Bioconjugate Chemistry

EDITORIAL: No More Hardcopy Submissions

As of January 1, 2006, the journal will no longer accept hardcopy submissions of manuscripts and Supporting Information. All must be submitted through the ACS Paragon System. This change should have little effect on our authors, who have overwhelmingly migrated to Web submission already. Other, minor changes in procedure are described in the new *Bioconjugate Chemistry* Guidelines for Authors, available on the journal Web page and in this print issue.

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2005 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the sixteenth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following page.

Synthesis and Characterization of a Head−Tail Type Polycation Block Copolymer as a Nonviral Gene Vector

Atsushi Harada,* Masanori Kawamura, Takashi Matsuo, Toshinari Takahashi, and Kenji Kono

Department of Applied Chemistry, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 599-8531, Japan . Received September 29, 2005; Revised Manuscript Received December 5, 2005

A head−tail type polycation block copolymer, which is composed of the polyamidoamine (PAMAM) dendron and poly(L-lysine) (PLL) blocks, was newly designed as a nonviral gene vector in this study. This block copolymer (PAMAM dendron-PLL) was successfully synthesized in two steps: the synthesis of the PAMAM dendron block and the polymerization of the PLL block from the PAMAM dendron block. PAMAM dendron and PLL blocks in block copolymer showed independent deprotonation behavior, and their pK_a were determined to be 6.8 and 9.0, respectively. The complexation with pDNA was evaluated by gel retardation assay and dye exclusion assay, and both assays indicated that pDNA was selectively complexed with PLL block of block copolymer. Also, the PAMAM dendron-PLL poplyplexes showed 10^2 fold higher transfection efficiency to HeLa cells as that for PLL polyplexes. This might be due to the buffering effect of the PAMAM dendron block. This block copolymer could produce a function share in each block, i.e., tail block complexed with pDNA and head block showed a buffering effect. This molecular design of the head−tail type block copolymer might provide a new approach for realizing in vivo gene therapy.

The delivery of nucleic acids to cells as well as the instability in blood are important subjects for successful in vivo gene therapies. The design of synthetic polycation as nonviral gene vectors has received considerable attention for the purpose of realizing in vivo gene therapy (*1*−*4*). Although numerous polycations have been designed and synthesized, the rational design of polymers as in vivo gene vector systems has not yet been established. The use of polycations with relatively low pK_a values are mentioned as one of the guidelines. Polycations with low pK_a values, such as polyethyleneimine (PEI) and polyamidoamine (PAMAM) dendrimer, exhibit a high transfection efficiency due to the buffering effect (*5*−*8*), and PEI and PAMAM dendrimer are marketed under the trade names of ExGene and SuperFect, respectively. However, these have relatively weak affinity to DNA compared with cationic polymers, such as poly(L-lysine) (PLL) having a high pK_a value. One looks forward to the design of polycations, which combines stable complex formation under physiological conditions and a buffering effect. Recently, Kataoka et al. reported the polyplex vectors from A−B−C type triblock copolymers with spatially ordered layering of the condensed pDNA and buffering units for enhanced intracellular gene delivery (*9*). Such a molecular design, which produces a function share in each block of the copolymer, could be effective in realizing in vivo gene therapy. Here, we have newly designed a head−tail type polycation block copolymer, which is composed of the PAMAM dendron as the head block and PLL as the tail block, as a nonviral gene vector (Figure 1). In the design of the block copolymer composed of polycation blocks with different pK_a values as the gene vector, it is important that the pK_a values of the polycation block with a relatively low pK_a value be maintained even after the block copolymerization with different kind of polycations as well as the complexation with the pDNA. Consequently, the PAMAM dendron was selected as a buffering block with a low pK_a value, since the tertiary amino groups in the interior of the PAMAM dendron cannot be easily influenced by another polycation block due to steric hindrance. It was expected that the head and tail blocks exhibit a buffering action and complexation with pDNA, respectively.

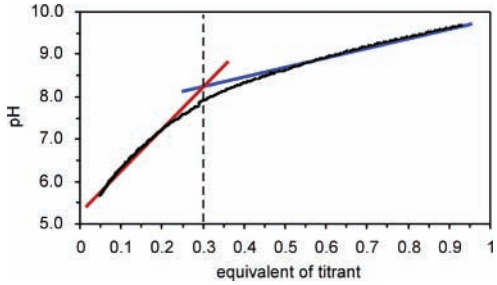

Figure 2. Titration curve of PAMAM dendron-PLL. 150 mg of PAMAM dendron-PLL in 45 mL of 0.01 M HCl was titrated with 0.01 M NaOH. The titrant was added in 0.1 mL quantities at 25 °C.

block and the polymerization of the PLL block from the PAMAM dendron block. Briefly, the PAMAM dendron block was synthesized by the repetitive exhaustive Michael addition with methyl acrylate using *tert*-butyl *N*-(2-aminoethyl)carbamate], for which one amino group of ethylenediamine is protected by a *tert*-butoxycarbonyl (Boc) group, as the starting reagent and subsequent exhaustive amidation with ethylenediamine (*10*). With four repetitions of the Michael addition and three amidations, the PAMAM dendron (Boc-PAMAM dendron) was made. To polymerize the PLL block from the PAMAM block, the Boc group at the root of the PAMAM dendron was removed by CF_3COOH treatment. The polymerization of the ϵ-benzyloxycarbonyl L-lysine *N*-carboxy anhydride [Lys(Z)-NCA], which was synthesized by the Fuchs−Farthing method using triphosgene (*11*), was then initiated from the primary amino group at the root of the PAMAM dendron in DMF at 40 °C. The obtained PAMAM dendron-PLL(Z) was converted to the PAMAM dendron-PLL by acid treatment using 30% HBr/AcOH in TFA. Also, the peripherial group of the PAMAM dendron block (methyl ester group) was removed by alkali treatment and converted to a carboxylate group. The finally obtained PAMAM dendron-PLL had 16 carboxylate groups at the periphery of the head block, 15 tertiary amino groups in the interior of the head block, and 70 primary amino groups in the tail block.

The deprotonation behavior of the PAMAMA dendron-PLL was important for determining the properties as a gene vector. The change in the ionization state vs the pH change was evaluated by an acid−base titration. Figure 2 shows the acid−base titration curve, pH vs equivalent of titrant, of the PAMAMA dendron-PLL. Obviously, two independent deprotonation processes were observed bound at equivalents of titrant = 0.3. The deprotonation at equivalents of titrant < 0.3 was due to the deprotonation of the tertiary amino groups in the interior of the PAMAM dendron block and carboxylate groups at the periphery of the PAMAM dendron block, and the deprotonation at equivalents of titrant > 0.3 was due to the primary amino groups of the PLL block. This might be a reasonable quantity for deprotonation, since the numbers of ionizable groups were 70 for the PLL block and 31 for the PAMAM dendron block. The pK_a values for each block were 9.0 for the PLL block and 6.8 for the PAMAM dendron block. Such a property vs the pH change (independent deprotonation behavior) as shown in Figure 2 was quite important in the design of the polycation block copolymer which makes a function share in each block. In the case of the design of polyelectrolytes having different kinds of weakly ionizable groups with different pK_a values, it is difficult to maintain the pK_a values for each ionizable group, because the pK_a value of a weakly ionizable group is shifted by the effect of the neighboring groups (*12*). Also, by pH change from physiological pH (7.4) to endsomal pH (less than 6.0), equivalents of titrant changed from 0.23 to 0.08. This suggests that the PAMAM dendron block exhibits a proton sponge nature in the uptake process into the cells.

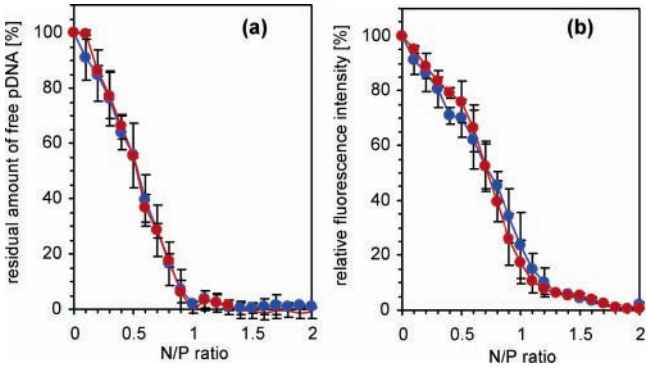

Figure 3. Complexation of pDNA with PAMAM dendron-PLL (red) and PLL (blue) evaluated by gel retardation assay (a) and dye exclusion assay (b). In part a, the gel electrophoresis was carried out at 100 V/cm for 30 min with 0.6 w/w% agarose gel, and residual amounts of free pDNA was determined by analyzing the magnitude of ethidium bromide-stained bands for free pDNA. In part b, fluorescence intensities for the polyplex solutions containing 10 μg of pDNA/mL and 2.5 μg of ethidium bromide (EtBr)/mL were measured. The excitation and emission wavelengths were 510 and 590 nm, respectively. For both experiments, the N/P ratio was defined as the number of ϵ-amino groups of PLL vs the number of phosphate groups of pDNA, and the data are presented as the average of three experiments ± SD.

The polyplex solutions were prepared by mixing pDNA and polycation solutions, after pDNA and polycations, PAMAM dendron-PLL or PLL, were separately dissolved in 20 mM Tris-HCl buffer (pH 7.4). The complexation of the PAMAM dendron-PLL with pDNA was evaluated by two assays, i.e., the dye exclusion assay and gel retardation assay (Figure 3). For both assays, the PAMAM dendron-PLL and PLL showed identical profiles with the change in the N/P ratios, in which the N/P ratio was defined as the number of ϵ-amino groups of PLL vs the number of phosphate groups of pDNA, nevertheless, the PAMAM dendron-PLL has tertiary amino groups in the PAMAM dendron block. Also, the addition of the Boc-PAMAM dendron to pDNA did not induce any complexation, since the tertiary amino groups in the interior was not protonated at pH 7.4. The protonation of the tertiary amino groups in the PAMAM dendron block was not facilitated by the complexation with pDNA via electrostatic interactions between pDNA and PLL. It was expected that the tertiary amino groups of the PAMAM dendron block in the PAMAM dendron-PLL might show a buffering effect.

From the transfection efficiency toward the culture cells (HeLa cells), it was indirectly evaluated whether the PAMAM dendron-PLL vector exhibits the buffering effect. It was known that the polyplexes of pDNA with the PLL homopolymer required the use of a lysosomotropic reagent such as chloroquine in order to express a sufficient transfection efficiency. Indeed, the PLL polyplexes showed a very low transfection efficiency to HeLa cells in the absence of the lysosomotropic reagent (Figure 4). On the other hand, the PAMAM dendron-PLL system showed a considerably high transfection efficiency compared with the PLL polyplex. Comparing the transfection efficiency at N/P = 3.5, at which PAMAM dendron-PLL polyplexes showed highest transfection efficiency, PAMAM dendron-PLL polyplexes showed 10^2 times as high transfection efficiency as PLL polyplexes, suggesting a buffering effect during endosomal/lysosomal processes. Also, when pDNA was complexed with the mixture of PLL and the Boc-PAMAM dendron, the complexes did not exhibit a sufficient transfection efficiency, and there was no difference with as significant their transfection efficiency as transfection efficiency of PLL polyplexes in the evaluated N/P ratio range. That is, the block copolymerization with the PAMAM dendron was required for expressing the buffering effect. Further, it should be noted the

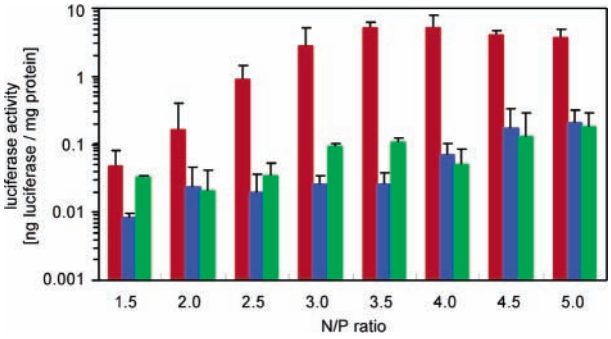

Figure 4. Transfection efficiency of PAMAM dendron-PLL polyplexes (red), PLL polyplexes (blue), and the mixture of PAMAM dendron and PLL (green) to HeLa cells. The cells (5×10^4) were treated with the polyplexes including 1 μg of pDNA. The N/P ratio was defined as the number of ϵ-amino groups of PLL vs the number of phosphate groups of pDNA. The data are presented as the average of three experiments $\pm$ SD.

difference in the effect of N/P ratio between the complexation (Figure 3) and transfection efficiency (Figure 4). The transfection efficiency of PAMAM dendron-PLL was increasing to N/P = 3.5, although both residual amounts of free pDNA and relative fluorescence intensity were almost no change at N/P > 1. This might worry the influence of free PAMAM dendron-PLL, i.e., uncomplexed PAMAM dendron-PLL, to an increase in transfection efficiency. To confirm the change in the property of polyplexes, the zeta-potential measurements were carried out for the PAMAM dendron-PLL polyplexes prepared at varying N/P ratios. The zeta-potentials of the complexes of PAMAM dendron-PLL with pDNA changed in this N/P ratio range ($1 < N/P < 3.5$), and the zeta-potentials of pDNA/PAMAM dendron-PLL at N/P = 1.0, 1.5, 2.0 and 3.5 were -20.9 ± 1.7, 9.1 ± 0.7, 15.8 ± 0.9 and 24.7 ± 2.4 mV, respectively. This indicates that the properties of pDNA/PAMAM dendron-PLL changed with an increase in N/P ratio even at $1.0 < N/P < 3.5$. Consequently, the increase in transfection efficiency at $1.5 < N/P < 3.5$ shown in Figure 4 might be induced by the effect of increasing the relative number of PAMAM dendron block, which exhibit a buffering effect, against pDNA and the effect of the change in the complex properties including zeta-potentials.

In conclusion, a head−tail type polycation block copolymer, which is composed of a PAMAM dendron as the head block and PLL as the tail block, was newly designed as a nonviral gene vector. The head−tail type block copolymer complexed with pDNA is driven by electrostatic interactions between pDNA and PLL block. Also, the polyplexes of the head−tail type block copolymer showed a sufficient transfection efficiency due to the buffering effect of the PAMAM dendron block even in the absence of a lysosomotropic reagent. This molecular design of the head−tail type block copolymer might provide a new approach to the realization of in vivo gene therapy.

Water-Soluble Dendrigrafts Bearing Saccharidic Moieties: Elaboration and Application to Enzyme Linked OligoSorbent Assay (ELOSA) Diagnostic Tests

Julien Bernard,[†] Michel Schappacher,[†] Alain Deffieux,*[,†] Pascal Viville,[‡] Robert Lazzaroni,[‡] Marie-Hélène Charles,[§] Marie-Thérèse Charreyre,*[,§] and Thierry Delair[§]

Laboratoire de Chimie des Polymères Organiques, UMR 5629 CNRS-ENSCPB-Université Bordeaux I, 16 Avenue Pey Berland, 33607 Pessac, France, Unité Mixte CNRS-bioMérieux, UMR-2714, ENS-Lyon, 46, Allée d'Italie 69364 Lyon Cedex 07, France, and Service de Chimie des Matériaux Nouveaux, Université de Mons-Hainault, Mons, Belgium. Received December 7, 2004; Revised Manuscript Received September 15, 2005

The synthesis of a series of water-soluble galactopyranose-functionalized polystyrene−polyvinyl ether dendrigrafts and their characterization (in solution and thin solid deposits) have been achieved. The presence of external galactopyranose groups on dendritic polymers has been exploited to prepare dendrigraft−oligonucleotide conjugates using a simple one-step coupling procedure with amino-ended oligonucleotides (ODNs). Several parameters such as the peripherical density of hydrophilic branches, the polymerization degree of polystyrene or poly(hydroxyethyl vinyl ether) blocks, and the number of galactopyranose groups were tuned. A capture test with short labeled complementary ODNs (25 bases) confirmed the presence of covalently bound ODNs on various kinds of dendrigrafts. The ability of the dendritic polymers to enhance the sensitivity of enzyme-linked oligosorbent assay (ELOSA) diagnostic tests (detection of hepatitis B virus, DNA target of 2400 bases) was then evaluated, especially the influence of the macromolecular architecture and the impact of the structural parameters. The dendrigraft−ODN conjugate with the lower saccharide external density was found to lead to a very significant amplification of the fluorescence signal, corresponding to a limit of sensitivity of 10^9 DNA copies per milliliter (instead of 10^{11} DNA copies per milliliter without using dendrigrafts). Conversely, the dendrigrafts exhibiting a very high number of branches and galactopyranose groups at their periphery were not able to induce a better sensitivity due to steric hindrance generated by the peripheral congestion on these polymers.

INTRODUCTION

Contrary to the traditional ELISA[1] diagnostic tests, ELOSA tests are based on the capture and detection of nucleic acids and provide a direct and specific detection of genetic or infectious diseases. The principle of these tests lies, first, in the capture of a target material (single-stranded DNA sequences) by oligonucleotide probes anchored onto a solid support and, second, in the detection and quantification of the captured DNA target (colorimetric or fluorescent signal). As the quantities of target material are typically very low, this strategy generally includes either amplification of the target sequence (*1*) or signal amplification, to enhance the sensitivity of the test. Since the target amplification strategy gives rise to numerous drawbacks such as cross-contamination or poor reproducibility, attention has then been paid to the second approach.

Several signal amplification strategies have been proposed, either based on the introduction of multiple reporter groups such as biotin (*2*), fluorophores (*3*), or 2,4-dinitrophenyl (*4*) in the ODN used for the detection or focusing on the use of branched oligonucleotides (*5*, *6*) in combination with detection probes labeled with an enzyme. However, the increase of sensitivity obtained by these routes is still limited.

An alternative way consists of the preparation of (co)-polymer−ODN amplification structures (conjugates). With this aim, a number of new polymer supports, consisting of functional (co)polymers bearing different reactive groups (activated ester, anhydride, aldehyde), have been developed to immobilize ODNs (*7*−*17*). The conjugates were typically prepared either by binding amino-ended single-stranded oligonucleotide probes (synthesized via automated synthesis with an $-NH_2$ group at the 5′ position) onto reactive (co)polymers via amination or amidation reaction (*7*−*15*) or by direct synthesis of the ODNs from the polymer backbone (*16*−*17*). Both kinds of conjugates enable the capture of complementary DNA targets through hybridization and lead to an increase in the sensitivity of the ELOSA test.

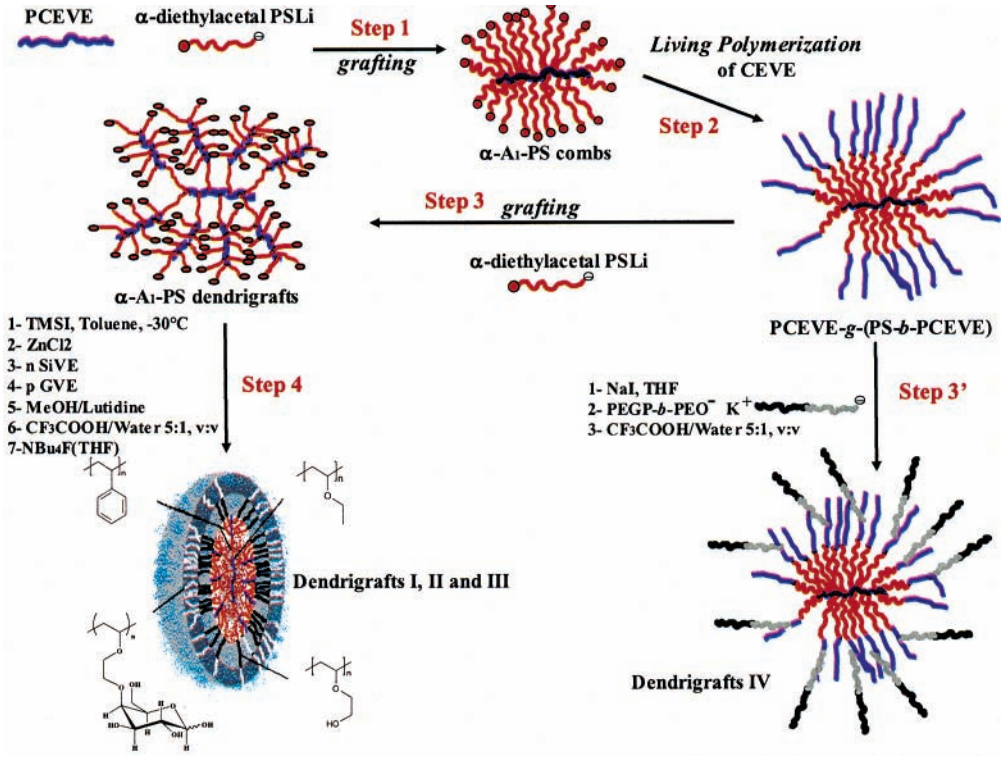
Scheme 1. Reaction Pathways for the Elaboration of Hydrophobic Hyperbranched Precursors [PCEVE-*g*-(PS-*b*-PCEVE) or PCEVE-*g*-(PS-*b*-(PCEVE-*g*-PS))] and Amphiphilic Dendrigrafts [PCEVE-*g*-(PS-*b*-(PCEVE-*g*-(PEO-*b*-PEGP))) or PCEVE-*g*-(PS-*b*-(PCEVE-*g*-(PS-*b*-PHEVE-*b*-PGVE)))]



Concerning polymer−ODN conjugate properties desirable for an effective enhancement of the signal, it was shown that accessibility of the immobilized ODNs (rather than their number) was a major issue. Among the above-mentioned functional (co)polymers, various architectures have been designed such as (i) linear (co)polymers, namely poly(maleic anhydride-*co*-methyl vinyl ether) (*8*), poly(*N*-vinylpyrrolidone-*co*-*N*-acryloxysuccinimide) (*7*, *10*), poly(*N*-(2,2-dimethoxyethyl)-*N*-methyl acrylamide) (*11*), and synthetic glycopolymers (*9*, *12*, *13*), (ii) graft (co)polymers (*14*, *15*), and (iii) latex particles (*18*, *19*). However, to our knowledge, no study describing the use of dendrigrafts as supports for ODN immobilization has been previously reported.

In a recent article, we described the synthesis of hydrosoluble amphiphilic dendrigrafts bearing saccharide groups located at the periphery (*20*). These polymers were prepared from functional arborescent PS precursors (*21*) by taking advantage of the presence of terminal acetal functions on every PS branch to grow poly(vinyl ether) blocks of poly(*tert*-butyldimethylsilyloxyethyl vinyl ether) and poly(1,2:3,4-di-*O*-isopropylidene-6-*O*-(2-vinyloxyethyl)-D-galactopyranose) via living cationic polymerization. After deprotection, the dense hydrophilic PVE shell (PHEVE and PGVE) surrounding the PS core ensured the solubilization of the dendrigrafts in water. The presence of both PHEVE blocks (acting as hydrophilic spacers) and PGVE external blocks (bearing galactopyranose groups with the potential ability to covalently immobilize amino-ended oligonucleotides (*13*, *15*)) on these dendritic polymers encouraged us to evaluate their efficiency as supports for ELOSA diagnostic tests. In addition, we also developed a second route to galactopyranose-functionalized water-soluble dendrigrafts based on the coupling of living polyoxirane chains onto PCEVE-*g*-(PS-*b*-PCEVE) precursors during this work.

In this article, we report the synthesis and the characterization of a series of galactopyranose-functionalized dendrigrafts. Several parameters such as the peripheral density of branches, the polymerization degree of PS or PHEVE blocks, and the number of Gal groups were tuned. The ability of these polymers to enhance the sensitivity of ELOSA tests was then evaluated, especially the influence of the macromolecular architecture and the impact of the structural parameters on the results of the test.

EXPERIMENTAL PROCEDURES

Materials. Toluene (99.5%, J. T. Baker, Deventer, The Netherlands) was purified by distillation over calcium hydride and stored over polystyryllithium seeds. Tetrahydrofuran (99%, J. T. Baker, Deventer, The Netherlands) was purified by distillation over calcium hydride and stored over potassium/benzophenone. Ethylene oxide (99.5%, Sigma Aldrich Chimie, St Quentin Fallavier, France) was purified and stored over calcium hydride. Dimethyl sulfoxide (99.9%, Sigma Aldrich Chimie, St Quentin Fallavier, France), dimethyl formamide (99.9%, Sigma Aldrich Chimie, St Quentin Fallavier, France), *N*-methylpyrrolidone (99.9%, Sigma Aldrich Chimie, St Quentin Fallavier, France), epichlorhydrine (99%, Sigma Aldrich Chimie, St Quentin Fallavier, France), 2-hydroxyethyl vinyl ether, 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose, and potassium (98%, Sigma Aldrich Chimie, St Quentin Fallavier, France) were used as received. SiVE was prepared as described previously by Fukui et al. (*22*) from 2-hydroxyethyl vinyl ether and distilled over calcium hydride twice before use. DiGVE was prepared as recently described by D'Agosto et al. (*13*). EGP was synthesized from epichlorhydrine and 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose according to the procedure reported by Koell et al. (*23*).

Synthesis of the PCEVE/PS Dendrigraft Precursors. The dendrigraft precursors 200/50/50/$A_1$50 (A) ($\overline{DP}_{n\mathrm{PCEVE1}}/\overline{DP}_{n\mathrm{PS1}}/\overline{DP}_{n\mathrm{PCEVE2}}/\overline{DP}_{n\mathrm{A1-PS2}}$, A_1 = α-acetal group), 200/50/50/$A_1$5 (B), and 200/120/40 (C) used in this work were elaborated according to a previously reported procedure (*21*, *24*) (Scheme 1).

PCEVE/PS dendrigraft precursor properties. A: $\overline{M}_w$ = 3.8×10^7 g·mol^{-1}; PDI = 1.05; R_g = 34.5 nm; R_h = 34 nm. **B**:

$\overline{M_w} = 0.6 \times 10^7 g \cdot mol^{-1}$; PDI = 1.18; R_g = 22.5 nm; R_h = 25 nm. **C**: $\overline{M_w} = 0.3 \times 10^7 g \cdot mol^{-1}$; PDI = 1.13.

Synthesis of Amphiphilic Dendrigrafts (I, II, III) with a Hydrophilic PVE Shell. The dendrigrafts were prepared as previously described (*20*) via a "grafting from" procedure: initiation of living cationic polymerization of SiVE and DiGVE from the diethylacetal ends of PS branches of the PCEVE/PS hyperbranched cores, using trimethylsilyl iodide and zinc dichloride as a catalytic system. Typically, the chain extension was carried out under nitrogen in toluene at −30 °C in a 250 mL baked flask with a double-way stopcock equipped with a magnetic stirring bar. The PS precursor (200/50/50/$A_1$50, 5 g, 1 mmol acetal termini) was dissolved in anhydrous toluene and vacuum-dried to remove traces of moisture. The polymer and SiVE (19 g, 93 mmol) were subsequently dissolved in anhydrous toluene (100 mL) under nitrogen. Trimethylsilyl iodide (0.17 mL, 1.2 mmol) was then added to the solution and vigorously stirred for 1 h. A $ZnCl_2$ solution (1 mL, 3 mmol·L^{-1} in diethyl ether) was added to initiate the polymerization of SiVE. After complete conversion of SiVE (12 h), DiGVE (5 g, 15 mmol) was added to the living polymer solution to grow a third block and generate external PS-*b*-PSiVE-*b*-PDiGVE branches. After 10 h, the polymerization was stopped by adding a methanol/lutidine mixture. The polymer was washed several times with potassium thiosulfate aqueous solution (2 wt %) and then with water. The solvent was evaporated, and the polymer was precipitated in methanol. The deprotection of the saccharidic moieties was achieved by treatment with a trifluoroacetic acid/water mixture (v/v, 5/1, 3 h, room temperature), and the hydroxyl functions on PSiVE were regenerated via a treatment with NBu_4F in THF (3 h, room temperature). After deprotection of the hydroxyl groups of SiVE and DiGVE, the dendrigrafts were purified by dialysis against pure water (I, II) or methanol (III) for 3 days (membrane Spectra/Por 7).

On the basis of the previously measured PS precursor characteristics ($\overline{M_w}$, $\overline{DP_{n\mathrm{PS2}}}$, number of external branches) and assuming quantitative initiation from the precursor acetal ends, PSiVE and PDiGVE degrees of polymerization were evaluated by ^{1}H NMR, from the relative integration of PS aromatic (5H), *tert*-butyldimethylsilyl group (15H), and saccharidic protons (1H, H1 or H2). The molecular weight of the dendrigrafts was calculated with the following equation: $\overline{M_{n\mathrm{RMN}}} = \overline{M_n}(\mathrm{precursor}) + (\overline{DP_{n\mathrm{PSiVE\ (RMN)}}} \times m_{\mathrm{SiVE}} + \overline{DP_{n\mathrm{PDiGVE\ (RMN)}}} \times m_{\mathrm{DiGVE}})$, with *n* equal to the number of branches in the precursor. The number of galactopyranose groups per dendrigraft was determined from the number of PS_2 external branches and the degree of polymerization of PDiGVE (Nber of Gal = Nber of external branches × $\overline{DP_{n\mathrm{PDiGVE}}}$).

^{1}H NMR ($CDCl_3$) δ (ppm): −0.1−0.2 (−Si−CH_3), 0.7−1.1 (−Si−C−CH_3), 1−2.2 (PSiVE and PDiGVE backbones: −CH_2−CH−O−; PS backbone: −CH_2−CH−; PDiGVE: CH_3−C−O), 3−3.8 (PSiVE and PDiGVE backbones: −CH_2−CH−O−; PSiVE and PDiGVE pendent groups: O−CH_2−CH_2−O; PDiGVE pendent groups: O−CH_2−CH−), 3.8−4 (PDiGVE, H5), 4.1−4.3 (PDiGVE, H3 and H4), 4.5−4.7 (PDiGVE, H2), 5.4−5.6 (PDiGVE, H1), 6.2−7.2 (PS, Ph).

Synthesis of Amphiphilic Dendrigrafts (IV) with a Hydrophilic Polyoxirane Shell. *(a) Preparation of the PEGP-b-PEO−K^+ Diblocks.* The synthesis of PEGP-*b*-PEO chains was carried out by living anionic polymerization. The potassium alcoholate salt of 1,2:3,4-di-*O*-isopropylidene-D-galactopyranose was first prepared under vacuum by addition of 1 g of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (3.8 mmol) dissolved in 150 mL of distilled THF in a flask containing an excess of potassium (0.3 g, 7.7 mmol, ∼2 equiv). After reacting for 24 h at room temperature, the slightly yellow solution of alcoholate was filtered under vacuum to eliminate residual potassium. Polymerization of EGP was carried out in THF at 50 °C in a 500 mL flask equipped with a magnetic stir bar after addition to the potassium alcoholate solution of 6 g of EGP (19 mmol) dissolved in 50 mL of dry THF. After reacting for 24 h, an aliquot of the solution was collected and analyzed by size exclusion chromatography in THF, confirming the complete polymerization of EGP. Ethylene oxide (15 g, 0.34 mol) was then added to the "living" polymer solution at room temperature in order to grow the second block. After 24 h of reaction, an aliquot of PEGP-*b*-PEO^- K^+ block copolymer solution was deactivated by addition of degassed methanol and then analyzed by SEC in THF, ^{1}H NMR in $CDCl_3$, and VPO in toluene.

Copolymer characteristics: $\overline{DP_n}$(PEGP) = 5; $\overline{DP_n}$(PEO) = 90 (calculated from ^{1}H NMR spectrum and VPO measurement of PEGP-*b*-PEO); $\overline{M_{w\mathrm{GPC}}}$ = 4200 g·mol^{-1}; $\overline{M_{w\mathrm{VPO}}}$ = 5880 g·mol^{-1}; PDI = 1.14.

(b) Synthesis of Amphiphilic Dendrigrafts IV by the Grafting onto Procedure. The synthesis of the amphiphilic dendrigrafts bearing a polyoxirane shell was performed by grafting the living PEGP-*b*-PEO^- K^+ chains onto the $PCEVE_2$ blocks of ($PCEVE_1$-*g*-(PS_1-*b*-$PCEVE_2$)) comblike precursors.

Typically, the comb copolymer (C, 1.1 g, 3.2 mmol of chloroethyl functions) and NaI (20 mg, 0.13 mmol) were dissolved in 25 mL of anhydrous THF in a 500 mL flask equipped with a double-way stopcock and a magnetic stir bar. To remove traces of moisture, the solvent was evaporated under vacuum and the polymer was vacuum dried for 1 h at 60 °C. This operation was repeated twice. The polymer was then redissolved in 20 mL of anhydrous THF, and the solution containing the "living" oxanionic polyoxirane chains was then slowly added. After 3 weeks, the reaction was deactivated by addition of degassed methanol and 250 mL of CH_2Cl_2 was introduced. The polymer solution was washed several times with potassium thiosulfate/water (2 wt %), to eliminate iodine, and then with water. The organic solution was then dried with magnesium sulfate, filtered, and precipitated in diethyl ether and redissolved in acetone. The dendrigraft was isolated from unreacted polyoxirane chains by selective precipitation in an acetone/diethyl ether mixture. The pure arborescent polymer was then characterized by SEC (THF), SLS (THF), DLS (THF), and ^{1}H NMR ($CDCl_3$). Deprotection of the saccharidic groups (1 g of polymer in 10 mL of THF) was achieved by acidic treatment with a 5:1, v:v CF_3COOH/H_2O mixture (10 mL) for 3 h. After neutralization of the solution by addition of aqueous NaOH (1 M), the polymer was purified by dialysis against pure water (membrane Spectra/Por7, molecular weight cutoff ca. 1000) for a week.

^{1}H NMR ($CDCl_3$) δ (ppm): 1−2.2 (PCEVE backbone: −CH_2−CH−O−; PS backbone: −CH_2−CH−Ph; PEGP: CH_3−C−O), 3.4−3.8 (PCEVE backbone: −CH_2−CH−O−; PCEVE: −O−CH_2−CH_2−Cl, −O−CH_2−CH_2−Cl; PEO backbone: −CH_2O−; PEGP backbone: O−CH_2−CH−O−, O−CH_2−CH−O−), 3.9−4.1 (PEGP, H5), 4.2−4.4 (PEGP, H3 and H4), 4.5−4.7 (PEGP, H2), 5.4−5.6 (PEGP, H1), 6.2−7.2 (PS, Ph).

Binding of ODN onto Galactopyranose-Functionalized Dendrigrafts. NH_2-terminated oligonucleotides were synthesized by standard DNA cyanoethyl *N*,*N*-di-isopropylamino phosphoramidite chemistry. They were modified at their 5′ positions with an aminohexyl spacer arm for coupling to the polymer. The following sequence was used (given from the 5′ to 3′ position): 5′-TCA-ATC-TCG-GGA-ATC-TCA-ATG-TTA-G-3′.

To optimize the conditions for ODN coupling onto the dendrigrafts, several organic solvents (DMF, DMSO, and NMP), different aqueous buffer to organic solvent ratios, and various pH and ionic strength values of the aqueous buffer were tested.

Typically, 10.2 μL of an aqueous solution of oligonucleotides (5 nmol) and 27 μL of borate buffer (20 mM, pH = 7.2) were introduced in an Eppendorf tube. After removing water under reduced pressure (speed-vac), the pellet (ODNs and salts) was redissolved in 21.7 μL of pure water. Next, 5.3 μL of an aqueous solution of dendrigrafts IV (100 nmol of galactopyranose moieties) and 243 μL of DMF was introduced in the tube (run 11, total volume 270 μL, 10/90 v/v aqueous buffer/DMF). The tube was finally placed under stirring at 50 °C for 5 days.

Capture Test: Dendrigraft−ODN Conjugate Characterization. The binding of ODNs onto the dendrigraft was indirectly confirmed by evaluating the ability of the dendrigraft−ODN conjugates to capture short complementary ODN sequences labeled with an enzyme (alkaline phosphatase). These capture tests were performed on bioMérieux's Vidas immunoanalysis system. The dendrigraft−ODN conjugates (300 μL, 15 nmol) were first physically adsorbed onto the Vidas solid-phase receptacle. After a washing step, the capture step was performed over a period of 1 h with complementary labeled ODNs (300 μL, 10 nmol). After another wash and addition of the enzyme substrate (methyl umbelliferyl phosphate), the emitted signal was measured and expressed by the Vidas detector in relative fluorescence units (RFU). Each series of tests included one control sample without conjugate (labeled ODNs only).

ELOSA Tests. Complete ELOSA tests were performed as previously described (*9*, *10*) with the conjugates providing a significant signal in the capture tests. The dendrigraft−ODN conjugates (300 μL, 15 nmol) were first physically adsorbed onto the Vidas solid phase (coating step). After a washing step, the capture step was carried out with increasing concentrations of HBV DNA target (2339 base pairs) (0, 10^7, 10^8, 10^9, 10^{10}, and 10^{11} DNA copies per mL, 200 μL). Intermediate detection probes (called Mix) ensured the link between the captured DNA targets and the polymer−ODN detection conjugate (300 μL, 15 nmol). This detection conjugate was based on a saccharidic graft copolymer (AF 112) (*15*). The fluorescent signal (RFU) was finally produced by labeled ODNs hybridized on the polymer−ODN detection conjugate.

Polymer Characterization. ^{1}H NMR spectra were recorded in $CDCl_3$ or in D_2O on a Bruker AC 200 FT apparatus. Size exclusion chromatography (SEC) measurements of PVE amphiphilic dendrigrafts (I, II, III) before deprotection were performed in tetrahydrofuran at 25 °C (flow rate 0.7 mL/min) on a Varian apparatus equipped with refractive index (Varian) and laser light scattering (Wyatt Technology) dual detection, and fitted with four TSK gel HXL columns (250, 1500, 10^4, and 10^5 Å). For the light scattering measurements, the d*n*/d*c* values of the different PVE and polyoxirane dendrigrafts were determined in THF at 25 °C with a laser source operating at 633 nm.

Size exclusion chromatography analyses of PEO-*b*-PEGP blocks, dendrigrafts IV, and deprotected PVE dendrigrafts I, II, and III were performed at 25 °C in a water/methanol mixture (v/v 80/20) containing $NaNO_3$ (1.27 g/L) on a Varian apparatus equipped with a refractive index detector and four TSK PWXL columns (300 × 7.7 mm; 250, 1500, 10^4, and 10^5 Å), at a flow rate of 1 mL/mn.

Dynamic light scattering measurements were performed at 25 °C in THF and in water on a Malvern apparatus (Zetasizer 3000HS) equipped with a laser source (633 nm). Correlation functions were analyzed by the Contin method. Latex particles were used as calibration standards.

VPO measurements were performed on a Gonotec Osmomat 090 in toluene. Samples for AFM of the dendrigrafts and their precursors were prepared by solvent casting at ambient conditions on substrates, starting from either MeOH solutions of dendrigrafts or THF solutions for the precursors. Typically, 20 μL of a dilute solution (0.002−0.1 wt %) was cast on a 1 × 1 cm^2 freshly cleaved mica substrate. Samples were analyzed after complete evaporation of the solvent at room temperature. All AFM images were recorded in air with a Nanoscope IIIa microscope operated in tapping mode. The probes were commercially available silicon tips with a spring constant of 24−52 N/m, a resonance frequency lying in the 264−339 kHz range, and a typical radius of curvature in the 10−15 nm range. Both the topography and the phase signal images were recorded with the highest sampling resolution available, i.e., 512 × 512 data points.

RESULTS AND DISCUSSION

The hydrosoluble dendritic polymers were synthesized from functional PCEVE/PS dendrigraft (A, B) or comb (C) precursors. As previously reported, these monodispersed polymers were prepared by covalently assembling elementary macromolecular blocks by repeated grafting of α-end-functionalized polystyryllithium onto chloroethyl vinyl ether units of linear or comblike chains (obtained via living cationic polymerization) as described in Scheme 1, steps 1, 2, and 3. Two strategies have been developed to prepare hydrosoluble dendritic polymers suitable for DNA immobilization, from these hydrophobic precursors.

Synthesis of the Water-Soluble Dendrigrafts I, II, and III. The first route (*20*) was based on the use of acetal-terminated PCEVE$_1$-*g*-(PS$_1$-*b*-(PCEVE$_2$-*g*-A$_1$PS$_2$)) (precursors A and B) as multifunctional initiators to grow a surrounding hydrophilic shell with galactopyranose units available at the periphery. As previously described, this was achieved by initiation—from the terminal acetal groups—of the living cationic polymerization of two types of poly(vinyl ether) blocks (see Scheme 1, step 4**)**: the PSiVE block that ensured the solubilization of the dendrigrafts in aqueous solution after deprotection of hydroxyl groups (PHEVE) and the PDiGVE block that enabled the binding of NH_2-ended oligonucleotides after deprotection of the saccharidic moieties. To evaluate the influence of parameters such as the length of the hydrophilic spacer (PHEVE) or the number of the GVE units on the immobilization of ODNs and on the ability of the resulting conjugates to provide an amplification enhancement, we prepared three different dendrigrafts tuning the degree of polymerization of the external PS ($\overline{DP_n}_{PS2}$ = 5 or 50), PSiVE, and PDiGVE blocks. The dimensions and the main characteristics of dendrigrafts I, II, and III are indicated in Table 1. The growth of the PVE blocks was confirmed by ^{1}H NMR. The increase of the hydrodynamic

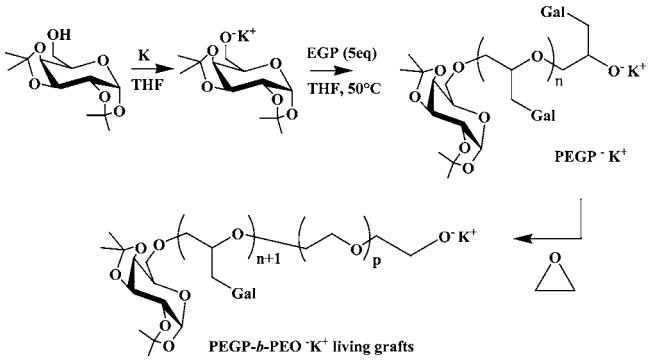
Scheme 2. Synthesis of PEGP-*b*-PEO Living Chains via Anionic Polymerization



radii (in THF) from 34 nm (A) to 55 nm (I**)**, and from 25 nm (B) to 44 (II) and 36 nm (III**)** corroborated the successful chain extension from the acetal termini. Consistent with a living polymerization process, the resulting polymers exhibited unimodal and narrow molar mass distributions. The molecular weights of the dendrigrafts (evaluated by ^{1}H NMR and SLS) were ranging from 2.8 to 16.3 $\times$ 10^7 g·mol^{-1}, and the number of galactopyranose groups introduced on each dendrigraft scaled from 25 $\times$ 10^3 (III) to 96 $\times$ 10^3 (I). It is worth noting that the number of Gal per macromolecule is significantly higher than the values reported with linear or graft saccharidic copolymers (typically less than 2000 Gal/macromolecule) (*14*, *15*).

After regeneration of the hydroxyl functions, I and II were soluble in water while III could only be dissolved in MeOH, likely due to the presence of short PHEVE and PGVE blocks. Dynamic light scattering analysis confirmed that the unprotected dendrigrafts behave as unimeric macromolecules in water (I and II).

Synthesis of the Water-Soluble Dendrigrafts IV. The second approach aimed at the preparation of water-soluble dendrigrafts with PEO-*b*-PEGP external branches, considering that the PEGP blocks bearing the reactive saccharidic groups would enable the binding of NH_2-terminated oligonucleotides, while the PEO blocks would ensure the water solubility of the dendrigraft and improve, as spacers, the accessibility of the Gal units. The synthesis of these amphiphilic dendrigrafts was achieved by grafting living polyoxirane chains onto the activated chloroethyl functions of PCEVE external blocks of $PCEVE_1$-*g*-(PS_1-*b*-$PCEVE_2$) precursors (C: 200/120/40).

Living PEGP-*b*-PEO^- K^+ diblock copolymers were first obtained by anionic polymerization (Scheme 2). SEC analysis clearly established the preparation of narrow dispersed diblock chains (PDI = 1.14). The exact composition and molar mass of the copolymer were determined by ^{1}H NMR and VPO analysis of PEGP-*b*-PEO: $\overline{DP}_{n\mathrm{PEGP}} = 5$; $\overline{DP}_{n\mathrm{PEO}} = 90$.

Amphiphilic dendrigrafts IV were subsequently prepared by grafting living PEGP-*b*-PEO^- K^+ oxanionic species onto $PCEVE_1$-*g*-(PS_1-*b*-$PCEVE_2$) precursors (C) in the presence of NaI as activator (see Scheme 1**,** step 3′). After reaction, the hyperbranched polymer was separated from free PEGP-*b*-PEO chains by selective precipitation. The SEC analysis of the dendrigrafts (Figure 1) confirmed the unimodal and narrow molar mass distribution of IV. The main dimensional characteristics of IV are collected in Table 2. The previous characterization of C enabled us to calculate, by ^{1}H NMR, the yield of PEGP-*b*-PEO grafting, the final molar mass of dendrigraft IV, and the number of Gal units per dendrigraft. The poor reactivity of the oxanionic species resulted in low efficiency of grafting (15%), giving birth, after deprotection of the hydroxyl groups, to water-soluble dendrigrafts displaying a low peripheral density and bearing about 6100 Gal units each. In contrast to the cases of dendrigrafts I and II, the dynamic light scattering analysis revealed the presence of a few aggregates (constituted of two to three dendrigrafts) in aqueous solution (see Figure 2).

Characterization by Tapping-Mode Atomic Force Microscopy (TMAFM). TMAFM characterization of PHEVE- and PGVE-functionalized dendrigrafts (especially I) with a high grafting density of PVE hydrophilic blocks has been described in a previous paper (*20*). In this case, individual molecules can be easily observed as unique olivelike shaped objects with a diameter of about 100 nm (Figure 3, left). In this work, we mainly focused on the molecular characteristics of dendrigraft IV with PEO_{90}-*b*-$PEGP_5$ external hydrophilic blocks, which exhibits a lower peripheral grafting density (15%). The typical morphology of submonolayer deposits obtained by drop casting of 0.02 wt % MeOH solutions on mica is shown in Figure 3, right. Deposits of IV exhibit both globular and wormlike structures. The globular structures, more clearly seen in the topographic image inset (c) of Figure 3, correspond to unimeric dendrigrafts exhibiting a narrow size distribution (diameter = 22 nm $\pm$ 2 nm), in agreement with the low polydispersities measured in solution by SEC. The much reduced size of IV measured here by AFM, compared to the DLS data of Table 2 (diameter 22 nm as solid deposit vs 60 nm in THF), most probably arises from the fact that AFM measurements are performed in the dry state while the DLS values in a good

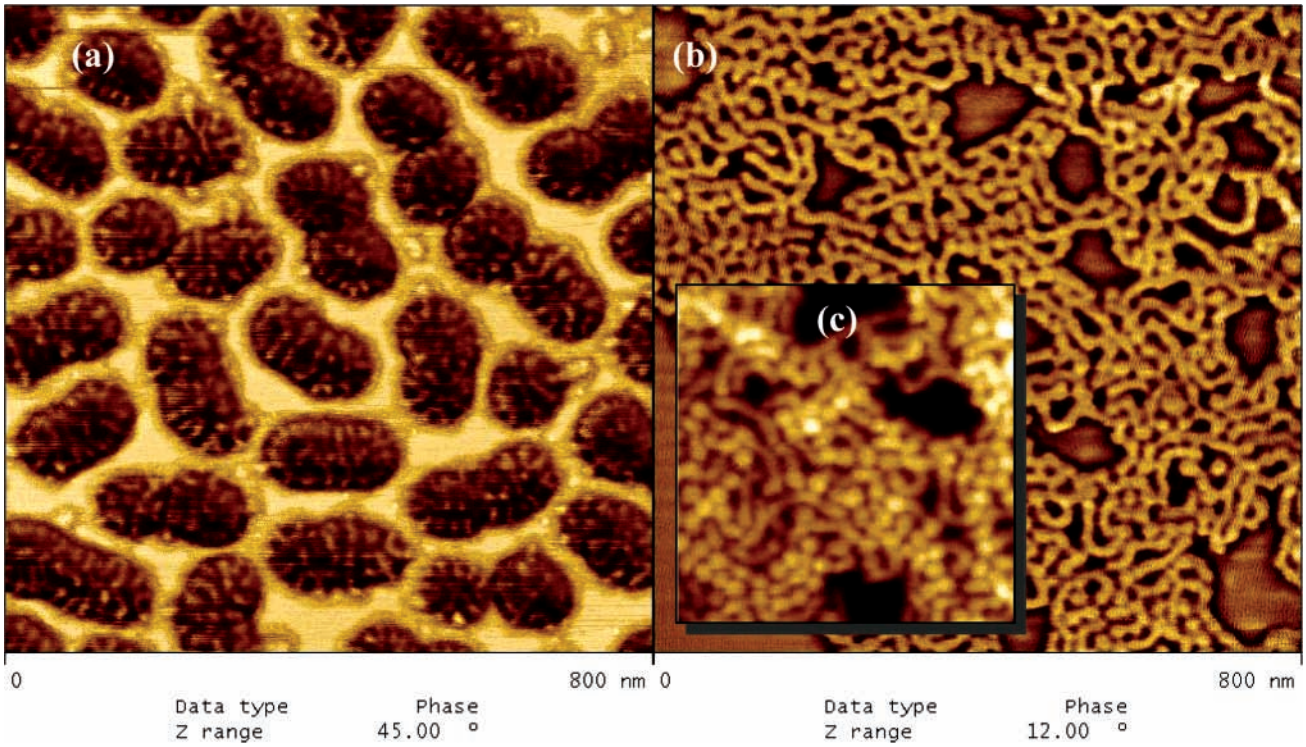

Figure 3. Tapping mode AFM (800 × 800 nm^2) phase image of a monolayer of the dendrigraft IV obtained from a 0.002 wt % methanol solution deposited on mica (b). The inset (c) shows a higher resolution (400 × 400 nm^2) topographic image. The left image (a) shows, as a comparison, the morphology of the dendrigraft I deposited from a 0.01 wt % THF solution on mica.

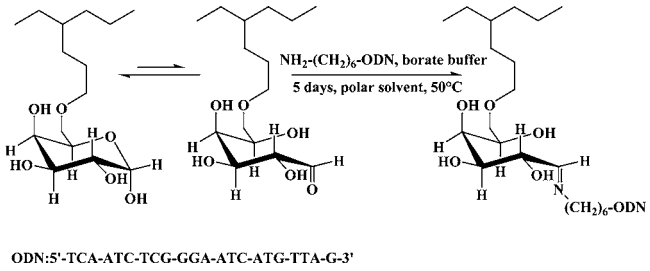
Scheme 3. Preparation of Dendrigraft−ODN Capture Conjugates Using a Simple One-Step Coupling Procedure (Schiff Base) with Amino-Ended ODNs



ODN:5'-TCA-ATC-TCG-GGA-ATC-ATG-TTA-G-3'

solvent correspond to swollen molecules. This is in contrast with the close diameter observed for I in the dry state and in solution (100 nm as solid vs 110 nm in THF). The presence of wormlike structures for IV, with a length up to 300 nm and a constant width corresponding to the diameter of unimeric dendrigrafts, clearly results from unidirectional assemblies of a large number of dendrigrafts. This organization also strongly contrasts to the one observed for dendrigraft I. Such an intermolecular organization and the size reduction of IV could be interpreted as the consequence of the quite low density of peripheral branches, which allows hydrophobic (PCEVE, PS) and hydrophilic domains of several dendrigrafts to interpenetrate, whereas the much higher lateral grafting density in I makes it much more compact, avoiding swelling and interpenetration phenomena.

Preparation of Dendrigraft−ODN Conjugates and ELOSA Tests. The covalent binding of DNA sequences on the dendrigraft surface was performed in aprotic polar solvent (DMSO, DMF, or NMP)/(aqueous buffer) mixtures, by reaction of the primary amine at the 5′-end of the ODNs with the aldehyde function at the anomeric position of the galactopyranose residues (formation of a Schiff base) as shown in Scheme 3. Various parameters such as the Gal/ODN molar ratio, the (organic solvent)/(aqueous buffer) volume ratio, the nature of the solvent, the ionic strength, and the pH of the aqueous buffer were tuned to optimize the coupling reaction. Due to the size of the dendrigraft−ODN conjugates and their tendency to form aggregates in organic/aqueous mixtures, it was not possible to follow the coupling reaction by SEC as previously reported (*7*, *9*, *10*) by comparing the relative peak areas of the bound ODNs and the unreacted ODNs. Formation of aggregates during the coupling reaction had already been reported for polymer−ODN conjugates (*7*) and had been attributed to possible side reactions from heterocyclic base amino groups and/or hydrogen bondings between the polymer and the ODNs. Finally, the presence of covalently bound ODNs on the dendrigrafts was indirectly evaluated by a capture test.

The ability of the prepared dendrigraft−ODN conjugates to capture short complementary ODNs (25 bases) through hybridization was studied on the Vidas instrument. As these complementary ODNs were labeled with an alkaline phosphatase enzyme, addition of methylumbelliferyl phosphate substrate led to the appearance of a fluorescence signal (Scheme 4A). The main results of the capture tests performed with I, II, III, and IV dendrigraft−ODN conjugates are reported in Table 3.

Except III, the dendrigrafts were all suitable for the elaboration of dendrigraft−ODN capture conjugates, as revealed by the high fluorescence signal obtained under specific coupling conditions. The nature of the organic solvent, the (organic solvent)/(aqueous buffer) volume ratio, and the Gal/ODN molar ratio appeared to be the main parameters of the coupling reaction. In contrast, no influence of the buffer ionic strength or pH was observed.

To estimate the proportion of ODNs immobilized on the dendrigrafts by physical adsorption, a run was carried out using an ODN without an amino spacer arm (run 6 to be compared with run 4). This test indicated that the amount of adsorbed ODNs was low (the signal was of the same order of magnitude as that of the control run performed without dendrigrafts). Although partially due to adsorption phenomena, the fluorescence signals obtained with I−ODN, II−ODN, or IV−ODN capture conjugates clearly confirmed the presence of ODNs

Table 3. Preparation Conditions of the Dendrigraft−ODN Conjugates and Performance of the Capture Tests

run	dendrigraft	solvent	org/aq v/v ratio	pH of borate buffer	Gal/ODN ratio (nmol)	optimal signal (RFU) capture test
1	I	NMP	97/3	9.2	∼60	1100
2	I	DMF	97/3	9.2	∼60	9400
3	II	DMF	50/50	7.2	20	2200
4	II	DMF	50/50	7.2	100	6800

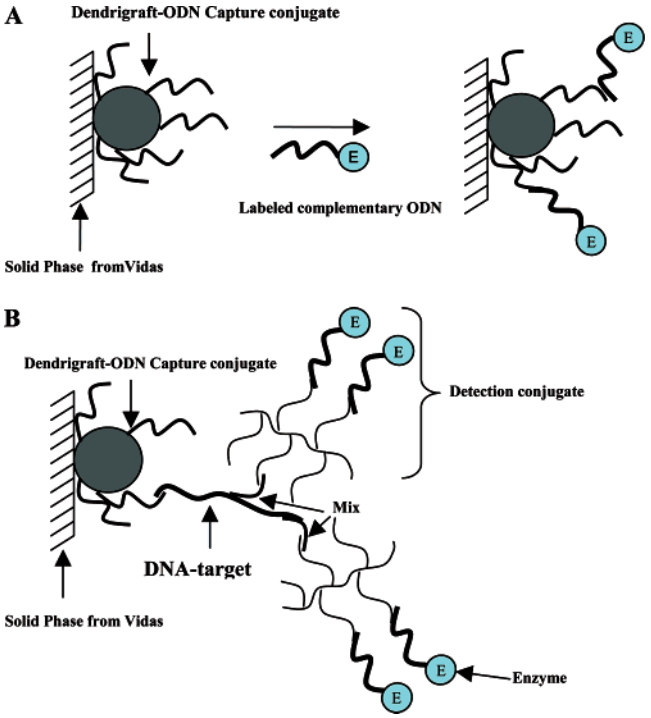
[a] "Coupling reaction" performed using ODNs without NH_2-ended spacer arm. [b] Control run without dendrigrafts (labeled ODNs only).

Scheme 4. Principles of the Capture Test (A, top) and of the Complete Sandwich Hybridization Assay (ELOSA Diagnostic Test) with Capture and Detection Amplification (B, bottom)



bound at the periphery of the dendrigrafts and their availibility for hybridization. In contrast, concerning III−ODN conjugates (run 7), the detected signal was attributed only to the presence of some adsorbed ODNs, since the run performed using ODNs without an amino spacer arm produced a similar fluorescence signal (run 8). This result clearly underlines the influence of the hydrophilic spacer block (PHEVE) on the ODN coupling reaction and the necessity to grow long PHEVE blocks (III: $\overline{DP}_{n\mathrm{PHEVE}} = 11$; I and II: $\overline{DP}_{n\mathrm{PHEVE}} = 90$ and 110, respectively) to improve the accessibility of the Gal moieties and consequently to favor the binding of ODNs.

The conjugates synthesized from I and IV provided high fluorescence signals with moderate Gal/ODN ratios (4−60) (see runs 2, 9, 10, and 11) whereas in the case of II it was necessary to perform the coupling reactions with high Gal/ODN ratios (∼100−300) to obtain a significant signal (runs 4 and 5). Although it remains difficult to draw conclusions, this unexpected trend could be correlated to the short saccharidic block ($\overline{DP}_n = 4$) at the periphery of dendrigraft II. In addition, in opposition to the case of I or IV, the ODN coupling reaction with II was more efficient at a higher water content (50% v/v instead of 10% v/v).

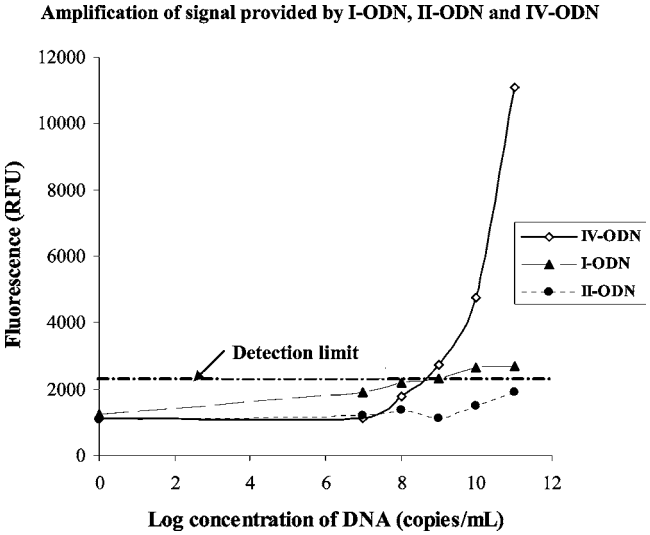


Figure 4. Complete sandwich hybridization assays (ELOSA tests) with capture and detection amplification (I−ODN, II−ODN, and IV−ODN, runs 2, 5, and 11).

Finally, IV appeared to have the best structure to favor the binding of ODNs, since a Gal/ODN ratio of 4 was enough to give a saturation signal (run 9). In comparison with I, IV is smaller ($R_h = 30$ instead of 55 nm in THF) and thus has a much higher specific area (1086 instead of 155 m^2 per gram). In addition, each dendrigraft IV bears an average of 6100 Gal residues (instead of 96 000 for dendrigraft I) and thus a lower saccharidic density at the surface which favors accessibility (0.32 and 2.52 Gal/nm^2 for IV and I, respectively). Consequently, the more favorable structure for the binding of ODNs seems to correspond to dendrigrafts of 60 nm diameter bearing a moderate number of Gal residues located at the end of long hydrophilic spacer arms.

Complete sandwich hybridization assays (ELOSA tests) with capture and detection amplification were further performed with a HBV DNA target (∼2400 bases) (Scheme 4B). Each dendrigraft−ODN capture conjugate which had provided a high fluorescence signal in the capture test was evaluated (I−ODN, II−ODN, and IV−ODN, runs 2, 5, and 11, respectively). The different dendrigraft−ODN capture conjugates were independently compared in the presence of a detection conjugate prepared from a saccharidic graft copolymer (AF112) (*14*, *15*). The results of the different tests are presented in Figure 4.

Despite the presence of ODNs on each conjugate, the results clearly showed that the conjugates made from IV (the dendrigraft of lowest external branch density) were the only ones leading to an increase in sensitivity. I- and II-based conjugates did not provide a significant increase in sensitivity since the signal/noise ratio remained very low (≤2) even at high

Table 4. Amplification Performances of IV−ODN Conjugates in Complete Sandwich Hybridization Assays (ELOSA Diagnostic Tests) with Capture and Detection Amplification

polymer−ODN capture conjugate	signal/noise ratio (10^{11} DNA copies/mL)	signal/noise ratio (10^9 DNA copies/mL)
AF112−ODN[a]	13.5	2.9
IV−ODN (run 9)	7.6	1.7
IV−ODN (run 11)	10	2.5
capture ODN[b]	1.4	1

[a] Polymer−ODN capture conjugate made from a saccharidic graft copolymer (AF112) (*15*) bearing an average of 650 Gal residues per copolymer. [b] Control run without dendrigraft−ODN capture conjugate (ODNs alone).

concentrations of DNA (10^{11} copies/mL). The difference of behavior between I−ODN, II−ODN, and IV−ODN conjugates was correlated with the relative steric hindrance induced by the external structure of conjugates I and II. In comparison with the case of IV−ODN, the high external density of saccharidic residues could affect the availability of the immobilized capture ODNs and/or prevent either the approach or the hybridization of the target of 2400 nucleic bases and/or prevent the approach or the hybridization of the detection conjugate. It was not possible to determine which of these steps was finally responsible for the low resulting signal.

In the case of IV−ODN, the signal/noise ratio was equal to 8−10 at 10^{11} DNA copies per mL and was still superior to 2 (which is the detection limit) at 10^9 DNA copies per mL (Table 4). In comparison, the same test without dendrigrafts (with capture ODNs alone) reached the same detection limit for 10^{11} DNA copies per mL and thus was 100 times less sensitive. Moreover, the background signal provided by the IV−ODN conjugate was relatively low (1000 RFU, a value similar to that of linear copolymers) (*9*).

Finally, it was interesting to compare these dendrigraft−ODN conjugates (IV−ODN) with a capture conjugate based on a saccharidic graft copolymer, AF112−ODN, bearing on average 650 ODNs per copolymer chain. In both cases, the sensitivity of the test reached 10^9 DNA copies per mL (Table 4), confirming the interest of the less crowded dendrigrafts bearing a moderate number of external branches and Gal residues for such diagnostic tests.

In summary, two families of amphiphilic water-soluble dendrigrafts exhibiting well controlled dimensions and bearing saccharidic moieties have been synthesized. The presence of external galactopyranose groups on these polymers has been exploited to prepare dendrigraft−oligonucleotide capture conjugates via a simple one-step coupling procedure (Schiff base) using amino-ended ODNs. A capture test with short labeled complementary ODNs (25 bases) confirmed the presence of covalently bound ODNs on various kinds of dendrigrafts (I, II, and IV) except for the dendrigraft (III) displaying short hydrophilic spacer blocks, which led exclusively to some ODN adsorption.

The conjugates made from I, II, and IV were finally evaluated in a nucleic acid detection test with a real DNA target from hepatitis B virus, HBV DNA with 2400 nucleic bases. The IV−ODN conjugate which possesses a low saccharidic external density (6120 Gal per dendrigraft) was the only capture conjugate leading to a significant amplification of the fluorescence signal, corresponding to a limit of sensitivity of 10^9 DNA copies per mL (instead of 10^{11} DNA copies per mL without using dendrigrafts) and a low background signal. Conversely, despite the large number of galactopyranose groups located at their periphery (respectively 96 000 and 33 000), I and II were not able to induce a better sensitivity of the test, probably due to the steric hindrance generated by the peripheral congestion of these polymers.

ACKNOWLEDGMENT

The authors would like to thank Arnaud Favier (Unité Mixte CNRS-bioMérieux) for the sample of the saccharidic graft copolymer AF112 and Aude Dassonville (Unité Mixte CNRS-bioMérieux) for some help with the ELOSA tests. We would also like to acknowledge the cooperation agreement (Tournesol) between France (LCPO) and the Communauté Française de Belgique (Mons) for financial support.

Unilamellar Liposomes with Enhanced Boron Content

Tiejun Li, Julie Hamdi, and M. Frederick Hawthorne*

Department of Chemistry and Biochemistry, University of California, Los Angeles, 607 Charles E. Young Drive East, Los Angeles, California 90095. Received May 5, 2005; Revised Manuscript Received October 20, 2005

A new type of boron-rich, DSPC-free, unilamellar liposomes was formed using the novel dual-chain, ionic, *nido*-carborane lipid, K[nido-7-($C_{16}H_{33}OCH_2$)$_2$CHOCH$_2$-7,8-$C_2B_9H_{11}$] (DAC-16), and cholesterol for encapsulation of an aqueous buffer core. Since DSPC was not necessary for the formation of stable DAC-16 liposomes, the boron concentration of these vesicles was increased dramatically to approximately 8.8 wt % in the dry lipid; these liposomes had a high bilayer boron incorporation efficiency of 98%. DSPC-free liposomes exhibited a size distribution pattern of 40−60 nm, which was in the range normally associated with selective tumor uptake. This size distribution was maintained throughout storage at room temperature for several months. Additionally, optimized liposome formulations incorporating DAC-16, DSPC, and cholesterol were identified having stable size distribution patterns after storage for more than two months at a variety of temperatures. Although animal studies indicate that DAC-16 liposomes are toxic, this new ionic *nido*-carborane lipid allows the formation of liposomes of high boron content for in vitro applications that require the delivery of large amounts of boron.

INTRODUCTION

Unilamellar liposomes have been studied as drug delivery agents for more than 30 years because of their many unique properties, most notably the ability to selectively deliver large quantities of a wide variety of encapsulated agents to tumor sites (*1*, *2*). Rapidly growing tumors have leaky vasculature and immature capillary endothelia through which small liposomes (<100 nm) can pass (*3*). Because liposomes provide this tumor-targeting property, it is not necessary for the incorporated agent to have its own tumor-seeking capability. Additionally, liposome-encapsulated drugs have longer circulation life spans than the free drug, making it possible to achieve the same therapeutic level of treatment using a lower injected dose (*4*). At the same time, the toxic side-effects of some drugs are markedly reduced when the drug is encapsulated by liposomes that maintain their structural integrity in blood (*5*). Currently, there are several FDA-approved liposomal drugs available commercially and many more are in clinical trials (*6*).

In addition to their proven role as drug carriers, liposomes provide a promising solution to a major obstacle in the continued development of boron neutron capture therapy (BNCT), the selective delivery of therapeutic quantities of ^{10}B atoms to tumor cells (*7*−*9*). Nearly 30 years before the identification of liposomes as encapsulating drug carriers, BNCT was first proposed by Locher (*10*). BNCT is a binary cancer treatment based on the nuclear reaction of two essentially nontoxic species, ^{10}B and thermal neutrons. The neutron capture reaction produces $^7Li^{3+}$ and $^4He^{2+}$ ions together with 2.4 MeV of kinetic energy and a 480 keV photon. With a range of only one cell-diameter, these highly energetic ions are cytotoxic to the cell in which they are generated, allowing for the selective destruction of cells containing a minimum number of ^{10}B atoms (10^9 ^{10}B atoms per cell, representing approximately 30 mg ^{10}B per kg of tumor). The limited investment in the thorough evaluation of boron delivery agents has been one of the major limitations of the clinical development of BNCT. Another contributing factor has been the clinical preoccupation with glioblastoma multiforme, a fatal type of brain cancer. Over the past decades, various boron delivery methods have been explored in small animals, including boronated porphyrins, monoclonal antibodies, nucleosides, amino acids, oligomers, and liposomes (*11*−*13*), with varying degrees of success. The utilization of liposomes as ^{10}B delivery agents is a promising approach to meet the requirements of BNCT of tumors other than gliomas (*4*, *14*, *15*).

Liposomes for Use as Potential BNCT Agents. Small unilamellar liposomes, because of their tumor-targeting ability and biphasic nature (*1*, *2*), are ideal carriers for the transport of large quantities of both lipophilic and hydrophilic boron-containing species. Two distinct methods of boron localization in liposomes are possible: incorporation of lipophilic molecules into lipid bilayers and/or entrapment of hydrophilic compounds into a liposome's aqueous core. Previous work (*7*−*9*, *16*−*19*) has demonstrated this in the formation of three types of unilamellar liposomes (identified as liposome types A, B, and C) for the delivery of therapeutic quantities of boron (30 μg ^{10}B per gram of tumor tissue, or 10^9 ^{10}B atoms per tumor cell) (*20*) to tumor cells with high tumor/blood ratios using low injected doses. Liposomes of type A involved the encapsulation of hypertonic solutions of soluble borane salts within a distearoylphosphatidylcholine (DSPC)/cholesterol bilayer (*7*, *8*, *16*, *17*), while type B liposomes utilized a DSPC/cholesterol bilayer doped with boron-containing lipids to encapsulate an isotonic buffer solution (*9*, *18*), and type C liposomes represented a combined approach: the encapsulation of either a hyper- or isotonic aqueous solution of a borane salt within a bilayer composed of DSPC, cholesterol, and lipophilic borane compounds (*9*, *19*).

