Nonviral vectors for gene therapy have recently received an increased impetus because of the inherent safety problems of the viral vectors, while their transfection efficiency is generally low compared to the viral vectors. The lack of the ability to escape from the endosomal compartments is believed to be one of the critical barriers to the intracellular delivery of noviral gene vectors. This study was devoted to the design and preparation of a novel ABC triblock copolymer for constructing a pH-responsive and targetable nonviral gene vector. The copolymer, lactosylated poly(ethylene glycol)-*block*-poly(silamine)-*block*-poly[2-(*N*,*N*-dimethylamino)ethyl methacrylate] (Lac-PEG-PSAO-PAMA), consists of lactosylated poly(ethylene glycol) (A-segment), a pH-responsive polyamine segment (B-segment), and a DNA-condensing polyamine segment (C-segment). The Lac-PEG-PSAO-PAMA spontaneously associated with plasmid DNA (pDNA) to form three-layered polyplex micelles with a PAMA/pDNA polyion complex (PIC) core, an uncomplexed PSAO inner shell, and a lactosylated PEG outer shell, as confirmed by ^{1}H NMR spectroscopy. Under physiological conditions, the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles prepared at an N/P (number of amino groups in the copolymer/number of phosphate groups in pDNA) ratio above 3 were found to be able to condense pDNA, thus adopting a relatively small size ($<$ 150 nm) and an almost neutral surface charge ($\zeta \sim +5$ mV). The micelle underwent a pH-induced size variation (pH = 7.4, 132.6 nm $\rightarrow$ pH = 4.0, 181.8 nm) presumably due to the conformational changes (globule-rod transition) of the uncomplexed PSAO chain in response to pH, leading to swelling of the free PSAO inner shell at lowered pH while retaining the condensed pDNA in the PAMA/pDNA PIC core. Furthermore, the micelles exhibited a specific cellular uptake into HuH-7 cells (hepatocytes) through asialoglycoprotein (ASGP) receptor-mediated endocytosis and achieved a far more efficient transfection ability of a reporter gene compared to the Lac-PEG-PSAO/pDNA and Lac-PEG-PAMA/pDNA polyplex micelles composed of the diblock copolymers and pDNA. The effect of hydroxychloroquine as an endosomolytic agent on the transfection efficiency was not observed for the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles, whereas the nigericin treatment of the cell as an inhibitor for the endosomal acidification induced a substantial decrease in the transfection efficiency, suggesting that the protonation of the free PSAO inner shell in response to a pH decrease in the endosome might lead to the disruption of the endosome through buffering of the endosomal cavity. Therefore, the polyplex micelle composed of ABC (ligand-PEG/pH-responsive segment/DNA-condensing segment) triblock copolymer would be a promising approach to a targetable and endosome disruptive nonviral gene vector.

INTRODUCTION

Nonviral vectors for gene therapy have recently received increased attention because of the concerns over the safety issues of viral vectors, including immunogenicity, oncogenicity, and potential virus recombination (*1*−*3*). Most of the nonviral vectors developed so far, however, show low transfection efficiency compared to the viral vectors, because the latter have evolved multi-functionality to overcome the critical barrier to efficient gene delivery by directing the specific cellular uptake and enhancing transport to the cytoplasm from the endosomal compartment. Recently, a new class of nonviral gene vectors has been developed based on the supramolecular assembly between plasmid DNA (pDNA) and poly(ethylene glycol) (PEG)-*block*-polyamine copolymers (polyplex micelles) (*4*−*10*). Because of the highly dense PEG shell surrounding the polyion complex (PIC) core, the polyplex micelles exhibited excellent solubility in aqueous media, high tolerability toward nuclease degradation, and minimal interaction with biological components, including proteins and cells, compared to the other conventional polyplex and lipoplex systems. Furthermore, ligand-installed polyplex micelles prepared from lactosylated PEG-*block*-poly[2-(*N*,*N*-dimethylamino)ethyl methacrylate] copolymer and pDNA showed an increase in the cellular uptake through a receptor-mediated endocytosis process compared to those without lactose (ligand) moieties (*11*). To observe an appreciable effect of the ligand molecules on gene expression, however, the presence of hydroxychloroquine (100 μM) as an endosomolytic agent (*12*, *13*) has so far been required. This indicates that endosomal escape should be the most critical

barrier to intracellular gene delivery by polyplex micelles (*14*−*16*). Therefore, approaches are needed to devise polyplex micelles with a function to escape from the endosome where the pH is 1.4−2.4 units lower than the physiological pH of 7.4 (*17*−*20*). In this regard, poly(ethylenimine) (PEI) derivatives are of interest as a pH-responsive polyamine component to accomplish endosomal escape by taking advantage of their substantially lowered value of apparent pK_a (∼5.5) ("buffer or proton-sponge effect") (*21*). However, the buffer effect of the PEI segment occurs only when an excess of amino groups with respect to DNA phosphate groups (high N/P ratio) is present in the system, where a considerable amount of the amino groups in PEI is in the free-base form. This fact strongly suggests that free PEI, which is not complexed with pDNA, is likely to play a crucial role in the buffer effect, because amino groups in the PEI/pDNA polyplex generally undergo facilitated protonation due to the zipper effect or the neighboring group effect during the polyion complexation (over-protonation) to decrease the buffering capacity (*22*). Therefore, a strategy is needed to satisfy the prevention of overprotonation of the pH-responsive polyamine segment in the polyplex, as well as the achievement of efficient condensation of pDNA into the PIC core to exert efficient stability. Worth noting in this regard is a concomitant incorporation of the polyamine segment with a high pK_a and one with a low pK_a into a single PEG-based strand, as an ABC triblock copolymer (*23*). A polyamine segment with a high pK_a as the C block preferentially forms a polyion complex with phosphate groups in pDNA (DNA-condensation segment), whereas the pH-responsive polyamine segment (B block) with a comparatively low pK_a, located between the PEG segment (A block) and the pDNA-condensation segment (C block), is expected to retain a substantial fraction of unprotonated amino groups (free-base) even in the polyplex due to the low protonation ability. As a consequence, the polyion complexation between such an ABC triblock copolymer and pDNA may lead to the formation of a three-layered polyplex micelle possessing an unprotonated pH-responsive polyamine segment as an intermediate layer to function as a buffering moiety for facilitated endosomal escape.

We herein synthesized a novel ABC triblock copolymer composed of a targetable and biocompatible polymer segment, a pH-responsive polyamine segment, and a DNA-condensing polyamine segment to form a three-layered polyplex micelle: lactosylated PEG-*block*-poly(silamine) (PSAO) -*block*-poly[2-(*N*,*N*-dimethylamino)ethyl methacrylate] (PAMA) [Lac-PEG-PSAO-PAMA]. Here, PSAO was selected as the pH-responsive polyamine segment showing two-step protonation (Figure 1, pK_{a1} = 8.6 and pK_{a2} = 5.8) along with a unique conformational transition at the critical pH (*24*−*29*). The unprotonated PSAO is insoluble in water, assuming a globular conformation with high flexibility, whereas fully protonated PSAO is soluble in water, assuming a rodlike conformation with rigid and expanded polymer strands. Such a unique conformational transition (rod-globule transition) can be explained by the rotational hindrance around the polymer chain due to the protonation of the amino groups along with the counteranion binding to the Si atoms (Figure 1). On the other hand, PAMA (pK_a = 7.2) is known to condense pDNA to form a compact structure, the size of which is less than 200 nm under physiological conditions (*8*, *30*, *31*). This fact suggests that polyion complexation between the Lac-PEG-PSAO-PAMA and pDNA may form a targetable and endosome disruptive polyplex micelle with a well-defined three-layered structure (Figure 2).

EXPERIMENTAL SECTION

Materials. 2,2′-Azobisisobutyronitrile (AIBN), dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), and nigericin (NR) were purchased from Wako and used without further purification. Asialofetuine (ASF) and hydroxychloroquine sulfate (HCQ) were purchased from Sigma and Acros Organics, respectively. Potassium naphthalene was used as a THF solution, whose concentration was determined by titration. Water was purified using a Milli-Q instrument (Millipore). 2-Propanol and diethyl ether (Et_2O) were used as received without further purification. Lysotraker Red DND-99 was purchased from Molecular Probes. Plasmid DNA (pDNA) encoding firefly luciferase (pGL3-Luc, Promega; 5256 bpa) was amplified using EndoFree Plasmid Maxi or Mega kits (QIAGEN). The DNA concentration was determined by reading the absorbance at 260 nm.

Polymer Analysis. ^{1}H NMR (400 MHz) spectra were obtained in $CDCl_3$, DMSO-d_6, or D_2O (pD = 7.4 and 4.0) with 0.15 M NaCl using a JEOL EX400 spectrometer. Chemical shifts were reported in ppm relative to $CDCl_3$ (δ7.26, ^{1}H), DMSO-d_6 (δ 2.50, ^{1}H), or D_2O buffer (δ 4.76, ^{1}H). Size exclusion chromatography (SEC) was performed using a TOSO

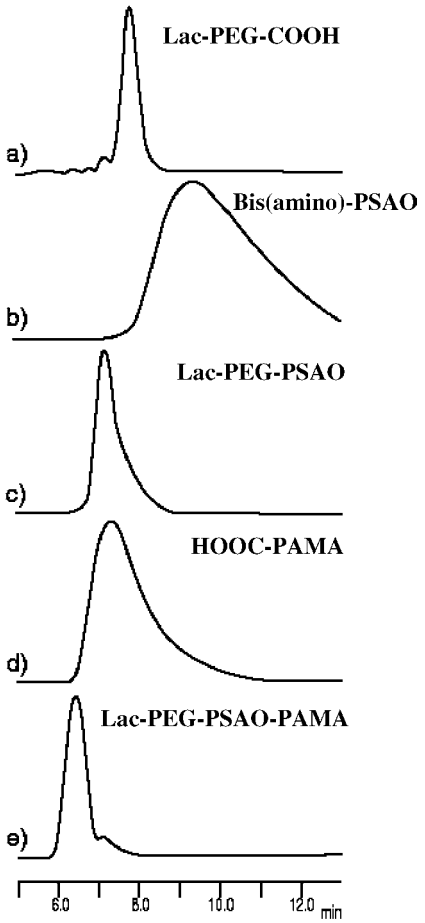

Figure 3. SEC chromatograms of the (a) Lac-PEG-COOH, (b) bis-(amino)-PSAO, (c) Lac-PEG-PSAO block copolymer, (d) HOOC-PAMA, and (e) Lac-PEG-PSAO-PAMA triblock copolymer.

HLC-8020 equipped with an internal refractive index (RI) detector (RID-6A) with the combination of TSK $G4000_{HR}$ and $G3000_{HR}$ columns using THF as the eluent.

Synthesis of Lactose-PEG-*block*-PSAO. Bis(amino)-PSAO was synthesized according to our previous report (*24*−*29*). The Lac-PEG-COOH (0.100 g, 16 μmol) and an excess amount of bis(amino)-PSAO (1.244 g 800 μmol, M_n = 1550, DP = 6) were dissolved in $CHCl_3$ (5.0 mL) together with DCC (6.3 mg, 32 μmol) and NHS (2.3 mg, 20 μmol). The reaction mixture was stirred at room temperature for 72 h. To remove the unreacted bis(amino)-PSAO and other chemicals, the reaction mixture was poured into Et_2O (200 mL). The obtained polymer was further purified by reprecipitation into Et_2O (200 mL) and then freeze-dried with benzene to obtain the lactose-PEG-*b*-PSAO (0.102 g, 83% yield). Figures 3c and 4a, respectively, show the SEC chromatogram and ^{1}H NMR spectrum of Lac-PEG-PSAO with assignment. SEC M_n = 7170, M_w/M_n = 1.15 (calcd. M_n = 7850); ^{1}H NMR ($CDCl_3$, in Figure 4a) δ 0.10 (s, 36H, H_k), 0.63−0.79 (m, 24H, H_j), 1.02 (t, J = 7.3 Hz, 36H, H_i), 1.10 (t, J = 7.1 Hz, 3H, H_i''), 1.16 (t, J = 7.1 Hz, 3H, H_i'), 1.77−2.02 (m, 4H, H_d+H_f), 2.42 (t, J = 7.1 Hz, 2H, H_g), 2.47−2.62 (m, 80H, H_h), 2.62−2.73 (m, 2H, H_c), 3.61 (s, 617H, H_a+H_b+H_e)

Synthesis of Lactose-PEG-*block*-PSAO-*block*-PAMA. A PAMA homopolymer bearing a carboxylic acid group at the α-end (HOOC-PAMA) was synthesized via anionic polymerization of 2-(*N*,*N*-dimethylamino)ethyl methacrylate (*32*) using the allyl alcohol/potassium-naphthalene initiator system, followed by the radical addition of 3-mercaptopropionic acid in the presence of AIBN. The Lac-PEG-PSAO (0.051 g, 7.8 μmol) and an excess amount of HOOC-PAMA bearing a carboxylic acid group at the α-end (0.5017 g, 88.5 μmol, M_n = 5670, DP = 35) were dissolved in $CHCl_3$ (5.0 mL) together with DCC (3.2 mg, 16 μmol) and NHS (1.6 mg, 10 μmol). The reaction mixture was stirred at room temperature for 72 h. To remove the unreacted HOOC-PAMA and other chemicals, the polymer was recovered by precipitation into cold 2-propanol (−15 °C, 200 mL) and centrifuged for 45 min at 6000 rpm. Further purification was carried out by dialyzing against distilled, deionized water (cutoff MW 3500) and then freeze-dried to obtain Lac-PEG-PSAO-PAMA (0.0383 g, 37% yield). Figures 3e and 4b, respectively, show the SEC chromatogram and ^{1}H NMR spectrum of Lac-PEG-PSAO-PAMA with assignment. SEC M_n = 10850, M_w/M_n = 1.29 (calcd. M_n = 13450); ^{1}H NMR ($CDCl_3$, in Figure 4b) δ 0.10 (s, 36H, H_d), 0.63−0.79 (m, 24H, H_c), 0.80−1.16 (m, 94H, H_g), 1.02 (t, J = 7.3 Hz, 42H, H_e), 1.16−2.17 (m, 64H, H_f), 2.23 (s, 185H, H_j), 2.37−2.84 (m, 143H, H_b + H_i), 3.61 (s, 617H, H_a), 4.08 (s, 62H, H_h).

Light Scattering Measurements of Polyplex Micelles. To prepare stock solutions, specific amounts of each of the block copolymers (Lac-PEG-PSAO-PAMA, Lac-PEG-PSAO, and Lac-PEG-PAMA) were dissolved in 10 mM Tris-HCl buffer (pH 7.4) or distilled, deionized water, followed by adjustment of the pH to 7.4. Both solutions were filtered through a 0.1-μm filter to remove dust prior to the measurement. For the dynamic light scattering (DLS) measurements as a function of pH, the Lac-PEG-PSAO-PAMA copolymer in distilled water at pH 7.4 including 0.15 M NaCl was mixed with pDNA at an N/P ratio of 3 [N/P = (amino group in the block copolymer)/(phosphate groups in pDNA)] at pH 7.4 to obtain the final concentration of 33.3 μg/mL of pDNA in the solution. The sample solutions were adjusted to the desired pH using small aliquots of 0.1 or 0.01 M HCl, and the DLS was measured at each pH point (pH = 7.0, 6.5, 6.0, 5.5, 5.0, 4.5, and 4.0).

For the DLS measurements of the samples prepared at various N/P ratios, the block copolymer in 10 mM Tris-HCl buffer (pH 7.4) was mixed with pDNA at various N/P ratios (N/P = 1, 2, 3, 4, 5, 7, and 10), followed by the addition of 10 mM Tris-HCl buffer (pH 7.4) including 0.3 M NaCl to adjust the pDNA concentration (33.3 μg/mL) and the ionic strength of the solution to physiological conditions (0.15 M NaCl).

A light-scattering spectrometer (DLS-7000, Photal, Otsuka Electronics) equipped with a 75 mW Ar-laser that produces a vertically polarized incident beam at λ_0 = 488 nm was used in the present study for the DLS measurements.

During the DLS measurements, the autocorrelation function was analyzed using the cumulant method in which

$$g^{(1)}(\tau) = \exp[-\bar{\Gamma}\tau + (\mu_2/2)\tau^2 - (\mu_3/3!)\tau^3 + \cdots] \quad (1)$$

yielding an average characteristic line width of $\bar{\Gamma}$. The z-averaged diffusion coefficient was obtained from the $\bar{\Gamma}$ based on the following equations:

$$\bar{\Gamma} = Dq^2 \quad (2)$$

$$q = (4\pi n/\lambda)\sin(\theta/2) \quad (3)$$

where q is the magnitude of the scattering vector, n is the refractive index of the solvent, and θ is the detection angle. The hydrodynamic radius, d, can then be calculated using the Stokes−Einstein equation:

$$d = k_B T/(6\pi\eta D) \quad (4)$$

where k_B is the Boltzmann constant, T is the absolute temperature, and η is the viscosity of the solvent. Also, the polydispersity index (PDI = μ_2/Γ^2) was derived from eq 1.

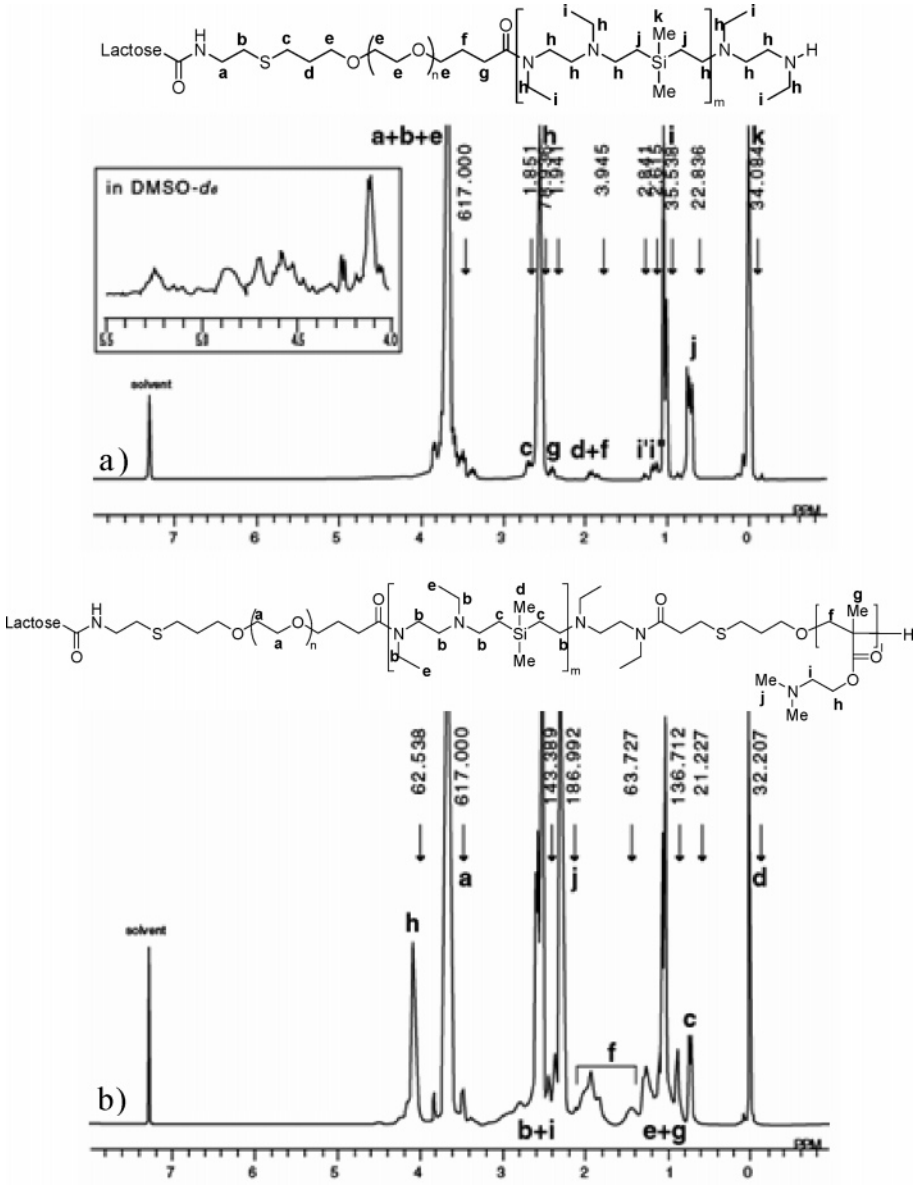

Figure 4. [1]H NMR spectra of (a) Lac-PEG-PSAO diblock copolymer and (b) Lac-PEG-PSAO-PAMA triblock copolymer.

Zeta-Potential Measurements. Laser-Doppler electrophoresis measurements of the polyplex micelles were carried out in 10 mM Tris-HCl buffer (pH 7.4) without NaCl (ELS-600, Photal, Otsuka Electronics). From the determined electrophoretic mobility, the zeta-potential (ζ) was calculated according to the Smoluchouski equation as follows:

$$\zeta = 4\pi n\eta\mu u/\epsilon \qquad (5)$$

where η is the viscosity of the solution, u is the electrophoretic mobility, and ϵ is the dielectric constant of the solvent.

Ethidium Bromide Exclusion Assay. The polyplex micelle solutions at various N/P ratios were mixed with ethidium bromide (EtBr) solution, and the final concentration was adjusted to [pDNA] = 20 μg/mL and [EtBr] = 0.4 μg/mL. The fluorescence of the intercalated EtBr was measured on a spectrofluorometer (F-2500, Hitachi) by exciting at 510 nm while monitoring emission at 590 nm.

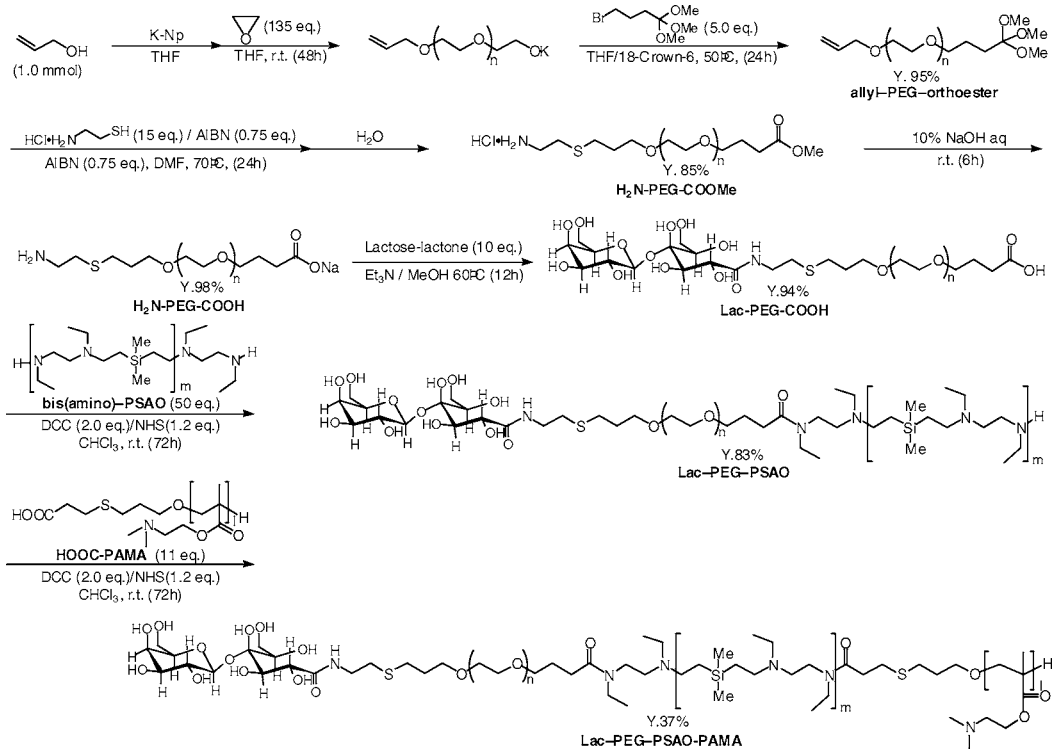
Agarose Gel Retardation Studies. Aliquots (10 μL) of the above polyplex micelle solutions with various N/P ratios were mixed with 13 μL of running buffer of 3.3 mM Tris-AcOH with 1.0 mM EDTA2Na (pH 7.4) and loaded onto a 0.9 wt % agarose gel (50 V, 2 h). The amount of pDNA was adjusted to 0.3 μg of pDNA/lane. After EtBr (0.5 μg/mL) staining for 1 h, retardation of pDNA was visualized under UV irradiation.

Cell Culture. HuH-7 human cancer cells, derived from a hepatocarcinoma cell line, were obtained from the Cell Resource Center for Biomedical Research, Institute of Development, Aging and Cancer, Tohoku University. The cells were grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% FBS, 100 units/mL penicillin, and 100 μg/mL streptomycin at 37 °C in a humidified 5% CO_2 atmosphere.

Fluorescent Microscopy. Fluorescein isothiocyanate (FITC)-labeled pDNA was prepared using a Label IT nucleic acid labeling kit (Panvera). HuH-7 cells were seeded at a density of 5×10^5 cells/dish in a 35-mm glass bottom dish (Iwaki, Japan) and kept overnight at 37 °C in 5% CO_2 atmosphere. The Lac-PEG-PSAO-PAMA/pDNA polyplex micelles (N/P = 3) were added at a pDNA concentration of 30 μg/mL and incubated at 37 °C in 5% CO_2 atmosphere in the presence or absence of ASF (10 mg/mL) for 60 min. The cells were washed with phosphate buffered saline (PBS) three times and imaged directly in the cell culture medium using an Olympus IX70 with an appropriate filter.

Confocal Fluorescent Microscopy. HuH-7 cells were seeded at a density of 5×10^5 cells/dish in a 35-mm glass bottom dish

Scheme 1. Synthetic Route of Lac-PEG-PSAO-PAMA Block Copolymer



(Iwaki, Japan) and kept overnight at 37 °C in 5% CO_2 atmosphere. The Lac-PEG-PSAO-PAMA/pDNA and the Lac-PEG-PAMA/pDNA polyplex micelles (N/P = 3) containing FITC-labeled pDNA were added at a pDNA concentration of 30 μg/mL and incubated at 37 °C in 5% CO_2 atmosphere in the presence of Lysotraker Red DND-99 (50 nM) for 30 and 120 min. The cells were washed with PBS three times and imaged directly in the cell culture medium using an Olympus IX81 equipped with a confocal IX2-DSU system and an appropriate filter.

Transfection to HuH-7 Cells. HuH-7 cells were plated in a 24-well plate (5×10^4 cells/well) to reach about 50% confluence after 24 h at transfection, and the medium was then changed to fresh DMEM with 10% FBS (225 μL/well). For each well, the polyplex micelles or B-PEI/pDNA polyplexes at various N/P ratios (25 μL/well) were added with a pDNA concentration of 30 μg/mL. After 24 h incubation, the transfection medium was changed to fresh DMEM with 10% FBS, and the cells were further incubated for 24 h. For the preincubation study with serum, a medium containing 20% FBS was added to the solution of the polyplex micelles or B-PEI/pDNA polyplexes and incubated at 37 °C for 6 h prior to the transfection study. The cells were lysed, and the luciferase activity of the lysate was monitored with the a Luciferase Assay kit (Promega) and ARVOSX-1 (PerkinElmer). The results were expressed as light units per milligram of cell protein determined by a micro BCA assay kit (Pierce).

RESULTS AND DISCUSSION

Synthesis of Lactosylated Poly(ethylene glycol)-*block*-poly(silamine)-*block*-poly[2-(*N*,*N*-dimethlyamino)ethyl methacrylate] Triblock Copolymer. A synthetic route to lactosylated poly(ethylene glycol)-*block*-poly(silamine)-*block*-poy[2-(*N*,*N*-dimethlyamino)ethyl methacrylate] (Lac-PEG-PSAO-PAMA) triblock copolymer is shown in Scheme 1. A heterobifunctional PEG bearing an allyl group at the α-end and an ortho ester group at the ω-end (allyl-PEG-ortho ester) was synthesized via the anionic ring-opening polymerization of ethylene oxide using the allyl alcohol /potassium-naphthalene initiator system, followed by termination with trimethyl 4-bromoorthobutyrate in the presence of 18-Crown-6. The radical addition of 2-aminoethanethiol hydrochloride to the allyl-PEG-ortho ester quantitatively afforded an amine-PEG-methoxycarbonyl (H_2N-PEG-COOMe). Conversion of the ortho ester group into a methoxycarbonyl group (COOMe) occurred due to the hydrolysis of the ortho ester group during the purification (dialysis) process. The H_2N-PEG-COOMe was then converted into an amine-PEG-carboxylic acid (H_2N-PEG-COOH) by hydrolysis with 10% NaOHaq. The SEC (data not shown), ^{1}H NMR, and MALDI-TOF MS analyses (see Supporting Information) revealed that the determined molecular weight of the H_2N-PEG-COOH (SEC: $M_n = 6200$, $M_w/M_n = 1.04$, TOF-MS: $M_n = 6190$, $M_w/M_n = 1.03$) agrees well with the calculated value (calcd. $M_n = 6130$), and an amino group and carboxylic acid group were quantitatively introduced into the α-end and ω-end of PEG, respectively, to confirm the successful synthesis of allyl-PEG-ortho ester and H_2N-PEG-COOMe. The introduction of a lactose group to the amine end of H_2N-PEG-COOH was performed by reaction with an excess amount of lactose-lactone (*33*). In the ^{1}H NMR spectrum of Lac-PEG-COOH, the degree of lactose functionality was determined to be 72% (see Supporting Information).

To obtain the lactosylated PEG-PSAO block copolymer, bis-(amino)-PSAO ($M_n = 1550$, the degree of polymerization (DP) = 6) was prepared as reported previously by the anionic polyaddition of dimethyldivinylsilane with *N*,*N*′-diethylethylenediamine in the presence of a catalytic amount of *n*-BuLi in THF at 60 °C (*24*−*29*). The conjugation of the Lac-PEG-COOH with bis(amino)-PSAO was performed by activating the terminal carboxylic acid of Lac-PEG-COOH using dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS). A large excess (50 equiv) of the bis(amino)-PSAO was used to suppress the formation of triblock coplymer viz., Lac-PEG-PSAO-PEG-Lac. After the conjugation reaction, unconjugated bis(amino)-PSAO and other chemicals were removed by precipitation into Et_2O. Figures 3c and 4a, respectively, show the SEC chromatogram and ^{1}H NMR spectrum of the Lac-PEG-PSAO block

[a] Conditions for DLS measurements: detection angle, 90°; solvent, 10 mM Tris-HCl, pH 7.4, including 0.15 M NaCl; temperature, 37 °C. [b] Conditions for zeta-potential measurements: solvent, 10 mM Tris-HCl, pH 7.4; temperature, 25 °C.

copolymer with assignments. As seen in the SEC chromatograms (Figure 3), Lac-PEG-PSAO (Figure 3c) gave a unimodal peak at a high molecular weight position (i.e., shorter elution time) compared to the Lac-PEG-COOH (M_n = 6300, M_w/M_n = 1.05, Figure 3a) and bis(amino)-PSAO (M_n = 1550, M_w/M_n = 2.01, Figure 3b). Note that the unreacted Lac-PEG-COOH and bis(amino)-PSAO were not observed in the SEC chromatogram (Figure 3c) of the Lac-PEG-PSAO (obsd. M_n = 7150, M_w/M_n = 1.15, calcd. M_n = 7850). In the ^{1}H NMR spectrum (Figure 4a), the peaks corresponding to both of the PEG and PSAO segments were clearly observed, consistent with the formation of a diblock copolymer. Note that the peaks corresponding to the terminal lactose moiety were also observed at δ 4.0−5.3 ppm in the ^{1}H NMR spectrum in DMSO-d_6. From the integral ratio between the PEG-backbone protons (3.7 ppm -OCH_2CH_2-) and the methyl protons of PSAO segment (0.1 ppm, $SiMe_2$), the DP of the PSAO segment in the block copolymer was calculated to be 5.67, which is in good accordance with that of the starting bis(amino)-PSAO (DP = 6).

To obtain the Lac-PEG-PSAO-PAMA triblock copolymer, the conjugation of the Lac-PEG-PSAO diblock copolymer and HOOC-PAMA was performed in a manner similar to the conjugation of Lac-PEG-COOH and bis(amino)-PSAO. After the conjugation reaction, unconjugated HOOC-PAMA and other chemicals were removed by precipitation into cold 2-propanol, followed by centrifugation. Figures 3e and 4b, respectively, show the SEC chromatogram and ^{1}H NMR spectrum of the Lac-PEG-PSAO-PAMA triblock copolymer with assignments. The Lac-PEG-PSAO-PAMA (Figure 3e, M_n = 10850, M_w/M_n = 1.29, calcd. M_n = 13450) had a shorter elution time compared to the Lac-PEG-PSAO (M_n = 7170, M_w/M_n = 1.15, Figure 3c) and HOOC-PAMA (M_n = 5670, M_w/M_n = 1.50, DP = 35, Figure 3d), indicating an increased molecular weight due to the formation of the triblock polymer. Nevertheless, a slight portion of unreacted Lac-PEG-PSAO and/or HOOC-PAMA seems to still remain (about 10%) in the sample as indicated by the small accompanying peak appearing after the main fraction (Figure 3e). In thethe ^{1}H NMR spectrum (Figure 4b), the peaks corresponding to the PEG, PSAO, and PAMA segments were clearly observed, suggesting the formation of a triblock copolymer. From the integral ratio between the PEG-backbone protons (3.7 ppm -OCH_2CH_2-) and methylene protons of the PAMA segment (4.08 ppm, -COOCH_2CH_2N(CH_3)$_2$), the DP of the PAMA segment was calculated to be 31.3 (DP of starting PAMA = 35). This result indicates that the purity of the triblock copolymer was 89%.

Furthermore, Lac-PEG-PSAO (M_{nPEG} = 6300, DP_{PSAO} = 6, number of amino groups = 12) and Lac-PEG-PAMA (M_{nPEG} = 6300, DP_{PAMA} = 55, number of amino groups = 55) diblock copolymers were prepared in a similar manner as the controls for the Lac-PEG-PSAO-PAMA (M_{nPEG} = 6300, DP_{PSAO} = 6, DP_{PAMA} = 35, total number of amino groups = 47).

Physicochemical Characterization of Polyplex Micelles. The obtained triblock (Lac-PEG-PSAO-PAMA) and diblock (Lac-PEG-PAMA and Lac-PEG-PSAO) copolymers form polyplex micelles through the mixing with pDNA based on electrostatic interaction. The size and surface charge of the polyplex micelles (Lac-PEG-PSAO-PAMA/pDNA, Lac-PEG-PAMA/pDNA, and Lac-PEG-PSAO/pDNA) was respectively evaluated by dynamic light scattering (DLS) and Laser-Doppler electrophoresis measurements at various N/P ratios, as summarized in Table 1. In the DLS measurements, the diameter (d) and polydipersity index (PDI; μ_2/Γ^2) of all the polyplex micelles decreased with increasing N/P ratios and reached plateau values of ca. 150 nm and 0.2, respectively, at an N/P ratio higher than 5. Concomitantly, as the N/P ratios increased, the zeta-potential (ζ) of all the polyplex micelles gradually shifted from a negative value ($\zeta < 0$) to a positive value ($\zeta > 0$). Nevertheless, the zeta-potential of all the polyplex micelles retained only a slightly positive value (ζ = +5 mV) even when the N/P ratio was increased to 10, suggesting the formation of a PEG corona surrounding the PIC core. These phenomena are consistent with the DNA condensation (coil-globule transition) upon complexation with the polycation segment in the block copolymers (*5*, *9*, *10*). It should also be noted that the N/P ratio to induce complete DNA condensation substantially shifted to a higher value from a stoichiometric mixing ratio (N/P = 1). A similar tendency was observed for the polyplex micelle from the PEG-PAMA block copolymer and pDNA (*4*).

To further clarify the behavior of DNA condensation, the quenching of the fluorescence intensity of the DNA intercalating dye, EtBr, was observed under physiological conditions for all of the polyplex micelles. Note that cationic EtBr is excluded from the DNA minor groove with the progress of the charge neutralization and the subsequent condensation of DNA due to the interaction with polycations, and therefore, this characteristic of EtBr is frequently utilized to estimate the degree of DNA condensation through complexation with a polycation. The profiles are shown in Figure 5a. In line with a trend in the hydrodynamic diameter and zeta-potential variations as shown in Table 1, the fluorescence intensity of EtBr decreased with increasing N/P ratios for all of the polyplex micelles, and the quenching of the fluorescence still continued even in the region of N/P > 1, suggesting that DNA condensation was not completely finished at the stoichiometric mixing ratio (N/P = 1) and that a nonstoichiometric complex may form in the range of N/P > 1. It should be noted that the amino groups of both PAMA and PSAO segments are incompletely protonated at physiological pH (= 7.4) because of their relatively lowered pKa values (PAMA: pK_a = 7.2, and PSAO: pK_{a1} = 8.6, pK_{a2} = 5.8). This may be a reason for the shift of the DNA-condensation point from a stoichiometric mixing ratio (N/P = 1). It should also be noted that a 35% decrease in fluorescence intensity compared to the initial value was observed for Lac-PEG-PSAO, whereas a decrease is more significant (50∼55%)

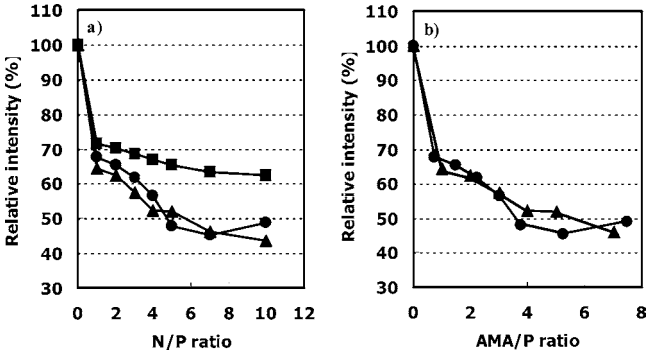

Figure 5. Ethidium bromide (EtBr) exclusion assay for the Lac-PEG-PSAO-PAMA/pDNA (circle), Lac-PEG-PAMA/pDNA (triangle), and Lac-PEG-PSAO/pDNA (square) systems. (a) Change in relative fluorescence intensity with the N/P ratio. (b) Change in relative fluorescence intensity with the AMA/P unit ratio ([amino groups in the PAMA segment]/[phosphate group in the pDNA]) (solvent, 10 mM Tris-HCl buffer including 0.15 M NaCl (pH 7.4); temperature, 37 °C).

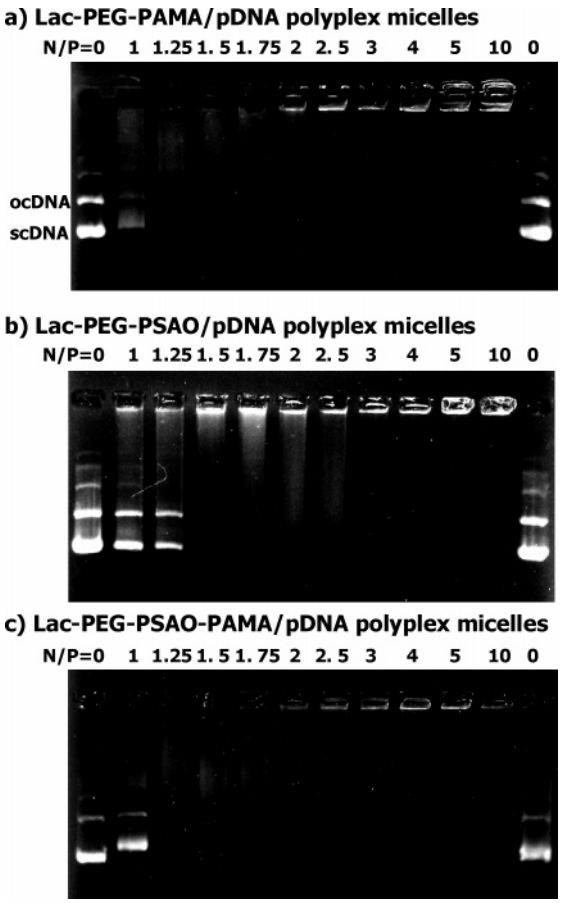

Figure 6. Agarose gel electrophoresis of the (a) Lac-PEG-PAMA/pDNA, (b) Lac-PEG-PSAO/pDNA, and (c) Lac-PEG-PSAO-PAMA/pDNA polyplex micelles prepared at various N/P ratios.

for Lac-PEG-PAMA and Lac-PEG-PSAO-PAMA, and their fluorescence intensities of Lac-PEG-PSAO-PAMA were almost identical when the N/P ratio was converted to the AMA/P ([amino groups in the PAMA segment]/[phosphate group in the pDNA]) unit ratio (Figure 5b), suggesting that the PAMA segment may preferentially take part in the complexation with DNA in the Lac-PEG-PSAO-PAMA/pDNA system, bearing the PSAO segment in the free form.

To evaluate the stability of the polyplex micelle, an agarose gel retardation assay at various N/P ratios was carried out. As shown in Figure 6, two topologically different forms of pDNA, i.e., supercoiled (scDNA) and open circular (ocDNA), were clearly observed in the absence of the block copolymer (at N/P = 0). In the cases of Lac-PEG-PSAO-PAMA/pDNA and Lac-PEG-PAMA/pDNA polyplex micelles, pDNA migration was completely retarded at an N/P ratio ≥ 1.5 (Figure 6a,c). Alternatively, a higher N/P ratio (≥ 3) was required for the complete retardation of pDNA for Lac-PEG-PSAO/pDNA polyplex micelles (Figure 6b). Presumably, excess cationic component may be needed for the Lac-PEG-PSAO block copolymer with a shorter cationic segment to induce effective DNA stabilization.

The polyplex micelle from Lac-PEG-PSAO-PAMA and pDNA was characterized by ^{1}H NMR spectroscopy in D_2O containing 0.15 M NaCl at pD = 7.4. Figure 7f shows the ^{1}H NMR spectrum of the polyplex micelle prepared at N/P = 3, where the residual molar ratio of the protonated PAMA segment in the block copolymer, calculated from the pK_a value, to the phosphate groups in pDNA is estimated to be unity at physiological pH (= 7.4). Note that the DNA condensation process was almost completed at N/P = 3, as shown in Table 1. Obviously, the peaks from the PAMA segment, which were clearly observed in the spectrum of the free polymers (Figure 7c), nearly disappeared upon complexation with pDNA (Figure 7f), whereas the peaks from the PSAO segment were still clearly observed in the spectrum. The selective disappearance of PAMA peaks upon complexation strongly suggests that the PAMA segment predominantly forms a PIC with pDNA to cause significant peak broadening. On the other hand, observation of the peaks from the PSAO segment even in the spectrum of the polyplex micelle suggests the presence of the uncomplexed PSAO fraction. Eventually, these results are consistent with the formation of the three-layered structure of the polyplex micelle with a PAMA/pDNA PIC core, a free PSAO inner shell, and a lactosylated PEG outer shell, as illustrated in Figure 2. In sharp contrast to the Lac-PEG PSAO-PAMA/pDNA system, peaks corresponding to polyamine segments (PAMA and PSAO) completely disappeared in the NMR spectra of the polyplex micelles from diblock copolymers (Lac-PEG-PAMA/pDNA (Figure 7d) and Lac-PEG-PSAO/pDNA (Figure 7e)) due to the limited molecular motion in the complex form.

pH Response of the Polyplex Micelles. To estimate the effect of the environmental pH on the hydrodynamic diameter of the polyplex micelles, the Lac-PEG-PSAO-PAMA/pDNA, Lac-PEG-PSAO/pDNA, and Lac-PEG-PAMA/pDNA polyplex micelles were prepared in 0.15 M NaClaq (pH 7.4) at N/P = 3. By decreasing the pH from 7.4 to 4.0, the diameter (d) of the Lac-PEG-PSAO-PAMA/pDNA and Lac-PEG-PSAO/pDNA polyplex micelles proportionally increases with a unimodal distribution ($\mu_2/\Gamma^2 < 0.25$), reaching a 2.7-times larger hydrodynamic volume at pH 4.0 compared to that at pH 7.4, as shown in Figure 8. On the contrary, there was negligible change in the hydrodynamic diameter of the Lac-PEG-PAMA/pDNA polyplex micelle with decreasing pH from 7.4 to 4.0. This pH-induced size variation observed for the system containing the PSAO segment is most likely to be related to the conformational changes in the PSAO chain due to progressive protonation with decreasing pH. In the ^{1}H NMR spectrum of the Lac-PEG-PAMA/pDNA polyplex micelle (N/P = 3) at pD = 4.0, the peaks from the PAMA segment almost disappeared, indicating that pDNA was still condensed even at pD = 4.0 by the PAMA segment (see Supporting Information). Furthermore, the ^{1}H NMR spectrum of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelle at pD = 4.0 shows only the peaks assigned to the PSAO segment along with the PEG segment, suggesting the three-layered structure even at pD = 4.0 (see Supporting Information). This result supports the plausible scheme that the globule-to-rod conformational changes in the uncomplexed PSAO segment in the three-layered Lac-PEG-PSAO-PAMA/pDNA polyplex

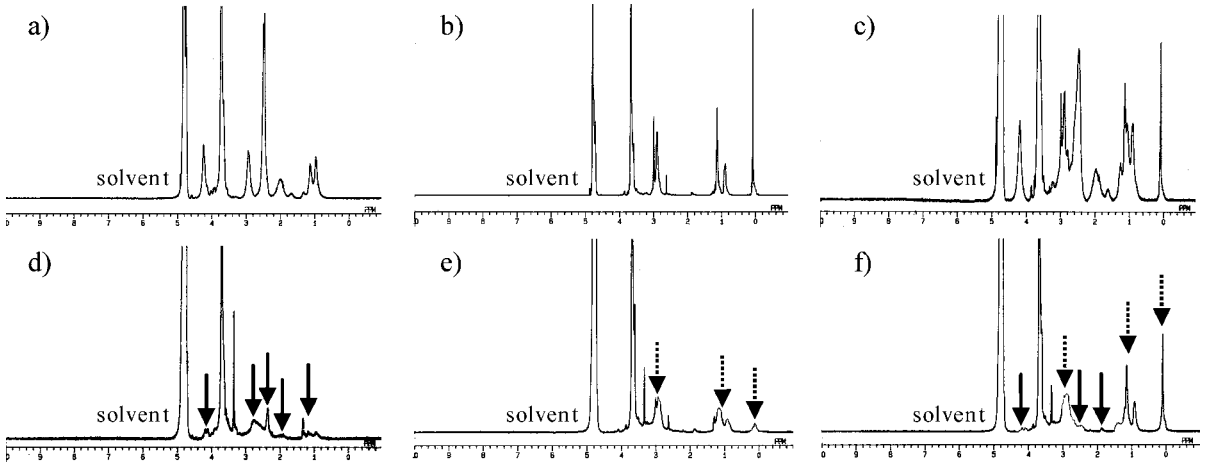

Figure 7. ^{1}H NMR spectra of (a) the Lac-PEG-PAMA block copolymer at pD = 7.4, (b) the Lac-PEG-PSAO block copolymer at pD = 7.4, (c) Lac-PEG-PSAO-PAMA triblock copolymer at pD = 7.4, (d) the Lac-PEG-PAMA/pDNA polyplex micelle at pD = 7.4, (e) the Lac-PEG-PSAO/pDNA polyplex micelle at pD = 7.4, and (f) the Lac-PEG-PSAO-PAMA/pDNA polyplex micelle at pD = 7.4 in D_2O containing 0.15 M NaCl at 37 °C. The solid and dotted arrows indicate the peaks corresponding to the PAMA segment and PSAO segment, respectively.

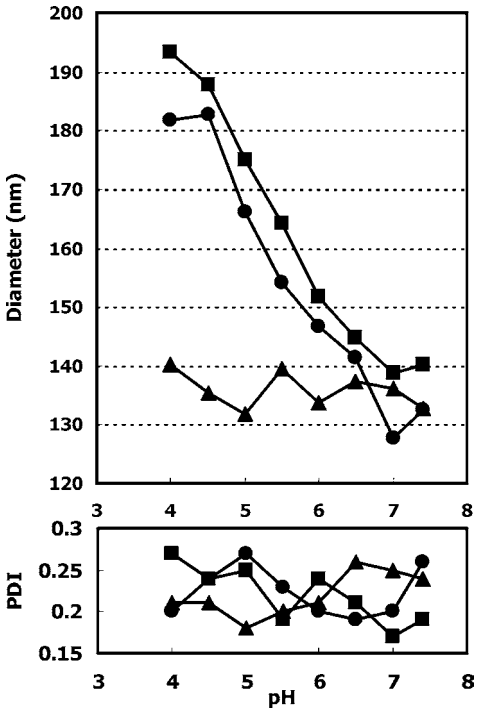

Figure 8. pH vs diameter (d) and PDI (μ_2/Γ^2) of the Lac-PEG-PSAO-PAMA/pDNA (circle), Lac-PEG-PAMA/pDNA (triangle), and Lac-PEG-PSAO/pDNA (square) polyplex micelles at N/P = 3 (angle, 90°; solvent, distilled water including 0.15 M NaCl; temperature, 37 °C).

micelle may induce the selective expansion of the PSAO inner shell while retaining the condensed pDNA in the PAMA/pDNA PIC core, leading to the remarkable pH-induced size variation. However, the observed size variation is clearly too large compared with the calculated PSAO length as the fully stretched chains for coil-state (pH 7.4) and rod-state (pH 4.0), indicating that the expansion of the PSAO inner shell is not sufficient to account for the size variation of the micelles. Although other possible factors probably exist, we believe that the expansion of the PSAO inner shell is one of the factor for the size variation of the micelles. On the other hand, the peaks from the PSAO segment clearly appeared in the ^{1}H NMR spectrum of the Lac-PEG-PSAO/pDNA polyplex micelle at pD = 4.0, suggesting that the conformational changes (globule-rod transition) of the complexed PSAO segment in the Lac-PEG-PSAO/pDNA polyplex micelle presumably leads to the formation of a loose PIC core (see Supporting Information). Apparently, the high rigidity of the protonated PSAO chain in the lower pH region should be unfavorable for triggering the DNA condensation upon complexation. As a consequence, a loose complex may form between pDNA and the PSAO segment without condensation in the lower pH region, showing an appreciable size increase.

Evaluation of the Biological Efficacy of the Polyplex Micelles. The cytotoxicity of the Lac-PEG-PSAO-PAMA, Lac-PEG-PAMA, and Lac-PEG-PSAO block copolymers against HuH-7 cells (hepatocytes) was studied using an MTT assay (see: Supporting Information). The viability of cells treated with the Lac-PEG-PSAO block copolymer was less than 20% at a polymer concentration of 100 μg/mL (IC_{50} < 30 μg/mL). In contrast, cells incubated with Lac-PEG-PSAO-PAMA or Lac-PEG-PAMA retained 65∼70% viability relative to controls even at concentrations up to 100 μg/mL. This result indicates that the inclusion of PSAO segment into the Lac-PEG-PSAO-PAMA triblock copolymer seems to substantially reduce its inherent cytotoxicity.

To examine whether the lactose moiety (galactose terminal) on the surface of Lac-PEG-PSAO-PAMA/pDNA polyplex micelle is recognized by the asialoglycoprotein (ASGP) receptors existing on the HuH-7 cells (*34*, *35*), the cellular association and internalization of the polyplex micelle (N/P = 3) with fluorescein isothiocyanate (FITC)-labeled pDNA were visualized under a fluorescence microscope at 60 min of incubation in the presence and absence of asialofetuine (ASF). Note that the ASF is known to function as a competitive inhibitor for the ASGP receptor-mediated endocytosis (*36*). The cellular association and internalization of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelle to HuH-7 cells in the absence of ASF were clearly observed as shown in Figure 9b,d. On the contrary, substantially reduced cellular association and internalization of the micelles were observed in the presence of ASF as shown in Figure 9a,c. This result indicates that the cellular association and internalization of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelle occur mainly through the ASGP receptor-mediated process, which is inhibited in the presence of ASF (*37*).

To estimate the transfection ability of the Lac-PEG-PSAO-PAMA/pDNA, Lac-PEG-PAMA/pDNA, and Lac-PEG-PSAO/pDNA polyplex micelles with various N/P ratios, a transfection study using HuH-7 cells was carried out in the presence of 10% FBS. A pGL-3 control plasmid DNA encoding firefly luciferase was used as a reporter gene. In addition, the B-PEI/pDNA polyplex was used as a control vector at the optimal N/P ratio of 10 to show the highest transfection efficacy. As shown in Figure 10, the transfection efficiency of the Lac-PEG-PSAO-

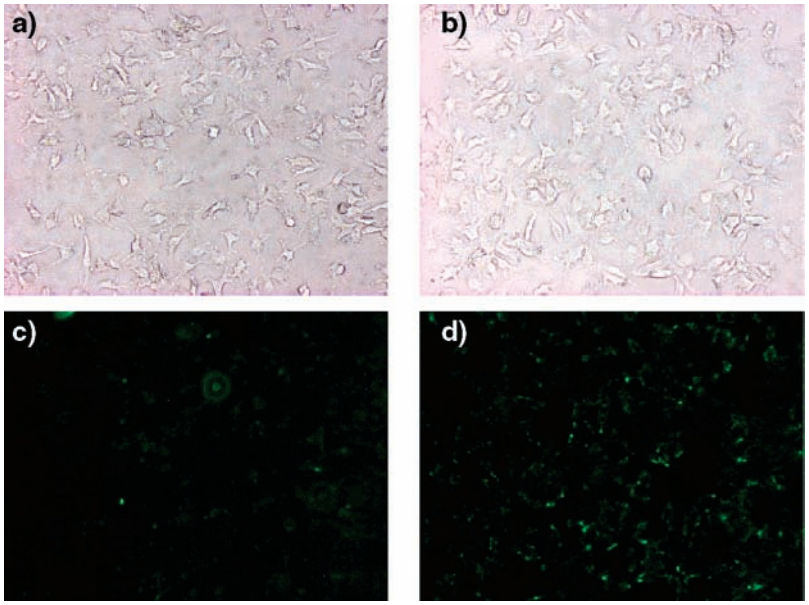

Figure 9. Association and internalization to HuH-7 cells of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles prepared at N/P = 3 after 60 min incubation. (a) ASF (+) (phase-contrast image), (b) ASF (−) (phase-contrast image), (c) ASF (+) (fluorescent image), and (d) ASF (−) (fluorescent image).

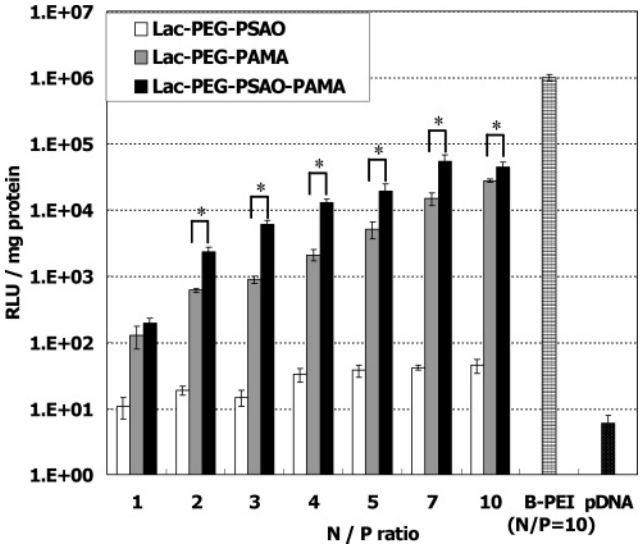

Figure 10. Transfection efficiency to HuH-7 cells of the Lac-PEG-PSAO-PAMA/pDNA, Lac-PEG-PAMA/pDNA, and Lac-PEG-PSAO/pDNA polyplex micelles prepared at various N/P ratios with a fixed pDNA amount. The plotted data are the average of triplicate experiments ± SD ($P^* < 0.05$).

PAMA/pDNA and Lac-PEG-PAMA/pDNA polyplex micelles was substantially improved with an increasing N/P ratio. In particular, 1 order of magnitude increase in transfection efficiency was achieved by increasing the N/P ratio from 1 to 2 ($P < 0.05$), corresponding to the formation of a stable polyplex structure judging from the agarose gel retardation assay, seen in Figure 6. Alternatively, the Lac-PEG-PSAO/pDNA polyplex micelles exhibited only limited transfection efficiency, presumably due to the low DNA condensing capacity of the PSAO chain as indicated from the results of the EtBr exclusion assay shown in Figure 5. Thus, polyplex micelles formed from Lac-PEG-PSAO may not be stable enough to be tolerated in the culture medium containing a substantial amount of serum proteins. Of interest, the transfection efficiency of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles always revealed a higher transfection efficiency than the Lac-PEG-PAMA/pDNA polyplex micelles in the range of N/P ratios between 2 and 10 ($P < 0.05$).

To determine whether the difference in the transfection efficiency between the Lac-PEG-PSAO-PAMA/pDNA and Lac-PEG-PAMA/pDNA polyplex micelles is related to the endosomal escape function, confocal microscope experiments were performed on the HuH-7 cells treated with the polyplex micelles containing FITC-labeled pDNA. Cells were co-incubated with LysoTracker Red DND-99 probe, which specifically stains acidic organelles such as endosomes and lysosomes. Thus, the colocalization of the polyplex micelles and the LysoTracker Red probe in an acidic compartment (endosome and lysosome) should be detected as yellow (or orange) fluorescence due to the merging of green and red colors. In the case of the Lac-PEG-PAMA/pDNA polyplex micelles (Figure 11a,b), the yellow and red fluorescences were observed without isolated green fluorescence even after a 120-min incubation, indicating that the polyplex micelles localized in the endosomes and/or lysosomes with the LysoTracker Red probe. The Lac-PEG-PSAO-PAMA/pDNA polyplex micelles localized in the endosomes and/or the lysosomes with the LysoTracker Red probe after a 30 min incubation (Figure 11c), as suggested by the partially yellow fluorescence. At 120 min of incubation, diffused green fluorescence was observed in the cytoplasm (Figure 11d), indicating that the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles gradually escaped from the endosomes and/or lysomes into the cytoplasm in a time-dependent manner. These results suggest that both the PAMA segment as a DNA-condensing polycation and the PSAO segment as the buffering moiety may synergistically contribute to enhance the transfection efficiency of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles. Although the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles showed 1 order of magnitude lower transfection efficiency than the B-PEI/pDNA polyplex at N/P = 10 ($P < 0.05$), this value may still be appreciable considering that the polyplexe micelles have hydrophilic and neutral PEG palisades on their surface to shield the cationic character.

To verify that the improved transfection ability of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles is a result of the facilitated endosomal escape function as well as the enhanced cellular uptake through ASGP-mediated endocytosis, the transfection study at N/P = 3, 5, and 10 was carried out in the presence or the absence of hydroxychloroquine (HCQ) as an endosomolytic agent, nigericin (NR) (*38*) as an inhibitor of the

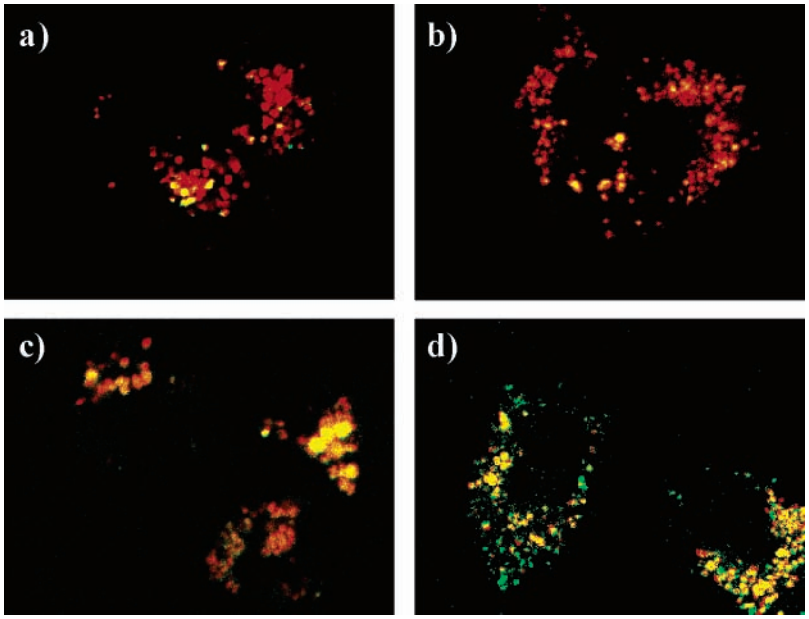

Figure 11. Confocal fluorescent microscope images of the HuH-7 cells in the presence of Lysotracker Red DND-99 and polyplex micelles prepared at N/P = 3 with FITC-labeled pDNA. (a) Lac-PEG-PAMA/pDNA polyplex micelles (incubation time: 30 min), (b) Lac-PEG-PAMA/pDNA polyplex micelles (incubation time: 120 min), (c) Lac-PEG-PSAO-PAMA/pDNA polyplex micelles, (incubation time: 30 min), (d) Lac-PEG-PSAO-PAMA/pDNA polyplex micelles (incubation time: 120 min). These images are the typical image of triplicate experiments.

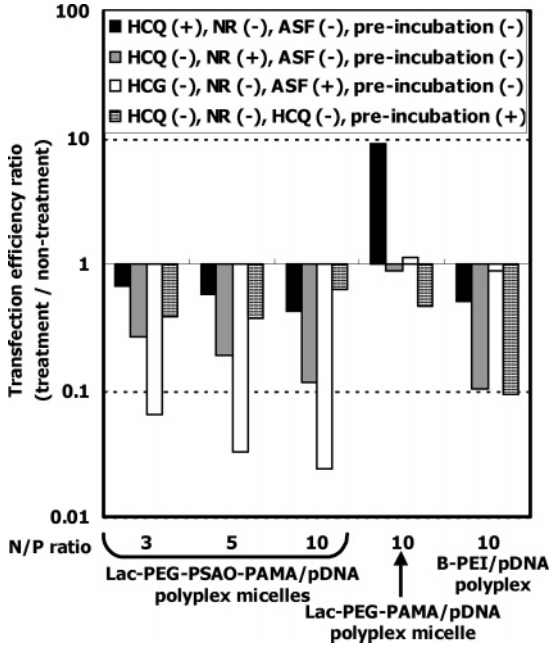

Figure 12. Effect of the HCQ (100 μM), NR (5 μM), ASF (4 mg/mL), and 20% serum preincubation on the transfection efficiency to HuH-7 cells of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelle, Lac-PEG-PAMA/pDNA polyplex micelle, and B-PEI/pDNA polyplex as a function of N/P ratios at a fixed pDNA amount. Transfection efficiency ratio is described as [value of RLU/mg of protein treated with additive (HCQ, NR, and ASF)]/[value of RLU/mg of protein in Figure 11]. The plotted data are the average of triplicate experiments ± SD.

endosomal acidification, and ASF as an inhibitor of the ASGP-mediated endocytosis. As shown in Figure 12, HCQ treatment (100 μM) had no contribution in increasing the transfection efficiency for the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles and the B-PEI/pDNA polyplex compared with the Lac-PEG-PAMA/pDNA polyplex micelle (about 1 order of magnitude increase in transfection efficiency), whereas it showed an appreciable decrease in the transfection efficiency in the presence of NR (5 μM) for the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles and the B-PEI/pDNA polyplex. This is in line with the assumption that the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles may be equipped with an endosome escaping function due to the unprotonated pH-responsive PSAO segment in the polyplex micelles.

A significant decrease in the transfection efficiency of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles was observed in the presence of ASF, consistent with the results of cellular uptake, as shown in Figure 9. Alternatively, no effect of ASF was observed even for the Lac-PEG-PAMA/pDNA polyplex micelle, suggesting that the endosomal escape may be the most critical barrier to intracellular gene delivery by Lac-PEG-PAMA/pDNA polyplex micelle. Thus, it may be reasonable to conclude that an appreciable fraction of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles is taken up into HuH-7 cells through the ASGP receptor-mediated endocytosis process mediated by the cluster of the large number of lactose moieties on the surface of the polyplex micelles, followed by the effective disruption of the endosome by the buffer effect of the unprotonated pH-responsive PSAO segment in the polyplex micelles.

It is well-known that components of the serum may interact with the polyplex to induce its structure change, resulting in decreasing transfection efficiency. Thus, we examined the effect of the 20% serum preincubation for 6 h on the transfection efficiency of Lac-PEG-PSAO-PAMA/pDNA, Lac-PEG-PAMA/pDNA polyplex micelles, and B-PEI/pDNA polyplexes. As shown in Figure 12, 1 order of magnitude decrease in the transfection efficiency was observed for B-PEI/pDNA polyplexes after preincubation with 20% serum probably due to the nonspecific interaction of the cationic polyplexes with negatively charged biomacromolecules, inducing the decrease in the cellular uptake. In a sharp contrast, the polyplex micelle sytems still retained sufficient transfection efficiency toward HuH-7 cells even after preincubation with 20% serum. The almost neutral surface charge ($\zeta \sim +5$ mV in Table 1) of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles with the highly lactosylated PEG outer shell surrounding the PIC core and the PSAO inner shell may induce the micelles to tolerate serum components, allowing the cellular specific interaction through ASGP receptor-mediated endocytosis to retain efficiency even after the serum preincubation.

CONCLUSIONS

In conclusion, this study demonstrates the pH-responsive nature of novel three-layered polyplex micelles composed of a lactosylated-PEG-PSAO-PAMA triblock copolymer and pDNA, aimed at the development of a targetable and endosome-disruptive gene delivery system. The Lac-PEG-PSAO-PAMA triblock copolymer bearing a PAMA segment as the DNA-condensing polyamine and a PSAO segment as the pH-responsive polyamine was successfully synthesized. The Lac-PEG-PSAO-PAMA triblock copolymer, thus prepared, spontaneously associated with pDNA to form three-layered polyplex micelles with a PAMA/pDNA PIC core, a free PSAO inner shell, and a lactosylated PEG outer shell, as confirmed by ^{1}H NMR spectroscopy. Under physiological conditions, the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles prepared at an N/P ratio above 3 were found to be able to condense pDNA (EtBr assay), thus forming polyplex micelles with a relatively small size ($<$ 150 nm, DLS measurements), and an almost neutral surface charge ($\zeta \sim +5$ mV, zeta-potential measurements). The Lac-PEG-PSAO-PAMA/pDNA polyplex micelle formed at N/P = 3 exhibited a pH-induced size variation (pH = 7.4, 132.6 nm $\rightarrow$ pH = 4.0, 181.8 nm) corresponding to the conformational changes (globule-rod transition) in the uncomplexed PSAO chain in response to pH. The swelling of the free PSAO inner shell is likely to occur in this process while retaining the condensed PIC core composed of the PAMA segment and pDNA. The fluorescence microscopic observation revealed that the interaction of the polyplex micelle entrapping FITC-labeled pDNA with HuH-7 cells was significantly reduced in the presence of ASF compared to the condition without ASF, suggesting that ASGP receptor-mediated endocytosis would be a major route of the cellular uptake of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles. Furthermore, the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles exhibited more efficient transfection ability than Lac-PEG-PSAO/pDNA and Lac-PEG-PAMA/pDNA polyplex micelles. Presumably, the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles might have an endosomal escape function, and thus, hydroxychloroquine as an endosomolytic agent was not required to observe appreciable transfection. Several important factors are likely to be synergistically involved in the pronounced transfection efficiency of the Lac-PEG-PSAO-PAMA/pDNA polyplex micelles, such as minimal interaction with serum proteins, enhancement of the cellular uptake through ASGP receptor-mediated endocytosis, and effective transport to the cytoplasm from the endosomal compartment (endosomal escape). Therefore, the polyplex micelle composed of the ABC triblock copolymer, thus described here, would be a promising vector for smart gene delivery.

Received January 6, 2006; Revised Manuscript Received March 14, 2006

Iberiotoxin (IbTx) is a scorpion venom peptide that inhibits BK Ca^{2+}-activated K^+ channels with high affinity and specificity. Automated solid-phase synthesis was used to prepare a biotin-labeled derivative (IbTx−LC-biotin) of IbTx by substitution of Asp19 of the native 37-residue peptide with *N*-ϵ-(D-biotin-6-amidocaproate)-L-lysine. Both IbTx−LC-biotin and its complex with streptavidin (StrAv) block single BK channels from rat skeletal muscle with nanomolar affinity, indicating that the biotin-labeled residue, either alone or in complex with StrAv, does not obstruct the toxin binding interaction with the BK channel. IbTx−LC-biotin exhibits high affinity (K_D = 26 nM) and a slow dissociation rate ($k_{off} = 5.4 \times 10^{-4}$ s^{-1}) in a macroscopic blocking assay of whole-cell current of the cloned human BK channel. Titration of IbTx−LC-biotin with StrAv monitored by high performance size exclusion chromatography is consistent with a stoichiometry of two binding sites for IbTx−LC-biotin per StrAv tetramer, indicating that steric interference hinders simultaneous binding of two toxin molecules on each of the two biotin-binding faces of StrAv. In combination with fluorescent conjugates of StrAv or anti-biotin antibody, IbTx−LC-biotin was used to image the surface distribution of BK channels on a transfected cell line. Fluorescence microscopy revealed a patch-like surface distribution of BK channel protein. The results support the feasibility of using IbTx−LC-biotin and similar biotin-tagged K^+ channel toxins for diverse applications in cellular neurobiology.

INTRODUCTION

The human genome contains at least 75 different genes for K^+ channel proteins as cataloged by the International Union of Pharmacology (Gutman et al., 2003). These membrane proteins are classified into seven distinct subfamilies (K_V1-6, K_V8, K_V9; K_V7; K_V10-12; $K_{Ca}1$, $K_{Ca}4$, $K_{Ca}5$; $K_{Ca}2$, $K_{Ca}3$; K_{2P}; K_{ir}) based on phylogenetic analysis of sequence similarity that reflects common structural relationships. From a parallel evolutionary perspective, at least 60 different peptide toxins that target K^+ channels have thus far been discovered in scorpion venoms (Zhu et al., 2004). Sequence analysis of these toxin peptides has identified at least 12 subfamiles of scorpion K^+ toxins that block various members of the K^+ channel family in a complex pattern of selective and overlapping specificity (Tytgat et al., 1999; Rodriguez de la Vega et al. 2003). Evidently, over the course of evolution, scorpion species have waged a biological arms race to produce an ever more diverse array of venom peptide toxins that recognize a similarly diverse variety of K^+ channel proteins in the interplay of natural selection.

This natural peptide library constitutes an important resource for biomolecular engineering of derivatives of K^+ channel toxins with numerous basic and clinical applications. For example, fluorescent and biotin-labeled derivatives of such peptides have already been used for cellular localization, flow cytometry analysis, and single-molecule microscopy of various K^+ channels (Roibtaille et al., 1993; Schütz et al., 2000; Pragl et al., 2002; Jimenez-Gonzalez et al., 2003; Beeton et al., 2004; Hafadi et al., 2005). The growing database of X-ray crystal structures of K^+ channel proteins (MacKinnon, 2003; Gulbis and Doyle, 2004) and NMR structures of K^+ toxins (Bontems et al., 1992; Johnson and Sugg, 1992; Renisio et al., 1999; Rodriguez de la Vega et al., 2003) provides a unique vantage point for molecular modeling and design of toxin derivatives engineered for specific applications.

Converting a collection of natural peptide toxins into a practical toolbox of molecular probes requires concerted efforts to develop optimal methods for synthesis and pharmacological assay of activity, affinity, and stability of the designed molecules. Toward this goal, we have synthesized and characterized a biotin-derivative of iberiotoxin (IbTx[1]), a toxin from the Indian red scorpion, *Mesobuthus tamulus* (formerly known as *Buthus tamulus*) (Galvez et al., 1990; Strong et al., 2001), for use as a probe in molecular and cellular studies of the large conductance Ca^{2+}-activated K^+ channel ($K_{Ca}1.1$). $K_{Ca}1.1$ is also called the BK channel, the maxi K_{Ca} channel, or HSlo, the latter term designating the human α-subunit protein that forms the channel tetramer (Wallner et al., 1995). The BK channel is synergistically activated by membrane depolarization and intracellular Ca^{2+} and is known to function in neurotransmitter release at

nerve terminals, regulation of smooth muscle contractility, and auditory functions of cochlear hair cells (Toro et al., 1998; Orio et al., 2002; Hafadi et al., 2005).

IbTx (αKTx1.3) is a 37-residue peptide with three disulfide bonds that belongs to the same K^+ toxin subfamily as charybdotoxin (ChTx or αKTx1.1), an extensively studied model of K^+ toxin-channel interaction (Galvez et al., 1990; Miller, 1995; Tenenholz et al., 2000). Whereas ChTx blocks various K^+ channels of both K_V and K_{Ca} gene families, IbTx appears to be a specific, high-affinity inhibitor of HSlo and other mammalian BK channels (Galvez et al., 1990; Rodriguez de la Vega et al., 2003). Extensive studies of the structure−activity relationships of ChTx, IbTx, K_V channels, BK channels, and the prokaryotic K^+ channel, KcsA, have led to a detailed model of the complex of IbTx docked to the external vestibule of the BK channel (Lucchesi et al., 1989; Giangiacomo et al., 1993; Goldstein et al., 1994; Stampe et al., 1994; Doyle, D. A. et al., 1998; MacKinnon et al., 1998; Mullmann et al., 1999; Cui et al., 2001; Gao and Garcia, 2003; Yu et al., 2005). Guided by this trove of information, we describe a direct method for synthesizing IbTx−LC-biotin and characterize its biochemical interactions with respect to block of BK channels, binding to streptavidin (StrAv), and cellular imaging of BK channels by fluorescence microscopy.

EXPERIMENTAL PROCEDURES

Materials. Streptavidin, Alexa488-streptavidin, Alexa488-anti-biotin antibody, and biotin-4-fluorescein were obtained from Molecular Probes (Eugene, OR). The Fmoc derivatives of *N*-ϵ-(D-biotin-6-amidocaproate)-L-lysine and *S*-acetamidomethyl-L-cysteine were purchased from Anaspec (AnaSpec, San Jose CA).

Synthesis and Purification of IbTx−LC-Biotin. Automated peptide synthesis based on the linear sequence of IbTx was performed via solid-phase Fmoc coupling chemistry by the Keck Peptide Facility at Yale Medical School (New Haven, CT). In place of the native Asp residue at position 19, *N*-ϵ-(D-biotin-6-amidocaproate)-L-lysine was substituted to produce the toxin derivative illustrated in Figure 1. Cleavage from the support resin and removal of protecting groups were accomplished using trifluoroacetic acid (TFA). Molecular mass determined by MALDI MS for the reduced product after cleavage, ether extraction, and lyophilization was MH^+ 4588.0 Da vs the theoretical monoisotopic mass of 4587.1 Da. A portion of the crude product (20 mg) was sonicated in 40 mL of buffer (2 M urea, 0.1 M NaCl, 0.1 M glycine, pH 7.8) and allowed to oxidize in air by stirring at 22 °C for 18 h. Final purification was achieved by C18 reverse-phase HPLC first on a semipreparative column followed by a narrow-bore Vydac C18 column both using a linear separation gradient of 0.01% TFA/Aq to 60% CH_3CN in 0.08% TFA/Aq over 60 min. UV absorption was monitored at 223 nm. Electrospray mass spectroscopy of pure oxidized peptides was performed on a Thermo Finnigan spectrometer. Peptide concentration of IbTx−LC-biotin was determined from integrated area of the HPLC peak (absorbance monitored at 280 nm) of the sample relative to that of a reference standard of synthetic IbTx previously quantified by amino acid analysis.

IbTx-D19C-Acm was synthesized in a similar manner by automated Fmoc solid-phase chemistry. In place of the native Asp residue at position 19, *S*-acetamidomethyl-L-cysteine was substituted to produce the toxin derivative. IbTx-D19C-Acm was oxidized, purified and quantified, as described above.

Planar Bilayer Assay. Single-channel recording of BK channels from rat skeletal muscle in planar lipid bilayers was performed as previously described (Favre and Moczydlowski, 1999). The recording solution was 200 mM KCl, 10 mM Mops-KOH, pH 7.4 on both sides of the bilayer, with 0.2 mM $CaCl_2$ on the intracellular side and 0.1 mM EDTA plus 0.1 mg/mL bovine serum albumin on the extracellular side as defined by native asymmetry of the channel.

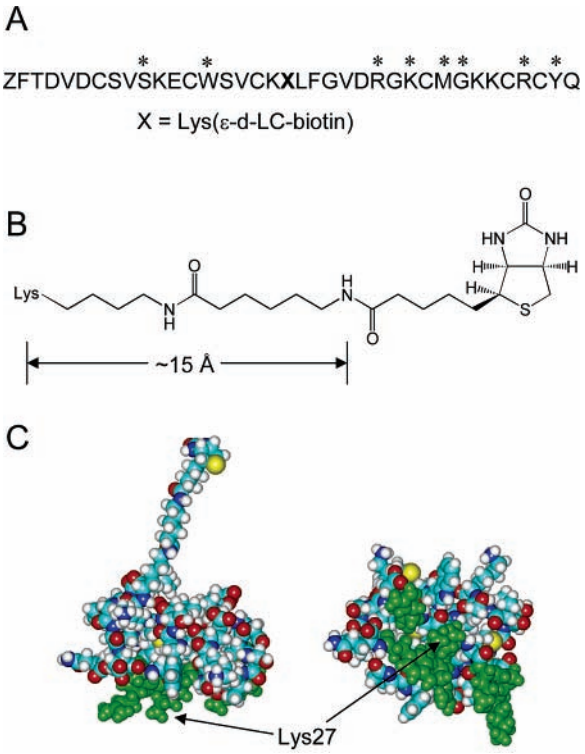

Figure 1. Design strategy and molecular model of IbTx−LC-biotin. (A) Sequence of synthetic IbTx−LC-biotin showing substitution of native residue D19 with Lys(ϵ-D-LC-biotin). Asterisks (*) mark eight residues important for toxin binding to BK channels. (B) Chemical structure of the side chain of the biotin derivative showing the ~15 Å linker between the Lys α-carbon atom and the biotin moiety buried in the complex with streptavidin. (C) Molecular model of IbTx−LC-biotin. Left panel is a side view of a model of the IbTx derivative with the BK channel binding surface at the bottom and the biotin-derivative side chain at the top. A 90° rotation of the latter structure back into the plane of the paper was used to generate the image for the right panel, which shows green colored residues (marked * in A) at the toxin−channel interface.

Whole-Cell Electrophysiology. HEK293 transformed human embryonic kidney cells were stably transfected using G418 selection with a pcDNA3 vector encoding a His_6-Flag-epitope-tagged version of the human BK channel (HSlo) originally cloned by Wallner et al. (1995). The tagged version of HSlo (kindly supplied by Dr. Andrew Tinker, University College London) contained the N-terminal tag sequence, MVHHHH-HHDYKDDDDK, linked directly to the second amino acid (D2) of the native HSlo sequence. HEK293/HSlo cells were grown in DMEM medium (Gibco) supplemented with 10% fetal bovine serum, 10 000 U/mL penicillin/streptomycin (Gibco), and 0.6 mg/mL Geneticin (G418, from Gibco) at 37 °C in a humidified atmosphere of 5% CO_2 in air. Cells were seeded on small chips of glass cover slips coated with polylysine 2−4 days prior to patch-clamp recording.

Whole-cell patch recording was performed using a low volume cell recording chamber (RC24E, Warner Instruments) mounted on a Nikon TE200 inverted microscope. The recording chamber was continuously perfused at 0.5 mL/min with control and various bath solutions containing toxins and inhibitors. Patch pipets with a resistance of 1−2 MΩ were fabricated from glass capillaries (Kimax-51, Fisher Scientific) with a PP-83 puller (Narishige). Whole-cell current was measured at room temperature with an Axon 200B amplifier controlled by PC-based Clampex software (Axon Instruments) for voltage pulse delivery

and digital current acquisition. Currents were low pass filtered at 5 kHz and corrected for capacitance transients and leak current using a negative P/5 pulse protocol. The composition of standard pipet (intracellular) solution with 500 nM free Ca^{2+} (Strobaek et al., 1996) was 150 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1.3 mM EGTA, 10 mM Hepes-KOH, pH 7.2. The bath solution contained 145 mM NaCl, 5 mM KCl, 2 mM $CaCl_2$, 2 mM $MgCl_2$, 10 mM Hepes-KOH, pH 7.4 and various peptide toxins or 1 μM paxilline (Sigma) as described.

Streptavidin Binding Interaction. Streptavidin (StrAv) concentration was standardized by the method of Kada et al. (1999) based on fluorescence quenching of biotin-4-fluorescein (e.g., Figure 6A), a ligand known to bind stoichiometrically to four sites of StrAv and avidin with high affinity. Sequential additions (5 nM) of biotin-4-fluorescein were made to a stirred cuvette containing ~11 nM StrAv in 100 mM NaCl, 50 mM Hepes-NaOH, pH 7.3. Fluorescence emission spectra excited at 484 nm were recorded 5 min after each addition of biotin-4-fluorescein using a QuantaMaster-4 spectrofluorimeter (Photon Technology International, Lawrenceville, NJ). The concentration of biotin-4-fluorescein was based on the reported extinction coefficient of 68 000 $M^{-1}cm^{-1}$ at 494 nm (Haugland, 2002).

Complex formation between standardized IbTx−LC-biotin and StrAv was analyzed by high performance size-exclusion chromatography using a Phenomenex BioSep-SEC-S 2000 column (300 × 7.5 mm) with buffer delivery and detection controlled by a Waters Alliance 2695 HPLC system equipped with a 995 photodiode array detector (wavelength scan at 200−400 nm). The column was equilibrated with buffer (100 mM NaCl, 50 mM Hepes-NaOH, pH 7.3) and run isocratically at a flow rate of 0.5 mL/min. Dextran blue (~2000 kDa) and uridine (244.2 Da) were used to determine the void volume and column volume, respectively. Fixed samples of IbTx−LC-biotin (250 pmol) were incubated for 24 h in separate vials containing increasing amounts of StrAv ranging from 0 to 375 pmol in 18 μL of running buffer. Each sample was separately injected on the column and monitored by absorbance at 280 nm. Binding of IbTx−LC-biotin (5 kDa molecular mass) to StrAv (52.8 kDa molecular mass) was followed by the decrease in area of the IbTx−LC-biotin peak and appearance of peaks corresponding to bound and free StrAv eluting at a higher mass range as observed upon increasing addition of StrAv (e.g., Figure 5).

Fluorescence Microscopy. Native HEK293 cells and stably transfected HEK293/HSlo cells were grown either in tissue culture flasks for labeling of cells in suspension or on cover slips coated with poly-D-lysine in a 12-well culture plate for attached-cell labeling. Cells grown on cover slips were washed once with 125 mM NaCl, 25 mM NaP_i, pH 7.4 (PBS) followed by an optional endogenous biotin-blocking protocol following kit instructions (E-21390) from Molecular Probes. Cover slips were next incubated in PBS containing 1 mg/mL bovine serum albumin (BSA) and 50 to 100 nM IbTx−LC-biotin for 30 min at room temperature and then washed three times in PBS. This step was followed by incubation in the dark for 20 min at room temperature in the same buffer containing either 3 μg/mL Alexa488-StrAv or 4 μg/mL Alexa488-anti-biotin antibody. A final wash step, three times in PBS, was performed before observing cells using a Nikon Eclipse TE2000-E inverted epifluorescence microscope. Incubation and wash conditions were similar for labeling dissociated cells removed from tissue culture flasks by gentle pipetting except that the washing steps were performed by low-speed microcentrifugation. Labeled cells were either observed directly or after fixation with 2% formaldehyde in PBS for 20 min followed by washing in PBS and mounting on glass slides using VectaShield mounting media (Vector Laboratories). Digital Images were captured using with a Hamumatsu Orca CCD camera and IPLab acquisition software (Scanalytics).

RESULTS

Design and Synthesis of a Biotin Derivative of IbTX. Similar to other αKTx1 toxins such as ChTx and Lq2 (Bontems et al., 1992; Renisio et al., 1999), the three-dimensional (3D) solution structure of IbTx (sequence given in Figure 1A) is characterized by a short α-helix at residues 13−21 and a two-stranded antiparallel β-sheet comprised of residues 25−36 (Johnson and Sugg, 1992). Three disulfide bonds between Cys residues 7−28, 13−33, and 17−35 tightly constrain the structure of αKTx1 toxins and render them quite resistant to denaturation by heating and other treatments in the folded, oxidized state (Smith et al., 1986). Structure−activity studies including mutagenesis, X-ray crystallography, NMR, Brownian dynamics simulation, and molecular modeling approaches have yielded a rather detailed picture of the probable molecular basis of interaction of αKTx1 toxins with various K^+ channels (Goldstein et al., 1994; Stampe et al., 1994; Doyle et al., 1998; Tenenholz et al., 2000; Cui et al., 2001; Schroeder et al., 2002; Gao and Garcia, 2003; Yu et al., 2005). Binding of αKTx1 toxins is primarily determined by molecular interactions between critical residues that lie on the β-sheet face of the toxin and particular residues within the outer vestibule of K^+ channels. K^+ channel residues critical for toxin binding lie either in the "turret" formed by an extracellular linker between the outer membrane helix (M1 or S5) and the so-called pore helix, or in a second extracellular linker between the selectivity filer and the inner membrane helix (M2 or S6) (MacKinnon et al., 1998; Gao and Garcia, 2003). Eight residues predicted to lie on the interaction surface of IbTX (S10, W14, R25, K27, M29, G30, R34, Y36) are marked with asterisks in Figure 1A. Modification of these latter residues typically lowers the affinity of the αKTx1 toxin−channel interaction, requiring the identification of other noncritical residues for toxin derivatization.

On the basis of the observation that certain residue substitutions on the toxin surface opposite to the channel interaction surface do not interfere with blocking activity, Shimony et al. (1994) identified residue R19 near the C-terminal end of the α-helical region of charybdotoxin as a favorable site for derivatization. Using a "spinster cysteine" strategy, *N*-[^{3}H]ethylmaleimide derivatives of the R19C mutant of charydotoxin and a D19C mutant of IbTx have previously been developed as radioligands used in binding assays for Shaker and BK K^+ channels (Shimony et al., 1994; Sun et al., 1994; Knaus et al., 1996).

We followed a similar approach in this work by substituting *N*-ε-(D-biotin-6-amidocaproate)-L-lysine [Lys(ε-D-LC-biotin)] in place of native residue D19 of IbTx in automated solid-phase synthesis of IbTx−LC-biotin. Figure 1B illustrates the chemical structure of the unnatural amino acid side chain substituted at residue 19 of IbTx−LC-biotin and also denotes the ~15 Å chemical linker between the α-carbon atom of the peptide backbone and the carboxy tail of the biotin moiety that is virtually buried upon binding to streptavidin (Henrickson et al., 1989). Lys(ε-D-LC-biotin) was selected as the replacement residue to evaluate the use of biotin−avidin labeling technology for biochemical and cellular studies of BK channels. As illustrated in Figure 1C, a plausible extended conformation of a molecular model of IbTx−LC-biotin shows that the biotin-tagged side chain is physically well separated from the channel-interaction surface of the toxin. We expected that the relatively long linear linker of this particular biotin-amino acid derivative (17 atoms from the peptide backbone to the biotin ring) may facilitate unhindered binding of streptavidin or avidin to the toxin-channel complex.

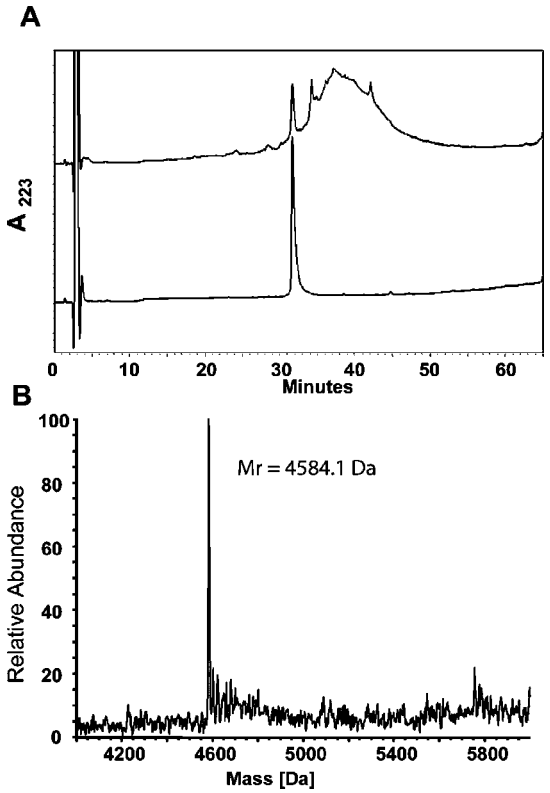

Figure 2. Purification and mass analysis of IbTx−LC-biotin. (A) Reverse phase HPLC chromatogram of crude oxidized (top trace) and purified (bottom trace) synthetic IbTx−LC-biotin. Samples were run on a Vydac C18 column and eluted with a linear gradient of buffer A to buffer B (A = 0.1% TFA, B = 60% CH_3CN in 0.08% TFA, over 60 min). (B) Electrospray MS analysis of pure oxidized IbTx−LC-biotin demonstrating a deconvoluted average mass of 4584.1 Da.

After automated synthesis and cleavage from the resin were performed, the crude peptide product was solubilized in folding buffer at pH 7.8, allowed to oxidize in air for 18 h, and analyzed by reverse phase HPLC as described in Experimental Procedures. The HPLC chromatogram exhibited a broad peak of heterogeneous product superimposed upon a major sharp peak at 32 min that comprised about ∼5% of the total material (Figure 2, top trace). Purification of this latter peak yielded about ∼1 mg of pure IbTx−LC-biotin per 100 mg of the crude synthetic product (Figure 2A, lower trace). Electrospray mass spectroscopy of the latter peak confirmed the identity of oxidized IbTx−LC-biotin, with an observed deconvoluted mass of 4584.1 Da (Figure 2B) compared to a theoretical average mass of 4584.5 Da predicted for the sequence in Figure 1A with three disulfide bonds.

Electrophysiological Assays of BK Channel Block by IbTX−Biotin. We first investigated the biological activity of synthetic IbTx−LC-biotin by the planar bilayer assay method (Miller et al., 1985; Smith et al., 1986; Lucchesi et al., 1989). Addition of IbTx−LC-biotin to the external side of bilayers containing single BK channels resulted in the appearance of discrete long-lived blocked states characteristic of αKTx1 toxins such as ChTx, Lq2, and IbTx (Miller et al., 1985; Lucchesi et al., 1989; Candia et al., 1992; Giangiacomo et al., 1992). As illustrated in Figure 3A, under control conditions (200 mM symmetrical KCl, 0.2 mM internal Ca^{2+}, holding voltage = +30 mV) in the absence of toxin, typical current records of a single BK channel from rat skeletal muscle exhibit a high probability of opening with the majority of brief closures lasting less than 1 s. Long silent periods ranging from seconds to minutes observed after addition of 4 nM IbTx−LC-biotin to the external side of a single BK channel (Figure 3B) correspond to blocking

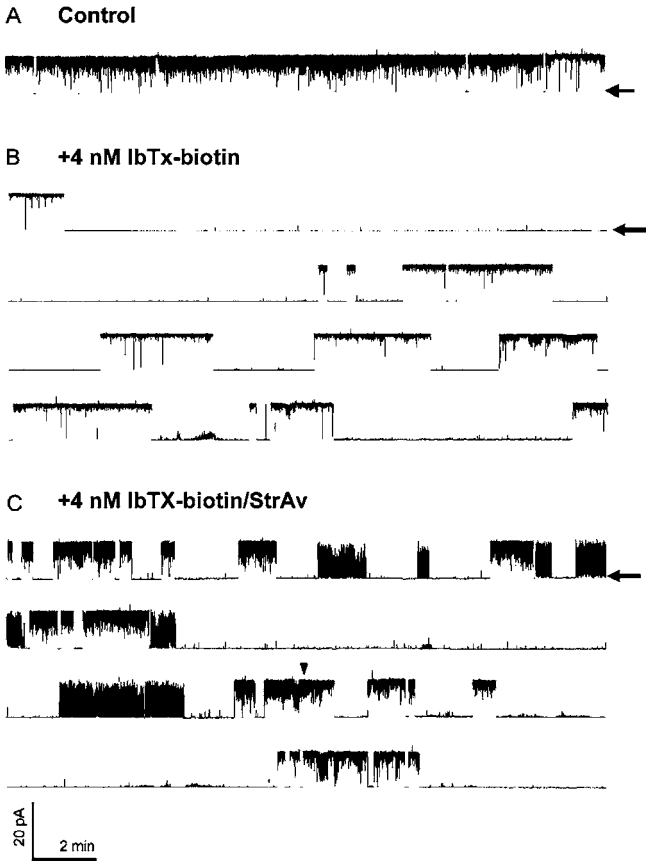

Figure 3. Bilayer assay of BK_{Ca} channel block by IbTx−LC-biotin in the absence and presence of StrAv. (A) Current record of a single BK_{Ca} channel from rat skeletal muscle under control conditions in the absence of toxin. (B) Record of a BK_{Ca} channel with 4 nM IbTx−LC-biotin on the external side. (C) Record of a BK_{Ca} channel in the presence of 4 nM IbTx−LC-biotin plus 16 nM StrAv on the external side. A small triangle in the third line marks where data are spliced from another bilayer recorded under identical conditions. Control conditions: Holding voltage = +30 mV. The solution on both sides of the bilayer was 10 mM Mops-KOH, pH 7.4, 200 mM KCl. The internal solution also contained 200 μM $CaCl_2$, and the external solution contained 0.2 mM EDTA plus 0.1 mg/mL bovine serum albumin. Arrows to the right indicate zero current level or the closed state of the channel. Low conductance noise superimposed on IbTx-blocked events in Figure 3B,C is due to activity of extraneous, non-BK channels occasionally observed in planar bilayer recordings.

events or residence times of single toxin molecules similar to those produced by native IbTx (Candia et al., 1992; Giangiacomo et al., 1992). To test whether IbTx−LC-biotin retains blocking activity after complex formation with StrAv, we preincubated IbTx−LC-biotin with a 4-fold excess of StrAv tetramer and tested the mixture on single BK channels. As illustrated in Figure 3C, single channel records in the presence of 4 nM complex of IbTx−LC-biotin /StrAv exhibit long-lived blocked events similar to those produced by IbTx alone, demonstrating that the toxin-StrAv complex is fully capable of binding to the toxin receptor site on BK channels.

Single-channel analysis of IbTX-blocking kinetics is technically rather difficult due to the long duration of IbTx-blocked state events; however, we estimated kinetic parameters with limited sets of blocking events pooled from several single-channel bilayers using a standard analysis for a one-site blocking reaction (Moczydlowski, 1992; Favre and Moczydlowski, 1999). For IbTx−LC-biotin, this analysis yields the following kinetic constants: $k_{off} = 4.7 \times 10^{-3}$ s (dissociation rate constant), $k_{on} = 1.9 \times 10^{6}$ $s^{-1}M^{-1}$ (association rate constant), and $K_D = 2.5$ nM (equilibrium dissociation constant). The corresponding values estimated for the complex of IbTx−LC-biotin and StrAv

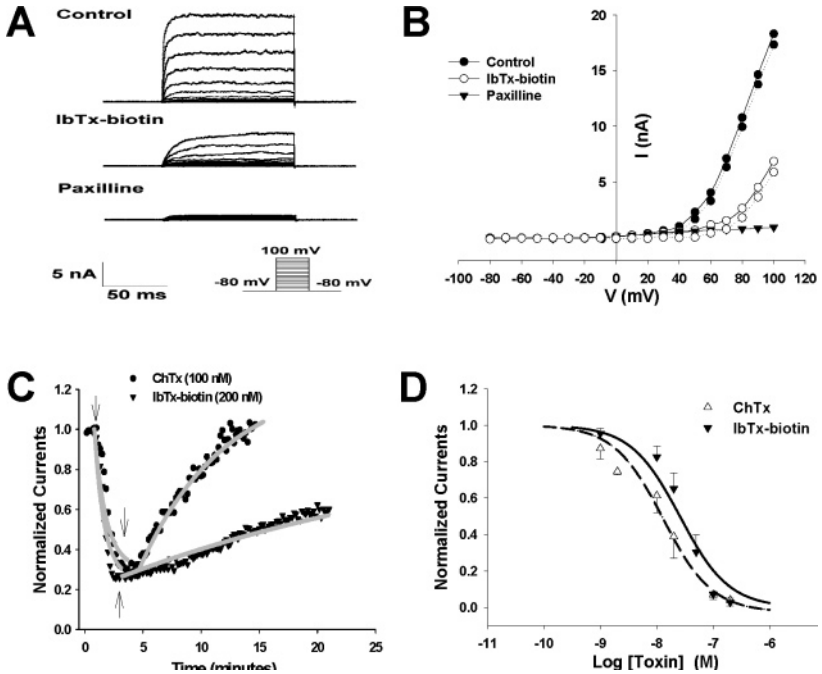

Figure 4. Electrophysiological assay of IbTx−LC-biotin and ChTx on the whole-cell current of HSlo expressed in HEK293 cells. (A) Effect of IbTx−LC-biotin and paxilline on whole-cell currents. Top panel shows a family of current traces elicited by stepping membrane voltage from a holding potential of −80 mV up to +100 mV in consecutive steps of +10 mV for a duration of 100 ms. Middle and bottom panels were recorded after addition of 100 nM IbTx−LC-biotin and 1 μM paxilline, respectively, to the extracellular bathing solution. (B) Plot of whole-cell current from panel A at the end of the 100 ms depolarization vs the step voltage. Solid and dotted lines for control and 100 nM IbTx−LC-biotin correspond to current values before and after subtraction of background current measured in the presence of 1 μM paxilline, respectively. (C) Time course of inhibition by toxins and recovery after perfusion. Peak current was monitored by 50 ms voltage steps from −80 mV to +50 mV once every 10 s. IbTx−LC-biotin (200 nM) or ChTx (100 nM) was added to the extracellular perfusion solution at the time of the first arrow and replaced by toxin-free solution at the time of the second arrow. Data points are normalized to the first few points before addition of toxin. Solid lines overlays are fits to an exponential time course. (D) Titration curves of toxin inhibition. HSlo current at steady state in the presence of various concentrations of IbTx−LC-biotin or ChTx is normalized to values measured before toxin addition. Data are fit to a single-site inhibition isotherm ($I_{norm} = K_D/(K_D + [\text{toxin}])$ with K_D values of 26 nM for IbTx−LC-biotin and 13 nM for ChTx.

are $k_{off} = 8.5 \times 10^{-3}$ s^{-1}, $k_{on} = 3.4 \times 10^6$ s^{-1} M^{-1}, and $K_D = 2.5$ nM. Although these kinetic parameters have large uncertainties in the range of 12−60%, they imply that the complex of IbTx−LC-biotin and StrAv has somewhat faster dissociation and association rates in comparison to IbTx−LC-biotin but retains an equilibrium binding affinity in the low nanomolar range, similar to that of native IbTx (Candia et al., 1992; Giangiacomo et al., 1992).

We next investigated the effect of IbTx−LC-biotin in a macroscopic assay of whole-cell currents of the cloned human BK channel (HSlo) stably expressed in the HEK293 cell line. Using an intracellular solution containing 500 nM free Ca^{2+}, BK currents are activated at voltages more positive than +40 mV under these conditions (Figure 4A,B). Greater than 95% of outward K^+ current recorded in this cell line is sensitive to inhibition by 1 μM paxilline (Figure 4A,B), a potent inhibitor of mammalian BK channels (Knaus et al., 1994; Strobaek et al., 1996). Addition of 200 nM IbTx−LC-biotin to the bath solution substantially inhibits BK current (Figure 4A,B), and such inhibition is slowly reversed by perfusion with toxin-free solution (Figure 4C). The titration curve of steady-state inhibition of peak outward BK current by IbTx−LC-biotin is well described by one-site behavior with a K_D of 26 nM (Figure 4D). By fitting the time course of development of IbTx−LC-biotin and washout with a single exponential and assuming one-site kinetics (Figure 4C), we obtained values of apparent rate constants, $k_{on} = 9.9 \times 10^4$ s^{-1} M^{-1} and $k_{off} = 5.1 \times 10^{-4}$ s^{-1}, which are respectively, 19- and 9-fold slower than the corresponding rate constants measured for the bilayer experiments of Figure 3. Inhibition of whole-cell BK current by native ChTx in this assay system exhibited a K_D value of 13 nM (Figure 4D), and apparent rate constants of $k_{on} = 1.3 \times 10^5$ s^{-1} M^{-1} and $k_{off} = 3.2 \times 10^{-3}$ s^{-1} (Figure 4C). These results demonstrate that synthetic IbTx−LC-biotin is a potent inhibitor of the cloned HSlo BK channel with a slower dissociation rate than charybdotoxin, as originally observed for blocking interactions of the native toxins (Candia et al., 1992; Giangiacomo et al., 1992; Stampe et al., 1994).

Binding Interaction of IbTx−LC-Biotin with Streptavidin. To characterize complex formation between IbTx−LC-biotin and StrAv, a fixed amount of IbTx−LC-biotin (250 pmol) was preincubated for 24 h with increasing amounts of tetrameric StrAv ranging from 0 to 375 pmol, and the resulting samples were analyzed by size exclusion chromatography. Superimposed absorbance profiles of the separate chromatography runs from this experiment are shown in Figure 5. In the absence of StrAv (mass ∼ 52 800 kDa), IbTx−LC-biotin (mass = 4.6 kDa) runs as a single peak (22.2 min) that elutes near the total column volume (12.4 mL; 24.8 min; 0.5 mL/min flow rate). Preincubation of the synthetic toxin with a low amount of StrAv results in a decrease in the absorbance of peak corresponding to the free toxin and the appearance of a higher mass peak (at 17.2 min) that corresponds to complex(es) of IbTx−LC-biotin and StrAv. As shown in Figure 5, at a molar ratio greater than 0.5 mole of StrAv tetramer per mole of IbTx−LC-biotin, a new peak is observed corresponding to the elution time (18.1 min) of free, uncomplexed StrAv. This observation indicates that the StrAv tetramer binds a maximum of two molecules of IbTx−LC-biotin under the conditions of this experiment in comparison to the theoretical capacity of four molecules corresponding to the four known biotin sites on the tetrameric protein (Hendrickson et al., 1989; Green, 1990). This surprising result was verified by measuring the concentration of total biotin binding sites in the commercial StrAv preparation using a method based on

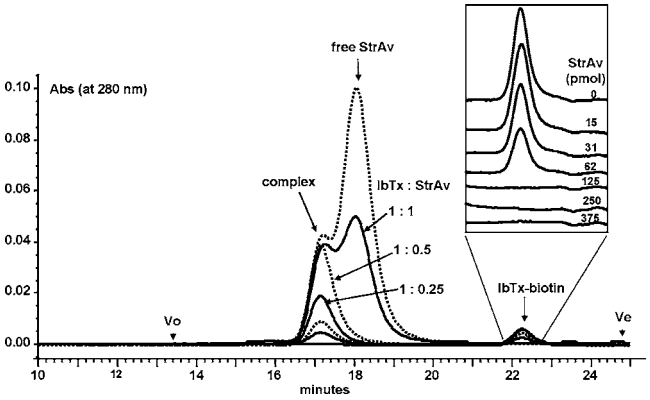

Figure 5. Analysis of complex formation between IbTx−LC-biotin and StrAv by size exclusion chromatography. A fixed amount of IbTx−LC-biotin (250 pmol) was incubated with increasing amounts of StrAv in the range of 0 to 375 pmol, and samples were subjected to HPSEC as described in Experimental Procedures. Overlayed consecutive traces of the absorbance profile are alternated using solid and dashed lines for the sake of clarity. The inset shows seven traces underlying the peak corresponding to unbound IbTx−LC-biotin that have been enlarged and vertically displaced. Triangles mark column calibrations: Vo, void volume; Ve, column volume.

fluorescence quenching of biotin-4-fluorescein (Kada et al., 1999). As shown in Figure 6A, this method reliably gives the total number of biotin binding sites in a StrAv sample from the break point of the fluorescence titration with biotin-4-fluorescein. On the basis of the standardized concentration of StrAv tetramer, titration experiments of IbTx−LC-biotin and StrAv (Figure 5) clearly demonstrate an equivalence point of two binding sites for IbTx−LC-biotin per molecule of StrAv tetramer (Figure 6B).

This result implies that binding of one molecule of IbTx−LC-biotin sterically interferes with binding of another IbTx−LC-biotin molecule on the StrAv tetramer. In fact, such "anti-cooperative" binding has been previously observed for titration of StrAv with certain long chain derivatives of biotin-fluorescein (Gruber et al., 1998). This unusual behavior is attributed to the particular 3D relationship of biotin binding sites in StrAv. The quaternary structure of StrAv tetramer consists of a dimer of dimers, with two adjacent biotin sites on neighboring StrAv monomers located within ~19 Å of each other on each of two separate faces of the tetramer (Hendrickson et al., 1989; Green, 1990; Freitag et al., 1997). Biotin derivative molecules with long chain linkers have a propensity to interfere with pairwise binding of each other across the two separate binding faces of the tetramer. In the present situation, the potential likelihood of this behavior can be appreciated by comparing the space filling models of StrAv and IbTx−LC-biotin (Figure 6D). The molecular models show that the dimensions of IbTx−LC-biotin are comparable to the distance of separation of two biotin binding sites across the binding face of the tetramer. Steric interference or physical occlusion of an unoccupied site by a toxin molecule bound to an adjacent site may explain the 2:1 binding stoichiometry observed for titration of IbTx−LC-biotin with StrAv. Figure 6A also shows that preincubation of 11 pmol of StrAv with 3 equiv (33 pmol) of IbTx−LC-biotin is sufficient to completely block binding of biotin-4-fluorescein to StrAv as shown by the lack of a detectable linear region of quenched fluorescence. This latter result implies that binding of IbTx−LC-biotin also interferes with binding of the smaller biotin-4-fluorescein molecule to an adjacent biotin site on StrAv.

Cellular Imaging of BK Channels with IbTx−LC-Biotin. The interactions with StrAv and BK channels described above suggest that IbTx−LC-biotin may be useful for studies of the cellular localization of BK channels by fluorescence microscopy. To evaluate IbTX−LC-biotin as an imaging probe, HEK293 cells stably expressing a version of the human BK channel,

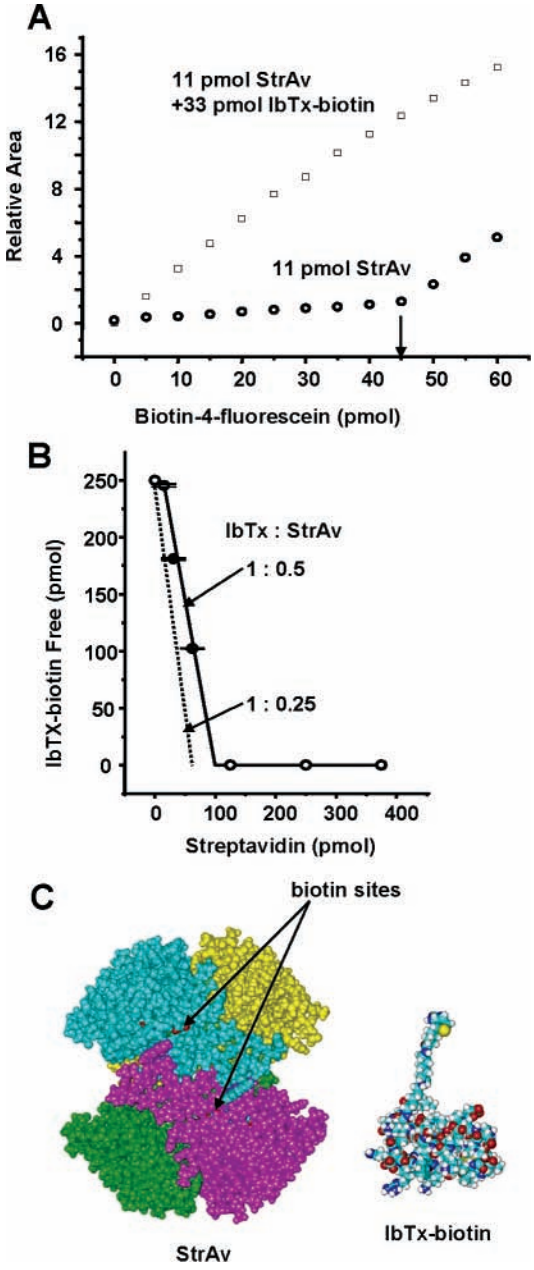

Figure 6. Stoichiometry of IbTx−LC-biotin binding to StrAv. (A) Fluorescence titration of 11 pmol of StrAv with biotin-4-fluorescein. Open circles, StrAv alone; open squares, StrAv preincubated with 33 pmol of IbTx−LC-biotin. The arrow indicates the equivalence point at ~44 pmol of biotin-4-fluorescein. (B) Titration of IbTx−LC-biotin with increasing StrAv. Peak areas corresponding to free IbTx−LC-biotin for various samples in Figure 4 were normalized to the control taken in the absence of StrAv and plotted versus the amount of added StrAv. Titration data are consistent with an equivalence point near 125 pmol of StrAv or a molar ratio of 1:0.5 for IbTx−LC-biotin/StrAv. Dashed line shows theoretical expectation for four IbTx−LC-biotin binding sites per StrAv. (C) Space-filling molecular models of StrAv complex with biotin on the left (structure 1SWE from Protein Data Bank) and IbTx−LC-biotin on the right at the same scale. Arrows mark the location of two adjacent biotin sites on the front face of the StrAv tetramer.

HSlo, were sequentially incubated with 100 nM IbTx−LC-biotin and 10 μg/mL StrAv conjugated with Alexa488, a fluorophore with spectral properties similar to fluorescein (Panchuk-Voloshina et al., 1999). The labeled cells were washed, fixed, and examined with a 100× oil immersion objective in an inverted fluorescence microscope. As shown by comparison of fluorescence and DIC (differential interference contrast) imaging of cells on processed coverslips, virtually all of the HEK293/

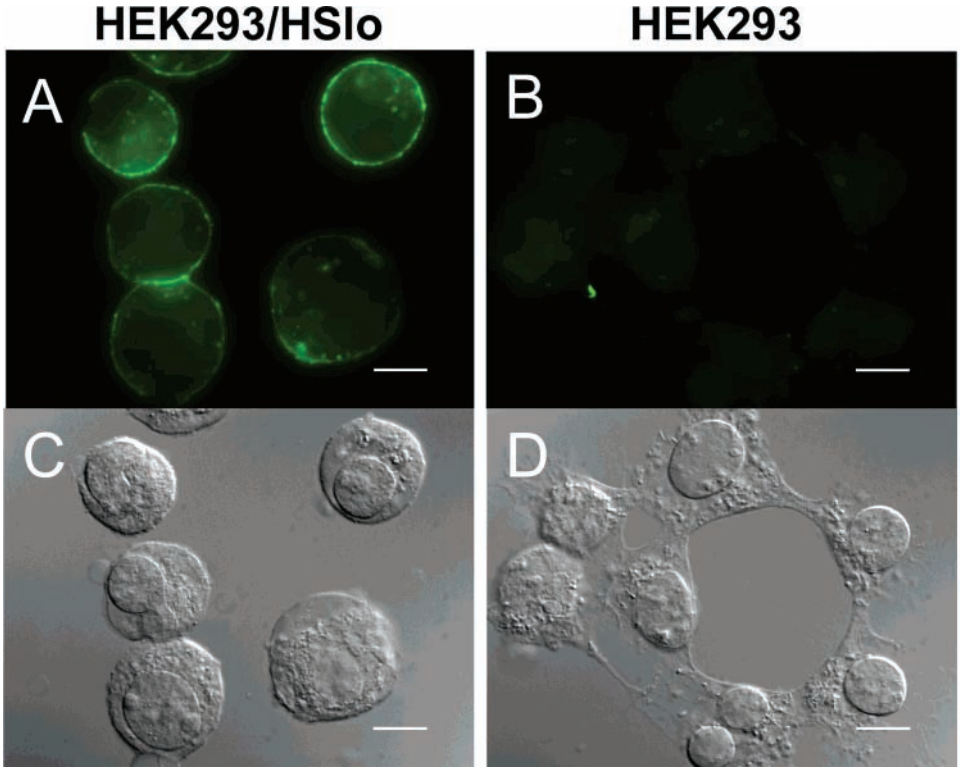

Figure 7. Fluorescence microscopy of transfected cells expressing HSlo using IbTx−LC-biotin. (A, C) Stably transfected HEK293/HSlo cells. (B, D) Untransfected HEK293 cells. (A, B) Fluorescence images acquired under identical conditions. (C, D) DIC image of the same fields in A and B, respectively. Cells grown on coverslips were processed for microscopy by incubation with 100 nM IbTx−LC-biotin, then washed and incubated with 10 μg/mL Alexa488-StrAv, washed again, fixed in 2% formaldehyde, and viewed using a 100× oil immersion objective as described in Experimental Procedures. Scale bar = 10 μm.

HSlo cells exhibited intense fluorescence on the perimeter of the plasma membrane (Figure 7A,C) consistent with the G418 antibiotic selection procedure for growth of cells stably transfected with the pcDNA3 vector containing the HSlo gene. In contrast, the plasma membrane of control untransfected HEK293 cells processed for imaging in an identical manner (Figure 7B,D) showed only faint and diffuse background fluorescence, consistent with weak nonspecific adsorption of the labeling reagents and the fact that this fibroblast-like cell line has very low levels of endogenous BK current (Yu et al., 1998).

Analysis of 0.5 μm Z-sections of single cell images by fluorescence deconvolution enhancement showed that virtually all the fluorescence signal in HEK293/HSlo cells is localized to the cell surface, consistent with membrane impermeability and lack of cellular uptake of the imaging reagents under the labeling conditions. Supplementary Figure 1 (Supporting Information) is a movie file that shows a series of consecutive two-dimensional (2D) 0.5 μm Z-sections through a single HEK293/HSlo cell labeled with IbTX−LC-biotin/Alexa488-StrAv, imaged by fluorescence microscopy, and processed by deconvolution enhancement. This visualization method reveals a nonrandom distribution of fluorescence on the cell plasma membrane. Supplementary Figure 2A−C (Supporting Information) contains movie files of HEK293/HSlo cells imaged in a similar fashion, reconstructed in three dimensions by software, and displayed by rotation of the reconstructed fluorescence image of the cell or cell pairs. These data also show a punctate-like distribution of fluorescence on the cell surface. A similar patch-like surface distribution of BK channels was also observed by processing fixed HEK293/HSlo cells for fluorescence microscopy with an anti-Flag antibody that recognizes the extracellular Flag epitope on the tagged HSlo channel (not shown). Thus, the patch-like surface distribution of BK channels observed by IbTX−LC-biotin labeling is not a peculiar feature of the toxin-labeling method. The patch-like distribution of BK channels revealed in these experiments indicates that cellular mechanisms operating in this transfected cell line result in preferential clustering of BK channels on the membrane surface. Clustering and co-localization of BK channels with various signal-transduction proteins has previously been observed described in diverse cell types (Alioua et al., 2002; Eghbali et al., 2003; Liu et al., 2004) and is thought to be an important mechanism for coupling of BK channel activity to specific cellular functions.

In certain histochemical applications, StrAv-based labeling techniques are prone to background signals due to nonspecific adsorption and endogenous biotin (Haugland, 2002). To test for this possibility, we used a commercial biotin-blocking procedure according to the manufacturer's instructions (Molecular Probes; Eugene, OR) but found that this treatment made little difference in the background fluorescence (not shown). To further examine the specificity and versatility of IbTx−LC-biotin imaging, a number of additional control experiments were performed. As shown in Figure 8A,B, fluorescence labeling of HEK293/HSlo cells by 50 nM IbTx−LC-biotin and 3 μg/mL Alexa488-StrAv is effectively blocked by 5 μM IbTX-D19C-Acm, a nonbiotinylated derivative of IbTx. This result shows that excess untagged IbTx effectively competes with BK channel labeling by IbTx−LC-biotin, demonstrating that the fluorescence signal is specific for IbTx-binding sites. The latter experiment was performed with unfixed cells demonstrating potential utility in live cell applications where fixation treatments are to be avoided. Figure 8C,D shows results of a similar control experiment where IbTx−LC-biotin was simply omitted in the labeling procedure, again demonstrating specificity for the BK channel toxin. As an alternative to the use of StrAv, the experiment of Figure 8E,F shows that a commercially available monoclonal antibody, Alexa488-antibiotin antibody, is also effective as a secondary fluorescent reagent in visualizing IbTx−LC-biotin bound to BK channels expressed on the cell surface.

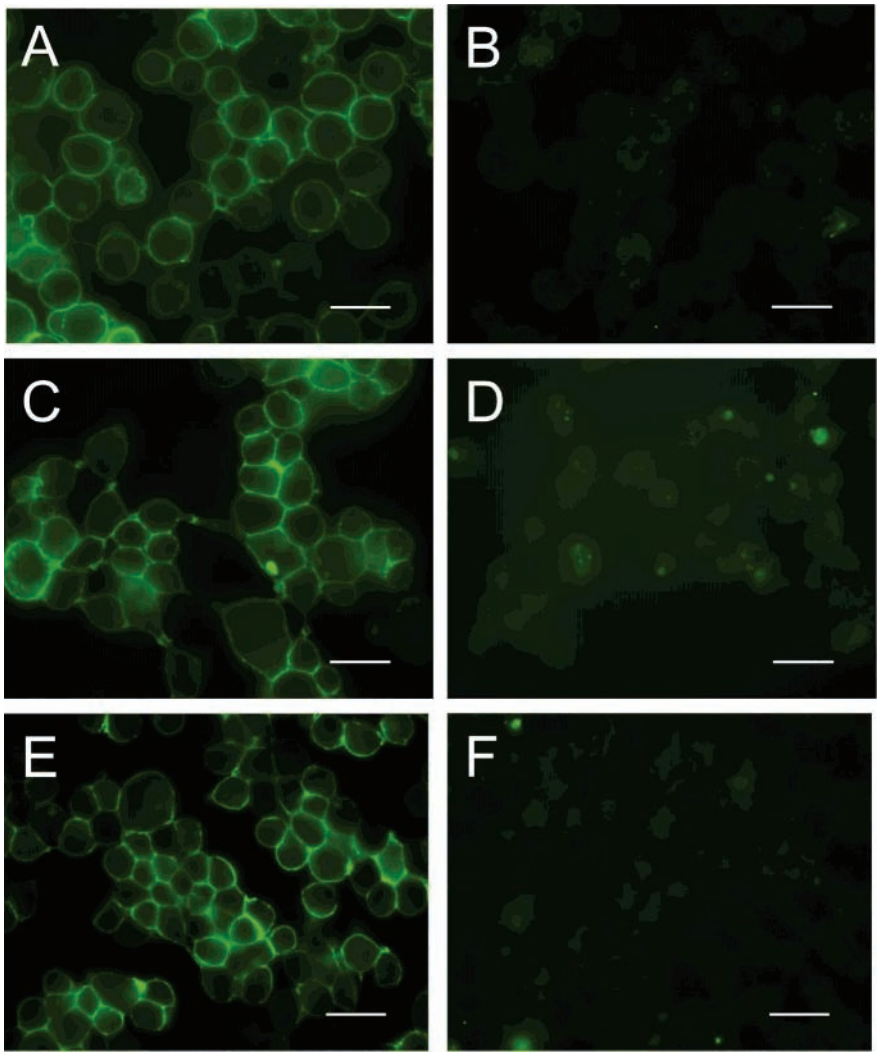

Figure 8. Specificity of fluorescence labeling by IbTx−LC-biotin assessed by various controls. (A, B) Live (unfixed) HEK293/HSlo cells after processing with 50 nM IbTx−LC-biotin and 3 μg/mL Alexa488-StrAv. Control coverslip in B was treated identically to A except that 5 μM IbTx-D19C-Acm was added before exposure to IbTx−LC-biotin. (C, D) HEK293/HSlo cells after processing with 50 nM IbTx−LC-biotin, 3 μg/mL Alexa488-StrAv, and fixation with 2% formaldehyde. Control coverslip in D was treated identically to C except that IbTx−LC-biotin was omitted. (E, F) HEK293/HSlo cells after processing with 50 nM IbTx−LC-biotin, 4 μg/mL Alexa488-antibiotin antibody, and fixation with 2% formaldehyde. Control coverslip in F was treated identically to E except that IbTX−LC-biotin was omitted. Cells were processed for microscopy and viewed with a 40× oil immersion objective as described in Experimental Procedures. Scale bar = 30 μm.

DISCUSSION

The growing inventory of natural K^+ channel peptide toxins discovered in venoms of insects, scorpions, spiders, sea anemones, cone snails, and snakes has motivated efforts to develop radioactive and fluorescent derivatives of these molecules for applications in biochemistry and neuroscience. K^+ channel toxins from scorpions are attractive candidates for probe development due to their small size (<40 residues) and selective affinity for particular members of the K^+ channel family. Peptide toxins and mutant toxin derivatives can be readily produced by synthetic gene technology and recombinant expression in *Escherichia coli* (Park et al., 1991; Koschak et al., 1997); however, this approach involves numerous steps required to express, cleave, and purify the recombinant toxins. Alternatively, numerous disulfide-linked toxins such as ChTx and IbTx have also been produced by automated peptide synthesis (e.g., Sugg et al., 1990; Toth et al., 1995). The latter methodology permits direct incorporation of non-native amino acids during linear synthesis of the peptide as illustrated here by substitution of Lys-ϵ-D-LC-biotin at position 19 of the IbTx sequence. Biotin tags or fluorescent labels may also be coupled to peptide toxins by appropriate chemical modification reactions [(e.g., alkylation of the thiol group of a spinster cysteine (Shimony et al., 1994)] after synthesis and oxidation of paired disulfides. However, a practical coupling strategy requires high-yield labeling reactions and efficient purification of the bioactive derivative. Improvements in biomolecular engineering, i.e., design, synthesis, and labeling of K^+ channel toxins, are needed to make these promising molecular tools more widely available to researchers in the field of ion channel biology.

Interesting findings previously reported with ChTx labeled with a biotin moiety at the N-terminus (Robitaille et al., 1993), IbTx randomly labeled with rhodamine red succinimidyl ester at native Lys residues (Jimenez-Gonzalez et al., 2003) or IbTx-D19C labeled with Alexa488 (Hafidi et al., 2005) warrant further development of ChTx and IbTx derivatives for fluorescence imaging applications in native cells and tissues. In this respect, the goal of the present work was to synthesize a derivative of IbTx with a biotin tag at a "backside" residue and to characterize its relevant activities under defined model conditions. The results indicate that synthetic IbTx−LC-biotin avidly binds to mammalian BK channels as demonstrated by

its blocking activity against rat muscle BK channels in planar bilayers (Figure 3) and human BK channels expressed in a cultured cell line (Figure 4).

Previous studies have shown that measured equilibrium constants for block and binding of charybdotoxin and IbTx are strongly dependent upon the ionic strength of the extracellular assay medium (Anderson et al., 1988; Garcia-Calvo et al., 1991; Vasquez et al., 1989; Koschak et al., 1997) and the association of particular isoforms of four known accessory beta subunits with the BK channel alpha subunit in native tissues (Hanner et al., 1997; Wallner et al., 1999; Giangiacomo et al., 2000; Meera et al., 2000). For example, when the BK channel is coexpressed with the β1 subunit, the dissociation rate of ChTx is slowed by ~10-fold (Hanner et al., 1997; Gianciacomo et al., 2000). Thus, the performance of IbTx−LC-biotin in particular imaging applications may be expected to be strongly dependent upon the cellular preparation and the specific conditions of labeling. In transfected HEK293 cells, we find that incubation of cells with 50 nM IbTx−LC-biotin is sufficient to obtain high-quality fluorescence imaging (Figure 8), but use of lower toxin concentrations may be possible. It may also be possible to further improve the specific fluorescence signal by exposing cells to a low concentration of IbTx−LC-biotin in combination with paxilline, an alkaloid that acts to enhance binding of scorpion toxins to BK channels by an allosteric mechanism (Knaus et al., 1994; Hanner et al., 1997; Koschak et al., 1997). The absolute affinity of a probe molecule for specific receptor sites is an important factor in fluorescence imaging, since the greater the difference between specific and nonspecific binding to cell membranes, the greater the signal-to-noise ratio in visualization of receptor localization.

Our results generally support the use of biotin-StrAv methodology as a feasible approach to toxin-based imaging and localization of K^+ channels. Placement of a biotin-tag with a long chain linker on backside residue 19 of IbTx preserves both specific binding to the BK channel and efficient access to two of the four biotin sites of StrAv. A potential advantage of this method is the ability to combine IbTx−LC-biotin with a wide array of detection methods accessible through commercially available conjugates of StrAv and avidin including numerous fluorophores, enzyme conjugates, nanogold particles, and quantum dots (Woldin et al., 1999; Haugland, 2002; Watson et al., 2003). Since fluorescent conjugates of StrAv typically contain multiple fluorophores per StrAv molecule (Panchuk-Voloshina et al. 1999), this detection method may provide greater sensitivity than IbTx probes directly coupled to a single fluorophore. The apparent restriction of IbTx−LC-biotin binding to one site on each of the two binding faces of the StrAv tetramer would be expected to limit or prevent 2D cross-linking of BK channels via multiple interactions with a single tetravalent StrAv molecule. The latter issue, also a problem with bivalent antibodies, may be of concern in situations where observation of natural clustering of BK channels is of special interest. In cellular preparations where StrAv-based secondary detection results in excessive background fluorescence, visualization of bound IbTx−LC-biotin with fluorescent anti-biotin antibody (Figure 8E) may provide a satisfactory alternative.

In summary, we have described synthesis of a novel biotin-derivative of IbTx that has high binding affinity for both mammalian BK channels and StrAv. The combination of IbTx−LC-biotin and Alexa488-StrAv can be used to image the surface distribution of BK channels on stably transfected HEK293 cells. Such images reveal a nonrandom, patch-like distribution of BK channels indicative of an endogenous mechanism for BK channel clustering. Further improvements in design, synthesis, and imaging protocols for scorpion toxin probes may be expected to enhance research on numerous aspects of the cell biology of K^+ channels.

Diethylenetriaminepentaacetic Acid−Gadolinium (DTPA-Gd)-Conjugated Polysuccinimide Derivatives as Magnetic Resonance Imaging Contrast Agents

Ha Young Lee,[†,‡] Hye Won Jee,[‡] Sung Mi Seo,[‡] Byung Kook Kwak,[§] Gilson Khang,[†] and Sun Hang Cho*[,‡]

Department of Advanced Organic Materials Engineering, Chonbuk National University, Jeonju, Jeonbuk, Republic of Korea, Nanobiomaterials Laboratories, Korea Research Institute of Chemical Technology, Daejeon, Republic of Korea, and College of Medicine, Chung-Ang University, Seoul, Republic of Korea. Received January 23, 2006; Revised Manuscript Received March 19, 2006

Biocompatible polysuccinimide (PSI) derivatives conjugated with diethylenetriaminepentaacetic acid gadolinium (DTPA-Gd) were prepared as magnetic resonance imaging (MRI) contrast agents. In this study, we synthesized PSI derivatives incorporating methoxy-poly(ethylene glycol) (mPEG) as hydrophilic ligand, hexadecylamine as hydrophobic ligand, and DTPA-Gd as contrast agent. PSI was synthesized by the polycondensation polymerization of aspartic acid. All the synthesized materials were characterized by proton nuclear magnetic resonance (^{1}H NMR). Critical micellization concentrations were determined using fluorescent probes (pyrene). Micelle size and shape were measured by electro-photometer light scattering (ELS) and atomic force microscopy (AFM). The formed micelle size ranged from 100 to 300 nm. The T1-weighted MR images of the phantom prepared with PSI−mPEG-C_{16}−(DTPA-Gd) were obtained in a 3.0 T clinical MR imager, and the conjugates showed a great potential as MRI contrast agents.

INTRODUCTION

Magnetic resonance imaging (MRI) utilizes a strong magnetic field to image the human body (*1*). Recently, MRI contrast agents have been used specifically to improve the image contrast between normal and pathological tissue. These MRI contrast agents must have contrast enhancing ability, high stability, and favorable pharmacokinetic properties (*2*).

Several poly(amino acid) derivatives have been investigated as a type of delivery system (*3*, *4*). Particularly, polysuccinimide (PSI) is one of the most promising particle carriers since it was demonstrated to possess suitable physicochemical characteristics for development of macromolecular prodrugs, due to the biocompatibility, biodegradability, and the ease of synthesis and functionalization (*5*−*11*).

Micellization of biologically active substances prepared by advanced bioconjugation technology is a useful method to increase the solubility, stability, and bioavailability of lipophilic drugs and nutrients (*12*, *13*). The rational design of polymeric bioconjugates represents a key issue to achieve derivatives that have the desired physicochemical and biopharmaceutical properties. Therefore, the introduction a of specific pendant group in the polymer backbone is often carried out to modify the carrier properties (*14*−*16*). Especially, the polymeric micelle system can offer some advantages such as wide applicability to drugs and small particle size (*17*−*19*).

Polymeric micelles having hydrophilic/hydrophobic groups were prepared by conjugating a hydrophilic methoxy-poly (ethylene glycol) (mPEG) and a hydrophobic group to PSI, a biodegradable polymer, that is known to be excreted by the kidney (*20*, *21*). The size of micelles with different molecular weights of mPEG and lengths of hydrophobic chains was measured by electro-photometer light scattering (ELS).

We also attached an MRI contrast agent, Gd-DTPA, to the polymeric micelles, PSI. Diethylenetriaminepentaacetic acid (DTPA) is a very efficient chelating agent for lanthanide metal ions. Due to its contrast enhancement and high stability in vivo, a DTPA complex has been clinically used as a contrast agent in MRI (*22*, *23*), but because this DTPA-Gd complex has a low molecular weight and is removed rapidly from the blood pool, the study has been directed toward stable DTPA-Gd complexes that can circulate for a longer time in blood (*24*, *25*).

In this study, we synthesized PSI−mPEG-C_{16}−(DTPA-Gd) which formed a micelle. The size diameter of the micelles was 100−300 nm which is suitable for a particle carrier to be well incorporated into the internal organs (*26*, *27*). Furthermore, we investigated the potential of PSI−mPEG-C_{16}−(DTPA-Gd) as a MRI contrast agent by an MRI test of the phantom.

EXPERIMENTAL PROCEDURES

Materials. D,L-Aspartic acid and hexadecylamine were purchased from Aldrich Co., Milwaukee, WI. Methoxy-poly-(ethylene glycol)-amine [mPEG-NH_2, number-average molecular weight (M_n) ≈ 5000] was purchased from Fluka, Buchs, Switzerland. Reagents for DTPA preparation were obtained from Fluka and Aldrich. Phosphoric acid, sulfolane, *N*,*N*-dimethylformamide (DMF), methyl alcohol (MeOH), and diethyl ether were commercially available and were used without further purification. Omniscan was purchased from Guerbet Co., Germany.

Synthesis of Polysuccinimide (PSI). Polysuccinimide was synthesized by a polycondensation reaction. A suspension of D,L-aspartic acid (25 g, 0.188 mol) and phosphoric acid (9.4 mmol) in sulfolane (80 g) was stirred at 160 °C under a nitrogen atmosphere. After 24 h, the reaction solution was precipitated by into MeOH. PSI was filtered, washed with MeOH, and dried under vacuum.

Synthesis of Poly(succinimide-ethylene glycol) (PSI−mPEG). A solution of mPEG-NH_2 (0.1×10^{-4} mol) in DMF (5 mL) was added dropwise to a solution of PSI (2.5×10^{-4}

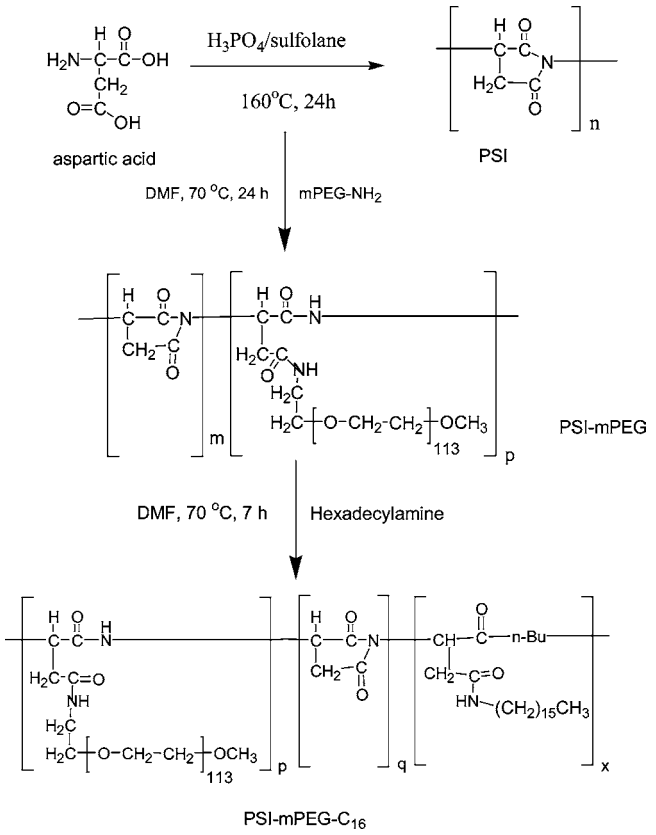

Figure 1. The overall synthetic scheme of PSI−mPEG-C_{16} from poly(aspartic acid).

mol) in DMF (50 mL). The mixture was stirred at 70 °C, under a nitrogen atmosphere. After 24 h, the reaction solution was precipitated and filtered with ethyl ether for removal of DMF and unreacted materials. The filtered PSI−mPEG was washed with ether and dried under vacuum.

Synthesis of PSI−mPEG-C_{16}. A solution of hydrophobic ligand, hexadecylamine (2×10^{-4} mol), in DMF (5 mL) was dropped to a solution of PSI−mPEG (2.5×10^{-4} mol) in DMF (30 mL). The mixture was stirred at 70 °C under a nitrogen atmosphere. After 7 h, the reaction solution was precipitated and filtered with ethyl ether. The filtered PSI−mPEG-C_{16} was washed with ethyl ether and dried under vacuum. The distribution of micelle size was experimentally evaluated.

Synthesis of PSI−mPEG-C_{16}−(DTPA-Gd). Lysine-DTPA *tert*-butyl ester was prepared according to the method reported in the literature (*22*). The solution of DTPA (3.75×10^{-4} mol) in DMF (5 mL) was added dropwise to a solution of PSI−mPEG-C_{16} (2.5×10^{-4} mol) in DMF (20 mL). The mixture was stirred at room temperature. After 18 h, ethyl ether was added. The precipitate was filtered, washed with ethyl ether, and dried under vacuum. The dried residue was dissolved in formic acid and stirred at 100 °C to perform the deprotection of *tert*-butyl group, according to the literature (*1*). After 3−5 h, the reaction solution was evaporated under vacuum condition. The residue was dissolved in water and stirred at room temperature for 3 h. Thereafter, the mixture was filtered and lyophilized.

To support gadolinium in PSI−mPEG-C_{16}-DTPA, a solution of $GdCl_3$ (1.5×10^{-3} mol) in water (5 mL) was added dropwise to a solution of PSI−mPEG-C_{16}−DTPA (1.5×10^{-3} mol) in water (30 mL), maintaining the solution mixture at pH 7−8. After 1 h, the reaction mixture containing PSI−mPEG-C_{16}−(DTPA-Gd) was precipitated by addition of acetonitrile and was filtered. The filtered solid was washed with ethyl ether and dried under vacuum.

Table 1. Degree of Derivatization (DD) of mPEG and C_{16}

sample	mPEG DD (mol %)	C_{16} DD (mol %)
PSI−mPEG	13.5	-
PSI−mPEG- C_{16}	14.7	1.37

Characterization Analysis. The molecular weight of PSI was confirmed by GPC ((PL-GPC220, Polymer Laboratory, England) analysis. GPC had two columns (10 μm, MIXED-B $\times$2. 50 nm), and DMF (Aldrich) was used as mobile phase. Polystyrene (Showa Denko, Japan) was used as the standard sample. The flow rate was 1 mL/min. The results of polymerization were confirmed by ^{1}H NMR (Bruker 300, 500 MHz). Dimethyl sulfoxide (DMSO, Aldrich) was used as solvent. The size of micelles and shape were confirmed by ELS (ELS-8000, Otsuka Electronics, Japan) and AFM (Nanoscope IV). Also, Gd incorporation and Gd content were confirmed by EA, EDS, and ICP-AES. Fluorescence studies were carried out using a F-4500 fluorescence spectrophotometer (Hitachi Co. Ltd., Japan).

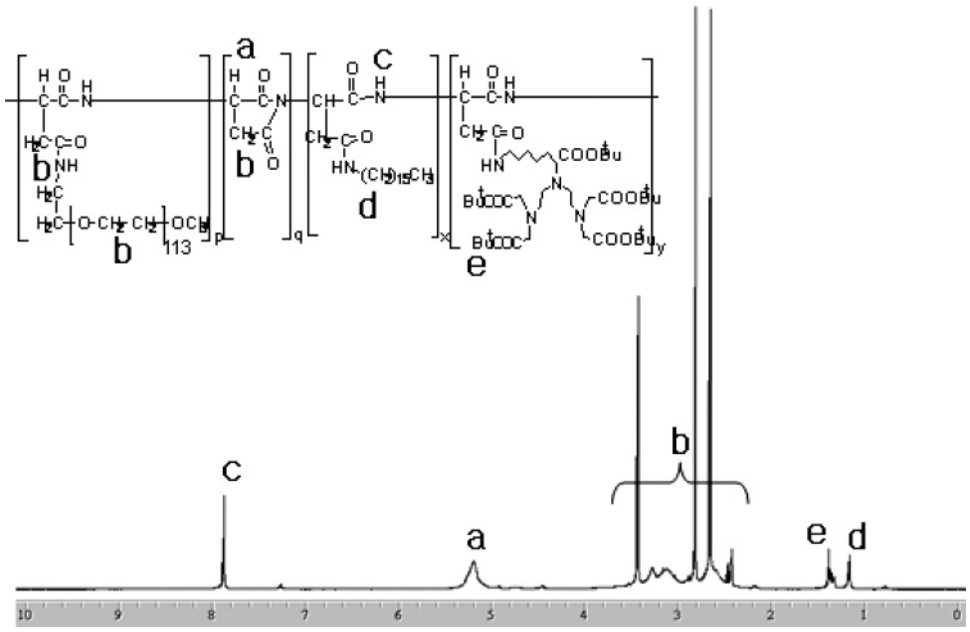

Figure 4. ^{1}H NMR spectrum of PSI−mPEG-C_{16}−DTPA *tert*-butyl ester.

Table 2. Elemental Analysis of Complex

complex	element	elemental anal. average (%)
PSI-mPEG-C_{16}−DTPA	nitrogen	8.911348
	carbon	44.71717
	hydrogen	6.167405
PSI−mPEG-C_{16}−(DTPA-Gd)	nitrogen	4.997967
	carbon	22.12623
	hydrogen	2.562378

In Vitro Contrast Effect Measurement. In vitro MR imaging test was performed with a 3.0T magnet at Philips Achieva 3.0T MRI (Philips Co., Netherlands). The T1-weighted MR images of the prepared compounds and a commercially available contrast agent, Omniscan, were obtained. MR images were taken with different concentrations of Gd solution (1×10^{-3} M Gd/L to 5×10^{-6} M Gd/L). The experimental condition was as follows: TR (recycle time) = 9.6 ms, TE (echo delay time) = 4.6 ms, flip angle: 8.0, field of view: 10×5 cm^2.

RESULTS AND DISCUSSION

Synthesis and Characterization of PSI−mPEG-C_{16}. To prepare the micelle-formed MRI contrast agent with Gd, at first, PSI, PSI−mPEG, and PSI−mPEG-C_{16} were sequentially synthesized following the literature (*28*). The overall synthetic route of PSI−mPEG-C_{16} is shown in Figure 1. PSI was synthesized by the polycondensation polymerization of aspartic acid. The yield and weight average molecular weight of PSI were 80% and 21000 by GPC measurement.

^{1}H NMR spectra of PSI, PSI−mPEG, and PSI−mPEG-C_{16} are shown in Figure 2a−c. In the PSI spectra, the signals at 5.04 ppm were assigned to the methyne proton (a) of the repeating succinimide unit and the signals at 2.5−3.5 ppm were assigned to the methylene protons (b) (*29*).

The degree of derivatization (DD) of PEG was determined by ^{1}H NMR and was calculated by comparing the integral of the NH peak at δ 7.9 that appears during the opening of the ring when being combined with PEG to the integral of the peak at δ 5.04 assigned to protons that belong to the PSI unit.

The DD of C_{16} was calculated by comparing the integral of the CH_2 peak at δ 1.2 of hexadecylamine to the integral of the peak at δ 5.04 to protons that belong to the PSI unit (*28*). The DD values of PSI−mPEG and PSI−mPEG-C_{16} are reported in Table 1.

Synthesis and Characterization of PSI−mPEG-C_{16}−(DTPA-Gd). The overall synthetic route of PSI−mPEG-C_{16}−(DTPA-Gd) from PSI−mPEG-C_{16} is shown in Figure 3. DTPA used as a chelating agent was combined with PSI−mPEG-C_{16}, and Gd was incorporated into the complex. Figure 4a,b shows ^{1}H NMR analysis data of PSI−mPEG-C_{16}−DTPA and PSI−mPEG-C_{16}−(DTPA-Gd). These spectra show the existence of a *tert*-butyl peak at 1.2−1.8 ppm before formic acid treatment. Incorporation of Gd into the polymer chain was confirmed by EDS (energy dispersive spectroscopy) analysis and EA (elemental analysis) data. Table 2 showed that the content of C, H, N decreased after incorporation of Gd. Figure 5 showed that the peak of Gd appeared after incorporation of Gd. The content of Gd was measured by ICP (Table 3). The results showed that a moderately consistent amount of Gd was incorporated in the polymer from two different batches, because the binding site of PSI involved in the conjugation of DTPA was limited.

Critical Micelle Concentration (CMC). The CMC of PSI−mPEG, PSI−mPEG-C_{16}, and PSI−mPEG-C_{16}-(DTPA-Gd) were determined using pyrene emission (*30, 31*). The concentrations of sample solution were varied from 1×10^{-5} to 1 mg/mL. The ratio I_3/I_1 of the intensities of the first ($\lambda_1 \approx 335$ nm) and the third ($\lambda_3 \approx 338$ nm) vibronic band is a sensitive measure for pyrene. This ratio increases with increasing hydrophobicity in the core because pyrene is expected to be distributed in hydrophobic regions of a self-organized system in solution due to low water solubility. Figure 6 shows the fluorescence emission spectra of pyrene incorporated into PSI−mPEG, PSI−mPEG-C_{16}, and PSI−mPEG-C_{16}−(DTPA-Gd) in water, respectively. The ratio I_3/I_1 increases rapidly, indicating that interactions between pyrene and the hydrophobic core are occurring and pyrene is in the micellar core. The critical micelle concentration (CMC) was determined by the interception of two straight lines. This CMC data indicate that the CMC values increase with increasing hydrophilic groups such as PEG and DTPA-Gd and that all prepared copolymers form micelles.

Size Distribution. The size effect of micelles with different molecular weights of mPEG is shown in Figure 7. This result shows that the size of micelles is decreased as the molecular weight is increased. The decrease in micelle size could be due to increased hydrophilicity when more mPEG units are added.

The size effect of micelle with the length of alkyl chain is shown in Figure 8. This result showed that the size of micelles increased as the length of hydrophobic chain increased. Figure

In Vitro MRI Test. T1-weighted MR images of the phantom are shown in Figure 10. In the phantom image, when the concentration of Gd was above 9.4×10^{-4} M, the image contrast

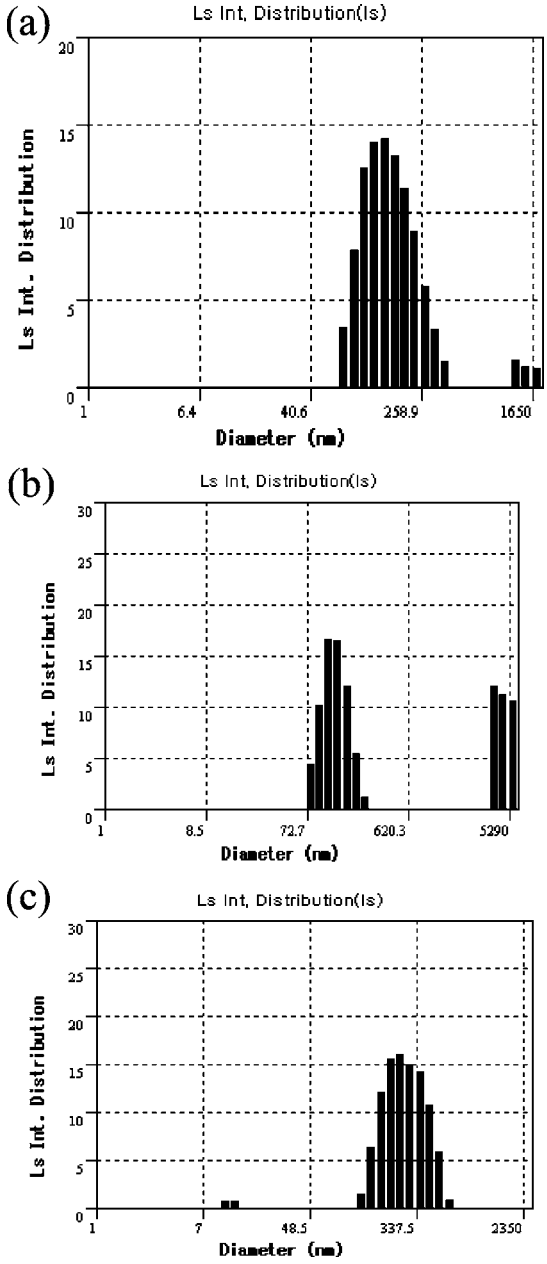

Figure 8. The size distribution of micelles with different hydrophobic ligand lengths by ELS analysis; (a) PSI−$mPEG_{5000}$-C_8 micelles average size: 238 nm, (b) PSI−$mPEG_{5000}$-C_{14} micelles average size: 288 nm and (c) PSI−$mPEG_{5000}$-C_{18} micelles average size: 342 nm.

showed similar patterns, but when the concentration of Gd was below this amount, the image contrast seemed better than that of Omniscan. Table 4 shows relaxivity values according to different concentrations of Gd. From these data, we can know that the signal intensity value of PSI−mPEG-C_{16}−(DTPA-Gd) in 1.2×10^{-4} M (Gd) is similar with the signal intensity value of Omniscan in 4.7×10^{-4} M (Gd). These results showed that the prepared sample had better contrast imaging at a lower concentration than that of Omniscan.

CONCLUSION

In this study, we have prepared PSI micelle conjugates by combining PSI with a hydrophilic chain, a hydrophobic chain, and a contrast agent. We have tested the compounds to determine its potential use as a carrier and a contrast agent. First, PSI with various molecular weights was synthesized through condensation polymerization with different reaction

6.0×10^{-5} M	580.96	1043.42

times and catalyst contents using aspartic acid and catalyst. The synthesized PSI was combined with the hydrophilic mPEG, the hydrophobic chain, and the contrast agent, and the variation of micelle size was measured with different molecular weights of hydrophilic group and different lengths of hydrophobic chain. The size of micelles was confirmed by ELS and AFM. The diameter of micelles was 100−300 nm. In vitro, the prepared micelles showed the enhancement of MRI contrast over five times of commercially available products. From these results, it was concluded that PSI conjugates possessing mPEG, a hydrophobic ligand, and DTPA-Gd might be exploited as carriers and contrast agents due to their biocompatibility, good stability, and good contrast imaging.

Received January 23, 2006; Revised Manuscript Received March 30, 2006

Combination therapy can help overcome limitations in the treatment of heterogeneous tumors. In the current study, we examined whether multiple therapeutic agents could be targeted to anti-dansyl single-chain antibodies (DNS scFv) that were anchored on the plasma membrane of cancer cells. Functional DNS scFv could be stably expressed on CT-26 colon cancer cells both in vitro and in vivo. Dansyl moieties were covalently attached to recombinant β-glucuronidase (βG) and interleukin 2 (IL-2) via a flexible poly(ethylene glycol) linker to form DNS−PEG−βG and DNS−PEG−IL-2 conjugates. The conjugates displayed enzymatic and splenocyte-stimulatory activities, respectively, that were similar to those of the unmodified proteins. The conjugates selectively bound CT-26 cells that expressed anti-DNS scFv (CT-26/DNS cells) but not CT-26 cells that expressed control scFv (CT-26/phOx cells). DNS−PEG−βG preferentially activated a glucuronide prodrug (BHAMG) of *p*-hydroxy aniline mustard at CT-26/DNS cells in culture and accumulated in subcutaneous CT-26/DNS tumors after intravenous administration. Systemic administration of DNS−PEG−IL-2 or DNS−PEG−βG and BHAMG significantly delayed the growth of CT-26/DNS but not control CT-26/phOx tumors. Combination treatment with DNS−PEG−βG and BHAMG followed by DNS−PEG−IL-2 therapy significantly suppressed the growth of CT-26/DNS tumors as compared to either single-agent regimen. These results show that at least two DNS-modified therapeutic agents can be selectively delivered to DNS scFv receptors in vitro and in vivo, allowing combination therapy of DNS scFv-modified tumors.

INTRODUCTION

Conventional cancer treatment is often limited by unacceptable toxicity to normal tissues and associated side effects (*1*, *2*). Methods to selectively target therapeutic agents to tumor cells can improve treatment efficacy and reduce the exposure of normal tissues to cytotoxic agents. Antibody-directed enzyme prodrug therapy (ADEPT), in which an immunoenzyme is employed to preferentially activate prodrugs at cancer cells, has demonstrated advantages for tumor therapy in animal models including high accumulation of drug in tumors (*3*), bystander killing of antigen-negative tumor cells (*4*), and improved efficacy compared with conventional chemotherapy with reduced side effects (*5*). Our previous results also demonstrated that an immunoenzyme composed of monoclonal antibody RH1 conjugated to β-glucuronidase could target rat AS30D hepatocellular carcinoma tumors and specifically convert a glucuronide prodrug (BHAMG[1]) of *p*-hydroxy aniline mustard to active *p*-hydroxy aniline mustard (pHAM) (*6*, *7*). Rats cured of malignant hepatocellular carcinoma ascites by ADEPT with BHAMG possessed long-lasting protective immunity to subsequent tumor challenges, suggesting that ADEPT can synergize with the immune system to provide increased therapeutic efficacy (*6*, *7*). The immunogenicity of synergistic malignancies can also be increased by targeting cytokines to the tumor microenvironment (*8*). For example, antibody−IL-2 fusion proteins can effectively suppress tumor growth (*9*) and amplify the T cell mediated immune responses induced by cancer vaccines (*10*, *11*). Based on these findings, an attractive therapeutic strategy can be envisioned in which the major bulk of tumors is reduced by ADEPT and targeted immunocytokine therapy is then employed to potentiate the immune response generated during prodrug therapy, thereby eliminating residual and disseminated disease.

One approach to target therapeutic agents to tumors is to create artificial anti-hapten receptors on cancer cells that can bind to hapten-derivatized molecules. We previously demonstrated that expression on tumor cells of a membrane-anchored

scFv with specificity for the hapten 4-ethoxymethylene-2-phenyl-2-oxazoline-5-one (phOx) allowed selective trapping of phOx-derivatized βG at the cells for activation of glucuronide prodrugs (*12*). phOx, however, is unstable in serum, resulting in the progressive loss of phOx antigenicity. In contrast, a bivalent dansyl probe [$(DNS)_2$-DTPA-^{111}In] was stable in serum and could be specifically bound by tumor cells that expressed DNS scFv receptors in vitro and in vivo (*13*). The DNS moiety is therefore more suitable for in vivo hapten-directed targeting.

In the present study, we wished to test the hypothesis that multiple therapeutic agents can be simultaneously targeted to cells expressing anti-hapten receptors. This was examined by expressing DNS scFv receptors on CT-26 colorectal cancer cells and attaching DNS molecules to recombinant βG and IL-2 via flexible poly(ethylene glycol) spacers (Figure 1a). We then tested the hypotheses that (1) DNS-modified molecules could be selectively bound by anti-DNS scFv on cells, (2) accumulation of DNS-modified βG at DNS scFv-positive cells would allow activation of glucuronide prodrugs, (3) DNS-modified IL-2 could stimulate splenocyte proliferation at receptor-positive cells, and (4) treatment of established tumors with hapten-modified βG for prodrug activation in combination with hapten-modified IL-2 could provide improved therapeutic efficacy as compared with either individual treatment regimen. The results of our study show that hapten-directed therapy does allow more than one therapeutic agent to be targeted to tumors for combination cancer therapy.

EXPERIMENTAL PROCEDURES

Reagents. The syntheses of pHAM and BHAMG have been described (*14*). Recombinant βG containing a his-tag was purified by metal chelate chromatography on His-Bind resin (Novagen) as described (*15*). Recombinant mouse IL-2 was produced in *Pichia pastoris* (kindly provided by Dr. Mi-Hua Tao, Institute of Biomedical Sciences, Academia Sinica, Taipei) and purified by metal chelate chromatography on His-Bind resin (Novagen, San Diego, CA). Dansyl chloride, dansyl cadaverine, fluorescamine, and *p*-nitrophenyl-β-D-glucuronide were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). PEG_{3400}-disuccinimidyl succinamide (3400 Da) was purchased from Nektar Therapeutics (Birmingham, AL). Dansyl chloride and 4-ethoxymethylene-2-phenyl-2-oxazoline-5-one (phOx) were linked to fluorescein via a diaminopentane spacer to generate phOx-FITC and dansyl-FITC as described (*12*). The anti-poly(ethylene glycol) antibody, E11 (IgG_1), which binds to the repeating ($O-CH_2-CH_2$) subunits of the PEG backbone and can detect and clear PEG-modified proteins, has been described (*16*).

Cells and Animals. CT-26 colon carcinoma cells were obtained from the American Type Culture Collection (Manassas, VA). Cells were cultured in DMEM supplemented with 10% heat-inactivated bovine calf serum, 100 units/mL penicillin and 100 μg/mL streptomycin. BALB/c mice were obtained from the National Laboratory Animal Center, Taipei, Taiwan. Animal experiments were performed in accordance with institute guidelines.

Transfection of Receptor Transgenes. pLNCX-DNS-B7 and pLNCX-phOx-B7 plasmids encode membrane-bound scFv with specificity for DNS and phOx, respectively (*12*). To produce pseudotyped retroviruses, pLNCX-DNS-B7 and pLNCX-phOx-B7 were cotransfected in GP2-293 cells (Clontech, Mountainview, CA) with pVSVG (Clontech), which expresses the G protein of vesicular stomatitis virus (VSV) under the transcriptional control of the cytomegalovirus immediate early gene promoter. Two days after transfection, the culture medium was filtered, mixed with 8 μg/mL Polybrene and added to CT-26 colon carcinoma cells. The cells were selected in G418 and sorted on a flow cytometer to generate CT-26/DNS and CT-26/phOx cells that expressed similar levels of DNS or phOx scFv receptors, respectively.

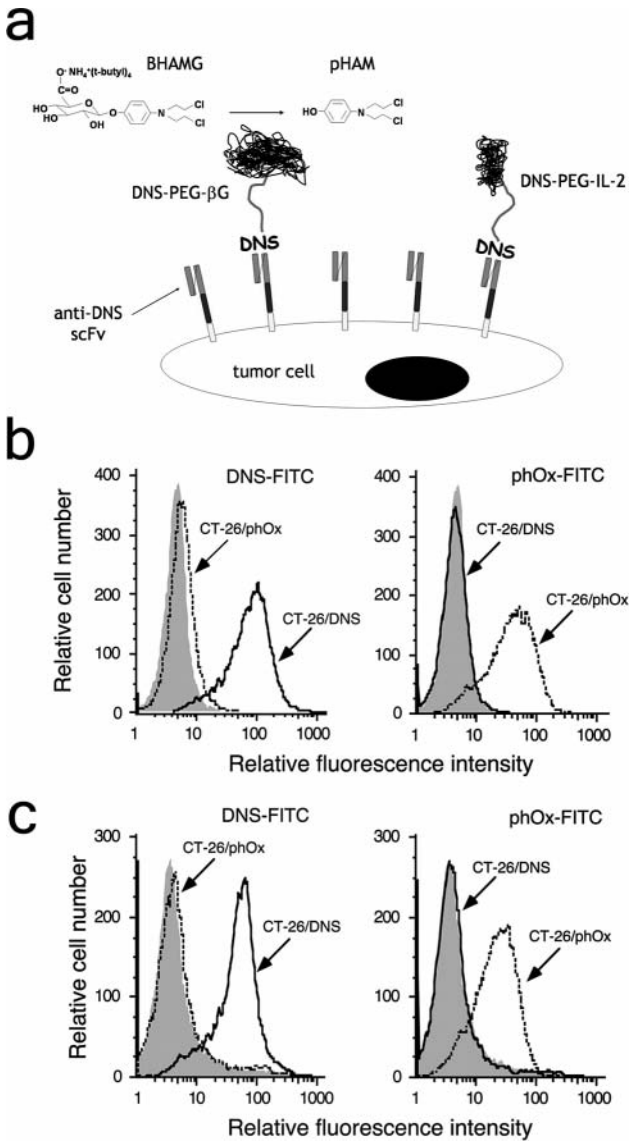

Figure 1. Combination cancer therapy by hapten-targeted prodrug-activating enzymes and cytokines. (a) Anti-DNS scFv expressed on the surface of tumor cells can bind and trap DNS−PEG−βG on the cells. The glucuronide prodrug BHAMG can then be selectively hydrolyzed to the active alkylating agent pHAM at the tumor cells. Likewise, binding of DNS−PEG−IL-2 to anti-DNS scFv on the cancer cells can also allow accumulation of the cytokine at the tumor site to boost tumor immunity. (b) The immunofluorescence of CT-26 (shaded curve), CT-26/DNS cells (solid line), and CT-26/phOx (dashed line) cells is shown after staining with 1 μM DNS−FITC (left panel) or phOx-FITC (right panel). (c) Established CT-26 (shaded curve), CT-26/DNS (solid line), and CT-26/phOx (dashed line) tumors were excised from BALB/c mice and disaggregated by collagenase treatment. The cells were cultured for 24 h and stained with DNS−FITC (left panel) or phOx-FITC (right panel), and the immunofluorescence of the cells was measured on a flow cytometer.

Functional Expression of scFv Receptors in Vitro and in Vivo. Five million CT-26/DNS or CT-26/phOx cells were incubated with 1 μM phOx-FITC or DNS-FITC at 4 °C for 1 h. After removal of unbound probe by extensive washing, the surface immunofluorescence of viable cells was measured on a FACScaliber flow cytometer (Becton Dickinson, Mountain View, CA) and fluorescence intensities were analyzed with

Flowjo V3.2 (Tree Star, Inc., San Carlos, CA). In vivo expression of scFv receptor was examined by injecting BALB/c mice sc with 2×10^6 CT-26/DNS or CT-26/phOx cells. After 14 days, tumors (200−300 mm^3) were resected, cut into small fragments, and digested with 0.5 mg/mL collagenase in Hanks balanced saline solution containing Ca^{2+} and Mg^{2+} for 1 h at room temperature. The cells were cultured in complete medium for 24 h before the surface expression of scFv receptors was measured in a FACScaliber flow cytometer.

Generation and Characterization of DNS−PEG−βG and DNS−PEG−IL-2. PEG_{3400}-disuccinimidyl succinamide (SSA_2-PEG) was reacted with dansyl cadaverine at a molar ratio of 2:1 in CH_2Cl_2 containing 0.1% triethylamine at room temperature for 1 h. The resulting DNS−PEG_{3400}-succinimidyl succinamide (DNS−PEG_{3400}-SSA) was detected under UV illumination, eluted from silica gel with dichloromethane−methanol (9:1 v/v), and then dried (*16*). βG and IL-2 were passed through a Sephadex G-25 column equilibrated with 0.1 M $NaHCO_3$, pH 7.5 and then concentrated by ultrafiltration to 1 mg/mL. DNS−PEG_{3400}-SSA (2.5 w/w βG, 2 w/w IL-2) was added for 2 h at room temperature. One-tenth volume of a saturated solution of glycine (pH 8.0) was added to stop the reaction. Unreacted PEG was removed by gel filtration on a Sephacryl S-200 HR column. Protein concentrations were determined by the bicinchoninic acid assay (Pierce, Rockford, IL) with bovine serum albumin used as the reference protein. The number of PEG molecules introduced in the proteins was estimated by measuring amine groups before and after PEG modification with fluorescamine. After 7 min of reaction, the fluorescence was measured on a Fluostar Galaxy fluorometer with an excitation wavelength of 390 nm and emission at 475 nm (*17*). An average of 3.5 and 2.5 DNS_{3400}−PEG chains were attached to βG and IL-2 to form DNS−PEG−βG and DNS−PEG−IL-2 conjugates, respectively. The catalytic activity of DNS−PEG−βG was assayed by measuring hydrolysis of *p*-nitrophenol β-D-glucuronide; the absorbance of *p*-nitrophenol was measured in a microtiter plate reader (Molecular Devices, Menlo Park, CA) at 405 nm (*18*). The activity of DNS−PEG−IL-2 was assayed by measuring splenocyte proliferation. 10^6 splenocytes/well were incubated with DNS−PEG−IL-2 or IL-2 (1 μg/mL) in 96-well microtiter plates for 24, 48, 72, and 96 h. Splenocyte proliferation was assayed by the luminescence ATP detection assay system according to the manufacturer's instructions (Perkin-Elmer Life and Analytical Sciences, Boston, MA).

Binding of DNS−PEG−βG and DNS−PEG−IL-2 to anti-DNS scFv Receptors. CT-26/DNS and CT-26/phOx cells were incubated with DNS−PEG−βG (1 μg/mL), DNS−PEG−IL-2 (1 μg/mL), or PBS at 4 °C for 1 h. The cells were washed twice with cold PBS and sequentially stained with rabbit anti-βG serum (1:1000), rabbit anti-mIL-2 serum (1:1000), or rabbit normal serum at 4°C for 1 h, washed twice with cold PBS, and incubated with FITC-conjugated goat anti-rabbit antibody (5 μg/mL) at 4 °C for 1 h. The cells were then washed twice with cold PBS, and the surface immunofluorescence of 10 000 viable cells was measured on a FACSCaliber flow cytometer.

Specific Activation of BHAMG by DNS−PEG−βG. 10^6 CT-26/DNS or CT-26/phOx cells were seeded overnight in 96-well microtiter plates. DNS−PEG−βG (5 μg/mL) was added to the cells at room temperature for 1 h before the cells were washed twice with PBS and graded concentrations of *p*-hydroxyaniline mustard (pHAM) or BHAMG were added to the cells in triplicate for 24 h at 37 °C. The cells were subsequently incubated until hour 48 in fresh medium. Cell viability was determined by the ATPlite luminescence ATP detection assay system (Perkin-Elmer). Results are expressed as percent inhibition of luminescence as compared to untreated cells by the following formula:

$$\% \text{ inhibition} = 100 \times \frac{\text{sample luminescence} - \text{background luminescence}}{\text{control luminescence} - \text{background luminescence}}$$

Specific Stimulation of Splenocytes by DNS−PEG−IL-2. DNS−PEG−IL-2 (1 μg/mL) was incubated with CT-26, CT-26/DNS, or CT-26/phOx cells in 96-well microtiter plates at room temperature for 1 h. The cells were treated with pHAM (100 μM) for 2 h at 37 °C to inhibit cellular proliferation and then washed twice with PBS. 10^6 BALB/c splenocytes were added to the wells for 24, 48, 72, or 96 h. Proliferation of splenocytes was measured by the ATPlite luminescence ATP detection assay system.

In Vivo Clearance of DNS−PEG−βG. Groups of 3 BALB/c mice bearing established CT-26/DNS (right flank) or CT-26/phOx (left flank) tumors were iv injected with 150 μg of βG or DNS−PEG−βG at time zero. Blood samples (30 μL) were removed at 0.17, 1.5, 4, 7, 11, 23 h before iv injection at hour 24 of 150 μg of mAb E11 to accelerate the clearance of DNS−PEG−βG from the circulation. Additional blood samples were taken at subsequent times (3.5, 6, 24 h), and the serum concentration of DNS−PEG−βG was measured by a βG enzyme microassay as described (*18*). Sample concentrations were calculated by comparison of absorbance values with a standard curve constructed from known concentrations of DNS−PEG−βG or βG.

Tumor Localization of DNS−PEG−βG. BALB/c mice bearing established CT-26/DNS (right flank) or CT-26/phOx (left flank) tumors were iv injected with 150 μg of DNS−PEG−βG. After 24 h, mice were iv injected with 150 μg of mAb E11 to accelerate the clearance of DNS−PEG−βG. After 3.5 h, the tumors were excised, embedded in Tissue-Tek OCT in liquid nitrogen, and cut into 10 μm sections. Tumor sections were stained for βG activity with the β-glucuronidase reporter gene staining kit (Sigma). Briefly, the sections were placed in fixation solution (10 mM MES, pH 5.6, with 300 mM mannitol and 0.3% formaldehyde) at room temperature for 45 min, washed three times with wash solution (10 mM sodium phosphate, pH 7.0, with 0.2 mM EDTA), and stained with 5-bromo-4-chloro-3-indolyl-β-D-glucuronide (X-GlcA) at 37 °C for 3 h. The sections were then stained with nuclear fast red (Sigma) as a counterstain. All sections were examined on an upright microscope (Olympus BX41, Japan).

Cocktail Therapy. Groups of 5 BALB/c mice were sc injected in the right flank with 10^6 CT-26/DNS or CT-26/phOx cells. After 7 days, the mice were iv injected with PBS or 150 μg of DNS−PEG−βG. Twenty-four hours later, the mice were iv injected with 150 μg of E11 to accelerate the clearance of DNS−PEG−βG. Mice were iv injected 4 h later with three fractionated doses of 15 mg/kg BHAMG at 1 h intervals. Control groups of tumor-bearing mice were treated with BHAMG (15 mg/kg × 3), or PBS alone. All groups of BHAMG-treated mice were iv injected 24 h later with three fractionated doses of 15 mg/kg BHAMG at 1 h intervals. On day 10, specific groups of mice were ip injected with 20 000 units of DNS−PEG−IL-2. These mice received a total of 5 rounds of DNS−PEG−IL-2 over 10 days. Tumor volumes (length × width × height × 0.5) and body weight were measured twice a week.

Data Analysis. Statistical significance of differences between mean values was estimated with Excel (Microsoft, Redmond, WA) using the independent *t*-test for unequal variances.

RESULTS

Surface Display of Functional Anti-Dansyl scFv Receptors. The retroviral vectors pLNCX-DNS-eB7 and pLNCX-phOx-

eB7 encode membrane-anchored forms of DNS scFv and phOx scFv receptors in which anti-DNS or anti-phOx scFv is fused to the Ig-like C type domain, the transmembrane, and the cytoplasmic tail of murine CD80 (*12*). CT-26 colon cancer cells were infected with recombinant retroviral particles, selected in G418, and sorted for high expression of DNS or phOx scFv receptors to obtain stable CT-26/DNS and CT-26/phOx cell lines. The surface expression and antigen-binding activity of the receptors were examined by immunofluorescence staining using DNS−FITC or phOx−FITC probes. These probes contain a single hapten moiety (DNS or phOx) linked to a fluorescein residue. DNS−FITC bound to CT-26/DNS cells but not to CT-26/phOx cells whereas phOx−FITC displayed the opposite cellular specificity (Figure 1b). These results demonstrate that functional scFv receptors were expressed on the surface of CT-26 cells with retention of hapten-binding specificity.

The expression of DNS and phOx scFv receptors in vivo was examined by recovering single cells from established CT-26/DNS and CT-26/phOx tumors and then measuring the expression of the receptors on the recovered cells by staining with DNS−FITC or phOx−FITC. Similar levels of DNS and phOx receptors were detected on the cells as compared with cells maintained in culture, demonstrating that functional receptors were stably expressed in vivo (Figure 1c).

Characterization of DNS and PEG Modified Proteins. DNS moieties were covalently attached to βG and IL-2 via a flexible poly(ethylene glycol) linker to minimize steric barriers between DNS and the DNS scFv receptors on cells. Addition of PEG to proteins can also prolong their circulation half-life and improve in vivo stability. An average of 3.5 and 2.5 molecules of DNS−PEG_{3400} were attached to each molecule of βG or IL-2 to form DNS−PEG−βG and DNS−PEG−IL-2, respectively. The electrophoretic mobilities of DNS−PEG−βG and DNS−PEG−IL-2 were slower than those of unmodified βG and IL-2 as determined by SDS−PAGE, demonstrating successful conjugation of DNS−PEG_{3400} to βG and IL-2 (Figure 2a). The bioactivity of the conjugates was assayed by measuring the hydrolysis of *p*-nitrophenol-β-D-glucuronide by DNS−PEG−βG or the stimulation of splenocyte proliferation by DNS−PEG−IL-2. Both conjugates displayed activities similar to those of the unmodified proteins (Figure 2b,c). The ability of DNS−PEG−βG and DNS−PEG−IL-2 to bind to DNS scFv receptors was examined by incubating the conjugates with CT-26/DNS and CT-26/phOx cells and then staining the cells with rabbit anti-βG or anti-IL-2 antibodies followed with FITC-conjugated second antibodies. Both DNS−PEG−βG and DNS−PEG−IL-2 bound to CT-26/DNS cells (Figure 3, upper panel) but not to control CT-26/phOx cells (Figure 3, lower panel), demonstrating that DNS−PEG-modified proteins could specifically bind DNS scFv receptors.

Specific Bioactivity of DNS−PEG−βG and DNS−PEG−IL-2. To examine whether targeting DNS−PEG−βG to DNS scFv receptors could allow selective activation of the glucuronide prodrug BHAMG to pHAM at cancer cells, CT-26/DNS and CT-26/phOx cells were incubated with DNS−PEG−βG, washed, and then exposed to BHAMG or pHAM. The rate of cellular ATP synthesis after drug treatment was measured as an index of cell viability. The IC_{50} value of BHAMG to both CT-26/DNS and CT-26/phOx cells was >2000 μM, demonstrating that prodrug displayed low toxicity to these cells (Figure 4a). CT-26/DNS cells that were preincubated with DNS−PEG−βG were sensitive to BHAMG with an IC_{50} value of 6.25 μM, similar to the IC_{50} value observed when the cells were treated with pHAM (IC_{50} = 5.72 μM), showing that DNS−PEG−βG efficiently converted BHAMG to pHAM at CT-26/DNS cells (Figure 4a, upper panel). By contrast, incubation of CT-26/phOx cells with DNS−PEG−βG before addition of BHAMG did not result in additional cell killing as compared to cells treated with BHAMG alone (Figure 4a, lower panel), demonstrating that prodrug activation required specific capture of DNS−PEG−βG by DNS scFv receptor-positive cells.

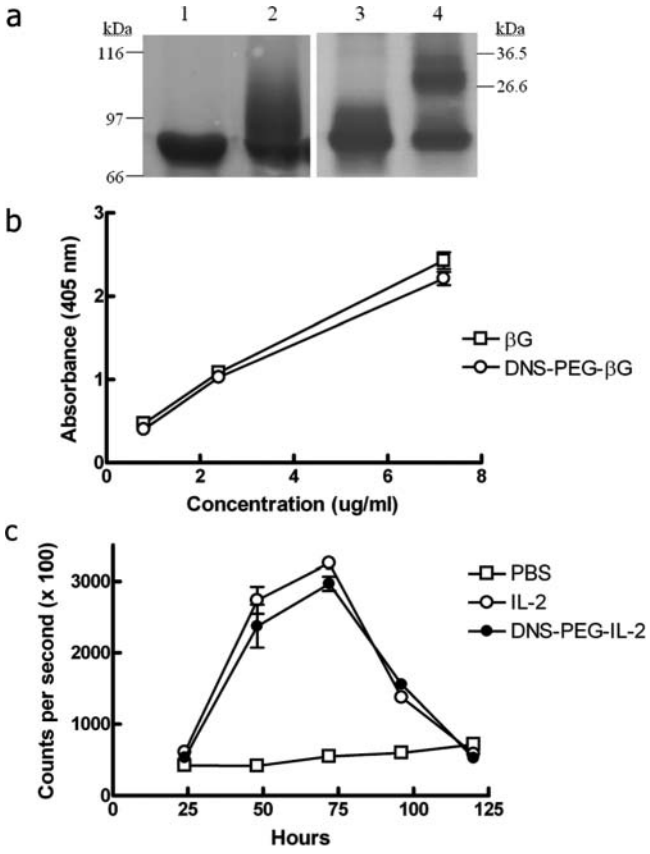

Figure 2. Biological activity of DNS−PEG-modified βG and IL-2. (a) Proteins were electrophoresed on a reducing 10% SDS polyacrylamide gel and stained with Coomassive Blue R-250. Lane 1: βG. Lane 2: DNS−PEG−βG. Lane 3: IL-2. Lane 4: DNS−PEG−IL-2. (b) The catalytic activities of unmodified βG (□) and DNS−PEG−βG (○) were measured by monitoring the release of *p*-nitrophenol from *p*-nitrophenol-β-D-glucuronide at 405 nm (n = 3; bars SE). (c) Splenocytes were incubated with 1 μg/mL DNS−PEG−IL-2 (●), IL-2 (○), or medium (□) before cellular proliferation was assayed by the luminescence ATP detection assay system (n = 3; bars, SE).

We also examined whether DNS−PEG−IL-2 that was captured on cells by DNS scFv receptors could stimulate splenocyte proliferation. CT-26/DNS and CT-26/phOx cells were incubated with DNS−PEG−IL-2, washed twice with PBS, and then incubated with murine splenocytes. Figure 4b shows that incubation of DNS−PEG−IL-2 with CT-26/DNS cells, but not CT-26/phOx cells, induced splenocyte proliferation, demonstrating that DNS−PEG−IL-2 targeted to DNS scFv receptors retained T cell stimulatory activity.

In Vivo DNS−PEG−βG Clearances and Localization. We previously showed that the PEG modification of βG prolonged serum half-life, reduced spleen uptake, and enhanced tumor localization of antibody−βG conjugates (*15*). The long serum half-life of PEG-modified βG, however, prevents administration of prodrug when maximal tumor accumulation of the immunoconjugate is achieved. Intravenous anti-PEG antibodies can accelerate the clearance of PEG-modified proteins from the circulation and allow earlier administration of prodrug (*15*). DNS−PEG−βG displayed an initial serum half-life of 4.4 ± 0.2 h as compared to 0.84 ± 0.03 h for unmodified βG. Intravenous administration of the anti-PEG mAb E11 rapidly reduced the concentration of DNS−PEG−βG in blood by 37-fold (2.6 to 0.07 μg/mL) within 3.5 h after administration (Figure

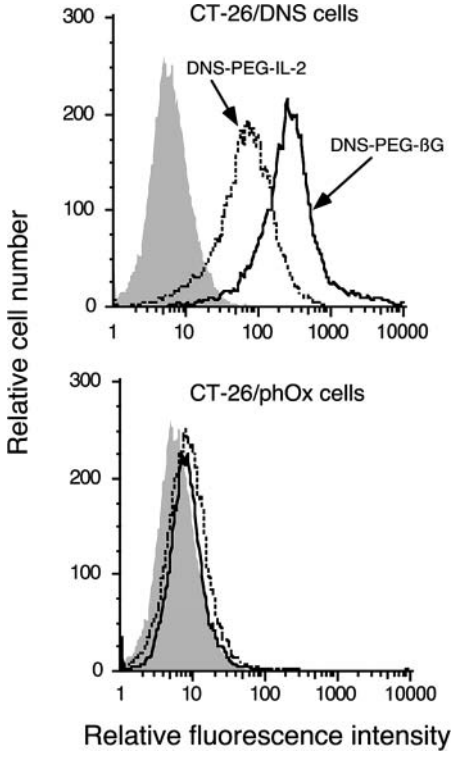

Figure 3. Specificity of DNS−PEG−βG and DNS−PEG−IL-2. CT-26/DNS (upper panel) or CT-26/phOx (lower panel) cells were incubated with DNS−PEG−βG (open curve), DNS−PEG−IL-2 (dashed line), or PBS (solid line). Cells were washed and stained with rabbit anti-βG, anti-IL-2 antibody, or PBS followed by FITC-conjugated second antibody. The surface immunofluorescence of viable cells was measured on a flow cytometer.

5a). The localization of DNS−PEG−βG in CT-26/DNS and CT-26/phOx tumors after E11-accelerated clearance was examined by staining tissue sections for βG activity. CT-26/DNS tumor sections clearly displayed βG activity (Figure 5b, right panel) whereas only background activity was observed in CT-26/phOx tumors (Figure 5b, left panel), demonstrating that βG was selectively retained in CT-26/DNS tumors after E11-mediated clearance of DNS−PEG−βG.

In Vivo Antitumor Activity. The antitumor activity of prodrug treatment in combination with DNS−PEG−IL-2 was examined in BALB/c mice bearing 50−100 mm^3 CT-26/DNS or CT-26/phOx tumors. Prodrug therapy consisted of an intravenous bolus of DNS−PEG−βG, clearance with mAb E11, and fractionated intravenous administration of BHAMG on days 8 and 9. Starting on day 10, some mice received 20 000 units of DNS−PEG−IL-2 every 2 days over 10 days. Groups of tumor-bearing mice were also treated with DNS−PEG−IL-2 alone, BHAMG, or PBS. Figure 6 shows that targeted prodrug therapy ($p \leq 0.005$) or DNS−PEG−IL-2 therapy ($p \leq 0.005$) significantly delayed the growth of CT-26/DNS tumors but not control CT-26/phOx tumors as compared to therapy with BHAMG or PBS. Combined treatment with prodrug and DNS−PEG−IL-2 further significantly ($p < 0.001$) delayed CT-26/DNS tumor growth as compared to each individual treatment and cured one of 5 mice. No significant weight loss was observed in any of the treatment groups (data not shown).

DISCUSSION

This report evaluated simultaneous targeting of hapten-derivatized therapeutic molecules to anti-hapten scFv receptor-positive cells for combination cancer therapy. Our results demonstrate that functionally active DNS−PEG-derivatized βG and IL-2 could specifically bind to DNS scFv receptors on

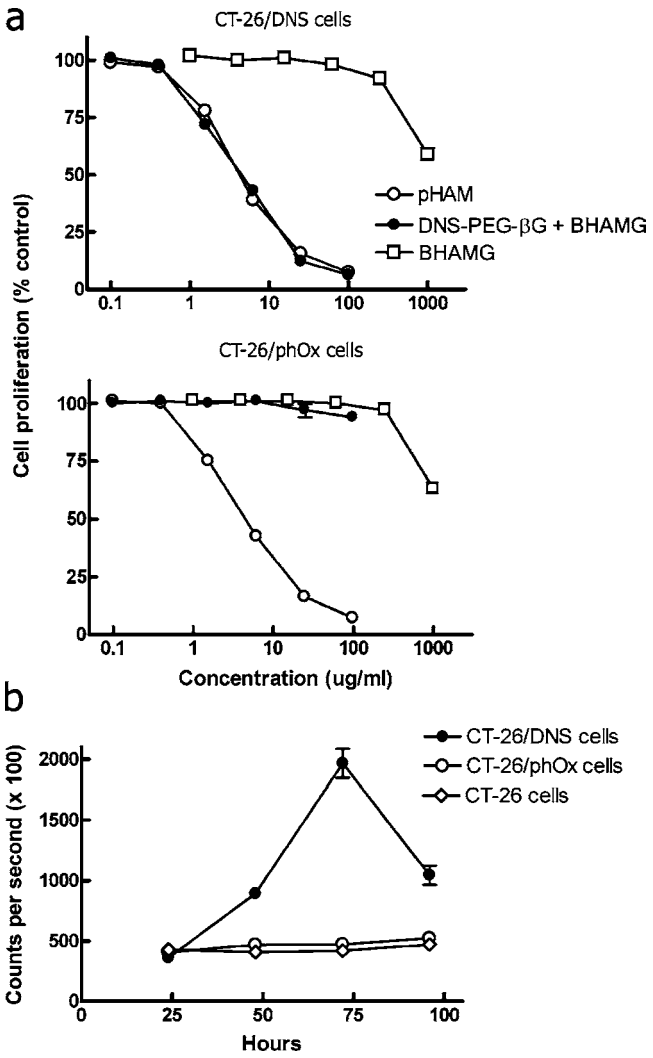

Figure 4. Specific bioactivity of DNS−PEG−βG and DNS−PEG−IL-2. (a) Specific activation of BHAMG at DNS positive cells. CT-26/DNS (upper panel) and CT-26/phOx (lower panel) cells were treated with graded concentrations of pHAM (○), BHAMG (□), or DNS−PEG−βG followed by BHAMG (●). Results show the cell viability of treated cells as compared to untreated cells ($n = 3$; bars, SE). (b) Specific stimulation of splenocytes by DNS−PEG−IL-2. CT-26/DNS (●), CT-26/phOx (○), and CT-26 (◇) cells were incubated with DNS−PEG−IL-2 and then treated with pHAM to inhibit cellular proliferation, washed, and then coincubated with murine splenocytes. The rate of cellular ATP synthesis was measured as an index of splenocyte proliferation. Bars, SE of triplicate determinations.

cancer cells to selectively convert the glucuronide prodrug BHAMG to pHAM and stimulate the proliferation of splenocytes, respectively. Combination treatment of established CT-26/DNS scFv receptor-positive tumors by prodrug therapy and DNS−PEG−IL-2 significantly suppressed tumor growth as compared to treatment with prodrug therapy or DNS−PEG−IL-2 alone. Our results therefore show that two therapeutic molecules can be targeted to tumor cells to increase therapeutic efficacy.

Successful targeting of hapten-derivatized molecules requires efficient expression of functional DNS scFv receptors on cells as well as prolonged retention of the hapten-derivatized molecules at the cells. The B7-1 TM and cytosolic tail employed to anchor the DNS scFv receptors on cells allow enhanced surface expression and reduced shedding of chimeric scFv receptors in vitro and in vivo (*19*, *20*). The anti-DNS scFv possesses high affinity ($K_D = 1.4 \times 10^{-8}$ M^{-1}) for DNS (*21*), allowing prolonged retention of DNS-modified molecules on

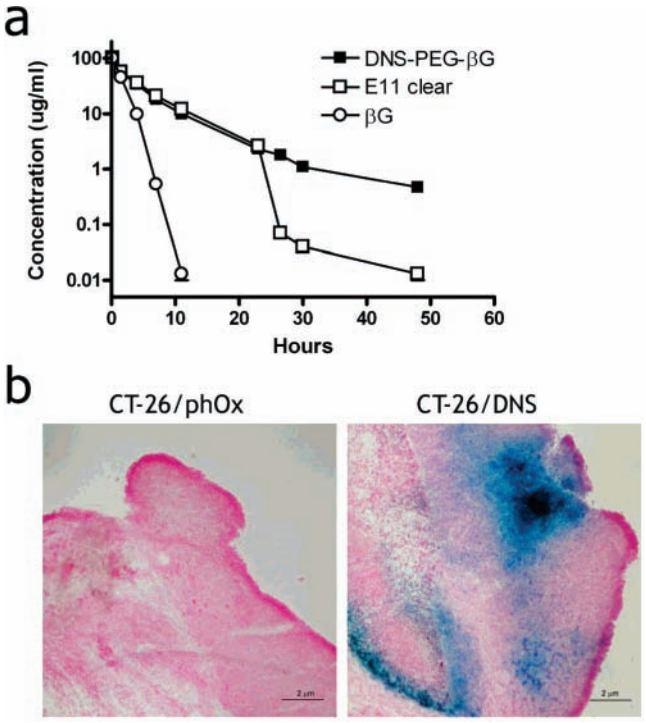

Figure 5. In vivo clearance and localization of DNS−PEG−βG. (a) Groups of 3 BALB/c mice bearing 100−200 mm^3 CT-26/DNS or CT-26/phOx tumors were iv injected with 150 μg of βG (○) or DNS−PEG−βG (□, ■) at time zero. PBS (■) or 150 μg of mAb E11 (□) was administered at 24 h, and the serum concentration of DNS−PEG−βG was measured. (b) Specific localization of DNS−PEG−βG. Twenty-four hours after injection of DNS−PEG−βG, mice were iv injected with E11 mAb to clear DNS−PEG−βG; 3.5 h later, CT-26/phOx (left) and CT-26/DNS (right) tumors were excised and sections were stained with X-GlcA for βG activity and counterstained with nuclear fast red. Magnification: ×40.

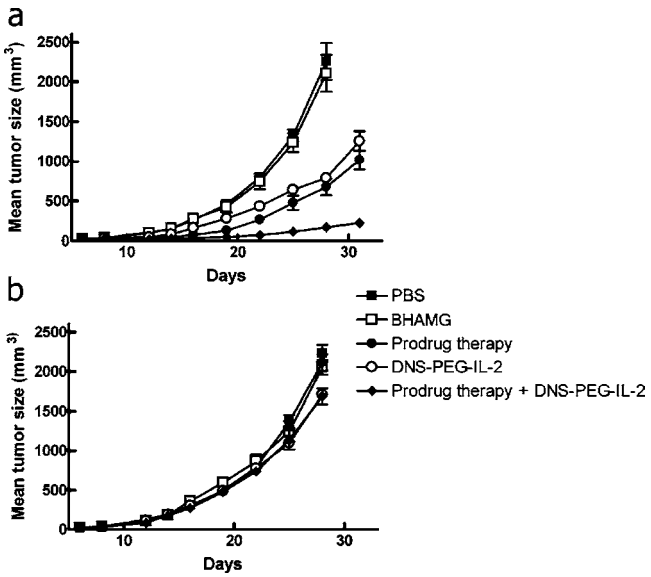

Figure 6. Cocktail therapy of CT-26/DNS tumors. Groups of 5 BALB/c mice bearing CT-26/DNS (a) or CT-26/phOx (b) tumors were iv injected with PBS (■), BHAMG (□), DNS−PEG−IL-2 (○), DNS−PEG−βG and BHAMG (●), or DNS−PEG−βG, BHAMG, and then DNS−PEG−IL-2 (◆) as described in Experimental Procedures. Bars, SE.

the cell surface. Surface localization of DNS−PEG−βG is important for efficient activation of hydrophilic glucuronide prodrugs (*22*) and bystander killing (*4*). IL-2 also requires surface localization for efficient stimulation of immune cells (*23*).

The specificity and stability of the hapten is also critical for the successful localization of hapten-modified molecules to anti-hapten scFv receptors on cells. We previously employed phOx for hapten-directed enzyme−prodrug therapy (HDEPT) but found that phOx is susceptible to hydrolysis in serum, resulting in the progressive loss of phOx antigenicity (*12*). DNS is a small molecule which has been extensively employed to derivatize proteins. $(DNS)_2$−DTPA−^{111}In was stable in serum at 37 °C for 24 h and specifically bound to B16-F1 cells that expressed DNS scFv receptors in vitro and in vivo (*13*), indicating DNS-derivatized molecules possess sufficient stability and specificity to allow effective targeting to DNS receptors in vivo. The results of the current study support the notion that DNS is suited for in vitro and in vivo targeting applications.

Effective localization of hapten-modified ligands requires ensuring adequate half-lives of the therapeutic agents in vivo. PEG modification of βG can extend its serum half-life, decrease normal tissue uptake, and increase tumor uptake of antibody−βG−PEG conjugates for targeted activation of glucuronide prodrugs (*24*). Our present results showed that DNS−PEG-modified βG exhibited more than 5-fold increase in serum half-life as compared with unmodified βG. PEG modification was also critical for retention of enzymatic activity and for attachment of multiple DNS moieties on the proteins. Direct linkage of 3.7 DNS molecules to βG resulted in the loss of 80% of enzyme activity (unpublished results) whereas attachment of 3.5 DNS−PEG molecules to βG allowed retention of over 90% of enzyme activity. The large size of the hydrophilic DNS−PEG_{3400} molecules may retard interactions with lysines in the active site of βG, resulting in less damage to enzyme activity. Attachment of DNS through a PEG spacer may also allow more conformational flexibility in binding of DNS to the anti-DNS scFv receptors on cells, thereby promoting multivalent interactions between the DNS-modified proteins and the scFv receptors. Multivalent binding is highly desirable. For example, Cortens and colleagues reported that in a two-step approach for radioimmunotargeting of cancers, the tumor uptake of bivalent DTPA−^{111}In was better than that of monovalent DTPA−^{111}In due to increased avidity (*25*). Similarly, we found increased uptake of a divalent $(DNS)_2$−DTPA−^{111}In probe by anti-DNS scFv receptors on B16/DNS tumors (*13*). The ability to attach multiple DNS groups on βG and IL-2 with retention of nearly full biological activity is therefore an important advantage of using PEG as a spacer.

The slow clearance of PEG-modified conjugate from the circulation can cause low tumor-to-blood ratios that delay prodrug injection. Antibody−βG−PEG conjugates can be rapidly cleared from the circulation and uptake of conjugate in the liver can be induced by systemic administration of an IgM anti-PEG antibody without affecting the accumulation of the conjugate in tumors (*24*). In the present study, we found that the clearance of DNS−PEG−βG from the blood could be accelerated by systemic administration of an IgG anti-PEG antibody. High concentrations of DNS−PEG−βG can therefore be maintained in the blood to maximize tumor accumulation until anti-PEG antibody is given shortly before prodrug administration.

PEG-modified IL-2 has been demonstrated to possess a markedly prolonged circulating half-life and increased antitumor potency as compared to unmodified IL-2 (*26*, *27*). For example, Morrison et al. showed that specifically targeting antibody−IL-2 to cancer cells can provide a specific and effective T cell response capable of eliminating tumors (*28*), and Zimmerman et al. showed that a lower dose and less frequent administration of PEG−IL-2 could provide the same tumor-growth-inhibiting effect compared with IL-2 (*29*). In our study, DNS−PEG−IL-2 required tumor-targeting to exhibit antitumor activity since CT-

26/phOx tumors were completely refractory to DNS−PEG−IL-2 (Figure 6b).

Combination cancer treatment by chemotherapy and immunotherapy is attractive because the treatments have different mechanisms of action and toxicities, possess potential therapeutic synergies, and have general applicability to many cancer types (*30*). It was not evident a priori, however, that combination therapy with IL-2 and BHAMG would produce additional therapeutic benefits over each individual agent since alkylating agents such as pHAM, the hydrolysis product of BHAMG, can induce dose-limiting leukopenia (*31*), which could in turn antagonize the effects of IL-2 therapy. We previously showed that treatment of rats bearing established malignant hepatocellular carcinoma ascites by ADEPT with BHAMG produced only a limited reduction in white blood cell numbers as compared to treatment with pHAM (*6*), suggesting that local generation of alkylating agents at the tumor site may spare bone-marrow progenitors and allow initiation of an antitumor immune response against antigens released from dying tumor cells. An important finding of this study was that ADEPT did not cure tumor-bearing rats depleted of $CD4^+$ and $CD8^+$ T cells, demonstrating that T cells provide substantial antitumor activity in ADEPT with BHAMG therapy (*7*). In addition, Lode, H.N et al. also showed that tumor-targeted IL-2 amplifies T cell mediated immune responses (*10*). Based on these results, T cells likely play an important role in the combination treatment with DNS−PEG−βG and BHAMG followed by DNS−PEG−IL-2 therapy.

In summary, our results demonstrate that selectively targeted DNS−PEG−βG/BHAMG to reduce the bulk of tumors and subsequent DNS−PEG−IL-2 therapy to potentiate the immune response resulted in improved therapeutic efficacy. A major strength of hapten-directed targeting is the ability to employ multiple agents that possess different mechanisms of actions. Importantly, a single small anti-DNS scFv receptor gene can be employed for gene-expression imaging (*13*) as well as for delivering multiple therapeutic agents for the combination therapy of tumors.

Efficient DNA Alkylation by a Pyrrole-Imidazole CBI Conjugate with an Indole Linker: Sequence-Specific Alkylation with Nine-Base-Pair Recognition

Toshikazu Bando, Shunta Sasaki, Masafumi Minoshima, Chikara Dohno, Ken-ichi Shinohara, Akihiko Narita, and Hiroshi Sugiyama*

Department of Chemistry, Graduate School of Science, Kyoto University, Sakyo, Kyoto 606-8501, Japan. Received January 30, 2006; Revised Manuscript Received April 6, 2006

Conjugates **7**, **8**, and **10** of *N*-methylpyrrole (Py)-*N*-methylimidazole (Im) polyamides and 1,2,9,9a-tetrahydrocyclopropa[1,2-*c*]benz[1,2-*e*]indol-4-one (CBI) with a 5-amino-1*H*-indole-2-carbonyl linker were synthesized by Fmoc solid-phase synthesis and a subsequent liquid-phase coupling procedure. The DNA alkylating abilities of conjugates **7**, **8**, **6b**, and **10** were examined using Texas Red-labeled PCR fragments and high-resolution denaturing gel electrophoresis. CBI conjugates **7** and **8** exhibited highly efficient sequence-specific DNA alkylation comparable with previous CBI conjugates with a vinyl linker. In particular, conjugate **10**, with a 10-ringed hairpin Py-Im polyamide, alkylated at the adenine of 5′-ACAAATCC**A**-3′. Introduction of an indole linker greatly facilitated the synthesis of sequence-specific alkylating Py-Im polyamides.

INTRODUCTION

DNA is often the target of anticancer agents, which covalently bond to or oxidatively damage bases and deoxyriboses. DNA alkylating agents, which include well-known anticancer drugs such as cyclophosphamide and mitomycin C, are used routinely in cancer treatment. However, these drugs are extremely toxic because they attack normal cells and cause severe adverse effects. One intriguing question to consider is whether the introduction of sequence selectivity to an alkylating agent can improve its efficacy as an anticancer agent (*1*−*3*). To address this question, we have developed various types of sequence-specific alkylating agents by conjugating alkylating agents and *N*-methylpyrrole (Py)-*N*-methylimidazole (Im) polyamides and have investigated their DNA alkylating activity and biological functions (*4*, *5*). Importantly, the insertion of a vinyl linker between Segment A of DU-86 (*6*) and the Py-Im polyamides dramatically enhances DNA alkylating reactivity (*7*−*10*) and cytotoxicity against human cancer cell lines by more than 100-fold compared with compounds with no vinyl linker (*11*, *12*). Alkylation of the coding region of the template strand by Py-Im polyamides with vinyl linkers effectively terminates transcription, producing truncated mRNA (*13*). We have also demonstrated that alkylating Py-Im polyamides, such as **1a**, causes gene silencing of GFP in mammalian cells (*14*). These results encouraged us to test alkylating Py-Im polyamides in animal studies, such as in xenografts of human cancers. For this purpose, we changed the alkylating moiety to 1,2,9,9a-tetrahydrocyclopropa[1,2-*c*]benz[1,2-*e*]indol-4-one (CBI), which can be synthesized from commercially available naphthalene-1,3-diol or 4-amino-1-naphthol (*15*−*18*). We demonstrated that CBI conjugate **1b** tethered to Py-Im hairpin polyamides with a vinyl linker have higher sequence-specific DNA alkylating activity and cell toxicity than does CPI conjugate **1a** (Figure 1**)** (*19*). More recently, we found that CBI conjugate **1b** specifically alkylates at adenines, despite having a binding orientation similar to the corresponding CPI conjugate **1a** (*20*). Additional sequence specificity relative to CPI conjugates will be useful for biological applications.

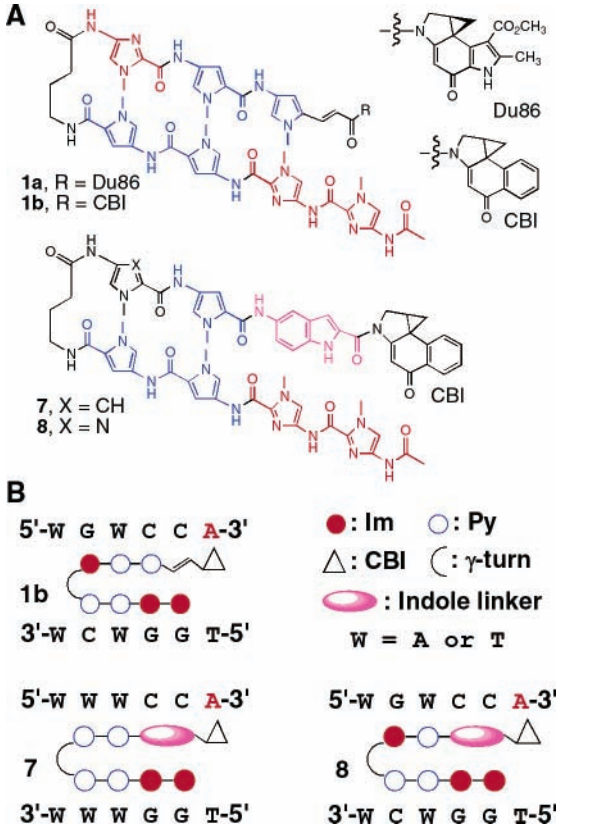

Figure 1. (A) Structures of compounds **1a**,**b**, **7**, and **8**. (B) Schematic representations of the DNA alkylation of the specific sequence by compounds **1b**, **7**, and **8**.

Here we report the synthesis and evaluation of hairpin Py-Im polyamide−CBI conjugates **7**, and **8** and seco-CBI conjugates **6b** and **10**, which specifically alkylate DNA. In particular, compound **10**, with a 10-ringed hairpin Py-Im polyamide specifically alkylated at adenine of the targeted nine-base-pair matching sequence, 5′-ACAAATCC**A**-3′ at nanomolar concentrations.

[a] Reaction conditions: (i) Fmoc solid-phase synthesis then 1 N NaOH, DMF; (ii) HATU, $^{i}Pr_2NEt$, DMF then **3**, $^{i}Pr_2NEt$, DMF; (iii) **5**, EDCI, $NaHCO_3$, DMF; (iv) 5% aq. $NaHCO_3$: DMF = 1:1.

EXPERIMENTAL PROCEDURES

Materials. Reagents and solvents were purchased from standard suppliers and used without further purification. Abbreviations of some reagents: $^{i}Pr_2NEt$, *N*,*N*-diisopropylethylamine; DMF, *N*,*N*-dimethylformamide; HATU, *O*-(7-azabenzotriazole-1-yl)-1,1,3,3-tetramethyluronium; EDCI, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloric salt. NMR spectra were recorded with a JEOL JNM-A 500 nuclear magnetic resonance spectrometer, and tetramethylsilane was used as the internal standard. Proton NMR spectra were recorded in parts per million (ppm) downfield relative to tetramethylsilane. Electrospray ionization mass spectrometry (ESI-MS) and electrospray ionization time-of-flight mass spectrometry (ESI-TOFMS) were produced on a API 150 (PE SCIEX) and BioTOF II (Bruker Daltonics) mass spectrometer. Polyacrylamide gel electrophoresis was performed on a HITACHI 5500-S DNA sequencer. Ex Taq DNA polymerase and Suprec-02 purification cartridges were purchased from Takara Co.; the Thermo Sequenase core sequencing kit and loading dye (dimethylformamide with fuschin red) from Amersham Co. Ltd; 5′-Texas Red-modified DNA oligomer from Proligo Co. Ltd; and 50% Long Ranger gel solution from FMC Bioproducts.

AcImImPyPy-γ-ImPy-CO_2H (2b). AcImImPyPy-γ-ImPy-CO_2-oxime resin was synthesized in a stepwise reaction by Fmoc solid-phase protocol (Fmoc$PyCO_2H$, Fmoc$ImCO_2H$, FmocγCO_2H, HATU, DIEA, DMF). A sample of resin was cleaved with alkali conditions (1 N NaOH in DMF, 1 h, 55 °C) and purified by HPLC using a Chemcobond 5-ODS-H column (0.1% AcOH/CH_3CN 0−100% linear gradient, 0−30 min, 254 nm), to produce **2b** (20 mg, 23%) as a yellow powder. ^{1}H NMR (500 MHz, DMSO-d_6) δ 10.32 (s, 1H; NH), 10.29 (s, 1H; NH), 10.23 (s, 1H; NH), 10.00 (s, 1H; NH), 9.91 (s, 1H; NH), 9.32 (s, 1H; NH), 8.02 (s, 1H; NH), 7.56 (s, 1H; Im-H), 7.50 (s, 1H; Im-H), 7.45 (s, 1H; Py-H), 7.44 (s, 1H; Im-H), 7.27 (s, 1H; Py-H), 7.16 (s, 1H; Py-H), 7.14 (s, 1H; Py-H), 6.92 (s, 1H; Py-H), 6.89 (s, 1H; Py-H), 4.00 (s, 3H; NCH_3), 3.97 (s, 3H; NCH_3), 3.93 (s, 3H; NCH_3), 3.84 (s, 3H; NCH_3), 3.81 (s, 3H; NCH_3), 3.79 (s, 3H; NCH_3), 3.19 (m, 2H; CH_2), 2.34 (m, 2H; CH_2), 2.03 (s, 3H; $COCH_3$), 1.78 (m, 2H; CH_2); ESI-TOFMS *m*/*e* calcd for $C_{39}H_{45}N_{16}O_9$ [M^+ + H] 881.35, found 881.36. A synthetic protocol similar to that used for the preparation of compound **2b** was followed to prepare compound **2a** using Fmoc solid-phase protocol.

H_2N-Indole-CO_2H (3). Compound **3** was synthesized by two stepwise reactions from commercially available ethyl 5-nitroindole-2-carboxylate (hydrolysis by 1 N aq. NaOH, then hydrogenation by hydrogen gas catalyzed by palladium−carbon), which was used in the next coupling step without further purification. ^{1}H NMR (500 MHz, DMSO-d_6) δ 11.22 (s, 1H; NH), 7.11 (d, 1H, *J* = 8.5 Hz; CH), 6.75 (d, 1H, *J* = 2.0 Hz; CH), 6.67 (s, 1H; CH), 6.65 (dd, 1H, *J* = 2.0, 8.5 Hz; CH), 3.31 (brs, 2H; NH_2 and H_2O); ESI-TOFMS *m*/*e* calcd for $C_9H_9N_2O_2$ [M^+ + H] 177.06, found 177.02.

AcImImPyPy-γ-ImPy-Indole-CO_2H (4b). To a solution of compound **2b** (3.5 mg, 4.0 μmol) in DMF (0.1 mL) was added $^{i}Pr_2NEt$ (1.4 μL, 8.0 μmol) and HATU (1.4 mg, 3.7 μmol), The reaction mixture was stirred for 4 h at room temperature. After the conversion from **2b** to activated ester was confirmed by HPLC and ESI-MS analysis, **3** (1.3 mg, 7.4 μmol) and $^{i}Pr_2NEt$ (1.3 μL, 7.5 μmol) were added to the reaction vessel. The reaction mixture was stirred for overnight at room temperature under N_2 atmosphere. Evaporation of the solvent gave a yellow residue by filtration, which was washed with chloroform (2 mL × 2) and water (2 mL × 2) to produce **4b** (3.0 mg, 73%) as a yellow powder. **4b** was used in the next step without further purification. ^{1}H NMR (500 MHz, DMSO-d_6) δ 11.33 (brs, 1H; NH), 10.34 (s, 1H; NH), 10.33 (s, 1H; NH), 10.27 (s, 1H; NH), 9.92 (s, 2H; NH), 9.73 (s, 1H; NH), 9.32 (brs, 1H; NH), 8.01 (brt, 1H; NH), 7.94 (s, 1H; CH), 7.56 (s, 1H; Im-H), 7.50 (s, 1H; Im-H), 7.46 (s, 1H; Im-H), 7.40 (brd, 1H, *J* = 8.5 Hz; CH), 7.31 (brd, 1H, *J* = 8.5 Hz; CH), 7.30 (d, 1H, *J* = 1.5 Hz; Py-H), 7.26 (d, 1H, *J* = 1.5 Hz; Py-H), 7.17 (d, 1H, *J* = 1.5 Hz; Py-H), 7.16 (s, 2H; Py-Hx2), 6.90 (d, 1H, *J* = 1.5 Hz; Py-H), 6.85 (brs, 1H; CH), 4.00 (s, 3H; NCH_3), 3.97 (s, 3H; NCH_3), 3.95 (s, 3H; NCH_3), 3.85 (s, 3H; NCH_3), 3.84 (s, 3H; NCH_3), 3.80 (s, 3H; NCH_3), 3.20 (dt, 2H, *J* = 6.0, 7.5 Hz; CH_2), 2.36 (t, 2H, *J* = 7.5 Hz; CH_2), 2.04 (s, 3H; $COCH_3$), 1.79 (qu, 2H, *J* = 7.5 Hz; CH_2); ESI-TOFMS *m*/*e* calcd for $C_{48}H_{51}N_{18}O_{10}$ [M^+ + H] 1039.40, found 1039.39.

AcImImPyPy-γ-ImPy-Indole-seco-CBI (6b). To a solution of compound **4b** (9.5 mg, 9.2 μmol) in DMF (0.4 mL) was added seco-CBI **5** (2.1 mg, 9.2 μmol), EDCI (3.5 mg, 18.3 μmol) and $NaHCO_3$ (1.5 mg, 18.3 μmol). The reaction mixture was stirred for 3 h at room temperature. Evaporation of the solvent gave a yellow residue, which was subjected to column chromatography (silica gel, 5−10% MeOH in CH_2Cl_2, gradient elution) to produce compound **6b** (4.4 mg, 3.5 μmol: 38% yield) as a yellow powder. ESI-TOFMS *m*/*e* calcd for $C_{61}H_{61}ClN_{19}O_{10}$ [M^+ + H] 1254.51; found 1254.45.

AcImImPyPy-γ-ImPy-Indole-CBI (8). To a solution of compound **6b** (1.1 mg, 0.9 μmol) in DMF (0.1 mL) was added 5% aqueous $NaHCO_3$ (0.1 mL). The reaction mixture was stirred for 1 h at room temperature. Evaporation of the solvent gave a brown residue, which was subjected to column chromatography (silica gel, 5−10% MeOH in CH_2Cl_2, gradient elution) to produce compound **8** (1.1 mg, 0.9 μmol: quantitative yield) as a brown powder. After further purification by HPLC using a Chemcobond 5-ODS-H column (0.1% AcOH/CH_3CN 0−50% linear gradient, 0−40 min, 254 nm), **8** was used in the DNA alkylation reaction.^{1}H NMR (500 MHz, DMSO-d_6) δ 11.77 (s, 1H; NH), 10.32 (s, 1H; NH), 10.29 (s, 1H; NH), 10.26 (s, 1H; NH), 9.95 (s, 1H; NH), 9.92 (s, 1H; NH), 9.82 (s, 1H; NH), 9.33 (s, 1H; NH), 8.08 (s, 1H; CH), 8.01 (brs, 1H; NH), 8.00 (d, *J* = 7.5 Hz, 1H; CH), 7.60 (t, *J* = 7.5 Hz, 1H; CH), 7.56 (s, 1H; CH), 7.53 (d, *J* = 8.5 Hz, 1H; CH), 7.50 (s, 1H; CH), 7.46 (s, 1H; CH), 7.43 (t, *J* = 7.5 Hz, 1H; CH), 7.42 (s, 1H; CH), 7.31 (s, 1H; CH), 7.27 (s, 1H; CH), 7.24 (d, *J* = 8.5 Hz, 1H; CH), 7.22 (s, 1H; CH), 7.19 (s, 1H; CH), 7.16 (d, *J* = 7.5 Hz, 1H; CH), 7.06 (s, 1H; CH), 6.95 (s, 1H; CH), 6.89 (s, 1H; CH), 4.62 (dd, *J* = 10.0, 5.0 Hz, 1H; NCH_2), 4.48 (d, *J* = 10.0 Hz, 1H; NCH_2), 4.00 (s, 3H; NCH_3), 3.97 (s, 3H; NCH_3), 3.95 (s, 3H; NCH_3), 3.86 (s, 3H; NCH_3), 3.84 (s, 3H; NCH_3), 3.80 (s, 3H; NCH_3), 3.20 (m, 2H; CH_2), 2.90 (m, 1H; CH), 2.35 (m, 2H; CH_2), 2.03 (s, 3H; $COCH_3$), 1.79 (m, 2H; CH_2), 1.76 (dd, *J* = 7.5, 5.0 Hz, 1H; CH), 1.70 (t, *J* = 5.0 Hz, 1H; CH); ESI-TOFMS *m*/*e* calcd for $C_{61}H_{60}N_{19}O_{10}$ [M^++H] 1218.48, found 1218.48.

AcImImPyPy-γ-PyPy-Indole-CBI (7). A synthetic procedure similar to that used for the preparation of compound **8** was followed to prepare compound **7**, with a yield of 6% for two steps from **2a**. After further purification by HPLC using a Chemcobond 5-ODS-H column (0.1% AcOH/CH_3CN 0−50% linear gradient, 0−40 min, 254 nm), **8** was used in the DNA alkylation reaction. ESI-MS *m*/*e* calcd for $C_{62}H_{61}N_{18}O_{10}$ [M^+ + H] 1217.5, found 1217.4.

AcImImPy-β-PyPyIm-γ-PyPyP-β-Py-CO_2H (9). AcImImPy-β-PyPyIm-γ-PyPyPy-β-$PyCO_2$-oxime resin was synthesized in a stepwise reaction by Fmoc solid-phase protocol. A sample of resin was cleaved with alkali conditions (1 N NaOH in DMF, 1 h, 55 °C) and purified by HPLC using a Chemcobond 5-ODS-H column (0.1% AcOH/CH_3CN 0−100% linear gradient, 0−30 min, 254 nm), to produce **9** (31 mg, 21%) as a yellow powder. ^{1}H NMR (400 MHz, DMSO-d_6) δ 10.29 (s, 1H), 10.26 (s, 1H), 10.24 (s, 1H), 9.90 (s, 1H), 9.89 (s, 1H), 9.87 (s, 1H),

9.86 (s, 1H), 9.85 (s, 1H), 9.81 (s, 1H), 9.34 (s, 1H), 8.07 (s, 1H), 8.03 (s, 1H), 8.01 (s, 1H), 7.55 (s, 1H), 7.49 (s, 1H), 7.48 (s, 1H), 7.31 (s, 1H), 7.28 (s, 1H), 7.23 (s, 1H), 7.23 (s, 1H), 7.22 (s, 1H), 7.18 (s, 1H), 7.15 (s, 1H), 7.06 (s, 1H), 7.02 (s, 1H), 6.96 (s, 1H), 6.88 (s, 1H), 6.86 (s, 1H), 6.82 (s, 1H), 6.65 (s, 1H), 3.99 (s, 3H), 3.97 (s, 3H), 3.93 (s, 3H), 3.84 (s, 3H), 3.83 (s, 3H), 3.82 (s, 3H), 3.81 (s, 3H), 3.80 (s, 3H), 3.79 (s, 3H), 3.78 (s, 3H), 3.43 (m, 6H), 2.50 (m, 4H), 2.27 (m, 2H), 2.03 (s, 3H), 1.81 (m, 2H); ESI-TOFMS *m*/*e* calcd for $C_{69}H_{79}N_{26}O_{15}$ [M^+ + H] 1511.61; found 1511.63.

AcImImPy-β-PyPyIm-γ-PyPyPy-β-Py-Indole-seco-CBI (10). A synthetic procedure similar to that used for the preparation of compound **6b** was followed to prepare compound **10**, with a yield of 14% for two steps from **9**. After further purification by HPLC using a Chemcobond 5-ODS-H column (0.1% AcOH/CH_3CN 0−50% linear gradient, 0−40 min, 254 nm), **10** was used in the DNA alkylation reaction. ESI-TOFMS *m*/*e* calcd for $C_{91}H_{95}ClN_{29}O_{16}$ [M^+ + H] 1884.71; found 1884.70.

Preparation of 5′-Texas Red-Modified DNA Fragments. The 5′-Texas Red-modified 537-bp DNA fragment, λ-DNA F10960*-11496, was prepared by polymerase chain reaction (PCR) with 5′-TexasRed-modified-ATCAGGGCAACTCAACCCTGTCC-3′ (λ-DNA forward, 10960−10982) and 5′-CAGGACGACCAATATCCAGC-3′ (λ-DNA reverse, 37007−37026). The 5′-Texas Red-modified 488-bp DNA fragment, λ-DNA F30990*-31477, was prepared by polymerase chain reaction (PCR) with 5′-Texas Red-modified-TGCATTCCGTGGTTGTCATACC-3′ (λ-DNA forward, 30990−31011) and 5′-GCATTATGTCGTGATTGAGC-3′ (λ-DNA reverse, 17045−17064). Fragments were purified by filtration using Suprec-02, and their concentrations were determined by UV absorption. The asterisk indicates Texas Red modification and the nucleotide numbering starts with the replication site.

High-Resolution Gel Electrophoresis. The 5′-Texas Red-labeled DNA fragments (10 nM) were alkylated by various concentration of **7**, **8**, and **6b** in 10 μL of 5 mM sodium phosphate buffer (pH 7.0) containing 10% DMF at 23 °C for 15 h. The reaction was quenched by the addition of calf thymus DNA (1 mM, 1 μL) and heating for 5 min at 90 °C. The DNA was recovered by vacuum centrifugation. The pellet was dissolved in 8 μL of loading dye (formamide with fuschin red), heated at 94 °C for 20 min, and then immediately cooled to 0 °C. A 2-μL aliquot was subjected to electrophoresis on a 6% denaturing polyacrylamide gel using a Hitachi 5500-S DNA Sequencer.

Molecular Modeling Studies. Density functional calculations were performed at the B3LYP/6-31G* level utilizing Spartan 04 (Wave function, Irvine, CA) program. Energy minimizations of d(ATACAAATCCAAT)/d(ATTGGATTTGTAT)-**11** were performed with the Discover (Accelrys, San Diego, CA) program using CFF force-field parameters. The starting structure was built on the basis of the NMR structure of the ImPyPy-γ-PyPyPy-d(CGCTAACAGGC)/d(GCCTGTTAGCG) complex (*21*) and the Duo-Dist-octamer complex (*22*). The connecting parts between them were built using standard bond lengths and angles. The CBI unit of the assembled initial structure was energy minimized using a distance-dependent dielectric constant of $\epsilon = 4r$ (r stands for the distance between atoms i and j) and with convergence criteria having an RMS gradient of less than 0.001 kcal/mol Å. Eighteen Na cations were placed at the bifurcating position of the O−P−O angle at a distance of 2.51 Å from the phosphorus atom. The resulting complex was soaked in a 10-Å layer of water. The whole system was minimized without any constraint, to the stage where the RMS was less than 0.001 kcal/mol Å.

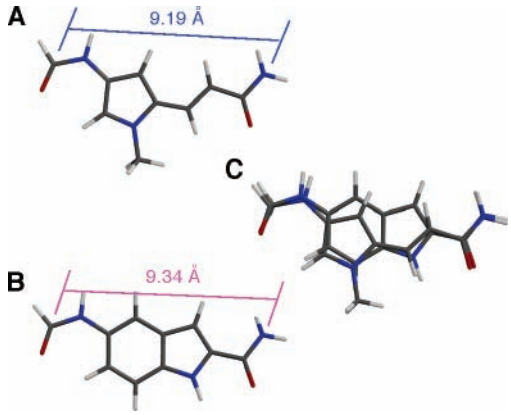

Figure 2. Geometry optimized structures of (*E*)-3-(4-formamido-1-methyl-1*H*-pyrrol-2-yl)acrylamide (A) and 5-formamido-1*H*-indole-2-carboxamide (B) and their superimposition (C) obtained by density functional calculation at the B3LYP/6-31G* level.

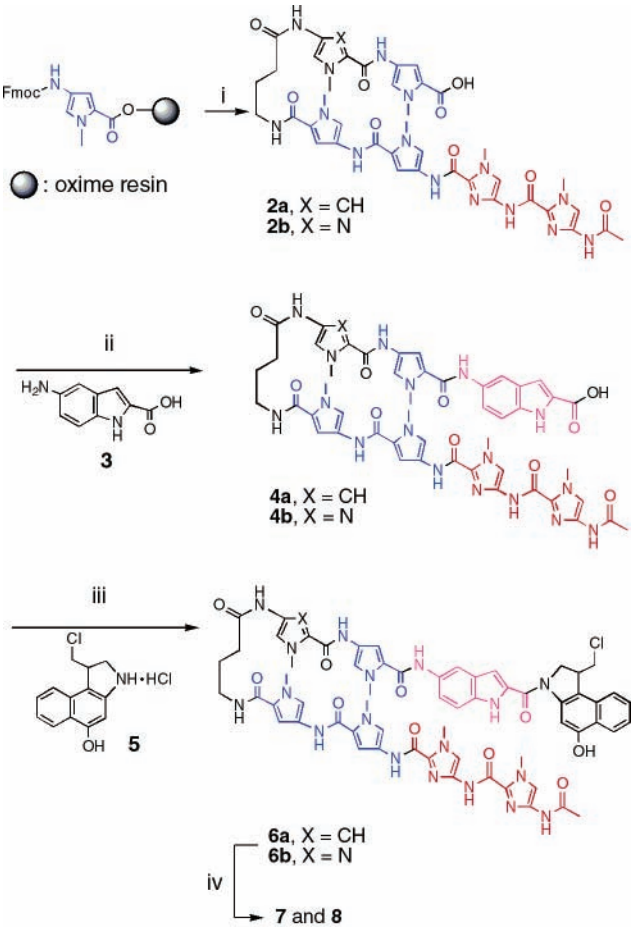
RESULTS AND DISCUSSION

Molecular Design of Linker Unit. A vinyl linker between the Py-Im polyamides and CBI moiety is highly advantageous for DNA alkylation, as it facilitates highly specific DNA alkylation by adjusting the position of the CBI moiety in the minor groove. However, the vinyl linker moiety has certain disadvantages in the molecular design of alkylating Py-Im polyamides, as it is relatively unstable under acidic and basic conditions, and it suffers from low chemical yields. Because ethyl 3-(4-amino-*N*-methyl-pyrrol-2-yl)acrylate is extremely unstable, Py-Im polyamides prepared by a solid phase method cannot easily be employed in the synthesis of alkylating agents which possess vinyl linkers. Therefore, we synthesized various alkylating Py-Im polyamides by a combination of time-consuming liquid-phase coupling reactions.[4] To overcome these problems, we searched for a new linker that could provide almost the same geometry as Py with a vinyl linker and is stable.

We chose a 5-amino-1*H*-indole-2-carbonyl linker (indole linker) as the new linker, because amide linkages of this unit are approximately superimposable with Py with a vinyl linker. Similarity of structures between 5-formamido-1*H*-indole-2-carboxamide and (*E*)-3-(4-formamido-1-methyl-1*H*-pyrrol-2-yl)-acrylamide was estimated by density functional calculation at the B3LYP/6-31G* level (Figure 2). We expected that Py-Im polyamide-indole−CBI conjugates **7** and **8** would alkylate DNA in a sequence-specific fashion (Figure 1b). Indole linker unit has already been used in the synthesis of derivatives of CC-1065 (*23*).

Synthesis of Hairpin Py-Im Polyamide−CBI Conjugates with Indole Linker, 7 and 8. Conjugates **7** and **8** were synthesized as shown in Scheme 1. The six-ring Py-Im polyamides **2a** and **2b**, both of which have terminal carboxylic acid groups, were prepared by Fmoc solid-phase synthesis using an oxime resin (*24*−*26*), and purified by reversed-phase HPLC. Indole linker unit **3** was synthesized by hydrolysis of commercially available ethyl 5-nitro-1*H*-indole-2-carboxylate, followed by reduction using palladium−carbon and H_2 gas. The carboxylic acids **2a** and **2b** were converted to activating esters with HATU and $^iPr_2NEt$, followed by coupling with **3** to give **4a** and **4b**. The DNA alkylating moiety, seco-CBI **5**, was prepared according to procedures from the literature (*16*). Conjugates **6a** and **6b** were synthesized by the coupling of **4a** and **4b** with seco-CBI **5** using EDCI and $NaHCO_3$. Treatment of **6a** and **6b** with aqueous 5% $NaHCO_3$ provided **7** and **8**, respectively. Use of Fmoc solid phase synthesis greatly facilitates the synthesis of alkylating Py-Im polyamides. For example, conjugate **8** was synthesized with an overall yield of 6.4%. In contrast, conjugate **1b** with a vinyl linker, prepared by the 22

Scheme 1 [a]



steps of a convergent liquid-phase synthesis, gave an overall yield of 0.1% (*19*). The purity and identity of conjugates **7** and **8** were verified by reversed-phase analytical HPLC and ESI-TOF mass spectrometry.

Evaluation of DNA Alkylating Activity. Sequence-selective alkylation by compounds **7**, **8**, and **6b** was investigated using the 5′-Texas Red-labeled 537 bp DNA fragments λ-DNA F10960*-11496 using an automated DNA sequencer. Alkylation was carried out at 23 °C for 15 h, followed by quenching by the addition of calf thymus DNA. The samples were heated at 94 °C under neutral conditions for 20 min. The alkylation sites were visualized by thermal cleavage of the DNA strand at the alkylated sites. Under these heating conditions, all the purine N3 alkylated sites in the DNA almost quantitatively produced cleavage bands on the gel. Sequencing analysis of the alkylated DNA fragments after heat treatment is shown in Figure 3. The conjugates with indole linkers, **7** and **8**, produced discrete cleavage bands at nanomolar concentrations. Efficient alkylation by **7** occurred at site 1, 5′-AATCC**A**-3′, and site 2, 5′-TAACC**A**-3′, only at a concentration of 10 nM (lane 3). Similarly, alkylation by **8** was observed at the four match sites, 3−6, 5′-WGWCC**A**-3′ (W = A or T; lanes 7−10) with no alkylation at the mismatch site. These results clearly indicate that **7** and **8** efficiently alkylate DNA in a sequence-specific fashion at nanomolar concentrations, as does **1b** (*19*), and the indole moiety acts as an appropriate substitute for the vinyl linker.

We confirmed that seco-CBI conjugate **6b**, which is quantitatively converted to **8** under basic conditions, efficiently alkylates DNA at target sequences, 5′-WGWCC**A**-3′ (lanes 12−14), as does CBI conjugate **8**. It is assumed that **6b** readily converts to **8** in aqueous buffered solution. Analogous in situ cyclization to reactive aziridines for DNA alkylation was found

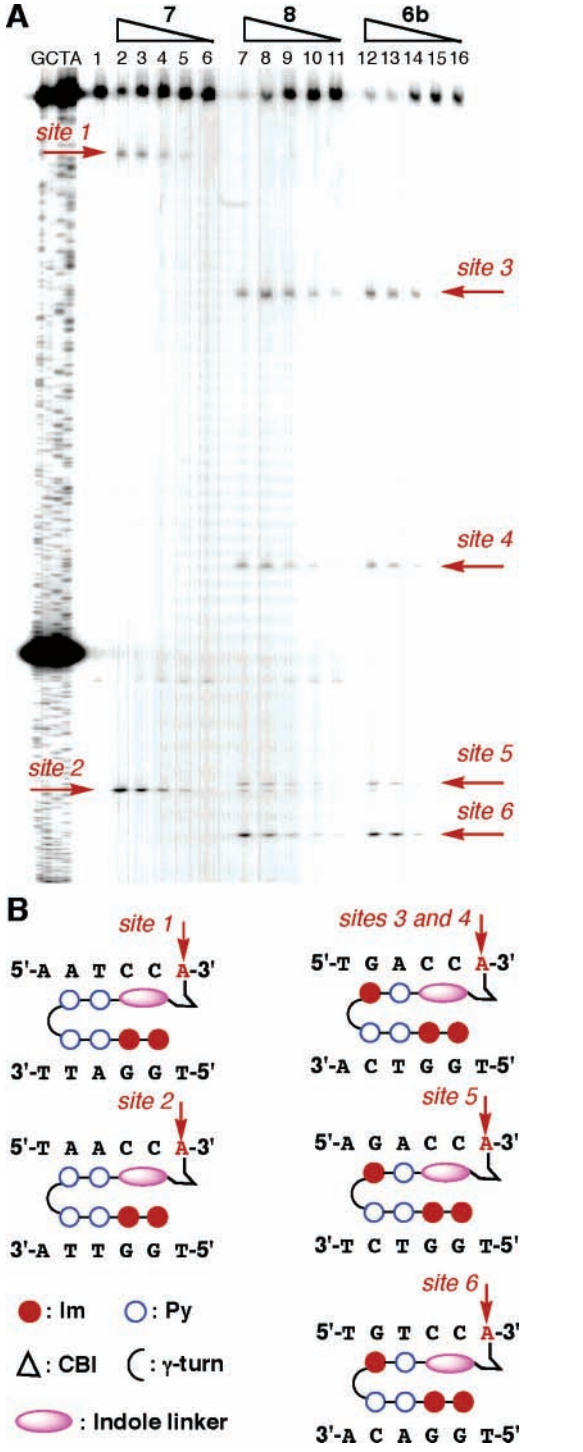


Figure 3. (A) Thermally induced strand cleavage of the 5′-Texas Red-labeled 537 bp DNA fragment λ-DNA F10960*-11496 by conjugates **7**, **8**, and **6b** at 23 °C for 15 h: Lane 1 = DNA control; Lanes 2−6 = 20, 10, 5, 2, and 1 nM of **7**; Lanes 7−11 = 20, 10, 5, 2, and 1 nM of **8**; Lanes 12−16 = 20, 10, 5, 2, and 1 nM of **6b**. for both mitomycin C and nitrogen mustard (*23*). In addition, this result is consistent with the previous results for Py-Im derivatives with seco-CBI (*27*).

Synthesis and Evaluation of DNA Alkylating Activity using seco-CBI Conjugate 10. Toward the goal of sequence-specific alkylating agents that target specific genes, alkylating polyamides that recognize longer sequences are desirable. Thus, we designed and synthesized seco-CBI conjugate **10** by coupling of carboxylic acid **9**, prepared by Fmoc solid-phase synthesis

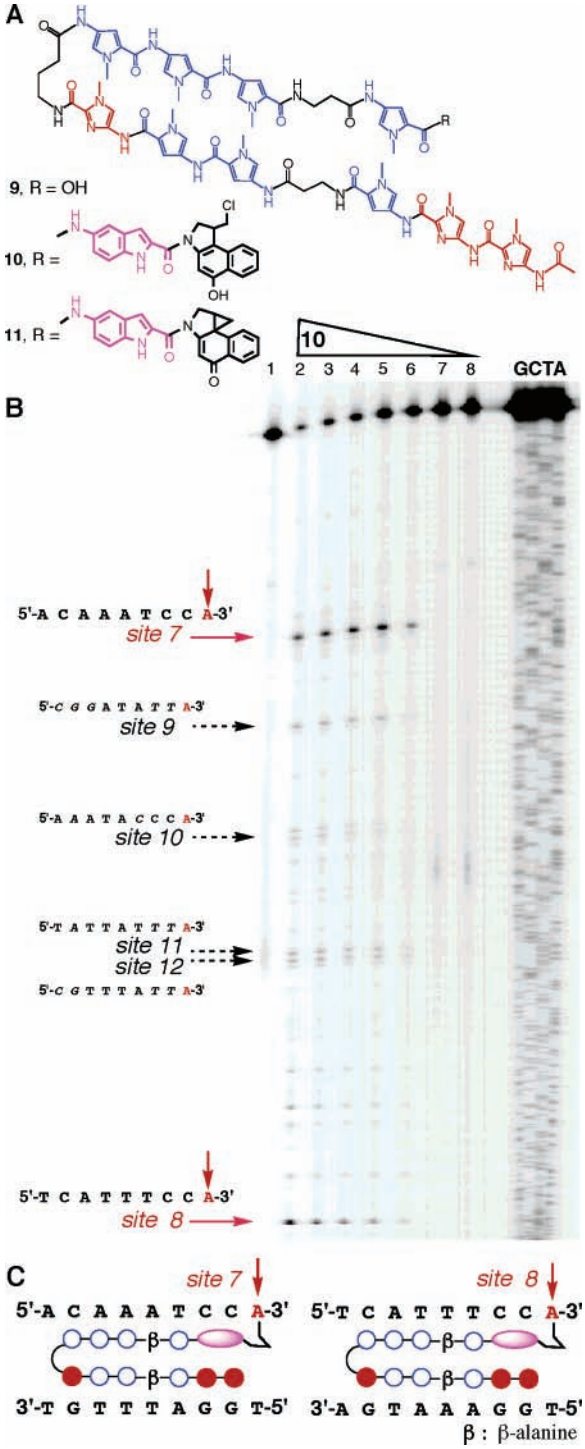

Figure 4. (A) Chemical structures of compound **9**, **10**, and **11**. (B) Thermally induced strand cleavage of the 5′-Texas Red-labeled 488 bp DNA fragment, λ-DNA F30990*-31477, by conjugate **10** at 37 °C for 15 h: Lane 1 = DNA control; Lanes 2−8 = 1000, 800, 600, 400, 200, 100, and 50 nM of **10**. Sites 7 and 8 = match sequences, sites 9−12 = mismatch sequences. (C) Schematic representation of the recognition in matching sequences by **10**. The arrows indicate the site of alkylation. The alkylating base is shown in red bold, and the mismatch-binding base is shown in italics.

