these isomodification contours would be straight lines, as explained above under eq 1. Superimposed on the theoretical contour curves are the data on which they are based. For each biotinylation reaction, the open symbol marks the actual concentrations of protein and reagent, whereas the associated horizontal bars plot the reagent concentration R that according to eq 1 would theoretically be required to achieve the biotinylation levels m actually measured for that sample (one bar for each of the duplicate determinations). The closeness of the bars to each other testifies to the excellent reproducibility of the biotin determinations; the closeness of the bars to their corresponding open symbols testifies to the excellent fit between the observed data and the theoretical calculations over a wide range of protein and reagent concentrations. Also included in the upper part of Figure 3 (but not considered in optimizing the IgG parameter values) are four reactions with rabbit IgG; here, too, the observed biotinylation levels closely match the predictions of eq 1. This graph illustrates dramatically how eq 1 allows results of a handful of pilot experiments to be parlayed into reliable projections covering a broad continuous range of concentrations of the same protein and the same reagent under the same reaction conditions.

As Figure 3 shows, eq 1 (or, when applicable, its corollary eq 2) applies in form to biotinylation of both IgG and BSA, although the optimal parameter values are different for the two proteins as will be detailed in the next subsection. It is probable that eq 1 will likewise apply in form to almost any amine

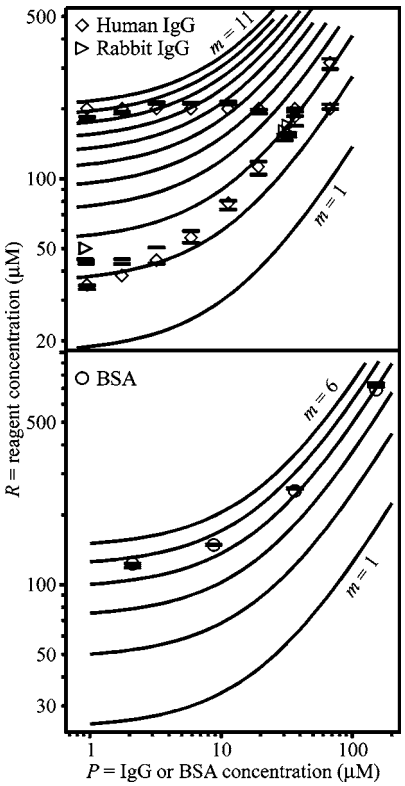

Figure 3. Graph of NHS−PEO_4−biotin concentration R required to biotinylate human and rabbit IgGs (upper part) and BSA (lower part) to various modification levels m as a function of protein concentration P. The theoretical curves are iso-modification contours for $m = 1-11$, calculated according to eq 1 (IgG) or eq 2 (BSA) with the following optimized parameter values: $k_h/k_m = 2274$ μM, $Q/k_m = 25.60$, and $M = 128.9$ accessible amines per molecule for IgG; and $k_h/k_mM = 24.1$ μM per accessible amine and $Q/k_mM = 0$ for BSA. The open symbols plot the protein and reagent concentrations for each reaction; the associated pair of horizontal bars represent the duplicate results for that reaction, as explained in the text.

modification reaction that goes to completion, because it appeals only to basic principles of mass action that successfully describe the great majority of chemical interconversions. In accord with this supposition, for example, Larson et al. (*8*) found that the degree of modification of IgG at constant concentration with amine-reactive poly(ethylene glycol) (PEG) polymer chains was directly proportional to the concentration of the PEGylating reagent, as predicted by eq 2. The mathematical model's most vulnerable assumption is kinetic homogeneity of the accessible aminess, but it is not necessary for that assumption to be literally true for eq 1 to be empirically useful: all that is required is that there exist compromise values of the parameters that give a reasonable approximation to the overall kinetic behavior of the amines. Equation 1 may be much less successful if extended to high degrees of modification, when the homogeneity assumption would be more severely challenged, but in most applications calling for the kinetic predictability afforded by eq 1, only modest modification levels are of practical interest.

The ratio $[(Q/k_mM)P)/((k_h/k_m)M] = QP/k_h$ gauges the relative contribution of protein-dependent and protein-independent hydrolysis to consumption of the reagent. For IgG that ratio reaches 0.75 at the highest IgG concentrations P, when hydrolysis as a whole is relatively unimportant compared to modification, but declines proportionally at lower IgG concentrations as hydrolysis comes to dominate. For BSA the ratio vanishes altogether. The data therefore do not support the existence of a significant protein-dependent route for hydrolysis of NHS−PEO_4−biotin. When protein-mediated hydrolysis is negligible and the modification level m is modest compared to the total number of

Table 2. Dependence of the Kinetic Parameters of Equation 1 on Reagent, Protein, and Reaction Conditions and Sensitivity of Predictions of Equation 1 to Variations in Those Parameters[a]

	expected dependence of parameter on			
parameter	reagent	protein	conditions	sensitivity of reaction kinetics to variations in parameter
k_h	strong	none	strong	strong
k_m	strong	none	strong	strong
M	weak	proportional to amines?	strong	strong
Q	strong	proportional to MW?	strong	weak

[a] See text for details.

accessible amines *M*, eq 2 reduces further to the single-parameter approximation

$$R \approx \left(P + \frac{k_h}{k_m M}\right)m \quad \text{when } \frac{m}{M} \ll 1 \text{ and } \frac{QP}{k_h} \ll 1 \qquad (3)$$

It is entirely possible that protein-dependent hydrolysis may be much more important for amine-reactive reagents other than NHS−PEO_4−biotin, however—particularly when the reactive function is something other than an NHS ester.

It is evident from Figure 3 that at the lowest protein concentrations *P* explored the curves are nearly horizontal because consumption of reagent by modification of protein amines or protein-mediated hydrolysis is negligible compared to consumption by non-protein-mediated hydrolysis. In those circumstances eq 3 further simplifies to the approximation

$$R \approx \left(\frac{k_h}{k_m M}\right)m \quad \text{when } \frac{m}{M} \ll 1 \text{ and } \left(1 + \frac{Q}{k_m M}\right)P \ll \frac{k_h}{k_m M} \qquad (4)$$

and it is not necessary to know the protein concentration accurately to modify it to a specified level. This case underscores the inadequacy of reagent/protein ratio *R*/*P* alone as a description of the conditions of a modification reaction, as emphasized in the previous subsection (Mathematical Model).

Applicability to Different Proteins, Reagents, and Conditions. The three parameters of eq 1 are composed of four fundamental parameters that arise directly from the underlying kinetic model and that respond in different ways to changes in the protein, reagent, and reaction conditions (pH, buffer composition, and temperature). The parameters k_h and k_m, respectively, gauge the susceptibility of the reagent to protein-independent hydrolysis and its intrinsic reactivity with an accessible amine; they are therefore specific to the reagent but independent of the protein. In contrast, *M* gauges the total number of accessible amines on the protein molecule; it is therefore specific to the protein and may also depend somewhat on the reagent to the degree that the reagent's structure affects its access to amines. For a given reagent *M* should vary roughly in proportion to the total number of amines, although of course there will be excursions from this trend because of variations in protein shape and other properties. Finally, *Q* parametrizes the rate of protein-dependent hydrolysis and, in general, may depend on both reagent and protein. This mode of hydrolysis is presumably due to various surface groups on the protein, and because the nature of those groups is unknown, the best guess is that *Q* for a given reagent is roughly proportional to total protein molecular mass. All four fundamental parameters might depend strongly on pH and temperature, but probably only weakly on buffer composition provided no strong nucleophiles are included. These theoretical dependencies are summarized in the second, third, and fourth columns of Table 2. The last column of the table summarizes the sensitivity of reaction kinetics (*R* as calculated from eq 1) to variation in the four kinetic parameters. The value of each parameter was halved and doubled relative to its optimal value for the IgG data, keeping the other three parameters constant, and the resulting overall deviations from the original values of *R* were scored. This sensitivity analysis reveals that halving or doubling *Q* changes the theoretical predictions of eq 1 only slightly, reflecting the finding that protein-dependent hydrolysis is minor or nonexistent (see above). In contrast, halving or doubling the other three parameters drastically changes the predictions of eq 1 in at least some circumstances.

Because eq 1 is based on an oversimplification of the true kinetic situation (particularly the simplifying assumption that all modifiable amines are kinetically homogeneous), the parameter values that optimize the fit to actual data may represent compromise values in which the theoretical dependencies in Table 2 are somewhat blurred. For example, the optimal value of the parameter *M* for IgG in Figure 3, 129 modifiable amines per molecule, certainly cannot be interpreted literally, in that it greatly exceeds the number of accessible IgG amines [~30 as determined at saturating concentrations of another NHS ester, *N*-succinimidyl *S*-acetylthioacetate (*1*)], and indeed exceeds the total number of amines in a typical IgG (~90). Because the conditions of eq 2 apply to a good approximation for most of the IgG reactions, the overall fit of eq 1 to the IgG data can evidently be improved by exaggerating the value of *M* substantially while keeping the ratios Q/k_mM and k_h/k_mM roughly the same. The improvement is slight: the best fit to the data with *M* fixed at 30 is nearly as good as the overall best fit. Despite these reservations to the theoretical parameter dependencies, though, it is reasonable to accept them as first approximations in extrapolating results from one combination of protein, reagent, and reaction conditions to another. For instance, whatever the discrepancy between the optimal value of *M* for IgG and that protein's actual content of modifiable amines, when one is extrapolating from IgG to other proteins, it is reasonable to assume that *M* scales as the total amine content to a first approximation. The BSA data in Figure 3 provide an opportunity to test the validity of such projections. Because BSA has 44% of the molecular mass and 66.7% of the total amine content of IgG, parameters k_h/k_mM and Q/k_mM for biotinylation of BSA are projected to be $(k_h/k_m)/M \approx 2274/0.667 \times 129 = 26.4\ \mu M$ per accessible amine and $(Q/k_m)/M \approx (0.44 \times 25.6)/(0.667 \times 129) = 0.13$ per accessible amine. Actual results for BSA biotinylation optimally fit values of 24.1 and 0 for those parameters, respectively (Figure 3 caption). The agreement for the first parameter (24.1 predicted, 26.5 observed) is quite close, whereas the discrepancy for the second (0.13 predicted, 0 observed) is of little significance because protein-dependent hydrolysis seems to be very minor. By the same token, the observed BSA modification levels were only 11−19% higher than those projected on the basis of the IgG results. The BSA data thus suggest that results for modification of one protein can be used to make reasonable predictions about modification of another with the same reagent under the same reaction conditions. Such extrapolations—especially if supported by a handful of additional proteins—are of great practical usefulness because they bypass the need for preliminary investigation of modification kinetics for each new protein to be modified (provided great precision is not required). For modifications such as biotinylation that are difficult to quantify accurately (see Experimental Procedures), a great deal of effort can thereby be saved. For proteins in very short supply, valuable material can be spared. It remains to be ascertained if other additional useful generalizations will emerge from further investigation with additional reagents, proteins, and reaction conditions.

Synthesis, Photophysical Effects, and DNA Targeting Properties of Oxazole Yellow−Peptide Bioconjugates

Martin Thompson*

Department of Chemistry, Michigan Technological University, 1400 Townsend Drive, Houghton, Michigan 49931. Received October 17, 2005; Revised Manuscript Received January 19, 2006

The design of a dsDNA-sensitive fluorescent bioconjugate capable of targeting a specific DNA sequence with high efficiency is described. The bioconjugate has the molecular recognition features of the polypeptide from a DNA-binding protein and the dsDNA-dependent fluorescence of an intercalating dye. The DNA sequence selectivity of the probe was characterized, as were the changes in photophysical properties of the dye upon covalent linkage to the peptide to assess whether such bioconjugates could function as molecular probes of gene sequences. The oxazole yellow−peptide bioconjugate exhibits DNA recognition and binding affinity comparable to the native Hin recombinase protein. Examination of photophysical effects to dye conjugation indicates a negligible affect on the fluorescence quantum yield. Fluorescence studies indicate this molecular probe is useful to determine the presence of a given DNA target sequence and gives negligible fluorescence in the absence of a given target site. Using the synthetic route described here, bioconjugates could be designed using different combinations of DNA recognition polypeptides and cyanine dyes to generate an array of sequence specific and wavelength specific probes.

INTRODUCTION

Small molecular mimics of DNA-binding proteins have previously been shown to be useful as synthetic nucleases (*1*−*4*), inhibitors of protein interactions (*5*−*7*), and transcriptional activators (*8*). In fact, recent studies indicate thiazole orange−peptide bioconjugates can act as synthetic nucleases via two competing mechanisms, which depend on environmental conditions (*4*). The functionality responsible for targeting in the bulk of such studies is derived from a segment of a DNA-binding protein comprising the protein−DNA interface (*3*, *9*). Using short polypeptides as recognition molecules, however, has the drawback that alone they bind with low affinity. This is largely because many of the native protein−DNA contacts at the interface, including numerous electrostatic interactions between backbone phosphates and positively charged side chains located in nearby regions of the protein, are lost. To develop molecular probes of DNA sequence and structure, these peptide−dye bioconjugates need to be highly sequence-specific due to the low ratio of specific to nonspecific sites in genomic DNA, and bind with sufficiently high affinity to ensure it remains bound long enough to be a useful probe of its local environment.

The sequence specific DNA targeting region of a native DNA-binding protein can be excised from the full-length protein without altering its molecular recognition features. This means that short peptides can be constructed with strategically positioned fluorophores to generate sequence specific molecular probes capable of being highly fluorescent when bound to a DNA target site, yet effectively invisible in the absence of this site. Such polypeptides can readily be made using solid-phase synthesis in conjunction with specific chemistries required to add non-native functional probes at specific positions along the peptide chain. The resulting bioconjugates spatially orient the probe and optimize its interaction with DNA (*3*, *4*, *10*, *11*). Furthermore, this approach overcomes time-consuming and low yield strategies, such as cloning using standard molecular biology techniques, followed by the incorporation of mutant side chains to conjugate fluorophores or other reporter groups at specific positions within the protein sequence. Oftentimes, cysteines are used for the selective incorporation of non-native reporter groups. This requires several workup steps and can significantly decrease yields due to oxidative cross-linking of free thiols into disulfide linkages. The strategy described here is a direct synthesis strategy that avoids such low yield workup steps and results in high yield, high purity preparations of fluorescent DNA targeting probes.

The polypeptide used in these studies was derived from the Hin recombinase of *Salmonella typhimurium.* Hin belongs to the invertase class of DNA-cleaving enzymes that catalyzes the inversion of a 1-kb segment of the chromosome to control flagellin gene expression by switching the orientation of the promoter (*12*). The Hin proteins bind as dimers to attain high affinity and high site selectivity by targeting left (hixL) and right (hixR) DNA sites that flank the invertible segment. Structural information about the Hin protein shows that it uses a helix-turn-helix motif to position a helix in the major groove at the hix target site (*13*). Hin interacts with the hixL half-site with higher affinity than the right half-site and therefore is used as the cognate site throughout these studies.

The intercalating dye used in this work is the cyanine dye oxazole yellow (YO)[1], which exhibits increased emission enhancement upon intercalation into dsDNA (*14*, *15*). Intercalation between the DNA bases forces the cyanine dye to adopt a planar conformation, which has a longer-lived excited state than the free (not DNA bound) dye. This feature makes the cyanine dyes ideal for use as a molecular probe of DNA, as it is effectively invisible when not bound to DNA. Oxazole yellow is widely used in cytology as a DNA stain due to its emission

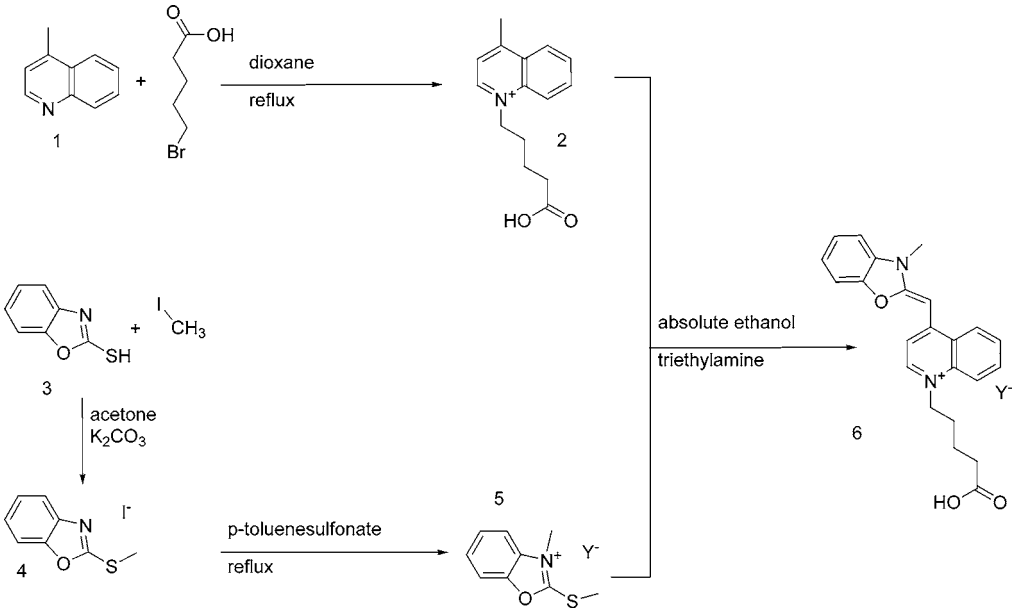
Scheme 1. Reaction Scheme for Synthesis of the Carboxylic Acid Derivative of Oxazole Yellow



enhancement of up to 2000-fold in going from a free to a DNA-bound state (*14*).

Solid phase peptide synthesis (SPPS) was used to couple the cyanine dye oxazole yellow at a strategically positioned lysine within an amino acid sequence derived from Hin recombinase (HIN). The oxazole yellow−Hin recombinase (YOHIN) bioconjugate probe has been prepared and characterized to understand the effects of peptide conjugation on dye photophysics, and to assess whether such probes would be useful as DNA sequence and wavelength sensitive stains. Fluorescence analysis is also used to characterize probe sensitivity to mutant hixL sequences to determine the extent to which the peptide moiety reproduces the binding features of the native protein. From design to functional application, synthetic bioconjugates represent an opportunity to develop systematically rational strategies for site-specific nucleic acid targeting by small readily made complexes. Furthermore, by using different combinations of DNA recognition polypeptides and cyanine dyes, groups of bioconjugates could potentially be synthesized with custom-made sequence and wavelength specificities.

EXPERIMENTAL PROCEDURES

Materials. Lepidine, 5-bromovaleric acid, 2-mercaptobenzoxazole, dipotassium carbonate, trimethyloxonium tetrafluoroborate, *p*-toluenesulfonate, iodomethane, acetone, dichloromethane, dioxane, anhydrous ethanol, and triethylamine were purchased from Aldrich (Milwaukee, WI) and used without further purification, except dioxane, which was distilled prior to use. F-moc amino acids and peptide synthesis reagents were purchased from Advanced Chemtech (Louisville, KY). The F-moc-Lys (Mtt)-OH was purchased from Anaspec (San Jose, CA).

Instrumentation. NMR spectra were recorded on a Varian 400 MHz spectrometer using a deuterated solvent and were referenced to TMS. Peptides were synthesized on a 9050 peptide synthesizer (Millipore, Bedford, MA). Purification of synthetic peptides was performed using high-performance liquid chromatography (HPLC). Bioconjugate characterization was performed using matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF) mass spectrometry with α-cyanohydroxycinnamic acid as matrix. Absorbance measurements were made on a Cary V spectrophotometer (Varian Instruments, Palo Alto, CA). Steady-state fluorescence measurements were performed on a Quantamaster-6/2003 Spectrofluorometer in T-format, with a 75W xenon lamp and analyzed with Felix32 Fluorescence Analysis Software (PTI, Canada).

Synthesis and Characterization of Carboxylic Acid Derivative of Oxazole Yellow. The synthesis of a carboxylic acid derivative of YO for use in SPPS of the bioconjugate was adapted from published procedures (*4*, *16*) and is shown in detail in Scheme 1. The YO derivative and intermediates were purified on silica gel 60−200 mesh using a 2:2:1 (v/v) acetic acid:water:ethyl acetate solvent solution characterized by ^{1}H NMR using a deuterated solvent (DMSO-d_6), referenced to tetramethylsilane (TMS) and confirmed with MALDI-TOF mass spectrometry.

Synthesis of 4-methyl-1-(4′-carboxybutyl)quinolinium (2) was performed by refluxing lepidine (1, 1.4 mL, 11 mmol) and 5-bromovaleric acid (5.7 g, 32 mmol) in 30 mL of distilled dioxane under nitrogen overnight. The reaction mixture was allowed to cool to room temperature and filtered. The precipitate was washed twice with 10 mL of dioxane followed by 50 mL of petroleum ether to yield 2.6 g (70%) of pure 4-methyl-1-(4′-carboxybutyl)quinolinium bromide (**2**). MALDI-TOF gave a molecular weight (*m*/*z*) of 244.9 (244.3, calculated for $C_{15}H_{18}NO_2^+$). ^{1}H NMR (400 MHz, DMSO-d_6) δ 1.42−1.52(m, 2H, CH_2), 1.87−1.97 (m, 2H, CH_2), 2.21 (t, J = 7.79 Hz, 2H, CH_2), 3.09 (s, 3H, CH_3), 4.93 (t, J = 7.39 Hz, 2H, NCH_2), 8.10−8.20 (m, 2H, Ar), 8.12−8.20 (m, 1H, Ar), 8.71−8.90 (m, 2H, Ar), 9.66 (d, J = 5.83 Hz, 1H, Ar).

Synthesis of 2-methylmercapto-3-methylbenzoxazole (5) was performed in a two-step reaction by first mixing 2-mercaptobenzoxazole (3, 2.0 g, 11 mmol), iodomethane (8.0 mL, 55 mmol), and K_2CO_3 (1.0 g, 7 mmol) in 100 mL of acetone for 60 min at 70 °C. Reaction mixture was filtered hot, and filtrate was dried in vacuo. Recrystallization from ethanol:diethyl ether gave 1.3 g (40%) of pure 2-methylmercaptobenzoxazole iodide (*4*). Next, 2-methylmercaptobenzoxazole (4, 1.0 g, 3 mmol) and trimethyloxonium tetrafluoroborate (1.1 g, 3.3 mmol) of were mixed in 50 mL of dichloromethane in a nitrogen environment for 5 h at room temperature. Precipitation with diethyl ether was followed by filtration and yielded 3.5 g (90%) of pure 2-methylmercapto-3-methylbenzoxazole (*5*). MALDI-TOF gave a molecular weight (*m*/*z*) of 179.8 (180.2, calculated for $C_9H_{10}NOS^+$). ^{1}H NMR (400 MHz, DMSO-d_6) δ 3.31 (s, 3H, SCH_3), 3.91 (s, 3H, NCH_3), 7.50−7.61 (m, 1H, Ar), 7.84−

7.88 (m, 1H, Ar), 8.00 (d, $J = 8.82$ Hz, 1H, Ar), 8.61 (d, $J = 7.66$ Hz, 1H, Ar).

Alternate synthesis of 2-methylmercapto-3-methylbenzoxazole (5) was performed by reflux of 2-methylmercaptobenzoxazole (4, 1.0 g, 3 mmol) in *p*-methyltoluenesulfonate (10 mL, 66 mmol) under nitrogen for 60 min. The reaction mixture was allowed to cool to room temperature, filtered, and washed with diethyl ether. Recrystallization from ethanol:diethyl ether gave 1.5 g (70%) of pure 2-methylmercapto-3-methylbenzoxazole tosylate (*5*). MALDI-TOF gave a molecular weight (*m*/*z*) of 180.5 (180.2, calculated for $C_9H_{10}NOS^+$).

Synthesis of Carboxylic Acid Derivative of Oxazole Yellow (6). 1-(4-Carboxybutyl)-4-[(3-methylbenzoxazol-2(3*H*)-ylidene)-methyl]quinolinium was synthesized by mixing 4-methyl-1-(4-carboxybutyl)quinolinium bromide (**2**, 1.0 g, 3 mmol) and 2-methylmercapto-3-methylbenzoxazole (**5**, 1.0 g, 3 mmol) in 30 mL of absolute ethanol with slight heating for 5 min. To this solution, triethylamine (840 μL, 6 mmol) was added causing the reaction mixture to immediately turn a deep red color. Heating was discontinued and the reaction allowed to stir for 60 min. Product was precipitated by addition of 150 mL of diethyl ether. Recrystallization from acetone:diethyl ether gave 1.4 g (80% yield) of pure 1-(4-carboxybutyl)-4-[(3-methylbenzoxazol-2(3*H*)-ylidene)methyl]quinolinium (**6**). MALDI-TOF gave a molecular weight (*m*/*z*) of 375.8 (375.5, calculated for $C_{23}H_{23}N_2O_3^+$). ^{1}H NMR (400 MHz, DMSO-d_6) δ 1.27−1.41 (m, 2H, CH_2), 1.87−1.99 (m, 2H, CH_2), 2.22 (t, $J = 7.93$ Hz, 2H, CH_2), 4.13 (s, 3H, NCH_3), 4.54 (t, $J = 7.54$ Hz, 2H, NCH_2), 6.91 (s, 1H, CH), 7.18 (d, $J = 7.62$ Hz, 1H, Ar), 7.61−7.66 (m, 1H, Ar), 7.57−7.67 (m, 1H, Ar), 7.71−7.85 (m, 2H, Ar), 8.01−8.11 (m, 1H, Ar), 8.26 (d, $J = 7.29$ Hz, 1H, Ar), 8.45 (d, $J = 7.83$ Hz, 1H, Ar), 8.62 (d, $J = 7.38$ Hz, 1H, Ar), 8.87 (d, $J = 8.81$ Hz, 1H, Ar).

Peptide Bioconjugate Synthesis and Characterization. All labeled and nonlabeled peptides were synthesized on PAL-PEG-PS resin by automated solid-phase peptide synthesis using F-moc protection and *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*^{9},*N*^{9}-tetramethyluronium hexafluorophosphate (HATU) coupling chemistry. The carboxylic acid derivative of the cyanine dye is attached to a F-moc-Lys (Mtt)-OH, which can be inserted anywhere in the polypeptide sequence and selectively deprotected. The Mtt protective group is removed by a mild treatment with 1% trifluoroacetic acid (TFA) in dichloromethane (DCM), leaving all other protective groups requiring 90% TFA for removal to remain intact. This process was performed by exchanging the solvent from *N*′,*N*′-dimethylformamide (DMF) to DCM, followed by washing the resin-bound peptide with the 1% TFA in DCM solution. Because Mtt removal results in a deep yellow change in color, the TFA/DCM wash was continued until no further color change was observed. After solvent exchange back to DMF, the carboxylic acid derivative of the appropriate dye was coupled to the lysine using HATU activated coupling chemistry. This dye attachment protocol was carried out either immediately after addition of F-moc-Lys (Mtt)-OH or after completion of the normal peptide synthesis. Peptides were purified by RP-HPLC on a Zorbax C8 column (9.4 mm × 25 cm) (Agilent Tech.,Palo Alto, CA) using a flow rate of 1 mL/min and a water (0.1% TFA)−acetonitrile (0.1% TFA) gradient from 20 to 60% acetonitrile over 40 min. Identities of the peptides were confirmed MALDI-TOF mass spectrometry. Stock solution concentrations of all peptide samples were determined using a Bradford Assay with BSA as a reference.

Oligonucleotide Sample Preparation. All oligonucleotides were synthesized on a DNA synthesizer using phosphoramidite chemistry and gel purified on a 12% denaturing polyacrylamide gel. Bands were cut out and recovered by soaking the crushed gel pieces in 50 mM Tris, (pH 8.0) 100 mM NaCl buffer for 4−6 h. Extractions were combined and the urea and salts removed by spin filtration or a Sephadex G-15 size exclusion column (Aldrich). Concentrations for purified single-stranded oligonucleotides were calculated from 260 nm absorbance using an extinction coefficient calculated from the nearest neighbor method (*17*, *18*). Oligonucleotides were annealed using the same molar equivalent of each oligonucleotide. The oligonucleotide sequences used in these studies are shown in Figure 1.

Figure 1. Peptide and oligonucleotide sequences used in this study. (A) The primary sequence of the oxazole yellow−Hin recombinase (YOHIN) bioconjugate used in these studies. The amino acid sequence derived from residues 139−190 of the native Hin recombinase was tethered to the cyanine dye oxazole yellow (shown in brackets). The underlined residues are those having α-helical secondary structure. (B) Oligonucleotides used in this study are 35-bases in length and derived from the native hixL recognition site. Native hixL sequence (HIN) is underlined. Note that as the binding site is progressively lost in going from HIN1 to HIN4, only native bases are underlined to highlight the sequence variation.

Determination of Spectral Properties. Absorbance spectra were taken over a concentration range of 0.5 to 5 μM for all samples under the indicated conditions. The DNA samples used were 1 to 10 μM dsDNA (2-fold molar excess was used for each measurement) that contained the appropriate cognate site. Samples for the free dyes were prepared by dilution of a dimethyl sulfoxide (DMSO) stock solution into the indicated solvent or aqueous buffer. Measurements were made in polypropylene cuvettes to minimize surface adsorption of the cyanine dyes in aqueous solutions. Serial dilutions were taken to ensure adherence to the Beer−Lambert law. The calculation of the extinction coefficient was performed by plotting absorbance versus concentration for different dilutions giving the slope, which is equivalent to the extinction coefficient.

Samples for determination of the quantum yield contained 50 to 500 nM conjugate in 20 mM Tris, (pH 7.6) 100 mM NaCl with 500 nM of the appropriate cognate DNA to ensure complete binding of the conjugate. Fluorescence quantum yields (Φ_F) for these samples were determined relative to fluorescein in 0.1 M NaOH ($\Phi_F = 0.90$) by integration of corrected emission spectra (*19*). Solutions used for fluorescence quantum yield determination for the conjugates were made to have the same absorbance (ca. 0.03) at absorbance maximum for each dye. The relative emission quantum yields were calculated as described by Demas and Crosby (*20*).

Fluorescence lifetime measurements were made using the time-correlated single photon counting method. The fundamental output from a Spectra Physics Tsunami laser was doubled by a Spectra Physics Model 3980 frequency doubler and pulse selector. The excitation rate was 4 MHz, pulse width 2 ps, average power ca. 1.1 W. A microchannel plate photomultiplier (Hamamatsu R2809U-11) was used to detect the fluorescence emission after passing the emission through a polarizer set at the magic angle with respect to excitation and through a single grating monochromator. The instrument response time was ca. 60 ps (full width at half maximum), as verified by scattering from Ludox AS-40. The spectrometer was controlled by software based on a Lab View program from National Instruments. Lifetime analysis was performed using the same samples and buffers as described above for the steady-state measurements

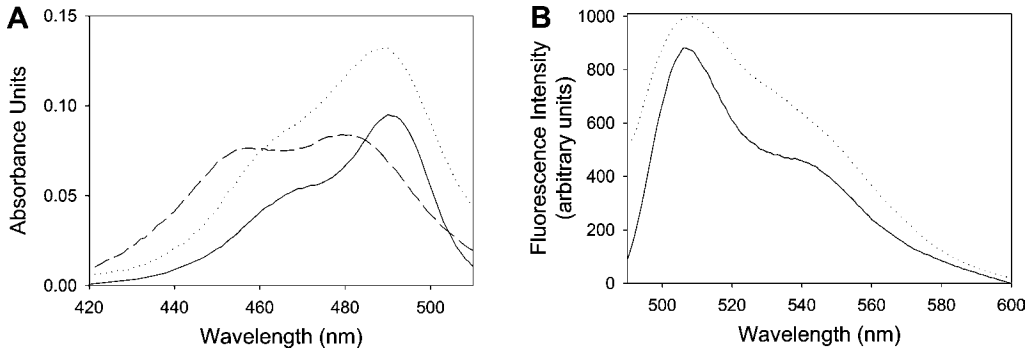

Figure 2. Comparison of the effect of conjugation on the spectral properties for the YOHIN bioconjugate in the presence and absence of the HIN1−DNA sequence. (A) Absorbance spectra used a concentration 2 μM for YOHIN in the absence (dashed line) and presence (solid line) of 4 μM DNA. (B) Fluorescence spectra of 50 nM of the bioconjugate (solid line) and 100 nM HIN1−DNA. Unconjugated oxazole yellow (dotted line) in the presence of DNA is shown in A and B for comparison. Excitation of the dyes are at 480 nm.

except that samples contained 100 nM YOHIN, and 200 nM DNA and no titrations were performed. Excitation of samples was at 440 nm and emission detection was at 510 nm. Fluorescence decays were analyzed by fitting to a sum of exponential decay terms convoluted with the measured instrument response function. This was done either at single measurement wavelengths or simultaneously to data taken at several emission wavelengths (*21*, *22*). The values for amplitude and lifetime are solved using MATLAB by use of an application called ASUFIT, which deconvolutes the individual lifetime components and their respective amplitudes.

Steady-state fluorescence measurements were performed as reverse titrations as described previously (*4*, *9*). Reverse titrations using 1 to 5 nM of the peptide−dye bioconjugate were performed by varying the concentration of nonlabeled DNA. Excitation was at 480 nm and emission detection at 510 nm for oxazole yellow samples. Measurements were carried out in 20 mM Tris (pH 7.6), 100 mM NaCl. Each measurement was performed at least three times and curves were fit as previously described (*4*). For fluorescence spectra, excitation was at 480 nm and emission spectra were taken from 500 to 600 nm with a 1 nm bandwidth on the excitation and emission monochromator.

RESULTS AND DISCUSSION

Bioconjugate Synthesis. Synthesis of the oxazole yellow−peptide bioconjugate using SPPS requires a carboxylic acid derivative of oxazole yellow to be synthesized (Scheme 1). Lepidine was reacted with bromovaleric acid to make the quaternary amine. The resulting charged quinolinium (**2**) was allowed to react with 2-methylmercapto-3-methylbenzoxazole (**5**), generating the carboxylic acid derivative of oxazole yellow (**6**). This product was characterized by ^{1}H NMR and mass spectrometry, indicating the desired products (see Experimental Procedures). The carboxylic acid derivative of YO was coupled to the ϵ-amine of a lysine strategically incorporated at the indicated position in the peptide sequence (Figure 1). This unique lysine has the Mtt protective group, which can be selectively deprotected to yield the free ϵ-amine of its side chain. To this lysine the HATU activated dye is coupled, forming an amide linkage between the lysine side chain and the dye. For HIN peptide samples without conjugated YO, the dye was simply not added. The amino acid sequence of the DNA-binding region of Hin recombinase (HIN) used in this study is shown in Figure 1. An HPLC analysis of purified bioconjugate and unlabeled HIN peptide showed only one peak in each respective chromatograph, which confirms the purity of these preparations. The expected mass of the purified YOHIN bioconjugate (oxazole yellow conjugated to the Hin DNA binding region) is 6522.3, and a sharp peak in its mass spectrum is observed for the singly charged species at (m/e) = 6523.8. The solid-phase synthesis of the bioconjugate was successful in giving a high-purity product in high yield with no detectible residual dye. This is important, as these dyes have an inherent affinity for intercalation into DNA, making any residual free dye a complication in interpreting results.

Spectral Profile. The spectral features of the peptide−bioconjugate are attributed exclusively to YO in the visible spectrum. Variations in YO photophysics are dependent on environmental changes resulting from peptide attachment. Absorbance spectra of the peptide bioconjugate in the presence and absence of DNA was examined to determine if DNA binding effects by YO behaves similar to when it is unconjugated (Figure 2). The visible absorbance spectrum of purified YOHIN in the absence of DNA shows two roughly equivalent peaks at 460 and 479 nm. After a 10 min incubation of YOHIN with DNA containing the HIN1 sequence, the absorbance maxima redshifts to 490 nm, with a much less pronounced shoulder to the blue side of the peak. The unconjugated YO shows a similar redshift upon DNA intercalation to 489 nm and a less prominent shoulder at 471 nm. This redshift in going from a highly solvated unbound YO dye to a less solvated, DNA intercalated state was also observed for other cyanine dyes, such as thiazole orange, indicating the environmentally sensitive spectral features are an inherent property of the cyanine family of dyes. It was previously shown that free thiazole orange underwent an approximately 10 nm redshift, with an increase in the absorbance maxima upon DNA addition (*23*). Figure 2 shows comparable effects of DNA-binding by dye, suggesting the dye is intercalated in both the unconjugated and bioconjugate form.

Based on the observed differences in the absorption profiles of unconjugated and conjugated YO, extinction coefficients for the YOHIN bioconjugate were determined in the absence and presence of DNA containing the HIN1 sequence. The extinction coefficient changes from 40 500 to 45 700 M^{-1} cm^{-1} upon DNA binding, representing an increase of more than 10%. This increase in the oscillator strength accompanies the observed 479 to 490 nm redshift that occurs upon DNA intercalation by the dye (Figure 2A). For comparison, the extinction coefficient of unconjugated YO decreases by approximately 20% in going from methanol to a Tris buffer (66 000 to 52 000 M^{-1} cm^{-1}). When incubated with DNA in an aqueous buffer, the unconjugated YO shows a slight increase in the extinction coefficient to 52 900 M^{-1} cm^{-1} that accompanies the aforementioned redshift upon DNA intercalation.

Next, fluorescence analysis was performed to characterize the photophysical effects of dye−peptide linkage on the fluorescence properties of the bioconjugate. The fluorescence

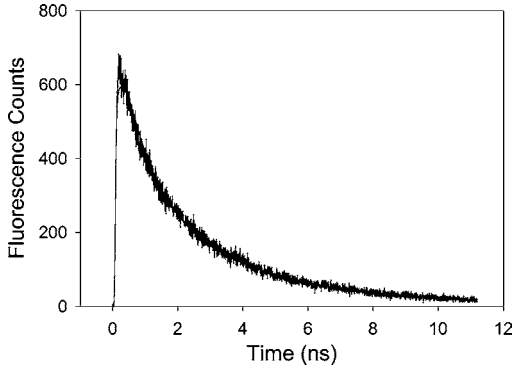

Figure 3. Time correlated single photon counting measurement of YOHIN bioconjugate bound to HIN1−DNA. Samples of 100 nM YOHIN bioconjugate preincubated for 10 min with 200 nM HIN1−DNA were examined using 440 nm excitation and 510 nm emission detection.

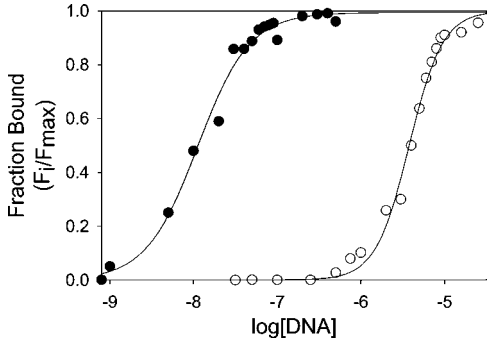

Figure 4. Fluorescence titrations of unconjugated and conjugated YO. Fluorescence measurements are given as a fraction of total fluorescence (F_i/F_{max}) versus the HIN1−DNA concentration. Total fluorescence from 1 nM YOHIN (●) and YO (○) when titrated with increasing concentrations of HIN1 is plotted and fit to a two-state binding model (*4*).

spectra for YOHIN is taken after 10 min incubation with DNA containing the HIN1 site (Figure 2B). The fluorescence spectra for the unconjugated or peptide conjugated dye is comparable, although there is a decrease in the signal intensity and shape of the spectral profile. For the cyanine dye-based probes, samples measured in the absence of DNA had very low fluorescence counts that were not significantly above the background (data not shown). The quantum yields for the YO and YOHIN were estimated by using fluorescein as a reference. The fluorescence quantum yield of HIN1−DNA-bound YOHIN bioconjugate is 0.37. The YOHIN in the absence of DNA shows negligible fluorescence, as is the case for the unconjugated YO (data not shown). The unconjugated YO was also determined to establish a basis of comparison to the known literature values and was found to be the comparable ($\Phi_F = 0.437$) within experimental error. The quantum yield for unconjugated YO intercalated into CT-DNA was previously determined to be 0.44 (*15*). For comparison, the fluorescence quantum yield for the unconjugated oxazole yellow in the absence of DNA was shown to be 4.8×10^{-4}. If it is assumed that the unbound bioconjugate exhibits the same low fluorescence quantum yield observed for the unbound YO, then the emission enhancement is approximately 770 for the DNA-bound YOHIN. The emission enhancement of unconjugated YO bound to CT-DNA was determined to be 920 (*15*), which is a difference of roughly 15%. This is a rather modest effect when compared to fluorescein, which shows a 50% decrease in quantum yield upon conjugation (*24*) and rhodamine, which is known to exhibit solvent, pH, and conjugation-dependent changes in its photophysical properties (*25*).

The fluorescence lifetimes are measured for the YOHIN conjugate bound to HIN1−DNA. Average lifetimes are calculated by summing the products of the emission lifetimes and their corresponding relative emission amplitudes. The lifetime values were determined from a global fit of three sets of spectra for each sample taken over the emission wavelength range of 510 to 530 nm (Figure 3). The fluorescence lifetimes and relative amplitudes of the emission decay fits (shown in parentheses) are 0.75 ns (0.58) and 3.14 ns (0.42), to give an average fluorescence lifetime of 1.92 ns. Unconjugated YO exhibits a lifetime of 2.22 ns when bound to CT-DNA, although sequence-dependent variations were also observed. YO has fluorescence lifetimes of 2.16 ns and 3.19 ns when intercalated into $d(AT)_6$ and $d(GC)_6$ sequences, respectively (*15*). The decrease in lifetime upon conjugation may reflect sequence-dependent effects, as the peptide forces the dye to intercalate at a narrowly defined region, two to three bases flanking the peptide binding site (*4*) or may be due to the peptide forcing the dye into binding modes that have lower quantum yields (*23*).

In summary, the photophysical properties of the dye are comparable for the unconjugated YO and YOHIN bioconjugate because the interaction of the dye with DNA is predominantly due to intercalation in both cases. The small decrease in the fluorescence quantum yield and lifetime compared to the unconjugated YO may be due to two reasons; the sequence-dependent photophysical properties previously observed (*15*), or the existence of two different DNA-binding modes by YO. The existence of a sub-population of bioconjugates where the dye moiety is bound to the DNA via electrostatic interactions was shown to be the case for a single zinc finger attached to thiazole orange (*4*, *26*). This external binding mode is known to be fluorescent, but with a lower quantum yield because rotation about the central methine bridge is more accessible than is the case for fully intercalated dye (*23*). This may be an additional mode with which the dye of the bioconjugate interacts with DNA and may explain the slight decrease in fluorescence quantum yield and lifetime. Single molecule studies support this notion of multiple DNA-binding modes by the dye, suggesting that the bound peptide moiety might force the dye to bind by intercalation or electrostatic interaction with the backbone (*26*, *27*). If the YO moiety of the YOHIN bioconjugate has two binding modes and fluorescence quantum yield varies with each binding mode (*23*), then the emission enhancement would depend on the relative populations of each binding mode.

DNA Targeting Properties. The equilibrium dissociation constants (K_D) were determined for the unconjugated YO and the YOHIN bioconjugate with the HIN1−DNA sequence. Binding data indicates a significant enhancement in the affinity of the bioconjugate for dsDNA over the dye alone (Figure 4). Together, the YOHIN bioconjugate has a $K_D \sim 10$ nM, indicating the contribution of both moieties. Individually, the HIN bound to HIN1−DNA has a $K_D \sim 120$ nM and the dye alone has a $K_D \sim 2$ μM. The dissociation constant is larger than the product of the individual dissociation constants from the polypeptide and the oxazole yellow, indicating that the binding of YO and HIN in the YOHIN bioconjugate is noncooperative. The binding event may act noncooperatively because both the dye and the peptide individually alter the structure of DNA. The dye has been shown to untwist the DNA approximately 20° (*28*), which may adversely affect peptide binding. Conversely, the crystal structure of the hixL-bound Hin recombinase shows the recognition helix alters base stacking at the protein−DNA interface (*13*, *29*). It is possible these structural perturbations force the dye to adopt alternate binding modes.

The interaction of YOHIN with cognate and noncognate DNA sequences, designed based on several mutant sequences known to adversely affect binding of the native Hin recombinase, was

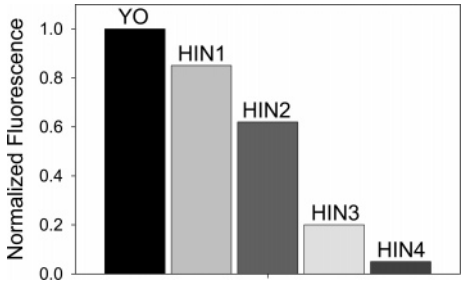

Figure 5. Total fluorescence intensity measurements of YOHIN incubated with the indicated HIN sequence. Measurements were performed at ambient temperature using concentrations of 20 nM YOHIN and 50 nM HIN−DNA in 20 mM Tris (pH 7.6), 100 mM NaCl. All data were normalized to the fluorescent counts for 20 nM unconjugated YO incubated with the HIN1−DNA sequence.

measured by steady-state fluorescence spectroscopy. The goal here was to determine if the bioconjugate reproduces the sequence-specificity of the native protein and to assess its usefulness as a suitable fluorescent probe for the detection of specific DNA sites. YOHIN was incubated with one of four HIN sequences; the appropriate native DNA-binding site or one of three mutated binding sites to quantify the relative fluorescence intensity of each (Figure 5). At 20 nM bioconjugate, the native DNA-binding site gives the highest fluorescence intensity with a progressive decrease in the fluorescence intensity as mutations in the binding site accumulate. These sequence-dependent variations in fluorescence are consistent with previous binding studies of the native Hin protein, which show roughly a 40% decrease in protein−DNA complex formation for the point mutation given in HIN2 (*12*, *30*, *31*). A thymine is mutated to a cytosine in HIN2, causing a critical contact with the thymine methyl to be lost. For comparison, the bioconjugate shows a 35% decrease in fluorescence counts in binding HIN2 versus the HIN1 cognate site. Fluorescence signal is progressively lost, as mutations accumulate in the region of the cognate site known to form the major groove−Hin contact interface (*13*, *31*, *32*). Nonspecific binding of HIN4 by YOHIN showed roughly 5% of the fluorescence signal observed for the cognate HIN1 sites.

The fact that the YOHIN bioconjugate reproduces the binding features of native Hin recombinase indicates the peptide moiety drives site recognition. This is in agreement with similar studies using polyamides, short peptides, single zinc fingers or helix-turn-helix motifs as the DNA-targeting element, which show the cyanine dye makes significant contributions to binding affinity but exerts negligible effects on sequence specificity (*4*, *33*, *34*). This is, in part, because the monomeric form of the dye has no sequence preference and intercalates with equal affinity to d(AT), d(GC), and poly(G)-poly(C) repeats as it does to calf-thymus DNA (*23*).

Determination of nonspecific binding at HIN4−DNA concentrations 10-, 50-, and 100-times higher show less than 50% of the maximum fluorescence intensity observed with the cognate site (data not shown). Similarly, 100 times the bioconjugate concentration was required to reach greater than 90% of the total fluorescence observed for YOHIN bound to HIN1−DNA. Unconjugated YO showed no sequence-dependent change in fluorescence intensity. The HIN conjugated dye is only able to intercalate DNA and emit fluorescence signal when the peptide is bound with high affinity to its native cognate site. The fluorescence from YOHIN incubated in the presence of DNA containing the target sequence is comparable in intensity to the same amount of the intercalating dye bound to DNA. This implies that the fluorescence yield and the level of occupancy of the dye on the DNA in the assembled bioconjugate DNA complex is comparable to that observed for unconjugated dye bound to DNA. The range of concentrations used in the screen described above limits the amount of nonspecific binding and makes the bioconjugate a very sensitive probe of sequence within the nanomolar concentration range.

In summary, the fluorescent intercalating dye, oxazole yellow (YO), has been tethered to the ϵ-amine of a lysine specifically positioned within the amino acid sequence of the HIN recombinase DNA-recognition region. YO has been shown to be several orders of magnitude more fluorescent upon intercalation into DNA, making it a very sensitive probe of DNA interaction (*14*, *23*). Here, we have used the DNA recognition features of the polypeptide to control DNA-sequence targeting and the ability of the dye to fluoresce only when bound to DNA. These studies reveal three main points: first, the photophysical properties of the probe show a small effect on the fluorescence lifetime and quantum yield upon conjugation to the peptide, second, the dye is only able to intercalate DNA and emit appreciable fluorescence signal when the peptide is bound with high affinity to its native cognate site, and third, that the specificity of the probe reproduces the molecular recognition features of the native protein. The roughly 10% loss of emission enhancement upon conjugation of YO to the peptide is most likely due to sub-populations of the dye adopting different DNA-binding modes known to have a lower quantum yield. In fact, recent single molecule measurements of a thiazole orange−histone H3 bioconjugate reconstituted into nucleosomes suggest that there may be multiple binding configurations of the dye molecule (*7*). Also, at low concentrations it seems the dye of the bioconjugate is unable to intercalate with noncognate DNA, indicating the peptide moiety is the driving force determining DNA-sequence specificity. For the YOHIN bioconjugate studied here, there is a 10-fold contribution to the HIN binding affinity by YO. While covalent attachment of oxazole yellow to the Hin recombinase DNA-binding region has been shown to greatly increase the DNA-binding affinity, it does not adversely effect the sequence specificity. The results of this work indicate that by using the strategy described here, bioconjugates could be designed using different combinations of DNA recognition polypeptides and cyanine dyes to generate an array of sequence specific and wavelength specific probes.

ACKNOWLEDGMENT

We thank Dr. Neal Woodbury for discussion and providing samples used in this study and Dr. Dan Brune for assistance with the peptide synthesizer.

Received November 3, 2005; Revised Manuscript Received January 19, 2006

Cancer targeting with peptides has become promising with the emergence of combinatorial peptide techniques such as phage display. Using phage display under stringent screening conditions, we selected five distinct peptides that specifically recognized the CD21 receptor, a cell surface marker of malignant B cell lymphoma. Two highly hydrophobic sequences were excluded (RLAYWCFSGLFLLVC and PVAAVSFVPYLVKTY). The binding affinity toward CD21 of the other three selected peptides (RMWPSSTVNLSAGRR, PNLDFSPTCSFRFGC, and GRVPSMFGGHFFFSR) was analyzed with fluorescence quenching. Their dissociation constants were determined to be within the micromolar range. On the basis of the results of phage ELISA, competitive phage ELISA, and fluorescence quenching, the binding sites of the three selected peptides were found to reside within the first four short consensus repeats of CD21 (SCR1−4). The peptide RMWPSSTVNLSAGRR (**P1**) was bound to the *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer, a potential drug carrier for chemotherapeutic agents, and the surface binding properties of HPMA copolymer−**P1** conjugates were investigated. Specific interactions were observed between HPMA copolymer−**P1** conjugates and surface-bound receptor. Binding of HPMA copolymer−**P1** conjugates was directly related to the amount of surface (MaxiSorp plate) bound receptor, and the binding of the conjugates could be inhibited by the application of a 3−4 orders-of-magnitude excess of free peptide over the peptide concentration in conjugates. The enhanced binding of polymer-bound peptide was ascribed to multivalent interactions between the HPMA copolymer−**P1** conjugate and the surface-bound CD21 receptor.

INTRODUCTION

Cancer therapy has entered a new era since the introduction of monoclonal antibodies (mAbs) for the treatment of various cancers (*1*−*4*). To date, nearly 10 monoclonal drugs have been approved by the United States Food and Drug Administration; examples include Rituxan (*5*) (Anti-CD20 mAb), Herceptin (*6*) (anti-Her2/*neu* mAb), and Bexxar (*7*) (^{131}I labeled Anti-CD20 mAb). mAbs alone may affect antitumor activity through the mechanisms of antibody-dependent cellular cytotoxicity and complement-dependent cytotoxicity. mAbs have also been extensively used to specifically deliver cytotoxic agents to tumor sites, due to the highly specific interaction between mAbs and their corresponding tumor antigens (*4*). Compared with conventional chemotherapy, therapy with immunoconjugates (targeting mAbs conjugated with anticancer drugs) results in significantly enhanced tumor-killing activity with minimal side effects (*8*).

An alternate approach is targeting with receptor-binding peptides (*9*). Because of their small molecular size, precise control of their chemical makeup and their chemical stability provides a variety of choices to construct sophisticated targeting arrangements, such as graft, starlike, and dendritic structures.

Peptide targeting has become feasible due to the advent of combinatorial peptide library techniques (*10*, *11*), such as phage display (*12*, *13*). Phage display is a powerful technique for bioscreening: by engineering the DNA structure of phage, a phage peptide library is constructed, so that millions of different peptides are displayed on the phage capsid and are accessible for interaction with target proteins. Peptides with desired properties can be selected and identified with appropriate screening methods. Phage display has been extensively used for epitope mapping (*14*), vaccine discovery (*15*), and ligand identification (*16*). There are also many successful examples using phage display to identify peptide ligands for cancer targeting (*11*, *17*). Proteins uniquely expressed or overexpressed by cancer cells can provide suitable targets. Although library screening with purified proteins is the most straightforward method, when the target protein is known and has been isolated, successful screening has been reported using targets other than purified proteins, such as in vitro screening with cancer cells (*18*), tumor tissues (*19*, *20*), and even directly applied to the entire cancer patient's body (*21*).

With phage display, peptides targeting the CD21 receptor, a surface marker for malignant B cell lymphoma phenotyping, may be selected (*22*). CD21 receptor (complement receptor 2, CR2) is a 145-kDa transmembrane glycoprotein that is expressed primarily on mature B lymphocytes, epithelial cells, thymocytes, and follicular dendritic cells (*23*). The extracellular region consists of 15−16 short consensus repeats (SCRs),[1] of which SCR1 and SCR2 are responsible for the interaction with several natural ligands, such as C3d, C3dg, and Epstein Barr virus (EBV). The expression of CD21 on B and T lymphocytes is upregulated by infection with the lymphocytotropic virus EBV and HTLV (*24*, *25*). CD21 receptor mediates internalization through endocytosis (*26*); therefore, it is regarded as a suitable target for the treatment of lymphoma with chemotherapy. Two different forms of CD21 receptors, soluble CD21 (sCD21) (*27*) and recombinant short CD21 (rsCR2.1−4) (*28*), were used in this work. sCD21 is a 135-kDa protein generated from shedding

and cleavage of the extracellular portion of CD21 receptor, while rsCR2.1−4 is a recombinant short CD21 receptor containing SCR1−4. Both sCD21 and rsCR2.1−4 are fully functional in interaction with ligands that specifically bind to SCR1−4.

Our goal is to select high-affinity peptide ligands of CD21 receptor, determine their biorecognizability, and use them as targeting moieties in a potential anticancer drug delivery system. A well-characterized polymer for delivery of cancer therapeutics is the water-soluble synthetic polymer, poly[*N*-(2-hydroxypropyl)methacrylamide] (PHPMA). The advantages of using HPMA copolymer as a drug carrier include (*29*): improved physical properties of polymer−drug conjugates such as enhanced drug solubility, elongated blood circulation time, passive accumulation in solid tumors, and the potential to overcome efflux-pump related multidrug resistance (MDR) (*30*, *31*). To enhance targeting efficiency, it is possible to incorporate several peptide ligands into one HPMA copolymer macromolecule (*32*), thus increasing the apparent binding affinity through multivalent interactions (*33*).

Targeting peptides have been used previously to direct HPMA copolymers to tumor sites. A nonapeptide (EDPGFFNVE) (*34*), a portion of EBV virus envelope glycoprotein gp350/220, assumed to be responsible for the binding of EBV virus to CD21 receptor (*34*), has been incorporated into HPMA copolymer. The cytotoxicity of peptide-targeted HPMA copolymer−doxorubicin conjugates was dependent on the amount of peptide per macromolecule (*32*, *35*, *36*). In vitro studies by Nan et al. revealed that cellular uptake of HPMA copolymer increased significantly after it was modified with the peptide, WHYPWFQNWAMA, which targets human squamous cell carcinoma of the head and neck (*37*). In vivo studies with HPMA copolymer containing the integrin-targeting peptide, KACDCRGDCFCG, demonstrated not only passive accumulation of polymer conjugate at the tumor site, but also active targeting of polymer conjugate mediated by the peptide (*38*). The work described above suggested that HPMA copolymers equipped with peptides as targeting moieties may work as a promising approach to targeted chemotherapy.

In this work, peptide ligands recognizable by CD21 receptor were selected with phage display. Specific binding between selected peptides and CD21 receptor was confirmed by phage ELISA, and the binding affinities were determined with fluorescence quenching. To evaluate the efficiency of targeting lymphoma with selected peptides, we synthesized HPMA copolymer−peptide **P1** (RMWPSSTVNLSAGRR) conjugates. Specific interactions were verified between HPMA copolymer−peptide conjugates and surface-bound CD21 receptor using ELISA experiments. We further investigated the effect of the spacer between the peptide and polymer, and the effect of peptide content per macromolecule upon surface binding of HPMA copolymer−**P1** conjugate.

EXPERIMENTAL PROCEDURES

Materials. *Escherichia coli* strain K91 kan and the fuse-5 15-mer phage library (*39*) were gifts from Dr. G. P. Smith (University of Missouri, Columbia). HB5 anti-CD21 mAb was a gift from Dr. A. Tang. sCD21 (*35*) and rsCR2.1−4 (*28*) were prepared as previously described. 2-Chlorotrityl chloride resin, hydroxymethylbenzoic acid (HMBA) resin, and all N-α-Fmoc protected amino acids were purchased from Novabiochem.

Screening of CD21 Specific Binding Phage with fUSE5 15-mer Phage Library. MaxiSorp plate (NUNC, Denmark) was coated with 200 μL (20 μg/mL) of sCD21 receptor at 4 °C overnight and blocked with 4% skim milk for 2 h at room temperature. The plate was then washed with 0.1% Tween/PBS. Before exposing the phage to the receptor, the plate was preblocked by incubation with 2% BSA in PBS for 15 min. Approximately 10^{12} phage virions were incubated with receptor-coated plate for 3 h. The nonspecific bound phage was removed with stringent washing: washing with TPBS (pH 7.4) 15 times, followed by washing with TPBS (pH 5.0) 5 times, and finally washing with PBS 5 times. The bound phage was eluted with glycine hydrochloride buffer (0.1 M HCl, pH adjusted to 2.2 with glycine). The eluted phage was neutralized with 1 M Tris-buffer (pH 9.1) and amplified. An additional three rounds of selection were performed as described above with decreased phage incubation time: 1 h, 30 and 15 min, respectively. In the fourth round of selection, to minimize the selection of nonspecific bound phage caused by nonspecific elution with glycine hydrochloride buffer, the bound phage was eluted with 4 μg of sCD21 receptor in 200 μL of PBS. After the fourth round of selection, 21 randomly chosen phage clones were tested with preliminary phage ELISA and the DNA of nine phage clones with the highest binding was sequenced using the primer 5′-TCCACAGACAGCCCTCATAG-3′.

Phage ELISA and Competitive Phage ELISA. Receptors sCD21 and rsCR2.1−4 (200 ng in 100 μL of PBS) were coated onto a MaxiSorp plate by incubation overnight at 4 °C. The plate was blocked with 2% BSA in PBS for 2 h at room temperature. Phage **P1** ($\sim 1 \times 10^7$ virion/mL) was incubated in the plate for 1 h at room temperature. The plate was then washed eight times with TPBS. After washing, horseradish peroxidase (HRP)/anti-M13 mAb conjugate (Pharmacia Biotech, Uppsala, Sweden) was diluted 1:5000 with 1% BSA/TPBS and incubated in the plate for 1 h. Again, the plate was washed five times with TPBS, followed by incubation with HRP substrate (ImmunoPure TMB Substrate kit, PIERCE Biotech. Inc.), a mixture of 3,3′,5,5′-tetramethylbenzidine (TMB) and peroxide solution, for 30 min. The reaction was stopped by addition of 100 μL of 1 N H_2SO_4, and the absorbance was read using a microplate reader at 450 nm and background subtraction at 630 nm.

For the competitive phage ELISA, the plate surface was coated with sCD21 and blocked with 2% BSA. Phage **P1** was preincubated with different amounts of (competitor) rsCR2.1−4 (0, 0.45, 0.9, 1.35, and 1.8 μg, respectively, in 100 μL of TPBS containing 1% BSA) for 30 min before the mixture was placed in sCD21 coated plate; there, the mixtures of phage and rsCR2.1−4 were incubated with surface-bound sCD21. The detection of bound phage was the same as that used for the phage ELISA.

Synthesis of Peptides. Peptides, RMWPSSTVNLSAGRR (**P1**), PNLDFSPTCSFRFGC (**P2**), and GRVPSMFGGHFFFSR (**P3**), were synthesized manually on a solid support of 2-chlorotrityl chloride resin using standard Fmoc chemistry. The synthesized peptides were cleaved from resin with a mixture of TFA/H_2O/phenol/TIS (88:5:5:2, v/v/w/v) for 4 h at room

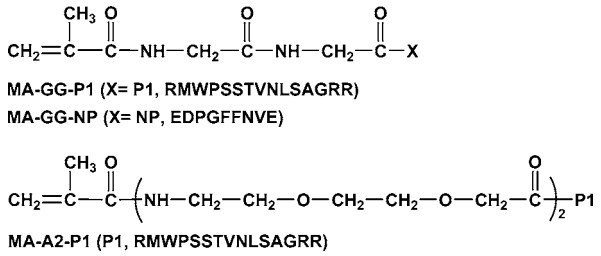

Figure 1. Structures of peptide monomers.

temperature. All synthesized peptides were purified with RP-HPLC and verified with MALDI-TOF MS. MALDI-TOF MS calculated for **P1** (MH^+) 1717.88, found 1718.25; MALDI-TOF MS calculated for **P2** (MH^+) 1702.73, found 1702.78; MALDI-TOF MS calculated for **P3** (MH^+) 1728.84, found 1728.89.

Fluorescent Labeling of rsCR2.1−4. To a solution of rsCR2.1−4 in 200 μL of PBS (0.5 mg/mL), 20 μL of 1 M $NaHCO_3$ (pH 9.0), and 23.3 μL of FITC in DMSO (10 mg/mL) was added, and the reaction was stirred for 5 h at room temperature in the dark. To remove free FITC, the reaction mixture was diluted to 0.5 mL with PBS and immediately applied to a PD-10 column (Amersham Biosciences) preequilibrated with PBS buffer. The concentration of the fluorescently labeled protein and labeling efficiency were determined using UV spectrometry.

Determination of Peptide Binding Constants with Fluorescence Quenching. A series of mixtures of the labeled receptor rsCR2−FITC at 0.02 μM, and peptides, **P1**, **P2**, and **P3**, at different concentrations were prepared in 150 μL of PBS. The mixtures were incubated at room temperature for 5 h. The fluorescence intensity of each sample was measured in duplicates with a LS-55 luminescence spectrometer (Perkin-Elmer) with excitation and emission wavelengths of 495 and 515 nm, respectively. The fluorescence background caused by the peptides was negligible within the concentration range used. The association constant was estimated by fitting the quenching data to eq 1 with software KaleidaGraph (version 3.0) (*40*).

$$Q = \frac{Q_m K_a [P]}{1 + K_a [P]} \quad (1)$$

$$Q = \frac{F_0 - F}{F} \quad (2)$$

where Q is the quenching value defined in eq 2, and Q_m represents maximal fluorescence quenching, K_a is the association constant of peptide binding, and $[P]$ is the concentration of free peptide. F_0 and F are fluorescence intensities of fluorescently labeled rsCR2.1−4 in the absence and presence of peptide ligands, respectively.

Synthesis of Peptide Monomers (MA-GG-P1, MA-A2-P1, MA-GG-NP). Peptide monomers MA-GG-**P1**, MA-A2-**P1** and MA-GG-NP (see structures in Figure 1) were synthesized on HMBA resin using standard Fmoc chemistry. After the last amino acid residue of **P1** (or NP) was attached on the resin, the peptides were extended with additional spacers: a GG spacer was added by coupling with MA-GG-OH (*N*-methacryloylglycylglycine); A2 spacer was added by coupling with two repeats of Fmoc-A (9-fluorenylmethoxycarbonyl-8-amino-3,6-dioxaoctanoic acid, Peptides International) and capped with methacryloyl chloride. All peptide monomers were purified with RP-HPLC and were verified with MALDI-TOF MS. MALDI-TOF MS calculated for MA-GG-**P1** (MH^+) 1898.97, found 1898.93; MALDI-TOF MS calculated for MA-A2-**P1** (MH^+) 2076.06, found 2076.11; MALDI-TOF MS calculated for MA-GG-NP ($M + Na^+$) 1257.50, found 1257.54.

Synthesis of MA-PEG_{3400}-biotin and biotin-PEG-P1. *Synthesis of MA-PEG-biotin. N*-(3-Aminopropyl)methacrylamide hydrochloride (MA-NH_2) (2.7 mg) was dissolved in 200 μL of DMF and 6.7 μL of *N*,*N*-diisopropylethylamine (DIPEA) was added. The temperature of the solution was lowered to 0 °C with an ice bath. Biotin-PEG_{3400}-NHS (PEG, poly(ethylene glycol), mol wt 3400; NHS, *N*-hydroxysuccinimide ester; Nektar Therapeutics) dissolved in 200 μL of DMF was added dropwise. The reaction was kept at 0 °C for 30 min and then left overnight at room temperature. Then, the crude product was diluted 1:1 with water and MA-PEG_{3400}-biotin purified on a PD-10 column. Molecular weight as determined by MALDI-TOF MS was M_w = 3.89 kDa; M_n = 3.86 kDa; M_w/M_n = 1.01.

*Synthesis of biotin-PEG-***P1**. Peptide **P1** (5 mg) was dissolved in 0.5 mL of 0.1 M $NaHCO_3$ (pH 8.5). The temperature was lowered to 0 °C with an ice bath. A DMF solution of biotin-PEG-NHS (5 mg in 100 μL) was added dropwise to the peptide solution. The reaction was kept 0 °C for 30 min and then left overnight at room temperature. The solvent was removed by evaporation, and the biotin-PEG_{3400}-**P1** was purified with RP-HPLC. The identity of biotin-PEG_{3400}-**P1** was confirmed by MALDI-TOF MS. Molecular weight as determined by MALDI-TOF MS was M_w = 5.31 kDa; M_n = 5.29 kDa; M_w/M_n = 1.01.

Synthesis of Biotin-Labeled HPMA Copolymer−Peptide Conjugates (Figure 2). The synthesis of HPMA copolymer−peptide conjugate P^B-GG-**P1** (P^B is HPMA copolymer backbone labeled with a PEG_{3400}-biotin graft) is described as an example: HPMA (11.7 mg), MA-GG-**P1** (10 mg), MA-PEG_{3400}-biotin (3 mg) (molar ratio, 93:6:1), and initiator AIBN (1.6 mg) were dissolved in 155 μL of DMSO in a glass ampule. The solution was bubbled with nitrogen for 10 min and polymerized in the sealed ampule at 50 °C for 24 h. After the reaction was finished, the reaction solution was diluted to 3 mL with H_2O and dialyzed against water in dialysis tubing with molecular cutoff of 12−14 kDa for 3 days. After dialysis, the polymer water solution was lyophilized. P^B, P^B-A2-**P1**, and P^B-GG-NP were synthesized similarly, except that P^B contains no peptide. The polymers were analyzed with size-exclusion chromatography on an ÄKTA FPLC system (Pharmacia). The content of peptide was determined by amino acid analysis, and the content of biotin was determined with an EZ Biotin Quantitation kit (PIERCE Biotech. Inc.).

ELISA of HPMA Copolymer−Peptide Conjugates. The receptor rsCR2.1−4 (150 ng) was coated onto a MaxiSorp plate by overnight incubation at 4 °C. The plate was blocked with 4% milk at room temperature for 1.5 h, washed with TPBS, and incubated with HPMA copolymer−peptide conjugates (0.02 μM) for 30 min. Then, the plate was washed eight times with TPBS, followed by incubation with streptavidin/HRP (Zymed Laboratories) for 30 min. The plate was washed 5 times with TPBS; then TMB substrate was added to the plate and incubated for 30 min. The absorbance was read at 450/630 nm.

For the inhibitive ELISA of P^B-GG-**P1**, plate surface was coated with rsCR2.1−4 (150 ng) and blocked with 4% milk. Different concentrations of free peptide **P1** (0−100 μM) were preincubated with surface-bound rsCR2.1−4 in 100 μL of TPBS for 15 min. Then, P^B-GG-**P1** was added to each plate well (final concentration 0.02 μM) and incubated for 30 min. The bound P^B-GG-**P1** was detected as described above.

RESULTS

Identification of Peptide Ligands for CD21 Receptor. Peptide ligands for the CD21 receptor were selected with a 15-mer phage library based on the phage vector fUSE 5 using sCD21 as the target molecule. To select specifically bound phage and exclude nonspecifically bound phage, a stringent biopanning process was performed including several measures: extensive

Table 1. Screening Results of CD21 Receptor Binding Phages

selected phage	sequence	occurrence
P1	R M W P S S T V N L S A G R R	4
P2	P N L D F S P T C S F R F G C	1
P3	G R V P S M F G G H F F F S R	1
P4	R L A Y W C F S G L F L L V C	2
P5	P V A A V S F V P Y L V K T Y	1

washing with TPBS (pH 7.4) (*41*), stringent washing with TPBS (pH 5.0) (*41*), decreasing the incubation time in each round of selection (*42*), and elution with sCD21 at the last round selection (*42*). After four rounds of selection, a preliminary phage ELISA of 21 individual phage colonies was performed, and the DNA of the nine phages with the highest binding was sequenced (Table 1). Five different sequences were obtained; four phages shared the sequence RMWPSSTVNLSAGRR (**P1**) and two shared the sequence RLAYWCFSGLFLLVC (**P4**). It is interesting to note that two sequences, PNLDFSPTCSFRFGC (**P2**) and **P4**, contained two cysteine residues. The distance between the two cysteines are five (**P2**) and eight (**P4**) amino acid residues, respectively. Consequently, the formation of cyclic peptide structures with constrained conformations is more probable than cross-linking. Except for **P1**, all sequences of selected peptides, **P2**−**P4**, consisted mostly of hydrophobic residues, which may participate in hydrophobic interactions with the CD21 receptor. However, the five sequences did not show obvious homology with each other.

Phage ELISA and Competitive Phage ELISA. The binding affinity of the selected peptides toward the CD21 receptor was first verified by phage ELISA with sCD21 and rsCR2.1−4 (Figure 3). As expected, all the selected phages were found to bind to sCD21 specifically, and all showed little binding to the surface in the absence of receptor. Since rsCR2.1−4 represents only the first four SCRs of the whole CD21 receptor, it was unexpected that all the selected phages bound to rsCR2.1−4, indicating that the binding sites of selected peptides are all localized in this region (Figure 3). Furthermore, the binding of the different phages to sCD21 correlated very well with their binding to rsCR2.1−4. Even though phage **P4** showed the highest signal in the presence of CD21 receptors, it also showed significant binding to the surface in the absence of CD21

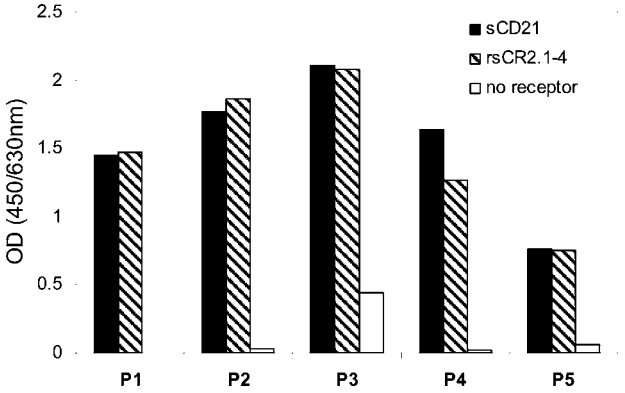

Figure 3. The specificity of selected phage with different sequences was confirmed by phage ELISA. The plate surface was coated with two different forms of CD21 receptor, sCD21 and rsCR2.1−4. The absorbance was compared with the control surface without receptor.

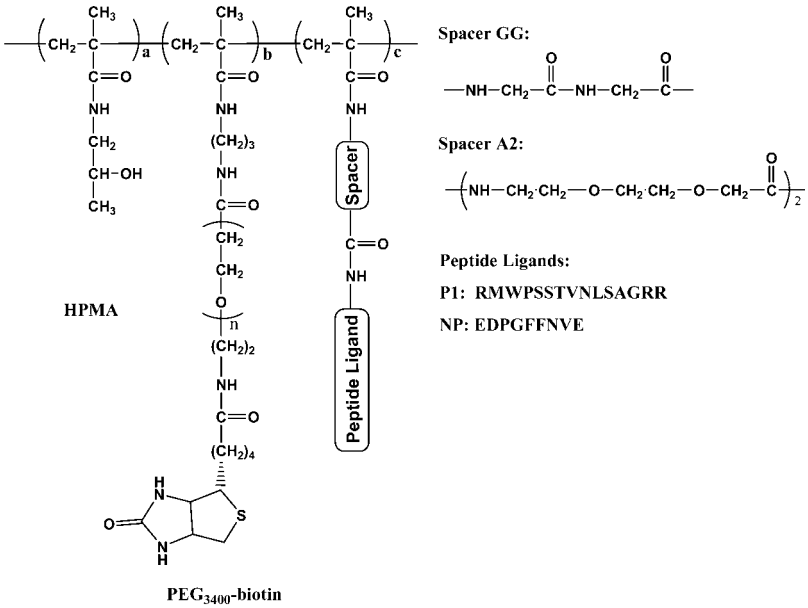

Structure of conjugate[a]	Polymer Backbone	Peptide	Spacer[a]	Peptide position

[a]HPMA copolymer backbone labeled with a PEG$_{3400}$-biotin graft; [b]peptide attached to the HPMA copolymer backbone via GG side-chains; [c]peptide attached to the HPMA copolymer backbone via A2 (dimer of 8-amino-3,6-dioxaoctanoic acid) side-chains; [d]peptide attached to the carboxy end of PEG.

Figure 2. Structures of HPMA copolymer−**P1** conjugates and PEG−**P1** conjugate. HPMA copolymer−peptide conjugates consist of three components: an HPMA copolymer backbone, a PEG-biotin graft used as a label for immunoassay, and peptide ligands with spacers of different lengths, GG and A2. Each polymer chain of the HPMA copolymer−peptide conjugates contains several copies of peptide, while each polymer chain of biotin-PEG$_{3400}$-**P1** contains only one peptide.

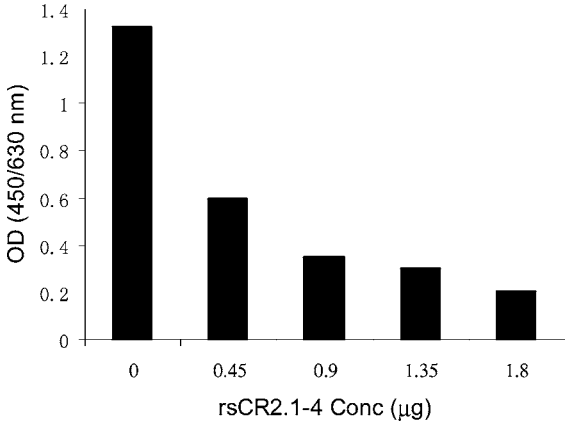

Figure 4. Competitive phage ELISA. Different amounts of rsCR2.1−4 were used to compete with surface-bound sCD21 for binding to phage **P1**.

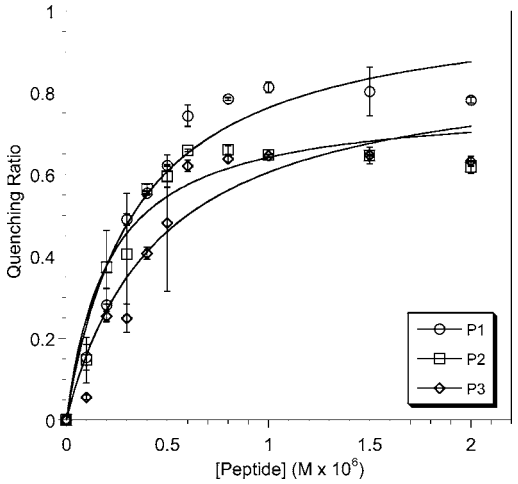

Figure 5. Fluorescence quenching of fluorescein labeled rsCR2.1−4 as a function of peptide concentration. Data are depicted as mean ± standard deviation from duplicate measurements.

receptor, which possibly is a result of the three consecutive phenylalanine residues in its structure.

We further verified that the binding sites of selected peptides are within the first four SCRs using competitive phage ELISA. Using phage **P1** as an example, whole receptor sCD21 was immobilized on a MaxiSorp plate surface and rsCR2.1−4 was co-incubated with **P1** as a competitor to surface-bound sCD21. As shown in Figure 4, with increasing concentration of competitor the number of phage bound to sCD21 decreased, as indicated by the decreasing ELISA signal. The binding of sCD21 with **P1** was inhibited by rsCR2.1−4, which confirmed that the binding site of **P1** is within first four SCRs. This result provided a basis for using rsCR2.1−4 for the binding constant determination of the selected peptides.

Binding Constant Determination with Fluorescence Quenching. The rsCR2.1−4 receptor was fluorescently labeled with FITC, and it was found that the extent of labeling had a significant effect on the fluorescence quenching effect. When the labeling of rsCR2.1−4 was low (F/P $\approx$ 1), the quenching effect was not apparent (data not shown). When the labeling of rsCR2.1−4 was high (F/P $\approx$ 5), the quenching effect was pronounced—over 80% quenching was observed, as shown in Figure 5.

Our previous studies of the binding kinetics of peptide LVLLTRE (a peptide derived from one-bead one-compound peptide library, to be published) with rsCR2.1−4-FITC indicated that at least 3 h are needed to reach equilibrium. Therefore, the peptides were incubated with the receptor for 5 h, before measuring the fluorescence intensity. The association constants of peptides **P1**, **P2**, and **P3** were determined to be 2.9×10^6 M^{-1}, 4.7×10^6 M^{-1}, and 2.2×10^6 M^{-1}, respectively (Figure 5). **P2** (PNLDFSPTCSFRFGC) contains two cysteine residues and can form a cyclic structure. To evaluate the impact of conformation constrain on biorecognition, the binding affinities of cyclic **P2** and linear **P2** were compared. Linear **P2** in reduced form showed poor aqueous solubility. Its quenching study was carried out with the assistance of a small amount of DMF for solubilization. The binding constant of linear **P2** was estimated to be 2×10^6 M^{-1} (data not shown). Therefore, the cyclic structure of **P2** enhanced the binding about 2-fold when compared with linear **P2**.

Synthesis and Characterization of HPMA Copolymer−Peptide Conjugates. All HPMA copolymer conjugates were synthesized by copolymerization of monomers of HPMA, peptide, and biotin. The composition of the synthesized polymers is summarized in Table 2. The weight-average molecular weight was determined with size-exclusion chromatography on a Sepharose 6B column calibrated with PHPMA standards. The concentration of the peptide monomers, MA-GG-**P1** and MA-A2-**P1**, in the feed was 6 mol %, but only about 1 mol % of peptide-containing comonomer was incorporated into the copolymer. Peptide monomer, MA-GG-NP, possessed a better incorporation efficiency: 2.6 mol % of peptide monomer was incorporated to a content identical to the feed composition. We synthesized P^B-GG-NP using a feed composition of 4% MA-GG-NP, so that the content of NP in P^B-GG-NP was comparable to the content of peptide **P1** in conjugates P^B-GG-**P1** and P^B-A2-**P1**. (One may speculate that the difference of incorporation efficiency relates to the length of the peptide; however, more experiments would be needed to verify this hypothesis.) The copolymers were labeled with biotin by incorporation of a small amount of the MA-PEG_{3400}-biotin comonomer. Biotin was used to detect surface-bound conjugates in the ELISA experiments. Only 1 mol % of MA-PEG_{3400}-biotin was used in the monomer feed, and approximately 0.3−0.4% of biotin-containing comonomer was incorporated into the HPMA copolymer (Table 2). This corresponds to about one biotin per macromolecule.

ELISA of Peptide HPMA Copolymer Binding to Surfaces with Different Amounts of rsCR2.1-4. Two experiments were performed to evaluate the impact of peptide conjugation with HPMA copolymers on biorecognition by the CD21 receptor, including (a) the dependence of binding on receptor surface density and (b) competitive inhibition with free peptide **P1**. For the receptor density dependent study, MaxiSorp plate was coated with different amounts of rsCR2.1−4 (0−640 ng), and the binding of P^B-GG-**P1** (0.02 μM) was detected with ELISA using biotin/streptavidin/HRP as the reporting system. To minimize the nonspecific interaction between plate surface and polymer−peptide conjugate, we tried several blocking agents and found that 4% milk produced the lowest background. We are aware that milk may contain some amount of endogenous biotin, which may interact with the biotin/streptavidin/HRP detection system; however, in our experiment, this did not seem to be a problem. If the endogenous biotin were to interact with the detection system, it can be masked with egg white and milk (*43*).

The binding of P^B-GG-**P1** to surface-bound receptor was directly related to the receptor density: the higher the receptor density, the higher the amount of surface-bound P^B-GG-**P1** (Figure 6). These data indicate a specific interaction between P^B-GG-**P1** and surface-bound receptor. This experiment also provided the binding profile of P^B-GG-**P1**, so that an optimum amount of receptor density could be identified. In the final surface binding experiments, 150 ng of rsCR2.1−4 was used to coat the surface.

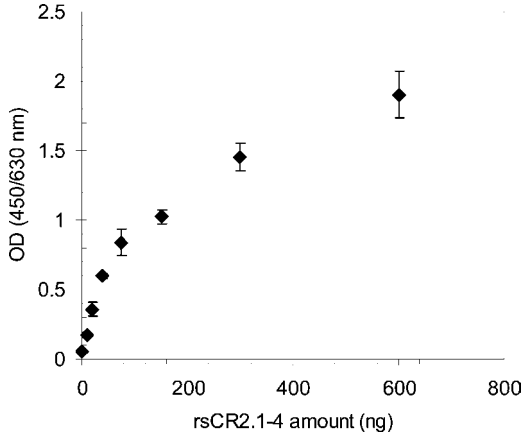

Figure 6. The relationship between the binding of P^B-GG-**P1** and amount of surface coating receptor. Data are depicted as mean ± standard deviation from duplicate measurements.

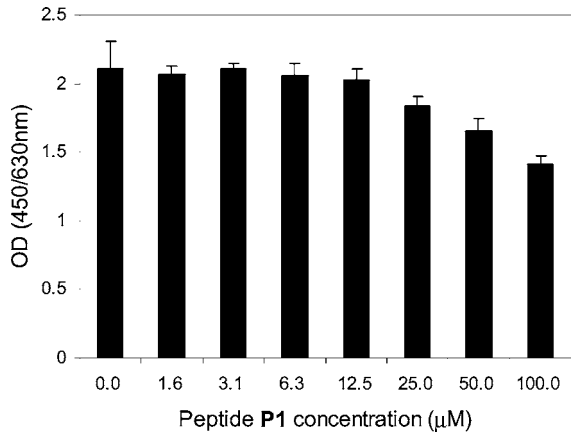

Figure 7. Inhibition of P^B-GG-**P1** binding to surface-bound receptor by free peptide **P1**. The data represent mean ± standard deviation from duplicate measurements.

Competitive Inhibition of Binding with Free Peptide. To further demonstrate the binding specificity of HPMA copolymer−peptide conjugate and CD21 receptor, we investigated binding of conjugate P^B-GG-**P1** (0.02 μM) in the presence of different concentrations of free peptide **P1** (0−100 μM). Free **P1** was able to inhibit the binding of P^B-GG-**P1** at concentrations higher than 25 μM (Figure 7). However, no apparent inhibition was observed when the concentration of free peptide was below 6.25 μM, and the inhibition was only 25% even at the **P1** concentration of 100 μM. This fact implied that the binding affinity of P^B-GG-**P1** is much higher than that of free peptide, given that binding concentration of P^B-GG-**P1** was only 0.02 μM. One could expect that the biorecognition (binding) of the peptide in a polymer conjugate may decrease due to the sterical hindrance of the polymer backbone on the formation of the ligand−receptor complex. However, the binding affinity of the HPMA copolymer-bound peptide was enhanced (Figure 7). The enhanced binding could be ascribed to the effect of multivalent interactions between P^B-GG-**P1** and surface-bound receptor. Each polymer chain of P^B-GG-**P1** contained about 4.4 grafted peptides (Table 2A). With the appropriate receptor density on the surface, multivalent interactions between P^B-GG-**P1** and receptor apparently occurred, resulting in a binding affinity enhanced by 3−4 orders of magnitude. A separate experiment, described below, was devoted to clarify the effect of multivalent interactions on the binding of HPMA copolymer−peptide conjugates.

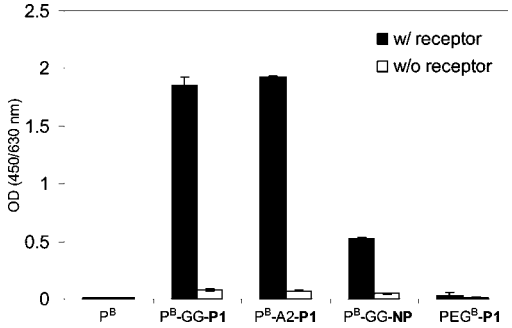

Figure 8. ELISA results of different polymer−peptide conjugates binding to surface-bound receptor. Data are depicted as mean ± standard deviation from duplicate measurements.

Surface Binding of the Conjugates with Varying Structure. Biotin-labeled HPMA copolymer−**P1** conjugates, differing in the structure and length of the spacer separating the peptide and the HPMA copolymer backbone, were synthesized (Table 2A), and their binding to CD21 was evaluated. Two spacers, namely, GG (glycylglycine) and A2 (dimer of 8-amino-3,6-dioxaoctanoic acid), and two peptides, **P1** and NP were used. As controls, biotin-labeled HPMA copolymer (no peptide) and biotin-labeled PEG-**P1** conjugate were evaluated.

P^B (HPMA copolymer containing no peptide) did not show any binding to the surface with or without receptor. As in experiments described above, HPMA copolymer containing the peptide ligand **P1** (P^B-GG-**P1**) demonstrated receptor-specific binding (Figure 8). Polymer conjugate (P^B-GG-NP) containing

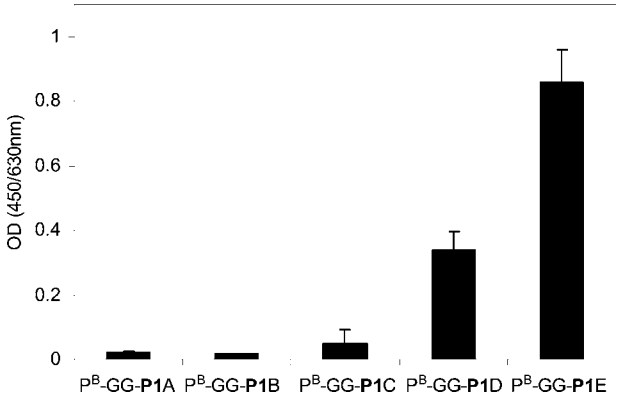

Figure 9. The binding of HPMA copolymer−**P1** conjugates (P^B-GG-**P1**A-E; containing different amounts of peptide **P1**) to the CD21 receptor. For composition of copolymers, see Table 2B. Data are depicted as mean ± standard deviation from duplicate measurements.

a nonapeptide (EDPGFFNVE) ligand of CD21 receptor reported by literature (*34*), also demonstrated specific binding to CD21 receptor, however, to a lesser degree compared with P^B-GG-**P1**.

The binding of biotin-labeled PEG-**P1** conjugate (PEG^B-**P1**) was also evaluated. PEG^B-**P1** is composed of a 3400-Da poly(ethylene glycol) macromolecule with one terminus modified with peptide **P1** and the other with biotin. However, no appreciable binding of PEG^B-**P1** to receptor was detected (Figure 8). This conjugate (PEG^B-**P1**) contains only one peptide per macromolecule. Consequently, it interacts with the receptor only in a monovalent manner. In contrast, each polymer chain of P^B-GG-**P1** has 4−5 copies of peptide **P1**, thus capable of multivalent interactions with surface-bound receptor. This difference in biorecognition may be attributed to the difference in the binding mode (multivalent vs monovalent interactions).

The Effect of Peptide Accessibility on the Binding Affinity. Both PHPMA and the peptide may influence the physical properties of HPMA copolymer−peptide conjugates. PHPMA itself is water-soluble; its conformation in solution is a random coil (*44*). When hydrophobic moieties are attached to HPMA copolymer side chains, the conformation of the macromolecule in the solution may change as a result of intramolecular and/or intermolecular association of side chains (*45*). On the other hand, the polymer backbone, due to its constant mobility, may have a shielding effect on the accessibility of peptide to the target. To investigate this possibility, the peptide **P1** was conjugated to HPMA copolymer via two different spacers, GG and A2 (Figure 1). Spacer A2 is four times as long as spacer GG. It is also more flexible because the amide bonds limit the flexibility of GG. Therefore, the peptide in P^B-A2-**P1** may be better exposed and should have more accessibility than that in P^B-GG-**P1**. However, no obvious binding differences between P^B-GG-**P1** and P^B-A2-**P1** were observed (Figure 8). This suggests that in both conjugates, peptide **P1** was sufficiently exposed for interaction with the target receptor, and the spacer effect was minimal. Because **P1** is a peptide 15 amino acid residues long, the results do not eliminate possible spacer effects using shorter peptides.

Demonstration of Multivalent Interaction in Surface Binding. To evaluate the relationship between the amount of peptides per macromolecule and biorecognition, biotin-labeled HPMA copolymers containing different amounts of GG-**P1** side chains were synthesized (Table 2B), and their binding properties were determined. When the peptide content of conjugates (P^B-GG-**P1**A and P^B-GG-**P1**B) was low, less than one peptide per polymer chain, the binding of the conjugates was negligible (Figure 9). Conjugate P^B-GG-**P1**C (1.7 peptide per polymer chain) showed minimal binding; however, both P^B-GG-**P1**D (4.5 peptide per polymer chain) and P^B-GG-**P1**E (4.4 peptide per polymer chain) demonstrated extraordinary binding. Although the number of peptide grafts per macromolecule in P^B-GG-**P1**D and P^B-GG-**P1**E was similar, the latter showed much better binding than P^B-GG-**P1**D. This may be explainable by the higher mol % of peptide in P^B-GG-**P1**E (the difference is due to the lower molecular weight of conjugate P^B-GG-**P1**E than that of P^B-GG-**P1**D). The above results demonstrated the importance of multivalent interaction in the binding of HPMA copolymer−peptide conjugates to the CD21 receptor.

DISCUSSION

Identification of CD21 Ligands with Phage Display. Two forms of CD21 receptor, soluble CD21 (sCD21) and recombinant short CD21 rsCR2.1−4 were prepared. SCD21 contains the whole extracellular portion of CD21 receptor, while rsCR2.1−4 only the first four SCRs. sCD21, about four times as large as rsCR2.1−4, is expected to have more binding sites than rsCR2.1−4. Therefore, biopanning with whole sCD21 should select peptides not only binding to SCR1−4, but also to SCR5−16. Since the goal was to find suitable peptide ligands for the CD21 receptor, sCD21 was used, instead of rsCR2.1−4, for phage display, to find the best peptide binders of the whole CD21 receptor. Surprisingly, all peptide ligands selected with sCD21 also bound to SCR1−4 as indicated by phage ELISA with rsCR2.1−4 and competitive phage ELISA, demonstrating that the binding sites of all selected peptides were located within the first four SCRs. Several factors might contribute to this result: SCR1−4 is well exposed and accessible for interaction with phage; SCR1−4 consists of binding sites most suitable for peptide binding; peptides binding outside of SCR1−4 are relatively weaker and cannot withstand stringent screening.

Another feature of selection results is the lack of obvious homology among all of the selected peptides, which implies that SCR1−4 is not the only antigenic region, but also a multi-antigenic region. It has several distinctive binding sites, which was verified by epitope mapping with different antibodies. Although the epitopes of anti-CD21 antibodies, FE8 (*46*), OKB7 (*47*), mAb171 (*48*), and mAb1048 (*48*) are all located in SCR1−2, they are distinct from each other. The binding sites of C3d and EBV have been extensively studied, but the results had been controversial until the X-ray crystallographic structure of C3d-CD21 complex was published (*49*). There is evidence that the binding sites of C3d and EBV are far from each other (*50*). Therefore, it was not surprising that the selected peptides exhibited no homology. Moreover, the phage display results further confirmed that the CD21 receptor is multi-antigenic.

Affinity Analysis by Fluorescence Quenching. Fluorescence spectrometry is most suited for protein−ligand interactions with dissociation constants in the range 10^{-4} to 10^{-8} M. The formation of the protein−ligand complex usually induces a conformational change of the protein and an alteration of the microenvironment of the fluorophore. Some fluorescence parameters such as anisotropy and intensity are sensitive to such changes, and the variation of fluorescence intensity upon the formation of protein−ligand complex can be used for affinity analysis (*51*).

By comparing on the crystal structure of both free CD21 (SCR1−2) (*50*) and the complex (*49*) of CD21 (SCR1−2) and C3d, it was found that the binding of C3d with CD21 is an induced-fitting process. Not only does the conformation of the local binding site change upon binding, but the global conformation also changes (*50*). This implies that the CD21 receptor (or at least SCR1−2) is a relatively flexible protein. The conformational change of CD21 receptor upon binding with ligands should be detectable with fluorescence spectrometry. The recombinant short CD21 receptor, rsCR2.1−4, was used

for affinity analysis by fluorescence quenching. It is a much smaller molecule compared to the whole CD21 receptor. With a smaller molecule, the change of fluorescence parameters is more sensitive to conformational change. Although selected peptides are only 15 amino acid residues long, their interaction with rsCR2.1−4 induced enough conformational change to be detected by fluorescence quenching. The dissociation constants of three synthesized peptides were determined to be within the micromolar range, which is typical for most phage display results (*11*). We are aware that the binding affinity of selected peptides might be affected, to some extent, by the labeling of rsCR2.1−4 with FITC.

Synthesis of HPMA Copolymer−Peptide Conjugates. There are two different ways to synthesize HPMA copolymer−peptide conjugates: polymer-analogous reactions and copolymerization. In polymer-analogous reaction, a HPMA copolymer precursor containing, e.g., reactive *p*-nitrophenyl ester groups at side chain termini is prepared first, followed by the attachment of the peptide to the HPMA copolymer precursor by aminolysis of the active ester (*32*). However, this approach has some limitations, as the peptide should have only one free amino group to achieve site-specific conjugation. This can be inconvenient because most peptides usually contain more than one reactive group; therefore, protection during synthesis is required. In comparison, copolymerization using peptide-containing monomers with HPMA, in an appropriate solvent, does not present this limitation. Because **P1** contains three arginine residues and one amino group reactive toward the active ester of the HPMA copolymer precursor, P^B-GG-**P1** was prepared by the copolymerization of HPMA, MA-GG-**P1**, and MA-PEG-biotin in DMSO (a good solvent).

Affinity Analysis of Polymer-Bound Peptides. Several different targeting moieties have been incorporated into HPMA copolymers, including lectins (*52*), antibodies (*53*), and antibody fragments (*54*). Successful targeting with peptides will undoubtedly expand the application of HPMA copolymer as an anticancer drug carrier. Therefore, it is necessary to examine the biorecognizability of selected peptides after they are conjugated with HPMA copolymer. We chose peptide **P1** for this purpose, since **P1** is quite soluble in water, thus avoiding the possible complications caused by inter/intramolecular hydrophobic interactions.

When multiple copies of a peptide are incorporated into a polymer-based drug delivery system, the properties of both the peptides and the polymer may change accordingly. On one hand, the targeting efficiency of the peptides may be partially masked by the polymer. On the other hand, the polymer structure may be influenced by the composition of peptides, especially when peptides contain a large number of hydrophobic or charged residues. Therefore, the interaction between the HPMA copolymer−peptide conjugates and the surface-bound receptor was investigated. It was found that conjugation of **P1** with HPMA copolymer did not impair its binding affinity toward the CD21 receptor as demonstrated by receptor-dependent surface binding and inhibition experiments using free peptide. On the basis of the binding results of P^B-GG-**P1** and P^B-GG-NP, the selected peptide **P1** showed better recognizability than the previously reported nonapeptide (NP) when incorporated into HPMA copolymer−peptide conjugates (*32*).

By changing the spacer from GG to GFLG, the binding affinity of HPMA copolymer−peptide NP conjugates increased as determined by the whole cell binding assay (*32*, *36*), implying that extended spacer length may improve the interaction between the NP and the cell surface receptor. However, in our experiment, the spacer effect (A2 is four times as long as GG) was not significant. It was noted that **P1** is a 15-amino-acid peptide and NP is a 9-amino-acid peptide. It was speculated that length of peptide ligands may account for the spacer effect on different HPMA copolymer−peptide conjugates—the longer the peptide length, the less the spacer effect.

The enhanced surface binding affinity of P^B-GG-**P1** compared with free peptide and PEG^B-**P1** suggested multivalent interactions of HPMA copolymer conjugates. Because each PEG chain contained only one peptide, while each HPMA copolymer chain contained 4−5 copies of peptide, HPMA copolymer−peptide conjugates are capable of multivalent interaction with surface-bound receptor. This multivalent effect was also observed in inhibitive ELISA by free peptide: noticeable inhibition was observed only when free peptide concentration was 3−4 orders of magnitude higher than peptide concentration in conjugates. The binding affinity test with peptide conjugates of different peptide contents confirmed the importance of multivalent interaction in the surface binding of HPMA copolymer−peptide conjugates. Also shown in whole cell binding assays, the binding affinity of HPMA copolymer NP conjugates increased with the increase of NP content in the conjugates (*32*, *36*). This observation is directly correlated to our results in this work: multivalent interaction played an important role on the binding of HPMA copolymer not only in our plate surface model but also in the cell surface system. Therefore, HPMA polymer−peptide conjugates are beneficial to recognize a target, which is capable of multivalent interaction.

A soluble form of CD21, shed from the cell membrane, may compete with the binding of HPMA copolymer−peptide conjugates to lymphoma cells, thus reducing its targeting specificity. This fact further strengthens the importance of the multivalent capability of HPMA−peptide conjugates; if multivalent interactions are achievable with the membrane-bound receptor, then the competition by the soluble receptor will be significantly minimized.

CONLUSIONS

Five peptide sequences were identified as ligands for CD21 receptor using phage display. The binding affinity of selected peptides was confirmed by phage ELISA, and the binding constants of three peptides were determined with fluorescence quenching. Using surface binding studies, it was demonstrated that the peptide RMWPSSTVNLSAGRR (**P1**) retained its recognizability by the CD21 receptor after its incorporation into HPMA copolymer. The specificity of its recognition was confirmed with competitive inhibition by free peptide. The spacer effect for this peptide in the HPMA copolymer conjugates was minimal. The importance of multivalent interaction for biorecognition of HPMA copolymer−peptide conjugates toward the CD21 receptor was confirmed.

ACKNOWLEDGMENT

This work was supported in part by NIH Grants CA88047 and CA51578 from the National Cancer Institute. We thank Dr. G. P. Smith for providing the fUSA-5 15-mer phage library, Dr. A. Tang for valuable discussions and the gift of HB5 anti-CD21 mAb, and J. Callahan for carefully revising the manuscript.

Study of the Interaction between Actin and Antitumor Substance Aplyronine A with a Novel Fluorescent Photoaffinity Probe

Takeshi Kuroda, Kiyotake Suenaga, Akira Sakakura, Tomohisa Handa, Kazuhito Okamoto, and Hideo Kigoshi*

Department of Chemistry, University of Tsukuba, 1-1-1 Tennoudai, Tsukuba, Ibaraki 305-8571, Japan. Received November 11, 2005; Revised Manuscript Received February 9, 2006

The interaction between actin and aplyronine A, a potent antitumor and actin-depolymerizing substance of marine origin, was investigated by photoaffinity labeling experiments. Photoaffinity probes consisting of a side-chain portion of aplyronine A as a ligand, a diazirine moiety as a photoaffinity group, and a fluorophore as a detecting group were synthesized. Photolabeling experiments between actin and the probe were carried out. Actin was successfully photolabeled by the fluorescent probe and visualized clearly. The present results provide the first chemical evidence for the direct interaction between actin and the side-chain portion of aplyronine A.

INTRODUCTION

Aplyronine A (**1**) (Figure 1) is a 24-membered macrolide isolated from the sea hare *Aplysia kurodai*. Aplyronine A (**1**) exhibits strong cytotoxicity and exceedingly potent antitumor activities in vivo against P388 murine leukemia (T/C = 545%, 0.08 mg/kg), Lewis lung carcinoma (T/C = 556%, 0.04 mg/kg), Ehrlich carcinoma (T/C = 398%, 0.04 mg/kg), colon 26 carcinoma (T/C = 255%, 0.08 mg/kg), and B16 melanoma (T/C = 201%, 0.04 mg/kg) (*1*−*5*). Aplyronine A (**1**) has been found to inhibit the polymerization of globular actin (G-actin) to fibrous actin (F-actin) and to depolymerize F-actin to G-actin by severing (*6*). Actin is one of the most abundant and common proteins in the cytoskeleton and regulates various cell functions. It is worth noting that actin is related to tumor metastasis and invasion into the basement membrane (*7*). Although several actin-depolymerizing compounds, such as mycalolide B and cytochalasin D (Figure 2), have been found to be cytotoxic in vitro (*8*), the antitumor activities in vivo of these compounds have not been reported. Thus, aplyronine A (**1**) is interesting from the viewpoint of the mode of antitumor activity.

Details of the structure−actin-depolymerizing activity relationships of aplyronine A (**1**) were investigated using natural and synthetic analogues (*9*, *10*): the side chain portion of aplyronine A (**1**) is essential for actin-depolymerizing activity, and compound **2**, which consists only of the side-chain portion of aplyronine A (**1**), exhibits strong activity, considering the size of the molecule. Therefore, compound **2** is suitable for analysis of the interaction between aplyronine A (**1**) and actin. Even though aplyronine A (**1**) has been found to exhibit actin-depolymerizing activity, little is known of its interactions with actin at the molecular level. Recently, X-ray structure analyses of complexes of actin and several actin-depolymerizing macrolides possessing side chain portions similar to that of aplyronine A (**1**) were reported (*11*). We are now interested in the binding manner between aplyronine A (**1**) and actin and its relationships to biological activities. Insight into specific residue interactions has been gained through the use of photoaffinity probes.

The photoaffinity labeling experiment has become a powerful method in postgenomic science, as confirmed by the identification of target proteins of biologically active compounds and elucidation of their binding sites (*12*). The design of a photoaffinity probe requires the following three components: (i) a ligand that binds strongly and specifically with a target protein; (ii) a photoaffinity group that forms a stable covalent bond between the ligand and its target protein (*13*); (iii) a detective group to make the labeled products easy to be detected. Radioisotopes or biotin are frequently used for the third demand (*14*, *15*). However, radioisotopes are environmentally problematic, and biotin requires highly expensive reagents for detection. Recently, non-RI and nonbiotin photoaffinity labeling methods have been developed (*16*). In this report, we describe the design of a fluorescent probe and an analysis of the interaction between aplyronine A (**1**), an antitumor substance, and actin.

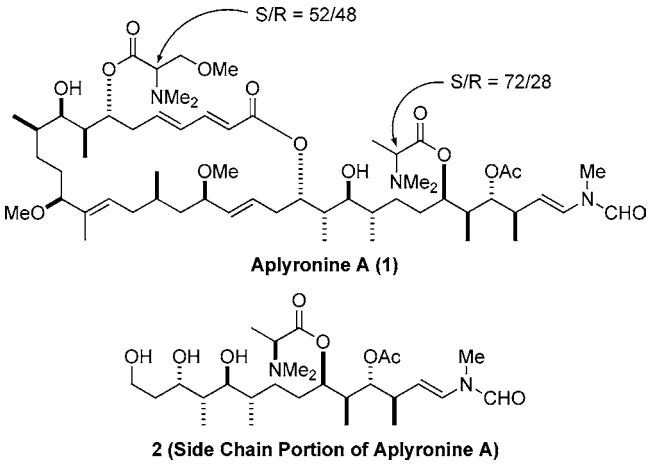

Figure 1. Structure of aplyronine A (**1**) and compound **2**, the side-chain portion of aplyronine A (**1**).

EXPERIMENTAL SECTION

General. Compound **2**, a side-chain portion of aplyronine A (**1**), and activated ester **5** were prepared as previously described (*10*, *13*). Aplyronine A (**1**) was isolated from the sea hare *Aplysia kurodai* by the method described previously (*1*). Actin for photoaffinity labeling experiments was obtained from Cytoskeleton Inc. Pyrenyl actin for measurement of actin-depolymerizing activity was prepared by the method described previously (*6*). Other chemicals and solvents were the best grade available and were used as received from commercial sources. ^{1}H NMR spectra were recorded on a JEOL JNM-EX-270 (270

MHz) instrument. Proton chemical shifts are reported as parts per million (δ) relative to internal tetramethylsilane ($\delta = 0.00$ ppm) or solvent signals ($\delta = 3.31$ ppm for CHD_2OD, 7.26 ppm for $CHCl_3$). Mass spectra were measured with Applied Biosystems QStar pulser i instrument.

6-*tert*-Butoxycarbonylamino-2-[4-(3-trifluoromethyl-3*H*-diazirin-3-yl)benzoylamino]hexanoic Acid Methyl Ester. To a solution of activated ester **5** (42.7 mg, 137 μmol) and H-Lys(Boc)-OMe·HCl (77.8 mg, 262 μmol) in dichloromethane (0.5 mL) was added triethylamine (55 μL) at room temperature. After being stirred at room temperature for 2 h, the reaction mixture was concentrated. The residual oil was chromatographed on aluminum oxide (1 g, dichloromethane) to give the desired product (59.7 mg, 92%) as a colorless oil. ^{1}H NMR (270 MHz, $CDCl_3$) δ 7.73 (d, $J = 8.4$ Hz, 2 H), 7.11 (d, $J = 8.4$ Hz, 2 H), 6.93 (br d, $J = 6.8$ Hz, 1 H), 4.59−4.12 (m, 2 H), 3.64 (s, 3 H), 2.98 (m, 2 H), 1.90−1.15 (m, 6 H), 1.25 (s, 9 H); MS (ESI) *m*/*z* 495.2 $(M + Na)^+$; HRMS calcd for $C_{21}H_{27}F_3N_4NaO_5$ $(M + Na)^+$: 495.1831 Found 495.1858.

Carboxylic Acid 6. To a solution of 6-*tert*-butoxycarbonylamino-2-[4-(3-trifluoromethyl-3*H*-diazirin-3-yl)benzoylamino]hexanoic acid methyl ester (8.2 mg, 17 μmol) in dioxane (0.17 mL) was added a 0.50 M solution of lithium hydroxide in water (0.17 mL, 85 μmol) at room temperature. After being stirred at room temperature for 2 h, the mixture was diluted with brine (1 mL), acidified with 1 M aqueous sulfuric acid to pH 1, and extracted with ether (5 × 1 mL). The combined extracts were dried (sodium sulfate) and concentrated to give carboxylic acid **6** (7.9 mg, 100%). ^{1}H NMR (270 MHz, CD_3OD) δ 7.94 (d, $J = 8.4$ Hz, 2 H), 7.35 (d, $J = 8.4$ Hz, 2 H), 4.57 (dd, $J = 4.6$, 8.9 Hz, 1 H), 2.94 (t, $J = 5.9$ Hz, 2 H), 1.95−1.06 (m, 6 H), 1.39 (s, 9 H); MS (ESI) *m*/*z* 503.1 $(M-H + 2Na)^+$; HRMS calcd for $C_{20}H_{24}F_3N_4Na_2O_5$ $(M - H + 2Na)^+$: 503.1494, Found 503.1497.

Probe 3. To a mixture of compound **2** (5.1 mg, 9.6 μmol), carboxylic acid **6** (16.0 mg, 35.0 μmol), 4-(dimethylamino)-pyridine (8.5 mg, 70 μmol), and (±)-camphorsulfonic acid (8.1 mg, 35 μmol) was added a 0.35 M solution of dicyclohexylcarbodiimide in dichloromethane (0.10 mL, 35 μmol) at room temperature. The mixture was stirred at room temperature for 1 day and diluted with dichloromethane (0.5 mL) and trifluoroacetic acid (0.5 mL) at 0 °C. The mixture was stirred at 0 °C for 30 min and filtered. The filtrate was concentrated and purified by column chromatography on ODS (1 g, 60% MeOH) to give a crude amine. To a solution of the amine in *N*,*N*-dimethylformamide (0.1 mL) were added triethylamine (0.1 mL) and fluorescein-4-isothiocyanate (7.8 mg, 10 μmol) at room temperature. The mixture was stirred at room temperature for 4 h and concentrated. The residue was purified by preparative HPLC (Develosil ODS-HG-5 20 × 250 mm, 70% MeOH-0.1% TFA, 5 mL/min, detection at UV 470 nm, t_R 32.3−36.7 min) to give probe **3** (2.8 mg, 23% from ester **6**) as a yellow oil. ^{1}H NMR (270 MHz, $CDCl_3$−CD_3OD = 3:1) δ 8.20 (s, 0.7 H, CHO), 8.05−7.95 (m, 1.3 H, CHO, fluorescein), 7.83 (d, $J =$ 8.3 Hz, 2 H, aryldiazirine), 7.78 (m, 1 H, fluorescein), 7.19 (d, $J = 8.3$ Hz, 2 H, aryldiazirine), 7.04 (d, $J = 8.4$ Hz, 1 H, fluorescein), 6.63 (d, $J = 2.4$ Hz, 2 H, fluorescein), 6.59 (d, J = 8.6 Hz, 2 H, fluorescein), 6.46 (dd, $J = 2.4$, 8.6 Hz, 2 H, fluorescein), 6.50 [7.07] (m, 1 H, C34), 5.05−4.88 (m, 2 H), 4.70−4.53 (m, 2 H), 3.57 (m, 2 H), 2.96 [3.02] (s, 3 H, enamide NMe), 2.85 [2.80] (br s, 6 H, NMe_2), 2.50 (m, 1 H), 1.95 [2.02] (s, 3 H, CH_3COO), 2.00−1.70 (m, 3 H), 1.70−1.40 (m, 15 H), 1.00−0.70 (m, 12 H). Signals of five protons (dimethylalanine-α, C21, C23, and C25) were overlapped with the solvent signals. The minor counterparts of doubled signals in the ratios of 2:1 are in brackets; MS (ESI) *m*/*z* 630.7 $(M + 2H)^{2+}$; HRMS calcd for $C_{63}H_{77}F_3N_7O_{15}S$ $(M + H)^+$: 1260.5151, Found 1260.5165.

2-Benzoylamino-6-*tert*-butoxycarbonylaminohexanoic Acid Methyl Ester. To a solution of H-Lys(Boc)-OMe·HCl (0.10 g, 0.35 mmol) in dichloromethane (1.0 mL) were added a triethylamine (0.40 mL) and benzoyl chloride (0.17 mL, 1.5 mmol) at room temperature. After being stirred at room temperature for 5 h, the mixture was concentrated. The residual oil was chromatographed on silica gel (5 g, hexanes−ethyl acetate−methanol = 30:1:1→15:1:1→14:1:1→12:1:1→10:1:1) to give the desired product (85 mg, 67%) as a colorless oil. ^{1}H NMR (270 MHz, $CDCl_3$) δ 7.82 (d, $J = 7.0$ Hz, 2 H), 7.57−7.39 (m, 3 H), 6.96 (br d, $J = 7.6$ Hz, 1 H), 4.84−4.76 (m, 2 H), 3.76 (s, 3 H), 3.15−3.05 (m, 2 H), 2.00−1.70 (m, 2 H), 1.60−1.25 (m, 4 H), 1.40 (s, 9 H); MS (ESI) *m*/*z* 387.2 $(M + Na)^+$; HRMS calcd for $C_{19}H_{29}N_2NaO_5$ $(M + Na)^+$: 387.1896, Found 387.1877.

2-Benzoylamino-6-*tert*-butoxycarbonylaminohexanoic Acid. To a solution of 2-benzoylamino-6-*tert*-butoxycarbonylaminohexanoic acid methyl ester (85 mg, 0.24 mmol) in dioxane (4.8 mL) was added a 0.50 M solution of lithium hydroxide in water (2.2 mL, 1.1 mmol) at room temperature. After being stirred at room temperature for 1 h, the mixture was diluted with brine (10 mL), acidified with 1 M hydrochloric acid to pH 1, and extracted with ethyl acetate (6 × 20 mL). The combined extracts were washed with brine (20 mL) and concentrated to give the desired product (79 mg, 96%). ^{1}H NMR (270 MHz, CD_3Cl) δ 10.3 (br s, 1 H), 7.71 (m, 2 H), 7.40−7.15 (m, 4 H), 4.85−4.65 (m, 2 H), 3.02 (m, 2 H), 2.05−1.65 (m, 2 H), 1.55−1.25(m, 4 H), 1.31 (s, 9 H); MS (ESI) *m*/*z* 351.2 $(M + H)^+$; HRMS calcd for $C_{18}H_{27}N_2O_5$ $(M + H)^+$: 351.1920, Found 351.1954.

Compound 4. To a mixture of compound **2** (1.8 mg, 3.4 μmol), 2-benzoylamino-6-*tert*-butoxycarbonylaminohexanoic acid (2.4 mg, 6.8 μmol), 4-(dimethylamino)pyridine (3.4 mg, 27 μmol), and (±)-camphorsulfonic acid (3.0 mg, 14 μmol) was added a 0.2 M solution of dicyclohexylcarbodiimide in dichloromethane (70 μL, 14 μmol) at room temperature. The mixture was stirred at room temperature for 40 h, washed with aqueous sodium bicarbonate (3 mL), and concentrated. The residual oil was purified by column chromatography on silica gel (500 mg, dichloromethane-acetone-methanol = 2:1:0→1:1:0→10:10:1→5:5:1→1:1:1) to give compound **4** (1.6 mg, 55% from compound **2**) as a colorless oil. ^{1}H NMR (270 MHz, $CDCl_3$) δ 8.29 [8.08] (s, 1 H, CHO), 7.82 (d, $J = 6.8$ Hz, 2 H), 7.55−7.40 (m, 3 H), 6.87 (br s, 1 H), 6.51 [7.16] (d, $J = 14.3$ [15.3] Hz, 1 H, C34), 5.05−4.90 (m, 2 H), 4.80−4.50 (m, 3 H), 4.44 (m, 1 H), 4.29

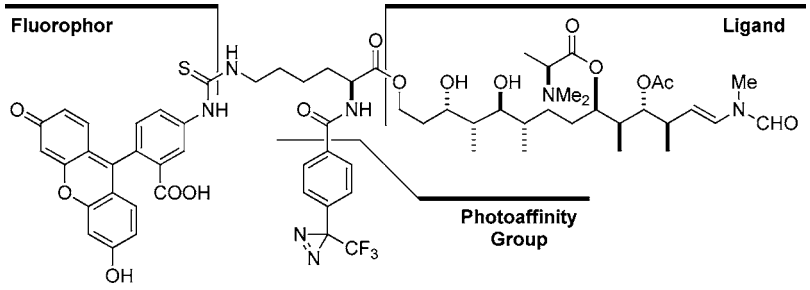

Figure 3. Designing of the fluorescent photoaffinity probe **3**.

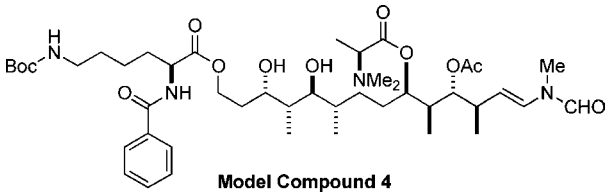
(m, 1 H), 4.08 (m, 1 H), 3.34 (m, 2 H), 3.10 (m, 2 H), 3.04 [3.08] (s, 3 H, enamide NMe), 2.70 (m, 1 H), 2.18 [2.13] (s, 6 H, NMe_2), 1.95 [2.02] (s, 3 H, CH_3COO), 2.00−1.40 (m, 18 H), 1.40 (s, 9 H), 1.00−0.70 (m, 12 H). The minor counterparts of doubled signals in the ratios of 2:1 are in brackets; MS (ESI)-*m/z* 863.5 $(M + H)^+$; HRMS calcd for $C_{45}H_{75}N_4O_{12}$ $(M + H)^+$: 863.5382, Found 863.5373.