Type A liposomes were prepared from a lipid mixture containing equimolar quantities of DSPC and cholesterol to achieve enhanced serum stability while encapsulating an aqueous solution of borane salts such as $Na_3B_{20}H_{17}NH_3$ (TAC) (*7*, *8*, *16*, *17*). The size of the resultant liposomes is regulated by the liposome-formation method chosen: the reverse-phase evaporation method results in larger vesicles than are obtained by probe sonication. Although it was found that liposomes of up to 400 nm in diameter could still penetrate the tumor cell wall (*21*), liposomes created by probe sonication resulted in small unilamellar vesicles less than 100 nm in diameter that displayed

selective uptake by tumor tissue and had a longer half-life in circulation than those with a larger diameter (*22*, *23*). Many water-soluble boron compounds encapsulated within these smaller type A liposomes were tested as BNCT agents (injected does of approximately 15 μg B per gram body weight), resulting in selective delivery of up to 47 μg of boron per g of tumor in BALB/c mice bearing EMT6 tumors without serious toxicity problems (*7*, *8*). Uptake of liposomes by the liver and spleen was normally observed and paralleled tumor uptake with time. Maximum boron content in tumor tissue was usually observed near 30 h postinjection (*8*, *17*).

In contrast to the many water-soluble borane ions investigated, only a few amphiphiles have been studied as bilayer addends to create type B liposomes that encapsulated a hyper- or isotonic saline or HPS (10 mM HEPES/375 mM NaCl, pH 7.4) buffer solution. The first amphiphilic carborane compound incorporated into a lipid bilayer, K[*nido*-7-$CH_3(CH_2)_{15}$-7,8-$C_2B_9H_{11}$] (referred to as MAC-16) (**1**), was synthesized and evaluated in biodistribution studies reported in 1994 (*9*, *18*). The compound had a high incorporation efficiency of 70% in liposome bilayers composed of DSPC and cholesterol. Biodistribution studies of these lipsomes in BALB/c mice bearing EMT6 tumors indicated that, 30 h postinjection, tumor-boron concentrations of up to 35 ppm were maintained following injected doses ranging from 99 to 188 μg of boron, while only very slight uptake by the liver and spleen was noted (*9*, *18*).

Further work revealed that in addition to incorporating lipophilic boron-containing species in the bilayer, it was also possible to create type C liposomes that encapsulated salts such as TAC within the aqueous cores of DSPC/cholesterol liposomes doped with **1** (*9*, *19*). These stable liposomes (**1**:DSPC: cholesterol ratio equals 1:3:3) displayed good biodistribution properties resulting in significantly enhanced boron delivery of up to 71 μg of boron per g of tumor in BALB/c mice bearing EMT6 tumors. Liposomes constructed with smaller molar proportions of DSPC and cholesterol stabilizer resulted in lower observed incorporation efficiencies and decreased physical stabilities. This restriction limited the amount of boron that could be incorporated into liposomes using **1** as a bilayer addend in type B and C liposomes. To improve the performance of these liposomes, the boron content of the amphiphilic bilayer addend could be increased while maintaining the necessary structural components, or alternatively, the DSPC and cholesterol might be removed and the bilayer formed completely from an amphiphilic boron derivative.

To pursue this concept, the synthesis and liposome-forming characteristics of a new amphiphilic addend composed of a *nido*-carborane anion appended to a dual hydrocarbon chain (**2**, see below) was reported (*24*) which formed liposomes of type B. In this paper the properties of the resulting liposomes and preliminary information obtained from initial animal toxicity studies is presented.

Recently, Nakamura and co-workers also reported the synthesis of a dual-chain *nido*-carborane compound, **3** (*25*), as illustrated in Figure 1. Similar to the results we report, liposomes formed from this compound showed suitable stability and addend incorporation properties, demonstrating that such *nido*-carborane species possess satisfactory liposome-forming properties and further support the results presented here. Unfortunately, biodistribution and in vivo toxicity data are not reported (*25*) for these liposomes.

EXPERIMENTAL SECTION

General. All reactions were performed under N_2 or Ar using Schlenk techniques. All reagents were purchased from commercial suppliers and used without further purification, while solvents were dried and distilled before use. Silica gel was obtained from Sorbent Technologies (60 Å, 32−63 μm).

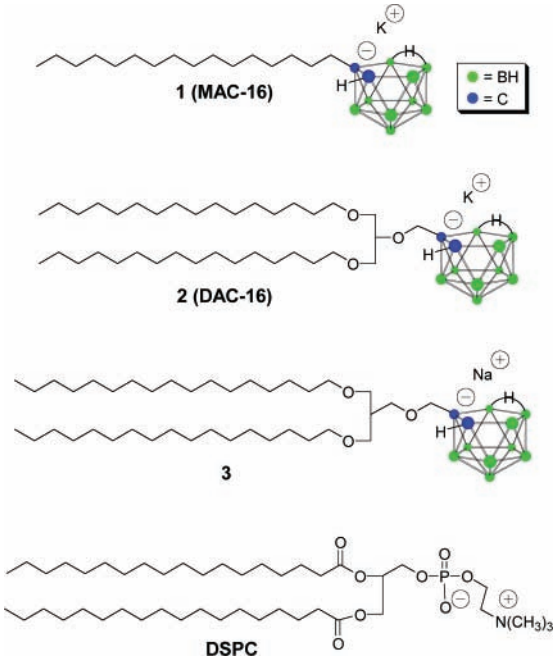

Figure 1. Structures of **1**, **2**, **3**, and DSPC.

The ^{11}B NMR spectra were obtained with a Bruker ARX500 spectrometer at 160 MHz and were externally referenced to BF_3·Et_2O; peaks upfield of the reference are designated as negative. The ^{1}H and ^{13}C NMR spectra were acquired at 500 and 126 MHz with Bruker ARX500 and AVANCE500 spectrometers, respectively. Mass spectra were obtained at the UCLA Pasarow Mass Spectrometry Laboratory. High-resolution EI spectra were acquired using a Micromass GCT EI Time-of-Flight Instrument; MALDI and electrospray spectra were acquired on an Ionspec 7.0 Ultima FTMS utilizing MALDI and ESI sources. The ICP-AES analysis of boron was performed at Idaho National Engineering and Environmental Laboratory (INEEL, Idaho Falls, ID) using a Thermo Iris instrument. The toxicity evaluation was performed at Washington State University.

1,3-Bis-hexadecyloxy-propan-2-ol (4). According to previously reported literature precedent (*26*), sodium hydride (60% in mineral oil, 2.1 g, 53 mmol) was added in small portions to 1-hexadecanol (26.5 g, 109 mmol) at 100 °C. After stirring for 0.5 h, epichlorohydrin (1.0 mL, 12.8 mmol) was added dropwise to the hot mixture and maintained at 100 °C overnight, after which water (2 mL) was added to quench the reaction. The filtrate (obtained in ether after extraction of the crude reaction mixture) was washed with water (3 × 100 mL) and dried with anhydrous $MgSO_4$ before the ether was removed under reduced pressure. Excess 1-hexadecanol was removed by vacuum distillation. The crude product was recrystallized from ethyl acetate at 4 °C to yield a white solid (6.16 g, 89.0%) that was isolated by filtration and dried under vacuum. Mp 54−55.2 °C. ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.88 (t, 6H, ^3J = 6.9, CH_3), 1.25 (br, 52H) ($(CH_2)_n$), 1.55 (m, 4H, OCH_2CH_2), 2.47 (d, ^{1}H, ^3J = 4.1, O*H*), 3.45 (m, 8H, OCH_2), 3.93 (m, 1H, C*H*). ^{13}C-{^{1}H} NMR (500 MHz, $CDCl_3$): δ 14.0 (CH_3), 22.6 (CH_3CH_2), 26.0 ($OCH_2CH_2CH_2$), 29.2−29.6 ($(CH_2)_n$), 31.8 (OCH_2CH_2), 69.4 (CH), 71.6 (OCH_2), 71.7 (OCH_2). IR: 3481.44 cm^{-1} (OH stretch), 2957.91−2849.30 cm^{-1} (sp^3-CH stretch), 1471.64 cm^{-1} (sp^3-CH bend), 1126.41 cm^{-1} (C−O stretch), and 719.62 cm^{-1} (CH_2 long-chain band).

1,3-Bis-hexadecyloxy-2-(prop-2-ynyloxy)-propane (5). Into a 25 mL round-bottom flask were added 1,3-bis-hexadecyloxy-propan-2-ol (1.0 g, 1.8 mmol), NaOH (4.0 g, 100 mmol), NBu_4HSO_4 (0.4 g, 1.2 mmol), water (3 mL), and benzene (12 mL). After stirring for 5 min, propargyl bromide (80% in toluene,

0.23 mL, 2.1 mmol) was added dropwise. The reaction mixture was stirred at room temperature for 3 days and then extracted with ether and brine. The organic layer was collected, and the solvent was removed under reduced pressure. Purification by column chromatography on silica gel (5% ether in pentane) yielded the pure product as a white solid (0.44 g, 41%). Mp 43.8−45.5 °C. ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.87 (t, 6H, ^3J = 7.0, CH_3), 1.25 (br, 52H) ((CH_2)$_n$), 1.55 (m, 4H, OCH_2CH_2), 2.39 (t, 1H, ^4J = 2.4, CCH), 3.41−3.54 (m, 8H, OCH_2), 3.83 (m, 1H, C*H*), 4.33 (d, 2H, ^4J = 2.4, $CHCCH_2$). ^{13}C{^{1}H} NMR (126 MHz, $CDCl_3$): δ 14.0 (CH_3), 22.7 (CH_3CH_2), 26.1 ($OCH_2CH_2CH_2$), 29.4−29.7 ((CH_2)$_n$), 31.9 (OCH_2CH_2), 57.6 ($CHCCH_2$), 70.8 (OCH_2), 71.7 (OCH_2), 73.9 (*C*HC), 76.6 (*C*H), 80.3 (CH*C*). Vesicle Preparation. Suspensions of DSPC-free liposomes were prepared by probe sonication of a dried film composed of an equimolar ratio of **2** and cholesterol (195.9 mg **2**, 104.1 mg cholesterol, 300 mg total weight) in PBS buffer solution (6 mL) at room temperature for 0.5 h. After sonication, the liposome suspensions were eluted with buffer solution through Sephadex G-25 (medium) columns to remove any unincorporated impurities. The eluent was diluted with blank buffer solution (∼12 mL) to a lipid concentration of 23−24 mg/mL and sterilized by filtration through a 0.22-μm Millipore membrane. The boron content of the liposome suspensions was determined by ICP-AES and reported in ppm (μg boron per g of suspension). The liposomal size distribution was determined by dynamic light scattering, with typical volume-weight mean vesicle diameters (m_v) averaging 40 nm.

The incorporation efficiency of **2** was determined separately using a second liposome sample prepared in a manner similar to that described above. After sonication, the unincorporated DAC-16 was separated from the lipid mixture by centrifugal filtration with Centricon membrane instead of elution with a Sephadex column. After centrifugation, the retentate contained the pure lipid mixture, while the filtrate contained the unincorporated compound, the quantity of which was determined by ICP-AES. In this manner the incorporation efficiency was determined to be 98% for DSPC-free liposomes that were 8.8% boron by weight in the dry lipid, resulting in a liposome suspension with a boron concentration of 1600 ppm (measured by ICP-AES).

Other liposome formulations from lipid mixtures containing DSPC (see Table 3) were prepared as described above, with the exception that the sonication temperature was raised from 23 to 60 °C. The workup and sterilization of these liposomes follows the procedure described above using Sephadex G-25 (medium) columns and 0.22-μm Millipore membranes.

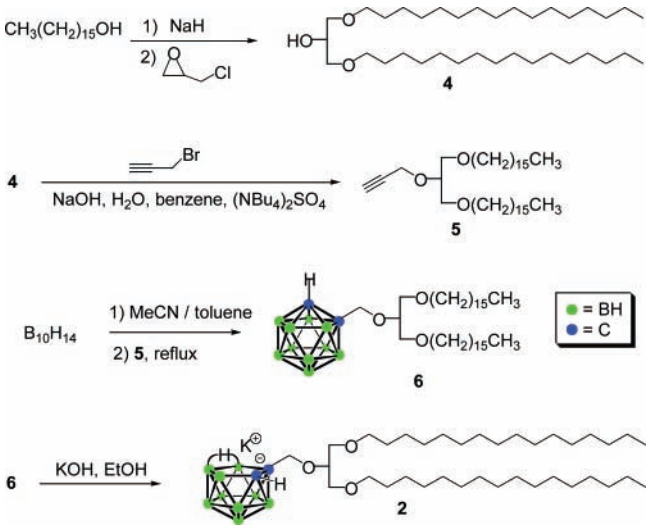
Partition Coefficient Measurement of 2, 1, DSPC, and Phenylboronic Acid. The water and 1-octanol used in this study were mutually presaturated with each other prior to use. Stock solutions of the compounds (1.00×10^{-3} M) were prepared in 1-octanol. A mixture of each 1-octanol solution (10 mL) in water (40 mL) was shaken for 2 h to reach equilibrium before the emulsion that formed was broken by centrifugation. The concentration of the solute in the 1-octanol and water layers was measured by ICP-AES to determine the partition coefficient.

Preliminary in Vivo Evaluation of 2. The toxicity assessment of **2** was performed at Washington State University with BALB/c and normal mice according to their availability. Five sets of experiments were performed using liposomes composed of **2**, DSPC, and cholesterol in varying proportions to create vesicles with boron content ranging from 0 to 8.8% in the dry lipid (see Table 3). Serial dilution of each liposome suspension with PBS buffer was used to obtain diluted samples ranging in concentration from 300 to 1525 ppm. Samples of liposome suspensions (0.2 mL, representing injected doses of 6.0−30. mg B/kg mouse) were introduced through the tail vein and the behaviors of the mice were monitored over 2 days. With the exception of mice injected with the control formulation (1:1 ratio of DSPC:cholesterol), all mice injected with liposomes incorporating the potassium salt of **2** were dead within 24 h of the injection. Mice injected with liposomes incorporating the sodium salt of **2** appeared to be in shock after 24 h and were dead within 48 h.

RESULTS AND DISCUSSION

Lipidic DSPC is a commonly used structural component in the formulation of synthetic unilamellar liposomes. Like most phospholipids, DSPC consists of a zwitterionic choline-based headgroup in addition to the two hydrocarbon chains that make

Scheme 1. The Synthesis of 2



up the lipophilic tail moiety. The facile incorporation of **1** into phospholipid bilayers can be explained by its physical similarity to DSPC (Figure 1). Characterized by a 16-carbon alkyl chain appended to a negatively charged *nido*-carborane, **1** effectively mimics amphiphilic phospholipids leading to successful bilayer incorporation with an efficiency of about 70% (*8*, *9*). The negative surface charge of MAC-16 liposomes could also lead to better delivery efficiency of the encapsulated species, enhanced tumor selectivity, and increased stability (*27*) of these small unilamellar liposomes. These encouraging results led to the design of an anionic *nido*-carborane derivative to even more accurately imitate the structure of phospholipids such as DSPC. The species K[*nido*-7-$(C_{16}H_{33}OCH_2)_2CHOCH_2$-7,8-$C_2B_9H_{11}$] (referred to as DAC-16) (**2**) was synthesized in fulfillment of this goal (Figure 1). It was hoped that structurally sound boron-containing liposomes of increased boron content could be prepared from **2** and cholesterol in the absence of DSPC.

K[*nido*-7-$(C_{16}H_{33}OCH_2)_2CHOCH_2$-7,8-$C_2B_9H_{11}$] (DAC-16, 2). The synthesis of **2** began by reaction of the alkoxide ion derived from 1-hexadecanol and NaH with epichlorohydrin, according to the procedure described in the literature (*28*), to give 1,3-bis-hexadecyloxy-propan-2-ol (**4**) in 89% yield. Upon addition of propargyl bromide to the two-phase system comprised of benzene and aqueous 50% NaOH in the presence of NBu_4^+, **4** was converted (*29*) to 1,3-bis-hexadecyloxy-2-(prop-2-ynyloxy)-propane (**5**) in 41% yield. The reaction of $B_{10}H_{12}(CH_3CN)_2$, formed from the reaction of decaborane with acetonitrile in toluene, with the alkyne **5** (*30*−*32*) produced *closo*-1-$(C_{16}H_{33}OCH_2)_2CHOCH_2$-1,2-$C_2B_{10}H_{11}$ (**6**) in moderate yield (52%). Deboronation of **6** to form the corresponding anionic *nido*-derivative, **2**, was easily accomplished with potassium hydroxide in hot ethanol (*33*), and the product was purified by recrystallization from benzene (Scheme 1). The ^{11}B NMR spectrum of **2** contained resonances at −33.1 ppm and −37.5 ppm, which unequivocally confirmed the presence of the anionic *nido*-carborane derivative.

Liposome Formation. Species **2** and DSPC have comparable structural features, the most obvious similarity being the dual alkyl chains comprising their lipophilic regions. Like **1**, the ionic *nido*-carborane moiety of **2** serves as a hydrophilic group. On the basis of these features and the previously published work regarding MAC-16 and DSPC/cholesterol bilayer formation (*4*, *9*, *18*), **2** and DSPC/cholesterol were expected to display similar liposome-forming properties.

An assortment of Type B liposomes, composed of DSPC, cholesterol, and **2** in varying proportions, was prepared by probe sonication of the components in PBS buffer. The resulting small unilamellar liposomes incorporating isotonic saline buffer all exhibited excellent stability and size distribution patterns. The volume-weighted mean vesicle diameters (m_v) ranged from 40 to 60 nm, with all vesicles in the size range of 20 to 100 nm. In addition, DSPC-free liposomes composed of equimolar quantities of **2** and cholesterol were also prepared. Interestingly, the absence of DSPC did not inhibit bilayer formation, and resulted in liposomes with a markedly increased boron concentration that were stable for several months at room temperature. DSPC-free liposomes incorporating **2** (**2**:cholesterol ratio of 1:1) consisted of 8.8% boron by weight in the dry lipid mixture, a nearly 4-fold increase in boron concentration over the previous report (*18*) of optimized liposomes incorporating **1**, which contained 2.5% boron by weight in the dry lipid component (**1**:DSPC:cholesterol in a ratio of 1:3:3).

log P[c]	1.282	1.069	1.673	1.623 (1.58) (*37*)

[a] The concentration of phosphorus in the solution was measured by ICP-AES. [b] μg of B/mL. [c] $\log P = \log([B_{octanol}]/[B_{water}])$.

Before conducting in vivo studies, the hydrophobicity of **2** was investigated in an attempt to determine the effect of the additional hydrocarbon chain on the liposome incorporation efficiency. The relative hydrophobicity of **2** was determined by measuring the partition coefficient (log P_{oct}) of **2** in a biphasic 1-octanol/water system (*34*, *35*) using inductively coupled plasma-atomic emission spectroscopy (ICP-AES). In 1998 Gulati outlined four classes of molecules, categorized by their solubility and hydrophobicity, and defined the characteristics of each group (*36*). In general, compounds with log $P_{oct} < -0.3$ are highly hydrophilic and are likely to be found in a liposome's aqueous core, while those with log $P_{oct} > 5$ are very hydrophobic and will be located almost exclusively in the lipid bilayer. Amphiphilic molecules, with log P_{oct} between 1.7 and 4, have lower bilayer incorporation efficiencies than lipophilic species, and they are more easily lost from the bilayer because their biphasic nature allows for rapid transfer between the lipid and aqueous phases.

The partition coefficients of **2**, **1**, DSPC, and phenylboronic acid were determined by measuring the concentration of boron or phosphorus present in each of the 1-octanol and water layers after equilibrium was reached. The previously studied phenylboronic acid (*37*) was included to validate the method when using ICP-AES boron analyses. As expected, the results (Table 1) indicated that **2** (log $P = 1.282$) was more hydrophobic than **1** (log $P = 1.069$), while less lipophilic than DSPC (log $P = 1.673$). Because of its increased hydrophobic character, lipids incorporating **2** are expected to do so with higher efficiency than lipids incorporating **1**.

After formation of the liposomes by sonication, the unincorporated DAC-16 was separated from the lipid mixture through centrifugal filtration with Centricon membranes. The incorporation efficiency for DSPC-free DAC-16 liposomes (1:1 ratio of **2**:cholesterol) was determined by ICP-AES analysis of the unincorporated DAC-16 in the filtrate and was found to be 98% for the DSPC-free liposomes, compared to the previously observed (*18*) average incorporation efficiency for **1** of 70% in the optimized formulation. This remarkably high incorporation efficiency indicates that, in the absence of DSPC, almost all of the DAC-16 carborane derivative is incorporated by the bilayer membrane of the liposomes.

Because of applications in drug delivery the long-term stability of liposomes is another important property for consid-

eration, the ideal liposomes must have a long shelf life throughout which structural integrity is maintained. The stability of liposomes incorporating **2** into DSPC/cholesterol vesicles was tested by storing two different samples for two months, one at room temperature and the other at 4 °C. The size distribution pattern of the two samples was monitored frequently throughout this time interval, with no obvious changes in vesicle diameters (m_v) observed during this period (Table 2).

Studies of 2 in Vivo. Liposomes formed from *nido*-carborane, **2**, have a much higher boron content than liposomes incorporating *nido*-carborane, **1**; the enhanced incorporation efficiency of **2** into lipid bilayers is likely due to the increased hydrophobicity of the DAC-16 lipid. The increased boron content resulting from incorporation of **2** could also affect the biological behavior of the consequent liposomes. The biodistribution studies of such liposomes, containing **2**, DSPC, and cholesterol in varied proportions, were performed at Washington State University using male BALB/c mice (about 10 g body weight) bearing small EMT-6 tumors. Typically 200 μL of each liposome suspension was injected into the tail vein, and the behavior of the mice was followed for up to 48 h. Unfortunately, in each case, the liposomes were found to be very toxic: no mouse survived longer than 48 h following injection of doses ranging from 6 to 30 mg of boron per kg of body weight. Since high potassium ion concentrations present in **2** could have been the cause of the observed toxicity, one liposome formulation contained the sodium salt of **2**, but these liposomes also proved to be lethal (Table 3). A control formulation, containing only DSPC and cholesterol, clearly proved that the toxicity was attributable to **2**, since mice injected with the control liposomes showed no adverse effects well past 48 h. Because of this result, further biodistribution tests were halted and no data were obtained on DAC-16 tumor boron concentration or tumor:blood ratio prior to animal death.

For evaluation purposes, this information was compared to previously unpublished biodistribution data (*38*) obtained for the free uncomplexed DAC-16 compound, performed under similar conditions as reported above for the lipidic DAC-16. These results indicated acceptable tumor boron uptake with good tumor:blood ratios early in the trial period. Tumor boron values steadily increased over the course of the study, reaching 4.8 μg of B per gram of tumor tissue 50 h postinjection with a tumor:blood ratio of greater than 3 upon injected dose of 61 μg of B. Though the free DAC-16 did not indicate the same degree of toxicity seen for the compound in the complexed lipidic-version, all BALB/c mice involved in the study were clearly affected and barely survived. Attempts to minimize this toxicity are under investigation. Although liposomes containing DAC-16 cannot be used as boron delivery vehicles for BNCT, the use of DAC-16 does provide a method of preparing liposomes of high boron content that may be suitable for other applications.

CONCLUSION

A new family of liposomes is reported here, assembled with DSPC, cholesterol, and a novel dual-chain *nido*-carborane amphiphilic lipid of high boron content, **2**. The resulting small liposomes exhibit satisfactory stability and size distribution with m_v in the range of 40−60 nm. Also, the new lipid component exhibited very high bilayer incorporation efficiency (98%) during liposome formation. A DSPC-free liposome was produced when using a lipid mixture containing only equimolar ratios of **2** and cholesterol. Because DSPC was not required, the boron content of the resulting liposomes is markedly increased compared to previously synthesized DSPC-containing liposomes (*9*, *18*). Although the animal studies showed liposomes derived from **2** to be too toxic for use in BNCT, these liposomes contain a new type of bilayer constituent of high boron content, and they may prove to be suitable for applications involving boron delivery in vitro.

ACKNOWLEDGMENT

This research was performed under the auspices of the Department of Energy (DOE) under contract DE-FG03-95ER61975 with the additional assistance of a grant-in-aid from U.S. Borax, Inc. Support for equipment was provided by the National Science Foundation under equipment grant numbers CHE-9974928 and CHE-0092036.

Generic Bioaffinity Silicone Surfaces

Hong Chen,[†,‡,§] Michael A. Brook,*[,‡] Heather D. Sheardown,*[,†] Yang Chen,[‡] and Bettina Klenkler[†]

Department of Chemical Engineering and Department of Chemistry, McMaster University, 1280 Main Street W., Hamilton ON Canada, L8S 4M1. Received June 18, 2005; Revised Manuscript Received October 17, 2005

Synthetic polymer surfaces require surface modification to improve biocompatibility. A generic route to biocompatible silicone elastomers is described involving high yield surface functionalization of standard silicones with hydrosilanes, hydrosilylation using asymmetric, allyl-, NSC-terminated PEO of narrow molecular weight, and covalent modification in one step with amine-containing biological molecules including oligopeptides (YIGSR, RGDS), proteins (EGF, albumin, fibrinogen, mucin), and glycosaminoglycans (heparin). Efficient, high-density binding (e.g., 0.2 EGF molecules/nm^2) was demonstrated using radiolabeling studies. The resulting surfaces were demonstrated to be biocompatible by further reaction with biomolecules, for example, thrombosis suppression on surfaces modified by heparin + ATIII, and the formation of confluent corneal epithelial cell layers on EGF, RGDS, or YIGSR surfaces.

INTRODUCTION

When synthetic biomaterials are implanted, they are met with a complex and aggressive biological system that ultimately passivates the material or creates a fibrotic capsule, essentially walling the material off from the system. Various synthetic strategies have made impressive inroads to the problems of preparing compatible biomaterials (*1*). One promising approach exploits the plasma polymerization of hydrophilic monomers such as alkylamines or tetraglyme onto an existing polymer surface (*2*−*4*). However, the most general and powerful methods (*5*) involve the formation of layers of hydrophilic polymers on the surface, of which oligo- (*6*−*8*) and poly(ethylene glycol) (*9*−*12*) are exemplary. The polymers either bloom from polymer blends to an aqueous interface or are covalently grafted onto an activated polymer surface (*13*, *14*). While promising, it is clear that more biocompatible surfaces can be produced when constituents of the local biology are harnessed to "bioactivate" or "biopassivate" the surface (*15*), either alone or in combination with hydrophilic polymers. Such approaches include modification with amino acids, cell adhesion peptides, proteins, and glycosaminoglycans. These materials have traditionally been tethered at multiple sites, reducing the mobility of the linking chain. The specific spacing of the tethered biomolecules from the polymer interface is not normally controllable.

Silicone polymers offer many advantages as biocompatible supports, including their very high oxygen transmissibility and the ease with which a variety of different substrates can be conformally coated using several chemically different cross-linking processes. Silicones suffer, however, from an extremely high surface hydrophobicity to which biomolecules readily adhere (*16*, *17*) generally resulting, in the case of proteins, in the subsequent mediation of biological reactions (*15*, *18*). Herein we describe the development of a flexible, narrow molecular weight range, asymmetric linker that provides a facile route to convert hydrophobic silicones into activated ester-terminated, PEO-modified surfaces. These surfaces react effectively with alcohols and particularly amines and thus serve as key intermediates in the preparation of saccharide-, amino acid-, peptide-, and nucleotide-modified surfaces. We report on the preparation of high density films on silicone of biomolecules including the cell adhesion peptides, RGDS and YIGSR, proteins (EGF, lysozyme, albumin, fibrinogen, and mucin), and the glycosaminoglycan heparin, to which ATIII was complexed. The resulting surfaces are thus tailored to be selectively repellent or adherent to biomolecules and, as a result, biocompatible in a variety of environments.

EXPERIMENTAL PROCEDURES

Reagents. Poly(ethylene glycol) monoallyl ether (average MW 500) was obtained as a gift from JuTian Chemical Co. (Nanjing, China). It was dried by azeotropic distillation with toluene before use. *N*,*N*′-Disuccinimidyl carbonate, *o*-xylene (97%, anhydrous), triethylamine (99%), acetonitrile (99%, anhydrous), Karstedt's Pt catalyst (2−3 wt % in xylene, $[(Pt)_2(H_2C{=}CH{-}SiMe_2OSiMe_2CH{=}CH_2)_3]$), 2-mercaptoethanol, and CF_3SO_3H were purchased from Aldrich Chemical Co. Sylgard 184 (a platinum cured silicone rubber $H_2C{=}CH{-}$silicone + HSi-silicone → silicone-CH_2CH_2Si-silicone) and DC1107 $(Me\text{-}HSiO)_n$ were purchased from Dow Corning (Midland, MI). Human serum albumin (HSA), Tyr-Ile-Gly-Ser-Arg (YIGSR), Arg-Gly-Asp-Ser (RGDS), and Sephadex G-25 columns were obtained from Sigma. Epidermal growth factor (EGF) was obtained from Research Diagnostics Incorporated. Fibrinogen was obtained from Enyzme Research Laboratories. Toluene was dried by refluxing over Na prior to distillation, and MeOH was dried by refluxing over Mg and was distilled before use.

Materials Characterization. ^{1}H and ^{13}C NMR spectra were recorded at 30 °C on a Bruker AC-200 spectrometer (at 200 and 50.3 MHz for ^{1}H and ^{13}C, respectively). Attenuated total reflection Fourier transform IR spectroscopy (ATR-FTIR) measurements were carried out on a Bruker VECTOR 22 Fourier transform infrared spectrometer (Bruker Instruments, Billerica, MA) equipped with a Harrick ATR accessory MUP with GeS crystal; 200 scans were collected for each sample. Electrospray mass spectra (ESI-MS) were recorded on a Micromass Quattro Ultima LC, triple quadruple MS.

Water Contact Angle. Advancing and receding sessile drop contact angles were measured on PEO-grafted surfaces using

Ramé Hart NRL C.A. goniometer (Mountain Lakes, NJ). Milli-Q water (18 MΩ/cm) was used with a drop volume of approximately 0.02 mL. Results are presented as an average of 18 measurements or more on at least three different surfaces. Contact angles were also measured using the captive bubble method, where an air bubble was injected from a syringe onto an inverted sample surface immersed into Milli-Q water. Results are presented as the average of at least 10 measurements on three different surfaces.

X-ray photoelectron spectroscopy (XPS) was performed at Surface Interface Ontario, University of Toronto, using a Leybold Max 200 X-ray photoelectron spectrometer with a MgK-α nonmonochromatic X-ray source.

Preparation of *N*-Succinimidyl Carbonate PEG-Grafted PDMS Surfaces. *Synthesis of* α*-Allyl-*ω*-*N*-succinimidyl Carbonate−Poly(ethylene glycol),* ***2.*** To a solution of poly(ethylene glycol) monoallyl ether (2.0 g, 4.0 mmol) and triethylamine (1.62 g, 16 mmol) in CH_3CN (10 mL) was added *N*,*N*′-disuccinimidyl carbonate (4.1 g, 16 mmol). The mixture was allowed to stir at room temperature over 10 h under N_2. After removal of the solvent in vacuo, the residue was dissolved in dry toluene (25 mL), and the solution was cooled to 0 °C. A pale brown precipitate was filtered off. The toluene was removed under reduced pressure. This procedure was repeated three times. The resultant compound **2** was a yellow oil (1.2 g, 60% yield). IR (neat): 1739 (N*C*═*O*), 1788 (O*C*═*O*). ^{1}H NMR (200.2 MHz, $CDCl_3$, Scheme 1, see also Suppporting Information): δ 2.78 (s, 4H, O═CCH_2CH_2C═O), 3.57 (bs, 40H, PEO's OCH_2), 3.72 (bs, 2H, OCH_2CH$_2$OC═O), 3.95 (d, 2H, J = 5.6 Hz, CH$_2$═CHCH_2O), 4.39 (m, 2H, OCH$_2$CH_2OC═O), 5.20 (m, 2H, CH_2═CHCH$_2$O), 5.82 (m, 1H, CH$_2$═C*H*CH$_2$O) ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ 25.2 (O═C*C*H$_2$*C*H$_2$C═O), 68.1 (O*C*H$_2$CH$_2$-OC═O), 69.2 (O═CO*C*H$_2$CH$_2$O), 70.4 (PEG's O*C*H$_2$), 72.0 (CH$_2$═CH*C*H$_2$O), 117.0 (*C*H$_2$═CHCH$_2$O), 134.5 (CH$_2$═*C*HCH$_2$O), 151.4 (O*C*═OO), 168.5 (N*C*═OCH$_2$) ppm. MS (ESI): m/z = 745.6 (M + NH_4^+, n = 12 100).

Elastomer Preparation. Silicone elastomers were prepared according to the procedure provided by Dow Corning. Sylgard 184 PDMS prepolymer and catalyst was mixed thoroughly with its cross-linker in a 10:1 ratio (w/w) in a plate mold and degassed under vacuum. Films were allowed to cure at room temperature for 48 h. After being cured, the silicone elastomer films were punched into disks, approximately 5 mm in diameter and 0.5 mm thick. The disks were washed with hexane and then dried under vacuum for further use.

Si−H Surface Functionalization 1. For Si−H functionalization of the surface, 20 silicone elastomer disks were immersed in a mixture of DC1107 (3 mL) and methanol (5 mL). To this was added F_3CSO_3H (0.02 mL, 0.26 mmol). After being stirred at room temperature for 30 min, the functionalized surfaces were rinsed with methanol and hexane and dried under vacuum (for surface characterization, see below).

Addition of PEG Derivative, 3. Si−H modified silicone surfaces **1** were incubated in a solution of 2-methoxyethyl ether solvent and **2** (80:20 wt %:wt %, 3 mL). Pt-catalyst (platinum-divinyltetramethyldisiloxane complex, 1 drop) was added, and the mixture was stirred for 15 h at room temperature. Following modification, the PEG-modified surfaces **3** were washed thoroughly with dry acetone and dried under vacuum.

Characterization of NSC and Modified Surfaces. *ATR-FTIR.* As described above, *N*,*N*′-disuccinimidyl carbonate was used to activate the hydroxy-terminal of α-allyl-ω-poly(ethylene glycol). The desired compound **2** was characterized by ^{1}H NMR, with the resonance of the CH_2CH_2 on the NHS (2.78 ppm) being particularly diagnostic. Two types of C═O groups were observed on the NSC-activated termini (O−C(O)−O and imide) by ^{13}C NMR (168.8 and 151.7 ppm, respectively). Assignments of the FT-IR spectrum of the NSC-activated PEO are shown in Figure 1. The band at 1739 cm^{-1}, representing the C═O stretch of the NHS group, can be further used to diagnose the succinimidyl carbonate PEG grafting process.

H−Si-functionalized silicone surfaces **1** were obtained by acid-catalyzed equilibration of a silicone elastomer in the presence of $(MeHSiO)_n$ as noted above. The ATR-FTIR spectra of the resulting surfaces exhibited a band at 2166 cm^{-1} due to the Si−H stretch.

Succinimidyl carbonate PEO **2** was grafted onto the silicone rubber surfaces via a hydrosilylation reaction with the H−Si groups. In the ATR-FTIR spectrum of the succinimidyl carbonate PEG-grafted surfaces **3**, the band at 2166 cm^{-1} due to H−Si

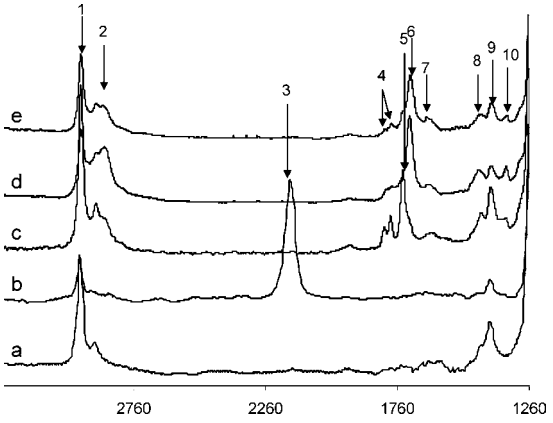

Figure 1. FT-IR spectra of (a) PDMS, (b) Si−H-modified PDMS, (c) succinimidyl carbonate PEO-modified PDMS surfaces **3**, (d) RGD-modified **4**, and (e) YIGSR-modified **5** PDMS surfaces, respectively.

Table 1. XPS Surface Analysis of Unmodified PDMS, Succinimidyl Carbonate PEO-Modified 3, RGDS−PEO-Modified 4, and YIGSR−PEO-Modified 5 PDMS Surfaces

elemental at. %	control PDMS	NSC−PEO **3**	RGDS−PEO **4**	YIGSR−PEO **5**
C1s	46	52.2	54.6	55.4
N1s	0	0.9	1.9	2.7
O1s	26.5	26.3	25.2	26.5
Si2p	27.4	20.6	18.4	15.5

was no longer visible following the reaction. There were two C═O stretches at 1741 and 1789 cm^{-1}, respectively, which were assigned to the C═O groups at the succinimidyl carbonate termini, and the O−C(O)−O linkage, which was also present in the starting material. The PEO CH_2 scissoring band at 1454 cm^{-1}, the antisymmetric stretch mode of the CH_2-O-CH_2 chain at 1351 cm^{-1}, and the symmetric stretch mode of the CH_2-O-CH_2 chain at 1258 cm^{-1} indicated the presence of PEO chains on the resulting surface.

XPS. NSC−PEO binding to the surface **3** was further confirmed by the presence of an N1s signal in the XPS survey scan due to the amine groups in the NSC−PEO polymer (Table 1, see Supporting Information). The C1s high-resolution spectrum shows a distinct peak at 286.4 eV which corresponds to the C−C−O bond in PEO repeat unit.

Conjugation of Various Molecules to the NSC-Modified Surface. *Peptide Conjugation.* The covalent conjugation of peptides to the functionalized surfaces was carried out in a phosphate-buffered saline (PBS) buffer solution (pH 7.5). The *N*-succinimidyl carbonate PEG-grafted surfaces **3** were immersed in PBS buffer containing the peptide RGDS or YIGSR, (10 μg/mL) for 12 h to give **4** or **5**, respectively.

Washing Protocol. All samples were rinsed three times with PBS for 10 min, for a total of 30 min, and the surfaces were dried under vacuum. For radioactive samples, residual adherent buffer was removed by wicking onto filter paper and transferred to clean tubes, and the surface radioactivity was determined by counting using a gamma counter. Radioactivity counts were converted to surface protein concentrations. One milliliter of a 2% sodium dodecyl sulfate (SDS) solution was then added to each tube and left at room temperature for 4 h and overnight at 4 °C. After three PBS rinses, the surfaces were transferred to clean tubes and radioactivity was measured to determine the levels of the protein remaining after the SDS treatment, which indicated that the growth factor was covalently immobilized to the surface (Table 2).

Characterization. The IR spectra of modified surfaces **3**−**5**, respectively, are presented in Figure 1 (see also Supporting Information). Distinct bands at 1652 and 1656 cm^{-1} due to amides were observed on both the RGDS- and YIGSR-modified surfaces: the C═O stretch mode at 1741 cm^{-1}, due to the NHS group, disappeared in both cases following modification. These spectral changes indicated the coupling of the succinimidyl carbonate PEG to the peptides. Peptide immobilization was further demonstrated by an increase in the XPS N1s signal to 1.9 and 2.7% for RGDS and YIGSR, respectively, due to the amine groups in the peptides and a decrease in the Si2p signal (Table 1, see Supporting Information). Note that the starting succinimidyl carbonate PEO-modified PDMS **3** showed a very weak nitrogen peak due to the presence of a single nitrogen in NHS. The nitrogen intensity, postmodification, was much higher.

EGF Conjugation 6. EGF was first labeled with ^{125}I (ICN Pharmaceuticals, Irvine CA) using the iodogen method. The *N*-succinimidyl carbonate PEG-grafted surface **3** was immersed in a PBS buffer (pH 7.4) containing radiolabeled EGF (10 μg/mL) for 2 and 24 h and rinsed three times with PBS for 10 min each (Table 2).

Human Serum Albumin Conjugation 7. Human serum albumin was labeled with ^{125}I (ICN Pharmaceuticals, Irvine CA) using the ICl method. The labeled protein was passed through an AG 1-X4 column (Bio-Rad Laboratories, Hercules, CA) to remove any free iodide. For measurement of nonspecific adsorption of protein from buffer and covalent coupling of albumin to the surfaces, a mixture of labeled and unlabeled protein (1:20) at a total concentration of 1 mg/mL was prepared. NSC−PEO-modified surfaces **3** were incubated with albumin for 2 h at room temperature, rinsed three times with PBS for 10 min, (250 μL per rinse per disk, 30 min total).

The modification of surfaces by albumin, via adsorption or covalent grafting, is shown in Figure 3B. Figure 3D also shows the results of fibrinogen adsorption on the albumin pretreated surfaces.

Fibrinogen Adsorption 11. Fibrinogen was labeled with ^{131}I (ICN Pharmaceuticals, Irvine CA) using the ICl method. The labeled protein was passed through an AG 1-X4 column (Bio-Rad Laboratories, Hercules, CA) to remove any free iodide. The untreated control (PDMS elastomer) surface, ^{125}I-albumin-pretreated control surface, and ^{125}I-albumin-pretreated NSC−PEG-modified surfaces **7** were incubated in PBS solution containing the radiolabeled fibrinogen at a concentration of 1

mg/mL for 2 h. The fibrinogen amounts on various surfaces were determined radioactively as described above (Figure 3D).

Conjugation of Mucin 8. NSC surfaces **3** were incubated in 5 mg/mL solution of mucin from bovine (submaxillary glands, Type I-S, Sigma) in PBS buffer (pH = 8.0) for 6 h. Surfaces were subsequently rinsed three times with fresh PBS.

Conjugation of Lysozyme 9, 12. Lysozyme adsorption and conjugation to various surfaces was carried out in a phosphate-buffered saline (PBS, pH 7.4). Lysozyme was labeled with ^{125}I (ICN Pharmaceuticals, Irvine CA) using the ICl method. The *N*-succinimidyl carbonate PEG-grafted surface **3**, PEG350-grafted surface, mucin-modified surface **8**, and control surface, respectively, were immersed in a PBS buffer (pH 7.4) containing (unlabeled:radiolabeled = 9:1) lysozyme (1 mg/mL) for 3 h and rinsed three times with PBS (Table 2).

Heparin Conjugation 10. NSC surfaces **3** were incubated in 10 mg/mL solution of heparin (Sigma Aldrich) in PBS buffer (pH = 8.0) for 6 h. Surfaces were subsequently rinsed three times with fresh PBS. The density of heparin on the NSC surface **10** was 0.68 μg/cm^2, as shown by a toludine blue assay (see next section).

For the assay, a series of heparin standard solutions with concentrations varying from 0 to 20 μg/mL were prepared by diluting a stock solution. The stock solution was obtained by dissolving 10 mg heparin in an aqueous 0.2 wt % NaCl solution.

Toluidine blue (Sigma-Aldrich Canada, 50 mg) was dissolved in HCl (1 mL, 0.01 N solution), in which 0.2 wt % NaCl had been previously added and dissolved. The 50 mg/mL toluidine blue solution was diluted with deionized water to give a 0.005 mg/mL (0.0005%) solution. The solution (1.0 mL) was added to a 5 mL tube, followed by 0.1 mL of the above heparin 10 mg/mL standard solution. The mixed solution was vortexed for 30 s. *n*-Hexane (Aldrich-Sigma Canada, 1 mL) was added, and the solution was vigorously mixed for 30 s and then allowed to separate into two phases over 5 min. The heparin−toluidine blue complex was extracted into the upper transparent organic layer. After the organic layer was removed, the absorbance of the aqueous layer at 631 nm was measured on a Beckman DU640UV/VIS spectrophotometer. A linear standard calibration curve was obtained by plotting absorbance at 631 nm versus concentration of heparin in the aqueous NaCl solution. The amount of heparin immobilized on the polymer surfaces was determined using this calibration curve.

Prior to testing, polymer samples were incubated in 0.05 M Tris-buffered saline (TBS) with pH 7.4 at room-temperature overnight to hydrate the surfaces. For each experiment, 0.1 mL of 0.2% NaCl solution and 1.0 mL of 0.005 mg/mL (0.0005%) toluidine blue solution were mixed in a 5 mL polypropylene test tube. The heparin-modified (polymer) surfaces **10** (0.77 cm^2

area) were immersed in the solution, which was vortexed for 30 s. Then, 1 mL *n*-hexane was added and shaken well. The mixture was allowed to phase-separate for 5 min after removal of the surfaces. As above, the upper organic layer was removed and the absorbance of the aqueous layer at 631 nm was investigated on a Beckman DU640 UV/vis spectrophotometer. The density of total heparin immobilized on the surfaces was calculated from the above calibration curve. For each surface, the heparin density was expressed by mass per unit surface area (μg/cm^2).

Thromboresistant Properties. Platelin was obtained from Organon Teknila Corp., Durham, NC (No. 35501). TBS/Ca^{2+}/Platelin (0.1 M $CaCl_2$ with a 1:10 dilution of platelin) buffer solution was made by dissolving $CaCl_2$ (1.11 g) and four standard vials of Platelin in 10 mL of Milli-Q water (10 mL). The volume was then brought to 100 mL with TBS (0.05 M, pH = 7.4). Thrombin substrate *N*-*p*-tosyl-gly-pro-arg *p*-nitroanilide (Sigma-Aldrich) (5 mg) was dissolved in TBS (10 mL) to give a solution with a final concentration of 0.5 mg/mL.

To passivate the walls of the 96-well microtitration plate, the wells were exposed to human serum albumin in TBS (10 mg/mL) overnight at 4 °C. The albumin solution was then withdrawn from the wells, and the wells were aspirated and washed three times with fresh TBS (0.3 mL/well/time) before adding the unmodified and heparin-modified silicone surfaces. The heparin-modified surface **10** was incubated in antithrombin III in TBS buffer solution (0.25 mg/mL) for 30 min before testing.

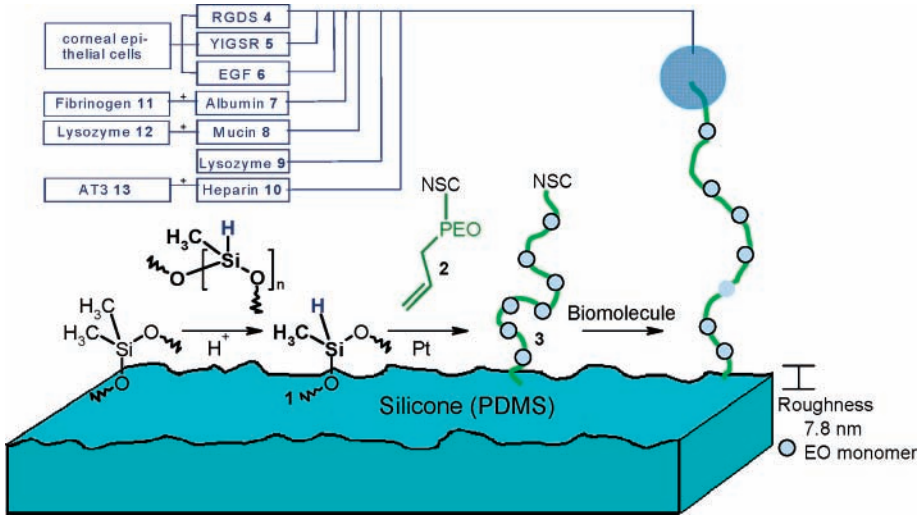
The disks were placed vertically in the wells, and 10% diluted pooled human citrated plasma (200 μL) was added to the wells. After the plate was warmed to 37 °C, TBS/Ca^{2+}/platelin buffer solution (20 μL) and thrombin substrate (30 μL of 0.5 mg/mL) were added. The release of *p*-nitroaniline by thrombin was measured as a function of time by recording the optical density at 405 nm and 37 °C using a UV−vis plate reader (Figure 4).

Cell Culture on Peptide-Modified-Surfaces. Surfaces (~5 mm disks) **4** or **5** as well as controls were washed three times with PBS supplemented with antibiotics (penicillin, streptomycin, and gentamycin) and subsequently stored overnight at 4 °C in Keratinocyte Serum Free Medium (KSFM, Invitrogen, Grand Island, NY) medium containing antibiotics. Under sterile conditions, the surfaces were transferred to a 24-well plate and plated with human corneal epithelial cells (HCECs, 10^4 cells per well) in KSFM supplemented with penicillin, streptomycin, gentamycin, and EGF. Surfaces **6** were cultured under identical conditions except the cells were grown in medium only; no exogenous EGF or antibiotics were added. The cells were cultured at 37 °C in a 5% CO_2 atmosphere. Samples were imaged regularly. All images were taken at 100× magnification (Figure 5). Epithelial cell morphology was confirmed by AE5 staining.

RESULTS

Unlike most polymers, silicones can be readily formed and degraded under thermodynamic control (*19*). Thus, treatment of monomers and/or polymers with endcapping molecules in the presence of acid or base allows the preparation of homo- or copolymers of various molecular weights. By carefully controlling the swelling conditions using relatively poor solvents for silicone, such as methanol, it was possible to preferentially introduce Si−H functional groups at the surfaces of a variety of pre-cured silicone elastomer by a redistribution polymerization with triflic acid (*20*), giving **1**, as shown by the characteristic strong IR absorption at 2166 cm^{-1} (Scheme 1, Figure 1, see also Supporting Information). The Si−H group underwent efficient hydrosilylation with a series of olefins, including allyl-PEO (*13*, *14*) and, more importantly, allyl-PEO−NSC **2**, prepared by the reaction of allyl-PEO-OH with bis-*N*-hydroxysuccinimidyl carbonate to give a high density, reactive NSC

Scheme 2: Generic Route to Biomolecule Attachment to Silicone Surfaces



surface **3**. Surface properties (ATR-IR, Figure 1, Table 1, XPS, see also Suporting Information) were determined using traditional methods. It should be noted that, unlike model systems prepared on flat gold films (*21*), these functional surfaces can be prepared from any dimethylsilicone elastomer, and on objects with both simple and complex shapes.

Surface **3** was modified, in phosphate-buffered saline (PBS) solutions (pH = 8.0), with a series of peptides and proteins, respectively, including the cell adhesion peptides Arg-Gly-Asp-Ser **4** (RGDS)and Tyr-Ile-Gly-Ser-Arg **5** (YIGSR), epidermal growth factor **6** (EGF), human serum albumin **7** (HSA), mucin **8**, lysozyme **9**, and the glycosaminoglycan heparin **10**. Selected modified surfaces were further exposed to additional proteins. Thus, the HSA surface **7** was modified with fibrinogen **11**, a mucin-modified surface **8** was treated with lysozyme **12**, and heparin surface **10** was exposed to antithrombin III **13** (Scheme 2).

The biologically modified silicones were characterized by IR, XPS, and contact angle (Figure 1, Figure 2, Table 1, see also Supporting Information). The total quantities of the surface linked and adsorbed peptides or proteins were determined by radioactivity assays before and after exhaustively washing the modified surface with sodium dodecyl sulfate (SDS) (Table 2). This method also provided a minimum estimate of the total graft density of the surface. For example, after 24 h of reaction of surface **3** with EGF, the resulting surface **6** exhibited a surface concentration of 190 ng/cm^2 (ca. 0.2 EGF molecules/nm^2): after washing with SDS, the control surface showed only 26 ng/cm^2 while the EGF-*g*-PEO surface was essentially unchanged (Figure 3A). The smaller molecule YIGSR was found at a surface concentration of 19 ng/cm^2, also about 0.2 molecules/nm^2. Larger molecules, such as lysozyme (MW ca. 14400), also efficiently grafted, 402 ng/cm^2 (0.15 molecules/nm^2), to the surface to give **9** after extensive washing with SDS. Similarly, heparin bound to the surface **10** with a graft density of 0.68 μg/cm^2 (see below).

The silicone surfaces are not molecularly flat, and thus it is not possible make direct comparison of EO surface packing on these silicones with model systems, such as planar self-assembled monolayer-modified gold surfaces (*21*). The cross-sectional area of an anhydrous EO oligomer when coiled in a helix is on the order of 0.2 nm^2. Thus, an ideal PEO brush, rarely achieved with the exception of self-assembled monolayers on noble metal surfaces (*9*), could pack about 20−25 anhydrous EO chains/nm^2 (*22*). Water-swollen PEO chains occupy significantly more space (*23*). We did not directly assess the packing density of PEO on these surfaces. . However, as noted above, approximately 0.2 molecules/nm^2 of peptides and EGF, and 0.15 molecules/nm^2 of the larger lysozyme, were bound to the surface, surface densities which approach a monolayer (the diameter of lysozyme is approximately 3.0 nm (*24*)). These molecules cast a larger shadow on the surface than a PEO helix, and therefore efficiency of surface binding is more dependent on the size of the biomolecules to be tethered than on the PEO density: multiple attachments to the surface are anticipated. We note that the ability to tether biomolecules in high density in active form to rough, instead of smooth model, surfaces is a major advantage of the method: any silicone surface can be functionalized.

Albumin, the most abundant protein in blood, can be used to passivate implanted synthetic surfaces (*25*). Less protein was initially found on the NSC-modified surface **7** than on the control (0.22 vs 0.18 μg/cm^2, Figure 3B). However, the control surface was mostly washed free of the ^{125}I-labeled protein with SDS (0.05 μg/cm^2 remained), while more than 90%, 0.17 μg/cm^2, remained on the functionalized surface. These data are consistent with initial, patchy, protein physisorption that changed to chemisorption **7** before the protein could migrate across the NSC surface to form a coherent monolayer. That is, the albumin binds on contact, leaving a noncoherent film and accessible interstitial areas. Attempts to form a coherent albumin film prior to covalent linkage, by controlling the rate of surface binding, have not so far been successful.

The ability to displace the albumin by ^{131}I-labeled fibrinogen, from control and **7** surfaces, respectively, was examined. Fibrinogen adsorbed effectively to the control surface (0.58 μg/cm^2). However, much less fibrinogen was able to contact and bind to the albumin adsorbed surface (0.20 μg/cm^2), and even less was found on the albumin-passivated NSC surface **11**, Figure 3D (0.045 μg/cm^2). This is consistent with a control surface in which albumin can be "nudged aside" by fibrinogen, but a covalently linked surface **7** in which only a few interstitial spaces are sufficiently large to accommodate the large fibrinogen molecule (340 kD) giving **11**.

Lysozyme, one of the proteins responsible for ophthalmic disinfection, was exposed to a variety of modified silicones. Significantly more lysozyme was adsorbed to the pregrafted mucin **8** (post SDS, 423 ng/cm^2) and NSC surfaces **3** (post SDS, 402 ng/cm^2) than to the control silicone (post SDS, 42 ng/cm^2) or simple methoxy PEO-modified (post SDS, 0.3 ng/cm^2) silicone surfaces (Figure 3C) (*13*, *26*, *27*). The natural surface with which lysozyme interacts in the eye is mucin (*28*). Thus, this modified polymer may prove useful as a model system to examine surface fouling by lysozyme in ophthalmic applications.

Heparin, a highly sulfonated, anionic polysaccharide that is a well-known antithrombotic agent was analogously grafted to the surface **3** in high density (0.68 μg/cm^2) giving **10**. The surface was subsequently exposed to thrombin, via the interaction of $CaCl_2$ with plasma, in the presence of the chromogenic substrate *N*-*p*-tosyl-gly pro-arg *p*-nitroanilide. Release of the *p*-nitroaniline hydrolysis product was followed over 3 h (Figure 4A). Although nitroaniline was formed in the presence of **10**, it did so at a significantly lower rate and with a significantly longer half-life than observed with plasma alone, or in the presence of the control silicone surface or the NSC−PEO-modified surface **3**. The heparinized surface was demonstrably less thrombogenic than the other surfaces examined and was comparable to those previously described (*29*). Also of interest was the observation that antithrombin III (ATIII) covalently linked to the heparin surface **10**, giving **13**, was far more efficient at inhibiting thrombin than ATIII directly bound to the surface (after reaction with **3**, Figure 4B).

The most important criterion for any biomedical surface is the degree to which it is accepted by the local biological environment. To test the hypothesis that cell-compatible surfaces could be prepared using this method, human corneal epithelial cells (HCEC) were cultured on NSC surfaces modified with the cell adhesion peptides RGDS and YIGSR, **4** and **5**, respectively, under serum-free conditions as well as on surfaces modified with EGF cultured under serum-free and exogenous EGF-free conditions. In this case, unlike other studies in which various proteins including EGF and a bovine pituitary extract are added back to the medium, potential exogenous stimulatory effects of adsorbed and soluble proteins in the medium were eliminated. As shown in Figure 5C,D, cells readily adhere to, spread, and mitose on the peptide-modified surfaces **4** and **5**, respectively, to give confluent monolayers in less than 96 h. Significantly lower levels of confluence were observed on both the control and on the PEO-modified silicone surfaces (*13*), respectively (Figure 5A,B; see also Supporting Information).

The lack of cell adhesion on the PEO-modified surfaces in particular is not surprising given that PEO has been widely described as cell and protein repellent. In fact, under conditions where there were no exogenous factors present in the medium, the surfaces were completely cell-free after 5 days of culture. Confluent epithelial cell monolayers could be formed on the EGF-modified surfaces **8** as rapidly in as rapidly as 5 days, demonstrating that the tethered EGF was active and able to stimulate the production of extracellular matrix proteins (Figure 5E, see also Supporting Information).

DISCUSSION

The NSC group, related to NHS esters, has become one of the 'workhorse' functional groups for the attachment of biological molecules to various supports because it is mild and selective for amines over alcohols, and it reacts with both groups faster than with water (*30*). PEO is a polymer widely exploited by the biomaterials community because of the water-swollen layer it forms that is known, particularly in in vitro assays, to passivate surfaces from adsorption by various biomolecules (*8*). We chose to combine these two elements in the development of our generic surfaces **3**. In this regard, we have borrowed from a key finding of Castner, who described the use of polyfunctional silanes, including NHS groups, for the preparation of well-defined gold surfaces on to which protein absorption could be studied (*21*). The preparation of NHS surfaces as self-assembled monolayers on gold surfaces are excellent model systems. However, these surfaces are not readily adaptable to complex devices themselves or to coatings on devices composed of other polymers.

There are important distinctions between this work and previous reports. First, an advantage of this method is that any silicone elastomer will suffice for the biological surface modification described. Thus, one can exploit the ability of silicone materials to form complex shapes, for example, in various molding applications, or their ability to form conformal films on a variety of substrates.

Second, a network is not formed on the surface. Instead, a series of monofunctional PEO chains, of approximately the same length (dependent on the original PEO polydispersity), are grafted onto a silicone. That is, the NSC functional PEO chains act as a brush to which biological molecules can covalently adhere. The concentration of these groups is enhanced by the absence of water in the brush-forming process, such that PEO swelling is reduced (*9*). These monofunctional species provide a more predictable distribution of functional groups along the surface than can a network system and, of course, the functional groups are only arrayed across the surface XY plane.

The generic utility of these modified silicone surfaces **3** to create biologically modified surfaces is amply demonstrated by the wide variety of biomolecules that can be readily grafted to them, in high density (ca.0.1−0.2 molecules/nm^2), to give **6**−**10**, and the maintenance of the bioreactivity of the tethered molecules after modification (**11**−**13**), which can make the surface compatible and/or render it usefully bioactive.

A simple two-step synthetic process, hydrosilylation of NSC−PEO onto a Si−H functional silicone and reaction of the NSC group with a biomolecule, permits generic modification of silicone substrates or conformal silicone coatings. The density of groups can be varied as can the nature of groups to facilitate rejection or attraction of available biomolecules. Proteins including enzymes, peptides, or polysaccharides are readily attached in stable form to give biocompatible, PEO-stabilized surfaces.

Synthesis and Evaluation of Novel Dendrimers with a Hydrophilic Interior as Nanocarriers for Drug Delivery

Renu Singh Dhanikula and Patrice Hildgen*

Faculty of Pharmacy, University of Montreal, Montreal, Québec, Canada, H3C 3J7. Received June 27, 2005; Revised Manuscript Received August 9, 2005

Novel polyester-*co*-polyether dendrimers consisting of a hydrophilic core were synthesized by a combination of convergent and divergent syntheses. The core was synthesized from biocompatible moieties, butanetetracarboxylic acid and aspartic acid, and the dendrons from PEO (poly(ethylene oxide)), dihydroxybenzoic acid or gallic acid, and PEG monomethacrylate. The dendrimers, Den-1-(G 2) (second generation dendrimer-1) and Den-2-(G 2) (second generation dendrimer-2) consisting of 16 and 24 allyl surface groups, respectively, were obtained by coupling the dendrons to the core. The dendrimer (Den-1-(G 2)-OH) with hydroxyl groups at the surface was synthesized by oxidation of the allyl functional groups of Den-1-(G 2), which was divergently coupled to the dendrons to obtain the third generation dendrimer Den-1-(G 3) consisting of 32 surface groups. The modifications in surface groups and generation of dendrimers were shown to influence the shape of dendrimers in the AFM studies. The aggregation as well as self-assembly of dendrimers was observed at high concentration in water by light scattering studies; however, it was reduced on dilution and in the presence of sodium chloride. Dendrimers demonstrated good ability to encapsulate the guest molecule, with loading of 15.80 and 6.47% w/w for rhodamine and β-carotene, respectively. UV spectroscopy proved the absence of any $\pi-\pi$ complexation between the dendrimer and encapsulated compounds. ^{1}H NMR and FTIR studies showed that the physical entrapment and/or hydrogen bonding by PEO in the interior and branch of the dendrimer are the mechanisms of encapsulation. The release of the encapsulated compounds was found to be slow and sustained, suggesting that these dendrimers can serve as potential drug delivery vehicles.

INTRODUCTION

The discovery and development of new and potent drug molecules is time-consuming and a costly process. It is estimated that every new drug takes 12 to 15 years to develop, at an approximate cost of $800 million (*1*, *2*). A more economical and viable strategy is to devise effective delivery systems for drugs that have failed to provide optimum therapeutic benefit. It is stated that controlled release of drug at specific target can significantly improve the effectiveness of a drug and thereby increase the therapeutic benefit (*3*). The two most common delivery systems that have been explored for this purpose are liposomal and polymeric systems. The poor stability of liposome-based delivery systems has limited their applicability and market potential. On the other hand, polymeric systems remain one of the most widely sought delivery vehicles by virtue of their high stability. Furthermore, advances in the polymer chemistry have constantly provided avenues to the drug delivery scientists to explore these polymeric architectures for providing more efficient drug delivery. Various categories of polymeric materials that have been discovered in the past century include linear, cross-linked, branched, and dendritic polymers (*4*). Among these polymeric scaffolds, dendrimers have well defined nanoscopic dimensions, with highly branched structure and a discrete number of end functional groups. These characteristics endow them with many intriguing properties such as globular shape (resembling proteins), monodisperse size, and presence of internal cavities. By virtue of these properties, evaluation and application of dendrimers in drug delivery is becoming one of the most lucrative areas of drug research.

Dendrimers can be used to deliver drugs either by encapsulating the drug in an internal cavity or by conjugating it to surface functionalities *(5)*. Since the conjugation of drugs to polymers is a time-consuming process and could sometimes result in decreased therapeutic benefit (due to failure of conversion to parent drug or decreased permeability of the conjugate) (*6*, *7*), the encapsulation of the drug by dendrimers seems to be the more attractive approach. Recent studies have shown that they can act as potential carriers for small guest molecules (*8*−*11*). However, the biocompatibility and cytotoxicity of these polymers are the major concerns for drug delivery application. The most widely used dendrimers, such as PAMAM, poly(propylene imine) and poly(aryl ether) dendrimers, are rendered cytotoxic by virtue of the presence of aromatic rings or amino groups at the periphery. The covalent attachment of poly(ethylene glycol) (PEG) to the PAMAM dendrimers has shown to reduce the cytotoxicity (*12*). PEGylation of dendrimers can also significantly reduce immunogenecity and antigenecity by shielding the system from recognition by the defense mechanism of the body. It also prevents sequestration and uptake by reticuloendothelial system (*13*) and thereby prolongs circulation time in the body. Another major concern on application of these dendrimers to drug delivery is the presence of amidoamine and ether linkages that are inherently resistant to degradation and hence limits their biodegradability. Incorporation of hydrolyzable linkages such as the ester bond is of particular interest to increase biodegradability of these delivery vehicles (*14*).

It is a rationale in drug delivery that the presence of a hydrophobic core is essential for encapsulating hydrophobic drug molecules, and, in general, polymeric micelles are tailored based on this concept. However, recently Ooya et al. synthesized polyglycerol dendritic polymers and reported a 3-fold increase in the water solubility of paclitaxel (*10*). Due to the absence of

Published on Web 11/30/2005

the hydrophobic region in the dendrimer, hydrotropic solubilization was proposed to be the probable mechanism of solubilization of paclitaxel. PEG is a biocompatible polymer, utilized as a *cosolvent* or hydrotropic agent (*15*) to enhance the solubility of poorly water soluble drugs (*16*). There are a number of reports in the literature on the use of PEG grafts of various dendrimers to increase the encapsulation of drugs (*8, 17*−*19*). It is also reported that PEG 400 increases the aqueous solubility of β-estradiol by 4- to 5-fold at high concentrations (*20*). On the basis of these observations, we hypothesized that introduction of poly(ethylene oxide) (PEO) in the cavity of the dendrimer will not only increase the size of the cavity but also will provide the dendrimers ability to encapsulate both water soluble and poorly water soluble compounds, in contrast to drug carriers with a hydrophobic core, which preferentially encapsulate hydrophobic compounds. Thus, we devised a new approach to enhance the solubility of compounds as well as the encapsulation of drugs by using PEO in the dendrimer cavity.

The aim of this study was to synthesize dendritic nanocarriers with a hydrophilic interior/cavity composed of PEO as drug delivery vehicles. Dendrimers were synthesized using butanetetracarboxylic acid as core molecule and composed of allyl or hydroxyl groups as surface functionalities. The synthesized dendrimers were characterized for their chemical and physical properties. Their ability to act as drug carrier was evaluated by encapsulating rhodamine and β-carotene as model hydrophilic and hydrophobic compounds, respectively. Further, the mechanism of encapsulation of compounds by dendrimers was also studied.

EXPERIMENTAL SECTION

Materials. Rhodamine, β-carotene, 1,2,3,4 butanetetracarboxylic acid, L-aspartic acid, PEG (M_n 400), PEG monomethacrylate (M_n 360), 3,5-dihydroxybenzoic acid (DHBA), 4-(dimethylamino)pyridine (DMAP), 1-ethyl-3-[3-(dimethylamino)-propyl]carbodiimide hydrochloride (EDC), gallic acid, hydroxybenztriazole (HOBT), borane−tetrahydrofuran complex (BH_3−THF, IM), *p*-toluenesulfonic acid monohydrate (TsOH), chromium trioxide (CrO_3), hydrogen peroxide (H_2O_2), triethylamine, sodium chloride, sodium hydroxide (NaOH), urea, activated carbon 4−14 mesh granular, and filter aid Celite521 were purchased from Sigma-Aldrich Inc., (St. Louis, MO). Anhydrous pyridine, *N*,*N*-dimethylformamide (DMF), dimethyl sulfoxide-d_6 (99.9% D) (DMSO-d_6), and $CDCl_3$ (99.9% D) were supplied from Aldrich Chemicals Inc. (Milwaukee, WI). Acetone, dichloromethane, methanol, chloroform, anhydrous diethyl ether, tetrahydrofuran (THF), sulfuric acid, and silica gel (70−230) were purchased from Laboratoire Mat. (Montreal, Québec), and thionyl chloride was purchased from A & C Chemicals Ltd. (Montreal, Québec). THF was dried over sodium while dichloromethane was dried with molecular sieves; all other solvents were used without purification unless specified otherwise.

Characterization Techniques. ^{1}H NMR and ^{13}C NMR spectra were recorded with Bruker ARX400 NMR spectrometer (Bruker Biospin, Billerica, MA) at 400 MHz using tetramethylsilane (TMS) as internal reference. FTIR spectroscopy was performed using a Bruker vector 22 spectrometer (Bruker Optik GmbH, Ettlingen, Germany), and the matrix-associated laser desorption ionization-time-of-flight (MALDI-TOF) mass spectroscopy of dendrimers was performed on a Bruker Autoflex (Bruker Daltonik GmbH, Bremen, Germany) in linear, positive ion mode using dithranol as matrix and sodium iodide as cationizing agent. The molecular weights of dendrimers were also determined by gel permeation chromatography (GPC) with Waters system (Waters, Milford, MA) equipped with refractive index detector, using DMF as mobile phase at a flow rate of 1 mL/min.

Synthesis of Core (3). Butane-1,2,3,4-tetracarboxylic acid (**1**) (5.00 g, 0.021 mol) was dried under vacuum for 24 h. Thionyl chloride (5 mL) was added dropwise to the reactant over a period of 15 min, followed by reflux at 50 °C for 6 h under nitrogen atmosphere. Subsequently, thionyl chloride was removed by evaporation under reduced pressure, and the product was dried under vacuum for 48 h to obtain compound **2**.