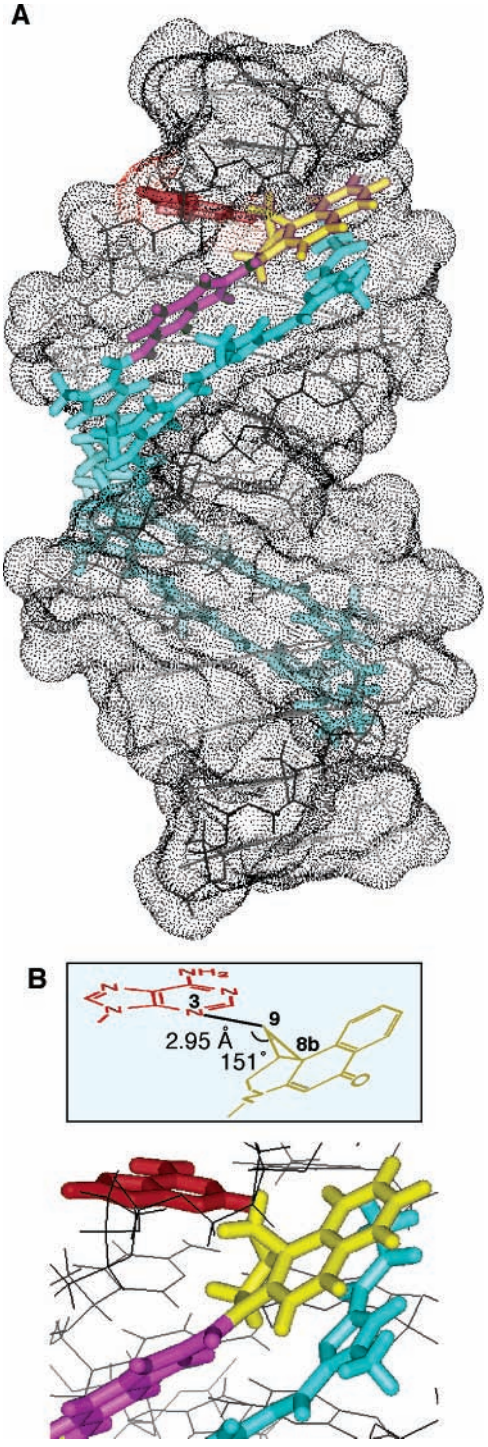

Figure 5. The energy-minimized structure of d(ATACAAATCCAAT)/d(ATTGGATTTGTAT)-**11** (A). The alkylating base is shown in orange and the minor-groove-binding Py-Im polyamide is shown in blue. The indole linker is shown in purple, and the CBI moiety is shown in yellow. Schematic representation of distance and angle of N3 of adenine and CBI (B).

in 21% yield, with **3** and successively with seco-CBI **5** (Figure 4a). It is important to note that the synthesis of the larger polyamide proceeded as smoothly as for **7** and **8**. Sequencing gel analysis clearly indicated that the seco-CBI conjugate **10** alkylated predominantly at the adenine of the nine-base-pair matching sequence 5′-ACAAATCC**A**-3′ (site 7) and 5′-TCATTTCC**A**-3′ (site 8, lanes 2−6), together with faint mismatch alkylations at the A of 5′-*CGG*ATA*TT***A**-3′ (site 9), 5′-A*A*ATA*CCC***A**-3′ (site 10), 5′-T*A*TTATT*TT***A**-3′ (site 11) and 5′-*CG*TTTA*TT***A**-3′ (site 12). It is assumed that **10** readily converts to **11** under the reaction conditions. Differences in reaction rates for each sequence can be a consequence of many associated factors, which require further investigation for detailed understanding. To the best of our knowledge, the present result is the first example of the sequence-specific Py-Im alkylating polyamide recognizing a nine-base-pair sequence.

Model of Binding of 11 to Target Oligonucleotides. To gain an insight into the location of the seco-CBI conjugate **10** in the DNA minor groove, we constructed the d(ATACAAATCCA$_{11}$AT)/d(ATTGGATTTGTAT)-**11** complex, which is based on the predictable structure of the CBI conjugate in the DNA minor groove. The energy-minimized structures suggest that binding of **11** to the minor groove of d(ATACAAATCCA$_{11}$AT)/d(ATTGGATTTGTAT) is located in close proximity to the nucleophilic N3 of the A$_{11}$ residues: 2.95 Å, with the angle of the N3−C9−C8b bond = 151° (Figure 5). The similar binding orientations of the vinyl-linked CPI and CBI conjugates would indicate induction of alkylation at a specific nine-base-pair sequence.

CONCLUSIONS

We have successfully synthesized Py-Im hairpin polyamide CBI conjugates **7** and **8**, and the corresponding seco-CBI conjugates with indole linker, **6a** and **b**, together with the longer alkylating conjugate **10** using Fmoc solid phase synthesis and a subsequent liquid phase coupling procedure. We have evaluated these DNA alkylating polyamides in detail using high-resolution denaturing gel electrophoresis employing DNA fragments. The results clearly indicate that Py-Im CBI conjugates **7**, **8**, **6b**, and **10** efficiently alkylate at specific DNA sequences. Importantly, the selectivity and the efficiency of DNA alkylation by **8** were as good as those of the corresponding CBI conjugate **1b**. In particular, we have clearly demonstrated successful sequence-specific DNA alkylation by the seco-CBI conjugate **10**, which alkylates a specific nine-base-pair sequence, 5′-ACAAATCC**A**-3′. Furthermore, introduction of an indole linker greatly facilitated the synthesis of sequence-specific alkylating Py-Im polyamides. To open the next door toward the goal of developing antitumor agents, the design of new indole−CBI conjugates will allow further biological studies.

Folate Immobilized and PEGylated Adenovirus for Retargeting to Tumor Cells

In Kyung Oh, Hyejung Mok, and Tae Gwan Park*

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, 373-1 Guseong-dong, Yuseong-gu, Daejeon 305-701, Korea. Received February 4, 2006

The surface of adenovirus (ADV) was modified with folate−poly(ethylene glycol) (FOL−PEG) conjugate to overcome the inherent problems associated with viral gene therapy. The ADV coding the green fluorescent protein (GFP) gene was used to immobilize PEG or FOL−PEG conjugate on the viral surface to comparatively evaluate their extents of retargeting and immune response, as compared to those of naked ADV. The FOL−PEG immobilized ADV exhibited a greatly enhanced level of GFP expression than naked or PEG immobilized ADV for a folate receptor overexpressing cell line (KB cells), but not for a folate receptor deficient cell line (A549 cells), suggesting that the retargeting of ADV could be achieved by immobilizing FOL−PEG conjugate. The ADV immobilized with PEG or FOL−PEG also significantly lowered innate immune response, as judged from the amount of interleukin 6 released from macrophage cells.

INTRODUCTION

Gene therapy employs a variety of viral and nonviral vectors. An ideal vector system for practical in vivo applications is yet to be used. Viral vectors show very high transfection efficiency, but have inherent safety problems mainly relating to undesirable immune responses. In contrast, nonviral vectors mostly using cationic lipids and polymers exhibit relatively lower gene transfection efficiencies than the viral vectors, but elicit little immune reactions. Adenovirus (ADV) has been used extensively for gene therapy (*1*). The ADV, which can carry foreign DNA of a relatively big size (*2*), normally exhibits high transduction and gene expression efficiencies in many human dividing and nondividing cells, compared to other available viral vectors (*3*). The knob domain of fiber proteins protruded on the viral surface forms a high-affinity complex with a host cell surface receptor protein (coxsackie-adenovirus receptor (CAR)) (*4*). CAR-mediated viral infection is known to be a major route of cellular uptake for many types of cells expressing CAR on the surface (*4*). This limits the versatility of ADV vectors for target-specific gene therapy. They have to be administered locally with repeated injections to maintain a long-term sustainable effect. Most ADV vectors derived from serotype 5 have defective replication abilities, also requiring repetitive administrations. As a result, serious innate and adaptive immune responses are provoked (*5*).

Several strategies were introduced to overcome the immune response problems of ADV vectors: use of immunosuppressants (*6*), coadministration of interferon γ or interleukin 12 (*7*), and the use of ablative agents (*8*). Recently, a new approach for minimizing the immune response from ADV was explored with use of poly(ethylene glycol) (PEG) (*9*−*13*). PEG modification (PEGylation) is a well-established technique for therapeutic peptides and proteins that need prolonged circulation in the bloodstream (*9*). Additionally, it is known that PEGylated proteins elicit immune responses to a lesser extent. It was previously shown that PEGylated ADV could retain considerable transfection efficiency even in the presence of ADV-neutralizing antibodies (*14*−*16*) and exhibited prolonged resistance in the blood (*17*). However, PEGylated ADV still transfected cells in a nonspecific manner via a CAR-mediated viral infection mechanism. To solve this problem, genetically modified ADV expressing cell recognizable peptide and protein ligands on the surface were constructed to achieve cell-specific retargeting (*7*, *17*, *29*)

In this study, the surface of ADV having a GFP gene was immobilized with folate (FOL) as a retargeting moiety using a PEG spacer. It was postulated that the immobilized PEG could minimize the innate immune response problem to some extent, and the FOL moiety at the distal end of the PEG chain could redirect the ADV to FOL receptor overexpressing tumor cells in a specific manner. FOL receptors are overexpressed in many cancerous cells (*18*−*19*), which was exploited for specifically targeting anticancer agents, gene, and imaging agents to the tumor cells by using FOL-conjugated nanoparticulate carriers (*20*−*22*). In our previous studies, FOL−PEG conjugates were attached to nonviral cationic polymers to promote cell-specific gene transfection efficiency (*23*−*27*). To this end, FOL−PEG conjugate was synthesized and immobilized on the surface of ADV to comparatively evaluate the extent of cell-specific GFP transfection using FOL receptor overexpressing and deficient cell lines. The extent of immune response elicited by the surface modified ADV was also analyzed by determining the amount of interleukin 6 released from macrophage cells.

MATERIALS AND METHODS

Materials. ADV containing the GFP gene was obtained from QBIOgene (AD5.CMV5-GFP) (Montreal, Canada). Hetero-bifunctional poly(ethylene glycol) derivative (NH_2-PEG-COOH, MW 3400), methoxy-PEG-NHS (MW 3400), and fluorescein-PEG-NHS (MW 3400) were purchased from Nektar (Huntsville, AL). Folate (FOL, MW 440), dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), DMSO, acetone, $CsCl_2$, sucrose, fluorescamine, and Triton-X 100 were purchased from Sigma (St. Louis, MO). Cell culture media and materials were products of Gibco-BRL (Grand Island, NY). HEK293 cells, A549 cells, and RAW 264.1 macrophage cells were purchased from the Korea Cell Line Bank (Seoul, Korea), and KB cells (CCL-17) were purchased from ATCC (Manassas, VA). All other chemicals were of analytical grade.

Methods. Synthesis of FOL−PEG-COOH Conjugate. FOL−PEG-COOH conjugate was synthesized according to the previous method (*23*). Briefly, FOL was activated with di-

cyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS) at a 1:2:2 molar ratio in DMSO for 12 h under nitrogen atmosphere and filtered with a syringe filter (pore size: 0.2 μm). A hetero-bifunctional poly(ethylene glycol) derivative (NH_2-PEG-COOH, MW 3400) was added to the solution at a molar ratio of 15:1 (FOL:PEG). After reaction for 4 h under nitrogen atmosphere, the reactants were precipitated with acetone and centrifuged to remove free FOL residues. FOL−PEG-COOH conjugate in the supernatant was dialyzed against deionized water (SpectraPor6, MW cutoff: 1000) and freeze-dried. FOL conjugation to PEG chain was confirmed by ^{1}H NMR and matrix-assisted time-of flight mass spectrometer (MALDI-TOF, Bruker, Germany).

ADV Preparation. For expansion of ADV, 1.2×10^7 HEK293 cells were plated in a 150 mm tissue culture dish. The media used was Dulbecco's Modified Eagle Medium (DMEM) with 10% fetal bovine serum (FBS) and penicillin G sodium at 100 U/mL and streptomycin sulfate at 100 μg/mL. After reaching 60% of confluency, 1×10^{10} of ADV particles (pts) was added and continued to cultivate at 37 °C under humidified 5% CO_2 atmosphere. When over 60% of the cells were detached from the culture plate (about 30 h after virus infection), the cells were collected and lysed. The cell suspension was frozen in a liquid nitrogen bath and thawed at 37 °C three times to break up the cells. The cell lysate was centrifuged at 1500*g* for 10 min, and the supernatant containing infected adenoviral particles was collected. ADV particles were isolated using $CsCl_2$ gradient ultracentrifugation according to the established procedure (*28*). The number of ADV particles was determined by a spectrophotometer. The ADV solution was diluted to an appropriate ADV concentration with 10 mM Tris pH 8.1 and A_{260} of the diluted solution was measured. To determine the approximate number of viral particles (pts) per mL, the following equation was used: $A_{260} \times$ dilution factor $\times 10^{12} =$ pts/mL. Phosphate-buffered saline (PBS) solution containing 3% (w/v) sucrose was used as a blank (*28*).

PEGylation of ADV (ADV−PEG−FOL, ADV−PEG, and ADV−PEG−FITC). Various amounts (10^0−$10^{7.8}$ pmol) of FOL−PEG-COOH conjugate were dissolved in 3 mL of PBS solution with 5% (w/v) sucrose and preactivated with EDC and NHS (1:10:10; molar ratio of FOL−PEG-COOH/EDC/NHS) for 1 h at room temperature. To the solution, 6.02×10^{11} pts of ADV (PEG: ADV = 10^0−$10^{7.8}$:1, molar ratio) suspended in 5% sucrose/PBS solution (pH 8.1) were added to produce FOL−PEG immobilized ADV (ADV−PEG−FOL). For preparing PEGylated ADV (ADV−PEG) and FITC−PEGylated ADV (ADV−PEG-FITC), methoxy-PEG-NHS, and fluorescein-PEG-NHS were used to conjugate to ADV, respectively. After reacting for 4 h at room temperature, PEGylated ADVs were dialyzed against 3% (w/v) sucrose/PBS solution (SpectraPor 6, MW cutoff: 50 000) at 4 °C and kept at −20 °C until use.

Determination of Degree of PEGylation. An amine reactive dye, fluorescamine, was dissolved in acetone at a concentration of 7 mg/mL. One hundred microliters of fluorescamine solution was added to 900 μL of PBS containing 1.0×10^{11} pts of ADV, mixed immediately, and incubated in the dark for 15 min. The fluorescence intensity was detected by spectrofluorometer (excitation wavelength at 390 nm and emission wavelength at 475 nm). PEG-diamine (Sigma, MW: 3550) was used to construct a calibration curve.

Determination of Size and Surface Charge. The sizes and surface charges of ADV, ADV−PEG, and ADV−PEG−FOL were measured using a dynamic light scattering instrument (Zeta plus, Brookhaven, New York) equipped with a He−Ne laser at a wavelength of 632.2 nm.

Cellular Uptake of PEGylated ADV. HEK 293 cells were cultured in 10% FBS media (DMEM). Cells were maintained at 37 °C in a humidified 5% CO_2 incubator. The cells at a seeding density of 2×10^5 were plated in a four-chamber tissue culture slide well containing 1 mL of 10% FBS media. After 24 h, the cell culture medium was replaced with 500 μL of 2% FBS media containing ADV−PEG-FITC. The seeding density of ADV−PEG-FITC was 2000 pts per cell. After 4 h incubation, the cells were washed twice with PBS. To visualize the cell cytoplasm, 500 μL of 5 μM CellTracker Probe (Molecular Probes C34552, Eugene, OR) dissolved in serum-free medium was added to each well and incubated for 20 min. The cells were washed with PBS and fixed with 1% formaldehyde in PBS for 20 min at room temperature. ADV−PEG-FITC particles present within the cells and the dye stained cytoplasm were visualized by confocal laser microscopy (LSM510, Zeiss Pascal, Jena, Germany) at excitation wavelengths of 488 and 543 nm, respectively

Cell Transfection. FOL receptor overexpressing epithelial cancer cells (KB cells) and FOL receptor deficient lung carcinoma cells (A549 cells) were cultured in FOL free RPMI1640 medium. Each cell culture medium was supplemented with 10% FBS, 100 U/mL penicillin G sodium and 100 μg/mL streptomycin sulfate. KB and A549 cell lines were seeded on a six-well-plate at a cell density of 3×10^5 cells/well. After 1 day, the culture media was replaced with 2% FBS media (FOL free RPMI) and 1.2×10^9 pts of ADV, ADV−PEG, and ADV−PEG−FOL were added to each well. After 2 days, the cells were treated with 1% (w/v) Triton-X 100 for cell lysis and centrifuged at 14 000 rpm to remove cell fragments. The supernatant was used for detection of GFP expression (excitation at 488 nm and emission at 520 nm). For counting the number of cells transfected, the cells incubated for 2 days after transfection were washed with PBS and fixed with 1% formaldehyde in PBS for 20 min at room temperature and visualized by confocal laser microscopy (LSM510, Zeiss Pascal, Jena, Germany) at excitation wavelengths of 488 and 543 nm, respectively.

Assay of Immune Response. RAW 264.1 macrophage cells were seeded on a six-well-plate at a cell density of 1×10^6/well containing RPMI1640 supplemented with 10% FBS, 100 U/mL penicillin G sodium, and 100 μg/mL streptomycin sulfate. After 1 day, the culture media was replaced with 2 mL of fresh media containing 2×10^{10} pts of ADV, ADV−PEG, and ADV−PEG−FOL. After 24 h, level of interleukin-6 in the culture media was determined by ELISA (R&D Quantikine, M6000B, MN). DNA was isolated from cells using a DNeasy tissue kit (Qiagen, CA). The total DNA amount from the cultivated macrophage was determined by measuring absorbance at 260 nm. To qualitatively determine the amount of viral particles within the cells, polymerase chain reaction (PCR) was performed on the extracted DNA from RAW 264.1 cells with viral hexon primers having forward sequence (5′-GAACAAGC-GAGTGGTGGCTC-3′) and reverse sequence (5′-CATTGCG-GTGGTGGTTAA-3′) (Bioneer, Daejeon, Korea) and using *rTaq* polymerase (Takara, Seongnam, Korea), according to the protocol (*29*). The operating parameters used were 1 cycle at 50 °C for 2 min, 1 cycle at 95 °C for 10 min, and 23 cycles at 95 °C for 15 s and 6 °C for 1 min. The PCR products were checked by 12% polyacrylamide gel electrophoresis.

RESULTS

FOL−PEG conjugate was synthesized by activating a γ-carboxylic acid in FOL with DCC/NHS and conjugating to a primary amine group of a hetero-bifunctional PEG derivative (NH_2-PEG-COOH) as reported previously (*23*). The resultant FOL−PEG-COOH conjugate was analyzed by ^{1}H NMR and MALDI-TOF. The ^{1}H NMR data suggested that the conjugation percent of FOL was almost 100% (data not shown) and the

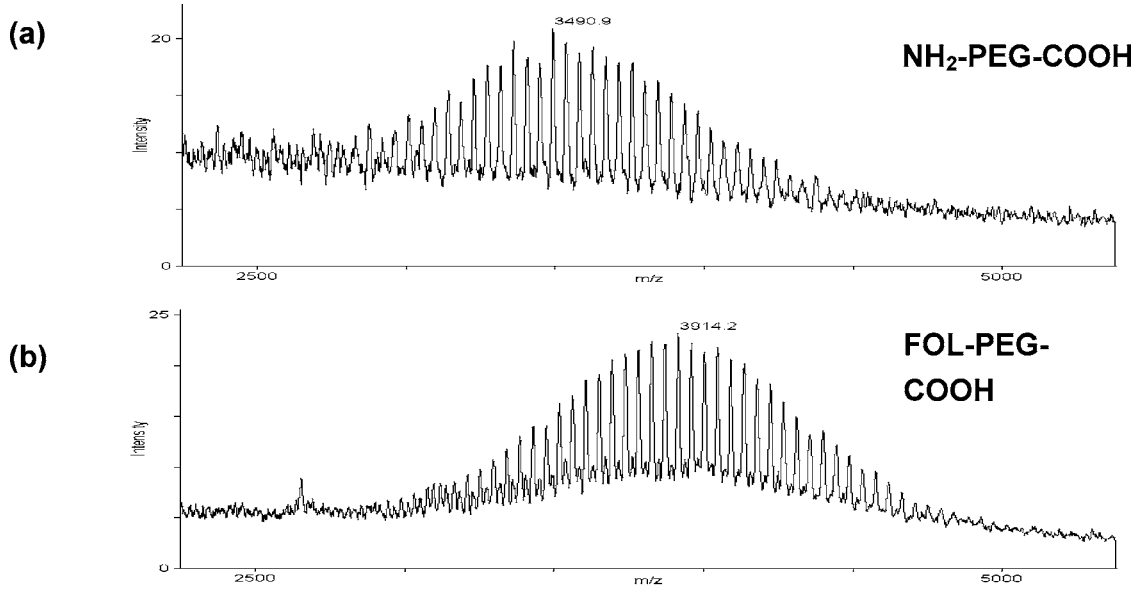

Figure 1. MALDI-TOF spectra of (a) NH_2−PEG-COOH and (b) FOL−PEG-COOH conjugate

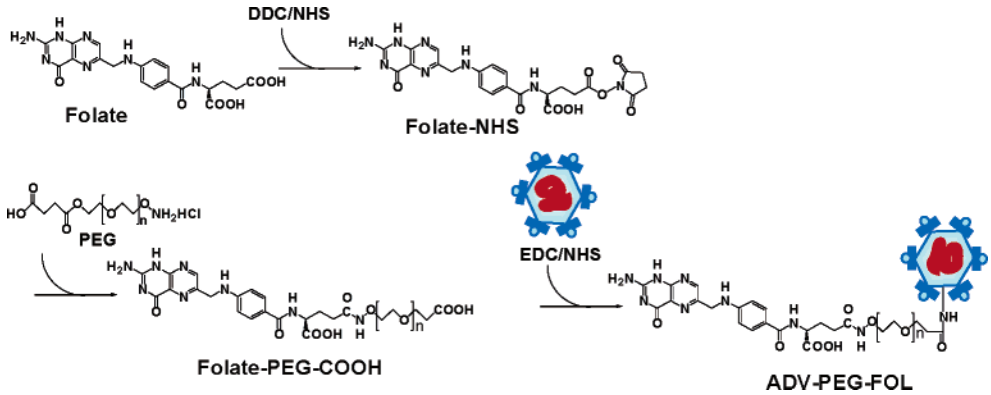
Scheme 1. Scheme of ADV−PEG−FOL Conjugation



MALDI-TOF result indicated that FOL−PEG-COOH conjugate was successfully synthesized without any contaminants. As shown in Figure 1, the FOL−PEG-COOH conjugate shows a maximum peak at 3914.2 Da, while NH_2−PEG-COOH exhibits at 3490.9 Da. The difference of 423.3 Da before and after the FOL conjugation was matched with the molecular weight of conjugated FOL (423 Da), indicating that FOL was indeed conjugated to the amino terminus of the PEG derivative without any side products. FOL−PEG-COOH was then immobilized on the surface of ADV using EDC and NHS coupling agents. Figure 2 shows the reaction percent of surface amine groups of ADV with increasing amount of FOL−PEG-COOH in the feed. The number of ADV pts for PEG immobilization was fixed at 6.02×10^{11}. The total concentration of surface amine groups of ADV was determined by a fluorescamine assay. To calculate the percent immobilization of FOL−PEG on the surface of ADV, the remnant amount of surface amine groups after PEG immobilization was determined. It can be seen that the PEGylation degree of ADV increases with increasing amount of FOL−PEG-COOH in the feed. Since an excess PEGylation degree to ADV could critically damage the structure and function of ADV such as viral infection and gene expression, an optimum PEGylation degree is highly desirable to attain maximized gene expression (*9*, *31*). From preliminary GFP expression experiments using ADV with different PEGylation degrees, it was found that FOL−PEG immobilized ADV prepared from using 1×10^5 pmol FOL−PEG-COOH in the feed, corresponding to 24.1 ± 6.5% FOL−PEG immobilization out of total surface amine groups, showed the highest GFP expression. Thus, ADV with about 24.1 ± 6.5% PEGylation was selected for further experiments.

The size and surface zeta potential value of PEGylated ADV samples were measured by dynamic light scattering (DLS), as shown in Figure 3. The effective diameters of naked ADV, ADV, with PEG conjugation (ADV−PEG), and ADV with FOL−PEG conjugation (ADV−PEG−FOL) were 71.8 ± 13.8, 144.6 ± 17.9, and 148.5 ± 14.7 nm, respectively. The surface charge values of ADV, ADV−PEG, and ADV−PEG−FOL

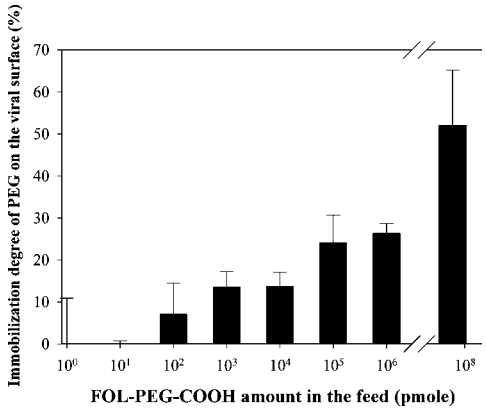


Figure 2. PEGylation degree of ADV immobilized with different amounts of NH2−PEG-COOH in the feed. 6.02×10^{11} particles of ADV was used for PEGylation. Unreacted free amine groups in ADV were determined by fluorescamine assay to calculate the PEGylation degree.

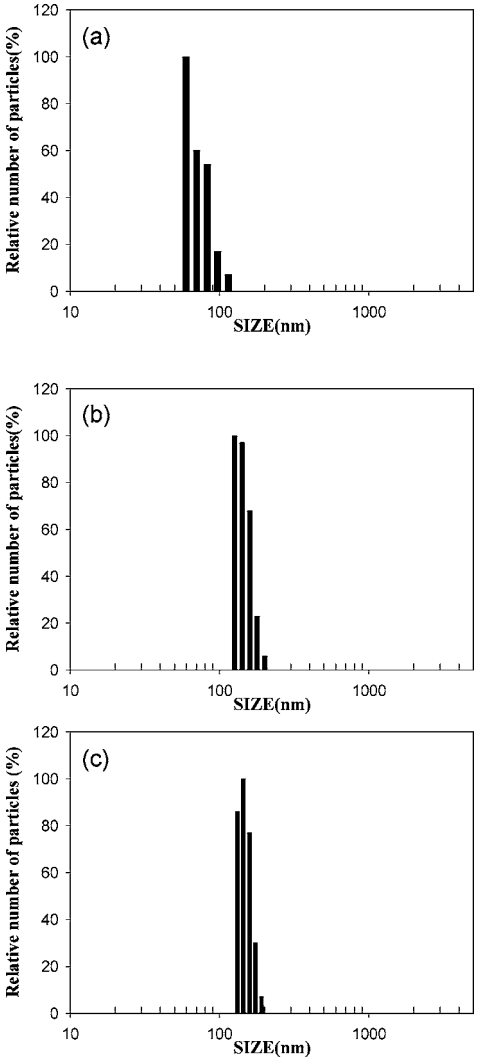

Figure 3. Size distribution of PEGylated ADV particles. The size and surface charge values of (a) ADV, (b) ADV−PEG, (c) ADV−PEG−FOL. PEGylation degree was 24.1 ± 6.1%.

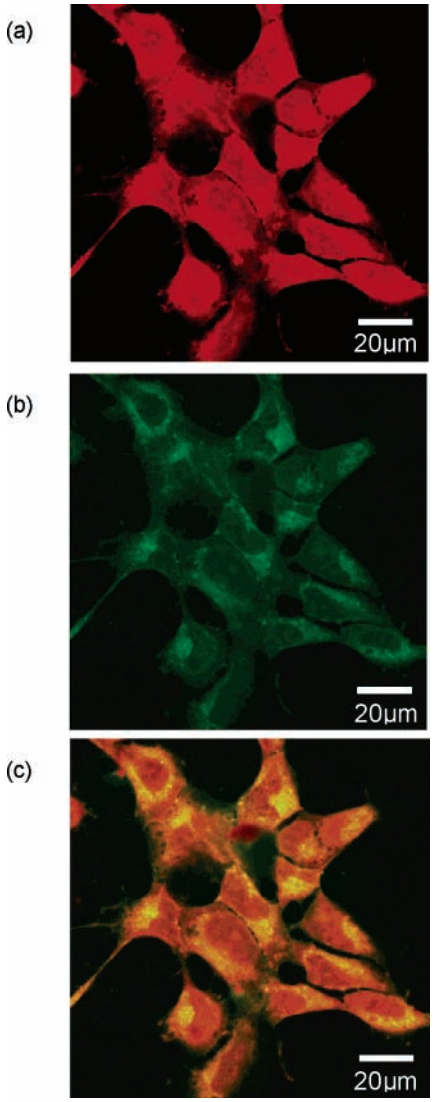

Figure 4. Cellular uptake of PEGylated ADV observed by confocal laser scanning microscopy. (a) Cells stained with a cell-tracker dye (red color), (b) ADV particles labeled with FITC (green color), and (c) a merged image of parts a and b.

were −20.3 ± 2.4, −7.0 ± 1.2, and −4.2 ± 1.7 mV, respectively. The PEGylated ADV had larger sizes than the naked ADV due to the increased hydrodynamic volume of immobilized PEG chains on the surface. They also had less negative surface charge values because immobilized neutral PEG chains on the surface masked the highly negative surface charge of naked ADV. The DLS results provided clear evidence that ADV was indeed PEGylated on the surface. However, it was not obvious why the sizes of ADV−PEG and ADV−PEG−FOL were about two times larger than that of naked ADV. It was likely that ADV dimer species were formed by noncovalent aggregation during the PEGylation process.

To visualize cellular uptake of PEGylated ADV, a FITC-labeled PEG derivative (FITC-PEG-NHS) was conjugated to ADV. The resultant ADV−PEG-FITC was transfected into HEK293 cells. Figure 4a shows a confocal laser microscopic view of cells treated with Celltracker that specifically stains the cytoplasm in red color. Figure 4b shows the cells stained with green color, resulting from the presence of ADV−PEG-FITC in the cytoplasm. In a merged image as shown in Figure 4c, it can be clearly seen that yellow ADV−PEG-FITC particles are located in the cell cytoplasm.

ADV, ADV−PEG, and ADV−PEG−FOL were transfected to FOL receptor overexpressing KB cells and FOL receptor deficient A549 cells. Figure 5 shows comparative GFP expression levels between the two cells determined by counting the number of transfected cells (Figure 5a) and measuring the fluorescence intensity after cell lysis (Figure 5b). The GFP expression percent of ADV−PEG decreased to 62.3 ± 6.1% and 43.4 ± 8.1% compared to that of ADV for KB and A549 cells, respectively. However, ADV−PEG−FOL exhibited fully recovered GFP expression percent as similar as that of ADV for KB cells, but not for A549 cells. In terms of GFP expression level by measuring total fluorescence intensity of transfected cells, ADV−PEG decreased to 66.7 ± 9.3% and 23.3 ± 5.5% compared to that of ADV for KB and A549 cells, respectively. In contrast, ADV−PEG- FOL increased to 145 ± 4.6% for KB cells, but decreased to 7.6 ± 0.4% for A549 cells. The above results suggest that ADV−PEG−FOL could be taken up by KB cells by FOL receptor-mediated endocytosis, but not by CAR-mediated endocytosis.

To determine comparatively the extent of immune response, ADV, ADV−PEG, and ADV−PEG−FOL were infected to macrophage cells (RAW264.1), and the release amount of interleukin-6 (IL-6) was measured (Figure 6 (a)). IL-6 is one of the important cytokines secreted from macrophage cells, and the secreted amount is directly related to the extent of immune response. The released IL-6 amounts were normalized to the total DNA amount extracted from RAW264.1 cells infected with ADV, ADV−PEG, and ADV−PEG−FOL. Untreated cells

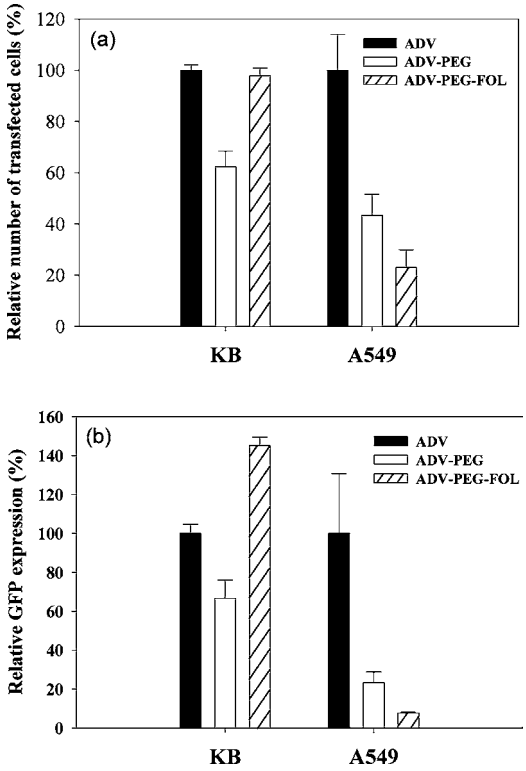

Figure 5. Quantitative measurement of GFP expression levels as determined from (a) the number of transfected cells and (b) from total fluorescent intensity of GFP in the transfected cells.

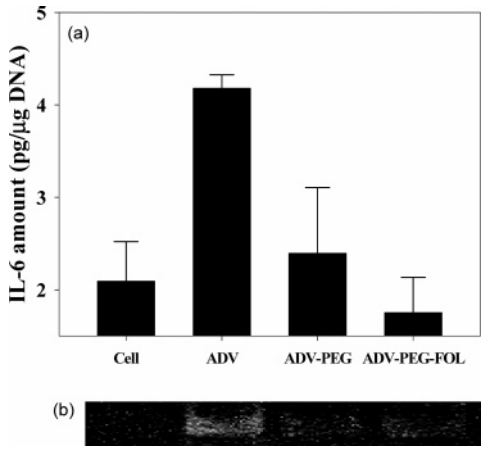

Figure 6. (a) The amount of IL-6 released from RAW264.1 macrophage cells after infection with ADV, ADV−PEG, and ADV−PEG−FOL. (b) PCR results for hexon DNA in ADV present within the macrophage cells. The amount of ADV taken up by macrophages corresponds to the band intensity.

released IL-6 to a concentration of 2.1 ± 0.4 pg/μg DNA after 24 h, while the cells cultured with ADV released 4.1 ± 0.1 pg/μg DNA. This indicates that ADV alone elicited immune response to some extent. However, IL-6 amounts for cells cultured with PEGylated ADV were much lower than that for ADV. The IL-6 amount for ADV−PEG was 2.4 ± 0.7 pg/μg DNA and that for ADV−PEG−FOL was 1.7 ± 0.4 pg/μg DNA. The reduced amounts of IL-6 released from macrophage cells suggest the PEGylated ADV could minimize the adverse immune response problems often associated with ADV gene therapy. Figure 6b shows viral hexon DNA bands amplified by PCR. The amount of viral hexon DNA fragments in the cell extract was qualitatively determined to indirectly correlate with the amount of viral particles within the macrophage cells. ADV−PEG and ADV−PEG−FOL had weaker band intensities than naked ADV, suggesting that they were taken up lesser than ADV by the stealth effect of PEG chains on the viral surface. Thus, the lower levels of IL-6 for ADV−PEG and ADV−PEG−FOL were attributed to the reduced extent of phagocytosis by macrophage cells.

DISCUSSION

PEGylation is a well-known technique for modification of peptide and protein drugs to prolong circulation time in the blood and minimize immune response. More recently, PEG has been used to decorate the surface of various nanoparticulate drug and gene carriers. To achieve retargeting of ADV while concomitantly reducing immune reactions, the surface of ADV was immobilized with FOL−PEG-COOH conjugate. FOL−PEG-COOH was synthesized and confirmed by MALDI-TOF analysis (Figure 1). It was previously reported that PEGylated ADV reduced transfection efficiency because the inherent CAR-mediated cellular uptake mechanism of ADV is hampered as a result of PEGylation (*9*, *31*). Surface immobilized PEG chains on ADV were likely to prevent the initial docking event of ADV to CAR on the host cell membrane. It is important to select an optimal PEGylation degree for maximizing gene transfection efficiency while substantially reducing the extent of immune response. With increased PEGylation degree on ADV, the extent of immune response would be reduced, but the gene transfection efficiency would be lowered substantially at the same time. An excessive PEGylation of the viral surface could also change the conformation of a viral surface capsid protein, which might prevent viral DNA from being delivered to the nucleus. The capsid protein plays an important role in dismantling the viral envelope structure for releasing DNA. Hence, the structural damage of the capsid protein by PEGylation could additionally lower the transfection efficiency. This means that excessively PEGylated ADV would result in not only a reduced extent of cellular uptake, but also a lower level of DNA release from the viral envelope within the cells. From this reason, PEGylation degree was preoptimized to approximately 1×10^5 PEG chains per viral particle for further gene transfection experiments. This corresponds to 24.1 ± 6.5% PEGylation based total amine groups on the ADV surface (Figure 2). After PEGylation, the size of ADV−PEG−FOL changed from 71.8 ± 13.8 nm to 148.5 ± 14.7 nm with increasing surface zeta potential values. It was likely that less negatively charged PEGylated ADV particles were prone to aggregation forming dimeric ADV particles. Cellular entrance of PEGylated ADV was examined by using ADV−PEG-FITC. It is known that within minutes after infection, ADV can escape from the endosome and translocate along microtubule tracks at a rate of 2 μm/s, converge at the perinuclear envelope, and undergo further dismantling for transport of viral DNA into the nucleus (*34*). Figure 4 shows that ADV−PEG-FITC particles are located primarily around the nucleus. The cellular entry of ADV−PEG-FITC was likely to occur via a nonspecific endocytic mechanism since CAR-mediated cellular entry was blocked to some extent due to PEGylation. In this study, FOL was used as a cancer targeting moiety for ADV. As shown in Figure 5, GFP expression levels of ADV−PEG and ADV−PEG−FOL were significantly different for KB and A549 cells. For KB cells, ADV−PEG−FOL showed similar or greater GFP expression levels than ADV, whereas for A549 cells, it showed decreased GFP expression levels. ADV−PEG−FOL could fully recover the loss of GFP gene expression by ADV−PEG only for KB cells, but not for A549 cells. This result clearly reveals that ADV could be delivered in a more specific manner to target cells and tissues without undergoing a CAR-mediated viral infection mechanism. Retargeting of ADV is feasible by conjugating an appropriate targeting moiety on the surface without compromising gene

transfection efficiency. Generally, ADV is administered repeatedly into a local site for clinical practices. The chromosome of genetically engineered ADV does not integrate into the host genome, thus repeated administration is often needed. This leads to serious immune response that is the biggest hurdle to practical applications of ADV for therapeutic treatments. PEGylated ADV could be one viable strategy in diminishing innate immune response as previously reported. There are several studies on PEGylated ADV to circumvent the immune response problems (*3*, *9*, *31*). In this study, a targeting moiety was conjugated to the distal end of PEG chain to provide an additional opportunity for retargeting of ADV. Chemical modification of the ADV surface with a targeting moiety is a more straightforward and versatile method than genetic modification of ADV surface with cell-recognizable proteins such as antibodies. One of the advantages of nonviral vector systems using cationic polymers and lipids are their ease of chemical modification with various targeting moieties with/without immobilizing PEG chains. The current study extended such surface modification strategies to ADV viral vectors for attaining only the merits from viral and nonviral vectors. To further validate the current findings and extend applications for other viral vectors, in vivo animal experiments are definitely required in the future.

CONCLUSIONS

We demonstrated that ADV was immobilized with a FOL−PEG conjugate on the surface to retarget the surface engineered ADV to FOL-receptor overexpressing cells and to reduce innate immune response. The two most serious problems for viral gene delivery vectors, targeting and immune response, could be partially overcome by immobilization of FOL−PEG conjugate on the viral surface. PEGylated ADV decorated with specific cell-recognizable targeting ligands could be potentially applied for many clinical applications in gene therapy.

Interactions of polycationic polymers with supported 1,2-dimyristoyl-sn-glycero-3-phosphocholine (DMPC) lipid bilayers and live cell membranes (KB and Rat2) have been investigated using atomic force microscopy (AFM), cytosolic enzyme assays, confocal laser scanning microscopy (CLSM), and a fluorescence-activated cell sorter (FACS). Polycationic polymers poly-L-lysine (PLL), polyethylenimine (PEI), and diethylaminoethyl-dextran (DEAE-DEX) and sphere-like poly(amidoamine) (PAMAM) dendrimers are employed because of their importance for gene and drug delivery. AFM studies indicate that all the polycationic polymers cause the formation and/or expansion of preexisting defects in supported DMPC bilayers in the concentration range of 1−3 μg/mL. By way of contrast, hydroxyl-containing neutral linear poly(ethylene glycol) (PEG) and poly(vinyl alcohol) (PVA) do not induce hole formation or expand the size of preexisting defects in the same concentration range. All polymers tested are not toxic to KB or Rat2 cells up to a 12 μg/mL concentration (XTT assay). In the concentration range of 6−12 μg/mL, however, significant amounts of the cytosolic enzymes lactate dehydrogenase (LDH) and luciferase (LUC) are released. PEI, which possesses the greatest density of charged groups on its chain, shows the most dramatic increase in membrane permeability. In addition, treatment with polycationic polymers allows the small dye molecules propidium idodide (PI) and fluorescein (FITC) to diffuse in and out of the cells. CLSM images also show internalization of PLL labeled with FITC dye. In contrast, controls of membrane permeability using the neutral linear polymers PEG and PVA show dramatically less LDH and LUC leakage and no enhanced dye diffusion. Taken together, these data are consistent with the hypothesis that polycationic polymers induce the formation of transient, nanoscale holes in living cells and that these holes allow a greatly enhanced exchange of materials across the cell membrane.

INTRODUCTION

The water soluble synthetic polycationic polymers poly-L-lysine (PLL), polyethylenimine (PEI), diethylaminoethyl-dextran (DEAE-DEX), and polyamidoamine (PAMAM) dendrimers have been employed in a variety of gene and drug delivery system applications (*1*−*3*). The generally accepted mechanism for internalization of these polymers is polycation-mediated endocytosis, a three-step process composed of binding with phospholipids and/or glycolipids in the membrane, internalization into cells, and exit from the endosome (*4*−*7*). Having particular interest in the first step of the process, several research groups have used model systems including phosphatidylethanolamine containing anionic vesicles to study the membrane/particle interaction (*8*−*10*). Studies of model systems have provided good evidence for membrane disruption caused by cationic macromolecules such as PEI, PAMAM dendrimers, and poly-(*N*-ethyl-4-vinylpyridinium bromide) as measured by changes in fluorescence intensity of artificial vesicles containing dyes such as fluorescein (FITC) after exposure to the polycations (*10*−*12*). Several reports using living cell membranes have also demonstrated increased membrane permeability as determined by cytotoxicity (cytosolic enzyme leakage such as LDH) using assay techniques (*13*, *14*). However, no clear connection has been made between proposed models and in vitro studies.

We recently reported that positively charged PAMAM dendrimers cause membrane disruption (dendroporation), allowing the diffusion of molecules in and out of cells (*15*). This in vitro result is in good agreement with the proposed hole formation mechanism, as suggested by atomic force microscopy (AFM) on a supported 1,2-dimyristoyl-sn-glycero-3-phosphocholine (DMPC) model membrane (*16*−*19*). On the basis of our previous results, we wanted to explore if nanoscale hole formation could be caused by less exotic polycationic polymers such as PEI, PLL, and DEAE-DEX which are substantially cheaper and more commonly used materials than the PAMAM dendrimers. The key hypotheses we address in this paper are as follows:

(1) Commercially available polycationic polymers, PEI, PLL, and DEAE-DEX cause nanoscale hole formation in supported lipid bilayers.

(2) Commercially available polycationic polymers, PEI, PLL, and DEAE-DEX cause substantial permeability of the cell plasma membrane allowing enhanced enzyme and dye diffusion.

(3) Under the same conditions, neutral linear polymers (PEG and PVA) do not cause nanoscale hole formation in supported lipid bilayers nor do they generate comparable enhancements in cell membrane permeability.

In this study, we employed AFM to observe the effect of

polymers upon supported DMPC lipid bilayers. Polymer interactions with cells in vitro were investigated in terms of morphological studies using confocal laser scanning microscopy (CLSM) as well as toxicological studies using XTT, lactate dehydrogenase (LDH), and luciferase (LUC) assays and flow cytometry. AFM studies revealed that the presence of polycationic polymers induces nanoscale hole formation and/or the expansion of preexisting defects in the supported DMPC bilayers. The presence of polycationic polymers in the cell medium made the cell membrane permeable to molecules such as cytosolic enzymes (LDH and LUC), propidium iodide (PI), and FITC. These results directly support the three hypotheses described above and suggest an alternative model to polycation-mediated endocytosis for the transport of materials across cell membranes in the presence of polycationic polymers.

EXPERIMENTAL PROCEDURES

Materials and Measurement of Molar Masses. PLL, PLL−FITC conjugate (PLL−FITC), PEI, and DEAE-DEX were purchased from Sigma-Aldrich. G5 PAMAM dendrimers were synthesized and then conjugated with FITC at the Michigan Nanotechnology Institute for Medicine and Biological Sciences, University of Michigan (*15*). DMPC lipids were provided by Avanti Lipids, Alabaster, AL. Chemical structures of the polycationic polymers used in this paper are illustrated in Figure 1.

The molar mass moments and molar mass distribution of each polymer sample was measured using gel permeation chromatography (GPC). The number average molar mass (M_n) and polydispersity index (PDI), a commonly used measure of the breadth of the molar mass distribution defined as the ratio of the weight and number average molar masses (M_w/M_n), of individual samples are listed in Table 1. GPC experiments were performed using an Alliance Waters 2690 separation module (Waters Corp., Milford, MA) equipped with a Waters 2487 UV absorbance detector (Waters Corp.), a Wyatt Dawn DSP laser photometer (Wyatt Technology Corp., Santa Barbara, CA), an Optilab DSP interferometric refractometer (Wyatt Technology Corp.), and TosoHaas TSK-Gel Guard PHW 06762 (75×7.5 mm, 12 μm), G 2000 PW 05761 (300 × 7.5 mm, 10 μm), G 3000 PW 05762 (300 × 7.5 mm, 10 μm), and G 4000 PW (300 × 7.5 mm, 17 μm) columns. Column temperatures were maintained at 25 ± 0.2 °C with a Waters temperature control module. Citric acid buffer (0.1 M) with 0.025% sodium azide in water was used as a mobile phase. The pH of the mobile phase was adjusted to 2.74 using NaOH, and the flow rate was maintained at 1 mL/min. Sample concentration was approximately 2 mg/mL, and an injection volume of 100 μL was used for all samples. Molar mass moments of the polymers were determined using Astra software (version 4.7) (Wyatt Technology Corp.).

Preparation and AFM Observation of Supported DMPC Lipid Bilayers. A 0.67 mg/mL suspension of small, unilamellar vesicles (SUVs) was prepared as previously reported (*15, 16, 20*). Supported lipid bilayers were formed by depositing 80 μL of liposome suspension on a 1 × 1 cm^2 piece of freshly cleaved mica. After an incubation time of approximately 20 min, the sample was gently rinsed with water to remove excess lipids and placed in the AFM for imaging as described in previous studies. All AFM measurements were performed in tapping mode on a Nanoscope IIIa Multimode scanning probe microscope from Digital Instruments (DI, Veeco Metrology Group, Santa Barbara, CA). The AFM was equipped with a liquid cell (DI) and a silicon nitride cantilever (DI model NPS, spring constant 0.32 N/m, length 100 μm) operating at a drive frequency of 6−9 kHz. After taking an initial image of the bilayer, approximately 20 μL of polymer solution was injected into the liquid cell. All solutions were prepared using high purity water (Nerl Diagnostics, East Providence, RI). The temperature inside the liquid cell was 28 °C and therefore above the gel to liquid transition temperature of supported DMPC bilayers.

Cell Lines. The KB and Rat2 cell lines were purchased from the American Type Tissue Collection (ATCC, Manassas, VA) and grown continuously as a monolayer at 37 °C and 5% CO_2 in RPMI 1640 medium (Mediatech, Herndon, VA) and Dulbecco's modified Eagle's medium (DMEM, Gibco, Eggenstein, Germany), respectively. The Rat2 cell line was transfected to permanently express the LUC gene using PAMAM dendrimer-mediated gene transfection as previously described (*15, 21, 22*). The LUC expressing Rat2 cells are noted as Rat2pLUC. The RPMI 1640 and DMEM media were supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), and 10% heat-inactivated fetal bovine calf serum (FBS) before use.

XTT, LUC, and LDH Assays and Flow Cytometry. Cytotoxicity of the polycationic polymers was assessed with a 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-[(phenylamino)carbonyl]-*2H*-tetrazolium hydroxide (XTT) assay kit (Cell Proliferation Kit II, Roche Molecular Biochemicals, Mannheim, Germany). KB and Rat2 cell lines (at a concentration of 5 × 10^4 cells/well) were prepared as monolayers in 96 well plates, followed by incubation with polymers in phosphate-buffered saline (PBS) with Ca^{2+} and Mg^{2+} at 37 °C under 5% CO_2 for 4.5 h. Polymer solutions (supernatants) were removed and followed by washing with PBS twice. Mitochondrial activities in the cells were then measured using the assay kit.

The LDH and LUC activities in the cell supernatant after 3 h incubation were respectively analyzed using an LDH assay kit (Promega Co., Madison, WI) and a chemiluminescence assay(Promega Co., Madison, WI) as previously described (*15*). The measured LDH and LUC activities were either recalculated by percentage to the activities of cell lysates of intact cells (% LDH released) or adjusted for the protein concentration of the sample (relative light unit (RLU)/mg protein). Flow cytometry was also performed according to our report (*15*). Fluorescence signal intensities were measured by a Coulter EPICS/XL MCL Beckman-Coulter flow cytometer and data were analyzed using Expo32 software (Beckman-Coulter, Miami, FL).

CLSM Observation. A concentration of 2 × 10^4 cells/mL of Rat2 cells was seeded on MatTek glass bottom Petri dishes (35 mm) and incubated at 37 °C under 5% CO_2 for 24 h. The DMEM was removed and 2 mL of each PLL−FITC and dendrimer−FITC conjugates in PBS (Ca^{2+}, Mg^{2+}) solution was added into the appropriate dish. The dishes were incubated with added solutions at 37 °C under 5% CO_2 for 1 h. The conjugate-

Table 1. Physicochemical Properties of Polycations Used in This Study

polymer	M_n (PDI)[a]	order of amines (deg)	charge/monomer ratio[b]	zeta potential (mV)[c]	shape of chain
PLL	11210 (1.67)	1, 2	0.007519	17.59 ± 0.39	linear, flexible

[a] Measured by GPC. [b] Theoretical number of charged groups per molecular weight of polymeric monomer. [c] Measured by zeta potential/particle sizer NICOMP 380 ZLS (PSS·NICOMP, Santa Barbara, CA). The maximum count rate was 5 MHz and the measurements were carried out for 5 min. All the polymer samples were at a concentration of 1 mg/mL, pH 7.4, and measurements for each polymer were repeated five times.

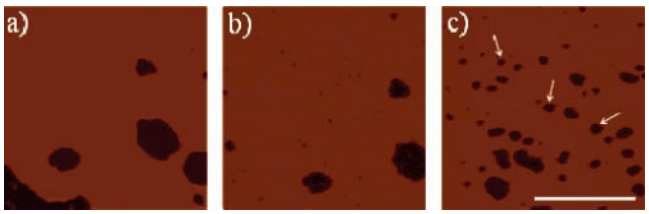

Figure 2. AFM images of supported DMPC lipid bilayers upon exposure to poly-L-lysine (PLL). 20 μL of 10 μg/mL PLL injected following image a, resulting in a final concentration of ~1.0 μg/mL in the AFM liquid cell. Total time between a and c is approximately 50 min. White arrows indicate formation of several new holes in the lipid bilayers caused by PLL. Bar: 500 nm. Z-scale: 20 nm.

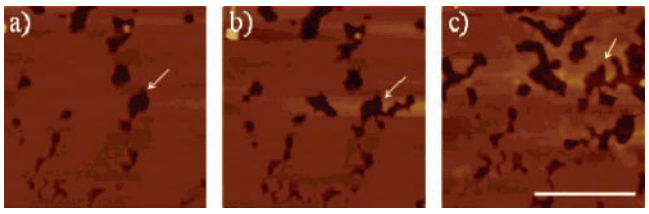

Figure 3. AFM images of supported DMPC lipid bilayers upon exposure to poly(ethylenimine) (PEI). 20 μL of 5 μg/mL PEI injected following image a, resulting in a final concentration of ~0.5 μg/mL. An additional 20 μL of 10 μg/mL was injected after b, resulting in a final concentration of ~1.5 μg/mL. Total time between a and c is approximately 40 min. Note that there is no new hole formation but instead the preexisting defects are expanded. One of the preexisting defects and expansion of the defect is indicated by white arrows in each image. Bar: 500 nm. Z-scale: 20 nm.

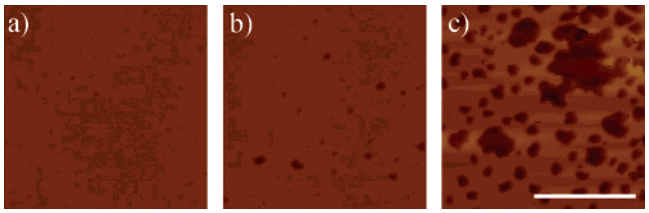

Figure 4. AFM images of supported DMPC lipid bilayers upon exposure to diethylaminoethyl-dextran (DEAE-DEX). 50 μL of 5 μg/mL DEAE-DEX injected following image a, resulting in a final concentration of ~1.3 μg/mL. Total time between a and c is approximately 90 min. Unlike that PLL and PEI create or expand defects in the lipid bilayers, DEAE-DEX induces membrane thinning. The newly formed defects are 2−4 nm deep instead of complete removal of the lipid bilayers (~4−5 nm deep). Bar: 500 nm. Z-scale: 20 nm.

containing solutions were removed, and the resulting cell monolayer was washed with PBS. Cells were fixed with 2% formaldehyde in the PBS (Ca^{2+}, Mg^{2+}) at room temperature for 10 min, followed by washing with PBS twice. Confocal and differential interference contrast (DIC) images were taken on an Olympus FV-500 confocal microscope using a 40×, 1.2 NA oil immersion objective. For the confocal images, the 488 nm line of an argon ion laser was used for excitation and the emission was filtered at 505 nm.

RESULTS

Polycation-Induced Hole Formation on Aqueous Supported DMPC Lipid Bilayers. The polycation polymers used in this study (PLL, PEI, and DEAE-DEX) were all shown to disrupt DMPC-supported lipid bilayers. Several controls were performed for the AFM study. Before the introduction (through injection) of polymers into the solution containing the aqueous supported lipid bilayers, the bilayers were imaged alone for 8 to 10 min. These preimaging steps were done to ensure that the bilayers were stable and that preexisting defects that appeared were not due to the act of imaging itself. A blank injection of water (the solvent in which the polymers were dissolved) was completed and resulted in no change to the bilayer over the course of a normal imaging session (60 to 90 min). This shows that the injection itself is not responsible for the formation of defects. Finally, injections of 1 μg/mL of poly(ethylene glycol) (PEG) and poly(vinyl alcohol) (PVA), two neutral polymers, were performed and resulted in no change to the supported bilayers over normal imaging time.

Images taken using AFM show the three polycationic polymers (PEI, PLL, and DEAE-DEX) disrupt DMPC supported lipid bilayers. Figures 2, 3, and 4 are representative data sets of the polycationic polymers and DMPC lipid bilayer interactions. Although there is some variation, several repetitions were completed for each polymer confirming that the degrees of membrane/polymer interactions are qualitatively similar. Following the addition through injection of PLL into the AFM liquid cell at a final concentration of ~ 1 ug/mL (Figure 2), new defects in the bilayer are formed. The depth of these defects in the membrane is primarily in the range of 4.0−4.8 nm. Addition of PEI onto the bilayer, however, results in mostly the expansion of preexisting defects (Figure 3). These expanded defects have measured 4.4 to 5.1 nm in depth which is consistent with the removal of a full bilayer. Interestingly, the introduction of DEAE-DEX to supported DMPC bilayers results in only 2−4 nm deep depressions.

Cytotoxicity of Polycation and Polycation-Induced Enzyme Leakage. The cytotoxicity of the polymers was determined using an XTT assay (Figure 5). The relative cell viability was calculated as:

$$[OD_{492nm}]_{sample}/[OD_{492nm}]_{control} \times 100$$

The assay results show that the polymers are not cytotoxic up to a 12 μg/mL concentration (>80% cell viability) for both KB and Rat2 cells. Based on these data, the assays performed to investigate the cytosolic enzyme release were carried out in polymer concentrations of 6 and 12 μg/mL. Within this range, the polymers are noncytotoxic, so the observed enzyme release can be ascribed to an increase in cell membrane permeability as opposed to general lysis due to cell death.

The effect of positively charged polymers on the cell membranes was investigated in terms of cytosolic enzyme release from the cells using LDH and LUC assay techniques.

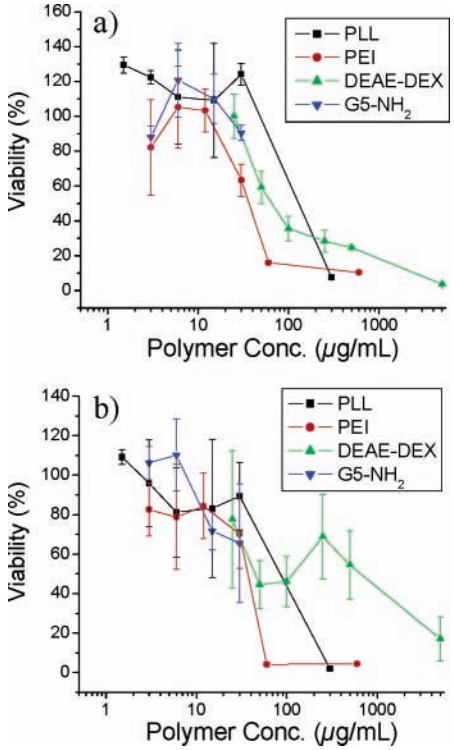

Figure 5. Cell viability determined by XTT assay of (a) KB and (b) Rat2 cells after incubation with PLL, PEI, DEAE-DEX, and G5-NH_2 PAMAM at 37 °C for 4.5 h. Note that all the polymers are not cytotoxic up to a concentration of 12 μg/mL.

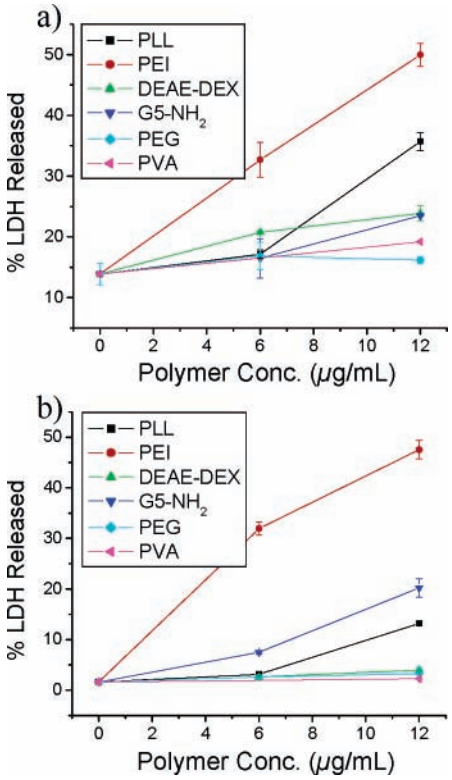

Figure 6. Dose-dependent LDH release from (a) KB and (b) Rat2 cell lines incubated with PLL, PEI, DEAE-DEX, G5-NH_2 PAMAM, PEG, and PVA at 37 °C for 3 h. All the polycationic polymers induce LDH leakage but the neutral polymers PEG and PVA do not cause any significant leakage.

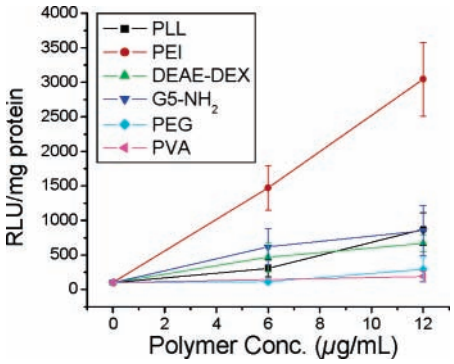

Figure 7. Dose-dependent luciferase (LUC) release from Rat2pLUC cell line incubated with PLL, PEI, DEAE-DEX, G5-NH_2 PAMAM, PEG, and PVA at 37 °C for 3 h. Before the incubation, Rat2 cells were transfected by PAMAM dedrimer-mediated cell transfection to express LUC in their cytosols. As seen in the LDH assay data in Figure 6, all the polycationic polymers used in this study also cause LUC leakage but the neutral polymers do not.

As the polymer concentration increases, the amounts of both LDH and LUC released increased as illustrated in Figures 6 and 7. Induced membrane permeability as measured by LDH release shows a degree of cell type (KB and Rat2) dependence as shown in Figure 6. In both cell types (Figure 6), however, PEI induced more LDH leakage as compared to the other polycationic polymers. This is not surprising because PEI possesses a much greater charge/monomer ratio (see Table 1) as compared to the other polymers. G5-NH_2 and PLL cause similar amount of LDH release and the least LDH was released from the cells after exposure to DEAE-DEX among the polycationic polymers, particularly in the case of the Rat2 cells. PEG and PVA did not cause enzyme leakage. LUC release from Rat2pLUC exhibits a trend similar to the LDH release from cells seen as discussed above (Figure 7).

Binding and Internalization of PLL−FITC. PLL−FITC conjugate was used for direct observation by CLSM. This experiment was carried out to compare the internalization behavior of common commercial polycationic polymers to that of dendrimeric G5-NH_2. Figure 8 shows that PLL−FITC is internalized into the Rat2 cells resulting in strong fluorescence of FITC from inside the cells. In particular, the intracellular location of the internalized conjugates appears to exclude the nucleus. This internalization behavior is particularly interesting because penetration of the polymers into the nucleus should be avoided for nontoxic gene delivery as it may alter the DNA sequence. G5-Ac−FITC, which remains neutral in water due to the conversion of all the surface primary amines groups to acetamide groups, is not internalized as shown in Figure 8e, allowing the conjugate to be used as a negative control (*15*). The DIC image is provided to show that an appropriate cell density was used (Figure 8f).

Diffusion of Small Molecules through the Permeabilized Membranes. It is known that PI and fluorescein diacetate (FDA) can be employed as indicators of diffusion-in and out, respectively (*15*, *23*). PI is readily internalized into cells with disrupted membranes but is excluded from cells with intact membranes. In contrast, FDA is able to traverse intact membranes and is then converted to fluorescein (FITC) by endogenous esterase in cells. The resulting FITC is unable to travel across intact membranes but is able to traverse permeabilized membrane. Therefore, it is assumed that PI fluorescence should increase and FITC fluorescence should decrease with increasing membrane permeability. Figure 9a shows the increase in PI signal intensity induced following the incubation of KB cells with the polycationic polymers. The greatest PI intensity increase is seen using PEI, followed by G5, DEAE-DEX, and PLL. Charge neutral PVA and PEG do not induce PI internalization.

On the other hand, FITC fluorescence intensities are decreased after exposure to the polycationic polymers in a concentration-dependent manner (Figure 9b). The largest amount of intensity

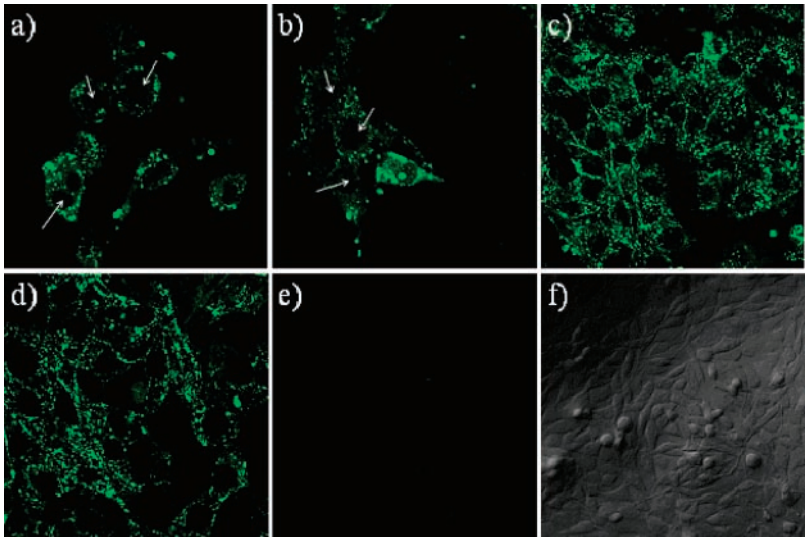

Figure 8. Confocal microscopy images of Rat2 cells incubated with (a) 6 μg/mL PLL−FITC and (b) 12 μg/mL PLL−FITC conjugates. (c) A zoomed-out image of b. Rat2 cells incubated with (d) 6 μg/mL G5-NH_2−FITC and (e) 12 μg/mL G5-Ac−FITC conjugates. (f) Differential interference contrast (DIC) image. Image f illustrates that there are a sufficient number of cells at the focal plane although nothing can be seen in fluorescence image e. Note that the green fluorescence from either PLL−FITC or G5-NH_2−FITC does not occur from within cell nuclei which are indicated by several white arrows. The location of the nuclei and the exclusion of the polycationic polymers were confirmed in previously published work using DAPI staining of the nucleus (*15*).

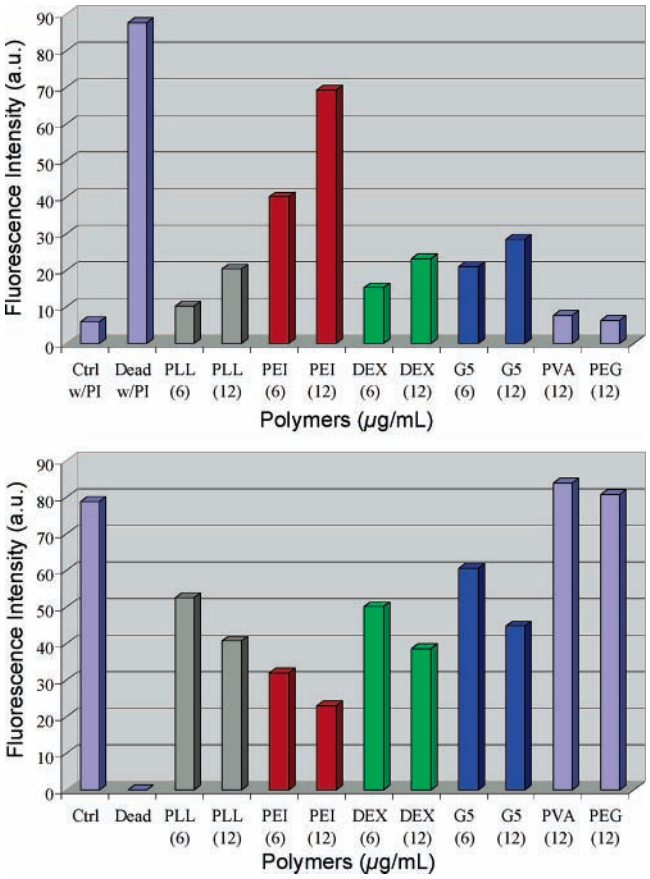

Figure 9. Fluorescence intensity of (a) propidium iodide (PI) and (b) fluorescein (FITC) from KB cells measured by flow cytometer. Note that fluorescence intensity of PI should increase while that of FITC should decrease with increase of membrane permeability. All the polycationic polymers cause an increase of PI fluorescence intensities and a decrease of FITC fluorescence. However, the neutral polymers do not cause such changes.

drop is observed in the PEI case, although DEAE-DEX, PLL, and G5 also show a decrease in FITC fluorescence intensity. As expected, PVA and PEG do not induce FITC escape.

DISCUSSION

Evidence for Hole Formation by Polycationic Polymers PEI, PLL, and DEAE-DEX. We previously reported nanoscale hole formation on both supported lipid bilayers and cellular membranes induced by positively charged PAMAM dendrimers (*15*−*19*). In this study we test the possibility of extending the proposed mechanism of dendrimer/membrane interactions, i.e., hole formation by sphere-like PAMAM dendrimers, to the more common and inexpensive polycationic polymers PEI, PLL, and DEAE-DEX. Polycationic polymer-induced disruption of various supported phospholipid bilayers including dioleoyl phosphatidyl choline (DOPC), dioleoyl phosphatidyl serine (DOPS), 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphatidic acid (POPA), and their mixtures has been reported using various methods. These techniques include quartz crystal microbalance with dissipation, leakage assay, ^{31}P NMR, and electrophoretic mobility (*9*, *10*, *24*). Furthermore, polycationic polymer-induced permeabilization of living cell membranes has also been observed in vitro using enzyme assays and flow cytometry (*13*, *15*). In this paper, we correlate two separate types of studies (model membrane and in vitro studies) by performing simultaneous experiments at similar conditions to provide a better understanding of polymer/membrane interactions.

There are two basic types of disruption seen in AFM images: membrane hole formation and membrane thinning. 'Membrane hole formation' is the complete removal of the lipid bilayer from the mica surface, resulting in defects of 4 to 5 nm in depth. The apparent discrepancy between the expected depth for a removal of a full bilayer, 5 nm, and the depths experimentally measured in this study can be explained by the varying degrees of polymer adsorption to the surface of the mica. 'Membrane thinning', which could result from the reorientation of lipids or the removal of a layer of lipid from the lipid bilayer, yields depressions ranging between approximately 2 and 3 nm (*25*−*28*).

Although the effect of each of the polymers used in the study varies in degree, each of these commercial polycationic polymers induce disruption of the bilayers as shown in the AFM images (Figures 2−4). This study is consistent in terms of observing bilayer disruption but differs in both the type of disruption and concentration dependence as compared with the previous studies which examined the interaction of positively charged dendrimers

with a DMPC-supported lipid bilayers (*16*). Our in vitro study shows enzyme (LDH with MW 135−140 kDa and ∼4.3 nm in radius and LUC with MW 61 kDa and ∼2.7 nm in radius) leakage out of the cells, polymer internalization into the cells, and diffusion in and out of small molecular probes (PI and FITC respectively) through the living cell membranes (Figures 6−9) which are also consistent with our previous report using cationic PAMAM dendrimers (*15*). Therefore, it is clear that PEI, PLL, and DEAE-DEX also cause the formation of defects in both supported lipid bilayers and cell membranes.

Relationship between Polymer Properties and Membrane Permeabilization. As modern biotechnology tends toward the adaptation of biocompatible polymers for advanced biomedical applications, a fundamental understanding of these polymers, particularly in physiological conditions, should be obtained. In this paper, we try to provide a better understanding of the relationship between physical properties of polymers and biological membranes. GPC measurement enables us to rank hydrodynamic radii of the polycationic polymers in the following order: DEAE-DEX > PEI > PLL > G5 PAMAM. According to our AFM and in vitro studies, however, the size of the polymers does not seem to markedly affect their ability to induce hole formation in the membranes. Instead, it was found that the degree of membrane permeability is strongly dependent on the number of formal charges on the polymer chain. As shown in Table 1, PEI has the greatest density of charged groups on its single polymeric chain among the polymers used in this study. Not surprisingly, a significantly high amount of LDH and LUC was released in both cell lines after incubation with PEI. Furthermore, changes in fluorescence in PI and FITC as a result of interactions between PEI and cells were greater than changes induced by the other polycationic polymers. This indicates that charge interactions play a key role in inducing changes of membrane permeability, i.e., nanoscale hole formation. Our data on PLL, DEAE-DEX, and G5-NH_2, however, suggests that electrostatic interactions are not the only factor contributing to the effectiveness of polymer-induced nanoporation. Although PLL has an order of magnitude higher charge/monomer ratio than DEAE-DEX and G5-NH_2, the difference among those polymers in terms of enzyme leakage, PI internalization, and FITC escape is not remarkable. One possible explanation is that efficacy of hole formation is dependent on the architecture of polymers. That is, sphere-like (PAMAM), branched (PEI), or ring-containing (DEAE-DEX) molecular structures are likely more effective than linear polymers (PLL) at increasing membrane permeability. Mecke et al. also suggested that the macromolecular architecture is an important factor in the polymer/membrane interactions (*16*).

Taken as whole, it is found that the common, commercial polycationic polymers PEI, PLL, and DEAE-DEX result in the formation of defects on supported lipid bilayers, enzyme leakage out of cells, polymer internalization into cells, and diffusion in and out of small molecular probes (PI and FITC) through cell membranes. Our results directly support our hypotheses: (1) commercially available polycationic polymers, PEI, PLL, and DEAE-DEX cause nanoscale hole formation in supported lipid bilayers, (2) commercially available polycationic polymers, PEI, PLL, and DEAE-DEX cause substantial permeability of the cell plasma membrane leading to enzyme and dye diffusion, and (3) charge-neutral linear polymers do not induce hole formation in supported lipid bilayers or induce a significant change in membrane permeability. The proposed hypotheses are also consistent with our previous study using PAMAM dendrimers (*15*). An interesting addition to hypothesis 1 was raised by the DEAE-DEX experiments showing membrane thinning. Polycationic polymers appear capable of both nanoscale hole formation and membrane thinning events. Our data suggest that these polycationic polymer agents may be internalized into cells through the nanoscale holes generated in the membranes and that this is also a route of internalization for other materials.

In summary, we directly observe that polycationic polymers induce hole formation in supported lipid bilayers. Our in vitro results showing that polycationic polymers permeabilize living cell membranes allowing for the diffusion of molecules in and out, are consistent with a hole-formation mechanism (*15*, *16*). Once the concentration is above the nontoxic range (up to ∼12 μg/mL), the polymers cause substantial membrane damage resulting in cell death. From this point of view, these polycationic polymers are not ideal as biocompatible drug or gene delivery agents. Instead, charge-neutral polymers that do not cause nanoscale hole formation and cell membrane permeabilization would likely serve as a better choice when paired with a targeting moiety (*29*−*31*).

Received January 26, 2006; Revised Manuscript Received March 24, 2006

We developed a molecular imaging agent (MIA), a conjugable form of PK11195 (conPK11195) coupled to a lissamine dye (Liss−ConPK11195), which targets the peripheral benzodiazepine receptor (PBR). To determine that our compound specifically binds to this 18 kDa protein, primarily expressed on the mitochondria, we performed classic binding studies on live MDA-MB-231 breast cancer cells and measured fluorescence in cell fractions of C6 glioma cells. We found that conPK11195 conjugated to the fluorophore retained significant binding to its target. Here we demonstrate the utility of the agent for in vitro imaging of live cells by specific binding to the protein of interest.

INTRODUCTION

Molecular imaging (MI) has the potential to revolutionize biological investigations and diagnostic medicine. For example, discrete intracellular molecular events can be followed in vitro in real time (*1*, *2*), and MI agents allow the in vivo study of disease progression and therapeutic efficacy monitoring (*3*−*5*). Numerous ligands have been functionalized for nuclear imaging such as autoradiography (*6*) and positron emission tomography (PET) (*7*), yet synthetic complexity, short half-life of radioligands, and expense of the detection methodologies are limitations to these applications of molecular imaging. Immunohistochemistry continues to be a valuable tool for cellular scale imaging in vitro, but the numerous steps involved in this technique make this a somewhat tedious process. The development of targeted imaging agents for in vitro screening of protein expression as well as in vitro therapy efficacy monitoring is an emerging concept in MI. Fluorescent agents with high specificity and attractive spectroscopic properties are therefore needed in the biomedical research community.

The peripheral benzodiazepine receptor (PBR), reported to be expressed primarily by mitochondria (*8*, *9*), is known to be associated with numerous biological functions including regulation of cellular proliferation, immunomodulation, regulation of cholesterol transport and steroidogenesis, and apoptosis (*10*). The precise biological relevance and clinical significance of PBR in disease progression has remained somewhat elusive, yet the overexpression in cancer (*11*, *12*) and neurodegenerative disease (*13*−*15*) is well-documented as is its correlation with metastasis and poor clinical prognosis (*16*−*18*).

Several exogenous PBR ligands have been developed which bind PBR with high affinity, including PK11195 (*19*), DAA1106 (*20*, *21*), and Ro5-4864 (*22*). Both ^{3}H- and ^{11}C-PK11195 have been used for human imaging of glioma (*23*−*26*), neurodegenerative disease (*27*), and stroke (*28*).

Papadopolous et al. reported an agent for in vitro analysis, NBD-FGIN 1-27, utilizing a fluorophore (NBD) that is not optimal for in vitro imaging (*29*). With the principal excitation and emission wavelengths for NBD (7-nitro-2,1,3-benzoxadiazole) at 466 nm and 536 nm, respectively (*30*), the effective signal-to-noise ratio for detection in cells and tissues tends to be limited by autofluorescence and scatter, especially when compared to longer wavelength dyes (*1*). Furthermore, the fluorescence sensitivity of NBD agents is limited by relatively low ($\sim$8000 L mol^{-1} cm^{-1}) aqueous phase molar extinction coefficients (*30*). More recently, Chen et al has prepared PBR targeted photodynamic therapy (PDT) probes based on pyropheophorbide metal complexes (*31*). These probes appear to have utility for therapeutic purposes, but the potential for performing imaging with these compounds is less clearly defined (*31*).

We recently reported another PBR targeted MI agent, a lanthanide chelate (Ln-PK11195) (*32*, *33*). This agent is unique because it has the potential to provide both an optical and MR signature depending on the metal ion that is chelated (i.e. Eu^{3+} for optical and Gd^{3+} for MR) (*34*). While we demonstrated optical microscopy of live cells using the europium chelate (*34*), excitation of the sensitizing antenna at 320 nm is unattractive due to the high energy of UV radiation, and the attenuated transmission through glass optical trains of standard microscopes limits the usefulness of this agent.

To address this limitation, we have prepared Liss−ConPK11195, which has a relatively high molar extinction coefficient, thus allowing improved sensitivity for microscopy imaging and high-throughput screening detection in multiwell plates. Here we report the synthesis and spectroscopic characterization of Liss−ConPK11195, demonstrate specific binding in live cells, and confirm the intracellular location by isolation of the mitochondrial fraction.

EXPERIMENTAL PROCEDURES

Synthesis and Spectroscopic Characterization of Liss−ConPK11195. Lissamine−Rhodamine B sulfonyl chloride was

purchased from Molecular Probes. Conjugable PK11195 (as previously reported (*33*)) was dissolved in dry chloroform along with 1 equiv of triethylamine (TEA). Next, 1.5 equiv of Lissamine−Rhodamine B sulfonyl chloride was added in one part. The vessel was purged with argon, and the reaction was allowed to continue overnight. Formation of the product was monitored via thin-layer chromatography (TLC) ($R_f = 0.8$, 9:1 chloroform/methanol). Purification of the product was achieved using column chromatography on silica, eluting with a 30:1:0.1 mixture of chloroform, methanol, and aqueous ammonia. Absorbance was measured using a Shimadzu 1700 spectrophotometer, and fluorescence was recorded using a PTI fluorometer.

^{1}H NMR ($CDCl_3$): δ 1.31 (t, 12H), 1.42 (m, 2H), 1.54 (m, 2H), 1.67 (bs, 4H), 2.90 (q, 2H), 3.39 (m, 2H), 3.57 (q, 8H), 6.70 (d, 2H), 6.87 (d, 2H), 7.20 (m, 3H), 7.46−7.57 (m, 6H), 7.65 (m, 1H), 7.73 (m, 1H), 8.03 (d, 1H), 8.22 (t, 1H), 8.36 (d, 1H), 8.63 (s, 1H), 8.73 (s, 1H).

ESI MS+ (calcd: found): (921.32: 922.45 and 944.44 M + Na^+).

Tissue Culture. C6 glioma cells were cultured in Dulbecco's modified Eagle medium (DMEM)−F12 medium (Gibco/Invitrogen) supplemented with 0.1% gentamicin sulfate (Biowhittaker). Standard medium pH was adjusted to 7.4. Cells were maintained in a tissue culture incubator (Forma Scientific) at 37 °C, 5% CO_2. MDA-MB-231 cells were cultured in closed cap flasks, with 90% Leibovitz's L-15 medium, supplemented with 2 mM L-glutamine and 10% fetal bovine serum.

PBR Binding Affinity Determinations. A standard fluorescence calibration curve for Liss−ConPK11195 was prepared using a Beckman Coulter DTX 880 plate reader and found linear over the concentration range 0−10 μM. Twenty-four hours prior to performing the binding experiments, MDA-MB-231 cells were plated into NUNC 96 well (optical) plates at a density of 4×10^4 cells (80% confluence). To measure specific binding, cells were incubated in triplicate for 30 min with standard dilutions of Liss−ConPK11195 (0, 1 μM, 3.2 μM, 10 μM, 32 μM) without and with excess (10 μM "cold") unlabeled DAA1106 (prepared as previously reported) (*35*). The plate was subsequently rinsed with MEM/Cellgro and read on the plate reader. When the values for the nonspecific binding were subtracted from the total, the specific binding signal was revealed. These data were analyzed by Scatchard analysis using Graphpad Prism software.

Live Cell Imaging. Cells were plated in MaTek dishes and incubated with the imaging agent by first aspirating the growth media and then adding media containing the contrast agent. Incubation concentrations ranged from 1 nM to 100 μM, although concentrations above 10 μM seemed to produce nonspecific staining in the microscopy experiments (data not shown). The cells were incubated with the imaging agent for 45 min at 37 °C, 5% CO_2 as previously reported (*29*). At the end of the incubation time, cells were rinsed with fresh medium three times and imaged.

PBR Functional Displacement of Liss−ConPK11195. Forty-eight hours prior to imaging, 2.5×10^4 C6 glioma cells were plated into MaTek dishes and propagated at 37 °C under 5% CO_2. The cells were either incubated for 45 min with 1 μM Liss−ConPK11195 or coincubated for 45 min with 1 μM Liss−ConPK11195 and 100 μM PK11195 (Sigma-Aldrich). The cells were subsequently rinsed with saline to remove any unbound contrast agent, and then imaged using fluorescence microscopy. The cellular fluorescence intensity was evaluated by measuring the gray scale intensities of individual cells from multiple assays. A one-way ANOVA (Prism 4.0) at the 95% confidence level was used to indicate the statistical significance of the data.

Microscopy. Microscopy was performed using a Nikon TE 2000-U inverted microscope, coupled to a Q-Imaging Retiga-EXi camera. Image acquisition was controlled using Metamorph (version 6.2). The optical train used to image Liss−ConPK11195 consisted of a mercury lamp and a Texas Red filter set (Chroma, excitation 575 nm × 20 nm, emission 625 nm × 50 nm). Confocal microscopy was performed using a Zeiss LSM510 confocal microscope, 543 nm excitation line and emission collected through a 620 nm × 50 nm filter.

Mitochondrial Fractionation Assay. Cellular Disruption. A total of ninety (90) 10 cm culture flasks of C6 glial cells were propagated to near confluency. Half of the plates (45) were incubated with 1 μM Liss−ConPK11195 for 45 min, and the other half (45) were left unincubated as control. At the end of the incubation time, each plate of cells was rinsed with approximately 5 mL of ice-cold disruption buffer ("H" buffer, 5 mM HEPES, 0.21 M D-mannitol, 0.07 M sucrose, 2 mM benzamidine, 2 mM α-toluenesulfonyl fluoride, 4 mM magnesium chloride, pH 7.4) (5×), and then the monolayer was scraped from the surface of the dish. The combined scrapings from the labeled and unlabeled plates were separately resuspended in ice-cold disruption buffer to yield 10 mL total volume. The cells were then ruptured by 50 strokes with a glass homogenizer, type A pestle. The homogenates were centrifuged at 200*g* for 1 min. The resulting pellet was then rehomogenized in ice-cold disruption buffer (diluted to 1/4 strength) and centrifuged at 200*g* for 1 min. Next, the supernatants were combined and centrifuged at 200*g* for 1 min. The resulting supernatant was filtered through four layers of cheesecloth and centrifuged at 0.6K × *g* for 20 min (fraction 1). The resulting supernatant was then centrifuged at 10K × *g* for 2 h, and the pellet (fraction 2) was separated from the supernatant (fraction 3).

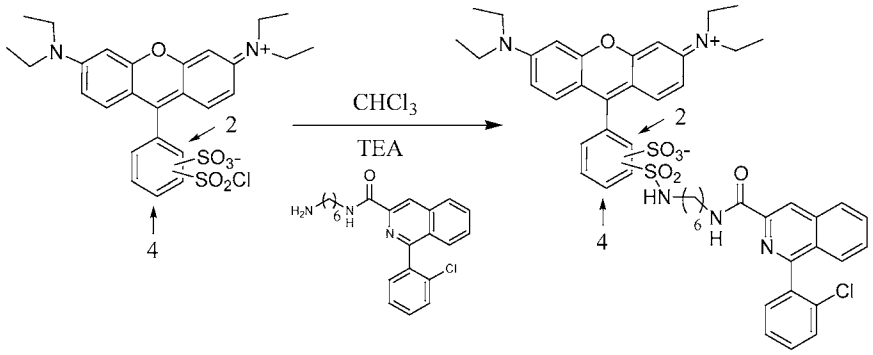
Mitochondrial Fluorescence Assay. Fluorescence measurements were made using a PTI fluorimeter and standard quartz cuvettes. A fluorescence calibration curve was prepared using increasing concentrations of Liss−ConPK11195 solution in PBS (1−20 nm). Samples (1.5 mg/mL) from fractions 1 and 2 were prepared by diluting the pellet 100:1 in PBS. Fraction 3 was run neat. Samples were excited at 571 nm, and the emission was scanned from 580 nm to 630 nm. The principal emission band was found at 585 nm, and the reported fluorescence values are from said wavelength.

Corrected Mitochondrial Activity. Succinate dehydrogenase activity was assayed via the colorimetric reduction of iodonitrotetrazolium (INT) chloride using a protocol previously reported (*36*). Briefly, to prepare the enzyme solution, a 20 μL protein suspension (1.5 mg/mL verified by the Bradford assay) was added to 500 μL of freshly prepared INT reagent (~35 °C) and absorbance was continuously monitored at 500 nm for 10 min (triplicate measurement). The INT reagent without succinate, subtracted from the sample rates, served as a control. The specific activity was calculated according to the following equation: units/mL = ΔA/min × 5.18. A one-way ANOVA (Prism 4.0) at the 95% confidence level was used to indicate the statistical significance of the data. INT reagent = 100 mM triethanolamine, 0.5 mM EDTA, 2 mM INT, 12 g/L Tween 20, 20 mM succinic acid.

RESULTS AND DISCUSSION

We synthesized a PBR targeted MI agent, Liss−ConPK11195, by labeling our previously reported conjugable PK11195 ligand (*33*) with Lissamine−Rhodamine B sulfonyl chloride (Scheme 1). The agent was easily purified using standard column chromatography on silica gel. To determine whether the structure/function relationship of the dye was changed upon coupling, we measured the absorbance and fluorescence properties of Liss−ConPK11195 in aqueous media (Figure 1). The absorption maximum was centered at 571 nm, and emission was centered at 585 nm, similar to that of the

Scheme 1. Synthesis of Liss−ConPk11195



free dye. The molar extinction coefficient for Liss−ConPK11195 was determined to be 35 000 L mol^{-1} cm^{-1} in water, enabling sensitive detection of the imaging agent and demonstrating that conjugation did not significantly alter the function of the dye. While the absorbance and emission bands for Liss−ConPK11195 do not show as large a Stokes shift as the previously reported lanthanide chelate agent−PBR agent (*33*), it does have spectral characteristics leading to utility for fluorescence microscopy and commercially available fluorescence plate readers.

We next determined that conjugation of the dye to the ligand did not prevent binding to the target and that it was specific for PBR. We performed a classic binding assay in a multiwell plate in a live-cell format. Binding affinity (K_d) of Liss−ConPK11195 to PBR was calculated to be 1 μM (data not shown). While this value is higher than expected for an unperturbed PK11195 analogue, the imaging work shown here and by others (*31*) demonstrates that PBR targeted agents with micromolar binding affinities still have utility for cellular targeting applications. It is likely that the presence of the bulky, charged fluorophore and the minor structural differences between PK11195 and the conjugable PK11195 analogue contribute to a reduced binding affinity (*33*).

Fluorescence microscopy was used to characterize the cellular uptake and distribution of Liss−ConPK11195 in PBR overexpressing C6 glioma and MDA-MB-231 breast cancer cells. We first incubated live C6 glioma cells with the imaging agent (10 μM) and then rinsed the cells and imaged them using an epi-illumination fluorescence microscope. As controls, we imaged a similar population of cells with Lissamine after incubation with the free dye (nontargeted, 10 μM) and another population of unincubated cells to evaluate the level of autofluorescence. As seen in Figure 2A−D, both controls (unlabeled (A, B) and free Lissamine labeled (C, D) C6 cells) lack fluorescence, while cells incubated with Liss−ConPK11195 (Figure 2E,F) show perinuclear fluorescence. Fluorescence was also easily detected by microscopy in C6 cells at a concentration of 100 nM (data not shown). MDA-MB-231 breast cancer cells were imaged identically with a 100 nM concentration Liss−ConPK11195 yielding bright perinuclear fluorescence (Figure 3). Controls were the same as with the C6 cells and are shown in Figure 3A−D.

Confocal microscopy verified that Liss−ConPK11195 was internalized in C6 cells labeled with the MI agent as previously described. Fluorescence appeared to be perinuclear while no fluorescence was visualized on the cell surface (Figure 4). These images are consistent with previous reports describing the

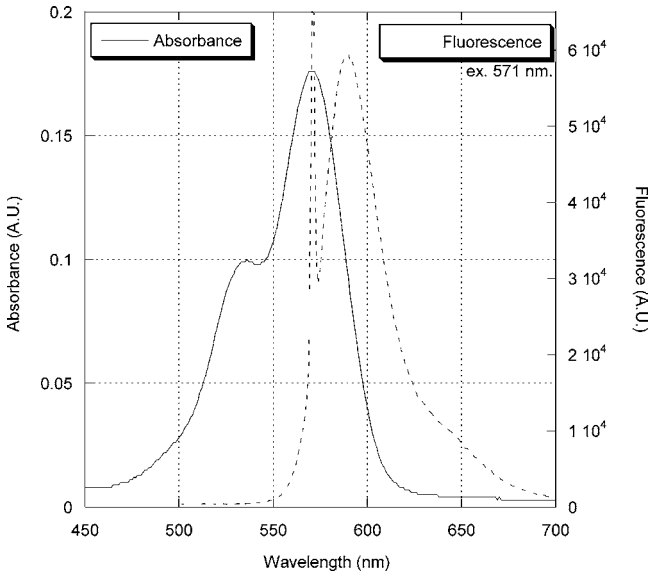


Figure 1. Liss−ConPK11195 aqueous spectroscopy (agent concentration = 5 μM).

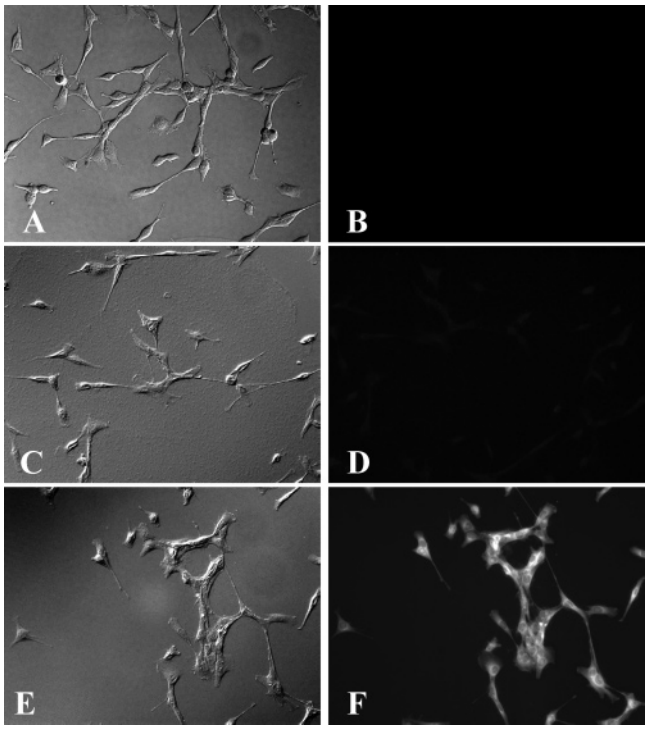

Figure 2. Fluorescent labeling studies of PBR in C6 glioma cells using Liss-PK11195. Figure 4. Confocal imaging of PBR in C6 rat glioma cell line. C6 cells were labeled with 1 μM Liss−ConPK11195 and imaged using a Zeiss confocal microscope. False color fluorescence image/DIC overlay demonstrating typical cellular morphology and predominately perinuclear fluorescence.

primary intracellular location of PBR and immuohistochemical PBR staining (*29*).

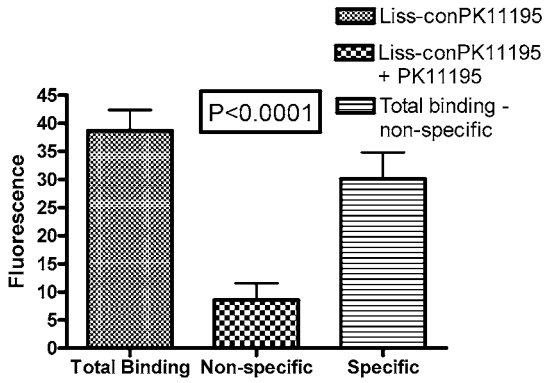

Figure 5. Live cell fluorescence displacement of 1 μM Liss−ConPK11195 with 100-fold excess PK 11195 in C6 glioma cells. Left bar: total binding. Middle bar: nonspecific binding. Right bar: specific binding. Autofluorescence was subtracted from each value. *P* value was calculated via one-way ANOVA, comparing fluorescence intensity of total, nonspecific, and specific binding.

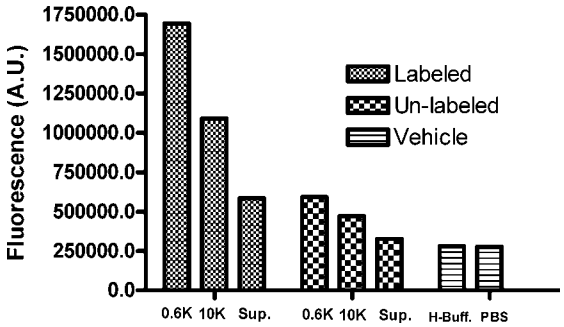

Figure 6. Fluorescence intensity from C6 cellular fractionations, 10K $\times$ *g*, 0.6K $\times$ *g*, and supernatant. Bars represent fluorescence intensity from labeled, unlabeled, and vehicle (control) samples.

An optical competitive binding assay was performed with live C6 glioma cells using excess "cold" PK11195 as the competitor with the dye. Labeled, unlabeled, and PK11195 challenged cells were imaged with fluorescence microscopy. Conservation of imaging settings, including integration time, binning, and magnification, gave a direct comparison of the cells labeled under the various medium conditions, and we quantified the displacement by subtracting the nonspecific binding from the total binding. Figure 5 shows total, specific, and nonspecific binding, with the statistical significance of all three measurements verified by one-way ANOVA analysis ($P < 0.0001$).

Cellular fractionation (*37*) confirmed the observations of the intracellular localization made by microscopy. A standard fluorimeter was used to measure fluorescence in mitochondrial and cytosolic cell fractions. C6 glioma cells were incubated with and without (control) Liss−ConPK11195, rinsed, and then mechanically disrupted. Lysates were then purified using a protocol that yields two mitochondrial-rich fractions (0.6K $\times$ *g* and 10K $\times$ *g*) (*37*). Next, we measured the relative fluorescence emission (excitation 571 nm, emission 580−630 nm) of all the cellular fractions collected (cytosol, 0.6K $\times$ *g* fraction, and 10K $\times$ *g* fraction). Liss−ConPK11195 fluorescence was detected in all three fractions with significant binding in the 0.6K $\times$ *g* and the 10K $\times$ *g* mitochondrial fractions (Figure 6). Fluorescence in the cytosolic fraction (supernatant) was detectable, yet miniscule in comparison to the other fractions measured, and suggests either nonspecific binding or binding to another protein in the cytosolic fraction. Fluorescence values for unlabeled cells and vehicle (as control) represent the bacK $\times$ ground signal and indicate some autofluorescence at the measured wavelength. Mitochondrial content of the assayed fractions was confirmed by measuring succinate dehydrogenase

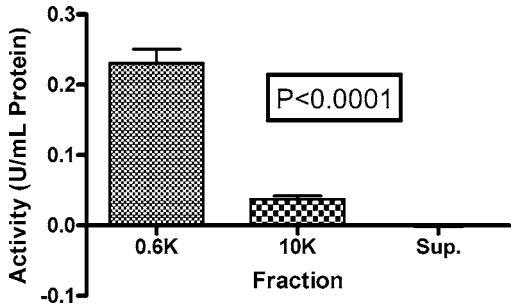

Figure 7. Corrected specific succinate dehydrogenase (mitochondrial) activity (U/mL) for the three assayed cellular fractions. Value represents the difference between the experimental and control (nonspecific) activities for each sample. *P* value calculated via one-way ANOVA.

activity (Figure 7). As expected, the mitochondrial fractions had statistically significant succinate dehydrogenase activity compared to the cytosolic fraction ($P < 0.0001$).

CONCLUSIONS

In this report we have demonstrated the synthesis, spectroscopic, and biological characterization of a novel optical molecular imaging agent targeting PBR. Liss−ConPK11195 specifically binds to PBR and displays attractive optical properties for live cell fluorescence microscopic imaging and high-throughput plate reader assays. While immunofluorescence has been a valuable technique for measuring proteins of interest in fixed cells, live cell molecular imaging has the potential to be translated to rapid high-throughput screening of therapies and to in vivo imaging. With molecular imaging being used increasingly in medical diagnostics, it is important to identify potential agents for reporting physiological processes such as protein expression. Here we show that simple synthetic chemistry can be used to enhance in vitro studies of disease processes, by targeting PBR expression with an optical imaging agent.

ACKNOWLEDGMENT

The authors would like to acknowledge Dr. Vassilios Papadopoulos for helpful discussions and assistance with the mitochondrial assay.

Apoptosis, or programmed cell death, plays an important role in the etiology of a variety of diseases, including cancer and myocardial infarction. Visualization of apoptosis would allow both early detection of therapy efficiency and evaluation of disease progression. To that aim, we synthesized two types of lipid-based bimodal contrast agents that enable the detection of apoptotic cells with both MRI and optical techniques. MR contrast was provided either by entrapment of iron oxide particles within pegylated micelles or by incorporation of Gd-DTPA-bis(stearylamide) (Gd-DTPA-BSA) lipids within the lipid bilayer of pegylated liposomes. The resulting contrast agents were approximately 10 and 100 nm in diameter, respectively. Additional fluorescent lipids were incorporated in the lipid (bi)layer of the contrast agents to allow parallel detection with optical methods. Multiple human recombinant annexin A5 molecules were covalently coupled to introduce specificity for apoptotic cells. Both annexin A5-conjugated contrast agents were shown to significantly increase the relaxation rates of apoptotic cell pellets compared to untreated control cells and apoptotic cells that were treated with nonfunctionalized nanoparticles. Increased relaxation rates were confirmed to originate from association of the contrast agents to apoptotic cells by confocal microscopy. The targeted nanoparticles presented in this study, which differ both in size and in magnetic properties, may have applications for the in vivo detection of apoptosis.

INTRODUCTION

Apoptosis, or programmed cell death, is an important feature of normal tissue development and homeostasis. Deregulation of the apoptotic program plays a key role in a variety of diseases, including cancer, autoimmune diseases, neurodegenerative diseases, atherosclerosis, and myocardial infarction (*1*, *2*). Therefore the apoptotic pathway appears to be a promising target for therapeutic purposes. Stimulation of the apoptotic program is, for example, used for tumor treatment (*3*) by irradiation or cytotoxic chemotherapy, whereas myocardial infarct size due to reperfusion injury was shown to be reduced by early application of anti-apoptotic treatment (*4*). Visualization of apoptosis is therefore of great importance for the early detection of therapy efficiency and the evaluation of disease progression.

Traditionally the detection of apoptosis has been based on changes in the morphology and the cytoplasmic compartment of the cell (*5*). More recently several studies have been performed in which translocation of the phospholipid phosphatidylserine (PS) was used for the detection of apoptosis (*6*). PS is exposed on the outer leaflet of the apoptotic cell membrane for recognition by surface proteins on macrophages and fibroblasts, which subsequently engulf these cells prior to lysis (*7*). The expression of PS can also be exploited as a marker for apoptosis that can be detected by annexin A5 or synaptotagmin I conjugates (*8*). Both proteins bind with high affinity to PS in the presence of Ca^{2+}. Several fluorescent annexin A5 conjugates have been successfully used for the detection of apoptosis in vitro (*8*, *9*) and in vivo (*10*, *11*). Radiolabeled annexin A5 was shown to enable the in vivo visualization of apoptosis in animal models (*12*), as well as in patients with acute myocardial infarction (*13*).

Both nuclear and optical techniques allow the detection of contrast agents at nano- to picomolar concentrations. However optical imaging techniques suffer from limited tissue penetration depth, whereas nuclear techniques provide images with a low spatial resolution against a poor anatomical background. Magnetic resonance imaging (MRI) allows the noninvasive detection of MR contrast agents in the micro- to millimolar concentration range in high spatial resolution anatomical images throughout the complete living animal. Conjugation of annexin A5 to cross-linked iron oxide particles (CLIO) was shown to enable the detection of apoptosis with MRI both in vitro (*14*) and in vivo (*15*). As an alternative to annexin A5, the C_2 domain of synaptotagmin I was conjugated to either superparamagnetic iron oxide particles (SPIO) or multiple Gd-DTPA molecules (*16*). Additional labeling of MRI contrast agents with fluorescent dyes would allow for colocalization of the detected contrast agent in MR images at the macroscopic level and at the cellular level with optical techniques. Several bimodal probes have been proposed that have one or multiple fluorescent dyes conjugated to either low molecular weight MR contrast agents, gadolinium-tetraazacyclododecanetetraacetic acid (Gd-DOTA) (*17*), or high molecular weight MR contrast agents, for example, complexes of polymers and gadolinium-dietjylenetriaminepentaacetric acid (Gd-DTPA) (*17*, *18*), paramagnetic liposomes (*19*, *20*), or iron oxide particles (*21*, *22*).

Here we present the synthesis of two types of lipid-based nanoparticulate contrast agents, which differ both in size and

magnetic properties. The first bimodal nanoparticle is based on liposomes of ~100 nm diameter in which both paramagnetic lipids, Gd-DTPA-bis(stearylamide) (Gd-DTPA-BSA), and fluorescent lipids are incorporated in the lipid bilayer. The second bimodal nanoparticle of ~10 nm was prepared by enclosure of hydrophobic iron oxide particles in a fluorescent lipid containing micellular shell. The resulting nanoparticles can be referred to as positive and negative MR contrast agents, respectively. Amphiphiles with a functional headgroup were incorporated in the lipid layer(s) of both contrast agents to allow the covalent coupling of multiple recombinant annexin A5 proteins for targeting. In addition, the contrast agents were pegylated for improved bioavailability and circulation time (*23*).

In this study, apoptotic Jurkat cells were incubated with both annexin A5-functionalized nanoparticles to determine their ability to detect apoptosis with MRI and fluorescence microscopy in vitro.

EXPERIMENTAL PROCEDURES

Materials. 1,2-Distearoyl-*sn*-glycero-3-phosphocholine (DSPC), cholesterol, 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG2000−DSPE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide-(poly(ethylene glycol))2000] (Mal−PEG2000−DSPE), and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(carboxyfluorescein) (PE−carboxyfluorescein) were obtained from Avanti Polar Lipids (Albaster, AL). Gd-DTPA-bis(stearylamide) (Gd-DTPA-BSA) was purchased from Gateway Chemical Technology (St. Louis, MO). An ultrastable colloidal suspension of oleic acid coated magnetite (Fe_3O_4) particles of 3−15 nm in toluene carrier liquid (ferrofluid) was obtained from the University "Polytehnica" of Timisoara (Romania). Liposomes were sized with a Lipofast Extruder (Avestin, Canada). Polycarbonate filters that were required for liposome extrusion were obtained from Costar (Cambridge, MA). Dynamic light scattering (DLS) was performed with a Malvern 4700 system using an argon-ion laser (488 nm) operating at 10.4 mW (Uniphase) and PCS (photon correlation spectrometry) software for Windows, version 1.34 (Malvern, U.K.).

N-2-Hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) and ethylenediaminetetraacetic acid (EDTA) (Titriplex) were purchased from Merck (Darmstadt, Germany). An iron standard solution ($Fe(NO_3)_3$) was obtained from Merck. All other chemicals were of analytic grade or of the best grade available.

Preparation of Bimodal Lipid-Based Contrast Agents. *Preparation of Superparamagnetic Micelles.* Water-insoluble iron oxide particles were coated with phospholipids (Figure 1A) according to a modified procedure previously described for quantum dots (*24*). Typically, 20 μL of oleic acid coated iron oxide particles (magnetite) in toluene (50 g of magnetite/100 mL) with a mean diameter of 5 nm were diluted in 1 mL of chloroform. A chloroform solution containing 95 μmol of PEG2000−DSPE and 5 μmol of Mal−PEG2000−DSPE, of which the latter allowed conjugation of annexin A5 to the distal ends of the PEG chains, was added to the iron oxide particle solution. For fluorescence microscopy and flow cytometry, 1 mol % PE−carboxyfluorescein was added as well. The solvent was evaporated to dryness by rotary evaporation, and the obtained mixed film was heated to 65 °C. Next, the film was hydrated with a 65 °C HEPES buffer (20 mM HEPES, 135 mM NaCl, pH 6.7). This suspension was vigorously vortexed and heated to 65 °C until a clear solution was obtained, indicative of a small size for the formed aggregates. Thereafter, the sample was centrifuged (1 h at 500 000*g*) to separate micelles with a magnetite core from empty micelles. The supernatant was removed gently, and the pellet was resuspended in 1 mL HEPES buffer and filtered through a 200 nm polycarbonate filter. The mean size was determined to be approximately 10 nm with dynamic light scattering.

Preparation of Paramagnetic Liposomes. Paramagnetic liposomes were prepared by lipid film hydration (Figure 1B) of a lipid mixture that typically contained a total lipid amount of 100 μmol. Gd-DTPA-BSA, DSPC, cholesterol, PEG2000−DSPE, and Mal−PEG2000−DSPE were added at a molar ratio of 0.75/1.1/1/0.075/0.075. Mal−PEG2000−DSPE was included for conjugation of annexin A5 to the distal ends of the PEG chains. The lipid mixture was dissolved in chloroform/methanol 1:1 (v/v) and 0.1 mol % PE−carboxyfluorescein was added to allow the detection of the paramagnetic liposomes with flow cytometry and fluorescence microscopy. The solvent was subsequently removed by rotary evaporation, followed by additional drying under nitrogen. The completely dried lipid film was hydrated in 4 mL of HEPES-buffered saline (20 mM HEPES and 135 mM NaCl, pH 6.7) at 65 °C. The resulting large multilamellar vesicles were downsized by extrusion at 65 °C through a stack of two 200 nm filters (four times), followed by extrusion through a stack of two 100 nm filters (10 times). The mean size was determined to be approximately 100 nm with dynamic light scattering.

Annexin A5-Functionalized Nanoparticles. *Annexin A5-cys.* Recombinant human annexin A5 was labeled with fluorescein−isothiocyanate (Amersham Biosciences). To allow easy coupling of annexin A5 to maleimide-functionalized biomolecules, a variant of annexin A5 was engineered having a single cysteine residue in the N-terminal tail (annexin A5-cys). The PS and apoptotic cell binding properties of annexin A5-cys are identical to those of recombinant human annexin A5 as was measured by ellipsometry (*25*) and flow cytometry (*26*), respectively.

Coupling of Annexin A5-cys. Annexin A5-cys was conjugated to the maleimide groups of both Mal−PEG2000−DSPE-containing contrast agents by sulfhydryl−maleimide coupling. Prior to conjugation, annexin A5-cys was reactivated by cleavage of sulfide bridges with 10 mM DTT at 37 °C. After 1.5 h, 10 mM EDTA was added to stop this reaction. DTT and EDTA were subsequently removed by dialysis of 1 mL of activated annexin A5-cys in a 12−14 kD MWCO membrane (Pierce) against 1000 mL of dialysis buffer (25 mM Hepes, 140 mM NaCl, 1 mM EDTA, pH 7.4). Dialysis was performed overnight at 4 °C followed by a change of the dialysis buffer to continue dialysis of the activated annexin A5-cys for another 4 h at room temperature.

For the superparamagnetic micelles, 100 μg of purified activated annexin A5-cys was added per micromole of total lipid, whereas for the paramagnetic liposomes 25 μg of purified activated annexin A5-cys was added per micromole of total lipid. Coupling was performed overnight at 4 °C. The resulting mixture was ultracentrifuged (2 times, 45 min at 60 000 rpm) to separate the annexin A5-conjugated contrast agents from unbound annexin A5-cys.

Contrast Agent Characterization. *Cryo Transmission Electron Microscopy.* Size and morphology of the lipid-based nanoparticles were measured with cryo transmission electron microscopy (cyro-TEM). Suspensions of the contrast agents were vitrified according to a procedure previously described by Frederik and Hubert (*27*). The vitrified specimens were stored under liquid nitrogen and observed at 103 K (Gatan 626 cryoholder) in a Philips CM12 microscope, operating at 120 kV.

Nanoparticle Concentration. The concentration of the paramagnetic liposomes used for in vitro targeting experiments was based on the total lipid concentration, which was determined by phosphate analysis according to Rouser (*28*) after destruction with perchloric acid. The concentration of the superparamagnetic micelles that were used for the in vitro targeting experiments

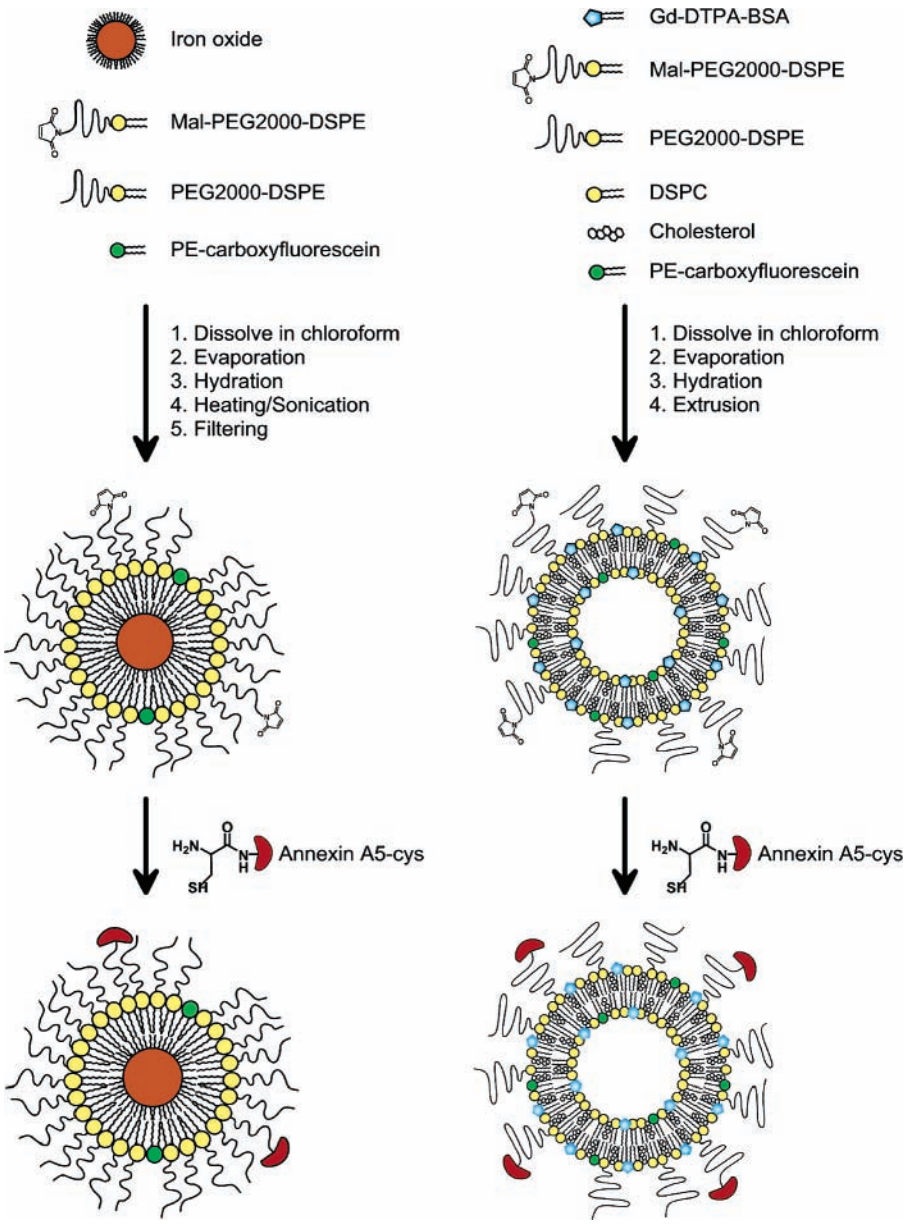

Figure 1. Preparation of annexin A5-functionalized superparamagnetic micelles (left) and annexin A5-functionalized paramagnetic liposomes (right). In both systems, fluorescent lipids were incorporated in the lipid layer for fluorescence microscopy or flow cytometry. MR contrast was obtained by incorporation of superparamagnetic iron oxide in the micellular core (left) or by incorporation of paramagnetic Gd-DTPA-BSA in the lipid bilayer of the liposomes (right). Both contrast agents were functionalized with annexin A5.

was based on the total iron content, which was measured with atomic absorption spectrometry (Philips, PU 9100X). For atomic absorption spectrometry (AAS) measurements, the micellular iron oxide particles were destructed in 100 μL of perchloric acid at 180 °C and subsequently diluted to a volume of 1.5 mL with ultrapure water. The same procedure was followed for calibration samples containing known amounts of iron from the iron standard solution ($Fe(NO_3)_3$).

Relaxivities. The ability of an MR contrast agent to reduce the intrinsic T_1 or T_2 relaxation times of water is generally described by the so-called molar relaxivities r_1 and r_2, respectively, which are expressed in units of $(mM^{-1}\ Gd)\cdot s^{-1}$ or $(mM^{-1}\ Fe)\cdot s^{-1}$. Relaxivities r_1 and r_2 of both lipid-based contrast agents were measured in HEPES-buffered saline (20 mM HEPES and 135 mM NaCl, pH 7.4) at room temperature (RT) with a tabletop 20 MHz NMR spectrometer (Bruker, Minispec). T_1-relaxation times were measured with an inversion recovery sequence. A CPMG sequence was used for T_2 measurements. To determine the r_1 and r_2 of the lipidic paramagnetic nanoparticles, the gadolinium concentration was measured with NMR using the following procedure. Liposomes were destructed with perchloric acid at 180 °C. The resulting mixture was evaporated to dryness and dissolved in a known volume of ultrapure water. The gadolinium concentration was determined from calibration samples containing known amounts of $GdCl_3$ for which the same protocol was performed. Concentrations obtained with this procedure were essentially identical to the values that were measured with inductively coupled plasma atomic emission spectroscopy (ICP-AES). Iron concentrations of the superparamagnetic micellular iron oxide particles were measured by AAS, as described above.

Specificity of the Nanoparticles for Phosphatidylserine. *Ellipsometry.* The PS binding properties of the annexin A5-conjugated lipidic nanoparticles were measured by ellipsometry as described in ref *25*. Briefly, a silicium plate was coated with a bilayer of PS and phosphatidylcholine (PC) in a molar ratio of 20:80. Binding of the nanoparticles to this surface was assessed in binding buffer (10 mM HEPES, 150 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 2.5 mM $CaCl_2$, pH 7.4) and monitored by continuously measuring the polarization angle of the reflected

elliptically polarized light. Once the polarization angle reached its steady state, 5 mM EDTA was added to investigate Ca^{2+} dependency.

In Vitro Targeting. *Cell Culture.* The T-lymphoma cell line Jurkat (ATCC) was grown in RPMI 1640 medium (Gibco), which was supplemented with 10% fetal calf serum and a mixture of antibiotics (100 units mL^{-1} penicillin, 0.1 mg mL^{-1} streptomycin (Biochrom AG)). Cells were grown at 37 °C in a humidified atmosphere and 5% CO_2. To induce apoptosis, Jurkat cells were resuspended to 10^6 cells mL^{-1} of medium and treated with 200 ng mL^{-1} anti-Fas (CD95 human monoclonal antibody, Beckman Coulter B.V.) for 3 h at 37 °C in a humidified atmosphere and 5% CO_2, which initiates apoptosis in approximately 40−50% of the cells.

Flow Cytometry. Flow cytometry measurements (Coulter EPICS-XL-MCL) were performed to determine whether the cell population was successfully stimulated to undergo apoptosis. For flow cytometry, 25 000 cells were resuspended in 250 μL of binding buffer and incubated with annexin A5−FITC (250 ng/mL) during 5 min. Cell populations containing ≥30% apoptotic cells were used to measure binding of both the nonfunctionalized and the annexin A5-conjugated nanoparticles.

MRI and Confocal Laser Scanning Microscopy. Apoptotic Jurkat cells were incubated with both nonfunctionalized and annexin A5-conjugated contrast agents to study the ability of these contrast agents to change the relaxation times of apoptotic cells. Each sample contained approximately 5×10^6 cells to obtain a loosely packed pellet that was sufficient for slice-planning in MRI experiments. Experiments were performed as follows. After stimulation with anti-Fas, cells were harvested and resuspended to 10^6 cells mL^{-1} of binding buffer or HEPES-buffered saline that was supplemented with EDTA (25 mM HEPES, 140 mM NaCl, and 5 mM EDTA, pH 7.4). Annexin A5-conjugated superparamagnetic micelles or paramagnetic liposomes were added to a final concentration of 5 μg mL^{-1} iron or 0.2 mM total lipid, respectively. Control cells were either treated with equivalent amounts of nonfunctionalized contrast agents or not exposed to contrast agents at all. All cell samples were incubated with the contrast agents for 30 min on a rollerbench at room temperature. Subsequently each sample was washed 3 times (5 min, 300 g) in a buffer that was identical to the buffer in which the incubation was performed. All samples were subsequently resuspended in a 4% paraformaldehyde solution (pH 8), which was prepared either in binding buffer or in HEPES-buffered saline that was supplemented with 5 mM EDTA. The cells were allowed to settle as a loosely packed pellet in a 250 μL PCR tube overnight at 4 °C.

MRI on Apoptotic Cell Pellets. MRI on cell pellets was performed at 6.3 T (Bruker, BioSpec), using a 3 cm send and receive birdcage coil (Rapid Biomedical). A maximum of four samples were measured at once in a custom-made sample holder to prevent artifacts from B_1 inhomogeneities. A T_2-weighted image of a pellet of cells that were incubated with superparamagnetic micelles was obtained with a multislice spin−echo sequence (TE 14.7 ms, TR 6000 ms). For quantification of T_2-relaxation times a series of T_2-weighted images with 20 echo times in the range of 4−200 ms was obtained with a multislice spin−echo sequence (TR 6000 ms). All T_2-weighted images were obtained with a slice thickness of 1 mm, field of view 1.5 $\times$ 2.5 cm^2, matrix size of 64 $\times$ 64, and four averages. A T_1-weighted image of a pellet of cells that were treated with paramagnetic liposomes was obtained with a multislice spin−echo sequence (TE 4.3 ms, TR 950 ms). For quantification of T_1-values, a series of FLASH images were obtained after inversion of the longitudinal magnetization (segmented IR). Images were obtained with a slice thickness of 1 mm, field of view 3 $\times$ 3 cm^2, matrix size of 128 $\times$ 128, 16 segments, TE 1.5 ms, TR 3 s, α 15°, and four averages. A total of 50 images were obtained following inversion with the following parameters: first inversion delay 73.5 ms, separation time 48 ms, and inversion repetition 20 s.

Pixel-by-pixel T_2 and T_1 maps were reconstructed from the acquired T_2- and T_1-weighted images, respectively, using a nonlinear least-squares data fitting procedure by the Gauss−Newton method programmed in Matlab. T_1 maps were corrected for saturation as described by Haase et al. (*29*). Average T_2 and T_1 values within the cell pellets were determined in a region of interest typically containing 10 pixels.

Confocal Laser Scanning Microscopy. Confocal microscopy (Axiovert 100M, Zeiss) was performed on cells that were previously used for MR experiments to enable localization of the lipid-based contrast agents at the cellular level.

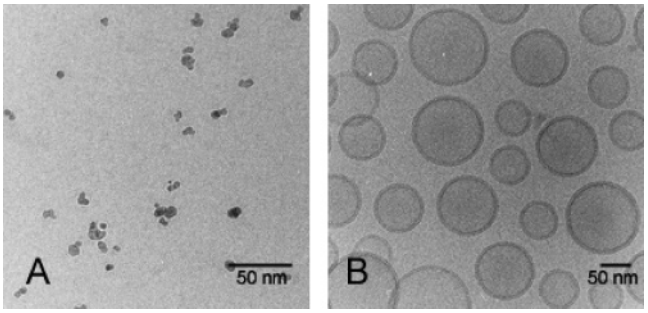

Figure 2. Cryo-TEM images of superparamagnetic micelles (A) and paramagnetic liposomes (B).

Table 1. Relaxivities r_1 and r_2 Expressed in (mM^{-1} Fe) s^{-1} or (mM^{-1} Gd) s^{-1} for the Superparamagnetic Micelles and Paramagnetic Liposomes, Respectively[a]

	r_1	r_2	r_2/r_1

paramagnetic liposomes	4.1	6.8	1.7

[a] Measurements were performed at 20 MHz and room temperature.

RESULTS

Characterization of the Contrast Agents. Morphology and size of the contrast agents that were prepared following the schematic overview given in Figure 1 were studied with cryo transmission electron microscopy (Figure 2). In cryo-TEM images of the superparamagnetic micellular contrast agent, single nanoparticles could be discriminated of which only their iron oxide core with a diameter of approximately 5 nm was visible (Figure 2A). The total diameter of the conjugate was measured to be approximately 10 nm with dynamic light scattering. The resulting micellular iron oxide particle showed a relatively high r_2/r_1 ratio (Table 1), which is typical for negative MR contrast agents. The paramagnetic liposomal contrast agents were confirmed to be spherical bilayer particles that were sized to a diameter of approximately 100 nm (Figure 2B). An r_2/r_1 ratio of approximately 1.7 (Table 1) was found for these particles, indicating that these contrast agents are very well applicable as T_1-reducing agents.

Specificity of the Nanoparticles for Phosphatidylserine. *Binding to PS/PC Bilayers.* Wild-type annexin A5 was shown to bind to the PS/PC-coated silicium plate in the ellipsometry setup in the presence of 2.5 mM Ca^{2+} (Figure 3). Nonfunctionalized paramagnetic liposomes showed no significant binding to an identical PS/PC bilayer, whereas the polarization angle changed approximately 6° due to binding of the annexin A5-conjugated liposomes in the presence of Ca^{2+} (Figure 3). Addition of EDTA caused an immediate drop of the polarization angle for both the wild-type annexin A5 and the annexin A5-conjugated liposomes, which confirmed specific, Ca^{2+}-depend-

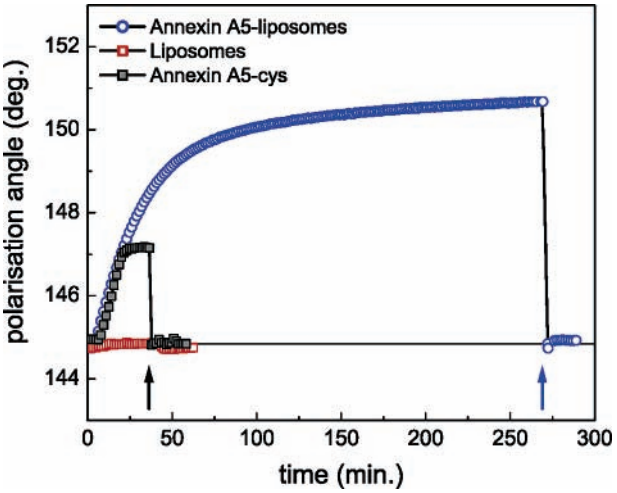

Figure 3. Ellipsometry measurement of binding of annexin A5-cys (black square), nonfunctionalized paramagnetic liposomes (red square), or annexin A5-functionalized paramagnetic liposomes (blue circle) to a PS/PC (20:80) bilayer in the presence of 2.5 mM Ca^{2+}. EDTA (5 mM) was added at the time points indicated by the arrows.

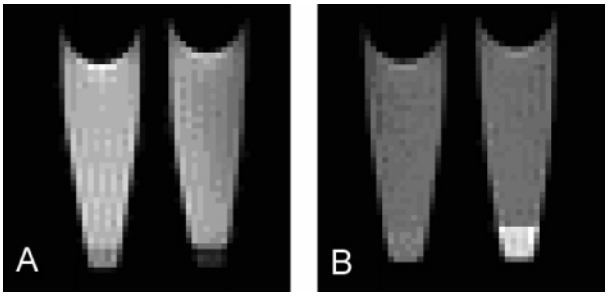

Figure 4. MR images of loosely packed cell pellets: (A) T_2-weighted spin-echo image of a pellet of apoptotic cells that were incubated with annexin A5-functionalized superparamagnetic micelles (right) or not exposed to contrast agents (left), TE 14.7 ms, TR 6000 ms; (B) T_1-weighted spin-echo image of apoptotic cells that were incubated with paramagnetic annexin A5-liposomes (right) or not exposed to contrast agents (left), TE 4.3 ms, TR 950 ms.

ent binding to PS (*25*). Ellipsometry measurements of superparamagnetic micelles were impossible because of the magnetic properties of the contrast agent.

MRI of Apoptotic Cell Pellets. Apoptotic cells that were incubated with annexin A5-functionalized superparamagnetic micelles in the presence of Ca^{2+} appeared as a hypointense pellet compared to untreated control cells in the T_2-weighted MR image (Figure 4A). In contrast, apoptotic cells that were incubated with annexin A5-conjugated paramagnetic liposomes appeared as a hyperintense pellet compared to control cells in a T_1-weighted MR image (Figure 4B). Relaxation times that were measured within all cell pellets were expressed as relaxation rates R_1 and R_2, that is, inverse relaxation times, since both relaxation rates are linearly dependent on the contrast agent concentration. The relaxation rate R_2 of apoptotic cells was shown to be approximately 172% increased after incubation with annexin A5-funtionalized micellular iron oxide particles in the presence of Ca^{2+}, whereas an increase of only 19% was measured in the presence of EDTA (Figure 5A). Nonfunctionalized superparamagnetic micelles were also shown to minimally increase the intrinsic R_2 of apoptotic cells.

The R_1 of apoptotic cells was shown to be approximately 258% increased after incubation with annexin A5-conjugated paramagnetic liposomes in the presence of Ca^{2+} compared to untreated apoptotic cells (Figure 5B). An increase of approximately 22% was observed after incubation with nonfunctionalized liposomes, both in the presence of Ca^{2+} and EDTA.

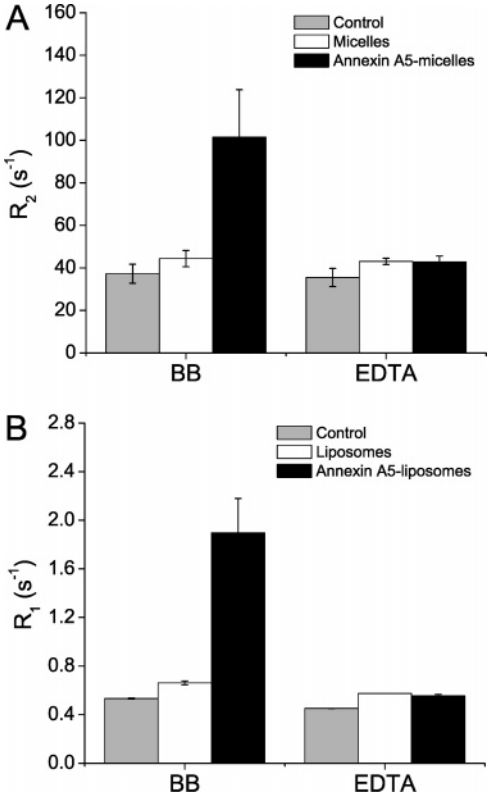

Figure 5. Relaxation rates within the cell pellets. R_2 or R_1 values were obtained for apoptotic Jurkat cells that were either untreated (control), incubated with 5 μg of Fe/mL of annexin A5-functionalized superparamagnetic micelles (A), incubated with 0.2 μmol of lipid/mL of annexin A5-functionalized paramagnetic liposomes (B), or incubated with their corresponding nonfunctionalized contrast agents (A,B). Cells were incubated for 30 min either in the presence of Ca^{2+} (BB) or in the presence of EDTA (EDTA). Error bars represent the standard deviation for $n = 3$.

A similar minimal increase was measured for apoptotic cells that were incubated with annexin A5-conjugated paramagnetic liposomes in the presence of EDTA. Since Ca^{2+} is required for both annexin A5 conjugates to significantly increase the relaxation rates of apoptotic cells, it may be concluded that both contrast agents bind to the exposed negatively charged phospholipids.

Confocal Laser Scanning Microscopy of Apoptotic Cell Pellets. Confocal transmission and fluorescence images of all cell samples were obtained to determine the spatial location of the contrast agents that contributed to the measured relaxation rates within the pellets. Apoptotic cells that were incubated with nonfunctionalized superparamagnetic micelles showed presumably unspecific association of these contrast agents to less than 1% of the cells (Figure 6A). On the other hand, annexin A5-funtionalized superparamagnetic micelles were found to be associated to a relatively large fraction of cells (Figure 6B). In confocal fluorescence images of apoptotic cells that were treated with nonfunctionalized liposomes, no contrast agents were observed to be associated with apoptotic cells (Figure 6C). However, some remaining liposomal aggregates were found occasionally, probably due to insufficient washing of the cell preparation. In contrast, annexin A5-conjugated paramagnetic liposomes were observed to be massively associated with apoptotic cells (Figure 6D). These observations were confirmed by flow cytometry measurements, which showed significant binding of the annexin A5-conjugated paramagnetic liposomes to apoptotic Jurkat cells, whereas little association was observed for the nonfunctionalized liposomes (Figure 3).

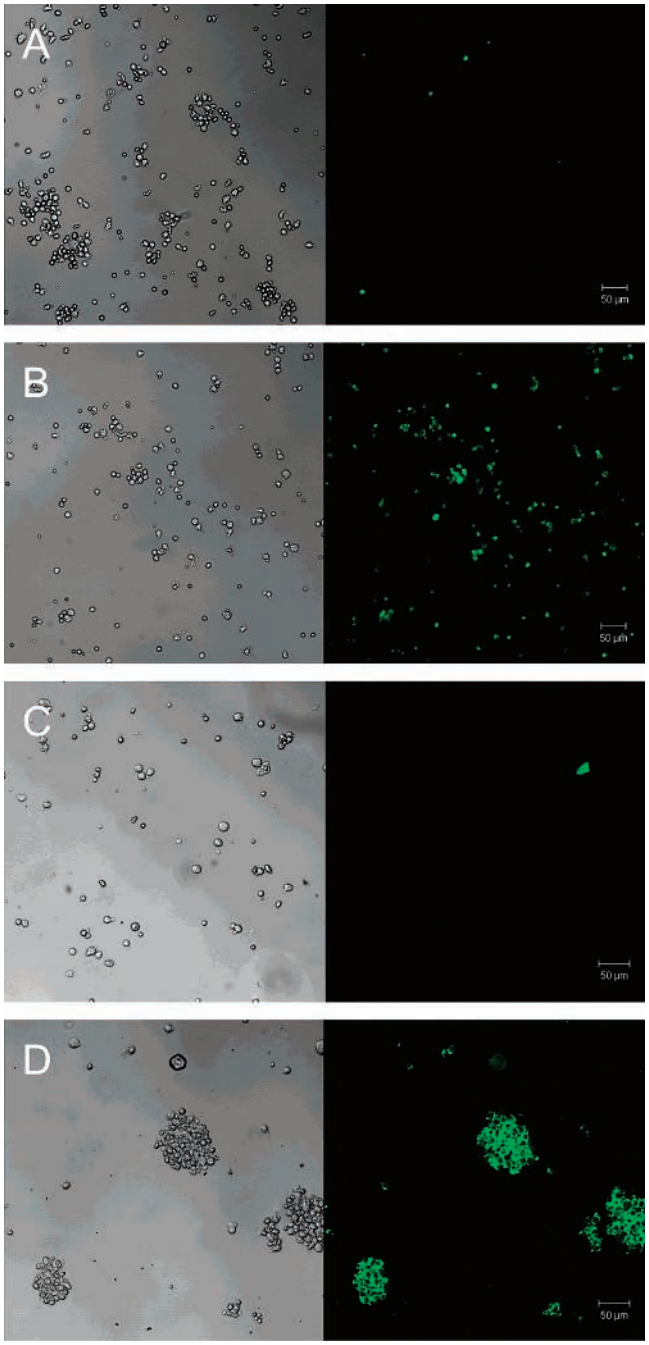

Figure 6. Confocal transmission (left) and fluorescence images (right) of fixed apoptotic Jurkat cells after incubation with superparamagnetic micelles (A, B) or paramagnetic liposomes (C, D) for 30 min in the presence of Ca^{2+}. Images were acquired after treatment with both nonfunctionalized (A, C) and annexin A5-functionalized (B, D) lipid-based contrast agents.

DISCUSSION

In this study, we presented two types of lipid-based bimodal nanoparticles that were functionalized with the protein annexin A5 for targeting to apoptotic cells. Both annexin A5-functionalized contrast agents were shown to bind specifically to apoptotic cells as confirmed by MRI and confocal laser scanning microscopy.

No typical bilayer structure was found in the cryo-TEM images of the superparamagnetic micelles (*30*), suggesting that the oleic acid coated superparamagnetic particles were enclosed by a lipid monolayer. The resulting superparamagnetic micelles were measured to be ~10 nm in diameter by DLS, whereas their core diameter was found to be ~5 nm in cryo-TEM images (Figure 2A). This suggests that each micelle contains approximately one magnetite particle, which provides the contrast agents with a relatively large r_2/r_1 ratio of 12.0 compared to r_2/r_1 ratios of 2.2 that were measured for other small iron oxide particles at the same field strength, including AMI 227 and MION-46 (*31*). r_2/r_1 ratios of the magnitude reported here suggest that the magnetite particles were aggregated (*32*). However, nonaggregated superparamagnetic micelles were predominantly found on the cryo-TEM images. Whether this high r_2/r_1 ratio was caused by the use of a micellular coating consisting of 100% PEG polymers, instead of the commonly used dextran coating remains to be investigated. Altogether the micellular iron oxide preparation may be classified as an ultrasmall and extremely potent T_2-reducing contrast material. Conjugation of annexin A5 to the micellular iron oxide particles was shown to specifically decrease the T_2 of apoptotic cell pellets by approximately 70% (Figure 5A), which was clearly visible on a T_2-weighted MR image (Figure 3A). Schellenberger et al. previously showed the ability of annexin A5−CLIO to specifically reduce the T_2 relaxation times of apoptotic cells (*21*, *33*). Additional coupling of the near-infrared fluorophore Cy5.5 allowed successive near-infrared imaging (*21*). As an alternative to covalent coupling of annexin A5 to iron oxide particles, Jung et al. presented a two-step approach, where biotinylated C_2A domain of synaptotagmin I was subsequently labeled with streptavidin−SPIO nanoparticles (*16*). This approach was successfully used to reduce the T_2 relaxation times of apoptotic cells in vitro; however its in vivo application is expected to suffer from the immunogenecity of streptavidin. The mean size of the used streptavidin−SPIO label is 20−30 nm (*16*), whereas the mean size of the annexin A5−CLIO−Cy5.5 was measured to be approximately 50 nm (*21*). Consequently the application of these particles for molecular imaging purposes of extravascular targets may be limited by their size. The mean size of the superparamagnetic micelles presented in this study was determined to be approximately 10 nm, which is at least 2 times smaller than the iron oxide particles that were previously described for the detection of apoptosis. Consequently the micellular iron oxide particles are thought to show facilitated extravasation compared to these iron oxide particles.

It was shown by Kim et al. that the size of magnetomicelles scales with the number of iron oxide particles entrapped in the micellular core, which was determined by the starting ratio between the concentration of magnetite particles and the polymers (*34*). In this manner, the size of the contrast agents may be optimized for the target of interest. In addition, the incorporation of multiple iron oxide particles in the micellular core could also be used to enhance the magnetic properties of the superparamagnetic micelles presented here. Alternatively, multiple superparamagnetic particles with a hydrophilic coating could be entrapped inside the internal water compartment of liposomes. The resulting particles can be sized to approximately 40 nm and are often referred to as magnetoliposomes (*35*). Magnetomicelles and magnetoliposomes that show sufficient magnetism could be simultaneously used as MRI contrast agents and for magnetic-nanoparticle-induced hyperthermia (*36*). As an alternative to magnetothermal therapy a mixture of magnetite particles and hydrophobic drugs could be incorporated in the micellular core to allow targeted therapy with particles that can be detected both with MRI and with optical imaging.

Targeted molecular imaging of sparsely expressed receptors in tissues, where positive contrast is preferred due to intrinsic T_1 and T_2 relaxation times, requires amplification strategies because of the relatively low relaxivities of T_1-reducing ions, including Gd^{3+}. Therefore it is advantageous to use liposomes in which a large payload of paramagnetic lipids can be incorporated in the bilayers, resulting in efficient T_1- and T_2-

shortening lipidic nanoparticles (*37*). Minor differences were observed between the ionic relaxivity r_1 and r_2 of Gd-DTPA and that of Gd-DTPA-BSA incorporated in the liposomal bilayer. However, the molar relaxivities r_1 and r_2, expressed in $(mM^{-1}$ nanoparticle$)\cdot s^{-1}$, are tremendously increased compared to free Gd-DTPA due to the large payload of Gd-DTPA-BSA (~40 000/liposome). Consequently, for annexin A5−Gd-DTPA conjugates with a 1:1 stoichiometry, the concentration of annexin A5 should be at least 400-fold higher than for annexin A5-conjugated paramagnetic liposomes to produce comparable changes in the relaxation times of apoptotic cells, assuming that a maximum of 100 annexin A5-cys proteins were conjugated to each liposome. An alternative gadolinium-based contrast agent for the detection of apoptosis was presented by Jung et al., who conjugated a maximum of about 100 Gd-DTPA molecules to one biotinylated C_2A domain of the protein synaptotagmin I through biotin−avidin interaction (*16*). Only a small decrease in T_1 was observed for apoptotic cells after incubation with this contrast agent, indicating that further amplification strategies are desirable to obtain significant contrast enhancement of apoptotic tissue in T_1-weighted images.

Besides diagnostics, these contrast agents could also be used for therapeutic applications by additional incorporation of water-soluble drugs inside the liposomal lumen. Pegylated liposomes have been successfully used as drug carriers, which has primarily found its clinical application in tumor treatment (*38*). Incorporation of anti-apoptotic drugs in the annexin A5-conjugated paramagnetic liposomes presented here would allow for the combination of multimodal detection of apoptotic cells and anti-apoptotic treatment. In cases of reversible PS exposure, these cells could be rescued from dying. Since liposomes are approximately 100 nm in size, these particles can only be used to target the extravascular space in tissue with enhanced permeability or intravascular compartments. Alternatively the size of the nanoparticles could be reduced by incorporation of Gd-DTPA-BSA lipids in a micellular lipid monolayer to allow the multimodal detection of more extravascular targets. Hydrophobic drugs can be additionally incorporated in the micellular core for targeted therapy (*39*).

The bimodal lipid-based contrast agents that were designed as efficient T_1- or T_2-reducing agents could be localized at the subcellular level with fluorescence microscopy due to additional incorporation of fluorescent lipids in the lipid (bi)layer. However, flow cytometry experiments with the annexin A5-functionalized superparamagnetic micelles were hindered by their relatively weak fluorescent signal, which was also observed on the confocal fluorescence images. Nevertheless the contrast agent could be detected on the confocal fluorescence images since no autofluorescence was observed for cells in 4% paraformaldehyde solution. Unfortunately, their spatial location was difficult to define based on these images. The fluorescent headgroups that were incorporated in the micellular lipid layer for fluorescence microscopy and flow cytometry were in close proximity to the iron oxide core, which might induce fluorescent quenching. Josephson et al. also observed extensive fluorescent quenching after attachment of fluorescein to magnetic nanoparticles (*40*). Therefore, the fluorescent moiety should be positioned at a more distant location from the iron oxide core, for example, by covalent coupling of the fluorophores to the distal ends of PEG polymers. It was shown by Nitin et al. that fluorescent properties of Texas Red were maintained after conjugation to PEG phospholipids that were incorporated in micellular coated iron oxide nanoparticles (*41*).

The obtained confocal fluorescence images of the annexin A5-conjugated paramagnetic liposomes suggest that these contrast agents are only found on the outer leaflet of the cell membrane. Since Jurkat cells have a relatively large nucleus additional staining for cell membrane markers should be performed to confirm exclusive binding of the contrast agents to the cell membrane. Cells with associated annexin A5-conjugated paramagnetic liposomes were mainly found to be clustered, which was already observed during the incubation period of 30 min. It is known that contrast agent clustering may alter its T_1- and T_2-reducing ability compared to more homogeneously distributed contrast agents. Therefore the r_2/r_1 ratio of cell-associated annexin A5-conjugated paramagnetic liposomes was measured (van Tilborg, unpublished observations). An r_2/r_1 ratio of approximately 6 was found for homogeneously distributed annexin A5-conjuated paramagnetic liposomes in HEPES buffer at 6.3 T, whereas an r_2/r_1 ratio of approximately 39 was measured in a 4% paraformaldehyde solution at 6.3 T after association of the annexin A5-conjugated paramagnetic liposomes to apoptotic cells. Whether this increase results only from clustering or also from cell association per se should be further investigated. In contrast to annexin A5-conjugated paramagnetic liposomes, no cell aggregation was observed in the presence of annexin A5-functionalized micellular iron oxide particles.

In this study, it was shown that a fraction of apoptotic cells >30% within the region of interest could be easily detected with MRI using the described annexin A5-conjugated lipid-based nanoparticles in vitro. The fraction of apoptotic cells found in vivo varies from <1% in viable tissue to 4% in tumor tissue. These values may be increased to approximately 20% in diseased tissue, including cardiomyocytes in intact myocardial tissue that were exposed to transient ligation of the left descending coronary artery (LAD) during 30 min (*10*). Sosnovik et al. observed local abnormal contractility within a well-defined area of the mouse myocardium after transient ligation of the LAD. Intravenously injected annexin A5−CLIO−Cy5.5 (2 mg of Fe/kg) was shown to reduce the T_2* relaxation time within this region up to 39% (*22*). Furthermore, irradiation or cytotoxic chemotherapy was shown to locally increase the apoptotic fraction in tumor tissue up to 30%. In this animal model, the intravenous administration of 20 mg of Fe/kg of synaptotagmin I-conjugated SPIO was found to decrease the signal intensity up to 15% in well-defined areas of the tumor (*15*). Consequently, the increased apoptotic fraction within diseased or successfully treated tumor tissue should also be detectable with the annexin A5-functionalized lipid-based contrast agents presented here if a sufficient dose of the contrast agent can be targeted to the tissue of interest. Since both nanoparticles are pegylated, they are expected to exhibit improved circulation times and bioavailability, which has been extensively studied for similar lipid-based aggregates in which no MR contrast agent was incorporated (*42*, *43*).

The nanoparticles that were prepared for this study are examples of lipid-based bimodal contrast agents that differ both in size and in magnetic properties. Consequently these contrast agents are suitable for all kinds of diagnostic MR imaging applications, varying from magnetic resonance angiography (MRA) to molecular and cellular imaging. The superparamagnetic micellular contrast agent is relatively small and is therefore expected to be suitable for the visualization of both intravascular and extravascular targets. In contrast, extravasation of the paramagnetic liposomes is limited by their size, which makes the contrast agent best suited for targeting intravascular receptors. Interestingly, with these systems, diagnostics could be extended to targeted therapeutic applications either by additional incorporation of drugs or alternatively by exploitation of the magnetic properties of the micellular iron oxide particles for so-called magnetothermal therapy.

ACKNOWLEDGMENT

This study was financially supported by the BSIK program entitled Molecular Imaging of Ischemic Heart Disease (Project Number BSIK03033) and the European Union Network of Excellence Diagnostic Molecular Imaging (EC - FP6-project DiMI, LSHB-CT-2005-512146). The authors thank Mircea V. Rasa for helping us find suitable iron oxide particles for this study and for reading the manuscript. We thank Peter M. Frederik and Paul H. Bomans from the EM unit of the University of Maastricht for the acquisition of the TEM images and Cécile Lejeune for the ellipsometry measurements.

Cell-penetrating peptides (CPPs) are characterized by their ability to be internalized in mammalian cells. To investigate the relative potency of CPPs as carriers of medicinally relevant cargo, a positive read-out assay based on the ability of a peptide nucleic acid (PNA) oligomer to promote correct expression of a recombinant luciferase gene was employed. Seven different CPPs were included in the study: Transportan, oligo-arginine (R_{7-9}), pTat, Penetratin, KFF, SynB3, and NLS. The CPP−PNA conjugates were synthesized by different conjugation chemistries: continuous synthesis, maleimide coupling, and ester or disulfide linkage. Under serum-free conditions PNA−SS-Transportan-amide (ortho)−PNA was found to be the most potent conjugate, resulting in maximum luciferase signal at a concentration of 1−2 μM. (D-Arg)$_9$−PNA showed optimal efficacy at 5 μM but gave rise to only one-third of the luciferase signal obtained with the Transportan conjugate. The pTat− and KFF−PNA conjugates showed significantly lower efficacy. The penetratin−, SynB3−. and NLS−PNA conjugates showed only minimal or no activity. Serum was found to have a drastic negative impact on CPP-driven cellular uptake. PNA−SS-Transportan-acid (ortho) and (D-Arg)$_9$−PNA were least sensitive to the presence of serum. Both the chemical nature and, in the case of Transportan, the position of the peptide PNA coupling were found to have a major impact on the transport capacity of the peptides. However, no simple relationship between linker type and antisense activity of the conjugates could be deduced from the data.

INTRODUCTION

Over the past decade a group of cell-penetrating peptides (CPPs) have been identified. CPPs are characterized by their ability to become internalized by mammalian cells and, in some cases, to cotransport macromolecules to the cellular interior. Proteins, peptides, oligonucleotides, and other macromolecules with a therapeutic potential related to intracellular processes are prospective cargos for CPPs. The most intensively studied CPPs include protein-derived peptides such as pTat, pAntp (Penetratin), and VP22 and synthetic or chimeric peptides such as oligo-arginine and Transportan, respectively (*1*−*7*).

The mechanism underlying the translocation of CPPs across the lipid bilayer of mammalian cells is yet not fully understood. Initially, a "passive" passage over the membrane based on a temperature- and energy-independent "physicochemical" mechanism was suggested (*8*−*10*). However, later studies strongly suggested that (at least some of) the peptides designated CPPs are internalized in cells by classic endocytotic pathways (*11*−*13*), and most recently evidence for multiple pathways has emerged (*14*, *15*). Thus, further investigations on the mechanism of CPPs are warranted.

Another largely unresolved aspect of CPPs is their (relative) potency as transport vehicles for therapeutically relevant macromolecules. Due to the large diversity in application, cell type, and methodology, it is not possible to make a relevant comparison of the CPPs based on meta-analysis of the many data reported. Moreover, only a few studies (comprising only a few CPPs) have been concerned with a direct comparison of CPP performance (*2*, *5*, *11*, *16*−*19*).

Therefore, to establish data on the relative efficacy of some of the most prominent CPPs, we employed a transgenic reporter cell line, pLuc 705 HeLa, in which a PNA targeted to an aberrant splice site in luciferase mRNA is known to induce correct splicing and thus produce a positive read-out signal in the form of increased luciferase activity (*20*, *21*). We use this assay to evaluate the potency of seven different CPPs as vehicles for intranuclear delivery of PNA. We chose to analyze pTat, pAntp (Penetratin), and Transportan, as these peptides are some of the most widely used CPPs that have also been employed in earlier studies with PNA (*11*, *22*, *23*). We also included oligo-arginine, KFF, SynB3, and NLS. Oligo-arginine peptides have been shown to be potent cellular delivery vehicles for morpholino oligomers (*2*). Like PNA oligomers, morpholino oligomers have uncharged backbones. KFF has been shown to induce cellular uptake of PNA in prokaryotic cells (*24*, *25*), but data from eukaryotic cells are lacking. SynB3 has been claimed to enhance passage of the blood−brain barrier of conjugated molecules such as doxorubicin (*26*) and morphine-6-glucuronide (*27*) but has not previously been tested as a cellular vehicle for PNA. NLS was included in the study as earlier papers have claimed this peptide to promote PNA translocation over the plasma cell membrane (*28*). NLS is not usually perceived as having capacity to transgress membranes other than the nucleolemma. In addition to the PNA−peptide conjugates, we tested a PNA−biotin

conjugate. This was done to assess the surprising finding that biotin by itself can promote cellular uptake of conjugated PNA (*29*).

EXPERIMENTAL PROCEDURES

Synthesis of PNAs and Peptide−PNA Conjugates. PNA oligomers and peptide−PNA conjugates were synthesized on an MBHA[1] resin LL (100−200 mesh, 0.40−0.80 mmol/g, Novabiochem), which was downloaded to approximately 0.15 mmol/g by the first building block. The remaining sites were capped using the capping mixture described below. The compounds were typically synthesized on 100 mg of resin using a standard peptide Bo protocol: deprotection (TFA/DCM/anisole 50:45:5, 2−3 min), DCM wash, DMF wash, base wash (DIEA/DCM 5:95), DMF wash, coupling (30 min), DMF wash, DCM wash, capping (Ac_2O/Et_3N/DCM 5:10:85, 1 min), DCM wash, DMF wash, and DCM wash.

The couplings were performed with a volume of 0.9 mL of a preactivated (1 min) mixture of PNA monomer (3.6 equiv), NMM (7.2 equiv), and HBTU (3.5 equiv) in DMF or NMP. For natural amino acids, the concentrations were doubled for all three reagents, and cysteine was activated in situ. The couplings were monitored by the Kaiser test and repeated until complete.

Cleavage. The compounds were cleaved from the resin using a low-high TFMSA protocol.

- The *N*-terminal Boc-group was removed with TFA/DCM/anisole (50:45:5, 2 min).
- If a formyl protective group on tryptophan was present, it was cleaved with piperidine/DMF (10:90, 120 min).
- The side-chain protective groups were removed with TFA/dimethyl sulfide/*m*-cresol/TFMSA (55:30:10:5, 60 min).
- The resin was washed with TFA/DCM/anisole (50:45:5).
- The compounds were cleaved from the resin using TFMSA/TFA/*m*-cresol (2:8:1, 90 min). For cysteine-containing compounds, ethanedithiol was added to prevent oxidation. Alternatively, the cleavage procedure was performed under nitrogen.

The liquid phase, plus TFA (0.5 mL) from washing the resin, was added to diethyl ether (8 mL), when the product precipitated. It was isolated by centrifugation (3000 min^{-1}, −4 °C), washed with diethyl ether (8 mL), and dissolved in H_2O (4 mL).

Formation of Disulfide Linkage between Peptide and PNA. The formation of a disulfide-linked peptide−PNA conjugate was performed by a solution-phase reaction between a peptide with a 3-nitro-2-pyridinesulfenyl (Npys) activated cysteine and a cysteine-conjugated PNA. Npys-peptides were obtained from K. J. Ross-Petersen (Copenhagen, Denmark).

The conjugation was performed in thoroughly degassed solvents to prevent oxidation of the cysteine−PNA. The Npys-activated peptide (10 mM, NMP, 130 μL, 1.3 equiv) was added to the cysteine−PNA (1.0 mM, NMP/H_2O 1:1, 1000 μL) followed by the addition of acetate buffer (1.0 M, pH 5.0, 100 μL). The mixture was heated to 37 °C for 4 h, then quenched with TFA/H_2O (5:95, 200 μL), and diluted with H_2O to a volume of 5.0 mL. A yellow color during the reaction indicates the cleavage of the Npys group upon reaction with another cysteine.

PNA−peptide maleimide conjugates were prepared as previously described (*30*) using a cysteine-modified peptide, which was reacted with a maleimide-modified PNA. The latter was prepared by reacting the terminal amino group of purified PNA oligomers with an *N*-hydroxysuccinimide cyclohexylmaleimide reagent. Ester-rontaining conjugates were prepared from PNAs containing a glycyl(hydroxymethyl)benzoic acid unit at the N terminus (*31*).

Purification, Solubility, and Stability. Preparative chromatography was performed using a Gilson FAST Prep HPLC system equipped with a Vydac C18 column (10 μm, 22 × 250 mm) or a YMC column (10 μm, 10 × 50 mm) for disulfide-containing compounds. Fractions were analyzed on a Waters Alliance HT 2790 HPLC system using a YMC C18 column (3 μm, 2 × 150 mm). Electrospray mass spectra were recorded using an Agilent 1100 single-quadrupole LC-MS instrument. MALDI-TOF mass spectra were obtained on a Kratos MALDI II instrument.

Synthesized products were in general purified using a preparative Vydac column and a 0.1% TFA/H_2O/ethanol gradient (5−40%) over 7 column volumes. Compounds containing a disulfide bridge between the PNA and the peptide part of the molecule did, however, not elute very well from the Vydac column, and a method using a YMC column and a 0.5% HOAc/H_2O/acetonitrile gradient (5−40%) over 9 column volumes was therefore introduced. Purity of collected fractions was measured by analytical HPLC, and correct masses were verified by LC-MS and/or MALDI-TOF. The calculated masses and the masses found by MALDI-TOF mass spectrometry and the purities determined by analytical HPLC are listed for each conjugate in Table 1. With two exceptions all conjugates were found to be at least 90% pure. SynB3 was 86% pure. Transportan-6 was only 60% pure. HPLC analysis showed one major closely eluting and inseparable impurity. Therefore, the concentration of this conjugate is probably overestimated throughout the study. We comment on this when relevant under Results.

All conjugates were soluble in water to concentrations of at least 50 μM. No sign of insolubility (precipitation) was seen when the conjugates were added to the cell media at the test concentrations (up to 10 μM).

All conjugates were found to be highly stable in water. The only exceptions were the conjugates containing the ester linkage, which we have shown earlier to have a half-life of approximately 6 h at pH 7.4 at 37 °C (*31*). Stock solutions of ester-linked conjugates were prepared just before addition to culture. This procedure ensured minimal breakdown of the conjugates before they were applied in the assay.

Cellular Uptake Experiments Using the Positive Readout Reporter Cell Line, pLuc705 HeLa. The pLuc705 HeLa cell line was purchased from Gene Tools (Philomath, OR). pLuc 705 HeLa cells are derived by stable integration of the pLuc705 plasmid into HeLa S2 cells as described in Kang et al. (*20*). The plasmid has luciferase downstream and out-of-frame with a dominant splice mutation in the β-globin intron position 705. The recombinant luciferase gene is under control of the immediate early cytomegalovirus promoter. Binding of PNA (of sequence H-CCT CTT ACT CCA GTT ACA-NH_2) to a region covering the splice mutation results in restoration of wild-type splicing, which generates a transcript with luciferase in-frame (*21*, *31*).

pLuc 705 HeLa cells were grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with penicillin/streptomycin (10 μg/mL) (antibiotics) and 10% fetal calf serum (Gibco, Invitrogen, Taastrup, Denmark). Cell cultures were maintained at 37 °C in a humidified atmosphere containing 5% CO_2 (standard conditions). For transfection with the PNA conjugates, the cells were seeded in a 96-well microtiterplate (Nunc, Invitrogen, Roskilde, Denmark) in a volume of 200 μL and at cell densities of (50−100) × 10^3 cells/mL unless otherwise stated. The following day the semiconfluent cells were prepared for uptake experiments. This was done by washing

[a] The calculated (calcd) masses and the masses found by MALDI-TOF mass spectrometry and the purity found by HPLC are listed for each of the conjugates. Also, the position of the N terminus of the PNA with respect to the conjugated peptide is listed for each of the conjugates. [b] These PNAs yielded relatively weak MALDI signals and less sharp peaks. [c] Two closely migrating and inseparable peaks (absorbing at 260 nm) were observed. However, the MALDI spectrum did not indicate the presence of any other large molecular weight component.

the cells once in fresh DMEM containing antibiotics but no serum (serum-free DMEM) and adding 80−90 μL of the serum-free DMEM (unless otherwise stated) to the cells afterward. The cells were then incubated at standard conditions for 1−2 h before the cells were given CPP−PNA conjugates in the concentrations mentioned in the text. Typically, the cells were given 2−10 μL of a 100 μM stock. All additions were made in at least triplicates. Control cells were given sterilized water in volumes similar to each different volume of added CPP−PNA stock. This was done to avoid any misinterpretations due to volume effects. After 2−4 h, 10 μL of fetal calf serum was added to all cultures. After incubation at standard conditions for 16−20 h, luciferase activity was measured by use of the Stedy-Glo Luciferase Assay System (Promega, Ramcon A/S, Birkerød, Denmark) and a Victor^2 Multilabel Counter (Wallac, Perkin-Elmer Danmark A/S, Allerød, Denmark) according to the manufacturer's instructions.

Cell viability was assessed by indirect ATP measurements performed on cells run in parallel and treated exactly as the cells used for luciferase determinations. ATP was determined by use of the ATPlite assay (Perkin-Elmer Danmark A/S) according to the manufacturer's instructions.

RESULTS

The 19 PNA−peptide conjugates used in this study are listed in Table 1. As can be seen from the table, Transportan was studied in seven different configurations. These configurations comprise six conjugates in which PNA is linked to either a cysteine at the amino (N) terminus or at the ϵ N of lysine 13 (ortho position) of Transportan (amide) by a maleimide, an ester, or a disulfide linkage, respectively. In addition, a conjugate was prepared from the free carboxylic acid form of Transportan in which PNA is linked to the ortho (Lys13) position via a disulfide linkage. The different chemical linkers employed are depicted in Figure 1.

Oligo-arginine−PNA conjugates were prepared by continuous solid-phase synthesis. Furthermore, two arginine (9) conjugates were made through maleimide coupling. The pTat(48−60)−PNA conjugates were prepared via direct synthesis or ester maleimide conjugation, respectively. The truncated pTat(48−57)−PNA conjugate was prepared via maleimide coupling. The Penetratin−PNA conjugate was also prepared using maleimide conjugation. The SynB3 conjugate was prepared from disulfide coupling, and NLS− and KFF−PNA conjugates were prepared via continuous synthesis.

It is noted that maleimide and disulfide conjugation, as performed, links the PNA (N terminus) to the N terminus of the peptide, whereas continuous synthesis links the PNA (N terminus) to the C terminus of the peptide.

The antisense activity of the PNA−peptide conjugates was studied in the pLuc 705 HeLa cells (see Experimental Procedures). This cell line has successfully been exploited to quantitatively study the potency of antisense agents, and we have recently used it in a comprehensive study on transfection of modified and unmodified PNA (*32*). This study emphasized the value of the pLuc 705 HeLa cells as a model system for a precise, reproducible, and quantitative assessment on cellular uptake and nuclear delivery of PNA. However, it also pointed out that the assay is sensitive to even little (and sometimes uncontrollable) variations in cell density, cell viability, and luciferase assay performance. These factors influence assay performance in a way that is mainly reflected in the absolute luciferase activities. Therefore, to increase the transparency of the data, the results in this paper are not given as absolute luciferase signals. Instead, luciferase expression resulting from treatment of the cells with a conjugate was in each case normalized to the basal luciferase expression found in control cells. Control cells were given sterilized water in volumes similar to the volumes of conjugate solution added to the test cultures. Essentially, this presentation should eliminate errors due to variations in cell density and mRNA expression level as well as variations in the luciferase assay performance. It is important to point out that the resulting normalized ratios [called the relative luciferase signals (RLS)] must not be perceived as absolute and are most likely not directly comparable in different experiments. A direct (head-to-head) experimental evaluation of two conjugates is necessary to make an optimal evaluation of the relative activity. However, we found it useful to always include one or two "reference" conjugates (Tat-1 and/or Transportan-6) in a given experiment. Thereby, the relative

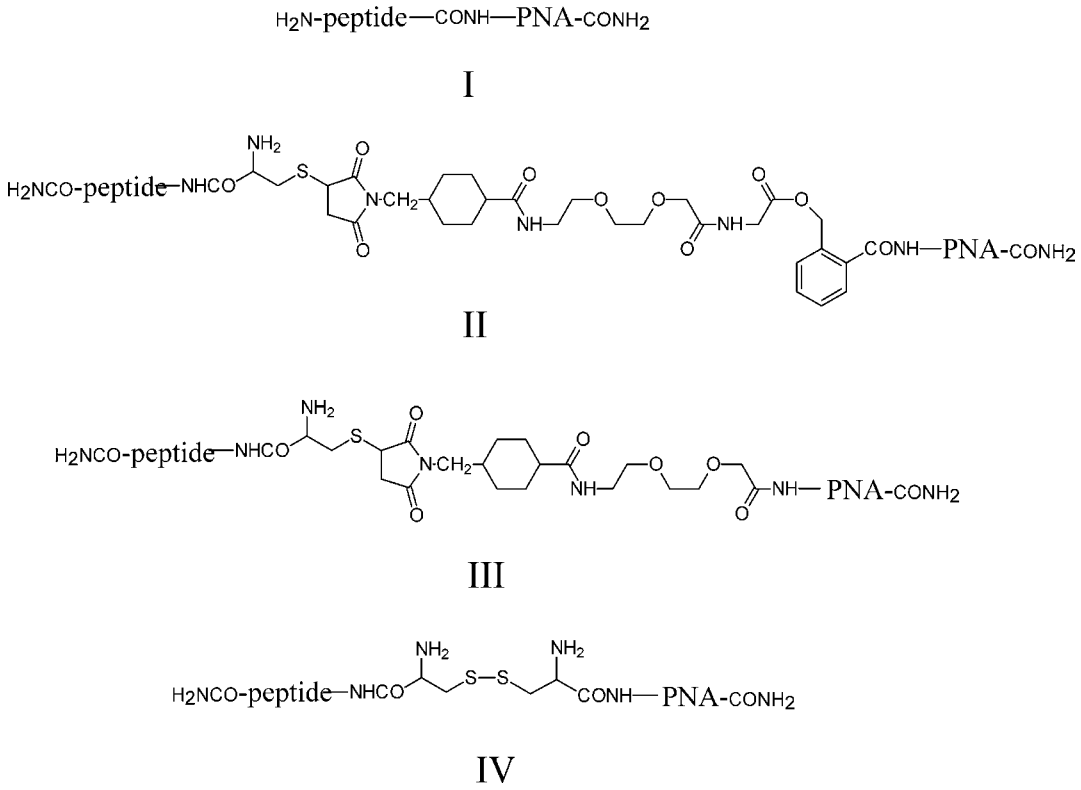

Figure 1. The structure and length of the four different linkers resulting from direct synthesis (I), ester maleimide (II), stable maleimide (III), and disulfide conjugation (IV), respectively.

activity of two different conjugates not tested in the same experiment could still be estimated from their relative activity compared to one or two of the reference conjugates.

Effect of Serum on the Relative Activity of the Conjugates. At an early stage of the study, serum was found to have a profound (inhibitory) effect on the efficiency of the CPP−PNA conjugates. However, the effect was not equally strong with respect to all of the conjugates. This indicates that the relative activity of the peptides as carriers for PNA depends on the presence or absence of serum. Therefore, these two different situations must be evaluated separately. The data shown in Figure 2 illustrate this finding. In this experiment a number of conjugates are evaluated during conditions varying only with respect to serum. Thus, the cells in this experiment were seeded, incubated, washed, incubated with the conjugates, and analyzed for luciferase activity in complete parallel in a 96-well microtiterplate. The only difference is that half of the cells were given serum-free medium, whereas the other half of the cells were given medium containing 10% fetal calf serum before addition of the conjugates. The cells in serum-free medium were then given serum to a concentration of 10% after approximately 2 h. In this experiment we studied four of the most frequently used CCPs, penetratin, Tat-peptide, Arg9, and Transportan (either as the C-terminal amide or as the free carboxylic acid). In the absence of serum, 2 μM Transportan-6 resulted in a RLS of approximately 130, that is, 4−70 times higher than that obtained with Transportan-7, Arg(9)-1, Tat-1, or Penetratin (left part of Figure 2). At 4 μM the antisense activities of Transportan-7 and Transportan-6 were equal, possibly indicating saturation of the effect for Transportan-6.

The right side of the Figure 2 shows the results obtained with the same conjugates when the cells were not allowed serum-free conditions during the first hours of incubation. It is seen that serum dramatically reduces the activity of the two Transportan conjugates as compared to serum-free conditions. However, the results also show that the amide derivative of the Transportan conjugate (Transportan-6) is more sensitive than

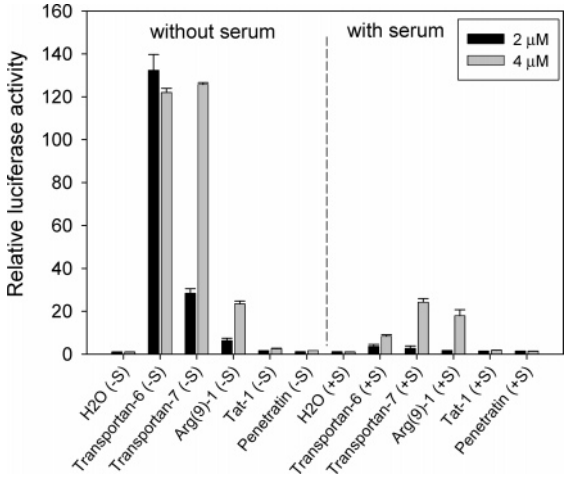

Figure 2. Effect of serum on the antisense activity of five different CPP−PNA conjugates. The indicated conjugates were tested in pLuc 705 HeLa under conditions varying only with respect to the concentration of serum (either 0 or 10%) during the first 2 h after addition of the conjugates. For details see the text. All samples were tested in triplicates. Control cultures were given sterilized water in volumes equal to the volumes (2 and 4 μL, respectively) of conjugate solutions added to obtain the test concentrations. Luciferase activities were normalized to the relevant controls and are given as the average values ± standard deviations.

the free acid derivative (Transportan-7) to the inhibitory effect of serum. Furthermore, the oligo-arginine conjugate [Arg(9)-1] was found to be even less sensitive than Transportan-7 to the inhibitory effect of serum. The little uptake seen with Tat-1 and Penetratin (at 2 and 4 μM) was almost completely suppressed by the presence of serum.

Relative Activity of the Conjugates in the Presence of Serum. A number of experiments were performed to further evaluate the relative efficiency of the conjugates during conditions with constant presence of serum. Two of these experiments

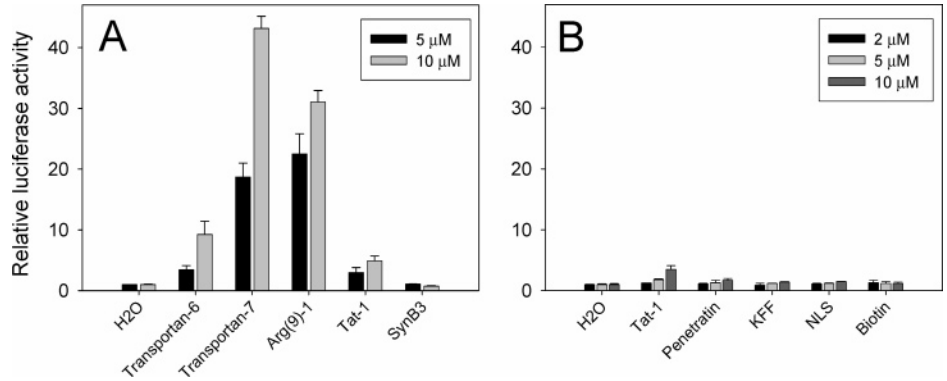

Figure 3. Relative antisense activity of different CPP−PNA conjugates tested in the presence of 10% serum. Panels A and B represent two separate experiments in which the indicated CPP−PNA conjugates (and biotin-PNA) were tested head-to-head. For details see the text. All samples were tested in triplicates. Control cultures were given sterilized water in volumes equal to the volumes (2, 5, and 10 μL, respectively) of conjugate solutions added to obtain the test concentrations. Luciferase activities were normalized to the relevant controls and are given as the average values ± standard deviations.

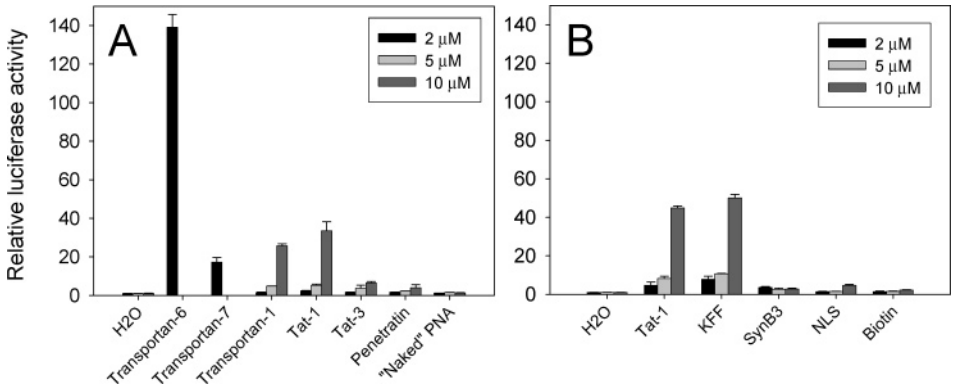

Figure 4. Relative antisense activity of different CPP−PNA conjugates tested during serum-free conditions. Panels A and B represent two separate experiments in which the indicated CPP−PNA conjugates (and biotin-PNA and unmodified PNA) were tested head-to-head. For details see the text. All samples were tested in triplicates. Control cultures were given sterilized water in volumes equal to the volumes (2, 5, and 10 μL, respectively) of conjugate solutions added to obtain the test concentrations. Luciferase activities were normalized to the relevant controls and are given as the average values ± standard deviations.

are summarized in Figure 3. Panels A and B of Figure 3 represent two separate experiments evaluating a number of conjugates at concentrations up to 10 μM. From Figure 3A it is seen that the relative activities of Transportan-6, Transportan-7, and Arg(9)-1 are maintained when these conjugates are tested at higher concentrations than employed in the experiment presented in Figure 2. Furthermore, the results show that among the tested peptides, only Transportan-6, Transportan-7, and oligo-arginine conjugates resulted in RLS above 10 in the presence of serum.

If the cells were not washed and given fresh serum but rather kept in conditioned medium and the conjugates were tested directly in this medium, activities were in general found to be considerably higher (approximately 2-fold) than seen when the conjugates were tested in the presence of fresh serum/medium (results not shown). However, the highest activities were always observed when CPP−PNA conjugates were allowed to act during a period of 2−4 h in serum-free medium (serum-free conditions). We therefore focused the rest of the study on such conditions.

Relative Activity of the Conjugates under Serum-free Conditions. In Figure 4 are shown two separate experiments comparing the antisense activity of a number of CPP−PNA conjugates tested under serum-free conditions. Note that Transportan-6 and Transportan-7 were tested at only 2 μM, whereas all other conjugates in these experiments were tested at 2, 5, and 10 μM. It is immediately clear from these data that Transportan-6 is—by far—the most potent conjugate among the ones tested. Not only Transportan-6, but also Tat-1, was used as internal reference in most of the experiments. From Figure 4A, it is seen that 10 μM Tat-1 induces a RLS of 34, corresponding to one-fourth of the saturating luciferase signal (SLS). Thus, a 5 times higher concentration of pTat results in a 4 times lower activity when compared to Transportan-6. Even at 5 μM, we found almost no activity of pTat-1. This is consistent with an earlier study in which we were unable to trace fluorescein-labeled pTat−PNA (and penetratin−PNA) conjugate to the nucleus when applied in concentrations of 2 μM [instead, we found a massive uptake to vesicular compartments (endosomes) in the cytoplasm] (*11*).

It is seen from Figure 4B that the activity of the KFF conjugate is comparable to that of the Tat-1. Furthermore, it is seen that the Penetratin and the SynB3 conjugates along with the NLS and the truncated Tat conjugates induced only very limited luciferase activation even at concentrations of 10 μM. Comparison with data from a recent publication (also performed in the pLuc HeLa cell system) indicate that the relative activities found for oligo-arginine, pTat, and Penetratin in the present study reflect a general order of strength between these peptides rather than being a special case relating to PNA as the cargo. It was found for phosphorodiamidate morpholino oligomers (PMO) that the arginine-9 peptide constitutes a more potent delivery vehicle than pTat, which in turn was more efficient than penetratin. Transportan was not included in the PMO study (*2*). The biotin conjugate showed practically no activity above background. Most interestingly, the Transportan-1 conjugate is dramatically less active than the Transportan-6 and Transportan-7 conjugates (Figure 4A). This indicates that the position

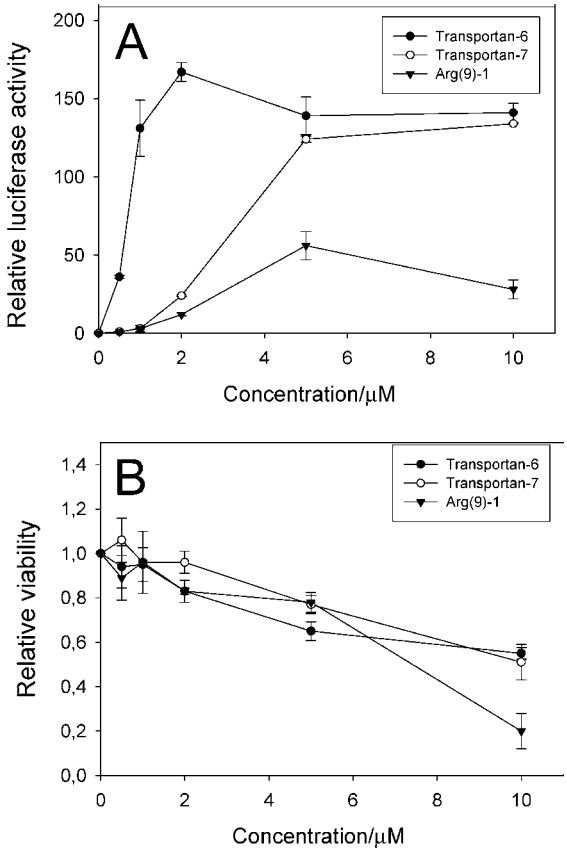

Figure 5. Antisense activity and toxicity of Transportan-6, Transportan-7, and Arg(9)-1 tested during serum-free conditions. The three conjugates were tested head-to-head in the pLuc 705 HeLa cells in concentrations between 0.5 and 10 μM (A). Cell viability was determined in parallel cultures by indirect ATP determinations (B). For details see the text. Control cultures were given sterilized water in volumes equal to the volumes (0.5, 1, 2, 5, and 10 μL, respectively) of conjugate solutions added to obtain the test concentrations. Luciferase activities and cell viability were normalized to the control cultures. All samples were tested in triplicates, and results are given as the average values ± standard deviations.

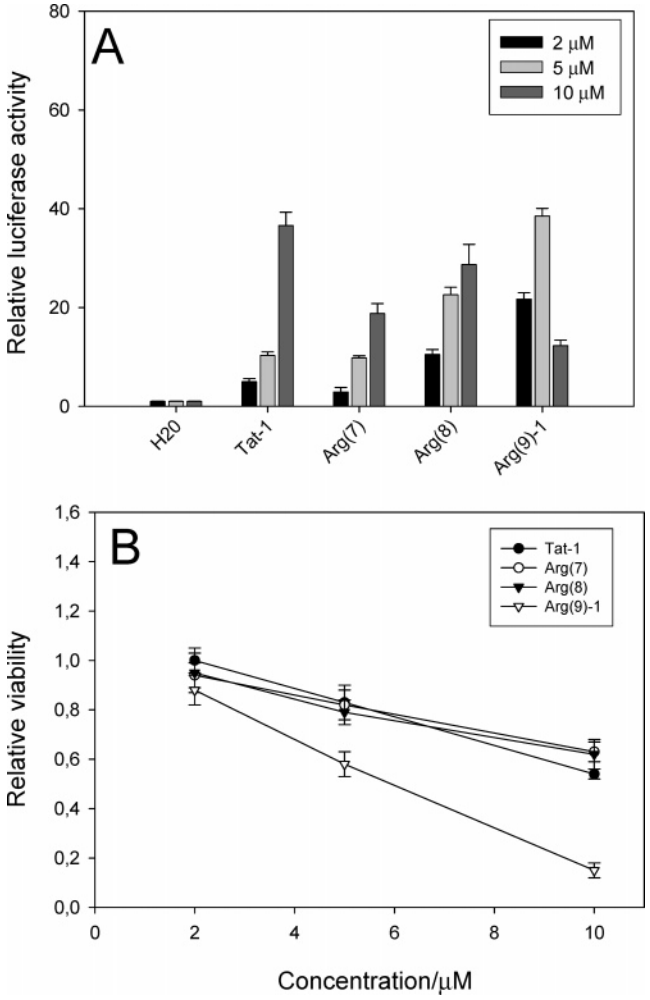

Figure 6. Antisense activity and toxicity of oligo-arginine-PNA conjugates. Arg(6), Arg(7), Arg(8), and Arg(9)-1 (and pTat-1) were tested head-to-head in the pLuc 705 HeLa cells in the indicated concentrations (A). Cell viability was determined in parallel cultures by indirect ATP determinations (B). For details see the text. Control cultures were given sterilized water in volumes equal to the volumes of conjugate solutions added to obtain the test concentrations. Luciferase activities and cell viability were normalized to the control cultures. All samples were tested in triplicates, and results are given as the average values ± standard deviations.

and/or chemical nature of the linker between the peptide and the PNA is of critical importance for activity/cellular uptake. This point is elaborated in much more detail in the separate experiments described later (Figures 7 and 8).

Relative Efficacy and Toxicity of Transportan-6, Transportan-7, and Arg(9)-1. The experiments shown in Figure 4 did not include any of the oligo-arginine conjugates. However, parallel experiments showed Transportan-6, Transportan-7, and Arg(9)-1 to have the highest activities among all of the tested conjugates. Therefore, additional experiments were performed to make a precise comparison among these three conjugates. In Figure 5 are shown the results of testing Transportan-6, Transportan-7, and Arg(9)-1 under serum-free conditions at concentrations up to 10 μM. The viability data on fully parallel cultures (Figure 5B) are based on indirect ATP determinations and reflect the number of living cells. The results clearly demonstrate that Transportan-6 is the most potent conjugate of the three and also show that all three conjugates exhibit significant cellular toxicity above 3−5 μM.

In the experiment shown in Figure 5, maximum activity for Transportan-6 was found at a concentration of 2 μM. In other experiments the maximum value for Transportan-6 was found to be at 1 μM. This was typically the case when the serum-free incubation time was prolonged (>3 h). If serum-free incubation times were shortened (<2 h), then maximum uptake values were found at higher concentrations (see Figure 8). This indicates that the cellular uptake as a prerequisite for antisense activity is time-dependent. It is noteworthy that the maximum luciferase activity obtained with the Arg(9)-1 conjugate is only approximately one-third of that obtained with the Transportan conjugates (Figure 5A). Most likely, this difference reflects a higher relative toxicity of the Arg-9 peptide at higher concentrations (Figure 5B).

Relative Activity and Toxicity of Different Oligo-arginine Conjugates. Initial screening of a series of oligo-arginine conjugates showed Arg(9)-1 to have the highest potency. The result of a direct comparison between Arg(7), Arg(8), and Arg(9)-1 is shown in Figure 6. Clearly, increasing the number of arginine residues results in more active conjugates, as also recently concluded in a parallel study with morpholino-type antisense agents (*2*). It is noteworthy that very similar toxicity is observed for conjugates with seven or eight arginine residues. However, when the number of arginine reaches nine, the toxicity seen at concentrations of 5 and 10 μM was significantly higher for Arg(9)-1 than for the rest of the conjugates. Thus, the data convincingly show that increasing the number of arginine residues in the poly-arginine peptides correlates with increased antisense activity, but also to some extent with increased toxicity (and at some point toxicity appears to become a limiting factor

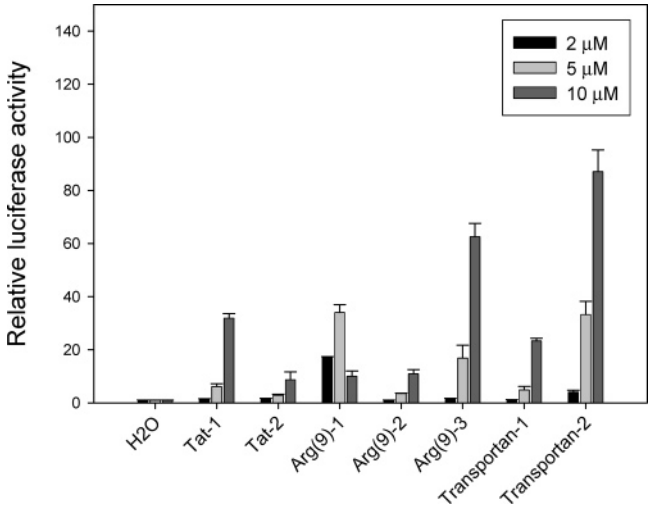

Figure 7. Effect of a biolabile ester linker on CPP−PNA antisense activity. Three ester-linked conjugates [pTat-2, Arg(9)-3, and Transportan-2] were tested in the pLuc 705 HeLa cells head-to-head with conjugates of the same CPP/PNA composition but prepared from either continuous synthesis [Tat-1 and Arg(9)-1] or stable maleimide coupling [Arg(9)-2 and Transportan-1]. For details see the text. Control cultures were given sterilized water in volumes equal to the volumes (2, 5, and 10 μL, respectively) of conjugate solutions added to obtain the test concentrations. Luciferase activities were normalized to the relevant controls and are given as the average values ± standard deviations.

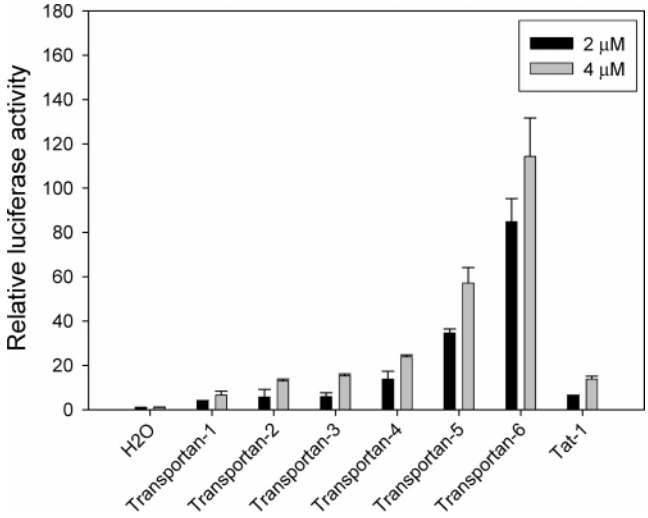

Figure 8. Effect of linker type and linker position in Transportan−PNA conjugates. Six different Transportan−PNA conjugates were tested head-to-head in the pLuc 705 HeLa cells. PNA is linked to the amino (N) terminus of Transportan (end position) or to the ϵ N of lysine 13 of Transportan (ortho position) by either stable maleimide (Transportan-1 and -4), by ester-maleimide (Transportan-2 and -5), or by disulfide linkage (Transportan-3 and -6). The conjugates were tested in concentrations of 2 and 4 μM and were allowed to incubate at serum-free conditions for only a relatively short period of time (1.5 h versus normally 2−4 h). These conditions were chosen to accurately reveal the differences in antisense activity reflecting both uptake potency and kinetics between the conjugates. For details see the text. Control cultures were given sterilized water in volumes equal to the volumes (2, 5, and 10 μL, respectively) of conjugate solutions added to obtain the test concentrations. Luciferase activities were normalized to the relevant controls and are given as the average values ± standard deviations.

for the activity of the poly-arginine conjugates). The problem of toxicity is most serious in the case of oligo-arginine peptides of more than eight arginine residues

Effect of a Biolabile Ester Linker on Uptake Efficiencies. Recently, we have found that conjugation of fatty acids to PNA via an ester-linkage increased antisense activity of PNA−lipid conjugates by a factor of 2 compared to similar conjugates not containing the ester linker. The ester linker is biolabile as it was shown to be cleaved by intracellular esterases (*31*). Inspired by these findings, we set out to investigate whether incorporation of this ester linker would also improve activities of CPP−PNA conjugates compared to CPP−PNA conjugates linked via a more biostable linkage. For this purpose, three ester-containing conjugates were made: pTat(48−60)-ester−PNA (Tat-2), Transportan-ester−PNA (Transportan-2) in which PNA is linked to the N terminus of the peptide, and (D-arginine)$_9$-ester−PNA [Arg(9)-3].

The data of Figure 7 show the results of an experiment designed to compare the three ester-linked conjugates with control conjugates of the same CPP/PNA composition but not containing the ester linkage and prepared by continuous synthesis [Tat-1 and Arg(9)-1] or maleimide coupling [Arg(9)-2 and Transportan-1]. From a comparison of the results with Tat-1 and Tat-2 it is seen that linking PNA to the Tat peptide through the ester linker apparently reduced performance about 2-fold compared to the continuous synthesis construct. However, continuous synthesis results in conjugates having the peptide and PNA in identical orientations (N terminus of PNA is bound directly to the C terminus of the peptide), whereas maleimide and disulfide coupling (via a cysteine residue in the N terminus of the PNA) results in conjugates having the peptide and PNA in opposite orientations. Therefore, when the Tat-1 and Tat-2 conjugates were compared, the orientation of the peptide was also reversed, and this could affect the activity as well.

The results with the three Arg(9) conjugates address this question. First of all, it is seen that conjugating the arginine(9) peptide and the PNA via the maleimide coupling [Arg(9)-2] severely reduces the activity compared to continuous synthesis [Arg(9)-1]. As observed for the Tat−PNA conjugates the ester-linked arginine conjugate [Arg(9)-3] is also less potent than the Arg(9)-1 conjugate prepared by continuous synthesis [the relatively high activity of Arg(9)-3 at 10 μM compared to Arg(9)-1 was due to less toxicity of the Arg(9)-3 conjugate compared to Arg(9)-1 at this concentration (results not shown)]. However, the ester-linked conjugate Arg(9)-3 is considerably (4−5-fold) more active than the chemically comparable nonester control Arg(9)-2 conjugate, differing only by the absence of the ester amino acid moiety. This result strongly emphasizes the advantage of including the biolabile (ester) linkage between the antisense oligomer and the carrier peptide.

This conclusion is supported by the finding that linking PNA to the N terminus of Transportan by an ester linker results in a much more efficient conjugate than that obtained from stable maleimide conjugation of PNA to the same end of Transportan (Figure 7). (Due to the length of the peptide, and the associated synthetic difficulties, a PNA−Transportan conjugate was not prepared by continuous synthesis.)

Direct comparison of the ester-linked conjugates [Tat-2, Arg(9)-3, and Transportan-2] and the maleimide-coupled conjugates [Arg(9)-2 and Transportan-1] consistently points at Transportan to possess the highest potency for cellular transport of PNA but also indicates that conjugation chemistry and position are critical.

Influence of Linker and Position of the Linker in Transportan−PNA Conjugates. Inspired by the results obtained with the different linkers described above and the high activity seen with Transportan-6 (in which the PNA is linked via a disulfide bridge to an amino acid positioned in the middle of the peptide), we decided to make a more elaborate study on the influence of linker and position of the linker in Transportan−PNA conjugates. For this purpose we employed six Transportan−PNA conjugates: three conjugates in which PNA is linked to the amino (N) terminus of Transportan (end position) and three conjugates in which PNA is linked to the ϵ N of lysine 13 of

Transportan (ortho position) by either stable maleimide (Transportan-1 and -4), ester maleimide (Transportan-2 and -5), or disulfide linkage (Transportan-3 and -6). The results (Figure 8) show two clear tendencies. First, linking the PNA to lysine 13 of the peptide in general results in higher antisense activity (up to 4-fold) of the PNA than if PNA is linked to the N terminus of the peptide. Second, disulfide linking results in more potent compounds (about 2-fold) than ester linking, which in turn performs better than stable maleimide coupling of the PNA to the peptide. However, it should be noted that the ortho ester-linked conjugate, Transportan-5, was purified to only 60%. Therefore, the spectroscopically determined concentration of Transportan-5 was probably underestimated, and the activity of this conjugate may be closer to the activity of Transportan-6 than indicated by the results shown in Figure 8.

The reasons for the observed differences in activity due to the position and chemistry of the linkage are not obvious. In a recent study on arginine-rich CPP delivery vectors for PMO in which a number of different linker types were tested, it was concluded that linker length rather than conjugation chemistry (maleimide, ether, or disulfide) affected the antisense activity of the conjugates. Thus, a consistent and positive relationship between linker length and antisense activity was found, whereas no consistent relationship was found between conjugation type and antisense activity (*2*). However, our results do not comply with such a simple rule. In fact, we found the most active conjugates to have the shortest linkers (disulfide and direct coupling/synthesis compared to stable maleimide and ester maleimide). Taken together, our results indicate a complex dependence of the antisense activity/cellular uptake on factors such as orientation of the PNA−CPP conjugate and position and type of the linker connecting these two domains. Thus, further data are needed to decipher the important relationship between the chemical structure of CPP−cargo conjugates and cellular delivery efficacy.

Considerations Regarding the Choice of Test System. In this study we have employed a biological antisense endpoint read-out for evaluating functional cellular uptake. We find this assay to be more relevant than other methods such as confocal microscopy using fluorescently labeled PNA−CPP conjugates. Confocal microscopy implicates many modifications of the experimental procedure (such as labeling of the PNA, growth of the cells in special chambers, and fixation of the cells), and these modifications are likely to influence the observed results. Moreover, quantitative analysis by confocal microscopy is by itself associated with a large number of pitfalls, which easily may give rise to incorrect or biased results (*23*, *33*). The positive read-out offered by the pLuc 705 HeLa cell system is highly superior to analysis by confocal microscopy and therefore may stand alone in a comparative study such as the present, which emphasizes precision and relevance for antisense applications. However, this analysis is also restricted by certain inherent limitations. First of all, the assay reflects only nuclear delivery of the active antisense agents because splicing, and thus correction of aberrant splicing, is confined to the nucleus. Thus, the pLuc 705 HeLa cells cannot provide us with exact information on the extranuclear compartmentalization of the CPP−PNA constructs. This is a significant limitation. Some targets for PNA antisense such as translation and HIV reverse transcriptase may theoretically be targeted equally well or better in the cytoplasm compared to the nucleus (*34*, *35*). Another shortcoming of the test system based on pLuc 705 HeLa cells is the limited information provided on the dynamics of the cellular uptake. This limitation follows from the reporter having to be translated before it is measurable. Thus, it will take a thorough analysis of all dynamic parameters involved in the process of luciferase expression (i.e., factors such as RNA stability, translations rate, luciferase stability) to make a relevant analysis of the kinetics underlying the observed data, and still it will not be possible to decide if the active antisense probe is delivered to the nucleus within (for example) seconds or minutes.

DISCUSSION

We have employed an easily quantifiable positive read-out assay, believed to directly reflect relative cellular uptake, to compare the antisense activity of 19 different CPP−PNA conjugates. A number of clear conclusions can be drawn from the data. First, we found the activity of most of the tested CPP−PNAs to be dramatically reduced if serum was present during treatment. Two conjugates, PNA−SS-Transportan-acid (ortho) and $(D\text{-Arg})_9$−PNA, were less sensitive to serum than the rest of the conjugates. We found no correlation between the type of linkage in the conjugate and serum sensitivity.

Under conditions where the conjugates were delivered in the absence of serum for a period of 2−4 h, a transportan−PNA conjugate, Transportan-6, was found to be the most active of the tested conjugates. An oligo-arginine−PNA conjugate, Arg-(9)-1, was found to be the second most potent conjugate, showing approximately $^1/_{10}$ of the activity seen with Transportan-6. Furthermore, Arg(9)-1 was found to be more toxic than Transportan-6. pTat-1 and the KFF−PNA conjugate were the third most active conjugates, whereas the Penetratin, SynB3, NLS, and biotin conjugates showed only minimal or no activity.

A significant finding of our study is the strong dependence of delivery efficacy on the chemical nature and position of the linker. Our results strongly suggest that biologically cleavable ester and especially disulfide linkages between the delivery peptide and the antisense agent result in more active conjugates. The results also show that the molecular site of conjugation (N terminus versus C terminus or "ortho" of the peptide) can dramatically affect the antisense (and thus implicitly the cell penetration) potency of the conjugate. However, a simple relationship between the type (and position) of the linker of a CPP−PNA conjugate and its antisense activity is not obvious at this stage.

ACKNOWLEDGMENT

This work was supported by the Danish Research Council and the 6th Framework Program of the European Union (EUROXY Project). The excellent technical assistance provided by Masumeh Chavosi and Anna Bay Nielsen is greatly appreciated.

Linear Topology Confers in Vivo Gene Transfer Activity to Polyethylenimines

B. Brissault,[‡] C. Leborgne,[§] C. Guis,[‡] O. Danos,[§] H. Cheradame,[‡] and A. Kichler*[,§]

Laboratoire Matériaux Polymères aux Interfaces UMR 7581, Université d'Evry, 91025 Evry Cedex, France, and Genethon - UMR 8115 CNRS, Department of Gene Transfer, BP 60, 91002 Evry Cedex, France. Received September 30, 2005; Revised Manuscript Received March 15, 2006

Although polyethylenimines (PEIs) are frequently used transfection agents, it is still unclear which of their properties are required for efficient gene delivery. This is even more striking when working in vivo since some PEIs are able to generate significant gene expression, whereas others are not. To facilitate a rational development of compounds with improved transfection activities, studies aimed at identifying the properties involved in the transfection process seem indispensable. In the present work, we investigated how transfection with linear PEI of 22 kDa allows for high reporter gene expression in lungs after intravenous injection, whereas the branched PEI of 25 kDa does not. To this end, we synthesized L-PEI derivatives that are intermediates between linear and branched PEIs. Our results show that the topology plays a crucial role in obtaining in vivo reporter gene expression, whereas the content of primary, secondary, and tertiary amines is only of minor importance.

INTRODUCTION

Introduction of nucleic acids into mammalian cells by using synthetic compounds such as cationic polymers has become a routine technology in many research fields. It allows for example the expression of a foreign or tagged protein by transfection of plasmid DNA or selective silencing of mRNAs by delivering small interfering RNAs into the target cell. However, to be useful as a gene delivery system for the treatment of human diseases, the efficiency of the currently existing nonviral transfection systems has to be significantly improved. One way to reach this goal is by synthesizing new transfection agents or by improving the performance of the currently existing ones. Alternatively, a better understanding of the molecular requirements for successful gene delivery will allow rational design of new vectors. In line with this latter approach, we undertook a detailed analysis of the key features of polyethylenimines (PEIs).[1]

PEIs belong to the most efficient synthetic gene transfer agents developed so far. Although these cationic polymers are available in a wide range of molecular weights (*1*), only two of them, namely, the linear PEI 22 kDa (L-PEI) and the branched PEI of 25 kDa (B-PEI), are commonly used as transfection reagents. Interestingly, although both polymers were described to possess high in vitro transfection efficiencies (*2, 3*), they differ profoundly in their ability to mediate in vivo gene transfer. Indeed, the L-PEI mediates in vivo reporter gene expression orders of magnitude higher than that of the branched PEI (*3*−*6*). It was largely unknown why two closely related compounds show such a difference in their in vivo transfection capacities. We therefore decided to identify the properties conferring the in vivo gene transfer capabilities of L-PEI.

To this end, we evaluated the role of the two parameters that differ between the L-PEI and the B-PEI, namely, their topology and their content of primary, secondary, and tertiary amines. We synthesized polymers presenting short amino residues grafted on the linear L-PEI backbone and containing various proportions of primary, secondary, and tertiary amino nitrogens. Our in vivo gene transfer experiments clearly demonstrate that the class of amines only plays a minor role in the transfection activity. The dominant effect for efficient in vivo gene transfer is based on the topology of the polymer.

EXPERIMENTAL PROCEDURES

Materials. Tetrahydrofuran (sds) was distilled over calcium hydride. *N*-(2-Chloroethyl)acetamide (Acros), 2-(dimethylamino)ethyl chloride hydrochloride (Aldrich), anhydrous ethyl alcohol (sds), methyl alcohol (sds), diethyl ether (sds), methylene chloride (sds), and sodium hydroxide pellets (Aldrich) were used as received. The linear PEI of 22 kDa was synthesized as described (*7*). The polyethylenimine of 25 kDa was from Aldrich. SMD2-LucΔ*I*TR (7.6 kb) is an expression plasmid encoding the firefly luciferase gene under the control of the human cytomegalovirus (CMV) immediate-early promoter.

Synthesis of Poly(ethylenimine-*co*-*N*-(2-aminoethyl)ethylenimine) (L-PEI-g-$CH_2CH_2NH_2$) (PEI-2). *N*-(2-Chloroethyl)-acetamide (1.57 g, 12.9 mmol) was dissolved in 20 mL of EtOH before dropwise addition to a solution of L-PEI (1.24 g, 0.06 mmol) in THF (20 mL) and stirred for 4 h at 65 °C. After the sample was evaporated, the product was dissolved in MeOH and precipitated by dropwise addition of diethyl ether to remove the excess of *N*-(2-chloroethyl)acetamide. The polymer was first isolated by filtration, and then dissolved in 50 mL of water with NaOH pellets (1.5 g, 37.5 mmol). The reaction mixture was stirred refluxing for 64 h. At room temperature, the product precipitated spontaneously, and after filtration and washing with water, it was dried in vacuo (952 mg, 83%).

^{1}H NMR ($CDCl_3$): δ (ppm) = 2.7 (bs, CH_2); 1.7 (bs, NH and NH_2). ^{13}C NMR ($CDCl_3$): δ (ppm) = 54.9 (NCH_2CH$_2$-NH$_2$); 52.4, 52.1 (−CH_2N(CH$_2$CH$_2$NH$_2$)CH_2-); 49.4 (−CH_2-NHCH_2-); 48.5−47.0 (−CH$_2$(H$_2$NCH$_2$CH$_2$)NCH_2CH$_2$NH-); 41.7 (NCH$_2$CH_2NH$_2$).

Synthesis of Poly(ethylenimine-*co*-N-(2-dimethylaminoethyl)ethylenimine) (L-PEI-g-$CH_2CH_2N(CH_3)_2$) (PEI-4). To a solution of L-PEI (1 g, 0.04 mmol) in EtOH (30 mL), a solution of 2-(dimethylamino)ethyl chloride hydrochloride (1.1 g, 7.64

mmol) in EtOH (10 mL) was added dropwise during 4 h at 65 °C, and the mixture was stirred at 65 °C for 2 h. The solution was concentrated on the rotavapor to precipitate a byproduct, i.e., a cyclic dimer of 2-(dimethylamino)ethyl chloride. After filtration, the organic layer was evaporated. The residue was dissolved in water at room temperature, and then NaOH pellets (1.2 g) were added for neutralization. To remove the excess NaOH and residual byproduct, the polymer was dissolved in methylene chloride, and then the organic layer was evaporated in vacuo. Yield was 457 mg (65%). ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.7 (bs, CH_2); 2.2 (m, N-(CH_3)$_2$).

Cell Culture. Dulbecco's modified Eagle medium (DMEM; GIBCO-BRL) was supplemented with 2 mM L-glutamine, 100 units/mL of penicillin, 100 μg/mL streptomycin, and 10% heat-inactivated foetal calf serum (HyClone). Human hepatocarcinoma cells (HepG2 cells; American Type Culture Collection) were used for the in vitro studies.

DNA Retardation Assay. DNA binding was studied by means of agarose gel retardation assays. Plasmid DNA (1 μg) and increasing amounts of PEI were each diluted in 25 μL of 150 mM NaCl and mixed. After a period of 15 min, samples (20 μl) were electrophoresed through a 1% agarose gel using Tris-borate-EDTA buffer, and DNA was visualized after ethidium bromide staining.

Particle Size Measurements. DNA (25 μg) and the desired amount of PEI were each diluted in 625 μL of either 5% glucose, 150 mM NaCl or 0.5 HBS (75 mM NaCl, 2.5% glucose, 10 mM Hepes). After the solutions were mixed and left for 10 min at room temperature, particle size was measured using a Zetasizer nano ZS (Malvern).

Preparation of DNA Complexes. Four micrograms of plasmid DNA and the desired amount of PEI were diluted into 100 μL of 150 mM NaCl and gently mixed. DNA complexes were prepared at various N/P ratios. After 15 min of incubation, the mixture was diluted with serum-free medium to a final volume of 1 mL.

For the in vivo experiments, the DNA complexes were formulated in 5% glucose since previous work showed that in vivo PEI-mediated transfection is more efficient when complexes are prepared in glucose than in sodium chloride (*5*, *6*). DNA and PEI were each diluted in 175 μL of 5% glucose and then gently mixed. After 15 min, complexes were ready for use.

Transfection Experiments. HepG2 cells were plated in 24-well plates 1 or 2 days before use. For transfection, 0.5 mL of serum-free transfection medium was put into each well. After 3 h of incubation at 37 °C, the medium was replaced with fresh one containing 10% of serum. Luciferase activity was assayed about 30 h after transfection. Each experiment was carried out several times; within a series, experiments were done in duplicate with 2 μg of DNA per well. The transfection experiments involving bafilomycin A1 were done in the same way as described above except that the drug was added after dilution of the complexes with DMEM, just before addition of the transfection medium to the cells.

The luciferase assay was performed as described (*8*). Luciferase background was subtracted from each value, and the transfection efficiency is expressed as total light units (10 s)$^{-1}$ (mg of protein)$^{-1}$ and the values are the means of duplicates. Protein content was measured by using the BioRad protein assay (Bradford).

Cell Viability Assay. Cytotoxicity was evaluated by performing the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT; Sigma) assay. Briefly, 1 day after transfection, the cell culture medium was removed and replaced by serum-free DMEM containing 0.5 mg/mL MTT. After incubation at 37 °C for 4 h, the medium was removed, and 200 μL of DMSO was added to each well to dissolve the formazan crystals produced from the reduction of MTT by viable cells. Absorbance was then measured at 570 nm. Untreated cells were used as control.

In Vivo Experiments. Experiments were conducted with five animals/condition. A total of 350 μL of PEI/50 μg CMV-Luc solution were slowly injected into the tail vein of female Balb/C mice (6−8 weeks old, Iffa-Credo). To facilitate the injection, vasodilation was achieved by working under a heating lamp. Mice were sacrificed 20 h post-administration.

For the measurement of luciferase levels in lungs, the following protocol was used: 500 μL of lysis buffer containing a cocktail of protease inhibitors (Sigma) were added to the collected organs. Each organ was then homogenized for about 30 s with an Ultra-turrax (Ika), and the homogenate was centrifuged for 10 min at 8000*g* at 4 °C. A 5 μL aliquot of the supernatant was used for luciferase assay.

RESULTS AND DISCUSSION

Synthesis of Poly(ethylenimine-*co*-N-(2-aminoethyl)ethylenimine)s (LPEI-*g*-$CH_2CH_2NH_2$). The synthesis of the copolymers containing both ethylenimine and grafted *N*-(2-aminoethyl)ethylenimine units was carried out in two steps: introduction of 2-acetamidoethyl residues (ACE) on the L-PEI backbone followed by alkaline hydrolysis to obtain short 2-aminoethyl side groups (Scheme 1, route a). In the first step, L-PEI was mixed with *N*-(2-chloroethyl)acetamide to give grafted *N*-(2-acetamidoethyl)ethylenimine units according to the reaction conditions summarized in Table 1. After solvent evaporation and precipitation in diethyl oxide to remove

[a] Ethylenimine units concentration of starting L-PEI. [b] Theoretical content of grafted ethylenimine units calculated from the initial concentration ratio of alkyl halide and secondary amino sites (100× [R−Cl]/[NH]). [c] Experimental content of grafted ethylenimine units calculated from ^{1}H NMR spectrum. [d] *N*-(2-Chloroethyl)acetamide concentration. [e] $Grafted_{ACE}$ ethylenimine units content. [f] 2-(Dimethylamino)ethyl chloride hydrochloride concentration. [g] $Grafted_{DMAE}$ ethylenimine units content.

unreacted *N*-(2-chloroethyl)acetamide, the polymers were collected under their protonated form. The modified L-PEIs were then analyzed by NMR spectroscopy to estimate the grafting efficiency. This conjugation experiment was conducted under various conditions of time, solvent, reaction temperature, and initial feed ratio [RCl]/[NH]. It can be noticed that a high reaction temperature was required to functionalize ethylenimine units by an acetamide side function (Table 1, run 1). ^{1}H NMR spectra of polymers collected in runs 2 and 3 revealed, besides the presence of peaks corresponding to modified L-PEI, the characteristic peaks of poly(*N*-acetylethylenimine) (PMeOXZ) at 2.1 and 3.5 ppm (*9*). The formation of this byproduct is explained by dehydrohalogenation of the chloroamide compound (favored by the presence of basic amino sites in starting and modified L-PEIs), leading to methyloxazoline monomer, which polymerizes with starting chloride agent (Supporting Information Scheme 1) (*10, 11*). To avoid this side reaction, acetamide was added dropwise to the polyamine solution in a THF/EtOH mixture making profit of the good solubility of modified L-PEIs in this medium (runs 4, 5, and 6). ^{1}H NMR spectra of poly(ethylenimine-*co*-*N*-(2-acetamidoethyl)ethylenimine)s in D_2O showed, besides the methylene protons of unreacted ethylenimine units at 2.9 ppm (H_a), two triplets and a broad singlet, respectively, at 3.7 (H_d), 3.1 (H_c), and 2.2 (H_e) ppm corresponding to 2-acetamidoethyl side groups introduced on polymer backbone (Figure 1a). Further, two new resonance peaks also appeared at 3.6 and 3.9 ppm with areas 2-fold higher than those of methylene protons (3.7, 3.1 ppm) of the amide side groups. The peak at 3.6 ppm was attributed to methylene protons near the protonated secondary amino groups (H_f), whereas resonance at 3.9 ppm was assigned to protons in α position of tertiary amines formed on L-PEI chain (H_b), probably downfield shifted by intramolecular hydrogen bond established between these nitrogens and acetamido residues. The assignments were also supported both by ^{13}C NMR and 2D-^{1}H NMR analyses (Supporting Information, Scheme 2). The experimental content of grafted acetamido (ACE) ethylenimine units in polymers was calculated by ^{1}H NMR spectroscopy from the peak integration ratio of methyl protons of 2-acetamidoethyl group (h_{He}) to the sum of those corresponding to methylene groups belonging to the L-PEI backbone ($h_{Ha} + h_{Hb} + h_{Hf}$), using the relationship: $grafted_{ACE} = (4/3)h_{He}/(h_{Ha} + h_{Hb} + h_{Hf})$ (Figure 1a).

The poly(ethylenimine-*co*-*N*-(2-acetamidoethyl)ethylenimine)s obtained in runs 4, 5, and 6 were fully hydrolyzed in alkaline conditions giving, respectively, poly(ethylenimine-*co*-*N*-(2-aminoethyl)ethylenimine) copolymers PEI-1, PEI-2, and PEI-3. The composition in the three classes of nitrogen groups of these polymers were determined from the initial contents of acetamido (ACE) and secondary amino units present in the precursor polymers (Table 2). Moreover, the ^{13}C NMR analysis of PEI-2 in $CDCl_3$ was compared to those of L-PEI and commercial B-PEI ($N_I/N_{II}/N_{III}$: 1/1/1) (Figure 2). It clearly showed the presence of methylene groups bonded, respectively, to tertiary and primary nitrogen atoms in the copolymer, thanks to the peaks observed above and below 49.4 ppm as proof of the grafted structure of the modified L-PEIs (*12*).

Synthesis of Poly(ethylenimine-*co*-*N*-2-dimethylaminoethyl)ethylenimine)s (LPEI-*g*-$CH_2CH_2N(CH_3)_2$). The synthesis of poly(ethylenimine-*co*-*N*-(2-dimethylaminoethyl)ethylenimine) copolymers was performed by direct reaction of 2-(dimethylamino)ethyl chloride hydrochloride with L-PEI (Scheme 1, route b). Several runs were carried out in EtOH solution stirred at 65 °C, using different [RCl]/[NH] feed ratios and time conditions (Table 1). As the reaction proceeded, a white precipitate appeared in the reaction medium, which was isolated by filtration. After solvent evaporation, the crude protonated grafted polymers were analyzed by ^{1}H NMR spectroscopy. The spectra showed the expected peaks corresponding to methyl protons of neutral and charged 2-dimethylaminoethyl moieties (DMAE) bonded to the L-PEI backbone, clearly distinguishible at 2.3 (H_j) and 2.8 (H_e) ppm. (Figure 1b). These resonance signals do not correspond to unreacted aminoethyl chloride since the triplet peak characteristic of methylene near of the halogen atom, usually seen at 3.7 ppm in D_2O, was absent on the spectra of the isolated polymers. The extent of polymer modification ($grafted_{DMAE}$ content) was calculated using the integrations of these peaks on one hand, and those of peaks present in the range 3−3.6 ppm ascribed to all methylene groups of compound on the other hand. Of note, the spectrum of the product obtained on run 8 showed also two peaks at 4.0 and 3.4 ppm corresponding to a non-negligible amount of a byproduct that partially precipitated in the reaction medium. To understand its formation, a NMR study of 2-(dimethylamino)ethyl chloride hydrochloride behavior in sodium hydroxide D_2O solution was performed and it showed the production of the same compound (witnessed by the same peaks increasing with time). Its chemical structure was established by mass spectroscopy as a cyclic quaternary ammonium dimer of 2-(dimethylamino)ethyl chloride formed in the medium owing to the basic character of L-PEI (Supporting Information Scheme 3). Of note, the formation of this product implies first the partial neutralization of the dimethylamino sites in the medium and also that the reaction easily undergoes on haloamine itself and consequently unfavored with L-PEI. This side reaction was reduced by dropwise addition of 2-(dimethylamino)ethyl chloride hydrochloride in the medium (runs 9, 10, and 11) leading, after neutralization, to poly(ethylenimine-*co*-*N*-(2-dimethylaminoethyl)ethylenimine) copolymers with short amino side groups, such as PEI-4 obtained from run 9, which has a secondary and tertiary amino composition rather close to the B-PEI one but without primary nitrogen groups (Table 2).

Gel Mobility Shift Assay and in Vitro Transfection Activity. To summarize the chemical part, we developed two types of grafted L-PEIs: the first series consist of modified L-PEIs characterized by the presence of different ratios of primary, secondary, and tertiary amines (Table 2). The second derivative contains only secondary and tertiary amines. Of note, PEI-2 presents almost the same ratios of I, II, and III amino groups compared to the branched PEI of 25 kDa. This particular derivative thus allows us to clearly distinguish the influence of the topology versus the content in I, II, and III amines on DNA transfection.

L-PEI	22000		0	100	0
B-PEI	25000		25	50	25

[a] Experimental grafted ethylenimine monomer units content in the copolymers. [b] N_I, N_{II}, and N_{III} are, respectively, the primary, secondary, and tertiary amine content of copolymers determined from NMR. [c–e] L-PEI-*g*-$CH_2CH_2NH_2$ obtained, respectively, after hydrolysis of runs 4, 5, and 6 (Table 1). [f] L-PEI-*g*-$CH_2CH_2N(CH_3)_2$ was obtained from run 9 (Table 1).

The DNA binding capacity of the grafted L-PEIs was evaluated by DNA retardation assays. The results summarized in Table 3 show that, as expected, all the derivatives were able to efficiently complex DNA. We then measured the transfection efficiency of all the polymers. Therefore, increasing amounts of PEI were complexed with a constant amount of a luciferase expression plasmid, and the resulting complexes were incubated with HepG2 cells. The luciferase assay showed that the four PEI derivatives (PEI-1 to -4) displayed similar capacities for reporter gene expression compared to the L- and B-PEI polymers (Figure 3). This confirms that the topology and the content in I, II, and III amines do not play a critical role when transfecting cell lines in vitro.

Proton Sponge Activity. We recently reported that the transfection efficiency of PEIs partly relies on their capacity to buffer endo-lysosomes (*8*)—a mechanism called proton sponge that leads to the release of DNA from the endosomes into the cytosol (*13*). Our demonstration was based on the use during transfection of drugs able to inhibit acidification of endocytic vesicles. Here, we investigated whether DNA transfection performed in the presence of bafilomycin A1, an antibiotic that selectively inhibits vacuolar type H^+-ATPases (*14*), results in

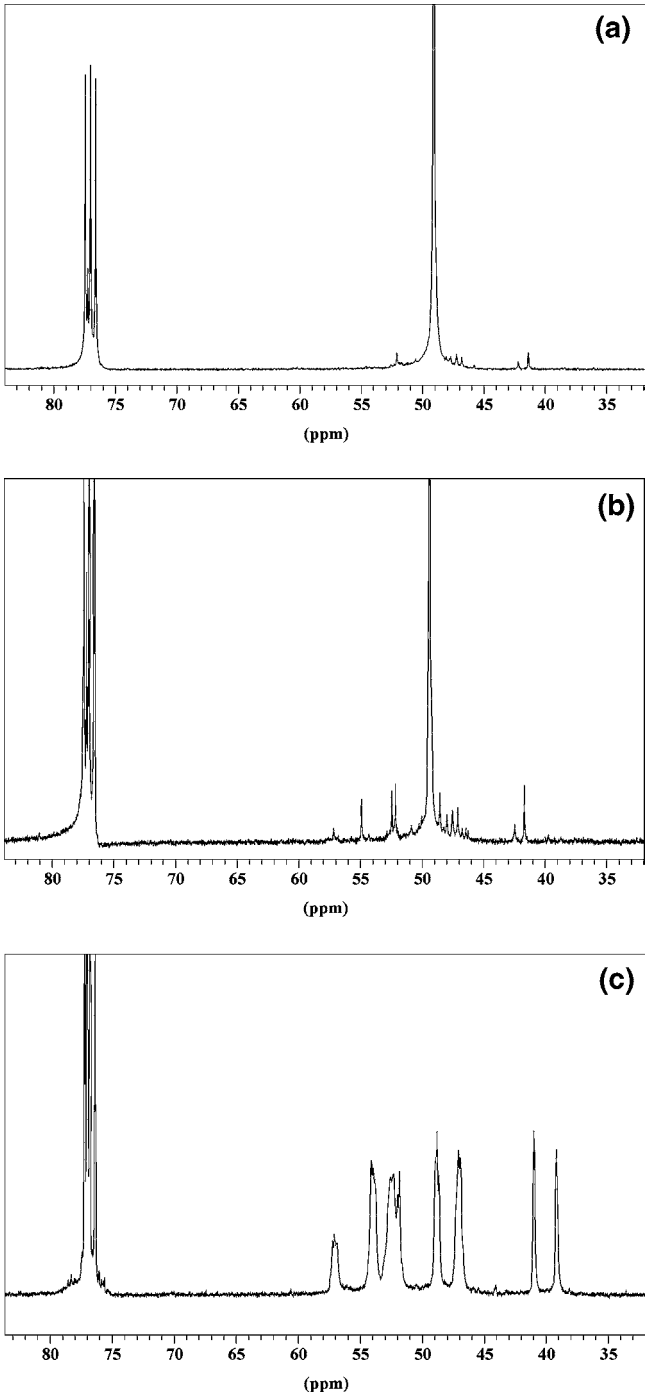

Figure 2. 300 MHz ^{13}C NMR spectra of (a) L-PEI; (b) L-PEI-*g*-CH_2-CH_2NH_2 (PEI-2) (Table 2); (c) commercial B-PEI ($N_I/N_{II}/N_{III}$: 1/1/1) in $CDCl_3$ (scans: 16000).

a similar severe drop in reporter gene expression for all the L-PEI derivatives. As shown in Figure 4a, bafilomycin A1 treatment led to luciferase levels about 100-fold lower than those obtained in the absence of drug. To ensure that the inhibition of transfection was not due to cytotoxicity of the drug, we measured the protein content and performed a MTT-based cell viability assay. The results indicate that incubation with bafilomycin A1 reduced the protein content as well as the cell viability to about 50% (Figure 4b). This latter value, however, cannot alone explain the 2 orders of magnitude decrease of reporter gene expression. Moreover, the efficiency of the monocationic lipid DOTAP, which was used as a control since its protonation state is not altered in the pH range 5−7.5, remained identical in the presence of the inhibitor, although the cytotoxicity was

Table 3. Characterization of Grafted L-PEIs/DNA Complexes

polymer	DNA retardation[a] (μg)	N/P ratio[b]	zeta potential[c] (mV)	particle size (nm)[d] 5% glucose	particle size (nm)[d] 150 mM NaCl
PEI-1	0.5	58	+17	72	895
PEI-2	0.5−1	15	+20	74	1028
PEI-3	0.5	19.5	+16	74	891
PEI-4	0.25−0.5	15	+21	72	760
L-PEI	0.5−1	13	+22	69	1178
B-PEI	0.5	13	+23	59	113

[a] Indicates the minimal amount of PEI required to completely retard 1 μg of plasmid DNA. [b] N/P ratios used for the zeta-potential and size measurements. [c] Complexes were generated in 150 mM NaCl, and the size measurement was performed about 20 min after complexes formation. [d] The size was measured 10 min after having mixed PEI with DNA.

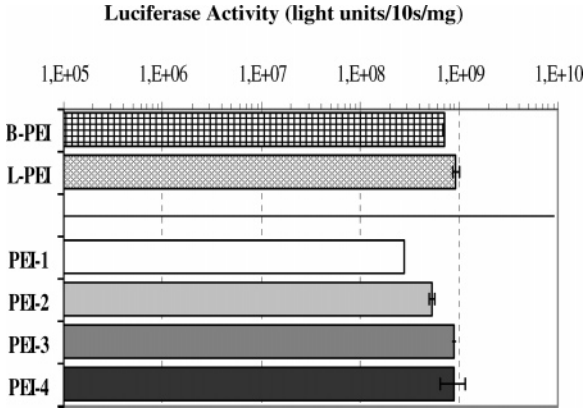

Figure 3. Evaluation of the transfection efficiency of grafted L-PEI derivatives on HepG2 cells. Increasing amounts of polymer were mixed with a constant amount of plasmid DNA (4 μg per duplicate). The complexes were incubated with the cells in serum-free culture medium for 3 h. The luciferase activity was measured 39 h thereafter. The transfection efficiency was expressed as total light units $(10\ s)^{-1}$ (mg of protein)$^{-1}$. For each compound, only the optimal condition is shown (N/P = 13 for B- and L-PEI; N/P = 11.5 for PEI-2 and PEI-4; N/P = 19.5 for PEI-3 and 58 for PEI-1).

similar compared to that observed with the polymers (Figure 4b). Taken together, these results suggest that the buffering capacities of all the PEIs are comparable.

Tail Vein Injection of PEI/DNA Complexes. Next, we evaluated the in vivo activity of PEI-2 and -4, which are the two most interesting derivatives among PEI-1 to -4 due to their amino contents. Polyplexes containing 50 μg of CMV-Luc and increasing amounts of polymer were generated and slowly injected into the tail vein. The levels of luciferase were measured in the lungs, where it is known that the expression is the highest. In agreement with the literature, the L-PEI demonstrated a 1000-fold higher transfection efficiency compared to the one displayed by the branched PEI (Figure 5). Of note, in our hands and in our conditions, we could not use N/P ratios higher than 7 with the B-PEI without inducing high mortality rates. Interestingly, the grafted L-PEIs 2 and 4 allowed for significantly higher luciferase expression compared to that with the B-PEI. In fact, PEI-2 and -4 were only 4 and 9 times less efficient than L-PEI, respectively. Taken together, these results clearly demonstrate that the topology plays a more crucial role than the content in I, II, and III amines for in vivo transfection.

Characterization of the Polyplexes. Previous work revealed that the linear PEI of 22 kDa and the branched PEI of 25 kDa show differences in some of their properties. In particular, Wightman and colleagues (*15*) found a stronger propensity of L-PEI compared to B-PEI to aggregate. This behavior may explain, to some extent, the differences observed in vivo between the two polymers. Indeed, it is known that large complexes are more efficient in mediating gene transfer than small ones (*16*),

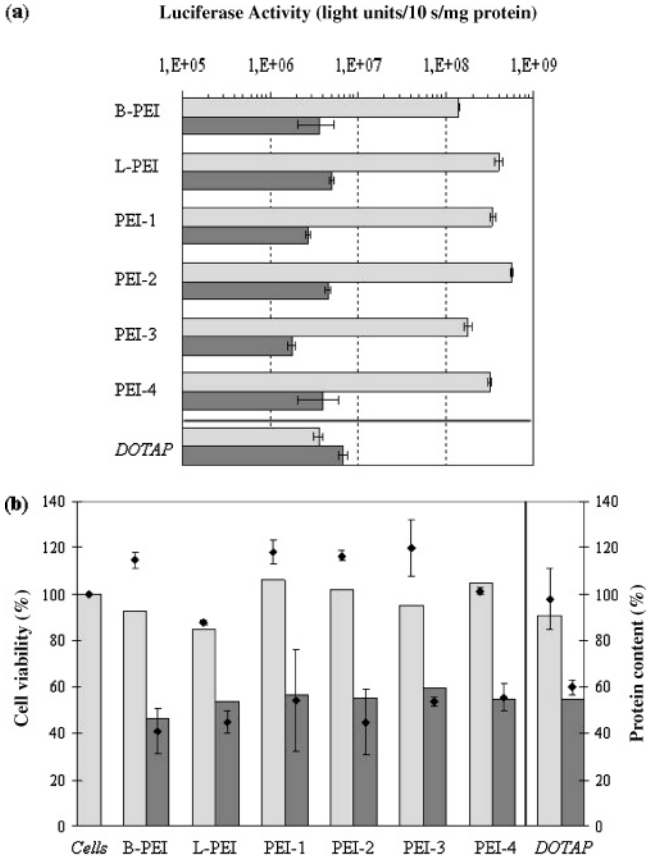

Figure 4. Effect of bafilomycin A1 on PEI-mediated transfection efficiency. HepG2 cells were transfected with PEIs (same N/P ratios as those described in legend of Figure 3) in the absence (light gray) or presence (dark gray) of 175 nM of the proton pump inhibitor bafilomycin A1. After about 3 h of incubation at 37°C, the transfection medium was removed and replaced with DMEM containing 10% of serum. (a) The luciferase activity was measured 30 h later. (b) The protein content measurements (the black diamonds represent the average of duplicates) and the MTT based cell viability assay ($n = 1$; light gray bars in the absence and dark bars in the presence of bafilomycin A1) were done as described in materials and methods.

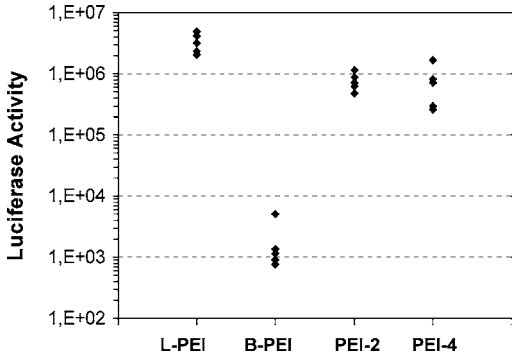

Figure 5. Evaluation of the in vivo efficiency. Complexes were prepared in 5% glucose with 50 μg of CMV-Luc mixed with increasing amounts of PEI. 350 μL of the solution was then slowly injected intravenously and 20 h postinjection, the luciferase levels were measured from the processed lungs ($n = 5$). For each compound, only the optimal condition is shown (N/P = 23 for PEI-2; N/P of 10 for PEI-4 and N/P ratios of 7 and 14 for the B- and L-PEI, respectively).

most probably because the endosomal release through the proton sponge effect is highly dependent on PEI concentration. Since the linear PEI-2 showed significant in vivo gene transfer capacity, we asked whether its aggregation properties are close to those of the L-PEI. To this end, we measured at different time points the particle size of DNA/grafted L-PEI complexes prepared in salt-free (5% glucose), in 0.5 HBS and in salt-rich

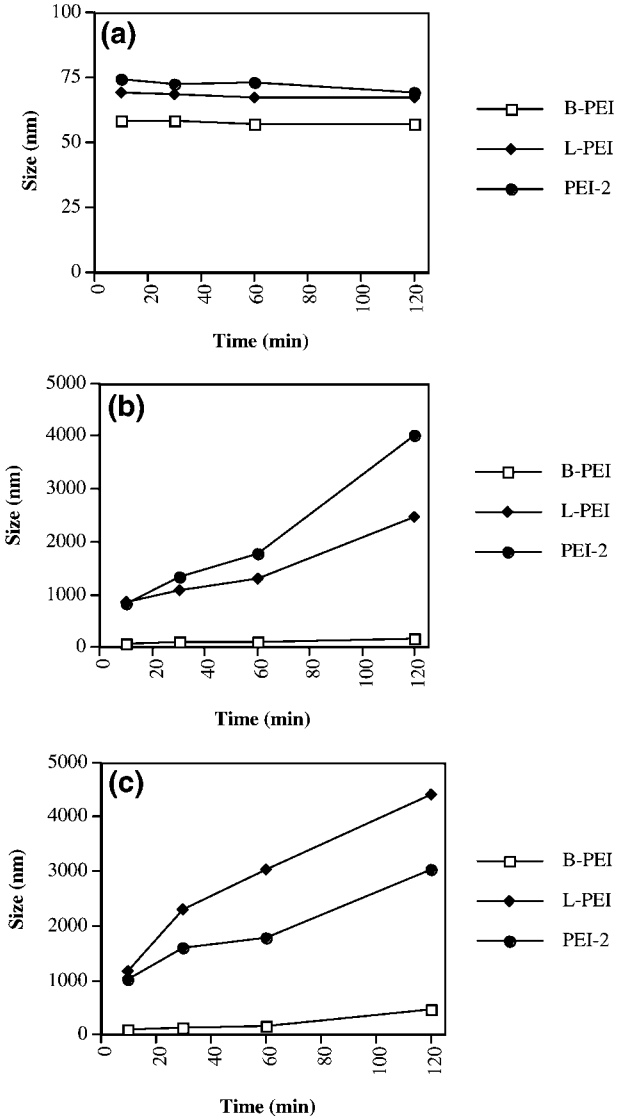

Figure 6. Measurement of particle size of complexes generated in varying salt conditions. PEI/DNA complexes (N/P = 13 for B- and L-PEI and 15 for PEI-2) were generated either in 5% glucose (a), 0.5 HBS (b) or 150 mM NaCl (c). The size of the particles was monitored at 10, 30, 60, and 120 min after complex formation.