The Actin-Depolymerizing Activity. The actin-depolymerizing activity of compounds was measured as previously described (*6*) with minor modifications. To the 3.7 μM solution of actin (0.30 mL, containing 10% pyrenyl actin) in G-buffer was added a 0.15 M solution of $MgCl_2$ (2.0 μL), and the mixture was stirred at room temperature for 1 h to polymerize G-actin to F-actin. To the solution of F-actin were added various concentrations of compounds in dimethyl sulfoxide (2.0 μL) with stirring, and the time course of depolymerization was continuously monitored by measuring fluorescence of pyrenyl actin (10% of total actin) with a fluorometer (HITACHI, F-4000, equipped with a magnetic stirrer) at 25 °C at 365 nm excitation and 407 nm emission wavelengths. The IC_{50} values were concentration required to depolymerize F-actin to 50% of its control amplitude. The values were the average of three assays, and the errors were calculated in SD values.

Photoaffinity Labeling Experiments. Photoaffinity labeling of actin with probe **3** was performed as previously reported for similar photoaffinity labeling experiments (*16*) with minor modifications. An 11 μM solution of actin (44 μL, 0.48 nmol, Cytoskeleton Inc., final concentration was 10 μM) in G-buffer (2.0 mM Tris-HCl, 0.20 mM $CaCl_2$, 0.50 mM β-mercaptoethanol, 0.20 mM ATP, pH 8.0) was incubated with various concentrations of solutions of probe **3** in dimethyl sulfoxide (4.0 μL; 120, 240, 480, 960 μM; final concentration, 10, 20, 40, 80 μM, respectively) in Eppendorf tubes at 0 °C for 1 h. For competition studies, an 11 μM solution of actin (44 μL, 0.48 nmol) in G-buffer was incubated with various concentrations of solutions of probe **3** in dimethyl sulfoxide (2.0 μL; 240, 480, 960, 1900 μM; final concentration, 10, 20, 40, 80 μM, respectively) and 2.4 mM solution of aplyronine A in dimethyl sulfoxide (2.0 μL, final concentration 100 μM) in Eppendorf tubes at 0 °C for 1 h. The samples were irradiated with a handhold 365 nm UV lamp at 0 °C for 15 min, and SDS−PAGE sample buffer was added. After SDS−PAGE, the gels were subjected to laser-scanning with a fluorescent imaging analyzer (BIO-RAD, molecular imager FX, excitation and detection filter for FITC) followed by CBB-stained.

SEC−HPLC Analysis. A 100 μM solution of actin (48 μL, 4.8 nmol, Cytoskeleton Inc.) in G-buffer (2.0 mM Tris-HCl, 0.20 mM $CaCl_2$, 0.50 mM β-mercaptoethanol, 0.20 mM ATP, pH 8.0) was incubated with 1.3 mM solution of probe **3** in dimethyl sulfoxide (2.0 μL; final concentration, 100 μM) in an Eppendorf tube at 0 °C for 1 h. The sample was irradiated with a handhold 365 nm UV lamp at 0 °C for 15 min. To the mixture was added 10 mM solution of aplyronine A in dimethyl sulfoxide (2.0 μL, final concentration, 400 μM), and the mixture was incubated at 0 °C for 1 h. The resulting mixture was analyzed by HPLC (TOSOH TSK-GEL $G2000SW_{XL}$ 7.8 × 300 mm, 0.1 M phosphate buffer−10% dimethyl sulfoxide, 1.0 mL/min, detection at UV 254 nm, fluorescence at 480 nm excitation, 540 nm emission).

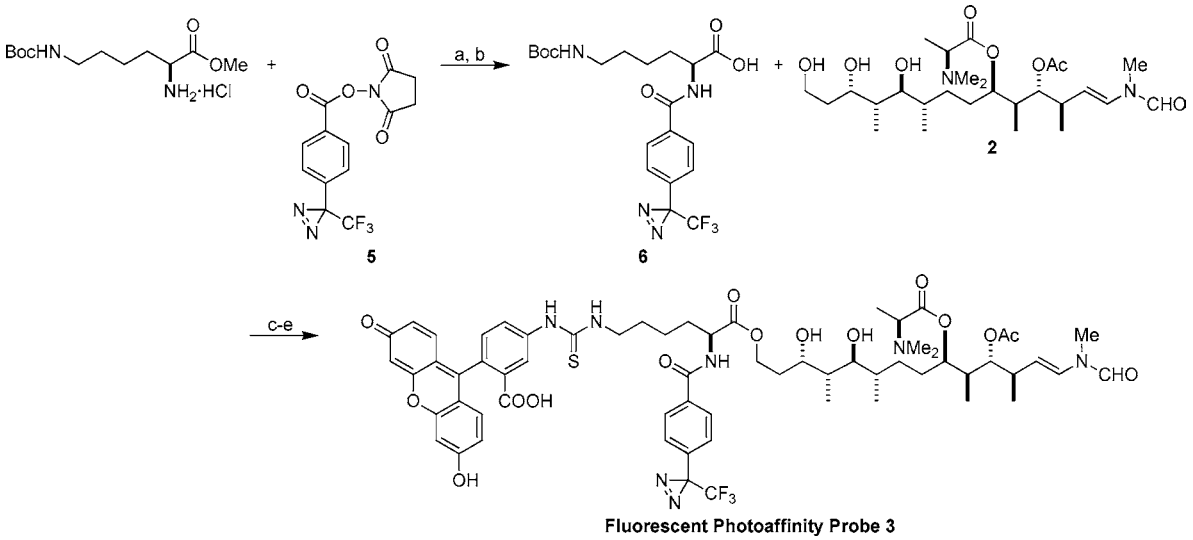
RESULTS

The designed probe **3** is shown in Figure 3. Probe **3** includes the side-chain portion of aplyronine A (**1**) as a ligand, an aryldiazirine group as a photoaffinity group, and a fluorescein group as a fluorescent detective group (*17*). Although a few photoaffinity probes that possess a fluorophore have been reported (*18*), fluorescence quenching often occurs. To avoid loss of the photoadducts due to weakened fluorescence, the fluorescein group, which has a high quantum yield and strong fluorescent intensity, was selected for the detective group.

Probe **3** was readily synthesized from compound **2** in three steps (Scheme 1). Because the fluorophore was introduced to the probe molecule in the very last step of the synthetic route, the fluorescent probe could be easily customized by optimizing the fluorophors (solubility, exiting or emission wavelength, molecular size, etc.). Acylation of H-Lys(Boc)-OMe·HCl with activated ester **5** (*19*) followed by hydrolysis afforded carboxylic acid **6** (95% in two steps). Condensation between compound **2** (*10*) and **6** followed by removal of the *t*-butoxycarbonyl (Boc) group and thioamidation with fluorescein-4-isocyanate (FITC) provided probe **3** (23% from **6**). The fluorescence quenching of the fluorescein likely occurred by the photoaffinity group, but the fluorescence was strong enough to be detected with a fluorophotometer or fluorescent imaging analyzer. Probes that have the other fluorophore such as pyrene or NBD (*20*, *21*) were also synthesized, but their solubility in water was low and their fluorescence intensities were very weak. Therefore, the fluorescein probe **3** was chosen for the photolabeling experiment.

Prior to a photoaffinity labeling study, the ability of the probe to interact with actin should be evaluated. However, the activity of the probe **3** could not be determined in a pyrenyl-actin assembly assay (*6*) due to the fluorescence of **3** itself. Therefore, model compound **4**, which lacks a fluorophore, was synthesized, and its activity was evaluated. Synthesis of the model compound **4** was accomplished by the following procedure. Acylation of H-Lys(Boc)-OMe·HCl with benzoyl chloride, hydrolysis of methyl ester, and esterification with compound **2** afforded the model compound **4** (35% in three steps).

Scheme 1[a]



[a] (a) Et_3N, CH_2Cl_2, rt, 96%, (b) LiOH, dioxane, H_2O, rt, 99%, (c) DCC, DMAP, CSA, CH_2Cl_2, rt, (d) TFA, CH_2Cl_2, 0 °C, (e) FITC, Et_3N, DMF, rt, 23% (three steps).

Table 1. Actin-Depolymerizing Activity of Aplyronine A (1), 2, and 4

compounds	actin-depolymerizing activity[a]	
	IC_{50} (μM)[b]	relative potency[c]
aplyronine A (**1**)	1.6 ± 0.1	100
2	7.9 ± 1.5	20
4	9.7 ± 1.7	16

[a] Activity was monitored by measuring the fluorescence intensity of pyrenyl actin (*6*). [b] IC_{50} indicates the concentration required to depolymerize F-actin (3.7 μM) to 50% of its control amplitude, the value is the average of three assays, and the errors are given in SD values. [c] The relative potencies were calculated from the IC_{50} values of the compound (aplyronine A = 100).

The actin-depolymerizing activities of model compound **4**, aplyronine A (**1**), and its analogue **2** are shown in Table 1. Model compound **4** retained the activity comparable to that of analogue **2**. This result indicates that the potent activity of analogue **2** was not influenced by the functionalization of its primary hydroxyl group. These findings suggest that probe **3** holds promise for use in photolabeling studies.

Using the fluorescent photoaffinity probe **3**, we carried out the photoaffinity labeling experiment (*12*). Probe **3** was incubated in various concentrations with actin for 1 h at 0 °C in the absence or presence of aplyronine A (**1**). The mixtures were photoirradiated using a portable UV-lamp, denatured, and then subjected to SDS-polyacrylamide gel electrophoresis (SDS−PAGE) using 12.5% polyacrylamide gels in the Laemmli buffer system (*22*). The gels were directly visualized by laser scanning in a fluorescent imaging analyzer (Figure 4). Actin was successfully photolabeled, and labeled-actin was clearly visualized. The intensity of fluorescent bands of the labeled-actin increased with an increase in the dose of **3** (lane 1, 3, 5, 7). All of the fluorescent signals were decreased by coincubation with excess amounts of aplyronine A (**1**, lane 2, 4, 6, 8), indicating that the photolabeling proceeded specifically at the aplyronine A (**1**) binding site.

Inhibition study with other actin depolymerizing reagents, mycalolide B and cytochalasin D, was preformed. Although mycalolide B possesses a side-chain portion, which is very similar to that of aplyronine A (**1**), it exhibits only cytotoxicity in vitro, and no antitumor activity in vivo was reported. Cytochalasin D depolymerizes actin by a capping mechanism different from that of aplyronine A (**1**) (*8*). Probe **3** (20 μM) was incubated with actin (10 μM) for 1 h at 0 °C in the absence

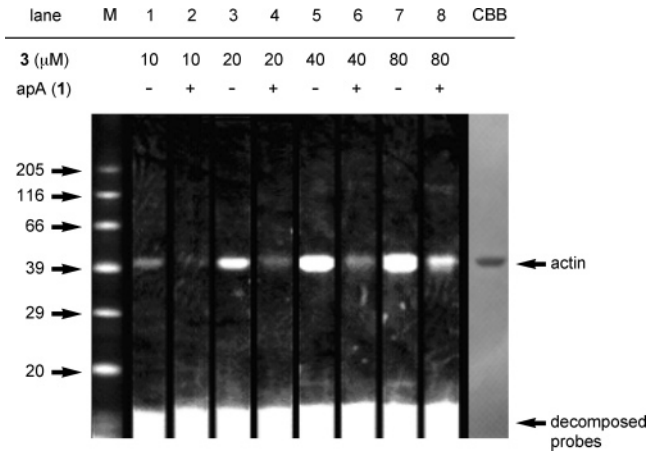


Figure 4. SDS−PAGE analysis of actin (10 μM) photolabeled in various concentrations of probe **3** in the absence (−) or presence (+) of aplyronine A (100 μM). For comparison, Coomassie brilliant blue (CBB)-stained actin is shown in the rightmost lane. The fluorescent signal was visualized by laser-scanning of the electrophoresed gel with a fluorescent imaging analyzer (BIO-RAD, molecular imager FX, and an excitation and detection filter for FITC). Lane M shows the fluorescent high molecular weight marker (Sigma).

or presence of additives (aplyronine A, mycalolide B, or cytochalasin D, 100 μM). The mixtures were photoirradiated and subjected SDS−PAGE analysis as stated above (Figure 5). Mycalolide B inhibited the photolabeling as well as aplyronine A (**1**, lane 2, 3); however, cytochalasin D did not inhibit it (lane 4).

The photoirradiated mixtures were also analyzed using size-exclusion chromatography (SEC) (Figure 6). Generally, the peak of actin was broadened due to the equilibrium between F-actin and G-actin in the column. To obtain a sharp peak for G-actin, the mixtures were coincubated with 100 μM aplyronine A (**1**), a potent actin-depolymerizing reagent, for 20 min at room temperature, before SEC analysis. Analytical conditions were chosen so that the probe was dissolved in the moving phase and a peak of G-actin, the molecular weight of which is 42 kDa, was completely separated from the other side products. The photolabeled actin exhibited fluorescence, as shown in the chromatographic profile. The photolabeled actin (retention time = 7.0−8.0 min) was unseparable from the intact actin (retention time = 7.0−8.0 min) in this condition but fully

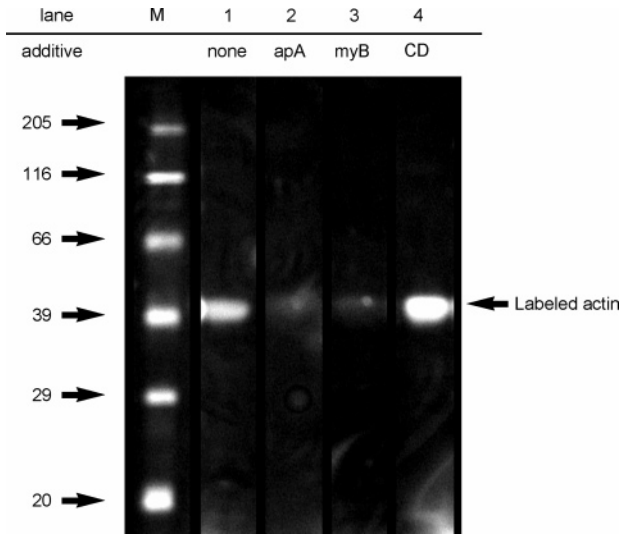

Figure 5. SDS−PAGE analysis of actin (10 μM) photolabeled with probe **3** (20 μM) in the absence or presence of well-known actin depolymerizing reagents: aplyronine A (apA, 100 μM), mycalolide B (myB, 100 μM, wako), and cytochalasin D (CD, 100 μM, wako). Visualization was performed in the same way as described above in the Figure 4. Lane M shows the fluorescent high molecular weight marker (Sigma).

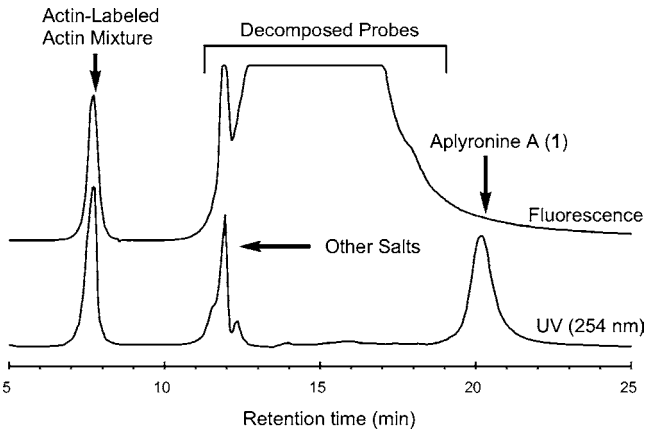

Figure 6. Size-exclusion chromatogram of the photoirradiated mixture with actin (100 μM) and probe **3** (100 μM), in 0.1 M phosphate buffer−10% DMSO (detect with UV 254 nm absorption, fluorescence at 480 nm excitation, 540 nm emission). TOSOH TSK-GEL G2000SW$_{XL}$ 7.8 × 300 mm was used. Aplyronine A (**1**) (400 μM) was added to the mixture prior to injection to depolymerize actin to obtain a sharp peak of monomer actin on a chromatographic profile. The retention times of 7.0 min to 8.0 min and beyond 11.0 min correspond to molecular weights of 40 kDa and below 1 kDa, respectively.

resolved from the decomposed probe and other salts (retention time = 11.0−20.0 and 11.0−13.0 min, respectively).

DISCCUSION

Actin was successfully photolabeled with probe **3**. The coincubated study showed that aplyronine A (**1**) competitively inhibits the binding of the probe **3** to actin. Therefore, probe **3**, which possesses the side-chain portion of aplyronine A (**1**), bound to actin specifically at the aplyronine A (**1**) binding site. These results indicate that the side-chain portion of aplyronine A (**1**) has actin-binding ability, which is consistent with the fact that the side-chain portion of aplyronine A (**1**) plays a key role in the actin-depolymerizing activity (*10*). The present results provide the first chemical evidence for a direct interaction between actin and the side-chain portion of aplyronine A (**1**). Furthermore, mycalolide B inhibited the binding of **3** to actin, whereas cytochalasin D did not. This result indicated that mycalolide B binds to actin at the same site as the probe **3**, and cytochalasin D is irrelevant to binding between the probe **3** and actin. Therefore, it is reasonable to suppose that aplyronine A (**1**) and mycalolide B bind to actin at the same site by using the similar side-chain portion.

Thus, we developed a fluorescent photoaffinity probe. Although a few instances have been reported for the successful visualization of photolabeled proteins with fluorescence, some posttreatments have been often required to visualize the adducts. Because probe **3** possesses a fluorescent group ab initio, labeled actin was visualized directly on polyacrylamide gels or HPLC without any posttreatments. Combination of a fluorescent group and a photoaffinity group was essential to gaining a high fluorescent intensity. The fluorescein group gave the best result due to its high quantum yield, fluorescent intensity, and solubility in water.

Although removal of a decomposed probe from a labeled protein mixture was often problematic, separation of the actin and labeled-actin mixture from the decomposed probe was completely achieved by SEC−HPLC. Exploring the HPLC condition revealed that a broad actin peak can be shifted to a sharp G-actin peak by the addition of aplyronine A as an actin-depolymerizing agent. The separated mixture can be subjected to enzymatic digestion, HPLC, and mass spectroscopic analysis to identify the binding site of the aplyronine A (**1**) against actin.

In conclusion, we have obtained chemical evidence that actin directly interacts with the side-chain portion of aplyronine A (**1**) based on a photolabeling experiments with fluorescent probe **3**. The photolabeled actin was visualized by electrophoresis and analytical SEC with satisfactory sensitivity. This fluorescent probe system can be successfully employed in photoaffinity labeling studies from both an economical and environmental perspective. Aplyronine A (**1**) was found to bind to actin not at the cytochalasin D binding site but at the mycalolide B binding site. It is interesting that aplyronine A (**1**) exhibits antitumor activity in vivo, in spite that aplyronine A (**1**) binding site is same as that of mycalolide B, whose in vivo antitumor effect has not been reported. Further analyses of the labeled actin are underway in an effort to identify the specific amino acid residues and to identify the aplyronine A (**1**) binding manner.

ACKNOWLEDGMENT

We would like to thank Emeritus Professor Kiyoyuki Yamada for his helpful discussions and comments. We are also grateful to Professors Hiroshi Ozaki and Masatoshi Hori for their donation of actin and their helpful advice and discussions. We would like to thank Professor Hideyuki Shigemori and Dr. Kosumi Yamada for their generous assistance with the electrophoretic analysis. This study was supported in part by the 21st Century COE program and Grants-in-Aid for Scientific Research from Ministry of Education, Culture, Sports, Science, and Technology, Shorai Foundation for Science and Technology, The Asahi Glass Foundation, Suntory Institute for Bioorganic Research, University of Tsukuba Research Projects, TARA project (University of Tsukuba), and Research Fellowships of the Japan Society for the Promotion of Science for Young Scientists (JSPS) to T.K.

Synthesis and Characterization of a Hemoglobin−Ribavirin Conjugate for Targeted Drug Delivery

Steve Brookes, Pieter Biessels, Nancy F. L. Ng, Caroline Woods, David N. Bell,* and Gord Adamson

Hemosol Corporation, 2585 Meadowpine Boulevard, Mississauga, Ontario, Canada L5N 8H9. Received November 17, 2005; Revised Manuscript Received January 26, 2006

A novel conjugate of human hemoglobin (Hb) and the nucleoside analogue ribavirin (RBV) was synthesized to demonstrate the utility of Hb as a biocompatible drug carrier for improved drug delivery in the treatment of liver disease. RBV is used in combination with interferon for the treatment of hepatitis C, but its side effects can result in dose limitation or discontinuation of treatment. Targeted delivery of RBV may help to prevent or minimize its toxicity. The hemoglobin−ribavirin conjugate (Hb−RBV) was designed to release bioactive drug upon endocytosis by cells and tissues involved in extracellular Hb catabolism and clearance. Ribavirin-5′-monophosphate (RBV-P) was prepared from RBV and activated as the 5′-monophosphorimidazolide (RBV-P-Im) for reaction with carbonmonoxyhemoglobin to yield Hb−RBV consisting of multiple RBV drugs covalently attached as physiologically labile phosphoramidates via their 5′-hydroxyl groups. A molar drug ratio of six to eight RBV molecules per Hb tetramer was obtained with near complete haptoglobin (Hp) binding of the drug modified Hb maintained. The conjugate complex (Hp−Hb−RBV) was selectively taken up *in vitro* by cells that express the hemoglobin−haptoglobin receptor, CD163. Recovered ribavirin enzymatically cleaved from Hb−RBV showed equipotent antiproliferative activity compared to control unconjugated RBV against human HepG2 and mouse AML12 liver cell lines. Based upon the reported high level of Hb uptake in the liver, Hb−RBV may be useful in the treatment of certain liver diseases, as well as inflammatory disorders associated with CD163-positive macrophages.

INTRODUCTION

Many therapeutic drugs do not achieve optimal efficacy due to systemic toxicity and side effects that require dose reduction, or due to inherent limitations in drug stability, half-life, and solubility (*1*). Targeted drug delivery to diseased tissues is one strategy for improving drug efficacy and reducing systemic side effects. One common targeting strategy employs chemical conjugation of drugs to a ligand capable of binding to specific cell surface receptors. The premise is that, following internalization and metabolism of the ligand−drug conjugate, the attached drug is released intracellularly to exert its therapeutic effect (*2*). Examples of ligands that have been used for targeted drug delivery include transferrin, hormones, growth factors, lectins, folic acid, carbohydrates, asialoglycoproteins, glycoproteins, and antibodies (*1*−*3*). In addition, natural and non-natural agents such as liposomes, polymers, and modified carbohydrates (*4*−*6*) have been used to target drugs through tissue-specific clearance pathways for the particular macromolecular carrier.

We have developed a novel drug targeting strategy using hemoglobin (Hb) as a natural carrier to target the delivery of drugs to the liver by taking advantage of the natural Hb clearance pathways. Hemoglobin is the most abundant blood protein and consists of two α and two β chains ($\alpha_2\beta_2$) which are noncovalently associated within erythrocytes (red blood cells) as a 64.5 kDa tetramer (*7*, *8*). The main function of Hb is to bind oxygen in the lungs for delivery to respiring tissues (*7*). Extracellular Hb released as a result of red blood cell deterioration and senescence dissociates into two 32 kDa $\alpha\beta$ dimers (*8*) which are rapidly and essentially irreversibly bound ($K_D < 10^{-15}$ M) by the plasma protein haptoglobin (Hp) (*9*−*12*). Three major organs are known to take up and degrade Hb−Hp complexes: liver, spleen, and bone marrow, with the liver being the principal (>70%) site of Hb catabolism (*9*, *13*, *14*). The liver was confirmed recently as the principal site of Hb uptake; radiolabeled Hb was found primarily in the liver following Hb dosing at near Hp-saturating levels in rats (*15*). Multiple mechanisms exist for liver uptake of Hb. Hepatocyte receptors for Hb−Hp complexes have been reported (*16*, *17*) to account for the majority of liver uptake. Liver macrophages (Kupffer cells) specifically recognize and internalize Hb−Hp complexes via Hb−Hp scavenger receptors such as CD163 (*18*, *19*). This receptor is expressed by cells of the monocyte/macrophage lineage, with Kupffer cells expressing the highest levels of CD163 mRNA (*20*). Cellular expression of CD163 is also elevated in association with certain liver diseases and inflammatory disorders (*19*, *21*). In addition to the specific receptor-mediated uptake by hepatocytes and Kupffer cells, Hb is taken up by the liver through Hp-independent mechanisms (*22*) and via uptake into transendothelially located hepatocytes through open fenestrations in the sinusoidal endothelial cells (*23*). By using Hb as a drug carrier, the natural mechanisms of Hb clearance can be utilized to selectively transport therapeutic drugs to the liver for the treatment of both liver and macrophage-associated diseases.

Ribavirin (RBV) is a nucleoside analogue currently approved for use in combination with interferon-α for the treatment of chronic hepatitis C virus (HCV) infection, and most recently in combination with PEGylated forms of interferon-α (*24*, *25*). The major toxic side effect of RBV therapy is a dose-dependent hemolytic anemia in approximately 10% of the treatment-eligible population which results from high drug accumulation in red blood cells (*26*). Accordingly, RBV is contraindicated for certain subpopulations of HCV patients with concurrent medical disease. We have selected RBV as a model drug for conjugation to Hb to demonstrate the feasibility of Hb-based drug delivery.

RBV is both an antiviral agent and an immunomodulator (*27*), making it an ideal choice for targeted delivery to cells of the liver for the treatment of viral infections and inflammatory disorders. Increased drug potency may result from increased RBV bioavailability through targeted delivery. An additional benefit may be realized through a reduction in side effects such as hemolytic anemia in susceptible patients. Fiume and coworkers have demonstrated reduced toxicity of RBV through coupling of the drug to lactosaminated poly-L-lysine, a carrier polymer that is specific for asialoglycoprotein receptors on hepatocytes (*28*, *29*).

We describe the synthesis, characterization, and physical properties of a novel Hb−ribavirin conjugate designed for targeted delivery and release of bioactive drug within cells capable of taking up and internalizing the drug conjugate. We have chosen phosphoramidate conjugation chemistry (*30*, *31*) because of the labile nature of this linkage within the endosomal compartment, thereby allowing release of free drug following endocytosis.

EXPERIMENTAL PROCEDURES

Materials. All chemicals, proteins, and enzymes used were purchased from Sigma-Aldrich (Oakville, ON, Canada) unless otherwise indicated. Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) was obtained from Inter-Chemical Ltd. (Shenzhen, China). Pure human Hb was derived from expired whole blood according to established procedures at Hemosol Corp. (*32*) and used in the carbonmonoxy form (COHb). Human Hp (mixed phenotype) was from Athens Research and Technology, Inc. (Athens, GA). Human plasma was obtained from informed donors, and mouse plasma was obtained from Balb/c mice (Charles River, St. Constant, QC, Canada). Alexa Fluor 488 was purchased from Molecular Probes (Cedarlane Laboratories, Ltd., Hornby, ON, Canada). Phosphate buffered saline (PBS), AIMV, fetal bovine serum (FBS), Dulbecco's modified eagle medium (DMEM), insulin transferrin selenium supplement (ITSS), and Ham's F12 culture media were all purchased from Invitrogen (Burlington, ON, Canada). Lactated Ringer's solution (Ringer's Lactate) was purchased from Abbott Laboratories (Montreal, QC, Canada). Chinese hamster ovary (CHO), human hepatoma HepG2, and mouse hepatocyte AML12 cells were from the American Type Culture Collection (ATCC, Manassas, VA). The bromodeoxyuridine (BrdU) cell proliferation enzyme-linked immunosorption assay (ELISA) kit was from Roche (Mississauga, ON, Canada). Electrospray ionization (EI) and matrix-assisted laser desorption ionization (MALDI) mass spectral analyses were performed at the Proteomic and Mass Spectrometry Centre, Faculty of Medicine, University of Toronto (Toronto, ON, Canada). ^{31}P NMR (121.5 Hz) analyses were performed at the Department of Chemistry, University of Toronto.

Cell Lines and Culture Conditions. HepG2 (ATCC HB-8065) human hepatoma and mouse AML12 (CRL-2254) hepatocyte cells were cultured in DMEM/Ham's F12 supplemented with 10% FBS, ITSS, and dexamethasone. Chinese hampster ovary (CHO) cells expressing human CD163 (variant 1, CHO/CD163) were cultured in Ham's F12 supplemented with 10% FBS.

HPLC Analyses. All high performance liquid chromatography (HPLC) analyses were performed using a Beckman HPLC Gold system. Anion exchange chromatography was performed on a Poros H/HQ (4.6 mm × 100 mm) column, using a pH gradient of 8.3−6.3 over 10 min (25 mM Tris pH 8.3 buffer, 25 mM bisTris pH 6.3 buffer) at a flow rate of 4 mL/min, with absorbance monitoring at 280 nm (to detect total protein) and 414 nm (to detect only heme protein). C_4 reverse-phase HPLC was performed on a Vydac C_4 column (4.6 mm × 250 mm) using a gradient of 20−60% acetonitrile in water containing 0.1% trifluoroacetic acid (TFA) over 90 min, at a flow rate of 0.9 mL/min, and absorbance was measured at 220 nm (*33*). C_{18} reverse-phase HPLC was performed on a C_{18} Phenomenex Luna column (4.6 mm × 250 mm) eluted with water (0.1% TFA), pH 2.9, at a flow rate of 1 mL/min, and absorbance was measured at 210 and 254 nm. Size-exclusion chromatography (SEC) was performed using a Pharmacia Superdex 200 column (10 mm × 310 mm) eluted with 0.5 M magnesium chloride in 25 mM Tris buffer, pH 7.2, at a flow rate of 0.4 mL/min, and absorbance was measured at 280 nm (to detect total protein) and 414 nm (to detect only heme protein).

Synthesis of Ribavirin-5′-monophosphate. Ribavirin-5′-monophosphate (RBV-P) was prepared by reaction of RBV with phosphorus oxychloride ($POCl_3$) and trimethyl phosphate (TMP) according to the method of Allen (*34*), with progress of the reaction monitored by C_{18} reverse-phase HPLC. RBV (2 mmol) was reacted with $POCl_3$ (8 mmol) and purified water (2 mmol) in 8.3 mL of TMP. Following completion of the reaction (5 h), the product was poured over 20 g of ice and 2 N sodium hydroxide solution was added to bring the pH up to 3. The product was allowed to hydrolyze overnight at room temperature. The hydrolyzed product was extracted with 2 × 20 mL portions of chloroform. The product RBV-P in chloroform was mixed with 10 g of fine charcoal (100−400 mesh). The reaction mixture/charcoal slurry was centrifuged at 2000*g* for 15 min, and the supernatant was recovered. The wash steps were repeated until no inorganic phosphate (P_i) could be detected in the supernatant by C_{18} reversed-phase HPLC or by the Ames method (*35*). The charcoal was extracted three times with ethanol/water/ammonium hydroxide (10:10:1), and the pooled extract was evaporated to dryness. The resulting RBV-P ammonium salt was converted to the free acid by ion exchange using BioRAD AG 50W-X2 (H form) resin and elution of product with water according to the method by Streeter (*36*). The isolated yield after purification was 70%. The RBV-P was characterized using two assays: C_{18} reverse-phase HPLC quantification of the RBV released by enzymatic cleavage using acid phosphatase (acid phosphatase assay, described below), and quantification of total inorganic phosphate (P_i) by the Ames method (*35*). EI mass spectral analysis: $m/z = 323.2$ (calculated 324). ^{31}P NMR (D_2O): δ 0.95 ppm.

Synthesis of Ribavirin-5′-phosphorimidazolide. Purified RBV-P was converted to ribavirin-5′-monophosphorimidazolide (RBV-P-Im) according to the procedure of Fiume (*30*, *31*) with slight modifications. The reaction was performed under dry nitrogen using anhydrous solvents. RBV-P (324 mg, 1 mmol) was dissolved in 10 mL of *N*,*N*′-dimethylformamide (DMF). Carbonyldiimidazole (CDI, 5 mmol) dissolved in 5 mL of DMF was added to the RBV-P solution with stirring, followed by addition of 5 mmol of imidazole freshly predissolved in 5 mL of DMF. The reaction mixture was stirred at room temperature for 45 min followed by removal of the DMF by evaporation. The resulting waxy solid was dissolved in 2 mL of ethanol, followed by precipitation of the RBV-P-Im product by slow addition of 20 mL of ether. The precipitate was washed twice with ether, and residual ether was evaporated using a gentle stream of dry nitrogen. The RBV-P-Im was isolated in >90% yield and used immediately for conjugation to Hb. EI mass spectral analysis: $m/z = 373.2$ (calculated 374). ^{31}P NMR (D_2O) analysis: δ 20.3 ppm, trace P_i (3.3 ppm), and pyrophosphate (−10.3 ppm).

Conjugation of Ribavirin-5′-phosphorimidazolide to Hemoglobin. COHb (6.67 μmol, 430 mg) (4.3 mL of a 100 mg/mL solution in purified water) was mixed with 1 mmol of RBV-P-Im dissolved in 8.6 mL of 0.1 M sodium bicarbonate, pH 9.5, buffer (150:1 ratio of RBV-P-Im to Hb). The pH of the

reaction mixture was maintained at pH 9.5−9.6 over the first hour by addition of 0.2 M sodium carbonate solution as required. After the pH of the reaction mixture had stabilized, the reaction vessel was charged with carbon monoxide (CO) for 15 min and the reaction was allowed to continue under positive CO pressure with mixing at 37 °C for 96 h. The degree of Hb modification was monitored by anion exchange HPLC. The final reaction mixture was purified by dialysis (10 kDa molecular weight cutoff) against Ringer's Lactate (3 × 0.5 L exchanges), sterile filtered (0.2 μm filter), charged with CO, and stored at −80 °C. The final Hb concentration following the reaction was 15 mg/mL.

Determination of Molar Drug Ratio (MDR). The RBV/Hb molar drug ratio (MDR) in the hemoglobin−ribavirin conjugate (Hb−RBV) was determined by C_{18} reverse-phase HPLC quantification of RBV released by enzymatic cleavage using the acid phosphatase assay (described below), and determination of total inorganic phosphate (P_i) using the Ames inorganic phosphate assay (described below). The molar concentration of Hb was determined using the Drabkin's assay (Sigma Diagnostics). The MDR was also assessed by MALDI mass spectrometry. Hb−RBV MALDI mass spectra were analyzed in the *m*/*z* range corresponding to 15−20 kDa to identify [α globin + *n*] or [β globin + *n*] peaks, where the mass of the α globin chains was measured as 15145 g/mol, β globin chains were measured as 15869 g/mol, and *n* is the calculated number of attached RBV-P (307 g/mol).

Acid Phosphatase Assay. RBV-P analysis: 20 μL of 30 μmol/mL RBV-P (0.6 μmol) was diluted into 0.3 mL of 1 mM sodium acetate buffer, pH 4.8, containing 3 units of acid phosphatase (type IV-S, potato). Conjugate analysis: 20 μL of 15 mg/mL Hb−RBV in Ringer's Lactate solution (0.3 mg, 5 nmol) was diluted into 0.3 mL of 1 mM sodium acetate buffer, pH 4.8, containing 3 units of acid phosphatase. The mixtures were incubated at 37 °C for 2 h. Precipitates were removed by centrifugation through a Centricon concentrator (Amicon, 10 kDa molecular weight cutoff), and RBV in the supernatant was quantified by C_{18} reverse-phase HPLC against standard calibration curves of RBV and Hb + RBV admixture solutions also treated with acid phosphatase.

Inorganic Phosphate Assay. Total inorganic phosphate (P_i) was determined using the Ames method (*35*) using potassium phosphate solutions as standards. 80 μL of 10% magnesium nitrate in ethanol was used for analysis of 5 nmol of the Hb−RBV sample (25 μL of ∼15 mg/mL Hb−RBV solution). Samples were ashed over an open flame in a test tube and then hydrolyzed with 0.4 mL of 0.5 M hydrochloric acid solution in a 100 °C water bath for 2 h. The samples were filtered to remove precipitates and adjusted back to 0.4 mL with water. 1.0 mL of the Ames color reagent (prepared by mixing 1 part 10% ascorbic acid solution with 6 parts of 0.42% ammonium molybdate in 1.0 N sulfuric acid solution) was added and incubated at 37 °C for 45 min. The absorbances of the samples were measured at 820 nm, and the P_i concentration was determined using a standard curve generated from the phosphate standards.

Haptoglobin-Binding Assay. Hb−RBV (500 μL of a 1 mg/mL solution in PBS, 7.7 nmol) was mixed with a 10% molar excess of human Hp (85 μL of a 10 mg/mL solution in PBS, 8.5 nmol), at room temperature for 1 h to allow complex formation of Hb−RBV with the added Hp. The extent of Hb−RBV binding to Hp was determined by SEC analysis of the mixture. Hb-containing species were detected at 414 nm. Hp-bound complexes appear as high molecular weight early-eluting species, predominantly 164 kDa, but up to as high as 400 kDa due to the heterogeneous molecular weight of the mixed phenotype polymerized Hp (*10*, *11*). Noncomplexed Hb species appear as late-eluting low molecular weight species (∼32 kDa) due to dissociation of the tetrameric $\alpha_2\beta_2$ Hb into $\alpha\beta$ dimers under the high salt elution conditions. The Hb−Hp complex, however, is stable under the dissociating elution conditions. The extent of Hb−RBV binding to Hp was determined by comparing the amount of Hp-bound early-eluting Hb species to the amount of nonbound late-eluting Hb species remaining in the Hp-containing incubation mixture injected.

Stability Assay. Approximately 15 nmol of Hb−RBV (1 mg in 75 μL of PBS) was mixed with an equal volume of freshly prepared plasma (human and mouse) and adjusted to a final volume of 0.2 mL with PBS. Samples were removed for analysis after incubation at 37 °C for 0.5, 1, and 2 h. Samples were centrifuged through a Centricon concentrator (Amicon, 10 kDa molecular weight cutoff), and the filtrate was analyzed for RBV by C_{18} reverse-phase HPLC. Plasma samples were prepared with known amounts of Hb and RBV as standards to achieve a RBV standard curve against which released RBV in the incubated samples could be measured by comparing HPLC peak areas. The standards were processed and analyzed identically and in parallel to account for any loss of RBV due to plasma protein binding and removal from the supernatant. Percent release was estimated by dividing the measured RBV concentration determined at each time point by the initial conjugated RBV concentration (calculated by multiplying the amount of Hb−RBV treated (15 nmol) by the MDR determined from the acid phosphatase and Ames' assays, and dividing by the volume of the sample, 0.2 mL). The amount of RBV released in plasma over time was compared with the known MDR to assess conjugate stability.

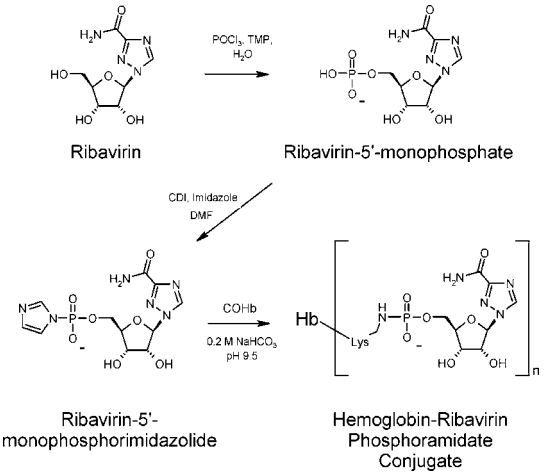
Labeling Haptoglobin with Alexa Fluor 488. Hp was fluorescently labeled (fHp) with Alexa Fluor 488 (a dye containing an amine-reactive carboxylic acid tetrafluorophenolate ester tethering functionality) to allow characterization of cell binding and uptake of Hp−Hb−RBV *in vitro*. Human Hp (500 μL of a 2 mg/mL solution in PBS) was labeled according to the Alexa Fluor 488 kit procedure, and the extent of the labeling was determined using the formula below:

$$\text{moles of fluor/moles of Hp} = (A_{495\text{fHp}} - A_{495\text{Hp}})/\epsilon_{\text{F495}} \times d/C_{\text{Hp}}$$

where ϵ_{F495} is the published extinction coefficient for the fluor (71 000 $\text{cm}^{-1}\cdot\text{M}^{-1}$, Molecular Probes, Inc., Eugene, OR), *d* is the assay dilution factor, C_{Hp} is the concentration of the labeled Hp sample, and $A_{495\text{fHp}}$ and $A_{495\text{Hp}}$ are the measured absorbance values for fHp and Hp, respectively. Typically, 2−3 fluors were attached per Hp to give fluorescently labeled Hp (fHp).

Hp−Hb Cell Internalization Assay. To evaluate uptake of Hp−Hb−RBV by cells expressing a known Hb−Hp receptor (CD163), internalization assays were performed using wild type CHO cells (CHO/WT) and proprietary CHO cells stably transfected with CD163 variant 1 (CHO/CD163). Both cell types were incubated with Alexa Fluor 488-labeled Hp (fHp) complexed with either Hb or Hb−RBV. The flow cytometry analysis procedure was adapted from the method published by Schaer et al. (*37*). CHO/WT and CHO/CD163 cells were plated in media overnight in a 24-well plate at 1 × 10^5 cells/well. fHp−Hb and fHp−Hb−RBV complexes were prepared fresh for the assay by combining fHp with Hb and Hb−RBV at a 1.1:1 molar ratio and incubated for 1 h at room temperature in the dark prior to dilution to the appropriate concentrations (spanning a Hb concentration range from 0 to 100 μg/mL) with AIMV culture medium. The cell culture medium was removed, and the cells were rinsed with PBS. 200 μL aliquots of fHp, fHp−Hb, and fHp−Hb−RBV in AIMV were added to the wells and incubated for 1 h at 37 °C. The labeling medium was removed from the cells, and the cells were washed with PBS. The cells were removed from the wells using trypsin and transferred to a

Scheme 1. Hemoglobin−Ribavirin Conjugate Synthesis



5 mL polypropylene flow tube. PBS was combined with the cells in the tube, and the cells were pelleted at 1500 rpm at 4 °C for 10 min. The supernatant was removed, and the cells were resuspended in 500 μL of PBS in flow tubes. Fluorescent intensity was measured by flow cytometry. FL-1% is the percentage of cells within the sampled population fluorescing above baseline, and X-mean is the mean relative fluorescence of the cell population on a logarithmic scale expressed as relative fluorescence units (RFU). A high X-mean indicates that the cells are highly fluorescent and is related to the amount of fluor taken up in the form of fHp.

Recovery of Ribavirin from Hb−RBV. RBV was cleaved from Hb−RBV by enzymatic hydrolysis and isolated for evaluation of bioactivity. Hb−RBV (500 μL of a 15 mg/mL solution in PBS, ∼120 nmol, 7.5 mg) was treated with 100 U of acid phosphatase in a final volume of 2 mL of 0.2 M sodium acetate buffer, pH 4.8, at 37 °C for 3 h. The reaction mixture was centrifuged through a Centricon concentrator (Amicon, 10 kDa molecular weight cutoff) to remove precipitated Hb, and the supernatant was analyzed by C_{18} HPLC (according to the acid phosphatase assay) to quantify the amount of RBV and then was lyophilized and reconstituted in PBS prior to *in vitro* activity evaluation.

***In Vitro* Ribavirin Bioactivity Assay.** RBV recovered from acid phosphatase cleavage of Hb−RBV was evaluated for bioactivity in an *in vitro* cell proliferation assay using a BrdU incorporartion cell proliferation ELISA. Human HepG2 and mouse AML12 cells were plated at a density of 4×10^4 cells/well in flat bottom 96-well plates. The cells were allowed to grow for 24 h, at which time they were treated in quadruplicate with RBV or RBV cleaved from Hb−RBV. Cells were incubated for 6 h at 37 °C over a dose range of 0−200 μM RBV. Following incubation, the medium was removed, fresh medium containing BrdU was added to the wells, and the incubation was continued for 18 h to allow for incorporation of BrdU into the DNA. The extent of BrdU incorporation is a measure of cell proliferation and was determined by ELISA using an antibody directed to BrdU according to the kit protocol. The growth inhibitory effect of RBV with respect to dose was expressed as a percent of control with untreated cells set as 100% proliferation.

RESULTS

Synthesis of Hb−RBV. The preparation of Hb−RBV is shown in Scheme 1. The synthesis of RBV-P was carried out using $POCl_3$ in TMP to phosphorylate the 5′-hydroxyl group of RBV according to the procedure by Fiume (*30*, *31*). More than 95% of RBV was modified according to C_{18} reverse-phase HPLC, where RBV-P had an earlier-eluting peak than RBV. Figure 1 is a normalized overlay of the C_{18} chromatograms of purified RBV-P, RBV, and inorganic phosphate (P_i) byproduct, illustrating the different retention times. Instead of using a charcoal column to separate RBV-P from inorganic phosphate, the reaction solution was mixed with charcoal to adsorb RBV-P, and then the charcoal containing RBV-P was washed/centrifuged several times. This resulted in sufficient P_i removal compared to product loss. Washing was stopped when P_i was no longer detected in the supernatants using the indicator from the Ames inorganic phosphate assay (*35*) or by C_{18} HPLC. The ammonium salt of RBV-P was extracted from the charcoal with ethanol/water/ammonium hydroxide, converted to its free acid form, and lyophilized. Analysis of the recovered RBV-P showed it to contain less than 5% of unmodified RBV. The product was also evaluated using acid phosphatase to convert the RBV-P to RBV, which was quantified by C_{18} HPLC analysis. This assay indicated more than 90% of the purified product RBV-P could be cleaved into RBV and P_i. The Ames inorganic phosphate assay was used to determine the purity of the RBV-P as measured by free P_i liberated upon pyrolysis. The measured phosphate accounted for >95% of the theoretical phosphate content. The overall yield from RBV after charcoal purification was 60%. This product was used in the next step to form the 5′-monophosphorimidazolide, RBV-P-Im.

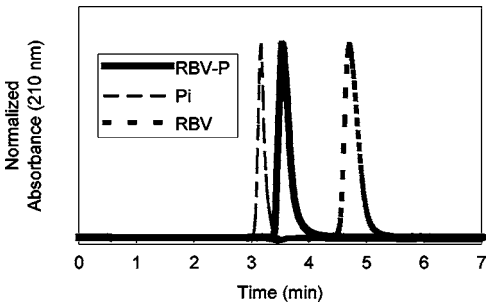


Figure 1. Overlaid C_{18} chromatography profiles of RBV, P_i byproduct, and RBV-P, illustrating how reaction progress was monitored based on elution time.

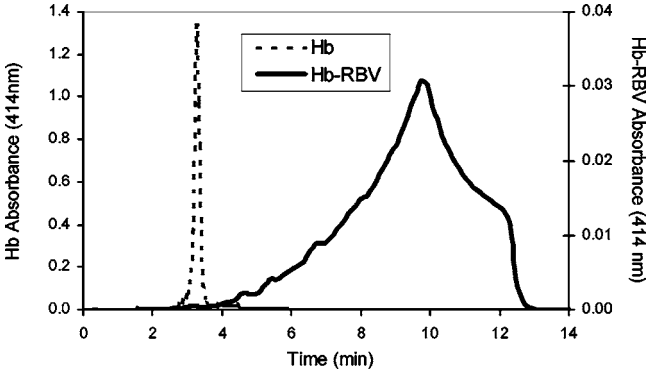

Figure 2. Anion exchange chromatographic profile of Hb−RBV showing the conjugate eluting later than native Hb (concentration-equivalent injection) due to a greater net negative charge on the Hb imparted by attached RBV.

Synthesis of the intermediate RBV-P-Im was achieved by activating RBV-P with CDI and imidazole followed by evaporation of DMF solvent. Numerous precipitations from ethanol with ether yielded an off-white powder after drying. RBV-P-Im was conjugated to Hb immediately and without further purification.

Reacting RBV-P-Im in a 150-fold molar excess over Hb (COHb) with the pH held constant at 9.5 was found to provide the highest ratio of RBV to Hb in the final conjugate. Anion exchange chromatographic analysis (Figure 2) indicated a lowering and broadening of the Hb isoelectric point, consistent

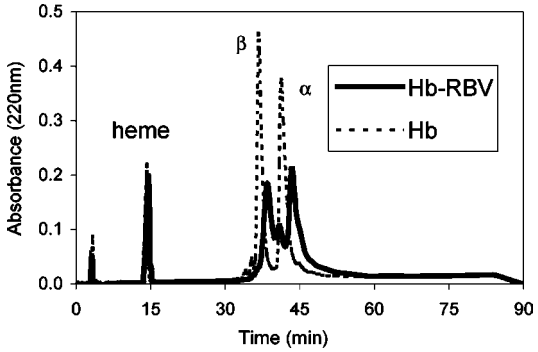

Figure 3. C_4 reverse-phase HPLC profile of Hb−RBV showing the shift in retention time of the individual globin chains due to conjugation of RBV to native Hb chains.

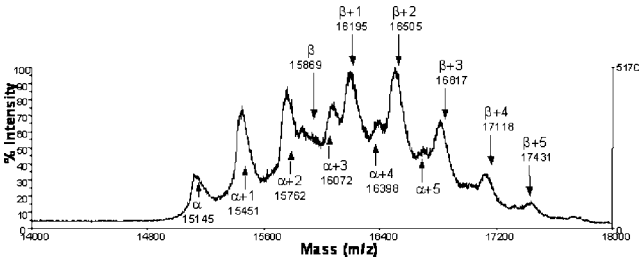

Figure 4. MALDI mass spectral analysis of the Hb−RBV conjugate showing several [α globin + *n*] and [*β* globin + *n*] peaks, where *n* is the calculated number of RBV-P attached. The average MDR estimated from this distribution is between 4 and 12.

Table 1. Hb−RBV Molar Drug Ratio (MDR)

	RBV conc	Hb conc	MDR
acid phosphatase assay	100 μM	16 μM	6
inorganic phosphate assay	2.36 mM	0.29 mM	8

with addition of multiple negatively charged RBV-P moieties to the protein resulting in increased retention time. Greater than 95% of the starting Hb was modified in the reaction. C_4 reverse-phase HPLC analysis (Figure 3) showed modification of both the α and *β* chains, as indicated by a shift of the peaks to slightly longer retention times and by peak broadening. The molar drug ratio (MDR) of the product mixture was calculated by dividing either the acid phosphatase-cleaved RBV concentration (acid phosphatase assay) or the P_i concentration (Ames inorganic phosphate assay) by the Hb concentration (Drabkin's assay), taking into account any dilutions. The MDR was found to be between 6 and 8 RBV moieties attached per hemoglobin tetramer (Table 1). MALDI mass spectral analysis (Figure 4) indicated the attachment of 1−3 RBV drugs per α or *β* globin chain (the [α + *n*] and [*β* + *n*] peaks were within 0.2% of the expected values based on 307 g/mol RBV-P incremental mass additions). This corresponds to a MDR distribution of 4−12 if the α and *β* monomers were recombined in the Hb $\alpha_2\beta_2$ tetrameric form and is consistent with the average 6−8 MDR determined by the acid phosphatase and Ames assays, which give the ratio per $\alpha_2\beta_2$ tetramer. SEC analysis of Hb−RBV under high magnesium chloride salt conditions that dissociate 64.5 kDa $\alpha_2\beta_2$ Hb into 32 kDa $\alpha\beta$ dimers revealed the conjugate mixture to contain predominantly 32 kDa material (82%) eluting at 41 min, as well as some 64.5 kDa material (18%) that appeared as an earlier-eluting 38.5 min shoulder on the 32 kDa 41 min peak (Figure 5).

Binding of Hb−RBV to Hp. Approximately 90% of the Hb−RBV mixture bound to human Hp (mixed phenotype), which accounted for all of the 32 kDa Hb−RBV species (Figure 5) but only some of the 64.5 kDa Hb−RBV species. The lower molecular weight Hb−RBV species moved completely to an earlier elution time by SEC analysis, indicating Hp-binding, whereas most of the higher molecular weight Hb−RBV species did not change elution time, indicating no Hp-binding. Incubation overnight did not increase binding of this species to Hp. The non-Hp-bound, high molecular weight Hb−RBV can be removed by preparative SEC due to the 10 min difference in elution times; however, this was not done for any of the MDR or *in vitro* analyses described in this report.

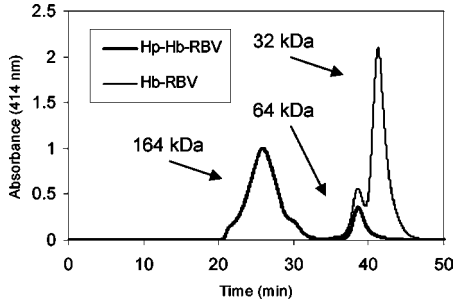

Figure 5. Overlaid SEC profiles of Hb−RBV and Hp−Hb−RBV showing a shift of all of the 32 kDa Hb−RBV to higher molecular weight upon Hp-binding, but only some of the 64 kDa Hb−RBV.

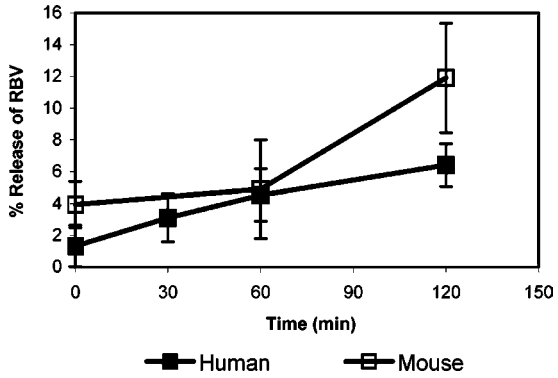

Figure 6. Release of RBV from Hb−RBV in human and mouse plasma after 2 h (mean ± std dev).

Stability of Hb−RBV in Plasma. The stability of Hb−RBV in fresh human and mouse plasma was tested *in vitro* to provide an estimate of its expected stability in circulation *in vivo*. Incubation of the Hb−RBV in plasma resulted in increasing levels of free RBV with the same elution time as that of RBV control by C_{18} reversed-phase HPLC. There was no evidence of release of RBV−P from the conjugate. Hb−RBV was more stable in human plasma in this experiment, with release of only 6 ± 1.3% of the conjugated RBV load compared to 12 ± 3.4% release in the mouse plasma after 2 h (Figure 6).

$CD163^+$ Cell-Specific Uptake of Hb−RBV. Fluorescent labeling of Hp for cell uptake studies did not interfere with Hb-binding when analyzed by SEC (data not shown). At 50 μg/mL (Hb) incubation concentration, a 100% FL-1 (percent of cells fluorescing) was measured for the CHO/CD163 cells with Hb and Hb−RBV, indicative of binding of fluor (in the form of fHp-bound Hb complexes) to the transfected cells. Much lower FL-1 values were observed for all the CHO/WT cell samples and the CHO/CD163 cells incubated with fHp, indicative of minimal binding. X-mean (relative brightness of the fluorescent cells as measured by RFU) increased in a linear fashion over time for the CHO/CD163 cells, indicating binding and uptake (data not shown), in contrast to the case of CHO/WT cells, which showed only low nonspecific binding and no uptake. Figure 7 shows the results of uptake after 1 h by CHO/WT and CHO/CD163 cells incubated with 50 μg/mL fHp-bound Hb, 50 μg/mL fHp-bound Hb−RBV, or fHp control (80 μg/mL; the concentration of fHp bound to Hb and Hb−RBV in the 50 μg/mL Hb samples). CHO/WT cells did not take up fHp,

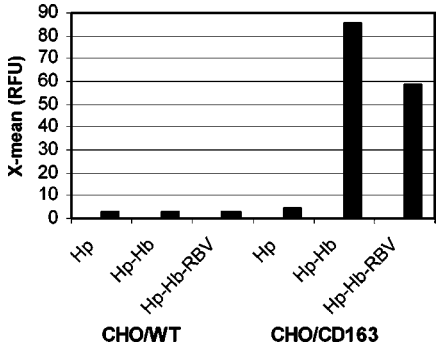

Figure 7. Relative fluorescence uptake (RFU) of fHp, fHp−Hb, and fHp−Hb−RBV into CHO/WT and CHO/CD163 at 50 μg/mL Hb (80 μg/mL Hp) after 1 h.

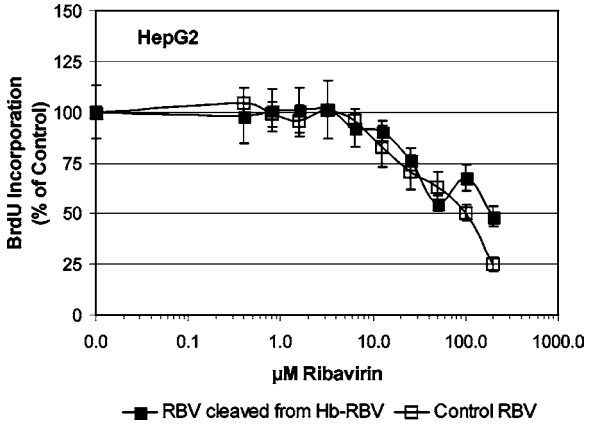

Figure 8. Antiproliferative activity of RBV control and RBV enzymatically cleaved from Hb−RBV against human HepG2 cells. Determined by measuring the extent of BrdU incorporation relative to control untreated cells (mean ± std dev).

fHp−Hb, or fHp−Hb−RBV complexes above the background level. CHO/CD163 transfectants bound and internalized fHp−Hb (85 RFU) and fHp−Hb−RBV (60 RFU) but did not internalize fHp, indicating that binding was specific for Hp−Hb complexes and occurred only in cells expressing the Hp−Hb receptor (CD163).

Bioactivity of Hb−RBV. The bioactivity of RBV released from Hb−RBV by enzymatic hydrolysis was assessed using the known antiproliferative activity of RBV (*27*, *38*) in an *in vitro* cell proliferation assay based on BrdU incorporation into DNA by actively dividing HepG2 cells. Proliferation of HepG2 cells was decreased by RBV in a concentration-dependent manner (Figure 8). RBV posthydrolysis and control unmodified RBV had similar dose-response curves, demonstrating that the conjugated RBV could be released in active form through enzymatic action. The antiproliferative activities of the control and cleaved RBV were also assessed in mouse AML12 cells, yielding similar dose-response curves (Figure 9).

DISCUSSION

A novel conjugate of human Hb and RBV was prepared to demonstrate the utility of Hb as a biocompatible carrier for improved drug delivery for the treatment of liver disease and diseases affecting Hb−Hp receptor bearing cells. Ribavirin is a drug currently approved for use in the treatment of HCV, but it suffers from dose-limiting toxicity associated with its systemic biodistribution. A Hb−RBV conjugate was prepared with releasable bioactive drug through stepwise synthesis from purified human Hb and RBV. RBV was first phosphorylated at its 5′-hydroxyl and subsequently activated to a phosphorimidazolide and reacted with COHb to yield a phosphoramidate

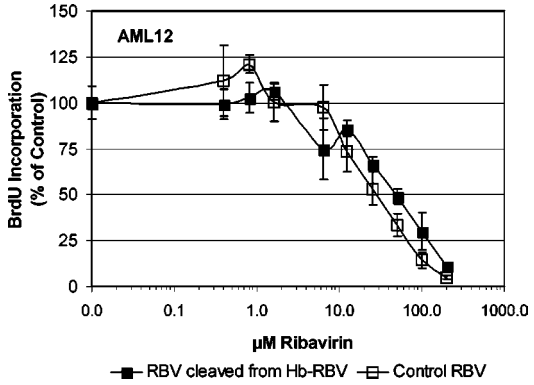

Figure 9. Antiproliferative activity of RBV control and RBV enzymatically cleaved from Hb−RBV against mouse AML12 cells. Determined by measuring the extent of BrdU incorporation relative to control untreated cells (mean ± std dev).

attachment of ribarivin to amino groups on hemoglobin. The attachment chemistry is similar to that developed by Baddiley (*39*), Staab (*40*), and Fiume (*30*, *31*). Hb was maintained in the carbonmonoxy ligation state instead of the oxygenated or deoxygenated state to prevent heme oxidation, methemoglobin formation, and protein precipitation under the reaction conditions. Sites of drug attachment include some of the approximately 40 surface lysine residues of Hb and possibly terminal amino groups of the globin chains. Several lysine residues on the α and β globin chains of Hb, as well as the β globin valine (Val1) amino termini, have been shown to be reactive toward a range of amine-directed Hb modifiers (*41*), supporting the selection of an amino group-directed chemistry to achieve a high molar drug ratio. The MDR of the Hb−RBV conjugate was determined to be 6−8 RBVs per Hb tetramer with little unmodified hemoglobin remaining after 96 h of reaction. It is important that all Hb molecules contain some drug to minimize competition of the unmodified Hb for binding to Hp and cell receptors. Native Hb−Hp may be a more effective competitor for cell receptors than the Hp−Hb−RBV complex and may explain the difference in CHO/CD163 cell binding and uptake for these two species (see CHO/CD163 cell uptake data and explanation below).

The Hb−RBV formulation consists of two species: (1) a Hb that dissociates into two 32 kDa Hb−RBV $\alpha\beta$ dimers under dissociating conditions (magnesium chloride containing buffer) and binds Hp despite the extensive modification by RBV, and (2) an ~64 kDa Hb−RBV species that does not dissociate and which essentially does not bind Hp. The sequence homology of haptoglobin is highly conserved across species (*42*), and cross-species compatibility of Hb−Hp binding has been demonstrated in our lab using rat Hp and human Hb (unpublished data). In addition, Hp has been shown to bind a range of modified Hbs (*43*, *44*), providing evidence for the ability of Hp to accommodate a variety of Hb surface features. However, Hp does not bind Hb cross-linked between the α globin chains but does bind Hb cross-linked between the β globin chains (*44*, *45*). The high molecular weight Hb component that does not bind Hp as observed on SEC under dissociating conditions is most likely cross-linked across the α chains, while the fraction that binds Hp is most likely cross-linked across the β chains. It is possible that Hb subunit cross-linking can occur through the secondary 3′ and 5′ hydroxyl groups of RBV, a consequence of ribavirin-3′,5′-diphosphate (RBV-P_2) and ribavirin-3′,5′-diphosphorimidazolide (RBV-[P-Im]$_2$) formation during the activation of RBV which is carried through to the conjugation step. Supporting this concept is the observation of a lone contaminant with $m/z = 403$ identified in the MALDI mass spectrum of RBV-P, corresponding to RBV-P_2, with a calculated

mass of 404 g/mol. The α chains are easily cross-linked by molecules of this size (*44*), which explains why most of the fraction did not bind Hp. Retention of Hp-binding by the Hb−drug conjugates is important for CD163-mediated cellular uptake since this receptor has been reported to bind and internalize complexes of Hb and Hp. However, multiple mechanisms including direct uptake of free Hb (*22*) and cross-linked Hb (*15*) appear to be necessary to account for the high capacity of the liver for Hb uptake. For subsequent *in vitro* and *in vivo* studies, residual cross-linked Hb−RBV was readily removed from the Hp−Hb−RBV complex using preparative SEC based upon the ∼100 kDa size difference. SEC purification was not performed on the initial formulations used in the characterization experiments presented in this report. However for *in vivo* studies, it is important that all Hb−RBV is bound to Hp to minimize rapid renal clearance of unbound 32 kDa Hb (*46*, *47*). Aside from eliminating renal clearance, Hp complexation helps to selectively target Hb−Hp receptor bearing cells such as liver macrophages and aids in overall liver targeting (*9*−*12*). The Hb−RBV conjugate was sufficiently stable in plasma to allow for efficient liver clearance, which is expected to occur within minutes of administration (half-life of clearance on the order of 9−12 min)(*9*−*12*). It is expected that most of the conjugate would be rapidly taken up by liver cells and metabolized before significant release of free drug into plasma could occur as a result of conjugate degradation.

To investigate receptor binding and uptake of Hb−drug conjugates, CHO cells expressing CD163 (CHO/CD163) were constructed. The Hp−Hb−RBV conjugate complex was taken up by CHO/CD163 cells but not by wild type cells lacking CD163 (CHO/WT). Fluorescent labeling of Hp did not impair Hb-binding and did not appear to prevent recognition and uptake by CD163. On the other hand, CD163 did not internalize fluorescently labeled Hp as an individual entity. These data indicate that Hb−RBV is specifically bound and internalized by Hb−Hp receptor bearing cells and provide evidence for the receptor-mediated uptake of Hp−Hb−RBV by cells that express CD163, primarily cells of the monocyte/macrophage lineage (*48*). The CD163 membrane protein has been identified as the macrophage scavenger receptor for Hb−Hp complexes, as part of a Hb uptake and iron recovery pathway (*18*, *21*). A similar receptor or process may mediate the uptake of Hb−Hp by hepatocytes; however, a related receptor has not yet been identified. Tissue macrophages are ideal targets for Hb-based drug delivery, particularly with conjugated RBV due to the known presence of CD163 on such cells. Several studies have shown that RBV alters the Th1/Th2 cytokine expression ratio during an immune response (*27*).

In the design of the Hb−RBV conjugate, a linkage was used that would be cleavable by lysosomal enzymes. A phosphoramidate linkage was employed due to the lability of phosphoramidates *in vivo* (*30*, *31*, *39*, *40*). As a model of cellular metabolism, RBV was enzymatically hydrolyzed and cleaved from the Hb−RBV conjugate using acid phosphatase *in vitro*. Released RBV was shown to retain bioactivity similar to that of unmodified RBV against HepG2 and AML12 cells, indicating active drug would be released following exposure of the Hb−RBV to hydrolytic enzymes in the lysosome following endocytosis (*49*). Also, nonphosphorylated RBV was detected by HPLC in this simulation of lysosomal release of drug. However, drug activity is expected from release of either RBV or RBV-P (phosphorylated form).

One mechanism by which RBV exerts its antiviral effect is through conversion to RBV-P, which inhibits inosine monophosphate dehydrogenase, resulting in reduced guanosine triphosphate (GTP) levels, thereby allowing RBV to ultimately compete against GTP in the host cell for incorporation into growing viral RNA (*38*, *50*, *51*). Successive phosphorylation steps ultimately lead to the RBV-5′-triphosphate nucleotide (*52*), which exerts antiviral activity through inhibition of viral RNA polymerase and causes mutations through error-prone replication when incorporated into growing viral RNA in place of GTP (*51*). Presumably, it is this form of RBV that is responsible for the antiproliferative effect on HepG2 and AML12 cells reported here.

Due to the dual immunomodulatory and antiviral mode of action of RBV, a Hb−RBV conjugate is expected to be suitable for the treatment of HCV infection, a viral disease affecting both hepatocytes and macrophages. Recent studies have already demonstrated the enhanced activity of the drug conjugate in a model of acute viral hepatitis, in which significantly lower amounts of conjugated RBV provided improved outcomes relative to the case of free RBV (*53*).

As a protein−drug conjugate, it is anticipated that Hb−RBV would be administered intravenously. As an injectable form of targeted RBV, Hb−RBV may serve as a more potent source of RBV that is particularly suited to acute stages of viral infection or the prevention of HCV recurrence following liver transplant, when free RBV cannot be used due to unacceptably high toxicity. RBV conjugated to Hb is in essence sequestered and prevented from entering red blood cells, thus minimizing the associated toxicities of systemic administration of the drug while targeting the drug to the cells of the liver where therapeutic benefit may be greatest. Thus, treatment of hepatitis C patients with Hb−RBV may reduce the dose-limiting toxicity of hemolytic anemia (*26*, *54*, *55*). Further work is being conducted to determine the clinical potential of this novel conjugate.

Development of Contrast Agents Targeted to Macrophage Scavenger Receptors for MRI of Vascular Inflammation

Björn Gustafsson,‡ Susan Youens,‡ and Angelique Y. Louie*

Department of Biomedical Engineering, University of California, Davis, California 95616. Received January 25, 2006; Revised Manuscript Received February 7, 2006

Atherosclerosis is a leading cause of death in the U.S. Because there is a potential to prevent coronary and arterial disease through early diagnosis, there is a need for methods to image arteries in the subclinical stage as well as clinical stage using various noninvasive techniques, including magnetic resonance imaging (MRI). We describe a development of a novel MRI contrast agent targeted to plaques that will allow imaging of lesion formation. The contrast agent is directed to macrophages, one of the earliest components of developing plaques. Macrophages are labeled through the macrophage scavenger receptor A, a macrophage specific cell surface protein, using an MRI contrast agent derived from scavenger receptor ligands. We have synthesized and characterized these contrast agents with a range of relaxivities. In vitro studies show that the targeted contrast agent accumulates in macrophages, and solution studies indicate that micromolar concentrations are sufficient to produce contrast in an MR image. Cell toxicity and initial biodistribution studies indicate low toxicity, no detectable retention in normal blood vessels, and rapid clearance from blood. The promising performance of this contrast agent targeted toward vascular inflammation opens doors to tracking of other inflammatory diseases such as tumor immunotherapy and transplant acceptance using MRI.

INTRODUCTION

Atherosclerosis-related diseases are a leading cause of death and impairment in the United States. According to the American Heart Association, cardiovascular disease affects over 70 million people and was the cause of 38.0% of all deaths in 2002. Over half of these deaths were due to coronary disease, which is primarily diagnosed by X-ray angiography. Researchers are investigating use of MRI angiography as a nonionizing alternative (*1, 2*). Nontargeted roentgen graphic visualization of the blood vessels after injection of a radioopaque substance, or MR angiogram with blood pool contrast agents, can reveal only the vessel lumen and silhouette of lesions that impinge upon the lumen (*3*). The appreciation that a considerable atherosclerosis burden, including plaques vulnerable to rupture or susceptible to erosion, can be accommodated in the vessel wall without impingement on the lumen has led to a new imperative for direct plaque imaging (*4*). In fact, 4−16% of patients suffer from "silent" lesions that do not restrict blood flow but are still vulnerable to rupture (*5*).

One of the earliest cellular components of plaques are macrophages (*6*). Macrophages are attracted to lesions where they take up and accumulate oxidized and other modified low-density lipoproteins (LDLs) from the bloodstream. Over time they become filled with lipid-laden droplets so as to appear foamy under microscope, and they are then termed "foam cells" (*2*). The formation of foam cells is a key event in atherogenesis, and the massive uptake of modified LDLs by macrophages is believed to be mediated by scavenger receptors (*7, 8*). The scavenger receptors are a diverse family of receptors; one of the best studied has been the class A receptor (*9*−*11*). Scavenger receptor class A (SR-A) is primarily expressed by mature macrophages, including Kupffer cells, and alveolar, splenic, and some other tissue macrophages. Class A scavenger receptors are present in high numbers on macrophages, and in vessel lumens they are unique to macrophages, i.e., they are not expressed by endothelial cells lining normal vessels (*12, 13*). SR-A is expressed on the endothelial lining of the liver, on adrenal sinusoids, and on the high endothelial cells of the postcapillary venules in the lymph nodes; but, immunohistochemical staining analysis could not detect SR-A expression in the aortic endothelium of cows, mice, and humans (*13*). SR-A is strongly localized in the cap and interiorly in lesions at all stages (*14, 15*). This makes the receptors an attractive target for a diagnostic or therapeutic agent.

SR-A has broad ligand specificity for a diverse array of polyanionic macromolecules, such as maleylated bovine serum albumin (mal-BSA), oxidized LDL, malondialdehyde modified LDL, and polyinosinic acid (*7, 16*−*20*). Recognition is not dependent upon specific amino acid sequence or carbohydrate structures. Because of their role in inflammation, SR-A receptors are not down regulated with ligand concentration, mediate very efficient and rapid internalization of bound ligand, and repeatedly recycle through the endosomal compartment (*21, 22*), illustrating desirable traits as targets for labeling. Potentially efficient delivery of the contrast agent to plaque sites is also suggested by the significantly increased vascular permeability in the sites of plaque inflammation and relatively small size of the maleylated BSA macromolecule (8 nM (*23*)). We describe here the synthesis and characterization of MRI contrast agents based on scavenger receptor ligands conjugated to multiple Gd-DOTA groups. The ligand maleylated BSA was selected due to its strong affinity and specificity for the SR-A receptor (*20, 24, 25*). The results presented here demonstrate targeting of macrophages in culture using the contrast agents, low toxicity on cells, and negligible labeling of normal arteries.

EXPERIMENTAL PROCEDURES

Synthesis of mal-BSA (Gd-DOTA)$_n$. Covalent linkage coupling of protein to *p*-isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (*p*-SCN-Bz-DOTA) fol-

lows closely as described in Mirzadeh et al. (*26*). A typical preparation proceeded as follows: a suspension of bovine serum albumin (10 mg/ml solution, Acros Organics, Belgium, distributed by Fisher Scientific) was dissolved in 16 mL of 0.1 mM of sodium bicarbonate (pH 8.5). To this albumin solution a 60 molar excess of *p*-SCN-Bz-DOTA·4HCl (20 mg/mL, Macrocyclics, TX) suspended in dimethyl sulfoxide (DMSO) was added in 100 μL to 200 μL aliquots with rapid stirring at room temperature. The pH was monitored continuously during the additions and adjusted by dropwise addition of 1 M sodium bicarbonate (pH 9.0). Once the reaction had reached completion, as shown by no further change in pH, the mixture was stirred an additional 36 h at room temperature, yielding 18 DOTA per BSA molecule. An aliquot was removed, exhaustively dialyzed in ddH_2O, and lypophilized for analysis by ionized matrix assisted laser desorption ionization mass spectrometry (MALDI-MS). The same 36 h incubation with decreasing DOTA:BSA ratios (45:1, 30:1, 15:1) yielded 15, 10, and 5 DOTA per BSA, respectively. In addition, increasing incubation time to 47 h for the 60:1 synthesis resulted in 22 DOTA per BSA. The remaining solution was dialyzed in 50 000 MW pore bags (SpectraPor 7) for 12 h, in 0.1 M of sodium bicarbonate (pH 8.5) at 4 °C and then maleylated following the method of Butler and Hartley (*27*). Maleyl groups were incorporated into the BSA molecule using the remaining free lysylamines. The reaction of maleic anhydride with amines is competitive with hydrolysis of the reagent in water; therefore, 600 molar excess of solid maleic anhydride was added in small quantities to the buffered well stirred BSA $(DOTA)_n$ protein solution. The pH was monitored continuously and adjusted by the addition of solid sodium carbonate. Reaction was complete when no further acid is liberated, and the maleylated protein was recovered by dialysis. An aliquot of product was removed for analysis by MALDI-MS. Typically this yielded maximal coverage of maleic blocking groups on the protein molecule in excess of the 37 groups needed for its activation as a recognized ligand.

The resulting solution was dialyzed in 50 000 MW pore bags and exchanged to 0.1 M of sodium citrate (pH 6.6) no more than 9 h at 4 °C, with minimum of four changes of buffer. The dialyzed maleylated albumin−DOTA solution was then treated with 1.2 molar excess (Gd:DOTA) of gadolinium chloride solution added dropwise while stirred. The pH was maintained between 6.6 and 7.0 using aliquots of 1 M sodium citrate. After the pH was stabilized, the sample was stirred for an additional 24 h at room temperature. The mal-BSA $(Gd\text{-}DOTA)_n$ complex was purified by an exhaustive dialysis (SpectraPor 7) at 4 °C with minimally six changes of ddH_2O water within a 36 h period at 4 °C. The purified solution of mal-BSA $(Gd\text{-}DOTA)_n$ was then lyophilized, stored, and desiccated, at 4 °C. Gadolinium content was determined using ICP-MS. We have found that similar results can be obtained by purification using standard desalting columns (Bio-Rad, Dallas TX) rather than dialysis, with less loss of product.

Synthesis of FITC-mal-BSA. BSA was maleylated by the method of Butler and Hartley (*27*), desalted to remove unreacted maleic anhydride, and then lyophilized. The product was resuspended in PBS, pH 7.4. The extent of acylation of the protein amino groups was determined using *o*-phthalaldehyde (OPA) fluorescent protein assay according to a method modified from Roth (*28, 29*). FITC labeling followed a modified protocol from Molecular Probes. Due to differential accessibility of lysines on the BSA molecule and the increased blocking of free amines by maleyl groups, fluorescent labeling required increasing stoichiometric ratios of FITC to mal-BSA with higher degree of maleylation. Therefore FITC:protein ratios of 2:1, 5:1, 10:1, 20:1, and 30:1 were employed for BSA maleylated at 0%, 8−20.5%, 29−69%, 82%, and 89%, respectively. Briefly, FITC (10 mg/mL in DMSO) was added to mal-BSA in small aliquots over the course of 1 h at room temperature while stirred. The pH was maintained at 8.5 using aliquots of fresh 1 M sodium bicarbonate solution. After completion of the reaction, as indicated by no further changes in pH, unreacted FITC was removed using a standard desalting column. Absorbance spectroscopy against a BSA standard was used to determine the protein concentration and fluorophore:protein ratio, using 68000 cm^{-1} M^{-1} as the molar extinction coefficient of the dye at pH 8.0 at 494 nm. Resulting fluorophore-to-protein ratios (f/p) were as follows: 1.14 for BSA, 1.85 for 8% maleylated, 1.09 for 20.5% maleylated, 1.15 for 29% maleylated, 1.24 for 43% maleylated, 1.04 for 54% maleylated, 1.57 for 69% maleylated, and 1.34 for 89% maleylated.

Mass Spectrometry. Mass Spectrometery (Finnigan LCQ Deca XP Plus Ion Trap Mass Spectrometer) was used to identify the proportion of chelates to maleyl groups conjugated to the protein molecule and to determine final molecular weight of the contrast agent. Samples were ionized by matrix-assisted laser desorption ionization (MALDI) and the resulting ions analyzed by a mass analyzer hybrid of quadrupole and time-of-flight (TOF). Serum albumin, which is characterized by a broad, low intensity peak susceptible to noise, reduces the method accuracy to an estimated ±500Da.

ICP-MS. To verify the incorporation of gadolinium to DOTA chelators and purification success, inductively coupled plasma mass spectrometry (ICP-MS) was utilized for analysis of gadolinium content. Quadrupole ICP-MS (Agilent Technologies 7500a) is capable of analyzing a large number of elements with detection sensitivity at the ppb-ppt level. Samples were prepared in 10 mL vials of 3% nitric acid. All samples were prepared in triplicate. Indium solution was spiked into all solutions (i.e. calibration standards and samples) as an internal standard in order to correct instrumental drift during analysis. Isotopes ^{157}Gd and ^{115}In were used for determination.

Magnetic Resonance Measurements. *Relaxivity at 0.6 T.* Relaxivity data was measured using a GE-NMR CSI-2 system with a Tecmag console and a 450 mm clear bore horizontal magnet operating at 0.6 T. Experiments were performed at room temperature (25 °C). A typical 180° pulse was 15 μs, and the reproducibility of the T_1 data was within 3%. Spin−lattice relaxation times were measured using an inversion recovery technique with least-squares fitting applied to the semilog representation of 10 to 12 inversion times ranging from 50 to 3000 ms in an exponential fashion. In all samples, the region of interest was evaluated for a 100 μL NMR tube volume containing contrast agent, typically ranged between 0.1 mM to 1 mM gadolinium, dissolved in distilled, deionized water, pH 7.0 (Gibco, Ultrapure).

Imaging and Relaxivity at 7 T. Relaxivity and MR cell studies were also performed using Bruker Avance Biospec system (Billericia, MA) equipped with a 95 mT/m max gradient set and 72 mm ID coil operating at 300 MHz, at ambient temperature (25 °C). MR measurements were carried out using freshly harvested lysed cells in suspensions of distilled water. Imaging was performed with a T_1-weighted saturation recovery sequence with differing repetition times and an echo delay time of 16 ms, and a flip angle of 90° was used for imaging. The T_2 effects are minimized through the use of a short TE. In all experiments, the FOV was 6 cm × 6 cm, matrix size was 256 × 256 and slice thickness was 1 mm. From the images a T_1 map was calculated using Paravision System software.

Cell Studies. Agents were prepared as described and employed in cell assays. All agents used for cell studies were 60% maleylated unless otherwise noted, and the number of gadolinium per molecule of agent is indicated by the subscript

'*n*' in $(Gd\text{-}DOTA)_n$. Although the gadolinium content for the probes used may differ from figure to figure, all controls were matched to the gadolinium content of the experiment group, so the data are self-consistent.

Dependence of Cellular Uptake on Degree of Maleylation. P388D1 cells (ATCC.com) were maintained in RPMI 1640 supplemented with L-glutamine and 10% fetal bovine serum (FBS). For the uptake experiments cells at 70−80% confluency in 35 mm dishes were incubated with 100 μg/mL FITC-mal-BSA in medium supplemented with lipoprotein-deprived serum (LPDS) for 1 h at 37 °C. LPDS was substituted for fetal bovine serum to remove competing modified lipoproteins (e.g. oxidized LDL) and maximize the cell's SR-A receptor expression during experimentation. All samples were prepared in triplicate unless otherwise noted. After incubation cells are washed three times with PBS and placed in warmed PBS for confocal imaging. Cells dishes were imaged using a BioRad upright confocal microscope.

Cellular Uptake. P388D1 cells on 48 well plates were incubated with increasing concentrations of mal-BSA $(Gd\text{-}DOTA)_n$ where $n = 10$ or 15 for 1 h. After incubation, the wells were washed twice and then cells were lysed by addition of ddH_2O and imaged by MRI at 7 T. Typical preparations consisted for 3×10^5 cells lysed in 150 μL of water. Gd content for each well was assessed by ICP-MS.

Specificity of Uptake. To verify that uptake was specific, cells were incubated with either mal-BSA or control of BSA labeled with Gd-DOTA. BSA is not recognized by the scavenger receptor. The mal-BSA and BSA agents used here were prepared as matched pairs, with synthesis proceeding through the addition of Gd-DOTA and then splitting the product to two samples, one of which was subjected to maleylation (for mal-BSA). Equal Gd-DOTA load was confirmed by mass spectroscopy and ICP-MS. Cells were incubated for 1 h at 37 °C and then washed twice and lysed for imaging as described above.

To verify that cellular uptake was receptor specific, competition experiments were conducted and characterized by MRI and ICP-MS. Cells in 48-well plates were incubated with 200 μM contrast agent ($n = 22$) in the presence of unlabeled mal-BSA or BSA as control in 0, 0.1, 1, 10, and 20-fold excess concentrations. BSA was used as nontargeted control in a separate set of wells.

Cytotoxicity Studies. *Cell Culture.* Mouse fibroblast 3T3 cells were cultured as a monolayer in high glucose DMEM (Cellgro) and supplemented with 10% calf bovine serum (v/v) and 5 mM L-glutamine. Exponentially growing cultures were maintained in a humidified atmosphere of 5% CO_2 at 37 °C.

MTT Assay. The MTT assay performed in this study was a modification of the procedure described by Carmichael (*30*). 3T3 cells at 10 000 cells/well were plated in a 96-well plate. The MTT assay was performed after a 24 h adhesion time. Cytotoxicity was then assessed for mal-BSA $(Gd\text{-}DOTA)_{15}$ and chlorpromazine, for comparison. The assays were carried out in parallel and in triplicate. Cells were counted and plated evenly in a 96-well plate. After a 24 h adhesion time, varying concentrations of mal-BSA $(Gd\text{-}DOTA)_{15}$ (0, 45, 90, 225, and 445 μM) or chlorpromazine (0, 10, 25, 50, and 100 μM) were placed on the cells. After a 4 and 24 h agent exposure time at 37 °C, the MTT assay was performed. After the appropriate incubation times, media was removed from the wells, replaced with 100 μL of fresh media containing 1.0 mM MTT (Invitrogen), and incubated for 3 h at 37 °C. To dissolve the insoluble MTT formazan crystals, 75 μL of media was removed and 50 μL of DMSO was added to the wells. The plate was incubated at 37 °C for an additional 10 min. Well solutions were mixed thoroughly just before absorbance measurement with a Tecan Safire^2 UV/Vis spectrophotometer. Triplicate assays were performed at all drug concentrations. Chlorpromazine was obtained from MP Biomedicals Inc. Mal-BSA $(Gd\text{-}DOTA)_{15}$ was synthesized in the lab as previously described.

Biodistribution Studies. To determine in vivo accumulation sites of the agent and to study the blood clearance dynamics, mal-BSA $(Gd\text{-}DOTA)_{15}$ was labeled with a positron emitter, i.e. ^{64}Cu ($T_{1/2} = 12.7$ h: β^+: 0.653 MeV, 17.4%; β^-: 0.578 MeV, 39%), and biodistribution studies on rats were performed by positron emission tomography (PET). Under isoflorane anaesthesia three male rats (Sprague−Dawley and Fisher), ~200−230 g, were injected via the tail vein with 889, 1045, and 816 μCi, respectively, of the ^{64}Cu-labeled compound in 0.3 mL of PBS buffer followed by a 0.5 mL saline flush. Blood samples were drawn at five approximate time points between 2 and 200 min postinjection, and activity was measured. At 1, 4, 24, and 48 h postinjection, the animals were scanned on a MicroPET II (developed at UCD) or a Siemens Preclinical Imaging Focus 120. An ^{18}FDG calibration scan was also performed in order to determine the absolute values of the radioactive dose in affected organs. At 2, 15, 33, 60, and 200 min postinjection, blood samples (mass between 0.013 and 0.089 g) were collected via tail nicking and activity counted by a Perkin-Elmer Wizard 1470 Automatic Gamma Counter with an energy window setting of 425−640 keV. The raw data are acquired and the unreconstructed images produced by the software MicroPET Manager 2.2.4.0 (MPM) (Concorde Microsystems Inc. (now Siemens Preclinical Solutions)). The emission images ($128 \times 128 \times 359$; pixel size 0.60 mm) were then iteratively MAP reconstructed (field of view 3.85 cm) using the MPM plus the MicroPET MAP Files 1.0.3.0. For analysis of the images, ASIPro 6.0.5.0 was used.

Synthesis of ^{64}Cu-Labeled mal-BSA $(Gd\text{-}DOTA)_{15}$. A typical procedure incorporated 1 mCi of activity to 0.1 mM of contrast agent: the mal-BSA $(Gd\text{-}DOTA)_{15}$ and required amount of $^{64}Cu^{2+}$-solution were dissolved in 0.25 M NH_4OAc (pH 7) separately. The solutions were added together and incubated at 40 °C for 30 min. The resulting solution was then purified according to Penefsky (*31*).

RESULTS AND DISCUSSION

There are theoretically 60 free amines on BSA through which Gd-DOTA could be conjugated; however, some fraction of these must be occupied by maleyl groups for recognition by the scavenger receptor. The number of maleyl groups incorporated, however, must be balanced with the number of Gd-DOTA that must be attached to achieve significant contrast enhancement. To evaluate the minimum number of maleyl groups to satisfy receptor recognition we synthesized a series of mal-BSA molecules with varying degrees of maleylation. Significant conformation changes with maleylation are believed to facilitate access to lysines that are buried in unmodified BSA (*32*). These molecules were also tagged with FITC and applied to macrophages in culture to assess uptake. As shown in Figure 1 optimal uptake is achieved with greater than 80% of the free amines modified by maleyl groups. Figure 1 present confocal images for cells incubated for 1 h with mal-BSA from 0 to 89% maleylation carrying ~1 FITC per molecule. Confocal images were obtained on a BioRad system using 488 nm excitation. Significant increases in fluorescence intensity are observed as the degree of maleylation is increased, indicating increased uptake. Although optimal at 80% maleylation, cellular internalization is still significant for 40−80% maleylated molecules. These results are consistent with previous studies performed

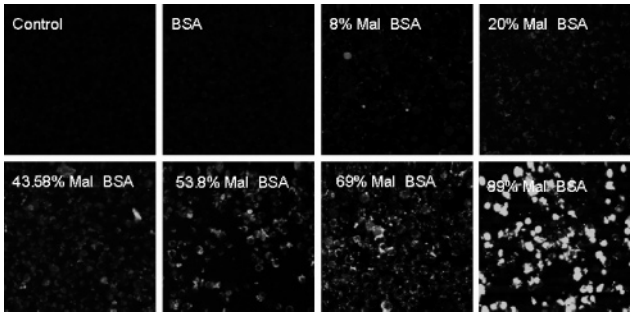

Figure 1. Macrophage uptake is dependent on degree of maleylation. Cells were incubated with FITC-labeled derivatives of mal-BSA bearing different numbers of maleyl groups. Signal intensity increases with increasing maleylation, with significant uptake at greater than 50% maleylation. Optimal uptake is observed for 80% maleylation and above.

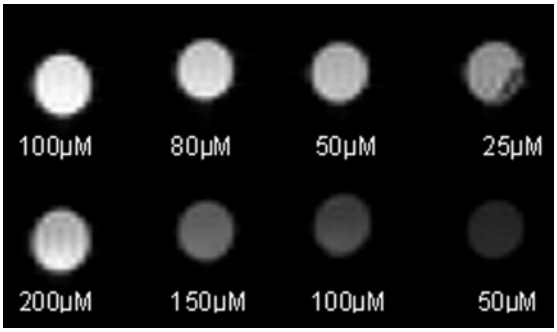

Figure 2. Contrast enhancement correlates with number of Gd-DOTAs bound. Solutions of mal-BSA $(Gd\text{-}DOTA)_n$ with $n = 10$ (bottom row) or 18 (top row) in distilled, deionized water, pH 7.0, were imaged at 7 T at ambient temperature (25 °C). Signal intensity increases as concentration increases (from right to left), and greater signal intensity is observed for the more heavily labeled agent. Contrast enhancement is observed for concentrations greater than 25−50 μM.

using radiolabeled ligands (*33*). In a study with rat endothelial sinusoidal liver cells, SR-A uptake activity correlated with different degrees of BSA modification labeled with ^{125}I (*33*). Scavenger receptor mediated endocytosis (uptake) of maleylated BSA indicated that 60% maleylation, or >37 lysyl amino residues, sharply increased ligand activity. Radioligand data supported that all lysyl amino groups are accessible for maleylation or DOTA conjugation. Based on the results of Figure 1, subsequent labeling with Gd-DOTA was performed on 60% maleylated BSA in order to maximize the number of free-amines for Gd-DOTA conjugation. At 60% maleylation, there should be up to 24 available free amines for conjugation of Gd-DOTA groups.

Additions of increasing numbers of DOTA groups to mal-BSA $(Gd\text{-}DOTA)_n$ increased the number of paramagnetic centers, improving the relaxivity of the contrast agent as shown in Table 1. Observed relaxivities for the mal-BSA contrast agents are summarized in Table 1. Incorporation of DOTA groups was verified by mass spectrometry, and Gd content was analyzed by ICP-MS. Close agreement between the DOTA:BSA ratio, determined by mass spectroscopy, and Gd:BSA ratio, determined by ICP-MS, suggests formation of the Gd:DOTA chelate with no nonspecific binding to the protein despite reported affinity sites for gadolinium on the BSA molecule (*34*). Relaxivity of mal-BSA (Gd-DOTA) increases with increasing Gd-DOTA per molecule and then plateaus at >15 Gd/molecule, attaining a maximum of 33 $mM^{-1}\ s^{-1}$. The relaxivity values are comparable to those for literature reported and commercial agents such as isothiocyanato-benzyl-diethylenetriamine-pentaacetic acid (ITCB-DTPA-Gd), albumin (30.3 $mM^{-1}\ s^{-1}$ at 29 MHz, 24 °C) (*35*), and MS-325, a Gd chelate that reversibly and noncovalently binds native albumin with relaxivity at maximum loading of albumin equal to 33 $mM^{-1}\ s^{-1}$ and relaxivity under in vivo conditions of 17.3 $mM^{-1}\ s^{-1}$ (*36*). Relaxivities for mal-BSA $(Gd\text{-}DOTA)_{>15}$ are significantly higher than those reported for a related albumin-$(Gd\text{-}DTPA)_{19}$ (14.9 $mM^{-1}\ s^{-1}$ at 10.7 MHz, 37 °C) (*37*) or for Magnevist, a small molecule gadolinium chelate (3.4 $mM^{-1}\ s^{-1}$ at 42 MHz, 37 °C). The reported values for the albumin compounds were obtained a slightly higher temperature and with different field strength instruments, so the values are not directly translatable. However, these results show that the relaxivities for the prepared agents are on the order or better than expected values. R_1 values are also improved over free Gd-DOTA preparations such as Magnevist. Conjugation of Gd-DOTA to larger molecules is known to increase relaxivity by reducing rotational correlation time (*38*). This has been observed for lipophilic Gd-DOTP and Gd-DOTA complexes that bind to albumin (*39*, *40*), as well as for other Gd-DOTA conjugates (*41*, *42*).

MR images of solutions of the contrast agent at 7 T demonstrated that these levels of labeling with Gd-DOTA were sufficient to affect contrast at physiologically reasonable concentrations. As shown in Figure 2 contrast was increased in a concentration dependent manner by the Gd-DOTA conjugates, with greater enhancement by more heavily labeled molecules. Figure 2 presents mal-BSA that has been conjugated to 18 or 10 Gd-DOTA, and greater contrast is seen with 18 attached Gd-DOTA for the top row of solutions, as expected. For the 18 Gd-DOTA molecule, significant contrast enhancement is seen for concentrations greater than 50 μM.

Uptake by cells was assessed on P388D1 macrophages in culture. Cells were incubated with 15 and 10 Gd-DOTA labeled mal-BSA for 1 h and then lysed for MR imaging. As shown in Figure 3 macrophages show increasing contrast in an MRI image with increasing concentration of the Gd-DOTA-labeled compounds. Incubation with greater than 50 μM of either labeled agent was sufficient to produce observable contrast in the MR image. Results from ICP-MS indicate that femtomoles of gadolinium could be found inside a cell after 1 h incubation.

That uptake by cells is specific was confirmed by incubating cells with mal-BSA carrying 22 Gd-DOTA, or with a Gd-DOTA matched BSA control. These control molecules were prepared from the same batch of Gd-DOTA-labeled BSA but were not maleylated for scavenger receptor recognition. Images at 7 T, Figure 4, from incubated cells show that there is no uptake of the BSA compound (bottom row) while the maleylated partner

Table 1. Relaxivities of Prepared Agents Compared to Other Reported Agents. Relaxivities Increase with Increasing Gd-DOTA Incorporation, Reaching an Apparent Plateau above 15 Gd/Molecule

contrast agent	r_1 per Gd ($mM^{-1}\ s^{-1}$)	temp and field strength	molecular weight BSA-DOTA only (Da)	final molecular weight (Da)	Gd ion per DOTA
Mal-BSA $(Gd\text{-}DOTA)_{22}$	29.1	RT, 26 MHz	79142	85898.7	19.8
Mal-BSA $(Gd\text{-}DOTA)_{18}$	33.4	RT, 26 MHz	76607.5	82317.2	11.9
Mal-BSA $(Gd\text{-}DOTA)_{15}$	31.2	RT, 26 MHz	74844.5	82455	14
Mal-BSA $(Gd\text{-}DOTA)_{10}$	20.0	RT, 26 MHz	71702.2	77490.6	6.7
Mal-BSA $(Gd\text{-}DOTA)_6$	12.2	RT, 26 MHz	69535.6	75954.1	4.4
Mal-BSA $(Na\text{-}DOTA)_6$	0.09	RT, 26 MHz	69535.6	−	0

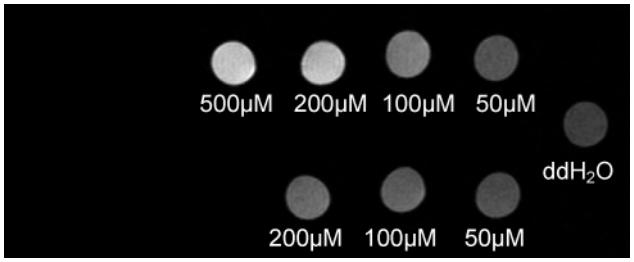

Figure 3. Mal-BSA (Gd-DOTA)$_n$ is taken up by macrophages. P388D1 cells were incubated with $n = 15$ (top row) or $n = 10$ (bottom row) mal-BSA (Gd-DOTA)$_n$ for 1 h then imaged at 7 T. Contrast increases in a concentration dependent manner (right to left) indicating uptake of the contrast agent by the cells. Contrast enhancement is observed for an application of as low as 50 μM contrast agent to the cells (top row, rightmost column). Actual T_1 values were, left-right: (top row) = 0.84 s, 0.96 s, 1.49 s. 2.33 s; (bottom row) = 1.79 s, 1.96 s, 2.51 s; (water) = 3.44 s.

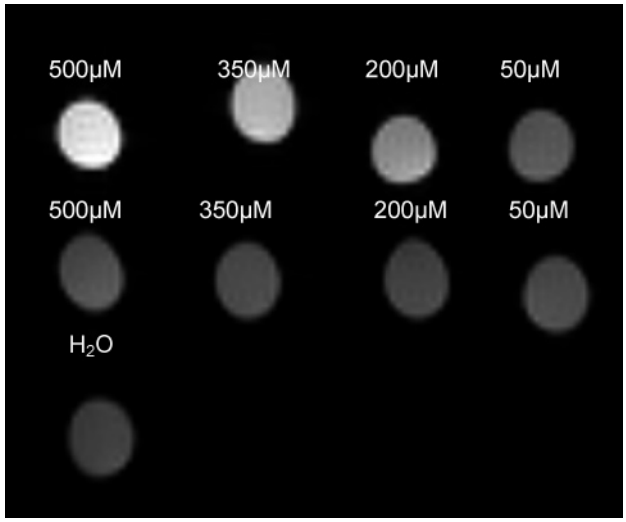

Figure 4. Uptake of mal-BSA (Gd-DOTA)$_n$ is specific. P388D1 cells were incubated with either mal-BSA (Gd-DOTA)$_n$ or a matched BSA control, $n = 22$ for both. Cells were imaged at 7 T. Macrophages demonstrate uptake of the maleylated agent (top row) but do not recognize the nonmaleylated control (middle row). Contrast enhancement after uptake of mal-BSA (Gd-DOTA)$_{22}$ is observable for as little as 25 μM of the agent applied to cells. Actual T_1 values were, left-right: (top row) = 0.58 s. 0.89 s, 1.46 s, 2.53 s; (bottom row) = 2.81 s, 2.90 s, 3.09 s, 2.85 s; (water) = 3.50 s.

is taken up in a concentration dependent manner (top row). Specificity of uptake was further confirmed by competition studies in which cells were incubated with a fixed concentration of mal-BSA (Gd-DOTA)$_{15}$ and increasing excess of unlabeled mal-BSA. If uptake were receptor-mediated, the excess unlabeled ligand should compete for uptake. Nonspecific uptake is strictly concentration-dependent and would not be affected by additional ligands in the solution. Receptor-mediated uptake is confirmed by the results seen in Figure 5: increasing amounts from 0 to 20-fold excess competitor reduce uptake as expected for a receptor-mediated process.

One of the primary concerns regarding the use of biomolecules labeled with gadolinium chelates as contrast agents is whether sufficient amounts of gadolinium can be accumulated in sites of interest to be visible on an MR image (*43*). The final amount of contrast agent required to produce sufficient contrast in an MRI scan depends on a host of factors including the precise pulse sequence and parameters used for acquisition (*2, 23*). Nevertheless, this issue has been studied by a number of investigators, and estimations can be made. One of the earliest theoretical models for the minimum amount of Gd(III) complex, of a given relaxivity, to produce detectable contrast enhancement

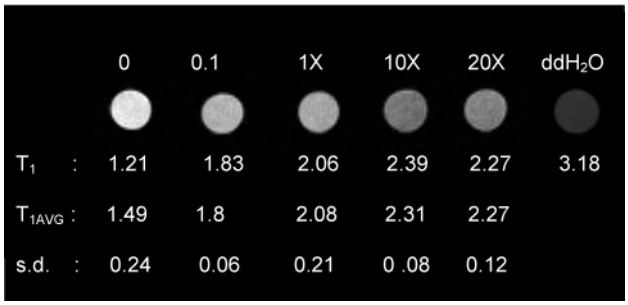

Figure 5. Uptake of mal-BSA (Gd-DOTA)$_n$ is receptor-mediated. P388D1 cells were incubated with a fixed concentration of mal-BSA (Gd-DOTA)$_{15}$ and increasing molar excesses of unlabeled mal-BSA. Representative samples are shown with molar excesses of competitor as indicated above each sample. Actual T_1 values for the image appear below each sample, as well as average and standard deviation T_1 for triplicate repeats. All values are given in seconds. Cells were imaged at 7 T. Increasing molar excess of unlabeled agent inhibits uptake of the labeled agent and reduced signal in the image. T_1 decreases dramatically with molar excess of competitor. Competition by unlabeled ligand confirms that uptake of the contrast agent is receptor-mediated.

was tested against microinjections of Gd(III) into Xenopus eggs (*44*). These trials established that measurable contrast was visualized when the concentration of agent in the egg is on the order of 10−100 μM (at 500 MHz). The Xenopus embryo system is unique, and while similar to some types of human tissue, the eggs are quite fatty and are different from many tissues of interest in mammals. More recent empirical results at 7 T have shown that for contrast agents with relaxivities in the range of 5−7 mM^{-1} s^{-1}, the minimum amount of Gd(III) to produce contrast is on the order of 2×10^9 molecules per cell; while for an agent with relaxivity on the order of 80 mM^{-1} s^{-1} (20 MHz) contrast is observed for concentrations on the order of 4×10^7 Gd(III) per cell (*45*). These observations were made using apoferritin as a carrier for the Gd(III), which is taken up by receptors found on the cell surface at a density of 4×10^4 per cell, $K_d = 1$ nM.

Relaxivities are also field-dependent. NMRD curves for Gd-DOTA show that relaxivity does not change much up to about 2 MHz and then begins to fall off rapidly, so the relaxivity at typical clinical field strengths (1.5−3 T) should actually be a bit higher than that observed on typical research instruments (4.7−11.7 T) (*40*). Thus, the amount of Gd-DOTA required would be less at lower field strengths. We estimated that the relaxivity for our multilabeled mal-BSA molecules would be similar to that observed for Gd-labeled albumin (26:1 Gd:albumin) = 192 mM^{-1} s^{-1} (per mM agent) at 4.7 T (*46*). At 1.5 T this value would be higher. With this estimate of relaxivity, based on the criteria just described, the amount of Gd(III) required to produce contrast at 1.5 T should be less than 4×10^7 molecules per cell.

The scavenger receptor is a high affinity (pM−nM, depending upon ligand) receptor present in high numbers on macrophages, on the order of 5×10^5 receptors per cell P388D1 (*18, 25, 47, 48*). Thus, ~20−80 Gd(III) must be taken up per receptor during the course of incubation (depending on cell type used) to reach the concentrations required per cell. Scavenger receptors uptake and process modified lipoproteins through a classic coated pit pathway, similar to the LDL pathway, wherein the receptor takes up ligand, brings ligand into the cell, dissociates from the ligand, and recycles back to the surface in a highly efficient manner. The scavenger receptor has an estimated $t_{1/2}$ for internalization of the ligand−receptor complex of 2.8−4 min (*22*). Recycling of receptors in the scavenger receptor pathway has not been fully characterized, but in the LDL pathway, receptors recycle on the order of 10 min (*49−51*). If this is similar for the scavenger receptor pathway then 500 000

receptors can uptake $\sim 3 \times 10^6$ ligands per hour. Based on the values given above, this would be sufficient for contrast with 13:1 Gd:ligand complex and 1 h incubation. As our results show, modification with 10 and greater Gd-DOTA per mal-BSA was sufficient to produce contrast with micromolar applications to cells. Moreover, the cell densities used for these studies is on the order of that found for macrophages in isolated human plaques, indicating that these imaging results will be applicable to the in vivo case (*52*−*56*).

There are number of examples in the literature of efficient cellular uptake of Gd(III) complexes using Gd-DOTA-derived molecules (*57*−*60*). More recent efforts have sought to maximize the load of Gd delivered per receptor by tethering carrier molecules to dendridic polymers containing high numbers of Gd(III) (*61*). Uptake through the folate receptor has been demonstrated by this means as has avidin−biotin antibody-based targeting (*59, 62, 63*). Again, definitive measurement of the amount of Gd required to produce contrast depends on the imaging parameters employed, and these must also be evaluated when testing the new contrast agents. But on the basis of the approximate calculations shown here, and these similar studies in the literature, we predicted that MRI contrast could be achieved for the scavenger receptor system using feasible ratios of Gd:ligand, and this was confirmed by the results reported here.

Recent literature has investigated MRI contrast agents targeted to other molecular markers in plaque, but these tend to be geared for imaging of more advanced stages of disease. For example, 5-HT-DOTA(Gd) targets myeloperoxidase (MPO), a heme-containing enzyme secreted by a number of neutrophils, for selective imaging of MPO activity in a model system (*64*). Myeloperoxidase secretion has been correlated with plaque instability. The described agent is a serotonin derivative of Gd-DOTA that polymerizes after oxidation by myeloperoxidase-catalyzed reduction of hydrogen peroxide. Polymerization resulted in increased relaxivity attributed to decrease in rotational correlation time and demonstrated contrast enhancement in the presence of at least 650 U of enzyme. This agent is geared toward more advanced plaques that would have significant secretion of MPO and may be vulnerable to rupture. Other examples in the literature describe the use of Gd-DTPA-labeled fibrin binding peptides to label thrombi in animal models (*65, 66*). Each agent carries four gadolinium chelates and binds to mural thrombi, rather than atherosclerotic plaque. Thrombosis occurs after plaque rupture, and these agents are designed to aid in guiding thrombolytic therapy.

Fewer reports describe MRI agents able to detect earlier stages of disease. One example is low-density lipoprotein (LDL) complexed with manganese-mesoporphyrin (MnMeso) (*67*). These agents are also targeted to macrophages in that the modified LDL was demonstrated to be taken up by foam cell cultures. However, the MnMeso is not covalently bound to the lipoprotein and therefore may transfer off LDL to other plasma proteins and lipoproteins. In addition, there is concern about possible cardiotoxicity and accumulation of Mn^{2+} agents in the brain after intravenous injection (*68, 69*). Dextran-coated iron oxide nanoparticles have also been observed to be taken up by macrophages in plaques, due to the phagocytic nature of the cells to engulf particles (*70*). However these rely on nonspecific uptake of the nanoparticles, which is an inefficient process, outside of the liver, and the agent must be delivered in severalfold excess of standard clinical doses in order to accumulate enough contrast agent in the plaque after clearance through by renal system.

A possible limitation to administering mal-BSA $(Gd\text{-}DOTA)_n$ in a clinical setting is possible humoral immune response to this macrocyclic chelated agent (*71, 72*). By targeting macrophages, we are in effect aiming for increased recognition by these immune cells. However, our aim is for internalization of mal-BSA and removal from blood without negative systemic effects. Studies on methods to increase immunogenicity of antigens for vaccine development have examined maleylation (*21*). In those studies, immunogenicity, i.e. uptake by macrophages, of maleylated antigens was increased compared to unmodified antigens upon repeated injections in mice without adjuvants present (*21*). Upon repeated exposure, animals exposed to mal-BSA shows higher serum anti-immunogen antibody concentration than those exposed to BSA. In addition, maleylation disrupts native B cell epitopes on the antigens, for example, maleylated diphtheria toxoid (DT) is not recognized by antibodies to native DT. New epitopes seem to be created that can cross-react between various maleylated proteins regardless of amino acid sequence. It is likely then that the epitopes are purely maleylation dependent. While mice produced antibodies against the antigen, no systemic toxicity was reported. Possible toxic or other negative immune responses of mal-BSA require further study. The scavenger receptor recognizes a number of different ligands (*9*−*11, 13*), and these can also be investigated as carriers should mal-BSA prove undesirable in vivo.

From the MTT cell toxicity studies, dose−response curves suggest that mal-BSA $(Gd\text{-}DOTA)_{15}$ has a low toxicity when compared to chlorpromazine, as shown in Figures 6A and 6B. Chlorpromazine is a phenothiazine drug, primarily used as a psychotropic agent since the 1950s, with a low toxicity (*73*−*75*). Its toxicity has been well documented, and therefore it has been employed as a standard in toxicity assays (*74*−*76*). The EC_{50} can be interpolated from these plots and used to directly compare the toxicity of mal-BSA $(Gd\text{-}DOTA)_{15}$ to chlorpromazine. From Figure 6A, EC_{50} is not reached at even the highest concentration tested for 4-h incubations with mal-BSA $(Gd\text{-}DOTA)_{15}$. For 24 h incubations, EC_{50} was found to be 40 μM. Both values are less toxic than those found for chlorpromazine, Figure 6B, which showed $EC_{50} = 84$ μM for 4 h, and $EC_{50} = 24$ μM for 24 h incubations, respectively.

Biodistribution studies show a very fast clearance from the bloodstream. More than 97% of the injected dose of radiolabeled contrast agent is cleared out within 2 min as seen in Figure 7. From the PET studies of biodistribution it was found that the main sites for accumulation are the liver, kidneys, and the urinary bladder. The highest accumulation is in the liver (Figure 8). After 1 h about 50% of the injected dose remains in the liver. During the next 3 h the activity drops to 30% of the injected dose. This is equivalent to 30 μM agent in the liver after 1 h and 18 μM after 4 h. The activity then remains stable at 18 μM (Figure 9). Comparing these accumulated concentrations to the concentrations from the cell toxicity studies, $EC_{50} = 40$ μM for 24 h incubation, suggests that in these experiments in vivo accumulation is at less than toxic levels. Accumulation observed in the other organs is even less and thus also below toxic EC_{50}. For the kidneys, about 1% of the injected dose is found in each kidney, and the levels are stable for the duration of the whole experiment. In the urinary bladder 2.5% of the injected dose remains after 1 h; this clears to approximately 0.2−0.5% of injected dose during the first 24 h and falls to undetectable levels after 48 h. By comparison, the blood pool agent albumin$(Gd\text{-}DTPA)_{30}$ is largely retained in the intravascular space with a half-life of 88 min after intravenous injection and can remain in the bloodstream and extravascular compartment two weeks after injection (*77, 78*). These undesirably long retention times have precluded its use in the clinic.

In conclusion, we describe the preparation, characterization, and successful in vitro targeting of a paramagnetic contrast agent, mal-BSA $(Gd\text{-}DOTA)_n$, for use in MRI. This novel contrast agent builds upon previously reported studies on anionic

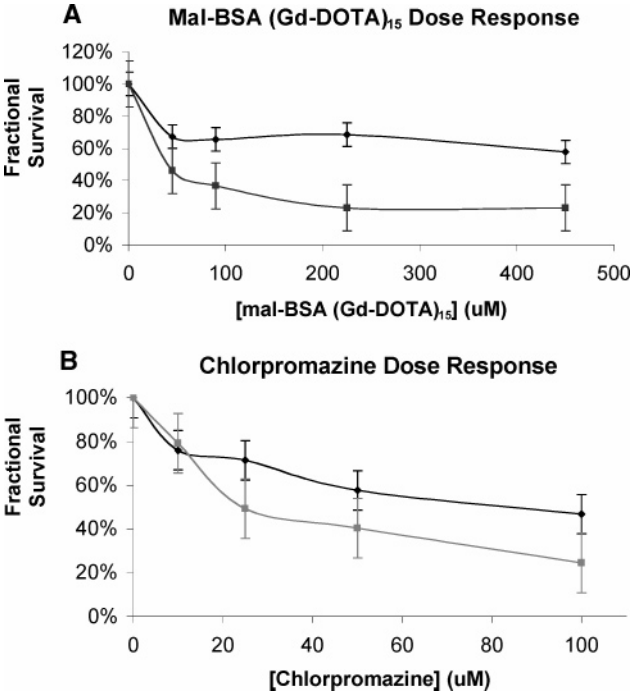

Figure 6. Toxicity of mal-BSA. Cytotoxicity was assessed for mal-BSA $(Gd\text{-}DOTA)_{15}$ and chlorpromazine as a positive control. The assays were carried out in parallel and in triplicate. Cells were counted and plated evenly in a 96-well plate. After a 24-h adhesion time, varying concentrations of mal-BSA $(Gd\text{-}DOTA)_{15}$ (0, 45, 90, 225, and 445 μM) or chlorpromazine (0, 10, 25, 50, and 100 μM) were placed on the cells. After a 4 and 24 h agent exposure time at 37 °C the MTT assay was performed. Dose−response curves at 4 (black) and 24 (gray) hours are shown for mal-BSA $(Gd\text{-}DOTA)_{15}$ (Figure 6A) and chlorpromazine (Figure 6B). For 4 h mal-BSA incubation, toxic dose EC_{50} is not reached for the concentrations of agent tested ($EC_{50} > 450$ μM). For the 24 h mal-BSA, $EC_{50} = 40$ μM. This is in contrast with chlorpromazine with $EC_{50} = 84$ μM for 4 h incubation and $EC_{50} = 24$ μM for 24 h incubation. Toxicity of mal-BSA (Gd-DOTA) is less that that of the chlorpromazine standard. Error bars reflect standard error.

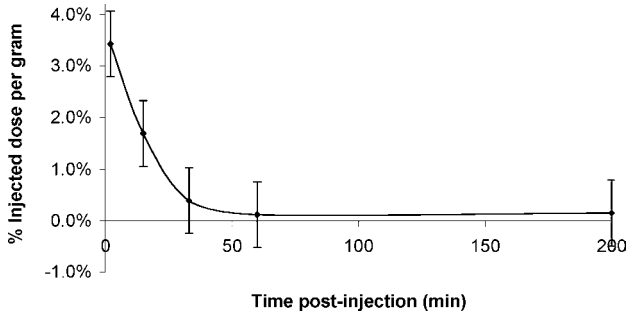

Figure 7. Blood clearance. Blood samples were collected by tail nicking at 2, 15, 33, 60, and 200 min postinjection of contrast agent and quantitated by gamma counting. Clearance from the blood is rapid with ~97% of the injected agent cleared out from the bloodstream after 2 min; 0.5% of injected dose remaining after 30 min and undetectable levels in the blood after 1 h. Error bars reflect standard error.

modifications of BSA and knowledge of the SR-A receptor. Mal-BSA $(Gd\text{-}DOTA)_n$ has physical properties that permit localization to the target and demonstrated high specific uptake of agent by macrophages; also low toxicity and fast clearance dynamics are shown. The synthesis process outlined here allows controllable degrees of maleylation and paramagnetic labeling of known lysines on the BSA molecule. Mal-BSA $(Gd\text{-}DOTA)_n$ demonstrated relaxation effects comparable to or better than similar commercial and experimental plaque-targeted or albumin-based agents. An optimal payload of 22 Gd-DOTA with mal-BSA $(Gd\text{-}DOTA)_{22}$ showed contrast effects comparable to

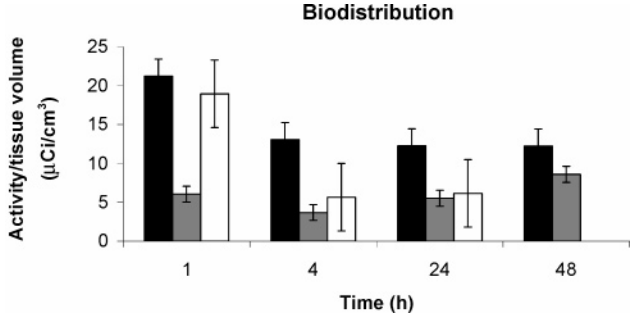

Figure 8. Biodistribution in the rat model. Primary sites of accumulation of the agent in normal tissues are in liver (black), kidneys (gray), and urinary bladder (white). Clearance from kidneys is rapid in first hour. Signal from bladder falls to negligible levels by 48 h. Error bars reflect standard error.

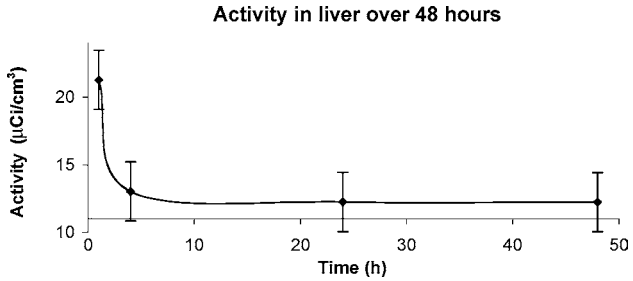

Figure 9. Liver pharmacokinetics. The clearance of the agent from the liver is initially rapid. The activity per tissue volume of the agent decreased over 60% the first 4 h after injection. Calculated corresponding concentration of the agent falls to 18 μM after 4 h, well below the EC_{50} found for macrophages in culture ($EC_{50} > 450$ μM for 4 h, $EC_{50} = 40$ μM for 24 h). Error bars reflect standard error.

albumin $(Gd\text{-}DTPA)_{30}$, which is used as a standard to evaluate performances of novel intravascular agents (*79*−*82*).

Though further studies are required to evaluate immunogenicity of the agent, the high specificity of mal-BSA $(Gd\text{-}DOTA)_n$ shows promise for reducing dosage of administration and toxicity compared to high dose nonspecific contrast agents currently employed in the clinic. Future work includes isolating the regional domains of maleylated BSA that afford targeting in order to circumvent immune responses that may be provoked by full length protein. Through the modification with other diagnostic agents, such as the ^{64}Cu positron emitter or fluorophores, this carrier system shows potential to act as a multimodality imaging agent for diagnosis and study of atherosclerotic and restenotic lesions.