L-Aspartic acid (7.71 g, 0.058 mol) was added to compound **2** (4.50 g, 0.0144 mol), and the flask was purged with nitrogen for 15 min to displace any moisture. Anhydrous pyridine (20 mL) was added dropwise at room temperature under nitrogen atmosphere. The above solution was refluxed at 60 °C for 12 h. Pyridine was evaporated by rotavaporation, and the white product obtained was purified by column chromatography using dichloromethane:acetone:water (1:2:0.5). The solvents were evaporated under reduced pressure, and product obtained was dried under vacuum for 48 h. Yield: 90%; ^{1}H NMR (δ, ppm, D_2O): 5.52 (q, 4H, C*H*NH), 4.93 (d, 2H, N*H*CO), 4.91 (d, 2H, N*H*CO), 3.92 (q, 2H, C*H*CO), 3.30 (d, 8H, CH_2COOH), 2.85 (d, 4H, CH_2CO); ^{13}C NMR (δ, ppm, D_2O): 174.94, 174.11, 173.44, 42.83, 34.15, 33.87, 14.75; Anal. calculated (%): C (41.51), H (4.35), N (8.07); observed (%): C (41.53), H (4.80), N (8.65).

Synthesis of Poly(oxyethylene) (POE) Monomethacrylate Carboxylic Acid (4). PEG monomethacrylate (20 g, 0.055 mol) was dissolved in 200 mL of acetone at room temperature. The solution was cooled to 0 °C by placing the flask in ice bath. Later, 9 mL of Jones reagent (containing 0.02 M CrO_3) was added dropwise over a period of 15 min. The flask was removed from ice bath after 30 min, and the reaction was allowed to occur at room temperature for 18 h. The reaction was quenched by adding 5 mL of isopropyl alcohol. Subsequently, 2 g of finely powdered activated carbon (10% w/w) was added and stirred for 2 h. This was filtered over wet Celite, and the filtrate was evaporated on a rotavapor. The viscous liquid obtained was dissolved in water and extracted with dichloromethane, and the extracts were combined and evaporated to obtain the product which was dried under vacuum for 48 h. Yield: 95%; ^{1}H NMR (δ, ppm, DMSO): 6.02 (s, 1H, trans CH_2═CH), 5.64 (s, 1H, cis CH_2═CH), 4.18 (t, 2H, CH_2), 3.62 (t, 2H, CH_2), 3.46 (m, 24H, OCH_2CH_2O), 1.83 (s, 3H, CH_3); ^{13}C NMR (δ, ppm, DMSO): 167.15, 159.40, 73.45, 70.80, 69.28, 64.70, 61.70, 18.18. Anal. calculated (%): C (51.66), H (8.39); observed (%): C (51.65), H (8.88). FTIR (neat) ν_{max} cm^{-1}: 2883, 1753, 1467, 1358, 1279, 1239, 1145, 1101, 1062, 967, 842, 528.

Synthesis of POE−DHBA (6). Compound **4** (11.00 g, 0.029 mol) was purged with nitrogen for approximately 15 min, and thionyl chloride was added dropwise at room temperature. It was then refluxed at 50 °C for 7 h. Thionyl chloride was evaporated under reduced pressure, and the viscous liquid obtained was dried under vacuum to obtain compound **5**.

Compound **5** (11.00 g, 0.028 mol) was dissolved in pyridine under nitrogen atmosphere, and to this solution was added DHBA (1.96 g, 0.0127 mol). Reactants were refluxed at 50 °C for 18 h. Thereafter, pyridine was evaporated by rotavaporation and product was precipitated in diethyl ether. It was further purified by gel chromatography (Sepharose CL-4B) using water at pH 7.4 as eluent. The product was recovered as a viscous liquid by freeze-drying. Yield: 93%; ^{1}H NMR (δ, ppm, DMSO): 6.77 (d, 2H, C*H*-aromatic), 6.40 (t, 1H, C*H*-aromatic), 6.00 (s, 2H, trans CH_2═CH), 5.65 (s, 2H, cis CH_2═CH), 4.15 (t, 4H, CH_2), 3.63 (t, 8H, CH_2), 3.50 (m, 54H, OCH_2CH_2O), 3.42 (t, 4H, CH_2), 3.39 (t, 4H, CH_2), 3.37 (t, 4H, CH_2), 1.85 (s, 6H, CH_3); ^{13}C NMR (δ, ppm, DMSO): 168.41, 167.55, 159.44, 147.13, 142.80, 136.80, 133.41, 128.29, 108.31, 73.33, 70.78, 69.26, 64.76, 61.19, 18.99. Anal. calculated (%): C (53.75), H (7.51); observed (%): C (54.29), H (7.43). FTIR (neat) ν_{max}

cm^{-1}: 2936, 2872, 1713, 1599, 1540, 1453, 1296, 1097, 1004, 944, 860, 772, 682, 608, 519.

Synthesis of Dendron 1, POE−DHBA−PEG (7). Compound **6** (5 g, 5.77 mmol) was dissolved in dichloromethane, followed by addition of PEG (400) (2.8 g, 7.00 mmol) and TsOH (1.14 g, 5.99 mmol). A Dean−Stark trap was placed on the mouth of the flask, and it was connected to refluxed condenser. The reaction was carried out at 50 °C for 24 h. Solvent was evaporated under reduced pressure, and the product was precipitated in diethyl ether. Subsequently, it was purified by column chromatography using a mobile phase composed of dichloromethane, ethanol, and acetic acid (2:1:0.05). The product was further purified by dialysis against deionized water for 72 h (Spectra/Por no.1 dialysis tubing, MWCO 1000 Da). The dialysate was freeze-dried to obtain the product (79% yield).

Another method was also employed to synthesize dendron 1. In this method, compound **6** (8 g, 0.0092 mol) was dissolved in dichloromethane. Later, PEG (400) (4.4 g, 0.011 mol), EDC (2.76 g, 0.014 mol), DMAP (0.15 g, 0.0012 mol), and HOBT (0.2025 g, 0.0015 mol) were added to the flask. The reaction was allowed to occur for 24 h at room temperature. The precipitate of EDCU (1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide urea) was removed by filtration, and solvent was evaporated. The precipitate was purified by using the same procedure as mentioned in the previous method and was freeze-dried to obtain the product (88% yield). The later method was found to improve the product yield as well as purity; thus, it was used for other synthetic steps. ^{1}H NMR (δ, ppm, DMSO): 6.81 (d, 2H, C*H*-aromatic), 6.48 (t, 1H, C*H*-aromatic), 6.01 (s, 2H, trans CH_2═CH), 5.67 (s, 2H, cis CH_2═CH), 4.42 (s, 4H, CH_2), 4.15 (t, 4H, CH_2), 3.69 (t, 4H, CH_2), 3.65 (t, 8H, CH_2), 3.49 (m, 98H, OCH_2CH_2O), 3.45 (t, 4H, CH_2), 3.43 (t, 4H, CH_2), 2.07 (t, 1H, OH), 1.85 (s, 6H, CH_3); ^{13}C NMR (δ, ppm, DMSO): 168.41, 167.54, 159.45, 146.94, 142.92, 136.81, 133.41, 128.24, 108.31, 73.34, 70.79, 69.26, 64.76, 64.61, 62.99, 61.19, 53.95, 51.93, 18.19. Anal. calculated (%): C (53.99), H (8.11); observed (%): C (53.09), H (8.39). FTIR (neat) ν_{max} cm^{-1}: 2933, 2873, 1716, 1598, 1540, 1453, 1295, 1185, 1128, 1003, 946, 862, 815, 771, 680, 597.

Synthesis of Dendrimer-1-(G 2) (8). Dendrimer was synthesized by coupling the core with dendron 1. Briefly, compound **7** (2.02 g, 1.60 mmol) was dissolved in DMF. To this were added compound **3** (0.124 g, 0.18 mmol), EDC (0.35 g, 1.83 mmol), and DMAP (0.18 g, 1.48 mmol). The reaction was allowed to occur for 96 h at room temperature. The EDCU precipitate was filtered, and the filtrate was precipitated in diethyl ether. The product obtained was dialyzed (Fisher Scientific dialysis tubing, MWCO 3500 Da) against deionized water for 72 h, and the dialysate was freeze-dried. Yield: 75%; ^{1}H NMR (δ, ppm, DMSO): 8.27 (d, 16H, C*H*, aromatic), 7.02 (t, 8H, C*H*, aromatic), 6.03 (s, 16H, trans CH_2═CH), 5.69 (s, 16H, cis CH_2═CH), 4.36 (s, 2H, N*H*CO, core), 4.34 (s, 2H, N*H*CO, core), 4.19 (t, 32H, CH_2), 4.14 (t, 32H, CH_2), 4.07 (t, 64H, CH_2), 3.93 (s, 4H, C*H*-NH, core), 3.79 (t, 32H, CH_2), 3.65 (m, 32H, CH_2), 3.42 (m, 386H, OCH_2CH_2O), 3.19 (t, 32H, CH_2), 2.95 (2H, C*H*CO, core), 2.20 (s, 8H, CH_2CO, core), 2.17 (s, 4H, CH_2, core), 1.88 (s, 6H, CH_3); ^{13}C NMR (δ, ppm, DMSO): 165.39, 165.31, 164.64, 164.58, 159.76, 159.68, 152.60, 152.19, 131.69, 131.24, 126.85, 122.41, 115.83, 108.76, 71.57, 70.80, 69.21, 64.76, 61.91, 61.22, 44.61, 26.91, 19.01. Anal. calculated (%): C (52.61), H (7.88), N (0.70); observed (%): C (51.97), H (8.34), N (0.80). FTIR (neat) ν_{max} cm^{-1}: 2935, 2870, 1728, 1649, 1540, 1454, 1350, 1100, 947, 878, 771.

Synthesis of Dendrimer-1-(G 2)-OH (9). The allyl surface functional groups in dendrimer (Den-1-(G 2)) were oxidized to the hydroxyl group to obtain den-1-(G 2)-OH. For this purpose, compound **8** (0.1 g, 12.9 μmol) was dissolved in a mixture of DMF and THF (1:20; dried over molecular sieves) at room temperature. Later, the solution was cooled to 0 °C by placing the flask in ice bath. Thereafter, BH_3−THF (12.9 μmol) was added dropwise over a period of 5 min, and the contents were stirred at 0 °C for another 15 min. The reaction was allowed to occur at room temperature for 18 h. The excess reagent was hydrolyzed by addition of water, and 3 N NaOH (11.6 μmol) was added. After 15 min, 30% H_2O_2 (25.8 μmol) was added dropwise, and the solution was stirred for another 5 h. The product was purified by dialysis (MWCO 3500 Da) against deionized water for 72 h. Yield: 85%; ^{1}H NMR (δ, ppm, DMSO): 7.67 (d, 16H, C*H*, aromatic), 7.18 (s, 8H, C*H*, aromatic), 4.47 (s, 16H, OH), 3.90, 3.79 (m, 379H, OCH_2CH_2O), 3.61 (s, 4H, C*H*NH, core), 3.57 (t, 64H, CH_2), 2.91 (s, 2H, C*H*CO, core), 2.90 (s, 8H, CH_2CO, core), 2.13 (s, 4H, CH_2, core), 1.37 (d, 48H, CH_3); ^{13}C NMR (δ, ppm, CD_3OD and pyridine-d_5): 164.73, 160.23, 159.97, 153.05, 15.84, 145.14, 131.78, 114.91, 104.43, 79.87, 75.84, 70.92, 68.06, 65.08, 59.11, 54.65, 30.93, 30.11, 23.72. Anal. calculated (%): C (50.78), H (7.99), N (0.67); observed (%): C (50.91), H (8.07), N (1.30). FTIR (neat) ν_{max} cm^{-1}: 3280, 2949, 2873, 2360, 1917, 1868, 1835, 1732, 1649, 1599, 1543, 1513, 1451, 1291, 1188, 1132, 1083, 1000, 947, 867, 807, 770, 673.

Synthesis of Dendrimer-1-(G 3) (10). Compound **9** (0.10 g, 0.013 mmol) was dissolved in DMF, and compound **6** (0.22 g, 0.28 mmol), EDC (0.07 g, 0.36 mmol), and DMAP (0.028 g, 0.23 mmol) were added to this solution. Reaction was allowed to occur for 96 h at room temperature. The EDCU precipitate was filtered, and the filtrate was dialyzed (MWCO 3500 Da) against deionized water for 72 h. The product obtained by precipitation of dialysate in diethyl ether was dried under reduced pressure. Yield: 81%; ^{1}H NMR (δ, ppm, DMSO): 6.97 (d, 32H, C*H*, aromatic), 6.51 (t, 32H, C*H*, aromatic), 6.00 (s, 64H, trans CH_2═CH), 5.66 (s, 64H, cis CH_2═CH), 4.35 (t, 64H, CH_2), 4.16 (t, 64H, CH_2), 3.61 (t, 128H, CH_2), 3.44 (m, 1239H, OCH_2CH_2O), 3.01 (t, 64H, CH_2), 1.84 (s, 192H, CH_3); ^{13}C NMR (δ, ppm, DMSO): 163.18, 163.16, 162.15, 158.27, 158.25, 144.33, 130.18, 130.16, 121.91, 107.25, 89.43, 87.79, 75.30, 69.38, 67.76, 64.25, 49.98, 23.92, 17.52. Anal. calculated (%): C (54.05), H (7.63), N (0.27); observed (%): C (55.47), H (6.15), N (0.60). FTIR (neat) ν_{max} cm^{-1}: 3334, 2949, 2874, 2361, 2335, 1916, 1867, 1835, 1792, 1738, 1648, 1598, 1549, 1514, 1452, 1341, 1289, 1187, 1130, 1082, 1000, 948, 863, 810, 770, 672, 585, 514.

Synthesis of POE-Gallate (11). Gallic acid (1.44 g, 0.0085 mol) was added to compound **5** (11 g, 0.028 mol), and the flask was purged with nitrogen to remove any moisture. Pyridine was added dropwise to the flask under nitrogen atmosphere, and the contents were refluxed at 50 °C for 18 h. Pyridine was evaporated under reduced pressure after completion of the reaction, and product was precipitated in diethyl ether. Finally, the product was dried in a vacuum for 48 h. Yield: 92%; ^{1}H NMR (δ, ppm, DMSO): 6.92 (s, 2H, C*H*-aromatic), 6.02 (s, 3H, trans CH_2═CH), 5.67 (s, 3H, cis CH_2═CH), 4.18 (t, 6H, CH_2), 3.81 (t, 6H, CH_2), 3.62 (m, 70H, OCH_2CH_2O), 1.86 (s, 9H, CH_3); ^{13}C NMR (δ, ppm, DMSO): 167.60, 146.39, 145.96, 143.98, 136.80, 128.75, 127.83, 126.87, 109.85, 71.55, 70.79, 69.26, 65.31, 64.76, 61.21, 18.96. Anal. calculated (%): C (52.96), H (7.69); observed (%): C (51.23), H (7.12). FTIR (neat) ν_{max} cm^{-1}: 2871, 1714, 1634, 1488, 1451, 1349, 1318, 1297, 1247, 1171, 1097, 1037, 945, 851, 775, 684, 579, 523.

Synthesis of Dendron 2, POE-Gallate-PEG (12). Compound **11** (5 g, 4.1 mmol) was dissolved in dichloromethane, followed by addition of PEG (400) (1.85 g, 4.6 mmol), EDC (1.33 g, 6.9 mmol), DMAP (0.55 g, 4.5 mmol), and HOBT (0.061 g, 0.45 mmol). Reaction was allowed to occur for 48 h at room temperature. Afterward, the EDCU precipitate was

filtered and filtrate was concentrated by rotavaporation. The product obtained was precipitated in a hexane and diethyl ether mixture (1:1). Finally, it was subjected to dialysis against deionized water for 72 h (MWCO 1000 Da). The product was obtained by freeze-drying of dialysate. Yield: 86%; ^{1}H NMR (δ, ppm, DMSO): 6.89 (s, 2H, C*H*-aromatic), 6.00 (s, 3H, trans CH_2═CH), 5.66 (s, 3H, cis CH_2═CH), 4.19 (t, 4H, CH_2), 4.03 (t, 6H, CH_2) 3.77 (t, 12H, CH_2), 3.46 (m, 106H, OCH_2CH_2O), 1.85 (s, 9H, CH_3); ^{13}C NMR (δ, ppm, DMSO): 167.36, 151.53, 149.53, 147.46, 146.51, 143.31, 136.55, 126.74, 110.13, 72.05, 70.62, 69.08, 64.92, 64.60, 64.51, 62.89, 61.08, 52.82, 50.80, 26.32. Anal. calculated (%): C (52.34), H (7.43); observed (%): C (52.51), H (7.42). FTIR (neat) ν_{max} cm^{-1}: 2870, 1715, 1635, 1540, 1507, 1488, 1456, 1349, 1297, 1096, 1032, 944, 844, 757, 682, 567.

Synthesis of Dendrimer-2-(G 2) (13). For the synthesis of den-2-(G 2), compound **12** (1.8 g, 1.11 mmol) was dissolved in DMF, and compound **3** (0.083 g, 0.12 mmol) was added to it. Later, EDC (0.27 g, 1.41 mmol) and DMAP (0.12 g, 0.98 mmol) were added. The reaction was allowed to occur at room temperature for 96 h. Subsequently, EDCU precipitate was filtered and the filtrate was dried under reduced pressure. The product obtained was precipitated in diethyl ether and dried under reduced pressure. It was later dialyzed (MWCO 3500 Da) against deionized water for 72 h, and the dialysate was freeze-dried to obtain the dendrimer. Yield: 73%; ^{1}H NMR (δ, ppm, DMSO): 7.29 (s, 16H, C*H*-aromatic), 5.57 (s, 24H, trans CH_2═CH), 5.52 (s, 24H, cis CH_2═CH), 3.48 (t, 16H, CH_2), 3.33 (m, 755 H, OCH_2CH_2O), 2.87 (s, 8H, CH_2CO, core), 2.71 (s, 4H, C*H*CH$_2$CO, core), 1.85 (s, 4H, CH_2, core), 1.69 (s, 2H, C*H*, core), 1.47 (t, 72H, CH_3). ^{13}C NMR (δ, ppm, DMSO): 167.56, 165.32, 163.44, 163.65, 151.66, 149.48, 147.26, 146.31, 143.45, 136.61, 126.82, 72.25, 70.82, 69.11, 65.02, 64.73, 64.65, 63.00, 61.16, 53.05, 50.95, 26.75, 18.93. Anal. calculated (%): C (52.34), H (7.17), N (0.55); observed (%): C (52.41), H (7.25), N (1.11). FTIR (neat) ν_{max} cm^{-1}: 2932, 2361, 1715, 1677, 1560, 1508, 1453, 1319, 1262, 1175, 1082, 1029, 947, 890, 754, 647, 540.

Determination of Acid Value of Core. The acid value of the core was determined by classical titration method. In brief, approximately 0.2 g of the compound was dissolved in 50 mL of water. The solution was titrated with 0.1 N NaOH using phenolphthalein as an indicator. The method was standardized using monocarboxylic acid (hexanoic acid), dicarboxylic acid (oxalic acid, succinic acid), and tetracarboxylic acid (butanetetracarboxylic acid) prior to determination of acid value of the core.

Acid value represents milliequivalents of NaOH per milligram of compound; it was calculated using the following equation:

$$\text{acid value} = (\text{mg of acid})/(\text{normality of NaOH}) \times (\text{mL of NaOH used in titration})$$

The theoretical acid value for a compound was obtained by normalizing molecular weight of compound by number of carboxylic groups.

Determination of the Hydroxyl Value of Dendrimer-1-(G 2)-OH. Pyridine-catalyzed acetylation and phthalation are standard methods for the determination of the hydroxyl value, which is the indicator of the number of hydroxyl groups in the compound. DMAP-catalyzed acetylation with acetic anhydride, reported to have specific catalytic activity 10^4 times greater than that of pyridine-catalyzed reactions (*21*), was utilized in this study. Approximately, 5−6 mequiv of the dendrimer (lyophilized to remove traces of moisture) was transferred to a dried stoppered tube under nitrogen atmosphere and was dissolved in 1 mL of pyridine (anhydrous). To this solution, 1 mL of freshly prepared acetic anhydride solution consisting of acetic anhydride and pyridine (1:4) was added. This was followed by the addition of 0.5 mL of a catalyst solution (2% w/v of DMAP in anhydrous pyridine). The reaction was carried out in strictly anhydrous conditions. The stoppered tubes were maintained at 50 °C for 18 h, because shorter reaction times have yielded incomplete acetylation of the dendrimer. After 18 h, 5 mL of water was added to the tube, and contents were brought to room temperature. Later, 25 mL of water was added to the solution (to ascertain complete hydrolysis of excess of acetic anhydride), and samples were incubated for approximately 15 min. All the samples were titrated with 0.1 N NaOH using phenolphthalein as indicator. A blank determination was carried out in exactly the same way. The hydroxyl value was calculated as follows:

$$\text{hydroxyl value} = ((V_{sample} - V_{blank}) \times N \times 1.701)/W_{sample}$$

where, V_{sample} is volume of 0.1 N NaOH used for sample, V_{blank} is volume of 0.1 N NaOH used for blank, N is normality of NaOH, and W_{sample} is the weight of sample used.

Particle Size Measurements. The size of the dendrimers was determined by Coulter Nanosizer, N4 plus (Coulter Corporation, Hialeah, Florida) and ALV/LSE−5003 (ALV-GmbH, Langen, Germany). Dendrimers were suspended in water (filtered through 0.22 μm) to obtain a concentration of 0.1 mg/mL. The samples were vigorously agitated and subsequently filtered through a 0.22 μm or 0.1 μm filter (wherever specified) to remove dust particles. Each experiment was performed in triplicate at 25 °C and at angle of 90°.

Differential Scanning Calorimetry (DSC). The thermal properties of dendrimers were determined by employing DSC as a tool. The experiments were performed in triplicate on Metler TA 4000 (Metler Toledo, Switzerland) which was calibrated by using indium as a reference. Samples weighing between 3 and 5 mg were placed in a standard aluminum pan with a pinhole and were scanned in the temperature range of −70 °C to 380 °C at a heating rate of 10 °C/min under nitrogen atmosphere.

Atomic Force Microscopy (AFM). AFM was done with Nanoscope IIIa, Dimension 3100 (Digital Instruments, Santa Barbara, CA) in tapping mode. In this mode, the tip spends less time on the sample surface, and as a result the lateral forces on the sample are reduced. Thus, it provides an opportunity to image delicate samples without severe distortion. Samples were prepared by dissolving the dendrimers in DMF at room temperature and later diluting with water. These were deposited on a freshly cleaved mica surface by spin coating (WS,-400A-6NPP/LITE, Laurell Tech Corporation, North Wales, PA) at 2000 rpm for a period of 1 min. The samples were allowed to dry at room temperature. Subsequently, they were imaged in air at ambient conditions using etched silicon probes with a tip radius of 5−10 nm and spring constant in the range of 20−100 N/m, oscillated at its fundamental resonant frequency (200−400 kHz).

Encapsulation Studies. The ability of the dendrimers to act as host for the molecules was determined by encapsulating rhodamine and β-carotene as hydrophilic and hydrophobic model compounds, respectively. The weighed amount of dendrimer was transferred to screw-capped vials and was dissolved in DMF. Later, a defined weight of compound to be encapsulated was added to the vials and stirred at room temperature. The unencapsulated drug was removed by dialysis of the solution against deionized water for approximately 18 h. The sink conditions for removal of β-carotene were maintained by increasing volume of water and addition of ethanol (10% v/v) in the dialysis medium. The dialysate was lyophilized to obtain freeze-dried dendrimer with encapsulated compounds. For the determination of the loading and encapsulation efficiency, a weighed amount of freeze-dried dendrimer was dissolved in

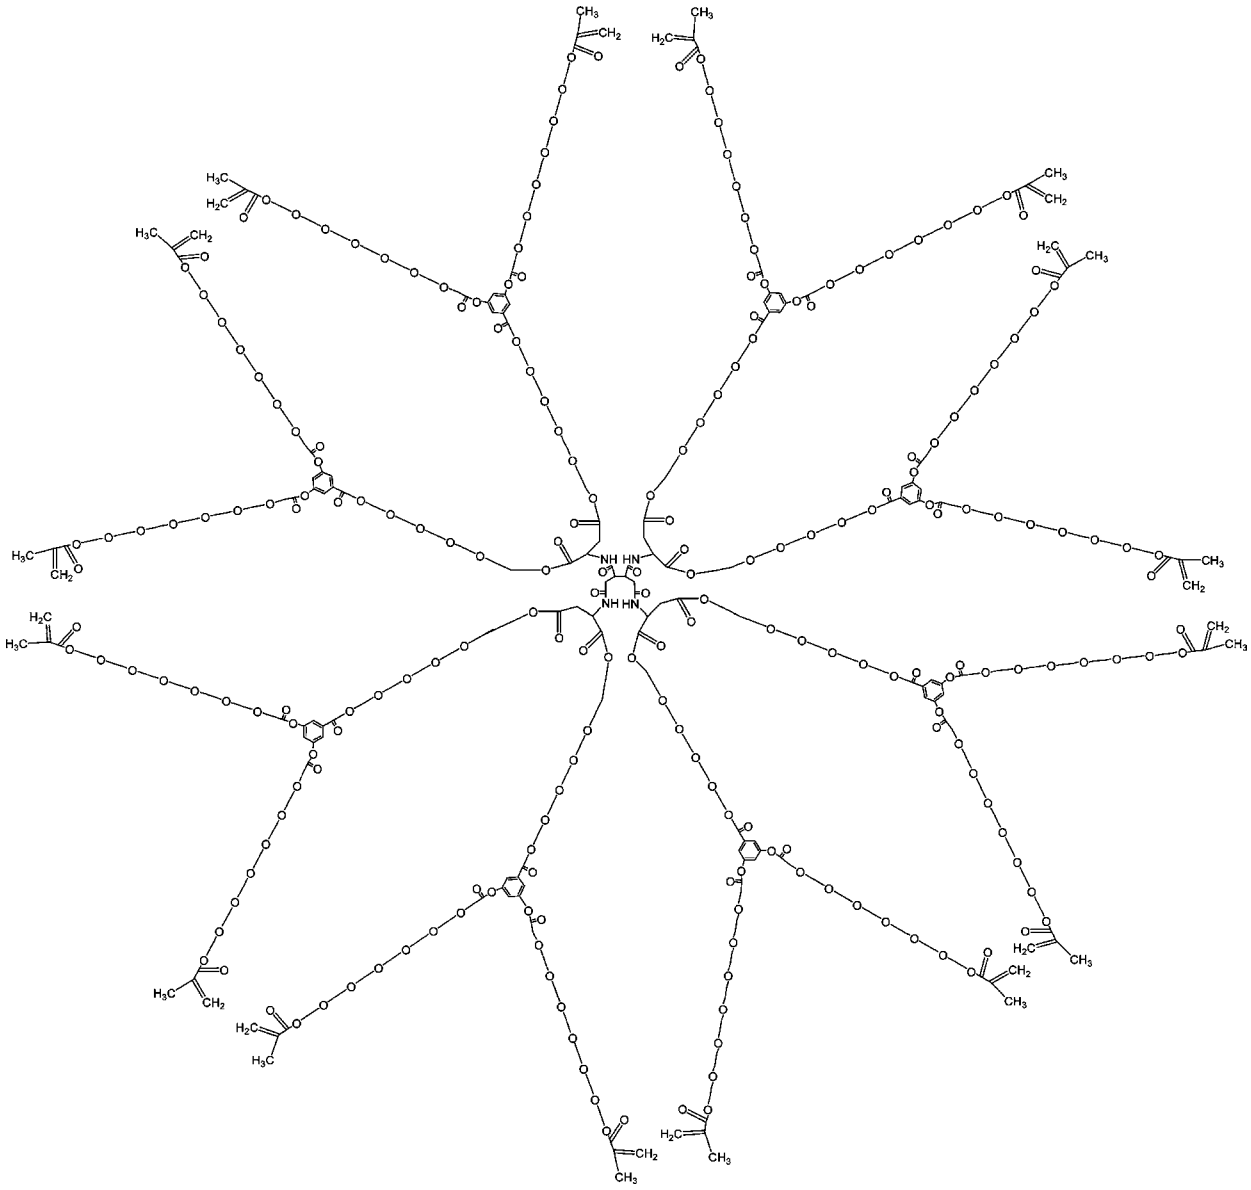

Figure 1. Structure of dendrimer-1 (den-1(G 2)).

DMF, and samples were analyzed with appropriate blank corrections for the dendrimer. Rhodamine was assayed fluorimetrically (excitation and emission wavelength 550 and 625 nm) using a SAFIRE microplate reader (Tecan, Salzburg, Austria), while β-carotene was determined at 460 nm (λ_{max}) using a UV spectrophotometer U-2001 (Hitachi High Technologies, Orlando, FL).

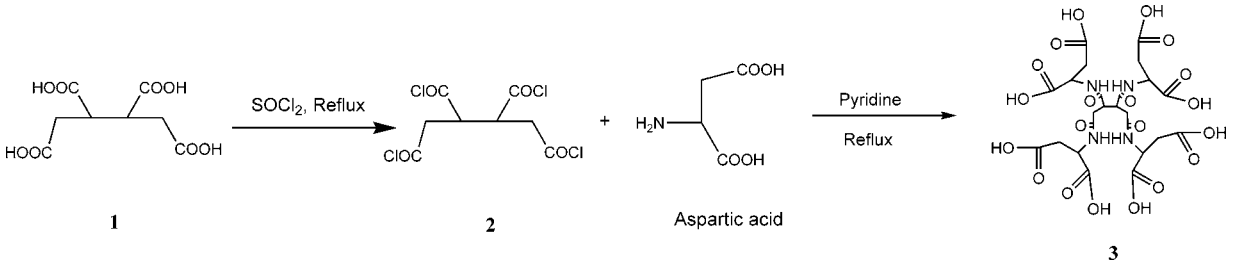
Release Studies. The release of encapsulated compounds from the dendrimers was studied using vertical, jacketed Franz diffusion cells with an area of 0.79 cm^2 (Permgear). The experiments were carried out at 37 °C, and phosphate buffer (0.1 M, pH 7.4) was used as the release medium for studying rhodamine release while ethanol and 0.1 M phosphate buffer (2:1) were used to maintain the sink conditions for β-carotene release experiments. A definite amount of dendrimer with encapsulated compound was added to 800 μL of respective release medium and was transferred into the donor compartment. It was separated from the receptor compartment containing 5 mL of release medium by a dialysis membrane MWCO of 3500 Da (equilibrated overnight with release medium at 37 °C). The samples were taken with replacement from the receptor compartment at each predetermined time point (1, 2, 3, 4, 6 h and later, after every 24 h) and assayed as mentioned in the previous section.

RESULTS AND DISCUSSION

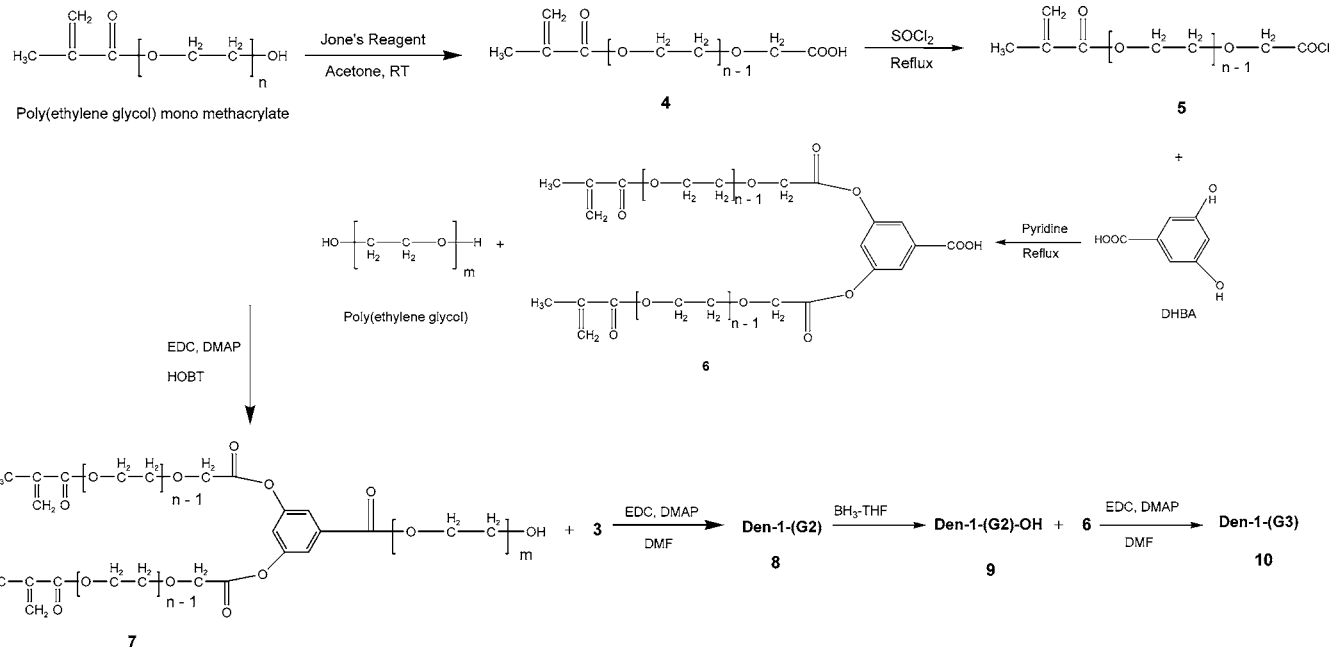
Dendrimers can be synthesized by an iterative sequence of steps using either a divergent or convergent procedure (*22*). The divergent approach is reported to lead to structural defects and some difficulties in purification of the final product. However, the convergent approach is stated to minimize these synthetic problems, but it seems that steric hindrance in coupling of the dendron to the core molecule limits the synthesis of a higher generation of dendrimer by this approach. Thus, in the present work, dendrimers were synthesized using a strategic combination of both approaches, i.e., the core molecule was grown divergently to obtain multifunctional core, and this was then coupled to the dendron synthesized convergently, to obtain the final dendrimer. The higher generation dendrimer was synthesized by divergently coupling lower generation dendrimer to the dendrons. To the best of our knowledge, this is the first report on the combination of these two synthetic approaches for the synthesis of these dendrimers.

Synthesis and Characterization of Dendrimers. The polyester-*co*-polyether dendrimers containing PEO in the cavity were

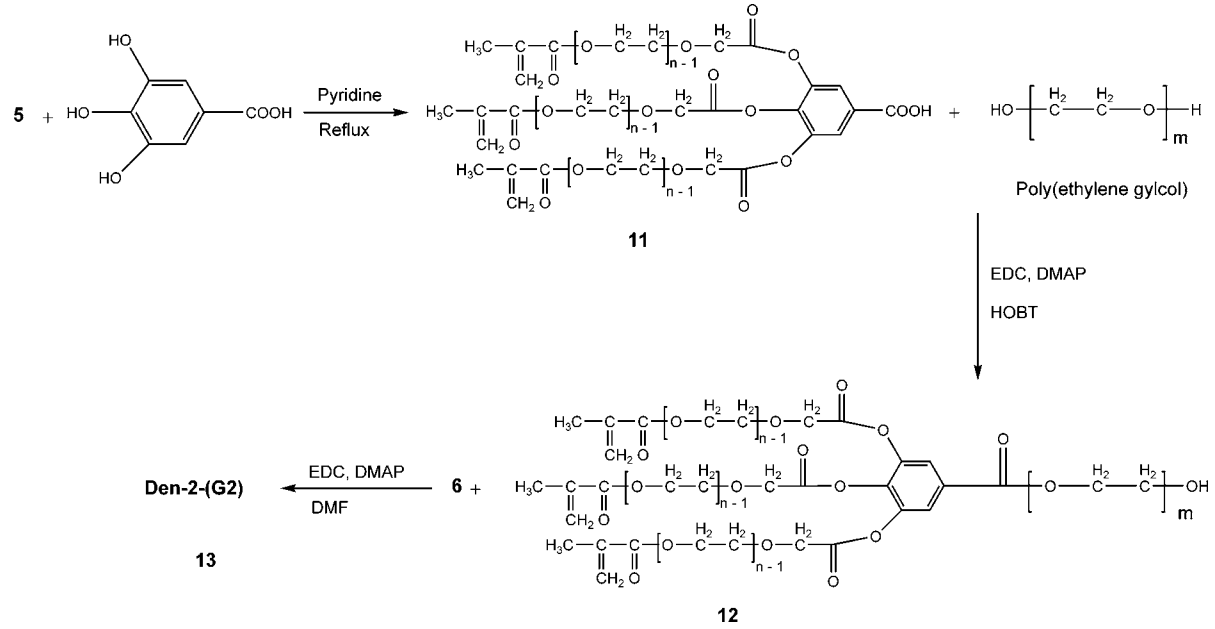
Scheme 1. Synthesis of the Core



Scheme 2. Synthesis of Den-1-(G 2), Den-1-(G 2)-OH, and Den-1-(G 3)



Scheme 3. Synthesis of Den-2-(G 2)



synthesized using a simple synthetic scheme by which den-1-(G 2) (Figure 1) could be obtained in seven reaction steps (Schemes 1 and 2). The use of PEO as a major building block helped in obtaining the desired molecular architecture in less synthetic steps. Trollsås et al. have also reported a similar strategy to obtain high molecular weight dendrimers of specific architecture by using poly(ϵ-caprolactone) as the building block (*23*). The synthesis was initiated by esterification of butanetetracarboxylic acid with an amino acid, aspartic acid, to obtain the core. The ^{1}H NMR, ^{13}C NMR, and elemental analysis showed successful synthesis of the core. To estimate the number of carboxylic acid groups in the core, the acid value/neutralization equivalent was determined (Table 1). The acid value for the core obtained by the titration method was within the

Table 1. Acid Value of the Core Determined by the Titration Method

	sample	theoretical acid value	observed acid value[a]	calcd no. of carboxylic groups[b]
1	butane-tetracarboxylic acid	58.50	60.60 ± 0.26	3.86
2	core	86.75	88.58 ± 0.58	7.83

[a] Data are mean value ± SD ($n = 4$). [b] Average acid value was used for calculation.

experimental error of the method. Since the acid value is specific for each compound, it can be used as a derivative to identify it. This parameter can also be used to back calculate the number of carboxyl groups if the molecular weight is known. For the core, an acid value of 7.8 was obtained, substantiating that the synthesized core has eight carboxylic groups at the surface.

The dendron was synthesized convergently by esterification of compound **5** with DHBA for the synthesis of den-1-(G 2) and to gallic acid for the synthesis of den-2-(G 2) (Scheme 3), followed by esterification with PEG 400. The esterification was monitored by FTIR spectroscopy; the appearance of the ester C═O peak in the FTIR spectra of compound **6** (Figure 2) gave the evidence about the formation of an ester bond. In addition, the characteristic stretch of the alkene group at 1540 cm^{-1}, PEO between 1300 and 1500 cm^{-1}, and the C−O−C stretch at 1000−1200 cm^{-1} proved the incorporation of PEG monomethacrylate in compound **6**. Further esterification of compound **6** by PEG 400 was supported by the splitting of ester C═O and C−O ether peaks in the spectra of compound **7**, which confirmed the synthesis of a new ester bond as well as introduction of new ether bonds in the dendron.

It is reasonable to speculate that the methacrylate ester present in PEG monomethacrylate could be cleaved during the synthesis. To circumvent this probability, the reactions were carried out in the mildest possible conditions, and the peaks due to the allyl group of PEG methacrylate were followed throughout the synthesis as the marker. The existence of peaks due to cis and trans protons of the allyl group of PEG methacrylate in FTIR and ^{1}H NMR spectra (Figure 3 and 4) of compounds **5**−**8** indicated that the methacrylate moiety was not cleaved during the synthesis. Additionally, the relative integration area of allyl proton and benzyl protons showed the presence of two PEG methacrylate units per dendron in case of compound **6**, **7**, and **8** and three units in case of **11**, **12**, and **13**, respectively. Summarizing these observations, it was concluded that polyester-co-polyether dendrons with two and three allyl surface functionalities have been synthesized. Later, dendrons **7** and **12** were coupled to the multifunctional core to build dendrimers den-1-(G 2) and den-2-(G 2), respectively.

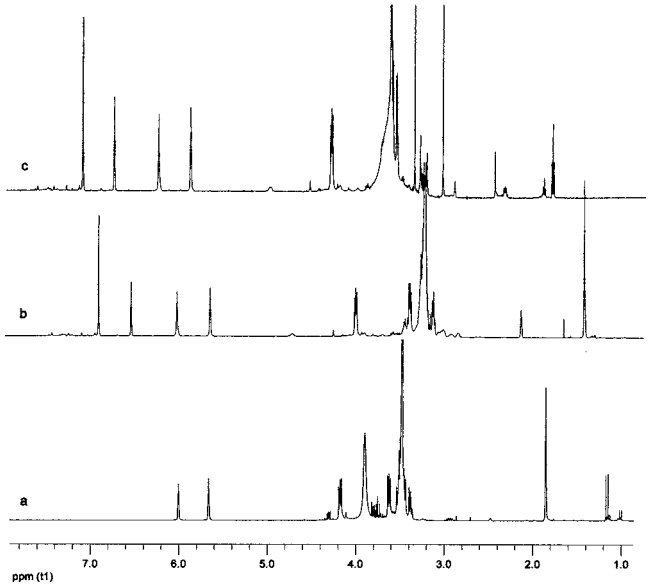

Figure 3. ^{1}H NMR spectra of (a) PEG-methacrylate, (b) POE-DHBA, (c) POE-DHBA-PEG in DMSO at 400 MHz.

The dendrimer den-1-(G 2)-OH was synthesized by hydroboration of dendrimer den-1-(G 2) (Scheme 2). The conversion of allyl functional group to hydroxyl was monitored by disappearance of the peak in the ^{1}H NMR spectra due to allylic protons (Figure 5) as well as by determination of hydroxyl value of the product. Initial incubation of 18 h was allowed to ensure complete addition of BH_3 to the allyl groups, and further reaction time of 5 h was found to be adequate to convert all allyl groups to hydroxyl groups.

It was previously reported that steric hindrance offered by hyperbranched polymers could lead to incomplete acetylation of hydroxyl groups and thus result in lower than expected hydroxyl values (*24*). Thus, to minimize the possibility of this experimental limitation, acetylation was performed at higher temperature and for a longer duration of time. Further, it was also reported that the presence of ethylene oxide units in the polymer could lead to erroneous results, and often hydroxyl values obtained are overestimated (*25*). Keeping this factor in consideration, dendrimers without any hydroxyl groups (i.e. den-1-(G 2)) were always titrated under similar conditions and were used to correct the final values obtained. The experimental hydroxyl value determined by titration was found to be 4.12 ± 0.57, which is in close agreement with the calculated value of 3.63 (calculated on the basis of molecular weight (M_n) of the dendrimer), thus confirming that all the allyl groups have been oxidized.

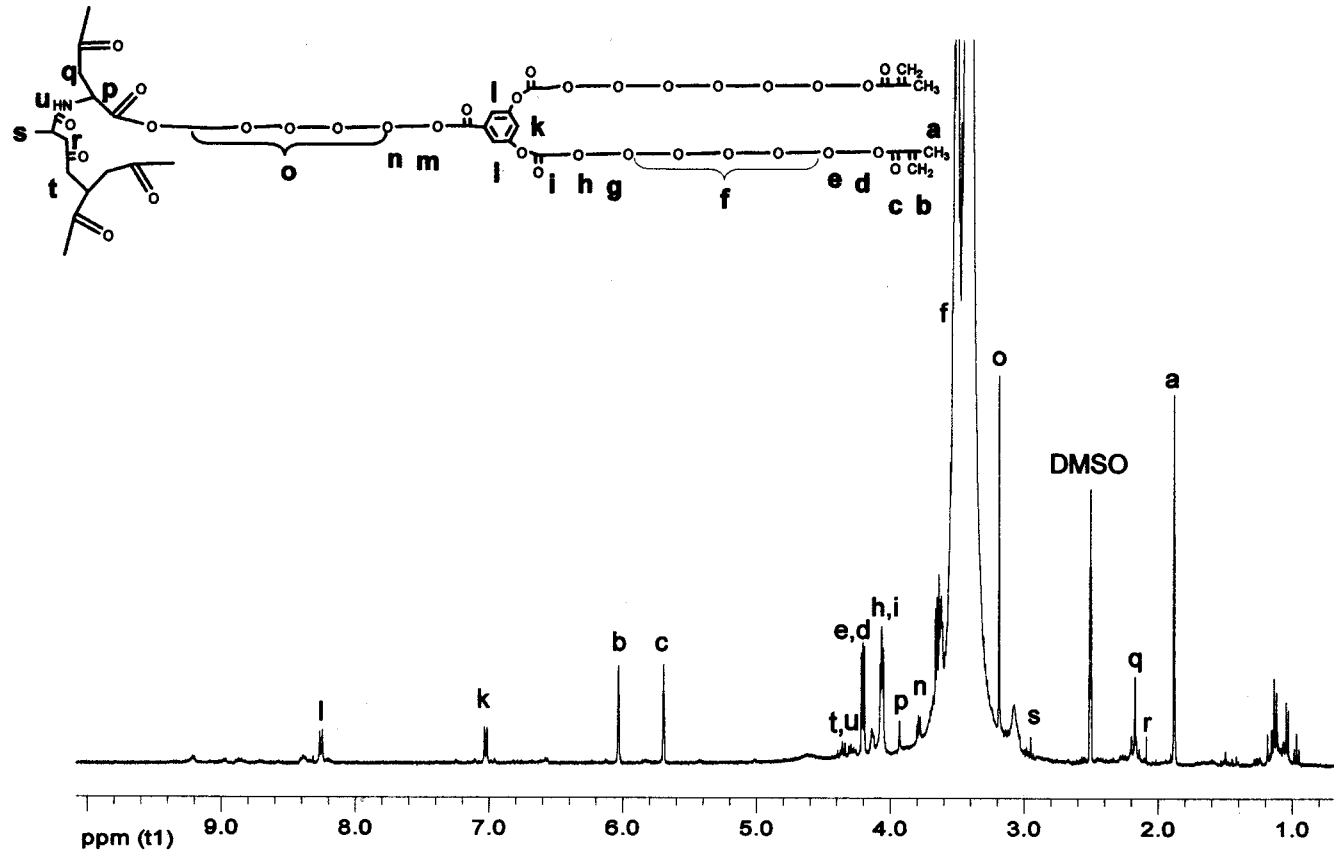

Figure 4. [1]H NMR spectrum of the dendrimer (Den-1-(G 2)) in DMSO at 400 MHz.

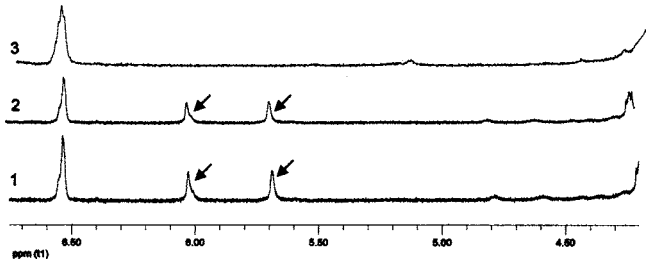

Figure 5. [1]H NMR spectra showing the disappearance of allylic cis and trans protons during oxidation to hydroxyl groups (1) with out any oxidation, (2) after approximately 50% oxidation, (3) after complete oxidation.

The higher generation dendrimer, den-1-(G 3), was synthesized by divergently coupling den-1-(G 2)-OH to POE-DHBA (**6**) in the presence of EDC and DMAP (Scheme 2). Characterization of den-1-(G 3) by routine instrumental techniques showed successful synthesis.

The characteristics of all the synthesized dendrimers are presented in Table 2. The M_n of dendrimers was determined by [1]H NMR, GPC, and MADLI-TOF. The M_n values determined by GPC are less than the expected theoretical values. This deviation is due to differences in hydrodynamic volume between dendrimers and linear PEG standards.

Particle Size Measurements. The size of the dendrimers was determined in water at various concentrations (data not shown). At a concentration of 1 mg/mL, size of about 200 nm was observed which indicated a high aggregation of the dendrimers. At lower concentrations (0.5 mg/mL), bimodal size distribution with an average size of 200 nm and a small population with an approximate size between 10 and 30 nm was observed for all dendrimers. It was also found that even after filtration through a 0.10 μm membrane, a dendrimer population with a size around 200 nm was obtained (data not shown), which indicated self-assembly of dendrimer after filtration of the sample. Percec et al. and Wang et al. have also reported self-assembly of dendrimers, which they explained to be mediated by various nondirectional forces such as hydrophobic, electrostatic interactions, and Coulombic forces, etc. (*26*, *27*). To overcome this problem, experiments were performed at a lower concentration (0.1 mg/mL), and the effect of various additives such as triethylamine, NaOH, HCl, DMF, methanol, acetone, urea, and sodium chloride was examined. Although triethylamine and methanol were found to reduce aggregation of dendrimers, they had no significant influence on self-assembly. Sodium chloride (0.25−0.35 M) inhibited not only aggregation but also the self-assembly phenomenon. Thus, hydrodynamic sizes of all the dendrimers were determined in sodium chloride solution, and results are shown in Table 2. Even though dendrimers showed aggregation under in vitro conditions, it is speculated that after in vivo administration, these aggregates will breakdown due to high dilution as well as presence of various biological substances (*28*). The absence of aggregates is significantly important for improved in vivo efficacy because the size of the drug carrier influences not only the circulation time in blood but also the endocytosis or uptake by the cells. The smaller particles are rapidly taken up by cells; thus, they can provide intracellular delivery and thereby increase the therapeutic efficacy.

Thermal Properties. It is reported that polymeric carriers undergo glass−rubber transition during the penetration of water, and this influences the drug release profile (*29*). Thus, thermal properties of polymers not only influence the stability but also the release of drug (*30*). All the synthesized dendrimers were investigated for their thermal properties and, in particular, glass transition temperature (T_g) by DSC. The T_g for PEG-methacrylate (**1**) was observed to be −67.50 °C which is close to the reported value of −65 °C. The T_g values for POE-DHBA and POE-DHBA-PEG were found to be −31.10 °C and −21.45 °C, respectively (Table 3), indicating an increase in the transition

Table 2. Characteristics of Dendrimers

	dendrimer	surface functional group	number of functional group	M_n (NMR)[a]	M_n (GPC)[b]	M_n (MALDI-TOF)	particle size (nm) (AFM)[c]	particle size (nm) (DLS)

[a] Calculated based on the relative integration ratio of peaks with respect to the peak of the $CH{=}CH_2$ cis/trans proton or aromatic proton (in case of Den-1-(G 2)-OH). [b] Determined using PEG standards and DMF as mobile phase at a flow rate of 1 mL/min; value in brackets is polydispersity index. [c] Data are the mean value, determined by ≥30 measurements. [d] Data are the mean ± SD ($n = 3$).

Table 3. Details of Thermal Events for Various Dendrons and Dendrimers Obtained by DSC

	sample	T_g (°C)	T_m (°C)
1	PEG methacrylate	−67.50	-
2	POE-DHBA	−31.10	234.60
3	POE-DHBA-PEG	−21.45	293.20
4	dendrimer-1-(G 2)	−12.52	311.90
5	dendrimer-1-(G 3)	−10.89	308.30
6	dendrimer-1-(G 2)-OH	−13.50	300.60
7	POE-gallate	−45.50	218.50
8	POE-gallate-PEG	−41.70	231.60
9	dendrimer-2-(G 2)	−21.37	298.20

temperature. Further, the transition temperature for den-1-(G 2) (−12.52 °C) is higher than that of POE−DHBA−PEG. These increases in transition temperature could be explained by an increase in molecular weight as well as by the decrease in chain flexibility as the branching increases (*31*, *32*). A similar trend was observed for in POE-gallate, POE-gallate−PEG, and den-2-(G 2); however, the T_g values were always less than that for the den-1-(G 2) series. This is probably due to a higher number of PEG chains present per dendron (POE-DHBA has two PEG chains, while POE-gallate has three PEG chains) in the later case. Interestingly, only one T_g was observed for all the polymers analyzed, which suggests that all the polymers had no unreacted monomers, and also there was no nanophase separation due to clustering of the polar groups as reported by Sunder et al. for hyperbranched polymers (*24*). Minor melting peaks were also observed for all the polymers, which indicate the existence of amorphous as well as crystalline nature.

Atomic Force Microscopy. AFM is a versatile technique which offers the opportunity to obtain high resolution topographic images of nanoscale polymeric materials. All the dendrimers were imaged in tapping mode after depositing the sample by spin coating on a freshly cleaved mica surface. The spin coating results in the formation of monolayer of polymer at low concentrations; in addition, the centrifugal forces operating during the process aids in breaking the aggregates.

A dendrimer height between 1.39 and 3.55 nm was observed on the mica surface, which indicates the absence of pillarlike aggregation. The scope trace of the surface as well as the topographical view showed the presence of few aggregates, but a majority of the dendrimers were present as isolated molecules. All the dendrimers appeared flattened on the substrate in the surface plot as has been reported for other hydrophilic dendrimers (*33*). However, as seen in Figure 6, den-1-(G 2) and den-2-(G 2) were approximately spherical in shape, while den-1-(G 2)-OH was slightly oval in shape and den-1-(G 3) showed a spherical shape with floral pattern, which indicates that the shape of dendrimer is influenced not only by surface groups but also by the generation (each scan was repeated 3−4 times to ascertain the reproducibility). This observation is in agreement with various simulations and molecular modeling reports of dendrimers (*34*−*36*) where the shape of dendrimer was found to be influenced by surface groups, solvents, and generation.

AFM was also exploited as a tool to determine the size of the dendrimers. For this purpose, all the images were treated offline by using a particle size analysis function, which is designed for analyzing the lateral and vertical dimensions of isolated particles on the substrate surface based on the height of pixel data. The dimensions obtained slightly deviate from that observed by DLS (Table 2). Müller et al. found that residual water in the sample that remained after the drying procedure can lead to overestimation of dendrimer size by AFM (*37*). Further, it is also reported (*33*, *38*−*40*) that hydrophilic and flexible dendrimers (such as PAMAM) flatten and laterally expand on hydrophilic substrates such as mica. This flattening and lateral expansion is enhanced by the large forces exerted by residual water on absorbed species (*37*). All these factors could contribute to overestimation of the diameter of these hydrophilic dendrimers.

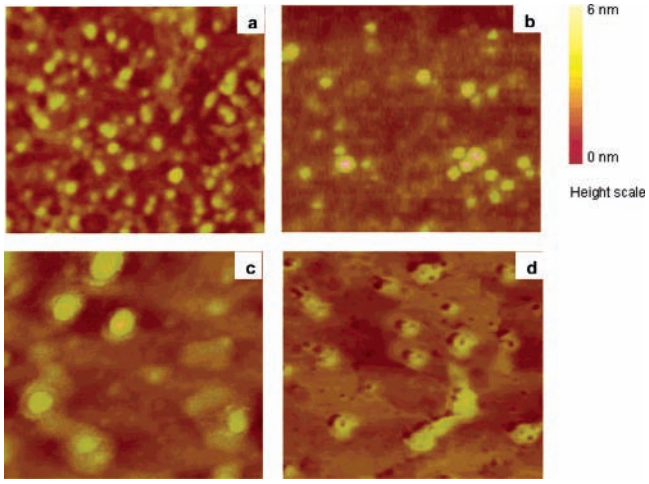

Figure 6. Topographical tapping mode AFM images of (a) den-1-(G 2), (b) den-2-(G 2), (c) den-1-(G 2)-OH, and (d) den-1-(G 3), spin coated on a freshly cleaved mica surface. The scan area is 200 × 200 nm.

Table 4. Encapsulation of Rhodamine and β-Carotene in Dendrimer-1 (Den-1-(G 2))

		drug:dendrimer feed ratio (1:4.5)[a]		drug:dendrimer feed ratio (1:3.6)[b]	
	compound	loading (% (w/w))	encapsulation efficiency (%)	loading (% (w/w))	encapsulation efficiency (%)
1	rhodamine	10.76 ± 1.06	63.27 ± 0.75	15.80 ± 0.14	64.52 ± 0.58
2	β-carotene	5.86 ± 0.24	33.49 ± 0.68	6.47 ± 0.02	33.66 ± 1.08

[a] Mean ± SD ($n = 3$). [b] Mean ± SD ($n = 2$).

Encapsulation and Release Studies. Rhodamine, a hydrophilic fluorescent compound, and β-carotene, a highly hydrophobic compound, were encapsulated in a dendrimer (den-1-(G 2)). As shown in Table 4, at the drug/dendrimer feed ratio of 1:4.5, loading of 10.76% w/w was achieved for rhodamine and 5.86% w/w for β-carotene. It was observed that upon increasing the drug/dendrimer feed ratio to 1:3.6, rhodamine loading increased to 15.80% w/w and that of β-carotene was increased to 6.47% w/w. Further increase in drug/dendrimer feed ratio had no increase in loading for either of the compounds. Kojima et al. also reported a similar observation where an increase in drug/dendrimer feed ratio resulted in an increase in

the drug loading (mol/mol), which reached a maximum value at a certain feed ratio (*8*). The lower loading of β-carotene could be due to the highly hydrophobic nature as well as linear shape of the molecule. It was reported by Namazi and Adeli that size and polarity of the guest molecule affect the ability of dendrimers to encapsulate drug (*11*). They also reported that the encapsulation of pyridine, mefanamic acid, and acetylsalicylic acid in second generation citric acid dendrimers on dendrimer/drug ratio basis was 20, 32, and 49 mol % (i.e. 0.8, 3.8, and 4.4% w/w), respectively. In another study, PMAM dendrimers with PEG grafts had shown maximum encapsulation of 6.5 mol/mol (drug/dendrimer mole ratio) i.e., 2.7% w/w for doxorubicin and 26 mol/mol (10.9% w/w) for methotrexate (*8*). As seen above, drug loading is dependent upon of the size and solubility of the molecule: a lower solubility results in lower loading, and a smaller size increases the loading for molecules with comparable polarity. Although pyridine (79 Da), mefanamic acid (241 Da), and acetylsalicylic acid (180 Da) are smaller and more soluble than β-carotene (537 Da), the loading obtained for β-carotene in this study is much higher. Further, comparatively the loading of rhodamine (479 Da) is higher than that of methotrexate (454 Da). This clearly indicates significantly improved drug loading by these dendrimers and thus substantiates that incorporation of PEO in the interior of the dendrimer increased the size of the internal cavity and thereby increased the encapsulation. Furthermore, it also provided a favorable environment to encapsulate hydrophilic as well as large and hydrophobic molecules. Thus, incorporation of PEO in the core of drug carriers can provide an attractive approach to deliver both water soluble and poorly water soluble compounds.

Since the dendrimer employed for encapsulation studies had no ionizable surface group, it was speculated that encapsulation is largely due to hydrogen bonding by PEO in the cavity and branch (*9*) and/or physical entrapment of molecule in the cavity, rather than being a complexation phenomenon as has been reported for PAMAM dendrimers (*41*). To provide evidence for this hypothesis, the mechanism that involved the encapsulation of these compounds in the dendrimer was investigated. The absorbance spectra of both the compounds before and after encapsulation in dendrimer were recorded and are presented in Figure 7. No shift in absorption maxima was observed for either compounds. The absence of shift in absorption maxima indicates absence of any $\pi-\pi$ complexation, because such complex formation is evidenced by formation of a new chromophore (*42, 43*). NMR spectroscopy is reported to furnish important information on direct interaction between compound and dendrimers (*10, 41, 44*). Thus, the ^{1}H NMR spectra of rhodamine and β-carotene encapsulated in dendrimer were acquired, and the chemical shifts of rhodamine as well as β-carotene in DMSO before and after encapsulation in dendrimer were determined. No significant shift in the peaks of the aromatic rings as well as ethyl amino group was observed in spectra of rhodamine encapsulated in the dendrimer, but a few peaks were suppressed (Figure 8), which implies that the compound is physically encapsulated. To further investigate the mechanism of encapsulation and interactions between encapsulated compound and dendrimer, FTIR spectroscopy was employed as a tool. The FTIR spectra of rhodamine alone, den-1(G 2), and rhodamine encapsulated in den-1(G 2) were acquired as neat samples. The spectrum of den-1(G 2) was subtracted from that of rhodamine encapsulated in den-1(G 2) to obtain the spectral features of rhodamine after encapsulation in dendrimer. It was observed that the carboxylic OH which appears in the region of 3300−2500 cm^{-1} and is overlapped by the C−H stretch (*45*) had increased in intensity as well as broadened after encapsulation in the dendrimer. The absence of peak splitting around 1372−1344 cm^{-1} was also seen (Figure 9). These peaks in the range of 1370−1310 cm^{-1} are assigned to the aromatic tertiary amine C−N stretch. Further, the shift in the peak at 1223 cm^{-1}, attributed to the aromatic C−O stretch, was also seen. Since these changes are associated with OH, C−N, and C−O stretching frequencies, they are generally attributed to hydrogen bonding interactions. Thus, weak hydrogen bonding between dendrimer and rhodamine is postulated to exist. In addition, the significant decrease in intensity of peaks in the region of 1650−1500 cm^{-1} (aromatic ring stretch) was observed, indicating either that the aromatic region is surrounded by the PEO chain of the dendrimer or there are dipole−dipole/induced dipole interactions. The changes in FTIR spectral features of rhodamine after encapsulation indicated the presence of weak hydrogen bonding or dipole−dipole/induced dipole interactions. Thus, hydrogen bonding of the molecule by PEO together with physical entrapment of molecule in the dendrimer is the probable mechanism of encapsulation. It was previously reported that at high concentration, PEG 400 self-associates by hydrogen bonding and disrupts the water structure to a certain extent (*46*). Since these dendrimers have a high density of PEO, it is possible that self-association of PEO chains could also occur, resulting in hydrotropic solubilization of the compounds.

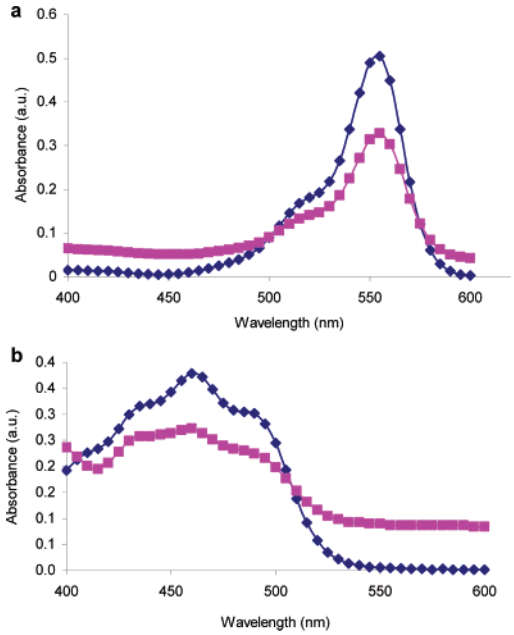

Figure 7. Absorbance spectra of (a) rhodamine and (b) β-carotene before and after encapsulation in the dendrimer, determined to study the effect of encapsulation on the fluorophore and chromophore. Key: ◆ before encapsulation; ■ after encapsulation.

The release of drug molecules from polymeric carriers occurs by either diffusion and/or degradation of the polymer. Approximately 90% of both encapsulated compounds was released in 172 h, i.e. 7 days (Figure 10), and the preliminary in vitro biodegradation studies have shown that degradation of den-1(G 2) ensues after 10 days of incubation. Therefore, in vitro release of both compounds under will be mainly governed by diffusion. The release of rhodamine was slow and almost linear till 120 h, after which it reached a plateau phase. Approximately 82% of rhodamine was released from the dendrimer in 120 h, and 90% was released after 172 h. Since rhodamine is a water soluble compound, the slow release profile demonstrates the ability of these dendrimers to provide sustained release of even water soluble drugs.

β-Carotene is practically insoluble in water, and hence ethanol was added to the release medium to obtain necessary sink conditions. In the absence of necessary sink conditions the hydrophobic compounds exhibit a slow release profile. Thus,

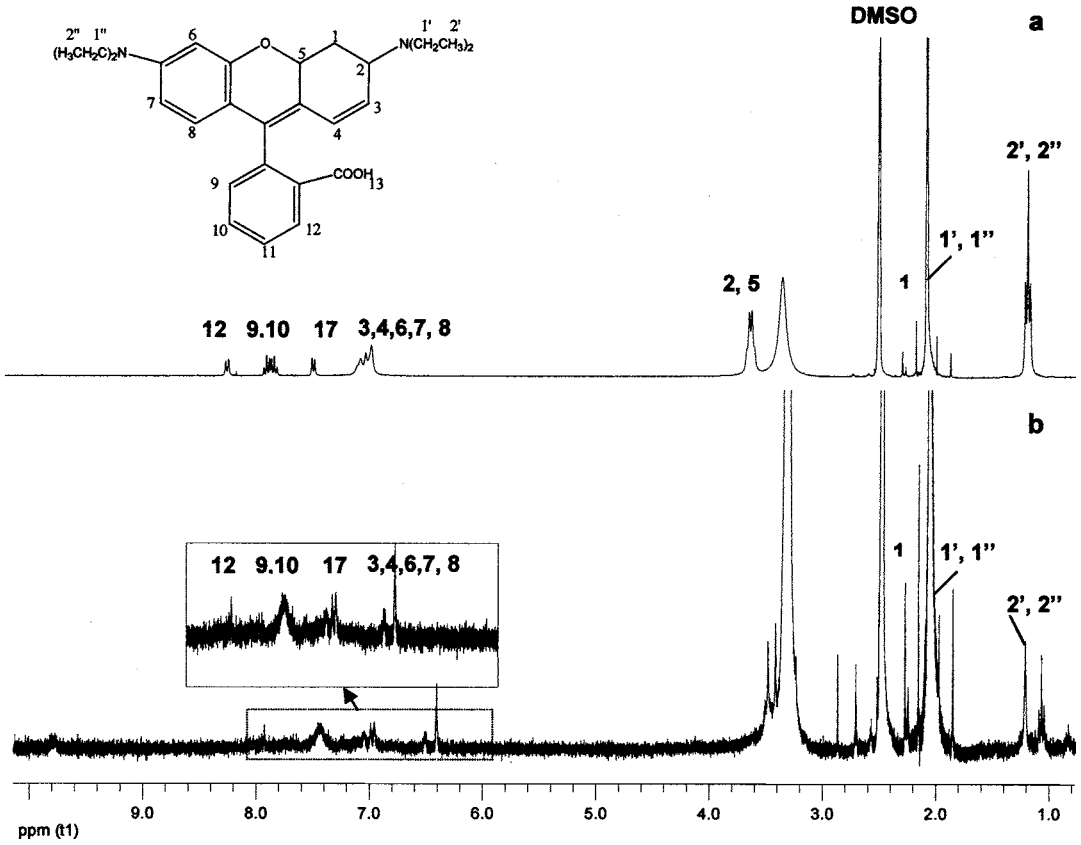

Figure 8. ^{1}H NMR spectra of (a) rhodamine (10 μM) and (b) rhodamine encapsulated in dendrimer (Den-1-(G 2)) (4 μM) measured in DMSO at 400 MHz.

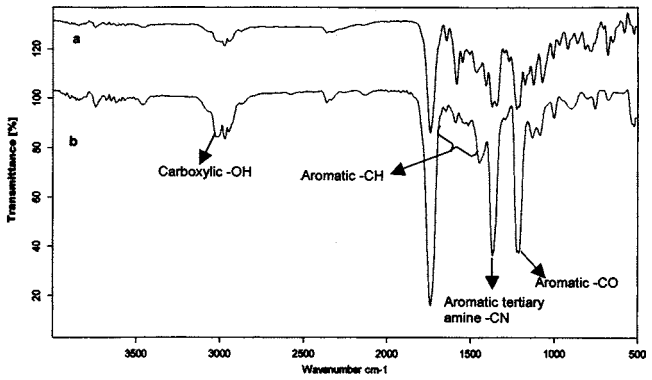

Figure 9. FTIR spectra of (a) free rhodamine and (b) encapsulated rhodamine (obtained by subtracting spectrum of den-1-(G 2) from spectrum of rhodamine encapsulated in den-1-(G 2)).