(150 mM NaCl) conditions. In salt-free conditions L- and B-PEI, as well as PEI-2, generate stable particles with a diameter below 100 nm (Figure 6). This is in agreement with results from the literature (*15*). However, in the presence of salt, differences between the branched and the grafted/linear PEIs appeared: while the particle size of B-PEI/DNA complexes only slowly increased in size with time, complexes generated with the L-PEI and PEI-2 rapidly aggregated, and particle size became micrometric within 10 min. These results clearly show that PEI-2 shares the same aggregating properties compared to the L-PEI. Size measurements performed with the other PEI derivatives confirmed that the linear topology amplifies complex aggregation in the presence of salt (Table 3). Of note, in these assays, all the complexes had a positive surface charge, the zeta potential being around +20 mV (Table 3).

Taken together, our results show that PEI-2, like the L-PEI, generates small complexes in salt-free conditions, whereas in the presence of salt, aggregation occurs in a time-dependent manner. It is interesting to note that L-PEI/DNA complexes generated in 150 mM NaCl are significantly less efficient in vivo than particles prepared in 5% glucose (*15*). This suggests that at the time of injection the particles have to be small, but

once in the blood or once complexes reached the target tissue—mainly the lung after intravenous injection—aggregation of the complexes has to occur to obtain efficient cell transfection.

Conclusion. In the present work, we describe a way to modify linear PEIs, allowing for the introduction of primary and tertiary amino groups. DNA transfection with such compounds clearly demonstrated that the topology of a polymer plays a more critical role than the content in I, II, and III amines to obtain efficient in vivo gene transfer. Of note, we have recently shown that it is possible to synthesize linear PEI derivatives (L-PNPEIs) having high buffering capacities while being significantly less efficient than the nonmodified L-PEI (*7*). Together, these results demonstrate that even polymers that possess a linear topology and a capacity to buffer endo-lysosomes are not necessarily efficient in vivo transfection agents. Therefore, other parameters such as flexibility of the polymer, as suggested by Szoka and colleagues for dendrimers, may be of importance (*17*).

Temperature Dependent Gene Expression Induced by PNIPAM-Based Copolymers: Potential of Hyperthermia in Gene Transfer

Arkadi Zintchenko,* Manfred Ogris, and Ernst Wagner

Pharmaceutical Biology-Biotechnology, Department of Pharmacy, Ludwig-Maximilians-Universität, Butenandstr 5−13, Munich, D-81377, Germany. Received October 5, 2005; Revised Manuscript Received March 16, 2006

The objective of this work was to obtain gene delivery vectors with high efficiency induced by application of local hyperthermia. As a building construct for the polyplex particles, block copolymers were used, in which one block represents poly(ethyleneimine) (PEI) and another block a statistical copolymer of poly(*N*-isopropylacryamide) (PNIPAM) and different hydrophilic monomers (acrylamide or vinylpyrrolidinone). The block copolymers were synthesizized by radical polymerization of the corresponding monomers directly onto PEI. The complexation of DNA with these copolymers led to small, charge neutral particles, which aggregated upon increasing the temperature from 37 °C to 42 °C. This aggregation was found to be responsible for the enhanced transfection efficiency of these formulations under hyperthermic conditions. Gene expression in cells treated by hyperthermia was found to be nearly 2 orders of magnitude higher in comparison to cells transfected at physiological temperature. The mechanism by which hyperthermia influences the gene transfection efficiency is proposed.

1. INTRODUCTION

Nonviral gene delivery vectors are becoming increasingly attractive as delivery vehicles because of a great flexibility regarding the type and size of DNA delivered, their low production costs, and low immunogenicity, which enables repeated applications. However, they show rather low efficiency compared to viral vectors. Therefore, the main directions in development of nonviral vectors are to increase specificity and transfection efficiency and to decrease toxicity. Specificity can be achieved by targeting of the delivery vehicle to a specific site. The targeting strategies developed at present can be divided into two types (*1*): Targeting based on incorporation of specific cell binding ligands into the gene transfer vector enables an increased and specific accumulation of particles within the target tissue. Physical targeting is achieved by local application of an external force; this provides higher efficiency of gene expression at the site where it is applied. Physical targeting can be achieved by application of ultrasound (*2*, *3*), magnetic (*4*), or electric field (*5*, *6*), heat (*7*, *8*), and light (*9*, *10*). Regional hyperthermia is an approved method for treatment of solid tumors (*11*) by selectively heating tumor tissue to 40−44 °C. Above 42.5 °C a direct cytotoxic effect on tumor cells is observed, whereas below that temperature an immunstimulatory effect and radiation- and chemosensibilization take place. Additionally, application of heat to the targeting site increases the permeability of the tissue and allows the extravasation of macromolecular drugs, e.g. liposomes, into the interstitium (*12*, *13*). This effect can in principle also be utilized for delivery on particulate gene delivery systems, e.g. polyplexes.

Transfection studies with thermosensitive polymers were reported previously using poly(*N*-isopropylacrylamide) (PNIPAM)[1]-based copolymers. PNIPAM is a nonionic polymer, which is known to undergo hydrophilic to hydrophobic phase transition by increasing the temperature above 32 °C. The authors synthesized either statistical copolymers of NIPAM with cationic comonomer (*14*, *15*) or block copolymers with polycation (*16*). In all cases they found an increased expression of the reporter gene for the cells being incubated at room temperature during transfection. An increased transfection in these works was attributed to partial dissociation of the polyplexes and better availability of DNA for cell translation machinery. However, for practical applications the low temperature is not easy to achieve in vivo.

In this study we synthesized copolymers of PEI as a cationic block, and statistical copolymers of NIPAM with hydrophilic comonomers such as acrylamide (AAm) or vinylpyrrolidinone (VP). Hydrophilic comonomers are known to increase the transition temperature of PNIPAM depending on the monomer ratio (*17*−*19*). By their incorporation into the PNIPAM chain, the transition temperature can be easily tuned above 32 °C. Varying the copolymer composition enables adjustment of the copolymer phase transition temperature between 37 °C and 42 °C. At physiological temperatures, such copolymers being covalently attached to the surface of DNA/polycation polyplexes can shield the particles from unspecific interactions and provide their stability in a similar fashion as PEGylation of polyplexes. During hyperthermia they can destabilize the particles and lead to their aggregation. Also, PNIPAM above the phase transition point is known to destabilize liposomal membranes (*20*, *21*), which suggests that it also might enhance release of the particles from intracellular lipid vesicles such as endosomes.

Here we describe the synthesis of block copolymers between branched PEI and thermosensitive PNIPAM-based polymers. On the basis of these polymers, we obtained DNA polyplexes with temperature-dependent gene transfection efficiency.

2. EXPERIMENTAL SECTION

2.1. Materials. Ammonium persulfate (APS) was purchased from Amersham Biochemicals (Freiburg, Germany), and mercaptoethanol (ME) was purchased from Merck (Darmstadt,

Germany). Acrylamide (AAm), *N*,*N*-isopropylacrylamide (NIPAM), 1-vinyl-2-pyrrolidinone (VP), and branched poly(ethyleneimine) (PEI) (M_w = 25 kDa) were purchased from Aldrich (Munich, Germany). PEI22−PEG20 (PEI-22 kDa, linear form, conjugated with PEG 20kDa) was synthesized and purified as previously described in Kursa et al. (*26*).

Cell culture media, antibiotics, and fetal calf serum (FCS) were from Life Technologies (Karlsruhe, Germany). Plasmid pCMVLuc (*Photinus pyralis* luciferase under control of the CMV enhancer/promoter) described in Plank et al. (*22*) was purified with the EndoFree Plasmid Kit from Qiagen (Hilden, Germany).

2.1.1. Synthesis of the Copolymers. Copolymers poly(NIPAM-*stat*-AAm)-*block*-PEI and poly(NIPAM-*stat*-AAm)-*block*-PEI were prepared by radical copolymerization of NIPAM with AAm or VP in water using APS as initiator in the presence of PEI. PEI served as a promoter as well as a starting block. The mixture contained 0.6 g of PEI and 0.06 mol of monomer mixture. To avoid cross-linking due to recombination of radicals, ME (17.5 μL) was added to the copolymerization mixture. Argon was bubbled through the solution during 15 min to remove oxygen. The molar ratios of monomers in the feed are presented in Table 1. Thereafter APS (200 μL 5% APS w/v) was added to the reaction mixture. The amount of added APS corresponded to a molar ratio of APS/PEI of 2/1. Copolymerization was carried out at room temperature for 2 h. The final product was dialyzed against water using a cellulose acetate membrane (Roth, Karlsruhe, Germany) with a molecular weight cut off of 18 kDa for 2 days and freeze-dried. PEI content in the copolymers was determined as a number of primary amino groups by TNBS assay at 405 nm (*23*). The cloud point was determined on a fluorimeter (Varian Eclipse, Varian, Mulgrave, Australia) in HBS buffer (20 mM HEPES, pH 7.1, 150 mM NaCl) with emission and excitation wavelengths set to 500 nm.

2.2. Polyplex Formation. DNA was condensed with PEI at a molar ratio of PEI nitrogen to DNA phosphate (N/P ratio) of 6. DNA/PEI polyplexes were prepared at a final DNA concentration of 20 or 200 μg/mL by flash-mixing of plasmid DNA (1 mg/mL) with PEI or PEI copolymer (15 or 150 μg/mL PEI) in HEPES-buffered glucose (HBG, 5% glucose, 20 mM HEPES, pH 7.1). Polyplexes were allowed to stand for at least 20 min at room temperature before use.

2.3. Methods. *2.3.1. Chromatography.* Cation exchange was performed on a Macro-Prep High S, HR 10/10 column (Bio-Rad, Munich, Germany) in water, NaOH gradient from 0 to 0.1 M NaOH at a flow rate of 1 mL/min.

2.3.2. ^{1}H and ^{13}C NMR Measurements. The ^{1}H and ^{13}C NMR measurements of the copolymers were performed in D_2O on a Bruker 400 MHz instrument. To avoid any influence of the Nuclear Overhauser effect (NOE), all ^{13}C spectra used for quantitative analysis were recorded using inverse gated decoupling pulse sequences. The ratios between primary, secondary, and ternary amines was calculated as described in ref 24.

2.3.3. Ethidium Bromide (EtBr) Displacement Assay. The ability of the copolymers to condense DNA was studied using an ethidium bromide (EtBr) assay. Copolymer solution was added stepwise to plasmid DNA solution (10 μg/mL) in HBG containing EtBr (0.4 μg/mL). After each step, fluorescence intensity was monitored (λ_{ex} = 510 nm, λ_{em} = 590 nm). The fluorescence intensity of the EtBr solution in the presence of free DNA corresponded to 0% condensation, whereas the fluorescence intensity without DNA corresponded to 100% DNA condensation.

2.3.4. Measurement of Particle Size and Zeta-Potential. Particle size of transfection complexes was measured by laser-light scattering using a Malvern Zetasizer 3000HS (Malvern Instruments, Worcestershire, UK). Polyplexes were generated at DNA concentration of 20 μg/mL and subsequently diluted to 2 μg/mL prior to measurement. For estimation of surface charge, transfection complexes were diluted in 10 mM NaCl to give a final DNA concentration of 2 μg/mL and the zeta-potential was measured as previously described (*25*).

2.3.5. Cell Culture and Transfection. Neuro2A cells (ATCC CCL-131) were grown at 37 °C in a 5% CO_2 humidified atmosphere in DMEM containing Glutamax I, 20 mM HEPES, and 10% fetal calf serum (FCS). Cells were plated in 96-well plates with 1×10^4 cells per well 24 h prior to transfection. Transfection complexes containing 200 ng of pCMVL plasmid DNA were added per well in serum free medium. After 4 h of incubation (if not otherwise indicated), transfection medium was replaced by fresh culture medium. The cells were treated with hyperthermia in a cyclic regime in which 30 min heat shock at 42 °C was followed by 30 min at 37 °C. The heat shock was introduced either during incubation with complexes or after change of culture medium. The total duration of hyperthermia was between 0 and 6 h. Luciferase gene expression was measured after 24 h as described (*26*). Values are given as relative light units and represent the luciferase activity per 10^4 cells as mean ± standard deviation of at least triplicates. Two nanograms of recombinant luciferase (Promega, Mannheim, Germany) correspond to 10^7 light units.

2.3.6. In Vitro Cytotoxicity Using MTT Assay. Neuro2A cells were seeded into 96-well microtiter plates at a density of 1×10^4 cells/well. After 24 h the culture medium was replaced with 100 μL/well of serial dilutions of polymer stock solutions in DMEM. Alternatively, polyplexes with a final DNA concentration of 200 μg/mL were formed in HBG, serially diluted, and added in a fixed volume of 10 μL to the cells. After a 4 h incubation period medium was replaced by fresh culture medium. After 24 h MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) (Sigma-Aldrich, Germany) was dissolved in phosphate-buffered saline at 5 mg/mL, and 10 μL was added to each well reaching a final concentration of 0.5 mg MTT/mL. After an incubation time of 1 h, unreacted dye with medium was removed. The purple formazan product was dissolved in 100 μL/well dimethyl sulfoxide and quantified by a plate reader (Tecan, Groedig, Austria) at 590 nm with background correction at 630 nm. The relative cell viability (%) relative to control wells containing cell culture medium without polymer was calculated by ([A] test/[A] control) × 100.

2.3.7. Covalent Labeling of Plasmid DNA and Flow Cytometry. Plasmid pCMVLuc was covalently labeled with the fluorophore Cy5 using the Label IT kit (MIRUS, Madison, WI) according to the manufacturers instructions. On average, one Cy5 molecule was bound per 50 bp.

For analysis by flow cytometry, cells were seeded in six-well plates at a density of 2×10^5 cells per well 24 h prior to transfection. Polyplexes containing Cy5-labeled DNA (20% Cy5-DNA) were added to the cells at a DNA concentration of 2 μg/well in 1 mL of fresh culture medium, and cells were harvested after 1 h incubation at 37 °C or 42 °C by treatment with collagenase solution (Invitrogen GmbH, Karlsruhe, Germany). Cell association of polyplexes was assayed using a Cyan MLE flow cytometer (DaKoCytomation, Copenhagen, Denmark). The fluorophore Cy5 was excited at 635 nm and emission was detected at 665 ± 20 nm. Data were analyzed in logarithmic mode. To discriminate between viable and dead cells and to

exclude doublets, propidium iodide was added to the cell suspension and cells were appropriately gated by forward/side scatter, pulse width, and propidium iodide fluorescence. 1×10^4 gated events per sample were collected. Median channel values ± SD of triplicates (representing the median intensity of cell-associated DNA) were determined and presented as analytical fluorescence units (AFU).

3. RESULTS AND DISCUSSION

3.1. Synthesis and Characterization of the Copolymers. The initiating system based on tetramethylethylendiamine (TMEDA) and APS is well-known from the literature and widely used in laboratory practice (i.e. for preparation of acrylamide gels). APS itself is able to decompose only at high temperature; noticeable formation of free radical is observed only at 50−60 °C. TMEDA is able to catalyze the decomposition of APS and shift the formation of radical to room temperature. Moreover, during the decomposition, a free radical is formed on one of the methyl groups of TMEDA. Thus, TMEDA serves not only as a promoter in decomposition of APS, but it is also a starting block for the further polymerization (*27*). TMEDA was found to be an optimal promoter for APS decomposition. However, the efficiencies of many similar structures were extensively studied. It was found that the increase of the distance between two amines by additional methylene groups inactivates the promoter. The substitution of methyl groups to longer aliphatic radicals in the basic structure decreases the rate of decomposition. However, the activity of the promoter is still sufficient to induce the polymerization (*28*). Since the structure of PEI is very similar to the structure of TMEDA, PEI should be able to promote the decomposition of APS, so that polymerization could start directly on the PEI chain. The advantage of this strategy is the formation of the product in one step, in comparison to the alternative way, namely synthesis of NIPAM copolymer with further conjugation to PEI molecule.

Two hydrophilic comonomers, AAm and VP, were used for NIPAM polymerization. Since the lower critical solution temperature (LCST) of pure NIPAM in water is approximately 32 °C, the introduction of hydrophilic residues into the polymer chain should increase the solubility of the final polymer. The composition of the copolymer could be adjusted in such way to obtain the optimal characteristics of the system for hyperthermic treatment, namely with a LCST between 37 °C and 42 °C.

ME was added to copolymerization mixture for control of the molecular weight of the growing chains and to avoid the cross-linking as a result of recombination of growing radicals.

The addition of APS to the reaction mixture led to heating of the sample due to the start of polymerization. In case of the polymerization of pure NIPAM the increase of the temperature of the reaction mixture was accompanied with the increase of turbidity of the solution. The temperature of the reaction mixture seems to rise in this sample above the LCST of NIPAM (32 °C), which was not the case for all other copolymers. In contrast, after the addition of APS to monomer solution without PEI this effect was not observed. Thus, PEI is indeed able to act as a promoter of APS decomposition and starting block for polymerization.

It is known from the literature that acrylates are able to react with primary and secondary amines by Michael addition. To estimate the extent of this side reaction, ^{13}C NMR spectra of copolymers were compared with the spectrum of PEI (data not shown). The primary amines are known to be more reactive in Michael addition in comparison to secondary amines. Thus, the side reaction should decrease the signals, corresponding to primary amines and increase the signals, corresponding to the secondary amines. However, no significant changes in the ratio between signals of two generations of amines were found. The ratio between primary, secondary, and ternary amines in PEI was 29/42/29%. For PVP10 the ratio 31/40/29% was found. These data are similar to those found for the same PEI sample in ref 24. Therefore, Michael addition was considered to have no influence on the structure of the copolymers.

To prove the binding of NIPAM chains to PEI, the polymer sample was applied cation exchange column under pH gradient. The collected fractions were tested for primary amines by TNBS assay. The fractions containing PEI were freeze-dried, dissolved in D_2O, and measured by ^1H NMR. The peak of methyl protons corresponding to NIPAM was found in PEI containing fractions, which indicates the formation of block copolymer. The comparison of NMR spectra of the copolymer before and after purification (δ 2.3−3.4 ppm for PEI protons and δ 1.2 for methyl group in NIPAM) reveals that about 50% of PNIPAM chains in the initial sample are not bound to PEI. For example, in case of PVP10 sample the ratio between PEI protons and NIPAM was 2.1:1 before and 4.3:1 after purification. Similar results were obtained for other copolymers. Such observation is in accordance with the mechanism of decomposition of APS in the presence of TMEDA (*27*). APS produces two radicals: one on the carbon of TMEDA, and the other is a free hydroxyl radical. Therefore, in the presence of chain transfer agent (ME) only half of the PNIPAM chains are expected to be bound to PEI. It is likely that the following dialysis did not lead to separation of the free PNIPAM chains from block copolymer.

Since free PNIPAM copolymer did not show any influence on the transfection (see Supporting Information), for all investigations the samples were used without further purification.

Different contents of hydrophilizing comonomer (AAm or VP) in the feed were used for polymerization (Table 1). The content of PEI in final copolymers (from TNBS assay) and their cloud points, attributed to the first temperature, at which the turbidity of the polymer solution starts to increase, are presented in Table 1. The cloud points of the copolymers increase with the increase of the content of hydrophilizing comonomer in the feed. Samples AAm25 and PVP10 fulfill the requirements for hyperthermic treatment, namely, their LCST is between 37 °C and 42 °C. These copolymers were used for further studies.

3.2. Complex Formation between DNA and Copolymers. It is known from the literature that block copolymers of PEI and PEG show lower ability to condense DNA in comparison to pure PEI. Therefore, at first the efficiency of DNA condensation by the copolymers was studied by EtBr displacement assay. Both, PEI and PEI copolymers behaved similarly, with 90% of EtBr exclusion at N/P 2.5 and above.

The sizes of the particles formed by mixing of PEI or of the copolymers with DNA in HBG were around 150−200 nm. However, PEI polyplexes were strongly positively charged (ζ-potential +30 mV), whereas polyplexes with copolymers were neutral (ζ-potential − 3 to +2 mV). Increasing the ionic strength of the complex solution to physiological NaCl concentration led to relatively fast aggregation of PEI polyplexes. The size of the polyplexes was already in the micrometer range, after 15 min of incubation. In contrast, copolymer polyplexes and PEGylated polyplexes remained small after addition of NaCl for at least 4 h at 37 °C. Obviously, the hydrophilic chains of the copolymer coating decrease the surface charge and sterically stabilize the particles against aggregation.

The increase of temperature to 42 °C led to relatively fast aggregation of the copolymer-based particles. Large aggregates in micrometer range could be observed already after 15 min of incubation at high temperature. The copolymer chains become hydrophobic at 42 °C and collapse, which leads to loss of colloidal stability of the particles and aggregation. In case of

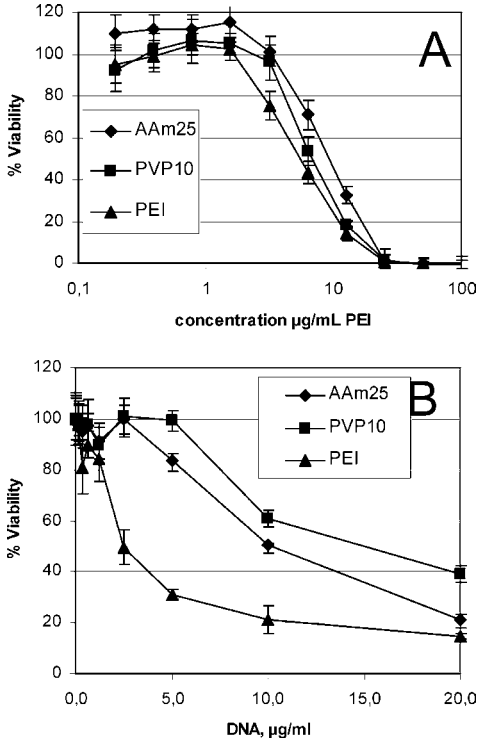

Figure 1. Cellular viability after 24 h incubation (A) with polycations, as a function of concentration in μg/mL PEI or (B) with the corresponding polyplexes N/P = 6 as a function of DNA concentration in μg/mL.

PEGylated polyplexes no significant changes in particles size after incubation at 42 °C was observed.

3.3. In Vitro Cytotoxicity Using MTT Assay. The cytotoxicity normalized to the concentration of PEI was similar for all copolymers and corresponded to the cytotoxicity of PEI (Figure 1a). However, the complexes of copolymers with DNA showed significantly lower toxicity, compared to PEI-based polyplexes (Figure 1b). Apparently, the hydrophilic shell around the particles prevents the interactions of copolymer-based polyplexes with cells and decreases the toxicity. It is necessary to note that in all gene transfection studies the final concentration of PEI in the culture medium was 1.45 μg/mL, where no toxic effects were observed.

3.4. Transfection Efficiency of Complexes. The influence of different temperature regimes on gene expression of various polyplexes was studied. Since long hyperthermic treatment is associated with high cytotoxicity (A. Zintchenko, unpublished observations), short heat shocks (30min) were repeatedly introduced (1−8 times) to cell culture followed by incubation at physiological temperature (30 min). In other words, one cycle of hyperthermia means 30 min at 42 °C and 30 min at 37 °C. No significant cytotoxicity was detected even after eight cycles.

The gene transfection efficiencies of different formulations without hyperthermia and with eight cycles hyperthermia (four during incubation with polyplexes, four after medium change, "4 + 4" regime) are presented in Figure 2. In case of pure PEI polyplexes or PEGylated PEI polyplexes, reporter gene expression is independent of hyperthermia treatment. In contrast, hyperthermia led to an increase in reporter gene expression by 2 orders of magnitude when using polyplexes formed with thermally responsive copolymers AAm25 and PVP10. Without hyperthermia the gene expression of these complexes corresponds to the moderate expression of PEGylated complexes, whereas with hyperthermia it increases to the high level of pure PEI polylexes. In case of AAm15 (the copolymer with LCST below physiological temperature), the expression is high in both

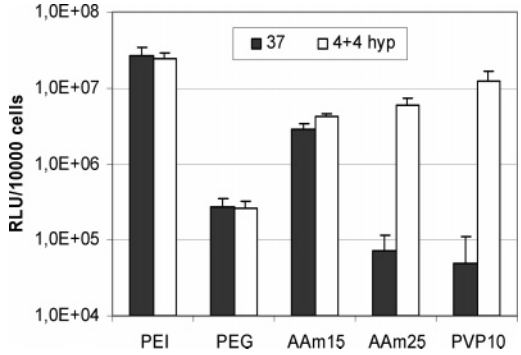

Figure 2. Luciferase gene expression after transfection with polyplexes (N/P = 6) based on pure PEI ('PEI'), PEI/PEI−PEG 90/10 ('PEG'), or copolymers AAm15, AAm25, PVP10. Black bars, no hyperthermia; white bars, four cycles of hyperthermia during incubation with complexes + four cycles after change of the medium ("4 + 4 regime").

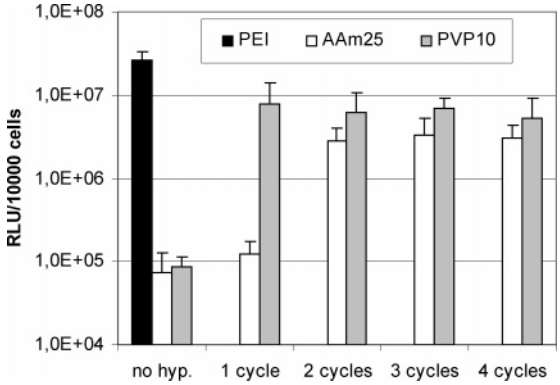

Figure 3. Luciferase gene expression after transfection with polyplexes (N/P = 6) based on PEI (black bars) or copolymers AAm25 (white bars) and PVP10 (grey bars) for a different number of hyperthermia cycles (1−4) and without hyperthermia. The hyperthermic treatment was applied during incubation of the complexes with the cells. The medium was changed after 4 h of incubation.

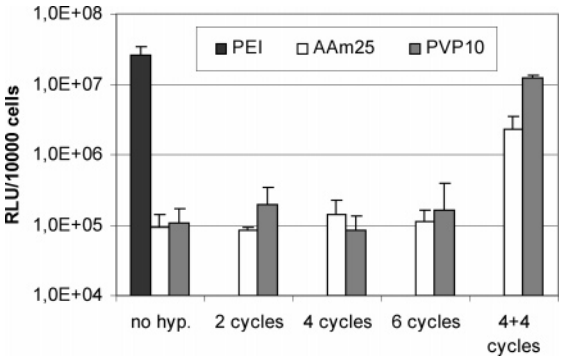

Figure 4. Luciferase gene expression after transfection with polyplexes (N/P = 6) based on PEI (black bars) and copolymers AAm25 (white bars) and PVP10 (grey bars) with different number of hyperthermia cycles (2−6) and without hyperthermia. The hyperthermic treatment was applied after the medium change. For comparison the gene expression after the "4 + 4 regime" is presented.

cases. These data demonstrate that the copolymers AAm25 and PVP10 at the temperature above LCST show thermally induced high gene transfer and are suitable for activation by local hyperthermia at a clinically relevant temperature of 42 °C.

To find out at which stage of the transfection process the hyperthermic treatment plays the most important role, the heat shock was applied to the cells either during incubation with complexes or after the change of medium (Figures 3 and 4). In case of PVP10, after one hyperthermic cycle during incubation with the complexes, the gene expression had already reached the maximum level (Figure 3). Further cycles did not increase

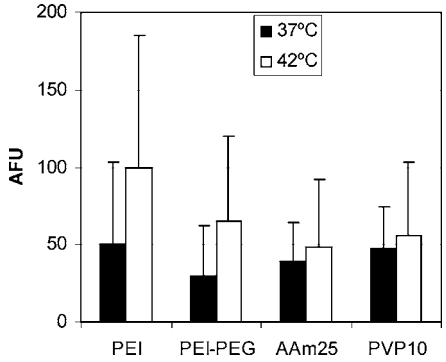

Figure 5. Median fluorescence of the cells 1 h after transfection with Cy5-labeled DNA for PEI ('PEI')-, PEI/PEI−PEG 90/10 ('PEG')-, AAm25-, and PVP10-based complexes.

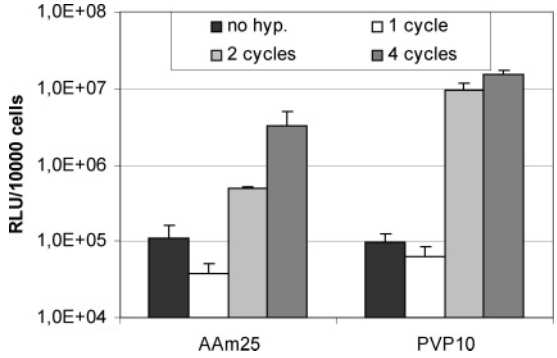

Figure 6. Luciferase gene expression after transfection with polyplexes (N/P = 6) based on PEI and copolymers AAm25 and PVP10 for a different number of hyperthermia cycles (1−4) and without hyperthermia. The hyperthermic treatment was applied during incubation of the complexes with the cells. After the indicated number of cycles, the transfection medium was replaced by fresh culture medium.

the transfection efficiency. In case of AAm25 the gene expression gradually increased during three cycles and was saturated thereafter.

In contrast, heat treatment applied after medium change did not lead to higher gene expression even after six cycles applied (Figure 4). These data allow the conclusion that the changes in the system before cellular internalization of the complex, namely particle aggregation, play the most important role. Also, it seems that the collapsed PNIPAM chains are not able to enhance the escape of particles from the endosome. Otherwise, the gene transfection efficiency would increase with the increasing number of hyperthermia cycles after medium change, acting on internalized particles.

The aggregation of the particles could lead to enhanced interaction with the cell membrane and consequently increase their cell association. Flow cytometry studies showed that cell association increases during hyperthermia (Figure 5). However, the increase is observed for all systems, even for PEI− and PEI−PEG-based polyplexes, where no temperature dependence in gene expression was observed (see above). This can be explained by the fact that only thermosensitive formulations changed their aggregation behavior after hyperthermia, whereas PEI−PEG polyplexes remained small and PEI polyplexes were already aggregated without hyperthermia leading to maximal trasngene expression (see also Figure 2). It is known from literature that PEG-PEI particles do not further aggregate inside endosomes and are therefore inefficient in terms of endosomal escape and subsequent transgene expression (*29*). Apparently the aggregation state of polyplexes is of greater importance for improved intracellular trafficking and increased transgene expression then a 2-fold increase in cell association (see also Figure 7 and discussion). Thus, the enhanced cell association during hyperthermia is not the decisive factor providing the enhanced transfection efficiency.

Nevertheless, cell association and internalization are still the important steps during transfection. The change of the transfection medium after one cycle of hyperthermia greatly decreases gene transfection efficiency (Figure 6), whereas one or two cycles of hyperthermia without medium change were sufficient to achieve elevated levels of reporter gene expression (Figure 3), as demonstrated when the incubation of cells with polyplexes was extended for a further 3 h before medium change. Hyperthermia induces aggregation of particles, but it does not enhance the rate of their uptake into the cells. Only one cycle of hyperthermia is sufficient for particles to aggregate, but the long incubation times with aggregates are still necessary to achieve a high gene expression.

4. DISCUSSION

All these observations support a mechanism by which hyperthermia can increase the transfection efficiency of thermosensitive polyplexes (see Figure 7). In the case of pure PEI-based polyplexes, initially small particles formed in HBG rapidly aggregate in culture medium. In contrast, PEGylated polyplexes are stable in culture medium and therefore remain small (*30*, *31*). Thereafter, either big (PEI) or small (PEG−PEI) particles are internalized (see also (*29*). After internalization, big aggregates are more effective in their escape from the endosomal compartment compared to small ones due to the proton sponge effect induced by PEI (*31*). Small particles, which contain less PEI material per endosome, are not able to induce sufficient osmotic pressure inside the endosome. Consequently, the endosomal release is hindered. In the case of big particles the endosomes contain remarkably more PEI material, the osmotic pressure inside is much higher and the particles are easier to release (*32*).

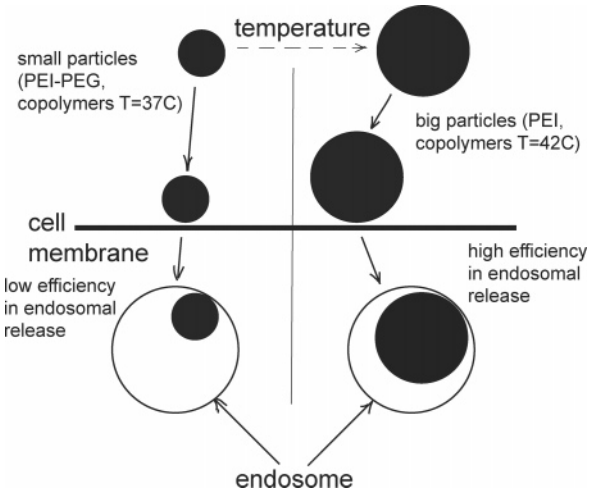

Figure 7. Schematic representation of the mechanism of cell transfection by thermosensitive polyplexes.

Thermosensitive polyplexes at physiological temperature, where hydrophilic copolymer stabilizes the particles against aggregation, acting similarly to PEGylated particles. They are small and not effective in endosomal release. At a higher temperature the shielding copolymer undergoes phase transition, becomes hydrophobic, and is not able to stabilize the particles any more. As a consequence the polyplexes aggregate and form big particles in micrometer size. Similar to pure PEI-based polyplexes, they have a higher ability to escape from the endosomal compartment. These conclusions are well supported by the observation that the levels of gene expression of the thermosensitive polyplexes without hyperthermia correspond to the level of PEGylated polyplexes. When hyperthermia during

incubation of thermosensitive polyplexes with cells is applied the gene expression level correlates with that of pure PEI-based polyplexes.

The aggregation of the thermosensitive polyplexes during hyperthermia proceeds relatively fast. One to two cycles are already sufficient to reach maximum gene expression. However, the internalization seems to be much slower. Therefore, the hyperthermia treatment together with a shorter incubation with the polyplexes dramatically decreases the gene transfection efficiency. Such results are consistent with findings with pure PEI polyplexes (*33*).

5. CONCLUSIONS

In this study we developed a transfection vector which shows enhanced gene transfection efficiency in combination with hyperthermia. We synthesized a set of different block copolymers. The PEI block is able to condense DNA, whereas the statistical copolymer of NIPAM with AAm or VP is a thermosensitive block. The latter undergoes transition from hydrophilic to hydrophobic state upon the increase of the temperature. Synthesis of block copolymers was achieved by polymerization of a NIPAM/AAm or NIPAM/VP monomer mixture directly onto PEI chains in the presence of APS. The copolymers effectively condensed DNA and formed small, charge neutral particles. Gene transfection of thermosensitive polyplexes increased by 2 orders of magnitude after hyperthermia. The reason was found to be the aggregation of the particles prior to internalization. To our knowledge this is the first report of a nonviral, polymeric gene delivery system which can be selectively activated by hyperthermia at clinically relevant temperatures.

Received October 7, 2005; Revised Manuscript Received February 24, 2006

Synthetic bifunctional probes based on [4,7-bis-carboxymethyl-10-(2-aminoethyl)-1,4,7,10-tetraaza-cyclododec-1-yl]-acetic acid (DO3A-ethylamine) preloaded with gadolinium were prepared for applications in targeted magnetic resonance imaging (MRI) and optical imaging. A convenient route of synthesis is reported, which allowed conjugation of this probe with biomolecules for the preparation of model MR contrast agents for targeted imaging. The conjugated probes have the following interesting properties: (1) GdDO3A-ethylamido-biotin (**Gd-9**) can be used for targeted imaging using an avidin−biotin system. (2) The fluorescent probe GdDO3A-ethylthiourea-fluorescein (**Gd-12**) is a bimodal compound, which can be used for both MR and optical imaging. The precursors, DO3A-ethylamidopropyl-maleimide (**11**) and DO3A-ethyl-isothiocyanate (**13**) contain a highly reactive moiety, which can interact with free SH-terminals and N-terminals of biological molecules, respectively. In vitro MR relaxivity studies were performed at 300 MHz using different concentrations and chemical environments. MR relaxivity for ligand **Gd-9** at pH 7.4, r_1 was (3.32 ± 0.03) s^{-1} mM^{-1} and r_2 was (5.02 ± 0.14) s^{-1} mM^{-1}. For the mixture of **Gd-9** with avidin, at pH 7.4, relaxivity increased linearly with the avidin concentration. A relaxivity enhancement of 45% for r_1 and more than 400% for r_2 with respect to the unbound biotinylated Gd^{3+} complex was found at a ratio of 4:1. MR relaxivity for ligand **Gd-12**, r_1 was (5.36 ± 0.05) s^{-1} mM^{-1} at pH 7.4. Fluorescence microscopy and spectroscopy of **Gd-12**-labeled 3T3 mouse fibroblasts showed a concentration-dependent intracellular uptake, accompanied by a slight dose-dependent increase in toxicity up to 150 μM. MR studies on labeled cells indicated a contrast enhancement in both T_1- and T_2-weighted images by the internalized compound, with the effect being more pronounced in T_2-weighted images. Our results indicate that DO3A-ethylamine is a multipurpose precursor, from which various targeted contrast agents can be synthesized after a single-step conjugation with organic/bioorganic molecules.

INTRODUCTION

Magnetic resonance imaging (MRI) possesses an unsurpassed potential for the exploitation of intrinsic tissue and structural differences visualized as image contrast by using a wide variety of pulse sequences. Typically, MRI contrast depends on endogenous differences in water content and relaxation time in the tissue of interest. The specificity and sensitivity of MR imaging can be further enhanced by the utilization of contrast agents (CAs) based on paramagnetic metals such as gadolinium (Gd). These low molecular weight compounds distribute rapidly in blood and the extracellular fluid space and enhance image contrast by shortening the longitudinal relaxation time (T_1) and transverse relaxation time (T_2) *(1−4)*. The Gd metal ion has a high magnetic moment and long electronic relaxation times, making it most suitable for this purpose due to strong dipolar interactions with water nuclei protons. However, the introduction of paramagnetic ions directly in vivo is limited by inherent toxicity. Therefore, acyclic and macrocyclic polyamino-carboxylates are used as strong ligands to sequester the material and prevent toxicity. These ligands occupy eight of the nine available coordination sites in Gd forming kinetically and thermodynamically stable complexes *(5)*. The ninth coordination site remains available for fast exchange of coordinated water molecules with those surrounding the complex to transmit the paramagnetic relaxation effect to bulk solvent. Wide ranges of nonspecific CAs are being used in clinical applications for evaluation of physiological parameters. However, to be able to detect focal anomalies or functions, the need arises for functionalized and targeted ligands that enable the relaxivity of the CAs to indicate the function of a particular variable.

Targeted CAs localize to specific molecular targets with high affinity and specificity, thus enhancing the diversity of MR applications. They are able to recognize specific target molecules and induce an enhancement of water proton relaxation rate on binding with the target molecule *(2, 6, 7)*. A diverse variety of targeting ligands have been chemically coupled with CAs depending on the nature of final specific application of the CA. Asialoglycoproteins have been used for liver-specific application due to their high affinity for ASG receptors located uniquely on hepatocytes *(8, 9)*. Tumor selective accumulation of porphyrin-based CA is attributed to high affinity of these compounds for necrotic tissue *(10)*. DTPA-bisamide-based ligands

have been used for diagnosis of several types of malignancy on the basis of molecular recognition of sialic acid residues *(11)*. Monoclonal antibodies (MoAbs) and antibody fragments provide highly specific target recognition and binding for CAs. Breast cancer cells expressing Her-2/neu receptors were imaged in vivo with a two step labeling protocol using biotinylated Herceptin MoAb and avidin−GdDTPA conjugates *(12)*.

On the basis of previous reports on the synthesis and applications of targeted CAs, we have developed straightforward synthetic routes for the preparation of targeted CAs derived from DO3A-ethylamine (DO3A-EA), with potential for further conjugation with other molecules containing appropriate reactive groups.

In an effort to obtain a precursor that can enable noninvasive imaging of imperative processes in vivo using MRI, Gd-loaded DO3A-ethylamido-biotin has been synthesized by conjugating DO3A-EA with biotin. Similar systems based on DOTA after loading with metallic radionuclides such as yttrium or indium are also being explored at an in vivo level for application in radioimmunotherapy (*13*−*17*). This technology has found useful application in the medical field to localize and image cancer cells in vivo and to pretarget drugs to tumors *(18)* where MoAb−avidin/biotin act as targeting macromolecule/effector molecule pairs *(19)*. Pretargeting approach takes advantage of the fact that biotin binds strongly to the proteins avidin and streptavidin, resulting in signal amplification.

The second conjugate GdDO3A-ethylthiourea−FITC possesses fluorophore fluorescein on one arm and is intended to obtain a precursor for bimodal imaging where the macrocyclic part serves for MRvisualization and the FITC part for optical imaging. CAs intended for cell labeling can be designed from this precursor for tracking cells in vivo by MR and/or fluorescence imaging. Over the past few years, some cell therapies have developed sufficiently to enter clinical trials. However, the pace of progress toward an effective cell-based therapy has been slowed by the paucity of technology for tracking cells' fate in vivo. Recently de Vries et al. reported the use of MRI for tracking transplanted cells and obtained a detailed view of cell biodynamics in vivo (*20*−*22*). Agents based on the use of bimodal imaging have been applied to disease detection by attaching a target-specific site *(23)* or to observe cellular localization and migration *(24*−*26)*. This gives rise to the need to develop intracellular CAs that will facilitate improved contrast; the precursor presented here can serve as a template for obtaining such agents.

Additionally, to encompass the complete range of chemical reactivity, the nucleophilic "arm" of DO3A-EA was exchanged with electrophile groups, and two new precursors were designed and synthesized. The amino group of DO3A-EA was transformed to isothiocyanate, resulting in the formation of DO3A-ethyl isothiocyanate. This molecule possesses selective reactivity toward amines, thus providing the possibility of using it as a precursor for conjugation with biomolecules such as proteins, peptides and MoAbs *(27*−*30)*. The other precursor, DO3A-ethylamidopropyl-maleimide, obtained by coupling of amine with 4-maleimidobutyric acid, further enhances the diversity of application by exploiting its reactivity toward sulfydryl groups and therefore, prospects for combining with thiol-containing peptides, dendrimers, oligonucleotides *(31*−*34)*. These precursors can serve as important building blocks for designing targeted CAs with desirable traits.

EXPERIMENTAL PROCEDURES

Chemicals. All solvents and reagents were used at the purest grade commercially available without further purification/distillation. Cyclen was purchased from Strem, France. Bromoethylamine hydrobromide, *tert*-butyl bromoacetate, methyl bromoacetate, thiophosgene, trifluoroacetic acid, biotin, *N*-methylmorpholine (NMM), 1-hydroxybenzotriazole hydrate (HOBt), *N*′-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride (EDC), *N*,*N*-dimethylformamide (extra dry), toluene, diethyl ether, and lithium hydroxide were purchased from Aldrich, Germany. Fluorescein isothiocyanate (FITC) and chloroform were purchased from Acros Organics, Germany. Sodium carbonate, 4-maleimidobutyric acid, acetonitrile (anhydrous), carbon tetrachloride, methanol, dichloromethane, *n*-hexane, ethyl acetate, gadolinium chloride hexahydrate, hydrogen chloride, silica gel 60 (70−230 mesh), sodium bicarbonate, tetrahydrofuran, sodium sulfate and potassium carbonate were purchased from Fluka, Germany. Pure water (18 MΩ cm^{-1}) was used throughout. All glass labware was washed with a mixed acid solution and thoroughly rinsed with deionized, distilled water *(35)*.

Reversed Phase High-Performance Liquid Chromatography (HPLC). HPLC was performed at room temperature on a Varian PrepStar Instrument, Australia, equipped with PrepStar SD-1 pump heads. UV absorbance was measured using a ProStar 335 photodiode array detector at 214 and 254 nm. This detector is equipped with a dual-path length flow cell which enables measurement of absorption of analytical and preparative samples without changing the flow cell. Reversed-phase analytical HPLC was performed in a stainless steel Chromsep (length 250 mm, internal diameter 4.6 mm, outside diameter 3/8 in. and particle size 8 μm) C_{18} column and preparative HPLC was performed in a stainless steel Chromsep (length 250 mm, internal diameter 41.4 mm, outside diameter 2 in. and particle size 8 μm) C_{18} column (Varian, Advanced Chromatographic Solutions). The compounds were purified using one of the following two methods. Method A: the gradient was used with the mobile phase starting from 95% solvent A (water) and 5% of solvent B (MeOH) to 70% B in 10 min, 100% B in 18 min, 100% B isocratic till 24 min and decreased to 5% B in 28 min. Alternatively, in method B, isocratic mode was maintained with mobile phase starting from 97% solvent A (water) and 3% of solvent B (MeOH) for 8 min. The flow rate generally used for analytical HPLC was 1 mL/min and for preparative HPLC 41 mL/min. All the solvents for HPLC were filtered through a nylon-66 Millipore filter (0.45 μm) prior to use.

Spectroscopy. NMR spectra were recorded on a Bruker 250 MHz system for ^{1}H and ^{13}C NMR. Mass spectra (ESI-LRMS in positive and negative ion mode) were performed on ion trap SL 1100 system (Agilent, Germany) and ESI−HRMS were performed on Bruker Daltonics Apex II FT-ICR-MS (Bruker, Germany).

Synthesis. *[4,7-Bis-carboxymethyl-10-{2-[5-(2-oxo-hexahydro-thieno[3,4-d]imidazol-4-yl)-pentanoylamino]-ethyl}-1,4,7,10-tetraaza-cyclododec-1-yl]-acetic Acid (**9**, DO3A-ethyl-amido-biotin).* A solution of **8** (0.1 g, 0.15 mmol) in 10 mL of THF:MeOH:water (3:2:2) was stirred at 0−5 °C for 15 min, and then LiOH (12 mg, 0.5 mmol) was added. The reaction mixture was stirred for 3 h at room temperature. The progress of the reaction was monitored by ESI-LRMS. After completion, the solvent was evaporated under reduced pressure and the residue was purified by preparative HPLC [method A, $\lambda = 214$ nm, retention time (t_R) = 9.4 min]. After lyophilization, 72 mg (77%) of **9** as a white solid compound was obtained. ^{1}H NMR (D_2O, 250 MHz), δ (ppm): 1.37−1.45 (m, 2H); 1.61−1.68 (m, 4H); 2.27 (t, $J = 6.87$ Hz, 2H); 2.74−3.23 (m, 14H); 3.32−3.38 (m, 9H); 3.48 (s, 3H); 3.75 (s, 3H); 4.39−4.44 (m, 1H); 4.58−4.62 (m, 1H). ^{13}C NMR (D_2O, 62.9 MHz), δ (ppm): 22.7; 25.4; 25.7; 28.0; 33.0; 33.2; 37.5; 46.1; 46.8; 48.3; 49.1; 52.7; 53.1; 54.4; 58.0; 59.8; 163.0; 169.3; 174.7. ESI−HRMS (+): calcd $C_{26}H_{45}N_7O_8S$: *m*/*z* 616.31231 $[M + H]^+$, found 616.31194 $[M + H]^+$.

*[4,7-Bis-carboxymethyl-10-{2-[4-(2,5-dioxo-2H-pyrrol-1(5H)-yl)-butanamido]-ethyl}-1,4,7,10-tetraaza-cyclododec-1-yl]-acetic Acid (**11**, DO3A-ethylamidopropyl-maleimide).* A solution of **10** (0.1 g, 0.17 mmol) in 14 mL of THF:MeOH:water (3:2:2) was stirred at 0−5 °C for 15 min, and then LiOH (20 mg, 0.83 mmol) was added. The reaction mixture was stirred for 3 h at room temperature. The progress of the reaction was monitored by ESI-LRMS. After completion, the solvent was evaporated under reduced pressure and the residue was purified by preparative HPLC (method A, $\lambda = 214$ nm, $t_R = 5.8$ min). After lyophilization, 72 mg (86%) of **11** as an off-white solid compound was obtained. ^{1}H NMR (D_2O, 250 MHz), δ (ppm): 1.80−1.94 (m, 2H); 2.37 (t, $J = 7.48$ Hz, 2H); 3.03 (t, $J = 6.10$ Hz, 2H); 3.20−3.31 (m, 10H); 3.40−3.51 (m, 15H); 3.83 (s, 4H). ^{13}C NMR (D_2O, 62.9 MHz), δ (ppm): 25.5; 35.4; 38.0; 41.0; 51.1; 51.6; 53.1; 53.7; 53.9; 54.9; 56.8; 58.9; 137.1; 173.8; 175.8; 178.3. ESI−HRMS (+): calcd $C_{24}H_{38}N_6O_9$: *m/z* 555.27730 $[M + H]^+$, found 555.27740 $[M + H]^+$.

*[4,7-Bis-carboxymethyl-10-(2-fluoresceinthioureaethyl)-1,4,7,10-tetraaza-cyclododec-1-yl]-acetic Acid (**12**, DO3A-ethylthiourea−FITC).* A solution of DO3A-EA (**7**) (0.1 g, 0.26 mmol) in 10 mL of water was stirred at room temperature, and FITC (0.11 g, 0.28 mmol) was added at pH 8.5. During stirring, pH was maintained at 8.0−8.5 by addition of 1 M Na_2CO_3. The reaction mixture was stirred for 18−20 h at room temperature in the dark. The reaction was monitored by ESI-LRMS. The reaction mixture was evaporated under reduced pressure and the residue was purified by preparative HPLC (method A, $\lambda = 254$ nm, $t_R = 6.8$ min). After lyophilization, 0.11 g (55%) of **12** as a dark orange solid compound was obtained. ^{1}H NMR (D_2O, 250 MHz), δ (ppm): 2.86−2.99 (m, 18H); 3.38−3.42 (overlapped s, 6H); 3.75 (bs, 2H); 6.52 (s, 1H); 6.53 (s, 1H); 6.55 (s, 1H); 6.59 (s, 1H); 7.16 (t, $J = 4$ Hz, 2H); 7.20 (s, 1H); 7.49 (d, $J = 6.4$ Hz, 1H); 7.66 (s,1H). ^{13}C NMR (D_2O, 62.9 MHz), δ (ppm) 43.5; 52.5; 53.2; 53.7; 53.9; 55.0; 59.9; 106.3; 115.1; 125.7; 127.7; 128.9; 132.1; 133.7; 134.2; 143.5; 161.4; 161.4; 176.8; 179.5; 179.8 183.3. ESI−HRMS (+): calcd $C_{37}H_{42}N_6O_{11}S$: *m/z* 779.27050 $[M + H]^+$, found 779.27051 $[M + H]^+$.

*[4,7-Bis-carboxymethyl-10-(2-isothiocyanatoethyl)-1,4,7,10-tetraaza-cyclododec-1-yl]-acetic Acid (**13**, DO3A-ethyl-isothiocyanate).* A solution of **7** (0.2 g, 0.5 mmol) in water (10 mL) was stirred at room temperature and thiophosgene (0.18 g, 1.5 mmol) in 5 mL of CCl_4 was added dropwise. The pH of the mixture was maintained at 7.5−8 using 1 M Na_2CO_3. The reaction was monitored by ESI-LRMS. The reaction mixture was evaporated and the residue was purified by preparative HPLC (method B, $\lambda = 214$ nm, $t_R = 2.7$ min). After lyophilization, 0.13 g (59%) of **13** as a light yellow solid was obtained. ^{1}H NMR (D_2O, 250 MHz), δ (ppm): 3.23−3.79 (m, 20H); 4.20 (br. s, 6H). ^{13}C NMR (D_2O, 62.9 MHz), δ (ppm) 42.8; 48.5; 51.4; 51.9; 52.8; 55.9; 57.9; 129.3; 178.1; 179.0. ESI−HRMS (+): calcd $C_{17}H_{29}N_5O_6S$: *m/z* 449.21768 $[M + NH_4]^+$, found 449.21790 $[M + NH_4]^+$.

Preparation of Gd Complexes. Gd complexes of DO3A-ethylamido-biotin (**Gd-9**) and DO3A-ethylthiourea−FITC (**Gd-12**) were prepared from respective solution of the ligand (1 equiv) and solution of $GdCl_3 \cdot 6H_2O$ (1.1 equiv). The reaction mixture was stirred at 50−60 °C for 12−16 h. The pH was periodically checked and adjusted to 7.0−8.0 using a solution of Na_2CO_3 (1 M) and HCl (1 N) as needed. After 12−16 h, the reaction mixture was passed through chelex-20 to trap free Gd ions, and the Gd-loaded complex was eluted. The fractions were lyophilized and white solids were obtained. The absence of free Gd^{3+} was checked with xylenol orange indicator *(36)*.

Gd-9. ESI-LRMS (−): calcd $C_{26}H_{42}GdN_7O_8S$: *m/z* 770.2; found 769.1 $[M - H]^-$.

Gd-12. ESI-LRMS (−): calcd $C_{37}H_{39}GdN_6O_{11}S$: *m/z* 932.2; found 931.3 $[M - H]^-$.

Effect of Gd-12 on Cells in Vitro. Experiments on cells were done in 96-well microplates by inoculation of NIH-3T3 mouse fibroblasts (1×10^4 cells/well) cultured in Dulbecco's Modified Eagle's Medium supplemented with 10% fetal bovine serum, 4 mM L-glutamine, 100 μg/mL streptomycin, and 100 U/mL penicillin (all purchased from Biochrom AG, Germany). After 24 h, cells were incubated with various concentrations (up to 150 μM) of **Gd-12** for an additional 18 h. After repeated cell washing with Hanks' buffered saline (Biochrom AG, Germany), cell-related FITC fluorescence (Ex 485 nm/Em 530 nm) was evaluated in a multiplate reader (BMG Labtech, Germany). Subsequently, fluorescence microscopy was performed with the same cells on a Zeiss Axiovert 40 CFL (Germany) to observe the cellular localization of **Gd-12**.

Evaluation of cytotoxicity was done by addition of propidium iodide and a detergent with subsequent fluorescent reading (Ex 530 nm/Em 645 nm). In addition, by combination of the two fluorescence readings, a correlation is established between the FITC fluorescence and the total cell number per well. Experiments were run three times each with six replicates. Statistical analysis was performed by ANOVA with Dunnett's post test. P values < 0.05 were considered significant.

MR Measurements. *Relaxivity Measurements.* Different concentrations (0.8 mM, 0.6 mM, 0.4 mM, 0.1 mM) of **Gd-9** and (1 mM, 0.7 mM, 0.4 mM, 0.1 mM) of **Gd-12** were prepared in phosphate buffer in 1.5 mL Eppendorf tubes at physiological pH to measure relaxivity.

The measurement of the relaxation rates R_1 and R_2 (longitudinal and transverse relaxation) of the **Gd-9** was performed at 300 MHz on a vertical 7 T/60 cm MRI Biospec system (Bruker Biospin, Germany), which was described recently *(37)*. Up to 16 tubes could be measured simultaneously. The relaxation rate measurements of the samples were performed at room temperature (~21 °C).

For R_1, a spin−echo saturation recovery sequence was used, varying the repetition time TR and keeping the echo time TE minimal and constant. Typical parameters were: field of view 17×6.9 cm^2, matrix 512×256, slice thickness 4 mm, SW 70 kHz, TE 15 ms, TR 40−8000 ms (logarithmic time steps, 80 images). For R_2, a multi-spin−echo sequence was used with a long TR between excitations. Similar parameters were used, but TR = 8 s and TE = 17−850 ms (linear echo time steps, 50 echoes).

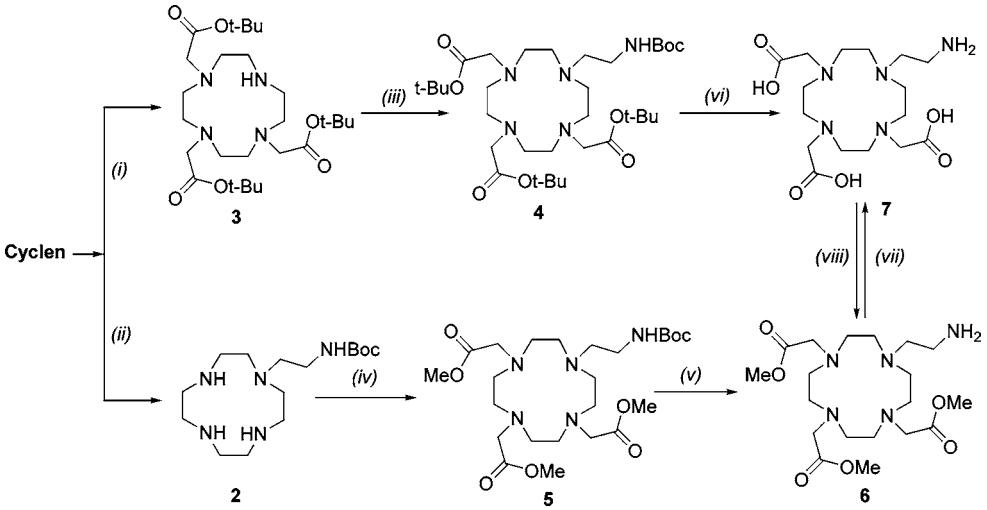
MR Study of the Avidin−Gd-9 Interaction. To measure the enhancement of R_1 and R_2, MRI experiments were performed with increasing concentrations of avidin (Fluka, Germany) proportional to a constant concentration of **Gd-9** (0.4 mM) incubated for 3 h at 37 °C. The longitudinal relaxivity (r_1) and transverse relaxivity (r_2) was determined from concentration-dependent measurements of relaxation rates (R_1 and R_2) of **Gd-9**.

In Vitro MR Studies of Gd-12 with Cells. For MR imaging of cells, exponentially growing 3T3 cells were labeled with 80 and 150 μM **Gd-12** in 175 cm^2 tissue culture flasks for 18 h. After repeated washing with Hanks' buffered saline, cells were trypsinized, centrifuged, and resuspended in 1.5 mL Eppendorf tubes at 1×10^7 cells in 500 μL of complete DMEM. Cells were allowed to settle before making MR measurements. Tubes with medium only, cells without **Gd-12**, and cells resuspended in medium containing the extracellular contrast agent Magnevist (Schering, Germany) at 50 μM served as controls.

MRI of the cell pellets was also performed at 300 MHz using T_1- and T_2-weighted spin−echo sequences at room temperature (~21 °C), as in the above description.

The axial slice of interest was positioned through the cell

Scheme 1[a]



[a] Reagents and conditions: (i) *tert*-butyl bromoacetate, $NaHCO_3$, MeCN, 71%; (ii) *N*-Boc-bromoethylamine (**1**), toluene, 68%; (iii) **1**, K_2CO_3, DMF, 72%; (iv) methyl bromoacetate, Na_2CO_3, MeCN, 82%; (v) DCM, TFA, 80%; (vi) TFA, 64%; (vii) LiOH; THF:MeOH:H_2O (3:2:2), 64%; (viii) MeOH.HCl, 95%.

pellet. Experimental parameters for T_1 were as follows: field of view 17 × 6.9 cm^2, matrix 512 × 256, slice thickness 1.5 mm, SW 70 kHz, TE 14.6 ms, TR 40−6000 ms, two averages (logarithmic time steps, 80 images). For T_2, similar parameters were used, but TR = 8 s and TE = 15−675 ms (linear time steps, 45 echoes).

Sagittal images were obtained with a field of view 11.3 × 6.9 cm^2, matrix 256 × 256, slice thickness 2 mm, SW 70 kHz, TE 10.9 ms, TR 1600 ms, 4 averages for T_1 weighted images, and a field of view 12.5 × 6.8 cm^2, matrix 256 × 256, slice thickness 2 mm, SW 70 kHz, TE 90 ms, TR 8000 ms, 2 averages for T_2 weighted images.

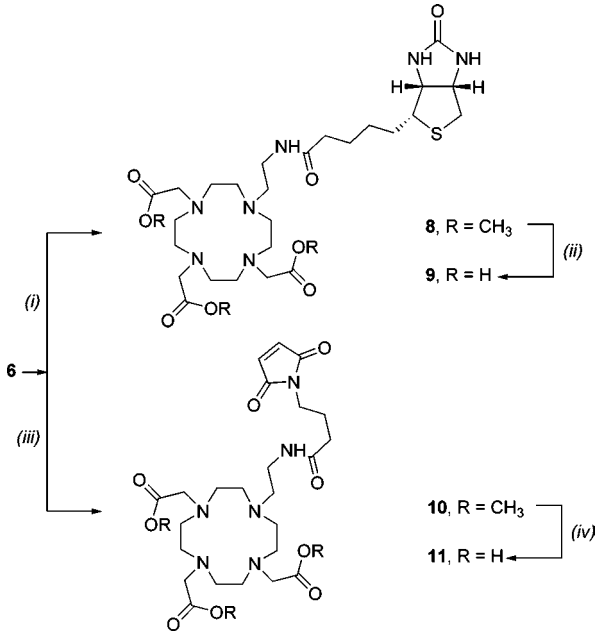
Data Analysis. Data analysis was performed by the *fitting* to relaxivity curves with self-written routines under MATLAB 6.5 R13 (The Mathworks Inc.). For a detailed description, see Supporting Information.

RESULTS AND DISCUSSION

Synthesis of Ligands. DO3A-EA (**7**) is a bifunctional ligand *(38)*, bearing an amine group that is readily reactive toward most electrophiles such as aldehydes, carboxylic acids, and isothiocyanates to form various molecules for the development of targeted CAs. Though DO3A-EA has already been part of several synthetic schemes *(39−41)*, we report here the application of DO3A-EA in a new context, as a precursor for the synthesis of CAs to design relaxometric MRI as well as optical probes. We have developed dual synthetic routes to obtain **7** depending on the choice of protection and deprotection method (Scheme 1).

In the first route **7** was obtained from cyclen at a yield of 39% over three steps, by reaction with *tert*-butyl bromoacetate to obtain the trisubstituted product **3** *(42)*. Alkylation with **1** *(43)* gave **4** and the corresponding carboxylate derivative **7** was obtained by cleaving the *tert*-butyl groups by treatment with neat TFA at room temperature. Attempted selective deprotection of Boc group in compound **4** led to deprotection of *tert*-butyl ester groups and the formation of multiproduct mixtures. Thus, an alternative three-step route was designed also when starting from cyclen to form the methyl ester **6**. After monoalkylation of cyclen *(41)* with **1**, **2** was isolated at a yield of 63%. By alkylation with methyl bromoacetate, ligand **5** was obtained and the acid labile Boc protecting group of amine was cleaved with TFA to obtain methyl-protected ligand **6**; subsequent treatment with LiOH then gave **7**.

Scheme 2[a]

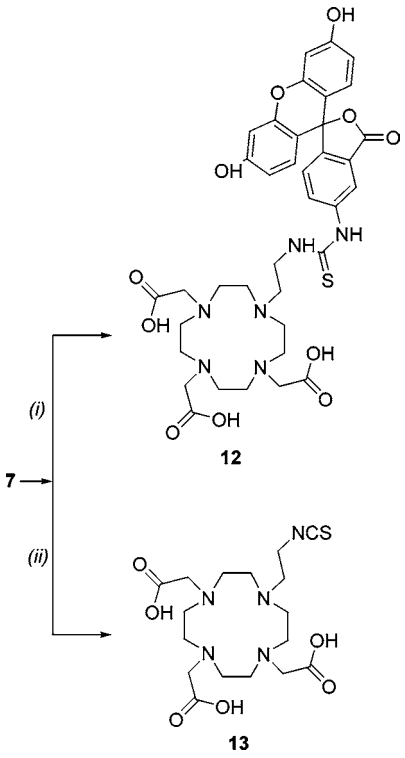


[a] Reagents and conditions: (i) biotin, NMM, HOBt, EDC, DMF, 55%; (ii) LiOH, THF:MeOH:H_2O (3:2:2), 77%; (iii) 4-maleimidobutyric acid, NMM, HOBt, EDC, DMF, 66%; (iv) LiOH, THF:MeOH:H_2O (3:2:2), 86%.

After the successful synthesis of precursors, the bioconjugate ligand **9** was synthesized in a two-step reaction (Scheme 2). Biotin-conjugated DO3A-EA compound **8** was obtained by the coupling of biotin with ligand **6** using EDC/HOBt/NMM in DMF. The choice of such mild conditions for the conjugation of biotin with DO3A-EA and amide bond formation was mandatory due to the sensitivity of biotin toward the harsh conditions (temperature etc). In the following step, ligand **9** was obtained at a yield of 77% by deprotection of methyl groups with LiOH in THF:MeOH:H_2O (3:2:2).

In a similar manner, a novel precursor **11** bearing a maleimide arm was synthesized when starting from **6** as described for biotin conjugates. It is well-known that the maleimide group reacts selectively with sulfydryl groups to form different macromolecules *(27−30)*. Two maleimide conjugates were synthesized, compound **10**, obtained from compound **6** by using 4-maleimidobutyric acid and EDC/HOBt/NMM in DMF at room

Scheme 3[a]



[a] Reagents and conditions: (i) FITC, water, Na_2CO_3, 55%; (ii) $CSCl_2$, water, CCl_4, 59%.

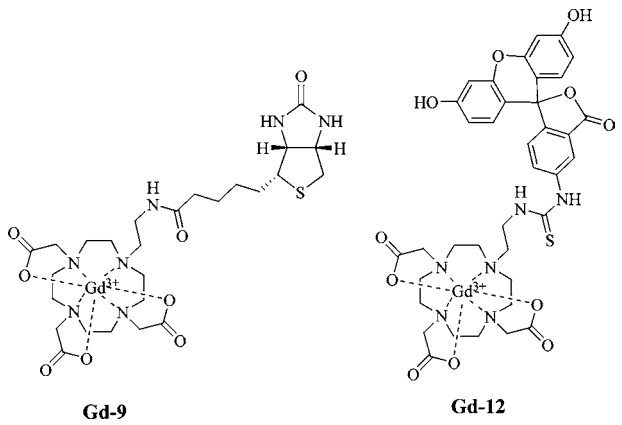


Figure 1. Structures of Gd^{3+} complexes of **9** and **12**.

temperature, and ligand **11**, obtained by deprotection of methyl groups in the presence of LiOH (Scheme 2).

Two molecules were synthesized in single step reactions when starting from **7** (Scheme 3). The first ligand **12** possessed two moieties, the fluorescence unit, and the macrocycle that can complex with paramagnetic metals which was synthesized by coupling FITC with **7** at pH 8. During the reaction, the pH was not allowed to exceed 8.5 because at pH > 9, lactone cleavage of the FITC part occurs, leading to the formation of a side product. The second molecule (**13**) was synthesized in one step by transforming the amino group into NCS with thiophosgene. The yield of the reaction was moderate (59%), although a molecule obtained this way provides possibility for further coupling with amine-containing organic and bioorganic molecules to form the desired product *(31−34)*.

Finally, Gd complexes were synthesized for ligands **9** and **12** (Figure 1). During loading Gd into biotin-containing ligand **9,** the reaction temperature was kept under 60 °C because of possible degradation of the biotin moiety. For loading Gd into FITC-containing compound **12,** the pH of the solution was

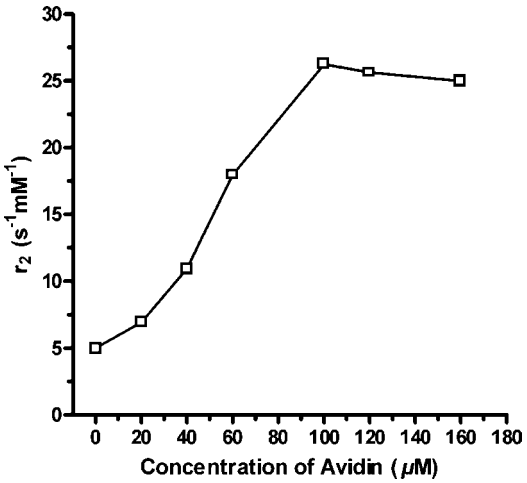

Figure 2. In vitro MR measurement of transverse relaxivity, r_2 **Gd-9** with varying concentrations of avidin. MR experiment was performed at 300 MHz (21 °C) with constant concentration of **Gd-9** (400 μM) and increasing amount of avidin in different tubes. A linear relaxation enhancement was observed up to 100 μM (0.25 equiv). At higher ratios, relaxivity r_2 remained constant. [Error for all r_2 values was less then ($\pm$ 0.6) s^{-1} mM^{-1} and is not displayed].

maintained in the range 7−8, because at lower pH, precipitation of the ligand was observed.

As a summary of the synthetic schemes described above, we would like to point out that the presented straightforward and easy synthesis, although not quite novel, is very suitable for the ready preparation of precursors in the design and preparation of targeted CAs. With the same methodology, it was possible to synthesize various targeted model probes, quite different in their behavior and potential application, which should actually be the major advantage of such approach.

BIOCHEMICAL APPLICATIONS

In Vitro Relaxometry of Gd-9. The biotin−avidin association has found widespread applications in biomolecule detection, medical diagnostics, immunoassays, cytochemistry, and nanoscience *(44−48)*. This is primarily due to the strength of the interaction between the ligand and the tetrameric protein ($K_d \approx 1.3 \times 10^{-15}$ M) which in turn allows for the cross-linking of different biotinylated molecules *(48)*.

To scrutinize the effect of binding on longitudinal and transverse relaxivities, we performed MRI experiments with increasing concentrations of avidin proportional to a constant concentration of **Gd-9** (0.4 mM). A linear enhancement in relaxivity was observed demonstrating strong binding of **Gd-9** in the biotin-binding pocket of tetrameric avidin (Figure 2). This gain in relaxivity suggests a decrease in molecular rotational correlation time τ_R. Similar to reports in the literature proposing that one avidin molecule strongly binds four equivalents of biotin *(48)*, we obtained saturation in relaxivity at ratios higher than 4:1 between **Gd-9** and avidin. MR longitudinal relaxivity, $r_1 = (3.32 \pm 0.03)$ s^{-1} mM^{-1} and transverse relaxivity, $r_2 = (5.02 \pm 0.14$ s^{-1} $mM^{-1})$ of **Gd-9** (0.4 mM) was observed at pH 7.4. The mixture of **Gd-9** and avidin showed maximum relaxivity enhancement of 45% in $r_1 = (4.82 \pm 0.09)$ s^{-1} mM^{-1} and 423% in $r_2 = (26.24 \pm 0.58)$ s^{-1} mM^{-1} relative to the unbound biotinylated Gd^{3+} complex.

In future applications, the MRI contrast sensitivity can therefore be improved by designing CAs using the above precursor, as the biotin−avidin association is expected to enhance the signal by means of in situ accumulation of the agent. Avidin has already been utilized for drug delivery through the blood−brain barrier *(49)*. This is important for future noninvasive, e.g. human research, applications, where intracranial

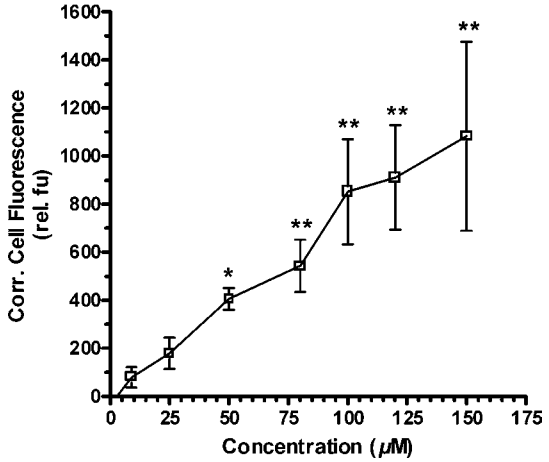

Figure 3. Increase influorescence intensity of cells labeled with different concentrations of **Gd-12**. Cells were incubated with different concentrations of **Gd-12** for 18 h, washed several times and fluorescence measured. After the addition of propidium iodide (PI) and detergent, PI fluorescence was measured to correlate the cell-bound fluorescein fluorescence with cell number resulting in corrected cell fluorescence. Values are relative fluorescence units (rel. fu) as mean ± SD ($n = 3$); *$p < 0.05$; **$p < 0.01$, statistically significant differences compared to control.

injections cannot be considered. Additionally, there is the possibility of utilizing this precursor for diagnosis and imaging using MR, based on a pretargeting approach in combination with avidin-coupled MoAbs. Pretargeted delivery of radionuclides has shown promising results in treatment of lymphoma and solid tumors but remains a sophisticated approach requiring optimization of dose and administration schedules (*14*−*16*). Although our model precursor has potential for use in MR imaging, translation to a system for in vivo application is hampered by certain drawbacks. Hydrolysis of DTPA−biotin and DOTA−biotin by endogenous biotinidase has been reported (*50*). This problem has been successfully overcome by chemically modifying the structure in order to effectively block biotinidase (*17*, *51*). In addition, endogenous biotin levels (10^{-8}−10^{-7} mol/L), immunogenicity of avidin as well as high and prolonged renal uptake markedly affect the efficacy of avidin- and streptavidin-based pretargeting strategies (*18*, *52*, *53*). Efforts are being made to develop an appropriate delivery method to overcome these problems (*54*, *55*).

In Vitro Cell Studies of Gd-12. MR relaxivity of **Gd-12** at pH 7.4 was $r_1 = (5.36 \pm 0.05)$ s^{-1} mM^{-1} and $r_2 = (7.52 \pm 0.16)$ s^{-1} mM^{-1}. In vitro studies of this Gd-loaded complex were done with NIH-3T3 mouse fibroblast cultures to demonstrate its potential for developing multifunctional CAs. **Gd-12** up to 150 μM did not show significant cytotoxicity after 18 h of incubation (propidium iodide assay), although a decrease in the number of cells was observed at concentrations > 100 μM (data not shown). However, a concentration-dependent increase in cell-related FITC fluorescence was observed, indicating cell binding/internalization of the compound (Figure 3). At concentrations higher than 50 μM this increase was statistically significant.

Fluorescence microscopy of living cells revealed a faint but detectable uptake of the compound into cells at concentrations > 50 μM. Figure 4 shows examples of cellular localization of **Gd-12** after incubation with 80 and 150 μM for 18 h and subsequent washing. Beside a faint diffused fluorescence, (asterisks), vesicles showing brighter fluorescence (arrows) were located around the nuclear area of the cells, indicating to an endosomal uptake mechanism.

Figure 5 shows the results of the MR study on 3T3 cells. The presence of Magnevist in the medium enhanced the contrast

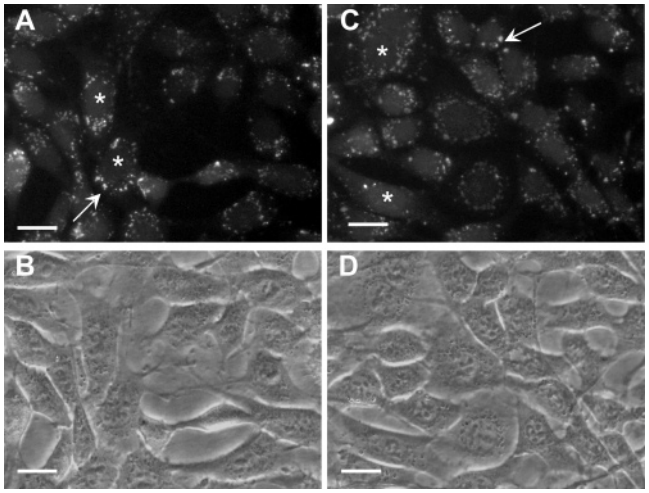

Figure 4. Optical evidence for intracellular localization of **Gd-12** in unfixed NIH 3T3 cells. Cells were incubated with 80 (A, B) and 150 μM (C, D) of **Gd-12** for 18 h as described in Materials and Methods. A and C show fluorescein fluorescence and B and D corresponding phase-contrast pictures. The scale bars represent 20 μm. Arrows point toward vesicles while asterisks indicate diffused fluorescence.

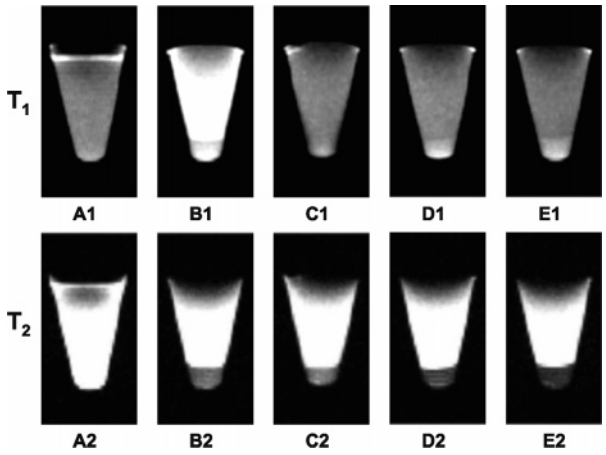

Figure 5. T_1- and T_2-weighted images of control and NIH 3T3 cell pellets labeled with **Gd-12** for 18 h. (A1-E1): T_1-weighted images. (A1) Medium only. (B1) Pelleted cells in medium with 50 μM Magnevist. (C1) Pelleted cells in medium. (D1) Pelleted cells labeled with 80 μM **Gd-12** in medium. (E1) Pelleted cells labeled with 150 μM **Gd-12** in medium. (A2-E2): Respective T_2-weighted images.

in T_1-weighted images by increasing brightness of supernatant, whereas there is almost no difference in T_2. Cells themselves induce only a minor change in T_1-weighted images in comparison to medium only. In T_2-weighted images, the cell pellet is distinguished by the darker image intensity at the bottom of the container which can be viewed also in the absence of any CA. **Gd-12**-labeled cells show a sufficient uptake of the compound to enhance contrast in T_1- and, especially, T_2-weighted images at concentrations above 80 μM. The corresponding relaxation rate R_1 in the cell layer was significantly increased in comparison to control (121% and 131% of control for 80 μM and 150 μM, respectively). A more pronounced enhancement in R_2 was observed (144% and 152% of control, respectively).

Interestingly, contrast enhancement in T_2-weighted images was found to be larger in comparison to T_1. The pronounced T_2 shortening may be caused by the accumulation of the compound in intracellular vesicles inducing local magnetic field inhomogeneities due to compartmentalization. Such behavior is generally observed in the presence of superparamagnetic particles with large magnetic moment, which also show strong compartmentalization *(56)*.

Our results indicate that this model agent is detectable inside cells by both MR and fluorescence methods. Thus, it can serve as a precursor to develop substances that can be used for bimodal (MR and fluorescence) imaging, as well as for development of intracellular contrast agents optimized for cellular internalization. In addition, this molecule can be further modulated for disease detection and diagnosis, gene/drug delivery, elucidating signaling pathways or to study biological and biochemical mechanisms *(57, 58)*. For early disease detection, a bimodal contrast agent Gd^{3+}-DTPA coupled with Oregon Green 488 containing an angiogenesis-specific site cNGR has been recently reported *(23)*. A similar dual mode approach was used by Modo et al. to investigate how neural stem cells migrated and integrated into various brain regions in the same individual over time *(24, 25)*. Aime et al. used Gd-chelate of HP-DO3A as a T_1-agent for MRI visualization, with the corresponding Eu-chelate as a reporter in fluorescence microscopy to detect localization and migration of stem cells *(26)*.

In conclusion, we report the potential of the ligand DO3A-EA as a multipurpose precursor, from which various targeted CAs can be synthesized after single step conjugation with organic molecules/biomolecules. With such methodology, two new targeted agents and two new precursors were synthesized and characterized. MR experiments verified the strong and specific interaction between biotin functionalized DO3A-EA (**Gd-9**) and avidin. Cell studies and relaxivity measurements indicate that FITC-conjugated DO3A-EA (**Gd-12**) can serve as a model to develop agents that can be used for imaging both by MR and fluorescence methods. Maleimide functionalized DO3A-EA (**11**) and DO3A-ethyl isothiocyanate (**13**) precursors having a potential for the specific binding with biomolecules via sulfydryl and amino groups, respectively, have been synthesized. Additionally, the presented precursors **7**, **11**, and **13** cover the entire range of reactivity for the coupling to electrophilic and nucleophilic groups. They possess great potential for coupling with biological molecules, proteins, vitamins, and antibodies for the simple and easy synthesis of various kinds of targeted contrast agents.

ACKNOWLEDGMENT

The authors thank Prof. Dr. Klaus Albert, Department of Organic Chemistry, University of Tübingen, for helpful discussions and providing access to the analytical facilities. The authors also thank Dr. Goran Angelovski for the help with the preparation of the manuscript and Michael Beyerlein for help with the relaxivity measurements. This work was supported by the Max-Planck Society, the Louis-Jeantet Foundation, and the Hertie Foundation.

Nonviral Gene Carriers Based on Diblock Copolymers of Poly(2-ethyl-2-oxazoline) and Linear Polyethylenimine

Ging-Ho Hsiue,*,† Hou-Zen Chiang,‡ Chau-Hui Wang,§ and Tzuoh-Min Juang‡

Department of Chemical Engineering, National Tsing Hua University, Hsinchu, 300 Taiwan, ROC, Department of Applied Chemistry, National Chiao Tung University, Hsinchu, 300 Taiwan, ROC, and Polymer Technology Division, Union Chemical Laboratories, Industrial Technology Research Institute, Hsinchu, 300 Taiwan, ROC. Received November 4, 2005; Revised Manuscript Received December 30, 2005

Diblock copolymers that consist of poly(2-ethyl-2-oxazoline) (PEOz) and linear polyethylenimine (LPEI) were prepared for use as nonviral gene carriers. The PEOz-*b*-LPEI copolymers were synthesized by coupling PEOz with LPEI in a thiol−disulfide exchange reaction between the sulfhydryl and pyridyl disulfide terminal groups. A polymer/DNA weight ratio (P/D) of over 12 was required to enable PEOz-*b*-LPEI to condense DNA completely. The DNA-condensing capability of the diblock copolymers was increased with increasing the hydrolytic degrees of the LPEI segment. The PEOz-*b*-LPEI polyplexes were stable in 150 mM NaCl aqueous solution and had a mean diameter around 190 nm, whereas BPEI and LPEI polyplexes formed large aggregates in the range 300−500 nm. In addition, these polyplexes exhibited the sensitivity to solution pH and were dissociated in the acidic buffers (pH ≤ 5.5). The results of in vitro cell viability and luciferase assay indicated that PEOz-*b*-LPEI showed not only low cytotoxicity but also high transfection efficiency in gene expression.

INTRODUCTION

Nonviral vectors, such as liposomes and cationic polymers, have recently attracted increasing interest. They are usually considered to be safer and able to be designed with more flexible structures and chemical properties (*1*−*3*). Among the various types of polymer gene carriers, branched polyethyleneimine (BPEI) is the most effective vector for delivering genes because the BPEI/DNA polyplexes exhibit great transgene expression both in vitro and in vivo (*4*, *5*). The high transfection efficiency of BPEI is probably attributed to its large buffering capacity, which disrupts the endosomal membrane, resulting in the release of the polyplex into the cytoplasm (*6*). Additionally, linear polyethylenimine (LPEI) which can be obtained by hydrolyzing poly(2-ethyl-2-oxazoline) (PEOz) has indicated that the in vitro transfection activity of LPEI is as high as that of BPEI, but its cytotoxicity is lower (*7*).

However, the application of cationic homopolymers is hampered by their poor solubility due to charge neutralization and aggregation under physiological conditions, such as in salt or bovine serum albumin (*8*, *9*). A potential solution to these problems is to conjugate a hydrophilic polymer to the polycations. Poly(ethylene glycol) (PEG) is the polymer that is most often used for this purpose (*10*−*14*). Following complexation with plasmid DNA, the PEGylated polycation/DNA complexes exhibit neutral surface charge, low cytotoxicity, and high solubility in water. PEOz is a biocompatible and hydrophilic polymer that is ionized at acidic pH and leads to the formation of intra- and intermolecular hydrogen bond (*15*, *16*). Hence, PEOz has been investigated for use in the controlled release drug delivery systems (*16*, *17*). However, it has never been exploited as a vector in gene therapy.

The authors' previous work studied the ability of amphiphilic block copolymers that consist of LPEI and poly(L-lactide) (PLLA) to modulate the delivery of plasmid DNA (*18*). In this work, gene carriers were prepared by coupling PEOz and LPEI with various percentages of hydrolysis. The resultant diblock copolymers condensed plasmid DNA and formed micelles with core−shell structure. The physicochemical and biological characteristics of the copolymer/DNA micelles were evaluated herein.

EXPERIMENTAL SECTION

Materials. 2-Ethyl-2-oxazoline (Acros) and methyl *p*-toluenesulfonate (Aldrich) were purified by vacuum distillation over CaH_2. Acetonitrile (Tedia) was dried over CaH_2 and distilled under dry nitrogen. Potassium thioacetate, 2,2′-dithiodipyridine, and ammonia in methanol solution were purchased from Acros. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) was purchased from ICN Biomedicals, Inc. pUHC 13-3 encoding for luciferase as a reporter gene was received as a gift from Prof. Jia-Ling Yang at National Tsing Hua University, Taiwan. Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), and trypsin−EDTA were the products of Gibco-BRL. HeLa human adenocarcinoma cells were provided by Prof. Yu-Chen Hu of National Tsing Hua University, Taiwan. Dialysis tubing was obtained from Spectrum Medical Industries, Inc.

Synthesis of Poly(2-ethyl-2-oxazoline) Thioacetate (PEOz-SAc). A solution of methyl *p*-toluenesulfonate (370 mg, 1.98 mmol) and 2-ethyl-2-oxazoline (20 mL, 197.72 mmol) in dry acetonitrile (60 mL) was heated to 100 °C and stirred for 24 h in an atmosphere of nitrogen. The living PEOz polymer chains were terminated by adding potassium thioacetate (0.7 g) at 0 °C; the solution was then stirred for 24 h. The polymer solution was filtered through the silica gel and purified by precipitation in diethyl ether. After complete drying, a brown powdery product was obtained. The molecular weight and polydispersity of PEOz-SAc were determined by gel permeation chromatography (GPC). ^{1}H NMR ($CDCl_3$): $\delta = 0.98$ ppm ($N(COCH_2CH_3)$), 2.35 ($N(COCH_2CH_3)$), 3.42 ($N(COCH_2CH_3)CH_2CH_2$), 3.00 ($CH_3N(COCH_2CH_3)$), 2.92 ($CH_2CH_2S(CO)CH_3$). Elemental

anal. (mass fraction): (C: 60.42, H: 9.08, N: 14.01, S: 0.36). Calculated: (C: 60.39, H: 9.13, N: 14.00, S: 0.32).

Synthesis of Linear Polyethylenimine Pyridyl Disulfide (LPEI-ssPy). PEOz-SAc (1 g, 0.1 mmol) and 2,2′-dithiodipyridine (111 mg, 0.5 mmol) were dissolved in ammonia/methanol solution (7 N, 20 mL). The mixture was stirred in a nitrogen atmosphere at room temperature for 24 h. After the solvent had been removed, the solid residue was redissolved in dichloromethane and then precipitated in diethyl ether several times. The purified product was vacuum-dried to yield a yellow powder. PEOz-ssPy (1 g) was heated with a mixture of concentrated hydrochloric acid (10 mL, 35%) and water (8 mL) at 100 °C for 3 h. The pH of the polymer solution was adjusted to 9−10 by adding NaOH pellets. The product was then purified by dialysis method for 3 days using cutoff dialysis tubing with a molecular weight of 3500. After completely drying in a vacuum, the viscous semisolid product was obtaied. ^{1}H NMR ($CDCl_3$): δ = 2.77 ppm ($NHCH_2CH_2$), 7.094, 7.601, 8.41 (pyridyl ring). Elemental anal. (mass fraction): (C: 57.54, H: 10.48, N: 24.31, S: 1.03). Calculated: (C: 57.47, H: 10.46, N: 24.35, S: 1.10).

Synthesis of Diblock Copolymer Poly(2-ethyl-2-oxazoline)-*block*-Linear Polyethylenimine (PEOz-*b*-LPEI). LPEI-ssPy (1 g, 0.196 mmol) and PEOz-SAc (235 mg, 0.065 mmol) were dissolved in ammonia/methanol solution (7 N, 15 mL). The reaction was carried out in a nitrogen atmosphere at room temperature for 24 h. The unreacted LPEI-ssPy and byproducts were purified by dialysis (with a molecular weight cutoff of 6000−8000) against methanol and distilled water for 3 days, respectively. After evaporation, the obtained diblock copolymer was then dried in vacuo and stored at −20 °C before use. Elemental anal. (mass fraction): (C: 58.51, H: 10.11, N: 20.31, S: 0.73). Calculated: (C: 58.56, H: 10.01, N: 20.38, S: 0.68).

Preparation of Polyplexes. An amount of 4 μg of Luciferase encoding plasmid pUHC-13−3 and the desired amount of polymer were each diluted in 100 μL of distilled water and gently mixed. The polyplex formulation was incubated at room temperature for 30 min before it was used.

Gel Retardation Assay. Various formulations of polyplexes were prepared as described above before they were loaded into the gel. The samples were electrophoresed on 1% agarose gel in 1× Tris−boric acid−EDTA (TBE) buffer at 100 mV until the 1× loading dye ran through 80% of the gel. A 1 kb DNA marker (Violet), used to determine the size of DNA, was also run. The gel was stained with 0.5 μg/mL ethidium bromide for 45 min and analyzed using an UV transilluminator.

Measurement of Particle Size and Zeta Potential. The size of the particles of the polyplexes prepared in distilled water or 150 mM NaCl was measured at 25 °C by dynamic light scattering using a Zetasizer 3000 HS from Malvern Instruments, Worcestershire, U.K. The viscosity (0.89 mPa/s) and the refractive index (1.333) of water at 25 °C were used to analyze the data. The zeta potential of the polyplexes prepared in distilled water was determined by laser Doppler anemometry in the standard capillary electrophoresis cell of the Zetasizer 3000 HS from Malvern Instruments at 25 °C. The mean values of the zeta potential were calculated from the data obtained in five runs.

pH-Sensitivity Testing. The polyplexes formed by mixing plasmid DNA and diblock copolymers were incubated in the phosphate buffer (pH 7 and 6.5) and succinate buffer (pH 6, 5.5, 5, 4.5) solutions at room temperature for 1 h. Then, the aliquots obtained from the buffer solutions were analyzed with 1% agarose gel electrophoresis.

In Vitro Cell Viability. Human cervix carcinoma HeLa cells (1×10^4 cells/well) were cultured onto a plate with 96 wells in DMEM media supplemented with 10% fetal bovine serum (FBS) in a humid atmosphere of 5% CO_2 at 37 °C for 24 h. The growth medium was replaced with a medium that contained the desired amount of polymers. Cells were incubated for 24 h, and cell viability was assayed by adding 100 μL of medium that contained 10 μL of MTT PBS solution (5 mg/mL). After incubation for 4 h, the formazan crystals were dissolved in 100 μL of DMSO. The absorbance of each well was measured using a microplate reader (Stat Fax 2100, Awareness) at a test wavelength of 570 nm and a reference wavelength of 630 nm.

In Vitro Transfection and Total Protein Assay. Human cervix carcinoma HeLa cells (2×10^5 cells/well) plated in six-well plates were incubated in DMEM media supplemented with 10% FBS in a humid atmosphere of 5% CO_2 at 37 °C for 24 h. Transfection was conducted after the cells had become approximately 80% confluent. A 2 mL volume of growth medium that contained DNA or polyplexes that contained finally 4 μg of plasmid was incubated for 48 h at 37 °C. Following transfection, the cells were washed with cold PBS and then lysed using 400 μL of 1× cell lysis buffer. The cell lysate was then transferred into eppendorf tubes and centrifuged for 15 s at 12 000 rpm. Luciferase activity was measured in relative light units (RLU), using a 96-well plate luminometer (Wallac 1420 Multilabel Counter, Perkin-Elmer) and a luciferase assay kit (Promega). The total amount of protein was measured at 595 nm using a BioRad protein assay.

RESULTS AND DISCUSSION

Synthesis of Diblock Copolymer PEOz-*b*-LPEI. Scheme 1 presents the synthesis of PEOz-*b*-LPEI. Cationic ring-opening polymerization of 2-ethyl-2-oxazoline using the monofunctional

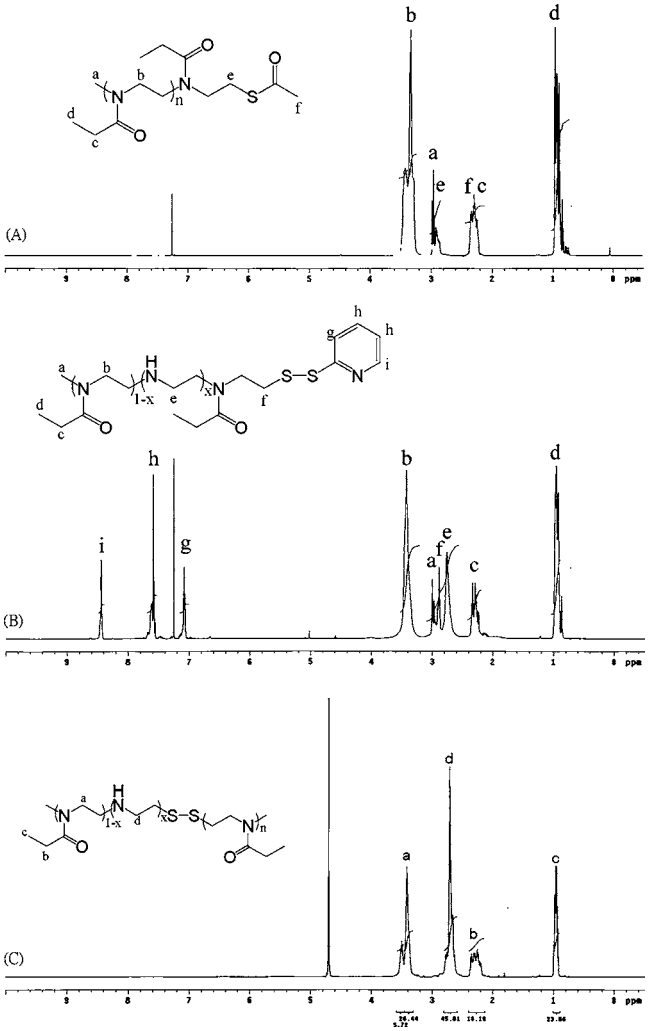

Figure 1. ^{1}H NMR spectra of (A) PEOz-SAc in $CDCl_3$, (B) LPEI-ssPy in $CDCl_3$, and (C) PEOz-*b*-LPEI in D_2O.

initiator methyl *p*-toluenesulfonate is a typical method for synthesizing PEOz (*19*, *20*). The oxazolinium salt structure of the growing polymer can readily react with nucleophiles, such as amines or water to introduce functional groups into the end of polymer chain (*21*). A thiol is used herein to couple the PEOz and LPEI via disulfide bond. However, the thiol was susceptible to oxidation to the formation of dimer; thus, the more stable form of thioacetate was desired. Adding potassium thioacetate to terminate the reaction capped the end of PEOz with the thioacetate functional group. The number average molecular weight (M_n) and polydispersity index (PDI) of PEOz-Sac determined by GPC were 10000 and 1.12, respectively. Figure 1A shows the ^{1}H NMR spectrum of PEOz-SAc dissolved in $CDCl_3$.

LPEI was prepared by the acid hydrolysis of PEOz. Because the terminal thioacetate group could be hydrolyzed as well, it was first deacetylated by treating with ammonia/methanol solution and then converted to pyridyl disulfide group by thiol−disulfide exchange reaction with 2,2′-dithiodipyridine before performing hydrolysis reaction. Figure 1B shows the ^{1}H NMR spectrum of LPEI-ssPy in $CDCl_3$. The percentage of LPEI-ssPy hydrolyzed was calculated by comparing the integral peak area of the ethylenimine groups to the *N*-propionylethylenimine groups from the ^{1}H NMR spectrum. The molecular weight of the LPEI-ssPy was estimated from the percentage of hydrolysis.

Diblock copolymers were synthesized by coupling the PEOz-SAc and LPEI-ssPy via a disulfide exchange reaction of the deprotected sulfhydryl goup of the PEOz and the pyridyl

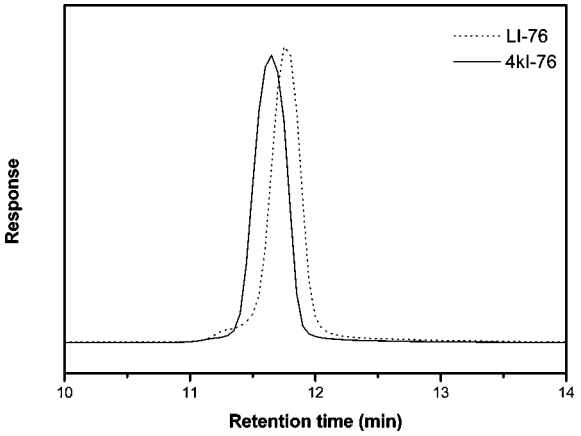

Figure 2. GPC chromatograms before and after LPEI conjugation.

Table 1. Compositions of LPEI and PEOz-*b*-LPEI

polymer	M_n (PEOz)	M_n (LPEI)	EI content (%)
L-76	-	5700	76
L-89	-	5000	89
4k-76	3600	5700	56
4k-89	3600	5000	66

disulfide group of LPEI. The disulfide bond of the diblock copolymer is cleavable intracellularly, but it is relatively stable in the extracellular milieu (*22*). Figure 1C shows the ^{1}H NMR spectrum of PEOz-*b*-LPEI in D_2O. The Mn and PDI of PEOz-SAc used in this step were 3600 and 1.18, respectively. The GPC chromatogram before and after LPEI conjugation was shown in Figure 2. The molecular weight was increased after successfully coupling PEOz and LPEI, and the unreacted polymers were completely removed. Table 1 presents the compositions of the LPEI and PEOz-*b*-LPEI. For comparison, a commercially available BPEI of 25 kDa was also evaluated in this work.

Gel Retardation Assay. Agarose gel electrophoresis was conducted to evaluate the capacity of BPEI, LPEI and PEOz-*b*-LPEI to interact with plasmid DNA. Figure 3 shows the result of gel retardation assay for polycations/DNA complexes. As the concentration of the polycation increased, the mobility of the plasmid DNA was reduced by increasing DNA condensation and compaction. BPEI was the most efficient that it could completely retard DNA migration at a polymer/DNA (P/D) ratio (w/w) of 1 while it required P/D ratios of 8 and 6 for the L-76 and L-89 to complex DNA, respectively (Figure 2A). The 4k-76 began to form polyplexes at a P/D ratio of 14, and a P/D ratio of 12 was required for 4k-89 to complex DNA completely (Figure 2B). These results demonstrated that the DNA binding capacity of LPEI increased with the hydrolytic degrees.

Particle Size and Zeta Potential. After determining the amount of the different polycations for polyplexes formation, the particle size of the polyplexes was estimated by laser light scattering. The polyplexes prepared in either an aqueous solution of physiological salt (150 mM NaCl) or in distilled water were used to measure the size of polyplex to elucidate whether the ionic strength of the media influences the stability of the polyplexes. During the measurement, we found the lowest P/D ratio for stable polyplexes formation of each polymer. The polyplexes that formed below this P/D ratio usually led to aggregation. Figure 4 presents the particle sizes of BPEI, LPEI, and PEOz-*b*-LPEI polyplexes at the lowest P/D ratio for the formation of stable polyplexes. The BPEI polyplex had a mean diameter of 100 nm in water that was reasonably consistent with the findings of Tang and Szoka (*2*). The sizes of LPEI and PEOz-*b*-LPEI polyplexes were around 190 nm. When the polyplexes were dispersed in 150 mM NaCl solution, BPEI and

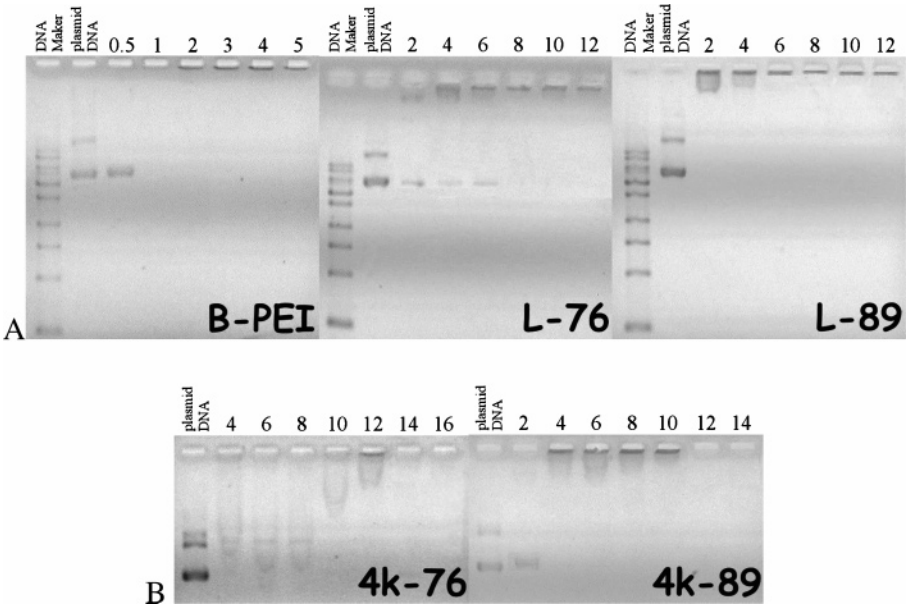

Figure 3. Gel retardation assay of the polyplexes: (A) BPEI and LPEI, (B) PEOz-*b*-LPEI. The numbers in the first row above each panel noted the P/D ratios of the complexes.

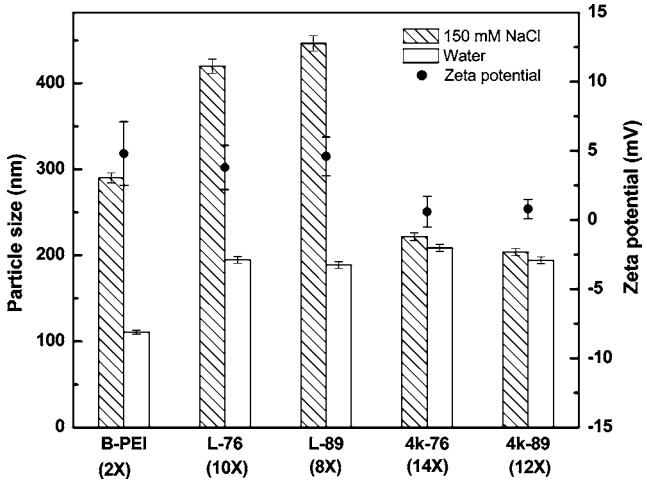

Figure 4. Particle size and zeta potential of BPEI, LPEI, and PEOz-*b*-LPEI polyplexes at the optimum P/D ratios.

LPEI polyplexes all aggregated as larger particles. However, the PEOz-*b*-LPEI polyplexes did not show any aggregation in salt-containing media.

The zeta potential of the polyplexes wasmeasured by mixing the polyplexes at the lowest P/D ratio to stabilize them. Figure 4 shows that BPEI and LPEI polyplexes all had moderate positive surface charges, but the zeta potentials of PEOz-*b*-LPEI polyplexes were almost zero. When BPEI and LPEI were mixed with DNA at a P/D ratio that was slightly less than the lowest P/D ratio for the formation of stable polyplexes, the polyplexes also had a neutral surface charge (data not shown). This result indicates that the neutral BPEI and LPEI polyplexes were prone to aggregate due to the lack of electrostatic repulsion, so the polyplexes with a positive surface charge were stable. However, the PEOz-*b*-LPEI polyplexes were stable and had a neutral surface charge probably because they possessed a core−shell structure with a hydrophobic LPEI/DNA core and a hydrophilic PEOz shell, which prevented the polyplexes from aggregating.

pH-Sensitivity Testing. The recent study conducted in our laboratory showed that the PEOz was a pH-sensitive polymer that would become a hydrogen-bonded complex at acidic buffer solutions, because of the ionization of the amide groups (*18*).

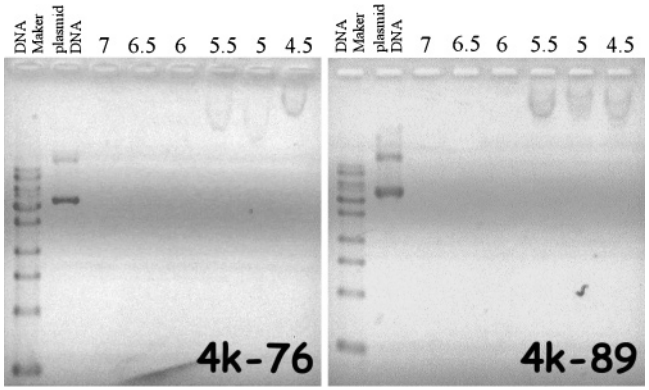

Figure 5. The pH-sensitivity of PEOz-*b*-LPEI polyplexes in various buffer solutions. The numbers in the first row above each panel noted the pH values of the buffer solutions.

The PEOz-*b*-LPEI polyplexes were incubated in buffer solutions at pH values from 7 to 4.5, to determine whether the introduction of PEOz to L-PEI made the polyplexes sensitive to pH. The integrity of the polyplexes was consistent with the analysis made by agarose gel electrophoresis. Figure 5 shows the gel electrophoresis results for PEOz-*b*-LPEI polyplexes. The 4k-76 polyplex was stable at pH $\geq$ 6, but began to dissociate at pH $\leq$ 5.5. The 4k-89 polyplex also had the same behavior as 4k-76. The LPEI polyplexes were also examined. They remained intact in all tested buffer solutions (Data not shown). These results demonstrate that the sensitivity of PEOz-*b*-LPEI polyplexes to pH does stem from the tendency of PEOz and cause the polyplexes to dissociate in acidic environments.

In Vitro Cell Viability. The in vitro cytotoxicities of the different polycations at various concentrations were quantitated by MTT assay using HeLa human cervix carcinoma cells. The wells that contained only media without polycation were treated as positive controls, with a cell viability of 100%. The relative cell viability was calculated as $[\text{Abs}]_{\text{sample}}/[\text{Abs}]_{\text{control}} \times 100$. Figure 6 compares the cell viability of HeLa cells at various polymer concentrations of BPEI, LPEI, and PEOz-*b*-LPEI, revealing that BPEI was the most toxic polycation and the cell viability was below 10% as the polymer concentration $\geq$ 0.1 mg/mL. The cell viability of LPEI declined as the hydrolyzed percentage increased, as it did in the case of PEOz-*b*-LPEI.

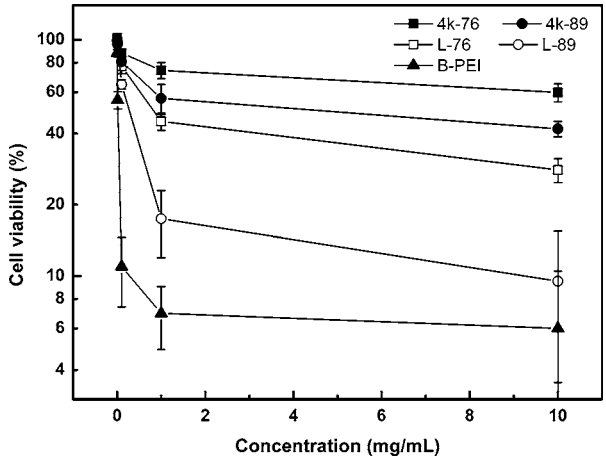

Figure 6. The cell viability of HeLa cells at various polymer concentrations ($n = 6$).

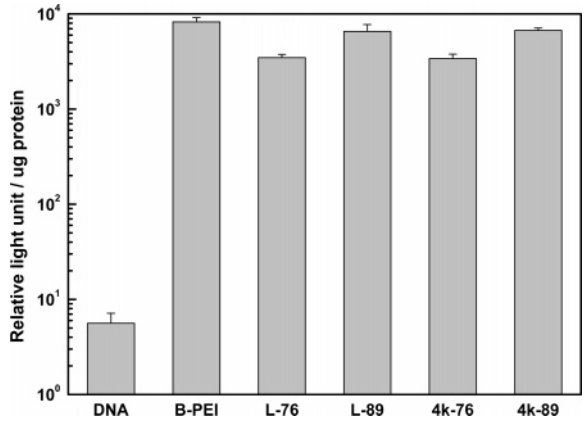

Figure 7. Luciferase gene expressions of the naked DNA, BPEI, LPEI, and PEOz-*b*-LPEI at the optimum P/D ratios ($n = 3$).

Furthermore, the PEOz-*b*-LPEI was less toxic than the corresponding LPEI. These results demonstrated that the charge density in the LPEI strongly affected cell viability. Therefore, PEOz-coupled LPEI further reduced the cationic charge density and the cytotoxicity.

In Vitro Transfection and Total Protein Assay. The total protein production, which is an indirect measure of induced toxicity, was analyzed and normalized to be expressed in relative light unit (RLU). Figure 7 presents the luciferase gene expressions of the naked DNA, BPEI, LPEI, and PEOz-*b*-LPEI at optimum P/D ratios. The results showed that all the polycationic gene carriers exhibited greater transfection efficiency than naked DNA. BPEI polyplex mediated the strongest gene expression of all polycations. The transfection efficiency of PEOz-*b*-LPEI was as high as that of LPEI. PEOz-coupling did not affect the transfection efficiency of the LPEI. Moreover, the protein production of PEOz-*b*-LPEI exceeded that of BPEI and LPEI, indicating that PEOz-*b*-LPEI polyplexes had lower cytotoxicity than others.

CONCLUSION

In this study, the pH-sensitive diblock copolymers PEOz-*b*-LPEI were synthesized by coupling PEOz with LPEI, and the physicochemical and biological characteristics were evaluated. The polyplexes of the PEOz-*b*-LPEI were shown to have neutral surface charge and stably sized particles, unlike LPEI and BPEI. These diblock copolymer polyplexes exhibited a pH-sensitivity that caused them to dissociate at pH values lower than 5.5, suggesting that they may release DNA intracellularly. The results also demonstrated that the PEOz-*b*-LPEI had low cytotoxicity and high transfection efficiency. Accordingly, the diblock copolymers have potential for application in nonviral gene therapy.

ACKNOWLEDGMENT

The authors thank the Industrial Technology Research Institute of Taiwan (ITRI) for financially supporting this research (A341XS6500). Prof. Jia-Ling Yang at the Institute of Biotechnology of National Tsing Hua University is appreciated for her assistance with luciferase expression assay.

Delivery of therapeutics and imaging agents to target tissues requires localization and activation strategies with molecular specificity. Cell-associated proteases can be used for these purposes in a number of pathologic conditions, and their enzymatic activities can be exploited for activation strategies. Here, molecules based on the D-arginine octamer (r_8) protein-transduction domain (PTD, also referred to as molecular transporters) have been adapted for selective uptake into cells only after proteolytic cleavage of a PTD-attenuating sequence by the prostate-specific antigen (PSA), an extracellular protease associated with the surface and microenvironment of certain prostate cancer cells. Convergent syntheses of these activatable PTDs (APTDs) are described, and the most effective r_8 PTD-attenuating sequence is identified. The conjugates are shown to be stable in serum, cleaved by PSA, and taken up into Jurkat (human T cells) and PC3M prostate cancer cell lines only after cleavage by PSA. These APTD peptide-based molecules may facilitate targeted delivery of therapeutics or imaging agents to PSA-expressing prostate cancers.

INTRODUCTION

Targeted delivery systems are critical for refining effective molecular imaging approaches and enhancing therapeutic intervention by achieving tissue-specific localization. In oncology, a number of tumor-associated molecules have been identified, and many of these have enzymatic functions that can be exploited for cancer imaging and treatment. Prostate cancer, for example, expresses PSA, a cancer-specific enzyme that can be utilized for prodrug applications.

Currently, there is no treatment that significantly prolongs survival in the setting of metastatic prostate cancer (*1*). Androgen ablation therapy, although of substantial palliative benefit, has little impact on overall survival, and the mortality rate from prostate cancer continues to increase (*2*, *3*). The low proliferation rate of androgen-independent prostate cancer requires that standard antiproliferative chemotherapeutic agents be administered over prolonged periods risking induction of dose-limiting toxicities (*4*, *5*).

Likewise, no single imaging strategy has been identified as ideal for prostate cancer at this time. Imaging modalities that rely on anatomic changes in tissue (e.g., computed tomography, CT) lack sensitivity for small tumor-containing lymph nodes and lack selectivity for large tumor-free nodes merely reacting to local inflammation. Therefore, there has been much emphasis on the development of biologically based imaging techniques such as positron emission tomography (PET) and single photon emission computed tomography (SPECT) because they have the potential to more accurately assess nodal disease. The low metabolic rate of prostate cancer provides little uptake of the most widely utilized PET radiopharmaceutical, the glucose analogue ^{18}F-fluoro-deoxy-glucose (FDG). A few radiopharmaceuticals exploiting other molecular pathways, such as ^{11}C-acetate, have demonstrated higher levels of uptake within prostate cancer than FDG (*6*). ^{11}C-Acetate and its fluorinated counterpart, ^{18}F-fluoroacetate, are promising imaging agents for detection of prostate cancer recurrence (*7*, *8*). ^{11}C-Choline and its fluorinated counterpart, ^{18}F-fluorocholine, have also demonstrated greater uptake in prostate cancer than FDG and may be particularly useful in identifying osseous and lymph node metastases (*9*−*11*). While the relationship between their molecular target and their potential role in the choice of therapeutic management is clearer than many of the other radiopharmaceuticals, the radiolabeled androgens have not shown as high a sensitivity for prostate cancer in initial investigations (*12*−*14*). Gamma-emitting radiopharmaceuticals for SPECT, such as indium-111 (^{111}In)-radiolabeled prostate specific membrane antigen (PSMA) monoclonal antibody, have demonstrated challenges such as long blood clearance and localization times, nonspecific localization, redistribution, and poor tissue penetration (*15*−*17*).

Although many of the molecular methods currently employed in prostate cancer imaging and therapy utilize a mechanism to concentrate the delivery molecule in the cancer cell, these concentration mechanisms are often tied to a metabolic pathway that has a finite transporting capacity. Clearly, it would be useful to develop other strategies to deliver cytotoxic therapeutics or imaging agents specifically to prostate cancer cells, and exploitation of cell-selective enzymes such as PSA opens the door to unique mechanisms of delivery. Cell-specific targeting based on protease expression remains a challenge, and intracellular delivery appears to be a key in several approaches to

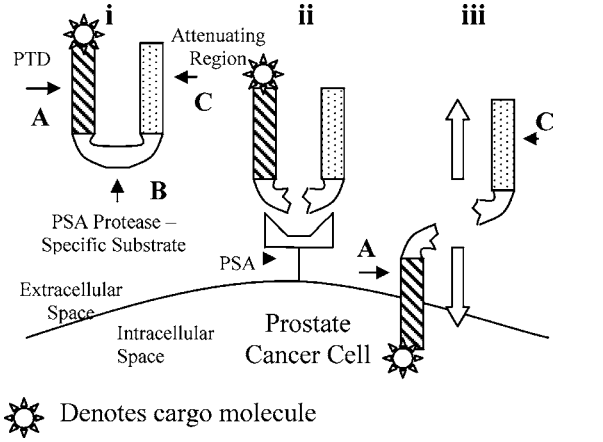
imaging and therapy. Protein transduction domains (PTDs) or cell-penetrating peptides (CPPs) and more generally molecular transporters (MTs) are molecules that can be conjugated to a cargo to enable its entry as a conjugate into cells (*18*−*20*). An example of such a molecule in this rapidly emerging field of molecular transporters is the highly basic region (Tat_{49-57}, RKKRRQRRR) of the nuclear transcription activator protein (Tat) encoded by human immunodeficiency virus type 1 (HIV-1) (*21*−*23*). Our previous structure−function studies of the TAT nonamer have demonstrated that D-oligoarginine peptides as well as spaced oligoarginine peptides (rXrXrXrXrXr), guanidine-rich peptoids with 1,4-spaced side chains, guanidinylated dendrimers, and guanidinylated oligocarbamates are superior to Tat_{49-57} in cellular uptake and offer significant cost and availability advantages (*24*−*28*). Conjugates of these transporters and various probes (e.g., fluorescein) or drugs (e.g., cyclosporin A) are highly water soluble and rapidly enter cells and tissues (*25*, *28*−*30*), enabling their advancement into human trials (*25*). Cargoes ranging in size from metal chelates and fluorescent dyes (*31*, *32*) to iron oxide nanoparticles (*33*), proteins (*30*), and liposomes (*34*) can be transported into cells.

Based on a previously published mechanistic theory (*35*) of oligoarginine translocation through cell membranes, we hypothesized that conjugates in which negatively charged residues are covalently attached to an r_8 PTD would enter cells less readily, if at all. We therefore developed protransporter agents for PSA-mediated prostate cancer targeting in which r_8 PTD-containing peptides would be inactivated for cellular uptake through intramolecular complexation with attached polyanionic residues. This inactivated form would be expected to distribute systemically but would subsequently be activated for cellular uptake by PSA-mediated proteolytic cleavage at the site of prostate cancer metastases. To produce an "activatable" protein transduction domain (Figure 1, Scheme 1; APTD), an r_8 PTD would be attached to an attenuating domain (C) through a cleavable linker (CHSSKLQG) (B), a well-studied sequence selected for its balance of enzyme selectivity and cleaving kinetics (*3*, *36*, *41*−*42*). Intramolecular association of residues in C with the r_8 PTD would disfavor intermolecular association of the r_8 PTD with cell surface moieties and thereby disfavor uptake by the translocation mechanism. Tissue-selective proteolytic cleavage of B by prostate specific antigen (PSA), a protease associated with the extracellular membrane of prostate cancer cells, would eliminate internal inactivation of r_8 PTD by C, thereby enabling r_8 PTD-directed cellular entry. Together, these three components make up a complete APTD that remains

Scheme 1. Proposed Mechanism for Selective Uptake of APTDs in PSA-Expressing Prostate Cancer Cells[a]



[a] (i) Intact APTD conjugate with r_8 PTD (A), PSA-protease-specific substrate linkage (B), and r_8 PTD-attenuating sequence regions (C). (ii) Upon encountering PSA associated with the surface of a prostate cancer cell, the PSA-specific substrate (B) is cleaved. (iii) Cleavage of APTD in step ii allows the fluorophor cargo-carrying r_8 PTD to enter the prostate cancer cell while the r_8 PTD-attenuating sequence remains in circulation.

extracellular until the specific peptide link is cleaved by a PSA (*37*−*39*). A similar approach based on a different protease has been recently utilized by another group to deliver imaging fluorophores into cells and squamous cell cancer xenografts in mice (*40*).

Herein, we describe the design, synthesis, and characterization of "activatable" PTDs (APTDs) that localize in cells after cleavage by PSA. The r_8 PTD-attenuating sequences were designed to disable the transmembrane transporting ability of the r_8 PTD. A variety of r_8 PTD-attenuating sequences combining charge-complementing aspartic acid residues spaced with varying numbers of glycine residues were developed. Because the critically important requirements for the attenuation component of the APTD and proteolytic release were unknown, a library of attenuated r_8 PTD peptide molecules was synthesized and the efficiency of r_8 PTD transport attenuation of various sequences was studied. These molecules were found to be cleaved by PSA and subsequently transported into Jurkat and PC3M prostate cancer cell lines. These results provide a new strategy for selective delivery of agents into prostate cancer cells and represent a new opportunity for targeted delivery of therapeutic and imaging agents based on r_8 PTDs.

EXPERIMENTAL PROCEDURES

General Methods. Unless otherwise stated, all reagents and solvents were obtained from commercial sources and used without further purification. Reverse-phase high-performance liquid chromatography (RP-HPLC) was performed with a Varian ProStar 210/215 preparative HPLC using Alltec Alltima C18, 250 mm × 22 mm, column or analytical RP-HPLC (Hewlett-Packard with Agilent 1100 series automated injector) with analytical Zorbax SB C18, 150 mm × 4.6 mm, column. The products were eluted utilizing a solvent gradient (solvent A = 0.1% trifluoroacetic acid (TFA)/H_2O; solvent B = 0.1% TFA/CH_3CN).

Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometric analysis was carried out using a Voyager-DE PRO biospectrometry workstation (PerSpective Biosystem Inc.). Ten microliters of each HPLC fraction was mixed with 20 μL of matrix solution (α-cyano-4-hydroxycinnamic acid) in 60% acetonitrile/0.1% trifluoroacetic acid/water solution. The spectra were acquired in the linear

mode, which, in general, provides values a few daltons higher than the monoisotopic mass values.

Fluorescent images were obtained using an IVIS 50 imaging system (Xenogen Corp., Alameda, CA), which consists of a cooled CCD camera detector system incorporating a xenon light source and appropriate filters for excitation and emission wavelengths. The images were acquired and processed using LivingImage 2.50 software. Flow cytometry (FACScan, Becton Dickinson, Franklin Lakes, NJ) was performed using standard FITC filters.

Automated Peptide Synthesis (Peptides 1−4). All reagents for peptide synthesis including *N*-methylpyrrolidone (NMP), diisopropylethylamine (DIEA), *N*,*N*-dimethylformamide (DMF), 1-hydroxybenzotriazole (HOBt), *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU), and piperidine were purchased from Aldrich, NovaBiochem (CA), BaChem (CA), or Applied Biosystems (CA). Fmoc-protected amino acids and resins were purchased from NovaBachem or BaChem in their appropriately protected form. All automated peptide syntheses were performed on a PE Biosystems model 433A automated peptide synthesizer using the standard FastMoc coupling strategy. The peptide was assembled on Fmoc-Rink amide resin on a 0.1 or 0.25 mmol scale with all amino acids used in 4- to 10-fold excess (1 mmol).

The purity of all peptides and peptide conjugates was established as a single peak by analytical HPLC (Hewlett-Packard with Agilent 1100 series automated injector) with an analytical Zorbax SB C18, 150 mm × 4.6 mm, column at a flow rate of 1.0 mL/min in the indicated acetonitrile/water buffer containing 0.1% trifluoroacetic acid using 5−45% gradient over 15 min followed by 5 min wash at 100% acetonitrile buffer. The identity of all peptides and peptide conjugates was established using matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometric analysis.

Manual Peptide Synthesis. Fmoc-Rink amide resin was mixed in DMF under nitrogen in a fritted peptide vessel (20 min). The Fmoc-protecting group was removed by mixing resin in a 20% piperidine/DMF solution (10 mL/g of resin) for 15 min (2×). The vessel was drained via vacuum and washed with DMF (3×). The chloranil resin test was performed by adding one drop of 2% acetaldehyde in DMF followed by one drop of 2% *p*-chloranil in DMF to the resin with a positive test (indicating a free amine) resulting in blue-stained beads. A small sample of resin also underwent the Kaiser resin test where two drops each of (i) 5 g of ninhydrin in 100 mL ethanol, (ii) 80 g of liquefied phenol in 20 mL of ethanol, and (iii) 0.001 M aqueous sodium cyanide (2 mL) in 98 mL of pyridine were added and the mixture was shaken to mix and heated to 120 °C for 4 min. A positive test (indicating a free primary amine) resulted in blue-colored beads.

Deprotection was repeated until the chloranil or Kaiser resin test was positive. The Fmoc-protected amino acid (5 equiv), HOBt (5 equiv), and HBTU (5 equiv) were dissolved in DMF (5 mL/g of resin) followed by the addition of DIEA (10 equiv). This mixture was added to the resin and agitated gently for 30−60 min or until a negative resin test was obtained. After coupling, the resin was washed with DMF (3×). This Fmoc deprotection and coupling sequence was repeated until the desired peptide was assembled.

Fluorescein Labeling. The fluorescent tag was attached through either the free amine of the N-terminus or a lysine side chain of the fully protected peptide while still attached to the solid support. The resin (0.1 mmol) was suspended in dry DMF in a polypropylene tube. Diisopropyl ethylamine (0.17 mL, 1 mmol, 10 equiv) and fluorescein isothiocyanate (200 mg, 0.5 mmol, 5 equiv) were added in one portion to the mixture. The solution was agitated for 18 h followed by vacuum filtration for removal of solvent. The resin was washed twice with DMF and once with DCM to remove any residual base and reagent.

Deprotection and Cleavage of Peptides. The peptide-bound resin was washed well with DCM and dried under nitrogen for several hours. The peptide was deprotected and cleaved from the solid support by exposing the resin to a solution (10 mL/0.1 mmol of peptide) of 95% TFA and 5% triisopropylsilane (TIS) for non-cysteine-containing peptides or a solution of 94% TFA, 2.5% water, 2.5% 1,2-ethane dithiol (EDT), and 1% triisopropylsilane (TIS) for cysteine-containing peptides. The mixture was placed in a polypropylene tube and mixed for 24 h at ambient temperature. After 24 h, the solution was filtered and concentrated under reduced pressure to provide a crude oil. The oil was dissolved in a minimal volume of TFA, placed in a centrifuge tube and triturated with diethyl ether. The material was pelleted via centrifugation, and the ether was removed by decanting. The pellet was washed two additional times with dry diethyl ether and dried under nitrogen. The crude peptide was dissolved in 0.1% TFA/water then purified by reverse-phase HPLC (C18 packed column; water−acetonitrile, 0.1% TFA v/v) to afford a solid after lyophilization.

Synthesis of Attenuating Sequences (Peptides 5−11). The Fmoc-Asp(OtBu)-OH or Fmoc-Gly-OH residues or both were manually attached to the resin as described above. The Boc-Cys(NPys)-OH residue was coupled using *N*,*N*′-diisopropylcarbodiimide (DIC) (5 equiv) and HOBt (6 equiv) in 80:20 DMF/dichloromethane (DCM) (5 mL). The DIEA coupling strategy could not be employed due to the base-labile nature of the 3-nitro-2-pyridinesulfenyl (Npys) protecting group. After 16 h, the peptide was washed with DMF (3×) and DCM (3×) and dried under argon for several hours. Side-chain deprotection and cleavage from the resin was achieved by mixing the resin-bound peptide in a 95:5 TFA/triisopropylsilane (TIS) solution for 5 h. Washing and purification was performed as described above.

Synthesis of the CHSSKLQG-r8-K-(FITC)NH_2 Conjugate (12). The peptide was assembled manually via solid-phase peptide synthesis on a 0.1 mmol scale using the coupling strategy described above. Amino acids Fmoc-Lys(Mtt)-OH, Fmoc-D-Arg(Pbf)-OH, Fmoc-Gly-OH, Fmoc-Gln(tBu)-OH, Fmoc-Leu-OH, Fmoc-Lys(Boc)-OH, Fmoc-Ser(OtBu)-OH, Fmoc-His-(Trt)-OH, and Fmoc-Cys(Trt)-OH (NovaBiochem, CA) were used in 4-fold excess (0.4 mmol). A solution of acetic anhydride (100 μL) and DIEA (350 μL) in DMF (2 mL) was then added, and the mixture was sparged with nitrogen gas for 1 h or until the chloranil resin test (see above) was negative indicating N-terminal acetylation. The resin was filtered via vacuum and washed with DMF (2 mL, 3×) and DCM (2 mL, 3×). A solution of TFA (1%) and TIS (3%) in DCM (96%) was then added, and the mixture was agitated under a nitrogen atmosphere for 5 min. This was repeated until a positive resin test was obtained (5×) indicating removal of the Mtt protecting group. To the free amine of the lysine side chain was added the fluorescein label according to the general procedure described above. The resin was dried for several hours under nitrogen before deprotection and cleavage (see general procedure above). Orange solid (189.7 mg, 36% yield). Analytical RP-HPLC (0.1% TFA in H_2O/CH_3CN): >98% purity. MALDI MS: calculated for $C_{111}H_{180}N_{48}O_{26}S_2$ (M + H), 2667.05; found, 2667.10.

Synthesis of the Final Attenuated Peptide Conjugates (APTD Compounds 13−19). To the attenuating peptide sequences (**5**−**11**) (4 μmol) in 0.1% TFA−water (0.5 mL) was added a solution of peptide **12** (5.3 mg, 2 μmol) in 0.1% TFA−water (1 mL). The mixture was stirred at room temperature for 24 h before quenching with ethyl acetate (2 mL). The layers were separated, and the aqueous phase was extracted and

[a] FITC = fluorescein isothiocyanate; r_8 = arginine octamer; all other letters correspond to standard single-letter abbreviations for amino acids. [b] Without counter ions. [c] 3-Nitro-2-pyridinesulfenyl (Npys)-protected cysteine has been used for synthesis of peptides **5**−**11**.

concentrated in vacuo. The APTD conjugated peptide was purified by RP-HPLC to give the desired conjugated peptide as a bright yellow sticky solid (90−95% yield). Analytical RP-HPLC (0.1% TFA in H_2O/CH_3N): >99% purity. MALDI MS: see Table 1.

Serum Stability Studies. The serum stability of APTD conjugates was evaluated by incubation in fetal calf serum (FCS) (50% FCS/50% phosphate-buffered saline (PBS), pH 7.4) at 37 °C for 4 h using a standard protocol (*47*, *48*). The percentage of intact APTD peptide after incubation was determined by precipitation of the serum proteins with 70% acetonitrile in 0.1% TFA and separating degradation products by analytical RP-HPLC using a 15 min, 10−30% linear acetonitrile gradient (0.1% TFA/water).

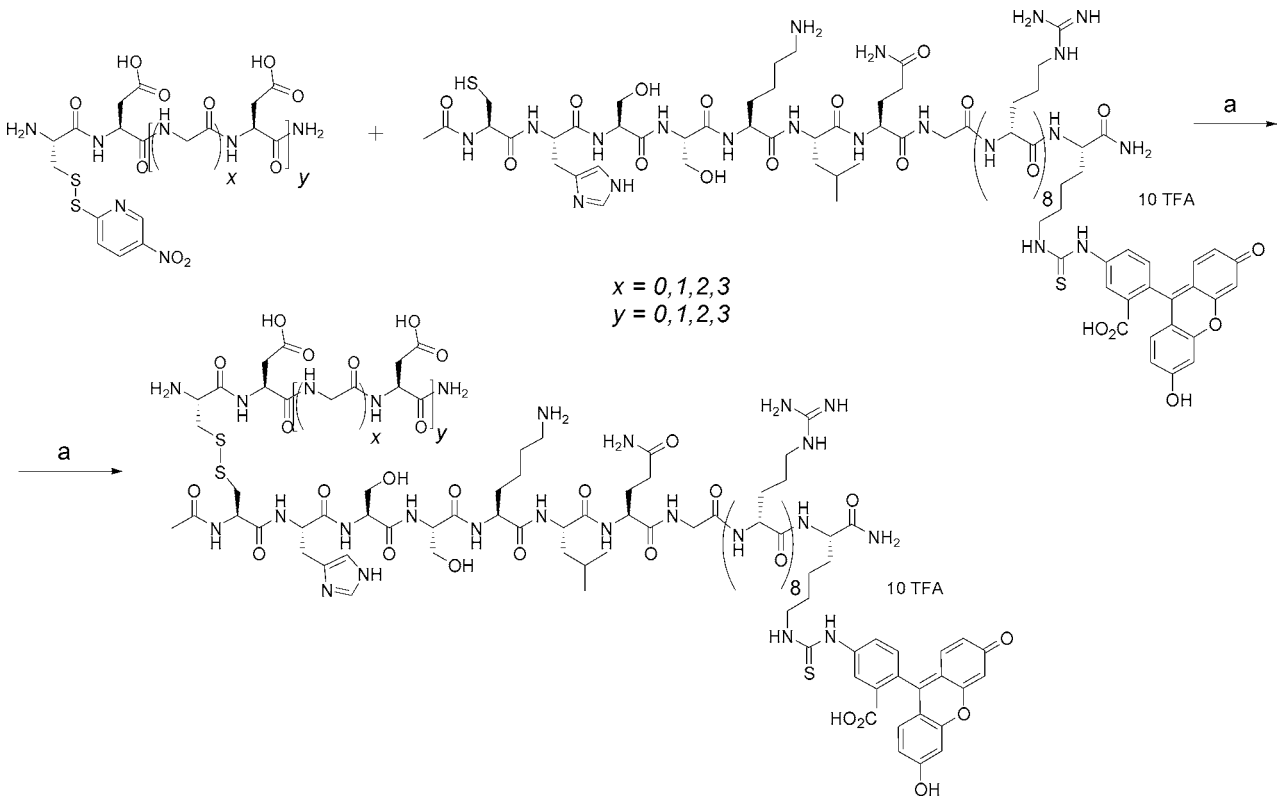
Kinetic Analysis of Substrate Hydrolysis by PSA. The activity of human PSA protease (Calbiochem) was tested prior to experiments with a PSA substrate fluorogenic test kit (Mu-His-Ser-Ser-Lys-Leu-Gln-AFC, 2TFA (Mu = 4-morpholinoureidyl); Calbiochem). Subsequently, 100 μL of 50 μM PSA substrate solution in PSA buffer (50 mM Tris, pH 7.5, 150 mM NaCl) was added to 5.4 μL (concentration = 1.84 mg/mL) of enzymatically active PSA solution in the same buffer, and the mixture was incubated at 37 °C for 4 h. Buffer without PSA enzyme was used as control. Progress of the enzymatic cleavage was monitored by reverse-phase analytical HPLC. Aliquots were drawn at specific times from 0 to 4 h. Ten microliters of the sample was diluted with 90 μL of 0.1% TFA to yield pH $\approx$ 2. After filtration (0.2 μM membrane filter, Anatop Laboratory), 80 μL of the resulting samples were applied to an analytical HPLC column using a 15 min, 5−30% linear acetonitrile gradient (0.1% TFA/water). Fractions were collected manually in Eppendorf tubes (1.5 mL) and dried completely, and masses were analyzed by mass spectroscopy (MALDI).

Cell Uptake Assay: Jurkat Cells. The synthesized APTDs were each dissolved in PBS buffer (pH 7.2), and their concentrations were determined spectrophotometrically by absorption of fluorescein at 490 nm (ϵ = 67 000) (*21*). Varying concentrations (50 and 0.4 μM) of each peptide (nonattenuated CHSSKLQG-r_8-K(FITC)NH_2 (**12**, see Table 1) and all attenuated APTD forms) were added to 3×10^6 Jurkat cells (human T cell line, grown in 10% FCS and DMEM) for 5 min in microtiter plates (96 well) at 37 °C.

Peptides r_5-K(FITC)NH_2 (**3**) and r_4-K(FITC)NH_2 (**4**) were selected as controls. Previous work has shown that a minimum of six arginine residues is required for significant cell uptake to occur (*25*). Following incubation, the microtiter plates were centrifuged, and the cells were isolated, washed, and resuspended in PBS buffer containing 0.1% propidium iodide. The cells were analyzed by fluorescent flow cytometry (FACScan; Becton Dickinson), and cells stained with propidium iodide were excluded from the analysis. The data presented are the mean fluorescent signal for the 10 000 cells collected. Measurements were also made for cells exposed to APTD conjugate peptides after they were subjected to PSA-mediated cleavage. One hundred microliters of 400 μM APTD conjugate solutions in PBS buffer were incubated with 10.8 μL (concentration = 1.84 mg/mL) of enzymatically active PSA solution (Calbiochem) for ~4 h at 37 °C. Samples of each of the resulting peptide solutions were analyzed by HPLC to establish the completeness of the cleavage. Each of the cleaved APTD peptide solutions was then incubated in triplicate with Jurkat cells as described above.

Confirmation of Intracellular Uptake into PC3M Prostate Cancer Cells. Ten micromolar solutions of r8-K(FITC)NH_2 (**1**), r4-K(FITC)NH_2 (**4**), and DGGDGGDGGDCCHSSKLQG-r8-K(FITC)NH_2 (**19**) were preincubated with active PSA solution (5.4 μL, c = 1.84 mg/mL for ~4 h at 37 °C). The incubated peptides and conjugates were then added to 30 000 PC3M cells/well (200 μL total volume) for 15 min. Following incubation, the cells were washed, and the samples were visualized using fluorescence laser confocal microscopy (wavelength λ = 484

Scheme 2. Synthesis of APTD Conjugates[a]



[a] (a) 0.1% TFA in deionized water, 14−24 h, 90−95%.

nm). The PC3M cells were also imaged using the IVIS fluorescent camera, and the photon flux (photons/s) was measured.

Data Analysis. All data were analyzed statistically using the Student's t-test to determine the significance of differences in cell uptake of the various peptide conjugates.

RESULTS

APTD Conjugate Library Synthesis and Purification. A peptide with sequence CHSSKLQG-r8-K, incorporating both the r_8 PTD and linking sequences separated by a single glycine spacer, was synthesized with a fluorescein isothiocyanate (FITC) fluorophore attached to a side chain of lysine at the carboxy-terminus. Multiple potential r_8 PTD-attenuating sequences of the form $C(D)_x$, $CD(GD)_x$, and $CD(GGD)_x$ ($x = 1$, 2, or 3) were synthesized, and each was subsequently conjugated to the CHSSKLQG-r_8-K(FITC)NH_2 peptide through a disulfide bond of the cysteine residues (Scheme 2). Limited peptide solubility, aggregation, or both were observed for r_8 PTD-attenuating sequences with more than four aspartate residues; therefore, the library was not expanded beyond those peptides listed in Table 1. TFA counterions were subsequently ion-exchanged for chloride ion after the disulfide coupling of the CHSSKLQG-r_8-K(FITC)NH_2 and r_8 PTD-attenuating sequences.

Serum Stability Studies. Peptide conjugates **14**−**19** (Table 1) were investigated for their stability in serum (*43*, *44*). After 4 h of incubation in serum at 37 °C, the decomposition of the peptide conjugates ranged from 1% to 5%. The most effectively attenuated APTD conjugate **19** (DGGDGGDGGDCCHSSKLQG-r8-K(FITC)NH_2) was found to be 97% intact after 4 h of incubation at 37 °C.

PSA Cleaving Studies. Following incubation in PSA-containing phosphate buffer solution, tested APTD conjugates demonstrated three distinct peaks on analytical HPLC, where one of these peaks corresponded to uncleaved APTD conjugate while the other two peaks corresponded to the expected cleavage products. Peak assignment was accomplished by collection of the new peaks following cleavage and determination of their masses by mass spectrometry (MALDI). The MALDI data indicated that proteolysis took place between glutamine and glycine residues of the PSA substrate (HSSKLQ−G), as predicted, giving products such as NH_2-DGGDGGDGGDCH-SSKLQ (MW calculated 1764.76, found 1766.12) and G-r8-K(FITC)NH_2 (MW calculated 1841.12, found 1843.38) in the case of the APTD conjugate **19** cleaving study. The time required to cleave half of the substrate varied between the APTD conjugates but was generally in the range of 1.8−2 h. Kinetics of PSA proteolysis of the most effectively attenuated APTD (peptide conjugate **19**) is shown in Figure 1. No detectable decomposition was observed after incubation of the APTD conjugates in phosphate buffer solution without PSA enzyme at 37 °C for 4 h. These data were in agreement with that previously published by other groups (*3*, *36*, *41*−*42*).

Differential APTD Uptake prior to and following PSA-Mediated Cleavage. The APTD conjugates composed of an r_8 PTD, a PSA-selective cleavage sequence (HSSKLQG), and an r_8 PTD-attenuating sequence ($CD(GGD)_x$), where $x = 2$ or 3 (compounds **18** and **19**, respectively) were incubated in PSA-containing media for 4 h prior to the introduction of either Jurkat or PC3M cells for 5 or 15 min, respectively. Flow cytometry and fluorescence laser confocal microscopy were utilized to assess intracellular peptide uptake. Control experiments consisted of cell incubation in peptide-containing media that had not been exposed to PSA, as well as incubation in solutions containing fluorescently labeled control compounds such as octamer of arginine (r_8) **1** (high uptake) and tetramer (r_4) or pentamer (r_5) of arginine (compounds **3** and **4**, insignificant uptake). The results of these studies are summarized in Figure 2, panel A (Jurkat cells) and panel B (PC3M prostate cancer cells). APTD cleavage by PSA significantly enhanced uptake in both Jurkat cells and prostate cancer cells at all time points and concentrations ($p < 0.05$);

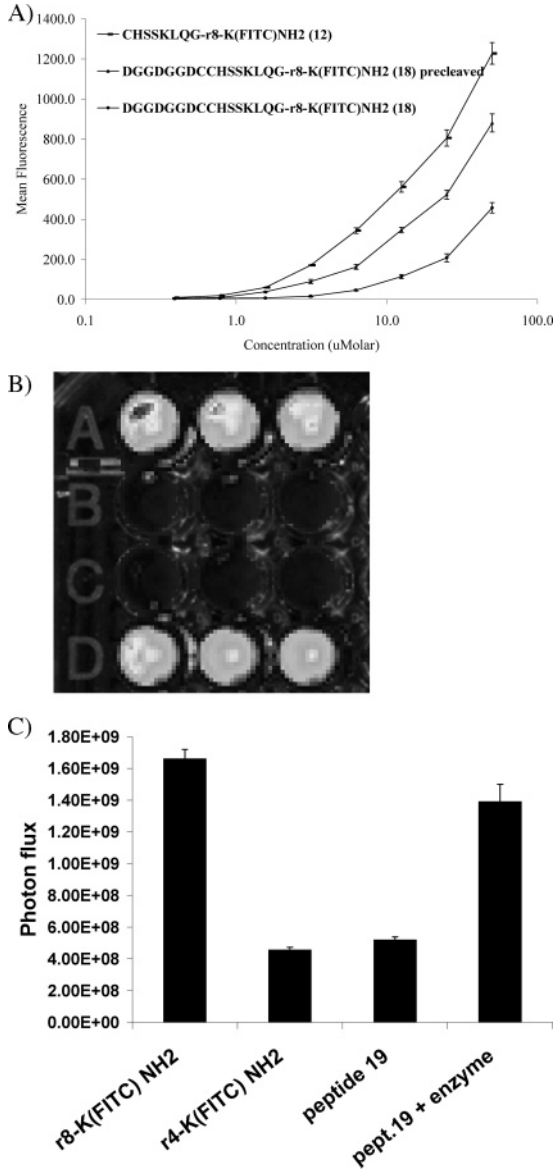


Figure 2. Comparison of cell uptake of APTD with and without prior PSA-mediated peptide cleavage: (A) Jurkat cells. Jurkat cells were incubated with each APTD conjugate solution for 5 min and washed twice. Uptake of each peptide was measured using flow cytometry. The level of cell uptake of the precleaved PSA-targeting APTD was between the levels of uptake of uncleaved APTD and r_8 PTD. Standard deviations are shown for each point; however, their magnitudes were, in many cases, less than 5% of the datapoint. (B) PC3M cells. In triplicate, row A contains r_8-K(FITC)NH_2 (**1**) positive control, row B r_4-K(FITC)NH_2 (**4**) negative control, row C DGGDGGDGGDCCH-SSKLQG-r_8-K(FITC)NH_2 (**19**), and row D DGGDGGDGGDCCH-SSKLQG-r_8-K(FITC)NH_2 (**19**) preincubated with enzymatically active PSA enzyme. This image was obtained using an IVIS 50 imaging system (Xenogen Corp., Alameda, CA) with the level of fluorescence indicated by a color scale ranging from black (no fluorescence) to white (greatest measured fluorescence). The level of fluorescence reflects the level of uptake of the APTD or nonattenuated peptide transporters (r_8 or r_4). Uptake of the PSA targeting APTD takes place only after release of r_8 PTD-attenuating sequence via PSA-specific substrate hydrolysis, as is demonstrated by fluorescence in row D but not in row C. Uptake of the cleaved APTD approaches but does not equal that of the nonattenuated r_8 PTD (row A). Panel C presents bar representation of uptake of fluorescently labeled PSA-targeting peptide **19** in PC3M prostate cancer cells with and without precleavage by PSA. FITC = fluorescein isothiocyanate; r_8 = arginine octamer; all other letters correspond to standard single-letter abbreviations for amino acids in the order from C- to N-terminus.

however, cell uptake of cleaved APTD remained significantly less than that of nonattenuated r_8 PTD ($p < 0.05$).

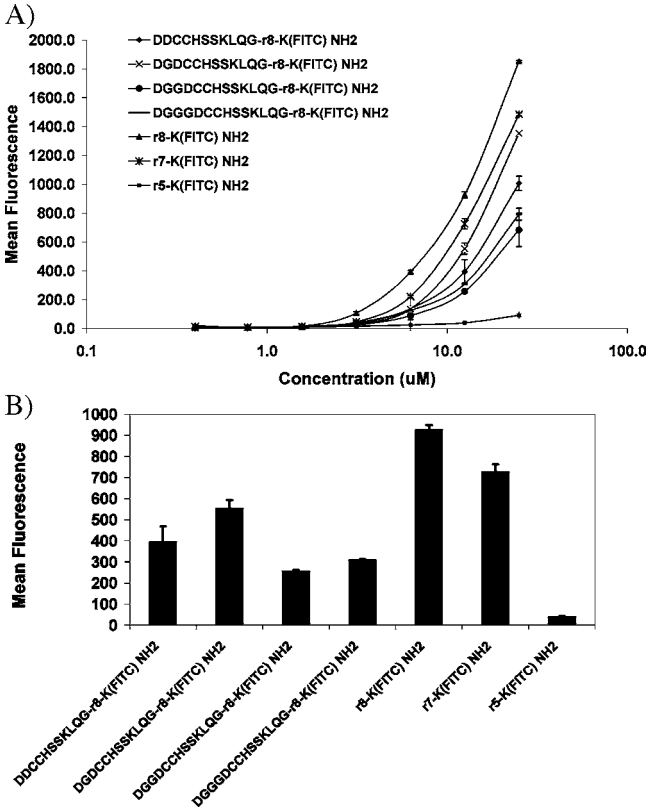

Figure 3. (A) Uptake of various concentrations of APTD conjugates incorporating r_8 PTD, a PSA enzyme-specific sequence, and one of a library of r_8 PTD-attenuating sequences composed of two aspartates spaced with different numbers of glycine residues (DD, DGD, DGGD, DGGGD). Standard deviations are shown for each point; however, their magnitudes were, in many cases, less than 5% of the datapoint. (B) Bar graph demonstrating APTD conjugate uptakes at a single concentration (20 μM), extracted from data shown in panel A. This experiment demonstrates that the number of glycine spacing residues changed the effectiveness of r_8 PTD transport attenuation by as much as 2-fold, with the order of decreasing effectiveness of 2 (greatest) > 3 > 0 > 1 ($p < 0.05$ for difference of attenuation achieved with a spacer of two glycine residues when compared to all other glycine spacer lengths).

Cell Partitioning and Attenuation/Spacing Experiments. The ability of various r_8 PTD-attenuating sequences with different spacing to prevent the r_8 PTD-containing peptide conjugates from entering cells was characterized by incubating Jurkat cells with different concentrations of APTD. The results of these experiments are presented in Figure 3A,B. All of the tested r_8 PTD-attenuating sequences significantly decreased cell uptake of the r_8 PTD transporter when compared to r_8 PTD alone at concentrations of 3 μM and above ($p < 0.01$). The r_8 PTD-attenuating sequence that included aspartic acid residues spaced with two glycines demonstrated the greatest transport-attenuating effect. The number of glycine spacing residues changed the effectiveness of attenuation by as much as 2-fold between the most and the least efficient r_8 PTD-attenuating sequence. At concentrations of 3−12 μM, the attenuation of transport activity achieved when aspartate residues were spaced with two glycine residues was significantly greater than the attenuation achieved when they were spaced by zero, one, or three residues ($p < 0.05$). Otherwise, spacing of aspartate residues with three glycine residues tended to provide greater transport attenuation than spacing with zero or one glycine residue; however, the differences in attenuation were not significant.

The level of r_8 PTD transport attenuation increased significantly with each aspartate residue added ($p < 0.05$) until three aspartate residues had been included. At most concentrations tested, the level of transport attenuation achieved by the

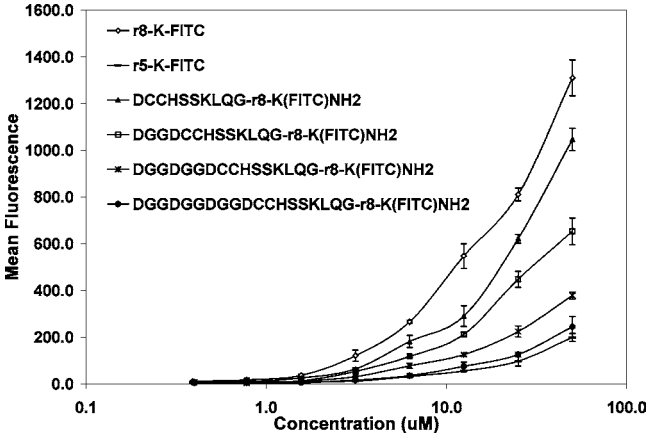

Figure 4. Characterization of the efficiency of r_8 PTD transport attenuation of APTDs with increasing number of apartates (0−4) in comparison with the control compounds r_8-K(FITC)NH_2 (**1**) (high uptake) and r_5-K(FITC)NH_2 (**3**) (no significant uptake). Abbreviations: r_8 = arginine octamer; r_5 = arginine 5-mer; all other letters correspond to standard single-letter abbreviations for amino acids.

inclusion of four aspartate residues was not significantly different from that obtained with three. The presence of four aspartates in the r_8 PTD-attenuating sequence exhibited a low level of uptake in Jurkat cells that was not significantly different from the level of uptake in r_5 and r_4 controls ($p = 0.08-0.36$) (Figure 4). Results from the APTD **19**, which demonstrated the best attenuation, were compared to r_5 and r_4 controls using PC3M cells. The results summarized in Figure 2B demonstrated similar inhibition of uptake between intact APTDs and control peptides (no significant difference).

DISCUSSION

We report the development of a group of APTD conjugates that incorporate an r_8 PTD connected to an r_8 PTD-attenuating sequence via a protease cleavable linker ([r_8 PTD-attenuating sequence]−[cleavable linker]−[r_8 PTD]). The APTD conjugates themselves do not readily enter cells because the r_8 PTD-attenuating sequence disables the r_8 PTD molecular transporter through internal complexation, but upon cleavage of the linker by a specific protease, the activity of the r_8 PTD transporter is restored and cell entry of the cargo-carrying r_8 PTD is observed. Although PTDs have been used by many investigators to facilitate the delivery of imaging agents and therapeutics in vitro and in vivo, the selective delivery of PTDs and their cargos to specific cell types is only beginning to be investigated. This initial research has mainly focused on antibody- and liposome-mediated strategies (*33*, *45*−*47*). Although antibodies have occasionally been successful in targeting tumors (*48*), their bulk hinders penetration of solid tumors and excretion of unbound reagent (*49*), and elaborate reengineering is required to minimize immunogenicity (*50*, *51*). Other investigators have recently reported the development of molecules selectively taken up by cancers expressing matrix metalloproteinase-2 (MMP-2) or MMP-9 following cleavage of the molecule to release a labeled polyarginine transporting peptide (*40*). By incorporation of the selective transporter component into the small molecule, there is greater potential for molecular delivery into deep tissues. The present work provides further evidence for the utility of this promising selective targeting strategy for cargo delivery based on the level of local protease expression. In addition, the results presented here emphasize the achievements in decreased molecular size and specific targeting that can be accomplished by careful engineering of the molecular components of APTDs.

In this study, a modular approach was taken during the design and synthesis of the APTDs, and many combinations of modules containing (1) the r_8 PTD and cleavable linker and (2) one of several r_8 PTD-attenuating sequences were tested. The r_8 PTD itself is a well-established facilitator of molecular transport across cell membranes. Although the detailed mechanisms and subcellular localization of these transporters is not fully understood and is expected to vary as a function of conjugate size, we have recently reported a mechanistic hypothesis for how water-soluble guanidinium-rich transporters attached to small cargoes (MW ca. <3000) can migrate across the nonpolar lipid membrane of a cell and enter the cytosol (*35*). The first step of this mechanism, referred to as adaptive translocation, involves the formation of bidentate hydrogen bonds between the polar, positively charged, water-soluble octamers of arginine (r_8) and negatively charged, bidentate hydrogen bond acceptor groups of endogenous membrane constituents on the cell surface (phosphates, sulfates, carboxylates), leading to the formation of membrane-soluble ion-pair complexes. This step in the mechanism of r_8 PTD-mediated cell entry provides a basis for understanding why conjugates in which negatively charged residues are covalently attached to an r_8 PTD would enter cells less readily, if at all, relative to the free r_8 PTD (*36*). At the molecular level, the attenuating effect is thought to arise through the intramolecular formation of ion pair bidentate hydrogen bond complexes between carboxylate and guanidinium groups with each complex reducing the ability of the transporter to form related intermolecular ion pair complexes as required for cell entry. We hypothesize that intramolecular affinity of the r_8 PTD and the r_8 PTD-attenuating sequence dominates over their intermolecular interaction because they are entropically constrained through the tether of the linking sequence. Thus, of the eight arginines in the r_8 PTD, only four to five arginines would be available for interaction with the membrane when as few as three or four aspartate residues are present in the r_8 PTD-attenuating sequence. We have previously found that arginine conjugates containing one to five arginine residues free for interaction with the cell membrane exhibited markedly lower uptake than conjugates of seven to nine arginines (*27*, *29*).

In the APTD strategy, such negatively charged residues can be arranged in various ways to achieve attenuation of r_8 PTD intracellular transport. The present study utilized r_8 PTD-attenuating sequences composed of aspartate residues alone or spaced with glycine residues. Those sequences incorporating aspartate and glycine residues were found to provide the greatest interference with r_8 PTD transmembrane transport. A combination of greater peptide flexibility with spacing and more optimal positioning of aspartate residues is likely to be responsible for these results because the inclusion of glycine spacers increased the effectiveness of transport attenuation. A greater number of glycines between each aspartate was not found to have a clear effect on cell uptake. These results may have been due to specific spatial orientations achieved using these various lengths of glycine spacers, or there may be an optimal degree of flexibility above which the preference for intramolecular association is lost. The r_8 PTD-attenuating sequence DGGDGGDGGD demonstrated the most effective transport attenuation of any sequence tested (APTD conjugate **19**). The level of r_8 PTD transport attenuation increased as a greater number of aspartates were incorporated into the r_8 PTD-attenuating sequence, as could be expected. The presence of four aspartates in the r_8 PTD-attenuating sequence spaced with two glycines showed as little uptake in Jurkat cells as the r_5 (**3**) or r_4 (**4**) controls, previously shown to have insignificant uptake in Jurkat cells (Figure 4) (*27*, *29*). A greater number of aspartates in the r_8 PTD-attenuating sequence resulted in aggregation and solubility problems.

Prostate cancer was chosen as a model system to demonstrate the feasibility of the APTD targeting approach. Prostate cancer

cells in humans express an abundance of PSA, which was chosen as a target protease because of its relatively specific expression by prostate cancer cells and its postulated low activity within the circulation due to potential rapid inactivation in blood by major serum protease inhibitors ACT and α_2-macroglobulin (*3*). In addition to prostate cancers, PSA is found in high concentrations in the seminal plasma, where the major proteolytic substrates for PSA are the gel-forming proteins in freshly ejaculated semen, Sg I and Sg II (*38*). Using the PSA cleavage map for Sg I and Sg II, Denmeade and co-workers have identified a peptide with the amino acid sequence His-Ser-Ser-Lys-Leu-Gln-Gly (HSSKLQG) that is selectively cleaved by PSA at the carboxylic end of glutamine with a favorable balance of kinetic and binding characteristics (*3*, *36*, *41*−*42*). The peptide sequence is a well-characterized PSA protease substrate that has been used to selectively deliver chemotherapeutics such as doxorubicin (*36*), thapsigargin (*41*), and 5-fluorouracil (*42*) as prodrugs to prostate cancer. Hence, this sequence was introduced as a linker between r_8 PTD and the r_8 PTD-attenuating sequences. In the present study, APTD constructs incorporating r_8 PTD, the HSSKLQG linker sequence, and the r_8 PTD-attenuating sequence underwent cleavage in the linker subunit during incubation with PSA. For example, the APTD conjugate DGGDGGDGGDCCHSSKLQG-r8-K(FITC)NH_2 (**19**) was cleaved into two parts (DGGDGGDGGDGGDCCHSSKLQ and G-r8-K(FITC)NH_2) by PSA, as demonstrated by HPLC and mass spectrometry. Upon cleavage from the r_8 PTD-attenuating sequence, the r_8 PTD demonstrated the ability to rapidly transport its attached cargo (FITC) into Jurkat and PC3M prostate cancer cells. This was observed from flow cytometry experiments and confirmed with laser confocal microscopy. The efficiency of this uptake approached that of nonattenuated r_8 PTD (**1**). This finding provides evidence that, once cleaved, the r_8 PTD and r_8 PTD-attenuating sequence components of the APTD molecules are capable of dissociation despite their ionic and polar attractive forces.

The APTD molecules developed in the present study provide a foundation for selective intracellular delivery of cargo to PSA-expressing prostate cancer cells. The dependence of cell uptake on the presence of PSA makes the described molecules promising candidates for the targeted delivery of therapeutics and imaging agents to prostate cancer tissues. However, studies of these molecules to date have been limited to the in vitro setting. With a focus on a cleavable sequence that is highly selective for PSA, it is anticipated that future in vivo localization of the molecules to prostate cancer will take place in a highly selective manner. However, peptide sequences designed for enzymatic cleavage can only achieve a certain level of enzyme specificity before the kinetics of their hydrolysis prevent them from being useful. Thus, while the APTD molecules were found to be stable in serum (FBS) in the present studies, there may be other enzymes present within the circulation in vivo that are capable of cleaving the APTD in a nonspecific manner. Any nonspecific cleavage of the molecule while in circulation could allow rapid intracellular localization of the r_8 PTD within the most proximal cells and could thereby both decrease the fraction of administered molecule localizing to the site of prostate cancer and increase background uptake. Future preparation for in vivo studies of these APTDs will include investigation of their stabilities in solutions of other proteases present widely within the circulation of animals and humans. Because the APTD conjugates will be tested in animal models of prostate cancer in immediate future studies, FCS was used as a model of these circulatory conditions to only grossly assess the nonspecific APTD cleavage that could be expected.

In the studies presented, a 4 h incubation of the APTD in PSA was utilized to demonstrate cell uptake of the cleaved APTD. Actual time of contact between the enzyme and the APTD in vivo may be much shorter due to factors such as blood flow and diffusion. Another potential challenge for in vivo application of the APTD strategy may be the short circulation times of peptides in general. Circulation must be long enough for a substantial fraction of the APTD to be cleaved, enabling localization in prostate cancer cells. The kinetics of APTD cleavage observed in the present study suggest that these molecules may need to be modified in future in vivo studies (e.g., through the attachment of poly[ethylene glycol]) to enable long circulation times for adequate uptake into foci of prostate cancer. However, it is difficult to extrapolate data regarding enzymatic activity from the in vitro setting to the in vivo setting where higher local concentrations of the enzyme and the optimal environment for enzymatic activity may allow more rapid substrate cleavage. Intracellular localization of the APTD following cleavage is anticipated to be rapid. In the studies presented, cells were incubated in solutions containing APTD for 5 (Jurkat) or 15 (PC3M) min with similar results. The residence time of the APTD in the extracellular matrix in vivo cannot be predicted, and in vivo studies are required to explore the impact of all of the above factors on localization of the APTD in prostate cancers. A sensitive imaging modality, such as PET or potentially SPECT, will likely be required to identify uptake of cleaved PSA-targeting APTD in vivo.

Protease-based targeting is a promising strategy in cancer therapy and imaging. This concept can be further adapted to other activation strategies such as those employing locally restricted enzymes, light, or pH gradients. The presented work demonstrates the feasibility of selective delivery of cargo to the intracellular compartments of prostate cancer cells using molecules incorporating an r_8 PTD and an r_8 PTD-attenuating sequence linked by a sequence that serves as a substrate for the PSA enzyme. Future development of these APTDs will focus on transitioning their use to in vivo models of prostate cancer.

Synthesis and in Vitro/in Vivo Evaluation of Novel $^{99m}Tc(CO)_3$-Folates

Cristina Müller,[†] P. August Schubiger,[†,‡] and Roger Schibli*[,†,‡]

Center for Radiopharmaceutical Science ETH-PSI-USZ, Paul Scherrer Institute, 5232 Villigen-PSI, Switzerland, and Department of Chemistry and Applied Biosciences of the ETH Zurich, 8093 Zurich, Switzerland. Received November 10, 2005; Revised Manuscript Received March 22, 2006

Novel organometallic $^{99m}Tc(I)$-folate derivatives have been synthesized and evaluated in vitro and in vivo in order to assess the influence of the overall charge of the radioconjugates and the spacer entity on the affinity and pharmacokinetic profile. Folic acid has been functionalized at the γ-carboxylate group of the glutamate moiety with (i) a hydrophilic diethoxyethyl spacer bearing a picolylamine monoacetic acid chelate, (ii) a hexyl spacer bearing an iminodiacetic acid chelate, and (iii) a hexyl spacer with a bis(pyridylmethyl)amine chelating system. Coordination of the $^{99m}Tc(CO)_3$-core resulted in neutral complex **21**, anionic complex **22**, and cationic complex **23** in excellent yields (>90%) at ligand concentrations of 10^{-4} M. Complexes **21**−**23** were HPLC purified for in vitro and in vivo experiments. In the case of **23**, separation from the unlabeled folate analogue was incomplete, leading to low specific activity and, hence, significantly inferior in vivo uptake in folate-receptor-positive (FR-positive) organs and tissues (tumors and kidneys). Time dependent in vivo studies were performed in female, athymic nude mice bearing subcutaneous FR-positive human KB cell xenografts at 1, 4, and 24 h post injection (p.i.) of the radiotracers. Tumor uptake ranged between 1.9−2.7% ID/g, 4 h p.i. and 1.6−2.2% ID/g, 24 h p.i. for **21** and **22**, and 0.9% ID/g, 4 h p.i. and 1.1% ID/g, 24 h p.i. for **23**. Blood clearance was fast for all derivatives (≤0.2% ID/g 1 h p.i.). Significant fractions of radioactivity were found in nontargeted and FR-negative organs and tissues (particularly in the liver and the intestines/intestinal contents) at early time points p.i. Coadministration of folic acid reduced radioactivity in FR-positive tissues and organs to background levels. In conclusion, overall charge and the nature of the spacer entity seemed to have a relatively minor influence on receptor affinity and the in vivo pharmacokinetic profile of the tested radiofolates.

INTRODUCTION

The folate receptor (FR) represents a promising molecular tumor marker for selective delivery of bioactive agents, since it is overexpressed on a wide variety of cancers, but highly restricted in most normal human tissues (*1*, *2*). In the past decade the use of folic acid as a "Trojan horse" for targeting of FR-positive tumors has been effectively exemplified (*3*−*9*). Several radiolabeled folate analogues are currently under preclinical and clinical investigation for potential application in diagnostic nuclear medicine (*10*−*15*). The ^{99m}Tc radioisotope features almost ideal physical decay properties (6 h half-life, 140 keV γ-radiation) for diagnostic purposes. For that reason and because of its ready availability, ^{99m}Tc is still the most common radionuclide in routine nuclear medicine. The development of ^{99m}Tc-based folate radiotracers is therefore very attractive as a method of imaging FR-positive, malignant tissue. We recently reported the synthesis and in vitro/in vivo evaluation of folate and pteroate conjugates radiolabeled with the $[^{99m}Tc(CO)_3]^+$ core (*16*, *17*). We were able to demonstrate that these folate and pteroate conjugates fully retain their ability to bind specifically to the FR with high affinity comparable to that of folic acid. However, we noticed less favorable biodistribution of the pteroate derivative in targeted and nontargeted sites compared to folate conjugates (*17*). These findings might be ascribed to the lack of the glutamate entity and the increased lipophilicity of the pteroate derivative, which eventually leads to altered pharmacokinetic characteristics. Based on these observations, we supposed that chemical modifications would positively influence the pharmacological profile of folate derivatives in vivo.

The goal of the present study was to synthesize new folate derivatives, to assess the in vitro and in vivo behavior of the corresponding ^{99m}Tc-complexes, and to compare them with ^{99m}Tc-folate derivatives previously published by our group and others. The three novel folate analogues comprised different chelating systems and/or spacer groups, giving rise to complexes of different overall charge and with varied hydrophilic properties. The radiotracers were tested both in KB cell cultures (human nasopharyngeal cancer cell line, overexpressing the FR) and in KB tumor xenografts in athymic nude mice. Furthermore, the biodistribution of the complexes in nontargeted organs and tissues was assessed and compared.

EXPERIMENTAL PROCEDURES

Materials. Reagents and solvents for syntheses were purchased from Aldrich Chemical Co. or Fluka, Buchs, Switzerland. Solvents were dried according to standard methods. The Boc-protected α-glutamate methyl ester (Boc-Glu-OMe) was purchased from Bachem AG, Bubendorf, Switzerland. The N2-*N*,*N*-dimethylaminomethlylene-10-formylpteroic acid was generously provided by Merck Eprova AG, Schaffhausen, Switzerland. A detailed description of the synthesis and characterization of the folate derivative **20** and the corresponding Tc-99m complex **24** has been reported elsewhere (*16*). Precursor $[^{99m}Tc(CO)_3(OH_2)_3]^+$ was prepared as previously reported using the IsoLink kit (Mallinckrodt-Tyco, Petten, The Netherlands). $[Na][^{99m}TcO_4]$ was eluted from a $^{99}Mo/^{99m}Tc$ generator (Mallinckrodt-Tyco, Petten, The Netherlands) using a 0.9% saline solution. KB cells (CCL-17) were purchased from ATCC (American Type Culture Collection, Manassas, VA). Special RPMI cell culture medium (FFRPMI: without folic acid,

vitamin B_{12}, phenol red) was purchased from Cell Culture Technologies GmbH, Gravesano/Lugano, Switzerland. HPLC analyses were performed on a Merck-Hitachi L-6200A system, equipped with an L-3000 tunable absorption detector, a Berthold LB 508 radiometric detector, and an XTerra (Waters) MS C-18 reversed phase column (5 μm, 15 cm × 4.6 mm). HPLC solvents were aqueous 0.05 M triethylammonium phosphate buffer, pH 7.0 (solvent A), and methanol (solvent B). The HPLC system started with 100% A with a linear gradient to 20% A and 80% B over 15 min followed by 5 min of 100% A with a flow rate of 1 mL/min. TLC analyses of organic syntheses were performed with silica gel 60 (F254, Merck) using CH_2Cl_2/methanol = 9/1 as an eluent. Nuclear magnetic resonance spectra were recorded on a 300 MHz Varian Gemini 2000 spectrometer. The ^{1}H and ^{13}C chemical shifts were reported relative to residual solvent protons as a reference. IR spectra were recorded on a Perkin-Elmer FT-IR 16PC using KBr pellets. MS analyses were performed with a Micromass LCT Premier (KD048, Waters) mass spectrometer (ionization mode: ESI-TOF). Radioactivity (γ-radiation of ^{99m}Tc) was measured with a γ-counter (Cobra II, model B 5003, Packard). Protein concentrations for the in vitro experiments were measured with a micro plate reader (Bio-Rad, model 550), using a Micro BCA protein assay kit (product no. 23235), Socochim.

Synthesis of Compound 1. Compound **1** was synthesized according to a previously published procedure, starting from 2,2′-(ethylenedioxyl)diethylamine (*18*). Yield: 90%. Analytical data for **1**: ^{1}H NMR ($CDCl_3$) δ 1.51 (s, 9H), 2.90−2.98 (m, 2H), 3.32−3.42 (m, 2H), 3.54−3.64 (m, 4H), 3.68 (t, 4H); ^{13}C NMR ($CDCl_3$) δ 28.5 (3C), 40.4, 41.9, 70.3 (2C), 70.4, 73.6, 79.1, 156.1; IR (KBr) 1704 cm^{-1}.

Synthesis of Compound 2. The following procedure is based on literature procedures with a slight modification (*19*). Molecular sieves and pyridine-2-carboxaldehyde (192 μL; 2.01 mmol; 1 equiv) were added to a solution of compound **1** (500 mg; 2.01 mmol; 1 equiv) in dry toluene (20 mL) and stirred for 30 min at room temperature. After 4 h reflux the solution was filtered, evaporated, and dried in a vacuum. The yellow oil of the imine was dissolved in methanol (15 mL), and the reduction was performed with $NaBH_4$ (76 mg; 2.01 mmol; 1 equiv), with stirring at room temperature for 4 h. After addition of water to quench residual $NaBH_4$, the organic solvent was removed in a vacuum. The aqueous solution was extracted three times with ethyl acetate, and the organic layer was dried over Na_2SO_4, evaporated, and dried in a vacuum to obtain a yellow oil. Yield: 86%. Analytical data for **2**: ^{1}H NMR ($CDCl_3$) δ 1.55 (s, 9H), 2.96−3.08 (m, 2H), 3.38−3.48 (m, 2H), 3.68 (t, 2H), 3.70−3.82 (m, 6H), 4.08 (s, 2H), 7.25−7.32 (m, 1H), 7.42−7.49 (m, 1H), 7.72−7.80 (m, 1H), 8.64−8.70 (m, 1H); ^{13}C NMR ($CDCl_3$) δ 28.5 (3C), 40.5, 48.9, 55.1, 60.5, 70.4 (2C), 70.7, 79.2, 122.1, 122.4, 136.6, 149.4, 156.2, 159.5; IR (KBr) 1709 cm^{-1}; MS (ESI) *m*/*z* (%) 340 [M$^+$ + H] (50), 362 [M$^+$ + Na] (100).

Synthesis of Compound 3. The following procedure is based on literature procedures with a slight modification (*19*). Compound **2** (585 mg; 1.72 mmol; 1 equiv) was dissolved in dry tetrahydrofuran (20 mL). Methyl bromoacetate (475 μL; 5.16 mmol; 3 equiv) and triethylamine (720 μL; 5.16 mmol; 3 equiv) were added, and the solution was refluxed for 4 h. After cooling to room temperature, the reaction solution was filtered and evaporated. The crude product was purified by chromatography on silica gel using CH_2Cl_2/methanol (9/1) as an eluent. After drying in a high vacuum the product **3** was obtained in 60% yield. Analytical data for **3**: ^{1}H NMR ($CDCl_3$) δ 1.56 (s, 9H), 3.12 (t, 2H), 3.38−3.48 (m, 2H), 3.65−3.70 (m, 6H), 3.72 (s, 2H), 3.76 (t, 2H), 3.84 (s, 3H), 4.20 (s, 2H), 7.28−7.36 (m, 1H), 7.68−7.75 (m, 1H), 7.78−7.86 (m, 1H), 8.64−8.70 (m, 1H); ^{13}C NMR ($CDCl_3$) δ 28.6 (3C), 40.5, 51.6, 53.6, 55.4, 60.5, 70.0, 70.3 (2C), 70,4, 79.2, 122.4, 123.6, 137.1, 148.7, 156.1, 158.9, 171.8; IR (KBr) 1740, 1708 cm^{-1}; MS (ESI) *m*/*z* (%) 434 [M$^+$ + Na] (100).

Synthesis of Compound 4. The Boc-deprotection of compound **3** (420 mg; 1.02 mmol; 1 equiv) was performed quantitatively in 6 N HCl (10 mL) at room temperature, monitored by TLC/ninhydrin. The solvent was evaporated and the compound **4**·HCl was dried in a vacuum. Analytical data for **4**: ^{1}H NMR (CD_3OD) δ 3.28−3.34 (m, 2H), 3.78−3.86 (m, 6H), 3.91 (t, 2H), 3.96 (s, 3H), 4.08 (t, 2H), 4.55 (s, 2H), 5.16 (s, 2H), 8.22−8.30 (m, 1H), 8.48−8.52 (m, 1H), 8.76−8.824 (m, 1H), 9.09−9.14 (m, 1H); ^{13}C NMR (CD_3OD) δ 39.4, 52.5, 54.4, 55.3, 55.5, 65.8, 66.6, 70.0 (2C), 127.5, 129.1, 143.5, 146.2, 146.8, 167.5; IR (KBr) 1748 cm^{-1}; MS (ESI) *m*/*z* (%) 312 [M$^+$ + H] (100).

Synthesis of Compound 5. 1-Hydroxybenzotriazole hydrate (162 mg; 1.07 mmol; 1 equiv) was added to a solution of Boc-Glu-OMe (280 mg; 1.07 mmol; 1 equiv) in dry CH_2Cl_2 to form a suspension. Addition of *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (226 mg; 1.18 mmol; 1.1 equiv) resulted in a transparent solution. After 4 h of stirring at room temperature, the reaction solution was extracted three times with water to remove impurities. The organic layer was dried over Na_2SO_4, evaporated, and dried in a vacuum to obtain a white solid (yield: 95%). The crude product was used directly for further coupling reactions. Compound **4**·HCl (340 mg, 1.02 mmol; 1 equiv) and *N*-ethyldiisopropylamine (348 μL; 2.04 mmol; 2 equiv) dissolved in dry *N*,*N*-dimethylformamide were added in two portions to a solution of the activated Boc-Glu-OMe (386 mg, 1.02 mmol; 1 equiv) in dry *N*,*N*-dimethylformamide. After stirring overnight at 50 °C, the solution was distilled to remove *N*,*N*-dimethylformamide. The reaction mixture was dissolved in CH_2Cl_2 and washed once with water. The organic layer was dried over Na_2SO_4, filtered, and evaporated. The crude product **5** was purified by chromatography on silica gel using CH_2Cl_2/methanol (9/1). Yield: 42%. Analytical data for **5**: ^{1}H NMR ($CDCl_3$) δ 1.55 (s, 9H), 2.02−2.16 (m, 1H), 2.22−2.36 (m, 1H), 2.38−2.46 (m, 2H), 3.06−3.14 (m, 2H), 3.51−3.60 (m, 2H), 3.59 (s, 2H), 3.62−3.72 (m, 6H), 3.72−3.78 (m, 2H), 3.83 (s, 3H), 3.84 (s, 3H), 4.19 (s, 2H), 4.33−4.46 (m, 1H), 7.29−7.38 (m, 1H), 7.65−7.72 (m, 1H), 7.78−7.87 (m, 1H), 8.62−8.72 (m, 1H); ^{13}C NMR ($CDCl_3$) δ 28.5 (3C), 32.5, 36.7, 39.5, 51.7, 52.4, 53.4, 53.6, 55.5, 60.5, 70.0 (2C), 70.4 (2C), 80.0, 122.5, 123.5, 137.2, 148.8, 159.0, 162.7, 172.0 (2C), 173.0; IR (KBr) 1744, 1712, 1662 cm^{-1}; MS (ESI) *m*/*z* (%) 555 [M$^+$ + H] (100).

Synthesis of Compound 6. Compound **5** (238 mg, 0.43 mmol; 1 equiv) was quantitatively deprotected in TFA/CH_2Cl_2 (1/9) (6 mL) at room temperature for 5 h, monitored by TLC/ninhydrin. The reaction solution was evaporated and dissolved in pure CH_2Cl_2. The crude product **6** was washed once with a saturated solution of $NaHCO_3$. The organic layer was dried over Na_2SO_4, filtered, evaporated, and dried in a vacuum. Analytical data for **6**: $C_{21}H_{34}N_4O_7$ (455.24) calcd C 55.49, H 7.54, N 12.33; found C 55.71, H 7.32, N 12.54; ^{1}H NMR (CD_3OD) δ 2.22−2.42 (m, 2H), 2.56−2.64 (m, 2H), 3.37−3.43 (m, 2H), 3.48−3.55 (m, 2H), 3.65−3.78 (m, 6H), 3.82−3.88 (m, 2H), 3.91 (s, 3H), 3.98 (s, 3H), 4.15 (s, 2H), 4.21−4.28 (m, 1H), 4.69 (s, 2H), 7.84−8.06 (m, 2H), 8.40−8.50 (m, 1H), 8.86−94 (m, 1H); ^{13}C NMR (CD_3OD) δ 25.9, 31.0, 39.1, 51.6, 52.3, 52.5, 54.6, 54.9, 56.8, 67.4, 69.1, 69.8, 69.9, 125.0, 125.2, 143.1, 143.9, 153.7, 169.3, 170.1, 172.8; IR (KBr) 1751, 1673 cm^{-1}; MS (ESI) *m*/*z* (%) 456 [M$^+$ + H] (100), 478 [M$^+$ + Na] (60).

Synthesis of Compound 9. Compound **9** was synthesized according to a previously published procedure, and the analyses

were in agreement with the literature (*18*). Yield: 80%. Analytical data for **9**: ^{1}H NMR ($CDCl_3$) δ 1.38−1.50 (m, 6H), 1.50−1.66 (m, 2H), 1.55 (s, 9H), 2.79 (t, 2H), 3.16−3.29 (m, 2H).

Synthesis of Compound 10. The following procedure is based on literature procedures with a slight modification (*19*). Methyl bromoacetate (1.30 mL; 13.87 mmol; 6 equiv) and triethylamine (1.95 mL; 13.87 mmol; 6 equiv) were added to a solution of compound **9** (400 mg; 2.31 mmol; 1 equiv) in 20 mL of dry tetrahydrofuran (20 mL) and refluxed for 4 h. After cooling to room temperature the reaction mixture was filtered and evaporated. The crude product was dissolved in CH_2Cl_2 and extracted 3 times with brine. The organic layer was dried over Na_2SO_4, evaporated, and dried in a vacuum. Yield: 95%. Analytical data for **10**: ^{1}H NMR ($CDCl_3$) δ 1.39−1.50 (m, 4H), 1.50−1.67 (m, 4H), 1.57 (s, 9H), 2.82 (t, 2H), 3.18−3.30 (m, 2H), 3.68 (s, 4H), 3.83 (s, 6H); ^{13}C NMR ($CDCl_3$) δ 26.7, 26.9, 27.9, 28.6 (3C), 30.1, 40.6, 51.7 (2C), 54.4, 55.0 (2C), 79.3, 156.1, 171.7 (2C); IR (KBr) 1747, 1712 cm^{-1}; MS (ESI) *m*/*z* (%) 383 [M^+ + Na] (90).

Synthesis of Compound 11. The Boc-deprotection of compound **10** (790 mg, 2.19 mmol; 1 equiv) was performed quantitatively in 6 N HCl (15 mL) for 2 h at room temperature, monitored by TLC/ninhydrin. The solvent was evaporated and compound **11**·HCl was dried in a vacuum. Analytical data for **11**: ^{1}H NMR (CD_3OD) δ 1.38−1.52 (m, 4H), 1.66−1.74 (m, 2H), 1.74−1.84 (m, 2H), 2.94 (t, 2H), 3.36−3.46 (m, 2H), 3.84 (s, 6H), 4.36 (s, 4H); ^{13}C NMR (CD_3OD) δ 23.4, 25.4, 26.8, 34.4, 39.1, 52.4 (2C), 53.9, 56.5 (2C), 166.4 (2C); IR (KBr) 1748 cm^{-1}; MS (ESI) *m*/*z* (%) 261 [M^+ + H] (100).

Synthesis of Compound 12. 1-Hydroxybenzotriazole hydrate (355 mg; 2.35 mmol; 1 equiv) was added to a solution of Boc-Glu-OMe (614 mg; 2.35 mmol; 1 equiv) in dry CH_2Cl_2. After addition of *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (497 mg; 2.59 mmol; 1.1 equiv) a transparent solution was obtained. After 4 h of stirring at room temperature, the UV-active product was detected by TLC analysis (R_f = 0.9). The reaction solution was extracted three times with water to remove impurities, and the organic layer was dried over Na_2SO_4, evaporated, and dried in a vacuum to obtain a white solid in 95% yield, used directly in the further coupling reaction. Compound **11**·HCl (650 mg, 2.19 mmol; 1 equiv) and *N*-ethyldiisopropylamine (750 μL; 4.38 mmol; 2 equiv) dissolved in dry *N*,*N*-dimethylformamide were added in two portions to a solution of the activated Boc-Glu-OMe (830 mg, 2.19 mmol; 1 equiv) in dry *N*,*N*-dimethylformamide. After 10 h at 50 °C, the solution was distilled to remove *N*,*N*-dimethylformamide and the crude product was purified by chromatography on silica gel using CH_2Cl_2/methanol (9/1) to obtain product **12**. Yield: 50%. Analytical data for **12**: ^{1}H NMR ($CDCl_3$) δ 1.28−1.38 (m, 4H), 1.43 (s, 9H), 1.45−1.53 (m, 4H), 1.86−1.98 (m, 1H), 2.11−2.21 (m, 1H), 2.22−2.28 (m, 2H), 2.72 (t, 2H), 2.18−3.27 (m, 2H), 3.56 (s, 4H), 3.70 (s, 6H), 3.73 (s, 3H), 4.12−4.38 (1H); ^{13}C NMR ($CDCl_3$) δ 26.7 (2C), 27.6, 28.5 (3C), 29.3, 29.5, 32.9, 39.6, 51.8 (2C), 52.6, 53.2, 54.3, 54.8 (2C), 80.2, 156.0, 171.6 (2C), 171.9, 172.9; IR (KBr) 1755, 1734, 1717, 1654 cm^{-1}; MS (ESI) *m*/*z* (%) 526 [M^+ + Na] (50).

Synthesis of Compound 13. Compound **12** (550 mg, 1.09 mmol; 1 equiv) was quantitatively deprotected in TFA/CH_2Cl_2 (1/9) (10 mL) at room temperature for 5 h, monitored by TLC/ninhydrin. The reaction solution was evaporated and dissolved in pure CH_2Cl_2. The crude product **13** was extracted once with a saturated solution of $NaHCO_3$. The organic layer was dried over Na_2SO_4, filtered, evaporated, and dried in a vacuum. Analytical data for **13**: $C_{18}H_{33}N_3O_7$ (403.23) calcd C 53.58, H 8.24, N 10.41; found C 53.78, H 8.04, N 10.22; ^{1}H NMR (CD_3OD) δ 1.45−1.61 (m, 4H), 1.61−1.73 (m, 2H), 1.82−1.96 (2H), 2.20−2.43 (m, 2H), 2.54−2.63 (m, 2H), 3.32 (t, 2H), 3.47−3.55 (m, 2H), 3.99 (s, 3H), 4.00 (s, 6H), 4.19−4.27 (m, 1H), 4.45 (4H); ^{13}C NMR (CD_3OD) δ 23.7, 25.8, 26.0, 26.1, 28.8, 31.0, 39.0, 52.4, 52.5 (3C), 53.8 (2C), 56.6, 166.5 (2C), 169.3, 172.6; IR (KBr) 1754, 1685, 1674 cm^{-1}; MS (ESI) *m*/*z* (%) 404 [M^+ + H] (100).

Synthesis of Compound 15. The following procedure is based on literature procedures with a slight modification (*20*−*22*). Pyridine-2-carboxaldehyde (465 μL; 4.85 mmol; 2.1 equiv) dissolved in 5 mL of dry 1, 2-dichloroethane was added to a solution of compound **9** (500 mg; 2.31 mmol; 1 equiv) in 10 mL of dry 1,2-dichloroethane and stirred for 2 h at room temperature. The reaction solution was cooled to 0 °C before slow addition of sodium triacetoxy borohydride (1125 mg; 5.31 mmol; 2.3 equiv) in portions. After 24 h of stirring at room temperature, water was added to quench residual sodium triacetoxy borohydride and the reaction mixture extracted twice with CH_2Cl_2. The organic layer was extracted with water and brine, dried over Na_2SO_4, evaporated, and dried in a vacuum. Yield: 75%. Analytical data for **15**: ^{1}H NMR ($CDCl_3$) δ 1.10−1.66 (m, 8H), 1.38 (s, 9H), 2.54−2.72 (m, 2H), 2.92−3.3.10 (m, 2H), 3.93 (s, 4H), 7.09−7.18 (m, 2H), 7.55−7.70 (m, 4H), 8.44−8.54 (m, 2H); ^{13}C NMR ($CDCl_3$) δ 26.3, 26.4, 26.7, 28.4 (3C), 29.9, 40.4, 53.8,?59.6 (2C), 79.0, 122.5 (2C), 123.8 (2C), 136.7 (2C), 149.0 (2C), 150.1, 156.0 (2C); IR (KBr) 1687 cm^{-1}; MS (ESI) *m*/*z* (%) 399 [M^+ + H] (100).

Synthesis of Compound 16. The Boc-deprotection of compound **15** (690 mg, 1.73 mmol; 1 equiv) was achieved quantitatively in 6 N HCl (15 mL) after 4 h at room temperature as determined by TLC/ninhydrin. After addition of 10 N NaOH to obtain a pH value of 5, the reaction mixture was evaporated and dried in a vacuum. Methanol was added and the mixture was filtered to remove the precipitated salt. Yield: 93%. Analytical data for **16**: ^{1}H NMR (CD_3OD) δ 1.20−1.48 (m, 4H), 1.48−1.72 (m, 4H), 2.66−2.99 (m, 2H), 2.80−2.96 (m, 2H), 4.39 (s, 4H), 7.74−7.96 (m, 2H), 8.05−8.10 (m, 2H), 8.42−8.52 (m, 2H), 8.78−8.85 (m, 2H); ^{13}C NMR (CD_3OD) δ 25.2, 25.6, 26.1, 26.9, 39.2, 54.9, 55.8 (2C), 125.8 (2C), 126.6 (2C), 142.5 (2C), 145.6 (2C), 152.8 (2C); IR (KBr) 1526, 1619 cm^{-1}; MS (ESI) *m*/*z* (%) 299 [M^+ + H] (100).

Synthesis of Compound 17. 1-Hydroxybenzotriazole hydrate (275 mg; 1.82 mmol; 1 equiv) was added to a solution of Boc-Glu-OMe (475 mg; 1.82 mmol; 1 equiv) in dry CH_2Cl_2 to form a suspension. Addition of *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (384 mg; 2.00 mmol; 1.1 equiv) resulted in a transparent solution. The reaction was stirred for 4 h at room temperature and monitored by TLC analysis (R_f = 0.9). The reaction solution was extracted three times with water to remove impurities. The organic layer was dried over Na_2SO_4, filtered, evaporated, and dried in a vacuum to obtain a white solid. Yield: 95%. The product was processed without further purification. Compound **16**·HCl (515 mg, 1.73 mmol; 1 equiv) and *N*-ethyldiisopropylamine (295 μL; 1.73 mmol; 1 equiv) dissolved in dry *N*,*N*-dimethylformamide were added in two portions to a solution of the activated Boc-Glu-OMe (655 mg, 1.73 mmol; 1 equiv) in dry *N*,*N*-dimethylformamide. After 16 h of stirring at room temperature, the solution was distilled to remove *N*,*N*-dimethylformamide and the crude product was purified by silica gel using CH_2Cl_2/methanol (9/1) to obtain the product **17**. Yield: 52%. Analytical data for **17**: ^{1}H NMR ($CDCl_3$) δ 1.13−1.33 (m, 4H), 1.33−1.50 (m, 2H), 1.38 (s, 9H), 1.56−1.72 (m, 2H), 1.80−1.98 (m, 1H), 2.20−2.18 (m, 1H), 2.23 (t, 2H), 2.68−2.85 (m, 2H), 3.10−3.22 (m, 2H), 3.68 (s, 3H), 4.06 (s, 4H), 4.12−4.25 (m, 1H), 7.14−7.26 (m, 2H), 7.58−7.72 (m, 4H), 8.46−8.58 (m, 2H); ^{13}C NMR ($CDCl_3$) δ 25.4, 26.2 (2C), 28.3 (3C), 28.7, 28.9, 32.6, 42.0, 52.3, 53.7, 58.6, 60.3 (2C), 79.9, 118.3 (2C), 123.2 (2C), 137.4 (2C), 148.7

(2C), 154.8 (2C), 156.0, 172.1, 172.7; IR (KBr) 1743, 1705, 1652 cm^{-1}; MS (ESI) *m/z* (%) 564 [M^+ + Na] (40), 542 [M^+ + H] (100).

Synthesis of Compound 18. Compound **17** (485 mg, 0.90 mmol; 1 equiv) was quantitatively deprotected in TFA/CH_2Cl_2 (1/9) (10 mL) at room temperature overnight as determined by TLC/ninhydrin. The reaction solution was evaporated and dissolved in pure CH_2Cl_2. The crude product **18** was washed once with a saturated solution of $NaHCO_3$. The organic layer was dried over Na_2SO_4, filtered, evaporated, and dried in a vacuum. Analytical data for **18**: $C_{24}H_{35}N_5O_3$ (441.27) calcd C 65.28, H 7.99, N 15.86; found C 65.02, H 8.19, N 16.06; ^{1}H NMR (CD_3OD) δ 1.20−1.36 (m, 4H), 1.36−1.50 (m, 2H), 1.60−1.74 (m, 2H), 2.00−2.22 (m, 2H), 2.34−2.44 (m, 2H), 2.92−3.03 (m, 2H), 3.03−3.19 (m, 2H), 3.79 (s, 3H), 4.00−4.08 (m, 1H), 4.44 (s, 4H), 7.59−7.67 (m, 2H), 7.68−7.75 (m, 2H), 8.08−8.17 (m, 2H), 8.68−8.74 (m, 2H); ^{13}C NMR (CD_3OD) δ 24.5, 25.8, 26.0 (2C), 28.6, 30.9, 38.9, 52.2, 52.3, 54.9, 56.4 (2C), 124.8 (2C), 125.0 (2C), 126.9 (2C), 141.1 (2C), 151.3 (2C), 169.1, 172.4; IR (KBr) 1753, 1672 cm^{-1}; MS (ESI) *m/z* (%) 464 [M^+ + Na] (100), 442 [M^+ + H] (60).

Synthesis of Compound 8, 14 and 19. N2-*N*,*N*-Dimethylaminomethlylene-10-formylpteroic acid **7** was activated according to Nomura et al. (*16*, *23*). Compound **6**, **13**, or **18** (1 equiv) and *N*-ethyldiisopropylamine (1.5 equiv) were dissolved in dry CH_2Cl_2 and added in two portions to a solution of **7**. The coupling reaction was stirred overnight. The reaction solution was extracted once with water; the organic layer was dried over Na_2SO_4 and filtered and the solvent evaporated. The crude product was deprotected in 1 N NaOH (10 equiv) after stirring for 5 h at room temperature, monitored via HPLC. After neutralization with 1 N HCl the pH was brought to 3 by addition of 0.1 N HCl. The yellow product precipitated on addition of ethanol. After centrifugation the crude products were washed three times with ethanol and dried in a vacuum to obtain the pure products **8**, **14**, and **19** as orange powders. Yield: 10−12%. Analytical data for **8**: $C_{33}H_{40}N_{10}O_9$ (720.30) calcd C 54.99, H 5.59, N 19.43; found C 54.56, H 6.09, N 19.93; ^{1}H NMR (DMSO) δ 1.22−1.32 (m, 2H), 1.84−1.98 (m, 1H), 1.98−2.10 (m, 1H), 2.16−2.24 (m, 2H), 2.78−2.85 (m, 2H), 3.12−3.20 (m, 2H), 3.30−3.50 (m, 6H), 3.40 (s, 2H), 3.93 (s, 2H), 4.22−4.30 (m, 1H), 4.46−4.52 (m, 2H), 6.59−6.67 (m, 2H), 7.22−27 (m, 1H), 7.46−7.50 (m, 1H), 7.62−7.68 (m, 2H), 7.74−7.78 (m, 1H), 8.44−8.50 (m, 1H), 8.64 (s, 1H); ^{13}C NMR (DMSO) δ 26.6, 31.9, 45.9, 52.9, 55.2, 56.0 (2C), 60.0, 68.9, 69.9, 69.5 (2C), 111.2 (2C), 117.7, 122.2, 122.7, 128.9 (2C), 131.1, 136.6, 148.6, 150.8, 152.0, 154.0, 157.1, 159.5, 160.9, 167.2, 168.0, 171.7, 172.3, 173.8; IR (KBr) 1701, 1684, 1643 1603 cm^{-1}; MS (ESI) *m/z* (%) 720 [M^+] (60), 743 [M^+ + Na] (100). Analytical data for **14**: $C_{29}H_{37}N_9O_9$ (655.27) calcd C 53.12, H 5.69, N 19.23; found C 53.42, H 5.88, N 19.01; ^{1}H NMR (D_2O) δ 1.22−1.72 (m, 8H), 1.98−2.40 (m, 4H), 2.75−2.90 (m, 2H), 3.00−3.10 (m, 2H), 3.70 (s, 4H), 4.25−4.38 (m, 1H), 4.57 (s, 2H), 6.70−6.80 (m, 2H), 7.55−7.62 (m, 2H), 8.67 (s, 1H); ^{13}C NMR (D_2O) δ 25.0, 26.5, 26.8, 26.9, 28.0, 34.3, 40.6, 47.1, 56.6, 57.3, 58.4 (2C), 114.1, 116.8 (2C), 130.5 (2C), 150.7, 151.0, 151.8, 152.3, 170.6, 171.0, 171.8, 171.9 (2C), 172.0, 176.8, 179.7; IR (KBr) 1718, 1681, 1650, 1636 cm^{-1}; MS (ESI) *m/z* (%) 656 [M^+ + H] (10), 328 [M^{2+} + H] (100). Analytical data for **19**: $C_{37}H_{43}N_{11}O_5$ (721.34) calcd C 61.57, H 6.00, N 21.35; found C 61.11, H 5.88, N 21.02; ^{1}H NMR (DMSO) δ 0.90−1.30 (m, 6H), 1.30−1.46 (m, 2H), 1.75−1.90 (m, 1H), 1.90−2.04 (m, 1H), 2.04−2.16 (m, 2H), 2.78−2.98 (m, 2H), 3.20−3.60 (m, 2H), 3.72 (s, 4H), 4.12−4.26 (m, 1H), 4.40 (s, 2H), 6.50−6.62 (m, 2H), 7.12−7.22 (m, 2H), 7.38−7.48 (m, 2H), 7.52−7.62 (m, 2H), 7.62−7.82 (m, 2H), 8.36−8.44 (m, 2H), 8.57 (s, 1H); ^{13}C NMR (DMSO) δ 26.6, 26.8 (2C), 29.6, 30.1 (2C), 40.7, 53.9, 54.0, 57.0, 60.2 (2C), 109.0, 111.6, 121.7 (2C), 122.5 (2C), 123.0 (2C), 128.4 (2C), 129.4 (2C), 136.9 (2C), 149.1, 151.1, 154.0, 160.0, 163.0 (2C), 166.6 (2C), 171.6, 174.2, 179.7; IR (KBr) 1718, 1684, 1631, 1613 cm^{-1}; MS (ESI): *m/z* (%) 745 [M^+ + Na] (100).

Preparation of the Radiotracers 21−24. Complexes **21−23** and complex **24** (previously reported by our group (*16*)) were prepared according to the following general procedure: $[^{99m}Tc(CO)_3(OH_2)_3]^+$ (100 μL; ~1 GBq/mL), phosphate buffered saline (PBS pH 7.4, 350 μL), and a stock solution of the corresponding derivative (**8**, **14**, **19**, **20**) in PBS (10^{-3} M, 50 μL) were placed in a sealed glass vial. After 30 min of reaction time at 75 °C the vial was cooled on ice. HPLC analyses of the complexes **21−24** revealed yields between 92% and 98%. The radiolabeled complexes **21−24** were separated from unlabeled compounds **8**, **14**, **19**, **20**) by HPLC and diluted in PBS to obtain a concentration of 1 MBq/mL for in vitro experiments or 3.7 MBq/mL for in vivo experiments, respectively.

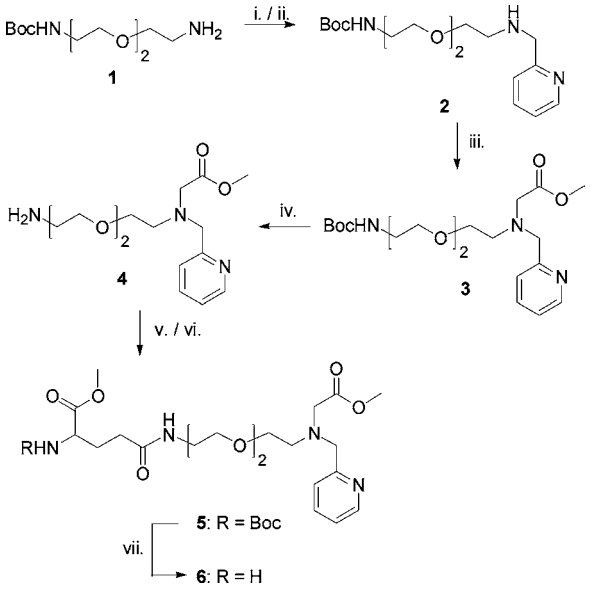
Cell Cultures. KB cells (human, nasopharyngeal carcinoma cell line) were cultured continuously in a 150 cm^2 flask as monolayers at 37 °C in a humidified atmosphere containing 7.5% CO_2. The cells were folate-starved using a folate-deficient special RPMI 1640 medium (FFRPMI: modified RPMI 1640 medium without folic acid, vitamin B_{12} and phenol red), supplemented with 10% heat-inactivated fetal calf serum (FCS) as the only source of folate, L-glutamine, and antibiotics (penicillin 100 IU/mL, streptomycin 100 μg/mL, fungizone 0.25 μg/mL). Cell culture media such as FCS-supplemented FFRPMI are known to feature a final folate concentration of ~3 nM, i.e., a value at the low end of the physiological concentration in human serum (*24*).

Cell Preparation for in Vitro Experiments. Eighteen hours prior to each experiment, the cells were seeded in 12-well plates (8×10^5 cells/well) to form confluent monolayers overnight. The experiments were performed in triplicate.

Cell Preparation for in Vivo Experiments. For subcutaneous inoculation of the mice, subconfluent cells were harvested by treatment with EDTA (1 mM) in PBS (1×, pH 7.4). The cells were then washed once with PBS and pelleted by spinning at 1000*g* for 5 min at 20 °C. The cells were resuspended in PBS to the corresponding concentration (50×10^6 cells/mL).

Cell Binding Studies. Cell binding experiments of the folate radiotracers **21−24** were performed according to the following general procedure: Cell monolayers were rinsed twice with ice-cold PBS (pH 7.4). Pure FFRPMI medium (without FCS/L-glutamine/antibiotics, 975 μL) was added into each well. Blocking studies were performed with FFRPMI medium (475 μL) and a folic acid solution (200 μM, 500 μL). The well plates were preincubated at 37 °C for 40 min. A solution of the $^{99m}Tc(CO)_3$-labeled radiotracer (25 μL, 1 MBq/mL) was added, and the well plates were incubated again for 1 h at 37 °C. The monolayers were then washed several times. The radioactivity counted in samples washed with only PBS (pH 7.4) could be ascribed to the sum of FR-bound radiotracer on the cell surface and the internalized fraction. Cell samples, washed with stripping buffer (an aqueous solution of 0.1 M acetic acid and 0.15 M NaCl, pH 3) in order to release radiotracer from FRs on the cell surface, enabled determination of the internalized fraction of radioactivity (*25*, *26*). The monolayers were dissolved in 1 N NaOH (1 mL), transferred to 4 mL tubes, and homogenized by vortex. The radioactivity of each sample was measured with a γ-counter. The concentration of proteins was determined for each sample by a Micro BCA protein assay kit, in order to normalize measured radioactivity of the samples with respect to the averaged sample protein content. The raw data were converted from counts per minute (cpm) into percentage of total radioactivity added.

Scheme 1[a]



[a] (i) Pyridine-2-carboxaldehyde, toluene, reflux, 3 h; (ii) $NaBH_4$, methanol, rt, overnight; (iii) methyl bromoacetate, triethylamine, tetrahydrofuran, reflux, 5 h; (iv) HCl 6 N, rt, 3 h; (v) Boc-Glu-OMe, 1-hydroxybenzotriazole hydrate, *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride, CH_2Cl_2, rt, 4 h; (vi) *N*-ethyldiisopropylamine, *N*,*N*-dimethylformamide, 50 °C, overnight; (vii) TFA/CH_2Cl_2 (9:1), rt, overnight.

Biodistribution Studies. Four to five week old female nude mice (CD1-Fox1n/nu) were purchased from Charles River Laboratories (Sulzfeld, Germany). Mice were housed under conditions of controlled temperature (26 °C), humidity (68%), and daily light cycle (12 h light/12 h dark). The animals were maintained on a folate-deficient rodent chow (in order to reduce their serum folate to a level near that of human serum). After an acclimation period of 5−7 days, the mice were inoculated subcutaneously with 0.1 mL of tumor cell suspension (5×10^7 cells/mL) into the subcutis of the axilla. Radiotracer distribution studies were performed 12−14 days after tumor cell inoculation. The radiotracers **21**−**24** (100 μL, 3.7 MBq/mL) were administered via a lateral tail vein. Blockade studies have been performed by coadministration of folic acid (100 ± 10 μg/mouse in 100 μL of PBS, pH = 7.4) 5 min prior to the radiotracer. At the indicated points in time, the animals were sacrificed and dissected. The selected tissues were removed and weighed, and the radioactivity was counted by a γ-counter to determine distribution of the relevant radiotracer within the test animal. The results were tabulated as percentage injected dose per gram (% ID/g) of weight tissue.

RESULTS AND DISCUSSION

Organic Syntheses. The synthetic concept described below was chosen because it leads directly and exclusively to γ-folate derivatives. Thus, cumbersome and inefficient chromatographic separation of mixtures of γ- and α-folate products (which are formed when coupling is performed directly to folic acid) could be avoided. Syntheses of various chelating systems with the spacer entities are presented in Schemes 1−3. We followed the recently published general synthetic strategy for the preparation of tridentate chelating systems with variable spacer groups comprising a terminal, primary amine functionality (*16*, *19*, *20*). Chelators and spacer entities were prepared as follows: For the synthesis of compound **2**, mono-Boc-protected 2,2′-(ethylenedioxyl)diethylamine **1** was reacted with pyridine-2-carboxyldehyde to form a Schiff base, followed by an in situ reduction using sodium borohydride. This compound was alkylated with methyl bromoacetate in the presence of base to form intermediate **3** (Scheme 1). After purification of the crude product by chromatography on silica gel, compound **3** was obtained in 60% yield. For compound **10** mono-Boc-protected diaminohexane was N-alkylated with 2 equiv of methyl bromoacetate (Scheme 2). Product **10** was obtained from an organic reaction solution after aqueous extraction. Compound **15** was synthesized by reacting mono-Boc-protected diaminohexane with 2 equiv of pyridine-2-carboxaldehyde and a slight excess of sodium triacetoxy borohydride for in situ reduction of the imine intermediate (Scheme 3). The aqueous reaction mixture was extracted with dichloromethane and washed with water and brine. Boc-deprotection of compounds **3**, **10**, and **15** was achieved in the presence of 6 N HCl to yield compounds **4**, **11**, and **16**. These intermediates were coupled to the accessible γ-carboxylate group of N_α-Boc-protected α-glutamate methyl ester using standard peptide coupling reagents (1-hydroxybenzotriazole hydrate, *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride) to form the corresponding intermediates **5**, **12**, and **17** in good yields (Schemes 1−3). After Boc-deprotection, compounds **6**, **13**, and **18** were coupled to activated

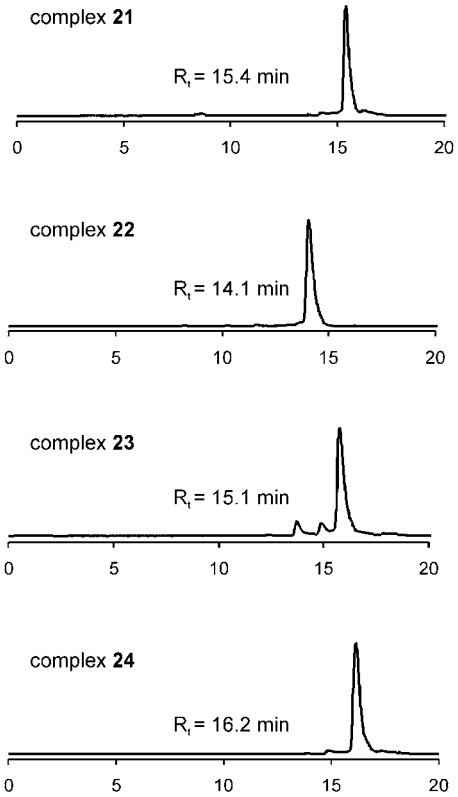

Figure 1. Radioactive HPLC-traces (γ-trace) of the $^{99m}Tc(CO)_3$-folate radiotracers 21−24, performed on an XTerra MS C-18 reversed phase column with a linear gradient (100% buffer to 80% methanol).

N2-*N*,*N*-dimethylaminomethlylene-10-formylpteroic acid (Scheme 4). Finally, all folate intermediates were fully deprotected in a single step in the presence of excess NaOH, to obtain, after 4−5 h of stirring at room temperature, the crude folate derivatives **8**, **14**, and **19**. After neutralization, followed by stepwise acidification of the aqueous solution, the pure products **8**, **14**, and **19** precipitated as yellow-orange powders and could be filtered and dried in a high vacuum.

Radiolabeling of the Folate Derivatives. Radiolabeling with $[^{99m}Tc(CO)_3(OH_2)_3]^+$ was performed at ligand concentrations of 10^{-4} M (**8**, **14**, **19**, **20**) for 30 min at 37 °C (Scheme 5). The formation of the $^{99m}Tc(CO)_3$-complexes, monitored by HPLC, showed generally a shift to longer retention times compared to the free precursor $[^{99m}Tc(CO)_3(OH_2)_3]^+$ ($R_t = \sim 7$ min) and the folate ligands (**8**, $R_t = 10.3$ min; **14**, $R_t = 10.2$ min; **19**, $R_t =$ 15.9. min; **20**, $R_t = 12.3$ min). Radiolabeling yields were >92% for all of the derivatives **21**−**24** (Figure 1). Formation of small amounts of (unidentifiable) byproducts was observed only in the case of ligand **19** and the corresponding complex **23**. Separation of the radioactive complexes from unlabeled folate derivates was necessary in order to avoid folate-receptor saturation. In the case of complexes **21**, **22**, and **24** HPLC separation was efficient. Ligand **19** and complex **23** revealed almost identical retention times. Separation was therefore difficult, hence the specific activity was significantly lower for complex **23**. This circumstance directly impaired FR targeting particularly in vivo (vide infra). The HPLC purified products showed no evidence of degradation in PBS or human plasma over a period of 24 h at 37 °C.

In Vitro Evaluation. In vitro experiments were performed with KB cells, which express a continuous, high level of FRs. In order to investigate the potential of our three novel complexes **21**−**23** and complex **24** for specific FR targeting, we performed cell binding studies (Table 1). The cells were incubated with the relevant radiotracer (**21**−**24**) at 37 °C for 1 h. After washing the cell monolayers with PBS (to remove unbound radiotracers), we found 40−55% of total radioactivity in the cell lysate, which represents FR-bound as well as cell-internalized radiotracers. Treatment of the cell monolayers with stripping buffer (pH 3) enabled the release of the radiotracers on the cell surface (specifically bound to FRs). The acid-resistant, internalized fraction of radiotracer in the cell lysates reached 13−25% of the total radioactivity. Preincubation of the cells with excess folic acid (final concentration 100 μM) for saturation of the FRs resulted in an almost complete blockade (<1% of the total added radioactivity). These studies clearly indicated high FR specificity of each of the folate radiotracers **21**−**24** and negligible unspecific cell binding. Variations with respect to percentage of bound radioactivity among the complexes were statistically not significant.

Biodistribution Studies. Time dependent biodistribution studies with the new radiotracers **21**−**23** have been performed in athymic nude mice, bearing KB cell xenografts. Compound **24** has been recently characterized by our group and was included in these studies for comparison (*17*). Data for these pre−clinical in vivo experiments are summarized in Table 2 (complexes **21**, **22**, and **24**) and Table 3 (complex **23**). Clearance from the blood pool was fast and efficient for all derivatives (≤0.2% ID/g already at 1 h p.i.). Tumor uptake of complexes **21**, **22**, and **24** ranged from 1.3% ID/g (**24**) to 2.4% ID/g (**22**) after 1 h and reached a maximum after 4 h (1.9% ID/g for **21**; 2.7% ID/g for **22**). After 24 h, more than 80% of the maximum radioactivity was retained in the tumors. A significant amount of radioactivity was localized in the kidneys. At 1 h p.i. an average of 17 ± 2% ID/g and at 24 h p.i. an average of 11 ± 4% ID/g were found in the cases of the neutral (**21**, **24**) and anionic (**22**) complexes. In the case of the cationic complex **23**, tumor uptake was only about 50% (0.91 ± 0.14% ID/g, 1 h p.i.) of that observed for the other complexes. At the same time complex **23** revealed also an approximately 50% lower uptake in the kidneys (average 7% ID/g at 1, 4, and 24 h p.i.).

Accumulation of radioactivity in the kidneys was not a surprise, since abundant FR expression in the proximal tubule cells of the kidney is widely described in the literature (*27*−*35*). This specific FR-mediated accumulation of folate radiotracers in the renal tissue is a general feature and potential drawback of radioactive folate derivatives (*10, 13, 36*). The significantly reduced uptake of complex **23** in the tumor and in the kidneys is most likely due to its low specific activity, leading to partial FR saturation with unlabeled folate ligand **19** and not because of its overall cationic charge. The absolute values of the injected dose per gram tissue for compound **23** therefore have to be interpreted with caution.

Biodistributions of all four tested complexes in other non-targeted tissues and organs were virtually identical within the standard deviations. An appreciable fraction of radioactivity was found in the liver at 1 h p.i. (e.g. 2.43 ± 0.80% ID/g for **23**; 6.53 ± 3.57% ID/g for **22**), as well as in the intestines (up to 5.01 ± 1.25% ID/g in case of **22**) and the intestinal contents (e.g. 9.31 ± 5.94% ID/g for **24** and 45 ± 34.37% ID/g for complex **21**). These data evidence a significant contribution of unspecific hepatobiliary excretion of all radiotracers independent of their physicochemical characteristics. However, clearance from these sites was efficient and at 4 h p.i. radioactivity in the liver had reached significantly lower values ranging from 2.37 ± 2.85% ID/g (complex **24**) to 0.74 ± 0.51% ID/g (complex **22**) and in the intestines from 1.58 ± 0.86% ID/g (complex **21**) to 0.71 ± 0.40% ID/g (complex **23**). Radioactivity found in other organs and tissue was generally <1% ID/g. FR-blockade experiments were performed by coadministration of folic acid at a dose of 100 ± 10 μg/mouse 5 min prior to administration of the radiotracers. These experiments showed

Table 1. Cell Binding Studies of the Complexes 21−24

	total cell binding [%]	internalized fraction [%]	+ excess folic acid [%]
complex **21**	40.6 ± 3.7	24.3 ± 0.8	0.06 ± 0.01
complex **22**	53.9 ± 3.9	22.2 ± 0.4	0.04 ± 0.00
complex **23**	49.0 ± 1.9	13.3 ± 0.9	0.17 ± 0.05
complex **24**	52.0 ± 2.4	13.8 ± 2.9	0.04 ± 0.00

an attenuation of radioactivity to background level in FR-positive tumors and the kidneys (Tables 2 and 3). This proved the high efficacy of all our folate derivatives to target FRs in vivo. Distribution in other organs and tissue was not significantly altered under blockade conditions.

The absolute values of the biodistribution experiments display a heterogeneous picture. None of the compounds revealed significantly and constantly superior or different results (assuming that results of **23** are an artifact due to low specific activity). We therefore reevaluated the complexes with respect to their tumor-to-nontumor ratios (tumor-to-kidney, tumor-to-blood, and tumor-to-liver) over time. This also allowed comparisons with other ^{99m}Tc-folates recently described in the literature. The highest tumor-to-kidney ratio was found at 4 h p.i. for the negatively charged compound **22** (0.26 ± 0.06). This result was significantly better than those obtained with complexes **23** and **24** (tumor-to-kidney = 0.13 ± 0.02) and the neutral complex **21** (tumor-to-kidney = 0.09 ± 0.01), featuring a diethoxyethyl spacer entity. The tumor-to-liver ratio determined for complex **22** (4.54 ± 2.06) was slightly superior to that of the other folate radiotracers. Finally, high tumor uptake

[a] Folate receptor blocked by co-injection of folic acid at a dose of 100 ± 10 μg/mouse. [b] Low specific activity due to incomplete separation of radioactive complex **23** and nonradioactive precursor **19** is presumably responsible for low uptake of **23** in FR-positive kidneys and tumors compared to complexes **21**, **22**, and **24**.

and fast blood clearance of complex **22** gave rise also to a more favorable tumor-to-blood ratio (104.0 ± 7.11, 4 h p.i.) compared to those of the other complexes **21** (11.43 ± 8.68, 4 h p.i.) and **24** (58.0 ± 12.2, 4 h p.i.). One has to acknowledge, however,

that these trends in favor of complex **22** were less pronounced or not significant at early (1 h) and later time points (24 h) after administration of the radiotracers.

Green and co-workers published data of a presumably negatively charged DTPA-folate radiolabeled with the $^{99m}Tc(CO)_3$-core (*36*). $^{99m}Tc(CO)_3$-DTPA-folate exhibited better tumor uptake (KB cell xenografts, 3.3 ± 0.2% ID/g, 4 h, p.i.), than our derivatives but the high tumor uptake was accompanied by much higher kidney uptake. $^{99m}Tc(CO)_3$-DTPA-folate also revealed high and prolonged retention of activity in the liver (7.6 ± 0.5% ID/g, 4 h p.i.). On the other hand activity in the intestinal tract was significantly lower. The authors speculate that this might be due to clearance of $^{99m}Tc(CO)_3$-DTPA-folate from the liver back into the blood. Surprisingly such a mechanism seemed ineffective for complexes **21**−**24**. For $^{99m}Tc(CO)_3$-DTPA-folate it was also observed that coadministration of free folic acid was able to mitigate liver uptake (in addition to the tumor and the kidney uptake), which would indicate a specific, FR-mediated uptake in this organ. We observed little or no effect of free folic acid on the liver uptake of complexes **21**−**24**.

The technetium(V)−oxo folate ^{99m}Tc-EC20, which is currently in phase II clinical trials for detection of ovarian or endometrial cancer, displayed tumor-to-nontumor ratios similar to those found for our compounds (e.g. tumor-to-kidney ratios 0.12 ± 0.1; tumor-to-blood 50.6 ± 8.2; tumor-to-liver 4.83 ± 0.29, 4 h p.i.), although the absolute values for % ID/g in different tissues and organs were generally higher (*13*, *37*). Also for ^{99m}Tc-EC20 the radioactivity detected in the intestines and intestinal contents was much lower than in the case of our radiofolates.

CONCLUSION

Three novel, site-specifically modified folate derivatives have been prepared. The radiolabeling with the IsoLink precursor $[^{99m}Tc(CO)_3(OH_2)_3]^+$ was straightforward and efficient, giving rise to neutral and charged complexes in high yields. All ^{99m}Tc-complexes were successfully tested for their ability to target the FR on human KB cancer cells in vitro and in vivo. Comparative in vivo studies demonstrated that modification of the linker or chelating system does not dramatically alter the pharmacokinetic profile of the corresponding organometallic ^{99m}Tc-radiofolate. The present data suggest that overall the new $^{99m}Tc(CO)_3$-folates show competitive tumor-to-nontumor ratios compared with other ^{99m}Tc-labeled folates published in the literature. The significant hepatobiliary clearance and the resulting high fraction of radioactivity in the intestines and intestinal contents seem to be a peculiarity of our radiofolates. This is a potential drawback for clinical application. However, at the moment it is premature to draw final conclusions and further experiments are ongoing in order to assess the full potential of organometallic radiofolates for the detection of FR-positive tumors.

Cyclic and Acyclic Oxorhenium(V)−Peptide Conjugates as New Ligands of the Human Cyclophilin hCyp-18

Cécile Clavaud, Marion Heckenroth, Charlotte Stricane, André Ménez, and Christophe Dugave*

CEA/Saclay, Département d'Ingénierie et d'Etudes des Protéines, Bâtiment 152, 91191 Gif-sur-Yvette, France. Received November 17, 2005; Revised Manuscript Received April 7, 2006

Peptide metalloconstructs display interesting conformations, activities, and resistance to proteolysis. However, introduction of a metal core close to the residues that interact with the protein might strongly affect the binding. We investigated the effects of a coordinated oxorhenium core on the binding of model peptides to cyclophilin hCyp-18, a protein implicated in important biological processes and several diseases. For this purpose, we synthesized a series of linear metalloconstructs bearing an oxorhenium(V) core (ReO^{3+}), as well as a peptide cyclized through oxorhenium(V) coordination. All these peptides contain an Ala-Pro-Xaa-*p*NA moiety (Xaa = Cys derivative) and are anticipated to bind simultaneously to the S1−S1′ and S2′−S3′ subsites of hCyp-18. Therefore, the metal core is coordinated to both the cysteine residue and exogenous or endogenous NS_2 tridentate systems. Cyclization of the peptide through metal coordination did not affect the affinity whereas bimolecular oxorhenium metalloconstructs bind hCyp-18 with a slightly better affinity than the corresponding nonmetalated peptide. Peptide labeling with a $^{99m}TcO^{3+}$ core was also carried out successfully.

INTRODUCTION

Engineered peptide metalloconstructs bearing a technetium core or a rhenium core have important applications in nuclear medicine due to their radiochemical properties (*1*, *2*), stabilized conformations, and resulting enhanced resistance to proteolysis (*3*). Technetium and rhenium both belong to the group VIIB transition metals and share common similar coordination geometries, atom size, and bond lengths. They form stable complexes with a variety of organic groups, in particular with thiolates, thioethers, amines, amides, and carboxylates, all of which may be found in peptides or in synthetic bifunctional chelating agents (BFCAs) grafted onto peptides. In a first strategy called the integrated approach, the peptide backbone plus the side chains coordinate the metal core without any exogenous motif, but metalation often results in dramatic changes in geometry and steric hindrance relative to the nonmetalated peptide and thus greatly alters its biological activity (*4*). Conversely, the peptide can bind the metal core via coordination to a BFCA grafted either onto the N-terminus or onto an amino acid side chain, provided these moieties do not interact with the biological target (*5*). The latter approach has yielded a large number of peptide and protein radiopharmaceuticals (*1*, *2*).

Several reports have described the design, synthesis, and biological characterization of peptide hormones cyclized through rhenium and technetium metal coordination (*6*). In particular, Quinn and co-workers have designed α-melanotropin (α-MSH) peptide analogues that display an enhanced affinity for the α-MSH receptor relative to the linear peptide, due to additive constraints upon metalation (*4*, *7*−*9*). A similar strategy was utilized by Gilon's research team to cyclize a GnRH analogue (*10*). Sharma et al. also reported the metal-mediated cyclization of melanocortin and tuftsin peptides (*11*). Recently, Gilon and co-workers have described the synthesis of a library of metal-cyclized somatostatin analogues (*12*).

We investigated the biochemical activity of short peptides bearing an oxorhenium(V) core coordinated via either an intermolecular (acyclic complexes) or an intramolecular (cyclic complex) NS_2/S chelating agent. These metalloconstructs all contain a minimal tripeptide sequence Ala-Pro-Xaa-*p*NA which specifically binds to cyclophilin hCyp-18, an important peptidyl prolyl isomerase which plays a critical role in protein folding and cell division and communication, and is implicated in a large number of diseases including AIDS, cancer, and neurodegenerative disorders (*13*). Introduction of a ReO^{3+}/$^{99m}TcO^{3+}$ metal core inside short ligands of cyclophilin might yield interesting substrate analogues with stabilized, biologically active conformations. Moreover, incorporation of technetium and rhenium radioisotopes might lead to the development of a new generation of radiopharmaceuticals that target hCyp-18. However, no information regarding the effect of the introduction of a rhenium complex close to the active site of hCyp-18 was available. In this study, we investigated the effect of the oxorhenium core on the binding properties of peptides derived from Suc-Ala-Ala-Pro-Phe-*p*NA **1**, a known model substrate of hCyp-18 which displays a moderate affinity for cyclophilin.

EXPERIMENTAL PROCEDURES

Materials and Methods. All reagents and solvents were purchased from Sigma-Aldrich, Fisher, or Novabiochem and were of the highest purity available. THF was distilled from sodium/benzophenone immediately prior to use. ^{99m}Tc was used as a commercial ^{99}Mo/^{99m}Tc eluate (Schering). Reaction progress and flash chromatography elution (Merck silica gel 40−63 μm) were monitored by analytical thin-layer chromatography (Merck $60F_{254}$). Spots on TLC were visualized using UV light (254 nm), and spots were revealed by ninhydrin or phosphomolybdic acid. RP-HPLC analysis and purification were conducted on a Waters 600 Millennium chromatography system coupled to a Waters diode array detector. Separations were achieved on a Vydac C^{18} column eluted with an isocratic system (100% A) from 0 to 5 min, a linear gradient system (100% A to 100% B) from 5 to 25 min, and then an isocratic system (100% B) at a flow rate of 1 mL·min^{-1} (analytical column 4.5 × 250 mm, 5

μm) or 4 mL·min^{-1} (semipreparative column 10 × 250 mm, 10 μm) (A, 0.1% aqueous solution of trifluoroacetic acid; B, acetonitrile). ^{1}H and ^{13}C NMR spectra were recorded on Bruker AVANCE 250 and 400 NMR spectrometers; δ and J are reported in ppm relative to TMS and Hz, respectively. Electrospray mass spectrometry (ES/MS) was performed on a Quattro II (Micromass, Altricham, U.K.).

(βAla-Ala-Pro-Cys-pNA)$_2$ 2. (Boc-Cys-*p*NA)$_2$, Boc-Pro-OH, Boc-Ala-OH and Boc-βAla-OH were coupled successively by the DCC, HOBt method to give the disulfide peptide (Boc-βAla-Ala-Pro-Cys-*p*NA)$_2$. This peptide was deprotected in 4 N HCl/dioxane and purified by HPLC, to give peptide **2.** HPLC t_r = 18.6 min. ^{1}H NMR (D_2O): δ 8.12 + 7.56 (2d, J = 9.1 Hz, 8H), 4.72 (m, 2H), 4.55 (m, 2H), 4.43 (m, 2H), 3.84−3.63 (2m, 4H), 3.35−3.04 (2m, 8H), 2.66 (m, 4H), 2.27 (m, 2H), 2.04−1.87 (m, 6H), 1.31 (d, 6H). ^{13}C NMR (D_2O): δ 174.9, 174.0, 172.5, 170.9, 144.3, 143.7, 125.7, 121.2, 65.0, 61.2, 54.3, 50.0, 48.4, 39.4, 36.2, 32.3, 18.2, 24.1, 16.0. ES/MS (positive ionization): *m*/*z* 960.4 (M + H$^+$, 100%).

***N-tert*-Butyloxycarbonyl-bis(thioacetoethyl)amine 6.** Diethanolamine (21.1 g, 200 mmol) was treated with di-*tert*-butyldicarbonate (44.1 g, 200 mmol) and DIPEA (71.1 mL, 400 mmol) in methanol (250 mL) overnight at room temperature. After removal of the solvent, the residue was dissolved in ethyl acetate and the organic layer was washed successively with 10% citric acid, saturated sodium bicarbonate, and brine. The organic layer was dried over sodium sulfate, and the solvent was evaporated in vacuo. The crude product was purified by silica gel flash chromatography (eluent: ethyl acetate:hexane 10:90) to give **6** (40.6 g, 99%). ^{1}H NMR ($CDCl_3$): δ 4.27 (bs, 2H), 3.78 (bs, 4H), 3.42 (bs, 2 × 2H), 1.46 (s, 9H). ^{13}C NMR ($CDCl_3$): δ 156.59, 80.50, 61.04, 52.49, 28.58.

Diisopropylazodicarboxylate (24.87 mL, 120 mmol) was added dropwise to a solution of triphenylphosphine (31.79 g, 120 mmol) in dry THF (250 mL) at 0 °C. After formation of the white ylide precipitate, the solution was stirred for 30 min. A solution of *N-tert*-butyloxycarbonyl-diethanolamine (8.21 g, 40 mmol) in 40 mL of dry THF and thioacetic acid (9 mL, 120 mmol) were added successively. The reaction was stirred for 1 h at 0 °C and then overnight at room temperature. After reduction of the volume, the residue was washed and dried as described above. The crude product was purified twice by silica gel flash chromatography (eluent: ethyl acetate:hexane; first purification 10:90, second purification 5:95) to provide the bis-thioacetate **5** (11.1 g, 87%). ^{1}H NMR ($CDCl_3$): δ 3.40−3.35 (t, J = 6.6 Hz, 4H, 3.06−3.00 (bt, J = 7.3 Hz, 4H), 2.34 (s, 3H), 1.47 (s, 9H). ^{13}C NMR ($CDCl_3$): δ 155.2, 80.3, 47.6, 47.4, 30.7, 28.4, 27.9, 27.4. ES/MS (positive ionization): *m*/*z* 322.1 (M + H$^+$). Elemental anal. (%): calcd C (48.57), H (7.21), N (4.36), S (19.95); found C (48.49), H (7.04), N (4.42), S (20.22).

***N-tert*-Butyloxycarbonyl-bis(thioethyl)amine Disulfide 7.** Sodium methanolate (1.39 g, 25.7 mmol) was added to a solution of **6** (4.12 g, 12.8 mmol) in methanol (100 mL). The mixture was stirred over 5 days at room temperature in an open flask. The solvent was removed under reduced pressure, and the crude product was purified by silica gel flash chromatography (eluent: ethyl acetate:hexane 20:80) to provide disulfide **7** (1.96 g, 71%). ^{1}H NMR ($CDCl_3$): δ 3.75−3.68 (bq, J = 5.7 Hz, 4H), 3.02−2.93 (dt, J = 5.7 Hz, J' = 10.1 Hz, 4H), 1.47 (s, 9H). ^{13}C NMR ($CDCl_3$): δ 154.98, 79.94, 51.21, 50.77, 38.10, 28.49. ES/MS (positive ionization): *m*/*z* 236.7 (M + H$^+$). Elemental anal. (%): calcd C (45.93), H (7.28), N (5.95), S (27.25); found C (46.25), H (7.21), N (6.13), S (26.81).

***N-tert*-Butyl-bis(thioethyl)glycinate Disulfide 3a.** Compound **7** (1.96 g, 8.4 mmol) was treated with a 50:50 trifluoroacetic acid:DCM solution for 30 min. Then the solvent was evaporated in vacuo and a solution of *tert*-butyl-bromoacetate (1.9 mL, 12.6 mmol) and DIPEA (2.2 mL, 12.6 mmol) in DCM (60 mL) was added. The mixture was stirred overnight at room temperature. After removal of the solvent in vacuo the crude product was purified by silica gel flash chromatography (eluent: ethyl acetate:hexane 30:70) to provide the disulfide **3a** (1.72 g, 83%). ^{1}H NMR ($CDCl_3$): δ 3.44 (s, 2H), 3.34−3.29 (bt, J = 2.9 Hz, 4H), 2.91−2.87 (bt, J = 4.5 Hz, 4H), 1.47 (s, 9H). ^{13}C NMR ($CDCl_3$): δ170.98, 81.15, 57.24, 55.85, 39.86, 28.24. ES/MS (positive ionization): *m*/*z* 250.0 (M + H$^+$). Elemental anal. (%): calcd C (48.16), H (7.68), N (5.62), S (25.71); found C (48.22), H (7.56), N (5.55), S (25.51).