ACKNOWLEDGMENT

The authors thank National Institutes of Health (EB000993-01A1) and the Whitaker Foundation (RG-02-0740) for their support of this work; Dr. Jeff Walton for assistance with MRI, Dr. Ryoji Shiraki for assistance with ICP-MS, David Kukis for assistance with radioactive labeling, Chris Griesemer for assistance with animal studies, Lily Wong for her assistance with chemical coupling and tissue culture, and Christina Takanishi and Edgar Sanchez for assistance with cell toxicity studies.

TECHNICAL NOTES

Preparation of LL-37-Grafted Titanium Surfaces with Bactericidal Activity

Matthias Gabriel,*,† Kamran Nazmi,‡ Enno C. Veerman,‡ Arie V. Nieuw Amerongen,‡ and Andrej Zentner†

Received March 23, 2005; Revised Manuscript Received December 12, 2005

Modification of material surfaces aimed at bestowing them with antimicrobial properties is a promising approach in the development of new biomaterials. Antimicrobial peptides (AMPs) are an attractive alternative to conventional antibiotics because of lack of toxicity, inherently high selectivity, and absence of immune response. As the antimicrobial mode of action of the AMP cathelin LL37 is formation of pores and disruption of microbial membrane, the purpose of the present study was to develop and test a method of covalent immobilization of LL37 on titanium surface. The application of a flexible hydrophilic poly(ethylene glycol) spacer and selective N-terminal conjugation of LL37 resulted in a surface peptide layer which was capable of killing bacteria on contact.

INTRODUCTION

Bacterial contamination may cause serious complications of implant surgery. Implant removal is usually the only treatment option because the biofilm mode of bacterial growth on the implant surface protects the microorganisms from the immune response and antibiotic treatment. There is a substantial interest in developing biomaterials with inherent properties, which would not only prevent bacterial adherence and colonization but would also be capable of killing microorganisms. Previous studies (*1*, *2*) have described bactericidal activity of quaternary ammonia salts covalently bound to biomaterial surfaces. Another approach to prevent microbial contamination would be the application of antimicrobial peptides (AMPs) (*3*, *4*). These peptides play an important role in the innate and adaptive immune system of various organisms and have a broad-spectrum activity against bacteria and fungi, while exhibiting low cytotoxicity. AMPs share a number of common molecular features: they are maximally 40−50 amino acid residues long, are rich in cationic amino acid residues, and form an amphiphilic α-helix in which clusters of hydrophobic and cationic amino acids are spatially separated. These characteristics promote their binding and insertion into the negatively charged phospholipid bilayers of bacteria and fungi, and disruption and impairment of vital membrane functions. Although the exact mechanisms by which AMPs kill bacteria are not precisely understood, it has been shown that peptide−lipid interactions leading to membrane permeation, possibly via transient formation of membrane-associated pores, might play an important role. An attractive advantage of AMPs over conventional antibiotics is the fact that they do not evoke immune response. In this study we have explored the potential use of the AMP cathelin LL37, a cryptic peptide obtained by enzymic cleavage of its precursor cathelicidin which is stored in granulocytes (*5*). The aim of this study was to render LL37 indiffusible by means of covalent immobilization while retaining its antimicrobial activity. Titanium (Ti) was chosen as implant material because methods of binding of biologically active molecules to a titanium surface by means of silanization are readily available (*6*, *7*). The limited information on the precise mechanisms of bactericidal action of LL37 made several assumptions necessary. First, to permit effective bactericidal activity, immobilized LL37 needs to be conjugated to a rather long and flexible spacer molecule enabling lateral diffusion of the peptide molecules in the lipid double layer of the microbial membrane. Second, the α-helices need a parallel arrangement in order to ensure interactions within the peptide molecules and enable formation of membrane pores. Functionalized poly(ethylene glycol) (PEGs) molecules are appropriate for this purpose and have the beneficial side-effect of rendering coated surfaces nonadhesive (*8*). A method of exclusive N-terminal coupling was developed for the purpose of the parallel alignment of immobilized peptide molecules.

EXPERIMENTAL SECTION

Materials. Ti was purchased from Alfa Aesar (Karlsruhe, Germany). Heterobifunctional PEGs were obtained from Nektar Therapeutics (San Carlos, CA). Sulfosuccinimidyl 4-(4,4′-dimethoxytrityl)butyrate (sulfo-SDTB) and *N*-maleimidopropionic acid succinimide ester (NHS-Prop-Mal) were bought from Pierce (Etten-Leur, The Netherlands). Propidium iodide and general chemicals were from Sigma (Zwijndrecht, The Netherlands). Organic solvents were dried over 3 Å molecular sieves if necessary.

Peptide Synthesis. Fmoc-protected amino acids were purchased from NovaBiochem (Läufelingen, Switzerland). Peptides were synthesized using Fmoc chemistry on a MilliGen 9050 peptide synthesizer (MilliGen/Biosearch, Bedford, MA) and purified by reversed phase HPLC JASCO HPLC System (Jasco, Tokyo, Japan) as previously reported (*9*). The peptide LL37 with the amino acid sequence LLGDFFR KSKEKIGKEF KRIVQRIKDF LRNLVPRTES was used in the native form or with an additional N-terminal cysteine residue (Cys-LL37).

Silanization. Ti platelets of 10 × 10 mm^2 size were cut from 2 mm thick foil. One side of each platelet was ground with

600- and 1200-grid sandpaper and cleaned by etching in a solution of 9% $NH_4F{\cdot}HF$ (w/v), 8.5% H_2SO_4 (v/v), and 0.5% urotropin (w/v) in deionized water for 2 min at room temperature. Passivation was accomplished by treatment with a 1:1 mixture of 30% H_2O_2 and concentrated H_2SO_4 (Piranha solution) for 1 h (*6*). Ti specimens were silanized with a solution of 2% 3-aminopropyl triethoxysilane (amino silane) and glycidyloxypropyl triethoxysilane (epoxy silane), respectively, in dry toluene for 18 h at room temperature. After being washed with toluene and methanol, the silanized samples were cured at 80 °C for 1 h.

Direct and Spacer-Mediated Random Binding. Figure 1 shows schematically various coupling reactions. Epoxy-silanized platelets were incubated for 3 h with 0.5 mg/mL LL37 in 10 mM carbonate buffer, pH 8.5, for 2 h at room temperature. Subsequently they were washed with buffer containing 0.1% Tween-20 followed by washing with water and drying. To produce spacer-mediated coupling, the specimens were first covalently coated (PEGylated) using α-amino-ω-carboxy-PEG hydrochloride (H_2N-PEG-COOH) (MW 5400, 0.2 mg/mL) in dry dimethylformamide (DMF) for 2 h, rinsed thoroughly with DMF, and dried. A mixture of 0.1 M dicyclohexyl carbodiimide (DCC) and 0.1 M NHS-Prop-Mal in dry DMF was prepared, and the PEGylated samples were incubated for another 2 h. After washing with DMF, Ti samples were treated with peptide solution in the same manner as described for directly immobilized peptide, followed by washing as above.

Table 1. Surface Density of Immobilized Peptide As Estimated by the Sulfo-SDTB Method

peptide	surface density, mol/cm^2
Ti-LL37	1.11×10^{-10}
Ti-CysLL37	7.86×10^{-11}
Ti-PEG-LL37	1.42×10^{-10}
Ti-PEG-CysLL37	1.47×10^{-10}

Direct and Spacer-Mediated Site-directed Binding. Selective N-terminal coupling of Cys-LL37 was performed using a two-step procedure. First, direct binding of the peptide was achieved by treating amino-silanized Ti with NHS-Prop-Mal, 0.1 M in DMSO, for 4 h at room temperature. Second, after being washed with DMSO, the samples were reacted with Cys-LL37 (0.5 mg/mL in PBS pH 7.3) for 3 h. They were then rinsed with buffer and water and dried. Amino-silanized Ti was treated with a solution of α-*N*-hydroxysuccinimidyl-ω-maleimidyl-PEG (NHS-PEG-Mal) in dry DMF (0.2 mg/mL) similarly to the protocol described above. Incubation with Cys-LL37 (0.5 mg/mL in PBS, pH 7.3) was performed for 2 h, followed by washing steps. This procedure results in a Michael-type coupling of the peptide to the PEG spacer exclusively at the N-terminus of the peptide (*15*).

Estimation of Surface Density of Amino Groups. LL37 contains six lysine residues at positions 8, 10, 12, 15, 18 and 25 (*4*). Together with the N-terminus the peptide provides seven primary amino groups available for modification. Assuming that only one of these moieties is involved in the conjugation, seven amino groups are left for binding with a colorimetric reagent. The density of immobilized peptide was estimated using the sulfo-SDTB test according to manufacturer's instructions. One milliliter of a solution containing 3 mg sulfo-SDTB, first dissolved in 0.5 mL of DMSO, then in 50 mL of carbonate buffer (10 mM, pH 8.5) was pipetted into wells of 24-well microtiter plates containing Ti specimens and incubated for 1 h. Subsequently the specimens were washed thrice with buffer. An addition of 400 μL of 35% hypochloric acid to each well resulted in color formation measured photometrically at $\lambda =$ 498 nm. Concentration of released dye and, therefore, of surface amino groups was calculated with $\epsilon = 70\,000$ cm^2/mol for the chromophore (*12*).

Bacterial Killing Assay. *E. coli* (strain K12) was grown overnight in brain−heart infusion (BHI; Becton, Dickinson Microbiology Systems, Sparks, MD). Bacteria were harvested by centrifugation and grown in BHI to a density of $OD_{570} =$ 0.8. After a second centrifugation step, bacteria were resuspended in 10 mM phosphate buffer (pH 7.5), and 100 μL of bacterial suspension, containing 6 μM of propidium iodide (PI), was added to each well with pretreated or uncoated titanium platelets. Enhancement of PI fluorescence caused by intercalation of PI into the DNA of dead cells (*11*) was monitored after 30 min as a measure of bacterial death. Excitation at $\lambda = 520$ nm and emission at $\lambda = 620$ nm was measured using a microtiter plate reader (Fluostar Galaxy BMG Laboratories, Offenburg, Germany).

RESULTS

The determination of surface concentration of immobilized peptide yielded by the sulfo-SDTB method is shown in Table 1. The values were calculated from the optical densities on the basis of the assumption that each peptide molecule was conjugated by only one primary amino group. Within the limits

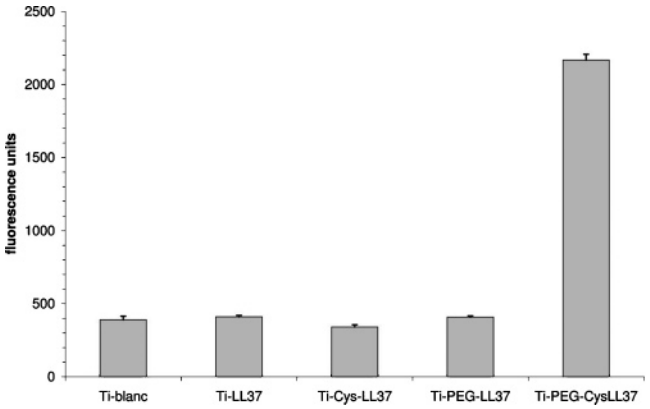

Figure 2. Fluorescence detection of bactericidal activity.

of this method, different coupling efficiencies were observed. PI permeabilization assay was used to estimate the extent of *E. coli* death at the various titanium surfaces. Ti samples with exclusively N-terminally spacer-conjugated Cys-LL37 (Ti-PEG-CysLL37) expressed antimicrobial activity against *E. coli*, as shown by the enhanced PI fluorescence (Figure 2). In contrast, compared to untreated Ti, no killing was observed when bacteria were exposed to Ti with randomly immobilized peptide, both with and without the use of a spacer (Ti-PEG-LL37, Ti-LL37). In addition, directly N-terminally bound LL37 (Ti-CysLL37) showed no killing activity under the conditions of the present study.

DISCUSSION

Immobilization of AMPs as accomplished in the present study is a novel approach toward endowing material surfaces with bactericidal properties. In the present study silanization was used as a versatile method of covalent binding of biologically active molecules to Ti. Various multistep procedures of binding the peptide to Ti were tested in order to meet the aim of developing a method which would optimally preserve the antibacterial activity of the AMP LL37. The amine-reactive NHS-group and the thiol-reactive maleimide-moiety were chosen for site-specific conjugation (*15*).

The amounts of surface-bound AMP-molecules were estimated by means of the sulfo-SDTB test (*12*), which in the case of LL37 was facilitated by the relative abundance of amino groups on the basic peptide. The measurements obtained were within 1 order of magnitude, suggesting that the mere presence of properly immobilized peptide molecules was responsible for the observed bactericidal activity, and that the latter was independent of the relative peptide concentration on Ti surfaces. As for a successful operation, this assay deals with very low absolute amounts of functional groups on the target molecules. These measurements represent only a rough estimate restricting a direct comparison between the various coupling strategies.

Assuming that the potential bactericidal mechanism of the helical AMP LL37 is its interaction with the bacterial membrane, lateral mobility of peptide molecules is required. This assumption was confirmed indirectly by the absence of bactericidal activity of directly immobilized LL37 (Figure 2) and the finding that only the peptide properly bound to the PEGylated Ti surface was capable of killing *E. coli* on contact. Such an orientation necessary for the above lateral mobility was achieved by the use of long flexible spacer molecule PEG.

At least two features seem to be essential for effective bactericidal activity. First, the assumed necessity of a long spacer with a flexible molecular chain granting lateral mobility of surface-bound AMP and facilitating interactions with bacterial membrane seems to be confirmed by the observations made in the present work. Second, only N-terminal conjugation permits appropriate parallel orientation of the peptide helices, which is required for interaction among the peptide molecules and between the peptides and the lipid double layer during membrane pore formation. Presumably, C-terminal immobilization of the peptide might have similar effects. A positive side-effect of PEGylation is the intrinsic antiadhesiveness of the treated surface (*14, 15*), which is also applicable to other hydrophilic spacer molecules (*13*). Further work is warranted to test these assumptions and to expand and if necessary, modify the biomedical application of the present method of antibacterial surface modification to a wider range of pathogenic microorganisms.

Truman Memorial Veterans' Hospital, Columbia, Missouri 65201. Received July 22, 2005; Revised Manuscript Received December 12, 2005

An efficient and highly versatile method for the synthesis of amino acid-modified peptide nucleic acid (PNA) monomers is described. By using solid-phase Fmoc techniques, such monomers can be assembled readily in a stepwise manner and obtained in high yield with minimal purification. Protected neutral hydrophilic, acidic, and basic amino acids were coupled to 2-chlorotrityl chloride resin. Following Fmoc removal, innovative conditions for the key step, reductive alkylation with *N*-Fmoc-aminoacetaldehyde, were developed to circumvent problems encountered with previously reported methods. Activation and coupling of pyrimidine and purine nucleobases to the resulting secondary amines afforded amino acid-modified PNA monomers. The mild reaction conditions utilized were compatible with sensitive and labile functional groups, such as *tert*-butyl ethers and *tert*-butyl esters. PNA monomers were obtained in 36−42% overall yield and very high purity, after cleavage and purification. Using standard solid-phase Fmoc chemistry, two of these monomers were incorporated with high coupling efficiency into a variety of modified PNA oligomers, including four tetradecamers designed to target *bcl-2* mRNA. Such modified oligomers have the potential to enhance water solubility and cell portability, while maintaining hybridization affinity and promoting favorable biodistribution properties.

INTRODUCTION

Peptide nucleic acids (PNAs)[1] are DNA-like molecules having unique binding properties to either single-stranded DNA and RNA or double-stranded DNA (*1*, *2*). In recent years, much attention has been focused on synthetic (*3*−*5*), biomedical (*6*−*9*), and bioconjugate (*10*−*12*) applications of PNAs. The major advantage of using PNAs for DNA and RNA hybridization and targeting is due to the presence of an uncharged, achiral, acyclic amide backbone composed of (2-aminoethyl)glycine units. This structural feature can give rise to considerable conformational flexibility, as well as stability toward degradation by nucleases and proteases (*2*). These properties, coupled with high sequence specificity (*13*, *14*), make PNAs important molecules for various biological applications such as gene silencing (*7*, *15*, *16*). However, the poor water solubility and extremely low cellular uptake of PNAs necessitated incorporation of modifications that can enhance cell portability (*17*−*19*).

We recently synthesized and evaluated several fluorescent and radiometal-labeled cell-permeating peptide−PNA conjugates for targeting the B-cell lymphoma/leukemia-2 (*bcl-2*) gene at the mRNA expression level (*20*, *21*). While the use of a cell-permeating peptide resulted in efficient internalization of *bcl-2* antisense PNA in tumor cells in vitro, such a peptide delivery vehicle is likely to have little or no in vivo specificity. We subsequently prepared an ^{111}In-labeled anti-*bcl-2* PNA conjugated to a peptide receptor ligand designed for in vivo tumor targeting (*22*). When labeled with ^{111}In, this PNA−peptide conjugate is zwitterionic but has sufficient water solubility for in vitro and in vivo applications. However, evaluation of a corresponding PNA conjugate complementary to the large splice variant of the B-cell lymphoma/leukemia-X gene (*bcl-X$_L$*) was limited by its extremely poor water solubility (*23*).

At present, it is not possible to predict the water solubility of a PNA−peptide conjugate a priori. Nielsen, Buchardt, and co-workers showed that replacing some of the glycine residues of PNA with hydrophilic or charged amino acids (*24*) improved water solubility. The incorporation of positively charged amino acids, such as D-lysine, afforded modified PNAs with superior

hybridization affinity for single-stranded DNA (*24*). However, a recent in vivo study indicated that radiometal-labeled PNAs accumulate in the kidneys of tumor-bearing mice (*25*). Conjugation of these PNAs to a tumor-targeting peptide improved renal clearance (*26*), but kidney uptake persisted out to 24 h postinjection. Another recent report demonstrated that a ^{64}Cu-labeled antisense PNA, conjugated to a cell-permeating peptide with high positive charge density, could be used to image mouse tumor xenografts, albeit with renal uptake as high as 280% ID/g (*27*). On the basis of these findings, we reasoned that judicious incorporation of neutral hydrophilic and/or negatively charged residues may enhance water solubility and cell portability of radiolabeled PNAs, while maintaining hybridization affinity and promoting renal clearance. Though our goal was to make thymine monomers (**1**, **2**) as our lead compounds, we also synthesized additional monomers with a basic amino acid (**3**, lysine) and containing a purine nucleobase (**4**, guanine), to show the versatility and robustness of this methodology.

There are a number of strategies available for synthesis of side chain-modified PNA monomers (*10*, *28*−*33*). Modifications can be made either on the glycine unit or on the aminoethyl unit. When oligomers are synthesized from these modified monomers, the presence of bulky side chains on the aminoethyl unit may pose difficulties during coupling reactions and may also exert steric hindrance on base pair formation. Moreover, preparation of N-protected, 2-substituted aminoacetaldehyde requires two steps from the commercially available amino acid, sometimes affording low yields and/or unstable products (*34*, *35*). Another approach uses a Mitsunobu reaction between the N-protected amino acid and N-protected β-amino alcohols (*28*). In this method, every step requires chromatographic purification, and the incorporation of carboxylic acid functionalities such as aspartic acid is not compatible with reduction using Vitride or sodium borohydride. Thus, the present work focused on modifications of the glycine unit, where most of the appropriately protected starting materials are commercially available, and a simple N-protected aminoacetaldehyde can be employed for synthesis of the aminoethyl unit.

A very recent report describes the solution phase synthesis of a single, modified PNA monomer having glutamic acid as the amino acid derivative (*33*). The formation of the pseudopeptide backbone was attempted using two methods, reductive N-alkylation or Mitsunobu condensation. It was found that the second method afforded higher yields and fewer byproducts. However for this route, the amine nitrogen on the pseudopeptide backbone had to be protected with an *N*-*o*-nitrobenzenesulfonyl group.

Recently it was shown that modified PNA monomers and oligomers can be synthesized readily on a solid support, using Fukuyama−Mitsunobu alkylation of the desired α-amino acid, followed by acylation with the desired nucleobase-acetic acid derivative (*36*). However, in this case even thymine has to be protected in order to be used in the synthesis.

The overall goal of the present work was to develop a robust synthetic method for introduction of amino acid-modified residues into PNA oligomers. The construction of oligomers with these modifications first required an efficient synthesis of appropriate PNA monomers. We report herein a facile solid-phase synthesis of various PNA monomers prepared from different amino acid derivatives and containing either a pyrimidine or a purine as the nucleobase.

We initially chose to synthesize modified derivatives of thymine for two reasons. First, protected nucleobase-acetic acid derivatives for adenine, guanine, and cytosine are not readily available from commercial sources. Second, the thymine derivative requires no protecting group using the conditions employed here. In addition, PNA hybridization stability can be highly sensitive to amino acid modifications, particularly at internal sequence positions (*24*). Judicious incorporation of a neutral or negatively charged hydrophilic side chains at or near the end of a duplex structure, such as the C-terminal thymine complimentary to the start codon of mRNA, may yield more water soluble PNA oligomers without abrogating target binding.

The solid-phase strategy described here affords higher yields and higher purity crude products than analogous solution-phase methods. Unlike previously reported solid-phase methods, the mild conditions utilized are compatible with 9*H*-fluoren-9-ylmethoxycarbonyl (Fmoc) PNA and peptide chemistry. To show the generality of the newly developed method, we also synthesized a lysine derivative of thymine and a serine derivative of guanine. In addition, we showed that two of these monomers can be incorporated efficiently into a variety of PNA oligomers in various sequence positions.

EXPERIMENTAL PROCEDURES

General. All reagents were HPLC or peptide synthesis grade. *N*-α-Fmoc-L-Ser(OtBu)-OH, *N*-α-Fmoc-L-Asp(OtBu)-OH, *N*-α-Fmoc-L-Lys(Boc)-OH, and 2-cholorotrityl chloride resin were obtained from Novabiochem (San Diego, CA). *N*-α-Fmoc-ethanolamine and thymine-1-acetic acid were purchased from Aldrich (Milwaukee, WI). PNA monomers Fmoc-A(Bhoc)-OH, Fmoc-C(Bhoc)-OH, Fmoc-G(Bhoc)-OH, and Fmoc-T-OH, as well as Fmoc-XAL PEG PS resin, were obtained from Applied Biosystems (Foster City, CA). All laboratory glassware was washed with a mixed acid solution (*37*) and thoroughly rinsed with ultrapure water (18 MΩ-cm resistivity). Manual reaction vessels were obtained from Chemglass, Inc. (Vineland, NJ). ^{1}H NMR analysis of purified monomers was performed using a Bruker DRX 300 MHz spectrometer (Bruker BioSpin, Westmont, IL), and elemental analysis was performed by Atlantic Microlab (Norcross, GA). ESI-MS analyses were performed on a Finnigan TSQ7000 mass spectrometer (Thermo Finnigan, San Jose, CA). A Waters (Milford, MA) NovaPak C18 column (3.9 × 300 mm) was used for LC-MS analysis.

Analytical and preparative reversed-phase HPLC were performed on a Waters 600 chromatograph equipped with a Waters Delta 600 pump, a Rheodyne 7725i injector, Waters 2487 dual wavelength UV detector, Waters 600 controller, and the Empower Pro software package (Build No. 1154). A Phenomenex (Torrance, CA) C-18 Jupiter column (4.6 × 250 mm, 5 μm, 300 Å) was used for analytical HPLC. For preparative HPLC, a Phenomenex Jupiter Proteo column (21.2 × 250 mm, 10 μm, 90 Å) was used. The flow rate was maintained at 1.0 mL/min for analytical runs and at 3.0 mL/min for preparative purification. The wavelengths used for UV detection were 214 and 280 nm for analytical HPLC and 280 nm for preparative HPLC, respectively. Eluents used in all runs consisted of solvent A (0.1% TFA/H_2O) and solvent B (0.1% TFA/CH_3CN). Two different gradients were used: (1) "Analytical Gradient": sequential linear from 30% to 80% solvent B in 40 min (step 1) and 80% to 95% solvent B in 10 min (step 2), or 30% to 80% solvent B in 40 min (step 1) and 80% to 95% solvent B in 20 min (step 2); or (2) "Prep Gradient" (optimized for preparative purification of monomers): sequential linear from 35% to 65% solvent B in 60 min (step 1), 65% to 80% solvent B in 30 min (step 2), and 80% to 100% solvent B in 10 min (step 3).

Monomer Synthesis. Syntheses of PNA monomers having serine, aspartic acid, or lysine derivatives were performed manually, using Fmoc chemistry and 2-chlorotrityl chloride resin at a substitution level of 0.6 mmol/g. All reactions were carried out at room temperature.

Amino Acid Coupling. In a typical experiment, 350 mg of the resin was charged to the reaction vessel. The resin was

washed with DCM (4 × 3 mL), DMF (2 × 3 mL), and DCM/NMP (1:1, 2 × 3 mL). A preactivated mixture of 215 mg (561 μmol) of *N*-α-Fmoc-L-Ser(OtBu)-OH or 230 mg (559 μmol) of *N*-α-Fmoc-L-Asp(OtBu)-OH or 262 mg (560 μmol) of *N*-α-Fmoc-L-Lys(Boc)-OH and 389 μL (289 mg, 2.24 mmol) of DIPEA, dissolved in 3 mL of 1:1 DCM/NMP, was charged to the reaction vessel, and a stream of argon was used for mixing. After 45 min the activation and coupling reactions were repeated, and the resin was washed with DCM/NMP (1:1, 3 × 3 mL), DCM/CH_3OH/DIPEA (17:2:1, 2 × 3 mL), and DMF (3 × 3 mL). A solution of 25% piperidine in 3 mL of DMF was charged to the reaction vessel and Fmoc removal was carried out for 30 min. The deprotection reaction was repeated, and the resin was washed with DMF (3 × 3 mL) and TMOF (2 × 3 mL).

***N*-Fmoc-aminoacetaldehyde Coupling.** *o*-Iodoxybenzoic acid (IBX) was synthesized according to the literature procedure (*38*). *N*-Fmoc-ethanolamine was oxidized using IBX (*39*), and the corresponding aldehyde, *N*-Fmoc-aminoacetaldehyde, was obtained as a single pure product in 90−95% yield. The aldehyde (81 mg, 282 μmol) was dissolved in TMOF (3 mL) and charged to the resin. A small amount (∼0.3−0.5 mL) of DMF was added to increase the solubility of the aldehyde. After 40 min, a few drops of acetic acid were added, followed by sodium (triacetoxy)borohydride (60 mg, 283 μmol), and the resulting suspension was mixed under argon for 20 min. The resin was washed with TMOF (2 × 3 mL) and DMF (3 × 3 mL).

Nucleobase Coupling. In the case of the L-serine monomer, thymine-1-acetic acid (81 mg, 440 μmol) or benzyloxypurine-9-acetic acid (132 mg, 441 μmol) was activated with 71 mg of DhbtOH (436 μmol) and 69 μL of DIC (55 mg, 437 μmol) in 3 mL of DMF. This mixture was added to the resin, and the resulting suspension was mixed under argon for 6−8 h. The activation and coupling steps were repeated using benzyloxypurine-9-acetic acid. For the L-aspartic acid monomer, the activation and coupling steps were also repeated. Then the resin was washed with DMF (3 × 3 mL) and DCM (3 × 3 mL).

Cleavage and Purification of *S*-3-*tert*-Butyloxy-2-{2*N*-[(9*H*-fluoren-9-ylmethoxycarbonyl)aminoethyl]-2-[(thymine-1-acetyl)-amino]}-propanoic Acid (1), *S*-3-*tert*-Butyloxycarbonyl-2-{2*N*-[(9*H*-fluoren-9-ylmethoxycarbonyl)aminoethyl]-2-[(thymine-1-acetyl)-amino]}-propanoic Acid (2), *S*-6-*tert*-Butyloxycarbonylamino-2-{2*N*-[(9*H*-fluoren-9-ylmethoxycarbonyl)aminoethyl]-2-[(thymine-1-acetyl)-amino]}-hexanoic Acid (3), and *S*-3-*tert*-Butyloxy-2-{2*N*-[(9*H*-fluoren-9-ylmethoxycarbonyl)aminoethyl]-[2-(2-amino-6-benzyloxypurine-9-acetyl)-amino]}-propanoic Acid (4). A small amount of each resin was removed from the reaction mixture and washed with DMF, DCM, and CH_3OH. The final products were cleaved from the resin using 0.5% TFA in DCM for 30 min and precipitated using diethyl ether. The precipitate was dissolved in CH_3CN:H_2O (1:1) and analyzed by HPLC ("Analytical Gradient") to confirm completion of nucleobase coupling. The remainder of the resin was then washed, and the final products were cleaved and isolated by precipitation as described above. The side chain-modified PNA monomers were purified by either preparative HPLC ("Prep Gradient") or flash chromatography on silica gel, using DCM:CH_3OH (10:1) as the mobile phase. After purification, 60.0 mg (42.2%) of **1** (T_S) was obtained as a white powder. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.08 (s, 9H), 1.76 (s, 3H), 2.87 (br, 1H), 3.37−3.40 (m, 2H), 3.50 (s, 2H), 3.76−3.82 (m, 2H), 3.88−3.90 (m, 1H), 4.11−4.17 (m, 2H), 4.37 (d, 1H), 4.58 (d, 1H), 4.69 (br, 1H), 6.15 (s, 1H), 6.78 (s, 1H), 7.20−7.23 (m, 2H), 7.30−7.33 (m, 2 H), 7.49−7.52 (m, 2H), 7.66−7.70 (m, 2H), 10.2 (br, 1H). ESI-MS *m*/*z* calcd for $C_{31}H_{36}N_4O_8$ $(M + H)^+ = 593.7$, found 537.2 $(M + H - tBu)^+$, 593.2 $(M + H)^+$, 615.1 $(M + Na)^+$. Anal. ($C_{31}H_{36}N_4O_8 \cdot CH_2Cl_2$): C, H, N.

Chromatographic purification afforded 48.0 mg (36.8%) of **2** (T_D) as a white powder. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.40 (s, 9H), 1.77 and 1.85 (2s, 3H), 2.78−2.87 (m, 2H), 3.01−3.20 (m, 2H), 3.46 (s, 1H), 3.57 (s, 1H), 3.79−3.82 (d, 1H), 3.95 (br, 1H), 4.09−4.20 (m, 1H), 4.37 (d, 1H), 4.52−4.54 (m, 1H), 4.72 (d, 1H), 5.83 (s, 1H), 6.81 and 6.86 (2s, 1H), 7.19−7.21 (m, 2H), 7.30−7.37 (m, 2 H), 7.48−7.54 (m, 2H), 7.62−7.73 (m, 2H), 10.62 (br, 1H). ESI-MS *m*/*z* calcd for $C_{32}H_{36}N_4O_9$ $(M + H)^+ = 621.7$, found 565.1 $(M + H - tBu)^+$, 621.4 $(M + H)^+$, 643.3 $(M + Na)^+$. Anal. ($C_{32}H_{36}N_4O_9 \cdot CH_2Cl_2 \cdot 1/2 (CH_3CH_2)_2O$): C, H, N.

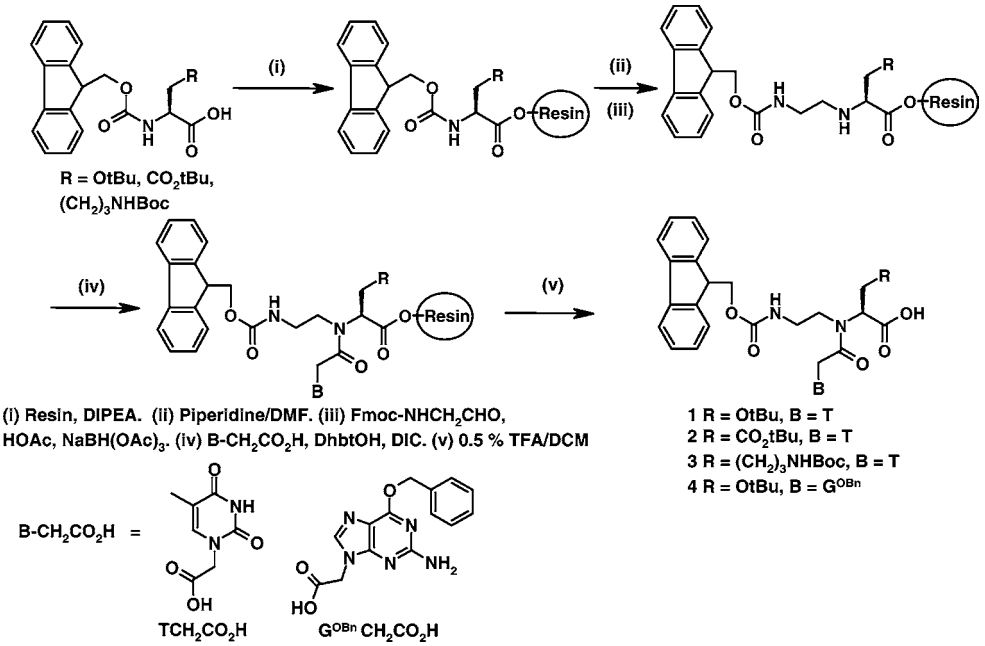
Chromatographic purification afforded 68.0 mg (38.0%) of **3** (T_K) as a white powder. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.31 (t, 1H), 1.46 and 1.49 (2s, 9H), 1.59 (s, 1H), 1.76 (s, 1H), 1.82 and 1.86 (2s, 3H), 1.92−2.03 (m, 1H), 2.72 (br, 1H), 2.94 (s, 1H), 3.10 (s, 2H), 3.28 and 3.37 (m, 2H), 3.49 (s, 1H), 3.67 (br, 1H), 3.82 (m, 1H), 4.20 (d, 1H), 4.39, (d, 1H), 4.66 (d, 1H), 4.82 (m, 1H), 6.12 (s, 1H), 6.98 (s, 1H), 7.27−7.29 (m, 2H), 7.35−7.42 (m, 2 H), 7.53−7.62 (m, 2H), 7.70−7.82 (m, 2H), 10.52 (br, 1H). ESI-MS *m*/*z* calcd for $C_{35}H_{43}N_5O_9$ $(M + H)^+ = 678.7$, found 579.2 $(M + H - Boc)^+$, 700.1 $(M + Na)^+$. Anal. ($C_{35}H_{43}N_5O_9 \cdot CF_3CO_2H$): C, H, N.

Chromatographic purification afforded 64.0 mg (36.2%) of **4** (G_S) as a white powder. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.14−1.17 and 1.22−1.23 (d, 9H), 2.84−3.04 (m, 1H), 3.08−3.20 (m, 1H), 3.45−3.79 (m, 2H), 3.80 (t, 1H), 3.91 (s, 1H), 4.06 (s, 1H), 4.12−4.25 (m, 2H), 4.31 (s, 1H), 4.55 (dd, 1H), 4.90 and 4.96 (s, 1H), 5.05 (q, 1H), 5.49−5.57 (m, 2H), 6.30 (s, 1H), 7.26−7.29 (m, 4H), 7.32−7.41 (m, 4H), 7.42−7.49 (m, 2H), 7.51−7.58 (m, 2H), 7.64−7.71 (m, 1H), 7.73−7.78 (m, 2H), 10.62 (br, 1H). ESI-MS *m*/*z* calcd for $C_{38}H_{41}N_7O_7$ $(M + H)^+ = 708.8$, found 708.3 $(M + H)^+$. Anal. ($C_{38}H_{41}N_7O_7 \cdot 2 CF_3CO_2H$): C, H, N.

Synthesis of Model PNA Tetramers (5−11). Syntheses of PNA tetramers using **2** were performed according to a previously published procedure (*20*), using Fmoc-XAL PEG PS resin at a substitution level of 0.15 mmol/g. Compound **2** was incorporated into tetramers **5** ($AAGT_D$; T_D = aspartic acid derivatized thymine residue), **6** (GAT_DA), **7** (AT_DCG), **8** (T_DACA), **9** (AT_DGC), **10** ($AGAT_D$), and **11** (T_DCAA) on a 1 μmol scale. After cleavage, deprotection, precipitation with diethyl ether, and lyophilization, 0.8−1.0 mg (68−86%) of **5**−**11** were obtained as white powders. ESI-MS (**5**) *m*/*z* calcd $(M + 2H)^{2+} = 592.4$, found 592.4; (**6**) *m*/*z* calcd $(M + 2H)^{2+} = 593.4$, found 592.2; (**7**) *m*/*z* calcd $(M + 2H)^{2+} = 581.4$, found 580.2; (**8**) *m*/*z* calcd $(M + 2H)^{2+} = 573.4$, found 572.2; (**9**) *m*/*z* calcd $(M + 2H)^{2+} = 580.9$, found 580.4; (**10**) *m*/*z* calcd $(M + 2H)^{2+} = 592.9$, found 592.6; (**11**) *m*/*z* calcd $(M + 2H)^{2+} = 572.9$, found 572.4.

Synthesis of *bcl-2* Antisense Tetradecamers (12−15). Compounds **1** and **2** were each incorporated into sequence positions 1 or 8 of four *bcl-2* antisense PNA tetradecamers: **12** ($CCAGCGTGCGCCAT_S$; T_S = serine derivatized thymine residue), **13** ($CCAGCGT_SGCGCCAT$), **14** ($CCAGCGTGCGCCAT_D$), and **15** ($CCAGCGT_DGCGCCAT$). The syntheses were carried out on a 5 μmol scale, using Fmoc-XAL PEG PS resin at a substitution level of 0.15 mmol/g and modifications of a method reported previously (*20*). After cleavage, Bhoc deprotection, and precipitation with diethyl ether, the N-terminal Fmoc-protected tetradecamers were purified by preparative reversed-phase HPLC, using a sequential linear gradient of 5% to 15% solvent B in 10 min (step 1), 15% to 55% solvent B in 40 min (step 2), 55% to 75% solvent B in 30 min (step 3), 75% to 85% solvent B in 20 min (step 4), 85% to 95% solvent B in 20 min (step 5), and 95% to 100% solvent B in 10 min

Scheme 1



(step 6). The fractions corresponding to the major products were collected, pooled, and lyophilized. Fmoc removal was carried out in 25% piperidine in DMF for 30 min at room temperature, after which the products were isolated by precipitation with diethyl ether and dried to give 1.2−1.3 mg (6.3−6.8%) of **12**−**15** as white powders. ESI-MS (**12**) *m*/*z* calcd $(M + 3H)^{3+} = 1268.9$, $(M + 4H)^{4+} = 951.7$; found, 1268.2, 951.7; (**13**) *m*/*z* calcd $(M + 3H)^{3+} = 1268.9$, $(M + 4H)^{4+} = 951.7$; found, 1268.4, 951.6; (**14**) *m*/*z* calcd $(M + 3H)^{3+} = 1278.2$, $(M + 4H)^{4+} = 958.7$; found, 1277.8, 958.5; (**15**), *m*/*z* calcd $(M + 3H)^{3+} = 1278.2$, $(M + 4H)^{4+} = 958.7$; found, 1277.3, 958.3.

RESULTS AND DISCUSSION

Initially the solution-phase synthesis previously reported for similar amino acid-modified PNA monomers (*11*) was attempted. To obtain the desired products, protection and deprotection of the C-terminus was mandatory, most steps required chromatographic purification of the intermediates, and the overall yields were <15%. Some of the intermediate deprotection conditions (e.g., TFA) are optimized for Boc chemistry and are likely to result in unwanted removal of the tBu protecting group from the serine and aspartic acid derivatives used. Moreover, Fmoc removal under solution-phase conditions was complicated by persistent contamination of the desired products with excess piperidine. Although alternative Fmoc deprotection conditions have been reported (*40*), they cannot be applied to amino acids bearing the acid labile tBu protecting group. For these reasons, an alternate solid-phase method (Scheme 1) was developed to overcome the inherent shortcomings of solution-phase synthesis.

To develop a mild method, compatible with even tBu side chain protection, 2-chlorotrityl resin was used for the present synthesis. The initial step in the synthesis was coupling of the first submonomer unit, namely the fully protected chiral amino acid to 2-chlorotrityl chloride resin. Initial coupling was carried out at an amino acid loading capacity of 0.6 mmol/g in DCM/NMP (1:1). The reaction was carried out for two 45-min cycles, after which the Fmoc group was cleaved using a standard procedure (*41*).

The incorporation of the aminoethyl unit can be achieved by two simple methods: (1) Mitsunobu coupling of an N-protected ethanolamine or (2) reaction of an N-protected aminoacetaldehyde followed by reduction. The first method is well documented (*36*), but DMT, which has been used as a protecting group for the aminoethyl unit (*36*), is not compatible with 2-chlorotrityl resin. A strong base is also required, and this coupling can lead to dialkylation, which is a very common side reaction (*33*). Therefore, reductive alkylation with an N-protected aminoacetaldehyde was utilized in the present synthesis. The presence of tBu side chain protection on serine and aspartic acid was incompatible with Boc protection of the N-terminus. A number of compatible N-protecting groups are available, such as Cbz, Bn, Bz, and Fmoc (*42*). However, most of these protecting groups require metal-catalyzed removal or strong acidic conditions, with the exception of Fmoc. For the preparation of PNA−peptide conjugates labeled with metallic radionuclides (*20*−*22*), the presence of trace metal contamination from a metal-catalyzed deprotection could severely inhibit radiometal incorporation. Therefore, Fmoc protection was the most logical choice for preparation of the aminoethyl synthon. Fmoc-*N*-aminoacetaldehyde is not commercially available, and reports using this compound (*11*) did not specify how it was prepared. An attempt was made to synthesize Fmoc-*N*-aminoacetaldehyde from N-protected aminoacetaldehyde dimethyl acetal. Introduction of Fmoc was attempted using two reagents, Fmoc succinimidyl carbonate (Fmoc-OSu) and Fmoc chloride (Fmoc-Cl). The use of Fmoc-Cl resulted in the formation of numerous products, and obtaining the desired N-protected aminoacetaldehyde was difficult. When Fmoc-OSu was employed, the desired product was obtained in pure form and 90−95% yield within 30 min. All attempts to deprotect the resulting N-protected dimethyl acetal under well-established conditions, e.g., HCl, silica gel/DCM, or TFA (*43*) in various solvents failed to give the desired Fmoc-*N*-aminoacetaldehyde. In another route, Fmoc-glycine was converted to Weinreb amide and reduced using lithium aluminum hydride (*44*). Though the desired product was obtained, the workup was cumbersome and the yields were low, necessitating a third approach. In this reaction, Fmoc-aminoethanol was easily oxidized to the corresponding aldehyde in nearly quantitative yield, using IBX in ethyl acetate (*39*). The various syntheses of *N*-Fmoc-aminoacetaldehyde attempted are shown in Scheme 2.

The next reaction sequence, solid-phase aldehyde condensation followed by reduction, was initially met with poor yields.

Table 1. Comparison of Different Reducing Agents and Solvents for Reductive Alkylation Using Fmoc-NHCH$_2$CHO

solvent	reducing agent	% yield[a]
THF	$NaBH_3CN$	61
DMF	$NaBH_3CN$	53
TMOF	$NaBH_3CN$	68
DCE	$NaBH_3CN$	34
THF	$NaBH(OAc)_3$	62
DMF	$NaBH(OAc)_3$	55
TMOF	$NaBH(OAc)_3$	88
DCE	$NaBH(OAc)_3$	40

[a] Based on Fmoc evaluation.

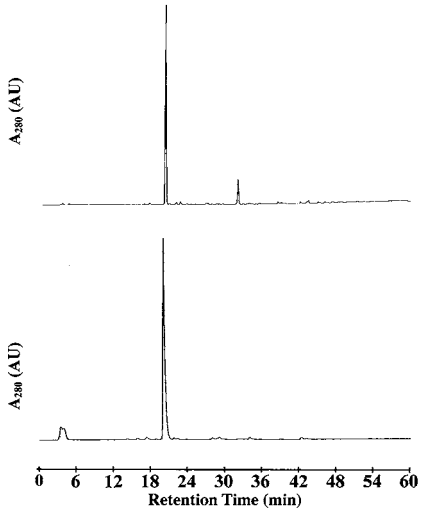

Figure 1. Analytical reversed-phase HPLC chromatograms of crude (top) and purified (bottom) **1**, using Analytical Gradient conditions. The peak at a retention time of 20.9 min represents the desired product, while the peak at 18.1 min represents the unreacted secondary amine precursor. The small peaks in the chromatogram of the purified product are injection artifacts.

It was found that methanol, which is commonly used in analogous solution-phase synthesis, was not compatible with 2-chlorotrityl resin. A systematic investigation was carried out to optimize the solid-phase reductive alkylation. First, to make the imine formation complete, the aldehyde was allowed to react with the amine for 40 min, and then the reducing agent was added. A mild reducing agent, sodium cyanoborohydride, was employed, and the use of sodium (triacetoxy)borohydride was also evaluated. Reactions with various combinations of the two reducing agents and several solvents, including DCE, THF, DMF, and TMOF, were carried out. On the basis of quantitation of Fmoc incorporation on the resin, it was found that the sodium (triacetoxy)borohydride in TMOF gave optimal results for this step (Table 1). Although a previously published synthesis reported no product formation using Fmoc-aminoacetaldehyde (*45*), systematic modification of the reaction conditions made it possible to obtain the desired product on the resin in typical yields of 80−90%. Appropriate precautions, such as measuring amino acid loading of the resin, sufficient reaction time, and use of inert atmosphere, were essential to reduce the most common side reaction, dialkylation. To the best of our knowledge, this is the first reported solid-phase reductive alkylation using *N*-Fmoc-aminoacetaldehyde.

Finally, thymine-1-acetic acid was activated under various conditions, using uronium or phosphonium salts, and was coupled to the secondary amine on the solid support. It was found that coupling conditions based on anhydride formation using DIC (*46*), TBTU/PyBOP (*47*), HOBT/HBTU (*48*), and HOBT/EDCI (*49*) were ineffective. However, DhbtOH/DIC or HATU (*50*) afforded efficient coupling of thymine-1-acetic acid to the secondary amine. In the case of the serine derivative, a single coupling gave the crude product in high purity (Figure 1, top). For the aspartic acid (Figure 2, top) and lysine (Figure 3, top) derivatives, two couplings of activated thymine-1-acetic acid were required to obtain optimal yields of the desired product, although 5−10% of unreacted secondary amine remained. In the case of guanine, benzyloxypurine-9-acetic acid was synthesized according to the literature method (*51*). That work also provides potential routes to amino acid-modified cytosine and adenine PNA monomers, using modifications of the present methods. The protected guanine nucleobase was attached to the protected (aminoethyl)serine intermediate, using the same coupling conditions twice. The final products were cleaved from the resin using 0.5% TFA in DCM and precipitated with diethyl ether. These products could be isolated in typical overall yields of 36−42%, after purification by preparative reversed-phase HPLC or flash chromatography on normal silica. As determined by analytical reversed-phase HPLC, these

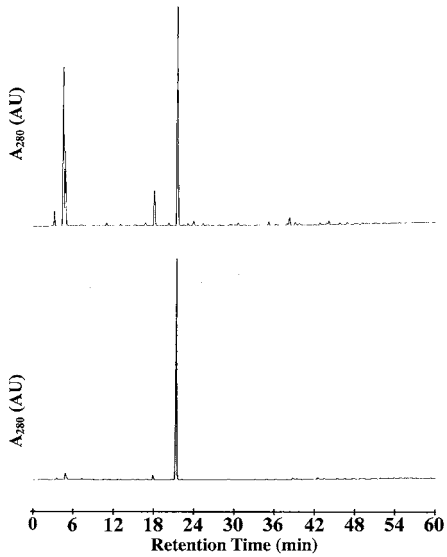

Figure 2. Analytical reversed-phase HPLC chromatograms of crude (top) and purified (bottom) **2**, using Analytical Gradient conditions. The peak at a retention time of 22.0 min represents the desired product, while the peak at 18.7 min represents the unreacted secondary amine precursor. The other small peaks in the chromatogram of the purified product are injection artifacts.

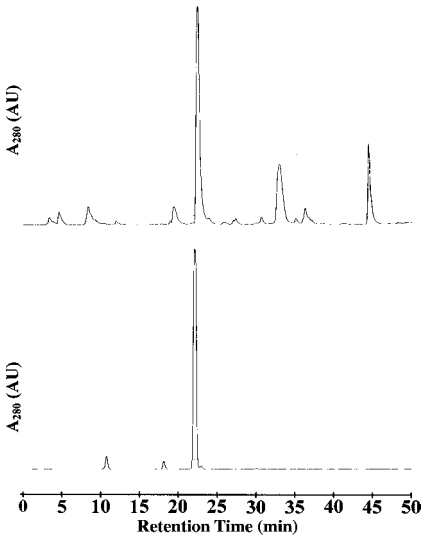

Figure 3. Analytical reversed-phase HPLC chromatograms of crude (top) and purified (bottom) **3**, using Analytical Gradient conditions. The peak at a retention time of 22.1 min represents the desired product, while the peak at 18.7 min represents the unreacted secondary amine precursor. The other small peaks in the chromatogram of the purified product are injection artifacts.

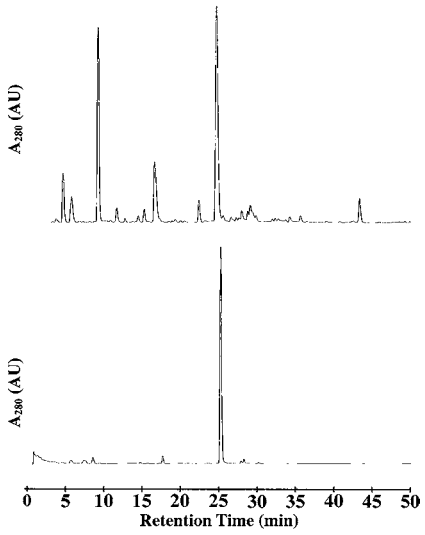

Figure 4. Analytical reversed-phase HPLC chromatograms of crude (top) and purified (bottom) **4**, using Analytical Gradient conditions. The peak at a retention time of 25.2 min represents the desired product, while the peak at 18.1 min represents the unreacted secondary amine precursor. The other small peaks in the chromatogram of the purified product are injection artifacts.

methods yielded **1** in near quantitative purity (Figure 1, bottom), **2** in 98.6% purity (Figure 2, bottom), **3** in 98.0% purity (Figure 3, bottom), and **4** in 98.8% purity (Figure 4, bottom). In the case of **2**, **3**, and **4**, the only impurity (1.2−2.0%) after HPLC or flash chromatography purification was the secondary amine precursor. All compounds could be purified to homogeneity using a subsequent reversed-phase separation.

Using compound **2**, PNA tetramers were synthesized in which the position of an aspartic acid derivatized thymine residue (T_D) was varied in seven model sequences: $AAGT_D$ (**5**), GAT_DA (**6**), AT_DCG (**7**), T_DACA (**8**), AT_DGC (**9**), $AGAT_D$ (**10**), and T_DCAA (**11**). Compound **2** was incorporated into all four sequence positions, from the C-terminus to the N-terminus (including direct coupling on the resin) and attached to a cytosine residue, an adenine residue, or a guanine residue. After cleavage, deprotection, and precipitation, the purity of each of the crude products was >95% by reversed-phase HPLC analysis

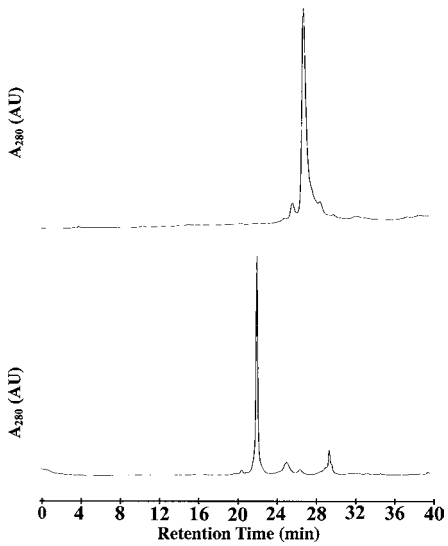

Figure 5. Analytical reversed-phase HPLC chromatograms of serine derivatized tetradecamers **12** ($CCAGCGTGCGCCAT_S$, top) and **13** ($CCAGCGT_SGCGCCAT$, bottom), using a sequential linear gradient of 5% to 25% solvent B in 20 min (step 1), 25% to 45% solvent B in 10 min (step 2), and 45% to 95% solvent B in 10 min (step 3). The peaks at a retention times of 26.9 min (top) and 22.2 min (bottom) represent the desired products.

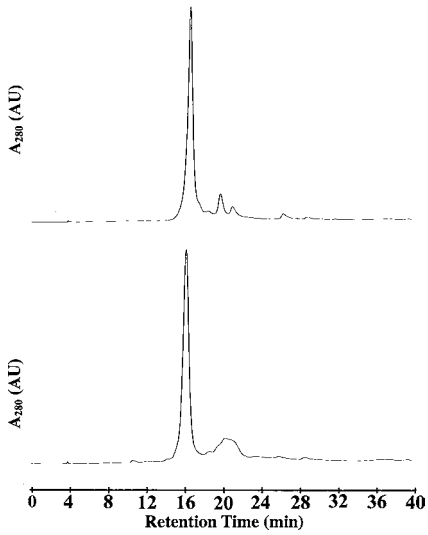

Figure 6. Analytical reversed-phase HPLC chromatograms of aspartic acid derivatized tetradecamers **14** ($CCAGCGTGCGCCAT_D$, top) and **15** ($CCAGCGT_DGCGCCAT$, bottom), using a sequential linear gradient of 5% to 25% solvent B in 20 min (step 1), 25% to 45% solvent B in 10 min (step 2), and 45% to 95% solvent B in 10 min (step 3). The peaks at a retention times of 16.8 min (top) and 16.3 min (bottom) represent the desired products.

(data not shown). The high purity of the tetramer preparations indicated that the coupling efficiency of **2** was comparable to that of commercially available glycine monomers. For each of the tetramers, ESI-MS analysis was consistent with the structures of the desired products.

Finally, four tetradecamers, complementary to the translational start sequence of *bcl-2* mRNA, were synthesized using compounds **1** and **2**. A serine (T_S) or an aspartic acid (T_D)-derivatized thymine residue was incorporated at the C-terminus (position 1) or coupled to a guanine residue in position 8 of the respective tetradecamers: $CCAGCGTGCGCCAT_S$ (**12**), $CCAGCGT_SGCGCCAT$ (**13**), $CCAGCGTGCGCCAT_D$ (**14**), and $CCAGCGT_DGCGCCAT$ (**15**). After cleavage, Bhoc deprotection, HPLC separation, Fmoc removal, and precipitation, reversed-phase HPLC analysis of **12** (Figure 5, top), **13** (Figure

5, bottom), **14** (Figure 6, top), and **15** (Figure 6, bottom) indicated that the purity of each of the modified oligomers was approximately 90%. ESI-MS of the major products was consistent with the structures of the respective tetradecamers. Minor impurities (~10%) present in the tetradecamer preparations may represent truncated species not removed by preparative reversed-phase HPLC. However, these syntheses demonstrated that two of these amino acid-modified monomers (T_S and T_D) can be incorporated with high efficiency into PNAs sufficiently long for statistically unique targeting in the human RNA pool (*52*).

CONCLUSION

We have developed a convenient, efficient, and high yielding synthesis of amino acid-modified PNA monomers requiring minimal purification using solid-phase techniques. Amino acids represented neutral hydrophilic (serine), acidic (aspartic acid), and basic (lysine) residues, and the nucleobases included a pyrimidine (thymine) and a purine (protected guanine), to afford a wide variety of compounds. Furthermore, we have synthesized several PNA tetramers and *bcl-2* antisense tetradecamers in which two of these modified residues have been incorporated into various sequence positions, with coupling efficiencies comparable to those of commercially available glycine analogues. Studies evaluating the water solubility and DNA hybridization properties of PNAs containing these amino acid modifications are currently in progress.

Efficient Monitoring of Enzymatic Conjugation Reaction by Surface-Enhanced Laser Desorption/Ionization Time of Flight Mass Spectrometry for Process Optimization

Teresa Freire,[†] Jacques D'Alayer,[‡] and Sylvie Bay*[,†]

Unité de Chimie Organique URA CNRS 2128 and Plate-forme d'Analyse et de Microséquençage des Protéines, Institut Pasteur, 25-28 rue du Dr. Roux, 75724 Paris, Cedex 15, France. Received September 5, 2005; Revised Manuscript Received January 16, 2006

Efficient analysis of bioconjugation reactions is one the most challenging task for optimizing and eventually achieving the reproducible production of large amount of conjugates. In particular, the complexity of some reaction mixtures precludes the use of most of the existing methods, because of the presence of large amounts of contaminants. As an alternative method, we used surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF MS) for monitoring an in vitro enzymatic transglycosylation of *N*-acetylgalactosamine (GalNAc) residues to a recombinant mucin protein MUC6. For this reaction, catalyzed by the uridine 5′-diphospho-*N*-acetylgalactosamine:polypeptide *N*-acetylgalactosaminyltransferases (ppGalNAc-Ts), we used either a recombinant ppGalNAc-T1 or a mixture of ppGalNAc-Ts contained in MCF7 tumor cell extracts. In the present study, we show that SELDI-TOF MS offers unique advantages over the traditional methodologies. It is a rapid, accurate, sensitive, reproducible, and very convenient analytical method for monitoring the course of a bioconjugation, even in heterogeneous samples such as cell extracts. SELDI-TOF MS proved very useful for optimizing the reaction parameters of the transglycosylation and for achieving the large scale preparation of Tn antigen-glycosylated mucins for antitumor immunotherapy applications.

INTRODUCTION

Bioconjugation technology has been widely used in nearly every discipline of life sciences research (*1*, *2*). One of the application areas is the preparation of hapten−carrier conjugates for immunization purposes, antibody production, and vaccine research. Indeed, small hapten molecules such as carbohydrates cannot elicit an efficient immune response on their own. To make them immunogenic, they must be coupled to a suitable carrier molecule, typically a protein. The characteristics of the resulting conjugate play a critical role in the intensity and the quality of the immune response. In particular, several groups have reported the influence of the hapten density on the level, the specificity, and the affinity of the produced antibodies (*3*−*6*). Careful follow-up of the conjugation is therefore very important to achieve the reproducible production of conjugates.

Different approaches are commonly employed to analyze these conjugates and to ascertain their optimal preparation. The choice of the method depends on the physicochemical properties of both hapten and carrier, as well as on the cross-linking strategy. The most frequently used procedures involve mass spectrometry, sometimes associated with high performance liquid chromatography (HPLC) (*4*, *6*−*8*), gel filtration (*2*), absorption (*9*) and fluorescence (*6*, *7*) spectroscopy, gel electrophoresis (*5*, *6*, *8*), and colorimetric assay for reactions involving sulfhydryl groups (*10*), amino groups (*11*), or carbohydrate residues (*12*). Although efficient, these existing methods suffer from several drawbacks. First, they often require further treatment of the samples, they are time-consuming, and they are not easy to perform when multiple samples are to be analyzed. Moreover, they are usually not very accurate and only give a rough estimate of the conjugate's molecular mass and integrity. Finally, the complexity of some reaction mixtures (cell extracts, sera, tissue homogenates, etc.) can affect the effectiveness of the analysis adversely, due to the presence of large amounts of other compounds (lipids, detergents, salts, other proteins, etc.).

Therefore, there is a need for rapid and sensitive analytical methods for monitoring bioconjugation reactions, particularly with complex and heterogeneous samples. Additionally, such efficient methods are essential in development, for optimizing the process and scaling up the production of the conjugates, while ensuring a batch-to-batch consistency.

ProteinChip array technology or surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF MS) allows the analysis of complex protein mixtures by combining two powerful techniques: chromatography and mass spectrometry. After selective retention on a chip surface, the compounds of interest are subsequently analyzed by a laser desorption/ionization mass spectrometer. This technique has been successfully used in many fields such as biomarker discovery, study of biomolecular interactions, protein profiling, analysis of posttranslational modifications, etc. (*13*, *14*).

As compared to these applications, very few examples have been described so far showing the use of SELDI-TOF for the monitoring of a reaction (whether chemical or enzymatic) or for the analysis of the resulting product. Recently, the direct analysis of peptides or proteins after either enzymatic digestion (*15*−*17*) or limited acid hydrolysis (*18*) has been successfully performed on-chip, with the aim of identifying protein sequences. On-chip enzymatic reactions and subsequent characterization have also been performed in order to study posttranslational modifications. Using this method, the degree of glycosylation of a recombinant antibody has been monitored with a deglycosylation procedure using PNGase F (*19*) and the

phosphorylation state of a peptide or a protein has been evaluated after the action of a kinase (*20*) or a phosphatase (*21*). This last example included a time course study. In another characterization study, Hubalek et al. (*41*) have described the analysis of biotinylated tryptic peptides after digestion of biotinylated recombinant human monoamine oxidases and subsequent purification on an affinity column. Similarly, a peptide enzymatically released from a synthetic peptide related to the proteinase-activated receptor 2 was identified by SELDI-TOF MS (*22*). Interestingly, SELDI-TOF MS has also allowed the course of the autoactivation process of a bacterial protein to be followed, directly from the culture supernatant (*23*). Finally, the utility of SELDI-TOF MS has been demonstrated for monitoring the attachment of bacterial oligosaccharides to a protein, by a conjugation method using squaric acid diester chemistry (*24*, *25*). However, the reaction was a chemical ligation in a simple mixture composed of the synthetic linker-derivatized oligosaccharide, the protein carrier, and the buffer. To our knowledge, SELDI-TOF MS has never been used for monitoring an in vitro enzymatic conjugation reaction in a complex mixture.

Among the hapten molecules, carbohydrates are of particular interest since they are part of bacterial determinants, and they are also tumor-associated antigens (TAA). As a result, a large number of carbohydrate−protein conjugates have been developed as vaccines against infectious diseases (*26*) and cancer (*27*). In previous works, we and others have prepared various conjugates displaying the Tn antigen (α-D-GalNAc−Ser/Thr) (*28*−*30*) which is a carbohydrate TAA overexpressed in breast, lung, prostate, and colon cancers (*31*, *32*). The resulting glycopeptides (*28*) or glycoproteins (*29*, *30*) have been shown to be highly promising vaccine candidates for targeting cancers. However, the preparation of such conjugates relies on multistep tedious syntheses and/or time-consuming purifications. To circumvent these difficulties, we developed an enzymatic approach for producing a protein glycoconjugate with a high Tn density.

Tn-mucins are attractive targets for antitumor immunotherapy since carbohydrates have been shown to be an essential part of tumor-associated structures within the mucins (*33*). As the protein backbone, we chose the MUC6 gastric mucin (*34*) which has been described in different tumors, including lung (*35*, *36*) and breast (*37*, *38*) carcinomas. This mucin is a natural substrate of the uridine 5′-diphospho-*N*-acetylgalactosamine:polypeptide *N*-acetylgalactosaminyltransferases (ppGalNAc-Ts, EC 2.4.1.41) which are the enzymes responsible for the Tn antigen synthesis in vivo.

To achieve the large scale preparation of MUC6-Tn conjugates for antitumor immunotherapy, we performed the in vitro enzymatic GalNAc antigen transfer onto the mucin acceptor. We describe herein the monitoring of the conjugation by SELDI-TOF MS and we show that this method is very rapid and efficient for optimizing the reaction parameters, including in complex mixtures.

EXPERIMENTAL PROCEDURES

MUC6 Cloning and Expression in *E. coli*. A cDNA clone containing one tandem repeat of MUC6 was isolated from total cDNA of MCF7 breast cancer cells by RT-PCR and cloned into pGem-T (Promega, France). The PCR products were designed to encode a half tandem repeat (87 amino acids) that were amplified with *Pfu* DNA polymerase and the primers MUC6-F, 5′-cgggatccTCCACCTCCTTGGTGACT-3′ and MUC6-2R 5′-ggaagcttATTAGGATGGTGTGTGGA-3′ (lowercase characters indicate restriction sites for *BamH*I and *Hind*III in the forward and reverse primers, respectively). Following digestion with *BamH*I and *Hind*III, each product was cloned into the pET28a(+) vector (Novagen, Fontenay-sous-Bois, France), so as to encode for a protein carrying a six-histidine tail at the N-terminus. *E. coli* DH5α transformants were selected on LB plates containing 50 μg/mL kanamycin, and the positive clones were confirmed by PCR and sequencing. Plasmids were purified from selected clones and used to transform *E. coli* BLi5 chemically competent cells. The recombinant was expressed in *E. coli* BLi5 by induction with 1 mM IPTG and purified over Ni^{2+}-nitriloacetic acid columns under denaturing conditions according to the manufacturer's (Qiagen, Germany) instructions. The MUC6 protein was characterized by amino acid analysis (AAA), SELDI-TOF MS, and electrospray mass spectrometry (ESMS: 12148.05; calculated: 12147.45). These analyses, together with a N-terminal sequencing, show that the protein lacks the N-terminal methionine residue.

Breast Cancer Cell Line Extracts. Breast cancer cell line MCF7 was grown to 90% confluence in Dulbecco's modified Eagle's medium (Life Technologies, Inc.) with 10% fetal bovine serum, 1 mM pyruvate, and 2 mM glutamine and 5% CO_2 at 37 °C. After trypsinization, cells were washed three times with phosphate-buffered saline (PBS), resuspended in 250 mM sucrose, and homogeneized. Cells were then centrifuged at 3000*g* for 10 min at 4 °C. The resulting supernatant was again centrifuged at 100000*g* for 1 h at 4 °C. The pellet was resuspended in 0.1 M imidazole pH 7.2 and 0.1% Triton X-100. Cell extracts were aliquoted and stored at −80 °C. Protein concentration was determined by the BCA method (Sigma Chemical Co., St Louis, MO).

Recombinant Bovine Polypeptide GalNAc Transferase 1. A soluble form of the bovine ppGalNAc-T1 (ppGalNAc-T1), kindly given by F. Piller and V. Piller, was expressed in the yeast *Pichia pastoris* KM71H strain (Invitrogen, Cergy Pontoise, France) using the pPICZαA expression vector (Invitrogen). The recombinant ppGalNAc-T1 (from amino acids 52 to 559) carrying a N-terminal 6His-tag was expressed (induction in 0.5% methanol for 120 h) and purified on Ni-NTA-agarose (Qiagen, Hilden, Germany). The specific activity of the recombinant ppGalNAc-T1 was tested as previously described (*39*) and estimated to 3 U/mg protein (1 unit transfers 1 μmole of GalNAc per min at 37 °C to the acceptor peptide $[STP]_5$).

In vitro GalNAc Transfer to MUC6 Protein. Microsome fractions of MCF7 breast cancer cells were incubated at 37 °C for 48 h with uridine 5′-diphospho-*N*-acetylgalactosamine (UDP-GalNAc) and purified recombinant MUC6 (40−80 μM) in 50 mM imidazole pH 7.2 containing 50 mM $MnCl_2$ and 0.1% Triton-X100. When recombinant ppGalNAc-T1 was used, the MUC6 purified protein (40−80 μM) was incubated with UDP-GalNAc in 50 mM MES, pH 6.5 for 24 h at 37 °C. Aliquots were taken at different times and frozen at −20 °C. The different reaction conditions are detailed in Table 1. The resulting MUC6-Tn were purified using Ni-NTA-agarose (Qiagen, Hilden, Germany) (only when cell extracts were used) and then subjected to reversed phase HPLC using a Perkin-Elmer pump system with an UV detector at 230 nm. The column was a Symmetry 300 C18 (5 μm, 300 Å, 3.9 × 250 mm) (Waters, France). Elution was carried out with a linear gradient of 10−60% acetonitrile in 0.1% trifluoracetic acid in water at a flow rate of 1 mL/min (over 30 min). The peak was collected and then lyophilized. The MUC6-Tn glycoproteins were characterized by amino acid analysis and SELDI-TOF MS.

Reaction Monitoring by SELDI-TOF. The SELDI-TOF mass spectrometer was purchased from Ciphergen Biosystems (Fremont, CA). IMAC30 ProteinChip array surfaces were activated with 100 mM $NiCl_2$ at room temperature for 15 min and then washed with water and PBS. Spots were incubated with total glycosylation mix aliquots for 40 min at room temperature using the Bioprocessor system and then washed

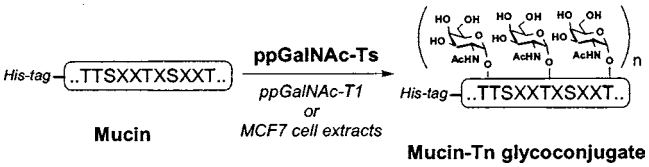
[a] The molar equivalent amount is expressed as compared to potential *O*-glycosylation sites (47 serine and threonine residues). [b] 65 μg was added at the beginning of the reaction and then at 24 h. [c] The average molecular mass of the neoglycoconjugate was calculated from the medium peak which is marked with an arrow on Figures 1 and 3. [d] Calculated average mass of GalNAc $M_g = 203.193$ Da.

Scheme 1. Enzymatic Transglycosylation of GalNAc from UDP−GalNAc to the MUC6 Mucin Using Either Recombinant ppGalNAc-T1 or MCF7 Tumor Cell Extracts



with 0.1% Triton-X100 in PBS (2 × 5 min), PBS (3 × 2 min), and 5 mM HEPES (2 × 5 min). The matrix (2 × 0.6 μL of sinapinic acid saturated in 50% acetonitrile/0.5% TFA) was applied on each spot and allowed to air-dry. Chips were then read in the PBS II Reader, and each array spot was laser-sampled. Spectra were generated at a laser setting of 220 with a detector sensitivity of 8 and an acceleration energy of 20 kV. The laser intensity at these values corresponds to ~8 μJ. Optimization range of the time lag focusing was set between 10 and 20 kDa. The instrument was externally calibrated with bovine ubiquitin (8564.8 Da), bovine cytochrome C (12230.9 Da), and bovine β-lactoglobulin (18363.3 Da) (all from Ciphergen Biosystems) with the matrix and the settings as described above for the MUC6 samples. Spectra were treated using the Ciphergen ProteinChip software 3.2.1.

RESULTS AND DISCUSSION

The recombinant MUC6 protein was subjected to the transglycosylation reaction from the carbohydrate activated donor UDP-GalNAc in the presence of the enzyme, either a recombinant ppGalNAc-T1 (*39*) or a mixture of ppGalNAc-Ts contained in MCF7 tumor cell extracts (Scheme 1). Small aliquots of the reaction were withdrawn at different times and directly analyzed by SELDI-TOF MS after immobilization on the ProteinChip surface through immobilized metal affinity capture (IMAC30). The reaction progress was monitored by the shift to higher masses, caused by the transfer of GalNAc residues, as compared with the mass of the starting material (Figures 1 and 3). The spectra displayed a set of peaks showing the incremental molecular masses of the conjugates and allowing to determine the average hapten−protein stoichiometry, as well as the distribution of the conjugates. The transglycosylation reactions were studied under various experimental conditions (Table 1).

The ppGalNAc-T1 was shown to catalyze very efficiently the in vitro transfer of GalNAc residues onto the MUC6 protein (Figure 1). The extent of transfer was first analyzed with 2 equiv of UDP-GalNAc donor (the molar equivalent amount refers to the potential *O*-glycosylation sites, i.e., the total serine and threonine residues) and variable amounts of the recombinant ppGalNAc-T1, after 24 h incubation. As shown in Figure 1

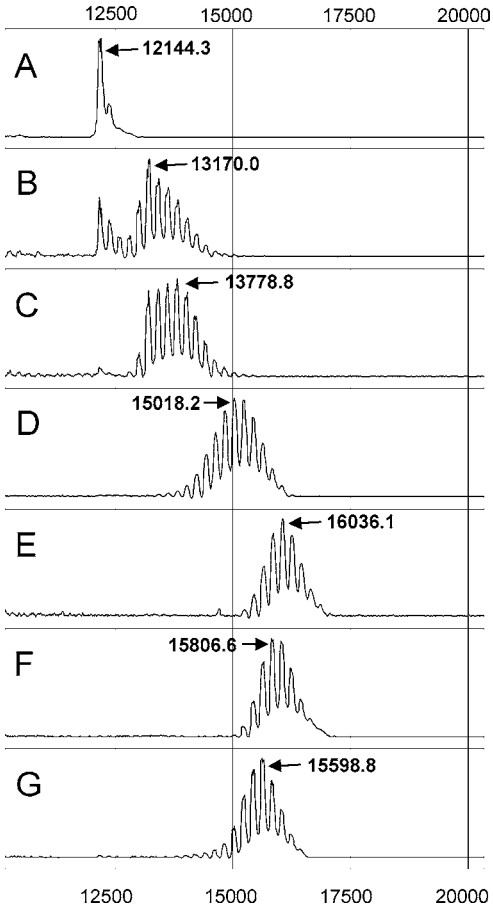


Figure 1. SELDI-TOF MS analysis of the progress of the GalNAc transglycosylation on MUC6 (molecular mass: 12144.3 Da, Panel A) using ppGalNAc-T1, depending on the donor (panels B−E) or the enzyme amount (panels E−G). The panel A (incubation reaction without UDP-GalNAc) served as a control for the starting material, i.e., the nonglycosylated MUC6 protein. The average mass/charge (*m*/*z*) values (in daltons) are shown in each panel on the medium peak marked with an arrow. The conditions of the tranglycosylation reactions, and the average GalNAc amount of the resulting conjugates are given in the Table 1.

(Panels B−E), the addition of enzyme results in a pronounced and progressive spectra shift showing significant increase in glycosylation with an average Tn amount from 5 (Panel B) to 19 (Panel E). Further addition of enzyme alone or enzyme together with UDP-GalNAc did not significantly improve the transfer (data not shown). Likewise, longer incubation period than 24 h did not produce any observable increase in molecular mass, showing that a maximum Tn level has been reached, at least under these experimental conditions (data not shown).

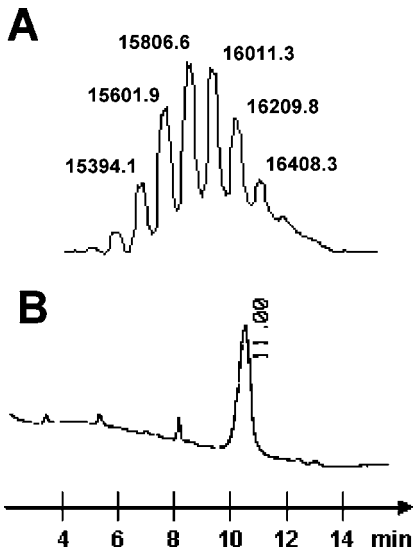

Figure 2. Comparison of the resolution by SELDI-TOF MS and HPLC analysis. Products from the experiment of Figure 1F (1 equiv of UDP-GalNAc and 1 μg of ppGalNAc-T1/10 μg of MUC6) were analyzed by SELDI-TOF MS (A) and reversed-phase HPLC (B). Enlarged SELDI-TOF mass spectrum shows the mass increment details (*m*/*z* values in daltons). Chromatographic conditions: Waters Symmetry C18 (5 μm, 300 Å, 3.9 × 250 mm), flow rate of 1 mL/min, gradient with water (0.1% trifluoracetic acid)/acetonitrile (10−60%) over 30 min.

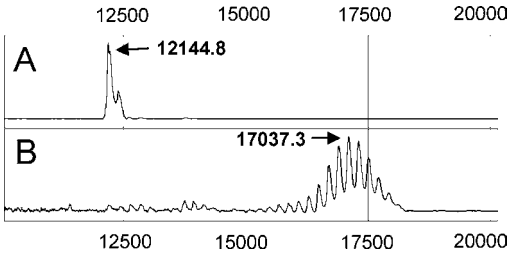

Figure 3. SELDI-TOF MS analysis of the conjugation reaction using MCF7 tumor cell extracts. The panel A (incubation reaction without UDP-GalNAc) served as a control for the starting material, i.e., the nonglycosylated MUC6 protein. The average mass/charge (*m*/*z*) values (in daltons) are shown in both panels on the medium peak marked with an arrow. The conditions of the tranglycosylation reaction, and the average GalNAc amount of the resulting conjugate are given in the Table 1.

The effect of the amount of donor is presented in Figure 1E−G. When lower quantities of UDP-GalNAc were used, the SELDI-TOF MS profile was found to be comparable, although a slight decrease in transfer was observed with 0.5 equiv of donor (Figure 1G).

To produce large amounts of conjugates while saving the expensive donor UDP-GalNAc, we chose the experimental conditions of Figure 1F for scaling up the reaction (1 equiv of UDP-GalNAc and 1 μg of enzyme/10 μg of MUC6). When the transglycosylation was performed on semipreparative quantities (mg range of mucin), the number of transferred GalNAc residues was found to be virtually the same as the one obtained at the analytical level (data not shown). As a result, the preparation of milligrams of neoglycoconjugates has been achieved, and the evaluation of their immunological properties will be reported separately (T. Freire et al., *Glycobiology*, in press).

Enlargement of the representative spectrum with the selected conditions (Figure 1F) shows the mass increment details (Figure 2A). The difference between each peak corresponds to the expected average mass of a single GalNAc residue (203.193 Da), demonstrating that SELDI-TOF MS allows a good resolution, at least in this molecular mass range. In contrast, the reverse phase HPLC profile did not show any separation of the different species (Figure 2B).

SELDI-TOF MS was then applied to the analysis of a transglycosylation in complex mixtures, by using the ppGalNAc-Ts contained in extracts from MCF7 tumor cells (Figure 3). The mass distribution obtained with the crude mixture was similar to the one observed with the recombinant enzyme. However, the transfer rate was better since an average density of 24 Tn/protein molecule was achieved after 48 h of reaction and two additions of cell extracts (Figure 3B). With the ppGalNAc-T1 and the cell extracts, the maximum Tn level was found to be, respectively, 40% and 51% of the potential glycosylation sites. The fact that the maximum Tn-protein stoichiometry was higher in this last case suggests that the additional GalNAc may have been transferred by other ppGalNAc-Ts that are present in the cell extracts. Interestingly, the presence of numerous contaminants in the cell extracts hardly affect the signal-to-noise ratio, showing that SELDI-TOF can be useful for such complex analysis.

We show here that the monitoring of a chemical conjugation reaction can be done for an enzymatic reaction in a crude and complex mixture (cell extracts) without any interference from contaminants, although such monitoring with simple samples has been reported previously by P. Kováč and co-workers (*24*, *25*). These results imply that SELDI-TOF MS is a powerful tool for monitoring a bioconjugation reaction. Indeed, this technique provides a very efficient alternative to the traditional analysis methods.

First, it is a sensitive and accurate method since the conjugates could be efficiently analyzed from as few as 10 ng (1 pmol range), at least in the molecular mass range of 10000−20000 with mass increments of approximately 203 Da. The traditional protein carriers which are used for immunization purposes have usually higher molecular mass, from approximately 60000 Da (bovine serum albumin or BSA, diphtheria toxoid) to several million Da (keyhole limpet hemocyanin or KLH). The accuracy and resolution of SELDI-TOF MS will be most probably limited in these higher molecular mass ranges, in particular for the KLH. This will also depend on the molecular mass of the hapten. To overcome these problems, the use of Zip Tip pipette tips can be considered. This method involves a microscale cleanup of the sample which then can be applied to high performance mass spectrometers (MALDI or electrospray), allowing efficient analyses in the high molecular weight range. However it is noteworthy that, for low molecular weights, ProteinChip array technology remains simpler since it allows the purification step and the mass analysis on the same device. This eliminates the need for a transfer step and results in an optimal recovery of the sample.

Second, SELDI-TOF MS is very rapid since it can be performed directly on the crude reaction without the need to purify or to derivatize the sample prior to analysis. In addition, the fact that several samples can be easily analyzed in parallel can be very valuable for studying the impact of various conditions on the efficiency of the conjugation. SELDI-TOF MS is therefore potentially very useful for high-throughput optimization strategies. Finally, the present study indicates that SELDI-TOF MS is suitable for analyzing complex crude samples from in vitro enzymatic conjugations. It may thus be directly applicable to the monitoring of intracellular reactions performed in vivo. Such analyses have already been reported on crude fermentation or cell culture sources in order to optimize recombinant protein production (*19*, *40*) or to analyze the secretion and autoactivation of a bacterial protein (*23*). Similar studies on mucin proteins are currently underway in the laboratory.

ACKNOWLEDGMENT

The authors are thankful to V. Piller and F. Piller for providing the recombinant ppGalNAc-T1 and to C. Leclerc for the critical review of the manuscript. We gratefully acknowledge financial support from the Association pour la Recherche sur le Cancer and the ECOS France-Uruguay Program. T.F. was financed by la Ligue Nationale contre le Cancer, la Fondation pour la Recherche Médicale, and a Vasant and Kusum Joshi grant.

Single-Drug Multiligand Conjugates: Synthesis and Preliminary Cytotoxicity Evaluation of a Paclitaxel−Dipeptide "Scorpion" Molecule

Ahmad Safavy,*,§ Kevin P. Raisch,§ Damien Matusiak,⊥ Saloni Bhatnagar,§ and Lawrence Helson‡

Department of Radiation Oncology and the Comprehensive Cancer Center, University of Alabama at Birmingham, Birmingham, Alabama 35294, Department of Medicine, University of Illinois at Chicago and Jessie Brown Veterans Administration Medical Center, Chicago, Illinois 60612, and Tapestry Pharmaceuticals, Boulder, Colorado 80301. Received July 26, 2005; Revised Manuscript Received March 7, 2006

To improve the targeting properties of receptor-directed drug-peptide conjugates, a multiligand approach was proposed and a model "scorpion" conjugate (**6**, Figure 1), consisting of two peptide "claws" and a paclitaxel (PTX) "tail", was synthesized. The cell surface receptor-directed peptide used in this single-drug multiligand (SDML) model was a segment of the amphibian peptide bombesin (BBN) which had the $Y^6Q^7W^8A^9V^{10}G^{11}H^{12}L^{13}M^{14}$-$NH_2$ sequence, designated here as BBN[6−14] (**2**, Figure 2). Due to the lipophilic nature of both PTX and BBN-[6−14], compound **6** had a low water solubility. To enhance the solubility, PEG derivatives of this conjugate were prepared with the polymer inserted either in the claws or in the tail regions. In a preliminary random screening, conjugate **6** showed superior cytotoxic activity in several GRPR-positive human cancer cell lines as compared to free PTX and two single-drug single-ligand (SDSL) conjugates. In a receptor blocking experiment, addition of excess unconjugated BBN[6−14] ligand reduced the cytotoxicity of conjugate **6**, indicating the receptor-mediated mechanism of drug delivery. The PEG-derived conjugates showed activities which were intermediate between SDSL and the SDML congeners. Also, an increase in the number of the PEG segments lowered cytotoxicity, possibly due to steric hindrance against ligand−receptor binding. Taken together, these results demonstrate the potential of the multiligand approach in the design of receptor-targeting conjugates for tumor-specific drug delivery.

INTRODUCTION

Targeted delivery of antitumor agents is an active and promising area of oncology research (*1*, *2*). Two of the main classes of *targeting* molecules used for the delivery of cytotoxic agents are MAbs[1] (*3*, *4*) and tumor cell surface receptor-directed

small-molecule peptides (SMPs) (*5*, *6*). The interest in the use of SMPs for drug targeting is related to their better tumor penetration and faster circulatory clearance when compared to the large MAb molecules. Although the use of SMPs in oncology started mainly with radiolabeled analogues (*7*−*9*), research on the development of drug-conjugated SMPs has also attracted interest. To this end, peptides targeting a variety of tumor cell membrane receptors with different drugs have been evaluated (*10*, *11*). An SDSL-type PTX-BBN conjugate (structure **1**) was recently reported by our group which showed a higher cytotoxic activity against a human non small cell lung cancer cell line, and as compared to the unconjugated PTX (*12*).

As therapeutic agents, peptide conjugates may suffer from short circulation half-lives, and thereby, low tumor uptake (*13*, *14*). This, in turn, may prevent the tumor tissue from receiving a therapeutically significant dose of the drug.

By analogy to the divalent antigen-binding feature of MAbs, which along with their long circulation times account for their characteristic high tumor uptake, we hypothesized that doubling the number of the peptide segments of an SDSL conjugate might improve the tumor targeting ability of the molecule. This hypothesis may be supported by the previously reported investigations on receptor-directed multivalent peptide and protein ligands (*15*−*17*). The improvement was expected to be the result of an increase in the frequency of ligand−receptor collisions and/or an augmented stability of the ligand−receptor complex. This communication reports on the synthesis of a PTX-derived SDML peptide conjugate as well as on its cytotoxic activity against some human cancer cell lines. To evaluate only the effect of the ligand multiplicity on the overall activity, the drug:conjugate molar ratio was kept at 1 and equal to that in the previously reported SDSL (*12*). The SDML conjugates are part of a study on the design, synthesis, and evaluation of multidrug multiligand drug conjugates currently underway in this laboratory.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. The tyrosylbombesin (BBN[6−14], **2**) used in this work was synthesized by standard solid-phase peptide synthesis methods using Rink amide resin and the Fmoc protocol. After TFA cleavage, the peptide was purified by reversed-phase HPLC and identified by ESMS.

For all products, reversed-phase (RP) HPLC analysis/purification were performed with a Beckman System Gold instrument consisting of a SG 125 solvent module and a SG 166 UV/vis detector, operated by Beckman 32 Karat Version 5.0 software. For analytical HPLC, a 4.6 × 250 mm C18 column (Vydac, Hesperia, CA), and for preparative runs, a Vydac 2.5 × 25 Cm C8 column, were used. Columns were eluted with 0.1% TFA/water (solvent A) and a 10% to 90% gradient of 0.1:60:40, TFA:CH_3CN:H_2O (v/v) (solvent B). Analytical retention times (t_R) in minutes are reported with the corresponding percent purities in parentheses.

Paclitaxel-2′-hemisuccinate was prepared as described previously (*18*).

PTXGlu(BBN[6−14])$_2$, 6. To a solution of Boc-Glu (**3**, Fluka, Milwaukee, WI, 3.4 mg, 13.8 μmol) in dry DMF were added solutions of BBN[6−14] (**2**, 36.7 mg, 27.6 μmol) and HOBT (5.6 mg, 41.4 μmol) in the same solvent. Under argon, DIEA (20 μL) and then DCC (23 mg, 111.5 μmol) were added and the solution was stirred at ambient temperature for 48 h. A second and a third addition of **2** (19.5 mg, 14.7 μmol), HOBT (1.6 mg, 11.8 μmol), and DCC (7 mg, 34 μmol) were made and stirring continued for 48 h. Product formation was monitored by peak separation and identification by RP-HPLC and ESMS, respectively. On reaction completion, the Boc protection of the intermediate **4** was removed by adding 3 mL of a deblocking cocktail consisting of 5:1:1:0.5, v/v, TFA:DCM:TIPS:TA, and incubation at ambient temperature for 1 h. The intermediate product **5** was purified by preparative RP-HPLC. Yield: 28 mg (87.5%); HPLC, t_R: 18.8 min (96%); ESMS: 1159 (M + 2H), 773 (M + 3H).

Compound **5** (20 mg, 7.52 μmol) was dissolved in dry DMF, and the vessel was cooled in an ice bath under dry argon. PTXSX (13.3 mg, 15.6 μmol), NHS (5.4 mg, 46.9 μmol), and EEDQ (7.7 mg, 31.2 μmol) were added in sequence and the solution was stirred at 4 °C for 24 h. The final product **6** was purified by RP-HPLC. Yield: 23.5 mg (89.8%); HPLC, t_R: 24.4 min (93%); ESMS: 1627 (M + 2H), 1085 (M + 3H).

PTXGlu(OH)YBBN[6−14], 9. The same procedure as for **6** was used except that equal molar amounts of Boc-Glu, DCC, and BBN[6−14] were used with no HOBT. The peptide was added 1 h after the addition of DCC. The intermediate conjugate **7** was not isolated and was converted directly to the deprotected

derivative **8**. The latter conjugate and the final product **9** were purified by RP-HPLC. **8**: Yield: 1.85 mg (37.7%); HPLC, t_R: 19.3 min (95%); ESMS: 1232 (M + H), 616 (M + 2H) **9**: Yield: 1.3 mg (89.8%); HPLC, t_R: 24.0 min (85%); ESMS: 2167 (M + H), 1084 (M + 2H).

General Procedure for PEG Conjugation. Fmoc-PEG-NHS, the *N*-Fmoc-protected NHS ester of amino-PEG carboxylic acid, with an average MW of ∼3400 (Nektar, Huntsville, AL) was used as the solubilizing linker. The peptide component (1 equiv) was added in dry DMF to the solution of Fmoc-PEG-NHS (**10**, 1.2 equiv) followed by the addition of DIEA (1 equiv) at 0 °C. On reaction completion, piperidine (as 50% DMF solution, v/v) was added and the mixture was incubated for 20 min at ambient temperature. The intermediate conjugates **11**, **12**, **14**, **15**, and **17**−**19** were purified by dialysis against water and were identified by MALDI MS. The final products were purified by RP-HPLC and identified by MALDI MS. The analytical data for these PEG conjugates are shown in Table 1.

PTX Conjugation. All PTX couplings (including that for conjugate **21**) were carried out according to the procedure of Scheme 1 (last step), described above for the synthesis of conjugate **6**.

Quantitative Immunohistochemistry. All reagents were supplied as a kit by DAKO (Carpentaria, CA). Cells were plated on two-well permonox chamber slides (Nalge Nunc International, Rochester, NY) at a density of 25 000 cells/well and allowed to grow in defined media. Cells were fixed in 3.7% formaldehyde in PBS for 20 min at 37 °C, followed by rinsing and permeabilizing with TBST. Immunohistochemistry was performed using a two-step indirect immunoperoxidase technique. Cells were incubated in 0.03% H_2O_2 solution and were rinsed with water and TBST in sequence. The primary (rabbit anti-GRPR) antibody was applied for 1 h at room temperature before rinsing with TBST. The secondary antibody (Labeled Polymer Rabbit HRP) was added with incubation for 30 min. After TBST rinse, the cells were incubated with DAB+Chromogen for 5 min, rinsed with water, and counterstained for 2 min with hematoxylin. Slides were washed with TBST and covered. Control cells were processed identically except that they were not exposed to the primary antibody. Slides were cover-slipped using pristine mount (Invitrogen, Carlsbad, CA).

Chromogen abundance was quantified by quantitative immunohistochemistry as previously described (*19*, *20*). Briefly, images were acquired using a Diagnostic Instruments SPOT RT

Digital Scanning Camera (Sterling Heights, MI) attached to a Nikon E600 microscope (Stamford, CT). The amount of chromogen per pixel was determined by subtracting the mathematical energy (E_M) of the control slide from that in the homologous region of the experimental slide exposed to primary antibody. Chromogen quantity (E_M) is expressed as energy units per pixels (eu/pix).

Cytotoxicity Assays. Tumor cells were grown as monolayers in 25-cm^2 tissue culture flasks using their respective cell culture medium. All media contained 10% fetal bovine serum. Incubation was at 37 °C under a 5% CO_2:air atmosphere (standard conditions) for 5 days. The cells were harvested when in mid-log growth, and their concentration was determined using a Coulter particle counter. An aliquot of the cell suspension was diluted in culture medium for delivery to a 96-well plastic plate at a range of 3000 to 10 000 per 100 μL media. Twenty-four hours later, sextuplicate wells were inoculated with either 100 μL per well of medium (controls), or 100 μL of medium containing PTX or a conjugate. Concentrations were adjusted to deliver 0.1 μg/mL of PTX equivalent to all treatment groups. After 1 h incubation, the wells were aspirated and refilled with 200 μL conjugate-free medium. Following an additional 120 h incubation under standard conditions, and removal of the floating nonviable cells by aspiration, the plate-attached viable cells were counted and normalized to the percent of untreated controls. The extent of cytotoxicity in treated wells as compared to the controls, were calculated using a Magellin software program (Dynex Technology, Chantilly, VA).

Receptor-Blocking Assay. Tumor cells were cultured, in sextuplicate, in 96-well plates as described above. After a 24 h incubation, 100 μL of medium containing DMSO (control), or 100 μL of medium containing PTX, **6**, BBN[6−14], BBN[6−14]+PTX, or BBN[6−14]+**6** was added to sextuplicate wells. Additions were such that a 120 nM of PTX or **6**, and 2400 nM of BBN[6−14] were delivered to each well. The BBN[6−14]+PTX or BBN[6−14]+**6** were mixed immediately prior to the addition of the agents to their respective wells. After 1 h incubation at 37 °C, the medium was removed, the cells were washed 1× with PBS, and 200 μL drug-free medium was added to each well. Following an additional 120 h incubation period, the cells were washed 1× with PBS, then detached with trypsin-EDTA and counted with a hemacytometer (Hausser Scientific, Horsham, PA). The cell counts were normalized to the percent of untreated control cells. The data were statistically analyzed using Microsoft Excel Software (Microsoft Corporation, Redmond, WA).

Table 2. Cytotoxicity[a] of PTX-Di-BBN SDML Conjugates in Different Human Cancer Cell Lines as Compared to Those of PTX and Mono-Ligand Conjugates[b,c]

conjugate	structure	SKNAS[d]	FADU	MO59J	JNPRSLT1	HuTu-80
6	PTXGlu(BBN[6−14])$_2$	87 ± 4.9	89 ± 2.8	64 ± 4.2	86 ± 1.6	93 ± 0.93

RESULTS AND DISCUSSION

The amino acid sequence of the peptide used in this work (BBN[6−14], **2**, Figure 2) made possible the solution-phase synthesis of the final conjugates without side-chain protection.[2]

As the central branching scaffold, N^{α}-(*tert*)-butyloxycarbonyl-L-glutamic acid (Boc-Glu, **3**, Scheme 1) was used to which the BBN[6−14] segments were connected. A standard DCC/HOBT coupling reaction worked satisfactorily although some condition manipulations seemed to improve both the yield of product recovery and the product purity. Briefly, starting with a 2:1 mole ratio of **2**:**3**, and a larger excess of HOBT/DCC with respect to Boc-Glu, it was noticed that a gradual increase in the molarities of **2** and the reagents resulted in better product yields. Removal of the Boc protection from compound **4**, and condensation of the bis-peptide **5** with an equivalent of paclitaxel-2′-hemisuccinate, afforded the target conjugate **6**. A mono-BBN conjugate (compound **9**) was also prepared for studying the effect of BBN duplicity on cytotoxicity. Synthesis of this product was through the formation of Boc-Glu cyclic anhydride followed by the α-addition of BBN[6−14]. The preferential α-opening of the anhydride by the peptide was presumably due to the presence of the electron-withdrawing Boc group (*21*). Chromatographic and mass spectrometric analyses indicated formation of only one major product.

The low water solubility of paclitaxel has been one of the disadvantages of this drug, which has necessitated the use of solubilizing excipients (e.g., cremophore EL, a poly-ethoxylated castor oil) in the clinically used formulations (*22*, *23*). These additives have been reported to be the cause of allergic reactions and posttreatment toxicities (*22*, *23*). We, and others, have reported the use of PEG as a solubilizing attachment to PTX (*24*) and its peptide conjugate (*12*). In the latter case, PEG was inserted between the drug and the peptide segments resulting in high overall aqueous solubility. Here, a PEG amino acid (from Fmoc-PEG-NHS, **10**, Schemes 3−5) was used as the solubilizing linker. Furthermore, to study the effect of positional isomerism on both solubility and biological activity, the PEG linker was inserted, separately, in both the claws and the tail regions. Conjugates with one (**13**, Scheme 3) or two (**16**, Scheme 4, and **20**, Scheme 5) PEG linkers were synthesized. It should be noted that addition of only one PEG to each claw (conjugate **20**) results in the formation of a regioisomer of compound **16**. Analytical data for these readily water-soluble derivatives are presented in Table 1.

Prior to the cytotoxicity experiments, the cell lines were screened for the presence of BBN-related receptors (BBNRs). Immunohistochemistry assays demonstrated the presence of GRP receptors, the mammalian counterpart of BBNR (*25*, *26*) in four of the cell lines (Figure 3). The results of cytotoxicity assays (Table 2) indicated a superior activity for the scorpion conjugate, as compared to both free PTX and the mono-BBN-[6−14] control (conjugate **21**) in all tested cell lines.[3] The MO59J cells, with the lowest GRPR expression (35 000 eu/pix), showed a weaker response to the di-BBN conjugate than did the other, high-density lines. The human squamous cell tu-

[2] Numbering based on the native bombesin sequence. This sequence includes an N-terminal tyrosine residue. Although not relevant to this report, the tyrosine would serve as a radioiodination site for the synthesis of radiolabeled analogues.

[3] Selection of the cell lines of Table 2 is for elucidating the general trend of cytotoxicity of the conjugates. The cell lines have different sensitivity towards PTX, and therefore each column of the table has to be viewed individually.

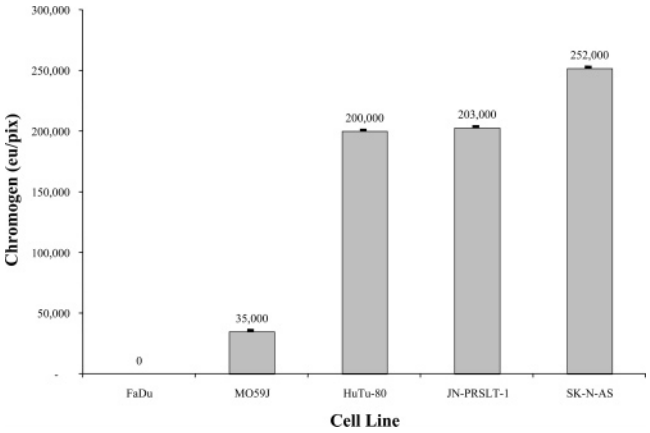

Figure 3. Density of GRPR expression in different human cancer cell lines as determined by immunohistochemistry. Each bar is the mean of values from four independent experiments. Error bars are too small to be visible.

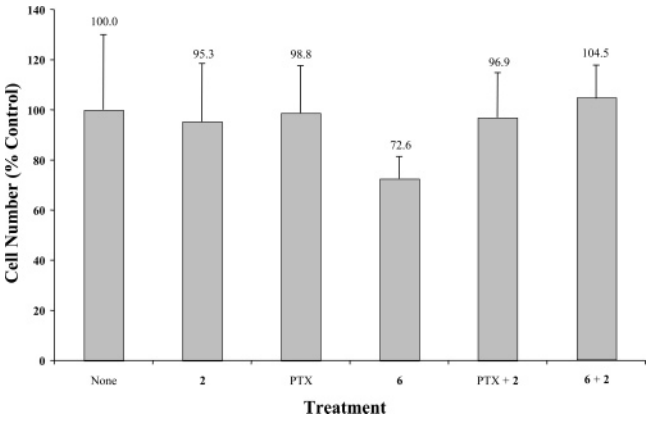

Figure 4. Reduction of PTXGlu(BBN[6−14])$_2$ (**6**) cytotoxicity due to receptor blockage by excess BBN[6−14] (**2**) in JNPRSLT1 human desmoplastic small cell tumor. Each bar shows the percentage of viable cells after treatment. The untreated controls were normalized to 100%.

mor of the pharynx, FADU, does not express BBN/GRP receptors (Figure 3) but is highly sensitive to paclitaxel. To verify the receptor-mediated drug delivery of conjugate **6**, a blocking experiment was carried out using the JN-PRSLT-1 cell line (GRPR 203 000 eu/pix). Addition of a 20-fold molar excess of the free BBN[6−14] ligand (structure **2**) reduced the cytotoxicity of **6** by about 45%whereas it did not have a significant effect on PTX cytotoxicity (Figure 4). On the other hand, when no-GRPR FADU cells were used, both PTX and conjugate **6**, with or without the blocker **2**, killed the cells to the same extent (Figure 5), presumably due to the extreme sensitivity of this cell line to PTX. And for reasons not clear at this time, this sensitivity is reflected in the cytotoxicity of **6** but not with any other conjugate of Table 2.

Activity enhancement due to the simultaneous presence of two BBN moieties in the same molecule was also demonstrated by the low relative cytotoxicity of **9**. It should be noted that the higher activity of conjugate **9** against the other mono-BBN compound (**21**) might be due to a higher water solubility of the former under the experimental conditions. Separation of the ligand segment from the bulky PTX by the Glu spacer in **9** also might have reduced the PTX-resulted steric hindrance (SH) and facilitated the peptide−receptor binding.

Addition of one PEG spacer to the tail region (compound **13**) lowered the activity probably due to a more crowded environment around the molecule, and thereby, jeopardizing conjugate−receptor interactions (e.g., collision), in this case due to the large size of the PEG segments relative to those of the

Figure 5. [a] Calculated from values of Table 2.

peptide moieties. This SH-caused deactivating effect was more apparent when addition of a second PEG in conjugate **16** led to a considerably lower activity.

Incorporation of PEG segments into the claws (compound **20**) caused deactivation with respect to both **6** and free PTX. At the same time, conjugate **20** was more cytotoxic than its regioisomer **16**, indicating that a regional separation between the PEG segments, even when located in the proximity of the ligands, had less of a deactivating effect than a tandem arrangement.

An outline of the cytotoxicity results, in the form of conjugate-to-PTX activity ratios, is shown in Table 3.

Advantage of a multiligand approach in the design of receptor-targeted drug delivery molecules was demonstrated in this work by the synthesis of a di-bombesin−paclitaxel conjugate. With the exception of the highly PTX-sensitive FaDu cells, the SDML conjugate showed enhanced cytotoxicity when screened against both the unconjugated drug and mono-ligand conjugates, in a panel of GRPR-positive human cancer cell lines. The cytotoxicity was reduced with receptor blocking by the free ligand and increased with increases in GRPR density. On the basis of these results, further investigation of these conjugates, including antitumor activity studies, is warranted and is underway in this laboratory.

ACKNOWLEDGMENT

Valuable assistance and contributions of Dr. Madhavi Chander and Mark Jones (Tapestry Pharmaceuticals), Marion C. Kirk, D. Ray Moore, Landon Wilson (UAB Comprehensive Cancer Center Mass Spectrometry Core Facility), and David Fisher (UAB Medical Education and Design Services) is greatly acknowledged.

Fast Water-Exchange Gd^{3+}-(DO3A-like) Complex Functionalized with Aza-15-Crown-5 Showing Prolonged Residence Lifetime in Vivo

Cong Li,[†] Ying-Xia Li,[‡] Ga-Lai Law,[†] Kwan Man,[§] Wing-Tak Wong,*[,†] and Hao Lei*[,‡]

Department of Chemistry and Open Laboratory of Chemical Biology of the Institute of Molecular Technology for Drug Discovery and Synthesis, Department of Surgery, The University of Hong Kong, Pokfulam Road, Hong Kong, and State Key Laboratory of Magnetic Resonance and Atomic and Molecular Physics, Wuhan Institute of Physics & Mathematics, The Chinese Academy of Sciences, Wuhan, P. R. China . Received January 7, 2006; Revised Manuscript Received March 17, 2006

A bis-hydrated Gd^{3+} complex based on tris acetic acid-1,4,7,10-tetraazacyclododecane (DO3A) that was functionalized with aza-15-crown-5 demonstrated a nearly optimal water-exchanging rate ($k_{ex} = 3.1 \times 10^7\ s^{-1}$) and low acute cytotoxicity. Efficient magnetic resonance signal intensity enhancements and prolonged residence lifetime induced by this small molecular complex in vivo were demonstrated even with one-fifth of the standard dosage used in the clinic.

Small molecular gadolinium complexes, such as Gd-DOTA (Dotarem), and its derivatives, are widely used as magnetic resonance imaging (MRI) contrast agents (CAs) to aid the diagnosis of pathologies by enhancing the morphology and functionality of the tissue with the advantage of low inherent toxicity (*1*). However, their pharmacokinetic properties, especially the transient retention lifetime in the blood pool, result in their poor performance in cardiovascular and tumor imagings (*2*). Additionally, these small complexes demonstrate relatively low relaxivity, so a high dosage is required to achieve a satisfactory signal enhancement. To overcome the problems, Gd^{3+} complexes were covalently bound to macromolecules, such as proteins (*3*), antibodies (*4*), dendrimers (*5*), and micellar aggregates (*6*) because their large sizes not only lead to the confinement and a long circulation lifetime in the vasculature (*7*) but also improve the relaxivity by increasing their rotational correlation time τ_R (*8*). Unfortunately, the increasing toxicity induced by the slow clearance rate and the inefficient delivery of these macromolecules to the targeting sites seriously limit their applications (*5*, *7*, *9*). In response to the problems, Lu et al. designed the biodegradable macromolecular agents, in which a Gd^{3+} complex was grafted with poly(ethylene glycol) (PEGs) through the disulfide bond (*10*, *11*). After the imaging, Gd^{3+} chelates can be released from the macromolecules and excreted in time through the cleavage of the disulfide bond by disulfide−thiols exchange. However, because of the low concentration of endogenous thiols in human plasma, multiple administrations of extraneous thiols are needed to keep the efficient cleavage of the disulfide bond. For the above reasons, innovative designs for MRI contrast agents with high relaxivity and moderate excretion rates in vivo are needed.

PEGs are nontoxic and nonantigenic polymers that have been widely used in the modification of biomolecules to improve their biocompatibility and pharmacokinetics (*12*). Covalently bound PEGs not only promote the passive accumulation of the conjugates into the tumors (*13*) but also decrease their clearance rate from the circulation system (*14*). Crown ethers as artificial molecules have been extensively investigated in supramolecular chemistry (*15*). What attracts us here are their well-known amphiphilicity (*16*), identical building block (ethylene glycol) as PEGs, and much smaller molecular weights as compared to PEGs. Considering these properties of crown ethers, a compromise between a prolonged circulation lifetime and low inherent toxicity is expected after functionalization of the crown ether moiety to the Gd^{3+} chelates.

In this communication, we report the synthesis and preliminary evaluation of the crown ether functionalized Gd^{3+} complex. Tris acetic acid-1,4,7,10-tetraazacyclodecane (DO3A) was chosen as the chelate here because its Gd^{3+} complexes not only demonstrated a satisfactory thermodynamic stability [$\log K = 22.0$, 298 K] (*17*), but also a maximum of two binding sites is left for water molecules, which makes their relaxivity increase substantially because the inner-sphere proton relaxivity is proportional to the q values (*8*, *18*). Meanwhile, aza-15-crown-5 was selected because of its moderate ring size and the modification availability of the secondary amine.

The synthesis of **LnL1** is depicted in Scheme 1. Mono-crown ether alkylated cyclen **1a** (*19*) was prepared straightforwardly with high yield according to our previous method. **1a** reacted with excess *tert*-butyl bromoacetate to afford **1b**. Following a deprotection step, the resulting ligands **L1** were treated with $Ln_2(CO_3)_3$ to give the desired Gd^{3+}, Tb^{3+}, and Eu^{3+} complexes. To clarify the effect of the pendant crown ether to relaxivity and other relaxometric parameters, Ln^{3+} complexes of DO3A grafted with ethylamine **LnL2** as control molecules were prepared (*20*, *21*). The luminescent lifetimes of **TbL1** ($\tau_{H_2O} = 1.39$ ms, $\tau_{D_2O} = 2.94$ ms) and **TbL2** ($\tau_{H_2O} = 1.25$ ms, $\tau_{D_2O} = 3.05$ms) were measured in H_2O and D_2O, respectively, and both of their hydration numbers q were given as 2 (*22*).

The water proton relaxivity r_{1p} of **GdL1** and **GdL2** at 20 MHz, 25 °C was measured as 9.5 and 5.9 $mM^{-1}\ s^{-1}$, respectively at pH 7.0. Significantly, the r_{1p} of **GdL1** nearly doubled compared with its parent complex Gd-DO3A (5.7 $mM^{-1}\ s^{-1}$) (*23*). A main reason that determines the lower relaxivity of small molecular complexes compared to their theoretical prediction is their water/proton residence lifetime

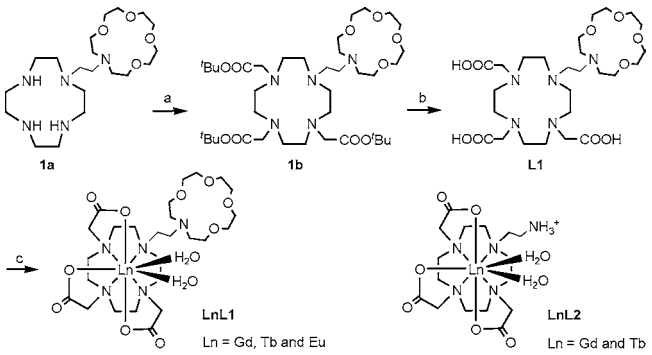
Scheme 1. Synthesis Procedure of LnL1[a]



[a] Reagents and conditions: (a) 3.3 equiv of *tert*-butyl bromoacetate, Na_2CO_3/THF-H_2O, r.t., 4 h, 84%; (b) TFA/CH_2Cl_2, r.t., 2 h, 96%; (c) $Ln_2(CO_3)_3$, H_2O, 70 °C, 10 h, Ln = Gd, Tb, and Eu. Yields of the lanthanide complexes range from 88−95%.

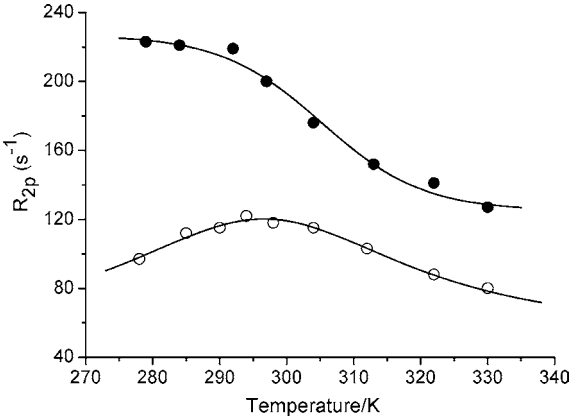


Figure 1. VT-^{17}O NMR transverse relaxation rate of **GdL1** and **GdL2** at 2.1 T, 25 °C, pH 7.0. **GdL1**, filled circle; **GdL2**, open circle.

τ_M (τ_M is the reciprocal of the water exchange rate, k_{ex}) is far from optimal values (*8*). Therefore, many efforts have been dedicated to investigating ligand systems for Gd^{3+} ion by optimizing the water exchange rate k_{ex} (*24*, *25*). To clarify the unusually high r_{1p} of **GdL1**, the measurement of the water ^{17}O NMR transverse relaxation rate, R_2, at variable temperature (VT), which allows a precise assessment of the water residence lifetime τ_M, was conducted. The VT ^{17}O NMR curve of **GdL1** (Figure 1) demonstrated that it is a typical system within the fast exchange regime. The τ_M value of 32 ns ($k_{ex} = 3.1 \times 10^7$ s^{-1}) for **GdL1** at 25 °C was provided by analyzing the curve in terms of the Swift-Connick equation (*3*). Notably, this τ_M value is rather rare for a neutral complex and very close to its optimal range of 20−30 ns (*24*). τ_M is generally determined by several factors including steric crowding at the water binding site, the overall charge of the complex as well as the geometry of the complex. In comparison to **GdL2** (τ_M = 240 ns, $k_{ex} = 4.2 \times 10^6$ s^{-1}, Figure 1) and Gd-DO3A (τ_M = 159 ns, $k_{ex} = 6.3 \times 10^6$ s^{-1}) (*23*), the fast water exchange rate of **GdL1** could arise from the increasing negative charge density and steric congestion around the Gd^{3+} ion upon the approach of the crown ether, which promotes the departure of the bound water molecules. Therefore, the fast water-exchanging rate of **GdL1** should be an important reason for its high relaxivity.

Besides the relaxivity, another important factor to evaluate the potential application of Gd^{3+} complexes as MRI contrast agent is their toxicity, which is generally caused by the free gadolinium ion. To determine the cytotoxic effect of **GdL1**, an MTT assay (*26*) (MTT = 3-(4,5-dimethythiazol-2-yl)-2,5-diphenyltetrazolium bromide) was performed on the human nontumotigenic immortalized liver cell line (MIHA) (*27*). In this work, the commercial available MRI contrast agent, Gd-DOTA, and Gd-DO3A with two bound water molecules were used as the control molecules under the same condition. The experimental results demonstrated that the cell's proliferation and viability were not obviously affected after incubating from 1 to 24 h, while the concentration of **GdL1** ranged from 0.5 to 10 mM (Figure 2, Figure S1, Supporting Information). Additionally, the morphology of live MIHA cells in response to 100 μM **GdL1** was monitored by laser scanning confocal microscopy after 1, 2, 8, and 24 h incubation at 37 °C (Figure S2, Supporting Information). Compared to the cells in the control experiments, no obvious morphological changes of the MIHA cell were detected. The MTT assay showed that the acute cytotoxicity of **GdL1** is quite low in the concentration range required for obtaining the detectable MR signal.

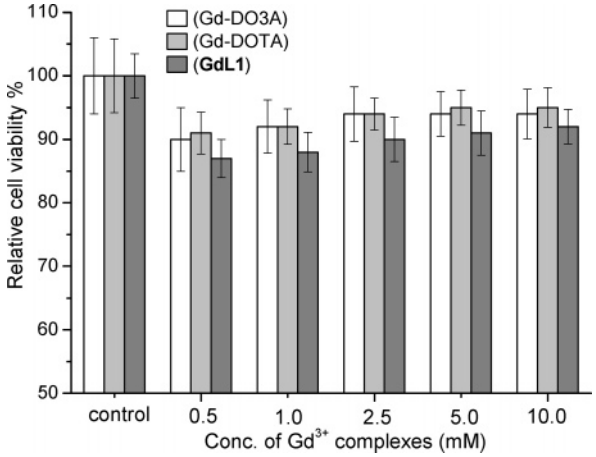

Figure 2. Results obtained from the MTT assay showing the effect of Gd-DOTA (white bars), Gd-DO3A (light gray bars), and **GdL1** (gray bars) on MIHA cells. The viability (%) refers to the growth inhibition induced by the Gd^{3+} complex in comparison to the cells in the absence of Gd^{3+} complex. Error bars represent the standard deviation (± SD) on a triplicate analysis (n = 3).

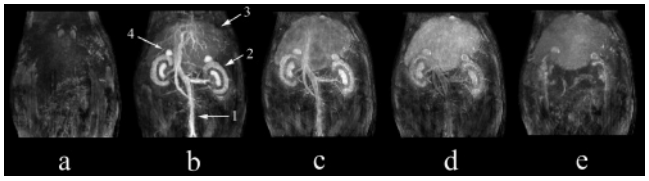

Figure 3. 3D maximum intensity projection T_1-weighted MR images of a rat at preinjection (a), 4 (b), 30 (c), 100 (d), and 200 (e) min after administration of **GdL1** (0.04 mmol/kg). In panel b, the MR signal in abdominal aorta (1), kidney (2), liver (3), and adrenal gland (4) was enhanced significantly and attained their maximum at different times.

In vivo T_1-weighted images were acquired after the administration of **GdL1**, Gd-DOTA, and the liver-specific CA Gd-BOPTA (MultiHance) to anesthetized rats. Figure 3 shows the three-dimensional (3D) maximum intensity projection (MIP) abdomen images of a rat before and after intravenous injection of **GdL1** at 0.04 mmol/kg. MR signals in the kidney, liver, adrenal gland, and abdominal aorta were enhanced significantly. Time dependent MR signal intensity enhancements (IEs) after administration of different CAs were demonstrated in Figure 5. **GdL1** offered much higher vascular and renal contrast enhancements than commercial available Gd-DOTA under the same dosage (Figure 5A,B). The IEs in the abdominal aorta from **GdL1** remained strong in the first 30 min, and still visible at 45−100 min (Figures 3 and 5A), while the enhancement in kidney cortex was even longer; obvious renal IEs lasted for more than 3 h (Figures 4A and 5B). Comparatively, the IEs induced by Gd-DOTA in the blood vessel and kidney vanished completely in less than 15 and 40 min, respectively. To clarify the prolonged resident lifetime of **GdL1** in vasculature, the titration

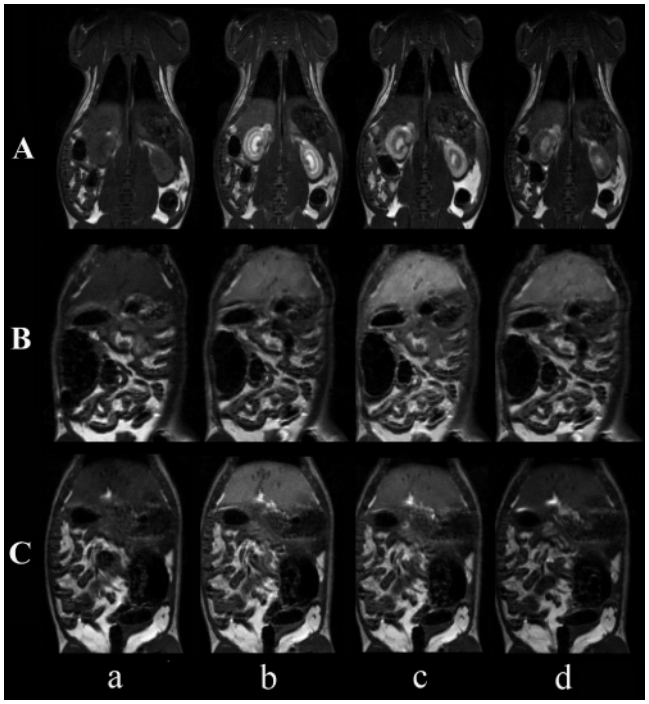

Figure 4. 2D axial T_1-weighted renal and hepatic MR images of rats before (a) and 10 (b), 100 (c) and 200 (d) min after the administration of **GdL1** (A, B) and Gd-BOPTA (C) in the dosage of 0.04 mmol/kg.

of human serum albumin (HSA) to this complex was conducted at pH 7.4 (Figure S3, Supporting Information). The r_{1p} (20 MHz, 25 °C) of **GdL1** increased substantially with the concentration of HSA, and the binding constant K_a of 3009 M^{-1} was measured. This result implied that the nonspecific binding between the amphiphilic crown ether moiety and serum proteins resulted in the prolonged resident lifetime of **GdL1** in vasculature (*28*).