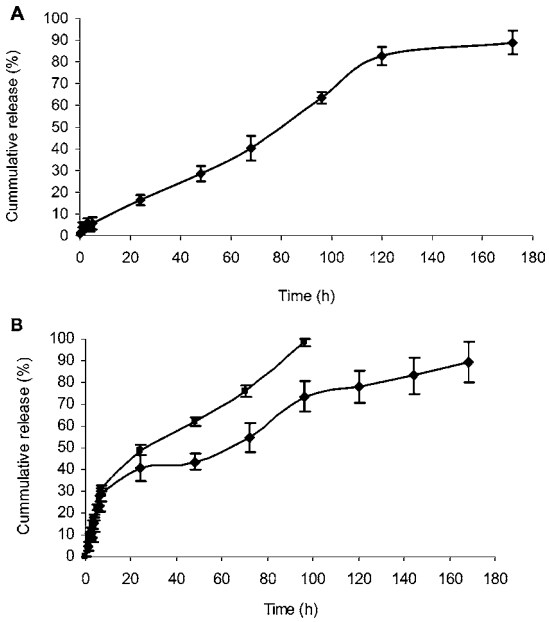

Figure 10. Cumulative release profile of (A) rhodamine encapsulated in den-1-(G 2) and (B) β-carotene encapsulated in den-1-G 2 (diamonds) and β-carotene suspension (squares). Data are mean ± SD.

the slow release of the drug from the carrier could be due to the absence of sink conditions and not due to the influence of drug delivery vehicle. To overrule the factor that slow release of β-carotene is due to an absence of sink conditions or slow dissolution of drug, release of β-carotene from suspension was performed under the same conditions but at 10 times higher amount. It also allowed comparison of the release characteristics of drug from dendrimer and suspension. Even though drug concentration in suspension was much higher, approximately 100% of the drug was released from suspension in 96 h as compared to 70% from dendrimers, indicating sustained release of drug encapsulated from the dendritic architecture. A triphasic release profile was observed in the case of dendrimers, with an initial rapid release phase during which 30% of drug was released in 7 h, followed by a slower release with drug release up to 70% in 96 h and another slow release with 90% of encapsulated drug being released in 168 h. The absence of burst release in the case of both rhodamine and β-carotene also ascertains the nonexistence of surface-bound drug. Comparatively, release of rhodamine was slower than that of β-carotene; this is in contrast to the general trend where hydrophobic compounds exhibit slower release as compared to hydrophilic compounds. This slower release of rhodamine is due to the hydrogen boding interaction of the former with the PEO, which retards the diffusion and hence release of the drug. This interesting observation highlights the ability of these dendrimers

to prolong the release of encapsulated drugs and thus demonstrates their potential to act as carriers for sustained release of both hydrophilic and hydrophobic drugs. The ability to encapsulate both hydrophilic and hydrophobic drugs is advantageous because it eliminates the need to tailor polymeric architectures specifically for hydrophilic or hydrophobic drugs. Further, it provides an opportunity for combination therapy, wherein drugs with different solubilities can also be encapsulated simultaneously and delivered to the target site.

These dendrimers have hydrolyzable ester linkages and are composed of mainly PEG, a biocompatible polymer that has shown to reduce the cytotoxicity, immunogenecity, and antigenecity of various dendrimers as well as other drug delivery vehicles (*12, 13*). Further, due to the absence of cationic groups at the surface, it is speculated that the synthesized dendrimers will be biodegradable and biocompatible.

CONCLUSIONS

Novel polyester-*co*-polyether second and third generation dendrimers were synthesized by simple synthetic schemes using butanetetracarboxylic acid as the core molecule by combination of divergent and convergent synthesis. PEO was incorporated in the interior of the dendrimers to increase the size of the cavity as well as to provide a hydrophilic interior region. The dendrimers demonstrated the ability to encapsulate both hydrophilic and hydrophobic model compounds, with sufficiently high drug loading. Further, the release of both rhodamine and β-carotene was found to be slow and sustained, with approximately 90% of drug being released in 170 h. The study indicates that polymeric architectures with a PEO interior can potentially be used for delivery of hydrophobic and hydrophilic drugs, which provides an advantage over drug carriers with hydrophobic core that have preferential ability to deliver hydrophobic compounds. It is postulated that by virtue of their small size and slow release characteristics these dendrimers can be used as nanocarriers for intracellular drug delivery.

ACKNOWLEDGMENT

The authors thank Dr. Françoise Winnik for providing the DLS and FTIR facility. Renu Singh also expresses sincere thanks to Julie Boivin for help provided throughout the MALDI-TOF experiments.

Received June 30, 2005; Revised Manuscript Received October 28, 2005

The physical and biological properties of a water-soluble polymeric contrast agent based on a complex of *N*-(2-hydroxypropyl)methacrylamide copolymer with gadolinium (HE-24.8) were investigated, and its potential for experimental magnetic resonance (MR) angiography was assessed. Relaxivities of Gd-DTPA-BMA, Gd-DTPA-HSA (human serum albumin), and HE-24.8 were determined at 1.5 T. Thermic stability and biocompatibility of HE-24.8 were assessed in vitro and by analyzing kinetics and organ distribution in rats for up to 2 weeks. For comparison, HE-24.8- and Gd-DTPA-HSA-enhanced micro-MR angiographies of brain, chest, and subcutaneous tumors in rats were performed. T_1 relaxivity of HE-24.8 (21.3 ± 1.1 mM^{-1} s^{-1}) was 5-fold higher than that of Gd-DTPA-BMA (4.1 ± 0.1 mM^{-1} s^{-1}) and twice as high as that of Gd-DTPA-HSA (12.4 ± 0.2 mM^{-1} s^{-1}). Varying the molecular weight of the polymer (15−46 kDa) did not significantly change the T_1 relaxivity. In rats, 20 and 10% of the injected dose of HE-24.8 was detected at 24 and 168 h postinjection, respectively. Upon a relatively rapid initial renal clearance, no specific retention in any organ was noted, with some exception for the reticulo-endothelial system. No measurable release of gadolinium from the polymer−Gd complex or cell toxicity was observed during its incubation in aqueous environment. Excellent display of rat and tumor vascularization was achieved with Gd-DTPA-HSA and HE-24.8; however, contrast of vessels was higher in HE-24.8-enhanced scans. HE-24.8 is considered a macromolecular contrast agent highly suited for experimental MR studies.

INTRODUCTION

Clinically approved contrast agents for magnetic resonance imaging (MRI) are small chelates of gadolinium often complexed with diethylenetriaminepentaacetic acid (DTPA)[1] (*1*, *2*). They are characterized by an early extravasation, a fast renal clearance, and a low toxicity (*1*, *2*). This makes them suitable for many clinical implementations such as the detection and delineation of pathologically altered tissue (*3*−*5*) or first-pass angiographies of larger vessels (*6*−*8*). However, their use for studying micro-vascularization often is problematic: For visualizing microvessels, long scanning times are required to achieve a suitable signal-to-noise ratio, and these are not compatible with the kinetics of small gadolinium chelates. Furthermore, in functional experiments on tissue vascularization, the fast extravasation may not allow it to catch differences in vessel permeability in a reliable manner (*9*, *10*).

Therefore, numerous attempts have been undertaken to design contrast agents with larger molecular sizes to circumvent these limitations (*11*, *12*). First attempts included the labeling of plasma proteins such as albumin with gadolinium complexes (*13*, *14*). These gadolinium-labeled albumin compounds were marked by long circulation times and a high degree of hepatic metabolism of the altered proteins, which make clinical implementation questionable. As a consequence, with the outlook to a clinical assessment, dendrimeric contrast agents with a medium molecular size like Gadomer (*15*) and contrast agents with affinity to plasma proteins such as MS325 (*16*) were designed, which show a moderate intravascular half-life of several minutes and are largely cleared by the kidneys (*11*, *15*). Indeed, these contrast agents show the potential to improve functional studies on tumor vascularization including the assessment of vessel permeability during anti-angiogenic treatments (*10*, *17*) and to visualize microvessels in vivo (*18*, *19*). An alternative is the use of labeled polymers such as the PGC-derivates (*20*). As an advantage, these can be synthesized with variable configurations and molecular sizes, thus enabling optimization of their pharmacokinetic properties to the biological target (*20*). Furthermore, contrast-giving agents can easily be connected to these molecules and double or triple labeling for example with a fluorescence dye, a radioactive isotope and a lanthanide or superparamagnetic agent can be performed (*21*, *22*). Furthermore, they can be used as a matrix for molecular contrast agents by connecting them with one or more ligands

to the biological target and the signal-enhancing molecules as described above (*22*).

Copolymers based on *N*-(2-hydroxypropyl)methacrylamide (HPMA) are water-soluble, biocompatible, and nonimmunogenic macromolecular carriers that have been studied as potential drug delivery systems for a variety of low-molecular-weight drugs such as doxorubicin (*23*), campthotecin (*24*), paclitaxel (*25*), and platinates (*26*). Conjugates of this highly biocompatible polymer with cytotoxic drugs have already been used in early clinical trials (*27*−*29*). At this, it was shown that the uptake of HPMA-based copolymers in tumors depends on the molecular weight of the copolymer molecule (*29*−*31*). In contrast, in the molecular weight range between 23 and 60 kDa, the distribution of HPMA copolymer in normal organs was quite similar (*31*). Synthesis and properties of the HPMA copolymer labeled with ^{99m}Tc used for scintigraphic imaging were described in ref *32*, and the HPMA copolymer-linked nitroxides were already studied as potential MR agents (*33*). It was shown that organ biodistribution of the copolymer significantly depends on its molecular weight, that the ^{99m}Tc complexes are relatively stable, and that polymer nitroxides exhibit higher relaxivity than does Gd-DTPA-BMA.

Taking the advantages of the high flexibility in polymer synthesis and the existing preclinical and clinical experiences with HPMA polymers, the aim of this study was to use HPMA copolymers as carriers of gadolinium-based MR contrast agents. As compared with the results of Wang (*34*), who had already presented initial results with Gd-containing HPMA copolymers, in this study an alternative way of integrating gadolinium into the polymer structure was chosen. Several Gd-containing HPMA polymers with different molecular weights were synthesized. Of those, a Gd-HPMA polymer with an intermediate molecular weight of 24.8 kDa (named HE-24.8) was used to collect the first experiments addressing its cell toxicity in vitro, the blood half-life in rats, and the organ distribution during 2 weeks. Furthermore, first results using HE-24.8 as a MR contrast agent are presented including the determination of the T_1 and T_2 relaxation times and its in vivo use as a contrast agent for micro-MR angiography. The HE-24.8-enhanced MR angiographies were also compared with those performed after administration of Gd-DTPA-HSA (human serum albumin), the latter being a standard experimental contrast agent with a long blood half-life.

EXPERIMENTAL PROCEDURES

Chemicals. Methacryloyl chloride, 1-aminopropan-2-ol, 6-aminohexanoic acid, L-aspartic acid, di-*tert*-butyl dicarbonate ($(Boc)_2O$), thionyl chloride, triethylamine (Et_3N) *N*,*N*′-dicyclohexylcarbodiimide (DCC), isobutyl chloroformate, 2,2′-azobis-(isobutyronitrile) (AIBN), and trifluoroacetic acid (TFA) were purchased from Fluka (Czech Republic), and L-tyrosinamide was from Sigma-Aldrich s.r.o. (Czech Republic). All other chemicals and solvents were of analytical grade.

Synthesis of Monomers and Copolymers. *N-(2-Hydroxypropyl)methacrylamide (HPMA)* was synthesized as described earlier (*35*). *N*-Methacryloyl tyrosinamide ($Ma\text{-}TyrNH_2$) was prepared by reaction of methacryloyl chloride with tyrosinamide in distilled water as described earlier (*36*).

Synthesis of Ma-Acap-Asp-[(Asp-(OMe)$_2$]$_2$. *Synthesis of N-tert-Butyloxycarbonyl-L-aspartic Acid, Boc-Asp-OH.* L-Aspartic acid (10 g, 0.075 mol) and sodium hydroxide (6.0 g, 0.15 mol) were dissolved in distilled water (100 mL). The solution was cooled to 0 °C, and dioxane (100 mL) was added. $(Boc)_2O$ (18.0 g, 0.083 mol) was added dropwise during 1 h. The reaction mixture was stirred in an ice bath for 2 h and then for another 2 h at room temperature. The reaction mixture was concentrated on a vacuum evaporator. The unreacted $(Boc)_2O$ was removed by extraction into diethyl ether. The aqueous layer was separated and acidified to pH 2 with a saturated solution of sodium hydrogen sulfate, and the product was extracted into ethyl acetate. The organic phase was separated, dried with sodium sulfate, and concentrated on a vacuum evaporator. Boc-L-Asp-OH was crystallized from a mixture of ethyl acetate/hexane. Yield: 13.4 g (76.5%), mp 116−118 °C.

Synthesis of L*-Aspartic Acid Bis-methylester Hydrochloride HCl·Asp-(OMe)$_2$.* Methanol (100 mL), dried with calcium hydride, was put into a 250-mL two-neck round-bottom flask equipped with a stirrer and condenser. Methanol was cooled to −10 °C, and the thionyl chloride (16.4 mL, 0.225 mol) was added dropwise during 30 min. L-Aspartic acid (15.0 g, 0.112 mol) was added, and a reaction mixture was stirred and refluxed for 5 h. The reaction mixture was cooled to room temperature and concentrated on a vacuum evaporator. The final product was crystallized from a mixture methanol/diethyl ether. Yield: 18.3 g (82.5%), mp 115−117 °C.

Synthesis of TFA·Asp-[Asp-(OMe)$_2$]$_2$. Boc-Asp-OH (1.475 g, 6.33 mmol), HCl.Asp-$(OMe)_2$ (2.5 g, 12.66 mmol), and Et_3N (1.77 mL, 6.33 mmol) were mixed in 50 mL of tetrahydrofurane (THF), and the suspension was cooled to −10 °C. DCC (3.12 g, 15.1 mmol) was dissolved in 20 mL of THF, and the solution was cooled to −10 °C. The cool solution of DCC was added to the suspension, and the reaction mixture was kept for 1 h at −10 °C and then overnight at 5 °C without mixing. The reaction mixture was warmed to room temperature, acetic acid (0.1 mL) was added, and the mixture was stirred for 30 min at room temperature. Precipitated *N*,*N*′-dicyclohexylurea (DCU) and triethylamine hydrochloride (Et_3N·HCl) were filtered off, and the filtrate was concentrated on a vacuum evaporator. The resulting oily residue was diluted with ethyl acetate (100 mL) and gradually extracted with 2 wt % aqueous sodium hydrogen carbonate (50 mL), 0.5 wt % citric acid (50 mL), and water (50 mL) in a last step. The organic layer was dried with sodium sulfate, and the product was crystallized from a mixture ethyl acetate/hexane. Yield: 2.1 g (64.5%), mp 115−116 °C, TLC: (silica gel, ethyl acetate, $R_f = 0.54$). Elemental analysis: calcd/found C = 48.55/48.85, H = 6.40/6.50, N = 8.09/8.05. The Boc protection group was removed by TFA. Boc-Asp-[Asp-$(OMe)_2]_2$ (2.0 g) was dissolved in TFA (8.0 mL) and stirred for 30 min at room temperature. The excess TFA was evaporated, the mixture was diluted three times with dry methanol, and the solvent was evaporated again. The oily residue was triturated with diethyl ether to form crystals of TFA·Asp-[Asp-$(OMe)_2]_2$. Yield 1.6 g (77.9%).

Synthesis of N-methacryloyl-6-amino Hexanoic Acid, Ma-Acap-OH (Ma = methacryloyl). The Schotten-Baumann acylation method with methacryloyl chloride in an aqueous alkaline medium was used for methacryloylation of 6-aminohexanoic acid (*37*). (mp 52−53 °C, elemental analysis: calcd/found C 60.28/60.43, H 8.60/8.37, N 7.03/6.98).

Synthesis of Ma-Acap-Asp-[(Asp-(OMe)$_2$]$_2$. N-Methacryloyl 6-aminohexanoic acid (0.5 g, 2.51 mmol) and Et_3N (0.385 mL, 2.76 mmol) were dissolved in THF (5 mL). The solution was cooled to −10 °C, and isobutyl chloroformate (0.36 mL, 2.76 mmol) was added. After 10 min, the reaction mixture was added to a cooled mixture of TFA·Asp-[Asp-$(OMe)_2]_2$ (1.47 g, 2.76 mmol) and Et_3N (0.424 mL, 3.04 mmol) in THF (5 mL). The reaction mixture was stirred for 4 h at room temperature. The precipitated Et_3N·HCl was filtered off, and THF was evaporated in a vacuum. The residue was dissolved in ethyl acetate (20 mL) and gradually extracted with 2 wt % aqueous sodium hydrogen carbonate (5 mL), 0.5 wt % citric acid (5 mL), and water (5 mL). The organic layer was dried with sodium sulfate, and the product was crystallized from a mixture of ethyl acetate/

hexane. Yield 0.5 g (33%), mp 110−113 °C, elemental analysis: Calcd/found C = 51.99/50.31, H = 6.71/6.34, N = 9.33/8.93.

Synthesis and Characterization of the Copolymer P-Acap-Asp-[(Asp-(OH)$_2$]$_2$. The copolymer was prepared by solution radical copolymerization of HPMA with Ma-Acap-Asp-[(Asp-(OMe)$_2$]$_2$ in methanol at 60 °C. HPMA (1.0 g, 6.98 mmol) and Ma-Acap-Asp-[(Asp-(OMe)$_2$]$_2$ (0.221 g, 0.368 mmol) were dissolved in methanol (7.0 mL), and initiator AIBN (0.068 g, 0.41 mmol) was added. The solution was transferred into a glass ampule and bubbled with nitrogen. The ampule was sealed, and polymerization was carried out at 60 °C for 24 h. The polymer was isolated by precipitation into a mixture of acetone and diethyl ether (3:1), filtered off, washed with acetone, and diethyl ether, and dried in a vacuum. Yield: 0.998 g (81.7%).

The HPMA copolymer used for kinetic and biodistribution studies (HE-radiolabel) was prepared by terpolymerization of HPMA (1.0 g, 6.98 mmol), Ma-TyrNH$_2$ (0.037 g, 0.15 mmol), Ma-Acap-Asp-[(Asp-(OMe)$_2$]$_2$ (0.221 g, 0.368 mmol), and AIBN (0.070 g, 0.42 mmol) in methanol (7.0 mL) at 60 °C for 24 h.

The methyl ester groups from both copolymers mentioned above were removed by alkaline hydrolysis. Briefly, the copolymer (0.8 g) was dissolved in distilled water, and the pH of the solution was maintained at 11.5 with addition of 0.1 M NaOH for 6 h at room temperature. Then, the pH was lowered to 2 with diluted hydrochloric acid, and the copolymer was dialyzed in a Visking dialysis tube with a molecular weight cut off of 3500 for 2 days and lyophilized. Yield: 0.75 g.

The weight-average molecular weight M_w and polydispersity M_w/M_n were determined by size exclusion chromatography on the HPLC system ÄKTA explorer (Amersham Biosciences) equipped with RI and multiangle light scattering detectors DAWN DSP-F (Wyatt Technol. Corp., USA) on Superose 6 column.

The side chain (amino acids) content was determined after hydrolysis of polymers HE 24.8 and HE-radiolabel with 6 N HCl at 115 °C for 16 h using a HPLC amino acid analyzer (LDC Analytical, USA) with a reverse-phase column Nucleosil 120-3 C_{18} (Macherey-Nagel, 125 × 4 mm) using precolumn derivatization with phthaldialdehyde, and detection with a fluorescence detector (excitation at 229 nm, emission at 450 nm). Gradient elution: 0−100% of solvent B within 65 min and flow rate 0.5 mL min^{-1} (solvent A: 0.05 M sodium acetate buffer, pH 6.5; solvent B: 300 mL of 0.17 M sodium acetate and 700 mL of methanol).

HPMA copolymers differing in chemical composition and molecular weight characteristics could be easily prepared by changing monomers ratio (HPMA: Ma-Acap-Asp-[(Asp-(OMe)$_2$]$_2$), initiator concentration, concentration of monomers in the polymerization mixture, and polymerization temperature. Several copolymers with a content of Ma-Acap-Asp-[(Asp-(OMe)$_2$]$_2$ up to 30% and molecular weights between 15 and 200 kDa could be prepared. From these, gadolinium-containing HPMA polymers with an average weight of 16.2, 21.7, 22.2, 24.8, 27.7, 43.9, and 45.6 kDa were used for comparison of T_1 relaxivities.

Synthesis of P-Acap-Asp-[Asp-(OH)$_2$]$_2$ Gadolinium Complex HE-24.8 (P Means HPMA Copolymer Chain). HPMA copolymer P-Acap-Asp-[Asp-(OH)$_2$]$_2$ (0.45 g) was dissolved in distilled water, and gadolinium chloride (0.045 g) was added. The pH of the solution was gradually increased to 6.0 by addition of 0.1 M NaOH during 1 h. The excess of gadolinium was removed from a complex by dialysis using a Visking dialysis tube with a cut off of 3500 for 48 h in water. The polymer−gadolinium complex was lyophilized. The yield was 0.41 g of the complex.

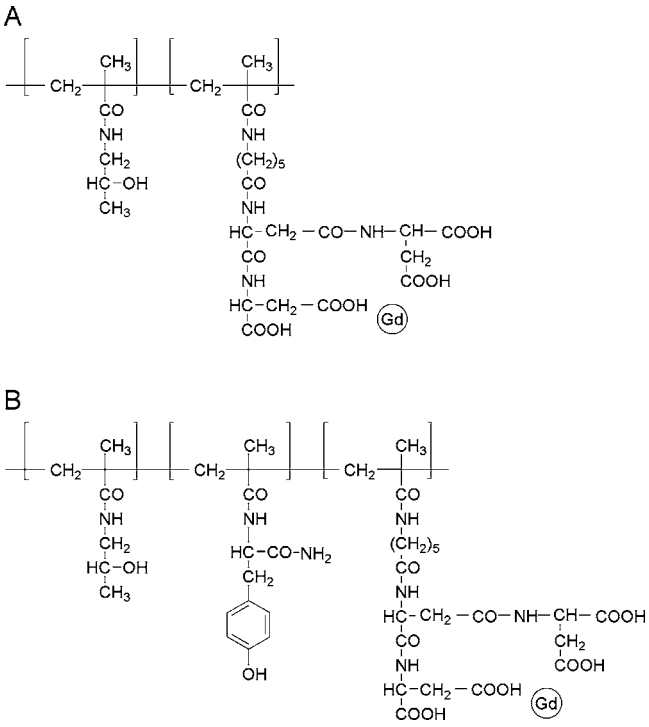

Figure 1. Chemical structures of the 24.8 kDa HPMA copolymer-based contrast agent HE-24.8 (A) and HE-radiolabel (B), the latter being used for the scintigraphic pharmacokinetic analysis in vivo.

The gadolinium content in the polymer complexes was 5.2 ± 0.3 as determined by inductively coupled plasma-mass spectrometry (ICP-MS).

Structures and characteristics of the HPMA copolymer−Gd complexes are given in Figure 1 and Table 1.

Determination of the Thermic Stability. A total of 1 μmol of the Gd-HPMA polymers and 100 μmol of tri-sodium-citrate were diluted in 11 mL of PBS (pH7.4). Samples of the stock solution with 1 mL each were incubated at 60 °C for 1, 5, and 25 h, respectively. At each time point, 100 μL were removed and diluted with 900 μL of PBS, then filtered (5 kDa MW filter, Millipore, Billerica, USA) to remove free gadolinium. The citrate complexed Gd-content was determined by plasma mass spectrometry.

Gd-DTPA-human Serum Albumin (Gd-DTPA-HSA). Gadolinium-DTPA-labeled albumin conjugates were synthesized at the German Cancer Research Center (DKFZ, Heidelberg, Germany) as described previously (*13*), by covalently binding gadolinium-DTPA to albumin.

In Vitro Determination of Cell Toxicity. Human fibroblasts (MSU) and human hepatoma cells (HEP-G2) were used. MSU and HEP-G2 cell lines were obtained from the German Cancer Research Center, Heidelberg, Germany.

Cells were grown in 75 cm^2 plastic culture flasks (TPP, Switzerland) in 10 mL of medium at 37 °C and in a humidified 5% CO_2 atmosphere. Human fibroblasts were maintained in Dulbecco's MEM-medium (Biochrom. AG, Berlin) supplemented with 10% fetal bovine serum (FBS), 1% sodium pyruvate, and 100 U penicillin/streptomycin. HEP-G2 cells were grown in RPMI 1640-medium (GIBCO, UK) with 5% FBS, 1% glutamine, and 100 U penicillin/streptomycin. Media were replaced every 4 days, and cells were split upon confluence at a split ratio of 1:5. For incubations, 24-bottom well plates with plastic cover slips of 13-mm diameter (Nalge Nunc International, Denmark) were used. A total of 500 μL of cell suspension was added to each well.

To investigate toxicity, cells were incubated with either HE-24.8 or Gd-DTPA-BMA (Omniscan, Amersham Health, Prin-

Table 1. Characteristics of HPMA Copolymer−Gd Complexes

ceton, USA) in equimolar gadolinium concentrations (0.05 and 0.5 mmol of Gd/L) for 24 and 48 h. Cells grown in unmodified medium served as controls.

Viability was determined by Trypan blue (GIBCO, Gland Island, NY) exclusion following the manufacturer's instructions. The fraction of nonviable cells was determined using a Neubauer's counting chamber by analyzing five vision fields and calculating means and standard deviations (SD).

Cell survival was compared using the Student's t-test and $p < 0.05$ was considered to indicate a significant difference.

Animals and Tumors. All experiments were approved by the governmental review committee on animal care. Four healthy Copenhagen rats were used to study kinetics, biodistribution, and tolerability of HE-24.8. To perform tumor micro-angiographies, five Copenhagen rats with subcutaneous Dunning R3327-AT1 prostate tumors were used. Tumors were induced in the right upper thigh by injection of 2×10^5 cells in 1 mL of 0.9% NaCl. Tumors were grown for 3 weeks.

Kinetics, Biodistribution, and in Vivo Toxicity. To assess circulation time, organ accumulation and elimination, an analogous HPMA copolymer−Gd complex to HE-24.8 containing tyrosinamide in its side chain was synthesized, to allow radio labeling with ^{131}I (HE-radiolabel). The radiolabeled conjugate was injected into the tail vein of four healthy Copenhagen rats. Blood samples and scintigraphic images were taken at indicated time points. Two weeks after intravenous injection, the animals were sacrificed, and their organs were removed. Residual activity was corrected for radioactive decay. During the two-week follow-up period, the animals were monitored for signs of toxicity.

MR Imaging. Magnetic resonance imaging (MRI) was performed on a clinical 1.5 T whole-body MR system (Siemens Symphony, Erlangen, Germany) using a custom-made radio frequency-(rf) coil for rf excitation and signal reception. The rf coil was designed as a cylindrical volume resonator with an inner diameter of 83 mm and a useable length of 120 mm. To optimize the available signal-to-noise ratio, manual tuning and matching of the coil's resonance circuitry was performed for each measurement individually.

Determination of the Relaxivity of HE-24.8, Gd-DTPA-HSA, and Gd-DTPA-BMA. Relaxivity measurements of HE-24.8, Gd-DTPA-HSA, and Gd-DTPA-BMA were performed using a 1.5 T MR scanner (Magnetom Vision, Siemens Erlangen, Germany) and a standard head coil (Siemens Erlangen, Germany). Increasing concentrations of contrast medium (0.0, 0.01, 0.05, 0.1, 0.5, 1.0 mmol of Gd/L of 0.9% NaCl) were transferred to phantom vials and placed in the isocenter of the coil. T_1 times were determined with a saturation-recovery turbo FLASH-sequence (TR/TE = 10 ms/4 ms, flip-angle: 12°, T_{rec} = 53−9000 ms). The relaxation rates were plotted against concentrations and fitted by linear regression to achieve the relaxivity.

High-Resolution MR Angiography. For MR examination and catheterization, rats were anaesthetized by inhalation of a mixture of isofluorane (1.5%), N_2O (35%), and O_2 (60%). A tail vein was catheterized using a 24 G indwelling cannula (Introcan, B. Braun Melsungen AG, Melsungen, Germany), which was connected with a 1 mL syringe (Braun Melsungen AG, Melsungen, Germany) filled with 1 mL of the contrast agent (0.05 mmol of Gd/kg of body weight for both HE-24.8 and Gd-DTPA-HSA).

MR examinations of the rats were initiated by a T_2 weighted turbo spin−echo sequence: TR = 4000 ms, TE = 96 ms, 1 acquisition, echo train length = 7, TA = 1 min 49 s, field of view = 50 × 37.5 mm, matrix = 140 × 256, slice thickness = 2 mm, voxel size = 2.0 × 0.36 × 0.15 mm^3.

Four animals were examined with HE-24.8-enhanced scans, one after administration of Gd-DTPA-HSA. The contrast agent was injected before the first MR angiography scan. In three of four rats, which were examined with HE-24.8-enhanced scans and in the animal with Gd-DTPA-HSA at first the tumors were investigated using a three-dimensional gradient echo pulse sequence (TR/TE = 28.0/8.6 ms, flip-angle = 70°, field of view = 12.8 × 30 × 50 mm^3, matrix = 128 × 317 × 512, reconstructed voxel size = 100 × 98 × 98 μm^3, 2 acquisitions, total scan time = 24 min). Subsequently, the chest was imaged using again a three-dimensional gradient echo pulse sequence with the following parameters: TR/TE = 10.2/3.8 ms, flip-angle = 70°, field of view = 30 × 55 × 110 mm^3, matrix = 60 × 256 × 512, reconstructed voxel size = 500 × 215 × 215 μm^3, 4 acquisitions, total scan time = 5.18 min. In the remaining animal, which was scanned with HE-24.8, a high resolved examination of the brain was performed using the first men-

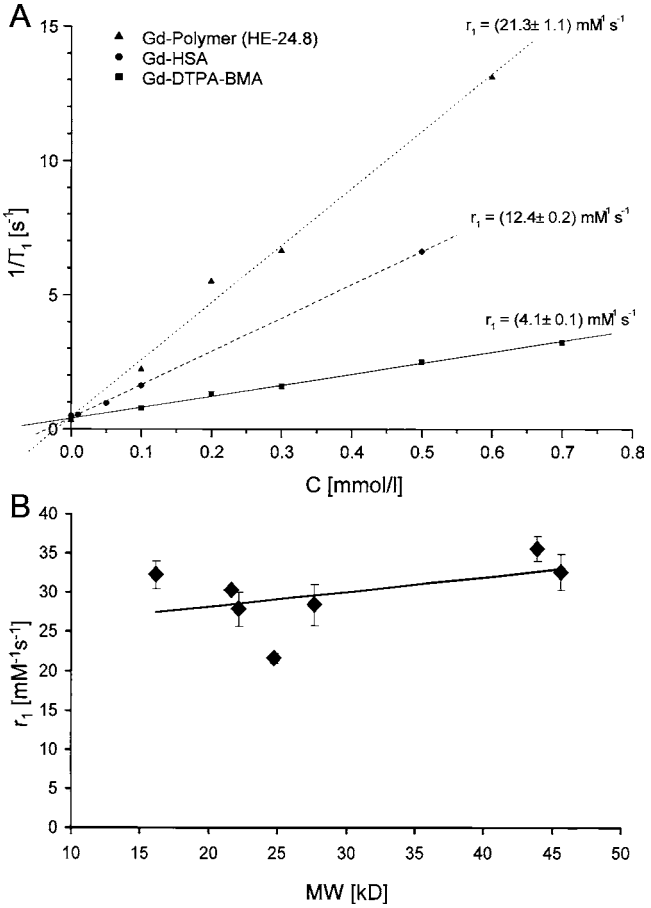

Figure 2. (A) Results of the T_1 relaxivity (r_1) measurements of Gd-DTPA-BMA, Gd-DTPA-HSA, and HE-24.8 measured at 1.5 T. (B) T_1 relaxivity (r_1) of HPMA copolymer−Gd complexes with different sizes (16.2, 21.7, 22.2, 24.8, 27.7, 43.9, and 45.6 kDa; $n = 5 \pm$ SD).

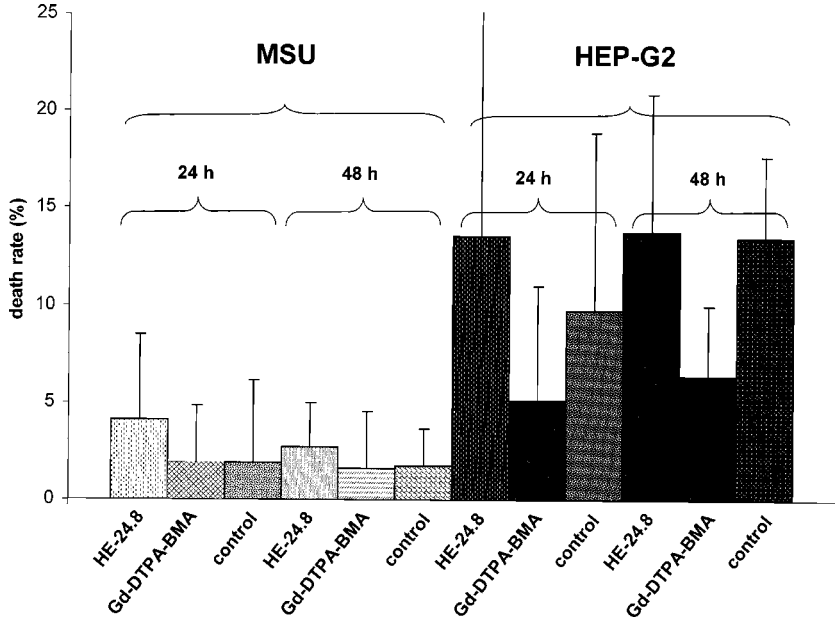

Figure 3. Death rates of human fibroblasts (MSU) and hepatocarcinoma cells (HEP-G2) after incubation with HE-24.8 and Gd-DTPA-BMA in dosages of 0.5 mmol of Gd/L of growth medium. Incubation times were 24 and 48 h. Data presented as mean ($n = 10 \pm$ SD).

tioned gradient echo pulse sequence. Afterward, the tumor was investigated as described previously.

Comparison of Vessel Contrast in HE-24.8- and Gd-DTPA-HSA-Enhanced Scans. To compare the in vivo contrast of vessels in HE-24.8- and Gd-DTPA-HSA-enhanced scans circular ROIs ($n = 5$) were placed in the left ventricle of the heart, the aorta, the caval vein, the brachial vein, and the neck musculature. Signal intensities (SI) of vessels and heart were normalized to the mean SI of the muscle. Data were compared using the Student's t-test, and $p < 0.05$ was considered to indicate a significant difference.

Histological and Immunofluorescence Examination. For histological diagnosis and assessment of vital tissue and its vascularization, tumors were dissected, covered with "tissue tek" (Sacura, Zoeterwoude, Netherlands), and frozen in liquid nitrogen vapor. 5-μm-thick sections were cut with a Reichert-Jung Frigocut 2700 microtome. For histology, sections were stained with hematoxilin and eosin (HE). Blood vessels were visualized by immunofluorescence using a polyclonal antibody against collagen IV (Progen, Heidelberg, Germany) and a Cy3-labeled secondary anti-rabbit IgG antibody (Dianova, Hamburg, Germany). Tissue sections were viewed by fluorescence microscopy using an Olympus AX-70 microscope. Images were captured with a digital camera at ×4 magnification and composed using the Soft-Imaging-System analysis software. From immunofluorescence images, the mean diameters of the 10 largest vessels either tumor periphery or center were analyzed to obtain information about the minimal vessel diameters, which were resolved by MR-angiography using Gd-DTPA-HSA or HE-24.8, respectively.

RESULTS

In Vitro Experiments: Thermic Stability, Relaxivity, and Toxicity. *Chemical Characterization of the Polymers.* New polymeric MRI contrast agents based on HPMA copolymers bearing in the side chains aspartic acid residues complexed with Gd were synthesized. Structures and characteristics of the HPMA copolymer−Gd complexes are given in Scheme 1 and Table 1.

Thermic Stability of HE-24.8. The gadolinium content of nonfiltered samples containing the Gd−HPMA polymers in PBS was 11.6 ± 0.1 μg of Gd/mL. After the polymers were removed

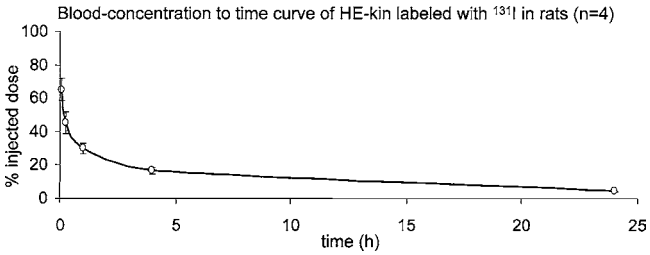

Figure 4. Blood concentration to time curve of HE-radiolabel (^{131}I) in rats ($n = 4$). After 15 min, less than 50% and after 24 h less than 5% of the injected dose was found in the blood.

by filtration with a 5 kD MW filter 0.07 ± 0.01 μg of Gd/mL were left in the probe. Incubation of the polymer at 60 °C did not increase the amount of filtered gadolinium significantly. A constant level of 0.05 ± 0.01 μg of Gd/mL was determined after 1, 5, and 25 h, respectively.

Relaxivity. HE-24.8 showed a T_1 relaxivity of 21.3 ± 1.1 mM^{-1} s^{-1} at 1.5 T, which was higher than the relaxivity of Gd-DTPA-HSA (12.4 ± 0.2 mM^{-1} s^{-1}) and Gd-DTPA-BMA (4.1 ± 0.1 mM^{-1} s^{-1}). In consequence, a higher T_1 contrast was achieved in MR angiography (Figure 2A). T_2 relaxivity of HE-24.8 at 1.5 T was 29.4 ± 0.3 mM^{-1} s^{-1}. When comparing Gd-labeled HPMA copolymers of different sizes, it was observed that the T_1 relaxivity of the different compounds was similar in the used molecular size range (Figure 2B), which is desirable when using such substances for studying vessel permeability in vivo.

Cell Toxicity. Cell survival experiments were performed to study toxicity and stability of the HPMA copolymer−Gd complex HE-24.8. No increased cell death rates were observed after incubation of the cells with HE-24.8 or Gd-DTPA-BMA at concentrations of 0.05 and 0.5 mmol of Gd/L in growth medium. After 24 h incubation of the cells with 0.5 mmol of Gd/L the ratio of nonviable MSU cells was lower than 5% for both contrast agents and thus comparable to the control cells in which the death rate was 2%. Also after incubation times of 48 h mean death rates were always lower than 5% (Figure 3).

The excellent tolerance of HE-24.8 was underlined by toxicity experiments with HEP-G2 cells, where no significantly increased death rates were observed, although the baseline rate of dead cells was higher for all incubation conditions (Figure 3).

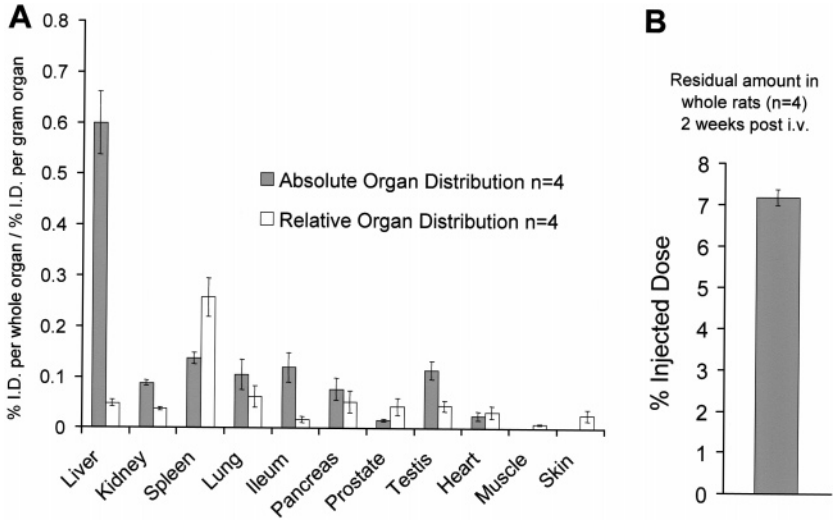

Figure 5. Radioactive counts representing the absolute and relative organ concentrations of HE-radiolabel in rats 14 days after administration (A). The mean absolute concentration for the entire animal ($n = 4$) is shown in B.

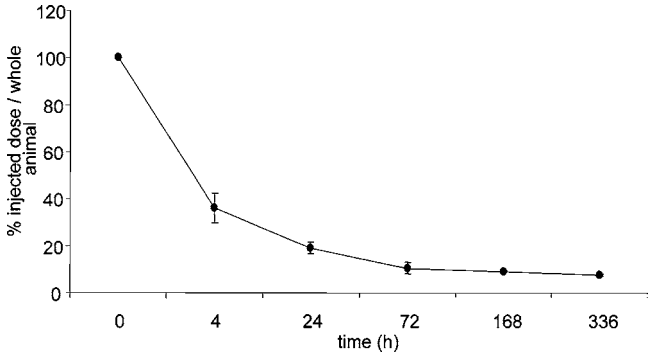

Figure 6. The mean relative number of counts in rats ($n = 4$) from scintigraphic detection of HPMA copolymer−Gd complex labeled with ^{131}I is shown during a two-week follow up. The total number of counts after 1 h measured in rats, which were kept under continuous anesthesia, was set at 100%.

Kinetics, Biodistribution, and in Vivo Toxicity. Lack of toxicity in cell culture experiments encouraged us to initiate animal studies.

As shown in Figure 4, HE-radiolabel circulates for significantly prolonged periods of time as compared with data known from the literature about low-molecular-weight gadolinium chelates. After 15 min, less than 50% of the injected dose (ID) was left in the systemic circulation. Four hours postintravenous injection, the concentration in the systemic circulation had decreased to 16.9% ID. A total of 24, 168, and 336 h after injection, 4.67, 0.36, and 0.15% ID could be attributed to the vascular compartment, respectively (Figure 4).

Two weeks after intravenous injection of HE-radiolabel, animals were sacrificed, organs were removed, and radioactive counts were analyzed. HE-radiolabel did not accumulate in any organ specifically, when expressed as a percentage of ID. Relatively, the largest fraction of contrast agent accumulated in the spleen, with 0.25% ID/g of tissue (Figure 5). In most other tissues, retention rates were comparable with approximately 0.05% ID/g of tissue. Absolutely, i.e., when taking organ weight into account, at 336 h postinjection, most of the conjugate ended up in the liver. Hepatic uptake was very acceptable, with only 0.6% per whole liver.

At the level of the entire animal, 37.6, 20.0, and 8.0% ID were still detected by scintigraphic imaging at 4, 24, and 336 h postinjection, respectively (Figure 6).

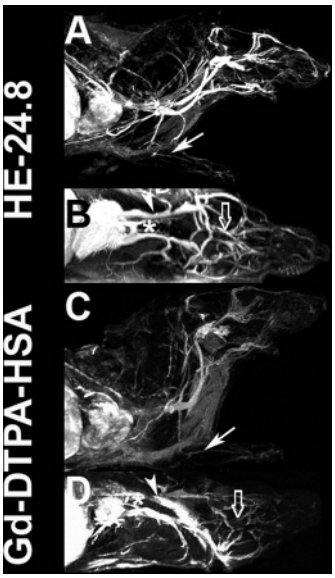

Figure 7. MR angiography scans of the chest of rats using HE-24.8 (A, B) and Gd-DTPA-HSA (C, D). Images give sagittal (A, C) and coronal (B, D) views of the animal. Both contrast agents give an excellent display of larger veins of the chest (arrowheads) and the brain (open arrow: jugular vein) as well as of the heart with its ventricles. While the contrast of larger vessels is better in the He-24.8-enhanced scan, in smaller vessels such as the brachial vein (arrow) the vessel contrast is comparable. *: aortic arc.

No decreased overall activity, no reduction in food intake, and no substantial signs of weight loss were observed during the experiments.

MR Angiography. To get an idea of the in vivo contrast characteristics of HE-24.8, micro-MR angiographies of rats and experimental tumors were performed and compared with images of Gd-DTPA-HSA-enhanced MR angiographies. Both contrast agents showed an excellent display of larger veins of the chest and the brain as well as of the heart with its ventricles (Figure 7). However, as expected from the higher T_1 relaxivity, the contrast of heart ventricles, larger arteries, and veins was more than 70% higher using HE-24.8 (Figures 7 and 8). For smaller peripheral veins such as the brachial vein no significant differences in vessel contrast was found (Figure 8). In the subcutaneous tumors (Figure 8), both contrast agents showed the potential to visualize the small and fragile tumor neovascularization. However, vessel architecture of tumors was not displayed in higher detail in HE-24.8-enhanced scans, which

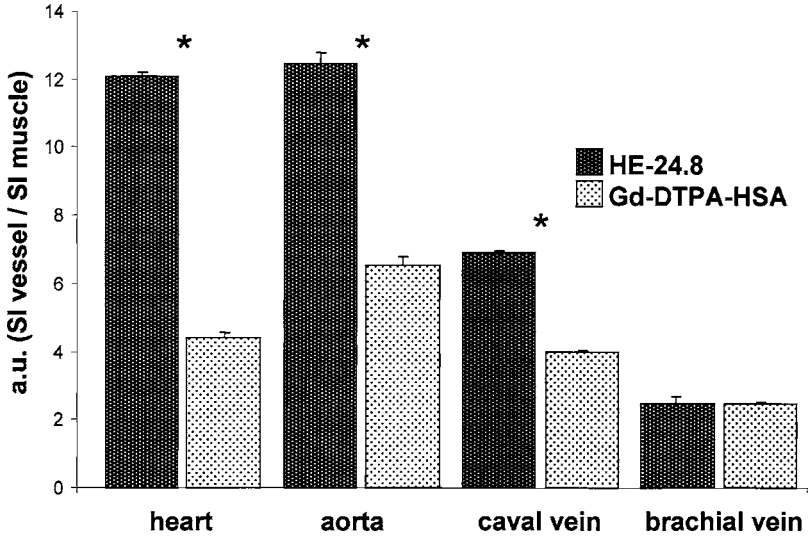

Figure 8. Comparison of vessel contrast in HE-24.8- and Gd-DTPA-HSA-enhanced scans. Using HE-24.8, significantly higher vessel contrast was found in the heart, aorta, and caval vein. In contrast, vessel contrast in the brachial vein was not significantly different. Data presented as mean of 5 ROI analyses + SD. *$p < 0.05$.

was most probably reasoned by the limited resolution and signal-to-noise ratio of the clinical 1.5 T MR scanner. Predominantly larger vessels localized at the tumor periphery were visualized by MR angiography and reconstructed three-dimensionally (Figure 9). Determining the mean diameters of peripheral vessels on histological images, it was clearly shown that these had diameters of 96 ± 51 μm, which is in line with vessel sizes resolved by other groups using 1.5 T MR angiography (*18,19*). The small vessels found in the tumor center with a mean diameter of 12 ± 5 μm (SD) were not depicted by MRI either using Gd-DTPA-HSA or HE-24.8.

Also in the brain HE-24.8 proved its potential as an excellent experimental angiographic contrast agent by clearly visualizing the vascular network with the feeding carotic artery, the draining jugular vein, and the basal cerebral arteries of the circulus arteriosus cerebri. Even the middle cerebral artery and some of its branches could be detected at 1.5 T using HE-24.8 (Figure 10).

DISCUSSION

In this paper, an MR contrast agent based on an HPMA copolymer−Gd complex is presented. In this context, the synthesis of a new comonomer Ma-Acap-Asp-[(Asp-$(OMe)_2$]$_2$ and its two copolymers with HPMA is described. The synthesis enables preparation of a broad range of copolymers differing in molecular weight and copolymer composition. The copolymers after deprotection of carboxylic groups form complexes with gadolinium exhibiting an excellent thermostability in aqueous solutions, which was tested for a temperature of up to 60 °C. The copolymer HE-radiolabel contains small amount of tyrosinamide in its structure enabling radiolabeling and the use of this copolymer for pharmacokinetic studies. Copolymer HE-24.8 consists of HPMA and Ma-Acap-Asp-[(Asp-$(OH)_2$]$_2$-Gd units. In both polymer complexes, Gd was embedded in side chains of the hydrophilic polymer formed by three aspartic acid residues extending four carboxylic groups for complexation with Gd. As a basis for further studies, the biological behavior of HE-24.8 was examined in vitro and in vivo. Furthermore, initial results are presented using this contrast agent to visualize tumor microvasculature, and the contrast of vessels was compared between HE-24.8- and Gd-DTPA-HSA-enhanced scans.

Embedding the gadolinium atoms in a HPMA copolymer results in a high T_1 relaxivity, which is superior to those of Gd-DTPA-BMA and Gd-DTPA-HSA. The high T_1 relaxivity can be attributed to the new type of structure of the Gd complex leading to an improved interaction of the gadolinium with surrounding protons. It may be further supported by the integration of the gadolinium into a highly hydrophilic HPMA copolymer, which is also known to increase T_1 relaxivity of contrast agents, where gadolinium compounds were coupled or bound to proteins (*38*−*40*) and other tracers (*11*, *15*, *20*). Relaxivity of Gd-DTPA-HSA may also increase when binding more Gd-DTPA molecules to the albumin or by modifying the way of binding (*41*). However, the low number of Gd-DTPA molecules bound to HSA was chosen to reduce hepatic elimination, which is highly influenced by the loading rate of albumin (*42*).

It is a further advantage of the HPMA copolymer−Gd complexes that the T_1 relaxivities of compounds with molecular sizes between 15 and 46 kDa were not significantly different. This predetermines the HPMA copolymer−Gd complexes for studies on vessel permeability in vivo, e.g., to find optimal polymer sizes to visualize neoplastic tissue.

There were no indications of release of free gadolinium in the in vitro experiments, which would result in high cell toxicity. Likewise, no toxic effects were observed in vivo. However, studies with higher animal numbers and monitoring over longer periods of time are necessary to confirm this preliminary result. Although the HPMA polymer carrier is not immunogenic, it is also important to exclude immunogenic reactions, which may be induced by the gadolinium chelate derivates and which are for example known from Gd-DOTA.

For visualization of microvessels using a clinical 1.5 T MR scanner, long acquisition times are required to reveal a sufficiently high signal-to-noise ratio. In this study, extended acquisition times could be chosen due to the longer intravasal persistence of HE-24.8 as compared to the clinically used small Gd-chelates. On the other hand, long circulation times go along with a delayed systemic elimination of the compound.

Comparable with native and cytostatic drug-loaded HPMA copolymers (*30*, *31*), and other uncharged polymeric drug and tracer carriers such as PEG, HPMA copolymer−Gd complex did not accumulate in any organ specifically. In general, such carriers are initially cleared by the kidneys, and later on more dominantly by the reticulo-endothelial system. Thus, it is plausible that the highest uptake of HE-24.8 per gram of tissue was found in the spleen, where the substance was most probably accumulated by macrophages via phagocytosis.

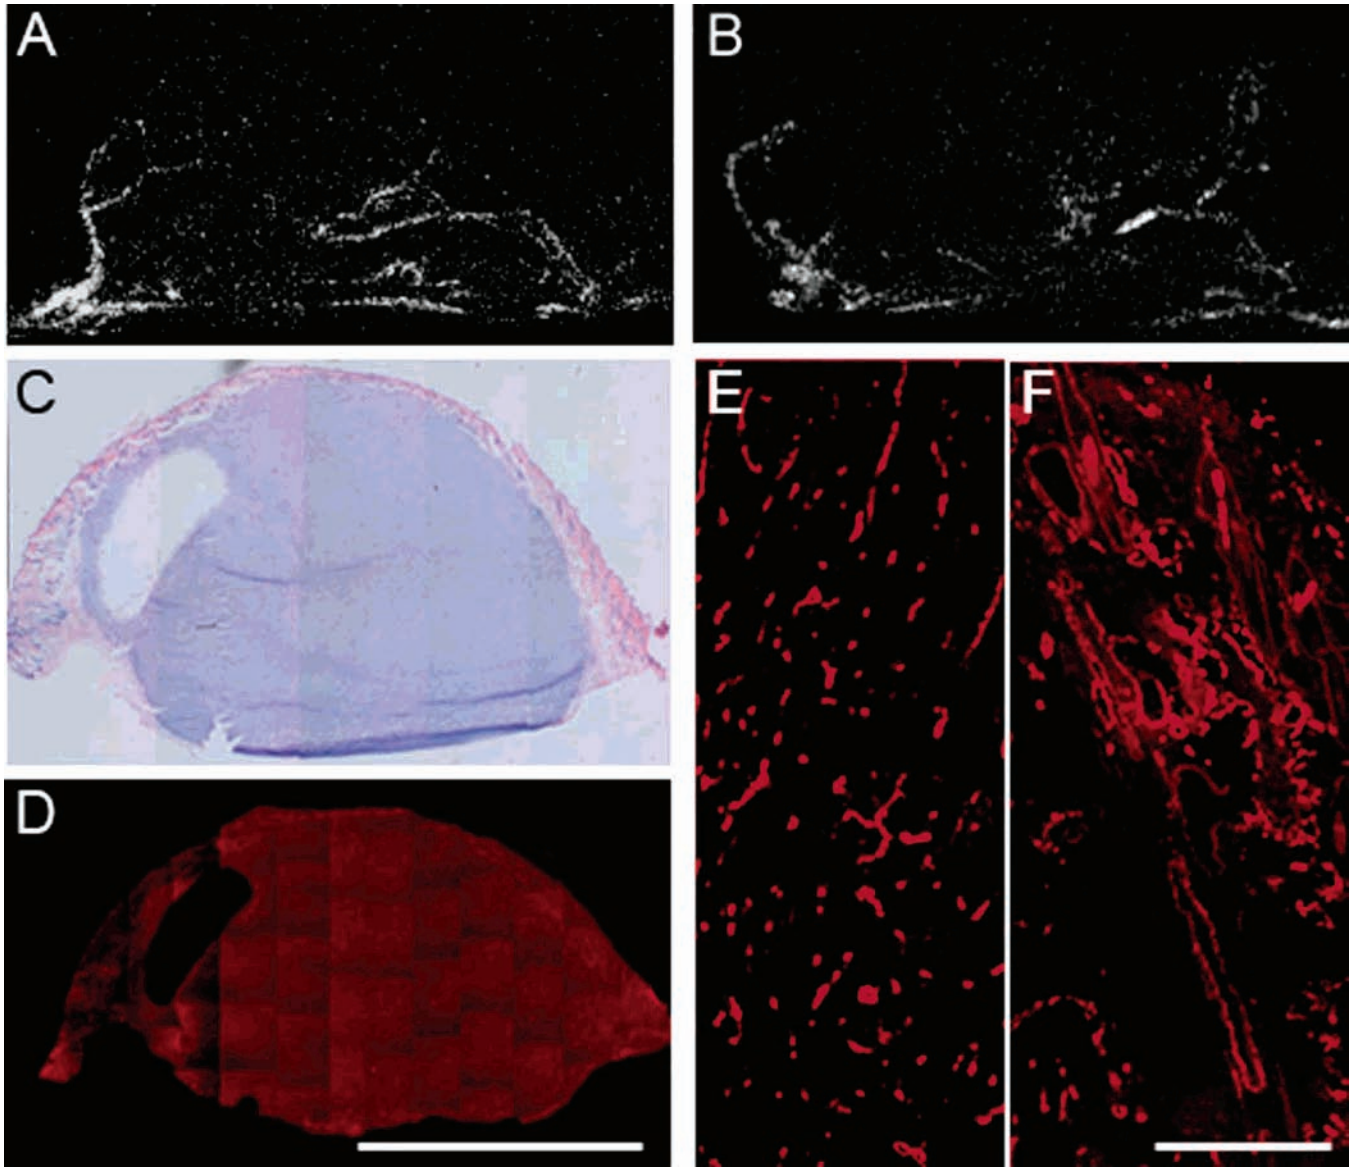

Figure 9. Maximum intensity projections (MIP) of a subcutaneous Dunning prostate carcinoma in rats using HE-24.8 (A) and Gd-DTPA-HSA (B). Histological compound images of the tumor shown in A are demonstrated using a hematoxilin and eosin stain (C) and an immunofluorescence stain against the vessel collagen type IV (D), respectively. Magnifications of the immunofluorescence image taken from representative areas of the tumor periphery (E) and center (F) show the differences in vessel architecture with larger vessels of approximately 91 ± 51 μm at the tumor periphery and small capillary vessels of less than 12 ± 5 μm diameter in the center. Bars: 5 mm (D), 0.4 mm (F).

When comparing HE-24.8 with comparable macromolecules (*13*, *20*), it is a great advantage that the liver does not accumulate HE-24.8 in higher amounts. Only 0.6% of the injected dose was found in liver two weeks postinjection. Thus, we conclude that the hydrophilic nature of the HPMA polymer chain, neutral loading, the absence of structural inhomogeneities, e.g., as present in liposomes and the random coil configuration, reduce the immunological detection of HE-24.8.

We are aware that for clinical use the intracorporal persistence of approximately 7.6% of HE-24.8 after 14 days is still too high. The molecular weight of approximately 25 kDa was chosen for the synthesis of HE-24.8 to be in the size range of HPMA copolymer constructs loaded with cytostatic drugs. Currently, at least six HPMA copolymer-based drug conjugates of comparable size are being evaluated in various clinical stages (*43*). Ultimate goal of these studies was, however, to increase circulation time and tumor accumulation of the delivered drug and to better control its side effects by substantially altering biodistribution. Because the nature of the polymers allows us to flexibly modify its size, structure, and stability, there is still room for further developments. Currently, we are evaluating conjugates of significantly smaller size, and in the future we may try to establish comparable, but biodegradable, contrast-enhancing conjugates (*44*, *45*), to boost elimination in the first two weeks after injection.

MR angiographies showed a detailed display of rat and tumor vasculature even for vessels with relatively slow blood flow like most of the tumor vessels. For these vessels, the signal enhancement by flow effects is considerably low, and as a consequence the vessel contrast is more dependent on the contrast agent. Compared with Gd-DTPA-HSA, the contrast of vessels was higher, while the amount of vessels was not increased. The lack of displaying smaller vessels, however, can be attributed to the voxel sizes, which could not be chosen smaller at an acceptable signal-to-noise ratio with the clinical 1.5 T MR-scanner. In the extremities, the difference in vessel contrast between HE-24.8- and Gd-DTPA-HSA-enhanced scans was reduced as compared with larger central vessels of the chest. This may be because if only a part of the voxel contains the vessel, the signal intensity change after application of contrast

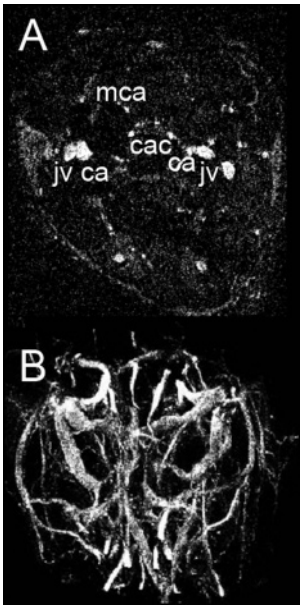

Figure 10. Coronal image (A) and MIP (B) of HE-24.8-enhanced scans of the rat head. The carotic artery (ca) and the jugular vein (jv) are clearly shown on both images. Also smaller vessels as those of the circulus arteriosus cerebri (cac) or the middle cerebral artery (mca) with some of its larger branches are visualized.

agent becomes lower. Thus, the signal enhancement, which is achieved with contrast agents with higher or lower T_1 relaxivity, equalizes. The advantages of HE-24.8 to image smaller vessels would most probably become more evident at higher field strength (>1.5 T), where differences in T_1 relaxivity between Gd-DTPA-BMA, Gd-DTPA-HSA, and HE-24.8 become more important (own unpublished results), and the voxel sizes of the MR angiography sequence could be chosen smaller.

In summary, a new polymeric contrast agent is presented, which can be synthesized with flexible molecular weight and structure. Besides its suitability for experimental studies on micro-MR angiography, the independency of the T_1 relaxivity of the Gd-labeled HPMA compounds on the polymer sizes makes it an interesting tool to study vessel permeability in tumors. For a future clinical approach, however, further chemical refinement seems necessary to fasten the corporal elimination.

ACKNOWLEDGMENT

Carbohydrate and Protein Immobilization onto Solid Surfaces by Sequential Diels−Alder and Azide−Alkyne Cycloadditions

Xue-Long Sun,*[,†] Cheryl L. Stabler,[†] Chrystelle S. Cazalis,[†] and Elliot L. Chaikof*[,†,‡]

Departments of Surgery and Biomedical Engineering, Emory University, Atlanta, Georgia 30322, and School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332. Received July 29, 2005; Revised Manuscript Received December 6, 2005

We demonstrate the applicability of sequential Diels−Alder and azide−alkyne [3 + 2] cycloaddition reactions (click chemistry) for the immobilization of carbohydrates and proteins onto a solid surface. An α,ω-poly(ethylene glycol) (PEG) linker carrying alkyne and cyclodiene terminal groups was synthesized and immobilized onto an *N*-(ϵ-maleimidocaproyl) (EMC)-functionalized glass slide via an aqueous Diels−Alder reaction. In the process, an alkyne-terminated PEGylated surface was provided for the conjugation of azide-containing biomolecules via click chemistry, which proceeded to completion at low temperature and in aqueous solvent. As anticipated, alkyne, azide, cyclodiene, and EMC are independently stable and do not react with common organic reagents nor functional groups in biomolecules. Given an appropriate PEG linker, sequential Diels−Alder and azide−alkyne [3 + 2] cycloaddition reactions provide an effective strategy for the immobilization of a wide range of functionally complex substances onto solid surfaces.

INTRODUCTION

Robust immobilization techniques that preserve the activity of biomolecules have many potential applications. For example, microarrays, microbeads, and biosensor chips play increasingly important roles in characterizing the function and interaction of biomolecules, purification schemes, and point-of-care diagnostics (*1*). In addition, appropriate surface functionalization remains a critical variable for the optimal performance of a wide range of implantable medical devices (*2*). The design of solid-phase-based assays and bioactive implant surfaces often requires the immobilization of proteins and carbohydrates in their native state. Current immobilization techniques have relied on adsorption, direct covalent immobilization to chemically activated surfaces, or on the biosynthetic expression of a polypeptide 'tag' that mediates immobilization on an appropriately derivatized surface (*3*). Although appropriate for many applications, these schemes can, at times, be limited by the reduction in biomolecular activity due to protein denaturation, unintended reactions at or near the 'active' domain, or random orientation at the solid−liquid interface that reduces access to molecular recognition sites.

Diels−Alder cycloaddition has been recognized as an exceedingly useful bioconjugation procedure (*4*). The reaction takes place between an electronically matched pair of a double bond (dienophile) and a conjugated diene to form a six-membered unsaturated ring. Recently, this scheme has been applied to the immobilization of biomolecules onto a solid surface (*5*). Crucial to the selection of Diels−Alder cycloaddition as a preferential strategy for surface immobilization of biomolecules is (i) the recognition that water has an extraordinary rate-accelerating effect on the reaction process; (ii) the reaction occurs efficiently at room temperature; and (iii) cyclodiene and *N*-(ϵ-maleimidocaproyl) (EMC) are independently stable and easy to introduce.

The Cu(I)-catalyzed 1,3-dipolar cycloaddition of azide and alkyne to form a triazole, termed 'click' chemistry, has been recently established as an important tool for chemically and biologically modifying biomolecules (*6*). The reactants, alkyne and azide, are convenient to introduce, independently stable, and do not react with common organic reagents or functional groups in biomolecules. Triazole formation is irreversible and usually quantitative. In addition, this reaction benefits from an extremely mild and regioselective copper(I) catalyst system that is surprisingly indifferent to solvent and pH. Thus, the potential for this reaction to modify a wide range of functionally complex substances is significant. The unique properties of this reaction appears transferable to surface-bound reactants and will likely provide access to a growing variety of novel functionalized surfaces (*7*). Indeed, azide-containing compounds have been successfully captured to alkynes via the Cu(I)-catalyzed 1,3-dipolar cycloaddition reaction (*8*). Therefore, azide/alkyne-based click chemistry can be expected to provide a robust strategy for uniform, high-density biomolecular surface immobilization using a conjugation scheme that is both covalent and displays a high degree of selectivity.

Poly(ethylene glycol) (PEG) is widely used as an inert and biocompatible linker in surface engineering and in the modification of proteins and peptides for drug delivery (*9*). Monofunctional PEG coupled to proteins is known to prolong circulation half-life and reduce immunogenicity (*10*). Moreover, PEG-modified liposomes have been used for cell targeting applications (*11*). While carboxyl or amine-terminated PEGs are widely available, they remain expensive and require further chemical modification to convert their corresponding groups. Further, these functional PEGs are available mainly as higher molecular weight compounds (>3400 Da), which under many conditions may limit grafting density onto solid surfaces due to steric repulsive effects. In this report, we describe the synthesis of a bifunctional short PEG linker with alkyne and cyclodiene groups at opposite chain termini to facilitate surface bioconjugation based upon sequential Diels−Alder and azide−alkyne cycloadditions. We demonstrate that this linker is suitable for the immobilization of biomolecules onto solid surfaces in a chemi-

cally and biologically orthogonal fashion (Figure 1). Specifically, the alkyne and cyclodiene moieties are capable of conjugating under aqueous conditions and in a selective fashion to azide and EMC groups, respectively. As a covalent conjugation scheme that is orthogonal to diverse functionalities intrinsic to biological systems, this approach provides an attractive alternative to other currently available immobilization protocols.

EXPERIMENTAL PROCEDURES

General Methods. Thin-layer chromatography (TLC) was performed on Whatman silica gel aluminum backed plates of 250 μm thickness on which spots were visualized by UV light or by charring the plate after dipping in 10% H_2SO_4 in methanol. ^{1}H NMR spectra were recorded at 400 MHz at room temperature using a Varian INOVA 400 spectrometer. Fluorescence images were acquired using a Zeiss LSM 510 epifluorescence microscope under 10× magnification and illuminated using an argon ion laser at 485 nm. Images were acquired using eight co-added scans in line mode on air-dried glass slides stained with FITC-labeled proteins. Post-image processing was not performed.

Materials. All solvents and reagents were purchased from commercial sources and were used as received, unless otherwise noted. Amino PEG_4 azide **7** was prepared, as reported in the literature (*12*). 2-Azide-ethyl-*O*-lactoside **9** was synthesized, as previously reported (*18*). *N*-Hydroxsuccinimidobiotin and the lectin (*Arachis hypogaea*)-FITC were purchased from Sigma. The recombinant thrombomodulin construct (*r*TM-N_3) with an azide group and S-tag at the C- and N-termini, respectively, was prepared as previously reported (*21*). The FITC-conjugated S-protein and FITC-conjugated streptavidin, which specifically bind to S-Tag and biotin, respectively, were obtained from Novagen. EMC functionalized glass slides were purchased from XENOPORE Corp.

Synthesis of Bifunctional PEG Spacers. *O-Propargyl-tetra(ethylene glycol) (2).* To a solution of tetra(ethylene glycol) (**1**, 2 g, 5.30 mmol) in 20 mL of THF was added NaH (60% w/w in mineral oil, 272 mg, 11.34 mmol, 1.1 equiv.) at 0 °C with frequent venting. After stirring for 15 min, propargyl bromide (80% in toluene, 1.68 mL, 11.34 mmol, 1.1 equiv) was added slowly, and the mixture was stirred at 0 °C for 2 h and then 23 °C for an additional 2 h. The reaction mixture was passed through a silica gel column eluted with ethyl acetate to give the purified product **2** (1.552 g, 65%) as a clear oil. ^{1}H NMR ($CDCl_3$) δ: 4.16 (d, 2 H, J = 2.4 Hz, $OCH_2C{\equiv}CH$), 3.65−3.61 (m, 14 H, $-(OCH_2CH_2)O-$), 3.56 (t, 2 H, J = 4.4 Hz, OCH_2CH_2OH), 2.75 (br. s, 1 H, −OH), 2.40 (t, 1 H, J = 2.4 Hz, $OCH_2C{\equiv}CH$).

O-Propargyl-tetra(ethylene glycol) tosylate (3). *p*-Toluenesulfonyl chloride (1 g, 5.4 mmol) and DMAP (25 mg, 0.2 mmol) were added to a solution of **2** (1.044 g, 4.5 mmol) in 1:1 pyridine-dichloromethane (10 mL). After 5 h, the solution was poured into ice−water (20 mL), and the aqueous phase was extracted with dichloromethane (3 × 20 mL). The combined organic phases was washed with NH_4Cl (20 mL) and brine (20 mL), dried over anhydrous Na_2SO_4, and concentrated. The yellow oil was chromatographed on silica gel (EtOAc:hexane 3:1) to yield **3** (1.404 g, 81%) as a clear oil. ^{1}H NMR ($CDCl_3$) δ: 7.75 (d, 2 H, J = 8.4 Hz, Ph), 7.26 ((d, 2 H, J = 8.4 Hz, Ph), 4.19 (d, 2 H, J = 2.4 Hz, $OCH_2C{\equiv}CH$), 4.16 (t, 2 H, J = 7.8 Hz, OCH_2CH_2OTs), 3.70−3.55 (m, 14 H, $(OCH_2CH_2)O$), 2.54 (s, 3 H, Ph-CH_3), 2.52 (t, 1 H, J = 2.4 Hz, $OCH_2C{\equiv}CH$).