General Procedure for the Preparation of Compounds 3b and 3c. Bromoacetyl bromide (90 μL, 1 mmol) and DIPEA (190 μL, 1 mmol) were successively added to a solution of *tert*-butylamine or piperidine in DCM (10 mL) to provide the bromoacetamides **8b** and **8c**. The mixture was stirred for 30 min at 0 °C. The solvent was removed under reduced pressure. Compound **7** was treated with a 50:50 trifluoroacetic acid:DCM solution (20 mL) for 30 min. After removal of the solvent in vacuo and chase of toluene on the crude product, the residue was dissolved in methanol (5 mL). Solutions of bromoacetamide and amine resulting from the acidolysis of **7** were mixed together and treated overnight with sodium methanolate (118 mg, 2.1 mmol). After removal of the solvent in vacuo the crude product was purified by silica gel flash chromatography.

***N-tert*-Butyl-bis(thioethyl)glycinamide Disulfide 3b.** *tert*-Butylamine (106 μL, 1.03 mmol) was treated as describe above (eluent: ethyl acetate:hexane 50:50) to provide the disulfide **3b** (59 mg, 54%). ^{1}H NMR ($CDCl_3$): δ 7.35 (s, 1H), 3.36 (s, 2H), 3.31−3.23 (bt, J = 5.4 Hz) + 2.91−2.87 (bt, J = 5.9 Hz) (4H), 1.38 (s, 9H). ^{13}C NMR ($CDCl_3$): δ 169.81, 62.50, 57.48, 51.22, 39.67, 28.96. ES/MS (positive ionization): *m*/*z* 248.6 (M + H$^+$). Elemental anal. (%): calcd C (48.35), H (8.12), N (11.28), S (25.82); found C (48.41), H (8.69), N (10.97), S (25.44).

***N*-Piperidyl-bis(thioethyl)glycinamide Disulfide 3c.** Piperidine (105 μL, 1.03 mmol) was treated as describe above (eluent: ethyl acetate:hexane 50:50) to give disulfide **3c** (78 mg, 29%). ^{1}H NMR ($CDCl_3$): δ 3.57 (s, 2H), 3.57−3.48 + 3.43−3.39 (2bt, 4H), 3.39−3.29 (bt, J = 5.8 Hz) + 2.98−2.90 (bt, J = 5.8 Hz) (4H), 1.61 + 1.23 (2m, 6H). ^{13}C NMR ($CDCl_3$): δ 168.8, 57.2, 55.87, 46.5, 42.9, 39.9, 26.5, 25.8, 24.6. ES/MS (positive ionization): *m*/*z* 260.8 (M + H$^+$). Elemental anal. (%): calcd C (50.73), H (7.74), N (10.76), S (24.63); found C (50.43), H (8.09), N (10.43), S (24.22).

***N*-Bis-(thioethyl)glycine Disulfide Hydrochloride 9.** Compound **3a** (1.72 g, 6.9 mmol) was treated with 50/50 1 N HCl in acetonitrile for 1 h. After evaporation of the solvent in vacuo, toluene was chased twice over the residue. The hydrochloride salt **9**·HCl was quantitatively isolated (1.57 g, 100%). ^{1}H NMR (D_2O): δ 4.30 (s, 2H), 3.97−3.94 (bt, J = 5.6 Hz, 4H), 3.31−3.26 (bt, J = 5.9 Hz, 4H). ^{13}C NMR (D_2O): δ 169.0, 58.9, 34.6. ES/MS (positive ionization): *m*/*z* 192.9 (M +H$^+$). Elemental anal. (%): calcd C (31.37), H (5.26), N (6.10), S (27.91); found C (31.13), H (5.53), N (5.76), S (27.63).

Methyl *N*-ϵ-Bis-(thioethyl)glycyl(*N*-α-*tert*-butyloxycarbonyl)lysinate Disulfide 10. Compound **9** (101.5 mg, 0.4 mmol), HATU (205 mg, 0.6 mmol), and DIPEA (313 μL, 1.6 mmol) were added to a solution of Boc-Lys-OMe (104.1 mg, 0.4 mmol) in anhydrous DMF (14 mL), and the mixture was stirred overnight at room temperature. After removal of the solvent under reduced pressure, the crude product was purified twice by silica gel flash chromatography (eluent: dichloromethane: methanol; first purification: 95:5, second purification: 98:2) to give **10** (149.7 mg, 86%). ^{1}H NMR ($CDCl_3$): δ 7.50 (s, 1H), 5.08 (bd, 1H), 4.28 (m, 1H), 3.74 (s, 3H), 3.38 (s, 2H), 3.32−3.24 (m, 6H), 2.92−2.88 (m, 4H), 1.82−1.50 (3m, 3 × 2H),

1.44 (s, 9H). ^{13}C NMR ($CDCl_3$): δ 173.3, 156.5, 150.5, 79.9, 57.3, 52.3, 39.6, 38.6, 32.3, 29.3, 28.3, 22.7. HRMS (TOF/ES): *m*/*z* calcd for $C_{18}H_{33}N_3O_5S_2$ 435.1920; found 435.1913.

Sodium *N*-ϵ-Bis-(thioethyl)glycyl(*N*-α-*tert*-butyloxycarbonyl)lysinate Disulfide 11. Compound **10** (71.5 mg, 0.16 mmol)-was treated with lithium hydroxide (6.58 mg, 0.16 mmol) in acetonitrile:water 3:1 for 45 min. The solvent was removed to give the lithium salt **11**, which was used in the further step without purification. ES/MS (positive ionization): *m*/*z* 423.05 ($M + H^+$).

(Boc-Lys($COCH_2N(CH_2CH_2S)_2$)-Ala-Pro-Cys-*p*NA)$_2$ 13. Compound **11** was coupled with (Ala-Pro-Cys-*p*NA)$_2$ disulfide by the DCC, HOBt method to give peptide **13** (70 mg, 78%). t_r = 22.2 min. ^{1}H NMR ($CDCl_3$): δ 10.16 (s, 2H), 8.22 + 7.85 (2d, J = 9.1 Hz, 8H), 7.56 + 7.15 (2s, 2 × 2H), 5.22 (s, 2H), 4.71 (m, 2H), 4.11 (m, 4H), 3.65 (m, 4H), 3.46 (m, 8H), 3.26 (m, 8H) 3.11 (m, 4H,), 2.92 (m, 4H), 2.23−1.97 (2m, 2 × 4H), 1.91 (bd, 10H), 1.67 (m, 8H), 1.44 (s, 18H). ^{13}C NMR ($CDCl_3$): δ 157.5, 143.9, 143.7, 125.0, 119.4, 80.1, 61.7, 54.3, 49.2, 34.0, 28.3, 25.6, 24.9. ES/MS (positive ionization): *m*/*z* 356.92 (M − 2Boc + 4H$^+$, 100%).

(Lys($COCH_2N(CH_2CH_2S)_2$)-Ala-Pro-Cys-pNA)$_2$ 14. Compound **13** (70 mg, 0.04 mmol) was treated with 4 N HCl−dioxane (5 mL) for 4 h at 0 °C. After removal of the solvent in vacuo, the residue was dissolved in methanol and purified by HPLC (eluent: A, 0.1% aqueous solution of trifluoroacetic acid; B, acetonitrile; A:B 100:0 from 0 to 5 min, 10 min linear gradient from 100:0 to 70:30, 8 min isocratic 70:30, 12 min linear gradient from 70:30 to 0:100, then 0:100 for 5 min at a flow rate of 4 mL·min^{-1}) to give peptide **14** (13.0 mg, 23%), t_r = 18.6 min. ^{1}H NMR (D_2O): δ 8.24 + 7.62 (2d, J = 7.4 Hz, 8H), 7.56 + 7.15 (2s, 2 × 2H), 4.64 (m, 2H), 4.46 (bt, 2H), 4.11 (m, 2H), 3.83 (s, 6H), 3.68 (m, 4H), 3.57 (s, 8H) 3.32 (m, 4H), 3.07 (m, 12H), 2.30−2.04 (2m, 2 × 4H), 1.4 (m, 8H), 1.8 (bd, 6H). ^{13}C NMR (D_2O): δ 143.9, 143.7, 125.0, 119.4, 83.5, 61.71, 54.3, 49.2, 35.6, 28.3, 25.6, 24.9. HRMS (TOF/ES): *m*/*z* calcd for $C_{58}H_{86}N_{16}O_{14}S_6$ 1422.4988; found 1422.4978.

***β*Ala-Ala-Pro-Cys(Acm)-pNA 15.** Peptide **2** (96 mg, 0.1 mmol) was treated successively with tributylphosphine (38 μL, 2.2 equiv) in wet THF (6 mL) for 40 min. After removal of the solvent in vacuo, the crude product was treated with iodoacetamide (44 mg, 2.2 equiv) and cesium carbonate (72 mg, 0.22 equiv) in DMF (6 mL) overnight at room temperature. Purification by RP-HPLC using the standard gradient program described above gave compound **15** (40.7 mg, 38%); t_r = 15.8 min. ^{1}H NMR (CD_3CN): δ 8.19 + 7.98 (2d, 4H, J = 9.3 Hz), 6.82 (bs, 1H), 6.49 (bs, 1H), 5.94 (bs, 1H), 4.80−4.72 (m, 2H), 4.55−4.50 (m, 1H), 3.76−3.68 (m, 2H), 3.49−3.37 (m, 4H), 2.96 (s, 2H), 2.13−1.74 (2m, 4H), 1.47 (m, 2H), 1.22 (t, 3H). ^{13}C NMR (CD_3CN): δ 172.8, 171.9, 169.0, 144.0, 143.5, 124.8, 119.6, 61.2, 58.5, 53.7, 47.7, 47.6, 36.5, 36.2, 35.2, 33.9, 25.3, 24.9, 17.5. ES/MS (positive ionization): *m*/*z* 538.35 (M + H$^+$, 100%).

General Procedure for Preparation of Complexes 4a−c. Solutions of **2** and **3a−c** in methanol were treated with 10% tributylphosphine in methanol for 30 min under argon before addition of [^{n}Bu$_4$N][ReOCl$_4$] and 10% triethylamine in methanol. A brown precipitate immediately formed. After stirring for 2 h, the crude mixture was centrifuged. The precipitate was washed twice with methanol, dissolved in dimethylsulfoxide, and purified by HPLC.

Complex 4a. HPLC t_r = 21.9 min. ^{1}H NMR (D_2O): δ 8.17 + 7.68 (2d, J = 8.0 Hz, 4H), 4.96 (m, 1H), 4.56 (m, H), 4.48 (m, H), 4.22 (bs, 2H), 3.80−3.59 (m, 6H), 3.18 (m, 4H), 2.94 (m, 4H), 2.70 (m, 2H), 2.28−2.02 (m, 4H), 1.45 (s, 9H), 1.33 (m, 3H). ES/MS (positive ionization): *m*/*z* 930.2 (^{185}Re, M + H$^+$, 53%) + 932.40 (^{187}Re, M + H$^+$, 100%).

Complex 4b. HPLC t_r = 19.5 and 21.0 min. ^{1}H NMR (D_2O): δ 8.23 + 7.68 (2d, J = 7.5 Hz, 4H), 4.80 (m, 1H), 4.64 (m, 1H), 4.48 (m, 1H), 4.22 (s, 2H), 3.68−3.59 (m, 6H), 3.16 (m, 4H), 2.70 (m, 4H), 2.29 (m, 2H), 2.20−2.05 (m, 4H), 1.41 (m, 12H). ES/MS (positive ionization): (first isomer) *m*/*z* = 929.1 (^{185}Re, M + H$^+$, 53%) + 931.00 (M + H$^+$, 100%); (second isomer) *m*/*z* 929.1 (^{185}Re, M + H$^+$, 50%) + 931.00 (M + H$^+$, 100%).

Complex 4c. HPLC t_r = 18.9 and 20.5 min. ^{1}H NMR (D_2O): δ 8.26 + 7.70 (2d, J = 8.9 Hz, 4H), 4.97 (m, 1H), 4.56 (m, H), 4.47 (m, H), 4.39 (s, 2H), 4.11 (m, 2H), 3.76−3.58 (m, 8H), 3.24 (m, 6H), 3.15 (m, 2H), 2.83 + 2.70 (2m, 2 × 1H), 2.02−1.92 (m, 4H), 1.86−1.54 (bs, 6H), 1.38 (m, 3H). ES/MS (positive ionization): (first isomer) *m*/*z* = 941.2 (^{185}Re, M + H$^+$, 52%) + 943.2 (^{187}Re, M + H$^+$, 100%); (second isomer) *m*/*z* 941.2 (^{185}Re, M + H$^+$, 59%) + 943.2 (^{187}Re, M + H$^+$, 100%).

Complex 5. A solution of **14** (4.1 mg, 2.9 μmol) in methanol (115 μL) was treated with a 10% methanolic solution of tributylphosphine (15 μL) for 30 min under argon. Then methanolic solutions of [^{n}Bu$_4$N]ReOCl$_4$ (43 μL, 5.7 μmol) and 10% Et$_3$N (35 μL, 22.8 mol) were added successively. A brown precipitate immediately formed. After stirring for 2 h, the crude mixture was centrifuged. The precipitate was washed twice with methanol, then dissolved in DMSO, and purified by HPLC. t_r = 19.9 min. ^{1}H NMR (d_6-DMSO): δ 10.5 (bs, 1H), 8.23 + 7.87 (2d, J = 7.2 Hz, 4H), 7.82 (s, 1H), 4.63 (m, 1H), 4.55 (bt, 1H), 4.35−4.31 (m, 2H), 3.62 (s, 3H), 3.19 (m, 2H), 3.10−2.99 (m, 4H), 2.89 (m, 2H), 2.10−1.80 (2m, 2 × 2H), 1.56−1.53 (m, 4H), 1.15 (bd, 3H). ESMS (positive ionization): *m*/*z* 913.1 (^{185}Re, M + H$^+$, 52%) + 915.2 (^{187}Re, M + H$^+$, 100%).

Determination of Dissociation Constants (K_d). Fluorimetric determination of K_d values was done using a JASCO FP-750 spectrofluorimeter equipped with a 200 μL thermostated cell. Increasing concentrations of rhenium complexes (dissolved in DMSO) were added to solutions of hCyp-18 (1.1 μM, 180 μL) in HEPES buffer (35 mM, pH 7.8). Fluorescence at 345 nm ($\lambda_{excitation}$ = 285 nm, $\lambda_{emission}$ = 324 nm) was recorded at 20.0 ± 0.1 °C. K_d values were obtained as the fitted points of inflection from the sigmoid log *F*/*C* profiles. A concentration-dependent fluorescence enhancement was observed with CsA whereas a concentration-dependent fluorescence quenching was observed with *p*NA derivatives.

Reaction with Glutathione. A solution of complexes **4a−c** or **5** (500 μL, 50 μM) in a 35 mM HEPES buffer pH 7.4 was treated by an aqueous solution of glutathione (100 μL, 60 mM) at room temperature. For blank, distilled water was used instead of glutathione. All the solutions were purged with argon prior to use. Aliquots of the mixture (30 μL) were analyzed by RP-HPLC after 5, 15, 30, 60, and 120 min.

^{99m}Tc Radiolabeling Experiments. The [^{99m}Tc^{V}O](NS$_2$/S) mixed ligand complexes **16a−c** and **17** were obtained by ligand-exchange reaction using the [^{99m}Tc^{V}O]gluconate precursor which was produced by mixing solutions of stannous chloride (4 μL, 2 mg·mL^{-1}) in HCl 0.1 N, 50 mM gluconate (20 μL), and a [^{99m}Tc]pertechnetate solution (200 μL, 11−30 MBq) eluted from a ^{99}Mo/^{99m}Tc Elumatic III generator, Schering. The resulting [^{99m}Tc^{V}O]gluconate solution was treated for 1 h at 50 °C with disulfides **2**, **3a−c**, or **14** (100 μL of a 20 mM solution) previously reduced as reported above. Aliquots of these solutions were analyzed by RP-HPLC.

RESULTS AND DISCUSSION

Cyclophilin hCyp-18 binds a large variety of proteins and peptides that display a canonical Xaa-Pro sequence, with a marked preference when Xaa is Ala, Gly, and Glu (Figure 1) (*13*−*15*). It also accommodates short pseudopeptide analogues of compound **1** (*16*, *17*) as well as peptides derived from the

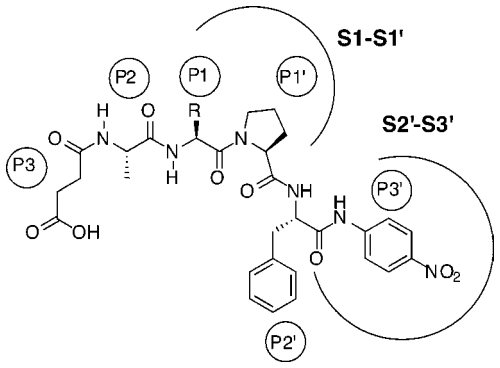

Figure 1. Structure of peptide **1** (R = CH_3) and schematic drawing of hCyp-18 subsites S1−S1′ and S2−S2′.

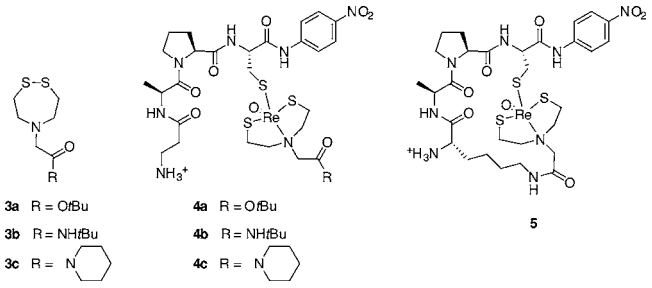
Scheme 1



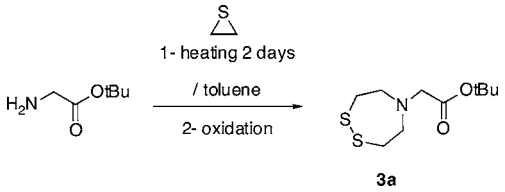
HIV-1 capsid (*18*) and cyclopeptides such as cyclosporine (*13*−*15*). hCyp-18 also binds some non-peptide compounds, in particular the macrolide sanglifehrin (*19*, *20*) and cymbimicins (*21*), as well as small molecules such as dimedone amino acid derivatives (*22*), constrained Gly-Pro mimetics (*23*), and aniline derivatives (*24*−*26*). All these compounds interact simultaneously with the two subsites S1−S1′ and S2′−S3′ and usually enhance the fluorescence of Trp121 which is located at the edge of the S2′−S3′ subsite, though peptide **1** causes a fluorescence quenching due to the presence of the *p*-nitroanilide moiety (*13*, *17*, *18*).

We investigated the potential of acyclic and cyclic metalloconstructs derived from the model tetrapeptide **1** as hCyp-18 ligands. All these peptides contain a Cys-*p*NA moiety which is anticipated to interact with the S2′−S3′ subsite via two H-bonds with Trp121 and Arg 148 (*27*, *28*) and provides the S motif for metal coordination. In cyclic metalloconstructs, the complementary tridentate chelating motif N(CH_2−CH_2−S)$_2$ (noted NS_2) is grafted onto the N-terminal sequence of the peptide (P2 position), which does not play a significant part in the binding (Scheme 1) (*29*, *30*).

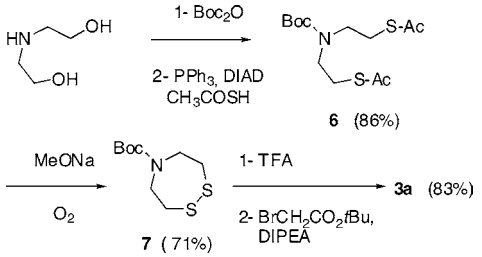
We first checked that coordination of a metal core at P2′ in a linear peptide containing the Ala-Pro sequence did not interfere with the binding of the peptide to hCyp-18. For this purpose, the disulfide tetrapeptide (βAla-Ala-Pro-Cys-*p*NA)$_2$ **2** was readily prepared as a common precursor that could be connected to compounds **3a**−**c** via coordination of an oxorhenium(V) core after reduction of disulfides, in order to provide complexes **4a**−**c**. Compounds **3a**−**c** possess the NS_2 motif which is connected to 3 different substituents in order to check that variation in this position affects neither the coordination of the metal core nor the biochemical properties of the peptides (Scheme 1). We also investigated the ability of the intramolecular complex **5** to bind to hCyp-18. Compound **5**, a cyclic analogue of complexes **4a**−**c**, restricts the positioning of the rhenium core relative to the acyclic rhenium complexes.

Several syntheses of functionalized NS_2 motifs have been reported in the literature, but they necessitated the use of dangerous reagents such as ethylene sulfide (toxic) (*31*, *32*) or liquid ammonia (toxic, hazardous) (*33*). Therefore, these methods were not easily transposable to batch preparation. In particular, the double nucleophilic opening of ethylene sulfide by a variety of amines requires prolonged heating under pressure. Moreover, in our hands, the synthesis of disulfide **3a** starting from ethylene sulfide and glycine *tert*-butyl ester gave very low yields (2−5%). Results seem to depend strongly on the temperature of addition of all reactants and on the presence of polymers. Previous reports have underlined that use of excess ethylene sulfide essentially gives byproducts along with polymers resulting from the opening of ethylene sulfide by the intermediary bis-mercaptan moiety (*34*). Moreover, we found that the reaction product was not usable in further steps due to the existence of nonseparable side products (Scheme 2).

Scheme 2



Scheme 3



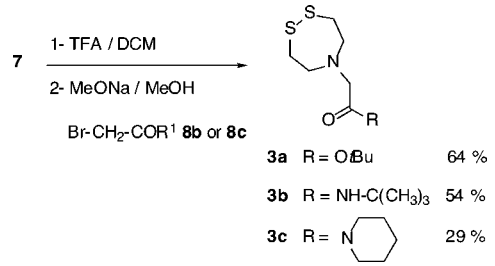
Another approach developed by Chiotellis and co-workers was based on the attractive reductive amination of 2,2′-dithiobis(2-methylpropanal) using sodium cyanoborohydride. However, this synthesis was not compatible with nonsubstituted disulfides (*35*). All these reasons prompted us to develop a simple and reproducible route to prepare large quantities of disulfides **3a**.

Selective N-protection of diethanolamine with di-*tert*-butyl dicarbonate followed by bis-thioacetylation with thioacetic acid, triphenylphosphine, and diisopropylazodicarboxylate (*36*) gave compound **6** in high yield (Scheme 3). In contrast, derivatization of the diol with 2 equiv of methanesulfonyl chloride or triphenylphosphine/carbon tetrabromide, and substitution with a salt (potassium or diisopropylethylammonium) of thioacetic acid, gave compound **6** in poor to moderate yields.

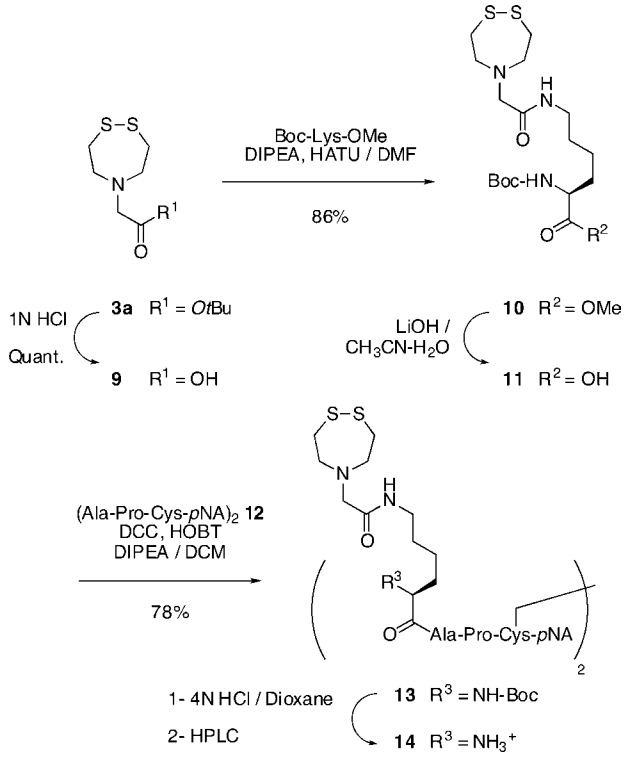
Methanolysis of the bis-thioacetate was carried out for 5 days in an open flask under high dilution conditions (Scheme 3). In fact, removal of the acetyl groups was completed in a few hours but it gave the desired disulfide mixed with the corresponding bis-thiol, which was anticipated to react irreversibly with electrophiles employed in further steps. Under these conditions, precursor **7** was isolated by silica gel flash chromatography in 71% yield. After removal of the Boc group of compound **7** with TFA, N-alkylation with *tert*-butyl bromoacetate in the presence of diisopropylamine (DIPEA) gave compound **3a** in 83% yield. The reaction was carried out reproducibly on the 25−120 mmol scale.

Compounds **3b** and **3c** were obtained as follows: after acidolysis of the Boc group of precursor **6**, treatment with bromoacyl-*tert*-butylamine **8b** and bromoacetyl-piperidine **8c** (obtained respectively by acylation of *tert*-butylamine or piperidine with bromoacetyl bromide) and sodium methanolate gave the corresponding disulfides **3b** and **3c**. Compound **3a** was also obtained by this procedure, but the yield was significantly lower than that obtained with DIPEA (Scheme 4).

Scheme 4



Scheme 5



Compound **3a** was also used to synthesize peptide **14**, the precursor of the cyclic metalloconstruct **5** by the synthetic route depicted in Scheme 5. Unexpectedly, deprotection of the t*ert*-butyl group of **3a** with 50% trifluoroacetic acid in dichloromethane gave a complex mixture of compounds resulting putatively from the reaction of the disulfide with the intermediary *tert*-butyl cation. Therefore, the *tert*-butyl ester was cleaved under very mild conditions (1 N aqueous HCl in acetonitrile) to give compound **9** in quantitative yields (Scheme 5). Coupling to the side chain of Boc-lysine methyl ester with HATU in DMF gave the corresponding adduct **10** in 86% yield. In contrast, coupling with DCC afforded compound **10** in lower yields. Saponification of the methyl ester gave the modified Boc-lysine **11**, which can be used directly in peptide synthesis. Standard coupling of compound **11** with 1/2 equiv of disulfide peptide **12** led to peptide **13** in good yields. Removal of the Boc groups with a 4 N solution of hydrogen chloride in dioxane gave peptide **14**, the oxidized precursor of complex **5**, which was purified by RP-HPLC.

Complexes **4a**−**c** were assembled by reducing peptide **2** on the one hand and compounds **3a**−**c** on the other with tributylphosphine in methanol and then mixing the resulting crude products with tetrabutylammonium tetrachlorooxorhenate(V) to give the corresponding rhenium coordinates **4a**−**c**. After reduction of peptide **14** as reported above, metalation with commercial $[Bu_4N][ReOCl_4]$ (*37*) gave the peptide−oxorhenium complex **5**. All complexes precipitated and were thoroughly washed with

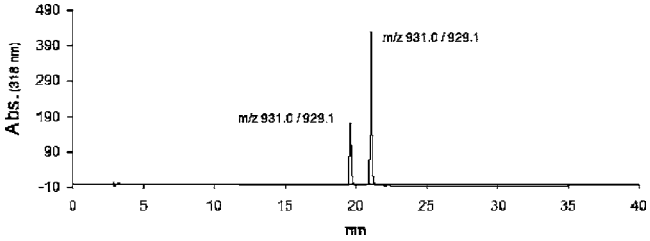


Figure 2. RP-HPLC chromatogram of peptide **2** (A) and complex **4b**: Vydac C^{18} column (5 μm, 4.6 mm, 250 mm) eluted with a binary gradient system (A, 0.1% aqueous solution of trifluoroacetic acid; B, acetonitrile; A:B 100:0 from 0 to 5 min, 25 min linear gradient from 100:0 to 0:100, then 0:100 for 5 min at a flow rate of 1 mL·min^{-1}).

methanol and dried prior to characterization by NMR and mass spectrometry. Analysis by RP-HPLC on a C^{18} column showed that compound **4a** appeared as a single peak whereas **4b** and **4c** were eluted as two peaks that had identical mass spectra, suggesting the existence of at least two diastereomers resulting from either the up or the down Re═O position relative to the peptide moiety, or from a syn/anti isomerism about the coordinated tertiary amine (Figure 2). This was not observed with the cyclic complex **5**, which gave a single but slightly shouldered peak which might correspond either to the coexistence of several diastereomers that do not separate under these conditions, or might result from a slow cis−trans isomerization about the alanyl-proline peptide bond (*38*) as suggested by the 400 MHz NMR spectrum (data not shown). In all cases, crude complexes were free of residual reduced or oxidized forms of peptides **2** or **14** as assessed by RP-HPLC and mass spectrometry analysis (Figure 3). In particular, all products' mass spectra show multipeak motifs that reflect the coexistence of ^{185}Re−^{187}Re and ^{32}S−^{34}S isotopic mixtures. In all cases, the experimental profile was identical to the calculated motif (Figure 3).

The standard fluorescence titration assay (*18*) was employed for the determination of the apparent dissociation constants (K_d) of the ligands as previously reported. Excitation of the indole moiety of Trp121 at 285 nm and recording of fluorescence at 324 nm for increasing concentrations in peptide showed a classical sigmoid curve drawn from the relation % fluorescence = *f*(log[ligand]). We first ensure that Phe to Cys change at P2′ (disulfide **2** and its thioalkylated equivalent **15**) does not perturb the binding of the peptide to hCyp-18. Peptide **15** (βAla-Ala-Pro-Cys(Acm)-*p*NA) was simply prepared by reduction of peptide **2** with tributylphosphine and quenching of the free thiol with iodoacetamide. The experiments showed that increasing the concentration of peptides **2** and **15** produces a fluorescence quenching which is very similar to that observed with the model peptide **1** (Figure 4). This suggests that these compounds interact at the S2′−S3′ subsite to produce an extinction of the Trp121 fluorescence and hence that the Phe to Cys mutation has no significant effect on the affinity. The same curve profile was observed with all oxorhenium complexes (Table 1). This clearly shows that coordination of a rhenium core at P2′ does not affect the affinity of the 4-mer peptide sequences for the protein. As anticipated, the "R" group of complexes **4a**−**c** (see Scheme 1) does not seem to influence the binding to hCyp-18 since it might protrude outside the active site. Complex **5** exhibits an affinity for hCyp-18 that is equivalent to that of peptides **1** and **14**, suggesting that the rhenium core does not perturb the binding, though the cyclic structure of the complex is assumed to maintain the metal core close to the protein structure.

A structural examination of several cyclophilin-ligand complexes, including hCyp-18:**1**, has shown that the side chain of the P2′ residue cannot interact with the protein since it stands out from the protein:ligand complex (*27*). This allows a relatively free positioning of the P2′ side chain, and, therefore, the highly polarized oxorhenium core is not anticipated to

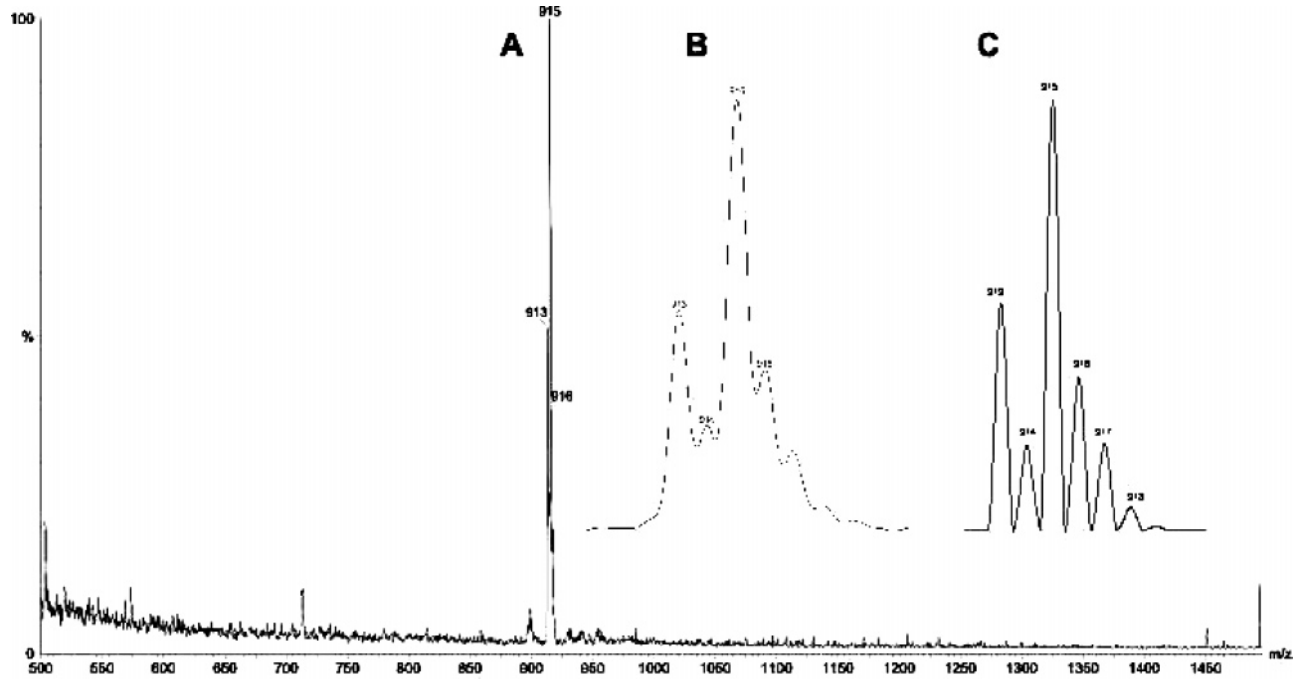

Figure 3. Electrospray mass spectrum of complex **5** (*m*/*z*): Experimental spectrum (A and B); calculated spectrum (C); the existence of several distinct signals of incremented masses relative to the theoretical values may be explained by the presence of rhenium isotopes ^{185}Re and ^{187}Re and sulfur isotopes ^{32}S and ^{34}S.

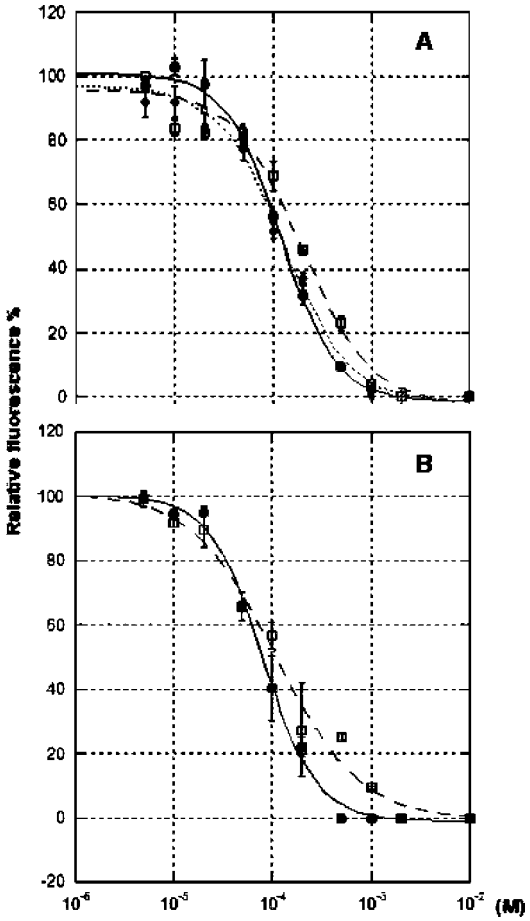

Figure 4. Fluorimetric determination of the apparent dissociation constants (K_d) of peptides **1** (■), **14** (□), and **15** (●) (A) and complexes **4a** (■) and **5** (□) (B).

interact with the protein or therefore to disturb the positioning of the peptide backbone inside the active site. In particular, Arg155 and His126 and Asn102 are located within 6−7 Å of the rhenium atom (*27*) and are not anticipated to interact directly with the metal, although deleterious effects of the oxorhenium dipole on the protein structure cannot be precluded. These results indicate that introduction of a ReO^{3+} core inside peptidic ligands of hCyp-18 does not perturb the interaction.

Table 1. RP-HPLC Retention Times[a]

compound	HPLC t_r (min)	ES/MS (*m*/*z*)[b]	K_d (μM)
1			135 ± 20

[a] Vydac C^{18} column: 10 μM, 4.6 mm, 250 mm. Eluted with an isocratic system (100% A) from 0 to 5 min, a linear gradient system (100% A to 100% B) from 5 to 25 min, and then an isocratic system (100% B) at a flow rate of 1 mL·min^{-1} (A, 0.1% aqueous solution of trifluoroacetic acid; B, acetonitrile). ES/MS *m*/*z* values and apparent affinity constants (K_d) of complexes **4a**−**c** and **5** and peptides **1**, **2**, **14**, and **15**, calculated from fluorescence titration experiments [b] Observed as $M + H^+$. [c] Observed as $M + 4H^+$.

We also investigated the possibility that complexes **4a**−**c** and **5** might interact nonspecifically with hCyp-18. For this purpose we preincubated cyclosporin A (CsA) with hCyp-18 prior to addition of compounds **4a**−**c** and **5**. In fact, CsA, a cyclic undecapeptide, binds simultaneously to S1−S1′ and S2′−S3′ subsites and produces an enhancement of fluorescence (*39*). Therefore, CsA was anticipated to compete with the rhenium complexes. Preincubation with CsA effectively prevented binding of the complexes, and resulted in a concentration-dependent recovery of fluorescence, suggesting that compounds **4a**−**c** and **5** interact with hCyp-18 in a specific way and bind to the S1−S1′ and S2′−S3′ subsites simultaneously since they possess both a proline residue and a *p*NA moiety. We checked that these complexes also showed satisfactory stabilities when incubated with hCyp-18 for 24 h since the peptide adducts were recovered without any detectable degradation as assessed by RP-HPLC.

We investigated the resistance of complexes to thiol-contain-

ing reducing agents by treating the complexes **4a**−**c** and **5** with 1 mM glutathione (GSH) in pH 7.4 buffer. As anticipated, complexes **4a**−**c** are sensitive to GSH which replaces the βAla-Ala-Pro-Cys-*p*NA peptide to give the corresponding glutathione-containing complexes (*40*). Conversely, complex **5** is extremely resistant to glutathione, although up to 20% of the starting material is degraded in the first 5 min whereas 80% of the complex was recovered after 30 min at 20 °C. The presence of bimolecular head-to-tail complexes might account for this result, since complexation was performed with concentrated solutions. However, only one peak was observed by RP-HPLC and no other rhenium-containing species was detected by mass spectrometry. Another explanation might be the existence of multiple non-interconvertible (up/down−syn/anti−cis/trans) isomers which might differ in their resistance to GSH.

Finally, labeling of the peptides was carried out with ^{99m}Tc using standard procedures. Pertechnetate obtained from a ^{99}Mo/^{99m}Tc generator was reduced with stannous chloride at room temperature. The [^{99m}Tc^{V}O]gluconate precursor was complexed by an equimolar amount of peptide **2** and compounds **3a**−**c** previously reduced with tributyl phosphine to give complexes **16a**−**c**. Complex **17** was prepared from peptide **14** by a similar procedure. The metalated peptides **16a**−**c** and **17** were analyzed by RP-HPLC and gave elution profiles similar to those of the corresponding rhenium complexes.

In conclusion, we synthesized a series of bimolecular acyclic complexes **4a**−**c** and a cyclic peptide complex **5** through coordination of the oxorhenium core. The rhenium complexes were assayed as ligands of cyclophilin and display satisfactory stabilities under the conditions employed for the binding assay. Results clearly indicate that all complexes interact with hCyp-18 with an affinity which is equivalent to that of the substrate tetrapeptide **1** and suggest that it is possible to produce novel acyclic and cyclic cyclophilin ligands respectively by assembly or cyclization through metal coordination. The low affinity of these compounds certainly limits their use in vivo, but application of this strategy to more complex peptides such as CsA and SfA analogues might yield interesting radiopharmaceuticals to target cyclophilin.

ACKNOWLEDGMENT

We gratefully acknowledge Dr. L. Le Clainche (CEA/Saclay, DIEP) for help in radiolabeling experiments and Dr. J. Barbier and F. Beau (CEA/Saclay, DIEP) for assistance in the analysis of ^{99m}Tc complexes. We thank Dr. M. Moutiez (CEA/Saclay, DIEP) for purification of the recombinant cyclophilin hCyp-18. We are indebted to Dr. E. Zeckri (CEA/Saclay, DBJC) for NMR experiments at 400 MHz and to Dr. J. Le Gal (CEA/Saclay, DIEP) for critical reading of the manuscript.

Formaldehyde is frequently used to inactivate, stabilize, or immobilize proteins. The treatment results in a large variety of chemical modifications in proteins, such as the formation of methylol groups, Schiff bases, and methylene bridges. The purpose of the present study was to identify the stable formaldehyde-induced modifications in a small protein. Therefore, insulin was treated with excess formaldehyde (CH_2O) or deuterated formaldehyde (CD_2O). In a separate experiment, insulin was modified by formaldehyde (CH_2O vs CD_2O) and glycine. The mixture of CH_2O-treated and CD_2O-treated insulin was digested by the proteinase Glu-C. The peptide fragments obtained were analyzed by liquid chromatography−mass spectrometry (LC-MS). Seven intramolecular cross-links were identified in formaldehyde-treated insulin. Furthermore, eight out of the sixteen potentially reactive sites of the insulin molecule were modified by incubation with formaldehyde and glycine. Both the location and the chemical nature of the modifications could be assigned based on the mass increase of potential adducts as elucidated in our previous study (B. Metz et al. (2004) *J. Biol. Chem. 279*, 6235−6243). To confirm the assigned structures, LC-MS measurements with collision-induced dissociation (LC-MS/MS) were performed on insulin fragments. The results of the LC-MS/MS analyses agreed excellently with the assignments. The study showed that arginine, tyrosine, and lysine residues were very reactive. However, eight theoretically reactive residues did not show detectable modifications, probably because of their low intrinsic reactivity, inaccessibility, or both. The asparagine, glutamine, and histidine residues were not converted in insulin. The N-termini of insulin were partly converted to the expected imidazolidinone adducts, indicating that the protein conformation affects the accessibility and reactivity of these residues. In conclusion, this study shows that, based on our current insights in the chemistry of the reactions between proteins and formaldehyde, we are able to elucidate the location and nature of formaldehyde-induced modifications in a small protein. The approach followed in this study may be generally applicable to larger formaldehyde-treated proteins, such as toxoids used in vaccines.

INTRODUCTION

In the biochemical and pharmaceutical fields, chemical modifications are often introduced in proteins to add useful properties. Chemical treatment is utilized for bioconjugation of biologicals to reduce the immunogenicity (*1*−*3*), for stabilization of biopharmaceuticals to protect against proteolytic activity (*4*−*7*), and for coupling of functional groups to proteins (*8*−*10*). Formaldehyde is one of the well-known chemicals that is frequently applied as a cross-linking agent, for example, for the preparation of vaccines (*11*−*14*), for isotope-labeling of proteins (*15*−*17*), and for studying protein−protein interactions (*18*−*20*). However, the identification of the formaldehyde-modified sites in the primary sequence of proteins is cumbersome because numerous chemical modifications occur in proteins during the treatment with formaldehyde. During the past 60 years, extensive studies have revealed that formaldehyde can modify several amino acid residues (*4*, *21*−*28*). Only a few of these articles describe investigations of formaldehyde-induced modifications in proteins (*25*−*28*), but the nature of each specific modification and the exact location of the modified residues were not identified.

tyrosine	*b*	*b*	87/174
N-terminal amino acid	*b*	12	99

[a] Results from studies with peptides (*29*). [b] No modification observed.

In a recent study with model peptides, we elucidated the structures of formaldehyde-induced modifications and the intrinsic reactivity of each amino acid residue (*29*). The reaction of formaldehyde with a peptide or protein starts with the formation of unstable methylol adducts on amino and thiol groups of arginine, cysteine, histidine, lysine, and tryptophan residues (Table 1). The methylol groups partially dehydrate on lysine and tryptophan residues, yielding labile Schiff bases (Scheme 1). The Schiff base on a lysine residue can form stable cross-links with several amino acid residues, including arginine, asparagine, glutamine, histidine, tryptophan, and tyrosine. Also, our previous study confirmed other studies showing that the N-terminal residues are modified after formaldehyde treatment

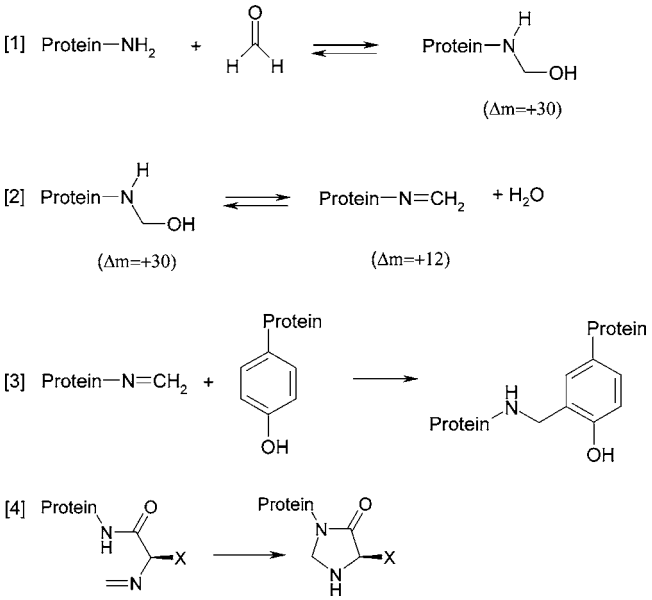
Scheme 1: The Reaction of Formaldehyde with Proteins[a]



[a] The reaction starts with the formation of methylol adducts on amino groups [1]. The methylol adducts of primary amino groups are partially dehydrated, yielding labile Schiff bases [2], which can form cross-links with several amino acid residues, for example, with tyrosine [3]. After addition of formaldehyde, a 4-imidazolidinone adduct can be formed at the N-terminal site of the protein, probably via a Schiff base intermediate [4].

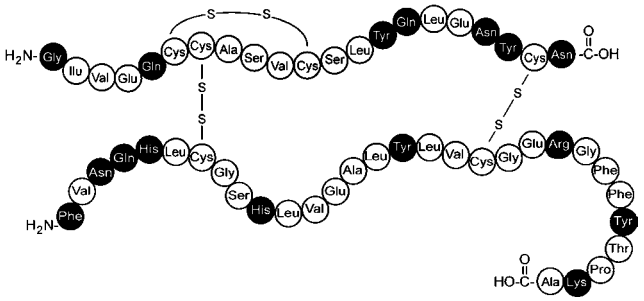


Figure 1. The primary structure of bovine insulin. The A-fragment and B-fragment of insulin are connected to each other via two disulfide bridges. Furthermore, the A-fragment has an intrachain disulfide bridge. In theory, residues given in black are reactive with formaldehyde and glycine.

resulting in an imidazolidinone (*29*−*32*). However, the effect of the protein conformation on the reactivity of amino acid residues cannot be studied in model peptides. In addition, the position and local environment of each intrinsically reactive amino acid in the protein may affect the reactivity.

The aim of the present study was to investigate whether we can elucidate formaldehyde-induced and formaldehyde/glycine-induced modifications in proteins by applying the knowledge obtained from our previous study with model peptides (*29*). For this purpose, bovine insulin was used as a model protein. Insulin is composed of two polypeptide chains: the A-chain consists of 21 amino acid residues, and the B-chain contains 30 amino acid residues; the two chains are interconnected via two disulfide linkages, Cys^{A7}−Cys^{B7} and Cys^{A20}−Cys^{B19} (Figure 1). Moreover, the A-chain contains an intrachain disulfide bridge (Cys^{A6}−Cys^{A11}). The protein can also appear in different quaternary structures, as monomers, dimers, and hexamers (*33*). For example, insulin molecules associate into hexameric complexes in the presence of two zinc ions and at a neutral pH (*34*). In this study, insulin was treated with either native formaldehyde or deuterated formaldehyde (CH_2O vs CD_2O). In a parallel experiment, formaldehyde treatments of insulin were also performed in the presence of glycine. The reaction conditions were largely based on the detoxification process of diphtheria toxin for vaccine production (*11*). After the chemical treatment, mixtures of equimolar amounts of CH_2O-treated and CD_2O-treated insulin were enzymatically digested into small peptides, which were subsequently analyzed by reversed-phase liquid chromatography, electrospray ionization mass spectrometry (LC-MS), and LC-MS measurements with collision-induced dissociation (LC-MS/MS). Using this approach, we were able to unequivocally identify the chemical nature and location of the formaldehyde-induced modifications in the protein.

Table 2. Composition of Reaction Mixtures Used in This Study

mixture	insulin, 0.35 mM (mL)	formaldehyde, 1 M (μL)	glycine, 1 M (μL)	$NaCNBH_3$, 1 M (μL)
1	3.36	320	*a*	*a*
2	3.36	320	320	*a*
3	3.36	320	*a*	320

[a] Not applicable.

MATERIALS AND METHODS

Chemicals. Formaldehyde (37% (w/v) in water with 10% methanol), formic acid (99%), glycine, potassium dihydrogen phosphate ($KH_2PO_4 \cdot 3H_2O$), and dipotassium hydrogen phosphate ($K_2HPO_4 \cdot 3H_2O$) were purchased from Merck (Amsterdam, The Netherlands). Formaldehyde-D_2 (CD_2O) was delivered from C/D/N Isotopes Inc. (Utrecht, The Netherlands). Insulin from bovine pancreas, β-lactoglobulin, DL-dithiotreitol (DTT), and sodium cyanoborohydride ($NaCNBH_3$) were obtained from Sigma (Zwijndrecht, The Netherlands). Endoproteinase Glu-C was bought from Roche Applied Science (Almere, The Netherlands).

Size-Exclusion Chromatography. Size-exclusion chromatography (SEC) was performed to determine the quaternary structure of bovine insulin prior to chemical treatment. The method used was adapted from Ahmad et al. (*35*). SEC was performed on a Waters Alliance 2695 instrument equipped with a Superdex 75 10/300GL column from GE healthcare (exclusion limit 1×10^5 Da) at a flow rate of 0.5 mL/min with detection at 280 nm. Bovine insulin (MW 5.7 kDa) was dissolved in 10 mM potassium phosphate, pH 8.5 (the buffer used for the reactions with formaldehyde), or in 20% acetic acid (in which hexameric insulin dissociates to form monomers (*35*)) to a final concentration of 0.35 mM. In addition, β-lactoglobulin (MW 36 kDa) was used as a marker. Aliquots of 200 μL were loaded on the column, which was equilibrated with 10 mM potassium phosphate, pH 7.2.

Reactions of Insulin with Formaldehyde. Three different reactions with insulin were performed in this study: (i) insulin with formaldehyde, (ii) insulin with formaldehyde and glycine, and (iii) insulin with formaldehyde and $NaCNBH_3$. For each reaction, two identical mixtures were prepared except for the type of formaldehyde: either native formaldehyde (CH_2O) or deuterium-labeled formaldehyde (CD_2O) was used. Prior to the reactions, insulin was dissolved in 10 mM potassium phosphate, pH 8.5, to a final concentration of 0.35 mM, with formaldehyde (CH_2O or CD_2O), glycine, and $NaCNBH_3$ at a concentration of 1.0 M. The compositions of the reaction mixtures are given in Table 2. The final concentration of insulin during the reaction was 0.30 mM, and the final concentrations of formaldehyde, glycine, and $NaCNBH_3$ were 80 mM. After mixing, the solution was incubated for 1 week at 35 °C. Samples were extensively dialyzed against 10 mM potassium phosphate, pH 8.5 (MWCO 1000). After incubation and dialysis, equimolar amounts of CH_2O-treated and CD_2O-treated insulin were mixed. All samples were stored at 4 °C prior to digestion with proteinase Glu-C.

Digestion by Endoproteinase Glu-C. Nontreated insulin and formaldehyde-modified insulin samples were digested by mixing 50 μL of these samples with 5 μL of 1.0 M potassium phosphate buffer, pH 9.0, 1.0 μL of 1 μg/μL endoproteinase Glu-C solution, and 44 μL of water. The mixtures were incubated for 24 h at 37 °C. To reduce disulfide bonds, 1 μL of 1.0 M DTT was added to the digests, and the samples were incubated for 1 h at 37 °C. Subsequently, the samples were stored at −20 °C prior to LC-MS analysis.

Nano-electrospray MS. Insulin was diluted to a concentration of 1 μM in water containing 5% (v/v) DMSO and 5% (v/v) formic acid. Gold-coated nano-electrospray needles (length 600−700 μm; internal diameter 1−2 μm; homemade) were loaded with 10 μL of the sample. The protein solution was analyzed by electrospray ionization mass spectrometry using a Q-TOF Ultima API mass spectrometer (Waters, England). MS scans were obtained from *m*/*z* 350 to 2000 amu. Spectra were deconvoluted using the MaxEnt 1 tool in the MassLynnx MS software (Waters).

LC-MS. Protein digests were analyzed by nanoscale reversed phase liquid chromatography electrospray ionization mass spectrometry (Q-TOF Ultima API), essentially as previously described by Meiring et al. (*36*). Briefly, each digested sample was diluted in water containing 5% (v/v) DMSO and 5% (v/v) formic acid to a concentration, corresponding to 2.5 nM of the original insulin concentration. An injection volume of 10 μL was used for analysis. Analytes were trapped on a trapping column of 15 mm (length) × 100 μm (inner diameter) with Aqua C18 (5 μm; Phenomenex) at a flow rate of 3 μL/min with 100% solvent A (0.1 M acetic acid in water) as eluent for 10 min. Then, analytes were separated by reversed phase chromatography by using a 25 cm L × 50 μm i.d. analytical column with Pepmap (5 μm; Dionex) at a flow rate of 125 nL/min. A linear gradient was started from 5% solvent B (0.1 M acetic acid in acetonitrile) to 60% solvent B in 55 min.

The digested peptides were measured in the MS mode (*m*/*z* 300−2000) to determine the masses of peptides in the mixture. The mass spectrometer was adjusted to following conditions: the electrospray voltage was set to 1.8 kV, the TOF voltage to 9.1 kV, and the MCP voltage to 2.2 kV. Peptides containing formaldehyde modifications typically appeared as mass spectral doublets as a result of the use of native (CH_2O) and deutrated (CD_2O) formaldehyde. The location and the nature of a formaldehyde-induced modification was assigned on the basis of the measured mass, the number of incorporated formaldehyde molecules, and the knowledge of potential formaldehyde adducts, the structures of which were elucidated in our previous study with synthetic model peptides (*29*). From the LC-MS results, a list of masses was compiled of formaldehyde-modified peptides, which were measured in a second run by LC-MS/MS to obtain sequence information and to verify the modified residues. Therefore, the peptides were analyzed by data-dependent scanning comprising a survey MS scan (*m*/*z* 300−2000) followed by collisional activated decomposition (CAD) of the abundant ion in the MS spectra from the compiled list. The collision energy was set between 15 and 25 V.

Accessibility of Amino Acid Residues. The accessibility of each amino acid residue was calculated from the crystal structure of bovine insulin (*37*) using a described method of Fraczkiewicz and Werner (*38*). The accessible surface area of the amino acid residues in monomeric insulin varied from 0% for completely buried residues to 100% for surface residues. Several amino acid residues were not observed as entire structural entities in the crystal structure of bovine insulin (*37*). Therefore, the accessibility of the residues Gln^{A5}, Tyr^{A14}, Gln^{A15}, Asn^{B3}, and Gln^{B4} was taken from corresponding residues in human insulin (*39*). Furthermore, for certain residues, the accessibility in the hexameric form differs from that in the monomeric form (*40*). For these residues, the accessibilities in both forms were considered because of the presence of hexameric insulin.

Table 3. List of Expected and Detected Insulin-Derived Peptides after Digestion of Insulin with Proteinase Glu-C

peptide	fragment	sequence	MH^+ (Da)[a]

6	$B^{22}-B^{30}$	RGFFYTPKA	1086.5 (−0.1)
		Peptides Connected with Disulfide Links	
7	A^5-A^{17} and B^1-B^{13}	QCCASVCSLYQLE FVNQHLCGSHLVE	2924.6 (0.3)
8	$A^{18}-A^{21}$ and $B^{14}-B^{21}$	NYCN ALYLVCGE	1377.6 (0.0)

[a] Eight masses were observed that could be ascribed to peptides from bovine insulin. Deviation from the calculated masses given between brackets. [b] Mass difference of 2 Da most probably due to nonreduced intrachain disulfide bridge ($C^{A6}-C^{A11}$) or reoxidized cysteine residues.

Conversion of Amino Acid Residues. The conversion (Conv) of a particular residue was estimated based on the peak areas of the modified (A_{mod}) and nonmodified peptide (A_{non}) containing that particular residue, according to the equitation $\text{Conv}\ (\%) = 100 \times A_{mod}/(A_{mod} + A_{non})$. For this estimation, it is assumed that the specific response (peak area/mole) is equal for the modified and nonmodified peptide.

RESULTS

Characterization of Untreated Insulin. Bovine insulin was chosen as a small model protein to study the possible reactions of formaldehyde with amino acid side chains of proteins. Prior to formaldehyde treatment, the composition and purity of the insulin were examined by size-exclusion chromatography (SEC) and nano-electrospray MS analysis. The protein, which can appear as monomers, dimers, and hexamers (*33*), was analyzed by SEC, which revealed one single peak with an elution time of 25.7 min (data not shown). The elution was close to that of β-lactoglobulin (ca. 21.7 min; MW of 36 kDa), indicating that the insulin dissolved in potassium phosphate buffer (pH 8.5) is completely assembled into hexamers (MW of 34 kDa). The elution time of monomeric insulin (MW of 5.7 kDa) dissolved in 20% acetic acid was 41 min.

Nano-electrospray MS analysis showed that the major compound had a mass of 5729 Da (arbitrary intensity 100%), close to the theoretical mass of bovine insulin (5730 Da). Insulin was observed as a monomeric compound by MS as a result of the low concentration and the low pH used for ionization (*41*, *42*). Also three other masses of 5659, 5792, and 5855 Da were observed with relative intensities of 9%, 33%, and 7%, respectively. The mass of 5659 Da can be ascribed to insulin lacking the alanine residue at the C-terminus of the insulin, probably as a result of a wrong cleavage of the proinsulin. The other two masses can be explained by the binding of one or two Zn^{2+} ions, each taking the position of two hydrogens ($\Delta m = 65 - 2$ Da).

Insulin was digested into small peptides by using proteinase Glu-C. This protease cleaves proteins at the C-terminal site of glutamate and aspartate residues (*43*, *44*). In theory, complete cleavage of the insulin and reduction of disulfide bridges will result in six nonoverlapping peptides (Table 3, peptides 1−6). All six expected peptides were detected. Peptide 2 was observed with a mass difference of 2 Da with regard to the expected mass, which is most probably due to nonreduced intrachain disulfide

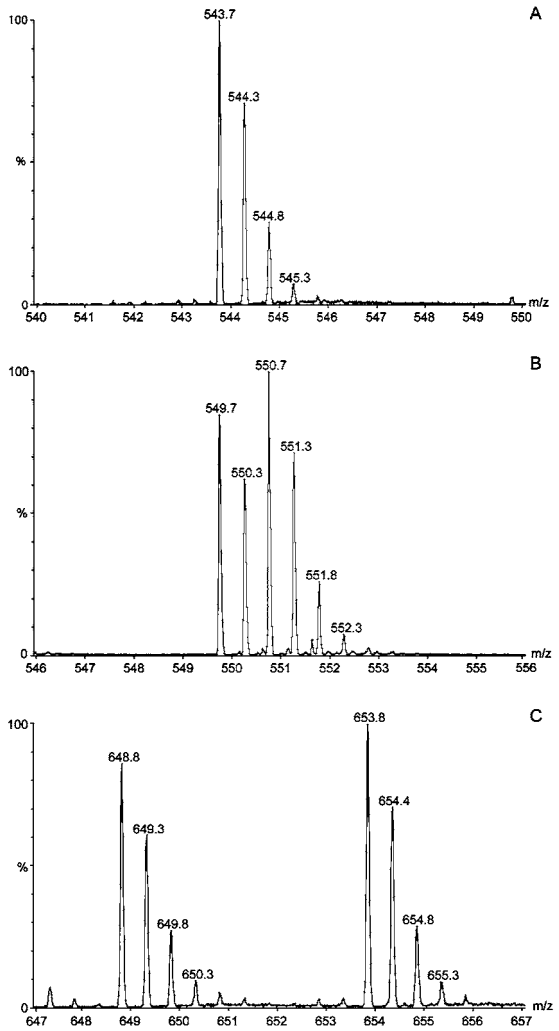

Figure 2. Examples of mass spectra of a native peptide (A), a formaldehyde-modified peptide (B), and a formaldehyde/glycine modified peptide (C). These three peptides were observed as double protonated ions (MH_2^{2+}), corresponding to (A) $MH^+ = 1086.5$ (Table 3, peptide 6), (B) $MH^+ = 1098.5$ (Table 4, peptide 4), and (C) $MH^+ = 1296.4$ (Table 5, peptide 14). From the distance between peptide pairs (B and C), the number of incorporated formaldehyde molecules can be determined. In peptides B and C, one and five formaldehyde molecules were incorporated, respectively.

bridge (Cys^{A6}−Cys^{A11}) or reoxidized cysteine residues. Also due to incomplete reduction, peptide fragments of the A- and B-chains were observed that are connected to each other with disulfide links (Table 3, peptides 7 and 8). Besides the peptides shown in Table 3, four minor peaks were observed with masses that were 16 Da heavier than the theoretical mass. Also a few masses with minor intensities were found that could not directly be related to insulin (not shown). Altogether, the digestion of insulin with proteinase Glu-C resulted in a total number of eight peptides that cover the whole protein. In principle, this permits the complete mapping of formaldehyde/glycine-induced modifications in hexameric insulin.

Formaldehyde-Induced Modifications in Insulin. In two separate samples, the insulin hexamers were treated with either CH_2O or CD_2O. The experiment was aimed to reveal intramolecular cross-links in insulin as a result of the chemical treatment. After the reaction, these two samples were mixed, digested by proteinase Glu-C, and analyzed by LC-MS (details given in Materials and Methods). This approach provided us with a method to discriminate formaldehyde-modified peptides (showing peptide pairs) from unmodified ones (no peptide pairs, see Figure 2A). Peptides containing formaldehyde modifications typically appear as mass spectral doublets because the use of CH_2O or CD_2O results in peptide pairs with mass differences of n(2 Da), where n is the number of formaldehyde residues incorporated in the peptide. Indeed the LC-MS analyses revealed seven of these peptide pairs, which eluted simultaneously from the LC column (Table 4). A representative example of a peptide pair is given in Figure 2B. The mass difference between each peptide pair was 2 or 4 Da. The total mass increment of the modified peptides, as compared to the nonmodified peptides, was 12 or 24 Da for CH_2O-treated peptides and 14 or 28 Da for CD_2O-treated peptides (Table 4). These mass increases correspond to the formation of one and two formaldehyde cross-links in the peptide ($-CH_2-$ or $-CD_2-$). So, the observed doublets could be assigned to peptides with an intrachain cross-link.

In addition, LC-MS/MS measurements were done to reveal the exact location of individual cross-links in these peptides. The MS/MS spectra showed an increased mass of 12 Da for residues Gly^{A1}, Cys^{A7}, Tyr^{A19}, Phe^{B1}, Tyr^{B16}, and Tyr^{B26}. Also a mass increment of 24 Da was observed for the residue Tyr^{B26}. Previous reactions with model peptides demonstrated that primary amino groups and thiol groups react primarily with formaldehyde and form subsequently cross-links with amino acid residues, for example, tyrosine and glutamine residues (*29*). Based on the present LC-MS/MS results and the previous study, we conclude that the intrapeptide cross-links had occurred between the Tyr^{A19} and Cys^{A20} residues, the Tyr^{B16} and Cys^{B19}, the Tyr^{B26} and Lys^{B29} residues (Figure 2) and, probably, the Gln^{A5} and Cys^{A7} residues. The formaldehyde-induced modifications of the N-terminal residues, Gly^{A1} and Phe^{B1}, are consistent with the formation of a 4-imidazolidinone, as has been described in many other studies (*31*, *32*, *45*) (Scheme 1, reaction 4).

Formaldehyde/Glycine-Induced Modifications in Insulin. In a parallel experiment, insulin hexamers were treated with either CH_2O or CD_2O in combination with glycine. In our previous paper (*29*), we showed that nine different amino acid residues in proteins are modifiable by formaldehyde and glycine (Table 1). According to that study, 16 amino acid residues in insulin can be modified (as indicated in Figure 1), provided that they are easily accessible to formaldehyde and glycine. MS analysis of intact formaldehyde-treated insulin resulted in a broad peak, demonstrating the heterogeneous character of the product (results not shown). Subsequently, the digest of modified insulin was analyzed by LC-MS. The measurements showed 21 masses from peptide pairs, each of which represents one or more formaldehyde/glycine-induced modifications (Table 5). The mass difference between the observed peptide pairs was n(2 Da), with n ranging from one to six, corresponding to the number of incorporated formaldehyde residues (CH_2O vs CD_2O). An example of a formaldehyde/glycine-modified peptide pair containing five formaldehyde residues is given in Figure 2C. All masses listed in Table 5 could be traced back as modified peptide fragments from insulin. The assignments were based on the insulin sequence and the earlier described formaldehyde modifications (*29*). Moreover, the number of incorporated formaldehyde molecules corresponded with the prediction. The resulting mass difference with the nonmodified peptides varied between 12 and 372 Da (Table 5).

LC-MS/MS measurements were performed to verify the assigned peptide sequences as listed in Table 5 and to reveal the exact location of individual modifications in the peptides. Two examples of MS/MS spectra are given in Figure 3. From the data presented in Figure 3, it appears that the formaldehyde−glycine attachments are not resistant to fragmentation during MS/MS analysis. Apparently, this fragmentation started with the loss of a part of the formaldehyde−glycine adduct from the peptide backbone, followed by backbone fragmentation.

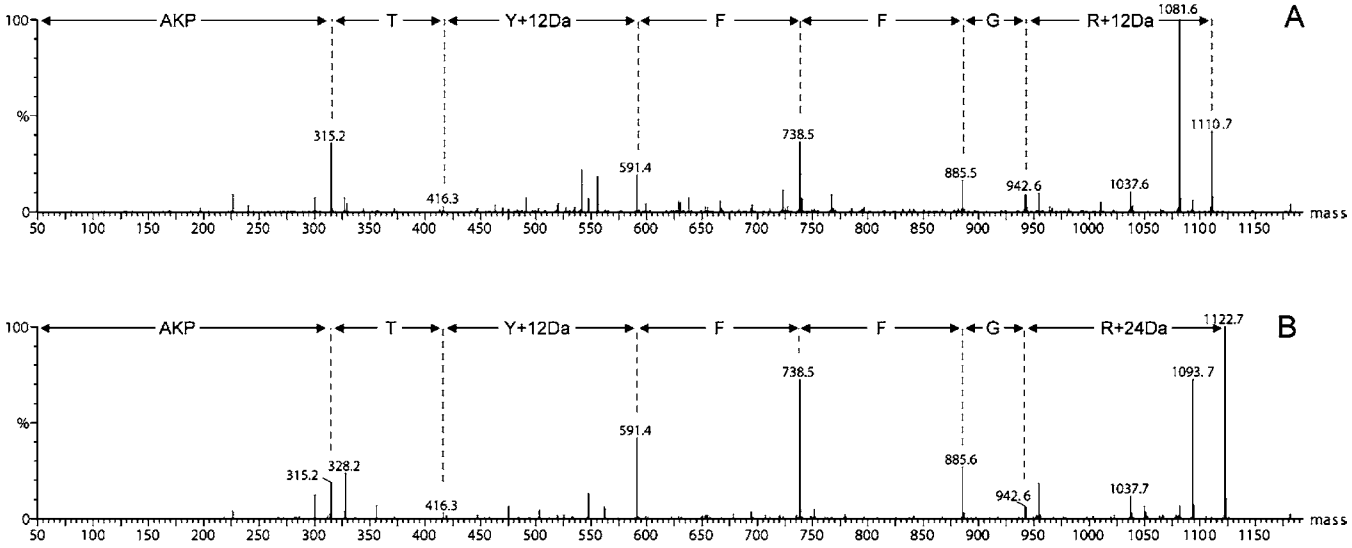

Figure 3. MS/MS analysis of two peptide fragments of insulin containing formaldehyde-induced modifications. Spectrum A is obtained from the peptide (Table 5, peptide 11, $MH^+ = 1272.1$) that contained a formaldehyde−glycine adduct on an arginine (B^{22}) and on a tyrosine (B^{26}) residue and is dominated by a y-ion series. Spectrum B is acquired from the peptide (Table 5, peptide 14, $MH^+ = 1296.4$) with an intramolecular cross-link between a tyrosine (B^{26}) and a lysine (B^{29}) residue and two formaldehyde−glycine adducts on the arginine residue.

Fortunately, a small mass tag of 12 Da was left on the modified residue and enabled the identification of the modified sites. When two formaldehyde−glycine adducts were attached to tyrosine or arginine residues (resulting in mass increments of 174 and 198, respectively), the LC-MS/MS analyses demonstrated a residual mass tag of 24 Da. All peptides were sequenced by MS/MS, and the results corresponded to the assignment based on MS data. Formaldehyde-induced modifications were observed on eight residues: Gly^{A1}, Tyr^{A14}, Tyr^{A19}, Phe^{B1}, Tyr^{B16}, Arg^{B22}, Tyr^{B26}, and Lys^{B29}. However, there was

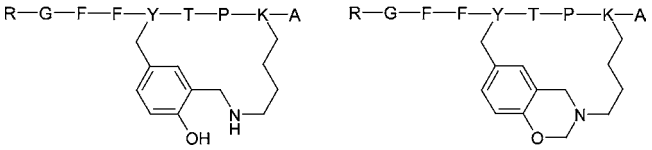

Figure 4. Formaldehyde-induced cross-links in an insulin-derived peptide (Table 4, peptide 4 and 5).

no evidence of modification of eight other residues, Gln^{A4}, Gln^{A15}, Asn^{B3}, Asn^{B3}, Asn^{B3}, Gln^{B4}, His^{B5}, and His^{B10}, although these types of residues have been shown before to be reactive with formaldehyde and glycine (*29*). The same intramolecular cross-links were expected in insulin as those observed after the reaction with formaldehyde alone. Indeed, nine insulin-derived peptides could be ascribed to peptides with an intrachain cross-link and verified by LC-MS/MS (Table 5). In summary, LC-MS/MS analyses could identify the modified amino acid residues in insulin.

Conversion and Accessibility of Formaldehyde/Glycine Modifiable Residues. In the previous section, the identification of formaldehyde/glycine-induced modifications in insulin hexamers was described. However, eight expected modifications in insulin were missing, for example, the formaldehyde−glycine adducts upon asparagine, glutamine, and histidine residues. No or little conversion observed is most probably due to poor intrinsic reactivity (*29*), poor or partial accessibility, or both in the native insulin molecule (*37*−*39*).

In this section, the accessibility and the intrinsic reactivity are compared to the conversion of the formaldehyde reactive residues. The conversion of each modified residue was calculated based on the peak areas of the formaldehyde/glycine-modified peptide and the corresponding nonmodified peptide (Table 6). The intrinsic reactivity values for each modifiable residue were previously assessed (*29*) and are also given in Table 6. Furthermore, the accessibility of each amino acid residue was calculated from the crystal structure of both monomeric and hexameric bovine insulin (*37*) using a described method of Fraczkiewicz and Werner (*38*, *39*) (Table 6).

Consistent with our previous study (*29*), it was shown that arginine and tyrosine residues were very reactive (Table 6). Nevertheless, a large variation in conversion was found between the different tyrosine residues, probably, as a result of accessibility. The most accessible tyrosine residue (Tyr^{A14}) was highly modified by formaldehyde and glycine (97%), whereas a buried residue (Tyr^{A19}) was converted in a much lesser degree (36%). Substantial conversion (59%) was observed for a fully buried tyrosine residue (Tyr^{B26}), but 32% of this conversion was due to the formation of methylene bridges between Lys^{B29} and Tyr^{B26}. A methylene bridge ($-CH_2-$) is smaller than a formaldehyde−glycine adduct, which might explain the relatively high conversion of this tyrosine residue. No modifications of asparagine, glutamine, and histidine residues were observed. The low intrinsic reactivity of these residues together with their poor accessibility (between 13% and 68%) in hexameric insulin are likely key to the absence of conversion.

Only moderate conversion of the N-terminal amino groups (residues Gly^{A1} and Phe^{B1}) into imidazolidinone adducts was observed after either formaldehyde treatment or formaldehyde−glycine treatment (Tables 4 and 6). However, high conversion was expected, because in general imidazolidinone adducts are rapidly formed by the reaction of formaldehyde with N-terminal amino groups (*29*−*32*). Therefore, the reactivity of N-terminal amino groups in insulin for formaldehyde was studied in more detail. Insulin was treated with formaldehyde (CH_2O or CD_2O) and $NaCNBH_3$ to study the accessibility to formaldehyde of the N-terminal residues Gly^{A1} and Phe^{B1}. Full accessibility would be reflected by full conversion of the N-terminal amines to dimethylated amine groups. Indeed, LC-MS analyses revealed masses corresponding to N-terminal insulin fragments of the A-chain and the B-chain with a dimethylated Gly^{A1} or a dimethylated Phe^{B1} residue as confirmed by MS/MS. Moreover, these residues, Gly^{A1} and Phe^{B1}, were completely converted (100%). We can therefore conclude that poor accessibility of the N-termini to formaldehyde was not the reason for the partial imidazolinone formation observed. Instead, the second step in the imidazolidinone formation may be hampered in the A-chain and B-chain of insulin as a result of poor access to the adjacent residues, Ile^{A2} and Val^{B2}, which take part in the reaction with formaldehyde (*20*). Indeed, according to the crystal structure, these amino acids are buried by surrounding residues: the accessibility of Ile^{A2} and Val^{B2} is 1.0% and 0.0%, respectively (*37*, *38*). These results underline the vital influence of protein conformation on the conversion of intrinsically reactive sites.

Table 6. Formaldehyde/Glycine-Reactive Residues in Insulin

residue[a]	position	expected Δm	observed Δm	accessibility[c,e] (%)	intrinsic reactivity[f] (%)	conversion[g] (%)

[a] Possible formaldehyde/glycine-reactive amino acid residues in bovine insulin are listed based on our previous study (*29*). [b] Formaldehyde treatment causes intramolecular cross-links between lysine residues and other amino residues, resulting in a mass increase of 12 or 24 Da (*29*). [c] Accessibility of amino acids in monomeric bovine insulin (see Materials and Methods for further details). [d] The accessibility of these residues was calculated based on the structure of monomeric human insulin (*48*). [e] Values given in parentheses represent the accessibility of the residue in hexameric insulin (*40*). [f] The intrinsic reactivity of each type of amino acid residue was assessed previously, except for the lysine residue (*29*). The table lists the expected conversions after a reaction time of 48 h. [g] The conversion was determined after a reaction time of 1 week (see Materials and Methods for further details). Mean ± SD; $n = 3$. [h] No change. [i] Unknown.

DISCUSSION

This study demonstrates a great diversity of chemical modifications in the model protein insulin caused by the treatment either with formaldehyde or with formaldehyde and glycine. Eight different amino acid residues were modified by the reaction of formaldehyde and glycine. Furthermore, seven distinct intrachain cross-links were identified. The results showed that arginine, tyrosine, and lysine residues were very reactive, whereas a little or no conversion was observed for asparagine, glutamine, and histidine residues, which is consistent with our earlier study with model peptides (*29*). Moreover, the data indicate that the protein conformation can have a serious effect on the reactivity of particular amino acid residues, because formaldehyde and glycine do not or only slightly convert the poorly accessible amino acids that are potentially reactive.

Insulin was used as a model protein to study the reaction of formaldehyde with amino acid residues. The protein was chosen because of its defined structure (*35*, *37*, *39*−*42*). In this study, hexameric insulin was used, which has a moderate size (34 kDa). Complete digestion of native insulin by proteinase Glu-C resulted is a small set of six peptides (Table 3). Nevertheless, after formaldehyde treatment 21 different masses were detected that could be assigned to these peptides containing different modifications (Table 5). As a consequence of the formaldehyde treatment, several modifications formed are distributed on different (monomeric) insulin molecules. This finding underscores the structural heterogeneity of formaldehyde-treated proteins, which will be even more pronounced for proteins larger than monomeric insulin.

In conclusion, we have provided a practical method to reveal the site and chemical nature of each particular formaldehyde-induced modification in proteins. The approach may be useful to study the complex modifications of larger proteins, such as the formaldehyde treatment of bacterial toxins for preparation of vaccines. The detoxification process of the bacterial toxins is of utmost importance for the antigenicity, immunogenicity, and residual toxicity of the resulting toxoid (*11*, *46*, *47*). Detailed knowledge about the chemical modifications in these antigens can help to gain a better insight into the relationship between the structure of the antigens and the safety and efficacy of the corresponding vaccines. Moreover, our strategy used to identify chemical modification sites in proteins may be applicable to many other bioconjugations.

ACKNOWLEDGMENT

We thank Wilma Witkamp, Sytse Piersma, Bert Zomer, and Anne Jan Metz for their contributions to this work. This study was, in part, supported by a grant from the "Platform Alternatieven voor Dierproeven" (the Dutch platform on alternatives to animal experiments), Grant No. 3170.0039.

Receptor-Mediated Hepatic Uptake of M6P−BSA-Conjugated Triplex-Forming Oligonucleotides in Rats†

Zhaoyang Ye,‡ Kun Cheng,‡ Ramareddy V. Guntaka,*,§ and Ram I. Mahato*,‡

Departments of Pharmaceutical and Molecular Sciences, University of Tennessee Health Science Center, Memphis, Tennessee 38163. Received January 13, 2006; Revised Manuscript Received March 23, 2006

Excessive production of extracellular matrix, predominantly type I collagen, results in liver fibrosis. Earlier we synthesized mannose 6-phosphate−bovine serum albumin (M6P−BSA) and conjugated to the type I collagen specific triplex-forming oligonucleotide (TFO) for its enhanced delivery to hepatic stellate cells (HSCs), which is the principal liver fibrogenic cell. In this report, we demonstrate a time-dependent cellular uptake of M6P−BSA−^{33}P-TFO by HSC-T6 cells. Both cellular uptake and nuclear deposition of M6P−BSA−^{33}P-TFO were significantly higher than those of ^{33}P-TFO, leading to enhanced inhibition of type I collagen transcription. Following systemic administration into rats, hepatic accumulation of M6P−BSA−^{33}P-TFO increased from 55% to 68% with the number of M6P per BSA from 14 to 27. Unlike ^{33}P-TFO, there was no significant decrease in the hepatic uptake of $(M6P)_{20}$−BSA−^{33}P-TFO in fibrotic rats. Prior administration of excess M6P−BSA decreased the hepatic uptake of $(M6P)_{20}$−BSA−^{33}P-TFO from 66% to 40% in normal rats, and from 60% to 15% in fibrotic rats, suggesting M6P/insulin-like growth factor II (M6P/IGF II) receptor-mediated endocytosis of M6P−BSA−^{33}P-TFO by HSCs. Almost 82% of the total liver uptake in fibrotic rats was contributed by HSCs. In conclusion, by conjugation with M6P−BSA, the TFO could be potentially used for the treatment of liver fibrosis.

INTRODUCTION

Cirrhosis, the advanced stage of liver fibrosis, is the 12th leading cause of medial mortality in 2002 (*1*). To date, there are no FDA approved antifibrotic drugs (*2*). Fibrosis is characterized by excessive production of extracellular matrix (ECM) components, especially type I and III fibrillar collagens within the perivascular and interstitial space of tissues (*3, 4*). Although multiple liver cell types, including periportal and pericentral fibroblasts, produce collagen and lead to liver fibrosis, hepatic stellate cells (HSCs, also known as lipocytes, Ito cells, and perisinusoidal cells) have attracted the most attention (*5*). HSCs are distributed throughout the hepatic lobule and serve as the principal storage sites for vitamin A. Upon liver injury, infiltrating leukocytes (neutrophils, lymphocytes, and monocytes) along with resident marcrophages (Kupffer cells) release various inflammatory cytokines and growth factors, leading to activation of quiescent HSCs into actively proliferating α-smooth muscle actin (α-SMA) positive myofibroblast-like cells (*2, 6*).

Directly inhibiting the type I collagen synthesis by HSCs is a potential way to prevent liver fibrosis (*7*). Expression of type α1(I) collagen gene is regulated at the transcriptional and posttranscriptional level, producing an increase in the mRNA steady-state levels by 60−70-fold in activated HSCs compared with quiescent HSCs (*8*). Mammalian α1(I) collagen gene promoter contains two contiguous 30 bp polypurine tracts C1 and C2, located at −141 to −170 and −171 to −200 upstream from the transcription start site (*9*). Earlier we developed a triplex-forming oligonucleotide (TFO), which can form a stable triplex with the target gene sequence and inhibit the transcription of rat type α1(I) collagen gene in vitro. Therefore, this TFO molecule is a potential candidate for treating liver fibrosis.

Following systemic administration, oligonucleotides (ODNs) widely distribute throughout the body with higher uptake in the liver and kidney (*10−12*). There are several reports on targeted delivery of ODNs to hepatocytes, Kupffer cells, and liver endothelial cells (*13−15*). We have tested the in vivo distribution of the TFO molecules in normal and fibrotic rats (*16*). Almost 45% of the injected dose was deposited in the liver in normal rats, but only 35% of injected dose in fibrotic rats. The intrahepatic distribution was nonspecific, with Kupffer and endothelial cells contributing 40% of total liver uptake, HSCs contributing 40%, and heptocytes 20%.

HSCs comprise only 5−15% of all the liver cells (*17*). Mannose 6-phosphate/insulin like growth factor II (M6P/IGF II) receptor is expressed on HSCs, and its expression is up-regulated upon activation of these cells due to acute or chronic liver injury (*18, 19*). To maximize TFO delivery to the liver in general and to HSCs in particular, we recently synthesized mannose 6-phosphate−bovine serum albumin (M6P−BSA) and conjugated to type α1(I) collagen gene promoter specific TFO via a disulfide bond (*37*). Following tail vein injection into normal rats, $(M6P)_{20}$−BSA−^{33}P-TFO rapidly cleared from the circulation and accumulated mainly in the liver. TFO concentration residing in the HSCs was shown to be much higher with $(M6P)_{20}$−BSA−^{33}P-TFO than that with ^{33}P-TFO (1093 vs 215 ng/mg cell protein).

In the present study, we determined the cellular and nuclear uptake of $(M6P)_{20}$−BSA−^{33}P-TFO by HSC-T6 cells, which is an immortalized rat hepatic cell line. The effect of M6P−BSA−TFO on type α1(I) collagen gene transcription has also been determined by real time RT-PCR. We then determined the effect of number of M6P in M6P−BSA−TFO on biodistribution and hepatic uptake of M6P−BSA−^{33}P-TFO as well as the intrahepatic distribution after intravenous administration into both

normal and fibrotic rats. Subcellular distribution of M6P−BSA−^{33}P-TFO in nuclei and cytoplasm of the liver cells was also determined at 30 min and 4 h post intravenous injection in rats.

MATERIALS AND METHODS

Materials. Bovine serum albumin (BSA) (fraction V, purity > 98%) was purchased from USB Corporation (Cleveland, OH). *p*-Nitrophenyl-α-D-mannopyranoside (pnpM), phosphorous oxide chloride, palladium (10 wt % on activated carbon), thiophosgene, 0.04% trypan blue, dimethylnitrosamine (DMN), deoxyribonuclease 1 (DNase 1) and Pronase were purchased from Sigma-Aldrich (St. Louis, MO). RNA STAT 60 reagent was purchased from Ambion RNA Diagnositics (Austin, TX). MultiScribe reverse transcriptase reagent was from Applied Biosystems Inc. (Branchburg, NJ). SYBR Green-1 dye universal master mix was from Applied Biosystems Inc. (Foster, CA). [γ-^{33}P]dATP was purchased from MP Biomedicals (Irvine, CA), and T4 polynucleotide kinase was from New England Biolabs (Beverly, MA). Soluene-350 (tissue solubilizer) and Hionic Fluor (scintillation fluid) were purchased from Perkin-Elmer (Boston, MA). Hydrogen peroxide (H_2O_2) was purchased from Fisher Chemical (Fair Lawn, NJ). Heparin was purchased from American Pharmaceutical Partners, Inc. (Los Angeles, CA). Dulbecco's modified Eagle's medium (DMEM), penicillin G (5000 unit/mL), streptomycin sulfate (5000 μg/mL), Trypsin-EDTA, and type IV collagenase were from Invitrogen Life Technologies (Carlsbad, CA). Heat-inactivated fetal bovine serum (FBS) was purchased from Altanta Biologicals (Lawrenceville, GA). Ca^{2+}/Mg^{2+}-free Hanks balanced salt solution and phenol red free Hanks balanced salt solution (Cellgro) were purchased from MediaTech (Washington, DC). Isoflurane was purchased form Baxter Pharmaceutical Products, Inc. (Deerfield, IL). Nycodenz AG was purchased from Greiner Bio-One, Inc. (Longwood, FL). All solvents and other chemicals used in this study were used as available without further treatment.

TFO, which was a 25 mer antiparallel fully phosphothioate ODN (3′-GAG GGG GGA GGA GGG AAA GGA AGG G-5′) targeting α1(I) collagen gene promoter of rats, was synthesized by The Midland Certified Reagent Company, Inc. (Midland, Texas), and the same TFO modified with a sulfhydryl group at the 3′ end (MW: 8684 Da) was synthesized by Invitrogen Life Technologies (Carlsbad, CA).

Synthesis and Characterization of M6P−BSA−TFO. We synthesized M6P−BSA and conjugated it to TFO via a disulfide bond formation as described in our recently published paper (*37*). Briefly, *p*-nitrophenyl-α-D-mannopyranoside (pnpM) (0.3 g, 1 mmol) was phosphorylated at the 6 position by reacting with phosphorous oxide chloride (0.4 mL, 4.4 mmol) in pyridine (0.4 mL, 5 mmol), acetonitrile (1 mL, 19 mmol), and water (0.04 mL, 2.2 mmol) for 1 h on an ice−water bath to give *p*-nitrophenyl-6-phospho-α-D-mannopyranoside (pnpM6P). PnpM6P (0.25 g, 0.66 mmol) was reduced with 100 mg of 10% palladium on activated carbon under H_2 (1 atm) in 20 mL of a 4:1 (v/v) methanol−water mixture for 2 h to give *p*-aminophenyl-6-phospho-α-D-mannopyranoside (papM6P). Thiophosgene (55 μL, 0.73 mmol) in 10 mL of chloroform was added to papM6P (50 mg, 0.14 mmol) in 10 mL of 0.1 M sodium carbonate buffer, pH 8.6, and the mixture was vigorously stirred for 1 h to give *p*-isothiocyanatophenyl-6-phospho-α-D-mannopyranoside (itcM6P). ItcM6P (26−75 mg) in 2.0 mL of 0.1 M sodium carbonate buffer, pH 9, and 0.15 M NaCl was added to 30 mg (0.45 μmol) of BSA in 2.0 mL of the same buffer. The reaction mixture was kept at room temperature for 18 h with stirring and then applied to a PD-10 column. All the intermediate products were verified with ^{1}H NMR and ESI-MS. The conjugates were verified on 8% sodium dodecyl sulfate−polyacryamide gel electrophoresis (SDS−PAGE). To have activated disulfide bonds for conjugation with TFOs, 20 mg of BSA or M6P−BSA was dissolved in 1 mL of 0.1 M sodium borate buffer, pH 8.6 and *N*-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP) (4 mg; 12.8 μmol) in 0.65 mL of ethanol and the mixture was stirred for 20 h at room temperature. The products were purified on a PD-10 column. The sugar content and number of PDP groups coupled to M6P−BSA or BSA were determined as described previously. TFO modified with sulfhydryl group at the 3′ end was first treated with DTT to generate a 3′-thiol functional group and then reacted with 2.5 mg of $(M6P)_{20}$−BSA−PDP in glycine buffer. The product was eluted with PBS on a G75 column (1 × 25 cm). The formation of $(BSA)_{20}$−M6P−TFO conjugate was verified by electrophoresis on a 20% native polyacryamide gel at room temperature. We obtained M6P−BSA−TFO with different numbers of M6P residues (14, 20, or 27) by altering the molar ratio of itcM6P and BSA. There was one TFO molecule conjugated to M6P−BSA based on the chromatography on a G75 column. TFO was labeled by adding γ-^{33}P to the 5′-end using [γ-^{33}P]-ATP and T4 polynucleotide kinase as described (*16*).

Uptake of M6P−BSA−^{33}P-TFO by HSC-T6 Cells. Immortalized rat liver stellate cells (HSC-T6) (kindly provided by Dr. Friedman, SL, Mount Sinai School of Medicine, New York, NY) were seeded in 6-well plates at a density of 3.5 × 10^5 cells/well in 2 mL of DMEM supplemented with 10% FBS, penicillin G (100 units/ml) and streptomycin sulfate (100 μg/mL). After 24 h of incubation, the medium was removed and incubated with 1 mL of DMEM containing ^{33}P-TFO or $(M6P)_{14}$−BSA−^{33}P-TFO, $(M6P)_{20}$−BSA−^{33}P-TFO, and $(M6P)_{27}$−BSA−^{33}P-TFO (3 × 10^4 cpm, 0.4μM) at 37 °C. The cells were harvested at different time points (5, 20, 70, 120, 180, 240, 300, and 330 min) by removing the medium, washing with ice-cold PBS three times, and trypsinization. Cell pellets were digested with Soluene-350 for 4 h at 55 °C and then overnight at room temperature. After neutralization with H_2O_2, Hionic Fluor was added and the radioactivity was counted using a liquid scintillation counter. Total cellular protein was measured by BCA assay. The TFO concentration was expressed in terms of ng of TFO/μg of cell protein.

Polyacrylamide Gel Electrophoresis. To determine the amount of intact TFO taken up by HSC-T6 cells, 3.5 × 10^5 cells/well were incubated with ^{33}P-TFO or $(M6P)_{20}$−BSA−^{33}P-TFO (2 × 10^5 cpm, 0.4 μM) at 37 °C for up to 24 h. Cells were harvested at 0.5, 1, 2, 4, 8, 12, and 24 h. The cell pellet was lysed with 500 μL of 1% SDS lysis buffer (10 mM Tris-HCl, pH 7.4, 150 mM NaCl, and 1% sodium dodecyl sulfate) at 37 °C for 1 h. The lysate was centrifuged at 12000*g* for 10 min, the supernatant was collected and extracted with an equal volume of phenol/chloroform (v/v, 1/1), the extract was centrifuged for 5 min at 12000*g*, and the supernatant was collected in microcentrifuge tubes. TFO was precipitated by adding sodium acetate to 0.3 M and a 3-fold volume of 100% ethanol and keeping at −20 °C overnight. The solution was centrifuged at 12000*g* for 30 min, the supernatant was removed, and the precipitate was air-dried. The TFO pellet was redissolved in 20 μL of distilled water and analyzed by gel electrophoresis using a 20% polyacrylamide gel at 80 V for 2 h. The gel was autoradiographed for 2 days at 4 °C.

Isolation of Nuclei from HSC-T6 Cells. HSC-T6 cells (5 × 10^5 cells/well) were cultured in 6-well plates until 80% confluence. Then, $(M6P)_{20}$−BSA−^{33}P-TFO or ^{33}P-TFO (∼1.0 × 10^5 cpm, 0.4 μM) was added in 1 mL of DMEM media in the absence of FBS. At 4 h incubation at 37 °C, the cells were harvested and the nuclei were isolated from cytoplasm using Nuclei EZ PREP nuclei isolation kit (Sigma, St. Louis, MO) following the supplier's protocol. The purity and number of isolated nuclei was determined under microscopy by trypan blue

assay. Isolated nuclei and cytoplasm fraction were digested with Soluene-350 overnight. Hionic Fluor was added and the radioactivity was determined using a liquid scintillation counter. The percentage of nuclear uptake of the TFO was calculated as % of total cellular uptake.

Inhibition of Transcription in HSC-T6 Cells. HSC-T6 cells (5×10^5 cells/well) were cultured in 6-well plates until 70% confluence in DMEM containing 10% of FBS. The media were replaced with 1 mL of FBS-free DMEM containing TFO at a concentration of 0.5 μM or $(M6P)_{20}$−BSA−TFO at TFO concentrations of 0.2, 0.5, and 1 μM and incubated for 24 h at 37 °C. Cells treated with 1 mL of FBS-free DMEM were used as control. Then an additional 1 mL of DMEM containing 20% of FBS was added, and cells were incubated for another 24 h.

Cells were harvested and total RNA was isolated using RNA STAT 60 reagent. Total RNA (1 μg) was treated with DNase I and then converted to cDNA using MultiScribe reverse transcriptase reagent and random hexamers. One hundred nanograms of the cDNA was amplified by real time PCR using SYBR Green-1 dye universal master mix on ABI Prism 7700 Sequence Detection System. The forward primer specific for type α1(I) collagen mRNA was 5′-TGGTCCCAAAGGTTCTCCTGGT-3′, and the reverse primer 5′-TTAGGTCCAGGGAATCCCAT-CACA-3′. The forward and reverse primers specific for type α1(I) collagen primary mRNA were 5′-CCAGCCGCAAA-GAGTCTACATGTC-3′ and 5′-TCACCTTCTCATCCCTC-CTAA-3′, respectively. The PCR product is 234 bp. Primers (forward, 5′-GTCTGTGATGCCCTTAGATG-3′, and reverse, 5′-AGCTTATGACCCGCACTTAC-3′) specific for 18S ribosomal RNA were used as internal control for real time PCR. To confirm PCR specificity, the PCR products were subjected to a melting-curve analysis and agarose gel electrophoresis. Relative transcript levels were normalized to 18SrRNA genes. For comparison, transcript levels of control cells were set as 1 and experimental data are shown as fold decrease of control.

Induction of Liver Fibrosis. Dimethylnitrosamine (DMN) induced liver fibrosis in rats has been shown to have a pathology closely resembling that of human cirrhosis (*20*). Male Sprague−Dawley rats weighing 120−140 g (Harlan Co., San Diego, CA) were housed individually under controlled light (12/12 h) and temperature conditions and had free access to food and water. To induce liver fibrosis, DMN was injected intraperitoneally into rats at a dose of 10 mg/kg of body weight. Injections were given on the first three consecutive days of each week over a 4-week period. After the DMN injection for 4 weeks, 3 rats were killed for examination for liver fibrosis development and measurement of hydroxyproline content (*21*).

Biodistribution of M6P−BSA−^{33}P-TFO. The protocol of animal use and care was approved by the Comparative Department of the University of Tennessee Health Science Center. Male Sprague−Dawley rats weighing 150−170 g were anesthetized by inhalation of isoflurane, and then 250 μL of ^{33}P-TFO or $(M6P)_{20}$−BSA−^{33}P-TFO in saline (~2.2×10^5 cpm) was injected intravenously into rats at a dose of 0.2 mg of TFO/kg of body weight. After 30 min postinjection, blood (0.2−0.3 mL) was collected by cardiac puncture in heparinized tubes, and urine was also collected directly from the urinary bladder using a 26-gauge needle syringe. Major organs, such as liver, spleen, kidney, lung, heart, and muscle, were isolated, washed with saline, blotted dry, weighed, and stored at −86 °C. Blood was centrifuged, and plasma was separated. One hundred fifty microliters of plasma or 150−200 g of each tissue was incubated with 2 mL of solubilizer Soluene-350 for 3 h at 55 °C first and then overnight at room temperature. Two hundred microliters of 30% H_2O_2 was added to each sample, and each sample was incubated for another 30 min. Ten milliliters of Hionic Fluor scintillation fluid was added to each tissue, plasma, and urine sample, and the radioactivity of each sample was measured using a scintillation counter.

Competition in Hepatic Uptake of M6P−BSA−^{33}P-TFO. One minute before the injection of M6P−BSA−^{33}P-TFO at a dose of 0.2 mg/kg (specific activity: 1×10^6 cpm/mL), rats received 10 mg/kg of M6P−BSA. At 30 min postinjection, blood and urine were collected; other major organs were harvested as described above for radioactivity measurement.

Hepatic Cellular and Subcellular Distribution. To determine the effect of M6P on the hepatic uptake of TFOs by parenchymal cells (hepatocytes) and nonparenchymal cells (Kupffer, endothelial, and Stellate cells), the liver was perfused in situ after intravenous administration of ^{33}P-TFO or $(M6P)_{20}$−BSA−^{33}P-TFO (2×10^5 cpm) at a dose of 0.2 mg of TFO/kg of body weight as described before (*37*). Briefly, at 30 min postadministration, rats were anesthetized, 100 units of heparin was injected, the abdomen was opened, and the portal vein was cannulated with a PE-60 polyethylene tube. The liver was then perfused with 200 mL of Ca^{2+}/Mg^{2+}-free Hanks balanced salt solution and then with Hanks balanced salt solution containing 0.05% type IV collagenase and 0.1% Pronase for an additional 250 mL. All the perfusion solutions were incubated at 37 °C. After perfusion, different liver cell types were separated and radioactivity was measured as described before (*16*). The contributions of various cell types to the total liver uptake were calculated as % of total hepatic uptake.

To isolate nuclei from the whole liver cells, the livers were collected at 30 min or 4 h postinjection of ^{33}P-TFO or $(M6P)_{20}$−BSA−^{33}P-TFO (4×10^5 cpm) at a dose of 0.2 mg of TFO/kg of body weight, washed, and blotted dry. One gram of fresh liver tissue was used for isolation of nuclei using Nuclei PURE Prep nuclei isolation kit according to the supplier's protocol (Sigma-Aldrich, St Louis, MO). The purity and number of isolated nuclei were determined under microscopy by dilution in trypan blue solution. The yield of nuclei was calculated to be 40−50% by comparing the number of isolated nuclei to the starting cell number. Isolated nuclei were digested with Soluene-350 overnight. Hionic Fluor was added, and the radioactivity was determined using a liquid scintillation counter. The percentage of nuclear uptake of the TFO in the liver was calculated as % of total hepatic uptake.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD). $P < 0.05$ was considered statistically significant. Statistics were calculated based on unpaired Student's *t* test using SPSS 13.0 for windows software.

RESULTS

To enhance the cellular uptake and nuclear translocation of the TFO, we conjugated M6P−BSA to the 3′ end of the TFO via a disulfide bond. M6P−BSA−TFO was then characterized in terms of in vitro cellular and nuclear uptake and transcription inhibition of type α1(I) collagen gene in HSC-T6 cells. This was followed by biodistribution at whole body, organ (liver), and hepatic cellular and subcellular levels after intravenous injection into normal and fibrotic rats.

In Vitro Cellular and Nuclear Uptake of M6P−BSA−TFO. We have previously shown that M6P−BSA−TFO could enhance the TFO accumulation in the liver and thus concentrated TFO molecules inside HSCs compared to free TFO molecules (*37*). However, we still need to determine whether this enhanced TFO deposition is contributed to by an increase in M6P−BSA−TFO uptake by the HSCs via the M6P/IGF II receptor-mediated endocytosis. We first incubated HSC-T6 cells with ^{33}P-TFO or M6P−BSA−^{33}P-TFO for different time periods. As shown in Figure 1a, a larger amount of TFO was taken up by these cells when treated with M6P−BSA−^{33}P-TFO compared to that of ^{33}P-TFO treated cells. The TFO amount was around 1 ng/μg of

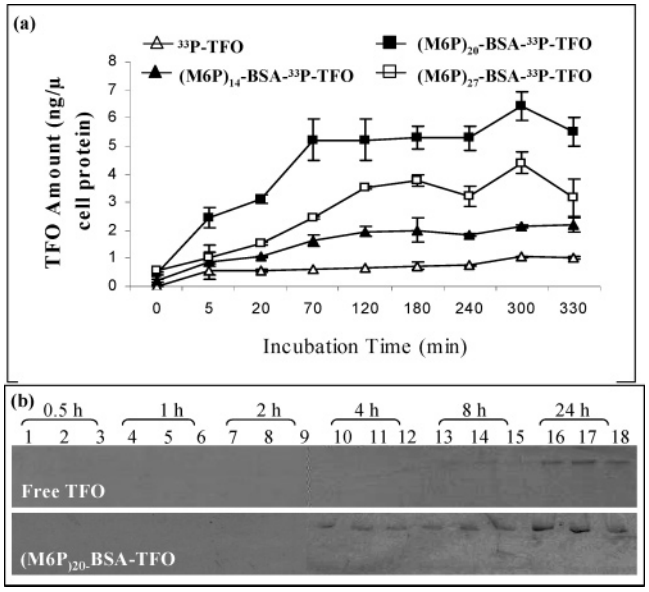

Figure 1. Cellular uptake of M6P−BSA−TFO by HSC-T6 cells. (a) Time profile of the cellular uptake of M6P−BSA−^{33}P-TFO and ^{33}P-TFO by HSC-T6 cells. HSC-T6 cells were incubated with ^{33}P-TFO or M6P−BSA−^{33}P-TFO (3×10^4 cpm, 0.4 μM) at 37 °C, and then cells were harvested at the indicated time for measurement of associated radioactivity. TFO concentration was expressed in terms of ng of TFO/μg of cell protein. Values are mean ± SD of 3 independent experiments. (b) Polyacrylamide gel electrophoresis (PAGE) of the TFO extracted from HSC-T6 cells. HSC-T6 cells were incubated with ^{33}P-TFO or (M6P)$_{20}$−BSA−^{33}P-TFO at 37 °C for up to 24 h. Cells were harvested at the indicated time and lysed with 1% SDS lysis buffer. TFO was extracted and analyzed by gel electrophoresis using a 20% polyacrylamide gel. Each time point was presented with 3 independent experiments.

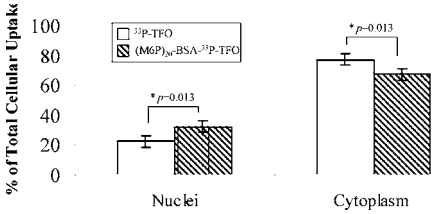

Figure 2. Subcellular distribution of (M6P)$_{20}$−BSA−^{33}P-TFO and ^{33}P-TFO in HSC-T6 cells at 4 h postincubation at 37 °C. Cells were harvested and the nuclei were isolated from the cytoplasm using Nuclei EZ PREP nuclei isolation kit (Sigma, St Louis, MO). The subcellular distribution was expressed as % of total cellular uptake, and values are mean ± SD of 3 independent experiments. Asterisk: statistically significant.

cell protein for unconjugated TFO. Conjugates with different numbers (x) of M6P residues (x = 14, 20, and 27) showed different cellular uptake, with 2, 5, and 3 ng of TFO/μg of cell protein, respectively. The optimal number of M6P for M6P−BSA−TFO is 20. The enhanced cellular uptake of the conjugates was also confirmed by polyacrylamide gel electrophoresis (Figure 1b). Bands clearly appeared at 4 h postincubation with (M6P)$_{20}$−BSA−^{33}P-TFO; however, the control TFO appeared only after 24 h of treatment. Moreover, the cellular uptake of M6P−BSA−^{33}P-TFO was time dependent (Figure 1a,b).

Since the TFO molecules have to function inside the nucleus of the hepatic stellate cells by forming a triplex with the target genomic DNA sequence (*22*), we also determined the nuclear translocation of M6P−BSA−^{33}P-TFO. As shown in Figure 2, relatively more TFO translocated into the nucleus (~32% of total cellular uptake) in the case of (M6P)$_{20}$−BSA−^{33}P-TFO compared to nonconjugated TFO molecules (~23% of total cellular uptake), possibly due to the efficient cellular uptake of M6P−BSA−^{33}P-TFO by HSC-T6 cells.

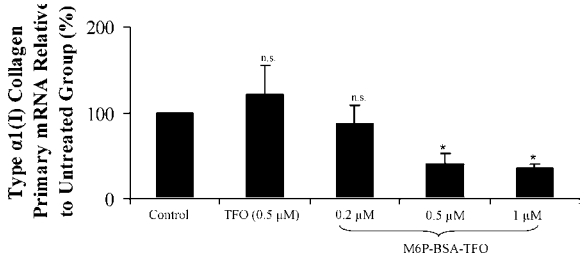

Figure 3. Relative type α1(I) collagen gene transcription in HSC-T6 cells treated with TFO or (M6P)$_{20}$−BSA−TFO by real time RT-PCR assay. HSC-T6 cells were treated with unconjugated TFO (0.5 μM) or (M6P)$_{20}$−BSA−TFO at the indicated concentrations in 1 mL of FBS-free DMEM for 24 h, and then 1 mL of DMEM containing 20% of FBS was added and incubated for another 24 h. Relative transcript levels were normalized using 18S rRNA as a housekeeping gene. Control means no treatment. Values are mean ± SD of 3 independent experiments. Asterisk: statistically significant compared to control group. n.s.: not significant.

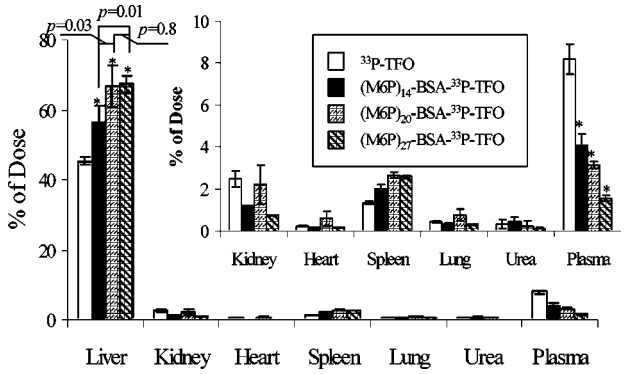

Figure 4. Effect of number of M6P per BSA on biodistribution of M6P−^{33}P−BSA−TFO in normal rats. At 30 min postinjection of M6P−BSA−^{33}P-TFO (~2.2×10^5 cpm) at a dose of 0.2 mg/kg, blood was collected by cardiac puncture and urine from the urinary bladder. Rats were sacrificed; major organs were isolated, washed with saline, blotted dry, and subjected to scintillation counting. Values are mean ± SD of 4 rats in each group. Asterisk: statistically significant comparing to naked TFO group.

Inhibition of Type α1(I) Collagen Gene Transcription. Higher cellular uptake of M6P−BSA−TFO was expected to have higher efficiency in inhibiting the transcription of type α1(I) collagen gene. We used real time RT-PCR to quantify the primary mRNA levels. It was found that at the concentration of 0.5 μM, free TFO molecules had no clear effect on the transcription inhibition. In contrast, for (M6P)$_{20}$−BSA−TFO, we observed dose-dependent transcription inhibition. Transcription product was decreased to 87% of control group at 0.2 μM, 40% at 0.5 μM, and 35% at 1 μM (Figure 3).

Effect of Number of M6P on Biodistribution of M6P−BSA−^{33}P-TFO. Since M6P is a ligand for the M6P/IGF II receptor expressed on the surface of the HSCs, the degree of M6P substitution per BSA molecule is likely to have a significant effect on the hepatic uptake and biodistribution of M6P−BSA−^{33}P-TFO. Therefore, we determined the effect of the number of M6P per BSA on the biodistribution of M6P−BSA−^{33}P-TFO. As shown in Figure 4, there was a significant increase in the amount of radioactivity in the liver compared to free TFO and as the number of M6P per BSA increased from 14 to 27, the hepatic uptake was 56.3%, 66.6%, and 67.4% for (M6P)$_{14}$−BSA−^{33}P-TFO, (M6P)$_{20}$−BSA−^{33}P-TFO, and (M6P)$_{27}$−BSA−^{33}P-TFO, respectively. However, no statistical difference was found between the (M6P)$_{20}$-^{33}P-TFO and (M6P)$_{27}$-^{33}P-TFO injected groups for the hepatic uptake (66.6% vs 67.4% of the injected dose). The amount of radioactivity in the spleen also increased (2.0%, 2.7%, and 2.6%, respectively) with increase in the number of M6P per BSA. In contrast, there was

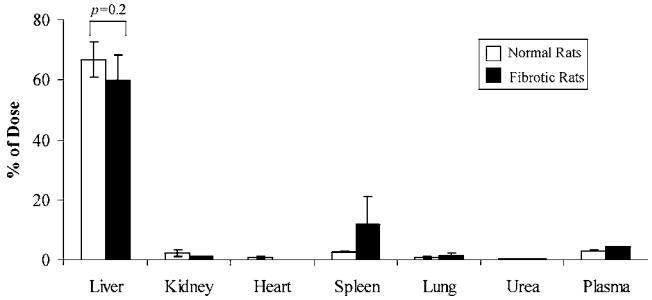

Figure 5. Effect of fibrosis on hepatic uptake of $(M6P)_{20}$−BSA−^{33}P-TFO after systemic administration into DMN-induced fibrotic rats. At 30 min postinjection of $(M6P)_{20}$−BSA−^{33}P-TFO (~2.2×10^5 cpm) at a dose of 0.2 mg/kg, blood was collected by cardiac puncture and urine from the urinary bladder. Rats were sacrificed; major organs were isolated, washed with saline, blotted dry, and subjected to scintillation counting. Values are mean ± SD of 4 rats in each group.

a significant decrease in the plasma concentration compared to free TFO, and with increase in the number of M6P per BSA, the dose in the plasma was 4.1%, 3.1%, and 1.6%, respectively. The accumulation of different M6P−BSA−TFO in heart and lung was trivial. Since there was no significant difference in the hepatic uptake of $(M6P)_{20}$−BSA−^{33}P-TFO and $(M6P)_{27}$−BSA−^{33}P-TFO (Figure 4), we selected $(M6P)_{20}$−BSA−^{33}P-TFO for further studies.

Effect of Fibrosis on Biodistribution of M6P−BSA−^{33}P-TFO. In the liver fibrosis process, activation of HSCs leads to accumulation of scar (fibril-forming) matrix, which in turn contributes to the loss of hepatocyte microvilli and sinusoidal fenestrae (*2*). These microstructural changes in the liver may prevent efficient drug delivery to HSCs.

We recently demonstrated that ^{33}P-TFO accumulation in the liver decreased from 43% in normal rats to 33% in fibrotic rats at 30 min postinjection (*16*). Therefore, we determined the biodistribution of $(M6P)_{20}$−BSA−^{33}P-TFO in DMN-induced liver fibrotic rats. As shown in Figure 5, there was no significant decrease in the hepatic uptake of $(M6P)_{20}$−BSA−^{33}P-TFO, which showed higher accumulation in both normal and fibrotic rats.

Competition in Hepatic Uptake of M6P−BSA−TFO. The role of M6P/IGF II receptor on biodistribution of M6P−BSA−^{33}P-TFO in normal and fibrotic rats was assessed by determining the effect of excess M6P−BSA on the accumulation of M6P−BSA−TFO in the liver. By administration of excess M6P−BSA, the M6P/IGF II receptor can be saturated. Prior administration of M6P−BSA caused a significant decrease in the hepatic uptake of M6P−BSA−^{33}P-TFO at 30 min postinjection, suggesting the involvement of M6P/IGF II receptor in their hepatic uptake. The hepatic uptake of $(M6P)_{20}$−BSA−^{33}P-TFO decreased from 66.6% to 41.0% in the case of normal rats (Figure 6a), but from 59.7% to 14.3% in the case of fibrotic rats (Figure 6b). When we used BSA−TFO as a control, TFO accumulation in the liver was also significantly increased. However, there was only minimal decrease in its liver accumulation due to the prior injection of excess M6P−BSA (10 mg/kg), suggesting that its hepatic uptake is not mediated by M6P/IGF II receptor-mediated endocytosis (data not shown).

Hepatic Cellular and Subcellular Localization of M6P−BSA−TFO. Upregulation of M6P/IGF II receptors during fibrosis should increase M6P−BSA−TFO uptake by the HSCs and cancel out any adverse effect created by decreased sinusoidal gap. Therefore, the intrahepatic cellular localization of M6P−BSA−TFO was compared between normal and fibrotic rats, since HSCs are quiescent in normal rats, but get activated in fibrotic rats. The liver was perfused at 30 min post tail vein injection of $(M6P)_{20}$−BSA−^{33}P-TFO and ^{33}P-TFO as described before (*16*). Hepatocytes, Kupffer and endothelial cells, and

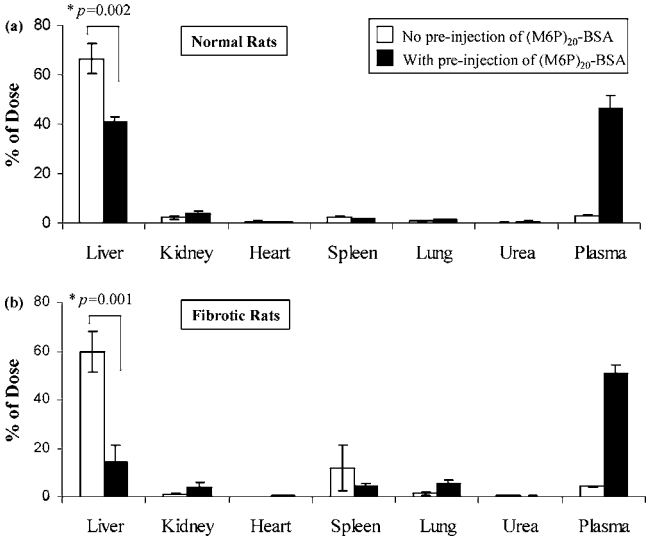

Figure 6. Inhibition of M6P−BSA on biodistribution of $(M6P)_{20}$−BSA−^{33}P-TFO in normal rats (a) and in fibrotic rats (b). $(M6P)_{20}$−BSA (10 mg/kg) was injected intravenously into rats 5 min before the injection of $(M6P)_{20}$−BSA−^{33}P-TFO in normal and fibrotic rats at a dose of 0.2 mg/kg. At 30 min postinjection, rats were sacrificed; major organs were isolated, washed with saline, blotted dry, and subjected to scintillation counting. Values are mean ± SD of 4 rats in each group. Asterisk: statistically significant.

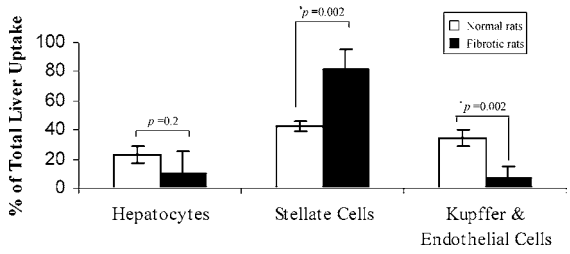

Figure 7. Intrahepatic distribution of $(M6P)_{20}$−BSA−^{33}P-TFO in normal and fibrotic rats. The liver was perfused in situ by collagenase/Pronase digestion after intravenous administration of ^{33}P-TFO or $(M6P)_{20}$−BSA−^{33}P-TFO at the dose of 0.2 mg of TFO/kg of body weight. Hepatocytes, Kupffer and endothelial cells, and stellate cells were separated, and the associated radioactivity was measured. The contribution of each cell type was expressed as % of total liver uptake. Values are mean ± SD of 5 rats in each group. Asterisk: statistically significant.

HSCs were isolated, and the amount of radioactivity in these cells was determined. Figure 7 shows the percentages of contribution by different cell types in terms of total liver uptake of $(M6P)_{20}$−BSA−^{33}P-TFO after systemic administration in normal and fibrotic rats. In normal rats, 42.3% of total liver uptake was contributed by HSCs, 34.4% by Kupffer and endothelial cells, and 23.3% by hepatocytes. In contrast, in fibrotic rats, 82.0% of the total hepatic uptake was by HSCs, only 7.4% by Kupffer and endothelial cells, and 10.6% by hepatocytes. However, in the case of free TFO, there was not much difference for HSC contribution between normal and fibrotic rats (40% versus 44%) (*16*).

To study the subcellular distribution of the conjugate in vivo, we isolated the nuclei from rat liver at 30 min or 4 h after intravenous injection of $(M6P)_{20}$−BSA−^{33}P-TFO. Fractionation by sucrose gradient gave pure and intact nuclei (Figure 8), with a recovery of 40−50%. The majority of the TFO stayed in the cytoplasm of liver cells, and the TFO in the nuclei was only 4% of the total hepatic uptake at 30 min but increased up to 6% at 4 h. However, it is important to note that only half of the cell nuclei could be isolated. Therefore, the actual nuclear distribution of the TFO should be higher than this number.

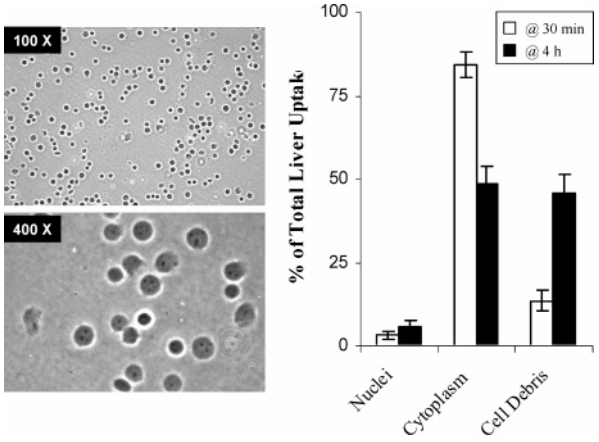

Figure 8. Subcellular distribution of $(M6P)_{20}$−BSA−^{33}P-TFO in the liver. At 30 min and 4 h after intravenous administration of $(M6P)_{20}$−BSA−^{33}P-TFO into normal rats at a dose of 0.2 mg/kg, rats were sacrificed and the livers were removed. The nuclei, cytoplasm, and cell debris were isolated from liver tissues using a sucrose gradient. Distribution in the nuclei, cytoplasm, and cell debris were given as % of the total liver uptake, and values are mean ± SD of 4 rats in each group.

DISCUSSION

Fibrosis is characterized by excessive production of ECM composed primarily of type I collagen. Antisense ODNs have been shown to inhibit type α1(I) collagen gene expression in NIH 3T3 cell in culture (*23*). Compared to quiescent HSCs, activated HSCs contain 60−70-fold more collagen α1(I) mRNA (*8*, *24*). Therefore, transfection of activated HSCs with molecular decoy and small interfering double stranded RNAs (siRNA) could significantly decrease α1(I) collagen mRNA (*24*, *25*). However, these authors did not attempt to deliver ODNs and siRNA to liver fibrogenic cells in vivo. Systemic administration of siRNA against Fas or Caspase 8 has shown some promise in controlling liver fibrosis (*26*, *27*). However, these authors used high volume hydrodynamic administration, which is not feasible in a clinical setting. Moreover, siRNA is known to have an "off-target" effect.

To avoid the use of polycations, Rajur et al. (*28*) conjugated ODNs to asialoglycoprotein via a disulfide bond. Direct conjugation of molecules to the TFO often tends to disturb the triplex-forming ability of the TFOs, which is essential for transcription inhibition. In contrast, conjugation of M6P−BSA to TFO via a disulfide bond is stable in the circulation, but will be cleaved inside the cells by glutathione and/or redox enzymes. In the current study, we used a TFO molecule, which can specifically inhibit the transcription of type α1(I) collagen gene by forming triplex at the promoter region (*9*, *29*). One of the main advantages of the TFO over antisense ODNs and siRNA is that it targets two alleles of the target gene per cell rather than the mRNA, which is usually present in hundreds or thousands of copies per cell (*22*). After intravenous administration of the TFO, 35% of the injected dose accumulated in the liver of fibrotic rats and the intrahepatic distribution was nonspecific for HSCs (*16*).

M6P is a ligand for M6P/IGF II receptor, which is upregulated in fibroblast-like cells such as activated HSCs during liver fibrosis (*18*, *19*). Coupling of M6P to albumin increased selective uptake of this modified albumin by HSCs during liver fibrosis (*30*). Conjugation of M6P to recombinant interleukin-10 (rIL-10) significantly increased the hepatic uptake of IL-10 by the liver. We synthesized M6P−BSA, conjugated to TFO via a disulfide bond, and determined the biodistribution of $(M6P)_{20}$−BSA−^{33}P-TFO after intravenous injection in normal rats (*37*). Significant increase in the hepatic uptake of the TFO was observed. Since the hepatic uptake and bioactivity of $(M6P)_x$−BSA−TFO are likely to be dependent on the dose and number of M6P per BSA, in this study, we synthesized $(M6P)_x$−BSA−TFO, where $x = 14$, 20, and 27 for both in vitro and in vivo studies.

HSC-T6 cell is a good cell culture system for studying the characteristics of activated HSCs in vitro (*31*). As shown in Figure 1, after conjugation with M6P−BSA, there was a significant increase in the TFO uptake by HSC-T6 cells. This is in a good agreement with the work of Bonfils et al. (*32*), who showed increased uptake of M6P−BSA−ODN by fibroblast-like BHK cells, which also expressed M6P/IGF II receptors. However, these authors had not tested their glycoconjugates in vivo. Also, $(M6P)_{20}$−BSA−TFO gave the highest cellular uptake, so there was an optimal number of M6P attached to BSA (Figure 1a).

For triplex formation with genomic DNA, TFO must dissociate from M6P−BSA and translocate to the nucleus. TFO molecules were shown to be efficiently getting into the nucleus varying from 18.5% to 60.6% of total cellular uptake depending on different cell lines (*33*). We determined the nuclear uptake of $(M6P)_{20}$−BSA−^{33}P-TFO at 4 h postincubation to be around 32% and higher than that of ^{33}P-TFO in HSC-T6 cells (Figure 2). The increased nuclear translocation of the TFO was not expected, since there is no apparent reason for M6P−BSA−TFO to enhance the nuclear entry of the TFO molecules. The TFO was covalently conjugated with M6P−BSA via a disulfide bond, thus upon getting inside the cells, the disulfide bonds are expected to be cleaved and TFO molecules would enter the nucleus in an unconjugated form (*37*). So, this increased nuclear translocation of TFO molecules may be due to the relatively higher and faster cellular uptake of M6P−BSA−TFO by these cells than TFO alone, as shown in Figure 1. However, we observed a much less nuclear localization of M6P−BSA−^{33}P-TFO in vivo. It was only 4% at 30 min, but increased to 6% at 4 h (Figure 8). However, these values were underestimated since we could isolate only 40−50% of the nuclei from the liver tissue. The overall nuclear translocation of the TFO in the liver is likely to be as high as 15% at 4 h.

Previously, we have reported that the TFO can form triplex with the type α1(I) collagen gene promoter sequence and inhibit the gene expression using a reporter plasmid containing the type α1(I) collagen gene promoter sequence (*9*). However, we did not show direct inhibition of type α1(I) collagen gene expression by the TFO. Since the half-life of type α1(I) collagen mRNA is 20-fold longer in activated HSCs than that of quiescent HSCs (*34*), it is impossible to detect the effect of TFO at the mRNA level in cell culture. Therefore, we designed primers specific for type α1(I) collagen primary mRNA to avoid this problem and demonstrated the gene inhibition effect of TFO. Higher cellular uptake was expected to have a more potent inhibitory effect on type α1(I) collagen gene transcription. TFO molecules did not show any inhibitory effect at 0.5 μM. In contrast, for M6P−BSA−TFO, we saw 60% inhibition at 0.5 μM and 65% at 1 μM. Thus, M6P−BSA−TFO could efficiently increase the cellular uptake of TFO and also strengthen the TFO bioactivity.

The hepatic accumulation of M6P modified human serum albumin (M6P−HSA) was shown to be dependent on the number of M6P per HSA molecule and the highest hepatic accumulation and uptake by HSCs when HSA was substituted with 28 of M6P moieties (*30*). Therefore, we substituted 14, 20, and 27 M6P moieties per BSA for TFO delivery. As shown in Figure 4, the percentage of the injected dose accumulated in the liver significantly increased with increase in M6P density. Almost 56.3% of the injected dose was accumulated in the liver for $(M6P)_{14}$−BSA−TFO, and an increase in the molar ratio of M6P:BSA to 27 resulted in an increased liver accumulation to

67.4%. Our results did not correlate well with the work of Beljaar et al. (*30*), who showed only a trivial accumulation of $(M6P)_x$−HSA in the liver when x was equal to 10 or below, but 59.2% as the hepatic uptake when x was equal to 28. This discrepancy is possibly due to the following two reasons: (i) we used M6P−BSA, since it was also shown that 52.6% accumulated in the liver for $(M6P)_{21}$−BSA (*30*); (ii) in our case, M6P−BSA was further conjugated with TFO, which is a polyanion with molecular weight of >8000Da, and must have some influence on the biodistribution of M6P−BSA. Apparently, there was a saturation in the hepatic uptake of M6P−BSA−TFO, since $(M6P)_{20}$−BSA−TFO and $(M6P)_{27}$−BSA−TFO were not significantly different in the hepatic uptake (Figure 4). This saturation was also observed for galactose modified BSA (Gal-BSA) by Staud et al. (*35*).

Since there is a concern that the fibrotic liver would prevent efficient drug delivery to the liver (*30*), we confirmed that there was no decrease in the hepatic uptake of $(M6P)_{20}$−BSA−TFO. This is in contrast to our recent findings on the biodistribution of ^{33}P-TFO, where we observed significant decrease in the hepatic uptake of ^{33}P-TFO when injected into fibrotic rats (*16*). This may be due to the fact that M6P/IGF II receptors are upregulated during fibrosis (*18*, *19*), which should increase uptake by HSCs via receptor-mediated endocytosis and cancel out any adverse effect created by decrease in sinusoidal gap.

To determine whether the hepatic accumulation of M6P−BSA−^{33}P-TFO is mediated by M6P/IGF II receptor-mediated endocytosis, we preinjected rats with excess $(M6P)_{20}$−BSA. This resulted in a significant decrease in the hepatic disposition of M6P−BSA−^{33}P-TFO, and this decrease was even more significant in fibrotic rat liver (Figure 6). This confirmed the specific receptor-mediated uptake of M6P−BSA−^{33}P-TFO. When M6P/IGF II receptor was upregulated in fibrotic rats, the hepatic accumulation was almost completely inhibited by blocking this receptor. Rachmawati et al. also demonstrated almost 50% inhibition in the hepatic uptake of M6P−IL-10 conjugate in fibrotic rats (*36*).

Finally, we should make sure the conjugate was really targeted to HSCs. We observed that 42.3% of the hepatic uptake was in the HSCs of normal rats, but increased to 82.0% in the HSCs of fibrotic rats, which means $(M6P)_{20}$−BSA−TFO not only increased TFO accumulation in the liver in general but also specifically targeted to HSCs in fibrotic rats. At the same time, the contribution of Kupffer and endothelial cells was greatly inhibited compared to that in normal rats (7.4% vs 34.4%). Unconjugated TFO was mostly taken up by Kupffer and endothelial cells, possibly through the scavenger receptors (*16*). Thus, the biodistribution of TFO was changed by conjugation with M6P−BSA.

Although we isolated nuclei from the whole liver rather than from different isolated liver cells, we assume that the nuclear translocation of the TFO of different liver cells would be similar. Since most of the TFO accumulated in the HSCs of the fibrotic rats (Figure 7), we expect that TFO concentration inside the nuclei of HSCs would be much higher for M6P−BSA−TFO than that for free TFO and thus could greatly increase the potency of TFO molecules in vivo.

In conclusion, conjugation with M6P−BSA significantly enhanced the uptake of the TFO by HSCs both in vitro and in vivo. Therefore, M6P−BSA−TFO is a suitable delivery system for targeting TFO against type α1(I) collagen gene promoter to HSCs for treating liver fibrosis.

Development and Properties of β-Glucuronide Linkers for Monoclonal Antibody−Drug Conjugates

Scott C. Jeffrey,* Jamie B. Andreyka, Starr X. Bernhardt, Kim M. Kissler, Toni Kline, Joel S. Lenox, Ruth F. Moser, Minh T. Nguyen, Nicole M. Okeley, Ivan J. Stone, Xinqun Zhang, and Peter D. Senter

Seattle Genetics, 21823 30th Drive SE, Bothell, Washington 98021. Received January 26, 2006; Revised Manuscript Received March 27, 2006

A β-glucuronide-based linker for attaching cytotoxic agents to monoclonal antibodies (mAbs) was designed and evaluated. We employed the cytotoxic auristatin derivatives MMAE (**1a**) and MMAF (**1b**) and doxorubicin propyloxazoline (DPO, **2**) to give the β-glucuronide drug-linkers **9a**, **9b**, and **17**, respectively. Cysteine-quenched derivatives of **9b** and **17** were determined to be substrates for *E. coli* β-glucuronidase, resulting in facile drug release. The β-glucuronide MMAF drug-linker **9b** was highly stable in rat plasma with an extrapolated half-life of 81 days. Each drug-linker when conjugated to mAbs c1F6 (anti-CD70) and cAC10 (anti-CD30) gave monomeric antibody−drug conjugates (ADCs) with as many as eight drugs per mAb and had high levels of immunologically specific cytotoxic activity on cancer cell lines. cAC10−**9a** displayed pronounced antitumor activity in a subcutaneous Karpas 299 lymphoma tumor model. A single dose treatment led to cures in all animals at the 0.5 mg/kg dose level and above, and the conjugate was well tolerated at 100 mg/kg. In mice with subcutaneous renal cell carcinoma xenografts, the MMAF conjugate c1F6−**9b** was tolerated at 25 mg/kg and efficacious at 0.75 mg/kg. These results demonstrate that the β-glucuronide linker system is an effective strategy for targeting cytotoxic agents providing ADCs with high degrees of efficacy at well-tolerated doses.

INTRODUCTION

Monoclonal antibody (mAb) therapies are gaining momentum as adjunct and front-line treatments for cancer. Agents such as Avastin (anti-VEGF) and Erbitux (anti-EGFR, HER1 and c-Erb-1) for colon cancer (*1*, *2*), Rituximab (anti-CD20) for non-Hodgkin's lymphoma (*3*) and Herceptin (anti-Her2) for breast cancer (*4*) provide convincing proof that mAb therapies impact disease progression and patient survival. This work has been extended by using mAbs for the delivery of cytotoxic agents to cancerous tissue (*5*−*7*), leading to the approved agents Mylotarg, Zevalin, and Bexxar.

Some considerations in making effective and well-tolerated antibody−drug conjugates (ADCs) include using highly potent drug payloads, addressing aggregation due to drug and linker hydrophobicity, circumventing issues such as multidrug resistance mechanisms and off-target toxicity, and incorporating stable linker technologies (*5*). Promising data have been reported for ADCs composed of highly potent drugs such as calicheamicins (*8*, *9*), doxorubicin (*10*−*12*), maytansinoids (*13*, *14*), taxanes (*15*), minor groove binders (*16*−*20*), and auristatins (*21*−*23*). These drugs have been attached through linkage systems comprised of hydrazones, disulfides, and peptides (*24*). Upon binding to the antigen on the surface of a cancer cells, the ADC−antigen complexes are internalized into endosomal/lysosomal compartments through a process known as receptor-mediated endocytosis. Once this occurs, the ADC is exposed to lysosomal enzymes, acidic pH, and intracellular reducing agents, all of which can be exploited for drug release (*24*).

A limitation with many hydrazone- and disulfide-based linkers is they are known to be labile in circulation, resulting in release of drug outside the targeted tissue (*12*, *14*) which can increase systemic toxicity and compromise therapeutic efficacy. We have focused our approaches on peptide-based linker strategies that provide high ADC stability (*21*). The resulting ADCs are well tolerated and efficacious, validating the development of highly stable linker technologies. Here we extend this work through the synthesis and evaluation of a novel β-glucuronic acid-based linker in which hydrolysis by the lysosomal enzyme β-glucuronidase releases active drug. We anticipated that linker systems incorporating highly hydrophilic β-glucuronides would circumvent the tendency of ADCs, particularly those incorporating hydrophobic drugs (*19*), to undergo aggregation. We were drawn to this particular mechanism for drug release based on reports indicating that β-glucuronidase is abundantly present within lysosomes and is overexpressed in some tumor types (*25*). Indeed, there have been previous examples of β-glucuronide-based prodrugs for anticancer monotherapy (*26*). One of the attractive features of such a linker system is that the enzyme activity outside cells is low, providing the possibility of high ADC stability in the systemic circulation. Our ultimate goal in developing this linker technology is to further our understanding of how linker solubility, stability, and the mechanism of drug release affect ADC activity and tolerability. Drug-linkers employing the β-glucuronide linker with the antimitotic agents monomethyl auristatin E (MMAE; **1a**) (*21*), monomethyl auristatin F (MMAF; **1b**) (*27*), and doxorubicin propyloxazoline (DPO; **2**) and the corresponding ADCs were prepared and evaluated. The resulting ADCs were found to be highly stable in plasma, well tolerated at high doses, and efficacious both in vitro and in vivo.

EXPERIMENTAL PROCEDURES

General Methods and Materials. Unless otherwise indicated, all anhydrous solvents were commercially obtained and stored in Sure-seal bottles under nitrogen. All other reagents and solvents were purchased as the highest grade available and used without further purification.

NMR spectra were recorded on Varian Mercury 400 MHz Instrument. Chemical shifts (δ) are reported in parts per million

(ppm) referenced to tetramethylsilane at 0.00, and coupling constants (*J*) are reported in hertz. Low resolution mass spectral data were acquired on a Micromass ZMD mass spectrometer interfaced with an HP Agilent 1100 high performance liquid chromatography instrument (HPLC). Products were eluted on a C12 Phenomenex Synergi 2.0 × 150 mm, 4 μm, 80 Å MAX reverse phase column using a linear gradient of mobile phase B (CH_3CN with 0.05% HCO_2H) in A (0.05% aqueous HCO_2H) at 0.4 mL/min. Unless otherwise specified, the reported retention times (t_R) are those from LC-MS. High-resolution mass spectral data were obtained at the University of Washington Medicinal Chemistry Mass Spectrometry Center on a Bruker APEXIII 47e [FT(ICR)]MS. Analytical HPLC was conducted on a Waters 2695 instrument using a Waters 2996 PDA and Millenium^{32} software and a C12 Phenomenex Synergi 4.6 × 150 mm, 4 μm, 80 Å MAX reverse phase column. Products were eluted with either acidic (A) linear gradients of mobile phase B (CH_3CN with 0.05% HCO_2H; 10% to 95% over 8 min) in A (0.05% aqueous TFA), or neutral (N) linear gradients of mobile phase B (CH_3CN; 10% to 90% over 10 min, then hold at 90% for 5 min) in A (5.0 mM $NH_4H_2PO_4$) at a flow rate of 1.0 mL/min. Preparative HPLC purifications were performed on a Varian instrument equipped with C12 Phenomenex Synergy MAX-RP 4 μm 250 × 21.2 mm reversed phase column, eluting with 0.05% formic acid in a water and acetonitrile gradient at a flow rate of 4.6 mL/min (gradient 1: 10% organic for 5 min followed by a ramp up to 70% organic over 25 min; gradient 2: 10% organic for 3 min followed by a ramp up to 50% organic over 50 min). Radial chromatography was performed on a Chromatotron instrument (Harrison Research, Palo Alto, CA) on normal phase silica plates (Analtech, Newark, DE). The syntheses of MMAE (**1a**) and MMAF (**1b**) have been described (*21, 27*).

(2*S*,3*S*,4*S*,5*R*,6*S*)-Methyl 6-(2-(3-(((9*H*-Fluoren-9yl)methoxy)carbonylamino)propanamido)-4-(hydroxymethyl)-phenoxy)-3,4,5-triacetoxy-tetrahydro-2*H*-pyran-2-carboxylate. To a solution of the aniline **5** (74 mg, 0.163 mmol) in dichloromethane (6 mL) was added DIPEA (57 μL, 0.33 mmol). The acid chloride **6** (65 mg, 0.20 mmol) was added, and the mixture was stirred for 30 min. The mixture was poured into saturated aqueous sodium bicarbonate and was extracted with ethyl acetate (3 × 50 mL). The combined extracts were washed with water and brine and were dried over sodium sulfate. Filtration and concentration gave a residue that was purified via radial chromatography using 5% methanol in dichloromethane as mobile phase to give 106 mg (87%) of **11** as a white solid: ^{1}H NMR (DMSO-d_6) δ 1.98 (s, 3H), 1.99 (s, 6H), 2.52 (m, 2H) 3.27 (m, 2H), 3.32 (s, 3H), 4.20 (m, 1H), 4.26 (m, 1H), 4.39 (d, 2H, J = 6.3 Hz), 4.70 (d, 1H, J = 9.7 Hz), 5.04 (t, 1H, J = 9.6 Hz), 5.15 (m, 2H), 5.48 (t, 1H, J = 9.4 Hz), 5.54 (d, 1H, J = 7.6 Hz), 5.75 (s, 1H), 7.02 (q, 2H, J = 4.3 Hz) 7.30 (m, 2H), 7.39 (t, 4H, J = 7.72 Hz), 7.67 (d, 2H, J = 7.6 Hz), 7.80 (s, 1H), 7.87 (d, 2H, J = 7.6 Hz), 8.72 (s, 1H); LC-MS *m*/*z* (ES$^+$), 749.04 (M + H)$^+$.

(2*S*,3*S*,4*S*,5*R*,6*S*)-Methyl 6-(2-(3-(((9*H*-Fluoren-9yl)methoxy)carbonylamino)propanamido)-4-(((4-nitrophenoxy)-carbonyloxy)methyl)phenoxy)-3,4,5-triacetoxy-tetrahydro-2*H*-*pyran*-2-carboxylate (7). To a mixture of benzyl alcohol **11** (105 mg, 0.14 mmol) in DMF (4 mL) was added bis *p*-nitrophenyl carbonate (85 mg, 0.28 mmol) and DIPEA (36 μL, 0.21 mmol). The mixture was stirred for 16 h at an ambient temperature and was concentrated under reduced pressure to an oily residue. This material was dissolved in dichloromethane and aspirated directly onto a 1 mm radial Chromatotron plate and eluted with 50% ethyl acetate in hexanes followed by ethyl acetate to give 106 mg (83%) of **7** as a solid: ^{1}H NMR (*d6*-DMSO-d_6) δ 1.98 (s, 3H), 1.99 (s, 3H), 1.99 (s, 3H), 2.52 (m, 2H), 3.28 (m, 2H), 3.62 (s, 3H), 4.20 (m, 1H), 4.27 (m, 2H), 4.73 (d, 1H, J = 9.8 Hz), 5.05 (t, 1H, J = 9.6 Hz), 5.18 (t, 1H, J = 9.4 Hz), 5.21 (s, 2H), 5.49 (t, 1H, J = 10.2 Hz), 7.10 (d, 1H, J = 8.2 Hz), 7.22 (m, 1H), 7.30 (m, 2H), 7.39 (m, 4H, J = 7.0 Hz), 7.55 (d, 2H, J = 9.2 Hz), 7.67 (d, 2H, J = 5.2 Hz), 7.87 (d, 2H, J = 7.0 Hz), 7.97 (s, 1H), 8.29 (d, 2H, J = 9.0 Hz), 8.83 (s, 1H); LC-MS *m*/*z* (ES$^+$), 914.03 (M + H)$^+$.

MMAF Carbonate (8). To a mixture of the *p*-nitrophenyl carbonate **7** (30 mg, 0.033 mmol) and monomethyl auristatin F (**1**; 29 mg, 0.039 mmol) were added DMF (0.8 mL) and pyridine (0.2 mL). DIPEA (7 μL, 0.04 mmol) was added followed by HOAt (1 mg, 7 μmol). The reaction mixture was stirred for 16 h at an ambient temperature. The mixture was concentrated under reduced pressure and was chromatographed on a 1 mm Chromatotron plate, eluting with a 1 to 5% methanol in dichloromethane gradient containing 1% acetic acid. The final UV active (254 nm) band to elute was product. This gave 44% (22 mg) of **8** as a white solid that was carried forward without analytical characterization.

MMAF Glucuronide Amine. To a mixture of the MMAF carbamate (22 mg, 0.015 mmol) in methanol (1 mL) at 0 °C was added a solution of LiOH monohydrate (5.5 mg, 0.132 mmol) in water (1 mL). The mixture was stirred for 15 min at 0 °C and the reaction mixture was neutralized using acetic acid (8 μL) and was concentrated under reduced pressure: LC-MS *m*/*z* (ES$^-$), 1364.09 (M − H)$^-$, 9.78 min. The resulting material was dissolved in DMF (0.8 mL) and treated with piperidine (0.2 mL). The mixture was stirred for 5 min and concentrated under reduced pressure. The material was taken up in water and purified via preparative HPLC (gradient 1) to give 12 mg (72%) as a white solid: ^{1}H NMR (CD_3OD) δ 0.52 (d), 0.59 (d), 0.75−1.1 (m), 1.1−1.35 (m), 1.32−1.67 (m), 1.70−2.10 (m), 2.15−2.50 (m), 2.83−3.05 (m), 3.11 (s), 3.15−3.42 (m), 3.45−3.68 (m), 3.85 (m), 3.95 (m), 4.00−4.18 (m), 4.19−4.30 (m), 4.50−4.97 (m), 5.00−5.20 (m), 7.09−7.29 (m), 7.65 (d), 7.75 (d), 7.82 (d), 7.88 (d), 8.18 (d), 8.25 (m), 8.35 (d), 8.40 (d), 8.59 (d); LC-MS *m*/*z* (ES$^-$), 1144.66 (M − H)$^-$.

MMAE Glucuronide Maleimide (9a). Compound **9a** was prepared in a manner identical to **9b** starting with MMAE (**1a**) and compound **7**. Compound **9a** was obtained as a white solid: ^{1}H NMR (CD_3OD); δ 0.64−1.01 (m, 24H), 1.12 (t, J = 6.9 Hz, 3H), 1.16 (d, J = 6.5 Hz, 1H), 1.23 (m, 1H), 1.4 (m, 1H), 1.45−1.63 (m, 5H), 1.67−1.98 (m, 2H), 2.19 (m, 3H), 2.42−2.54 (m, 1H), 2.63 (m, 2H), 2.96 (m, 4H), 3.1 (s, 2H), 3.12−3.39 (m, 3H), 3.40−3.73 (m, 9H), 3.85−3.96 (m, 1H), 4.04 (m, 1H), 4.13−4.27 (m, 2H), 4.52 (m, 1H), 4.59−4.68 (m, 2H), 4.65−5.0 (m, 2H), 5.0−5.17 (m, 2H), 6.78 (s, 2H), 7.09 (m, 1H), 7.20 (m, 3H), 7.3 (m, 3H), 7.38 (d, J = 7.6 Hz, 3H), 7.75−8.01 (m, 2H), 8.26 (d, J = 9.0 Hz, 1H), 8.32 (m, 1H); LC-MS *m*/*z* (ES+) 1323.01 (M + H), 6.88 min; HRMS *m*/*z* for $C_{66}H_{97}N_8O_{20}Na_2$ (M − H + 2Na)$^+$ calcd, 1367.6615; found, 1367.6616. Supporting Information for PDA-HPLC chromatograms of **9a** under neutral (N) and acidic (A) conditions, and HRMS data.

MMAF Glucuronide Maleimide (9b). To a mixture of the amine (12 mg, 0.011 mmol) in DMF (1 mL) was added MC-OSu (**10**; 5.2 mg) followed by DIPEA (6 μL). After 15 min, the reaction mixture was concentrated under reduced pressure, was dissolved in a mixture of water and DMSO (1:1; 1 mL) and was purified via preparative HPLC (gradient 1). This gave 9.4 mg (64%) of **9b** as a white solid: ^{1}H NMR (CD_3OD) δ 0.66−1.05 (m, 22H), 1.10−1.27 (m, 9H), 1.33−1.43 (m, 2H), 1.44−1.62 (m, 6H), 1.66−2.05 (m, 5H), 2.15−2.35 (m, 4H), 2.40−2.50 (m, 2H), 2.60−2.68 (m, 2H), 2.84−2.98 (m, 9H), 3.10 (s, 2H), 3.22 (s, 2H), 3.25−3.68 (m, 12H), 3.85 (dd, J = 8.6, 2.0 Hz), 3.93 (d, J = 10 Hz), 4.05 (m, 1H), 4.13 (m, 1H), 4.22 (q, J = 10 Hz), 4.48−4.58 (m, 1H), 4.63−4.75 (m, 2H), 4.81 (d, J = 7.8 Hz, 2H), 5.02−5.17 (m, 3H), 6.77 (s, 2H),

7.10 (m, 1H), 7.15−7.29 (m, 8H), 7.82−8.01 (m, 2H), 8.16 (d, J = 8.4 Hz, 1H), 8.24 (s, 1H), 8.35 (m, 1H); LC-MS m/z (ES^+), 1337.03 $(M + H)^+$, 8.50 min; HRMS m/z for $C_{66}H_{95}N_8O_{21}Na_2$ $(M - H + 2Na)^+$ calcd, 1381.6407; found, 1381.6428. See Supporting Information for PDA-HPLC chromatograms of **9b** under neutral (N) and acidic (A) conditions, and HRMS data.

4-(*tert*-Butyldiphenylsilyloxy)butan-1-ol. To a solution of 1,4-butanediol was added sodium hydride (1.0 g of a 60% dispersion in mineral oil). This mixture was allowed to stir at an ambient temperature for 1 h, before TBDPSCl (5.0 mL, 18.2 mmol) was added. The mixture was stirred overnight at ambient temperatures, poured into water, and extracted with ether (3 × 100 mL). The combined extract was washed with water and brine and dried over sodium sulfate. Filtration and concentration gave an oily residue, which was purified via radial chromatography on a 4 mm plate eluting with 25% ethyl acetate in hexanes, followed by 50% ethyl acetate in hexane. This gave 3.36 g (56%) of desired product as clear oil. ^{1}H NMR ($CDCl_3$); δ 1.24 (s, 9H), 1.65 (m, 4h), 3.65 (m, 4H), 7.40 (m, 6H), 7.64 (d, 2H, J = 1.5 Hz).

4-(*tert*-Butyldiphenylsilyloxy)butanal. To a solution of the 4-(*tert*-butyldiphenylsilyloxy)butan-1-ol (0.5 g, 1.5 mmol) in dichloromethane (20 mL) was added Dess−Martin periodinane (775 mg, 1.83 mmol). The mixture was stirred for 1 h. The reaction mixture was poured into hexanes, and the resulting white precipitate was removed via filtration. The solution was concentrated to give a slurry, which was dissolved in dichloromethane (5 mL) and again poured into hexanes resulting in the precipitation of white solid. The solids were removed via filtration and the resulting solution was concentrated. This gave 475 mg (97%) of a clear oil: ^{1}H NMR ($CDCl_3$); δ 1.04 (s, 9H), 1.89 (m, 2H), 2.55 (m, 2H), 3.69 (t, 2H, J = 6.1 Hz)), 7.38 (m, 6H), 7.63 (d, 4H, J = 1.7 Hz), 9.79 (t, 1H, J = 1.8 Hz).

2-(3-(*tert*-Butyldiphenylsilyloxy)propyl)oxazolidine (12). A mixture of the 4-(*tert*-butyldiphenylsilyloxy)butanal (235 mg, 0.72 mmol) in benzene (3 mL) was added dropwise to a solution of hydroxy ethylamine (44 μL, 0.72 mmol) in benzene (3 mL). Powdered molecular sieves (4 Å, 600 mg) were added, and the mixture was stirred for 1.5 h, before being filtered through a 20 μm Millipore syringe filter and concentrated. This gave **12** which was used immediately in the synthesis of **13**: ^{1}H NMR (C_6D_6); δ 1.18 (s, 9H), 1.65−1.82 (m, 2H), 2.62 (m, 2H), 3.33 (dd, 3H, J = 6.1, 7.5 Hz), 3.69 (t, 3H, J = 6.1 Hz), 4.26 (t, 1H), 7.23 (dd, 6H, J = 1.9, 3.1 Hz), 7.79 (m, 4H).

3-(3-(((9*H*-Fluoren-9-yl)methoxy)carbonylamino)propanamido)-4-((2*S*,3*R*,4*S*,5*S*,6*S*)-3,4,5-triacetoxy-6-(methoxycarbonyl)-tetrahydro-2*H*-pyran-2-yloxy)benzyl 2-(3-(*tert*-Butyldiphenylsilyloxy)propyl)oxazolidine-3-carboxylate (13). To the benzyl alcohol (50 mg, 0.067 mmol) in dichloromethane (10 mL) was added pyridine (63 μL, 0.8 mmol). The mixture was cooled to −78 °C, diphosgene (16 μL, 0.134 mmol) was added, and the mixture was stirred for 1 h. Oxazolidine **12** (formed from 65 mg of 4-(*tert*-butyldiphenylsilyloxy)butanal) was added as a dichloromethane solution (3 mL) dropwise down the cooled inside wall of the reaction flask. The reaction mixture was allowed to slowly warm to −20 °C over several hours and was then poured into ethyl acetate and washed with saturated aqueous sodium bicarbonate, water, and brine. The organic phase was dried over sodium sulfate, filtered and concentrated. Purification of the resulting residue via radial chromatography (eluting with dichloromethane) provided 54 mg (70%) of **13**: ^{1}H NMR (DMSO-d_6); δ 0.95 (s, 9H), 1.55 (m, 2H), 1.63 (m, 1H), 1.82 (m, 1H), 1.98 (m, 9H), 2.4−2.52 (m, 2H), 3.27 (m, 2H), 3.54−3.66 (m, 6H), 3.70 (q, 1H, J = 10.0 Hz), 3.98 (m, 1H), 4.20 (m, 1H), 4.26 (m, 3H), 4.70 (d, 1H, J = 10.0 Hz), 4.90−5.10 (m, 4H), 5.16 (t, 1H, J = 9.6 Hz), 5.48 (t, 1H, J = 9.4 Hz), 5.57 (d, 1H, J = 7.6 Hz), 7.0−7.15 (m, 3H), 7.29 (m, 2H), 7.36−7.45 (m, 8H), 7.57 (d, 4H, J = 7.2 Hz), 7.66 (d, 2H, J = 7.2 Hz), 7.86 (d, 3H, J = 7.6 Hz), 8.75 (m, 1H); LC-MS m/z (ES^+), 1143.88 $(M + H)^+$, 13.76 min.

3-(3-(((9*H*-Fluoren-9-yl)methoxy)carbonylamino)propanamido)-4-((2*S*,3*R*,4*S*,5*S*,6*S*)-3,4,5-triacetoxy-6-(methoxycarbonyl)-tetrahydro-2*H*-pyran-2-yloxy)benzyl 2-(3-Hydroxypropyl)oxazolidine-3-carboxylate. To a mixture of the silyl ether **13** (52 mg, 0.042 mmol) in THF (2 mL) and pyridine (2 mL) was added HF-pyridine complex (400 μL). The reaction mixture was stirred for 3 h and was poured into saturated aqueous sodium bicarbonate and was extracted with ethyl acetate (3 × 100 mL). The combined extracts were washed with water and brine and dried over sodium sulfate, before filtration and concentration. The resulting oil was purified via radial chromatography on a 1 mm plate with 5% methanol in dichloromethane as eluant yielding 36 mg (86%) of a solid residue: ^{1}H NMR (CD_3OD); δ 1.55 (bs, 2H), 1.68 (m, 1H), 1.87 (m, 1H), 1.95 (s, 3H), 2.01 (m, 6H), 2.67 (oct, 2H, J = 6.8 Hz), 3.30 (m, 1H), 3.50 (m, 3H), 3.65 (m, 1H), 3.69 (m, 3H), 3.82 (q, 1H, J = 8.0 Hz), 4.01 (m, 1H), 4.23 (m, 1H, J = 7.0 Hz), 4.25−4.40 (m, 2H), 4.47 (d, 1H, J = 10.0 Hz), 5.0−5.15 (m, 3H), 5.19 (t, 1H, J = 9.8 Hz), 5.28 (dd, 1H, J = 6.0, 9.6 Hz), 5.39 (d, 1H, J = 7.6 Hz), 5.49 (m, 3H), 7.11 (m, 2H), 7.17−7.32 (m, 3H), 7.34 (t, 2H, J = 7.4 Hz), 7.62 (d, 2H, J = 7.6 Hz), 7.77 (d, 2H, J = 7.6 Hz), 8.07 (s, 1H); LC-MS m/z (ES^+), 927.87 $(M + Na^+)^+$, 9.79 min.

3-(3-(((9*H*-Fluoren-9-yl)methoxy)carbonylamino)propanamido)-4-((2*S*,3*R*,4*S*,5*S*,6*S*)-3,4,5-triacetoxy-6-(methoxycarbonyl)-tetrahydro-2*H*-pyran-2-yloxy)benzyl 2-(3-Oxopropyl)-oxazolidine-3-carboxylate (14). To a solution of the alcohol (36 mg, 0.04 mmol) in dichloromethane (3 mL) was added Dess−Martin periodinane (20 mg, 0.048 mmol). After 1 h, an additional quantity of the Dess−Martin reagent was added (20 mg) and stirring was continued for an additional hour. The reaction mixture was aspirated onto a 1 mm radial Chromatotron plate and eluted with 5% methanol in dichloromethane. This gave a quantitative yield (36 mg) of the aldehyde **14**: ^{1}H NMR (DMSO-d_6); δ 1.89 (s, 3H), 1.91 (m, 1H), 1.98 (s, 3H), 1.98 (s, 3H), 2.41 (m, 1H), 3.27 (m, 2H), 3.75 (m, 1H0, 3.61 (s, 3H), 3.77 (q, 1H, J = 7.8 Hz), 3.95 (m, 1H), 4.15−4.30 (m, 3H), 4.71 (d, 2H, J = 9.0 Hz), 4.97−5.13 (m, 4H), 5.16 (dd, 1H, J = 7.8, 9.9 Hz), 5.45 (t, 1H, J = 9.6 Hz), 5.58 (d, 1H, J = 8.0 Hz), 7.05 (d, 1H, J = 8.4 Hz), 7.12 (d, 1H, J = 7.6 Hz), 7.29 (dd, 2H, J = 5.3, 7.4 Hz), 7.39 (t, 2H, J = 7.4 Hz), 7.67 (d, 2H, J = 5.4 Hz), 8.77 (s, 1H), 9.57 (s, 1H), 11.97 (s, 1H); LC-MS m/z (ES^+), 903.96 $(M + H)^+$, 10.48 min.

3-(3-(((9*H*-fluoren-9-yl)methoxy)carbonylamino)propanamido)-4-((2*S*,3*R*,4*S*,5*S*,6*S*)-3,4,5-triacetoxy-6-(methoxycarbonyl)-tetrahydro-2*H*-pyran-2-yloxy)benzyl 2-(3-(3-Hydroxy-2-methyl-6-((3*S*)-3,5,12-trihydroxy-3-(2-hydroxyacetyl)-10-methoxy-6,11-dioxo-1,2,3,4,6,11-hexahydrotetracen-1-yloxy)-tetrahydro-2*H*-pyran-4-ylamino)propyl)oxazolidine-3-carboxylate (16). To the aldehyde **14** (36 mg, 0.04 mmol) in acetonitrile:water (2:1; 4.5 mL total) at 0 °C was added doxorubicin-HCl (**15**) followed by stirring until all the solids were dissolved. The mixture was treated with a solution of sodium cyanoborohydride (1.0 M solution in THF; 20 μL, 0.02 mmol). The reaction mixture was stirred for 2 h and the mixture was poured into water and extracted repeatedly with dichloromethane (5 × 50 mL). The combined organics were washed with water and brine and were concentrated under reduced pressure. The resulting residue was dissolved in 5% methanol in dichloromethane and was aspirated directly onto a 1 mm radial Chromatotron plate and eluted with 20% methanol in dichloromethane. The first major band was collected to give 23.6 mg (41%) of **16**: ^{1}H NMR (*d6-DMSO*); δ 1.14 (d, 3H, J

= 6.5 Hz), 1.36−1.60 (b, 2H, 1.62−1.78 (b, 2H), 1.97−1.99 (m, 9H), 2.14 (b, 3H), 2.95 (s, 3H), 3.18−3.32 (m, 2H), 3.52 (b, 1H), 3.60 (s, 3H), 3.75 (q, 1H, J = 6.8 Hz), 4.95 (bs, 1H), 3.96 (s, 3H), 4.09 (b, 1H), 4.17 (t, 1H, J = 6.5 Hz), 4.25 (d, 2H, J = 6.1 Hz), 4.54 (d, 2H, J = 6.3 Hz), 4.70 (d, 1H, J = 10.0 Hz), 4.86 (t, 1H, J = 5.9 hz), 4.92−5.07 (m, 3H), 5.15 (t, 1H, J = 8.2 Hz), 5.25 (bs, 1H), 5.04 (d, 1H, J = 2.0 Hz), 5.48 (t, 1H, J = 10.0 Hz), 5.55 (d, 1H, J = 8.0 Hz), 7.0−7.11 (m, 2H), 7.28 (m, 2H), 7.37 (t, 3H, J = 7.3 Hz), 7.65 (d, 3H, J = 7.0 Hz), 7.85 (d, 2H, J = 7.6 Hz), 8.75 (b, 1H); LC-MS *m*/*z* (ES^-), 1428.9 $(M - H)^-$, 7.9 min.

(2*S*,3*S*,4*S*,5*R*,6*S*)-6-(2-(3-Aminopropanamido)-4-((2-(3-(3-hydroxy-2-methyl-6-(3*S*)-3,5,12-trihydroxy-3-(2-hydroxyacetyl)-10-methoxy-6,11-dioxo-1,2,3,4,6,11-hexahydrotetracen-1-yloxy)-tetrahydro-2*H*-pyran-4-ylamino)propyl)oxazolidine-3-carbonyloxy)methyl)phenoxy)-3,4,5-trihydroxy-tetrahydro-2*H*-pyran-2-carboxylic Acid. To a 0 °C mixture of the doxorubicin oxazolidine **16** (30 mg, 0.021 mmol) in methanol (4 mL) was added a solution of LiOH monohydrate (8.8 mg, 0.21 mmol) in water (2 mL). The mixture was stirred for 35 min and was neutralized with acetic acid (8 μL, 0.21 mmol) to pH 7. The mixture was concentrated under reduced pressure to give a residue which was dissolved in DMF (4 mL) and treated with piperidine (1 mL). The reaction mixture was stirred for 5 min before being concentrated under reduced pressure. The residue was purified via preparative HPLC (gradient 2) to yield 6.1 mg (27%) of product: LC-MS *m*/*z* (ES^+), 1069.13 $(M + H)^+$, 5.64 min.

(2*S*,3*S*,4*S*,5*R*,6*S*)-6-(2-(3-(6-(2,5-Dioxo-2*H*-pyrrol-1(5*H*)-yl)hexanamido)propanamido)-4-((2-(3-(3-hydroxy-2-methyl-6-((3*S*)-3,5,12-trihydroxy-3-(2-hydroxyacetyl)-10-methoxy-6,11-dioxo-1,2,3,4,6,11-hexahydrotetracen-1-yloxy)-tetrahydro-2*H*-pyran-4-ylamino)propyl)oxazolidine-3-carbonyloxy)-methyl)phenoxy)-3,4,5-trihydroxy-tetrahydro-2*H*-pyran-2-carboxylic Acid (17). To a mixture of the amine (6.1 mg, 5.7 μmol) in DMF (0.2 mL) was added MC-OSu (**10**; 4 mg, 14 μmol) followed by DIPEA (3 μL, 17 μmol). The reaction mixture was concentrated under reduced pressure and then dissolved in a mixture of water and DMSO (1:1, 2 mL). The mixture was purified via reverse-phase preparative HPLC (gradient 2) to yield 2.1 mg (26%) of **17** as a red solid: ^{1}H NMR (CD_3OD); δ 1.1−1.25 (b, 2H), 1.29 (d, 3H, J = 6.6 Hz), 1.35−1.62(b, 3H), 1.65−1.90 (b, 3H), 2.02−2.13 (m, 4H), 2.67 (s, 4H, *N*-hydroxysuccinimide impurity), 3.00−3.10 (m, 4H), 3.41−3.57 (m, 3H), 3.57−3.70 (m, 3H), 3.81 (m, 2H), 3.94 (d, 1H, J = 9.6 Hz), 4.02 (b, 1H), 4.05 (s, 3H), 4.29 (q, 1H, J = 7.0 Hz), 4.71 (s, 3H), 4.73 (m, 1H), 5.06 (m, 1H), 5.12 (b, 1H), 5.49 (s, 1H), 6.78 (s, 2H), 6.82−7.09 (b, 2H), 7.57 (d, 1H, J = 6.4 Hz), 7.84 (t, 1H), J = 7.4 Hz), 7.95 (sd, 1H, J = 7.4 Hz), 8.08 (bs, 1H); LC-MS *m*/*z* (ES^-), 1260.24 $(M - H)^-$, 6.49 min.

ADC Preparation. The mAbs (>5 mg/mL) in PBS containing 50 mM sodium borate, pH 8.0, were treated with dithiothreitol (DTT; 10 mM final) or tris(2-carboxyethyl)phosphine hydrochloride (TCEP; used in the preparation of ADCs for in vivo experiments) at 37 °C for 30 min. After gel filtration (G-25, PBS containing 1mM DTPA), thiol determination using 5,5′-dithiobis(2-nitrobenzoic acid) indicated that there were approximately eight thiols per mAb (approximately four thiols per mAb with 2.25 equiv. TCEP). To the reduced mAb at 4 °C was added the maleimide drug derivatives (1.2 equiv/SH group) in ice-cold DMSO (20% v/v). After 1 h, the reactions were quenched with excess cysteine, the conjugates were concentrated by centrifugal ultrafiltration, gel filtered (G-25, PBS), and sterile filtered. The molar ratio of drug substitution was determined according to previously published methods (*23*, *28*). Size-exclusion HPLC was used to determine the levels of monomer and aggregates within each ADC, and RP-HPLC established that there was less than 0.5% unconjugated cysteine-quenched drug.

***β*-Glucuronidase Reactivity.** To water (90 μL) was added cysteine (12.5 μL of a 0.1 mM solution) and pH 9 borate buffer (12.5 μL of a 30 mM solution). This was followed by the addition of **9b** (10 μL of a 10 mM DMSO solution). HPLC inspection after 5 min revealed complete conversion to cys-**9b**. To 440 mL of PBS was added the cys-**9b** solution (50 μL; 40 nmol) followed by a solution of *E.coli* β-glucuronidase (Sigma: EC 3.2.1.31 Type IX-A; 10 μL of a 1 mg/mL solution in PBS; 3.6 μg, 13 pmol), and the reaction mixture was incubated at 37 °C. Aliquots (50 μL) were taken at t = 0, 25, 60, and 90 min and analyzed by HPLC (gradient A). Results were based on the area under the curve (AUC) of remaining cys-**9b** at each time point as a percentage of the AUC for cys-**9b** at t = 0.

Rat Plasma Stability Assay. To **9b** (2 mg, 1.5 μmol) was added the DTT solution (150 μL; 1:1 sodium borate: PBS, pH 9.0). The reaction mixture was incubated at 40 °C overnight. LC-MS revealed quantitative conversion to dihydro-**9b**. The solution of dihydro-**9b** (10 μL) was added to the sterile rat plasma (Biochemed Pharmacologicals). Aliquots (50 μL) were taken at t = 0, 2 h, 19 h, 43 h, and 7 days. The aliquots were treated with 100 μL of ice-cold methanol to precipitate plasma proteins and ultra centrifuged for 6 min. The supernatants were removed and analyzed by LC-MS (10 μL injection). The stability of dihydro-**9b** was determined by comparing the AUC for the total positive ion current (TIC^+) for materials ionizing to 732.5 Da (MMAF+H; **1b**) for each time point, relative to the t = 0 time point. Both dihydro-**9b** and free **1b** peaks displayed the 732.5 Da signal.

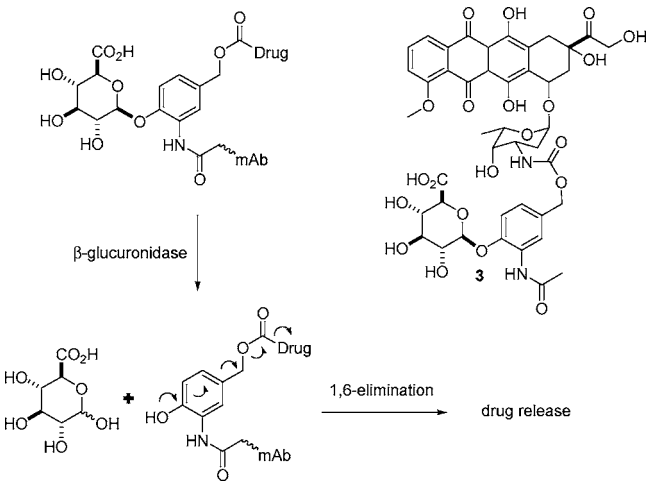
In Vitro Cytotoxicity Assay. Cells were collected and plated in 96-well black-sided plates at a density of 10000 cells/well in 150 μL of medium. Serial dilutions of the ADC (50 μL) were added, and incubation was carried out for 92 h at 37 °C. Resazurin (0.25 mM, 50 μL, Sigma, St. Louis, MO) in medium was added, and incubation was continued for 4 h. The plates were read on a Fusion HT microplate reader (Packard, Meriden, CT) using an excitation wavelength of 525 nm and an emission wavelength of 590 nm. Data from all assays were reduced using GraphPad Prism Version 4 for Windows (GraphPad Software, San Diego, CA). The IC_{50} concentrations compared to untreated control cells were determined using a four-parameter curve fit.

In Vitro Drug Release Assay. CD70 positive cell lines 786-O and Caki-1 were plated at 1.3×10^4 cells/cm^2 in 50 mL of medium in T-150 flasks (786-O cells in RPMI 1640, supplemented with 1 mM sodium pyruvate and 10% fetal bovine serum; Caki-1: McCoy's 5A modified and 10% FBS). When cell layers reached confluency (2−4 days), the medium was replaced and cultures were treated with 200 ng/mL ADC. Incubation was at 37 °C in a humidified 5% CO_2 atmosphere for 24 h. The cells were harvested with trypsin-EDTA and washed with ice cold PBS (approximately 2.0×10^7 viable cells per flask). Cell pellets were resuspended in 250 μL complete culture medium and extracted by mixing with two volumes of ice cold MeOH. The suspensions were kept at −20 °C for at least 30 min and centrifuged at 13200 rpm (16100*g*) for 5 min. Supernatants were evaporated by speed-vac. The resulting residues were redissolved in 110 μL of 33% MeCN and were analyzed by reverse phase HPLC coupled to time-of-flight mass spectrometry (Q-TOF).

RESULTS AND DISCUSSION

Design and Synthesis of *β*-Glucuronide Drug-Linkers. The design of the β-glucuronide linker system described here is based

Scheme 1



on the β-glucuronide prodrug **3** (Scheme 1) (*29*). We envisioned an antibody attachment site could be incorporated by functionalizing the aniline nitrogen with a maleimide-containing side chain. Under the action of β-glucuronidase, the drug-linker would be hydrolyzed at the glycosidic bond and undergo 1,6-elimination with loss of carbon dioxide to liberate drug. The initial ADCs based on this linker design employed the potent antimitotic drugs MMAE (*21*) (**1a**) and MMAF (*27*) (**1b**) and doxorubicin propyloxazoline (DPO; **2**), which is a labile precursor to highly potent 2-pyrrolinodoxorubicin (**4**), as shown in Scheme 2 (*30*−*32*). Compound **4** effects cell death through alkylation of double-stranded DNA (*33*).

The starting point for the synthesis of β-glucuronide drug-linker with MMAF (**1b**) was the previously described β-glucuronide **5** bearing the free aniline and hydroxy groups (Scheme 3) (*29*). This compound was acylated with the acid chloride **6** and then converted to the *p*-nitrophenyl (PNP) carbonate **7**. Reaction with MMAF (**1b**) afforded the carbamate **8**. This molecule was converted to the desired glucuronide drug-linker **9b** by first saponifying the acetate and methyl ester protecting groups with lithium hydroxide (*34*), Fmoc removal with piperidine, and capping of the resulting free amine with maleimidocaproyl *N*-hydroxysuccimidyl ester (MC-OSu; **10**). A final preparative HPLC purification afforded **9b**. The glucuronide-MMAE drug linker (**9a**) was prepared in an identical fashion starting with **5** and **1a**.

The construction of the β-glucuronide linker with DPO (**2**) required a different strategy (Scheme 4). Intermediate **11** was activated with diphosgene and then reacted with oxazoline **12** (prepared in three steps from 1,4-butanediol) to afford the desired oxazoline carbamate **13**. Removal of the silyl protecting group with fluoride was followed by oxidation to give aldehyde **14**. This compound was used in a reductive alkylation reaction with doxorubicin·HCl (**15**) to give the doxorubicin derivative **16**. Last, the β-glucuronide protecting groups and Fmoc group were removed in a two-step sequence with lithium hydroxide and piperidine, and the resulting primary amine was capped with **10** to give the desired β-glucuronide DPO linker **17**.

***β*-Glucuronidase Reactivity.** The susceptibility of this linker to enzymatic cleavage was determined by treatment of the cysteine adduct of compound **9b** with β-glucuronidase. *E. coli* β-glucuronidase (EC 3.2.1.31) rather than human enzyme was used in this study due to commercial availability. Our linker is structurally very similar to the doxorubicin prodrug **3** which was shown to be efficiently cleaved by a human lysosomal β-glucuronidase fusion protein (*29*), suggesting that our linker is likely to be a substrate for the human lysosomal enzyme as well. An HPLC assay was used to monitor the loss of cys-**9b** at 37 °C. The specific activity of the *E.coli* β-glucuronidase for cys-**9b** was 0.13 μmol/min/mg. The cleavage of β-glucuronide from cys-**9b** resulted in 1,6-elimination of MMAF (**1b**) which was identified by LC-MS. No MMAF-containing phenolic intermediates could be detected by LC-MS. Thus the 1,6-elimination appears to be rapid.

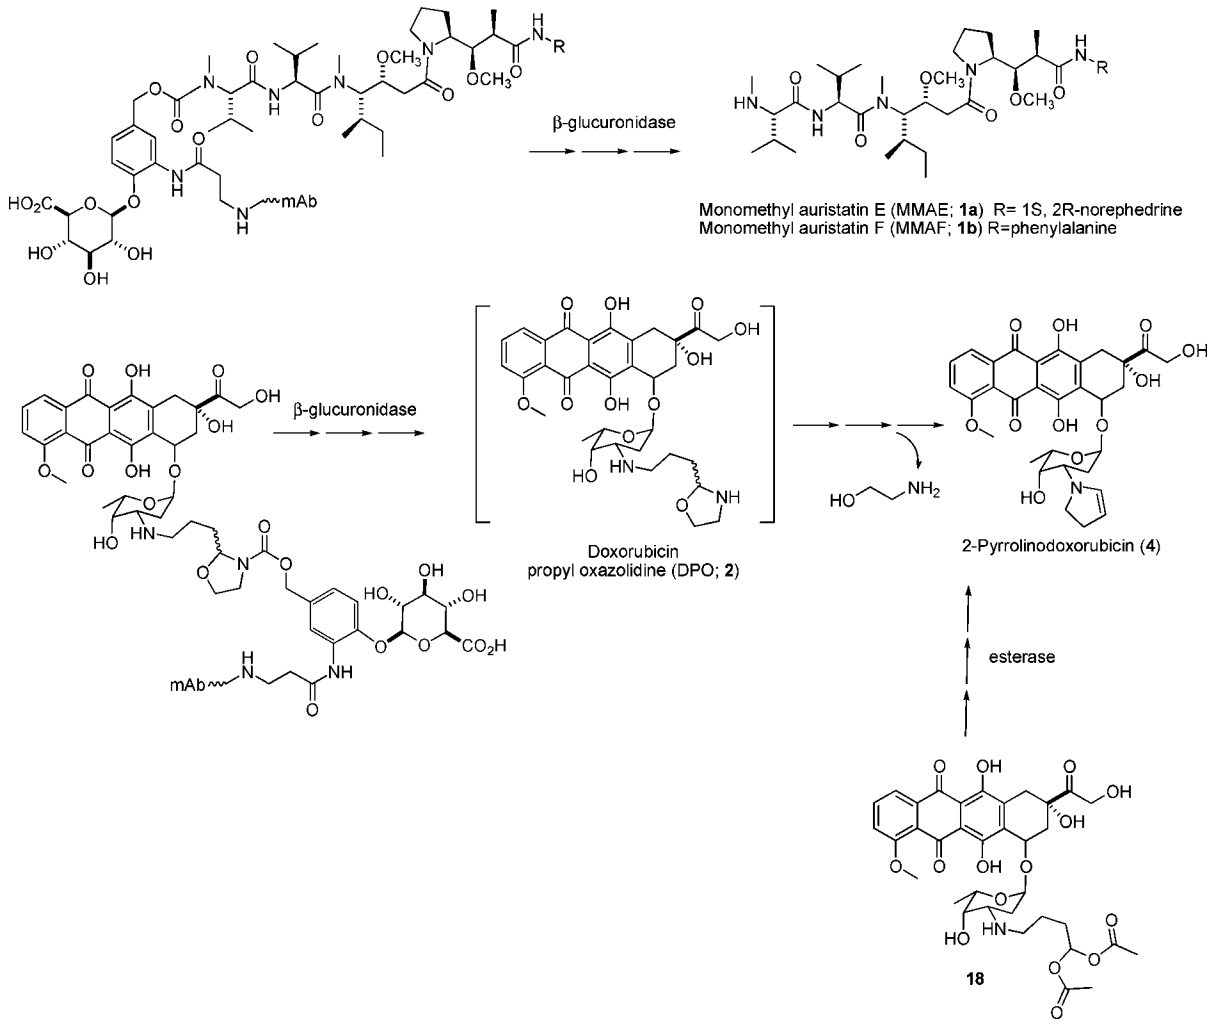
In a similar experiment with cys-**17**, treatment with β-glucuronidase yielded the 2-pyrrolinodoxorubicin (**4**) directly as confirmed by LC-MS. Controls indicated both cys-**9b** and cys-**17** were stable in the absence of β-glucuronidase. These two experiments demonstrated that the linker is a substrate for a β-glucuronidase enzyme and that the drug is readily liberated once the β-glucuronide hydrolysis occurs.

Rat Plasma Stability Assay. To determine the plasma stability of the glucuronide linker, the reactive maleimide double bond of **9b** was reduced with excess DTT to afford dihydro-**9b**. This material was added to rat plasma and incubated at 37 °C for a period of 7 days. Aliquots were taken at various time points and the plasma proteins were precipitated and centrifuged, and the supernatant was recovered. Each supernatant was analyzed by LC-MS, and the total positive ion current (TIC+) chromatogram was scanned for the masses of parent compound dihydro-**9b** and released MMAF (**1b**). After 7 days, the TIC+ for dihydro-**9b** (including the ring-opened succinimide hydrolysis adduct) was 89% of the sample taken immediately after dihydro-**9b** was injected into plasma. Free drug **1b** could be detected but was not quantified. Assuming first-order kinetics, extrapolation of these data suggest a half-life of 81 days for dihydro-**9b**. In a parallel experiment, the rat plasma stability of the maleimide reduced valine-citrulline (val-cit) dipeptide linked MMAF (*11*, *21*, *27*) was found to be 6.25 days. Thus the β-glucuronide linker system was more stable than previously reported disulfide (*14*), hydrazone (*12*), and peptide-based systems. It is possible that the stability of the β-glucuronide linker within an ADC will be increased further, as has been previously shown for another linker technology (*35*).

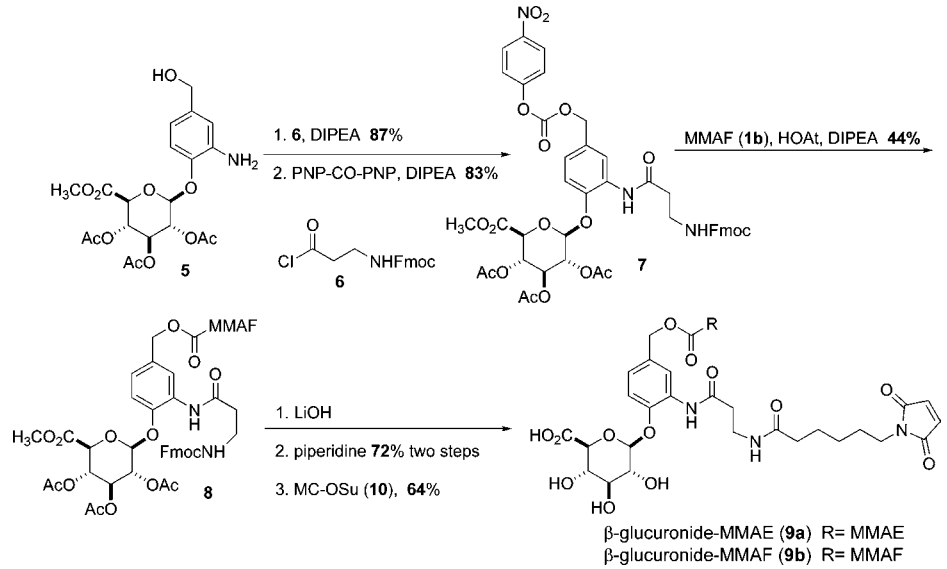
ADC Preparation. ADCs of **9a**, **9b**, and **17** were prepared with the chimeric mAbs cAC10 (IgG1 against the CD30 antigen) and c1F6 (IgG1 against the CD70 antigen). The CD30 antigen is found on activated B cells and is a marker for both Hodgkin's lymphoma and anaplastic large cell lymphoma (ALCL) (*22*, *36*). The CD70 antigen is overexpressed on renal cell carcinoma (RCC) lines as well as some hematologic malignancies (*37*, *38*). Conjugates of **9a**, **9b**, and **17** were prepared as described previously (*21*). Briefly, the mAbs were reduced with excess DTT or stoichiometric TCEP, purified, and treated with 1.2 equiv of drug-linker/sulfhydryl group. After 1 h, the reaction mixtures were quenched with cysteine to consume unreacted drug-linker. The conjugates were purified via gel filtration after which no free drug derivatives could be detected. As demonstrated earlier for related auristatin ADCs (*28*), the conjugates described here retained full binding activity, as assessed by flow cytometry. The cysteine residues modified during conjugation are located in the hinge region of the mAb, away from the binding domain.

Drug loading for the doxorubicin-containing conjugates cAC10−**17** and c1F6−**17** was determined by measuring the absorbance at 280 and 490 nm (doxorubicin absorbance). It was found that the cAC10 and c1F6 ADCs had 6.8 and 8.3 drugs/mAb, respectively. Due to the weak UV absorbance of the drug-linkers **9a** and **9b**, the drug per mAb ratios of the corresponding ADCs were determined through chromatographic resolution of the light and heavy chains at each drug loading level (0−1 drugs for light chains; 0−3 drugs for heavy chains) and calculation of the overall average from the peak areas at each loading level (*23*, *28*). The levels were shown to be 3.7 and 4.5 for cAC10−**9a** and c1F6−**9a**, and 7.6 and 7.0 for the cAC10−**9b** and c1F6−

Scheme 2



Scheme 3



9b conjugates, respectively. The six ADCs were primarily monomeric with 2% or less aggregate being observed in the cAC10-based conjugates and 7% or less aggregate for the c1F6-based conjugates.

In Vitro Evaluation of Cytotoxic Agents and ADCs. In vitro evaluation of both MMAE (**1a**) and **18** (the esterase labile prodrug of 2-pyrrolinodoxorubicin (**4**)) revealed these compounds to be highly cytotoxic (below 0.2 nM) on the CD70+ cell lines Caki-1 and 786-O and the CD30+ line Karpas 299 (Table 1). Compound **18** proved to be 300−6500-fold more cytotoxic than doxorubicin (**15**), which is consistent with previous findings for this class of doxorubicin derivative (*30*). In contrast to **1a** and **18**, the free carboxylic acid MMAF (**1b**) was significantly less active on these cell lines with IC_{50} values

Scheme 4

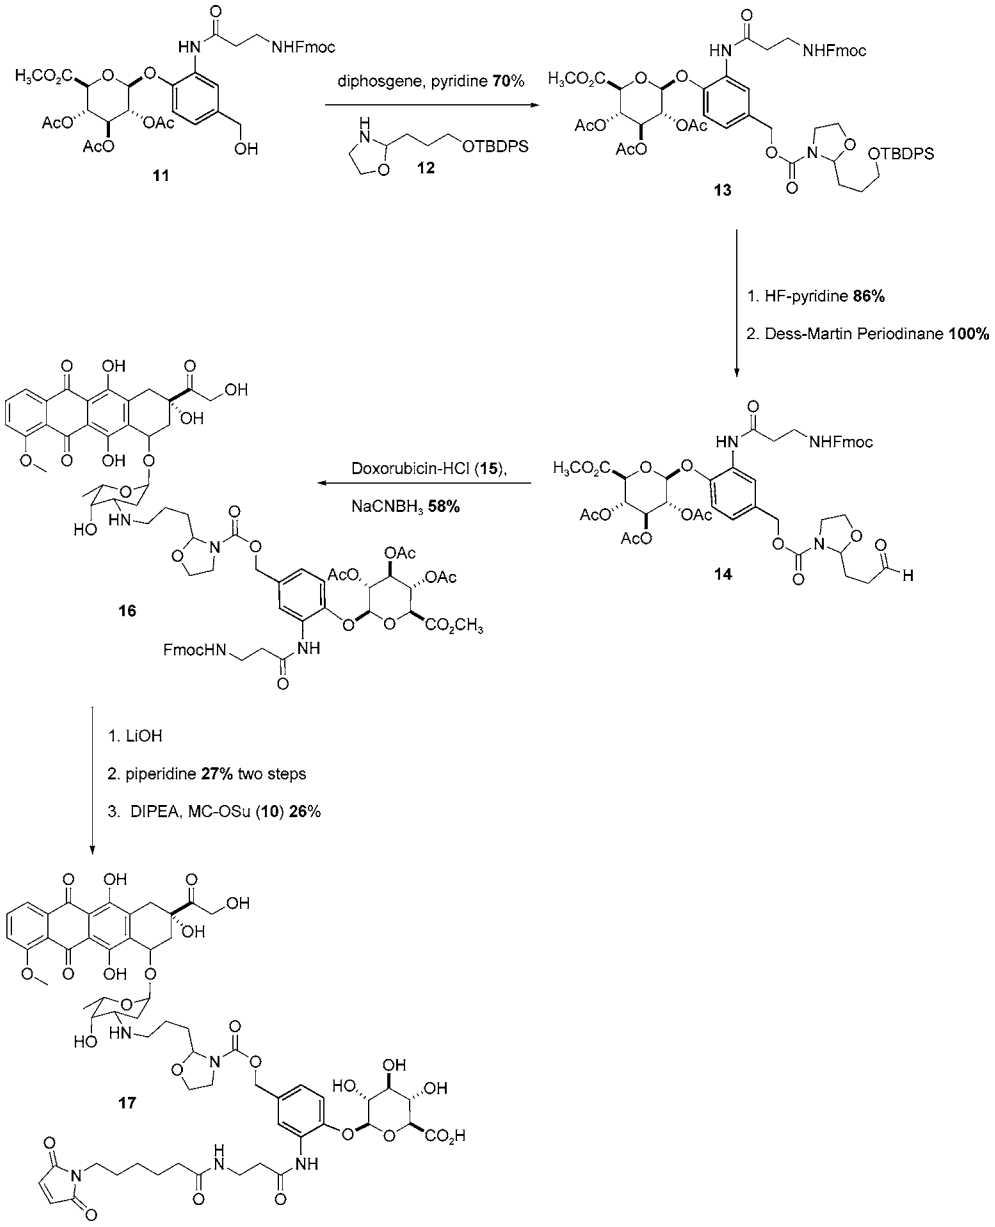


Table 1. Characterization and in Vitro Cytotoxic Activity of Free Drugs and ADCs

compound	target antigen	active drug	drug loading	% aggregation	Caki-1 (CD70+, CD30-) IC_{50} drug nM	786-O (CD70+, CD30-) IC_{50} drug nM	Karpas 299 (CD30+, CD70-) IC_{50} drug nM
1a	-	-	-	-	0.11	0.19	0.09
1b	-	-	-	-	270	300	100
15	-	-	-	-	110	65	29
18	-	**4**	-	-	0.04	0.01	0.1
c1F6−**9a**	CD70	**1a**	4.5	2	0.45	-	>30

c1F6−**17**	CD70	**4**	8.3	3.5	2.0	2.7	>55
cAC10−**17**	CD30	**4**	6.8	<1	>45	>45	1.2

[a] Cells were exposed to the test agents for 96 h, and viability was determined using rezasurin metabolism as a measure of cytotoxic activity. The IC_{50} values were determined compared to untreated cells.

in the 100−200 nM range. As described earlier, the negative charge associated with the carboxylate group of **1b** leads to reduced cytotoxic activity, presumably due to impaired intracellular access (*27*).

In vitro evaluation of cAC10 and c1F6 conjugates of **9a** demonstrated that the linker delivered active drug to the target cells with immunologic specificity (Figure 1). A comparison of the activity of the two conjugates on the CD30+ line Karpas 299 revealed that the anti-CD30 conjugate cAC10−**9a** titrated to an IC_{50} value of 0.06 nM (drug content), where the nonbinding conjugate c1F6−**9a** had no cytotoxic activity up to 30 nM, the highest concentration tested. The anti-CD70

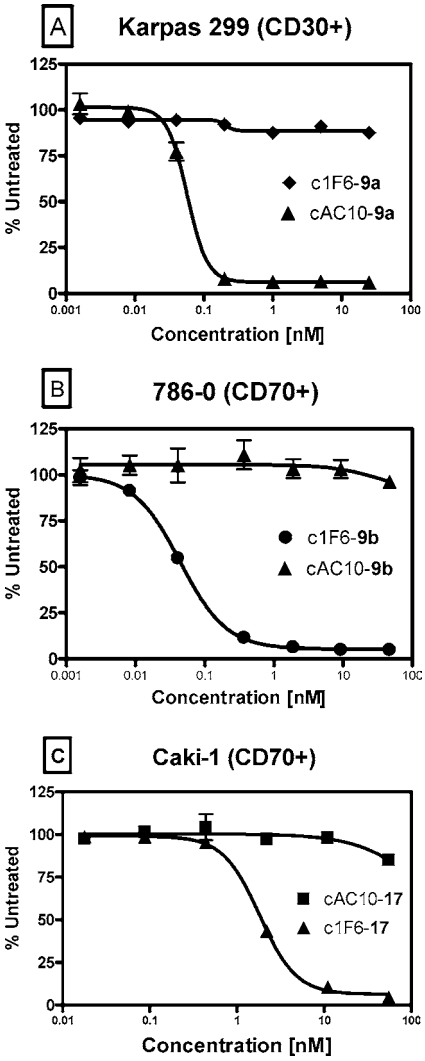

Figure 1. In vitro cytotoxic activity of ADCs on CD30+ and CD70+ cancer cell lines: (A) Karpas 299 (CD30+) ALCL cells treated with anti-CD30 ADC cAC10−**9a** and nonbinding control c1F6−**9a**. (B) 786-O (CD70+) RCC cells treated with anti-CD70 ADC c1F6−**9b** and nonbinding control cAC10−**9b**. (C) Caki-1 (CD70+) RCC cells treated with c1F6−**17** and nonbinding control cAC10−**17**. Results are shown as mean ± SD.

conjugate c1F6−**9a** was quite potent on the CD70+ cell line Caki-1 (IC_{50} 0.45 nM).

The ADCs of **9b** effectively delivered **1b** to the targeted cells. Conjugates of **9b** displayed immunologic specificity and were highly effective against the CD70+ lines Caki-1 and 786-O with IC_{50} values of 0.08 and 0.20 nM, respectively. The corresponding nonbinding cAC10−**9b** was inactive on these cell lines representing specificity levels of >250-fold. The anti-CD30 conjugate cAC10−**9b** was highly effective on the CD30+ line Karpas 299 with an IC_{50} value of 50 pM. Conjugates of doxorubicin drug-linker **17** gave the same general profile, with effective cell kill on antigen positive cell lines and specificity values >16-fold.

To determine the identity of drug released in ADC-treated cells, 786-O cells were treated with h1F6-β-glucuronide-MMAF, which was formed with a variant of **9b** in which the caproyl maleimide was replaced with a bromoacetamide (see Supporting Information). After 24 h, cell extracts were analyzed by LC-MS. The ion mass at 732.7 Da corresponds to the release of **1b** in cells treated with h1F6-β-glucuronide-MMAF while untreated cells showed no signal above background at this mass (Figure 2). The HPLC retention time of the material derived from cell extracts closely matched that of the **1b** standard (data not shown). Similar results were obtained in cells treated with h1F6-β-glucuronide-MMAE (data not shown). While efforts are ongoing to determine the efficiency of drug-release, these results suggest that β-glucuronide hydrolysis takes place within the target cell population.

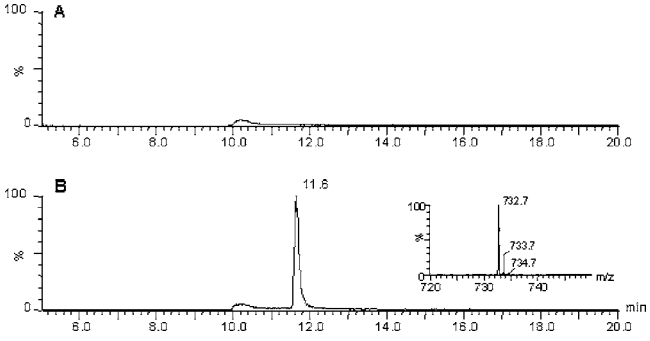

Figure 2. A. LC-MS extracted ion chromatogram (*m*/*z* 732.5 Da) of material isolated from untreated CD70+ 786-O RCC cells. B. LC-MS extracted ion chromatogram (*m*/*z* 732.5 Da) of isolate from 786-O cells treated with h1F6-β-glucuronide-MMAF ADC for 24 h. The inset shows that the mass of material at 11.6 min corresponds to free MMAF (**1b**) released inside ADC treated cells, but not present in untreated cells.

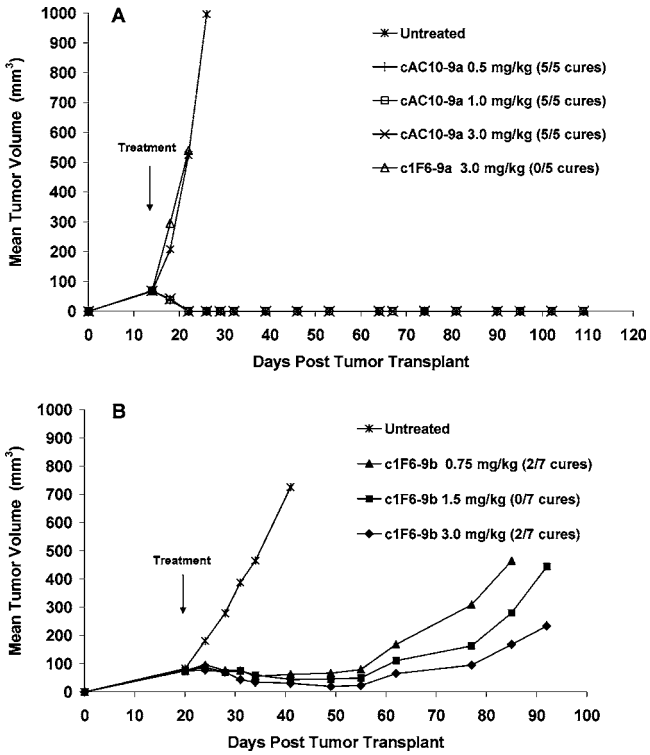

Figure 3. A. Therapy experiment with cAC10−**9a** on CD30+ Karpas 299 (ALCL) subcutaneous tumor bearing SCID mice. A single treatment (arrow: day 14) of mice with 0.5 (+), 1.0 (□), and 3.0 (×) mg/kg gave cures in 5/5 animals for each group. A dose of 3 mg/kg of nonbinding control conjugate c1F6−**9a** (△) resulted in no tumor response as with the untreated group (*). B. Therapy experiment with c1F6−**9b** on CD70+ 786-O (RCC) subcutaneous tumor bearing SCID mice. Single treatment (arrow: day 20) of mice with 0.75 (▲), 1.5 (■), and 3.0 (◆) mg/kg single dose gave tumor regressions. Cures (2/7) were seen in the 0.75 and 3 mg/kg dose groups. All animals in the untreated group (×) were sacrificed on or before day 40.

In Vivo Evaluation. ADCs of the auristatin derivatives **9a** and **9b** were evaluated for toxicity and efficacy. The maximum tolerated dose (MTD) of cAC10−**9a** (4 drugs/mAb) was determined in female Balb/c mice. cAC10−**9a** was well tolerated at 100 mg/kg, but toxic at 150 mg/kg. Conjugate c1F6−**9b** was well tolerated at 25 mg/kg, but was toxic at the 50 mg/kg dose. The MTDs of the glucuronide ADCs therefore

appear to be comparable to the corresponding peptide-linked MMAE (**1a**) (*21*) and MMAF (**1b**) (*27*) ADCs that were previously described. This was somewhat unexpected based on the increased ex vivo stability of the β-glucuronide linker in plasma. Further studies are required to determine in vivo β-glucuronide stability and potential differences in biodistribution compared to the peptide-linker ADCs. These will be the subject of further experiments. Studies to understand the difference in toxicity between MMAE and MMAF-based ADCs are currently underway.

An in vivo therapy experiment with cAC10−**9a** was undertaken in nude mice with subcutaneous Karpas 299 ALCL tumors. The animals (5 per group) were treated with a single intravenous dose of cAC10−**9a** at 0.5, 1.0, and 3 mg/kg (mAb component) on day 14 post tumor implant at which time the tumors were staged (mean = 70 mm^3) and rapidly growing. Specificity was determined using c1F6−**9a** as a nonbinding control ADC that was injected at 3 mg/kg dose. Cures were obtained in all animals treated with cAC10−**9a** at each of the three dosing levels (Figure 3A). In contrast, the nonbinding ADC c1F6−**9a** displayed no antitumor efficacy. Previous studies with unmodified cAC10 and free drug **1a** revealed no significant antitumor activity in this model (data not shown). Since the MTD of cAC10−**9a** is approximately 100 mg/kg, the therapeutic index was >200, which is as pronounced as the val-cit-MMAE ADC reported earlier (*23*).

The effects of c1F6−**9b** were determined in mice with subcutaneous 786-0 renal cell carcinoma implants. Significant levels of antitumor activity were obtained at all three dose levels (0.75, 1.5, and 3.0 mg/kg), again without any signs of toxicity or adverse events (Figure 3B). As with the c1F6−**9a** ADC, this was achieved at a small fraction of the MTD. Neither unmodified c1F6 nor free drug **1b** showed antitumor activity in this model (data not shown).

CONCLUDING REMARKS

We have described a novel β-glucuronide-based linker system for ADCs that complements previously described hydrazone, disulfide, and peptide linker technologies (*11*, *14*, *39*, *40*). The distinguishing features of the β-glucuronide linker are high aqueous solubility, serum stability, and facile drug release within antigen positive tumor cells. The high aqueous solubility of the β-glucuronide may be particularly useful for hydrophobic drugs such as DNA minor groove binders which tend to cause aggregation (*19*).

Compounds **9a**, **9b**, and **17** are the first examples of drug-linkers designed to exploit lysosomal β-glucuronide cleavage for mAb-based targeted drug delivery to cancer cells. Biological evaluation of the cAC10 and c1F6 conjugates of **9a**, **9b**, and **17** revealed them to be highly active and immunologically specific in vitro. In vivo evaluation of cAC10−**9a** showed pronounced efficacy in the Karpas 299 model, comparable to the val-cit-PABA linker system previously described (*23*). Similar trends were observed with c1F6−**9b**, an ADC that led to cures of established renal cell carcinoma xenografts in nude mice. The studies reported here demonstrate that β-glucuronide-based linkers provide well tolerated and efficacious ADCs. We are currently assessing the potential advantages of this linker technology compared to others, and are applying it to several new drug classes.

ACKNOWLEDGMENT

The authors would like to thank Steven C. Alley for his contributions to the maleimide reduction studies.

Synthetic Modification of Silica Beads That Allows for Sequential Attachment of Two Different Oligonucleotides

Gali Steinberg-Tatman, Michael Huynh, David Barker, and Chanfeng Zhao*

Illumina Inc., 9885 Towne Centre Drive, San Diego, California 92121. Received January 19, 2006; Revised Manuscript Received February 22, 2006

We developed a simple and elegant synthesis strategy that enables us to attach controlled (equimolar) amounts of two different oligonucleotides onto one silica bead. The method involves addition of orthogonally protected lysine followed by activation and derivatization of each amino group with a different moiety. This sequential oligonucleotide attachment enables the use of a combinatorial scheme to generate millions of bead types, each characterized by its two oligo tags. (In our randomly assembled arrays each bead type can then be identified by a series of hybridizations of fluorescently labeled decoder oligos to the address tags.) To demonstrate feasibility of such a scheme we created over 1000 bead types, which were characterized by their two oligo tags. The method enables genotyping or gene expression assays at multiplex levels of hundreds of thousands to millions.

INTRODUCTION

DNA array technology uses microscopic arrays of DNA molecules immobilized on solid supports for biomedical analysis of gene expression, polymorphism or mutation detection, DNA sequencing and gene discovery (*1*, *2*).

Conventional microarrays are manufactured by spotting or synthesizing probes at known locations on a two-dimensional substrate (*3*−*5*).

Illumina's novel approach (*6*) enables the production of randomly assembled arrays in which the location of a probe is initially unknown (*7*). Random bead loading combined with decoding, described in detail previously (*6*), avoids the need for physical addressing of each element and thus achieves very high packing densities by using relatively simple bulk processes. The decoding process is efficient and extremely accurate (*6*). However, it requires at least one fluorescently labeled decoder oligo for each unique bead type. For very large numbers of bead types (tens to hundreds of thousands), a more practical decoding approach uses two different address oligos on each bead. This reduces the number of decoder oligos required to two times the square root of the number of unique beads. For example, to decode 1 million different bead types would require only 2000 oligo decoders. Figure 1 illustrates three potential schemes for attaching two different oligonucleotides to the same bead. In this paper, we focus on methods for groups A and B.

To enable sequential attachment of two distinct moieties to one bead, we developed an alternative chemistry scheme involving the use of orthogonally protected lysine. The two amino groups on the lysine are sequentially activated, permitting sequential addition of two different oligonucleotides. The approach is general and could be used to attach different chemical moieties to the same bead, such as an oligo and a peptide.

EXPERIMENTAL PROCEDURES

Chemical Reagents. Silica beads in water (3 μm diameter, $\sim 5 \times 10^{10}$ beads/g) were obtained from Bangs Laboratories Inc., Carmel, IN. Silanization reagent, 3-aminopropyltrimethoxysilane, was obtained from United Chemical Technologies (UCT), Bristol, PA. Succinimidyl 4-formylbenzoate (SFB) and succinimidyl hydraziniumnicotinate hydrochloride (SHNH) were obtained from Solulink, San Diego, CA. Oligonucleotides were obtained from Operon Technologies, Alameda, CA, or synthesized in house. All oligonucleotides obtained from Operon Technologies were HPLC purified. Other reagents were obtained from NovaBiochem, Aldrich, or Sigma. All solutions were prepared with OmniPur (sterile, nuclease free) water from Merck.

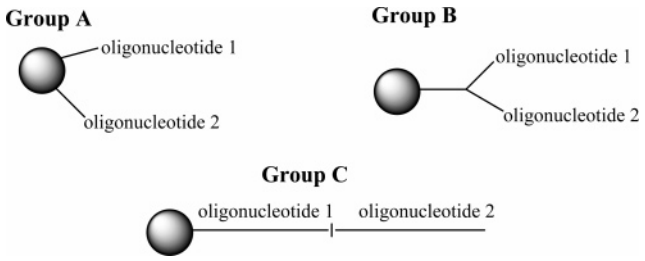

Figure 1. Potential schemes for two oligonucleotide attachment.

Surface Modifications. *Silanization.* Silica beads (1 g) were washed with 10 mL ethanol (HPLC grade). The beads were then suspended in 10 mL of ethanol followed by addition of 50 μL (0.5%) silane reagent, and shaken for 1 h at room temperature. Following silanization they were washed 5 times with 10 mL of ethanol and 3 times with 10 mL of ether, dried, and stored at room temperature. (Silanization is shown in Figure 2.)

Ninhydrin Test. Completion of various reaction steps was monitored (qualitatively) using the ninhydrin test as follows: A small amount of ninhydrin solution (10 wt % ninhydrin in ethanol) was heated to 120 °C, a smidgen of beads was added to one test tube, and another was used as reference. When primary amines were present on the beads, ninhydrin solution turned blue; otherwise, the color of the solution remained unchanged.

Chemical Modifications of Silanized Beads. Figure 2 shows the synthetic approach to sequential oligonucleotide attachment, as demonstrated in the potential scheme in Figure 1 group A.

Coupling of Fmoc and t-Boc Protected Glycines to Silanized Beads. Aminopropyl beads (100 mg) were suspended in DMF

(1 mL), followed by addition of 35 μL of *N*,*N*-diisopropylethylamine (DIEA) (0.2 mmol). The suspension was sonicated, and an equimolar (1:1) mixture of *N*-α-*t*-Boc-glycine (8.75 mg, 0.05 mmol) and *N*-α-Fmoc-glycine (14.85 mg, 0.05 mmol) was added. This was followed by the addition of 52 mg (0.1 mmol) of PyBOP (benzotriazole-1-yl-oxy-tris-pyrrolidinophosphoniumhexa fluoro phosphate). The beads were shaken overnight at room temperature. They were then washed 6 times with 1 mL of DMF and 3 times with methylene chloride.

Amine Deprotection (from t-Boc). Beads coupled to the modified lysine (100 mg) were suspended in a solution of 50% trifluoroacetic acid in methylene chloride (1 mL) and shaken for 30 min at room temperature. They were then washed 3 times with 1 mL of methylene chloride and 3 times with 1 mL of acetonitrile.

Cyanuric Chloride Activation. Amino beads (100 mg) were suspended in acetonitrile (1 mL), followed by addition of 20 μL (0.12 mmol) of DIEA. After a brief sonication, 10 mg (0.05 mmol) of cyanuric chloride was added and the reaction mixture was shaken for 2 h at room temperature. The beads were washed 3 times with 1 mL of acetonitrile and twice with 1 mL of 0.05 M sodium borate buffer (pH 8.5).

Amine Deprotection (from Fmoc). Beads coupled to the modified lysine (100 mg) were suspended in a solution of 20% piperidine in DMF (1 mL) and shaken for 30 min at room temperature. They were then washed 3 times with 1 mL of DMF and 3 times with 1 mL of acetonitrile.

Figure 3 shows the potential schemes of group B from Figure 1. Both address and assay oligonucleotide sequences that can be attached to beads in these schemes.

Figure 4 shows the synthetic approach to sequential oligonucleotide attachment, as demonstrated in the potential scheme in Figure 1 group B.

Coupling of Orthogonally Protected Lysine to Silanized Beads. Aminopropyl beads (100 mg) were suspended in DMF

(1 mL), followed by addition of 35 μL of DIEA (0.2 mmol). The suspension was sonicated and *N*-α-Fmoc-*N*-ϵ-1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)-3-methylbutyl-L-lysine (53 mg,0.1 mmol) was added followed by addition of 52 mg (0.1 mmol) of PyBOP (benzotriazole-1-yl-oxy-tris-pyrrolidinophosphoniumhexa fluoro phosphate). The beads were shaken overnight at room temperature. They were then washed 6 times with 1 mL of DMF.

Amine Deprotection (from Dde(iv), (4,4-Dimethyl-2,6-dioxocyclohexylidene)-3-methylbutyl). Beads coupled to the modified lysine (100 mg) were suspended in a solution of 2% hydrazine in DMF (1 mL) and shaken for 30 min at room temperature. They were then washed 6 times with 1 mL of DMF.

Figure 5 shows alternative approaches to the activation of the second amino group and immobilization of second oligonucleotide.

Coupling to Succinimidyl Hydraziniumnicotinate Hydrochloride (SHNH). Amino beads (100 mg) were suspended in DMF (1 mL), followed by addition of SHNH (28.6 mg, 1 mmol) and 48 μL of DMAP solution (dimethyl amino pyridine in DMF 0.5 M). The beads were shaken overnight at room temperature and then washed 3 times with DMF and 3 times with 0.1 M sodium citrate buffer, pH 5.0.

Coupling of amino beads to PDITC (1,4-phenylene diisothiocyanate), 4-nitrophenyl chloroformate, 4-carboxybenzaldehyde,

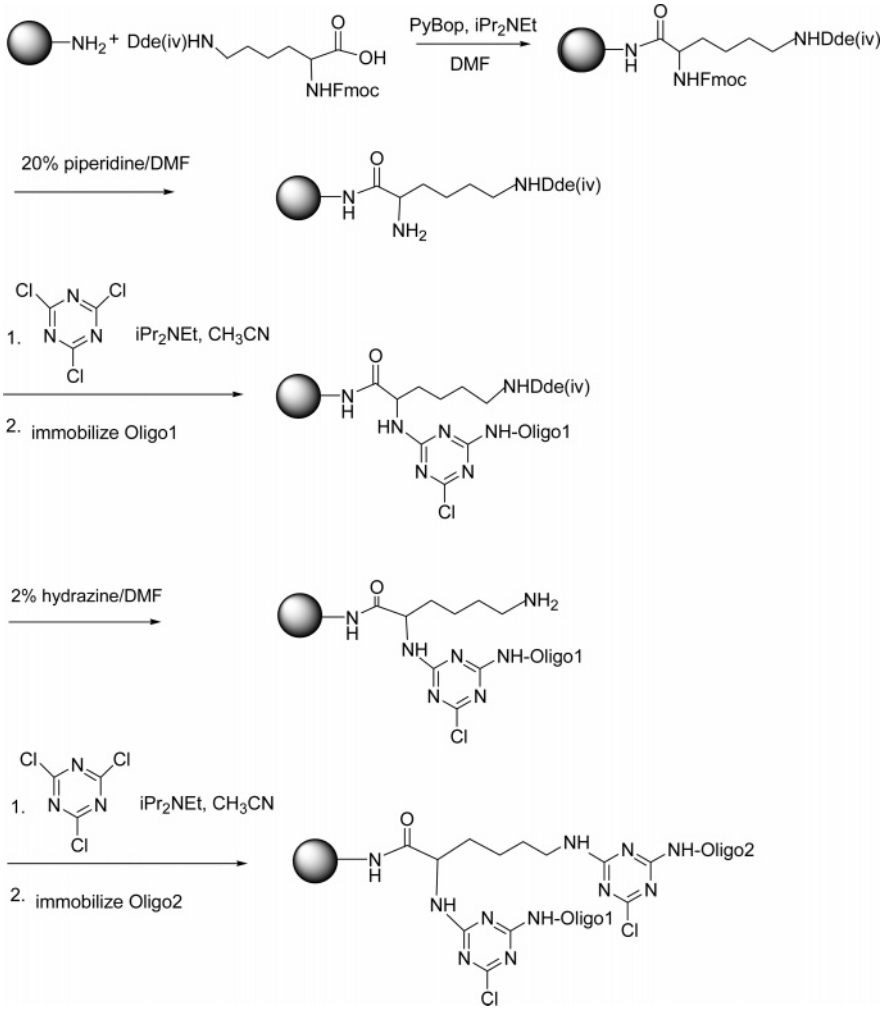

Figure 4. Detailed chemical modifications of amino silanized beads leading to two oligonucleotide attachment, as depicted in Figure 1, group B.

and succinimidyl 4-formylbenzoate (SFB) has been previously described **(*8*)**, see Figure 5A−D.

Oligo Immobilization. *Amino Oligonucleotide Immobilization.* A 5′-amino oligonucleotide (100 nmol in 0.05 M sodium borate buffer, pH 8.5) was added to 2 M sodium chloride solution (100 μL). The oligonucleotide solution was added to cyanuric chloride activated beads (25 mg beads in 100 μL of 0.05 M sodium borate buffer, pH 8.5). The beads were shaken overnight and then washed 3 times with OmniPur water.

5′-Amino oligonucleotides were synthesized in house using the standard coupling conditions and 5′-amino modifier phosphoramidite commercially available from Glen Research, Sterling, VA.

Aldehyde Oligonucleotide Immobilization. A 5′-aldehyde oligonucleotide (100 nmol in 0.1 M sodium citrate/citric acid, pH 5.0) was added to 2 M sodium chloride solution (100 μL). The oligonucleotide solution was added to hydrazine-activated beads (25 mg of beads in 100 μL of 0.1 M sodium citrate/citric acid, pH 5.0). The beads were shaken overnight and then washed 3 times with OmniPur water.

5′-Aldehyde oligonucleotides were synthesized in house using the standard coupling conditions and 5′-aldehyde phosphoramidite commercially available from Solulink, San Diego, CA.

Complementary Oligonucleotide (Target) Hybridization. Hybridization of complementary oligo (target) to beads containing immobilized probes was carried out in solution, and a fluorescence activated cell sorter (FACS) was used to measure hybridization intensity.

Hybridization was done in solution as follows. About 1 mg of probe-immobilized beads was suspended in 30 μL of hybe buffer (0.1 M potassium phosphate, 1 M sodium chloride, 0.1% Tween-20, and 5% ethanol, pH 7.6), followed by addition of 15−20 μL of ∼1 mM target (in 0.05 M borate buffer, pH 8.5) and then shaken for 2 h. The beads were washed 2 times with hybe buffer to remove excess target oligonucleotides. For the release of target from the beads, the beads were incubated with 50 μL of 0.1 M sodium hydroxide solution for 10 min.

Detection of Hybridization. Hybridization in solution was measured with FACS (Becton Dickinson Biosciences). We used constant laser power of 15 mW and a photomultiplier tube (PMT) gain of 659 for all measurements. Following hybridization in solution (described in the previous section), a small amount of beads was added to 0.2 mL of FACS flow buffer (in a FACS-compatible test tube), and average fluorescence intensity was recorded for at least 10 000 beads.

RESULTS AND DISCUSSION

Addressing Beads with Multiple Oligonucleotides. Various schemes, shown in Figure 1, were considered in an attempt to generate millions of bead types using a combinatorial approach. These schemes can be divided into 3 main groups: group A (where two orthogonally protected glycines are coupled to the beads followed by sequential oligonucleotide immobilization), group B (where one orthogonally protected lysine is coupled to the beads followed by sequential oligonucleotide immobilization), and group C (where one long oligonucleotide, which includes both address sequences, is immobilized).

The scalability of these schemes was evaluated based on the required number of oligonucleotides, the number of decoder

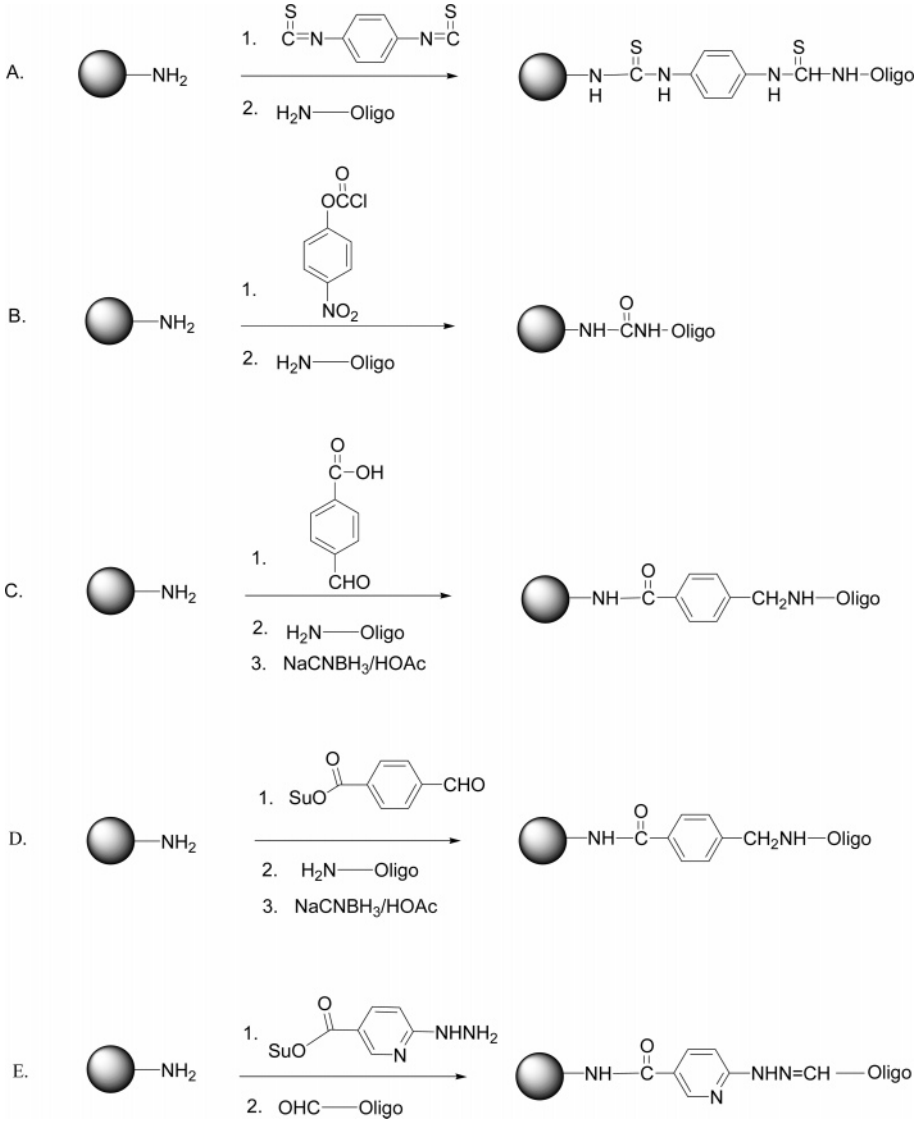

Figure 5. Alternative activation/immobilization schemes for second oligonucleotide attachment.

oligonucleotides, and the number of split and pool synthesis steps that would be necessary to implement a particular chemistry in an automated, high-throughput environment.

Group C schemes, while this study was carried out, involving one very long (100-mer) oligonucleotide, were not considered because low synthesis yields would be expected. Group A type schemes were evaluated first. The synthesis, shown in Figure 2, involved coupling of two orthogonally protected glycines to aminopropyl (silanized) beads as described in Experimental Procedures. The coupling was followed by deprotection of the *t*-Boc protected glycine and its activation with cyanuric chloride. The activation was followed by immobilization of an amino modified oligonucleo-tide. Following immobilization, the Fmoc protected glycine was deprotected with 20% piperidine solution, and the amine was activated with cyanuric chloride. Finally, another amino modified oligonucleotide (containing assay specific sequence) was immobilized as well.

Group A schemes, however, have an inherent problem. Since two orthogonally protected glycines are coupled to the beads simultaneously, it is hard to control the amount of each glycine that will couple to the amino beads. As a result, it is difficult to control the ratio of immobilized oligonucleotides, which can impact the decoding and/or assay robustness. In schemes from group B the aforementioned problem is avoided as only one orthogonally protected amino acid is coupled to the amino beads. The potential schemes for group B are shown in Figure 3.

The synthesis of group B schemes, shown in Figure 4, involved coupling of a lysine, with two orthogonally protected amino groups, to aminopropyl (silanized) beads as described in Experimental Procedures. The coupling was followed by the deprotection of the Fmoc protected amino group and its activation with cyanuric chloride. Immobilization of a single amino modified address oligonucleotide or an equimolar mix of two amino modified address oligonucleotides followed the activation. Then the second protecting group (Dde(iv)) was removed with 2% hydrazine in DMF solution and the second amine was again activated with cyanuric chloride. Finally amino modified oligonucleotide (containing assay specific sequence) was immobilized (as described in Experimental Procedures).

Variation in Signal Intensities of Oligonucleotides. After the first amino group was activated with cyanuric chloride (see Figure 4), an equimolar mix of oligonucleotide 1 and oligonucleotide 2 was immobilized onto the bead (Figure 3b). In spite of using only HPLC purified oligos, hybridization intensities for the various oligonucleotides varied sometimes by more than 10-fold. Even for the same oligonucleotides, signal intensity varied up to 2−3-fold depending on the neighboring sequence (i.e. the other oligonucleotide that was immobilized with it).

Although not as pronounced, these variations in hybridization signals were observed even on beads with a single oligonucleotide immobilized on them. To understand the reasons behind the variation in hybridization signals we first looked at beads

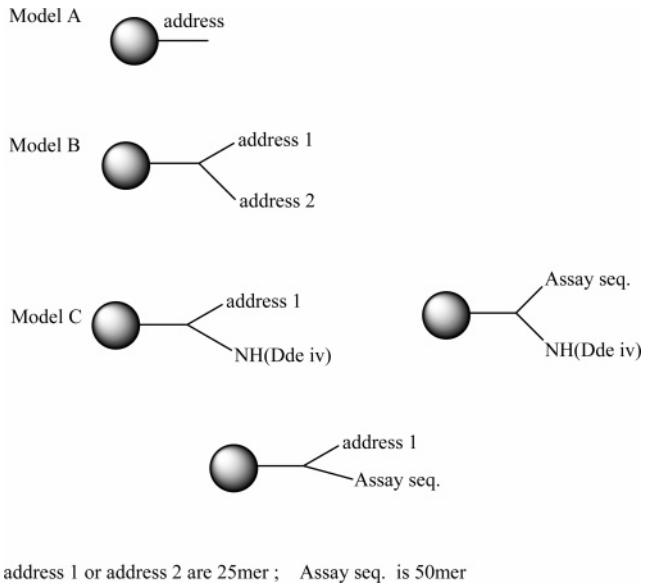

Figure 6. Bead models used for proof of various principles.

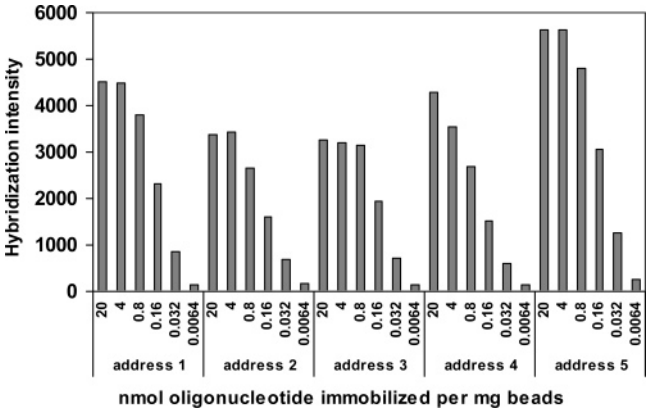
Chart 1. Effect of Titration of Oligonucleotide Amount on Beads for 5 Random Address Sequences (25mers)



immobilized with only a single type of oligonucleotide (Figure 6, model A). Since we use excess oligo during the immobilization process (4 nmol of oligo per 1 mg of beads), we believe that the amount of oligo immobilized is consistent regardless of the sequence involved. To demonstrate the fact that a consistent amount of oligonucleotide is immobilized, the beads were immobilized at six different oligonucleotide concentrations ranging from 20 to 0.0064 nmol per mg of beads. These titration results for five address sequences are shown in Chart 1.

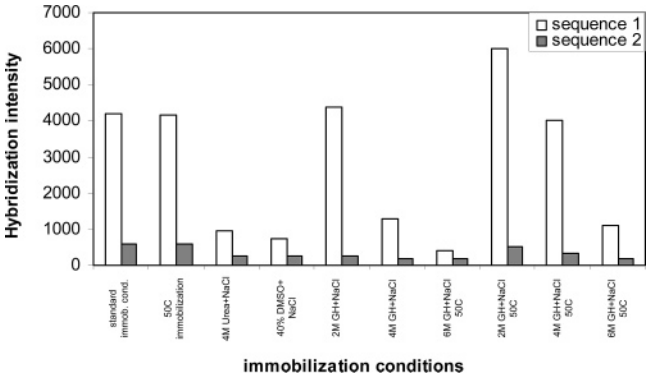
Another possible reason for variation in hybridization intensities could be variation in hybridization efficiency. This can be a result of sequence dependence or a result of variation in material quality.

To address variation in material quality, several oligonucleotides from different synthesis batches were immobilized on beads (single oligonucleotide immobilization) and then hybridized to the same target labeled oligos. The intensity of hybridization signals was measured using FACS.

Results show that there is similarity between hybridization intensities of the same sequences from different synthesis batches. This observation suggests that the major contribution to the variation in hybridization intensities comes from sequence variation, although material quality also contributes somewhat.

When two oligonucleotides are immobilized simultaneously (as in Figure 3b), the picture becomes even more complex, since oligonucleotide interactions can now come into play. Since immobilization kinetics can be different for different sequences,

Chart 2. Effect of Various Immobilization Conditions (Known To Disrupt Secondary Structure) on Hybridization Intensities of Two Oligonucleotides Immobilized Simultaneously[a]



[a] Standard immobilization conditions (described in detail in Experimental Procedures) include 2 M NaCl and room temperature (a). To disrupt secondary structure immobilization was done at 50 °C (b), urea was added to a final concentration of 4 M (c), dimethyl sulfoxide (DMSO) was added to a final concentration of 40% (d), guanidinium hydrochloride (GH) was added to a final concentration of 2 M (e), 4 M (f), and 6 M (g). Also guanidinium hydrochloride was added to a final concentration of 2 M (h), 4 M (i), or 6 M (j) and immobilization was done at 50 °C.

we could have unequal amounts of the two oligonucleotides immobilized on the beads, which could result in very different hybridization intensities. To test whether the source of variation in the hybridization signals of oligonucleotides (immobilized simultaneously) is a result of unequal amounts of oligonucleotides immobilized on the beads, we attempted to equalize their immobilization kinetics by disrupting their secondary structure.

The immobilization procedure was carried out both under the usual conditions (see Experimental Procedures) and under conditions which are known to disrupt secondary structures, such as high temperatures (50 °C) and high concentrations of either urea (4 M) or guanidinium hydrochloride (6 M).

Chart 2 shows that, despite disruption of secondary structure, sequence 1 continues to yield much higher hybridization intensities than sequence 2. These observations suggest that, since equal amounts of the two oligonucleotides are immobilized, the variation in hybridization signals is a result of differences in hybridization efficiency for different sequences. It is still unclear why the variation in hybridization signals becomes more pronounced when two oligonucleotides are immobilized simultaneously on the bead.

We concluded that, if the scheme in Figure 3b were chosen, all oligonucleotides would have to be prescreened prior to use to select pairs with similar hybridization signals after immobilization. Since this problem is mainly sequence related, the screening would have to be done only once. Another way to avoid the problem would be to use the scheme in Figure 3a or the scheme in Figure 3c where immobilizations of the different oligonucleotides are done sequentially.

Immobilization of Second Oligonucleotide (Genespecific Assay Sequence). After either one or two oligonucleotides were immobilized on the first amino group (Figure 3a−c), the second amino group was then activated prior to the immobilization of the second oligonucleotide. As shown in Figure 4, the amine was deprotected with 2% hydrazine/DMF solution and then activated with cyanuric chloride. Following activation, a severe drop in the hybridization intensity of the first oligonucleotide(s) was observed. Apparently, cyanuric chloride damages the oligonucleotides already present on the beads and leaves them unable to hybridize well.

Table 1. Hybridization Intensities of First and Second Sequences Resulting from the Different Activation/Attachment Chemistries for the Second Sequence

1st Sequence: S9 5′ (NH_2) TTTGATGTCCCATTCCCCACGCGTT					
2nd Sequence: S13 5′ (NH_2 or CHO) TTTGATCGTAGCCGGTATGCGACGG					
immobilization chemistries for 2nd attachment	5A	5B	5C	5D	5E

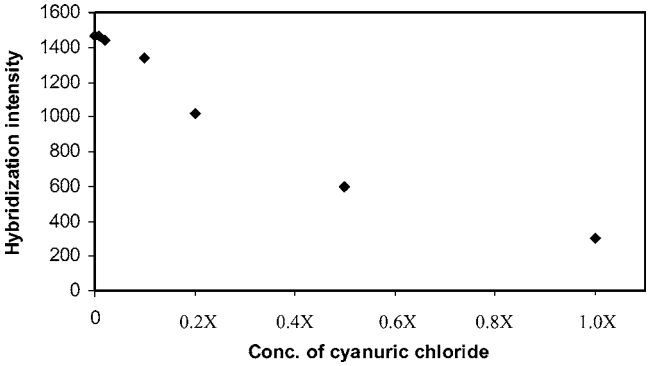
hybridization intensity of the 2nd sequence	1400	108	800	820	4800

Chart 3. Effect of Cyanuric Chloride Concentration on the Ability of Capture Probes To Hybridize Their Complement (Target)[a]



[a] During this experiment oligo-immobilized beads were shaken with cyanuric chloride for 2 h. 1X is the concentration normally used to activate our beads with cyanuric chloride, prior to oligonucleotide attachment.

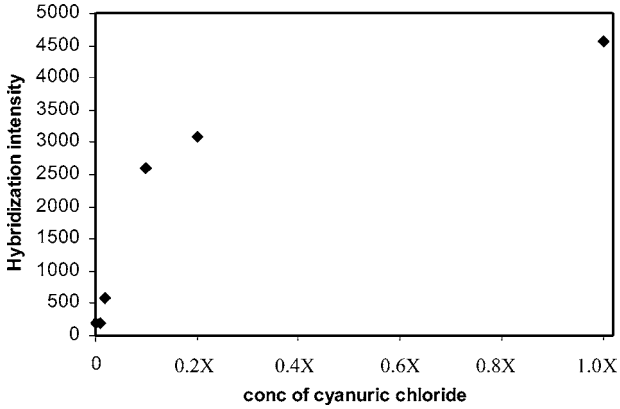
The effect of cyanuric chloride concentration on the ability of capture probes to hybridize with their complement (target) was examined on a model bead (Figure 6, model A). The amount of cyanuric chloride that was added to oligo-immobilized beads was titrated as shown in Chart 3 (the beads were shaken with various amounts of cyanuric chloride for 2 h to emulate the conditions of an activation reaction).

Titration results show that, when the standard amount of cyanuric chloride (1X = 0.05 mmol) is shaken with oligonucleotide-immobilized beads for 2 h, up to a 5-fold drop in hybridization signal results (relative to beads that are not treated with cyanuric chloride). We then examined the effect of reducing cyanuric chloride concentration on the hybridization signal of oligonucleotides being immobilized. Chart 4 shows that reducing the amount of cyanuric chloride will decrease the hybridization signal of the oligonucleotide that is being immobilized.

This model study suggests that, if we use our standard cyanuric chloride concentration for the activation of the second amine group, up to 80% loss in hybridization intensity may be observed for the first oligonucleotides attached. If the amount of cyanuric chloride is reduced for the activation of the second amine group, there will be loss of hybridization intensity for the second oligonucleotide immobilized. Several attempts to optimize the amount of cyanuric chloride to be used during second amine activation proved unsuccessful. To prevent the drop in hybridization intensities of the first address oligos, new activation schemes were considered for the second amine. In all cases we examined the effect of a particular activation reaction on the hybridization intensities of the first oligonucleotide as well as the second oligonucleotide.

Based on results from our previous paper (*8*), where various amino group activation (and oligonucleotide immobilization) schemes were tested, the reaction schemes shown in Figure 5 were considered.