Pronouncedly different time courses of hepatic IEs were observed between **GdL1** and Gd-BOPTA (Figures 4B,C and 5C). IE induced by Gd-BOPTA reached its maximum within the first 10 min, while the peak value of **GdL1** appeared in 80−100 min after administration. Notably, the significant hepatic IEs induced by **GdL1** was sustained for more than 4 h. Moreover, it is worth mentioning that the vascular, renal, and hepatic enhancements of **GdL1** reached their maximal values at different time windows, which implies this complex can be used to image multiple organs successively after the single injection. Even though the mechanism of extended residence lifetime of **GdL1** in liver parenchyma is not very clear, the experimental results suggest that, like the pendant phenyl group in Gd-BOPTA, amphiphilic crown ether can enhance the passive accumulation of **GdL1** in the reticuloendothelial system (RES). Moreover, the uptake of this complex by hepatocytes, and following biliary excretion, may be other reasons for the prolonged hepatic IE (*29*). Dosage-dependent MR signal IE behaviors induced by these three complexes were also investigated (Figure S4, Supporting Information). Even in 0.02 mmol/kg, one-fifth of the standard dosage used in the clinic, bishydrated **GdL1** achieved higher and longer IEs in blood vessel, kidney, and liver compared to two other commercial available CAs. Additionally, it is noteworthy that all rats recovered spontaneously from anesthesia after the MRI studies, which further indicates that **GdL1** has no acute fatal toxicity at the dosage used.

In conclusion, this work describes a fast water-exchange Gd^{3+}-DO3A complex showing efficient MR signal enhancements, an extended excretion rate, and low acute cytotoxicity. The relaxometric and in vivo imaging studies demonstrate the crown ether moiety as a functional group is a potential choice

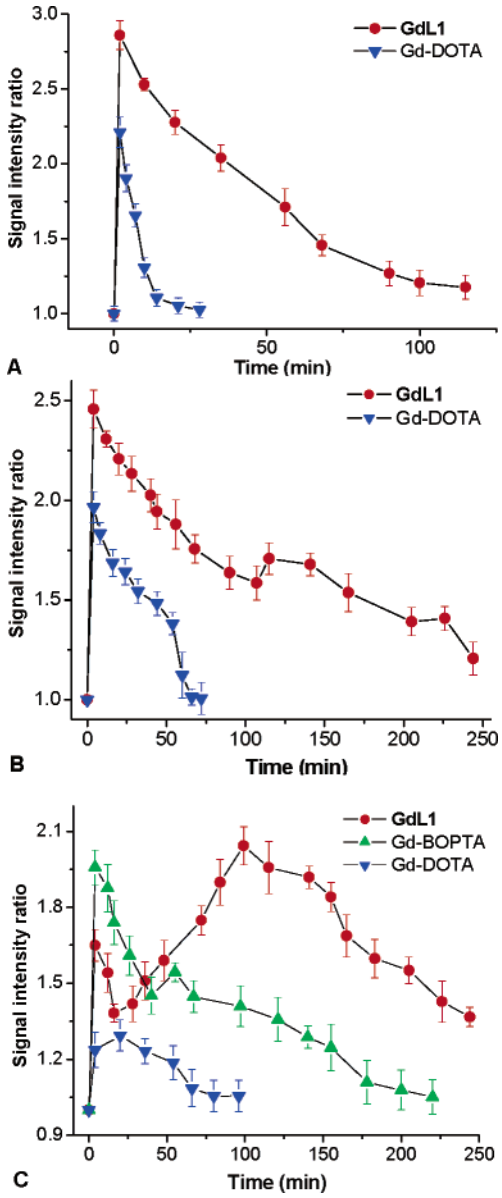

Figure 5. Time-dependent abdominal aortic (**A**), renal (**B**), and hepatic (**C**) IEs induced by **GdL1**, Gd-DOTA, and Gd−BOPTA at the dosage of 0.04 mmol/kg. Error bars represent the standard deviation (± SD) on a triplicate analysis ($n = 3$).

to realize the compromise between the prolonged excretion rate and the low toxicity of MRI contrast agents.

Carbohydrate-Labeled Fluorescent Microparticles and Their Binding to Lectins

Timothy L. Kelly, Michael C. W. Lam, and Michael O. Wolf*

Department of Chemistry, University of British Columbia, Vancouver, British Columbia, Canada, V6T 1Z1. Received November 23, 2005; Revised Manuscript Received February 17, 2006

The preparation of micrometer-sized, cross-linked poly(*p*-phenyleneethynylene) (PPE) beads to which simple monosaccharides are attached is reported. Mannose, glucose, and galactose derivatives have been synthesized. The fluorescence properties, size distribution, and morphology of these microparticles have been elucidated through fluorimetry, fluorescence confocal microscopy, and scanning electron microscopy. Protein binding assays were carried out using Concanavalin A tagged with the fluorophore Texas Red, and the resultant bioconjugates were imaged using confocal microscopy. The microparticles are shown to exhibit efficient binding to lectins and may have potential application as fluorescent probes, biocapture agents, or column packing material for affinity chromatography.

The binding of proteins to cell surface carbohydrates is of critical importance in molecular biology and mediates a wide variety of responses, including inflammation (*1*), viral attack on host cells (*2*), and blood antigenicity (*3*). This versatility in function makes carbohydrates attractive additions to many synthetic molecules and polymers and can lend them the capacity for biocompatibility and biorecognition. The interaction of carbohydrate-binding proteins (lectins) with sugars is multivalent (*4*). Monomeric interactions are typically weak, whereas presenting the lectin with an array of carbohydrate ligands results in significant enhancement in the binding. Thus, there is a growing interest in neoglycopolymers as multivalent ligands which can inhibit viral agglutination, act as biological sensors, and serve as models for complex biological processes (*5, 6*).

The preparation of micrometer or nanometer diameter particles that have been labeled with carbohydrates is of particular interest. This geometry offers an advantage over linear or dendritic structures in that it more closely mimics the cell surface that is the natural substrate for lectins. As such, multivalent carbohydrate liposomes (*7*−*10*), magnetic beads (*11*, *12*), quantum dots (*12*−*14*), and polymer beads (*15*) have all been explored with the aim of elucidating fundamental properties of molecular biology. π-Conjugated neoglycopolymers are also particularly useful as multivalent ligands for lectins; owing to their electrical conductivity and luminescence, they can act as signal transduction elements in biological probes and sensors. Linear sugar-functionalized poly(*p*-phenyleneethynylene)s (PPEs) have recently been prepared as fluorescence based sensors for *E. coli* bacteria, as well as a number of proteins (*16*−*21*). Similarly, Charych describes polythiophene-based biosensors for both *E. coli* and influenza virus (*22*). Additionally, the formation of conjugated networks through cross-linking has been shown to lead to enhanced charge-transfer properties (*23*). Combination of the functional properties of sugar-substituted π-conjugated cross-linked polymers with the advantages of a micro- or nanoscale spherical geometry is therefore an attractive target.

In this Communication, we report the preparation of spherical cross-linked PPE beads having diameters in the range 0.5−5 μm. Preparation of the glycoside monomers **1a**−**c** was accomplished by coupling the α-D-sugar trichloroacetimidates with 1,4-diiodo-2,5-hydroquinone using boron trifluoride diethyl etherate as a catalyst. This yields **1a**−**c** with complete inversion of stereochemistry, and no evidence for either the α-anomer or mixed α−β-anomer was found in the ^{1}H NMR spectrum. The stereochemistry was confirmed by the $J_{H1-H2} = 3$ Hz coupling constant in **1a** and the $J_{H1-H2} = 8$ Hz coupling constant in **1b** and **1c**. Subsequent reaction of **1a**−**c** with 1,4-diethynyl-2,5-dimethoxybenzene (**2**) and 1,2,4-tribromobenzene (**3**) under Sonogashira conditions (Scheme 1) forms cross-linked, insoluble polymers. To prepare micrometer-sized beads **4a**−**c**, the polymerization was carried out in an emulsion of toluene/diisopropylamine in an aqueous solution of sodium dodecyl sulfate (SDS) (*24*). The polymerization is templated by the formation of the organic micelles, and the SDS helps to stabilize smaller micelles of micrometer dimensions. The particles were washed with copious quantities of toluene and methanol in order to remove both oligomers and linear polymer. Subsequent treatment with ca. 0.5 M sodium methoxide in methanol

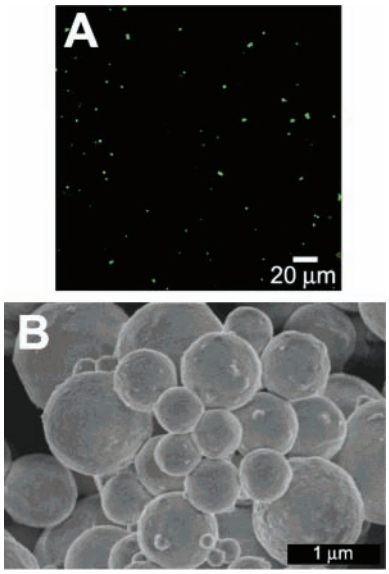

Figure 1. (A) Fluorescence confocal micrograph (*Z*-axis projection) of **4c**, exciting at 488 nm. (B) Scanning electron micrograph of **4c** showing a cluster of polymer beads. Results for **4a** and **4b** are similar.

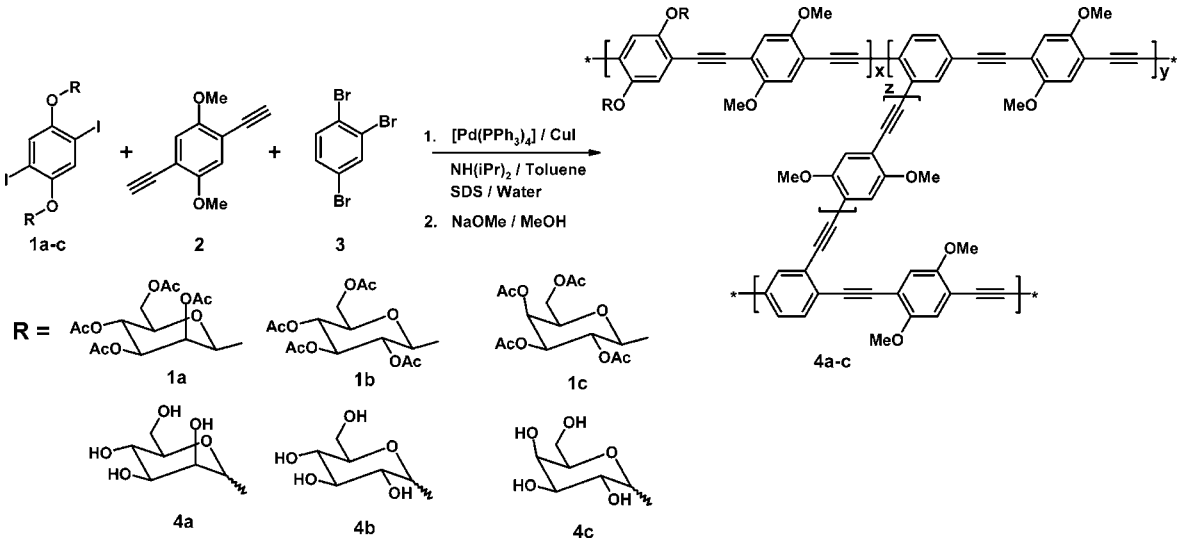
Scheme 1. Polymerization under Sonogashira Conditions To Form Cross-Linked PPE Microparticles[a]



[a] R = β-D-mannose tetraacetate (**1a**), β-D-glucose tetraacetate (**1b**), β-D-galactose tetraacetate (**1c**), D-mannose (**4a**), D-glucose (**4b**), and D-galactose (**4c**).

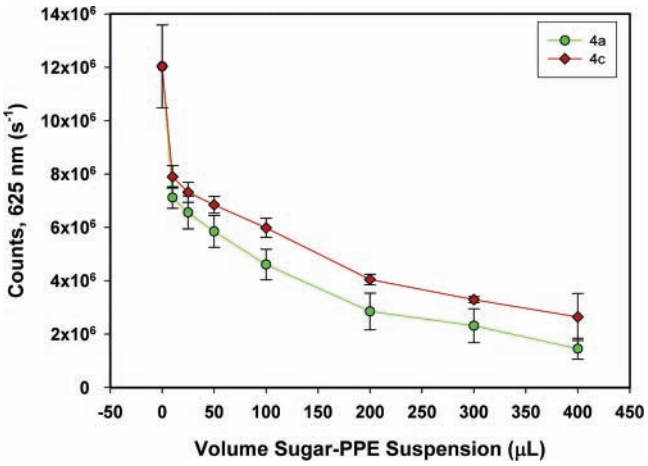


Figure 2. Plot showing the extraction of Concanavalin A-Texas Red conjugate by the mannose-modified (**4a**, green circles) and galactose-modified (**4c**, red diamonds) microparticles. Data are averaged from binding assays on two separate preparations of microparticles.

removes the acetate protecting groups on the precursors to polymers **4a**−**c**. Successful removal of the acetate groups is evidenced by the absence of the distinctive carbonyl stretch in the infrared spectrum (prior to deprotection, a distinctive carbonyl stretch at 1751 cm^{-1} was observed. After treatment with sodium methoxide, this signal disappeared).

Once deprotected, the particles are readily redispersed in polar solvents such as water or methanol by either vigorous shaking or sonication. Analysis of particle size by laser scanning confocal microscopy (Figure 1) shows a mean particle diameter of ≈4.9 μm. This number reflects the formation of aggregates in solution. When evaluated by scanning electron microscopy, the mean particle diameter was found to be ≈0.8 μm. As expected for polymers derived from the PPE backbone, **4a**−**c** were found to be emissive as suspensions in water and organic solvents, although only very weakly in the dry solid state. The emission band is centered at 560 nm in methanol, which is markedly red-shifted compared to linear PPEs in dilute solution (*18, 21*). Bunz and co-workers have shown that aggregation of alkyl-PPEs in solvent/nonsolvent mixtures or in thin films results in a substantial bathochromic shift of the emission spectrum (*25*). In this case, the short methoxy substituents are not long enough to prevent interchain aggregation, and both hydrogen bonding of the carbohydrate groups and cross-linking of the chains may encourage this phenomenon. While the emission spectra of the microparticles prepared by Weder (*24*) show no such shift, this is likely due to the bulkier 2-ethylhexyl and *n*-octyl substituents, which lead to a more porous bead structure that is readily swollen by organic solvents.

To probe the versatility of these PPE beads for potential biosensor, biocapture, or affinity chromatography application, their binding to lectins was examined. Suspensions (1 mg/mL) of **4a** (mannose-modified) and **4c** (galactose-modified) were prepared in 0.1 M PBS buffer (pH 7.2) containing 1 mM $CaCl_2$ and 1 mM $MnCl_2$, the cofactors required for the lectin Concanavalin A (*4*). Similarly, a 1 mg/mL stock solution of Concanavalin A−Texas Red (ConA-TR) conjugate was prepared

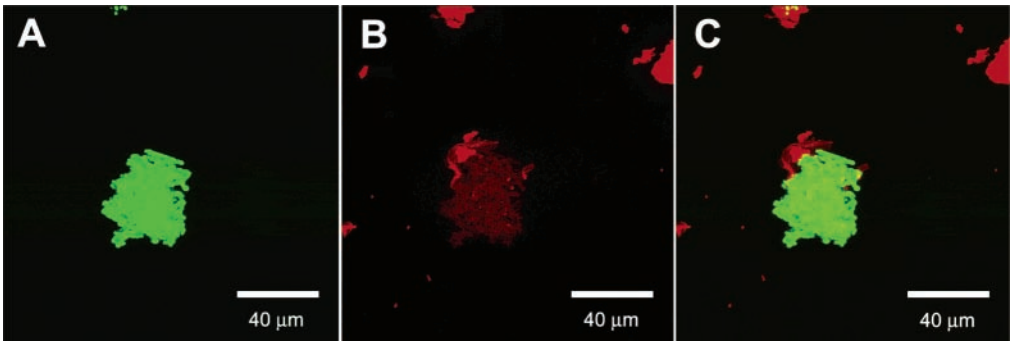

Figure 3. Fluorescence confocal micrographs (*Z*-axis projection). (A) 488 nm excitation, showing a cluster of mannose microparticles after incubation with ConA-TR. (B) 568 nm excitation, showing the presence of the tagged protein. (C) Merged image.

in the same matrix. Aliquots (100 μL) of the ConA-TR solution were mixed with varying amounts (0−400 μL) of the polymer suspensions. All samples were diluted to a total of 500 μL with PBS. After incubating for 4 h at room temperature, the samples were centrifuged at 7500 rpm for 5 min, and the supernatant was removed. The isolated supernatants were then analyzed for protein content by a fluorescence assay at 625 nm (quantifying Texas Red emission). As seen in Figure 2, there is clearly an extraction of the protein from the supernatant as compared to the blank (0 μL of polymer suspension), which is greater for **4a** compared to **4c**. Data in Figure 2 is averaged between two different preparations of microparticles. If multiple assays on a single batch of particles are performed, the results show less variability, suggesting that batch-to-batch differences in particle size distribution are significant. While Concanavalin A should exhibit no binding affinity toward galactose, there is clearly a nonspecific interaction present (*19*). This may be due to nonspecific van der Waals interactions, hydrogen bonding, or protein adsorption on the polymer bead.

Glucose also binds to Concanavalin A with a binding affinity lower than that of mannose, and the glucose microparticles (**4b**) were also investigated for their binding to lectin. Significant batch-to-batch differences in binding were observed. Additionally, **4b** showed an increased propensity for aggregation and sedimentation compared to **4a** and **4c**. Zeta potential measurements (ζ = −14, −30, and −11 mV for **4a**, **4b**, and **4c**, respectively) suggest a greater surface charge density for **4b**. At present this anomalous behavior is not understood, and the binding data is not included in Figure 2.

A competition experiment was also carried out, where 100 μL of ConA-TR solution, 200 μL of polymer suspension, and 200 μL of a 0.3 M D-mannose solution were incubated under identical conditions to those described above. For both **4a** and **4c** there was an increase in fluorescence intensity (20% and 9% respectively) of the supernatant, indicating a decrease in binding. The free sugar effectively competes for protein binding sites, and aqueous sugar solutions could presumably be used to remove bound protein from a sample of polymer.

The isolated protein-polymer bioconjugates were washed twice with 200 μL aliquots of fresh PBS buffer and suspended in 50 μL of PBS. Fluorescence confocal microscopy is used to confirm the binding to the microparticles; it shows colocalization of the polymer beads with the Texas Red fluorophore. Additionally, there appears to be some degree of aggregation among the individual polymer beads upon lectin binding. This phenomenon is quite similar to cellular agglutination, which is mediated by the multivalent character of lectins; by binding sugar residues on more than one cell, the proteins link the cells together in large aggregates (*4*). Owing to the similar size of these microparticles (ca. 5 μm) and erythrocytes (ca. 7 μm), their highly fluorescent properties, and their surface carbohydrate residues, these beads may prove to be useful models in the study of agglutination and other important biological processes. The mannose-substituted polymer beads may also form clusters with *E. coli* bacteria in a manner analogous to the mannosylated-PPE of Swager (*17*), making them useful as fluorescent tags for pathogens.

In conclusion, we have prepared sugar-substituted, cross-linked PPE microparticles by a templated Pd-catalyzed cross-coupling reaction. The polymer beads are fluorescent and exhibit a substantial bathochromic shift in the emission spectrum compared to linear, alkyl-substituted PPEs. Binding to the lectin Concanavalin A was demonstrated, with some evidence of agglutination, forming the basis of a potential blood erythrocyte mimic. These particles also hold promise as a high surface area packing material for the purification of lectins by affinity chromatography, and in biocapture and tagging applications for pathogenic agents such as *E. coli*, influenza, or ricin.

Received October 8, 2005; Revised Manuscript Received February 3, 2006

Biotin and avidin form one of the most stable complexes known ($K_D = 10^{-15}$ M^{-1}) making this pairing attractive for a variety of biomedical applications including targeted radiotherapy. In this application, one of the pair is attached to a targeting molecule, while the other is subsequently used to deliver a radionuclide for imaging and/or therapeutic applications. Recently, we reported a new single amino acid chelate (SAAC) capable of forming stable complexes with $Tc(CO)_3$ or $Re(CO)_3$ cores. We describe here the application of SAAC analogues for the development of a series of novel radiolabeled biotin derivatives capable of forming robust complexes with both Tc and Re. Compounds were prepared through varying modification of the free carboxylic acid group of biotin. Each ^{99m}Tc complex of SAAC−biotin was studied for their ability to bind avidin, susceptibility to biotinidase, and specificity for avidin in an in vivo avidin-containing tumor model. The radiochemical stability of the ^{99m}Tc$(CO)_3$ complexes was also investigated by challenging each ^{99m}Tc-complex with large molar excesses of cysteine and histidine at elevated temperature. All compounds were radiochemically stable for greater than 24 h at elevated temperature in the presence of histidine and cysteine. Both [^{99m}Tc$(CO)_3$(**L6**)]$^{+1}$ [**TcL6**; **L6** = biotinylamidopropyl-*N*,*N*-(dipicolyl)amine] and [^{99m}Tc$(CO)_3$(**L12a**)]$^{+1}$ (**TcL12**; **L12** = *N*,*N*-(dipicolyl)biotinamido-Boc-lysine; **TcL12a**; **L12a** = *N*,*N*-(dipicolyl)biotinamide-lysine) readily bound to avidin whereas [^{99m}Tc$(CO)_3$(**L9**)]$^{+1}$ [**TcL9**; **L9** = *N*,*N*-(dipicolyl)biotinamine] demonstrated minimal specific binding. **TcL6** and **TcL9** were resistant to biotinidase cleavage, while **TcL12a**, which contains a lysine linkage, was rapidly cleaved. The highest uptake in an in vivo avidin tumor model was exhibited by **TcL6**, followed by **TcL9** and **TcL12a**, respectively. This is likely the result of both intact binding to avidin and resistance to circulating biotinidase. Ligand **L6** is the first SAAC analogue of biotin to demonstrate potential as a radiolabeled targeting vector of biotin capable of forming robust radiochemical complexes with both ^{99m}Tc and rhenium radionuclides. Computational simulations were performed to assess biotin-derivative accommodation within the binding site of the avidin. These calculations predict that deformation of the surface domain of the binding pocket can occur to accommodate the transition metal−biotin derivatives with negligible changes to the inner-β-barrel, the region most responsible for binding and retaining biotin and its derivatives. The biological activity and biodistribution of the technetium complexes **TcL6**, **TcL9**, and **TcL12a** were examined in an avidin tumor model. In the avidin bead tumor localization model, **TcL6** demonstrated the most favorable localization with a 7:1 ratio of avidin bead implanted muscle versus normal muscle, while **TcL9** exhibited a 2:1 ratio. However, **TcL9** displayed no specificity for avidin.

INTRODUCTION

Biotin is a water-soluble member of the B-complex group of vitamins and is commonly referred to as vitamin H. The molecule acts as a carrier of CO_2 in the pyruvate carboxylase reaction, where biotin is linked to the ϵ-amino group of a lysine residue in the enzyme (*1*, *2*). Biotin is necessary for both metabolism and growth in humans, particularly in the production of fatty acids, antibodies, digestive enzymes, and in niacin (vitamin B-3) metabolism (*3*, *4*). Biotin has nine host molecules with which it is associated, including pyruvate carboxylase, β-methylcrotonyl-CoA carboxylase, propinyl-CoA carboxylase, and acetyl-CoA-carboxylase in humans. Biotin is also bound by avidin, a homotetrameric glycoprotein (molecular weight ~ 63 000 Da), each monomer of which binds a single biotin molecule. The noncovalent interaction between avidin and biotin is the strongest binding between a ligand and a protein known ($K_d = 10^{-15}M^{-1}$), resulting in important applications in immunology, bioanalytical chemistry (*5*), and targeted radiotherapy of cancer (*6*). These observations suggest that the effective linking of biotin to the radionuclides ^{99m}Tc and ^{186,188}Re would provide applications to imaging (*7*−*10*) and radiotherapy (*11*), respectively.

We have described the design of a family of bifunctional chelators from natural amino acids or synthetic analogues (single

amino acid chelates, SAAC), which provide for robust coordination of the $\{M(CO)_3\}^{+1}$ (M = Tc, Re) core and a linker group for attachment to biomolecules (*12*). It was further demonstrated that the SAAC−Re complexes could be incorporated within peptide sequences using an automated peptide synthesizer (*13*). These successful applications of the technology have encouraged us to extend the general approach to other biomolecules.

A variety of biotin derivatives incorporating a tridentate chelator for binding of $\{M(CO)_3\}^{+1}$ (M = ^{99m}Tc and ^{186,188}Re) have been prepared. These M(I)-tricarbonyl cores were chosen because of their useful properties for the development of radiopharmaceuticals (*14*−*16*). For instance, the precursor complexes to the radioconjugates, *fac*-$[M(CO)_3(H_2O)_3]^{+1}$, may be readily prepared in a kit formulation. The aqua ligands of the precursor complexes are readily substituted by a variety of donor groups. Moreover, the *fac*-$\{M(CO)_3\}^{+1}$ core is chemically robust, low-spin d^6, providing a useful platform for further chemical development. The organometallic nature of the M(I)-tricarbonyl cores combined with the tridentate chelate dipicolylamine (dpa), yields a highly stable metal complex which is a prerequisite for effective in vivo radiotargeting (*17*).

In this contribution, we discuss the syntheses and characterizations of novel biotin-chelate derivatives and of their $\{^{99m}Tc(CO)_3\}^{+1}$ and $\{Re(CO)_3\}^{+1}$ complexes, their stability toward biotinadase, their affinity and specificity for avidin, the ^{99m}Tc-labeling and the stability of the ^{99m}Tc conjugates toward cysteine and histidine challenges and the biodistribution of the radiolabeled compounds in an avidin tumor model. In addition, molecular modeling studies have been undertaken to explore the derivatized biotin−avidin interactions and to assess the structural implications of the work presented in this paper.

EXPERIMENTAL PROCEDURES

General. All reactions were performed under an inert atmosphere of argon, unless otherwise noted. Solvents and chemicals obtained from commercial sources were analytical grade or better and used without further purification. D-Biotin was purchased from Aldrich Chemical Co. (Milwaukee, WI). Avidin was purchased from Pierce Biotechnology (Rockford, IL) and used as a solution diluted with PBS to pH 7.2 as noted in the literature reference (*18*). All experiments were performed in duplicate or triplicate to ensure reproducibility.

Spectroscopy. ^{13}C NMR and ^{19}F NMR spectra were obtained on a Bruker Avance system at 500 and 300 MHz, respectively. Proton chemical shifts are expressed as parts per million versus tetramethylsilane in deuterated solvent. ^{13}C NMR data were obtained on a Bruker Avance 75 MHz system versus a C of the deuterated solvent. IR spectra were obtained as solutions dissolved in methanol and run on a Perkin-Elmer Paragon 1000 FT-IR spectrophotometer. HRMS data were obtained on a 3-Tesla Fourier Transform mass spectrometer with an ESI source in positive ion mode. Mass spectrometry samples were prepared in MeOH/THF with added NaCl. Melting points were obtained on a Barnstead International apparatus and are uncorrected.

Chromatography. Silica gel chromatography was performed using silica gel purchased from EM Science (Gibbstown, NJ), silica gel 60 Geduran, 40−63 μm. Alumina chromatography was performed using alumina purchased from Aldrich (Milwaukee, WI). Alumina used was weakly acidic aluminum oxide, activated Brockmann I standard grade 150 mesh, 58 Å. In addition, basic aluminum oxide, activated, 150 mesh, 58 Å was used as noted in the experimental descriptions.

SYNTHETIC PROCEDURES

2,3,5,6-Tetrafluorophenyl Trifluoroacetate (1). Compound **1** was prepared by following literature procedure (*19*).

Dipicolyl Propyl Phthalimide (2). Bromopropyl phthalimide (10.4 g, 38.8 mmol) was added to dry THF (85 mL) in a 100-mL round-bottom flask. Tetrabutylammonium iodide (2.9 g, 7.8 mmol) was added, and the clear, light yellow solution was stirred for 5 min at room temperature. Dipicolylamine (7.0 mL, 38.8 mmol) was added, followed by Na_2CO_3 (16.4 g, 155.0 mmol). After the sample was refluxed for 10 min, the solution turned a dark orange color. The mixture was heated to reflux overnight to give a dark, red-brown suspension which was filtered and the residue evaporated to a dark, red-brown oil. The oil was passed through a silica gel column with $CHCl_3$/MeOH (40:1) to yield a clear, orange oil isolated in 60% yield after purification. ^{1}H NMR ($CDCl_3$, δ, 300 MHz): 1.93 (t, J = 7.2 Hz, 2H), 2.64 (m, 2H), 3.68−3.74 (m, 2H), 7.11 (t, J = 6.3 Hz, 2H), 7.53, (d, 7.8 Hz, 2H), 7.62 (t, J = 7.8 Hz, 2H), 7.60−7.70 (m, 2H), 7.82 (dd, J_A = 5.3 Hz, J_B = 3.2 Hz, 2H), 8.48 (d, J = 4.2 Hz, 2H); ^{13}C NMR ($CDCl_3$,? δ, 75 MHz): 26.2, 36.2, 51.5, 60.3, 76.8, 121.9, 123.1, 132.1, 133.9, 136.4, 148.9, 159.6, 168.3; HRMS calcd for $C_{23}H_{22}N_4O_2Na^+$ 409.1635, found 409.1640; IR (MeOH): 1396 and 1700 cm^{-1}.

***N,N*-Dipicolyl Propylamine (4).** Dipicolyl propyl phthalimide (**2**) (10.3 g, 27.1 mmol) was added to EtOH (39 mL) in a 100-mL round-bottom flask. Hydrazine monohydrate (1 mL) was added, resulting in a clear orange solution that was heated to reflux for 3 h, whereupon HCl (35 mL, 12 M) was added. The solution was allowed to reflux an additional 2 h. Addition of HCl (12 M) to the cooled solution provided a light yellow precipitate. After partitioning between deionized water and $CHCl_3$, the aqueous layer was made basic with 1 M NaOH and extracted with $CHCl_3$. The clear, light yellow chloroform layer was dried over magnesium sulfate, filtered, and evaporated to yield a clear, light yellow-orange oil. Column chromatography over silica gel with CH_2Cl_2/MeOH (95:5) provided the product as a clear, light yellow oil in 90% yield. ^{1}H NMR ($CDCl_3$, δ, 300 MHz): 2.04 (t, J = 6.5 Hz, 2H), 2.75 (t, J = 5.57 Hz, 2H), 3.80 (s, 4H), 7.1 (dd, J_A = 6.3 Hz, J_B = 5.4 Hz, 2H), 7.31 (d, 7.2 Hz, 2H), 7.62 (t, 7.8 Hz, 2H), 8.69 (d, J = 5.1 Hz, 2H); ^{13}C NMR ($CDCl_3$, δ, 75 MHz): 31.4, 40.6, 52.0, 60.7, 122.1, 123.0, 136.5, 149.2, 160.0; HRMS calcd for $C_{15}H_{20}N_4H^+$ 257.1761, found 257.1746.

Biotin TFP-ester (5). Biotin TFP-ester was prepared using a modified literature procedure (*20*).

Biotinylamido-propyl (Dipicolyl)amine (L6). Biotin TFP-ester (**5**) (1.2 g, 2.9 mmol) was dissolved in DMF (10 mL) in a 25-mL round-bottom flask. Dipicolyl propylamine (**4**) (0.5 mL, 2.9 mmol) and NEt_3 (0.5 mL, 3.2 mmol) were added to (**5**) at room temperature, and the resulting clear, light yellow solution was heated to 50 °C and stirred overnight. The solution was then evaporated to give a dark green, sticky oil. The oil was evaporated in vacuo at 70 °C to give a hard, glassy greenish-white powder, which was washed with THF at room temperature (4 × 10 mL) to yield a white residue in >95% yield, mp 135−136 °C. ^{1}H NMR (DMSO-d_6, δ, 300 MHz): 1.2−1.7 (m, 8H), 2.02 (t, J = 7.2 Hz, 2H), 2.4−2.6 (m, 2H), 2.55 (d, J = 12.6 Hz), 2.81 (dd, J_A = 12.3 Hz, J_B = 4.8 Hz, 1H), 3.02−3.06 (m, 3H), 3.72 (s, 4H), 4.13 (m, 1H), 4.31 (m, 1H), 6.40 (d, J = 21.0 Hz, 2H), 7.25 (dd, J_A = 5.9 Hz, J_B = 5.9 Hz, 2H), 7.50 (d, J = 7.8 Hz, 2H), 7.76 (dd, J_A = 6.9 Hz, J_B = 6.9 Hz, 2H), 8.48 (d, J = 4.5 Hz, 2H); ^{13}C NMR (DMSO-d_6, δ, 75 MHz): 25.3, 26.7, 28.0, 28.2, 35.2, 36.7, 51.4, 55.4, 59.2, 59.6, 61.0, 79.2, 122.1, 122.6, 136.5, 148.7, 159.4, 162.7, 171.9; HRMS calcd for $C_{25}H_{34}N_6O_2SNa^+$: 505.2356, found: 505.2359; IR (MeOH): 1647 and 1699 cm^{-1}.

Biotinamide (7) and Biotinamine (8). Biotinamide and biotinamine were prepared by the literature methods (*21a*−*c*).

N,N-(Dipicolyl)biotinamine (L9). Biotinamine (**8**) (203 mg, 0.9 mmol) was added to DCE (11 mL) to give a clear, light

yellow-brown solution. Pyridine carboxaldehyde (0.2 mL, 1.8 mmol) was added, and the solution was stirred at room temperature for 30 min. Addition of $Na(OAc)_3BH$ (954 mg, 4.5 mmol), followed by holding at reflux overnight, provided a dark brown solution. The reaction was quenched with saturated $NaHCO_3$ solution (20 mL) and extracted with CH_2Cl_2 (5 × 20 mL). The combined organic phases were evaporated and purified on a silica gel column with CH_2Cl_2 (95:5) to yield a fluffy, light yellow powder in 55% yield. ^{1}H NMR ($CDCl_3$, δ, 300 MHz): 1.2−1.7 (m, 10H); 2.5 (t, J = 7.5 Hz, 2H); 2.90 (dd, J_A = 13.2 Hz, J_B = 4.8 Hz, 1H); 3.00 (d, J = 13.2 Hz, 1H); 3.1−3.2 (m, 1H); 3.73 (s, 4H); 4.2−4.3 (m, 1H); 4.7−4.8 (m, 1H); 7.22 (t, J = 6.9 Hz, 2H); 7.56 (d, J = 7.8 Hz, 2H); 7.73 (t, J = 8.1 Hz, 2H); 8.37 (d, J = 4.8 Hz, 2H); ^{13}C NMR ($CDCl_3$, δ, 75 MHz): 27.8, 28.3, 29.6, 30.1, 37.9, 55.6, 56.9, 60.9, 61.1, 124.0, 125.0, 138.8, 149.5, 160.8, 161.6; HRMS calcd for $C_{22}H_{29}N_5OSNa^+$: 434.1985, found 434.2008; IR (MeOH): 1702 cm^{-1}.

Biotin-Boc-lysine-OH (10) and Biotin-Boc-lysine-TFP ester (11). Biotin-Boc lysine and biotin-Boc-lysine-TFP ester were prepared by a modified literature procedure (*21a*−*c*).

***N*,*N*-(Dipicolyl)biotinamide-Boc-lysine (L12).** Biotin-Boc-lysine-TFP ester (**11**) (597 mg, 0.96 mmol) was added to a 10 mL round-bottom flask with DMF (4 mL). To the clear, light yellow solution was added Na_2CO_3 (204 mg, 1.92 mmol), followed by (**4**) (250 mg, 0.96 mmol). The solution was then heated to 40 °C and stirred overnight. After heating overnight, the clear, light brown solution was evaporated to dryness. The light brown powder was then purified by column chromatography on neutral alumina with CH_2Cl_2:MeOH (90:10), 1% NEt_3 and the product isolated in 85% yield. ^{1}H NMR ($CDCl_3$, δ, 300 MHz): 1.3−1.7 (m, 21H); 2.13 (t, J = 7.2 Hz, 2H); 2.54 (t, J = 6.6 Hz, 2H); 2.62 (d, J = 12.6 Hz, 1H); 2.86 (dd J_A = 12.6 Hz, J_B = 4.8 Hz, 1H); 3.1−3.2 (m, 1H); 3.73 (s, 4H); 4.2−4.3 (m, 1H); 3.9 (m, 1H); 4.30 (dd, J_A = 7.8 Hz, J_B = 5.1 Hz, 1H); 7.23 (t, J = 5.4 Hz, 2H); 7.54 (d, J = 7.8 Hz, 2H); 7.74 (t, J = 7.8 Hz, 2H); 8.39 (d, J = 4.8 Hz, 1H); ^{13}C NMR ($CDCl_3$, δ, 75 MHz): 24.0, 27.0, 28.0, 29.0, 30.0, 31.0, 32.0, 34.0, 37.0, 39.0, 40.0, 41.0, 54.0, 56.0, 57.0, 61.0, 62.0, 64.0, 81.0, 124.0, 125.0, 139.0, 150.0, 158.0, 161.0, 167.0, 175.0, 176.0; HRMS calcd for $C_{36}H_{54}N_8O_5SNa^+$: 733.3830, found 733.3818.

Biotinol (13). Biotinol was prepared using a reported procedure (*21a*,*c*).

[Re(CO)$_3$(L6)]Br (ReL6). The clear colorless solution obtained by dissolving **L6** (68 mg, 0.16 mmol) in CH_2Cl_2 (1 mL) was placed in a 10-mL round-bottom flask. $[NEt_4]_2[Re(CO)_3Br_3]$ (123 mg, 0.16 mmol) was added at room temperature. The resulting white slurry was heated to reflux for 3 h, then stirred at room-temperature overnight. The clear light yellow solution, mixed with a small amount of white precipitate, was evaporated to dryness and purified by chromatography with CH_2Cl_2/MeOH (95:5) over acidic alumina, giving the product in quantitative yield, mp: 70−71 °C. ^{1}H NMR ($CDCl_3$, δ, 300 MHz): 1.4−1.9 (m, 6H), 2.2−2.5 (m, 4H), 2.75 (d, J = 12 Hz, 1H), 2.88 (dd, J_A = 12 Hz, J_B = 4.5 Hz, 1H), 3.1−3.3 (m, 2H), 3.51 (m, 1H), 3.7−3.8 (m, 2H), 4.30−4.34 (m, 1H), 4.46−4.53 (m, 1H), 4.75 (dd, J_A = 18.9 Hz, J_B = 18.9 Hz, 2H), 5.37 (dd, J_A = 18.0 Hz, J_B = 12.0 Hz, 2H), 7.29−7.33 (m, 2H), 7.91 (dd, J_A = 4.4 Hz, J_B = 4.4 Hz, 2H), 8.8 (m, 2H); ^{13}C NMR (DMSO-d_6, δ, 75 MHz): 26.4, 27.0, 29.6, 29.9, 37.0, 37.7, 41.3, 57.2, 61.6, 63.4, 68.9, 69.8, 124.9, 127.0, 141.8, 153.2, 162.1, 166.0, 176.4, 196.5, 197.4; HRMS calcd for (M-Br) $C_{28}H_{34}BrN_6O_5ReS$: 753.1863, found: 753.1863; IR (MeOH): ν(C═O) of $\{Re(CO)_3\}^+$ unit: 1920 and 2028 cm^{-1}; ν(C═O) urea: 1691 cm^{-1}.

[Re(CO)$_3$(L9)]Br (ReL9). $[Re(CO)_3(H_2O)_3]Br$ was added to a clear, pale yellow solution of **L9** (35.0 mg, 0.08 mmol) in MeOH (3 mL) and the solution was heated to reflux overnight. A bright yellow precipitate of **ReL9** was obtained by slow evaporation of the solution in quantitative yield, mp: 202−204 °C. ^{1}H NMR (DMSO-d_6, δ, 300 MHz): 1.4−1.8 (m, 6 H), 1.8−2.0 (m, 2H), 2.67 (d, J = 12.9 Hz), 2.91 (dd, J_A = 12.6 Hz, J_B = 5.1 Hz), 3.3 (s, 4H), 3.8 (m, 2H), 4.30−4.34 (m, 1H), 4.46−4.53 (m, 1H), 7.30 (t, J = 6.1 Hz, 2H), 7.48 (d, J = 7.5 Hz), 7.8−7.9 (m, 2H), 8.80 (d, J = 5.1 Hz, 2H); ^{13}C NMR (DMSO-d, δ, 75 MHz): 26.3, 27.8, 29.8, 30.2, 41.2, 57.2, 61.9, 63.7, 69.0, 72.1, 124.9, 127.0, 141.8, 153.2, 162.4, 196.6, 197.4; HRMS calcd for (M-Br) $C_{25}H_{29}N_5O_4ReS^+$: 682.1492, found 682.1518; IR (MeOH): 1920 and 2028 cm^{-1}.

[Re(CO)$_3$(L12)]Br (ReL12). $[Re(CO)_3(H_2O)_3]Br$ (41 mg, 0.10 mmol) was added to a clear, pale yellow solution of **L12** (100 mg, 0.09 mmol) in MeOH (1 mL), and the solution was heated to reflux overnight. A pale yellow precipitate of **ReL12** was obtained by slow evaporation of the solution. The light yellow powder was then columned over weakly acidic alumina using CH_2Cl_2/MeOH (90:10) to yield a fine, fluffy light yellow powder quantitatively, mp: 191−192 °C. ^{1}H NMR (DMSO-d_6, δ, 300 MHz): 1.3−1.7 (m, 6 H), 2.13 (t, J = 7.2 Hz, 2H), 2.54 (t, J = 6.6 Hz, 2H), 2.64 (d, J = 12.6 Hz, 1H), 2.87 (dd, J_A = 12.6 Hz, J_B = 4.8 Hz, 1H), 3.1−3.2 (m, 1H), 3.25 (s, 4H), 4.24 (m, 1H), 4.43 (dd, J_A = 7.8 Hz, J_B = 5.1 Hz, 1H), 7.23 (t, J = 5.4 Hz, 2H), 7.54 (d, J = 7.8 Hz), 7.74 (t, J = 7.8 Hz, 2H), 8.40 (d, J = 4.8 Hz, 2H); ^{13}C NMR (CD_3OD, δ, 75 MHz): 24.5, 26.3, 27.0, 28.9, 29.6, 29.9, 30.2, 33.0, 36.9, 37.7, 40.1, 41.2, 56.7, 57.2, 61.7, 63.5, 68.0, 69.8, 80.5, 124.8, 127.1, 141.8, 153.3, 158.0, 162.3, 166.2, 176.0, 196.5, 197.3; HRMS calcd for $C_{39}H_{54}BrN_8O_8ReSH^+$: 981.3343, found 981.3369.

Technetium Chemistry. ^{99m}Tc is a γ-emitting radionuclide. Standard safety precautions were adhered to throughout the investigation.

Technetium-99m was obtained as $Na^{99m}TcO_4$ in saline, from a commercial ^{99}Mo/^{99m}Tc generator (Cardinal Health). Technetium-99m (^{99m}Tc) is a γ emitter (140 keV) with a half-life of 6 h. Complexes were characterized using HPLC (Varian Prostar 510; column: Vydac C18 (25 cm × 4.6 mm); gradient elution: 5−95%B from 3 to 21 min at 1 mL/min for 30 min; mobile phase: A = triethylammonium phosphate pH 2.5 and B = methanol; UV detector: Varian model 345 set at 254 nm; radioactivity detector: NaI(Tl) gamma detector, Bicron Friske Tech)

$[^{99m}Tc(CO)_3(H_2O)_3]^{+1}$ 22 was prepared using the following general procedure: 1.0 mL of $^{99m}TcO_4^-$ from a commercial generator (50−200 mCi) was added to commercially available Isolink kits (Mallinckrodt). The solution was heated in an oil bath at 100 °C for 30 min. The solution was then cooled for 5 min, vented, and 1 N HCl (150 μL) was added to neutralize the solution.

In a sealed vial, $[^{99m}Tc(CO)_3(H_2O)_3]^{+1}$ was mixed with the biotin derivative (**L6**, **L9,** and **L12**; 0.01 mg dissolved in 0.5 mL of methanol) and heated at 100 °C for 30 min. After the sample was cooled, the reaction mixture was analyzed by reverse phase-HPLC. The $[Tc(CO)_3(LX)]^{+1}$ complexes, **TcL6**, **TcL9**, and **TcL12a**, were then purified by HPLC as described above. The compound $[^{99m}Tc(CO)_3\{N,N$-(dipicolyl)biotinamido-lysine$)]^{+1}$ (**TcL12a**) was also prepared by heating $[^{99m}Tc(CO)_3\{N,N$-(dipicolyl)biotinamido-Boc-lysine$)]^{+1}$ (**TcL12**) in methanol in the presence of TFA at 100° C for an additional 30 min to effect the deprotection of the derivatized lysine.

^{99m}Tc Challenge Experiments. To test the stability of the metal complexes, the isolated ^{99m}Tc-biotin complexes (**TcL6**, **TcL9**, and **TcL12a**; 100 μL in 10% ethanol/saline) were incubated with 1 mL of 100 mM of cysteine and histidine in PBS pH 7.2 at 37 °C for 18 h. Aliquots of the incubation

mixtures were analyzed by HPLC to determine the degree of decomposition.

IN VITRO STUDIES

Biotinidase Resistance. Mouse blood (diluted 1:10 in PBS, pH 7.2) was used as a source of biotinidase to test the susceptibility of the ^{99m}Tc-biotin conjugates (**TcL6**, **TcL9**, and **TcL12a**). The HPLC isolated complexes were dried under N_2 and dissolved in 10% ethanol in saline. The HPLC-isolated ^{99m}Tc-complex (50 μL) was added to a vial containing 1 mL of diluted mouse plasma and incubated at 37 °C for 2 h. Biotinidase activity was quenched by adding 4-(hydroxymercuric)benzoic acid sodium salt in water (200 μL of 1 mg/mL solution). Subsequently, a molar excess of avidin (100 μL of 4.8 mg/8 mL water solution) was added and incubated at 37 °C for a further 30 min. The solutions were then filtered using a 30 kDa M. W. cutoff filter (Centricon YM-30). Each filter was washed three times with 1 mL of PBS pH 7.2 to ensure transfer from the membrane. The activity retained by the filter was assumed to be intact and avidin bound Tc-biotin complex. The degree of cleavage was determined as the percent radioactivity in the filtrate as compared to the total radioactivity, which was assayed using an automated gamma counter (LKB model 1282, Wallac Oy, Finland). A control for each complex was performed by adding the 4-(hydroxymercuric)benzoic acid sodium salt in water (200 μL of 1 mg/mL solution) to the mouse serum prior to addition of the Tc-biotin complex. In addition, each Tc-biotin complex was tested for binding to the filter membrane alone. Membranes were pretreated by exposure to a solution of lysine followed by washing with sterile water. Each ^{99m}Tc-biotin complex, **TcL6**, **TcL9**, and **TcL12a** was tested six times.

The filtrate was analyzed by HPLC to determine the presence of intact Tc-biotin complex. For **TcL6** and TcL9, the small amount of activity in the filtrate was shown to elute with a retention time consistent with the original complexes. For **TcL12a** > 80% of the activity eluted with retention times significantly different than the original complex.

Avidin Binding. Avidin binding was determined by incubating the HPLC-isolated ^{99m}Tc-complex (50 μL) with avidin (4.8 mg/ 8 mL water) for 30 min, followed by filtration through a 30 kDa MW cutoff filter (Centricon YM-30), and washing three times with 1 mL of PBS pH 7.2. Avidin binding was determined as the percent radioactivity retained on the filter as compared to the total radioactivity.

Protein Binding. To determine the degree of nonspecific protein binding of the complexes a 50 μL aliquot of HPLC-isolated ^{99m}Tc-complexes (in 10% ethanol in saline) were mixed with 1 mL of human serum albumin (10% in PBS pH = 7.2) and incubated for 2 h at 37 °C. The proteins were then precipitated using acetonitrile and separated using centrifugation. The protein pellet was washed twice with PBS. The pellet and washes were counted using a gamma counter and the percent protein binding was calculated as percent activity in the pellet compared to the total activity.

Biotin Competitive Binding Assay. To determine the specific avidin binding of the Tc-biotin complexes, we initially mixed radiolabeled biotin complexes with cold biotin at varying concentrations and then incubated the biotin solutions with fixed amounts of avidin. An aliquot of the HPLC-isolated ^{99m}Tc-complexes (2 μL) was added to varying concentrations of biotin in water (0, 4.7, 9.4, 36.4, 80.5, 133.3, 200 μM). A 2 μL aliquot of the Tc-biotin complex/cold biotin solutions was added to an aqueous solution of avidin (250 μL; 1×10^{-5} M). This allowed for a range in stoichiometry from 0.1:1 to 40:1. The solutions were incubated at 37 °C for 30 min, then filtered using a 30 kDa MW cutoff filter (Centricon YM-30). The filters were washed twice with 2 mL of PBS pH 7.2. Binding was determined as the percent activity remaining on the filter as compared to the total activity (filter + filtrate). All three ^{99m}Tc-biotin complexes, **TcL6**, **TcL9** and **TcL12a**, were tested in duplicate. A control was performed using 2 μL of the ^{99m}Tc-complexes added to 500 μL of water. The samples of the control were treated to the same filtration, washing, and assaying techniques as the other samples. The control ensured there was no significant binding of the complexes to the regenerated cellulose of the Centricon YM-30 filters.

IN VIVO STUDIES

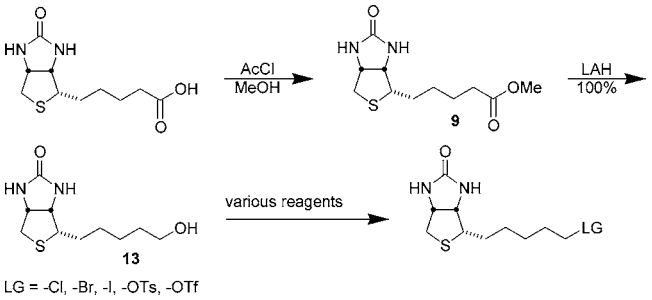
Biodistribution in the Avidin Bead Tumor Model. To assess the ability of these new biotin derivatives to target avidin in vivo, we have used an artificial tumor model of agarose beads coated with avidin injected intramuscularly, which has been previously described (*23*, *24*). Avidin coated beads (Sigma-Aldrich as avidin acrylic beads: 200−400 units/g of resin, with 1 unit binding 1.0 μg of biotin), were injected intramuscularly 24 h prior to injection of the ^{99m}Tc-labeled biotin derivatives in male rats (Sprague Dawley, at 180−200 g each, Charles River Laboratories, Burlington, MA). Groups of five rats were sacrificed at 2 and 24 h after intravenous injection of the ^{99m}Tc-labeled biotin derivatives. Tissue samples were taken including a sample of the "tumor" bearing muscle, weighed wet, and counted for radioactivity using an automated γ-counter (LKB Model 1282, Wallac Oy, Finland). An aliquot of the injected dose was also counted to allow for calculation of the percent of the injected dose in each tissue sample. The data were analyzed using Stat-View, running the application A Nova.

COMPUTATIONAL STUDIES

Molecular Mechanics/Molecular Dynamics. Molecular mechanics (MM) and molecular dynamics (MD) simulations (300 K) were performed with the program NAMD2 (*25a*). Version 22 of the CHARMM protein force field [CHARMM22] (*25b*) was used in all simulations for the avidin and was the basis for the generation of parameters of the biotin derivatives. The avidin−biotin complex starting geometry was taken from the PDB (*26*) crystal structure of its unique dimer, 1AVD (segment A), available in ref *27*. A previous study of the unbinding of biotin from avidin (*28*) saw the generation of a custom set of force field parameters and charge distributions (at the HF/6-31G* level of theory, see below) that were used in all biotin and biotin derivative MM/MD calculations. The avidin−biotin complex was studied by MM/MD simulations prior to the biotin-derivative calculations to determine what binding pocket changes occurred in the absence of crystal waters, crystallographic forces, etc., as a means of benchmarking all subsequent changes resulting from biotin modification. VMD (*29*), the graphical interface to NAMD, was used for visualization and image rendering.

The biotin−Re complexes were parametrized with the intent of reproducing molecular geometry to examine the effect of steric bulk on the binding pocket. Consequently, these biotin−Re force field parameters are an amalgam of standard CHARMM22 parameters and those generated from previous parametrization studies of transition metal complexes (*30*) based on the requirement of accounting for all of the bond, angle, and dihedral angle parameters needed to describe their molecular geometries. The molecular geometries and charge distributions of the biotin-Re pendant groups were calculated at the Restricted Hartree−Fock (RHF) level of theory with the PC-GAMESS version (*31*) of the GAMESS−US quantum chemistry package (*32*). The 6-31G* basis set (*33*) was used for all main group atoms, while the Re coordination center was treated with the

Scheme 1



SBKJC effective core potential (*34*). Full details of the computational studies are provided in the Supporting Information.

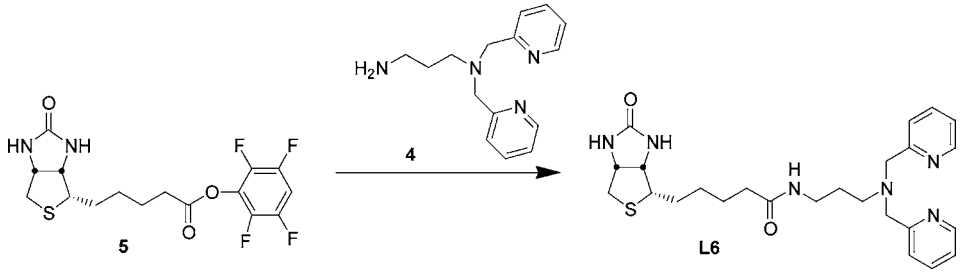
RESULTS AND DISCUSSION

Syntheses and Characterization. The literature detailing strategies for the derivatization of biotin is extensive (*35*−*39a*−*g*). A common procedure exploits reduction of the carboxylate function of biotin to the alcohol, followed by substitution with a variety of leaving groups, as illustrated in Scheme 1. However, attempts to displace the leaving groups with the potentially tridentate chelator dipicolylamine resulted in no reaction or decomposition, possibly due to the insolubility of the derivatives in common organic solvents.

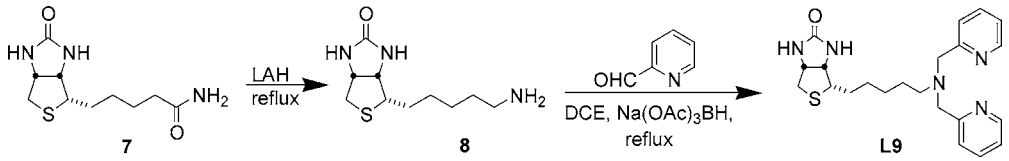
Biotin was successfully derivatized using the reaction route outlined in Scheme 2. Biotin-TFP-ester (**5**) was treated with dipicolylpropylamine (**4**) to provide biotinylamide-propyl-(dipicolyl)amine (**L6**). Alternatively, treatment of **5** with ammonium hydroxide provided biotinamide (**7**), which was then reduced with LAH to give the biotinamine (**8**). Reductive amination of **15** with the appropriate aldehydes (*40*) provided *N*,*N*-(dipicolyl)biotinamine (**L9**), as shown in Scheme 3. Similarly, the reaction of biotin-Boc-lysine-OH (**10**), prepared by the addition of Boc-lysine to biotin-TPF ester (**5**), with tetrafluorophenol and EDC provided biotin-Boc-lysine-TPF ester (**11**), which upon addition of dipicolylpropylamine (**11**) gave *N*,*N*-(dipicolyl)biotinamido-Boc-lysine (**L12**), as shown in Scheme 4.

While a number of ^{99}Tc-biotin complexes have been described previously (*41*−*48*), the chemistry of the {M(CO)$_3$} core remains largely unexplored (*49*, *50*). The rhenium tricarboxyl complexes of **L6**, **L9**, and **L12** were prepared by reactions of the ligands with [NEt$_4$]$_2$[Re(CO)$_3$Br$_3$] (*51*) or [Re(H$_2$O)$_3$(CO)$_3$]-Br (*52a*,*b*) to give [Re(CO)$_3$(**L6**)]Br (**ReL6**), [Re(CO)$_3$(**L9**)]Br (**ReL9**), [Re(CO)$_3$(**L12**)]Br (**ReL12**), respectively. It is noteworthy that the use of [Re(H$_2$O)$_3$(CO)$_3$]Br provides a much improved synthetic route as [NEt$_4$]$^{+1}$ containing byproducts are avoided, consequently obviating extensive purification procedures. The complexes were characterized by ^{1}H and ^{13}C NMR, IR, HMQC and by high-resolution mass spectrometry. A comparison of the ^{1}H NMR spectra of **ReL6**, **ReL9**, and **ReL12** with those for the biotin-chelates **L6**, **L9**, and **L12** shows that the chemical shift of the protons associated with the chelate are influenced strongly by the Re(I) core. Similarly, the ^{13}C NMR spectra of complexes **ReL6**, **ReL9**, and **ReL12** exhibited two additional peaks downfield in the 195−198 ppm region in a 2:1 ratio, assigned to the carbon atoms of the carbonyl ligands, a pattern reflecting the local symmetry of the complexes. The remaining carbonyl groups of the biotin-chelate showed no major changes from the free ligand to the complexes. Thus, the biotin ring carbonyl is observed in the 163−166 ppm region for **L6**, **L9**, and **L12** and in the range 162−167 ppm for **ReL6**, **ReL9,** and **ReL12**. The complex **ReL6** and the ligand **L6** exhibit

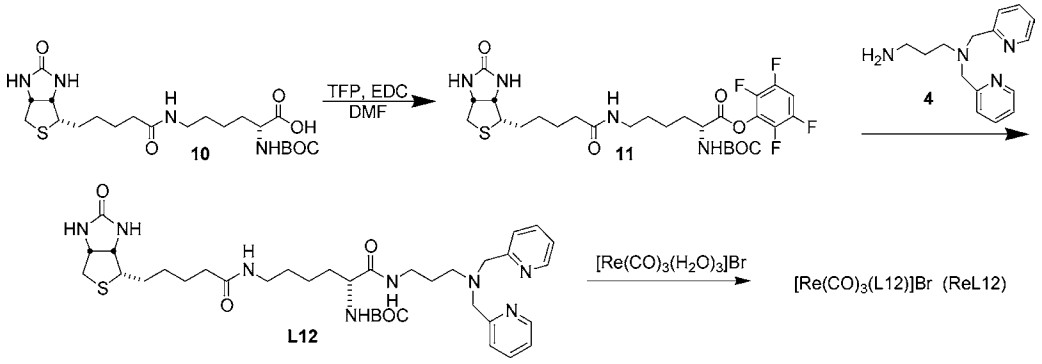
Scheme 2



Scheme 3



Scheme 4



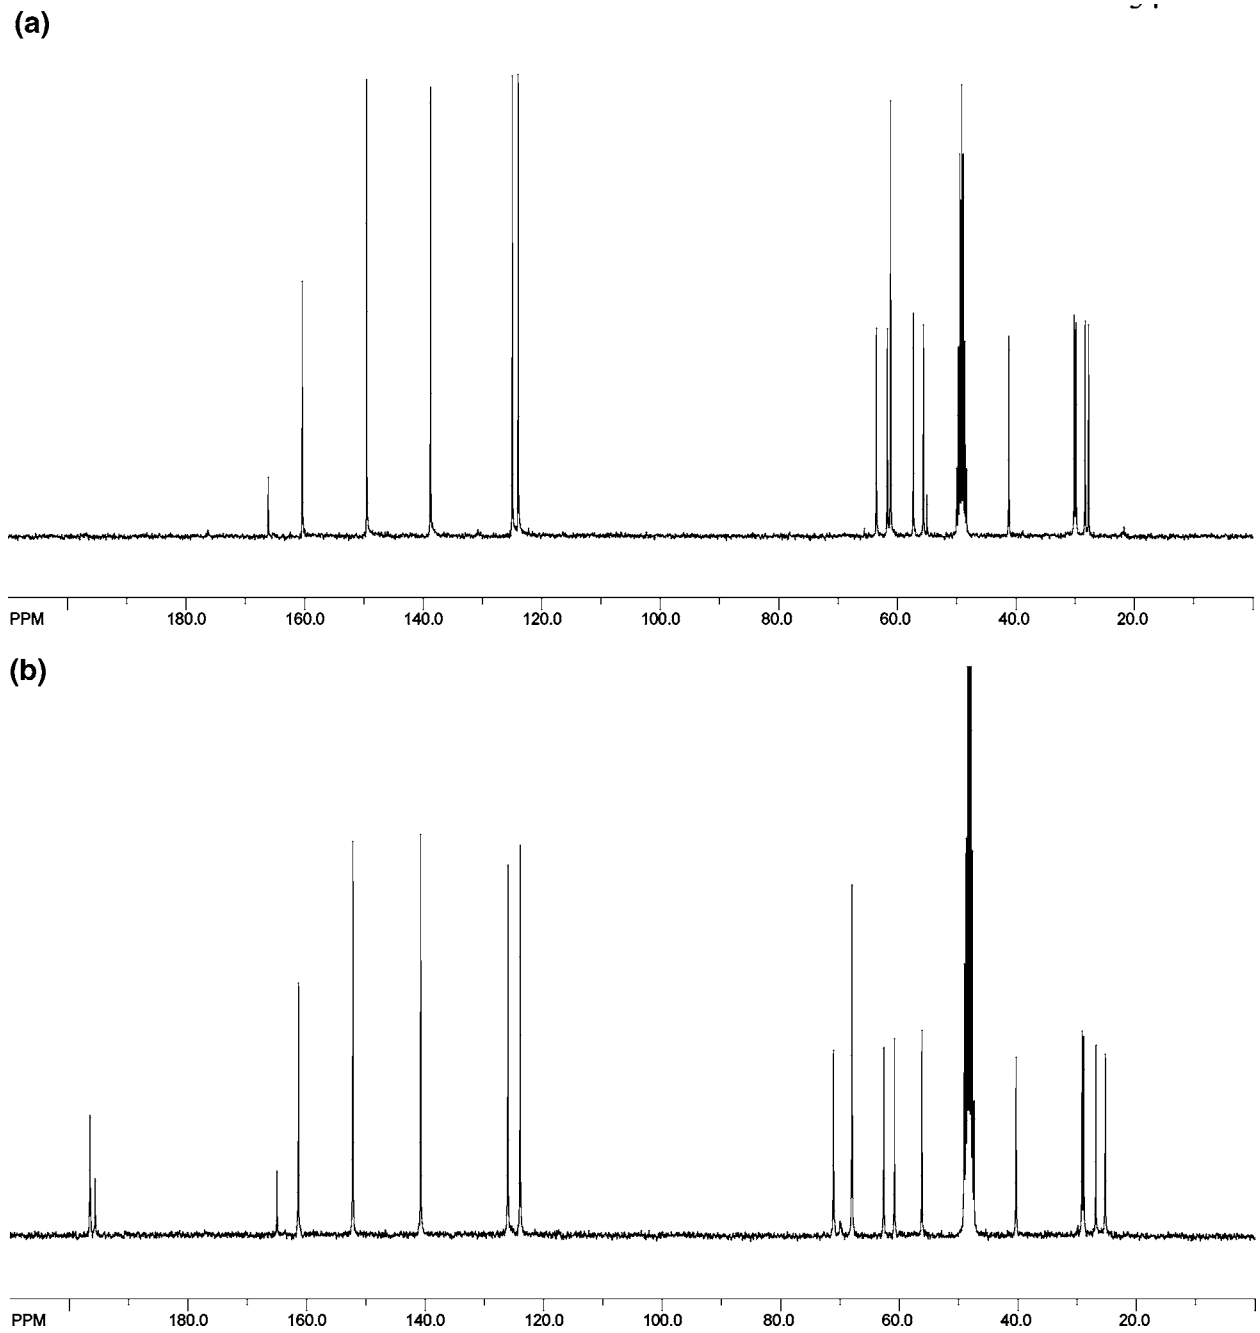


Figure 1. The ^{13}C NMR spectra of (a) **L9** and (b) **ReL9**.

cis/trans isomers associated with the amide carbonyl at 177 and 171.5 ppm, respectively. As shown in Figure 1, for **L9** and **ReL9**, only the carbon atoms in close proximity to the Re center exhibited significant shifts. The high-resolution mass spectra of the complexes, obtained in MeOH/THF were also consistent with the proposed structures.

The $[^{99m}Tc(CO)_3(H_2O)_3]^{+1}$ was mixed with the appropriate biotin derivatives **L6**, **L9**, and **L12** (0.01 mg) in 0.5 mL of methanol. The sealed vial was heated at 100 °C for an additional 30 min. After cooling of the sample, the reaction was checked for purity via HPLC, and methanol was used to elute the products. Purity, analyzed via C18 HPLC, showed >95% radiochemical purity. The radiochemical yields for all the derivatives was > 85%. The Tc-99m labeling was achievable using as low as 2 μg/mL. The ^{99m}Tc-complexes were completely stable in the presence of excess cysteine and histidine at elevated temperature over 18 h. An example of the labeling stability is depicted in Figure 2a,b, which demonstrates the HPLC purified complex **TcL9** pre- and postincubation at 37 °C with 1 mL of mouse plasma for 18 h, respectively.

IN VITRO RESULTS

Biotinidase Resistance of the ^{99m}Tc Complexes. One of several important criteria for successful design of radiolabeled biotin compounds as pretargeting agents in the treatment of cancer (*53a*−*c*) or as radioimaging agents (*54a*,*b*) is the stability of the biotin derivatives toward the enzyme biotinidase, as well as the affinity and specificity biotin displays for avidin.

Biotinidase is an enzyme present in both serum and tissues of animals in nanomolar concentrations (*55*), which is believed to be responsible for cleavage of the biotin amide bond of biocytin to release biotin for recycling in the system after peptidase degradation of biotin containing carboxylase enzymes (*56*). Previous investigations of the biotinidase activity toward amide bonds have revealed that the enzyme is not specific for

biocytin but readily cleaves biotin amide bonds present in other compounds as well (*18*).

We have studied the effect of biotinidase on three novel biotin $\{^{99m}Tc(CO)_3\}^{+1}$ complexes, **TcL6**, **TcL9**, and **TcL12a**. The complex **TcL6**, a biotin propyl amide complex, would potentially be susceptible to biotinidase activity due to the presence of the amide moiety but retain avidin binding affinity and specificity through the retention of the carboxyl group of the amide bond (*47*). The complex **TcL9** was prepared as the corresponding tertiary amine derivative, which would not be expected to undergo cleavage by biotinidase due to the lack of an amide bond and the robust nature of the tertiary amine toward biotinidase. The third complex investigated, **TcL12a**, as the lysine amide derivative, was expected to behave in a fashion similar to **TcL6**, exhibiting high avidin affinity and specificity as well but susceptible to biotinidase cleavage. The biotin derivatives were radiolabeled to a high degree of radiochemical purity (>95%) allowing for the evaluation of biotinidase cleavage of the biotin ^{99m}Tc complexes radiometrically.

The radiometric assay is based on the hydrolysis of the biotin amide bond, which results in separation of the biotin from the $\{^{99m}Tc(CO)_3(chelate)\}^{+1}$ fragment. The measurement of the degree of biotinidase cleavage was performed as described in the literature (*18*). The measurements were performed using Centricon 30K cutoff regenerated cellulose filters. The presence of radioactivity on the filter (still avidin bound) or in the filtrate (cleavage occurred) determined the percent of biotinidase cleavage. Consequently, lack of avidin binding radioactivity correlated with biotinadase cleavage.

The complex, **TcL6**, was stable to biotinidase activity, with approximately 82% of the activity associated with avidin binding after exposure to biotinidase. We have assumed that the radioactivity retained on the filter is associated with the avidin and therefore is the intact **TcL6** complex. HPLC analysis of the filtrate also demonstrated intact **TcL6**. Steric hindrance has been implicated as a factor in inhibiting biotinidase cleavage when the biotin derivatives are substituted at the position α to the carbonyl functionality, with sterically bulky substituents providing the greatest amount of biotinidase resistance, and less sterically demanding substituents providing little or no protection from biotinidase degradation (*37*). Presumably, the steric bulk of the $\{^{99m}Tc(CO)_3\}^{+1}$ core in **TcL6** prevents ready access to the biotinidase enzyme responsible for amide bond cleavage, in an effect analogous to α-substitution.

Complex **TcL9**, as predicted, was entirely biotinidase resistant (>90%), since **TcL9** does not possess an amide bond susceptible to cleavage. Consequently, **TcL9** provided a convenient internal control for the absence of biotinidase activity. Complex **TcL12a**, the biocytin analogue, was susceptible to biotinidase cleavage, with >80% cleaved. The side chain of the lysine, in contrast to **TcL6**, may provide a degree of conformational flexibility allowing greater access to the biotin amide bond, and resulting in more facile cleavage by biotinidase than that observed for **TcL6**.

Avidin Binding. The ^{99m}Tc-biotin complexes **TcL6**, **TcL9**, and **TcL12a** were also evaluated for affinity and specificity for avidin binding, as well as nonspecific binding to human serum albumin. Determination of the affinity was performed using a modification of a previously described method. The radiolabeled compounds were incubated in the presence of avidin for a period of 30 min, followed by centrifugation through a 30 K filter, and washing with 1 mL of PBS pH 7.2 three times. The radioactivity of both the filter (potentially avidin bound) and filtrate (nonbound) fractions were then counted. The percent binding of **TcL6**, **TcL9** and **TcL12a** were 92% ± 2, 93% ± 2, and 100% ± 2, respectively.

Competitive Binding Assay. Determination of the competitive binding of the radiolabeled biotin derivatives is crucial in evaluating efficacy of the complexes as potential therapeutic and diagnostic agents. Since D-biotin is present in the human body naturally, the competitive binding ratios of the radiolabeled ^{99m}Tc-biotin complexes in the presence of D-biotin were measured.

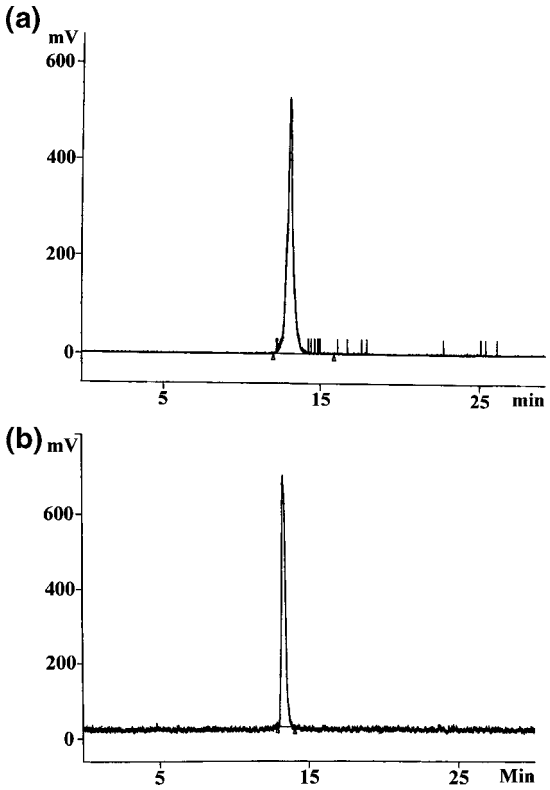

Figure 2. Radiochromatograms of HPLC purified **TcL9** (a) pre- and (b) postincubation at 37 °C with 1 mL of mouse plasma for 18 h.

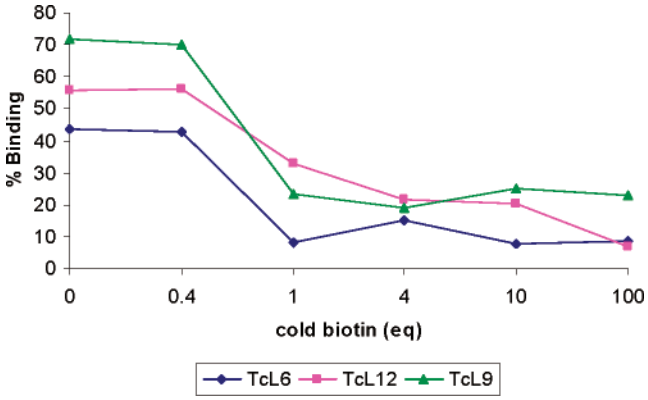

Figure 3. The saturation behavior of **TcL6**, **TcL9**, and **TcL12a**, expressed as percent binding of the radiolabeled compound as a function of the equivalents of "cold" biotin concentration.

Equivalent affinities of radiolabeled biotin and D-biotin for avidin would result in 50% molar activity bound to avidin at the saturation point of avidin, which is four molar equivalents, since avidin is capable of binding four biotin molecules. The saturation behavior of all three radiolabeled ^{99m}Tc-biotin complexes, shown in Figure 3, is similar in terms of profile, with **TcL6**, the biotin DPA amide complex, being displaced by D-biotin when between one and four equivalents of D-biotin are added. Compound **TcL9**, the biotin tertiary amine, reaches the dissociation point at approximately four equivalents of added D-biotin, and **TcL12a**, the biotin lysine derivative, achieves the saturation point between four and 10 equivalents of added D-biotin. Both **TcL6** and **TcL12a**, the biotin compounds

containing the carboxyl functional group, maintain the highest binding to avidin, with the tertiary amine complex **TcL9** exhibiting the greatest diminution of competitive avidin binding in the presence of D-biotin.

IN VIVO RESULTS

Biotin Biodistribution in the Avidin Bead Model for Tumor Localization. The avidin bead model has been utilized previously (*23*, *24*) as an effective tumor model to simulate biotin binding to pretargeted avidin in vivo. The model allowed us to explore the affinity and specificity of the three new ^{99m}Tc-biotin conjugates for avidin in vivo as well as allowing determination of the biodistribution the ^{99m}Tc-complexes. Each of the three ^{99m}Tc-biotin derivatives afforded good labeling yields (>95%) and were easily purified via HPLC. Table 1 shows the results of the biodistribution experiments obtained at 2 and 24 h postinjection of the ^{99m}Tc-radiolabeled biotin derivatives **TcL6**, **TcL9**, and **TcL12a**.

For compound **TcL6**, the tissue with the highest concentration at 2 h p.i. was the GI tract followed by the kidneys > liver > stomach > lungs > heart = blood. At 24 h, the highest concentration was found in the liver followed by kidneys > GI tract > stomach > spleen. The activity in the avidin "tumor" was the highest of the three complexes studied. Radioactive concentrations in this tissue were approximately five times that of normal muscle (4.9:1). At 24 h, the concentration had dropped by approximately 50%, but the ratios improved to 7.3:1 against normal muscle.

For compound **TcL9**, the tissues with the highest concentration at 2 h p.i. were the GI tract followed by the blood > kidneys > liver > bone > stomach = lungs. At 24 h p.i. the activity in the stomach had increased and was the highest, followed by the GI tract > kidneys > liver. The activity in the avidin "tumor" was approximately twice that of the normal muscle at 2 h (2.3:1), but activity washed out in both tissues resulting in a slightly lower ratio at 24 h (1.7:1).

For compound **TcL12a**, the highest concentration at 2 h postinjection was found in the kidney followed by the GI tract > liver > stomach > lungs. At 24 h p.i., the tissue with the highest concentration was the kidneys followed by the liver > stomach > GI tract. The activity in the avidin "tumor" was similar to normal muscle (1.2:1) and the concentration remained virtually unchanged at 24 h (1.1:1).

COMPUTATIONAL RESULTS

Molecular Modeling. Molecular mechanics/molecular dynamics (MM/MD) calculations were performed to consider the binding of the Re/Tc−biotin complexes with avidin. The MM/MD calculations began from the crystallographic coordinates of the avidin−biotin tetrameric complex (*27*). The modeling of these Re/Tc complexes from the coordinates of the avidin/unsubstituted biotin crystal structure then assumes that binding for these complexes occurs in a manner consistent with the unsubstituted biotin (i.e., retention of the hydrogen-bonding framework between the biotin ureido and thiophene rings and the avidin inner β-barrel pocket). Accommodation of biotin derivatives with avidin structural changes (*57*), as well as the binding of biotin itself to avidin (*27*), has been considered previously by experimental and computational methods. With the assumption that the binding of the Re/Tc−biotin derivatives within the avidin β-barrel is similar to that observed in the crystal structure for the unsubstituted biotin, the MM/MD calculations provide a means for examining structural changes to the binding pocket expected to occur due to the steric bulk of the Re/Tc complexes. Further, these MM/MD results can be used as predictive tools for the identification of structural modifications to the Re/Tc−biotin derivatives that might improve the binding properties of these molecules.

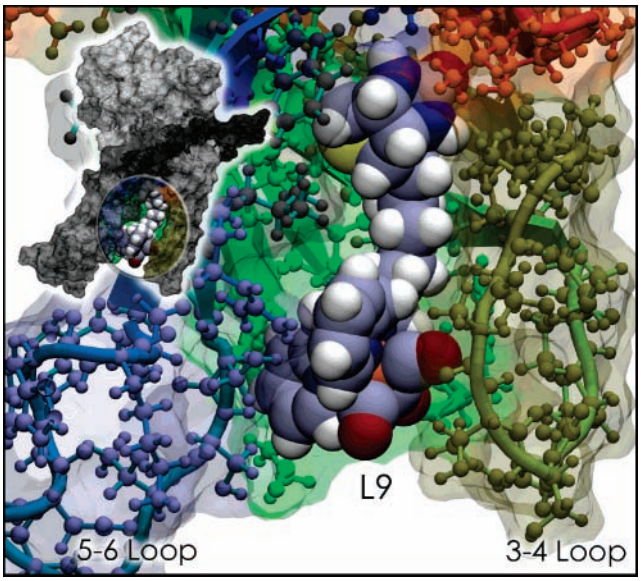

Figure 4. The biotin−Re ligand bound within the avidin−biotin binding pocket. The entire avidin−biotin−Re complex is shown (inset) with the binding pocket highlighted. The biotin−Re ligand is shown in van der Waals representation. The 3−4 loop is at bottom-right (gold).

Figure 4 shows a MM minimum energy structure of the biotin−Re complex **L9** bound to avidin. Significant differences between this structure and the avidin/biotin structure are, as

expected, localized to the 3−4 (Figure 4, gold) and 5−6 (Figure 4, blue) avidin loops, the sites of steric interactions with the Re coordination complex. The specific flex of the 3−4 loop is familiar to theoretical and experimental studies, as its motion is the only major structural change to occur upon biomolecule binding to biotin (*25*) and, from theoretical studies, the only significant motion required in the modeling of the unbinding of biotin from avidin (*28*). The ureido/thiophene biotin binding pocket within the avidin β-barrel is nearly identical in arrangement to that of the unsubstituted biotin/avidin complex. Both the **L9**/avidin and biotin/avidin MM structures differ from the crystal structure slightly for reasons that can be attributed to packing interactions between avidin proteins in the tetrameric crystal complex. With the retention of the ureido/thiophene binding pocket within the avidin β-barrel, the Re tail of derivative **L9** does not clear the external binding pocket of the avidin. The calculations indicate that the hydrocarbon tail of **L9** is long enough to position the Re complex within the 3−4/5−6 loop pocket and beyond the more constrained interior of the avidin β-barrel. A complete description of the binding interactions between biotin and avidin, the differences between the crystal and MM/MD avidin/biotin structures, and an analysis of the role of steric bulk on the change in avidin structure for other functionalized biotin molecules are provided in Supporting Information.

CONCLUSIONS

By exploiting the tridentate chelate concept of the single amino acid chelate approach (SAAC), we prepared a series of biotin derivatives capable of forming robust complexes with both technetium and rhenium. The ligands **L6**, **L9**, and **L12** (biotinylamidepropyl-*N*,*N*-(dipicolyl)amine, *N*,*N*-(dipicolyl)biotinamine, and *N*,*N*-(dipicolyl)biotinamido-Boc-lysine, respectively) were obtained by appropriate modification of the free carboxylic group of biotin. The Re complexes $[Re(CO)_3(\mathbf{L6})]Br$, $[Re(CO)_3(\mathbf{L9})]Br$, and $[Re(CO)_3(\mathbf{L12})]Br$ were prepared from $[NEt_4]_2[Re(CO)_3Br_3]$ and characterized by ^1H and ^{13}C NMR and mass spectroscopy. The corresponding $\{^{99m}Tc(CO)_3\}^{+1}$ core complexes **TcL6**, **TcL9**, and **TcL12a** were also prepared. The ^{99m}Tc complexes were stable in cysteine and histidine challenges. **TcL6** and **TcL9** were resistant to biotinidase activity, while the biocytin analogue **TcL12a** was susceptible to cleavage. The complexes **TcL6** and **TcL12a** bound readily to avidin, while **TcL9** showed minimal specificity in avidin binding. Molecular mechanics/molecular dynamics simulations are consistent with these results, since deformation of the surface domain can occur so as to accommodate the metal complexes of the biotin derivatives with negligible changes to the inner β-barrel, the most significant domain for binding biotin and its derivatives. Using an in vivo avidin tumor model, **TcL6** demonstrated the highest uptake followed by **TcL9** and **TcL12a**, respectively. Consequently, the ligand **L6** represents an example of a SAAC analogue of biotin showing potential as a radiolabeled targeting vector of biotin that forms robust radiochemical complexes with ^{99m}Tc.

ACKNOWLEDGMENT

This work was supported in part by a grant from the National Institutes of Health, National Institutes of Allergy and Infectious Diseases, STTR 1R41 A10044080-01. Mr. Eric Zelman and Apple Computers are thanked for their provision of resources for the theoretical work.

Supporting Information Available: The full details of the computational studies, together with an extensive discussion of the results. This material is available free of charge via the Internet at http://pubs.acs.org.

Isostructural Re and ^{99m}Tc Complexes of Biotin Derivatives for Fluorescence and Radioimaging Studies

Shelly James,[†] Kevin P. Maresca,[‡] John W. Babich,[‡] John F. Valliant,[§] Laurie Doering,[#] and Jon Zubieta*[,†]

Department of Chemistry, Syracuse University, Syracuse, New York 13244, Department of Chemistry, McMaster University, Hamilton, Ontario, Canada L8S 4M1, and Department of Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario Canada L8S 4M1, and Molecular Insight Pharmaceuticals, 160 Second Street, Cambridge, Massachusetts 02142. Received October 8, 2005; Revised Manuscript Received March 13, 2006

The reaction of biotinamine with two equivalents of 2-quinoline aldehyde in the presence of $Na(OAc)_3BH$ in dichloroethane provides *N*,*N*-bis(methylquinoline)biotinamine (**L1**), a molecule displaying a tridentate donor terminus which has proven effective in coordinating to the $\{M(CO)_3\}^+$ core (M = Tc, Re). Reaction of **L1** with $(NEt_4)_2[Re(CO)_3Br_3]$ yields $[Re(CO)_3(L1)]Br$, a compound with an absorbance at 350 nm and luminescence emission maxima at 425 and 580 nm. The luminescence lifetime of 11.4 μs, which is associated with the 580 nm emission, is sufficiently prolonged to enable time-gating techniques to be used during in vitro imaging studies and to overcome interference from endogenous fluorescence. Exposure of avidin beads to $\{Re(CO)_3(L1)]Br$ resulted in binding, which was qualitatively imaged using fluorescence microscopy. The ^{99m}Tc analogue $[^{99m}Tc(CO)_3(L1)]^{+1}$ was prepared by reacting **L1** with $[^{99m}Tc(CO)_3(H_2O)_3]^{+1}$ and purified by HPLC. The ^{99m}Tc complex is chemically robust and resistant to cysteine and histidine challenges. This study demonstrates that complementary fluorescent and radioactive biotin-derived probes may be readily prepared to allow direct correlation of in vitro and in vivo molecular imaging studies.

Biotin, a water-soluble member of the B-complex group of vitamins commonly referred to as vitamin H, binds to the homotetrameric glycoprotein avidin with one of the strongest known binding constants between a ligand and a protein ($K_d = 10^{-15}$ M^{-1}) (*1*). The high K_d has been used in a number of applications to biochemistry, immunology, bioanalytical chemistry (*2*), and targeted cancer radiotherapy (*3*). The effective linking of biotin to the radionuclides ^{99m}Tc and ^{186,188}Re would create new applications in nuclear imaging (*4*−*8*) and to radiotherapy (*9*), respectively. This is particularly true of the ^{99m}Tc conjugate because of the undisputed use of the isotope.

The development of radiopharmaceuticals is often hampered by the inability to image the behavior of these compounds at the cellular and subcellular level. This is problematic when attempting to determine mechanisms responsible for cellular specificity and localization. While visualization in vitro may be accomplished by substitution of the radiolabel with a fluorescent dye (*10*), in the case of biotin−fluorophore conjugates, such as pyrene, fluorescein, or tetramethylrhodamine, the fluorophore and radionuclide prosthetic groups have very different structures. Consequently, binding to avidin results in fluorescence quenching unless lengthy spacers are introduced between the biotin and the fluorophore units (*11*). The optimal system would exploit isostructural metal-based luminescent and radioactive prosthetic groups.

Re(I) complexes are attractive as luminescent probes, because of their useful photophysical properties, which include long lifetimes, polarized emission, and large Stoke's shift (*12*−*16*). These properties have been exploited recently in the conjugation of biotin to the $\{Re(CO)_3\}^{+1}$ core in $[Re(CO)_3(phen)(py\text{-}CH_2\text{-}NH\text{-}biotin)](PF_6)$ where phen is 1,10-phenanthroline and py-CH_2-NH-biotin is *N*-[(*N*-pyridyl)methyl biotinamide] (*17*). However, a potential disadvantage of this design is the monodentate coordination mode of the biotin derivative to the $\{Re(CO)_3\}^{+1}$ core, requiring a bidentate coligand to satisfy the coordination requirements of the rhenium(I) core.

Since the coordination chemistry of the group 7 congeners technetium and rhenium is similar, it should be possible to design an appropriate multidentate ligand that forms a robust Re fluorescent complex and a stable ^{99m}Tc complex. The ligand should also be linkable to the biotin so as to allow images obtained on a fluorescent microscope to be correlated with in vivo radioimaging studies since the two probe structures are identical.

Our recent design of Tc(I)/Re(I) binding bifunctional chelates based on natural or synthetic amino acid-derived bis(pyridyl)-amines, referred to as single amino acid chelates (SAAC) (*18*), provided inert complexes with the $\{M(CO)_3\}^{+1}$ core (M = Tc, Re) (*19*). Encouraged by these results, we modified the chelate terminus to provide a bis(quinolylmethyl)amine donor set, which resulted in a ligand whose Re complex is fluorescent and retains the ability to bind ^{99m}Tc (*20*). On the basis of these results, we have prepared *N*,*N*-bis(quinolylmethyl)biotinamine (**L1**) and its complexes with the $\{^{99m}Tc(CO)_3\}^{+1}$ and $\{Re(CO)_3\}^{+1}$ cores. The fluorescent properties of $[Re(CO)_3(L1)]^{+1}$ are described, as well as the uptake of the Re complex by avidin beads.

EXPERIMENTAL PROCEDURES

General. All reactions were performed under an inert atmosphere of argon, unless otherwise noted. Solvents and chemicals obtained from commercial sources were analytical grade or better and used without further purification. D-Biotin was purchased from Aldrich Chemical Co. (Milwaukee, WI). Avidin was purchased from Pierce Biotechnology (Rockford, IL) and used as a solution diluted with PBS to pH = 7.2 as noted in the literature reference (*21*). Avidin beads were purchased from Aldrich Chemical Co. (Milwaukee, WI). All experiments were performed in duplicate or triplicate to ensure

reproducibility. Melting points were obtained on a Barnstead International apparatus and are uncorrected.

Chromatography. Silica gel was purchased from EM Science (Gibbstown, NJ), silica gel 60 Geduran, 40−63 μm. Alumina chromatography was performed using alumina purchased from Aldrich (Milwaukee, WI): weakly acidic, activated Brockmann I standard grade 150 mesh, 58 Å. In addition, basic aluminum oxide, activated, 150 mesh, 58 Å was used as noted in the experimental descriptions.

HPLC Chromatography. Purification of **TcL1** was achieved through the use of HPLC purification and the following solvent system: Solvent A: TEAP (0.05 M) (tetraethylammonium phosphate buffer) adjusted to pH 2−2.5 with 1 M HCl; and Solvent B: MeOH.

Spectroscopy. ^{1}H NMR spectra were obtained on a Bruker Avance system, at 300 and 500 MHz. Proton chemical shifts are expressed as parts per million versus tetramethylsilane. ^{13}C NMR data were obtained on a Bruker Avance 75 MHz system using trimethylsilane or the protonated fraction of the deuterated solvent as the reference standards. IR spectra were obtained in methanol solution using a Perkin-Elmer Paragon 1000 FT-IR spectrophotometer for data collection. HRMS data were obtained on a 3-Tesla Fourier Transform mass spectrometer with an ESI source in positive ion mode. Mass spectrometry samples were prepared in MeOH/THF containing NaCl.

Fluorescence and UV Spectroscopy. Samples were flushed with nitrogen before use. All absorbance spectra were recorded using a Varian CARY 500 bio UV−visible spectrophotometer. Measurements were performed in double-beam mode baseline corrected in matched quartz cuvettes. A concentrated stock solution of the complex [Re(CO)$_3$(L1)]Br was prepared to give a 0.2 M solution in methanol. Emission spectra, lifetime and quantum yield data used steady-state measurements with a Jobin Yvon-SPEX Fluorolog-3 model 212 T-format spectrofluorimeter (ISA Instrument Int. Edison, NJ). Emission was monitored from 400 to 700 nm with an excitation wavelength of 366 nm in 1-nm increments with an integration time of 0.25 s and bandwidths of 5 nm. Methanol solutions of the rhenium compounds were prepared with optical densities no higher than 0.1 at 366 nm. The POPOP (1,4-bis(5-phenyl-2-oxazolyl)-benzene) standard was used to measure the quantum yield and was prepared in a concentration of 0.1 M and diluted to an optical density of 0.01 measured at 366 nm.

Synthetic Procedures. *N,N-Bis(methylquinoline)biotinamine (L1).* Biotin TPF ester (**1**), biotinamide (**2**), and biotinamine (**3**) were prepared following literature methods (*22*). Biotinamine (**3**) (171 mg, 0.74 mmol) was added to DCE (9 mL) in a 25-mL round-bottom flask. Quinoline aldehyde (236 mg, 1.1 mmol) was introduced, followed by Na(OAc)$_3$BH (784 mg, 3.7 mmol). The resulting blood red solution was heated to reflux overnight. The mixture was quenched with saturated Na_2CO_3 solution (5 mL) and extracted with CH_2Cl_2 (5 × 5 mL). The solution was evaporated to a red-brown oil, and the product, a light brown colored solid (341 mg, 60% yield) was eluted from a silica gel column using CH_2Cl_2/MeOH (95:5). ^{1}H NMR (CD_3OD, δ, 300 MHz): 0.9−1.4 (m, 6H), 1.4−1.6 (m, 4H), 2.5−2.6 (m, 3H), 2.74 (dd, J_A = 12 Hz, J_B = 4.8 Hz), 2.8−2.9 (m, 1H), 3.83 (s, 4H), 4.02 (dd, J_A = 7.8 Hz, J_B = 4.2 Hz), 4.29 (dd, J_A = 7.5 Hz, J_B = 4.8 Hz), 7.4−7.5 (m, 2H), 7.6−7.7 (m, 2H), 7.56 (t, J = 7.5 Hz, 1H), 7.68 (d, J = 8.4 Hz, 2H), 8.13 (d, J = 8.4 Hz, 2H); ^{13}C NMR (CD_3OD, δ, 75 MHz): 27.8, 28.1, 29.7 30.0 41.4, 54.9, 55.7, 57.2, 61.5, 62.2, 63.4, 122.6, 127.7, 128.9, 129.90, 131.0, 138.4, 148.2, 162.0, HRMS calc for $C_{30}H_{33}N_5OSNa^+$: 534.2298, found 534.2282; IR(MeOH): 1703 cm^{-1}. Melting point: 235−236 °C.

[Re(CO)$_3$(L1)]Br. (ReL1). $(NEt_4)_2[Re(CO)_3Br_3]$ (62 mg, 0.08 mmol) was added to **L1** (34.0 mg, 0.07 mmol) in methanol (4 mL) in a 10-mL round-bottom flask. The clear, light brown solution was held at reflux overnight, and the red-brown solution obtained was evaporated to give a dark red-brown powder that was purified by column chromatography using CH_2Cl_2/MeOH (95:5) over weakly acidic alumina, giving a quantitative yield of the Re complex.

^{1}H NMR (CD_3OD, δ, 300 MHz): 1.4−1.7 (m, 4H), 1.7−1.8 (m, 2H), 1.9−2.1 (m, 2H), 2.65 (d, J = 12 Hz, 1H), 2.87 (dd, J_A = 12 Hz, J_B = 4,9 Hz, 1H), 3.19 (m, 1H), 3.3 (s, 2H), 3.8 (dd, J_A = 8.3 Hz, J_B = 8.3 Hz), 4.26 (dd, J_A = 8.0 Hz, J_B = 4.35 Hz), 4.45 (dd, J_A = 7.8 Hz, J_B = 4.2 Hz), 7.60 (d, J = 7.8 Hz, 2H), 7.65 (t, J = 7.5 Hz, 2H), 7.83 (t, J = 7.8 Hz, 2H), 7.97 (d, J = 7.2 Hz, 2H), 8.46 (d, J = 9.9 Hz, 2H), 8.51 (d, J = 8.7 Hz, 2H); ^{13}C NMR (CD_3OD, δ, 75 MHz): 27.3, 27.9, 29.8, 30.2, 41.2, 57.2, 61.8, 63.6, 69.5, 121.0, 129.6, 129.7, 130.0, 131.1, 134.2, 143.1, 148.3, 166.3, 195.7, 197.3. Melting point: decomposes above 200 °C.

[Tc(CO)$_3$(L1)]Cl. (TcL1). (a) $[^{99m}Tc(H_2O)_3(CO)_3]^{+1}$ was prepared by minor modification of the literature procedure: a 10-mL sealed tubing vial containing the followed lyophilized formulation: 13 mg of L-tartaric acid, 7.6 mg of KBH_4, 20 mg of lactose, borate buffer at pH = 11.6, and CO in the headspace, was added to1.5 mL (20.5 mCi) of $^{99m}TcO_4^-$ from a commercial generator (50−200 mCi). The vial was shaken vigorously for 30 s and placed in a boiling water bath for 30 min. The solution was cooled for 5 min, and 1 N HCl (150 μL) added to the cooled solution. The ^{99m}Tc reagent (500 μL) was purified using reverse HPLC (C-18 column with a 0.05 M TEAP buffer adjusted to a pH = 2.25 and a MeOH gradient HPLC method). HPLC retention time for $\{^{99m}Tc(CO)_3(H_2O)_3\}^{+1}$: 4.0 min. (b) The reaction of $\{^{99m}Tc(CO)_3(H_2O)_3\}^{+1}$ (650 MBq (17.5 mCi) with **L1** (450 μg) 100 °C for 30 min afforded **TcL1** in 95% yield.

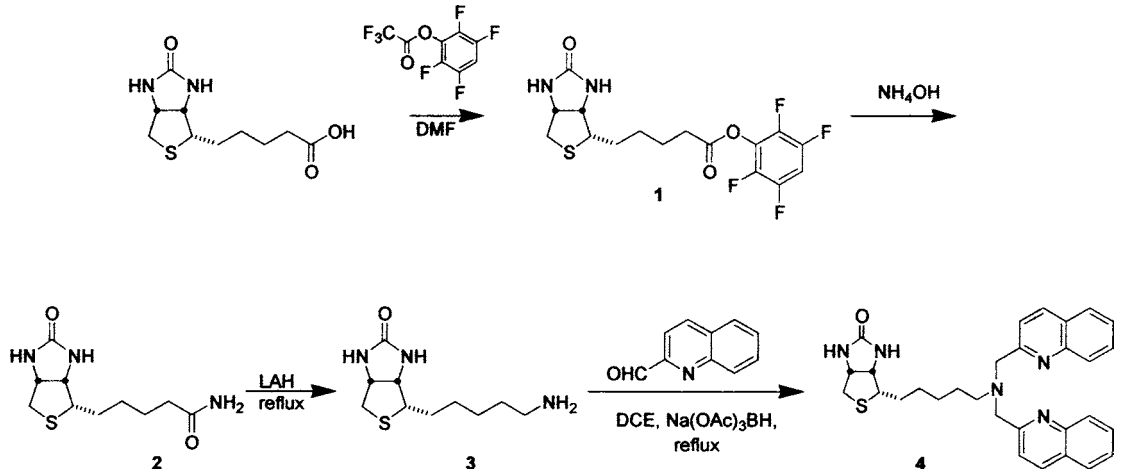
HPLC purification of **TcL1** was performed on a Varian instrument using a NUCLEOSIL column 300−5μ, C-18 analytical column. All solvents were HPLC grade and filtered prior to use in the HPLC system. A gradient method was utilized to purify the ^{99m}Tc complexes, with the following gradient elution conditions: 0−3 min: 100% A; 3−6 min: 100% A to 75% A; 6−9 min: 67% A; 9−20 min: 100% B; 22−25 min: 100% B; 25−30 min: 100% A. The total run time was 30 min, with an injection loop of 100 μL. The flow rate was 1.0 mL/min with 30 μL of compound injected. Detectors were β-ram (γ-detector) with 10 μL loop (1 s dwell time) and a UV/vis detector which was set at λ = 254 nm.

^{99m}Tc Labeling Studies. The concentration of the ^{99m}Tc compound **TcL1** was determined to be 36 μCi in 500 μL of 10 mM HCl (pH = 2). Na[$^{99m}TcO_4$], $[^{99m}Tc(CO)_3(H_2O)_3]$Cl, and the Re complex [Re(CO)$_3$(L1)]Br were introduced as standards under the operating conditions of the HPLC run. Na[TcO_4] retention time was noted as 11.2 min, while retention time for $[^{99m}Tc(CO)_3(H_2O)_3]^{+1}$ was 4.5 min and that of [Re(CO)$_3$(L1)]Br was 22.9 min. The retention time for **TcL1** was 22.0 min. The uncomplexed **L1** was also injected and had a retention time of 20.3 min. Radiochemical yield for all ^{99m}Tc complexes was >95%. Quantitative recovery of the complex **TcL1** was achieved by HPLC chromatography.

Avidin Binding. Avidin binding was determined by incubating the HPLC-isolated ^{99m}Tc-complex (50 μL) with avidin (4.8 mg/8 mL water) for 30 min, followed by filtration through a 30 kDa MW cutoff filter (Centricon YM-30), and washing three times with 1 mL of PBS pH 7.2. Avidin binding was determined as the percent radioactivity retained on the filter as compared to the total radioactivity.

Lipophilicity. 100 μL of compound **TcL1** (20.2 μCi) was placed in 10% EtOH/0.9 saline solution and added to a 1:1 solution of 1-octanol: PBS (pH = 7.2) for a total volume of 4 mL. The 1-octanol:PBS solution had been incubated for 24 h

Scheme 1



before use. The solution was then shaken for 5 min on an automixer and then vortexed for 30 s. After allowing the solution to settle into two distinct layers for a period of 5 min, 0.5 mL samples were removed from both the 1-octanol layer and the PBS layer. These samples were then placed into 0.5 mL of PBS buffer (pH = 7.2), shaken on the automixer for 5 min, and then vortexed for 30 s. 100 μL of the 1-octanol layer and the PBS layer were subsequently injected into the HPLC and the cpm recorded using a NaI detector. Three samples were studied to ensure reproducibility. The log *P* value represents the average of the three experimental values.

Qualitative Binding on Avidin Beads. The rhenium complex $[Re(CO)_3(L1)]Br$ was incubated with avidin beads at 37 °C for 30 min (0.5 mL beads diluted in 5 mL PBS pH = 7.2).

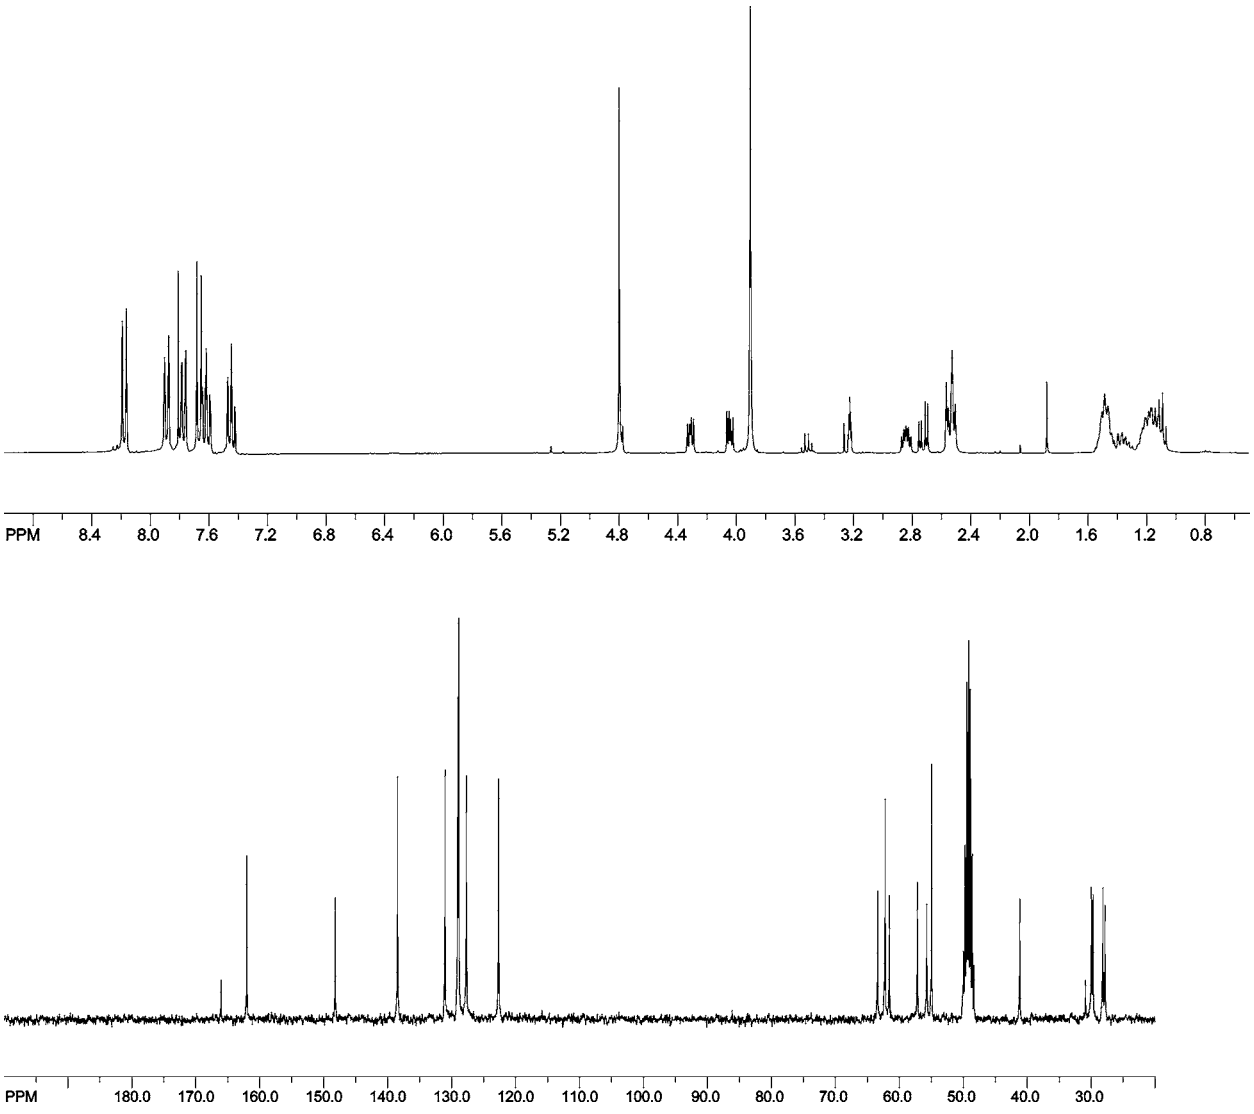


Figure 1. The ^{1}H NMR of **L1** (300 MHz, CD_3OD (top) at room temperature; the ^{13}C NMR of **L1** (75 MHz, CD_3OD) (bottom) at room temperature.

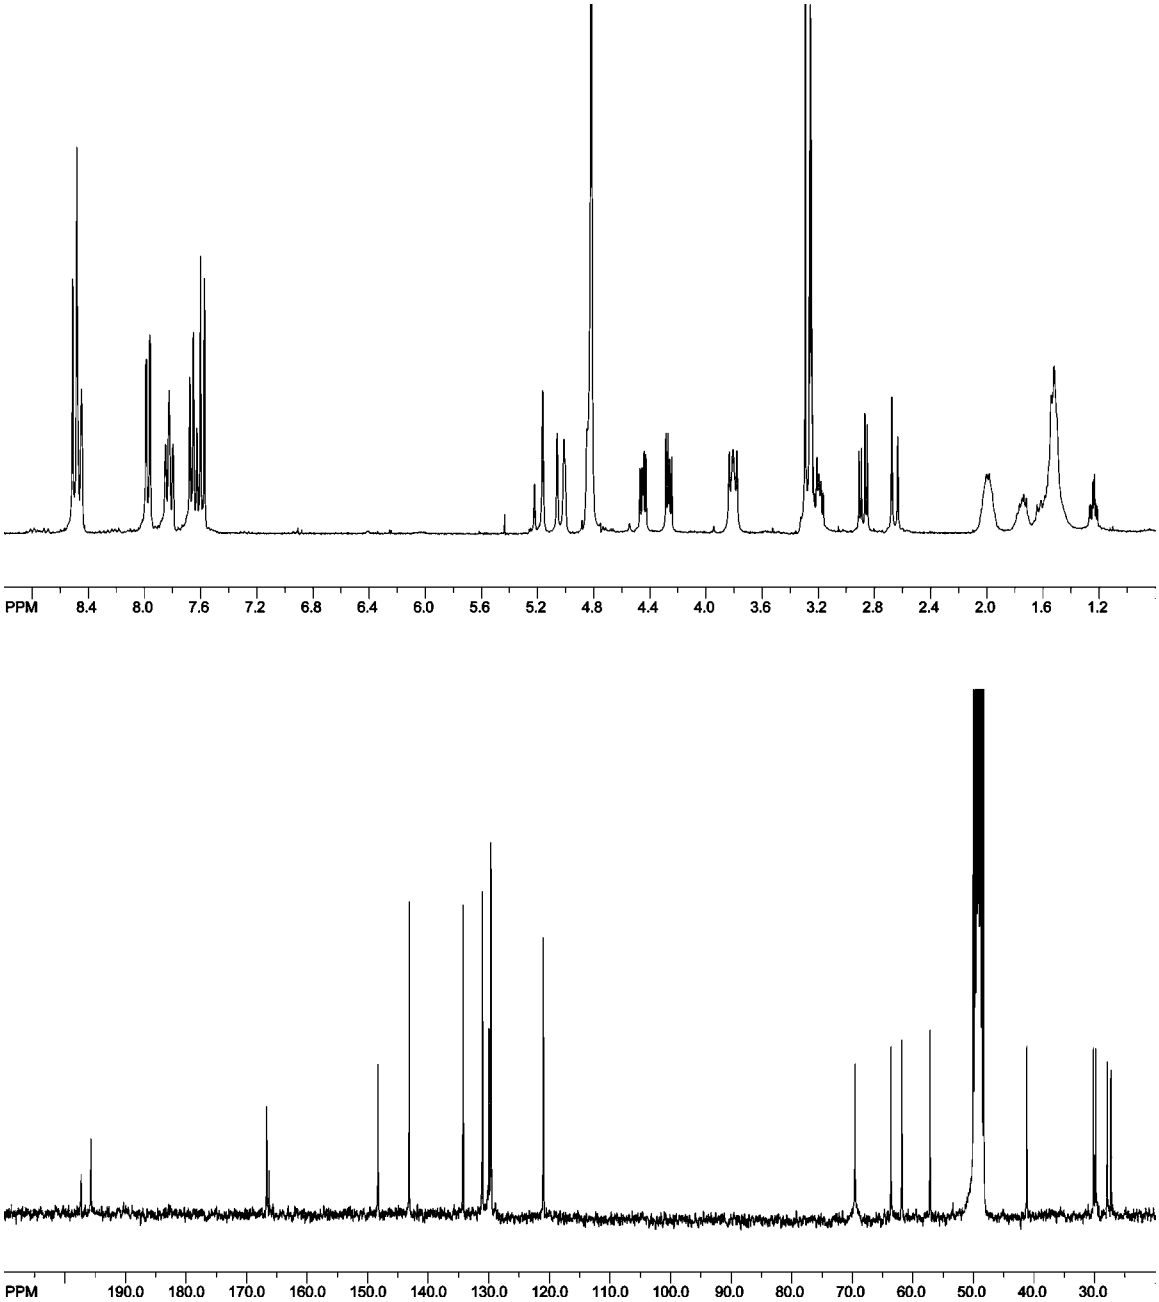

Figure 2. The ^{1}H NMR of **ReL1** (300 MHz, CD_3OD) (top) at room temperature; the ^{13}C NMR of **ReL1** (75 MHz, CD_3OD)(bottom) at room temperature.

Fluorescence microscopy images were taken prior to washing the beads 4× with PBS (pH = 7.4), followed by centrifuging and decanting. Fluorescence microscopy images were then recorded once again. The avidin beads with the bound rhenium complex were then subjected to a biotin challenge with an excess of biotin (>1000×) for a period of 30 min at a temperature of 37 °C, followed by reexamination by fluorescence microscopy.

RESULTS AND DISCUSSION

The ligand synthesis was performed as outlined in Scheme 1. The biotin TFP ester was prepared by the transesterification reaction of biotin with 2,3,5,6-tetrafluorophenyl trifluoroacetate in DMF and was subsequently treated with NH_4OH to give the biotinamide (**2**). Reduction of **2** with LAH gave biotinamine (**3**), which upon reductive alkylation with two equivalents of 2-quinolinecarboxaldehyde provided the ligand **L1** (*23*), whose ^{1}H and ^{13}C NMR spectra are shown in Figure 1. The reaction of **L1** with $(NEt_4)_2[Re(CO)_3Br_3]$ in methanol yielded a dark red-

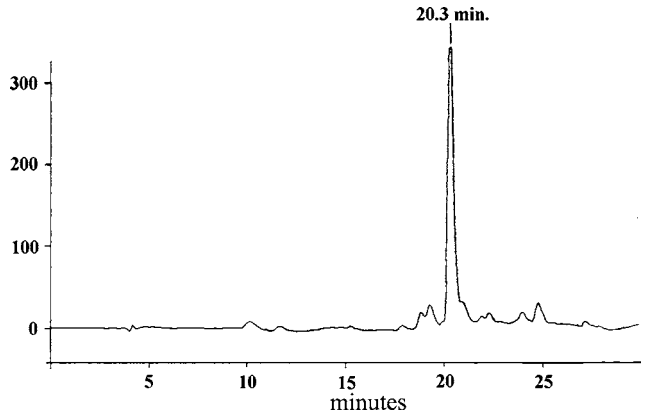

Figure 3. HPLC radiochromatogram of ^{99m}**TcL1**. The HPLC retention time (UV detector) for the corresponding rhenium compound **ReL1** was 19.9 min.

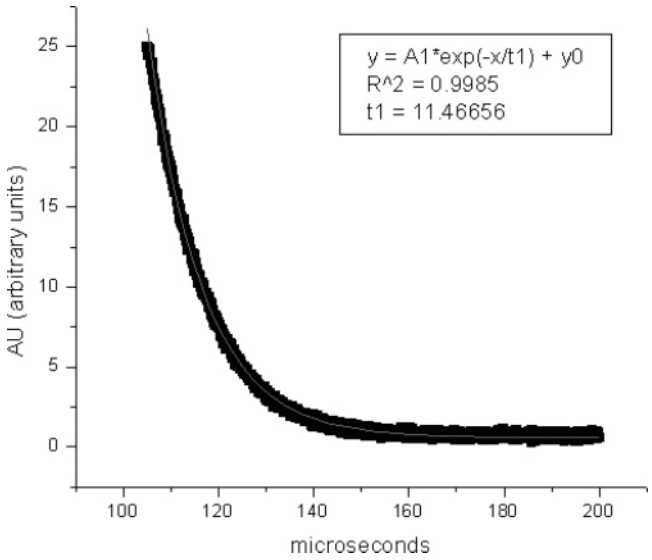

Figure 4. Emission decay trace for **ReL1** in methanol, monitored at 580 nm after 366 nm excitation. Monoexponential fit to the emission decay gave a lifetime of $\tau = 11.4$ μs.

brown powder of **[Re(CO)$_3$L1]Br** (**ReL1**) in quantitative yield. The ^{99m}Tc analogue of **ReL1** was prepared by the reaction of an aqueous solution of $[^{99m}Tc(CO)_3(H_2O)_3]^{+1}$ with **L1** to give $[^{99m}Tc(CO)_3L1]^{+1}$ in 95% radiochemical yield and >85% radiochemical purity.

The rhenium complex was characterized by ^{1}H and ^{13}C NMR spectroscopy, as shown in Figure 2. Comparison of the ^{1}H NMR spectra of **L1** with that of complex **ReL1** shows that the protons associated with the chelating groups are most strongly influenced by coordination of the $\{Re(CO)_3\}^{+1}$ core. In comparison to that of **L1**, the ^{13}C NMR spectrum of $\{Re(CO)_3\}^{+1}$ exhibits two additional peaks at 195.7 and 197.3 ppm in a 2:1 ratio, assigned to the carbon atoms of the carbonyl ligands. The pattern reflects the local C_{2v} symmetry of the $\{Re(CO)_3\}^{+1}$ facial subunit.

The ^{99m}Tc analogue **TcL1** was prepared by reacting **L1** with $[^{99m}Tc(CO)_3(H_2O)_3]^{+1}$, which had been prepared from $^{99m}TcO_4^-$ using a modified literature procedure. **TcL1** was purified by HPLC on a C-18 analytical column and exhibited a single radioactive peak after purification with a retention time consistent with that of the rhenium complex **ReL1** (Figure 3).

The ^{99m}Tc-biotin complex **TcL1** was also evaluated for avidin affinity binding. Determination of the affinity was performed using a modification of a previously described method. The radiolabeled compound was incubated in the presence of avidin for a period of 30 min, followed by centrifugation through a 30 K filter and washing with 1 mL of PBS pH 7.2 three times. The radioactivity of both the filter (potentially avidin bound) and the filtrate (nonbound) fractions was then counted. The percent binding of **TcL1** was 96% $\pm$ 2.