2-O-Propargyl-8-O-cyclopentadieneethyl tri(ethylene glycol) (4). Sodium cyclopentadienylide (0.75 mL, 2 M solution in THF) was added dropwise to a solution of **3** (390 mg, 1.01 mmol) in THF (10 mL) at −78 °C. The reaction mixture was stirred at −78 °C for 30 min and at room temperature for an additional 4 h. The solution was filtered through a pad of Celite, and the salts were washed thoroughly with THF. Evaporation of the filtrate and subsequent silica gel chromatography (EtOAc:hexane 1:1) afforded **4** (172 mg, 61%) as a clear oil. ^{1}H NMR ($CDCl_3$) δ: 6.44−6.05 (m, 3 H, cyclodiene), 4.18 (d, 2 H, J = 2.4 Hz, $OCH_2C{\equiv}CH$), 3.70−3.55 (m, 12 H, $(OCH_2CH_2)O$), 2.91 (dd, 2 H, J = 1.4, 9.8 Hz, OCH_2CH_2-cyclodiene), 2.66 (m, 2 H,-OCH_2CH_2-cyclodiene), 2.42 (t, 1 H, J = 2.4 Hz, $OCH_2C{\equiv}CH$).

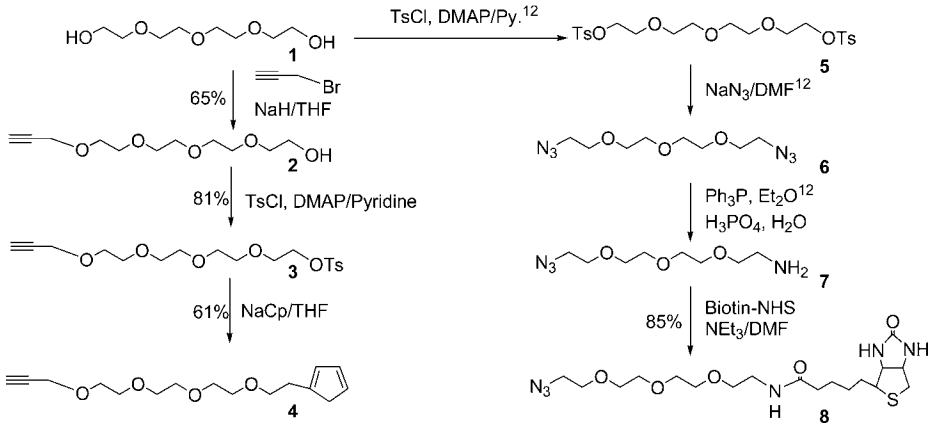
Azidoethyl-di(ethylene glycol) ethylamine (7) was synthesized from tetra(ethylene glycol) **1** as reported in the literature (*12*).

Azidoethyl-di(ethylene glycol) ethylamino biotin (8). Triethylamine (0.1 mL, 0.71 mmol) was added to a solution of **7** (200 mg, 0.917 mmol) in DMF (5 mL). After the solution was stirred for 30 min, a solution of *N*-hydroxsuccinimidobiotin (375 mg, 1.10 mmol) was added. The reaction mixture was stirred for 12 h at room temperature and then concentrated in a vacuum to give a residue, which was purified by silica gel column chromatography using acetone:hexane (4:1) as eluent to afford **8** (345 mg, 85%). ^{1}H NMR (CD_3OD) δ: 4.51 (m, 1 H, C*H*-1-Biotin), 4.32 (m, 1 H, C*H*-4-Biotin), 3.70−3.63 (m, 8 H, $O(CH_2CH_2O)$-PEG), 3.39 (m 4 H, CH_2NH and CH_2N_3-PEG), 3.20 (m 1 H, C*H*-3-Biotin), 2.93 (dd, 1 H, J = 4.8, 12.8 Hz, CH-2a-Biotin), 2.71 (m 1 H, CH-2b-Biotin), 2.23 (t, 1 H, J = 7.6 Hz, CH_2CO-Biotin), 1.76−1.43 (m, 6 H, $(CH_2)_3$-Biotin).

Aqueous Diels−Alder Alkyne PEGylation of EMC Solid Surface. An EMC functionalized glass slide (0.5 cm^2) was placed in a glass vial and incubated overnight on a shaker at room temperature in a solution of alkyne PEG cyclodiene **4** (0.5 mg) in 500 μL of H_2O-*tert*-BuOH (1:1). The PEG solution was removed, and the slide was washed three times with 1 mL of H_2O-*tert*-BuOH (1:1). The unreacted EMC groups were blocked by incubation in a 500 μL solution of cysteine (10 mg/L in PBS pH 7.4) for 1 h at room temperature, followed by three washes with dd water.

Click Biotinylation of an Alkyne PEGylated Glass Slide. A total of 75 μL of biotin PEG azide **8** (0.2 mg) in PBS was added to a glass vial containing an alkyne PEGylated glass slide (0.5 cm^2). This was followed by the sequential addition of 5 μL of *tert*-BuOH, 10 μL of 2 mM ligand (tris(triazolyl)amine) solution in PBS, 10 μL of 1 mM $CuSO_4$ solution, and 2 mM TCEP in PBS. The vial was shaken at 4 °C for 12 h. The reaction solution was removed and the slide washed three times with 1 mL of dd water.

Scheme 1. Synthesis of Bifunctional PEG Linkers



FITC-conjugated streptavidin (Novagen) was diluted 1:50 in PBST. The biotin-PEG immobilized slide was incubated in 500 μL of the diluted streptavidin solution (0.02 mg/mL) for 2 h at 4 °C and then washed three times with 1 mL of dd water.

Click Immobilization of Azide Lactose onto a Glass Slide. A total of 75 μL of lactose azide **9** (*18*) (0.2 mg) in PBS was added to a glass vial containing an alkyne PEGylated glass slide (0.5 cm^2). This was followed by the sequential addition of 5 μL of *tert*-BuOH and then 10 μL of 2 mM tris(triazolyl)amine solution in PBS, and 10 μL of 1 mM $CuSO_4$ and 2 mM TCEP solution in PBS. The vial was shaken at 4 °C for 14 h. The reaction solution was removed and the slide washed three times with 1 mL of dd water.

The lactose-PEG immobilized slide was incubated in 500 μL of a FITC-conjugated galactose binding lectin (*Arachis hypogaea*, Sigma) solution (0.5 mg/mL) in PBST for 5 h at 4 °C and then washed three times with 1 mL of dd water.

Click Immobilization of *r*TM-N_3 onto a Glass Slide. A total of 75 μL of *r*TM-N_3 (0.1 mg) in PBS was added to a glass vial containing an alkyne PEGylated glass slide (0.5 cm^2). This was followed by the sequential addition of 5 μL of *tert*-BuOH, 10 μL of 2 mM tris(triazolyl)amine solution in PBS, and 10 μL of 1 mM $CuSO_4$ solution in PBS. A small piece of Cu wire was placed in contact with the above mixture. The vial was incubated at 4 °C for 72 h without shaking. The reaction solution and the wire, which has become black due to oxidation, were removed and the slide washed three times with 1 mL of dd water.

The *r*TM-N_3 immobilized slide was incubated overnight at 4 °C in 500 μL of the diluted FITC-conjugated S-protein solution (1: 500 diluted commercial sample from Novagen as manufacture protocol in PBST) and then washed three times with 1 mL of dd water.

RESULTS AND DISCUSSION

1. Synthesis of Bifunctional PEG Spacers. The alkyne PEG_4 cyclodiene (**4**) was synthesized from tetra(ethylene glycol) (**1**, PEG_4) as shown in Scheme 1. First, PEG_4 **1** was converted to *mono*-alkyne-PEG_4 **2** by reacting with 1.1 equivalent of propargyl bromide in the presence of sodium hydride. Treatment of **2** with *p*-toluenesulfonyl chloride followed by reaction with sodium cyclopentadienylide afforded alkyne-PEG_4-cyclodiene **4** in good yield. For further functionalization of an alkyne-derivatized surface, biotin PEG_4 azide **8** was synthesized by biotinylation of amino PEG_4 azide **7** (*12*) with commercial available *N*-hydroxsuccinimidobiotin in good yield.

2. Alkyne PEG Surface Functionalization via an Aqueous Diels−Alder Reaction. An EMC-functionalized glass slide (XENOPORE Corp.) was incubated with alkyne-PEG_4-cyclodiene **4** in H_2O-*tert*-BuOH (1:1) at room temperature for 12 h, followed by three washes in H_2O-*tert*-BuOH (1:1) to provide an alkyne-PEG functionalized surface (Figure 2B). The unreacted EMC groups on the slide were blocked with cysteine by incubation in PBS solution at room temperature, followed by three washes with dd water.

A biotin PEG azide was used as a model compound to assess both the extent of Diels−Alder driven surface PEGylation and the capacity of this surface to be further functionalized via click chemistry. Biotin exhibits high affinity binding to strept(avidin) and has been widely used in bioconjugation (*13*) and surface immobilization applications (*14*). As shown in Figure 2, alkyne-PEG functionalized glass slides were treated with biotin-PEG-azide **8** in the presence of $CuSO_4$, tris(carboxethyl)phosphine (TCEP), and tris(triazolyl)amine in PBS (pH 7.0)-*tert*-BuOH (1:1) at 4 °C for 12 h followed by PBS and water washes. In this reaction, Cu(I) is the direct catalyst and is prepared in situ by reduction of inexpensive and air-stable Cu(II) salt $CuSO_4$ with TCEP, and tris(triazolyl)amine is used as ligand to enhance the reaction rate greatly and inhibit oxidative alkyne coupling. Notably, the low temperature condition was investigated for later protein immobilization since many proteins are thermally sensitive. The success of alkyne PEGylation and the capacity of this surface to participate in click immobilization chemistry are evident by confocal fluorescence images that demonstrate FITC-labeled streptavidin specifically binds to a biotinylated surface (C), with no binding to either untreated EMC-glass slides (A) or slides functionalized with alkyne-PEG alone (B) (Figure 2). In addition, binding was not observed upon incubation with either a biotin-saturated FITC-labeled streptavidin to biotinylated surfaces or to EMC slides deactivated with cysteine prior to PEG immobilization (data not show).

3. Immobilization of an Azide-Containing Sugar. Cells universally carry a sugar coating formed by glycoproteins, proteoglycans, and glycolipids, which are involved in highly specific recognition events between cells and proteins, hormones, antibodies, and toxins (*15*). Understanding the mechanism of these processes may lead to the development of new antimicrobial, anticancer, and antiinflammatory therapies. Therefore, simple and readily accessible methods for high-throughput analysis, such as carbohydrate microarrays or glycoarrays, are an area of active investigation (*16*). We investigated the click immobilization of carbohydrates onto alkyne-PEG-functionalized glass slides using lactose-N_3 as a model ligand (*17*).

As depicted in Figure 3, an alkyne-PEG functionalized glass slide was treated with an azide-derivate lactose **9** (*18*) in the presence of $CuSO_4$, TCEP, and tris(triazolyl)amine in PBS (pH 7.0)-*tert*-BuOH (1:1) at 4 °C for 14 h. Binding of a fluorescently labeled lectin confirmed the effectiveness of sugar immobilization. Specifically, uniform fluorescence was noted upon incubation of glycosylated test surfaces with FITC-lectin from *Arachis hypogaea* that binds to terminal β-galactose, but was not

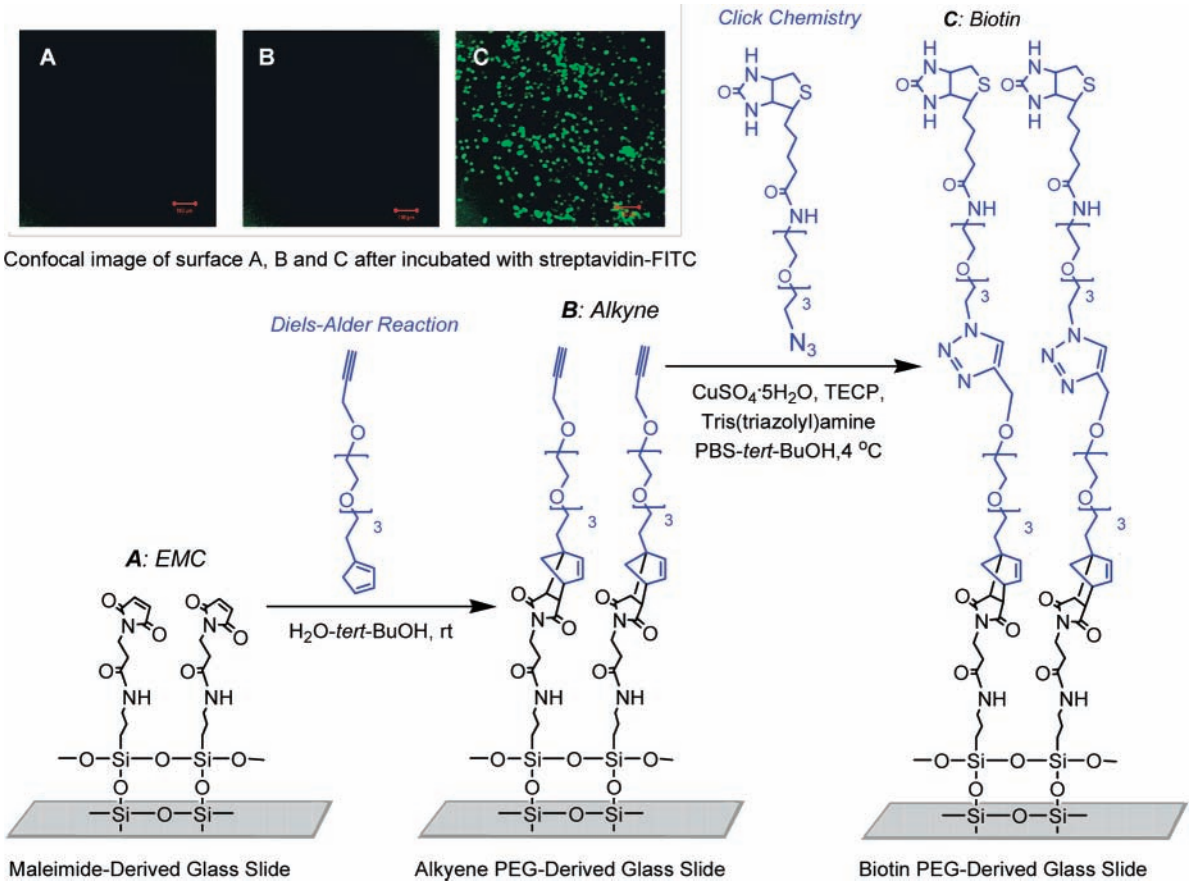


Figure 2. Diels−Alder cycloaddition was used to modify an EMC-derivatized substrate with an alkyne-terminated PEG linker, which was followed by surface biotinylation via click chemistry. Representative confocal image of initial EMC surface incubated with streptavidin-FITC (A); alkyne-derivatized surface incubated with streptavidin-FITC (B); and a biotinylated surface produced by sequential Diels−Alder and azide−alkyne cycloadditions incubated with streptavidin-FITC (C). Bar size: 100 μm.

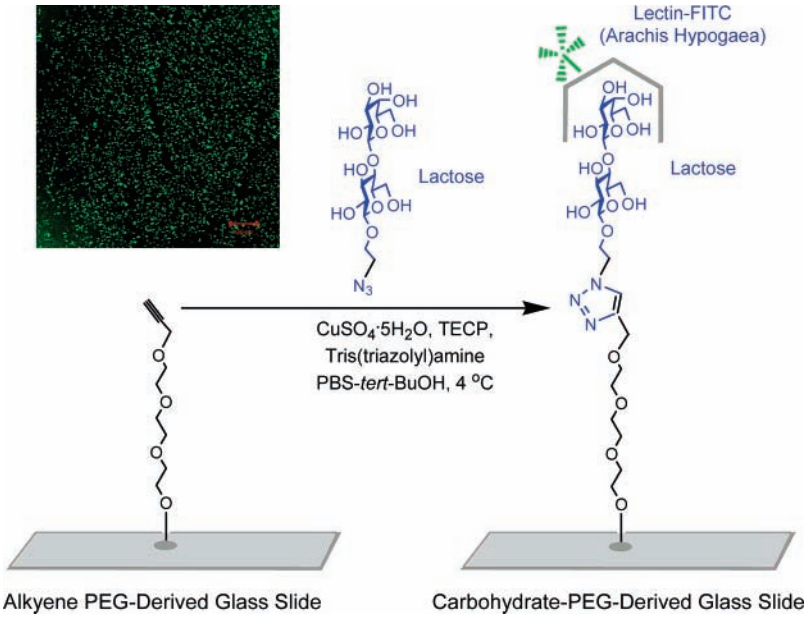

Figure 3. Immobilization of lactose-N_3 onto an alkyne-PEG-functionalized glass substrate via azide−alkyne cycloaddition. Representative confocal image of a lactose-derivatized surface after incubation with FITC-labeled *Arachis hypogaea*. Bar: 100 μm.

observed when untreated EMC or alkyne-derivatized glass substrates were used. Furthermore, binding was not observed when a glucose/mannose specific lectin, concavalian A was used (data not show).

4. Immobilization of a Recombinant Protein with a C-Terminal Azide Group. The immobilization of a protein onto a solid surface in the correct orientation is imperative for optimal interaction with other species in which it may form a functional complex. However, most current surface conjugation schemes offer somewhat limited control over the three-dimensional presentation of bound proteins due to their reliance on functional groups that are often abundantly present within the protein of interest. Falsey et al. has recently reported chemoselective N-terminal attachment of peptides onto glyoxylic

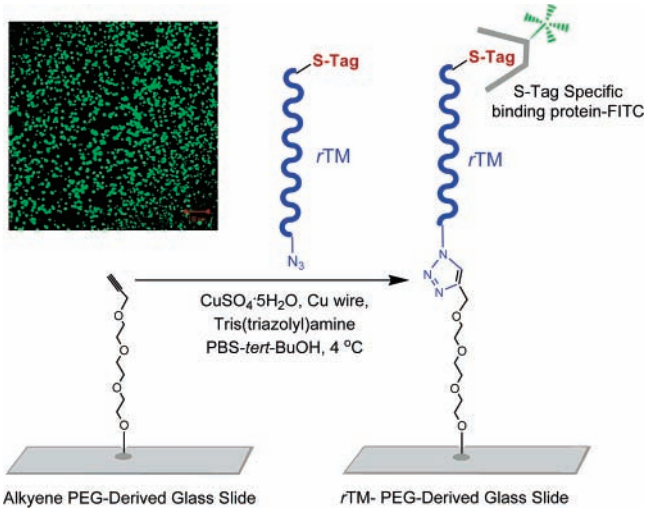

Figure 4. Immobilization of recombinant thrombomodulin (*r*TM-N_3) containing an N-terminal S-tag peptide seuqence onto an alkyne-PEG-functionalized glass surface via azide−alkyne cycloaddition. Representative confocal image of a thrombomodulin-derivatized surface after incubation with an S-tag binding FITC-labeled S-protein. Bar: 100 μm.

acid functionalized slides via oxime-bond or thiazolidine-ring ligation reaction (*19*). Although elegantly designed for site-specific coupling of peptides, the oxime bond is relatively unstable and its formation less selective. Zhu et al. has reported a method for site-specific immobilization of His-tag proteins on slides functionalized with Ni−NTA (*20*). Although an appropriate strategy for protein purification in which elution of the bound protein is required, the binding between His-tag proteins and the Ni−NTA complex is not very strong and is incompatible with many common chemicals such as DTT, SDS, and EDTA. Specifically, decoupling occurs outside pH 4−10 or when the buffer contains high concentrations of common salts. In the current report, the use of a recombinant protein containing a nonnatural azide-containing amino acid at the C-terminus provides an example of site-specific and regiospecific protein immobilization to an alkyne-derivatized surface.

We have recently reported a strategy for site-specific PEGylation of a truncated thrombomodulin (*r*TM-N_3) mutant through an azide group located at the C-terminus. The thrombomodulin (TM) construct was expressed in *E. coli* and contains epidermal growth factor (EGF)-like domains 4−6 and an azido-functionalized alanine analogue as a C-terminal linker (*21*). As shown in Figure 4, alkyne-PEG functionalized glass slides were treated with *r*TM-N_3 in the presence of $CuSO_4$, Cu wire, and tris-(triazolyl)amine in PBS (pH 7.0)-*tert*-BuOH (95:5) at 4 °C for 72 h. Cu wire was used for reduction of Cu(II) to Cu(I) and to avoid the risk of cleavage of the dithiosulfide bonds in the protein (6c and 6d). The recombinant TM also contains an N-terminal peptide sequence, referred to as an S-Tag that was used to qualitatively assess the extent of surface immbolization. As shown in Figure 4, the TM-functionalized surface was incubated with a FITC-labeled S-protein that specifically binds the S-tag (*22*) and examined by confocal microscopy. S-Tag binding was consistent with the production of a surface grafted at a high density with *r*TM-N_3. S-Protein binding was not observed for either untreated EMC-glass slides or for those functionalized with alkyne-PEG alone (data not show). On inspection of Figures 2−4, differences in surface domain size and morphology are noted, which likely reflects varying steric effects attributed to the use of ligands and binding proteins of varying size.

In conclusion, sequential Diels−Alder cycloaddition and azide−alkyne [3 + 2] cycloaddition reactions were successfully applied to the functionalization of EMC-derivatized glass slides with a diverse series of ligands, including biotin, lactose, and a recombinant thrombomodulin protein. This approach was enabled by the synthesis of a bifunctional poly(ethylene glycol) (PEG) linker carrying alkyne and cyclodiene groups at opposite chain termini. Significantly, azide, alkyne, cyclodiene, and EMC groups were stable under bioconjugation conditions and did not appear predisposed to unintended side reactions. In principle, the potential to immobilize a wide range of functionally complex substances onto solid surfaces can be achieved, which will likely extend design schemes directed at the fabrication of microarrays and medical devices whose performance is dictated by precisely defined surface molecular engineering.

Received August 14, 2005; Revised Manuscript Received October 27, 2005

The synthesis of multicolor fluorescent oligothiophene *N*-succinimidyl esters (TSEs) is reported, and their optical properties are discussed with the aid of ab initio calculations. The esters were coupled to proteins and to 3′-amino-modified oligonucleotides in mild conditions and with similar modalities. A comparative study of the bioconjugate of IgG_1 anti-CD3 antibody labeled with a blue fluorescent TSE and with fluorescein isothiocyanate (FITC) is reported, showing that the former achieves higher photoluminescence intensity and optical stability than the latter. Fluorescence resonance energy transfer experiments with TSE-labeled oligonucleotides and examples of cellular imaging via TSE-labeled proteins are reported.

INTRODUCTION

Fluorescence techniques are currently of wide use and are progressively replacing radioisotopes in analyses and clinical tests, while new optical imaging methodologies are being developed; see for example the application of optical tomography for breast cancer diagnosis based on a near-infrared-emitting indocyanine (*1*−*3*). The increasing use of fluorescence techniques for immunological labeling and pathological diagnosis generates new demands and user-oriented characteristics for the fluorophores, the instrumentation, and the light sources. Moreover, in vivo applications, which also entail the injection of solutions of the fluorophores (*1*), make the issue of fluorophore toxicity very stringent.

In recent years numerous families of organic and inorganic compounds have been developed as fluorescent labels for proteins, oligonucleotides, DNA, and live cells (*1*−*8*). In particular, many investigations have concerned quantum dots of cadmium selenide, i.e., semiconductor nanocrystals, characterized by great brightness, optical stability, and sharp fluorescence emission independent of the excitation wavelength (*4*−*8*). The use of nanocrystals as probes for biological molecules requires that they are encapsulated with a transparent organic polymer bearing functional groups capable to bind biomolecules, as shown, for example, in a recent study aimed to monitor in vivo tumor growth in rats (*7*). However, even polymer-protected cadmium selenide nanoparticules may be toxic to cells, and the issue of their toxicity and in vivo metabolism still lacks a definitive answer (*8*).

The characteristics that a good family of fluorescent probes should have are numerous and include photostability, sharp spectral emission, high absorbance, high fluorescence quantum yield, large differences between absorption and emission wavelengths, color tunability from blue to near-infrared, easy modalities for binding to biomolecules, lack of toxicity, and low preparation costs. A single family of small, suitably functionalized, organic dyes with fluorescence colors tunable by minor structural changes would ensure the easy binding to biomolecules and the standardization of staining methodologies, while low molecular weights would allow easy cell membrane permeability for multicolor live cell imaging. No family presenting simultaneously all the required properties has been described as yet, which justifies the continuous search for improvement.

Among the newcomers as optical sensors to monitor events of biological importance are conjugated semiconducting polymers, for which combined electrical and fluorimetric detection of biomolecules can also be envisaged. Single nucleotide mismatches between two DNA strands have been detected, both in solution and with the polymer patterned on a surface, by using a zwitterionic polythiophene electrostatically interacting with the negatively charged phosphate DNA groups (*9*). More recently, the specific detection in solution of zemptomolar amounts of genetic material using a positively charged polythiophene has been described (*10*).

Our group has focused its attention on short thiophene oligomers which have displayed a variety of useful properties, from white electroluminescence (*11*) to easy nanopatterning via nanoimprint lithography (*12*). The photostability and fluorescence color tunability of thiophene oligomers, mainly known for their semiconducting properties (*13*−*15*), suggested that they could also be fruitfully employed as fluorescent markers for biopolymers. Thus, we started an investigation aimed to explore this possibility and reported initial studies showing that, indeed, thiophene oligomers functionalized with the isothiocyanate group can be covalently bound to monoclonal antibodies via the ϵ-NH_2 lysine sites (*16*−*18*). We have now found that oligothiophenes functionalized with the *N*-succinimidyl group (TSEs) are easier to prepare and to conjugate to proteins, in agreement with previous studies on fluorescein-based fluorophores (*19*). Moreover, they can also be conjugated to oligonucleotides in similar conditions and be used to prepare fluorescent oligonucleotide probes.

We describe here the synthesis and the electronic and optical characterization of oligothiophene *N*-succinimidyl esters and demonstrate that they are optically stable and can achieve high

fluorescence sensitivity when bound to proteins and oligonucleotides (*20*). We also show for the first time that thiophene oligomers can be used for cell staining as well as for fluorescence resonance energy transfer experiments with oligonucleotides.

MATERIALS AND METHODS

Synthesis. General Details. 5-Bromo-2-thiophenecarboxaldehyde (**1**), 2-(tributylstannyl)thiophene (**4**), 2-(2-thienyl)ethanol (**6a**), 2-(methylthio)thiophene (**8a**), *N*-hydroxysuccinimide (HOSu), *N*,*N*′-dicyclohexylcarbodiimide (DCC), 2-methoxylethoxylmethyl chloride (MEMCl), *N*,*N*-diisopropylethylamine, 4-(dimethylamino)pyridine (DMAP), *N*-bromosuccinimide (NBS), *n*-butyllithium, tributyltin chloride, tris(dibenzylideneacetone)-dipalladium(0)−chloroform adduct, and triphenylarsine are commercially available compounds.

The syntheses of compounds **2**, **3**, **6d**, **8b**, **10**, and **14** are reported as Supporting Information.

General Procedure for the Preparation of Oligothiophene *N*-Succinimidyl Esters. To a 10 mL toluene solution containing 0.015 mmol of tetrakis(triphenylarsine)palladium(0) prepared in situ was added the desired thienyl bromide (0.5 mmol). The mixture was then heated to 80 °C and the appropriate thienyl stannane (0.5 mmol) dissolved in 3 mL of toluene added dropwise. The mixture was stirred for 2 h at this temperature, and then the solvent was evaporated under reduced pressure. The crude product was purified by flash chromatography (silica gel, petroleum ether/ethyl acetate 1:1). The analytical data for the specific compounds are given below.

2,2′-Bithiophenyl-5-carboxylic Acid 2,5-Dioxopyrrolidin-1-yl Ester, **5**. Yield: 83%. Microcrystalline white solid, mp 159−160 °C; EI-MS *m*/*z* 307 (M^+). ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.91 (d, ^3J = 4.0 Hz, 1H), 7.36 (dd, ^3J = 5.0 Hz, ^4J = 0.8 Hz, 1H), 7.33 (dd, ^3J = 3.6 Hz, ^4J = 0.8 Hz, 1H), 7.21 (d, ^3J = 4.0 Hz, 1H), 7.07 (dd, ^3J = 3.6 Hz, ^3J = 5.0 Hz, 1H), 2.89 (s, 4H); ^{13}C NMR ($CDCl_3$, TMS/ppm) δ 169.14, 157.09, 147.71, 137.52, 135.41, 128.32, 127.13, 126.19, 124.26, 124.05, 25.58. Anal. Calcd for $C_{13}H_9NO_4S_2$ (307.34): C, 50.80; H, 2.95. Found: C, 50.92; H, 3.02.

5′-[2-(2-Methoxyethoxymethoxy)ethyl]-[2,2′]bithiophenyl-5-carboxylic Acid 2,5-Dioxopyrrolidin-1-yl Ester, **7**. Yield: 82%. Pale yellow oil, EI-MS *m*/*z* 439 (M^+). ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.89 (d, ^3J = 4.0 Hz, 1H), 7.15 (d, ^3J = 4.0 Hz, 1H), 7.12 (d, ^3J = 4.0 Hz, 1H), 6.80 (d, ^3J = 4.0 Hz, 1H), 4.75 (s, 2H), 3.81 (t, ^3J = 6.0 Hz, 2H), 3.67 (m, 2H), 3.53 (m, 2H), 3.37 (s, 3H), 3.09 (t, ^3J = 6.0 Hz, 2H), 2.88 (s, 4H); ^{13}C NMR ($CDCl_3$, TMS/ppm) δ 169.14, 157.06, 148.09, 144.12, 137.48, 133.67, 126.57, 125.91, 123.59, 123.41, 95.43, 71.61, 67.70, 66.85, 58.89, 30.70, 25.52. Anal. Calcd for $C_{19}H_{21}NO_7S_2$ (439.50): C, 51.92; H, 4.82. Found: C, 51.95; H, 4.96.

5′-Methylsulfanyl-[2,2′]bithiophenyl-5-carboxylic Acid (2,5-Dioxopyrrolidin-1-yl) Ester, **9**. Yield: 81%. Microcrystalline light yellow solid, mp 181−182 °C; EI-MS *m*/*z* 353 (M^+). ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.90 (d,, ^3J = 4.0 Hz, 1H), 7.18 (d, ^3J = 4.0 Hz, 1H), 7.15 (d, ^3J = 4.0 Hz, 1H), 6.99 (d, ^3J = 4.0 Hz, 1H), 2.90 (s, 4H), 2.55 (s, 3H); ^{13}C NMR ($CDCl_3$, TMS/ppm) δ 169.08, 157.09, 147.21, 140.57, 137.53, 136.60, 130.84, 126.37, 124.08, 124.02, 25.63, 21.44. Synthesis of Oligonucleotides. Oligonucleotides were synthesized in our laboratory using a Gene Assembler II plus synthesizer using manufacturer protocols and commercial reagents. The 3′-amino modification was obtained using 3′-PT Amino-Modifier C6 CPG (Glenn Research). Dabcyl was linked at the 5′ position using dabcyl phosphoramidite (Chem Genes).

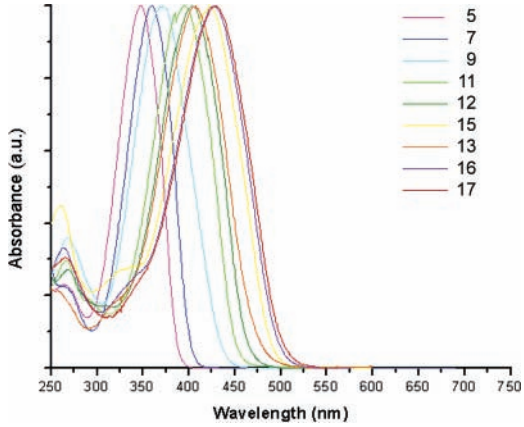

Figure 1. Normalized absorption spectra of compounds **5**, **7**, **9**, **11**−**13**, and **15**−**17** in CH_2Cl_2.

At the end of the synthesis, the oligonucloetides, DMTr off, were deprotected with 30% aqueous ammonia at 50 °C for 16 h and then lyophilized. The 3′-amino-modified oligonucleotides were purified by chromatography using a DEAE-Sephacell column (Pharmacia), eluting with a gradient of triethylammonium bicarbonate, and lyophilized. The dabcyl-oligonucleotide was purified by reversed phase chromatography on RP-18 silica gel with a gradient of CH_3CN in 0.1M triethylammonium acetate and then lyophilized. The lyophilized compounds were stored at −18 °C.

Protein Labeling. *Conjugation of Bithiophene N-Succinimidyl Ester* **9** *and FITC with anti-CD3 Antibody.* Anti-CD3 antibody dissolved in phosphate buffer saline solution (pH 7.4) was dialyzed (v:v = 1:1000) vs a 0.05 M carbonate buffer (pH 9.0) containing a non ionic detergent, and the dialysis was allowed to run for about 16 h at 4 °C. Then the solution was concentrated by microcon membrane (Amicon) with 50 kD cut off. Four vials containing a 2.6 mg/mL of anti-CD3 were prepared. To three of these aliquots was added **9** dissolved in DMSO (10 mg/mL) in the amounts needed to reach protein: fluorophore 1:10, 1:25, 1:50 molar ratios. The solutions were incubated for 3 h at room T under stirring. To the fourth vial of anti-CD3 was added a 10 mg/mL FITC solution in DMSO (protein:fluorophore 1:50 molar ratio), and the incubation was carried out in the dark. Afterward each conjugate was chromatographed on a desalting 1.0 mL G25 column in PBS pH 7.4. In the case of fluorophore **9** the separation of the labeled protein from the free dye could be followed by irradiating with a 15 mW lamp (see Figure 11 in the Supporting Information). The degree of labeling, namely F:P the average number of fluorophore molecules for protein, was obtained by absorption spectroscopy according to standard procedures (*2*). The absorbance of the protein at 280 nm was corrected for a factor corresponding to the contribution of the fluorophore at this wavelength (see Figure 1). The estimated F:P ratios varied from 2.5 to 6.7 for the mAb marked with **9**. For mAb marked with FITC the F:P ratio amounted to 7. The absorption spectra for the different experiments are given as Supporting Information.

Conjugation of Bithiophene N-Succinimidyl Ester **9** *with Saporin.* The plant toxin saporin (*21*) was conjugated with **9** as described above for anti-CD3 mAb.

Cells. HeLa cells, derived from a human cervical carcinoma, and Jurkat cells, derived from a human T-cell lymphoma, were cultured in RPMI 1640 medium supplemented with 10% FCS and antibiotics. HeLa cells were seeded on four-chambered culture slides (Falcon BD) (5000 cells/well) in complete medium. After 24 h cells were incubated with 10 μM saporin−**9** for 1 h at 37 °C. After treatment, cells were washed twice with PBS and then fixed with cold methanol at −20 °C for 15 min. Jurkat cells (10^7 cells/ml) were incubated at 4 °C for 30 min with the anti-CD3 mAb labeled with compound **13** (dilution 1:100). The reaction was carried out at 4 °C, to allow the specific binding of the anti-CD3 mAb to the corresponding antigen on cell surface while preventing the internalization of the immunocomplex. After treatment, cells were washed twice with PBS at 0 °C and fixed with 4% formaldehyde pH 7.5 for 30 min at room temperature. Drops of fixed Jurkat cells were dried on the slides.

Oligonucleotide Labeling. The oligothiophene *N*-succinimidyl ester (1 mg) was first dissolved in 60 μL of DMF in a microvial, and then about 10 OD (∼300 μg) of 3′-amino-modified oligonucleotide dissolved in 12 μL of a 0.1 mM buffered solution (pH 7.4) were added to the solution. The mixture was kept at 40 °C overnight. The reaction was checked by HPLC and diluted with 500 μL of deionized H_2O and the excess of fluorophore repeatedly extracted with a 1:4 methanol: methylene chloride solution using a syringe. The conjugated oligonucleotide was recovered from the aqueous phase by reversed phase chromatography, exploiting the lipophilicity of the conjugated dye. Up to 7 OD of pure conjugated oligonucleotide were recovered (70% yield).

Fluorescence Microscopy. Fluorescence microscopy was performed with a Nikon Eclipse E600W fluorescence microscope equipped with a 100× objective. Color photomicrographs were obtained using a Nikon-dedicated digital camera.

Absorption and Photoluminescence Measurements. Absorption and photoluminescence spectra in methylene chloride were obtained using 10^{-4}−10^{-6} M solutions (spectroscopic grade). Photoluminescence measurements were performed by exciting the solutions at optimum wavelengths for absorbances 0.1−0.2.

Theoretical Calculations. Calculations were carried out with the quantum-chemistry program package TURBOMOLE V5.7 (*22*, *23*). In particular, the RICC22 (*24*−*26*) module was used. In the CC2 calculations, core orbitals were removed from the active space. In addition, for the calculation of excitation energies, virtual orbitals with energies above 150 eV were freezed. All calculations were performed on an HP rx8620 Itanium-2 server.

RESULTS

I. Synthesis. Despite the great number of functionalization types realized for oligo and polythiophenes, the functionalization with the succinimidyl group has not yet been reported. To prepare oligothiophene *N*-succinimidyl esters we followed the synthetic pattern reported in Scheme 1, starting from commercial 5-bromo-2-thiophenecarboxaldehyde (**1**). It consists of repeated sequences of bromination and Stille coupling reactions (*27*) occurring in good yields. Generally, on increasing the oligomer size, the yield of the Stille coupling decreases, owing to the increased number of side reactions related to metal−halogen exchange. However, in this case, we did not observe the formation of side products ascribable to the presence of slow metal−halogen exchange equilibria, probably due to the high rate of the cross coupling reaction. As a consequence, the crude products were much easier to purify and the yields higher than generally observed in the preparation of conventional oligothiophenes. The $CH_2OCH_2CH_2OCH_3$ group (MEM) was used to increase the solubility in polar solvents.

II. Optical Properties. The maximum wavelength absorption, λ_{max} (nm), and emission, λ_{PL} (nm), and molar absorption coefficients, ϵ (cm^{-1} mol^{-1}), of oligothiophene succinimidyl esters **5**, **7**, **9**, **11**−**13**, and **15**−**17** are given in Table 1, while the normalized absorption and emission spectra of all compounds are shown in Figures 1 and 2. The emission colors vary from blue to deep orange, within a range of 160 nm, almost

twice that of the absorption range (85 nm). All compounds are characterized by very large differences between absorption and emission wavelengths, much greater than those measured for the most commonly used markers such as fluorescein and its derivatives (*2*). As already shown for oligothiophene isothiocyanates (*16*−*18*), TSEs can also undergo repeated irradiation cycles without any appreciable change in fluorescence intensity (see section IV, Figure 4D).

An estimate of fluorescence quantum yields of the compounds of Table 1 in methylene chloride was obtained using various dithienothiophene *S,S*-dioxides (*28*) as the standards. For **5**, **7**, and **9**, values of 63%, 36%, and 28%, respectively, were obtained using 3,5-dimethyldithieno[3,2-*b*;2′,3′-*d*]thiophene 4,4-dioxide (*28*) as the standard, for compounds **11** (21%), **12** (24%), and **13** (32%) using 3,5-dimethyl-2,3-bis(phenyl)dithieno[3,2-*b*;2′,3′-*d*]thiophene 4,4-dioxide (*28*), and for compounds **15** (5%) and **16** (3%) using 3,5-dimethyl-2,3′-bis(3-methylthiophene)-dithieno[3,2-*b*;2′,3′-*d*]thiophene 4,4-dioxide (*28*). The fluorescence quantum yields obtained in this way are approximate values, and measurements of absolute quantum yields of free fluorophores in organic solvents and of the fluorophores bound to biopolymers in water are currently under way using an integrating sphere.

Apparently, and contrary to what is observed for unsubstituted thiophene oligomers (*29*−*31*), the increase in size of TSEs is not accompanied by the increase in fluorescence efficiency, indicating that the decay relaxation mechanisms from the excited state in these compounds should be different.

III. Theoretical Calculations. To investigate the optical properties of TSEs, ab initio calculations on the smallest term of the series, namely compound **5**, were first carried out. Afterward, calculations on a model system, consisting of 2,2′-bithiophene bearing the $CONH(CH_2)_3CH_3$ group at one of the terminal positions and supposed to simulate the oligothiophene after the covalent binding to the biomolecule (see sections IV and V), were performed. We refer to this system as **AT2** (amide-bound bithiophene).

As it will be clear in the following, a density-functional theory approach is not accurate enough to study these systems. Thus, we choose a correlated method, namely the approximate coupled-cluster singles and doubles method (CC2) with the resolution of identity, which is a size-consistent method well suited to calculate excitation energies of large systems (*32*−*35*). The geometries of **5** and **AT2** were optimized with the CC2 method using a cc-pVDZ basis set (*22*−*26*).

The presence of several local minima very close in energy (about 0.20 kcal/mol) to the global minimum required a highly correlated ab initio method and a large basis set to identify the global minimum. In the optimized structures the two thiophene rings are in a s-trans configuration. In **5**, the plane of the succinimide group is almost perpendicular to the plane of its nearest neighboring thiophene ring. In **AT2**, the terminal group is turned from the sulfur side. As shown in Figure 3, in this system the bithiophene structure is slightly modified by the inclusion of the terminal group: the inter-ring distance between the two thiophene rings is 1.45 Å and the dihedral angle between the two rings is 29°.

Excitation energies of **5** and **AT2** were computed by the CC2 method, using the triple-ζ valence basis set with polarization functions (cc-pVTZ) (*24*−*26*). The results are summarized in Table 2. The calculations show that in compound **5** the lowest singlet state (S_1 at 3.57 eV) is almost optically forbidden. The optically active state, S2, is an admixture of HOMO → LUMO (52%) and HOMO−LUMO+1 (41%) transition, and it is calculated to be at 4.00 eV. As can be seen in Figure 3a, the HOMO is completely localized on the bithiophene, whereas the LUMO is completely localized on the succinimidyl group. Thus, the S2 state of **5** is mainly of charge transfer in character, so the excitation energies can be expected to be strongly dependent on the environment. In addition such charge-transfer excitation cannot be described by density functional theory due to the well known limitations of the current exchange-correlation functionals (*22*−*26*). The calculated excitation energy of the optically active state overestimates the experimental value (3.58 eV), due to basis-set effects, approximations of the CC2 method, and the omission of solvent polarization.

The first optically active state of the unsubstituted bithiophene at the same level of calculation is at 4.40 eV. Thus, the inclusion

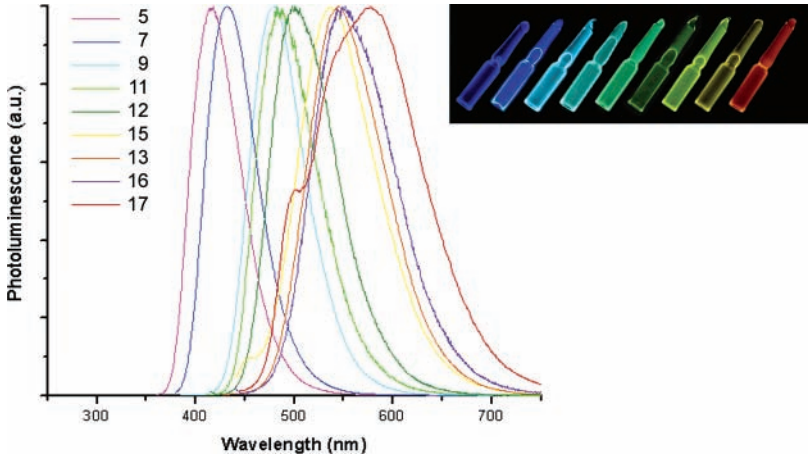

Figure 2. Normalized photoluminescence spectra of compounds **5**, **7**, **9**, **11**−**13**, and **15**−**17** in CH_2Cl_2. The emission colors on the right were obtained by irradiating with a single light source, a 15 W lamp with $\lambda = 364$ nm.

Table 2. Lowest Two CC2 Singlet Excitation Energies (eV) and Oscillator Strengths (OS) for 5 and the Model Compound AT2

	state	energy	OS
5	S1	3.57	$2.1\ 10^{-4}$
	S2	4.00 (3.58)	$7.1\ 10^{-1}$
AT2	S1	4.11	$5.9\ 10^{-1}$
	S2	4.35	$4.2\ 10^{-2}$

[a] Experimental value.

of the succinimide group causes a red-shift of 0.40 eV. This value is in complete agreement with the experimental one of 0.47 eV. The latter value is obtained by comparing the experimental absorption peak energy of **5** (i.e. 3.58 eV) with the experimental absorption peak energy of the unsubstituted bithiophene (4.05 eV (*36*)).

In the model compound **AT2** the optically active state is S1 which is mainly a HOMO → LUMO (88.3%) transition, i.e., the charge-transfer character of the transition is not present. As can be seen by inspection of Figure 3b, this is essentially a transition localized on bithiophene. The inclusion of the CONH-$(CH_2)_3CH_3$ group does not induce a strong perturbation on the bithiophene HOMO and LUMO orbitals, so the photophysical properties of bithiophene should be almost unaltered upon the binding to the biological system.

IV. Coupling to Proteins and in Vitro Cell Imaging. It is known that the fluorophores functionalized with the *N*-succinimidyl ester functionality react with the ϵ-NH_2 lysine groups of proteins forming a stable amide bond (*2*, *19*).

The coupling of oligothiophene *N*-succinimidyl esters, TSEs, to proteins was carried out at slightly basic pH according to the modalities described in the Experimental Section, which are very similar to those already reported for the coupling of oligothiophene isothiocyanates to monoclonal antibodies (*16*).

Figure 4 compares the photoluminescence spectra of the bioconjugate of anti-CD3 monoclonal antibody, a IgG1 isotype antibody which reacts with CD3, a 20 kDa molecular weight antigen normally expressed on the surface of T-lymphocyte cells (*37*), labeled with bithiophene succinimidyl ester **9** (Figure 4A,B), with that (Figure 4 C) of the same antibody marked with fluorescein isothiocyanate (FITC, the most commonly used fluorescent marker (*2*)). The corresponding absorption spectra are reported as Supporting Information.

The conjugation reaction was carried out using anti-CD3 to **9** molar ratios of 1:10, 1:25, and 1:50. At the end of each reaction and after the first UV measurements, the bioconjugate was stabilized with a solution of phosphate buffer saline containing 0,5% (w/v) of bovine serum albumine (BSA) and 0.1% (w/v) of sodium azide. The presence of BSA avoided the normal aggregation of IgG's biopolimeres at low concentration, keeping the total protein concentration at 4−5 mg/mL.

Owing to the photostability of **9**, the separation of the conjugated fraction from the free fluorophore could be followed by irradiation with an UV lamp (see the Experimental Section). The F/P (fluorophore-to-protein ratio) was determined on the basis of the relative absorbances of the fluorophore and the antibody, corrected for a factor corresponding to the weak absorption band around 270−280 nm present in the spectrum of **9** (see Figure 1) and overlapping the absorbance of the protein. The conjugation of FITC with the anti-CD3 antibody was carried out with the same modalities and using a 1:50 mAb: FITC molar ratio. The measured F/P values for the bioconjugate of **9** varied from a minimum of 2.5 to a maximum of 6.7, with a proportional increase in fluorescence intensity. The bioconjugate of anti-CD3 with FITC afforded a F/P value of nearly 7. The biological activity of the anti-CD3 antibody marked with **9** was checked for all dilutions by cytofluorimetry through indirect detection using a GAM IgG-FITC and found unaltered, as in the case of the antibodies marked with oligothiophene isothiocyanates (*16*).

Figures 4A and 4B show the photoluminescence spectra of the anti-CD3 antibody labeled with **9** and obtained using 1:50 and 1:10 molar ratios and corresponding to 6.7 and 2.5 F/P values, respectively. The figures show that decreasing the F/P ratio leads to a proportional decrease in photoluminescence

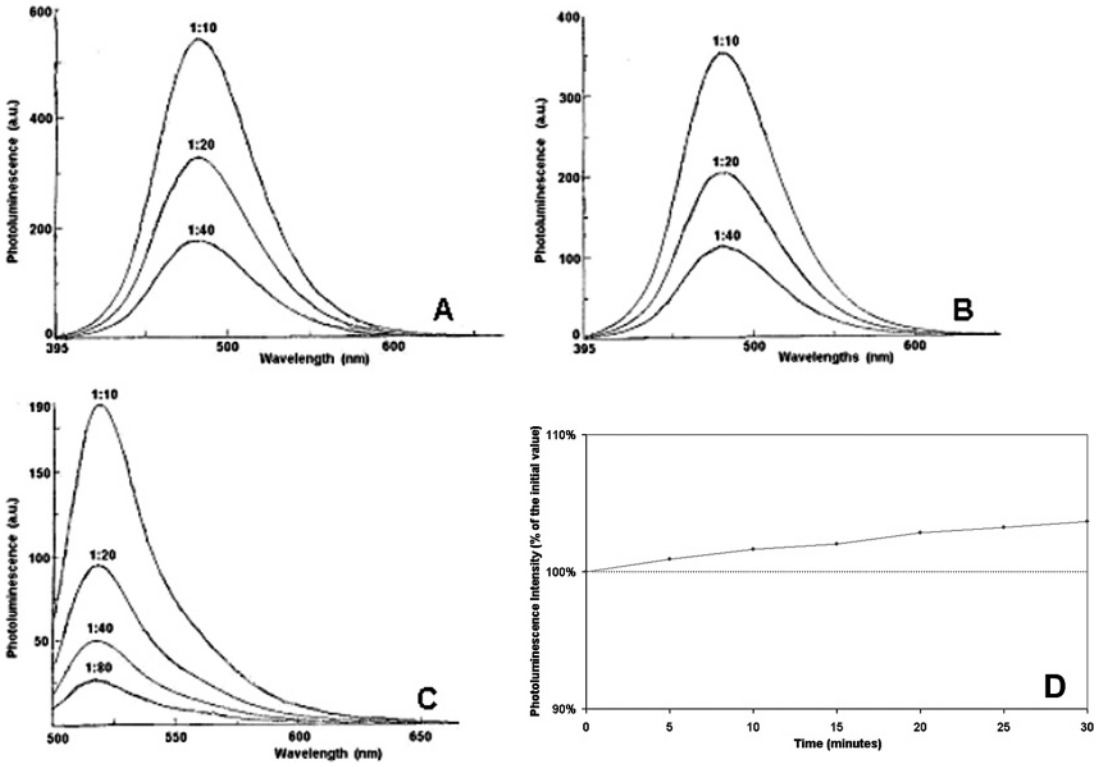

Figure 4. Photoluminescence of the IgG_1 anti-CD3 monoclonal antibody labeled with compound **9** (A, B, D) and with fluorescein isothiocyanate (C). A. PL spectra of anti-CD3:**9** bioconjugate with fluorophore-to-protein ratio 6.7. B. PL spectra of anti-CD3:**9** bioconjugate with fluorophore-to-protein ratio 2.5. C. PL spectra of anti-CD3: FITC bioconjugate with fluorophore-to-protein ratio 7. The different plots of each figure are the spectra corresponding to different dilutions of the bioconjugates (1:10, 1:20, 1:40, and 1:80 v:v). D. Photoluminescence intensity, in % of the starting value, of the bioconjugate of part A as a function of time under continuous excitation at a frequency corresponding to maximum absorption wavelength.

intensity. Figure 4C shows the photoluminescence spectra of the anti-CD3 antibody labeled with FITC. The different plots of each figure are the spectra corresponding to different dilutions of the bioconjugate (1:10, 1:20, 1:40, 1:80 v/v).

Comparison of Figures 4A and 4C shows that despite the sligthly lower F/P ratio and lower absorbance (see the Supporting Information), the photoluminescence intensity of the anti-CD3 antibody marked with **9** is higher than that of the antibody marked with fluorescein. Figure 4D shows the photoluminescence of the anti-CD3 antibody marked with **9** as a function of time, under continuous irradiation with the spectrofluorimeter lamp at a frequency corresponding to the maximum absorption wavelength. It is seen that after 30 min the PL intensity is slightly increased. On the contrary, and in agreement with what is already known (*2*), the photoluminescence signal of the bioconjugate with fluorescein faded quickly and after a few minutes of continuous irradiation at optimum wavelength became undetectable.

The slight fluorescence increase reported in Figure 4 is either due to photoactivation phenomena similar to those observed for quantum dots in cells (*38*) or phenomena related to the reorganization of the solvent cage (*19*). The phenomenon is currently under investigation.

To evaluate the suitability of oligothiophene *N*-succinimidyl esters for in vitro cells imaging, the anti-CD3 monoclonal antibody (mAb) labeled with compounds **9** and **13** were employed. The conjugation of the anti-CD3 mAb to **13** was carried out with the same modalities described above for **9**, using mAb to fluorophore molar ratios of 1:25 and 1:50.

To evaluate the cell binding, human T-lymphoma Jurkat cells were incubated at 4 °C for 30 min with the anti-CD3 mAb labeled with **13**. The reaction was carried out at $T = 4$ °C, to allow the specific binding of the anti-CD3 mAb to the corresponding antigen on cell surface while preventing the internalization of the immuno-complex. The resulting fluorescence microscopy image is shown in Figure 5A. The image shows the membrane fluorescence of the labeled cells.

To evaluate the cell binding and endocytosis, adherent human cervical carcinoma HeLa cells were treated with the plant toxin saporin, one of the type 1 ribosome-inactivating proteins most used to construct immunotoxin, chimeric proteins with specific efficacy (*21, 39*−*41*). Cells were incubated at 37 °C for 60 min with saporin, previously conjugated with fluorophore **9** as detailed in the Experimental Section. The binding was carried out at $T = 37$ °C in order to allow endocytosis. Since saporin has not a membrane receptor, the diffusion into the cells is not specific and occurs prevalently via pinocytosis. The corresponding fluorescence microscopy image is reported in Figures 5B, showing a brilliant fluorescence despite the bioconjugate widespread diffusion into the cell.

Figures 5A,B indicate that fluorophores TSEs are bright enough for effective cell labeling and, owing to the high excitation intensity at the focus of the objective of the microscope, also characterized by high photostability. Some blinking phenomena, namely fluorescence intermittency (*42*−*43*), were however observed, which are currently under investigation. Nevertheless, labeled cells observed after a few days showed no sign of decline of the optical characteristics.

V. Coupling to Oligonucleotides. Oligonucleotides functionalized at the 3′-position with the NH_2 group were coupled to oligothiophene *N*-succinimidyl esters in buffered solution at pH 7.4 (see the Experimental Section). As an example, the conjugates of oligothiophene *N*-succinimidyl esters **5** and **15** with the molecular beacons $^{5'}$GCGGTAGTGTGGTTCGAAGG-GTGGTACCGC$-(CH_2)_6NH_2{}^{3'}$ and $^{5'}$dabcyl-GCGGTAGTGTG-GTTCGAAGGGTGGTACCGC$-(CH_2)_6NH_2{}^{3'}$ are described.

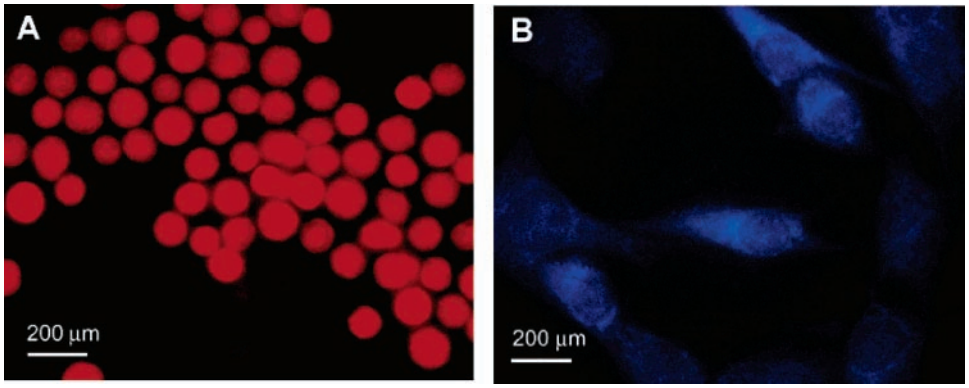

Figure 5. A: Immunofluorescent staining of Jurkat cells using the anti-CD3 monoclonal antibody labeled with fluorophore **13**. B: Binding and endocytosis of **9**-labeled saporin by HeLa cells.

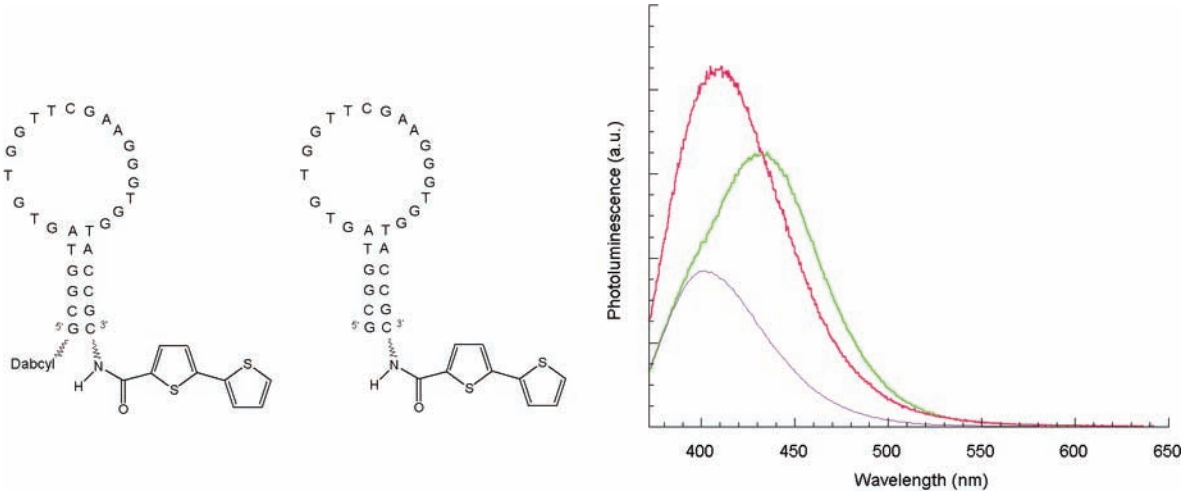

Figure 6. Left: 3′-Amino-terminated molecular beacon sequence coupled to oligothiophene *N*-succinimidyl ester **5** with and without the quencher dabcyl at the 5′-end. Right: Photoluminescence spectrum of free **5** (green, 10^{-7} M in H_2O), of the molecular beacon−**5** conjugate (red) and of the molecular beacon−**5** conjugate with dabcyl at the 5′-end (violet).

Molecular beacons (MB) (*44*) are single stranded oligonucleotides possessing a complementary set of bases at both ends of the sequence, thus enabling the formation of a hairpin conformation as shown in the scheme of Figure 6. Dabcyl is a well-known quencher used to probe nucleic acid structures, which is nonfluorescent and acts as energy acceptor in conjunction with fluorophores such as fluorescein (*45*). The emission spectra of **5** and **15** overlap the absorption spectrum of dabcyl (λ_{max} = 475 nm)**,** permitting energy transfer between the fluorophores and the quencher to occur when they are at appropriate distance (*44*−*47*). Thus, some fluorescence quenching is expected following the intramolecular interaction of the fluorophores with dabcyl in the molecular beacon bearing the fluorophore and dabcyl at the opposite ends.

Figure 6 compares the photoluminescence spectra of free **5** with that of the MB sequence labeled with **5** and the MB sequence labeled with both **5** and dabcyl at the 3′- and 5′-positions, respectively. It is seen that upon conjugation with MB, the photoluminescence of **5** increases by about 30% and undergoes a blue shift of about 20 nm. However, in the presence of dabcyl at the opposite end of the MB sequence, the quenching of the emission of **5** takes place and the PL intensity decreases to nearly half the value observed for the **5**-labeled oligonucleotide lacking dabcyl at the opposite end.

Figure 7 (red plot) illustrates the effect of the addition of a complementary strand to the photoluminescence of the MB sequence labeled with oligothiophene *N*-succinimidyl ester **15** at the 3′-end and with dabcyl at the 5′-end. The shape of the PL spectrum of the MB sequence bearing **15** at the 3′-end and dabcyl at the 5′-end (black plot) indicates that the intramolecular interactions of dabcyl with the tetrameric **15** are more complex than those observed for the dimeric fluorophore **5** and deserve deeper investigations to be fully understood. However, for the present purposes, what is significant is that upon addition of a complementary strand, i.e., of the probe sequence $^{3'}$CACAC-CAAGCTTCCCACCA$^{5'}$ (see the scheme of Figure 7), a sizable alteration of the emission of the fluorescent label is observed. Indeed, Figure 7 shows that upon addition of 3 equiv of the complementary oligonucleotide, the PL intensity is remarkably increased and the PL maximum wavelength blue shifted to 440−450 nm. This indicates that the presence of the complementary strand allows the opening of the loop, the removal of dabcyl from the proximity of the fluorophore, and the formation of a duplex with a significantly higher PL intensity and a large blue shift of the fluorophore.

The results reported in Figures 6 and 7 indicate that oligothiophene-based fluorophores are able to transfer the energy absorbed upon excitation to nearby molecules and are then worth testing in a variety of experiments for nucleic acid detection.

DISCUSSION

The most significant result reported here is that small and simple systems, such as bithiophene *N*-succinimidyl ester **9**, can behave as robust ‘nanolamps’ emitting even more light than fluorescein when bound to proteins, such as monoclonal antibodies, and with an incomparably greater optical stability. The result is important not only in view of the possible applications but also from a fundamental point of view. Indeed,

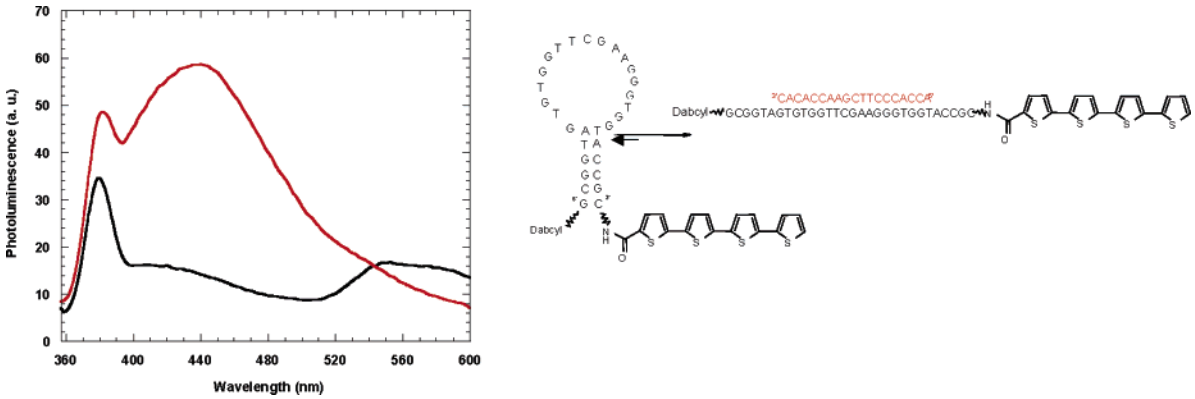

Figure 7. Effect of hybridization on the PL intensity of the MB sequence labeled with **15** at the 3′-end and dabcyl at the 5′- end in the presence of 3 equiv of the complementary strand. Black plot: before addition of the complementary sequence. Red plot: after duplex formation.

despite the large body of experimental data on the fluorescence properties of thiophene oligomers, with oligomers that emit in solution but not in solid, in solid but not in solution, or both in solution and in solid (*28, 48, 49*), there are still very few data on the relative importance of radiative and nonradiative de-excitation mechanisms in these systems (*29*−*31, 50*−*52*).

Compound **9** is a bithiophene bearing a donor (SCH_3) and an acceptor (−COO−*N*-succinimidyl) group at the terminal positions. It is poorly soluble in water but acquires high water solubility upon binding to proteins or oligonucleotides. There are a few experimental data indicating that molecules with donor−acceptor substituents increase their photoluminescence when the solvent polarity increases (*53*). This suggests that a possible explanation for the high fluorescence of **9** in water, when bound to biopolymers, could be related to its nature of donor−acceptor system, and we are currently investigating the phenomenon both theoretically and experimentally.

Theoretical calculations on bithiophene **5** show that *N*-succinidimyl esters are charge transfer compounds with the LUMO completely delocalized on the substituent and the lowest singlet S1 state almost optically forbidden. These results make oligothiophene *N*-succinimidyl esters interesting compounds in themselves. For the present purposes, however, it is important that when the −COO−*N*-succinidimyl substituent is replaced by the −CONH− linker that is formed upon reaction with the biopolymer, the characteristics of bithiophene are recovered. The optically active state becomes singlet S1 which is mainly a HOMO → LUMO transition, essentially localized on bithiophene. Figure 3 shows that there is still a large charge separation in the LUMO with an excess of negative charge on the thienyl ring bearing the linker. It is likely that this charge separation is accentuated by the presence of an electron donor at the opposite side of the molecule, such as the methylsulfanyl group of compounds **9**, **13**, and **17**.

As shown in Figure 2, dimers have narrow (60−70 nm at half-height) and symmetric PL spectra while trimers (∼70−90 nm at half-height) and tetramers (∼90−140 nm at half-height) have broader emission lines. The absorption spectra follow the same trend, albeit less accentuated. The fact that the absorption spectra vary within a much narrower range than the emission one is a favorable factor for multilabeling multicolor experiments using a single irradiation source. On the other hand, the fluorescence colors shown in Figure 2 were obtained by irradiation with a single UV 15 W lamp at $\lambda = 364$ nm, of those used for product revelation in thin layer chromatography.

Table 1 shows that the absorpitivities of the *N*-succinimidyl esters in methylene chloride are between 24.000 and 61.000 cm^{-1} mol^{-1} and increase with the oligomer size, as in the case of unsubstituted oligothiophenes. However, on the basis of our first approximate estimates, the fluorescence efficiency decreases on increasing the oligomer size, contrary to unsubstituted oligothiophenes (*29*−*31*). While this result needs to be confirmed by more accurate, absolute, fluorescence quantum yield measurements, we recall that the balance of factors affecting the radiative and nonradiative de-excitation patterns in thiophene oligomer changes on changing the nature of the substituents grafted to the aromatic backbone and needs accurate elucidation case by case.

The bioconjugates of *N*-succinimidyl esters with monoclonal antibodies are characterized by very clean photoluminescence spectra, as shown in Figures 4A,B for the bioconjugate of compound **9** with anti-CD3 antibody. The emission band is symmetric for all concentrations, contrary to the bioconjugate of the same antibody with FITC, which displays the presence of weak tails at red wavelegths (Figure 4C). The optical stability of the bioncojugates is documented in Figure 4D, showing the PL intensity of the bioconjugate of **9** with anti-CD3 antibody monitored for 30 min under continuous irradiation with the spectrofluorimeter light source. This result is in agreement with what was found for oligothiophene isothiocyanates (*16*). The photoluminescence intensity of the anti-CD3-**9** bioconjugate undergoes even a slight increase with time, a further phenomenon currently under investigation.

To our knowledge, the fluorescence microscopy images shown in Figure 5 are the first ones obtained using thiophene-based fluorophores. We used two different cell lines, Jurkat cells derived from a T lymphoma and HeLa cells derived from a carcinoma, in order to show different applications of fluorescence, in suspension and in adherent growing cells. Jurkat cells were used to evaluate specific membrane fluorescence by the binding of an anti-CD3 antibody whereas HeLa cells were used to evaluate a non specific fluorescence, due to a toxin (saporin) entering in vivo in the cells. Images 5A and 5B indicate that oligothiophene *N*-succinimidyl esters are valuable photostable probes for cell detection.

What we have still to demonstrate is that the esters allow multicolor tagging of cells for the simultaneous tracking of multiple biological events. We are currently planning such kind of experiments with the oligothiophene *N*-succinimidyl esters described here, since the absorption and emission spectra of Figures 1 and 2 show that at least one couple of well separated colors is available. Moreover, we are pursuing our synthetic effort to get better emission colors particularly for the red wavelengths, taking advantage of the easy functionalization of thiophene oligomers with a great variety of substituents. This objective demands a parallel effort to explore in more detail the relationship between the molecular structure and the optical characteristics of oligothiophenes, even with the aid of theoretical calculations, since the optical behavior of these compounds is so far scarcely predictable.

The results concerning the labeling of oligonucleotides with oligothiophene *N*-succinimidyl esters, shown in Figures 6 and 7, indicate that these fluoropores allow experiments that are generally carried out using FITC and its derivatives, with the non-negligeable advantage of a much greater optical stability. In particular, we have demonstrated the feasibility of fluorescence resonance energy transfer (FRET) experiments (*44*−*47*); see for example Figure 6 showing that the fluorescence is partially quenched when the oligonucleotide sequence bears dabcyl at the 5′-end. These kinds of experiments are commonly employed for monitoring hybridization of a fluorescent oligonucleotide probe to a complementary single-stranded DNA target (*44*−*47, 54*). When hybridization occurs, the markers at the opposite ends (the reporter and the quencher) are separated and the fluorescence signal increases again. In our case, Figure 7 shows that the expected changes in fluorescence upon hybridization are indeed observed with our fluorophores. Figure 7 also illustrates the complexity of the optical patterns associated to the intra- and intermolecular interactions of the longer oligothiophenes, a complexity that contains much information but that requires, once again, a great deal of further experimental and theoretical work to be elucidated.