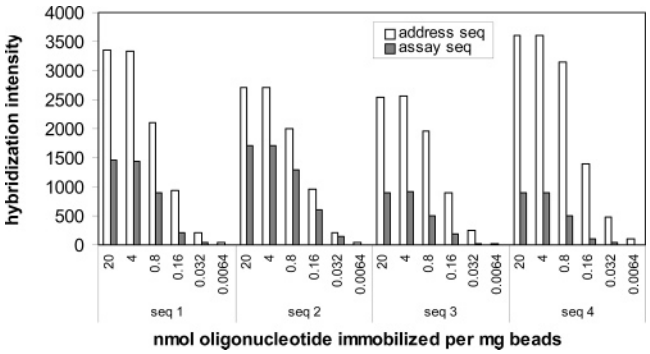
Chart 4. Effect of Cyanuric Chloride Concentration (during Activation of Amino Beads) on Oligonucleotide Immobilization and Consequently Hybridization Intensities of These Oligonucleotides



Model beads with two address sequences (Figure 6, model B) were synthesized, with the second amine group activated (and second oligonucleotide immobilized) according to the five different schemes shown in Figure 5. Table 1 summarizes hybridization intensities for both the first and second address sequences, for all of the schemes in Figure 5. The most promising scheme seems to be that in Figure 5E, where the amine was coupled to an activated ester hydrazine and a hydrazone bond was formed with the aldehyde-modified oligonucleotide. We observed very little signal loss for the first oligonucleotide and very good intensities for the second oligonucleotide.

Optimization of Capture Probe Loading. In our previous paper (*8*) we first optimized oligo loading (using 5′ amino labeled and 3′ Fmoc labeled oligos) and then measured the hybridization efficiency for single attachment beads. After coupling the beads to the modified lysine (see Figure 4) we have a different number of amino sites available for activation/immobilization and at a different proximity. As a result it is important to optimize the amount of oligo that we need to immobilize on these double-attachment beads in order to obtain the highest possible hybridization signals. In these experiments maximal hybridization efficiencies or oligo loading was not investigated; instead, when choosing the optimal oligo concentration for immobilization, we were more interested in hybridization intensities (functional results). Titration of oligonucleotide concentration during immobilization was done for several model beads. The titration was accomplished for beads with address oligonucleotides (25mers), beads with assay sequences (50mers), and beads with both oligonucleotides immobilized together on the two attachment beads (see Figure 6, model C). Chart 5 shows that maximal hybridization intensities were observed in the same range of oligonucleotide concentration (1−4 nmol of oligonucleotide per 1 mg of beads) regardless of oligonucleotide length. Similarly, maximal hybridization intensi-

Chart 5. Effect of Titration of Oligonucleotide Amount on Two Attachment Beads Shown in Figure 6 Model C, for 4 Random Address Sequences (25mers) and 4 Random Assay Sequences (50mers)



ties were observed in the same range of oligonucleotide concentration when both oligonucleotides were immobilized on the bead (results not shown).

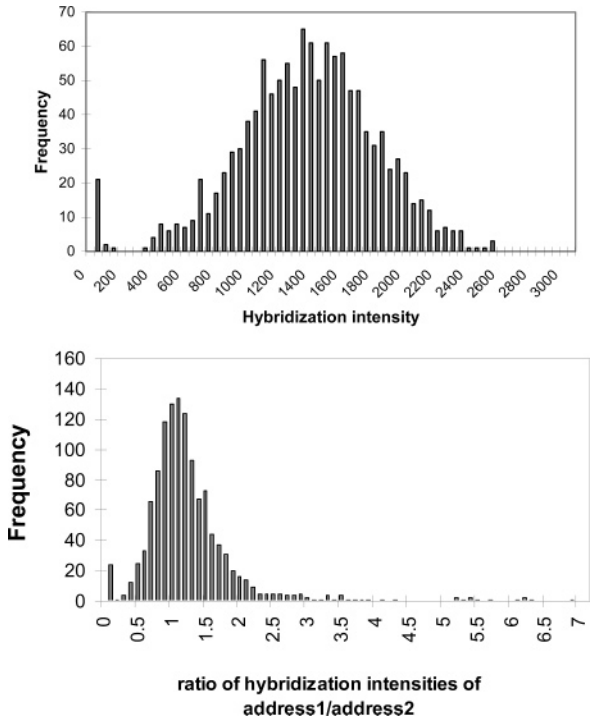
Scale-Up to Over 1000 Bead Types. In order to test the scalability of our schemes (Figure 3a,b, group B), we prepared over 1000 bead types (using each scheme). In each of these schemes two address oligos were used, allowing us to create over 1000 bead types with a mere 60−70 address oligonucleotides.

Since the number of address oligonucleotides required is two times the square root of the number of unique beads, to create 1225 bead types requires only 70 address sequences. These address sequences were chosen out of 1100 random address sequences following a quick screening process where 4−5 address sequences were immobilized on a bead simultaneously, and 70 sequences that give the highest as well as similar hybridization intensities were then chosen. The address sequences were divided into two groups (address sequence 1 and address sequence 2) of 35 oligonucleotides each. Initially synthesis steps described in Figure 4 were followed; then after the first amine activation the beads were distributed into thirteen 96 well plates and to each well an equimolar mix of address sequence 1 and address sequence 2 (all possible combinations) was added creating 1225 unique bead types (immobilization is described in Experimental Procedures). The immobilization was followed by deprotection of the second amine (see Figure 4). The beads were then hybridized to the complementary FAM labeled targets one at a time (either complement to address sequence 1 or to address sequence 2), and hybridization intensities were measured on FACS. Distribution of the hybridization intensities is shown in Chart 6.

Chart 6 shows that hybridization intensities for the various bead types range from 400 to 2400 counts, and the ratio of hybridization intensities of address sequence 1 to address sequence 2 is around one. These hybridization intensities appear to be sufficient for a robust decoding. The main drawback of this model is the prescreening that must be done for the address oligonucleotides due to the interactions that were observed between oligonucleotides (causing extreme variations in hybridization intensities) when two or more were immobilized simultaneously.

Similarly, the scale-up for the scheme in Figure 3a was done using 64 address sequences creating 1024 unique bead types. The scale-up for the scheme in Figure 3a was done using a model for the scheme to demonstrate feasibility of scale-up (see Figure 6, model B). The address sequences were divided into two groups (address sequence 1 and address sequence 2) of 32 oligonucleotides each. Initially synthesis steps described in Figure 4 were followed; then after the first amine activation the beads were distributed into a 96 well plate, and one of the

Chart 6. Distribution of Hybridization Intensities for 1225 Two Attachment Beads Hybridized to Complement of Address 1



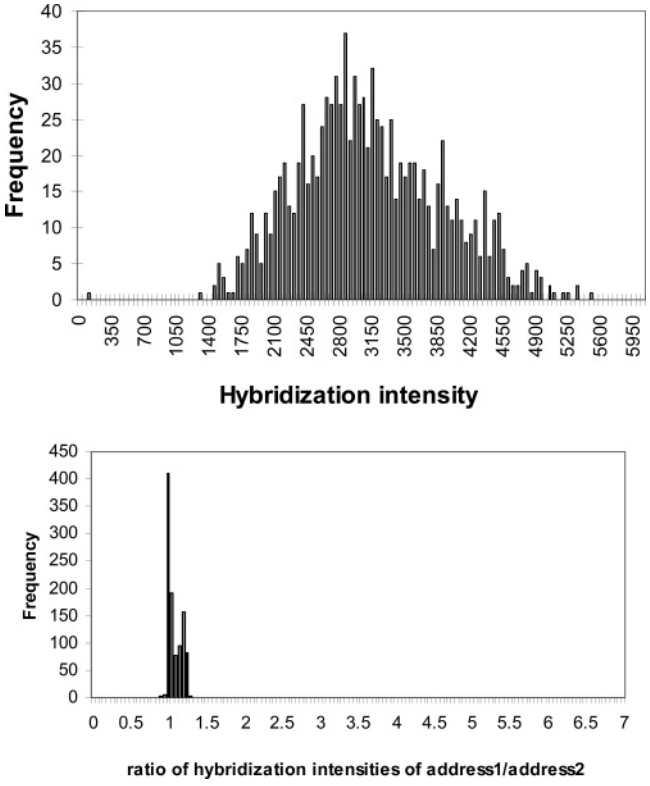
oligonucleotides from the first group (address sequence 1) was added to each well (immobilization is described in Experimental Procedures). The second amine was then deprotected and coupled to SHNH (see Figure 5 scheme E). Finally, beads from each well were distributed into 32 wells and immobilized with each of the 32 oligonucleotides from the second group (address sequence 2). The beads were then hybridized to the complementary FAM labeled targets one at a time (complement either to address sequence 1 or to address sequence 2), and hybridization intensities were measured on FACS. Distribution of the hybridization intensities is shown in Chart 7.

Chart 7 shows that hybridization intensities for the various bead types range from 1400 to 5000 counts, and the ratio of hybridization intensities of address sequence 1 to address sequence 2 is around one. The hybridization intensities are quite high and are more than sufficient for robust decoding. Even more importantly the address sequences were chosen completely at random yet hybridization intensities were fairly similar. We believe this is because the address sequences are immobilized separately and therefore there is no interaction between them during immobilization (see section about variation in signal intensities of oligonucleotides). One of our concerns was that there were reactive sites remaining after immobilization of oligo1; in such a case, oligo2 could immobilize on these reactive sites. However, the observation that the ratio of hybridization intensities of address sequence 1 to address sequence 2 is around one suggests that, if this type of immobilization is taking place, it is minimal; otherwise we would expect this ratio to be much less than one.

CONCLUSIONS

We evaluated several schemes for attaching two oligonucleotides on one bead. The schemes fall into 3 main groups. In the first group the oligonucleotides are sequentially immobilized following a simultaneous coupling (to the beads) of two orthogonally protected glycines. In the second group the oligonucleotides are sequentially immobilized following coupling of the beads to orthogonally protected lysine, and in the third group the oligonucleotides are synthesized in one long

Chart 7. Distribution of Hybridization Intensities for 1024 Two Attachment Beads Hybridized to Complement of Address 1



sequence and immobilized as one oligonucleotide. After schemes from group A and group C were rejected for various reasons (see Results and Discussion), we evaluated schemes from group B (shown in Figure 3). We found that, if two oligonucleotides are immobilized simultaneously (as in Figure 3b), they interact during immobilization and as a result their hybridization intensities can be vastly different. We also found that, in Figure 3a where the address sequences are immobilized sequentially, the differences in hybridization intensities are less pronounced, which allows us to avoid prescreening of the address sequences.

We also found that cyanuric chloride damages oligonucleotides and therefore activation of the second amine required a different chemistry. After testing five different approaches for amine activation and oligonucleotide immobilization, we showed that the best method involves amine coupling to an activated ester hydrazine and immobilization of an aldehyde-modified oligonucleotide.

Loading of oligonucleotides on beads was shown to be independent of oligonucleotide length and independent of whether one oligonucleotide or two (through lysine coupling) were immobilized.

Finally, in order to test the scalability of our schemes (Figure 3a,b) we prepared over 1000 bead types (using a model of each scheme). In each of these models two address oligos were used, allowing us to create over 1000 bead types with a mere 60−70 address oligonucleotides. We found that both approaches were successful. Hybridization intensities for all bead types were similar, and the ratio of hybridization intensities of address sequence 1 to address sequence 2 was around one. The hybridization intensities were quite high and were more than sufficient for robust decoding. The scheme in Figure 3a, however, has an advantage over the scheme in Figure 3b because the address sequences are immobilized separately and therefore there is no competition during immobilization so the address sequences can be chosen at random. In contrast, the scheme in Figure 3b requires prescreening of address sequences.

ACKNOWLEDGMENT

We would like to thank Dr. Semyon Kruglyak and Illumina's Bioinformatics group for all their help with image registration and analysis, and Dr. Igor Kozlov and the chemistry group for support and discussion.

TECHNICAL NOTES

Targeted Liposomes: Convenient Coupling of Ligands to Preformed Vesicles Using "Click Chemistry"

Fatouma Said Hassane, Benoît Frisch, and Francis Schuber*

Institut Gilbert Laustriat, UMR 7175 CNRS/Université Louis Pasteur (Strasbourg I), Département de Chimie Bioorganique, Faculté de Pharmacie, 74 route du Rhin, 67400 Illkirch, France. Received October 24, 2005; Revised Manuscript Received February 28, 2006

An efficient and convenient chemoselective conjugation method based on "click chemistry" was developed for coupling ligands to the surface of preformed liposomes. It can be performed under mild conditions in aqueous buffers; the use of a water soluble Cu(I) chelator, such as bathophenanthrolinedisulfonate, was essential to obtain good yields in reasonable reaction times. A model reaction was achieved in which, in a single step, an unprotected α-D-mannosyl derivative carrying a spacer arm functionalized with an azide group was conjugated to the surface of vesicles presenting a synthetic lipid carrying a terminal alkyne function. When liposomes composed of saturated phospholipids were used, the reaction conditions developed in the present work did not damage the membranes as measured by the absence of leakage of entrapped 5,6-carboxyfluorescein. Moreover, as assessed by agglutination experiments using concanavalin A, the mannose residues were perfectly accessible on the surface of the targeted vesicles.

INTRODUCTION

Liposomes, which are self-closed vesicular structures composed of (phospho)lipid bilayers, have attracted considerable interest because of their potential applications in various fields such as membrane models, diagnostics, and drug/gene delivery (*1*). Several liposomal formulations have reached clinical application during this past decade especially for the treatment of cancer and opportunistic diseases (*2*). The discovery of "stealth liposomes"—liposomes coated with, e.g., poly(ethylene glycol) (PEG) chains characterized by much increased circulation times and modified biodistributions—provoked a new impetus for the design of targeted bioactive molecule delivery systems. Such liposomes carry ligands that provide specific interactions with receptors/antigens expressed at the surface of target cells. The design of targeted liposomes is heavily dependent on the development of well-controlled bioconjugation reactions (for reviews see refs *3*−*6*) which in most cases involve the coupling of ligands to the surface of preformed vesicles that carry functionalized (phospho)lipid anchors. Among the many conjugation methods available, the most popular ones involve the reaction of thiol-containing ligands with anchors carrying thiol-reactive functions such as maleimide, bromoacetyl, or 2-pyridyldithio linkages, generating thioether or disulfide bonds (*7*−*9*). More recently peptide ligands were also coupled to the surface of liposomes via hydrazone and α-oxo hydrazone linkages (*10*).

Chemically controlled conjugation between preformed liposomes and ligands should ideally combine several features such as mild reaction conditions in aqueous media, high yields, and chemoselectivity. In search of new coupling strategies we have explored the application of "click chemistry" (*11*, *12*) to this field; it involves a copper(I)-catalyzed Huisgen 1,3-dipolar cycloaddition reaction of azides and alkynes yielding 1,4-disubstituted 1,2,3-triazole linked conjugates (*13*, *14*). This reaction is particularly appealing because it is highly regiospecific, chemoselective, and tolerant to a wide variety of other functional groups. Moreover the click reaction, which can also be performed almost quantitatively under mild conditions in aqueous buffers, was recently extended to bioconjugation applications (see, e.g., refs *15*−*23*). Herein we report the successful application of click chemistry to the conjugation, in a single step, of an unprotected α-D-mannosyl derivative carrying a spacer arm functionalized with an azide group, to the surface of liposomes that incorporate a synthetic lipid carrying a terminal triple bond. Reaction conditions were optimized for this model reaction, and mannosylated vesicles were obtained in excellent yield. As assessed by agglutination experiments with the lectin concanavalin A (Con A), the mannose residues were perfectly accessible on the surface of the vesicles and could engage into multivalent interactions.

EXPERIMENTAL PROCEDURES

General. Reagent-grade solvents were used without further purification. The phospholipids 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) and 1,2-dipalmitoyl-*rac*-glycero-3-phospho-*rac*-(1-glycerol) sodium salt (DPPG) were purchased from Sigma-Aldrich (Saint-Quentin-Fallavier, France), and their purity (over 99%) was assessed by TLC. Cholesterol was recrystallized in methanol. The amine **5** (Scheme 2), that contains 12 ± 2 ethyloxide units, was a kind gift from Dr. L. Lebeau. The lectin concanavalin A, type VI (Jack Bean), was obtained from Sigma. L-Ascorbic acid sodium salt and bathophenanthrolinedisulfonic acid disodium salt are from Acros-Organics (Noisy-le-Grand, France) and Lancaster-Synthesis (Strasbourg-Bischheim, France), respectively. Silica gel 60 F

254 plates for thin-layer chromatography (TLC) were purchased from Merck (Darmstadt, Germany). Column chromatographic separations were carried out as flash chromatography using silica gel (Merck) with a particle size of 0.040−0.063 mm. ^{1}H and ^{13}C NMR were recorded on Bruker Avance 200 (200 MHz) and DPX-300 (300 MHz) spectrometers. Chemical shifts are expressed as parts per million using $CHCl_3$ ($\delta = 7.27$ ppm for ^{1}H and 77.7 ppm for ^{13}C) or CH_3OH ($\delta = 3.35$ ppm for ^{1}H and 49.0 ppm for ^{13}C) as the internal standard ($\delta = 0.0$ ppm). Mass spectra (ES-MS) were recorded on a ESI/TOF Mariner mass spectrometer by electrospray.

4-[1-(2-(2-(2-(2-Hydroxyethoxy)ethoxy)ethoxy)ethyl)-1*H*-1,2,3-triazol-4-yl]butanoic Acid (3). To 5-hexynoic acid (Lancaster-Synthesis) (21 mg, 0.187 mmol) in 200 μL of *t*-BuOH were added 200 μL of freshly prepared solutions of $CuSO_4 \cdot 5H_2O$ (1 mg, 4 μmol) and sodium ascorbate (3.6 mg, 18.2 μmol) in water. Compound **1** (*24*) (40 mg, 0.182 mmol) was then added dissolved in 200 μL of water. The reaction mixture was stirred under argon at room temperature for 25 h. The solvent was then evaporated to dryness, and the product **3** was obtained without any purification. The yield was estimated at 91% according to NMR analysis. R_f: 0.51 (CH_2Cl_2:MeOH 19:1). ^{1}H NMR (200 MHz, $CDCl_3$:CD_3OD, 1:2): δ 7.56 (s, 1H, C*H* triazole); 4.52−4.47 (t, $J = 4.9$ Hz, 2H, CH_2N); 3.85−3.80 (t, $J = 4.9$ Hz, 2H, CH_2CH$_2$N); 3.73−3.57 (m, 10H, CH_2OCH_2CH$_2$OCH_2CH$_2$OH); 3.40−3.06 (t, $J = 5.0$ Hz, 2H, CH_2OCH$_2$CH$_2$N); 2.81−2.74 (t, $J = 7.2$ Hz, 2H, CH_2CCH); 2.39−2.32 (t, $J = 7.1$ Hz, 2H, CH_2-COOH); 2.06−1.91 (m, 2H, CH_2CH$_2$COOH). ES-MS *m*/*z*: 332.2656 ([M + H]$^+$), calcd 331.1743 for $C_{14}H_{25}N_3O_6$.

N-[(2-(2-Azidoethoxy)ethoxy$_{10}$)ethyl-(1-deoxy-2,3,4,6-tetra-*O*-acetyl-thio-α-D-mannopyranosyl)]propionamide (6). To a solution of **4** (*25*) (149 mg, 0.342 mmol) in 3 mL of CH_2Cl_2 were added DCC (85 mg, 0.41 mmol) and NHS (47 mg, 0.41 mmol). After 45 min of stirring at room temperature under argon, the amine **5** (*26*) (210 mg, 0.342 mole) in 1 mL of CH_2Cl_2 containing DIEA (47.5 μL, 0.273 mol) was added to the reaction mixture. After 18 h, 20 μL of DIEA and 0.2 equiv of **5** were again added. The stirring was continued during 48 h. The precipitate was then removed by filtration, and the organic phase was washed with 2 × 10 mL of a citric acid solution (5%, w/v) followed by water. After passage over $MgSO_4$, the solvent was evaporated to dryness. The reaction product **6** (129 mg; yield 30%, yellow oil) was obtained after purification by chromatography on silica gel eluted with CH_2Cl_2:MeOH 30:1. R_f: 0.42 (CH_2Cl_2:MeOH 9:1). ^{1}H NMR (200 MHz, $CDCl_3$): δ 5.39−5.10 (m, 4H, 3 C*H* Man + 1 CHα); δ 5.39−5.10 (m, 4H, C*H* Man); 4.28−4.23 (m, 2H, CH_2 Man); 4.04−3.99 (m, 1H, C*H*-CH$_2$OH Man); 3.56−3.30 (m, 52H, CH_2NH, CH_2O−CH_2, CH_2CH$_2$NH, CH_2N$_3$); 2.88−2.81 (t, $J = 6.9$ Hz, 2H, CH_2S); 2.47−2.40 (t, $J = 7.04$ Hz, CH_2CH$_2$S); 2.08, 2.02, 1.97, 1.90 (s, 12H, CH_3CO). ^{13}C NMR (50 MHz, $CDCl_3$): δ 170.99 (*C*ONH); 170.13 (*C*OOCH$_3$); 83.03 (C_1); 71.37, 71.00, 70.68, 70.44 (CH$_2$O-*C*H$_2$, *C*H$_2$CH$_2$NH); 70.15 (C_2); 69.81 (C_5); 69.43 (C_3); 66.75 (C_4); 62.87 (C_6); 51.08 (*C*H$_2$N$_3$); 39.79 (*C*H$_2$NH); 36.56 (*C*H$_2$CO); 27.33 (*C*H$_2$S); 21.30 (*C*H$_3$OCO). ES-MS *m*/*z*: 1055.6430 ([M + Na$^+$]), calcd 1032,4672 for $C_{43}H_{76}N_4O_{22}S$.

***N*-[2-(2-Azidoethoxy)ethoxy$_{10}$)-ethyl(1-deoxy-1-thio-α-D-mannopyranosyl)]propionamide (7).** Compound **6** (100 mg, 0.097 mmol) was dissolved in 3 mL of MeOH, and K_2CO_3 (20 mg, 0.145 mmol) was then added with a few drops of water. The deprotection reaction was performed under argon at room temperature for 4 h. The reaction product **7** (84 mg, yield 100%) was obtained as a yellow oil after filtration to remove the salts and evaporation of the solvents. R_f: 0.30 (CH_2Cl_2:MeOH 8:2). ^{1}H NMR (200 MHz, CD_3OD): δ 5.26 (s, 1H, C*H*α); 3.92−3.87 (m, 2H, CH_2 Man); 3.67−3.32 (m, 55H, C*H* Man, CH_2-NH, CH_2OCH_2, CH_2CH$_2$NH, CH_2N$_3$); 3.02−2.86 (m, 2H, CH_2S); 2.64−2.48 (m, 2H, CH_2CH$_2$S). ^{13}C NMR (50 MHz, CD_3OD): δ 174.22 (*C*ONH); 87.48 (C_1); 75.04 (C_2); 73.63 (C_5); 73.21 (C_3); 70.79 (*C*H$_2$O-*C*H$_2$, *C*H$_2$CH$_2$NH,); 68.90 (C_4); 62.85 (C_6); 51.70 (*C*H$_2$N$_3$); 40.22 (*C*H$_2$NH); 37.34 (*C*H$_2$CH$_2$S); 28.82 (*C*H$_2$S). Liposome Preparation and Characterization. Small unilamellar vesicles (SUV) were prepared by sonication. Briefly, phospholipids (DPPC, DPPG) and cholesterol (70/20/50 molar ratio) dissolved in chloroform/methanol (9:1, v/v) were mixed in a round-bottom flask. For functionalized vesicles, the lipid anchor **8** dissolved in chloroform/methanol (9:1, v/v) was added at given concentrations (between 5 and 10 mol %). After solvent evaporation under high vacuum, the dried lipid film was hydrated by addition of 1 mL of HBS (10 mM HEPES, 145 mM NaCl, pH 6.5) to obtain a final concentration of 10 μmol of lipid/mL. The mixture was vortexed, and the resulting suspension was sonicated for 1 h at 60 °C, i.e., above the T_m of the lipids, using a 3 mm diameter probe sonicator (Vibra Cell, Sonics and Materials Inc., Danbury, CT). The liposome preparations were then centrifuged at 10000*g* during 10 min to remove the titanium particles originating from the probe. The size of the liposomes was determined by dynamic light scattering using a submicron particle analyzer (Coulter, Hialeah, FL) or a Zetamaster 3000 (Malvern Instrument, Orsay, France). The different vesicle preparations were homogeneous in size and exhibited an average diameter between 90 and 130 nm. The phospholipid content in liposomes was determined according to Rouser (*28*) with sodium phosphate as standard.

Azidomannose Coupling to Liposomes by Click Chemistry. Solutions containing 8 mM $CuSO_4 \cdot 5H_2O$ (solution A), 145 mM sodium ascorbate (solution B), and 28 mM bathophenanthrolinedisulfonic acid disodium salt (ligand **L**, Scheme 3) (solution C) were freshly prepared in 10 mM HEPES (pH 6.5) completed with NaCl to obtain an osmolarity of 300 mOsm. To a suspension of functionalized liposomes in 200 μL of HBS adjusted to a 1 mM concentration of anchor **8** (i.e., ~0.5 mM surface available alkyne group) were added solutions A and B (respectively 286 and 355 μL) followed by 164 μL of solution C. Following addition of 15 μL of a 13.9 mM solution of azidomannose **7** in water, the reaction mixture was gently stirred under argon at room temperature for 1−24 h. Alternatively, the ligand **L** was first added to the liposome suspensions, followed by the extratemporaneously made mixture of solution A and solution B and finally by azidomannose **7**. Control experiments were performed under the same conditions in the absence of the ligand **7**. After the conjugation step, the liposomes were purified by exclusion chromatography on a 1 × 18 cm Sephadex G-75 (Amersham Biosciences) column equilibrated in HBS.

Liposome Stability under Coupling Conditions. Liposomes were prepared as above in 10 mM Hepes buffer (pH 6.5) containing 100 mM NaCl and 40 mM 5,6-carboxyfluorescein. Nonencapsulated dye was eliminated by gel filtration (see above). The dye-loaded liposomal suspensions were treated as above for the click-chemistry coupling step. The leakage of 5,6-carboxyfluorescein was assessed by determining the fluorescence increase (λ_{ex} 490 nm; λ_{em} 520 nm) observed in the presence of excess detergent. To measure the total fluorescence intensity corresponding to 100% dye release, Triton X-100 (0.1% w/v final) was added to the vesicles. The percentage of dye release caused by the coupling conditions was calculated using the equation $(F - F_0) \times 100/(F_t - F_0)$, where F is the fluorescence intensity measured after exposing the vesicles to the coupling conditions and F_0 and F_t respectively are the intensities obtained before the coupling conditions and after Triton X-100 treatment (*29*). F_t values were corrected for dilutions caused by the Triton X-100 addition.

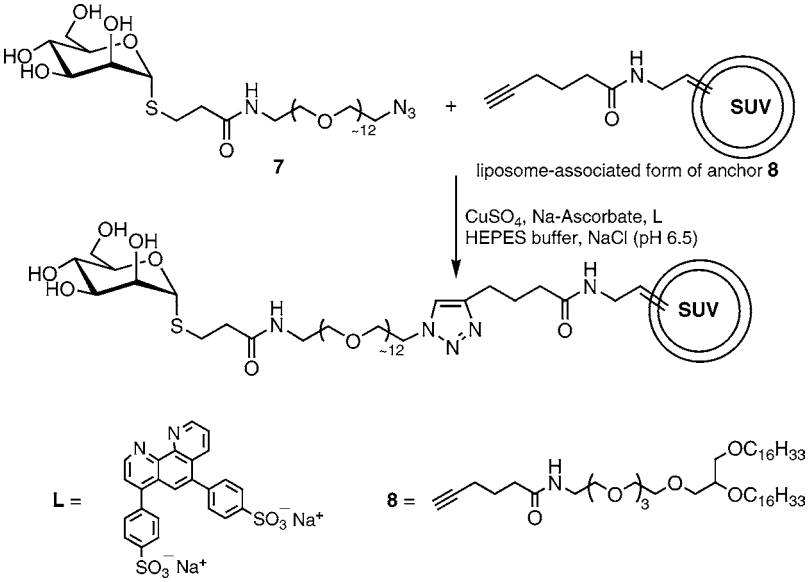
Lectin Binding Assay and Analytical Techniques. The lectin Con A (125 μg) was added to suspensions (1 mL final volume) of liposomes carrying mannose residues (60 nmol of lipids and ~3 nmol of surface coupled mannose residue) in HBS. The increase in turbidity was recorded at 360 nm at room temperature. Mannose coupled to the liposomes was quantified by the resorcinol−sulfuric acid method (*30*). The standard curve was established as follows: To a 12.2 × 100 mm glass tube containing 2−12 μg of reference mannose in 200 μL water were added successively 20 μL of 0.1% (w/v) Triton X-100, 200 μL of a 6 mg/mL aqueous solution of resorcinol, and 1 mL of 75% (v/v) H_2SO_4. The tubes were vortexed and covered with aluminum foil before heating in a boiling water bath for 12 min and then cooled to room temperature. The optical density was then recorded at 430 nm. Aliquots of conjugated liposomes (about 0.4 μmol of lipid) were first dried under vacuum using a Speed Vac (Savant Instrument Inc., Holbrook, NY). HBS (200 μL) was then added to the tubes and the mixtures, after vortex mixing, were treated as indicated above for the standards. Before optical density reading the samples were filtered through a 0.45 μm PTFE filter. The spectrophotometric determination of copper present in the final liposomal preparations was carried out using an atomic absorption spectrophotometer Varian SpectrAA 50B calibrated with a standard solution of $CuSO_4 \cdot 5H_2O$ (0.195−3.9 μg/mL). Samples (1 mL, about 0.65 μmol of phospholipids) were added to a solution of 5% nitric acid (5 mL) completed to 7 mL with water. The mixtures were vortexed and filtered on a 0.22-μm membrane (Millex, Millipore), and the copper content was determined.

RESULTS AND DISCUSSION

Chemistry. The synthesis of the azidomannose ligand **7** (Scheme 2), destined to be conjugated at the surface of preformed liposomes using a click reaction (Scheme 3), consisted in a coupling between the known mannosyl derivative **4** (*25*) and a PEG chain (n ~12) functionalized with amine and azide functions (compound **5**) synthesized as described previously (*26*). The carboxylic acid function of **7** was classically activated with dicyclohexylcarbodiimide and *N*-hydroxysuccinimide, at room temperature, in the presence of diisopropylethylamine. Compound **5** was then added, and the reaction was carried out for 48 h to give **6**, which, after quantitative deprotection of the acetyl groups with potassium carbonate in methanol, gave the ligand **7**. For the synthesis of the functionalized lipid anchor **8** (Scheme 3), 2-(2-(2-(2,3-bis(hexadecyloxy)propoxy)ethoxy)-ethoxy)ethoxyethanolamine was first synthesized in 7 steps starting from glycerol, triethylene glycol, and palmityl alcohol by an adaptation of a procedure we have described previously (*27*). The free amine of this compound was then reacted with the hydroxysuccinimide ester of 5-hexynoic acid, previously obtained by reaction of its acid function with *N*-hydroxysuccinimide in the presence of dicyclohexylcarbodiimide. The coupling reaction was carried out for 12 h, and the final product **8** was obtained with a satisfactory yield (58%).

Model Reaction. As a proof-of-concept we have explored the possibility to prepare mannosylated liposomes (Scheme 3) using click chemistry. Such liposomes, which have been prepared before (see, e.g., refs *27*, *31*−*34*), are easily characterized and serve as vehicles to target cells such as antigen presenting cells (*35*−*37*). For the conjugation step both alkyne and azide-terminated spacer arms between the mannose residue and the hydrophobic anchor associated with the liposomes can be envisaged. For that reason, in a first approach we have studied a model click reaction between a short PEG spacer functionalized with an azide (**1**, Scheme 1) and 5-hexynoic acid (**2**) catalyzed by copper(I) in solution. The reaction was performed in an aqueous solvent system with reagents that could be

Scheme 3. Coupling of the Ligand 7 to Preformed Liposomes That Incorporate the Alkyne Functionalized Anchor 8 by Click Chemistry in the Presence of the Cu(I) Ligand Bathophenanthrolinedisulfonate



extended, in principle, to the coupling of ligands to the surface of preformed vesicles. The procedure involving in situ generation of active Cu(I) catalyst via reduction of $CuSO_4$ by sodium ascorbate (*13*) proved highly satisfactory and reliable. When starting with an equimolar mixture of **1** and **2** the expected product **3** was obtained over 90% yield after 1 day of reaction, at room temperature, using a copper(II) (2 mol % with respect to reactants)/Na ascorbate (10 mol %) system. In the absence of copper catalyst no reaction was observed. The reaction mechanism of this "ligand-free" Cu(I) catalyzed process (see below), which involves the formation Cu-acetylide, has been outlined recently (*38*, *39*).

Conjugation of Mannose Residues to the Surface of Preformed Liposomes. To perform the coupling of unprotected α-D-mannosyl residues to the surface of preformed liposomes with the click reaction we have first synthesized the ligand **7** that carries an azide function (Scheme 2). We have given a preference to an α-thiomannosyl derivative because this glycosidic bond is very resistant, in vivo, especially toward the action of glycosidases. The mannosyl derivative **4** (*25*) was reacted with a relatively long PEG spacer arm of defined length (*26*), the purpose being to provide an optimal accessibility of the liposomal mannose ligands to their receptors (*40*). Next we have synthesized the anchor **8** (Scheme 3) that carries the alkyne moiety. This function was selected for the anchor because of its chemical "inertness" in vivo and—considering that about 50% of the anchor is oriented toward the interior of the vesicles—its absence of reactivity with (bio)molecules that can be entrapped within the liposomes. The molecule **8** was quantitatively incorporated in the liposomes during their formation.

Small unilamellar vesicles composed of saturated phospholipids (DPPC, DPPG) and cholesterol (70/20/50 molar ratio) and containing 10 mol % of the anchor **8** were prepared (average size: 90−130 nm). For the conjugation of the mannose ligand **7** (Scheme 3) to the preformed liposomes several conditions were tested in an aqueous buffer (pH 6.5). We have first tried to adapt the conditions that gave excellent yields in the model reaction (Scheme 1): i.e., generation of the catalytic Cu(I) by reduction of Cu(II) by sodium ascorbate. Keeping constant the concentrations of liposome (0.1 mM surface accessible anchor **8**) and azidomannose **7** (0.2 mM), the reaction time (24 h), the temperature (25 °C), and the ascorbate/$CuSO_4$ ratio (=5), we have varied the concentration of $CuSO_4$ (1−10 μM). Under these conditions, compared to Scheme 1, covalent coupling of mannose to the liposomes in appreciable yields failed. In fact, much higher concentrations of the ascorbate/$CuSO_4$ couple were needed to observe a conjugation which nevertheless remained relatively modest, i.e., about 25% coupling was observed in the presence of 2.3 mM $CuSO_4$ and 51.5 mM sodium ascorbate. This observation is in agreement with other works which showed that, for bioconjugations involving for example large molecular complexes, catalytic quantities of the ascorbate/$CuSO_4$ system are not enough to drive click reactions to completion. To circumvent this limitation we have added a ligand of copper ions. Indeed, stabilization of the Cu(I) oxidation state by specific heterocyclic ligands was shown to largely accelerate the 1,3-dipolar cycloaddition reaction between azides and alkynes (*41*, *42*). In our case, bathophenanthrolinedisulfonate (**L**; Scheme 3) provided a water soluble (*41*) and potent chelate catalyst for the click reaction. It allowed—when used in a 2-fold excess over copper to reduce the agglutination of the vesicles—a large increase in the yield of mannosylation and a decrease in the reaction time. For example, under standard conditions (24 h) the coupling yield increased from 23%, in the absence of **L**, to nearly completion in its presence. Moreover reaction times could also be decreased because, within 1 h in the presence of **L**, the observed conjugation of **7** was already about 80%. Altogether, we have routinely conjugated, in high yield, ligands such as **7** (2-fold molar excess) to the surface of preformed liposomes carrying alkyne functions in the presence of $CuSO_4$/Na-ascorbate/**L** (2.3, 50, and 4.6 mM) in an aqueous buffer (pH 6.5) at room temperature for 6 h (standard conditions).

In the liposome field it is of importance to verify the integrity of the vesicles after the coupling steps. To that end, using a dynamic light scattering technique, we have first verified whether the reaction conditions described above altered the size of the vesicles. Some changes were noticeable using our standard conditions, i.e., about 50% diameter increases were noted even under control conditions in the absence of ligand **7**. However, we found that this effect could be efficiently limited just by changing the order of reactants added to the liposome suspensions. Thus, when ligand **L** was added before the $CuSO_4$/ascorbate mixture followed by the mannosyl ligand **7**, no significant increase in size of the vesicles could be observed and, importantly, an identical yield of conjugation was measured. Next, to test whether the experimental conditions used for the click reaction could provoke some leakage of the vesicles, we have exposed to our standard conditions the same type of

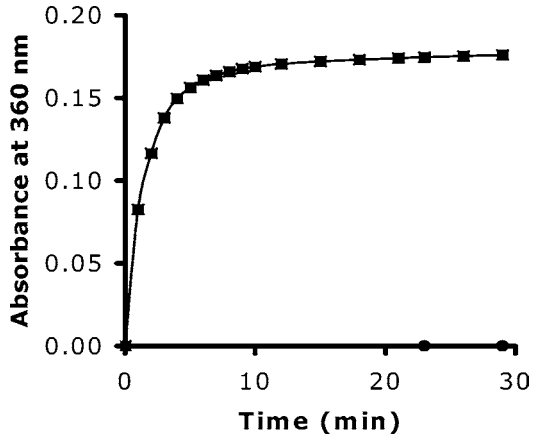


Figure 1. Turbidity changes of suspensions, in HBS (pH 6.5), of targeted liposomes composed of DPPC, DPPG, and Chol (70/20/50 molar ratio) after addition of Con A (125 μg/mL). The coupling time by click reaction (Scheme 3) for the targeted vesicles (−■−) that contained 10 mol % anchor **8** was 3 h; control liposomes (−●−). Liposome concentration = 60 μM lipids.

liposomes having encapsulated self-quenching concentrations of 5,6-carboxyfluorescein (*29*). Using a well-established method (*29*) based on fluorescence quenching determinations (see Experimental Procedures) we could demonstrate that, compared to vesicles incubated in the absence of the coupling reagents, essentially no leakage was triggered by the conjugation reaction. Importantly, these controls indicate that the standard conditions established here are harmless for liposomes made of saturated phospholipids.

Finally, residual copper in our targeted liposome preparations could be a potential concern. Determination by atomic absorption spectroscopy showed, that for our standard conditions, final copper concentrations in our constructs were in the low μM range, whereas using the modified protocol the presence of this ion was no more measurable (<0.03 μg/mL).

Determination of the Accessibility of the Mannose Residues at the Surface of the Liposomes. To determine whether the conjugated mannose residues were easily accessible at the surface of the liposomes we have incubated suspensions of targeted vesicles, that contained 10 mol % of α-thiomannosyl residues exposed at their surface, in the presence of concanavalin A. Addition of the lectin resulted in a gradual increase of turbidity, as assessed by an increase of OD at 360 nm which reached a plateau after about 15 min (Figure 1). In contrast, no absorbance change was observed with control liposomes. The subsequent addition of D-mannose (5.0 mM) to the aggregates triggered a prompt decrease in turbidity (not shown), confirming that the increase in turbidity was due to a specific recognition of the mannose residues on the surface of the vesicles by Con A that resulted in an aggregation due to multivalent interactions.

CONCLUSION

We have developed an efficient and convenient chemoselective conjugation method for coupling ligands onto the surface of preformed liposomes based on click chemistry (*13*). It can be performed under mild conditions in aqueous buffers; however, the use of Cu(I) chelators was essential to observe good yields under reasonable reaction times. Using liposomes composed of saturated phospholipids, the reaction conditions developed in the present work did not alter the integrity of the bilayers, in terms of leakiness, and provided perfectly functional targeted vesicles. This versatile approach, which is particularly suitable for the ligation of water soluble molecules and which can accommodate many chemical functions, is anticipated to be useful in the coupling of many other ligands. Nevertheless, it should be underlined that the mandatory use of copper catalysts in click chemistry could represent a limitation; indeed, vesicles made of unsaturated phospholipids are known to be readily (per)oxidized by copper ions in the presence of oxygen and become leaky (*43*, *44*). Alternative means of promoting catalyst-free ligation reactions between azides and alkynes have been described recently. They involve an activation of the alkyne partner either in strain-promoted activation of cycloalkynes in [3 + 2] cycloaddition reactions with azides (*45*) or 1,3-dipolar cycloadditions of azides with electron-deficient alkynes (*46*). These methods could constitute attractive extensions of the click reactions to biological systems that are sensitive to the action of copper ions.

Synthesis of Building Blocks for Solid-Phase Introduction of Diethylenetriaminepentaacetic Acid (DTPA) to Oligonucleotides and Oligopeptides

Jari Peuralahti, Lassi Jaakkola, Veli-Matti Mukkala, and Jari Hovinen*

PerkinElmer Life and Analytical Sciences, Turku Site, POB 10, FIN-20101 Turku, Finland. Received December 29, 2005; Revised Manuscript Received February 13, 2006

Synthesis of building blocks that allow site-specific incorporation of diethylenetriaminepentaacetic acid (DTPA) to oligonucleotides and oligopeptides using phosphoramidite and Fmoc chemistries, respectively, is described.

INTRODUCTION

Because of its excellent metal-chelating properties diethylenetriaminepentaacetic acid (DTPA) is one of the most widely used organic ligands in magnetic resonance imaging (MRI) and positron emission tomography (PET) (*1*−*3*). Indeed, the first FDA approved contrast agent in clinical use is the Gd^{3+} DTPA chelate (*4*). The corresponding ^{111}In and ^{68}Ga chelates are suitable for PET applications (*5*−*8*), while Eu^{3+}, Tb^{3+}, Sm^{3+}, and Dy^{3+} chelates can be used in dissociation enhanced lanthanide fluorescence immunoassay (DELFIA) based applications (*9*). ^{99m}Tc DTPA, in turn, has been applied for single positron emission computed tomography (SPECT) (*10*−*12*). Bioactive molecules labeled with ^{111}In or ^{117m}Sn DTPA may be used even as target-specific radiopharmaceuticals (*13*).

In several applications, covalent conjugation of DTPA to bioactive molecules is required. Accordingly, isothiocyanato, *N*-hydroxysuccinimide, or maleimide derivatives of the chelates are used in the labeling of the target molecules (*14*). Several bifunctional DTPA derivatives are currently commercially available. Because in all of these cases the labeling reaction is performed in the presence of an excess of an activated label, laborious purification procedures cannot be prevented. Especially when attachment of several label molecules is needed, purification and characterization of the desired biomolecule conjugate may be extremely difficult. The purification problems can be avoided by performing the labeling reaction on the solid phase. Hence, most of the impurities can be removed by washings when the biomolecule conjugate is still anchored to the solid support, and after release to the solution only one chromatographic purification is needed.

We have already developed a strategy for labeling of bioactive molecules with luminescent and nonluminescent lanthanide chelates on solid phase (*15*−*20*). The method involves synthesis of oligonucleotide and oligopeptide building blocks, which can be introduced to the biomolecule structure using commercial oligonucleotide and oligopeptide synthesizers by phosphoramidite and Fmoc chemistry, respectively. Upon completion of the chain assembly, the oligomer is deprotected and finally treated with the appropriate lanthanide(III) citrate to give rise to the desired biomolecule conjugate. Here our approach is used for the site-specific incorporation of diethylenetriaminepentaacetic acid (DTPA) to oligonucleotides and oligopeptides.

EXPERIMENTAL PROCEDURES

General Methods. Adsorption column chromatography was performed on columns packed with silica gel 60 (Merck). Reagents for oligonucleotide and oligopeptide synthesis were purchased from Proligo and Nova Biochem, respectively. Sodium sulfinate resin (200−400 mesh, 1% DVB, 1.3 mmol g^{-1}) was purchased from Tianjin Nankai Hecheng Science & Technology Company Limited (China). The oligopeptides and oligonucleotides were assembled on Applied Biosystems 433A and 3400 instruments, respectively, using recommended protocols. HPLC purifications were performed using a Shimadzu LC 10 AT instrument equipped with a diode array detector, a fraction collector, and a reversed phase column (LiChrocart 125−3 Purospher RP-18e 5 μm). Mobile phase: (buffer A): 0.02 M triethylammonium acetate (pH 7.0); (buffer B): A in 50% (v/v) acetonitrile. Gradient: from 0 to 1 min 95% A, from 1 to 21 min from 95% A to 100% B. Flow rate was 0.6 mL $min.^{-1}$ All dry solvents were from Merck, and they were used as received. NMR spectra were recorded on a Brucker 250 spectrometer operating at 250.13 MHz for ^1H and on a JEOL LA 400 spectrometer operating at 161.9 MHz for ^{31}P. The signal of TMS was used as an internal (^1H) and H_3PO_4 as an external (^{31}P) reference. ESI-TOF mass spectra and IR spectra were recorded on Applied Biosystems Mariner and PerkinElmer Spectrum One instruments, respectively.

4-Iodophenylalanine Methyl Ester, 1. Thionyl chloride (10 mL) was added dropwise to anhydrous methanol (40 mL) on an ice−water bath. The mixture was allowed to warm to RT, and it was stirred for 30 min. 4-Iodophenylalanine (4.90 g, 16.8 mmol) was added, and the mixture was heated overnight at reflux. All volatiles were removed in vacuo. The residue was triturated with diethyl ether, filtered, and dried in vacuo. Yield was 5.10 g (99%). ^1H NMR (DMSO-d_6): δ 8.15 (2H, br s); 7.70 (2H, d, *J* 8.2); 7.06 (2H, d, *J* 8.2); 4.30 (1H, t, *J* 6.6); 3.70 (3H, s); 3.07 (2H, d, *J* 6.6). IR (KBr) 1788 cm^{-1} (C═O). ESI-TOF-MS for $C_{10}H_{13}INO_2$ $(M+H)^+$: calcd, 306.04; found, 306.01.

2-Amino-*N*-(2-aminoethyl)-3-(4-iodophenyl)propanamide, 2. Compound **1** (5.10 g, 16.7 mmol) was added portionwise to ethylenediamine (35 mL) during 2 h. The mixture was stirred overnight at RT and concentrated. Aqueous ammonia (7 M; 30 mL) was added, and the product was extracted to dichloromethane (4 · 45 mL). The combined organic phases were dried over Na_2SO_4 and concentrated to give 5.57 g (93%) of compound **2**. ^1H NMR ($CDCl_3$): δ 7.64 (2H, d, *J* 8.2); 7.49 (1H, br t); 6.98 (2H, d, *J* 8.2); 3.59 (1H, dd, *J* 4.3 and 8.9); 3.30 (2H, q, *J* 6.1); 3.18 (1H, dd, *J* 4.3 and 13.8); 2.80 (2H, t,

J 6.4); 2.75 (1H, dd, *J* 8.9 and 13.1); 1.35 (4H, br s). IR (KBr) 1650 cm^{-1} (C═O). ESI-TOF-MS for $C_{11}H_{17}IN_3O$ $(M+H)^+$: calcd, 334.04; found, 334.04.

***N*¹-(2-Aminoethyl)-3-(4-iodophenyl)propane-1,2-diamine, 3.** Compound **2** (4.79 g, 14.4 mmol) was dissolved in dry THF (120 mL) and deaerated with argon. Borane-THF (1 M, 120 mL) was added dropwise during 30 min, and the mixture was heated overnight at reflux. The excess of borane was destroyed by cautious addition of water. All volatiles were removed in vacuo. The residue was dissolved in 6 M HCl and heated at reflux for 3 h and concentrated. The residue was suspended in concentrated ammonia (100 mL) and extracted with chloroform (5 ·75 mL). The combined organic layers were dried over Na_2SO_4, concentrated, and dried in vacuo. Yield was 2.9 g (63%). ^{1}H NMR ($CDCl_3$): δ 7.61 (2H, d, *J* 8.3); 6.95 (2H, d, *J* 8.3); 3.06 (1H, m); 2.79 (2H, m); 2.79 (4H, m); 2.51 (2H, m); 1.39 (5H, br s). ESI-TOF-MS for $C_{11}H_{19}IN_3$ $(M+H)^+$: calcd, 320.06; found, 320.06.

Pentamethyl 2-(4-Iodobenzyl)diethylenetriaminepenta-(acetate), 4. Compound **3** (2.7 g, 8.5 mmol) was suspended in dry DMF (80 mL), and the mixture was deaerated with argon. DIPEA (16.2 mL, 93 mmol), potassium iodide (1.54 g, 9.3 mmol), and methyl bromoacetate (7.2 mL, 75.8 mmol) were added, and the mixture was stirred overnight at RT. All volatiles were removed in vacuo. The residue was suspended on dichloromethane (140 mL), washed with sat. $NaHCO_3$ (3 ·55 mL), dried over Na_2SO_4, and concentrated. Purification on silica gel (eluent petroleum ether, bp 40−60 °C/ethyl acetate/ triethylamine 5:1:1, v/v/v) yielded 3.1 g (55%) of compound **4** as an oil. ^{1}H NMR ($CDCl_3$): δ 7.58 (2H, d, *J* 8.2); 6.97 (2H, d, *J* 8.2); 3.69 (6H, s); 3.66 (6H, s); 3.63 (3H, s); 3.57 (2H, s); 3.56 (2H, s); 3.54 (4H, s); 3.53 (2H, s); 3.10 (1H, p, *J* 6.6); 2.80 (1H, m) 2.74 (4H, m); 2.60 (1H, m); 2.47 (2H, m). ESI-TOF-MS for $C_{29}H_{39}IN_3O_{10}$ $(M + H)^+$: calcd, 680.17; found, 680.18. IR (film) 1747 cm^{-1} (C═O).

2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl)-3-(5-hexyn-1-yl)uridine, 5. 2′-Deoxy-5′-*O*-(4,4′-dimethoxy-trityl)uridine (5.0 g, 9.4 mmol), 5-hexyn-1-ol (1.25 mL, 11.3 mmol), and triphenylphosphine (3.0 g, 11.3 mmol) were dissolved in dry THF (50 mL). Diethylazodicarboxylate (1.80 mL, 11.3 mmol) was added dropwise during 30 min, and the reaction was allowed to proceed for 2 h at RT. All volatiles were removed in vacuo. Purification on silica gel using diethyl ether as the eluent gave 4.15 g (72%) of the title compound. ^{1}H NMR (DMSO-d_6): δ 7.70 (1H, d, *J* 8.1); 7.39 (2H, m); 7.31 (2H, m); 7.25 (5H, m); 6.90 (4H, d, *J* 8.0); 6.18 (1H, t, *J* 6.3); 5.49 (1H, *J* 8.1); 5.38 (1H, d, *J* 4.6; exch. with MeOD); 4.31 (1H, m); 3.90 (1H, m); 3.78 (2H, m); 3.74 (6H, s); 3.26 (1H, dd, *J* 5.4 and 10.7); 3.19 (1H, dd, *J* 2.9 and 10.7); 2.23 (3H, 3 · m); 1.63 (2H, p); 1.47 (1H, t); 1.43 (2H, m). ESI-TOF-MS for $C_{36}H_{39}N_2O_7$ $(M+H)^+$: calcd, 611.27; found, 611.29.

2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl)-3-{pentamethyl-2-[4-(5-hexyn-1-yl)benzyl]diethylene-triaminepentaacetato}-uridine, 6. Compounds **5** (1.15 g, 1.80 mmol) and **4** (1.00 g, 1.47 mmol) were dissolved in the mixture of dry THF (10 mL) and triethylamine (6 mL) under argon. $Pd(Ph_3P)_2Cl_2$ (22 mg, 0.03 mmol) and CuI (14 mg, 0.07 mmol) were added, and the mixture was stirred overnight at RT. The solid material was removed by filtration, and the filtrate was concentrated in vacuo. The residue was dissolved in dichloromethane (30 mL), washed with water (2 · 20 mL), and dried over Na_2SO_4. Purification on silica gel (eluent petroleum ether, bp 40−60 °C/ethyl acetate/ triethylamine 2:5:1, v/v/v) gave 1.30 g (74%) of compound **6**. ^{1}H NMR ($CDCl_3$): δ 7.74 (1H, d, *J* 8.2); 7.40−7.23 (11H, m); 7.11 (2H, d, *J* 8.2); 6.84 (4H, d, *J* 8.0); 6.32 (1H, t, *J* 6.4); 5.47 (1H, *J* 8.2); 4.55 (1H, m); 4.01 (1H, m); 3.97 (2H, m); 3.79 (6H, s); 3.68 (6H, s); 3.66 (6H, s); 3.62 (3H, s); 3.57 (2H, s); 3.55 (2H, s); 3.53 (4H, s); 3.47 (2H, m); 3.15 (1H, m); 2.85 (1H, m); 2.72 (2H, d, *J* 4.3); 2.58 (1H, m); 2.44 (2H, t, *J* 7.3); 1.82 (2H, m); 1.69 (2H, m). ESI-TOF-MS for $C_{62}H_{76}N_5O_{17}$ $(M+H)^+$: calcd, 1162.52; found, 1162.56.

2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl)-3-{pentamethyl-2-[4-(5-hexyn-1-yl)benzyl]diethylene-triaminepentaacetato}-uridine 3′-*O*-(2-cyanoethyl *N*,*N*-diisopropyl) Phosphoramidite, 7. Predried Compound **6** (1.43 g, 1.03 mmol) and 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphordiamidite (0.47 g, 1.55 mmol) were dissolved in dry acetonitrile (10 mL). 1*H* tetrazole (2.3 mL; 0.45 M in acetonitrile) was added, and the mixture was stirred for 30 min at room temperature before being poured into 5% $NaHCO_3$, extracted with dichloromethane, and dried over Na_2SO_4. Purification on silica gel (eluent petroleum ether, bp 40−60 °C/ethyl acetate/triethylamine 5:5:1, v/v/v) gave 0.88 g (52%) of compound **7**. ^{31}P NMR ($CDCl_3$): δ 149.58 (0.5 P); 149.13 (0.5 P). ESI-TOF-MS for $C_{71}H_{93}N_7O_{18}P$ $(M+H)^+$: calcd, 1362.62; found, 1362.59.

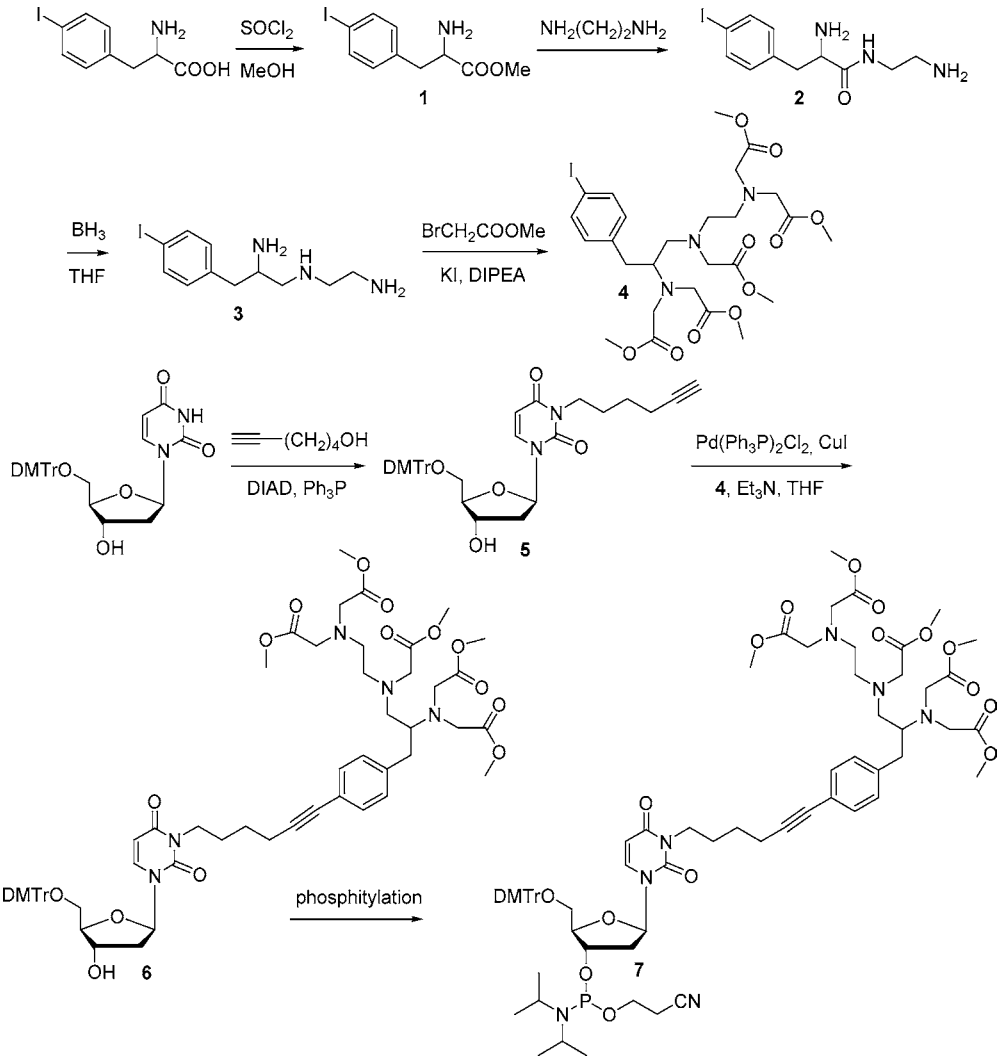
Penta-*tert*-butyl 2-{4′-{2-[2-allyloxycarbonyl-2-(fluorenylmethyloxycarbonylamino)]-ethylcarboxamido}benzyl}-diethylenetriaminepentakis(acetate), 9. Fmoc-Glu-OAll (1.31 g, 3.21 mmol), HATU (1.22 g, 3.21 mmol), and DIPEA (0.57 mL, 3.21 mmol) were dissolved in dry DMF (5 mL), and the mixture was stirred for 15 min at RT. Compound **8** (*21*) (2.50 g, 3.21 mmol; predissolved in 2 mL of dry DMF) was added, and the mixture was stirred for an additional 2 h. The mixture was diluted with dichloromethane (50 mL), washed twice with 10% citric acid, and dried over Na_2SO_4. Purification on silica gel (eluent CH_2Cl_2/MeOH 9:1, v/v) gave 2.84 g (82%) of compound **9**. ^{1}H NMR ($CDCl_3$): δ 8.31 (2H, br s); 7.75 (2H, d, *J* 7.3); 7.61 (4H, m); 7.39 (2H, t, *J* 7.3); 7.30 (2H, m); 7.02 (2H, d, *J* 8.6); 5.96 (1H, m); 5.89 (1H, m); 5.26 (1H, m); 4.65 (2H, d, *J* 5.4); 4.41 (2H, m); 4.22 (1H, t, *J* 6.7); 3.40−2.38 (17 H); 1.48 (36H, s); 1.42 (9H, s). ESI-TOF-MS for $C_{64}H_{92}N_5O_{15}$ $(M+H)^+$: calcd, 1170.66; found, 1170.59.

Penta-*tert*-butyl-2-{4′-{2-[2-carboxy-2-(fluorenylmethyloxycarbonylamino)]-ethylcarboxamido}benzyl}diethylene-triaminepentakis(acetate), 10. Compound **9** (1.00 g, 0.90 mmol) was dissolved in dry THF (20 mL) and deaerated with argon. $Pd(Ph_3P)_4$ (63 mg, 55 μmol) and sodium sulfinate resin (1.0 g) were added, and the mixture was stirred for 2 h at RT. The resin was filtered off and washed with THF. The filtrate was concentrated. The residue was dissolved in methanolic dichloromethane (5:95, v/v; 20 mL), washed with 10% citric acid (10 mL), dried over 4 Å molecular sieves, and concentrated to give compound **10** (0.70 g, 69%) as a pale yellow solid. ESI-TOF-MS for $C_{61}H_{88}N_5O_{15}$ $(M+H)^+$: calcd, 1130.63; found, 1130.65.

Synthesis and Purification of the Oligonucleotide Conjugates. A model sequence d(TAA TGT AGC CCC TGA A) was assembled on a 1.0 μmol scale using phosphoramidite chemistry and recommended protocols (DMTr-Off synthesis). One or five phosphoramidites **7** were coupled to the 5′-terminus of the oligonucleotide (coupling time 10 min, concentration 0.2 M). As the chain assembly was completed, the oligonucleotides were deprotected and converted to the gadolinium(III) chelates as the following: (i) treatment with 0.1 M NaOH for 4 h at RT, (ii) concentration in vacuo in the presence of ammonium chloride, (iii) treatment with concentrated aqueous ammonia for 16 h at 55 °C, and (iv) treatment with gadolinium(III) citrate (5 equiv per ligand) for 90 min at RT. Desalting by gel filtration and denaturing PAGE yielded the oligonucleotide conjugates.

Synthesis and Purification of the Oligopeptide Conjugates. One or five blocks **10** were coupled to an amide resin followed by a model sequence (RKEAASIKVAVS) in 10 μmol scale using Fmoc chemistry and recommended protocols (coupling time 30 min for natural amino acid analogues, and 2 h for **10**).

Scheme 1



When the chain assembly was completed, the resin was treated with the mixture of crystalline phenol (75 mg), ethanedithiol (25 μL), thioanisole (50 μL), water (50 μL), and trifluoroacetic acid (1 mL) for 4 h. The resin was removed by filtration, and the solution was concentrated in vacuo. The crude oligopeptide was precipitated with diethyl ether. The precipitate was redissolved in water and treated with gadolinium(III) citrate (5 equiv per ligand). Purification was performed on HPLC.

RESULTS AND DISCUSSION

Although the DTPA molecule has been known for decades, no structures that allow its direct solid-phase conjugation to oligopeptides or oligonucleotides have been described. The only solid-phase methods published involve synthesis of oligopeptides where one ϵ-amino group of K can be selectively deprotected, while the oligomer is still anchored to the resin (*22*, *23*). Then, an activated DTPA molecule (as an anhydride or an HOBt-ester) is coupled to the primary amino function, the oligopeptide is deprotected and converted to the appropriate DTPA chelate. One should in theory be able to incorporate multiple lysine residues that could be orthogonally deprotected, and thus obtain oligopeptides labeled with several DTPA molecules. However, the applicability of this approach has not been demonstrated in practice. Furthermore, since one of the DTPA carboxylic acid groups is used for conjugation, the resulting chelate is less stable than the parent DTPA molecule (*24*, *25*). This may be a serious problem in in vivo applications especially in MRI due to the high toxicity of the free Gd(III) ion. Accordingly, an alternative synthetic strategy would be desirable.

Synthesis of the Oligonucleotide Labeling Reactant is shown in Scheme 1. Initially, 4-iodophenylalanine was esterified using thionyl chloride to give **1**. Substitution reaction with ethane-1,2-diamine yielded the amide, **2**, borane reduction of which gave the amine **3**. Alkylation of this with methyl bromoacetate using potassium iodide as the catalyst gave the corresponding iminoacetic acid derivative, **4**. Sonogashira reaction between the iodide **4** and the hexynyl tethered nucleoside **5** gave **6** in high yield. The nucleoside, **5**, in turn, was obtained from 2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)uridine by the reaction with 5-hexyn-1-ol in the presence of DIAD and triphenylphosphine (*17*). Finally, **6** was phosphitylated to **7** in conventional manner by treatment with 2-cyanoethyl *N*,*N*,*N*′,N′-tetraisopropylphosphordiamidite in anhydrous acetonitrile using 1*H* tetrazole as the catalyst.

Synthesis of the Oligopeptide Labeling Reactant is shown in Scheme 2. Reaction of Fmoc-glutamic acid allyl ester with the amine **8** in the presence of HATU and DIPEA gave the protected ligand **9** in high yield. Purification was easily performed using silica gel column chromatography. By contrast, palladium catalyzed cleavage of the allyl group (*26*, *27*) was challenging. Reaction of **9** with $(Ph_3P)_4Pd$ using phenylsilane as the allyl scavenger (*17*, *28*) was unexpectedly slow: an overnight reaction was required, and an extensive amount of dark impurities were formed. The use of a thiol scavenger was

Scheme 2

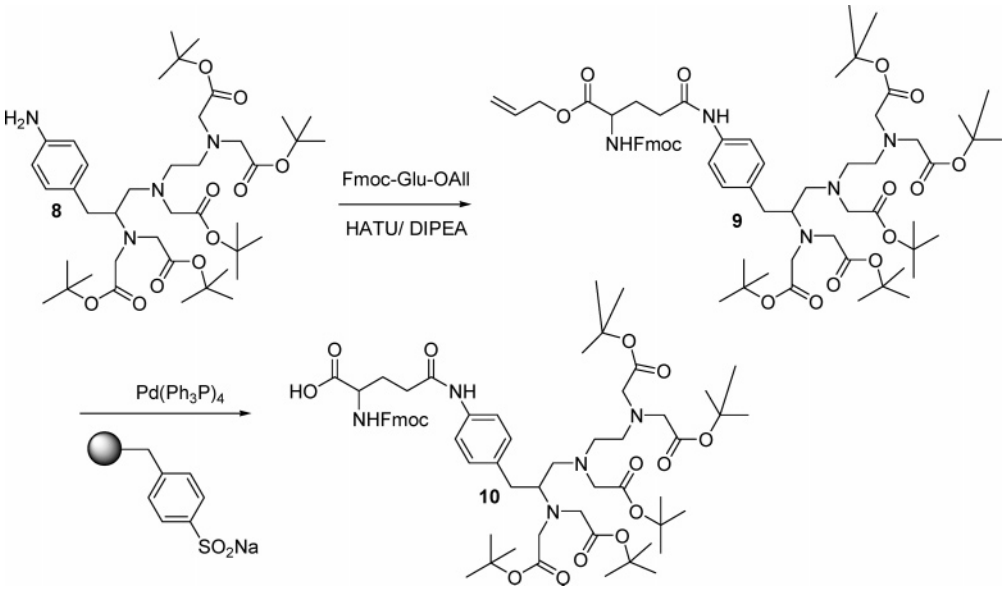


Chart 1

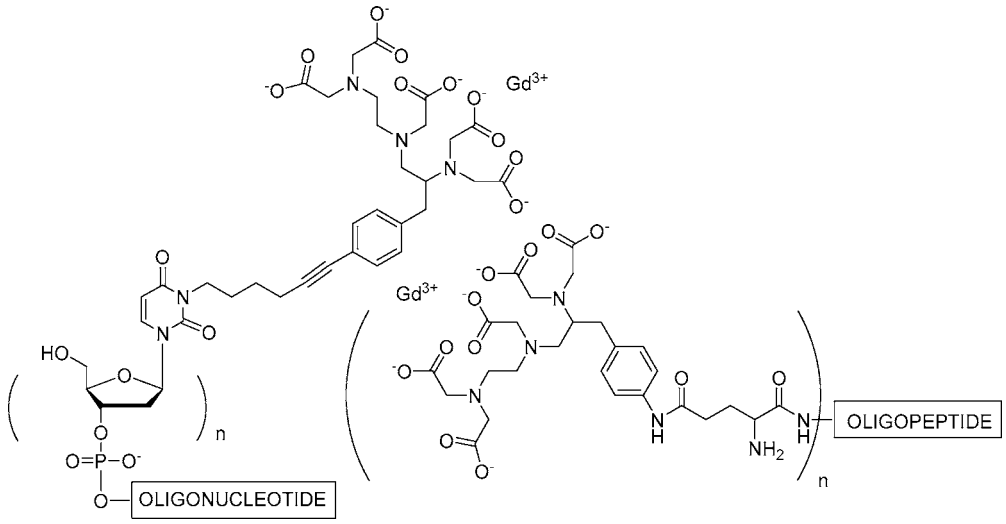

more successful: with sodium toluenesulfinate (*29*) the reaction was completed in 2 h at RT. However, removal of allyl-*p*-toluenesulfinate and some unidentified yellow impurities required silica gel column chromatography. Although these impurities could be removed with ease, the desired product, **10**, adsorbed tightly on silica gel. The product could not be completely eluted from the column even with highly polar solvent systems (up to 50% methanol in dichloromethane), which, in turn partially dissolved the matrix, causing additional problems. It is worth noting that all purification procedures involving extractions with strong aqueous bases and acids (*30*) had to be excluded due to the lability of the Fmoc and *t*-butyl groups of **10**, respectively. Fortunately, these problems could be solved using a commercially available scavenger resin. Accordingly, palladium-catalyzed allyl cleavage using resin-bound sodium *p*-toluenesulfinate produced **10** in 2 h at RT. The work up procedure was very simple, including removal of the resin by filtration, washing of the filtrate with 10% citric acid, and drying over 4 Å molecular sieves.

Synthesis of the Oligonucleotide and Oligopeptide Conjugates were performed on standard oligonucleotide and oligopeptide synthesizers using phosphoramidite and Fmoc chemistries, respectively. One or five building blocks (**7**, **10**) were coupled to the oligomers. Upon completion of the syntheses, the conjugates were deprotected and converted to the corresponding gadolinium(III) chelates by treatment with gadolinium(III) citrate. Finally, purification on gel electrophoresis (oligonucleotides) or reversed phase HPLC (oligopeptides) gave the desired bioconjugates (Chart 1). According to mass spectrometric analyses, the observed molecular weights were in accordance with the proposed structures.

As a summary, a simple method for the preparation of DTPA based labeling reactants is demonstrated. As shown here, the building blocks are suitable for site-specific introduction of MRI contrast agents to oligonucleotides and oligopeptides. Naturally, for PET and SPECT applications, the metal should be introduced as just prior to analysis.

Received February 22, 2006; Revised Manuscript Received April 11, 2006

Liposomes coated with the poly(amino acid) poly(hydroxyethyl-L-asparagine) (PHEA) show long-circulation properties comparable to the frequently used PEG-liposomes. The pharmacokinetic characteristics of long-circulating liposomes are dependent on the density of the shielding polymer on the liposome surface. Therefore, it is necessary to know the exact composition of the liposomes including the amount of coating polymer present on the liposome surface. In this study, a ^{1}H NMR method to establish the composition of liposomes coated with PHEA was developed and validated.

INTRODUCTION

The therapeutic use of nanoparticulate carriers for the targeted delivery of drugs, for example, liposomes and polymeric nanoparticles, can be significantly improved by coating them with sterically stabilizing polymers such as poly(ethylene glycol) (PEG) (*1*, *2*). Due to the hydrophilic PEG corona, these modified carriers display reduced recognition and uptake by cells of the mononuclear phagocyte system (MPS) and consequently show prolonged blood circulation times (*3*). Recently, we showed that liposome coatings based on poly(hydroxyethyl-L-asparagine) (PHEA) and poly(hydroxyethyl-L-glutamine) (PHEG) prolong liposome circulation to a similar extent as PEG (*4*). Such poly(amino acid) coatings are supposed to be biodegradable, as recently confirmed by the determination of the enzymatic degradation of PHEG (*5*).

In general, the pharmacokinetic characteristics of long-circulating colloidal drug carriers depend on the molecular weight of the stabilizing polymer and its density on the carrier surface (*6*). To address the latter aspect, it is necessary to quantify the amount of polymer that is grafted onto the carrier. For example, the composition of liposomes that are prepared by the film-hydration method is not exactly known since it is not ensured that all components are quantitatively incorporated into the liposome bilayer. Reliable methods to study the composition of liposomes are scarce. Proton nuclear magnetic resonance (^{1}H NMR) spectroscopy has been reported as an effective method for the quantitation and characterization of PEG−lipid conjugates in lipid mixtures (*7*), as well as on nanoparticle surfaces (*8*, *9*). The PEG−lipid is relatively easy to quantify because of its simple ^{1}H NMR spectrum. For the poly(amino acid) conjugates, however, quantitation is much more difficult because of strong peak overlap and partly broad signals of the polymer. In this study, a ^{1}H NMR method was developed and validated to accurately determine the composition of coated liposomes formed by the film-hydration method with emphasis on the new coating conjugate PHEA-DODASuc (Figure 1).

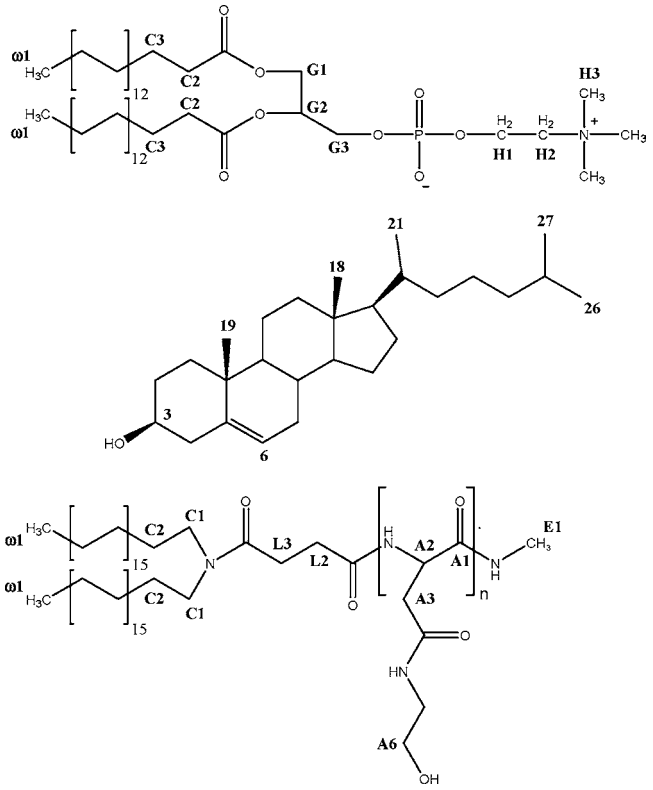

Figure 1. Molecular structure of DPPC, cholesterol, and PHEA-DODASuc ($n = 17$).

EXPERIMENTAL PROCEDURES

Materials. Poly(hydroxyethyl-L-asparagine)-*N*-succinyldioctadecylamine (PHEA-DODASuc) was synthesized as described previously (*4*). Dipalmitoylphosphatidylcholine (DPPC, Figure 1) was purchased from Lipoid GmbH, Ludwigshafen, Germany. α-Cyano-4-hydroxycinnaminic acid, cholesterol (Figure 1), deuteriochloroform (chloroform-*d*, 99.8 atom % D), and deuterated dimethyl sulfoxide (d_6-DMSO) were obtained from Sigma-Aldrich Chemie BV, Zwijndrecht, The Netherlands. All other reagents were of analytical grade.

MALDI-ToF Mass Spectrometry of PHEA-DODASuc. PHEA-DODASuc was dissolved in demineralized water to a

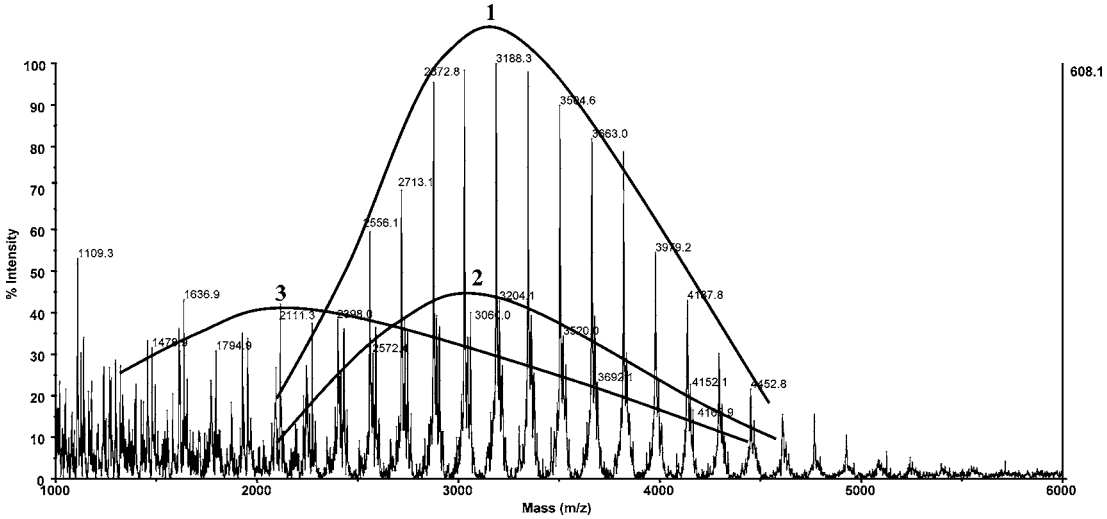

Figure 2. Mass spectrum of PHEA-DODASuc. The three major peak populations are indicated by approximated curves: population 1, Na^+ adduct of the conjugate; population 2, K^+ adduct of the conjugate; population 3, Na^+ adduct without the DODASuc anchor.

concentration of 1 mg/mL. The matrix compound α-cyano-4-hydroxycinnaminic acid was dissolved to a concentration of 10 mg/mL in acetonitrile/water (1:1) containing 0.1% trifluoroacetic acid and mixed in a ratio of 3:1 (v/v) with the conjugate solution. Three microliters of this mixture was put onto a sample deposition plate and left at room temperature to dry. The spectrum was acquired in the positive ion mode on a Voyager-DE STR MALDI-ToF mass spectrometer (Applied Biosystems, Foster City, CA). Ionization was initiated with a nitrogen laser operating at 337 nm with a repetition rate of 7.6 Hz. Delayed extraction linear mode with an accelerating voltage of 20 kV was used, and the acquisition mass range was 700−7000 Da. The spectrum was analyzed with the Applied Biosystems Data Explorer Software.

Sample Preparation for NMR Analysis. A mixture of $CDCl_3$ and d_6-DMSO in a ratio of 2:1 (v/v) was used for dissolving the samples containing DPPC, cholesterol, and PHEA-DODASuc. For signal assignment, DPPC and cholesterol were dissolved in $CDCl_3$, and PHEA-DODASuc was dissolved in d_6-DMSO (approximately 20 mg/mL). The lipid mixtures were prepared by mixing the required amounts of lipid stock solutions and adding $CDCl_3$ and d_6-DMSO to obtain the proper solvent ratio. For instance, for a lipid mixture of DPPC, cholesterol, and PHEA-DODASuc (molar ratio of 62:33:5), a stock solution of 81 μmol of DPPC and 43 μmol of cholesterol per milliliter was prepared in $CDCl_3$, and PHEA-DODASuc was dissolved to a concentration of 13 μmol/mL in d_6-DMSO. Two hundred microliters of the DPPC/cholesterol stock solution and 100 μL of the PHEA-DODASuc stock were mixed and further diluted with 200 μL of d_6-DMSO and 400 μL of $CDCl_3$. The total lipid concentration in the samples was approximately 20 mg/mL.

Liposome Preparation. Lipids (DPPC, cholesterol, PHEA-DODASuc, total lipid ≈ 75 mg) at different ratios were dissolved in about 2 mL of a mixture of chloroform and methanol (1:1 v/v). A film was obtained by evaporation of the solvents under reduced pressure at 50 °C in a 50 mL round-bottom flask. After flushing with nitrogen, the lipid film was hydrated in 5 mM NaCl solution (total lipid concentration 30 μmol/mL). Liposomes were sequentially extruded through two stacked polycarbonate filters (Poretics, 400, 200, 100, and 50 nm) with a high-pressure extrusion device to a final mean size of approximately 100 nm (confirmed by dynamic light scattering measurements). One milliliter of the liposome dispersion was freeze-dried overnight and dried further in a vacuum oven at room temperature for several hours. The dry cake was dissolved in a mixture of $CDCl_3$/d_6-DMSO (2:1) and subsequently analyzed by NMR.

Table 1. Peak Assignment in the Mass Spectrum of PHEA-DODASuc

population no.[a]	*m/z*	assignment of highest peak	repeating unit (r.u.)	range (r.u.)
1	3188.3	$[DODASuc\text{-}(PHEA)_{16} + Na]^+$	158	9−27
2	3204.1	$[DODASuc\text{-}(PHEA)_{16} + K]^+$	158	10−25
3	3060.0	$[(PHEA)_{19} + Na]^+$	158	7−27

[a] The peak population as depicted in Figure 2.

To separate liposomes from possible nonincorporated components, 1 mL of the liposome dispersion obtained after extrusion was subjected to ultracentrifugation at 200 000 g (30 min, 4 °C) using a Beckman LE-80K Ultracentrifuge. The supernatant was collected, freeze-dried, dissolved in d_6-DMSO, and analyzed by NMR. The pellet was dispersed in 1 mL of 5 mM NaCl solution and subsequently freeze-dried and vacuum-dried, dissolved in $CDCl_3$/d_6-DMSO (2:1), and analyzed by NMR.

NMR Analysis. Homonuclear correlation (COSY, TOCSY) and unidimensional analysis of DPPC, cholesterol, and PHEA-DODASuc for signal assignment were carried out with a Varian INOVA 500 spectrometer (Varian, Palo Alto, CA) at 500 MHz. Signals were assigned based on chemical shifts, peak intensities, and spin−spin coupling. Spectra of lipid and liposomal mixtures were recorded with a Varian G-300 spectrometer (Varian, Palo Alto, CA) at 300 MHz. The number of accumulated transients was set to 16−32, the pulse angle was 62.5°, and the relaxation delay D1 was set to 10 s.

RESULTS AND DISCUSSION

MALDI-ToF and NMR Analysis of PHEA-DODASuc. Figure 2 shows the mass spectrum of PHEA-DODASuc, and Table 1 gives the corresponding peak assignments. Three major peak populations are present in the spectrum. The most abundant population can be assigned to the Na^+ adduct of the conjugate (Figure 2, population 1). The two less abundant populations belong to the K^+ adduct of the conjugate (Figure 2, population 2) and the Na^+ adduct of PHEA without the DODASuc anchor (Figure 2, population 3). The presence of the latter compound is likely due to incomplete coupling during synthesis of the conjugate. Due to differences in ionization efficiency, no quantitative data can be obtained from this spectrum. The number-average molecular weight of PHEA-DODASuc based on the peak population of the Na^+ adduct of the conjugate was

4.1 + 4.3	G1 DPPC
4.2	H1 DPPC
4.6	A2 PHEA-DODASuc
5.1	G2 DPPC
5.2	C6 cholesterol
7.8−8.2	N PHEA-DODASuc (peptide, side chain and end group)

3300 Da and corresponds to an average degree of polymerization of 17. This is in good agreement with the molecular weight (M_n) of 4000, which was calculated after NMR analysis.

NMR Signal Assignment. A typical spectrum of a mixture of DPPC, cholesterol, and PHEA-DODASuc is shown in Figure 3. Table 2 gives the peak assignments based on chemical shifts and intensities and comparison with literature (*10*−*12*). The cholesterol signal chosen for calculation of the ratio of the three compounds in the lipid mixture was at δ 5.2 (proton at C6 at the double bond); for DPPC the signal at δ 5.1 (proton at G2, the middle glycerol carbon atom) and for PHEA-DODASuc the signal at δ 3.5 (protons at C8, side chain-CH_2 next to OH, two protons, for $n = 17$, $2 \times 17 = 34$ protons) were used. The chosen peaks are relatively narrow and sufficiently resolved to make correction for overlap unnecessary.

NMR Analysis of Lipid Mixtures: Accuracy, Precision, and Linearity. Accuracy and precision of the NMR analysis was assessed by analyzing a single lipid mixture with a DPPC/cholesterol/PHEA-DODASuc molar ratio of 62:34:4 on five consecutive days. The method allows for a relative quantitation of the lipid mixtures or, more precisely, assessing their molar composition. The integral values of the proton signals of DPPC (δ 5.1) and PHEA-DODASuc (δ 3.5, corrected for the number of protons by division by 34) were compared with the value of the cholesterol integral (δ 5.2), which was set to one. Results were expressed as percentage of the feed fraction. The DPPC amount was determined to be 98% ± 5% of the feed fraction. In the case of PHEA-DODASuc 104% ± 5% of the feed fraction was found. Thus, these findings are in excellent agreement with the actual composition of the lipid mixture.

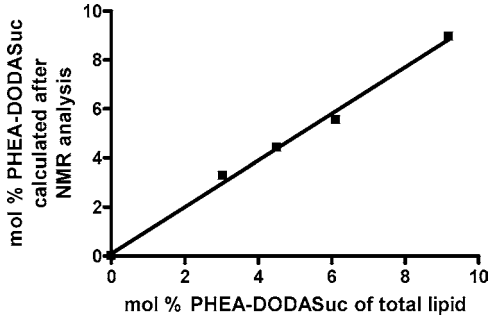

Figure 4. Correlation between the percentage of PHEA-DODASuc (mol % of total lipid) in the feed and the calculated percentage of PHEA-DODASuc after NMR analysis.

Additionally, the accuracy and precision of the sample preparation were investigated. Five lipid mixtures with the same composition (DPPC/cholesterol/PHEA-DODASuc, 62:34:4) were prepared and analyzed on five subsequent days. For DPPC 100% ± 6% of the feed fraction was found. The spectrum of PHEA-DODASuc revealed 101% ± 4% of the feed fraction. Again, these values are in excellent agreement with the actual composition of the lipid mixture. Hence, the sample preparation does not influence the accuracy of the method.

To study the linearity of the method, lipid mixtures with different amounts of PHEA-DODASuc were analyzed by NMR. Lipid ratios were chosen in a range relevant for liposome preparation (PHEA-DODASuc 3.0, 4.5, 6.1, and 9.2 mol % of total lipid). In Figure 4, the percentage of PHEA-DODASuc found after NMR analysis is plotted against the percentage of PHEA-DODASuc in the feed. This figure shows that the fraction of the coating conjugate in the mixture determined by NMR corresponds linearly with the feed fraction. The regression coefficient was >0.99. The NMR method is therefore suitable to accurately determine the composition of mixtures of DPPC, cholesterol, and PHEA-DODASuc.

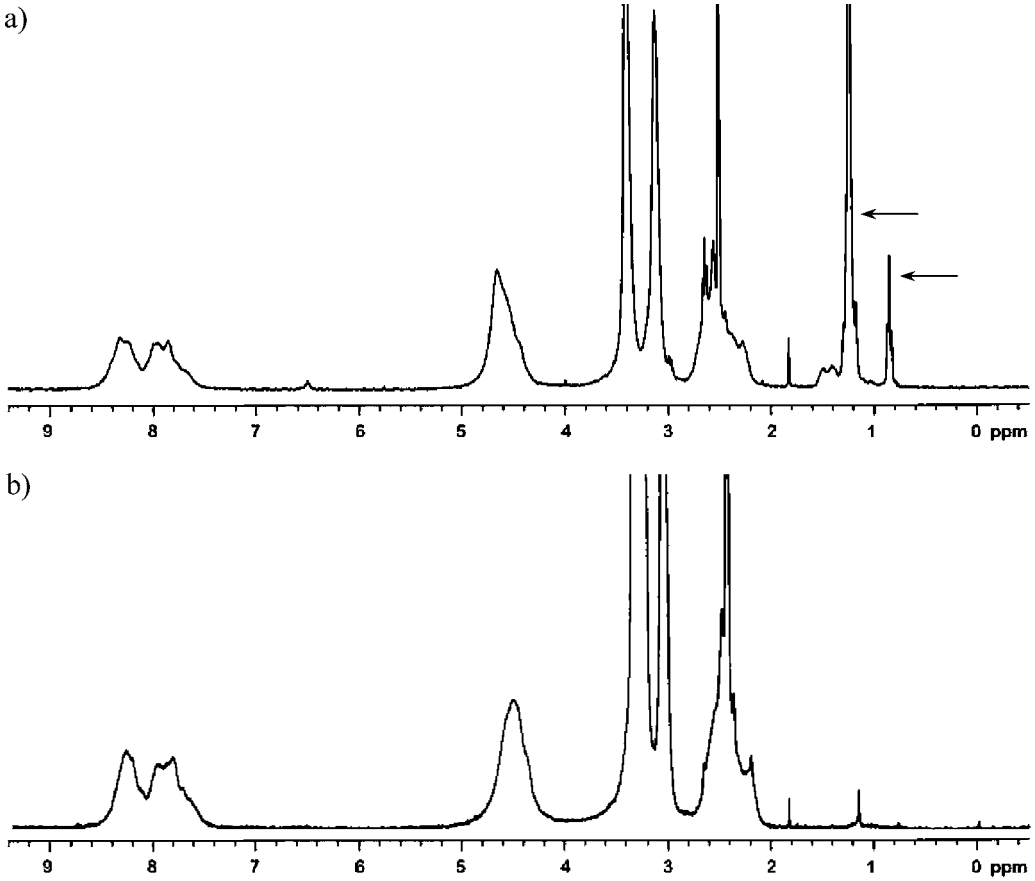

Figure 5. ^{1}H NMR spectrum of (a) native PHEA-DODASuc and (b) the freeze-dried supernatant of ultracentrifugation-treated liposomes, both in d_6-DMSO. The arrows indicate peaks of the DODASuc anchor.

Table 3. Amount of DPPC and PHEA-DODASuc Relative to Cholesterol in Two Liposomal Mixtures[a]

lipid composition DPPC/chol/ PHEA-DODASuc	DPPC % of feed		PHEA-DODASuc % of feed	
	before separation[b]	after separation[b]	before separation[b]	after separation[b]
65:33:2	96 ± 5	102 ± 5	98 ± 5	85 ± 5
62:33:5	100 ± 5	100 ± 5	107 ± 5	88 ± 5

[a] The results are expressed as the calculated value ± the error. [b] separation: removal of nongrafted conjugate from liposomes by ultracentrifugation (see Materials and Methods)

NMR Analysis of Liposomal Mixtures. Table 3 shows the results of the analysis of two freeze-dried liposomal dispersions. The compositions were determined before and after separation of nongrafted components from the liposomes by ultracentrifugation. The calculated fractions of DPPC, both before and after centrifugation, are in good agreement with the fraction in the feed. The fraction of PHEA-DODASuc in liposomes before ultracentrifugation is also in agreement with the feed fraction. This implies that the liposome preparation process does not alter the molar composition of the initial lipid mixture and the lipid film was fully converted into liposomes. After separation of nongrafted components by ultracentrifugation, however, the fractions of PHEA-DODASuc were 85% (17 nmol of PHEA/μmol of total lipid) and 88% (44 nmol of PHEA/μmol of total lipid) of the feed fractions, respectively. This indicates that not all of the PHEA molecules that are used for liposome preparation were attached to the liposome surface. It is likely that the nonincorporated fraction is the fraction of the added PHEA molecules that lack the lipid anchor (DODASuc) and therefore is not grafted onto the liposome bilayer. To evaluate this, an NMR spectrum of the supernatant of liposomes obtained after ultracentrifugation and freeze-drying was recorded. Figure 5b shows that the peaks that belong to the anchor part of the molecule at a chemical shift of δ 0.8−1.6 are absent in this spectrum (compare the spectrum of the native PHEA-DODASuc, Figure 5a). Whereas conjugate molecules with the anchor are likely quantitatively grafted onto the bilayers, the PHEA molecules without the anchor stay in solution. This means that approximately 85% of the PHEA molecules of the batch used in these experiments are attached to the DODASuc anchor and can be grafted onto the liposome bilayer. This is an important issue when studying the shielding properties of PHEA-DODASuc in relation to the grafting density.

In summary, this paper presents a fast, reproducible, and relatively sensitive NMR-based analysis method for the quantitation of PHEA-DODASuc in liposomes.

Apoptosis, or programmed cell death, plays an important role in the etiology of a variety of diseases, including cancer. Visualization of apoptosis would allow both early detection of therapy efficiency and evaluation of disease progression. To that aim we developed a novel annexin A5-conjugated bimodal nanoparticle. The nanoparticle is composed of a quantum dot that is encapsulated in a paramagnetic micelle to enable its use both for optical imaging and MRI. Multiple recombinant human annexin A5 protein molecules were covalently coupled to the nanoparticle for targeting. In this study the specificity of the annexin A5-conjugated nanoparticles for apoptotic cells was demonstrated both with fluorescence microscopy and MRI, which confirms its potential for the detection of apoptosis with both imaging modalities in vivo.

Apoptosis, or programmed cell death, is an essential biological process that both occurs in normal tissue homeostasis and in diseased tissue (*1*). In pathophysiological situations the measurement of apoptotic activity may greatly enhance possibilities for staging the disease, and, equally important, apoptosis may serve as an early indicator for the effect of therapeutic interventions. In antitumor therapies the induction of apoptosis by, for example, cytotoxic drugs leads to an arrest of tumor proliferation, since the unrestrained division of tumor cells is related to insufficient apoptosis (*2*). Other disorders, like reperfusion injury after myocardial infarction or stroke, are rather associated with excessive apoptosis. Several biochemical markers of apoptosis have been identified and could in principle be exploited for the detection of apoptosis. The exposure of the normally asymmetrically distributed phosphatidylserine (PS) at the outer monolayer of the cell membrane of apoptotic cells is an especially attractive hallmark of apoptosis, since the protein annexin A5 binds with high affinity to this negatively charged phospholipid (*3*). For the visualization of apoptosis, annexin A5 may be used as a targeting ligand, which requires the protein

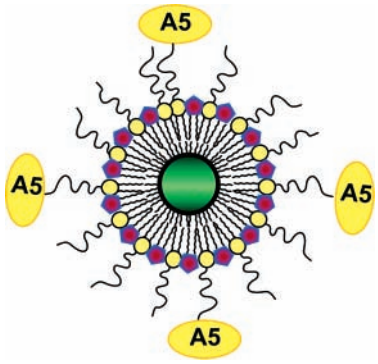

Figure 1. Schematic representation of a TOPO/HDA quantum dot with a paramagnetic lipid coating, to which multiple annexin A5 proteins are conjugated (A5-pQD). The lipids drawn with the yellow and red headgroups represent PEG-DSPE and Gd-DTPA-BSA, respectively. Annexin A5 (indicated with A5) is conjugated to the maleimide group of Mal-PEG-DSPE.

to be conjugated to a contrast agent for the imaging modality of choice. Fluorescently labeled annexin A5 for optical imaging and annexin A5 conjugated with a radioactive label for nuclear imaging have been used successfully to visualize apoptosis in animal models (*4*) and in patients (*5*), respectively. Recently, annexin A5 conjugated to a magnetic nanoparticle was used for the detection of apoptosis in tumors and after myocardial infarction in mice with magnetic resonance imaging (MRI) (*6*). Although MRI excels in depicting opaque soft tissue with higher spatial resolution and better contrast as compared to, for example, nuclear methods, it is a relatively insensitive technique and it lacks the microscopic resolution of the optical methods. The bimodal approach of using MRI in combination with optical imaging would therefore make it possible to visualize apoptosis at the microscopic and macroscopic level.

In this study we report on the development of a novel annexin A5-conjugated nanoparticle, which has excellent paramagnetic and fluorescent properties. The nanoparticle consists of a quantum dot (QD), which is encapsulated in a paramagnetic micelle. Quantum dots have received much attention lately as optical imaging agents because of their excellent photostability and sensitivity, and narrow and tunable emission wavelength (*7*). Because of the small size of this nanoparticle, less than 10 nm, compared to most other nanoparticulate MRI contrast agents, which are typically in the order of 50−250 nm (*8*, *9*), quantum dots may distribute more easily into diseased tissue. This improves the bioavailability and can be expected to enhance the binding to apoptotic cells.

CdSe/ZnS core/shell quantum dots were synthesized under a flow of argon by injection of the precursors into a hot coordinating solvent (*10*). The TOPO/HDA-capped quantum dots were coated with paramagnetic micelles according to an extended procedure described by Dubertret et al. (*11*). In short, TOPO/HDA-capped quantum dots were washed and suspended in chloroform. A mixture of 40 mol % 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG-DSPE), 10 mol % 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-*N*-[maleimide(poly(ethylene glycol))2000] (Mal-PEG−DSPE), and 50 mol % of the paramagnetic lipid Gd-DTPA-bis(stearylamide) (Gd-DTPA−BSA) dissolved in chloroform/methanol (20/1) was added to the quantum dots. The solvent was gently evaporated, and a solution of HEPES buffer (pH 6.7) that had been heated to 70 °C was added to the obtained mixed film. This mixture was rigorously heated and vortexed until a clear suspension was obtained. Empty micelles and micelles containing a quantum dot were separated with ultracentrifugation (1 h, 500000*g*). Both the gadolinium and the cadmium content of the annexin A5−pQD preparations were determined with inductively coupled plasma atomic emission spectrometry (ICP-AES). Furthermore it was measured with thermogravimetric analysis (TGA) that 56 mass % of the quantum dots consists of CdSe/ZnS. From these values an average value of 150−200 Gd-DTPA−BSA lipid molecules per nanoparticle could be derived.

The ability of the annexin A5-conjugated nanoparticle (A5-pQD) to reduce the intrinsic T_1 and T_2 values of water are described by its molar relaxivities r_1 and r_2, which are expressed in $mM^{-1}\ s^{-1}$. The ionic relaxivities of this nanoparticle at 37 °C and 60 MHz, were measured to be $r_1 = 12.4 \pm 0.7\ mM^{-1}s^{-1}$ and $r_2 = 18.0 \pm 0.1\ mM^{-1}s^{-1}$, respectively. The relaxivity per mM particles therefore is at least 150 times higher than the ionic relaxivity. Next, recombinant human annexin A5, containing a single free cysteine, was covalently linked to the maleimide group of Mal-PEG-DSPE via the thiol of the cysteine as described previously (*12*). A schematic representation of the annexin A5-conjugated nanoparticle (A5-pQD) is shown in Figure 1.

The specificity of this contrast agent for apoptotic cells was obtained in vitro. For that purpose the T-lymphoma cell line Jurkat (ATCC) was grown in RPMI1640 medium (Gibco), which was supplemented with 10% fetal calf serum and a mixture of antibiotics (100 units ml^{-1} penicillin, 0.1 mg ml^{-1} streptomycin). Cells were grown at 37 °C in a humified atmosphere and 5% CO_2. Apoptosis is naturally occurring without exposing the cells to apoptotic stimuli, typically involving 5 to 10% of the cells within the culture. To induce an increased number of apoptotic cells, the cells were resuspended to 10^6 cells ml^{-1} medium and treated with 200 ng ml^{-1} anti-Fas (CD95 human monoclonal antibody, Beckman Coulter B.V.) for 3 h, which initiates approximately 40 to 50% apoptosis. To allow fluorescence imaging and MRI of cell pellets, 5 million cells were treated with anti-Fas and subsequently incubated for 15 min with the annexin A5-conjugated nanoparticles at a final

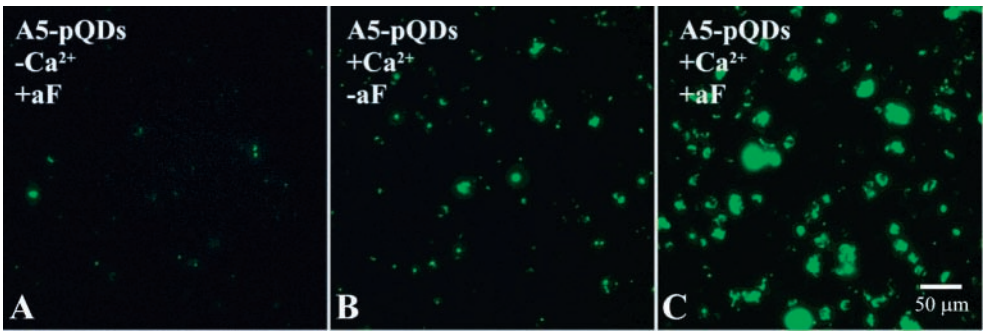

Figure 2. Fluorescence microscopy of Jurkat cells incubated with annexin A5-conjugated pQDs. (A) Apoptotic cells incubated in the presence of EDTA, (B) vital cells with a naturally occurring percentage of apoptotic cells, and (C) apoptotic cells. +aF denotes stimulation with anti-Fas, while −aF denotes no stimulation. $+Ca^{2+}$ indicates the presence of Ca^{2+}, while $-Ca^{2+}$ indicates incubation in the presence of EDTA to remove Ca^{2+}.

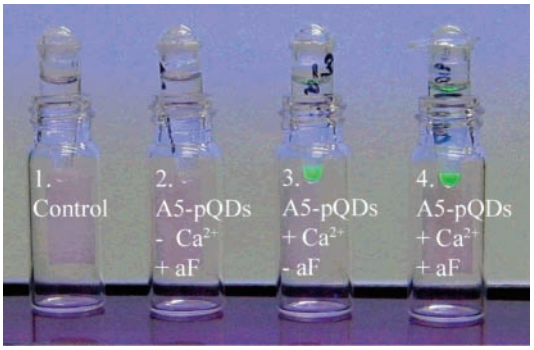

Figure 3. Cell pellets of the different incubations illuminated with 254 nm UV light. From left to right: Control cells (sample 1), apoptotic cells incubated with A5-pQDs in the presence of EDTA to remove Ca^{2+} (sample 2), vital cells incubated with A5-pQDs (sample 3), and apoptotic cells incubated with A5-pQDs (sample 4).

concentration of 392.4 μM quantum dots in Ca^{2+}-containing binding buffer (10 mM HEPES, 150 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 2.5 mM $CaCl_2$, pH 7.4). To further assess the binding specificity 5×10^6 cells that were not treated with anti-Fas were also incubated with A5-pQDs. Since annexin A5 binds to phosphatidylserine in a Ca^{2+}-dependent manner, the removal of Ca^{2+} will prevent binding. Therefore, A5-pQDs that were incubated in HEPES-buffered saline that was supplemented with EDTA (25 mM HEPES, 140 mM NaCl and 5 mM EDTA, pH 7.4) were also used as control. Following the incubations, all cell samples were extensively washed in binding buffer or HEPES-buffered saline supplemented with EDTA, respectively.

For fluorescence imaging and MRI of cell pellets, the 5 million cells of the different incubations were collected, fixed in a 4% paraformaldehyde solution, and put in small cups. Cells were allowed to settle as loosely packed cell pellets overnight at 4 °C Fluorescence microscopy of the apoptotic cells that were incubated with A5-pQDs in binding buffer showed bright fluorescence indicative for a massive association of the contrast agent with the cells (Figure 2C). On the contrary, the cells that were not stimulated with anti-Fas showed much less fluorescence (Figure 2B), because of the lower percentage of apoptotic cells. In the cell pellet that was incubated with A5-pQDs in the presence of EDTA almost no fluorescence was observed (Figure 2A). The observed low fluorescent intensity in sample 2 could not be induced by fluorescent quenching due to EDTA since the emission spectrum of paramagnetic quantum dots in HEPES-buffered saline was measured to remain unchanged after addition of EDTA to a final concentration of 5 mM.

In Figure 3 the different cups with loosely packed cell pellets, illuminated with 254 nm UV light, are depicted. The green emitting cell pellet that originated from the incubation of annexin A5 nanoparticles with apoptotic cells (Figure 3, sample 4) can clearly be distinguished from the other incubations (Figure 3, samples 1−3).

Following the above optical analysis, the cell pellets were measured with MRI. T_1-weighted images (Figure 4A) revealed a strong signal enhancement of the apoptotic cells incubated with A5-pQDs in binding buffer (sample 4) as compared to the three control incubations (samples 1, 2, and 3). The cells that were not treated with anti-Fas (sample 3) also showed association of the contrast material. This accounts for the low level of apoptosis that is commonly seen in cell suspensions even in the absence of apoptotic stimuli. For absolute quantification of the T_1 and T_2 relaxation times an MRI inversion recovery experiment and a multi-echo experiment were performed, respectively. From these data the T_1 and T_2 relaxation times of the different cell pellets were calculated. Since the concentration of a paramagnetic agent is proportional with the relaxation rate R_1 ($1/T_1$) and R_2 ($1/T_2$), these values were calculated for the different cell pellets. In Figure 4B and 4C the R_1 and R_2 relaxation rates of the different cell pellets are depicted. Control cells that were not incubated with the contrast agent (sample 1) showed the lowest R_1 and R_2. Cell pellets of apoptotic cells incubated with A5-pQDs in binding buffer (sample 4) showed the highest R_1 and R_2 values. The cell pellet of anti-Fas treated cells that were incubated with A5-pQDs in the presence of EDTA (sample 2), as well as the untreated cell pellet incubated with A5-pQDs (sample 3), had much lower relaxation rates than the anti-Fas treated cells that were incubated with A5-pQDs in the presence of Ca^{2+} (sample 4).

The novel annexin A5-conjugated nanoparticle presented in this study may be of great use for successive MRI and intravital microscopy of apoptosis in animal models of cardiac dysfunction or in tumor models. This allows the detection of apoptosis both at the macroscopic and the microscopic level in vivo. Dumont et al. have demonstrated the feasibility to detect apoptosis in the beating murine heart, following the administration of fluorescently labeled annexin A5 (*4*). A comparable setup could be used for intravital microscopy of subcutaneously grown tumors in mice. Recently, Stroh et al. have demonstrated simultaneous detection of multiple quantum dot species (*13*). The application of near-infrared quantum dots would additionally increase the penetration depth, which allows the real time investigation of tissue as deep as 1 cm (*14*). The technology developed in this study may also be applied to quantum dots with a different size and consequently with a different emission wavelength. This allows optimization of the nanoparticle both for the tissue of interest and the additional fluorescent dyes to be imaged.

In conclusion, we have developed a novel nanoparticulate contrast agent for the detection of apoptosis, with excellent paramagnetic and fluorescent properties. The in vitro results demonstrated a high specificity of this contrast agent for apoptotic cells, suggesting its potential for the detection of apoptosis in different animal models with both intravital fluorescence microscopy and MRI in vivo. Because of the relatively small size of this QD-based contrast agent compared

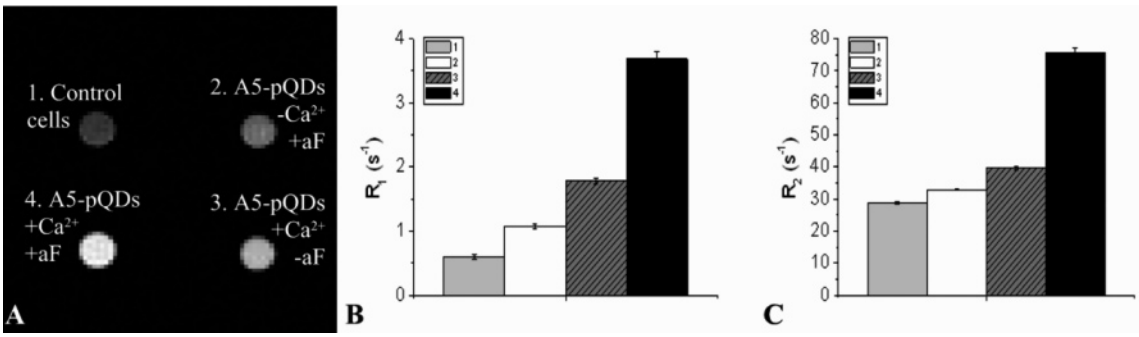

Figure 4. (A) T_1-weighted image of the different cell pellets. An Affinity-Based Method for the Purification of Fluorescently-Labeled Biomolecules

Trung Nguyen, Neel S. Joshi, and Matthew B. Francis*

Department of Chemistry, University of California, Berkeley, California 94720-1460, and Materials Sciences Division, Lawrence Berkeley National Labs, Berkeley, California 94720. Received May 22, 2006; Revised Manuscript Received June 17, 2006

Due to the difficulty of separating mixtures of labeled and unlabeled biomolecules, a general new method for the affinity purification of modified proteins has been developed. A Sepharose-based solid support bearing β-cyclodextrin groups was used to capture chromophore-modified proteins selectively, while unmodified proteins remained in solution. After isolation of the resin, the modified proteins were released by treating the sample with a competitive cyclodextrin binder, such as adamantane carboxylic acid. This procedure was demonstrated for several dyes displaying a wide range of spectral characteristics and diverse chemical structures. Preliminary studies have shown that this method can also be used to enrich modified peptide fragments present in proteolytic digests. This technique is anticipated to accelerate the development of new protein modification reactions and could provide a useful tool for proteomics applications.

The attachment of chromophores to biomolecules is a common practice in chemical biology, affording fluorescent probes that can track protein localization (*1a*), detect the binding of substrates (*1b*), and measure distances through fluorescence resonance energy transfer (FRET) (*1c*,*d*). Typically these labels are introduced through the reaction of lysine residues with NHS-esters, isocyanates, or isothiocyanates, or through the modification of cysteine residues with maleimides or iodoacetamides (*2*). However, these reactions commonly do not reach full conversion, yielding inseparable mixtures of labeled and unlabeled proteins. Although this is acceptable in some instances, many applications (such as FRET studies) would benefit from the removal of unreacted proteins from the sample. Unfortunately, no general method exists to achieve this separation under conditions mild enough to maintain the folded, native structure of the protein targets. To address this, we report herein a general affinity-based method that can isolate biomolecules that are labeled with small organic chromophores.

Numerous strategies have emerged for the formation of host−guest complexes through molecular recognition events (*3*). Of these, complexes formed with cyclodextrins and their derivatives are arguably the most general (*4*). A wide range of organic molecules has been found to form complexes with cyclodextrins with binding constants that span 6 orders of magnitude (*5*), and, as a result, cyclodextrins have found use in applications ranging from the solubilization of pharmaceutical compounds (*6*) to chiral chromatography (*7*). Several studies have established the ability of cyclodextrins to form host−guest complexes with fluorescent chromophores (*7b*, *8*, *9*); in contrast, we have found that they have little-to-no affinity for most proteins. We envisioned using biocompatible resins functionalized with cyclodextrins to sequester labeled biomolecules selectively, while leaving unlabeled species in solution, Figure 1b. After isolation of the resin, it was anticipated that the captured proteins could be released through the addition of a competitive binder, such as **3**.

A solid support suitable for this purpose was prepared through the exposure of commercially available NHS-ester functionalized Sepharose resin to amine-functionalized β-cyclodextrin (*9*) (**1a**), yielding resin **2a**, Figure 1a. The efficiency of the coupling reaction was monitored by UV analysis of the released NHS, indicating that a loading of 8.7 μmol of β-cyclodextrin/mL of dry resin was obtained. Following hydrolysis of any remaining NHS-esters using ethanolamine, the resin was thoroughly rinsed with water and stored in solution at 4 °C until use (*10*).

In light of the high cost of **1a**, we have also developed a more practical route for the preparation of the resin. Activation of inexpensive β-cyclodextrin with carbonyl diimidazole followed by treatment with excess propylenediamine afforded carbamate **1b** with only minimal amounts of doubly coupled product. This mixture was used to prepare resin analogue **2b**, which performed equivalently in the studies described below.

The ability of the cyclodextrin resin to purify labeled biomolecules was evaluated in the context of a typical lysine modification experiment. After exposure of a solution of myoglobin to 1 equiv of Oregon Green NHS-ester (yielding conjugate **4**) and subsequent removal of the small molecules using gel filtration, 320 μL of the resulting 1 mg/mL solution was exposed to 37 mg of resin **2a** for 5 min. UV−vis analysis indicated the complete disappearance of the Oregon Green absorbance from the supernatant (λ_{max} = 495 nm), while unlabeled myoglobin (λ_{max} = 410 nm) remained in solution, Figure 2a. SDS−PAGE analysis of the supernatant indicated that no fluorescent protein remained (Figure 2b, lane 2), and ESI-MS confirmed that virtually all of the labeled protein had been captured (Figure 2c,d). After isolation via filtration, it was found that the resin could be washed with several portions of water without releasing the bound protein.

Several competitive binders have been used to liberate the modified protein from the resin. Adamantane carboxylic acid (**3**, 10 mM in 100 mM ammonium chloride, pH 7) has been particularly useful in this regard, resulting in nearly complete release in under 1 min, Figure 2a,b. ESI-MS analysis of the resulting solution confirmed that >90% of the eluted protein had been modified, Figure 2e (*11*). Under saturating conditions, UV−vis analysis indicated that 100 mg of resin was able to capture 40 nmol (0.67 mg, in this case) of labeled protein.

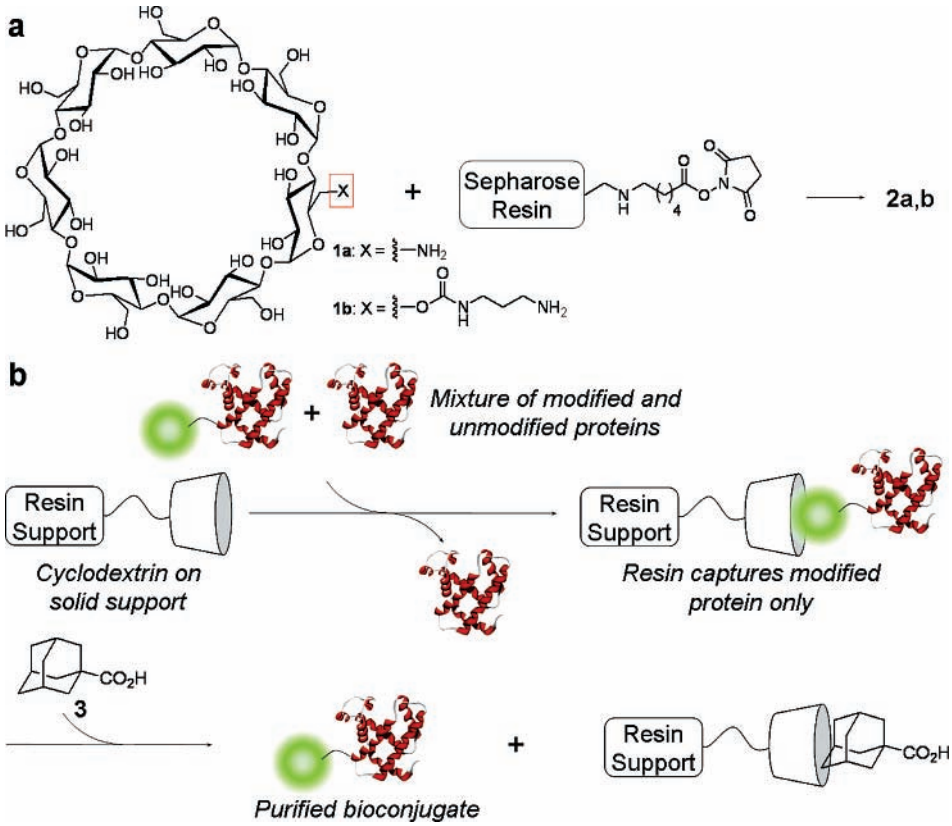

Figure 1. A general strategy for the purification of chromophore-labeled proteins. (a) The solid support used in this approach is prepared by reacting Sepharose-NHS resin with amino-substituted β-cyclodextrin **1a** or **1b**. (b) This resin can then be used to capture chromophore-labeled proteins selectively, allowing facile removal of unmodified protein via filtration. The captured proteins can be eluted from the resin using a competitive cyclodextrin binder, such as adamantane carboxylic acid (**3**).

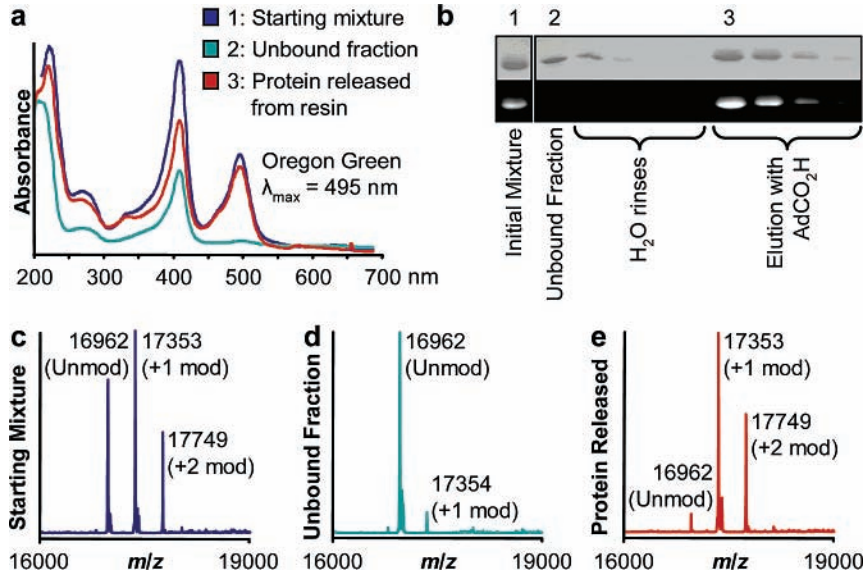

Figure 2. Purification of Oregon Green labeled myoglobin. (a) UV analysis of supernatants during the purification process. Blue = crude labeling solution. Cyan = supernatant after exposure to resin **2a**. Red = protein fraction released from isolated resin after treatment with **3**. The absorbance at 410 nm is due to the myoglobin heme group. The composition of each fraction was also verified using (b) SDS−PAGE and (c−e) ESI-MS analysis.

In terms of buffers, we have found that efficient capture of labeled proteins can be achieved in 50−100 mM HEPES (pH 7), although the use of increased amounts of resin was sometimes required to improve the amount of captured protein (Table 1, entries 2, 9). Other buffers, including phosphate, tris, and acetate, consistently afforded 60−90% yields of modified protein. The technique was also effective for chymotrypsinogen A labeled with FITC (**5**) in a variety of buffers (entries 8−12) and for subtilisin Carlsberg (entry 13). In all cases, MS analysis indicated that the fractions eluted with **3** contained only labeled proteins. Importantly, the chymotrypsinogen A was found to possess similar levels of proteolytic activity before and after the purification process (*12*). This technique has also been applied to the purification of TAMRA- (**6**), Cascade Blue- (**7**), and coumarin-labeled (**8**) proteins, Table 1, entries 15−17.

Consistent with cyclodextrin-dependent binding, resin prewashed with **3** was unable to capture either labeled or unlabeled protein. However, we have observed in several cases that

[a] For detailed procedure see Supporting Information. [b] Each experiment was carried out with 100 μL of protein solution at 50 μM in the indicated buffer at pH 7. [c] Total fluorescence eluted from the resin with **3** as a percentage of all detected fluorescence in bound and unbound fractions (based on SDS−PAGE analysis). Mass spectrometry and UV−vis spectroscopy indicated that samples eluted with **3** possessed only modified protein. [d] Sample quantitation was carried out by UV analysis.

protein−chromophore conjugates bind the resin stronger than a single dye alone; thus, secondary interactions between the protein and the solid support are also functioning. This is advantageous, as modified proteins can be isolated from crude labeling reactions that still contain excess reagents.

In initial experiments, the ability of this method to collect labeled biomolecules from mixtures has also proven useful for the analysis of proteolytic digests. As an example, a sample of myoglobin modified with TAMRA-NHS (yielding **6**) was denatured before incubation with trypsin. The resulting peptide mixture was exposed to resin **2a**, and the solid support was isolated and rinsed. After elution of the peptides into a minimal volume of the solution of **3** described above, LC-ESI-MS indicated enrichment in the modified peptides relative to digested samples that had not been exposed to resin **2a** (See Figure S8 in Supporting Information). A particular advantage of this method is its ability to isolate the modified fragments from unmodified peptides, denaturants, and peptide contaminants arising from trypsin autoproteolysis. The design of specific digest "tags" with improved cyclodextrin binding affinity is in progress.

In conclusion, a new general procedure has been developed for the isolation of modified proteins and peptides. This technique features mild conditions for the capture and release of biomolecular targets, ease-of-use, and the potential to purify a large number of synthetic modification products. It is anticipated that this method will also find use as a tool for proteomic analysis and will facilitate the development of new protein modification reactions. Current efforts are exploring the use of this strategy to separate singly labeled proteins from multiply labeled proteins, as well as the adaptation of this technique to afford continuous flow LC-based methods.

An Affinity-Based Method for the Purification of Fluorescently-Labeled Biomolecules

Trung Nguyen, Neel S. Joshi and Matthew B. Francis*

Department of Chemistry, University of California, Berkeley, CA 94720-1460, and Materials Sciences Division, Lawrence Berkeley National Labs, Berkeley, CA 94720

Supporting Information

General Procedures. Unless otherwise noted, all chemicals were obtained from commercial sources and used without further purification. All small molecule reactions were carried out under a nitrogen atmosphere in oven dried glassware unless otherwise noted. All organic solvents were removed under reduced pressure using a rotary evaporator. Pyridine was distilled under an inert atmosphere from calcium hydride. Water (ddH_2O) used in biological procedures or as a reaction solvent was deionized using a NANOpure™ purification system (Barnstead, USA). Myoglobin (M 1882) from horse heart, Subtilisin Carlsberg protease (P5380) from Bacillus licheniformis, and α-chymotrypsinogen A (P 5380) from bovine pancreas were purchased from Sigma (St. Louis, USA) and used without further purification. Size exclusion chromatography was performed using NAP™ 5 columns from Amersham Biosciences. Microspin™ G-25 columns were purchased from Amersham Biosciences. The pre-packed Sephadex resin was discarded and the columns were thoroughly washed prior to use. Dyes used for protein labeling experiments were purchased from Invitrogen and used without further purification. Samples were mixed using a Barnstead Thermolyne Labquake® Shaker Rotisserie. NHS-activated Sepharose™ 4 Fast Flow resin (17-0906-01) was purchased from Amersham Biosciences. 6-monodeoxy-6-monoamino-β-cyclodextrin (M 2314) and β-cyclodextrin hydrate (856088) were obtained from Aldrich Chemical Company.

Instrumentation and Sample Analysis Preparations. UV-Vis spectroscopic measurements were conducted on a Tidas-II benchtop spectrophotometer (J & M, Germany).

Matrix assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF MS) was performed on a Voyager-DE™ system (PerSeptive Biosystems, USA). All samples were co-crystallized using either an α-cyano-4-hydroxycinnamic acid or a sinapinic acid solution (10 mg/mL in 1:1 MeCN:ddH_2O with 0.1% TFA). Electrospray LC/MS analysis was performed using an API 150EX system (Applied Biosystems, USA) equipped with a Turbospray source and an Agilent 1100 series LC pump. Protein mass reconstruction was performed on the charge ladder with Analyst software (version 1.3.1, Applied Biosystems). Prior to MS analysis, biological samples were desalted and/or separated from small molecule contaminants using μC18 ZipTip® pipet tips (Millipore, USA), NAP-5™ columns (Amersham Biosciences, USA), Strata C-18E™ reversed-phase columns (Phenomenex, USA), or 3500 molecular weight cutoff Slide-A-Lyzer® Dialysis Cassettes (Pierce Biotechnology, Inc., USA) as indicated below. Intact protein chromatography was performed using a Jupiter 5u C5 300Å reversed phase column (2.0 mm x 150 mm) with a ddH_2O:MeCN gradient mobile phase containing 0.1% formic acid (250 μL/min). An Agilent Zorbax 3.5 μm 300SB-C8 reversed phase column (2.1 mm x 50 mm) was used for the analysis of trypsin digest fragments.

For protein analysis, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was accomplished on a Mini-Protean apparatus (Bio-Rad, USA), following the general protocol of Laemmli.[1] Crude reaction mixtures were diluted by a factor of 5

(v/v) in ddH_2O and combined 1:1 (v/v) with gel loading buffer containing SDS, DTT, and bromophenol blue. Samples were then loaded onto the gel without heating. After removal of the completed gels from their cassettes, the bottom portions containing free dye were excised promptly, after which the gels were submerged in water for rinsing and imaging. Commercially available markers (Bio-Rad, USA) were applied to at least one lane of each gel for calculation of apparent molecular weights. Fluorescence visualization of gels was obtained by UV transillumination at 302 nm. Visualization of protein bands was accomplished by staining with Coomassie® Brilliant Blue R-250 (Bio-Rad, USA). Gel imaging was performed on an EpiChem3 Darkroom system (UVP, USA).

General procedure for fluorescent labeling of proteins. In a typical procedure, 3.5 mL of a 0.1 mM myoglobin solution in 0.1 M $NaHCO_3$ pH 8.3 aqueous buffer was transferred to a centrifuge tube. An amine reactive fluorophore (~1 mg) in 20-40 μL of DMF was then added. The solution was stirred on a laboratory mixer for 2.5 h and then quenched with 0.1 M H_2NOH pH 7.2 (80 μL, 8.0 μmol) aqueous solution. The reaction was then mixed overnight at room temperature. For specific examples of protein labeling reactions refer to Table 1. A portion of the crude reaction was purified by size exclusion chromatography. The purified solution was analyzed by UV-vis spectroscopy, MALDI-TOF-MS or ESI-MS, and SDS-PAGE. The sample used for many of the experiments presented in the supporting information will be referred to as **S1** (see Table S1)

Table S1. Fluorescent labeling of myoglobin with amine reactive dyes.

Dye/fluorophore	Conjugate #	Eq. of dye added	Conjugates detected[1]
Oregon Green 488 carboxylic acid SE	**4**	1.0	Unmod, +1, +2
TAMRA-NHS	**6**	5.0	+2, +3, +4, +5
Cascade Blue acetyl azide	**7**	5.0	Unmod, +1, +2
Alexa Fluor 350 carboxylic acid SE	**8**	5.0	+2, +3, +4, +5
Oregon Green 488-X-succinimidyl ester	**S1**	5.0	Unmod, +1, +2, +3

[1]Extent of labeling was determined by MALDI-TOF or ESI-LC MS. Only predominant species present in the spectra were reported.

Quantification of sepharose resin coupling reaction. In order to quantify the degree of modification to the NHS-activated sepharose resin the Amersham literature procedure was employed. To analyze the amount of NHS hydrolyzed during a coupling experiment, a calibration curve was formed by monitoring the absorbance at 260 nm for serial dilutions of a 30 mM NHS aqueous solution in 0.2 M $NaHCO_3$/0.5 M NaCl pH 8 buffer. For coupling reactions to the NHS-activated resin, Amersham Biosciences literature values predicted concentrations of released NHS to be from 16-23 μmol/mL of resin.

Synthesis of β-cyclodextrin modified sepharose resin (2a). NHS-activated resin was transferred to a fritted column as a slurry and filtered to dryness. The resin occupied a volume of 17.5 mL. A solution of 6-monodeoxy-6-monoamino-cyclodextrin (0.44 g) in 10 mL 0.2 M $NaHCO_3$/0.5 M NaCl pH 8 aqueous buffer was added to the resin. The column was then capped and agitated on a laboratory shaker for 2 h. The reaction tube was drained and the eluting solvent was collected for subsequent analysis. Afterwards, the resin was subjected to the following series of washes:

- 3 washes of 0.2 M $NaHCO_3$/0.5 M NaCl pH 8 aqueous buffer (10 mL portions)
- 3 washes of 0.5 M ethanolamine/0.5 M NaCl pH 8.3 aqueous buffer (10 mL portions)

- 3 washes of 0.1 M acetate/0.5 M NaCl pH 4 aqueous buffer (10 mL portions)
- 1 wash of H_2O (10 mL portions)
- 2 washes of 25 mM phosphate buffer pH 7 (10 mL portions)
- 3 washes of H_2O (200 mL portions)

The resin was then stored as a slurry in H_2O at 4 ^oC.

The eluting fraction from the coupling reaction was determined to contain 153 μmol of NHS. This corresponds to a cyclodextrin loading of 8.7 μmol/mL of dry resin. Expected values for NHS release during this reaction were 280-403 μmol according to Amersham loading values.

Synthesis of amino β-cyclodextrin derivative (1b). β-cyclodextrin monohydrate was placed in a flask as a solid and dried under vacuum at 50 ºC overnight. The dry cyclodextrin (1.0 g, 0.86 mmol) was transferred to a new flask and dissolved in freshly distilled pyridine (3.0 mL). A solution of carbonyldiimidazole (140 mg, 0.86 mmol) dissolved in 1 mL of freshly distilled pyridine was added to the reaction mixture dropwise over 2 minutes while stirring. The activation reaction was allowed to proceed at rt for 2 h. After this time, the activated cyclodextrin solution was added dropwise to a flask containing 1,3-diaminopropane (360 μL, 4.32 mmol) while stirring. After 1 h, the cyclodextrin mixture was precipitated by adding the reaction solution dropwise to a flask containing 500 mL of CH_2Cl_2 with vigorous stirring. The flaky white precipitate was isolated *via* suction filtration through filter paper, then placed under vacuum overnight. The cyclodextrin mixture was analyzed by MALDI-TOF mass spectrometry (Figure S1) and used without further purification.

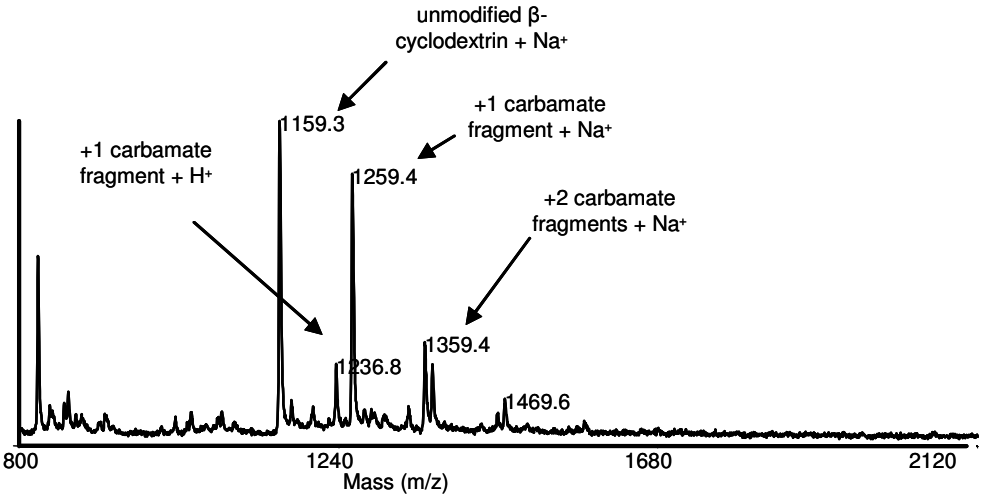

Figure S1. MALDI-TOF spectrum of **1b** using α-cyano-4-hydroxycinnamic acid matrix. Expected mass for β-cyclodextrin [M+Na]+ = 1158.0. Other peaks correspond to additions of the 100 Da carbamate fragment (see Figure 1 in main text).

Synthesis of β-cyclodextrin modified Sepharose resin (2b). Sepharose-NHS resin slurry (0.5 mL) was placed in a fritted tube and filtered. To the dry resin was added a solution of **1b** (75 mg in 1.5 mL of $NaHCO_3$ (0.1 M), NaCl (0.5 M), pH 8). The resulting slurry was agitated overnight. The resin was then subjected to the following rinses:

- 3x 1 mL of 0.5 M ethanolamine/0.5 M NaCl pH 8
- 3x 1 mL 0.1 M acetic acid/0.5 M NaCl pH 4
- 2x 20 mL H_2O

The resin was stored at 4 ^{o}C as a slurry in water.

General procedure for resin capture of proteins. First, the crude protein solution was purified by size-exclusion chromatography using a NAP^{TM} 5 column into pure H_2O or into the appropriate buffer solution. To a microcentrifuge tube containing 10-20 mg of dry CD modified sepharose resin, the

purified protein (100-200 μL of 60 μM solution) was added. Additional water was added to the heterogeneous solution to ensure proper mixing of the resin and protein solution. The solution was then agitated on a laboratory mixer for approximately 5 min. The heterogeneous solution was then transferred to a fritted microspin column and spun dry.

The eluting solvent was collected in microcentrifuge tubes. It was observed that the color of the protein solution had been transferred to the resin. Water (0.5 mL) was then added to the column and mixed by manual inversion for 1 min. The resin was rinsed with additional amounts of H_2O. To elute the protein, 0.5 mL of 10 mM adamantane carboxylic acid/100 mM NH_4Cl pH 7 was added to the resin and inverted by hand for 1 min. The color of the eluting solution resembled that of the beginning protein solution. Additional washes with the eluting solvent mixture were performed to achieve higher levels of protein recovery. The eluting fractions were analyzed by UV-vis spectroscopy (Figure S2), and SDS-PAGE (Figure S3).

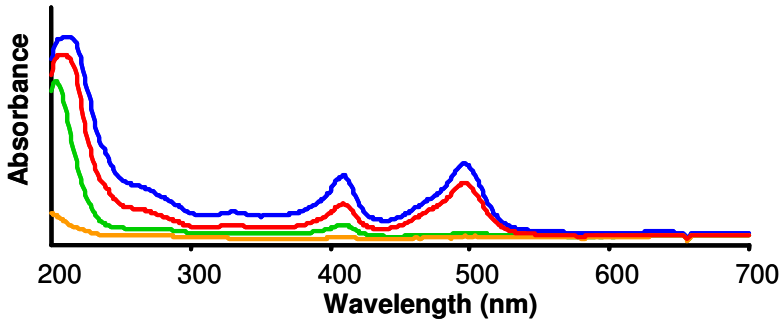

Figure S2. UV-vis spectrum of resin **2b** capture of **S1**: before exposure to resin (blue), flow through after resin exposure (green), H_2O washes of resin (orange), elution off of resin with 10 mM adamantane carboxylic acid, 100 mM NH_4Cl, pH 7 (red).

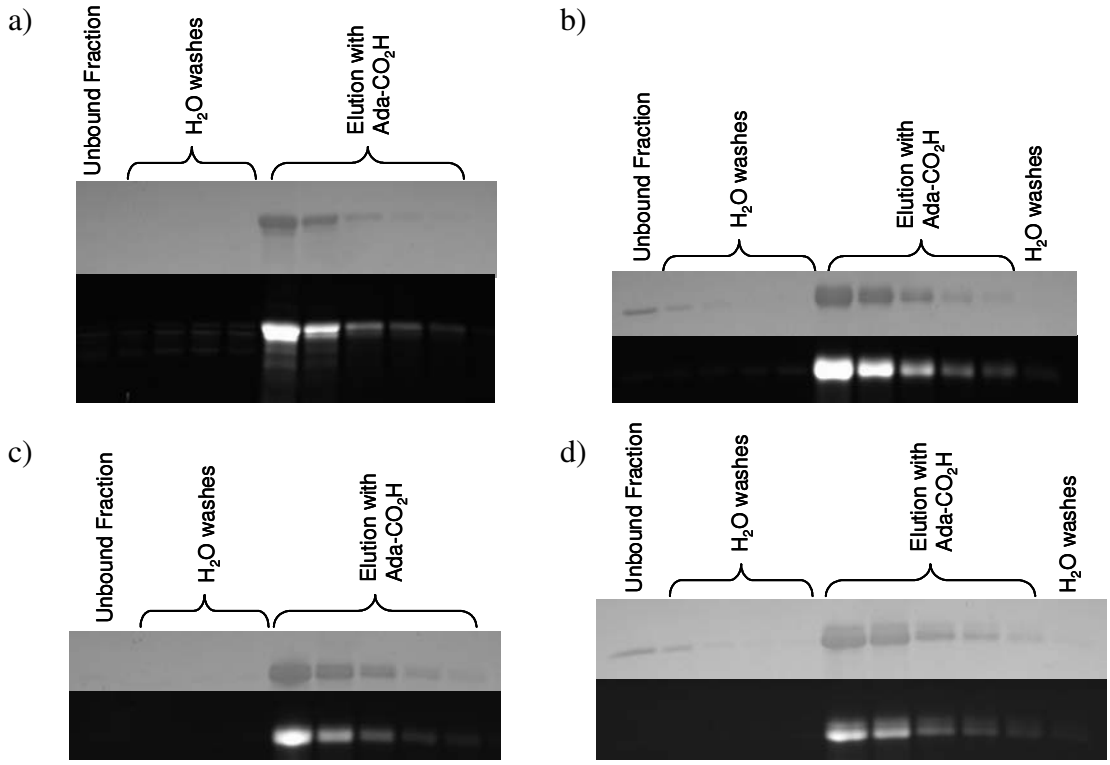

Figure S3. SDS PAGE analysis of eluting fractions for a) TAMRA labeled myoglobin b) Oregon Green labeled myoglobin c) Alexa Fluor 350 labeled myoglobin d) Cascade Blue labeled myoglobin.

SDS-PAGE quantification of modified protein recovery. SDS-PAGE analysis was used to quantify the amount of modified protein recovered by the resin. The values in the "% fluorescence" column of Table 1 were calculated in the following manner:

Using the fluorescent images of the gels in Figure S3 as an example,

% fluorescence = 100*(sum of fluorescence in elution lanes)/(sum of fluorescence in all lanes)

The fluorescence in each lane was quantified using ImageJ 1.34s, an image processing and analysis program available free from the NIH website (http://rsb.info.nih.gov/ij/download.html).

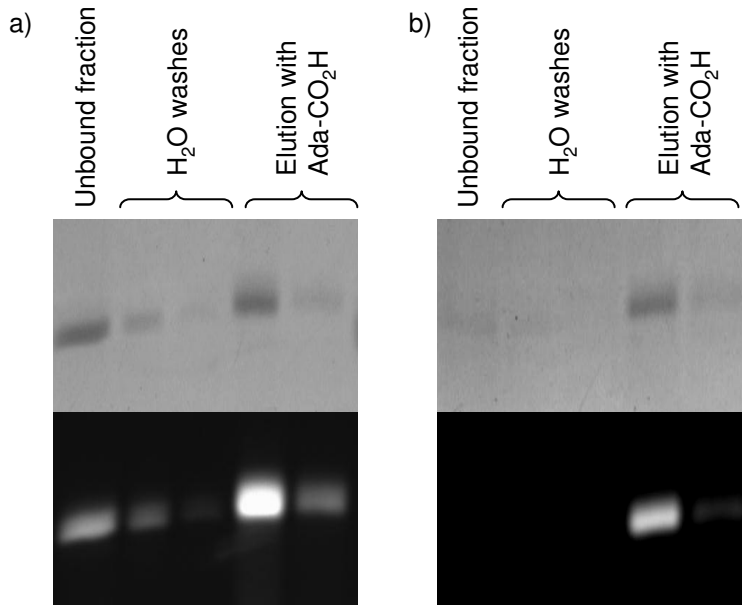

Figure S4. SDS-PAGE analysis of eluting fractions for Oregon Green-labeled myoglobin in the presence of a) 100 mM sodium phosphate buffer and b) 100 mM HEPES buffer. These samples correspond to entries 2 and 5 in Table S1.

Protein binding in commonly used buffer solutions. A solution of **S1** was diluted into 4 different buffers (Tris, HEPES, NH_4OAc, and phosphate) to a final buffer concentration of 0.1 M, pH 7. These solutions were then added to centrifuge tubes containing resin **2a**. The proteins were purified as described in the protein purification procedure. The eluting fractions were analyzed by SDS-PAGE and UV-vis spectroscopy (Figures S4 and S5).

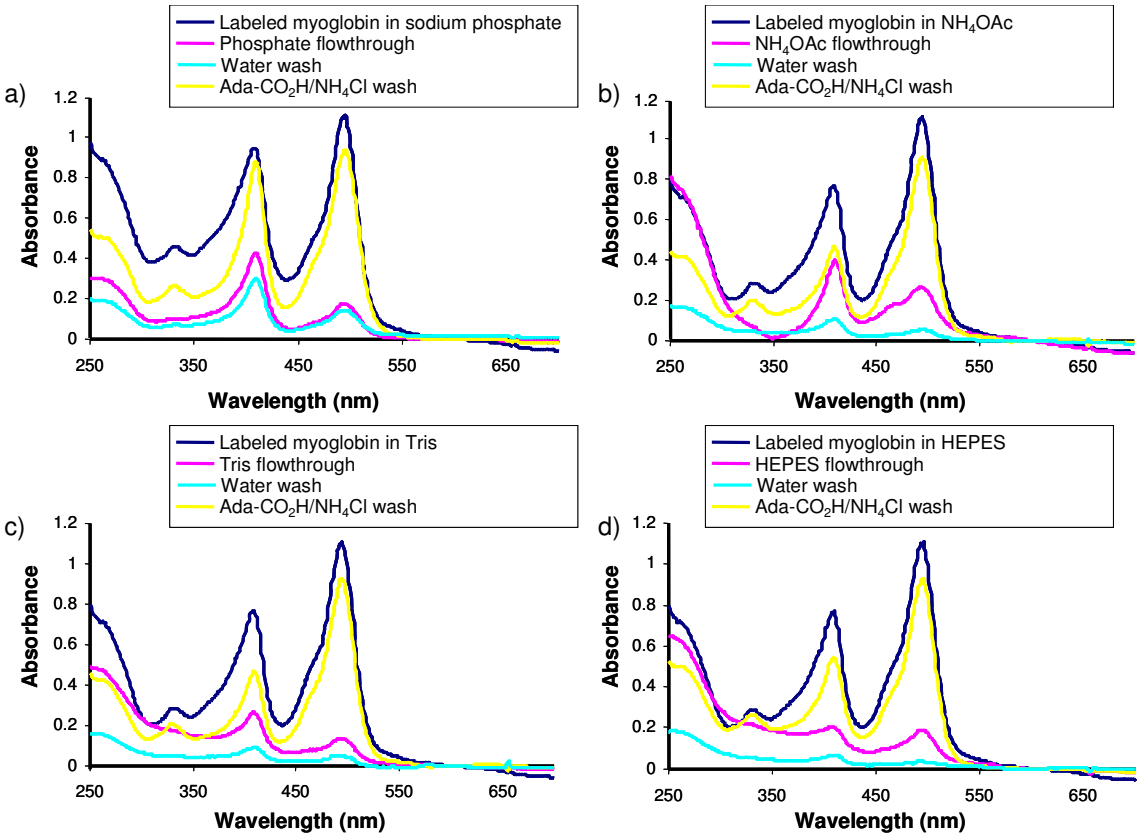

Figure S5. UV-vis spectra of Oregon Green-labeled myoglobin binding to resin **2a** in commonly used buffers (each 0.1 M, pH 7) a) sodium phosphate b) NH_4OAc c) Tris d) HEPES.

Adamantane effects on protein binding. Resin **2a** (71.4 mg) was suspended in 500 µL of 10 mM adamantane carboxylic acid/100 mM NH_4Cl pH 7 and then agitated for 15 min by a laboratory mixer. The solution was transferred to separate microspin columns and spun dry. A solution of **S1** (250 µL) was diluted to 1 mL and added to the respective resin in a centrifuge tube. The heterogeneous solution was mixed for 5 min. Afterwards, the solution was transferred to microspin column and spun dry. The eluent was analyzed by UV-vis spectroscopy. The resin was then washed with 500 µL H_2O (2x). The collected washes were analyzed by UV-vis spectroscopy. A final wash was performed with 500 µL 10 mM adamantane carboxylic acid/100 mM NH_4Cl (2x). The collected washes were also analyzed by UV-vis spectroscopy (Figure S6).

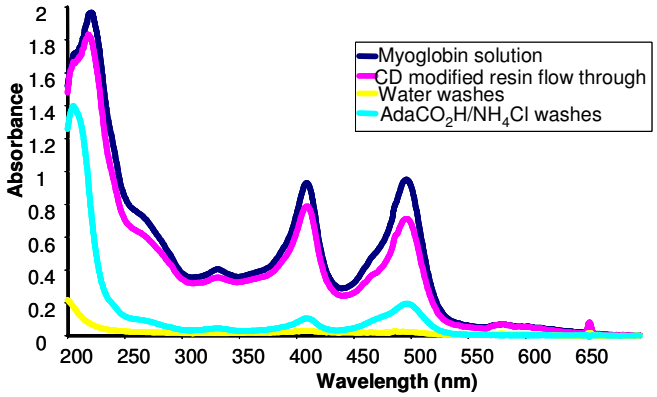

Figure S6. UV-vis spectra of **S1** exposed to resin **2a** pre-washed with 10 mM adamantane carboxylic acid/100 mM NH_4Cl pH 7 solution.

MALDI-TOF MS analysis of the resin. To resin **2a** (33.2 mg), 50 µL of myoglobin conjugate **4** and 250 µL of H_2O were added. After mixing for 5 min, the heterogeneous solution was spun dry in a microspin column. The resin was then washed with 500 µL of H_2O and a small portion of the dry resin was cocrystallized with sinapinic acid on a MALDI plate for analysis. The remaining resin was washed with 500 µL of 10 mM adamante carboxylic acid/100 mM NH_4Cl pH 7 buffer. The aqueous fractions were then analyzed by MALDI-TOF MS (Figure S7).

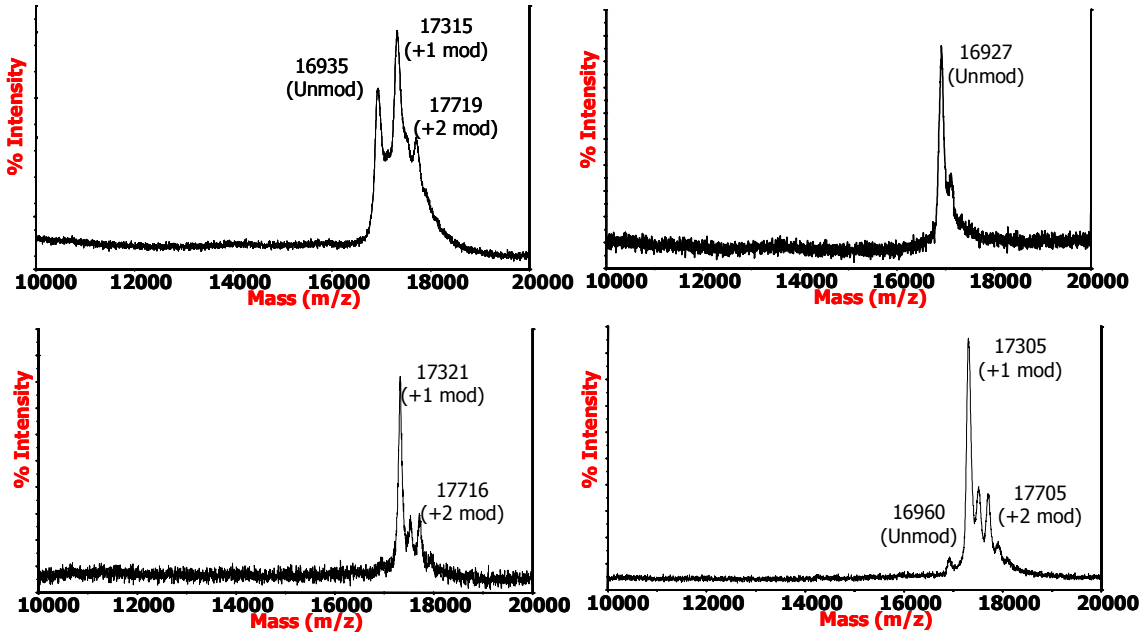

Figure S7. MALDI-TOF spectrum of a) Oregon Green labeled myoglobin b) aqueous flow through solution c) cyclodextrin modified sepharose resin after exposing to a solution of Oregon Green labeled myoglobin d) the eluting solution from the 10 mM adamantane carboxylic acid/100 mM NH_4Cl pH 7 wash

Procedure for enrichment of modified trypsin digest fragments. 50 mL of a solution of myoglobin conjugate **6** (1 mg/mL) was combined with 50 µL of acetonitrile. DTT was added to the resulting solution to a final concentration of 10 mM. The protein was denatured at 65 ºC for 1 h. The denatured protein solution was diluted by the addition of 0.45 mL of 50 mM NH_4HCO_3, pH 7.8. Trypsin (Promega Sequencing Grade) was then added to the myoglobin solution in a 1:100 (w/w) ratio. After 5 hours of incubation at 37 ºC, the proteolysis solution was lyophilized overnight. The peptide mixture was dissolved in 200 µL of water and divided into two 100 µL portions. To one portion was added 5 mg of dry resin **2a**. The heterogeneous mixture was agitated for 5 min before being transferred to an empty MicroSpinTM (Amersham) column and centrifuged at 14,500 rpm for 30 s. The dry resin, which appeared brown due to the capture of modified peptides, was washed twice with 200 µL aliquots of H_2O. The resin was then washed with one 100 µL aliquot of 10 mM adamantane carboxylic acid, 100 mM NH_4Cl, pH 7.

The brown color was transferred from the resin to the solution. Aliquots from before and after the resin capture procedure were both analyzed by LC-ESI MS (Figures S8).

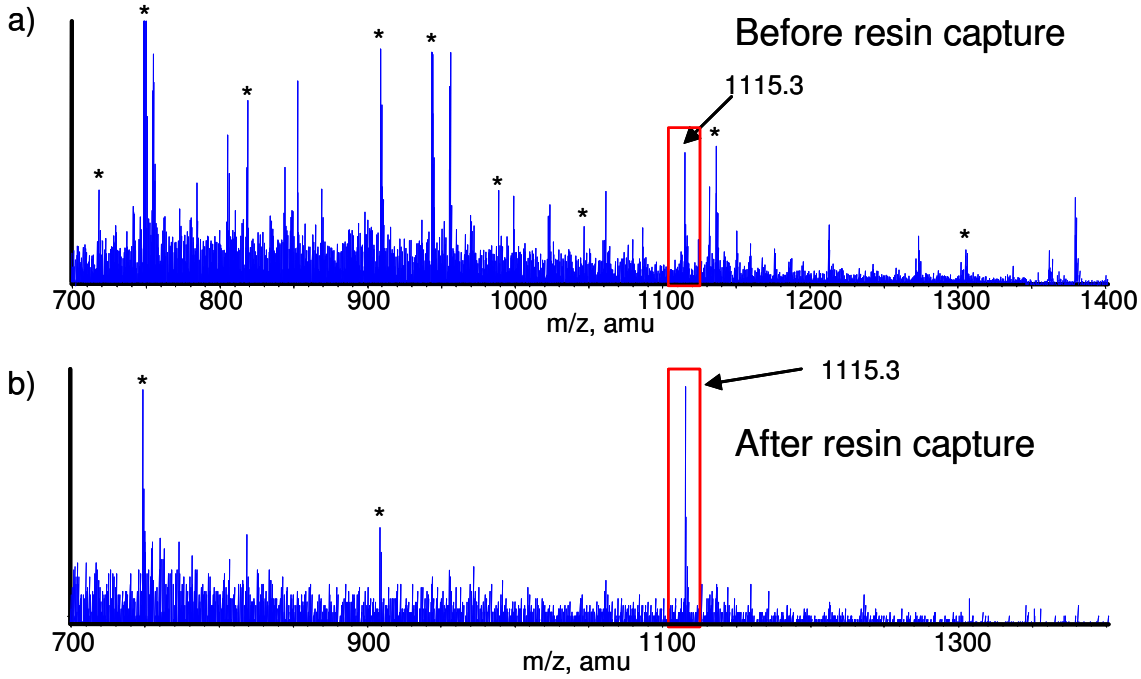

Figure S8. LC-MS analysis of modified trypsin fragments from digestion of TAMRA modified myoglobin: [a]mass spectrum of trypsin fragments before resin capture. Starred masses represent unmodifed trypsin digest fragments. [b]mass spectrum of trypsin fragments after elution from **2a** with adamantane-CO_2^- solution. Modified N-terminal fragment (GLSDGEWQQVLNVWGK) expected m/2 = 1115.5.

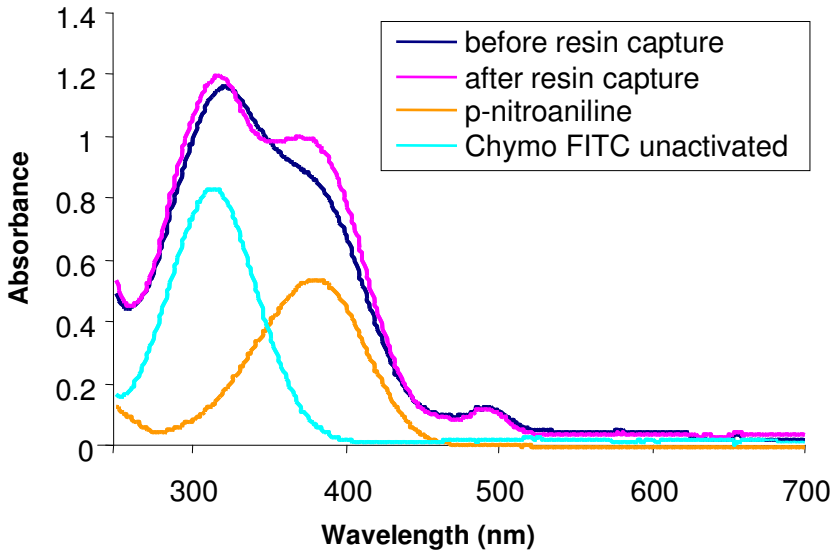

Figure S9. Normalized spectra for chymotrypsin activity assay. Absorbance at 380 nm indicates the hydrolysis of *p*-nitroaniline from the assay substrate. The intact assay substrate has an absorbance maximum at 305 nm. Chymotrypsin shows similar levels of activity before (blue) and after (pink) resin capture.

Activity assay of resin captured chymotrypsinogen. After a typical resin capture procedure was performed on chymotrypsinogen modified with **5**, the eluted fractions were assayed for chymotryptic activity. 20 uL of the released protein was treated with 2.9 uL of a 0.4 mg/mL trypsin solution in 50 mM acetic acid. The activation of the zymogen was allowed to proceed for 10 min at room temperature before the addition of 80 uL of 0.5 mM chymotrypsin substrate I, colorometric (Suc-GGF-pNA, Calbiochem 230912) in 50 mM Tris, 20 mM $CaCl_2$ buffer, pH 7.6. The hydrolysis of p-nitroaniline from the tripeptide substrate occurred at room temperature for 30 min. The progress of the hydrolysis reaction was followed by monitoring the absorbance at 390 nm (Figure S9).

Additional figures.

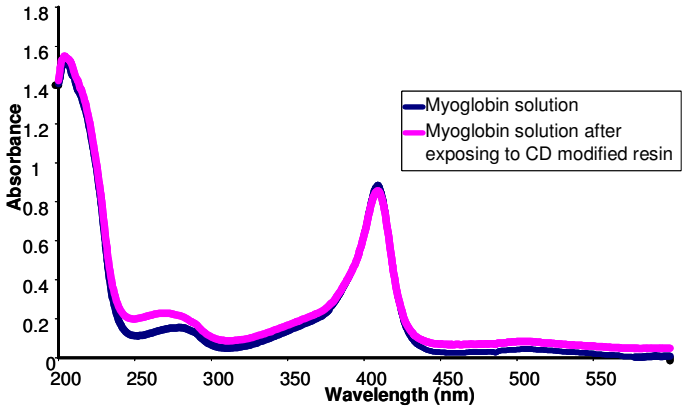

Figure S10. Complete recovery of unmodified myoglobin was obtained in the supernatant after exposure to resin **2a**, confirming that the protein does not bind in the absence of the fluorescent label.

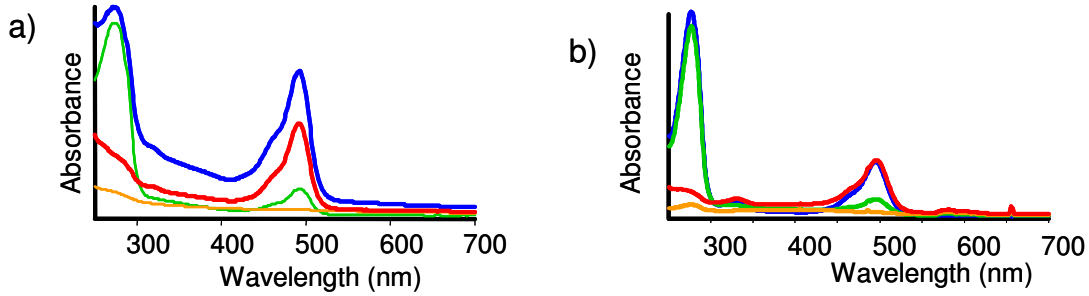

Figure S11. UV/vis spectra of modified protein resin capture: starting mixture (blue), flow through (green), water washes of resin (orange), elution with 10 mM adamantane carboxylic acid, 100 mM NH_4Cl, pH 7 (red). Hydrogels Formed by Multiple Peptide Ligation Reactions To Fasten Corneal Transplants

Michel Wathier,[†] C. Starck Johnson,[‡] Terry Kim,[‡] and Mark W. Grinstaff*[,†]

Departments of Biomedical Engineering and Chemistry, Metcalf Center for Science and Engineering, Boston University, Boston, Massachusetts 02215, and Department of Ophthalmology, Duke University Medical Center, Durham, North Carolina 27710. Received March 7, 2006; Revised Manuscript Received May 31, 2006

A stable cross-linked hydrogel was formed under mild aqueous conditions using pseudoproline peptide ligation chemistry. A cysteine-terminated lysine dendron containing four cysteines and a PEG macromolecule modified with terminal ester aldehydes were prepared. Upon mixing, the two macromers gave a stable hydrogel. This hydrogel along with sutures was used to successfully secure a corneal transplant in vitro.

Mild chemoselective reactions with biomacromolecules are of significant interest and of widespread use in chemistry, biology, and more recently in nano-biotechnology. Such reactions can afford bioconjugates for characterization of native functions (e.g., electron-transfer proteins) (*1*), attachment to solid substrates (e.g., chemiluminescence biosensor applications) (*2*), preparation of biohybrid structures (e.g., derivatized bacteriophage) (*3*), and introduction of new activity (e.g., photoresponsive membrane channels) (*4*). Of these reactions, chemical ligation is a particularly attractive approach to prepare large proteins that are otherwise unattainable using conventional solid-phase peptide synthesis (*5*−*8*). Moreover this mild coupling reaction can be performed in the presence of functional groups in aqueous solutions. Recently, we used multiple thiazolidines as the chemical ligation between macromolecules to render a cross-linked hydrogel for the repair of acute corneal wounds (*9*). For applications where a hydrogel adhesive is required for longer periods, such as in a corneal transplant, we are evaluating the use of pseudoproline ligations between a dendron and poly(ethyleneglycol) possessing N-terminal cysteines and aldehyde esters, respectively. Herein we report the synthesis, characterization, and capability of this in situ polymerizing hydrogel to fasten corneal transplants in vitro.

Pseudoproline formation is one type of chemoselective and orthogonal peptide ligation method that has been applied successfully to the synthesis of a variety of proteins (*5*, *6*, *10*, *11*). In this mild coupling strategy, a peptide possessing a C-terminal glycol aldehyde ester is reacted with another peptide possessing a N-terminal cysteine. The reaction occurs in a stepwise process with imine ligation and thiazolidine formation followed by an *O*,*N*-acyl migration to afford the pseudoproline linkage (Figure 1). For this approach to translate to a cross-linked network, two macromers are required where at least one possesses two and the other three or more reactive groups. Specifically, the dendron macromer (Figure 1) was prepared via successive amidations using the pentafluorophenyl activated esters of Lys (ZLys(Z)OPFP) and Cys (IsoCys(Boc)OPFP) (*9*). This macromer was selected because dendritic macromolecules provide a highly branched structure of defined composition with extensive surface functionalization capabilities (*12*−*17*), which facilitates subsequent intermolecular cross-linking to form a hydrogel. The two ester-aldehyde functionalities on the PEG macromer (MW 3400) were introduced as follows. The PEG diol was first reacted with succinic anhydride in pyridine to afford poly(ethylene glycol) disuccinic acid. Next, the cesium salt was prepared by neutralization of the acid with 1 M $CsCO_3$ until pH 8 followed by coupling bromoacetaldehyde dimethyl acetal in DMF to give the protected aldehyde. The acetal was deprotected using 10% TFA in DCM to afford the poly(ethylene glycol) diester-aldehyde (see Supporting Information for details).

Upon mixing an aqueous solution of the poly(ethylene glycol) diester-aldehyde and dendron macromers, a hydrogel (*18*, *19*) forms within about 30 s (20, 33, or 50 wt % polymer solutions). Cylindrical hydrogel samples of 8 mm diameter and 3 mm thickness were prepared in aqueous buffer pH = 7.4, and the mechanical properties were measured at a frequency of 1 Hz. The hydrogels exhibited viscoelastic properties. The compressive (*E*) and complex modulus (*G**) for the 20, 33, and 50 wt % hydrogels prepared were measured after 24 h of formation or after incubating for 24 h in an aqueous buffer solution at pH = 7.4 (Figure 2). As expected the mechanical properties increased with increasing macromer wt %. After swelling over 24 h, the moduli decrease relative to the unswollen hydrogels consistent with a more hydrated structure. The hydrogels are optically transparent with a UV cutoff of ≈300 nm (see Figure 4A).

The hydrogel formed between the dendron and poly(ethylene glycol) diester-aldehyde is stable and retains its shape and size over time. As shown in Figure 3, this pseudoproline-cross-linked hydrogel remains intact for more than 6 months with less than a 10% change in weight when placed in a humidity chamber. At six months the value for compressive modulus is ≈90% of the original value, indicating that an extensive network is still present. This result is in contrast to a hydrogel formed between the dendron and poly(ethylene glycol) dialdehyde (*9*). In this later reaction, a hydrogel is formed via formation of multiple thiazolidines. This reaction represents the first half of the reaction sequence shown in Figure 1. Given that thiazolidine formation is reversible, the hydrogel is intact for relatively short periods. When placed in a humidity chamber, the thiazolidine-cross-linked hydrogel loses its original cylindrical shape and is an unstructured gelatinous mass at approximately one week (see Figure 3). Confirmation of the thiazolidine and the pseudoproline

ligations was obtained using a model small molecular weight system in a manner analogous to that previously reported (see SI) (*20*).

We are interested in the design requirements and properties of hydrogels as sealants for the repair of ophthalmic wounds created as a result of injury, infection, or surgical procedure (*21*−*25*). For relatively small, acute wounds such as a cataract incision, the hydrogel adhesive formed via multiple thiazolidines (*9*) offers the advantages of securing the wound but not residing

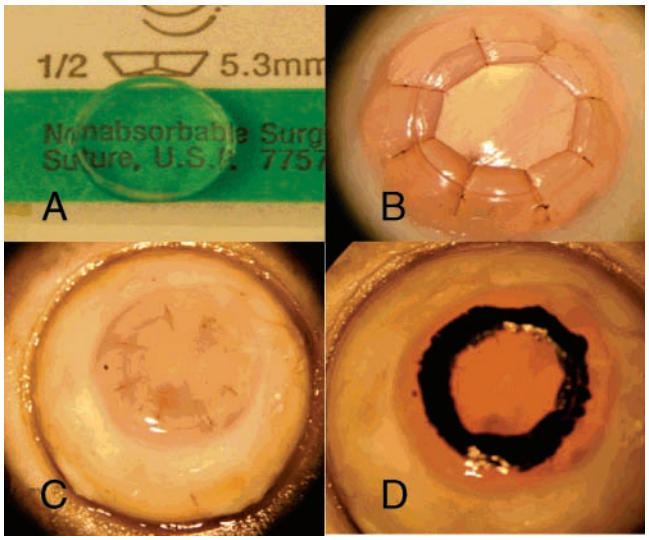

Figure 4. (A) Photograph of the hydrogel. (B) Photograph of a corneal autograft fastened with 8 interrupted 10-0 nylon sutures. long-term at the wound site. In fact corneal re-epithelization of a small wound in humans occurs within about 3 days (*26*). However, for the repair of large corneal wounds such as corneal transplants, a sealant is desired that can remain longer at the wound site.

Corneal transplantation or penetrating keratoplasty (PKP) is one of the most common and successful tissue transplants (*27*). In a corneal transplantation the recipient cornea undergoes a large circular full-thickness cutting, or trephination, to remove the diseased or damaged tissue and then a previously trephinated donor corneal button is manually sutured to the recipient corneal rim. The major disadvantages related to this procedure include delayed visual recovery, suprachoroidal hemorrhage, neovascularization, microbial keratitis, postoperative suture removal (typically nine-months after transplantation), and surgically induced astigmatism (*28*−*31*). Furthermore, these complications in PKP are often a result of the use of sutures. A sutureless corneal transplant procedure would significantly improve PKP

with regard to the multiple intraoperative and postoperative issues mentioned above. The idea of a sutureless keratoplasty is not new, but the development of a practical sutureless ophthalmic procedure has eluded the field since its original inception by Gradle in 1921, although there have been some encouraging results (*32*−*34*).

Toward this goal, we determined whether this in situ polymerizing hydrogel would reduce the number of sutures necessary to secure the incision between the host and graft corneal tissue. In this in vitro model, an 8 mm central corneal trephination was made in an enucleated eye and then this newly formed button was autografted back to the original eye. The host−graft tissue interface was secured using sutures, sutures plus the hydrogel sealant, or the hydrogel sealant alone (Figure 4). The leaking pressure for the autografted eyes was measured as we have done for corneal laceration studies to determine the extent to which the wound was sealed (*9*). The leaking pressure for autografts receiving 16 interrupted 10-0 nylon sutures was 13 ± 5 mmHg ($n = 4$). Today, this is a standard procedure for a PKP. Normal intraocular pressure (IOP) is ≈15 mmHg. When the hydrogel sealant was applied (33 wt %; 60 μL) to the sutured wound with 16 interrupted sutures, the leaking pressure increased to 63 ± 7 mmHg ($n = 4$). Increasing the macromer wt % to 50% (60 μL) with 16 interrupted sutures afforded a leaking pressure of 101 ± 5 mmHg ($n = 4$). Next, we evaluated if the hydrogel sealant in concert with 8 interrupted 10-0 nylon sutures would secure the wound. The autograft with 8 sutures had a leaking pressure of 5 mmHg or less ($n = 4$). When the hydrogel sealant at 33wt % % (60 μL) and 8 sutures were used to secure the autograft, the wound leaked at a pressure of 45 ± 6 mmHg ($n = 4$). This leaking pressure approaches the upper bounds of the physiologically relevant limit, and thus we decided to increase the wt % of the polymers to attain a stronger seal. Application of the 50 wt % formulation (60 μL) and 8 sutures afforded an autograft that leaked at a pressure of 77 ± 5 mmHg ($n = 4$). Application of the hydrogel sealant reduced the number of sutures required to secure the autograft. We were unable to secure the autograft to a safe high pressure when the hydrogel sealant was used alone, indicating that this hydrogel does not possess sufficient adhesivity by itself to secure a PKP. However, an additional benefit to this hydrogel sealant, beyond closing the wound with a reduced number of sutures, is the potential of the hydrogel barrier formed at the wound interface to protect the wound from postoperative infections. As a first indicator for the potential effectiveness of this hydrogel barrier, the transport of India ink across the hydrogel can be monitored as described by McDonnell (*35*). As shown in Figure 4D when India ink is applied to the wound, the dye does not penetrate into the anterior chamber, indicating that the wound interface is secured.

In summary, an in situ polymerizing hydrogel is described that forms in aqueous solution under mild conditions. This chemical-ligation strategy is attractive for hydrogel preparation since it allows synthetic flexibility in the use of a wide-range of macromer compositions, including potentially those with reactive groups, in a manner analogous to the reaction diversity obtained with previous bioconjugated proteins and enzymes. The hydrogel can be used in conjunction with a reduced number of sutures to successfully fasten a corneal transplant and secure the wound interface. The dendron macromer used in hydrogel formation belongs to a family of dendritic macromolecules composed of biocompatible building blocks (*21*, *22*). This macromer system enables efficient cross-linking, varied hydrogel properties, and aqueous polymer solutions for application to a wound site. Dendritic macromolecules, due to their unique properties, structure, and high degree of compositional preciseness, are finding ever-increasing uses in medicine, ranging from vehicles for drug delivery and imaging agents to biomaterials for wound management and tissue restoration.

Dendritic Cationic Lipids with Highly Charged Headgroups for Efficient Gene Delivery

Kai K. Ewert,* Heather M. Evans, Nathan F. Bouxsein, and Cyrus R. Safinya*

Department of Materials, Department of Physics, and Molecular, Chemical, and Developmental Biology Department, University of California, Santa Barbara, California 93106. Received October 24, 2005; Revised Manuscript Received April 10, 2006

Gene therapy is expected to lead to powerful new approaches for curing many diseases, a potential that is currently explored in worldwide clinical trials. Nonviral DNA delivery systems are desirable to overcome the inherent problems of viral vectors, but their current efficiency requires improvement and the understanding of their mechanism of action is incomplete. We have synthesized new multivalent cationic lipids with highly charged dendritic headgroups to probe the structure−transfection efficiency relationships of cationic liposome (CL)−DNA complexes, a prevalent nonviral vector. The lipid headgroups are constructed from ornithine cores and ornithine or carboxyspermine endgroups. The dendritic lipids were prepared on a gram scale, using a synthetic scheme that permits facile variation of the lipid building blocks headgroup, spacer, and hydrophobic moiety. They carry four to sixteen positive charges in their headgroups. Complexes of DNA with mixtures of the dendritic lipids and neutral 1,2-dioleoyl-*sn*-glycero phosphatidylcholine (DOPC) exhibit novel structures at high contents of the highly charged lipids, while the well-known lamellar phase is formed at high contents of DOPC. DNA complexes of the new dendritic lipids efficiently transfect mammalian cells in culture without cytotoxicity and, in contrast to lamellar complexes, maintain high transfection efficiency over a broad range of composition.

INTRODUCTION

Gene therapy is based on the use of DNA as a therapeutic agent. This novel medical approach is being investigated in numerous current clinical trials (*1*, *2*). Inherited diseases and cancers feature most prominently as targets, but cardiovascular and a large range of other diseases are amenable to gene therapeutic treatment as well (*3*). In addition, new therapeutic applications for the delivery of nucleic acids have been opening up (*4*) due to discoveries of novel pathways of gene expression and regulation, such as that of RNA interference (RNAi) (*5*−*8*).

Efficient and safe DNA carriers (vectors) are essential for the success of gene therapy. While engineered viruses are very efficient (*9*, *10*) both in vitro and in vivo, their carrying capacity is limited, their preparation is comparatively complex and concerns about their safety have recently been intensified by a few severe setbacks (*11*). Thus, there has been increasing interest in nonviral or synthetic vectors (*12*−*14*). Typically, these are complexes of DNA with cationic macroions, such as cationic liposomes (CLs) (*15*−*17*) or cationic polyelectrolytes (*18*, *19*). Synthetic vectors are facile to prepare and often allow a variation of the vector properties simply by modifying their composition; they lack immunogenic protein components and can transport DNA of unlimited length. However, their efficiency needs to be improved to render them viable for widespread therapeutic use (*20*).

Dendrimers are highly branched synthetic molecules typically based on AB_2 monomers. In contrast to branched polymers, however, dendrimers are monodisperse and typically assembled by adding generations of monomer to a core molecule (*21*−*23*). Some commercially available dendrimers with protonatable amino groups, such as poly(amidoamine) (PAMAM) and poly(propylenimine) (PPI) dendrimers, have been used as gene delivery vectors (*19*, *24*−*28*), and the structure of their DNA complexes has been investigated (*29*). Conjugates of dendritic molecules to PEG have also been used for gene delivery (*30*).

A large number of cationic and other lipids have been synthesized in efforts to improve the efficiency of CL−DNA complexes. Earlier work has been reviewed in detail (*31*−*33*), and several more recent reviews with a smaller scope have also appeared (*34*−*36*). Some lipid vectors have been commercialized, and many are able to efficiently transfect cultured mammalian cells. Nevertheless, establishing structure−efficiency relationships of CL−DNA complexes has turned out to be challenging. This is mainly due to the large number of relevant parameters, such as lipid structure, lipid composition, lipid/DNA charge ratio, and complex structure. To date, only a few unifying concepts regarding structure−efficiency relationships have emerged. For example, it has recently been shown that the transfection behavior of cationic lipids exhibits universal trends when properties of the self-assembled system as a whole, such as the membrane charge density σ_M, are used to plot the data from various lipids (*37*, *38*). The lipids described in this paper were designed to further explore this finding: their highly charged, dendritic headgroups allow for very high membrane charge densities.

The nanostructure of CL−DNA complexes has a significant impact on their mechanism and efficiency of transfection (*39*). Optimized complexes of either of the two well-known phases of CL−DNA complexes, the inverted hexagonal (H_{II}^C) (*40*), and the lamellar (L_α^C) (*41*) liquid crystal phase, show equally

high transfection efficiency. However, the transfection mechanisms of the two phases vary greatly as a consequence of their structures (*42*−*44*). A third, hexagonal phase of CL−DNA complexes (H_I^C), which also transfects cells efficiently, has recently been described (*45*). Which CL−DNA complex phase a particular mixture of lipids forms with DNA is governed by the composition and the rigidity of the membrane (*40*). Molecularly, the shape and corresponding preferred curvature of a lipid, encoded in the lipid structure, is a crucial parameter. DOPE with its cone-shaped structure, for example, favors formation of the H_{II}^C phase. Similarly, a complex structure with positive curvature should result from using lipids with large headgroups (corresponding to an inverted cone molecular shape). Multivalent lipids with 3 to 5 cationic charges in the headgroup, however, still form L_α^C complexes with DNA (*38*, *46*). Thus, we further increased the headgroup charge and size by synthesizing the lipids with dendritic headgroups described in this paper. Their headgroups have an ornithine-based core that is terminated by ornithine or carboxyspermine moieties, resulting in a maximum headgroup charge of +16 e at complete protonation. These lipids naturally extend the level of headgroup charge and, therefore, the accessible range of membrane charge density for multivalent lipids (*16*, *47*, *48*). They also bridge the gap to previously reported lipid−polymer and lipid−dendrimer hybrid materials (*49*−*53*).

The lipids have been prepared by an efficient synthetic scheme that permits their gram-scale synthesis. Modular assembly of the headgroup, spacer, and hydrophobic moieties allows facile variation of these components in the final lipid. Measurements of the headgroup charge of the lipids in complexes with DNA via an ethidium bromide displacement assay and their zeta potential show complete protonation of the headgroups. Mixtures of the dendritic lipids with DOPC at various ratios were used to prepare their DNA complexes. The structure of the complexes was investigated with X-ray diffraction, and their transfection efficiency was assessed using a luciferase reporter gene assay. X-ray diffraction shows formation of the L_α^C phase (*41*) for lipids with lower headgroup charge (4+) or lower contents of dendritic lipid in the membrane. For high contents of highly charged (8+, 16+) dendritic lipids, the observed scattering patterns are not consistent with any of the previously reported phases of CL−DNA complexes, except for a relatively narrow composition window that corresponds to the H_I^C phase (*45*). DNA complexes of the dendritic lipids efficiently transfect mammalian cells, at mol fractions of cationic lipid as low as 10%. For optimal transfection, a slightly higher lipid to DNA charge ratio than for the standard cationic lipid 2,3-dioleyloxy-propyl-trimethylammonium chloride (DOTAP) (*54*) is required. DNA complexes of the dendritic lipids are less cytotoxic than those of DOTAP, and no cytotoxicity is observed at the amounts required for transfection. In contrast to the lamellar complexes of less highly charged multivalent lipids, complexes of the dendritic lipids remain efficiently transfecting over a broad range of lipid composition, including high contents of cationic lipid (i.e. high membrane charge densities), pointing to differences in the transfection mechanism.

EXPERIMENTAL PROCEDURES

General Methods. NMR spectroscopy was carried out on a Bruker Avance 200 MHz spectrometer. MALDI-TOF mass spectrometry was performed on a Dynamo spectrometer from Thermal BioAnalysis Ltd. using 2,5-dihydroxybenzoic acid as the matrix and 30 vol.-% water in acetonitrile as the solvent. For thin-layer chromatography, silica covered plastic sheets with fluorescence indicator (Macherey-Nagel) were used. Detection of spots was achieved with UV light and ninhydrin reagent (300 mg in 95 mL of 2-propanol and 5 mL of acetic acid). By addition of methanol to a 4:2:1 (v/v/v) mixture of chloroform, methanol, and 25% ammonia until the mixture became homogeneous, solvent mixture A was obtained. Similarly, solvent mixture B was prepared starting with a 1:1:1 (v/v/v) mixture of the same solvents. Silica gel from Fisher Scientific with a mesh size of 200−425 was used for flash chromatography (*55*). Zeta potential measurements were performed as described (*56*).

Lipid Solutions. Stock solutions of the dendritic lipids were prepared in chloroform/methanol (9:1, v/v). DOPC and DOTAP were purchased as a solution in chloroform from Avanti Lipids. These lipid solutions were combined at the desired ratio of lipids and dried, first by a stream of nitrogen and subsequently in a vacuum for 8 to 12 h. To the residue, high conductivity (18.2 MΩ) water was added and the mixture was incubated at 37 °C for at least 12 h to give solutions of a final concentration of 30 mM for X-ray samples (15 mM for MVLBisG2). For transfection, aqueous lipid solutions were prepared at 0.6 mM. Lipid mixtures containing higher mol fractions of DOPC formed opaque suspensions, which were sonicated to clarity and filtered through 0.2 μm syringe filters. The lipid solutions were stored at 4 °C until use.

Ethidium Bromide (EtBr) Displacement Assay. Lipid−DNA complexes were prepared in duplicate in a 96 well plate. Each well contained 2.4 μg HPCT DNA, 0.28 μg EtBr, and the desired amount of lipid in a final volume of 250 μL. The emission at 605 nm was measured on a Cary Eclipse fluorescence spectrophotometer, following excitation at 519 nm.

Transfection. Mouse fibroblast L-cells were cultured at 37 °C in supplemented cell medium (Dulbecco's Modified Eagle's Medium (DMEM) with 1% penicillin−streptomycin and 5% fetal bovine serum, v/v; from Gibco BRL) in an atmosphere containing 5% CO_2 and were reseeded approximately every 72 h to maintain subconfluency. Measurements were performed in duplicate and are displayed as mean plus/minus standard deviation. The day before the transfection experiment, cells were seeded in 24-well plates. At the time of transfection, the cells were approximately 70% confluent. Luciferase plasmid DNA (pGL3 Control Vector, Promega) was prepared using a Qiagen Giga Kit. For each well, 0.4 μg of Luciferase plasmid DNA was used. Liposomes (0.6 mM) were added to the DNA, and the mixture was diluted to a final volume of 0.1 mL with nonsupplemented DMEM. The cells were incubated with this solution for 6 h, rinsed three times with phosphate-buffered saline (PBS, Invitrogen), and incubated with supplemented cell media for an additional 24 h. Luciferase gene expression was measured with the Luciferase Assay System (Promega), and light output readings were taken on a Berthold AutoLumat luminometer. Transfection efficiency, measured as relative light units (RLU), was normalized to the weight of total cellular protein determined using Bio-Rad Protein Assay Dye Reagent (Bio-Rad).

Cytotoxicity. Cytotoxicity was assayed by measuring extracellular levels of lactate dehydrogenase. At 18 h prior to treatment, cells were seeded in 96-well plates at 15 000 cells per well. Lipid−DNA complexes were prepared as above and added to the wells, adding a total of 0.08 μg DNA per well. After incubation for 6 h, 75 μL of CytoTox-ONE Homogeneous Membrane Integrity Assay (Promega) and 35 μL of culture medium were added to each well. Fluorescence was quantified on a Bio-Rad PharosFX Molecular Imager system and converted to percent cytotoxicity as described in the manufacturer's instructions.

Synthesis. Chemicals were from Fisher Scientific and at least of analytical grade unless otherwise indicated. They were used as received. Our syntheses of 3,4-dioleylbenzoic acid (DOB) (*59*) and of **MVLBG2** and the intermediates leading to it

(**Boc_2Orn**, **CbxSpr(Boc)$_4$**, **BocG2OMe**, **G2OMe**, **MVLBG2**, **BocBG2OMe**, **BocBG2En**) have been published previously (*45*).

General Procedure for TBTU-Mediated Coupling (dendron synthesis; amine compound with *n* amino groups). To a mixture of 1.1*n* mmol of acid component, 1.1*n* mmol of *O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU; Bachem), and 1.1*n* mmol of 1-hydroxybenzotriazole (HOBt) hydrate (Peptides International) in dimethylformamide (DMF) (peptide synthesis grade, Applied Biosystems) was added 2*n* mmol of *N*,*N*-diisopropylethylamine (DIEA; Aldrich). After 10 min, a mixture of 1 mmol of amine compound (hydrochloride or hydrotrifluoroacetate form) and *n* mmol of DIEA in DMF was added to the resulting solution with stirring. Stirring was continued at room temperature for 2 h, and chloroform and water were added with vigorous stirring after evaporation of most of the DMF (*57*). The phases were separated, and after extracting two more times with chloroform, the organic phases were combined and washed twice with 2 M HCl, twice with 2 M NaOH, and once with water. After drying (Na_2SO_4), the solvents were evaporated.

General Procedure for the Aminolysis of Methyl Esters with Diamines. The methyl ester was dissolved in methanol, if necessary, by addition of some chloroform. Twenty equivalents of diamine were added in one portion, and the mixture was stirred at room temperature until the reaction appeared complete by TLC. The solvent was evaporated, and water and chloroform were added. After agitation, the phases were separated, and the organic layer was washed two more times with water, dried (Na_2SO_4), and evaporated. The residue was then purified as required.

***N*1-(2-Aminoethyl)-(2*S*)-2,5-di[(1*S*)-1,4-di(*tert*-butyl-carbamoyl-amino)butyl]carboxamidopentanamide (BocG2En).** To a solution of 1.90 g (2.45 mmol) of **BocG2OMe** in 5 mL of methanol, 3.3 mL (2.96 g, 49.3 mmol) of ethylenediamine (Fluka) was added, and the mixture was stirred for 16 h at room temperature. After the addition of 100 mL water, the mixture was stirred vigorously at room temperature until the formed precipitate crystallized. Filtration and drying of the residue yielded 1.7 g (2.1 mmol, 86%) of **BocG2En** as colorless crystals: $R_f = 0.33$ ($CHCl_3$/MeOH 6:1, 1% concentrated NH_4OH); ^{1}H NMR ($CDCl_3$): $\delta = 0.8-2.1$ (m, C−CH_2−C), 1.35 (s, C(CH_3)$_3$), 2.34 (b, 2 H, NH_2) 2.76 (b, 2 H, CH_2−N), 2.9−3.5 (bm, 10 H, CH_2−N), 3.95−4.55 (2 bm, 3 H, C*H*), 4.9−5.7 (3 m, 2 H, C(O)N*H*), 5.7−6.3 (2 b, 2 H, C(O)N*H*), 7.2−7.7 (bm, 3 H, C(O)N*H*); ^{13}C NMR ($CDCl_3$): $\delta = 25.6$, 25.9 (CH$_2$−CH_2−CH$_2$), 28.3, 28.4 (C(**C**H$_3$)$_3$), 29.4, 29.9, 30.3 (CH$_2$−CH_2−CH), 38.4, 39.6, 39.8, 41.0, 41.8 (CH_2−N), 53.0, 53.6, 54.1 (**C**H), 78.9, 79.8, 79.9 (**C**(CH$_3$)$_3$), 156.1, 156.2 (O−*C*(O)−N), 171.9, 173.1, 173.2 (C−*C*(O)).

***N*1-2-[2-(2-Aminoethoxy)ethoxy]ethyl-(2*S*)-2,5-di[(1*S*)-1,4-di(*tert*-butyl-carbamoyl-amino)butyl]carboxamidopentanamide (BocG2NTEG).** As described in the general procedure for aminolysis, 2.00 g (2.58 mmol) of **BocG2OMe** was reacted with 2,2′-(Ethylenedioxy)diethylamine (NTEG, Aldrich) for 60 h. Extraction and evaporation yielded 1.89 g (2.13 mmol, 83%) of **BocG2NTEG** as a colorless solid: $R_f = 0.33$ ($CHCl_3$/MeOH 6:1, 1% concentrated NH_4OH); ^{1}H NMR ($CDCl_3$): $\delta = 0.8-2.0$ (m), 1.35 (s) (48 H, C−CH_2–C, C(CH_3)$_3$), 2.80 ("t", $J = 5.0$ Hz, 2 H, CH_2−NH$_2$), 2.9−3.2 (m, 4 H, CH_2−NBoc), 3.2−3.7 (m, 12 H, CH_2−N, CH_2−O), 4.0−4.5 (2 bm, 3 H, C*H*), 4.9−5.4 (2 m, 2 H, C(O)N*H*), 5.5−6.0 (2 b, 2 H, C(O)N*H*), 7.1−7.7 (m, 3 H, C(O)N*H*); ^{13}C NMR ($CDCl_3$): $\delta = 25.5$, 25.9, 26.0 (CH$_2$−CH_2−CH$_2$), 28.3, 28.4 (C(*C*H$_3$)$_3$), 29.3, 30.0, 30.2 (CH$_2$−CH_2−CH), 38.6, 39.1, 39.7, 39.8, 41.5 (*C*H$_2$−N), 52.6, 53.7, 53.9 (*C*H), 69.5, 70.0, 70.1, 73.0 (*C*H$_2$O), 78.9, 79.8 (*C*(CH$_3$)$_3$), 155.9, 156.1, 156.2 (O−*C*(O)−N), 171.5, 172.7, 173.1 (C−*C*(O)).

Methyl (2*S*)-2,5-Di[((1*S*)-1,4-di[(1*S*)-1,4-di(*tert*-butyl-carbamoyl-amino)butyl]carboxamidobutyl)carboxamido]-pentanoate (BocG3OMe). As described in the general procedure for dendron synthesis, 6.34 g (19.1 mmol) of **Boc_2Orn** was reacted for 3 h with 3.60 g (4.33 mmol) of **G2OMe**. For workup, the reaction mixture was evaporated and 600 mL of diethyl ether was added. The precipitate was isolated by filtration, and dichloromethane and 5% $NaHCO_3$ were added. The phases were separated, and the organic phase was washed once more with 5% $NaHCO_3$, twice with 5% citric acid, and once with water. It was then dried (Na_2SO_4) and evaporated to yield 5.51 g (3.38 mmol, 78%) of **BocG3OMe** as a colorless solid: $R_f = 0.72$ ($CHCl_3$/MeOH 6:1, 1% concentrated NH_4OH); ^{1}H NMR ($CDCl_3$): $\delta = 0.7-2.2$ (m), 1.37 (s) (100 H, C−CH_2−C, C(CH_3)$_3$), 2.9−3.4, 3.4−3.7 (2 m, 18 H, CH_2−N, OCH_3), 3.8−4.7 (bm, 7 H, C*H*), 4.7−6.2 (several bm, 6 H, N*H*), 7.0−8.0 (4 m, 8 H, N*H*); ^{13}C NMR ($CDCl_3$): $\delta = 25.2$, 25.8, 29.3, 30.0 (all b, C−CH_2−C), 28.1, 28.2 (C(*C*H$_3$)$_3$), 38.4, 39.6 (b, CH_2−N), 51.7, 52.2, 52.6, 53.7, 54.1 (O*C*H$_3$, *C*H), 78.8 (b, 4), 79.6 (b,4) (*C*(CH$_3$)$_3$),155.8, 156.2 (2 b, overlap, 6) (O−*C*-(O)−N), 171.9 (b, 2), 172.4, 172.9 (b,4) (C−*C*(O)).

***N*1-(2-Aminoethyl)−(2*S*)-2,5-di[((1*S*)-1,4-di[(1*S*)-1,4-di-(*tert*-butyl-carbamoyl-amino)butyl]carboxamidobutyl)carboxamido]pentanamide (BocG3En).** As described in the general procedure for aminolysis, 2.50 g (1.53 mmol) of **BocG3OMe** was reacted with ethylenediamine for 7 days. Extraction and evaporation yielded 1.58 g (0.95 mmol, 62%) of **BocG3En** as a colorless solid: $R_f = 0.40$ ($CHCl_3$/MeOH 6:1, 1% concentrated NH_4OH); ^{1}H NMR ($CDCl_3$/MeOH-d_4): $\delta = 0.7-1.9$ (m), 1.10 (s) (100 H, C−CH_2−C, C(CH_3)$_3$), 2.43 ("t", $J = 5.7$ Hz, 2 H), 2.55−3.1 (m, 16 H) (CH_2−N), 3.69, 3.99 (2 b, 7 H, C*H*); ^{13}C NMR ($CDCl_3$/MeOH-d_4,): $\delta = 25.0$, 25.5 (CH$_2$−CH_2−CH$_2$), 27.5, 27.6 (C(*C*H$_3$)$_3$), 28.4, 28.8, 29.3 (CH$_2$−CH_2−CH), 38.0, 39.2, 40.2, 41.5 (CH_2−N), 52.6, 53.0, 53.8, 54.4 (*C*H), 78.5, 79.3, 79.5 (*C*(CH$_3$)$_3$), 155.8, 156.2, 156.5 (O−*C*(O)−N), 171.8, 171.9, 172.2, 173.1 (C−*C*(O)).

General Procedure for the Synthesis of the Boc-Protected Lipids. A solution of 1.1 mmol of DOB (46,59) in dichloromethane was added to a mixture of 1.1 mmol of TBTU and 1.1 mmol of HOBt hydrate in DMF. Following the addition of 3 mmol of DIEA, the mixture was left to stand for 10 min and a solution of 1 mmol of amine compound in DMF was added. After standing for 4 h, the solvents were evaporated. Following the addition of chloroform and 5% citric acid and agitation, the phases were separated and the organic phase was washed one more time with 5% citric acid, twice with 10% $NaHCO_3$, and once with water. After drying (Na_2SO_4), the solvent was evaporated and the residue was purified as required.

General Procedure for the Deprotection of Boc-Protected Lipids. The protected lipid (0.9−1.6 g) was dissolved in 10 mL of 95% TFA (5% water), which had been saturated with nitrogen and cooled on ice. The mixture was left to stand at room temperature for 25 min with occasional swirling, and most of the TFA was then evaporated in vacuo. A mixture of diethyl ether/pentane (1:1, 30 mL/g protected lipid) was added with stirring, and the precipitate isolated by decanting. This was repeated twice, and the precipitate was dried in vacuo.

***N*1−2-[((1*S*)-1,4-Di[(1*S*)-1,4-diaminobutyl]carboxamidobutyl)carboxamido]ethyl-3,4-di[(*Z*)-9-octadecenyloxy]benzamide (MVLG2).** Deprotecting 1.25 g (868 μmol) of **BocMVLG2** as described in the general procedure yielded 1.06 g (712 μmol, 82%) of **MVLG2** as a colorless solid: $R_f = 0.31$ (solvent mixture A); ^{1}H NMR (MeOH-d_4): $\delta = 0.88$ ("t", 6 H, C*H*$_3$), 1.0−2.2 (m, lg. peaks at 1.28, 1.35, 68 H, C−C*H*$_2$−C), 2.8−3.7 (m, 10 H, N−C*H*$_2$), 3.8−4.1 (m, 6 H, O−C*H*$_2$, C*H*), 4.25−4.5 (m, 1 H, C*H*), 5.2−5.45 (m, 4 H, =C*H*−), 6.96 (d, $^3J = 9.1$ Hz, 1 H, H_{ar} *m*-C(O)), 7.3−7.5 (m, 2 H, H_{ar}), 7.8−8.8 (m, N*H*); ^{13}C NMR (MeOH-d_4): $\delta = 14.7$ (*C*H$_3$), 23.9, 24.2, 26.7, 28.3, 29.5, 29.7, 30.5, 30.6, 30.8, 30.9, 31.0, 33.2 (C−C*H*$_2$−C), 39.7, 40.1, 40.5 (C*H*$_2$−N), 53.7, 54.1, 54.5 (*C*H), 70.2, 70.7 (*C*H$_2$–O), 113.8, 114.3, 122.3 (C_{ar}H), 118.2 (q, $J = 294$ Hz, *C*F), 127.7 (C_{ar}−C(O)N), 130.9, 131.0 (=*C*H−CH_2), 150.2, 153.9 (C_{ar}−O), 163.2 (q, $J = 35$ Hz, TFA *C*(O)), 170.0, 170.16, 170.24, 174.3 (*C*(O)); MALDI-MS: $m/z = 1039.6$ (M + H$^+$).

RESULTS AND DISCUSSION

Lipid Design and Synthesis. Figure 1 shows the general structure of the new dendritic lipids. Their names, headgroup structures, spacer lengths, and charges are compiled in Table 1. All lipids share a hydrophobic moiety based on 3,4-dioleyloxybenzoic acid (DOB) (*46*, *59*). The oleyl chains prevent chain crystallization in the bilayer and confer stable membrane anchoring and miscibility with DOPC and DOPE. The amino acid ornithine is used as an AB$_2$ branching building block in the core of the headgroups. Using a core made up of one or three (1+2) ornithine molecules, and ornithine or carboxyspermine (*45*, *60*, *61*) as end groups, lipids bearing four to 16 amino groups in the headgroup have been prepared. An ethylendiamine- or triethyleneglycol-based linker connects headgroup and DOB. Thus, the lipids enable investigations of the effect of spacer length, high charge density, and charge arrangement (two headgroups bear eight charges, but in different geometry) on complex structure and transfection efficiency.

The synthesis of the dendritic headgroup building blocks is shown in Figure 2. It proceeds similarly to that of multiple antigenic peptides (MAPs) (*62*, *63*) and poly(ethylene glycol)-dendritic oligo-lysine block copolymers (*64*), doubling the number of available amino groups for each generation of ornithine that is coupled onto itself. Ornithine methyl ester is first coupled with 2.2 equiv of Boc-protected ornithine. After deprotection of the amino groups, this process is repeated. Alternatively, the initial or second coupling was performed using Boc-protected carboxyspermine (*45*, *60*, *61*) to yield headgroups of higher charge.

The synthesis of the lipids is illustrated in Figure 3, using MVLG2 and TMVLG2 as examples. The methyl ester of the headgroup building block is subjected to aminolysis with an

Table 1. Abbreviated Names and Spacer Lengths of the Synthesized Lipids, Their Charge, and the Chemical Structures of Their Headgroups

Lipid name	Charge / e		Headgroup structure
	Z_{max} [a]	Z_{exp} [b]

The lipids have the general structure shown in Figure 1. [a] Charge at full protonation. [b] Charge in complex determined by an ethidium bromide displacement assay: see text.

excess of ethylenediamine or 2-[2-(2-aminoethoxy)ethoxy]-ethanamine (α,ω-diaminotriethyleneglycol, NTEG) to yield an amine-functionalized spacer-headgroup building block. This was coupled with DOB (*46*, *59*), and the resulting Boc-protected lipids were purified by flash chromatography and deprotected with TFA. This synthetic route has been carried out on a gram scale and allows facile variation of the spacer length and the headgroup charge by employing other diamines and multivalent headgroup building blocks (*38*, *43*), respectively.

Determination of the Headgroup Charge. We determined the headgroup charge of the lipids effective in DNA complexation with an ethidium bromide (EtBr) displacement assay (*38*, *65*−*67*) and zeta potential measurements. Adding lipid to a mixture of DNA and EtBr reduces the measured fluorescence as EtBr is expelled from the DNA during complex formation and self-quenches in solution. Thus, increasing amounts of lipid were added to a constant amount of DNA and EtBr, recording the resulting fluorescence and normalizing it to the fluorescence without added lipid. The data from this assay is shown in Figure 4: initially, a steep drop in fluorescence with increasing amount of added lipid is observed. The fluorescence then reaches a baseline value. The isoelectric point is obtained from analysis of these data (*68*−*70*), yielding the lipid headgroup charges Z_{exp} documented in Table 1. These data show that the lipids essentially bear their maximal charge when incorporated in the complex. While the lipid charge is calculated from the onset of the baseline value, it is also evident from the data that this final value of the fluorescence varies with the headgroup charge: higher charge corresponds to a lower value for the final fluorescence intensity. Zeta potential measurements confirm the headgroup charges determined by the EtBr displacement assay. This is illustrated in Figure 5, which shows the zeta potential of MVLBG1−DNA complexes as a function of the lipid/DNA charge ratio ρ_{chg}. The zeta potential of the complexes changes sign when ρ_{chg}, calculated using Z_{exp} for the lipid, is unity. Similar results were obtained for lipids of different headgroup charge (MVLG2 and MVLBG2) and for mixtures of the cationic lipids with DOPC (data not shown).

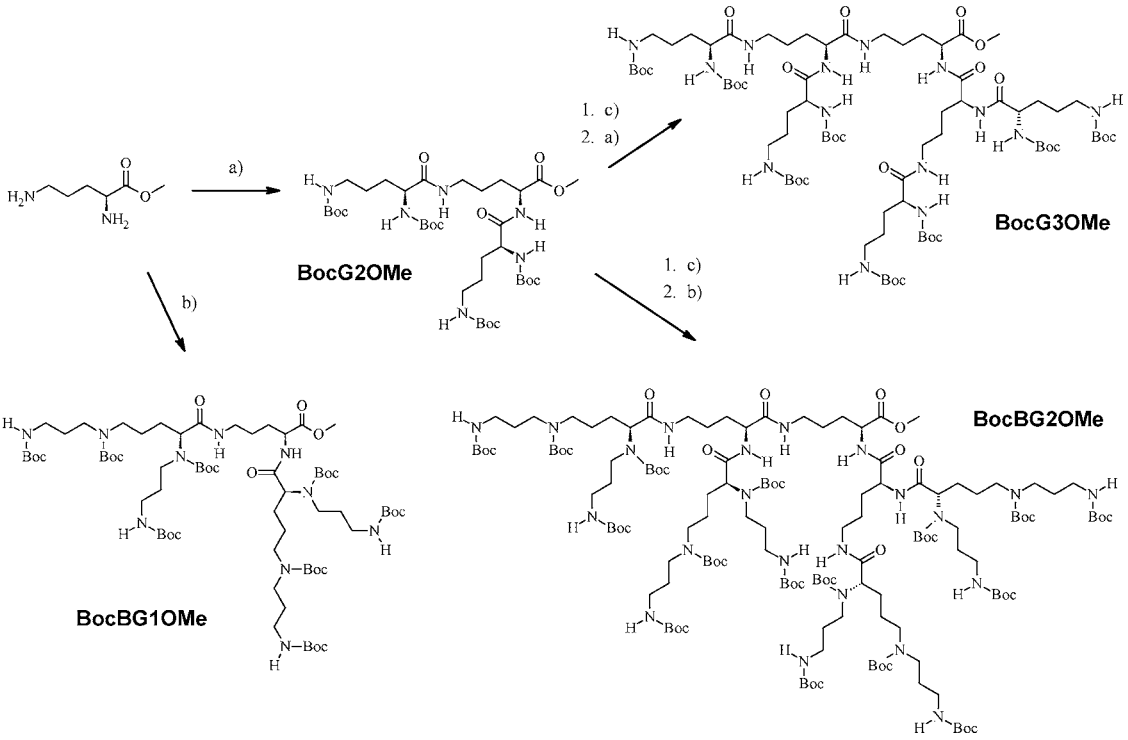

Figure 2. Synthesis of the dendritic headgroup building blocks, starting from ornithine methyl ester. Reaction conditions: (a) Boc-ornithine, TBTU, HOBt, DIEA; (b) Boc-carboxyspermine, TBTU, HOBt, DIEA; (c) TFA. HOBt: 1-hydroxybenzotriazole hydrate; DIEA: *N*,*N*-diisopropylethylamine; TBTU: *O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate; TFA: trifluoroacetic acid.

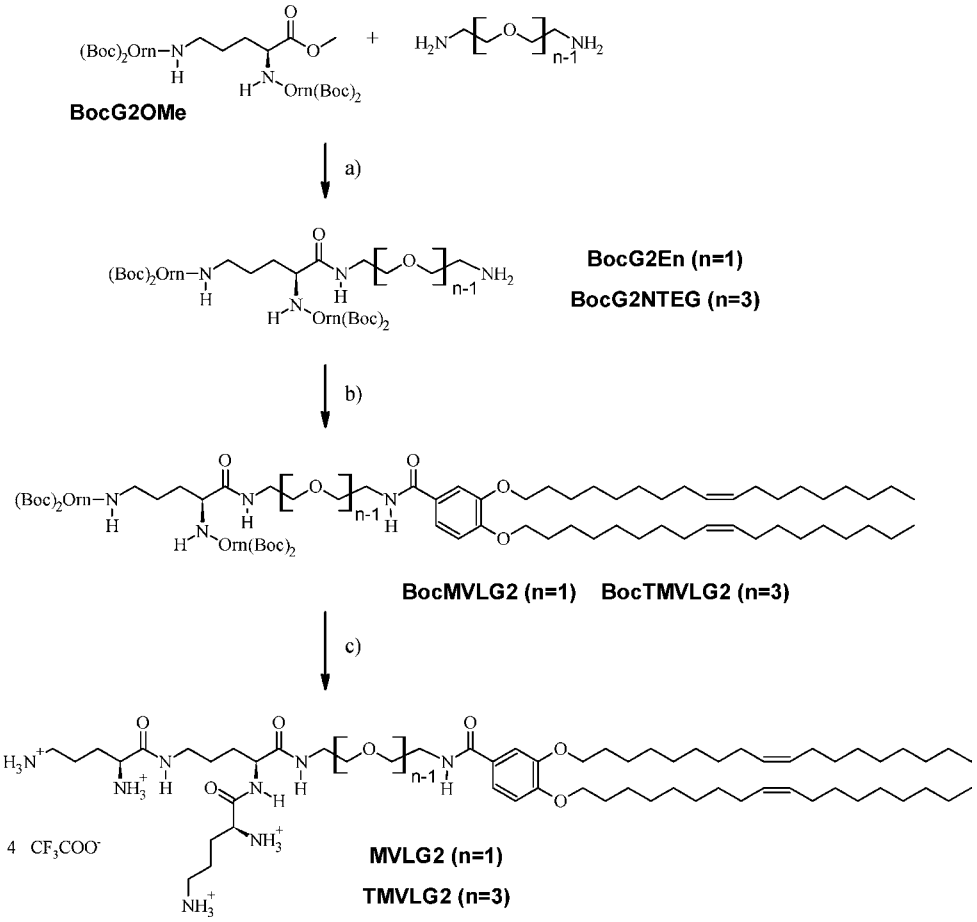

Figure 3. Synthesis of the dendritic cationic lipids **MVLG2** ($n = 1$) and **TMVLG2** ($n = 3$); $Orn(Boc)_2 = C(O)CH(NHBoc)(CH_2)_3NHBoc$. Reaction conditions: (a) excess diamine (20×) in MeOH; b) DOB, TBTU, HOBt, DIEA; (c) TFA. DOB: 3,4-dioleyloxybenzoic acid; HOBt: 1-hydroxybenzotriazole hydrate; DIEA: *N*,*N*-diisopropylethylamine; TBTU: *O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate; TFA: trifluoroacetic acid.

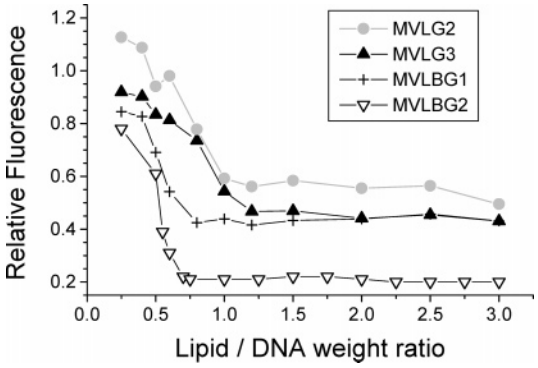

Figure 4. Data from an ethidium bromide (EtBr) displacement assay, used to measure the charge of the dendritic lipids in complexes with DNA. EtBr fluoresces when intercalated into DNA but is expelled by lipid−DNA complex formation, which results in reduced fluorescence intensity due to self-quenching of EtBr in solution. The fluorescence intensity is normalized to that of DNA with EtBr and no lipid.

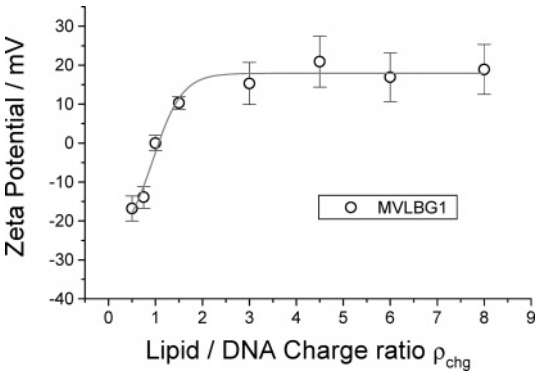

Figure 5. Zeta potential of MVLBG1-DNA complexes as a function of ρ_{chg}. The lipid/DNA charge ratio was calculated using Z_{exp} from the EtBr displacement assay. The line (sigmoidal fit) is a guide to the eye. Note that the zeta potential changes sign at approximately $\rho_{chg} = 1$.

Characterization of CL−DNA complexes. CL−DNA complexes were formed by combining DNA and aqueous lipid preparations consisting of mixtures of DOPC and a dendritic lipid or DOTAP. In addition to performing transfection experiments, we employed small-angle X-ray scattering (SAXS) to characterize the nanoscale internal structure of DNA complexes of the dendritic lipids. All SAXS experiments were performed in the presence of DMEM, the medium used in the transfection experiments. While their structure changes significantly with varying ratio of neutral to cationic lipid (see below), it is not affected by the lipid to DNA charge ratio (ρ_{chg}) above the isoelectric point (*71*). Lipids with identical headgroups but different spacer (MVLs vs TMVLs) and lipids of identical charge but different headgroup structure (G3 vs BG2) yield DNA complexes of similar structure (*71*). The characteristic scattering pattern of the lamellar phase is observed for all complexes of the least highly charged dendritic lipid MVLG2 (charge: 4+) as well as for complexes containing mol fractions below and including 50% and 15% of the lipids with G3/BisG1 (8+) and BisG2 (16+) headgroups, respectively (data not shown). Complexes at certain intermediate contents of highly charged dendritic lipids in the membrane exhibit SAXS patterns indicative of the H_I^C phase (*45*). However, the scattering patterns at the remaining compositions do not correspond to any previously described structure. A detailed investigation of the structures of these complexes is in progress and will be described elsewhere.

Under low ionic strength conditions, all lipid DNA complexes (at $\rho_{chg} \neq 1$) form particles of about 200 nm size. These aggregate in the higher salt conditions of, e.g., cell medium, resulting in μm-sized particles that vary in size over time (*56*).

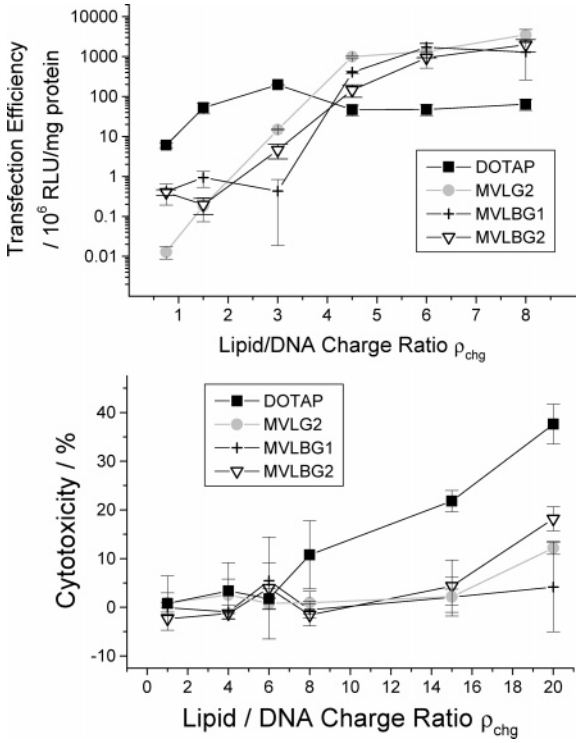

Figure 6. Transfection efficiency (top) and cytotoxicity (bottom) of DNA complexes containing 60 mol % cationic lipid at various lipid/DNA charge ratios. Note the difference in scale of the charge ratio axes. The amount of DNA is constant for all data points.

Consistent with this, fluorescence microscopy of dendriticlipid−DNA complexes shows colocalization of lipid and DNA and complex particles with dimensions on the μm scale, consisting of aggregates of globular submicron particles (*45*).

Cell Transfection and Cytotoxicity. We have measured the transfection efficiencies of DNA complexes of the dendritic lipids in mouse L cells using a luciferase reporter gene assay and compare them to the standard monovalent lipid DOTAP. The headgroup charge dominates the transfection behavior of the lipids, while neither the spacer length nor the headgroup architecture have a significant effect (*71*). Thus, in the following we show data for three lipids representing the three different headgroup charges, MVLG2 (4+), MVLBG1 (8+), and MVLBG2 (16+). In these experiments, both the lipid to DNA charge ratio ρ_{chg} and the ratio of cationic lipid and neutral DOPC in the membrane were varied.

For DOTAP, TE increases with ρ_{chg} up to a saturation value; this behavior is independent from the composition of the membrane (*72*). A similar trend is observed for the dendritic lipids, but with saturation occurring at a higher charge ratio: $\rho_{chg} = 3$ lies in the saturated regime for DOTAP, while all dendritic lipids require at least $\rho_{chg} = 4.5$ (*71*). This is illustrated in Figure 6 (top), which shows transfection efficiencies of complexes with 60 mol % cationic lipid for DOTAP, MVLG2, MVLBG1, and MVLBG2 at various values of ρ_{chg}. Cell toxicities of the complexes were measured using a commercially available assay that probes cell membrane integrity. Figure 6 (bottom) shows the cytotoxicity of CL−DNA complexes as a function of ρ_{chg}, at 60 mol % cationic lipid. Note the different scale of the ρ_{chg}-axis when comparing with the transfection efficiency plot. For all lipids, only charge ratios exceeding those required for efficient transfection produce any notable toxicity. Furthermore, the onset of the curve is much delayed for the dendritic lipids in comparison with DOTAP, demonstrating their reduced cytotoxicity.

In Figure 7 (top), TE of complexes at $\rho_{chg} = 6$ is plotted against the composition of the membrane. The plots for all lipids

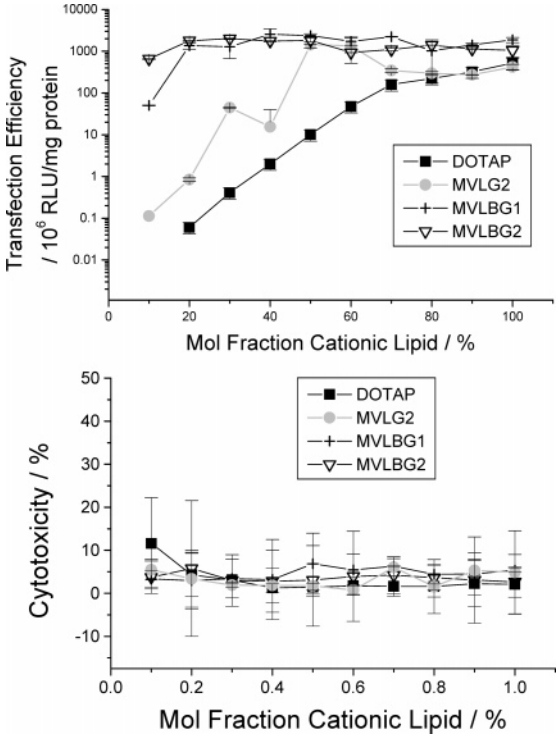

Figure 7. Transfection efficiency (top) and cytotoxicity (bottom) of DNA complexes of DOTAP, MVLG2, MVLBG1, and MVLBG2 plotted against the mol fraction of cationic lipid in mixtures with DOPC. All data points were taken at a lipid/DNA charge ratio of 6, using a constant amount of DNA.

show an initial, exponential rise with increasing mol fraction of cationic lipid. The higher the headgroup charge of the lipid, the lower the mol fraction of cationic lipid where this rise occurs, consistent with our previous findings on the relevance of membrane charge density (*37*, *38*). Thus, optimal transfection can be achieved with mol fractions as small as 10% (MVLBG2) or 20% (MVLBG1). Since the cationic lipid is the more expensive lipid component in CL−DNA complexes, this is advantageous for potential applications. Interestingly, the highly charged lipids MVLBG1 and MVLBG2 do not show the drop in TE at higher mol fractions (very high charge densities) that has been observed for multivalent lipids of charge 2+ to 5+ (*38*). This deviation coincides with a structural transition, away from the lamellar complex structure (*71*). As expected from the data shown in Figure 6, no significant cytotoxicity is observed for any of the complexes (Figure 7 (bottom)). This further confirms that the dendritic lipids are a safe and efficient DNA delivery vector. Of note, DNA complexes of MVLBG2 were shown to be much superior over those of DOTAP in a "hard to transfect" mouse embryonic fibroblast cell line (*45*).

Currently, we are conducting further experiments with the dendritic lipids. The high headgroup charge of multivalent lipids appears to be particularly advantageous for transfections with siRNA, which require very high lipid to DNA charge ratios.

Guanine-rich DNA sequences are widely dispersed in the eukaryotic genome and are abundant in regions with relevant biological significance. They can form quadruplex structures stabilized by guanine quartets. These structures differ for number and strand polarity, loop composition, and conformation. We report here the syntheses and the structural studies of a set of interconnected d(TG_4T) fragments which are tethered, with different orientations, to a tetra-end-linker in an attempt to force the formation of specific four-stranded DNA quadruplex structures. Two synthetic strategies have been used to obtain oligodeoxyribonucleotide (ODN) strands linked with their 3′- or 5′-ends to each of the four arms of the linker. The first approach allowed the synthesis of tetra-end-linked ODN (TEL-ODN) containing the four ODN strands with a parallel orientation, while the latter synthetic pathway led to the synthesis of TEL-ODNs each containing antiparallel ODN pairs. The influence of the linker at 3′- or 5′-ODN, on the quadruplex typology and stability, in the presence of sodium or potassium ions, has been investigated by circular dichroism (CD), CD thermal denaturation, ^{1}H NMR experiments at variable temperature, and molecular modeling. All synthesized TEL-ODNs formed parallel G-quadruplex structures. Particularly, the TEL-ODN containing all parallel ODN tracts formed very stable parallel G-quadruplex complexes, whereas the TEL-ODNs containing antiparallel ODN pairs led to relatively less stable parallel G-quadruplexes. The molecular modeling data suggested that the above antiparallel TEL-ODNs can adopt parallel G-quadruplex structures thanks to a considerable folding of the tetra-end-linker around the whole quadruplex scaffold.

INTRODUCTION

DNA quadruple helices (quadruplexes) based on guanine (G)[1] quartets have recently emerged as biologically important structures (*1*−*4*). G-rich sequences, which are found primarily in telomeric region at 3′-end of chromosomes, are able to fold into G-quadruplex structures. It has been suggested that quadruplex formation could inhibit the telomere maintenance provided by telomerase activity thus affecting the lifespan of the cells of a number of cancer types characterized by a high level of telomerase expression (*5*−*8*). Furthermore, studies on the oncogene *c-MYC*, involved in a number of malignancies, have demonstrated the existence of G-quadruplex structures in vivo which can be considered useful targets to repress c-MYC transcription (*9*−*11*). G-quadruplex structures are present in the scaffold of several aptamers provided with useful biological properties (*12*−*16*), as well as within the insulin gene-linked polymorphic region of the human insulin gene, in vivo, where they may play a role in the expression of the insulin gene (*17*). G-quadruplexes, have been also put forth as DNA structures capable of transferring electrons through the G-quadruplex π-stack and forming nanowires for molecular nanoelectronics (*18*−*20*). Within this framework, a number of studies have been undertaken to investigate the DNA G-quadruplexes and, particularly, to define the factors that can stabilize them as well as proposing synthetic ODN analogues capable of forming novel quadruplex typologies.

G-quadruplexes can be classified based upon the number of strands involved in the structure, their relative orientation and the glycosidic conformation of guanosine residues (anti or syn). The stability of G-quadruplexes mainly depends on the number of G-tetrad planes, the molecularity of the complex, and the nature of cations which accommodate themselves in the central channel of the quadruplex lowering the energy of the complex (*1*−*3*). Normally, the molecularity of the complex induces well defined patterns in the relative ODN strand orientation. The monomolecular complexes largely involved in biomolecular events (*1*−*4*) are prevalently of antiparallel type even if examples of parallel monomolecular complexes have been discovered (*21*−*24*). Tetramolecular complexes, which have recently displayed interesting biological properties (*25*−*27*), always show the four strands in a parallel orientation. However, the development of therapeutic applications for such ODN complexes has been so far prevented by their unfavorable kinetic and thermodynamic parameters. It is a fact that the in vitro formation of a tetramolecular quadruplex is very slow and may require high ODN and salt concentrations (*28*). On the contrary, monomolecular quadruplexes are mostly characterized by high stability and fast kinetic formation (*1*−*3*). On these bases, the construction of new and stable monomolecular quadruplexes possessing unusual strand orientation could expand their employment in both the study and control of important biological processes as well as in DNA-based nanotechnologies. Several studies have investigated the effect of loops on quadruplex stability and typology (*29*−*35*). With regard to

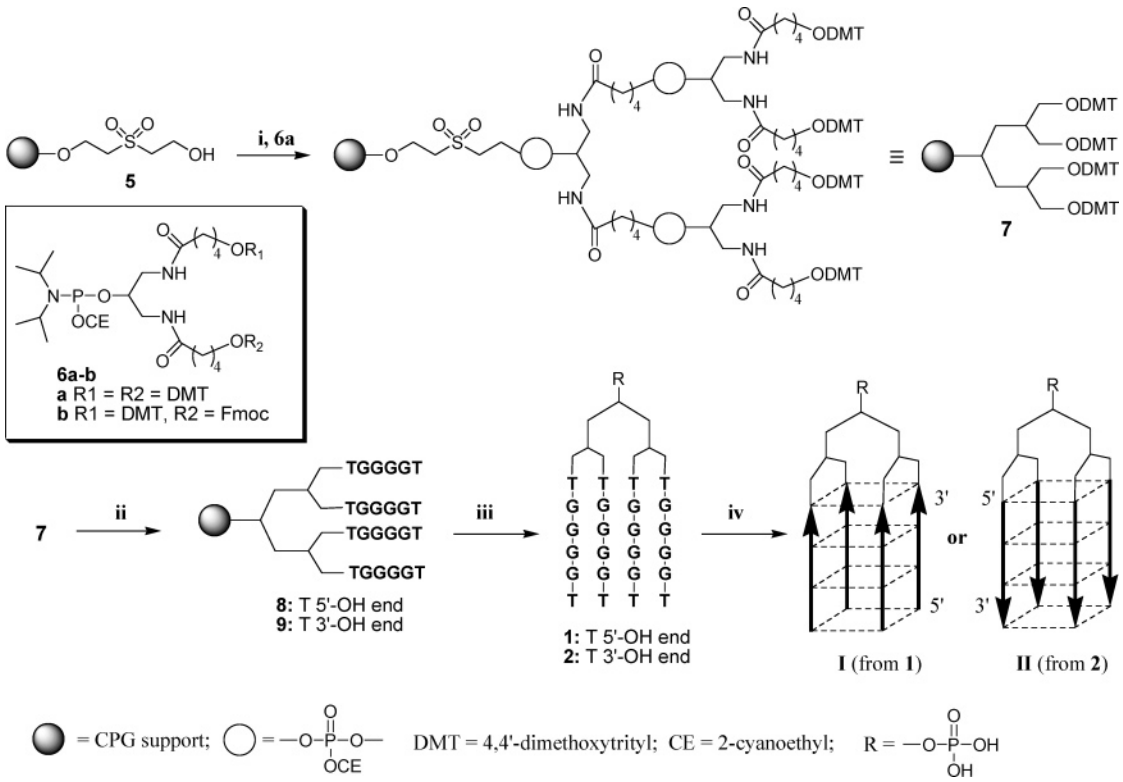
Scheme 1. Synthetic Procedures for Quadruplexes I and II[a]



[a] i: two couplings with **6a**; ii: ODN synthesis with 3′ or 5′-phosphoramidites; iii: detachment and deprotection with NH_4OH concd 32% (7 h, 55 °C); iv: HPLC purification and annealing.

nucleotidic loops, the base composition, the length, and the orientation of the phosphodiester linkage have already been examined (*29*−*34*). In addition, mono- or bimolecular quadruplexes formed by circular ODNs have been shown to display noteworthy thermal and enzymatic degradation stability (*35*). In another reported approach aimed at studying the effect of the connecting loops on the stability and typology of the monomolecular quadruplexes, non nucleotidic linkers have been inserted between d(GGG) tracts into a single ODN strand (*30*). In this case both the kinetics of the quadruplex formation and the complex stabilities were found to be affected by the nature of the linker.

Starting from these observations, we recently proposed the synthesis of a new modified ODN (TEL-ODN, **1**, Scheme 1) capable of forming the monomolecular parallel G-quadruplex **I** (Scheme 1) whose thermal stability has been proved to be significantly higher than that observed for its tetramolecular counterpart $[d(TG_4T)]_4$ (*36*). The main structural feature of this molecule is the presence of four ODN strands whose 3′-ends are attached to a non nucleotidic tetra-end-linker. Furthermore, TEL-ODNs were also shown to be a useful tool to study quadruplexes containing less stable quartets such as T-tetrad (*37*).

We wish to report here our study on the influence of the tetra-end-linker placement on the typology and stability of this kind of quadruplexes. Two synthetic strategies have been used to obtain $d(TG_4T)$ ODN strands which were linked with their 3′ or 5′-ends to each of the four arms of the linker. The first approach allowed the synthesis of the TEL-ODNs containing the four ODN strands with a parallel orientation (**1**, **2**, Scheme 1) while the latter synthetic pathway led to the synthesis of TEL-ODNs each containing antiparallel ODN pairs (**3**, **4**, Scheme 2). CD, CD melting, NMR spectroscopy, and molecular modeling have been used to investigate the solution structures of the resulting TEL-quadruplexes **I**−**IV** (Schemes 1 and 3) formed in the presence of sodium or potassium ions.

EXPERIMENTAL PROCEDURES

Reagents and Equipment. Chemicals and solvents were purchased from Fluka-Sigma-Aldrich. Reagents and phosphoramidites for DNA syntheses were purchased from Glen Research. ODN syntheses were performed on a PerSeptive Biosystems Expedite. HPLC analyses and purifications were performed by a JASCO PU2089 pumps equipped with UV detector 2075 Plus using a Merck Hibar (5 μm, 250−10) column. CPG support **5** and linkers **6a**,**b** were purchased from Glen Research. Tentagel carboxy resin, used as starting material for preparation of solid support **10**, was purchased from Novabiochem. Preparation of **10** was carried out in a short column (10 cm length, 1 cm i.d.) equipped with a sintered glass filter, a stopcock and a cap. The ODNs were assembled by a PerSeptive Biosystems Expedite DNA synthesizer using phosphoramidite chemistry. UV spectra were run with a Jasco V 530 spectrophotometer. CD spectra and thermal denaturation experiments were obtained with a Jasco 715 circular dichroism spectrophotometer equipped with a JASCO 505T temperature controller unit. NMR spectra were recorded on a Varian Unity Inova 500 MHz spectrometer. MALDI-TOF mass spectrometric analyses were performed on a PerSeptive Biosystems voyager-De Pro MALDI mass spectrometer using a picolinic/3-hydroxypicolinic acids mixture as the matrix. The ODN concentration was determined spectrophotometrically at $\lambda = 260$ nm and 90 °C, using the molar extinction coefficient $\epsilon = 57800\ cm^{-1}\ M^{-1}$ calculated for the unstacked oligonucleotide by the nearest neighbor mode (*38*).

Synthesis and Purification of TEL-ODNs 1 and 2. 50 mg of support **5** (0.048 mequiv/g) was used for each synthesis in the automated DNA synthesizer following standard phosphoramidite chemistry, using 45 mg/mL of solution of phosphoramidite **6a** (two coupling cycles) and 3′- or 5′-phosphoramidite nucleotide building block (six cycles) in anhydrous CH_3CN, thus obtaining the polymer bound ODN **8** and **9**, respectively. The coupling efficiency with nucleotide units was consistently

higher than 98% (by DMT spectrophotometric measurements). The solid support **8** (or **9**) was then treated with 25% aq ammonia solution for 7 h at 55 °C. The filtered solution and washings were concentrated under reduced pressure and purified by HPLC on a RP18 column eluted with a linear gradient CH_3CN in TEAB buffer (pH 7.0, from 0 to 100% in 60 min, flow 1.0 mL/min), retention time 26.1 and 27.0 min for **1** and **2**, respectively. The collected peaks furnished pure **1** and **2** (72 and 77 OD_{260} units, respectively) which, after lyophilization, were characterized by spectroscopic data.

TEL-ODN **2**: MALDI TOF-MS (negative mode): calculated mass (8763.7); found: 8762.6.

Preparation of Support 10. 500 mg of Tentagel carboxy resin (0.28 mequiv/g of COOH) suspended in CH_2Cl_2 were left

in contact with a CH_2Cl_2 solution (7.0 mL) containing 1,3-dihydroxypropane (0.56 mmol, 0.36 mL), NMI (0.56 mmol, 0.40 mL) and MSNT (0.056 mmol, 1.48 g) and the mixture was shaken for 36 h at room temperature. The obtained hydroxy-support **10** was exhaustively washed with CH_2Cl_2 and then dried under reduced pressure. The amount of hydroxyl groups, determined by DMT measurements after the successive coupling step with 3′-phosphoramidite nucleotide units, resulted to be in the range 0.18−0.20 mequiv/g.

Synthesis and Purification of TEL-ODNs 3 and 4. 50 mg of support **10** (0.18 mequiv/g) reacted, in the automated DNA synthesizer, with phosphoramidite **6b** (45 mg/mL in CH_3CN) following standard phosphoramidite chemistry at 15-μmol scale, yielded support **11** (0.17 mequiv/g of DMT groups). After removal of the DMT group by DCA/standard treatment, the second coupling cycle was performed in the same manner using phosphoramidite **6a**, thus obtaining support **12** (0.30 mequiv/g of DMT groups). **12** was then subjected to six coupling cycles using 3′-phosphoramidite nucleotide building blocks (45 mg/mL in CH_3CN, 15-μmol scale), followed by final DMT removal and 5′-OH capping with Ac_2O, to yield ODN-functionalized support **13**. The removal of Fmoc groups was achieved by treatment with piperidine/DMF solution (2:8 v/v, 30 min RT). The resulting support was then reacted with phosphoramidite **6a**, thus obtaining **14** (0.27 mequiv/g of DMT groups). On branches A of **14** the second ODN domain was assembled, performing six coupling cycles with the 5′-phosphoroamidite nucleotide building block as described for support **12**, yielding the polymer bound ODN **15**.

For the synthesis of **4**, support **10** (50 mg) was functionalized with **6a** and then **6b**, as described before, yielding the tetra-branched support **16** (0.28 mequiv/g of DMT groups). After removal of the DMT protecting groups, the first two ODN chains were assembled, using 3′-phosphoramidite nucleotide building blocks. After capping of the terminal 5′-OH functions by Ac_2O treatment, the Fmoc groups were removed as previously described, and the successive two ODN chains were assembled using 5′-phosphoroamidite nucleotide building blocks, thus obtaining the polymer bound ODN **17**.

TEL-ODNs were detached from the supports **15** and **17**, deprotected, and purified as described for **1** and **2**, thus obtaining **3** and **4** (retention time 25.8 and 25.2 min, respectively). After lyophilization, the final pure products **3** and **4** (68 and 62 OD_{260} units, respectively) were characterized by spectroscopic data.

TEL-ODN **3**: MALDI TOF-MS (negative mode): calculated mass (8821.7); found: 8820.5.

TEL-ODN **4**: MALDI TOF-MS (negative mode): calculated mass (8821.7); found: 8820.2

Preparation of Quadruple Helices (Annealing). Quadruplexes **I**−**IV** were formed by dissolving the TEL-ODNs **1**−**4**, in the appropriate buffer and annealed by heating to 90 °C for 20 min followed by slow cooling to room temperature. The solutions were equilibrated at 10 °C for 24 h before performing the experiments. The buffers used were 10 mM Na_2HPO_4, 70 mM NaCl, 0.2 mM EDTA (Na^+ buffer) or 10 mM K_2HPO_4 70 mM KCl, and 0.2 mM EDTA (K^+ buffer).

Native Gel Electrophoreses. Native gel electrophoreses were run on 20% nondenaturing polyacrylamide gels in 0.6x TBE buffer, pH 7.0, with 50 mM NaCl. ODN solutions, with a final concentration of 300 μM in quadruplex, were prepared in 50 mM Tris-borate pH 7.0, 80 mM NaCl, 1 mM spermine, and 3 mM $MgCl_2$ and annealed as above-described. At 2 μL of the ODN solution (300 μM in quadruplex) was then added 1 μL of 30% glycerol and the mixture charged on gel. The gels were run at room temperature at constant voltage (100 V) for 2.5 h. The bands were visualized by UV shadowing.

CD Experiments. CD spectra of the quadruplexes were registered on a Jasco 715 circular dichroism spectrophotometer in a 0.1 cm path length cuvette at 25 and 90 °C at 1.0×10^{-5} and 5.0×10^{-5} M quadruplex concentrations. The wavelength was varied from 220 to 320 nm at 5 nm min^{-1}. The spectra were recorded with a response of 16 s, at 2.0 nm bandwidth and normalized by subtraction of the background scan with buffer. CD thermal denaturation−renaturation experiments were performed monitoring the CD value (mdeg) at 264 nm in the range 25−90 °C with 1 °C/min heating rate.