Although factors other than lipo(hydro)philicity can affect the biodistribution profile of bioconjugate materials such as **TcL1**, high lipophilicity can result in predominantly hepatobiliary excretion patterns and high background activities, with concomitant low in vivo target-to-nontarget ratios. However, the route of excretion, whether hepatobiliary or urinary tract, seems to correlate with the log $P_{o/w}$ value of the reagent. In general, compounds may be grouped by log $P_{o/w}$ values into three categories: low, log $P_{o/w} \leq 1.5$; moderate, $1.5 \leq \log P_{o/w} \leq 4$; and high, log $P_{o/w} \geq 4$ (*24*). The log $P_{o/w}$ was determined to be 1.10, which corresponds to relatively modest lipophilicity. Consequently, the **TcL1** is expected to exhibit only modest hepatobiliary retention. Furthermore, the chemistry of the biotin subunit of the conjugate lends itself to derivatization, which

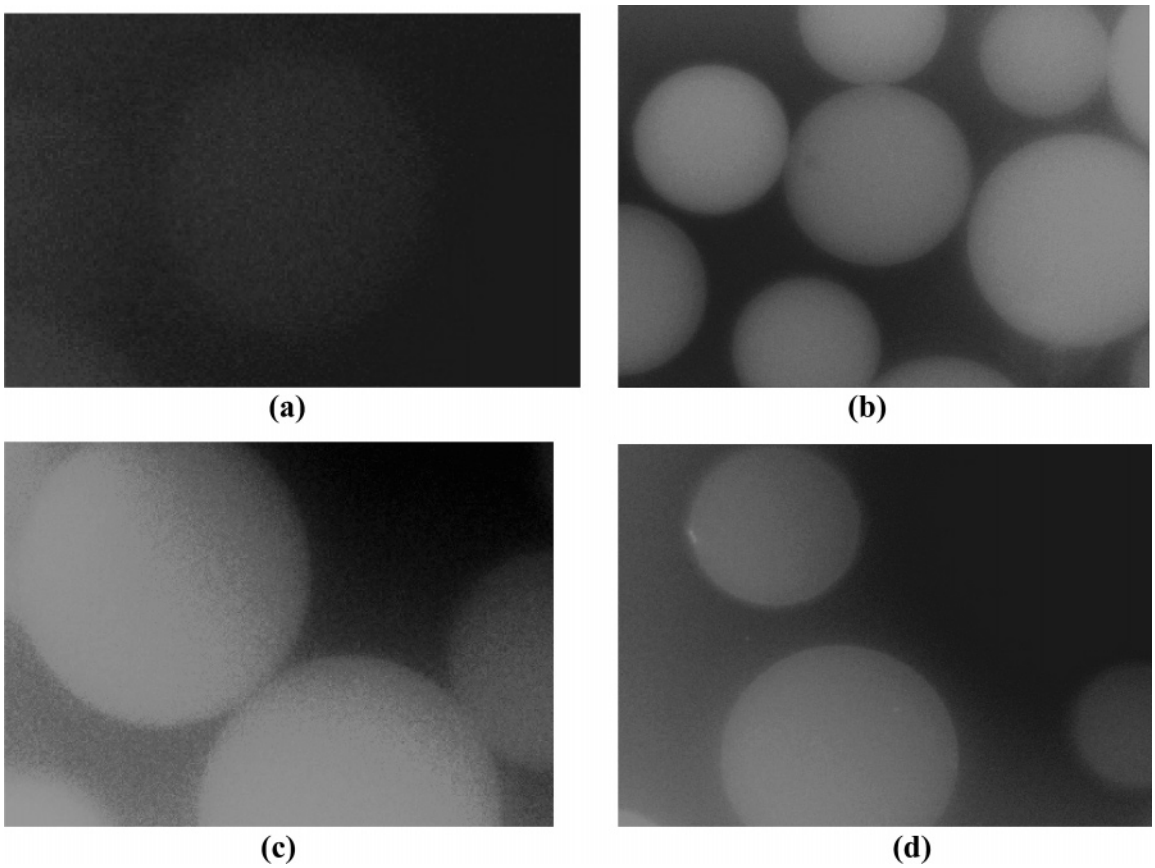

Figure 5. Fluorescence microscopy images of (a) avidin beads; (b) $[Re(CO)_3(L1)]^+$ bound to the avidin beads; (c) avidin bound-$[Re(CO)_3(L1)]^+$ after washing with PBS (pH = 7.4); (d) avidin bound-$[Re(CO)_3(L1)]^+$ after challenging with a 10^3-fold excess of biotin.

would allow the introduction of hydrophilic residues such as a carboxylate group.

Compound **ReL1** displays an appreciable absorbance in the UV and blue regions of the UV−visible spectrum with a peak absorbance at 350 nm. The emission spectrum shows that the rhenium probe has two distinct transitions giving rise to luminescence intensities at 420 and 580 nm. The emission at 580 nm has a lifetime of 11.4 μs (Figure 4), depending upon the solvent and amount of oxygen present. The sensitivity to oxygen is common for an emission that likely originates from a triplet metal-to-ligand charge transfer (^{3}MLCT) excited state (*25*). The quantum yield for **ReL1** of 0.0059 in MeOH under nitrogen is low but not significantly different from yields reported for other transition metal based fluorescent probes (*25*).

Having established that **ReL1** has the necessary properties to be used as a fluorescent probe, the binding of **ReL1** to avidin was studied using fluorescence microscopy. The background autofluorescence of the avidin beads was imaged initially (Figure 5a), followed by **ReL1** incubated with the avidin beads (30 min at 37 °C) (Figure 5b). The avidin beads bound to **ReL1** were subsequently washed with water (4×), centrifuged, decanted, and once again imaged under the fluorescence microscope (Figure 5c) to remove excess unbound luminescent probe from the avidin beads and leave behind only the biotin probe that was bound to the avidin beads. **ReL1**-bound avidin beads were then incubated with >1000-fold excess of biotin for 30 min at 37 °C and imaged (Figure 5d). The images demonstrate that there was no appreciable change in the fluorescence after washing or challenging with excess biotin, confirming that **ReL1** binds effectively to avidin and that the complex has the appropriate fluorescence properties to be used for in vitro microscopy.

CONCLUSIONS

Biotin has been derivatized to provide a tridentate *N*,*N*-bis(pyridylmethyl)amino terminus that is able to coordination the $\{M(CO)_3\}^{+1}$ core (M = Re, ^{99m}Tc). The rhenium complex $[Re(CO)_3(L1)]Br$ possesses the appropriate fluorescence properties to be used for in vitro fluorescence microscopy studies. The biotin ligand **L1** can also be labeled with ^{99m}Tc in high yield to provide a robust complex, **TcL1**. The log $P_{o/w}$ value of **TcL1** is 1.10, suggesting that the compound is only modestly lipophilic and should not exhibit unduly high hepatic retention. The study demonstrates that **L1** or its derivatives may be exploited for the preparation of complementary fluorescent and radioactive biotin probes. These reagents can then be used to perform correlated in vitro and in vivo imaging studies, such that work in isolated cells and studies carried out in living organisms may be compared. Of course, this presupposes that the partition coefficient of the bioconjugate meaningfully correlates with the lipophilicity and hepatic retention of the compound, such that in vivo target-to-nontarget ratios are useful.

The peptides comprising the sequence of HIV-1 Tat protein (positions 48−60), Antennapedia (positions 43−58), and HIV-1 Rev protein (positions 34−50) are known to be cell-permeating. In this study, we examined how the distribution of Fab fragments in rats is affected by conjugation with these peptides. Fab fragment was iodinated by a chloramine-T method and then chemically conjugated with cell-permeating peptide. The complex of ^{125}I-Fab and cell-permeating peptide was administered to male rats intravenously at a dose of 1 mg/kg, and whole-body autoradiography was performed at 4 and 24 h after administration. The patterns of distribution of ^{125}I-Fab exhibited remarkable variation depending on the cell-permeating peptide used. In particular, at 4 h, high concentrations of radioactivity were observed in the spleen, adrenal gland, renal medulla, and liver with Rev peptide−Fab complex, in the liver and spleen with Tat peptide−Fab complex, and in the spleen, adrenal gland, and liver with Antennapedia peptide−Fab complex. Even at 24 h, high concentrations of radioactivity were still observed in the spleen and renal medulla of rat with Rev peptide−Fab complex, and in the spleen and renal cortex of rat with Antennapedia peptide−Fab complex. These findings demonstrate that the patterns of distribution of peptide−^{125}I-Fab complexes can be modulated by selection of cell-penetrating peptides. Moreover, the patterns of retention of peptide−^{125}I-Fab complexes in internal organs also differed at 24 h after administration. These findings provide valuable information for the development of novel antibody pharmaceuticals and therapeutic systems.

INTRODUCTION

Antibodies are used in a variety of diagnostic methods and treatments for their high specificity and affinity to antigens. Their specificity of binding to viruses and bacteria, in particular, is associated with the prevention of viral and bacterial proliferation and infection, and antibody preparations are already available as therapeutic pharmaceuticals. However, although they are effective in blood, lymph, and similar tissues, antibodies are incapable of penetrating into cells and tissues and are thus nearly ineffective against latent viruses and bacteria.

Recently, a method of delivering high-molecular-weight proteins into cells using a cell-permeating peptide was developed, and the intracellular delivery of various proteins is now being studied (*1*−*9*). One of the most well-known cell-permeating peptides is that derived from positions 48−60 of Tat protein, a transcription regulator protein of HIV-1 (TAT). Antennapedia-derived peptide corresponding to positions 43−58 (ANP) has also been widely used (*10*−*12*). We have shown that the RNA binding site (positions 34−50: REV) of the HIV-1 Rev protein, which is involved in the cytosolic transport of viral mRNA, can act as a cell-permeating peptide (*13*−*15*). We are seeking to develop an innovative pharmaceutical by conjugating the REV peptide to an antibody. Although many individual studies of these cell-permeating peptides have been performed, there have been few comparative studies of them. In particular, there have been almost no such studies of the effects of attachment of these cell-permeating peptides to binding partner proteins on patterns of distribution in vivo.

In this study, we used REV, TAT, and ANP peptides as cell-permeating peptides. As a binding partner protein, we employed a Fab fragment (Fab), a functional low-molecular-weight antibody component. Each cell-permeating peptide was conjugated to iodinated Fab, radioisotope-labeled with ^{125}I in advance, and each complex was intravenously administered to rats. The patterns of distribution of complexes were examined by whole-body autoradiography (ARG), a method commonly used to examine the kinetics of labeled drugs in animals. The Fab was prepared from a polyclonal antibody (*16*), and each conjugate of cell-permeating peptide and Fab was prepared by a convenient method based on chemical modification (*13*).

EXPERIMENTAL PROCEDURES

General Procedures. The native Fab was prepared from a commercially available polyclonal antibody preparation (Venoglobulin-IH, Mitsubishi Pharma) using the ImmunoPure Fab Preparation Kit (Pierce). Cell-permeating peptides were synthesized using solid-phase methods at the Peptide Institute (Osaka, Japan). We employed REV, TAT, and ANP peptides as cell-permeating peptides, as shown in Table 1. The purities of these peptides were 95% or more as determined by HPLC. Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS) was measured using an Applied Biosystems Voyager-DE STR.

Preparation of Cell-Permeating Peptide−^{125}I-Fab. The Fab was first labeled with ^{125}I by the chloramine-T method (*17*, *18*). Iodinated Fab (^{125}I-Fab) was adjusted to 1 mg/mL with nonlabeled Fab solution. One hundred twenty micrograms of *N*-(6-maleimidocaproyloxy) succinimide ester (EMCS) (1 molar equiv to Fab) was added to 1 mL of ^{125}I-Fab solution, and this

Table 1. Cell-Permeating Peptides Used in This Study

peptide	amino acid sequence	purity (%)[a]
REV (HIV-1 Rev (34−50))	NH_2-TRQARRNRRRRWRERQR-GC-$CONH_2$	98.2
TAT (HIV-1 Tat (48−60))	NH_2-GRKKRRQRRRPPQ-C-$CONH_2$	98.0
ANP (Antennapedia (43−58))	NH_2-RQIKIWFQNRRMKWKK-GC-$CONH_2$	95.6

[a] HPLC conditions: column, Zorbax 300SB-C18 (4.6 mm i.d. × 150 mm); eluant, 1−60% CH_3CN/ 0.1% TFA (25 min); temperature, 50 °C; flow rate, 1.0 mL/min; detection, 220 nm.

mixture was gently stirred at room temperature for 2 h. The free EMCS was removed with a PD-10 column (Amersham) previously equilibrated with phosphate-buffered saline (PBS). Subsequently, the column effluent was concentrated by centrifugation using Microprep (Millipore), and this concentrate was adjusted to a final volume of 1 mL with PBS. One molar equivalent of REV, TAT, or ANP peptide (230 μL) was added to this reaction mixture, and the mixture was gently stirred at room temperature for 2 h. After excess peptide was removed using a PD-10 column, the protein fraction was concentrated by centrifugation using Microprep to obtain the complexes of REV, TAT, or ANP peptide with ^{125}I-Fab (REV−^{125}I-Fab, TAT−^{125}I-Fab, ANP−^{125}I-Fab). Each peptide−^{125}I-Fab complex was adjusted to a final protein concentration of 1 mg/mL and stored below −30 °C until use.

Radiochemical Purity of Cell-Permeating Peptide-Conjugated ^{125}I-Fab. The radiochemical purity of test substances was determined by radio-HPLC before administration. The analytical column used was a POROS R2/10 (PerSeptive Biosystems), with a nonlabeled complex used to confirm retention time. Subsequently, an aliquot of the dosing solution was separated and assayed for radioactivity before administration. After this mixed solution was centrifuged (3000 rpm, 15 min, 4 °C), the supernatant was removed, and the sediment was assayed for radioactivity. The ratio of the concentration of radioactivity of the TCA sediment fraction to that of the entire dosing solution was calculated. Radioactivities were determined using a γ counter (Cobra 5005, PerkinElmer).

Incorporation of Cell-Permeating Peptide-Conjugated ^{125}I-Fab into HeLa Cells. HeLa cells (in 24-well plates) were grown to subconfluence. After replacement of culture medium with 500 μL per well of fresh MEM medium, the cells were incubated at 37 °C for 3 h. Subsequently, 5 μL of peptide−^{125}I-Fab was added and the cells were incubated at 37 °C for 30 min. After washing three times with PBS, 200 μL of trypsin-EDTA solution was added to each well and incubated at 37 °C for at least 15 min to completely detach the cells. The cells and cell lysate were recovered from each well into a polystyrene tube, and radioactivity was determined using a γ counter (COBRA Quantum, PerkinElmer).

Preparation of Fluorescein-REV−Fab and Microscopic Observation. The fluorescently labeled conjugates of Fab with cell-penetrating peptides were prepared similarly to cell-permeating peptide−^{125}I-Fab conjugates. One hundred twenty micrograms of EMCS, together with 305 μg of fluorescein-5(6)-carboxamidocaproic acid *N*-hydroxy succinimide ester (FLUOS), was added to 1 mL of nFab solution (1 mg/mL), and this mixture was gently stirred at room temperature for 2 h. Free EMCS and FLUOS were removed with a PD-10 column (eluate, PBS). The first main peak was concentrated by centrifugation using Microprep, and this concentrate was adjusted to a final volume of 1 mL with PBS. One molar equivalent of REV peptide (230 μL) to EMCS was added to this reaction mixture, and the mixture was gently stirred at room temperature for 2 h. After excess peptide was removed using a PD-10 column, the protein fraction was concentrated by centrifugation using Microprep to obtain the conjugates of fluorescein-REV peptide with nFab (fluorescein-REV−Fab). Fluorescein-REV−Fab was stored below −30 °C until use.

For microscopic assay, 2×10^5 cells were plated into 35-mm glass-bottomed dishes (Iwaki) and cultured for 48 h. After complete adhesion, the culture medium was exchanged. The cells were then incubated at 37 °C with fresh medium (200 μL) containing the fluorescein-REV−Fab. The cells were washed five times with cold PBS. Distribution of fluorescein-REV−Fab in live cells was analyzed using a confocal scanning laser microscope FV300 (Olympus) equipped with a 40 × objective without fixation.

Determination of Concentrations of Radioactivity in Blood. At 0.25, 0.5, 1, 3, 6, and 24 h after administration of test substance, blood (approximately 0.4 mL) was drawn from the caudal vein using a glass capillary with an inner wall treated with 500 units/mL heparin sodium in physiological saline. A 0.1 mL portion of each blood sample was separated for determination of blood concentrations and transferred to a polystyrene tube, and the radioactivity in the sample was determined using a γ counter. Subsequently, 1 mL of physiological saline and 1 mL of 20% trichloroacetic acid (TCA) were added to the assayed sample, and this solution was subjected to centrifugation (3000 rpm, 15 min, 4 °C). After the supernatant was removed, 1 mL of physiological saline was added to the sediment, followed by centrifugation in the same manner. The supernatant was removed, and the radioactivity in the TCA sediment fraction was determined.

Whole-Body ARG. Animals receiving test substance were killed by ether anesthesia at 4 h after administration. After each animal body was clipped, an approximately 3% carboxymethylcellulose sodium salt (CMC-Na) solution was filled in the oral cavity, nasal cavities, earholes, and anus, and the animal was quickly frozen in a hexane−dry ice bath. The tail and extremities were then amputated, and the body was preserved in wrap at −20.4 to −17.0 °C for at least 24 h. An approximately 3% CMC-Na solution was applied to the body surface of the frozen fixed rat. Subsequently, the body was embedded in an approximately 5% CMC-Na solution and frozen in a hexane-dry ice bath to obtain a frozen block. Frozen sections 30 μm in thickness were prepared using a cryomicrotome. The sections were obtained in a median plane, in 2 planes containing kidney and other major tissues. Each section was freeze-dried at approximately −20 °C. The dry sections were applied to base paper and covered with Mylar film. The sections for ARG were brought into close contact with an imaging plate (IP), and exposed in a shield box for 12 h. After completion of exposure, the images were scanned using a bioimaging analyzer, and whole-body ARGMs were generated (gradation, 65536; resolution, 50 μm; sensitivity, 4000; latitude, 5, IP; BAS-MS2040). Images obtained by whole-body ARG were analyzed on a relative basis using the Image Gauge software program (version 3.46, Fuji Photo Film).

RESULTS

Preparation of Cell-Permeable Peptide−Fab Conjugates. When the in vivo distribution of cell-permeable peptide−Fab conjugates is examined, contamination of free Fab in the conjugates may make the analysis of results difficult, since the methods of biodistribution of conjugates may differ from that of free Fab. We therefore first established conditions in which no free Fab remained in the conjugates, with use of various amounts of the cross-linking agent EMCS and the peptides (Figure 1). SDS−PAGE of REV−Fab and nFab showed that the ranges of molecular weights of the conjugates shifted depending on the amounts of cross-linking agent (EMCS) and

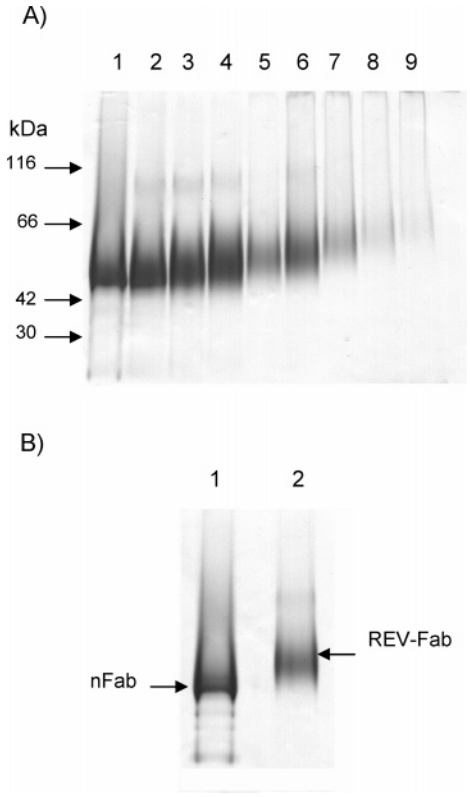

Figure 1. SDS−PAGE of REV peptide and Fab conjugate. (A) Lanes 1−9 correspond to conjugates prepared by the treatment of nFab with 0, ×1.5, ×3, ×6, ×12 (1/2 sample volume), ×12, ×24, ×36, and ×48 equiv of EMCS and REV peptide, respectively, at room temperature for 2 h. When ×12 equiv of these are employed, substantially no free Fab is observed in the sample (B). Lane 1, nFab, and lane 2, REV−Fab, correspond to samples prepared by the same conditions as samples administered to rats. A 4−12% gradient gel (NOVAX) was employed for the analysis.

Table 2. Stoichiometric Ratios of Fab and Cell-Permeable Peptide Conjugates

	molecular weight			
		complex[b]		stoichiometric ratio (*B*/*A*)
samples	peptide[a] (*A*)	main	diff[c] (*B*)	
nFab		48 000		
REV−Fab	2 597	61 000	13 000	5.0
TAT−Fab	1 821	57 000	9 000	4.9
ANP−Fab	2 406	60 000	12 000	5.0

[a] Molecular weight determined by electrospray ion mass spectroscopy (ESIMS). [b] Molecular weight determined by TOFMS. [c] The difference of molecular weight between peptide−Fab and nFab.

the peptides employed (Figure 1A). We selected use of ×12 equiv of EMCS and peptides each to Fab for preparation of the conjugates, with which no notable bands corresponding to unmodified nFab were observed on SDS−PAGE (Figure 1B). Since the cationic cell-penetrating peptides may neutralize the negative charges of SDS and may affect the mobility of samples in the gel, we further analyzed the molecular weights of the conjugates using MALDI-TOFMS.

Table 2 shows the stoichiometric ratios of cell-penetrating peptides and Fab in the conjugates prepared using the same conditions as determined above, which were also employed for chemical conjugation of ^{125}I-Fab in subsequent study. The average peptide:Fab ratios were thus estimated to be about 5:1 for each conjugate. In addition, no notable signals corresponding to the free Fab were observed (data not shown).

Cellular Uptake of Fluorescently Labeled REV−Fab Conjugate in HeLa Cells. Figure 2 shows results of confocal microscopic observation of HeLa cells treated with the fluorescently labeled REV−Fab conjugate (1 M) at 37 °C for 1 h. Significant internalization of the conjugate was observed, whereas internalization of the free, unconjugated Fab was poor.

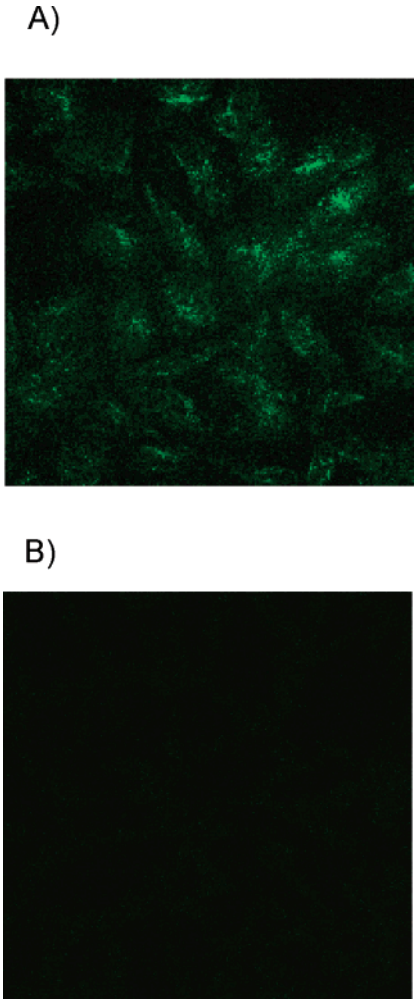

Figure 2. The cellular uptake of the fluorescently labeled REV−Fab conjugate by HeLa cells. The cells were observed without fixation. (A) Fluorescently labeled REV−Fab. (B) Fluorescently labeled nFab.

Table 3. Radiochemical Purities of the Cell-Permeable Peptide-Conjugated ^{125}I-Fabs

	radioactivity	radiochemical purity	
sample	(MBq mg^{-1} mL^{-1})	HPLC (%)	TCA insoluble (%)[a]
^{125}I-Fab	1.27	97.3	95.1
REV−^{125}I-Fab	1.45	98.5	96.5
TAT−^{125}I-Fab	1.49	98.4	96.2
ANP−^{125}I-Fab	1.27	98.5	94.3

[a] HPLC conditions: column, POROS R2/10 (4.6 mm diameter × 50 mm length); eluant, 1−100% CH_3CN/0.1% TFA (5.5 min); temperature, 23 °C; flow rate, 3.0 mL/min; detection, 280 nm.

Radiochemical Purity of Peptide−^{125}I-Fab Complexes. Table 3 shows the concentrations of radioactivity in and radiochemical purities of the samples given to rats. Rev peptide conjugated ^{125}I-Fab (REV−^{125}I-Fab), Tat peptide conjugated ^{125}I-Fab (TAT−^{125}I-Fab), and Antennapedia peptide conjugated ^{125}I-Fab (ANP−^{125}I-Fab) each had radiochemical purities above 97% as determined by HPLC. The radiochemical purities of the TCA sediment fractions of these samples were also 94% or higher.

Incorporation of Cell-Permeating Peptide Conjugated with ^{125}I-Fab into HeLa Cells. REV−^{125}I-Fab, TAT−^{125}I-Fab, ANP−^{125}I-Fab, or ^{125}I-Fab was added to the culture medium

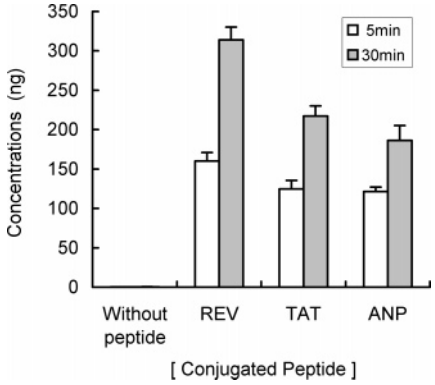

Figure 3. Effects of peptide binding on cellular uptake of ^{125}I-Fabs in HeLa cells. Values are the mean ± SD of the results for 4 wells.

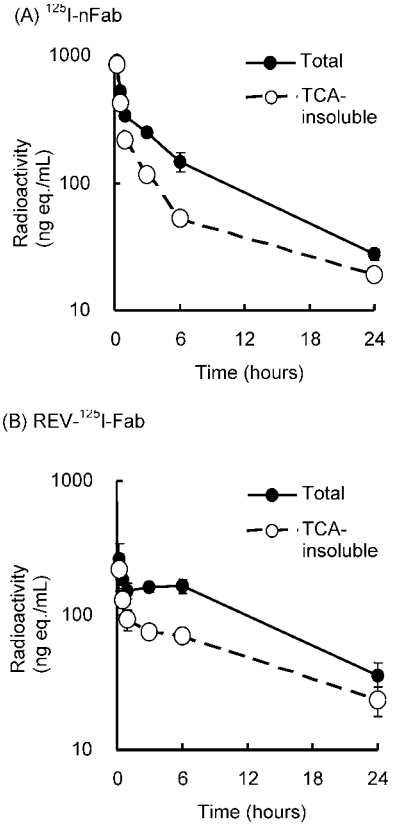

Figure 4. Concentrations of radioactivity in blood after intravenous administration of ^{125}I-Fab or REV−^{125}I-Fab to male rats. Values are the mean ± SD of results for 3 animals.

for HeLa cells, and uptake into cells was determined. Figure 3 shows findings for these peptides at 5 and 30 min after addition of samples. The level of incorporation of ^{125}I-Fab was very low at both times. On the other hand, the cell-permeating, peptide-conjugated Fabs each exhibited high intracellular incorporation. The order of cellular uptake was REV−^{125}I-Fab > TAT−^{125}I-Fab ≥ ANP−^{125}I-Fab at both time points.

Concentrations of Radioactivity in Blood Following Intravenous Administration. Figure 4 shows the time course of radioactive concentration in rat blood following intravenous administration of ^{125}I-Fab or REV−^{125}I-Fab. We measured the concentrations of radioactivity in whole blood and the TCA-insoluble fractions. ^{125}I-Fab without cell-permeating peptide exhibited a slow biphasic decline in concentration of radioactivity. On the other hand, a rapid decrease in concentration of radioactivity was observed for REV−^{125}I-Fab as early as within 1 h after administration, though the rate of decline subsequently slowed, with a plateau at 3 to 6 h after administration.

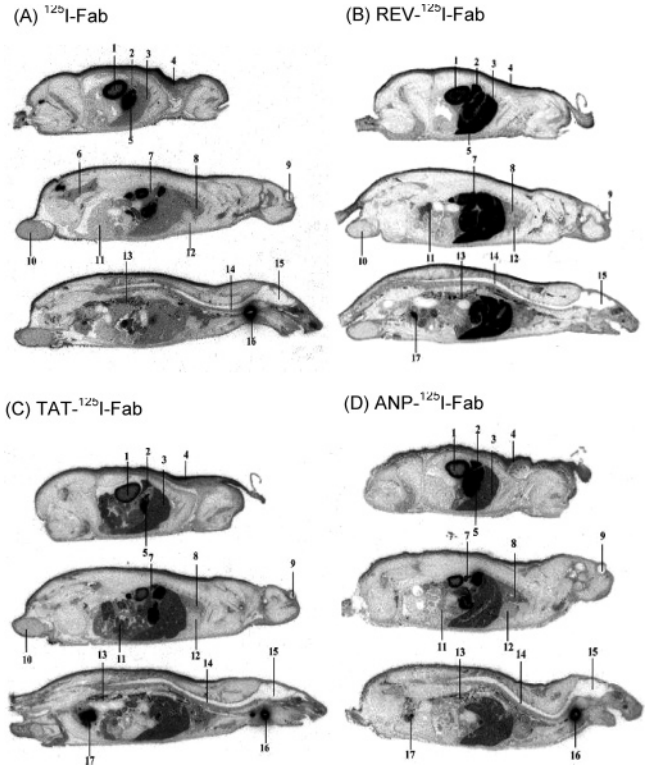

Figure 5. Whole-body autoradiograms at 4 h after intravenous administration of peptide−^{125}I-Fab complexes to rats: 1, kidney; 2, spleen; 3, liver; 4, skin; 5, gastric contents; 6, bone marrow; 7, adrenal gland; 8, lung; 9, eyeball; 10, testis; 11, intestinal contents; 12, heart; 13, blood; 14, spinal cord; 15, brain; 16, thyroid gland; 17, urinary bladder.

Whole-Body ARG. Single intravenous administration of REV−^{125}I-Fab, TAT−^{125}I-Fab, ANP−^{125}I-Fab, or ^{125}I-Fab to male rats was performed, and whole-body ARGMs were generated 4 and 24 h later. At 4 h after administration of ^{125}I-Fab, particularly high radioactivity was observed in the thyroid, renal cortex, and gastric contents, and relatively high radioactivity in the skin. However, little radioactivity was detected in the brain or spinal cord (Figure 5A). At 24 h after administration, particularly high radioactivity was observed in the thyroid and relatively high radioactive concentrations were observed in the renal cortex, gastric contents, and skin, but almost no radioactivity was detected in any other tissue (Figure 6A).

In the case of REV−^{125}I-Fab, particularly high radioactivity was observed in the spleen, adrenal gland, and liver at 4 h after administration, and relatively high radioactivity was observed in the renal medulla (Figure 5B). At 24 h after administration, relatively high radioactivity was observed in the spleen and renal medulla (Figure 6B). For TAT−^{125}I-Fab, particularly high radioactivity was observed in intestinal contents at 4 h after administration, and relatively high radioactivities were observed in the liver, spleen, and small intestinal contents (Figure 5C). At 24 h after administration, relatively high radioactivity was observed in intestinal contents, but almost no radioactivity was observed in any other tissue (Figure 6C). At 4 h after administration of ANP−^{125}I-Fab, relatively high radioactivities were observed in the spleen, adrenal gland, and liver (Figure 5D). At 24 h after administration, relatively high radioactivity was observed in the spleen and renal cortex (Figure 6D).

DISCUSSION

Whole-body ARG has been used for accurate analysis of the kinetics of labeled drugs and bioactive proteins in animals, and it yields precise findings useful for characterizing patterns of

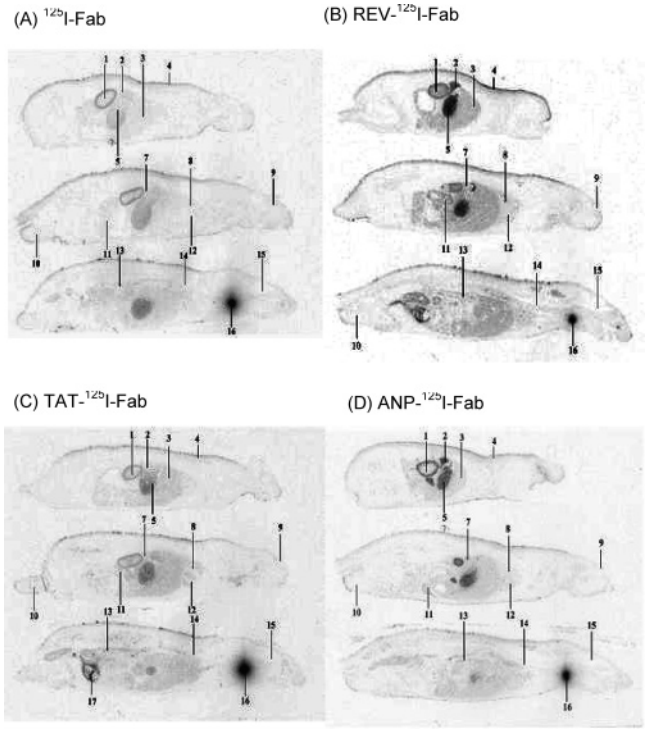

Figure 6. Whole-body autoradiograms at 24 h after intravenous administration of peptide−^{125}I-Fab complexes to rats: 1, kidney; 2, spleen; 3, liver; 4, skin; 5, gastric contents; 7, adrenal gland; 8, lung; 9, eyeball; 10, testis; 11, intestinal contents; 12, heart; 13, blood; 14, spinal cord; 15, brain; 16, thyroid gland; 17, urinary bladder.

distribution as well. Development of new antibody pharmaceuticals with the potential for penetration into cells is a challenge in antibody therapy. Determination of in vivo patterns of distribution is a very important part of this development. We therefore examined the patterns of distribution of peptide−antibody complexes in rat using whole-body ARG. In the present study, we used REV, TAT, and ANP peptides as cell-permeating peptides, which were chemically conjugated to Fab as an antibody component. The patterns of distribution of the complexes were compared with each other.

Contamination by free, unmodified Fab would make assessment of biodistribution of the peptide conjugates difficult due to the presence of two radioiodinated species (^{125}I-Fab and peptide−^{125}I-Fab); in this case, the biodistribution profiles of each peptide−^{125}I-Fab conjugate would be the sum of those of the two radiolabeled species. We therefore established conditions in which free Fab should not contaminate cell-permeating peptide−Fab conjugates in significant amounts (Figure 1). TOFMS analysis revealed that each peptide−Fab conjugate had a peptide:Fab stoichiometric ratio of about 5:1. Therefore, the differences in biodistribution of conjugates can be attributed to the nature of each peptide.

It would be ideal to use conjugates for which carrier peptides are modified to specific sites with a predefined stoichiometry. Generally speaking, it is not easy to obtain these by chemical modification. They may be obtained using genetically engineered proteins. However, considering the lack of information on antibody delivery using peptide carriers, we decided to employ chemical modification as a first step in our study.

Confocal microscopic observation of HeLa cells showed that cellular uptake of Fab was promoted by conjugation with the cell-permeating peptides. Others have reported similar observations (*23, 24*). Using ^{125}I-labeled Fab, we then examined the cellular uptake of REV−^{125}I-Fab, TAT−^{125}I-Fab, ANP−^{125}I-Fab, and unconjugated ^{125}I-Fab by HeLa cells. Each complex of ^{125}I-Fab conjugated with a cell-permeating peptide was rapidly incorporated into HeLa cells, though ^{125}I-Fab was not. These results are consistent with those of previous microscopic studies using fluorescently labeled conjugates (*12, 13*), suggesting that radioisotope labeling did not decrease the cellular permeability of these peptides.

We subsequently performed whole-body ARG for cell-permeating peptides conjugated to ^{125}I-Fab following intravenous administration to rats. The times for performance of whole-body ARG were determined based on the time courses of blood concentration of radioactivity following intravenous administration. ^{125}I-Fab exhibited a slow biphasic decline in the blood, whereas REV−^{125}I-Fab initially exhibited a rapid decline in blood following intravenous administration and then slowly entered a continuous phase about 3 to 6 h after administration. This initial rapid reduction in radioactivity in blood may be due to the quick penetration of REV−^{125}I-Fab into tissue.

One of the most successful studies of in vivo delivery using TAT and other cell-penetrating peptides is that by Schwarze et al. (*4*), who reported that intraperitoneal injection of conjugate of TAT and β-galactosidase to mouse resulted in distribution of the conjugates to various tissues including brain. They included tissue distributions at 4 h after administration. There have been several other in vivo studies, the majority of which present distributions in the body from 1 to 24 h (*20, 21, 25*−*27*). In order to compare our results with the preceding findings, we performed whole-body ARG at 4 and 24 h. The latter time point was also selected to assess the duration of the conjugates in tissues; this information is very important for designing effective delivery systems with low toxicity.

Conjugation of the cell-permeating peptides yielded remarkable changes in distributions of ^{125}I-Fab. At 4 h after administration, nonconjugated ^{125}I-Fab was present in the thyroid, gastrointestinal contents, renal cortex, and skin. On the other hand, peptide-conjugated ^{125}I-Fabs were distributed not only to these organs but to others as well, including the liver, spleen, and adrenal gland. Interestingly, distinct patterns of penetration were observed for each of the cell-permeating peptides. For REV−^{125}I-Fab, the highest concentrations of radioactivity were observed in the liver, spleen, and adrenal gland. TAT−^{125}I-Fab was nearly unobservable in the adrenal gland, although it was observed in the liver and spleen. The pattern of tissue distribution of ANP−^{125}I-Fab in tissues was similar to that of REV−^{125}I-Fab, though REV−^{125}I-Fab was characterized by greater penetration into the liver, spleen, and adrenal gland.

On whole-body ARG at 24 h after administration, the earliest elimination was observed for TAT−^{125}I-Fab, the levels of which had decreased nearly to those of ^{125}I-Fab in almost all organs examined. The finding of high levels of radioactivity in intestinal and gastric contents suggests that TAT−^{125}I-Fab might be excreted in the form of low-molecular-weight components. For REV−^{125}I-Fab, high retention compared to that of ^{125}I-Fab was observed in the spleen and renal medulla. Retention of ANP−^{125}I-Fab was observed in the spleen and renal cortex. These differences among peptides in localization and retention of Fab conjugates in vivo provide valuable information for the development of organ-specific antibody delivery systems.

The distribution of TAT−^{125}I-Fab at 4 h after administration in this study was similar to those of [99mTc]Tat peptide and ^{125}I-scFV−Cys-TAT in previous studies. Previous studies on the distribution of TAT peptide alone or complexes of it with proteins have revealed accumulation in the liver and spleen (*4, 19*−*22*), consistent with the present findings. It should be noted, however, that although relatively high pulmonary penetration was observed in previous studies, almost no pulmonary accumulation of TAT−^{125}I-Fab was observed in this study. This difference in findings might be due in part to differences among studies in binding partner proteins used or in methods used for

conjugation. In addition, although the existence of β-galactosidase activity in brain was reported by Schwarze et al. (*4*), none of the Fab conjugates tested in this study exhibited high levels of accumulation in brain or spinal cord. Schwarze et al. administered test samples intraperitoneally, whereas we employed the intravenous route for administration. This difference in route of administration might have affected passage through the blood−brain barrier.

In conclusion, this study has clearly demonstrated that appropriate selection of cell-penetrating peptides yields differences in in vivo distribution of Fab, with large changes in distribution observed in organs such as the liver, spleen, adrenal gland, and kidney. Moreover, conjugation of Fabs with cell-penetrating peptides was found to have profound effects on retention of such Fabs in internal organs. Further study using cell-penetrating peptides, especially on the effects of peptide: Fab stoichiometry and the precise kinetics/time course of biodistribution, will provide valuable information for the development of novel antibody pharmaceuticals and therapeutic systems.

ACKNOWLEDGMENT

Synthesis and Grafting of Thioctic Acid−PEG−Folate Conjugates onto Au Nanoparticles for Selective Targeting of Folate Receptor-Positive Tumor Cells

Vivechana Dixit,[†] Jeroen Van den Bossche,[‡] Debra M. Sherman,[#] David H. Thompson,*[,‡] and Ronald P. Andres*[,†]

School of Chemical Engineering, Department of Chemistry, Life Science Microscopy Facility, Purdue University, West Lafayette, Indiana 47907. Received November 22, 2005; Revised Manuscript Received February 16, 2006

This paper reports the creation of Au nanoparticles (AuNP) that are soluble in aqueous solution over a broad range of pH and ionic strength values and that are capable of selective uptake by folate receptor positive (FR+) cancer cells. A novel poly(ethylene glycol) (PEG) construct with thioctic acid and folic acid coupled on opposite ends of the polymer chain was synthesized for targeting the AuNP to FR+ tumor cells via receptor-mediated endocytosis. These folic acid−PEG−thioctic acid conjugates were grafted onto 10-nm-diameter Au particles in aqueous solution. The resulting folate−PEG-coated nanoparticles do not aggregate over a pH range of from 2 to 12 and at electrolyte concentrations of up to 0.5 M NaCl with particle concentrations as high as 1.5×10^{13} particles/mL. Transmission electron microscopy was used to document the performance of these coated nanoparticles in cell culture. Selective uptake of folate−PEG grafted AuNPs by KB cells, a FR+ cell line that overexpress the folate receptor, was observed. AuNP uptake was minimal in cells that (1) do not overexpress the folate receptor, (2) were exposed to AuNP lacking the folate−PEG conjugate, or (3) were co-incubated with free folic acid in large excess relative to the folate−PEG grafted AuNP. Understanding this process is an important step in the development of methods that use targeted metal nanoparticles for tumor imaging and ablation.

INTRODUCTION

Current anticancer agents suffer from several limitations—they are typically highly toxic and are often nonspecific in that they accumulate within normal as well as tumor cells. In many cases, they also have limited bioavailability due to poor solubility and limited stability in vivo, leading to short half-lives and rapid clearance from the body. An ideal solution to these problems would be to deliver biologically effective concentrations of the therapeutic agent(s) to the cancer cells with high specificity. One approach to this ultimate goal could be achieved by attaching the agents to the surface of a gold nanoparticle (AuNP)[1] that is small enough to be transported through the circulatory system, is not rapidly cleared from the body, and is selectively targeted to cancer cells.

AuNPs are the most chemically stable of metal nanoparticles. They have been studied as "soluble" gold since the fifth or fourth century B.C. both for their aesthetic and for their curative properties. In ancient times, they were used in the manufacture of ruby glass and in the treatment of a wide range of diseases (*1*). The use of AuNP in modern biology dates to their application as immunological staining agents for electron microscopy (*2*), wherein the AuNP are functionalized by simple covalent attachment or physisorption of an antibody or enzyme to the particle surface prior to exposure to tissue sections.

Recently, AuNPs have become the subject of increased interest in the context of the emerging fields of nanoscience and nanotechnology due to the ease of synthesizing monolayer-protected AuNP. These inorganic−organic constructs typically have a core−shell morphology consisting of a gold core, as small as 1−2 nm in diameter, surrounded by a covalently attached monolayer of organic molecules. The organic shell passivates the metallic core and imparts steric stabilization to the nanoparticles, permitting their manipulation as stable organic compounds. Recent reviews provide a compilation of the methods used to fabricate monolayer-protected AuNPs and highlight some of their important applications (*3*, *4*).

AuNPs must be water-soluble over a wide range of pH values and electrolyte concentrations to successfully target tumor cells. They must also resist recognition and subsequent removal by macrophages associated with the reticuloendothelial system. We anticipated that water solubility and biocompatibility could be achieved by coating the Au core with a biomedically accepted, water-soluble polymer such as poly(ethylene glycol) (PEG), since PEGylation of proteins (*5*) and liposomes (*6*−*9*) is known to increase their bioavailability, improve their pharmacokinetics, and decrease their immunogenicity.

One method of covalently attaching PEG chains to AuNP is through the use of a thiol-terminated PEG. Foos et al. (*10*) used this approach to synthesize water-soluble AuNP. Tshikhudo et al. (*11*) also synthesized water-soluble AuNP by terminating the PEG chain with an alkanethiol. The use of a short alkane chain between the Au surface and the PEG chain is thought to produce a dense, ordered "brush" morphology on the Au surface. Tokumitsu et al. (*12*) observed a conformational transition when alkanethiol-terminated PEG chains are grafted to a flat Au substrate, consistent with the theoretical predictions of Szleifer (*13*). The PEG chains exist in a so-called "mushroom" regime at low coverages; however, as the coverage increases, they undergo a transition to a more extended conformation (i.e., the "brush" regime) away from the surface. From the standpoint of producing stable AuNPs for in vivo use, chemisorption of PEG is preferred over physisorption. It is not clear, however, whether a more ordered PEG layer anchored by alkanethiol adsorption

on gold or a more amorphous monolayer provided by direct disulfide termination of the PEG chain is more desirable for imparting water solubility and biocompatibility to the Au nanoparticles.

A second method for covalently attaching PEG chains to AuNP is by replacing the terminal thiol substituent with a disulfide moiety. Mangenay et al. (*14*) have shown that hydrophilic polymers that are end-capped with a disulfide can be efficiently grafted onto citrate-stabilized AuNPs in aqueous solution. This is the method adopted in the present study. Thioctic acid was chosen as the grafting agent due to its low cost, simple coupling chemistry, and ease of handling relative to thiol-based conjugates.

Folic acid was chosen as the targeting agent. Folate is an essential precursor for the synthesis of nucleic acids and some amino acids, is not produced endogenously by mammalian cells, and requires internalization by cells via either receptor-mediated endocytosis or a carrier-based uptake mechanism (*15*−*17*). The folic acid receptor (FR)-based mechanism constitutes a particularly useful target for tumor-specific drug delivery because it is upregulated in many human cancers, including malignancies of the ovary, brain, kidney, breast, and lung. The FR density also appears to increase as the stage/grade of the cancer increases (*18*). An additional feature of FR that is particularly attractive for intravenous drug delivery strategies is the fact that FR generally becomes accessible to the vascular epithelium only after malignant transformation. This is because FR is selectively expressed on the apical membrane surface of normal polarized epithelial cells and is, therefore, protected from FR-directed therapeutics delivered in the plasma. Upon epithelial cell transformation, however, cell polarity is lost and FR becomes accessible to targeted drugs in blood circulation (*19*). The folate receptor has a high affinity for folic acid ($K_d \sim 0.1$ nM), which results in high uptake by FR+ cells, even at low folate loadings on the therapeutic agent (*17*, *19*). Because of these attractive characteristics, folate conjugation has become a widely used strategy for targeting liposomes (*20*−*25*), plasmid complexes (*26*−*33*), nanoparticles (*34*−*36*), polymer micelles (*37*), and other polymer constructs (*38*) for selective uptake by tumor cells.

The 10 nm AuNPs chosen for this study were a compromise between providing a reasonable surface area for attachment of PEG chains while at the same time enabling rapid nanoparticle penetration into solid tumors based on the enhanced permeation and retention effect (e.g., EPR) (*39*, *40*). The AuNPs were purchased as a citrate-stabilized aqueous colloid. Two PEG polymers were synthesized for grafting onto AuNPs, a mPEG−thioctic acid conjugate (mPEG2000−T) for steric stabilization and a folic acid−PEG−thioctic acid conjugate (F−PEG1500−T) that would enable both steric stabilization and tumor cell targeting. After the AuNPs were modified with either of these conjugates, they were monitored for colloidal stability by absorption spectroscopy. KB cells were then treated with either the mPEG−thioctic acid-modified AuNP (mPEG2000−T:AuNP) or the folate−PEG1500−thioctic acid-modified AuNP (F−PEG1500−T:AuNP) constructs (Scheme 1) and their capacity for internalization observed using TEM.

EXPERIMENTAL PROCEDURES

Materials and Methods. Size selected (10 nm) gold colloid was obtained from Ted Pella Inc. (Redding, CA). mPEG-NH_2 was purchased from Nektar Therapeutics (Huntsville, AL); all other chemicals were purchased from Sigma-Aldrich (St. Louis, MO) and used as received. All reactions were performed under anhydrous conditions and under an Ar atmosphere unless otherwise mentioned. All solvents were reagent grade and were distilled from CaH_2 under Ar before use. NMR spectra were recorded on Varian 200 or 300 MHz spectrometers using ^1H solvent peaks as internal reference. Column chromatography was typically performed on 230−400 mesh silica gel using HPLC grade eluents. Thin-layer chromatography was performed using Baker-flex IB−F plates (J. T. Baker) and visualized using UV, I_2 adsorption, $KMnO_4$/heat, and/or H_2SO_4/heat.

Synthesis of Functionalized PEG Polymers. *Synthesis of mPEG-NH−thioctamide (mPEG2000−T).* mPEG2000-NH_2 (1 g, 0.50 mmol) and NHS-activated thioctic acid (287 mg, 1 mmol; prepared as described by Ponpipom et al. (*41*) were dissolved in 20 mL anhydrous CH_2Cl_2. Triethylamine (1 mL, 6.9 mmol) was then added dropwise, and the resulting solution was stirred for 3 days at reflux. After cooling of the reaction to 25 °C, the mixture was evaporated, redissolved in 1 mL of CH_2Cl_2, and precipitated from a 1:1 Et_2O/hexane mixture at −20 °C. After filtration, the product was isolated via silica gel chromatography using 9:1 $CHCl_3$/MeOH as eluent. The white powder was determined to be pure by NMR analysis (>95% purity) Yield: 63%, R_F: 0.48 (9:1 $CHCl_3$/MeOH, I_2 stain), ^1H NMR ($CDCl_3$, 300 MHz): 6.32 (br s, 1H), 3.89 (t, 2H), 3.74−3.55 (m, 200H), 3.19 (m, 3H), 2.51 (m,2H), 2.37 (t, 2H), 2.23 (t, 2H), 1.96 (m, 3H), 1.7 (m, 8 H), 1.50 (m, 4H).

Synthesis of NH_2-PEG1500-NHBoc. NH_2-PEG1500-NH_2 (5 g, 3 mmol) in 50 mL anhydrous MeOH was added to a solution of Boc_2O (0.7 g, 3 mmol). Et_3N (1 mL, 6.9 mmol) was then added in dropwise fashion, and the resulting solution was stirred overnight at reflux. After cooling of the reaction to 25 °C, the

mixture was evaporated, dissolved in 5 mL of CH_2Cl_2, and precipitated from a 1:1 Et_2O/hexane mixture at −20 °C. After filtration, the product was isolated via silica gel chromatography using 89:10:1 $CHCl_3$/MeOH/NH_4OH as eluent. The off-white powder was determined to be pure by NMR (>95%). Yield: 27%, R_F: 0.3 (89:10:1 $CHCl_3$/MeOH/NH_4OH, I_2 stain), ^1H NMR ($CDCl_3$, 300 MHz): 5.03 (s, 3H), 3.75−3.52 (m, 150H), 3.21 (q, 2H), 2.1 (s, 3H), 1.76 (m, 2H), 1.44 (s, 9H).

Synthesis of tBocNH-PEG1500-NH−thioctamide. H_2N-PEG1500-NHBoc (1 g, 0.62 mmol) and NHS-thioctate (400 mg, 1.2 mmol) were dissolved in 10 mL CH_2Cl_2, and 1 mL of Et_3N was added dropwise. This mixture was stirred at reflux for 3 days, after which it was evaporated, redissolved in 1 mL of CH_2Cl_2, and precipitated from 1:1 Et_2O/hexane at −20 °C. After filtration, the product was purified by silica gel chromatography using 95:5 $CHCl_3$/MeOH as eluent. The off-white powder was pure by NMR (>95%) Yield: 61%, R_F: 0.25 (95:5 $CHCl_3$/MeOH, I_2 stain), ^1H NMR ($CDCl_3$, 300 MHz): 4.28 (t, 2H), 3.92−3.45 (m, 150H), 3.28 (m, 3H), 2.78 (s, 2H), 2.52 (m, 1H), 2.41 (t, 1H), 2.0−1.65 (m, 14H), 1.49 (s, 9H).

Synthesis of NH_2-PEG1500-NH−thioctamide. Boc-NH-PEG1500-NH−thioctamide (610 mg) was dissolved in 10 mL of a 1:1 (vol/vol) solution of TFA in CH_2Cl_2. This mixture was stirred at 25 °C for 3 h after which the solvent was evaporated. The recovered solid was redissolved in 1 mL of CH_2Cl_2 and precipitated from a 1:1 Et_2O/hexane mixture at −20 °C. The isolated solid was pure by TLC analysis. Yield: 98%, R_F: 0.14 (89:10:1 $CHCl_3$/MeOH/NH_4OH, I_2 stain), ^1H NMR ($CDCl_3$, 300 MHz): 4.24 (t,2H), 3.88−3.41 (m, 150H), 3.2 (q, 4H), 2.48 (m, 2H), 2.36 (t, 2H), 2.0 (m, 3H), 1.91 (m,1H), 1.67 (m, 3H), 1.5 (m,2H), 0.80 (s,1H).

Synthesis of Folate−NH-PEG-NH−thioctamide (F−PEG-1500−T). Thioctic acid−NH-PEG1500-NH_2 (200 mg, 0.11 mmol) and folic acid (100 mg, 0.20 mmol) were dissolved in 5 mL of anhydrous DMSO. Pyridine (500 μL) was added dropwise to this mixture, followed by DCC (100 mg, 0.6 mmol). The solution was stirred overnight at 70 °C, then cooled to 25 °C, and 50 mL of Et_2O was added. The precipitated product was redissolved and reprecipitated from 1:1 Et_2O/hexane at −20 °C, and the solid was further purified via silica gel chromatography using a 20:79:1 to 50:49:1 MeOH/CH_2Cl_2/NH_4OH step gradient elution. After purification, the isolated product was redissolved in CH_2Cl_2 and filtered through a PFTE filter to remove dissolved Si gel. The filtered solution was then evaporated and dissolved in 60:30:10 benzene/CH_2Cl_2/MeOH and lyophilized to give a yellow powder (>95% pure by NMR). Yield: 59%, R_F: 0.44 (50:49:1 MeOH/CH_2Cl_2/NH_4OH, I_2/UV visualization), ^1H NMR (DMSO, 300 MHz): 8.67 (d, 1H), 8.32 (br s, 1H), 7.92−7.85 (m, 2H), 7.72 (d, 1H), 7.64 (d, 1H), 7.43 (s, 1H), 7.20 (br s, 2H), 6.95 (q, 2H), 6.70 (t, 2H), 4.5 (t,3H), 4.18 (t, 2H), 3.80−3.11 (m, 150h), 2.70 (s, 1H), 2.49 (m, 2H), 2.37 (t, 2H), 2.29 (t, 1H), 2.20−1.80 (m, 4H), 1.64 (m, 5H), 1.44 (m, 2H), 1.30 (s, 1H).

Grafting of Functionalized PEG Polymers onto AuNP. All glassware was cleaned with aqua regia and rinsed with DI water. Citrate-stabilized gold colloid solution (3 mL, used as supplied at ~5.7×10^{12} particles/mL) was adjusted to pH 9−11 using 0.5 M NaOH. The AuNP suspension was then combined with 3 mL of 0.25 mM mPEG2000−T or F−PEG1500−T, and the solution was stirred at 25 °C for 16−18 h. The resulting suspension was split into two equal volumes and centrifuged twice at 13,000 rpm for 60 min at 8 °C with decantation of the supernatant and redispersion of the particles in DI water. The two rinsed samples of AuNP were then recombined in 1 mL of DI water.

The UV−Vis spectra of the AuNP in DI water were measured using a Jasco V-550 spectrophotometer operating at a resolution of 1 nm with a 400 nm/min scan rate. The concentration of nanoparticles in the final suspension was in the range 1.0×10^{13} to 1.5×10^{13} particles/mL as determined by absorption spectroscopy.

TEM Characterization of AuNP Samples. AuNP samples were prepared for TEM analysis by placing a drop of the colloidal solutions on Formvar+C-coated Cu TEM grids and air-drying the grid at 25 °C. The samples were viewed with a Philips CM-10 TEM using 80 kV accelerating voltage.

Cell Culture and AuNP Treatment. KB cells, a human cancer cell line of nasopharyngeal origin that is known to overexpress folate receptors, were cultured in folate-deficient Dulbecco's modified Eagle medium (FD-DMEM) supplemented with 10% heat inactivated fetal calf serum, 2 mM L-glutamine, and penicillin/streptomycin for 3 weeks to establish a folate deficiency. The folate-deficient KB cells were then subcultured in 75 cm^2 flasks at 37 °C in a 5% CO_2 atmosphere. Cells were used during the log phase of growth and discarded after the sixth passage.

WI-38 cells, a normal embryonic human diploid cell line, were used as a control. These cells were cultured in FD-DMEM supplemented with 10% heat inactivated fetal calf serum, 2 mM L-glutamine, and penicillin/streptomycin for 3 weeks. The WI-38 cells were subcultured in 75 cm^2 flasks at 37 °C in a 5% CO_2 atmosphere. Cells were used during the log phase of growth and discarded after the sixth passage.

Both the KB and the WI-38 cells were plated at ~250,000 cells/well in six-well plates and incubated for 48 h. At this point, 100 μL of AuNP solution (~1.5×10^{13} particles/mL; sterilized by filtration through a 0.22 μm filter) was added to three of the wells. After a 1 h incubation period, 100 μL of nanoparticle solution was added to the remaining three wells, and all were incubated for an additional 1 h before rinsing with fresh media to remove free AuNP before fixation.

TEM Imaging of AuNP Uptake by Cells. TEM imaging was used to evaluate the cellular uptake of AuNP. Gold intensification was used to enhance the observability of the 10 nm AuNPs followed by osmium fixation to delineate the cell membranes. Gold enhancement, unlike silver intensification, is not degraded by exposure to osmium tetroxide.

The samples were processed in a PELCO model 3450 microwave equipped with variable wattage, a Coldspot temperature regulator, and vacuum chamber (Ted Pella, Inc., Redding, CA). Processing times and wattage (P1 = 233 W, P2 = 345 W) are noted for each step. Cells were fixed in 2% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.4) containing 2 mM $MgCl_2$, 1 mM $CaCl_2$, 40 mM NaCl (P1: 1 min hold > 40 s on > 3 min hold). Samples were then washed with buffer three times followed by a water wash (P1: 40 s each). Cells were scraped from the wells and pelleted by centrifugation.

Samples were incubated for 2 min at 25 °C in GoldEnhance kit #2113 (Nanoprobes, Inc. Yaphank, NY) formulated according to kit directions to increase the size of the gold particles. Following a water wash (P1: 40 s), the pellets were post-fixed in reduced osmium (1% OsO_4 + 1.5% $K_4Fe(CN)_6$) for two 40 s cycles at P1). The samples were then enrobed with 1.5% agarose (Sigma Type VII) and processed further as tissue blocks.

Sample blocks were dehydrated through a graded ethanol series (P1: 30, 50, 70, 90 and 100%, two cycles each, 40 s per change), followed by propylene oxide (P1 × 40 s). They were then infiltrated in propylene oxide (LX-112 resin mix, 3:1, 1:1 for 30 min each followed by overnight in 1:3 mix plus accelerator on a rotator at 25 °C). Blocks were embedded in LX-112 resin mixture (Ladd Research Industries, Williston, VT) and polymerized at 60°C for 48 h.

Ultrathin sections (~100 nm) were picked up on Formvar+C coated 100 mesh Cu grids. The samples were viewed with a

Philips CM-10 TEM using 80 kV accelerating voltage. TEM negatives were scanned at 600 dpi and image processed using Adobe Photoshop.

RESULTS AND DISCUSSION

The methods developed for both mPEG−thioctamide (mPEG-2000−T) and folate−PEG−thioctamide (F−PEG1500−T) enable the synthesis of these constructs on the gram scale (Figure 1). Boc-protection of NH_2-PEG1500-NH_2 was found to be necessary since initial attempts at the direct synthesis of monosubstituted PEG-thioctamide resulted in inseparable mixtures. Boc protection results in a mixture of products that is easier to separate and produces acceptable yields of mono-Boc protected PEG. Coupling of this intermediate with NHS-thioctate, followed by deprotection and coupling with folic acid gives the desired F−PEG1500−T in reasonable yield.

Initial attempts at grafting the thioctic acid-functionalized polymers onto citrate-capped AuNP under a wide variety of conditions and concentrations in aqueous solution proved unsuccessful. However, it was found that efficient displacement of citrate by the thioctic acid functionalized polymers could be achieved by adjusting the solution pH to 9−11 with NaOH.

UV−Vis absorption spectra for the 10-nm-diameter, citrate-stabilized AuNP, with and without a chemisorbed F−PEG-1500−T coating in deionized H_2O, are presented in Figure 2. These spectra have a strong absorption feature at ∼520 nm due to the characteristic surface plasmon resonance of AuNPs (*3*). The height of this feature is proportional to the concentration of AuNPs in solution, while peak position and width are indicative of the size, size distribution, aggregation, and surface coating of the particles. Figure 2 shows that there is minimal broadening of the peak and only a small red-shift in the position of the maximum when the citrate-capped particles are coated with F−PEG1500−T. This is an indication that the AuNPs are not aggregated in solution. Adding HCl, NaOH, or NaCl to an aqueous suspension of the AuNP (∼1.5×10^{13} particles/mL) does not markedly affect the UV−Vis spectra (i.e., cause particle aggregation) over a pH range of 2−12 and an electrolyte concentration range of 0−0.5 M NaCl. Aqueous suspensions of AuNP within these ranges of pH and electrolyte concentration are observed to be stable for up to a year as determined by their absorption spectra.

Figure 3 shows TEM micrographs illustrating the diameter and size distribution of the citrate-capped AuNPs and F−PEG-1500−T:AuNPs. Although the nanoparticles aggregate due to surface tension as the water evaporates during sample preparation, the Au cores of the particles do not coalesce and fuse. Analysis of the mean diameter and size distribution of these two AuNP preparations shows that the Au cores of the F−PEG1500−T coated particles are similar to those of the citrate-capped particles. These data indicate that AuNP integrity is unaffected by F−PEG1500−T grafting.

Of the two known mechanisms of folic acid transport into cells, only the receptor-mediated endocytosis pathway enables the uptake of folate conjugates by mammalian cells (*42*) (Scheme 2). A series of experiments were undertaken to determine whether the 10-nm-diameter F−PEG1500−T:AuNPs are selectively internalized by FR+ tumor cells. The nanoparticles were added to the cell cultures at a particle concentration of ∼5×10^{11} particles/mL or a loading of ∼6×10^6 AuNPs/cell, and the cells were incubated for periods of 1 and 2 h. After the incubation period, the cells were rinsed with FD-DMEM, chemically fixed, washed, and processed as described in the Experimental Section prior to TEM analysis.

KB cells were incubated with mPEG−T:AuNP as a control to establish that (1) nontargeted PEG-coated AuNPs are not internalized and that (2) AuNPs not taken up by the cells are eliminated in the washing process. Figure 4A shows a typical micrograph of a KB cell exposed to mPEG-T:AuNP. Only an occasional Au nanoparticle was observed inside the cells, which

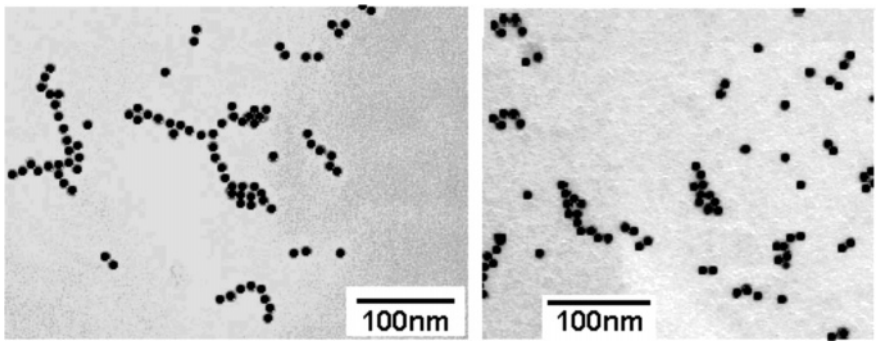

Figure 3. TEM micrographs of 10 nm diameter Au nanoparticles: left micrograph citrate-capped AuNPs; right micrograph T−PEG−F-coated AuNPs.

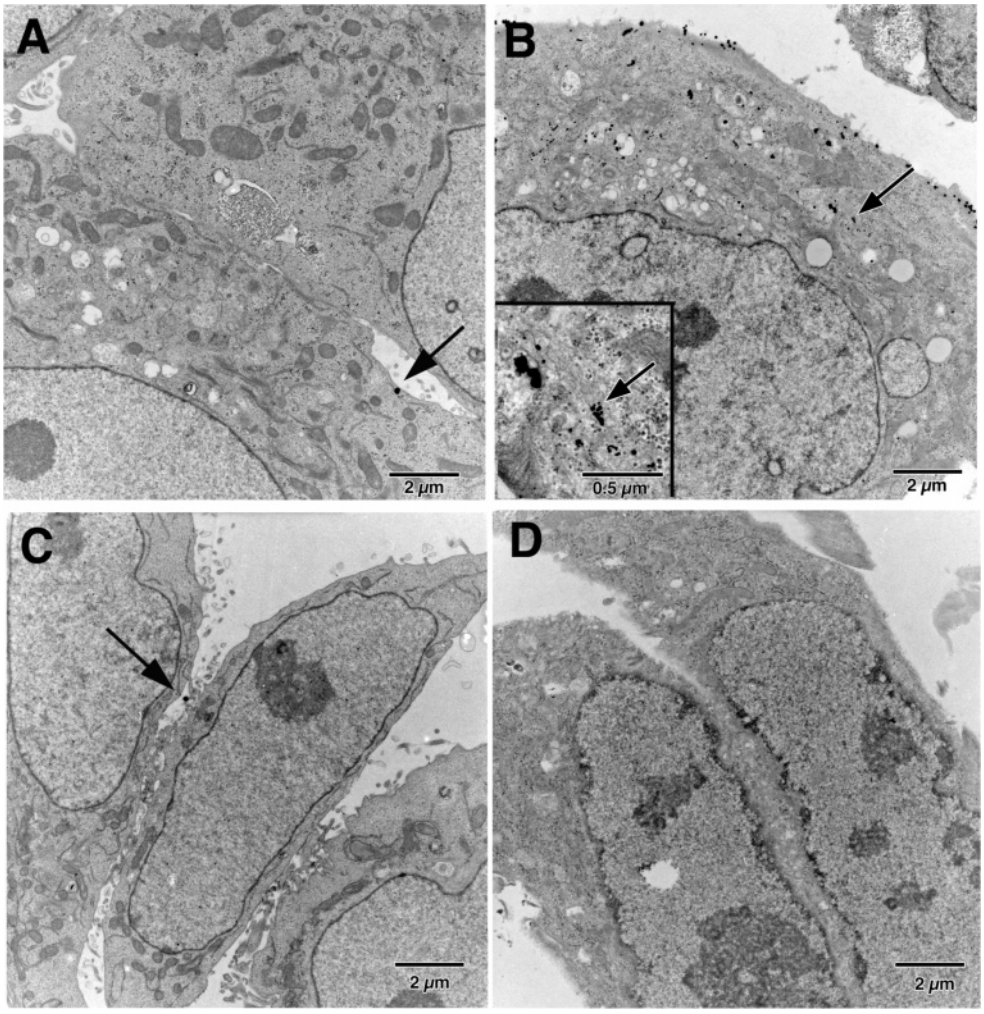

Figure 4. TEM Micrographs of thin sections of cells that were incubated for 2 h with various AuNP constructs. Magnification of primary images is 6000×; the inset is shown at 28000×. (A) KB cells incubated with mPEG2000−T:AuNP. Occasionally, AuNP are found adjacent to the cell plasma membrane (arrow), but most are removed by washes during sample preparation. (B) KB cells incubated with F−PEG1500−T:AuNP. Region corresponding to the higher magnification inset is denoted by the arrow which shows significant uptake of nanoparticles throughout the cytoplasm. (C) KB cells incubated with F−PEG−T:AuNP in the presence of excess folic acid. (D) WI-38 cells incubated with F−PEG−T:AuNP.

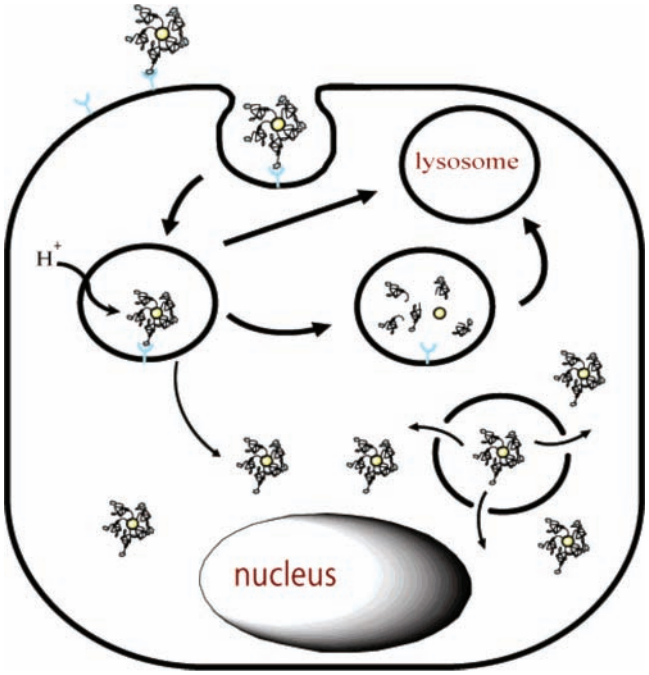
was presumably internalized via nonspecific adsorption to the cell surface. The number of nanoparticles observed outside the cell membrane was also extremely small as indicated by the single AuNP imaged in Figure 4A. These data support the expectation that mPEG2000−T-coated particles are not internalized to a significant extent by KB cells. The absence of a specific binding event between the mPEG2000−T:AuNPs and the folate receptor on the surface of these cells prevents their uptake, enabling their facile removal from the cells by washing.

Figure 4B shows a typical micrograph of a KB cell that was incubated with F−PEG−T:AuNPs. After both 1 and 2 h of exposure, about 20% of the KB cells were found to contain a large number of the folate functionalized nanoparticles. The intracellular distribution of the nanoparticles was similar to that observed with folate-targeted liposomes (*21*), i.e., localization within lysosomes near the nucleus and within endosomes distributed throughout the endosomal pathway. It should be noted that gold intensification of AuNPs enclosed inside the cells resulted in a nonuniform particle size distribution and caused particles adjacent to each other to coalesce as seen in

Scheme 2. Conceptual Diagram of Folate Receptor-Mediated Binding, Internalization, Endosomal Acidification, Intracellular Trafficking, and Endosomal Escape of F−PEG1500−T:AuNP by Folate Receptor-Positive Cells (*43*).



the high magnification inset in Figure 4B. This phenomenon and the random nature of the sectioning process made accurate estimation of the AuNP density within the cells difficult. However, by taking multiple high magnification images, it was possible to estimate the particle density in the thin sections. Assuming these thin sections to be 100 nm thick, this analysis yields an estimated density of $0.25-1.0 \times 10^{15}$ nanoparticles/mL of cell volume, which is 2−3 orders of magnitude greater than the particle density in the growth medium. Variations in the incubation times (e.g., 1, 2, or 12 h) of the cells with F−PEG1500−T:AuNP did not appear to affect the number of particles internalized.

Two additional control experiments lend further support for the uptake of F−PEG1500−T:AuNP via receptor-mediated endocytosis. When F−PEG1500−T/AuNP were incubated with KB cells in a medium that was augmented with free folate (i.e., 2 μM folic acid added to the FD-MEM during nanoparticle incubation with the cells), the KB cells did not internalize the nanoparticles (see Figure 4C). Furthermore, it was observed that WI-38 cells rarely internalized any of the particles when incubated with F−PEG1500−T:AuNP (see Figure 4D). Since the WI-38 cells lack the folate receptor, they are incapable of internalizing significant amounts of the folate-functionalized nanoparticles.

CONCLUSIONS

Poly(ethylene glycol) conjugates bearing either methoxy and thioctic acid or folic acid and thioctic acid substituents at opposing ends of the polymer have been synthesized. These conjugates have been grafted onto 10-nm-diameter Au nanoparticles, via the thioctic acid moiety. The PEG−folate-coated nanoparticles are soluble in water over a pH range of 2−12 and electrolyte concentration range of 0−0.5 M and exhibit selective uptake by a folate receptor positive (FR+) cell line when the AuNP construct contains folic acid. These sterically stabilized nanoparticles may have potential uses in targeted drug delivery to FR+ cancer cells.

It is interesting to note that only about 20% of the KB cancer cells exposed to the F−PEG1500−T/AuNP actively took up the particles. However, these cells took them up in large numbers. It is not clear whether this is related to the metabolic state of the cells during the initial exposure to the particles or to other physiological reasons unique to this type of cell. Additional experiments will be done to increase the uptake efficiency and further develop the responsiveness of the system.

ACKNOWLEDGMENT

We would like to acknowledge the use of the Life Science Microscopy Facility and the expertise of Chia-Ping Huang in preparation of samples for TEM. Dr. Vivechana Dixit performed the AuNP coating, spectroscopy, and stability studies. Mr. Jeroen Van den Bossche performed the PEG syntheses and the cell culture experiments. This study was supported by the Showalter Trust.

Functional genomics and proteomics have been very active fields since the sequencing of several genomes was completed. To assign a physiological role to the newly discovered coding genes with unknown function, new generic methods for protein production, purification, and targeted functionalization are needed. This work presents a new vector, pCYSLIC, that allows rapid generation of *Escherichia coli* expression constructs via ligation-independent cloning (LIC). The vector is designed to facilitate protein purification by either Ni-NTA or GSH affinity chromatography. Subsequent proteolytic removal of affinity tags liberates an N-terminal cysteine residue that is then used for covalent modification of the target protein with different biophysical probes via protein ligation. The described system has been tested on 36 mammalian Rab GTPases, and it was demonstrated that recombinant GTPases produced with pCYSLIC could be efficiently modified with fluorescein or biotin in vitro. Finally, LIC was compared with the recently developed In-Fusion cloning method, and it was demonstrated that In-Fusion provides superior flexibility in choice of expression vector. By the application of In-Fusion cloning Cys-Rab6A GTPase with an N-terminal cysteine residue was generated employing unmodified pET30a vector and TVMV protease.

INTRODUCTION

Sequencing of several pro- and eukaryotic genomes and the subsequent advent of structural and functional genomics projects have created a need for a spectrum of new protein analysis methods. Although traditional biochemistry includes investigation of a few selected proteins often studied by individually tailored assays, the postgenomic era requires the study of hundreds of proteins simultaneously. This calls for standardization and automation of protein generation and handling methods. The obligatory first step in protein research, namely, in vivo protein expression, was greatly facilitated by the development of rapid cloning techniques based on recombination systems such as Gateway or ligation-independent cloning (LIC) (*1*). Both of these systems are employed to almost equal extent in high-throughput cloning projects because, whereas the LIC approach relies on cheap generic reagents, the more expensive Gateway method is simpler and faster when genes must be moved among several vectors (*2*). A disadvantage shared by both methods is the necessity to design vectors carrying recombination sites, which often leads to the introduction of unwanted sequences to or elimination of wanted sequences from the open reading frame. A newly introduced system called In-Fusion has the potential for avoiding this problem. In this system an undisclosed enzyme recombines linearized vector with a PCR product flanked by homology regions of 15 nucleotides to 5′ and 3′ ends of the vector (*3*).

The combination of rapid cloning approaches with various tag systems allows rapid isolation of resulting recombinant proteins for subsequent structural or functional investigations (*4*). Whereas in structural studies proteins are directly used for crystallization or NMR studies, the functional assays require further derivatization of proteins to provide a generic and easily detectable readout for their activity. Although the methods applied vary widely, two modifications dominate: immobilization and covalent labeling with affinity groups, fluorophores, or isotopes. Although the molecular toolbox currently available to researchers is filled with reporter groups suitable for protein research, the methods for their conjugation to polypeptides are far less developed. This is largely due to the lack of chemistries that enable the modification of proteins at defined sites with a predictable outcome. The two most commonly used approaches that are based on chemical coupling to sulfhydryl groups or to primary amines result in different labeling patterns on different proteins as a consequence of the unique content and distributions of cysteine and lysine residues in a given protein. A recently developed approach referred to as expressed protein ligation (EPL) provides a possible solution to this problem (*5*). In this approach proteins are expressed in C-terminal fusion with an intein domain and an affinity tag. The resulting fusion proteins can be separated from the proteins of the expression host on an affinity matrix. Treatment of the immobilized protein with a high concentration of thiol leads to the cleavage of the peptide bond between intein and target protein. The cleaved protein carries a thioester group on the C terminus that can be coupled to a peptide (or, in fact, any molecule) bearing a cysteine at its N terminus according to the method of native chemical ligation to generate a native peptide bond at the coupling site (Figure 1) (*6*). Although this approach was successfully used for protein engineering, its shortcomings are related to the necessity of expressing a large fusion protein that may influence the solubility and folding of the target protein and the different efficiencies of intein splicing due to the influence of the flanking

residues of the target protein (*7*). An alternative configuration was proposed whereby a thioester-conjugated functionality such as a fluorophore is coupled onto the N-terminal cysteine of a recombinant protein (*8*). However, generation of recombinant proteins with N-terminal cysteine is not straightforward. In some cases cysteine on position 2 becomes N-terminal upon methionine cleavage by aminopeptidase of the expression host, although the efficiency varies among proteins (*9*). In an alternative configuration an N-terminal cysteine is created by self-cleavage of an intein domain fused N-terminally to the target protein. As in the case of C-terminally fused intein domains, cleavage does not always occur with the desired efficiency. Finally, the N-terminal cysteine residue can be generated by proteolytic cleavage of a properly engineered protease cleavage site. Among proteases that were shown to tolerate cysteine at the +1 position of the cleavage site are factor X, Precision protease, and TEV proteases (*10*, *11*). The latter protease became particularly popular due its high processivity, selectivity, and related ease of recombinant production, which promoted interest in other proteases of plant viruses such as TVMV (*12*). In this work we compare LIC and In-Fusion cloning for rapid production of recombinant proteins with N-terminal cysteine mediated by TEV and TVMV proteases.

EXPERIMENTAL PROCEDURES

Construction of pCYSLIC Vector. The His−GST tag fusion gene was amplified using oligonucleotides Xba-GAT_for TAGATCCTCTAGAAATAATTTTGTTTAACTTTAAG AAGGAG and TEV_LIC_rev TTATTATCCCATATGGGTATACATTACCCAATAATA TTGAAAATAAAGATTTTCATCAGCCATACTTAC that encode the TEV protease recognition sequence and *Xba*I and *Ssp*I restriction sites. The resulting PCR product was digested with *Xba*I and *Ssp*I and ligated into plasmid pMCSG7 linearized with the same enzymes (*13*). The integrity of the GST ORF and LIC site of the resulting pCYSLIC vector was verified by sequencing using T7 promoter and T7 terminator primers.

Cloning of Rab6A into pCYSLIC Vector. To amplify Rab6A ORF, oligonucleotide primers 5′-AAAATCTTTATTTTCAATGCATGTCCACGGGCGGAGACT-3′ and 5′-TTATCCACTTCCAATGTTAGCAGGAACAGCCTCCTTCA-3′ were used. The primers are complementary to the 5′- or 3′-ends of the ORF, respectively, at 3′-ends and to sequences flanking the *Ssp*I site of the pCYSLIC vector at 5′-ends (underlined). Both PCR fragments of 663 bp and *Ssp*I-digested pCYSLIC vector were purified by electrophoresis in 1% agarose gel and isolated with QIAquick gel extraction kit (Qiagene). Five hundred nanograms of vector DNA and 50 ng of the PCR fragment were treated with 0.7 unit of T4 DNA polymerase in the presence of 2.5 mM dGTP and 2.5 mM dCTP, respectively, at 22 °C for 30 min. The enzyme was inactivated by heating at 75 °C for 20 min. Thirty nanograms of vector DNA and 10 ng of PCR fragment were mixed in a total volume of 3 μL (molar ratio of vector to fragment approximately 1:3) and incubated at 22 °C for 10 min. Then 1 μL of 25 mM EDTA was added, and incubation was continued for another 10 min. *Escherichia coli* Top10 competent cells were transformed with the above mixture, followed by selection on LB agar supplemented with 60 μg/mL ampicillin. Ten recombinant clones were picked and screened by PCR with primers complementary to the vector sequences upstream and downstream of the insert. All 10 screened clones contained the insert of interest. The integrity of the open reading frame was verified by sequencing.

In-Fusion Cloning of TVMV-Rab6A into the pET30a Vector. The open reading frame of Rab6A was amplified with the primers TVMV_Rab6_p30_dir AAGGCCATGGCTGATGAGACCGTTCGCTTTCAGTGCATGTCCACGGGCGGAGACTTCG and TVMV_Rab6_p30_rev GAATTCGGATCCGATTCAGCAGGAACAGCCTCCTTCAC containing the 15 bp region of homology to the pET30a vector upstream and downstream of the *Eco*RV site. The 3′ primer also contains the recognition sequence for TVMV protease, where the S residue in the sequence E-T-V-R-F-Q-S is substituted by cysteine. The PCR product was gel purified and mixed in 1:1 molar ratio with pET30a vector linearized by the *Eco*RV enzyme and incubated with In-Fusion reaction mix (BD Bioscience) for 30 min at room temperature. The reaction mixture was transformed into Fusion-Blue Competent Cells, and recombinant clones were selected on LB agar plates supplemented with 30 mg/L kanamycin.

Cloning, Expression, and Purification of Mammalian RabGTPases. For cloning of a library of mammalian RabGTPases the oligonucleotides were designed to start with the sequence AAAATCTTTATTTTCAATGC followed by the nucleotides encoding the target protein. The antisense primers

start with the sequence AATAGGTGAAGGTTAC followed by the complement of stop codon and the C terminus of the target protein. The cDNAs for mammalian RabGTPases were obtained from RZPD GmbH and used as templates for PCR reactions. PCR products were then treated with T4 polymerase and annealed with the pCYSLIC vector. The mixture was transformed into *E. coli* Top10 competent cells, and the positive clones were identified as described above. The sequence of the inserts was verified by sequencing with specific primers.

Test protein expressions were performed in BL21(DE3)RIL cells (Stratagene) cultured in 2 mL of LB medium supplemented with 100 μg/mL ampicillin and 34 μg/mL chloramphenicol. The cells were grown at 37 °C to OD_{600} = 0.5, and protein expression was induced by the addition of 1 mM IPTG for 4 h at 37 or 20 °C. To determine the amount and solubility of the recombinant protein, the cells were disrupted by sonication and cell debris was removed by centrifugation. The total cellular lysates, the cells debris, and supernatants were analyzed by SDS−PAGE followed by Coomassie Blue staining.

For large-scale purification cultures were pregrown to OD_{600} = 0.5 in 1−10 L of LB, and protein expression was induced by the addition of 0.1 mM IPTG for 12 h at 20 °C. Cells were resuspended in buffer A containing 50 mM NaH_2PO_4, pH 8.0, 0.3 M NaCI with 1 mM PMSF, and 2 mM BME and lysed using a fluidizer (Microfluidics Corp.). Clarified lysates were loaded onto a 5 mL Hi-Trap Ni column (Amersham) equilibrated with buffer A. The protein was eluted with a gradient of 10−150 mM imidazole in buffer A. The fractions containing recombinant protein were pooled, and TEV or TVMV protease was added at 1:20 molar ratio. The resulting mixture was dialyzed against protease cleavage buffer: 25 mM NaH_2PO_4, pH 8.0, 2 mM EDTA, and 2 mM BME for 12 h at 4 °C. Next, the excess EDTA was quenched by the addition of excess $MgCl_2$, and cleaved 6His-GST-tag, His-tagged protease, and impurities were removed from the dialyzed mixture by passing it over an Ni−NTA column. The collected flow-through was concentrated in Centricon 10 concentrators up to ≈8 mL and loaded onto a gel filtration column (Superdex-75) equilibrated with 25 mM Hepes, pH 7.2, 40 mM NaCl, 2 mM $MgCl_2$, 10 μM GDP, and 2 mM DTE. The fractions were concentrated with Centriprep 10, frozen, and stored at −80 °C.

Expression vectors pRK1035_TVMV and pRK1037_TEV were a generous gift of D. Waugh. Expression and purification of the enzymes were performed essentially as described previously (*12*).

Biotin and Fluorescein Thioester Synthesis. Biotin benzylthioester **1** was prepared according to a procedure described by Schuler and Pannell (*8*). To a cooled mixture (0 °C) of 2.0 M trimethylaluminum (10 mL; 20 mmol) in heptane and anhydrous dichloromethane (40 mL) was slowly added benzyl mercaptan (2.35 mL; 20 mmol). The reaction mixture was allowed to warm to room temperature over a 20−30 min period. Twenty milliliters of this solution was added to a solution of biotin succinimidyl ester (110 mg; 0.322 mmol) in anhydrous DMF (5 mL). After 2 h of stirring at room temperature, the solvents were removed and the remaining yellow oil was dissolved in dichloromethane. Wet silica gel was added to the solution to quench the excess aluminum complex. After evaporation, the crude product was purified by flash chromatography ($CHCl_3$/MeOH, 95:5). Fractions containing the biotin benzylthioester were pooled, evaporated, and dried under vacuum to give a white powder (109.5 mg; 0.312 mmol; 97% yield): ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.24−7.14 (m, 5H, Ph), 4.45−4.41 (m, 1H), 4.23−4.20 (m, 1H), 4.04 (s, 2H), 3.08−3.03 (m, 1H), 2.83 (dd, 1H, J = 4.8 Hz, J = 12.8 Hz), 2.65 (dd, 1H, J = 0.4 Hz, J = 12.8 Hz), 2.52 (t, 2H, J = 7.4 Hz), 1.70−1.55 (m, 4H), 1.44−1.31 (m, 2H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 198.7, 163.7, 137.6−127.1, 61.9, 60.1, 55.3, 43.3, 40.5, 33.1, 28.1, 25.4; MALDI-TOF MS, calcd for $C_{17}H_{22}N_2O_2S_2$ $(M + H)^+$ 351.5067, found 351.5827.

Synthesis of the water-soluble biotin **2** and 5(6)-carboxyfluorescein **3** thioesters was performed as described by Tolbert et al. (*14*), using *tert*-butyl mercaptoacetate (*15*). D-Biotin thioester **2**: ^{1}H NMR ($(CD_3)_2CO$, 400 MHz) δ 5.95 (s large, 1H, NH), 5.89 (s large, 1H, NH), 3.85 (dd, 1H, J = 4.8 Hz, J = 8.0 Hz), 3.68 (ddd, 1H, J = 5.2 Hz, J = 8.0 Hz), 3.22 (s, 2H), 2.64 (ddd, 1H, J = 4.8 Hz, J = 6.4 Hz, J = 8.0 Hz), 2.37 (dd, 1H, J = 5.2 Hz, J = 12.4 Hz), 2.17 (t, 2H, J = 7.4 Hz), 2.12 (d, 1H, J = 12.4 Hz), 1.20−1.10 (m, 4H), 1.06−0.85 (m, 2H); MALDI-TOF MS, calcd for $C_{12}H_{18}N_2O_4S_2$ $(M + H)^+$ 319.0786, found 319.2774. 5-(and -6)-carboxyfluorescein-thioester **3**: ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.74 (s, 1H), 8.73 (s, 1H), 8.10 (d, 1H), 8.09 (d, 1H), 7.27 (s, 1H), 7.25 (s, 1H), 6.88 (d, 4H), 6.63−6.58 (m, 4H), 6.56−6.50 (m, 4H), 3.84 (s, 4H); MALDI-TOF MS, calcd for $C_{23}H_{14}O_8S$ $(M + H)^+$ 451.0487, found 451.2801.

Labeling of Peptides and Proteins with Biotin and Fluorescein Thioesters. *Peptide Labeling.* The RBD[1] peptide (5 mg) was dissolved in 375 μL of a buffer containing 6 M GdmCl and 100 mM sodium phosphate, pH 7.5, and 4% thiophenol was added. The biotin benzylthioester **1** was dissolved in DMF at a concentration of 15 mM, and then 50 μL was added to the peptide solution. The reaction mixture was vortexed and incubated at room temperature. The reaction progress was monitored by analytical reversed phase HPLC.

Protein Labeling. A solution of Cys-Rab6A protein (8.0 μL; 531 μM) in 50 mM NaP_i, 1 mM $MgCl_2$, and 100 μM GDP, pH 7.5, was mixed with 30 mM TCEP, 200 mM MesNa in 100 mM NaP_i buffer (4.5 μL), and a 5 mM solution of water-soluble thioester **2** or **3** in 100 mM NaP_i buffer (1.5 μL) at pH 8.0. The reaction mixture was vortexed and incubated at room temperature (22 °C). In the case of the 5(6)-carboxyfluorescein thioester, 1 μL of 3 mM labeling reagent **3** in 100 mM NaP_i buffer at pH 8.0 was added each 8 h. In the case of the biotin thioester, 1 μL of 3 mM labeling reagent **2** in 100 mM NaP_i buffer at pH 8.0 was added once after 12 h.

HPLC and Mass Spectrometry. HPLC analysis of peptides and proteins was performed with an analytical RP-C4-column (Vydac) at a flow rate of 1 mL/min over 30 min with a gradient from 5 to 65% (v/v) buffer B (acetonitrile, 0.08% TFA) in buffer A (water, 0.1% TFA). Peptide and protein masses were determined by electrospray ionization mass spectrometry on an LCQ Advantage Max (Finnigan) operating in positive ion mode.

RESULTS AND DISCUSSION

Construction of pCYSLIC Vector and Preparation of Recombinant Cys-Rab6A GTPase. To design a generic vector suitable for rapid construction of a large number of expression constructs that yield recombinant polypeptides selectively derivatizable with a range of chemical entities, we attempted to combine recent advances in molecular cloning and protein chemistry. The proposed vector should contain sequence(s) coding for one or two affinity tags operably linked to a site for LIC, which should allow rapid in-frame cloning of PCR-amplified genes. The expressed polypeptide should be readily isolatable by, preferably, a single-step chromatography and then be amenable to site-directed modification with a range of chemical groups. The functional assembly that satisfies the above-described requirements is presented in Figure 2. The gene of interest is cloned via LIC after a tandem of the 6His-GST tag and the TEV protease cleavage site. Use of the tandem tag

[1] Amino acids 96−131 from the Ras-binding domain of cRaf-1 carrying a C-terminal His6 tag.

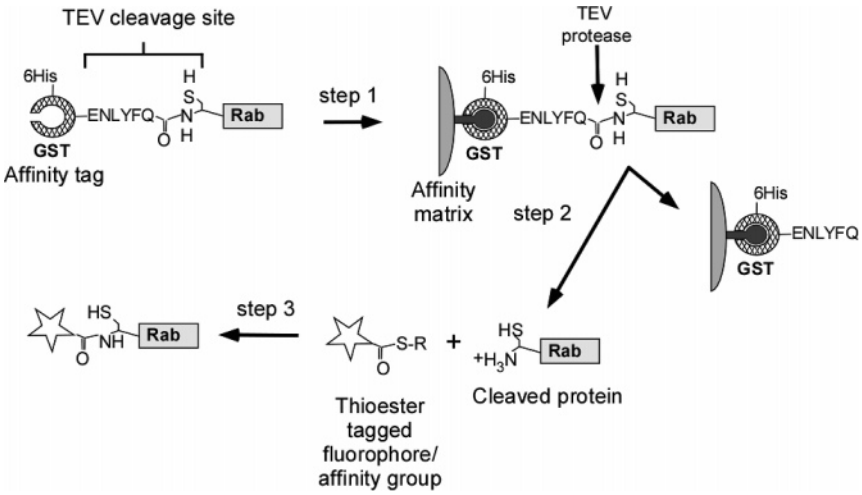

Figure 2. Principal scheme for generic generation of N-terminal cysteine in recombinant proteins and its subsequent labeling via in vitro protein ligation: step 1, isolation of the fusion protein on the affinity matrix; step 2, cleavage of the fusion protein with TEV protease and separation of the target protein; step 3, ligation of the thioester-tagged functional group to the N-terminal cysteine of the target protein.

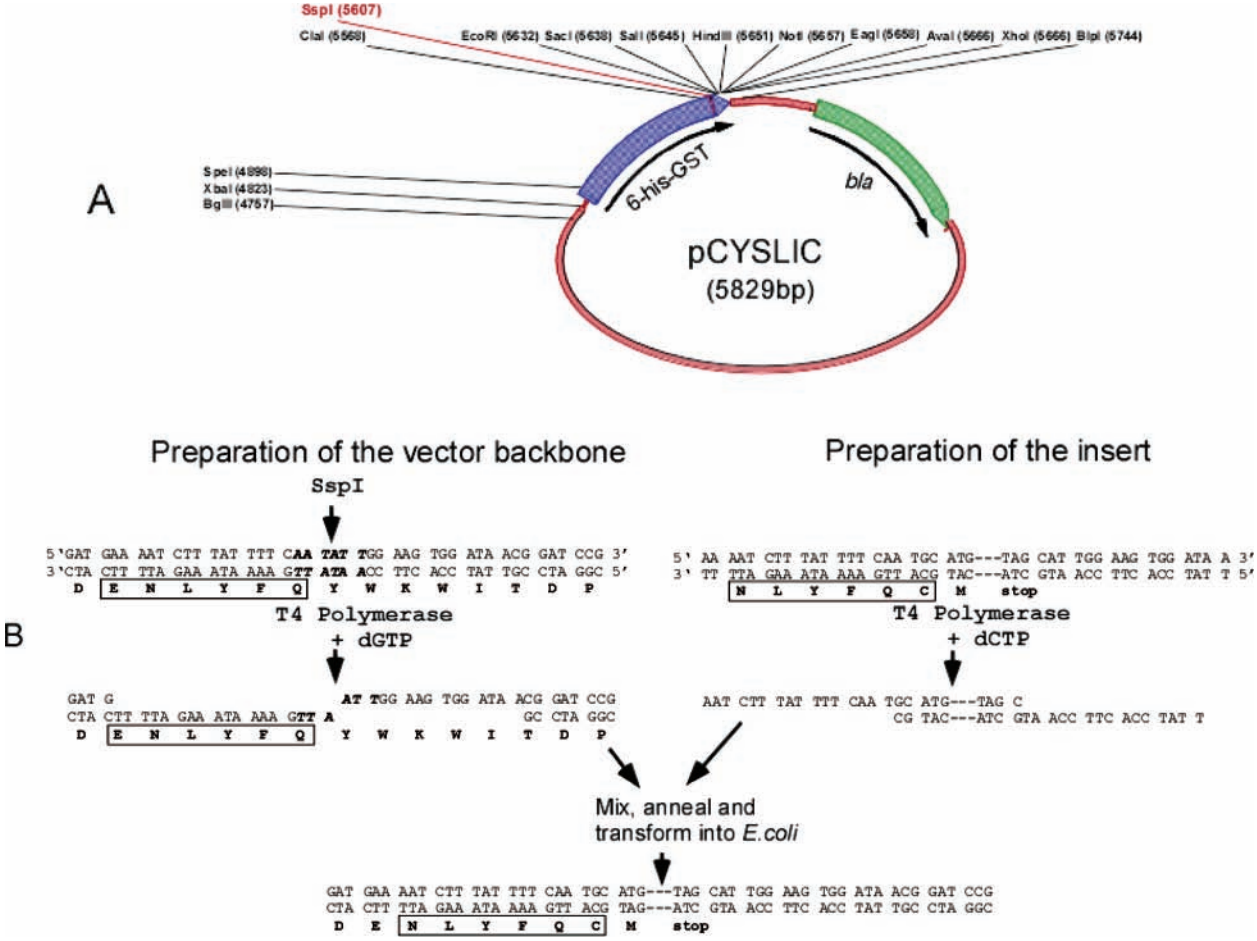

Figure 3. (A) Map of pCYSLIC vector. The unique restriction sites before and after the 6-His-GST fusion gene are shown. (B) Organization of the LIC site of pCYSLIC vector and the PCR product and the flowchart of cloning reaction. The TEV protease cleavage site is boxed.

allows two-step affinity purification if the target protein is not sufficiently pure after the first purification step. The TEV protease cleavage site is modified in such a way that upon cleavage a cysteine is left on the N terminus of the resulting polypeptide that can be used for ligation of molecules bearing the reactive thioester group. To construct such a vector, we combined *E. coli* expression vector pGATEV, which contains tandem 6His-GST tags followed by a TEV protease cleavage site (*16*), and pMCSG7 vector that combines a LIC cloning site with a 6His tag removable via TEV cleavage (*13*). The resulting vector was termed pCYSLIC (Figure 3A). For cloning of a gene of interest into this vector the backbone is digested with blunt cleaving *Ssp*I enzyme and treated with T4 polymerase in the presence of dGTP (Figure 3B). This results in the formation of long (14−18 nucleotides) overhangs that are then used for capturing the insert. The gene of interest is PCR amplified with the primers containing a sequence complementary to the regions flanking the *Ssp*I site of the pCYSLIC (Figure 3B). The PCR products are treated with T4 polymerase in the presence of dCTP leading to the formation of single-stranded regions complemen-

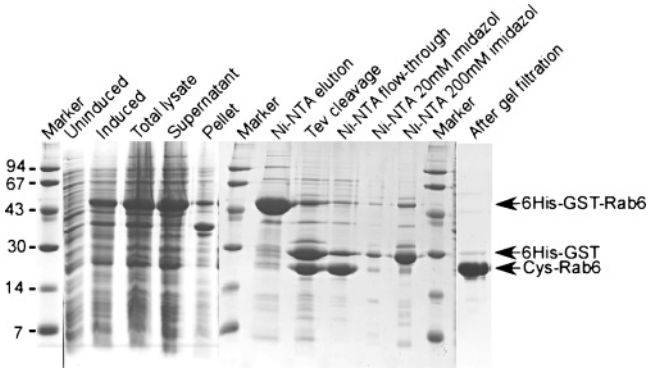

Figure 4. Expression and purification of the Cys-Rab6A using pCYSLIC vector. Aliquots of *E. coli* culture, cell lysates, and purification steps were resolved on 15% SDS−PAGE and stained with Coomassie Blue stain. The positions of fusion protein and cleavage products are indicated by arrows.

tary to those of the backbone. The backbone and the insert are mixed and transformed into the *E. coli* strain. The resulting clones are screened by colony PCR for the presence of the desired insert.

To test the vector we PCR amplified the ORF of human GTPase Rab6A and cloned it using the above-described approach into the pCYSLIC vector. The efficient cloning depended on the high quality of backbone linearization with the *Ssp*I enzyme, which was achieved by increasing the enzyme to DNA ratio as described before (*13*) (Experimental Procedures). Following the optimization a cloning efficiency of >90% was routinely achieved. The resulting pCYSLIC−Rab6A vector was introduced into *E. coli* BL21(DE3) RIL strain, and the suspension culture was induced with IPTG as described under Experimental Procedures. As can be seen in Figure 4 6His-GST-Rab6A was highly overexpressed and found predominantly in the soluble fraction. Chromatography of the supernatant on Ni−NTA resin resulted in >70% pure 6His-GST-Rab6A

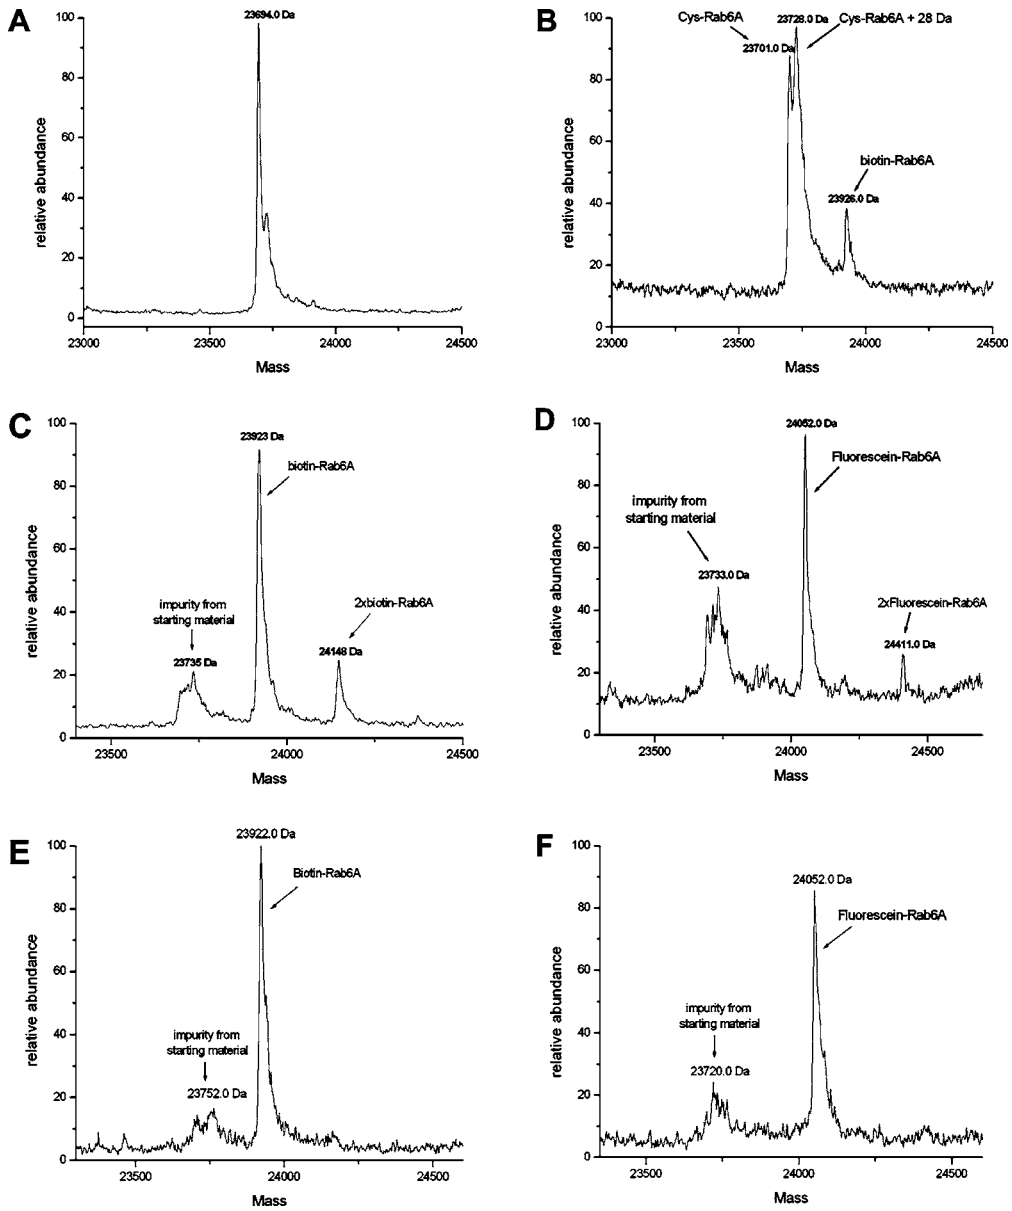

Figure 5. ESI-MS spectra of cleaved and labeled Rab6A protein: (A) deconvoluted mass spectrum of Cys-Rab6A, calculated molecular mass 23695.9 Da; (B) deconvoluted mass spectrum of Cys-Rab6A after 24 h of reaction with **1** at room temperature in a non-denaturing buffer (20 mM sodium phosphate, 1 mM $MgCl_2$, 100 μM GDP, pH 7.5) and 5−10% of DMF; (C) deconvoluted mass spectrum of Cys-Rab6A labeled with biotin thioester **2** after 24 h at 22 °C; (D) deconvoluted mass spectrum of Cys-Rab6A labeled with 5(6)-carboxyfluorescein thioester **3** after 24 h at 22 °C; (E) deconvoluted mass spectrum of Cys-Rab6A labeled with biotin thioester **2** after 3 h of hydroxylamine (50 mM) treatment; (F) deconvoluted mass spectrum of Cys-Rab6A labeled with fluorescein thioester **3** after 3 h of hydroxylamine (50 mM) treatment.

protein. To remove the tags and to liberate the N-terminal cysteine, the sample was dialyzed against 25 mM NaP_i, pH 8.0, 2 mM EDTA, and 2 mM BME at 4 °C in the presence of TEV protease. The cleavage reaction was monitored by SDS−PAGE and typically reached >80% completion after 12 h. The cleaved 6His-GST fusion and TEV protease were removed by passing the mixture over Ni−NTA resin (Figure 4). The obtained Rab6 was >80% pure and migrated on the size exclusion chromatography as a single peak with an apparent molecular mass of ≈25 kDa, indicating that the protein was properly folded (not shown).

Synthesis of and Labeling with Biotin and Fluorescein Thioesters. Having developed an expression system for rapid generation of pure proteins competent for in vitro chemical ligation, a strategy for their rapid and site-selective modifications with various labels was devised. This labeling procedure is based on the nucleophilic attack of the cysteine thiol group on the thioester moiety of the labeling molecules and subsequent formation of an amide bond, as described for linking peptide segments via native chemical ligation (*6*) (Figure 1). However, reaction conditions and obtainable yields depend heavily on the nature of the label and the protein used. We sought to develop a general procedure for the synthesis of labeling reagents carrying a thioester and to identify conditions that ensure site-specific monolabeling of peptides/proteins in high yields without side reactions. In a first set of experiments we used a biotin benzylthioester **1** that was synthesized following a two-step reaction procedure presented first by Schuler and Pannell for conversion of a fluorescent dye into its thioester derivative (*8*). The benzylthioester **1** was obtained at very high yield (97%) from a biotin succinimidyl ester derivative. An aluminum complex, prepared from a stoichiometric mixture of trimethylaluminum and benzyl mercaptan, was allowed to react with the biotin succinimidyl ester at room temperature, generating **1** (Figure 1). Initially this water-insoluble compound was applied in organic solvents such as DMF, DMSO, THF, or dioxane to ligation reactions with Rab6A (Cys-Rab6A calculated mass = 23695.9 Da, ESI-MS observed mass = 23694.0 Da). To avoid precipitation of **1**, a concentration of 5−10% DMF was used during our initial experiments, reacting Rab6A and **1** under denaturing or native conditions in the presence of 4% thiophenol. Mass spectrometry indicated the formation of a side product (protein mass + 28 Da) and of the expected biotin labeled protein (calculated mass = 23922.2 Da, ESI-MS observed mass = 23926.0 Da; Figure 5). Optimization of reaction conditions [longer reaction times, use of MesNa (2-mercaptoethanesulfonic acid, sodium salt) instead of thiophenol] did not lead to complete conversion of Rab6A to the biotinylated species, possibly indicating a modification of the N-terminal cysteine residue of Rab6A. Such a modification would prevent any reaction with **1**. The replacement of DMF by other organic solvents such as DMSO, THF, or dioxane led to a decrease in labeling efficiency, probably due to less efficient solubilization of **1**. However, the occurrence of the nonreactive side product was prevented. To exclude the possibility that the observed phenomenon was protein-specific, a similar series of experiments was performed with the N-terminal cysteine containing the 42 amino acid peptide RBD96-131/His_6-tag (*17*). The results corroborated those obtained with the Rab6A protein, including the low efficiency of the reaction, under either denaturing (6 M GdmCl) or native conditions, and the formation of a side product (peptide mass + 28). To overcome the problems encountered with the largely water-insoluble compound **1**, we decided to prepare water-soluble thioester labeling reagents. Synthetic access to such compounds has been established by Tolbert et al. (*14*), using *tert*-butyl mercaptoacetate (*15*), and we obtained water-soluble biotin and 5(6)-carboxyfluorescein thioesters with yields of

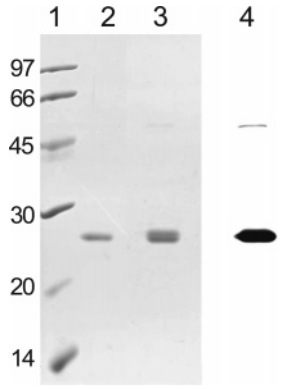

Figure 6. SDS−PAGE analysis of Rab6A labeling with 5(6)-carboxyfluorescein: lane 1, protein marker; lane 2, Cys-Rab6A; lane 3, fluorescein-Rab6A; lane 4, fluorescence scan of Cys-Rab6A labeled at λ_{ex} = 473 nm and λ_{em} = 510 nm.

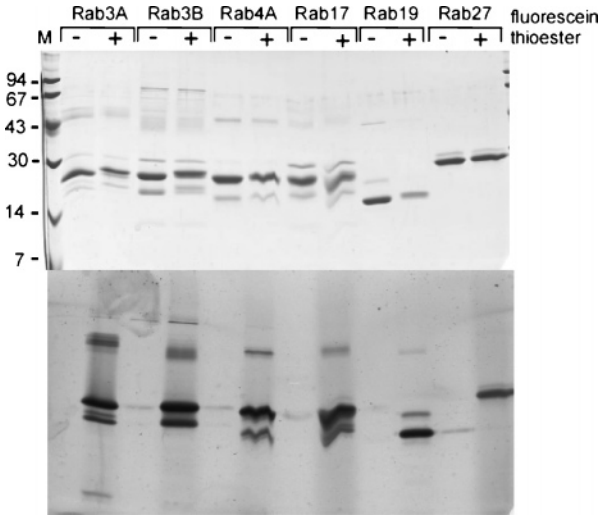

Figure 7. SDS−PAGE analysis of six Rab proteins before and after ligation with 5(6)-carboxyfluorescein thioester. The reactions were carried out and analyzed as in Figure 4. The bottom panel represents the fluorescent scan of the gel, whereas the top panel shows the same gel stained with Coomassie Blue. The high molecular weight fluorescent bands represent GTPase dimers.

between 22 and 45% following their procedure. In the first ligation experiment using 1.78 mM **3** and a 370 μM solution of Rab6A in the presence of β-mercaptoethanol (1 mM) and 2-mercaptoethanesulfonic acid (25 mM), we observed low labeling yields of Rab6A and the occurrence of a small fraction of doubly labeled Rab6A protein. The latter was rationalized as thioester exchange between cysteine side chains in the protein and the labeling reagents **2** and **3**. Different reaction conditions using various amounts of MesNa as an inducer of thioester exchange, TCEP as an additional reducing agent, or a combination of both reagents were tested without significant reduction in unspecific labeling. Such multiple labeling essentially defeats the potential advantages of using native chemical ligation for protein labeling. Optimization of the labeling conditions to suppress the unwanted multiple labeling revealed a marked cysteine reactivity difference of biotin and carboxyfluorescein thioesters. We observed that regular additions, approximately every 8 h for carboxyfluorescein thioester **3** (final concentration = 1 mM) and once after 12 h for biotin thioester **2** (final concentration = 1 mM), produced almost only monolabeled protein within 24 h. The reaction progress was monitored by LC-MS, and the respective deconvoluted mass spectra showed in each case the formation of the monolabeled protein as the major product (calculated molecular mass = 23922.2 Da, Rab6A + **2** and 24054.2 Da Rab6A + **3**; observed molecular mass =

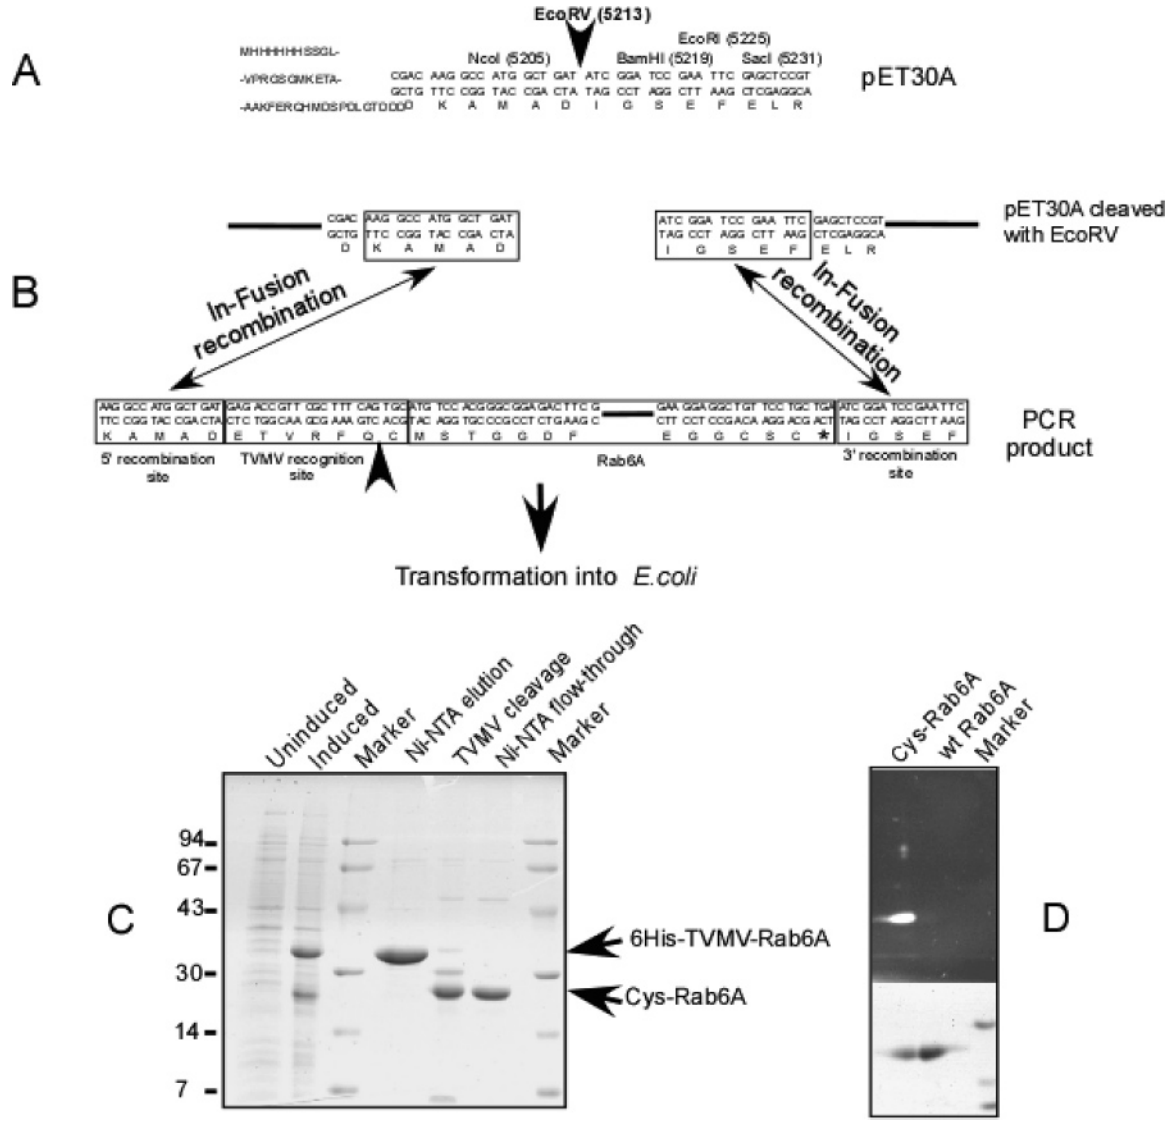

Figure 8. Use of In-Fusion cloning for generation of the 6His-TVMV-Rab6A fusion protein: (A) multicloning site of the pET30A vector (the *Eco*RV site used for vector linearization is marked by an arrow); (B) flowchart of cloning reaction and design of the PCR product; (C) expression in *E. coli*, purification and cleavage of 6His-TVMV-Rab6A with TVMV protease; (D) ligation of TVMV-processed Cys-Rab6A protein with 5(6)-carboxyfluorescein thioester. The samples were processed as in Figure 7.

23922.0 and 24052.0 Da, respectively), as well as the impurity already contained in the starting material and a small peak belonging to the dilabeled protein (calculated molecular mass = 24148.5 Da + **2** and 24412.5 Da + **3**; observed molecular mass = 24146.0 and 24411.0 Da, respectively; Figure 5). In cases when the dilabeled product interferes with the intended use of the labeled protein, the additional label that is attached to the protein via a thioester bond can be efficiently removed by treatment with hydroxylamine (50 mM in aqueous buffer, 3 h).

Cloning, Expression, Purification, and Labeling of Mammalian Rab GTPases. To establish the general applicability of the designed vector and the labeling procedure on a larger set of test proteins, we chose to clone a subset of mammalian RabGTPases into the pCYSLIC vector. We amplified 39 ORFs of RabGTPases and cloned them into the pCYSLIC vector. The cloning procedure was very robust with typical cloning efficiency of >90%. The resulting clones were verified by sequencing and tested for expression in BL21(DE3)RIL strains at 37 and 20 °C (see Supporting Information). Approximately 50% of the proteins were either completely or partially soluble at 20 °C. We purified a subset composed of Rab3A, Rab3B, Rab4A, Rab19, and Rab27 to >70% purity by Ni−NTA chromatography followed by subsequent cleavage of GST tag with TEV protease. Incubation of the purified proteins with carboxyfluorescein thioester resulted in the formation of a fluorescent product easily detectable by SDS−PAGE. Labeling of most proteins resulted in a slight (≈0.5 kDa) decrease in electrophoretic mobility of the ligation product, which suggests that the majority of the protein was labeled efficiently (Figure 6). Proteins retained their solubility, indicating that labeling does not significantly affect protein folding or solubility.