CONCLUSION

For the easy synthesis, fluorescence sensitivity, optical stability, color tuning, large shifts between absorption and emission wavelengths, and the easy conjugation modalities to proteins and oligonucleotides, oligothiophene *N*-succinimidyl esters are among the best classes of organic fluorescent markers described so far. They also represent a remarkable improvement with respect to the family of oligothiophene isothiocyanates previously described (*16*), particularly regarding fluorescence intensities and absorption and emission bandwidths of the bioconjugates. The conjugates of oligothiophene *N*-succinimidyl esters with proteins and oligonucleotides display high water solubility and do not show any sign of photobleaching even after hours of continuous irradiation. The fact that they can even achieve fluorescence intensities higher than those of the same bioconjugates with fluorescein indicates that they have the potential to replace the most commonly used markers for detection and quantitation of biopolymers in clinical diagnostics, molecular biology, environment analysis, etc. Furthermore, the first examples reported here of cell imaging by fluorescence microscopy using oligothiophene *N*-succinimidyl esters are greatly encouraging regarding the possibility of multicolor experiments for the simultaneous tracking of different cell events.

Finally, it is worth noting that the optical stability and color tunability of thiophene-based fluorophores would also be of great interest for monoclonal antibodies and DNA cytofluorimetric analyses. Unfortunately, the flow cytometry currently in use, mainly developed for fluorescein and its derivatives (*2*), employs the argon laser at 488 nm as irradiation source, while thiophene oligomers absorb around 400 nm and would require instrumentation with a very expensive blue laser as excitation source. Owing to the recent great interest in polythiophenes as optical sensors (*9*−*10, 55*−*57*), it cannot be excluded that cheaper blue lasers and instrumentation will rapidly be developed. As an alternative, there is the engineering of thiophene-based light emitters with the appropriate characteristics for detection with the currently used instrumentation. Considering the increasing importance of fluorescence detection techniques, the large place left for fundamental research in order to understand the photophysics of thiophene-based fluorophores and the versatility of thiophene chemistry, this is a challenge that it is worth accepting.

ACKNOWLEDGMENT

This work was partially supported by the project FIRB RBNE01YSR8 NanObioMoleculAr Devices (NOMADE), and by the University of Bologna, Funds for Selected Research Topics, the Ministry of Instruction, University and Research, the Ministry of Welfare and the Pallotti's Legacy for Cancer Research. Thanks are also due to R. Ahlrichs for providing the TURBOMOLE program package and G. Aloisio for his support.

Diabodies are single chain antibody fragments (scFvs) that spontaneously form bivalent dimers of molecular size 50−55000. Radiolabeled diabodies are almost ideal tumor targeting agents due to their high avidity (bivalent) binding to tumor antigens and small size (50−55000) that leads to improved tumor-to-blood ratio compared to intact antibodies (150000). However, due to their high retention and metabolism in the kidney, radioiodine is the current radiolabel of choice for diabodies since radioiodine is rapidly excreted from the kidney once metabolized. We have previously shown that ^{111}In-DOTA-diabody gives higher tumor uptake in nude mouse xenografts than ^{125}I-diabody, but has extremely high kidney retention since its ^{111}In-labeled metabolites are retained by and only slowly excreted from the kidney. When a diabody is conjugated to a bifunctional PEG-3400 derivative followed by reaction with cysteinyl-DOTA, the resulting product has an apparent molecular size of 75000 and a Stokes radius of 35 Å on size exclusion chromatography, compared to a Stokes radius of 25 Å for intact diabody. When radiolabeled, the conjugate gives high yields of ^{111}In-labeled product, retains high immunoreactivity, and gives improved biodistributions (30−40%ID/g, 12−48 h) compared to ^{111}In-DOTA-diabody (12−13%ID/g, 6−12 h). We show that the improved biodistribution is due to an increase in Stokes radius caused by the linear PEG-3400 since conjugation of diabody with multiple $(PEG)_{12}$ linkers followed by reaction with cysteinyl-DOTA does not reduce kidney accumulation. We also show that ^{111}In-cysteinyl-DOTA-PEG3400-diabody gives excellent tumor images in the nude mouse xenograft model and that ^{125}I-PEG3400-diabody gives equivalent images to ^{125}I-minibody (molecular size, 80000), but improved tumor-to-liver ratios, suggesting that this imaging agent can be used to image liver metastases.

INTRODUCTION

To be effective tumor imaging agents, tumor-targeted radiolabeled antibodies must give both high tumor uptake and high tumor-to-blood ratios (*1*). At one extreme, monoclonal antibodies (150 kda) have a relatively slow blood clearance ($t_{1/2\ \beta}$ = 48−72 h), allowing ample time for high accumulation in the tumor, but suffer from low tumor-to-blood ratios. At the other extreme, single chain (sc) Fv recombinant antibodies (25 kDa) are rapidly cleared from the blood ($t_{1/2\ \beta}$ = 0.5−2.0 h) resulting in high tumor-to-blood ratios but low overall accumulation of radioactivity in the tumor. To predict optimal tumor imaging, one must account for both parameters using pharmacokinetic analytic indicators such as the Imaging Figure of Merit (IFOM). The IFOM indicator was derived by us by comparing the biodistributions (%ID/g over time) of a series of radioiodinated recombinant anti-CEA antibodies of molecular sizes 25000, 50000, 80000, and 150000 in a nude mouse xenograft model (*1*). From these studies we concluded that the best combination of high tumor uptake and high tumor-to-blood ratio requires at least a bivalent antibody of size 50−80000. However, a drawback to radioiodinated antibodies is that they may be rapidly metabolized in tissues, including the tumor, especially if the antigen undergoes internalization upon antibody binding. Although most anti-CEA antibodies undergo negligible internalization, we and others have observed higher tumor uptake and persistence at the tumor site for radiometal-labeled anti-CEA antibodies compared to radioioinated anti-CEA antibodies (*2*). For radiometal-labeled recombinant antibody fragments, this improvement is offset by high kidney retention, indicating that the radiometal-labeled antibody was filtered, reabsorbed, and metabolized by the kidney, but the radiometal metabolic products are retained or only slowly excreted compared to radioiodine metabolic products. Indeed, we have identified ^{111}In-DOTA-ϵ-lysine as the ultimate metabolic product in the kidney when anti-CEA antibody fragments are conjugated to the NHS-active ester of DOTA and radiolabeled with $^{111}InCl_3$ (*3*).

In light of these findings, we and others have sought to improve the utility of radiometal-labeled recombinant antibody fragments by decreasing kidney retention. In one approach kidney uptake is partially blocked by the administration of intravenous L- or D-lysine (*4*, *5*). In a second approach, we have designed unique metabolizable linkers between the antibody and DOTA that have decreased kidney retention by up to 4-fold

over NHS-DOTA conjugates (*6*). A third approach is to increase the blood retention of antibody fragments by increasing their molecular weight through conjugation to poly(ethylene glycol) (PEG) polymers (*7*). This approach was successfully applied to recombinant cytokines such as IL-2 where the increase in the beta phase of blood clearance was greater than 8-fold (*8*). In the case of anti-CEA F(ab′) fragment A5B7 conjugated to MPEG6000, tumor retention increased by 5.7-fold and serum half-life by 5-fold (*9*). In the case of anti-mucin scFv CC49/218 conjugated to PEG-5000, a 14-fold increase in serum half was observed (*10*). In the latter study, the authors conclude that greater improvements were observed with increasing size of PEG polymers rather than total amount of PEG, which in addition, often led to decreased immunoreactivity of the conjugate. In this respect, recombinant antibodies have been designed to allow site-specific attached of PEG to prevent alterations in immunoreactivity (*11*). As yet, no biodistributions have been published on site-specific PEG- antibody conjugates.

In this study we selected a commercially available bifunctional PEG3400 for conjugation to an anti-CEA diabody that we have previously characterized (*2*). This linear polymer has an NHS-active ester at one end and vinyl sulfone at the other end. Reaction conditions were adjusted to conjugate approximately 1 PEG3400 per diabody molecule (at lysine residues), followed by reaction with cysteinyl-DOTA, a chelate with high metal complex stability that we have previously described (*12*). The resulting cys-DOTA-PEG3400-diabody conjugate had an apparent molecular size of 75000 and a Stokes radius of 35 Å, compared to an apparent molecular size of 50000 and a Stokes radius of 25 Å for intact diabody, demonstrating a net gain of 50% in its Stokes radius. The conjugate was radiolabeled with high efficiency (>90%) to high specific activity (2−4 μCi/ug) with $^{111}InCl_3$, retained high immunoreactivity (90%), and showed improved tumor uptake and blood retention compared to ^{111}In-DOTA-diabody. In addition, kidney retention was decreased by over 4-fold compared to ^{111}In-DOTA-diabody, and excellent tumor images were obtained. We also conjugated PEG3400 to a site-specific cys-diabody, a diabody with C-terminal cysteines (*13*) that were reduced and conjugated to DO3A-vinyl sulfone to chemically separate DOTA from PEG3400. This conjugate also gave high efficiency labeling to high specific activity and gave identical biodistributions compared to cys-DOTA-PEG3400-diabody. Since cys-DOTA-PEG3400-diabody has an apparent molecular size similar to a "minibody" construct (scFv-hinge-C_H3) made from the same parent antibody (*14*), we decided to compare the two radioiodine-labeled antibodies in the same animals. Within experimental error, the two constructs behaved identically and gave similar images. Since most scFv antibodies are easily expressed as diabodies in bacteria or yeast, while minibodies are best expressed in myeloma cells, we conclude that diabodies conjugated to this bifunctional PEG3400 offer a simple route to the rapid generation of useful imaging agents. A potential drawback is that, due to their small size, conjugation of PEG3400 to a diabody may reduce immunoreactivity.

EXPERIMENTAL PROCEDURES

Materials, Radiolabeling, Immunoreactivity, and Mass Spectrometry. NHS-PEG3400-VS (Cat No 4M5B0F02) was obtained from Nektar (San Carlos, CA). MAL-dPEG12-NHS ester (Cat No 10284) was obtained from Quanta Biodesign Ltd. (Powell, OH). The synthesis of cysteinyl-DOTA (cys-DOTA) and DO3A-VS were previously described (*12*, *15*). All other reagents were obtained from Aldrich-Sigma (St. Louis, MO). LS-174T cells were obtained from ATCC and maintained in maintained in sterile growth media consisted of Eagle's Minimal Essential Media 1X (EMEM) (Cellgro, Herndon, VA) supplemented with 10% heat inactivated fetal bovine serum (FBS) (Omega Scientific, Tarzana, CA), and 1% L-glutamine, 10 mM sodium pyruvate, 0.1 mM nonessential AA. The production and purification of anti-CEA T84.66 diabody, Cys-Diabody, and Minibody have been previously described (*13*, *16*). Chelate-conjugated antibodies were radiolabeled either with ^{111}In (Amersham, 2−3 mCi/mg of protein) as previously described (*17*) or with ^{125}I or ^{131}I by the iodogen method (*2*). Percent labeling was determined by ITLC or by size exclusion chromatography (SEC) on a Superose 6 column (1 × 30 cm, Amersham). Radiolabeled antibody was purified by SEC on the same column (in saline, flow rate 0.5 mL/min, fraction size was 0.5 mL). Immunoreactivity was determined by mixing the radiolabeled sample with a 20-fold excess by mass of CEA and running the sample over a Superose 6 column. Percent immunoreactivity was calculated as counts in CEA conjugate complex/ total counts × 100. MALDI-MS was performed on Perkin-Elmer-Sciex prOTOF 2000 using sinapinic acid (10 mg/mL in TFA/water/acetonitrile (0.1/99/100 v/v/v) as a matrix. Prior to mixing with matrix the sample was desalted on a Sephadex G25 spin column (100−200 mg in a 250 μL pipet tip), equilibrated in water.

Cys-DOTA-PEG3400-Diabody Conjugate. The reaction conditions for a molar ratio of 20:1 NHS-PEG3400-VS to diabody at pH 6.0 are given here. NHS-PEG3400-VS (3.0 mg, 0.8 μmol) was mixed with 2 mg (0.04 μmol) of diabody in 0.62 mL of pH 7.0 PBS, the pH was adjusted to 6.0 with 0.1 M NaOH, and allowed to react for 2 h at RT. In other reactions, the molar ratios and reaction pH were varied (see Results). When the reaction was monitored by SDS gels, it appeared to be >70% complete at the end of 2 h. At the end of 2 h the entire reaction mixture was applied to a Superdex 75 column (1 × 30 cm, Pharmacia), monitored at 214 and 280 nm, and eluted at a flow rate of 0.5 mL/min with PBS. The first peak that eluted at 18 min was the conjugate followed by unconjugated diabody at 22 min and free NHS-PEG3400-VS at 35−40 min (see Results). The conjugate (4 mL) was concentrated to 0.3 mL in a Amicon Ultra-4 (Millipore, Bedford, MA) and mixed with 1.0 mg (2 μmol) of cys-DOTA, the pH adjusted to 8.5, and reaction continued on a sample rotator for 17 h at RT. The product was dialyzed vs 3 × 1.5 L of PBS containing 1.5 g Chelex 100, followed by 2 × 1.5 L of 0.9% NaCl or 0.25 M ammonium acetate, pH 7.0. The dialysate was concentrated to 2−4 mg/L on a Centricon 10 and sterile filtered. The conjugate was characterized by both SDS and IEF gel electrophoresis (see Results).

Cys-DOTA-Mal-PEG$_{12}$-Diabody Conjugate. Diabody (0.5 mL of 4 mg/mL; 0.04 μmol)) in PBS was mixed with 0.93 mg (0.8 μmol) of NHS-PEG$_{12}$-maleimide, the pH was adjusted to 6.0 with 0.1 M NaOH, reacted for 2.5 h at RT, and the conjugate purified by SEC on a Superdex 75 column as above. The major peak (see Results) was collected and concentrated to 0.7 mL by centrifugation on an Amicon Ultra-4. The conjugate was mixed with 1 mg (1.0 μmol) of cys-DOTA, the pH adjusted to 8.3, and reaction continued overnight at RT. The product was characterized by SDS and IEF gel electrophoresis (see Results) and dialyzed vs PBS (1.5 L), saline (1.5 L) and then concentrated to 0.3 mL (3.6 mg/mL) on an Amicon Ultra-4.

DO3A-VS-cys-Diabody-PEG3400 Conjugate. Cys-diabody (2 mg, 0.04 μmol) in 0.38 mL of pH 7.5 PBS was reduced with 6 μL of freshly made 0.2 M TCEP (tris-carboxyethylphosphine, 0.12 μmol) for 2 h at 37 °C. The sample was run through a 1 mL spin column (Sephadex G25 in PBS) to remove excess TCEP and run on a nonreducing SDS gel to verify complete reduction from 50 kDa to 25 kDa. The reduced sample was mixed with 0.9 mg (2.0 μmol) of DO3A-VS and reacted at 25 °C for 2 h. Reaction with DO3A-VS was verified by running

an IEF gel where the conjugate was shifted to a lower pI (see Results). The conjugate was reacted with 3.0 mg (0.8 μmol) of NHS-PEG3400-VS at pH 6.0 for 2 h at RT and purified on a Superdex 75 column as described above. The final product (0.28 mL) was dialyzed into 0.25 M, pH 7.0 ammonium acetate and concentrated to 2.0 mg/mL.

Determination of Stokes Radius of Cys-DOTA-PEG3400-Diabody Conjugate. The elution volumes (V_e) of proteins of known Stokes radii were measured by SEC on a Superdex 75 column (1 × 30 cm, Pharmacia) in PBS with a flow rate of 0.5 mL/min. The standards were catalase (250000, 52 Å), alcohol dehydrogenase (150000, 46 Å), bovine serum albumin (65000, 35 Å), carbonic anhydrase (29000, 24 Å), myogobin (19000, 19 Å), and cytochrome *c* (17000, 12.4 Å). Stokes radii were plotted vs $K_d^{1/3}$ where $K_d = (V_e - V_o)/(V_t - V_g - V_o)$ (*18*). The void volume (V_o) was determined as 7.71 mL using Dextran Blue. The values for V_t (24 mL) and V_g (0.84 mL) were obtained from Pharmacia. The V_e for diabody was 11.0 mL, corresponding to a Stokes radius of 25 Å, and 9.8 mL for Cys-DOTA-PEG3400-diabody conjugate, corresponding to a Stokes radius of 35 Å.

LS-174T Xenograft Model. Female, athymic nu/nu mice (Charles River), 10−12 weeks old, were injected with LS-174T cells (5×10^6) sc in the flank. Tumors were established within 7−10 days postinjection. Athymic mice bearing LS-174T xenografts were tail vein injected with 200 μL of 4 μCi/2−3 μg ^{111}In-labeled DOTA-conjugates, 4 μCi/2 μg I-labeled minibody, or 4 μCi/1 μg of ^{125}I-labeled PEG3400 diabody. Five mice per time point were sacrificed at 0, 2, 4, 6, and 18 h postinjection and biodistributions performed (blood, liver, spleen, kidneys, lungs, tumor, and carcass). Results were calculated as percent injected dose per gram (%ID/g) vs time. For radioimaging, mice were injected with 40 μCi/20 μg ^{111}In-labeled DOTA conjugates or 20 μCi/5μg of ^{125}I PEG3400 diabody and imaged using a BIOSPACE γ Imager instrument with settings of 154−188 keV and 220−270 keV, respectively.

RESULTS

Optimization of Cys-DOTA-PEG3400-Diabody Conjugate. PEG-antibody conjugates have demonstrated the ability for improved blood retention over their unconjugated cognates but have the drawback of reducing immunoreactivity if over-conjugated (*10*). We searched for a commercially available PEG reagent of moderate size that could be both conjugated to diabody and to a chelate without over-derivatizing the diabody. We chose the bifunctional reagent NHS-PEG3400-VS because, in theory, it could first be conjugated to the ϵ-amino group of lysines in the diabody, followed by reaction with a chelate possessing a free thiol group (Scheme 1). Indeed, we had such a chelate (cysteinyl DOTA) in hand that previously had been shown to have high metal binding stability when conjugated via linkers to antibody (*12*). We were further interested in the use of vinyl sulfone as a functional group because its reaction toward thiols is rather pH specific (*15*) and the products are more stable than maleimide derivatives (*12*) which are also commercially available. The bifunctional reagent NHS-PEG3400-VS was first reacted with diabody over a range of conditions to determine the optimal reaction conditions to retain maximal immunoreactivity (Table 1). From these studies we determined that a NHS-PEG3400-VS to diabody ratio of 20:1 at pH 6.0 was a good compromise since >80% of the diabody reacted under these conditions (Figure 1) retaining 90% of its immunoreactivity (Table 1). At higher ratios (e.g., 50:1), more PEG3400 reacted with diabody resulting in lowered immunoreactivity (e.g., 40−54%, Table 1). In addition, we found that the reaction products of the first step must be purified by SEC and not by dialysis because NHS-PEG3400-VS remained in the dialysate (10 kDa cutoff) and interfered with the subsequent reaction with cys-DOTA. Although the diabody-PEG3400-VS conjugate could not be completely separated from unreacted diabody by SEC at this ratio (Figure 1A vs 1C), we were able to estimate the apparent molecular size of the conjugate as 75000 with a Stokes radius of 35 Å by SEC. In contrast, intact diabody has an apparent molecular weight of 50000 with a Stokes radius of 25 Å. Since SDS gel electrophoresis revealed that the PEG3400 conjugated diabody was >90% monosubstituted (Figure 1B and 1D), and the predicted molecular size of the monosubstituted product was only 28400 (diabody plus PEG3400), we conclude that the addition of the linear PEG polymer to the diabody led to a dramatic change in its Stokes radius as analyzed by SEC. The final product was also characterized by MALDI-MS. In this analysis intact diabody gave three peaks corresponding to monomer, dimer, and trimer species in the gas phase (Figure 1E). The PEG3400-modified monomer peak increased in mass from 25771 Da to 29944 Da, an increase in agreement with the addition of PEG3400 and Cys-DOTA (507 Da).

Table 1. Optimization of Reaction Conditions on the Formation of Diabody-PEG Conjugates[a]

conjugate	conj pH	conj ratio	labeling ratio	mCi/mg	% IR
Cys-DOTA-VS-PEG3400-DB	7	50:1	97	3	40
Cys-DOTA-VS-PEG3400-DB	6	50:1	96	3	54
Cys-DOTA-VS-PEG3400-DB	6	20:1	60−70	2−3	83−95
Cys-DOTA-VS-PEG3400-DB	6	10:1	70−94	3	88
Cys-DOTA-Mal-PEG_{12}-DB	6	20:1	95	2−3	85
DO3A-VS-cys-DB-PEG3400	6	20:1	95−98	2−8	90−97

[a] Reaction conditions include pH and molar ratio of PEG bifunctional reagent to diabody. The products were compared after further conjugation to cys-DOTA by labeling efficiency, labeling ratio (mCi/mg), and % immunoreactivity (IR).

Cys-DOTA-PEG3400-diabody (pH 6.0, 20:1 ratio) was radiolabeled with $^{111}InCl_3$ in good yield (60−90% efficiency, 2−3 mCi/mg labeling ratio, and immunoreactivity 83−95%, Table 1), suitable for biodistribution studies. Stability studies performed by radiolabeling the sample (stored at 4 °C) and remeasuring immunoreactivity and molecular size over a 3 month interval demonstrated no loss in activity or aggregation over this period (data not shown).

Biodistribution and Imaging of ^{111}In-Cys-DOTA-PEG3400-Diabody Conjugate in a Nude Mouse LS174T Xenograft Model. The cys-DOTA-PEG3400-diabody conjugate obtained from the pH 6.0, 20:1 ratio reaction was radiolabeled with $^{111}InCl_3$, purified by SEC, and injected into nude mice bearing LS174T (CEA positive) xenografts. The results of the biodistributions shown in Figure 2 demonstrate high tumor uptake, reaching a maximum of about 40% ID/g at 12 h that is sustained through 48 h. Over the same period blood levels drop to about 10% ID/g at 12 h, and to about 2% ID/g by 48 h. Thus, the tumor-to-blood ratios increase from 5:1 at 12 h to 25:1 at 48 h. The combination of high tumor uptake and high tumor-to-blood ratios gives exceptionally high IFOM values (see below). As expected, the uptake in kidney is high but, unlike unmodified ^{111}In-DOTA-diabody (*2*), is similar to tumor levels at all time points tested. Kidney reaches a maximum of about 50% ID/g at 24 h and remains high at 48 h. Thus, the tumor-to-kidney ratio at 24 h is about 0.8, a significant improvement over that seen for ^{111}In-labeled DOTA-diabody at 12 h (0.08, see ref 2). Importantly, low liver levels (<10% ID/g) are seen throughout the biodistribution, suggesting that this agent may be used to image liver metastases. Finally, we performed radioimmunoimaging on several of the mice that were injected with larger amounts of radiolabeled conjugate (Figure 3). Tumor is

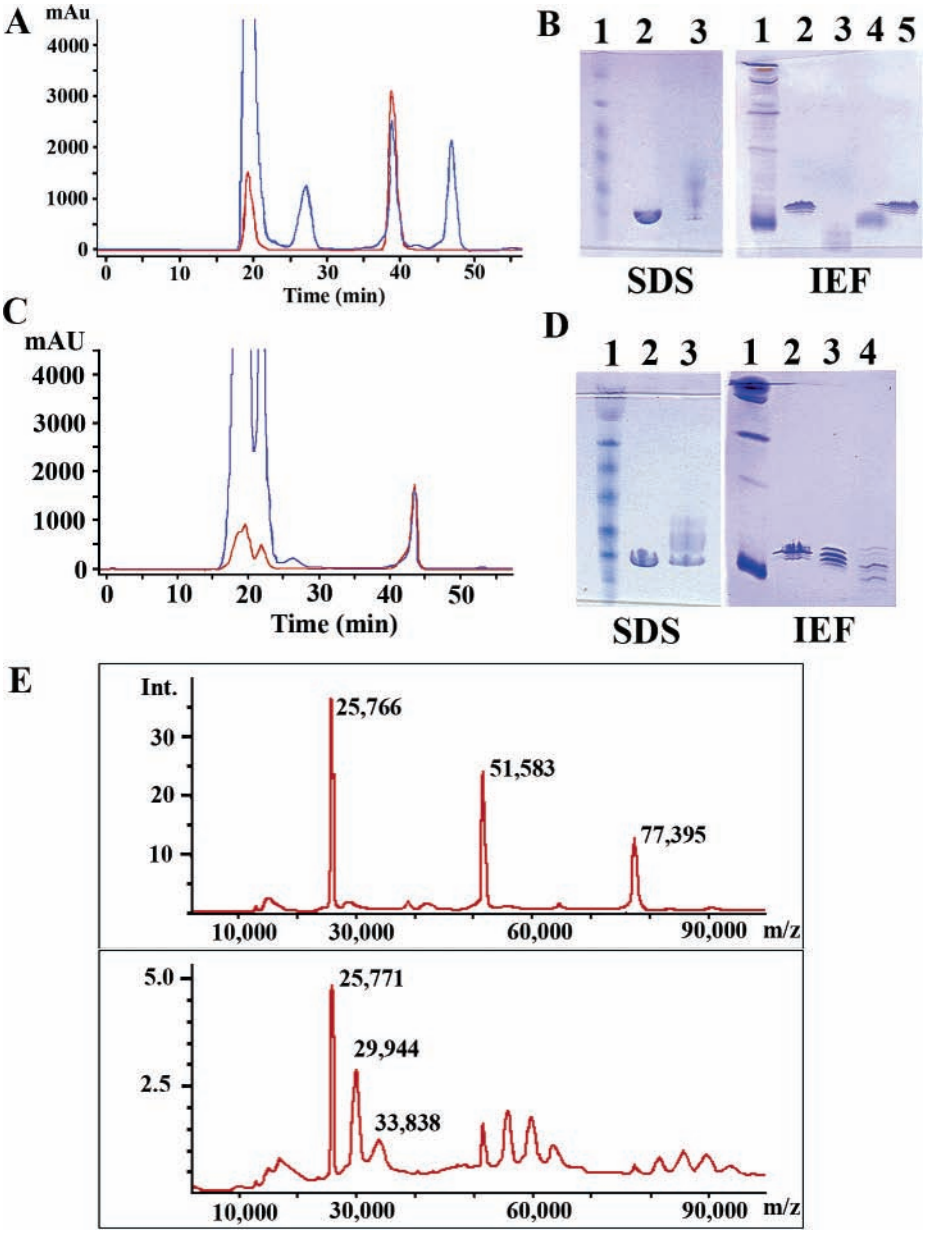

Figure 1. Characterization of cys-DOTA-PEG3400-diabody conjugates. A. SEC profile of PEG3400-diabody, for a conjugation ratio of PEG3400 to diabody of 50:1 at pH 6. Prior to reaction with cys-DOTA, the product was purified on Superdex 75 and monitored at 214 nm (blue) and 280 nm (red). B. Analysis of conjugation products by SDS and IEF gel electrophoresis. SDS: 1 = MW markers, 2 = diabody, 3 = PEG3400-diabody. IEF: 1 = IEF markers, 2 = diabody, 3 = cys-DOTA-PEG3400-diabody, 4= PEG3400-diabody, 5= diabody. C. SEC profile of PEG3400-DB, for ratio of PEG3400 to diabody of 20:1 at pH 6. Prior to reaction with cys-DOTA, the product was purified on Superdex 75 and monitored at 214 nm (blue) and 280 nm (red). D. Analysis of the conjugation products by SDS and IEF gel electrophoresis. SDS: 1 = MW markers, 2 = diabody, 3 = PEG3400-diabody. IEF: 1 = IEF markers, 2 = diabody, 3 = PEG3400-diabody, 4 = cys-DOTA-PEG3400-diabody conjugation. E. MALDI-TOF analysis of cys-DOTA-PEG3400-diabody. Upper: diabody control. Lower: cys-DOTA-PEG3400-diabody conjugated at the ratio of 20:1 (PEG3400 to diabody) at pH 6.

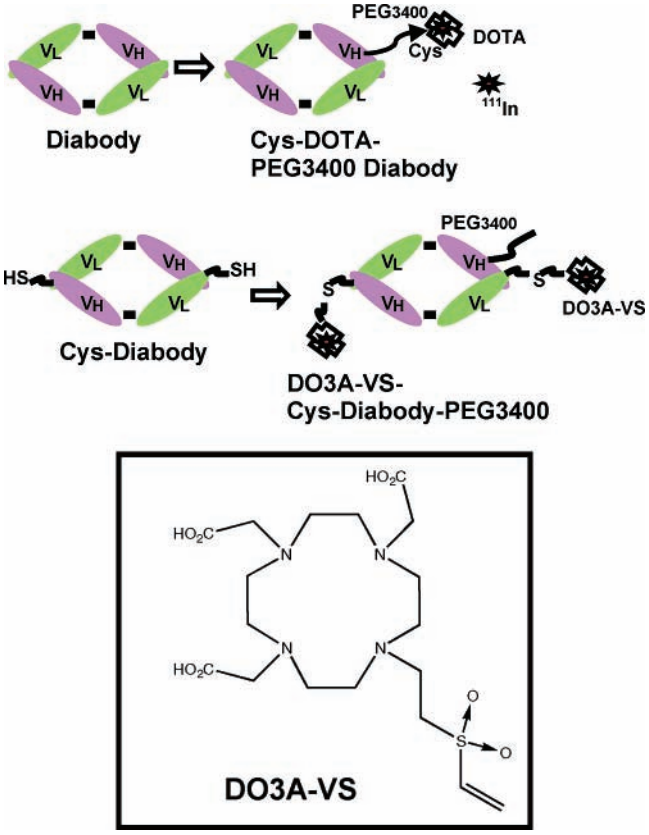
positively imaged as early as 2 h and is of similar intensity to kidneys over the period 12−48 h, in agreement with the biodistribution studies.

Comparison of ^{125}I-PEG3400-Diabody Conjugate with ^{131}I-Minibody in a Nude Mouse LS174T Xenograft Model. The high tumor uptake and apparent molecular size of 75000 of the PEG3400-diabody conjugate compares well with that of the scFv-hinge-C_H3 "minibody" construct engineered from the same parent T84.66 anti-CEA antibody (*2*). Thus, it was of interest to directly compare the two in the same mouse model and preferably in the same animals. Comparisons of this sort can be performed by labeling one antibody with ^{125}I and the other with ^{131}I. The results shown in Figure 4 indicate that the biodistributions are essentially identical, thus confirming the idea that the apparent molecular size of the antibody fragment dominates the biodistribution, as long as both have the same relative affinities and immunoreactivities. This experiment also demonstrates that radioiodine-labeled antibodies have low kidney and liver accumulations at all time points due to rapid removal of metabolized products in these organs. To a lesser extent, the same is true for the tumor where we observe about a 50% in reduction in tumor uptake at 12−48 h compared to the radiometal-labeled antibodies (Figure 3 and ref 2). In addition, animals were imaged with ^{125}I-PEG3400-diabody, demonstrating excellent tumor imaging results with no normal organ activity from 19 to 43 h (Figure 5).

Although we did not compare the two radiometal-labeled antibodies in the same animals, we have compared our previously published data for ^{111}In-DOTA minibody (*2*) to the results obtained in this study. At 12 h ^{111}In-DOTA minibody has an

Scheme 1. Schematic Model of Diabody (top left) Showing the Cross Pairing of V_L (green) and V_H (purple) Domains[a]



[a] NHS-PEG3400-VS is randomly conjugated to lysines on the surface of the diabody via the NHS active ester of NHS-PEG3400-VS, followed by reaction with Cys-DOTA via the vinyl sulfone (VS) moiety of NHS-PEG3400-VS (top right). The final conjugate is radiolabeled with ^{111}In (top right). In a control reaction, Cys-diabody (bottom left), that has C-terminal cysteine residues on V_H domains, is first reacted with DO3A-VS (inset) and then NHS−PEG3400 to physically separate the chelate from the PEG3400 (bottom right).

absolute uptake of 24(± 6) %ID/g in the tumor with a T/B ratio of 6.8, compared to the ^{111}In-cys-DOTA-PEG3400 diabody which had 49(±3) %ID/g in the tumor with a T/B ratio of 5.4. At 48 h ^{111}In-DOTA minibody gives 11(±1) %ID/g for tumor uptake and a T/B ratio of 66 compared to 50 (±30) %ID/g tumor uptake and a T/B ratio of 25 for ^{111}In-cysDOTA-PEG3400-diabody. On the basis of these comparisons alone, it is necessary to calculate IFOMs (a measure of both tumor-to-tissue ratio and absolute uptake over time) for both to determine which would be the better imaging agent in the mouse model. At 20−24 h the tumor to blood IFOMs are 25 for ^{111}In-cys-DOTA-PEG3400 diabody and 15 for ^{111}In-DOTA minibody (Figure 6). The results are even more impressive when comparing tumor to liver IFOMs where ^{111}In-cys-DOTA-PEG3400 diabody performs as well as the tumor to blood IFOM for minibody. The tumor to liver IFOM for ^{111}In-DOTA minibody (not shown) is similar to the tumor to kidney IFOM for ^{111}In-cys-DOTA-PEG3400 diabody (Figure 6), predicting that tumors cannot be positively imaged with ^{111}In-DOTA minibody in these organs. On the basis of these considerations, both imaging agents have certain drawbacks. On one hand ^{111}In-DOTA minibody has high liver uptake (19%ID/g at 12 h) compared to ^{111}In-cys-DOTA-PEG3400-diabody (9%ID/g at 12 h). On the other hand ^{111}In-cysDOTA-PEG3400-diabody has high kidney uptake (50%ID/g at 12 h) compared to ^{111}In-DOTA minibody (12%ID/g at 12 h). The final choice of imaging agent must take into account the potential interference of uptake in either the kidney or the liver, thus offering one the choice of agents.

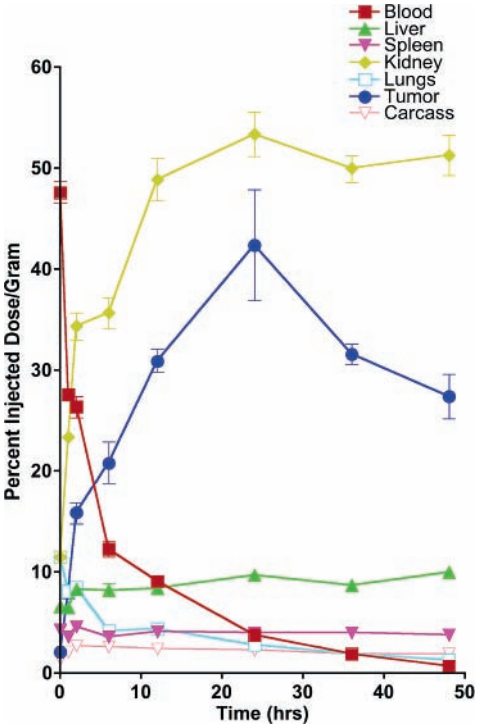


Figure 2. Biodistribution of ^{111}In-cys-DOTA-PEG3400-diabody in nude mice bearing LS174T xenografts. The average %ID/g (± std dev) of five animals per tissue analyzed is shown.

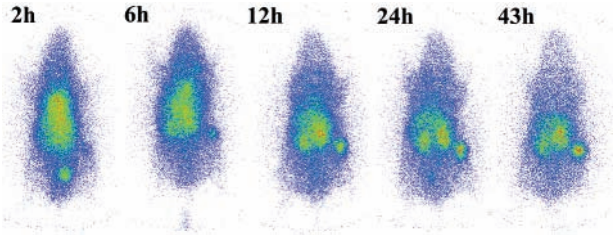

Figure 3. Radioimmunoimaging of ^{111}In-cys-DOTA-PEG3400-diabody in nude mice bearing LS174T xenografts. The time points are shown. The tumor is on the right flank. At 2 h. the large central mass is blood pool, liver, and kidneys: bladder is also imaged. By 12 h, the central mass is mostly kidneys and tumor is seen on the right side.

Control Experiments. Since the concept of attaching a chelate to an engineered antibody fragment via a bifunctional PEG linker is novel, we felt obligated to run several controls. First, we injected ^{111}In-cys-DOTA-PEG3400 into tumor bearing animals to demonstrate that tumor uptake was not due to cleavage of the linker from the diabody in some organ and redistribution into the tumor. As can be seen in Figure 7, ^{111}In-cysDOTA-PEG3400 is rapidly cleared from the blood with little or no accumulation in tumor or other organs counted. Next we considered the possibility that the conjugation of multiple PEGs of smaller size, rather than the conjugation of one larger sized PEG would lead to equivalent results. To explore this possibility, we conjugated commercially available NHS-PEG_{12}-Mal to diabody (Table 1). While this bifunctional linker has a maleimide rather than a vinyl sulfone moiety, it is otherwise homologous to NHS-PEG3400-VS in terms of chemical reactivity, but has a molecular weight of only 865 Da. The cys-DOTA conjugated product gave high efficiency labeling, high specific activity, and good immunoreactivity (Table 1). When the product was analyzed by SDS gel electrophoresis, the apparent size was only slightly largely than the monomeric size of diabody (25−27 kDa), a result in agreement with the predicted mass of the addition of several PEG_{12} adducts. However, when run on a Superdex 75 column, the apparent molecular size (Figure 8)

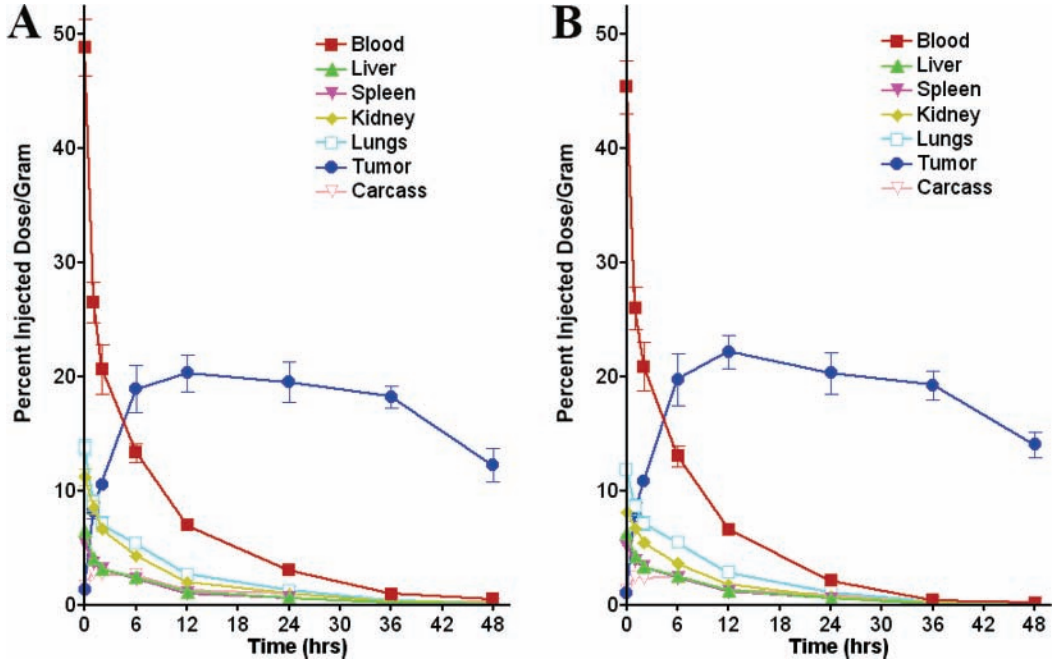

Figure 4. Biodistribution of ^{125}I-PEG3400-diabody and ^{131}I-minbody in nude mice bearing LS174T xenografts. The average %ID/g (± std dev) of five animals per tissue analyzed is shown. A: ^{125}I-labeled PEG3400 diabody. B: ^{131}I-labeled minibody.

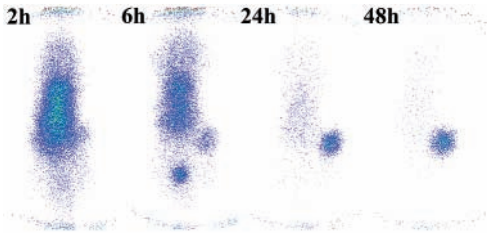

Figure 5. Radioimmunoimaging of ^{125}I-PEG3400-diabody in nude mice bearing LS174T xenografts. The time points shown. The tumor is on the right flank. At 2 h the large central mass is blood pool. By 6 h, tumor is visible on the right side, as well as bladder at the bottom of the image. By 48 h, only tumor is imaged.

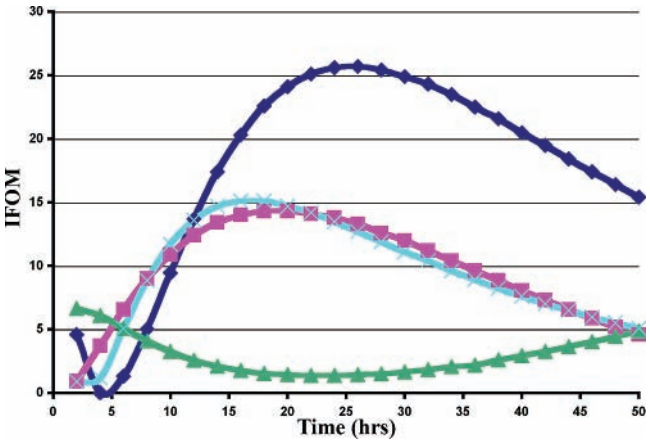

Figure 6. IFOM values for ^{111}In-DOTA minibody vs ^{111}In-cys-DOTA-PEG3400-diabody. IFOM (imaging figure of merit) values were calculated according to Williams et al. (*1*) and plotted vs time for both ^{111}In-DOTA minibody vs ^{111}In-cys-DOTA-PEG3400-diabody. The values take into account both absolute uptake in %ID/g and the tumor-to-tissue ratio vs time. Dark blue (diamonds)= cys-DOTA-PEG3400-diabody tumor/blood. Magenta (squares) = cys-DOTA-PEG3400-diabody tumor/liver. Light blue (X) = minibody tumor/blood. Green (triangles)= cys-DOTA-PEG3400-diabody tumor/kidney. Data for ^{111}-In-DOTA minibody was taken from Yazaki et al. (*2*).

was similar to that of cysDOTA-PEG3400-diabody (Figure 1), suggesting the presence of noncovalent trimers or tetramers. When the ^{111}In-labeled product was injected into nontumor bearing nude mice it showed high kidney uptake (ca. 50%D/g) and rapid blood clearance ($t_{1/2}$ of 7 h) (Figure 9), suggesting that its biodistribution was intermediate between that of ^{111}In-DOTA-diabody and ^{111}In-cysDOTA-PEG3400-diabody.

Finally, we separated the chelate from the bifunctional PEG linker by first conjugating the bifunctional chelate DO3A-VS to reduced site-specific cys-diabody which has C-terminal cysteine residues and then reaction with NHS-PEG3400-VS (Scheme 1) When run on Superdex 75, the apparent size of the conjugate is similar to cys-DOTA-PEG3400-diabody (Figure 10). When radiolabeled with $^{111}InCl_3$, the % labeling, specific activity, and immunoreactivity were uniformly high (Table 1). When ^{111}In-DO3A-VS-cys-diabody-PEG3400 was injected into tumor bearing animals the biodistributions (Figure 11) were essentially identical to those seen for ^{111}In-Cys-DOTA-PEG3400-diabody (Figure 2).

DISCUSSION

Although much progress has been made in designing radiolabeled antibodies for tumor targeting, many challenges still exist. In this study, we explored the use of a bifunctional PEG reagent for fine-tuning the biodistributions of an ^{111}In-labeled anti-CEA diabody. We chose the diabody construct because it is the smallest bivalent (high affinity) recombinant antibody that can be produced in multigram quantities in the lab (*16*). However, its molecular size (50 kDa) lies just below the kidney filtration threshold, creating a problem of high kidney retention due to the reabsorption process in the kidney glomeruli. While this problem is not observed for radioiodine-labeled diabody due to metabolism of the radiolabel within the glomeruli, it is a major problem for the nonmetabolizable radiometal-chelate conjugated antibodies. As a first approach to solving this problem, we conjugated our anti-CEA diabody to NHS-PEG3400-vinyl sulfone, purified the product, and then conjugated it to cys-DOTA, a macrocyclic chelate that we had previously shown to bind radiometals ($^{111}InCl_3$ and $^{90}YCl_3$) with the same relative strength as to unconjugated DOTA. In the first step, the NHS active ester of the bifunctional PEG was reacted with surface lysines on the diabody at pH 6 while preserving the vinyl sulfone moiety. In the second step, the pH

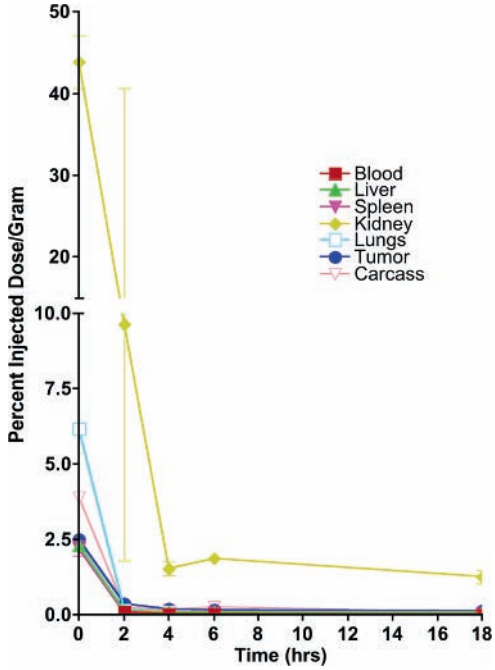

Figure 7. Biodistribution of ^{111}In-cys-DOTA-PEG3400 in nude mice bearing LS174T xenografts. The average %ID/g (± std dev) of five animals per tissue analyzed is shown. The large standard deviation for kidney at 2 h is due to a single animal, otherwise all standard deviations are within 10%.

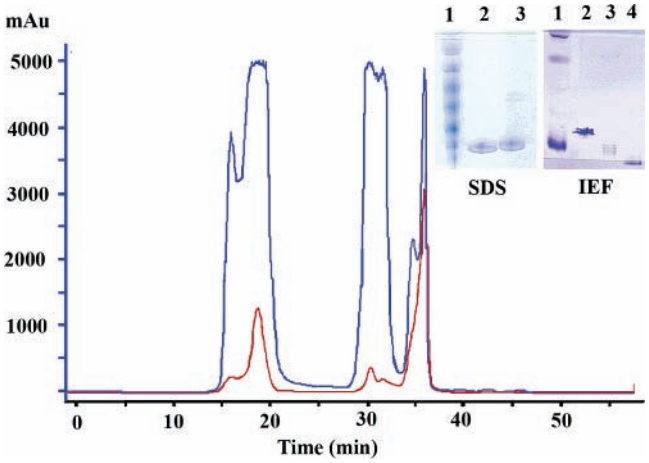

Figure 8. Characterization of cys-DOTA-Mal-PEG$_{12}$-diabody. SEC profile of Mal-PEG$_{12}$-diabody conjugate for a conjugation ratio of Mal-PEG$_{12}$ to diabody of 20: 1 at pH 6. Prior to reaction with cys-DOTA, the product was purified on Superdex 75 and monitored at 214 nm (blue) and 280 nm (red). The inset shows the conjugates run on SDS and IEF gels. SDS: 1 = MW markers, 2 = diabody, 3 = Mal-PEG$_{12}$-diabody. IEF: 1 = IEF markers, 2 = diabody, 3 = Mal-PEG$_{12}$-diabody, 4 = cys-DOTA-Mal-PEG$_{12}$-diabody.

was raised and the vinyl sulfone moiety of the bifunctional PEG was reacted with the thiol group on cys-DOTA. Thus, we were able to place the DOTA moiety at the end of a very long linker, namely PEG3400, perhaps allowing ^{111}In to react preferentially with DOTA rather than the diabody protein surface. We were able to demonstrate that the final product retained high immunoreactivity, but only if the conjugation ratio of bifunctional PEG to diabody was strictly controlled. Although we can routinely conjugate 3−4 DOTA moieties to the lysines of this diabody without affecting immunoreactivity (*2*), it appears that attachment of more than one PEG3400 to the diabody adversely affects its immunoreactivity. Since this problem has been observed by others (*7*, *9*−*11*), it appears that it is a general feature of conjugating high molecular weight, linear PEGs to

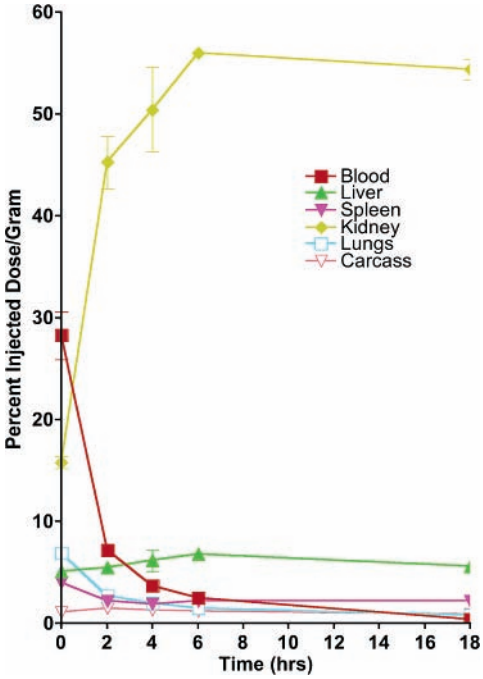

Figure 9. Biodistribution of ^{111}In-cys-DOTA-Mal-PEG$_{12}$-diabody in nontumor bearing nude mice. The average %ID/g (± std dev) of five animals per tissue analyzed is shown.

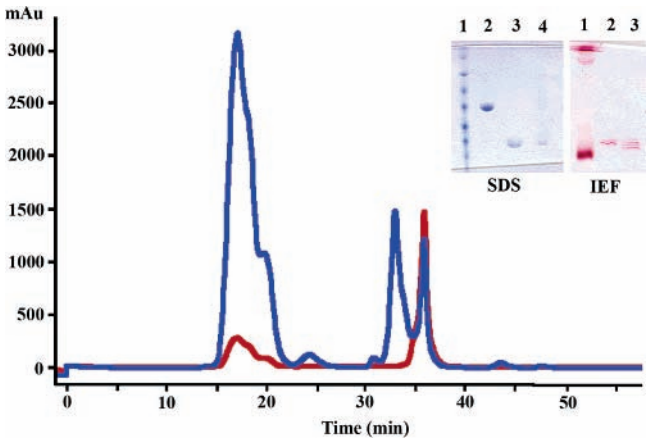

Figure 10. Characterization of DO3A-VS-cys-Diabody-PEG3400. SEC profile of DO3A-VS-cys-Diabody-PEG3400. Cys-diabody was reduced with TCEP, desalted on a Spehadex G25 spin column, and reacted with DO3A-VS at a ratio of 50:1 (DO3A-VS to cys-diabody). The intermediate conjugate was analyzed by SDS and IEF gel electrophoresis and then reacted with NHS-PEG3400-VS at a ration of 20:1 (PEG to diabody ratio) at pH 6 for 2h. The final conjugate was purified by SEC on Superdex 75 to remove excess PEG3400 (monitored at 214 nm (blue) and 280 nm (red)). The inset shows the conjugates analyzed by SDS (nonreducing) and IEF gel electrophoresis. SDS: 1 = MW markers, 2 = cys-diabody, 3 = TCEP reduced cys-diabody, 4 = DO3A-VS-cys-diabody-PEG3400. IEF: 1 = IEF markers, 2 = TCEP reduced cys-diabody, 3 = DO3A-VS-cys-diabody.

antibody fragments. As expected the product had an increased molecular size (75000) due to an increase in its Stokes radius (35 Å) compared to intact diabody (25 Å). Thus, this approach can be successfully used to fine-tune the apparent molecular size of a recombinant antibody fragment.

The final conjugate, cys-DOTA-PEG3400-diabody was radiolabeled with $^{111}InCl_3$ with high efficiency (>90% labeling) to suitably high specific activities (2−3 mCi/mg) for both biodistribution and radioimmunoimaging studies in nude mice bearing CEA-positive xenografts. Although the radiolabeled conjugate contains up to 20% unconjugated diabody, the presence of unconjugated diabody was not expected to adversely

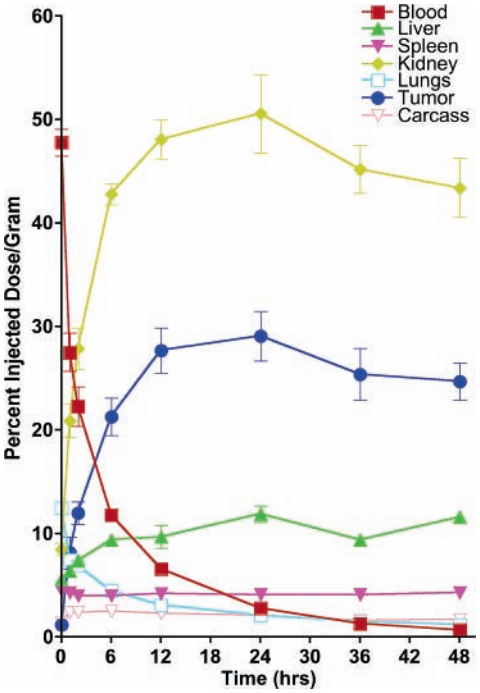

Figure 11. Biodistribution of ^{111}In-DO3A-VS-cys-diabody-PEG3400 in nude mice bearing LS174T xenografts. The average %ID/g (± std dev) of five animals per tissue analyzed is shown.

affect tumor targeting because nonsaturating amounts of total diabody were injected into animals and intact diabody was expected to clear more rapidly from the blood than conjugated diabody. The results were very encouraging in that tumor accumulation was higher than that seen for ^{111}In-DOTA-diabody and essentially equivalent to that seen for ^{111}In-DOTA minibody which has a molecular mass of 80 kDa. Since the molecular masses of the minibody and PEG3400-diabody are almost equivalent, we decided to compare their biodistributions side by side in the same animals. In this comparison, one was radiolabeled with ^{125}I and the other with ^{131}I to take advantage of discriminatory counting and the wealth of data (including IFOM analysis) we have on our radioiodine-labeled recombinant antibody fragments. As expected, the biodistributions were essentially equivalent. However, the question remained as to whether the radiometal-labeled conjugates were equivalent. This was an important question since ^{111}In-DOTA minibody has a problem with high liver uptake and ^{111}In-cys-DOTA-PEG3400-diabody has a problem with high kidney uptake. When the IFOM analysis was performed on the two, the ^{111}In-cys-DOTA-PEG3400-diabody was clearly superior to ^{111}In-DOTA minibody, in fact, the tumor to liver IFOMs of ^{111}In-cys-DOTA-PEG3400-diabody at 24 h were equivalent to the tumor to blood IFOMs of ^{111}In-DOTA minibody at 24 h. Since our experience with imaging tumors in patients with ^{111}In-DOTA minibody have been excellent (unpublished data), based on these IFOM calculations, we expect that ^{111}In-cys-DOTA-PEG3400-diabody will be superior to ^{111}In-DOTA minibody in areas both outside and inside the liver. Since a nude mouse, liver metastasis model is available for CEA positive LS174T cells (*19*), we are currently testing this hypothesis. If these predictions are verified in the clinic, then ^{111}In-cys-DOTA-PEG3400-diabody will be a decided improvement as a radioimmunoimaging agent over all the agents we have tested so far and may permit us to positively image liver metastases with a radiometal-labeled imaging agent for the first time. The remaining problem with the high kidney uptake should not be an issue with imaging CEA positive colorectal or breast cancer patients where kidney metastases are rarely observed. Since the kidney uptake is roughly equivalent to tumor uptake, the problem is somewhat lessened compared to the use of ^{111}In-DOTA diabody where kidney uptake is roughly 10-fold higher than tumor uptake at 12 h (*2*). Nonetheless, we are committed to further reducing the kidney uptake by combining other approaches such as the use of metabolizable linkers (*6*) and adminstration of intravenous lysine (*20*). If successful, we may have a fully optimized approach to radioimmunoimaging with radiometal-labeled antibody fragments.

Tunable DNA Release from Cross-Linked Ultrathin DNA/PLL Multilayered Films

Kefeng Ren, Jian Ji,* and Jiacong Shen

Department of Polymer Science and Engineering, Zhejiang University, Hangzhou 310027, China. Received August 28, 2005; Revised Manuscript Received November 6, 2005

A novel ultrathin enzymatically degradable multilayered film using DNA as building blocks was fabricated by the layer-by-layer (LbL) technique. The UV−vis spectrometry and AFM experiments showed that the buildup of DNA and poly-L-lysine (PLL) was a kind of "exponentially growing films". The dye adsorption experiment suggested that the DNA molecules in the multilayered films were effectively protected by PLL. The films were further cross-linked by glutaraldehyde (GA). The cross-linking density of the films was modulated through the simple controlling of the time of the GA incubation process. An *in vitro* enzymatic degradation was carried out to investigate the DNA release profiles. The UV−vis spectrometry and fluorescence measurements indicated that the DNA release profiles were accordingly changed with the cross-linking density of the films. The nanoscale, easily processed enzymatically biodegradable PLL/DNA film with the ability to precisely control DNA release profiles may serve as a novel DNA delivery system, which may have great potential for gene therapy applications in implantable materials and biomedical devices.

INTRODUCTION

Gene therapy, which can be defined as a method to efficiently transfer the genetic material into the somatic cells of individual patients to produce specific therapeutic proteins to prevent, diagnose, correct, or modulate disease has been increasingly clinically applied in the field of severe diseases such as cancer (*1*, *2*). Safe and effective gene delivery is the main objective in gene therapy. Therefore, driven by the development of new methods to provide precisely controlled gene delivery, numerous strategies are developed and have become a major concern over the past few decades. Naked DNA was first used and directly transferred into the mouse muscle (*3*). Then, controlled delivery of DNA from hydrogel (*4*, *5*), tissue engineering scaffolds (*6*), and nanoparticles (*7*, *8*) have been developed. These gene delivery systems can localize and sustain the presence of a therapeutic gene at targeted cells relative to traditional delivery methods such as injection. Recently, a growing interest has been focused on the sustained release or delivery of DNA from ultrathin films or coatings. For example, Levy et al. have demonstrated the controlled release of DNA from a thin polymer coating, and it could be useful as delivery systems for candidate vectors for gene therapy of cardiovascular diseases (*9*). They also investigated a gene delivery system through the surface attachment of replication-defective adenoviruses using an anti-adenovirus antibody tethering mechanism for local gene therapy of heart-valve disease and vascular disorders (*10*). Lynn et al. recently reported an ultrathin film constructed by hydrolytically degradable polymer and DNA. Such film sustained the release of DNA and localized delivery DNA to cells (*11*, *12*).

Polyelectrolyte multilayered films, which are formed by layer-by-layer (LbL) deposition of polyanions and polycations from aqueous solutions, have raised considerable interest (*13*, *14*). This technique allows nanoscale control over the deposition of a large variety of functionalized materials including proteins (*15*, *16*), DNA (*17*−*19*), dyes (*20*), and nanoparticles (*21*, *22*) into several 10−100 nm films. A variety of architectures and properties of films such as thickness, roughness, molecular structure, surface wettability, and surface charge can be precisely engineered (*13*, *14*, *23*). Consequently, the versatility of the LbL technique presents biotechnical applications such as the construction of cytophilic/cytophobic films (*24*) and procoagulation/anticoagulation films (*25*).

Recently, we have constructed DNA multilayered films through LbL deposition of DNA and poly-L-lysine (PLL) (*26*, *27*). The PLL/DNA ultrathin films have demonstrated to be sensitive to the enzyme and degraded under 5 units/mL α-chymotrypsin in phosphate-buffered saline (PBS) at 37 °C. It is known that, during some biological events such as tumor angiogenesis and metastasis, wound healing, and coronary artery restenosis, a number of enzymes will be secreted or locally activated to degrade and remodel extracelluar matrix or targeted proteins (*28*−*30*). With the feature of sensitizing to enzymatic activities, the PLL/DNA film may be very useful as a DNA delivery system for gene therapy in those diseases. Furthermore, taking the advantages of the LbL technique, the PLL/DNA ultrathin film can be deposited onto any kind and shape of material surface such as implantable materials and biomedical devices including vascular stents, intervention catheters, and tissue engineering scaffold (*31*, *32*). The films thickness, namely, the amount of DNA, can be controlled with a nanoscale by simply adjusting the number of PLL/DNA bilayers.

The objective of the present study is to assess the possibility of protecting the DNA structure via the multilayered polyelectrolyte complexes and controlled release of DNA through cross-linking of the PLL/DNA film. PLL is one of the first research polycations served as a gene carrier (*33*). It can interact with DNA to form complexes in aqueous solution. The complexes can effectively reduce the degradation of DNA by DNase, resulting in a more efficient gene expression *in vivo*. It is found that, during the LbL deposition of PLL and DNA, the PLL/DNA complexes will also form, and such complexes could serve as a mechanism to protect the DNA from DNase attack. It is known that the aim from the gene delivery system varies according to the application. For example, the disease of gene dysfunction like hypercholesterolemia needs a prolonged and sustained gene expression, while in the case of most cancer gene therapy strategies, a short period of gene expression is sufficient

(*34*). Thus, a DNA delivery system with controllable DNA release kinetics can play a more important role in clinical application. In this study, we demonstrate that the DNA molecules in the multilayered films were effectively protected by PLL and the ultrathin PLL/DNA film with 150 nm thickness (10 bilayers) is able to be cross-linked by glutaraldehyde (GA). The density of cross-linking can be modulated by simply controlling the time of the cross-linking process. More importantly, different DNA release profiles are observed, which suggest that the DNA release kinetics can be precisely modulated by the GA cross-linking method.

EXPERIMENTAL PROCEDURES

Materials. Poly-L-lysine (PLL, MW of 83 000) and bisBENZIMIDE (Hoechest 33258) were purchased from Sigma. Deoxyribonucleic acid (DNA, fish sperm, sodium salt), *N*-[2-hydroxyethyl] piperazine-*N*′-[2-ethanesulfonic acid] (HEPES, free acid, high-purity grade), and trypsin (250 N.F. units/mg of protein) were purchased from AMRESCO. GA (25% water solution) was purchased from Shanghai Chemical Reagent Factory, China. Ethidium bromide (EtBr) was purchased from BBI. The water used was distilled 3 times. All reagents were used as received.

PLL/DNA Films Fabrication. Alternating PLL/DNA films were LbL-deposited onto quartz substrates (10 × 20 mm). The first layer of PLL was adsorbed onto the quartz surface by immersing the quartz substrate in a 0.5 mg/mL PLL/HEPES buffer (20 mM HEPES with 20 mM NaCl) at pH 7.4 for 10 min. Substrates were then dipped in water 5 times, followed by drying under a stream of N_2. DNA was then attached to the PLL layer by immersing the quartz substrate in a 0.5 mg/mL DNA/HEPES buffer (20 mM HEPES with 20 mM NaCl) at pH 7.4 for 10 min, followed by the water wash and N_2 drying. The process was repeated until a desired number of bilayers had been deposited. Before the measurements, all samples were dried in a vacuum desiccator under room temperature for at least 12 h.

Characterization of PLL/DNA Films. The growth of the PLL/DNA bilayer was followed by UV−vis spectrometry on a UV−vis spectrophotometer (CARY 100 BIO). The surface topographic feature of the films was monitored on an atomic force microscope (AFM, SPA400, Seiko, Japan) in tapping mode in air. The root-mean-square (rms) roughness values were obtained from the software. For an experiment designed to visually observe the film, a $(PLL/DNA)_{10}$ film was embedded by epoxy resin for microtome and then the cross-section of the film was investigated by a transmission electron microscope (TEM, Jem-1230 at 80 kV, JEOL, Japan). For an experiment designed to characterize the DNA in the film, a $(PLL/DNA)_9$-PLL (PLL is the outmost layer) and a $(PLL/DNA)_{10}$ film (DNA is the outmost layer) were immersed into a EtBr aqueous solution (0.5 mg/mL) for 12 h. After that, the samples were pulled out from the EtBr solution, rinsed sufficiently with water, and then measured by a UV−vis spectrophotometer. All measurements were carried out under room temperature.

GA Cross-Linking of PLL/DNA Films. The $(PLL/DNA)_{10}$ films were immersed into a GA aqueous solution (1 wt %) for varying times under room temperature. After that, the samples were pulled out from the GA solution and immersed into aqueous solution overnight to remove free GA. Before the measurements, all samples were dried in a vacuum desiccator under room temperature for at least 12 h.

***In Vitro* Enzymatic Degradation of PLL/DNA Films.** An enzymatic degradation study was carried out, and trypsin was selected as the model protease to investigate the DNA release profiles from cross-linked PLL/DNA films. Unless stated, the $(PLL/DNA)_{10}$ film was selected as the degradation samples.

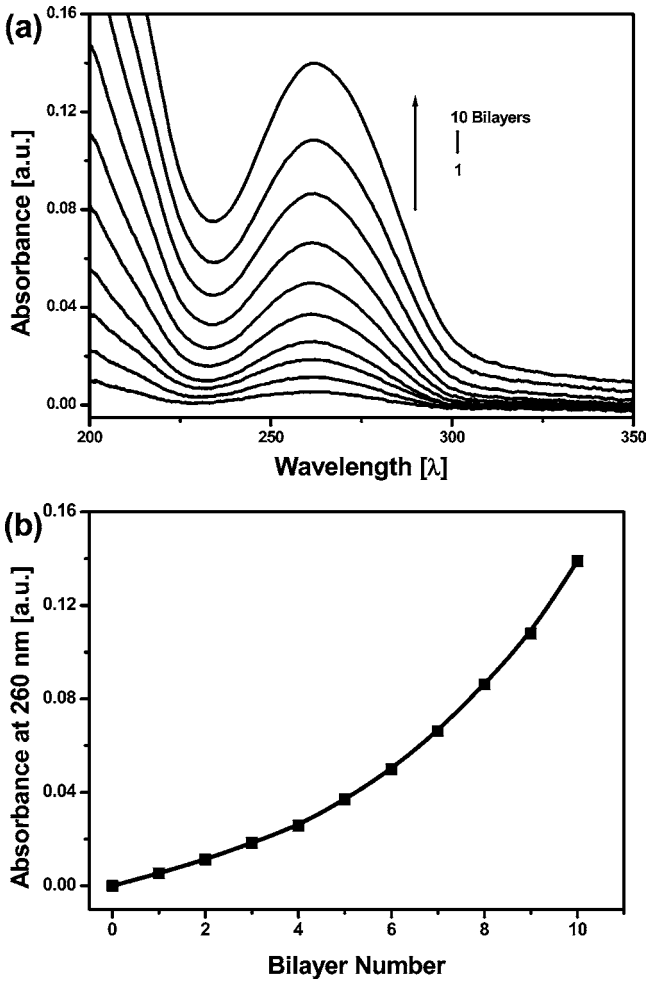

Figure 1. UV−vis absorption spectra of PLL/DNA films and a plot of DNA absorption at 260 nm as a function of the bilayer number are shown in a and b, respectively.

Films were exposed to a trypsin solution (0.1 mg/mL trypsin in PBS at pH 7.4) at 37 °C. The samples were removed from the incubation solution at appropriate time intervals, washed, and then dried in a vacuum desiccator under room temperature for at least 12 h.

Characterization of DNA Release Kinetics. A UV−vis absorption spectrum change of the PLL/DNA films was measured on a UV−vis spectrophotometer. The incubation solution that contained released DNA was added (1:2, vol %) Hoechest 33258 solution (0.15 μg/mL, pH 7.4) and then incubated for 10 min in darkness under room temperature. After that, the solutions were measured on a spectrofluorophotometer (RF-5301PC, Shimadzu, Japan) with an excitation wavelength of 346 nm, a 5 nm slit, and an emission wavelength of 460 nm with a 5 nm slit. All measurements were carried out under room temperature.