^{1}H NMR Experiments. ^{1}H NMR data were collected on a Varian Unity INOVA 500 spectrometer equipped with a broad-band inverse probe with z-field gradient and processed using Varian VNMR software package. 1D NMR spectra were acquired as 16384 data points with a recycle delay of 1.0 s at temperatures in the range 25−85 °C. Data sets were zero filled to 32768 points prior to Fourier transformation and apodized with a shifted sinebell squared window function. Pulsed-field gradient WATERGATE (*39*) sequence was used for H_2O suppression. All NMR samples **I**−**IV** were prepared in H_2O/D_2O (9:1, v/v) at 0.5 mM of quadruplex concentration with a final salt concentration of 100 mM KCl and 10 mM K_2HPO_4 or 100 mM NaCl and 10 mM Na_2HPO_4 for K^+ or Na^+ buffer, respectively.

Molecular Modeling. The conformational features of the quadruplexes **III** and **IV** have been explored by means of molecular modeling study. All the calculations were performed on a personal computer running the HyperChem 7.5 suite of programs. The AMBER force field based on AMBER 99 parameter set was used (*40*). The initial coordinates for the starting model of $[d(TGGGGT)]_4$ quadruplex were taken from the NMR solution structure of the $[d(TTGGGGT)]_4$ quadruplex (Protein Data Bank entry number 139D), choosing randomly one of the four available structures. The initial $[d(TGGGGT)]_4$ quadruplex models were built by deletion of the 5′-end tymidine residue in each of the four TTGGGGT strands. The complete structures of **III** and **IV** were then built using the HyperChem 7.5 building tool. Partial charges for each of the tetra-end-linker atoms were assigned using the Gasteiger-Marsili algorithm (*41*) implemented in the QSAR module of HyperChem suite. The resulting coordinates of tetra-end-linker's atoms were energy-minimized in a vacuum, keeping all DNA coordinates frozen (500 cycles of the steepest descent method). Three sodium ions were manually positioned in the central channel, equidistant from adjacent G-tetrads to allow octahedral coordination with G carbonyl oxygen O6 atoms. The two complexes were neutralized by addition of further 26 sodium ions placed in the most negative positions of the systems. Each quadruplex was then solvated by a periodic TIP3P water box (5833 water molecules) (*42*), which extended to a distance of 10 Å from each atom. The minimal distance between water and system atoms was set to 2.3 Å. The whole systems were initially subjected to energy minimization followed by 50 ps of molecular dynamics at 300 K, and then the systems were slowly cooled at 10 K. The obtained structures were further minimized using 1000 cycles of the steepest descent method followed by conjugate gradient method until convergence to a rms gradient of 0.1 kcal mol^{-1} $Å^{-1}$.

RESULTS AND DISCUSSION

Synthesis and Purification of TEL-ODNs 1−4. In the synthesis of the TEL-ODNs **1**−**4** we used two hydroxy-functionalized solid supports (**5** and **10**) and the bifunctional linkers **6a,b**. Support **5** (0.048 mequiv/g), by way of two coupling cycles with **6a** by an automatic DNA synthesizer, was turned into support **7** bearing a symmetrical tetra-end-linker with four protected primary alcoholic functions prone to ODN-chain

assembly (0.085 mequiv/g of OH functions, by DMT spectrophotometric test). Support **7** was used to synthesize the TEL-ODNs **1** and **2** in which the four ODN strands were attached to the tetra-end-linker by the same end (3′- and 5′-end, respectively). ODN chains were assembled on **7** by using 3′- or 5′-phosphoramidite nucleotide building blocks, thus obtaining the polymer bound TEL-ODNs **8** and **9**, respectively. In both syntheses coupling yields were higher than 98% per cycle, thus reducing the amounts of TEL-ODNs having one or more truncated chains. The presence of a β-sulfone phosphodiester function connecting the linker to the solid support, allows the release of the TEL-ODN via a β-elimination under basic treatment. In this way supports **8** and **9**, treated with concentrated NH_4OH (7 h, 55 °C), afforded crude TEL-ODNs **1** and **2**, which after HPLC purification and the annealing procedure, furnished the quadruplex **I** and **II**, respectively.

As a further step of this work we synthesized the TEL-ODNs **3** and **4** (Scheme 2). In **3** a pair of strands was linked to the primary linker branch A through the 5′-ends whereas the second pair is linked to the primary branch B through the 3′-ends. Instead **4** is characterized by both branches (A and B) carrying two strands linked through opposite ends. For the preparation of **3** and **4**, we adopted two synthetic strategies both based upon bifunctional linker **6b** in which the two alcoholic functions, thanks to the orthogonal protection with Fmoc and DMT groups, allowed the sequential synthesis of the ODN chains with opposite polarity. **10** was used as solid support since, when **5** was used, we observed the release of ODN material from the support during the Fmoc deprotection step, due to the concomitant β-elimination at the sulfone group. Therefore, we prepared the hydroxy-functionalized support **10** bearing an ester function, stable under Fmoc deprotection conditions but cleavable by ammonia treatment, to release the assembled TEL-ODN. Support **10** (0.18−0.20 mequiv/g of OH groups), prepared by reacting a carboxy-functionalized Tentagel resin (0.28 mequiv/g of COOH groups) with 1,3-dihydroxypropane in the presence of MSNT and NMI (*43*), was used in two synthetic pathways leading to the TEL-ODNs **3** and **4**. Support **10**, by reaction with the phosphoramidite linker **6b** yielded the asymmetrical protected bifunctional support **11** (0.17 mequiv/g by DMT test) which, after removal of DMT protection from the branch B and successive reaction with linker **6a** furnished the three-functionalized support **12**. Six coupling cycles with 3′-phosphoramidite units, performed as described for **7**, and a final capping step of the 5′-OH ODN ends, gave **13**. Then the 5′-Fmoc group was removed from the branch A by piperidine treatment, and the successive coupling with **6a** yielded **14**. On **14** the second ODN domain was assembled using 5′-phosphoramidite units, thus obtaining polymer bound TEL-ODN **15**. The synthetic pathway to obtain **4** started with reaction of **10** with **6a** and subsequently **6b** as described above, thus obtaining the tetra-branched support **16** (0.28 mequiv/g by DMT). The removal of DMT groups, followed by ODN synthesis with 3′-phosphoramidite units, allowed the assembly of the first pair of ODN chains. After Fmoc deprotection, the remaining ODN pair having opposite polarity was then assembled using 5′-phosphoramidite units, thus obtaining **17**. Detachment from the solid support and complete deprotection of the TEL-ODNs **3** and **4** were achieved treating supports **15** and **17** with concentrated NH_4OH as described for **1** and **2**. Analyses and purifications of crude products **1**−**4** were carried out by HPLC using an RP18 column. The purity of the products was checked by PAGE, and the structures were confirmed by ^1H NMR and MALDI-MS data. The quadruple helices were obtained by dissolving the samples **1**−**4** in Na^+ or K^+ buffers and by the annealing procedure to ensure the correct formation of quadruplex structures.

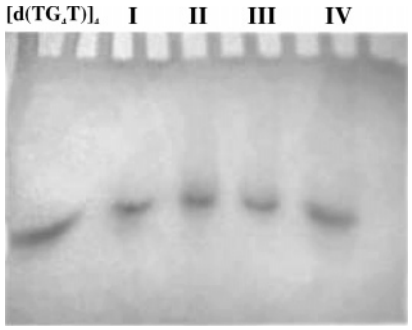

Figure 1. Nondenaturing gel analysis of **I**−**IV** and $[d(TG_4T)]_4$ (20% polyacrylamide), Tris-borate (TBE), pH 7.0. The samples were annealed in Na^+ buffer. The bands were visualized by UV shadowing.

Native Gel Electrophoresis. The purity of the products **1**−**4** and the molecularity of the complexes obtained were investigated by performing a nondenaturing polyacrylamide gel electrophoresis (Figure 1) in comparison to the tetramolecular quadruplex $[d(TG_4T)]_4$. The samples (300 μM quadruplex) were annealed in Na^+ buffer, and the electrophoretic analysis was carried out using a 20% polyacrylamide gel in TBE buffer. TEL-quadruplexes **I**−**IV** and $d[(TG_4T)]_4$ migrated as single bands demonstrating quite similar mobilities. This result, besides indicating the purities of **I**−**IV**, strongly suggests that they form monomeric species at this concentration.

CD and CD Thermal Analysis. To investigate whether TEL-ODNs **2**−**4** adopt quadruplex structures and, if such is the case, determine their nature and stability, we carried out CD studies, including CD thermal denaturation experiments, which were compared with those already reported for **1** (*36*) and their tetramolecular counterpart $[d(TG_4T)]_4$ (*27*, *38*). The ODN samples were analyzed in Na^+ or K^+ buffers after the annealing procedure. CD spectra (Figure 2) were performed at 25 and 90 °C at a quadruplex concentration of 1.0×10^{-5} and 5.0×10^{-5} M. TEL-ODNs **1**, **2** and $[d(TG_4T)]_4$ showed almost identical CD profiles in K^+ buffer at 25 °C, characterized by positive and negative bands centered around 264 and 244 nm, respectively, which are indicative of a parallel stranded G-quadruplex structure (*36*, *44*−*47*). Upon the basis of these findings, it is reasonable to hypothesize that the TEL-ODN **2**, bearing the tetra-end-linker at the 5′-end of quadruplex, adopts the parallel G-quadruplex structure **II**. The data also suggest that **3** and **4** adopt parallel G-quadruplex structures which, considering the mutual antiparallel orientation of the ODN pairs, can be explained only by hypothesizing that a considerable folding of the linker around the whole G-quadruplex takes place. The parallel structures adopted by **3** and **4** were substantiated by molecular modeling studies (see below) that clearly indicate that these conformations are obtainable and stable as a result of the linker arrangement as shown in Figure 4 and schematically depicted in **IIIa** and **IVa** (Scheme 3).

CD spectra of **1**−**3** and $[d(TG_4T)]_4$ in Na^+ buffer at 25 °C match those observed in K^+ showing positive and negative bands at 262 and 244 nm, respectively, whereas in the CD profile of **4** in Na^+ buffer a slight shift of the positive and negative bands at 259 and 239 nm, respectively, takes place. Furthermore, in the latter the presence of a new lower positive band centered at 289 nm is observable. These data indicate that even in Na^+ buffer, possessing a lower stabilizing effect on G-quadruplex structures when compared to K^+ buffer (*3*, *48*), the TEL-ODN **1**−**3** are structured in parallel quadruplexes. For **4** in Na^+ buffer we hypothesize the coexistence of two or more conformational species, among which the parallel (main) **IVa** and the antiparallel (minor) **IVb**,**c** structures are present, considering that most antiparallel G-quadruplexes are characterized by a positive band centered at 290−295 nm and a negative

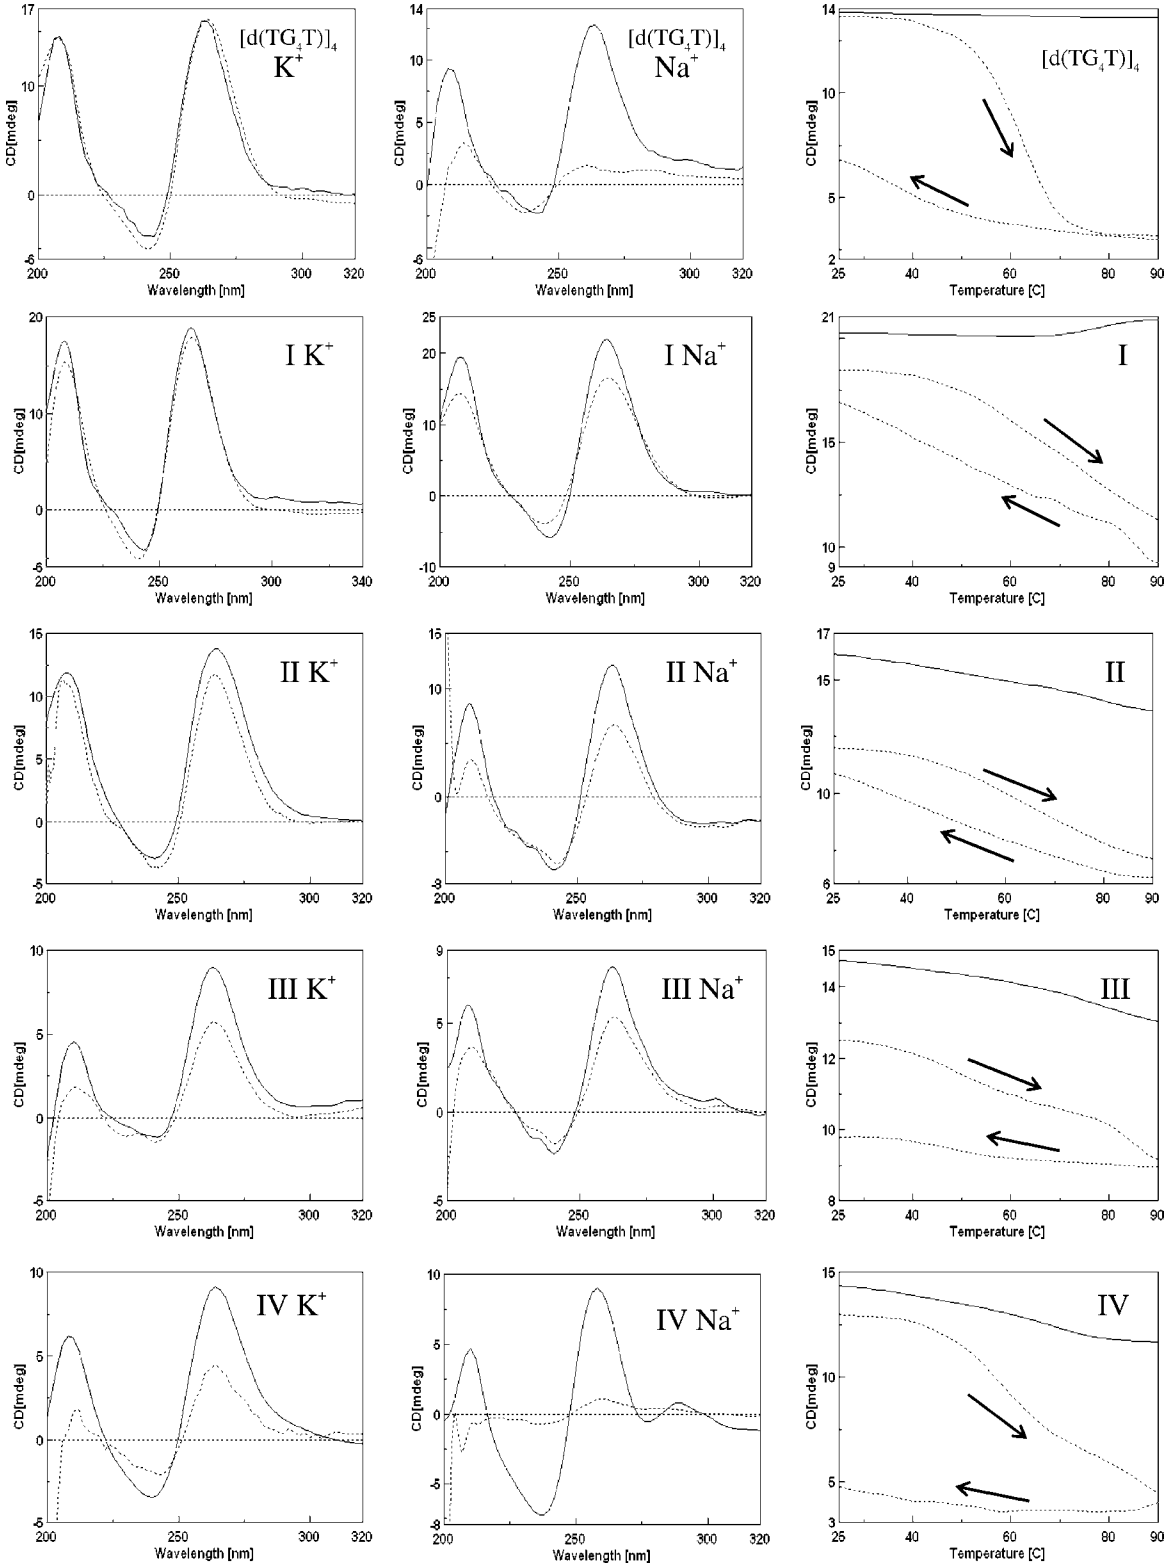

Figure 2. CD and CD melting spectra of **I**−**IV** and d[$(TG_4T)]_4$ in K^+ buffer (left column), in Na^+ buffer (middle column) at 25 °C (solid line) and 90 °C (dotted line). CD_{265} melting profiles (right column) in K^+ (solid line) and Na^+ (dotted line).

band centered around 265 nm (*44*−*47*). CD spectra of **1**−**4** and d[$(TG_4T)]_4$ at 90 °C for both buffers are reported in Figure 2. The data in K^+ buffer confirm that the parallel G-quadruplex structures are completely retained in the complexes **I** and **II** while a detectable destructuration can be observed for complexes **III** and **IV**. CD spectra in Na^+ at 90 °C suggest that complexes **I**−**III** retain, to some extent the characteristic parallel G-quadruplex profile, while complex **IV** and d[$(TG_4T)]_4$ are completely unstructured to random coils.

CD thermal denaturation−renaturation experiments were performed monitoring the CD value (mdeg) at 265 nm in the range 25−90 °C with 1 °C/min temperature scan rate. CD melting curves in K^+ buffer for quadruplexes **I**, **II** and d[$(TG_4T)]_4$ underwent irrelevant or low CD_{265} variations up to 90 °C while a relatively high CD_{265} variation was shown by the complexes **III** and **IV**. The melting profiles of the complexes **I**−**IV** and d[$(TG_4T)]_4$ in Na^+ showed higher CD_{265} variation with respect to the corresponding values registered in K^+;

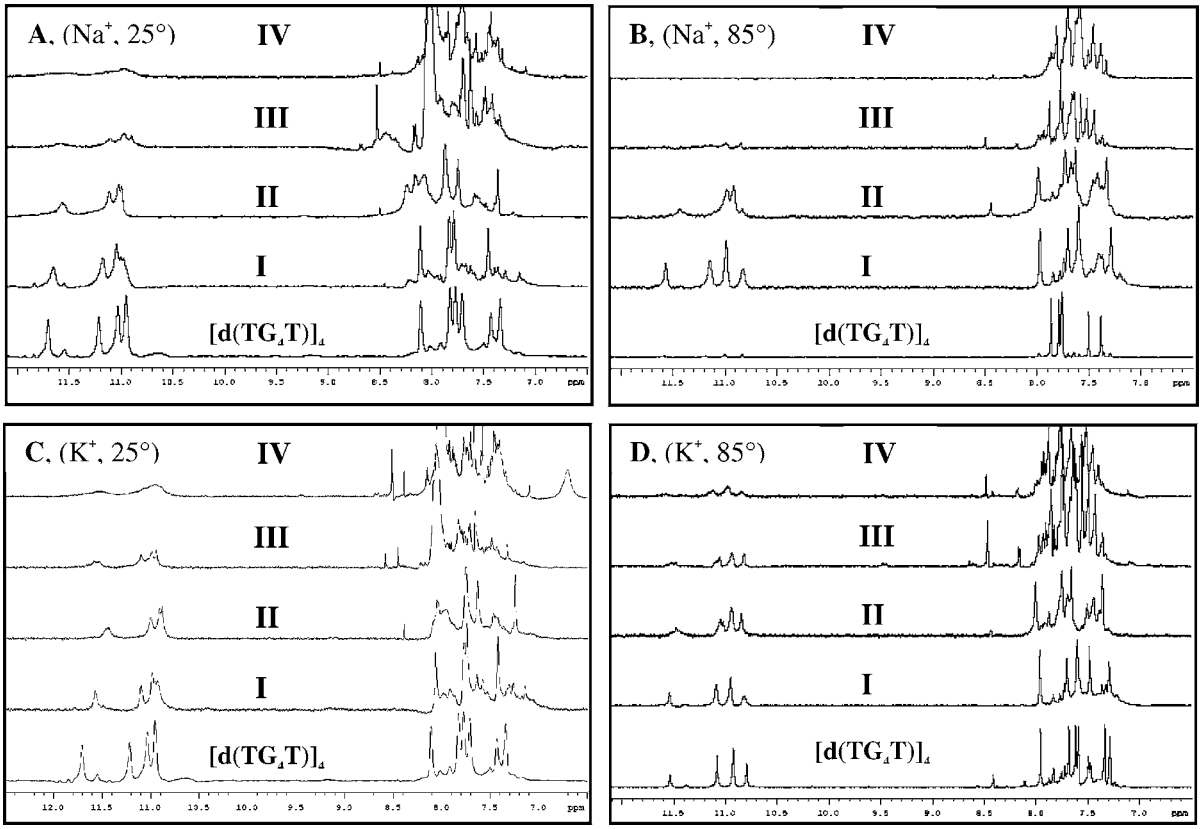

Figure 3. ^{1}H NMR (500 MHz) spectra of **I**−**IV** and $[d(TG_4T)]_4$ in Na^+ and K^+ buffers. The spectra were registered in H_2O/D_2O, (9:1, v/v) solution at 0.5 mM of quadruplex at 25 and 85 °C. The aromatic and imino proton regions of the spectra are reported.

however, only for the $[d(TG_4T)]_4$ complex was a typical and derivatizable sigmoidal curve (T_m = 59 °C) registered. These data indicate that the melting process for the complexes **I**−**III** in Na^+ is not complete at 90 °C, while a complete melting of **IV** can be observed in Na^+ at this temperature. However, considering the shape of the apparent sigmoidal curve and the possible polymorphism of **IV**, we could not determine its melting temperature in both buffers. We also registered the CD_{265} thermal renaturation curves for all complexes in the range 90−25 °C. For the tetramolecular $[d(TG_4T)]_4$ complex, as expected, a very slow renaturation process and a high hysteresis phenomenon was indicated by the profile of the renaturation curve at 1 °C/min scan rate. The renaturation curves of **I** and **II** showed relatively low hysteresis at the same temperature scan rate. The fast reformation of the complexes **I** and **II** was also confirmed by the CD spectrum profiles registered at the end of the renaturation processes (data not shown). In the case of complexes **III** and **IV** the renaturation curves showed high hysteresis associated with low restructuration levels.

^{1}H NMR Studies on Quadruplexes I−IV and $[d(TG_4T)]_4$. ^{1}H NMR studies on quadruplexes **I**−**IV** were performed, after annealing, in the same buffers used for CD measurements. The spectrum of **I** and **II**, recorded in Na^+ buffer at 25 °C (Figure 3A), showed the presence of four singlets in the range 10.9−11.8, two of them partially overlapped, attributable to exchange protected imino protons involved in Hoogsteen N(1)/O(6) hydrogen bonds of G-quartets (*45*, *48*, *49*). These signals were almost superimposable with those observed in the spectrum of the $[d(TG_4T)]_4$ complex already characterized by NMR data (*50*). The ^{1}H NMR spectra recorded in Na^+ buffer at 85 °C (Figure 3B) indicated that **I** is completely stable at least up to 85 °C. **II** is partially preserved (only two imino proton signals are still detectable at this temperature), whereas the tetramolecular complex $[d(TG_4T)]_4$ is completely unstructured as indicated by the disappearance of all the imino proton signals. Upon the basis of these data, it appears that quadruplex **II** in Na^+ buffer is more stable than the tetramolecular counterpart, yet it is less stable than quadruplex **I**. The ^{1}H NMR spectra of **I**, **II**, and $[d(TG_4T)]_4$ recorded in K^+ buffer displayed quite similar signal patterns; however, it was not possible to observe any quenching of the imino proton signals up to 85 °C (Figure 3D). This observation is in accordance with reported data about the capability of K^+ cations to form more stable quadruplex structures in comparison with those observed in Na^+ buffer (*51*). As expected, ^{1}H NMR spectra of **III** indicated that this compound is more structured in K^+ than in Na^+ buffer. In K^+ buffer it was possible to detect the four imino proton signals up to 85 °C (Figure 3C and 3D), whereas in Na^+ the spectrum showed large imino proton signals at 25 °C (Figure 3A) which almost disappeared at 85 °C (Figure 3B). The ^{1}H NMR spectra of **IV** at 25 °C showed very large and overlapped imino proton signals both in Na^+ (Figure 3A) and K^+ buffers (Figure 3C). The increase of temperature for ^{1}H NMR spectra of **IV** led to the sharpening of all imino proton signals both in Na^+ and K^+ buffers. In K^+ buffer at least three imino proton signals are clearly detectable even at 85 °C (Figure 3D), whereas in Na^+ buffer all imino proton signals are completely lost since 65 °C (data not shown). These data, which are consistent with UV and CD experiments, indicate that both complexes **III** and **IV** result in less stable quadruplex structures than **I** and **II**. Furthermore, **III** results more stable than **IV** especially in K^+ buffer.

Molecular Modeling. To explore the capability of TEL-ODNs **3** and **4** of adopting the parallel quadruplex structure **IIIa** and **IVa**, respectively, a modeling study was performed. The minimized structures obtained are shown in Figure 4. Inspection of these structures reveals that in both **IIIa** and **IVa**, the tetra-end-linker is able to span the distance between the 5′- and 3′-ends of the strands assembled in parallel quadruplex structure. It can be noted that the orientation of the linker with respect to the helical axis is different in **IIIa** and **IVa**

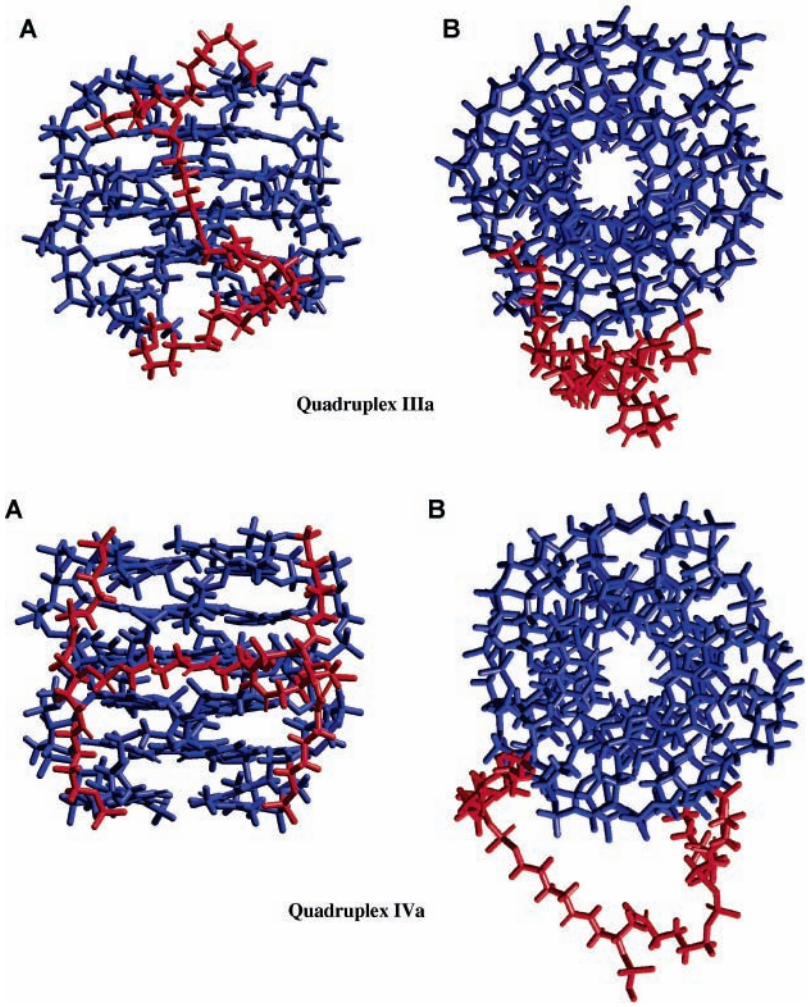

Figure 4. Molecular model pictures of quadruplex structures **IIIa** and **IVa**; A: front view; B: top view. The tetra-end-linker is in red.

quadruplexes. For both the complexes the interatomic distances between the linker atoms and the quadruplex groove hydrogen bonding sites suggest the possibility of favorable nonbonded interactions. Although the integrity of the G-tetrads is maintained after energy minimization for both complexes, a detailed analysis of the H-bonds scheme inside the G-tetrads reveals some differences between the quadruplexes. In particular, in **IIIa**, each G-tetrad shows the same hydrogen bond scheme with an optimum distance and angle between donor and acceptor atoms, resulting in strong hydrogen bonds. Indeed in **IVa** there is a change of hydrogen-bond distances and angles between adjacent quartets, and, on average, two hydrogen bonds for each G-tetrad are lost. Furthermore, the degree of coplanarity between the G residues in each G-tetrad is greater in **IIIa** than in **IVa**. It is important to point out that the perturbation of each G-tetrad directly affects the stacking energy of the neighboring G-tetrads. In summary, the TEL-ODN **3** can form a parallel quadruplex structure **IIIa** without causing any distortion in the G-tetrad region, whereas in the TEL-ODN **4**, which forms the quadruplex **IVa**, a major readjustment of the G-tetrads occurs. These findings appear consistent with the experimental CD and NMR data revealing the formation of a more stable quadruplex **III** in comparison to **IV**.

The results described in this paper confirm the potential of TEL-ODNs as a new class of ODN analogues prone to adopt stable intramolecular quadruplex structures. In each case the T_m values are higher in potassium- than in sodium-containing buffer. It is noteworthy that, irrespective of the ends by which the four strands are attached to the tetra-end-linker, the CD spectra of the obtained complexes are typical of parallel quadruplex structures, displaying positive maxima centered at 264 nm, in contrast to maxima at 295 nm observed for antiparallel structures. The only exception concerns the CD spectrum of **4** in Na^+ buffer, in which a positive shoulder at 295 nm is present, indicating that a mixture of parallel and antiparallel forms could exist (quadruplex **IVa**−**c**). The whole of data, including molecular modeling calculations, suggest that the tetra-end-linker used in the present study is long and flexible enough to allow the organization of the ODN strands into a parallel quadruplex structure and (ii) that, at least in the presence of potassium ions, this form is favored over the antiparallel one, even if it is at the cost of a major readjustment of G-tetrads, which is the case of **IVa**. We believe that TEL-quadruplexes with suitable sequences and predetermined strand orientations could be used as aptamers, decoy and molecular probes, when used in a labeled form. Furthermore, TEL-ODNs may prove to be important tools for structural studies of alternative less stable quartets such as A-tetrads (*52*, *53*), C-tetrads (*54*), T-tetrads (*55*), and mixed tetrads (*56*) as well as tetrads formed by modified nucleosides (*57*, *58*). To confirm these conclusions as well as to get hold of a suitable tool to prepare monomolecular quadruplex structures with a preordered strand orientation, the syntheses of several TEL-ODNs characterized by shorter branched spacers and/or longer DNA stretches are currently in progress in our laboratory.

Induction of Differential T-Cell Epitope by Plain- and Liposome-Coupled Antigen

Maiko Taneichi,[†] Yuriko Tanaka,[†] Michiyuki Kasai,[†] Masahito Mori,[‡] Mitsuhiro Nishida,[‡] Hiroyuki Yamamura,[‡] Junichiro Mizuguchi,[§] and Tetsuya Uchida[†,*]

Department of Safety Research on Blood and Biological Products, National Institute of Infectious Diseases, Tokyo 208-0011, Japan, Drug Delivery System Development Division, Nippon Oil and Fat Corporation, Tokyo 150-6019, Japan, and Department of Immunology, Tokyo Medical University, Tokyo 160-8402, Japan. Received January 31, 2006; Revised Manuscript Received April 30, 2006

The T-cell receptors of $CD4^+$ T lymphocytes recognize immunogenic peptide sequences bound within the groove of MHC class II molecules, and the peptides that bind to these molecules are known to share common structural motifs. For example, $OVA_{323-339}$, an I-A^d-binding peptide, involves a motif of the I-A^d peptide-binding groove. In the present study, OVA peptides of up to 26-mer were sequentially synthesized and screened, and two additional I-A^d binding OVA peptides, OVA_{20-43} and $OVA_{264-286}$, were found to stimulate $CD4^+$ T cells of OVA-immune BALB/c mice. OVA_{20-43} involved structural motifs of the I-A^d peptide-binding groove, while $OVA_{264-286}$ did not. The ability of these three I-A^d binding OVA peptides to induce antigen-specific cytokine production was compared among $CD4^+$ T cells of mice immunized either with alum-adsorbed OVA (OVA−alum) or OVA chemically coupled to the surface of liposome (OVA−liposome). $CD4^+$ T cells of mice immunized with OVA−alum produced more cytokines when stimulated with $OVA_{264-286}$ than with $OVA_{323-339}$, while $CD4^+$ T cells of mice immunized with OVA−liposome conjugates produced more cytokines when stimulated with $OVA_{323-339}$ than with $OVA_{264-286}$. OVA_{20-43} induced production of comparable levels of cytokines in mice immunized either with OVA−alum or OVA−liposome. Confocal laser scanning microscopic analysis demonstrated that chemically coupled OVA and liposomes were colocalized in APCs until OVA received processing. Three-dimensional structural analysis demonstrated that both $OVA_{264-286}$ and $OVA_{323-339}$ were present on the surface of OVA, but OVA_{20-43} was not. These results suggested that the chemical coupling of OVA to liposome affected antigen processing in APCs and thus resulted in the induction of differential T-cell epitopes as compared with those induced by plain OVA.

INTRODUCTION

In general, T-cell receptors (TCRs) of $CD4^+$ T cells do not recognize native protein antigens, but do recognize antigenic peptides displayed in association with major histocompatibility complex (MHC) class II molecules by antigen-presenting cells (APCs). TCRs occur as either of two distinct heterodimers, $\alpha\beta$ or $\gamma\delta$. The $\alpha\beta$ TCR heterodimer-expressing cells predominate in most lymphoid compartments (90% to 95%) of humans and mice and are responsible for the classical helper or cytotoxic T cell responses. In most cases, the $\alpha\beta$ TCR ligand is a peptide antigen bound to the class I and class II MHC molecule (*1*). Class I and II molecules encoded by genes within the MHC play a central role in regulating immune responses through their ability to bind and display small peptides derived from foreign antigens.

Grey and co-workers identified ovalbumin (OVA) peptide 323−339 as being immunodominant in H-2^d mice (*2*) and showed that this peptide binds to I-A^d, but not I-E^d, the latter of which is an Ia molecule that will not present this peptide (*3*). Ever since $OVA_{323-339}$ was identified, it has been used extensively to study the nature of class II MHC-peptide binding and T-cell activation (*4*−*9*). However, this peptide is responsible for 25−35% of the T-cell responses in BALB/c mice immunized with whole ovalbumin (*2*), suggesting the presence of other I-A^d binding OVA peptides with T-cell stimulatory activity while, at present, no other I-A^d binding OVA peptides have been reported.

We previously reported that OVA chemically coupled to the surface of liposomes via glutaraldehyde (OVA−liposome conjugates) induced IgE-selective unresponsiveness in mice (*10*). The IgE-selective unresponsiveness was induced by antigen−liposome conjugates, regardless of the coupling procedure of antigen and liposomes (*11*), using liposomes of different lipid formulations (*12*), or using different antigens such as tetanus toxin (*13*) or Shiga-like toxin (*14*). Thus, antigen−liposome conjugates are expected to be applicable as part of a novel protocol for the development of vaccines that would induce minimal IgE synthesis.

In the present study, sequentially synthesized OVA peptides were screened for the ability to stimulate OVA-specific $CD4^+$ T cells of BALB/c (H-2^d) mice and two additional I-A^d binding OVA peptides, OVA_{20-43} and $OVA_{264-286}$, were found. The ability of these three OVA peptides to stimulate $CD4^+$ T cells of OVA-immune BALB/c mice was compared among the $CD4^+$ T cells of mice immunized either with OVA−alum or with OVA−liposome conjugates. The aim of this study was to investigate the effect of antigen modification on the in vivo induction of T cell epitopes.

EXPERIMENTAL PROCEDURES

Mice. BALB/c mice (female, 8 weeks of age) were purchased from Charles River, Kanagawa, Japan. The mice were maintained in sterile cages under specific pathogen-free conditions at the Division of Experimental Animals Research (National Institute of Infectious Diseases, Tokyo, Japan).

Antigens. Ovalbumin (OVA, Grade VII) was purchased from Sigma (St. Louis, MO). For analysis of the processing of liposome-coupled OVA by macrophages, DQ−OVA, which exhibits green fluorescence upon proteolytic degradation, was purchased from Molecular Probes, Inc. (Eugene, OR).

OVA Peptides. OVA peptides consisting of 20−26 amino residues were sequentially synthesized, and the ability of each peptide to induce cytokine production by $CD4^+$ T cells of BALB/c mice immunized with OVA was investigated. All OVA peptides used in the present study were synthesized and supplied by Operon Biotechnologies, K. K. (Tokyo, Japan). Precursor peptide material attached to polystyrene resin was synthesized by an automated peptide synthesizer (model 433A; Applied Biosystems, Foster City, CA) using Fmoc (9-fluorenylmethoxycarbonyl) chemistry. Then, the resins on the peptide C-terminus and the building blocks on the peptide side chain were removed by trifluoroacetic acid. The purification of the peptide was performed by high-performance liquid chromatography (HPLC) using an automated system (HPLC-10A; Shimazu Co., Kyoto, Japan) with a 35−55% acetonitrile gradient in the acidic aqueous phase. As a result, the highly purified material was obtained with a >95% area ratio on the HPLC elution chart and was determined by mass spectroscopic analysis with the matrix-assisted laser desorption/ionization time-of-flight method using Applied Biosystems Voyager DE. The peptide solution was lyophilized and used for the subsequent experiments.

Fluorescence Labeling of OVA. OVA were labeled with fluorescence using an Alexa Fluor 488 protein labeling kit (Molecular Probes, Inc.) following the manufacturer's protocol. The estimated F:P ratio of Alexa Fluor 488−OVA conjugate was 1.4:1.

Chemicals. All phospholipids were obtained from NOF Co., Tokyo, Japan. Reagent grades of cholesterol were purchased from Wako Pure Chemical Industries, Osaka, Japan.

Liposomes. The liposomes used in the present study consisted of dipalmitoyl phosphatidylcholine, dipalmitoyl phosphatidyl ethanolamine, cholesterol, and dimyristoyl phosphatidyl glycerol in 4:3:7:2 molar ratios. The crude liposome solution was passed through a membrane filter (Nucleopore polycarbonate filter, Coster, Cambridge, MA) with a pore size of 0.2 μm.

Red-Labeled liposome. Red-labeled liposomes were prepared by adding 1,2-dimyristoyl-sn-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (Product Number: 810157, Avanti Polar Lipids Inc, Alabaster, AL) into the above lipid constituent of liposomes.

Coupling of OVA to Liposomes. Liposomal conjugates with plain OVA, Alexa−OVA, or DQ−OVA were prepared essentially in the same way as described previously (*15*) via glutaraldehyde. Briefly, to a mixture of 90 mg of liposomes and 6 mg of OVA in 2.5 mL of phosphate buffer (pH 7.2) was added 0.5 mL drops of 2.5% glutaraldehyde solution. The mixture was stirred gently for 1 h at 37 °C, and then 0.5 mL of 3 M glycine−NaOH (pH 7.2) was added to block excess aldehyde groups. This was followed by incubation overnight at 4 °C. The liposome-coupled OVA and uncoupled OVA in the resulting solution were separated using CL-4B column chromatography (Pharmacia Fine Chemical Co., Upsala, Sweden). The amount of lipid in the liposomal fraction was measured using a Phospholipid-Test-Wako phospholipid content assay kit (Wako Pure Chemical Industries). The OVA−liposome solution was adjusted to 10 mg lipid/mL in RPMI-1640, sterile-filtered using a Millex-HA syringe filter unit (0.45 μm, Millipore Corp., Bedford, MA), and kept at 4 °C until use.

Immunization. The mice were immunized intraperitoneally (ip) with 200 μL of 10 μg of OVA adsorbed with 100 μg of alum (Alhydrogel, Superfos Biosector, Vedbaek, Denmark) in PBS or with 200 μL of OVA−liposome conjugates, at 0 and 4 weeks.

Preparation of Splenic Adherent Cells. Splenic adherent cells (SACs) were used as antigen-presenting cells in the cultures of the $CD4^+$ T cells and OVA peptides. SACs were obtained from naive BALB/c mice as follows. Spleen cell suspensions were prepared in RPMI-1640 containing 10% fetal calf serum (FCS). Cells (5×10^7) in 5 mL of medium containing 10% FCS were plated into 50-mm plastic tissue culture dishes (No. 3002; Becton-Dickinson Labware, Franklin Lakes, NJ) and incubated at 37 °C in a humidified 5% CO_2 atmosphere for 2 h. After culture, nonadherent cells were removed by three vigorous washings in warm media, and adherent cells were then harvested with a cell scraper.

Preparation of $CD4^+$ T Cells. $CD4^+$ T-cell purification from spleen cells of mice immunized with OVA−alum was performed with the MACS magnetic cell sorter system (Miltenyi Biotec GmbH, Bergisch Gladbach, Germany) according to the manufacturer's protocol and using anti-CD4 antibody-coated microbeads (No. 492-01; Miltenyi Biotec). $CD4^+$ T cells were suspended in RPMI-1640 containing 10% FCS at a cell density of 2×10^6/mL. In the present study, OVA peptides at a final concentration of 10 μM with 1 and 5 d culture periods were employed for the production of the Th1 (IL-2, IFN-γ) and Th2 (IL-4, IL-5) cytokines, respectively. The $CD4^+$ T-cell suspension was plated at 250 μL per well onto 48-well culture plates (No. 3047; Becton-Dickinson Labware), and 500 μL of 20 μM OVA peptide solution and 250 μL of 8×10^5/mL SAC in the same medium were added to the plates. After incubation in a CO_2 incubator, the culture supernatants were collected and assayed to determine the concentrations of cytokines.

Cytokine Assays. IL-5 and IFN-γ in the culture supernatant were measured using the Biotrak mouse ELISA system (Amersham International, Buckinghamshire, UK). All test samples were assayed in duplicate, and the standard error in each test was always less than 5% of the mean value.

Cloned Macrophage Hybridoma. Macrophage hybridoma clone No. 39, obtained from the fusion of splenic adherent cells from CKB mice and $P388D_1$ (*16*), was maintained in RPMI-1640 (Gibco Laboratories, Grand Island, NY) supplemented with 10% heat-inactivated FCS (Hyclone Laboratories, Logan, UT), 100 U/mL of penicillin, and 100 μg/mL of streptomycin (Gibco Laboratories) in a 75 cm^2 flask (No. 3111; Becton Dickinson Labware, Franklin Lakes, NJ).

Flow Cytometry. To investigate the processing of OVA coupled to liposome by macrophages, #39 macrophage clone was incubated for 15 to 60 min at 37 °C in the presence of DQ−OVA−liposome conjugates that contained a final concentration of 4 μg/mL OVA. After incubation, the cells were washed with ice-cold PBS and then were analyzed on a FACS Calibur flow cytometer (BD Biosciences, Mountain View, CA). The histograms of fluorescence distribution were plotted as the number of cells versus fluorescence intensity on a logarithmic scale.

Confocal Laser Scanning Microscopy. To investigate the processing of liposome-coupled OVA by macrophages, macrophage clone No. 39 was cultured for 18 h at 37°C on 8-hole heavy Teflon-coated slides (Bokusui Brown, New York, NY) and then incubated with DQ−OVA−liposome conjugates for 2 h at 37 °C. The slides were washed with MEM and fixed with 4% paraformaldehyde in PBS for 10 min at room temperature. After fixation, they were incubated for 10 min in 0.1 M glycine-HCl, pH 7.0, to block the remaining ardehyde residue. They were then washed two times in PBS. After washing, the slides were sealed with PBS/glycerin (PBS:glycerin = 1:9). They were then analyzed under a confocal laser scanning

[a] Each peptide was assessed for its ability to induce cytokine production by CD4 T cells of mice immunized with OVA−alum. CD4 T cells were cultured in the presence of OVA peptides as described in Experimental Procedures. Data represent mean cytokine concentration (pg/mL) and SE of triplicate cultures. ND, not detected.

microscope system, LSM410 (Carl Zeiss Co., Germany). Internalization of Alexa−OVA−red liposome conjugates in the macrophages was investigated in essentially the same manner as above.

Analysis of Three-Dimensional Structure of OVA. The three-dimensional structure of OVA reported by Stein et al. (*17*, *18*) was obtained from DBGET database links (http://www.genome.jp/dbget/), and the locations of the OVA peptides were displayed using ProteinAdviser (Fujitsu Kyusyu System Engineering Ltd., Fukuoka, Japan).

RESULTS

OVA Peptides Capable of Inducing Cytokine Production by OVA-Specific CD4$^+$ T Cells of BALB/c Mice. A series of sequentially synthesized OVA peptides shown in Table 1 were screened for the ability to induce cytokine production by CD4$^+$ T cells of BALB/c mice immunized with OVA−alum. Since, under the culture conditions described in Materials and Methods, no cytokine production was observed in the absence of OVA, nor by the use of CD4$^+$ T cells of naive BALB/c mice, the data shown in Table 2 were considered to represent antigen-specific cytokine production. In addition to well-known $OVA_{323-339}$, two OVA peptides, OVA_{20-43} and $OVA_{264-286}$, were found to induce significant production of all cytokines tested. The levels of cytokines induced by OVA_{20-43} and $OVA_{264-286}$ were even higher than those induced by $OVA_{323-339}$ in all cytokines tested. OVA_{20-43} involved the core motif of the I-A^d peptide-binding groove, OVA_{31-36}, but $OVA_{264-286}$ did not.

Cytokine Production by OVA-Specific CD4$^+$ T Cells Of Mice Immunized with OVA−Alum or OVA−Liposome, after Stimulation with OVA Peptides. The next attempt was performed using newly found OVA peptides, OVA_{20-43} and $OVA_{264-286}$, and a well-known OVA peptide, $OVA_{323-339}$. Splenic CD4$^+$ T cells were obtained from mice immunized either with OVA−liposome or OVA−alum and were cultured with OVA_{20-43}, $OVA_{264-286}$, or $OVA_{323-339}$ in the presence of APCs. As shown in Figure 1, the levels of cytokines produced by CD$^+$ T cells of mice immunized with OVA−liposome were significantly ($p < 0.01$) higher when the T cells were cultured either with OVA_{20-43} or $OVA_{323-339}$ than when they were cultured with $OVA_{264-286}$. On the other hand, in the culture of the CD4$^+$ T cells of mice immunized with OVA−alum, OVA_{20-43} and $OVA_{264-286}$ induced significantly higher levels of IL-5 and IFN-γ as compared to those induced by $OVA_{323-339}$, consistent with the results shown in Table 1. Similar results were obtained for the other cytokines, IL-2, IL-4, and IL-10 (data not shown).

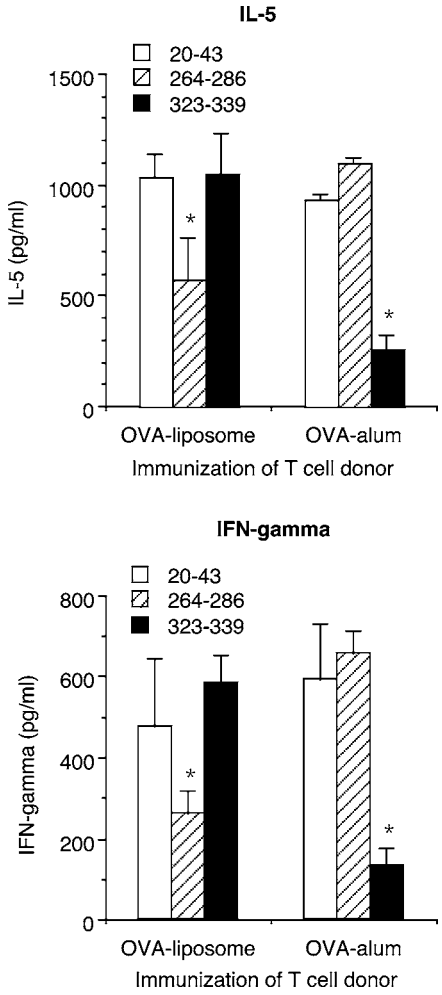

Figure 1. Cytokine production by CD4$^+$ T cells of mice immunized with OVA−liposome or OVA−alum, after in vitro stimulation with OVA peptides. CD4$^+$ T cells were taken from OVA-immune mice and cultured with OVA peptides as described in Materials and Methods. Data represent mean cytokine concentration (pg/mL) and SE of triplicate culture. Data are representative of three independent experiments.

Duration of Processing of Liposome-Coupled OVA in APCs. DQ−OVA coupled to liposome was cultured for 15 to 60 min with macrophage clone No. 39, and FACS analysis was performed. Figure 2a shows the fluorescence intensity of macrophages. A maximal processing of OVA was observed at 60 min. A consistent result was observed by confocal microscopic analysis (Figure 2b); the green fluorescence in the macrophages increased gradually within 60 min, suggesting that liposome-coupled OVA received processing significantly within 60 min after onset of the culture.

Internalization of Alexa−OVA−Red Liposome Conjugates in Macrophages. Alexa−OVA−red liposome conjugates, which appear yellow due to association with the green in Alexa−OVA and the red in the liposome, were cultured with macrophage clone No. 39 for 15 to 60 min, and confocal

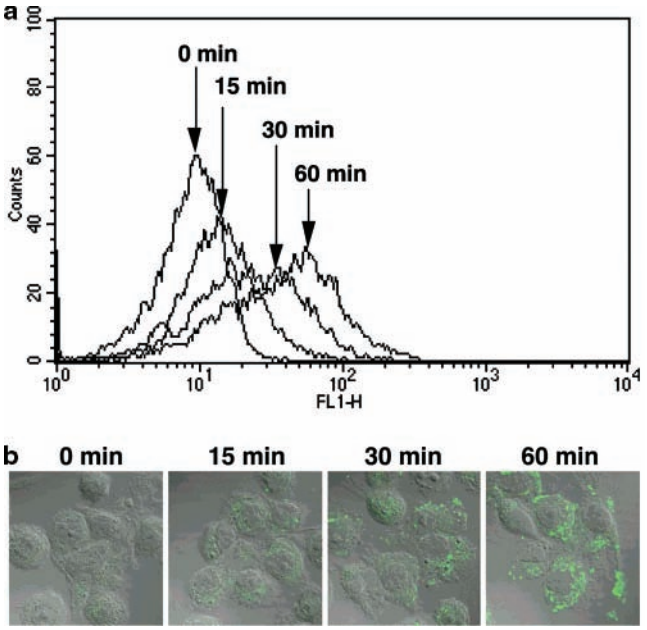

Figure 2. Digestion of liposome-coupled OVA by macrophages. DQ−OVA coupled to the surface of liposomes were added to the macrophage culture. Zero to 60 min after the onset of the culture, the macrophages were recovered and analyzed using flow cytometry (a) and confocal laser scanning microscopy (b).

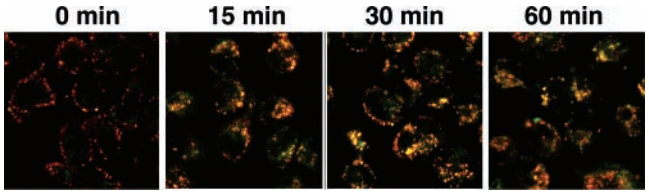

Figure 3. Association of OVA and liposomes in macrophages. Conjugates of Alexa488-labeled OVA and red-labeled liposomes were added to the macrophage culture. Zero to 60 min after the onset of the culture, the macrophages were recovered and analyzed using confocal laser scanning microscopy. The yellow spots observed in the macrophages are the result of the association with the Alexa488 (green) and red-labeled liposomes.

scanning microscopic analysis was performed. As shown in Figure 3, yellow spots were observed up to 60 min, suggesting that the OVA and liposomes were associated until liposome-coupled OVA received processing (Figure 2).

OVA Peptides in Three-Dimensional Structure of OVA. The locations of the three OVA peptides, OVA_{20-43}, $OVA_{264-286}$, and $OVA_{323-339}$, in the three-dimensional structure of OVA were analyzed. As shown in Figure 4, both $OVA_{264-286}$ and $OVA_{323-339}$ located on the surface of OVA in the three-dimensional structure, while OVA_{20-43} was situated inside the three-dimensional structure of OVA.

DISCUSSION

In the present study, OVA_{20-43} and $OVA_{264-286}$ were newly found among sequentially synthesized OVA peptides to stimulate $CD4^+$ T cells of OVA-immune BALB/c mice for cytokine production. A length of six residues has been proposed for core motifs of the I-A^d peptide-binding groove, with the first, third, and fourth residues being hydrophobic and the sixth generally being alanine or serine (*5*, *19*). OVA contains at least eight different epitopes with the I-A^d-binding motif, including $OVA_{327-332}$ which is involved in $OVA_{323-339}$. OVA_{20-43} involved core motifs of the I-A^d peptide binding groove, OVA_{31-36} and OVA_{32-37}, while $OVA_{264-286}$ did not. In addition, although OVA_{1-20}, OVA_{53-78}, $OVA_{220-245}$, and $OVA_{302-327}$ involved the core motifs OVA_{1-6}, OVA_{63-68}, $OVA_{230-235}$, and $OVA_{312-317}$, respectively, none of them induced OVA-specific cytokine production by $CD4^+$ T cells of OVA-immune BALB/c mice (Table 2). These results suggest that the involvement of structural motifs of the MHC class II peptide binding groove in an antigenic peptide is not an essential condition for the activation of antigen-specific $CD4^+$ T cells. Also, regarding class I, although OVA contains six potential epitopes with the H-$2K^b$-binding motif (*20*), the CTL response is dominated by just one, $OVA_{257-264}$ (*21*−*23*). Thus, immunodominance would be directed by more than just the presence of an appropriate class I- or class II-binding motif.

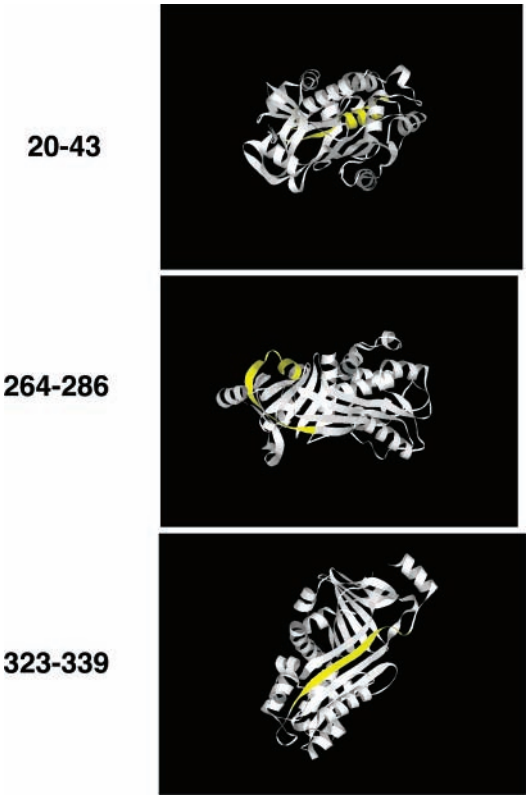

Figure 4. Location of OVA peptides in the three-dimensional structure of OVA. The OVA peptides in the three-dimensional structure of OVA are indicated as yellow strings.

The $\alpha\beta$ TCR comprises disulfide-linked α and β chains, each of which has a membrane-distal variable (Vα or Vβ) and membrane-proximal constant (Cα and Cβ) immunoglobulin superfamily (IgSF) domain, transmembrane regions, and short cytoplasmic segments (*24*). The peptide-MHC binding site is formed primarily from three complementary-determining regions (CDRs) or loops contributed by each Vα and Vβ domain. TCRs dock to the peptide-MHC in a topologically constrained manner, i.e., with the Vα domain of the TCR positioned over the N-terminal half of the peptide and the Vβ domain over the C-terminus (*25*, *26*). Thus, the shape of the TCR and/or peptide-MHC binding surfaces might limit the number of docking orientations (*24*). Therefore, the processing of both OVA_{20-43} and $OVA_{264-286}$ in APC to produce the "essential" length of the I-A^d-binding peptides sequence would be indispensable for the presentation of those peptides to $CD4^+$ T cells via the interaction between the peptide-MHC and TCRs.

Each Ia is considered to possess a single peptide binding site, based on the observation that unrelated peptides restricted by the same Ia molecule are capable of inhibiting the binding of one another to that particular Ia (*27*). This in turn supports the concept that a single site on Ia is capable of recognizing a structural motif common to many antigens (*5*). However, in the

present study, among two newly found I-A^d-binding OVA peptides, although each were found capable of stimulating antigen-specific $CD4^+$ T cells, one was demonstrated to involve a structural motif of the I-A^d peptide-binding groove but the other was not, suggesting the existence of another motif of the I-A^d peptide-binding groove.

$OVA_{323-339}$ induced a significantly higher level of cytokine production by $CD4^+$ T cells of mice immunized with OVA−liposome than that induced by $OVA_{264-286}$. However, in contrast, $OVA_{323-339}$ induced a significantly lower level of cytokine production by $CD4^+$ T cells of mice immunized with OVA−alum than that induced by $OVA_{264-286}$. These results suggest that the modification of OVA by the chemical coupling of OVA with liposomes may interrupt or alter antigen processing in APCs and result in the presentation of a differential set of peptides to T cells. In fact, the results of the present study demonstrated that the OVA and liposomes were associated until liposome-coupled OVA was processed (Figures 2 and 3). In the previous study (*13*), antigen−liposome conjugates were shown to be stable for at least 6 months if stored at 4 °C, and, if tetanus toxoid was coupled to liposomes and lyophilized, their efficacy was maintained for 6 months at 37 °C. The fact that both $OVA_{264-286}$ and $OVA_{323-339}$ were present on the surface of the three-dimensional structure of OVA made it reasonable to consider the effect of antigen-modification on the antigen processing in APCs. On the other hand, OVA_{20-43}, which induced a comparable level of cytokine production in both OVA−alum- and OVA−liposome-immune mice, was present inside the structure of OVA and likely not affected by the antigen-modification.

It is unlikely that the antigen-modification by the chemical coupling of antigen to liposomes detracts from the efficacy of vaccines when liposome-coupled antigen is applied to the vaccination protocol, since liposome-coupled toxins successfully induced protection against the tetanus toxin (*13*) or Shiga-like toxin (*14*, *28*, *29*) in mice (*13*, *14*) and also in monkeys (*28*). Nor it is unlikely that the difference between the two OVA peptides, $OVA_{264-286}$ and $OVA_{323-339}$, in the ability to induce cytokine production by $CD4^+$ T cells is reflected by the difference of immunodominance (i.e., affinity to bind I-A^d) in these two OVA peptides, since these peptides yielded opposite results in the stimulation of OVA-specific cytokine production by $CD4^+$ T cells of mice immunized by two different ways of immunization, i.e., OVA−alum and OVA−liposome. Thus, the results in the present study suggested that the modification of antigen affects antigen processing in APCs and results in the induction of differential T-cell epitopes as compared with those induced by plain antigen.

Imaging Pancreatic Cancer with a Peptide−Nanoparticle Conjugate Targeted to Normal Pancreas

Xavier Montet, Ralph Weissleder, and Lee Josephson*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Building 149, 13th Street, Charlestown, Massachusetts 02129. Received February 13, 2006; Revised Manuscript Received April 14, 2006

Designing molecules that bind to targets that become upregulated or overexpressed as normal cells become cancerous is an important strategy for both therapeutic and diagnostic drug design. We hypothesized that pancreatic ductal adenocarcinoma (PDAC) might be imaged with the inverse strategy, that is by the design of a nanoparticle−conjugate targeted to bombesin (BN) receptors present on normal acinar cells of the pancreas. Using the fluorescein hapten visualization method to assess the presence of bombesin (BN) receptors, we first demonstrated BN receptors in the normal mouse and human pancreas, but then the lack of BN binding receptors in 13 out of 13 specimens of PDAC. The BN peptide−nanoparticle conjugate, BN−CLIO(Cy5.5), was synthesized and accumulated in the mouse pancreas in receptor dependent fashion, but not in a receptor dependent fashion in other tissues, based on tissue fluorescence measurements. The BN−CLIO(Cy5.5) nanoparticle decreased the T2 of normal pancreas and enhanced the ability to visualize tumor in a model of pancreatic cancer by MRI. The use of BN−CLIO(Cy5.5) nanoparticle as a normal tissue-targeted, T2-reducing contrast agent offers a promising approach to imaging PDAC.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) ranks as the fourth leading cause of cancer death in the US. In 2004, an estimated 32 000 cases will be matched with 31 500 deaths. The mean survival averages 6 months, and less than 5% of all patients survive beyond 5 years (http://seer.cancer.gov/). The dire situation in PDAC relates to the tumor's intense drug resistance and late diagnosis, among other factors. Late diagnosis is due to the lack of specific symptoms and limitations in diagnostics, allowing the disease to elude detection during its formative stages. Though improved imaging methods are needed to assist in the detection and treatment, few agents have been designed to image molecular targets expressed by PDAC. This is in part due to the fact that many molecularly targeted, radioactive peptides (somatostatin, secretin, bombesin, CCK, VIP) employed in tumor imaging in nonpancreatic organ settings have limited utility as pancreatic imaging agents because of the expression of these receptors on cells of the noncancerous pancreas (*1*−*6*).

The large number of receptors present on normal pancreatic stroma, however, suggests an alternative strategy for tumor visualization, one where agents target receptors expressed on normal cells. The strategy of targeting normal rather than tumor cells has worked well with magnetic nanoparticles which selectively decrease the T2 of the normal liver and lymph nodes by targeting macrophages in those tissues and enhance tumor visualization in those tissues by MRI (*7*, *8*). We refer to this approach as a normal tissue-targeted nanoparticle/T2 reduction strategy.

We therefore hypothesized that a peptide−nanoparticle conjugate targeted to the bombesin peptide binding receptors on normal pancreatic acinar cells might enhance the visualization of pancreatic tumors in an orthotopic animal model and, potentially, in human PDAC. We noted that the literature suggested a molecular target(s), bombesin peptide binding receptors, was present in the normal pancreas and not PDAC (*9*). The distribution of the bombesin binding receptors in PDAC and the normal pancreas is discussed below. Second, bombesin binding receptors internalize ligands, offering a potentially dynamic mechanism of nanoparticle accumulation and amplification (*10*−*12*). The broad goal of developing a nanoparticle targeted to normal pancreas for imaging PDAC by MRI included the following subaims: (i) to develop a nanoparticle targeted to bombesin peptide binding receptors in the normal pancreas, (ii) to demonstrate that the nanoparticle decreased the T2 of normal pancreas and, (iii) to demonstrate enhanced tumor/normal visualization on T2 weighted pancreatic images.

MATERIALS AND METHODS

Peptide−Nanoparticle Conjugate Synthesis. Peptides were synthesized by the Tufts Core Facility (Tufts University Core facility, Boston, MA) to obtain a bombesin-like peptide (FITC)-BCDDDGQRLGNQWAVGHLM or BN, as well as a scrambled version of the bombesin-like peptide, (FITC)BCDDDGQM-LGNHLAVGQWR or ScrBN. Peptides were C-terminal amides. B stands for betalanine and FITC for fluorescein isothiocyanate. The 13 C-terminal amino acids are found in bombesin. Three negatively charged aspartate residues (DDD) were employed as spacers and provide a negative charge bias on the nanoparticle; these increase nanoparticle solubility and decrease nonspecific interactions with negatively charged cells. The amino-CLIO nanoparticle, synthesized as described (*13*, *14*), was first reacted with the *N*-hydroxysuccinimde ester of Cy5.5 (Amersham Biosciences Corp, Piscataway, NJ) to obtain a ratio of 5.1 dyes per nanoparticle which is denoted CLIO(Cy5.5) (*15*). The majority of amines remained available for reaction with succinimidyl iodoacetic acid, which then reacted with the sulfhydryl group of the BN or ScrBN peptides (*15*, *16*). The resulting nanoparticles, BN−CLIO(Cy5.5) and ScrBN−CLIO(Cy5.5), were identical in composition, but because of the sequence difference, the ScrBN nanoparticle was unable to bind receptors for bombesin. Fluorescein, attached to peptides before conjugation to the nanoparticle, does not appear in this notation; it allows characterization of the peptide:iron ratio based on its absorption at 493 nm. The resulting nanoparticles, BN−

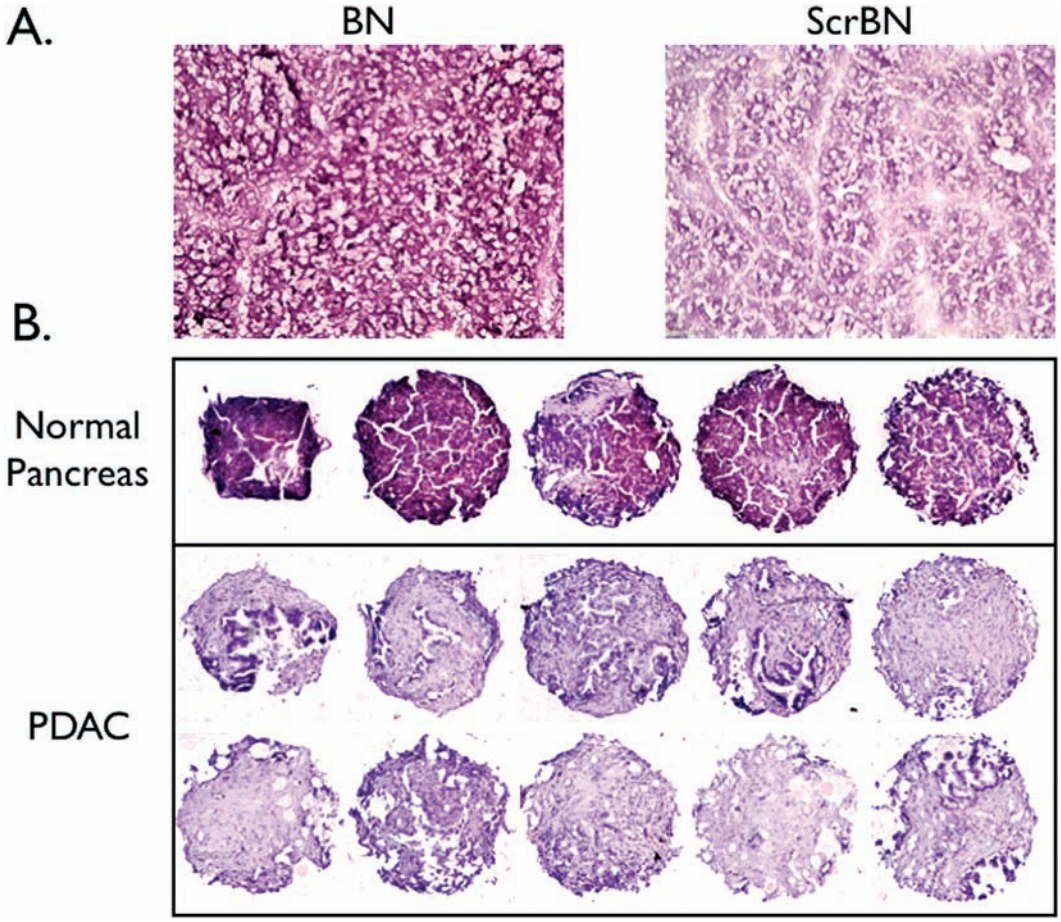

Figure 1. Binding of bombesin peptide to normal pancreas. (A) Bombesin peptide (BN) or scrambled version (ScrBN) were exposed to normal mouse pancreas. The fluorescein on the peptide is visualized by an anti-fluorescein horseradish peroxidase conjugate. Normal pancreas stained dark purple. BN stains more darkly than ScrBN, indicating specific binding. (B) BN was exposed to a human tissue microarray of normal human pancreas and pancreatic ductal adenocarcinomas. Normal tissue stained more darkly than pancreatic adenocarcinomas.

CLIO(Cy5.5) and ScrBN−CLIO(Cy5.5), had diameters of 35 and 41 nm by laser light scattering, relaxivities of 70 and 62 $mM^{-1}\ s^{-1}$, and 50 and 48 peptides per nanoparticle, respectively. The numbers of dyes or peptides per nanoparticle were based on 8000 iron atoms per amino-CLIO nanoparticle, obtained by the viscosity/light scattering method for estimating nanoparticle core weights (*17*). The design of the peptide−nanoparticles used here is shown schematically in Figure 1 of Koch (*15*), except (i) Cy5.5 replaced Cy3.5 as the fluorochrome attached to the dextran, and (ii) peptides coupled were the BN and ScrBN peptides rather than the tat peptide. In both conjugations succinimidyl iodoacetic acid was used to attach the thiol of a cysteine group to the amine of the nanoparticle, so the linker chemistry in the current study is that shown by Koch.

To determine the binding of the BN peptide and ScrBN peptides to the normal mouse pancreas, the fluorescein hapten visualization (FHV) and assay (FHA) methods were used, a more complete analysis of which has been published (*18*). Tissue sections of mouse pancreas, 7 μm thick, were snap frozen. To determine the binding of BN peptide to human tissue specimens, tissue microarrays of pancreatic tumor were obtained (Tristar Technology Group, LLC, Bethesda, MD), which contained 13 cancers and 5 normal pancreas specimens. Tissue microarrays or normal mouse pancreas specimens were incubated for 1 h at room temperature with either BN or ScrBN peptides at 1 μg/mL diluted in PBS containing 10% rabbit serum, 0.3% sodium azide w/v, and 0.5% H_2O_2 to block the endogenous peroxidases. Unbound peptide was removed by washing three times with the PBS. An anti-FITC horseradish peroxidase conjugate (Molecular Probes, Eugene OR), diluted into PBS containing 2% human serum to 5 μg/mL, was applied to the sample for 40 min. Unbound conjugate was removed by washing three times with the PBS. Enzyme activity was developed for 8 min using the Vectastain Elite ABC kit (Vector Laboratories, Burlingame, CA). For the fluorescein hapten assay, specimens were fixed as above, incubated with ligand, and washed free of unbound ligand as above for the fluorescein hapten receptor visualization method. The immunoassay for immunoreactive fluorescein was employed to quantitate bound fluorescein (*19*). To the slide chamber was added 500 μL of lysis buffer (PBS, 0.1% BSA, 0.1% Triton X-100, 1 mM 8-anilino-1-naphthalenesulfonic acid with 40 ng/mL of anti-fluorescein-HRP. Incubation was for 2 h at room temperature. Duplicate 200 μL volumes were then transferred to a 96-well plate (MaxiSorp, Nunc) coated with 12.5 ng/mL FITC-labeled BSA (Sigma-Aldrich, St, Louis, MO) and incubated for 1 h at room temperature. Plates were then washed three times (PBS, 0.1% BSA, 0.1% Tween) to remove unreacted anti-fluorescein-HRP, and bound peroxidase was quantitated by absorbance at 650 nm using 200 μL of 3,3′,5,5′-tetramethylbenzidine dihydrochloride after 30 min incubation at room temperature. The concentration of fluoresceinated ligand was determined from a standard curve of fluoresceinated ligand diluted in PBS, 0.1% BSA, 0.1% Tween.

To determine nanoparticle tissue distribution, normal athymic female nude mice (20−25 g) ($n = 13$) were divided in three groups. Group 1 ($n = 3$) was injected with PBS and was used to measure the intrinsic fluorescence of each organ. Groups 2 and 3 ($n = 5$) were injected with BN−CLIO(Cy5.5) or ScrBN−CLIO(Cy5.5) (10 mg Fe/kg), respectively, and sacrificed after 24 h. Tissue fluorescence was obtained using a commercially

available fluorescence reflectance imaging system (BonSAI system, Siemens, Malvern, PA). Slices of tissues (about 1 mm thick, roughly 5 mm in diameter) were placed on a dark plate. Fluorescence was determined using operator-defined regions-of-interest (ROI) on tissues from both injected and uninjected animals. Background fluorescence was subtracted and the values of BN−CLIO(Cy5.5) and ScrBN−CLIO dependent tissue fluorescence were obtained.

To examine whether the BN−CLIO(Cy5.5) could enhance visualization of pancreatic tumors by MRI an orthotopic tumor model was employed. The pancreatic tumor cell line, MIA-PaCa 2 from the American Tissue Culture Collection (ATCC, Manassas, VA), was cultured according to the manufacturer's instructions. Following anesthesia (Isofluorane, 2%), a paramedian laparotomy allowed access to the pancreas and two million MIA-PaCa2 cells in 10 μL were implanted directly in the pancreatic tail of athymic nude female mice. Histology indicated a single, well-defined tumor per pancreas in all animals with a lack of micrometastases ($n = 5$).

Mice were imaged on a 4.7T Bruker system (Pharmascan, Karlsruhe, Germany) 6 days after implantation, followed by BN−CLIO(Cy5.5) tail vein injection (10 mgFe/kg), with postcontrast images acquired 24 h later. Isofluorane 2% was used for anesthesia during imaging. Coronal T2* maps were generated using the parameters: TR = 2000 ms, 16 different TE values from 6.5 to 104 ms, flip angle = 90°, matrix size = 128 × 64, number of average = 4, field of view = 4.24 × 2.12 cm, slice thickness = 0.8 mm. Tumor to normal contrast (CNR) ratio was obtained at TR = 2000 ms, TE = 52 ms where CNR was taken as the difference in signal intensity of the tumor and normal pancreas divided by the standard deviation of the noise. Hand-drawn regions of interest of clearly hyperintense signal (1−3 mm) were taken as tumor, whose dimensions and position were verified by dissection and histology. After the second MR imaging session, tissues were removed, snap frozen, and cut into 7 μm sections (for hemotoxylin and eosin) or into 15 μm for direct fluorescence microscopy.

To characterize the presence of BN binding receptors, the pancreas from athymic female nude mice was removed and digested with collagenase/Dispase enzymes solution (Roche Diagnostics, Penzberg, Germany) for 1 h at 37 °C. Cell suspensions were filtered through strainers of 100 μm (BD Biosciences, Franklin Lakes, NJ) and centrifuged (1000 rpm for 5 min) to obtain disaggregated pancreatic cells. Cells were then incubated with either BN or ScrBN and an anti-acinar cell antibody, obtained from the Developmental Studies Hybridoma Bank developed under the auspice of the NICHD and maintained by the University of Iowa (Department of Biological Sciences, Iowa City, IA) (*20*). FACS analysis was performed on a FACScalibur (Becton Dickinson, Franklin Lakes, NJ). All animal studies were approved by the MGH animal care committee.

RESULTS

Tissue-based radioreceptor assays have found bombesin binding receptors to be absent in human pancreatic ductal adenocarcinomas (*9*), while studies of GRP receptor mRNA expression in different tissues found bombesin binding receptor mRNA to be abundant in the normal human pancreas (*21, 22*). (The presence of bombesin binding receptors in the pancreas is discussed more fully below.) To determine if the BN peptide had the desired interaction with normal pancreatic tissue, we used the recently developed fluorescein hapten visualization (FHV) and fluorescein hapten assay (FHA) methods for bound peptide. Here the binding of fluoresceinated peptides to receptors in tissues is visualized or assayed using an anti-fluorescein−horseradish peroxidase conjugate and horseradish peroxidase substrate (*18*). An FHV method with normal mouse pancreas is shown in Figure 1A, where the tissue was treated with the BN peptide or ScrBN peptides; the former produced a notably darker stain that appeared to be homogeneous. To verify the visual difference in stain intensity from the two peptides, tissues were exposed to either peptide, a volume of lysis buffer was added to dissolve the tissue, and the fluorescein in the lysate was quantified by the fluorescein immunoassay, a procedure we term an FHA method (*18*). There was 3.5 times more BN peptide than the ScrBN peptide on tissue specimens. The binding of the BN peptide to acinar cells in the mouse pancreas was also evident when disaggregated cells from the pancreas were exposed to the peptide and analyzed by FACS, see Figure 4D. We applied that FHV method to a tissue microarray consisting of 5 normal human pancreas specimens and 13 pancreatic ductal adenocarcinomas. The binding of the BN peptide was assessed using the anti-fluorescein−horseradish peroxidase conjugate. As shown in Figure 1B, the BN peptide produced a notably darker peroxidase stain with normal pancreatic specimens than ductal adenocarcinoma specimens. On the basis of a limited number of specimens, it appears that the BN peptide binds normal human pancreas and not pancreatic adenocarcinomas.

To determine the tissue specificity of the BN−CLIO(Cy5.5) nanoparticle, we compared the uptake of the nanoparticle in the pancreas with that of ScrBN−CLIO(Cy5.5), a nanoparticle which has identical physical properties to BN−CLIO(Cy5.5) but which is made with a peptide having a scrambled sequence (Figure 1). As shown in Figure 2A, the pancreas of animals injected with BN−CLIO(Cy5.5) was distinctly brighter than those injected with ScrBN−CLIO(Cy5.5). Organ fluorescence obtained with each nanoparticle, together with tissue autofluorescence, is shown in Figure 2B. The hepatic uptake reflects the fact that nanoparticles are too large for renal elimination, and both BN−CLIO(Cy5.5) and ScrBN−CLIO(Cy5.5) are withdrawn by Kupffer cells of the liver in a nonreceptor dependent fashion. The uptake of the two nanoparticles was similar ($p > 0.11-0.57$) for all tissues except the pancreas, which had a 3-fold higher fluorescence with BN−CLIO(Cy5.5) than ScrBN−CLIO(Cy5.5), ($p < 0.003$); see Figure 2C. On the basis of the ratio of fluorescence, receptor-mediated targeting of BN−CLIO(Cy5.5) occurred with the pancreas, with high nonpeptide dependent uptake by the liver and spleen. This method of demonstrating receptor specificity (receptor binding and nonreceptor binding nanoparticles) was employed because the BN peptide has a shorter blood half-life than the BN−CLIO(Cy5.5) nanoparticle and the peptide cannot block receptor-mediated interactions in vivo (Montet and Josephson, unpublished observations).

We next examined whether the injection BN−CLIO(Cy5.5) could improve the contrast between normal pancreas and tumor as shown in Figure 3. T2 weighted MR images (TR = 2000 ms, TE = 52 ms) before and after the injection of BN−CLIO(Cy5.5) of a mouse with a tumor-bearing pancreas are shown in Figure 3A and 3B, respectively. Tumor (arrow) is not visible or barely visible in the precontrast image but after the injection of BN−CLIO(Cy5.5), and darkening of normal pancreas, tumor mass became readily discernible, see Figure 3C (magnified version of 3B). A colorized map of pancreatic T2 values is shown in Figure 3D, superimposed on the T2 weighted image. Tumors were present as well-defined single masses (no micrometastases), whose location was confirmed on dissection, see Figure 3E. With a cutoff of 53 ms for tumor versus normal pancreas, T2 values were 62 ± 6 and 62 ± 5 ms ($n = 5$) for tumors, pre- and postinjection, respectively. The average T2 values of the normal pancreas decreased from 46 ± 5 to 39 ± 5 ms ($n = 8$) with BN−CLIO(Cy5.5) injection ($p = 0.036$). Thus BN−CLIO(Cy5.5) enhanced tumor visualization by selectively decreasing the T2 of the normal pancreas.

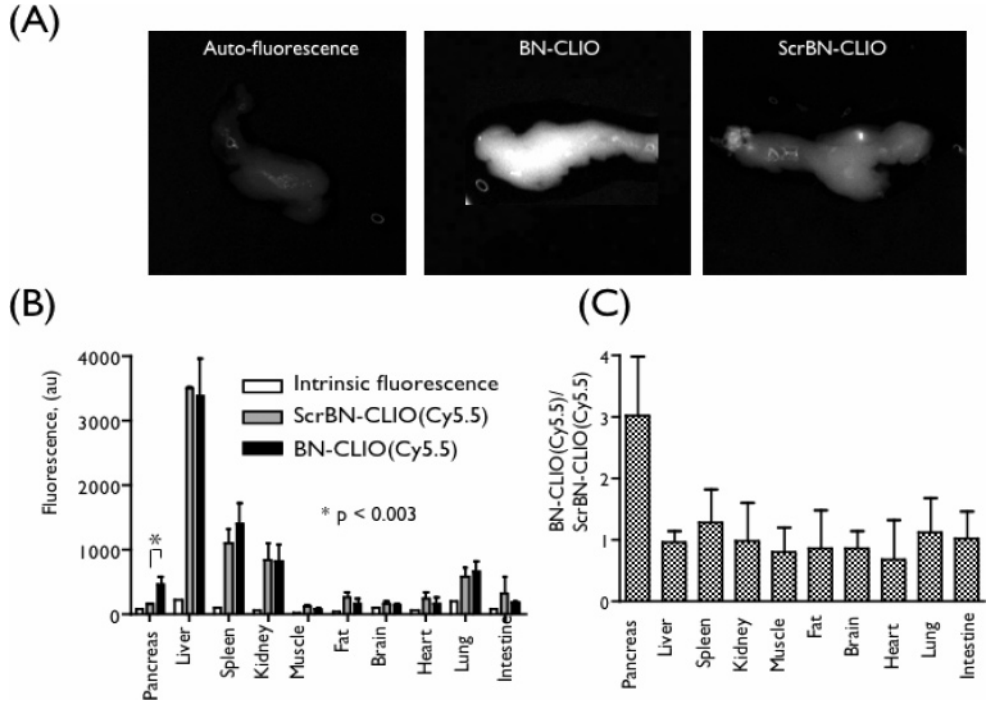

Figure 2. BN peptide targets the BN−CLIO(Cy5.5) nanoparticle to the normal mouse pancreas. (A) Tissue autofluorescence and tissue fluorescence postinjection of ScrBN−CLIO(Cy5.5) or BN−CLIO(Cy5.5) nanoparticle for a normal mouse pancreas. (B) Fluorescence of dissected tissues after injection with nanoparticles and from uninjected animals. (C) Ratio of tissue fluorescence for BN−CLIO(Cy5.5) and ScrBN−CLIO(Cy5.5), obtained after background subtraction. The pancreas was the only organ to preferentially accumulate the BN−CLIO(Cy5.5).

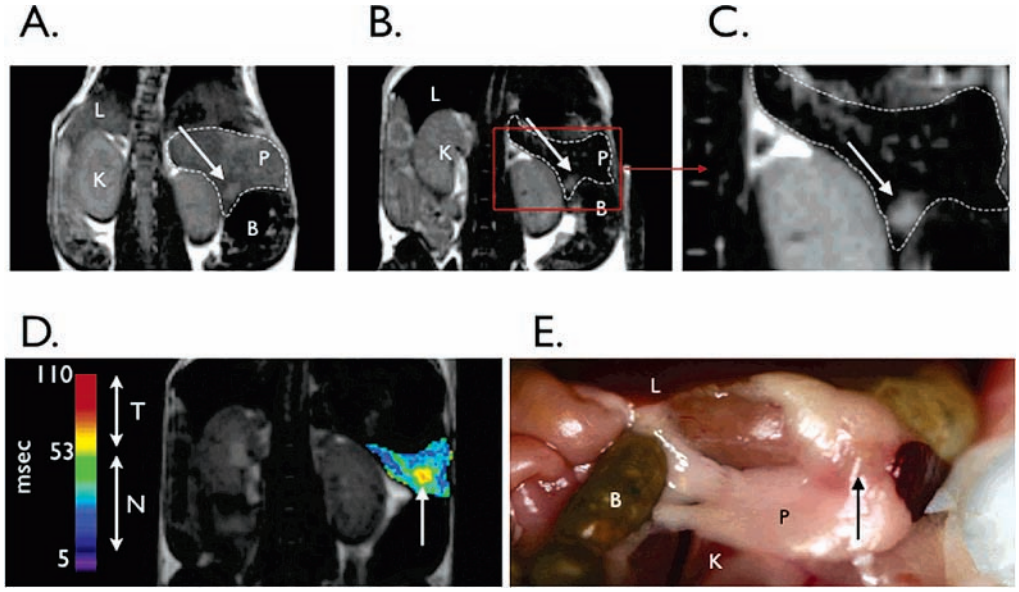

Figure 3. T2 weighted images of pancreas and tumor. Preinjection (A) and postinjection (B) of pancreas and tumor. (C) Image from B at higher magnification. BN−CLIO(Cy5.5) permits tumor (arrows) to be seen. Arrow indicates bulk tumor. (D) Postcontrast agent, colorized T2 map of a pancreas with implanted tumor. Tumor has higher T2s than normal pancreas. Abbreviations: L, liver; P, pancreas; K, kidney; B, bowel. (E) Photograph of partially dissected mouse with pancreas and tumor visible.

We next examined the distribution of BN−CLIO(Cy5.5) within the pancreas by fluorescence microscopy and FACS as shown in Figure 4. Figure 4A and 4B show the tumor margin with H and E stain or fluorescence microscopy, respectively. As shown in Figure 4B, the nanoparticle was preferentially accumulated at the border of the tumor, with substantial regions of low nanoparticle accumulation elsewhere in the micrograph. The BN−CLIO(Cy5.5) nanoparticle was visible in the fluorescein channel, due to fluorescein on the BN peptide or Cy5.5 channel, due to Cy5.5 attached directly to the nanoparticle. Background fluorescence in these channels was corrected using tissues from noninjected animals. We also injected a mouse, disaggregated the pancreas, and ran the disaggregated cells through a single channel FACS as shown in Figure 4C. Some 8% of the cells were labeled as a distinct population with a median fluorescence of 198 au compared to the median fluorescence of 21 au obtained for the unlabeled cell fraction from the injected animal. We characterized cells from the disaggregated pancreas using a specific anti-acinar cell antibody using dual wavelength FACS as shown in Figure 4D and 4E. Some 33−34% of the cells bound the anti-acinar antibody and these cells also bound the BN peptide and an anti-gastrin

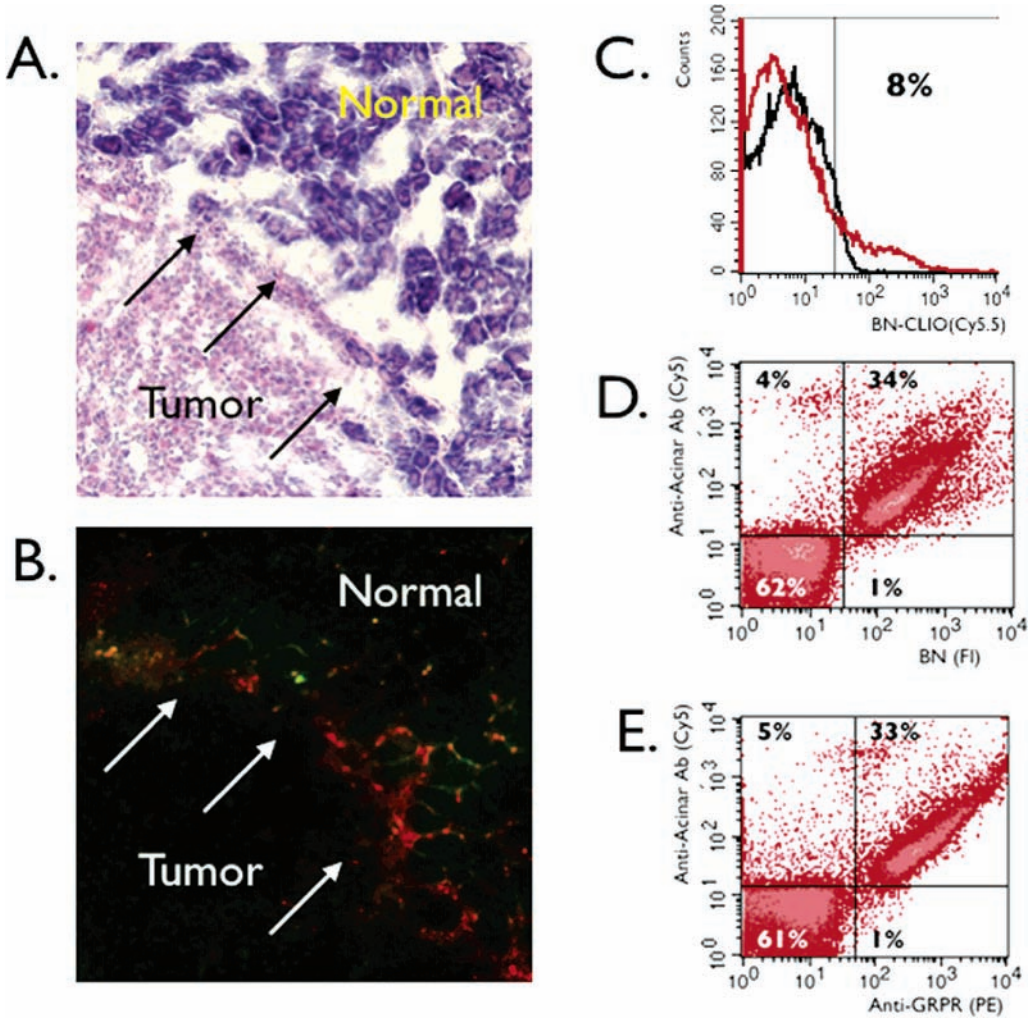

Figure 4. Accumulation of the BN−CLIO(Cy5.5) nanoparticle in the mouse pancreas. (A) Border (arrows) between tumor and normal pancreas with H and E stain. (B) Fluorescent microscopy of the adjacent tissue slice to that shown in (A). Cy5.5 fluorescence (red) and fluorescein fluorescence (green) are shown. Nanoparticle concentrates at tumor border (arrows). (C) Single channel FACS of disaggregated normal mouse pancreas after injection of BN−CLIO(Cy5.5). Some 8% of cells have Cy5.5 fluorescence. (D) Dual wavelength FACS of cells from disaggregated pancreas binding Cy5 labeled anti-acinar antibody and BN peptide (fluorescein labeled). (E) Cells from disaggregated pancreas binding anti-acinar antibody and anti-GRP. Acinar cells (34% of total pancreatic cells) express GRP receptor and bind BN peptide.

releasing peptide receptor antibody. Since only 8% of the cells were labeled, it appears that most acinar cells (34% of total) cells did not internalize BN−CLIO(Cy5.5).

DISCUSSION

A feature of the postinjection BN−CLIO(Cy5.5) images of the mouse pancreas was the heterogeneous signal intensity obtained (Figure 3C). Though we did not correlate local changes in pancreatic signal intensity with higher or lower concentrations of nanoparticles in specific regions of the pancreas, two lines of evidence indicate a generally heterogeneous particle distribution within the pancreas. First, fluorescence microscopy (Figure 4B) showed regions of higher and lower nanoparticle concentration in the nontumor bearing, normal pancreas. Second, FACS analysis of disaggregated acinar cells (Figure 4C, D, E) showed the nanoparticle concentrated in a small percentage of cells. In contrast to these results for the postinjection distribution of BN−CLIO(Cy5.5) nanoparticle in the pancreas, examination of dissected pancreatic tissue showed a uniform binding of the BN peptide. First, dual wavelength FACS of cells from the disaggregated pancreas indicated all acinar cells both expressed the GRP receptor (Figure 4E) and bound the BN peptide (Figure 4D). Second, by histochemistry the binding of the BN peptide to the normal mouse pancreas was uniform (Figure 1A). It seems likely that the heterogeneous change in signal intensity post BN−CLIO(Cy5.5) injection reflects selective regions within the exocrine pancreas which are permeable to BN−CLIO(Cy5.5) and that after extravasating the nanoparticle binds the GRP receptor and is internalized by acinar cells. This hypothesis is supported by the fact that the pancreatic exocrine vasculature is heterogeneous, consisting of both fenestrated and nonfenestrated capillaries (*23*).

We employed a peptide with the 13 C-terminal amino acids of bombesin, see above, which can bind to any of three receptors, the NMB receptor (BB1), the GRP receptor (BB2), or the orphan bombesin binding receptor BB3. These three receptors comprise the bombesin peptide binding receptors in mammals, though they are different gene products with somewhat different ligand specificities. We made no effort to determine whether the NMB, GRP, or BB3 receptors bound the BN peptide or the BN−CLIO(Cy5.5) nanoparticle, noting only that the binding of the BN peptide to pancreatic ductal adenocarcinoma was decreased relative to that seen with normal pancreas and providing a rationale for the development of a BN peptide−nanoparticle conjugate. The distribution of bombesin binding receptors is discussed further below.

For the approach we have taken to be useful clinically, receptors binding the BN−CLIO(Cy5.5) nanoparticle must be

(i) absent in PDAC and (ii) present in the normal pancreas. **Absence on PDAC (prior studies):** Bombesin binding receptors have been found on dissected cancers from the lung, prostate, and breast, and on many tumor cell lines (*5*, *24*). However, PDAC appears to be different from other cancers; bombesin binding was absent when 29 PDAC specimens were examined using a radiolabeled bombesin peptide (*9*). **Presence on normal pancreas (prior studies):** Though the same authors did not detect bombesin binding in the normal human pancreas (*9*), the mRNA for the GRP receptor is expressed at high levels in the pancreas of primates (*21*, *22*) and the expression of bombesin binding receptors in the rodent pancreas is observed with injected radiolabeled bombesin peptides (*4*, *12*, *25*). **Absence on PDAC and presence on normal pancreas (our studies):** To clarify this situation with respect to the presence of bombesin binding receptors in the normal human pancreas, and verify the observations of Fleischman (*9*) that receptors are missing in human PDAC, we examined the binding of the BN peptide, first to the normal mouse pancreas (Figure 1A) and then to normal human pancreatic tissue and PDAC specimens. In agreement with Fleischman et al., we could *not* detect bombesin binding in human PDAC specimens, but were able to detect the binding of our BN peptide in the normal human pancreas (Figure 1B). We therefore conclude that bombesin binding receptors are absent in PDAC and present in the both the normal rodent and normal human pancreas. Difference in results may be due to different detection limits of the methods used, different specificity of peptides or nucleic acid binding probes, or different definitions of what comprises a truly normal, noncancerous specimen of human pancreas.

A variety of radioactive bombesin-like peptides have been used to image the overexpression of bombesin binding receptors in animal tumor models (*4*, *12*, *25*−*28*) and clinically (*29*−*32*). We have taken the inverse targeting approach termed a "normal tissue targeted nanoparticle/T2 reduction strategy", designing a nanoparticle-based MR contrast agent image targeted to bombesin binding receptors of the normal pancreas. The approach of enhancing tumor visualization by targeting normal tissue takes advantage of the spatial localizing ability of MR, that is its ability to determine the signal from individual voxels, without interference from adjacent voxels. Thus a nanoparticle agent can enhance tumor/normal contrast if it decreases the T2 of normal tissue surrounding a tumor more than the T2 of tumor. Similarly, T2 reductions in other organs such as the liver do affect contrast enhancement in the pancreas. It should be noted that the condition for a normal tissue-targeted nanoparticle, T2 reducing contrast agent is not a complete loss of gene expression/activity in the cancerous state, but only relatively higher activity in a normal tissue than that of tumor. Obviously, the decrease of expression/activity of the marker responsible for selective nanoparticle accumulation in normal tissue should decrease in a highly uniform fashion for a significant class of cancers. Radiolabeled peptides are generally targeted to tumors, and uptake by normal tissue raises background and reduces tumor visualization.

In conclusion, we have designed a magneto/fluorescent nanoparticle conjugate that was successfully targeted to the bombesin binding receptors of the rodent pancreas and used it to enhance the visualization of a tumor with a normal tissue targeted nanoparticle/T2 reduction strategy. Heterogeneous changes in the T2 of the normal pancreas were inferred to be due to a heterogeneous vasculature limiting nanoparticle delivery to acinar cells. Preliminary experiments indicate that this heterogeneity can be overcome by using an intraperitoneal mode of administration for BN−CLIO(Cy5.5), which can increase pancreatic targeting of high molecular weight liposomes (*33*) or chemotherapeutic agents (*34*). However, even with relatively inefficient receptor specific targeting of the pancreas obtained with intravenous administration, the peptide was targeted to the pancreas by tissue fluorescence, reduced the T2 of the normal pancreas, and enhanced the visualization of an implanted tumor.

Self-Assembled "Dock and Lock" System for Linking Payloads to Targeting Proteins

Marina V. Backer,* Vimal Patel, Brian T. Jehning, and Joseph M. Backer

SibTech, Inc., Newington, Connecticut 06111. Received February 14, 2006

Random conjugation of therapeutic or diagnostic payloads to targeting proteins generates functionally heterogeneous products. Conjugation of payloads to an adapter that binds to a peptide tag engineered into a targeting protein provides an alternative strategy. To progress into clinical development, an adapter/docking tag system should include humanized components and be stable in circulation. We describe here an adapter/docking tag system based on mutated fragments of human RNase I that spontaneously bind to each other and form a conjugate with a disulfide bond between complimentary cysteine residues. This self-assembled "dock and lock" system utilizes the previously described fusion C-tag, a 1−15 aa fragment of human RNase I with the R4C amino acid substitution, and a newly engineered adapter protein (Ad-C), a 21−127-aa fragment of human RNase I with the V118C substitution. Two vastly different C-tagged recombinant proteins, human vascular endothelial growth factor (VEGF) and a 254-aa long N-terminal fragment of anthrax lethal factor (LFn), retain functional activities after spontaneous conjugation of Ad-C to N-terminal or C-terminal C-tag, respectively. Ad-C modified with pegylated phospolipid and inserted into the lipid membrane of drug-loaded liposomes (Doxil) retained the ability to conjugate C-tagged proteins, yielding targeted liposomes decorated with functionally active proteins. To further optimize the system, we engineered an adapter with an additional cysteine residue at position 88 for site-specific modification, conjugated it to C-tagged VEGF, and labeled with a near-infrared fluorescent dye Cy5.5, yielding a unique functionally active probe for in vivo molecular imaging. We expect that this self-assembled "dock and lock" system will provide new opportunities for using functionally active proteins for biomedical purposes.

INTRODUCTION

Conjugation of therapeutic or diagnostic "payloads" (e.g. drugs, radionuclides, nanoparticles, liposomes) to targeting proteins encounters a well-recognized problem of functional heterogeneity of the final products (*1*, *2*). The protein−payload conjugates are usually synthesized via random modification of available chemical groups, most often ϵ-amino groups of lysine residues, and are inevitably heterogeneous, both structurally and functionally. One approach to solving this problem is to engineer targeting proteins with an additional cysteine residue that does not interfere with protein folding and can be used for a site-specific conjugation (*3*−*7*). Alternatively, native cysteines dispensable for target recognition can be coupled to a payload, as it has been recently reported for cysteines involved in the interchain disulfide bonds in IgG molecules (*8*, *9*). Although these strategies eliminate or decrease heterogeneity of the conjugates, they do not solve sterical problems associated with coupling of either bulky or highly charged payloads, which might interfere with functional activity of the resulting conjugates. To minimize this interference, payloads can be linked to an adapter protein that can be docked to a "tag" engineered in targeting protein. Currently, streptavidin/biotin is the most popular adapter/docking tag system, although it is hardly suitable for clinical development (*10*−*13*). Another promising but highly specialized approach is the engineering of bispecific recombinant antibodies recognizing one epitope on the cell surface and the other one on a drug carrier (*14*, *15*).

We have recently developed and tested in vitro and in vivo a fully humanized adapter/docking tag system based on high affinity interactions between two fragments of human RNase I,

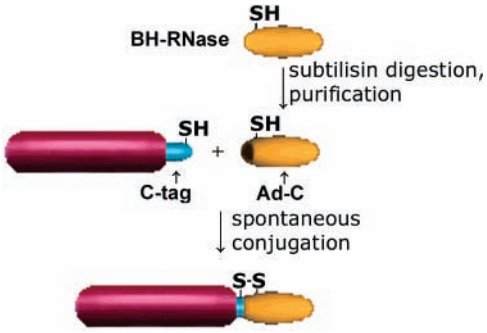

Figure 1. "Dock and lock" system.

a 1−15 aa fragment (Hu-tag) fused to a targeting protein as a docking tag, and a 21−127 aa fragment (HuS) as an adapter (*16*, *17*). However, the utility of this, as well as all other noncovalent adapter/docking tag systems, depends on their stability in a complex environment of the human bloodstream. We reasoned that "locking" of an adapter/docking tag complex with an intra-complex disulfide bond would eliminate a stability problem. We describe here such a "dock and lock" system, which is based on appropriately mutated fragments of human RNase I (Figure 1). Docking tag, named C-tag, contains a cysteine in position 4; it has been recently used for direct site-specific modification of C-tagged VEGF with derivatized dendrimers (*7*). An adapter, named Ad-C, contains cysteine in position 118 (positions are indicated for full-length human RNase I). This choice of cysteine positions was based on an observation that stability of human RNase I (R4C,V118C) double mutant is increased relative to wild-type molecule, suggesting possible formation of an intramolecular C4−C118 disulfide bond (*18*).

We hypothesized that C4 and C118 introduced in C-tag and Ad-C, respectively, would spontaneously form a disulfide bond

in the adapter/tag complex. To test this hypothesis, we used two proteins: a newly constructed LFn-C, a 254-aa long catalytically inactive N-terminal fragment of anthrax lethal factor with no native cysteines, fused to C-terminal C-tag, and previously described human C-tagged $VEGF_{121}$ (18 native cysteines per dimer), expressed with an N-terminal C-tag (*7*). Here we report that both C-tagged proteins covalently bind Ad-C without compromising their respective activities. We demonstrate that doxorubicin-loaded liposomes can be decorated with Ad-C and then coupled to either C-tagged protein, providing a simple and efficient method for molecular targeting of bulky payloads. Furthermore, an additional cysteine introduced in Ad-C in position 88 allowed for site-specific modification of VEGF-Ad conjugate with a charged near-infrared fluorescent dye, Cy5.5. This approach yielded a functionally active molecular probe for in vivo imaging, while direct conjugation of Cy5.5 resulted in a significant drop of VEGF functional activity.

MATERIALS AND METHODS

Construction and Purification of Chimeric BH-RNase-(V118C) Mutant. Chimeric $^{1-29}B/^{30-127}H$-RNase (BH-RNase) consisting of a 1−29-aa fragment of bovine RNase A and a 30−127-aa fragment of human RNase I has been constructed as described (*19*). The V118C mutation was introduced in the pET29/$^{1-29}B/^{30-127}H$-RNase plasmid DNA by site-directed mutagenesis (Gene-Tailor Site Directed mutagenesis kit, Invitrogen) using primers: 5′-AA GGC TCT CCG TAC GTT CCG TGT CAT TTC gac gcg (sense, the mutation underlined) and 5′-CGG AAC GTA CGG AGA GCC TTC GCA TGC AAC (antisense). BH-RNase(V118C) was used for construction of double mutant BH-RNase(N88C,V118C) by introducing the N88C amino acid substitution as described (*20*). The V118C substitution and double V118C, N88C mutations were confirmed by sequencing. BH-RNase(V118C) and BH-RNase(N88C,-V118C) were expressed in BL21(DE3) *E. coli* (Novagen, Madison WI), refolded from inclusion bodies, and purified by ion-exchange chromatography on HiTrap SP Sepharose Fast Flow (1-mL prepacked columns, Amersham Biosciences, Piscataway, NJ) as described for wild-type BH-RNase (*19*). The yield of BH-RNase(V118C) was 45−50 mg/L, while double mutant BH-RNase(N88C,V118C) yielded 20−25 mg/L. Free cysteines were tested by reaction with *N*-(1-pyrene)maleimide (Molecular Probes, Eugene, OR) followed by RP HPLC analysis as described (*21*) Briefly, *N*-(1-pyrene)maleimide dissolved in DMSO was added to protein at the molar ratio of 10:1, incubated for 1 h at RT, and analyzed by RP HPLC.

Purification of Mutant Adapter Ad-C. To release Ad-C, which is a 21−127-aa fragment of BH-RNase(V118C), BH-RNase(V118C) was digested with subtilisin (Sigma) at the protein to protease w/w ratio of 10:1 for 15−20 min at 4 °C. Subtilisin digestion was stopped by 1% ice-cold TFA. After a 5-min incubation on ice, the reaction mixture was purified by ion-exchange chromatography on SP Sepharose Fast Flow as described (*19*, *20*). Digested BH-RNase(V118C) was purified by affinity chromatography on a Hu-column carrying CA-extended Hu-peptide (CA-KESRAKKFQRQHMDS synthesized by Genemed Synthesis, Inc., South San Francisco, CA) as described (*16*). Protein eluted from Hu-column with 0.1 M citric acid was neutralized with 1 M Na_2HPO_4 and analyzed by RP HPLC on C18 Waters Nova-Pack 5 μm column (150 × 3.9 mm) with elution at 0.75 mL/min with 0.1% TFA (v/v) and a linear gradient of acetonitrile (5−50% over 20 min). The concentration of Ad-C was calculated using 216-nm integral absorption in HPLC profiles with bovine S-protein (Sigma) serving as a standard.

Construction of the pET/$(G_4S)_3$Hu-R4C Vector. The pET/Hu-R4C$(G_4S)_3$ vector for bacterial expression of recombinant proteins with N-terminal C-tag was constructed as described (*7*). To construct a vector for expression of proteins with C-terminal C-tag, a DNA fragment encoding Hu-tag (described in *16*) was cloned in *Nde-Kpn* sites of the pT7Blue vector (Novagen). Then a single-stranded DNA fragment encoding a $(G_4S)_3$ linker 5′- pTAT GGG TGG CGG TGG TAG TGG TGG TGG CGG TTC AGG CGG TGG TCA and a complimentary fragment 5′- pTAT GAC CAC CGC CTG AAC CGC CAC CAC CAC TAC CAC CGC CAC CCA (synthesized by GeneLink, Thornwood, NY) were annealed with reconstitution of *Nde*I sites on both termini and ligated immediately upstream of Hu-tag into *Nde* I site of the pT7Blue-Hu vector. Plasmid DNA with correct orientation of the cloned fragment was selected by sequencing, and the inner *Nde* I site was destroyed by site-directed mutagenesis (Gene-Tailor Site Directed mutagenesis kit, Invitrogen). A DNA fragment encoding $(G_4S)_3$-Hu-tag was amplified from pT7Blue$(G_4S)_3$Hu vector with primers introducing an *Nde*I site to the 5′-terminus, a stop codon and a *Kpn*I site to the 3′-terminus and cloned into *Nde-Kpn* of the pET29a(+) bacterial expression vector (Novagen). The R4C amino acid substitution was introduced in Hu-tag of the pET/$(G_4S)_3$Hu vector by site-directed mutagenesis and confirmed by sequencing. The resulting vector for bacterial expression of proteins fused to C-terminal C-tag via a $(G_4S)_3$ linker was designated pET/$(G_4S)_3$Hu-R4C.

Cloning and Expression of C-Tagged Proteins. Coding sequence for a 1−254-aa fragment of anthrax lethal factor (LFn) was amplified from the pGEX-KG LF254 plasmid (kindly provided by Dr. S. Leppla, National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD). For construction of LFn-C (C-terminally fused C-tag), primers introduced *Nde* I sits (italicized): 5′- CTACCT *CATATG* GCG GGC GGT CAT GGT GATG (sense) and 5′- CTACCT *CATATG* TAG ATT TAT TTC TTG TTC GTT AAA TTT ATC (antisense). For construction of C-LFn (N-terminally fused C-tag), primers introduced *Nco* I sits, and the fragment was cloned in *Nco* I site of the pET/Hu-R4C$(G_4S)_3$ vector downsream of the $(G_4S)_3$ linker. Clones with correct orientation of LFn fragment were selected by PCR using a T7-promoter-based sense primer and then confirmed by sequencing. Both C-tagged LFn fusion proteins were expressed in BL21(DE3). The expression was induced by 1 mM IPTG at the optical density of 0.5−0.7 unit at 600 nm. After induction, cultures were grown for 2.5−3 h at 37 °C with shaking at 300 rpm, harvested by centrifugation, and ruptured using EmulsiFlex-C5 (Avestin, Ottava, Canada). The soluble part of bacterial lysate was dialyzed against 200 volumes of 20 mM Tris-HCl pH 8.0 for 20 h at 4 °C, clarified by centrifugation (15 000*g* for 20 min), and passed through Sepharose Q FF column. C-LFn-containing fractions were pooled together, dialyzed against 100 volumes of 20 mM NaOAc pH 6.5 for 20 h at 4 °C, and further purified on Heparin HP Sepharose followed by hydrophobic interaction chromatography on Butyl FF Sepharose (1-ml prepacked columns, Amersham). The yield of Hu(R4C)-LFn was 8−10 mg/L, purity >98% by SDS−PAGE followed by SimplyBlue Safe Stain (Invitrogen). Human $VEGF_{121}$ was expressed with N-terminal C-tag and recovered from inclusion bodies as described (*7*). Hu-VEGF, human $VEGF_{121}$ fused to Hu-tag, was cloned and expressed as described (*16*).

Synthesis of VEGF/Ad-Cy5.5 Conjugate. BH-RNase(N88C,-V118C) was deprotected with DTT and digested with subtilisin as described for BH-RNase(V118C). Purified double mutant adapter was mixed with C-tagged VEGF at the molar ratio of 3:1 and incubated for 4 °C for 16 h. Cy5.5-maleimide (GE Healthcare) dissolved in dimethylformamide was added then to the reaction mixture to a final protein-to-Cy molar ratio of 1:10, incubated at RT for 1 h, and purified by RP-HPLC on a

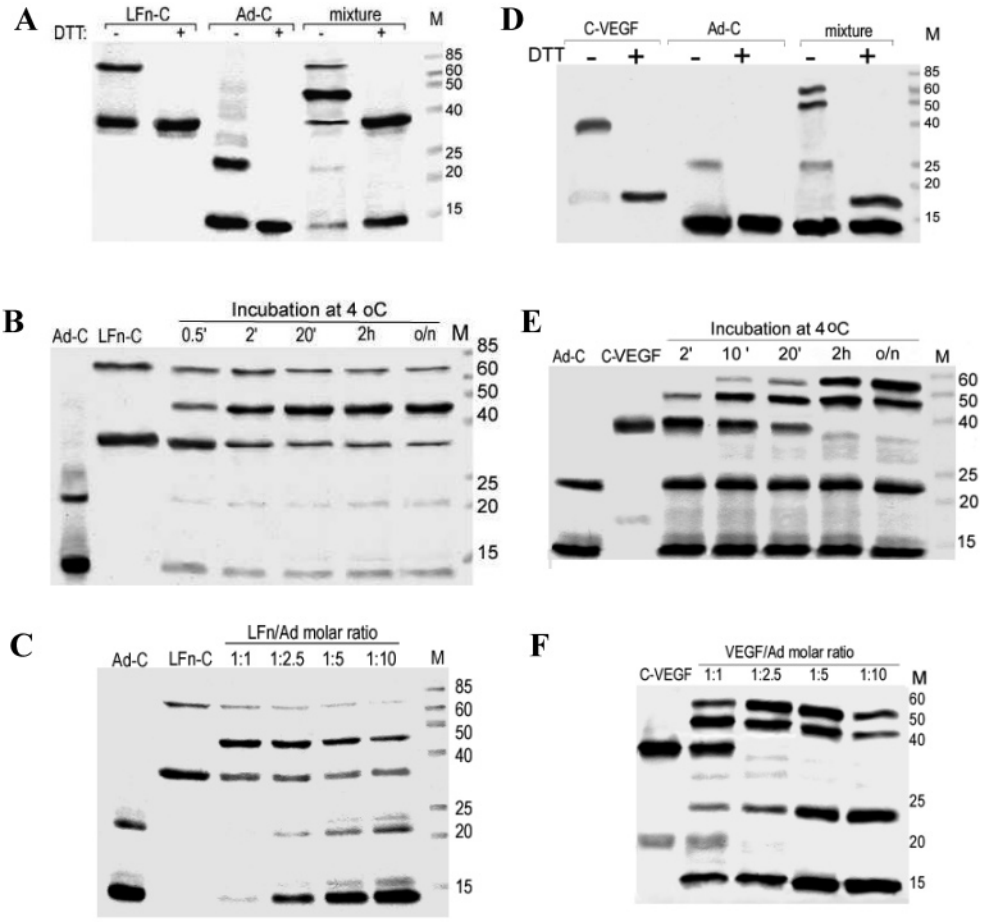

Figure 2. Self-assembly of Ad-C/C-tag conjugates. Ad-C was mixed with LFn-C (panel A) at a molar ratio of 1:1 or C-tagged VEGF (panel D) at a molar ratio of 3:1 and incubated for 16 h at 4 °C. Samples were analyzed by nonreducing (−DTT) and reducing (+DTT) SDS−PAGE on 17.5% gels followed by Bio-Safe Coomassie G-250 staining (Bio-Rad). In panels B and E, nonreducing SDS−PAGE analysis of kinetics of conjugation. Ad-C was mixed with LFn-C at a 1:1 molar ratio (B) or with C-VEGF at a 3:1 ratio (E) and incubated at 4 °C for indicated periods of time. In panels C and F, nonreducing SDS−PAGE analysis of conjugation dose-dependencies: varying amounts of Ad-C were mixed with LFn-C (C) or C-VEGF (F) and incubated at 4 °C for 2 h.

preparative C-4 column (GE Healthcare). The extent of modification was calculated as a ratio of integral peak intensities at 216 nm (for protein) and at 598 nm (for Cy5.5).

Cells. HEK293 human transformed embryonic kidney cells (CRL-1573) and RAW 264.7 mouse monocytes (TIB-71) were from American Type Culture Collection (Rockville, MD). 293/KDR cells expressing 2.5×10^6 VEGFR-2/cell have been developed in SibTech, Inc. (*22*). PAE/KDR porcine aortic endothelial cells expressing 2.5×10^5 VEGFR-2/cell were kindly provided by Dr. B. Terman (Albert Einstein School of Medicine, Bronx, NY). 4T1luc mouse breast carcinoma cells expressing firefly luciferase was developed as described (*23*). All cells were grown in DMEM with 10% FBS, 2 mM L-glutamine and antibiotics at 37 °C, 5% CO_2.

In Vivo Imaging. Female 5−6 weeks old BALB/c mice were from Charles River Laboratories (Wilmington, MA). 4T1luc cells were implanted subcutaneously in the backs (5−10,000 cells/mouse). For imaging, mice with 10−14 days old tumors received 5−7 μg of VEGF/Ad-Cy5.5 per mouse via the tail vein, 5 min later were injected intraperitoneally with aqueous luciferin (0.5 mg/mouse), and anesthetized 5 min later with ketamine/xylazine mixture as described (*7*). Images were obtained on Kodak Image Station 4000. The protocol for the animal studies was approved by the Institutional Animal Care and Use Committee at the University of Connecticut Health Center.

Insertion of Ad-C into Doxorubicin-Loaded Liposomes. Ad-C was modified with 2-fold molar excess Traut's reagent (Sigma) in a buffer containing 50 mM NaPi, 150 mM NaCl, 1 mM EDTA, pH 8.0 for 2 h. Ten-fold molar excess of mPEG-DSPE maleimide (FW 3400, Nectar Technologies) was added to the reaction mixture and incubation continued for 4 h. Equal volume of Doxil (pegylated liposomal doxorubicin, OrthoBiothech) was added to the reaction and incubated at 37 °C for 16 h followed by gel-filtration on Sephadex 4B as described (*20*). The efficiency of Ad-C/DSPE insertion into liposomes was analyzed by RP HPLC, as described elsewhere (*20*). C-Tagged proteins were mixed with Ad-C/Doxil at the C-tag to Ad-C molar ratio of 1:3 and incubated for 16 h at 4 °C followed by purification on Sepharose 4B. C-Tagged protein concentration in purified liposomes was determined by Western blotting.

RESULTS

Preparation Adapter Protein for "Dock and Lock". To obtain Ad-C, an adapter protein that binds to and forms a disulfide bond with C-tag, we engineered the V118C amino acid substitution in BH-RNase, a source of adapter protein (*19*). BH-RNase comprising a 1−29aa long fragment of bovine RNase A and a 30−127 aa long fragment of human RNase I carries a unique subtilisin cleavage site between S20 and A21, making it possible to release a 21−127aa fragment (adapter protein) after limited subtilisin digestion. Enzymatically active BH-RNase(V118C) was expressed, refolded in glutathione-containing Red-Ox buffer, and purified as described elsewhere (*20*). On the basis of our experience with another BH-RNase mutant containing the N88C amino acid substitution (*20*), we expected

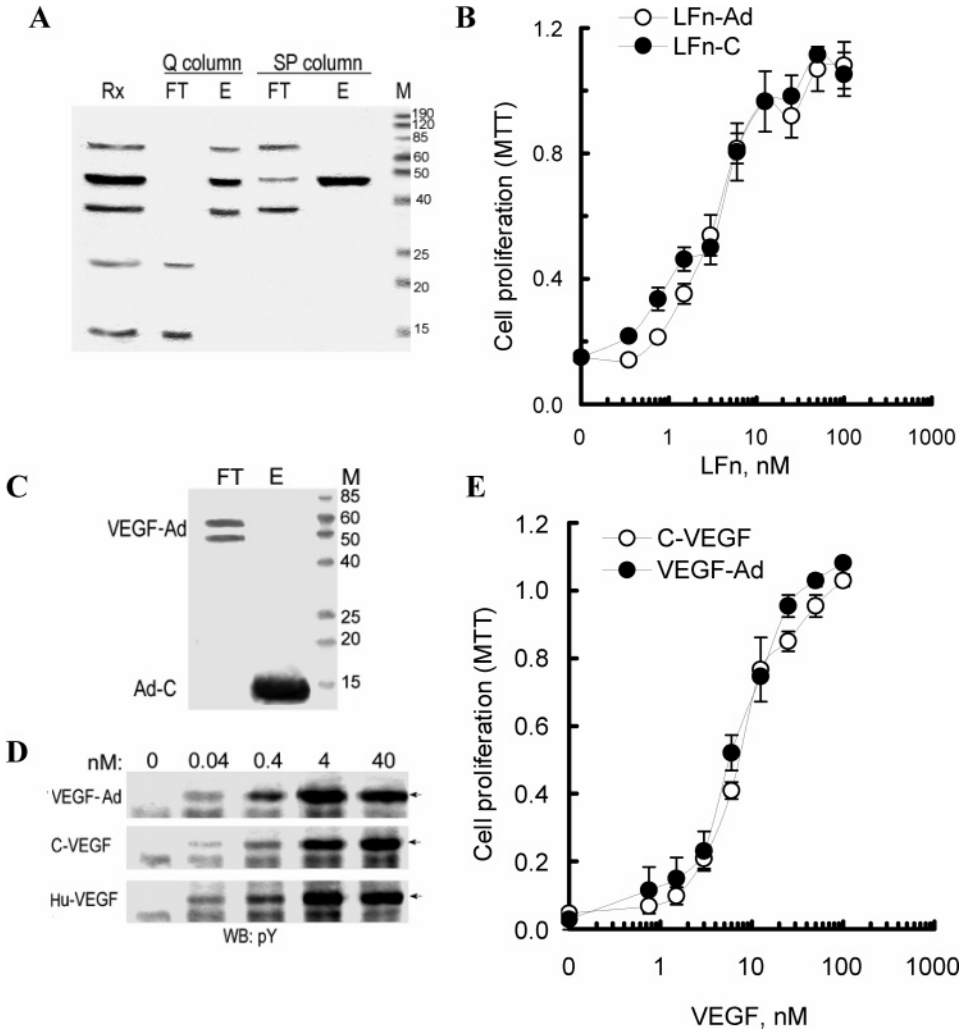

Figure 3. Conjugation to Ad-C does not affect functional activity of C-tagged proteins. In panel A, purification of LFn-Ad by ion-exchange chromatography on a Q-column followed by a SP-column. Rx, reaction mixture; FT, flow-through; E, elution. In panel B, competition of LFn-Ad with LF for binding to RAW cells in the presence of PA. Cells were plated on 96-well plates 15×10^3 cells/well 20 h before the experiment. Varying amounts of LFn-C or LFn-Ad were mixed with LF and PA (List Biological, Campbell, CA) in DMEM complete culture medium and added to cells in triplicate wells to final concentrations of 2 nM PA and 0.2 nM LF. After 2.5 h of incubation at 37 °C in 5% CO_2, viable cell numbers were determined by CellTiter 96 AQ_{ueous} One Solution Cell Proliferation Assay kit (Promega). In panel C, purification of VEGF-Ad conjugate by affinity chromatography on Hu-peptide column. FT, flow-through fraction; E, elution. In panel D, induction of VEGFR-2 tyrosine autophosphorylation in 293/KDR cells. After overnight starvation (DMEM/0.5% FBS), cells were shifted to serum-free DMEM with 0.5 mM sodium vanadate for 20 min at 37 °C and then stimulated for 10 min at 37 °C, lysed, and analyzed by Western blotting using anti-phosphotyrosine RC20:HRPO conjugate (BD Transduction Labs, San Diego, CA). C-VEGF, C-tagged $VEGF_{121}$; Hu-VEGF, Hu-tagged $VEGF_{121}$. Arrows indicate positions of VEGFR-2. In panel E, competition with SLT-VEGF chimeric toxin. 293/KDR cells were plated on 96-well plates 20 h before the experiment, 1000 cells/well. Varying amounts of VEGF-Ad or C-tagged $VEGF_{121}$ were mixed with SLT-VEGF in complete culture medium, and added to cells in triplicate wells to a final SLT-VEGF concentration of 1 nM. Viable cells were quantitated 96 h later by a CellTiter 96 AQ_{ueous} One Solution Cell Proliferation Assay kit (Promega, Madison, WI).

that unpaired C118 in BH-RNase(V118C) would be involved in a mixed disulfide with glutathione. Indeed, modification of BH-RNase(V118C) with a sulfhydryl-directed reagent *N*-(1-pyrene)maleimide varied between 0 and 0.3 mol/mol for different preparations. However, after a mild DTT treatment (1.5-fold molar excess DTT at 4 °C for 16 h), modification of BH-RNase(V118C) reached ~1 mol/mol, suggesting that a single thiol group per protein was "deprotected". BH-RNase-(V118C), with or without deprotection, was digested with subtilisin, and Ad-C was purified by affinity chromatography on Hu-peptide affinity column as described (*20*). The resulting protein was more than 98% pure by SDS−PAGE (Figure 2). Under nonreducing conditions, a part of Ad-C migrated as a dimer that was absent in the presence of DTT reflecting dimerization of Ad-C via unpaired C118 residues.

Self-Assembly of Conjugates between Ad-C and C-Tagged Proteins. We expected that the close proximity of C4 and C118 thiol groups in Ad-C/C-tag complex might lead to formation of a C4−C118 disulfide bond, even when one or both thiol groups were involved in mixed disulfides with glutathione. We first tested this hypothesis using Ad-C and LFn-C, a catalytically inactive fragment of anthrax lethal factor with C-terminal C-tag. LFn-C was bacterially expressed and purified from a soluble fraction through a process that did not require red-ox refolding, and therefore C4 thiol group was available for conjugation. LFn-C, Ad-C, and their 1:1 mixture were incubated at 4 °C for 16 h and then analyzed by SDS−PAGE. As expected, for both LFn-C and Ad-C incubated separately, part of each protein migrated in DTT-sensitive bands corresponding to homodimers of these proteins (Figure 2A). However, in the LFn-C/Ad-C mixture, the majority of protein was found in a DTT-sensitive band corresponding to ~46 kDa LFn-Ad conjugate (Figure 2A). Thus, this conjugation occurs even when the majority of C118 thiol groups in Ad-C were involved in mixed disulfide bonds with glutathione. Importantly, LFn-Ad conjugation was more efficient than homodimer formation, supporting the notion that

the process proceeded in the noncovalent complex between C-tag and Ad-C, rather than via random collisions. We found that conjugation was detectable after 30 s of incubation at 4 °C and reached a plateau by 20 min (Figure 2B). Interestingly, an increase of the Ad-C to LFn-C molar ratio did not enhance the yield of the conjugate (Figure 2C), suggesting that a fraction of LFn-C was proteolytically degraded and thus has a nonfunctional C-tag.

To test the ability of protected C4 thiol group to form a disulfide bond with Ad-C, we used recently described C-tagged human $VEGF_{121}$, a dimeric protein with C-tag fused to the N-terminus of each monomer (*7*). This protein was recovered from inclusion bodies and had both C4 thiol groups in the form of mixed disulfides due to refolding in a glutathione-containing red-ox buffer (*7*). C-Tagged $VEGF_{121}$, Ad-C, and their mixture at a molar ratio of 1:3 were incubated at 4 °C for 16 h and then analyzed by SDS−PAGE. As shown on Figure 2D, under nonreducing conditions, C-tagged $VEGF_{121}$ migrated in a DTT-sensitive band corresponding to a native dimer, while only a part of Ad-C (smaller in this Ad-C preparation, than in the one shown on Figure 2A) migrated as a dimer. However, in the protein mixture, virtually all C-tagged VEGF was found in DTT-sensitive bands corresponding to ~45 kDa and ~57 kDa VEGF-Ad conjugates with either one or two adapter molecules per VEGF dimer, respectively (Figure 2D). Thus, the presence of glutathione on both C4 and C118 did not prevent formation of VEGF-Ad conjugate.

Conjugation of C-tagged VEGF and Ad-C mixed at the molar ratio of 1:3 was detectable after a few minutes of incubation at 4 °C and reached a plateau by 2 h (Figure 2E). Free VEGF disappeared from the reaction mixture at 2.5-fold molar excess of Ad-C (Figure 2F), although complete VEGF modification, e.g. two Ad-C molecules per each VEGF dimer, was not achievable. As with LFn-Ad conjugate, we explain it by possible N-terminal proteolysis during protein purification. Deprotection of C4 and/or C118 by mild DTT treatment did not accelerate conjugate formation (data not shown), suggesting that freeing the thiol groups from the form of mixed disulfide was not a limiting step in this process.

Functional Activities of Adapter-Conjugated C-Tagged Proteins. LFn-Ad conjugate was purified from the reaction mixture by anion-exchange chromatography that removed unconjugated Ad-C, followed by cation-exchange chromatography to remove free LFn-C and its dimers (Figure 3A). Purified LFn-Ad was tested for its ability to rescue RAW 264.7 cells from cytotoxicity of anthrax lethal toxin, a combination of full-length lethal factor (LF) and protective antigen (PA). It was demonstrated previously that LFn completely retained the ability to bind to PA, while it displayed no toxicity for target RAW 264.7 cells (*24*). We found that in this assay, purified LFn-Ad conjugate competed with LF as effectively as free LFn-C, rescuing RAW 264.7 cells with IC_{50} of ~3 nM (Figure 3B), indicating that the conjugation did not affect the ability of LFn to interact with PA.

VEGF-Ad conjugate was purified from unreacted Ad-C by affinity chromatography on a Hu-peptide column that retained free Ad-C (Figure 3C). Purified VEGF-Ad conjugate was found to be as active as free $VEGF_{121}$ in a short-term 10-min assay, induction of VEGF receptor (VEGFR-2) tyrosine autophosphorylation (Figure 3D). In a long-term 3-day assay, VEGF-Ad was tested for the ability to rescue VEGFR-2-expressing cells from the cytotoxicity of SLT-VEGF chimeric toxin (*25*, *26*). In this assay VEGF-Ad was as effective as C-tagged $VEGF_{121}$, rescuing 293/KDR cells with the IC_{50} of ~8 nM (Figure 3E), which was also similar to previously reported IC_{50} value for Hu-$VEGF_{121}$ (*26*). Thus, both assays demonstrated that conjugation did not affect the ability of $VEGF_{121}$ to bind to VEGFR-2.

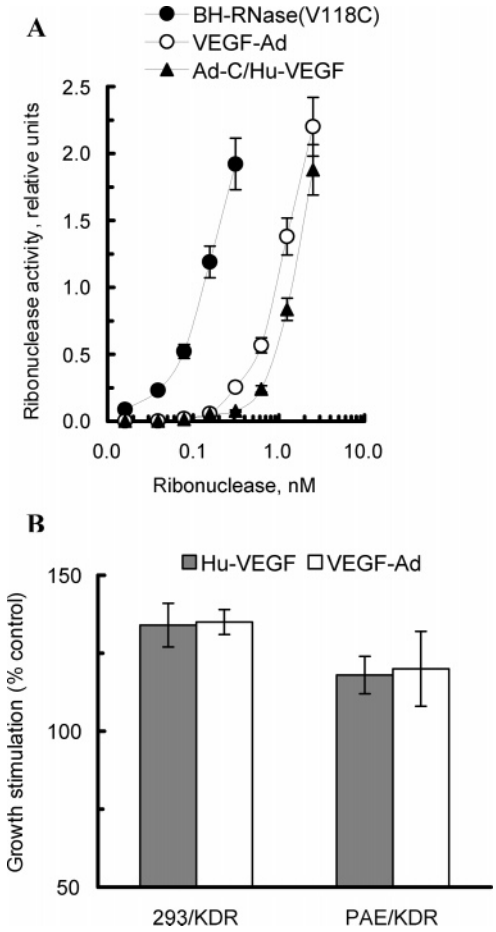

Figure 4. Reconstituted ribonuclease activity of VEGF-Ad conjugate is not cytotoxic. In panel A, BH-RNase(V118C), VEGF-Ad conjugate, or a equimolar mixture of Ad-C and Hu-VEGF was added, separately, to a buffer containing 20 mM Tris-HCl, 100 mM NaCl, pH 7.5, 0.1 mg/mL polyC and incubated for 5 min at RT. Ribonuclease activity was measured by 280-nm absorbance of the reaction mixtures cleared from TCA-precipitated material. One optical unit of TCA-soluble material released from polyC under these conditions was defined as one relative unit of ribonuclease activity (the method is described in details in 16). In panel B, VEGF induced growth stimulation of VEGFR-2 expressing cells. 293/KDR and PAE/KDR cells were plated on 96-well plates at densities of 500−1000 cell/well. Varying amounts of VEGF-Ad, or control Hu-VEGF, were added to cells in triplicate wells 20 h later. Cells were allowed to grow for 72−96 h and then quantitated by a CellTiter 96 AQ_{ueous} One Solution Cell Proliferation Assay kit (Promega).

Since ribonuclease activity is reconstituted in noncovalent complexes of Hu-tagged proteins with Ad (*16*), we tested whether introduction of C4 and C118 affected proper alignment of RNase fragments. We found that both VEGF-Ad and LF-Ad conjugates displayed similar ribonuclease activity (Figure 4A, for VEGF-Ad). Although VEGF-Ad activity was ~10-fold lower than that of BH-RNase(V118C), the conjugate was more active than noncovalent complexes between Ad-C and Hu-VEGF (Figure 4A). To address the issue of potential cytotoxicity of "dock and lock" complexes, we tested the effects of VEGF-Ad conjugate on cell growth. VEGFR-2-expressing cells of different tissue origin were plated at low densities and allowed to grow for 72−96 h in the presence of 10 nM VEGF-Ad conjugate. Both cell lines displayed low but significant growth stimulation in response to either VEGF-Ad or Hu-VEGF served as a control, indicating no toxic effects of VEGF-Ad (Figure 4B).

Self-Assembly of Conjugates between C-Tagged Proteins with Ad-C Decorated Liposomes. To assess self-assembly of "dock and lock" conjugates in the presence of bulky payloads,

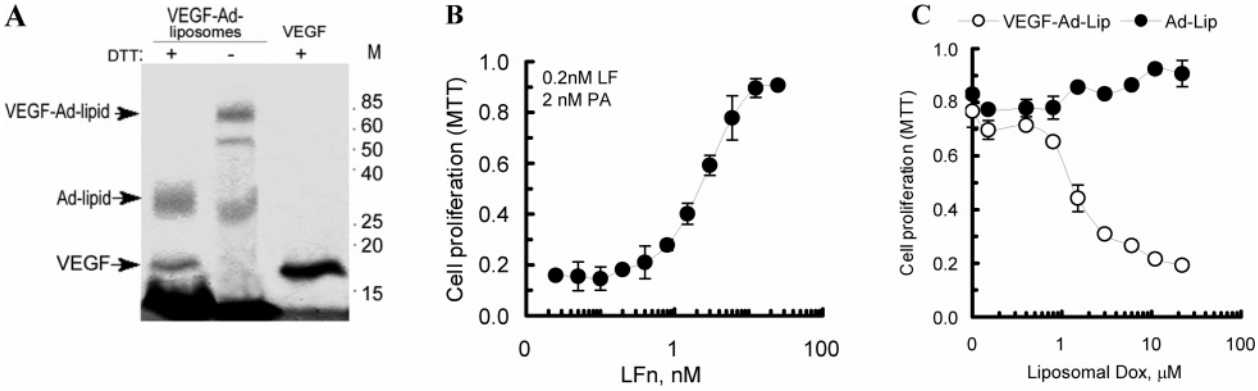

Figure 5. C-Tagged proteins conjugated to liposomes derivatized with Ad-C retain the functional activity. In panel A, VEGF-Ad-liposomes purified on Sepharose 4B were analyzed by SDS−PAGE as described in legend to Figure 2. In panel B, LF-Ad-liposome competition with the full length LF in the presence of PA on Raw cells was done as described in legend to Figure 4. In panel C, 293/KDR cells were plated on 96-well plates, 1000 cell/well. Twenty hours later, varying amounts of VEGF-Ad-liposomes or equivalent amounts of Ad-liposomes were added to cells in triplicate wells. After a 2-h incubation at 37 °C, liposome-containing media were removed, and cells were shifted to complete culture medium and allowed to grow for 96 h under normal culture conditions. Cells were quantitated by a CellTiter 96 AQ_{ueous} One Solution Cell Proliferation Assay kit (Promega).

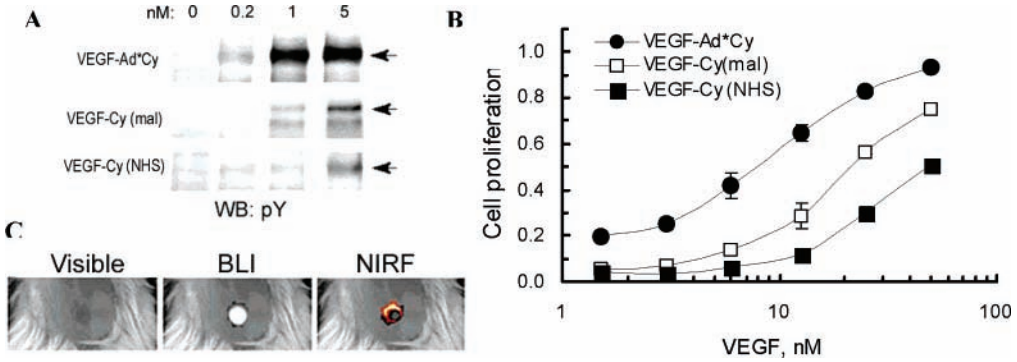

Figure 6. Functionally active Cy5.5-labeled VEGF-Ad* conjugate. VEGF modified with Cy5.5 directly using Cy5.5-maleimide (mal), or Cy5.5-NHS (NHS) or modified via adapter (VEGF-Ad*Cy) was purified and analyzed in VEGFR-2 tyrosine phosphorylation assay (panel A), or SLT-VEGF protection assay (panel B) as described in legend to Figure 3. In panel C, mice bearing 2-week old sc 4T1Luc tumors ($n = 5$) received ip injection of 0.5 mg luciferin and iv injection of 5 μg VEGF-Ad*Cy and were anesthetized and imaged. BLI, bioluminescent image; NIRF, pseudocolored in a "fire" range near-infrared image.

we used commercially available pegylated doxorubicin-loaded liposomes (Doxil). Ad-C with protected C118 was first modified with Trout's reagent to provide one free thiol group per Ad-C molecule and then modified with mPEG-DSPE maleimide, connecting a phospholipid moiety to Ad-C via 3.4 kDa poly-(ethylene glycol) linker. The lipidation mixture was then incubated with Doxil for 16 h at 37 °C and purified by gel-filtration on Sepharose 4B, as described elsewhere (*20*). Purified adapter-decorated liposomes were conjugated to either C-tagged $VEGF_{121}$ or LFn-C for 16 h at 4 °C and purified by gel filtration, and the resulting liposomes were analyzed by SDS−PAGE. We found that all liposome-associated C-tagged $VEGF_{121}$ and LFn were present in the DTT-sensitive bands corresponding to conjugates formed with lipidated adapter (Figure 5A, for C-tagged $VEGF_{121}$). Although a fraction of liposome-associated Ad-C remained free, the conjugation yielded ~25−50 molecules of C-tagged proteins per liposome and was sufficient for in vitro testing.

LFn-decorated liposomes were tested for their ability to protect RAW 264.7 cells from LF/PA toxicity and found to be as active as free LFn or LFn-Ad conjugate at the equal protein concentrations (Figure 5B, compare to Figure 3B). $VEGF_{121}$-decorated liposomes were tested for their ability to deliver cytotoxic doxorubicin into 293/KDR cells via receptor-mediated endocytosis. In these experiments, untargeted liposomes served as a control for nonspecific toxicity. We found that only $VEGF_{121}$-decorated liposomes were highly cytotoxic under selected conditions, indicating that the liposome payload did not prevent binding to VEGFR-2 and receptor-mediated endocytosis (Figure 5C).

Adapter for Covalent Self-Assembly and Site-Specific Labeling of Conjugates. To eliminate heterogeneity in Ad-C labeling, we have engineered Ad*-2C adapter by introducing the N88C substitution that provided a thiol group suitable for site-specific conjugation (*20*). We found that Ad*-2C can be recovered from the corresponding BH-RNase(N88C,V118C) mutant and self-assembled into functionally active conjugates with C-tagged $VEGF_{121}$ and LFn, as readily as Ad-C (data not shown). Ad*-2C was first deprotected by mild DTT treatment and then conjugated to C-tagged $VEGF_{121}$, and the conjugate was labeled with a near-infrared fluorescent dye Cy5.5 via maleimide chemistry to the molar ratio of one Cy5.5 per $VEGF_{121}$ monomer. The functional activities of Cy5.5-labeled VEGF-Ad* conjugate were close to that of C-tagged $VEGF_{121}$ in VEGFR-2 tyrosine phosphorylation assay (Figure 6A) and identical to that in protection from SLT-VEGF cytotoxicity (Figure 6B). In contrast, direct labeling of C-tagged $VEGF_{121}$ with either Cy5.5-maleimide or Cy5.5-NHS to the same ratio of one Cy5.5 per $VEGF_{121}$ monomer resulted in a significant decrease of functional activity, in both assays (Figure 6A,B). For in vivo testing, Cy5.5-labeled VEGF-Ad* conjugate was injected intravenously into mice bearing subcutaneous 4T1luc tumors. Since tumor cells were engineered to express luciferase, 4T1luc tumor could be visualized by bioluminescent imaging after intraperitoneal injection of luciferin (*23*). We found that Cy5.5-labeled VEGF-Ad* conjugate rapidly and selectively

accumulated in the tumor region visualized by bioluminescent imaging (Figure 6C). As expected, the strongest Cy5.5 fluorescence was observed at the growing edges of the tumor, which are enriched with VEGFR-2 overexpressing cells (Figure 6C).

DISCUSSION

We describe here self-assembled "dock and lock" conjugates between C-tagged targeting proteins and Ad-C adapter protein, which are based on a unique intermolecular disulfide bond. Since both C-tag and Ad-C are mutated fragments of human RNase I, reconstitution of ribonuclease activity in Ad-C/C-tag conjugate indicates their proper folding and alignment (*16*). Self-assembly proceeds remarkably rapidly, even when both complimentary cysteines are involved in mixed disulfides with glutathione, suggesting that C4−C118 bonding is facilitated by formation of Ad-C/C-tag complex.

The "dock and lock" system presents a flexible platform for linking payloads to targeting proteins. The human origin of both components makes it suitable for potential clinical development. Combined size of C-tag (15-aa) and adapter (105-aa) is significantly smaller than that of biotin/streptavidin complex and is comparable to that of the adapter arm of recombinant diabodies. Importantly, C-tag can be fused to either N- or C-terminus, making it compatible with various targeting proteins. The "dock and lock" self-assembly appears to be a robust process: two completely different C-tagged proteins readily formed functionally active conjugates with Ad-C even when it was associated with such a bulky payload such as a liposome.

On the basis of our previous work on site-specific modification of RNase I derived adapter (*20*), we further optimized "dock and lock" system by engineering an Ad*-2C adapter protein with the N88C substitution. Not only Ad*-2C allows for site-specific modification eliminating heterogeneity of randomly modified Ad-C, but it also positions a payload as far as possible from the tag, protecting C-tagged proteins from potential interactions with the payload (*20, 27*). By design, C88 and C118 are released from mixed disulfides first, and then deprotected Ad*-2C is conjugated to C-tagged protein, leaving the C88 thiol group available for site-specific modification. This procedure was used to prepare VEGF-Ad* conjugate carrying a near-infrared fluorescent dye Cy5.5 that appeared to be fully active in vitro and in vivo. In contrast, direct conjugation of Cy5.5 to thiol groups in deprotected C-tagged $VEGF_{121}$ results in significant loss of VEGF activity, most likely because of interactions between negatively charged Cy5.5 and VEGF lysine residues involved in receptor binding (*28*). These observations suggest that insertion of Ad*-2C between C-tagged $VEGF_{121}$ and Cy5.5 might prevent such interactions, allowing for full activity of the final conjugate. Indeed, we have recently described functional conjugates of C-tagged $VEGF_{121}$ with 5th generation PAMAM boronated dendrimers derivatized with Cy5.5, where dendrimer was functionally "inserted" between C-tagged $VEGF_{121}$ and Cy5.5 (*7*).

Although we describe here conjugates with adapter-carrying therapeutic or diagnostic payloads, a similar approach might be used for surfaces derivatized with functionally active proteins, which might be useful for various devices, tissue scaffolds, and biosensors. In this strategy, the surface is first derivatized with adapter protein, and then conjugates are formed with "working" C-tagged protein(s). Taken together, our results suggest that self-assembled "dock and lock" conjugates might provide a standardized and versatile approach to using recombinant proteins for biomedical purposes.

Received February 21, 2006; Revised Manuscript Received May 16, 2006

We demonstrate the use of self-assembled luminescent semiconductor quantum dot (QD)−peptide bioconjugates for the selective intracellular labeling of several eukaryotic cell lines. A bifunctional oligoarginine cell penetrating peptide (based on the HIV-1 Tat protein motif) bearing a terminal polyhistidine tract was synthesized and used to facilitate the transmembrane delivery of the QD bioconjugates. The polyhistidine sequence allows the peptide to self-assemble onto the QD surface via metal-affinity interactions while the oligoarginine sequence allows specific QD delivery across the cellular membrane and intracellular labeling as compared to nonconjugated QDs. This peptide-driven delivery is concentration-dependent and thus can be titrated. Upon internalization, QDs display a punctate-like staining pattern in which some, but not all, of the QD signal is colocalized within endosomes. The effects of constant versus limited exposure to QD−peptide conjugates on cellular viability are evaluated by a metabolic specific assay, and clear differences in cytotoxicity are observed. The efficacy of using peptides for selective intracellular delivery is highlighted by performing a multicolor QD labeling, where we found that the presence or absence of peptide on the QD surface controls cellular uptake.

INTRODUCTION

Luminescent semiconductor nanocrystals or quantum dots (QDs)[1] are a relatively new class of fluorescent probe whose unique optical properties suggest that they are superior to conventional organic dyes for many biological applications (*1*−*5*). QD properties include high quantum yield, broad absorption spectra, large achievable Stokes shifts, narrow symmetric, size-tunable emission spectra, and exceptional resistance to photo- and chemical degradation (*2*−*6*). These properties are particularly appealing for the visualization of cellular processes, as they can potentially facilitate long-term and multicolor labeling of both fixed and living cells. An intensive exploration is currently underway by several groups to optimize methods for the intracellular delivery of QDs and QD bioconjugates and to characterize their long-term in vivo photophysical properties.

Three important criteria must be met for the successful development of QDs and QD bioconjugates as reliable reagents for cellular labeling and in vivo imaging. First, hydrophilic QD probes must be prepared in a facile and controlled manner. Second, their intracellular uptake must exhibit an element of selective delivery, and the QD probes must be able to access various subcellular compartments. Third, the QD bioconjugates must elicit minimal or no cytotoxicity over the time course required for efficient cellular delivery, labeling, subsequent targeting, and sensing. Reports describing QD bioconjugates that meet all three of these criteria, however, remain limited.

A few strategies for developing QD−cell penetrating peptide (CPP) bioconjugates for cellular delivery have been attempted and mixed results have been demonstrated in terms of providing effective cellular transmembrane delivery and labeling. Silver and Ou used commercially available QDs functionalized with streptavidin/poly(ethylene glycol) and complexed to both biotinylated and nonbiotinylated peptides expressing a 9-mer poly-arginine sequence (*7*). These bioconjugates were delivered to lysosomes and formed aggregates in both HeLa and baby hamster kidney cells. Coating the same QDs with protein A and complexing them with poly-L-lysine also produced equally effective cellular delivery, suggesting that charge alone may be the dominant translocation mediator in these cells. Lagerholm attached 25- to 50-fold excess of a biotinylated 9-mer poly-arginine containing peptide to streptavidin QDs and found intracellular labeling in Swiss 3T3, HeLa, and MG63 cells with a brightness 2 orders of magnitude stronger than unconjugated QDs alone (*8*). Rozenzhak used a noncovalently complexed 21-residue peptide carrier for cellular delivery of QDs into HeLa cells (*9*). This peptide, which is believed to function independently of endocytosis, consists of a hydrophobic tryptophan-rich domain for efficient membrane translocation and a lysine-rich domain for solubility. Efficient intracellular delivery of QDs with punctate cytoplasmic staining was reported using this peptide carrier. Hoshino reported that 48-62 copies of an 11-mer poly-arginine-containing sequence covalently attached to QDs facilitated their rapid cellular uptake and localization to the nucleus in Vero cells (*10*). In contrast, Derfus reported that complexing QDs with a Chariot peptide actually decreased HeLa cell uptake to levels below those of uncomplexed QDs (*11*). A similar Tat protein-derived sequence has been shown to

efficiently mediate the nuclear translocation of gold nanoparticles that were less than 5 nm in diameter (*12*).

Strategies for the intracellular delivery of QDs have relied largely on the use of receptor-mediated or nonspecific endocytosis (*1*, *13*). In a detailed report, Jaiswal et al. demonstrated passive endocytotic uptake of hydrophilic QDs capped with dihydrolipoic acid (DHLA) by incubating HeLa cells with solutions containing QDs at concentrations of 400−600 nM QDs for 3−4 h (*1*). QDs entering cells by this pathway remained largely sequestered within endocytic vesicles for several hours (*1*, *11*). Other methods for the cellular uptake of QDs that have been reported include: electroporation (*14*), cationic transfection reagents (*11*, *15*), and microinjection (*11*). Each of these methods has certain drawbacks, however. For example, microinjection is a limited throughput process, as individual cells must be manipulated one at a time, while electroporation necessitates forming pores in the cellular membrane. Peptide-mediated delivery on the other hand remains one of the more attractive methods due to the ease of use. This involves complexing QDs with cell penetrating peptides (CPP) to facilitate their transmembrane delivery. These peptide motifs are most often based on the HIV-1 Tat peptide (*16*), antennapedia (*17*), and transportan sequences (*18*). The classical or core CPP motif is derived from the HIV-1 Tat peptide and usually consists of 7−11 consecutive repeats of positively charged arginine residues (*19*). While the mechanism of CPP-mediated membrane translocation remains under investigation, increasing evidence points to the involvement of several types of endocytosis (*20*−*25*).

In this report, we describe the development and characterization of self-assembled QD−peptide bioconjugates for the specific intracellular delivery into several eukaryotic cell lines. A poly-histidine-appended peptide expressing an 8-mer polyarginine sequence is first self-assembled onto DHLA-capped CdSe−ZnS QDs, then used to facilitate QD transmembrane delivery. We found that once internalized, some, but not all, of the QD staining colocalizes with endosomal compartments. We also found that peptide-mediated QD uptake is dependent on conjugate concentration while exposure of cells to nonconjugated QDs results in negligible intracellular labeling. Significant differences in cellular toxicity are also noted for chronic (long-term) versus acute (short-term) cell incubation with QD−peptide conjugates. Selective intracellular labeling is further highlighted by performing a multicolor QD labeling experiment, where the presence or absence of peptide on the QD surface was found to determine whether cellular uptake can occur or not.

MATERIALS AND METHODS

Quantum Dots. CdSe−ZnS core−shell QDs with emission maxima centered at 510 and 551 nm were synthesized and made hydrophilic by exchanging the native trioctylphosphine/trioctylphosphine oxide (TOP/TOPO) capping shell with DHLA ligands as described previously (*26*). The QDs are identified by their wavelength of maximum emission, e.g., a sample of 510 nm QDs designates a population of QDs which exhibits maximum photoluminescence centered at 510 nm (see Figure 1B).

Peptide Synthesis. The cell-penetrating peptide (CPP) used in this study is composed of the sequence $(His)_8$ -Trp-Gly-Leu-Ala-Aib-Ser-Gly-$(Arg)_8$-amide, where Aib is α-aminoisobutyric acid and the C-terminus is blocked with an amide. The N-terminal polyhistidine $(His)_8$ tract mediates self-assembly onto DHLA-capped CdSe−ZnS QDs (*27*−*34*). The peptide was synthesized manually using in-situ neutralization cycles for Boc-solid-phase peptide synthesis on 0.2 mmol MBHA resin (4-methylbenzhydrylamine, Peptides International, Louisville, KY) using 1.1 mmol amino acid, 1.0 mmol HCTU ([2-(1*H*-6-chlorobenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate]), 2 mL of 0.5 M solution in DMF), and 0.5 mL DIEA

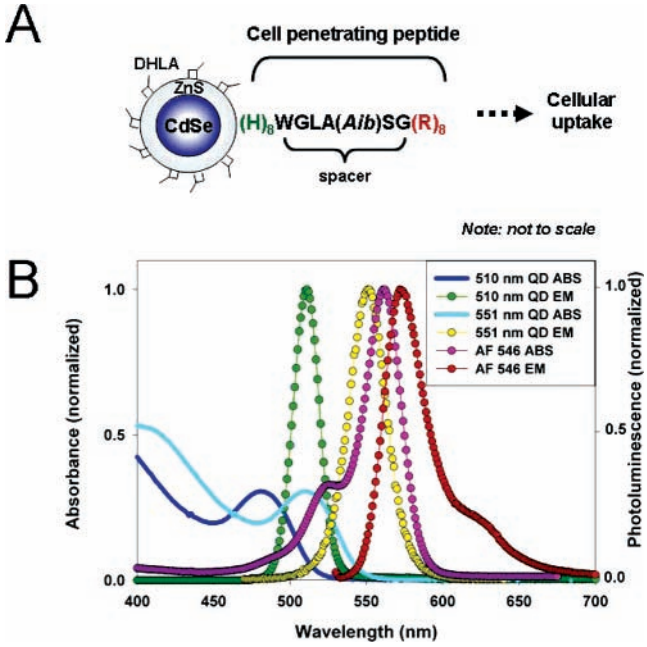

Figure 1. Schematic representation of a QD−peptide assembly and relevant absorbance/emission spectra for materials used in this study. (A) The peptide self-assembles onto the DHLA-capped CdSe/ZnS QD surface via $(His)_8$-Zn metal-affinity coordination. A short spacer separates the $(His)_8$ QD attachment domain from the HIV-1 Tat-derived $(Arg)_8$ cellular uptake sequence. Aib is α-aminoisobutyric. (B) Absorbance of 510 and 551 nm QDs are represented by the solid black and cyan lines, respectively. The fluorescence spectra of the QDs and AlexaFluor 546 are also shown.

(*N*,*N*-(diisopropyl)aminomethylpolystyrene) (*35*). Coupling times were typically 20 min. Following chain assembly, the peptide was cleaved from the resin with hydrofluoric acid and 10% anisole for 1 h at 0 °C, purified by HPLC, and characterized by electrospray ionization mass spectrometry using an API-III triple quadruple mass spectrometer (Sciex, Thornhill, CA). The peptide mass was calculated from the experimental mass to charge (*m*/*z*) ratios from all of the observed protonation states of the peptide using MacSpec software (Sciex). The observed peptide mass agreed with the calculated average mass within 0.5 Da.

Cell Culture. HEK 293T/17 and COS-1 cell lines (both from ATCC, Manassas, VA) were cultured as exponentially growing subconfluent monolayers in complete growth medium (Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 4 mM L-glutamine, 1 mM sodium pyruvate, 1% (v/v) antibiotic/antimycotic, and 10% (v/v) heat-inactivated fetal bovine serum (FBS)). Cells were grown on 60-mm dishes and incubated at 37 °C under 5% CO_2 atmosphere. A subculture was performed every 3−4 days.

Assembly of Quantum Dot−Cell Penetrating Peptide Bioconjugates. Self-assembled QD−CPP bioconjugates were prepared by incubating stock solutions of 1 μM QD with appropriate ratios of desalted CPP in 10 mM sodium tetraborate buffer pH 9.6 for at least 1 h. QD−CPP assemblies were diluted into complete growth medium immediately prior to use. Once diluted into growth medium, QD−CPP assemblies typically remained in solution for >24 h. We have found that if the peptide was not desalted prior to use, there were instances where the QD−CPP conjugates precipitated.

Cellular Uptake of Quantum Dot−Peptide Assemblies. All cellular internalization experiments were performed on microscope slides fitted with multiwell forms as described previously (*36*). Aminopropylsilane-functionalized glass slides (GAPSII, Corning) were coated overnight with 50 μg/mL fibronectin (Sigma) in sodium bicarbonate buffer (pH 8.5). Slides were washed twice with distilled water and dried under a stream of

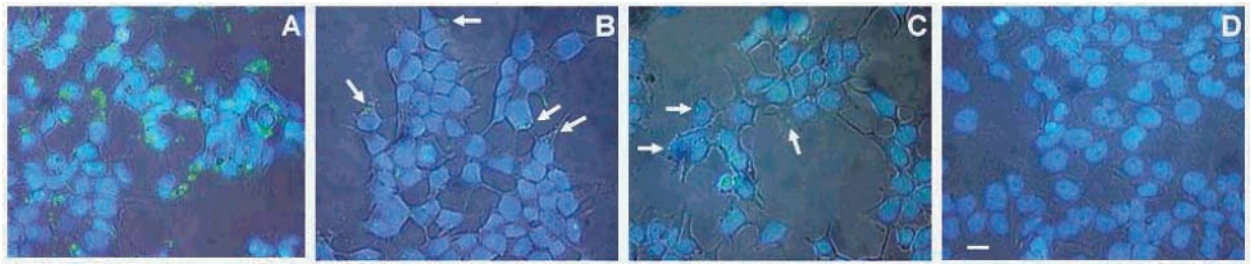

Figure 2. Dose-dependent cellular internalization of QD−CPP assemblies. HEK 293T/17 cells were incubated with 510-nm QD−CPP assemblies (QD:CPP ratio 1:50) at QD concentrations of 250 nM (A), 60 nM (B), 15 nM (C), or with 250 nM QDs without CPP (D); cells were also stained with DAPI. Overlay of phase contrast, QD fluorescence (green), and DAPI fluorescence (blue), show the dose-dependent nature of the QD−CPP delivery. Images also show that QD staining is nonnuclear, punctate fluorescence located in the cytoplasm. Negligible cell-surface associated fluorescence was observed. Arrows indicate regions of QD−CPP internalization at lower concentrations. Scale bar is 10 μm.

nitrogen, and an eight-well adhesive silicone form (Schleicher and Schuell) was affixed. Cells (2×10^4 cells/well) were seeded into the wells and cultured overnight. For delivery experiments, QDs or QD−CPP assemblies were diluted into complete culture medium and incubated with the cells at 37 °C for 1 h. For experiments aimed at assessing QD−CPP colocalization with endosomes, an Alexa Fluor 546-transferrin conjugate (AF546-transferrin, Molecular Probes) was included with the assemblies at a final concentration of 40 μg/mL. After incubation, excess unbound QDs were removed by washing three times with phosphate-buffered saline (PBS, pH 7.4). Cells were then fixed in 3.7% paraformaldehyde for 10 min at room temperature. The cells were washed twice with PBS and mounted in ProLong Antifade mounting media containing DAPI (Molecular Probes).

Fluorescence Microscopy and Image Analysis. Intracellular distribution of QD staining was analyzed by bright field and epifluorescence microscopy using a Nikon ES800 upright fluorescence microscope equipped with a 40× lens. Images were collected using standard Nikon filter sets for DAPI, FITC (for 510 QDs), and TRITC (for AF546−transferrin). Merged images were generated using Adobe PhotoShop. Images of cell cultures incubated with a mixture of two-color QDs were collected by scanning confocal fluorescence microscopy using a Zeiss LSM 510 inverted microscope equipped with a 60× oil immersion lens. Images were collected using the following excitation (ex) lines and emission (em) filters: 510 QDs, 488 nm (ex), 490−510 nm (em); 551 QDs, 488 nm (ex), 545−585 nm (em); AF546-transferrin, 546 nm (ex), 570 nm long-pass filter (em). Phase contrast images were collected using 633 nm laser illumination. Composite merged images were produced using the LSM Image Browser (Zeiss).

Cytotoxicity Assays. Cellular toxicity of the CPP, unconjugated QDs, and QD−CPP assemblies were assessed using the CellTiter 96 Cell Proliferation Assay (Promega, Madison WI) according to the manufacture's instructions. This assay is based upon the conversion of a tetrazolium substrate to a formazan product by viable cells at the assay end point (*37*). The formazan product absorbs at 570 nm. Cells (1×10^4 cells/well) were cultured in 96-well microtiter plates in complete growth medium in the presence of increasing concentrations of QDs, CPP, or QD−CPP assemblies. For the assessment of chronic toxicity, the QD materials were applied to cells and incubated for 24 h prior to assaying the number of viable cells. For acute toxicity studies, the materials were incubated with the cells for 1 h and removed, and the media was replaced with complete growth media. Cells were then cultured for 24 h prior to assaying for cell viability.

RESULTS AND DISCUSSION

Formation of Quantum Dot−CPP Assemblies. QD−peptide bioconjugates were formed by mixing the $(His)_8$-terminated CPP with DHLA-capped QDs for at least 30 min prior to use (Figure 1A). This allows the CPP to self-assemble onto the QD surface. We have previously shown that proteins and peptides expressing terminal polyhistidine sequences self-assemble onto DHLA-capped CdSe−ZnS QDs via metal-affinity coordination (*27*−*34*). Furthermore, this conjugation scheme allows control over the peptide-to-QD ratio in these conjugates. The dissociation constant of this interaction is estimated to be stronger than most antibody−antigen interactions ($K_d \geq 10^{-9}$ M) (*38*). We have found that upon addition of CPP to QD solutions a substantial increase in the solution photoluminescence (PL) intensity is measured; at a ratio of ∼10 peptides per QD−conjugate ∼100% enhancement in solution PL is measured in comparison to a control solution of unconjugated QDs. This observation is consistent with our previous results on self-assembled QD−protein-His and QD−peptide-His conjugates and we used it as an indicator of QD−CPP bioconjugate formation (*26*, *31*, *39*).

Cellular Uptake of Quantum Dot−CPP Assemblies. To determine the efficiency of CPP-mediated internalization, cells were incubated with either nonconjugated QDs or QD−CPPs assembled at QD:CPP ratios of 1:5, 1:25, or 1:50. Figure 2 shows epifluorescence/phase contrast image overlays of HEK 293T/17 cells that were incubated with nonconjugated 510 nm-emitting QDs or with a concentration series of QD−CPP assemblies (ratio of 1:50). The images clearly show that the presence of CPPs on the QD surface resulted in the concentration-dependent cellular uptake of the assemblies, with the highest intracellular QD fluorescence observed for cells incubated with solutions containing higher concentrations of QDs (Figure 2A). Punctate QD fluorescence was dispersed throughout the cytoplasm as well as in close proximity to the cell nuclei (perinuclear), but no nuclear staining was apparent. When the cells were incubated with lower concentrations of QD−CPP assemblies, the degree of cellular uptake was noticeably reduced (Figure 2B,C). In the absence of CPP, no intracellular QD fluorescence was observed (Figure 2D). Similarly, control experiments performed with a non-$(His)_8$-CPP peptide resulted in no noticeable cellular uptake. We also observed essentially no difference in the efficiency of uptake between QD−CPPs assembled at ratios of 1:50 and 1:25. However, a noticeable decrease in uptake occurred when the ratio was decreased to 1:5 (data not shown). Further, we observed no detectable fluorescence signal remaining on the plasma membrane, indicating a negligible degree of nonspecific binding of the QD−CPP assemblies to the cell surface after washing. These results provide strong evidence that complexing the CPPs with QDs allows for specific cellular internalization relative to the same concentration of nonconjugated QDs and also demonstrate the concentration-dependent nature of the peptide-facilitated uptake. We should emphasize that similar experiments performed with COS-1 cells resulted in an approximately 2- to 3-fold lower efficiency of QD−CPP conjugate uptake and likely point to

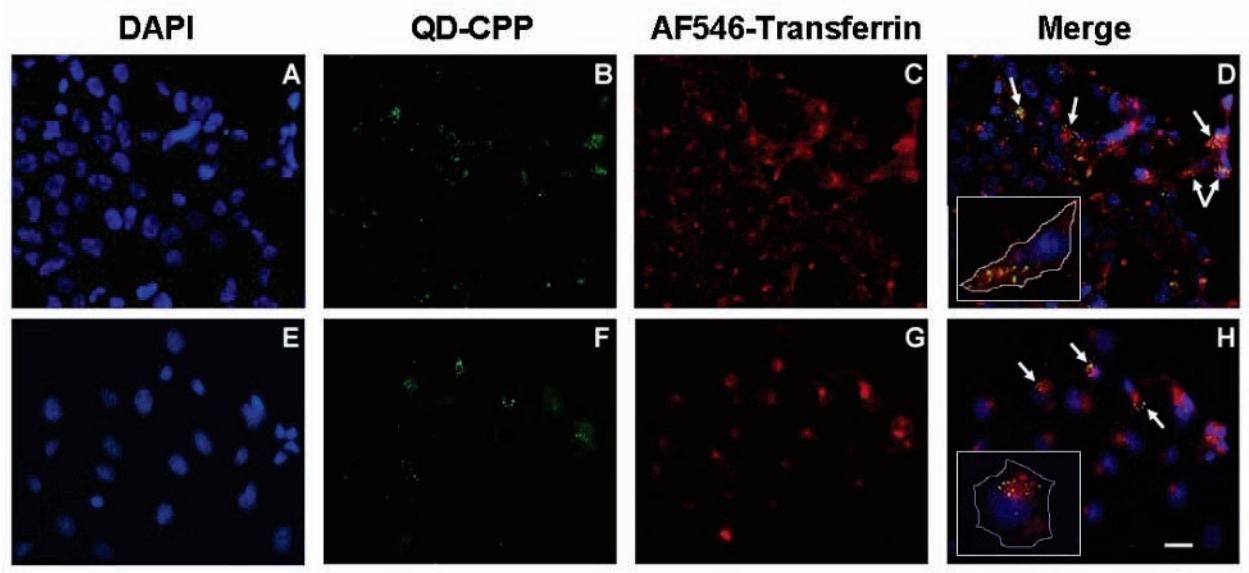

Figure 3. QD−CPP internalization and colocalization within endocytotic vesicles. HEK 293T/17 (A−D) and COS-1 (E−H) cells were coincubated with 510 nm QD−CPP assemblies (QD:CPP ratio 1:25) and 40 μg/mL AlexaFluor 546−transferrin for 1 h. Following washing and fixation, cells were imaged by epifluorescence. DAPI-stained nuclei are shown in panels A and E. QD fluorescence is shown in B and F and is largely perinuclear. Staining with AlexaFluor 546−transferrin, an endocytotic marker, is shown in C and G, and merged images appear in D and H. The insets in D and H show representative single cells with the cell membrane marked for clarity. Arrows indicate areas of colocalization. Scale bar is 10 μm.

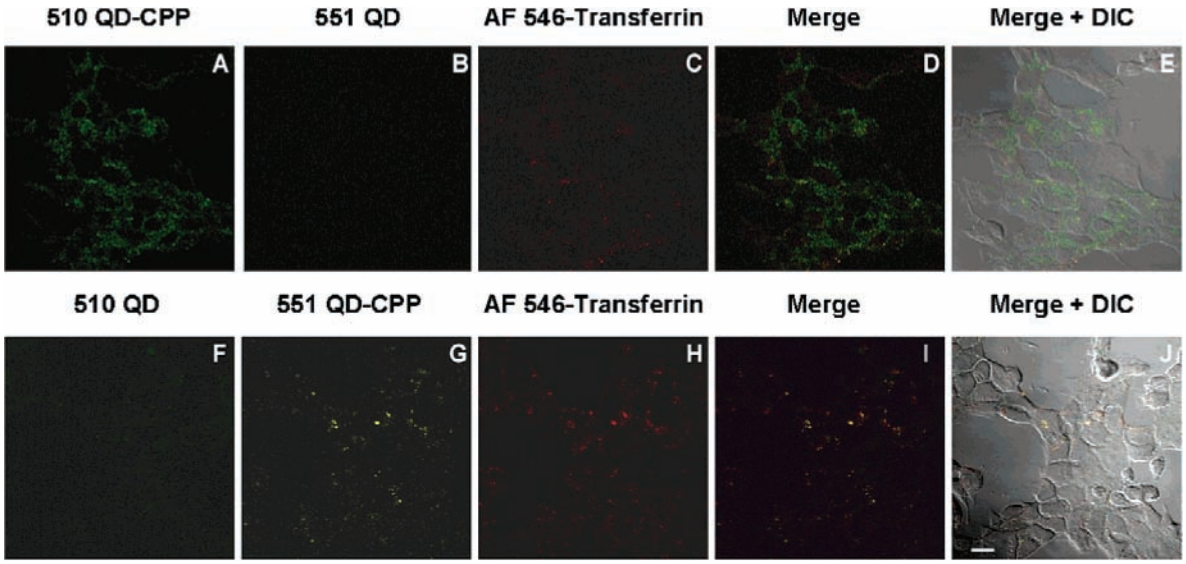

Figure 4. Selective cellular internalization of QD−CPP assemblies. HEK 293T/17 cells were incubated with mixtures of 510 nm QD−CPP (250 nM QD concentrated) and unconjugated 551 nm QDs (60 nM) (in A−E) or to unconjugated 510 nm QDs (60 nM in QDs) and 551 nm QD−CPP (250 nM QD concentrated) (in F−J). In both cases, cells were coincubated with 40 μg/mL AF546-transferrin. The merged/DIC images show that assemblies are excluded from the nucleus. Scale bar is 10 μm.

differences between the two cell lines used. Nonetheless, the amount of delivered QD cargos was large enough to produce a strong fluorescence signal and to carry out additional comparative experiments.

To monitor the fate of the internalized QD−CPP assemblies in HEK293T/17 and COS-1 cells, we examined the intracellular distribution of QD−CPP assemblies that were simultaneously delivered with AlexaFluor 546-conjugated transferrin (AF546−transferrin). Transferrin is an 80 kDa serum glycoprotein that mediates iron uptake in vertebrate cells via receptor-mediated endocytosis, and labeled transferrin is commonly used to monitor the endocytic pathway (*40*, *41*). To visualize the nuclei, the cells were also stained with DAPI (Figure 3, A and E). In both cell lines, a punctate and vesicular QD fluorescence pattern was observed within the cytoplasm and within perinuclear spaces (Figure 3, parts B and F). This punctate appearance is not unexpected for this type of DHLA-capped QD when present within the slightly acidic cellular environment and is consistent with previously published results (*1*, *11*). When the QD fluorescence pattern was merged with the vesicular staining pattern of AF546-transferrin (Figure 3, parts C and G), it was evident that at least a portion of the internalized QD−CPP assemblies were colocalized within endosomes (Figure 3, parts D and H). Simultaneous incubation with AF546-transferrin did not alter QD−CPP uptake or staining in any manner. Further, when cells were incubated with the QD−CPP assemblies at 4 °C, where endocytosis is inhibited, cellular uptake was completely eliminated (data not shown). These results strongly suggest a role for endocytosis in the uptake of the QD−CPP assemblies. Recent studies using live-cell imaging and FACS analysis have also established that arginine-rich CPPs and their conjugated cargos are internalized by endocytosis (*24*, *25*, *42*).

Selective Quantum Dot−CPP Cellular Uptake. To investigate the ability of cells to discriminate between two QD

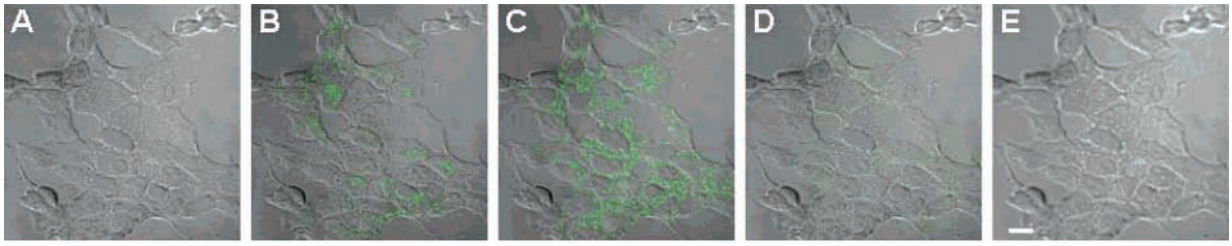

Figure 5. Laser scanning fluorescence images of cross-sectional slices along z-direction of internalized QD−CPP assemblies. HEK 293T/17 cells were incubated with a mixture of 510 nm QD−CPP conjugates (250 nM QD concentrated) and unconjugated 551 nm QDs (60 nM in QDs). Sequential images (~0.4 μm sections with ~0.25 μm overlap between adjoining sections) were acquired along the *z*-axis. Panel A is below the cells while panel E is above the cells. Images show that QD fluorescence is located exclusively in the cytoplasm and is nonnuclear. After washing, no nonspecifically bound QDs remaining on the cell surface were observed. Scale bar is 10 μm.

populations (colors) presenting distinct surface functionalities, HEK 293T/17 cells were incubated for 1 h with a mixture of 510 nm QD−CPP conjugates and unconjugated 551 nm QDs. The cells were then fixed and examined by scanning confocal fluorescence microscopy. As shown in Figure 4A, when cells were incubated with 510 nm QD−CPP assemblies (at a concentration of 250 nM QD) and unconjugated 551 nm QDs (at a concentration of 60 nM QD), internalization of only the 510 nm QDs was observed.[2] No intracellular QD fluorescence corresponding to the 551 nm QDs was observed (Figure 4B). Consistent with our previous experiments, the pattern of intracellular QD fluorescence was punctate in nature and was excluded from the nucleus. However, in contrast to our previous observations using epifluorescence microscopy, the more sensitive confocal analysis used here indicated a higher degree of intracellular QD fluorescence than what was previously measured above (see Figure 3) as demonstrated by the QD signal dispersed nearly homogeneously throughout the cytoplasm. When the pattern of QD fluorescence was compared to that of AF546-transferrin (Figure 4C), a modest degree of overlap was observed indicating partial colocalization of QDs within endosomes (Figure 4D). The majority of the QDs appeared to be excluded from endocytotic vesicles (Figure 4E). The presence of the QDs within the cytoplasm coupled with the lack of QD signal within the nucleus is notable in light of previous investigations which have shown that paraformaldehyde or methanol fixation protocols can cause an artificial redistribution of CPPs and CPP conjugates from the cytoplasm to the nucleus (*42*). The fact that we observed no nuclear translocation suggests that the radius of the QD (hydrodynamic radius ~5−6 nm) precluded the passive diffusion of the QD−CPP assembly through the nuclear pore complex whose hydrodynamic radius is approximately 5 nm (*43*).

In the converse experiment, HEK 293T/17 cells were incubated with mixtures of 551 nm QD−CPP assemblies (at a concentration of 250 nM QDs) and unconjugated 510 nm QDs (at a concentration of 60 nM QDs). Again, the cells internalized only QDs that were complexed with CPPs as only signal corresponding to the 551 nm QDs was apparent (Figure 4G). We did, however, note that the overall intracellular fluorescence of the internalized 551 nm QDs was lower than that previously observed for the CPP-mediated delivery of 510 nm QDs. This difference is attributable to the differential excitation efficiency of the two QD species with the 488 nm laser line, which corresponds to the first absorption peak of the 510 nm QDs while it coincides with the absorption "valley" of the 551 nm QDs (see Figure 1B). Also in contrast with the internalization of 510 nm QD−CPP assemblies, we found that the 551 nm QDs were almost exclusively colocalized with the transferrin conjugate, indicating the sequestration of the 551 QDs within endosomes (Figure 4, H and I). Minimal 551 nm QD fluorescence was dispersed within the cytoplasm (Figure 4J). While it is likely that the differential excitation efficiencies of the two QD species also contribute to these observed differences, it is worth noting that previous studies have demonstrated the ability of poly-L-histidine to increase the endosomal escape of plasmid DNA via the membrane destabilization of acidic endocytotic vesicles following protonation of the imidazole groups (*44*−*46*). It is possible that the CPP plays a contributing role in aiding the endosomal escape of the QD−CPP assemblies, as the CPP peptide contains a $(His)_8$ sequence.

Confocal analysis of these same samples also confirmed that the QD fluorescence was localized exclusively to the cell interior with no evidence of nonspecifically bound QDs on the cell membrane. Figure 5 (panels A−E) shows a sequential z-step analysis taken through HEK 293T/17 cells incubated with a mixture of 510 nm QD−CPP conjugates and unconjugated 551 nm QDs. Standard washing of the cells with PBS was sufficient to remove all loosely bound QDs from the cell surface. This is in contrast to other reports wherein trypsin digestion (*42*) or modification of the QD surface (e.g., with poly(ethylene glycol) ligands) (*47*) were required to remove nonspecific QD binding to the cell surface.

Cytotoxicity of Quantum Dot−CPP Assemblies. The cytotoxicity of the free CPP, unconjugated QDs, and QD−CPP assemblies was assessed by monitoring their ability to inhibit cellular proliferation. Using a colorimetric tetrazolium-based cell proliferation assay, we assessed the toxicity of both short-term (acute) and long-term (chronic) incubation of COS-1 cells and HEK 293T/17 cells to these materials. Under conditions of acute exposure, wherein cells were incubated with the materials for 1 h followed by rinsing and subsequent culture for 24 h, we observed no significant change in proliferation for the CPP (12.5 μM highest concentration tested), unconjugated QDs (250 nM QD highest concentration tested), or QD−CPP assemblies (CPP: QD ratio of 50:1, 12.5 μM CPP: 250 nM QD highest concentration tested) in either COS-1 or HEK 293T/17 cell lines relative to the untreated control (Figure 6 parts A and B, respectively). These exposure conditions are identical to those used to achieve the intracellular delivery of QD−CPP assemblies described in this report and illustrate that the acute exposure of either cell line to the QD−CPP assemblies does not result in any appreciable change in cell viability at the concentrations required for efficient cellular uptake. Under conditions of chronic exposure (incubation for 24 h or longer), however, a distinct dose-dependent cytotoxic effect of the materials was observed (Figure 6, parts C and D, respectively). For both cell lines, the QD−CPP assemblies had the greatest effect on cell proliferation, eliciting a slightly higher degree of toxicity in HEK 293T/17 cells than in COS-1 cells. This result is consistent with our observations of the slightly higher efficiency of QD−CPP

[2] For the unconjugated QDs, a concentration of 60 nM QD was used since our previous results demonstrated that no uptake of unconjugated QDs occurred when they were present at a concentration of 250 nM (see Figure 2).

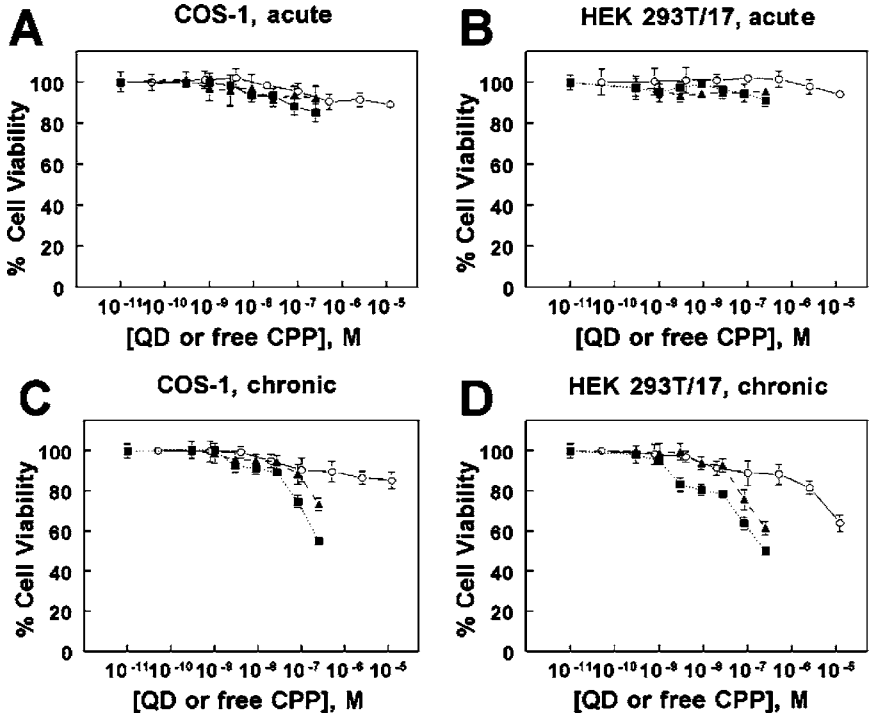

Figure 6. Differential cytotoxicity of QDs, CPP, or QD−CPP assemblies. The acute (short-term) and chronic (long-term) cytotoxicity of unconjugated QDs, free CPP, or QD−CPP assemblies (ratio QD:CPP = 1:25) was assessed using COS-1 and HEK 293T/17 cells. In the acute studies, COS-1 (panel A) and HEK 293T/17 (panel B) cells were incubated with the materials for 1 h, washed, and subsequently cultured for 24 h prior to viability assay. In the chronic studies, COS-1 (panel C) and HEK 293T/17 (panel D) cells were cultured for 24 h in the presence of the materials prior to viability assay. Symbols correspond to: QD−CPP (■), unconjugated QDs (▲), and free CPP (○). For QD−CPP or unconjugated QDs, the concentrations designate those of the QDs. Each data point represents the mean ± SD of triplicate measurements.

internalization by HEK 293T/17 cells. The unconjugated QDs were slightly less toxic than the QD−CPP assemblies. While the free CPP had only a slight effect on the proliferation of COS-1 cells, it was increasingly toxic to HEK 293T/17 cells at concentrations greater than ~750 nM.

While other studies have characterized the toxicity of unconjugated QDs (*48, 49*) and QD bioconjugates (*1*) or free CPPs (*50*) and their associated cargos (*51*), reports detailing the comparative effects of acute versus chronic incubation conditions across multiple cell lines remain limited. Importantly, our results demonstrate not only distinct differences between the two incubation conditions but may also point to cell type-dependent differences in the degree of toxicity.

CONCLUSIONS

We have demonstrated the effective use of cell penetrating peptides to drive the noninvasive intracellular delivery of hydrophilic QD cargos. The approach was applied to two different eukaryotic cell lines, HEK 293T/17 and COS-1. The QD−peptide bioconjugates described in this report are prepared by the facile self-assembly of a polyhistidine-appended cell penetrating peptide with DHLA-capped CdSe−ZnS core shell QDs. This assembly process may ultimately allow for the generation of mixed peptide surfaces, wherein each different peptide imparts a unique functionality to the resulting bioconjugate. A similar strategy has been suggested by Weiss (*52*).

We found that the level of intracellular uptake of the QD−CPP assemblies depends on the QD concentration, the number of QD-associated CPPs, and the cell type used. In the absence of CPP, the extent of QD internalization is essentially nonexistent. Our results show that QD fluorescence is localized to the cell interior with no nonspecific binding of QD−CPP to the cell surface. While other studies have detailed the use of covalent modification of the QD surface with poly(ethylene glycol) (*47*) ligands or trypsin digestion of cells (*42*) to reduce the non-specific binding of QDs, we found that the QD−CPP assemblies were easily removed from the cell surface by washing with PBS. Consistent with other reports that have established the role of endocytosis in the uptake of arginine-rich CPPs and their cargos (*24, 25, 42*), the partial colocalization of the internalized QD−CPPs within endosomes and the complete elimination of their uptake upon incubation at 4 °C provide strong evidence for the role of endocytosis in the uptake of our QD−CPP assemblies. Further, the use of QD−CPP conjugates allows for the intracellular delivery of QDs at lower concentrations and with shorter incubation times compared to other reports which have used nonspecific endocytosis of unconjugated QDs (*1*).

We also observed significant differences between acute and chronic exposure of cells to the QD−CPP complexes. While our chronic exposure results are consistent with those previously reported for unconjugated QDs (*49*), CPPs (*51*), and QD bioconjugates (*7*), the acute toxicity data presented here represents the first description of the minimal cytotoxicity associated with a delivery time course required for successful intracellular uptake. These results are very promising and indicate that cells can be exposed to these assemblies, effectively labeled, and used without significant alteration of their viability or function.

The fine degree of controlled QD−CPP delivery coupled with the minimal toxicity associated with that delivery now sets the stage for more elegant in vitro and in vivo labeling applications, such as the simultaneous delivery and tracking of multiple color QDs to different intracellular compartments (molecular "barcoding"). The use of multipeptide labeled QDs will likely facilitate these studies where each peptide contributes a different function such as cellular uptake, endosomal escape, and organelle targeting.

Enhanced Cellular Uptake with a Cobaltacarborane−Porphyrin−HIV-1 Tat 48−60 Conjugate

Martha Sibrian-Vazquez, Erhong Hao, Timothy J. Jensen, and M. Graça H. Vicente*

Department of Chemistry, Louisiana State University, Baton Rouge LA, 70803. Received February 24, 2006; Revised Manuscript Received April 24, 2006

A series of four porphyrin−cobaltacarborane conjugates have been synthesized, containing three or four cobaltabisdicarbollide anions linked by $O(CH_2CH_2O)_2$ groups to the porphyrin macrocycle and one of them containing a HIV-1 Tat 48−60 peptide sequence linked via a low molecular weight poly(ethylene glycol) (PEG) spacer. The cellular uptake, cytotoxicity, and preferential sites of intracellular localization of the conjugates were evaluated in human HEp2 cells. All conjugates are nontoxic in the dark at the concentrations studied. Upon exposure to low light dose (1 J cm^{-2}) only the porphyrin−cobaltacarborane−HIV-1 Tat 48−60 conjugate showed 30% inhibition of cell proliferation at a concentration of 10 μM. The cellular uptake was dependent on the number of carborane cages and was significantly enhanced by the presence of the cell penetrating peptide sequence HIV-1 Tat 48−60. All conjugates preferentially localized in the cell lysosomes.

INTRODUCTION

The efficient cellular delivery of porphyrin sensitizers for the boron neutron capture therapy (BNCT) and the photodynamic therapy (PDT) of tumors has been the subject of increasing interest in recent years (*1*−*3*). BNCT (*4*−*6*) and PDT (*7*, *8*) are binary therapies for cancer treatment that involve the activation of a tumor-localized sensitizer with low-energy neutrons (in BNCT) or with red light (in PDT), which generates highly cytotoxic species that cause tumor destruction. The main advantage of these localized therapeutic modalities is the selectivity of the treatment; upon activation of the sensitizing drug only those cells that incorporate it are killed. Both the amount and biodistribution of the porphyrin sensitizer within tumor tissue determine its biological effectiveness and, consequently, the outcome of the BNCT and PDT treatments (*9*, *10*). To date, two porphyrin-based drugs, Photofrin and Visudyne, have been approved by the Federal Drug Administration (FDA) for the PDT treatment of various cancers and the wet form of macular degeneration, respectively, but no porphyrin-based sensitizer has yet been approved for use in BNCT. One of the main challenges in BNCT is the discovery of boron-containing drugs capable of selectively delivering therapeutic amounts of boron-10, between 15 and 30 μg of boron/(g of tumor), depending on the exact location of the boron atoms, to target cells with minimum systemic toxicity (*11*, *12*). Porphyrin derivatives containing multiple boron clusters are particularly promising delivery vehicles for BNCT because of the usually low dark toxicity of this type of macrocycle, their ready detection by fluorescence, and their inherent ability to accumulate within tumors and to persist there during the entire radiation treatment (*1*, *13*, *14*). In addition, boronated porphyrin derivatives are being investigated as dual sensitizers for the BNCT and PDT of tumors (*15*−*17*).

Because of the high amount of boron needed for effective BNCT, the cellular uptake of boron-containing porphyrins is a crucial parameter in determining their biological effectiveness. Lipid vehicles such as Cremophor EL and liposomes have been used to enhance the solubility and tumor delivery of boronated porphyrin derivatives (*18*−*20*). The syntheses of carboranylporphyrins containing either a methoxy poly(ethylene glycol) (PEG) chain (*21*) or a positively charged peptide sequence (PKKKRKV) (*22*) have also been reported but their biological properties have not yet been studied. A particularly attractive strategy for increasing the cellular uptake of porphyrin macrocycles consists of their conjugation to a fusogenic or cell-penetrating peptide sequence, such as that found in the human immunodeficiency virus I transcriptional activator (HIV-1 Tat) (*23*). This short peptide sequence has been successfully used to enhance the cellular uptake of several drugs and macromolecules (*24*, *25*), and we have recently shown that it efficiently delivers a nonboronated porphyrin intracellularly (*26*). Although the porphyrin−HIV-1 Tat conjugate is expected to be taken up by both tumor and normal cells, a leaky tumor vasculature and poor lymphatic clearance might result in favorable differential boron concentrations between tumor and normal tissues and therefore selective tumor accumulation. Furthermore, the conjugation of a boronated porphyrin to the HIV-1 Tat peptide is expected to significantly enhance the delivery of boron to target tumors via convection enhanced delivery (*6*, *27*). Herein we report the synthesis of a new boronated porphyrin−HIV-1 Tat 48−60 conjugate containing PEG linkers between the macrocycle, the peptide sequence (GRKKRRQRRRPPQ), and the cobaltabisdicarbollide anions. We have previously shown that porphyrin−cobaltacarborane conjugates are efficiently prepared in high yields from reaction of a nucleophilic porphyrin with zwitterionic cobaltacarborane [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] (*28*). Furthermore we showed that the cellular uptake of a series of conjugates containing one to four cobaltabisdicarbollide anions increases with the number of carborane cages (*29*). In our continuing investigation of structure/activity relationships in carborane-containing porphyrins, we now report the synthesis and characterization of four new porphyrin−cobaltacarborane conjugates containing three or four cobaltabisdicarbollide anions and compare their cellular uptake, cytotoxicity, and intracellular localization in human HEp2 cells. We show that the presence of the HIV-1 Tat 48−60 peptide sequence significantly enhances the cellular uptake of porphyrin−cobaltacarborane conjugates while it does not alter the preferential sites of intracellular localization.

EXPERIMENTAL PROCEDURES

Syntheses. All commercially available starting materials were used directly without further purification, unless otherwise indicated. Reactions under anhydrous conditions were performed in dried and distilled solvents under an argon atmosphere. All reactions were monitored by thin-layer chromatography (TLC) using Sorbent Technologies 0.25 mm silica gel plates with UV indicator (60F-254). Silica gel Sorbent Technologies 32−63 μm was used for flash column chromatography. ^{1}H and ^{13}C NMR were obtained on either a DPX-250 or ARX-300 Bruker spectrometer. Chemical shifts (δ) are given in parts per million relative to acetone-d_6 (2.05 ppm, ^{1}H; 29.92 ppm, ^{13}C), unless otherwise indicated. Electronic absorption spectra were measured on a Perkin-Elmer Lambda 35 UV−vis spectrophotometer. Mass spectra were obtained on an Applied Biosystems QSTAR XL, a hybrid QqTOF mass spectrometer with a MALDI ionization source using either CCA or dithranol as the matrix. HPLC separation and analysis were carried out on a Dionex system equipped with P680 pump and a UVD340U detector. Semipreparative HPLC was carried out using a Luna C_{18} 100 Å, 5 μm, 10 × 250 mm (Phenomenex, USA) column and a stepwise gradient; analytical HPLC was carried out using a Delta Pak C_{18} 300 Å, 5 μm, 3.9 × 150 mm (Waters, USA) column and a stepwise gradient. 5,10,15,20-Tetra(4-hydroxyphenyl)-porphyrin (**1**) was purchased from Aldrich.

5,10,15-Tri(4-hydroxyphenyl)-20-(4-methoxyphenyl)porphyrin (2). To a solution of porphyrin **1** (170 mg, 0.250 mmol) in anhydrous dimethyl sulfoxide (DMSO; 40 mL) was added K_2CO_3 (280 mg, 2.03 mmol). After heating this mixture to 60 °C for 15 min under argon, iodomethane (0.016 mL, 0.26 mmol) was added in one portion and the final mixture was stirred at 60 °C overnight. The reaction mixture was cooled to room temperature, poured into 200 mL of brine, extracted with ethyl acetate until colorless, and dried over anhydrous sodium sulfate. The solvent was removed under vacuum, and the resulting purple residue was purified by flash column chromatography on silica gel using a gradient of chloroform/ethyl acetate (1:1 to 100% ethyl acetate) for elution. The title porphyrin was collected and further purified by recrystallization from ethyl acetate/hexanes to give 42.6 mg, 25% yield, of dark purple crystals. The ^{1}H NMR and UV−vis for the title porphyrin are in agreement with those reported in the literature (*30*). Mp > 300 °C; HRMS (MALDI-TOF) *m*/*z* 693.2468 $(M + H)^+$, calcd for $C_{45}H_{32}N_4O_4$ 693.2501.

5,10,15-Tri(4-hydroxyphenyl)-20-[4-(*tert*-butoxycarbonylmethyl)phenyl]porphyrin (3). To a solution of porphyrin **1** (500 mg, 0.737 mmol) in anhydrous DMSO (15 mL) was added Cs_2CO_3 (480 mg, 1.47 mmol). The mixture was heated at 50 °C for 1 h under argon before *tert*-butyl bromoacetate (287 mg, 1.473 mmol) was added in one portion and the final mixture heated at 60 °C for 2 h. After cooling to room temperature, ethyl acetate (100 mL) was added to the reaction mixture and the organic phase was washed with water (3 × 100 mL) and dried over anhydrous Na_2SO_4. The solvent was removed under vacuum, and the title porphyrin was purified by flash column chromatography on silica gel using chloroform/methanol 95/5 for elution to give 175 mg, 30% yield, of pure title porphyrin residue, mp > 300 °C. HPLC t_R = 5.90 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/(M^{-1} cm^{-1})) 421 (401 690), 522 (28 400), 553 (21 950), 596 (10 500), 654 (11 000). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.90−8.93 (m, 8H, β-H), 8.00−8.05 (m, 8H, PhH), 7.14−7.27 (m, 8H, PhH), 4.87 (s, 2H, CH_2), 1.56 (s, 9H, ^{t}Bu), −2.68 (s, 2H, NH). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 168.80, 159.18, 158.45, 136.52, 136.24, 135.84, 134.08, 121.13, 120.34, 114.75, 113.90, 82.39, 66.54. 28.38. HRMS (MALDI-TOF) *m*/*z* 793.3048 ($M + H^+$), calcd for $C_{50}H_{41}N_4O_6$, 793.3026.

General Procedure for Conjugation of Cobaltacarborane to a 4-Hydroxyphenylporphyrin. To a solution of 4-hydroxyphenylporphyrin (0.1 mmol) in acetone (20 mL) was added K_2CO_3 (0.6 mmol), and the mixture was heated to reflux for 30 min under argon. After cooling to room temperature [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] (0.3 mmol) was added and the final mixture was refluxed under argon overnight. A second portion of K_2CO_3 (0.3 mmol) and [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] (0.15 mmol) were added to the reaction mixture, and reflux continued for 1 day. A third portion of [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] (0.1 mmol) was added, and reflux continued for another day, while monitoring the reaction by HPLC. After 3 days the mixture was cooled to room temperature, the acetone removed under vacuum, and the residue dissolved in ethyl acetate. The organic phase was washed with water and dried over anhydrous Na_2SO_4 and the solvent removed under vacuum. The resulting solid residue was washed with ethyl ether (5 × 5 mL) to remove impurities, and the porphyrin−cobaltacarborane conjugate was dried under vacuum at 50 °C for 2 days.

Porphyrin Conjugate 4. This conjugate was prepared from porphyrin **2** and [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] as described above and obtained in 93% (64.2 mg) yield, mp = 230 °C (dec). HPLC t_R = 11.04 min. UV−vis (acetone) λ_{max} (ϵ/(M^{-1} cm^{-1})) 419 (593 000), 516 (23 900), 553 (18 000), 593 (9 000), 651 (8 900). ^{1}H NMR (acetone-d_6): δ 8.91−8.94 (m, 8H, β-H), 8.14 (d, 8H, J = 7.9 Hz, *o*-PhH), 7.34−7.37 (m, 8H, *m*-PhH), 4.45−4.50 (m, 6H, OCH_2), 4.37 (br, 6H, OCH_2), 4.30 (br, 6H, OCH_2), 4.11 (s, 3H, OCH_3), 4.02−4.06 (m, 6H, OCH_2), 3.74 (br, 12H, carborane-H), 1.30−1.60 (br, 51H, BH), −2.68 (s, 2H, NH). ^{13}C NMR (acetone-d_6) 160.3, 136.6, 135.5, 121.1, 114.2, 113.5, 73.4, 70.8, 69.8, 69.0, 60.9, 55.5, 47.7. HRMS (MALDI-TOF) *m*/*z* 1992.1954 $(M - 3K^+ + 3Na^+ + H^+)^+$, calcd for $C_{69}H_{117}B_{54}N_4O_{10}Co_3Na_3$ 1992.1899.

Porphyrin Conjugate 5. This conjugate was prepared from porphyrin **3** and [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] as described above, and the corresponding *tert*-butyl protected conjugate **5** was obtained in 91% yield, mp = 262−265 °C (dec). HPLC t_r = 12.52 min. UV−vis (acetone) λ_{max} (ϵ/(M^{-1} cm^{-1})) 419 (396 700), 516 (26 000), 552 (21 200), 593 (8 600), 650 (9 000). ^{1}H NMR (acetone-d_6, 250 MHz): δ 8.90−8.93 (m, 8H, β-H), 8.13 (d, 8H, J = 7.9 Hz, *o*-PhH), 7.36−7.43 (d, 8H, J = 8.5 Hz, *m*-PhH), 4.92 (s, 2H, CH_2), 4.50 (s, 6H, OCH_2), 4.33 (s, 6H, OCH_2), 4.28 (s, 6H, OCH_2), 4.04 (s, 6H, OCH_2), 3.75 (s, 12H, carborane-H), 1.6−3.0 (br, 51H, BH), 1.59 (s, 9H, CH_3), −2.70 (s, 2H, NH). ^{13}C NMR (acetone-d_6, 63 MHz): δ 168.5, 159.7, 158.9, 136.1, 135.5, 134.9, 131.8, 120.6, 120.2, 113.7, 82.1, 72.8, 70.2, 69.2, 68.5, 66.3, 65.8, 61.6, 54.8, 47.1, 28.1. LRMS (MALDI-TOF) *m*/*z* 2139.003 (M^+), calcd for $C_{74}H_{124}N_4O_{12}B_{54}Co_3K_3$ 2139.602. To a solution of this conjugate (100 mg, 0.0467 mmol) in chloroform (5 mL) was added TFA (5 mL) and the final mixture stirred at room temperature for 4 h. The solvent was removed under vacuum and the residue triturated with 5 mL of Et_2O. The resulting green precipitate was washed with Et_2O (6 × 10 mL) to remove residual TFA and dried under vacuum to give 93 mg, 95% yield, of pure conjugate **5**, mp = 283−285 °C (dec). HPLC t_r = 16.59 min. UV−vis (acetone) λ_{max} (ϵ/(M^{-1} cm^{-1})) 419 (408 000), 516 (17 800), 553 (14 250), 593 (8 300), 650 (8 800). ^{1}H NMR (acetone-d_6, TFA): δ 8.78 (br, 8H, β-H), 8.48 (br, 8H, *o*-PhH), 7.64 (br, 8H, *m*-PhH), 5.10 (s, 2H, CH_2), 4.53 (s, 6H, OCH_2), 4.36 (s, 6H, OCH_2), 4.29 (s, 6H, OCH_2), 4.05−4.06 (m, 6H, OCH_2), 3.73 (s, 12H, carborane-H), 0.77−2.43 (br, 51H, BH). LRMS (MALDI-TOF) *m*/*z* 2083.518 $(M + H)^+$, calcd for $C_{70}H_{116}N_4O_{12}B_{54}Co_3K_3$ 2083.498.

Porphyrin Conjugate 6. Peptidyl resin (0.02 mmol) was introduced into a glass synthesizer, swelled in dimethylforma-

mide (DMF) for 1 h, and then washed with DMF (2 × 5 mL). To the resin was added 500 μL of a solution containing 0.08 mmol of $FmocNH(CH_2CH_2O)_7CH_2CH_2NHCOCH_2OCH_2CO_2H$, 0.120 mmol of DIEA, 0.08 mmol of HOBt, and 0.08 mmol of TBTU. The reaction mixture was allowed to react until the Kaiser test was negative, and then the resin was washed with DMF (5 × 5 mL) to remove residual reactants. The Fmoc protecting group was removed by treatment with 20% piperidine/DMF, for 40 min at room temperature. The pegylated peptidyl resin was washed with DMF (5 × 5 mL) and then 500 μL of a solution containing 0.04 mmol of conjugate **5**, 0.120 mmol of DIEA, 0.04 mmol of HOBt, and 0.038 mmol of HATU was added. The reaction mixture was shaken 24 h at room temperature and then filtered to give a dark purple resin. This resin was washed to remove unreacted porphyrin, first with DMF until the filtrate was colorless, then with dichloromethane and methanol, before being dried under vacuum. Cleavage and deprotection was carried out by treatment of the dried resin with 3 mL of a mixture of TFA/phenol/TIS/H_2O, 88:5:2:5 at room temperature for 4 h. The resin was filtered and washed with TFA (3 × 2 mL), and the filtrates were combined and evaporated under vacuum to give a green residue. The conjugate was precipitated by addition of cold Et_2O, washed repeatedly with Et_2O, and dried under vacuum. The purification of the porphyrin conjugate was accomplished by reverse phase HPLC on a Luna C_{18} semipreparative column (10 × 250 mm, 5 μm) (Phenomenex, USA) using water/acetonitrile both containing 0.1% TFA as the mobile phase, with a stepwise gradient from 80 to 95%. The fraction containing the conjugate was collected and lyophilized to afford pure conjugate **6** (6.9 mg) in 8% yield, mp > 300 °C. The purity of conjugate **6** was > 98% as obtained by HPLC on an analytical Delta Pak C_{18} (3.9 × 150 mm, 5 μm) column. HPLC t_r = 7.29 min. UV−vis (methanol) λ_{max} (ϵ/(M^{-1} cm^{-1})) 421 (178 700), 559 (21 700), 553 (18 200), 593 (13 700), 654 (12 500). ^1H NMR (CD_3OH, 300 MHz): δ 7.66 (s, 8H, β-H), 7.50 (s, 8H, *o*-PhH), 7.33 (s, 8H, *m*-PhH), 3.92 (s, 6H, OCH_2) 3.89 (s, 6H, OCH_2), 3.63−3.77 (m, 32H, OCH_2, carborane-H and peptide-H), 0.99−2.64 (m, 84H, peptide-H and BH). LRMS (MALDI-TOF) *m/z* 4302.084 ($M - 3K^+ + 7Na^+)^+$, calcd for $C_{160}H_{283}N_{42}O_{26}B_{54}Co_3Na_7$ 4301.391.

Porphyrin Conjugate 7. This conjugate was prepared from porphyrin **1** and [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] as described above and obtained in 85% (106.1 mg) yield, mp = 290−292 °C (dec). HPLC t_R = 13.93 min. UV−vis (acetone) λ_{max} (ϵ/(M^{-1} cm^{-1})) 419 (383 000), 516 (13 700), 552 (9 900), 595 (3 900), 651 (4 600). ^1H NMR (acetone-d_6, 300 MHz): δ 8.94 (s, 8H, β-H), 8.17 (d, 8H, *J* = 8.5 Hz, *o*-PhH), 7.43 (d, 8H, *J* = 8.5 Hz, *m*-PhH), 4.48 (s, 8H, OCH_2), 4.37 (s, 8H, OCH_2), 4.30 (s, 8H, OCH_2), 4.05 (s, 8H, OCH_2), 3.76 (s, 16H, carborane-H), 1.6−3.0 (br, 68H, BH), −2.70 (s, 2H, NH). ^{13}C NMR (acetone-d_6, 75 MHz): δ 160.5, 136.8, 135.7, 121.3, 114.4, 73.6, 71.0, 69.9, 69.3, 55.9, 47.9. HRMS (MALDI-TOF) *m/z* 2411.4881 ($M - 4K^+ + 4Na^+ + H^+$), calcd for $C_{76}H_{143}N_4O_{12}B_{72}Co_4Na_4$ 2411.4855.

Cell Culture. All tissue culture media and reagents were obtained from Invitrogen. Human HEp2 cells were obtained from ATCC and maintained in a 50:50 mixture of DMEM/Advanced MEM containing 5% FBS. The cells were subcultured biweekly to maintain subconfluent stocks.

Cellular Uptake. HEp2 cells were plated at 10 000/well in a Costar 96 well plate and allowed to grow overnight. Conjugate stocks were prepared in a mixture of 9:1 DMSO/cremophore at a concentration of 1 mM and then diluted into medium to final working concentrations maintaining DMSO at 1%. The cells were exposed to 10 μM of each conjugate for 0, 1, 2, 4, 8, and 24 h. At the end of the incubation time the loading medium was removed and the cells were washed with PBS pH = 7.4. The cells were solubilized upon addition of 100 μL of 0.25% Triton X-100 (Calbiochem) in PBS. To determine the conjugate concentration, fluorescence emission was read at 410:650 nm (excitation/emission) using a BMG FLUOstar plate reader. Then the cell numbers were quantified using the CyQuant reagent (Molecular Probes).

Cytotoxicity. The HEp2 cells were plated as described above and allowed 36 h to attach. The cells were exposed to increasing concentrations of conjugate up to 10 μM and incubated for 24 h in the dark. The loading medium was then removed, and the cells washed twice with 100 μL of growing medium containing 50 mM HEPES pH 7.4 and then fed with medium containing Cell Titer Blue (Promega) as per manufacturer's instructions. The cell toxicity was then measured by reading the fluorescence at 520:584 nm using a BMG FLUOstar plate reader. The signal was normalized to 100% viable (untreated) cells and 0% viable (treated with 0.2% saponin from Sigma) cells. For the phototoxicity experiments the HEp2 cells were prepared as described above. After conjugate loading, the medium was removed and replaced with medium containing 50 mM HEPES pH 7.4. The cells were then placed on ice and exposed to light from a 100 W halogen lamp filtered through a 610 nm long pass filter (Chroma) for 20 min; the total light dose was approximately 1 J cm^{-2}. An inverted plate lid filled with water to a depth of 5 mm acted as an IR filter. The cells were returned to the incubator for 24 h, and the cytotoxicity was assayed as described above.

Microscopy. HEp2 cells were plated on Lab Tek II chamber coverslips and incubated for 48 h prior to exposure to conjugate. The conjugates were diluted from 10 mM stocks to a working concentration of 10 μM in medium. The cells were then loaded with conjugate by incubating overnight. Organelle tracers were obtained from Molecular Probes and incubated concurrently with conjugate for 30 min prior to microscopy. Mitochondria were visualized using MitoTracker Green FM at 250 nM, lysosomes with LysoSensor Green DND-189 at 50 nM, Endoplasmic Reticulum (ER) with ER Tracker Blue-White DPX at 100 nM, and Golgi Complex with BODIPY FL C_5-ceramide at 50 nM. The cells were then washed three times with medium containing 50 mM HEPES pH 7.4. Microscopy was performed using a Zeiss Axiovert 200M inverted fluorescent microscope fitted with an AxioCam MRm CCD camera (Zeiss).

RESULTS

Synthesis and Characterization. Porphyrins **2** and **3** were prepared from commercially available porphyrin **1** in 25−30% yields, by Williamson etherification using CH_3I and *tert*-butyl bromoacetate, respectively. The zwitterionic cobaltacarborane [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$(1′,2′-$C_2B_9H_{10}$)] was prepared from the reaction of cobaltabisdicarbollide anion $[Co(C_2B_9H_{11})_2]^-$ with 1,4-dioxane in the presence of BF_3**.**Et_2O, according to the literature (*31*). The nucleophilic ring opening reaction of the dioxane ring of cobaltacarborane [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$-(1′,2′-$C_2B_9H_{10}$)] using hydroxyporphyrins **1**, **2**, and **3** afforded the corresponding porphyrin−cobaltacarborane conjugates in 85−93% yield (*28*). The free carboxylic acid group of compound **5** was converted into the corresponding hydroxybenzotriazole ester and coupled to a pegylated−peptide−PAL−PEG−PS resin containing the HIV-1 Tat 48−60 sequence. After cleavage and deprotection from the solid support using 88:2:5:5 TFA/TIS/phenol/H_2O, the porphyrin−peptide−cobaltacarborane conjugate **6** was isolated by reverse-phase HPLC in 8% yield. This low yield may be due to the following: (1) the weak electrophilic character of the free carboxylate, (2) steric effects imposed by the close proximity of the macrocycle to the carboxylic group during the coupling reaction, (3) the formation of aggregates in the solvent used, and/or (4) to the "PEG effect" which seems to cause several conventional reactions to go less

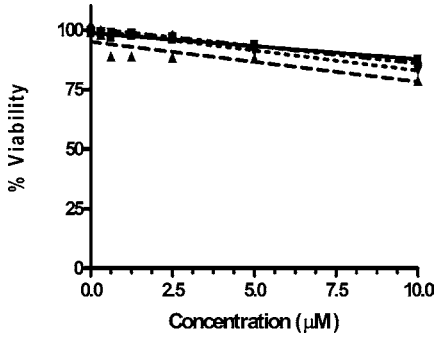

Figure 1. Dark toxicity of porphyrin conjugates **4** (—••—), **5** (— —), **6** (—), and **7** (--) toward HEp2 cells using the Cell Titer Blue assay.

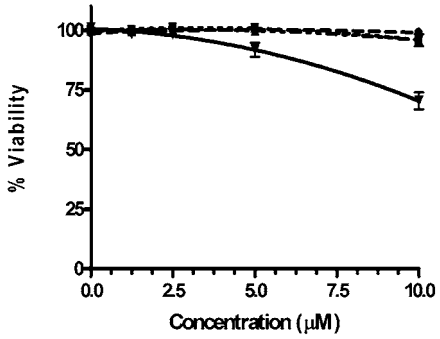

Figure 2. Phototoxicity of porphyrin conjugates **4** (—••—), **5** (— —), **6** (—), and **7** (--) toward HEp2 cells using 1 J cm^{-2} dose light.

effectively when there are $(CH_2CH_2O)_n$ motifs in the reactants. Conjugates **4** and **5** are soluble in polar organic solvents, such as acetonitrile, acetone, methanol, tetrahydrofuran (THF), and DMSO, but insoluble in water, while **6** and **7** are partially water-soluble and also show good solubility in polar organic solvents.

Cellular Studies. The dark and phototoxicity of conjugates **4**, **5**, **6**, and **7** were evaluated in human HEp2 cells, and the results obtained are shown in Figures 1 and 2, respectively. Due to their limited water solubility, both DMSO and Cremophor EL were used as delivery vehicles at low, nontoxic concentrations (0.9:0.1 DMSO/Cremophor EL) (*29*). At concentrations up to 10 μM (higher concentrations were not studied because of the low solubility of the conjugates in aqueous solution), all compounds are nontoxic to the cells in the dark, as determined using the Cell Titer Blue assay. Upon exposure to a low light dose (1 J cm^{-2}), only conjugate **6** shows mild cytotoxicity, with approximately 30% inhibition of cell proliferation at the highest concentration investigated in this study (10 μM). The cellular uptake of conjugates **4**−**7** depends significantly on the number of cobaltacarborane moieties linked to the porphyrin ring and on the presence of the HIV-1 Tat 48−60 peptide sequence. As shown in Figure 3, conjugate **7** containing four cobaltacarborane moieties is taken up to a larger extent at all time points studied than conjugates **4** and **5**, which contain only three cobaltacarborane units. The presence of an acetic acid group in place of a methyl does not have an effect on the cellular uptake nor on the dark toxicity and phototoxicity under the conditions studied. Conjugate **6** containing three cobaltacarborane moieties and the HIV-1 Tat 48−60 peptide sequence accumulated the most within cells of all conjugates at long time points (>2 h) (Figure 3). For example after 24 h, 11 times more conjugate **6** was found within cells than either **4** or **5** with the same number of cobaltacarboranes and three times more than **7**, which contains one more cobaltacarborane moiety. At short time points however, the uptake of **6** was similar to that of **7**, and always higher than that of conjugates **4** and **5**. Conjugates **6** and **7** were taken up rapidly in the first 2 h, after which the uptake of **7** reached a plateau, whereas that of **6** continued to steadily increase. The kinetics of uptake of conjugates **4** and **5** was similar to that of **7**, but the amount of conjugate taken up by cells was significantly lower than that of **7**.

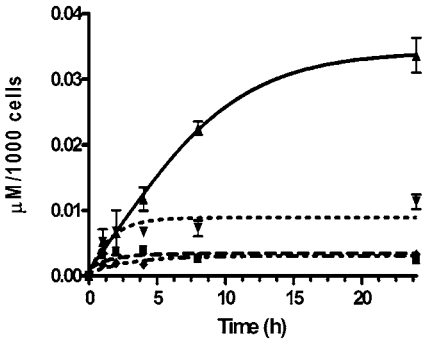

Figure 3. Time-dependent uptake of porphyrin conjugates **4** (—••—), **5** (— —), **6** (—), and **7** (--) at 10 μM by HEp2 cells.

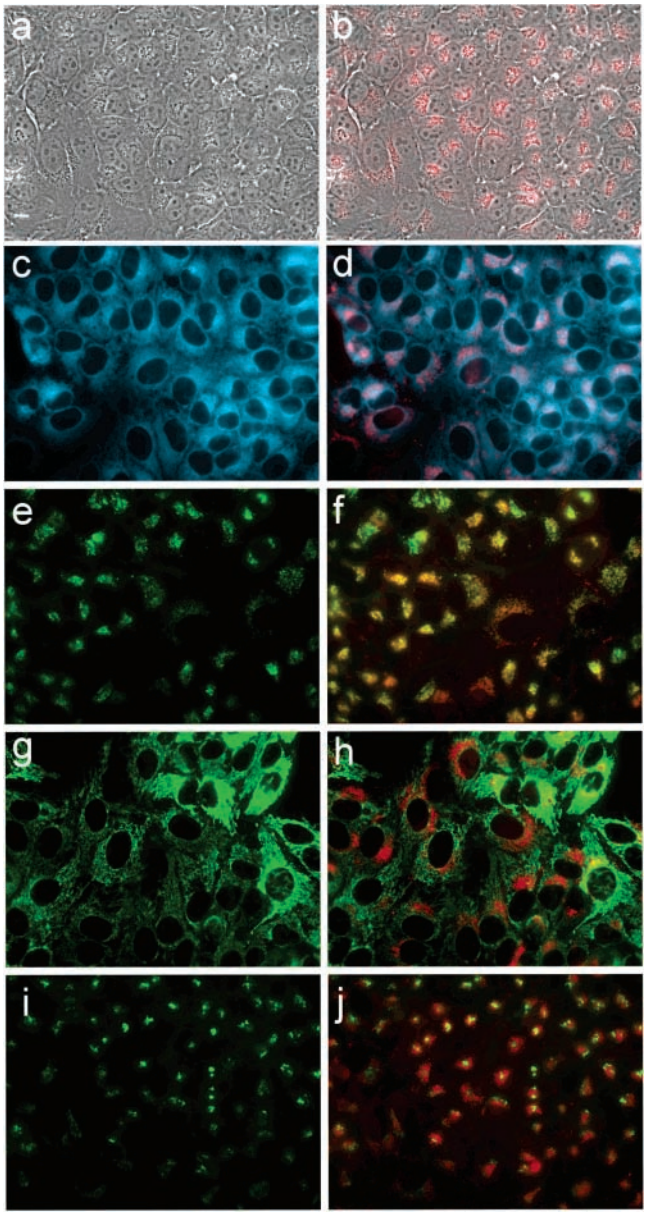

Figure 4. Subcellular localization of conjugate **6** in HEp2 cells at 10 μM for 18 h: (a) phase contrast, (b) overlay of **6** fluorescence and phase contrast, (c) ER Tracker Blue/White fluorescence, (e) LysoSensor Green fluorescence, (g) MitoTracker Green fluorescence, (i) BODIPY Ceramide, and (d, f, h, j) overlays of organelle tracers with **6** fluorescence. Scale bar: 10 μm.

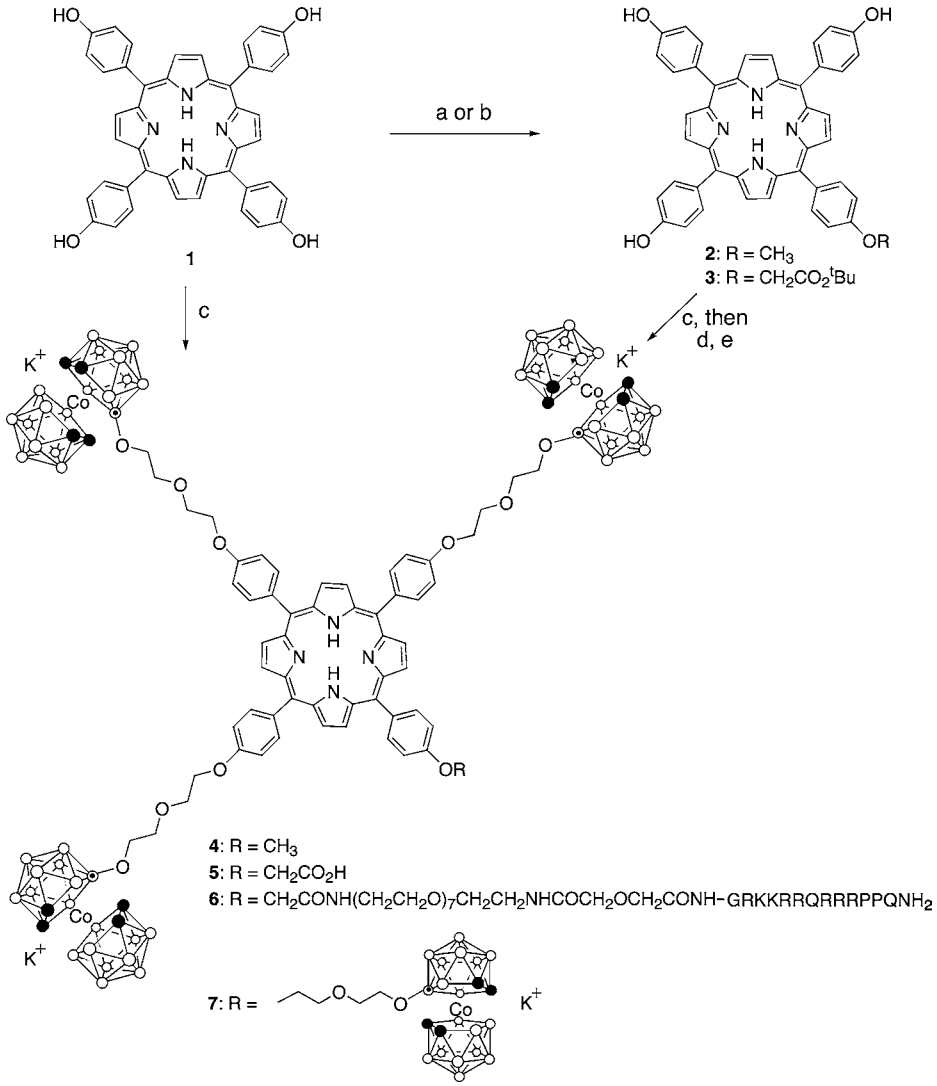
Scheme 1 [a]



[a] Conditions: (a) CH_3I, K_2CO_3, DMSO, 60 °C, overnight (25%); (b) $BrCH_2COO^tBu$, Cs_2CO_3, DMSO, 60 °C, 2 h (30%); (c) [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)], K_2CO_3, acetone, reflux, 72 h (85−93%); (d) TFA, CH_2Cl_2, rt, 4 h (95%); (e) HOBt, HATU, DIPEA, pegylated-peptidyl PAL−PEG-PS resin, DMF, rt, 24 h then TFA/TIS/H_2O/Phenol, 88:2:5:5 (8%).

The subcellular localization of conjugates **4**−**7** in HEp2 cells was evaluated by fluorescence microscopy, 24 h after exposure to the cells. Figure 4 shows the fluorescent patterns observed for the porphyrin−cobaltacarborane−HIV-1 Tat 48−60 conjugate **6**, and its overlay with the organelle specific fluorescent probes LysoSensor Green (lysosomes), Mitotracker Green (mitochondria), ER Tracker Blue-White (ER), and BODIPY Ceramide (Golgi). Similar figures were obtained for conjugates **4**, **5**, and **7** (see Supporting Information). The microscopy shows punctate, predominantly perinuclear staining that localized in vesicles for all compounds. These vesicles were quite large for conjugate **6** and are clearly visible in the phase contrast micrograph. All compounds showed clear co-localization with lysosomes as evidenced by a yellow to orange color in the fluorescence signal when the green organelle tracer signal is overlaid with the red conjugate signal.

DISCUSSION

Porphyrin−cobaltacarborane conjugates **4**−**7** were synthesized as shown in Scheme 1 from commercially available tetra-(hydroxyphenyl)porphyrin **1**. These conjugates were designed to have either three or four cobaltacarborane moieties linked to the porphyrin macrocycle via $O(CH_2CH_2O)_2$ chains, and, in the case of **6**, a HIV-1 Tat 48−60 peptide sequence attached via a low molecular weight PEG spacer. The PEG-based linkages were chosen because they tend to increase the water solubility of porphyrin macrocycles and to minimize their aggregation and intramolecular interactions in aqueous media (*26*). Furthermore, PEG-drug conjugates are known to exhibit enhanced serum life and tumor accumulation (*32*). Low molecular weight PEGs were preferred over high molecular weight PEGs because of the polydispersity of the latter.

The starting porphyrin **1** was monofunctionalized using the Williamson etherification reaction to produce porphyrins **2** and **3** in 25−30% yield (Scheme 1). The conjugation of porphyrins **1**−**3** with cobaltacarborane was performed in a single step in 85−93% yield, by the nucleophilic ring-opening of the dioxane ring of zwitterionic [3,3′-Co(8-$C_4H_8O_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)], as we have previously reported (*28*). The porphyrin−cobaltacarborane−peptide conjugate **6** was prepared by coupling conjugate **5** with the pegylated HIV-1 Tat 48−60 sequence on solid support, following our recently published procedure (*26*). All conjugates were isolated in >98% purity as determined by reverse phase HPLC and were characterized by MS, UV−vis, and NMR spectroscopy.

The achievement of therapeutic boron concentrations (15−30 μg/(g of tumor)) within tumors is still a major challenge in BNCT (*6*). Porphyrin−cobaltacarborane conjugates of high

boron content and with no dark cytotoxicity are potential promising boron delivery drugs for BNCT. We have previously reported that the cellular uptake of a series of zwitterionic porphyrin−cobaltacarborane conjugates increases with the number of cobaltacarborane moieties linked to the porphyrin macrocycle (*29*). To further increase the uptake of this type of compound, we designed and synthesized conjugate **6**, bearing a cell-penetrating peptide sequence. Indeed, conjugate **6** was taken up by cells to a significantly higher extent than conjugates **4** and **5**, containing the same number of cobaltacarborane moieties (Figure 3). At short time points (<2 h) conjugates **6** and **7** showed similar uptake into cells, indicating that both the number of cobaltacarborane residues and the presence of a fusogenic peptide increase cellular uptake. However at longer time points (>2 h), conjugate **6** was taken up to a much larger extent than **7**. These results are in agreement with previous reports by us (*26*) and others (*33*−*37*) showing that the Tat 48−60 peptide fragment from the HIV-1 Tat protein has the ability to efficiently translocate cellular membranes. Our results are also in agreement with our previous observation that the cellular uptake increases with the number of cobaltacarborane residues attached to the porphyrin macrocycle (*29*); at all time points studied the uptake of conjugate **7**, bearing four cobaltacarboranes, was always significantly higher than that of conjugates **4** and **5**, containing three cobaltacarboranes and therefore one less negative charge. On the other hand, the replacement of a methyl group (in **4**) for an acetic acid group (in **5**) had no effect on cellular uptake. All conjugates were found to be nontoxic in the dark at the concentrations studied (Figure 1) and only conjugate **6** showed mild phototoxicity at low light dose (1 J cm^{-2}) and concentrations > 5 μM (Figure 2), probably as a result of its large accumulation within cells.

Porphyrin−cobaltacarborane conjugates **4**−**7** preferentially localize within cells in vesicles and lysosomes, as evaluated by fluorescence microscopy (Figure 4), probably as a result of an endocytotic mechanism of uptake of all conjugates into cells. These results are in agreement with previous reports showing that negatively charged carboranyl-containing porphyrins localize mainly in the cell lysosomes (*38*−*41*). The presence of the HIV-1 Tat 48−60 peptide sequence in conjugate **6** significantly increased the cellular uptake of porphyrin−cobaltacarborane conjugates but did not alter their preferential sites of intracellular localization. Since the cytotoxic particles produced in BNCT, $^{4}He^{2+}$, and $^{7}Li^{3+}$ have average ranges in tissue of 9 and 5 μm, respectively, ^{10}B-loaded vesicles and lysosomes in the vicinity of tumor cell nuclei could potentially lead to effective tumor destruction upon activation with low-energy neutrons. The amount of boron needed for effective BNCT could be substantially lower than 30 μg/(g of tumor) if the boron-10 localizes within tumor cells rather than extracellularly, and further reduced if the boron-10 localizes inside or in the close proximity to the cell nucleus (*11*, *12*, *42*). Conjugates of boronated agents to the HIV-1 Tat peptide sequence could induce higher accumulation of boron within target tumors due to enhanced tumor retention compared with normal tissues, therefore resulting in a more efficient BNCT treatment.

ACKNOWLEDGMENT

The authors thank Martha Juban for HIV-1 Tat 48-60 peptide synthesis. This work was supported by the National Science Foundation, Grant No. CHE-304833, and the National Institutes of Health, Grant No. CA098902.

Intracellular Delivery of Proteins in Complexes with Oligoarginine-Modified Liposomes and the Effect of Oligoarginine Length

Masahiko Furuhata,[†] Hiroko Kawakami,[‡] Kazunori Toma,[‡] Yoshiyuki Hattori,[†] and Yoshie Maitani*[,†]

Institute of Medicinal Chemistry, Hoshi University, Shinagawa-ku, Tokyo 142-8501, Japan, and The Noguchi Institute, Itabashi-ku, Tokyo 173-0003, Japan. Received February 13, 2006; Revised Manuscript Received June 5, 2006

The intracellular delivery of proteins using cell-penetrating peptides (CPPs) including oligoarginine (oligo-Arg) carriers raises the possibility of establishing novel therapeutic methods. We compared the effect of the length of oligo-Arg in modified liposomes ($(Arg)_n$-L; $n = 4, 6, 8, 10$) on the delivery of proteins by flow cytometry, fluorescence microscopy, and spectrofluorimetry. As a free liposome, Arg4-modified liposome Arg4-L was most efficiently internalized in cells. The efficiency decreased depending on the length of oligo-Arg. For the intracellular delivery of proteins, $(Arg)_n$-L was physically associated with proteins. Concerning the effect of oligo-Arg length, liposome/protein complexes showed a different behavior. Arg4-L carried bovine serum albumin (BSA, 66 kDa) and β-galactosidase (β-Gal, 120 kDa) 6-fold higher than free BSA and free β-Gal. Arg10-L showed similar performance for these two proteins to Arg4-L. The enzymatic activity of β-Gal in the cells showed that proteins were transported as a biologically active form. Arg10-L carried 100-fold more immunoglobulin G (IgG, 150 kDa) than free IgG, and 3-fold more than Arg4-L into cells. Shorter oligo-Arg chain on liposomes may be enough for liposomes alone to be taken up in cells, but more Arg residues may be needed to form a complex with high molecular weight proteins and deliver them into cells. This information will aid in the design of $(Arg)_n$-L as a carrier for delivering proteins into cells.

INTRODUCTION

The development of therapeutic peptides and proteins is hampered by their poor ability to penetrate the plasma membrane because of their high hydrophilicity and molecular weight. Therefore, it is necessary to construct an efficient protein delivery system. One approach to solve this problem is to incorporate short peptides derived from protein-transduction domains (PTDs) or cell-penetrating peptides (CPPs), such as HIV-1 Tat fragments, penetratin and VP22. PTDs or CPPs are less than 30 amino acid residues in length and have the capability of crossing the plasma membrane (*1*−*6*). Since the PTDs and CPPs can deliver conjugated molecules, such as proteins, into cells (*7*, *8*), they are usually used as conjugates with cargo molecules, as part of a very strong and specific complex with biotin (*9*). However, these CPP carriers require cross-linking to the target peptide or protein. The only exception is pep-1, which has been reported to deliver a variety of peptides and proteins into several cell lines by forming physical assemblies without covalent chemical coupling (*6*). Since CPP-modified nanoparticles (*10*) and liposomes (*11*) can be taken up into cells, liposomes modified with Tat and penetratin were utilized in the intracellular delivery of drugs by entrapping the drugs in the liposomes (*12*). However, in the case of proteins, it is hard for them to be released from the liposomes, even if the liposomes are internalized in cells.

We synthesized oligo-Arg conjugates with an artificial lipid, and they were incorporated in liposomes for a protein delivery study. In our system, the surface of liposomes were modified with oligo-Arg ($(Arg)_n$-L; $n = 4, 6, 8, 10$), and proteins were physically associated on the surface. Cargo proteins were not entrapped in the liposomes. Therefore, the preparation of the complex between proteins and $(Arg)_n$-L is simple. Although investigations delineating the influence of Arg length on the uptake of oligo-Args alone have been reported (*5*, *13*−*15*), to our knowledge there is no report on $(Arg)_n$-L as a protein delivery system. $(Arg)_n$-L provides two characteristic interactions; a hydrophobic one by liposome, and a positively charged and hydrophilic one by (Arg)n. These two kinds of interactions were expected to help forming complexes with proteins.

The aim of this study is first to show that our system can transport proteins into cells, and then to examine the effect of oligo-Arg length on the protein delivery in human cervical carcinoma HeLa cells. Cellular uptake efficacy was evaluated by flow cytometry, spectrofluorimetry, and fluorescence microscopic observation of the cells. We also analyzed the interaction of $(Arg)_n$-L with proteins by fluorescence intensity distribution analysis (FIDA).

Our studies showed that the effect of oligo-Arg length on the intracellular delivery of proteins by $(Arg)_n$-L/protein complexes was different from that of $(Arg)_n$-L alone. Short oligo-Arg was enough for liposomes to be taken up into the cells, but longer oligo-Arg may be needed to form a complex with large proteins and deliver them into the cells.

EXPERIMENTAL PROCEDURES

Materials. All amino acid derivatives and coupling reagents were obtained from Kokusan Chemical Co., Ltd. (Tokyo, Japan). Egg phosphatidylcholine (EPC) was purchased from Q. P. Co., Ltd. (Tokyo, Japan). Cholesterol (Chol) and bovine serum albumin (BSA) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Calcein was obtained from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). Fluorescein isothiocyanate-labeled BSA (FITC−BSA), stearylamine, 3β-[*N*-(dimethylaminoethane)carbamoyl]cholesterol (DC−Chol), 5-(*N*-ethyl-*N*-isopropyl)amiloride (EIPA), phorbol 12-myristate 13-acetate (PMA) were from Sigma Chemical Co. (St. Louis, MO). FITC-immunoglobulin G (FITC−IgG) was provided by

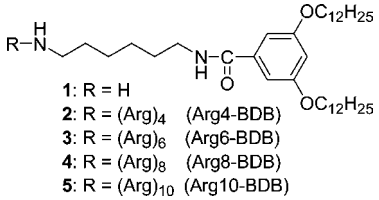

Figure 1. Chemical structures of $(Arg)_n$-BDBs.