Use of In-Fusion Cloning for Production of Proteins Containing N-Terminal Cysteine. The described approach based on LIC cloning is both sufficiently inexpensive and flexible to be adapted to an automated cloning platform. However, similar to most recombination-based cloning methods, it precludes the use of vectors not adapted to the chosen cloning method. Ideally one would like to be able to use any selection of vectors, particularly in cases when the protein displays folding or solubility problems. The recently introduced In-Fusion cloning procedure potentially provides a way to clone a PCR fragment into any linearized vector. We decided to test whether this approach could also be used for the rapid generation of the recombinant proteins with N-terminal cysteines. To this end, we chose a pET30a vector that features an N-terminal 6His tag

and is commonly used for the expression of recombinant proteins. We decided to incorporate into recombinant Rab6A a cleavage site for TVMV polymerase, which has not been previously used for the generation of an N-terminal cysteine residue. Hence, we included a modified recognition sequence of TVMV polymerase into the primers, which would result in substitution of the serine in the recognition sequence ETVRFQS by cysteine (cleavage normally occurs between Q and S). The primer design and recombination cloning procedure are depicted in Figure 8A−C and described under Experimental Procedures. The recombinant clones were readily obtained, and the fusion protein was expressed in *E. coli*, purified, and cleaved with recombinant TVMV protease under conditions used for TEV protease (Figure 8C). The cleavage was very efficient, demonstrating that TVMV could well tolerate S→C substitution in the cleavage site. Following a second purification by Ni−NTA, the protein was already >85% pure and could be used directly for downstream applications. To ensure that the generated N-terminal cysteine was functional in the ligation reaction, we incubated the recombinant protein with carboxyfluorescein thioester as described above. As can be seen in Figure 8D, this resulted in specific labeling of Rab6A.

CONCLUSIONS

In the current work we present a new *E. coli* expression vector pCYSLIC that allows rapid cloning of PCR fragments via ligation-independent cloning in frame with the 6-His-GST tag. The affinity tags were easily removed with TEV protease, leaving an N-terminal cysteine that was subsequently used to label the proteins with carboxyfluorescein and biotin via in vitro protein ligation reaction. The developed combination of inexpensive rapid cloning, purification, and functionalization procedures provides an advance in protein expression and derivatization. We compared this method to the recently developed In-Fusion cloning approach and demonstrated that, although more expensive, the In-Fusion cloning provides superior cloning vector flexibility compared with other cloning methods. We also showed that TVMV protease can be employed for the generation of recombinant proteins with N-terminal cysteine.

ACKNOWLEDGMENT

We acknowledge N. Lupilova, S. Thuns, and M. Terbeck for invaluable technical assistance. The pMCSG7 vector was kindly provided by M. I. Donnelly. We are grateful to F. Barr for the cDNAs of Rab6A and to D. Waugh for the gift of expression vectors for TVMV and TEV proteases. This work was supported in part by Grant DFG AL 484/7-2 to K.A.

Recombinant interferon-beta-1b (IFN-β-1b) is used clinically in the treatment of multiple sclerosis. In common with many biological ligands, IFN-β-1b exhibits a relatively short serum half-life, and bioavailability may be further diminished by neutralizing antibodies. While PEGylation is an approach commonly employed to increase the blood residency time of protein therapeutics, there is a further requisite for molecular engineering approaches to also address the stability, solubility, aggregation, immunogenicity and in vivo exposure of therapeutic proteins. We investigated these five parameters of recombinant human IFN-β-1b in over 20 site-selective mono-PEGylated or multi-PEGylated IFN-β-1b bioconjugates. Primary amines were modified by single or multiple attachments of poly(ethylene glycol), either site-specifically at the N-terminus, or randomly on the 11 lysines. In two alternate approaches, site-directed mutagenesis was independently employed in the construction of designed IFN-β-1b variants containing either a single free cysteine or lysine for site-specific PEGylation. Optimization of conjugate preparation with 12 kDa, 20 kDa, 30 kDa, and 40 kDa amine-selective PEG polymers was achieved, and a comparison of the structural and functional properties of the IFN-β-1b proteins and their PEGylated counterparts was conducted. Peptide mapping and MALDI-TOF mass spectrometric analysis confirmed the attachment sites of the PEG polymer. Independent biochemical and bioactivity analyses, including antiviral and antiproliferation bioassays, circular dichroism, capillary electrophoresis, flow cytometric profiling, reversed phase and size exclusion HPLC, and immunoassays demonstrated that the functional activities of the designed IFN-β-1b conjugates were maintained, while the formation of soluble or insoluble aggregates of IFN-β-1b was ameliorated. Immunogenicity and pharmacokinetic studies of selected PEGylated IFN-β-1b compounds in mice and rats demonstrated both diminished IgG responses, and over 100-fold expanded AUC exposure relative to the unmodified protein. The results demonstrate the capacity of this macromolecular engineering strategy to address both pharmacological and formulation challenges for a highly hydrophobic, aggregation-prone protein. The properties of a lead mono-PEGylated candidate, 40 kDa PEG_2−IFN-β-1b, were further investigated in formulation optimization and biological studies.

INTRODUCTION

Human interferon-beta (IFN-β[1]) is produced in many cell types in response to viral infection or exposure to double stranded RNA (*1*, *2*). Following binding of this glycoprotein to a heterodimeric cell receptor, IFNAR-1/IFNAR-2, a cascade of signaling events leads to expression of IFN-β inducible genes which modulate antiviral, antiproliferative, and immunomodulatory functions (*3*−*6*). Three recombinant IFN-β therapeutics are presently marketed for the treatment of the relapsing-remitting form of multiple sclerosis (*7*−*12*). IFN-β-1a preparations are glycosylated products expressed in mammalian cells and are similar to the 166 amino acid native human protein. IFN-β-1b is a nonglycosylated protein expressed in *E. coli*; it also differs from the human protein in that it lacks the N-terminal methionine and has a Cys17Ser substitution (*13*−16). These structural alterations may correlate with an apparent reduced bioactivity in vitro and an increase in neutralizing antibodies for patients treated with IFN-β-1b when compared with IFN-β-1a (*17*−*22*). While both of the Type I interferons, IFN-α and IFN-β, which bind to a common IFNAR-1/IFNAR-2 receptor (*23*−*25*), have proven to be among the most successful biotechnology products, the major obstacle to clinical development has not been biological potency. Rather, the physicochemical properties of these very potent compounds have led to challenges in frequent dosing, formulation, and immunogenicity. Among the human therapeutic cytokines, IFN-β-1b is a prime example of a hydrophobic protein difficult to purify and formulate, owing to the propensity of the molecule to form aggregates. The marketed IFN-β-1b product, Betaseron, is a lyophilized powder containing human serum albumin as an excipient. Clinical pharmacokinetic studies have demonstrated that IFN-β-1b has a very short terminal serum half-life and the

low serum concentrations challenge the limits of assay detection following subcutaneous administration (*14*, *26*).

The goals of the present study were to design IFN-β-1b molecules exhibiting (1) prolonged solubility in the absence of detergents, (2) diminished formation of protein aggregates, (3) diminished immunogenicity, (4) improved in vivo potency, and (5) tailored pharmacokinetic profiles with alternate routes of administration. We wished to employ bioconjugate and protein engineering approaches to investigate the performance of a series of designed IFN-β-1b compounds synthesized by site-specific or site-selective surface modification. PEGylation, the covalent attachment of poly(ethylene glycol) polymers to compounds, has become one of the best validated drug delivery methods for extension of serum half-life (*27*−*38*) and at least six PEGylated protein therapeutics are now on the market (*39*). Two PEGylated interferon-α products are included in this category (*40*−*45*) and initial progress on PEG−IFN-β-1a has been reported (*34*, *46*, *47*), but a general strategy for creating tailored PEGylated IFN-β-1b has not been developed after the1990 patent disclosure of Katre and Knauf (*48*). Conjugates composed of PEG and receptor-binding ligands frequently exhibit diminution or even loss of bioactivity, and these compounds may also demonstrate substantial product heterogeneity. In general, activated PEG polymers reactive with primary amines have been employed in multiple attachments with catabolic enzymes and other macromolecules which recognize small substrates. In comparison, PEGylation of cytokines, hormones, and other small protein ligands represents a greater challenge for enhancing clinical potency due to the opposing effects of reduced receptor binding affinity and prolonged conjugate circulating lives (*49*−*52*). A receptor binding site may constitute a large proportion of the ligand surface area; for example, 960 Å^2 of accessible surface is buried in each binding interface of the IFN-γ/IFN-γRα complex (*53*). Furthermore, reactive amines are prevalent moieties on the scaffold and contact regions of essentially all natural cytokine sequences (*2*). Consequently, extensive random conjugations may be inactivating either through direct attachment to receptor-binding contact residues or as a result of transient steric hindrance and diffusional constraints from the long polymer strands.

To investigate this macromolecular engineering approach, we expressed purified and re-engineered recombinant IFN-β-1b through construction of 20 disparate conjugate preparations with 12 kDa, 20 kDa, 30 kDa, and 40 kDa PEG polymers and performed a comparison of the structural and functional properties of the purified IFN-β-1b proteins and their PEGylated counterparts. Physicochemical analysis of selected mono-PEGylated IFN-β-1b compounds verified their composition, while several cell based assays, immunoassays, and chromatographic methods confirmed that the conjugates demonstrated superior monomeric stability and maintained functional activity dependent on microenvironment. Pharmacokinetic studies of the conjugates in rodents demonstrated that the circulating lives of the PEGylated IFN-β-1b proteins could be tailored with correspondence to the polymer molecular mass, reaching circulating times comparable to the major blood proteins for the conjugate compounds employing 40 kDa branched PEG polymers. These investigations demonstrate a practical approach for engineering IFN-β-1b, and perhaps other similar hydrophobic proteins, to achieve improved physical stability as well as improved pharmacological properties.

EXPERIMENTAL PROCEDURES

Materials. Recombinant human IFN-β-1b (30 MIU/mg) was supplied by Enzon Pharmaceuticals (Piscataway, NJ). Betaseron was purchased from the pharmacy. All activated PEG polymers were supplied by Enzon Pharmaceuticals, except mPEG2-ButyrALD-40 kDa-PEG, mPEG-SPA-20 kDa and mPEG2-NHS-40 kDa, which were purchased from Nektar Therapeutics (San Carlos, CA). Hiload Superdex 200, HiPrep 26/10, and PD-10 desalting columns were supplied by Amersham BioSciences (now GE Healthcare, Piscataway, NJ), and Poros HS was supplied by Applied Biosystems (Foster City, CA). Precast 4−20% Tris-glycine SDS PAGE gels and the gel running buffer were obtained from Invitrogen (Carlsbad, CA). Encephalomyocarditis virus (EMCV; VR-129B) and Vero cells (CCL-81) were from ATCC. Titrisol iodine solution was obtained from EM Science (Gibbstown, NJ).

IFN-β-1b Genetic Constructions. The synthetic genes for human IFN-β-1b and protein variants were constructed from the published sequence (*13*). Recombinant proteins were expressed in *E. coli* BL21(DE3), refolded, and purified to near homogeneity as previously described (*54*, *55*). The inclusion of 0.05% Zwittergent 3−14 in column and formulation buffers was needed to maintain protein solubility. DNA sequence confirmation of all IFN-β genes was performed on an ABI PRISM 310 Genetic Analyzer. Generation of lysine-free variants of IFN-β-1b followed the reported protocol (*52*).

PEGylation of IFN-β-1b. IFN-β-1b (0.8 mg/mL; 5−50 mL) in 100 mM sodium phosphate, 0.05% Zwittergent 3−14, 2 mM EDTA, pH 7.8, was conjugated with activated PEG polymers with PEG mass of 12 kDa, 20 kDa, 30 kDa, and 40 kDa. In random PEGylation of primary amines, PEG-NHS or PEG-T compounds were dissolved in 0.1 mM HAc (or in H_2O for T-PEG). With fast stirring without generating foam, the PEG solution was added at 0.5−1.0 g/min to a final 10-fold molar excess over protein. The reaction was conducted at 25 °C for 60 min for PEG-NHS, or 120 min for PEG-T, quenched by adding glycine to a final molar ratio of 50:1 (glycine:PEG), and filtered through a 0.2 μm membrane before the column purification.

N-Terminal PEGylation: IFN-β-1b (0.8 mg/mL) was reacted with ALD-PEG polymers at a 1:10 reaction molar ratio in 100 mM sodium acetate, pH 5.2, at 25 °C for 3 h. 1 M sodium cyanoborohydride in PEGylation buffer was added to the reaction to a final concentration of 15 mM. The reaction was conducted at 25 °C for 16 h.

Purification of PEG−IFN-β-1b. The PEGylation reaction (5 mL; 0.8 mg protein/mL) was purified by Superdex 200 High Load chromatography with a 10 mM sodium phosphate, pH 7.3, 0.05% Zwittergent running buffer at a flow rate of 2 mL/min. In the second step, 8 mL of peak fractions were loaded onto an HS-50 column with 10 mM sodium phosphate, pH 7.3, 5% mannitol running buffer. The PEG−IFN-β-1b was eluted with 1 M NaCl in equilibration buffer at 2 mL/min and 2 mL/fraction over a period of 40 min. Fractions identified on SDS−PAGE were combined and the pH of the sample was immediately adjusted to 3.7 with HAc. It was then dialyzed using a 30k-MW-cutoff membrane against 5% mannitol, 3 mM HAc, pH 3.7 at 4 °C for 12 h. The fractions were diafiltered on Amicon membranes to a final concentration of 0.5−1 mg/mL in 3 mM HAc, pH 3.7, 5% mannitol. The endotoxin levels of the IFN-β-1b conjugates were <1 EU/mg; contamination of *E. coli* proteins was below 0.002% by immunoassay (Cygnus Technologies); Zwittergent and SDS were undetectable by RP-HPLC using an ELSD detector (detection limit: 0.01%) and acridine-orange (detection limit: 0.001%), respectively.

Analytical Characterization of IFN-β-1b and PEG−IFN-β-1b. Protein concentrations were determined by UV absorbance at 280 nm, with an IFN-β-1b extinction coefficient of 1.5 mL/mg.cm. The concentration was also confirmed by the bicinchoninic acid assay (BCA) using a BSA standard.

Western blot analysis was performed with anti-huIFN-β rabbit antiserum as a primary antibody and goat anti-rabbit HRP was

used as a secondary antibody with a TMBM peroxidase substrate. Iodine staining of SDS PAGE gels was performed after gels were rinsed with distilled water and placed in 5% barium chloride solution. After 10 min of gentle mixing, the gels were again rinsed with water and placed in 0.1 M Titrisol iodine solution for color development.

Mass values of IFN-β-1b and PEG−IFN-β-1b conjugates were determined by matrix-assisted laser desorption ionization−time-of-flight mass spectrometry (MALDI-TOF; Bruker Daltronics OmniFlex NT) using an internal standard with similar molecular weight on the α-cyano-4-hydroxycinnamic acid (CHCA) matrix. Apparent molecular weights (Stoke radius) of the compounds were estimated using Superdex 200 HR 10/30 Gel Filtration column chromatography. Additionally, analysis of molecular masses on 4−20% SDS−PAGE gels was performed using protein and PEG-protein standards.

Peptide mapping was performed by published procedures (*57*).The PEG−IFN-β-1b (0.2 mg) was denatured and reduced in 6 M guanidine HCl, 1 mM EDTA, 5 mM DTT, then alkylated with iodoacetamide prior to digestion with TPCK-treated trypsin. The trypsin generated peptide mixture was fractionated by size exclusion chromatography (Superdex 75) with HPLC-grade water and analyzed by SDS−PAGE and iodine staining. The unique iodine-stained fraction was subjected to protein sequencing analysis (PROCISE, Applied Biosystems). Alternatively, the PEG-peptide fragments were isolated on RP-HPLC and subsequently subjected to sequencing. The percent isomer was calculated by dividing the amount of each isomer by the total amount of isomers in the first cycle of sequencing. Lys-C digested fragments from either IFN-β-1b or PEG−IFN-β-1b were also separated on RP-HPLC and identified by LC-MS. PEG-peptides were identified by comparative analysis.

Circular dichroism (CD) and the determination of enthalpy of folding were conducted as described (*58*). All samples were analyzed at 0.1 mg/mL in 5 mM acetic acid. Spectra were collected at 25 °C. Data were analyzed using the neural network software CDNN (*59*).

Flow cytometry for comparative analysis of fluorescence intensity was conducted on FACSCalibur as previously described (*28*). A549 cells were incubated sequentially with IFN-β-1b, rat anti IFN-β-1b or anti PEG−IFN-β-1b plasma, and PE conjugated goat anti- rat IgG polyclonal antibody (BD Biosciences).

Biacore analysis was performed as described (*28*). IFN-β-1b was immobilized on a CM5 chip and the preimmunized and postimmunized rat serum (1:100) were analyzed for antibodies against IFN-β-1b.

RP-HPLC. RP-HPLC was used to determine conjugate purity and stability. A Vydac C4 column was run at 55 °C. Samples (0.5 mg/mL in 5% mannitol, 3 mM HAc, pH 3.7) were analyzed using a 45−60% gradient over 25 min at 0.8 mL/min of buffer A (0.1% TFA in H_2O) and buffer B (0.1% TFA in acetonitrile).

SE-HPLC. Superdex 200 HR was used to analyze formation of soluble aggregates of the PEG−IFN-β conjugates. The mobile phase was composed of 100 mM sodium phosphate, pH 6.8, at 24 °C. Evaporative Light Scattering Detection (ELSD; Sedere, Inc.) allowed free PEG detection.

Antiviral Assays of IFN-β-1b. Specific antiviral activity from the cytopathic effect of IFN-β-1b was assayed by published methods (*60*) using Vero cells and EMCV virus, which were cultivated as recommended by the ATCC supplier. Vero cells were distributed on 96-well microtiter plates (20000 cells/well) in 0.05 mL of culture medium. Serial dilutions of 0.05 mL of the IFN-β samples were added and incubated at 37 °C, 5% CO_2, for 24 h. EMCV (200 pfu/20 μL) was added to each well at 25 °C for 30 min and then incubated at 37 °C for 24 h. After the addition of 20 μL of 10 mg/mL 3-(4,5-dimethyl-2-thiazoyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT; Promega, Madison, WI) dye solution to each well, incubation was continued for 4 h; then 100 μL of stop solution (1.2 N HCl in 2-propanol) was added to each well, and the plate was read at 570 nm in a 96-well plate reader (Molecular Devices, Sunnyvale, CA) to determine EC_{50} values, as analyzed with Softmax Pro software. Native IFN-β-1b and PEGylated IFN-β-1b were analyzed in triplicate on each plate. Conversion of mass to antiviral units was attained using specific activity of the parent compound (native or PEG−IFN-β-1b). A549 cells were also used in antiviral assays in this procedure.

Antiproliferation Assay. A549 cells were seeded in 96-well plates, 4000 cells/well, in 100 μL complete Ham's F12K medium containing 2 mM L-glutamine, 1.5 g/L sodium bicarbonate, and 10% fetal bovine serum. IFN-β-1b compounds were added to the cells (in triplicate) in serial dilutions, initiating at 125 ng/mL, which is equivalent to 4000 Units/mL of Betaseron activity. Cells were allowed to grow for 4 days, and cell proliferation was measured by the MTT assay.

Pharmacokinetic Analysis of PEG−IFN-β-1b in Mice. C57BL/6 mice (7−8 week, female) were supplied by Sprague Dawley Harlan (Madison, WI). Mice (5/group) were injected subcutaneously, intramuscularly, and intravenously with 100 μL per mouse (0.2 mg protein/kg) of IFN-β-1b, or its PEGylated conjugates. Following sedation with 0.09% avertin, sampling of blood was undertaken via the retro-orbital sinus into vials containing EDTA. At 2, 15, 30, and 60 min, the mice were bled 100 μL, and at 4, 24, 48, 72, and 96 h, the mice were terminally bled by cardiac puncture. The plasma was collected following centrifugation of the blood at 5000 rpm at 4 °C for 5 min and immediately frozen on dry ice. The concentrations of the compounds were analyzed by both antiviral activity and by ELISA. The data were modeled using WinNonlin software (WinNonlin Pharsight, Mountain View, CA) to determine pharmacokinetic parameters using a two compartment, bolus, first-order elimination model for the intravenous samples. The correlation between the observed and predicted model time point values was ≥95%.

Pharmacokinetic Analysis of PEG−IFN-β-1b in Rats. Sprague Dawley (Harlan) rats (150−300 g; 3/group) were injected subcutaneously, intramuscularly, or intravenously with 150 μL per rat (0.1−0.6 mg/kg) of IFN-β-1b, or its PEGylated conjugates. Following sedation with 30% O_2/70% CO_2, sampling of blood (250 μL) was undertaken via the retro-orbital plexus into vials containing EDTA, at times prior to compound administration and at 2 min, 60 min, 2 h, 4 h, 8 h, 24 h, and daily for 3 additional days. The plasma was collected following centrifugation of the blood at 5000 rpm at 4 °C for 5 min and immediately frozen on dry ice. The concentrations of the compounds were analyzed by both antiviral activity and by ELISA. The data were modeled using WinNonlin software (WinNonlin Pharsight, Mountain View, CA) by noncompartmental analysis with AUC estimated by the linear trapezoidal rule to determine pharmacokinetic parameters.

Immunogenicity of IFN-β-1b and PEG−IFN-β-1b in Rats. Sprague Dawley (Harlan) rats weighing 150−300 g (three in a group) were injected intramuscularly with either buffer, native IFN-β-1b (0.1 mg/kg), or NHS 40 kDa PEG_2−IFN-β-1b (0.1 mg protein/kg). Injections were given once per week for five weeks, and the plasma samples were collected before the next injection and at the end of the sixth week. Rat plasma antibodies were analyzed by direct ELISA, indirect ELISA, flow cytometry, Biacore, and antiviral neutralization assays.

Direct ELISA: As previously described (*61*), IFN-β-1b coated the microtiter plates (400 ng/50 μL). Rat anti IFN-β-1b or anti PEG−IFN-β-1b plasma was added in 1:2 serial dilutions. The secondary antibody was HRP conjugated rabbit anti rat IgG

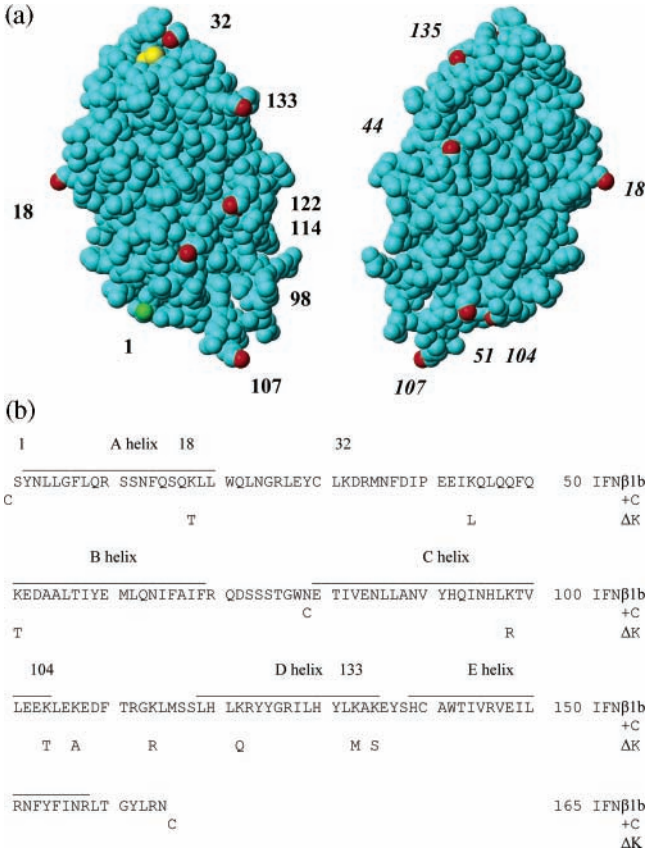

Figure 1. (A) Two views of the human IFN-β model based on the IFN-β-1a crystal structure (PDB File Name 1AU1). The space-filling model is shown from two different angles, rotated by 180°. The 11 lysines are numbered and highlighted with nitrogen in red. The right-hand model uses italics numbering for clarity. The N-terminal serine-1 amino group is green and the disulfide (S−S) bond between cysteine-30 and cysteine-140 is shown in yellow. Lysine-114 is not readily visible in this figure. (B) Amino acid sequence of 165-residue IFN-β-1b is shown with five helix structures. Locations of primary sites of PEGylation at lysines or the N-terminus are shown by numbering above the sequence. Below the sequence are shown site-specific mutant proteins corresponding to sites of single free cysteine insertion (+C) at either the N-terminus, C-terminus, or position 79. Also shown on the bottom line are the sequence substitutions in a lysine depleted variant protein (ΔK).

(Jackson Labs; 1:5000) with TMB peroxidase substrate (Moss, Inc.). Plates were read at 450 nm. The control mAb MMHB-3 was obtained from R&D Systems.

Indirect ELISA: The microtiter plates were coated with the capture antibody, anti- huIFN-β mAb (R&D Systems) at 200 ng/50 μL per well. After blocking, either 4 ng or 20 ng of the two test compounds, IFN-β-1b and NHS 40 kDa PEG_2−IFN-β-1b, were added in alternate wells and incubated 12 h at 4 °C. After washing, rat plasma samples were added in 1:2 serial dilutions, beginning at 1:100 or 1:1000 dilutions for IFN-β-1b or NHS 40 kDa PEG_2−IFN-β-1b, respectively. After 12 h incubation at 4 °C and plate washing with PBS, 0.05% Tween-20, pH 7.4, 50 μL of HRP conjugated goat anti rat IgG (1:5000; Jackson Labs) was added and after 2 h incubation at 22 °C and plate washing, TMBE−100 substrate (Moss, Inc.) was incubated for 20 min and the plates were read at 450 nm.

RESULTS AND DISCUSSION

Recombinant Human IFN-β-1b and Site-Selective PEGylation Strategy. A structural view of IFN-β-1b architecture is shown in Figure 1A and 1B (*13, 15*). In our investigations of PEGylation of this protein, we wished to examine multiple approaches which would include attachment of PEG polymers at several different positions on the protein surface. Other investigated parameters would include PEG size, PEG linker, and number of polymer attachments per protein. The key characteristics under evaluation for improved performance would include blood residency time, potency, solubility, aggregation, and immunogenicity. To minimize the potential for PEG polymer strands to sterically block the receptor-binding sites, our preferred designs place single attachments of PEG either (1) site-specifically at the N-terminus, (2) site-selectively on lysines in a stochastic mixture of mono-PEGylated products, or (3) site-specifically in engineered attachment sites. Several linear or branched electrophilic mPEG polymers of 12, 20, 30, and 40 kDa were included in the investigations of lysine modification, whereas, PEG-aldehyde was employed for N-terminal modification. Di- and tri-PEGylated IFN-β-1b proteins were also prepared for comparison to the preferred mono-PEGylated compounds.

Previous studies of PEGylation of IFN-α and IFN-β-1a demonstrate the utility in either random or site-specific modification with one large PEG polymer per protein (*40*, *41*, *43*, *46*). Since IFN-β-1b exhibits only about 35% sequence identity with the IFN-α family, and lacks the N-glycan, N-terminal methionine, and free thiol of IFN-β-1a, there may be limited guidance in the PEGylation approach for IFN-β-1b from these prior studies with other interferons.

Chart 1 displays the structures of the amine selective PEG polymers used in this study. These reagents react with primary amines with release of either the *N*-hydroxysuccinimide (NHS) or thiazolidine-2-thione (T) leaving group to form an acylated product. One example of bioconjugation of UA-PEG to primary amines is shown in Scheme 1. As shown in Figure 1A, eleven lysines and the N-terminal α-amine are available for modification by the well characterized activated PEG compounds such SC−PEG (*33*), XUS−PEG (*35*), T-PEG (*36*), and various NHS derivatives (*29*, *40*, *50*). ALD-PEG polymers may be employed to construct PEG conjugates selectively modified at low pH at the N-terminus, forming secondary amines by reduction with sodium cyanoborohydride (*37*, *46*). Mono-PEGylation of proteins using random amine-directed chemistries commonly produces positional isomers, which are conjugate mixtures with single PEG attachments at different sites on the protein surface. We conducted trypsin or Lys-C peptide mapping analysis, amino acid sequence analysis, LC/MS, and MALDI-TOF or SELDI-TOF MS on two of the most promising mono-PEGylated conjugates, which employed the branched 40 kDa PEG_2−NHS or 40 kDa PEG_2-ALD polymers, to evaluate preferred linkage sites. Figure 1B summarizes the major sites of attachment for these derivatives.

The 40 kDa ALD PEG_2 selectively modified the N-terminus; minor alternate sites (<15%) were not identified. Conjugation with the 40 kDa NHS PEG_2 polymer produced at least five major positional isomers corresponding to positions S1 plus K18 (42%), K104 (18%), K32 (15%), and K133 (14%), and other sites (11%). The N-terminal sequence analyses indicated that K18 was a slightly more preferred PEGylation site than the alpha amine of serine-1 on this N-terminal peptide. The structure of IFN-β-1a shows that the lysines with the most solvent exposed amino groups are K18, K107, and K133. Two of these lysines were shown in these analyses to be PEGylated in NHS 40 kDa PEG_2−IFN-β-1b. K107 is located within a tripeptide Lys-C fragment that eluted very early during C18 RP-HPLC, and this precluded a conclusive determination for this position. The available data suggest that K107, although well exposed, may be a minor site for PEGylation in this compound.

Using systematic mutational mapping of IFN-β-1a, Runkel et al. (*3*, *4*) proposed binding sites for the type I IFN (IFNAR-

1/IFNAR-2) receptor from Daudi cells. For example, K18, K32, K122, and K133 are located in the general proximity of the binding site for IFNAR-2 and PEGylation at these sites might compromise the efficiency of receptor binding to PEG−IFN-β-1b. For the purpose of our present investigations, the observed differences in distribution of positional isomers in these two conjugates provide a basis for subsequent comparison of functional properties in relationship to structural differences.

We also examined two alternate, entirely site-specific PEGylation approaches for PEG−IFN-β-1b engineering that were both found to be unsatisfactory in our investigations. A recent trend in PEGylation has been the generation of site-specific modification with a single large polymer (*40*, *43*, *49*). Designed protein variants containing one free cysteine may be effectively conjugated to maleimide activated polymers (*28*). We designed three such variants of IFN-β-1b wherein the free cysteine is engineered at either the N-terminus, the C-terminus, or at position 79, which is occupied by the N-glycan in the native protein (Figure 1B). All proteins were expressed and purified in similar yields and bioactivities, compared to IFN-β-1b. However, a completely site-specific modification with maleimide PEG polymers, by our previous protocol (*28*), proved to be challenging due to the lability of the protein disulfide (C30−C140) under reducing conditions. Although conducting the

[a] Following purification as described in Experimental Procedures of mono-, di-, and tri-PEG−IFN-β-1b derivatives, which contain one, two, or three PEG attachments per protein, respectively, the purified compounds were analyzed by SE-HPLC. The molar percent of each species in the purified compounds is based on SE-HPLC peak integration. In some cases, independent lots of a compound are shown. [b] The percent of antiviral activity per protein retained in the purified conjugates relative to native IFN-β-1b (30 MIU/mg = 100%).

conjugation reaction at acidic pH or with mild reducing reagents improved the maintenance of the disulfide linkage, the overall yield and complete site specificity of attachment were determined to be insufficient (data not shown).

Another reported approach for site-specific modification was described by Yamamoto et al. (*52*), wherein lysine depleted muteins were screened, thus producing variants with one or a few available primary amines. Our attempts to use this protocol with IFN-β-1b variants demonstrated limited success. Most variant proteins lost antiviral activity or maintained an unacceptably low residual activity such as the mutein shown in Figure 1B which retained only 1% of the native bioactivity. Therefore, we focused our detailed investigations of PEGylated IFN-β-1b on conventional amine selective chemistries under controlled reaction conditions.

PEGylation of IFN-β-1b. Amine directed PEGylation reactions and purification of either mono-PEGylated or di-PEGylated IFN-β-1b conjugates are described in Experimental Procedures. Seven previously described linker designs (*33*, *35*, *36*, *37*, *40*) were investigated including NHS, X-US, UA, T, SC, SPA and ALD. Four PEG masses were examined including 12 kDa, 20 kDa, 30 kDa, and 40 kDa. Table 1 summarizes the purity and bioactivity of the PEGylated IFN-β-1b derivatives investigated in a first screen of compounds. Isolation of mono-PEGylated derivatives was possible from the starting conjugate mixtures, with native IFN-β-1b and di- and tri-PEGylated conjugates present as either trace impurities or as significant species, depending on the conjugate category. The purification of the multi-PEGylated derivatives allowed an initial examination of the correlation of degree of modification with bioactivity. Figure 2 presents one representative SDS−PAGE analysis, including Coomassie Blue, Western, and iodine staining, of mono-PEGylated IFN-β-1b compounds with 12 kDa, 20 kDa, or 40 kDa polymers.

Relative to native IFN-β-1b, the mono-PEGylated compounds retained excellent activity. The retention of about 20−70% of antiviral activity in these derivatives compares favorably to the marketed PEGylated IFN-α drugs, PEG-INTRON and Pegasys, where in vitro antiviral activities are about 28% or 7% of the unmodified protein, respectively (*40*, *45*). It is apparent that the conjugates with the highest molecular weight 40 kDa PEG polymers have lower antiviral activity in vitro. There is no apparent distinction between different linkers and bioactivity within the mono-PEGylated derivatives. A significant observa-

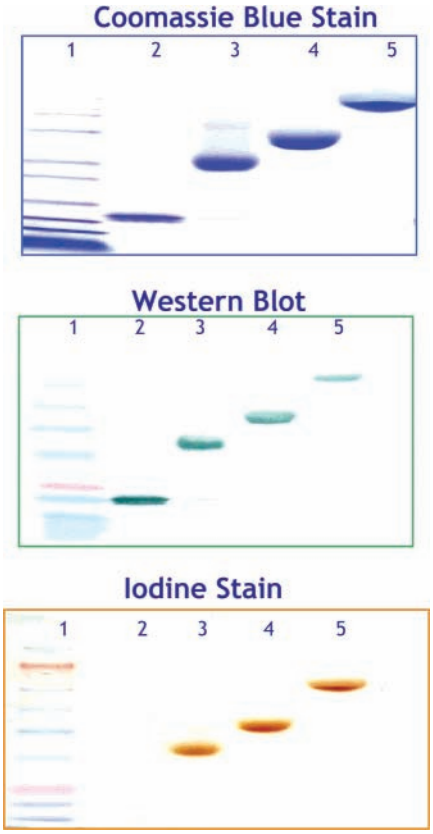

Figure 2. SDS−PAGE analysis of mono-PEGylated IFN-β-1b compounds. Molecular weight markers (lane 1), IFN-β-1b (lane 2), SC 12 kDa PEG−IFN-β-1b (lane 3), SPA 20 kDa PEG−IFN-β-1b (lane 4), and NHS 40 kDa PEG_2−IFN-β-1b (lane 5) are shown. The samples were denatured by heating at 85 °C for 3 min in the presence of 12 mM β-mercaptoethanol. Protein was identified by Coomassie Blue staining or Western staining with anti-huIFN-β mAb; PEG was detected by iodine staining.

tion from this study is the reduced or abolished in vitro bioactivity for the multi-PEGylated IFN-β-1b compounds. Attachment of two 40 kDa branched polymers, or attachment of three 12 kDa linear polymers diminished antiviral activities by about 100-fold. Independent analysis of bioactivity of the compounds by an anti-proliferation assay on A549 cells provided similar results (data not shown).

One especially interesting conjugate is the SPA 2 × 20 kDa di PEGylated IFN-β-1b compound, which does retain 21% of native antiviral activity. This conjugate is analogous to the branched 40 kDa PEG modified protein, except the two 20 kDa polymers are at disparate sites rather than at a common attachment position. Therefore, comparison of biological properties of these two conjugate types will be instructional. In addition to the isolation of conjugate species, the purification protocol was also able to remove free PEG polymers, SDS, and Zwittergent, as verified by light scattering detection, acridine orange assays, and RP-HPLC, respectively. Additional purity analysis of these conjugates, including analysis of endotoxin (<1 EU/mL) and *E. coli* protein contaminants (<15 ppm), were conducted prior to in vivo studies.

As shown in Table 2, MALDI-TOF MS confirmed the predicted molecular mass of IFN-β-1b and PEG−IFN-β-1b compounds, and gel filtration analysis demonstrated the capacity of PEGylated proteins to markedly expand in hydrodynamic volume resulting in a predicted molecular weight about 14-fold greater than the calculated mass in the case of the conjugates with single 40 kDa branched polymer attachments. Use of PEG polymer or PEG-protein standards also allowed an approximate measurement of mass with SEC or SDS−PAGE methods, respectively. An evaluation of the preliminary compounds in Table 1 and Table 2 was the basis for selection of several of these conjugates for further analytical and pharmacological investigations.

Stability, Solubility, and Aggregation Analysis. Marketed interferon-β drugs have encountered formulation challenges for this aggregation prone protein; Betaseron, Avonex, and Rebif are formulated with human serum albumin either as powder or in solution. One of the potential benefits of PEGylation for an exceptionally hydrophobic protein such as IFN-β-1b, which is particularly susceptible to aggregation, is increasing the solubility and stability of the conjugate molecule. This attribute was immediately apparent in our investigations of PEGylated IFN-β-1b conjugates. When native IFN-β-1b was formulated in aqueous solution in the absence of a surfactant, such as Zwittergent 3−14, the protein rapidly and quantitatively precipitated as insoluble aggregates within 7 days at neutral pH, whereas the 40 kDa PEGylated IFN-β-1b remained soluble during this duration. Using the selected formulation buffer (3 mM HAc, pH 3.7, 5% mannitol), we found that the NHS 40 kDa PEG_2−IFN-β-1b compound retained the initial antiviral bioactivity (8.5 MIU/mg ± 20%) for 6 months when stored in aqueous solution at 4 °C.

However, we wished to perform a stringent analysis of the physical behavior of PEG−IFN-β in stability studies in order to also examine the extent of formation of soluble aggregates of the bioconjugate. We used RP-HPLC to examine the physical integrity and purity of the conjugates, and SE-HPLC to examine the appearance of soluble aggregates in the PEG−IFN-β-1b preparations. As shown in Figure 3A and 3B, the chromatographic analyses distinguished the mono-PEGylated protein from both degradation products and aggregates. As shown in Table 3, the NHS 40 kDa PEG_2−IFN-1b compound (0.1 mg protein/ml) demonstrated no formation of soluble aggregates during 37-day storage at 4 °C at pH 3.7−4.0. However, storage at higher pH (5.0−8.5) resulted in increasing formation of soluble aggregates with higher pH. We further examined the stability of PEGylated IFN-β-1b compounds in plasma and confirmed no significant loss of antiviral activity in rat plasma incubated at 37 °C for 72 h for the seven conjugates used in subsequent in vivo studies. There was a trend toward better in vitro solubility and stability of the IFN-β-1b conjugates with increasingly higher molecular weight polymers. This may be compared to the successful formulation of the relatively more soluble IFN-α proteins with PEG polymers of intermediate size. Additionally, we examined the rate of degradation of IFN-β-1b and PEG-modified counterparts in rat liver and kidney extracts at 37 °C. The rates of degradation of the PEGylated proteins were approximately 15% of the native protein based on antiviral activity measurements (data not shown).

Finally, we wanted to examine the conformational and structural integrity of the PEGylated IFN-β-1b in a direct comparison to the native protein. In circular dichroism analysis of the NHS 40 kDa PEG_2−IFN-β-1b compound and native IFN-β-1b (0.1 mg/mL), the CD spectra were indistinguishable. As shown in Figure 3C, in additional studies of thermal unfolding of the helices (α helix content ∼ 60%), the thermal stability of the protein and conjugate were very similar and the thermal unfolding of the helices was uncooperative in character. The melting temperatures of IFN-β-1b (T_m = 61.8 °C) and two independent preparations of 40 kDa PEG_2−IFN-β-1b (T_m = 63.2 °C; T_m = 63.5 °C) were virtually identical. The CD data confirm that PEGylation does not impart a notable alteration in secondary structure or thermal stability of the IFN-β-1b protein.

Pharmacokinetic Analysis in Mice and Rats. A hallmark of the beneficial effects of PEGylation is an increased blood residency time of the bioconjugates. Pharmacokinetic properties of the IFN-β-1b and PEGylated IFN-β-1b compounds were determined in both mice and rats using antiviral bioassays for quantitation. While immunoassay methods for detection of total compound produced comparable results for the PEGylated derivatives, native IFN-β-1b cleared too rapidly for detection by ELISA. Three routes of administration—intravenous, subcutaneous, and intramuscular—were examined in both rats and mice. A comparison of the PK profiles in mice of native IFN-β-1b and the amine directed mono-PEGylated conjugates with

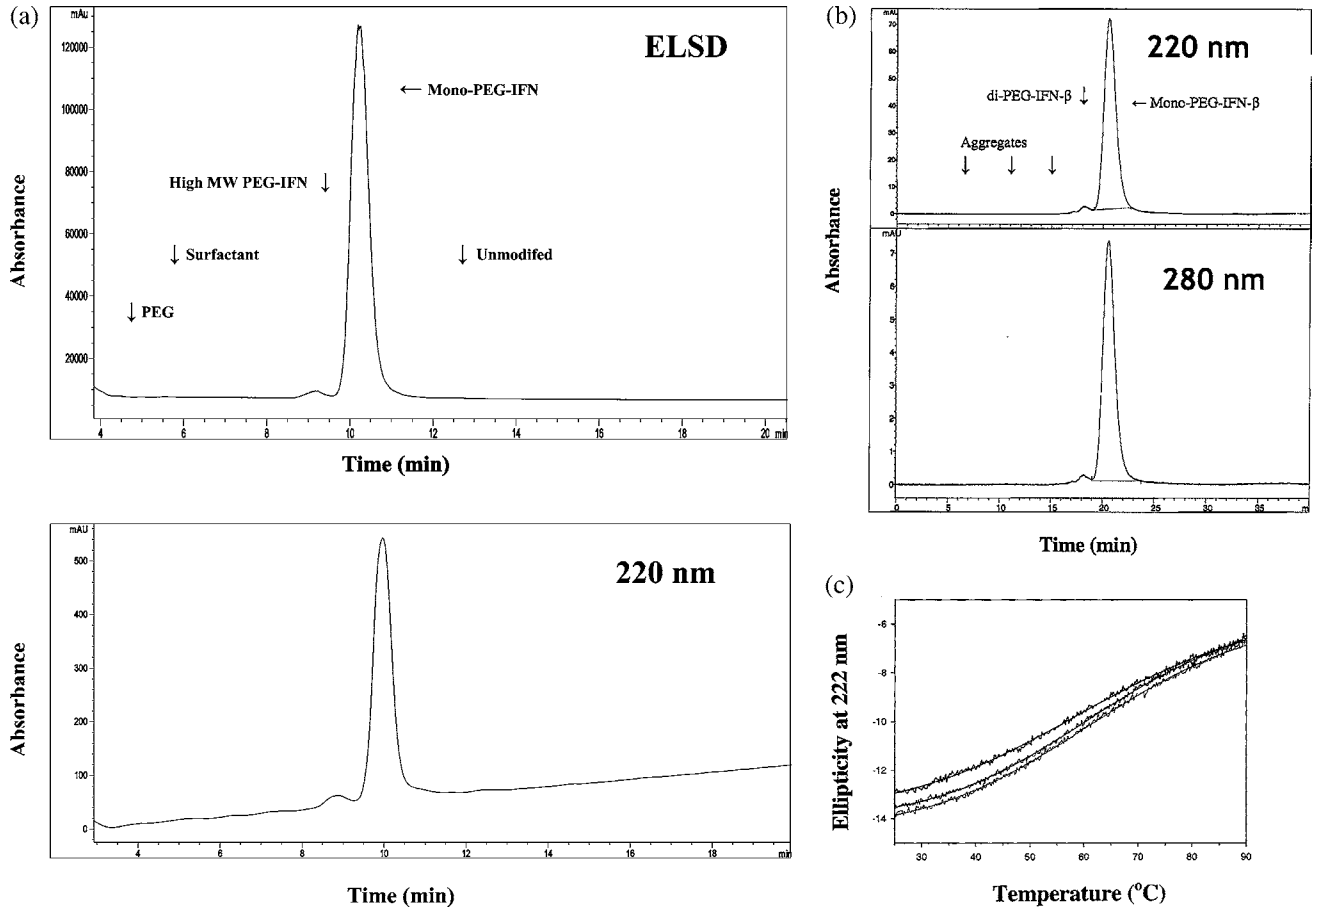

Figure 3. Analyses of physical integrity of PEG−IFN-β-1b. (A) RP-HPLC of NHS 40 kDa PEG_2−IFN-β-1b (0.48 mg/mL in 5% mannitol, 3 mM HAc, pH 3.7) on Vydac C4 at 55 °C with diode array and evaporative light scattering detectors. Upper graph is ELSD scan; lower graph is generated by a 220 nm UV detector. Buffer A: 0.1% TFA in H_2O; buffer B: 0.1% TFA in acetonitrile; gradient: 45−60% over 25 min; flow rate: 0.80 mL/min. Elution times of each species are shown. (B) SE-HPLC of NHS 40 kDa PEG_2−IFN-β-1b (0.88 mg protein/mL in 5% mannitol, 3 mM HAc, pH 3.7) on Superdex 200 HR at 24 °C. Running buffer is 100 mM sodium phosphate, pH 6.8; flow rate is 0.50 mL/min. Elution times of each species are shown. UV detectors scanned 220 nm (upper) and 280 nm (lower). (C) Circular dichroism analysis of IFN-β-1b (upper curve) and two independent preparations of NHS 40 kDa PEG_2−IFN-β-1b (lower two curves) in thermal denaturation investigations. Samples were 0.1 mg/mL (protein) in 5 mM HAc buffer, pH 3.7; CD was conducted at 25 °C. Ellipticity at 222 nm as a function of temperature (°C) is shown.

[a] Percent aggregates of mono-PEGylated NHS-40k-PEG_2−IFN were measured by SE-HPLC.

either NHS 40 kDa PEG_2, SPA 20 kDa PEG, or SC 12 kDa PEG polymers is shown in Figure 4A. Total exposure of the protein is markedly enhanced through PEGylation, and the rank order of exposure increased with increasing PEG mass. In Figure 4B, a similar trend is observed with the mono-PEGylated compounds employing aldehyde linkers. Greatest exposure is observed with the branched 40 kDa ALD-PEG polymer, while the native IFN-β-1b exposure is marginal. In all sets of PK experiments, a second control using Betaseron was included to confirm the comparability of the PK profile of the experimental IFN-β-1b protein (data not shown). As shown in Figure 4C, the mouse PK profile exhibited a similar outcome in side-by-side comparison of the 40 kDa PEG conjugates, including mono-PEGylated derivatives of NHS−PEG_2, ALD-PEG_2, UA-PEG, XUS−PEG, and a di-PEGylated derivative of SPA-20 kDa polymers. Native IFN-β-1b cleared rapidly from the mice, whereas each of the high molecular weight conjugates exhibited very similar absorption and elimination curves. Mice were administered 0.2 mg protein/kg of all compounds, or about 4 μg of interferon protein per mouse. Since the PEGylated IFN-β-1b compounds do not contain equivalent antiviral activity compared the native interferon, as shown in Table 1, the PEGylated conjugates were actually under-dosed relative the native control, with respect to units of activity. In some cases, subsequent conversions of units of bioactivity to ng of protein were performed with an internal standard for specific activity for each individual compound, corresponding to the analyzed sample administered to the animal. Table 4 presents representative pharmacokinetic parameters from the subcutaneous administration route in mice. All PEGylated conjugates exhibit an expanded area under the curve, relative to unmodified protein, of about 14-fold to 173-fold, which increases with polymer mass. The times of maximal concentration by the sc route were delayed in all of the PEGylated compounds by several hours relative to native IFN-β-1b.

The PEG_2-40 kDa polymers demonstrated exceptionally good performance and were selected for detailed studies in PK studies in rats. Figure 5A shows the side-by-side comparison of PK profiles of PEGylated IFN-β-1b compounds with 40 kDa mass

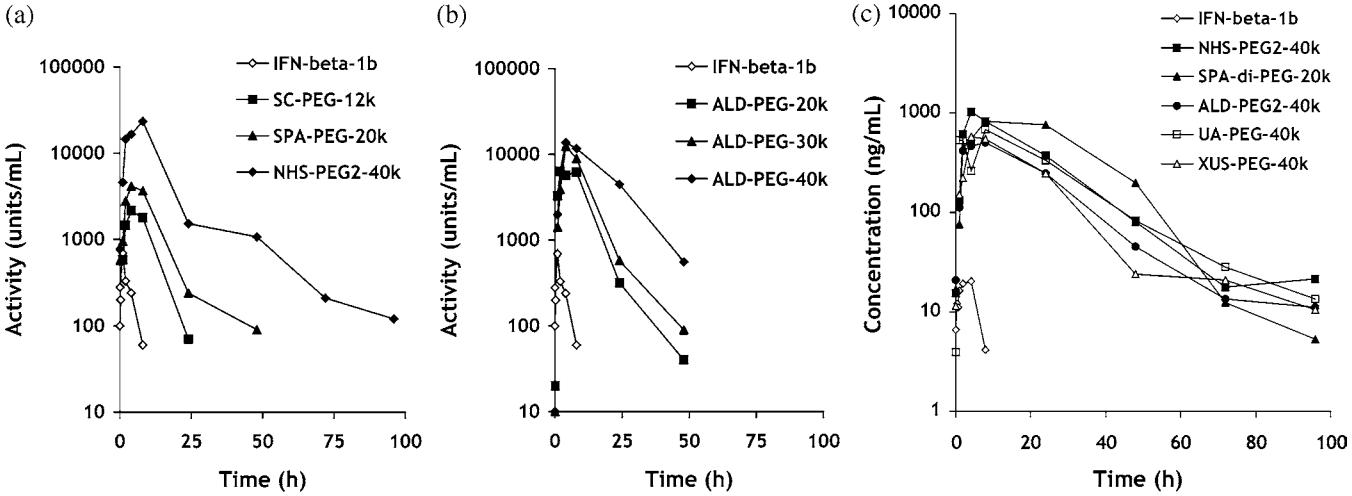

Figure 4. Pharmacokinetics of IFN-β-1b and mono-PEGylated IFN-β-1b in mice. [a] PK parameters of mono-PEGylated IFN-β-1b compounds and di-PEGylated SPA (2 × 20 kDa) PEG−IFN-β-1b compound were determined by using a two-compartment, first-order input, first-order elimination model. AUC, area under the curve; T_{max}, time of maximal concentration postadministration.

of PEG polymers per protein, but with three different linker chemistries and conformations. The two mono-PEGylated compounds, PEG_2-40 kDa and PEG-UA-40 kDa, employ an NHS ester on a branched polymer and generate an amide linkage, while the di-PEGylated IFN-β-1b compound uses a 20 kDa PEG with an SPA linker, and two random amide linkages with 20 kDa PEG polymers are formed in this PEG−IFN-β-1b compound. The PK results are comparable for these three compounds, which all demonstrated much greater exposure than the unmodified interferon. A dose−response investigation in rats, shown in Figure 5B, demonstrated that the AUC exposure of 40 kDa PEG_2−IFN-β-1b was relative to the administered dose. Rats receiving 0.1 mg/kg or 0.6 mg/kg of this compound displayed an AUC difference of 9-fold. Table 5 summarizes key PK parameters for two representative mono-PEGylated 40 kDa PEG−IFN-β-1b compounds administered to rats via the three routes of injection. Both molecules demonstrated comparable overall performance as sc or im administered compounds. Both bioconjugates displayed comparable terminal half-lives (18−23 h in sc route), while exhibiting an expanded Tmax (24−48-fold increase via sc) and increased Cmax (9−19-fold increase via sc) relative to the native protein. Similarly, the clearance via the sc route for the two PEGylated conjugates was diminished 125−210-fold relative the unmodified interferon. PK parameters for the di-PEGylated SPA-20 kDa-PEG−

NHS-40k-PEG_2−IFN-β-1b	mouse	0.2	0.1	22	42
IFN-β−1b	rat	0.6	0.6	1	3
NHS-40k-PEG_2−IFN-β-1b	rat	0.6	0.6	10	22

IFN-β-1b compound were similar to the conjugates with a single branched 40 kDa polymer (data not shown). The specific choice of preferred linker for the branched (2 × 20) kDa design might ultimately be based on practical considerations, such as ease and costs of synthesis.

One highlighted comparison of the three routes of administration with regard to bioavailability, based on total AUC exposure of activity units, is shown in Table 6. Bioavailability was superior for the 40 kDa PEG_2−IFN-β-1b conjugate compared to IFN-β-1b. The difference was greatest in rats where the bioconjugate exhibited 8-fold and 7-fold better bioavailability by sc and im routes, respectively. The overall bioavailability by im injection was excellent, which suggests this parenteral route might be an alternative to the currently used sc administration of Betaseron in patients. The enhanced exposure of the PEGylated IFN-β-1b compounds is expected to provide a much more potent drug than unmodified IFN-β-1b, with respect to AUC effects per mg of protein.

Immunogenicity in Rats. Immunogenicity is a central concern in the development and drug monitoring of protein therapeutics, including PEGylated proteins. Binding antibodies are commonly encountered, and neutralizing antibodies versus Betaseron and other IFN-β compounds have been reported (*17*−*22*). Measurement of the antibody response to a protein therapeutic is challenging. First, immunogenicity in animals is not sufficiently predictive of immunogenicity in humans. Second, an antidrug immune response may dissipate over time. Third, it is difficult to develop the perfect analytical method to measure an antibody response, since immunoassays normally measure titers, and the detection sensitivity of immunoassays will vary based in part on the affinity of the serum antibodies and test reagents. With these limitations in mind, we examined the immune response to IFN-β-1b and four PEGylated (40 kDa PEG) IFN-β-1b compounds in rats.

Rats received 0.1 mg/kg once weekly im injections of the compounds for six weeks. Rat plasma samples were collected each week and analyzed by direct ELISA, indirect ELISA, flow cytometry, Biacore, or antiviral activity neutralization. As shown in Figure 6A, the rat IgG response to the four PEGylated IFN-β-1b compounds was markedly diminished in week two through week six compared to the IgG response to unmodified IFN-β-1b. In this immunoassay, native IFN-β-1b coated the plates and the bound rat IgG was specifically detected by anti rat IgG reagents. Measurement of the antigen specific IgG antibody levels by direct ELISA was based on a control mAb versus human IFN-β. Direct ELISA analysis however demonstrated a similarity in IgM response for all compounds (data not shown). The rat plasma samples were also examined in an alternate capture ELISA format as shown in Figure 6B. Either IFN-β-1b or PEG−IFN-β-1b was captured on an anti human IFN-β mAb immobilized on the plate, and the plasma samples were analyzed on the plates for IFN-β-1b or PEG−IFN-β-1b binding IgG antibodies. High titers of IgG versus IFN-β-1b were produced in rats injected with the unmodified protein at week six, whereas much lower titers of IgG versus 40 kDa PEG_2−IFN-β-1b were produced in rats injected with the PEG conjugate. Most interestingly, the rat IgG antibodies versus native IFN-β-1b did not demonstrate significant binding to PEG−IFN-β-1b, whereas rat IgG versus PEG−IFN-β-1b did demonstrate significant binding to native IFN-β-1b. Since these ELISA plates were coated with an anti human IFN-β mAb, however, any rat plasma IgG directed against a common epitope to the immobilized anti−IFN-β mAb would likely be undetected in this immunoassay.

To further evaluate low affinity IFN-β-1b binding IgG, we performed analysis of the rat plasma samples by flow cytometry using cell line A549, which was incubated first with IFN-β-1b, and then with rat plasma and phycoerythrin conjugated anti-rat IgG reagents. As shown in Figure 6C, fluorescence measurements demonstrated that total IgG bound was greater in the plasma from rats injected with native IFN-β-1b. In Biacore analysis, IFN-β-1b was immobilized on the chip surface. Measurement of total bound antibodies, including IgM and low affinity IgG, also exhibited a trend to reduced titers in the plasma from rats injected with the PEGylated IFN-β-1b conjugate when compared to plasma from rats administered the unmodified protein (data not shown). Antiviral bioassays were employed to examine the capacity of the rat plasma samples to neutralize IFN-β-1b activity in cell culture. Neutralizing antibodies were detected at six weeks in plasma from rats injected with either the native or PEGylated protein, although the plasma from native IFN-β-1b produced a higher titer antibody response (data not shown). Also, rat antibodies raised versus either native or PEGylated IFN-β-1b were capable of neutralizing either the native or PEGylated interferon compounds.

Possibly, the immunoassay designs in Figures 6A and 6B detect a high affinity IgG response in the treated rats, whereas the remaining assays reflect the total high/low affinity IgG and IgM response. One concern for mono-PEGylated proteins is the potential for enhancement of the host immune response due to the large prolongation in blood residency time of the protein (*46*). This effect was not demonstrated in any of our studies. Rather, it seems possible that the solubilized and shielded PEGylated IFN-β-1b may be an inferior antigen for dendritic cells in sc or im administration compared to the aggregation-prone native protein. Further studies in primates and humans are needed to address the question of immunogenicity of these experimental compounds.

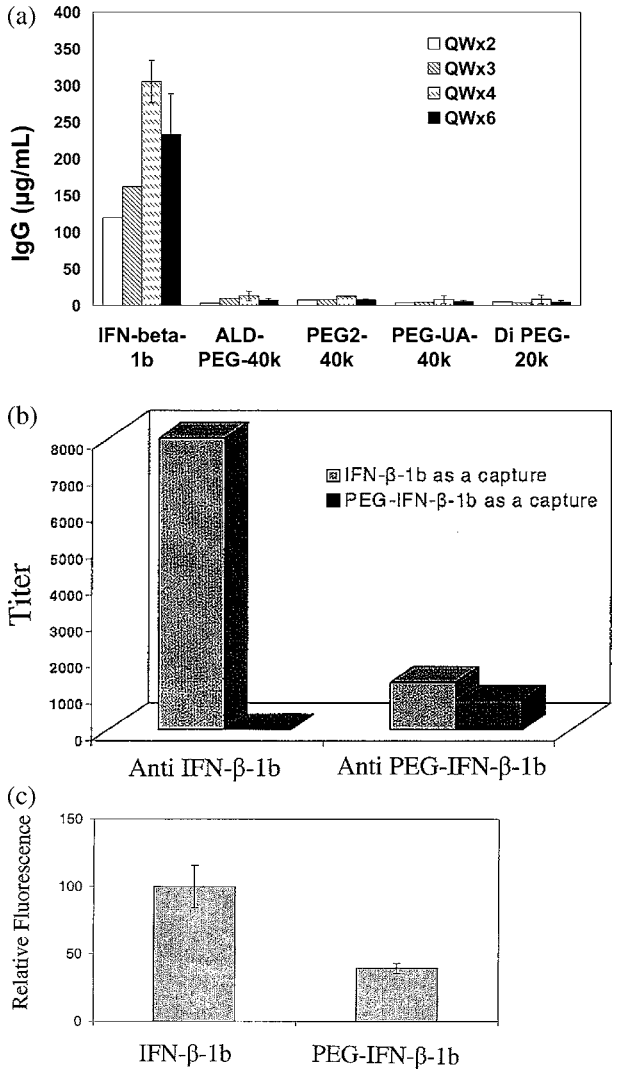

Figure 6. Immunogenicity of IFN-β-1b and PEGylated IFN-β-1b in rats. (A) IgG response, following weekly im injections (0.1 mg/kg), at weeks 2, 3, 4, and 6 to IFN-β-1b and four PEG−IFN-β-1b conjugates. QW × 2, QW × 3, QW × 4, and QW × 6 correspond to once per week dosing at weeks 2, 3, 4, and 6, respectively. IgG (μg/mL) were estimated based on a standard curve with anti-huIFN-β mAb MMHB-3. IFN-β-1b and PEG−IFN-β-1b compounds were coated on ELISA plates prior to incubation with rat plasma and anti-rat IgG-HRP conjugate. (B) Indirect (capture) ELISA assay of IgG response in rats to IFN-β-1b and NHS 40 kDa PEG_2−IFN-β-1b at week 6. Anti-huIFN-β mAb was immobilized on the plate to capture either native or PEGylated protein. Plasma from the rats injected with either of these two test articles were incubated independently on microtiter wells with the captured native or PEG IFN-β-1b, followed by detection with anti-rat IgG-HRP reagent. (C) Flow cytometry with relative fluorescence intensity results for A549 cells incubated with native IFN-β-1b, then incubated with rat plasma versus either native IFN-β-1b or NHS 40 kDa PEG_2−IFN-β-1b, and phycoerythrin-conjugated anti-rat IgG mAb.

CONCLUSIONS

We describe investigations of the physical and functional properties of mono-PEGylated IFN-β-1b compounds. Employment of PEGylation strategies for drug delivery often focus on one specific desired improvement in the drug features, and this is most often a need for improved circulating life. Our present studies illustrate the capacity of attachment of a PEG polymer to IFN-β-1b to improve five key attributes in the bioconjugate. In comparison to the unmodified protein, PEG−IFN-β-1b compounds exhibit better solubility, less propensity to insoluble and soluble aggregation, expanded in vivo exposure of bioactive protein, prolonged blood residency, and a reduced IgG response versus the bioconjugate. Many other protein ligands that have been proposed as therapeutics encounter similar challenges and these PEGylation strategies may be applicable in addressing formulation, stability, and pharmacology difficulties in other incommodious hydrophobic proteins. Our studies also illustrate both the difficulties in site-specific modification of engineered proteins and the ability to construct markedly differing bioconjugates, such as with either the 40 kDa mono-PEGylated NHS−PEG_2 and ALD-PEG_2 derivatives or the di-PEGylated SPA-(2 × 20 kDa) derivative, that nonetheless exhibited notably similar physical and biological properties. The mono-PEGylated IFN-β-1b compounds with a branched 40 kDa polymer appear especially beneficial with regard to prolonged blood circulation and in vitro stability. Of several promising bioconjugates in this study, we chose to further investigate the 40 kDa PEG_2−IFN-β-1b compounds in ongoing pharmacokinetic and pharmacodynamic studies in primates.

ACKNOWLEDGMENT

We thank Steve Youngster, Qing Dong, Lisa Hwang, Eun Jang, and Julia Zhu for performance of MALDI-TOF and LC-MS. We are also grateful to Anju Dang and Massy Rajabzadeh of Ciphergen, Inc. for assistance with SELDI-TOF-MS analysis. We thank Uli Grau and Pascal Bailon for their encouragement and support and Jack Lipman and Ivan Horak for a critical review of the manuscript.

A Molecular Toolkit for Highly Insulating Tethered Bilayer Lipid Membranes on Various Substrates

Vladimir Atanasov, Petia P. Atanasova, Inga K. Vockenroth, Nikolaus Knorr, and Ingo Köper*

Max Planck Institute for Polymer Research, Ackermannweg 10, 55128 Mainz, Germany. Received November 16, 2005; Revised Manuscript Received March 1, 2006

Tethered bilayer lipid membranes (tBLMs) are promising model architectures that mimic the structure and function of natural biomembranes. They provide a fluid, stable, and electrically sealing platform for the study of membrane related processes, specifically, the function of incorporated membrane proteins. This paper presents a generic approach toward the synthesis of functional tBLMs adapted for application to various surfaces. The central element of a tethered membrane consists of a lipid bilayer. Its proximal layer is covalently attached via a spacer unit to a solid support, either gold or silicon oxide. The membranes are characterized optically by using surface plasmon resonance spectroscopy (SPR) or ellipsometry and electrically by using electrochemical impedance spectroscopy (EIS). The bilayer membranes obtained show high electrical barrier properties and can be used to incorporate and study small membrane proteins in a functional form.

INTRODUCTION

Model membrane systems mimic properties of a natural biomembrane. One type of model system, solid supported bilayer membranes, provides an architecture that is accessible to many (surface-) analytical methods. Thus, they can easily be used as biotic−abiotic interfaces in various biosensing applications (*1*−*4*). In the last years, tBLMs have proved to be a powerful tool for producing solid supported membranes. They consist of a lipid bilayer with the proximal layer at least to some extend covalently attached to a solid support. If this substrate is an electrode, electrical characterization of the system is possible. To be considered as a suitable model system, such architectures should possess specific key features of a natural membrane. One requirement is that the membrane must serve as a barrier between an inner- and an outer-membrane environment. This implies that the leakage of small molecules and ions across the lipid bilayer is prevented. Transport processes should only be governed by protein function and not be due to defects in the bilayer structure. Additionally, some lateral fluidity or mobility is necessary to allow for the incorporation and proper function of membrane proteins.

As schematically depicted in Figure 1, the proximal layer of a tBLM can be divided into three distinct parts: (a) the lipid with a linking unit to (b) the spacer group and (c) the anchoring moiety.

In previous tBLM architectures, either saturated (*5*, *6*) or unsaturated (*7*−*9*) alkyl chains have been used as lipid tails. However, these lipids suffer from relatively high transition temperatures (e.g., the transition temperature of dipalmitoyl phosphatidylcholine is 41.5 °C (*10*)) and thus do not form fluid bilayer membranes at room temperature. To reduce the Krafft temperature (T_K), it is common to use branched alkyl chains. T_K is the critical temperature above which the solubility of the surfactant rapidly increases and micelles are formed. To modify this behavior, branched chains have been investigated by varying the branching types, including various short iso and antesio branches (*11*). Although the chain branching consistently lowers the T_K values, this is often not sufficient for the formation of fluid membranes, particularly for long alkyl chains. Highly branched alkyl chains show different properties. The most studied lipids are based on phytanyl with T_K values below 0 °C (*4*, *12*−*14*). The phytanyl functionality consists of a highly branched 3,7,11,15-tetramethylhexadecyl group. This moiety is well-known from extremophiles or archaea to form stable and fluid membranes in harsh environments (*15*).

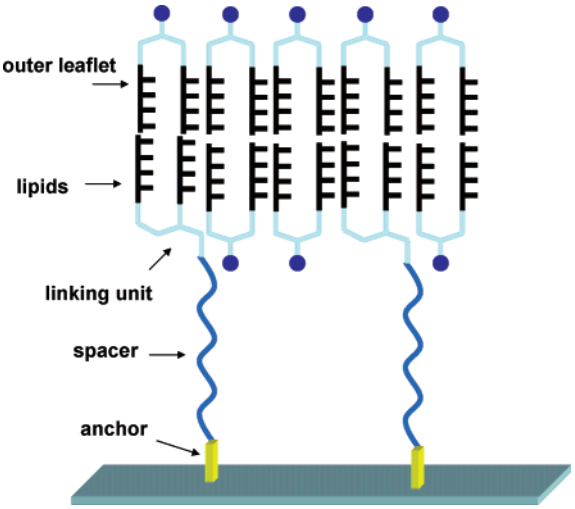

Figure 1. Schematic tBLM architecture. The proximal leaflet is formed by self-assembly of the anchor lipids, while the distal layer is completed by vesicle fusion. Defects and voids in the proximal leaflet might be filled during the fusion process.

The hydrocarbon tail of the lipid is coupled to a polar headgroup. Since this linkage is in a dynamic interfacial region in an aqueous suspension, even small changes of this moiety can significantly modulate the aggregation properties. Among various linkage functionalities such as oxyethylenes (*9*, *16*), sulfides (*13*), and 2-hydroxymethylglycerol (*17*), the glycerol linker is used most often (*12*). In natural lipids, this stable moiety occurs in a defined *sn*-2 stereochemistry configuration.

The spacer unit separates the lipid layer from the solid substrate while serving as a polymer cushion that compensates for surface roughness effects, protects embedded biomaterial from touching the surface (and thus losing their functionality

Published on Web 04/13/2006

due to denaturation), and provides an ion reservoir underneath the membrane. Various materials such as oligosaccharides (*18*), polymers based on acrylamide and its derivatives (*19*), ethylene glycol esters/amides of succinic acid/succinamide (*20*), and poly(ethylene glycol) (*21*, *22*) have been proposed. These moieties form a hydrophilic layer between the lipid membrane and the substrate surface. This reservoir shows a gellike structure that is permeable to ionic species (*17*). The characteristics of this reservoir have an important effect on the electrical properties of the tBLM (*23*).

Finally, surface immobilization of the lipid-spacer molecule is achieved by an anchor group, which forms, by matching chemistry, a covalent bond with the surface. Several anchor groups have been tested on gold surfaces, most of them are based on gold−sulfur interactions (*4*, *14*, *24*). Gold substrates are interesting because they can be used as an electrode for electrical read-outs as well as for many other surface analytical techniques. However, most devices in the microelectronics and semiconductor field are silicon-based. These substrates, as well as the large number of silica-like substrates (glass, metallic oxides, etc.) are easily accessible, if not commercially available. They can also be integrated into standard microelectronics fabrications processes.

Tamm et al. presented tBLMs on silicon oxide substrates using PEG−phospholipid conjugates with a triethoxisilane anchor group. The polymer-supported membrane (the PEG cushion has 77 repeat units) was used for detailed investigation on the lateral diffusion of proteins and lipids (*25*) and to study the vertical distances of the bilayer from the substrate (*26*). Investigations were carried out by using fluorescence recovery after photobleaching measurements and fluorescence interference−contrast microscopy. Similarly, Rossi et al. have presented a model membrane system with large polymeric spacer groups that can be anchored on a amino-silane treated glass substrate (*27*). Lateral mobility could be observed using fluorescence techniques. However, in both cases, no electrochemical measurements have been reported.

We present here a generic approach, a molecular toolkit that allows for the systematic modification of certain key components of tethered membrane architectures. Starting from a universal precursor molecule, different anchor groups that are suitable either for noble metal surfaces (e.g., Au, Ag, Pt, Cu, Fe, Ni, or Hg) or for oxide surfaces (e.g., SiO_x) can be added. The lipid headgroup consists of a diphytanyglycerol unit, while a short oligo(ethylene glycol) forms the spacer. The length of the spacer unit can easily be modified. These anchor lipids form stable bilayer membranes with high electrical sealing properties. The tBLMs can serve as a matrix for the functional incorporation of membrane proteins.

EXPERIMENTAL PROCEDURES

Electrochemical Impedance Spectroscopy (EIS). Measurements were conducted using an IM6 spectrometer (Zahner Electrics) or an AUTOLAB PGSTAT 12 impedance spectrometer. Three electrode measurements were performed in Teflon cells with the substrates as the working electrode, a coiled platinum wire as the counter electrode, and DRIREF-2 reference electrodes (World Precision Instruments). Spectra were recorded for frequencies between 2 mHz and 1 MHz at a controlled potential with an AC modulation amplitude of 10 mV. Raw data were analyzed using the ZVIEW software package (version 2.70, Scribner Associates). The Teflon cells have a buffer volume of 0.5 mL for the silicon oxide substrates and 1 mL for the gold substrates and an electrochemically active area on the substrates of 0.385 and 0.2 cm^2, respectively. The data obtained is fit using an equivalent circuit of capacitors and resistances. The final values are normalized to the electrode surface area.

Contact Angle Measurements. Contact angles were determined using a DSA 10 contact angle measuring system (Krüss, Germany). Software (Drop Shape Analysis, version 1.8) was employed to analyze the drops created by the sessile-drop method.

Ellipsometry. Measurements were carried out using an EP^3 ellipsometer (Nanofilm, Göttingen, Germany) with a 532 nm laser source. The angle of incidence was 70° for measurements in air and 60° for measurements in a fluid cell. Thickness values were fit with the EP^3View v2.01 software using a layer model with the following parameters: $n = 4.17$ and $k = 0.049$ for Si, $n = 1.4605$ and $k = 0$ for SiO_x, $n = 1.50$ and $k = 0$ for the monolayers, and $n = 1.45$ and $k = 0$ for the bilayer.

Surface Plasmon Resonance Spectroscopy (SPR). A setup in Kretschmann configuration, built in-house, with a 632 nm He/Ne laser was used. In the scan mode, reflectivity changes are monitored as a function of the angle of incidence of the incoming laser beam. In the kinetic mode, reflectivity changes occurring at a fixed angle are monitored as a function of time.

SPR spectra were analyzed using a three layer model including the prism, gold, and the thiolipid monolayer. After vesicle fusion, a fourth layer corresponding to the outer leaflet of the bilayer was added. The refractive indices for the mono- and bilayer were $n = 1.489$ and $n = 1.423$, respectively.

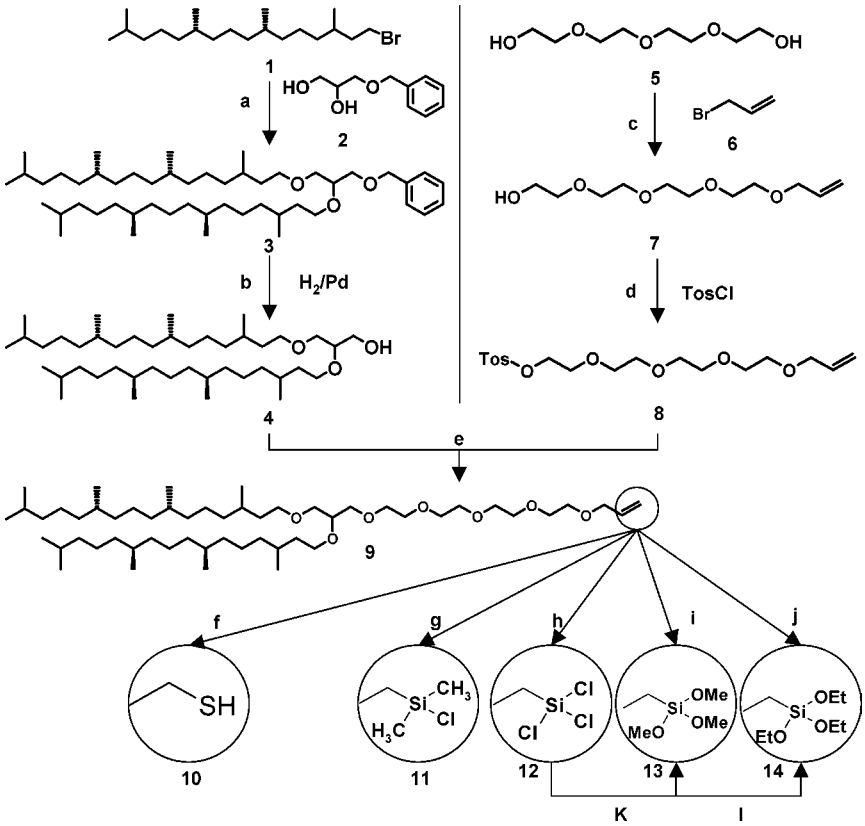
Analytical Instrumentation. ^1H and ^{13}C NMR spectra were recorded on a Brucker DXP 250 MHz NMR spectrometer. If not otherwise stated, NMR spectra were recorded at ambient conditions at 250 and 62.5 MHz for ^1H and ^{13}C NMR, respectively. The spectra were calibrated to the solvent signal as follows: 7.24 (^1H) and 77.0 (^{13}C) ppm for $CDCl_3$ and 5.23 (^1H) and 54.0 (^{13}C) ppm for CD_2Cl_2. Mass spectroscopy was performed using a VG ZAB2-SE-FPD Spectrofield spectrometer. IR spectra were measured on a Nicolet 730 FTIR spectrometer using an endurance diamant-ATR.

Chemicals. (±)-3-Benzyloxy-1,2-propanediol, tetra(ethylene glycol), and allylbromide (all purchased from Fluka) were dried over an A3 molecular sieve. Triethylamine (TEA, Acros) and tetrahydrofuran (THF, Fisher) were dried over CaH_2 and potassium−benzophenone complex, respectively. Trichlorosilane (Acros), triethoxysilane (Lancaster), thioacetic acid (Acros), and chlorodimethylsilane (Lancaster) were distilled prior to use. *p*-Toluenesulfonyl chloride (TosCl, Acros), platinum on activated charcoal (Pt/C, Fluka), hexachloroplatinic acid (H_2PtCl_6, Fluka), platinum-divinyltetramethyldisiloxane complex as 2.1−2.4% solution in hexane (ABCR), 2,2'-azobis(2-methylpropionitrile) (AIBN, Acros), hexamethyldisilazane (Fluka), and 1,2-di-*O*-phytanoyl-*sn*-glycero-3-phosphocholine (DphyPC) (Avanti Polar Lipids) were used as received.

Synthesis. We will describe the synthetic steps depicted in Scheme 1, especially the final modifications of the anchor groups. Most reactions were carried out until complete consumption of the starting material as monitored by thin-layer chromatography (TLC) using a THF/petrolether (1:4) elution system.

Precursor Synthesis, ***9.*** The synthesis of the precursor molecule has been previously described (28). The synthetic pathway is depicted in Scheme 1. The product can be obtained at high purity. ^1H NMR ($CDCl_3$) δ_H, ppm: 5.9 (m, $-CH{=}CH_2$), 5.3−5.1 (m, $-CH{=}CH_2$), 4.0 (d, $-OCH_2CH{=}CH_2$), 3.6−3.4 (overlapping signals $CH_{(2)}O-$), 1.5 (m, C*H*), 1.2 (overlapping signals $-CH_2-$), 0.8 (t, CH_3). ^{13}C NMR (CD_2Cl_2) δ_C, ppm: 135.5, 116.8, 78.4, 72.4, 71.7, 71.2, 70.9, 70.2, 70.0, 69.0, 39.8, 37.8, 37.2, 33.2 30.3, 28.4, 25.2, 24.8, 22.9, 22.8, 19.9. IR (ATR): 2952, 2925, 2868, 1462, 1377, 1300, 1250, 1107, 1043, 995, 992, 879, 735 cm^{-1}. Field desorption mass spectrum (FD-MS) (*m*/*z*) 869.8 (M^+), calcd ($C_{54}H_{108}O_7$)

Scheme 1. Reaction Pathway for the Synthesis of Lipids with Different Anchor Groups via a Unique Precursor Molecule (9)



= 869.43; 1737.9 ($M + M^+$), calcd ($2\times C_{54}H_{108}O_7$) = 1738.86; 2607.7 ($2M + M^+$), calcd ($3\times C_{54}H_{108}O_7$) = 2608.29 (see Figure 2).

*Synthesis of the Thiol Anchored Lipid **10** (Step f).* The conversion of a double bond to a mercapto group is a two step process: (a) radical addition of thioacetic acid to the double bond and (b) hydrolysis of the thioester to a thiol (*29*, *30*). (a) A mixture of **9** (1.85 g), thioacetic acid (1.97 g), and azobisisobutyronitrile (AIBN) (7 mg) in toluene (6 mL) was degassed and heated to 70 °C for 24 h. The reaction was monitored by TLC (R_f of the product = 0.35) of aliquots taken from the reaction mixture. After completion of the reaction, toluene and the remaining thioacetic acid were evaporated, and the residue was purified by flash chromatography (FC) (eluent THF/petroleum ether = 1:6). Yield: 1.53 g (76%). ^{1}H NMR ($CDCl_3$) δ_H, ppm: 3.6−3.4 (overlapping signals C$H_{(2)}$O−), 2.9 (t, −CH_2S−), 2.3 (s, −SC(O)CH_3), 1.8 (p, −OCH$_2$CH_2CH$_2$S−), 1.5 (m, CH), 1.2 (overlapping signals −CH_2−), 0.8 (t, −CH_3). ^{13}C NMR ($CDCl_3$) δ_C, ppm: 77.9, 71.5, 70.9, 70.6, 70.2, 70.0, 69.6, 68.9, 39.4, 37.4, 36.7, 32.8, 30.6, 29.9, 29.8, 29.6, 28.0, 26.0, 24.8, 24.5, 24.4, 22.7, 22.6, 19.7. FD-MS (*m*/*z*): 945.4 (M^+), calcd ($C_{56}H_{112}O_8S$) = 945.58.

(b) The product of step a (1.53 g) was treated with NaOH (1 M in water, 6.3 mL) in THF (40 mL) for 24 h at 50 °C. After completion as seen by TLC (R_f(**10**) = 0.53), the THF was evaporated, and the mixture was extracted with methylene chloride. The extracts collected were dried over $CaCl_2$, the methylene chloride was evaporated, and the residue was purified by FC (THF/petroleum ether = 1:4). Yield: 0.98 g (70%). ^{1}H NMR ($CDCl_3$) δ_H, ppm: 3.6−3.4 (overlapping signals −C$H_{(2)}$O−), 2.7 (t, −CH_2S−), 1.9 (p, −OCH$_2$CH_2CH$_2$S−), 1.5 (m, −CH), 1.2 (overlapping signals −CH_2−), 0.8 (t, −CH_3). ^{13}C NMR (CD_2Cl_2) δ_C, ppm: 78.4, 71.7, 71.2, 70.9, 70.6, 70.2, 69.6, 69.0, 68.1, 39.7, 37.8, 37.1, 35.8, 33.2, 30.5, 30.3, 29.7, 28.4, 26.0, 25.1, 24.8, 24.7, 22.8, 22.7, 19.8. IR (ATR): br 2952, 2925, 2865, s 1462, s 1377, s 1292, s 1248, s 1111, s 1070, s 916, s 860, s 737 cm^{-1}. FD-MS (*m*/*z*): 1804.5 ($M + M^+$)− dimerization due to oxidation, calcd for **10** ($C_{54}H_{110}O_7S$) = 903.54; calcd for dimer ($C_{108}H_{218}O_{14}S_2$) = 1805.06.

*Synthesis of **11** and **12** (Steps g and h) (31).* A reaction mixture of freshly distilled chlorosilane (see table below), Pt-catalyst, and **9** was refluxed under inert atmosphere until complete consumption of **9** (R_f(**9**) = 0.58, R_f(**11**, **12**) = 0.00). The mixture was filtered (0.2 μm PTFE) in a glovebox, and the residual chlorosilane was evaporated.

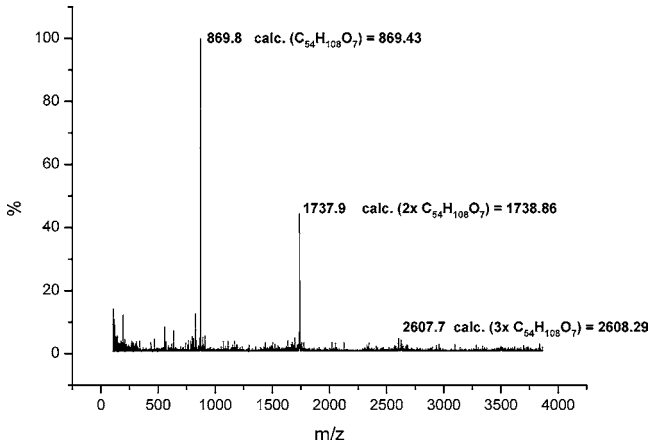


Figure 2. FD-MS spectrum of **9**. The formation of doublets and triplets occur during analysis with the spectrometer.

no.	chlorosilane (mL)	Pt catalyst (mg)	**9** (g)	time (h)	yield (g, %)
11	chlorodimethylsilane (10)	H_2PtCl_6 (100)	1.1	20	1.0, 82
12	trichlorosilane (10)	Pt/C (2%Pt) (100)	2.1	48	2.3, 95

*Characterization of **11**.* ^{1}H NMR (CD_2Cl_2) δ_H, ppm: 3.6−3.4 (overlapping signals −C$H_{(2)}$O−), 1.5 (m, −CH), 1.4−1.0

(overlapping signals $-CH_2-$), 0.8 (t, $-CH_3$), 0.4 (s, Si$-CH_3$). ^{13}C NMR (CD_2Cl_2) δ_C, ppm: 78.5, 73.8, 71.9, 71.4, 71.1, 70.7, 70.4, 69.2, 40.0, 38.0, 37.9, 37.4, 37.3, 33.4, 30.5, 28.6, 25.4, 25.0, 23.9, 23.0, 20.0, 15.8, 1.9. IR (ATR): br 2952, 2923, 2868, s 1462, s 1377, s 1299, s 1253, s 1108, s 941, s 845, s 845, s 735 cm^{-1}. FD-MS (*m*/*z*): 945.9 (M^+), calcd ($C_{56}H_{116}O_8Si$) = 945.63; 1874.2 ($M + M^+ - HCl$)—condensation product due to hydrolysis of **11**, calcd ($C_{112}H_{230}O_{15}Si_2$) = 1873.24.

Characterization of ***12.*** ^{1}H NMR (CD_2Cl_2) δ_H, ppm: 3.6−3.4 (overlapping signals $-CH_{(2)}O-$), 1.8 (m, $-SiCH_2CH_2$) 1.5 (m, $-CH$), 1.2 (overlapping signals $-CH_2$), 0.8 (t, $-CH_3$). ^{13}C NMR (CD_2Cl_2) δ_C, ppm: 78.5, 72.0, 71.9, 71.4, 71.1, 70.8, 70.6, 70.4, 69.2, 39.9, 38.1, 38.0, 37.9, 37.4, 37.3, 33.4, 30.5, 28.6, 25.4, 25.0, 23.3, 23.0, 21.5, 20.1, 20.0. IR (ATR): br 2952, 2924, 2867, s 1462, s 1377, s 1299, s 1250, s 1109, s 939, s 839, s 760, s 733, s 696, s588 cm^{-1}. FD-MS: characterization was not possible due to condensation reaction during the analysis.

Synthesis of ***13*** *and* ***14*** *(Steps i and j) (32).* Pt-complex (2.1−2.4% Pt), acetic acid, and **9** were added to freshly distilled trialkyloxysilane and refluxed under inert atmosphere (see table below). The reaction was monitored by TLC (R_f(**13**) = 0.48, R_f(**14**) = 0.53) of aliquots taken from the reaction mixture. After complete consumption of **9**, the mixture was filtered (0.2 μm PTFE) in a glovebox, and the remaining alkyloxysilane was evaporated.

no.	alkyloxysilane (mL)	Pt complex (μL)	acetic acid (μL)	**9** (g)	time (h)	yield (g, %)
13	trimethoxysilane (5)	1	3	0.52	48	0.55, 92
14	triethoxysilane (10)	1	3	1.10	72	0.94, 72

Alternative Synthesis of ***13*** *and* ***14*** *(Steps k and l) (33).* Compound **12** diluted in toluene (2 mL, see table below) was added dropwise to an ice-cold mixture of alcohol, triethylamine, and toluene (3 mL) under inert atmosphere, and the reaction was left at RT overnight. The mixture was filtered (0.2 μm PTFE) in a glovebox, and the solvent was evaporated.

no.	**12** (g)	alcohol (μL)	triethylamine (μL)	yield (g, %)
13	0.24	methanol (57)	128	0.23, 98
14	0.20	ethanol (66)	106	0.18, 96

Both synthetic routes for **13** (i and k) and **14** (l and j) led to products with identical characteristics.

Characterization of ***13.*** ^{1}H NMR δ_H, ppm: 3.6−3.4 (overlapping signals $-CH_{(2)}O$), 3.5 (s, $-SiOCH_3$), 1.5 (m, $-CH$), 1.2 (overlapping signals $-CH_2$), 0.8 (t, $-CH_3$), 0.6 (t, $-SiCH_2$). ^{13}C NMR δ_C, ppm: 77.9, 73.4, 71.5, 70.8, 70.6, 70.0, 68.9, 50.5, 39.4, 37.4, 36.7, 32.8, 29.9, 28.0, 24.8, 24.5, 24.4, 22.7, 22.6, 19.7, 5.2. IR (ATR): br 2950, 2925, 2867, s 1461, s 1377, s 1301, s 1248, s 1194, s 1087, s 945, s 885, s 835, s 737 cm^{-1}. FD-MS (*m*/*z*): 1011.8 ($M + Na^+$), calcd ($C_{57}H_{118}O_{10}Si$) = 991.66.

Characterization of ***14.*** ^{1}H NMR δ_H, ppm: 3.8 (q, $-SiOCH_2$-CH_3), 3.6−3.4 (overlapping signals $-CH_{(2)}O$), 1.5 (m, $-CH$), 1.2 (overlapping signals $-CH_2$), 0.8 (t, $-CH_3$), 0.6 (t, $-SiCH_2$). ^{13}C NMR δ_C, ppm: 77.9, 73.6, 71.4, 70.8, 70.6, 70.0, 68.9, 58.3, 39.3, 37.4, 36.7, 32.8, 29.9, 28.0, 24.8, 24.5, 22.9, 22.7, 22.6, 19.7, 18.3, 6.4. IR (ATR): br 2952, 2925, 2868, s 1462, s 1377, s 1365, s 1296, s 1450, s 1105, s 1061, s 955, s 795, s 775 cm^{-1}. FD-MS (*m*/*z*): 1056.2 ($M + Na^+$), calcd ($C_{60}H_{124}O_{10}$-Si) = 1033.74.

tBLM Assembly. Monolayers of the different compounds were obtained via self-assembly. The thiol-based tBLMs were prepared on template stripped gold slides as described previously (*24*). In short, 50 nm of gold is evaporated on a clean silicon wafer and glued to a clean glass slide using an epoxy glue. After curing, the silicon is stripped away, and the clean gold substrate is immersed for 24 h into an ethanolic self-assembly solution containing **10** (0.2 mg/mL). The substrates are thoroughly cleaned with ethanol and dried in a nitrogen stream.

The chlorosilane-based (**11** and **12**) tBLMs were prepared in a self-assembly process on highly boron p-doped (0.01 Ω cm) silicon single crystal (100) wafers as described by Purrucker et al. (*34*). In short, **11** and **12** were assembled by immersion of the silicon wafer in a solution of the respective lipid in toluene (typically 2−40 mM) for 24 h. Et_3N was used as a promoter and acid scavenger. For **11**, dried substrates were used. The surface reaction of **12** requires a small amount of water at the substrate (*35*). The electrical backside contact of the wafer is made by a 250 nm thick aluminum electrode.

First attempts using self-assembly of the alkoxysilanes (**13** and **14**) did not result in homogeneous mono- or bilayers. Further investigations will be made using Langmuir−Blodgett−Kuhn techniques.

RESULTS AND DISCUSSION

Syntheses. From a chemical point of view, our approach consists of the synthesis of a "universal" lipid precursor. It possesses all advantages of diphytanyl glycerol, that is, it forms fluid membranes under ambient conditions. The tethering spacer consists of tetra(ethylene glycol), because this moiety prevents the nonspecific adsorption of proteins to surfaces (*36*−*38*), does not absorb to lipid bilayers (*39*), and interacts only minimally with quartz and glass surfaces (*40*). A terminal C═C double bound can be transformed in a few steps into thiol, chlorosilane, and alkyloxysilane anchors (see Scheme 1).

We have previously published briefly the synthesis of the lipid precursor **9** as well as the synthesis of the lipids with chlorosilane anchors (*28*). The formation of tBLMs on silicon substrates and the functional incorporation of two different proteins have been reported. In the present study, we extend the chemical modification of the lipid anchor to thiols and alkoxysilanes for tBLM architectures on gold as well as on silicon substrates. Furthermore, the general synthetic strategy is discussed in more detail.

Lipid Precursor, ***9.*** The preparation of the lipid precursor **9** was achieved by the parallel synthesis of the hydrophobic lipid part (diphytanyl glycerol, **4**) and the tetra(ethylene glycol) tethering unit with a double bond **8**, followed by a Williamson reaction between both (Scheme 1, step e). The structure of the lipid precursor **9** could be shown by ^{1}H NMR and ^{13}C NMR; the purity is characterized by FD-MS. The related signal integrals at 5.9 and 5.3 ppm in ^{1}H NMR and 135.5 and 116.8 ppm in ^{13}C NMR show the double bond functional group. This will be important for the next steps, since the modification of the double bond functionality leads to the different anchor groups. A sequence of signals related to single, double, and triple *m*/*z* values of 870.2 (the calculated molecular weight of **9** is 869.43) are observed by FD-MS, as shown in Figure 2. This sequence may be due to the high affinity between the phytanyl chains. These physical interactions seem to be the main reason for the stability of membranes containing this residue. A similar sequence of signals was observed in the FD mass spectra of **1**, **3**, and **4** where phytanyl units were present. The formation of dimeric and trimeric macromolecules in terms of chemical interactions during the synthesis of the lipid precursor can be excluded because of the absence of any additional signals in ^{1}H NMR and ^{13}C NMR. However, the chemical interactions during the FD-MS measurements might be due to the high reactivity of the ionized lipid molecules that can undergo a number of chemical interactions (*41*). Thus, the purity of the lipid precursor **9** was determined to be higher than 98%.

*Lipids with −SH Anchor, **10**.* The transformation of a double bond into a thiol via thioacetals is a well-known reaction (*30*, *42*). The reaction applied to our precursor lipid **9** leads to lipids with thiol anchors that can be used for tBLMs on gold surfaces. The complete conversion of the double bond to the thioacetal in the first step is shown indirectly by the disappearance of the ^{1}H (5.9 and 5.2 ppm) and ^{13}C NMR (135.5 and 116.8 ppm) signals corresponding to the double bond functionality. Additionally, signals at 2.3 in ^{1}H NMR and 28.0 ppm in ^{13}C NMR appeared. These signals are related to the methyl protons of the thioacetal groups. After FC isolation of **10**, FD-MS was used to determine the structure. A single peak with $m/z = 1804.5$ corresponds to a dimer of **10** (calculated molecular weight of 903.54), which is formed through oxidation of **10**. The mechanism for the oxidation of thiols is a well-established process (*42*) resulting in −S−S− bridge formation and dimerization. The dimers are surface active and efficiently self-assemble on gold surfaces.

*Lipids with $-Si(CH_3)_2Cl$ or $-SiCl_3$ Anchors **11** and **12**.* Herein, we discuss the preparation of both lipids in more detail to understand their structure and chemical behavior and compare them with the other lipids (**10**, **13**, and **14**). Both lipids were prepared similarly using a hydrosilylation reaction in the presence of the corresponding hydrosilane (dimethylchlorosilane for **11** and trichlorosilane for **12**) and a platinum-based catalyst (see Scheme 1, steps g and h). The hydrosilane is in large excess of the precursor lipid **9** and also serves as reaction medium. The use of a heterogenic catalyst, such as platinum over charcoal (Pt/C), requires longer reaction times (48 h) and larger amounts of the catalyst than using homogenic catalysts, such as hexachloroplatinic acid and platinum-divinyltetramethyldisiloxane complex. However, the heterogenic catalyst can easily be separated from the reaction mixture either by filtration or by centrifugation. It should be pointed out that due to extremely high reactivity of chlorosilanes with protic substances (water, acids, alcohols, amines, etc.), the presence of chlorosilane groups drastically reduces the number of suitable purification and analytical methods (e.g., flash chromatography). Thus, most of the purification steps, for example, filtration through 0.2 μm PTFE filter to remove the solid residues such as catalyst or three-dimensional networks obtained by hydrolization of trichlorosilanes, were carried out in a glovebox. Excess of chlorosilanes, their dimers, and their trimers and of HCl (products of hydrolization of the chlorosilanes) could be removed in a vacuum (1×10^{-3} mbar). However, this does not purify the products (**11** and **12**) from unreacted **9.** Therefore, the reactions are stopped only after complete consumption of the starting material. The reaction progress can be monitored either by TLC, FD-MS, or ^{1}H NMR. The final products may still contain dimers, trimers, and oligomers of **11** and **12**, as well as the main side products for both reactions, which is the lipid precursor with hydrogenated double bonds (isolated by FC). Because they will not interact with the substrate, the presence of saturated lipid precursors in the final product will not significantly influence the self-assembly process. Dimers, trimers, or 2D-oligomers of **12** that possess available chlorosilane anchors can effectively self-assemble on a substrate.

The relatively fast hydrolysis of **12** to 1D-, 2D-, and 3D-oligomers causes the main difficulty during the analysis of the compound. It was impossible to detect any structure related fragments by FD-MS. Therefore, the disappearance of the proton signals corresponding to the double bond functionality of **9** by ^{1}H NMR and the drop of the retention factor (R_f) from 0.58 for **9** to 0.00 for **12** indirectly prove the termination of the reaction. In the case of **11**, FD-MS was more informative; dimers obtained by condensation reaction between hydrolyzed and nonhydrolyzed **11** were detected. The presence of signals at 0.39 ppm corresponding to methylsilane protons in the ^{1}H NMR were direct proof that the chlorodimethylsilane functionality was gained. Additionally, an indirect proof of the presence of chlorosilane anchors is accomplished by the formation of chemically adsorbed monolayers on silicon oxide surfaces, as well as by further modification of the trichlorosilane groups to alkoxysilanes.

Table 1. Surface Properties (Contact Angles (CA, deg) and Layer Thickness (nm)) of the Different Monolayers[a]

	static CA	advancing CA	receding CA	modeled thickness	thickness (ellipsometry)	thickness (SPR)
10	104 ± 3	105 ± 2	98 ± 3	4.5	*b*	3.3 ± 0.2
11	72 ± 4	86 ± 4	59 ± 3	4.6	1.3 ± 0.5	*b*
12	87 ± 4	91 ± 5	66 ± 4	4.6	1.8 ± 0.6	*b*

[a] An approximation of fully stretched molecules is used to model the system. [b] Not applicable.

*Lipid with $-Si(OCH_3)_3$ or $-Si(OC_2H_5)_3$ Anchors, **13** and **14**.* The lipids **13** and **14** were obtained by applying either hydrosilylation of **9** with trimethoxysilane or triethoxysilane (Scheme 1, steps i and j (*32*)) or substitution of chlorine of the trichlorosilanated lipid **12** with methanol or ethanol (Scheme 1, steps k and l (*33*)). Since hydrosilylation occurs similarly in the cases of chlorosilanes and alkoxysilanes, the alternative method, that is, substitution of trichlorosilane anchors of **12** with alcohols, is much simpler and faster once **12** is obtained. Moreover, the method indirectly proves the quantitative content of trichlorosilyl anchors in **12**. Similarly to **11** and **12**, the hydrolization of **13** and **14** in ambient conditions renders the quantitative analysis of the structures difficult, especially in the case of **13**, which hydrolyzes faster than **14** (*43*). However, FD-MS, ^{1}H NMR, and ^{13}C NMR directly prove the presence of the methoxy- (**13**) and ethoxysilane (**14**) anchors.

Indeed, both chlorosilanes (**11** and **12**) and alkoxysilanes (**13** and **14**) were prepared as lipids with appropriate anchors for silicon oxide surfaces. However, the different anchors differ in their hydrolyzation rates and, therefore, require individual immobilization techniques. Chlorosilanated lipids should be suitable for less homogeneous metal oxides (e.g., poorly oxidized metal) or less reactive (e.g., chemically modified) surfaces due to their high reactivity but poor control over the hydrolization process. On the other hand, alkoxysilanes hydrolyze more slowly, allowing a better control of the immobilization process. Additionally, the aggressive chlorosilanes can cause problems when adsorbed on surfaces obtained by layer deposition (e.g., plasma polymerized silicones or indium tin oxide (ITO) deposited on silicon wafers). Due to their high affinity for silicon oxide, these surface layers may get peeled off the substrate.

We obtained self-assembled monolayers using the chlorosilanated lipids **11** and **12**. Further experiments with **13** and **14** will be performed using Langmuir−Blodgett−Kuhn techniques and published separately.

tBLM Formation and Characterization. The hydrophobic character of the different self-assembled monolayers was investigated using contact angle measurements. The results in Table 1 show that all samples possess relatively high contact angles. In our experiments, this is a prerequisite to allow for successful fusion of vesicles.

Compound **10** forms a well-ordered monolayer, as can be seen by the small difference in advancing and receding contact angles. The further assembly and membrane formation of **10** is investigated by SPR. The formation of the outer leaflet of the lipid membrane by fusion with vesicles (50 nm by extrusion) results in an angular shift of the plasmon resonance. The kinetic scan recorded at 57.7° (Figure 3) shows the exponential character of the process, which reaches equilibrium after about 160 min. After 3 h, the vesicle fusion is completed at the final

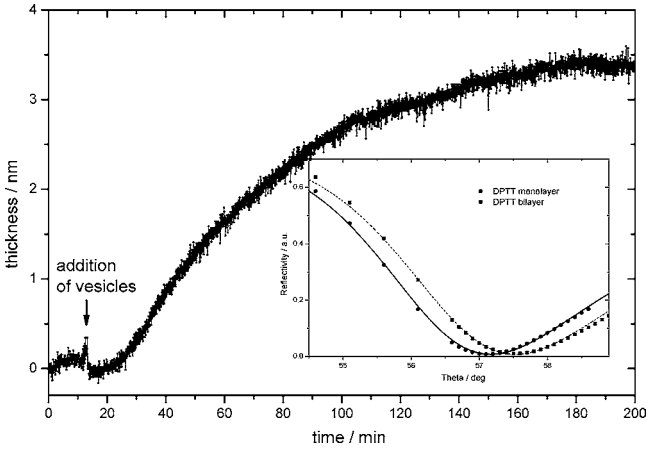

Figure 3. SPR scans for vesicle fusion experiments on a monolayer of **10**. The curve shows the evolution of the bilayer thickness with time. The inset shows the corresponding angular shift in the SPR curve before and after the addition of the vesicles.

Table 2. Electrical Properties of the Different tBLMs[a]

	R, MΩ cm^2	*C*, μF cm^{-2}
10	3.6 ± 1.1	1.1 ± 0.03
11	1.5 ± 1.1	0.88 ± 0.04
12	0.5 ± 0.5	0.78 ± 0.03

[a] The EIS data has been fit by an equivalent circuit. The values for the resistance and capacitance corresponding to the bilayer are listed.

thickness of the bilayer (6.7 nm). The inset in Figure 3 shows the angular scans before and after vesicle fusion. The fit parameters are summarized in Table 1. The optical properties of the bilayers composed of the lipids **11** and **12** were characterized using ellipsometry.

As shown in Table 1, the experimental thickness values of the different monolayers (as measured from SPR or ellipsometry) and the theoretical thickness differ significantly. The latter are obtained for a model of a densely packed layer of fully stretched molecules. This lack of agreement between measured and calculated thickness might be due to an incomplete coverage of the surface. This assumption is supported by a hysteresis in advancing and receding contact angles, revealing a rather inhomogeneous surface in the case of the silane-based monolayers. Furthermore, the hydrophobic tails have a tilted conformation and the ethylene glycol units adopt a helical structure, as seen by IR spectroscopy (Lipkowski, unpublished results).

By fusion of small unilamellar vesicles with monolayers of **10**, **11**, and **12**, we were able to create bilayers and investigate their electrical properties using electrochemical impedance spectroscopy. The spectra were analyzed using a passive equivalent model circuit of resistors and capacitances. For membranes based on **11** and **12**, a model with two RC elements in series with a feed resistance was used (R(RC)(RC)). Whereas for the thiol **10**, one RC element in series with a capacitor and a feed resistance was sufficient (R(RC)C). The values we obtained were normalized to the electrode surface area and are listed in Table 2.

The lower the capacitance is, the higher the charge separation. Here, the silane-based tBLMs show better electrical properties. However, the resistance values show an opposite trend, as the thiol-based tBLM shows the highest membrane resistance. The dense packing of the lipids is in agreement with the results from the contact angle measurements.

Due to the high electrical resistances our membranes allow minimal leakage across the membrane. Therefore, we were able to show the functional incorporation of ion carriers and ion channels (*37*).

CONCLUSION

We developed a new synthetic strategy for the systematic study of tethered bilayer lipid membranes. A toolkit-like approach using a precursor strategy allows for the synthesis of anchor lipids with various end groups. We showed the synthesis of a thiol anchor and four different silane anchors and their ability to form monolayers on gold or silicon oxide surfaces. These monolayers can be used to form highly insulating bilayers offering a synthetic platform for the incorporation of membrane proteins. This approach can be used as a central element in biosensing applications when the coupling of biological elements to electronics is needed. Furthermore, the synthetic strategy allows adaptation of the lipids to various kinds of surface architectures by matching anchor groups. Similarly, spacer units of various types or of different lengths can be easily included in the synthesis to facilitate protein incorporation.

This generic approach should allow for the design of tBLMs individually adapted to various substrates and biological compounds, for example, ion channels, receptors, and membrane proteins.

Bioconjugatable Porphyrins Bearing a Compact Swallowtail Motif for Water Solubility

K. Eszter Borbas,[‡] Pawel Mroz,[§,†] Michael R. Hamblin,[§,†,⊥] and Jonathan S. Lindsey*[,‡]

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695-8204, Wellman Center for Photomedicine, Massachusetts General Hospital, Boston, Massachusetts 02114-2605, Department of Dermatology, Harvard Medical School, Boston, Massachusetts 02115-6092, and Harvard-MIT Division of Health Sciences and Technology, Cambridge, Massachusetts 02142-1323. Received November 22, 2005; Revised Manuscript Received March 18, 2006

A broad range of applications requires access to water-soluble, bioconjugatable porphyrins. Branched alkyl groups attached at the branching site to the porphyrin meso position are known to impart high organic solubility. Such "swallowtail" motifs bearing a polar group (hydroxy, dihydroxyphosphoryl, dihydroxyphosphoryloxy) at the terminus of each branch have now been incorporated at a meso site in *trans*-AB-porphyrins. The incorporation of the swallowtail motif relies on rational synthetic methods whereby a 1,9-bis(*N*-propylimino)dipyrromethane (bearing a bioconjugatable tether at the 5-position) is condensed with a dipyrromethane (bearing a protected 1,5-dihydroxypent-3-yl unit at the 5-position). The two hydroxy groups in the swallowtail motif of each of the resulting zinc porphyrins can be transformed to the corresponding diphosphate or diphosphonate product. A 4-(carboxymethyloxy)phenyl group provides the bioconjugatable tether. The six such porphyrins reported here are highly water-soluble (≥20 mM at room temperature in water at pH 7) as determined by visual inspection, UV−vis absorption spectroscopy, or ^{1}H NMR spectroscopy. Covalent attachment was carried out in aqueous solution with the unprotected porphyrin diphosphonate and a monoclonal antibody against the T-cell receptor CD3ϵ. The resulting conjugate performed comparably to a commercially available fluorescein isothiocyanate-labeled antibody with Jurkat cells in flow cytometry and fluorescence microscopy assays. Taken together, this work enables preparation of useful quantities of water-soluble, bioconjugatable porphyrins in a compact architecture for applications in the life sciences.

INTRODUCTION

A large and growing number of applications in the life sciences require porphyrinic macrocycles that are water-soluble and are suited for conjugation in a variety of formats. The applications encompass flow cytometry, cellular and whole-organism imaging, sensing, photodynamic therapy, biomimetic catalysis, and radical scavenging. The success of these applications relies on a host of factors, including (1) significant solubility in aqueous saline solutions, thereby avoiding intermolecular aggregation (and excited-state quenching), (2) minimal nonspecific binding to cellular components, (3) incorporation of a single reactive group for conjugation, thereby avoiding cross-linking and the formation of product mixtures, and (4) robust synthesis affording ample quantities for experimentation.

The large hydrophobic face of a porphyrinic macrocycle presents a challenge to water solubilization. Traditional approaches to achieve water solubility of porphyrins have largely relied on uroporphyrin (*1*−*5*), *meso*-tetrakis[4-(*N*-methyl)-pyridinium]porphyrin (*6*), and *meso*-tetrakis(4-sulfophenyl)-porphyrin (*6*) (Chart 1). More recent approaches have entailed attachment of the following motifs to the porphyrin via a *meso*-aryl group: oligo(ethylene glycol) (OEG) chains (*7*, *8*), OEG dendrimers (*9*), glycosyl units (*10*), alkyl polyamine chains (*11*), branched polycarboxy units (*12*), or malonate groups (*13*). Solubilizing groups that do not incorporate an aryl group include 1,2-dihydroxyethyl at the porphyrin meso position (*14*) and a variety of substituents attached to the β-position of a sapphyrin (*15*). A lengthy review of water-soluble porphyrins has been prepared by Hambright (*6*). Each solubilizing group has merit; however, many are not compatible with bioconjugation reactions, and others are so large (mass >10-times that of the porphyrin) as to limit the scope of desired experiments.

The presence of a bioconjugatable group is essential for attachment of water-soluble porphyrins to substances ranging from nanoparticles to biological targeting agents. Indeed, porphyrinic molecules have been attached to diverse molecular entities such as peptides (*16*−*19*), estrogen (*20*), acridine (*21*), bovine serum albumin (*22*), antibodies (*23*−*27*), transferrin (*28*), epidermal growth factor (*29*, *30*), low-density lipoprotein (*31*), nucleic acids (*32*), and polymers such as polylysine (*33*) or poly(vinyl alcohol) (*29*, *30*). In some cases, the bioconjugation is carried out in organic solution, whereas in others aqueous media are employed. Regardless of medium, the choice of bioconjugatable group must enable conjugation to be carried out without interference with the functional groups that afford water solubility.

To meet the objectives stated above requires a water solubilization unit that is (1) compact, (2) synthetically accessible, preferably amenable for use in the building-block synthesis of meso-substituted porphyrins, and (3) compatible with bioconjugation procedures. Anionic substituents are particularly attractive in the water solubilization motif to minimize nonspecific binding to cellular components. A chief challenge is to solubilize the rather hydrophobic porphyrinic macrocycle so as to suppress cofacial interaction, a likely mechanism for aggregation and precipitation. We recently found that branched-

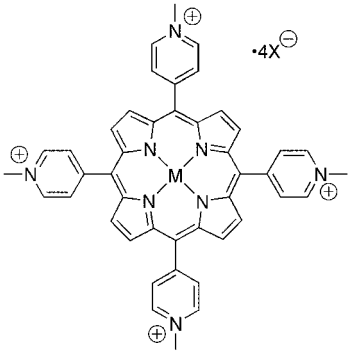
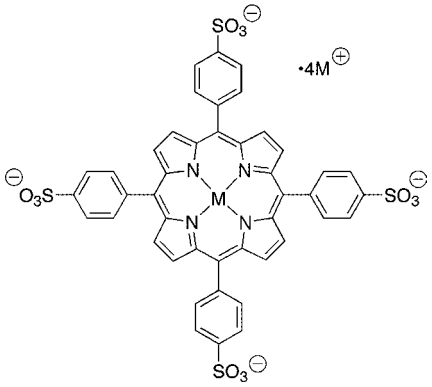
Uroporphyrin III





alkyl groups (e.g., tridec-7-yl) known as "swallowtail" substituents are very effective at imparting a high level of organic solubility to porphyrins (Figure 1) (*34*, *35*). The hydrocarbon chains of the swallowtail motif project over both faces of the macrocycle, suppressing $\pi-\pi$ interactions between porphyrin rings (*34*). Such hydrocarbon swallowtails were shown earlier to impart excellent solubility in organic media to perylene dyes, which otherwise are quite insoluble (*36*). We expected that swallowtail moieties modified with polar end groups could render porphyrins water-soluble. The swallowtail groups do not include a meso-aryl substituent and hence are compact, helping limit the overall molecular weight of the porphyrinic compound.

In this paper, we report the synthesis of *trans*-AB-porphyrins bearing one conjugatable group and one swallowtail motif. The presence of two small meso substituents affords a minimalist design suited for diverse applications. The swallowtail motif is a pent-3-yl group bearing a polar group (dihydroxyphosphoryl, dihydroxyphosphoryloxy) at each terminus. The conjugatable group is either 4-bromophenyl or 4-(carboxymethyloxy)phenyl. The solubility of the porphyrins has been examined in aqueous media. The bromo substituent is not directly useful for bioconjugation but can be substituted in Pd-mediated reactions. In addition, the porphyrin bearing the bromo substituent can serve as a benchmark for assessing the extent to which the swallowtail motifs are responsible for water solubilization without the polar, ionizable carboxylic acid. The favorable properties of the

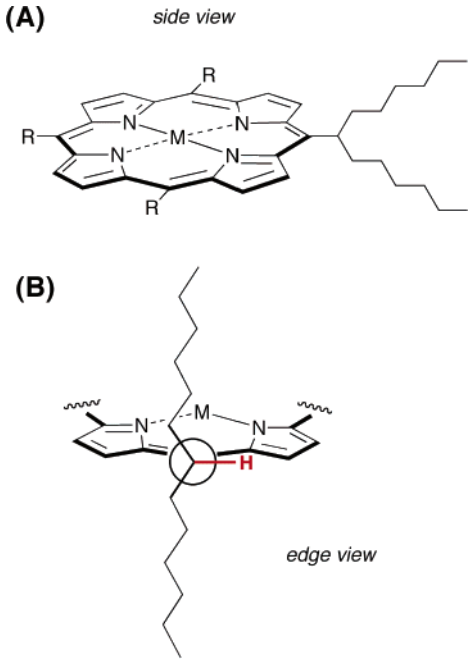


Figure 1. (A) Porphyrin bearing one swallowtail substituent and (B) Newman projection showing the alkyl chains of the swallowtail substituent above and below the plane of the porphyrin.

porphyrin allowed the facile preparation of soluble nonaggregated protein conjugates. The biological activity of the conjugated porphyrin was established by the stringent method of intracellular fluorescent staining using a monoclonal antibody against the epsilon invariant chain of the human T-cell receptor CD3, and assessing the performance by flow cytometry and fluorescence microscopy. This work establishes the foundation for the rational synthesis of porphyrins for applications where water solubility and bioconjugation are required.

EXPERIMENTAL PROCEDURES

General Methods. ^{1}H NMR (300 MHz) and ^{13}C NMR (75 MHz) spectra were recorded in $CDCl_3$ unless noted otherwise. Bulb-to-bulb distillation was performed using a standard-size Kugelrohr apparatus. Absorption spectra and fluorescence spectra were collected at room temperature in CH_2Cl_2 unless noted otherwise. Infrared absorption spectra were recorded as thin films. Hydrophobic porphyrins were analyzed in neat form by laser desorption mass spectrometry (LD-MS) (*37*). The water-soluble porphyrins were analyzed by direct infusion of water/methanol (40:60) solutions by atmospheric pressure electrospray ionization mass spectrometry (ESI-MS). Both in LD-MS and ESI-MS analyses, positive ions were detected unless noted otherwise. Melting points are uncorrected. Solvents were dried according to standard procedures. LDA was generated in situ (*38*). The mouse IgG1 anti-human CD3 intracellular ϵ-chain (clone UCHT) (*39*) and the same antibody derivatized with a fluorescein-isothiocyanate (FITC) label, were obtained from BD Biosciences (San Jose, CA). All other materials were used as received from commercial sources. Molecular mechanics calculations were carried out using PCMODEL for Windows version 7.50.00 (Serena Software).

Chromatography. Preparative chromatography was performed using silica (230−400 mesh) or alumina (80−200 mesh). Thin-layer chromatography was performed on silica or alumina. Samples were visualized by UV light (254 and 365 nm), Br_2 vapor, or $KMnO_4/K_2CO_3$. Dipyrromethanes and compounds **2**−**4** and **6a** were analyzed by GC as described previously (*40*). Reversed-phase preparative column chromatography was carried out using C-18-coated silica and eluants based on water admixed

with methanol. Analytical RP-HPLC was carried out using an ODS C-18 column (5 μm, 125 mm × 4 mm), flow rate = 1 mL/min, detection at 254, 410, and 417 nm, and the following elution program with solvents A (water containing 0.1% TFA) and B (acetonitrile containing 0.1% TFA): 0−2 min, 0% B; 2−20 min, 0→90% B; 20−23 min, 90% B.

2-(*tert*-Butyldimethylsilyloxy)ethyl Bromide (2). Following a published procedure (*41*), 2-bromoethanol (10.0 mL, 141 mmol) was added to a mixture of imidazole (12.5 g, 184 mmol) and *tert*-butyldimethylsilyl chloride (21.1 g, 140 mmol) in anhydrous DMF (25 mL). The reaction mixture was stirred at room temperature for 12 h. Water and diethyl ether were added. The phases were separated. The aqueous phase was extracted with diethyl ether. The organic phase was washed with water and brine. The solution was dried (Na_2SO_4). Evaporation of the solvent followed by bulb-to-bulb distillation (40−45 °C, 0.05 mmHg) yielded a colorless liquid (32.5 g, 97%): IR (film, ν_{max} cm^{-1}) 2951, 2859, 1471; ^{1}H NMR δ 0.07 (s, 6H), 0.89 (s, 9H), 3.36−3.41 (m, 2H), 3.85−3.90 (m, 2H); ^{13}C NMR δ −5.06, 18.49, 26.04, 33.45, 63.74; EI-MS 137/139, 181/183; Anal. ($C_8H_{19}BrOSi$) C, H.