RESULTS AND DISCUSSION

Characterization of PLL/DNA Films. LbL film growth on quartz slides can be easily monitored by UV−vis absorption spectrometry. The UV−vis absorption spectra of PLL/DNA film 1−10 bilayers are shown in Figure 1a. DNA contributes a characteristic absorption band at 260 nm. The plot of absorbance at 260 nm shows an increase curve with the bilayer number, as can be seen in Figure 1b, which means that DNA has been successively incorporated into the films. The data are similar to our previously reports (*26*−*27*); however, the absorbance of data points are slightly decreased. It may mainly be due to a

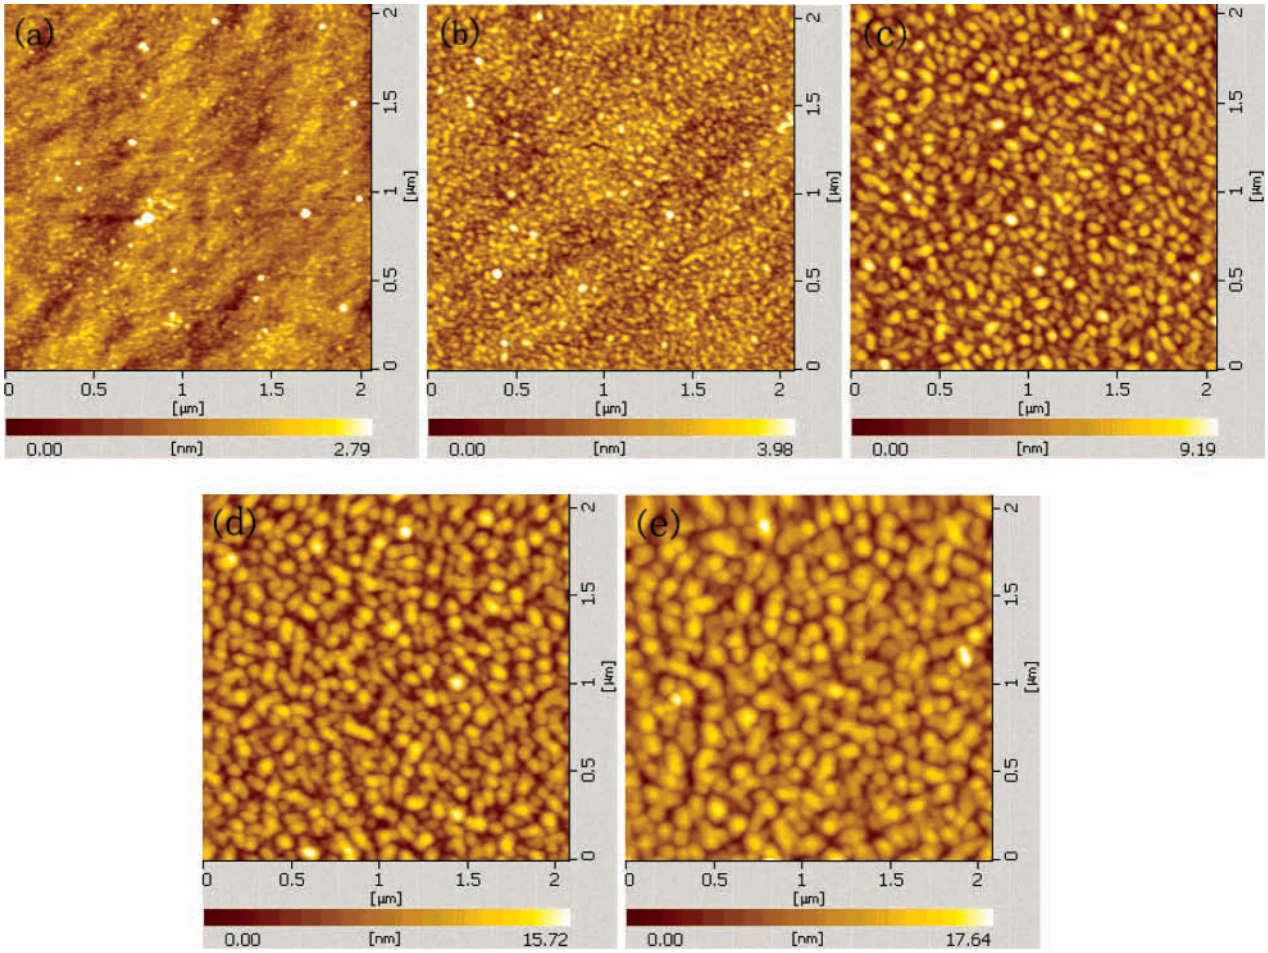

Figure 2. Topographical AFM micrographs of (a) 1 bilayer, (b) 2 bilayers, (c) 3 bilayers, (d) 4 bilayers, and (e) 5 bilayers film. The outmost layer is DNA.

decrease of the NaCl concentration of the aqueous solution (20 mM for this work and 75 mM for previous work), because the salt concentration can affect the polyelectrolytes adsorption during the LbL deposition. In general, a decrease of the salt concentration will lead to low polyelectrolyte adsorption. The data also show that the buildup of the films is followed as an exponential growth (the data are fitted well by an exponential growth curve, with $R^2 = 0.99$), rather than the linear relationship observed for some other DNA films, such as DNA/poly(allylamine hydrochloride) (PAH) (*17*), DNA/poly(ethylenimine) (PEI) (*18*), and DNA/poly(dimethyldiallylammonium chloride) (PDDA) (*19*). Several explanations have been presented for the exponential growth, including the diffusion of polyelectrolytes "in" and "out" of the film during the deposition steps, the formation of polyelectrolyte complexes, and the increase of film surface roughness with the layer number (*35*−*37*). Exponentially growing films are mainly observed in polypeptide or polysaccharide systems. In our case, the PLL (typical polypeptides with MW of 83 000) might play a key role in the exponentially growth of the PLL/DNA film. The ability to form thicker films is important, because the exponential growth could be beneficial to a greater amount of DNA incorporated into the films.

AFM is used to characterize the surface topographic feature of the PLL/DNA film. The AFM micrographs of PLL/DNA films 1, 2, 3, 4, and 5 bilayers with the topmost layer of DNA are shown in Figure 2. There are a lot of island-like domains on the film surface. It is mainly attributing to PLL/DNA complexes during the layer deposition. The complexes may coalesce and grow with the LbL deposition. At the early stages of the deposition, for $(PLL/DNA)_1$, small islands are seen with a characteristic height of 2−3 nm. Such a value is consistent with the width of a double-stranded DNA molecule (*38*). As the number of deposited bilayers increase, the islands become larger, which made the surface of the film rougher. Correspondingly, rms roughness increased from 0.40 (1 bilayer) to 2.82 nm (5 bilayers). This is very close to the observation made by Picart et al. (*37*) on the PLL/HA multilayer system and Richert et al. (*39*) on the HA/chitosan multilayer system. Rigoberto et al. (*40*) also demonstrated that the roughness and feature size of the multilayered films changed with an increasing thickness and that the thicker layers tended to produce larger feature sizes with increased roughness. Meanwhile, we find that the dimension of islands in the present work is smaller than that of our previous paper (*27*). It is reported that the salt concentration could dramatically affect the size of complexes in aqueous solution, and a low salt concentration generally lead to a small size of complexes (*33*). Thus, the relatively small islands should attribute to a low NaCl concentration. The island-like domains and rough surface might be the explanation for the exponential growth of the PLL/DNA film observed in the UV−vis measurement (*35*−*37*). The AFM micrographs indirectly indicate the LbL buildup again.

To further directly observe the PLL/DNA film, TEM is employed to investigate the $(PLL/DNA)_{10}$ film. Figure 3 presents a cross-section of the film. The micrograph clearly shows an ultrathin film fabricated by alternate deposits of the PLL and DNA layer. The TEM micrograph also indicates that the thickness of the $(PLL/DNA)_{10}$ film is about 150 nm, from which the average bilayer thickness of PLL/DNA is about 15 nm. Here, we should mention that, when we take the exponential growth of the films into account, the thickness of each bilayer may different and each bilayer may be thicker than the previous one.

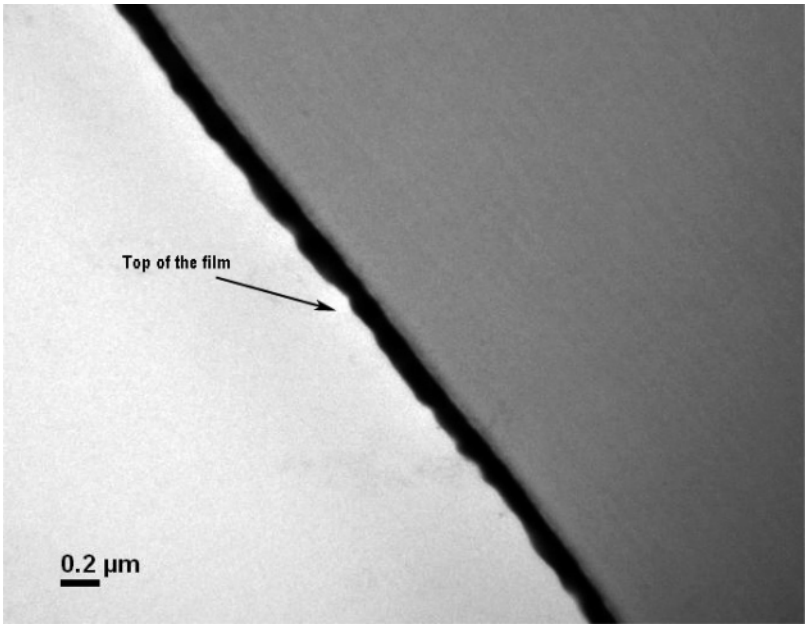

Figure 3. TEM micrograph shows a cross-section of the $(PLL/DNA)_{10}$ film.

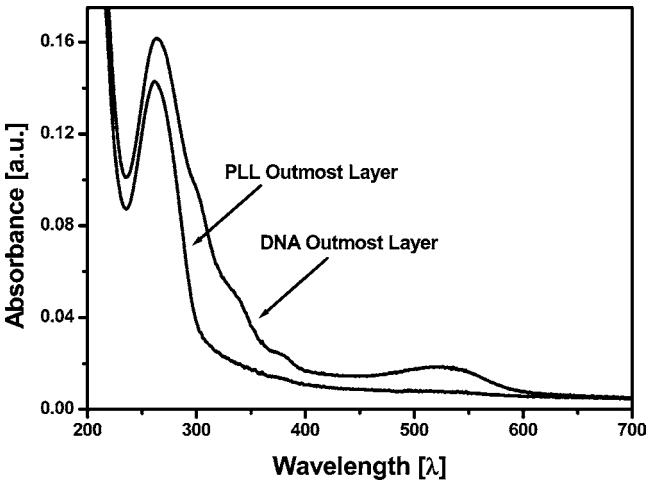

Figure 4. UV−vis absorption spectra of $(PLL/DNA)_9$-PLL (PLL as the outmost layer) and $(PLL/DNA)_{10}$ (DNA as the outmost layer) films interacting with EtBr aqueous solution.

The film is much thicker than some "linearly growing films" [40 nm for the $(DNA/PAH)_{10}$ film (*17*), 44 nm for the $(DNA/PEI)_{10}$ film (*18*), and 59 nm for the $(DNA/PDDA)_{10}$ film (*19*)]. These data suggest that, in our case, PLL/DNA is a kind of "exponentially growing film", and much larger amount of DNA can be obtained by a few numbers of LbL depositions. The observation is consistent with the conclusion drawn from the UV−vis spectrometric and AFM experiments. Because the polyelectrolytes in the film are penetrated by each other, there is not the absolutely layered structure in the film, while it is reasonable that the PLL/DNA film could be served as an ultrathin microgel film.

The fluorescence enhancement of EtBr is the most commonly used in nucleic acid stain. It can produce a strong fluorescence signal upon intercalation with double-stranded DNA (*41*). Here, we chose an EtBr stain assay to characterize two kinds of film: $(PLL/DNA)_9$-PLL (PLL as the outmost layer) and $(PLL/DNA)_{10}$ (DNA as the outmost layer). As shown in Figure 4, the UV−vis absorption spectra of $(PLL/DNA)_9$-PLL and $(PLL/DNA)_{10}$ are totally different. For the film with PLL as the outmost layer, the absorption band is found only at 260 nm, which characterized the DNA absorption. However, for the film with DNA as the outmost layer, the absorption band is found at 260 and 530 nm, which can be attributed to DNA and EtBr/DNA complex absorptions, respectively. It is reported that the absorption maximum of EtBr in aqueous solution appears at 480 nm (*42*). The shift of the peak from 480 to 530 nm is related to the intercalation of EtBr with DNA in solution (*43*). Therefore, it indicates that the EtBr/DNA complexes are formed on the surface of the $(PLL/DNA)_{10}$ film. However, almost no EtBr/DNA complexes are recorded on the surface of the $(PLL/DNA)_9$-PLL film. With the data of the AFM experiment, the PLL/DNA complexes are formed during the deposition of PLL and DNA. Similar complexes are found in other LbL films (*35*, *44*). Such complexes can effectively protect the DNA from the intercalation of EtBr. In brief, the UV−vis data suggest that (1) DNA can be effectively adsorbed onto the PLL layer and (2) the PLL layer can effectively protect the DNA layer from intercalation of EtBr molecules, which might serve as a mechanism to the protection of DNA from the degradation by DNase *in vivo*.

Characterization of DNA Release Kinetics. Previously, we have demonstrated that the PLL/DNA film is a kind of enzymatically biodegradable film (*26*, *27*). The film can be degraded by enzymes, and simultaneously, DNA that is incorporated into the film can be released. However, because the formation of the film is mainly driven by an electrostatic attractive force, the interaction between PLL and DNA molecules in the original (no cross-linked) PLL/DNA film is not very strong, which leads to a relatively quick and uncontrolled DNA release kinetics. As a novel DNA delivery system, the DNA release kinetics should have the ability to be controlled for a variety of clinical applications. Toward this goal, the PLL/DNA films are cross-linked by GA. GA gets many medical uses including tissue examinations, clinical diagnoses, and developmental studies based on its highly reactive chemical properties. It can react with the amino group of PLL and has almost no damage to DNA (*45*, *46*). We hypothesize that the DNA release kinetics might depend upon the cross-linking density, because it directly affects the degradation rate of the film. Thus, the cross-linking density of the film is modulated by controlling the time of the cross-linking process to achieve different DNA release profiles.

First, a $(PLL/DNA)_{10}$ film, which is cross-linked by GA for 30 min, is incubated in a trypsin solution to investigate the

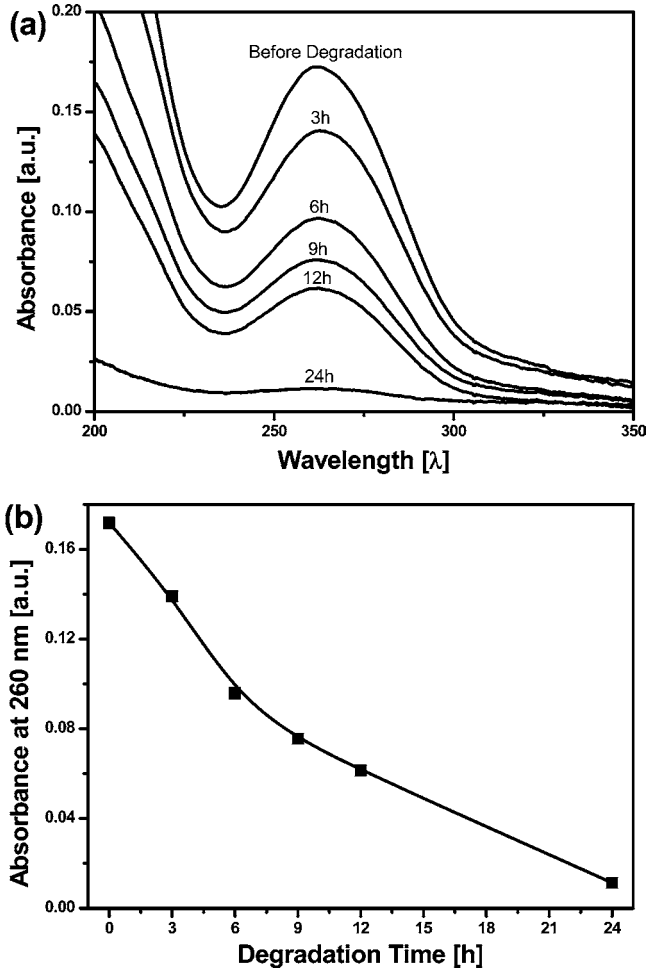

Figure 5. UV−vis absorption spectra of $(PLL/DNA)_{10}$ film and a plot of DNA absorption at 260 nm as a function of the bilayer number, shown in a and b, respectively, showing a degradation of the film. The film was cross-linked by GA for 30 min and then incubated in a trypsin solution at 37 °C. The films were removed from the incubation solution at appropriate time intervals for characterization.

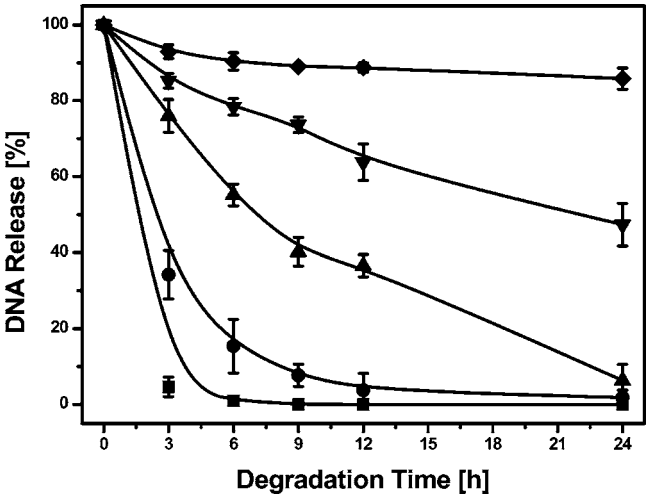

Figure 6. DNA release kinetics in a trypsin solution at 37 °C from PLL/DNA films with varying cross-linking time: (■) original film; (●) 10 min; (▲) 30 min; (▼) 60 min; and (◆) 180 min. A relative absorbance of 100% represents the absorbance of original PLL/DNA film, while 0% designates the absorbance of bare quartz substrates. Values are given as mean ± standard deviation ($n = 3$).

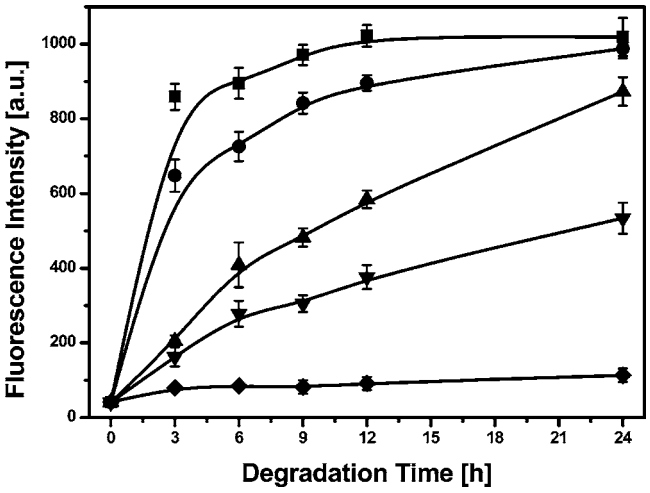

Figure 7. Fluorescence intensity of the incubation solution, in which incubated PLL/DNA films with varying cross-linking time: (■) original film; (●) 10 min; (▲) 30 min; (▼) 60 min; and (◆) 180 min. Values are given as mean ± standard deviation ($n = 3$).

degradation. As can be seen in Figure 5a, the DNA absorption band of 260 nm is decreased gradually with the degradation time over a period of 24 h, showing a deconstruction process, which means that DNA has been successively released from the films. The absorbance of the film at a band of 260 nm before degradation is 0.17. The value is then decreased to 0.01 after 24 h of degradation, as shown in Figure 5b. After that, the films with varying cross-linking density are recorded by the UV−vis measurement. DNA release profiles from the PLL/DNA film with varying cross-linking density are shown in Figure 6. The films are cross-linked for 10, 30, 60, and 180 min, respectively. Different DNA release profiles are observed. For the original film, the DNA releases very fast in an early incubation stage. Almost 95% of incorporated DNA is released within 3 h. Such a burst release is mainly attributed to the formation of a relatively weak interaction between PLL and DNA, because this interaction is mainly driven by electrostatic attractive forces. Thus, the enzymatic degradation of PLL would lead to fast bulk deconstruction of the film. However, the DNA release rates are significantly decreased with the cross-linking density. For example, from the 12 h of incubation in the trypsin solution, the amount of DNA that remains in the films that cross-linked for 0, 10, 30, 60, and 180 min is 0, 3.75 ± 4.47, 36.57 ± 2.92, 63.75 ± 4.8, and 88.72 ± 1.24%, respectively. These data suggest that the DNA release kinetics mainly depends upon the density of cross-linking. The more extent of cross-linking, the more difficult is the enzymatic degradation, which lead to a decreased DNA release rate.

The measurement of the amount of DNA that released into the incubation solution can probe the deconstruction behavior and the DNA release profiles. Hoechest 33258 is a bisBENZIMIDE DNA intercalator. It has been used to stain and to quantitate DNA (*47*). Here, we chose a Hoechest 33258 fluorescence assay to measure qualitatively the amount of DNA contained in the incubation solution. Throughout the 24 h of degradation experiments, as shown in Figure 7, the fluorescence intensity of the incubation solution, in which incubated PLL/DNA films with a varying density of cross-linking, increases gradually with time when the films are exposed to the trypsin solution. However, the films with a varying density of cross-linking lead to a different DNA release rate; the original PLL/DNA film achieves almost maximal fluorescence intensity within the first 3 h. A further increase in the incubation time does not increase the intensity, which means that the amount of DNA in the incubation solution is stable. The cross-linked films show the slower DNA release rate. Especially, the film that cross-linked for 180 min leads to a significant low

fluorescence intensity. These data suggest that the DNA release kinetics can be precisely controlled by GA cross-linking. The observation is consistent with the conclusion drawn from the UV−vis spectrometry experiment.

CONCLUSIONS

The ultrathin PLL/DNA film was successfully constructed by the LbL technique. The UV−vis spectrometry and AFM experiments showed the successful buildup of PLL and DNA with a kind of exponential growth. The TEM micrograph showed clearly an ultrathin film with a thickness value of 150 nm (10 bilayers). Furthermore, the EtBr adsorption experiment suggested that the DNA molecules in the film are being effectively protected by PLL.

The PLL/DNA film was able to be cross-linked by GA. The cross-linking density of the film can be modulated by controlling the time of the GA incubation process. The GA cross-linking procedure can effectively slow the enzymatic degradation of the film, which lead to the various DNA release profiles. Thus, the PLL/DNA film with the ability of precise controllable DNA release profiles could serve as a novel DNA delivery system in gene therapy applications in tissue engineering, medical implants, etc.

Ferrocene-Assisted Stabilization of Collagen Mimetic Triple Helices: Solid-Phase Synthesis and Structure

Subrata K. Dey and Heinz-Bernhard Kraatz*

Department of Chemistry, University of Saskatchewan, 110 Science Place, Saskatoon, Canada. Received September 5, 2005; Revised Manuscript Received November 8, 2005

A series of ferrocene-containing collagen models Fc-CO-(Pro-Hyp-Gly)$_n$-Cys (n = 4 (**1**), 6 (**2**), 7 (**3**), 8 (**4**), 9 (**5**)) were synthesized by solid-phase synthesis. Biophysical studies using circular dichroism (CD) show that these collagen analogues form triple-helical conformations, and the peptides showed a range of thermal stabilities ((T_m), 38−74 °C). Results also indicate that the ferrocene (Fc)-labeled collagen models possesses a higher triple-helical propensity than the unlabeled collagen models as demonstrated by the higher melting temperatures and thermodynamic parameters, and we conclude that the Fc group at the *N*-terminal position of the peptide strands increases the stability of the triple helix.

INTRODUCTION

The design of collagens with a high melting temperature (T_m) is a formidable task, which has attracted significant attention over the past few years. It has been well-known that the collagen molecule consists of three polypeptide chains; each undergoes a transition to a single coil state as the temperature increases (*1*). The thermal stability of the collagen triple helix depends on the identity and sequence of the amino acid residues Xaa and Yaa in the Gly-Xaa-Yaa sequence. H-Bonding on the interior of the triple helix holds the triple helix together. The imino acids, proline (Pro) and hydroxyproline (Hyp), are both stabilizing factors, so that the melting temperature T_m of collagen from many animals is proportional to the imino acid content (*2*). In general, the higher the Hyp content in the Yaa position, the higher the T_m. In addition, it was shown that amino acids such as 4-fluoroproline or 4-aminoproline influence the T_m, causing it to increase due to electronic effects (*3*). This may have interesting application for the formation of biomaterials that exhibit a higher stability under biological conditions (*4*). On the basis of the biophysical studies on (Gly-Pro-Pro)$_{10}$, Bhatnagar and co-workers suggested that the major stabilizing force in the Gly-Pro-Pro triple-helix is the interchain and/or interresidue nonbonded interactions, including close van der Waals contacts and hydrophobic interactions (*5*). Goodman and co-workers demonstrated that template-assembled collagen residues greatly enhance the conformational stability of the collagen triple helix, and recently they also reported the incorporation of an Fe^{3+}−catechol complex as a scaffold to assemble peptide chains into triple helices (*6*). As a part of our ongoing study into the electron transfer properties of peptides chemically linked to gold surfaces, we synthesized a series of Fc-labeled collagen mimetic structures composed of Pro-Hyp-Gly sequences (Scheme 1) equipped with a C-terminal Cys residue and began to assess the propensity for triple helix formation by variable temperature circular dichroism (CD) spectroscopy, thermodynamic studies, and molecular modeling. Here we present the results of this study indicating that Fc, a simple organometallic molecule, attached to the N-terminal end of the collagen helix enhances the stability of the triple helix.

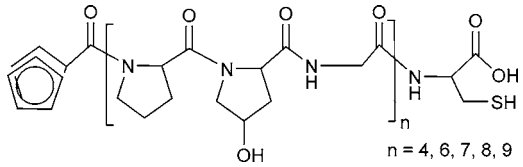
Scheme 1



MATERIALS AND METHODS

All chiral amino acids were of the L configuration. Amino acids, SPPS resins, and HOBt were purchased from SynPep. EDC was purchased from Novabiochem. DIEAP, TFA (HPLC-grade), TIS, piperidine, phenol, and ferrocene were purchased from Aldrich Chem. DMF (BDH; ACS grade) was used for synthesis. Acetone, CH_2Cl_2, diethyl ether (BDH; ACS grade), CH_3CN (Fischer; HPLC grade), and CH_3OH (Fisher, for electrochemistry, spectra-grade) were used for the purpose of purification. Reagents were used as provided. All solutions (for biophysical studies and HPLC purification) were prepared using deionized Millipore water (18.2 MΩ·cm) obtained from a Milli-Q water system.

General Procedure. A series of collagen models (both the modified model with ferrocene and unmodified model) were synthesized by the standard *N*-(9-fluorenyl)methoxycarbonyl (Fmoc)-based solid-phase protocol on a Quest Organic Synthesizer. Couplings were carried out on Fmoc-L-cysteine(trityl) Wang resin (Syn Pep, 0.50 mmol/g) using Fmoc amino acids (Fmoc-Gly-OH, Fmoc-Hyp-OH, and Fmoc-Pro-OH, 2 equiv each) in the presence of 1-ethyl-3-[3-(dimethylamino)propyl]-carbodiimide (EDC) (2.2 equiv) and *N*-hydroxybenzotriazole (HOBt) (2.2 equiv) as activating agents and diisopropylethylamine (4 equiv). To prepare ferrocene-attached collagen-like polypeptides, the specific peptide chains were built up on resin, and the ferrocene monocarboxylic acid was directly coupled to the N-termini of these chains before removal from the resin. The synthetic route is described in Scheme 2.

Coupling efficiency was monitored with Kaiser test (*7*), except for N-terminal proline residues where the chloranil test (*8*) was applied. The desired peptides were cleaved from the resin with trifluoroacetic acid (TFA) containing phenol (2.5% v/v) and triethylsilane (TIS; 2.5% v/v) and then precipitated with diethyl ether.

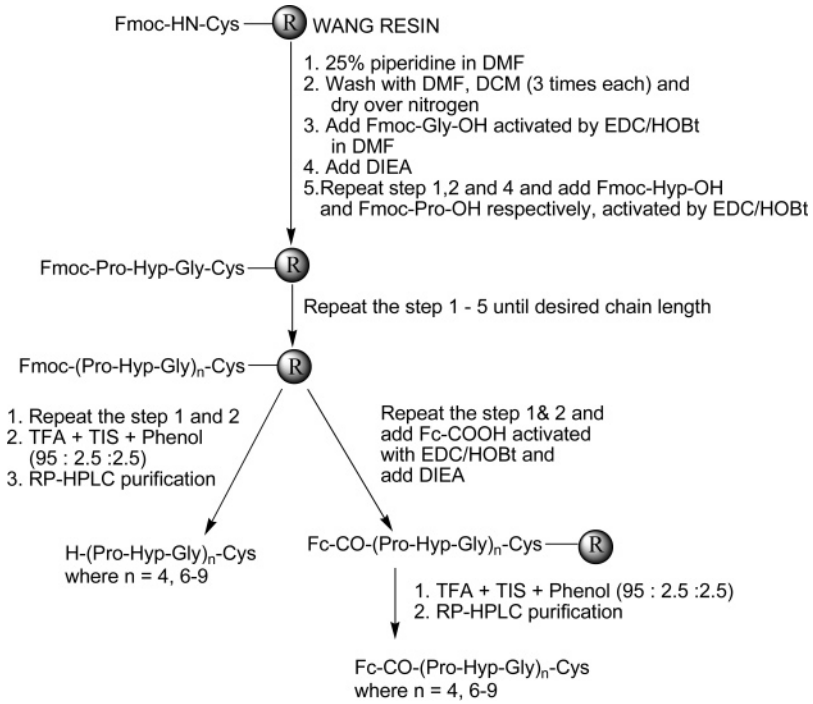
Scheme 2



Peptides are purified by reversed-phase high performance liquid chromatography (RP-HPLC) (Varian, Inc.) using a water−acetonitrile system and Vydac C-18, 25 × 2.2 cm preparatory column. Peptides were eluted with a gradient of aqueous acetonitrile containing TFA (0.1%, v/v) at a flow rate of 16.6 mL/min. Purified peptides were obtained by collecting the major peak with absorbance at 215 nm, which occurred between 32 and 77% acetonitrile. HPLC-purified peptides were analyzed by electrospray mass spectrometry using a QSTAR XL-MS/MS ionspray source.

Synthesis and Purification. The Fmoc-protected Wang-Cys resin (loaded: 0.50 mmol/g, taken 0.1 mmol) was treated with 25% piperidine in DMF (1 × 20 min, 1 × 10 min) and then washed successively with DMF (3 × 1 min), MeOH (3 × 1 min), and CH_2Cl_2 (3 × 1 min). Coupling of the first amino acid (Fmoc-Gly-OH) was performed with Fmoc-Gly-OH/EDC/HOBt/DIEA (2 equiv, 1:1.1:1.1:2) in DMF (2.5h) followed by washing with DMF (3 × 1 min), MeOH (3 × 1 min), and CH_2Cl_2 (3 × 1 min). Chain elongation was performed with Fmoc-Hyp-OH/EDC/HOBt/DIEA (2 equiv, 1:1.1:1.1:2) and Fmoc-Pro-OH/EDC/HOBt/DIEA (2 equiv, 1:1.1:1.1:2) sequentially up to the desired length. Fmoc cleavage from Fmoc-Pro-Peptidyl resin was carried out with 25% piperidine and 1% DBU in DMF (2 × 15 min) and washings with DMF (3 × 1 min), MeOH (3 × 1 min), and CH_2Cl_2 (3 × 1 min). In the final step, half of the polypeptide resin beads were taken out, the desired polypeptides were cleaved from the resin with trifluoroacetic acid (TFA) containing phenol (2.5% v/v) and triisopropylsilane (TIS; 2.5% v/v), and with the remainder of the beads, an additional Fc-coupling step was carried out. Fc-COOH/EDC/HOBt/DIEA (2 equiv, 1:1.1:1.1:2) was added to the remaining beads. The Fc-labeled collagen polypeptides were also cleaved from the resin using the same cleaving agent. All modified and unmodified collagen models were purified by RP-HPLC using a water−acetonitrile gradient and characterized by ESI-MS spectra. For the spectroscopic and electrochemical measurements, a portion of the material was further purified by preparative HPLC (ESI).

CD Spectroscopy. Circular dichroism (CD) spectra were recorded on a π*-180 spectrometer (Applied Photophysics Ltd, UK) equipped with a model 3016 isotemp refrigerator circulator (Fisher Scientific), interfaced to an Acorn PC. A rectangular 2 mm-path length cell was used. The spectrometer was routinely calibrated with an aqueous solution of (1*S*)-(+)-10-camphorsulfonic acid. Mean residue molar ellipticities were calculated according to the following equation:

$$[\theta] = [\theta]_{obs}/10 \times lcn$$

where $[\theta]_{obs}$ is the observed ellipticity measured in degrees, l is the path length of the cell in centimeters, c is the molar peptide concentration, and n is the number of amino acid residues in the peptide. The spectra for both modified and unmodified polypeptides were obtained as an average of eight scans using a slit width of 0.5 nm. The thermal denaturation results were obtained by measuring the ellipticity at 223 nm as a function of temperature using a 120 s thermal equilibration time between data points.

RESULTS AND DISCUSSION

In addition to nonnatural amino acids, one can expect that increasing the hydrophobicity at the N-terminal side of the collagens may also influence the melting behavior. In our efforts toward the design of collagen conjugates, we have synthesized a series of Fc-labeled collagen mimetic structures composed of Pro-Hyp-Gly sequences (Scheme 1) to assess their triple helical propensities and the role of Fc in triple helix stability by variable temperature circular dichroism (CD) spectroscopy, thermodynamic studies, and molecular modeling.

Fc-collagen conjugates Fc-CO-(Pro-Hyp-Gly)$_n$-Cys (n = 4 (**1**), 6 (**2**), 7 (**3**), 8 (**4**), 9 (**5**)) of increasing peptide length were synthesized by solid-phase synthesis on Wang resin using EDC/HOBt, cleaved off the resin by TFA, phenol, and triethylsilane (95:2.5:2.5), and then purified by preparative RP-HPLC on C18. All compounds were characterized by mass spectroscopy. The synthesis, purification, and characterization of the unlabeled collagens (lacking the Fc group) were carried out in the same fashion (Scheme 2). In water/methanol (99/1), compounds **1**−**5** exhibit a single broad absorbance in the visible region with a λ_{max} between 430 and 445 nm. For all of the complexes excitation within the region of 200−240 nm, the peptide bond

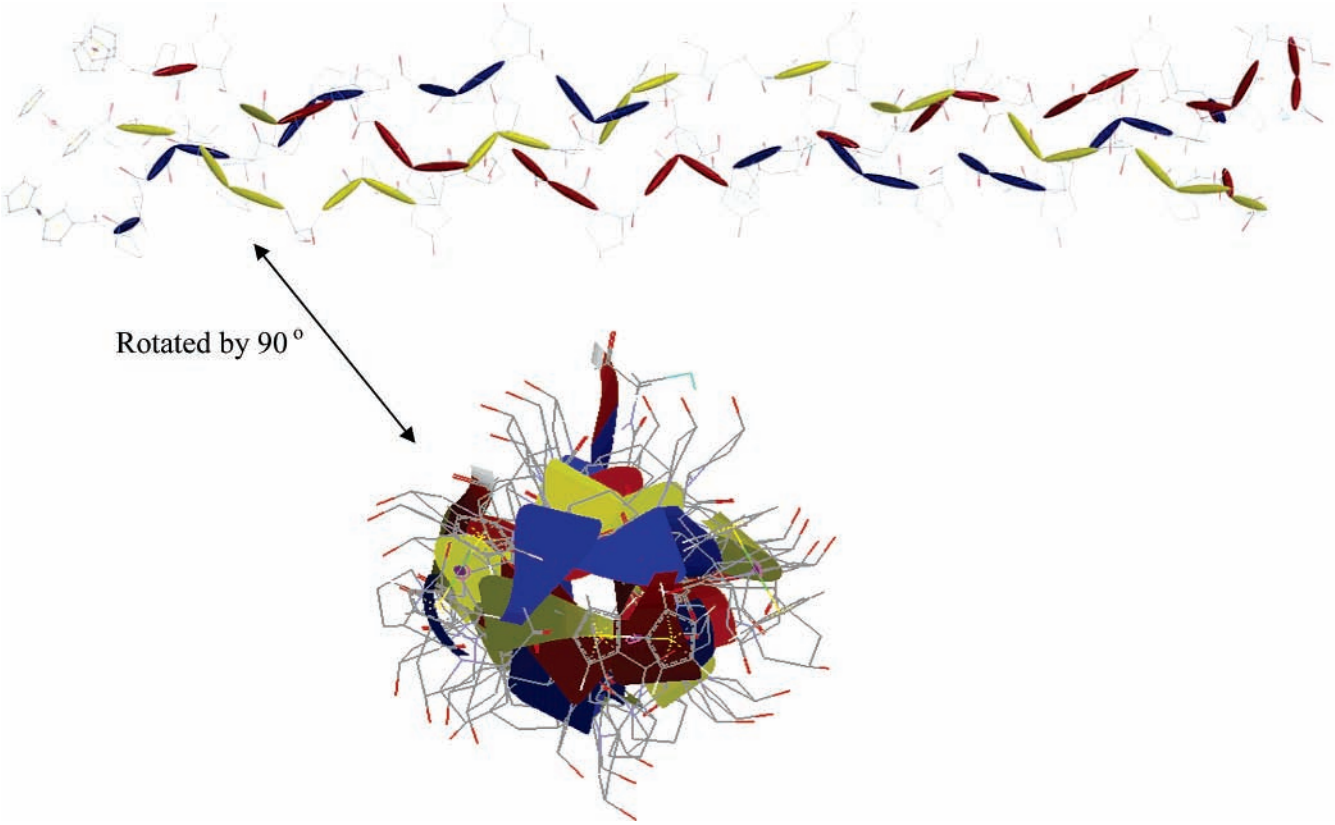


Figure 1. Modeling of the Fc-labeled collagen mimics (for compound **5**).

due to the n → π * transitions yields UV spectra dominated by the peptide bond absorptions. The solution electrochemistry in water/methanol (99/1) for compounds **1**−**5** shows a fully reversible oxidation wave of the Fc group with a half-wave potential $E_{1/2}$ at about 560 mV, a peak separation of 70 mV, and a ratio of anodic to cathodic peak currents close to unity (ESI, Table S1).

Molecular Modeling. Molecular models of triple-helical ferrocene-labeled compounds were created by modifying the structure of crystalline collagen (PDB entry 1CGD (*9*)). The side chain methyl group of the three alanine residues was replaced by a hydrogen atom. The one (Pro-Hyp-Gly) unit was deleted from the C-terminus (for **5**, Figure 1). This section was subjected to energy minimization for equilibrium geometry using Hartree−Fock method. Three Fc-CO groups were added to the N-terminal proline residues, and three Cys groups were added to the C-terminal glycine residues. The whole section was subjected to energy minimization, locking all the entire amide bonds by Hartree−Fock method except the cysteine amide group.

The molecular modeling of ferrocene-labeled triple helices includes two basic steps. First, the backbones of three Fc-CO-[Pro-Hyp-Gly]$_n$-Cys (where n = 4, 6−9) chains have to be assembled into a triple-helical assembly. Second, the conformational space accessible to the ferrocene group needs to be searched for minimum energy structures. The first step concerns only the chain backbone and simplifies the process of triple-helical assembly. The three Fc-CO-[Pro-Hyp-Gly]$_n$-Cys molecules were constrained to have the same backbone torsions as the structure proposed by Scheraga (*10*) for (Gly-Pro-Hyp)$_n$. This conformation has been shown to be very stable with respect to the unsubstituted compounds and is therefore possibly a good candidate to use as starting backbone conformation for minimizations. On the basis of our present study, we conclude that the Fc−collagen conjugates have an enhanced stability toward denaturation.

Determination of Triple-Helical Conformation in Solution. The solution conformation of compounds **1**−**5** was investigated by CD spectroscopy. Natural collagen has a CD spectrum exhibiting a low intensity maximum at 220 nm, a crossover at 213 nm, and a minimum at 197 nm (*11*). Using these data, the helicity of any collagen can be determined. The CD spectra for compounds **1**−**5** are shown in Figure 2. All compounds display a spectrum typical of collagen with a maximum at 223, a minimum at 201 nm, and a crossover at 218 nm. The spectral data is listed in Table 1 and is comparable to known collagen models, (Gly-Pro-Hyp)$_{10}$-NH$_2$ (*11*, *12*). As the length of the peptide increases in compounds **1**−**5**, the helical content increases up to the reported value for (Gly-Pro-Hyp)$_{10}$-OH (*12c*). The entire unmodified system also demonstrates a similar type

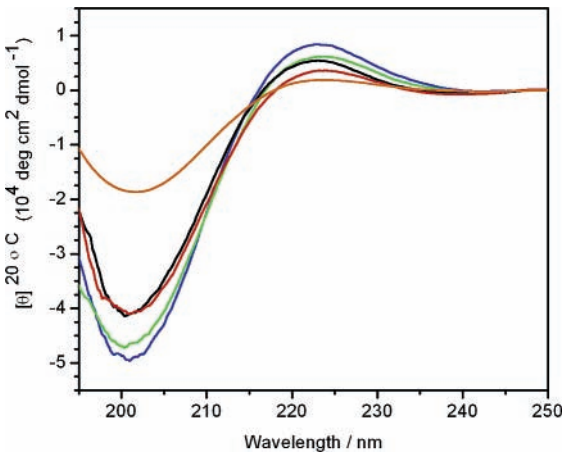

Figure 2. CD spectra of Fc-CO-(Pro-Hyp-Gly)$_n$-Cys where n = 4, 6−9 in water/methanol, 99/1, at pH 7.2 at 20 °C. Blue line for n = 9, green for n = 8, black for n = 7, red for n = 6, and orange for n = 4. The samples were kept in a refrigerator (4 °C) for at least 1 week so they would reach the equilibrium of triple-helix formation.

[a] CD spectra were obtained at 20 °C using a peptide concentration of 0.01 mM (water/methanol, 99/1). The peak intensities are indicated in the parentheses. [b,c] Estimated from published CD spectra: ref 12b,c.

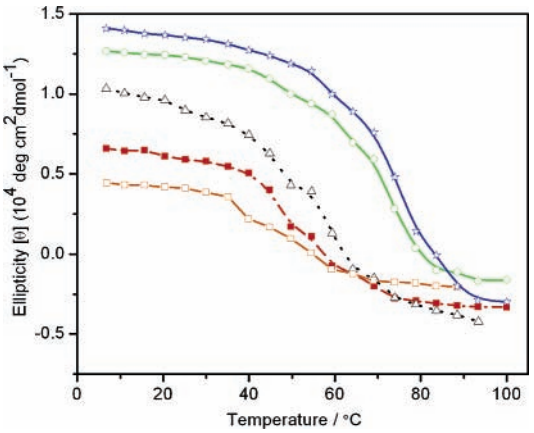

Figure 3. Thermal denaturation of ferrocene-labeled collagen triple helices at 223 nm (blue line for $n = 9$, green for $n = 8$, black for $n = 7$, red for $n = 6$, and orange for $n = 4$). The critical triple-helical concentration is ca. 0.01 mM (methanol/water). Ellipticities at 223 nm were monitored by circular dichroism spectroscopy as the temperature was increased by increments of 5 °C with 2-min equilibrium.

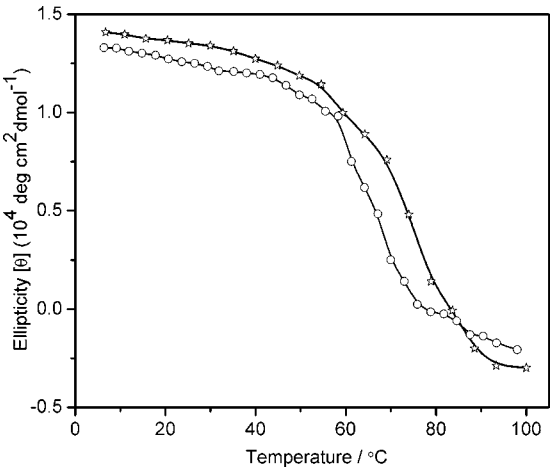

Figure 4. Thermal denaturation of ferrocene-labeled collagen triple helices at 223 nm ((☆) for modified system, Compd. **5**, and (○) for unmodified system of same length). The critical triple-helical concentration is ca. 0.01 mM (methanol/water). Ellipticities at 223 nm were monitored by circular dichroism spectroscopy as the temperature was increased by increments of 5 °C with 2-min equilibrium in both cases.

of spectrum with a maximum at 222 nm and a minimum at around 200 nm (e.g., compound **5**, modified and unmodified systems, ESI, Figure S1). To establish the triplex formation we have used the ratio of the positive peak intensity over negative peak intensity, R_{pn} (*12c*, *13*). For the synthetic Fc-collagen conjugates **1**−**5**, the R_{pn} values are summarized in Table **1**, including the values for the natural collagen (*13*) and for (Gly-Pro-Hyp)$_{10}$−OH (*11c*). On the basis of these R_{pn} values, the presence of triple-helical conformations is established for our ferrocene-labeled systems **1**−**5** at 20 °C and a concentration of 0.01 mM at pH 7.2. As the solution temperature was gradually increased from 5 to 100 °C, the CD spectrum for compounds **1**−**5** change gradually, showed a pattern featuring the triple-helix polypeptide with slight damage to the triple helix at higher temperatures. The positive Cotton effect disappeared at 223 nm (ESI, Fig. S2), which reflects the loosening of the triple helix and dissociation to single helical strands having polyproline-II conformations.

The resulting T_m value provides an indication of the conformational stability of a triple helix (Figure 3). The key result of our study is that the temperature of the triplex-to-singlex transition is higher for the Fc−collagen conjugates **1**−**5** than for the collagens lacking the N-terminal Fc group, indicating that the Fc group is stabilizing the triplex. The resulting T_m values, along with those of triple helices of same number of amino acids (lengths (in Å) for all of complexes were calculated from molecular modeling) without the Fc moiety are tabularized in Table 1 and compared in Figure 4 and Figure 5. This indicates that the modification of collagen by the Fc group stabilizes the triple helix, which can be due to changes in the local chemical environment, such as the additional hydrogen bond and/or hydrophobic interaction or the overall conformational change

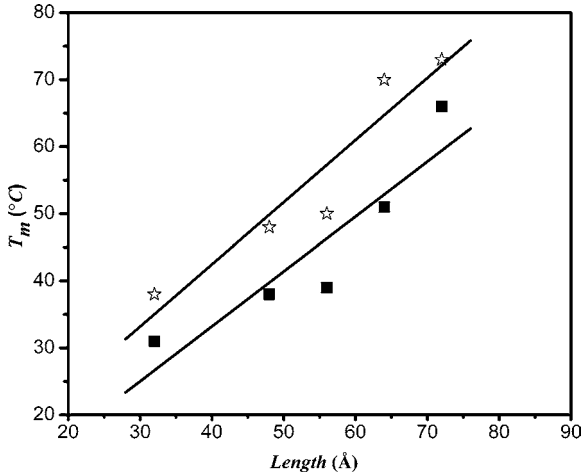

Figure 5. Comparison of thermal denaturation values of ferrocene-labeled collagen triple helices with unlabeled systems at 223 nm (star for the Fc-labeled systems, block for unlabeled systems).

including the whole Pro-Hyp-Gly moiety, which is induced by attachment of the hydrophobic Fc group.

Importantly, we observe a small hysteresis of the melting behavior, shown in Figure 6. Although, the overall features in the CD spectra recovered after heating and cooling of aqueous solutions of compounds **1**−**5**, the intensities of the bands were diminished. However, the positive and negative Cotton effects did not completely recover their intensities, but it proves that the conformational change in the triple helices was nearly reversible in aqueous solution.

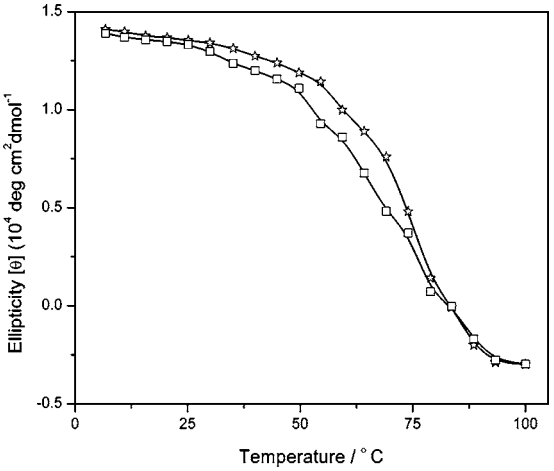

Figure 6. Thermal unfolding (☆) and refolding (□) of ferrocene-labeled collagen model (**5**) at 0.01 mM concentration in aqueous solution (pH 7.2) as monitored by CD at 223 nm. Melting and formation of the triple helix are virtually reversible.

Thermodynamic parameters are also estimated from CD transition profiles at 223 nm to understand the overall nature of the thermal stability of our Fc-labeled systems (ESI, Figures S3, S4). In thermal unfolding experiments, the thermodynamic parameters of the compounds **1**−**5** were calculated assuming two-state denaturation process (*14*) using Levenberg−Marquardt nonlinear least-squares method. The van't Hoff enthalpy, ΔH_m, was calculated by nonlinear least-squares fitting of the CD transition profile. The entropy change of the transition at T_m, ΔS_m, was calculated by dividing ΔH_m by T_m (see Table 1). Expectedly, ΔH_m increases with increasing the collagen chain length, which indicates an increase in stability as the collagen chain length increases. It is noteworthy to point out that this trend is reflected also in ΔH_m for Fc-labeled and unlabeled collagens (see ESI, Table S2, for $n = 9$), which again emphasizes that Fc-collagens appear stabilized compared to the corresponding unlabeled collagens in different ways. However, it should be noted that errors higher than 10% seem to be unavoidable for parameters derived from the van't Hoff equation.

CONCLUSION

We have presented the results of our comparative study showing that the attachment of an Fc group to the N-terminus of a collagen peptide stabilizes the formation of the collagen triple helix. These findings open an unexpected path for the design of stable and redox active collagen mimics and in the use of collageneous peptides for the studies on collagen structure, folding, and biochemistry. We are currently synthesizing some Fc-labeled collagen models in which individual amino acids are replaced. We are also investigating the possibility of electron-transfer reactions in Fc-labeled collagen films containing redox entities with a cysteine linker.

ACKNOWLEDGMENT

The Natural Science and Engineering Research Council of Canada supported this research. H.-B.K. is the Canada Research Chair in Biomaterials. Our thanks are also extended to Mr. Somenath Choudhury, Dr. Yitao Long, and Dr. Todd Sutherland Department of Chemistry, University of Saskatchewan, for their valuable discussion in the circular dichroism studies.

Transduction domains such as those derived from the HIV-TAT protein are candidate vectors for intracellular delivery of therapeutic macromolecules such as DNA and proteins. The mechanism by which they enter cells is controversial, and very little spatial information regarding the downstream fate of these peptides from the plasma membrane is available. We studied endocytic traffic of fluorescent conjugates of HIV-TAT peptide and octaarginine in human hematopoietic cell lines K562 ($CD34^-$) and KG1a ($CD34^+$) and substantiated our findings in epithelia cells. Both peptides were efficiently internalized to endocytic pathways of both hematopoietic cell lines; however, comparative analysis of the intracellular location of the peptides with endocytic probes revealed major differences in spatial organization of their endocytic organelles and their interaction with the peptides at low temperatures. Double labeling confocal microscopy demonstrates that prelabeled lysosomes of all the tested cells are accessible to internalized peptides within 60 min of endocytic uptake. Incubation of cells with nocodazole and cytochalasin D inhibited peptide traffic from early to late endosomal structures, demonstrating a cytoskeletal requirement for lysosomal delivery. Disruption of Golgi and endoplasmic reticulum dynamics was without effect on peptide localization, suggesting that endosomes and lysosomes rather than these organelles are the major acceptor compartments for these molecules.

INTRODUCTION

Peptides derived from a number of proteins are able to enter cells and gain access to the cytosol and nucleus, thus generating much interest in their potential use as vectors for intracellular delivery of therapeutic molecules (*1*−*4*). To date, the most studied include cationic peptides derived from proteins such as the HIV transcription factor TAT, the *Drosophila melanogaster* homeobox protein Antennapedia (penetratin), and the herpes simplex virus protein VP22. These have been classified as cell penetrating peptides or protein transduction domains (PTD).[1] Predominantly in cell models, these peptides have been shown to have potential as cellular delivery vectors for enhancing the activities of their associated cargo, whether they be small molecules such as cytotoxic drugs or macromolecules such as genes and proteins (*1*, *2*, *5*−*7*). Transition of their use from cell culture systems to animal disease models has been slow, but the ability of TAT conjugates to protect mice against ischemia, to inhibit tumor growth, and enhance gene delivery in aerosol formulations suggests that these offer wide ranging pharmaceutical applications for treating a range of diseases (*2*, *7*−*9*).

Much research has been directed toward understanding how the peptides, either alone or in conjugation with other molecules, traverse biological barriers such as the plasma membrane and those lining endocytic organelles and the nucleus. Recently a number of cellular localization and uptake observations, documented for PTDs in cell culture models, were found to be due to artifacts caused by fixation and extensive nonspecific binding of the peptides to the plasma membrane at physiological and low temperatures (*10*, *11*). Recent data suggest a major role for endocytosis in PTD uptake but an agreed mechanism for their intracellular traffic, following internalization, is yet to emerge (*10*, *12*−*17*).

On the classical endocytic pathway, TAT peptides have been shown to colocalize with markers of early/recycling endosomes such as transferrin and FM4-64 (*10*, *18*). Since TAT−DNA conjugates or complexes have the capacity to modify gene expression, a fraction of the peptides therefore escape, presumably from the endocytic pathway or associated organelles, in an undefined mechanism to the cytosol. Internalized TAT peptides have also been shown to colocalize with the Golgi marker BODIPY-ceramide and in agreement with direct traffic from early endosomes to the Golgi complex, no peptide was visualized in Lysotracker-labeled late endosomes and lysosomes (*14*). These data suggest that the peptides could utilize the retrograde secretory pathway via the Golgi complex and enter the cytosol from the endoplasmic reticulum. Earlier reports have demonstrated that TAT peptide fusion proteins enter neutral caveosomes via plasma membrane caveolae (*13*), but more recent reports suggest that caveolae are not required for uptake

(*16*). Conversely, TAT-conjugated liposomes were recently shown to enter acidic Lysotracker-positive compartments (*19*), and full-length TAT protein also entered acidic late endocytic structures containing the mannose 6-phosphate receptor (*20*). Indeed the ability of TAT protein to translocate to the cytosol was dependent on it reaching acidic organelles. For utilization of PTDs as cellular vectors for delivery of lysosome-fragile entities such as proteins and DNA, it is imperative that the trafficking route of these molecules downstream from the plasma membrane is delineated.

New nonviral systems for the delivery of macromolecules into hematopoietic cells are required for phenotype manipulation of precursor stem cells and for improved therapy against drug resistant leukemias (*21*). Green Fluorescent Protein conjugated to a TAT derivative and an alternate PTD were both found to be internalized into a number of primary hematopoietic cells, suggesting that this may be a promising avenue for delivery of macromolecular entities into these cells (*22*). In addition, overcoming multidrug resistance in leukemia cells via conjugation of a PTD to the anthracycline doxorubicin has also been demonstrated (*23*).

Overall it is clear that a greater understanding of PTD trafficking is a key requisite for extending their potential use in therapy. To address this we investigated and compared the intracellular traffic of fluorescent conjugates of TAT and octaarginine (R8) peptides in human leukemia KG1a-CD34$^+$ and K562-CD34$^-$ cells, that serve as models for primary hematopoietic stem cells and myeloid leukemia. In this report we show that despite the fact that the two cell lines have major differences in their interaction with PTDs at different temperatures and distinct organization of their endocytic pathways, they both deliver TAT-peptide and R8 to lysosomes. We extend these studies to adherent cells and demonstrate that lysosomal sequestration may be a common cellular fate following endocytic capture. Finally, the significance of these findings with respect to their potential as drug delivery vectors is discussed.

EXPERIMENTAL PROCEDURES

Reagents. Wortmannin, Cytochalasin D (CytD), 5-(*N*-ethyl-*N*-isopropyl)amiloride (EIPA), brefeldin A (BFA), nocodazole, and porcine intestinal mucosa heparin were from Sigma. Sheep anti-TGN46 was from Serotec, Oxford, UK, mouse anti-Lamp-II and anti-EEA1 antibodies were from DSHB, and BD Biosciences, Oxford, UK, respectively. Texas Red (TxR) (10000 Mw) and tetramethylrhodamine (TMR)−dextran conjugates, lysine fixable TxR-dextran (10000 Mw), TxR-transferrin (TxR-Tf), and Alexa594 and 488 labeled anti-sheep and anti-mouse antibodies were from Molecular Probes, Paisley, UK. Mounting medium containing 1.5 μg/mL 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI) was from Vector Laboratories, Burlingame, CA. All cell culture reagents were from Invitrogen, Paisley, UK.

Peptide Synthesis. All the peptides used in this study were chemically synthesized as described below, and their structures are shown in Figure 1. All peptides were purified by high performance liquid chromatography (HPLC), and the molecular masses were confirmed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS).

TxR-labeled R8 peptide: The peptide chain was constructed by Fmoc (= 9-fluorenylmethyloxycarbonyl)-solid-phase peptide synthesis on a Rink amide resin (*24*) as previously reported (*25, 26*). After removal of the N-terminal Fmoc group, the N-terminus of the peptide resin was fluorescently labeled by treatment with TxR-X succinimidyl ester mixed isomer (Molecular Probes) (*27*). The fluorescently labeled peptide resins were then treated with trifluoroacetic acid (TFA)−ethanedithiol (EDT) (95:5) at 25 °C for 2 h to yield TxR−(Arg)$_8$-amide.

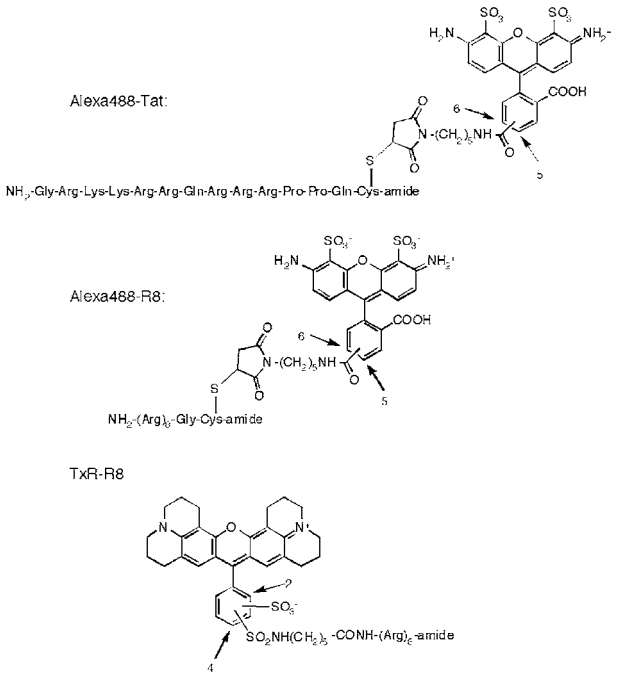

Figure 1. Structures of the fluorescently labeled peptides. In Alexa488-Tat and -R8, the linker is connected to the phenyl moiety at position 5 or 6, and in TxR-R8 the (sulfonamide) linker is connected at position 2 or 4 of the phenyl ring.

MALDI-TOFMS: 1969.0 [calcd for (M + H)$^+$: 1969.4]. Retention time in HPLC was 17.4 min [Column: Cosmosil 5C4-AR-300 (4.6 × 150 mm); Gradient: 5−95% B in A (A = H_2O containing 0.1% CF_3COOH, B = CH_3CN containing 0.1% CF_3COOH) over 40 min; Flow: 1 mL/min; Detection: 215 nm].

Alexa-labeled peptides (Alexa488-TAT or Alexa488-R8): The peptide segments bearing extra cysteine or glycylcysteine residues at the C-terminus of the arginine segments were prepared by Fmoc-solid-phase peptide synthesis followed by the treatment in TFA−EDT and HPLC purification. Peptides were then treated with Alexa488 C_5 maleimide sodium salt (Molecular Probes) and purified by HPLC. The sequences of the synthesized peptides are Alexa488-TAT, NH_2-Gly-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-Pro-Pro-Gln-Cys(Alexa)-amide; Alexa488-R8, NH_2-(Arg)8-Gly-Cys(Alexa)-amide. MALDI-TOFMS; Alexa-TAT: 2521.1 [calcd for (M + H)$^+$: 2520.9]; Alexa-R8: 2126.81 [calcd for (M + H)$^+$: 2126.4]. Retention time in HPLC: 3.1 min (Alexa488-Tat) and 3.0 min (Alexa488-R8) [Column: Chromolith Performance (4.6 × 100 mm); Gradient: 5−85% B in A (A = H_2O containing 0.1% CF_3COOH, B = CH_3CN containing 0.1% CF_3COOH) over 10 min; Flow: 4 mL/min; Detection: 215 nm].

Cell Culture. Cells were maintained at 37 °C in a humidified 5% CO_2 incubator. K562 cells, a gift from Dr. Paul Brennan (Cardiff University), and KG1a cells (ECACC 91030101) were maintained at a confluency of (0.5−5) × 10^6 in RPMI 1640 media supplemented with 10% fetal calf serum (FCS), 100 IU/mL penicillin, and 100μg/mL streptomycin. HeLa cells were maintained in D-MEM supplemented with 10% FCS, 100 IU/mL penicillin, and 100μg/mL streptomycin.

Fluorescence Microscopy. Images were acquired on either a Leica DMIRB inverted fluorescent microscope or a Leica SP2 RS confocal laser rapid scanning microscope as previously described (*28*). For double label live cell imaging, cells were loaded with endocytic markers or peptides as described below and washed in imaging medium, and aliquots were placed in eight-chambered coverglass slides (Nalgene Nunc International) prior to confocal microscopy. For this the cells were maintained at 37 °C/5% CO_2 and imaged at between 1.0 and 3.0 frames

s^{-1} using an UltraView RS real-time confocal system (Perkin-Elmer) consisting of a Zeiss Axiovert 200 microscope equipped with a 1.3 NA PlanFluar 100× objective and a three line Argon−Krypton laser. Images were merged and stacked using NIH ImageJ version 1.33 software, and the background fluorescence was removed using the 'despeckle' filter.

Transferrin Labeling in K562 and KG1a Cells. Cells (5×10^5) were incubated with 25 ng/mL TxR-Tf in 0.5 mL serum free media for 1 min at 37 °C prior to addition of 1 mL of ice cold 10 mM phosphate buffered serum, pH 7.4 (PBS). The cells were centrifuged for 1 min (1500*g*) at 4 °C and washed 4× in ice cold PBS containing 0.2% w/v BSA. The final cell pellet was resuspended in 70 μL of imaging medium (DMEM lacking Phenol Red containing 25 mM HEPES pH 7.4) and analyzed within 2 min by fluorescence microscopy.

For colocalization experiments of peptides with TxR-Tf, K562 cells were incubated with 3 μM Alexa488-TAT for 90 min prior to a further incubation in peptide free medium for 120 min. The cells were washed and incubated for 6 min at 37 °C with 50 ng/mL TxR-Tf in serum free medium containing 25 mM HEPES, pH 7.4. The cells were washed 3× in PBS and 1× in imaging medium prior to analysis by confocal microscopy.

Dextran Uptake and Distribution in K562 and KG1a Cells. For initial localization studies, 5×10^5 cells in 0.5 mL of complete medium were incubated for 60 min at 37 °C with 0.5 mg/mL TMR-dextran (*29*). The cells were then washed 4× in PBS and analyzed by fluorescence microscopy in imaging medium as described.

Peptide Uptake and Distribution in K562 and KG1a Cells. Cells (5×10^5) in 0.5 mL complete medium were incubated for 60 min at 37 °C with 1μM TxR-R8, Alexa488-R8 or 3μM Alexa-488 TAT. The cells were then washed 4× in PBS and analyzed by fluorescence microscopy in imaging medium as described. For BFA experiments cells were allowed to internalize the fluorescent peptides as above, washed and then incubated for 30 min at 37 °C in 5μg/mL BFA or control diluent. The cells were then analyzed by fluorescence microscopy.

Dextran and Peptide Uptake and Distribution in K562 and KG1a Cells. Cells (5×10^5) were incubated with TxR-dextran for 120 min as described, and the label was then chased into lysosomes via a further incubation in dextran-free medium for 300 min (chase) (*29*). At 120 and 180 min chase, the cells were washed to remove any recycled label. At the end of the chase period, the cells were washed and incubated with either 3 μM Alexa488-TAT or 1 μM Alexa488-R8 in complete medium for 60 min at 37 °C. The cells were washed 3× in PBS and analyzed by live-cell confocal microscopy as previously described. For analysis of the effects of pharmacological inhibitors of endocytic processes, dextran was internalized and chased as described prior to preincubation for 15 min at 37 °C with either 50 μM CytD or 10 μM nocodazole. In the continued presence of the drug the cells were then incubated at 37 °C for 60 min with Alexa488 peptides as described. The inhibitors were also present during the subsequent washing processes and confocal imaging.

Dextran and Peptide Uptake and Distribution in HeLa Cells. HeLa cells (1.2×10^5) were seeded on glass bottomed 35 mm culture dishes (MatTek Corporation, Ashland) and allowed to adhere for 15 h. The cells were then incubated for 120 min at 37 °C in complete medium containing 0.5 mg/mL TxR-dextran (*29*). Cells were washed and incubated for 240 min in complete medium prior to a further 60 min incubation in complete medium containing 2 μM Alexa488-TAT. The cells were washed and analyzed by confocal microscopy at 37 °C/5% CO_2.

Quantification of Alexa488-peptide Uptake by Flow Cytometry. K562 cells (5×10^5) were washed 2× in PBS and resuspended in 200 μL of RPMI 1640 medium supplemented with 10% FCS and containing either 10 μM EIPA, 150 nM wortmannin, 10 μM nocodazole, or their respective diluents. The cells were incubated for 15 min at 37 °C prior to the addition of 3 μM Alexa488-Tat or 1 μM Alexa488-R8 and incubated for 60 min in the continued presence of the drug. Equivalent aliquots of cells were precooled to 4 °C and incubated with the peptides on ice. Following all peptide incubations, the cells were washed 3× in PBS prior to incubation in 0.25 g/L trypsin for 5 min at 37 °C. Trypsinization was stopped by addition of an excess of ice cold PBS and cells were washed 2× in PBS, 3× in 15 μg/mL heparin/PBS and a further two washes in ice cold PBS. The cells were finally resuspended in 200 μL of PBS, and fluorescence was measured immediately on a Becton Dickinson FACSCalibur analyzer. The fluorescence of 10000 viable cells was acquired. Each experiment was performed at least two times, each condition was analyzed in triplicate, and statistical significance was assessed by analysis of variance (ANOVA), followed by Dunnett's multiple comparison between means.

Immunostaining. K562/KG1a cells: 1×10^6 cells were washed in PBS, fixed in 2% paraformaldehyde (PFA) in PBS for 15 min, and washed, and aliquots were transferred to wells on a multispot microscope slide (Hendley, UK). For some experiments, the lysosomes were preloaded as described with lysine fixable TxR-dextran prior to fixing. The cells were dried on to the slide and permeabilized with 0.1% Triton X-100 in PBS (for TGN46, EEA1 labeling) or acetone (for Lamp-II labeling) before blocking nonspecific binding sites with 10% v/v fetal calf serum/PBS for 10 min. Cells were then incubated with anti-TGN46, Lamp-II or EEA1 antibodies for 30 min in a humidified box at 37 °C. Cells were washed 3× with 0.1% Triton X-100 in PBS (TGN46, EEA1) or PBS alone (Lamp-II) and then incubated for 30 min with Alexa594 or Alexa488 conjugated secondary antibodies. The cells were washed as before and overlaid with 5 μL of mounting medium containing DAPI. The wells were covered with a coverslip and sealed with nail polish prior to analysis by confocal fluorescence microscopy. To test the effect of BFA on TGN46 labeling, cells were incubated with 5 μg/mL BFA in complete medium for 30 min at 37 °C prior to fixation and immunolabeling. HeLa cells: BFA treated (as above) or control cells were washed in PBS and processed for immunofluorescence microscopy as previously described (*28*) and labeled with antibodies against TGN46 or Lamp-II.

RESULTS

Distribution of TAT and R8 in Hematopoietic Cells. Numerous recent reports have provided strong evidence that endocytosis is a major entry route for PTDs such as TAT and penetratin. The ability to monitor and resolve traffic downstream of the plasma membrane in adherent cell culture models, using fluorescence microscopy, is hampered by the extensive binding of these peptides to the plasma membrane and tissue culture surfaces. We therefore investigated the uptake of two fluorescently conjugated PTD peptides TAT and R8 in nonadherent leukemia cell lines K562 and KG1a. For this, both cell lines were initially incubated with 3 μM Alexa488-TAT for 120 min at 37 °C, and after washing, the cellular localization of the peptide was analyzed by fluorescence microscopy. As fixing has been shown to cause major artifacts in the intracellular localization of PTDs, all fluorescence microscopy studies, unless otherwise specified, were performed in live cells. Figure 2 shows that although both cell lines contained internalized peptide, there were major differences in its subcellular distribution. In K562

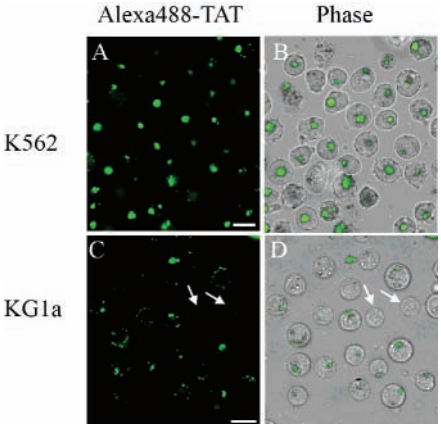

Figure 2. Distribution of Alexa488-TAT in myeloid leukemia cell lines. K562 (A,B) and KG1a (C,D) cells were incubated with 3μM Alexa488-TAT for 120 min at 37 °C prior to washing and analysis by fluorescence and bright field microscopy. Arrows denote KG1a cells containing very low amounts of fluorescence. Scale bars 25 μm.

cells, labeling was enriched in the perinuclear region; however, in KG1a cells, the peptide was predominantly localized in small disperse cytoplasmic vesicular structures. The majority of the cells contained labeled structures, but within each cell line there was variation in the intensity of labeling. Under these conditions, we could not detect significant nuclear or cytosolic labeling.