MP Biomedicals Co. (Irvine, CA). IgG was obtained from Oriental Yeast Co., Ltd. (Tokyo, Japan). β-Galactosidase (β-Gal) and the β-Gal staining kit were purchased from Active Motif, Inc. (Carlsbad, CA). Lumi-Gal 530 (Reporter assay kit of β-Gal) was from Toyobo Co., Ltd. (Osaka, Japan). Bicinchonic acid (BCA) protein assay reagent was obtained from Pierce (Rockford, IL). Dulbecco's modified Eagle's medium (DMEM) was purchased from Invitrogen Co. (Carlsbad, CA). Fetal bovine serum (FBS) was provided by Life Technologies (Grand Island, NY). 1,1′-Dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) was obtained from Lambda Probes & Diagnostics (Graz, Austria). All other reagents were of analytical grade.

Synthesis of $(Arg)_n$-BDBs. $(Arg)_n$-BDBs (**2**, **3**, **4**, and **5**) were synthesized similarly to other peptide−lipid conjugates of different amino acid sequences (*16*) (Figure 1). The oligo-Arg portion was extended similarly to the compounds with a PEG linker between oligo-Arg and BDB (*17*). For example, N^{α}-9-fluorenylmethoxycarbonyl-N^{g}-2,2,5,7,8-pentamethylchroman-6-sulfonyl-L-arginine (Fmoc-Arg(Pmc)-OH) was condensed with *N*-(6-aminohexyl)-3,5-bis(dodecyloxy)benzamide (**1**) by 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate and 4-(dimethylamino)pyridine in *N*,*N*-dimethylformamide, and the Fmoc protecting group was removed by piperidine. This amide condensation and Fmoc deprotection cycle was repeated four times to give the side chain protected **2**. MALDI-TOFMS (α-CHCA): found, 2280.24; calculated for $[M + H]^+$, 2278.33. Final trifluoroacetic acid deprotection of Pmc gave **2**. MALDI-TOFMS (α-CHCA): found, 1214.99; calculated for $[M + H]^+$, 1213.94.

Cell Culture. HeLa cells were kindly provided by Toyobo Co., Ltd. (Osaka, Japan). HeLa cells were grown in DMEM supplemented with 10% FBS at 37 °C in a humidified 5% CO_2 atmosphere.

Preparation of Liposomes. Four liposomal formulas were used: EPC, Chol, and $(Arg)_n$-BDB in a molar ratio of 7:3:0.05 or 7:3:0.5 for the oligo-Arg-modified liposome ($(Arg)_n$-L); EPC and Chol in a molar ratio of 7:3 for the control liposome (Con-L); EPC, Chol, and stearylamine in a molar ratio of 7:3:2 for the stearylmaine modified liposome (SA-L); EPC, Chol, and DC−Chol in a molar ratio of 7:3:0.5 for the DC−Chol modified liposome (DC-L) for the control liposomes containing cationic lipids. Liposomes were prepared by a dry film method with water or 20 mM calcein. For $(Arg)_n$-L, $(Arg)_n$-BDB, Chol, and EPC were dissolved in an appropriate volume of chloroform, which was then removed. The particle size distributions and the zeta-potentials were measured by the dynamic and the electrophoresis light scattering method, respectively (ELS-800, Otsuka Electronics Co., Ltd., Osaka, Japan), at 25°C, after the dispersion was diluted to an appropriate volume with water. pH titration of the zeta-potential was measured by Automatic Titrator GT-06 (Mitsubishi Chemical Corporation, Tokyo, Japan). For liposomes with calcein entrapped, this was followed by chromatography on Sephadex G-50 columns, and fractions of liposomes were collected. DiI-labeled liposomes were prepared as described above but with post-addition of DiI at 0.04 mol % of total lipids.

Uptake Experiments Using Flow Cytometry. An aqueous solution of FITC−BSA, FITC−IgG, or β-Gal was added to the $(Arg)_n$-L suspension with gentle shaking to form $(Arg)_n$-L/protein complexes. Each complex was left at room temperature for 10−15 min. Cell cultures were prepared by plating cells in a 35-mm culture dish 24 h prior to each experiment. The cells were washed three times with 1 mL of serum-free DMEM. Calcein-entrapped $(Arg)_n$-L (100 μg) alone or each $(Arg)_n$-L/protein complex ($(Arg)_n$-BDB: 5 μg of protein, from 50:1 to 1000:1 molar ratio), was diluted with serum-free DMEM to 1 mL and then gently applied to the cells. In this study, all samples were incubated with cells for 3 h at 37 °C in serum-free DMEM. At the end of the incubation of $(Arg)_n$-L/protein complexes or calcein-entrapped $(Arg)_n$-L with cells, the cells were washed three times with 1 mL of PBS and detached by incubating with 0.05% trypsin and EDTA solution at 37 °C for 3 min. The cells were centrifuged at 1500*g*, and the supernatant was discarded. The cells were resuspended with PBS (pH 7.4) containing 0.1% BSA and 1 mM EDTA and directly introduced into a FACSCalibur flow cytometer (Becton Dickinson, San Jose, CA) equipped with a 488 nm argon ion laser. Data for 10000 fluorescent events were obtained by recording forward scatter (FSC) and side scatter (SSC) with green (for FITC and calcein; 530/30 nm) and red (for DiI; 585/42 nm) fluorescence. To investigate the cellular uptake mechanism, cells were washed with serum-free medium and preincubated for 30 min at 37 °C with EIPA (25 μM) or PMA (1 μM). Subsequent incubation of the complex was carried out in the presence of the respective pharmacological reagents.

Spectrofluorimetric Quantification of Internalized FITC−BSA and IgG. At the end of the incubation of $(Arg)_n$-L/FITC-protein complexes with cells as described above, the cells were washed three times with 1 mL of PBS and lysed by incubating with 0.2% Triton X-100/PBS at 37 °C for 5 min, followed by centrifugation at 15000 rpm for 15 min. The supernatants were measured with a chemoluminometer (Ex = 485, Em = 535 nm) (Wallac ARVO SX 1420 multilabel counter, Perkin-Elmer Life Science, Japan, Co. Ltd., Kanagawa, Japan).

Fluorescence Microscopy. At the end of the incubation of $(Arg)_n$-L/protein complexes with cells as described in Uptake Experiments using Flow Cytometry, the cells were washed five times with 1 mL of PBS. Unfixed cells were observed with an Eclipse TS100/100-F for epifluorescence observations (Nicon, Tokyo, Japan). The level of contrast and the brightness of the images were adjusted.

***β*-Galactosidase Assay.** For the β-galactosidase assay, we used X-Gal staining and chemiluminescence measurements. For X-Gal staining, at the end of the incubation of $(Arg)_n$-L/β-Gal complex with cells as described in Uptake Experiments using Flow Cytometry, the cells were stained with the β-Gal staining kit and then observed with an Eclipse TS100/100-F for epifluorescence observations. The level of contrast and the brightness of the images were adjusted. For chemiluminescence measurements, β-Gal activity was measured according to the instructions accompanying the β-Gal assay system. Incubation of $(Arg)_n$-L/β-Gal complex with cells was terminated by washing the plates three times with cold PBS (pH 7.4). Cell lysis solution (Reporter assay kit of β-Gal) was added to the cell monolayers and subjected to freezing at −80 °C and thawing at 37 °C, followed by centrifugation at 15000 rpm for 2 min. Aliquots of 20 μL of the supernatants were mixed with 180 μL of Lumi-Gal 530 and then incubated for 30 min at 37 °C, and counts per second (cps) were measured with a chemoluminometer (Wallac ARVO SX 1420 multilabel counter). The protein concentration of the supernatants was determined with BCA reagent using BSA as a standard, and cps/μg protein was calculated.

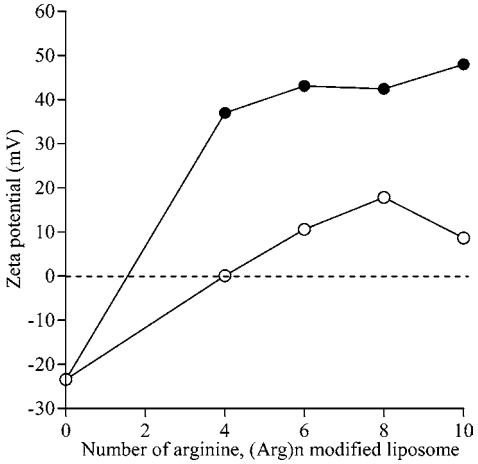

Figure 2. Effect of arginine number of $(Arg)_n$-L on the zeta potential. Open circle, liposome contained 0.5 mol % of oligo-Arg-BDB; Closed circle, liposome contained 5 mol % of oligo-Arg-BDB

Fluorescence Intensity Distribution Analysis (FIDA). FIDA was performed with a MF20 microplate reader (Olympus Corp. Tokyo, Japan) using the onboard 633-nm helium−neon laser at a power of 300 μW for excitation. Experiments were performed in 384-well glass-bottom plates using a sample volume of 50 μL. The FIDA data was analyzed with the MF20 software package. All single-molecule FIDAs were performed under identical conditions with respect to incubation (10 min) at room temperature. Protein-binding experiments were performed using the DiI-labeled Arg4-L and Arg10-L. The concentration of the labeled component was held constant whereas the concentration of BSA or IgG was varied in water.

Cytotoxicity. HeLa cells were seeded at a density of 1×10^4 cells per well in 96-well plates and maintained for 24 h before transfection in DMEM supplemented with 10% FBS. The cells were washed with PBS. The culture medium was replaced with serum-free DMEM (100 μL) including $(Arg)_n$-L/protein complex ($(Arg)_n$-BDB: 5 μg of protein = 50:1, molar ratio). After incubation for 3 h at 37 °C with serum-free DMEM (100 μL), the number of surviving cells was determined by a WST-8 assay (Dojindo Laboratories, Kumamoto, Japan). Cell viability was expressed as the ratio of the A_{450} of cells treated with the protein complex to that of the control samples.

Data Analysis. Significant differences in the mean values were evaluated using Student's unpaired *t*-test. A *p*-value of less than 0.05 was considered significant.

RESULTS

Characterization of $(Arg)_n$-L. We prepared five kinds of liposomes; a control liposome (Con-L) consisting of EPC and Chol at a molar ratio of 7:3, two positively charged control liposomes consisting of EPC, Chol, stearylamine or DC−Chol at a molar ratio of 7:3:2 or 0.5 (SA-L, DC-L, respectively), and two $(Arg)_n$-L (n = 4, 6, 8, 10) differing in $(Arg)_n$-BDB content, a molar ratio of EPC, Chol, and $(Arg)_n$-BDB at 7:3:0.05 and 7:3:0.5. Each particle size was adjusted to about 200 nm by sonication. To examine whether the liposomes were modified with Arg, we measured their zeta potential. Con-L was negatively charged, and the two $(Arg)_n$-L were positively charged (Figure 2). SA-L and DC-L were positively charged (over 50 mV in zeta potential, data not shown). The longer oligo-Arg had a higher zeta-potential, corresponding to the number of Arg residues. The zeta-potential of $(Arg)_n$-L containing 5 mol % of oligo-Arg lipid was higher than that of preparation containing 0.5 mol % (Figure 2). We used $(Arg)_n$-L containing 5 mol % of oligo-Arg lipid in the subsequent experiments, because we thought that highly positively charged carriers were desirable to form complexes with proteins and to deliver them into cells.

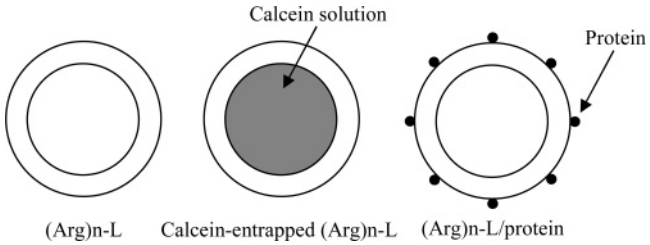

Figure 3. Schematic diagrams of the $(Arg)_n$-L, calcein-entrapped $(Arg)_n$-L and $(Arg)_n$-L/protein complex. ($(Arg)_n$-BDB in $(Arg)_n$-L): protein = 50:1, molar ratio.

Cellular Uptake of Calcein-Entrapped $(Arg)_n$-L, and $(Arg)_n$-L/FITC−BSA, and $(Arg)_n$-L/FITC−IgG Complexes. To examine the cellular uptake of $(Arg)_n$-L or the complex, cells were exposed to calcein-entrapped $(Arg)_n$-L alone, and $(Arg)_n$-L/FITC−BSA and $(Arg)_n$-L/FITC−IgG complexes for 3 h at 37 °C. Then, the cells were trypsinized and analyzed by flow cytometry. The cellular uptake of calcein-entrapped $(Arg)_n$-L decreased as the number of arginine residues increased (Figure 4A). The size of Arg4-L and Arg10-L was about 233 nm. The size of Arg4-L/FITC−BSA and FITC−IgG, and Arg10-L/FITC−BSA and FITC−IgG was about 289 nm, indicating that proteins were adhered to the surface of liposomes as schematically shown in Figure 3. The zeta potential of Arg10-L/BSA and Arg10-L/IgG was similar to that of Arg10-L at pH 3−11 when measured by the pH titration method (data not shown).

Free FITC−BSA, Con-L/FITC−BSA, SA-L/FITC−BSA, and DC-L/FITC−BSA were scarcely taken into the cell (Figure 4B). FITC−BSA in a complex with Arg4-L, Arg6-L, Arg8-L, and Arg10-L displayed a marked increase in fluorescence in the cells, showing about a 6-, 5-, 3-, and 6-fold higher intensity, respectively, than free FITC−BSA. Arg4-L and Arg10-L were most efficient at delivering FITC−BSA into the cells.

Free FITC−IgG (150 kDa), Con-L/FITC−IgG, SA-L/FITC−IgG, and DC-L/FITC−IgG complexes were scarcely taken up at all (Figure 4C). FITC−IgG in a complex with Arg4-L, Arg6-L, Arg8-L, and Arg10-L showed about 30-, 100-, 60-, and 100-fold greater cellular uptake, respectively, than free FITC−IgG. Arg6-L and Arg10-L showed the greatest efficiency in delivering FITC−IgG. However, FITC−IgG and Arg10-L without complex formation showed less cellular uptake of FITC−IgG than Arg4-L/FITC−IgG (data not shown).

We assayed the cellular internalization of the Arg4-L and Arg10-L/FITC−BSA or FITC−IgG complexes for a quantitative evaluation of the amount of internalized protein. Cells were exposed to the same conditions as for the flow cytometric analysis and lysed by 0.2% Triton X-100/PBS. FITC−BSA (5 μg/mL) was internalized in the cells at about 40% and 30% of the dose with Arg4-L and with Arg10-L, respectively. On the other hand, FITC−IgG was internalized at about 10% and 19% of the dose with Arg4-L and with Arg10-L, respectively.

Efficiency of the Cellular Uptake of Arg10-L/FITC−IgG Based on the Ratio of Arg10-L to IgG. We examined the optimal molar ratio of Arg10-BDB to IgG in the Arg10-L/FITC−IgG complex, assaying the cellular internalization of various Arg10-L/FITC−IgG complexes by flow cytometry (Figure 5). Here, the molar ratio of Arg10-L/FITC−IgG refers to the ratio of Arg10-BDB to FITC−IgG because the proportion of Arg10-BDB in liposomes was constant (5 mol %). Cells were exposed for 3 h to the Arg10-L/FITC−IgG complex and then trypsinized. The cellular uptake of FITC−IgG increased as the molar ratio of Arg10-L/FITC−IgG increased and seemed to reach a level of saturation above a molar ratio of 100. It could

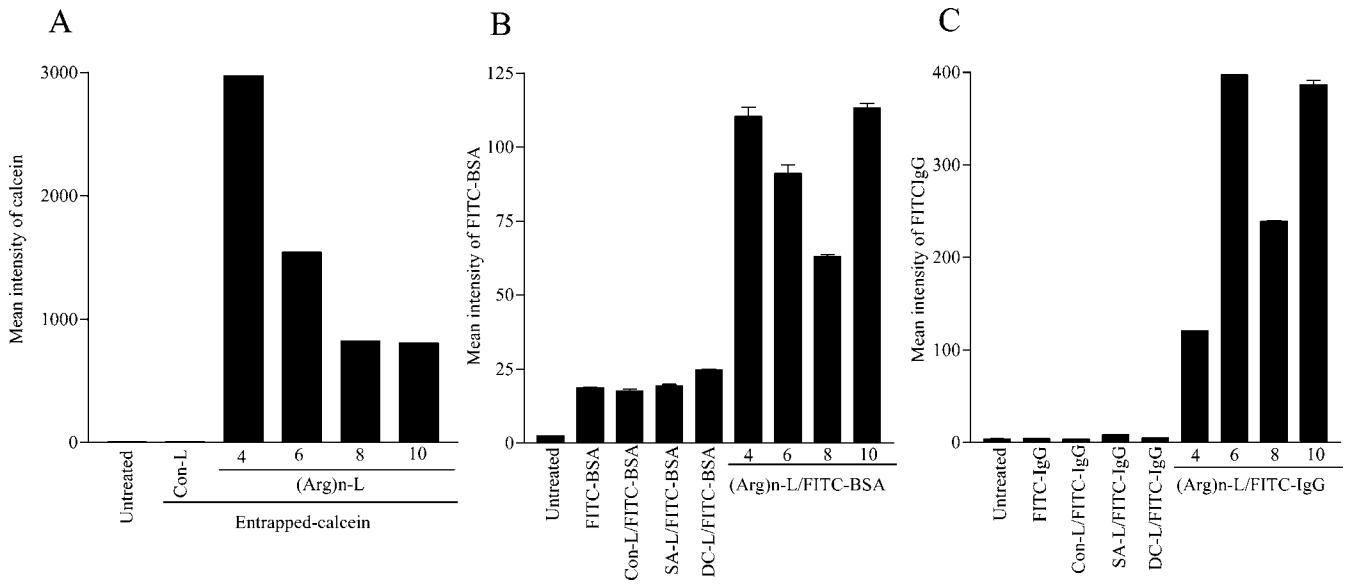

Figure 4. Cellular uptake of the calcein-entrapped $(Arg)_n$-L (A), and $(Arg)_n$-L in complexes with FITC−BSA (B) and FITC−IgG (C). Calcein-entrapped $(Arg)_n$-L (100 μg) alone or each $(Arg)_n$-L/protein complex (a variable $(Arg)_n$-BDB: 5 μg of FITC−BSA or FITC−IgG = 50:1, molar ratio) was diluted with serum-free DMEM to 1 mL and then gently applied to the cells, incubated with the cells for 3 h at 37 °C in serum-free DMEM, and treated with trypsin before FACS analysis. Con-L exhibits liposome without $(Arg)_n$-BDB. SA-L and DC-L exhibit liposome with stearylamine and DC−Chol, respectively. Each value is the mean ± SD of three separate determinations.

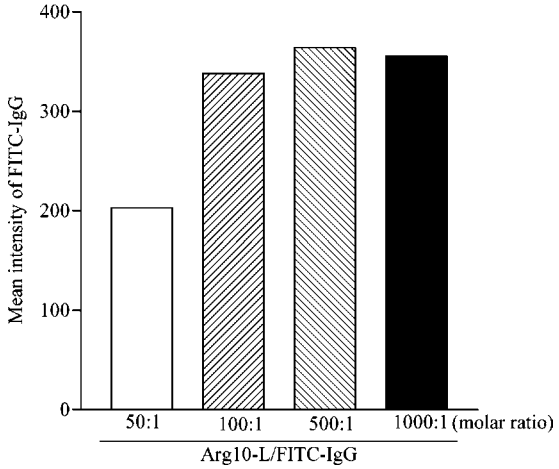

Figure 5. Cellular uptake of the Arg10-L/FITC−IgG complex as a function of the molar ratio between Arg10-BDB and FITC−IgG. Arg10-L/FITC−IgG (a variable Arg10-BDB: 5 μg of FITC−IgG, molar ratio from 50:1 to 1000:1) was diluted with serum-free DMEM to 1 mL and then gently applied to the cells and incubated with the cells at 37 °C for 3 h in serum-free DMEM and treated with trypsin before FACS analysis. Each value is the mean ± SD of three separate determinations.

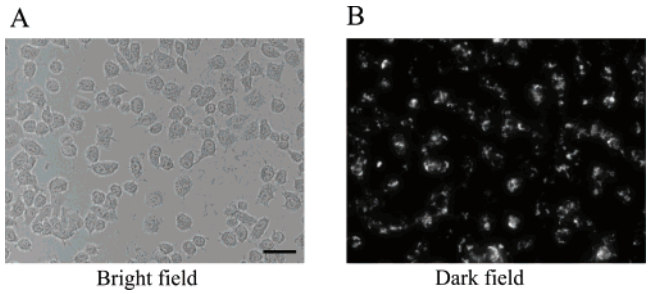

Figure 6. Analysis of FITC−IgG uptake by fluorescence microscopy. Arg10-L/FITC−IgG complex (Arg10:5 μg of FITC−IgG = 100:1, molar ratio) was diluted with serum-free DMEM to 1 mL, gently applied to the cells, and then incubated with the cells for 1 h at 37 °C in serum-free DMEM. The unfixed cells were observed with a fluorescence microscope (magnification × 200). Scale bar = 50 μm.

deliver about 1.5-fold more at a molar ratio of 100 than at 50 without change in the size of the complex.

To confirm the internalization and localization of FITC−IgG in the unfixed cells, we observed the cells by fluorescence microscopy after exposing them to the Arg10-L/FITC−IgG (100: 1) complex for 3 h and washing them five times (Figure 6A, B). FITC−IgG was observed to be taken into almost all cells.

Cellular Uptake of $(Arg)_n$-L/β-Gal Complexes. To examine whether the internalized protein is functional, we observed the enzymatic activity of β-Gal by microscopy. Cells were exposed to the Arg4-L and Arg10-L/β-Gal complexes for 3 h at 37 °C. Then, we observed the efficiency of protein delivery by monitoring the enzymatic activity of β-Gal using X-Gal staining (Figure 7). The cells treated with free β-Gal gave a similar image to untreated cells, suggesting that free β-Gal did not enter the cells (Figure 7A,B). About 70% and 50% of cells with Arg4-L and with Arg10-L, respectively, exhibited strong and uniform β-Gal activity (Figure 7C,D). At a higher magnification, we could confirm that β-Gal activity was present in the cytoplasm (Figure 7E,F). The β-Gal activity in the cells treated with Arg4-L and Arg10-L was about 5.9-fold and 4.4-fold stronger, respectively, than that of cells treated with free β-Gal, and β-Gal (5 μg/mL) was internalized in the cells at about 9.7% and 7.2% of the dose with Arg4-L and with Arg10-L, respectively in the chemiluminescence assay. Most notably, the presence of Arg4-L or Arg10-L did not alter the enzymatic activity of β-Gal upon delivery into cells. Arg4-L could deliver β-Gal (120 kDa) more efficiently than Arg10-L, similar to the transport of FITC−BSA. No cytotoxicity was observed for all $(Arg)_n$-L or $(Arg)_n$-L/protein complexes (data not shown).

FIDA Measurements. To examine whether there is a difference in the complex formation, we used FIDA to characterize the interaction of the $(Arg)_n$-L/protein complex. FIDA allows the characterization of fluorescently labeled molecules with respect to their molecular brightness and concentration at the single-molecule level (*18*). Briefly, the FIDA method is based on the collected photon numbers recorded in time intervals of fixed duration (time windows). Using this information, a count number histogram is built up. Then, a theoretical probability distribution of photon numbers is fitted against the obtained histogram, yielding specific brightness values (Q), corresponding to the concentrations (C), for all

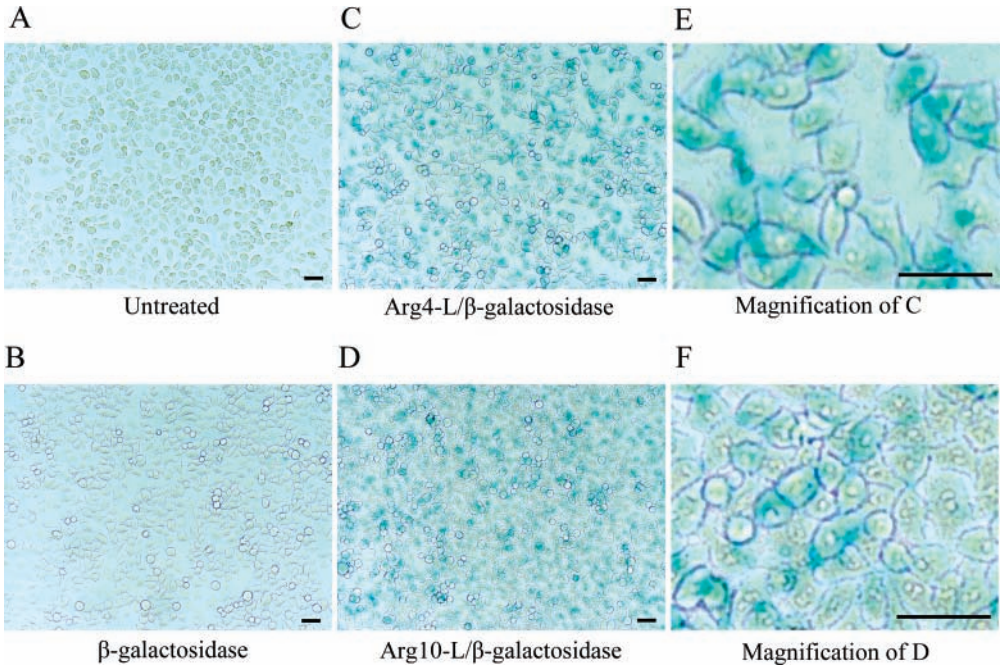

Figure 7. Analysis of β-galactosidase uptake by microscopy. Arg4-L, Arg10-L/β-galactosidase complex (Arg4-BDB or Arg10-BDB: 5 μg of β-galactosidase = 50:1, molar ratio), or 5 μg of β-galactosidase was diluted with serum-free DMEM to 1 mL and then gently applied to the cells and incubated with the cells for 1 h at 37 °C in serum-free DMEM. The cells were stained with a β-galactosidase staining kit and observed with a fluorescence microscope. Scale bar = 50 μm.

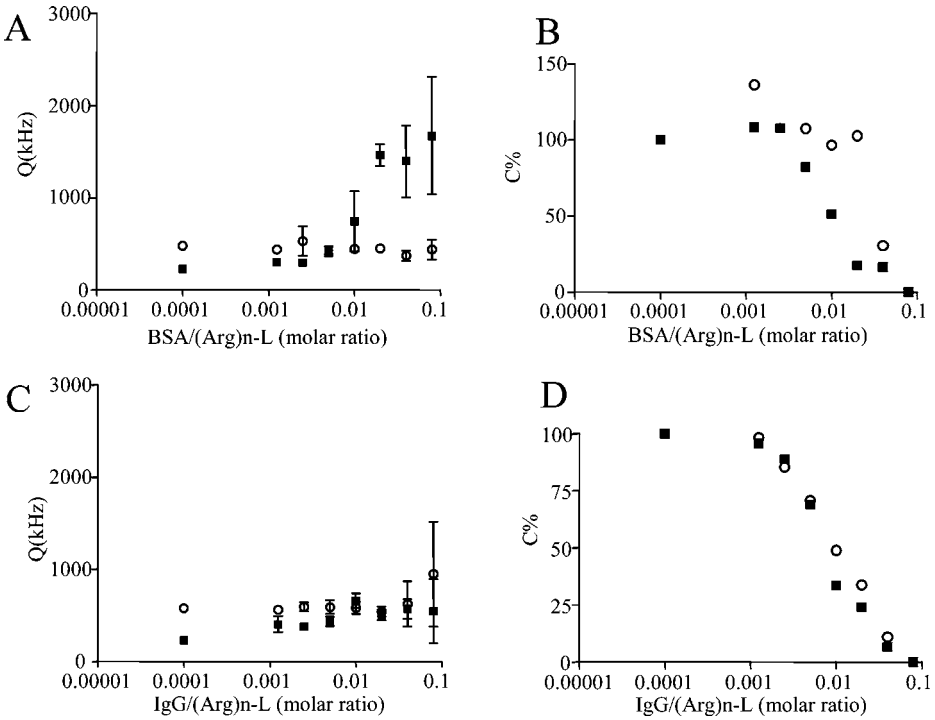

Figure 8. Fluorescence intensity distribution analysis (FIDA) of DiI-labeled Arg4- and Arg10-L/BSA or DiI-labeled Arg4-L and Arg10-L/IgG as a function of the molar ratio between Arg4- or Arg10-BDB and protein. Part A or C was the analytical result of the *Q* value. Part B or D was the analytical result of the ratio of the *C* value. Complex was diluted with water. Square, Arg4-L; Circle, Arg10-L. Each value is the mean ± SD of three separate determinations.

different species. To determine the interaction of the $(Arg)_n$-L with proteins, we measured fluorescence intensity distribution of lipid marker, DiI incorporated in the particle lipid layers as a function of the molar ratio between Arg4- or Arg10-L and protein. Here, the molar ratio of the Arg4-L or Arg10-L/protein complex refers to the ratio of Arg4- or Arg10-BDB to protein. *Q* value of Arg4-L increased at about 0.01 BSA/Arg4-L molar ratio, but that of Arg10-L did not (Figure 8A), corresponding to *C* value of Arg4-L decreased (Figure 8B). Increase of BSA might form complex with high molar ratio of Arg4-L, which increased brightness per complex (*Q* value) and decreased fluorescent Arg4-L number (*C* value). For Arg10-L, the ratio of Arg10-L/BSA in the complex was not changed in this range. Therefore, *Q* value of the complex was not changed. The interaction of IgG with Arg4-L and Arg10-L was similar (Figure 8C, D).

Mechanism of Cellular Uptake of Arg4-L, Arg10-L, and Complexes. To investigate the internalization mechanism of

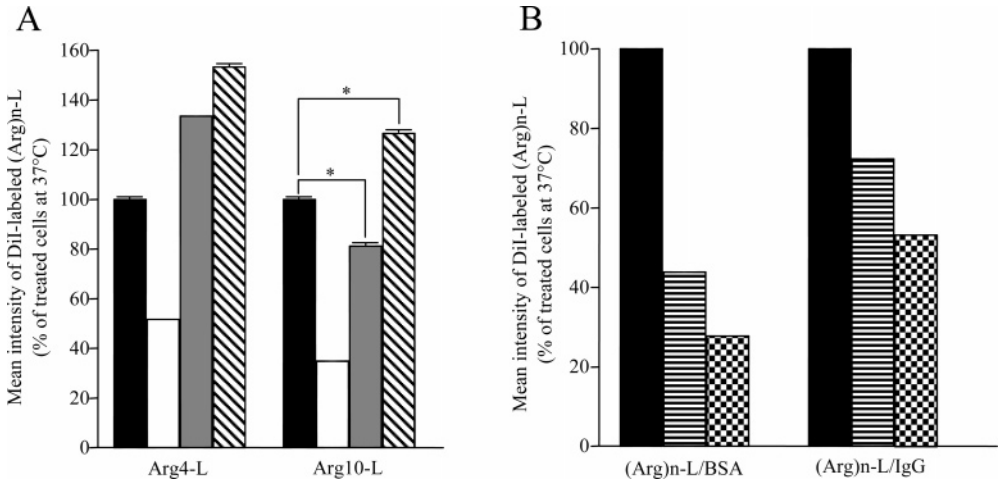

Figure 9. Effect of temperature and pharmacological reagents on the cellular uptake of DiI-labeled $(Arg)_n$-L (A) and $(Arg)_n$-L/protein complex (B). (A) HeLa cells were pretreated with EIPA (25 μM) or PMA (1 μM) at 37 °C for 30 min. The medium was replaced with fresh medium containing DiI-labeled Arg4-L or Arg10-L (100 μg/mL). The cells were incubated for 1 h at 37 °C in serum-free DMEM containing EIPA (25 μM) or PMA (1 μM) and then treated with trypsin before the flow cytometry. Dark bar, 37 °C or no pharmacological reagent; open bar, 4 °C; gray bar, EIPA; slashed bar, PMA. Each value is the mean ± SD of three separate determinations. (B) Effect of temperature on the cellular uptake of DiI-labeled Arg4-L and Arg10-L/protein complex. The experimental conditions were the same as in Figure 4B and C. Dark bar, 37 °C; sideline bar, Arg4-L at 4 °C; mosaic bar, Arg10-L at 4 °C. Each value is the mean ± SD of three independent experiments.

Arg4-L, Arg10-L and their complexes, we prepared DiI-labeled liposomes and examined the effect of temperature, a macropinocytosis inhibitor (EIPA) or an accelerator (PMA) on the cellular uptake of the liposomes. Cells were exposed to DiI-labeled Arg4-L or Arg10-L for 3 h at either 4 °C or 37 °C. Then, they were trypsinized and analyzed by flow cytometry. DiI-labeled Arg4-L and Arg10-L showed about a 50% and 65% lower internalization efficiency, respectively, at 4 °C than at 37 °C (Figure 9A). This finding suggests that the transport occurred through energy-dependent endocytosis. The cells were exposed to DiI-labeled Arg4-L or Arg10-L at 37 °C for 1 h in the absence or presence of EIPA or PMA (Figure 9A). The cellular uptake of Arg4-L increased about 34% in the presence of EIPA, and about 54% in the presence of PMA compared with untreated cells. The cellular uptake of Arg10-L significantly decreased about 20% in the presence of EIPA ($p < 0.05$), but significantly increased about 27% in the presence of PMA ($p < 0.05$) compared with untreated cells. The inhibition of cellular uptake at 4 °C for the Arg4-L/protein complex was lower than that for the Arg10-L/protein complex (Figure 9 B). This finding suggests that Arg4-L and Arg10-L/protein were taken up via an endocytotic pathway as well as Arg4-L or Arg10-L alone.

DISCUSSION

As a free liposome, Arg4-L was most efficiently internalized in the cells. The efficiency decreased depending on the length of oligo-Arg. To our knowledge, this may be the first experimental demonstration that the liposomes with shorter oligo-Arg-L alone were internalized more efficiently than those with longer ones. Besides the demonstration of the free $(Arg)_n$-L cellular uptake, our study reveals protein delivery by $(Arg)_n$-L. Concerning the effect of oligo-Arg length, liposome/protein complexes showed a different trend.

Generally, the cellular uptake of oligo-Arg increases in efficiency as the number of arginine residues increases (*5*). Both Tat and penetratin enhanced the efficiency of the uptake of liposomes in proportion to the number of peptides attached to the liposomal surface (*12*). In our experiments, the shorter oligo-Arg system, Arg4-L, penetrated the cells more efficiently than the longer one, Arg10-L, in the case of calcein-entrapped $(Arg)_n$-L.

To examine the internalization of liposomes, calcein, a water-soluble marker, was entrapped in $(Arg)_n$-L. Liposome−cell interaction on the surface might lead to the leakage of calcein due to liposome destabilization. However, the calcein leakage from $(Arg)_n$-L was small (data not shown). Uptake of DiI-labeled liposomes, which has label-lipid in the liposomes, also exhibited similar behavior to that of calcein-entapped liposomes (data not shown). These findings suggest that the calcein-entrapped $(Arg)_n$-L penetrated as liposomes, and that the difference in the cellular uptake of calcein corresponded to that of the liposomes.

FITC−BSA (66 kDa), β-Gal (120 kDa), and FITC−IgG (150 kDa) were used as model proteins. Cellular uptake of FITC−BSA was increased three to six times when it was in a complex with $(Arg)_n$-L. The highest level of cellular uptake of FITC−BSA was observed with Arg4-L and Arg10-L. For β-Gal, Arg4-L carried β-Gal 6-fold higher than free one. Arg4-L could deliver β-Gal more efficiently than Arg10-L. The enzymatic activity of β-Gal showed a protein to be transported as a biologically active protein. For FITC−IgG, Arg10-L gave the best result.

FIDA showed that the interaction of Arg4-L with BSA was stronger than that of Arg10-L with BSA, and the interaction of Arg4-L and Arg10-L with IgG was similar. At molar ratio of BSA/DiI labeled Arg4-L > 0.02, BSA associated on the surface of liposomes may interact with DiI or the complex may be aggregated. BSA may interact hydrophobic part of Arg4-L. The efficient cellular uptake of Arg4-L/BSA may reflect the strong interaction between Arg4-L and BSA. Also, DiI-labeled Arg4-L in a complex with proteins was taken up more efficiently than Arg10-L complex (data not shown). In the case of IgG, Arg10-L delivered about 3-fold more proteins than Arg4-L (Figure 4C). Because proteins formed complexes with $(Arg)_n$-L prior to the intracellular delivery, it can be postulated that the mode of interactions between proteins and $(Arg)_n$-L might be different depending on the protein.

The cellular uptake was also examined with the fluorescence microscope. To avoid artifacts caused by the fixation procedure, we observed live cells. Fixation was shown to cause significant artifacts regarding the cellular localization (*19*). From the microscopic observation, the fluorescence of FITC−IgG was observed in almost 100% of cells when transported as the Arg10-L complex (Figure 6). From the quantitative evaluation, Arg10-L delivered about 1.2-fold of IgG compared with Arg4-L, whereas FACS analysis indicated that Arg10-L delivered

almost 3-fold more than Arg4-L. The discrepancy could be explained by the sensitivity of fluorescein emission in the microenvironment and partial quenching in the endosomal structures of live cells used for the FACS analysis (*20*).

The cellular translocation by CPP was initially proposed to be an energy-independent process, because no difference was observed in cellular uptake between 37 °C and 4 °C (*2*, *5*). However, more recent papers suggest that the majority of the translocation occurs via an energy-dependent pathway, and that the translocation of CPP is reduced by endocytosis inhibitors (*21*−*23*). From the temperature-dependence, the internalization of Arg4-L and Arg10-L was shown to mainly involve endocytosis. Endocytosis represents a variety of mechanisms that fall into two broad categories, phagocytosis and pinocytosis. Phagocytosis is typically restricted to specialized mammalian cells, whereas pinocytosis occurs in most cells via at least four basic mechanisms: macropinocytosis, clathrin-mediated endocytosis, caveolae-mediated endocytosis, and clathrin- and caveolae-independent endocytosis (*24*). In the latest papers, the translocation of Tat peptide is suggested to occur through macropinocytosis which is dependent on lipidic microdomains (*25*), and that of octa-arginine (R8) peptide is also shown to involve macropinocytosis (*26*). EIPA inhibits the Na^+/H^+ exchange and has been shown to inhibit macropinocytosis (*25*). PMA is a protein kinase C activator and stimulates macropinocytosis by increasing membrane ruffles (*27*−*30*). The change in cellular uptake of Arg4-L and Arg10-L caused by a macropinocytosis inhibitor (EIPA) or an accelerator (PMA) suggests that the internalization of Arg10-L occurs mainly through macropinocytosis. Since the cellular translocation of Arg4-L did not decrease by EIPA, it might involve a different mechanism than macropinocytosis.

Pep-1 can efficiently deliver proteins into cells by forming physical assemblies with a variety of proteins at the optimal molar ratio of pep-1 and a protein (*6*, *31*). The internalization of pep-1 alone and pep-1/β-Gal complex is not dependent on the endocytotic pathway (*6*). The cellular uptake of the Arg10-L/FITC−IgG complex was greatly enhanced starting from a molar ratio of 50 up to 100 and reached a plateau thereafter. The difference in the behavior of pep-1 and Arg10-L concerning the molar ratio with a protein might also suggest differences in their uptake mechanism.

The most striking result of the present study is that the simple complex formation between oligo-Arg-modified liposomes and proteins, without the entrapment of proteins in the internalized space of liposomes, can produce a cellular transportable protein delivery system, which can deliver active proteins into cells. $(Arg)_n$-L will be useful to deliver macromolecules, which are difficult to entrap in liposomes, into cells. Furthermore, it could release proteins in the cytoplasm because proteins bind on the outer surface of the liposomes. A short oligo-Arg on $(Arg)_n$-L alone may be enough to be taken up in cells, but a longer Arg repeat might be needed to form a complex with large proteins and deliver them into cells. The most suitable (Arg)n-L for a protein delivery could be selected experimentally based on the results of $(Arg)_n$-L complexed with the protein. Such information will be helpful in the design of $(Arg)_n$-L as a carrier for delivering proteins into cells.

In summary, we synthesized $(Arg)_n$-BDB and prepared oligo-Arg modified liposomes as a novel carrier of proteins into cells. We found that the penetrating abilities of $(Arg)_n$-L alone and in complexes with proteins differed. The mechanism of cell membrane penetration of Arg4-L and Arg10-L, and their complexes with proteins, although not thoroughly understood, is probably different.

"SMART" Drug Delivery Systems: Double-Targeted pH-Responsive Pharmaceutical Nanocarriers

R. M. Sawant, J. P. Hurley, S. Salmaso, A. Kale, E. Tolcheva, T. S. Levchenko, and V. P. Torchilin*

Department of Pharmaceutical Sciences, Northeastern University, Boston, Massachusetts 02115. Received March 30, 2006; Revised Manuscript Received May 13, 2006

To develop targeted pharmaceutical carriers additionally capable of responding to certain local stimuli, such as decreased pH values in tumors or infarcts, targeted long-circulating PEGylated liposomes and PEG-phosphatidylethanolamine (PEG-PE)-based micelles have been prepared with several functions. First, they are capable of targeting a specific cell or organ by attaching the monoclonal antimyosin antibody 2G4 to their surface via pNP-PEG-PE moieties. Second, these liposomes and micelles were additionally modified with biotin or TAT peptide (TATp) moieties attached to the surface of the nanocarrier by using biotin-PE or TATp-PE or TATp-short PEG-PE derivatives. PEG-PE used for liposome surface modification or for micelle preparation was made degradable by inserting the pH-sensitive hydrazone bond between PEG and PE (PEG-Hz-PE). Under normal pH values, biotin and TATp functions on the surface of nanocarriers were "shielded" by long protecting PEG chains (pH-degradable PEG_{2000}-PE or PEG_{5000}-PE) or by even longer pNP-PEG-PE moieties used to attach antibodies to the nanocarrier (non-pH-degradable PEG_{3400}-PE or PEG_{5000}-PE). At pH 7.4−8.0, both liposomes and micelles demonstrated high specific binding with 2G4 antibody substrate, myosin, but very limited binding on an avidin column (biotin-containing nanocarriers) or internalization by NIH/3T3 or U-87 cells (TATp-containing nanocarriers). However, upon brief incubation (15−30 min) at lower pH values (pH 5.0−6.0), nanocarriers lost their protective PEG shell because of acidic hydrolysis of PEG-Hz-PE and acquired the ability to become strongly retained on an avidin column (biotin-containing nanocarriers) or effectively internalized by cells via TATp moieties (TATp-containing nanocarriers). We consider this result as the first step in the development of multifunctional stimuli-sensitive pharmaceutical nanocarriers.

INTRODUCTION

Ideally, a nanoparticular drug delivery system (DDS) should be able (a) to specifically accumulate in the required organ or tissue and then (b) penetrate inside target cells, delivering its load (drug or DNA) intracellularly. Organ or tissue (tumor, infarct) accumulation could be achieved by the passive targeting via the enhanced permeability and retention (EPR) effect (*1*, *2*) or by antibody-mediated active targeting (*3*, *4*), while the intracellular delivery could be mediated by certain internalizable ligands (folate, transferrin) (*5*, *6*) or by cell-penetrating peptides (CPPs, such as TAT or polyArg) (*7*, *8*). Such a DDS should simultaneously carry on its surface various active moieties, i.e., be multifunctional and possess the ability to switch on and switch off certain functions when necessary, under the action of local stimuli characteristic of the target pathological zone (first of all, increased temperature or lowered pH values characteristic of inflamed, ischemic, and neoplastic tissues). Another important requirement is that different properties of the multifunctional DDS are coordinated in an optimal fashion. Thus, for example, if the system is to be constructed that can provide the combination of the longevity allowing for the target accumulation via the EPR effect and specific cell surface binding allowing for its internalization by target cells, two requirements have to be met. First, the half-life of the carrier in the circulation should be long enough to fit EPR effect requirements, and second, the internalization of the DDS by the target cells should proceed fast enough not to allow for the carrier degradation and drug loss in the interstitial space. However, development of systems such as this still represents a challenge.

Intracellular transport of different biologically active molecules is one of the key problems in drug delivery in general. Nanoparticular DDS, such as liposomes and micelles, are frequently used to increase the efficacy of drug and DNA delivery and targeting (*9*, *10*). So far, multiple and not always successful attempts have been made to deliver various drug carriers directly into the cell cytoplasm, bypassing the endocytic pathway, to protect drugs and DNA from the lysosomal degradation, thus enhancing drug efficiency and DNA incorporation into the cell genome (*11*−*14*). Within the paradigm of multifunctional DDS, one can think about the development of a DDS built in such a way that during the first phase of delivery, a nonspecific cell-penetrating function is shielded by the function providing organ/tissue-specific delivery (sterically protecting polymer or antibody). Upon accumulating in the target, protecting polymer or antibody attached to the surface of the DDS via the stimuli-sensitive bond should detach under the action of local pathological conditions (abnormal pH or temperature) and expose the previously hidden second function allowing for the subsequent delivery of the carrier and its cargo inside cells. While such DDS should be stable in the blood for a long time (hours) to allow for an efficient target accumulation, it has to lose the protective coat inside the target almost instantly to allow for the fast internalization (minutes) to minimize the washing away of the released drug or DNA. The schematic pattern of such system is shown in Figure 1. Intracellular trafficking, distribution, and fate of the carrier and its cargo can be additionally controlled by its charge and composition, which can drive it to the nuclear compartment or toward other cell organelles.

Within the past few years, it has been demonstrated that certain proteins and peptides (CPPs, such as TAT peptide,

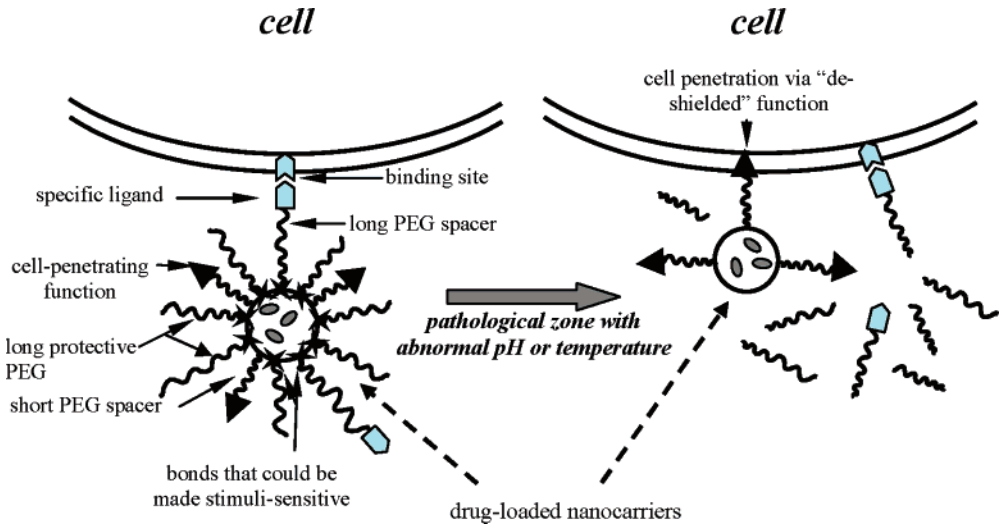

Figure 1. Interaction of the multifunctional pH-responsive pharmaceutical nanocarrier with the target cell. Local stimuli-dependent removal of protecting PEG chains or mAb-PEG moieties allows for the direct interaction of the CPP moiety with the cell membrane.

TATp) can enter cell cytoplasm directly and even target cell nuclei (*15*, *16*). CPPs have also been successfully used for the intracellular delivery of small drug molecules, large molecules (enzymes, DNA), and nanoparticulates (quantum dots, iron oxide nanoparticles, liposomes) (*13*, *17*−*22*). The mechanism of this phenomenon is still under investigation, although important progress has been already made, and it was shown that electrostatic interactions and hydrogen bonding lay behind the CPP-mediated direct transduction of small molecules (*23*, *24*), while the energy-dependent macropinocytosis is responsible for the CPP-mediated intracellular delivery of large molecules and nanoparticulates with their subsequent enhanced release from endosomes into the cell cytoplasm (*25*, *26*).

In this study, we have attempted to prepare and test in vitro stable targeted PEGylated DDS (liposomes and micelles) containing the second specific function (i.e. the intracellular internalization of the DDS), which, under normal conditions, is shielded by the protecting polymer or polymer−antibody conjugate, however can be "developed" upon brief incubation at lowered pH values characteristic of inflamed or neoplastic areas. As the first step on the way to multifunctional drug delivery systems, we have prepared liposomes and micelles sterically protected by the low pH-cleavable PEG chains and additionally containing a monoclonal antibody attached to the surface of the DDS via a noncleavable longer PEG spacer and an additional function (biotin or TATp) attached to the surface of the DDS via the noncleavable anchor shorter than the cleavable PEG chain.

MATERIALS AND METHODS

Materials. Cell lines, mouse fibroblast NIH 3T3 and human astrocytoma U-87 MG, were purchased from the American Type Culture Collection (Manassas, VA). All cell culture media, DMEM and RPMI 1640, heat-inactivated fetal bovine serum (FBS), and concentrated solutions of sodium pyruvate and penicillin/streptomycin stock solutions were purchased from Cellgro (Herndon, VA). TAT-peptide (11-mer: TyrGlyArgLys-LysArgArgGlnArgArgArg; molecular mass, 1560 Da; three reactive amino groups) was prepared by Research Genetics (Huntsville, AL). Monoclonal antibody (mAb) 2G4 was produced and purified in our laboratory. Also, pNP-PEG_{3400}-PE was synthesized and purified according to an established method in our laboratory (*27*). Egg phosphatidylcholine (PC), cholesterol, 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-750] (ammonium salt) ($mPEG_{750}$-PE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy (poly(ethylene glycol))-2000] (ammonium salt) ($mPEG_{2000}$-PE), 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(cap biotinyl) (sodium salt) (biotin-PE) 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol (sodium salt) (PE-SH), and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (ammonium salt) (Rh-PE) were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL). $mPEG_{2000}$-butyraldehyde ($mPEG_{2000}$-CHO) and $mPEG_{5000}$-butyraldehyde ($mPEG_{5000}$-CHO) was obtained from Nektar (Huntsville, AL). Control bovine antibody IgG was obtained from Serologicals Proteins, Inc. (Kankakee, IL). 3-(2-Pyridyldithio) propionyl hydrazide (PDPH) and Immobilized NeutrAvidin protein was purchased from Pierce Biotechnology, Inc. (Rockford, IL). Bovine serum albumin and all other chemicals and buffer solution components were from Sigma (St. Louis, MO) and were of analytical grade.

Synthesis of pH-Cleavable $mPEG_{2000}$-Hydrazone-Phosphatidylethanolamine ($mPEG_{2000}$-Hz-PE). Developing the method of coupling oxidized antibody to the PEG terminus through a hydrazone bond as suggested by Hansen et al. (*28*), we devised our own scheme of conjugate reaction for synthesis of pH-cleavable PEG-PE. The reaction was performed in two steps: first, the activation of $mPEG_{2000}$-CHO with PDPH, and second, the conjugation of 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol (sodium salt) (PE-SH) to activated mPEG-CHO.

For step I of the synthesis, 150 mg (64 μmol) of $mPEG_{2000}$-CHO was dissolved in dry chloroform containing 3.5 molar excess of 3-(2-pyridyldithio) propionyl hydrazide (PDPH) to obtain 50 mg/mL solution of $mPEG_{2000}$-CHO. The mixture was incubated for 48 h at room temperature with stirring under argon. Thin-layer chromatography (TLC) ($CHCl_3$:CH_3OH:H_2O, 80:20:2) revealed that the reaction was complete. The starting material $mPEG_{2000}$-CHO did not absorb UV and was positive to Dragendorff spray, while PDPH absorbed UV and was negative for Dragendorff spray. The product, $mPEG_{2000}$-Hz-PDP, absorbed UV and was positive to Dragendorff spray. Organic solvents were then removed using a rotary evaporator. $mPEG_{2000}$-Hz-PDP was then dissolved in deionized water (adjusted to pH 10−11 using 1 M NaOH) and purified from unreacted PDPH using Sepharose G25 column and deionized water (adjusted to pH 10.5 using 1 M NaOH). Pooled fractions containing $mPEG_{2000}$-Hz-PDP (Dragendorff and UV positive) were freeze-dried.

For step II of the reaction, 20 mg (26 μmol) of 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol (sodium salt) (PE-SH) was dissolved in dry chloroform containing 1.5 molar excess of $mPEG_{2000}$-Hz-PDP, to get a 10 mg/mL solution of

PE-SH. The solution was supplemented with 15 μL (approximately 3-fold molar excess over PEG) of triethylamine (TEA). The sample was incubated overnight at room temperature with stirring under argon. TLC ($CHCl_3$:CH_3OH:H_2O, 80:20:2) revealed that the reaction was complete. The starting material $mPEG_{2000}$-Hz-PDP was positive to Dragendorff spray and negative for molybdenum blue, while PE-SH was positive to molybdenum blue and negative for Dragendorff spray. The product, $mPEG_{2000}$-Hz-PE, was positive to both Dragendorff spray and molybdenum blue. The organic solvents were then removed using a rotary evaporator. The $mPEG_{2000}$-Hz-PE micelles were formed in deionized water (adjusted to pH 10.5 using 1 M NaOH) by vortexing. The micelles were separated from the unbound PEG and released pyridine-2-thione on CL-4B column using deionized water (adjusted to pH 10.5 using 1 M NaOH) as an eluent. Pooled fractions containing $mPEG_{2000}$-Hz-PE were freeze-dried and extracted with chloroform. $mPEG_{2000}$-Hz-PE was stored as 10 mg/mL chloroform solution at −80 °C under argon until further use. $mPEG_{5000}$-Hz-PE used in some experiments was synthesized in the same way starting with $mPEG_{5000}$-CHO.

Acidic pH Cleavability of $mPEG_{2000}$-Hz-PE. *TLC Analysis.* TLC-verified degradation of the polymer conjugates after pH treatment and spots corresponding to plain PEG and plain PE were observed after incubation of the polymers at pH 5.0 for 15 min at 37 °C.

HPLC Analysis. Micelles of $mPEG_{2000}$-Hz-PE were prepared containing 1 mol % of rhodamine-PE as fluorescent marker as follows. Lipid film was prepared by mixing chloroform solutions of both the lipids in a round-bottom flask and then removing chloroform using rotary evaporator. To ensure complete removal of any traces of chloroform further drying was done using lyophilizer. Appropriate volume of pH 8.5 phosphate buffer (100 mM phosphate, 150 mM sodium chloride) was added and vortexed for 2 min to form 0.5 mM solution of $mPEG_{2000}$-Hz-PE micelles. Sample was then divided into equal volumes and treated for different pH incubation. For pH 7.4 treatment, a 50 μL aliquot of the first half of the micelle formulation was applied, as is, to a Shodex KW-804 size exclusion column at regular intervals using pH 7.4 Phosphate buffer (100 mM phosphate, 150 mM sodium sulfate) was used as the eluent and run at 1.0 mL/min. Both UV (from 200 to 400 nm) and fluorescence (550/590) was used to monitor the micelles. To the second half of the micelle formulation an appropriate volume of 1 N HCl was added to get a final pH of ~5.0, aliquots of which were then analyzed as above at different intervals. As a control, micelles of $mPEG_{2000}$-PE (non-pH-sensitive micelles) were prepared and analyzed after treatment at both the pH values as above.

Kinetics of the pH-Dependent Degradation of $mPEG_{2000}$-Hz-PE. The degradation of the micelles spontaneously formed by $mPEG_{2000}$-Hz-PE under the action of the acidic pH was studied by following the presence or absence of micelles over the period of time in buffer solutions of different pHs (i.e. pH values 6.0, 7.0, 8.0, and 10). Rh-PE-labeled micelles of $mPEG_{2000}$-Hz-PE conjugate were prepared in phosphate buffer (10 mM phosphate, 150 mM NaCl) solutions of different pH values. The pH of the solution was adjusted using appropriate amounts of either 1 N HCl or NaOH. 50 μL aliquots were sampled out at different time intervals for size exclusion chromatographic analysis in 100 mM phosphate buffer (pH 7.0) containing 150 mM sodium sulfate using a fluorescence detector (EX: 550 nm, EM: 590 nm). The area under the micelle peak (mean retention time: 9.35 min) was determined for each chromatogram.

Preparation of pH-sensitive DDS. *Micelles.* For micelle preparations, a mixture of $mPEG_{750}$-PE, pH-sensitive $mPEG_{2000}$-Hz-PE, biotin-PE (or TATp-PE), and Rh-PE at molar ratio of 40:54:5:1 was prepared in chloroform. Chloroform was removed on a rotary evaporator followed by freeze-drying on a Freezone 4.5 (Labconco, Kansas City, MO). The film was hydrated with PBS, pH 8.0 (10 mM phosphate, 150 mM sodium chloride), at room temperature and vortexed for 5 min. Micelle size was controlled by using a Coulter N4 Plus submicron particle analyzer.

Liposomes. For liposome preparations, a mixture of phosphatidylcholine and cholesterol in 6:3 molar ratio and with the addition of various quantities (up to 18% mol) of PEG_{5000}-Hz-PE or $mPEG_{5000}$-PE was prepared in chloroform. When required, the composition for liposome preparation was supplemented with 0.5 to 1% mol of TATp- PEG_{2000}-PE (prepared as described earlier in (*13*)) and with 0.5% mol of Rh-PE (for the fluorescent labeling). Chloroform was removed on a rotary evaporator followed by freeze-drying on a Freezone 4.5 (Labconco, Kansas City, MO). The film obtained was hydrated with HBS buffer (pH 8.0) at room temperature for 5 min. The lipid dispersion was extruded 20 times through polycarbonate filters (pore size 200 nm) by using a Micro extruder (Avanti). Vesicle size was controlled by using a Coulter N4 Plus submicron particle analyzer.

Preparation of Immunocarriers. First, mAb 2G4 or nonspecific control bovine IgG was conjugated to pNP-PEG_{3400}-PE as in (*27*) with some modifications. Briefly, pNP-PEG_{3400}-PE and $mPEG_{750}$-PE was dried in a rotary evaporator and freeze-dryer to form a thin film. The film was hydrated with 5mM citrate buffered saline, pH 5.0, and vortexed. Antibody solution was prepared in 50mM tris-buffered saline, pH 8.7 and incubated with a 10-fold molar excess of pNP-PEG_{3400}-PE for 24 h at 4 °C to allow the attachment of the antibody to the activated PEG terminus with the simultaneous hydrolysis of nonreacted pNP groups, thus forming the antibody−micelle solution. Then, the required aliquot of this solution was added to liposomes or micelles prepared as described above and incubated for about 1 h to allow for the quantitative incorporation of the modified antibody into the appropriate DDS (*29*).

ELISA. An ELISA assay (indirect, using an enzyme-tagged secondary Ab) was performed to show the ability of the pH-sensitive immunocarriers to recognize the target antigen at different pH values (pH 8.0 and 5.0).

First, ELISA plates were coated with 50 μL of 10 μg/mL cardiac myosin and incubated overnight at 4 °C. Then, each well was washed three times with 200 μL of TBST (TBS containing 0.05% w/v Tween-20), and incubated with 50 μL of serial dilutions of 2G4 antibody (or nonspecific IgG) in TBST-casein (TBST with 2 mg/mL casein) for 1 h at RT. After incubation, the wells were washed as before and incubated with 50 μL/well of 1:5000 dilution of goat anti-mouse IgG peroxidase conjugate (ICN Biomedicals, Inc., Aurora, OH) in TBST-Casein for 1 h at RT. The wells were again washed as before, and each well was incubated with 100 μL of enhanced Kblue TMB peroxidase substrate (Neogen Corporation, Lexington, KY) for 15 min. The microplate was read at a dual wavelength of 620 nm with the reference filter at 492 nm using a Labsystems Multiskan MCC/340 microplate reader installed with GENESIS-LITE windows based microplate software.

Biotin−Avidin Binding. To test the binding of biotin-bearing Rh-PE-labeled DDS before and after incubation at lowered pH values, the corresponding samples were kept for 15 min at pH 8.0 or pH 5.0 and then applied onto the Immobilized NeutrAvidin protein column. The degree of the retention of the corresponding preparation on the column was estimated following the decrease in the sample rhodamine fluorescence at 550/590 nm after passing through the NeutrAvidin column.

Interaction of TATp-Containing pH-Sensitive DDS with

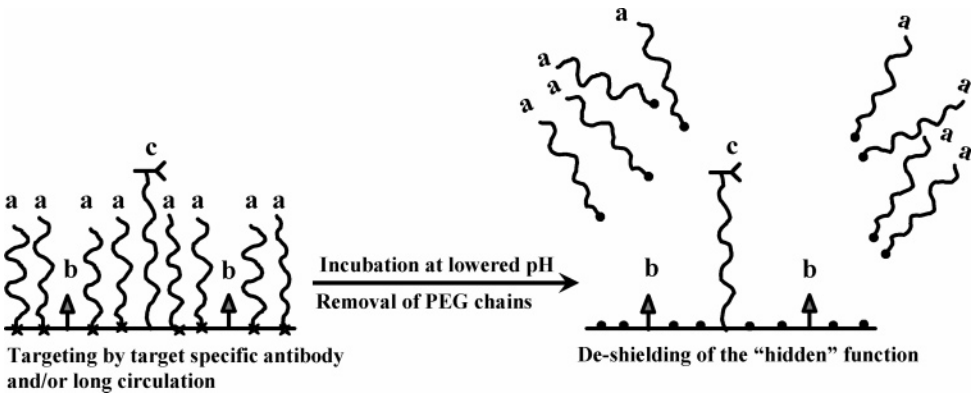

Figure 2. Schematic for the design of the multifunctional DDS used in this study that includes pH-cleavable PEG-Hz-PE (a), temporarily "shielded" biotin or TATp (b), and monoclonal antibody (c) attached to the surface of DDS via pH-noncleavable spacer.

Cells. For experiments with the micelles, NIH 3T3 cells (fibroblasts) have been chosen. After the initial passage in tissue culture flasks, NIH 3T3 cells were grown on coverslips in six-well tissue culture plates (100 000 cells per well) in DMEM with 10% BSA. After 48 h the plates were washed twice with PBS, pH 7.4 and then treated with various Rh-PE-labeled micelle samples (without and with preincubation for 15 min at pH 5.0) in serum-free medium (2 mL/well, 30 mg total PEG-PE/mL). After a 1 h incubation period, the media were removed and the plates washed with serum-free medium three times. Individual coverslips were mounted cell-side down onto fresh glass slides with PBS. Cells were viewed with a Nikon Eclipse E400 microscope under bright light or under epifluorescence with rhodamine/TRITC.

For experiments with the liposomes, U-87 MG cells (astrocytoma) have been chosen. After the initial passage in tissue culture flasks, U-87 MG cells were grown on coverslips in six-well tissue culture plates (20 000 cells per well) in DMEM with 10% BSA. After 48 h the plates were washed twice with PBS, pH 7.4, and then treated with various Rh-PE-labeled liposome samples (with and without preincubation for 20 min at pH 5.0) in serum-free medium (2 mL/well, 30 mg total lipid/mL). After a 1 h incubation period, the media were removed and the plates washed with serum-free medium three times. Individual coverslips were mounted cell-side down onto fresh glass slides with PBS. Cells were viewed with a Nikon Eclipse E400 microscope under bright light or under epifluorescence with rhodamine/TRITC.

RESULTS AND DISCUSSION

The particular design of the multifunctional DDS we have used in this study is presented in Figure 2. The suggested DDS (liposome or micelle) bears on its surface a "hidden" function (we have used biotin and TATp moieties for this purpose) inserted into the liposome membrane or micelle core via its modification with a PE moiety, protecting PEG chains (PEG_{2000}) attached to the surface via the pH-cleavable bond, and a specific antibody attached to the surface via a noncleavable long PEG spacer (PEG_{3400}). In some experiments with liposomes, cleavable PEG_{5000}-Hz-PE and noncleavable TATp-PEG_{2000}-PE conjugates have been used. Such DDS are expected to demonstrate specific targeted properties (via antibody-mediated recognition) at both normal (7.4−8.0) and acidic (5.0−6.0) pH values; however, the incubation of the DDS at lowered pH should eliminate (detach) protecting PEG chains and deshield the second function, i.e., after the exposure to the lowered pH, in addition to the immune recognition, such DDS should acquire the ability to bind with avidin column if the second, "hidden" function is biotin, or to demonstrate better internalization by cells if the second, "hidden" function is TATp. As an antibody, we have used the cardiac myosin-specific monoclonal 2G4 antibody (mAb 2G4) (*30*). The coupling of mAb 2G4 and biotin or TATp to the DDS surface was performed using the reactive derivative of poly(ethylene glycol)-phosphatidylethanolamine conjugate (PEG-PE) activated at free PEG terminus with a *p*-nitrophenylcarbonyl (pNP) group (pNP-PEG-PE) according to the protocol developed by us earlier (*27*).

Synthesis of pH-Cleavable PEG-PE Conjugate. The scheme of the synthesis of PEG-PE conjugated via the pH-cleavable hydrazone group (PEG-Hz-PE) is shown in the Figure 3. The synthesis was carried out in two steps. The first step involves the conjugation of 3-(2-pyridyldithio) propionyl hydrazide (PDPH) to $mPEG_{2000}$-CHO. The hydrazide group in PDPH reacts with the aldehyde group of $mPEG_{2000}$-CHO to form the acidic-pH-labile hydrazone bond. Since this bond is vulnerable to hydrolysis, efforts were taken to carry out the reaction in anhydrous conditions. Use of PDPH as the cross linker not only offers the advantage of forming the hydrazone bond but also introducing pyridyldisulfanyl groups for subsequent conjugation of PEG to the thiol component of 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol (PE-SH) in the second step of the synthesis. The PE-SH in the conjugate serves as a hydrophobic anchor to ensure its association with the lipid bilayer of the liposome or the hydrophobic core of micelles. All steps of the reaction were followed on TLC to confirm the progress of the reaction. The structure of the final conjugate, $mPEG_{2000}$-phospatidylethanolamine hydrazone ($mPEG_{2000}$-Hz-PE), was confirmed by the proton NMR characterization: ^{1}H NMR (500 MHz, $CDCl_3$) δ (ppm) for $mPEG_{2000}$-Hz-PE: 0.87 (t, CH_3 of lipid, 6H), 1.27 (b,s, CH_2, ≈ 56H), 2.29 (t, $OCOCH_2$, 4H), 2.40 (t, $COCH_2CH_2S$, 2H), 2.45 (t, SCH_2CH_2O, 2H), 2.5 (t, $COCH_2$-CH_2S, 2H), 2.59 (m, $CH_2CH{=}N$, 2H), 3.1 (t, CH_2CH, 2H), 3.39 (s, OCH_3 of PEG, 3H) and 3.5 (bm, PEG, ≈ 184H).

The stability of the conjugate and the kinetics of its degradation were analyzed by size-exclusion HPLC, following the area under the micelle peak on the chromatogram after conjugate incubation for different time intervals at different pH values (the conjugate spontaneously forms micelles in aqueous solutions similar to "normal" PEG-PE conjugate). Rhodamine-PE was incorporated into the micelles as a fluorescent tag, and the sample was monitored using a fluorescence detector with excitation at 550 nm and emission at 590 nm. As a typical example, HPLC for $mPEG_{2000}$-Hz-PE is shown in Figure 4; after appropriate pH treatment, the peak at retention time 9.7 min (peak for micelle) observed in case of intact micelle (pH 8.0) disappears after the incubation at pH 5.0. This disappearance of the peak is indicative of the destruction of the micelle structure due to the loss of PEG corona, while non-pH-sensitive micelles produce the peak at both pH values. Table 1 shows the representative data for the degradation kinetics of PEG_{2000}-

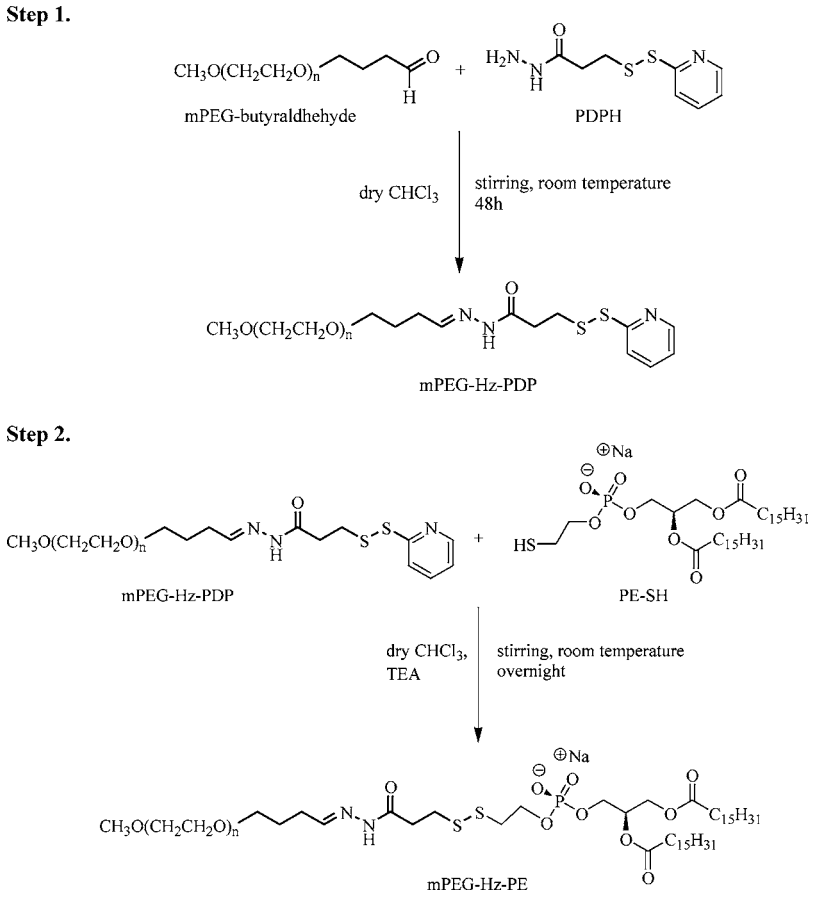

Figure 3. Schematic description of the conjugation reaction.

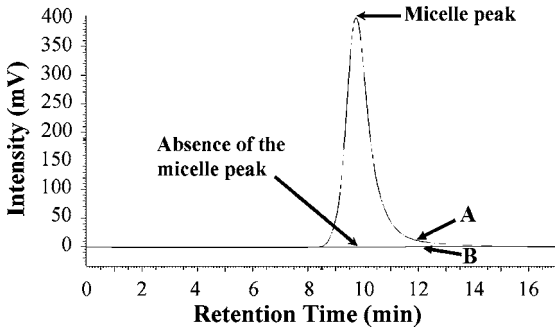

Figure 4. HPLC analysis of the pH-sensitive mPEG$_{2000}$-Hz-PE micelles after incubation in pH 8.0 (A) and after incubation in pH 5 (B) at room temperature.

Table 1. PEG$_{2000}$-Hz-PE Micelle Stability at Different pH Values (as percent of remaining micelles)

incubation tim, mine	pH 5.0	pH 7.0	pH 8.0	pH 10.0
20	3	56	94	99
40	2.5	28	62	99
60	2	10	53	99

Hz-DPPE micelles at different pH values. It is clearly seen from there that such micelles are quite stable at high pH value (8 and above), and they disintegrate within a few minutes at pH 5.0. This result was also confirmed by the TLC, when two different spots of PEG and PE were observed after a few minutes of incubation at pH 5.0 with no spot of PEG-PE seen after the incubation (data not shown).

Characterization of Liposomes and Micelles. According to the particle size analysis data, all prepared liposomes had the size within the 120-to-160 nm interval; micelle size was within the 7-to-15 nm interval. Critical micellation concentration (CMC) for both hydrolizable and nonhydrolyzable PEG-PE

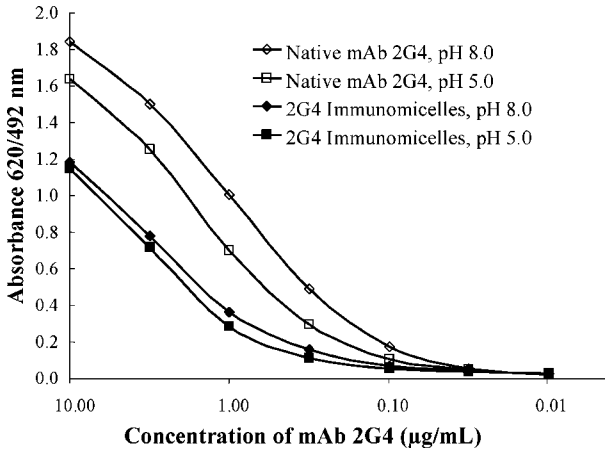

Figure 5. Binding of antimyosin mAb 2G4-PEG$_{2000}$-Hz-PE-immunomicelles to a monolayer of dog cardiac myosin in comparison to the native mAb 2G4 at corresponding pH values.

conjugates determined by the pyrene method as in ref 31 was around 1.1×10^{-5} M. The average number of antibody molecule per single 150 nm liposome determined as in ref 29 was between 60 and 80; the average number of antibody molecules per single 10 nm micelle was around 5.

Immunoreactivity of Multifunctional DDS. Fully assembled 2G4 antibody-bearing DDS demonstrated clear immunoreactivity toward the antigen. The monolayer of dog cardiac myosin in the standard ELISA test at both tested pH values, 8.0 and 5.0, are shown in Figure 5 (the results for PEG-PE-based 2G4-immunomicelles are shown). Although, one can observe some affinity decrease for the antibodies modified with the pNP-PEG-PE anchor and incorporated into the micelle structure (the same pattern is observed for immunoliposomes), this decrease is more

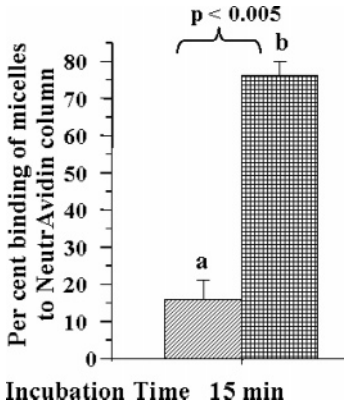

Figure 6. Binding of pH-sensitive biotin-micelles to NeutrAvidin columns after 15 min incubation at room temperature at pH 8.0 (a) and at pH 5.0 (b).

apparent than real, since not all DDS-attached antibodies, even if they remain active, can interact with the substrate because of their steric orientation on the DDS surface. In a previous study it was shown that this reduction of activity in some of the antibodies is well compensated by the multipoint interaction of the DDS with the target (*32*, *33*). Thus, the systems prepared are immunologically active at both chosen pH values. Control preparations bearing a nonspecific IgG exhibited no binding to myosin at any pH.

Avidin Binding of Multifunctional Biotin-Containing DDS. The avidin−biotin complexation was used initially as an easy-to-handle test system to follow the shielding and deshielding of the second hidden function in pH-sensitive DDS. Liposomes and micelles containing 5% mol of the biotin-PE in addition to 2G4-PEG_{3400}-PE and pH-sensitive PEG_{2000}-Hz-PE have been prepared and labeled with rhodamine-PE, and their ability to interact with avidin (NeutrAvidin affinity column) was investigated at pH 8.0 and after the brief (15 min) exposure at the lowered pH of 5.0. It was found that although biotin-containing 2G4-DDS have demonstrated identical immunoreactivity at both pH values, their ability to bind with avidin was dramatically different at pH 8.0 and after 15 min incubation at pH 5.0, which was expected to cleave away a substantial portion of the shielding PEG_{2000} micelle corona (or liposome coating). The data in Figure 6 (for micellar DDS) clearly show that while at pH 8.0 only about 15% of micelles were retained by the avidin column, after 15 min incubation at pH 5.0 about 75% of micelles were retained (the degree of the binding was estimated following the decrease in the sample rhodamine fluorescence at 550/590 nm after passing through the avidin column). This result clearly confirms that the elimination of the pH-cleavable PEG coat deshields the hidden biotin function and allows for more biotin moieties to interact with avidin on the column.

TATp-Mediated Interaction of Multifunctional DDS with Cells in Vitro. For cell culture experiments, we have used rhodamine-labeled DDS similar to those described above but containing TATp moieties attached to their surface instead of biotin groups. In this case, we have investigated DDS internalization by various cells (nontargets for the 2G4 antibody) at pH 8.0 and after the brief (20−30 min) exposure at the pH 5.0. It was found that TATp-containing DDS have also demonstrated a dramatically different ability to interact with cells at pH 8.0 and after the incubation at pH 5.0, which was expected to cleave away a substantial portion of the shielding PEG_{2000} micelle corona (or liposome coating). The data in Figure 7 clearly show that while cleavable PEG-PE-based TATp-containing micelles kept at pH 8.0 show only marginal association with NIH-3T3 murine fibroblasts, the same micelles preincubated for 30 min at pH 5.0 demonstrated dramatically enhanced association with the cells (higher fluorescence), i.e., better accessibility of TATp

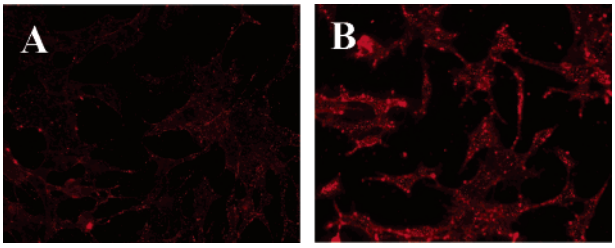

Figure 7. Fluorescence microscopy showing internalization of Rh-PE-labeled-TATp containing micelles by NIH 3T3 fibroblast cells after incubating micelles at pH 8.0 (A) and pH 5.0 (B) for 30 min.

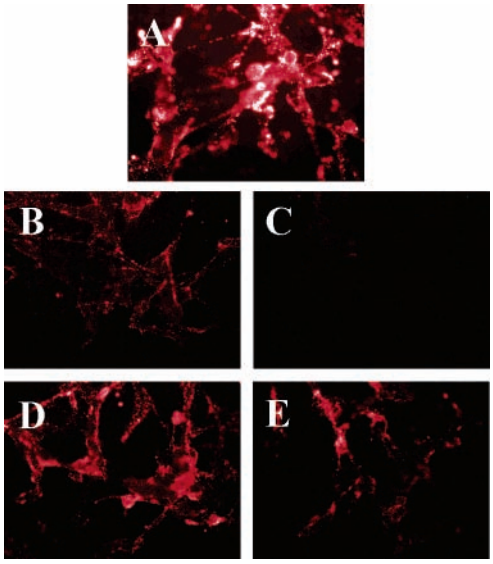

Figure 8. Fluorescence microscopy showing internalization of Rh-PE-labeled-TATp containing liposomes by U-87 MG astrocytoma cells using PEG-free TATp-liposomes (A), 9% mol pH-noncleavable PEG-PE at pH 7.4 (B), 18% mol pH-noncleavable PEG-PE at pH 7.4 (C), 9% mol pH-cleavable PEG-Hz-PE after incubation at pH 5.0 for 20 min (D)*, and 18% mol pH-cleavable PEG-Hz-PE after incubation at pH 5.0 for 20 min (E)*. *The pH of these formulations was raised back to pH 7.4 after their incubation at pH 5.0 and prior to incubation with cells.

moieties for cell interaction. In case of TAT-bearing liposomes (Figure 8), we have shown that the incorporation of 9% mol of PEG-PE strongly diminished TATp-uptake of liposomes (Figure 8B), and the incorporation of 18% mol of PEG-PE completely eliminated it (Figure 8C). However, when pH-degradable PEG-PE was used, 20 min preincubation of both preparations at pH 5.0 significantly increased the association of both preparations with cells, bringing the cell binding of the liposomes with 9% mol PEG (Figure 8D) almost back to the level of PEG-free TATp-liposomes (Figure 8A) and significantly improving the cell binding of the TATp-liposomes with 18% mol of the initial PEG (Figure 8E). These results clearly confirm that the elimination of the pH-cleavable PEG coat deshields the hidden TATp function and allows for better association of DDS with cells.

The development of the double-targeted drug carriers, which, in addition to prolonged circulation (via the attached PEG) and target recognition (via the attached antibody) carry the temporarily hidden function that can develop under the action of certain local stimuli (such as lowered pH), represent a significant step on the way toward "smart" multifunctional pharmaceutical nanocarriers capable of both target accumulation and intracellular penetration in a controlled fashion.

Synthesis of Twisted Intercalating Nucleic Acids Possessing Acridine Derivatives. Thermal Stability Studies

Imrich Géci, Vyacheslav V. Filichev, and Erik B. Pedersen*

Nucleic Acid Center, Department of Chemistry, University of Southern Denmark, Campusvej 55, DK-5230, Odense M, Denmark. Received March 7, 2006; Revised Manuscript Received May 3, 2006

Twisted intercalating nucleic acids (TINA) possessing acridine derivatives have been synthesized via the postsynthetic modifications of oligonucleotides possessing insertions of (*R*)-1-*O*-(4-iodobenzyl)glycerol (**8**) or (*R*)-1-*O*-(4-ethynylbenzyl)glycerol (**9**) at the 5′-end or in the middle as a bulge. In the first postsynthetic step, oligonucleotides **8** and **9** on the CPG support were treated with a Sonogashira coupling reaction mixture containing 9-chloro-2-ethynylacridine or 9-chloro-2-iodoacridine, respectively. After the postsynthetic step, treatment of the oligonucleotides with 32% aq ammonia or 50% ethanolic solution of tris(2-aminoethyl)amine led to the substitution of chloride on acridine concurrent with deprotection of the bases and cleavage of the oligonucleotides from CPG. Molecular modeling of the parallel triplex with a bulged insertion of the monomer (*R*)-3-*O*-[4-(9-aminoacridin-2-ylethynyl)benzyl]glycerol in the triplex-forming oligonucleotide (TFO) showed that the acridine moiety was stacking between the bases of the duplex, while phenyl was placed between the bases of the TFO. Thermal denaturation studies and fluorescence properties of TINA-acridine oligonucleotide duplexes and triplexes are discussed.

INTRODUCTION

Although double-stranded DNA (dsDNA) has long been known to form a triple-helical structure, only recently, new strategies of using triplexes in molecular biology became largely investigated. The sequence-specific recognition of dsDNA by triplex-forming oligonucleotide (TFO) has led to the transcriptional control, sequence selective treatment of genomic DNA aiming for mutated or recombined genes (*1*). Because of low stability of triplexes at physiological pH, much effort has been devoted to modifying the TFO to achieve better triplex stability.

Derivatives of 9-aminoacridine are well-known due to their broad biological activities. They are ascribed to the ability of planar acridine to stack between the nucleic acids bases (*2*). Derivatives of 6-chloro-2-methoxy-acridin-9-ylamine have been used for triplex stabilization as oligonucleotide conjugates, when covalently linked to the TFO in the middle or at the end of the sequence (*3*−*8*). In the case of 3′−3′ alternate-strand triple helix complexes, the stabilization effect has been observed, when the acridine moiety was placed on the nucleotide base flanking the 3′−3′ junction (*9*). 9-Aminoacridine conjugates stabilized Hoogsteen type triplexes with a single base pair inversion, when inserted to the oligonucleotide via a hexyl linker as a bulge. On the other hand, the absence of base pair inversion, or introduction of double base pair inversion, led to destabilization (*10*, *11*).

Recently, we observed the extraordinary stable Hoogsteen type triplexes and duplexes, when the monomer (*R*)-1-*O*-[4-(1-pyrenylethynyl)benzyl]glycerol (**1**, Figure 1) was inserted as a bulge in the middle of the TFO (*12*). At the same time, Watson−Crick duplexes were destabilized. Moreover, TINA was able to discriminate between matched and mismatched sequences. It was supposed that twisting around the triple bond could help the intercalator to fit properly inside of the dsDNA part of the triplex. Because of this property, this type of oligonucleotide was called a twisted intercalating nucleic acid (TINA).

Figure 1. TINA monomer.

In our present study, we focused on the synthesis of TINA bearing acridine derivatives instead of a pyrene-1-yl moiety in the structure of **1**. We suppose that this replacement should also lead to a high thermal stability of Hoogsteen type triplexes, as we have already seen for the naphthalene and pyrene systems (*12*). Acridine is also an attractive substituent for the incorporation of functional groups in different positions of the aromatic ring. This can be further exploited in the construction of peptide−oligonucleotide conjugates for delivery of DNA into the cell nucleus (*13*).

Here, we report the postsynthetic synthesis of (*R*)-3-*O*-[4-(9-aminoacridin-2-ylethynyl)benzyl]glycerol (**X**) and (*R*)-3-*O*-[4-(9-{2-[bis-(2-aminoethyl)amino]ethylamino}acridin-2-ylethynyl)benzyl]glycerol (**Y**) for the synthesis of the oligonucleotides **11** and **12**, respectively. Such incorporations led to an increased stability of parallel triplexes in comparison with unmodified triplexes, which were also correlated with molecular modeling and fluorescence studies.

EXPERIMENTAL PROCEDURES

Materials. Solvents were purchased from Bie and Berenstein Co., and chemicals were purchased from Aldrich Chemical Co. Solvents were sufficiently dried before they were used, and chemicals were used as purchased. Thin-layer chromatography (TLC) analyses were carried out with use of TLC plates 60 F254 purchased from Merck and were visualized in an UV light (254 nm). The silica gel (0.040−0.063 mm) used for column chromatography was purchased from Merck. Solvents used for column chromatography were distilled prior to use.

Spectroscopy. NMR spectra were measured on a Varian Gemini 2000 spectrometer at 300 MHz for ^{1}H using TMS (δ: 0.00) as an internal standard and at 75 MHz for ^{13}C using $CDCl_3$ (δ: 77.0) as an internal standard. Mass spectra of the synthesized compounds were determined on the Ionspec 4.7 T HiResMALDI Ultima Fourier transform (FT) mass spectrometer (Ion Spec, Irvine, CA). The $[M + Na]^+$ ions were peak matched using ions derived from the 2,5-dihydroxybenzoic acid matrix. Electrospray ionization mass spectra (ESI-MS) were performed on 4.7 T HiResESI Ultima (FT) mass spectrometer. Both spectrometers are controlled by the OMEGA Data System. MALDI-TOF mass spectra of isolated oligodeoxynucleotides (ONs) were determined on a Voyager Elite biospectrometry research station (PerSeptive Biosystems).

Molecular Modeling. Molecular modeling experiments and the construction of the modified triplex were performed using the program MacroModel 8.0. 2-Phenylethynyl-9-aminoacridine was energy-minimized with MM3 method before being inserted to the triplex. The starting 14-mer parallel triplex was built via consecutive superimposition of triples (CGC) and (TAT), which were generated with Insight II v9.72 from MSI and transported to MacroModel.

The insertion of the acridine intercalator was done in several steps. TFO was disconnected by deletion of the phosphate group in place of the predicted bulged insertion. Afterward, 2-phenylethynyl-9-aminoacridine was placed between the bases of the triplex, and minimization was performed to extend the triplex and create enough space for the intercalator. The triplex was reconnected by addition of the two phosphate groups with an ethyleneglycol linker between, which were supposed to be a part of the linker. The structure was again minimized. The intercalator was connected to the TFO backbone by creating the site chain, taking into consideration the stereochemistry of the linker and the whole structure possessing (*R*)-3-*O*-[4-(9-aminoacridin-2-ylethynyl)benzyl]glycerol as a bulge was again energy-minimized.

All molecular dynamics simulations were achieved with the AMBER* force field. The stochastic dynamics calculation generating 250 structures was performed using a water solvent model and extended cutoff potential. The simulation temperature was 300 K, the simulation time was 400 ps, and the equilibration time was 100 ps. In the next step, all 250 structures were minimized at the same time by a multiple minimization method. For classification of founded conformations, the XCluster program was used, in which the lowest energy representative structure was selected.

Measurement of Melting Temperatures (T_m). Melting profiles were measured on a Perkin-Elmer UV/vis spectrometer Lambda 35 fitted with a PTP-6 temperature programmer. The parallel triplexes were formed by mixing the two strands of the Watson−Crick duplex each at a concentration of 1.0 μM and the TFO at a concentration of 1.5 μM in the corresponding buffer solution. The solution was heated to 80 °C for 5 min and afterward cooled to 15 °C for 30 min. The antiparallel duplexes were formed by mixing the two strands, each at a concentration of 1.0 μM in the corresponding buffer solution followed by heating to 70 °C for 5 min and then cooling to room temperature. The absorbance of both triplexes and duplexes was measured at 260 nm from 10 to 70 °C with a heating rate of 1.0 °C/min. The melting temperatures (T_m, °C) were determined as the maximum of the first derivative plots of the melting curves.

Fluorescence Measurements. Fluorescence measurements were carried out on a Perkin-Elmer luminescence spectrometer LS-55 fitted with a Julabo F25 temperature controller. The spectra were recorded at 10 °C in the same buffer solution as for T_m studies using a 1.0 μM concentration of each ON. The excitation slit was set to 4 nm, and the excitation wavelength was 322 nm. The emission slit for **ON11** and **ON12** was set to 2.5 nm and for **ON4** and **ON5** was set to 0 nm.

Synthesis of 9-Chloro-2-ethynylacridine (3). 9-Chloro-2-iodoacridine (**2**, ref *17*) (0.34 g, 1 mmol), $PdCl_2(PPh_3)_2$ (14 mg, 0.02 mmol), and CuI (8 mg, 0.04 mmol) were added to a round-bottomed flask flushed with Ar. The flask was again flushed for the next 5 min with Ar. Afterward, THF (3 mL) and Et_3N (1 mL) were added, and Ar was bubbled through the mixture for 10 min. Trimethylsilylacetylene (TMSA, 0.155 mL, 1.1 mmol) was added, and the reaction was completed after 30 min at room temperature under Ar. The solvent was evaporated in vacuo. The residue was dissolved in CH_2Cl_2 (15 mL) and washed with H_2O (3 × 20 mL). The organic layer was dried (Na_2SO_4), filtered, and evaporated in vacuo. The crude product was purified using silica gel dry column vacuum chromatography with cyclohexan/acetone (1%, v/v). 9-Chloro-2-trimethylsilylethynylacridine was obtained in 98% yield (0.15 g) as a yellow powder. ^{1}H NMR (DMSO-d_6) δ 0.36 (s, 9H, 3 × CH_3), 7.63 (m, 1H, Ar), 7.80 (m, 2H, Ar), 8.17 (m, 2H, Ar), 8.38 (d, 1H, J = 9.2 Hz, Ar), 8.56 (d, 1H, J = 2.4 Hz, Ar); ^{13}C NMR (DMSO-d_6) 0.2 (3 × CH_3), 97.4, 104.6 (*C*≡*C*), 121.7, 123.8, 124.7, 127.2, 128.5, 129.8, 130.6, 130.9, 133.1, 140.8, 148.1, 149.2 (Ar); HR-MALDI-MS: *m*/*z* calcd for $C_{18}H_{17}NClSi$ $[M + H]^+$ 310.0813, found 310.0809.

The trimethylsilyl compound (0.15 g, 0.48 mmol) was dissolved in THF (6 mL), and $Et_3N{\cdot}3HF$ (26 μL, 0.48 mmol) was added. The reaction mixture was stirred at room temperature overnight. The solvent was evaporated in vacuo, and acridine **3** was purified using silica gel dry column vacuum flash chromatography with acetone (1%, v/v)/cyclohexane in quantitative yield (0.115 g). ^{1}H NMR (DMSO-d_6) δ 2.21 (s, 1H, C≡CH), 7.24−7.86 (m, 5H, Ar), 8.32 (d, 1H, J = 8.7 Hz, Ar), 8.62 (d, 1H, J = 2.2 Hz, Ar); ^{13}C NMR (DMSO-d_6) 82.3 (C≡*C*H), 97.9 (*C*≡CH), 116.2, 118.4, 119.8, 125.0, 132.2, 131.1, 133.6, 138.9, 139.6, 143.4, 147.5, (Ar); HR-MALDI-MS: *m*/*z* calcd for $C_{15}H_9NCl$ $[M + H]^+$ 238.0418, found 238.0427.

(*S*)-1-*O*-(4,4′-Dimethoxytriphenylmethyl)-3-*O*-(4-ethynylbenzyl)glycerol (5). To the solution of (*R*)-3-*O*-(4-iodobenzyl)-glycerol (**4**, 1.18 g, 4.2 mmol) in DMF (40 mL) was added Et_3N (5.8 mL), and Ar was bubbled through the solution for 30 min. Afterward, TMSA (0.67 g, 4.62 mmol) was dissolved under Ar, and CuI (48 mg, 0.25 mmol) and $Pd(PPh_3)_4$ (96 mg, 0.08 mmol) were added to the mixture. This was stirred at room temperature under Ar overnight, followed by the addition of $Et_3N{\cdot}3HF$ (0.38 mL, 2.38 mmol). After 30 min, CH_2Cl_2 (100 mL) was added, and the mixture was extracted with a 0.3 M aq solution of ammonium salt of EDTA (2 × 75 mL). The organic layer was washed with H_2O (3 × 100 mL), dried (Na_2SO_4), filtered, and evaporated in vacuo to dryness. The residue was coevaporated twice with toluene/EtOH (50 mL, 3:1, v/v) affording (*R*)-1-*O*-(4-ethynylbenzyl)glycerol as an oil. The oil was coevaporated with pyridine (20 mL) and then dissolved in anhydrous pyridine (75 mL) and cooled by an ice water bath, and 4,4′-dimethoxytrityl chloride (1.45 g, 4.41 mmol) was added under Ar. The mixture was stirred at room temperature for 16 h, and then an extra portion of 4,4′-dimethoxytrityl chloride (0.7 g, 2.1 mmol) was added. After 24 h, TLC showed no more starting material, and the reaction mixture was quenched by MeOH (2 mL), diluted with EtOAc (150 mL), and extracted with saturated aq $NaHCO_3$ (2 × 100 mL). The water phase was extracted with EtOAc (2 × 50 mL). The combined organic layers were dried (Na_2SO_4), filtered, and evaporated under diminished pressure. The residue was coevaporated twice with toluene/EtOH (25 mL, 1:1, v/v). The residue was dissolved in EtOAc (50 mL) and adsorbed on silica gel (2.5 g) by evaporation in vacuo and subsequently purified using dry column vacuum

chromatography with Et_3N (0.5%, v/v)/EtOAc (0−50%)/cyclohexane to afford (*S*)-1-*O*-(4,4′-dimethoxytriphenylmethyl)-3-*O*-(4-ethynylbenzyl)glycerol (**5**, 58%, 1.23 g) as a yellow foam. ^{1}H NMR ($CDCl_3$) δ 2.48 (br. s, 1H, OH), 3.06 (s, 1H, C≡CH), 3.21 (dd, 2H, J = 5.1 and 7.7 Hz, CH(OH)CH_2OCH_2), 3.57 (m, 2H, CH_2ODMT), 3.78 (s, 6H, 2 × OCH_3), 3.95 (m, 1H, *CH*OH), 4.52 (s, 2H, CH_2Ph), 6.80 (d, 4H, J = 8.8 Hz, DMT), 7.20−7.50 (m, 13H, CH_2−Ph and DMT); ^{13}C NMR ($CDCl_3$), 55.2 (OCH_3), 64.3 (*C*HOH), 69.9 (CH(OH)CH_2OCH_2), 71.6 (CH_2ODMT), 72.8 (CH_2-phenyl), 76.5 (C≡*C*H), 83.4 (*C*≡CH), 86.1 [*C*(Ar)$_3$], 121.3, 128.8, 132.1, 138.9 (phenyl), 113.1, 126.7−129.9, 135.9, 144.8, 158.5 (DMT); HR-MALDI-MS: *m*/*z* calcd for $C_{33}H_{32}Na^+O_5$ $[M + Na]^+$ 531.2142, found 531.2143.

(*S*)-2-*O*-[2-Cyanoethoxy(diisopropylamino)phosphino]-1-*O*-(4,4′-dimethoxy triphenylmethyl)-3-*O*-(4-ethynylbenzyl)-glycerol (6). (*S*)-1-*O*-(4,4′-Dimethoxytriphenylmethyl)-3-*O*-(4-ethynylbenzyl)glycerol (**5**, 1.2 g, 2.4 mmol) was dissolved under nitrogen in anhydrous CH_2Cl_2 (50 mL). *N*,*N*-Diisopropylammonium tetrazolide (0.62 g, 3.6 mmol) was added followed by dropwise addition of 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphordiamidite (0.95 g, 3.2 mmol) under external cooling with an ice water bath. After 24 h, analytical TLC showed no more starting material, and the reaction was quenched with H_2O (30 mL). Layers were separated, and the organic phase was washed with H_2O (30 mL). Combined water layers were washed with CH_2Cl_2 (25 mL). Combined organic phase was dried (Na_2SO_4) and filtered, and silica gel (1.5 g) and pyridine (0.5 mL) were added. The solvents were removed under reduced pressure. The residue was purified using silica gel dry column vacuum chromatography with Et_3N (0.5%, v/v)/EtOAc (0−25%)/cyclohexane. Combined UV-active fractions were evaporated in vacuo affording the final compound **6** (1.45 g, 85%) as a foam that was used in DNA synthesis. ^{31}P NMR ($CDCl_3$) δ 150.3, 150.4 in a ratio of 3:2; HR-MALDI-MS: *m*/*z* calcd for $C_{42}H_{49}N_2Na^+O_6P$ $[M + Na]^+$ 731.3220, found 731.3246.

Solid-Phase Synthesis of TINA-Acridine Oligonucleotides. DMT-on oligodeoxynucleotides were synthesized in a 0.2 μmol scale on CPG supports using Expedite Nucleic Acid Synthesis System Model 8909 (Applied Biosystems), using 4,5-dicyanoimidazole as an activator and a 0.075 M solution of the corresponding phosphoramidites **6** and **7** in a 1:1 mixture of dry MeCN/CH_2Cl_2. For insertion of the monomer **6** or (*S*)-2-*O*-[2-cyanoethoxy(diisopropylamino)phosphino]-1-*O*-(4,4′-dimethoxytriphen ylmethyl)-3-*O*-(4-iodobenzyl)glycerol (**7**, ref *12*), the increased coupling (2 min) and deprotection (100 s) time were used. DMT-on oligonucleotides **8** and **9** on a CPG supports were treated twice with a freshly prepared Sonogashira coupling reagent mixture consisting of $Pd(PPh_3)_4$ (8.7 mg, 0.08 mmol), CuI (1.4 mg, 0.25 mmol), DMF/Et_3N (3.5:1.5, 500 μL), and iodoacridine **2** (5.4 mg, 22.5 μmol) in the case of sequence **9** (Method B) or ethynylacridine **3** (7.6 mg, 22.5 μmol) in the case of sequence **8** (Method A, Scheme 3). The reaction mixture was prepared by weighing all the reagents in a 1 mL plastic syringe followed by flushing with Ar and the addition of DMF and Et_3N. The syringe was connected to the one side of the column with the oligonucleotide on a CPG support. This system was thoroughly shaken to dissolve reagents, and another syringe was connected to another end of the column. The reaction mixture was thoroughly flushed from one syringe to the other through the column several times, and this operation was repeated every 45 min for 3 h. Obtained DMT-on oligonucleotide **10** bound to CPG supports was treated with 32% aq ammonia (1 mL) or with a freshly prepared 50% ethanolic solution of tris(2-aminoethyl)amine (1 mL) at room temperature for 2 h and then at 55 °C overnight. Purification of 5′-*O*-DMT-on ONs was accomplished using a reverse-phase semipreparative HPLC on a Waters Xterra MS C_{18} column. DMT groups were cleaved with 80% AcOH (100 μL) for 20 min. Afterward, H_2O (100 μL) and 3 M aq AcONa (50 μL) were added, and ONs were precipitated from 99% EtOH (550 μL). Their purity was found to be over 80% by ion-exchange chromatography on a LaChrom system (Merck Hitachi) using a GenPak-Fax column (Waters).

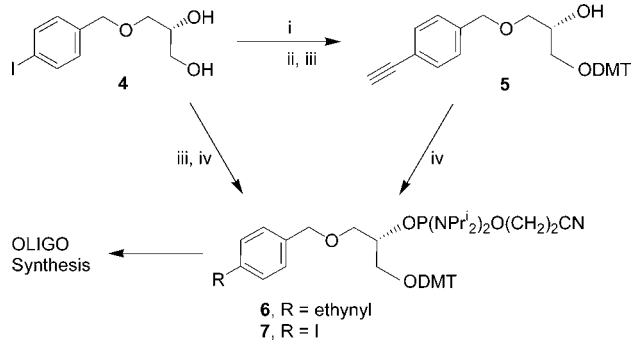
RESULTS AND DISCUSSION

Synthesis of TINA-Acridine. We decided to use 9-chloro-2-ethynylacridine (**3**, Scheme 1), which can be coupled by a Sonogashira reaction to the ONs possessing an insertion of the previously described monomer **7** (*12*). Afterward, the chloride in the nine position of the acridine can be substituted by primary amines. Free amino groups can be protonated under physiological conditions and therefore reduce the electrostatic repulsion between the phosphates of the nucleic acid backbones. This may stabilize nucleic acid duplexes and triplexes. Oligonucleotides possessing 2-methoxy-2-oxoethyl (*14*), methoxyoxalamido (*15*), and benzyl thioester (*16*) precursor groups have been successfully derivatized using different primary amines in high yields. Simultaneously, the base and phosphate protective groups were removed, and the desired oligonucleotides were cleaved from the solid support. The use of secondary amines (40% aq dimethylamine) resulted in a considerably lower conversion of the oligonucleotides (*14*).

The starting 9-chloro-2-iodoacridine (**2**, ref *17*) was prepared by Ullmann condensation from *o*-chlorobenzoic acid and *p*-iodoaniline in the presence of Cu and K_2CO_3 in refluxing *i*-amyl alcohol in 20% yield followed by cyclization with $POCl_3$ in 75% yield. The yield of the Ullmann condensation was increased to 48%, when the reaction was done in refluxing 2-methoxyethanol (*18*). In the next step, the Sonogashira reaction with TMSA took place selectively on iodine. When $PdCl_2(PPh_3)_2$ instead of $Pd(PPh_3)_4$ was used as a catalyst (2 mol %), the reaction was finished in 30 min in 99% yield as compared to 24 h and 20% yield for $Pd(PPh_3)_4$. In the latter case, the addition of the fresh portion of the catalyst did not increase the yield. To obtain the high yield of the product, it was also necessary to remove the oxygen from the reaction environment with argon. The Sonogashira reaction has been demonstrated on 9-chloroacridine (*19*), but the substitution of the iodine atom in compound **2** by TMSA was confirmed by the characteristic signals in ^{13}C NMR and by mass spectrometry. Thus, the shift from 93.2 ppm (compound **2**) to 121.7 ppm (compound **3**) in ^{13}C NMR was observed for the C-2 atom of the acridine ring, which corresponded to the substitution of iodine. At the same time, the chemical shift in ^{13}C NMR of the C-9 atom of the acridine bearing chlorine remained in the same region: 130.0 and 130.6 ppm for compounds **2** and **3**, respectively. The mass spectra (HiResMALDI) of **3** confirmed the presence of the chlorine atom in the structure. The protective trimethylsilyl group was removed using Et_3N·3HF in THF at room temperature, and acridine **3** was obtained in quantitative yield. The required TINA precursor (*R*)-1-*O*-(4-iodobenzyl)-glycerol phosphoramidite **7** was synthesized in four steps as previously described (*12*), and it was used in the synthesis of ON **8** (Method A).

Scheme 2. Synthesis of (4-Ethynylbenzyl)glycerol Phosphoramidite[a]



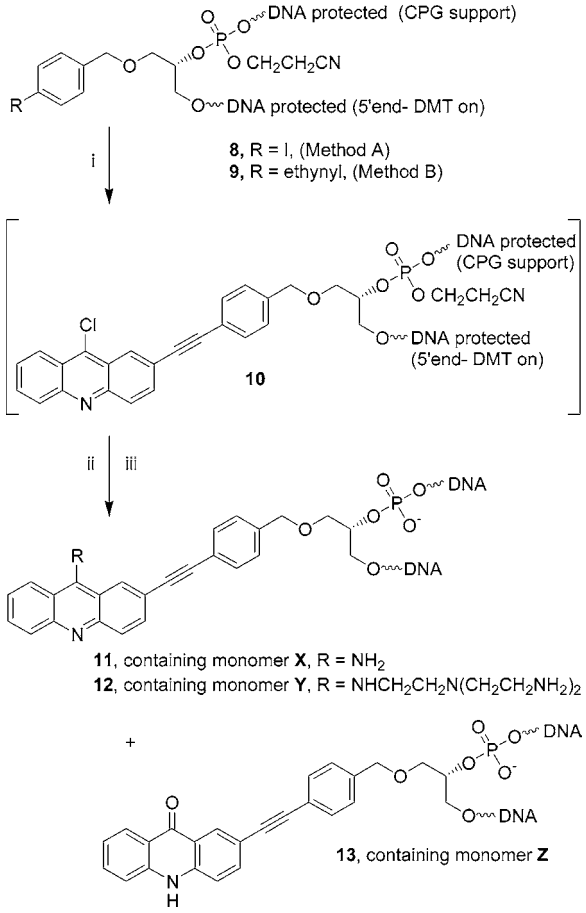
[a] (i) TMSA, CuI, $Pd(PPh_3)_4$, Et_3N/DMF, room temperature, Ar, overnight. (ii) $Et_3N{\cdot}3HF$, CH_2Cl_2. (iii) DMTCl, pyridine, 0 °C, Ar, 24 h. (iv) $NC(CH_2)_2OP(NPr^i_2)_2$, diisopropylammonium tetrazolide, CH_2Cl_2, 0 °C to room temperature, 24 h.

Because of the selectivity observed in the Sonogashira reaction between TMSA and acridine **2**, we decided to explore an alternative route using compound **2** for the conversion ONs into TINA-acridine oligonucleotides (Method B). For this purpose, the (*R*)-1-*O*-(4-ethynylbenzyl)glycerol phosphoramidite **6** was synthesized in four steps from (*R*)-3-*O*-(4-iodobenzyl)-glycerol (**4**) in 49% overall yield (Scheme 2). The latter compound was treated with the Sonogashira reaction mixture having TMSA followed by cleavage of the silyl protective group with $Et_3N{\cdot}3HF$, which was done in one pot affording (*R*)-3-*O*-(4-ethynylbenzyl)glycerol. This compound was used in the next step without chromatographic purification. Compound **5** was obtained in 56% overall yield from **4** after protection of the primary alcohol with DMTCl in dry pyridine. Treatment of compound **5** with 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphosphordiamidite in the presence of diisopropylammonium tetrazolide in dry CH_2Cl_2 overnight followed by silica gel purification gave the phosphoramidite **6**, which was used in DNA synthesis. Corresponding ONs **9** were prepared, applying the same conditions as for **8** (*12*). To avoid the transamination during the treatment with amines, dC^{Ac} phosphoramidite was used for the incorporation of 2′-deoxycytidine into ONs. Standard phosphoramidites for the incorporation of A, T, and G and commercial CPG solid supports were used.

For the postsynthetic Sonogashira type modification on a solid phase, ONs with an insertion of (*R*)-1-*O*-(4-iodobenzyl)glycerol (**8**) or (*R*)-1-*O*-(4-ethynylbenzyl)glycerol (**9**) in the middle and at the 5′-end were used. CPG supports with DMT-on ONs **8** or **9** were treated with a freshly prepared Sonogashira coupling reagent mixture possessing ethynylacridine **3** or iodoacridine **2**, respectively (Scheme 3). In both cases, the same product **10** on a solid support was obtained. However, we preferred to use Method B because the preparation of compound **9** is easy. In a previous study, it has been determined that double treatment of the CPG-bound oligonucleotides with a freshly prepared Sonogashira mixture increased the coupling efficiency (*12*). In our case, it was also obligatory due to the low solubility of acridines **2** and **3** in DMF/Et_3N at room temperature. We have now shown that the previously reported postsynthetic Sonogashira coupling on ONs can be extended to aromatic heterocyclic systems (*12*). Furthermore, this route was an advantage in our case because the required phosphoramidite for the synthesis of ONs **8** and **9** was readily available in our laboratory.

In the second postsynthetic step, the treatment of ONs **10** with 32% aq ammonia or a 50% ethanolic solution of tris(2-aminoethyl)amine at 55 °C overnight led to the substitution of the chlorine atom on acridine. The cleavage of ONs from the CPG support and deprotection of the bases and phosphates were performed in the same step. The reaction mixture was purified

Scheme 3. Postsynthetic Modification of Oligonucleotides[a]



[a] (i) Reaction of **8** with **3** or reaction of **9** with **2** both using $Pd(PPh_3)_4$, CuI, DMF/Et_3N, Ar. (ii) 32% NH_4OH or 50% ethanolic solution of tris(2-aminoethyl)amine, room temperature for 2 h then 55 °C overnight. (iii) RP-HPLC; 80% aq AcOH, 3 M aq AcONa, 99% EtOH.

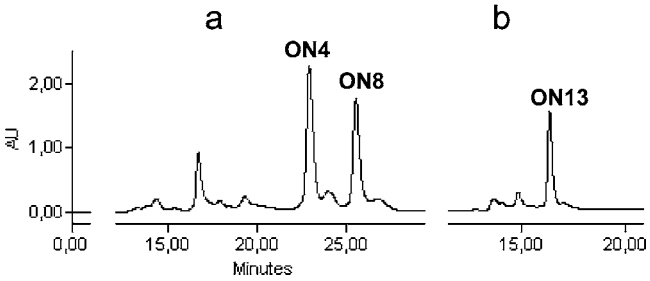


Figure 2. Reverse-phase HPLC profiles of oligonucleotides **11** (a) after treatment of ON **10** using 32% aq ammonia (isolated **ON4** at 22.4 min and **ON8** at 25.2 min). (b) After treatment of ON **10** using a 50% ethanolic solution of tris(2-aminoethyl)amine (isolated **ON13** at 16.4 min).

by semipreparative HPLC on a C_{18} column. UV-active fractions after evaporation of the solvent were treated with 80% aq AcOH to remove DMT protective groups followed by precipitation from EtOH. ONs were characterized by MALDI-TOF MS. Treatment of ONs **10** with secondary amines (*N*,*N*-dimethylethylenediamine or piperazin) gave no desired product after reaction at 55 °C for several days.

In the case of treatment of ON **10** with 32% aq ammonia, two peaks at 22.4 and 25.2 min were collected during HPLC purification (Figure 2a), which gave the same *m*/*z* values in MALDI-TOF. More accurate determination was performed using ESI mass spectrometry. For the fraction that appeared at 22.4 min, the *m*/*z* peak was detected at 4580.98 Da. For the second fraction, *m*/*z* was found to be 4581.99 Da. According

[a] [1] c = 1.0 μM each oligonucleotide in 140 mM NaCl, 10 mM sodium phosphate buffer, 1 mM EDTA, pH 7.0. [2]The T_m values were taken from a previous study (*12*). [3]Not determined. [4]Measured by MALDI-TOF MS.

to calculated mass, the fraction appearing at 22.4 min corresponded to **11** (**ON4**) containing the **X** monomer with 9-aminoacridine. One dalton difference *m/z* for the peak at 25.2 min means that the use of 32% aq ammonia for the modification of **10** resulted also in the formation of **13** (**ON8**) containing the **Z** monomer with 9-oxoacridine. It has been shown previously that in the reaction of 9-chloroacridine with amines, 9-oxoacridine also can be observed as a side product (*20*). From RP-HPLC profiles in Figure 2a,b, we observed a high conversion of ONs during the two postsynthetic steps. The lowest amounts of ONs were obtained in the case of treatment with a 50% ethanolic solution of tris(2-aminoethyl)amine.

Thermal Stability and Fluorescence Studies. Melting temperatures (T_m) of parallel triplexes and antiparallel duplexes consisting of **ON1**−**ON13** were estimated as the first derivative of melting curves and are shown in Tables 1 and 2. For comparison, previously published data for TINA possessing monomer **1** are also listed in Tables 1 and 2.

Stabilization of parallel triplexes was found in all cases when compared with the wild-type **ON1** at pH 5.0, 6.0, and 7.2 (Table 1). TINA-acridine intercalators **X**−**Z** gave less stable parallel triplexes, when inserted as a bulge in the middle of TFO as compared to **ON2** possessing a pyrene derivative **1** (*12*). In the case of **ON5** bearing 9-aminoacridine **X** at the 5′-end, the triplex stabilization was found to be similar as for TINA-pyrene (**ON3**). The similarity in T_m values for **ON4** and **ON8** means that the contribution of the amino group connected directly to the acridine ring (monomer **X**) into the triplex stabilization is negligible. The introduction of the 2-[bis-(2-aminoethyl)amino]-ethylamino group by reaction of **10** with tris(2-aminoethyl)-amine (monomer **Y**) in the middle of the TFO (**ON6**) led to lower triplex stabilization as compared with **ON4**. Moreover, the incorporation of the monomer **Y** at the 5′-end of the TFO (**ON7**) led to the least stabilized modified triplexes studied here. We suppose that the latter effect is due to electrostatic interactions between the positively charged cytosine of TFO and the protonated amino groups in the monomer **Y**.

When monomers **X** and **Y** were incorporated as a bulge in the middle of the oligodeoxynucleotides (**ON11** and **ON13**) (Table 2), destabilization of antiparallel DNA/DNA and DNA/RNA duplexes was observed when compared with the wild-type duplexes **ON9**/**ON14** and **ON9**/**ON15**. This destabilization effect was found to be smaller as compared with the TINA-containing pyrenyl moiety (**ON10**) ($T_{m\mathbf{ON11/ON14}} - T_{m\mathbf{ON10/ON14}}$ = 5.0 °C). Such a difference can be explained by a lower number of fused benzene rings in acridine than in pyrene and

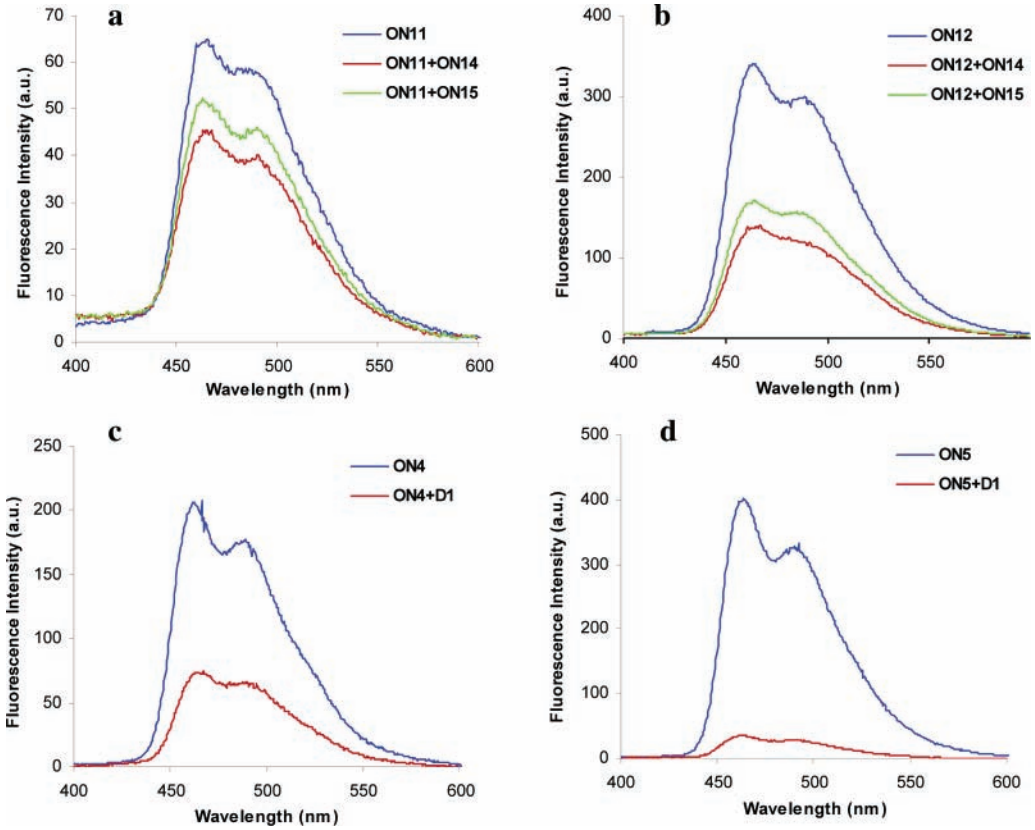

Figure 3. Fluorescence emission spectra of TINA bearing 9-aminoacridine inserted in the middle (a) and at the 5′-end (b) of the duplex and at the middle (c) and at the 5′-end (d) of the triplex.

by the presence of amino groups in **X** and **Y**. When the intercalator **X** was inserted at the 5′-end (**ON12**) as a dangling end, stabilization of the DNA/DNA ($\Delta T_m = +6.0$) and DNA/RNA ($\Delta T_m = +5.0$) duplexes was observed.

We studied fluorescence properties of TINA bearing 9-aminoacridine (**X**) in the middle and at the 5′-end of ONs in the structure of Hoogsteen type triplexes and Watson−Crick duplexes. When the modification was placed in the middle of the strand (**ON11**, Figure 3a), no quenching of the fluorescence intensity was observed for DNA/DNA and DNA/RNA duplexes, when compared with the single-strand **ON11**. However, the fluorescence intensity of **ON4** at the same excitation wavelength was quenched considerably, when a parallel triplex was formed (Figure 3c). Quenching was also observed upon both duplex and triplex formation with the oligonucleotides **ON12** and **ON5**, respectively, upon insertion of the acridine moiety at the 5′-end (Figure 3b,d). This can be explained by a partial quenching of the monomer fluorescence as a result of communication of the acridine with neighboring bases upon its insertion in the middle of the sequence. These results indicate that the acridine ring in the structure of TINA intercalates better, when inserted in the TFO strand of the parallel triplexes, than insertion of the TINA-acridine moiety in one of the strands of the antiparallel duplexes. This is also in agreement with the melting studies from the present work.

Molecular Modeling. Modeling studies were carried out to provide better structural understanding of binding of the acridine derivative in the parallel triplex mode used in triplex experiments (**ON4** + **D1**). Such a triplex structure was modified by the insertion of (*R*)-3-*O*-[4-(9-aminoacridin-2-ylethynyl)benzyl]-glycerol (**X**) as a bulge in the middle of the 14-mer sequence (Figure 4a,b).

According to the structure minimized by the AMBER* force field, 9-aminoacridine was stacked between the bases of the dsDNA, while the phenyl was placed in the TFO strand. Twisting around the triple bond of 19.3° was also observed for structure **X**, which is shown on the detailed view in Figure 4b. As it can be seen in Figure 4a, the amino group in the ninth position of the acridine was directed into the major groove of dsDNA. This can explain why the presence of both the amino group and the 2-[bis-(2-aminoethyl)amino]ethylamino group at position 9 of the acridine did not give a great contribution in thermal stabilization of the parallel triplex. With this orientation, these groups cannot reach the phosphates of the nucleic acid backbone and neutralize the negative charge. According to modeling, directing the amino group into the minor groove gave more energy-rich structures. It can be proposed that substitutions at positions 4 and 5 of the acridine ring or at position 10 of the acridone should direct aminoalkyl groups in the minor groove of dsDNA and point amines closer to phosphates by the appropriately chosen alkyl linker.

To elucidate the destabilization of duplexes, we simulated the intercalation of **X** in the modeling of the antiparallel duplex **ON11**/**ON14**. The amino group was directed into the minor or into the major groove, as is shown in Figure 4c,d, respectively. After the comparison of potential energies of the leading conformations obtained from AMBER* calculations, it was found that the preferable position of the acridine is when the amino group is directed into the minor groove. A twisting around the triple bond of 34.9° was observed. However, in both cases, the stacking of the intercalator between the bases was imperfect. These results are in agreement with the lower T_m values of the duplexes, and they explain also the negligible fluorescence quenching of the acridine upon duplex formation.

CONCLUSION

In this paper, we describe the postsynthetic synthesis of twisted intercalating nucleic acids possessing acridine derivatives. Using the Sonogashira reaction, 9-chloroacridine was

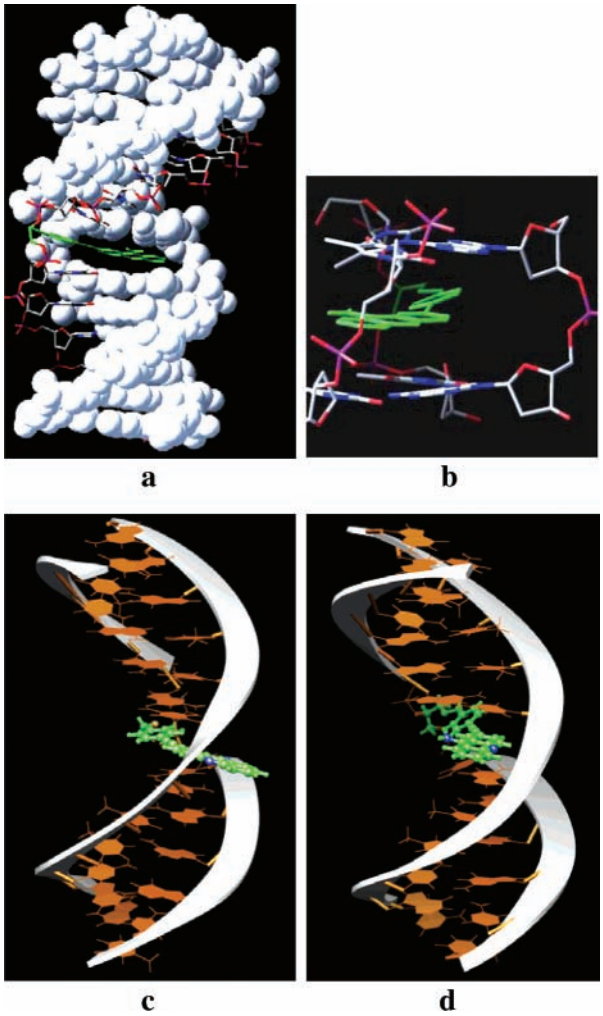

Figure 4. (a) Energy-minimized averaged AMBER* representative structure of the parallel triplex-containing (*R*)-3-*O*-[4-(9-aminoacridin-2-ylethynyl)benzyl]glycerol (**X**) (dsDNA displayed in CPK form in white, TFO in stick form as well as the TINA-acridine intercalator marked with green). (b) Detailed view of the monomer **X** placed between the two triples showing the torsion between the acridinyl and the phenyl ring connected via acetylene. (c) Representative structure of the antiparallel duplex-containing monomer **X** directed into the minor groove. (d) Representative structure of the antiparallel duplex-containing monomer **X** directed into the major groove.

introduced into ONs possessing TINA precursor monomers **8** and **9**. In the second postsynthetic step, treatment of ONs **10** with aq ammonia or ethanolic tris(2-aminoethyl)amine allowed substitution of the chlorine atom on acridine, cleavage from the CPG support, and deprotection of the bases in one pot.

Thermal denaturating studies showed that the introduction of acridine into TINA led to the stabilization of parallel triplexes. However, as compared with TINA possessing pyrene **1**, the stabilization effect of acridines **X**−**Z** was not as significant with the exception of the **ON5**-containing TINA-acridine monomer **X** at the 5′-end. It was supposed that the triplex thermal stability can be further increased by the introduction of primary amines into the acridine via an alkyl linker, which should reduce the electrostatic repulsion between phosphates. Nevertheless, the introduction of TINA-acridine **Y** possessing a tris(2-aminoethyl)amine moiety gave the least thermally stable parallel triplex. In the case of antiparallel duplexes, introduction of TINA acridines **X** and **Y** to the dsDNA structures resulted in less destabilized DNA/DNA and DNA/RNA Watson−Crick duplexes as compared with TINA **1**. The stabilization effect in the case of **ON12/ON14** and **ON12/ON15** was found when 9-aminoacridine **X** was inserted at the 5′-end of the ON.

Molecular modeling calculations showed that the triplex stabilization was due to the intercalation of the acridine moiety between the bases of the dsDNA and via the interaction of the phenyl ring with the bases of TFO. 9-Chloroacridine was found to be a good precursor for the incorporation of primary amines to the oligonucleotides. We believe that parallel triplex stabilization can be further improved by the appropriately chosen substitution on the acridine in the structure of TINA monomers.

Carbohydrate-Functionalized Dendrimers To Investigate the Predictable Tunability of Multivalent Interactions

Mark L. Wolfenden and Mary J. Cloninger*

Department of Chemistry and Biochemistry and Center for Bioinspired Nanomaterials, Montana State University, 108 Gaines Hall, Bozeman, Montana 59717. Received April 24, 2006; Revised Manuscript Received May 10, 2006

Multivalent protein−carbohydrate interactions mediate a wide variety of intercellular recognition processes with high selectivity and specificity. Many synthetic multivalent molecules have been designed to mimic and to inhibit these processes. Using carbohydrate functionalized dendrimers, our goal is to devise a system where the binding activity and the degree of protein clustering induced by the glycopolymer can be readily attenuated. In this paper, dendrimers were functionalized with mixtures of mannose, glucose, and galactose. Their association with concanavalin A was studied using precipitation and hemagglutination assays. With less idealized systems where the association was not optimized, mixtures of low- and high-affinity ligands caused smaller than the theoretically determined differences in binding activity, although linear binding trends were observed. When systems were optimized so that high-affinity binding was achieved, then mixing low- and high-affinity ligands on the dendrimer's surface showed a predictable trend for lectin binding.

INTRODUCTION

Multivalent carbohydrate displays are involved in a myriad of biological recognition processes (*1*−*4*). A variety of glycopolymers have been developed to decipher the mechanistic details of binding processes with lectins (*5*). Glycoconjugates include many frameworks, varying from linear polymers to virus cages and proteins to dendrimers (*6*−*30*). Multivalent compounds are now being tested for biological activity. Noteworthy examples include carbohydrate functionalized gold nanoparticles whose antiadhesive properties involving cancer cell lines have been reported by Penades and co-workers (*31*). Also, Kihlberg and co-workers reported antiviral properties of a glycoprotein using human serum albumin as a scaffold with up to 19 sialyllactose motifs attached (*32*). The glycoproteins were designed to inhibit binding of an adenovirus involved in causing epidemic koratoconjunctivitus and were found to generate a 1000-fold potency increase in the IC_{50} value. In addition, Seeberger and co-workers have reported carbohydrate functionalized fluorescent poly(*p*-phenylene ethynylene) polymers that serve as a detection system for bacteria (*33*).

Synthetic multivalent molecules are generally optimized for their particular application in an empirical fashion. However, model systems have been used to more generally evaluate the parameters governing multivalent protein−carbohydrate interactions. Concanavalin A (Con A) is the lectin that is used most commonly in model studies with glycopolymers. Con A is a plant lectin isolated from the jackbean, which exists as a homotetramer at pH 7. Each monomer unit has one sugar binding site. Con A has specificity for the α-pyranose forms of D-mannose and D-glucose, and the four sugar binding sites are 65 Å apart (*34*). In work that inspired our choice of the Con A model system for this report, Kiessling and co-workers compared Con A binding by various scaffolds (*35*), compared Con A binding by linear polymers bearing various glucose and mannose derivatives (*36*), and compared Con A binding by glucose functionalized linear polymers of varying lengths (*37*). In work that inspired our choice of the dendrimer framework, Roy and co-workers studied the binding of lactose functionalized dendrimers to several lectins (*38*).

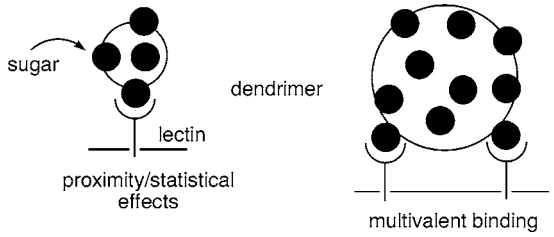

Figure 1. Proximity effects vs multivalent binding.

Nature augments weak monovalent protein carbohydrate interactions by using multivalency. Multivalency can be broadly described as many interactions that have a more than additive effect, making low-affinity interactions ($K_d \approx 10^{-3}$ M) into physiologically relevant affinities (*39*−*41*). Glycoside clustering has been previously defined as "affinity enhancement achieved by multivalent ligands over monovalent ones that is greater than would be expected from a simple effect of concentration increase" (*42*). For the discussion in this paper, we adopt this definition of glycoside clustering but apply it more specifically than it is sometimes used in the carbohydrate literature. Namely, we define multivalent binding (the ability of one dendrimer to bind to multiple lectin binding sites) and proximity/statistical effects (a ligand concentration effect) as two related but distinct terms. These definitions are shown pictorially in Figure 1.

Efforts to quantify the effects one would expect from the multivalent presentation of ligands have been reported. Page and Jencks' discussion of the chelate effect (*43*), and Jencks' presentation of a "connection Gibbs energy" (*44*) serve as an important introduction to this area. Jencks proposed that binding of a protein to a bivalent molecule could be described as the sum of the "intrinsic binding energies" of the component parts plus a "connection Gibbs energy" arising primarily from changes in the translational and rotational entropy upon bivalent binding (*44*). Two more recent examples of efforts to quantify components of multivalency have been presented by Lees et al. (*45*) and by Reinhoudt et al. (*46*) Lees and co-workers describe a binding enhancement value for divalent, pentameric, and linear

polymer systems (*45*), while Reinhoudt and co-workers relate the monovalent association constant to the multivalent association constant using an effective concentration value and a scaling factor (*46*). Both these methods progress the discussion of how monovalent association constants effect multivalent interactions, but both suffer from the difficulty of determining the appropriate value for the effective concentration.

In 1998, Whitesides et al. proposed a relationship between degree of multivalency and binding affinity with respect to the monomer (see eq 1 and Discussion below) (*39*). Recently, we published results that could be described well by this model; changes in activity could be predictably introduced into a multivalent dendritic system (*47*).

$$K_N^{poly} = (K^{mono})^{\alpha N} \quad (1)$$

Here, we describe our study in full detail, with a larger library of dendrimers bearing varying amounts of mannose, glucose, and galactose residues, and with additional assays to evaluate the protein−carbohydrate interaction. Binding trends are reported for dendrimers of different generations bearing presentations of ligands with varying affinities for Con A. Hemagglutination assay results to show changes in activity with Con A are presented, and precipitation assay results to show how protein activity and protein clustering can be independently attenuated are described.

EXPERIMENTAL PROCEDURES

Compounds 4a−n. Representative Procedure for the Synthesis of Heterogeneously Functionalized Generation 3.0 PAMAM-Based Thiourea-Linked 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside, 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside, and 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside. An aqueous solution of amine terminated G(3)-PAMAM dendrimer (1.925 g of a 18% (w/w) solution in water, 346 mg, 51 μmol) was lyophilized to leave a foamy residue. A 5.8 mL aliquot of dimethyl sulfoxide (DMSO) was then added to this residue to give a 60 mg/mL solution. A 47 μL aliquot of a 300 mM solution of **2a** (14.1 μmol, 6.8 mg) in DMSO was added to 0.5 mL of a 60 mg/mL G(3) PAMAM dendrimer (30 mg, 4.4 μmol) solution. The reaction was stirred for 48 h, and a 75 μL aliquot was removed for MALDI-TOF analysis. After MALDI-TOF indicated reaction completion, 0.17 mL of a 300 mg/mL solution of **2b** (49.4 μmol, 20.1 mg) was added. The solution was stirred for 48 h. A 75 μL aliquot was removed for analysis. After MALDI-TOF indicated reaction completion, 0.19 mL of a 300 mg/mL solution of **2c** (58.3 μmol, 23.4 mg) was added and was stirred for 48 h, and a 75 μL aliquot was removed for analysis. According to MALDI-TOF analysis, the final addition did not fully functionalize the remaining amine groups, so an additional spacer was added. 47 mg (30 μmol) of **3** in DMSO was added and was stirred at room temperature for 2 days. Again MALDI-TOF analysis indicated no further addition. This step was repeated with mild warming (up to 40 °C) and vigorous stirring. MALDI-TOF analysis again indicated no addition. Amounts of reagents used for formation of **4a−n**, and characterization data for **4a−n** are provided in the Supporting Information.

Compounds 5a−n. Representative Procedure for the Synthesis of Heterogeneously Functionalized Generation 4.0 PAMAM-Based Thiourea-Linked 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside, 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside, and 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside. An aqueous solution of amine terminated G(4) PAMAM dendrimer (2.48 g of a 17% (w/w) solution in water, 421 mg, 31 μmol) was lyophilized to leave a foamy residue. A 7.0 mL aliquot of DMSO was then added to this residue to give a 60 mg/mL solution. A 47 μL aliquot of a 300 mM solution of **2a** (14.1 μmol, 6.8 mg) in DMSO was added to 0.5 mL of a 60 mg/mL G(4) PAMAM dendrimer (30 mg, 4.4 μmol) solution. The reaction was stirred for 48 h, and a 75 μL aliquot was removed for MALDI-TOF analysis. After MALDI-TOF analysis indicated reaction completion, 0.17 mL of a 300 mM solution of **2b** (49 μmol, 25 mg) was added. The solution was stirred for 48 h. A 75 μL aliquot was removed for analysis. After MALDI-TOF analysis indicated reaction completion, 0.19 mL of a 300 mM solution of **2c** (57 μmol, 29 mg) was added and was stirred for 48 h, and a 75 μL aliquot was removed for analysis. According to MALDI-TOF analysis the final addition did not fully functionalize all remaining amine groups, so an additional spacer was added. 47 mg (30 μmol) of **3** in DMSO was added and was stirred at room temperature for 2 d. Again MALDI-TOF analysis indicated no further addition. This step was repeated with mild warming (up to 40 °C) and vigorous stirring. MALDI-TOF analysis again indicated no further addition. Amounts of reagents used for formation of **5a−n**, and characterization data for **5a−n** are provided in the Supporting Information.

Compounds 6a−l. Representative Procedure for the Synthesis of Heterogeneously Functionalized Generation 5.0 PAMAM-Based Thiourea-Linked 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside, 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside, and 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside. An aqueous solution of amine terminated G(5) PAMAM dendrimer (1.938 g of a 23% (w/w) solution in water, 446 mg, 18 μmol) was lyophilized to leave a foamy residue. A 7.4 mL aliquot of DMSO was then added to this residue to give a 60 mg/mL solution. A 39 μL aliquot of a 300 mM solution of **2a** (12 μmol, 6.0 mg) in DMSO was added to 0.5 mL of a 60 mg/mL G(5) PAMAM dendrimer (30 mg, 1.2 μmol) solution. The reaction was stirred for 48 h, and a 75 μL aliquot was removed for MALDI-TOF analysis. After MALDI-TOF analysis indicated reaction completion, 0.14 mL of a 300 mM solution of **2b** (42.4 μmol, 22 mg) was added. The solution was then stirred for 48 h. A 75 μL aliquot was removed for analysis. After MALDI-TOF indicated reaction completion, 0.15 mL of a 300 mM solution of **2c** (45 μmol, 23 mg) was added and was stirred for 48 h, and a 75 μL aliquot was removed for analysis. According to MALDI-TOF analysis, the final addition did not fully functionalize the remaining amine groups, so an additional spacer was added. A 47 mg (30 μmol) amount of **3** in DMSO was added and was stirred at room temperature for 2 days. Again MALDI-TOF analysis indicated no further addition. This step was repeated with mild warming (up to 40 °C) and vigorous stirring. MALDI-TOF analysis again indicated no addition. Amounts of reagents used for formation of **6a−l**, and characterization data for **6a−l** are provided in the Supporting Information.

Compounds 7a−l. Representative Procedure for the Synthesis of Heterogeneously Functionalized Generation 6.0 PAMAM-Based Thiourea-Linked 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside, 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside, and 1-*O*-(6-Thiourea-4-thiohexyl)-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside. An aqueous solution of amine terminated Starburst G(6) PAMAM dendrimer (2.78 g of a 17% (w/w) solution in water, 472 mg, 9.3 μmol) was lyophilized to leave a foamy residue. A 7.9 mL aliquot of DMSO was added to this residue to give a 60 mg/mL solution. A 33 μL aliquot of a 300 mM solution of **2a** (9.9 μmol, 5.1 mg) in DMSO was added to 0.5 mL of a 60 mg/mL G(6) PAMAM dendrimer (30

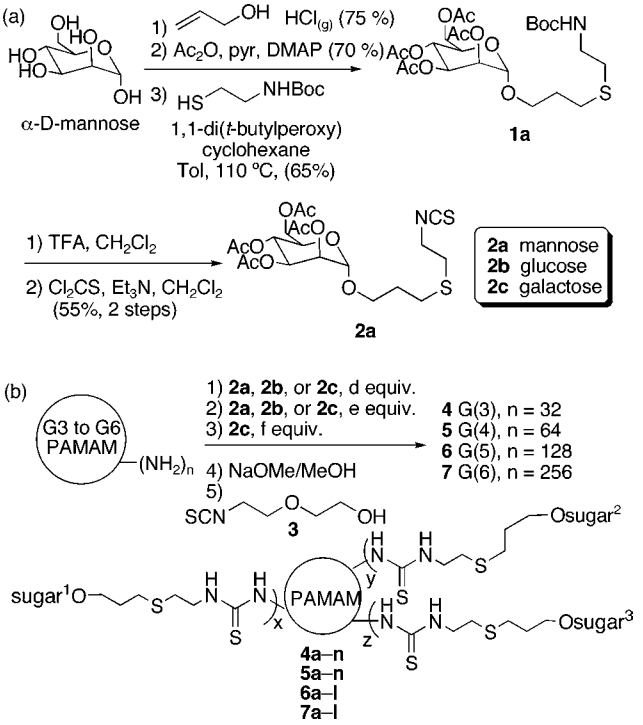
mg, 4.4 μmol) solution. The reaction was stirred for 48 h, and a 75 μL aliquot was removed for MALDI-TOF analysis. After MALDI-TOF analysis indicated reaction completion, 120 μL of a 300 mM solution of **2b** (36 μmol, 18 mg) was added. The solution was stirred for 48 h. A 75 μL aliquot was removed for analysis. After MALDI-TOF analysis indicated reaction completion, 140 μL of a 300 mM solution of **2c** (42 μmol, 22 mg) was added and was stirred for 48 h, and a 75 μL aliquot was removed for analysis. According to MALDI-TOF analysis the final addition did not fully functionalize the remaining amine groups, so an additional spacer was added. A 47 mg (30 μmol) amount of **3** in DMSO was added and was stirred at room temperature for 2 days. Again MALDI-TOF analysis indicated no further addition. This step was repeated with mild warming (up to 40 °C) and vigorous stirring. MALDI-TOF analysis again indicated no addition. Amounts of reagents used for formation of **7a**−**l**, and characterization data for **7a**−**l** are provided in the Supporting Information.

General Procedure for Deacylation of Dendrimers 4a−**n, 5a**−**n, 6a**−**l, and 7a**−**l.** To the lyophilized solid compounds **4a**−**n**, **5a**−**n**, **6a**−**l**, and **7a**−**l**, 1 mL of 1:1 water:methanol was added, at which point the dendrimer became a white precipitate. To this mixture was added 0.2 equiv of NaOMe (0.8 M in MeOH) for each peripheral carbohydrate, and the mixture was stirred for 3 h. If the mixture had not become a clear solution after 3 h, then a further 0.2 equiv of NaOMe (0.8 M in MeOH) was added, and this step was repeated until the mixture became a clear and colorless solution. HCl(aq) (0.1 M) was added slowly until the pH was ∼7. This neutralized solution was placed in a centrifugal filter device, diluted with 3 mL of 1:1 H_2O:MeOH, and filtered at 3500 rpm for 30 min. The filtrate was removed, and 3 mL of H_2O was added and filtered for 30 min at 3500 rpm. This procedure was repeated 2 more times. The remaining residue was taken up in Millipore water and lyophilized to give a white fluffy solid. Characterization data for all deprotected compounds are provided in the Supporting Information.

RESULTS

Synthesis and Characterization of Carbohydrate Functionalized PAMAM Dendrimers. A general procedure for functionalization of the dendrimers with two or three carbohydrates is shown in Scheme 1. Mannose/glucose/galactose, mannose/glucose, glucose/galactose, and mannose/galactose functionalized dendrimers were synthesized as shown for mannose in Scheme 1b. To retain the α-anomeric integrity of the carbohydrates, we chose to allylate the anomeric position and perform a thiol addition to the olefin (*48*). The subsequently formed peracylated isothiocyanto sugars **2** were added sequentially to a solution of PAMAM dendrimer in DMSO (*49*). When adding more than one sugar to the PAMAM dendrimer, incomplete loading was observed. The addition of excess isothiocyanato sugar with mild warming did not induce further loading to any significant extent. A third isothiocyanato sugar or isothiocyanato alcohol **3** also failed to give full loading (steps 3 and 5 in Scheme 1b; step 3 was omitted when only two carbohydrates were added to the dendrimer), indicating that any remaining primary amines on the dendrimer were inaccessible for reaction with the desired isothiocyanates. Global deprotection via Zemplen conditions in 1:1 MeOH:H_2O and purification by centrifugal filtration in water and lyophilization afforded compounds **4a**−**n**, **5a**−**n**, **6a**−**l**, and **7a**−**l**. The compound numbers **4**−**7** indicate the generation of the dendrimer that was used (G(3) = **4**, G(4) = **5**, G(5) = **6**, G(6) = **7**), and the letters indicate the number and nature of the sugars that are added to the dendrimers. The sugar compositions of each dendrimer are given in Tables 1−4. Although not shown in Scheme 1, addition of **3** to protected carbohydrate functionalized dendrimers

Scheme 1. Synthesis of Mannose, Glucose, and Galactose Functionalized Dendrimers[a]



[a] Letters after 4−7 correlate the number of mannose, glucose, and galactose residues present on each dendrimer (see Tables 1−4). The amount of **2** added in each reaction is provided in the Supporting Information.

(reversal of steps 4 and 5 in Scheme 1b) also failed to increase the carbohydrate loadings of the dendrimers.

Because previous studies indicated that 50% dendrimer functionalization with the binding ligand (mannose) produced optimal results (*50*), we synthesized a series of dendrimers with 50% mannose + glucose (plus additional galactose residues for spacing, Table 1), and we compared these dendrimers to a series of dendrimers with higher loadings of mannose + glucose (Table 2).

MALDI-TOF MS was used to determine the number of carbohydrate residues of each type on the dendrimers. Both the change in M_W after each sequential addition and the change in M_W after deacylation were used. Details of the calculations are provided in the Supporting Information. The MALDI-TOF MS-derived number of sugars tethered to each dendrimer is shown in Tables 1−4. Data for man/glc/gal functionalized dendrimers (where the total amount of man/glc loading is kept constant at 50%) are reported in Table 1, data for man/glc functionalized dendrimers are reported in Table 2, data for glc/gal functionalized dendrimers are reported in Table 3, and data for man/gal functionalized dendrimers are reported in Table 4.

Although NMR spectra revealed that the carbohydrates had been successfully added to the dendrimers (downfield thiourea peaks appear in the ^{1}H NMR spectra, for example), the spectra were broadened and overlapped such that the integration ratios could not be used to quantify carbohydrate loadings. The ^{1}H NMR spectra did reveal the level of deprotection of the acetyl groups, since these methyl groups caused sharp distinctive peaks at ∼2 ppm.

Hemagglutination Inhibition Assays. Hemagglutination inhibition assays were performed by adding erythrocytes to preincubated solutions of Con A (∼1 μM) with varying concentrations of dendrimer (*51*). We previously reported the synthesis and analysis of G(4) to G(6) PAMAM dendrimers with 50% mannose and glucose incorporation (*47*). These

dendrimers showed a linear trend for relative activity in the hemagglutination assay (on a per active sugar basis) versus percent mannose of the mannose/glucose mixture and were consistent with a divalent interaction in the model set out by Whitesides et al. (see Discussion below for full details) (*39*). Here, we have added the G(3) series of 50% mannose/glucose functionalized dendrimers. Mannose/galactose, glucose/galactose, and mannose/glucose dendrimers with higher carbohydrate loadings in generations 3−6 are also reported. Results of the hemagglutination assays are shown in Tables 1−4. The relative activity numbers in the tables are on a per carbohydrate (glc + man) basis and are relative to methyl mannose.

Some of the compounds appear in multiple tables, since assays were performed simultaneously for compounds when

their results were to be compared. Different samples of rabbit erythrocytes, and even the relative freshness of erythrocytes from the same blood sample, can affect the absolute (but not the relative) values that are obtained from the hemagglutination assay. The hemagglutination assay affords activity trends that are clearly reproducible, although the absolute values for the assays are more variable.

Precipitation Assays. To determine the lectin clustering ability of these dendrimers, we performed precipitation assays. As described by Brewer et al., the dendrimer was incubated at varying concentrations with a constant concentration of Con A (*52*). When the Con A concentration is sufficiently high, the mannose functionalized dendrimer forms a precipitate with the Con A. The supernatant is removed, and the precipitate is washed with cold buffer and subsequently redissolved with a solution of 0.1 M methyl mannopyranoside solution. The Con A concentration in the remaining solution is then determined by measuring the UV absorbance at 280 nm. At the point that maximum precipitation of Con A is observed, the maximum Con A to dendrimer ratio can be determined. The precipitation assay results are provided in Tables 1−4. As with the hemagglutination assay results, some compounds are listed in more than one table so that trends across a series of carbohydrate loadings are easier to evaluate.

DISCUSSION

Synthesis and Characterization of Carbohydrate Functionalized Dendrimers. Dendrimers, macromolecules that are comprised of a series of branches emanating from a central core (*53*), are the ideal frameworks for the study of how systematic structural changes alter the way that a glycopolymer interacts with a protein. Higher generation dendrimers (PAMAM generations 4−6) are large enough to span multiple binding sites on a lectin (see Figure 1b), while lower generation dendrimers (generations 1−3) are too small to bind to multiple binding sites on Con A (see Figure 1a). In addition to changing the dendrimer generation, the degree of carbohydrate loading on a dendrimer can also be readily changed by controlling the number of equivalents of isothiocyanate that are added to the dendrimer solution. Because systematic changes can readily be made and because the three-dimensional (roughly spherical) structure of the dendrimer lends itself well to data interpretation, we chose dendrimers as the structural frameworks for our synthetic multivalent systems. We chose to use mannose, glucose, and galactose as ligands because of their known differences in affinity when binding to Con A. Mannose has a 4-fold higher affinity for Con A than glucose does, and galactose has no affinity for Con A (*54*). Because of the tetrahedral arrangements of the Con A binding sites, even the largest dendrimers used in this study (G(6)) cannot simultaneously bind to more than two of the four binding sites. Thus, for the dendrimer−Con A system, monovalent (as in Figure 1a) and divalent (as in Figure 1b) associations can be expected to occur.

Previously, we reported the binding by Con A of mannose/hydroxyl functionalized dendrimers. Optimal activity in the hemagglutination assay was observed when the dendrimers had 50% mannose incorporation. Dendrimers with higher mannose loadings had reduced activities with Con A (on a per sugar basis), suggesting that unfavorable steric interactions precluded optimal binding at high carbohydrate functionalization (*50*). For the research reported here, our goal was to quantify the effect that functionalization of the dendrimer with monomers of varying affinities would have on the multivalent activity of the dendrimer with lectins. Because of the previously optimized mannose/hydroxyl functionalized dendritic system, we first synthesized dendrimers with 50% functionalization by mannose and glucose. The preliminary results with these compounds were reported in a recent communication (*47*). Full studies with mannose/glucose functionalized dendrimers at 50% combined loading of mannose and glucose are reported here. In addition, complete studies with mannose/glucose, mannose/galactose, and glucose/galactose functionalized dendrimers are reported.

The synthesis scheme for dendrimer functionalization is shown in Scheme 1. When multiple sugars were added to the PAMAM dendrimers, incomplete addition of the final carbohydrate was observed. The excess isothiocyanate could be monitored by ^{1}H NMR, with the methylene group alpha to the isothiocyanato group giving rise to a triplet at 3.8 ppm. To cap any remaining accessible terminal amines, reactions with excess isothiocyanato sugars and with isothiocyanato ethoxyethanol **3** were heated to 40 °C. When neither of these additions was successful, we concluded that no primary amines were accessible on the periphery of the carbohydrate functionalized dendrimers. Unfunctionalized primary amines near the dendrimer surface could be protonated at physiological pH and could cause nonspecific interactions with Con A during assays. However, control hemagglutination assay and precipitation assay experiments with unfunctionalized PAMAMs and Con A indicated no interaction between the amine-functionalized PAMAM dendrimers and the protein. The degree of carbohydrate functionalization was in all cases determined by MALDI-TOF MS. Details of the MALDI-TOF MS characterization procedure are provided in the Experimental Section and in the Supporting Information, and the resultant number of sugars is reported in Tables 1−4.

Hemagglutination Inhibition Assays Using Dendrimers with 50% Mannose/Glucose Incorporation. In Figure 2, the activity with Con A of dendrimers with 50% combined

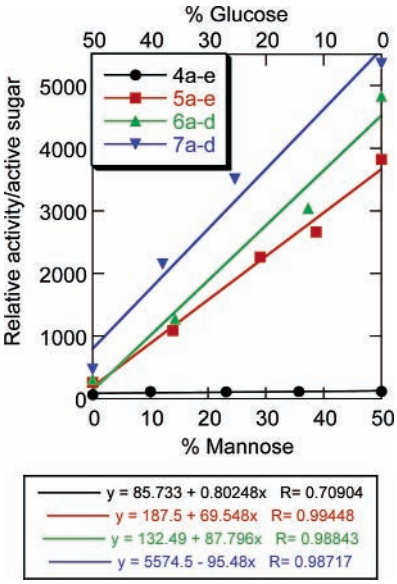

Figure 2. Relative activity per active sugar (man + glc) for dendrimers with 50% man/glc functionalization (see Table 1 for compound numbers and values).

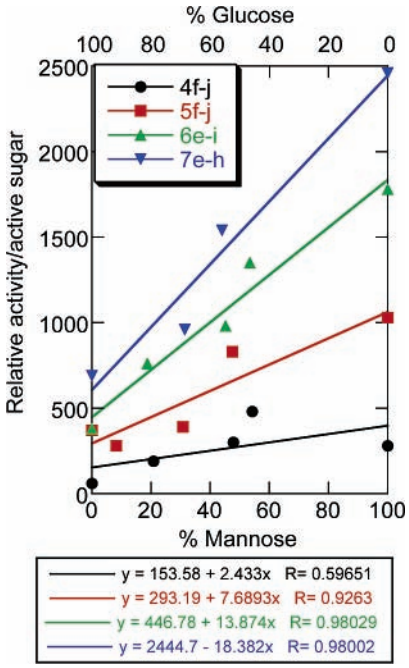

Figure 3. Relative activity per active sugar (man + glc) for man/glc functionalized dendrimers (see Table 2 for compound numbers and values).

functionalization by mannose and glucose (**4a**−**e**, **5a**−**e**, **6a**−**d**, **7a**−**d**) is shown. When dendrimers are 50% functionalized with man/glc mixtures, the relative amounts of glucose and mannose induce a linear change in the relative activity for generation 4, 5, and 6 dendrimers. The difference in relative activity between glucose functionalized and mannose functionalized dendrimers in the G(4) series (**5a** vs **5e**) is 14.7, the difference for G(5) dendrimers (**6a** vs **6d**) is 15.6, and the difference for G(6) dendrimers (**7a** vs **7d**) is 11.4. Dendrimers with partial mannose and partial glucose incorporation fall linearly between the all mannose and all glucose functionalized dendrimers. In the G(3) series, all of the dendrimers have comparable activities toward Con A. This is as expected, since carbohydrate functionalized G(3) PAMAMs are too small to bind divalently to Con A and only monovalent associations are likely.

Equation 1 was used to evaluate the hemagglutination assay data for compounds **5a**−**e**, **6a**−**d**, and **7a**−**d**. In eq 1, K^{mono} is the monovalent association constant, K_N^{poly} is the multivalent association constant, N is the number of receptor−ligand interactions, and α is the cooperativity factor. Here, a cooperativity constant α of 1 was used. Negatively cooperative, positively cooperative, and noncooperative systems are all theoretically possible. However, only one or two examples of protein−carbohydrate interactions with thermodynamic parameters suggestive of positive cooperativity have been reported (*39*). Negatively cooperative and noncooperative systems are much more common. We have chosen to leave $\alpha = 1$ because of the precedent where noncooperative associations were assumed for Con A (*55*) and because a Con A−dendrimer interaction where the first binding event at one binding site is thermodynamically significantly different from the second binding event at a second binding site is not expected. Although the appropriate value of N for this system cannot be assigned with absolute certainty (because precipitation occurs under conditions appropriate for ITC), N must surely be equal to 1 or 2. The shape of tetrameric Con A and the relative locations of the mannose binding sites on tetrameric Con A preclude trivalent or tetravalent binding by a roughly spherical, dendritic system. Although a value of $N = 1$ is possible, $N = 2$ is suggested for **5**−**7** by the results of precipitation assay experiments, transmission electron micrographs, and hemagglutination assays (*47*, *50*, *56*).

Using eq 1, and assuming $\alpha = 1$ and $N = 2$, one would predict that exchanging mannose for glucose would cause a 4^2 or 16-fold reduction in binding to Con A, since the relative activities of monomeric methyl mannose and methyl glucose vary by a factor of 4. This is very close to the values observed for G(4) (14.6), G(5) (15.6), and G(6) (11.4). Perhaps the larger deviation from 16 for G(6) is due to the larger size of G(6), which could allow for a compensatory effect due to increased sugar clustering around the binding sites (*40*). Alternatively, the curvature of the G(6) dendrimers may be different enough from G(4) and G(5) to change the shape complementarity between Con A and the dendrimer, which can significantly change the association motif (*57*).

Hemagglutination Inhibition Assays Using Mannose/Glucose Functionalized Dendrimers. The activity with Con A of man/glc functionalized dendrimers **4f**−**4j**, **5f**−**5j**, **6e**−**i**, and **7e**−**7h** is shown in Figure 3. Increasing the number of mannose residues while decreasing the number of glucose residues causes an increase in the relative activity with Con A. As with the dendrimers bearing 50% mannose/glucose loading, a linear relationship between man/glc loading and assay activity is observed for compounds in generations 4−6. However, the difference between fully mannose functionalized dendrimers and fully glucose functionalized dendrimers never approaches 16. For generation 3 compounds **4f**−**4j**, mannose functionalized compounds **4j** have a 5-fold higher relative activity with Con A than do the glucose functionalized compounds **4f**. For generations 4−6, the differences between mannose and glucose functionalized compounds are 2.8 (**5f** vs **5j**), 4.7 (**6e** vs **6i**), and 3.7 (**7e** vs **7h**), respectively. Also, having more than 50% loading by the active sugars decreases the assay activity (for example, **6b** is about twice as active as **6h**).

We previously attributed the lower affinity of dendrimers above 50% sugar loading to unfavorable steric interactions between the dendrimer and the protein (*50*). The deviation from the 16-fold affinity difference predicted by eq 1, and the reduced activity for compounds with higher than 50% loading suggest that the degree of clustering of the sugars may be more important for some compounds than for others. Dendrimers with higher glucose content have lower intrinsic binding affinities for Con

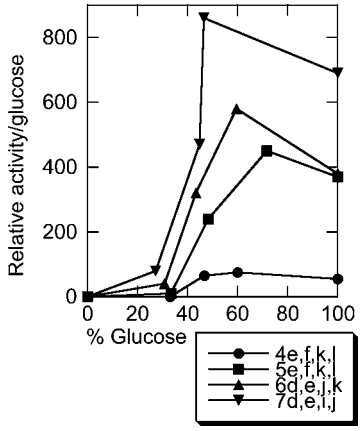

Figure 4. Relative activity per glucose for glc/gal functionalized dendrimers (see Table 3 for compound numbers and values).

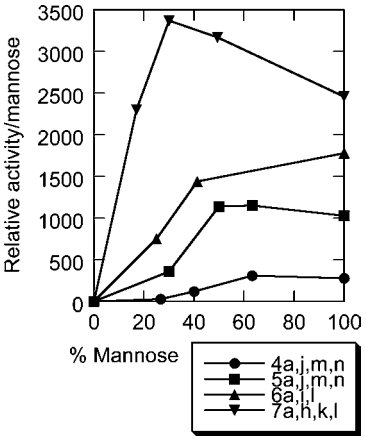

Figure 5. Relative activity per mannose for man/gal functionalized dendrimers (see Table 4 for compound numbers and values).

A (than highly mannose functionalized dendrimers) and may rely more on statistical binding effects (Figure 1a). Differences in how the dendrimers overcome unfavorable steric crowding coupled to differences in how important clustering of carbohydrates is could cause the cooperativity constant α to change from 1 and could account for the fact that the difference between mannose and glucose functionalized dendrimers is significantly lower than 16.

Hemagglutination Inhibition Assays with Mannose/Galactose and Glucose/Galactose Functionalized Dendrimers. The activities with Con A of glc/gal and man/gal functionalized dendrimers (**4e**,**f**,**k**−**n**, **5e**,**f**,**j**−**n**, **6d**−**f**,**j**−**l**, and **7d**,**e**,**i**−**l**) are shown in Figures 4 and 5. All of the glc/gal dendrimers have lower activities than their analogous man/gal dendrimers. In the G(3) series, the glc/gal dendrimers with the highest activity are four times less active than the highest activity man/gal dendrimers (**4j** vs **4l**). In generations 4−6, the glc/gal dendrimers with the highest activity are 2.6 times (**5n** vs **5l**), 2.5−3.1 times (**6a** or **6i** vs **6k**), and 3.7−3.9 times (**7a** or **7l** vs **7j**) less active. These differences are considerably lower than those observed for the 50% functionalized mannose/glucose series (Figure 2), where nearly 16-fold differences in activity were observed.

Following trends that were previously observed for mannose/hydroxyl functionalized dendrimers,[38] the fully carbohydrate functionalized dendrimers have lower relative activities (on a per sugar basis) than the partially carbohydrate functionalized dendrimers do. Man/gal functionalized dendrimers have optimum activity with Con A at 50−60% mannose incorporation (G(4)), 40−50% mannose incorporation (G(5)), and 30−40% mannose incorporation (G(6)). Higher glucose loadings are required to achieve optimal activity with glc/gal dendrimers; roughly 70, 60, and 50% glucose functionalization produced the highest activity with Con A for generations 4−6, respectively. This is of interest as it may indicate that, with a weaker interaction, proximity/statistical effects are more important to binding. Both the man/gal and the glc/gal G(3) dendrimers have relatively low activity toward Con A in the assay, as would be expected for small dendrimers where statistical enhancements on binding affinity (and not multivalency) are observed.

Hemagglutination Inhibition Assays in General. Hemagglutination assays display qualitative trends rather than absolute values. In our studies, performing the assay with different samples of erythrocytes changed the absolute values but never the relative trends for this assay. Taken together, the data from the four series of compounds above suggest that, for optimized systems, eq 1 works well to predict how monovalent ligands displayed on a multivalent framework attenuate binding activity. However, the system must be optimized, or affinity differences much lower than those predicted by eq 1 will be obtained. When low-affinity ligands (such as glucose) are present in significant quantities, proximity effects may become more important than they are when higher affinity ligands (such as mannose) are present as the major functionality.

Precipitation Assays. Graphs showing the maximum number of Con A lectins recruited by each dendrimer are shown in Figure 6. Figure 6a shows the Con A:dendrimer ratio for 50% mannose/glucose functionalized dendrimers, Figure 6b shows the Con A:dendrimer ratio for mannose/glucose functionalized dendrimers, Figure 6c shows the Con A:dendrimer ratio for mannose/galactose functionalized dendrimers, and Figure 6d shows the Con A:dendrimer ratio for glucose/galactose functionalized dendrimers. The maximum average number of Con A's that can fit around carbohydrate functionalized dendrimers

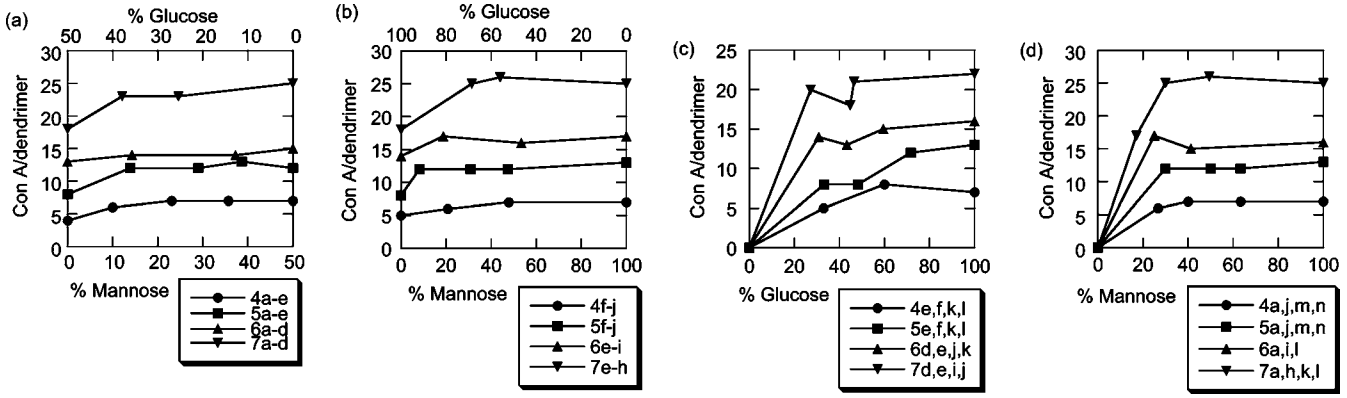

Figure 6. Number of Con A lectins per dendrimer (a) dendrimers with 50% man/glc functionalization, (b) man/glc functionalized dendrimers, (c) glc/gal functionalized dendrimers, and (d) man/gal functionalized dendrimers. Values are given in Tables 1−4.

was previously determined to be 9−10, 12−13, 15−16, and 22−23 for G(3) through G(6), respectively (*50*). For all of the series shown here, the G(3) dendrimers recruit less than the optimal number of Con A lectins. This suggests that Con A binds monovalently to all of the G(3) PAMAMs, reducing the strength of the association and causing unoptimized binding to occur (*58*). All carbohydrate functionalized G(4) and G(5) PAMAMs recruit the optimal number of Con A lectins, while the carbohydrate functionalized G(6) PAMAMs typically bind to slightly more than the theoretically determined number of proteins (*59*). The 50% man/glc functionalized compounds **5a**−**e, 6a**−**d**, and **7a**−**d** show no change in clustering until all the active sugar is glucose; then the ratios drop from 12−13 to 8, from 14−15 to 13, and from 23−25 to 18, respectively (Figure 6a). Comparable trends are observed for man/glc functionalized dendrimers with higher ligand loadings (Figure 6b). Similarly, in the man/gal series (Figure 6c) and the glc/gal series (Figure 6d), the maximum number of Con A lectins that can be recruited are clustered around the dendrimers when at least 25% of the carbohydrates are Con A binding ligands. Glc/gal dendrimers appear to show small increases in Con A recruitment with increased glucose functionalization, but man/gal dendrimers level off after 25% mannose incorporation. The number of Con A lectins recruited is the same for generations 3−5. For generation 6, man/gal functionalized dendrimers cluster consistently more Con A lectins (25−26 lectins) than glc/gal functionalized dendrimers do (18−22 lectins). Control dendrimers with only galactose functionalization fail to precipitate Con A. The precipitation assay results indicate that the number of Con A lectins that can be recruited by a dendrimer is not greatly affected when the relative activity (as determined in the hemagglutination assays) is altered by an order of magnitude.

CONCLUSION

Multivalent binding between proteins and carbohydrates mediates many biological events. The goal of the research reported here was to determine whether monovalent differences in affinity affect multivalent association constants in predictable ways. For optimized systems such as the dendrimers with 50% loading of mannose and glucose, the equation described by Whitesides and co-workers (eq 1) works well to predict how monovalent ligands displayed on a multivalent framework will attenuate binding activity. For more highly functionalized man/glc, man/gal, and glc/gal dendrimers, activity differences for hemagglutination assays with Con A that were much lower than those predicted by eq 1 were obtained. For this system, dendrimers with more glucose residues appear to compensate for the steric downfall of full functionalization by relying more on proximity enhancements than mannose functionalized dendrimers do. Although varying the ligands on the dendrimer can cause up to 16-fold differences in relative activity in the hemagglutination assay, only small differences in the maximum number of Con A lectins recruited by the dendrimers were observed.

The results reported here suggest that multivalency can be influenced in predictable—and therefore tunable—ways. Monovalent differences are amplified by multivalent associations, and mixtures of low- and high-affinity ligands can be used to attenuate multivalent binding activities. Attenuation of the binding activity (as studied in the hemagglutination assay) is largely independent of the degree of protein clustering (as measured in the precipitation assay). Natural systems likely use modulation of properties such as avidity and protein clustering to control physiological processes. Because of their ready tunability, the carbohydrate functionalized dendrimers described here should provide guidelines for the development of synthetic multivalent frameworks for many applications in chemical biology. Studies are currently underway to investigate how these results will transpose into more complex biological systems.

Site-Specific, Covalent Attachment of Proteins to a Solid Surface

Benjamin P. Duckworth,[†] Juhua Xu,[†] T. Andrew Taton,[†] Athena Guo,[‡] and Mark D. Distefano*,[†]

Department of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455 and MicroSurfaces, Inc., 4001 Stinson Boulevard, Suite 430, Minneapolis, Minnesota 55421. Received May 16, 2006; Revised Manuscript Received June 6, 2006

Immobilized and site-specifically labeled proteins are becoming invaluable tools in proteomics. Here, we describe a strategy to attach a desired protein to a solid surface in a covalent, site-specific manner. This approach employs an enzymatic posttranslational modification method to site-specifically label a target protein with an azide; an alternative substrate for protein farnesyl transferase containing an azide group was developed for this purpose. A bio-orthogonal Cu(I)-catalyzed cycloaddition reaction is then used to covalently attach the protein to agarose beads bearing an alkyne functional group. We demonstrate that both the azide incorporation and the capture steps can be performed on either a purified protein target or on a protein present within a complex mixture. This approach involves the use of a four-residue tag which is significantly smaller than most other tags reported to date and results in covalent immobilization of the target protein. Hence it should have significant applicability in protein science.

INTRODUCTION

The attachment of proteins and other biomolecules to surfaces in a site-specific, covalent manner is becoming increasingly important in the field of biotechnology. Immobilized proteins are instrumental in identifying protein−protein (*1*), protein−DNA (*2*), and protein−small molecule (*3*) interactions; they can also be used for a variety of diagnostic purposes (*4*). Several approaches exist for linking proteins to surfaces including covalent and noncovalent strategies. Most methods that involve covalent attachment rely on nonselective reaction between a protein's surface lysine residues and a solid support (*5*, *6*); this results in a heterogeneous ensemble of immobilized molecules. While this problem can be circumvented through the introduction of unique cysteine residues, that approach becomes difficult with larger proteins where multiple cysteines are present (*7*). A different strategy for protein immobilization relies on the use of peptide tags (*8*) or protein fusions (*9*). While these methods result in homogeneous attachment of proteins to surfaces, they accomplish this via noncovalent protein−protein interactions or kinetically labile protein−metal interactions and are consequently intrinsically less stable. Another approach relies on active-site directed covalent attachment of fusion proteins to surfaces (*10*, *11*). Although this does yield a covalent, specific attachment, it requires the fusion of a large polypeptide segment (>22 kDa) to the target protein (*12*). Numerous researchers have commented that this is not always desirable (*13*−*16*). One recent solution to that problem was reported by Camarero and coworkers, who successfully immobilized proteins using a traceless, protein trans-splicing method (*17*).

Recently, several approaches using enzymatic methods have been developed that allow proteins to be modified for the purpose of site specific labeling (*18*−*21*). Such strategies capitalize on the high specificity of enzymes to modify a protein at a unique site in a manner that facilitates subsequent functionalization. Here we present a strategy that involves the labeling of a desired protein with an azide via an enzyme-catalyzed reaction. The recognition tag for the enzyme protein farnesyltransferase (PFTase) is only four amino acids in length and is recognized by the enzyme only when present at the C-terminus of a protein. The azide-labeled protein is then coupled to a surface bearing an alkyne group using a bio-orthogonal reaction (*22*−*26*). Thus, this new strategy provides a method for both site-specifically and covalently anchoring proteins to solid surfaces without the need for large fusion proteins. Additionally, this strategy can be applied to virtually any protein and any surface.

EXPERIMENTAL PROCEDURES

Materials and Methods. All synthetic reactions were conducted under air atmosphere and stirred magnetically, unless otherwise indicated. Analytical TLC was performed on precoated (250 μm) silica gel 60 F-254 plates from Merck. All plates were visualized by UV irradiation, staining with potassium permanganate ($KMnO_4$) or with phosphomolybdic acid (PMA). Flash chromatography (silica gel, 60−120 mesh) was obtained from Mallinckrodt Inc. CH_2Cl_2, THF, and CH_3CN were dried using a Mbraun solvent purification system. Deuterated NMR solvents were used as obtained from Cambridge Isotope Laboratories, Inc. ^{1}H NMR spectra were obtained at 300 or 500 MHz. ^{13}C NMR spectra were obtained at 75 MHz. All NMR spectra were obtained on Varian instruments at 25 °C. Chemical shifts are reported in ppm and *J* values are given in Hz. Preparative HPLC was carried out using a Beckman model 127/166 instrument equipped with a UV detector and a Phenomenex C_{18} column (Luna, 10 μM, 10.0 × 250 mm) equipped with a 5 cm guard column. Analytical HPLC was carried out using a Beckman model 125/168 instrument equipped with a UV detector, ABI Analytical Spectroflow 980 fluorescence detector, and a Varian C_{18} column (Microsorb-MV, 5 μm, 4.6 × 250 mm). $CuSO_4$ was purchased from Mallinckrodt while TCEP was purchased from Invitrogen. All other chemical agents were purchased from Aldrich Chemical Co. unless otherwise noted.

(*E*,*E*)-3,7,11-Trimethyl-1-*O*-THP-2,6,10-dodecatriene (1). A mixture of farnesol (8.9 g, 40 mmol), 3,4-dihydro-2*H*-pyran (DHP, 5.0 g, 60 mmol), and pyridium *p*-toluenesulfonate (PPTS, 1.0 g, 4.0 mmol) in dry CH_2Cl_2 was stirred at room temperature for 4 h. After concentration in vacuo, the crude mixture was redissolved in Et_2O and the organic layer was washed with saturated $NaHCO_3$ (50 mL) and dried using Na_2SO_4, yielding

compound **1** (12 g, 98%). NMR assignments have previously been reported for compound **1** (*27*).

(*E*,*E*,*E*)-2,6,10-Trimethyl-12-*O*-THP-2,6,10-dodecatrienealdehyde (2). The allylic aldehyde **2** was prepared by a procedure based on several literature precedents. (*28*−*30*). Selenium dioxide (1.0 g, 9.0 mmol) and pyridine (3.0 mL) were added to a stirred solution of **1** (5.5 g, 18 mmol) in 50 mL of EtOH. The reaction mixture was heated to reflux for 4 h, after which the reaction was cooled to room temperature, filtered, and concentrated in vacuo. The residue was redissolved in Et_2O, washed with brine, and dried using Na_2SO_4. After removal of the solvent in vacuo, the crude product was dissolved in 50 mL of CH_2Cl_2, and to this solution was added 10 g (27 mmol) of pyridinium dichromate (PDC). The reaction mixture was stirred at room-temperature overnight and then filtered. Compound **2** was purified using column chromatography (flash silica) to yield 0.80 g (14%) of **2** as a colorless oil. (R_f = 0.63, hexanes:EtOAc = 3:1). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.55 (m, 5H), 1.63 (s, 3H), 1.67 (s, 3H), 1.74 (s, 3H), 1.82 (m, 1H), 2.0−2.25 (m, 6H), 2.46 (m, 2H), 3.51 (m, 1H), 3.89 (m, 1H), 4.02 (dd, J = 7.3 Hz, J = 12 Hz, 1H), 4.24 (dd, J = 6.3 Hz, J = 12 Hz, 1H), 4.62 (dd, J = 3.0 Hz, J = 4.5 Hz, 1H), 5.16 (t, J = 6.2 Hz, 3 H), 5.36 (dd, J = 6.3 Hz, J = 7.3 Hz, 1H), 6.46 (t, J = 7.2 Hz, 1H), 9.37 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 195.38, 154.53, 139.95, 133.71, 125.33, 121.75, 120.86, 97.91, 63.70, 62.35, 39.51, 38.01, 30.77, 27.45, 26.25, 25.55, 19.69, 16.47, 15.97, 9.28. HR-ESI-MS calcd for $C_{20}H_{32}NaO_3$ [M + Na]$^+$ 343.2244, found 343.2234.

(*E*,*E*)-3,7,11-Trimethyl-1-*O*-THP-2,6-dodecadiene-12-ol (3). Compound **3** was prepared by a procedure developed by Moody and co-workers (*31*). To a solution of **2** (2.0 g, 6.0 mmol) in benzene (35 mL) and water (31 mL) were added $Na_2S_2O_4$ (85%, 3.2 g, 24 mmol), Aliquat 336 (0.48 g, 1.2 mmol), and $NaHCO_3$ (2.5 g, 30 mmol). The stirred reaction mixture was heated to 80 °C for 4 h. After being cooled to room temperature, the organic phase was concentrated in vacuo and diluted with 40 mL of Et_2O. The mixture was washed with brine (3 × 20 mL) and dried using Na_2SO_4. Compound **3** was purified using column chromatography (flash silica) to yield 0.95 g (50%) of **3**, a colorless oil. (R_f = 0.24, hexanes:EtOAc = 3:1). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.84 (d, J = 6.9, Hz, 3H), 1.34 (m, 6H), 1.50−1.66 (m, 7H), 1.69 (s, 3H), 1.80 (m, 1H), 1.86−2.18 (m, 6H), 3.38 (m, 1H), 3.48 (m, 2H), 3.87 (m, 1H), 4.01 (dd, J1 = 7.5 Hz, J2 = 11.7 Hz, 1H), 4.21 (dd, J = 6.6 Hz, J = 11.7 Hz, 1H), 4.60 (d, J = 3.9 Hz, 1H), 5.10 (t, J = 5.7 Hz, 1H), 5.33 (dd, J = 3.0 Hz, J = 6.9 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 140.26, 135.37, 123.94, 120.65, 97.80, 68.32, 63.70, 62.33, 39.88, 39.68, 35.71, 32.73, 30.74, 26.21, 25.53, 25.27, 19.64, 16.65, 16.44, 15.93. ^{13}C DEPT NMR (75 MHz, $CDCl_3$). δ 35.71 ($HOCH_2CHCH_3CH_2$). HR-ESI-MS calcd for $C_{20}H_{36}NaO_3$ [M + Na]$^+$ 347.2557, found 347.2540.

(*E*,*E*)-12-Azido-3,7,11-trimethyl-1-*O*-THP-2,6-dodecadiene (4). To a flame-dried flask under a nitrogen atmosphere containing 10 mL of CH_2Cl_2 were added *p*-toluenesulfonyl chloride (520 mg, 2.7 mmol) and 4-(*N*,*N*-dimethylamino)-pyridine (400 mg, 3.2 mmol). To this solution was added **3** (880 mg, 2.7 mmol) in 5.0 mL of CH_2Cl_2, and the reaction mixture was stirred at room-temperature overnight. After removing the CH_2Cl_2 in vacuo, the crude mixture was washed with Et_2O (2 × 100 mL). The Et_2O was removed in vacuo, and the residue was dissolved in DMF (10 mL). To this solution was added sodium azide (350 mg g, 5.4 mmol), and the mixture was heated to 80 °C and stirred for 8 h. After cooling, the reaction mixture was mixed with 100 mL of water and extracted using Et_2O (2 × 100 mL). The organic phases were combined and dried over Na_2SO_4. Compound **4** was purified using column chromatography (flash silica) to yield 710 mg (76%) of **4**, a colorless oil (R_f = 0.68, hexanes:EtOAc = 3:1). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.91 (d, J = 4.5 Hz, 3H), 1.38 (m, 6H), 1.52 (m, 4H), 1.60 (s, 3H), 1.68 (s, 3H), 1.82 (m, 1H), 1.99−2.12 (m, 6H), 3.09 (dd, J = 6.9 Hz, J = 12 Hz, 1H), 3.20 (dd, J = 6.0 Hz, J = 12 Hz, 1H), 3.51 (m, 1H), 3.88 (m, 1H), 4.02 (dd, J = 7.5 Hz, J = 12 Hz, 1H), 4.24 (dd, J = 6.5 Hz, J = 12 Hz, 1H), 4.62 (dd, J = 3.0 Hz, J = 4.5 Hz, 1H), 5.01 (t, J = 1.2 Hz, 1H), 5.33 (dd, J = 6.0 Hz, J = 6.5 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 140.23, 135.10, 124.17, 120.69, 97.83, 63.69, 62.32, 57.86, 39.74, 39.68, 33.68, 33.50, 30.78, 26.29, 25.57, 25.12, 19.69, 17.73, 16.46, 15.91. ^{13}C DEPT NMR (75 MHz, $CDCl_3$) δ 33.50 ($N_3CH_2CHCH_3CH_2$). IR 2096 cm^{-1} (N_3). HR-ESI-MS calcd for $C_{20}H_{35}N_3NaO_2$ [M + Na]$^+$ 372.2621, found: 372.2616.

(*E*,*E*)-12-Azido-3,7,11-trimethyl-2,6-dodecadienol (5). PPTS (51 mg, 200 μmol) was added to a solution of **4** (710 mg, 2.0 mmol) in 10 mL of absolute EtOH, and the reaction was stirred at 55 °C for 6 h. After being cooled to room temperature, the solvent was removed in vacuo and **5** was purified using column chromatography (flash silica) to yield 530 mg (98%) of **5**, a colorless oil (R_f = 0.3, hexanes:EtOAc = 3:1). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.94 (d, J = 6.9 Hz, 3H), 1.10 (m, 4H), 1.58 (s, 3H), 1.68 (s, 3H), 1.71 (m, 1H), 1.99−2.16 (m, 6H), 3.11 (dd, J = 6.9 Hz, J = 12 Hz, 1H), 3.21 (dd, J = 6.0 Hz, J = 12 Hz, 1H), 4.16 (d, J = 6.9 Hz, 2H), 5.10 (t, J = 7.2 Hz, 1H), 5.42 (t, J = 6.9 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 139.81, 135.27, 124.07, 123.43, 59.49, 57.89, 39.74, 39.59, 33.66, 33.52, 26.29, 25.12, 17.75, 16.35, 15.94. ^{13}C DEPT NMR (75 MHz, $CDCl_3$) δ 33.52 ($N_3CH_2CHCH_3CH_2$). IR 3376 cm^{-1} (OH), 2096 cm^{-1} (N_3). HR-ESI-MS calcd for $C_{15}H_{27}N_3NaO$ [M + Na]$^+$ 288.2046, found 288.2035.

Diethyl-[(*E*,*E*)-12-azido-3,7,11-trimethyl-2,6-dodecadiene]-phosphate (6). To a stirred solution of **5** (130 mg, 500 μmol) in 4.0 mL of CH_2Cl_2 was added pyridine (60 mg, 700 μmol). After cooling to 0 °C, diethyl chlorophosphate (100 mg, 600 μmol) was added. After 3 h of stirring at 0 °C, Et_2O (60 mL) was added and the crude mixture was filtered. The solution was washed with dilute HCl (2 × 10 mL), saturated $NaHCO_3$ (2 × 10 mL), and saturated NaCl (1 × 20 mL). The organic layer was dried over Na_2SO_4 and concentrated in vacuo to give a colorless oil. Purification of **6** by column chromatography (flash silica) yielded 160 mg (82%) of **6**, a colorless oil (R_f = 0.14, hexanes:EtOAc = 3:2). Slow decomposition of the phosphate was observed by silica gel TLC during fraction analysis. ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.94 (d, J = 6.9 Hz, 3H), 1.31 (m, 10 H), 1.56 (s, 3H), 1.69 (s, 3H), 1.95−2.10 (m, 6H), 3.09 (dd, J1 = 6.9 Hz, J2 = 12 Hz, 1H), 3.19 (dd, J1 = 6.0 Hz, J2 = 12 Hz, 1H), 4.12 (m, 4H), 4.56 (t, J = 7.5 Hz, 2H), 5.06 (t, J = 6.0 Hz, 1H), 5.38 (t, J = 4.2 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 142.59, 135.42, 123.81, 119.03 (d, J = 6.8 Hz), 64.11 (d, J = 5.3 Hz), 63.65 (d, J = 5.8 Hz), 57.86, 39.72, 39.54, 33.67, 33.49, 26.18, 25.10, 17.72, 16.52, 16.27 (d, J = 6.8 Hz), 15.90. ^{13}C DEPT NMR (75 MHz, $CDCl_3$) δ 33.49 (N_3-$CH_2CHCH_3CH_2$). ^{31}P NMR (121 MHz, $CDCl_3$) δ −0.017 (s). FT-IR 2098 cm^{-1} (N_3).

(*E*,*E*)-12-Azido-3,7,11-trimethyl-2,6-dodecadiene-1-diphosphate (7). The following procedure was adapted from Coates's method for the synthesis of isoprenoid diphosphates (*32*). To a stirred solution of **6** (16 mg, 410 μmol) in dry CH_3CN (2.0 mL) was added $[(n\text{-}Bu)_4N]_3HO_7P_2$ (650 mg, 700 μmol). After dissolution, 4-Å molecular sieves were added and the flask was sealed and stirred at room temperature for 4 days. The solution was then filtered, and the filtrate was concentrated in vacuo. The crude mixture was resuspended in water (6.0 mL), and the suspension was applied to an ion exchange column (Dowex 50 W-X8, NH_4^+ form). The crude product was eluted with 25 mM NH_4HCO_3 with 2% 2-propanol, and the clear colorless eluent was lyophilized to dryness to yield a white solid, followed by

purification by reversed-phase HPLC using the following conditions: detection: 220 nm; flow rate: 5.0 mL/min; 5 mL injection loop; gradient: 0−60% solvent B in 60 min; solvent A: 25 mM NH_4HCO_3; solvent B: CH_3CN. Compound **7** eluted from 25% to 30% solvent B. Fractions containing pure **7** were pooled and lyophilized, yielding 54 mg (31%) of a fluffy white solid. ^{1}H NMR (D_2O and ND_4OD, 300 MHz) δ 0.76 (d, J = 6.9 Hz, 3H), 1.21 (m, 4H), 1.46 (s, 3H), 1.56 (s, 3H), 1. 61 (m, 1H), 1.84−2.02 (m, 6H), 3.10 (dd, J = 6.9 Hz, J = 12 Hz, 1H), 3.20 (dd, J = 6.0 Hz, J = 12 Hz, 1H), 4.31(t, J = 6.6 Hz, 2H), 5.08 (t, J = 6.6 Hz, 1H), 5.31 (t, J = 6.0 Hz, 1H).^{31}P NMR (D_2O and ND_4OD) δ −0.61 (d, J = 19 Hz, 1P) and −9.94 (d, J = 19 Hz, 1P). HR-ESI-MS calcd for $C_{15}H_{26}N_3O_7P_2$ [M − H]$^-$ 424.1408, found 424.1395.

Prenylation of *N*-Dansyl-GCVIA. To monitor the enzymatic incorporation of **7** by fluorescence spectroscopy, enzymatic reactions (500 μL) contained 50 mM Tris-HCl, pH 7.0, 10 mM $MgCl_2$, 10 μM $ZnCl_2$, 5.0 mM DTT, 2.4 μM *N*-dansyl-GCVIA, 10 μM **7**, 50 nM yeast PFTase, and *n*-dodecyl β-D-maltoside (0.04%, w/v). Reactions were equilibrated to 30 °C, initiated by the addition of yeast PFTase, and allowed to react for up to 5 min while the fluorescence (340 nm excitation, 505 nm emission) was monitored. Similar reactions containing FPP (10 μM) were run to compare the rate of **7** versus FPP incorporation. For HPLC analysis, enzymatic reactions (25 mL) contained 50 mM Tris-HCl, pH 7.0, 10 mM $MgCl_2$, 10 μM $ZnCl_2$, 5.0 mM DTT, 2.0 μM *N*-dansyl-GCVIA, 100 μM **7**, and 10 nM yeast PFTase. After the addition of the enzyme, the reaction was allowed to proceed for 1 h at 30 °C. The reaction progress was monitored by UV/Vis and fluorescence detection using analytical reversed-phase HPLC. The following conditions were employed: flow rate: 1.0 mL/min; 100 μL injection loop; gradient: 0−100% solvent B in 40 min; solvent A: 0.1% TFA in H_2O; solvent B: 0.1% TFA in CH_3CN.

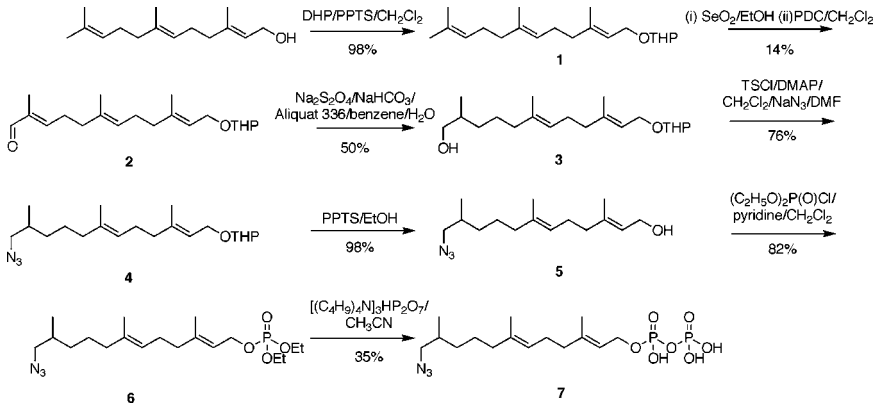
Mutagenesis, Expression, and Purification of eGFP−CVIA. The cDNA of the coding region of eGFP with a CVIA-tag at the C-terminus was obtained by PCR using designed primers (5′-CCGTACCTGCTCGACATGTTCACG CAGTAG-CGTACTTTCGAACCC-3′) and then subcloned into the pET 23c vector (Novagen). The resulting construct was transformed into BL21(DE3) pLysS supercompetent cells (Novagen). The procedure for the expression and purification of eGFP−CVIA (**8**) was adapted from Yakhnin's procedure for the purification of a GFP mutant (*33*). LB media (250 mL), supplemented with ampicilin (0.15 mg/mL), was inoculated with a single colony of cells containing the eGFP−CVIA plasmid and grown with shaking overnight at 37 °C. The overnight culture (10 mL) was added to four 4 L flasks, each containing 1 L of LB and ampicilin (0.15 mg/mL). The OD_{600} of the cells was brought to 0.7 with shaking at 37 °C for 2 h, and induction was initiated by the addition of IPTG to a final concentration of 0.5 mM. The cells were grown with shaking for 14 h at 28 °C after induction. The cells were recovered by centrifugation (24 g). Wet cells were resuspended in 150 mL of Buffer A (20 mM Tris-HCl, pH 8.0; 150 mM NaCl; 1.0 mM PMSF). The cells were lysed by sonication using 30 s pulses for 8 total minutes. The lysis extract was centrifuged (20 400g × 30 min) after which the soluble extract appeared bright green, indicating that **8** was soluble. Triethylamine and ammonium sulfate were added to the supernatant to a final concentration of 100 mM and 1.6 M, respectively. After the suspension was stirred at 4 °C for 1 h, the precipitated proteins were removed by centrifugation (5500g × 20 min) at 4 °C. Additional ammonium sulfate was added to afford 167 mL of a solution that was 70% saturated. A one-fourth volume of EtOH (42 mL) was added to the suspension followed by vigorous shaking. The organic and aqueous phases were separated by centrifugation (4000g × 5 min). In this biphasic mixture, **8** was clearly seen in the organic phase. A one-fourth volume of *n*-butanol (40 mL) was added to the organic phase and, after shaking, the phases were separated by centrifugation (4000g × 5 min). **8** partitioned completely into the lower aqueous phase in this step. An equal volume of chloroform (135 mL) was added to the aqueous phase, and the two phases were separated as described above. **8** was present predominantly in the aqueous phase, which was then set aside. To recover **8** present in the chloroform phase, the lower organic phase was extracted with an equal volume of 30% saturated $(NH_4)_2SO_4$ in water (120 mL) and combined with the aqueous phase mentioned above. Both aqueous phases were combined and loaded directly onto 40 mL of wet phenyl-Sepharose (Amersham, column size: 2.75 × 21 cm), equilibrated with 20% saturated $(NH_4)_2SO_4$ in Buffer B (20mM Tris-HCl, pH 8.0). The column was washed with 100 mL of a $(NH_4)_2SO_4$ linear gradient from 20 to 0% saturation in Buffer B. **8** was eluted from the column with 30 mL of H_2O. The concentration of **8** was determined by UV/Vis spectrophotometry using the extinction coefficient at 488 nm (55 000 L mol^{-1} cm^{-1}) (*34*).

Prenylation of eGFP−CVIA. Enzymatic reactions (40 mL) contained 50 mM Tris-HCl, pH 7.0, 10 mM $MgCl_2$, 10 μM $ZnCl_2$, 5.0 mM DTT, 2 μM **8**, 10 μM **7**, and 10 nM yeast PFTase. Reactions were allowed to proceed for 2 h at 30 °C. The reaction was then concentrated to 500 μL using Amicon Centriprep centrifugation devices, and excess azide was removed using a NAP-5 column (Amersham). For prenylation in crude cell lysate, **8** was first overexpressed, and its concentration was determined by UV/Vis as described above. Large scale enzymatic prenylation reactions (40 mL) containing 2 μM of **8** in crude cell lysate were carried out as described above.

Synthesis of Alkyne-Functionalized Agarose. 10 mL of drained, NHS-activated agarose resin (Amersham) was washed four times with 20 mL of cold 1 mM HCl. 140 μL of propargylamine was added to 4.9 mL of Buffer C (50 mM HEPES, pH 7.2). This 5 mL solution was added to the 10 mL of drained resin, giving a coupling solution:resin ratio of 0.5:1 (v/v). This suspension was mixed on a rotary shaker at room temp for 4.5 h. Unreacted NHS groups were capped by mixing the resin in 10 mL of ethanolamine overnight at 4 °C. The resin was washed with 20 mL of 50 mM Tris-HCl, pH 8.5, followed by 20 mL of 50 mM NaOAc, pH 3.5. This two step washing sequence was repeated twice to remove unbound ligand.

Cycloaddition Reaction on Agarose Beads. The agarose-alkyne suspension was washed (at least 3×) to remove storage EtOH. To the washed beads was added 6.8 μL of 50 mM NaH_2PO_4, pH 7.3, 1.2 μL of $CuSO_4$ (25 mM stock in water), 1.2 μL of TCEP, (25 mM stock in water), 1.8 μL of ligand (1.67 mM stock in DMSO:*t*-BuOH 1:4), and 19 μL of eGFP-N_3 (160 μM stock in 50 mM NaH_2PO_4, pH 7.3). The reactions were mixed using a rotary shaker at room temperature. After allowing the reaction to proceed for 15 h (or 1 h for the quantitative experiments), the beads were washed three times with 50 mM phosphate buffer, pH 7.3, containing 1 M NaCl. For the immobilization of eGFP-N_3 which had been prenylated in crude cell lysate, 33 μL of impure eGFP-N_3 (150 μM stock in 50 mM NaH_2PO_4, pH 7.3) was reacted with the click conditions described above. For studies containing 3% eGFP-N_3, 30 μg of pure GFP-N_3 was diluted with 1 mg of uninduced crude cell lysate. To produce solutions containing lower percentages of eGFP-N_3, 30 μg of pure azide-labeled protein was diluted with increasing amounts of crude cell lysate to yield the desired percentage. These samples were then subjected to the click reaction described above. Fluorescent microscope images were obtained by placing 10 μL of the bead suspension on a microscope slide. The slides were imaged using a Zeiss Atto

Scheme 1. Synthesis of 10,11-Dihydrofarnesyl Azide Diphosphate



Arc HBO 110W Upright Microscope with 20× magnification. FITC filters were used with $\lambda_{ex} = 480$ nm and $\lambda_{em} = 535$ nm. For fluorescence microtiter plate images, the bead suspension was placed in a black-walled, clear-bottom 96-well plate and imaged using a BioRad Gel Doc GS700.

Mass Spectrometry Studies of eGFP Immobilization. After covalent attachment of eGFP-N_3 to the alkyne-functionalized agarose beads, the beads were washed two times each with 400 μL of PBS containing 2.0% SDS, 400 μL of 6.0 M guanidine, and 400 μL of 50 mM NH_4CO_3, pH 8.0 to remove noncovalently bound proteins. The proteins attached to the beads were digested in 50 mM NH_4CO_3, pH 8.0, containing 5.0 mM $CaCl_2$ and 2.6 μg (260 μL) of modified, sequence grade trypsin (Promega) overnight at 37 °C. Beads were then washed sequentially with 50% and 75% CH_3CN in H_2O and lyophilized to dryness. Peptides were redissolved in 400 μL of CH_3CN containing 0.1% TFA. 0.7 μL of this mixture was spotted on a MALDI target along with 0.7 μL of cyano-4-hydroxycinnamic acid (CCA) matrix. A Bruker Reflex III MALDI time-of-flight system (Bremen/Leipzig, Germany) was used to obtain the mass spectral data from this peptide mixture.

RESULTS

The enzyme catalyzed reaction exploited in this study is a posttranslational modification known as protein prenylation. The enzyme, protein farnesyl transferase (PFTase), transfers a 15-carbon isoprenoid to substrate proteins which contain the C-terminal tetrapeptide, CVIA, and related sequences (*35*). Previous studies have shown that peptides containing CVIA at their C-terminus can be prenylated by PFTase with modified isoprenoid diphosphates (*21*, *36*−*38*). In particular, PFTase can prenylate a pentapeptide with a farnesyl diphosphate molecule bearing an azide moiety (*27*). On the basis of these precedents, we reasoned that if a CVIA tag was genetically fused to the C-terminus of a target protein, an azide could be site-specifically incorporated into that protein. To accomplish this, we synthesized 10,11-dihydrofarnesyl azide diphosphate (**7**, Scheme 1), to avoid the isomerism problems resulting from sigmatropic interconversion that occur with analogues containing an alkene at C-10 (*27*). To evaluate **7** as a substrate for PFTase, a continuous spectrofluorometric assay was employed. This assay measures the time-dependent increase in dansyl group fluorescence that occurs as the peptide *N*-dansyl-GCVIA, is prenylated. Incubation of **7** with *N*-dansyl-GCVIA in the presence of PFTase results in a 6-fold increase in fluorescence that is similar to what is observed when the natural substrate, FPP, is used. As shown in Figure 1, at saturating concentrations of **7** (10 μM), the rate of enzymatic prenylation is approximately 2.7-fold slower than the corresponding rate when FPP is used. Thus, it appears that the absence of the alkene in the third isoprene unit of FPP and the presence of the azide group have minimal effect on the reactivity of **7** in the reaction catalyzed by PFTase. The enzymatic incorporation of **7** into *N*-dansyl-GCVIA was also monitored by HPLC (Figure 2). The starting peptide is shown in the lower chromatogram at 21 min; after 1 h of reaction at 30 °C, complete conversion to the prenylated peptide is observed (peak at 34 min, upper chromatogram).

To allow rapid visualization of an immobilized protein, the enhanced Green Fluorescent Protein (eGFP) was used as the model protein for these studies (*39*). The tetrapeptide CVIA was appended onto the C-terminus of eGFP using site-directed mutagenesis, and eGFP−CVIA was overexpressed and purified. Substrate **7** was enzymatically linked to the cysteine of the CVIA tag using PFTase (Scheme 2) to produce eGFP-N_3 (**9**) using the conditions previously established with the peptide substrate to achieve efficient incorporation (100 μM, 10 nM

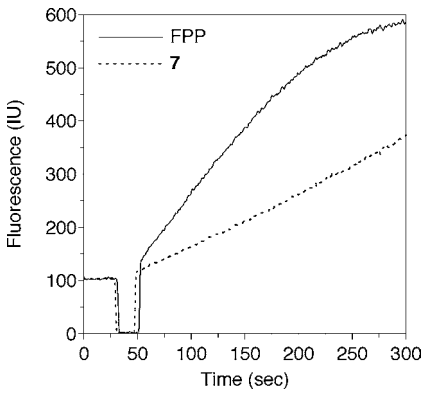


Figure 1. Spectrofluorometric enzyme assay for PFTase-catalyzed prenylation of *N*-dansyl-GCVIA with FPP or **7**. Reactions contained equal concentrations of enzyme (50 nM) and diphosphate substrate (10 μM).

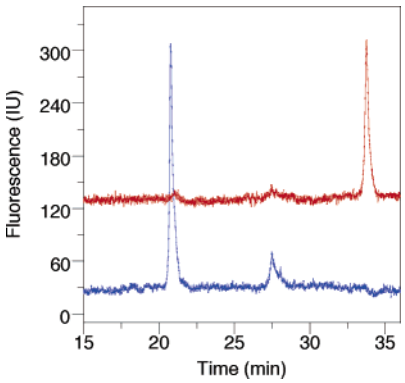

Figure 2. HPLC analysis of PFTase-catalyzed prenylation of *N*-dansyl-GCVIA with **7**. Reactions contained 10 nM enzyme and 100 μM **7**. Lower chromatogram: reaction prior to addition of **7**. Upper chromatogram: reaction after 1 h.

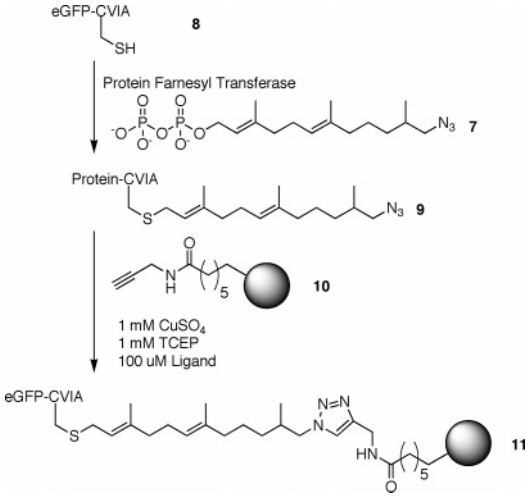
Figure 3. Fluorescence microscope image (top) and bright-field microscope image (bottom) of the capture of pure eGFP-N_3. (A) Reaction of eGFP-N_3 with alkyne-functionalized agarose (**10**) in the absence of $CuSO_4$. (B) Reaction of eGFP-N_3 with **10** in the presence of $CuSO_4$. Beads were incubated with eGFP-N_3 (100 μM), TCEP (1 mM), and ligand (100 μM) in NaH_2PO_4 (50 mM, pH 7.3) with or without $CuSO_4$ (1 mM). After 15 h, beads were washed with buffer containing 1 M NaCl followed by buffer containing 5 mM EDTA.

Scheme 2. Prenylation of a Protein with an Azide and Subsequent Ligation to Alkyne-Functionalized Agarose Beads



PFTase, 30 °C, 1 h); unreacted azide was removed by gel filtration chromatography. Alkyne-functionalized agarose beads (**10**), prepared by reacting NHS-functionalized agarose with propargylamine, were treated with eGFP-N_3, $CuSO_4$, TCEP, and ligand in NaH_2PO_4 buffer (click conditions) (*40*). The cycloaddition reaction was allowed to proceed for 15 h at 25 °C with mild shaking. Beads were then washed extensively with phosphate buffer containing 1 M NaCl to remove nonspecifically bound proteins.

Fluorescence labeling of the agarose beads was observed following reaction with eGFP-N_3 (Figure 3, Panel B). When $CuSO_4$ was omitted, no fluorescence was observed after extensive washing of the beads, indicating that no reaction had occurred between azide and alkyne (Figure 3, Panel A). If $CuSO_4$ is included in the reaction, however, the protein is covalently attached to **10** as indicated by the strong fluorescence of the beads. Fluorescence remained after washing with 1 M NaCl and 100 mM EDTA, consistent with the idea that the protein is covalently bound to the bead.

To confirm that the protein was covalently immobilized, agarose beads that had been reacted with eGFP-N_3 in the presence of the click conditions were washed extensively with

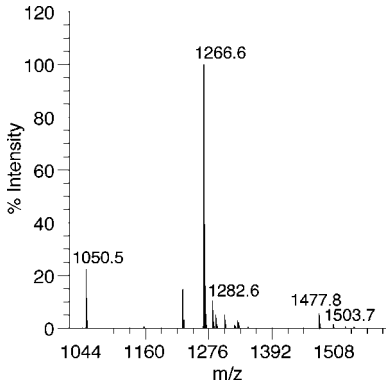


Figure 4. Mass spectrum (MALDI-TOF) of tryptic digest of eGFP immobilized on agarose beads. eGFP-N_3 was immobilized onto **10** using the click conditions described in the legend to Figure 3.

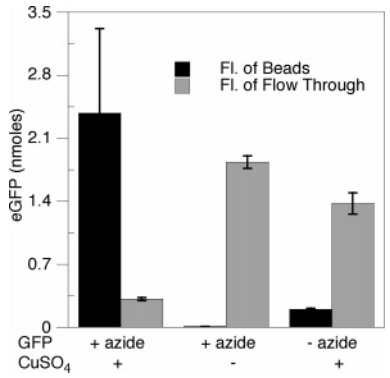

Figure 5. Quantitative analysis of eGFP immobilization. eGFP-N_3 was immobilized onto **10** using click conditions and the amount of eGFP on the beads and in the wash solution was quantified by fluorescence.

buffer containing 2% SDS and 6 M guanidine. This step was performed to ensure that any noncovalently bound species were removed from the beads prior to analysis. The eGFP-functionalized beads were then digested with trypsin overnight at 37 °C, and the eluted peptides were analyzed by MALDI-TOF-MS (Figure 4). Peptide fragments of *m*/*z* 1050.5, 1266.6 1282.6, 1477.8, and 1503.7 were observed, which correlate with tryptic peptide fragments of eGFP. It should be noted that the samples were not purified by ZipTip prior to spotting on the MALDI target, which might explain why only 5 out of roughly 40 tryptic peptides of eGFP were observed.

To determine the extent of the Cu(I)-catalyzed cycloaddition reaction, eGFP-N_3 was reacted with **10** under the click conditions for 1 h. Beads were then washed and resuspended in phosphate buffer, and the fluorescence intensity present in the suspended beads was measured. The moles of eGFP were directly calculated from the fluorescence intensity using a standard calibration curve. When azide-functionalized eGFP (2.5 nmol) was reacted with **10** under the click conditions, 2.4 nmol of eGFP (96%) was covalently immobilized onto the beads (Figure 5). However, when eGFP-N_3 was incubated with **10** in absence of $CuSO_4$, only 0.01 nmol of eGFP was covalently bound. Interestingly, 0.20 nmol of protein (8%) was immobilized when eGFP, which had not been prenylated with the azide, was incubated with **10** under the click conditions. This background labeling might be caused by the Cu(I)-induced activation of the alkyne-agarose, which can then react nonspecifically with proteins. Cravatt and co-workers have reported similar findings in their activity profiling experiments (*41*). The fluorescence of the flow through from the first washing of the beads after the cycloaddition reaction was also measured. When copper was omitted, approximately 83% of the eGFP was observed in the eluent. Alternatively, 18% of the fluorescent protein eluted after

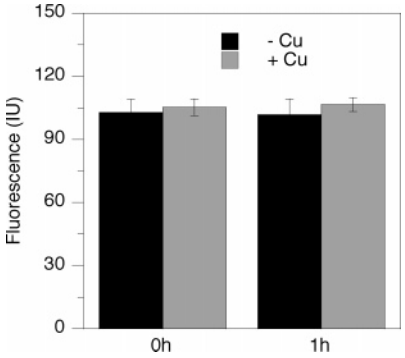

Figure 6. Effects of click conditions on eGFP fluorescence. 50 μM eGFP was incubated with 1 mM $CuSO_4$, 1 mM TCEP, 100 μM ligand in NaH_2PO_4 (50 mM, pH 7.3) for 1 h. The fluorescence intensity was measured ($\lambda_{ex} = 488$ nm; $\lambda_{em} = 508$ nm) and [eGFP] was determined using a standard calibration curve.

having been incubated with the click conditions for 1 h. These values are in general agreement with the moles of eGFP immobilized. Taken together, these two independent measurements suggest that when eGFP-N_3 is incubated with **10** under the click conditions for 1 h, more than 80% of the protein is covalently immobilized onto the beads.

We next tested whether the click conditions, specifically Cu(I), had deleterious effects on eGFP and its native fluorescence. The eGFP protein was incubated both in the presence and absence of $CuSO_4$, TCEP, and ligand for 1 h and the protein's fluorescence was measured (Figure 6). After incubation at room temperature for 1 h in the absence of the click conditions (protein + buffer), a 1% loss in the fluorescence of eGFP was observed. When the protein was incubated in the presence of the click conditions, no loss in the fluorescence of eGFP was observed. This indicates that the click conditions do not affect eGFP's native fluorescence.

In proteomic analysis, the desired target to be captured is not always pure or in high abundance, thus necessitating the need for specific modification strategies that function in a crude mixture. To test the ability of the above labeling and capture technique to target low abundance proteins, eGFP−CVIA was overexpressed and prenylated in the presence of crude cell lysate. The eGFP-N_3 concentration in that unpurified sample which was found to be 12% of the total protein content, was immobilized onto **10** only when copper was included in the reaction (data not shown). If copper is omitted, no cycloaddition reaction occurs between protein and bead. We next tested whether a sample containing a lower percentage of eGFP-N_3 could be immobilized. To accomplish this, uninduced, crude cell lysate was added to eGFP-N_3 (25 μM), so that the final amount of protein-azide was 3% of the total protein mixture. A sample of that protein mixture fractionated by SDS−PAGE is shown in Figure 7A; while eGFP-N_3 is still a major component in the mixture, it is clear many other proteins are present. The low abundance eGFP-N_3 sample was then subjected to the cycloaddition reaction in the presence and absence of $CuSO_4$ (Figure 7B). When copper was included in the reaction, the beads remained fluorescent even after extensive washing indicating the cycloaddition reaction occurred, while omission of copper resulted in no fluorescence. Lower percentages of eGFP-N_3 were also tested for their ability to be captured by **10** (Figure 7C). Pure eGFP-N_3 (25 μM) was diluted with varying amounts of crude cell lysate and reacted with **10** under the click conditions. Remarkably, protein mixtures containing as low as 1% eGFP-N_3 can be successfully ligated to the alkyne-functionalized agarose beads. Actually, this lower limit is probably dictated by the somewhat weak fluorescence of GFP and not the efficiency of the linking reaction.

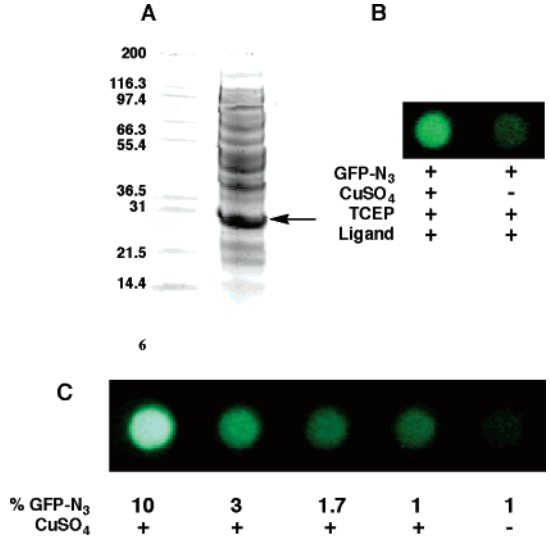

Figure 7. Capture of varying percentages of eGFP-N_3 in crude cell lysate. (A) SDS−PAGE analysis of 3% eGFP-N_3 in crude cell lysate. Lane 1: molecular weight standard; Lane 2: 3% eGFP-N_3; eGFP-N_3 is marked by the arrow. (B) Reaction of 3% GFP-N_3 with **10** in the presence and absence of $CuSO_4$. Uninduced crude cell lysate (1 mg, determined using the BioRad assay) was added to 30 μg of eGFP-N_3 to yield 3% GFP-N_3. (C) Labeling of agarose with varying percentages of eGFP-N_3. **10** was treated overnight with varying percentages of eGFP-N_3 in crude cell lysate in the presence of the click conditions described in the legend to Figure 3.

DISCUSSION

This work highlights the development of a method to covalently attach proteins to surfaces in a site-specific manner. This strategy offers several key advantages over other immobilization techniques. To date, most site-specific immobilization strategies have relied on the use of large (>20 kDa) protein fusions (*13*−*16*). While such systems have already proven to be useful for a variety of applications, there are some limitations to such approaches. The fusion protein strategy requires that the fusion protein be efficiently expressed and that the resulting chimeric molecule be soluble and free from problems of aggregation (*42-44*). Fusion proteins are also not always posttranslationally processed and/or localized in the same fashion as their parental progenitors (*45-47*). Finally, fusion domains may interfere with the function of the desired protein or enzyme (*48*). Recently, Camarero has introduced a method for proteins that uses a split-intein ligation method to achieve traceless immobilization (*17*). While that method has significant potential, it still requires the desired target protein to be initially expressed as a fusion prior to intein- mediated immobilization. It also requires chemical synthesis of a 39 residue C-terminal intein fragment and its linkage to a solid support for capture of the expressed target protein−intein fusion.

In the method described here, a small fusion (four residues) is used, and hence it is unlikely to impact the physical properties or the target protein. The specificity of PFTase ensures that the protein of interest is only modified on its C-terminus, which in most cases should not affect its function once attached to the surface. Additionally, the azide functional group can be coupled to a specific site within the protein even in the presence of multiple cysteines. A search of the Swiss-Prot Protein Database revealed 64 *E. coli* proteins with a cysteine located at the fourth residue from the C-terminus. However, none of these proteins have aliphatic residues at the two "X" positions within the CAAX box motif and a C-terminal residue (Ser, Met, Ala, Cys) that is recognized by PFTase. Therefore, only the protein of interest will be modified by **7** when using *E. coli* as the overexpression host. This method is also a procedure amenable

to large scale immobilization. The precursor for azide **7** is farnesol (**1**), a relatively inexpensive starting material; PFTase, used to incorporate the azide, is used in catalytic amounts. Additionally, the linkage is covalent and thus stable to a variety of conditions. Importantly, neither the enzymatic azide incorporation nor the subsequent immobilization chemistry require the target protein to be pure. Finally, it should be noted that the approach reported here is not limited only to the immobilization of target proteins. In principle, it can also be used to link a broad range of reporter groups ranging from low molecular weight fluorophores to proteins and nanoparticles to the C-termini of many proteins. Consequently, this chemoenzymatic approach should be broadly applicable for a variety of studies in proteomics and protein chemistry.

ACKNOWLEDGMENT

The authors thank the Cravatt and Sharpless labs for the gift of the ligand, and Byeong-Su Kim, Jin-Hwa Chung, and the University of Minnesota Biomedical Image Processing Lab for technical assistance. This work was supported by the National Institutes of Health (Grant No. GM008700 and GM58442).

A series of dendrimeric conjugates based on a PAMAM (polyamidoamine) backbone with macrocyclic Gd−DO3A-P^{ABn} complexes (monophosphinated analogue of DOTA) was prepared. The chelates were covalently attached to the G1-, G2-, and G4-PAMAM dendrimers through a thiourea linker in high loads (>90%). The prepared conjugates G1−(Gd−DO3A-P$^{BnN\{CS\}}$)$_8$, G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$, and G4−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{59}$ showed relaxivities of 10.1, 14.1, and 18.6 s^{-1} mM^{-1} at 20 MHz and 37 °C and pH = 7.5, respectively. A variable-pH study (range 2−12) revealed up to 30% increase in the relaxivity at low pH for the G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$ conjugate. As confirmed by ^{1}H NMR titration of the unmodified G2 dendrimer, this is due to protonation of core tertiary amines leading to a more open and rigid structure. The variable-temperature ^{17}O NMR and ^{1}H NMRD relaxometric studies confirmed that the relaxivity is not controlled by water exchange but by rotational dynamics. A multiparametrical data evaluation using the Lipari−Szabo approach revealed that the water residence lifetime, $^{298}\tau_M$, for the conjugates studied was ca. 45−70 ns, which is longer than the value found for the monomeric model compound Gd−DO3A-P^{ABn} (16 ns) but short enough so as not to limit the relaxivity. The global rotational correlation time, $^{298}\tau_{Rg}$, varied from 1.5 to 3.1 ns and seemed to indicate a sufficiently slow molecular tumbling to achieve the high relaxivities measured; however, the rigidity factor S^2 (∼0.26), describing the internal flexibility, was far from optimum. The overall relaxivity was significantly increased (e.g. by a factor of 1.8 for the G1−(Gd−DO3A-P$^{BnN\{CS\}}$)$_8$ conjugate) when a positively charged polyaminoacid like poly(Arg) or poly(Lys) was added to the conjugate solutions. The electrostatic interactions partially "freeze" the internal mobility of the conjugate and also slow down global motion. This assumption was confirmed by an evaluation of ^{1}H relaxometric data obtained for the G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$−poly(Lys)$_{59}$ adduct. Importantly, it was proved that the adduct formation did not hamper the water exchange process.

INTRODUCTION

The family of polyamidoamine (PAMAM) starburst dendrimers has been the first class of dendrimers well characterized and commercialized (*1*). They are based primarily on an aliphatic di- or multiamine core, which is surrounded by a shell synthesized in a successive addition reaction of methyl acrylate with ethylenediamine (*1*). By an iterative application of this step, the dendrimeric architecture grows and one concentric shell (generation) is covered by another. PAMAM dendrimers are highly water-soluble globular molecules with primary amino groups exposed on their surface (Chart 1).

The number of amino groups on the surface grows exponentially with the dendrimer generation: i.e. there are 8 amino groups on the dendrimer of a generation one (G1), 16 on G2, 32 on G3, 64 on G4, etc. (*2*). These dendritic structures are characterized by an extremely low polydispersity, nontoxicity, and an ease of chemical modification, and they have been exploited in a wide range of biomedical applications such as drug delivery, gene therapy, micelle mimics, decontamining agents, immunodiagnostics, and/or in vitro gene expression (*1*). For their broadly favorable properties, PAMAM dendrimers have been used also in the preparation of contrast agents (CA) for magnetic resonance imaging (MRI) (*3*), specifically as carriers able to covalently bind molecules responsible for the contrast enhancement effect.

MRI has become one of the most powerful and fastest developing diagnostic methods in medicine. In particular it has proved to be very effective in visualizing soft tissues with excellent spatial resolution. The principle of this method lies in a "mapping" of concentration and magnetic properties of tissue water by measuring signal intensity and magnetic relaxation times of protons in 3D space. These characteristics may vary significantly not only between different tissues but also within one type of a tissue resulting in a significant gain in image contrast. This contrast can be enhanced further by application of MRI CAs, which are routinely administered in more than 45% of MRI investigations. A molecule of CA catalyzes the magnetic relaxation of water protons in its vicinity and can increase further the contrast between healthy and pathological tissue. In the past two decades, chemists have made significant progress in the design and application of such compounds and have clarified the relationship between a CA's structure and its efficacy. The efficacy is measured by the

increase in the longitudinal relaxation rate of the water protons in a 1 mM solution of the CA; this parameter is known as *relaxivity*, r_1 (*4*−*7*). Among the most commonly used CAs affecting the longitudinal relaxation time T_1 are complexes of the highly paramagnetic Gd^{3+} ion. As this ion is highly toxic in a "free" state, it has to be bound as a thermodynamically stable and kinetically inert complex but should still allow for exchange of magnetic information between the metal center and bulk water. Linear polyamine (e.g. DTPA = diethylenetriamine-pentaacetic acid) or polyazamacrocycle (e.g. DOTA = 1,4,7,-10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) derivatives with coordinating acetate arms have been commercially employed as they form sufficiently stable Gd(III) complexes and leave one or two coordination sites available for water molecule(s) (Chart 2). Unfortunately, the typical relaxivities of these compounds are about 4−5 s^{-1} mM^{-1} (at 20 MHz and 298 K) whereas according to the theoretical model these values could be increased to more than 100 s^{-1} mM^{-1} for an ideal CA (*8*). In order to attain theoretical relaxivities and challenge the new emerging applications of MRI, e.g. in molecular imaging (*9*), the structure of the Gd(III) chelates must be optimized.

According to the Bloembergen−Solomon−Morgan (BSM) theory, which connects the macroscopic relaxivity with intrinsic structural parameters of Gd(III) complexes, the residence lifetime of the coordinated water molecules, τ_M, and the rotational correlation time, τ_R, are the most crucial factors. Optimal values of τ_M lie in the range 10−50 ns, but most commercial CAs show values that are approximately 1 order of magnitude higher. In the past few years, several systems endowed with a sufficiently fast water exchange have been developed. The rate of water exchange was shown to be dependent on the overall charge (*10*), coordination geometry (*11*), flexibility of the coordination polyhedron (*11*), and/or steric interaction with proximate groups of the ligand (*12*−*17*). For instance, when one acetate arm in DOTA (i.e. DO3A-P^{ABn}) is replaced by a bulky phosphinate group, the water residence lifetime for the corresponding Gd(III) complex (at 298 K) was found to change from 243 ns (*18*) to 16 ns (*16*).

For complexes with an optimized water exchange rate, the relaxivity is controlled primarily by the rotational correlation time: if the molecular tumbling is too fast, the relaxivity enhancement is limited. In order to increase the size of the molecule, the small Gd(III) complexes could be covalently conjugated to macromolecular carriers like PAMAM dendrimers. The conjugation may not only increase the rotational correlation time but also significantly improve the biochemical properties of the CA (*3*); however, most of the dendrimeric systems investigated in the past suffered from the same two primary limitations: (i) the slow water exchange process (*19*) and (ii) the high degree of an internal mobility which super-

imposes the global motion of the whole dendrimer (*20*). A few covalent conjugates with gadolinium(III) complexes, characterized by a rather fast water exchange, have been studied (*21*−*23*), but in all cases the relaxivity was limited by the internal mobility of the system.

To reduce this undesired effect, we explored systems where the fast-water-exchanging Gd−DO3A-P^{ABn} complex was covalently attached to PAMAM dendrimers and then the whole negatively charged structure made rigid by addition of cationic polyaminoacids such as poly(Arg) or poly(Lys). Recently, we published a brief account where it was shown that the adduct of G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ dendrimer with poly(Arg)$_{56}$ afforded relaxivity enhancement by a factor of 1.6 in comparison with the pure conjugate (*24*).

In this research four low- and middle-generation PAMAM-based gadolinum(III) complexes were studied: G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$, G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_9$, G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$, and G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$. The influence of a possible, undesired electronic Gd^{3+}−Gd^{3+} interaction was evaluated by comparison of the properties of the G2-Gd(III)/Gd(III) and mixed -Y(III)/Gd(III) complexes, and in addition to the routine solution characterization measurements such as variable-temperature ^{17}O NMR, ^{1}H NMRD, and pH-dependent relaxivity studies, relaxometric titrations with several polyaminoacids, poly(Arg)$_{56}$, poly(Arg)$_{320}$, poly(Lys)$_{56}$, and poly(Lys)$_{17}$, were also measured. For selected adducts, ^{1}H NMRD profiles and variable-temperature relaxivity measurements were performed to quantify the change of structural parameters during adduct formation.

EXPERIMENTAL SECTION

Materials. All reagents and solvents commercially available were used as received. DO3A-P^{NCS} and CS(DO3A-P^{NBn})$_2$ were prepared according to the procedure described in the literature (*25*). The starburst PAMAM dendrimers (producer, Dendritech Inc., Midland, MI) of generation 1 (G1), 2 (G2), and 4 (G4) with 8, 16 and 64 terminal primary amino groups were purchased as methanolic solutions from Aldrich, respectively. The lanthanide(III) chloride salts were obtained from Strem or Aldrich. Commercially available polyaminoacids were purchased from Sigma. Ultrafiltration equipment (UF-cell 8050 and 800 mL storage) including membranes YM3 and YM10 (Amicon, Bedford, MA) were purchased from Millipore. Analytical ^{1}H and ^{31}P spectra were recorded on a Varian ^{UNITY}-INOVA-400 spectrometer. All NMR samples were measured in D_2O (99.98%, Chemtrade, Germany) if not otherwise stated. Elemental analysis was performed by Redox S.n.c. (Monza, Italy). ICP-MS spectra were measured on an Element-2, Thermo-Finnigan spectrometer (Rodano, Italy). MS spectra of synthesized poly(Lys)$_{17}$ were acquired on a MALDI spectrometer in a positive reflection ion mode with delayed extraction on a Reflex III TOF instrument (Bruker Daltonics, Bremen, Germany) equipped with a 337 nm nitrogen laser. This instrument was located in the Laboratorio Integrato di Metodologie Avanzate (LIMA), Bioindustry Park of Canavese, Colleretto Giacosa, Ivrea, Italy.

Synthesis of PAMAM-DO3A-$P^{BnN\{CS\}}$ Conjugates. General Procedure. The synthesis of G1−(DO3A-$P^{BnN\{CS\}}$)$_8$, G2−(DO3A-$P^{BnN\{CS\}}$)$_9$, G2−(DO3A-$P^{BnN\{CS\}}$)$_{16}$, and G4−(DO3A-$P^{BnN\{CS\}}$)$_{59}$ followed the same protocol. For preparation of about 200 mg of conjugate, equimolar amounts of DO3A-P^{NCS} (per number of primary amino groups on PAMAM) and PAMAM were mixed in a small volume of H_2O (typically 5 mL), pH was adjusted to 9 with 1.5 M KOH, and the solution was stirred for 12 h at 40 °C. Then, an additional portion (0.5 molar equiv) of DO3A-P^{NCS} was added, the pH was readjusted to 9, and the mixture was stirred at 40 °C for an additional 12 h. Subsequently, the pH was adjusted to 7 by addition of concentrated HCl and the solution filtered through Millipore Millex 5 μm and 0.22 μm syringe filters into the ultrafiltration cell. The solutions were ultrafiltered in two cycles at 3 atm (i.e. concentrated from 50 mL to 10 mL and diluted again). For G1 and G2 conjugates, membranes YM3 (with cutoff at 3 kDa) were used, whereas the G4 conjugate was filtered through YM10 membrane (with cutoff at 10 kDa). The solutions were diafiltered at 4 atm until ca. 800 mL of elution water was collected. The resulting conjugate solution was evaporated to dryness, yielding a solidified, glassy product. The number of chelates attached to the dendrimer was determined by ^{1}H NMR spectrum integration (aromatic vs alkyl region) and by calculation of the nitrogen/sulfur ratio obtained from elemental analysis (*3*). The loadings indicated in this work are the averages from both methods; the observed loadings were quite similar with maximum differences of 0.5 chelate unit for the G1 and G2 conjugates and 1 chelate unit for the G4 conjugate.

Synthesis of Gd(III) and Gd(III)/Y(III) Complexes. For preparation of the full-loaded Gd(III) complexes, the conjugate (typically 200 mg) was dissolved in H_2O (8 mL) and 2 equiv of $GdCl_3$ (per one chelate unit attached to the dendrimer) was added. A small amount of bromothymol blue indicator was added and the pH adjusted to about 6.5−7.0 (green color of the solution) by addition of 1.5 M KOH, and the excess Gd(III) salt precipitated. The mixture was stirred overnight at 50 °C and 1.5 equiv of Na_2H_2EDTA (per total Gd(III) amount) added, the pH value readjusted, and the solution stirred for an additional 6 h at RT. Almost immediately after addition of Na_2H_2EDTA, the Gd(III) salt precipitate was complexed by EDTA and dissolved. The resulting clear green solution was filtered through Millipore Millex 5 μm and 0.22 μm syringe filters into the ultrafiltration cell, and the solution was concentrated twice and then diafiltrated until about 500 mL of water was collected. The slightly yellow solution of the complex was evaporated to obtain a glassy, solid product. The procedure for preparation of the mixed Gd(III)/Y(III) complex of G2−(DO3A-$P^{BnN\{CS\}}$)$_{16}$ was similar except that in the first step only 0.5 equiv of $GdCl_3$ (per number of chelates on the dendrimer) was added. After 12 h at 50 °C, 1.5 equiv of YCl_3 was added and the following workup was the same as in the previous case. Typical yields obtained from this procedure were about 80% calculated on the empirical formula obtained from elemental analysis. The exact Gd(III) loads were obtained from a comparison of the sulfur and the gadolinium contents determined by ICP-MS measurement. For G1−(DO3A-$P^{BnN\{CS\}}$)$_8$, G2−(DO3A-$P^{BnN\{CS\}}$)$_9$, G2−(DO3A-$P^{BnN\{CS\}}$)$_{16}$, and G4−(DO3A-$P^{BnN\{CS\}}$)$_{59}$ conjugates, 7.5, 8.5, 15.2, and 58.3 gadolinium ions per conjugate were found, respectively. In the case of G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ and G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$ complexes, the results from ICP-MS were compared with ^{1}H NMR relaxometric titrations and were in good agreement (see below). Unfortunately, we were not able to obtain any mass spectrometric data (ESI with ion-trap detector or MALDI-TOF) from the pure conjugates or their gadolinium(III) complexes. Most likely the procedure failed because of the polyanionic and complexing nature of the compounds responsible for the unavoidable capture of a large number of H^+, Na^+, and/or K^+ cations during the measurements.

Gd(III) Loads Determination by Relaxometric Titration. Diluted 1 mM and 0.2 mM solutions, respectively, were prepared from the conjugates G2−(DO3A-$P^{BnN\{CS\}}$)$_{16}$ and G4−(DO3A-$P^{BnN\{CS\}}$)$_{59}$. Solutions for the relaxometric titrations for both conjugates were divided into 13 vials (0.6 mL each) into which the $GdCl_3$ was added so as to vary the molar ratio of Gd per chelate from 0 to 2. The Gd(III) complex formed during stirring overnight at pH 7 and 50 °C; each solution was

subsequently passed through a syringe filter (5 μm) into an NMR tube. The relaxivities were measured and plotted against exact Gd^{3+} concentrations as determined by the bulk magnetic susceptibility shift (BMS) measurement (*26*). The sample without Gd^{3+} was used as a reference. In both cases, the relaxivity increased linearly with Gd^{3+} concentration up to the point where the theoretical equivalence was reached, and then the data deviated indicating an "overtitrated" solution wherein hydrolysis of the "free" Gd^{3+} occurred. This nonlinearity was ascribed to the presence of nonstoichiometric Gd-conjugate phase, wherein the Gd^{3+} was nonspecifically sorbed.

Synthesis of Poly(Lys)$_{17}$ Peptide. The peptide was prepared on an automatic robotic synthesizer Syro II (Multisintech GmbH, Germany) located at LIMA laboratories, Bioindustry Park of Canavese, Colleretto Giacosa, Ivrea, Italy. The Fmoc-protected amino acids were purchased from Advance Biotech srl (Italy), and the coupling reaction was carried out on Fmoc-PAL-PEG-PS resin (Applied Biosystem). The poly(lysine) chain was doped by three proline residues to avoid an aggregation. The sequence was $(Lys)_5$-Pro-$(Lys)_5$-Pro-$(Lys)_5$-Pro-$(Lys)_2$.