3-Cyano-1,5-bis(*tert*-butyldimethylsilyloxy)pentane (3). A solution of HMPA (12.0 mL) and LDA (33.5 mmol) in dry THF (39 mL) at −78 °C under argon was treated with acetonitrile (1.75 mL, 33.5 mmol). The solution was stirred for 30 min. Then, **2** (6.82 g, 29.0 mmol) in THF (30 mL) was added dropwise. Stirring was continued for 2 h, after which a second portion of LDA (33.5 mmol in 39 mL THF) was added. The solution was stirred for 30 min, after which **2** (6.82 g, 29.0 mmol) in THF (30 mL) was added dropwise. The reaction was allowed to proceed for 2 h. Saturated aqueous NH_4Cl was added, and the mixture was allowed to reach room temperature. Diethyl ether was added, the phases were separated, and the aqueous layer was extracted with diethyl ether. The organic phase was washed with water and brine, dried over Na_2SO_4, and concentrated. Chromatography [silica, petroleum ether/diethyl ether (40:1)] afforded a colorless liquid (7.79 g, 77%): IR (film, ν_{max} cm^{-1}) 2953, 2859, 1738, 1472; ^{1}H NMR δ 0.07 (s, 12H), 0.89 (s, 18H), 1.76−1.83 (m, 4H), 3.03−3.13 (m, 1H), 3.73−3.83 (m, 4H); ^{13}C NMR δ −5.24, 18.45, 24.82, 26.09, 35.32, 60.08, 122.15; EI-MS 115, 142/144, 156/157, 182/184, 198; Anal. ($C_{18}H_{39}NO_2Si_2$) C, H, N.

3-Formyl-1,5-bis(*tert*-butyldimethylsilyloxy)pentane (4). Following a published procedure (*41*), a solution of **3** (3.65 g, 10.2 mmol) in dry toluene (52 mL) at −78 °C under argon was treated with DIBALH (12 mmol, 8.3 mL, 1.5 M solution in toluene). The reaction was allowed to proceed for 1 h. Water (2.6 mL) was added, and the mixture was allowed to reach room temperature. Aqueous NaOH (2.6 mL, 4.0 M solution) was added, and stirring was continued for 15 min. Water (7.8 mL) was added, and the suspension was stirred for a further 15 min. The reaction mixture was dried with a large quantity of Na_2SO_4. The dried solution was concentrated at reduced pressure and chromatographed [silica, petroleum ether/diethyl ether (20:1)], affording a colorless liquid (2.70 g, 73%): IR (film, ν_{max} cm^{-1}) 2955, 2859, 1729, 1708, 1472; ^{1}H NMR δ 0.01 (s, 12H), 0.87 (s, 18H), 1.64−1.74 (m, 2H), 1.85−1.96 (m, 2H), 2.50 (m, 1H), 3.57−3.68 (m, 4H), 9.65 (d, J = 2.4 Hz, 1H); ^{13}C NMR δ −5.27, 18.45, 26.09, 32.15, 46.40, 60.80, 204.74; EI-MS 171/172, 141, 97, 75; Anal. ($C_{18}H_{40}O_3Si_2$) C, H; C calcd, 59.94; found, 58.15.

5-[1,5-Bis(*tert*-butyldimethylsilyloxy)pent-3-yl]dipyrromethane (5). Following a standard procedure (*40*), aldehyde **4** (4.61 g, 12.8 mmol) was dissolved in dry pyrrole (89.1 mL, 1.28 mmol), and the solution was flushed with argon for 10 min. $InCl_3$ (285 mg, 1.28 mmol) was added, and the reaction was allowed to proceed for 3 h. The reaction was quenched by addition of powdered NaOH (1.54 g, 38.5 mmol). The mixture was stirred for 45 min. The mixture was filtered. The filtrate was concentrated at reduced pressure. The residue was chromatographed [silica, ethyl acetate/CH_2Cl_2/hexanes (1:2:7)] affording a viscous, pale yellow liquid (5.87 g, 96%): IR (film, ν_{max} cm^{-1}) 3427, 1639; ^{1}H NMR δ 0.09 (s, 12H), 0.94 (s, 18H), 1.35−1.44 (m, 2H), 1.71−1.78 (m, 2H), 2.41−2.43 (m, 1H), 3.64−3.77 (m, 4H), 4.38 (d, J = 4.2 Hz, 1H), 6.03 (app s, 2H), 6.13−6.16 (m, 2H), 6.65−6.66 (m, 2H), 8.45−8.55 (br, 2H); ^{13}C NMR δ −5.08, 18.65, 26.29, 35.13, 35.37, 40.41, 62.18, 107.03, 108.27, 116.45, 132.25; LD-MS obsd 475.6; FAB-MS obsd 476.3255, calcd 476.3254 ($C_{26}H_{48}N_2O_2Si_2$); Anal. C, H, N.

5-(1,5-Dihydroxypent-3-yl)dipyrromethane (5-(OH)$_2$). A solution of **5** (3.81 g, 8.01 mmol) in THF (30 mL) was treated with TBAF (4.61 g, 17.6 mmol). The reaction was allowed to proceed until the starting material could not be detected by TLC [alumina, CH_2Cl_2/MeOH (97:3)]. The solvent was evaporated. The residue was dissolved in a mixture of ethyl acetate and water. The aqueous layer was extracted with ethyl acetate. The organic phase was washed with water and dried (Na_2SO_4). The solvent was removed, and the residue was chromatographed [neutral alumina, CH_2Cl_2/MeOH (2→10%)] to afford an off-white viscous oil (1.60 g, 89%): ^{1}H NMR δ 1.43−1.50 (m, 2H), 1.68−1.79 (m, 2H), 2.39−2.43 (m, 3H), 3.59−3.75 (m, 4H), 4.21 (d, J = 5.4 Hz, 1H), 6.04 (d, J = 0.9 Hz, 2H), 6.13−6.16 (m, 2H), 6.65−6.66 (m, 2H), 8.40−8.55 (br, 2H); ^{13}C NMR δ 25.88, 34.86, 35.60, 41.79, 61.25, 106.77, 108.38, 117.03, 131.84; FAB-MS obsd 248.1528, calcd 248.1525 ($C_{14}H_{20}N_2O_2$); Anal. C calcd, 67.71; found, 66.59; H calcd, 8.12; found, 8.62; N calcd, 11.28; found, 10.34.

5-[1,5-Bis(dimethoxyphosphoryloxy)pent-3-yl]dipyrromethane (5-(P)$_2$). A solution of **5-(OH)$_2$** (950 mg, 4.24 mmol) in CH_2Cl_2 (16 mL) was treated with DMAP (1.18 g, 9.67 mmol) followed by slow addition of a solution of dimethyl chlorophosphate (1.06 mL, 9.83 mmol) in CH_2Cl_2 (11 mL). The reaction mixture was stirred at room temperature for 8 h. The crude mixture was diluted with CH_2Cl_2 and water. The aqueous layer was extracted with CH_2Cl_2. The organic layer was washed with water. The organic layer was dried (Na_2SO_4), concentrated, and chromatographed [silica, CH_2Cl_2/MeOH (2→5%)], affording a pale yellow oil (1.19 g, 61%): IR (film, ν_{max} cm^{-1}) 3320, 1567; ^{1}H NMR δ 1.57−1.64 (m, 2H), 1.84−1.90 (m, 2H), 2.19 (m, 1H), 3.72 (s, 6H), 3.76 (s, 6H), 4.02 (q, J = 8.4 Hz, 4H), 4.28 (d, J = 5.1 Hz, 1H), 6.00−6.01 (m, 2H), 6.10−6.13 (m, 2H), 6.67−6.69 (m, 2H), 8.79 (br, 2H); ^{13}C NMR δ 31.16, 32.54, 32.62, 35.21, 40.76, 54.55, 54.65, 66.29, 106.85, 108.32, 117.22, 130.88; FAB-MS obsd 464.1480, calcd 464.1477 ($C_{18}H_{30}N_2O_8P_2$); Anal. C, H, N. Data for **5-(P/OH)**. TLC analysis of the crude mixture revealed the presence of a more polar component, which was isolated as an off-white oil: IR (film, ν_{max} cm^{-1}) 3320, 1566, 1450; ^{1}H NMR δ 1.45−1.87 (m, 4H), 2.44−2.46 (m, 1H), 3.66 (t, J = 5.1 Hz, 2H), 3.75 (s, 3H), 3.78 (s, 3H), 3.95−4.19 (m, 2H), 4.26 (d, J = 4.8 Hz, 1H), 6.03 (app s, 2H), 6.14 (app s, 2H), 6.68 (app s, 2H), 8.64 (br, 2H); ^{13}C NMR δ 33.07, 34.84, 35.23, 41.33, 54.67, 54.73, 61.02, 66.65, 66.71, 106.65, 106.96, 108.26, 108.34, 111.76, 117.08, 117.15, 131.27, 131.69; EI-MS 157/158, 230/231; FAB-MS obsd 356.2, calcd 356.2 ($C_{16}H_{25}N_2O_5P$); Anal. ($C_{16}H_{25}N_2O_5P\cdot 0.5CH_3OH$) C, H, N.

4-(*tert*-Butoxycarbonylmethoxy)benzaldehyde (6a). A solution of 4-hydroxybenzaldehyde (2.44 g, 20.0 mmol) in dry acetonitrile (8.0 mL) was treated with powdered, dried K_2CO_3 (3.04 g, 22.0 mmol) and NaI (304 mg, 2.00 mmol). The mixture was refluxed under argon for 30 min. *tert*-Butyl bromoacetate (1.48 mL, 1.95 g, 10.0 mmol) was added dropwise, and the reflux was continued for 12 h. Water and CH_2Cl_2 were added,

and the phases were separated. The aqueous layer was extracted with CH_2Cl_2. The organic phase was washed with water. The organic layer was dried (Na_2SO_4). Evaporation of the solvent and chromatography of the oily residue [silica, ethyl acetate/hexanes (3:7)] afforded a white, crystalline solid (2.18 g, 92%): mp 56−57 °C; IR (film, ν_{max} cm^{-1}) 1762, 1752, 1685, 1600; ^{1}H NMR δ 1.48 (s, 9H), 4.60 (s, 2H), 6.99 (d, J = 8.7 Hz, 2H), 7.84 (d, J = 8.7 Hz, 2H), 9.89 (s, 1H); ^{13}C NMR δ 28.25, 65.76, 83.17, 115.08, 130.82, 132.18, 163.00, 167.37, 190.98; EI-MS 105/107, 135, 193/194, 236/237; FAB-MS obsd 237.1120, calcd 237.1127 [(M + H)$^+$, M = $C_{13}H_{16}O_4$]; Anal. C, H.

5-[4-(*tert*-Butoxycarbonylmethoxy)phenyl]dipyrromethane (7a). Following a standard procedure (*40*), aldehyde **6a** (2.07 g, 8.78 mmol) was dissolved in dry pyrrole (56.0 mL, 880 mmol), and the solution was flushed with argon for 10 min. $InCl_3$ (666 mg, 0.800 mmol) was added, and the reaction was allowed to proceed for 3 h. The reaction was quenched by addition of powdered NaOH (977 mg, 24.4 mmol). The mixture was stirred for 45 min. The mixture was filtered. The filtrate was concentrated at reduced pressure. Chromatography [silica, ethyl acetate/CH_2Cl_2/hexanes (1:2:7)] afforded a pale yellow oil (2.73 g, 88%): IR (film, ν_{max} cm^{-1}) 1744, 1608; ^{1}H NMR δ 1.49 (s, 9H), 4.49 (s, 2H), 5.42 (s, 1H), 5.90 (app s, 2H), 6.15 (d, J = 2.7 Hz, 2H), 6.69 (app s, 2H), 6.83 (d, J = 9.0 Hz, 2H) 7.12 (d, J = 9.0 Hz, 2H), 7.93 (br, 2H); ^{13}C NMR δ 28.30, 43.35, 65.96, 82.66, 107.32, 108.61, 114.91, 117.40, 129.70, 132.96, 135.33, 157.13, 168.32; EI-MS 145, 229/230, 295/296, 352; FAB-MS obsd 352.1800, calcd 352.1787 ($C_{21}H_{24}N_2O_3$); Anal. H, N; C calcd, 71.57; found, 71.00.

5-[4-(*tert*-Butoxycarbonylmethoxy)phenyl]-1,9-diformyldipyrromethane (8a). Following a standard procedure (*42*), a solution of **7a** (2.66 g, 7.55 mmol) in DMF (7.53 mL) was cooled to 0 °C under argon, and phosphorus oxychloride (1.48 mL, 16.2 mmol) was added. The mixture was allowed to reach room temperature. Stirring was continued for 1 h. The solution was poured into aqueous sodium hydroxide (80 mL of 10 wt % solution) and was extracted into ethyl acetate (5 × 80 mL). The organic phases were combined, washed with water and brine, dried (Na_2SO_4), and concentrated. Chromatography [neutral alumina, CH_2Cl_2/MeOH (0.5→1%)] gave a pale brown solid (1.36 g, 45%): mp 84−85 °C (dec); IR (film, ν_{max} cm^{-1}) 1754, 1599; ^{1}H NMR δ 1.47 (s, 9H), 4.48 (s, 2H), 5.52 (s, 1H), 6.03 (d, J = 3.9 Hz, 2H), 6.81−6.85 (m, 4H), 7.15 (d, J = 8.4 Hz, 2H), 9.21 (s, 2H), 10.20−10.80 (br, 2H); ^{13}C NMR δ 28.48, 43.79, 65.94, 82.90, 111.64, 115.23, 12.36, 129.79, 132.90, 141.88, 162.82, 168.13, 179.17; FAB-MS obsd 408.1668, calcd 408.1685 ($C_{23}H_{24}N_2O_5$); Anal. H, N; C calcd, 67.63; found, 66.43.

Dibutyl[5-[4-(*tert*-butoxycarbonylmethoxy)phenyl]-1,9-diformyl-5,10-dihydrodipyrrinato]tin(IV) (8aSnBu$_2$). Following a standard method (*43*), a solution of **8a** (1.79 g, 4.39 mmol) in CH_2Cl_2 (3.6 mL) was treated with TEA (1.83 mL) and dibutyltin dichloride (1.33 g, 4.38 mmol). The solution was stirred at room temperature for 1 h. The reaction mixture was concentrated at reduced pressure. Chromatography [silica, CH_2Cl_2/TEA (99:1)] gave a dark orange oil (0.79 g, 28%): IR (film, ν_{max} cm^{-1}) 1753, 1599; ^{1}H NMR δ 0.70−0.79 (m, 6H), 1.10−1.57 (m, 23H), 4.46 (s, 2H), 5.46 (s, 1H), 6.11 (d, J = 3.3 Hz, 2H), 6.79 (d, J = 3.3 Hz, 2H), 7.03−7.06 (m, 2H), 9.15 (s, 2H); ^{13}C NMR δ 13.71, 13.78, 24.14, 24.56, 26.26, 26.50, 27.29, 27.33, 28.27, 66.01, 22.64, 82.60, 115.04, 124.11, 129.42, 136.85, 138.11, 152.52, 157.11, 168.21, 178.79; FAB-MS obsd 641.2004, calcd 641.2037 [(M + H)$^+$, M = $C_{31}H_{40}N_2O_5Sn$]; Anal. C, H, N.

5-[4-(*tert*-Butoxycarbonylmethoxy)phenyl]-1,9-bis(*N*-propylimino)dipyrromethane (9a). A solution of **8a** (1.49 g, 3.64 mmol) in THF (12 mL) was treated with propylamine (6.0 mL). The solution was stirred at room temperature for 1 h. The volatile components were evaporated. The crude product was dried at reduced pressure, affording a pale brown solid (quantitative): mp 119−121 °C; IR (film, ν_{max} cm^{-1}) 1755, 1639; ^{1}H NMR δ 0.88 (t, J = 7.5 Hz, 6H), 1.48 (s, 9H), 1.55−1.62 (m, 4H), 3.37 (t, J = 6.6 Hz, 4H), 4.47 (s, 2H), 5.36 (s, 1H), 5.88 (d, J = 3.6 Hz, 2H), 6.32 (d, J = 3.6 Hz, 2H), 6.81 (d, J = 8.7 Hz, 2H), 7.09 (d, J = 8.7 Hz, 2H), 7.88 (s, 2H); ^{13}C NMR δ 12.04, 24.51, 28.29, 43.76, 62.90, 66.01, 82.58, 109.31, 114.55, 114.96, 129.68, 130.39, 134.24, 136.73, 151.68, 157.21, 168.26, 20.98; FAB-MS obsd 491.3026, calcd. 491.3022 [(M + H)$^+$, M = $C_{29}H_{38}N_4O_3$]; Anal. C, H, N.

Zn(II) 5-[1,5-Bis(*tert*-butyldimethylsilyloxy)pent-3-yl]-15-[4-(*tert*-butoxycarbonylmethoxy)phenyl]porphyrin (Zn10a). A solution of **9a** (132 mg, 0.269 mmol) and **5** (142 mg, 0.298 mmol) in toluene (30.0 mL) was treated with $Zn(OAc)_2$ (550 mg, 3.00 mmol). The mixture was refluxed for 18 h open to the air. The toluene was evaporated. The residue was chromatographed (silica, CH_2Cl_2) to give a purple solid (62.0 mg, 24%): ^{1}H NMR δ −0.19 (s, 12H), 0.75 (s, 18H), 1.62 (s, 9H), 3.03−3.12 (m, 2H), 3.25−3.37 (m, 2H), 3.56−3.71 (m, 4H), 4.80 (s, 2H), 5.93 (m, 1H), 7.29−7.33 (m, 2H), 8.12−8.15 (m, 2H), 9.10−9.12 (m, 2H), 9.38−9.40 (m, 2H), 9.46−9.50 (m, 2H), 9.91 (d, J = 4.8 Hz, 1H), 10.04 (d, J = 5.1 Hz, 1H), 10.25 (s, 2H); LD-MS obsd 908.4; FAB-MS obsd 908.3694, calcd 908.3707 ($C_{49}H_{64}N_4O_5Si_2Zn$); λ_{abs} (log ϵ) 408 (4.64), 538 (3.68) nm; λ_{em} (λ_{exc} 408 nm) 580, 634 nm.

Zn(II) 5-(4-*tert*-Butoxycarbonylmethoxyphenyl)-15-(1,5-dihydroxypent-3-yl)porphyrin (Zn11a). A solution of **Zn10a** (48.7 mg, 0.0536 mmol) was dissolved in THF containing TBAF (3.0 mL of 1.0 M solution, water content ∼5%). The reaction mixture was cooled in an ice−water bath, and the reaction was allowed to proceed for 1 h. Then, the mixture was poured into ethyl acetate, and the organic phase was washed with water. The aqueous layer was extracted with ethyl acetate. The organic phase was washed with water and dried (Na_2SO_4). The sample was concentrated. Anhydrous zinc acetate (200 mg, 1.09 mmol) was added, and the mixture was stirred at room temperature for 15 min. Chromatography [neutral alumina, CH_2Cl_2/MeOH (2→10%)] afforded a bright purple solid (31.8 mg, 78%): ^{1}H NMR (THF-d_8) δ 1.53 (s, 9H), 2.95−2.99 (m, 2H), 3.19−3.24 (m, 2H), 3.48−3.52 (m, 4H), 4.74 (s, 2H), 5.71 (m, 1H), 7.21 (d, J = 7.8 Hz, 2H), 8.05 (d, J = 7.8 Hz, 2H), 8.95 (s, 2H), 9.24 (s, 2H), 9.32−9.33 (m, 2H), 9.69−9.70 (m, 1H), 9.80−9.81 (m, 1H), 10.06 (s, 2H); LD-MS obsd (−) 678.7; FAB-MS obsd 680.1963, calcd 680.1977 ($C_{37}H_{36}N_4O_5Zn$); λ_{abs} (log ϵ) 411 (5.22), 540 (4.34) nm; λ_{em} (λ_{exc} 411 nm) 583, 635 nm.

Zn(II) 5-(4-*tert*-Butoxycarbonylmethoxyphenyl)-15-[1,5-bis(dimethoxyphosphoryloxy)pent-3-yl]porphyrin (Zn12a). A solution of **9a** (211 mg, 0.431 mmol) and **5c** (200 mg, 0.431 mmol) in toluene (46 mL) was treated with anhydrous zinc acetate (0.810 g, 4.43 mmol). The mixture was refluxed open to the air for 18 h. The mixture was concentrated to dryness. The crude product was dried and chromatographed [silica, CH_2Cl_2/EtOAc (0→20%) then CH_2Cl_2/methanol (0→2%)], affording a deep red solid (87.0 mg, 22%): ^{1}H NMR δ 1.63 (s, 9H), 2.81−3.00 (m, 14H), 3.19−2.28 (m, 2H), 3.33−3.37 (m, 4H), 4.80 (s, 2H), 5.48−5.55 (m, 1H), 7.28−7.31 (m, 2H), 8.11−8.16 (m, 2H), 9.05−9.06 (m, 2H), 9.27−9.38 (m, 3H), 9.41−9.42 (m, 1H), 9.55−9.61 (m, 2H), 10.08 (s, 1H), 10.16 (s, 1H); LD-MS obsd 896.8; FAB-MS obsd 896.1970, calcd 896.1930 ($C_{41}H_{46}N_4O_{11}P_2Zn$); λ_{abs} (log ϵ) 412 (4.96), 541 (4.12) nm; λ_{em} (λ_{exc} 412 nm) 591, 638 nm.

5-[4-(Carboxymethoxy)phenyl]-15-[1,5-bis(dimethoxyphosphoryloxy)pent-3-yl]porphyrin (12a). A solution of **Zn12a** (41.9 mg, 0.0468 mmol) in CH_2Cl_2 (1.5 mL) was treated with

TFA (1.5 mL). The solution was stirred at room temperature for 3 h. The volatile components were evaporated. The dark green residue was dissolved in CH_2Cl_2. The solution was washed with water. The aqueous phase was extracted with CH_2Cl_2. The organic phase was washed with water, dried (Na_2SO_4), and concentrated, affording a dark green solid (29.6 mg, 76%): ^{1}H NMR δ 3.05−3.33 (m, 16H), 3.81−4.03 (m, 4H), 4.71 (s, 2H), 5.76 (m, 1H), 7.38 (d, J = 8.7 Hz, 2H), 8.02 (d, J = 8.7 Hz, 2H), 8.98−8.99 (m, 2H), 9.31−9.35 (m, 2H), 9.44−9.51 (m, 2H), 9.63−9.65 (m, 2H), 9.81−9.83 (m, 2H), 10.27 (s, 2H); LD-MS 778.6 $(M + H)^+$, 801.7 $(M + Na)^+$, 815.7 $(M + K)^+$; FAB-MS obsd 779.2247, calcd 779.2247 [$(M + H)^+$, M = $C_{37}H_{40}N_4O_{11}P_2$]; λ_{abs} 407, 505 nm; λ_{em} (λ_{exc} 407 nm) 635, 699 nm.

Cu(II) 5-(4-(Carboxymethoxy)phenyl)-15-[1,5-bis(dimethoxyphosphoryloxy)pent-3-yl]porphyrin (Cu12a). A solution of **12a** (16 mg, 0.021 mmol) in $CHCl_3$/CH_3OH (5.0 mL, 9:1 v/v) was treated with $Cu(OAc)_2 \cdot H_2O$ (42 mg, 0.21 mmol). The solution was stirred at room temperature for 12 h. Water was added to the reaction mixture. The phases were separated. The aqueous layer was extracted with CH_2Cl_2. The organic phase was washed with water, dried (Na_2SO_4), and concentrated, affording a dark orange solid (17 mg, 98%): LD-MS obsd 862.7, calcd 862.1 [$(M + Na)^+$, M = $C_{37}H_{38}CuN_4O_{11}P_2$]; λ_{abs} (log ϵ) 405 (4.47), 530 (2.50) nm.

5-(4-(Carboxymethoxy)phenyl)-15-[1,5-bis(dihydroxyphosphoryloxy)pent-3-yl]porphyrin (13a). A thoroughly dried sample of **12a** (11.8 mg, 0.0151 mmol) was dissolved in dry CH_2Cl_2 (2.0 mL) and then treated with TMS−Br (100 μL, 0.760 mmol). The reaction mixture was stirred at room temperature for 3 h under argon. The volatile components were evaporated at reduced pressure. The residue was dissolved in MeOH (3.0 mL). The solution was stirred for 1 h at room temperature. The volatile components were evaporated. The residue was dissolved in MeOH (3 mL). The solution was stirred for 1 h. The sample was concentrated. The solid residue was dissolved in ∼0.5 mL of dilute aqueous NaOH (0.1 M) and was diluted to ∼3 mL with water. The resulting solution was chromatographed [silica C-18, water/MeOH (0→50%)] to afford a dark red solid (8.20 mg, 76%): ^{1}H NMR (D_2O) δ 3.61 (m, 4H), 3.95 (m, 2H), 4.33 (m, 2H), 5.04 (s, 2H), 5.89 (m, 1H), 7.57 (d, J = 7.8 Hz, 2H), 7.94−7.97 (m, 2H), 8.91 (m, 2H), 9.28−9.34 (m, 2H), 9.78−9.82 (m, 2H), 10.24−10.33 (m, 4H); ESI-MS obsd (+) 362.1 $(M + 2H)^{2+}$, 723.1 $(M + H)^+$, 745.1 $(M + Na)^+$, (−) 721.1 $(M - H)^-$, calcd 722.15 (M = $C_{33}H_{32}N_4O_{11}P_2$); λ_{abs} 402, 506 nm; λ_{em} (λ_{exc} 402 nm) 628, 688 nm; HPLC t_R = 9.83 min.

Cu(II) 5-(4-(Carboxymethoxy)phenyl)-15-[1,5-bis(dihydroxyphosphoryloxy)pent-3-yl]porphyrin (Cu13a). A thoroughly dried sample of **Cu12a** (28.7 mg, 0.034 mmol) was dissolved in dry CH_2Cl_2 (1.5 mL) and then treated with TMS−Br (111 μL, 0.84 mmol). The reaction mixture was stirred at room temperature for 3 h under argon. The volatile components were evaporated at reduced pressure. The residue was dissolved in MeOH (3.0 mL). The solution was stirred for 1 h at room temperature. The mixture was concentrated. The solid residue was dissolved in ∼0.5 mL of dilute aqueous NaOH (0.1 M) and was diluted to ∼3 mL with water. Chromatography [silica C-18, water/MeOH (0→50%)] afforded an orange solid (12.2 mg, 12.2%, 46%): ESI-MS obsd (−) 782.4, 391.0, calcd 784.0, 391.5 [$(M - H)^-$, $(M - 2H)^{2-}$, M = $C_{33}H_{30}CuN_4O_{11}P_2$], also obsd 796.2 (M + methylene)$^+$; λ_{abs} 402, 530 nm.

5-(4-(*tert*-Butoxycarbonylmethoxy)phenyl)-15-(1,5-dibromopent-3-yl)porphyrin (14a). A sample of **Zn11a** was thoroughly dried by treatment overnight under vacuum (0.05 mmHg) at room temperature. Following a standard method (*44*), a solution of the dried sample of **Zn11a** (35.6 mg, 57 μmol) in dry CH_2Cl_2 (12 mL) was treated with CBr_4 (53.5 mg, 0.16 mmol). The solution was cooled in an ice−water bath for 10 min. Triphenylphosphine (84 mg, 0.32 mmol) was added. The solution was allowed to warm to room temperature. The reaction was allowed to proceed at room temperature for 12 h. Water was added, and the phases were separated. The aqueous phase was extracted with CH_2Cl_2. The organic phase was washed with water. The organic layer was dried (Na_2SO_4). Chromatography (silica, CH_2Cl_2) afforded a dark green solid (38.7 mg, 91%): ^{1}H NMR δ −2.86 (s, 1H), −2.82 (s, 1H), 1.64 (s, 9H), 3.24−3.39 (m, 6H), 3.65−3.75 (m, 2H), 4.85 (s, 2H), 5.83 (m, 1H), 7.35 (d, J = 8.1 Hz, 2H), 8.18 (d, J = 8.1 Hz, 2H), 9.08−9.11 (m, 2H), 9.37−9.60 (m, 5H), 9.98 (d, J = 4.2 Hz, 1H), 10.30 (s, 2H); LD-MS obsd 745.1; FAB-MS obsd 742.1166, calcd 742.1154 ($C_{37}H_{36}Br_2N_4O_3$); λ_{abs} (log ϵ) 407 (5.00), 503 (4.15) nm; λ_{em} (λ_{exc} 407 nm) 635, 701 nm.

5-(4-(*tert*-Butoxycarbonylmethoxy)phenyl)-15-[1,5-bis(dimethoxyphosphoryl)pent-3-yl]porphyrin (15a). A sample of **14a** (38.7 mg, 0.0521 mmol) was dissolved in $P(OCH_3)_3$ (10.0 mL). The solution was refluxed under argon for 1.5 days. The $P(OCH_3)_3$ was evaporated at reduced pressure. The residue was chromatographed [silica, CH_2Cl_2/MeOH (0→5%)] to yield a dark purple solid (24.6 mg, 65%): ^{1}H NMR δ 1.64 (s, 9H), 3.15 (m, 2H), 3.32−3.36 (m, 2H), 3.43 (s, 3H), 3.47 (s, 6H), 3.50 (s, 3H), 3.81−3.87 (m, 4H), 4.84 (s, 2H), 5.44 (m, 1H), 7.35 (d, J = 8.1 Hz, 2H), 8.17 (d, J = 8.1 Hz, 2H), 9.10 (s, 2H), 9.40 (s, 2H), 9.50−9.51 (m, 2H), 9.73−9.74 (m, 2H), 10.30−10.31 (m, 2H); LD-MS obsd 803.7; FAB-MS obsd 803.2983, calcd 803.2975 ($C_{41}H_{48}N_4O_9P_2$); λ_{abs} (log ϵ) 407 (4.90), 504 nm; λ_{em} (λ_{exc} 407 nm) 636 nm, 702 nm. Varying amounts of a less polar purple solid (**15a-Br**) were isolated along with small amounts of the starting material **14a** (limited characterization). Data for **15a-Br**: ^{1}H NMR δ 0.86−0.95 (m, 1H), 1.65 (s, 9H), 1.91−2.00 (m, 1H), 3.13−3.40 (m, 6H), 3.44 (s, 3H), 3.48 (s, 3H), 3.55−3.85 (m, 2H), 4.83 (s, 2H), 5.51−5.61 (m, 1H), 7.34 (d, J = 8.1 Hz, 2H), 8.17 (d, J = 8.1 Hz, 2H), 9.08−9.10 (m, 2H), 9.37−9.41 (m, 2H), 9.49−9.51 (m, 2H), 9.67−9.68 (m, 1H), 9.84−9.85 (m, 1H), 10.30 (s, 2H); LD-MS obsd 773.6, calcd 773.2 [$(M + H)^+$, M = $C_{39}H_{42}BrN_4O_6P_2$]; λ_{abs} 407, 502 nm; λ_{em} (λ_{exc} 407 nm) 634, 702 nm.

5-(4-(Carboxymethoxy)phenyl)-15-[1,5-bis(dihydroxyphosphoryl)pent-3-yl]porphyrin (16a). A solution of **15a** (19 mg, 0.024 mmol) in anhydrous $CHCl_3$ (2 mL) was flushed with argon for 10 min. Bromotrimethylsilane (400 μL, 3.03 mmol) was added, and the solution was refluxed for 4 h. The reaction mixture was allowed to cool to room temperature. The volatile components were evaporated. The residue was dissolved in MeOH (3 mL). The solution was stirred at room temperature for 1 h. The volatile components were evaporated. Aqueous NaOH (0.3 mL, 0.1 M) was added. The mixture was diluted to ∼3 mL with distilled water. The resulting solution was chromatographed (C-18 silica, H_2O/MeOH gradient) to yield a red solid (9.8 mg, 58%): ^{1}H NMR (D_2O) δ 1.31−1.36 (m, 2H), 2.10−2.15 (m, 2H), 3.16−3.62 (m, 4H), 5.03 (s, 2H), 5.60−5.72 (m, 1H), 7.55−7.60 (m, 2H), 7.82−7.96 (m, 2H), 8.82−8.94 (m, 2H), 9.32−9.40 (m, 2H), 9.84−9.93 (m, 2H), 10.35−10.48 (m, 4H); ESI-MS obsd 691.1 $(M + H)^+$, 346.1 $(M + 2H)^{2+}$, 713.2 $(M + Na)^+$, calcd 690.2 (M = $C_{33}H_{32}N_4O_9P_2$); λ_{abs} (H_2O) 402, 506 nm; λ_{em} (λ_{exc} 402 nm) 627, 688 nm; HPLC t_R = 9.37 min.

Zn(II) 5-(4-(Carboxymethoxy)phenyl)-15-[1,5-bis(dihydroxyphosphoryl)pent-3-yl]porphyrin (Zn16a) (by in Situ Metalation of 16a). A solution of **15a** (10.4 mg, 0.013 mmol) in anhydrous $CHCl_3$ (2 mL) was flushed with argon for 10 min. Bromotrimethylsilane (300 μL, 2.27 mmol) was added, and the solution was refluxed for 4 h. The reaction mixture was allowed to cool to room temperature. The volatile components were evaporated. The residue was dissolved in MeOH (2 mL). The

solution was stirred at room temperature for 1 h. The solvent was evaporated. Aqueous NaOH (0.3 mL, 15 wt %) was added. The sample was diluted with distilled water (3 mL). The mixture was treated with $Zn(OAc)_2$ (55 mg, 0.301 mmol) for 1 h. A second portion of aqueous NaOH (0.3 mL, 15 wt %) was added. The resulting solution was chromatographed [C-18 silica, water/MeOH (0→50%)] to yield a bright purple solid (9.1 mg, 93%): ^{1}H NMR (D_2O) δ 1.17−1.30 (m, 2H), 2.01−2.15 (m, 2H), 3.38−3.49 (m, 4H), 5.05 (s, 2H), 5.72 (s, 1H), 7.74 (d, J = 6.9 Hz, 2H), 8.37 (d, J = 6.9 Hz, 2H), 9.33 (app s, 2H), 9.71 (app s, 2H), 9.85−9.95 (m, 2H), 10.36−10.38 (m, 1H), 10.44−10.46 (m, 1H), 10.57 (s, 1H), 10.60 (s, 1H); ESI-MS obsd 376.9 $(M + 2H)^{2+}$, 753.0 $(M + H)^+$, 774.9 $(M + Na)^+$, calcd 752.0779 ($M = C_{33}H_{30}N_4O_9P_2Zn$); λ_{abs} (H_2O) 409, 544 nm; λ_{em} (λ_{exc} 409 nm) 590, 641 nm; HPLC t_R = 9.83 (27%), 12.10 (73%) min.

5-(4-Bromophenyl)dipyrromethane (7b). This compound was previously prepared by a less efficient method (*45*). Following a standard procedure (*40*), 4-bromobenzaldehyde (5.55 g, 30.0 mmol) was dissolved in dry pyrrole (208 mL, 3.00 mol), and the solution was flushed with argon for 10 min. $InCl_3$ (666 mg, 3.00 mmol) was added, and the reaction was allowed to proceed for 90 min. The reaction was quenched by addition of powdered NaOH (3.60 g, 90.0 mmol). The mixture was stirred for 45 min. The mixture was filtered. The filtrate was concentrated at reduced pressure. Chromatography [silica, ethyl acetate/CH_2Cl_2/hexanes (1:2:7)] afforded a pale yellow solid (8.29 g, 92%): mp 120−122 °C; IR (film, ν_{max} cm^{-1}) 1487; ^{1}H NMR δ 5.43 (s, 1H), 5.88−5.89 (m, 2H), 6.15−6.16 (m, 2H), 6.70−6.71 (m, 2H), 7.06−7.08 (m, 2H), 7.42−7.44 (m, 2H), 7.88−7.93 (br, 2H); ^{13}C NMR δ 43.66, 107.65, 108.80, 112.61, 117.73, 121.08, 130.36, 131.92, 141.40; EI-MS 145, 234/236, 300/302; FAB-MS obsd 300.0257, calcd 300.0262 ($C_{15}H_{13}BrN_2$); Anal. C, H, N.

5-(4-Bromophenyl)-1,9-diformyldipyrromethane (8b). Following a standard procedure (*42*), a solution of **7b** (1.51 g, 5.00 mmol) in DMF (5.00 mL) was cooled to 0 °C under argon, and phosphorus oxychloride (980 μL) was added. The mixture was allowed to reach room temperature. Stirring was continued for 1 h. The solution was poured into aqueous sodium hydroxide (50 mL of 10 wt % solution) and was extracted into ethyl acetate (5 × 50 mL). The organic phases were combined, washed with water and brine, dried (Na_2SO_4), and chromatographed [neutral alumina, CH_2Cl_2/MeOH (0.5→1%)] to afford a pale brown solid (1.43 g, 80%): mp 79−80 °C (dec); IR (film, ν_{max} cm^{-1}) 1645, 1485; ^{1}H NMR δ 5.54 (s, 1H), 6.03−6.05 (m, 2H), 6.85−6.87 (m, 2H), 7.17 (d, J = 7.1 Hz, 2H), 7.46 (d, J = 7.1 Hz, 2H), 9.18 (s, 2H), 10.60−10.70 (br, 2H); ^{13}C NMR δ 44.14, 112.07, 121.89, 122.68, 130.48, 132.27, 132.93, 138.63, 141.61, 179.37; FAB-MS obsd 356.0173, calcd 356.0160 ($C_{17}H_{13}BrN_2O_2$); Anal. C, H, N.

Dibutyl[5-(4-bromophenyl)-1,9-diformyl-5,10-dihydrodipyrrinato]tin(IV) (8bSnBu$_2$). Following a standard procedure (*43*), a solution of **8b** (1.55 g, 4.35 mmol) in CH_2Cl_2 (3.5 mL) was treated with TEA (1.82 mL) and dibutyltin dichloride (1.32 g, 4.34 mmol). The solution was stirred at room temperature for 1 h. The reaction mixture was concentrated at reduced pressure. Chromatography [silica, CH_2Cl_2/TEA (99:1)] gave a crystalline pink solid (0.410 g, 16%): mp 115−117 °C; IR (film, ν_{max} cm^{-1}) 1601; ^{1}H NMR δ 0.70−0.80 (m, 6H), 1.12−1.59 (m, 12H), 5.49 (s, 1H), 6.13 (d, J = 3.9 Hz, 2H), 7.00 (d, J = 8.1 Hz, 2H), 7.06 (d, J = 3.9 Hz, 2H), 7.39 (d, J = 8.1 Hz, 2H), 9.17 (s, 2H); ^{13}C NMR δ 13.72, 13.79, 24.16, 24.70, 26.25, 27.27, 27.37, 44.83, 112.62, 115.63, 121.09, 124.12, 130.01, 132.05, 138.24, 142.88, 151.45, 179.09; FAB-MS obsd 589.0500, calcd. 589.0513 [$(M + H)^+$, $M = C_{25}H_{29}BrN_2O_2Sn$]; Anal. C, H, N.

5-(4-Bromophenyl)-1,9-bis(*N*-propylimino)dipyrromethane (9b). Following a standard procedure (*42*), a solution of **8b** (488 mg, 1.37 mmol) in THF (4.6 mL) was treated with propylamine (2.25 mL, 27.4 mmol). The solution was stirred at room temperature for 1 h. The volatile components were evaporated, and the crude product was dried at reduced pressure, affording a pale brown solid: mp 136−138 °C; IR (film, ν_{max} cm^{-1}) 1634, 1485; ^{1}H NMR δ 0.85−0.89 (m, 6H), 1.52−1.55 (m, 4H), 3.31−3.39 (m, 4H), 5.36 (s, 1H), 5.88 (app s, 2H), 6.34 (app s, 2H), 7.05 (d, J = 7.1 Hz, 2H), 7.40 (d, J = 7.1 Hz, 2H), 7.90 (s, 2H), 8.80−9.05 (br, 2H); ^{13}C NMR δ 12.04, 24.53, 44.00, 62.77, 109.44, 114.62, 121.10, 130.35, 130.69, 131.74, 136.07, 140.59, 151.84; FAB-MS obsd 439.1503, calcd 439.1497 [$(M + H)^+$, $M = C_{23}H_{27}BrN_4$]; Anal. C, H, N.

Zn(II) 5-(4-Bromophenyl)-15-[1,5-bis(*tert*-butyldimethylsilyloxy)pent-3-yl] porphyrin (Zn10b). A solution of **9b** (132 mg, 0.269 mmol) and **5a** (142 mg, 0.298 mmol) in toluene (30.0 mL) was treated with $Zn(OAc)_2$ (550 mg, 3.00 mmol). The mixture was refluxed for 18 h open to the air. The mixture was concentrated, and the resulting residue was chromatographed (silica, CH_2Cl_2) to give a purple solid (62.0 mg, 24%): ^{1}H NMR δ −0.07 (s, 12H), 0.96 (s, 18H), 3.13−3.15 (m, 2H), 3.37−3.44 (m, 2H), 3.67−3.81 (m, 4H), 6.03 (m, 1H), 7.82−7.90 (m, 4H), 8.78−8.80 (m, 2H), 9.04−9.10 (m, 2H), 9.39−9.42 (m, 1H), 9.48−9.50 (m, 2H), 9.93−9.97 (m, 2H), 10.05−10.14 (m, 2H); ^{13}C NMR δ −0.11, 23.45, 23.80, 31.50, 43.96, 50.83, 67.50, 111.18, 111.46, 116.12, 123.12, 127.61, 129.08, 135.31, 136.46, 137.19, 137.34, 141.40, 147.07, 152.87, 154.27, 154.68, 155.94, 155.12, 155.52, 157.57, 174.92; LD-MS obsd 853.7; FAB-MS obsd 856.2232, calcd 856.2182 ($C_{43}H_{53}BrN_4O_2Si_2Zn$); λ_{abs} 409, 539 nm; λ_{em} (λ_{exc} 409 nm) 578, 633 nm.

Zn(II) 5-(4-Bromophenyl)-15-(1,5-dihydroxypent-3-yl)porphyrin (Zn11b). A sample of **Zn10b** (54 mg, 0.063 mmol) was dissolved in dry THF (1.26 mL) containing 1.0 M TBAF (1.3 mmol, 10.0 equiv), and the reaction mixture was stirred overnight at room temperature. The THF was evaporated. The residue was dissolved in ethyl acetate. The solution was washed with water. The aqueous layer was extracted with ethyl acetate. The organic phase was washed with water and brine, dried over Na_2SO_4, and concentrated. LD-MS indicated demetalation (obsd *m*/*z* 563), whereupon the solid was dissolved in $CHCl_3$/MeOH (10 mL, 9:1) and $Zn(OAc)_2$ (195 mg, mmol) was added. The mixture was stirred at room temperature for 1 h. The mixture was concentrated and chromatographed [neutral alumina, CH_2Cl_2/methanol (2→10%)], affording a bright red solid (34.5 mg, 87%): ^{1}H NMR (THF-d_8) δ 3.04−3.10 (m, 2H), 3.24−3.28 (m, 2H), 3.28−3.62 (m, 4H), 5.96 (m, 1H), 7.95 (d, J = 8.1, 2H), 8.14 (d, J = 8.1 Hz, 2H), 8.98−8.99 (m, 2H), 9.37−9.38 (m, 2H), 9.42−9.46 (m, 2H), 9.93 (d, J = 4.5 Hz, 1H), 10.05 (d, J = 4.5 Hz, 1H), 10.19−10.20 (m, 2H); LD-MS obsd 627.2 $(M - H)^-$; FAB-MS obsd 628.0424, calcd 628.0452 ($C_{31}H_{25}BrN_4O_2Zn$); λ_{abs} (CH_2Cl_2/MeOH, 97.5:2.5) (log ϵ) 408 (4.89), 538 nm; λ_{em} (λ_{exc} 408 nm) 589, 643 nm.

Zn(II) 5-(4-Bromophenyl)-15-[1,5-bis(dimethoxyphosphoryloxy)pent-3-yl]porphyrin (Zn12b). Method A: A solution of **Zn11b** (30.0 mg, 0.048 mmol) in dry pyridine (1.0 mL) was cooled in an ice−water bath. Dimethyl chlorophosphate (168 μL, 225 mg, 1.56 mmol) was added, and stirring was continued with cooling for 2 h. The reaction mixture was allowed to reach room temperature. The reaction was allowed to proceed for a further 12 h. The sample was poured into CH_2Cl_2 and was washed with brine. The aqueous layer was extracted with CH_2Cl_2. The organic phase was washed with brine and dried (Na_2SO_4). LD-MS analysis of the crude mixture indicated partial demetalation (obsd *m*/*z* 782), whereupon the residue was dissolved in $CHCl_3$/MeOH (15 mL, 9:1) and $Zn(OAc)_2$ (230 mg, 1.26 mmol) was added. The mixture was stirred at room temperature for 2 h. Chromatography [silica,

CH_2Cl_2/methanol (1→2%)] afforded a deep red solid (12.5 mg, 30%): ^{1}H NMR δ 2.75 (s, 3H), 2.78 (s, 3H), 2.84 (s, 3H), 2.88 (s, 3H), 3.18 (m, 6H), 2.75−2.88 (m, 2H), 5.42 (m, 1H), 7.90 (d, J = 8.1 Hz, 2H), 8.07 (d, J = 8.1 Hz, 2H), 9.00−9.02 (m, 2H), 9.26−9.62 (m, 6H), 10.09 (s, 1H), 10.21 (s, 1H); LD-MS obsd 842.5; FAB-MS obsd 844.0444, calcd 844.0405 ($C_{35}H_{35}BrN_4O_8P_2Zn$); λ_{abs} (log ϵ) 411 (4.92), 541 (4.01) nm; λ_{em} (λ_{exc} 411 nm) 587, 636 nm.

Method B: A solution of **9b** (247 mg, 0.50 mmol) and **5c** (247 mg, 0.53 mmol) in toluene (58 mL) was treated with anhydrous zinc acetate (1.03 g, 5.65 mmol). The mixture was refluxed open to the air for 18 h. The mixture was concentrated, dried, and chromatographed [silica, CH_2Cl_2/methanol (0→2%)], affording a deep red solid (95.5 mg, 21%) with the same physical properties (^{1}H NMR, LD-MS, λ_{abs}) as the sample obtained by method A.

5-(4-Bromophenyl)-15-[1,5-bis(dimethoxyphosphoryloxy)-pent-3-yl]porphyrin (12b). A solution of **Zn12b** (50.6 mg, 0.0600 mmol) in CH_2Cl_2 (2 mL) was treated with TFA (2 mL). The solution was stirred at room temperature for 30 min. The volatile components were evaporated. The dark green residue was dissolved in CH_2Cl_2. The solution was washed with water. The aqueous phase was extracted with CH_2Cl_2. The organic phases were combined and washed with water. The organic layer was dried (Na_2SO_4). Chromatography [silica, CH_2Cl_2/MeOH (97:3)] afforded a deep purple solid (46.0 mg, 98%): ^{1}H NMR δ 3.22−3.24 (m, 2H), 3.42−3.51 (m, 2H), 3.90−3.99 (m, 14H), 4.01−4.11 (m, 2H), 5.75−5.92 (m, 1H), 7.94−7.96 (m, 2H), 8.11−8.13 (m, 2H), 9.00−9.05 (m, 2H), 9.38−9.43 (m, 2H), 9.45−9.52 (m, 2H), 9.67−9.68 (m, 1H), 9.84−9.85 (m, 1H), 10.30 (s, 1H), 10.32 (s, 1H); LD-MS obsd (−) 782.8; FAB-MS obsd 782.1257, calcd 782.1270 ($C_{35}H_{37}BrN_4O_8P_2$); λ_{abs} 405, 504 nm; λ_{em} (λ_{exc} 405 nm) 635, 700 nm.

Cu(II) 5-(4-Bromophenyl)-15-[1,5-bis(dimethoxyphosphoryloxy)pent-3-yl]porphyrin (Cu12b). A solution of **12b** (16.5 mg, 0.0211 mmol) in $CHCl_3$/CH_3OH (5 mL, 9:1 v/v) was treated with $Cu(OAc)_2 \cdot H_2O$ (42.0 mg, 0.231 mmol). The solution was stirred at room temperature for 12 h. The volatile components were evaporated, and the residue was suspended in a small volume of CH_2Cl_2. Chromatography [silica, CH_2Cl_2/MeOH (95:5)] afforded an orange solid (17.6 mg, 99%): LD-MS obsd 846.7 $(M + H)^+$; FAB-MS obsd 843.0443, calcd 843.0410 ($C_{35}H_{35}BrCuN_4O_8P_2$); λ_{abs} 405, 504 nm.

5-(4-Bromophenyl)-15-(1,5-bis[dihydroxyphosphoryloxy)-pent-3-yl]porphyrin (13b). A thoroughly dried sample of **12b** (23 mg, 0.031 mmol) was dissolved in dry CH_2Cl_2 (1.0 mL) and then treated with TMS−Br (25 μL, 0.19 mmol). The reaction mixture was stirred at room temperature for 3 h under argon. The volatile components were evaporated at reduced pressure. The residue was dissolved in MeOH (3.0 mL). The solution was stirred for 1 h at room temperature. The methanol was evaporated. The resulting solid was dissolved in aqueous NaOH (0.3 mL, 0.1 M) and diluted to ∼3 mL with water. The solution was chromatographed [silica C-18, water/MeOH (0→50%)] to afford a red solid (9.6 g, 43%): ^{1}H NMR (D_2O) δ 3.63−3.68 (m, 4H), 3.67−3.99 (m, 2H), 4.30−4.35 (m, 2H), 5.91−5.96 (m, 1H), 7.40 (d, J = 6.3 Hz, 2H), 7.75 (d, J = 6.3 Hz, 2H), 8.44−8.51 (m, 2H), 8.99−9.02 (br, 1H), 9.13−9.16 (br, 1H), 9.79−9.87 (m, 2H), 10.15−10.18 (m, 1H), 10.33−10.40 (m, 3H); ESI-MS obsd (+) 726.3 $(M + H)^+$, 748.8 $(M + Na)^+$, (−) 724.9 $(M - H)^-$, calcd 726.1 ($M = C_{31}H_{29}BrN_4O_8P_2$); λ_{abs} (H_2O) 400, 504 nm; λ_{em} (λ_{exc} 400 nm) 624, 686 nm; HPLC t_R = 13.80 min.

Cu(II) 5-(4-Bromophenyl)-15-[1,5-bis(dihydroxyphosphoryloxy)pent-3-yl]porphyrin (Cu13b). A thoroughly dried sample of **Cu12b** (16.5 mg, 0.019 mmol) was dissolved in dry CH_2Cl_2 (800 μL) and then treated with TMS−Br (18 μL, 0.136 mmol). The reaction mixture was stirred at room temperature for 3 h under argon. The solvents were evaporated at reduced pressure. The residue was dissolved in MeOH (3.0 mL). The solution was stirred for 1 h at room temperature. The methanol was evaporated. The resulting solid was dissolved in aqueous NaOH (0.3 mL, 0.1 M) and diluted to ∼3 mL with water. The solution was concentrated and chromatographed [silica C-18, water/MeOH (0→50%)] to afford a red solid (10.1 mg, 68%): ESI-MS (−) obsd 786.1 $(M - H)^-$, calcd 787.0 ($M = C_{31}H_{27}BrCuN_4O_8P_2$), also obsd 800.1 (M + methylene)$^+$, 814.2 (M + 2methylene)$^+$; λ_{abs} (H_2O) 400, 528 nm.

5-(4-Bromophenyl)-15-(1,5-dibromopent-3-yl)porphyrin (14b). A sample of **Zn11b** was thoroughly dried by treatment overnight under vacuum (0.05 mmHg) at room temperature. Following a standard method (*44*), a solution of the dried sample of **Zn11b** (52 mg, 83 μmol) in dry CH_2Cl_2 (20 mL) was treated with CBr_4 (84 mg, 0.25 mmol). The solution was cooled in an ice−water bath for 10 min. Triphenylphosphine (132 mg, 0.504 mmol) was added. The solution was allowed to warm to room temperature. Water was added, and the phases were separated. The aqueous phase was extracted with CH_2Cl_2. The organic phase was washed with water. The organic layer was dried (Na_2SO_4). Chromatography (silica, CH_2Cl_2) afforded a dark green solid (44.5 mg, 78%): ^{1}H NMR δ −2.90 (s, 1H), −2.85 (s, 1H), 0.86−0.95 (m, 2H), 3.17−3.39 (m, 6H), 3.65−3.74 (m, 2H), 5.81−5.94 (m, 1H), 7.94 (d, J = 8.1 Hz, 2H), 8.11 (d, J = 8.1 Hz, 2H), 9.02−9.06 (m, 2H), 9.36−9.42 (m, 2H), 9.45−9.47 (m, 1H), 9.51−9.52 (m, 1H), 9.58−9.60 (m, 1H), 9.99 (d, J = 4.8 Hz, 1H), 10.30 (s, 2H); LD-MS 688.1; FAB-MS obsd 690.9700, calcd 690.9708 ($C_{31}H_{25}N_4Br_3$); λ_{abs} (log ϵ) 406 (4.96), 503 (4.01) nm; λ_{em} (λ_{exc} 407 nm) 633, 700 nm.

5-(4-Bromophenyl)-15-[1,5-bis(dimethoxyphosphoryl)pent-3-yl]porphyrin (15b). A solution of **14b** (33 mg, 0.047 mmol) was dissolved in $P(OCH_3)_3$ (8.0 mL). The solution was refluxed under argon for 2.5 days. The $P(OCH_3)_3$ was evaporated. The residue was chromatographed [silica, CH_2Cl_2/MeOH (0→5%)] to yield a dark purple solid (26 mg, 72%): ^{1}H NMR δ −2.93 (s, 1H), −2.85 (s, 1H), 1.35−1.42 (m, 2H), 1.86−2.03 (m, 2H), 3.12−3.50 (m, 16H), 5.30−5.46 (m, 1H), 7.95 (d, J = 8.1 Hz, 2H), 8.12 (d, J = 8.1 Hz, 2H), 9.04−9.05 (m, 2H), 9.41−9.51 (m, 4H), 9.74−9.75 (m, 2H), 10.31−10.33 (m, 2H); LD-MS obsd 749.1 $(M - H)^-$; FAB-MS obsd 751.1454, calcd 751.1450 [$(M + H)^+$, $M = C_{35}H_{37}BrN_4O_6P_2$); λ_{abs} 406, 503 nm; λ_{em} (λ_{exc} 406 nm) 633, 699 nm. Varying amounts of a less polar purple solid (**15b-Br**) were isolated along with small amounts of the starting material **14b** (limited characterization). Data for **15b-Br**: ^{1}H NMR δ 0.74−0.99 (m, 2H), 3.14−3.41 (m, 6H), 3.45 (s, 3H), 3.49 (s, 3H), 3.69−3.80 (m, 2H), 5.63−5.63 (m, 1H), 7.95 (d, J = 7.5 Hz, 2H), 8.12 (d, J = 7.5 Hz, 2H), 9.04−9.05 (m, 2H), 9.39−9.42 (m, 2H), 9.49−9.52 (m, 2H), 9.69 (d, J = 4.2 Hz, 1H), 9.86 (d, J = 4.2 Hz, 1H), 10.31−10.32 (m, 2H); LD-MS obsd 718.3, calcd 720.1 ($C_{33}H_{31}Br_2N_4O_3P$); λ_{abs} 406, 502 nm; λ_{em} (λ_{exc} 406 nm) 633, 699 nm.

5-(4-Bromophenyl)-15-[1,5-bis(dihydroxyphosphoryl)pent-3-yl]porphyrin (16b). A solution of **15b** (11 mg, 0.015 mmol) in anhydrous $CHCl_3$ (2 mL) under argon was treated with TMS−Br (300 μL, 2.27 mmol). The sample was refluxed for 4 h. The mixture was concentrated, and the residue was dissolved in MeOH (3 mL). The mixture was stirred for 1 h. Evaporation of the solvent yielded a dark green solid, which was dissolved in dilute aqueous NaOH. Chromatography (C-18 silica, water/MeOH gradient) yielded a dark red solid (6.1 mg, 60%): ^{1}H NMR (D_2O) δ 0.88−0.97 (m, 2H), 1.70−1.84 (m, 2H), 2.96−3.08 (m, 2H), 3.09−3.24 (m, 2H), 5.21−5.33 (m, 1H), 6.80−6.87 (br, 2H), 7.26−7.38 (br, 2H), 7.91−7.95 (m, 2H), 8.36−8.40 (br, 1H), 8.52−8.61 (br, 1H), 9.35 (br, 1H), 9.48 (br, 1H), 9.62 (br, 1H), 9.82 (br, 1H), 9.95 (s, 1H), 10.03 (s, 1H); LD-

MS obsd 693.8, ESI-MS obsd 695.0 $(M + H)^+$, 717.0 $(M + Na)^+$, 348.0 $(M + 2H)^{2+}$, calcd 694.1 ($M = C_{31}H_{29}BrN_4O_6P_2$); λ_{abs} (H_2O) 400, 504 nm; λ_{em} (λ_{exc} 400 nm) 625, 687 nm; HPLC $t_R = 13.48$ min.

Zn(II) 5-(4-Bromophenyl)-15-[1,5-bis(dihydroxyphosphoryl)pent-3-yl]porphyrin (Zn16b). A solution of **15b** (18.9 mg, 0.025 mmol) in anhydrous $CHCl_3$ (2 mL) under argon was treated with TMS−Br (200 μL, 1.51 mmol). The reaction mixture was refluxed for 4 h. The volatile components were evaporated, and the residue was dissolved in MeOH (3 mL). The mixture was stirred for 1 h. The mixture was treated with aqueous NaOH (0.2 mL of 15 wt % solution). $Zn(OAc)_2 \cdot 2H_2O$ (125 mg, 0.57 mmol) was added, and stirring was continued for 1 h. The mixture was concentrated, treated with 0.1 mL of aqueous NaOH followed by 3 mL of water, and chromatographed [C-18 silica, water/MeOH (0→50%)], affording a deep purple solid (7.7 mg, 41%): ^{1}H NMR (D_2O) δ 0.72 (dd, $J_1 = 13.2$ Hz, $J_2 = 15.6$ Hz, 2H), 1.64 (dd, $J_1 = 14.4$ Hz, $J_2 = 14.1$ Hz, 2H), 2.96−3.22 (br, 4H), 5.36 (br, 1H), 7.65−7.74 (m, 4H), 8.76 (m, 2H), 9.17 (m, 1H), 9.49 (m, 1H), 9.53 (m, 1H), 10.01 (m, 1H), 10.09 (m, 1H), 10.14 (m, 1H), 10.20 (m, 1H); ESI-MS obsd 755.7 $(M + H)^+$, 380.2 $(M + 2H)^{2+}$, calcd 756.0 ($M = C_{31}H_{27}BrN_4O_6P_2Zn$); λ_{abs} 409, 542 nm; λ_{em} (λ_{exc} 409 nm) 589, 640 nm; HPLC $t_R = 9.86$ (17%), 15.51 (83%) min.

***meso*-Tetrakis[1,5-bis(*tert*-butyldimethylsilyloxy)pent-3-yl]porphyrin (17).** Following a standard procedure (*34*), a solution of **4** (360 mg, 1.00 mmol) and pyrrole (70.0 μL, 1.00 mmol) in $CHCl_3$ (100 mL) was treated with NaCl (1.46 g, 25.0 mmol). The mixture was flushed with argon for 10 min. The reaction was initiated with $BF_3 \cdot OEt_2$ (41 μL, 0.30 mmol). Stirring was continued overnight. DDQ (172 mg, 0.758 mmol) was added, and the reaction mixture was stirred for 1 h. The solvent was removed at reduced pressure. Chromatography [silica, hexanes/CH_2Cl_2 (1:1)] yielded a dark purple solid (41 mg, 10%): ^{1}H NMR δ −2.46 (br, 2H), −0.15 (s, 48H), 0.86 (s, 72H), 2.88−2.92 (m, 8H), 3.11−3.16 (m, 8H), 3.61−3.69 (m, 16H), 5.57 (m, 4H), 9.49 (m, 4H), 9.66 (m, 4H); ^{13}C NMR δ −0.00, 23.72, 31.45, 35.18, 45.22, 50.33 (br), 67.33, 116.15, 174.86; LD-MS 1631.9; FAB-MS obsd 1631.0, calcd 1631.1 ($C_{88}H_{166}N_4O_8Si_8$); λ_{abs} 421, 522 nm; λ_{em} (λ_{exc} 421 nm) 665, 732 nm.

Zn(II) *meso*-Tetrakis[1,5-bis(*tert*-butyldimethylsilyloxy)pent-3-yl]porphyrin (Zn17). A solution of **17** (20 mg, 0.012 mmol) in $CHCl_3$/MeOH (5 mL, 9:1) was treated with $Zn(OAc)_2 \cdot 2H_2O$ (100 mg, 0.5 mmol). The reaction mixture was stirred at room temperature for 2 h. The volatile components were evaporated. Chromatography (silica, CH_2Cl_2) afforded a dark red solid (15.6 mg, 78%): ^{1}H NMR δ −0.19 (s, 48H), 0.84 (s, 72H), 2.92−2.98 (m, 8H), 3.17−3.21 (m, 8H), 3.61−3.68 (m, 16H), 5.65 (m, 4H), 9.49 (m, 4H), 9.66−9.68 (m, 4H); LD-MS 1686.9; FAB-MS obsd 1695.0, calcd 1692 ($C_{88}H_{164}N_4O_8Si_8Zn$); λ_{abs} 422, 556 nm; λ_{em} (λ_{exc} 422 nm) 606, 657 nm.

16a−anti-CD3ϵ. A mixture of **16a** (1.50 mg, 2.17 μmol) and EDCI (4.13 mg, 21.6 μmol) in PBS (50 μL) was added to a solution of IgG1 anti-human CD3 intracellular ϵ-chain (clone UCHT) (*39*) (125 μg in 50 μL PBS). The reaction was allowed to proceed at room temperature for 2 h. PBS (2.4 mL) was added to the reaction mixture, and the conjugate was isolated by chromatography (PD-10 size exclusion column, 1 mL fractions, PBS). The antibody conjugate was characterized by sodium dodecyl sulfate−polyacrylamide gel electrophoresis in a 5% nonreducing gel giving a single red fluorescent band migrating at 150 kDa. Absorption spectroscopy comparing predominant absorption by the antibody ($\lambda_{280\ nm}$) and porphyrin absorption ($\lambda_{410\ nm}$) indicated an average labeling efficiency of approximately two porphyrins per antibody.

Biological Experiments. Jurkat cells (human T-cell lymphoma, ATCC no. TIB-152) and murine Lewis lung carcinoma (LLC) cells (ATCC no. CRL-1642) were cultured in RPMI with L-glutamine and $NaHCO_3$ supplemented with 10% heat inactivated fetal bovine serum and penicillin (100 U/mL) and streptomycin (100 μg/mL) (all from Sigma, St Louis, MO) at 37 °C in a 5% CO_2 humidified atmosphere in 75 cm^3 tissue culture flasks (BD Falcon, Franklin Lakes, NJ). On the day of the experiment, when cells reached 80% confluence, the cells were washed with phosphate-buffered saline (PBS). The LLC cells were harvested with 2 mL of 0.25% trypsin−EDTA solution (Sigma), centrifuged, and counted with a hemocytometer, then resuspended in Cytofix/Cytoperm solution (BD Biosciences) and incubated for 30−40 min at 4 °C to permeabilize the membranes. The cells were washed twice in perm/wash buffer (BD Biosciences) and incubated at room temperature for 20−30 min with porphyrin conjugate **16a−anti-CD3ϵ** or a control antibody, FITC-conjugated anti-CD3ϵ IgG1 or FITC-conjugated IgG1 isotype (Sigma). Control cells were incubated with nothing. After incubation, cells were washed twice with perm/wash buffer. Flow cytometry analysis was performed using a FACSCalibur flow cytometry instrument (BD Biosciences) with laser excitation at 488 nm. Fluorescence emission was counted in several channels including FL1 (530 ± 30 nm) and FL3 (670-nm long pass) channels. For fluorescence microscopy, cells were seeded on glass slides by centrifugation and then analyzed with an Axiophot microscope (Carl Zeiss Inc, Thornwood, NY) fitted with a Spot camera and RT software, v 3.5 (Diagnostic Instruments, Stirling Heights, MI). Images were captured with a 40× objective and filter sets: FITC excitation 480−500 nm, emission 520−580 nm; rhodamine excitation 480−500 nm, emission 635-nm long pass.

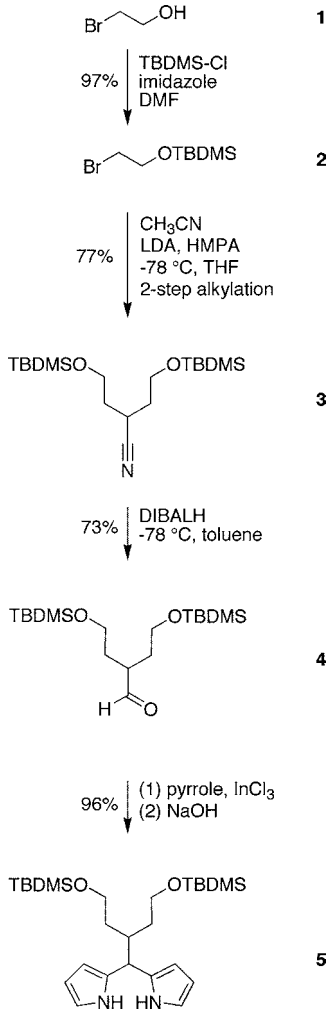
RESULTS AND DISCUSSION

1. Synthesis. The target porphyrins are of the *trans*-AB-type, bearing one swallowtail substituent, one bioconjugatable group, and no substituents at the flanking meso positions (Chart 2). We recently developed two rational routes to *trans*-AB-porphyrins: (1) reaction of a 1,9-bis(*N*,*N*-dimethylaminomethyl)-dipyrromethane and a dipyrromethane in the presence of zinc acetate in ethanol followed by oxidation with DDQ (*46*) and (2) reaction of a 1,9-bis(imino)dipyrromethane and a dipyrromethane in the presence of zinc acetate in ethanol (*42*). Both routes directly afford zinc porphyrins; the latter method was employed herein. The dipyrromethanes bearing appropriate substituents for preparing the target porphyrins are available via a one-flask reaction of an aldehyde and excess pyrrole (*39*).

A. Dipyrromethanes. The synthesis of a dipyrromethane bearing a swallowtail diol is shown in Scheme 1. The synthesis begins with 2-bromoethanol. Some early intermediates in the synthesis have been described in the literature but without complete characterization data (*41*). The complete synthesis is described as follows.

2-Bromoethanol (**1**) was protected by reaction with *tert*-butyldimethylsilyl chloride (TBDMS−Cl) in a mixture of imidazole and DMF. Aqueous workup followed by bulb-to-bulb distillation afforded the TBDMS-protected species **2** in 97% yield. A swallowtail nitrile was described by de Groot as a side-

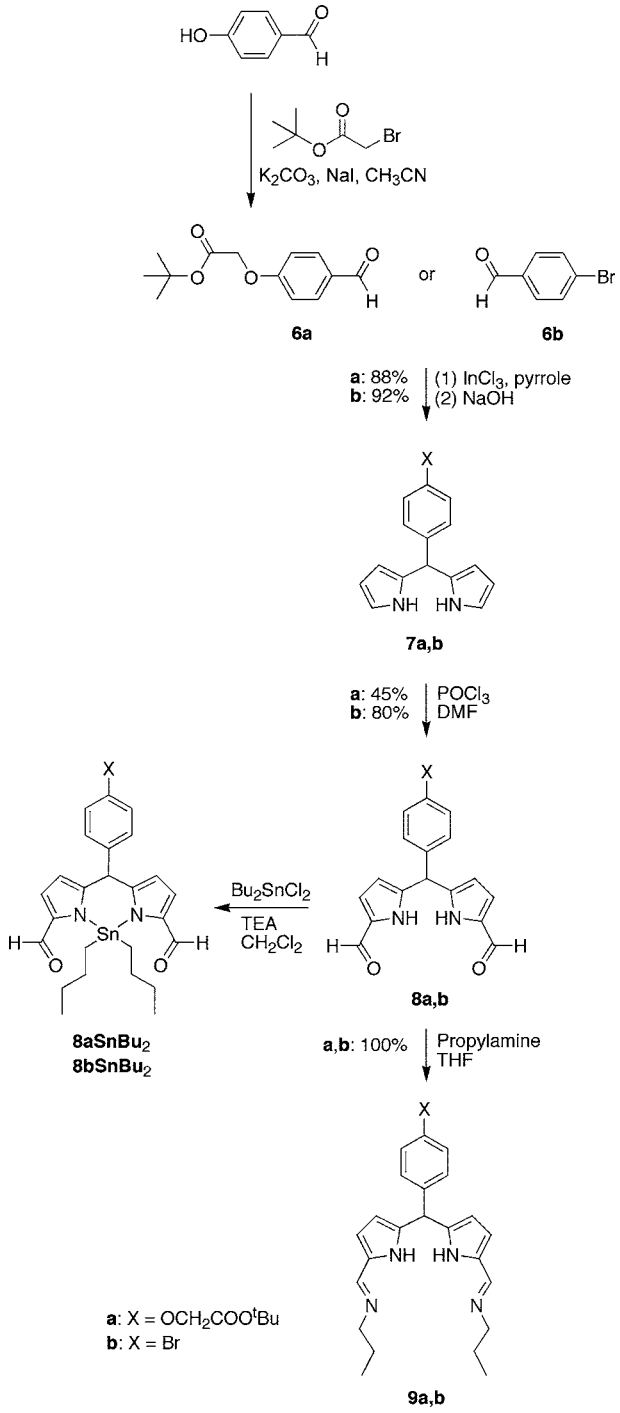
Scheme 1



product in the alkylation of acetonitrile (*41*). We modified the de Groot method by changing the ratios of reactants and by performing sequential alkylation in a two-step one-flask process. Thus, treatment of acetonitrile with LDA in the presence of HMPA followed by alkylating agent **2** and repetition of this deprotonation/alkylation sequence afforded the dialkylated nitrile as the major product. Silica column chromatography gave **3** in 77% yield, along with mono- and trialkylated nitriles and a small amount of recovered **2**. Reduction of **3** with DIBALH at −78 °C in toluene gave **4** in 73% yield. Aldehyde **4** reacted with excess pyrrole in the presence of $InCl_3$ to give the 5-substituted dipyrromethane **5** in 96% yield as a pale yellow, viscous oil.

The bioconjugatable site was constructed from 4-hydroxybenzaldehyde by O-alkylation with *tert*-butyl bromoacetate. The alkylation proceeded smoothly in anhydrous acetonitrile in the presence of potassium carbonate and a catalytic amount of sodium iodide, affording **6a** as a white, crystalline solid in excellent yield. The aldehyde **6a** was reacted with excess pyrrole in the presence of $InCl_3$ followed by silica column chromatography to give dipyrromethane **7a** as a pale yellow, viscous liquid in 88% yield (Scheme 2). Vilsmeier formylation of **7a** followed by basic workup and chromatography on neutral alumina gave the 1,9-diformyldipyrromethane **8a**. Yields were generally low (25−45%), presumably because of the sensitivity of the *tert*-butyl ester to the formylation conditions. For characterization purposes, the dibutyltin complex, **8aSnBu**$_2$, was prepared by derivatization of **8a** with dibutyltin dichloride in a standard reaction (*43*). A similar sequence of reactions led from 4-bromobenzaldehyde (**6b**) via the dipyrromethane **7b** (*45*) to 1,9-diformyldipyrromethane **8b**. Yields were comparable to those

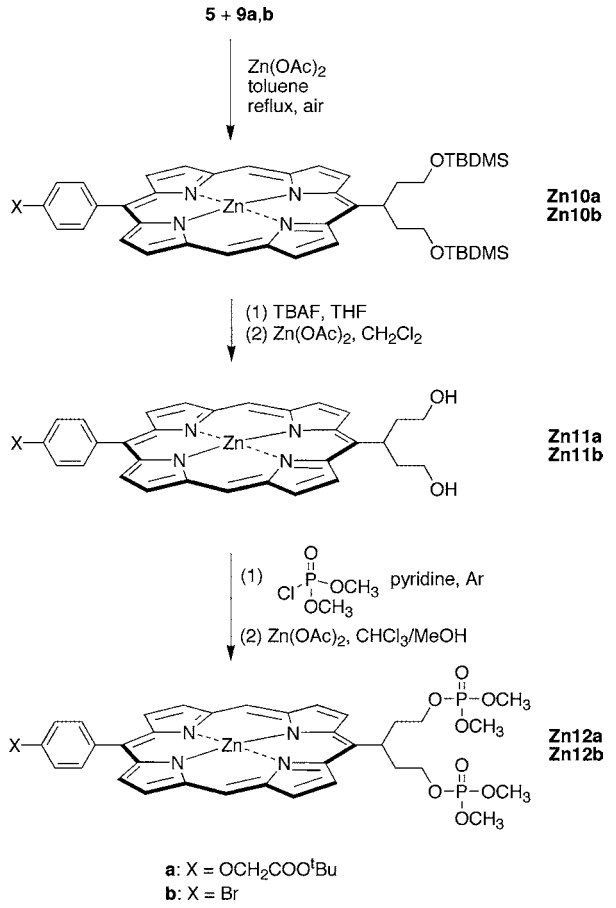
Scheme 2



obtained for the *tert*-butyl ester derivatives, with the exception of the Vilsmeier formylation, which proceeded in excellent yield. Treatment of **8a** or **8b** with excess propylamine at room temperature quantitatively afforded the bis-imine **9a** or **9b**, respectively.

B. Porphyrin Diphosphates. The condensation of the swallowtail dipyrromethane **5** and the bis(imino)dipyrromethane **9a** or **9b** was carried out in the presence of a 10-fold excess of anhydrous zinc acetate in refluxing dry toluene open to the air (Scheme 3). In the original publication (*42*), ethanol was the solvent of choice for porphyrin formation. Ethanol proved to be an excellent solvent for the synthesis of the 4-bromophenyl-substituted zinc porphyrin (**Zn10b**), affording the desired product in 24−27% yield. However, under the same conditions only very small amounts of **Zn10a** were isolated. The main

Scheme 3

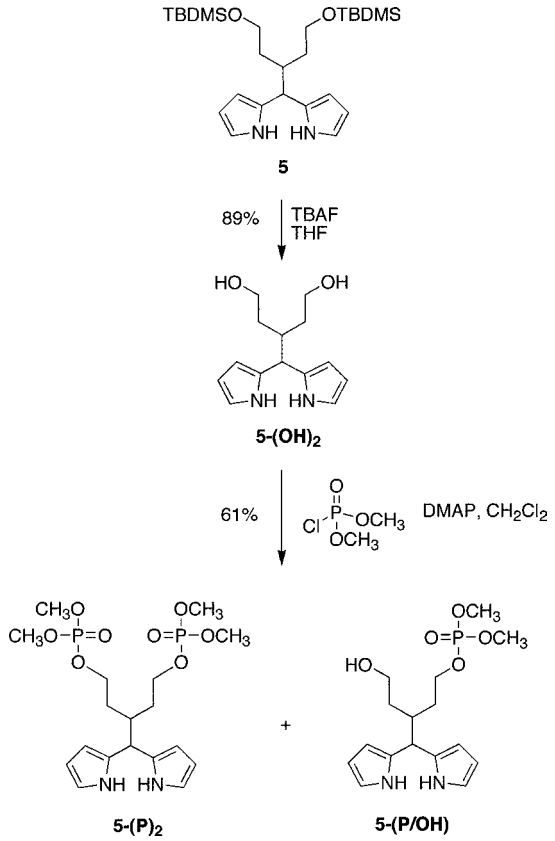


side reaction was hydrolysis of the *tert*-butyl ester. Also, some transesterification by the solvent occurred (either directly or via the free acid), as shown by LD-MS analysis of the crude reaction mixture and by ^{1}H NMR analysis of the pure porphyrin. Therefore, small-scale trial reactions were carried out in a number of solvents to find a substitute for ethanol. The use of chloroform resulted both in very low yields and in extensive scrambling (i.e., formation of other porphyrin products owing to fragmentation of dipyrromethane units and subsequent undesired recombination processes). Upon reaction in dry toluene, scrambling was not observed, and both **Zn10a** and **Zn10b** could be isolated after straightforward silica column chromatography. Treatment of **Zn10a** or **Zn10b** with TBAF in THF cleaved the TBDMS protecting groups and also caused some demetalation of the zinc porphyrin, in each case affording a mixture of the zinc chelate and the free base porphyrin as shown by LD-MS. Remetalation with zinc acetate followed by chromatography on neutral alumina gave the zinc porphyrin diol **Zn11a** or **Zn11b** in >80% yield. It was important to limit the reaction time for conversion of **Zn10a** to **Zn11a**, because prolonged exposure under these conditions resulted in hydrolysis of the *tert*-butyl ester group.

Porphyrin diols **Zn11a** and **Zn11b** are highly polar and are only sparingly soluble in most organic solvents. Reaction of **Zn11a** with dimethyl chlorophosphate in anhydrous pyridine gave no **Zn12a**, whereas similar reaction with **Zn11b** gave a very low yield of **Zn12b**. The poor yields are presumably due to the combination of low solubility and low reactivity on the part of the porphyrin diol starting materials. We assumed that incorporation of the dimethoxyphosphoryl groups at an earlier stage could provide a more efficient process.

Our attempts to introduce the phosphate groups to aldehyde **4** were unsuccessful. Phosphorylation of the hydroxy groups

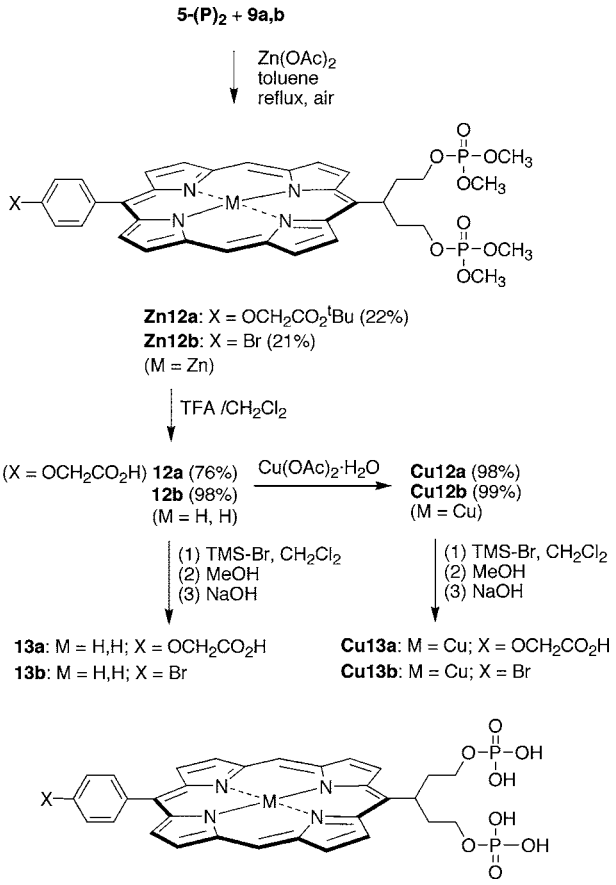
Scheme 4



of aldehyde **4** appeared attractive, but deprotection of **4** afforded the monocyclic hemiacetal and the bicyclic acetal of the corresponding 3-formylpentane-1,5-diol as an approximately 1:2 equilibrium mixture. None of the free diol was observed by ^{1}H NMR spectroscopy. Therefore, the phosphate groups were introduced at the dipyrromethane stage (Scheme 4). Treatment of the TBDMS-protected swallowtail dipyrromethane **5** with TBAF in THF at room temperature resulted in cleavage of the protecting groups. Aqueous−organic workup followed by chromatography on neutral alumina gave the dipyrromethane diol **5-(OH)$_2$** as a pale yellow oil in 89% yield. The dipyrromethane diol **5-(OH)$_2$** was reacted with dimethyl chlorophosphate in anhydrous CH_2Cl_2 to give the bis(dimethoxyphosphoryloxy)dipyrromethane **5-(P)$_2$** as a yellow oil in 61% yield. The monophosphate derivative **5-(P/OH)** was also isolated (20−30% yield) and could be transformed to **5-(P)$_2$**. Alternatively, **5-(P/OH)** could prove useful if a second functional group is to be introduced into the swallowtail moiety.

Reaction of **5-(P)$_2$** with bis-imine **9a** or **9b** in anhydrous toluene in the presence of zinc acetate furnished the corresponding zinc porphyrin **Zn12a** or **Zn12b** in ∼15% yield (Scheme 5). The spectroscopic yields of **Zn12a** and **Zn12b** were higher (30−45%) than the isolated yields. Two problems were encountered in handling the porphyrin diphosphate compounds **Zn12a** and **Zn12b**: (1) hydrolysis of the phosphates during purification, and (2) hydrolysis of the phosphates during "standard" conditions for methyl ester hydrolysis (*47, 48*). A lengthy series of experiments indicated that the loss of phosphate was facilitated by the presence of the centrally coordinated zinc atom (see Supporting Information for experiments and results). In summary, zinc porphyrins bearing phosphate-terminated swallowtail groups were not obtained for the pent-3-yl groups examined. Accordingly, we turned our attention to free base and copper analogues of the porphyrin diphosphates. Copper is strictly four-coordinate and was not expected to facilitate phosphate hydrolysis.

Scheme 5



The free base porphyrins **12a** and **12b** were prepared by demetalation of **Zn12a** and **Zn12b**, respectively, by treatment with a 1:1 mixture of TFA and CH_2Cl_2. The demetalation was essentially complete within 15 min (as determined by absorption spectroscopy), but **Zn12a** was allowed to react further to allow for the quantitative cleavage of the *tert*-butyl ester. The resulting free base porphyrins **12a** and **12b** maintained the phosphate protecting groups although **12a** contained a free carboxylic acid. Treatment of **12a,b** with copper acetate afforded the corresponding copper porphyrins (**Cu12a,b**). Compounds **Cu12a** and **Cu12b** were characterized by LD-MS, FAB-MS, and absorption spectroscopy (but not ^{1}H NMR spectroscopy because of the broadened spectra of copper porphyrins).

Cleavage of the phosphate protecting groups in the free base porphyrins (**12a,b**) and copper porphyrins (**Cu12a,b**) was carried out using TMS−Br. Porphyrin **12b** reacted smoothly with a slight excess of TMS−Br in dry CH_2Cl_2 at room temperature. Subsequent treatment with aqueous NaOH and reversed-phase column chromatography yielded the desired porphyrin diphosphate **13b** in excellent yield. The carboxylate-functionalized **12a** required a larger excess of TMS−Br, whereupon the desired fully deprotected carboxy-porphyrin diphosphate **13a** was obtained in 76% yield, along with a second fraction containing fully deprotected **13a** and monomethyl-**13a**. Increasing the amount of TMS−Br, the reaction time, or the temperature resulted in conversion of **12a** to the dibromo-substituted **14a**.

It is noteworthy that the copper complexes were only partially deprotected by the same amount of TMS−Br as used for the corresponding free base porphyrins. ESI-MS showed the dimethyl and monomethyl **Cu13a,b** as the major products. Increasing the amount of TMS−Br resulted in almost complete demetalation and a reduction in the deprotection yield. Small quantities of **Cu13a** and **Cu13b** could be isolated, but the samples were only partially characterized. Moreover, neither

Scheme 6

Zn16b	Br	Zn

diol **11a** nor **11b** (nor copper chelates thereof) was observed by LD-MS or ESI-MS during the deprotection reaction, by contrast with the case of the zinc chelates (**Zn12a,b** and **Zn13a,b**) where central metal atom coordination promoted hydrolysis. In summary, the free base and copper porphyrin diphosphates were prepared without the complications of loss of phosphate encountered with the corresponding zinc chelates.

C. Porphyrin Diphosphonates. For in vivo studies, the phosphate groups may be susceptible to cleavage by phosphatases. Therefore, porphyrin diphosphonates, which are stable to phosphatases, were prepared from the porphyrin diols **Zn11a** and **Zn11b** (Scheme 6). Montforts has reported the conversion of a porphyrin alcohol to the corresponding bromide upon reaction with CBr_4 and triphenylphosphine (*44*). Similar treatment of a thoroughly dried sample of **Zn11a** or **Zn11b** in anhydrous CH_2Cl_2 with CBr_4 at 0 °C followed by excess triphenylphosphine afforded the corresponding free base dibromo-porphyrin **14a** or **14b** in excellent yield. During the chromatographic purification of the products, a very nonpolar bluish-green compound was isolated, in addition to the desired **14a** or **14b**. This compound was not characterized due to lack of material (<1 mg) and its instability, but absorption spectroscopy suggested that it was a chlorin species (λ_{abs} 414, 641 nm). It is possible that the triphenylphosphine could reduce one of the porphyrin pyrrole rings, giving rise to the chlorin. Refluxing **14a** or **14b** in neat $P(OCH_3)_3$ under an inert

atmosphere for 36 h afforded **15a** or **15b** in moderate to good yield as a dark red solid. The reaction also produced the intermediate monobromo, monophosphonate porphyrins (**15a-Br**, **15b-Br**). Although conditions have been optimized for the production of **15a** and **15b**, it is possible that the intermediates could be obtained in good yields and serve as starting points for the introduction of two different polar groups into one molecule.

The cleavage of the phosphonate protecting groups (and the *tert*-butyl ester for **15a**) was investigated by treatment of **15a** or **15b** with TMS−Br beginning with the conditions we had employed earlier for cleaving porphyrin phosphonates (*49*, *50*). The phosphonate groups are more robust than phosphate groups (vide supra) and will tolerate use of excess reagent at higher temperature for prolonged reaction times. The use of excess TMS−Br in refluxing chloroform under argon gave good results, affording the free acids after methanolysis of the silyl intermediates. The resulting green solids were insoluble in a number of organic solvents and water. Addition of small quantities of dilute aqueous base (NaOH or $NaHCO_3$) rendered the porphyrins water-soluble. Treatment of the basic porphyrin solutions (prior to purification) with zinc acetate resulted in formation of the corresponding zinc chelates. Purification of each free base or zinc porphyrin was achieved by reversed-phase column chromatography upon elution with water/methanol. Removal of the solvent followed by freeze-drying of the aqueous samples yielded the desired porphyrin (**16a**, **16b**, **Zn16a**, and **Zn16b**) in good to excellent yield.

2. Characterization and Water Solubility. All of the hydrophobic porphyrins were analyzed by LD-MS, FAB-MS, ^{1}H NMR spectroscopy (except copper chelates), and absorption and emission spectroscopy. In certain cases O*H*, N*H*, and COO*H* signals were not observed owing to broadening, exchange with the solvent, or coincidence with the solvent peak. All of the deprotected porphyrin diphosphates and porphyrin diphosphonates were characterized by ^{1}H NMR spectroscopy, ESI-MS, and absorption and emission spectroscopy. Each ESI-MS spectrum exhibited a strong peak due to the parent molecule (protonated and sodium adduct in the positive-ion mode; deprotonated in the negative-ion mode), with no peaks owing to partially deprotected porphyrins. Each deprotected free base porphyrin sample was found to be homogeneous upon examination by reversed-phase HPLC, while the zinc chelates eluted as two separate peaks. The front peak (minor) had the same t_R as the corresponding free base porphyrin. Because the elution mixture contains TFA, partial demetalation during chromatography is likely. The free base porphyrins were not observed by ESI-MS, ^{1}H NMR spectroscopy, or absorption or emission spectroscopies (see Experimental Procedures section).

All of the porphyrin diphosphates and porphyrin diphosphonates examined herein were readily soluble in water across a wide pH range and exhibited sufficient solubility to enable ^{1}H NMR measurements in D_2O. Although good-quality ^{1}H NMR spectra were obtained at room temperature, the resolution increased substantially upon increasing the temperature to 60 °C. The higher temperature also enabled observation of the OCH_2 signal in the carboxylic acid, which at room temperature was coincident with the water signal. gCOSY experiments carried out on the porphyrin diphosphonates enabled the partial assignment of the signals.

Determination of the upper limit of water solubility was not possible given the amount of material in hand and the relatively high solubility encountered. Indeed, in each case examined, 8−10 mg of pure porphyrin (**13a**, **13b**, **16a**, **16b**, **Zn16a**, **Zn16b**) completely dissolved in 500 μL of distilled water, consistent with a concentration of ≥20 mM. The aqueous solutions are stable for days at room temperature when shielded from the light. Precipitation was not observed either with the naked eye or by absorption spectroscopy.

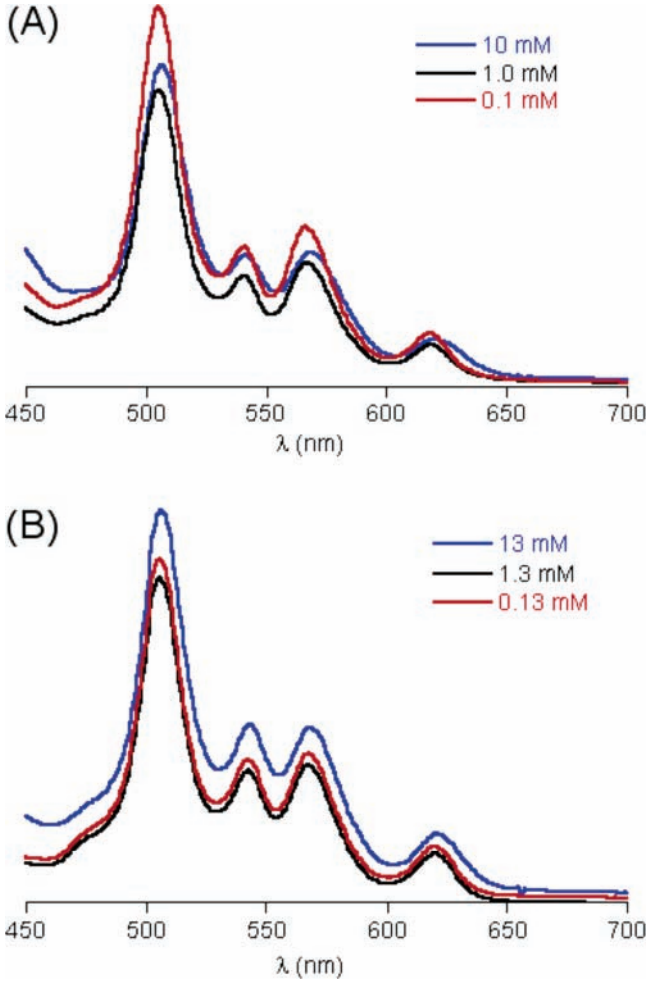

Figure 2. (A) Absorption spectra of porphyrin **16b**: (blue) $c \approx 10$ mM, $l = 0.1$ mm; (black) $c \approx 1$ mM, $l = 1$ mm; (red) $c \approx 0.1$ mM, $l = 10$ mm. (B) Absorption spectra of porphyrin **13a**: (blue) $c = 13$ mM, $l = 0.1$ mm; (black) $c = 1.3$ mM, $l = 1$ mm; (red) $c = 0.13$ mM, $l = 10$ mm.

A standard method for the detection of aggregation of porphyrin solutions is based on the comparison of absorption spectra at different concentrations. In the absence of aggregation, the absorption spectrum recorded at concentration c_1 and path length l_1 should be unaltered upon 10-fold dilution and simultaneous increase of l_1 to $10l_1$. For this purpose, a stock solution of each of the least polar water-soluble porphyrin (**16b**) and the most polar water-soluble porphyrin (**13a**) was prepared. The concentration ([**16b**] ≈ 10 mM, [**13a**] = 13.4 mM) was such that $A \approx 0.6$ for the visible absorption band near 505 nm. Then aliquots of both samples were diluted by 10-fold and 100-fold, and the absorption spectrum was recorded for each sample. For the most concentrated sample of **16b**, peak broadening in the 450−700 nm region indicated some aggregation at a concentration of ~10 mM. The absorption spectra of the 1 mM and the 0.1 mM samples were not broadened, consistent with a nonaggregated sample at these concentrations (Figure 2A). By contrast, no band broadening was observed for **13a** over a concentration of 0.13−13.4 mM (Figure 2B).

3. Structural Studies. The success of the hydrocarbon swallowtails in the lipophilization of extended aromatic systems has been explained by projection of the alkyl groups above and below the plane of the macrocycle, which prevents $\pi-\pi$ stacking and aggregation (Figure 1). Molecular mechanics calculations were carried out on a series of swallowtail por-

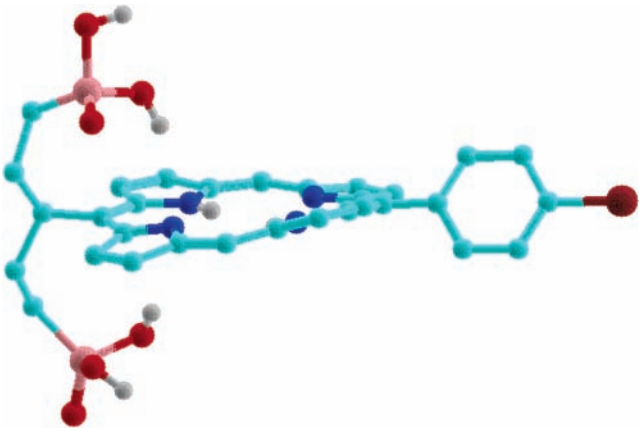

Figure 3. MMX-calculated gas-phase geometry of porphyrin **16b** bearing dimethoxyphosphoryl end groups. Hydrogens on carbons are omitted for clarity.

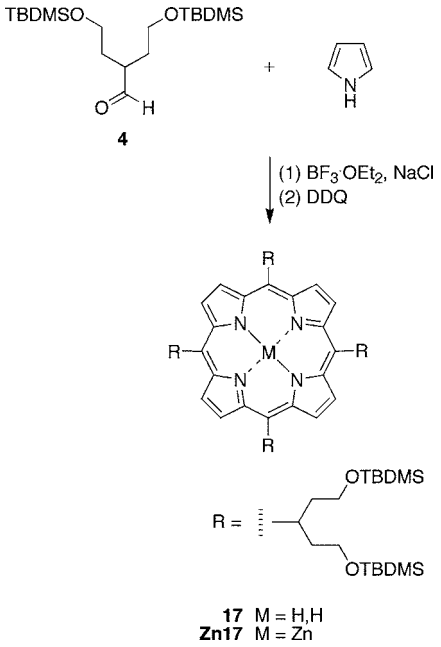
Scheme 7



phyrins wherein the swallowtail substituents were hydrophobic or terminated with polar substituents, including neutral or ionic groups. In all cases, the calculated geometries showed the projection of the substituents above and below the plane of the macrocycle. The geometry calculated for an ionic-functionalized swallowtail porphyrin is shown in Figure 3.

We carried out ^{1}H NMR studies (1 and 2D NMR, VT NMR) of a series of swallowtail porphyrins that were synthesized in this work as well as a porphyrin bearing a single hydrocarbon swallowtail group (*34*) to gain further insight concerning conformation of the swallowtail groups. An A_4-swallowtail porphyrin (**17**) was synthesized from **4** upon condensation with pyrrole via a standard procedure (*34*) followed by oxidation with DDQ. The corresponding chelate, **Zn17**, was prepared by metalation with zinc acetate (Scheme 7). The results are as follows.

The ^{1}H NMR spectrum of each A_4-swallowtail porphyrin in $CDCl_3$ (**17** and **Zn17**) contains two broad apparent singlets (~9.67 and ~9.49 ppm) in the aromatic region each with integration of 4. For an A_4-porphyrin with four magnetically equivalent substituents, the eight β-protons would resonate as *one* singlet in the aromatic region with an integration of eight. The signal corresponding to the CH protons of the swallowtail motifs (the branch site $C^{1'}H$) appears as a broad, structureless

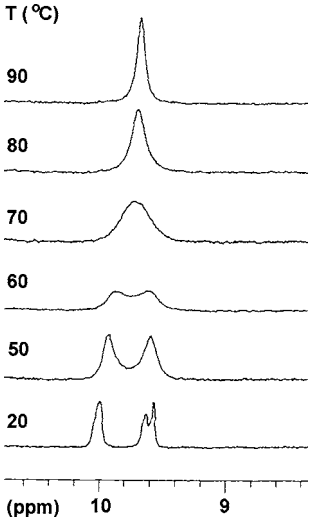


Figure 4. Changes in the β-proton signals in porphyrin **17** with increasing temperature.

multiplet (~5.56 ppm). NOESY experiments revealed that the two types of aromatic protons giving rise to the broad apparent singlets were closely juxtaposed and also that the one giving rise to the 9.67 ppm signal is close to $C^{1'}H$ (see Supporting Information). The spectra are consistent with restricted motion of the swallowtail substituent at the site of attachment to the porphyrin.

At room temperature in toluene-d_8, the spectrum of **17** was similar to that recorded in $CDCl_3$, although the signal at higher field consisted of two overlapping broad singlets. Increasing the temperature resulted in the broadening of the two aromatic signals (9.60 and 9.93 ppm). At ~70 °C, the two signals collapsed into one broad singlet (9.77 ppm), which eventually became a sharp singlet (9.72 ppm, 90 °C) with an integration of 8 (Figure 4). A similar but less pronounced sharpening was observed for the broad singlet at −1.72 ppm (NH) and the multiplet of $C^{1'}H$ (5.88 ppm) (see Supporting Information). The spectra at elevated temperature are consistent with a dynamic averaging on the NMR time scale of the conformation at the swallowtail branching site. On the basis of a coalescence temperature of 60 or 70 °C, an energy of activation of 68 or 70 kJ/mol is calculated for rotation of the swallowtail motif about the porphyrin meso carbon and the branch carbon $C^{1'}$.

The *trans*-AB-porphyrins examined (**Zn10b** and **Zn12b**) have nominally lower symmetries than the A_4-porphyrins **17** and **Zn17**. A *trans*-AB-porphyrin with simple A and B substituents is expected to exhibit signals in the aromatic region stemming from the four distinct porphyrin β-positions and the unsubstituted meso position. However, the ^{1}H NMR spectra of all swallowtail *trans*-AB-porphyrins (**Zn10a,b**−**Zn12a,b**, **12a,b**−**16a,b**, and **Zn16a,b**) studied in this work were more complex. Typically, two separate meso-proton signals were observed (at ~10.0 and 10.1 ppm). The four β-protons on the pyrrole units flanking the swallowtail substituents gave four doublets: a pair around 9.7 and 9.5 ppm with different coupling constants, and a pair at ~9.30 ppm (overlapping). In one case examined (**Zn12b**), increasing the temperature again simplified the spectrum, whereupon (1) the two meso-proton signals collapsed into one singlet (~100 °C, δ 10.03 ppm) and (2) the doublets corresponding to the two protons flanking the swallowtail group broadened out and moved closer to each other, although in the available temperature range (up to 100 °C) the doublets remained separate signals. Similarly to the A_4-porphyrin, NOESY experiments on **Zn12b** showed the proximity between $C^{1'}H$ and one of either swallowtail-flanking β-pyrrolic protons. Two of the four $C^{2'}H_2$ protons are pointing toward the other

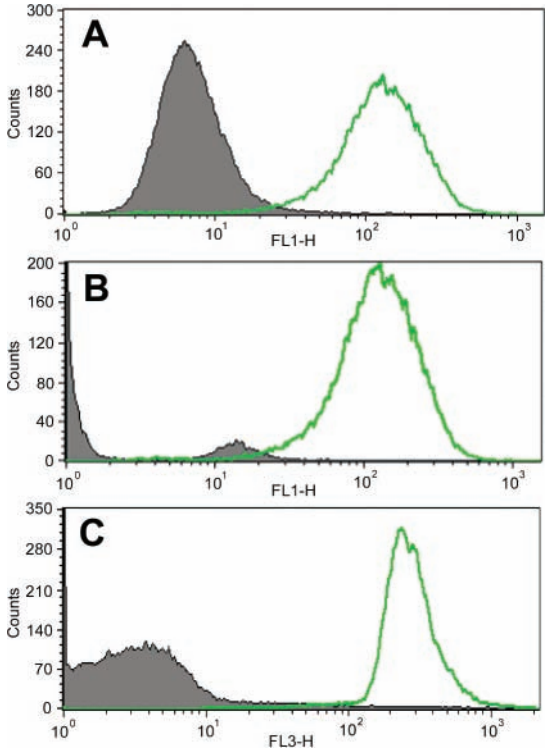

Figure 5. FACS analysis histograms: (A) green fluorescence (FL1) obtained with Jurkat cells stained with FITC−anti-CD3ϵ (open curve) or FITC isotype IgG1 (shaded curve); (B) green fluorescence obtained with Jurkat cells (open curve) or LLC cells (shaded curve) stained with FITC−anti-CD3ϵ; (C) red fluorescence (FL3) obtained with Jurkat cells (open curve) or LLC cells (shaded curve) stained with **16a**−**anti-CD3ϵ**.

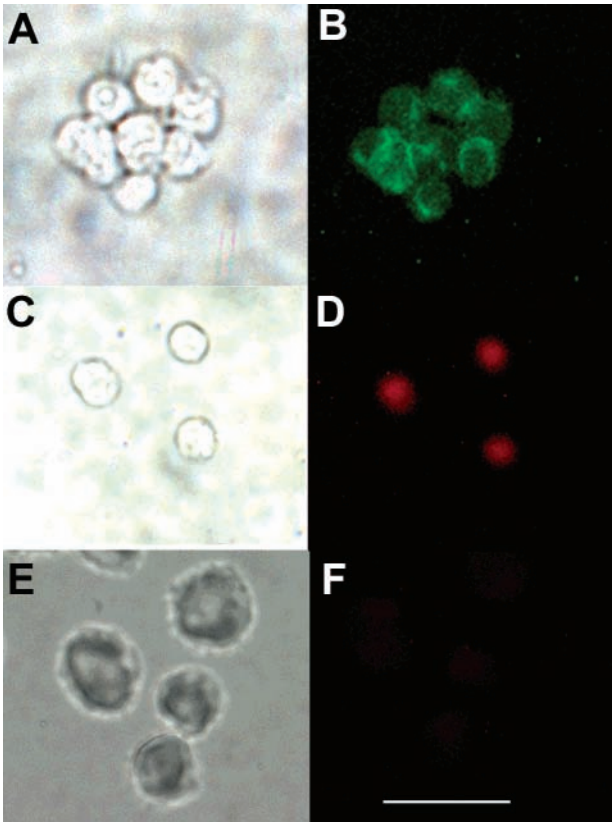

Figure 6. Fluorescence microscopy. The top panel shows Jurkat cells stained with FITC−anti-CD3ϵ under (A) bright field illumination or (B) green fluorescence detection. The middle panel shows Jurkat cells stained with **16a**−**anti-CD3ϵ** under (C) bright field illumination or (D) red fluorescence detection. The bottom panel shows LLC cells stained with **16a**−**anti-CD3ϵ** under (E) bright field illumination or (F) red fluorescence detection. The scale bar is 50 μm.

swallowtail-flanking β-proton (see Supporting Information). NOESY experiments carried out on a porphyrin bearing a single all-hydrocarbon swallowtail group (*34*) indicated a similar configuration.

These results suggest that the swallowtail alkyl groups not only preferentially occupy positions out-of-plane with the porphyrin ring but at room temperature are hindered in their rotation around the carbon−carbon single bond between the porphyrin meso position and the swallowtail branching site (i.e., $C^5-C^{1\prime}H$). The $C^{1\prime}H$ is more or less in the plane of the porphyrin macrocycle. This conformation results in the two sets of β-protons and the two different meso-proton signals. At increased temperature, the rotational barrier is more easily surmounted and the time-averaged C_2 symmetry of the porphyrin is restored. This geometry undoubtedly helps suppress cofacial interaction between porphyrin molecules at room temperature, thereby increasing solubility. The results of the NMR experiments are consistent with previous observations obtained via EPR spectroscopy (*34*) and provide additional evidence concerning the conformation of the swallowtail porphyrins in solution.

4. Bioconjugation Studies. The availability of water-soluble porphyrins each bearing a single bioconjugatable tether opens a number of applications in the life sciences. The porphyrin carboxylate **16a** was used to label a monoclonal antibody (IgG). The labeling was carried out in aqueous solution using the water-soluble carbodiimide reagent EDCI. Purification was achieved in aqueous solution via size exclusion chromatography. Absorption spectroscopy of the purified conjugate (**16a-anti**−**CD3ϵ**) indicated an average loading of two porphyrins per antibody. It is noteworthy that no precipitation was observed during conjugation or purification or on standing during the three-week period over which biological experiments were carried out.

The performance of the conjugate was examined for staining an intracellular epitope using both flow cytometry and fluorescence microscopy. The use of dye-tagged monoclonal antibodies for staining both extracellular and intracellular epitopes is well established. In the present case, we employed the human T-cell lymphoma cell line, Jurkat cells, for which monoclonal antibodies (and FITC-labeled analogues) against the CD3ϵ chain are available. The flow cytometry results upon intracellular staining are shown in Figure 5. Panel A demonstrates that Jurkat cells bind anti-CD3ϵ but do not bind IgG1 isotype control, thus confirming the expression of intracellular CD3ϵ on Jurkat cells and the lack of Fc receptors that can nonspecifically bind IgG molecules via Fc regions. Panel B demonstrates that the epithelial cancer cells LLC do not bind FITC−anti-CD3ϵ, consistent with their known lack of T-cell receptors. Panel C shows that Jurkat cells bind porphyrin conjugate **16a**−**anti-CD3ϵ** in an analogous fashion to the commercially available FITC−anti-CD3ϵ, thereby showing that porphyrin conjugation did not adversely affect the antigen recognition domain of the antibody. The TCR-negative LLC cells are also negative to **16a**−**anti-CD3ϵ**, thereby demonstrating the lack of any non-bound porphyrin present in the conjugate preparation that could have also bound nonspecifically to receptor-negative cells.

The specificity and functionality of the porphyrin conjugate **16a**−**anti-CD3ϵ** was assessed by fluorescence microscopy as shown in Figure 6. Panels A and B show the green fluorescence staining of Jurkat cells with FITC−anti-CD3ϵ. Panels C and D show the red fluorescence staining of Jurkat cells with the porphyrin conjugate **16a**−**anti-CD3ϵ**. Note that while the pattern of porphyrin staining is equally specific for target cells as the FITC counterpart, the subcellular pattern is somewhat different and appears to be more concentrated in the middle of the cell

for unknown reasons. Panels E and F show that the receptor-negative LLC cells give no red staining with **16a**−**anti-CD3ϵ**, a result that is consistent with the FACS data reported above.

OUTLOOK

A compact water-solubilizing motif has been developed for use with porphyrinic macrocycles. The water-solubilizing motif consists of a short, branched alkyl chain ("swallowtail") with polar end groups (phosphate, phosphonate) and does not include any aryl moieties. Incorporation of only one such swallowtail motif (based on a 1,5-disubstituted pent-3-yl group) at the meso position suffices to impart high aqueous solubility (≥20 mM) to a *trans*-AB-porphyrin, where the other meso substituent consists of a bioconjugatable group. The alkyl groups project above and below the hydrophobic porphyrinic macrocycle, thereby suppressing cofacial aggregation. The versatile synthetic chemistry for manipulating swallowtail substituents should facilitate their use as compact water-solubilizing motifs with a variety of porphyrinic macrocycles. The ability to carry out bioconjugations in aqueous solution is exceptionally valuable for use with diverse biomolecules. The requirement for only one swallowtail motif to achieve water solubility opens up a great deal of latitude in the design of porphyrinic-based molecular architectures for diverse applications in the life sciences.

ACKNOWLEDGMENT

This work was supported by the NIH (Grant GM36238 to J.S.L. and Grant CA/AI838801 to M.R.H.). Mass spectra were obtained at the Mass Spectrometry Laboratory for Biotechnology at North Carolina State University. Partial funding for the facility was obtained from the North Carolina Biotechnology Center and the NSF.

Supporting Information Available: Description of experiments concerning the hydrolytic lability of zinc porphyrin diphosphates, VT-NMR data for **Zn12b** and **17**, NOESY data for **Zn12b** and **17**, and evidence concerning water solubility of **Zn16b**. Numerous previously uncharacterized molecules resident within the low molecular weight circulatory proteome may provide a picture of the ongoing pathophysiology of an organism. Recently, proteomic signatures composed of low molecular weight molecules have been identified using mass spectrometry combined with bioinformatic algorithms. Attempts to sequence and identify the molecules that underpin the fingerprints are currently underway. The finding that many of these low molecular weight molecules may exist bound to circulating carrier proteins affords a new opportunity for fractionation and separation techniques prior to mass spectrometry-based analysis. In this study we demonstrate a method whereby nanoporous substrates may be used for the facile and reproducible fractionation and selective binding of the serum-based biomarker material, including subcellular proteins found within the serum. Aminopropyl-coated nanoporous silicon, when exposed to serum, can deplete serum of proteins and yield a serum with a distinct, altered MS profile. Additionally, aminopropyl-coated, nanoporous controlled-pore glass beads are able to bind a subset of serum proteins and release them with stringent elution. The eluted proteins have distinct MS profiles, gel electrophoresis profiles, and differential peptide sequence identities, which vary based on the size of the nanopores. These material surfaces could be employed in strategies for the harvesting and preservation of labile and carrier-protein-bound molecules in the blood.

INTRODUCTION

Since the introduction of the microscope along with laboratory methods revolutionized medical pathology practice, technologic advancement has unveiled increasingly sensitive and insightful views of disease processes. Following in this rich tradition of constant integration of new technologies, modern pathology is currently evaluating the applicability of novel testing methods for patient-based diagnostics. One such method rests on technical advances resulting in more sensitive mass spectrometry instruments. These instruments are currently being used to mine patient body fluid and tissue samples for potential diagnostic signatures (*1*). These efforts are part of a new discipline, namely tissue proteomics, wherein the measurements of a multiplexed combination of molecules within the patient tissues are being analyzed and correlated with disease states and outcomes. Because of the potential increase in both specificity and sensitivity using a combination marker approach, it may be possible to detect potentially lethal diseases in early stages when they are more curable.

Proteomic fingerprinting methods utilizing mass spectrometry coupled to bioinformatics analysis have yielded clues about the existence of potential diagnostic information content within the low molecular weight range of the blood and tissue proteome (*2*−*9*). Now that this information archive has been uncovered by these initial studies, efforts are underway to sequence and characterize the underlying components of these disease-related fingerprints.

The molecules that coalesce to form a diagnostic portrait are likely diverse small proteins, and protein fragments, shed by numerous tissues into the interstitial fluid with an equilibrium established between cells and the intravascular compartment. The constant synthesis and degradation of proteins by cells within the body should reflect the overall state of health, and some of the synthesized proteins and fragments are expected to be present within the serum. The expressed proteome within a host, in fact, represents a complex interplay between all cells (normal and diseased cells). It is for this reason that the body fluids such as serum are thought to be a rich source of information for the discovery of biomarkers and the development of diagnostic tests. Recent work indicates that the low molecular molecules that have comprised the previously described disease fingerprints actually exist bound to larger carrier molecules (*10*). In particular, high abundance carrier proteins such as albumin have been found to bind lower molecular weight proteomic species that could serve as potential biomarkers (i.e. proteolytic fragments of BRCA2) (*11*). On the basis of these findings, isolation of low molecular weight molecules as well as the resident carrier proteins that harbor them and protect them from renal clearance is now a primary object in MS-based tissue proteomics for discovery and sequencing of new biomarkers.

A more comprehensive and expansive analysis of the carrier protein-bound low molecular weight proteome requires the development of novel fractionation methods. Fabrication of nanoporous material surfaces is one strategy for methodically parsing the various subsets of proteins and protein fragments present within the circulation (*12*). These types of materials have the ability to be modified and functionally manipulated through specific chemical derivitization such that selective and custom binding and fractionation can ensue. Moreover, nanoporosity dramatically increases the surface areas of the system such that the selective fractionation and binding occurs with potentially higher efficiency and speed.

In this report, we describe the use of nanoporous material surfaces as a fractionation tool for serum-based analysis and biomarker discovery. Nanoporous silicon wafers are used to selectively deplete serum of a fraction of proteins. By the use of controlled-pore nanoporous glass beads, distinct subsets of the proteome are harvested from serum for subsequent elution and evaluation. Within these subsets subcellular proteins are identified, lending credence to the hypothesis that the serum reflects cellular pathology. The types of materials utilized hold significant promise as the next generation of fractionation and separation tools are developed for proteomic analysis and biomarker discovery. Future studies will focus on using these fractionation techniques to isolate low abundance molecules from the serum.

EXPERIMENTAL PROCEDURES

Serum Samples. The serum sample consisted of a reference pool from normal donors that was stored at −80 °C.

Chemicals. Acetonitrile (ACN) (HPLC grade), ammonium bicarbonate (NH_4HCO_3), iodoacetamide (97%), methanol (99+%), and dithiothreitol (DTT) were purchased from Sigma-Aldrich Co. (St. Louis, MO). Formic acid (88%) and acetic acid (glacial) were purchased from Mallinckrodt Baker (Phillipsburg, NJ). H_2O was doubly distilled in house with Kontes High Purity Water System. Porcine sequencing grade modified trypsin was purchased from Promega (Madison, WI).

Other Materials. Bovine serum albumin purchased from (Sigma-Aldrich Co, St. Louis, MO). SYPRO Ruby protein gel stain purchased from Molecular Probes (Eugene, OR). Precast 4−12% Bis-tris 1D gels, LDS sample and running buffers, antioxidant, and the prestained Benchmark protein ladder were purchased from Invitrogen Co. Fused silica is from Polymicro Technologies (Phoenix, AZ).

Nanoporous Silicon Wafer Fabrication. Boron-doped, (100) oriented silicon wafers (from Silicon Quest Inc) with resistivity $< 0.005\ \Omega\cdot$cm were used as the substrates. Wafers were cleaned in a piranha solution (H_2SO_4:H_2O = 1:1) at 120 °C for 30 min. This was followed by oxide removal in HF:H_2O = 1:10 and rinsing in deionized water. The porous silicon surfaces were prepared by electrochemical etching in a homemade Teflon cell. The wafers sit on the Teflon cell base with aluminum foil (0.1 mm thick) underneath to provide the electrical contact. A platinum mesh was positioned in the cell cavity as a counter electrode. The electrolyte was a 1:1 mixture by volume of 49% HF and ethanol. A constant current density 72 mA/cm^2 was applied for 65 s. Immediately after porous silicon formation, the sample was rinsed in deionized water and placed under vacuum to remove the moisture. The porous silicon was silanized in 10% APTES (aminopropyltriethoxysilane) in toluene. To remove the air bubbles from the nanopores, the porous silicon was placed under vacuum for 3 min. The reaction solution was refluxed for 3 h at room temperature in a sealed dish. The porous silicon was rinsed several times with toluene and acetone and dried in a N_2 flow. The Barret−Joyner−Halenda (BJH) model applied to the nitrogen desorption branch of the isotherms indicated a pore size distribution centered at 2−20 nm (data not shown) (*13*−*16*).

Partial Depletion of Serum Proteins Using a Nanoporous Silicon Wafer. Aminopropyl-coated nanoporous silicon wafers were placed in 1.5 mL tubes and washed four times in deionized water. Pooled serum samples (500 μL), diluted 1:5 in deionized water, were then applied to the wafers and the mixtures incubated at room temperature for 1.5 h. Following this incubation, the diluted serum supernatants were removed and stored for later MS analysis at −80 °C. For controls, diluted serum samples were frozen as well. As a further control, the wafers were also incubated with deionized water in place of diluted serum.

Proteomic Harvesting Using Nanoporous Controlled-Pore Glass Beads. Aminopropyl-coated controlled-pore glass beads, with pore sizes of 70 or 17 nm, were purchased from Sigma (St. Louis, MO). For each experiment, 10 mg of beads was measured into 1.5 mL tubes. The beads were washed four times in deionized water. Pooled serum, diluted 1:5 in deionized water, was then applied to the bead samples and the mixtures incubated at room temperature for 1.5 h. Following this incubation, the diluted serum supernatants were removed and saved. The beads were then washed two times using 1 mL of deionized water. Following this wash, 500 μL of elution buffer (5 mL of acetonitrile, 5 mL water, 10 μL of trifluoroacetic acid) was applied to the samples, which were then rotated for 0.5 h at room temperature. The eluant was then collected and stored for later MS analysis at −80 °C.

Mass Spectrometry Analyses. Low resolution mass spectrometry-generated spectral profiles were used as a generalized unbiased readout to assess fractionation performance. Weak cation exchange SELDI chips were processed using a Biomek 2000 bioprocesser (WCX2 ProteinChips, Ciphergen Biosystems, Inc.). HCl (10 mM, 100 μL) was applied to the chip followed by a 5-min incubation. The HCl was then removed via aspiration and was followed by a 1-min incubation with 100 μL of water. The water was aspirated and freshwater applied for an additional 1 min. This was followed by the addition of 100 μL of 10 mM ammonium acetate with 0.1% Triton X, applied to the chip for a 5 min incubation. The ammonium acetate mixture was then aspirated and discarded followed by another application of the ammonium acetate mixture for an additional 5-min incubation. After these preparative steps, the chips were dried with the assistance of a vacuum. Sample (5 μL) (such as serum) was then applied to the chip spots and incubated for 55 min. The chips were washed three times with 150 μL of phosphate buffered saline followed by 150 μL of water. The chips were then vacuum-dried and 1.0 μL of a 30% solution of cinnaminic acid in 50% (v/v) acetonitrile/0.5% trifluoroacetic acid was applied to each protein spot, twice with drying between applications. The chips were then assayed using a PBS-II mass spectrometer (Ciphergen Biosystems, Inc.). The spectrum for each spot was collected using the following protocol settings: detector voltage was 1800 V, focus mass was 6000 Da, the high mass limit was 20000 Da, the sensitivity gain was set to 5, the laser intensity was 145, 15 laser shots were taken per position, and the number of positions ranged from 20 to 80 incrementing every five positions. A protocol was created which processed all of the samples identically.

Protein Sequencing Studies. *Protein Assay.* Bead-fractionated samples from 17 μm and 70 μm pore beads were assayed by a traditional Bradford assay using bovine serum albumin (BSA) standard ranging from 200 ug/mL to 1 mg/mL monitored at 595 nm on a UV−Vis spectrophotometer (Spectromax Plus 384, Molecular Devices).

*1D Gel Separation and Digestion.*Amounts of 15 μg of each bead fractionated sample and 3 μL of raw serum were diluted

in 30 μL of LDS sample buffer and boiled for 5 min at 95 °C. The fractions were run on a 1D precast gel (4−12% Bis-tris) to isolate desired molecular weight regions of the complex protein mixture. The gel was washed thoroughly with ddH_2O, fixed in a 50% methanol/ 10% acetic acid solution for 30 min, stained with Sypro ruby stain overnight, and destained in ddH_2O for 3 h prior to UV excitation and visualization. The gel was sliced into 1 mm^2 gel regions, and the gel bands were destained in 50% methanol. Gel bands were reduced and alkylated with 10 mM DTT and 55 mM iodoacetamide, incubated at 4°C for 1 h in trypsin (20 ng/μL), and allowed to digest overnight (16 h) at 37 °C in 25 mM NH_4HCO_3. The following morning, proteins were extracted from the gel with repeated incubations of 70% ACN/5% formic acid solution.

μLC/MS/MS Analysis. The samples were lyophilized to near dryness and reconstituted in 6.5 μL of HPLC buffer A (94.9% H_2O, 5.0% ACN, 0.1% FA) for mass spec analysis. Microcapillary reverse phase LC/MS/MS analysis was performed with Dionex's LC Packings liquid chromatography system coupled online to a ThermoFinnigan LCQ Classic ion trap mass spectrometer (San Jose, CA) with a modified nanospray source. Reverse phase separations were performed with an in-house, slurry packed capillary column. The C_{18} silica-bonded column is 75 μm i.d., 360 μm o.d., 10 cm long fused silica packed with 5 μm beads with 300 Å pores (Vydac, Hesperia, CA). A μ-precolumn PepMap, 5 mm, C_{18} cartridge (Dionex) acts as a desalting column. Sample is injected in μL pick-up mode and washed with Buffer A for five minutes prior to a linear gradient elution with Buffer B (95% ACN/ 5% H_2O/ 0.1% formic acid) up to 85% over 95 min at a flow rate of 200 nL/ minute. Full MS scans are followed by four MS/MS scans of the most abundant peptide ions (in a data dependent mode), and collision-induced dissociation (CID) is performed at a collision energy of 38% with the ion spray voltage set to 2.00 kV, capillary voltage, and temperature to 22.80 V and 180 °C, respectively.

Data Analysis. Data analysis was performed by searching MS/MS spectra against the European Bioinformatics Institute of the nonredundant proteome set of Swiss-Prot, TrEMBL and Ensembl entries through the Sequest Bioworks Browser (ThermoFinnigan). Peptides were considered legitimate hits after filtering the correlation scores (refer below) and manual inspection of the MS/MS data. The criteria used to filter data in this manuscript are at least as stringent as most literature citations.

charge	X_{corr}	DeltaCN	ions	Rsp
+1	>1.9	>0.1	>50%	=1
+2	>2.5	>0.1	>50%	=1
+3	>3.5	>0.1	>50%	=1

Accepted peptide hits are required to have an X_{corr} ranking = 1 relative to all other peptides in the database.

RESULTS

Serum Depletion Using Nanoporous Silicon. One strategy for fractionating serum is to deplete the serum of a portion of its protein content, followed by analysis of the remaining protein species (Figure 1A). To try this approach, a nanoporous substrate was produced out of silicon with pore sizes ranging from 2 to 20 nm. Nanoporous silicon wafers possessing an asymmetric surface were incubated with pooled serum samples. After an 1.5 h incubation, the wafers were removed and the remaining proteins within the serum were subjected to MS evaluation (Figure 1B). Of note, the emergence of a new ion peak pattern from surface-enhanced laser desorption ionization (SELDI) mass spectrometry resulted from this fractionation technique. In fact, the entire spectra appeared dramatically different compared to unfractionated serum alone. In the case of this depletion experiment, two peaks within the MS spectra were markedly changed. More specifically, a peak at 8122 *m*/*z* was significantly enhanced in the depleted sample, when compared with the native serum sample. On the other hand, the 8927 *m*/*z* peak was markedly diminished within the depleted sample, when compared with its dominance in native serum. Thus, the incubation followed by the removal of the nanoporous particles altered the spectral qualities of the serum, enhancing the profile of a previously minor peak into the dominating area of intensity.

Molecular Harvesting Using Nanoporous Controlled-Pore Glass. As an alternative to measuring depleted serum for proteomic signatures, a bead harvesting strategy was developed for isolating molecular species for subsequent elution and profiling (Figure 2A). Similar aminopropyl-coated glass beads with distinct pore sizes (17 nm versus 70 nm) were incubated with serum for selective molecular isolation and release. Nitrogen adsorption and desorption isotherm analysis was used to characterize surface area and pore volume (data not shown) (*13*−*16*). The surface area of the 17 nm beads is 30.8 m^2/g and the pore volume is 0.032 cm^3/g. For 70 nm beads, the surface area is 130.5 m^2/g and the pore volume is 0.93 cm^3/g. While surface treatments and composition of the particles was similar, the surface area and pore volumes were distinct, allowing for comparison of their respective fractionation properties. Following incubation with serum, the beads were gently washed with water, and then the bound molecules were eluted using the elution buffer. The eluted species were then analyzed via SELDI MS and compared with the spectra of unfractionated serum (Figure 2B). Visual inspection of the 17 nm bead eluate revealed a unique MS spectral portrait when compared with unprocessed serum. A marked difference at the *m*/*z* of 7762 was noted when comparing the harvested sample and the native serum. While the 8927 *m*/*z* peak dominates the spectral landscape in normal serum, it is the 7762 *m*/*z* peak that assumes the dominant role in the harvested subset.

To assess the effect that the nanopore size and surface area played in the generation of unique spectral signatures, a 70 nm pore-sized controlled pore glass bead was used in an identical experiment. Strikingly, a different SELDI MS spectra resulted using the larger pore-sized controlled-pore glass beads (Figure 3). At 6629 *m*/*z*, a new major peak that dominated the spectral pattern eluted from the beads. The normal serum peak at the same *m*/*z* was barely discernible. In contrast, the 8927 peak in normal serum assumed a minor status within the set of proteins eluted from the larger pore beads.

To further characterize the molecular components eluted from either the 17 nm pore-sized or 70 nm pored-sized beads, 15 μg of protein from each sample was run on a 4−12% Bis-Tris SDS−PAGE gel followed by staining with Sypro Ruby Red (Figure 4). Throughout the molecular weight spectrum, distinct differences were noted between the eluates from the two types of beads. This finding was consistent with the marked differences noted in the SELDI-based analysis. Analysis of the molecular content of the eluants via one-dimensional electrophoresis provided additional visual confirmation that the beads were differentially fractionating the molecular content of serum.

To further characterize differences between the eluants from the 17 nm pore-sized beads and the 70 nm pore-sized beads, bands from a SDS−PAGE gel were excised and the protein content of the gel slices were digested using trypsin. The resulting peptide fragments were analyzed using electrospray ionization mass spectrometry. Following interrogation of the spectral data, peptide identities were assigned to the proteomic content of the gel (Figure 5). While there was some overlap of the peptide species identified between the 17 nm pore-sized beads and the 70 nm pore-sized beads (six peptides shared),

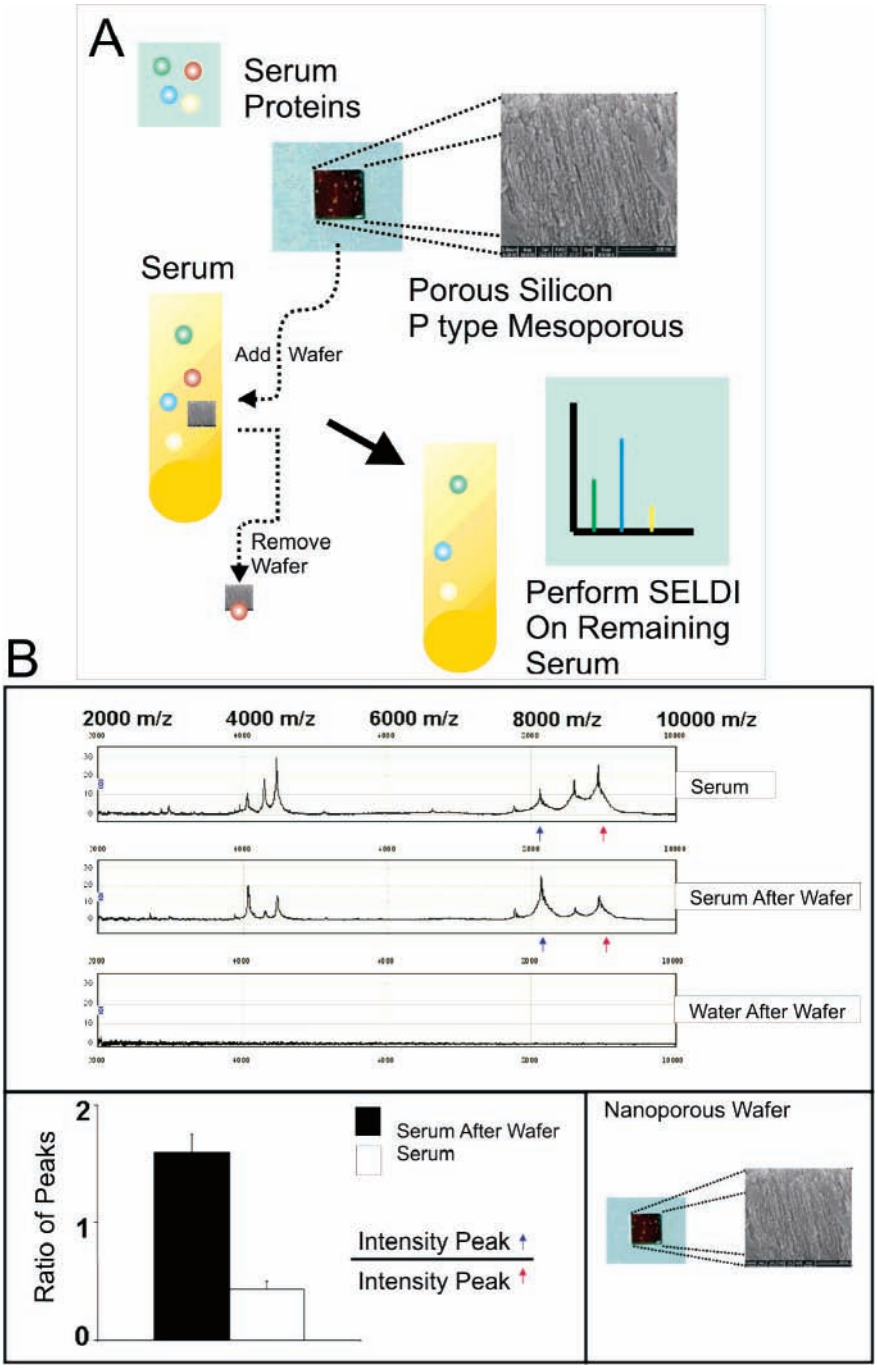

Figure 1. Serum depletion using nanoporous materials. (A) Strategy for partial depletion of serum using nanoporous silicon wafers. Porous silicon wafers are generated and incubated with serum. After an incubation period, the wafers are removed and the remaining serum sample is spotted on a weak cation exchange chip for SELDI analysis and compared to MS spectra from control serum not exposed to the wafer. (B) MS analysis of serum partially depleted using a nanoporous silicon wafer. Serum is incubated with a nanoporous silicon wafer coated with aminopropyl groups. Following incubation, the serum is bound to a weak cation exchange chip and then undergoes MS analysis. MS fingerprints are obtained. Native serum is compared with serum after wafer depletion. A dominant peak is present in serum (red arrow) that overshadows a smaller peak within a similar *m*/*z* range (blue arrow). In the serum partially depleted of its proteomic content by incubation with the nanoporous wafer, the peak designated by the blue arrow assumes a dominant profile when compared to the peak marked with the red arrow. When the ratio of relative peak intensity is compared between the blue and red peaks, a marked shift is demonstrated between native serum and serum after depletion using the nanoporous silicon wafer.

differences were observed, indicating that significant fractionation had occurred. Thus, three distinct analyses indicate that the glass beads with different pore sizes offer a means of fractionating serum components.

DISCUSSION

Proteomic profiling using mass spectrometry coupled with bioinformatics data mining approaches has revealed a complex and exciting information archive, contained within the low molecular weight range of the circulatory proteome, which may contain important diagnostic information. Nanoporous material surfaces, such as the silicon wafer and the controlled pore glass beads used in the present study, provide a new strategic means to fractionate and manipulate biologic information contained within body fluids such as serum. A systematic evaluation of nanoporous material surfaces combining MS analysis with bioinformatic interrogation may reveal certain fractionation schemes with enhanced disease detection properties, identify

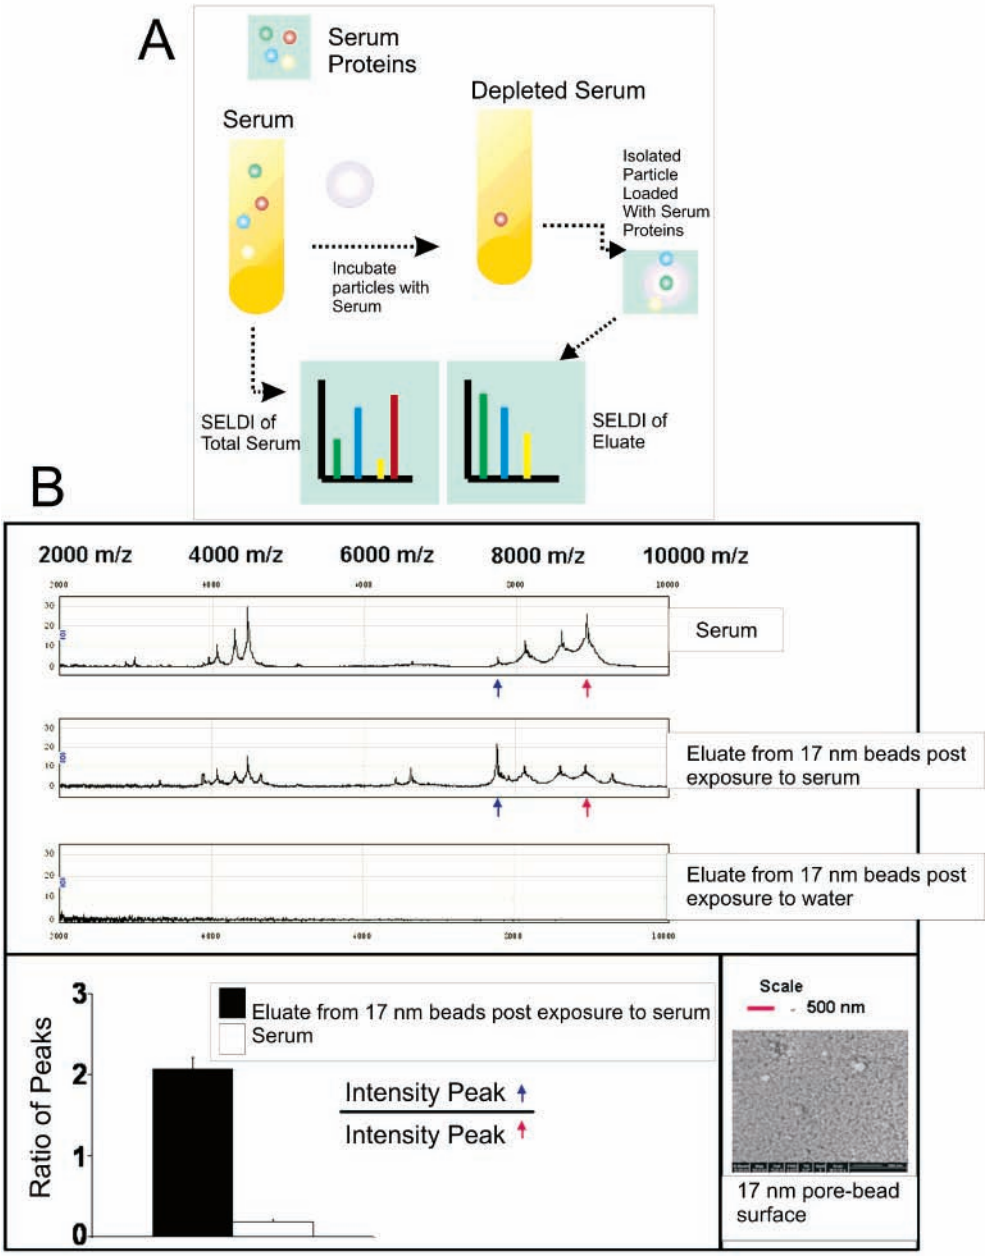

Figure 2. Harvesting molecules from serum using nanoporous glass beads. (A) Strategy for harvesting molecules from serum using nanoporous glass beads. Glass beads coated with aminopropyl groups are incubated with serum. After an incubation period, the beads are removed, washed, and bound molecules are eluted and spotted on a weak cation exchange chip for SELDI analysis and compared to MS spectra from control serum. (B) MS analysis of molecules harvested by nanoporous beads. Serum is incubated with glass beads coated with aminopropyl groups. Following incubation, the serum is bound to a weak cation exchange chip and then undergoes MS analysis. MS profiles are obtained. Native serum is compared with molecules harvested using 17 nm beads. A dominant peak is present in serum (red arrow) that overshadows a smaller peak within a similar *m*/*z* range (blue arrow). In the eluted sample, the peak designated by the blue arrow assumes a dominant profile when compared to the peak marked with the red arrow. When the ratio of relative peak intensity is compared between the blue and red peaks, a marked shift is demonstrated between native serum and molecules harvested and subsequently eluted from the beads.

an expanded set of molecules for workup and provide a more facile and robust means for purification, fractionation, and peptide/protein sequencing of the molecules themselves.

To that end, in this study, fractionation of serum using material surfaces with nanopores can result in significantly altered spectral profiles, altered 1-D electrophoretic profiles, and differential sequence identities. Each of these parameters suggest that a significant, unique fractionation had occurred using either the 17 nm pore-sized beads or the 70 nm pore-sized beads. Of note, while six of the peptide species identified by ESI MS were harvested using either of the bead types, there were distinct peptides that were isolated using only one type of the beads. The sequenced peptides included highly abundant plasma proteins as well as lower abundance species. In addition, subcellular protein species not traditionally associated with serum were identified. Using the 70 nm pore-sized beads, the protein named mediator of RNA polymerase II transcription subunit 8 homologue was isolated. In the 17 nm pore-sized bead fraction, histone 4 and golgi autoantigen were harvested. The presence of these molecular species, not traditionally thought of as serum proteins, supports the hypothesis that fragments of organismal proteins make their way into the serum and provide a potential portrait of the overall state of the organism.

The serum and circulatory proteome is a mixture of high and low abundance molecules, with most biomarkers that carry important diagnostic information thought to reside in the lower abundance region of the concentration range. Certainly, a challenge for tissue proteomics is the development of tools to

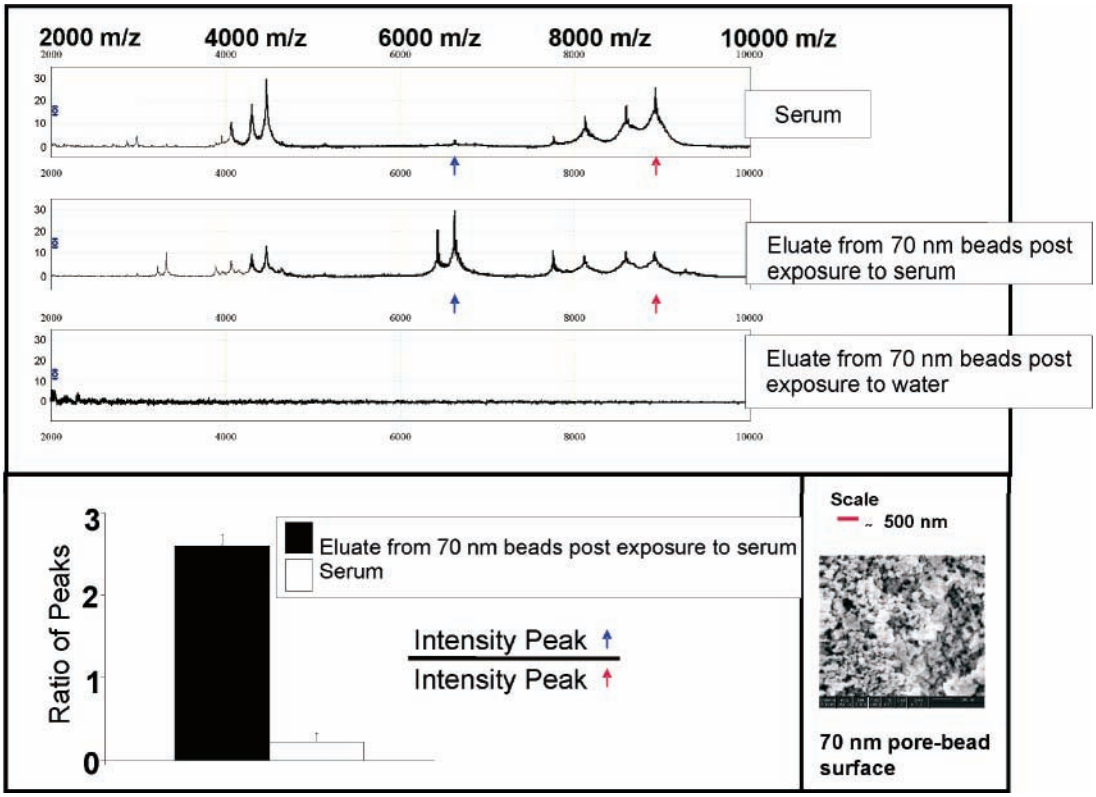

Figure 3. MS analysis of molecules harvested by 70 nm porous beads. Serum is incubated with glass beads with 70 nm pores and with coated aminopropyl groups. Following incubation, the serum is bound to a weak cation exchange chip and then undergoes MS analysis. MS profiles are obtained. Native serum is compared with molecules harvested using 70 nm beads. A dominant peak is present in serum (red arrow) that overshadows a smaller peak within a similar *m*/*z* range (blue arrow). In the eluted sample, the peak designated by the blue arrow assumes a dominant profile when compared to the peak marked with the red arrow. When the ratio of relative peak intensity is compared between the blue and red peaks, a marked shift is demonstrated between native serum and molecules harvested and subsequently eluted from the beads.

rapidly identify these low abundance molecules in complex biological samples. One approach is to develop flow through surfaces or depletion architectures for rapid, robust, and facile fractionation and selective purification. Material surfaces such as those used in the assays presented here are amenable to physicochemical modification whereby distinct pore sizes and charge characteristics can be added to the pore surfaces. These discriminatory properties would allow fine-tuning of the fractionation of proteins within the serum.

In the present study, the serum proteins were fractionated via noncovalent associations with the material surfaces. It is becoming increasingly apparent that low molecular weight, low abundance molecules are carried by high abundance serum proteins. In the future, it will be important to use methods such as those described above to capture and immobilize carrier proteins. For example, reactive groups could be added to the material surfaces that immobilize differentially isolated carrier proteins in order to further refine the fractionation properties of the substrate. Through immobilizing high abundance molecules such as albumin onto the highly porous, size-selective material surfaces, it may be possible to subsequently elute lower abundance molecules from the immobilized carrier proteins. It is likely that such an approach could maximize the retrieval of low abundance molecular information. Further studies are required to evaluate the relative abundance distribution over the molecular weight distribution using a fractionation strategy similar to the one described above. Similar strategies have been employed for discrimination of DNA molecules (*17*−*19*). The present study represents an initial step in the use of material surfaces to parse high and low abundance molecules into more manageable groupings.

These experiments reveal that fractionation of serum using material surfaces with nanopores can result in significantly altered spectral profiles.. Assessment of the power of this approach will require continued optimization of the methodologies such that a series of manipulations could dramatically expand the low molecular weight portrait observed. In the present study, incubation of the serum proteins with the substrates was performed under physiologic conditions. In this setting, it is likely that the low molecular weight serum molecules that are potential biomarkers remain bound to the

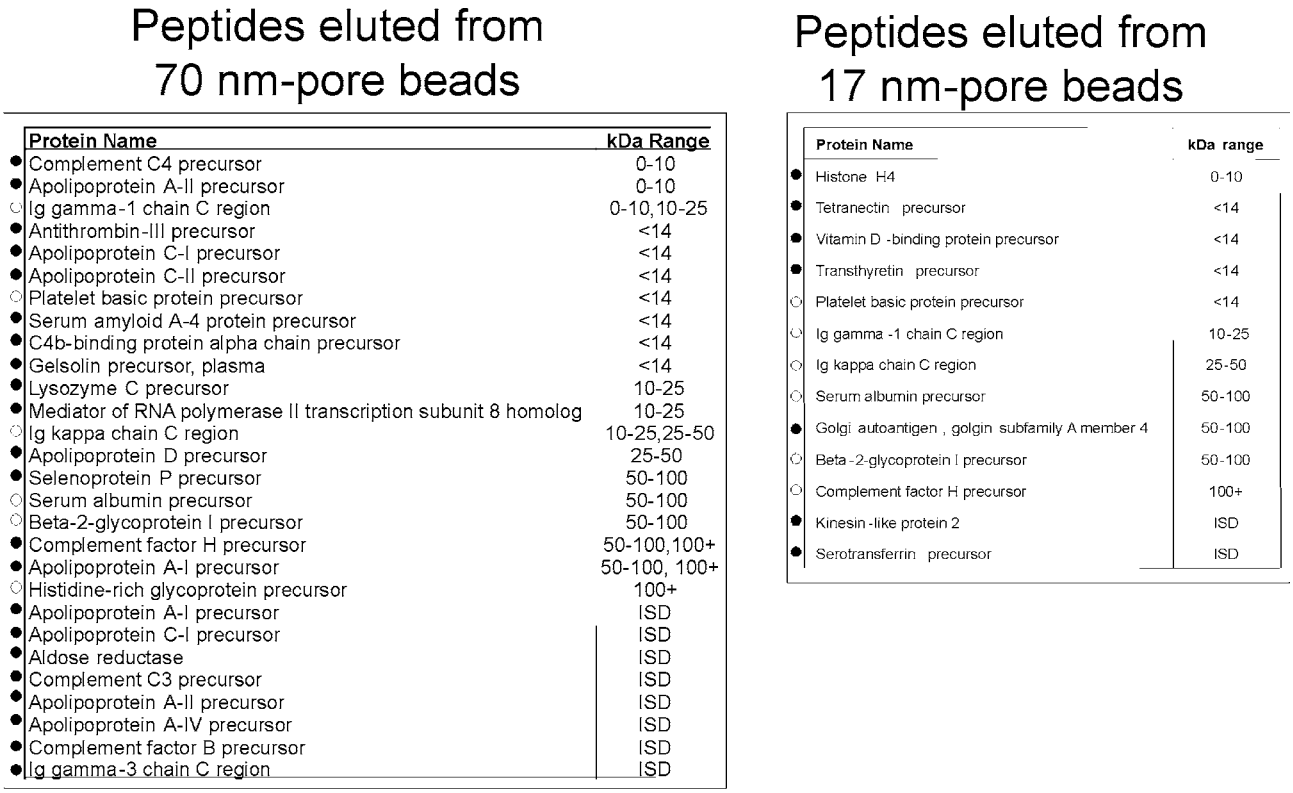

Figure 5. Peptide sequencing results showing protein sequences obtained from eluents of 17 nm pore-sized glass beads and 70 nm pore-sized glass beads. Black circles indicate peptide sequences unique to either the 17 or 70 nm pore-sized glass beads. The open circles indicate peptide sequences shared by the 17 and 70 nm pore-sized glass beads. The kDa ranges indicate the 1D gel slice size range from which the peptides were extracted prior to MS analysis.

high abundance proteins, like albumin, that carry them in serum. As an alternative approach, the serum proteins could be denatured through heat or pH treatment, which would disrupt the noncovalent association of the low molecular weight proteins from the larger carrier proteins. Liberated low molecular weight species could then more freely percolate into the pores of the particles, potentially enhancing the fractionation of the serum molecules. The solvents used as eluents could likewise be expanded in future studies. For example, a spectrum of salt concentrations could be tested in eluants in order to determine the optimal conditions for eluting low molecular weight species of interest.

One potential use for such surfaces is in collection devices for serum samples at the clinic. As labile molecules in the serum increasingly become interesting as biomarkers, standardized collection procedures will have to be initiated. Nanoporous substrates may offer one means of sequestering labile small molecules in a format readily adaptable to serum collection procedures. In this type of application, the specialized nanoporous substrate becomes akin to specialized tissue fixatives which are chosen in select cases to preserve specific tissue properties for subsequent visualization.

Because silicon can be fashioned into micron-sized particles, nanoporous substrates could be developed that would be in the size range of blood cells. These particles may be designed with a range of pore sizes and other physicochemical properties for fractionation of abundant serum proteins and the low molecular weight cargo they carry. As an added feature, the micron-sized particles could be coded with a discriminating tag, such as a metallic tag or quantum dot. Such a strategy would allow blood to be harvested and the particles isolated from the blood cells through a sorting or enrichment process (*20*−*22*). While these particles might initially be used in blood collection tubes, an eventual utilization might include infusion of the particles for longer term in vivo monitoring (*23*). Ultimate approval for this type of strategy would of course require biocompatibility and toxicity profiling of the particles, not unlike the safety profiling carried out for infused radiocontrast agents and indwelling medical devices.

This present study demonstrates the feasibility of nanoporous-based separation and fractionation as a means to selectively fractionate, purify, and analyze the circulatory proteome. The ultimate objective is to design a new method that will allow for the rapid isolation and sequence identification of new low molecular weight biomarkers for disease detection and risk stratification. Further analysis of this approach in specific disease states will be required to fully characterize the utility of these approaches. Additional pore sizes, surface modifications, and carrier protein (e.g. albumin) immobilization strategies will be screened as well for their abilities to achieve expanded and robust fractionation and purification of low molecular weight species.

Received December 2, 2005; Revised Manuscript Received February 26, 2006

2-Deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) has extensively been used for clinical diagnosis, staging, and therapy monitoring of cancer and other diseases. Nonradioactive glucose analogues enabling the screening of the glucose metabolic rate of tumors are of particular interest for anticancer drug development. A nonradioactive fluorescent deoxyglucose analogue may have many applications for both imaging of tumors and monitoring therapeutic efficacy of drugs in living animals and may eventually translate to clinical applications. We found that a fluorescent 2-deoxyglucose analogue, 2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-D-glucose (2-NBDG), can be delivered in several tumor cells via the glucose transporters (GLUTs). We therefore conjugated D-glucosamine with a near-infrared (NIR) fluorphor Cy5.5 and tested the feasibility of the Cy5.5−D-glucosamine (Cy5.5−2DG) conjugate for NIR fluorescence imaging of tumors in a preclinical xenograft animal model. Cy5.5−2DG was prepared by conjugating Cy5.5 monofunctional *N*-hydroxysuccinimide ester (Cy5.5−NHS) and D-glucosamine followed by high-performance liquid chromatography purification. The accumulation of Cy5.5−2DG and Cy5.5−NHS in different tumor cell lines at 37 and 4 °C were imaged using a fluorescence microscope. Tumor targeting and retention of Cy5.5−2DG and Cy5.5−NHS in a subcutaneous U87MG glioma and A375M melanoma tumor model were evaluated and quantified by a Xenogen IVIS 200 optical cooled charged-coupled device system. Fluorescence microscopy imaging shows that Cy5.5−2DG and Cy5.5−NHS are taken up and trapped by a variety of tumor cell lines at 37 °C incubation, while they exhibit marginal uptake at 4 °C. The tumor cell uptake of Cy5.5−2DG cannot be blocked by the 50 mM D-glucose, suggesting that Cy5.5−2DG may not be delivered in tumor cells by GLUTs. U87MG and A375M tumor localization was clearly visualized in living mice with both NIR fluorescent probes. Tumor/muscle contrast was clearly visible as early as 30 min postinjection (pi), and the highest U87MG tumor/muscle ratios of 2.81 ± 0.10 and 3.34 ± 0.23 were achieved 24 h pi for Cy5.5−2DG and Cy5.5−NHS, respectively. While as a comparison, the micropositron emission tomography imaging study shows that [^{18}F]FDG preferentially localizes to the U87MG tumor, with resulting tumor/muscle ratios ranging from 3.89 to 4.08 after 30 min to 2 h postadministration of the probe. In conclusion, the NIR fluorescent glucose analogues, Cy5.5−2DG and Cy5.5−NHS, both demonstrate tumor-targeting abilities in cell culture and living mice. More studies are warranted to further explore their application for optical tumor imaging. To develop NIR glucose analogues with the ability to target GLUTs/hexokinase, it is highly important to select NIR dyes with a reasonable molecular size.

INTRODUCTION

Positron emission tomography (PET)[1] has become a generally accepted technique for preclinical and clinical noninvasive imaging of diseases, especially cancer (*1*−*3*). Tracers enabling the targeting of specific cellular and molecular processes are major driving forces that have contributed to the rapid progress of PET imaging. One of these tracers, 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG), is very widely used in tumor diagnosis, staging, and monitoring therapeutic response. Currently, the majority (∼95%) of clinical PET scans use [^{18}F]FDG (*1*).

The molecular targets for [^{18}F]FDG are glucose transporters (e.g., GLUT1) and hexokinase. [^{18}F]FDG can first be recognized and transported into the cells by glucose transporters, which are located on the cell membrane, and it is then phosphorylated by hexokinase to form 2-deoxy-2-[^{18}F]fluoro-D-glucose-6-phosphate ([^{18}F]FDG-6-phosphate). Because [^{18}F]FDG lacks a hydroxyl group in the 2 position, [^{18}F]FDG-6-phosphate cannot be further metabolized and this polar compound is metabolically trapped inside the cells (*3*, *4*). The rationale for using [^{18}F]FDG as a general tumor marker relies on the fact that tumor cells often exhibit an increased glucose metabolism and an upregulation of GLUT and hexokinase compared to non-neoplastic cells (*5*). The preferential accumulation of [^{18}F]FDG metabolites inside tumor cells compared to that in surrounding normal tissues makes the detection of tumors using PET possible. [^{18}F]FDG can not only be used in diagnosis and staging of cancer but also is a powerful tool for monitoring disease recurrence and therapeutic efficacy (*6*−*8*). A recent excellent example of the

latter is the use of [^{18}F]FDG−PET for monitoring treatment effects of imatinib mesylate (STI-571) on gastrointestinal stromal tumors (*9*, *10*). The success of [^{18}F]FDG−PET for metabolic imaging of disease has prompt scientist to develop glucose analogues labeled with less costly or therapeutic isotopes such as ^{99m}Tc and $^{186/188}$Re (*11*, *12*). Recently, it was reported that ^{99m}Tc-labeled ethylenedicysteine−deoxyglucose (ECDG) can potentially be used for tumor imaging (*11*). However, further investigations are required to reveal the mechanism responsible for the accumulation of this probe in tumors, as well as to identify the specific molecular targets interacting with ^{99m}Tc-ECDG.

Although radionuclide imaging has several advantages, including intrinsically high sensitivity, capability of quantitation, and clinical translation, it often suffers from relatively low spatial resolution, high cost, and limited radiation to personnel. Moreover, PET imaging often requires an on-site cyclotron and a radiochemistry laboratory to produce short half-life radionuclides and radiolabeled agents. Therefore, optical imaging (bioluminescence and fluorescence imaging) has emerged as an attractive imaging modality to study the biological/molecular events in both cell culture and small living subjects. Optical imaging does not involve any ionizing radiation; it is inexpensive and highly sensitive and allows for a high throughput screening because the acquisition times for obtaining a good image using optical imaging can be as short as seconds (*13*, *14*). Because of the strong tissue penetration ability of light in the near-infrared (NIR) region (650−900 nm wavelengths), near-infrared fluorescence (NIRF) imaging has emerged as a powerful tool for small animal imaging. Many studies have demonstrated that it is a viable method to noninvasively monitor disease states at the molecular level, localize cancer, and even assess the antitumor efficacy of new therapeutic drugs (*15*−*18*).

Considering the extensive applications of [^{18}F]FDG in nuclear medicine and the rapid advancement in optical imaging, the development of NIRF deoxyglucose analogues may serve as novel probes with the ability to evaluate the glucose metabolic rate of tumors. These probes could be useful for (a) the accurate detection of abnormalities such as tumors and (b) the noninvasive monitoring of the therapeutic efficacy of drugs in living small animals. It was reported that a fluorescent derivative of 2-deoxyglucose, 2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-D-glucose (2-NBDG) (excitation, 475 nm; emission, 550 nm) can be delivered and trapped in cells via the GLUT/hexokinase pathway. Several studies demonstrated that the uptake of 2-NBDG (structure shown in Figure 1) can be inhibited by D-glucose but not L-glucose in different organisms (*19*−*23*). 2-NBDG can then be further metabolized to 2-NBDG-6-phosphate in *Escherichia coli* cells, which was confirmed by mass spectrometry (*21*). These results highlight the possibility of preserving the GLUT/hexokinase-targeting ability of the glucose analogues when they are conjugated with a bulk NIR fluorescent group at position 2 of deoxyglucose. A pyropheophorbide derivative of 2-deoxyglucose, Pyro−2DG (excitation, 667 nm; emission, 679 and 720 nm; structure shown in the Figure 1), was synthesized and also proven to be useful as both a tumor-targeted NIRF imaging probe and a photodynamic therapy agent for the treatment of tumors. Preliminary confocal fluorescence microscopy studies further shows that the uptake of Pyro−2DG in 9 L of glioma cells can be inhibited by 50 mM D-glucose, suggesting that Pyro−2DG is a substrate of GLUTs (*24*). Another interesting report tethered multiple D-(+)-glucosamines with cypate, a NIR chromophore core, to generate multivalent carbocyanine molecular beacons (structure of mono-D-(+)-glucosamine-containing cypate shown in the Figure 1). Biodistribution studies in tumor-bearing mice show that all of the NIR fluorescent glucosamine derivatives localized in the tumor. However, it is not clear whether their uptake and trapping in the tumor is through the GLUT/hexokinase pathway (*25*, *26*).

In this study, we first investigated the tumor cell uptake of 2-NBDG and the specificity of 2-NBDG toward GLUTs. We found that 2-NBDG is delivered and trapped in tumors cells via the GLUT, which is consistent with the recent literature (*27*). The NIR fluorescent dye Cy5.5 has been proven to be a very useful fluorochrome for labeling biomolecules for in vivo optical imaging by several groups (*28*−*35*). Encouraged by the specific tumor cell uptake of 2-NBDG, we conjugated Cy5.5 monofunctional *N*-hydroxysuccinimide (NHS) ester (Cy5.5−NHS) and D-glucosamine to prepare a Cy5.5−D-glucosamine (Cy5.5−2DG) conjugate (see their structure in the Figure 1) and tested its feasibility for NIRF imaging of tumors in preclinical xenograft tumor models. As a comparison, Cy5.5−NHS was also tested for its tumor-targeting ability in vitro and in vivo. Furthermore, [^{18}F]FDG as a radioactive probe was utilized to image mice bearing U87MG tumors with microPET. We demonstrate the tumor specificity and long-lasting tumor accumulation of both fluorescent agents in human primary tumor cells in mouse xenografts.

EXPERIMENTAL PROCEDURES

Materials and General Methods. Cy5.5−NHS was purchased from Amersham Biosciences (Piscataway, NJ). All other reagents were obtained from Sigma−Aldrich Chemical Co. (St. Louis, MO). Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI−TOF−MS) was performed by Stanford Protein and Nucleic Acid Biotechnology Facility, Stanford University, Stanford, CA. A Dionex Summit high-performance liquid chromatography (HPLC) system (Dionex Corporation, Sunnyvale, CA) equipped with a 170U 4-channel UV−vis absorbance detector was used for purification and analysis of the Cy5.5-labeled compound. UV detection wavelengths were 218, 280, and 590 nm for all of the experiments. Both semipreparative (Zorbax SB-C18, 9.4 × 250 mm) and analytical (Dionex Acclaim 120 C18, 4.6 × 250 mm) reversed-phase HPLC columns were used. The mobile phase was solvent A, 0.1% trifluoroacetic acid (TFA) in water, and solvent B, 0.1% TFA in acetonitrile (CH_3CN).

Synthesis and Characterization of Cy5.5−2DG. D-Glucosamine (30.2 mg) was dissolved in 302 μL of H_2O to make a concentration of 463.7 mM in solution. D-Glucosamine (34.5 μL, 16.0 μmol), sodium phosphate buffer (Na_2HPO_4 at pH 9.0, 0.1 M, 805.5 μL), and Cy5.5−NHS (1.81 mg, 1.60 μmol) dissolved in 160 μL of H_2O were then mixed together. After

overnight incubation at 4 °C in the dark, the reaction was quenched by adding 100 μL of 1% TFA. The crude product was then injected onto a semipreparative HPLC column [the flow rate was 3.0 mL/min, with the mobile phase starting from 5% solvent B (0.1% TFA in CH_3CN) and 95% solvent A (0.1% TFA in water) (0−3 min), to 65% solvent B and 35% solvent A at 33 min, and then going to 85% solvent B and 15% solvent A (33−36 min), maintaining this solvent composition for another 3 min (36−39 min) and returning to the initial solvent composition by 42 min]. Fractions containing Cy5.5−2DG conjugate (retention time of 14.3 min) were collected, lyophilized, and identified by MALDI−TOF−MS. The chemical purity of the product was determined by analytical HPLC (same gradient as used for semipreparative HPLC; flow rate of 1.0 mL/min). The product was redissolved in saline at a concentration of 1 mg/mL and stored in the dark at −80 °C until use. The absorbance spectrum of Cy5.5−2DG was rerecorded on an Agilent 8453 UV−visible ChemStation (Agilent Technologies, Wilmington, DE), and the fluorescence spectrum of Cy5.5−2DG was measured on a Fluoromax-3 fluorophotometer (JOBIN YVON/HORIBA, Edison, NJ).

Cell Lines and Tumor Xenografts. U87MG human glioblastoma cells, C6 rat glioma cells, A375M human melanoma cells, B16F10 murine melanoma cells, and MDA-MB-435 human breast cancer cells were all obtained from American Type Culture Collection (Manassas, VA). U87MG, C6, A375M, and B16F10 cells were cultured in Dulbecco's modified Eagle high glucose medium supplemented with 10% fetal bovine serum (FBS) and 1% penicillin−streptomycin (DMEM, Invitrogen Life Technologies, Carlsbad, CA). MDA-MB-435 was cultured in Leibovitz's L-15 medium with 2 mM L-glutamine supplemented with 0.01 mg/mL insulin, 10% FBS, and 1% penicillin−streptomycin (Invitrogen Life Technologies, Carlsbad, CA) in CO_2-free atmosphere. All the other cell lines were maintained in a humidified atmosphere of 5% CO_2 at 37 °C, with the medium changed every other day. A confluent monolayer was detached with trypsin and dissociated into a single-cell suspension for further cell culture.

Animal procedures were performed according to a protocol approved by the Stanford University Administrative Panels on Laboratory Animal Care (A-PLAC). Female athymic nude mice (*nu/nu*), obtained from Charles River Laboratories, Inc. (Cambridge, MA) at 4−6 weeks of age, were subcutaneously injected in the right shoulder with 5×10^6 U87MG glioblastoma cells suspended in 100 μL of phosphate-buffered saline (PBS, 0.01 mol/L; pH 7.4). When the tumors reached 0.4−0.6 cm in diameter (14−21 days after implantation), the tumor-bearing mice were subjected to in vivo imaging studies. In addition, 6-week-old Fox chase ICR scid (severe combined immunodeficient) mice were inoculated with 4×10^6 A375M human melanoma cells. A total of 3−4 weeks post-inoculation, the mice bearing A375M tumors were ready for further studies.

Fluorescence Microscopy and Cell-Uptake Studies of 2-NBDG. For fluorescence microscopy studies, U87MG cells (1×10^5) were cultured on 35 mm MatTek glass-bottom culture dishes (catalog number, P35G-0-14-C; Ashland, MA). After 24 h, the cells were washed with PBS and then incubated at 37 °C in the presence of 10 μM 2-NBDG for 10 min. After the incubation period, cells were washed 3 times with ice-cold PBS. The fluorescence signal of the cells was recorded using an Axiovert 200M fluorescence microscope (Carl Zeiss MicroImaging, Inc., Thornwood, NY) equipped with a GFP filter set (exciter, HQ 475/20 nm; emitter, HQ 540/30 nm). An AttoArc HBO 100 W microscopic illuminator was used as a light source for fluorescence excitation. Images were taken using a thermoelectrically cooled charged-coupled device (CCD) (Micromax, model RTE/CCD-576, Princeton Instruments, Inc., Trenton, NJ) and analyzed using MetaMorph Software version 6.2r4 (Molecular Devices Corporation, Downingtown, PA). The effect of D-glucose or L-glucose on 2-NBDG accumulation in U87MG cells was also examined. In these studies, cells were preincubated with medium containing either 50 mM D-glucose or L-glucose for 0.5 h at 37 °C. Cells were then incubated with 10 μM 2-NBDG for 10 min at 37 °C. After incubation, U87MG cells were washed 3 times with ice-cold PBS and subjected to fluorescence microscopy imaging.

The inhibition effect of D-glucose or L-glucose on 2-NBDG uptake in U87MG cells was also assessed by the measurement of the fluorescence intensity of cell lysates. Briefly, the cultured U87MG human glioblastoma cells were trypsinized, washed twice with PBS, and suspended at 10×10^6 cells/mL in PBS. Cells (1.0×10^6) were preincubated with either 10 or 50 mM D-glucose or 50 mM L-glucose for 30 min and then incubated with 50 μM 2-NBDG for another 1 h at 37 °C. The cells were centrifuged (at 250*g*) for 3 min and washed 3 times with cold PBS. Cell pellets were then lysed with 150 μL of cold spectral-grade water, following by freezing in dry ice. The frozen cell solution was thawed and centrifuged at 12000*g* for 5 min. The fluorescence intensity of 100 μL of cell lysate was measured on a Fluoromax-3 fluorophotometer.

Fluorescence Microscopy Studies of Cy5.5−2DG and Cy5.5−NHS. Fluorescence microscopy imaging was performed to study the uptake of Cy5.5−2DG and Cy5.5−NHS by several tumor cell lines such as U87MG, C6, A375M, B16F10, and MDA-MB-435, as well as to exam the effect of D-glucose or L-glucose on 2-NBDG accumulation in U87MG cells. The procedure described in the above section was followed in this experiment, except that 100 nM Cy5.5−2DG or Cy5.5−NHS was used for incubation with cells and a Cy5.5 filter set was used in the fluorescence microscope for the collection of the fluorescence signal.

Optical Imaging of Tumors in Mice. In vivo fluorescence imaging was performed with an IVIS 200 small animal imaging system (Xenogen, Alameda, CA). A Cy5.5 filter set was used for acquiring Cy5.5−2DG and Cy5.5−NHS fluorescence in vivo. Identical illumination settings (lamp voltage, filters, f/stop, field of views, binning) were used for acquiring all images, and fluorescence emission was normalized to photons per second per centimeter squared per steradian (p s^{-1} cm^{-2} sr^{-1}). Images were acquired and analyzed using Living Image 2.5 software (Xenogen, Alameda, CA). Mice bearing either U87MG or A375M ($n = 3$ for each imaging probe) were injected via the tail vein with 0.5 nmol of Cy5.5−2DG or Cy5.5−NHS and subjected to optical imaging at various time points postinjection (pi). For scid mouse bearing A375M tumor, the fur covered the tumor and the lower right flank was shaved to reduce light absorbance and scattering. All NIR fluorescent images were acquired using 1 s exposure time (f/stop = 4) and displayed in the same scale of fluorescent intensity.

Fluorescence Microscopy Imaging of Fresh Tissue Slides. After optical imaging, the mice bearing U87MG were euthanized 24 h pi of the fluorescent probe. Tumors were dissected, placed in tissue holders, then filled with Tissue-Tek Optimal Cutting Temperature Compound (Sakura Finetek USA, Inc., Torrance, CA), and immediately frozen in dry ice. They were sectioned into 200 μm transverse slices using a tissue slicer. Fluorescence microscopy imaging of fresh tissue slides was then performed to determine the localization and distribution of the probe in the tumor. The images were taken with a 10× objective.

MicroPET Imaging of the U87MG Tumor. PET imaging of tumor-bearing mice was performed on a microPET R4 rodent model scanner (Concorde Microsystems, Inc., Knoxville, TN). The mice bearing U87MG glioblastoma were injected with 5.55 MBq (150 μCi) of [^{18}F]FDG. At 30, 60, and 120 min pi, the

mice were anesthetized with 2% isoflurane and placed in the prone position near the center of the field of view of a microPET scanner (Siemens, Inc.). The 5-min static scans were obtained, and the images were reconstructed by a two-dimensional ordered subsets expectation maximum (OSEM) algorithm. Regions of interest (ROIs) were then drawn over the tumor on decay-corrected whole-body coronal images. The counts per pixel per minute were obtained from the ROI and converted to counts per milliliter per minute by using a calibration constant. When a tissue density of 1 g/mL was assumed, the ROI values were converted to counts per gram per minute. An image ROI-derived percentage ID per gram of tissue (%ID/g) was then determined by dividing the counts per gram per minute with the injected dose (ID).

Data Processing and Statistics. All of the data are given as the mean ± standard deviation (SD) of *n* independent measurements. Statistical analysis was performed using a Student's *t* test. Statistical significance was assigned for p values <0.05. For determining tumor contrast, maximum fluorescence intensities (p s^{-1} cm^{-2} sr^{-1}) of the tumor area at the right shoulder of the animal (*T*) and of the area at the right flank [normal tissue (*N*)] were calculated by the ROI function of Living Image software integrated with Igor (Wavemetrics, Lake Oswego, OR). Dividing *T* by *N* yielded the contrast between the tumor tissue and the normal tissue.

RESULTS AND DISCUSSION

NIRF imaging is emerging as a powerful tool for noninvasive imaging diseases in preclinical models. It also has a great potential for clinical use in providing both real-time surgical information and functional/molecular information of the disease. NIRF probes with the capability of imaging specific molecular targets and events are therefore under active investigation. Our research was intended to develop NIR fluorescent glucose analogues for imaging tumor metabolism in living subjects. Although several NIR 2-deoxyglucose analogues, which are able to accumulate in the tumors, were successfully synthesized recently (*24*−*26*), whether these compounds are delivered and trapped in tumor cells via the GLUTs/hexokinase pathway remains to be answered. Moreover, the ability of these NIR 2-deoxyglucose analogues to imaging tumor metabolism in small animals has not been demonstrated yet.

It was reported that 2-NBDG could be incorporated by glucose-transporting systems in living cells. More recently, it was found that 2-NBDG can accumulate into malignant tumor cells such as the MCF-7 breast cancer cells and the HepG2 liver cancer cells (*27*). In this work, the cell uptake of 2-NBDG by U87MG was also examined using fluorescence microscopy imaging. It was found that 2-NBDG did accumulate in the cytoplasm of U87MG cells (a and d of Figure 2A). We also found that this fluorescent glucose analogue showed good uptake in several other tumor cell lines such as C6, A375M, B16F0, and MDA-MB-435 (data not shown). More importantly, the uptake of 2-NBDG by U87MG was significantly inhibited by 10 and 50 mM D-glucose ($p < 0.05$) but not by 50 mM L-glucose (parts A and B of Figure 2), strongly indicating that the uptake of 2-NBDG is likely mediated by glucose transporters. However, the short excitation and emission wavelengths (excitation, 475 nm; emission, 550 nm) of 2-NBDG limit its applications for imaging small living subjects.

Encouraged by these results, we hypothesized that conjugation of D-glucosamine with a carefully designed NIRF dye may generate a fluorescence deoxyglucose analogue, which can be still recognized by GLUTs and hexokinase. Therefore, Cy5.5−2DG was synthesized and evaluated in both cell culture and mice, because of the longer excitation/emission wavelengths of Cy5.5 and its easy availability. Synthesis of Cy5.5−2DG was

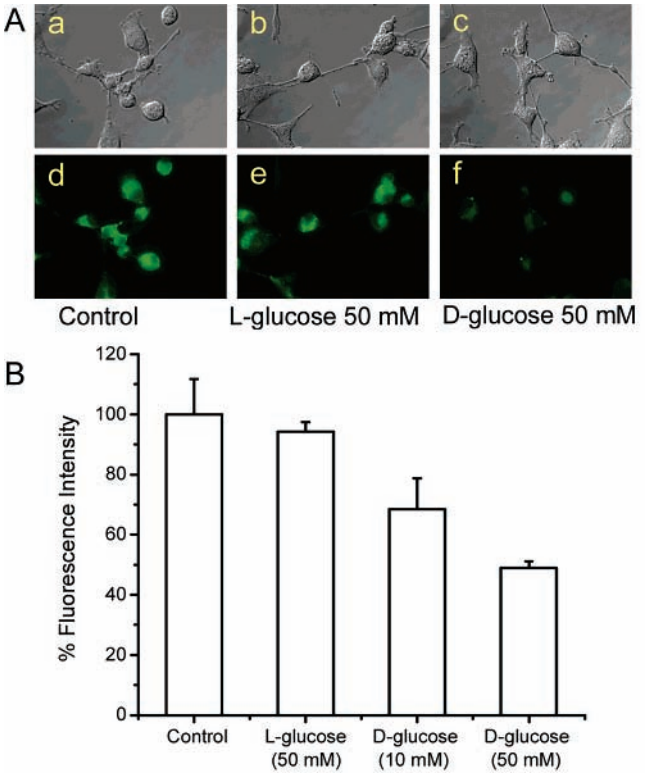

Figure 2. (A) Light (top) and fluorescence (bottom) images of U87MG cells. The cells were incubated with 10 μM 2-NBDG for 10 min at 37 °C in the absence of D-glucose or L-glucose (a and d) and presence of 50 mM L-glucose (b and e) and 50 mM D-glucose (c and f). The images show that 2-NBDG accumulates in the cytoplasm of cells and that the 2-NBDG fluorescence in cells can be competitively inhibited by D-glucose but not by L-glucose. (B) Significant inhibition of the 2-NBDG uptake by U87MG cells by 10 and 50 mM D-glucose ($p < 0.05$) but not by 50 mM L-glucose, as measured by fluorescence intensity with a spectrofluorometer.

achieved through conjugation of Cy5.5−NHS ester with the 2-amino group of the D-glucosamine. The desired products were purified by semipreparative HPLC. The retention time on analytical HPLC for Cy5.5−2DG was found to be 15.2 min. The yield of the Cy5.5−2DG conjugate was typically over 70%. The purity of Cy5.5−2DG was over 95% from analytical HPLC analysis. The purified Cy5.5−2DG was characterized by MALDI−TOF−MS. Cy5.5−2DG: *m/z* 1078.26 for $[M + H]^+$ ($C_{47}H_{56}N_3O_{18}S_4$, calculated molecular weight = 1078.24). The absorption and fluorescence emission characteristics of Cy5.5−2DG (λ_{ab} = 675 nm, λ_{em} = 695 nm) were identical to those of free Cy5.5, as apparent from the spectra measured in H_2O (Figure 3). The stability of Cy5.5−2DG was further evaluated by incubation of the compound with mouse serum for 1 h. No dissociation of Cy5.5 from the Cy5.5−2DG conjugate was found by using HPLC analysis, suggesting the good serum stability of Cy5.5−2DG.

Fluorescence microscopy imaging studies were performed to investigate the cell uptake of Cy5.5−2DG in different tumor cell lines. It was found that Cy5.5−2DG does accumulate in several tumor cell lines such as A375M, B16F10, C6, U87MG, and MDA-MB-435 at 37 °C, while the uptake at 4 °C was minimal. This result indicates that the cellular uptake of Cy5.5−2DG is due to an active and temperature-dependent process, instead of simple passive diffusion. To further elucidate whether its cell uptake is related to GLUTs, Cy5.5−2DG was incubated with either 50 mM D-glucose or L-glucose. However, Cy5.5−2DG localizes within U87MG cells with similar fluorescence intensity in the presence and absence of 50 mM D-glucose and L-glucose. D-Glucose failed to block the cell uptake of Cy5.5−

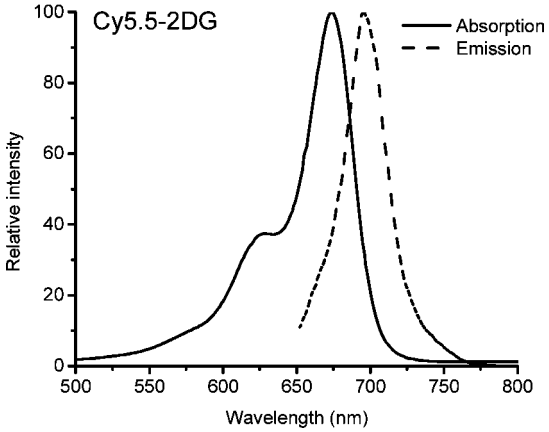

Figure 3. Absorption (675 nm) and emission fluorescence (695 nm) spectra of Cy5.5−2DG in water.

2DG, suggesting that GLUTs are not likely the transporter system responsible for Cy5.5−2DG uptake. To determine whether Cy5.5−2DG is a substrate for hexokinase, Cy5.5−2DG was incubated with glucose reagent (Infinity Glucose Reagent, ThermoDMA, Louisville, CO) at 37 °C for 3 min (*12*). From MALDI−TOF−MS analysis, we were not able to observe the formation of phosphorylated Cy5.5−2DG (data not shown). Cy5.5−2DG does not seem to mimic glucose/deoxyglucose phosphorylation. More studies are needed to pinpoint the uptake and retention mechanism of Cy5.5−2DG in cells.

For a comparison, Cy5.5−NHS was used as a control for staining the tumor cell lines. Fluorescence microscopy imaging studies demonstrate that Cy5.5−NHS can label these tumor cell lines as well as Cy5.5−2DG at 37 °C and also shows a negligible fluorescence signal when incubated at 4 °C. In a previous study (*28*), it was reported that very little Cy5.5−NHS accumulates in two breast cancer cell lines, MDA-MB-648 and MDA-MB-435. This is likely due to different filter settings and detection sensitivity of the fluorescence microscopes used in our study compared to the published study. In that paper, a 775/845 nm (excitation/emission) filter was equipped to obtain Cy5.5 fluorescence images. However, a Cy5.5 filter set (exciter, 650/20 nm; emitter, 675/35 nm) was used in our study. Considering that the maximum excitation and emission wavelengths of Cy5.5 dye are 675 and 694 nm respectively, the 775/845 nm filter set is not the proper setting, and one is unlikely to observe enough Cy5.5 fluorescence signal using such a filter.

Whole-body optical imaging of subcutaneous tumor xenografted mice was then performed by using an IVIS200 system to monitor in vivo biodistribution of Cy5.5−2DG and Cy5.5−NHS. As shown in Figure 4A, the subcutaneous U87MG tumor could be clearly distinguished from the surrounding background tissue from 30 min up to 24 h pi of either 0.5 nmol of Cy5.5−2DG or Cy5.5−NHS. Quantitative analysis of these images was performed, and the fluorescence intensities in the tumor and normal tissues as a function of time for Cy5.5−2DG and Cy5.5−NHS are depicted in parts B and C of Figure 4, respectively. It was found that both probes exhibited fast tumor targeting characteristics in vivo. The tumor uptake of Cy5.5−2DG and Cy5.5−NHS reached a maximum 30 min pi and slowly washed out over time. A similar pattern was found for the uptake of both probes in normal tissue. At all time points pi (0.5−24 h), there is no statistical significant difference in tumor and normal tissue uptake between Cy5.5−2DG and Cy5.5−NHS ($p > 0.05$) (parts B and C of Figure 4). The fluorescence intensity ratio between the tumor and normal tissue

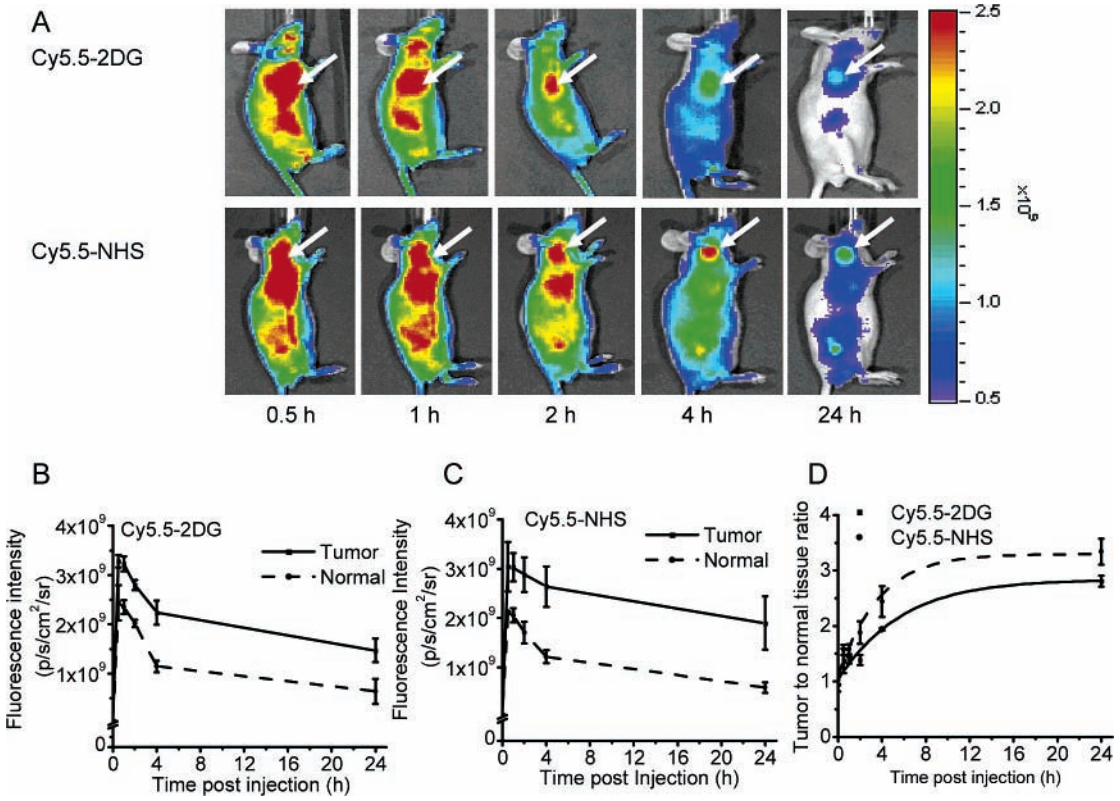

Figure 4. (A) In vivo fluorescence imaging of subcutaneous U87MG glioblastoma tumor-bearing nude mice after intravenous injection of 0.5 nmol of Cy5.5−2DG (top) or Cy5.5−NHS (bottom). The position of the tumor is indicated by an arrow. The fluorescence signal from probes was pseudo-colored red. Quantification and kinetics of in vivo targeting charactereristics of Cy5.5−2DG (B) and Cy5.5−NHS (C). The fluorescence intensity was recorded as photons per second per centimeter squared per steradian (p s^{-1} cm^{-2} sr^{-1}). Tumor fluorescence was higher than that in the normal tissue. (D) Tumor contrast (tumor/normal tissue ratio) as a function of time postadministration of Cy5.5−2DG (■, —) and Cy5.5−NHS (◆, ···). The tumor/normal tissue ratio of Cy5.5−NHS at 4 and 24 h pi is significantly higher than that of Cy5.5−2DG ($p < 0.05$).

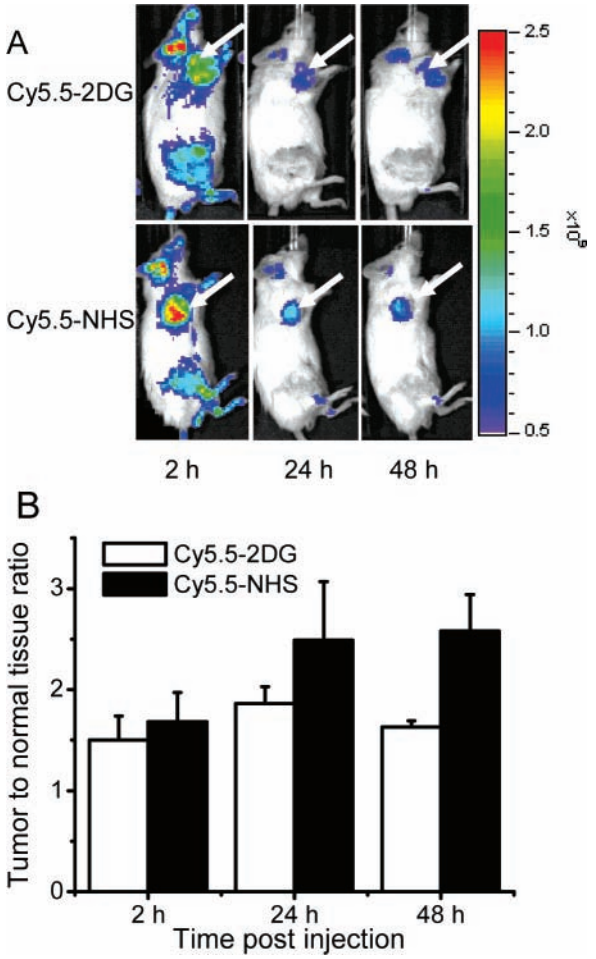

Figure 5. (A) In vivo NIRF images of subcutaneous A375M melanoma bearing scid mice after intravenous injection of 0.5 nmol of Cy5.5−2DG (top) and Cy5.5−NHS (bottom). The position of the A375M tumor is indicated by an arrow. The fluorescence signal from NIRF probes was pseudo-colored red. The tumor can be clearly visualized at 2−48 h pi. (B) Tumor/normal tissue ratio at 2, 24, and 48 h postadministration of Cy5.5−2DG (□) and Cy5.5−NHS (■). The tumor contrast of Cy5.5−NHS at 48 h pi is significantly higher than that of Cy5.5−2DG ($p < 0.05$).

(*T*/*N*) for Cy5.5−2DG (represented by −) and Cy5.5−NHS (represented by ···) was calculated and shown in Figure 4D. Cy5.5−NHS shows a significantly higher *T*/*N* ratio than Cy5.5−2DG at later time points (4 and 24 h) ($p < 0.05$). For example, *T*/*N* ratios for Cy5.5−2DG and Cy5.5−NHS are found to be 2.81 ± 0.10 and 3.34 ± 0.23, respectively, at 24 h pi. U87MG tumor tissues from the mice 24 h after administration of fluorescent probes were then taken out and sliced for NIRF imaging. Fluorescence and brightfield images for the tumor slices of mice injected with Cy5.5−2DG and Cy5.5−NHS were obtained. It was found that both probes accumulate in the tumor cells, and the fluorescence intensity is similar in both samples.

The tumor-targeting abilities in living subjects of Cy5.5−2DG and Cy5.5−NHS were also evaluated in the A375M xenografted mouse model. Figure 5A shows typical NIR fluorescence images of scid mice bearing subcutaneous A375M melanoma tumor after intravenous (iv) injection of 0.5 nmol of probe. Similar to the distribution in the U87MG mouse, both Cy5.5−2DG and Cy5.5−NHS show higher uptake in the tumor compared to normal tissue uptake. Moreover, a significant difference in *T*/*N* is observed between Cy5.5−2DG and Cy5.5−NHS at 48 h pi ($p = 0.01$). The *T*/*N* ratios for Cy5.5−2DG and Cy5.5−NHS at 48 h are 1.63 ± 0.06 and 2.58 ± 0.36, respectively (Figure 5B).

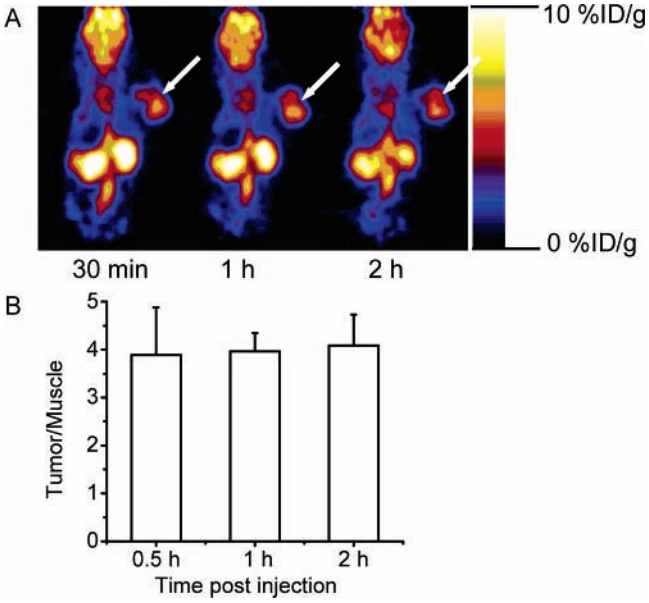

Figure 6. (A) Decay-corrected whole-body coronal microPET images of the nude mouse bearing human U87MG tumor at 30 min, 1 h, and 2 h (5-min static image) pi of 5.55 MBq (150 μCi) of [^{18}F]FDG. The position of the U87MG tumor is indicated by an arrow. (B) Tumor/normal tissue ratio at 30 min, 1 h, and 2 h pi of [^{18}F]FDG, with uptake values for organs derived from a multiple time-point microPET study. ROIs are shown as the mean %ID/g ± SD ($n = 3$).

The radioactive deoxyglucose analogue, [^{18}F]FDG, was then used to image the nude mice bearing human U87MG using microPET. [^{18}F]FDG preferentially localizes and is retained in U87MG tumors, as clearly shown in Figure 6A. The tumor/muscle ratios are 3.89 ± 0.99, 3.96 ± 0.39, and 4.08 ± 0.65, at 30 min, 1 h, and 2 h pi of the probe. Obviously, the tumor contrast for [^{18}F]FDG at these time points is significantly higher than that of Cy5.5−2DG (*T*/*N* ratios at 30 min to 2 h pi are all below 2, as shown in Figure 4D). This is probably caused by (1) the conjugation of D-glucose with a big fluorophor Cy5.5, resulting in a compound with reduced cell uptake and/or retention, and (2) autofluorescence of normal tissue, increasing the background signal. Furthermore, in comparison to optical imaging, [^{18}F]FDG−microPET is able to quantify the probe accumulation in most organs of interest such as the brain, heart, kidney, etc. However, except for the disadvantages as described in the Introduction, PET imaging can only monitor the [^{18}F]-FDG distribution up to several half-lives of F-18, while optical imaging can observe the Cy5.5−2DG NIR signal in living mice even several days pi.

The small animal optical imaging data shows that both Cy5.5−2DG and Cy5.5−NHS can accumulate very well in U87MG and A375M tumor models. Even 4 days pi of the probes, the tumor showed the high fluorescent signal and could be clearly visualized (data not shown). Another preliminary study also revealed that Cy5.5−2DG and Cy5.5−NHS can localize in the MDA-MB-435 tumor in an orthotopic tumor model (data not shown). Although it is not clear how Cy5.5−2DG and Cy5.5−NHS localize and are retained in the tumor, their high specificity, high accumulation, and retention in tumors will likely make them very useful in (1) labeling cancer cells for cell trafficking and (2) in vivo staining of tumors such as breast cancer, melanoma, and glioma for guidance of tumor surgery and radiation therapy in conjunction with proper optical imaging systems, etc. Moreover, conjugation of Cy5.5−NHS with cancer chemotherapeutical drugs or radionuclides such as F-18 may generate novel tumor-targeting agents.

The in vivo tumor-seeking ability of Cy5.5−NHS documented here is very different from the results reported previously

(*28*). In that paper, the authors did not observe any significant difference between the uptake in the tumor region and normal tissue region pi of Cy5.5−NHS. This inconsistency may be due to several factors such as the depth and size of the tumor, different settings of the optical imaging system, and the amount of dye injected (2.9 nmol/mouse in their report versus 0.5 nmol/mouse in our study), etc. Our finding also highlights the importance of a complete separation of free Cy5.5−NHS and Cy5.5-labeled biomolecules (peptides, antibodies, etc.) to avoid any false-positive results.

On the basis of our data reported here and previous literature (*19*−*23*), 2-NBDG has been proven to be a substrate of GLUTs, while Cy5.5−2DG is not a substrate of GLUTs. Considering that Cy5.5 is a much larger molecule than the 2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino] (NBD) moiety (Figure 1), it is likely that the size of the fluorophor in the 2 position is the reason that Cy5.5−2DG cannot be delivered and trapped in tumor cells via the GLUT/hexokinase pathway. It looks like the resulting conjugate no longer behaves like D-glucose if the dye gets too large. These results clearly suggest the importance of selection of NIR dyes for the preparation of NIRF D-glucose analogues.

In conclusion, the NIRF glucose analogues, Cy5.5−2DG and Cy5.5−NHS, both demonstrate tumor-targeting abilities in cell culture and living mice but not through the GLUT/hexokinase pathway. More studies are warranted to further explore these two imaging probes for optical tumor imaging in cell culture and living subjects.

ACKNOWLEDGMENT

We thank Dr. Bengang Xing for technical assistance on fluorescent microscopy imaging. A Blue-Green Absorbing Cross-Linker for Rapid Photoswitching of Peptide Helix Content

Lei Chi, Oleg Sadovski, and G. Andrew Woolley*

Department of Chemistry, University of Toronto, 80 Saint George Street, Toronto, ON M5S 3H6, Canada. Received December 23, 2005; Revised Manuscript Received March 15, 2006

Azobenzene derivatives can be used to reversibly photoregulate secondary structure when introduced as intramolecular bridges in peptides and proteins. Here we report the design, synthesis, and characterization of a disubstituted *N*,*N*-dialkyl azobenzene derivative that absorbs near 480 nm in aqueous solution and relaxes with a half-life of ∼50 ms at room temperature. The wavelength of maximum absorbance and the rate of thermal relaxation are solvent-dependent. An increase in the percentage of organic solvent leads, in general, to a blue shift in the absorbance maximum and a slowing of the relaxation rate. In accordance with the design, the thermal relaxation of the azobenzene cross-linker from cis to trans causes an increase in the helix content of one peptide where the linker is attached via cysteine residues spaced at *i*, *i* + 11 positions and a decrease in helix content of another peptide with cysteine residues spaced at *i*, *i* + 7. This cross-linker design thus expands the possibilities for fast photocontrol of peptide and protein structure.

INTRODUCTION

Reversible optical control of protein structure and function offers the possibility of probing and manipulating individual proteins within the complex environment of a living cell (*1*, *2*). Azobenzene, in particular, has been a popular choice as a photoswitching chromophore due to its robust photophysical properties and relative ease of synthesis (*3*, *4*). However, there is no wavelength at which only one azobenzene isomer absorbs; the absorption spectra of trans and cis forms overlap extensively. Thus, irradiation typically produces photostationary states composed of at most ∼80% cis or ∼95% trans isomers (*5*, *6*). This fact limits the degree of photoswitching that is possible; For example, the fraction of cis isomer can be changed from ∼5% to 80% (16-fold) or trans from ∼20% to 95% (∼5-fold) (*6*). Thermal isomerization, in contrast, yields >99.99% trans isomer (*7*). Therefore, if thermal isomerization is used to reset the switch, a much greater fold change in the cis isomer is then possible.

The half-life for thermal cis-to-trans isomerization of unmodified azobenzene is on the order of 3−4 days at room temperature (*6*). If one wished to probe a dynamic process in a living cell using thermal reversion to reset the switch, this half-life would likely be too long. Many cellular signaling processes, such as the actions of kinases and phosphatases, operate on the time frame of seconds to minutes (e.g., refs *8* and *9*). Indeed naturally occurring photoswitchable proteins reset in the dark in seconds or less (*10*, *11*).

Several groups have shown that the rate of thermal isomerization of azobenzenes can be varied substantially by altering the nature of substituents on the aromatic rings (e.g., refs *12*−*15*). Previously we reported the design and synthesis of thiol-reactive azobenzene derivatives bearing alkyl, amide, carbamate, and urea substituents that could be used to manipulate peptide secondary structure (*7*). The fastest of these, the urea-substituted compounds, relaxed with a half-life of ∼10 s at room temperature. While significantly faster than the parent compounds, these photoswitches may still be too slow for certain applications such as probing calcium signaling in myocytes or reversibly modulating neural activity with switchable ion channels (*9*, *16*).

In addition to a requirement for rapid thermal relaxation, a critical design feature of such photoswitches is the effective end-to-end distance and how this changes upon isomerization. The urea- and carbamate-substituted compounds, in particular, can accommodate a wide range of end-to-end distances in their cis states, a feature that may limit their effect on the conformation of an attached peptide or protein (*17*). A smaller number of bonds between the azo moiety and the peptide backbone would be likely to maximize the conformational switching effect.

Finally, the wavelength that causes photoisomerization can be of considerable practical importance if one wishes to achieve photocontrol in a biological context. Short wavelength UV light is damaging to proteins and nucleic acids (*18*). Wavelengths in the 330−370 nm range (where current azobenzene-based photoswitches operate), while compatible with biological systems (*1*, *2*), are less able to penetrate cells and tissues than longer wavelengths (*19*). Longer wavelength switches would also make possible the incorporation of separately addressable photoswitches into a single protein.

With these considerations in mind, we designed the thiol reactive dialkylamino-substituted azobenzene-based photoswitch **1**. We report here the synthesis and characterization of this new photoswitch.

EXPERIMENTAL PROCEDURES

All chemicals were purchased from Sigma-Aldrich Chemical Co. except if specified otherwise. All ^{1}H and ^{13}C NMR spectra were recorded using a Varian Unity 400 or a Varian Gemini 300 spectrometer. High-resolution mass spectra were obtained either by electron impact (EI) or electrospray (ESI) ionization. Peptide mass spectra were obtained either by ESI or matrix-assisted laser desorption (MALDI) ionization.

Synthesis of the Cross-Linker. *2-[Ethyl-(4-{4-[ethyl-(2-hydroxy-ethyl)-amino]-phenylazo}-phenyl)-amino]-ethanol (**3**).* Ten grams (36 mmol) of 4-(ethyl(2-hydroxyethyl)amino)-benzenaminium hydrogensulfate (**2**) was mixed with 100 mL of ethyl acetate, and a saturated solution of sodium bicarbonate was added (∼15 mL). The reaction mixture turned a red color,

and after the evolution of carbon dioxide was complete, the organic layer was separated. The water layer was extracted with ethyl acetate (3 × 50 mL), and the combined organic layers were dried with Na_2SO_4. The water layer was then mixed with ethanol (∼ 5 mL) and filtered through a pad of Na_2SO_4 and Al_2O_3. The pad was washed with CH_2Cl_2 (∼100 mL). The CH_2Cl_2 solution was combined with the ethyl acetate fractions, and the combined solution was evaporated, then dissolved again in CH_2Cl_2 and dried with Na_2SO_4. Removal of CH_2Cl_2 gave 4 g of the free amine of **2** (62% yield).

A mixture of 2-((4-aminophenyl)(ethyl)amino)ethanol (**2**; 4 g, 22 mmol) and manganese dioxide (20 g) was refluxed in dry benzene (200 mL) for 4 h. Removal of residual manganese dioxide and the solvent gave a residue, which was chromatographed on alumina. Elution with benzene gave 2.3 g of **3** (29% yield) as a slurry. ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 1.20 (t, J = 7.3 Hz, 6 H, $2CH_3$), 3.40−3.60 (m, 8 H, 4 CH_2), 3.90 (t, J = 5.9 Hz, 4 H, $2CH_2$), 6.80 (d, J = 9.1 Hz, 4 H, $4CH_{arom}$), 7.8 (d, J = 9.1 Hz, 3 H, $4CH_{arom}$). MS (ESI): calcd (MH+) $C_{20}H_{29}N_4O_2$ 357.47; obsd 357.2.

*N-(2-Bromoethyl)-4-((4-((2-bromoethyl)(ethyl)amino)phenyl)-diazenyl)-N-ethylbenzenamine (**4**).* Methanesulfonyl chloride (0.65 mL, 8.4 mmol) was added in small portions to a stirred solution of **3** (1 g, 2.8 mmol) and TEA (1.56 mL, 11 mmol) in dry THF (50 mL) under N_2 maintained at 0 °C. After being stirred for 1 h at 0 °C and 24 h at room temperature, the mixture was poured into cold water and extracted with CH_2Cl_2. The organic extract was washed with cold water, dried, and concentrated under reduced pressure. LiBr (1.2 g, 14 mmol) was added over the course of 15 min to a solution of the residue so obtained in acetone (100 mL), and the mixture was stirred for 48 h at room temperature. It was then poured into water (400 mL) and extracted with CH_2Cl_2. The organic extract was washed with water, dried, and purified by silica gel chromatography (CH_2Cl_2/hexane, 1:1) to yield **4** (0.9 g, 67%). ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 1.20 (t, J = 7.0 Hz, 6 H, $2CH_3$), 3.40−3.60 (m, 8 H, $4CH_2$), 3.70−3.80 (m, 4 H, $2CH_2$), 6.7 (d, J = 9.3 Hz, 4 H), 7.8 (d, J = 9.3 Hz, 4 H). ^{13}C NMR (300 MHz, $CDCl_3$) δ ppm: 12.72, 28.24, 45.74, 52.43, 111.39, 124.39, 144.33, 148.15. HRMS (ESI): calcd (MH+) $C_{20}H_{27}N_4Br_2$ 481.0596; obsd 481.0608.

*Methanethiosulfonic Acid S-{2-[Ethyl-(4-{4-[ethyl-(2-methanesulfonylsulfanyl-ethyl)-amino]-phenylazo}-phenyl)-amino]-ethyl} Ester (**1**).* Compound **4** (0.1 g, 0.2 mmol) and sodium methanethiosulfonate (80 mg, 0.6 mmol) were dissolved in dry DMF (10 mL) under Ar and heated to 60 °C. After 18 h of stirring at this temperature, the DMF was evaporated under reduced pressure. The crude product was dissolved in EtOAc and filtered, and the filtrate was evaporated under reduced pressure. Chromatography on silica (EtOAc/hexanes 1:1, R_f = 0.36) gave **1** (30 mg, 33%), as a brown-yellow solid. ^{1}H NMR (400 MHz, $CDCl_3$) δ ppm: 1.25 (t, J = 7 Hz, 6.H, $2CH_3$), 3.30−3.45 (m, 10 H, $2CH_2$, $2CH_3$), 3.5 (q, J = 7.3 Hz, 4 H, 2 CH_2), 3.80 (t, J = 7.Hz, 4 H $2CH_2$), 6.8 (d, J = 9 Hz, 4 H), 7.8 (d, J = 9 Hz, 4 H). ^{13}C NMR (300 MHz, $CDCl_3$) δ ppm: 12.53, 33.39, 45.78, 50.55, 50.72, 111.78, 124.45, 144.45, 148.20. HRMS (ESI): calcd (MH+) $C_{22}H_{33}N_4S_4O_4$ 545.1379; obsd 545.1390.

Peptide Cross-Linking. Peptides FK-11 (acetyl-EACAREAAAREAACRQ-amide) and JRK-7 (acetyl-EACARVAibAACEAAARQ-amide) were prepared using standard Fmoc-based solid-phase synthetic methods as described previously (*20*). Intramolecular cross-linking of cysteine residues was performed for FK-11 as follows: 2.0 mg (1.2 μmol) of FK-11 was dissolved in a total volume of 3.8 mL of a solvent consisting of 1.0 mL of 10 mM Tris·Cl, 1 mM EDTA buffer (pH 8.0) and 2.8 mL of DMSO. This solution was stirred, and 200 μL of a 14.5 mM solution of the linker **1** in DMSO was added dropwise. Then the mixture was left to stir for 2 h protected from light. The modified peptide was purified by Bio-gel P4 gel-filtration chromatography, followed by HPLC [Zorbax 300SB-C3 column; 20−80% acetonitrile/H_2O (+0.1% trifluoroacetic acid) linear gradient over the course of 30 min; elution at 54% acetonitrile]. The peptide molecular composition was confirmed by ESI-MS (calculated for $C_{85}{}^{13}C_2H_{139}N_{31}O_{24}S_4$ = 2133.5 Da; observed = 2133.4 Da).

For JRK-7, 0.5 mg (0.3 μmol) of peptide was dissolved in a total volume of 1.8 mL of a solvent consisting of 0.5 mL of 10 mM Tris·Cl, 1 mM EDTA buffer (pH 8.0) and 1.3 mL of THF. This solution was stirred, and 200 μL of a 3.65 mM solution of the linker **1** in THF was added dropwise. Then the mixture was left to stir for 2 h protected from light. The modified peptide was purified by HPLC [Zorbax 300SB-C3 column; 20−70% acetonitrile/H_2O (+0.1% trifluoroacetic acid) linear gradient over the course of 25 min; elution at 65% acetonitrile]. The peptide molecular composition was confirmed by electrospray ionization MS (calculated for $C_{85}H_{136}N_{28}O_{22}S_4$ = 2030.5 Da; observed = 2030.4 Da).

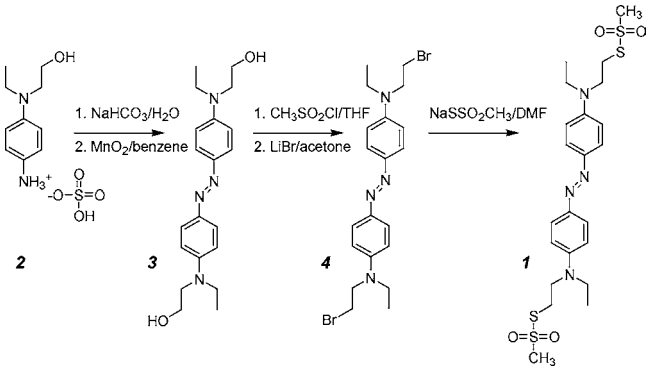
The glutathione derivative of **1** was prepared as follows: 2.8 mg (9.1 μmol) of glutathione was dissolved in a total volume of 4.5 mL of a solvent consisting of 1.5 mL of 10 mM Tris·Cl, 1 mM EDTA buffer (pH 8.0) and 3.0 mL of THF. This solution was stirred, and 200 μL of a 9.0 mM solution of the linker **1** in THF was added dropwise. Then the mixture was left to stir overnight protected from light. The modified peptide was purified by Bio-gel P4 gel-filtration chromatography, followed by HPLC [Zorbax 300SB-C18 column; 20−70% acetonitrile/H_2O (+0.1% trifluoroacetic acid) linear gradient over the course of 30 min; elution at 48% acetonitrile]. The peptide molecular composition was confirmed by electrospray ionization MS (calculated for $C_{40}H_{58}N_{10}O_{12}S_4$ = 999.2 Da; observed = 999.1 Da).

UV/Vis Spectra and Photoisomerization. Ultraviolet absorbance spectra were obtained using either a Perkin-Elmer Lambda 2 spectrophotometer or a diode array UV−vis spectrophotometer (Ocean Optics Inc., USB2000) coupled to a temperature-controlled cuvette holder (Quantum Northwest, Inc.). The latter arrangement was used to determine thermal relaxation rates of cross-linked species. Irradiation of the sample (at 90° to the light source and detector used for the absorbance measurements) was carried out using a xenon lamp (450 W) coupled to a double monochromator with slits at 16 nm and 16 nm. Rates of thermal cis-to-trans isomerization were measured for a series of temperatures by monitoring absorbance at 480 nm after irradiation to convert a percentage of the solution to the cis isomer. All curves could be fit well by single-exponential decay kinetics. Solution conditions are described in the figure legends.

For rapid (<1 s) measurements of thermal relaxation, photoisomerization was accomplished by irradiating thermostated cross-linked peptide solutions in a 10 cm path length, quartz, water-jacketed cell mounted in a microsecond flash photolysis apparatus operating in a manual single-shot mode. An Osram model XBO W/1 150-W xenon lamp was used as a continuous monitoring light source. The light that passed through the cell was focused by an Oriel model 77250 grating monochromator set at a wavelength of 480 nm, then detected by an Oriel model 7068 photomultiplier. Signals were displayed on a Tektronix 2225 50 MHz oscilloscope. The digitized outputs were fed into a PC computer for data analysis.

A molar extinction coefficient for the cross-linker of 16 200 $cm^{-1}\,M^{-1}$ at 480 nm (in 10% acetone/90% MeOH) was determined by quantitative NMR with CH_2Cl_2 as a reference material. Approximately 3 mg of cross-linker was dissolved in acetone-d_6, followed by addition of a known number of moles

Scheme 1



of CH_2Cl_2. The concentration of the cross-linker was then calculated by comparing the areas of the methylene resonance of CH_2Cl_2 with the area of the aromatic ring signals of **1**. The molar extinction coefficient of **1** at 480 nm (maximum absorbance) was then calculated using the concentration, the UV absorbance, and the path length of the cuvette.

Circular Dichroism Measurements. Circular dichroism (CD) measurements were performed on a Jasco model J-710 spectropolarimeter. Peptide concentrations were determined using a molar extinction coefficient for the cross-linker of 16 200 cm^{-1} M^{-1} at 480 nm. For fast CD measurements, the instrument was set to time-drive mode. A scan time of 8 min with a 2-s step resolution and 1-s response was used. All samples were dissolved in 75% MeOH/25% pH 7.0 sodium phosphate buffer. The temperature of the sample was 10 °C, and the nitrogen flow rate was increased 2-fold to minimize condensation on the cuvette. Samples in cuvettes were flashed 40 times with an Elinchrome EL1000 flash lamp (flash power 1000 W•s, flash duration 1 ms) passed through a water cell to block short-wavelength UV as well as IR radiation, then transferred immediately into the spectropolarimeter for the measurement.

Molecular Modeling. Models of cis and trans cross-linkers were built using HyperChem (v.7, Hypercube Inc.) with the linker terminated with methyl groups representing the β carbon of cysteine in the cross-linked peptide and minimized using the Amber99 force field. Restraints were added to the azo bond for the cis conformation (force constant 50). The bonds labeled a, b, c, and d between the rings and the nitrogen atoms (Figure 5) were treated as being in conjugation with the rings for the trans isomer, whereas only bonds labeled a and d were treated as delocalized in the cis isomer (b and c were treated a normal single bonds). For the trans isomer, four MD runs of 50 ns each were performed using the Amber99 force field and using different starting torsion angles of the bonds labeled a, b, c, and d (180,180,180,180; 0,180,180,180; 180,180,0,180; 0,180,0,-180). Similarly, for the cis isomer, four MD runs of 50 ns each were performed using starting torsion angles of the bonds labeled a, b, c, and d of 180,48,48,180; 0,48,48,180; 180,48,−133,-180; and 0,180,−133,180. Constant energy MD was performed in vacuo with a distance-dependent dielectric and 1−4 scale factors of 0.833 for electrostatic and 0.5 for van der Waals interactions, a step size of 1 fs, and 300 K as the simulation temperature. Trajectories were analyzed to verify that numerous torsion angle changes occurred for all single bonds during the course of the simulation to ensure that conformational space was adequately sampled. All points histograms were then produced for the S−S distance during the full set of simulations for each isomer. S−S distance ranges in the peptides were calculated using FOLDTRAJ as described previously (*21*).

RESULTS AND DISCUSSION

Design and Synthesis of the Cross-Linker. Based on previous studies (*15*), we expected that an azobenzene derivative with a dialkylamino substituent in the para position would exhibit a wavelength of maximal absorption substantially longer than alkyl- and amide-substituted azobenzene derivatives, together with a faster thermal relaxation rate. We therefore wished to prepare a dialkylamino-substituted derivative that was symmetrical (to avoid the formation of different isomers upon protein conjugation), contained a minimum number of single bonds connecting the azo group with the peptide backbone, and was thiol reactive.

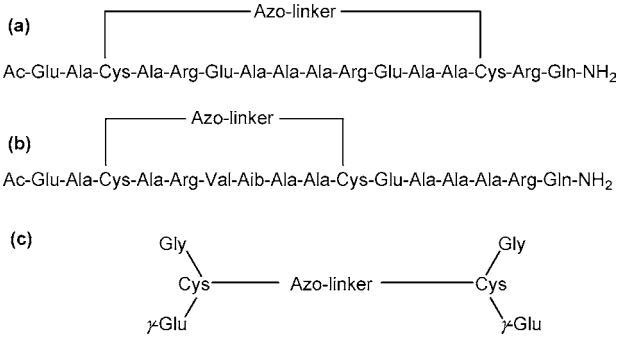


Figure 1. Primary sequences of the cross-linked peptides examined in this study: (a) FK-11 (azo-linker **1** reacted via cysteine residues spaced *i*, *i* + 11); (b) JRK-7 (azo-linker **1** reacted via cysteine residues spaced *i*, *i* + 7); (c) cross-linked glutathione.

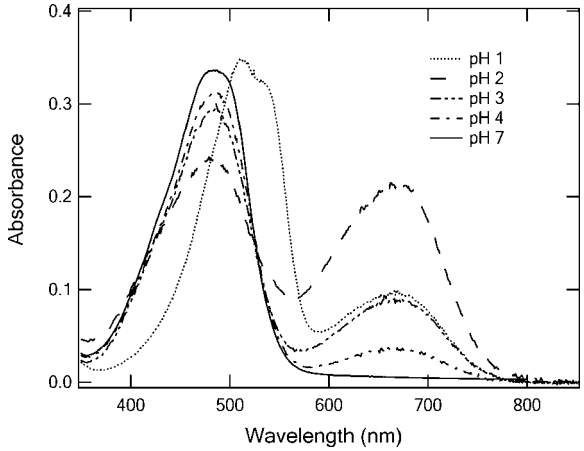

Figure 2. UV−vis spectra of the cross-linked FK-11 peptide (∼30 μM) in aqueous buffer at series of pH values.

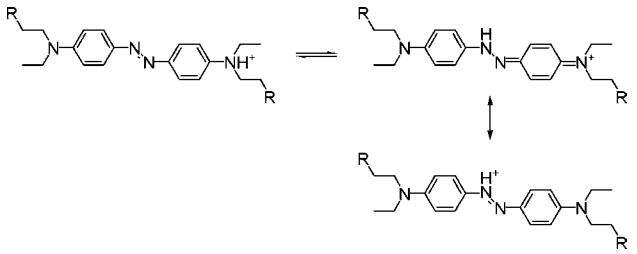
These considerations, together with the fact of the commercial availability of **2**, led us to the design of **1** (Scheme 1). Oxidation of **2** produced the symmetrical azo derivative **3**, which was subsequently converted to the dibromo derivative **4**. High reactivity and selectivity toward cysteine residues was then achieved by introducing methanethiosulfonyl groups. These groups enable reversible attachment of the cross-linker to peptides and proteins via disulfide linkages (*22*).

The cross-linker (**1**) was then reacted with the peptides shown in Figure 1. Reaction with FK-11 and JRK-7 produces an intramolecular cross-link between cysteine residues spaced *i*, *i* + 11 and *i*, *i* + 7, respectively. As a control, the cross-linker was also reacted with two molecules of the small tripeptide glutathione, which is too short to exhibit substantial secondary structure in solution. The cross-linked peptides were purified by HPLC and characterized by mass spectrometry.

UV Spectra: pH and Solvent Dependence. Figure 2 shows UV spectra of the cross-linked FK-11 peptide in aqueous buffer at a series of pH values. At pH values of 5 and above, a single maximum near 480 nm was observed. This value is at approximately 100 nm longer wavelengths than amide-substituted azobenzenes investigated previously. As the pH is lowered below 5, a second absorption band emerges at ∼680

Scheme 2



nm giving the solution a strong green color. Sawicki (*23*) and Jaffé (*24*) have studied the effect of ring substitutions on the pK_a's of azobenzene derivatives in detail. Based on their data, the singly protonated form of the cross-linker is expected to be a tautomeric equilibrium of the species shown in Scheme 2.

Lowering the pH below ~1.5 causes a further qualitative shift in the absorbance spectrum (Figure 2) consistent with the presence of a doubly protonated species (*23, 24*). Protonated forms of the cross-linker do not appear to isomerize. Thus the effective pH range of this cross-linker is pH 5 and above. Since most biological systems of interest operate in the region of pH 7, this pH sensitivity is not likely to present any difficulty.

Although this photoswitch is designed to be used with proteins in aqueous solution, the local environment of the switch will be determined primarily by the nature of the protein side chains near the cross-linking site. Amino-substituted azobenzenes, in contrast to alkyl- or amide-substituted species, are expected to be quite sensitive to local solvation (*15*). To ascertain the possible effects of local hydrophobicity, we examined the effects of modifying overall solvent polarity on the UV−vis spectra and thermal isomerization rates of peptide−cross-linker conjugates. Figure 3 shows UV absorbance spectra of cross-linked FK-11 with added organic cosolvents. As the percentage of methanol or DMSO is increased, the wavelength of maximal absorbance becomes shorter. In addition, fine structure in the spectra becomes more pronounced. Similar trends are observed for the glutathione-linked species (Figure 3).

For the JRK-7 cross-linked peptide, a more complicated solvent dependence is observed. Figure 4 shows spectra obtained in aqueous buffer (pH 7) with increasing fraction of methanol or DMSO. As the percentage of methanol or DMSO is increased from 0 to 50%, a bathochromic shift of absorption can be observed, and the fine structure in the spectra becomes less pronounced. Then, as the percentage of methanol or DMSO is increased from 50% to 100%, the spectra undergo a hypsochromic shift, and the fine structure becomes obvious again.

Similar solvent-induced effects on the electronic absorption spectra of related azobenzene derivatives have been observed previously (e.g., refs *15*, *25*, and *26* and references therein). Increased solvent polarity has been proposed to stabilize enhanced dipolar character in the excited state relative to the ground state. Chromophores in some cross-linked peptides (e.g., JRK-7) may experience especially complex local solvation processes compared to chromophores in bulk solution. Dipolar character similar to that in the excited state has been proposed to exist also in the transition state for isomerization (*25*). Thus increased solvent polarity may stabilize this transition state and increase the rate of isomerization. We therefore studied the effects of solvent polarity on isomerization rates.

Kinetics of Isomerization. The kinetics of thermal relaxation from cis to trans was studied for each peptide under a variety of solvent conditions at 25 °C. Cis isomers were produced by a brief exposure to 480 nm light. Recovery of the trans isomer

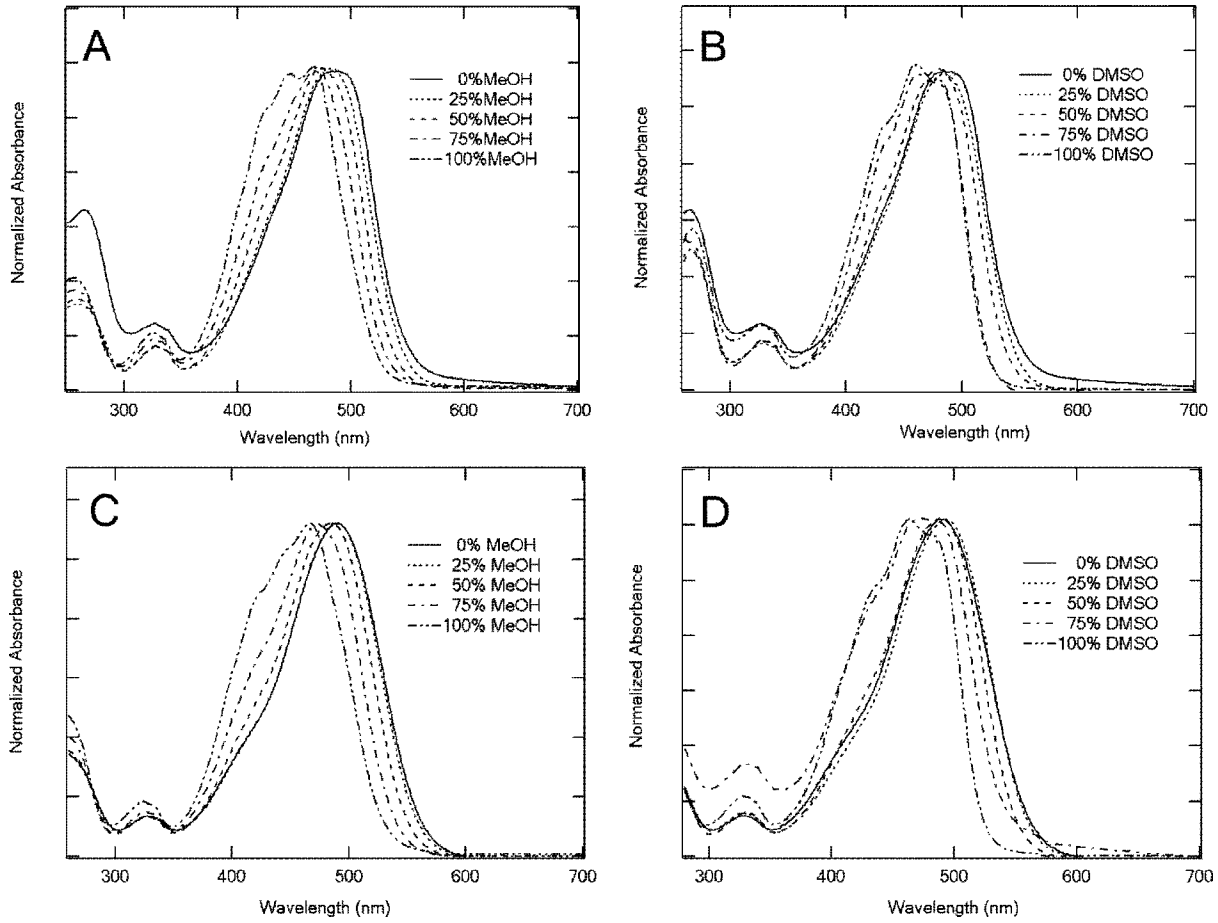


Figure 3. UV−vis spectra of the cross-linked FK-11 peptide (~70 μM) in aqueous buffer, pH 7, with added methanol (A) or DMSO (B) and for the glutathione-linked azo compound (~35 μM) in aqueous buffer, pH 7, with added methanol (C) or DMSO (D).

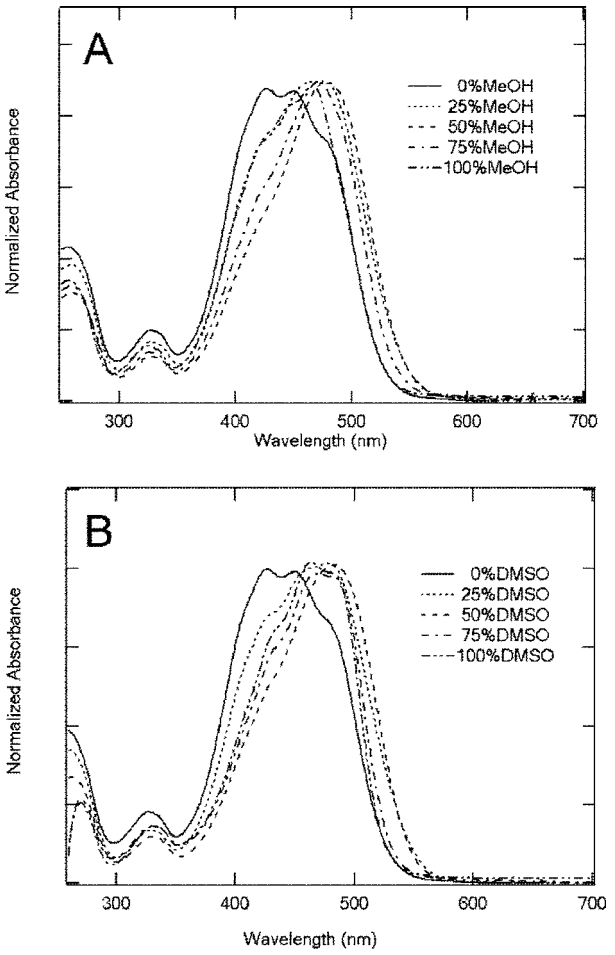

Figure 4. UV−vis spectra of the cross-linked JRK-7 peptide (~50 μM) in aqueous buffer, pH 7, with added methanol (A) or DMSO (B).

Table 1

organic solvent content (%)	$\tau_{1/2}$ (s) of cross-linked FK-11		$\tau_{1/2}$ (s) of cross-linked JRK-7		$\tau_{1/2}$ (s) of azobenzene glutathione derivative	
	DMSO	MeOH	DMSO	MeOH	DMSO	MeOH
0	0.076		0.0065		0.025	
25	2.4	1.1	4.2	2.2		
50	24.0	8.2	18.0	12.1	13.7	3.1
75	57.3	24.1	55.7	24.1	49.6	18.7
100	99.7	6.2	83.2	15.0	89.2	0.9

was measured by monitoring recovery of 480 nm absorbance over time using a low-intensity light source as desribed in the Experimental Procedures section. Half-lives were calculated by fitting absorbance vs time curves to the standard expression for a single-exponential decay process. These data are collected in Table 1.

In general, the half-lives of cis cross-linked FK-11 and JRK-7 become longer with increasing percentages of organic solvents. In 100% methanol, however, faster relaxation is observed in each case. The half-lives observed in aqueous buffer (between 10 and 100 ms) are the shortest recorded to date for a designed conformational switch (*3*, *7*). The half-live observed for JRK-7 was particularly short (6.5 ms). This may indicate that the local peptide environment of JRK-7 helps to stabilize the dipolar transition state for isomerization or that conformational preferences of the peptide act to destabilize the cis conformation of the cross-linker or both. To estimate the activation energy involved for cis to trans isomerization of the peptide systems in aqueous solution, we measured relaxation rates as a function of temperature. Calculated activation energies were as follows:

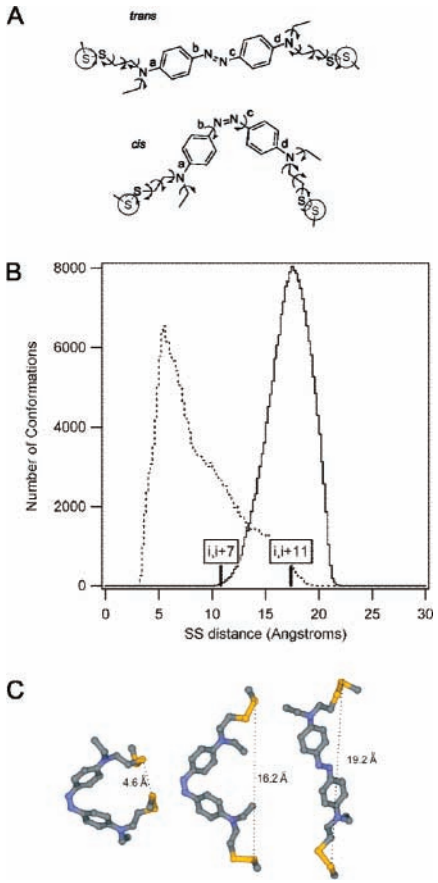

Figure 5. (A) Trans and cis forms of the cross-linker structure used for molecular dynamics simulations. Bonds labeled a−d were constrained as described in the Experimental Procedures section. (B) Probability distributions of distances between S atoms (circled in panel A) derived from the molecular dynamics simulations (cis (···), trans (—); distances between cysteine S atoms in ideal α-helices spaced *i, i* + 7 and *i, i* + 11 in the primary sequence are indicated. (C) Some representative structures and S−S distances observed during the simulations. Cis forms show a wider range of S−S distances.

cross-linked-FK11 is 6.5 ± 0.5 kcal/mol (27 ± 2 kJ/mol); cross-linked JRK-7 is 5.5 ± 1.4 kcal/mol (23 ± 6 kJ/mol); the cross-linked glutathione derivative is 6.5 ± 0.3 kcal (27 ± 1 kJ/mol).

Conformational Analysis of the Cross-Linker and Effects of Photoisomerization. To estimate the effects of the cross-linker on the conformational properties of attached peptides or proteins, we first examined the conformational properties of the cross-linker itself in cis and trans conformations. In particular, the range of end-to-end distances exhibited by the cross-linker provides a good first approximation for predicting its effect on conformational ensembles of helical peptides (*17*, *21*). Simplified models of **1** attached to a peptide (where the β position of a cysteine side chain is represented by a methyl group) in cis and trans conformation were built using HyperChem (Hypercube Inc.).

Figure 5a shows these structures together with the restraints that were added during molecular dynamics simulations. Sulfur−sulfur distances together with all bond torsion angles were monitored. Figure 5b shows histograms of the S−S distances for cis and trans isomers together with some representative structures (Figure 5c). The trans isomer has a most-probable end to end distance of ~18 Å (and a range from 11 to 21 Å), whereas the cis isomer shows a more complex distribution with a most probable distance of ~6 Å but is compatible with distances from ~4 to ~17 Å. When a peptide with cysteine residues spaced *i, i* + 11 is in an α-helical conformation, the distance between S atoms of the cysteine side chains is 17.4 Å.

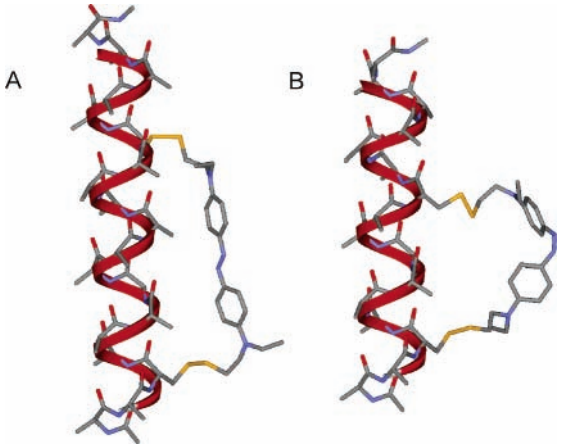

Figure 6. Molecular models of trans cross-linked FK-11 (A) and cis cross-linked JRK-7 (B) in a helical conformation.

When a peptide with cysteine residues spaced i, $i + 7$ is in an α-helical conformation, the distance between S atoms of the cysteine side chains is 10.8 Å (*17*, *21*). Based on observed effects with previous cross-linkers, one would predict that the trans form of the cross-linker (**1**) would be compatible with a helical conformation of FK-11 (Figure 6) and that isomerization from trans to cis would decrease the helical content. Conversely, a trans conformation of the cross-linker should be incompatible with standard helix formation for JRK-7 but isomerization from trans to cis should make helix formation more likely (Figure 6).

To test these predictions, we performed CD studies of the two cross-linked peptides in 75% methanol as described in the Experimental Procedures section. Under these solvent conditions, the cross-linked peptides isomerize slowly enough to monitor using a conventional CD instrument. The half-lives observed without an organic cosolvent are too short to permit CD measurements with a standard commercial instrument. We expect similar conformational behavior in aqueous solution although the magnitude of the helix content changes will likely be different.

Figure 7 shows the effects of photoisomerization on peptide conformation. For the FK-11 peptide, relaxation of the cross-linker from cis to trans after a light flash is expected to increase helicity. Consistent with this expectation, the CD signal at 225 nm recovers from a less negative to a more negative value (Figure 7A). Conversely, for the JRK-7 peptide, relaxation of the cross-linker from cis to trans after a light flash is expected to decrease helicity. Likewise, the CD signal at 225 nm recovers from a more negative to a less negative value (Figure 7B). The magnitudes of the observed changes are not particularly significant since they depend on the precise solvent composition, the temperature, and the time elapsed between the flash and the beginning of the measurement. From the time dependence of the signal however, the half-lives of cis forms of cross-linked FK-11 and JRK-7 can be calculated to be 80 ± 14 and 81 ± 6 s, respectively. These values are comparable to the time constants estimated from the UV data in Table 1 (∼40 s) assuming that the activation energy of the two peptides in 75% methanol is the same as that in phosphate buffer (pH 7.0).

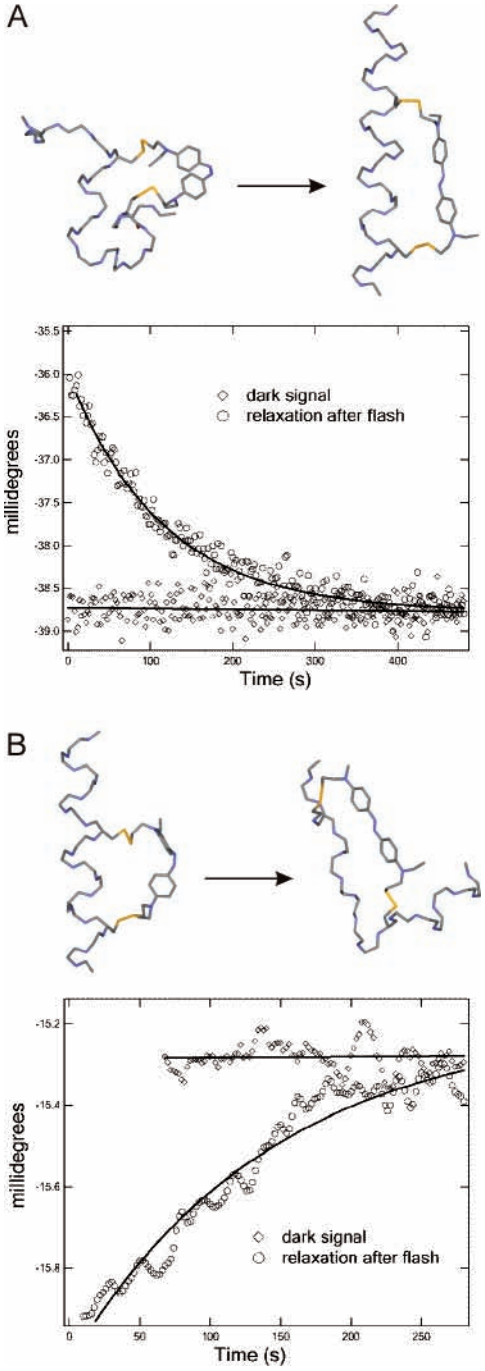

Figure 7. Time-dependent circular dichroism (CD) signal at 225 nm of (A) cross-linked FK-11 (∼25 μM, 1 cm cell) and (B) cross-linked JRK-7 (∼100 μM, 0.1 cm cell) observed after conversion of a percentage of each peptide to the cis isomer. In panel A, relaxation from cis-to-trans is associated with an increase in peptide helix content. In panel B, relaxation from cis-to-trans is associated with a decrease in peptide helix content. Solvent conditions were 75% methanol in 10 mM sodium phosphate buffer, pH 7.0, 10 °C.

SUMMARY

We have designed and synthesized a new methanethiosulfonate (MTS)-bearing thiol-reactive azobenzene cross-linker that is able to reversibly control the helical content of attached peptides. Its effects on helix content can be predicted by comparing the range of S−S distances in the intrinsic conformational ensemble of the peptide with the range compatible with the chemical structure of the linker. The wavelength for trans-to-cis photoswitching is ∼100 nm longer (λ_{max} = 480 nm) than cross-linkers previously described, and the half-life of the cis state (10−100 ms) is comparable to the time scale of many protein-based dynamic processes in biochemical systems. This switch may therefore prove useful as a tool for probing dynamic processes in biochemical systems using light.

ACKNOWLEDGMENT

We are grateful to Prof. Jerry Kresge for the use of his flash photolysis apparatus. This work has been supported by Natural Sciences and Engineering Research Council of Canada.