^{17}O NMR Measurements. Variable-temperature ^{17}O NMR relaxation measurements were performed on a JEOL EX-90 spectrometer (2.1 T, 12.2 MHz) with external locking system (D_2O). Experimental settings were as follows: spectral width 10 000 Hz, pulse width 7 μs (90°), acquisition time 10 ms, 2048 scans, and no sample spinning. The complex solutions were enriched by addition of $H_2{}^{17}O$ (6%, Yeda, Israel) to an overall ca. 0.2% ^{17}O concentration. Transversal ^{17}O NMR relaxation rates were calculated from the line widths of the ^{17}O signals at half-heights. The ^{17}O profiles were measured from 0 to 90 °C at 10 °C increments. All the samples were conditioned for 10 min at each temperature prior to the measurement to ensure the full temperature equilibrium. The temperature was calibrated using a thermocouple probe and is correct within ±0.5 °C. The time necessary for temperature stabilization has been established from a number of similar measurements made with this instrument. The exact concentrations of Gd^{3+} were determined by BMS measurements. As references, the samples of Gd-free conjugates at the same pH were used.

^{1}H NMRD (Nuclear Magnetic Relaxation Dispersion) Profiles. ^{1}H NMRD profiles were measured on a Stelar Spinmaster FFC-2000 fast-field cycling relaxometer (Mede, Italy) in a magnetic field range from 2.4×10^{-4} to 1.6 T (corresponding to 0.01−70 MHz of proton Larmor frequencies). For all measurements, the samples contained about 1 mM concentration of Gd^{3+} in nondeuterated water, but the exact concentrations of Gd^{3+} were determined by measurement of BMS. The ^{1}H T_1 relaxation times were acquired by the standard inversion recovery method with typical 90° pulse width of 3.5 μs, 16 experiments of 4 scans. The reproducibility of the T_1 data was ±5%. The temperature was controlled with a Stelar VTC-91 airflow heater equipped with a calibrated copper−constantan thermocouple (precision of ±0.1 °C). The NMRD profiles were measured at 25 and 37 °C.

pH and Temperature Dependence of Proton Relaxivity. The pH and VT studies of proton T_1 relaxation times were carried out on an FFC relaxometer at the fixed field of 0.45 T (corresponding to 20 MHz of proton Larmor frequency) and 25 °C. For the pH dependence measurements, 1 mL samples of 0.5−1 mM solutions of the conjugate (calculated per gadolinium) were prepared and about 100 μL was placed in a 5 mm NMR tube. The pH was adjusted by addition of 1 M KOH or concentrated hydrochloric acid to cover the range from 2 to 12. Some values were measured repeatedly to exclude any influence from increasing ionic strength or a changing concentration; the reproducibility of the values was good within the experimental error (±2%). The VT-^{1}H r_1 dependence was measured for the G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$−poly(Lys)$_{61}$ adduct at a molar ratio of poly(Lys)$_{56}$/conjugate of 10:1 and pH 7.5. The temperature was controlled by a Stelar VTC-91 airflow unit equipped with a calibrated copper−constantan thermocouple (precision of ±0.1 °C). The desired temperature was set up either by the internal heater or by an attached liquid nitrogen evaporator.

Interaction with Polyaminoacids. Relaxometric Study. The titrations were carried out at fixed concentrations of the dendrimer and variable concentrations of the polyaminoacid. For each study, 5 mL of the 0.5 mM batch solution (calculated per gadolinium) of the dendrimeric complex was prepared and this solution divided into 11−15 samples containing 300 μL each. In the second step, the polyaminoacids were dissolved in water to obtain solutions of about 1 mM concentration each. The titration sample for ^{1}H T_1 measurement was obtained by adding 50 μL of the polyaminoacid solution into the vial containing the dendrimeric complex and about 100 μL of the resulting solution transferred into a 5 mm NMR tube. In the next step, the batch solution of the polyaminoacid was diluted twice and the procedure repeated. In this way the dendrimer/aminoacid ratio changed during the titration by 3.5−4 orders of magnitude. The pH values of the samples were randomly checked and found to be about 7.5.

Data Processing, Evaluation, and Molecular Modeling. The simultaneous least-squares fitting of the ^{1}H NMRD and ^{17}O NMR T_2 data was performed with Micromath Scientist (*27*) fitting routines based on the Bloembergen−Solomon−Morgan (BSM) equations or the Lipari−Szabo modification (see Supporting Information). All data and charts were preprocessed and exported in Microcal Origin (*28*) or MSI WebLab Viewer (*29*). Molecular modeling was performed in Hypercube Hyperchem 7.5 (*30*). Acidity constants of the pure G2-PAMAM were obtained using the OPIUM package (*31*).

RESULTS AND DISCUSSION

Synthesis of Conjugates and Their Lanthanide(III) Complexes. All "full-loaded" conjugates were prepared by the same general procedure. The isothiocyanate derivative DO3A-P^{NCS} was prepared in advance according to the published procedure (*25*) and then added in two portions (50% overall excess) to the methanol/water solution of the corresponding free dendrimer. This approach leads to the higher loads because part of the isothiocyanate is wasted when it is added in one step due to the formation of the ditopic compound CS(DO3A-P^{NBn})$_2$ (Chart 2) arising from the reaction between the hydrolyzed isothiocyanate (i.e. the amine) and the other isothiocyanate molecule. The pure conjugates were obtained by ultrafiltration through a membrane with an appropriate cutoff. The "half-loaded" G2 conjugate was prepared by addition of 9 equiv of DO3A-P^{NCS} to a solution of the free G2 dendrimer. The subsequent workup of the reaction mixture followed the same procedure as described above. The loads of the chelate were determined by ^{1}H NMR signal integration and by elemental analysis using the N/S ratio. With both methods very similar results were obtained; since the isothiocyanate group is highly reactive under these conditions, full saturation was realized in G1 and G2 conjugates and 92% saturation for the G4 conjugate. For the "half-saturated conjugate", a 56% load was obtained, as expected, because the low-generation dendrimers adopt a flexible conformation in solution in contrast to that expected for the higher generations that tend to form internal cavities preventing the penetration of the reactant to the interior (*2*). The N/S ratio does not depend on water content, and, therefore, it was possible to calculate the amount of the pure conjugate in the solid samples; on average, all conjugates in solid form contained about 10% water. Characterization of the prepared conjugates by various mass

spectrometric techniques (MALDI or ESI) was attempted; however, it was not possible to observe any resolved signals as a consequence of a formation of multiply charged species containing a high number of H^+, K^+, and/or Na^+ counterions.

The Gd(III) complexes were prepared by mixing a solution of the appropriate conjugate with a 50% excess of $GdCl_3$. The noncomplexed Gd^{3+} ion was scavenged by addition of excess Na_2H_2EDTA, and all low-molecular-weight impurities were removed by ultrafiltration. A check for the presence of "free" Gd^{3+} ions in the gadolinium-loaded conjugates by the standard Xylenol Orange test was proved unreliable as the negatively charged conjugates may coordinate some number of Gd^{3+} ions in a nonspecific way. In order to determine the degree of loading of Gd^{3+}, relaxometric titrations and ICP-MS measurements were performed to get the exact number of gadolinium(III) per chelate. Both methods were in agreement and indicated that there were approximately 0.9 gadolinium atom per chelate in all conjugated complexes. Additionally, the value of relaxivity obtained by relaxometric titration indicated that the conjugates have one water molecule coordinated to the Gd^{3+} ion (Figure S1, Supporting Information).

The mixed Gd(III)/Y(III) G2 conjugate was prepared sequentially as follows: the free conjugate was mixed with 0.5 equiv of $GdCl_3$ per chelate and the solution heated (50 °C) and stirred overnight; 1 equiv of YCl_3 per chelate was added, and after incubation under the same conditions as before, Na_2H_2EDTA was added to scavenge any remaining lanthanide(III) salts and the resulting solution was ultrafiltrated. The amount of conjugate-bound gadolinium was determined by ICP/MS to be 44%.

The molecular structure of the complex should be the same as that observed for lanthanide(III) complexes of DOTA and the parent ligands, DO3A-P^{ABn} and CS(DO3A-P^{NBn})$_2$. As shown previously, in the solid state (*15*, *32*) as well as in the solution (*15*, *16*, *25*) the central ions are sandwiched between N4 (ring amine nitrogen atoms) and O4 (three acetate and one phosphinic acid oxygen atoms) coordination planes with one water molecule capping the O4 plane. As in other lanthanide(III) complexes with DOTA-like ligands, equilibrium between two distereoisomeric forms, SA (square-antiprism) and TSA (twisted square-antiprism), was observed in solutions of the complexes with the parent ligands (*15*, *16*, *25*).

Studies on pH-Responsive Structural Changes. It is well-known that PAMAM dendrimers as a class of polyelectrolytes can adopt a wide range of conformations in solution depending on the stage of protonation since, as the outer-shell and inner-shell amines are being protonated, the electrostatic repulsion results in a more expanded and more hydrated structure (*33*). This issue has been the subject of many physicochemical studies on pure PAMAMs; however, it was discovered quite recently by Merbach et al. (*22*) and us (*24*) that this phenomenon could have an impact on PAMAM-conjugated MRI CAs. It was demonstrated that the rotational correlation time increases by passing from an alkaline to an acidic environment (as a consequence of more expanded structure and higher hydration of the dendrimer core) and the relaxivity of a conjugated Gd(III) complex increases as well.

In order to gain insight into these protonation phenomena a ^1H NMR titration of the free G2 dendrimer was carried out. The spectra of such polyamines are rather complex, but it was possible to track reliably five signals of methylene protons in the pH range from 11 to 2 and record their chemical shifts (Figure S2, Supporting Information). Each profile is characterized by the position of an inflection point on the pH scale and by the differences in the chemical shift ($\Delta\delta_H$) between the protonated and deprotonated forms. There are two kinds of amino groups in the PAMAM structure that can be protonated: (i) the terminal primary amino groups (those are rather basic and converted to thioamides after a conjugation) and (ii) the tertiary branching amines including the core ethylenediamine moiety, which are neutral or slightly acidic (*2*). As a rough approximation we can assume that the protonation of any amino group is independent of the others so we can consider an equilibrium existing between three possibilities: (i) totally deprotonated species in very alkaline solutions, (ii) the species occurring in neutral solutions having all primary amines protonated, and (iii) totally protonated species in acidic solutions. Using this very simple model, a parallel fitting (*31*) of all measured chemical shifts was performed resulting in "average" pK_a values (assigned hereinafter as $\langle pK \rangle$) (*34*) for both protonation equilibria with a good precision: $\langle pK_1 \rangle = 5.76(3)$ (corresponding to protonation of the tertiary amines) and $\langle pK_2 \rangle = 9.12(3)$ (corresponding to the protonation of the primary amines). The pK values correspond well with those obtained from potentiometric titration data for the free G0-PAMAM dendrimer having four primary amino groups with pK_a 8.3−9.8, and for the tertiary amino groups of the ethylenediamine core with pK_a 6.6 and 2.8 (*35*).

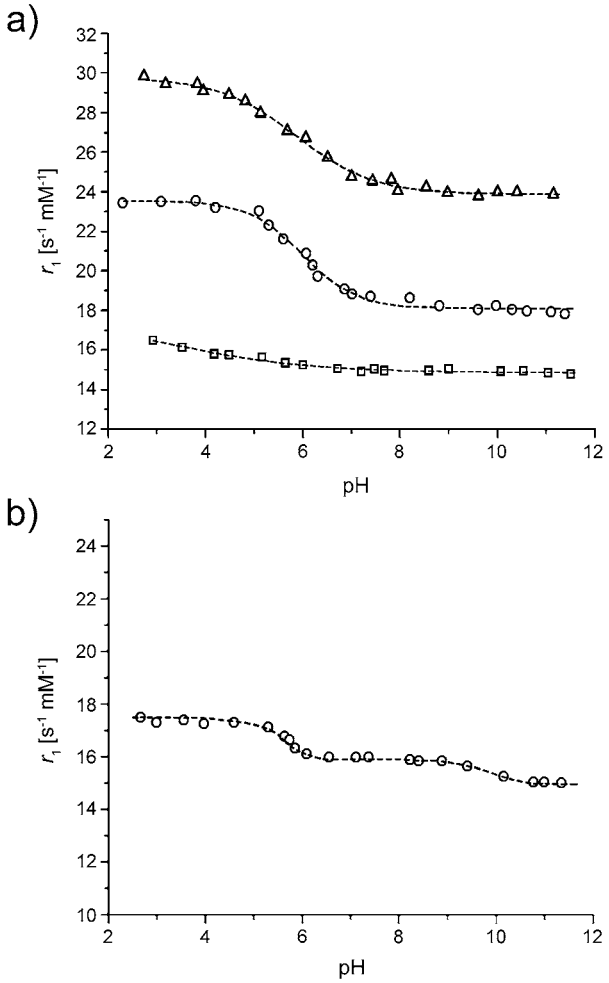

Figure 1. (a) r_1 vs pH profiles (20 MHz, 25 °C) for the G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$ (□), G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ (○), and G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$ (△) conjugates. The dashed lines are the result of a sigmoidal least-squares fitting of the data. (b) r_{1p} vs pH profile (20 MHz, 25 °C) for the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_9$ conjugate. The dashed line here is only a polynomial fit to guide the eyes.

Subsequently, the pH dependence of the relaxivity was measured for the "full-loaded" dendrimeric conjugates: G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$, G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$, and G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$ (Figure 1a). All profiles show inflection points at pH values corresponding to the $\langle pK_1 \rangle$ values assigned to the protonation of the tertiary branching amines inside the

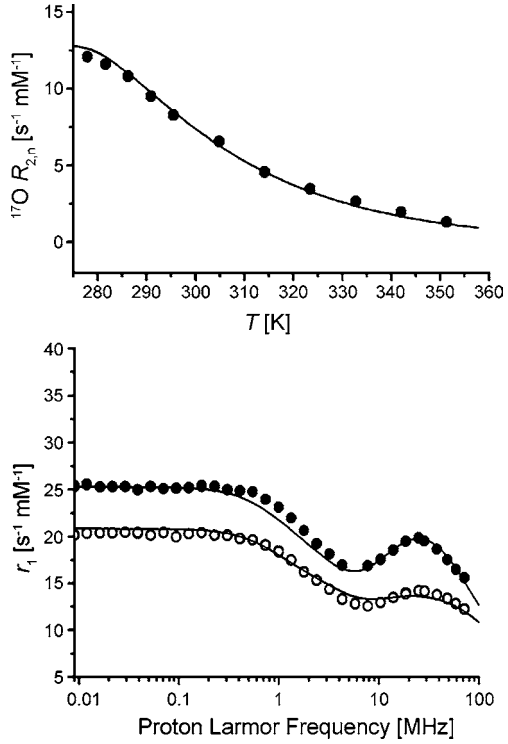

Figure 2. ^{17}O $R_{2,n}$ (top) and ^{1}H NMRD relaxation profiles (bottom; full circles 25 °C (●), open circles 37 °C (○)) for the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ conjugate. Transverse relaxation rates ($R_{2,n}$) were normalized to 1 mM concentration of gadolinium. The solid lines represent the best results of the simultaneous fitting to the experimental data (vide infra).

free G2-PAMAM dendrimer confirming that the relaxivity enhancement in acidic solutions is a direct consequence of the protonation of the PAMAM inner-shell amines. The relaxivity increase at low pH reflects the larger rotational correlation times of the Gd(III) complexes due to the more expanded structures of the dendrimers. Interestingly, a calculation of the relaxivities at pH 8 and at pH 3 for the given conjugates showed a 10% increase for G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$, 30% for G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ (ref *24*), and 20% for G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$. To explain the highest enhancement of the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ conjugate, the overall size and the flexibility of the internal structure of the conjugate must be considered. For the G1 conjugate, the size is rather small and the structure is dictated primarily by a repulsion of the negatively charged complexes on its surface thus limiting the effect of protonation; multiple protonation of the core amines also is more difficult so the inflection points are likely characterized by pK_a values covering a broader range. This latter effect may account for the lack of a well-defined inflection in the profile. For the G4 conjugate, the smaller inflection is probably due to the leveling off of the relaxivity with longer τ_R (vide infra, Figure 4).

Investigation of the influence of different loading of the G2 dendrimer on the pH-dependent relaxivity might be a potentially important issue especially in high-molecular-weight conjugates where loads are typically between 50% and 80% (*20*, *22*, *23*). The "half-loaded" conjugate (G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_9$) was synthesized and the dependence of its relaxivity on pH (Figure 1b) measured.

Overall this profile is significantly lower than for its "full-loaded" analogue (Figure 1a) and the relaxivity enhancement at low pH is much less pronounced. This could be the result of the much higher flexibility of the "half-loaded" structure. In addition to the inflection point at pH ∼5.5 observed for all other conjugates there is a minor step at pH ∼10 that clearly corresponds to the protonation of the primary amines. This small

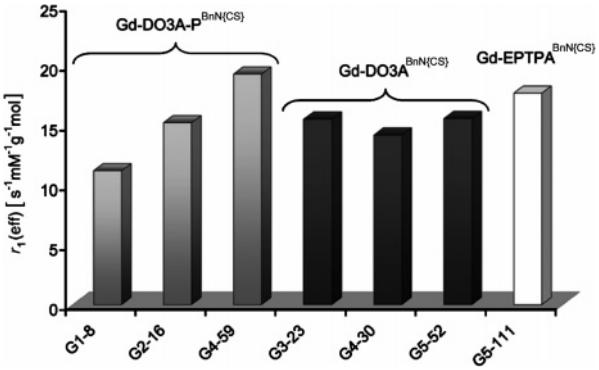

Figure 3. The comparison of effective relaxivities (20 MHz, 37 °C) for some PAMAM conjugates; Gd−DO3A$^{BnN\{CS\}}$ (ref *20*), Gd−EPTPA$^{BnN\{CS\}}$ (ref *22*).

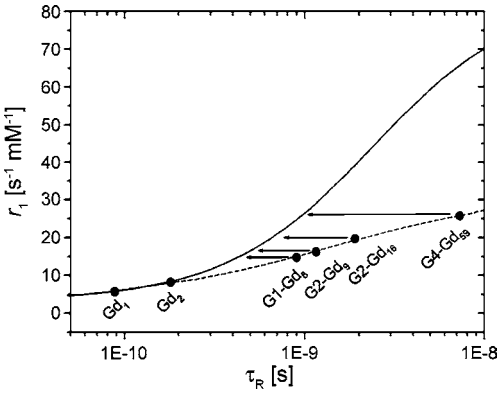

Figure 4. Experimental relaxivities (20 MHz, 25 °C) as a function of theoretical τ_R for our G*n*−(Gd−DO3A-$P^{BnN\{CS\}}$) conjugates together with parent Gd−DO3A-P^{ABn} and ditopic Gd$_2$−CS(DO3A-P^{NBn})$_2$ complexes. The dashed line is just to guide the eyes. The solid line is the simulation of relaxivity vs τ_R assuming $\tau_M = 50$ ns, $\tau_v = 30$ ps, $\Delta^2 = 0.1 \times 10^{20}$ s^{-2}, $q = 1$, $R_{GdH} = 3.1$ Å, $a = 3.5$ Å, $D = 2.24 \times 10^{-5}$ cm^2 s^{-1} (*37*).

relaxivity increase may arise from a more open structure due to the electrostatic repulsion between the charged amine groups and/or the result of more rigidity in the surface caused by hydrogen bonding between these protonated amines and the proximate (negatively charged) phosphinate groups of the chelate.

^{17}O and ^{1}H NMR Relaxometry. Relaxometry is a technique in which the solvent nuclei are investigated in order to obtain information on the solute molecules. It represents a fundamental tool for the study of the structural and dynamic properties of paramagnetic molecules in aqueous solutions. Measurements of the water ^{17}O NMR transverse relaxation rates R_2 at variable temperatures (12.1 MHz ≡ 2.1 T) and ^{1}H nuclear magnetic relaxation dispersion, NMRD, profiles (frequency dependence of r_1) at 25 and 37 °C were carried out at pH 7.5 on G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$, G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$, and G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$ conjugates (Figure 2 and Figure S3, Supporting Information).

Without any numerical evaluation, it is apparent from a simple inspection of the ^{17}O R_2 temperature profiles that relaxivity is not limited by a slow water exchange as the maxima for all systems are in the low-temperature region (*36*). This is also confirmed by the dependence of ^{1}H relaxivity vs temperature; as apparent from the NMRD profiles, the relaxivity in all cases is decreased with increasing temperature suggesting that, in terms of Bloembergen−Solomon−Morgan theory (BSM), the relaxivity is controlled primarily by the molecular tumbling rate (*37*). It is worth noting that this is an important difference from most of the dendrimeric conjugates of DOTA and DTPA reported previously (*19*, *20*, *38*). All NMRD profiles show

Table 1. Parameters Obtained from Simultaneous Fitting of ^{17}O NMR and ^{1}H NMRD Data Based on the Lipari−Szabo Approach[a]

[a] The conjugates are labeled in a shortcut form. [b] Reference *25*. [c] Reference *16*. [d] The relaxivity values were measured at 37/25 °C, 20 MHz; all solutions of the conjugates were measured at pH = 7.5; the underlined values were fixed during the fitting process.

shapes typical for high-molecular-weight systems with high-field peaks centered at ca. 20−30 MHz and roughly proportional to the molecular size (overall mobility) of the systems.

Recently, the use of the effective relaxivities per unit of mass has been suggested for comparing the efficacy of different multimeric paramagnetic complexes (*39*). We have calculated these values, at 37 °C and 20 MHz, which are plotted in Figure 3 and compared with those from similar systems reported in the literature.

Surprisingly, the effective relaxivities for different G2- and G5-dendrimeric conjugates are rather similar; apparently there is no additional benefit in loading more gadolinium(III) complexes on a larger PAMAM backbone. This saturation effect of r_{1p} in a series of macromolecular systems of increasing size has been observed previously, and often it has been attributed to the limiting effect of the slow rate of water exchange that becomes more important for longer values of τ_R. However, this is not the case for the present series of conjugates and for the G5 dendrimer conjugated to Gd−EPTPA$^{BnN\{CS\}}$ (Figure 3) (*22*) that are characterized by a sufficiently fast rate of water exchange. The second important factor that needs to be taken into account is the effective rotational correlation time, i.e. the presence of internal degree of rotation of the complexes superimposed to the global motion of the dendrimer.

As a result, the effective τ_R may be significantly shorter than that expected on the basis of the molecular weight of the system. This was observed previously on related DOTA, DTPA, or EPTPA conjugates (*19*, *22*). The importance of this effect is graphically represented in Figure 4 for the present series of conjugates. We plotted the relaxivities for the G*n*−(Gd−DO3A-P$^{BnN\{CS\}}$) conjugates together with the values obtained for the parent monomeric Gd−DO3A-P^{ABn} complex (*16*) and the ditopic Gd−CS(DO3A-P^{NBn})$_2$ complex (*25*) (Chart 2) as a function of the rotational correlation time. The τ_R values for the G1, G2, and G4 conjugates were calculated on the basis of the assumption of a linear correlation between τ_R and the molecular weight that is roughly valid for spheroidal molecules. For comparison, we also simulated the theoretical profile of relaxivity vs τ_R calculated on the basis of the BSM (*37*) and Freed's equations (*40*) for the inner-sphere and the outer-sphere contributions, respectively. In the simulation the water residence lifetime was adjusted to 50 ns (vide infra) and all the other parameters were set to their standard values (see the caption of Figure 4). It can be seen that the experimental points are below the theoretical values indicating that the effective rotational correlation times are much lower than expected on the basis of the molecular weight. This effect increases in importance with increasing size of the conjugate. These observations highlight the current limitation of the dendrimeric concept: for systems with an optimized rate of water exchange the relaxivity appears to be damped by lack of sufficient rigidity of the conjugated systems.

A comparison of the ^{1}H NMRD profiles for the G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$ conjugate at pH 7.5 and pH 4 (Figure S4, Supporting Information) indicates that τ_R increases with decreasing pH as can be seen by the higher relaxivity peak in the region 10−30 MHz. This observation corresponds well to the proposed (vide supra) change of structure toward a more expanded configuration; a similar effect has been observed in the case of Gd−EPTPA−PAMAM conjugates (*22*).

To obtain quantitative information about the solution dynamics (e.g. molecular tumbling rate, degree of internal motion, and/or water exchange rate), the ^{17}O and ^{1}H relaxation data were fitted simultaneously according to the established model of paramagnetic relaxation. It is well-known that the nuclear magnetic relaxation in the presence of multi-paramagnetic systems of this size and complexity cannot be described solely by the BSM set of spectral density functions (*41*) because the internal motion is, to some extent, always superimposed on the overall molecular tumbling. In order to solve this problem it is preferable the use of the Lipari−Szabo (LS) approach (*42*) that introduces an independent set of parameters for the local and global motions; this method has been successfully applied in the past (*19*, *22*, *23*). In addition, due to a slow overall motion of macromolecules, the interpretation of the electronic relaxation parameter values (τ_v and Δ^2) is quite difficult because the time evolution of the electronic correlation functions cannot be described within the Redfield theory (*41*). It should be emphasized, however, that the other parameters influencing relaxivity remain physically meaningful and significant insight can be realized by the parameters fitting. Selected results of simultaneous fitting of ^{1}H and ^{17}O NMR relaxation data at pH 7.5 for the present PAMAM conjugates based on the Lipari−Szabo approach are listed in Table 1 (see full set of equations and Table S1 in Supporting Information). The values obtained for G1−(Gd−DO3A-P$^{BnN\{CS\}}$)$_8$, G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$, and G4−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{59}$ are compared with those found for the parent Gd-CS(DO3A-P^{NBn})$_2$ and Gd−(DO3A-P^{ABn}) complexes.

Since the model uses a large set of parameters, some constraints needed to be applied to obtain a reasonable fit; for example, the value of the hyperfine coupling constant, $A/\hbar$, was set to -2.89×10^6 rad s^{-1}, the value found for the parent monomeric Gd−DO3A-P^{ABn} complex. Also, the number of water molecules directly coordinated to the Gd^{3+} ion, q, was set to 1. The distances between Gd^{3+} and the oxygen and hydrogen atoms of the inner-sphere water molecule, R_{GdO} and R_{GdH}, were fixed to standard values of 2.6 and 3.1 Å, respectively. The value of the free energy of the electronic relaxation, E_v, was set to 1 kJ, that found for the Gd−DOTA complex (*18*). Unfortunately, the use of only inner-sphere and outer-sphere contributions did not yield any meaningful results. The fit of the ^{1}H NMRD profiles showed an unacceptable deviation from the experimental points even in the high-field

region (>10 MHz), a region not usually affected by any inadequacy in the theory (*41*). A second-sphere contribution to relaxivity was then introduced into the model on the basis of the well-known property of phosphorus-containing pendants to provide an extra hydration by a hydrogen-bonding network, particularly in neutral and acidic solutions (*43*).

It is also quite reasonable that the PAMAM core itself could hold additional water molecules within its structure due to the rather hydrophilic amino-amide moieties. The best results were found by fixing the number of second-sphere water molecules q_{ss} to 2 (per Gd^{3+} ion). The complementary parameters, namely, the second-sphere water residence lifetime τ_{Mss}, the free exchange energy $\Delta H_{Mss}^{\#}$, and the average distance between the metal ion and the second-sphere water molecules R_{ss}, were constrained to those values used for the ditopic CS(Gd−DO3A-P^{NBn})$_2$ complex. The simulation of the observed relaxivity (at 20 MHz and 37 °C) showed that the second-sphere contribution represented on average about 10% of the overall value.

Comparison of the water residence lifetimes $^{298}\tau_M$ for the present series of conjugates indicated that there is a slight decrease in the water exchange rate by going from the smallest dendrimer ($^{298}\tau_M$ ∼50 ns) to the largest one ($^{298}\tau_M$ ∼70 ns); this could be ascribed to an increasing structural complexity of the conjugates as previously demonstrated for DOTA−PAMAM conjugates (*38*). Despite this, the water residence lifetimes for all our conjugates are rather close to the value found for the ditopic Gd_2−CS(DO3A-P^{NBn})$_2$ complex ($^{298}\tau_M$ = 53 ns) (*25*), indicating that the accessibility of the water binding site is not significantly affected by the conjugation itself. The global rotational correlation time $^{298}\tau_{Rg}$ smoothly increases with increasing molecular size of the conjugate up to 3.1 ns for the G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$ complex, a value typical for molecules of this size (*22*). On the other hand, the local rotational correlation time $^{298}\tau_{Rl}$ remains at around 115 ps, a value just between that for the parent monomeric (88 ps) and dimeric (183 ps) complexes. Therefore, the linking arm is not completely flexible but far from rigid, probably due to the rather free rotation around all CH_2 single bonds in the phosphinate pendant arm and/or in the PAMAM structure. The crucial parameter for assessment of the internal flexibility of the system is the S^2 term, the Lipari−Szabo factor of internal rigidity: its value is 1 for totally rigid structures and 0 if totally flexible. The value for the present conjugates of DO3A-P^{ABn} is about 0.26 indicating, unfortunately, a high degree of internal mobility, also indicated above (Figure 4). Comparison of the rigidity of our conjugates with other published systems indicates that it is lower than that of EPTPA−PAMAM conjugates (∼0.36) (*22*) or DTPA conjugated to linear polymers (∼0.35) (*44*) but slightly higher than the DOTA micelle systems (∼0.2) (*45a,b*).

Finally, we explored the possible influence of an electronic dipole−dipole interaction between Gd^{3+} ions on the surface of the conjugates. It was suggested by Merbach et al. that if two neighboring Gd^{3+} ions can have a mutual magnetic contact, their electronic relaxation rate is increased and the overall relaxivity of the multimeric complex is damped (*22*, *46*). This could be an important issue in low-generation dendrimeric conjugates as their surfaces are magnetically rather dense. The mixed G2−(Gd/Y−DO3A-$P^{BnN\{CS\}}$)$_{16}$ conjugate was prepared in order to test this interaction; the Gd^{3+} was "diluted" by Y^{3+} in a ratio of about 1:1, but the overall charge was maintained in order to minimize any perturbation of the structure. The ^{1}H NMRD profiles were measured and compared with those obtained for the full-Gd^{3+} analogue (Figure S5, Supporting Information). Both profiles differed less than 5% over the whole field range and thus exclude any negative influence of dipole−dipole interaction on the observed relaxivity. In addition, studies of CS(Gd−DO3A-P^{NBn})$_2$ and CS(Gd−DO3A-P^{NBn})(Y−DO3A-P^{NBn}) ditopic complexes have unambiguously proved there is no effect of the dipole−dipole interaction between two gadolinium(III) ions on the overall relaxivity even if the lanthanide atoms are separated only by 6.3 Å (*25*).

Interaction with Polyaminoacids. The conjugates prepared in this research are all polyanions (each complex moiety bears one negative charge), and, in addition, the phosphinate groups are able to set up strong hydrogen bonds with hydrogen atom donors (e.g. protonated amino groups); therefore, an investigation exploiting the electrostatic and hydrogen-bonding interactions between these conjugates and polycationic amines was carried out. In a preliminary communication, it was observed that the titration of the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ conjugate with poly(Arg) or poly(Lys) at pH 7.5 resulted in up to ∼60% enhancement of the relaxivity (*24*). To explore this effect in more detail, various titration experiments to determine (i) the extent of the enhancement factor ϵ* (defined in eq 1) as a function of length of the polyaminoacid chain and (ii) the dependence of maximum relaxivity enhancement ϵ^b for a given polyaminoacid on the size of the conjugate were initiated. In eq 1, the observed longitudinal relaxation rates refer to solutions

$$\epsilon^* = (R_{1,obs}^{Gd-Sub} - R_{1,obs}^{Sub})/(R_{1,obs}^{Gd} - R_{1,obs}^{water}) \qquad (1)$$

containing the conjugate complex and the polyaminoacid (Gd−Sub), the polyaminoacid (Sub), the conjugate complex (Gd), and the pure solvent (water), respectively. The limiting value of ϵ*, corresponding to the fully bound conjugate complex, is denoted with ϵ^b. All "full-loaded" conjugates, i.e. G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$, G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$, and G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$, were titrated with a solution of poly(Arg)$_{320}$ (M_W ∼ 60000).

For comparison, the same experiment with the ditopic Gd_2−CS(DO3A-$P^{BnN\{CS\}}$)$_2$ complex was carried out. The results are plotted in the form of a relaxivity enhancement factor ϵ* as a function of the polyaminoacid concentration on a logarithmic scale (Figure 5) (*47*).

Whereas ϵ^b ∼2.2 was found for the ditopic complex, the values for the conjugates vary from 1.8 for the smallest G1 conjugate (i.e. relaxivity varies from 14.5 to 26.0 s^{-1} mM^{-1} at 25 °C and 20 MHz) to 1.4 for the largest G4 conjugate. It is important to note that when the theoretical charge equilibria were reached in the titration, there was precipitation. Additionally, in all cases the plateau was reached when the theoretical concentration of a positive charge was in 30% excess; both observations clearly prove a pure electrostatic basis for the interaction. To verify our findings, the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ conjugate with the small poly(Lys_{17}−Pro_3) peptide (further denoted as poly(Lys)$_{17}$) was titrated and the result (Figure S6, Supporting Information) compared with those previously obtained from the titration of this conjugate with poly(Arg)$_{56}$, poly(Arg)$_{320}$, and poly(Lys)$_{61}$ (*24*). The values of ϵ^b for all the titration experiments are summarized in Table 2.

In order to understand the rules governing adduct formation, one must consider that the molecular weight ratio (conjugate/amino acid) changes dramatically with different combinations of the conjugate−polyaminoacid. For example, in the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$−polyaminoacid system this ratio varies from 3:1 for poly(Lys)$_{17}$ to 1:4 for poly(Arg)$_{320}$ and the enhancement factor ϵ^b changes from 1.2 to 1.6 (Table 2), indicating that the effect involves an increase in the global rotational correlation time τ_{Rg}. Since an approximately 6-fold increase in length of the poly(Arg) chain brings no further relaxivity enhancement, one can assume that the multimeric adducts are formed so that one polyaminoacid chain partially wraps around several molecules of the conjugate; and since the strand of the polyaminoacid is highly flexible, the interacting sites are essentially

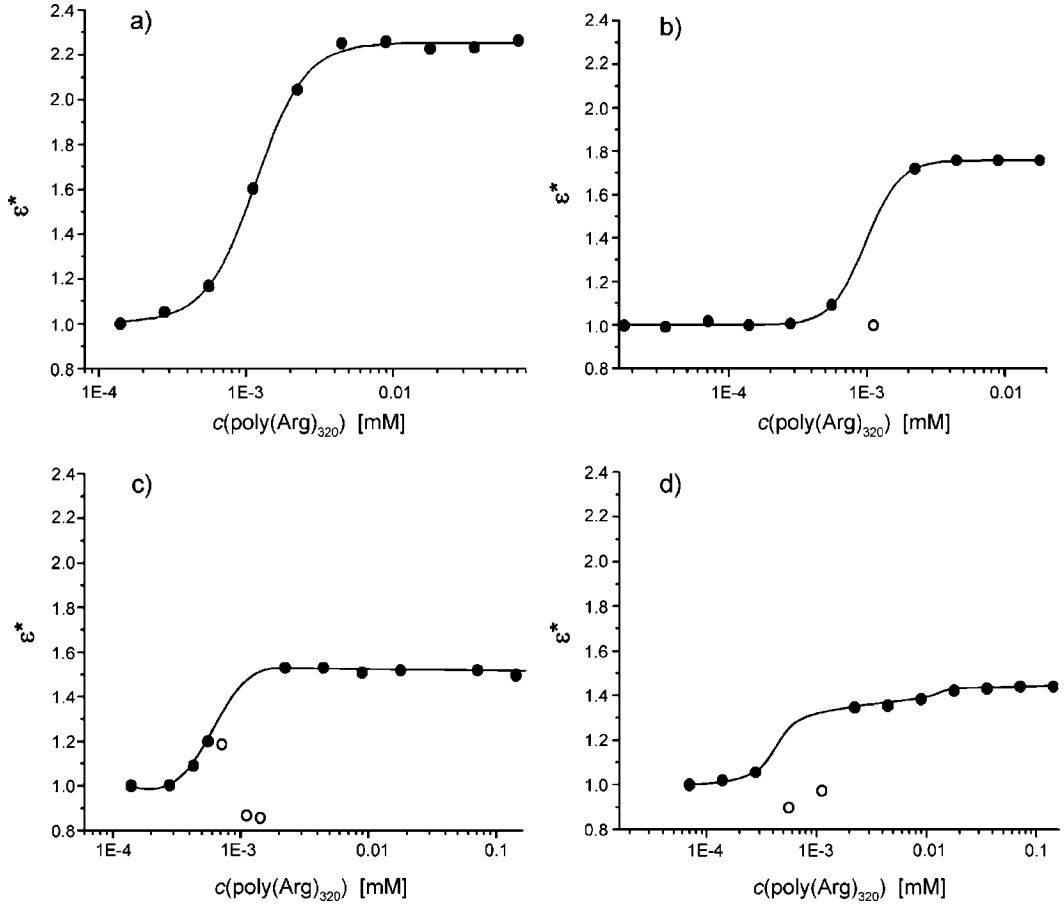

Figure 5. Results of the titration experiments with poly(Arg)$_{320}$: (a) Gd$_2$−CS(DO3A-P^{NBn})$_2$; (b) G1−(Gd−DO3A-P$^{BnN\{CS\}}$)$_8$; (c) G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$; (d) G4−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{59}$. The results are expressed as the relaxivity enhancement factor ϵ* as a function of poly(Arg)$_{320}$ concentration (in log scale). The solid lines are only to guide the eyes. The open points correspond to the solutions where precipitation occurred. All the experiments were performed at 20 MHz, 25 °C, and pH 7.5. The concentrations of the conjugates are not the same: the experiments were set up in a way to maintain the analytical concentration of gadolinium in each sample at ca. 0.5 mM.

Table 2. Summary of Maximal Relaxivity Enhancement Factors ϵ^b for All Studied Systems at pH 7.5[a]

	ϵ^b			
	Gd$_2$−CS(DO3A-P^{NBn})$_2$	G1-8	G2-16	G4-59
poly(Lys)$_{17}$	1.4	n/a	1.2	n/a
poly(Lys)$_{61}$	n/a	n/a	1.4[b]	n/a
poly(Arg)$_{56}$	2.1	1.8	1.6[b]	n/a
poly(Arg)$_{320}$	2.2	1.8	1.6[b]	1.4

[a] The Gd(III) conjugates are labeled in a shortcut form. [b] Reference *24*.

independent and the global τ_R is not increased further. The higher value of ϵ^b for the G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$−poly-(Arg)$_{56}$ adduct over the adduct of G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$−poly(Lys)$_{61}$ could be accounted for by a significantly higher pK_a of arginine moieties in comparison to those of lysine resulting in a higher positive charge density and, in turn, stronger electrostatic interaction. As mentioned above, for a given polyaminoacid, the enhancement for the different conjugates decreases as the size of the conjugate increases. To explain that, it is assumed that a molecule of a polyaminoacid serves as a "molecular glue" that reduces the internal mobility of the conjugate so that a strand of a particular polyaminoacid may wrap only around a certain part of the conjugate surface independent of conjugate size and charge density. A demonstration of the size ratios for the "full-loaded" conjugates and poly-(Arg)$_{56}$ studied in this research is shown in Figure 6.

As the size of the conjugate increases, a smaller fraction of its surface interacts with a particular chain of the polyaminoacid and the internal mobility is reduced. From this point of view, the enhancement factor for the ditopic compound ($\epsilon^b \sim 2.2$) can be considered as the maximum achievable effect because this molecule was shown to be quite rigid (*25*) and, moreover, wrapped by a polyaminoacid the most easily.

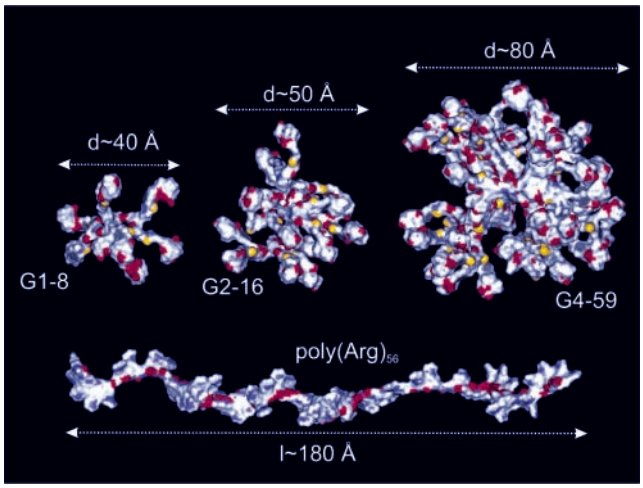

Figure 6. The demonstration of the size ratios for the G1-8, G2-16, and G4-59 conjugates and poly(Arg)$_{56}$. The sizes and the conformations of all species are the results from a molecular modeling. The surfaces represent the solvent accessibility areas (1.4 Å probe) in the following element color scheme: H, white; N, blue; O, red; S, yellow.

Additional support for our model was sought by measuring the relaxivity as a function of temperature for a particular system, G2−(Gd−DO3A-P$^{BnN\{CS\}}$)$_{16}$−poly(Arg)$_{56}$, in a molar ratio polyaminoacid/conjugate of ca. 10:1 (Figure 7a). The data

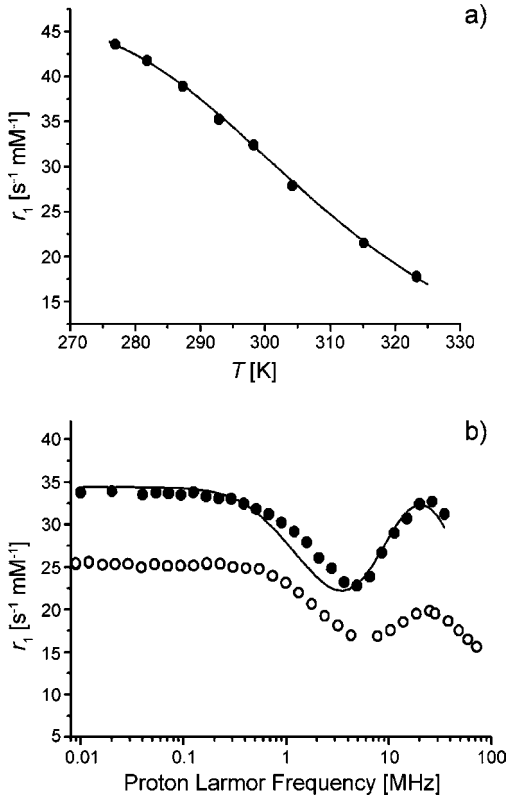

Figure 7. Relaxometric characterization of the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$−poly(Arg)$_{56}$ adduct: (a) proton relaxivity at variable temperature and 20 MHz; (b) ^{1}H NMRD profile at 25 °C for the adduct (●) and the free conjugate (○). The solid lines are the best simultaneous fits to the experimental points. Both measurements were done at pH 7.5 and at a poly(Arg)$_{56}$/conjugate molar ratio 10:1.

Table 3. Comparison of the Parameter Values Obtained from Simultaneous Fitting of Relaxometric Data for G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$−poly(Arg)$_{56}$ Adduct and G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ Conjugate

[a] The relaxivity values were measured at 25 °C and 20 MHz; molar ratio of poly(Arg)$_{56}$/conjugate 10:1; the pH values of all samples were 7.5; the underlined values were fixed during the fitting process.

were subsequently analyzed by means of the multiparametrical Lipari−Szabo fitting along with the ^{1}H NMRD profile at 25 °C (Figure 7b); the results are shown in Table 3.

Unfortunately, we were not able to measure any ^{17}O NMR data as it was not possible to obtain a sample with sufficient concentration. In particular, despite rather low statistical errors, the lack of longitudinal ^{17}O T_1 relaxation times significantly lowers the precision of the fitting results, which should consequently be taken just as rather rough estimations (but still fully relevant for the following discussion). During the fitting procedure, several parameters were fixed to be those of the pure conjugate (for full results see Table S2, Supporting Information). The decrease in relaxivity with increasing temperature indicates that the water access is not significantly blocked by interaction

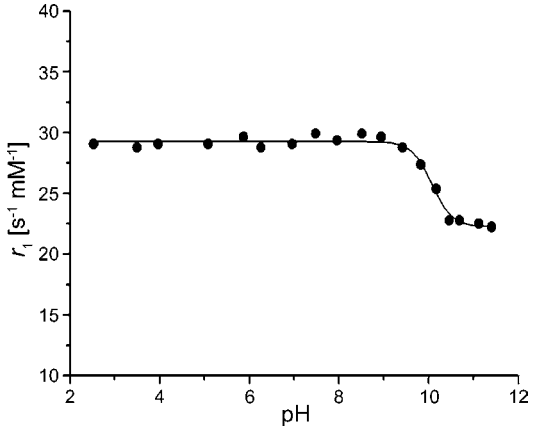

Figure 8. The dependence of relaxivity for the system G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$−poly(Lys)$_{61}$ on solution pH. The solid line is the best sigmoidal fit to the experimental points. The molar ratio poly(Lys)$_{61}$/conjugate was about 10:1.

with the polyaminoacid. The mean water residence lifetime of the adduct ($^{298}\tau_M$ ∼100 ns) is not much longer than that of the pure conjugate (∼70 ns); the global rotational correlation time τ_{Rg} increased by about 45% and the local rotational correlation time τ_{Rl} by about 70% in comparison to the free conjugate.

As the relaxivity is flattened with increasing τ_R (see Figure 4), it is noted that the most important factor for the enhancement is the reduction in the internal mobility indicated also by an increase in the S^2 factor. This is an important result since, for the first time, it was experimentally shown that a decrease of the rotational dynamics of the complex linked to a macromolecular substrate can result in a more than 40% increase of relaxivity. It was stated that, even in the noncovalent conjugate of MS-325 and human serum albumin (HSA) endowed with a very high relaxivity, the complex moiety exhibits almost free isotropic movement, which somewhat limits a maximum attainable relaxivity (*48*).

In addition to the response of the adduct structure to the pH of the solution, the dependence of the relaxivity on the pH value for the two adducts, G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$−poly(Lys)$_{61}$ (Figure 8) and G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$−poly(Arg)$_{320}$ (Figure S7, Supporting Information), was investigated.

Whereas, in the case of the poly(Arg)$_{320}$ adduct, the profile is almost flat, there is a significant change in the profile of the poly(Lys)$_{61}$ adduct at pH 10.06 ± 0.05 due to the different basicity of the amino and the guanidine groups. The guanidinium moieties of poly(Arg)$_{320}$ are rather basic and remain protonated even at high pH, whereas the primary amino groups of lysine have a pK_a around 10 (the pK_a's of lysine amino groups are 9.15 and 10.66) (*49*). Therefore, once the poly(Lys) chain is deprotonated in alkaline solution, the interaction with negatively charged molecules of the conjugate is almost "switched off" and the relaxivity sharply decreases. In fact, upon increase of pH up to 12, the relaxivity of the unbound dendrimeric complex is not fully restored likely due to a partial binding. This behavior is opposite to that observed for the Gd−(DO3A-squaric acid)−poly(Orn) covalent conjugate wherein the protonation increases the mobility of the whole molecule leading to a lowering of the overall relaxivity (*50*).

CONCLUSIONS

The macrocyclic DO3A-P^{ABn} ligand was attached to PAMAM dendrimers of generations 1, 2, and 4 by an effective benzylisothiocyanate linking strategy that allowed high loading yields to be achieved resulting in G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$ (100% theoretical loading), G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$ (100% theoretical loading), and G4−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{59}$ (92% theo-

retical loading) conjugates. The relaxivities measured under standard conditions (20 MHz and 37 °C) were 10.1, 14.1, and 18.6 s^{-1} mM^{-1}, respectively, and measurement of the relaxivity dependence on solution pH showed that the relaxivity values could be increased by a factor of 1.3 when the core amino groups of the conjugates became protonated. This was verified by the complementary ^{1}H NMR titration of the free G2 dendrimer. In addition it was shown that the "unused" primary amines on the dendrimer surface may contribute as well since, in the case of the "half-loaded" G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_9$ conjugate, a small relaxivity response at pH 8−11 was indicated. The relaxometric characterization of all "full-loaded" conjugates was carried out by means of VT-^{17}O NMR and ^{1}H NMRD measurements, and according to the numerical evaluation of the relaxometric data based on the Lipari−Szabo approach, the relaxivity is controlled by an insufficient rigidity of the structure, e.g. the S^2 factor indicating inner flexibility was approximately 0.26. The water residence lifetime $^{298}\tau_M$ increases from 48 to 68 ns as the molecular size of the conjugates increases; however, in comparison with the model ditopic Gd_2−CS(DO3A-P^{NBn})$_2$ complex's value of $^{298}\tau_M$ 53 ns, it appears that the conjugation to PAMAMs does not disturb the water binding site and all values are not far from the optimal values (10−50 ns). An attempt to partially "freeze" all types of molecular tumbling was carried out, and it was shown that the relaxivity was significantly increased by addition of a positively charged polyaminoacid, namely, poly(Arg) or poly(Lys) species; the highest enhancement factor $\epsilon^b = 1.8$ was found for the G1−(Gd−DO3A-$P^{BnN\{CS\}}$)$_8$−poly(Arg)$_{320}$ adduct. From a comparative study of adducts of the different conjugates with various poly(Arg)s and poly(Lys)s the data suggested that the interaction is based purely on an electrostatic effect and the structure of the adduct depends primarily on the size ratio of both components. A strand of a polyaminoacid partly wraps around the negatively charged surface of the conjugate, and the internal mobility of the complex moiety is reduced. As the effective molecular weight of the whole system increases, the global motion is slowed down, resulting in an additional increase in the relaxivity. This model is also supported by ^{1}H NMRD characterization of the G2−(Gd−DO3A-$P^{BnN\{CS\}}$)$_{16}$−poly(Arg)$_{56}$ adduct wherein the molecular tumbling modes were reduced. In addition, it was shown that the relaxivity of the system with poly(Arg) remains constant up to pH 12 whereas the adduct with poly(Lys) dissociates when lysine primary amines become deprotonated (relaxivity steeply decreases at pH >9.5).

The new supramolecular approach presented here opens new possibilities as to how one might reduce the internal motion of polymeric MRI CAs in order to increase the overall relaxivity. The dependence of adduct formation on solution pH offers the possibility to prepare, if properly designed, a new family of pH-responsive MRI CAs for applications in the physiological pH range.

ACKNOWLEDGMENT

The authors are thankful to Dr. Jan Kotek for help with the determination of dissociation constants. The authors also want to thank to Dr. Alessandro Barge for crucial help with the synthesis of the poly(Lys) peptide. We are grateful to the GAČR (Grants 203/03/0168 and 203/06/0467), GAUK (423/2004/B-CH/PrF), AV ČR (KAN 201110651), and MIUR (FIRB). M.B., P.H., K.I.H. and J.R. gratefully acknowledge the support of a NATO travel grant (No. PST.CLG 980045). The work was carried out in frame of COST D18 and the EU-supported NoE projects EMIL (No. LSHC-2004-503569) and DiMI (No. LSHB-2005-512146).

Self-Assembly of Natural Light-Harvesting Bacteriochlorophylls of Green Sulfur Photosynthetic Bacteria in Silicate Capsules as Stable Models of Chlorosomes

Yoshitaka Saga,[†,§] Sho Akai,[†] Tomohiro Miyatake,[‡] and Hitoshi Tamiaki[†,*]

Department of Bioscience and Biotechnology, Faculty of Science and Engineering, Ritsumeikan University, Kusatsu, Shiga 525-8577, Japan, and Department of Materials Chemistry, Faculty of Science and Technology, Ryukoku University, Otsu, Shiga 520-2194, Japan. Received November 26, 2005; Revised Manuscript Received May 17, 2006

Naturally occurring bacteriochlorophyll(BChl)s-*c*, -*d*, and -*e* from green sulfur photosynthetic bacteria were self-assembled in an aqueous solution in the presence of octadecyltriethoxysilane and tetraethoxysilane, followed by polycondensation of the alkoxysilanes by incubation for 50 h at 25 °C. The resulting BChl self-assemblies in silicate capsules exhibited visible absorption and circular dichroism spectra similar to the corresponding natural light-harvesting systems (chlorosomes) of green sulfur bacteria. Dynamic light scattering measurements indicated that the silicate capsules had an average hydrodynamic diameter of several hundred nanometers. BChl self-aggregates in silicate capsules were significantly stable to a nonionic surfactant Triton X-100, which was apt to decompose the BChl aggregates to their monomeric form, compared with conventional micelle systems. BChls in silicate capsules were more tolerant to demetalation of the central magnesium under acidic conditions than the natural systems.

INTRODUCTION

Photosynthesis is an excellent light-energy conversion system in nature, where sunlight energy is captured and is converted into chemical energy with high efficiency. In photosynthetic supramolecular systems, the photofunctional molecules chlorophyll(Chl)s and bacteriochlorophyll(BChl)s are highly organized by pigment−protein interaction and pigment−pitment interaction.

In a broad variation of photosynthetic supramolecules, extramembranous light-harvesting complexes, chlorosomes, of green photosynthetic bacteria are unique in terms of their supramolecular structures. Chlorosomes from green sulfur bacteria are ellipsoidal particles with 150-nm length, 50-nm width, and 25-nm height.[1,2] In chlorosomes, BChl-*c*, -*d*, and -*e* molecules (the molecular structures are shown in Figure 1) form self-aggregates only through pigment−pigment interaction, where the central magnesium of one BChl molecule is coordinated by the 3^1-hydroxy group of another BChl molecule and a hydrogen bond is formed between the 3^1-hydroxy group and 13-keto group of the third BChl molecule.[3−6] These BChl self-aggregates are surrounded by a lipid monolayer.

Green sulfur photosynthetic bacteria have BChl homologues that vary in the alkyl groups at the 8- and 12-positions (R_8 and R_{12} in Figure 1, respectively). Methyl, ethyl, *n*-propyl, and isobutyl groups at the 8- and 12-positions of chlorosomal BChls are denoted as M, E, Pr, and I. Such a diversity of molecular structures of BChl homologues affects supramolecular structures, spectral properties, and excited states of chlorosomal BChl self-aggregates.[1,3,7,8] However, precise effects of R_8 and R_{12} groups of BChl homologues on chlorosomal supramolecular structures and biological meaning of the homologue diversity of green sulfur photosynthetic bacteria have been ambiguous.

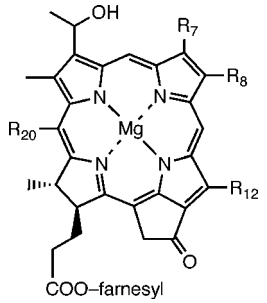

Figure 1. Molecular structures of light-harvesting [R_8,R_{12}]BChls-*c*, -*d*, and -*e* in green sulfur photosynthetic bacteria. BChl-*c*: $R_7 = CH_3$, $R_{20} = CH_3$, BChl-*d*: $R_7 = CH_3$, $R_{20} = H$, BChl-*e*: $R_7 = CHO$, $R_{20} = CH_3$. $R_8 = C_2H_5$ (E), *n*-C_3H_7 (Pr), *iso*-C_4H_9 (I). $R_{12} = CH_3$ (M), C_2H_5 (E).

The architecture of chlorosomal self-aggregates is in sharp contrast to other photosynthetic apparatus, where photofunctional pigments are embedded in proteins. Such supramolecular structures of chlorosomal self-aggregates can be appropriate for the construction of artificial photofunctional nanodevices. Self-aggregates of natural BChls[8,9] and their model compounds[10,11] have been extensively studied in aqueous micelles as structural and functional models of chlorosomes. These chlorophyllous pigments could be assembled in the envelope of lipids and surfactants by the same pigment−pigment interaction as that in natural chlorosomes. The chlorosomal self-aggregates in microheterogeneous media, however, did not have mechanical strength or stability to external perturbation.

Sol−gel methods[12−14] have recently been used for encapsulation of biomaterials such as enzymes,[15−17] heme proteins,[18−21] and photoactive proteins.[22,23] In porous sol−gel matrixes, many kinds of proteins achieve stability without loss of their functionality. The sol−gel process requires little or no heating for hydrolysis and polycondensation of alkoxides. Such mild reaction conditions are suitable for hybridization of biomaterials with inorganic materials toward bioactive devices. Additionally, sol−gel matrix is an attractive candidate to support photofunctional biomaterials because of optical transparency of the matrix.

We preliminarily reported the preparation of self-aggregates of synthetic zinc chlorins, which were model compounds of chlorosomal BChls, in a silicate micelle using the sol−gel process,[24] and demonstrated the excitation energy transfer from self-aggregates of zinc chlorins to bacteriochlorins in the silicate micelle.[25] These works indicated that alkoxysilane molecules possessing a long alkyl chain provided an appropriate hydrophobic microenvironment for self-assembly of zinc chlorins.

Here we report the preparation and characterization of stable self-assemblies of natural BChls-*c*, -*d*, and -*e* in silicate capsules by sol−gel processes. In the present sol−gel condition, natural BChls, which were more easily denatured than synthetic zinc chlorins, formed self-aggregates possessing similar spectral properties and particle sizes to natural chlorosomes. The resulting BChl self-assemblies could be hardly deaggregated by addition of a nonionic surfactant Triton X-100. Natural BChls in the present silicate capsule also had significant tolerance to the demetalation by addition of an aqueous acid.

MATERIALS AND METHODS

Apparatus. Visible absorption and fluorescence spectra were measured with Hitachi U-3500 and F-4500 spectrophotometers, respectively. CD spectra were measured with a JASCO J-720W spectropolarimeter. Dynamic light scattering measurements were performed with a Marvern Nano ZS particle size analyzer. HPLC was carried out with a Shimadzu LC-20AT pump and an SPD-M20A photodiode array detector.

Pigment Preparation. BChls-*c*, -*d*, and -*e* were extracted from harvested cells of green sulfur photosynthetic bacteria *Chlorobium* (*Chl.*) *tepidum* ATCC49652, *Chl. vibrioforme* NCIB8327 substrain containing BChl-*d*, and *Chl. phaeobacteroides* 1549, respectively, according to the procedures described previously.[26−28] Extracted BChls were purified by reverse-phase HPLC.[28,29] The homologue compositions of purified BChls were as follows: 8-ethyl-12-methyl([E,M])-: 8-ethyl-12-ethyl([E,E])-: 8-propyl-12-ethyl([Pr,E])-: 8-isobuthyl-12-ethyl([I,E])-BChl-*c* = 1:63:31:5, [E,M]-: [E,E]-: 8-propyl-12-methyl([Pr,M])-: ([Pr,E]+8-isobuthyl-12-methyl([I,M]))-: [I,E]-BChl-*d* = 7:18:11:48:16, and [E,E]-: [Pr,E]-: [I,E]-BChl-*e* = 46:41:13.

Preparation of Silicate Capsules. Octadecyltriethoxysilane (ODTES) and tetraethoxysilane (TEOS) were purchased from Shin-etsu Chemical Co., Ltd. and Nacalai Tesque, respectively, and were used without further purification. ODTES (200 μL) and TEOS (200 μL) were dissolved in 1.6 mL of ethanol, and 30 μL of 1 M HCl was added to the ethanol solution. After stirring for 30 min, 30 μL of 1 M NaOH was added to the mixture to neutralize pH of the solution. The resulting solution containing alkoxysilanes (10 μL) was mixed with 30 μL of an ethanol solution of chlorophyllous pigments (pigment concentration, ca. 0.9 mM), and the mixed solution was dispersed in distilled water (4 mL) at 50 °C. The prepared aqueous suspension was then incubated at 25 °C for 50 h.

Deaggregation by Triton X-100. A small aliquot of aqueous Triton X-100 solution was added in an aqueous suspension of BChl self-aggregates in silicate capsules, and the solution was rigorously mixed. After incubation in the dark for 4 min, the visible absorption spectra were measured.

Demetalation under Acidic Conditions. BChl self-aggregates in silicate capsules were incubated in 50 mM HCl solution, and changes of their visible absorption spectra were measured as a function of incubation time in the dark.

RESULTS

Preparation of Silicate Capsules. Three types of natural BChls were dispersed with prehydrolyzed alkoxysilanes (ODTES and TEOS) in aqueous media and incubated at 25 °C for 50 h.

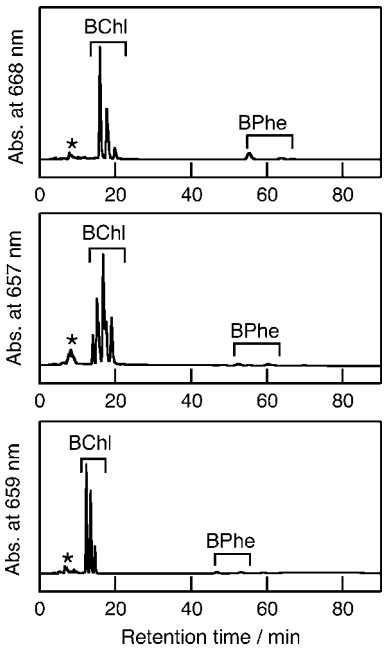

Figure 2. HPLC elution patterns of BChls extracted from silicate capsules after incubation at 25 °C for 50 h (Cosmosil 5C18-AR−II, 6 mmϕ × 250 mm, methanol/water = 96/4(v/v) as the eluent, 1.0 mL/min). Top, BChl-*c*; middle, BChl-*d*; bottom, BChl-*e*.

BChl molecules self-assembled to give visible absorption and CD spectra similar to the corresponding chlorosomes mentioned in the following section. DLS measurements showed that the average hydrodynamic diameter of silicate capsules containing self-aggregates of BChl-*c*, -*d*, and -*e* were 3.6×10^2, 4.6×10^2, and 2.7×10^2 nm, respectively. These values were comparable to the long axis (ca. 150 nm) of chlorosomes from green sulfur photosynthetic bacteria.

BChls in the prepared silicate capsules were extracted with ethanol and analyzed by reverse-phase HPLC. As shown in Figure 2, large amounts of natural BChls (denoted as BChl in the figure) remained intact. The denatured fractions around 50−70 min (denoted as BPhe) exhibited visible absorption spectra of bacteriopheophytin(BPhe)s, which were demetalated forms of natural BChls. Therefore, a little pheophytinization inevitably occurred during the preparation of silicate capsules containing natural BChls. In our preliminary procedure, where synthetic zinc chlorins were incubated overnight at a higher temperature (50 °C) with ODTES and TEOS, large amounts of natural BChls were denatured (data not shown). Small amounts of other fractions (denoted as * in Figure 2), which exhibited the same visible absorption spectra as those of BChls, appeared at around 10 min. These fractions might be ascribable to BChls whose ester groups at the 17-position were varied during the preparation. In the present procedure, we successfully prepared silicate capsules containing natural chlorosomal BChls, which tended to be decomposed easily, with slight denaturation.

Visible Absorption and CD Spectra. Figure 3 depicts visible absorption spectra of aqueous suspensions of natural BChl-*c*, -*d*, and -*e* in silicate capsules after incubation at 25 °C for 50 h, and these spectra are compared with those of the corresponding chlorosomes and monomeric pigments. The Soret and Q_y bands of chlorosomal BChls in silicate capsules in an aqueous solution were shifted to a longer wavelength relative to the monomeric bands in a polar organic solvent. BChl-*c* in silicate capsules had the Soret and Q_y bands at 460 and 752 nm, respectively (solid curve in Figure 3 top), whereas the peak positions of monomeric BChl-*c* were 436 and 667 nm (broken curve in Figure 3 top). The Q_y peak position of BChl-*c* self-aggregates in silicate capsules was shifted to a slightly longer

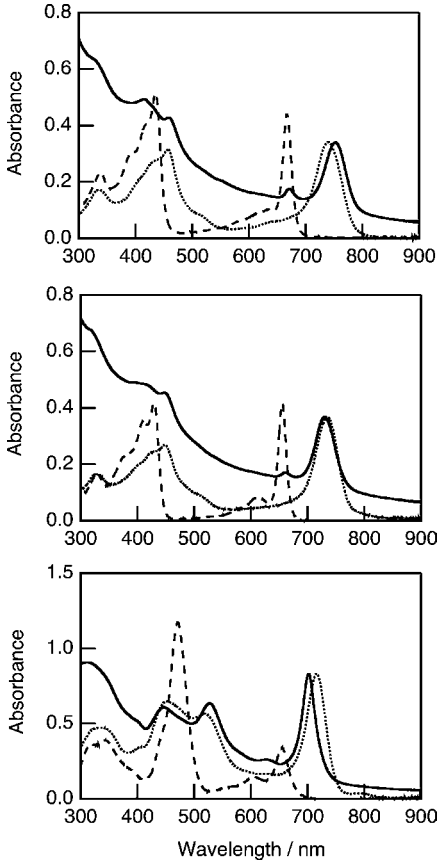

Figure 3. Visible absorption spectra of BChl self-aggregates in silicate capsules in aqueous solution (solid curve), chlorosomes in 50 mM Tris buffer, pH 8.0 (dotted curve), and BChl monomers in an ethanol solution (broken curve). Top, BChl-*c*; middle, BChl-*d*; bottom, BChl-*e*. BChls, ODTES, and TEOS concentrations were ca. 7 μM, 2.4×10^{-4}% (v/v), and 2.4×10^{-4}% (v/v), respectively. The spectra of chlorosomes were normalized with those of the silicate capsules at the Q_y peaks.

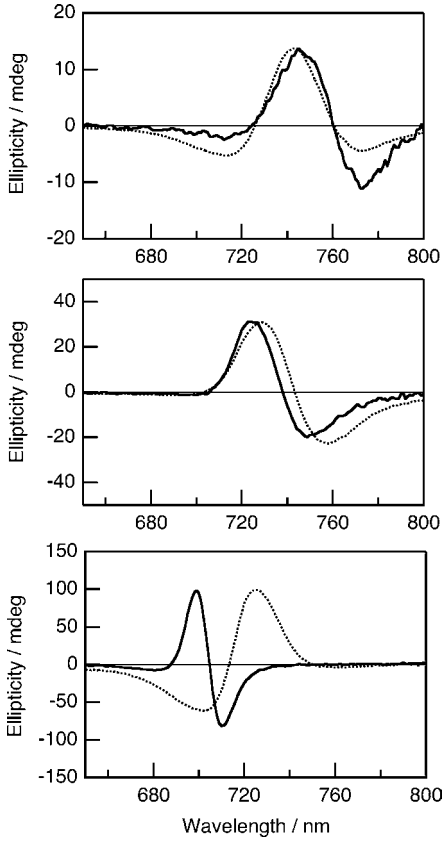

Figure 4. CD spectra of BChl self-aggregates in silicate capsules in aqueous solution (solid curve) and chlorosomes in 50 mM Tris buffer, pH 8.0 (dotted curve). Top, BChl-*c*; middle, BChl-*d*; bottom, BChl-*e*. The spectra of chlorosomes were normalized with those of the silicate capsules at the positive CD signals.

wavelength than natural chlorosomes from *Chl. tepidum* (dotted curve in Figure 3 top), and its bandwidth was very similar to the chlorosomal. These spectral properties indicate the chlorosome-like self-aggregation of BChl-*c* in silicate capsules formed by alkoxysilane molecules. BChl-*d* with alkoxysilanes in aqueous media exhibited a visible absorption spectrum with peak positions at 449 and 730 nm, which were also red-shifted relative to the monomeric (Figure 3 middle). The Q_y peak position and bandwidth of BChl-*d* aggregates in silicate capsules were almost the same as natural chlorosomes containing BChl-*d* from *Chl. vibrioforme*. A visible absorption spectrum of BChl-*e* in the presence of alkoxysilanes had two peaks at 446 and 527 nm in the Soret region, which were characteristic of chlorosomes containing BChl-*e* (Figure 3 bottom). The Q_y absorption band of BChl-*e* aggregates in silicate capsules was shifted to a longer wavelength compared with the monomeric band, and the spectral shape was close to that of natural chlorosomes from *Chl. phaeobacteroides*. In the cases of BChls-*c* and -*d* in silicate capsules, small monomeric absorption bands were observed around 670 and 660 nm, respectively.

CD spectra of natural BChls in silicate capsules are shown in Figure 4. Self-aggregates of three kinds of BChls exhibited intense inverse S-shaped CD signals in the Q_y region. Such intense CD signals in the Q_y region were characteristic of chlorosomal self-aggregates, since monomeric BChls hardly showed CD signals in an organic solution. The CD spectrum of BChl-*c* self-aggregates in silicate capsules resembled that of chlorosomes containing BChl-*c*, although the signals around 775 and 715 nm were intense and weak, respectively, compared with natural chlorosomes (Figure 4 top). CD signals of BChl-*d* self-aggregates in silicate capsules were similar to natural chlorosomes containing BChl-*d* (Figure 4 middle). BChl-*e* self-aggregates in silicate capsules also exhibited intense CD signals at almost the same position as natural chlorosomes containing BChl-*e*, although the polarity was the reverse of that of natural chlorosomes (Figure 4 bottom). It was reported that the polarity of in vivo CD signals in the Q_y region was changeable,[30] and in vitro BChl-*e* self-aggregates in a nonpolar organic solvent actually showed CD signals in the Q_y region that were the reverse of those of in vivo aggregates.[28]

Visible absorption and CD spectra of BChl self-aggregates in silicate capsules, which were similar to the natural corresponding chlorosomes, indicate that hydrophobic microenvironments formed by prehydrolyzed alkoxysilanes possessing a C18 alkyl chain are suitable for chlorosomal self-assemblies of these BChls.

Deaggregation by Triton X-100. Addition of a surfactant Triton X-100 transforms chlorosomal BChl self-aggregates into monomers. The deaggregation process can be easily monitored by visible absorption spectroscopy, where Soret and Q_y absorption bands of BChl self-aggregates around 450−520 and 720−750 nm, respectively, decrease accompanied by the increase of absorption bands of BChl monomers around 420−450 and 650−670 nm, respectively. Spectral changes of BChl-*c* self-aggregates with alkoxysilanes before and after incubation are shown in Figure 5. Most BChl-*c* aggregates before incubation changed to their monomeric form by addition of 0.3% (w/v) of Triton X-100 (see top of the left column in Figure 5). BChl-*c* aggregates with alkoxysilanes after incubation at 25 °C for 50 h, on the other hand, were significantly tolerant of Triton X-100. The ratio of Q_y absorbance of BChl-*c* self-aggregates in silicate capsules after incubation in 0.3% Triton X-100 solution to that

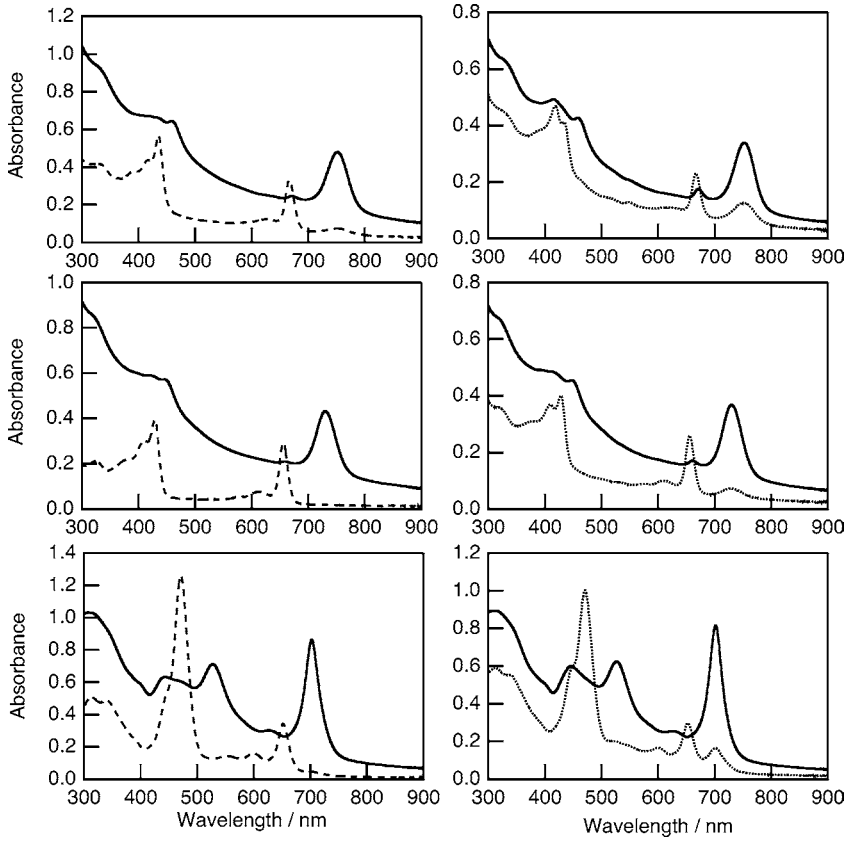

Figure 5. Spectral changes of BChl self-aggregates with alkoxysilanes in aqueous solution by addition of Triton X-100. Top, BChl-*c*; middle, BChl-*d*; bottom, BChl-*e*. Left column, before polycondensation; right column, after polycondensation at 25 °C for 50 h. Spectra at 0, 0.3, and 0.5% Triton X-100 are shown by solid, broken, and dotted curves, respectively.

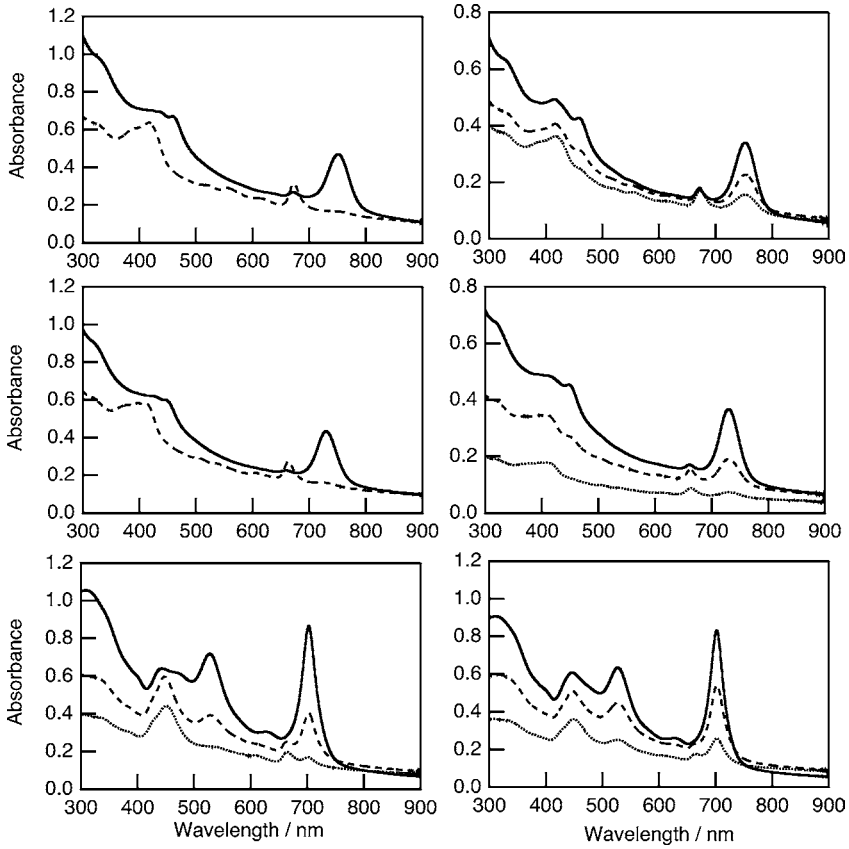

Figure 6. Spectral changes of BChl-*c* self-aggregates with alkoxysilanes in 50 mM HCl solution. Top, BChl-*c*; middle, BChl-*d*; bottom, BChl-*e*. Left column, before polycondensation; right column, after polycondensation at 25 °C for 50 h. Spectra at 0, 20, and 120 min after incubation in 50 mM HCl solution are shown by solid, broken, and dotted curves, respectively.

in distilled water (0% Triton X-100) was 0.36. The Q_y absorption band of BChl-*c* aggregates in silicate capsules after incubation around 750 nm remained even in 0.5% Triton X-100 solution (see top of the right column in Figure 5). This indicates that BChl-*c* self-aggregates were stabilized to a decomposer Triton X-100 by sol−gel polycondensation on the surface of chlorosomal capsules.

Similar tendency was observed in the cases of BChl-*d* and -*e* in silicate capsules, as shown in Figure 5. Most BChl-*d* and -*e* self-aggregates with alkoxysilanes before incubation were converted into their monomers by addition of 0.3% of Triton X-100, whereas 14% and 18% of Q_y absorbance of BChl-*d* and -*e* self-aggregates, respectively, remained in silicate capsules, which were prepared after incubation at 25 °C for 50 h, by addition of 0.3% (w/v) of Triton X-100. In 0.5% Triton X-100 solution, BChl-*d* and -*e* aggregates in silicate capsules after incubation still existed as shown in middle and bottom of the right column in Figure 5, respectively. These results indicate that polycondensation of alkoxysilanes makes natural BChl self-aggregates stable.

Demetalation under Acidic Conditions. Natural chlorophylls possessing magnesium as a central metal are easily demetalated under acidic conditions. This phenomenon is called pheophytinization. Pheophytinization of chlorosomal BChls in silicate capsules by an acid was examined to learn the stability of natural BChls in the present capsules. Figure 6 depicts the pheophytinization of BChls in silicate capsules with alkoxysilanes before and after incubation. BChl-*c* and -*d* self-aggregates before polycondensation of alkoxysilanes (before incubation) lost their Q_y absorption bands around 750 and 730 nm, respectively, by incubation in the acidic solution for 20 min, and new absorption bands appeared around 670 and 660 nm, which were ascribable to monomeric BPhes-*c*/*d*. BChl-*c* and -*d* self-aggregates after polycondensation of alkoxysilanes (after incubation at 25 °C for 50 h) were thereafter pheophytinized very slowly, and Q_y absorption bands of BChl self-aggregates remained even after 120 min under the acidic conditions.

In the case of BChl-*e*, self-aggregates both before and after polycondensation of alkoxysilanes were tolerant to the acid, compared with BChl-*c* and -*d* self-aggregates. This might be an inherent property of BChl-*e* molecules, since Chl-*b* possessing a formyl group at the 7-position is pheophytinized more slowly than Chl-*a* possessing a methyl group at the 7-position.[31] However, the pheophytinization process of BChl-*e* self-aggregates in silicate capsules after polycondensation was clearly different from that in micelles of alkoxysilanes before polycondensation; that is, these self-aggregates in silicate capsules after polycondensation had more resistance to the demetalation than those before polycondensation of alkoxysilanes. After 120 min incubation in 50 mM HCl solution, the absorbance ratio of BChl-*e* self-aggregates in silicate capsules (after polycondensation) was ca. 3-times larger than that before polycondensation of alkoxysilanes.

Figure 7 depicts time courses of the ratio of Q_y absorbance of BChl self-aggregates with alkoxysilanes incubated in 50 mM HCl solution to that in distilled water. In all cases, the absorbance ratio of the self-aggregates was gradually decreased with incubation time under the acidic conditions. In early phases of the pheophytinization processes, reaction rate constants, *k*, could be obtained by fitting the time courses of the Q_y absorbance ratio of BChl self-aggregates to the following kinetic formula:

$$\ln (A - A_\infty)/(A_0 - A_\infty) = -kt$$

where A_0, A, and A_∞ are Q_y absorbances of BChl self-aggregates with alkoxysilanes in distilled water, in 50 mM HCl solution at time *t*, and at the complete pheophytinization, respectively. The

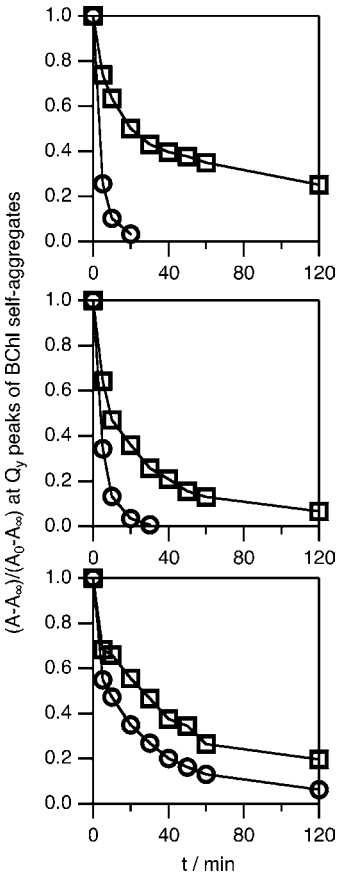

Figure 7. Time courses of the ratio of Q_y absorbance of BChl self-aggregates with alkoxysilanes in 50 mM HCl solution to that in distilled water. Open circles, before polycondensation; open squares, after polycondensation. Top, BChl-*c*; middle, BChl-*d*; bottom, BChl-*e*. A_0, A, and A_∞ are Q_y absorbances of BChl self-aggregates with alkoxysilanes in distilled water, in 50 mM HCl solution at time *t*, and at the complete pheophytinization, respectively.

Table 1. The Estimated Reaction Rate Constants *k* (min^{-1}) of Pheophytinization Processes of BChl Self-Aggregates with Alkoxysilanes Incubated in 50 mM HCl Solution

	k in micelles (before polycondensation)	*k* in capsules (after polycondensation)
BChl-*c*	0.23	0.022
BChl-*d*	0.20	0.035
BChl-*e*	0.029	0.016

estimated reaction rate constants are summarized in Table 1. The rate constants of the pheophytinization processes of BChl-*c* and -*d* self-aggregates before polycondensation of alkoxysilanes were 10.5- and 5.7-times larger than those in silicate capsules (after polycondensation), respectively. In the case of BChl-*e* self-aggregates, the rate constants were clearly different between the capsules after polycondensation of alkoxysilanes and the micelles before polycondensation. Therefore, the pheophytinization processes of three types of chlorosomal BChl self-aggregates indicate that the siloxane network on the surface made them significantly stable under the acidic conditions.

DISCUSSION

Natural light-harvesting BChls of green sulfur photosynthetic bacteria, which are well-known to be more unstable pigments than synthetic zinc chlorins in terms of pheophytinization, were successfully self-assembled in silicate capsules by the present sol−gel procedure to give similar supramolecular structures to those of chlorosomes. The BChl self-aggregates had enhanced stability to external perturbation such as addition of a surfactant and an acid.

It was reported that chlorophyll-*a* molecules in mesoporous silica enhanced their photostability.[32] Other reports of the inclusion of chlorophyllous pigments into mesoporous silica are available.[33,34] In these works, chlorophyllous pigments would be monomeric[33,34] or dimeric forms.[32] On the contrary, chlorosomal self-assemblies of light-harvesting BChls could be stabilized by encapsulation in sol−gel matrixes in this study. Such an encapsulation of photosynthetic supramolecules in sol−gel matrixes will provide a clue to constructing organic−inorganic hybrid supramolecules based on photosynthetic apparatus.[35,36]

The comparison between spectral changes of BChl self-aggregates before polycondensation and those after polycondensation clearly indicates that their stabilization in silicate capsules originates from the siloxane network on the surface of the aggregates. The rigid inorganic network would prevent the access of decomposers in solutions. Additionally, the rigidity of silicate cages might not allow BChl molecules to move for deaggregation in the capsules, as proposed in the case of proteins in sol−gel matrixes.[13,17]

BChl-*c* molecules in intact chlorosomes from *Chl. tepidum* were completely demetalated at pH 3.0 for 140 min at 40 °C, and monomeric BChl-*c* molecules in aqueous methanol (buffer (pH 4.0)/methanol = 1/9) were demetalated for 2 min.[37] BChls in silicate capsules thereafter possessed Q_y absorption bands of their self-aggregates even at pH = ca. 1.5 at ca. 25 °C for 120 min. Therefore, the present chlorosome-mimicking silicate capsules would become stable under acidic conditions compared with natural systems. The increase of stability of alkaline phosphatase in sol−gel matrixes to acidic conditions has recently been reported,[17] where sol−gel matrixes kept alkaline phosphatase active under highly acidic conditions (pH > 0.9). The extreme stability of these biomolecules in sol−gel matrixes under acidic conditions would be ascribable to hydrophobic microenvironments in the matrixes where little proton and few water molecules were present as well as a rigid siloxane network around the biomolecules. The present capsules including BChl self-aggregates will be useful for elucidation of precise supramolecular structures and functions of chlorosomes because of their high stability and will lead to artificial photosynthetic devices operating under non-native conditions.

Preparation and Stability of N-Terminal Mono-PEGylated Recombinant Human Endostatin

Yongjun Nie, Xin Zhang, Xinchang Wang, and Junhui Chen*

State Key Laboratory of Pharmaceutical Biotechnology, Department of Biochemistry, Nanjing University, Nanjing 210093, P.R. China. Received December 14, 2005; Revised Manuscript Received May 27, 2006

Endostatin can specifically inhibit endothelial proliferation and potently inhibit angiogenesis and tumor growth. N-Terminal site-specific mono-PEGylation of recombinant human endostatin (mPEG-rhES) was accomplished by using methoxy poly-ethylene glycol (mPEG) propionaldehyde with an average molecular weight of 5000 Da through a reactive terminal aldehyde group. The site-specific mPEG conjugation was conducted under optimal conditions, which were identified through a statistical $L_9(3^4)$ orthogonal test. In this study, we have investigated the stability and antitumor activity of mPEG-rhES. SDS−PAGE, RP-HPLC, and UV spectrophotometric analysis were used to identify the purity and stability of mPEG-rhES. When incubated with protease or placed in an extreme environment, mPEG-rhES was more stable than rhES. The unmodified and PEGylated rhES were tested for their ability to inhibit the tumor growth of mouse H22 liver cancer in male mice. In a multiple versus single doses comparison study, daily administration of 0.25, 0.50, and 1.00 μmol/kg of unmodified rhES for 7 days resulted in 26.9%, 43.0%, and 64.9% reductions in tumor weight, respectively, while single doses of 0.13, 0.25, and 0.50 μmol/kg of the PEGylated protein per day resulted in 24.8%, 38.0%, and 64.5% reductions, respectively. Both treatments resulted in statistically significant reductions in mean tumor weight as compared to the physiological saline solution (control)-treated mice, with the dose of mPEG-rhES being a half of rhES, respectively, while the tumor inhibition rates were similar. Therefore, it is suggested that PEGylation enhances the stability of rhES and improves its antitumor activity.

INTRODUCTION

Protein and peptide drugs have great potential as therapeutic agents. However, many of them are degraded by proteolytic enzymes in vivo, and they are rapidly cleared by the kidneys. In addition, B cells can generate neutralizing antibodies against these proteins and peptides. Therefore, these drugs usually have a short circulating half-life (*1*). Poly(ethylene glycol) (PEG) is a widely investigated polymer used for the covalent modification of biological macromolecules for many pharmaceutical and biotechnical applications, especially of peptides and proteins (*2*). By increasing the molecular mass of proteins and peptides and shielding them from proteolytic enzymes, PEGylation improves pharmacokinetics (*1*). A wide range of therapeutic proteins, including human growth hormone, interferon, insulin, granulocyte-colony stimulating factor (G-CSF), and interleukin II, have been PEGylated (*3*). The first few PEG−protein products, now on the market (Adagen, Oncospar, and PEG-Intron), were developed using first generation of PEG chemistry. The second generation of PEGylation was designed to avoid the problems of first generation chemistry, notably diactivated PEG impurities, restriction to low molecular weight mPEG, unstable linkages, and lack of selectivity in modification (*1*). Recently, site-specific PEGylation of proteins has been attempted using a special class of functionalized PEG derivatives under specific conjugation conditions. For example, N-terminal specific PEGylation of G-CSF was obtained by conjugating methoxy-PEG derivatives at acidic pH conditions (*4*). This strategy was based on the fact that primary amine residues in protein have different pK_a values: pK_a 7.8 for the N-terminal α-amino group and 10.1 for the ϵ-amino group in lysine residues (*5*). When the propionaldehyde or *N*-hydroxysuccinimide PEG was conjugated at lower pH conditions, PEGylation at the N-terminus site occurred preferentially due to the different pK_a values between the two kinds of ϵ and α primary amines (*6*).

Endostatin, a 20 kDa carboxy-terminal fragment of collagen XVIII, was isolated from the conditioned media of hemangioendothelioma (EOMA) cells. It specifically inhibits endothelial proliferation and potently inhibits angiogenesis and tumor growth (*7*). Endostatin is derived from elastase-mediated cleavage (*8*). Ongoing angiogenesis is essential for the rapid growth of solid tumors, and it appears that successful tumors actively influence the 'angiogenic switch' to sustain continuous cell proliferation (*9*). Interestingly, endostatin does not seem to induce drug resistance. Furthermore, repeated cycles of systemic endostatin administration in tumor-bearing mice caused sustained tumor dormancy in the absence of further treatment (*10*). Therefore, endostatin will become the new and important antitumor agent.

In this study, we PEGylated the N-terminus of rhES in a site-specific manner with PEG-propionaldehyde derivative (*4, 6*). Various characterization methods, such as fast protein liquid chromatography (FPLC) and reversed phase high-performance liquid chromatography (RP-HPLC) techniques were used to reveal that the mono-PEGylation reaction occurred site-specifically at the N-terminal α-amine group. In vitro stability experiments such as incubating with trypsin or chymotrypsin and being kept at an extreme pH or temperature and in vivo antitumor activity experiments investigated in mice with H22 liver cancer were performed to examine the therapeutic potential of mono-PEGylated endostatin.

EXPERIMENTAL PROCEDURES

Materials. Recombinant human endostatin (rhES) was donated by ZhongKai Bio-pharma (Suzhou, Jiangsu, China). The 5 kDa mPEG-propionaldehyde was purchased from SunBio

(Anyang city, Seoul, Korea); trypsin, chymotrypsin, sodium cyanoborohydride, and dialysis membranes (MW cutoff 1000) were from Sigma (St. Louis, MO); CM Sepharose FF was form Amersham Pharmacia Biotech (Buckinghamshire, UK); 5 μm pore size BDS C_{18} reversed phase column (150 × 4.6 mm) was from Hypersil (Shandon HPLC, Runcorn, Cheshire, UK); and mouse H22 liver cancer cells and KunMing mice were form SIPI (Shanghai, CN).

PEGylation of rhES with PEG-Propionaldehyde Derivatives. The optimal condition of the reaction was achieved through a statistical $L_9(3^4)$ orthogonal test. The four factors were pH, molar ratio of mPEG propionaldehyde to rhES, temperature, and time. Table 1 reports the three levels of each factor. The reactions were terminated by adjusting pH to 3.5 with 1 M HCl, and samples were analyzed by SDS−PAGE and Gelworks 1D intermediate software system.

Separation and Purification by ÄCTA FPLC. The reaction mixture was loaded onto a CM Sepharose FF cation exchange column (1.0 cm × 20 cm) preequilibrated with 20 mM sodium acetate, pH 4.5 (buffer A), at a flow rate of 1.0 mL/min using a Pharmacia LCC 501 Plus FPLC system. The column was washed with 300 mL of buffer A before a ladder gradient to 20%, 40%, and 60% buffer B (buffer A + 1 M NaCl) was applied about 5 column volumes per gradient. The fractions were analyzed by nonreducing SDS−PAGE and Gelworks 1D intermediate software system. The samples containing mono-PEGylated and unmodified rhES were collected sequentially. Samples were stored at −20 °C after dialysis and lyophilization.

UV Spectrophotometry. The protein content of PEGylated rhES can be determined by comparing the UV absorbance of pure rhES and mPEG-rhES at 280 nm. The purity and PEG-residue count of PEGylated rhES can be identified by the protein content.

Reversed Phase HPLC (RP-HPLC). PEGylated rhES or rhES was analyzed on a Hypersil BDS C_{18} column equilibrated with buffer C (H_2O containing 0.1% TFA) with a flow rate of 1.0 mL/min and monitored at 280 nm, and eluted with a linear gradient to 60% buffer D (CH_3CN containing 0.1% TFA) over 20 min.

In Vitro Proteolysis. 400 μL of mPEG-rhES (1.25 mg/mL, pH 7.4 phosphate buffer (PBS)) was incubated with 4 μL trypsin (1.0 mg/mL) or 20 μL chymotrypsin (2.0 mg/mL) at 37 °C. 20 μL of each sample was loaded onto a C_{18} column at different intermediate incubation time and identified by RP-HPLC. The peak area with mPEG-rhES characteristic retention time indicated the remaining mPEG-rhES. Meanwhile the rhES was taken as compared with mPEG-rhES.

Stability of mPEG-rhES at Extreme pH or Temperature. To obtain the effects of temperature on rhES and mPEG-rhES, the mPEG-rhES (1.25 mg/mL, pH 7.4 PBS, 400 μL) or rhES (1.0 mg/mL, pH 7.4 PBS, 400 μL) was incubated at 4, 25, 37, 45, 50, 55, 60, 65 °C, respectively. After 24 h of incubation, all samples were centrifuged at 15000 rpm for 10 min. The absorbance of supernatant was measured at 280 nm to determine the remaining protein.

Similarly, to obtain the effects of acid or alkali, the pH of mPEG-rhES (1.25 mg/mL, pH 7.4 PBS, 400 μL) or rhES (1.0 mg/mL, pH 7.4 PBS, 400 μL) was adjusted to 2, 3, 4, 5, 6 using acetic solution and 8, 9, 10, 11 using sodium hydroxide solution. The samples were incubated at 37 °C for 24 h and collected by centrifugation. The remaining protein in supernatant was measured by UV spectrophotometry.

Antitumor Activity of mPEG-rhES in Mouse H22 Liver Cancer Allografts. Well-growth ascites of mouse H22 liver cancer, obtained from SIPI (Shanghai Institute of Pharmaceutical Industry, Shanghai, CN), were aspirated and diluted with 4-fold volumes physiological saline solution. 0.2 mL of the diluted ascites was subcutaneously inoculated with a trocar needle into the axillary flank of each male KunMing mouse (age 4 weeks; weight 19−21 g). The next day after inoculation, the mice were randomly allocated to drug groups of 10 animals each and 0.2 mL drug injections were administered, respectively. The rhES was administered intravenously (i.v.) to the tail at doses of 0.25, 0.50, and 1.00 μmol/kg, respectively, once a day for 7 consecutive days, and mPEG-rhES at doses of 0.13, 0.25, and 0.50 μmol/kg, and physiological saline solution at a dose of 12.5 mL/kg in the control group. After 10 days, the mice were sacrificed, and tumors were harvested for weight-measuring. The following formula was used to calculate the antitumor effect: tumor inhibition rate (TIR%) = (1 − mean tumor weight of treatment group/mean tumor weight of untreated group) × 100. All animal experiments were carried out in accordance with the Guidelines for the Welfare of Animals in Experimental Neoplasia.

RESULTS

PEGylation of rhES. The statistical $L_9(3^4)$ orthogonal test analyzed by SDS−PAGE indicated mono-PEGylation was better in Lane 1 or 4 (Figure 1). The ratios of mono-PEGylated rhES were 66.80% and 63.08% in Lane 1 and 4, respectively. The higher PEG concentration led to a higher ratio of multi-PEGylated rhES (Lane 3, 6, 9 in Figure 1). After orthogonal analysis on the four factors, we found the factor which played the most important role in the reaction was the molar ratio of mPEG to rhES, followed by temperature, time, and pH (Table 2).

The mono-PEGylated rhES produced in the PEGylation acylation reaction was separated from multi-PEGylated rhES and the unreacted rhES molecules by cation exchange chromatography (Figure 2). After dialysis and lyophilization, the purity of the mono-PEGylated rhES was measured by SDS−PAGE (Figure 3), UV spectrophotometry, and RP-HPLC (Figure 4). The results of SDS−PAGE and PR−HPLC chromatography indicated that the mPEG-rhES were pure. The experimental protein content of PEGylated rhES was 80.21%, and its PEG-residue count was 1. This result not only indicated that mPEG-rhES was pure, but also exactly showed that the product was unitarily PEGylated.

Stability of mPEG-rhES. Quantitations of percent remaining rhES following incubation with trypsin or chymotrypsin, by C_{18} column RP-HPLC, showed that the PEGylated rhES was more

R[e]	4.79	25.50	12.11	7.41	

[a] The factor which played the most important role in the reaction was found out by the statistical orthogonal test. [b] The ratios of mono-PEGylated rhES (RMPES%) were worked out from the gel by Gelwoks 1D intermediate software system. [c] K value was the sum of the RMPES% of a certain factor with the same level. [d] $K_1/3$ meant that K_1 value was divided by 3. [e] To a certain factor, the minimal $K_x/3$ ($x = 1$, 2, or 3) subtracted from the maximal one gave the R value. The larger the R value, the more important the factor's role in the reaction. In a degressive order, the most important factor was the molar ratio of mPEG to rhES, followed by temperature, time, and pH.

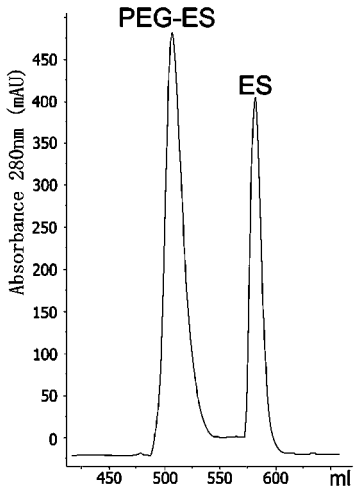

Figure 2. The profile of cation exchange fast protein liquid chromatogram (ÄCTA FPLC) of the PEGylated rhES.

resistant to trypsin or chymotrypsin proteolysis than rhES. After 40 min of incubation with trypsin, only 4% mono-PEGylated rhES in contrast to 90% of rhES was degraded (Figure 5). When mPEG-rhES and rhES were incubated with chymotrypsin, the results showed that the half-life of mPEG-rhES was about 60 min while that of rhES was about 24 min (Figure 6). Therefore, PEGylation distinctly increased the antiproteolytic stability of rhES.

Recombinant hES was stable during 4 °C to 40 °C just like mPEG-rhES. However when the temperature was increased to 50 °C, there was only 20% rhES remaining while almost 100% mPEG-rhES remaining. When the denaturalization ratio of rhES was 50% the temperature was about 47.6 °C, whereas the corresponding temperature of mPEG-rhES was about 62.6 °C (Figure 7). Therefore, PEGylation significantly increased the heat stability of endostatin.

Recombinant hES was stable during pH 2 to pH 7 as well as mPEG-rhES. When the pH exceeded 9, mPEG-rhES was significantly more stable than rhES. Even the pH rose to 10, mPEG-rhES was still stable while the denaturalization ratio of

rhES reached at 84.4% (Figure 8). Therefore, the N-terminus site-specific PEGylation also enhanced the acid−base stability of rhES significantly.

In Vivo Activity of Unmodified and PEGylated rhES. In a multiple versus single doses comparison study, daily administration of 0.25, 0.50, and 1.0 μmol/kg of unmodified rhES for 7 days resulted in 26.9%, 43.0%, and 64.9% reductions in tumor weight respectively, while single doses of 0.13, 0.25, and 0.50 μmol/kg of the PEGylated protein per day resulted in

24.8%, 38.0%, and 64.5% reductions respectively (Table 3). Both treatments resulted in statistically significant reductions in mean tumor weight as compared to the physiological saline solution (control)-treated mice at P-value < 0.001. The dose of mPEG-rhES was a half of rhES, repectively, while the tumor inhibition rate (TIR%) was rather closer.

DISCUSSION

The conjugation of PEG derivative to primary amine groups of endostatin takes place primarily via a nucleophilic substitution reaction: the attack of unprotonated amine group to the carbonyl groups of aldehyde. This indicated that all the primary amines

(α and ϵ) were equally reactive to PEGylation in basic conditions, so a heterogeneous mixture of multi-PEGylated species may be produced. In contrast, in the acidic condition, selective unprotonation of the N-terminal α-amine group could occur, making it more reactive than the ϵ-amine groups in lysine residues because of the difference of the pK_a values: 7−8 for α-amine, and 10−11 for ϵ-amine (*5*). This reductive amination reaction with the N-terminal α-amine group, in the presence of sodium cyanoborohydride as a reducing agent, possibly resulted in the site-specific mono-PEGylated CSF and EGF (*4*, *6*). Mono-PEGylated protein conjugates, such as endostatin, were similarly obtained through a selective conjugation at the N-terminal α-amine residue by a statistical orthogonal test.

After the simple purification steps of cation exchange chromatography and dialysis, the pure mono-PEGylated rhES conjugate could be obtained in the absence of rhES as evidenced by the SDS−PAGE and RP-HPLC analysis. The content of rhES protein in the mono-PEGylated rhES was measured by UV 280 nm. Through calculation, the protein content of mPEG-rhES was 80.21% and the PEG-residue count (n) was 1. This result not only indicated that mPEG-rhES was pure, but also adequately revealed that the molecular weights were in good agreement with the endostatin conjugate containing a single 5000 Da PEG derivative.

In the United States, phase I clinical trials of rhES therapy were performed with doses ranging from 15 to 600 mg/m^2, and the doses were generally well tolerated (*11*, *12*). In October 2002, rhES entered phase II clinical trials for neuroendocrine tumors and metastatic melanoma (*13*). Recently rhES therapy passed Phase III clinical trials in non small cell lung cancer in China (*14*), and rhES developed by Shandong Yantai Medgenn Co., Ltd., was approved by China State Food and Drug Administration in March 2005.

The dosage of rhES is 7.5−60 mg/m^2 per day (*14*, *15*). Such a dosage is a huge challenge to a recombinant gene product. However, the results of this study indicate that PEGylated rhES develops significant resistance to proteolysis and exhibits high stability to changes of temperature or pH. On the other hand, when we tested a 1 μmol/kg (20 mg/kg) dosage of rhES against mouse H22 liver cancer, the tumor inhibition rate (TIR%) was 64.9%. While the TIR% of mPEG-rhES was equivalent to rhES (64.5%), the dose of mPEG-rhES was just a half of rhES. Therefore, the PEGylation did not diminish the antitumor efficacy of rhES and also showed the possibility of reducing the administerial dosage in tumor treatments. In summary, it is suggested that PEGylation enhances the stability of rhES and improves its antitumor activity. Our data reveal the possibility to use a lower dosage of rhES in the clinic by the use of mono-PEGylation.

CONCLUSIONS

In this study, we showed that mPEG-propionaldehyde was specifically conjugated at the N-terminal α-amine group of rhES in a weak acidic pH environment. The stability of mono-PEGylated rhES, analyzed by protease degradation and an extreme environment in vitro, was enhanced significantly. Moreover, endostatin's antitumor activity, investigated in mice with H22 liver cancer, was also improved by PEGylation.

Chitosan−Pentaglycine−Phenylboronic Acid Conjugate: A Potential Colon-Specific Platform for Calcitonin

Reem Smoum,[†,§] Abraham Rubinstein,*[,‡] and Morris Srebnik*[,†]

Department of Medicinal Chemistry and Natural Products, School of Pharmacy, Faculty of Medicine, The Hebrew University of Jerusalem, and Department of Pharmaceutics, School of Pharmacy, Faculty of Medicine, The Hebrew University of Jerusalem, Jerusalem, Israel. Received December 19, 2005; Revised Manuscript Received June 7, 2006

Novel drug delivery vehicles based on the biodegradable, mucoadhesive polysaccharide chitosan covalently linked to a boronic acid protease inhibitor have been prepared and characterized. It was anticipated that these conjugates could protect a proteinaceous drug, such as salmon calcitonin, against proteolysis by serine proteases, an obstacle that prevents its oral administration. Specifically, 4-formylphenylboronic acid was linked to chitosan. Three types of conjugates were prepared. In the first, 4-formylphenylboronic acid was directly linked to chitosan. The other two conjugates employed glycylglycine and pentaglycine spacers. Enzyme-inhibition assays toward trypsin and elastase, in the presence of the enzyme chitosanase, demonstrated a strong inhibitory effect for the chitosan−pentaglycine−phenylboronic acid conjugates, while no inhibitory effect could be detected without chitosanase. The chitosan−pentaglycine−phenylboronic acid conjugate with the highest degree of substitution of 4-formylphenylboronic acid was able to decrease the salmon calcitonin degradation rate by trypsin. It is concluded that chitosan−pentaglycine−phenylboronic acid conjugates are a potential multifunctional, colon-specific vehicle for orally administered salmon calcitonin.

INTRODUCTION

Oral administration of peptide and protein drugs is a challenge because of their large size, their susceptibility to luminal and brush border proteolysis, and their limited stability (*1*). Consequently, protein drugs exhibit poor oral bioavailability (*2*). To increase their availability into the body after oral administration, proteinaceous drugs require absorption enhancers, protease inhibitors, or both (*3*). In this context, the colon is an interesting organ in the gastrointestinal (GI) tract. In addition to its improved ability to respond to absorption enhancers (*4*), reports in the literature indicate that proteolysis occurs into a lesser extent in the human colon compared with the small intestine (*5*). It was, therefore, suggested that colon-specific drug carriers could facilitate the oral absorption of proteinaceous drugs. Still, even the relatively lower proteolytic activity of the colon requires that protein drugs should be protected due to the longer residence time in the this organ (*6*). If protection is successful, the prolonged residence time could turn out to be advantageous because the drug would be exposed for extended periods of time to the absorptive epithelium. An efficient drug carrier would be the one that would provide ongoing protection over time. One possible solution is the development of synchronous release polymeric drug platforms, which would release drugs and enzyme inhibitors in a concomitant manner (*7*). An attractive alternative to the synchronous release formulations is the one in which the protease inhibitor is covalently bound to the drug carrier. In a recent study, antipain, chymostatin, elastatinal, and Bowman−Birk inhibitors were each covalently attached, together with ethylenediamine tetraacetic acid (EDTA), to chitosan to guarantee the inactivation of the pancreatic serine proteases, membrane-bound Zn-dependent peptidases, and carboxypeptidase A and B (*8*).

Boronic acids form reversible covalent adducts with the active site of serine proteases. The tetrahedral geometry of boron coordination mimics the high-energy tetrahedral geometry on the reaction center carbon during the hydrolysis reaction (*9*). For this reason, boronic acid inhibitors are often considered to be transition state analogue inhibitors. Peptide boronic acid inhibitors are usually tri- or tetrapeptides with a boronic acid group in place of the C-terminal carboxylate (*10*). When the peptide composition is based on the substrate specificity of a particular protease, the inhibitor combines the favorable geometry of the adduct formed by the boron atom in the active site with the enzyme−substrate interactions of the peptide chain. In this context, we propose to design new drug delivery vehicles based on a biodegradable polysaccharide linked to a peptide boronic acid. It is anticipated that such compounds could avoid protein hydrolysis by serine proteases such as trypsin and chymotrypsin.

A variety of vehicles have been developed to allow colon-specific delivery of drugs (*11*). Special efforts have been dedicated in our group to fermentable polysaccharides (*12*). Chitosan, a natural polysaccharide, is made of *N*-acetyl-D-glucoamine and D-glucosamine and the *N*-acetyl-2-amino-2-deoxy-D-glucopyranose units linked by (1 → 4)-β-glycosidic bonds. In the past decade, it became popular as a drug delivery vehicle due to its biocompatibility, degradation properties, and ability to be conjugated with a variety of substrates via its amine groups (*13*). Tozaki and co-workers have identified its ability to degrade in the human colon and suggested it as a colon-specific vehicle (*14*).

We, therefore, hypothesized that if a protease inhibitor was conjugated to chitosan, a novel colon-specific platform could be produced for protein drugs. In this study, 4-formylphenylboronic acid was found to inhibit the α-chymotrypsin, trypsin, elastase, and leucine aminopeptidase, and thus was selected as

the protease inhibitor that could be covalently attached to chitosan. The protein drug chosen was salmon calcitonin (sCT). Calcitonin is a 32 amino acid polypeptide used in the treatment of postmenopausal osteoporosis and Paget's disease and in the management of hypercalcemia (*15*). The current mode of administration of commercial sCT is intranasally, a route that suffers from large variability in bioavailability (0.3−30%) (*16*). For this reason, it is appealing to administer it orally if the barrier of serine proteases is overcome.

The specific goals of the present study were to (a) conjugate phenylboronic acid to chitosan with and without spacers, (b) study, in vitro, the inhibition properties of the polysaccharide conjugates, and (c) assess the possible protective effect of the optimal polysaccharide inhibitor conjugate(s) toward a model protein drug, sCT.

EXPERIMENTAL PROCEDURES

Chitosan [DS = 85% glucosamine (GlcN), 15% *N*-acetylglucosamine (GlcNAc)], trypsin, α-chymotrypsin, elastase, *N*-benzoyl-arginine-*p*-nitroanilide, *N*-benzoyl-tyrosine-*p*-nitroanilide, *N*-succinyl-$(Ala)_3$-*p*-nitroanilide, L-leucine-*p*-nitroanilide, 1-ethyl-3,3-dimethylaminopropyl carbodimide (EDAC), and sodium borohydride ($NaBH_4$) were all purchased from Sigma-Aldrich. Salmon calcitonin (sCT) was obtained from CALBIOCHEM. Solvents from Biolab were purchased as analytical grade. HPLC-grade trifluoroacetic acid (TFA) and acetonitrile were obtained from Biolab. All solutions and buffers were prepared with deionized water. All other materials were of reagent grade. ^1H, ^{13}C, and ^{11}B NMR was recorded on a Varian 300 MHz instrument at frequencies of 300, 75.9, and 96.29 MHz, respectively. Shift values were reported with respect to TMS (^1H, ^{13}C) and $BF_3{\cdot}OEt_2$ (^{11}B). Infrared spectra were run for samples as KBr disks on a Bruker Vector 22 FT-IR spectrophotometer. Biological assays were performed on a $UVIKON_{xs}$-BIO-TEK instrument.

Synthesis and Purification of Chitosan−Phenylboronic Acid Conjugates. Chitosan (50 mg, 0.3 mmol of NH_2) was dissolved in 5 mL of 1% acetic acid, and the mixture was stirred for 1 h to obtain a 1% (m/v) solution. Various amounts of 4-formylphenylboronic acid (Table 1) dissolved in 3 mL of methanol were added to the solution, which was stirred at room temperature. After 1 h, sodium borohydride ($NaBH_4$) (1.5%) in 2 mL of methanol was added. The reaction mixture was then incubated for 24 h at room temperature under continuous stirring. The precipitate formed was filtered and washed with water and methanol thoroughly.

Selected data for **3** are as follows: ^1H NMR (1% CD_3COOD in D_2O) δ 1.899 (s, NHAc), 3.012 (br m, H-2 of GlcN), 3.591−3.748 (br m, H-2,3,4,5,6 of β-D-glucose (Glc)), 4.577 (br, $-NHCH_2Ph$), 4.726 (br, H-1 of β-D-Glc), 7.36 (br, H-2,6 of Ar), 7.705 (br, H-3,5 of Ar). FT-IR (KBr, cm^{-1}) 3359, 2876, 1654.95, 1610.48, 1560.75, 1411.74, 1376.74, 1261.59, 1070.44, 65.17.

N-Succinylation of the Chitosan−Phenylboronic Acid Conjugates. Chitosan−boronic acid conjugate (20 mg) was dissolved in 2 mL of 1% acetic acid, and then the solution was diluted with 2 mL of methanol. Succinic anhydride (6 equiv = 72 mg) was added to the diluted solution and stirred at room temperature (rt). After the mixture was stirred for 24 h, the pH of the mixture was adjusted to 5.0 with 5% w/v aq NaOH to give a precipitate. The precipitate was collected by filtration and dispersed in water. The pH of the dispersion was adjusted to 10−12 with 5% w/v aq NaOH to give a solution. The solution was dialyzed using dialysis membrane (molecular weight cut off, 12 000−14 000) at room temperature for 2−3 days and lyophilized.

Table 1. Preparation of Conjugates 3 with Aldehyde 2

entry	**2** (equiv)	DS[a]	recovery[b] (wt %, g/g)	solubility in H_2O	elemental analysis C	H	N

5	3.0	58.0	79.9	moderate	46.02	6.60	4.94

[a] DS (degree of substitution) was determined from the peak area of phenyl protons (δ 7.0−7.4) and H-2 of GlcN and N-alkylated GlcN residues (δ 3.2) and from elemental analysis. [b] Recovery (%) was obtained by dividing the obtained product weight by the weight of the chitosan: Recovery (%) = [wt of product (g)/wt of DAC 85%] × 100.

N-Succinyl-conjugated chitosan (DS = 32.5%). ^1H NMR (D_2O) δ 2.085 (s, $-NH(CO)CH_2$), 2.3 (br s, $-NH(CO)CH_2$ and $-CH_2COONa$), 3.602 (br m, H-2,3,4,5,6 of GlcN), 7.259 (br, H2,6 of Ar), 7.620 (br, H3,5) of Ar.

Synthesis of Glycylglycine−Phenylboronic Acid Conjugates. To a 10 mL solution of glycylglycine (2.645 g, 20 mmol) in water containing NaOH (0.405 g, 10 mmol), ethanol (10 mL) was added. Then, 4-formylphenylboronic acid (1.5 g, 10 mmol) dissolved in 2 mL of ethanol was added. The resulting solution was stirred at room temperature for 30 min and then cooled to ca. 2 °C. Sodium borohydride (0.460 g, 12 mmol) in ethanol (5 mL), containing a few drops of a 2 M NaOH solution was then slowly added, a colorless solution being obtained. A few drops of 3 M HCl were added till pH 4−5 was reached, and the mixture was left overnight with stirring. A white precipitate formed, was collected by filtration, and was washed with cold water and diethyl ether. To this white solid, water at ca. 40 °C was added; the mixture was stirred for a few minutes and left at ca. 4 °C for several hours. The solid was filtered, washed with water and diethyl ether, and dried. Yield: 52.60%. ^1H NMR (CD_3OD): δ 3.723 (2H, s, CH_2COOH), 3.796 (2H, s, CH_2NH), 4.172 (2H, s, CH_2-phenol), 7.448 (2H, d, CH aromatic), 7.758 (2H, d, CH aromatic). ^{13}C NMR (CD_3OD) 42.775, 51.110, 128.761, 132.240, 133.642, 134.341, 166.028, 174.462. ^{11}B NMR 30.791. Anal. ($C_{11}H_{15}BN_2O_5$) C, H, N.

Synthesis of Pentaglycine−Phenylboronic Acid Conjugates. The procedure was similar to that of glycylglycine−phenylboronic acid. Yield: 64.46%. ^1H NMR (DMSO): δ 3.099 (2H, s, CH_2COOH), 3.674 (2H, s, CH_2NH), 3.713 (2H, s, CH_2NH), 3.750 (2H, s, CH_2NH), 3.768 (2H, s, CH_2NH), 4.439 (2H, s, CH_2-phenol), 7.284 (2H, d, CH aromatic), 7.707 (2H, d, CH aromatic). ^{13}C NMR (DMSO) 41.894, 42.509, 42.737, 45.010, 51.717, 53.144, 127.892, 134.746, 142.037, 166.795, 169.501, 169.790, 169.968, 171.733, 172.044. ^{11}B NMR 30.791. Anal. ($C_{17}H_{24}BN_5O_8$) C, H, N.

Synthesis and Purification of Chitosan−Spacer−Phenylboronic Acid Conjugates (Spacer = Glycylglycine or Pentaglycine). The covalent attachment of the spacer−phenylboronic acid conjugates to chitosan was achieved by the formation of amide bonds between amino groups of the polymer and the terminally located carboxylic acid group of the spacer−phenylboronic acid inhibitor. The general procedure was as follows: Chitosan (50 mg, 0.3 mmol NH_2) was dissolved in 5 mL of 1% acetic acid solution, and the mixture was stirred for 1 h to obtain a 1% (m/v) solution. Increasing amounts of spacer−phenylboronic acid conjugate (glycylglycine−phenylboronic acid in 3 mL of methanol or pentaglycine−phenylboronic acid in 2 mL of H_2O) were added to the solution, which was stirred at room temperature. After 1 h, 1-ethyl-3,3-dimethylaminopropyl carbodimide (EDAC) (1:1 mole ratio of EDAC/glycylglycine−phenylboronic acid; 2:1 mole ratio of EDAC/pentaglycine−phenylboronic acid) in 2 mL of methanol was added to mediate the formation of amide bonds between the amino groups of chitosan and the carboxyl groups of the

spacer−phenylboronic acid conjugate. The reaction mixture was then incubated for 24 h at room temperature under continuous stirring. The resulting polymer conjugate was isolated by exhaustive dialysis against deionized water for 2 days. Then the methanol was evaporated, and the purified product was lyophilized. The yellow solid (film) obtained was stored at room temperature until use. ^{1}H NMR (D_2O) for chitosan−glycyl-glycine−phenylboronic acid conjugates δ 2.924 (H, br m, H_2 of GlcN), 3.587 (10H, br m, H-2,3,4,5,6 of β-D-glucose (Glc), CH_2COOH and CH_2NH), 4.172 (2H, s, CH_2-phenol), 7.104 (2H, br m, CH-aromatic), 7.546 (2H, br m, CH-aromatic). FT-IR (KBr, cm^{-1}) 3421.15, 2926.78, 1653.77, 1637.15, 1560.03, 1409.70, 1377.45, 1316.99, 1259.65, 1154.28, 1073.13, 898.09, 653.53).

Synthesis and Purification of Chitosan−Pentaglycine−Phenylboronic Acid Conjugates. The procedure for the synthesis and purification of chitosan−pentaglycine−phenylboronic acid conjugates is similar to that of the chitosan−spacer−phenylboronic acid conjugates. ^{1}H NMR (D_2O) for chitosan−pentaglycine−phenylboronic acid conjugates δ 1.877 (s, NHAc), 2.669 (H, br m, H_2 of GlcN), 3.324 (6H, br m, H-2,3,4,5,6 of β-D-glucose (Glc)), 3.481 (H, s, CH_2CONH), 3.594 (2H, s, CH_2NH), 3.953 (2H, s, CH_2NH), 4.058 (2H, s, CH_2-phenol), 7.163 (2H, br s, CH-aromatic), 7.595 (2H, br s, CH-aromatic).

Determination of the Degree of Modification. ^{1}H NMR spectroscopy and elemental analysis were used to quantify the amount of phenylboronic acids, glycylglycine−phenylboronic acids and pentaglycine−phenylboronic acids conjugated to chitosan.

In Vitro Evaluation of the Protective Effect of 4-Formylphenylboronic Acid, Glycylglycine−Phenylboronic Acid, and Pentaglycine−Phenylboronic Acid Conjugates toward Serine Proteases and Leucine Aminopeptidase. α-Chymotrypsin, type II (EC 3.4.21.1) from bovine pancreas, was purchased from Sigma (MW 25 000). The inhibitors were tested by competitive assay against benzoyl-tyrosine-*p*-nitroanilide as a substrate. The hydrolytic reaction was carried out at 37 °C at pH = 7.00 with 50 mM Tris buffer and 0.02 M $CaCl_2$. Inhibitor stock solutions in DMSO/H_2O (1:10) were prepared with concentrations ranging from 6.02 to 0.0602 mM. A stock enzyme solution of 0.2 mg/mL was made in 1 mM HCl solution. A series of substrate concentrations (dissolved in 36.6% DMSO and 63.4% methanol) ranging from 0.043 to 0.43 mM was prepared. The assay was performed by adding 700 μL of Tris buffer to a 1.5 mL Epindorph tube followed by 100 μL of inhibitor and 100 μL of enzyme, and these were incubated for 10 min at 37 °C. Then 100 μL of substrate was added to the reaction followed by incubation for 20 min at 37 °C. The reaction was stopped by adding 200 μL of 30% acetic acid solution. The progress of the reaction was followed by monitoring the appearance of the absorption band of *p*-nitroaniline at 410 nm. K_i values for reversible competitive inhibitors were estimated by the method of Lineweaver and Burk. Data were fitted to the best straight line by the least-squares procedure.

Trypsin, type II-S (EC 3.4.21.4) from porcine pancreas, was purchased from Sigma. The inhibition constants were determined exactly as was done for chymotrypsin except that the substrate was benzoyl-arginine-*p*-nitroanilide dissolved in DMF.

Elastase, type II-A (EC 3.4.21.36) from porcine pancreas, was purchased from Sigma. The hydrolytic reaction was carried out at 37 °C, standard pH 7.5, with 50 mM phosphate buffer, 0.2 M NaCl, and the progress of the reaction was followed by monitoring the appearance of the absorption band of *p*-nitroaniline at 410 nm (substrate = *N*-succinyl-$(Ala)_3$-*p*-nitroanilide).

Leucine aminopeptidase, type VI (EC 3.4.11.2) from porcine kidney microsomes, was purchased from Sigma. The hydrolytic reaction was carried out at 37 °C, standard pH 7.5, with 50 mM phosphate buffer, 0.02 M $CaCl_2$, 10 vol % DMF, and the progress of the reaction was followed by monitoring the appearance of the absorption band of *p*-nitroaniline at 410 nm (substrate = L-leucine-*p*-nitroanilide).

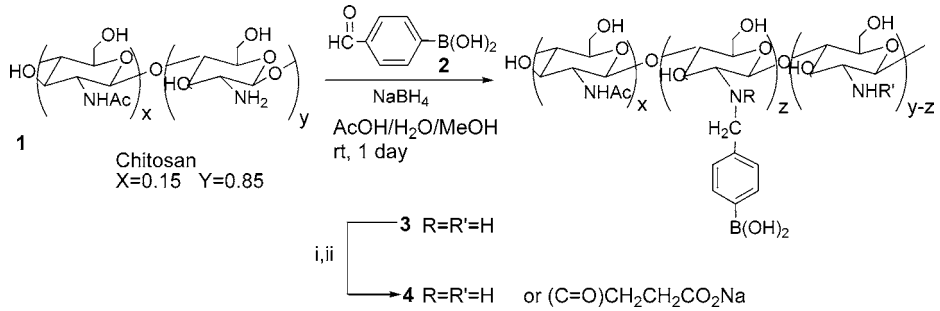
In Vitro Evaluation of the Protective Effect of the Succinylated Chitosan−Phenylboronic Acid, Chitosan−Glycylglycine−Phenylboronic Acid, and Chitosan−Pentaglycine−Phenylboronic Acid Conjugates toward Serine Proteases and Leucine Aminopeptidase. One to ten milligrams of the polymer−inhibitor conjugates was hydrated in 1 mL of 80 mM TBS buffer (Tris-HCl buffered saline), pH 6.8. Thereafter, trypsin (28.4 units), chymotrypsin (1 unit), elastase (0.4 units/mL), or leucine aminopeptidase (0.12 units/mL) dissolved in 100 μL of 80 mM TBS, pH 6.8, was added, and the mixture incubated for 1 h at room temperature. After addition of the corresponding substrates, each dissolved in a certain solvent as mentioned above, the reaction mixture was incubated for 20 min. The reaction mixture was stopped by adding 200 μL of 30% acetic acid solution. The absorbance (410 nM) caused by the formation of *p*-nitroanilide was recorded.

In Vitro Evaluation of the Protective Effect of the Succinylated Chitosan−Phenylboronic Acid, Chitosan−Glycylglycine−Phenylboronic Acid, and Chitosan−Pentaglycine−Phenylboronic Acid Conjugates toward Trypsin, Elastase, and Chymotrypsin in the presence of Chitosanase. The inhibitory activity of succinylated chitosan−phenylboronic acid, chitosan−glycylglycine−phenylboronic acid, and chitosan−pentaglycine−phenylboronic acid conjugates toward trypsin, elastase, and chymotrypsin was determined by the following enzyme assays. One milligram of the polymer conjugate was hydrated in 975 μL of 50 mM acetate buffer (pH 5.5). The solution was incubated for 5 min at 37 °C. Then, 50 μL of a chitosanase solution (chitosan *N*-acetylglucosaminohydrolase; EC 3.2.1.132 from *Streptomyces* species, 0.1 units dissolved in 55 mM acetate buffer, pH 5.5) was added, and the mixture was incubated for 1 h at 37 °C. Thereafter, 100 μL of the enzyme solution (trypsin (8.88 units/mL), elastase (0.4 units/mL), or chymotrypsin (156 units/mL)) in 50 mM acetate buffer, pH 5.5, was added, and the mixture was incubated at room temperature for 30 min. Following incubation, 100 μL (0.1 M solution) of the substrate (benzoyl-arginine-*p*-nitroanilide in DMF for trypsin, *N*-succinyl-Ala-Ala-Ala-*p*-nitroanilide in 20% DMF/H_2O for elastase, or benzoyl-tyrosin-*p*-nitroanilide in methanol/DMSO for chymotrypsin) was added, and the enzymatic reaction was allowed to proceed at room temperature for 40 min for trypsin and 20 min for both elastase and chymotrypsin. The enzymatic activity was stopped by adding 200 μL of 30% acetic acid solution. The progress of the reaction was followed by monitoring the appearance of the absorption band of *p*-nitroaniline at 405 nm. The controls used were the buffer and the unmodified chitosan.

Evaluation of the Protective Effect for Calcitonin. Salmon calcitonin solutions were freshly prepared prior to experiments conducted at a concentration of 1 mg/mL.

Three milligrams of succinylated chitosan−phenylboronic acid, chitosan−glycylglycine−phenylboronic acid, and chitosan−pentaglycine−phenylboronic acid conjugates were each dissolved in 950 μL of 50 mM acetate buffer, pH 5.5. Each solution was incubated for 5 min at 37 °C. Then, 50 μL of a chitosanase solution was added, and the solution was incubated for 1 h at 37 °C. Thereafter, 100 μL of a calcitonin solution (2 mg of salmon calcitonin dissolved in 100 μL of 50 mM acetate buffer, pH 5.5) was added, and the solution was incubated at room temperature for 20 min. Following this, 100 μL of the same buffer but containing trypsin (8.88 mg/mL) was added. Immediately after the addition of the enzyme solution, aliquots

Scheme 1[a]



[a] Reagents and conditions: (i) succinic anhydride, AcOH, H_2O, MeOH; (ii) 1% aq NaOH, room temp, 2 h.

of 60 μL were withdrawn and diluted with the same volume of 1% trifluoroacetic acid (TFA) used as stop solution to avoid any enzymatic degradation of the peptide. These first samples were used as reference values (time point zero). After that, aliquots of 60 μL were withdrawn at 1, 5, 10, 20, 30, and 60 min, and the enzymatic degradation was terminated as described above. All samples were centrifuged to remove any remaining polymer contents. For determining the remaining undigested calcitonin, 20 μL of the supernatant fluid was directly injected for HPLC analysis. Samples prepared in the same way but without adding chitosanase were used as controls. In addition, samples prepared in the same way but containing 3 mg of unmodified chitosan instead of chitosan−inhibitor conjugates served as controls.

HPLC Analytical Method. Salmon calcitonin (sCT) was analyzed by means of a validated HPLC method. HPLC Computer Controlled Waters Chromatography workstation with the following components was used: control 600, water pump 600, detector 996 photodiode array, and Millenium[32] chromatography software. Room temperature was maintained for the column, and chromatographic separations were performed on a Waters RP Symmetry C18 4.6 mm × 250 mm column. Twenty microliters of sample was injected into the column, and samples were analyzed by a reversed phase HPLC method. The mobile phase consisted of 0.1% v/v TFA/water (A) and 0.1% v/v TFA/acetonitrile (B). The gradient conditions were 20−35% B for 10 min, 35−37% B from 10 to 20 min, and 37−20% B from 20 to 25 min at a flow rate of 1 mL/min. The detection was achieved at a wavelength of 210 nm. Concentrations of sCT were quantified from integrated peak areas and calculated by interpolation from the standard curve.

RESULTS

Synthesis and Structural Analysis of Succinylated Chitosan−Phenylboronic Acid Conjugates. New chitosan derivatives were synthesized by direct reductive N-alkylation of chitosan with 4-formylphenylboronic acid, **2**. Scheme 1 shows the preparation of chitosan−phenylboronic acid conjugates **3** by reductive N-alkylation using sodium borohydride ($NaBH_4$). The degree of N-substitution could be controlled by increasing the amount of the aldehyde **2** in the reaction mixture (Table 1). The reactivity of **2** was found to vary in the range of 47−80%, which was caused by the simultaneous reduction of some of the aldehyde groups of **2** under the acidic conditions. The degree of N-substitution was calculated from the ratio of C% to N% in elemental analysis (*17*). In the FTIR spectra of chitosan and chitosan derivatives, the characteristic peaks of the amine NH vibration deformation appeared at 1595 cm^{-1} for chitosan, whereas it disappears in chitosan derivatives caused by the formation of $NH-CH_2$ band at C-2 in chitosan and a new peak at a higher wavelength (1611.31 cm^{-1}) due to C−C stretches in the aromatic ring. Characteristic absorption bands of para-substituted benzene appeared at 650.47, 816.05, 1515.33, 1560.80, and 1611.31.

[a] DS (degree of substitution) of phenylboronic acid residues. [b] DS of succinate residues. [c] Free amine residues. [d] Free acetylated amine residues.

Water-soluble material was only obtained moderately at high degree of substitution (DS = 79.9%). However, the other chitosan−boronic acid conjugates **3** were insoluble in neutral water and thus would not be useful for biological evaluation. To improve the solubility, the remaining amino groups of the conjugates **3** were transformed by succinylation with succinic anhydride to give conjugates **4** in 90−100% yields. The chemical structures of the succinylated conjugates **4** are summarized in Table 2. The degree of substitution for most compounds was between 32% and 34%. Despite using a large excess of succinic anhydride, some unreactive amino groups still remained in several conjugates. High-field ^1H NMR spectra also indicated that no succinylation had occurred at the N-glycosylation sites (δ H-1 of GclN−Neu5Ac). All succinylated products **4** were soluble in water.

Synthesis and Structural Analysis of the Chitosan−Spacer−Phenylboronic Acid Conjugates (Spacer = Glycylglycine or Pentaglycine). As shown in Scheme 2, 4-formylphenylboronic acid was attached to the spacer, glycylglycine or pentaglycine, by reductive N-alkylation using sodium borohydride ($NaBH_4$). The resulting spacer−phenylboronic acid conjugates were covalently coupled to the amino group of chitosan using EDAC, a water-soluble carbodiimide, Scheme 3. Two sets of conjugates were prepared (Figures 1 and 2); each consisted of different amounts of conjugated glycylglycine/pentaglycine−phenylboronic acids (Tables 3 and 4). The degree of N-substitution was determined by ^1H NMR and elemental analysis. As can be seen, there was a good correlation between the data obtained by the two methods. Conjugation was confirmed by the existence of an amide band at 1653.77 cm^{-1} from the FTIR spectrum of chitosan derivatives. The characteristic peaks of amine NH vibration deformation at 1595 cm^{-1} found in chitosan disappeared in the chitosan derivatives. Characteristic absorption bands of para-substituted benzene ring appeared at 653.53, 898.09, and 1560.03. All the conjugates prepared were soluble in water.

The inhibitory efficacy of the 4-formylphenylboronic acid, glycylglycine−phenylboronic acid, and pentaglycine−phenylboronic acid as well as their corresponding chitosan conjugates (succinylated chitosan−phenylboronic acid, chitosan−glycyl-

glycine−phenylboronic acid, and chitosan−pentaglycine−phenylboronic acid) toward serine proteases and leucine aminopeptidase was determined. In addition, the protective effect of these conjugates for salmon calcitonin toward the luminally secreted serine protease trypsin was evaluated.

Enzyme Inhibition Studies. Enzyme inhibition studies were carried out with trypsin, α-chymotrypsin, elastase, and leucine aminopeptidase N.

Inhibitory Efficacy of 4-Formylphenylboronic Acid, Glycylglycine−Phenylboronic Acid, and Pentaglycine−Phenylboronic Acid Conjugates. 4-Formylphenylboronic acid was chosen to be conjugated to chitosan because it is a simple molecule with an aldehyde group that can be conjugated to the amino group of the chitosan by reductive N-alkylation. This compound was checked for its ability to inhibit the serine proteases and leucine aminopeptidase. It was found that 4-formylphenylboronic acid is capable of inhibiting trypsin, chymotrypsin, elastase, and leucine aminopeptidase in a moderate range (Table 5).

2	0.6	28.20	76.4%	yes	40.58	6.52	9.43
3	0.8	29.00	72.7%	yes	40.38	6.48	9.48
4	1.0	43.75	78.6%	yes	40.69	6.33	10.46

[a] DS was determined from the peak area of phenyl protons (δ 7.0−7.4) and H-2 of GlcN and N-alkylated GlcN residues (δ 3.2) and from elemental analysis. [b] Recovery (%) was obtained by dividing the obtained product weight by the weight of the chitosan: Recovery (%) = [wt of product (g)/ wt of DAC 85%] × 100.

Table 5. Inhibition Constants (K_i in mM) for the 4-Formylphenylboronic Acid, Glycylglycine−Phenylboronic Acid, and Pentaglycine−Phenylboronic Acid as Measured with Chymotrypsin, Trypsin, Elastase, and Leucine Aminopeptidase

compound	chymotrypsin	trypsin	elastase	leucine aminopeptidase
4-formylphenylboronic acid	0.4	0.8	0.6	4
glycylglycine−phenylboronic acid	6	3	2	>10
pentaglycine−phenylboronic acid	5	3	3	8

4-Formylphenylboronic acid was then attached to two spacers, glycylglycine and pentaglycine. The influence of the spacers on the inhibition ability of 4-formylphenylboronic acid was checked. It was found that both the glycylglycine−phenylboronic acid and pentaglycine−phenylboronic acid were still able to inhibit trypsin, chymotrypsin, elastase, and leucine aminopeptidase (Table 5). However, the activities of these conjugates were an order of magnitude less than the original 4-formylphenylboronic acid.

Inhibitory Efficacy of Chitosan−Phenylboronic Acid Conjugates with and without Spacers. The chitosan−phenylboronic acid conjugates without any spacer were not soluble in water, DMSO, or methanol; however, they were soluble in 1% acetic

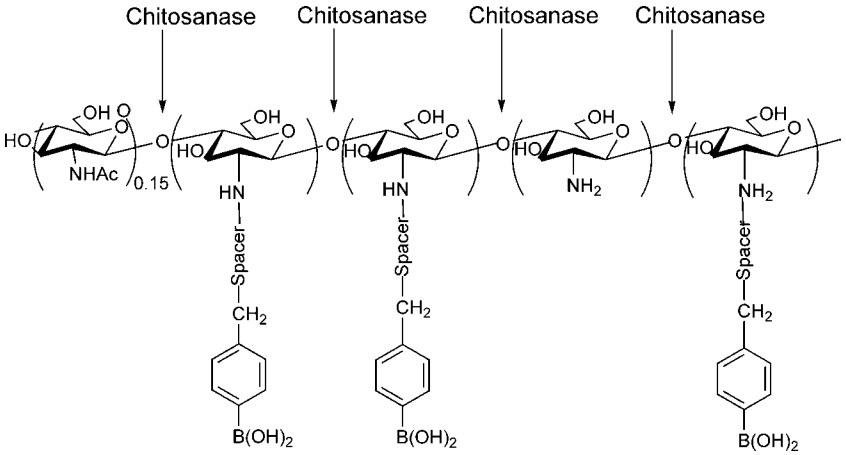

Figure 3. The assumed cleavage of chitosan−spacer−phenylboronic acid conjugate by the chitosanase enzyme (spacer = none, glycylglycine, or pentaglycine).

acid/H_2O. On the other hand, their succinylated derivatives were soluble in water, and therefore, they were used for biological evaluation. All the succinylated conjugates with different degrees of substitutions (Table 2) were checked for protease inhibition against the serine proteases trypsin, chymotrypsin, and elastase at concentrations up to 10 mg/mL. All conjugates with different degrees of substitution did not inhibit the serine proteases at any concentration.

In addition, the chitosan−glycylglycine−phenylboronic acid and the chitosan−pentaglycine−phenylboronic acid conjugates at all degrees of substitutions and at concentrations up to 10 mg/mL were tested for their ability to inhibit serine proteases. In the same manner, all these conjugates were not capable of inhibiting the enzymes.

Inhibitory Efficacy of Chitosan Conjugates with and without Spacers in the Presence of Chitosanase: A Proof of Concept. All the chitosan conjugates that contained phenylboronic acid without and with spacers did not inhibit the serine proteases. This may be because the conjugates were so bulky that the phenylboronic acid compound was not accessible to the active site of the enzyme even with the use of short and long spacers.

As mentioned before, chitosan is hydrolyzed by bacterial glycosidases in the colon (*14*). For the conjugated polymers prepared in this paper, this hydrolysis would allow the release of monomers, dimers, and oligomers of chitosan that are conjugated to 4-formylphenylboronic acid with or without spacers. These smaller conjugates may inhibit in turn the serine proteases and leucine aminopeptidase.

Therefore, this led to the idea of using an enzyme that would be able to hydrolyze the polymer conjugate into monomers, dimers, and oligomers similarly as would the bacterial enzymes in the colon. In this context, the enzyme chitosanase was chosen. Chitosanase is responsible for the endohydrolysis of β-1,4-linkages between GlcNAc−GlcN and GlcN−GlcN bonds in a partly acetylated chitosan (*18*) (Figure 3). Chitosanase is used as a model for glycosidases that can hydrolyze chitosan in the colon. The polymers were incubated with chitosanase for 1 h, a time that was calibrated for the complete hydrolysis of chitosan into monomers, dimers, and oligomers. This was followed by the addition of the required enzyme (trypsin, chymotrypsin, elastase, or leucine aminopeptidase) and incubation of the mixture for another 1 h, after which the substrate was added.

The results showed that only the conjugates with the pentaglycine spacer were able to inhibit trypsin and elastase, Figure 4. In these experiments, the buffer and the unmodified chitosan were used as controls. The inhibition increases with increasing the degree of substitution of the polymer conjugate. The polymer conjugate with the highest degree of substitution

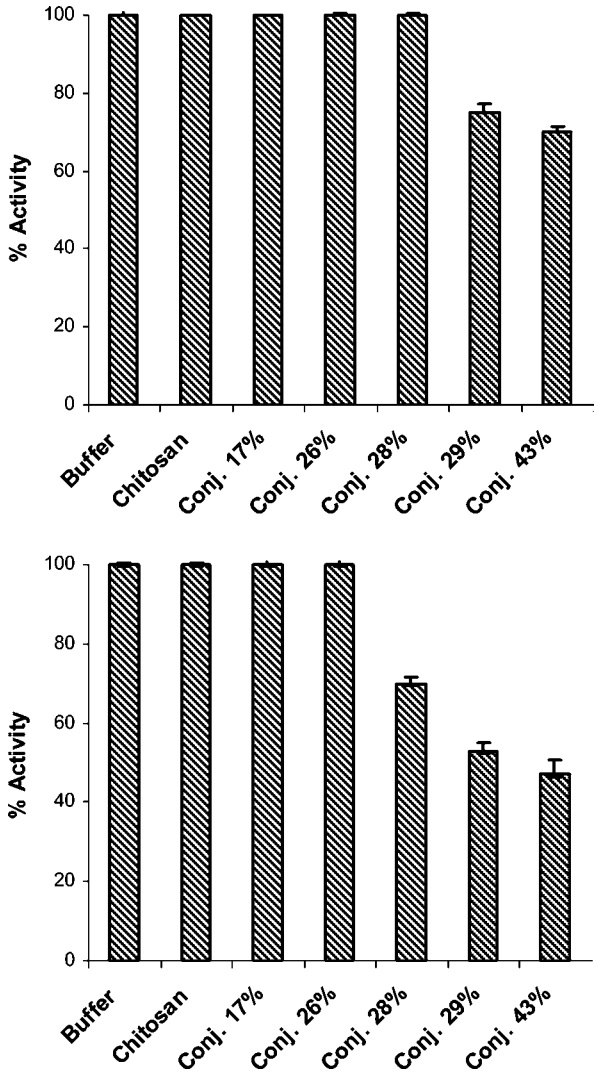

Figure 4. Effect of the buffer, chitosan, and the chitosan−pentaglycine−boronic acid conjugates with different degrees of substitutions on the relative activity of elastase (top) and trypsin (bottom).

(43%) demonstrated a strong inhibitory activity toward trypsin resulting in a significant decrease in the degradation of the trypsin substrate *N*-α-benzoyl-L-arginine-*p*-nitroanilide. After 40 min of enzymatic reaction, only 50% of the substrate was digested in the presence of 1 mg of chitosan conjugate, whereas at this reference point, 100% of the substrate was degraded in the presence of the same concentration of unmodified chitosan.

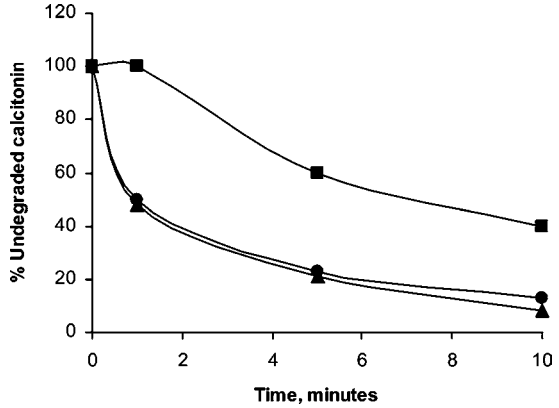

Figure 5. The degradation of sCT in the presence of chitosanase and (▲) 1 mg of chitosan$(Gly)_5B(OH)_2$ or (■) 3 mg of chitosan$(Gly)_5B(OH)_2$ or (●) 3 mg of chitosan$(Gly)_5B(OH)_2$ without chitosanase (control). Shown are the mean of 2 different measurements.

Also, elastase was inhibited by the same conjugate, but the effect displayed by the decrease in the degradation of the substrate succinyl-$(alanyl)_3$-*p*-nitroanalide was not as pronounced as in the case of trypsin.

The chitosan−spacer−phenylboronic acid conjugates were also evaluated with regard to their inhibitory activity toward α-chymotrypsin and leucine aminopeptidase in the presence of chitosanase, but no significant inhibition of the enzymes was observed.

Protective Effect toward Calcitonin. The chitosan−pentaglycine−phenylboronic acid conjugate with the highest degree of substitution (DS = 43%), which inhibited 50% of trypsin and 30% of elastase at 1 mg/ml concentration, was evaluated for a protective effect on the enzymatic degradation of calcitonin. After 10 min incubation with the proteases, only 8.4% of undegraded salmon calcitonin remained in a solution of chitosan−pentaglycine−boronic acid conjugate without the use of the chitosanase. With the use of chitosanase, only 13% undegraded salmon calcitonin remained in the presence of 1 mg of chitosan−pentaglycine−boronic acid. But by increasing the amount of the conjugate to 3 mg in the presence of chitosanase, 40% of undegraded calcitonin remained (Figure 5).

DISCUSSION

In the present study, novel boronated chitosan conjugates were prepared and tested for their ability to potentially serve as oral delivery systems of calcitonin.

Chitosan was selected due to its mucoadhesive properties (*19*), as well as strong permeation enhancing capabilities for protein drugs (*20*). It was shown that its mucoadhessiveness was maintained even after conjugation with enzyme inhibitors (*21*), allowing it to function in close proximity to the intestinal wall, while providing a continuous protection to its protein drug cargo. The combined use of mucoadhesive polymers and enzyme inhibitors could be interesting (*22*). However, there is always a risk of losing the protease inhibitor along the journey in the lumen of the gut. This can be resolved by their covalent attachment to polymeric drug carrier matrices, allowing them safety as long as the platform retains its integrity. Chitosan derivatives exhibiting a better solubility, stronger mucoadhesive capabilities, and enzyme inhibitory properties toward luminal secreted proteases and brush border membrane bound peptidases could be generated. These unique features make chitosan and in particular its derivatives an interesting excipient for the preoral administration of peptide drug (*23*).

4-Formylphenylboronic acid was found to be a moderate inhibitor of serine proteases. It was conjugated through its aldehydic group to chitosan by reductive N-alkylation. N-Succinylation of the prepared conjugates gave water-soluble succinylated chitosan−phenylboronic acid conjugates. In our study, succinylated conjugates were unable to inhibit serine proteases and leucine peptidase, probably due to the bulkiness of the polymer conjugate, so the inhibitor 4-formylphenylboronic acid was not accessible enough to the protease to inhibit it, even with the high degree of N-substitution. However, Bernkop-Schnürch and co-workers synthesized a series of mucoadhesive polymers that displayed strong protective effects toward all pancreatic proteases (*24*). In their study, the serine protease inhibitors antipain, chymostatin, and elastatinal were covalently linked to chitosan together with EDTA. These polymer conjugates showed a strong inhibitory activity toward trypsin, chymotrypsin, elastase, carboxypeptidases A and B, and aminopeptidase N.

To increase the accessibility of the 4-formylphenylboronic acid to the enzyme, we suggested using spacers. Two kinds of spacers were chosen, glycylglycine and pentaglycine spacers. The 4-formylphenylboronic acid−spacer conjugates inhibited serine proteases and leucine aminopeptidase moderately. However, after conjugating the spacer−phenylboronic acids to chitosan, no inhibition for the resulting polymer conjugates could be detected. The use of the longer pentaglycine spacer was thought to improve the inhibitory effect. Yet, inhibition studies revealed opposite results. Indeed, the inhibitory activity of chitosan−EDTA−ACE (ACE = antipain, chymostatin, elastatinal) conjugate toward elastase was markedly weaker than that of poly(acrylate) derivative−elastatinal conjugates and carboxymethylcellulose−elastatinal conjugates (*25*). A reason for the comparably stronger inhibitory effect of these already established polymer conjugates can be seen in the additional use of a spacer, providing an easy accessibility of the immobilized inhibitor for the corresponding protease. Moreover, Marschütz and co-workers reported recently that the use of a small rigid C4 spacer was highly advantageous compared to a long and more flexible poly(ethylene glycol) spacer (*26*). In our study, neither the short nor the long spacers had any effect on increasing the accessibility of the boronic acid to the active site of the protease.

To mimic the colonic enzyme cleavage of chitosan, chitosanase was used in our study. This enzyme is responsible for the endohydrolysis of β-1,4-linkages between GlcNAc−GlcN and GlcN−GlcN bonds in a partly acetylated chitosan (*18*). Surprisingly, it was observed in our study that only in the presence of chitosanase were the pentaglycine derivatives of the conjugates active in a ratio-dependent manner. At a concentration of 1 mg/mL of the chitosan−pentaglycine−phenylboronic acid conjugate with a 43% degree of substitution, 50% inhibition for trypsin and 30% inhibition for elastase were observed. We concluded that the chitosanase used in our study hydrolyzed the chitosan conjugates into monomers, dimers, and oligomers containing conjugated pentaglycine−phenylboronic acids. The higher the relative amount of pentaglycine−phenylboronic acid in the polymer, the more the degradation products, the monomers, dimers, and oligomers, were obtained. This observation supports the assumption that the polymer bulkiness was the reason for the interference with its enzyme inhibition capability.

The luminally secreted serine proteases seem to be the major cause for the digestion of salmon calcitonin (sCT). It has been shown that sCT is degraded by trypsin, α-chymotrypsin (*27*), and elastase (*28*). Although many attempts have been undertaken, the development of a commercially applicable oral delivery system for this peptide has failed so far (*3*). The use of mucoadhesive polymers is believed to provide a prolonged residence time of the drug at the absorption site, leading to an

improved bioavailability (*29*). To ascertain a protection within the polymeric carrier matrix (*28*), chitosan−enzyme inhibitor conjugates were added. Similar to the results obtained with thiolated polymers (*30*), our study showed that the conjugate with the highest degree of substitution (43%) was able to reduce the digestion of sCT by trypsin only in the presence of the chitosanase enzyme. Therefore, these conjugates seem to be promising agents in protecting sCT from intestinal pancreatic serine proteases. This study provides a proof of concept for further research aimed at identifying potent boron-based protease inhibitors.

In an attempt to develop efficient chemotherapeutic agents targeted at malignant cells that express receptors, we synthesized five new emodin derivatives and their gonadotropin-releasing hormone (GnRH) conjugates to be used as potential photoactive conjugates. Emodin was modified at its hydroxy groups and included different spacers for conjugation of the peptide. We used electron spin resonance (ESR) and spin trapping techniques to study the light-stimulated redox properties of the emodin derivatives and their GnRH conjugates. Upon irradiation, all new emodin derivatives and their conjugates stimulated the formation of singlet oxygen, that is, $^1O_2$, and oxygen radicals, that is, $O_2^{-\bullet}$ and $OH^\bullet$. However, substantial differences were found between the tested derivatives as to the efficacy of reactive oxygen species (ROS) production. Because of its superior ROS production properties, [D-Lys^6(MeoEmo)]GnRH was selected as a leading conjugate. En-route to evaluate its targeting capacity, this potentially cytotoxic conjugate was tested in vitro to determine its hormonal activity and binding affinity to GnRH receptors.

INTRODUCTION

Targeted chemotherapy has been conceived as a means to differentiate between healthy and cancer cells, by minimizing undesired toxicity and affording high drug concentrations at selected loci. These properties can be potentially achieved by conjugation of drugs to vectors that have unique affinities toward a variety of binding sites, such as monoclonal antibodies (*1*), proteins (*2*), peptides (*3*), or oligonucleotides (*4*). Since receptors to the gonadotropin-releasing hormone (GnRH) are overexpressed in gynecological cancer cells such as breast, prostate, ovarian, and endometrial (*5*−*9*) cancers, covalent conjugation of chemotherapeutic agents to GnRH analogues may improve the selectivity of these drugs toward tumor cells that overexpress GnRH receptors. Targeted chemotherapy with [D-Lys^6]GnRH employed as a vector has recently gained considerable attention (*10*−*13*). However, because healthy pituitary gonadotropes also express GnRH receptors, [D-Lys^6]GnRH may reach and damage these cells (*14*). Such undesirable side effects can potentially be overcome by the use of targeted photodynamic therapy (PDT).

PDT is a promising cancer treatment that involves the combination of light and a photosensitizer (PS). While each of these factors by itself is harmless, in the presence of oxygen they produce lethal reactive oxygen species (ROS) that can kill tumor cells. The phototoxicity of the PSs occurs most likely through two major reaction pathways—type I, involving radical cascade, and type II, involving singlet oxygen pathway (*15*). An ideal PS should preferentially accumulate in tumor tissues. However, most PSs are distributed in healthy cells too, causing direct damage as well as post-therapeutic complications, such as skin cytotoxicity following exposure to sunlight (*16*). Therefore, target-specific PSs are highly advantageous.

Hydroxylated 9,10-anthraquinones are natural compounds that display marked pharmacological activities and are used as anticancer and antimicrobial drugs (*17*). Due to their suitable reduction potential, these quinones could undergo enzymatic reduction leading to the generation of ROS and consequent degradation of proteins and nucleic acids (*4*, *18*−*20*). In addition to their redox activity, hydroxylated anthraquinones are also known as PSs (*21*, *22*). Emodin (1,3,8-trihydroxy-6-methyl-9,10-anthraquinone, Scheme 1) is a naturally occurring poly-hydroxylated anthraquinone and a well-known PS with broad anticancer and antiviral activities (*23*, *24*). In preliminary experiments carried out in our lab, emodic acid (Emo, Scheme 1) was found to produce high ROS production and elicit significant phototoxicity toward αT3-1 cells at a concentration of 10 μM. In an attempt to produce a model for an effective targeted PS against cancerous cells, this PS was conjugated to [D-Lys^6]GnRH. However, the thus produced conjugate, [D-Lys^6(Emo)]GnRH, exhibited poor ROS production and no cell toxicity (*25*, *26*).

In an attempt to improve the photodynamic properties of the conjugates, we derivatized the emodin moiety and attached different spacers between the resulting derivatives and the peptide carrier. Thus, new methoxylated derivatives of emodin were prepared and conjugated with [D-Lys^6]GnRH and [D-Glu^6]GnRH peptide analogues. We used electron spin resonance (ESR) and spin trapping techniques to study the light-stimulated redox properties of the emodin derivatives and their conjugates with peptides. Based on results presented here, [D-Lys^6(MeoEmo)]-GnRH was selected as the leading conjugate toward its targeting mission. This conjugate was tested in vitro to determine its hormonal activity and binding affinity to GnRH receptors.

EXPERIMENTAL PROCEDURES

Chemicals. 6-Methyl-1,3,8-trihydroxyanthraquinone (emodin) was obtained from Extrasynthese (La Rechassiere Genay, France). 2,2,6,6-Tetramethyl piperidine (TEMP), 5,5′-dimethylpyrroline *N*-oxide (DMPO), and nicotinamide adenine dinucleotide (NADH) were obtained from Sigma Chemical Co. (St. Louis, MO). The colored impurity present in the commercial DMPO was removed by treatment with neutral decolorizing charcoal (*27*).

Identification of Emodin Derivatives and Their Conjugates. Nuclear magnetic resonance (NMR) spectra were recorded at 25 °C on Brucker spectrometers (250 and 400 MHz,

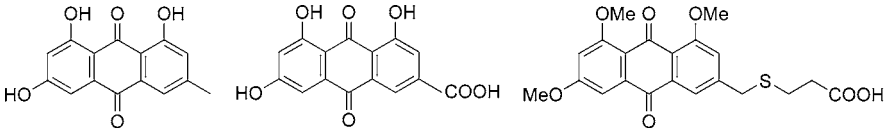
Scheme 1. Chemical Structure of Anthraquinonic Moieties[a]



[a] The chemical names are (1) 1,3,8-trihydroxy-6-methyl-9,10-anthraquinone (emodin), (2) 1,3,8-trihydroxy-6-oxy-9,10-anthraquinone (emodic acid), (3) 1,3,8-trimethoxy-9,10-anthraquinone mercaptopropanoic acid (MeoEmo).

Karlsruhe, Germany). Mass spectrometry was performed on a Micromass platform LCZ 4000 (Manchester, U.K.) utilizing the electron spray ionization (ESI) method. Reversed-phase high-performance liquid chromatography (HPLC) was performed on a Spectra-Physics SP-8800 liquid chromatography system equipped with an Applied Biosystems 757 variable wavelength absorbance detector at 220 nm. HPLC prepacked columns used were VYDAC RP-18 column (250 mm × 22 mm; Hesperia, CA; 10 mL/min) for semipreparative purification and Chromolith RP-18e column (4.6 mm × 100 mm; Merck, Darmstadt, Germany) for analytical purposes. HPLC purifications and analyses were achieved by using the following eluents: 0.1% trifluoroacetic acid (TFA) in water as solvent A and 0.1% TFA in 75% aqueous acetonitrile as solvent B. The purity of all synthetic peptides and conjugates was screened by analytical HPLC eluent composition of 10−100% B in 10 min, 3 mL/min. The crude synthetic peptides were purified using binary A/B gradients. Chromatograms were recorded on a Chrom-Jey SP-4270 electronic integrator. For amino acid composition analysis, peptides were hydrolyzed in 6 N HCl at 110 °C for 22 h under vacuum, and the hydrolyzates were analyzed with a Dionex automatic amino acid analyzer.

Synthesis. [D-Lys^6]GnRH and [D-Glu^6]GnRH were synthesized on an automatic multiple peptide synthesizer (AMS-422, Abimed-Technik GnbH, Langenfeld, Germany) with Rink amide resin as a polymeric support following the company's protocol for Fmoc strategy as described (*28*, *29*).

*1,3,8-Trimethoxy-9,10-anthraquinone (**2**).* A mixture of emodin, **1** (3.8 g, 18.5 mmol), K_2CO_3 (7.1 g, 50 mmol), and Me_2SO_4 (7.1 mL, 75 mmol) in Me_2CO (190 mL) was stirred under reflux for 19 h, cooled to room temperature, and concentrated under reduced pressure. The residue was well triturated with water (150 mL), and the product was filtered. Recrystallization from EtOH (400 mL) gave yellow-orange crystalline needles (2.71 g, 47% yield) that were collected by filtration and air-dried. Melting point: 238 °C. ^{1}H NMR ($CDCl_3$, δ, 250 MHz): 7.61(s, ar-H5), 7.30(d, J = 2.14 Hz, ar-H4), 7.07(s, ar-H7), 6.74-(d, J = 2.34 Hz, ar-H2), 3.96(s, OCH_3), 3.93(s, OCH_3), 3.92(s, OCH_3), 2.44(s, CH_3). MS (m/z): experimental [M + H$^+$] = 313.59; calcd m/z for $C_{18}H_{17}O_5$ [M + H$^+$] = 313.32.

*6-Bromomethyl-1,3,8-trimethoxy-9,10-anthraquinone (**3**).* To a solution of **2** (2.71 g, 8.65 mmol) and NBS (*N*-bromosuccinimide) (1.94 g, 10 mmol) in CCl_4 (250 mL), a catalytic amount of benzoyl peroxide was added, and the mixture was heated under reflux for 3 h. After cooling to room temperature, the mixture was concentrated under reduced pressure. Water (120 mL) was added, and the suspension was stirred for 1 h in an ice water bath. The yellow precipitate was filtered, washed with cold water and hexane, and recrystallized from toluene to give 2.67 g of product (79% yield). The precipitate contained also the 6-dibromomethyl-1,3,8-trimethoxy-9,10-anthraquinone product as an impurity (16% of the product), but the crude precipitate was used without further purification. Melting point: 230 °C. ^{1}H NMR ($CDCl_3$, δ, 250 MHz): 7.81(d, J = 1.67 Hz, ar-H5), 7.29(m, ar-H4,7), 6.75(m, ar-H2), 4.50(s, CH_2−Br), 3.99(m, OCH_3 1,3 and 8). MS (m/z): experimental [M + H$^+$]= 391.59 calcd m/z for $C_{18}H_{17}BrO_5$ [M + H$^+$] = 392.21.

*3-(4,5,7-Trimethoxy-9,10-dioxo-9,10-dihydro-anthracen-2-yl-methylsulfanyl)-propionic Acid, MeoEmo (**4**).* NaH (408 mg, 60% oil dispersion containing 10 mmol) was added gradually to a cooled solution (ice water bath) of 3-mercaptopropanoic acid (490 μL, 5.6 mmol) in DMF (5 mL) under argon. The suspension was stirred for 30 min in ice water bath and warmed to room temperature, and then compound **3** (2 g, 5.1 mmol) in DMF (35 mL) was added. The yellow suspension was stirred overnight at room temperature. The suspension was acidified with 5 N HCl solution and extracted with dichloromethane. The organic solvent was washed with brine and then dried over Na_2SO_4. The solvent was removed under reduced pressure to give a yellow-gray oil. After addition of ethyl acetate, the product solidified to give 1.07 g (50.5% yield). Melting point: 180 °C. ^{1}H NMR ($CDCl_3$, δ, 250 MHz): 7.71(d, J = 1.21 Hz, ar-H5), 7.29(d, J = 1.98 Hz, ar-H4,7), 6.75(d, J = 2.31 Hz, ar-H2), 3.98(s, OCH_3), 3.94(s, OCH_3), 3.93(s, OCH_3), 3.79(s, ar-CH_2S), 2.68(d, J = 6.13 Hz, CH_2S), 2.62(d, J = 5.79 Hz, CH_2COOH). MS (m/z): experimental [M − H$^+$] = 415.09; calcd m/z for $C_{21}H_{19}O_7S$ [M − H$^+$] = 415.45.

*3-(4,5-Dihydroxy-7-methoxy-9,10-dioxo-9,10-dihydro-anthracen-2-ylmethylsulfanyl)-propionic Acid, DihydroxyEmo (**5**).* A mixture of **4** (20 mg, 0.05 mmol), AcOH (5 mL), and 49% HBr/AcOH (0.5 mL) (a small amount of phenol had been added to the HBr to remove traces of Br_2) was heated at 100 °C for 4 h. The mixture was then cooled, and the solvent was removed under reduced pressure. The crude mixture was purified by preparative HPLC (10% B for 10 min and then increased linearly to 100% B in 60 min) to give 6 mg of pure product (30% yield). ^{1}H NMR (d^6-DMSO, δ, 400 MHz): 12.17 and 12.03(2s, ar-OH1 and ar-OH8), 7.70(d, J = 1.2 Hz, ar-H5), 7.33(d, J = 1.2 Hz, ar-H4), 7.21(d, J = 2.0 Hz, ar-H7), 6.90(d, J = 2.4 Hz, ar-H2), 3.94(s, OCH_3), 3.89(s, ar-CH_2S), 2.59(m, CH_2S), 2.52(m, CH_2COOH). MS (m/z): experimental [M − H$^+$] = 387.28; calcd m/z for $C_{19}H_{15}O_7S$ [M − H$^+$] = 387.39. The position of the methoxy group was determined by 1D NOE difference. By irradiation of the methoxy group at δ = 3.94 ppm, a response at the adjacent protons H2 and H4 confirmed the methoxy position at C3.

*3-(4,5,7-Trihydroxy-9,10-dioxo-9,10-dihydro-anthracen-2-yl-methylsulfanyl)-propionic Acid, TrihydroxyEmo (**6**).* A mixture of **4** (20 mg, 0.05 mmol), AcOH (5 mL), and 49% HBr/AcOH (0.8 mL) (a small amount of phenol was previously added to the HBr to remove traces of Br_2) was heated at 100 °C overnight. The mixture was then cooled, and the solvent was removed under reduced pressure. The crude mixture was purified by preparative HPLC (10% B for 10 min and then increased linearly to 100% B in 60 min) to give 5 mg of pure product (26% yield). ^{1}H NMR (CD_3OD, δ, 250 MHz): 7.76(d, J = 1.731 Hz, ar-H5), 7.26(d, J = 1.77 Hz, ar-H4), 7.21(d, J = 2.43 Hz, ar-H7), 6.58(d, J = 2.42 Hz, ar-H2), 3.84(s, ar-CH_2S), 2.70(m, CH_2S), 2.56(m, CH_2COOH). MS (m/z): M = 388 g/mol, 387 (M − 1), 412 (M + Na$^+$). MS (m/z): experimental [M − H$^+$] = 372.99; calcd m/z for $C_{18}H_{13}O_7S$ [M − H$^+$] = 373.37.

*3-Aminomethyl-1,6,8-trimethoxy-anthraquinone, MeoEmo-NH_2 (**7**).* 6-Bromomethyl-1,3,8-trimethoxy-9,10-anthraquinone (**3**) (100 mg, 0.3 mmol) was dissolved in 20 mL of dry THF. Ammonia gas (dried over sodium hydroxide) was bubbled for 3 h through the solution, and the reaction mixture was left

overnight in a closed round-bottom flask with stirring. The reaction was checked for completion by analytical HPLC. The reaction mixture was evaporated, and the crude product was used without further purification. A small portion of the crude product (5 mg) was purified by preparative HPLC, and the pure compound was characterized by MS and NMR. NMR (d^6-acetone/$CDCl_3$, δ, 250 MHz): 7.98(m, ar-H5), 7.79(m, ar-H4), 7.24(d, $J = 2.46$ Hz, ar-H7), 6.96(d, $J = 2.53$ Hz, ar-H2), 5.06-(s, ar-CH_2N), 3.98(s, OCH_3), 3.97(s, OCH_3), 3.96(s, OCH_3). MS (*m*/*z*): experimental [M − H^+] = 326.24; calcd *m*/*z* for $C_{18}H_{16}NO_5$ [M − H^+] = 326.33.

*N-(4,5,7-Trimethoxy-9,10-dioxo-9,10-dihydro-anthracen-2-yl-methyl)-succinic Acid, MeoEmo-N-Succinyl (**8**).* A mixture of MeoEmo-NH_2 (**7**) (32.7 mg, 0.1 mmol), succinic anhydride (20 mg, 0.2 mmol), and triethylamine (41 μL, 0.3 mmol) in 1 mL of DMF was stirred for 4 h at room temperature. Reaction progress was followed by analytical HPLC, and the crude mixture was purified by preparative HPLC (solvent gradient 10% B for 10 min and then increased linearly to 80% B in 70 min) to give 8 mg of pure product (19% yield). ^{1}H NMR (DMSO-d^6, δ, 250 MHz): 8.65(m, NH), 7.58(m, ar-H5), 7.39-(m, ar-H,7), 7.16(d, $J = 2.39$ Hz, ar-H,4), 6.98(d, $J = 2.39$ Hz, ar-H2), 4.37(d, $J = 5.69$ Hz, ar-CH_2−N), 4.01(s, 3H, OCH_3), 3.99(s, 6H, OCH_3), 3.79(s, ar-CH_2S), 2.42(m, CH_2CH_2COOH), MS (*m*/*z*): experimental [M − H^+] = 426.39; calcd *m*/*z* for $C_{22}H_{20}NO_8$ [M − H^+] = 426.40.

[D-Lys^6]GnRH Conjugates. [D-Lys^6]GnRH (10 mg, 8 μmol) was dissolved in *N*,*N*′-dimethylformamide (DMF, 500 μL). The emodin derivative (24 μmol), 4-methylmorpholine (NMM) (40 μL, 36 μmol), and benzotriazole-1-yl-oxy-tris-pyrrolino-phosphonium hexafluoro-phosphate (PyBOP) (18.8 mg, 40 μmol) were added. The mixture was stirred for 4 h at room temperature. The progress of the reaction was followed by the disappearance of [D-Lys^6]GnRH as revealed by analytical HPLC (see Scheme 3). Upon completion of the reaction, the crude peptide was precipitated with ice-cold *tert*-butyl methyl ether (3 mL), collected by centrifugation, and dried. The peptide was then purified by preparative HPLC (eluent composition was 10% B for the first 10 min and increased linearly to 100% B after 60 min, 10 mL/min). In this manner [D-Lys^6(MeoEmo)]GnRH, [D-Lys^6(DihydroxyEmo)]GnRH, [D-Lys^6(TrihydroxyEmo)]GnRH, and [D-Lys^6(MeoEmo-N-Succinyl)]GnRH were synthesized in solution and analyzed by HPLC, MS, amino acid analysis, and UV/visible spectra (data in Tables 2 and 3).

[D-Glu^6]GnRH Conjugate. A solution of [D-Glu^6]GnRH (1.5 mg, 2,4 μmol) and MeoEmo-NH_2 (1 mg, 4.8 μmol) in 1 mL of DMF was added with PyBOP (1.2 mg, 5 μmol) and *N*,*N*′-diisopropylethylamine (DIPEA, 2 μL, 10 μmol), and the mixture was stirred for 2 h at room temperature. Reaction progress was followed by analytical HPLC, and the crude product was purified by semipreparative HPLC (solvent gradient 10% B to 70% B in 60 min, semi-prep column Vydac 10 mm × 25 mm C18) to give 1 mg of pure product (26% yield).

ESR Studies. *Photoexcitation of Emodin Derivatives and Their Peptide Conjugates.* All spin trapping studies were performed with a Bruker electron paramagnetic resonance ER200D-SRC spectrometer at 25 °C. For ESR studies, the irradiation source was a KL 1500 electronic projector lamp (Schott, Germany). Irradiations were carried out with appropriate filters according UV/visible spectra (Figure 1) at band-pass of 320−510 nm with $\lambda_{max} = 400$ nm or cutoff filters of 355 nm. Samples were irradiated directly inside the ESR cavity with an optical fiber while the ESR spectra was recorded. For spin trapping studies, a mixture of DMPO (0.1 M) or TEMP (0.1 M) and emodin derivative/conjugate (1−2 mM) was irradiated in a 70 or 200 μL ESR flat cell. NADH was used as potential donor in phosphate buffered saline (PBS) solutions. For *g* factor

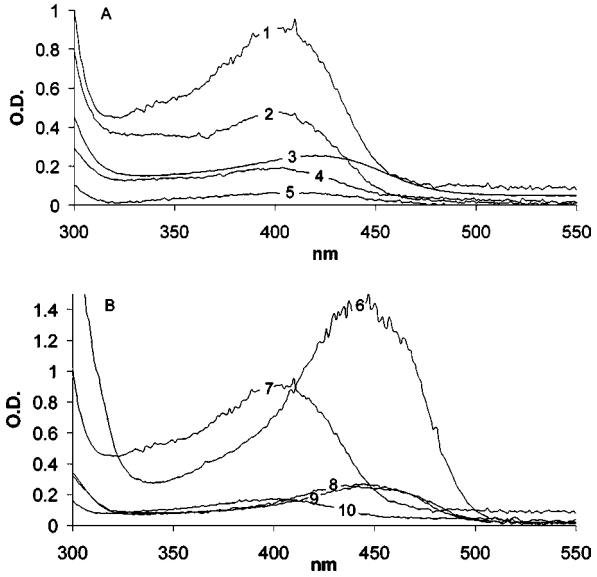


Figure 1. Relative absorption spectra (UV/vis): (A) emodin derivatives vs their conjugates in 0.1 mM DMSO/PBS (1 = MeoEmo(DMSO), 2 = MeoEmo-conj(DMSO), 3 = MeoEmo-conj(PBS), 4 = MeoEmo-N-Succinyl(DMSO), 5 = MeoEmo-N-Succinyl-conj(DMSO)); (B) emodin derivatives in 0.1 mM DMSO (6 = emodin, 7 = MeoEmo, 8 = DihydroxyEmo, 9 = TrihydroxyEmo, 10 = MeoEmo-NH_2).

measurements, we used 2,2-diphenyl-1-picrylhydrazyl (DPPH) as reference ($g = 2.0023$).

Receptor Binding Assay. [D-Lys^6]GnRH was iodinated by the chloroamine T method and purified by analytical HPLC. The binding affinities of the [D-Lys^6]GnRH analogues to preparations of rat pituitary receptors were obtained by competitive binding experiment (*30*). Briefly, crude preparation of rat pituitary membranes (about 25 μg of protein/tube, prepared from pro-estrous rats) in 0.4 mL of assay buffer (0.1% BSA in 10 mM Tris-HCl, pH 7.4) were incubated in duplicate with ^{125}I-[D-Lys^6]GnRH (40 000−50 000 cpm, 23.5 pM, 50 μL) in the presence (10^{-7}−10^{-10} M) or absence of [D-Lys^6]GnRH conjugate (50 μL) in a total volume of 500 μL of assay buffer for 90 min at 4 °C. The reaction was terminated by rapid filtration through Whatman GF/C filters presoaked in 2−3% polyethylenimine solution in 10 mM Tris-HCl to minimize filter absorption. The filters were washed three times with cold 10 mM Tris-HCl (3 mL each) and were counted in a Packard Auto-Gamma Counting System (Packard, Meriden, CT). Nonspecific binding was defined as the residual radioactivity in the presence of excess (1 μM) [D-Lys^6]GnRH. Specific binding was calculated by subtracting the nonspecific binding from the maximal binding, determined in the absence of any competing peptide.

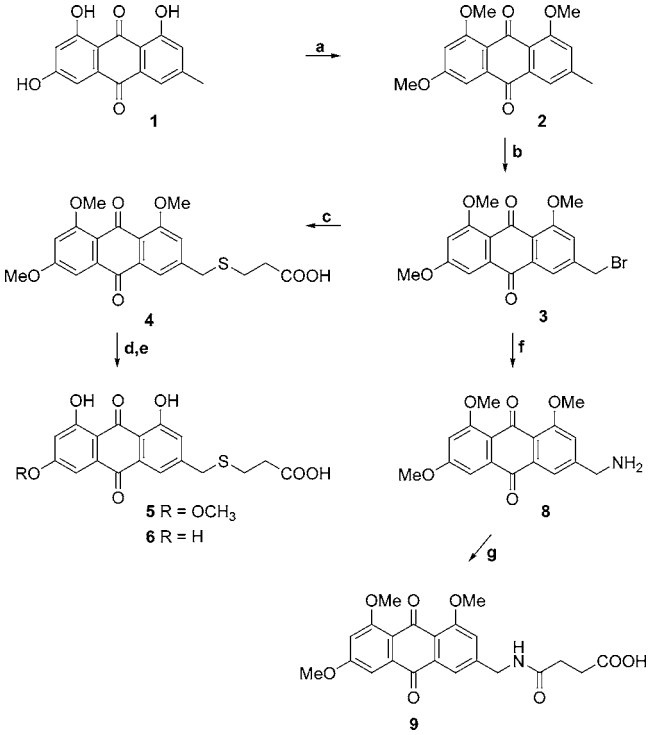
Effect of [D-Lys^6(MeoEmo)]GnRH on Luteinizing Hormone (LH) Release. The LH-releasing potencies of the GnRH conjugate and its precursor peptide were evaluated in primary pituitary cell cultures prepared from 21-day-old Wistar female rats as described earlier (*31*). The cultures were maintained in M-199 medium supplemented with 10% horse serum and antibiotics and were plated (50 000 cells/well) in 96-multiwell tissue culture dishes. After 48 h, the medium was replaced by phenol red- and serum-free M-199 containing the desired concentration of the peptides (three wells per experimental group) and incubated in the dark at 37 °C for 4 h. The experiments were carried out in the dark to avoid photoactivation of the emodin derivative moiety. At the end of the incubation period, supernatants (0.1 mL) were diluted with 1% BSA/PBS (0.9 mL) and analyzed for LH content by double-antibody radioimmunoassay (RIA) (*32*, *33*) using kits kindly supplied by the National Institute of Arthritis, Metabolism and Digestive Diseases (NIMDD).

Table 1. Characterization of the Emodin Derivatives

product no.	name	$[M - H^+]$ (calcd)[a] (g/mol)	λ_{max} (nm) 0.1 mM in DMSO
4	MeoEmo	415.09 (415.45)	404
5	DihydroxyEmo	387.28 (387.39)	445
6	TrihydroxyEmo	372.99 (373.37)	445
7	MeoEmo-NH_2	326.24 (326.33)	400
8	MeoEmo-N-Succinyl	426.39 (426.40)	404

[a] Calculated *m*/*z* values of $[M - H^+]$ are in parentheses.

Scheme 2. Synthetic Pathways towards Emodin Derivatives[a]



[a] Reagents and conditions: (a) K_2CO_3, Me_2SO_4, acetone, reflux for 19 h; (b) NBS, peroxide (catalytic), CCl_4, reflux for 3 h; (c) 3-mercaptopropanoic acid, NaH, DMF, rt, overnight; (d) HBr 49% in AcOH, 4 h at 130 °C; (e) HBr 49% in AcOH, overnight at 130 °C; (f) NH_3 in dry THF for 3 h; (g) succinic anhydride/Et_3N in DMF.

RESULTS

Synthesis. Emodin (1,3,8-trihydroxy-6-methyl-9,10-anthraquinone), a poly-hydroxylated, redox-active anthraquinone, was employed as a lead compound. Novel emodin derivatives and their conjugates with [D-Lys^6]GnRH and [D-Glu^6]GnRH were synthesized and characterized. The method of preparation of MeoEmo, **4**, was based on nucleophilic attack of 3-bromomethyl-1,6,8-trimethoxy-anthraquinone, **3**, by 3-mercapto-propanoic acid. The nucleophilic substitution of **3** led to the production of desired compound **4** (50% yield). DihydroxyEmo and TrihydroxyEmo, **5** and **6**, were synthesized from the MeoEmo by an acidolytic deprotection step in a yield of 30% and 26%, respectively. Amination of the brominated emodin, **3**, led to compound MeoEmo-NH_2, **7**, which was used directly for the next synthetic step. Addition of succinic anhydride as a spacer to the amino side group gave MeoEmo-N-Succinyl, **8** (19% yield) (Table 1, Scheme 2).

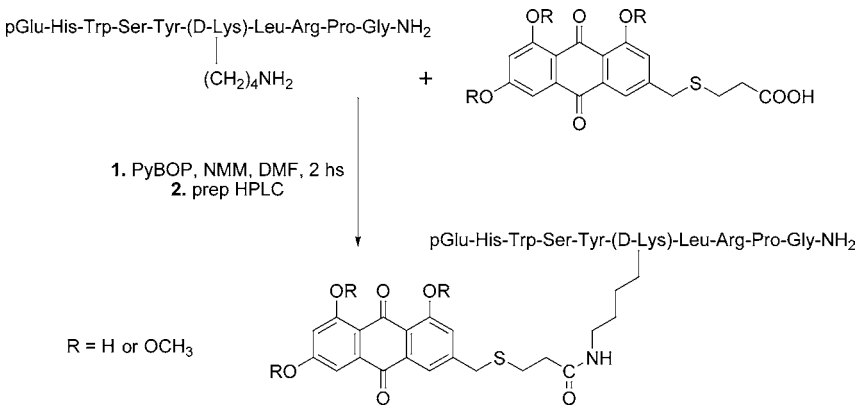
Synthesis of GnRH Analogs. [D-Lys^6]GnRH and [D-Glu^6]-GnRH were synthesized as described in the Experimental Procedures section. The synthesis of the corresponding emodin−peptide conjugates was carried out in solution according to Scheme 3. In the conjugation of [D-Lys^6]GnRH, the carboxylic moiety of the corresponding emodin derivative was activated, using benzotriazole-1-yl-oxy-tris-pyrrolidinophosphonium-hexafluorophosphate (PyBOP), and reacted with the free ϵ-amino group of [D-Lys^6]GnRH in the presence of 4-methylmorpholine (NMM) in DMF. The crude [D-Lys^6]GnRH conjugate was then purified by preparative HPLC. In this manner, [D-Lys^6(MeoEmo)]-GnRH, [D-Lys^6(DihydroxyEmo)]GnRH, [D-Lys^6(TrihydroxyEmo)]GnRH, and [D-Lys^6(MeoEmo-N-Succinyl)]GnRH were synthesized (Scheme 3). [D-Glu^6]GnRH was reacted with MeoEmo-NH_2, **7**, for rendering [D-Glu^6(MeoEmo-NH_2)]GnRH. The peptide was conjugated by activating the γ-carboxylic moiety of the peptide with PyBOP and diisopropylamine (DIPEA) as a base. The conjugates were analyzed by HPLC, MS, and amino acid analysis and tested for their λ_{max} (Tables 2 and 3).

ESR Studies. Filters for the ESR experiments were chosen according to the obtained visible−UV spectra in Figure 1A,B.

Singlet Oxygen ($^1O_2$) Photogeneration by Emodin Derivatives. Since the efficiency of quinones for inhibiting cancer cell growth is believed to be related, among other factors, to their capacity to produce ROS, the ability of the various potentially cytotoxic emodin derivatives to generate ROS was compared. For testing singlet oxygen, $^1O_2$, we used the spin trap TEMP, which produces a stable nitroxyl radical, TEMPO, having a triplet ESR signal ($a_N = 14.8-15$ G) as a result of a chemical reaction with a singlet oxygen (*34*). The kinetics of singlet oxygen formation was evaluated by measuring the initial rate of ESR signal of the central component of the TEMPO triplet.

As shown in Figure 2A,B, all emodin derivatives can generate singlet oxygen. We examined the influence of the different spacers (Figure 2A) and the influence of the methoxylated substitution (Figure 2B) on the emodin ROS production. The largest initial rate of the ESR signal was observed for MeoEmo and for MeoEmo-N-Succinyl, as compared with DihydroxyEmo,

Scheme 3. Synthesis of the [D-Lys^6]GnRH Conjugates with the Emodin Derivatives[a]



[a] See Experimental Procedures section for details.

Table 2. Characterization of the GnRH Conjugates of Emodin Derivatives

peptide conjugate	retention time (min) (HPLC)[a]	yield (%)	[M + H$^+$] (calcd)[b] (g/mol)	λ_{max} (nm) 0.1 mM in DMSO
[D-Lys^6(MeoEmo)]GnRH	7.74	38	1653.21 (1652.85)	403
[D-Lys^6(MeoEmo-N-Succinyl)]GnRH	7.19	85	1663.51 (1663.80)	410
[D-Lys^6(DihydroxyEmo)]GnRH	8.51	31	1625.05 (1624.79)	441
[D-Lys^6(TriydroxyEmo)]GnRH	8.67	75	1610.41 (1610.76)	*c*
[D-Glu^6(MeoEmo-NH$_2$)]GnRH	7.22	26	1565.30 (1564.67)	401

[a] Analytical HPLC. Eluent composition: from 0 to 100% B in 10 min, then 100% B for 4 min more. Solvent A was 0.1% trifluoroacetic acid (TFA) in water. Solvent B was 0.1% TFA in 75% aqueous acetonitrile. [b] Calculated (calcd) *m*/*z* values of [M − H$^+$] are in parentheses. [c] Not determined.

Table 3. Amino Acid Analysis of the Peptidic Conjugate after Acidic Hydrolysis[a]

	Glu	His	Ser	Tyr	Lys	Leu	Arg	Pro	Gly
[D-Lys^6]GnRH theoretical	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
MeoEmo[b]	1.00	1.00	0.90	0.98	1.06	1.05	1.16	0.95	1.03
MeoEmo-N-Succinyl[b]	1.00	1.02	0.89	0.98	1.02	1.03	1.17	1.00	1.01
DihydroxyEmo[b]	1.00	0.99	0.90	0.98	1.01	1.02	1.12	1.00	1.10
TriydroxyEmo[b]	1.00	0.94	0.89	0.98	1.02	1.08	1.13	0.96	1.00
MeoEmo-NH$_2$[c]	2.04	1.00	0.89	1.00		1.09	1.18	0.94	1.00

[a] Tryptophan could not be detected due to its destruction under the acidic conditions of hydrolysis. [b] Conjugate of [D-Lys^6]GnRH. [c] Conjugate of [D-Glu^6]GnRH. Theoretical composition: Glu 2.00; His 1.00; Ser 1.00; Tyr 1.00; Leu 1.00; Arg 1.00; Pro 1.00; Gly 1.00.

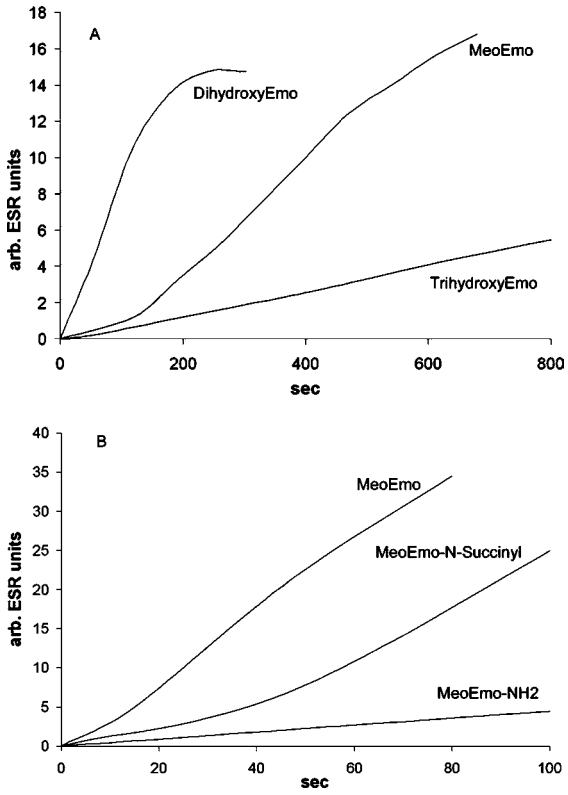


Figure 2. Effect of light on generation of TEMPO ESR signal in the presence of emodin derivatives: (A) 355 nm cutoff; (B) blue filter, λ_{max} = 400 nm. ESR conditions: microwave power 31 mW; TC 1.25 s; MA 1.1 G; temp 25 °C; solvent DMSO; components TEMP (0.1 M); quinones concentration, 1 mM.

TrihydroxyEmo, and MeoEmo-NH$_2$. TrihydroxyEmo showed much less reactivity compared with the other derivatives.

Singlet Oxygen ($^1O_2$) Photogeneration by the Conjugates [D-Lys^6(MeoEmo)]GnRH and [D-Lys^6(MeoEmo-N-Succinyl)]-GnRH. To study the influence of the peptide carrier on singlet oxygen production, the kinetics of TEMPO adduct formation of MeoEmo and [D-Lys^6(MeoEmo)]GnRH were compared. We found that incorporation of MeoEmo into the [D-Lys^6]GnRH peptide carrier significantly decreased the rate of TEMPO formation, though it still remained active. The same pattern, even more pronounced, was repeated when we tested MeoEmo-N-Succinyl and its GnRH conjugate under the same experimental conditions. Clearly, the peptide markedly decreases the singlet oxygen production of the quinone moiety (Figure 3).

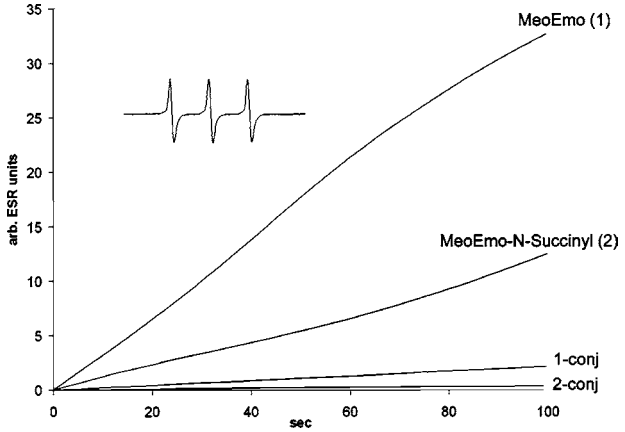

Figure 3. Influence of the [D-Lys^6]GnRH carrier on TEMPO formation (blue filter, λ_{max} = 400 nm). ESR conditions: microwave power 31 mW; MA 1.1 G; TC 1.1 s; temp 25 °C; solvent DMSO; components TEMP (0.1 M); quinones and conjugates concentration, 1 mM.

Oxygen Radicals Photogeneration by Emodin Derivatives. In an excited state, quinones produce ROS by energy transfer (reaction 2) and electron transfer (reaction 3−6). The ability to generate oxygen radicals was detected by the spin trap 5,5′-dimethyl-1-pyrroline *N*-oxide (DMPO), which reacts with short-lived radicals, for example, $O_2^{-\bullet}$, HO$^\bullet$, and $CH_3^\bullet$, to produce long-lived spin adducts, each of which possess a characteristic ESR spectrum.

$$Q \xrightarrow{h\nu} Q^* \quad (1)$$

$$Q^* + O_2 \rightarrow Q + {}^1O_2 \quad (2)$$

$$Q^* + D \rightarrow Q^{-\bullet} + D^{+\bullet} \quad (3)$$

$$Q^{-\bullet} + O_2 \leftrightarrow O_2^{-\bullet} + Q \quad (4)$$

$$O_2^{-\bullet} + O_2^{-\bullet} \xrightarrow{2H^+} H_2O_2 + O_2 \quad (5)$$

$$O_2^{-\bullet} + H_2O_2 \xrightarrow{\text{Fe (cat.)}} O_2 + HO^\bullet + OH^- \quad (6)$$

$$H_2O_2 + Fe(II) \rightarrow HO^\bullet + OH^- + Fe(III) \quad (7)$$

$$Q^{-\bullet} + Fe(III) \rightarrow Q + Fe(II) \quad (8)$$

where Q* represents quinone in an excited state, D is electron donor, and $Q^{-\bullet}$ is semiquinone.

Figure 4A shows the effect of light on MeoEmo in the presence of DMPO and demonstrates the influence of an additional physiological electron donor like NADH. The ESR signal found was a quartet ($a_N = a_H$ = 14.8 G and 1:2:2:1 ratio), typical for hydroxyl-DMPO spin adduct in water; a weak signal

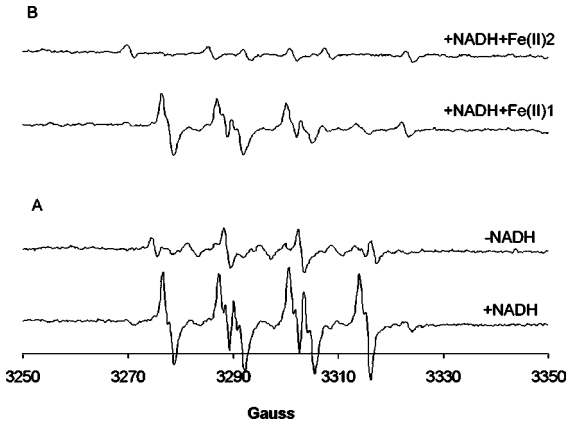

Figure 4. (A) Effect of NADH on ESR signal of MeoEmo in the presence of DMPO upon irradiation (blue filter, $\lambda_{max} = 400$ nm). ESR conditions: microwave power 31 mW, modulation amplitude 890 MG; time constant 640 MS; temp 25 °C; solvent 10% DMSO/90% PBS; components MeoEmo (1 mM), DMPO (0.1 M) with and without NADH (1 mM). (B) Effect of $FeSO_4$ on ESR signal of MeoEmo in the presence of DMPO (cutoff filter, 355 nm). ESR conditions: microwave power 31 mW, modulation amplitude 1.1 G, time constant 1.25 s; temp 25 °C; solvent 10% DMSO/90% PBS; components MeoEmo (1 mM), DMPO (0.1 M), NADH (1 mM), and $FeSO_4$ (0.01 mM)).

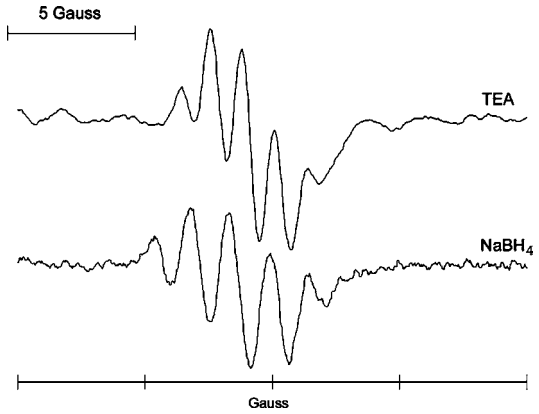

Figure 5. Effect of light on MeoEmo with electron donors produced semiquinone-like signal (blue filter, $\lambda_{max} = 400$ nm): (TEA) MeoEmo (1 mM), DMPO (1 mM), TEA (0.04 M) in 50% DMSO/50% PBS solution (ESR conditions: microwave power 31 mW; modulation amplitude 1.0 G; RG = 2×10^5; temp 25 °C); ($NaBH_4$) MeoEmo (1 mM), $NaBH_4$ (pH = 9) in 50% DMSO/50% H_2O solution (ESR conditions: microwave power 31 mW; modulation amplitude 630 MG; RG = 8×10^5; temp 25 °C.

of superoxide−DMPO spin adduct was also observed (a_N = 14.2 G, $a_H^\beta = 11.3$ G, $a_H^\gamma = 1.25$ G, 12 lines). Adding NADH to the MeoEmo−DMPO solution stimulated stronger superoxide DMPO ESR signal. Figure 4B shows changes in the ESR signal when Fe(II) was added. DMPO−superoxide spin adduct was converted with time (in the first 200 s of the experiment) to the sextet spectrum, typical for DMPO−CH_3 spin adduct ($a_N = 15$ G, $a_H = 22.2$ G).

The involvement of the semiquinone radical in the ROS mechanism was also assessed when triethylamine (TEA) was used as an electron donor. TEA (1 mM) acted as an enhancer of superoxide ESR signal, as predicted (data not shown). Moreover, when TEA (10% v/v) was used with MeoEmo in DMSO, a semiquinone-like signal appeared. The same ESR signal was observed by reduction of MeoEmo with $NaBH_4$ (Figure 5, $g = 2.0051$).

Figure 6A,B compares the effects of the emodin derivatives on photogeneration of ROS in the presence of NADH. As shown, MeoEmo and MeoEmo-N-Succinyl produced more intense ESR superoxide signal than the other derivatives tested.

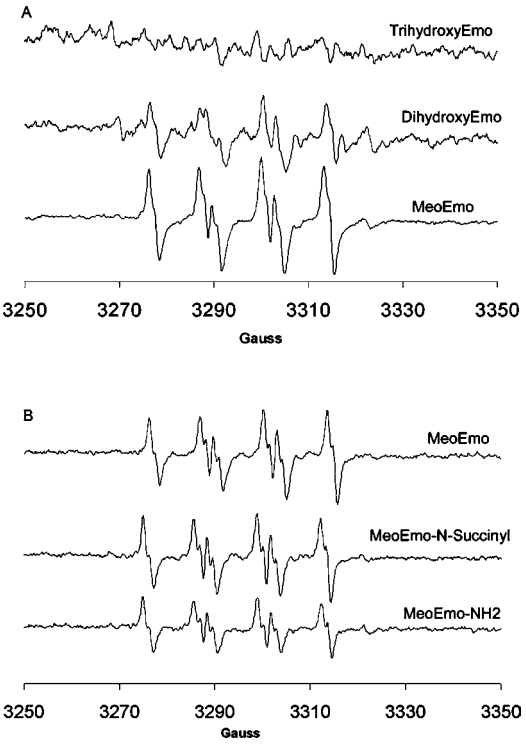

Figure 6. The ESR spectra of the DMPO−superoxide radical adduct produced upon irradiation of the emodin derivatives in 10% DMSO/90% PBS (components: quinones (1 mM), DMPO (1 mM), NADH (1 mM)): (A) cutoff filter 355 nm (ESR conditions: microwave power 31 mW; modulation amplitude 1.1 G; time constant 1.25 s; temp 25 °C; with different receiver gain (RG), for MeoEmo RG = 2.5×10^5, for DihydroxyEmo RG = 6.3×10^5, for TrihydroxyEmo RG = 8×10^5); (B) blue filter, $\lambda_{max} = 400$ nm (ESR conditions: microwave power 31 mW; modulation amplitude 890 MG; time constant 640 ms; temp 25 °C; RG = 2.5×10^5).

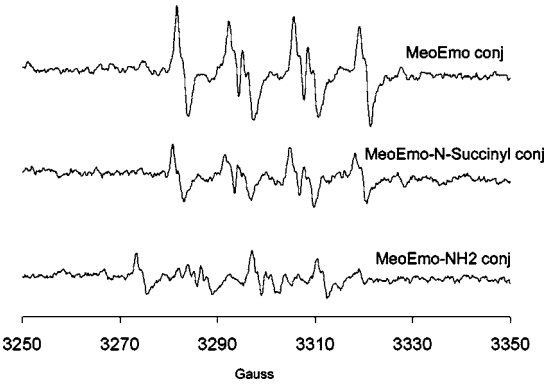

Figure 7. Effect of light on [D-Lys^6]GnRH and [D-Glu^6]GnRH conjugates upon irradiation. The ESR signals represent superoxide−DMPO spin adduct, 12 lines, $a_N = 14.2$ G, $a_H^\beta = 11.3$ G, $a_H^\gamma = 1.25$ G. PBS system containing 10% DMSO; components: DMPO (0.1 M), GnRH conjugates (1 mM), NADH (1 mM). ESR conditions: microwave power 31 mW; modulation amplitude 630 MG; RG = 1×10^6; time constant 1.25 s; temp 25 °C.

Oxygen Radical Photogeneration by Emodin Conjugates. In the case of the peptide conjugate, the ESR signal observed is typical for superoxide−DMPO spin adduct (Figure 7). Comparison of the emodin conjugates shows that MeoEmo conjugate gave the stronger peak compared with MeoEmo-N-Succinyl and MeoEmo-NH_2 conjugates.

Stability of the Conjugate toward ROS Generation. Generation of ROS by compounds under study can destroy, in principle, the peptide carriers. Stability of [D-Lys^6(MeoEmo)]GnRH toward the ROS produced by its own irradiation is a prerequisite for specific and efficient targeting. This aspect was evaluated

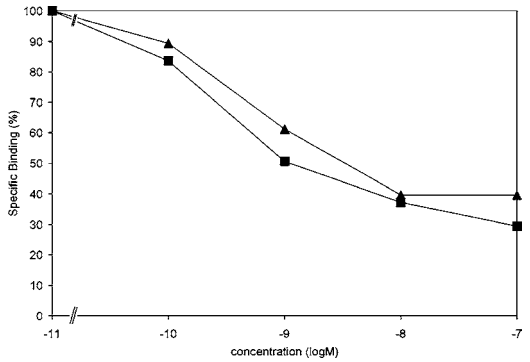

Figure 8. Displacement (%) of specific binding of ^{125}I[D-Lys^6]GnRH from pituitary membranes of pro-estrous rats by increasing concentrations of unlabeled GnRH analogues [D-Lys^6(MeoEmo)]GnRH (■) and [D-Lys^6]GnRH (▲). Membranes were incubated for 90 min at 4 °C with ^{125}I[D-Lys^6]GnRH and with unlabeled peptides. Nonspecific binding was defined as binding of the labeled ligand in the presence of 1 μM [D-Lys^6]GnRH and was extracted from the total binding for the calculation of specific maximal binding (MB). Results are the mean of an experiment carried out in duplicate.

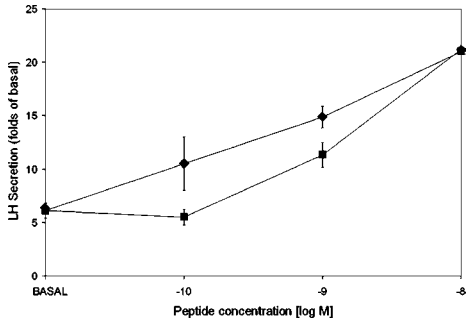

Figure 9. Effect of [D-Lys^6(MeoEmo)]GnRH on the secretion of LH from primary cultures of rat pituitary cells. Primary cultures of rat pituitary cells were incubated in M-199 medium containing the indicated concentrations of [D-Lys^6]GnRH (●) and [D-Lys^6(MeoEmo)]GnRH (■) for 4 h at 37 °C. The media were then collected, and LH concentration was determined by RIA. Results are the means ± SD of LH concentration of an experiment with 3 wells/experimental group. The basal release after 4 h of incubation in M-199 was 6.08 ± 0.52 ng/mL.

by an HPLC study. According to the ESR measurements, ROS were efficiently formed when the mixture of [D-Lys^6(MeoEmo)]-GnRH in phosphate buffer containing 10% DMSO was irradiated for 40 min. The mixture was then analyzed by analytical HPLC. Results showed that less than 3% of [D-Lys^6(MeoEmo)]-GnRH was degraded by the generated ROS, similar to other cytotoxic derivatives of [D-Lys^6]GnRH (*25*).

Biological Assays. *Evaluation of Binding Affinity and Bioactivity*. Introduction of a large/bulky quinone moiety to a peptide can perturb its binding properties. The ability of the [D-Lys^6(MeoEmo)]GnRH to bind to rat pituitary GnRH receptors was evaluated in vitro by displacement assays, using ^{125}I-[D-Lys^6]GnRH as a radioligand. As shown in Figure 8, the agonist-based conjugate, [D-Lys^6(MeoEmo)]GnRH, bound specifically to the GnRH receptor, although its binding affinity was slightly lower than that of the parent agonist (IC_{50} = 5 and 1.1 nM, respectively). For evaluating the LH-releasing potencies of the [D-Lys^6]GnRH conjugate, rat pituitary cells were incubated in M-199 containing the desired concentrations of the tested peptide in the dark at 37 °C for 4 h as described (*30*). The bioactivity of [D-Lys^6(MeoEmo)]GnRH and of the parent peptide [D-Lys^6]GnRH (Figure 9) demonstrated that the agonist conjugate exhibited lower LH-releasing activity than its parent peptide. This result followed the same pattern that we found with respect to binding affinity.

DISCUSSION

A large number of quinones have been tested for antitumor activity and presently form one of the largest classes of antitumor agents approved for clinical use (*17*, *35*). Among them, 9,10-anthraquinone derivatives are also known as PSs. Upon irradiation in the presence of molecular oxygen, these compounds are able to generate ROS (*21*). We chose the anthraquinone-derivatized emodin as a lead molecule to develop new derivatives that can be used as potentially phototoxic drugs for conjugation with a carrier. Five new derivatives of emodin and their GnRH conjugates were synthesized (Schemes 2 and 3). Two main modifications were done on the emodin molecule: (i) the hydroxy groups in positions 4, 5, and 7 were partly or fully substituted by methoxy groups to study their influence on the ROS production potential, and (ii) the methyl group in position 6 was functionalized with different spacers to develop new synthetic methods to attach the cytotoxic molecule to the carrier, for example, peptide.

One of the new spacers is based on mercapto-propanoic acid, which was attached to the aromatic ring through the methyl in position 6. Its carboxylic group was conjugated to Lys6 in the agonist GnRH analogue. Alternatively, the methyl group of the emodin aromatic ring was converted into methylene amine (MeoEmo-NH_2). The amine moiety was then attached to the D-Glu6 of the GnRH analogue to give [D-Glu^6(MeoEmo-NH_2)]-GnRH. Also, the methylene amine was reacted with succinic anhydride and the resulting compound (MeoEmo-N-Succinyl) was conjugated to [D-Lys^6]GnRH. Thus, both amino and carboxylic "handles" can be used for the appropriate conjugation.

All new emodin derivatives under study stimulated the formation of singlet oxygen, $^1O_2$ (Figure 2), and oxygen radicals (Figure 6) when irradiated. However, there were substantial differences in the ROS production efficacy by these derivatives. MeoEmo and MeoEmo-N-Succinyl, which contain a methoxy group, produced the strongest ESR signals of detected spin adducts, indicating that they might be the better candidates for further conjugation with peptides. Apparently, the methoxy substitution elevates the ROS production. This was also shown previously for cynodontin (6-methyl-1,4,5,8-tetrahydroxyanthraquinone) and its methoxylated derivative (1,4-dimethoxy-5,8-dihydroxyanthraquinone). It was suggested that this effect may be attributed to the electron-donating (methoxy) groups directly attached to the quinone ring system (*36*). This view is in accordance with the report that electron-donating functional groups such as amino and alkoxy groups enhance the photodynamic efficiency (*37*).

Quinones are known to participate in both type I and type II photochemical reactions (*38*, *39*). The photoexcited states of quinones are known to be quenched by molecular oxygen to generate ROS. The involvement of $^1O_2$ in the production of the ESR signal was assessed by irradiation of the MeoEmo in d^6- or H^6-DMSO. We found (see Supporting Information) a stronger TEMPO ESR signal in deuterated solvent in accordance with a previous study showing that the lifetime of $^1O_2$ is longer in deuterated solvent (*40*).

We next compared the effect of emodin derivatives on the stimulation of superoxide radicals. The enhancement of the superoxide ESR signal by NADH can be explained according to reactions 3−6, showing that an electron donor can enhance semiquinone production. The photoreduced quinone anion may be the precursor for the formation of oxygen radicals such as the superoxide radical.

It is well established that iron ions and their complexes, known to be present in most biological systems, play an important role in the generation of ROS (*41*). As the result of dismutation of superoxide radical (spontaneous or superoxide

dismutase stimulated), hydrogen peroxide (H_2O_2, reaction 5) is formed. Hydrogen peroxide reacts either with superoxide anion radical in the presence of trace amounts of transition metal ion like Fe(II) ion (Haber−Weiss reaction, reaction 6), or directly with Fe(II) ion to produce hydroxyl radical by the Fenton reaction (reaction 7). The product of their reaction, hydroxyl radical ($HO^{\bullet}$), is a very strong oxidant mediating most quinones cytotoxicity. Adding Fe(II) to the MeoEmo solution resulted in the appearance of first superoxide ESR signal and fast generation of the DMPO−CH_3 adduct (Figure 4B). The observed transformation can be explained by stimulation of hydroxyl radical ($OH^{\bullet}$) produced by Fe(II) and hydrogen peroxide (H_2O_2) interaction (reactions 6 and 7). DMSO is known to react with hydroxyl radical at a high rate to generate methyl radical ($CH_3^{\bullet}$), which can be trapped by a DMPO and identified by its characteristic hyperfine pattern (*4*).

The generation of semiquinone radicals is a precondition for the formation of ROS (*42*, *43*). The similarity between ESR spectra of semiquinone generated by photoreduction and those obtained by chemical reduction (Figure 5) strongly suggests generation of MeoEmo semiquinone following irradiation, according to reactions 3 and 4.

The peptide carrier can decrease ROS production ability by the emodin derivative moiety. However, unlike the poor ROS photogeneration efficacy obtained with the emodic acid conjugate (*25*, *26*), our new conjugates with both peptides, [D-Lys^6]-GnRH and [D-Glu^6]GnRH, showed relatively high ROS production (Figures 3 and 7). The conjugates of MeoEmo and MeoEmo-N-Succinyl were found most active in generation of ROS through type I and type II reactions. The stability of the [D-Lys^6(MeoEmo)]GnRH conjugate was tested under irradiation conditions, and less than 3% degradation was found after 40 min under the same irradiation conditions.

We hypothesized that the conjugation of quinones as PSs to GnRH analogues may be a selective way of destroying cancerous cells through selective illumination of the tumor site. Breast, prostate, and other types of cancers were shown to express GnRH receptors, and GnRH analogues have been found to exhibit direct antiproliferative effect on related cancer cells (*5-9*, *44*, *45*). Indeed, GnRH analogues carrying cytotoxic drugs bind with high affinity to GnRH receptors and are subsequently internalized (*10*, *13*, *46*). We have used two analogues of GnRH as carriers for the emodin derivatives. The agonist [D-Lys^6]-GnRH was chosen because it can be conjugated selectively to the emodin derivatives MeoEmo, DihydroxyEmo, TrihydroxyEmo, and MeoEmo-N-Succinyl via the only free amino group in position 6. In previous works, this GnRH analogue was successfully conjugated with several quinonic and photoporphyrin derivatives and found stable upon irradiation (*25*, *29*, *47*). Another GnRH analogue, [D-Glu^6]GnRH, was chosen based on previous studies showing that the incorporation of a D-amino acid substituting for glycine in position 6 enhances the bioactive β-turn conformation of GnRH at the Gly^6−Leu^7 bond and decreases the susceptibility of the peptide to proteolytic degradation (*48*, *49*). The GnRH analogue [D-Glu^6]GnRH was selectively conjugated to the MeoEmo-NH_2 via the only free carboxylic group in position 6.

The MeoEmo conjugate was chosen as the lead conjugate since it showed the best ROS production. We therefore studied its binding and bioactivity properties compared to the parent peptide, [D-Lys^6]GnRH. The capability of [D-Lys^6(MeoEmo)]-GnRH to bind to rat pituitary GnRH receptors was determined by competitive binding assay using ^{125}I[D-Lys^6]GnRH as a tracer (Figure 8). The results demonstrated that the binding affinity of this conjugate is similar to that of the parent peptide. Investigation of the in vitro LH-releasing potencies, carried out in the dark, demonstrated a correlation between binding affinity to GnRH receptors and bioactivity (Figure 9). Based on previous studies (*26*) and on the results presented here, it is expected that this potential cytotoxic conjugate would bind specifically to cells that express GnRH receptors.

ACKNOWLEDGMENT

We thank Mrs. Sara Rubinraut and Mrs. Aviva Kapitovsky for the synthesis of [D-Lys^6]GnRH and [D-Glu^6]GnRH peptides. M.F. is the Lester Pearson Professor of Protein Chemistry. Y.K. is the Adlai E. Stevenson III Professor of Endocrinology and Reproductive Biology. This work was supported by a grant of the Israel Science Foundation (No. 703939).

Solid-Phase Synthesis of 2-[^{18}F]Fluoropropionyl Peptides

Jan Marik, Sven H. Hausner, Lauren A. Fix, M. Karen J. Gagnon, and Julie L. Sutcliffe*

Department of Biomedical Engineering, University of California, Davis, California 95616. Received March 6, 2006; Revised Manuscript Received June 9, 2006

The 2-[^{18}F]fluoropropionic (2-[^{18}F]FPA) acid is used as a prosthetic group for radiolabeling proteins and peptides for targeted imaging using positron emission tomography (PET). Radiolabeling of compounds with more than one acylable functional group can lead to complex mixtures of products; however, peptides can be labeled regioselectively on the solid phase. We investigated the use of a solid-phase approach for the preparation of 2-[^{18}F]fluoropropionyl peptides. [^{18}F]FPA was prepared and conjugated to the peptides attached to the solid phase support. The ^{18}F-labeled peptides were obtained in 175 min with decay corrected yields of 10% (related to [^{18}F]-fluoride) and with a purity of 76−99% prior HPLC purification. The suitability of various coupling reagents and solid supports were tested for radiolabeling of several peptides of various lengths.

INTRODUCTION

Radiotracers labeled with fluorine-18 (^{18}F, β^+ $t_{1/2}$ = 109.7min) are extensively used for positron emission tomography (PET) imaging of various physiological and pathological processes (*1*). The use of biomolecules such as peptides, proteins, or nucleic acids labeled with ^{18}F as agents for PET is a rapidly growing field (*2*). Examples of labeled peptides include octreotide (*3*), vasoactive intestinal peptide (*4*, *5*), integrin specific peptides (*6*−*10*), N^{ϵ}-(γ-glutamyl)lysine (*11*), neurotensin analogues (*12*), human C-peptide (*13*), and insulin (*14*). Incorporation of ^{18}F into biomolecules, including peptides, is exclusively carried out by employing various prosthetic groups. A large number of prosthetic groups bearing ^{18}F have been developed. These include acylation agents (*3*, *15*−*20*), amidation agents (*14*), imidation agents (*21*−*23*), alkylation agents (*21*), and species for photochemical conjugation (*20*). Undoubtedly, 4-[^{18}F]-fluorobenzoic acid ([^{18}F]FBA) is the most common prosthetic group used for labeling peptides since it can be relatively easily prepared, activated as succinimidyl fluorobenzoate ([^{18}F]SFB), and subsequently conjugated to the purified peptide in aqueous media. The synthesis of [^{18}F]SFB has been automated using the GE TracerLab synthesizer (*24*). However, the in-solution conjugation of [^{18}F]SFB to the peptide is limited to sequences bearing only one acylation-prone nucleophilic group; otherwise a complex mixture of nonselectively radiolabeled products is obtained (*5*). The slight difference between the pK_a of a backbone N^{α} amino group and a N^{ϵ} of lysine can be utilized, to some extent, to control the selectivity of the acylation process (*25*). To overcome this drawback, we previously developed a solid-phase approach for the incorporation of [^{18}F]FBA into the protected peptide sequence attached to the solid support, followed by removal of the protecting groups and cleavage from the solid phase (*8*, *26*). Our approach brings into the radiochemistry field all the advantages of solid-phase organic chemistry which has been extensively developed in the last 20 years. Particularly, it significantly simplifies the handling and purification of the desired product.

In 1996, Wester et al. reported a study comparing various prosthetic groups for incorporation of ^{18}F into proteins (*20*). Among these reagents 2-[^{18}F]fluoropropionc acid ([^{18}F]FPA) (*3*, *18*) offers an interesting alternative to the widely used [^{18}F]FBA. Compared to the [^{18}F]FBA, it was suggested that the [^{18}F]FPA would not significantly alter the properties of the peptide required for the biological activity such as size and lipophilicity which may result, for example, in reduction of hepatobiliary excretion of the radiolabeled species (*20*). Previously, [^{18}F]FPA was successfully attached to D-Phe^1-octreotide and used for imaging of the somatostatin receptor (*3*) and was also used to radiolabel an RGD-containing glycopeptide (*9*, *10*, *27*, *28*). The radiolabeled glycopeptide showed specificity for the $\alpha_v\beta_3$ integrin during in vitro binding assays and for the $\alpha_v\beta_3$ integrin expressing tumors in vivo. In both cases, the [^{18}F]FPA was activated as a 4-nitrophenyl ester and conjugated to the peptide precursor in solution. The glycopeptide contained only one amino group; hence, the labeling using 4-nitrophenyl 2-[^{18}F]-fluoropropionate was accomplished in a single step. However, D-Phe^1-octreotide contains Lys in position 5 and the acylation of the amino group in its side chain would result in loss of the high affinity to the somatostatin receptor. Therefore, the prosthetic group was attached to the N-terminal amino group of the ϵ-Boc-Lys^5 protected octreotide followed by removal of the Boc protecting group using trifluoroacetic acid.

In this paper, we extend our previously published procedure for radiolabeling of peptides on the solid-phase support, and the method for radiolabeling of peptides with [^{18}F]FPA is described. Various coupling conditions and solid supports were investigated for the conjugation of the [^{18}F]FPA to the peptides assembled on solid support.

EXPERIMENTAL PROCEDURES

Materials. Solvents and chemicals were purchased from Aldrich (Milwaukee, WI) if not stated otherwise. Racemic (±)-2-fluoropropionic acid was obtained from Matrix Scientific (Columbia, SC). The protected amino acids and coupling reagents were purchased from NovaBiochem (San Diego, CA) or GL Biochem (Shanghai, China). Resins for solid-phase peptide synthesis were obtained from the following vendors: NovaGel HL (A) and Amino PEGA (F) from NovaBiochem (San Diego, CA), TentaGel S (G) from Rapp Polymere GmbH (Tubingen, Germany), PL-PEGA (E) from Polymer Laboratories (Amherst, MA), CLEAR Amide (C) from Peptides International, Inc. (Louisville, KY), Rink Amide-MBHA (B) from Tianjin Nankai Hecheng Sci. and Tech. Co. Ltd. (Tianjin, China), and

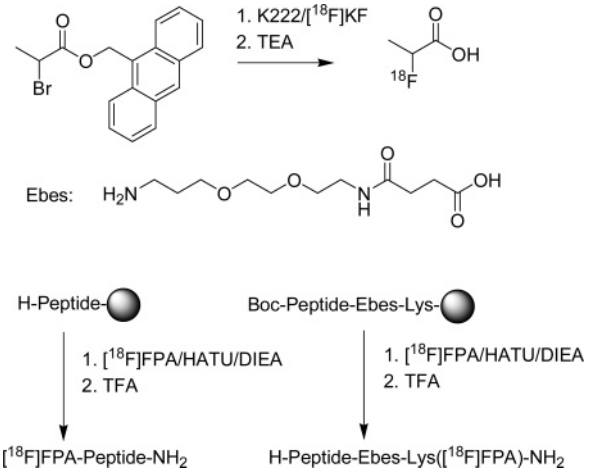
PAL-PEG-PS (D) from Applied Biosystems (Warrington, UK). Protected hydrophilic ethylene glycol-based linker 2,2′-(ethylenedioxy)bis(ethylamine)monosuccinamide (Fmoc-Ebes-OH) was synthesized according to the previously published procedure (*29*), and 9-methylanthranyl 2-bromopropionate was prepared according to the published procedure (*18*). Mass spectrometry analysis was performed using a Finnigan LCQ instrument. RP-HPLC was used to analyze and purify the products. Analytical reverse-phase HPLC system A: Phenomenex Jupiter 4 μm Proteo 90A (250 × 4.6 mm, 4 μm), linear gradient 0.05% TFA−acetonitrile 10−90% in 30 min, flow rate 1 mL/min. Semi-preparative reverse-phase HPLC system B: Phenomenex Jupiter 10 μm Proteo 90A (250 × 10 mm, 10 μm), linear gradient 0.05% TFA−90% acetonitrile 10−90% in 30 min, flow rate 3 mL/min; system C: Phenomenex Jupiter 10 μm C18 300A (250 × 10 mm, 10μm), isocratic 60% acetonitrile − 0.05% TFA, flow rate 3 mL/min. ^{18}F was produced from the ^{18}O(p,n)^{18}F nuclear reaction on [^{18}O]H_2O (Marshall Isotopes Ltd. (Tel Aviv, Israel)) using the CTI RDS 111 negative ion cyclotron. Sep-Pak SPE cartridges were obtained from Waters (Milford, MA).

Peptide Synthesis. The peptides **1**−**4** (Table 1) were synthesized on resin A. The synthesis was performed using a Pioneer continuous flow synthesizer ABI (Foster City, CA) using 4-fold excess of amino acid and DIC/HOBt activation and a 2 h coupling cycle followed by a 10 min Fmoc deprotection with 20% piperidine in DMF. Peptide **1** synthesized on resins **B**−**G** was prepared manually using 3-fold excess of amino acid and using HATU/DIEA activation for 30 min followed by Fmoc deprotection with 20% piperidine−DMF (2 × 10 min). The hydrophilic linker was incorporated into the peptide chain using a Fmoc-protected analogue (Fmoc-Ebes-OH) and HATU/DIEA activation. The N-terminal amino group in peptide **4** was protected by incubation of the resin with 3-fold excess of di-*tert.*-butyl dicarbonate and DIEA for 30 min to yield N-Boc-protected peptide. The allyloxycarbonyl (Alloc) protecting group in peptide **4** was removed using 0.2 equiv of Pd[PPh_3]$_4$ and 20 equiv of phenylsilane 2 × 30 min (*30*). The peptide resins were washed with DMF and methanol and dried in vacuo.

Synthesis of (±)-2-Fluoropropionyl Peptides. 2-Fluoropropionic acid ([^{19}F]FPA) was coupled to the peptide using 3-fold excess of [^{19}F]FPA and DIC/HOBt activation for 30 min. The progress of the reaction was monitored by ninhydrin-based Kaiser test (*31*). The [^{19}F]FPA-peptides **1**−**4** were cleaved from the solid support using trifluoroacetic acid/triisopropylsilane/water 95:2.5:2.5 v/v/v. The crude peptides were precipitated from the cleavage mixture by the addition of an excess of chilled diethyl ether. The solvent was then removed, and the solid product was triturated three times with diethyl ether. The peptides were purified on semipreparative HPLC (system B) and characterized using mass spectrometry. Analytical data for peptides **1**−**4**: **1** HPLC (system A) retention times 15.5, 15.6 min; MS ESI *m*/*z* 629.5 $[M + H]^+$; **2** HPLC (system A) retention time 14.6 min; MS ESI *m*/*z* 2236.8 $[M + H]^+$; **3** HPLC (system A) retention times 10.7, 11.0 min; MS ESI *m*/*z* 953.7 $[M + H]^+$; **4** HPLC (system A) retention time 9.4 min; MS ESI *m*/*z* 1311.8 $[M + H]^+$.

Radiochemical Synthesis of (±)-2-[^{18}F]Fluoropropionic Acid. The fluoride anion was captured on a QMA Sep-Pak cartridge and eluted with 1 mL of 4,7,13,16,21,24-hexaoxa-1,-10-diazabicyclo[8.8.8]hexacosane (K222) and potassium carbonate solution (10 mg of K222, 2 mg of K_2CO_3) in acetonitrile containing 6% water. The acetonitrile was evaporated at 100 °C under a gentle stream of nitrogen and dried by azeotropic distillation with 3 × 1 mL of acetonitrile. The solution of 9-methylanthranyl 2-bromopropionate in acetonitrile (2 mL) was added, and the mixture was heated in sealed vial to 100 °C for 15 min. The product was isolated on semipreparative HPLC (system C) retention time 18−20 min. The fraction containing the product was diluted with water to 10 mL, and the product was captured on a C-18 Sep-Pak cartridge. The cartridge was washed with 5 mL of water and dried with a stream of nitrogen. The 9-methylanthranyl 2-[^{18}F]fluoropropionate was eluted with 3 mL of dichloromethane, and the solvent was evaporated under a stream of nitrogen. The methylanthranyl ester was hydrolyzed using 200 μL of the hydrolysis mixture (9.5 mL water, 0.5 mL triethylamine) and 300 μL of DMF in a closed vial at 100 °C for 10 min. The solvent was evaporated at 100 °C under a stream of nitrogen, and the product was dried using azeotropic distillation with acetonitrile (3 × 1 mL). The product was obtained with a decay corrected yield of 63% and a synthesis time of 82 min (Scheme 1).

Scheme 1. Labeling of Peptides with 2-[^{18}F]fluoropropionic Acid ([^{18}F]FPA) on Solid Phase



Radiochemical Synthesis of (±)-2-[^{18}F]Fluoropropionyl Peptides (1−4). The coupling of [^{18}F]FPA to the peptide and the cleavage from the resin were carried out in a 1 mL syringe equipped with a frit at the bottom of the cylinder. The reagents and washing solvents were withdrawn and dispensed using the plunger. This procedure can be easily performed using robotic manipulators. The [^{18}F]FPA in 50 μL of DMF was added to 1−2 mg of the peptide resin swollen in DMF, followed with HATU (5 mg) in 50 μL of DMF, and DIEA (10 μL) in 50 μL of DMF. The reaction mixture was incubated with shaking at 30 °C for 30 min. The solvent was removed, and the solid support was washed with DMF (3 × 0.5 mL) and methanol (3 × 0.5 mL). The TFA-based cleavage mixture (0.7 mL of trifluoroacetic acid/triisopropylsilane/water 95:2.5:2.5 v/v/v) was withdrawn into the syringe, and the reaction mixture was incubated at 30 °C for (3 × 10 min). The product was collected, and the resin was washed with dichloromethane (0.5 mL). The

cleavage solution was evaporated under a stream of nitrogen, and the crude product was analyzed on radio-HPLC (system A). Analytical data for peptides **1**−**4** (the radiochemical yields were decay corrected to the end of [18F]FPA preparation): **1** HPLC (system A) retention time 15.7 min; yield 6%; **2** HPLC (system A) retention time 14.7 min; yield 3%; **3** HPLC (system A) retention times 11.0, 11.2 min; yield 4%; **4** HPLC (system A) retention time 9.6 min; yield 6%. The synthesis time from EOB was 175 min.

RESULTS AND DISCUSSION

The procedure for the preparation of [18F]FPA from racemic 9-methylanthranyl 2-bromopropionate provides both enantiomers; thus, two diastereoisomers of the final labeled peptide are obtained. The function of the prosthetic group is to introduce the radionuclide into the target molecule without changing its biological properties; therefore, the presence of two diastereoisomers of the product is not expected to have any effect on its pharmacological properties. To address this problem and the effect of the prosthetic group in general, two approaches for the introduction of the prosthetic group are presented (Scheme 1). In the first approach the prosthetic group was attached to the amino terminus of the peptide sequence (Table 1, compounds **1**−**3**) as previously reported (*8*, *26*). This strategy is the most straightforward method to introduce the prosthetic group into the molecule and does not significantly change its final size. However, when the prosthetic group is attached directly to the peptide, it can potentially have a deteriorating effect on the biological properties of the peptide, especially in the case where a free amino terminus is required for receptor binding. In the latter approach, the prosthetic group was attached to the C-terminal part of the molecule via the N^{ϵ} amino group of lysine. The ethylene glycol-based hydrophilic linker Ebes was inserted between the lysine bearing the prosthetic group and the peptide (Table 1, compound **4**) (*29*). The suitability of the first or second labeling strategy should be investigated for each particular application.

We slightly modified the previously published procedure for the preparation of [18F]FPA and its use for protein radiolabeling (*18*). The methylanthranyl 2-[18F]fluoropropionate was obtained from the 2-bromo precursor and purified on semipreparative HPLC followed by the hydrolysis of the 9-methylanthranyl ester using 5% aqueous triethylamine and DMF as a cosolvent. The obtained [18F]FPA was dried using azeotropic distillation with acetonitrile in the presence of DMF. We found that DMF prevented the undesired evaporation of the volatile product, and it did not have any significant effect on the subsequent coupling reaction as DMF is the reaction solvent.

Three different carboxylic acid activating reagents were used in this study: *N*,*N*′-diisopropylcarbodiimide (DIC), 2-(7-aza-1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), and diethyl cyanophosphonate (DECP). DIC activates the acid as the *O*-acyl diisopropyl urea derivative which reacts subsequently with the primary or secondary amine. HATU is a superior reagent used for coupling of "difficult" sequences in the peptide synthesis. The 7-aza-1-hydroxybenzotriazolyl ester is formed in the presence of base, and it reacts readily with nucleophiles such as a primary or secondary amine. DECP forms a mixed anhydride of 2-fluoropropionic acid and diethyl phosphonate which subsequently reacts with a primary or secondary amine in the presence of base (*32*). We found that HATU-mediated activation provided comparable results to the DECP activation for coupling [18F]FPA to the peptide **1**; however, the DIC activation did not provide satisfactory results. The yield of the coupling reaction using HATU was 16%, and the purity of the crude product was 90%. In the case of DECP activation the yield of the conjugation was 9% and the purity of the final product was 93%. The only radioactive material isolated from the activation mixture was unreacted [18F]FPA.

[18F]FPA was conjugated to various peptides listed in Table 1. The products were obtained in yields ranging from 6 to 16%, and only a slight dependency of the yield on the size and complexity of the peptide was observed. The radiochemical purity was confirmed by coinjection of the corresponding [19F]-FPA-labeled peptides. The standards were prepared by DIC mediated coupling of [19F]FPA to the N-terminus or NH^{ϵ} of lysine and analyzed using HPLC and mass spectrometry. The cleavage was performed at 30 °C, and the purity of the crude material was in the range of 90−99% in most cases. In solid-phase peptide synthesis, the purity of the crude products decreases with increasing length of the peptide chain; this accounts for the lower purity of the 20 amino acid long peptide **2**. The "no-carrier-added" (n.c.a) radiolabeled peptides were obtained with a specific activity greater than 37 GBq/μmol.

In the standard peptide synthesis strategy, 3-fold excess of the amino acid and coupling reagent and 6-fold excess of the base are used to accomplish the successful attachment of the amino acid to the free amino terminus of the peptide chain attached to the resin (*33*). Such conditions cannot be satisfied in the case of coupling of the n.c.a. prosthetic groups such as [18F]FPA, and as a result, the amount of the coupling reagent is in huge excess if compared to the amount of the acid. The excess of the uronium salt-based coupling reagents such as HATU could lead to the guanidylation of the N-terminus of the peptide (*33*). We investigated the effect of the amount of the HATU/DIEA in the reaction mixture, and we found that the yields of the coupling reaction were not changed when 1−10 mg of HATU was used together with 10 μL of DIEA in 200 μL of DMF. Lower amounts of HATU led to lower yields, and a lower amount of the base (DIEA) was not sufficient to adjust pH to the desired range 8−9. Unfortunately, the yield of the conjugation remained between 10 and 20%. Since the yield of the [18F]FPA coupling was comparable with that of DECP, which uses the mixed anhydride activation method, and the N-terminal guanidylation is not possible, the formation of the N-terminal guanidylation byproducts is therefore not a yield-limiting effect.

The presence of an auxiliary base required to prevent undesired evaporation of the [18F]FPA during azeotropic removal of the water from the mixture used for the hydrolysis of the precursor could affect the yield of the conjugation. The commonly used bases are tetralkylammonium hydroxides (*20*) or potassium carbonate K222 mixture (*34*). As mentioned above, we found that the high boiling point aprotic solvent DMF minimized the loss of the hydrolyzed acid during the azeotropic distillation. The presence of potassium carbonate K222 complex led to lower yields of the conjugation; however, the use of DMF provided the product with yields and purity identical to the previously reported tetramethylammonium hydroxide.

To further investigate the factors limiting the coupling of the prosthetic groups to the resin-bound peptides, we compared various commercially available solid-phase peptide synthesis (SPPS) resins. The common SPPS resins are polymer beads with a diameter of 100−300 μm. The linker allows selective detachment of the product from the solid support and is covalently attached to the polymer matrix. There are two factors which affect the behavior of the solid support: the composition of the polymer matrix and the nature of the linker. The polymer matrix used for SPPS is based on various cross-linked polystyrene (PS), poly(ethylene glycol) (PEG), polyamide or polyacrylamide copolymers, or grafted polymers. The amount of the linker attached to the beads determines the loading of the particular resin. The nature of the linker determines the nature of the C-terminus of the final product as well as the procedure

Table 2. Decay Corrected Yields of [^{18}F]FPA Coupling to the Peptide 1 Attached to the Different Solid Supports and Yields of the Product Cleavage[a]

[a] Yields and purity are given in %.

required for cleavage. In this study, we focused on the preparation of the peptide amides; thus, the acid-sensitive linkers Rink and PAL were used. The results are summarized in Table 2. We did not find any significant effect of the resin nature on the coupling step, and the best obtained yields remained below 20% for all resins evaluated. However, we found some resins more suitable for this radiochemical application due to better yields obtained during the cleavage step. The cleavage of the product from the solid support and simultaneous side chain protecting group removal were accomplished using a mixture of trifluoroacetic acid and appropriate scavengers. We found that the incubation of the resin with the cleavage mixture for 30 min provided 75% of the product from the Rink linker decorated resins, except the high loading NovaGel resin where the cleavage yields were below 50%. The resin containing the PAL linker provided 89% of the product in 20 min incubation. The use of very acid-labile linkers such as XAL has been previously reported to provide similar cleavage reaction yields (*8*, *26*). However, the stability of side chain protecting groups has to be considered in this case; when the cleavage time is short, some of them may not be fully removed.

In conclusion, [^{18}F]FPA was conjugated with various peptides. The ^{18}F-labeled peptides were obtained in 175 min with decay corrected yields around 10% (related to [^{18}F]fluoride) and with a purity of 76−99%. Several solid-phase synthesis supports were found suitable for this application.

ACKNOWLEDGMENT

We would like to thank Salma Jivan (radiochemist, Center for Molecular and Genomic Imaging) and Dave Kukis (Cyclotron Facilities Manager, Center for Molecular and Genomic Imaging) for radionuclide production.