In view of these data and the paucity of information on the subcellular organization of organelles at specific locations on the endocytic pathway in these cell lines, especially KG1a, we labeled distinct endocytic structures of both cell lines with fluorescent probes whose intracellular fate following endocytic capture is well defined. Transferrin enters cells via clathrin-coated vesicles after binding to the transferrin receptor and traffics through early and recycling endosomes en route for return to the plasma membrane (*30*). In this study we generally define early endosomes as organelles containing internalized probe after 0−10 min of uptake, late endosomes (10−30 min), lysosomes (30+ min) (*30, 31*). Plasma membrane derived vesicles and early endosomes were labeled in both cell lines by internalizing TxR-Tf for only 1 min, followed by immediate microscopic analysis. In both cell lines the plasma membrane was labeled, in addition to distinct punctate structures (Figure 3A−D). Endocytosis of dextran is also well characterized in terms of its fluid phase uptake into early endosomes, through late endosomes, and finally to lysosomes (*32, 33*). K562 and KG1a cells were incubated with TMR-dextran for 60 min, thus allowing labeling of early and late endosomal compartments. Similar to observations with Alexa488-TAT (Figure 2), dextran-labeled vesicles were strongly enriched in the perinuclear region of K562 cells (Figure 3E,F); however, in KG1a cells the dextran-labeled structures were distributed throughout the peripheral cytoplasm (Figure 3G,H). The subcellular distribution profiles of fluorescent TAT and R8 after internalization at 37 °C for 60 min were then compared. As shown in Figure 3I−P, the distribution patterns of both peptides were similar to each other in each respective cell line, indicative of trafficking to the same structures. We observed minimal plasma membrane labeling of the peptides at 37 °C, and the labeling was predominantly confined to internal punctate structures. Cells treated with peptides had normal morphologies, and using an apoptosis assay utilizing YO−PRO-1 and propidium iodide dyes followed by flow cytometry, we found no increase in permeability to these agents in either cell line when they were incubated with 3 μM TAT or R8 for up to 4 h (data not shown).

Effect of Endocytosis Inhibitors on Peptide Uptake. The contribution of endocytosis to peptide uptake was then investigated by flow cytometry after treating cells with pharmacological agents that disrupt endocytic processes. K562 cells were pretreated with wortmannin, nocodazole, or EIPA prior to addition of the peptides for 60 min in the continued presence of the drug. The PI 3-kinase inhibitor wortmannin affects uptake at the plasma membrane and several downstream trafficking events (*34, 35*), nocodazole depolymerizes microtubules and also affects numerous endocytic processes including uptake at the plasma membrane and delivery through the endocytic pathway (*36*), while the amiloride analogue EIPA has been shown to inhibit macropinocytosis (*37*). We observed, in most cases, similar effects on uptake of both TAT and R8 in the presence of these agents (Figure 4A). The addition of 10 μM EIPA resulted in only a minimal decrease in peptide uptake, with only the uptake of R8 being statistically significant. We also performed experiments at higher EIPA concentrations, but toxicity issues possibly related to increases in intracellular pH and apoptosis (*38*) predominated over uptake effects (data not shown). Microtubule depolymerization inhibited uptake of both peptides by ∼30%, and cells treated with wortmannin had significantly lower (∼50%) fluorescence. The effect of incubating cells with CytD and methyl-β-cyclodextrin to compare the requirements of the actin cytoskeleton and lipid rafts, respectively, on peptide uptake (*39*) was also investigated. However, even the relatively mild treatments that we used for reducing plasma membrane labeling following internalization led to a significant enhancement of minimal effects of CytD that were observed in the absence of trypsinization, and in the case of methyl-β-cyclodextrin, trypsinization led to significant increases in dead cells identified via trypan blue staining.[2]

Finally to determine whether peptide internalization in these cells is an energy-dependent process, the effects of reducing incubation temperature was examined. Incubating K562 cells with peptides on ice resulted in a >88% decrease in fluorescence compared to cells incubated with the peptide at 37 °C (Figure 4A). In KG1a cells, however, the fluorescence of cells incubated with peptide on ice was often equal to or even higher than those incubated at 37 °C. Using flow cytometry, we compared cell numbers versus fluorescence intensity profiles of K562 and KG1a cells after incubation with both peptides at 4 °C and 37 °C and for 5 and 60 min (Figure 4B). After 5 min there was a clear difference between the 37 °C and 4 °C profiles for both peptides in the two cell lines, with the expected increased fluorescence at the higher temperature. However, after 60 min there was significant fluorescence in KG1a cells incubated at 4 °C, and the mean fluorescence of a large population of these cells was often higher than those incubated at 37 °C. These experiments were performed three times with two batches of peptides, and although there was much higher variation in cell-associated fluorescence at 4 °C, the value was always at least 50% of the control 37 °C value and in some cases was 2-fold higher.

Peptide distribution in KG1a cells after incubation at the two temperatures was then analyzed by fluorescence microscopy. The left panel of Figure 4C shows that after incubating the cells with R8 peptide on ice for 60 min followed by trypsinization and heparin washes, cell-associated fluorescence was still clearly evident, but rather than being located in distinct punctate structures, as previously observed (see Figure 3O), the peptide diffusely labeled and outlined the entire cell. Although the staining pattern was the same in all cells, we observed a high degree of heterogeneity with respect to fluorescence intensity, as some cells were very bright and others had much lower fluorescence. This heterogeneity is clearly observed by comparing the fluorescence of the three cells in Figure 4C. In cells incubated with the peptide at 37 °C, and then treated with trypsin and heparin, the peptide was predominantly localized in

[2] A.T.J., personal communication.

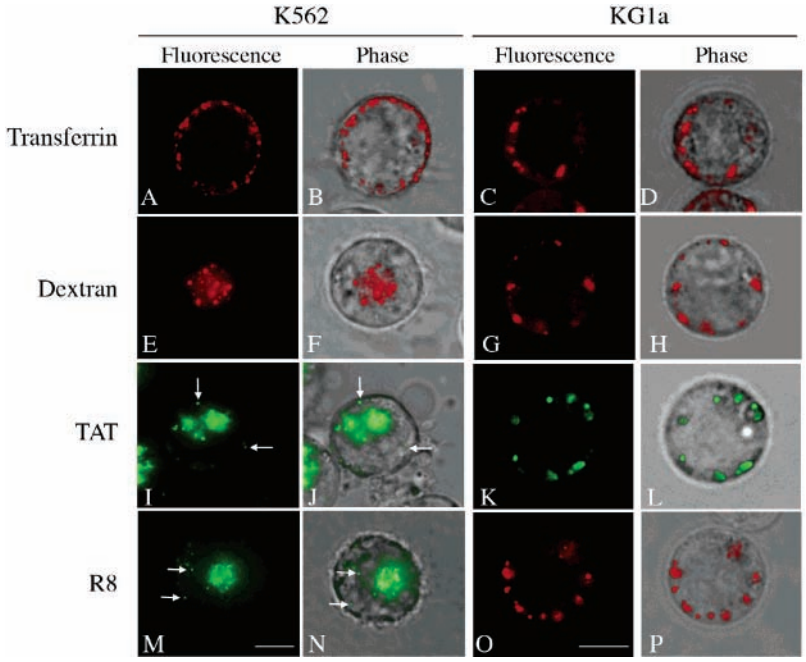

Figure 3. Comparison of cellular localization of endocytic probes with TAT and R8. (A−H) K562 (A,B, E,F) and KG1a (C,D, G,H) cells were incubated with Texas-red transferrin for 1 min (A−D) or TMR-dextran for 60 min (E−H) prior to washing and analysis by fluorescence and bright field microscopy. (I−P) K562 (I,J, M,N) and KG1a (K,L, O,P) cells were incubated with 3 μM Alexa488-TAT (I−L), 1 μM Alexa488-R8 (M,N) or 1 μM TxR-R8 (O,P) for 60 min prior to washing and analysis by fluorescence and bright field microscopy. Arrows show peptide-positive vesicles peripheral to the perinuclear structures. Scale bars 10 μm.

vesicular structures, similar to that seen in untreated cells. Increasing the trypsin concentration 2-fold, the length of the heparin washes to 5 min and the heparin concentration to 50 μg/mL did not significantly diminish the amount of peptide bound to the cells (data not shown).

Identification of Peptide Labeled Structures. Previous analysis of the intracellular traffic of TAT peptide in HeLa cells suggested that it bypasses late endosomal and lysosomal structures and traffics to the Golgi (*14*). We therefore further characterized the peptide labeled vesicles, initially in leukemia cells, and investigated whether they were morphologically sensitive to agents that disrupt membrane traffic on endocytic and secretory pathways. Cells treated with the phosphoinositide 3-kinase inhibitor wortmannin are characterized by the appearance of swollen vacuole-like endosomes (*35*, *40*). This is primarily due to inhibition of hVPS34 protein that is required for formation of phosphatilylinositol 3-phosphate on endosome membranes and vesicles within the lumen of the endosome (*41*). We therefore analyzed the localization pattern of Alexa488-TAT after uptake into cells pretreated with 150 nM wortmannin. Only minor wortmannin effects were observed in K562 cells (Figure 5A−D), but this was difficult to visualize, as the peptide, despite the presence of the drug, still accumulated in the perinuclear region. In KG1a cells a dramatic wortmannin-induced redistribution of both TxR-R8 and Alexa488-TAT into enlarged vacuole-like structures was observed (Figure 5E−J).

To investigate whether TAT and R8 peptides traffic to the Golgi, cells were incubated with either Alexa488-TAT or -R8 for 120 min and then incubated for 60 min in the presence of the Golgi-disrupting agent brefeldin A (BFA) (*42*). Figure 5A-D shows that in K562 cells, there was no visible difference in the Alexa488-TAT labeling pattern in the presence or absence of BFA. This experiment was also performed in KG1a cells, and they yielded the same results (data not shown). To analyze the localization of the Golgi in these cell lines and to assess the activity of BFA, cells incubated in the absence or presence of the drug were fixed and immunolabeled with antibodies against the *trans*-Golgi marker TGN46. Previous studies have shown that BFA collapses the *cis/medial* Golgi cisterna into the endoplasmic reticulum and causes the relocation of the *trans*-Golgi network (TGN) to a compact centrosomal location with some diffuse staining of the cytoplasm (*43*−*45*). In untreated K562 cells, TGN46 labeling was almost exclusively confined to a perinuclear region that was, as previously shown, conspicuous in cells incubated with the fluorescent peptides (Figure 6E,F). However, on treatment with BFA, a relocation of a significant fraction of the protein to diffuse cytoplasmic vesicles and reticular networks was observed (Figure 6G,H). The Golgi was also prominent in untreated KG1a cells (Figure 6I,J) and unlike in K562 cells which harbor both TGN46, TAT, and R8 in a perinuclear region, the TGN distribution in KG1a cells was markedly different to that of the internalized peptides (Figure 3O,P). TGN46 labeling in KG1a cells was also markedly sensitive to BFA (Figure 6K,L). Together, the data strongly suggest that the major fraction of internalized TAT and R8 does not traffic to the Golgi.

These data prompted us to design further experiments to characterize the organelles enriched with endocytosed TAT and R8. K562 cells were incubated with TxR-dextran for 120 min prior to washing and a further incubation in dextran-free medium for 5 h to allow the label to empty from early endosomes and traffic (chase) to lysosomal compartments (*29*, *33*, *46*, *47*). By this method, the label would be depleted from early and late endosomes, and the potential re-entry of recycled label was minimized by washing during the chase period. Dextran-loaded cells were then incubated for 60 min with Alexa488-TAT or -R8, and the subcellular location of both labels was analyzed by double-labeling confocal microscopy. We observed extensive colocalization of both R8 and TAT with dextran in highly motile perinuclear structures of the K562 cells (Figure 7A−C; Movie 1, Supporting Information). Some single-labeled structures were observed, possibly representing peptide that had not yet reached the dextran-loaded compartment; tubulation of TAT-labeled structures was also apparent. A similar degree of high colocalization was also observed when dextran-loaded cells were incubated with Alexa488-R8 (Figure 7D−F; Movie 2, Supporting Information).

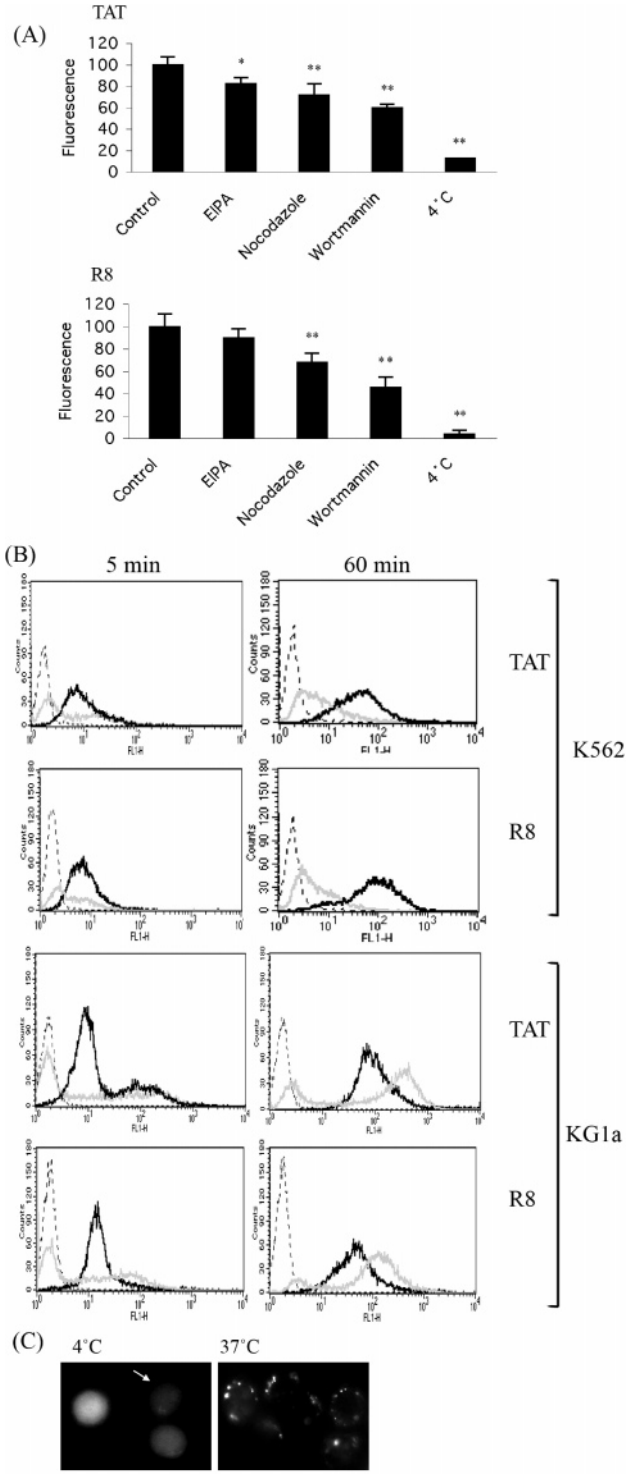

Figure 4. Effects of temperature and pharmacological inhibitors of endocytosis on uptake of TAT and R8. (A) K562 cells preincubated with diluent (control) or 10 μM EIPA, 10 μM nocodazole, and 150 nM wortmannin were incubated, in the continued presence of the drug, with 1 μM Alexa488-TAT (upper panel) or 3 μM Alexa488-R8 (lower panel) for 60 min prior to trypsin/heparin treatment and analysis by flow cytometry as described in Materials and Methods. Equivalent aliquots of cells were incubated with the peptides on ice (4 °C). (B) K562 and KG1a cells were incubated with 3 μM Alexa488-TAT or 1 μM Alexa488-R8 for either 5 or 60 min at 37 °C or 4 °C prior to trypsin/heparin treatment and analysis by flow cytometry. The number of cells (*y*-axis) is plotted against the fluorescence signal of cells (*x*-axis); 37 °C (black line), 4 °C (grey line) untreated cells dotted line. (C) KG1a cells were incubated with 1 μM Alexa488-R8 for 60 min at either 4 °C (left panel) or 37 °C (right panel) to prior to trypsin/heparin treatment and after by fluorescence microscopy. Arrow denotes cell with low fluorescence. * Statistically significant * $p < 0.05$, ** $p < 0.01$.

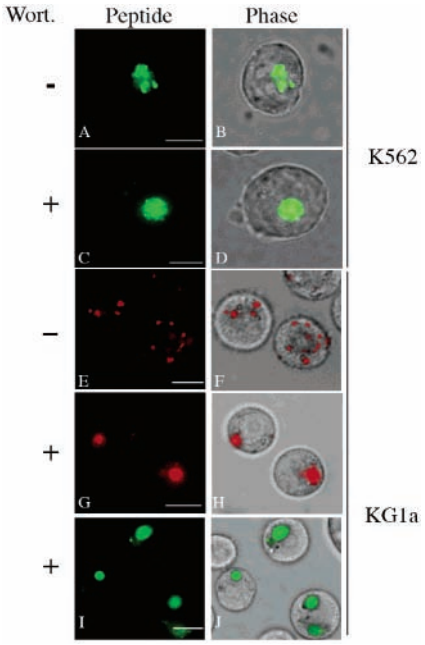

Figure 5. TAT and R8 distribution in wortmannin treated cells. K562 (A−D) or KG1a (E−J) cells were incubated for 15 min in control media (A,B, E,F) or media containing 150 nM wortmannin (C,D, G−J). The cells were then incubated with 3 μM Alexa488-TAT (A−D), 1 μM TxR-R8 (E−H) or 3 μM Alexa488-TAT (I,J) for 60 min in the continued presence of the drug or DMSO equivalent. The cells were washed and analyzed by fluorescence and bright field microscopy. Scale bars 10 μm.

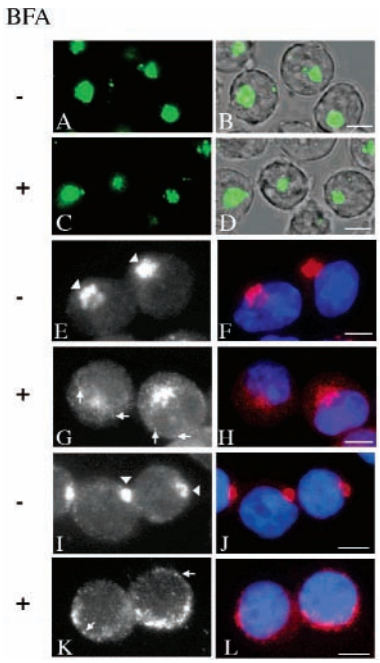

Figure 6. Cellular distribution of Alexa488-TAT in BFA treated K562 and KG1a cells. (A−D) K562 cells were incubated with 3 μM Alexa488-TAT for 60 min prior to washing and a further incubation for 30 min in control medium or medium containing (5 μg/mL) BFA. The cells were washed and analyzed by fluorescence and bright field microscopy. (E−L) K562 (E−H) or KG1a (I−L) cells were incubated in the absence or presence of 5 μg/mL BFA for 30 min prior to fixing and labeling with anti-TGN46 antibodies followed by secondary Alexa594 anti-sheep antibodies and analysis by fluorescence microscopy. Arrowheads denote compact Golgi staining in control cells, arrows denote TGN46-positive vesicles in BFA-treated cells. Scale bars 10 μm.

We then investigated whether the peptides, in a fashion similar to dextran, could be depleted from early endosomes and

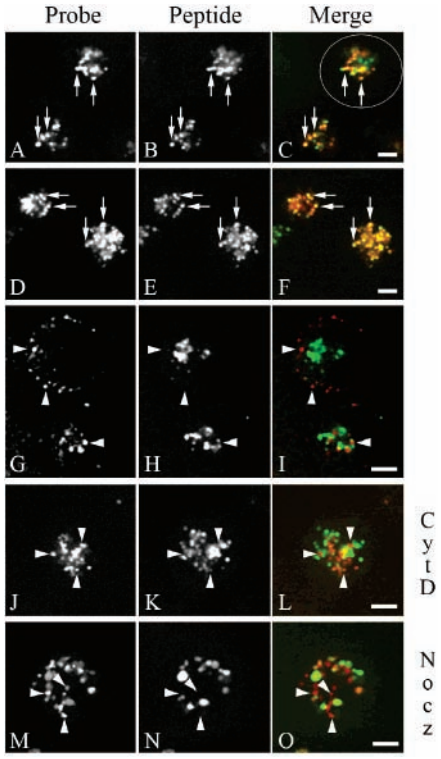

Figure 7. Colocalization of TAT and R8 with dextran in lysosomes of K562 cells. (A−F) K562 cells were incubated in the presence of TxR-dextran for 120 min and then washed and further incubated in dextran-free medium (chase) for 300 min. The cells were then allowed to internalize 3 μM Alexa488-TAT (A−C) or 1 μM Alexa488-R8 (D−F) for 60 min prior to washing and analysis by live-cell confocal microscopy. (G−I) K562 cells were allowed to internalize Alexa488-TAT for 90 min prior to washing and incubating in peptide free medium for 120 min. Cells were then incubated in 50 ng/mL TxR-Tf for 6 min prior to washing and analysis by live-cell confocal microscopy. (J−O) Cells were incubated with TxR-dextran as in A−F and following the chase period the cells were preincubated for 15 min with 50 μM CytD (J−L) or 10 μM nocodazole (M−O) and then incubated with 3 μM Alexa488-TAT in the continued presence of the drug. The cells were washed and analyzed by live-cell confocal microscopy. Arrows denote colocalization of peptide with dextran in the perinuclear region, and arrowheads denote uniquely labeled structures. The circle in C represents the plasma membrane of the cell. The data in A−O show the first frame of the accompanying movies: Movie 1 Image C, Movie 2 Image F, Movie 3 Image I, Movie 4 Image L, and Movie 5 Image O. Scale bars 10 μm.

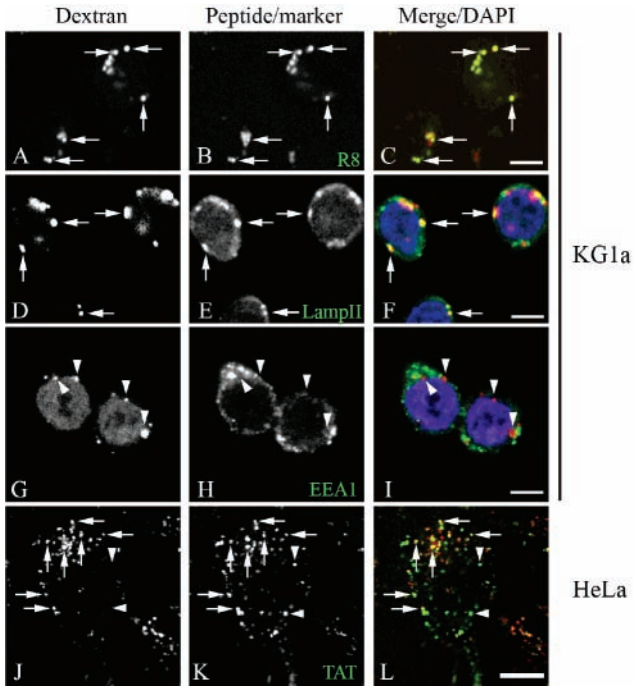

Figure 8. Colocalization of Alexa488-TAT and dextran in lysosomes of KG1a and HeLa cells. KG1a (A−I) and HeLa cells (J−L) were incubated in the presence of TxR-dextran (A−C, J−L) or (D−I) lysine fixable TxR-dextran for 120 min and then washed and further incubated in dextran-free medium (chase) for 300 min. (A−C, J−L). Cells were then incubated with 1 μM Alexa488-R8 (A−C) or 3 μM Alexa488-TAT (J−L) for 60 min prior to washing and analysis by live-cell confocal microscopy or immediately fixed and labeled with antibodies against Lamp-II (D−F) or EEA1 (G−I) and secondary Alexa488 conjugated anti-mouse antibodies and analyzed by confocal fluorescence microscopy. Arrows in A−C and J−L denote colocalization of TxR-dextran with Alexa488 peptides and arrowheads denote peptide unique structures. Arrows in D−F show colocalization of dextran with Lamp-II and arrowheads in G−I show dextran positive EEA1 negative structures. A−C, J−L show the first frame of the movies: Movie 6 Image C and Movie 7 Image L. Scale bars 10 μm.

chased into lysosomal structures. For this, K562 cells were allowed to internalize Alexa488-TAT for 120 min prior to washing and chasing the label through the endocytic pathway via a further 90 min incubation in peptide-free medium. Early endosomes were then labeled by a 6 min incubation with 50 ng/mL TxR-Tf prior to washing and live cell imaging. TxR-Tf was mainly localized to peripheral cytoplasmic structures, but interestingly in this short incubation time and during the imaging process a fraction of the ligand had traversed into a perinuclear location (Figure 7G−I; Movie 3, Supporting Information). The perinuclear staining is more prominent in the lower cell in Figure 7G; however, both peripheral and perinuclear structures were distinct from TAT-labeled structures with very little colocalization between the two labels. We next investigated whether actin disruption inhibited the delivery of TAT to dextran-labeled lysosomes. TxR-dextran was first chased into K562 lysosomes as previously described, and then the cells were preincubated with 50 μM CytD for 15 min prior to adding 3 μM Alexa488-TAT and incubating for a further 60 min in the continued presence of the drug. Figure 7J−L and Movie 4 (Supporting Information) show that there is very little colocalization of TAT and dextran in these cells with both probes labeling distinct vesicles. The distribution of peptide labeling was quite variable, but peptide-labeled structures were often peripheral to the lysosomes, the distribution of which were relatively unaffected by CytD. These observations strongly suggest that the traffic of TAT to lysosomes has a requirement for the actin cytoskeleton.

Lysosomes have been shown to be associated with microtubules, and loss of microtubule integrity has been shown to affect lysosome distribution, and delivery of material to late endocytic structures (*48, 49*). We therefore used the microtubule-disrupting agent nocodazole to investigate the involvement of microtubules in peptide traffic. K562 lysosomes were labeled with dextran as described, and then Alexa488-TAT was incubated in nocodazole pretreated cells in the continued presence of the drug. There was very little colocalization of the two probes in these cells (Figure 7M−O; Movie 5, Supporting Information), and both peptide and dextran were localized in vesicular structures that were scattered throughout the cytoplasm. In these experiments nocodazole appeared to inhibit traffic of the peptide to the perinuclear region and also to dissipate the perinuclear lysosomes. The movie also demonstrates that compared to control cells there was very little overall vesicular movement in cells treated with nocodazole. Large swollen TAT-labeled vesicles of the type shown in Figure 7N were observed in many cells but this was not a universal feature.

Colocalization of dextran with the two peptides in lysosomes was also investigated in KG1a cells, and Figure 8A−C and

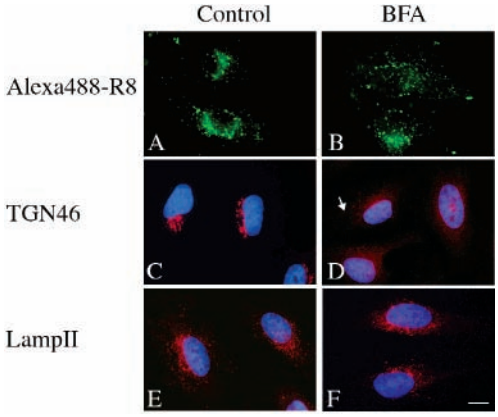

Figure 9. BFA does not affect the subcellular distribution of Alexa488-R8 in HeLa cells. (A−B) HeLa cells were incubated for 120 min with 1 μM Alexa488-R8 prior to incubation for 60 min in control diluent or 5 μg/mL BFA. The cells were then washed visualized by fluorescence microscopy. (C−F) HeLa cells were incubated for 60 min with control diluent or 5 μg/mL BFA prior to fixing and immunostaining with antibodies against TGN46 (C−D) or Lamp-II (E−F) and secondary Alexa594 conjugated anti-sheep (C−D) or anti mouse (E−F) antibodies. The cells were then analyzed by fluorescence microscopy. Arrow denotes BFA induced TGN46 positive tubule. Scale bar 10 μm.

Movie 6 (Supporting Information) show that Alexa488-R8 and dextran both labeled the same more diffusely labeled vesicles. Alexa488-TAT similarly colocalized with dextran in KG1a cells (data not shown). Together, these results demonstrate that TAT and R8 are delivered to lysosomal structures, and this process requires functional actin and microtubular networks.

To confirm that the dextran/peptide-positive organelles were conventional late endosomes and lysosomes, we fixed and labeled KG1a cells containing previously internalized and chased Lysine fixable TxR-dextran with antibodies against the early endosomal marker EEA1 and the late endosome/lysosome marker Lamp-II (*28, 50*). Figure 8D-I shows extensive colocalization between TxR-dextran and Lamp-II but minimal colocalization between EEA1 and dextran. Thus, a 5-h chase period is sufficient to deplete early endocytic organelles of internalized dextran and deliver the ligand to late endocytic, Lamp-II-positive, structures. Similar observations were observed in K562 cells (data not shown).

In view of the fact that we predominantly observed lysosome labeling as opposed to Golgi labeling in leukemia cells, we performed similar experiments in epithelial cells. For this, HeLa lysosomes were similarly labeled with TxR-dextran prior to incubation for 60 min with 3 μM Alexa488-TAT. A representative cell is shown in Figure 8J−L, and this together with Movie 7 (Supporting Information) demonstrates that both labels are located in mobile vesicular structures and short tubules. In agreement with the data from the K562 and KG1a cells, there are numerous examples of vesicles containing both labels, thus demonstrating that a significant fraction of TAT can be delivered to lysosomes within 1 h of incubation. As expected, there were also examples of vesicular structures positive for only one label.

To determine whether peptide distribution in HeLa cells is sensitive to Golgi disruption, cells were incubated with Alexa488-TAT for 120 min prior to a further 60 min incubation in the presence of 5 μg/mL BFA; separate control and BFA treated cells were also fixed and labeled with antibodies against TGN46. In agreement with the data in leukemia cells, BFA had no major effect on the distribution of Alexa488-R8 or -TAT (Figure 9A,B and data not shown). In the presence of BFA, the peptides remained localized in a typical vesicular pattern, enriched to differing extents in the perinuclear region. TGN46 labeling in these cells was highly sensitive to BFA treatment, and the protein dissipated from the perinuclear location to diffuse reticular and tubular structures (Figure 9C,D). We did not find similar TAT peptide-labeled structures in cells treated with BFA. Finally, HeLa cells were incubated with BFA for 60 min and then fixed and labeled with antibodies against Lamp-II and in agreement with our earlier findings, and concordant with other studies (*45*), we observed that the distribution of late endosomes and lysosomes was also predominantly unaffected by BFA treatment (Figure 9E,F).

DISCUSSION

The mechanism of entry and subsequent cellular location of cationic peptides such as those derived from HIV-TAT has received much focus due to their considerable potential as delivery vectors for a range of therapeutic entities. Based on a number of recent observations, there is now widespread acceptance that a large fraction of the material that crosses the plasma membrane does so by an endocytic mechanism. Whether uptake is mediated via a specific plasma membrane domain or receptors is unresolved, as agents that disrupt lipid rafts, macropinocytosis, and clathrin-mediated endocytic events can all inhibit peptide uptake to various extents.

Numerous reports also show that trypsinization and heparin washing can remove a significant fraction of cell-associated peptide confined to the plasma membrane. We and others have however shown that differences in cell-associated fluorescence between peptide incubations performed at 4 °C and 37 °C may be less than 50% (*27, 51*). The latter study also suggested that this is highly dependent on the sequence of the peptide, and that generally the extent of peptide binding at 4 °C is more heterogeneous compared with cells incubated with peptides at 37 °C. In agreement with other studies in HeLa cells (*52*), we observe in both K562 and KG1a cells some heterogeneity in the fluorescent intensities at 37 °C; however, the majority of peptide was confined to vesicular structures. There was very little cell-associated peptide in K562 cells incubated at 4 °C, but this was not the case for KG1a cells, suggesting that they have a very different repertoire of lipids and proteins at the plasma membrane; this may be a reflection of their more primitive differentiation status. Peptide distribution in KG1a cells was highly temperature specific, suggesting that distinct cellular interaction mechanisms operate at low and physiological temperatures.

Though 10 μM amiloride was shown to inhibit approximately 60% of TAT peptide in Namalwa cells (*39*), we previously showed in HeLa cells that 70% R8 uptake occurs in an amiloride insensitive manner (*27*). Here we show that TAT and R8 uptake in K562 cells was relatively insensitive to this drug; together these suggest that macropinocytosis is not the sole entry mechanism for these peptides. K562 cells do not express caveolin 1 and are phenotypically devoid of plasma membrane caveolae (*53*), and therefore, together with the data in HeLa cells, this supports previous observations that caveolae are not required for uptake of TAT and R8 (*16, 54*).

TAT-derived peptides have been localized to vesicular structures containing internalized transferrin, and these could either be early and/or recycling endosomes (*10, 52*). Thus, delivery from the plasma membrane is conventional inasmuch as an early endosome is the first peptide acceptor compartment. The downstream fate of the peptides from these early organelles was, previous to this study, unknown, but increased Antennapedia accumulation in cells treated with the endosomal acidification inhibitor bafilomycin A1 suggested this drug was protecting the peptide from degradation in late endosomes and lysosomes; however, little colocalization of peptides in late endosomes and lysosomes was observed (*14*). TAT uptake was later shown to be dependent on clathrin-coated vesicles and was then transported to an unspecified acidic component (*54*). Since

differential pH quenching experiments with fluorescein and Alexa488 were utilized in this study, it is possible that the peptide-positive organelles could be early or late endosome-like compartments, lysosomes, or possibly even the TGN, a compartment known to have an acidic pH of 6−6.2 (*55*). It was suggested, based on colocalization of BODIPY-ceramide with internalized TAT in HeLa cells and a corresponding lack of colocalization in Lysotracker-positive acidic compartments, that the peptide bypasses late endosomes and lysosomes and traffics to the Golgi. K562 cells have also been utilized for characterizing the uptake of cationic peptides that were shown to be internalized via endocytosis and localized to a perinuclear region, postulated to be of endosomal origin (*56*). Here we show comparable R8 and TAT distribution in K562 cells but extend the observations to show in this cell line and two others that these organelles are most likely lysosomes.

We were initially able to study peptide traffic by virtue of an ability to analyze their subcellular localization in leukemia cells using live cell confocal microscopy and dual labeling. These experiments were aided by the fact that we observed very little plasma membrane labeling at 37 °C, as they were removed from the original peptide-incubation container prior to microscopic analysis. This negated the usual problems of imaging peptide-loaded adherent cells by fluorescence microscopy and allowed for high-resolution spatial analysis of the peptides in organelles.

Internalization of endocytic probes for various time points allowed us to profile distinct subpopulations of endosomes, initially, in the two leukemia cell lines. This revealed major differences in the localization of late endosomes, lysosomes, and peptide-loaded vesicles. There was, however, similar extensive colocalization of dextran with the fluorescent peptides in these cells, after the former was initially allowed to traffic through the endocytic compartment for a minimum of 6 h and a maximum of 8 h. These dextran-labeled organelles should be regarded predominantly as lysosomes, as a number of studies have shown that late endosomes and lysosomes are accessible to plasma membrane-derived molecules within 10−30 min, and typically the half-life for delivery of a fluid phase label or one that is receptor internalized is between 90 and 120 min (*46, 47*). We confirmed this by showing that in fixed cells the dextran-positive compartments are labeled with antibodies against late endosomes and lysosomes but distinct from early endosomes. Previous studies have shown that the perinuclear region in a number of cell lines including K562 is enriched in recycling endosomes (*57*). Although we find transferrin in this region after ∼6 min internalization (Figure 7H and data not shown), it does not colocalize to any major extent with TAT that has previously been chased from early endosomes to late endosomes and lysosomes. In agreement with previous observations suggesting a role for microtubules in endosome to lysosome delivery in a number of cell lines, including K562 cells, (*58*), delivery of TAT to dextran-positive lysosomes was inhibited by nocodazole. The drug also caused a redistribution and scattering of lysosomes from the compact perinuclear region, and this is similar to SynB3 peptide labeling in nocodazole-treated K562 cells (*56*). The ability of this drug to inhibit the uptake of cationic peptides in K562 cells was highly sequence specific (*56*), and we observed only a 30% inhibition in nocodazole-treated cells. Cytochalasin D treatment also inhibited the delivery of peptides to lysosomes, suggesting that both an intact actin and microtubule network is required for delivery of these peptides to late endocytic structures.

To refute the possibility that lysosomal labeling of TAT was unique in these leukemia cells, dextran chase experiments were repeated in epithelia cells, and again we found a significant albeit reduced colocalization of the peptides with the lysosomal probe. This reduction in colocalization may reflect obvious differences in endosome dynamics between the cell lines and the possibility in HeLa cells that a greater fraction of the peptide is yet to reach the lysosomes or is trafficked to an alternative compartment(s). Both peptide and dextran were localized together or separately in distinct vesicles rather than in any larger or reticular organelles such as the Golgi and endoplasmic reticulum, respectively. In agreement with our findings that peptides are prevalent only in vesicles, there was a concordant insensitivity of peptide localization to the effects of BFA and a lack of overlap between peptide distribution and Golgi resident proteins. This was clearly shown by us in this study in the leukemia models, most notably in KG1a cells, and in our previous studies in HeLa cells (*28*). It therefore seems unlikely that the Golgi is a major acceptor compartment for these peptides. Fluorescence microscopy utilized in this way does not differentiate between intact and degraded conjugates in any subcellular organelle or the cytosol. As a large fraction of these peptides are delivered to lysosomes, the possibility exists for these and other studies that a heterogeneous population of peptide fragments and possibly free fluorophore are analyzed. Previous studies have shown that R8 and TAT are susceptible to degradation (*14, 59*); however, we previously established that R8 colocalizes extensively with its less proteinase-sensitive D form (*27*). Analysis of peptide stability in these cells lines is now a focus of our research.

Despite our finding of peptide traffic to lysosomes in the three cell lines, it may be as previously mentioned (*54*) that only a very small fraction is required to escape from the endocytic pathway or conceivably enter via a nonendocytic mechanism to elicit a cellular response. The intracellular traffic of these peptides in immature blood cells and epithelia cells as demonstrated in our study mirrors that of the full length HIV TAT protein in T-cells. In Jurkat T-cells the full length TAT protein was shown to be delivered to late endosomes and possibly lysosomes, and of particular significance was that translocation of this protein from the endocytic pathway was dependent on delivery to these late endocytic structures (*20*). Of note in the context of our data with BFA was their observation of very little colocalization of internalized full length TAT with Golgi proteins. On the basis of our observations, we favor a model where peptide translocation to the cytosol also occurs from an endocytic organelle; whether this occurs from an early endosome or a downstream compartment still remains to be determined.

ACKNOWLEDGMENT

The authors would like to thank Birgit Schramm, Brigitte Joggerst-Thomalla (EMBL), and Maria Manunta (Cardiff University) for technical assistance, and Randy Mrsny, Cardiff University, for critical reading of the manuscript. We also thank PerkinElmer and Leica Microsystems for continuous support of the EMBL Advanced Light Microscopy Facility.

Poly(glycoamidoamine)s for Gene Delivery: Stability of Polyplexes and Efficacy with Cardiomyoblast Cells

Yemin Liu and Theresa M Reineke*

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172. Received September 12, 2005; Revised Manuscript Received October 24, 2005

Polymeric vectors have potential as nucleic acid delivery vehicles for novel gene therapy and oligonucleotide treatments for cardiovascular disease. In this report, poly(glycoamidoamine)s that contain four secondary amines and either two or four hydroxyl units in the repeat unit with D-glucarate (**D4**), *meso*-galactarate (**G4**), D-mannarate (**M4**), and L-tartarate (**T4**) stereochemistry have been investigated for their pDNA-binding affinity, DNase protection effect, and polyplex stability in the presence of salt and serum. Also, the luciferase gene delivery and cellular internalization of polyplexes formed with these polymers have been investigated with rat cardiomyoblast [H9c2(2-1)] cells. The results demonstrate that the number of hydroxyl groups and the stereochemistry affect the biological properties. Polymers **T4** and **G4** have higher pDNA binding affinity, protect pDNA from nuclease degradation, and do not release pDNA in the presence of serum. Polymers **D4** and **M4** bind pDNA with lower affinity, which allows for some pDNA degradation and release in the presence of serum. Although **T4** forms the most stable polyplexes, vector **G4** reveals the highest luciferase gene expression in serum-free media and the greatest cellular internalization of fluorescein-labeled pDNA both in serum-free and serum-supplemented media. The results of these studies indicate that the polymer−DNA binding affinity, nuclease protection capability, and polyplex stability are important parameters to facilitate effective pDNA delivery with poly(glycoamidoamine)s in cultured cardiomyoblast cells. The carbohydrate type also plays an important role to increase cellular uptake and gene expression where the polymer with the galactarate stereochemistry (in **G4**) is found to be the most effective vector for pDNA delivery to cardiomyoblast cells in vitro.

INTRODUCTION

Gene therapy is actively being studied as a therapeutic option to treat cardiovascular disease (*1*). The development of suitable vectors that facilitate in vivo gene transfer is a large challenge facing the clinical application of this technique (*2*). The use of "naked" DNA (not complexed with a vector) has been significant in cardiovascular gene therapy trials in contrast to non-cardiovascular applications (*1*, *3*−*5*); however, delivery of naked DNA is inefficient and untargeted. Many current studies have focused on the use of viral vectors because of their promise to increase the magnitude and/or duration of gene expression (*1*). Unfortunately, severe problems associated with viral vectors in cardiovascular trials, such as irreproducible administration (*1*), insertional mutagenesis (*5*), and inflammatory and/or immune response (*3*), have hindered their further use in clinical trials. For myocardial gene transfer, specifically, replication-deficient adenoviruses are among the most efficient vectors that can vastly improve the tissue penetration and transgene expression in contrast to the use of naked DNA (*5*). Cytotoxicity (*6*) and humoral response (*7*) are associated with the first generation of replication-deficient adenoviruses, while the second and third generations require supplemental viral systems to facilitate their amplification (*8*) and can be difficult to purify, which can cause problems in vivo. Investigations of nonviral delivery vectors demonstrate that developing both nontoxic and highly efficient nonviral alternatives with clinical potential has become an urgent and important issue facing cardiovascular gene therapy.

Synthetic polymers have been increasingly proposed as practical nonviral vectors because of their numerous advantages such as the ease of synthesis (*9*), tissue-specific targeting (*10*−*13*), low immune response (*9*), and ability to complex an unrestricted amount of DNA (*14*). For example, polyethylenimine (PEI) (*15*), water-soluble lipopolymers (*15*), and Terplex (*4*) have been investigated for myocardial gene delivery. However, little is known about how specific chemical traits affect the biological properties of polymeric vectors (*16*−*19*). In an effort to understand such structure−bioactivity relationships, our lab has designed a library of poly(glycoamidoamine)s with secondary amine densities between chitosan (low nitrogen density, low cytotoxicity, and low delivery efficiency) and linear polyethylenimine (high nitrogen density, high cytotoxicity, and high delivery efficiency) (*16*, *20*−*24*). Previous investigations have shown that the poly(glycoamidoamine) structures containing four secondary amines between the carbohydrate repeat units deliver plasmid DNA (pDNA) containing the firefly luciferase reporter gene with high efficacy into a variety of mammalian cell lines (BHK-21, HeLa, and HepG2 cells) in a nontoxic manner (*16*, *20*, *21*). In addition, we have found that the biological properties, particularly the delivery efficiency of these polymers are cell-type dependent and are affected by the hydroxyl stereochemistry within the polymer repeat unit. We have chosen to further investigate the properties of poly(glycoamidoamine)s containing four amine groups in the repeat unit (named **D4**, **G4**, **M4**, and **T4)** to enhance our understanding of the structural effects of this polymer class on the observed biological properties. Here, we discover that the pDNA binding affinity, protection of pDNA against nuclease degradation, and the polyplex stability in the presence of salt and serum contribute greatly to the differences observed between these seemingly similar polymeric vectors. Also, the efficiency of both cellular uptake and gene expression of polyplexes formed with these polymers as a function of carbohydrate type are investigated via flow cytometry and luciferase gene expression experiments

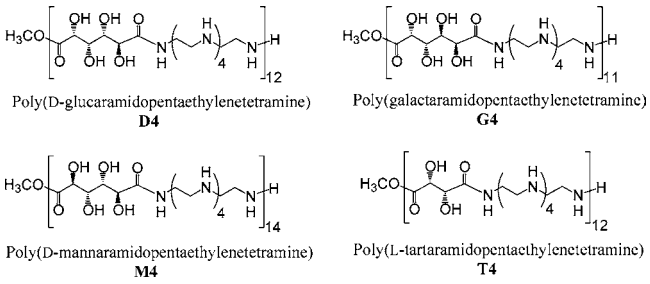

Figure 1. Poly(glycoamidoamine)s containing four secondary amines and either two or four hydroxyl groups per repeat unit with differing stereochemistry.

Table 1. Number Average Molecular Weight (M_n), Weight Average Molecular Weight (M_w), Polydispersity (M_w/M_n), and Degree of Polymerization (n) Data for the Poly(glycoamidoamine)s

polymer	M_n (kDa)	M_w (kDa)	M_w/M_n	n
D4	3.1	4.9	1.6	12
G4	3.1	4.6	1.5	11
M4	4.7	5.6	1.2	14
T4	3.6	4.3	1.2	12

with rat cardiomyoblast cells [H9c2(2-1) cells]. This model cell line was chosen due to its similarity to myocardial cells. This study represents our initial efforts to utilize these poly(glycoamidoamine)s to optimize the protocols for delivery of DNA to myocardial cells and to understand the chemical structure−biological property of polymeric vectors for cardiovascular targets.

EXPERIMENTAL PROCEDURES

Materials. The poly(glycoamidoamine)s (Figure 1) were synthesized through condensation polymerization of esterified D-glucaric acid (**D**), dimethyl *meso*-galactarate (**G**), D-mannaro-1,4:6,3-dilactone (**M**), or dimethyl L-tartarate (**T**) with pentaethylenehexamine (**4**) under conditions previously described (*16*, *20*, *21*). The molecular weight (M_n and M_w), polydispersity (M_w/M_n), and degree of polymerization (n) data are listed in Table 1. Media, supplements, nuclease-free water, and phosphate-buffered saline (PBS) were purchased from Gibco BRL (Carlsbad, CA). Plasmid DNA gWiz-Luc and pCMVβ were purchased from Aldevron (Fargo, ND) and PlasmidFactory (Bielefeld, Germany), respectively. Fluorescein-labeled pDNA was purchased from Mirus (Madison, WI). Heparin was purchased from Sigma (St. Louis, MO) as heparin ammonium salt from porcine intestinal mucosa. H9c2(2-1) cells, a cardiac-like myoblast cell line derived from BD1X rat heart tissue that exhibits properties of skeletal muscle, was purchased from ATCC (Rockville, MD). All reagents and polyplexes were prepared in nuclease-free water unless otherwise specified. N/P ratios (the ratio of the number of amines/phosphates from pDNA) were calculated by using the secondary amines in the polymer repeat unit only (not the amide nitrogens).

Heparin Competitive Displacement Assay. This experiment was performed as previously described for **D4**, **G4**, and **M4** (*21*). In brief, **T4** (10 μL) was mixed with pCMVβ (1 μg in 10 μL of H_2O) to form polyplexes at N/P = 20. The polyplexes were allowed to incubate for 30 min. A series of heparin solutions (400−600 μg/mL) were prepared by diluting aliquots of a heparin stock solution (2700 μg/mL). The polyplex solutions were incubated in 10 μL of each heparin solution above for 15 min. After the addition of loading buffer (1 μL), an aliquot (10 μL) of each sample was subjected to electrophoresis.

DNase Protection Assay. The experimental procedure used to measure DNase protection was modified from a reported method (*25*). One microgram of pCMVβ (in 5 μL) was complexed with 5 μL of **D4**, **G4**, **M4**, or **T4** at N/P = 5. Samples of the complexes were then incubated with 5 μL of fetal bovine serum (FBS) at 37 °C for 0, 1, 2, 4, and 6 h. After incubation, 1.5 μL of sodium dodecyl sulfate (SDS, 10% w/v) and 1.5 μL of loading buffer were added to the samples. SDS is used to release the pDNA from the polymers to evaluate the DNase protection capability of each poly(glycoamidoamine). The treated samples were incubated at 4 °C until gel electrophoresis was performed on an agarose gel (0.6% w/v) containing 60 μg of ethidium bromide/100 mL TAE buffer (40 mM Trisacetate, 1 mM EDTA). FBS only and DNA only were the negative controls in this experiment.

Measurement of Polyplex Size by Dynamic Light Scattering. Polyplex sizes were measured at 633 nm on a Zetasizer (Nano ZS) dynamic light scattering instrument (Malvern Instruments, Malvern, UK). pCMVβ (150 μL, 0.02 μg/μL in H_2O) was incubated with polymers **D4**, **G4**, **M4**, and **T4** (150 μL in H_2O) at N/P = 30 for 1 h to form the polyplexes. Each sample was then diluted to 900 μL with either Opti-MEM or supplemented DMEM (10% FBS) to determine the salt and serum stability of the polyplexes. The particle sizes were then measured at 37 °C and at time intervals of 0, 20, 40, and 60 min after dilution using a detection angle of 173°. The intensity-averaged particle size of each sample was reported as an average of 12 measurements.

Luciferase Reporter Gene Transfection and Cell Viability Assays. H9c2(2-1) cells were cultured according to ATCC specifications in Dulbecco's Modified Eagle medium (DMEM, supplemented with 10% FBS, 100 units/mg penicillin, 100 μg/mL streptomycin, and 0.25 μg/mL amphotericin) in 5% CO_2 at 37 °C. Prior to transfection, H9c2(2-1) cells were seeded at 4 $\times$ 10^4 cells/well in 24-well plates and were incubated for 24 h. **D4**, **G4**, **M4**, and **T4** (150 μL of an aqueous solution) were incubated with gWiz-Luc (150 μL, 0.02 μg/μL) at N/P ratios of 5, 10, 15, 20, 25, and 30 at room temperature for 1 h to form the polyplexes. The mixtures were then diluted to 900 μL with serum-free media (Opti-MEM, pH 7.2) or supplemented DMEM (10% FBS). Each well of cells was transfected with 300 μL of the polyplex solution containing 1 μg of gWiz-Luc. Untransfected cells and cells transfected with naked gWiz-Luc (1 μg) were used as negative controls. Four hours after transfection, 800 μL of the supplemented DMEM was added to each well. Twenty-four hours after transfection, the media was replaced with fresh supplemented DMEM (1 mL). Forty-seven hours after initial transfection, the media was removed and the cells were washed with 500 μL of PBS and treated with cell culture lysis buffer (Promega, Madison, WI). The amount of protein in the cell lysates (as milligrams of protein) was determined against a standard curve of bovine serum albumin (98%, Sigma, St. Louis, MO), using a Bio-Rad DC protein assay kit (Hercules, CA).

Cell lysates were analyzed for luciferase activity with Promega's luciferase assay reagent (Madison, WI). For each sample, luminescence was measured over 10 s in duplicate with a luminometer (GENios Pro, TECAN US, Research Triangle Park, NC), and the average was utilized. The gene delivery efficiency of each sample was characterized by firefly luciferase expression in H9c2(2-1) cells and denoted as relative light units (RLU)/mg of protein. The toxicity profiles were characterized by the amount of protein in the cell lysates. The protein level of untransfected cells was used to normalize the data obtained for the protein levels of the cells transfected with naked pDNA and polyplexes formed with **D4**, **G4**, **M4**, and **T4**.

Flow Cytometry. H9c2(2-1) cells were seeded on six-well plates at 2 $\times$ 10^5 cells/well and allowed to incubate in supplemented DMEM at 37 °C and 5% CO_2 for 24 h. The polyplexes were prepared by combining 250 μL of fluorescein-labeled pDNA (0.02 μg/μL) and 250 μL of **D4**, **G4**, **M4**, or **T4**

at N/P = 30. The cells were then transfected with 0.5 mL of polyplex solution (5 μg of pDNA/well) in 1 mL of serum-free media (OPTI-MEM) or 1 mL of advanced DMEM (2% FBS). The cells were incubated with each solution for 4 h to allow endocytosis and internalization of the polyplexes. After transfection, the cells were rinsed with PBS multiple times to remove the cell surface bound polyplexes. Supplemented DMEM was then added, and the cells were incubated for another 2 h to allow further polyplex internalization. Six hours after initial transfection, the cells were trypsinized, pelleted, and resuspended in PBS containing 2% FBS for fluorescent activated cell sorting (FACS) analysis. A FACSCalibur (Becton Dickenson, San Jose, CA) equipped with an argon ion laser to excite fluorescein (488 nm) was used. From 20 000 to 50 000 events were collected for each sample. The positive fluorescence level was established by visual inspection of the histogram of negative control cells such that less than 1% appeared in the positive region.

RESULTS AND DISCUSSION

The poly(glycoamidoamine)s examined in this study (**D4**, **G4**, **M4**, and **T4**) differ by the number and stereochemistry of hydroxyl groups, and each structure contains four secondary amine groups along the polymer chain (Figure 1). These polycations have been created with similar degrees of polymerization (11−14) (*16*, *20*, *21*) so that the chemical structure−biological property relationships of the polymers can be accurately compared (*24*). As previously shown, these polycations all complexed and compacted pDNA into small nanoparticles in water (in the proper range to be endocytosed) and displayed promising transfection efficiency and cell viability values with BHK-21, HeLa, and HepG2 cell lines (*16*, *20*, *21*). Here, we further investigated these poly(glycoamidoamine)s for their pDNA binding affinity, their ability to protect nucleic acids from nuclease degradation, and their stability in the presence of salt and serum. These investigations, along with analysis of the cellular uptake and gene expression properties of the polyplexes, were conducted to understand the efficacy difference between these similar polymer structures and to optimize their pDNA delivery with cardiomyoblast cells [H9c2(2-1) cells] for future in vivo myocardial delivery studies.

Structural Effects on pDNA Binding and Compaction. Previous studies with **D4**, **G4**, and **M4** found that the hydroxyl stereochemistry played a role in the polymer binding affinity to pDNA, which appeared to influence the transfection efficiency (*21*). It was found that **G4** demonstrated the strongest binding affinity and generally the best transfection and **M4** the weakest binding affinity and the lowest transfection; however, the results differed slightly with each cell line. Here, poly(L-tartaramidopentaethylenetetramine) (**T4**) was created to examine the biological effects of decreasing the amount of hydroxyl groups in the polymer repeat unit. In this polymer, the distance between the oligoamine moieties is shorter, which leads to an increase in amine density. A gel electrophoretic shift assay revealed that complete retardation of pDNA migration in electrophoresis field by **T4** started at N/P = 1, which was lower than the other three analogues **D4**, **G4**, and **M4** (these polymers retarded the migration of pDNA at N/P = 2, 2, and 3, respectively) (*21*). This indicates that the polymer−pDNA binding may become stronger by decreasing the hydroxyl number (in **T4**). The binding affinity of **T4** to pDNA was further investigated using a heparin competitive displacement assay. As previous reported (*21*), polyplexes formed between pDNA and **D4**, **G4**, and **M4** started to dissociate at heparin concentrations of 340, 440, and 240 μg/mL, respectively. Here, we have found that polyplexes formed with **T4** dissociate at a heparin concentration of 560 μg/mL (Figure 2b) and that the order of binding affinity is **T4** > **G4** > **D4** > **M4**. This result further suggests that decreasing the hydroxyl number (and thus increasing the amine density) along the backbone of poly(glycoamidoamine)s promotes stronger pDNA binding.

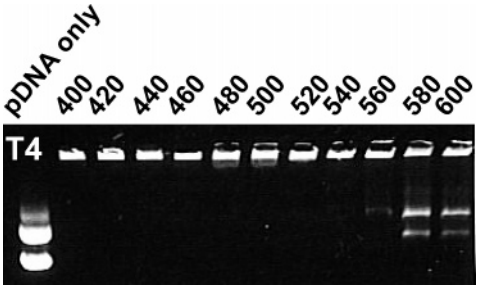

Figure 2. Heparin competitive displacement assay of **T4**. The first lane is uncomplexed pDNA. The numbers shown above the gel are the heparin concentrations tested to displace pDNA from the polyplexes.

Protection of pDNA from DNase Degradation. The ability of each poly(glycoamidoamine) to protect pDNA against DNase (present in FBS) degradation was investigated using a gel electrophoretic shift assay. It is important to determine the ability of the different polymers to protect pDNA from nuclease degradation to fully understand why the chemical and structural characteristics affect the cellular uptake and gene expression profiles. We performed the degradation experiments at a low N/P ratio (N/P = 5) to "simulate" the endosomal environment. During endocytosis, the polyplexes are exposed to an environment that contains a high concentration of negatively charged cell surface proteins, such as heparin. These polyanions can bind up excess polycations in the polyplexes and dissociate the polyplex slightly (this effect is shown in Figure 2; heparin competes with pDNA for polycation binding and dissociates the polyplexes, releasing the pDNA). This decreases the "effective" polyplex N/P ratio that is available for protection from DNase during cellular uptake. After incubation of the polyplexes with FBS, SDS was used to release the pDNA from the polyplexes to inspect the integrity of the pDNA and to assess and compare the protection effect of each polymer. As shown in Figure 3, degraded pDNA was visualized by the presence of band 5 and by a decrease in the intensity of bands 2 and 3. Plasmid DNA complexed with **M4** and **D4** began to degrade after 1 and 4 h of incubation with FBS, respectively. In addition, a decrease in the intensity of the pDNA bands (2 and 3) was also noticed after incubation of **D4** and **G4** polyplexes for 2 and 4 h with FBS, possibly indicating some pDNA degradation at these time points. When the four polymers were compared, **G4** and **T4** offered better pDNA protection from nuclease degradation. Particularly, **T4** completely protected pDNA after 6 h of exposure to FBS at 37 °C (a decrease in the intensity of pDNA bands was not observed). Again, this result shows that the hydroxyl number and stereochemistry affect the ability of the polymers to protect pDNA from nuclease degradation. The order of the ability of each polymer to protect pDNA from nuclease degradation is **T4** > **G4** > **D4** > **M4**, which is the same trend and likely related to the pDNA binding affinity of these polymers.

Effect of Salt and Serum on Polyplex Size. The stability of polyplexes formed with pDNA and **D4**, **G4**, **M4**, and **T4** was studied in the presence of media containing salt (serum-free Opti-MEM) and serum (DMEM supplemented with 10% FBS). This study is significant to understand how the polymer structure affects the polyplex stability under the conditions of the transfection experiments. After the polyplexes were formed in nuclease-free water, Opti-MEM or serum-supplemented DMEM was added for further incubation, and the polyplex solutions were analyzed at various time points (0, 20, 40, and 60 min) for the size measurements. As shown in Figure 4a, in

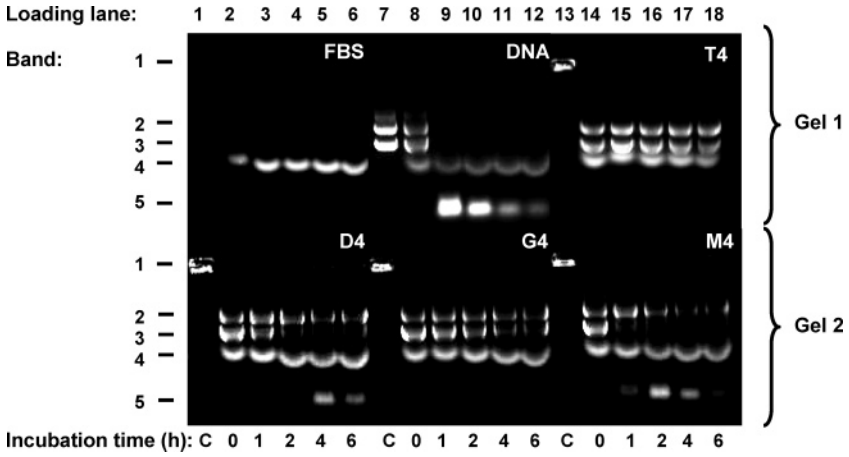

Figure 3. DNase protection of plasmid DNA by **T4** (lanes 13−18 of gel 1), **D4** (lanes 1−6 of gel 2), **G4** (lanes 7−12 of gel 2), and **M4** (lanes 13−18 of gel 2) complexed at N/P = 5. Fetal bovine serum (FBS, lanes 1−6 of gel 1) and naked pDNA (lanes 7−12 of gel 1) were used as controls. Control samples of FBS only (gel 1, lane 1, no band under UV), pDNA (gel 1, lane 7), and polyplexes formed with **T4** (gel 1, lane 13), **D4** (gel 2, lane 1), **G4** (gel 2, lane 7), and **M4** (gel 2, lane 13) without addition of FBS and SDS were also analyzed (labeled as C for the incubation time). Band 1 is the position of sample loading (polyplexes without FBS and SDS treatment). Bands 2 and 3 are relaxed and supercoiled pDNA forms. Band 4 results from combining both FBS and SDS. Band 5 is degraded pDNA.

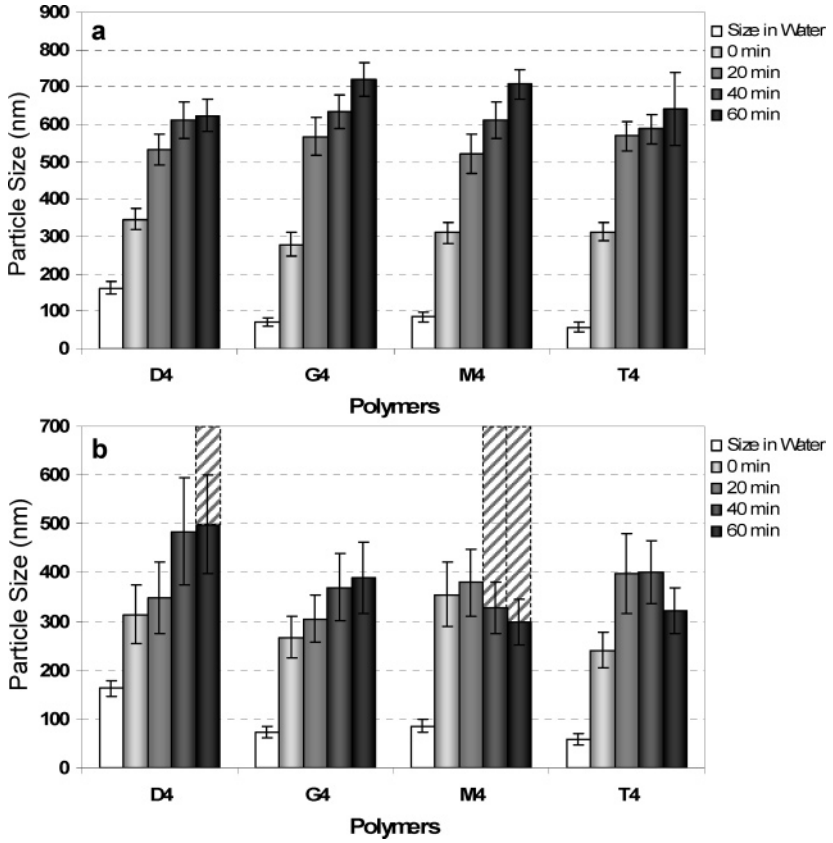

Figure 4. Polyplex stability of the poly(glycoamidoamine)s in the presence of salt and serum at N/P = 30. (a) Polyplex sizes in Opti-MEM at certain time intervals (0, 20, 40, and 60 min). (b) Polyplexes sizes in DMEM supplemented with 10% FBS at certain time intervals (0, 20, 40, and 60 min). The cross-hatched bars (shown behind **D4** at 60 min and **M4** at 40 and 60 min) indicate that a bimodal distribution is observed at these time points, where between 15 to 30% of the samples (by light scattering intensity) consist of particles around 3 μm.

Opti-MEM, all the polyplexes had similar particle sizes, and their sizes also increased in a similar manner with the incubation time. When the polyplexes were initially formulated in water, particles between 60 and 160 nm were formed. Upon addition of Opti-MEM, the polyplexes immediately aggregated to about 300 nm. After 20 min, the polyplexes further increased in size to 530−570 nm. After exposure to the salt solution for 40 and 60 min, the particle sizes continued to grow to 600−720 nm. Flocculation of **D4** polyplexes appeared to level off at 40 min (600 nm); however, **G4**, **M4**, and **T4** polyplexes continued to grow upon salt exposure.

In serum-containing DMEM (Figure 4b), the polyplexes formed with the poly(glycoamidoamine)s also aggregated but followed a different trend than that observed in the salt conditions. Polyplexes formed with **D4** aggregated rapidly and yielded the largest particles, where after 60 min, **D4** polyplexes were about 500 nm. In addition, a small amount of larger aggregates (around 3 μm) was observed in this sample (approximately 20% by light scattering intensity). Polyplexes formed with **M4** also aggregated, and a bimodal distribution of particles was also observed after 40 min of exposure to serum-containing DMEM, where about 15% of the sample at 40 min

and 30% of the sample at 60 min (percentages by light scattering intensity) contained aggregates larger than 3 μm. These large particles were also detected when measuring naked pDNA in FBS-supplemented DMEM, but they were not seen when the media only (the FBS-supplemented DMEM control) was measured. This result suggests that these particles may arise from the aggregation between naked pDNA and components in serum-containing media, which has also been observed by Moret et al. (*26*). Polyplexes formed with pDNA and polymers **G4** and **T4** did not reveal these large 3 μm aggregates but did flocculate to some degree (to about 400 nm), which was significantly smaller than the particle sizes observed in salt only conditions. This finding is again likely related to the binding affinities of these poly(glycoamidoamine)s with pDNA. The weaker-binding polymers, **D4** and **M4**, may release some pDNA into the media (due to competitive binding of negative serum proteins with the polycations). The pDNA then forms larger aggregates (around 3 μm) with positively charged serum proteins (*27*, *28*). However, the stronger pDNA binding polymers, **G4** and **T4**, do not appear to release pDNA, and polyplexes formed with these polymers are more stable in serum-containing media, which may help to increase pDNA delivery efficiency.

Luciferase Reporter Gene Expression with H9c2(2-1) Cells. The transfection efficiency of **D4**, **G4**, **M4**, and **T4** were characterized by firefly luciferase expression with H9c2(2-1) cells both in serum-free and serum-supplemented (10% FBS) media. Untransfected cells and naked gWiz-Luc were used as the negative controls. Previous studies with poly(glycoamidoamine)s have shown that gene expression is enhanced with an increase in N/P ratio (*20*, *21*), which is a common characteristic of low molecular weight polymeric vectors (*14*). Figure 5 reveals the luciferase expression values of polyplexes formed with pDNA and **D4**, **G4**, **M4**, and **T4** as a function of N/P ratio (between 5 and 30) in serum-free media with rat cardiomyoblast cells. The maximum luciferase expression of polyplexes formed with all four polymers occurred at N/P = 30. As shown in Figure 1, the carbohydrate moieties in **D4**, **G4**, and **M4** all have four hydroxyls that only differ by their stereochemistry. By comparing the transfection efficiencies of these three polymers, it was noticed that **G4** facilitated higher luciferase expression under serum-free transfection conditions. The increase in efficacy of **G4** over **D4** and **M4** may be due to the stronger pDNA binding affinity as demonstrated by the competitive displacement experiments with heparin (*21*). If the binding affinity is relatively weak, cell surface proteoglycans (such as heparin sulfate) may prematurely release the pDNA from the polyplex before cellular internalization. Also, **G4** protected pDNA better against DNase (Figure 3), which increased the pDNA resistance to enzymatic damage in the endocytotic pathway, thus resulting in higher pDNA delivery.

It is generally believed that enhancing the amine density improves gene expression (*16*, *21*, *29*). However, at higher N/P ratios, **T4** did not generally facilitate higher gene expression values than the other three polymer analogues (containing four hydroxyl groups), although at lower N/P ratios it was noticed that **T4** did have a higher expression profile. At N/P = 5, **D4**, **G4**, and **M4** did not transfect H9c2(2-1) cells higher than naked pDNA (N/P = 0 in Figure 5). However, **T4** presented a significant enhancement in gene expression at N/P = 5. This could be due to the higher binding affinity and DNase protection offered by **T4** as compared with **D4**, **G4**, and **M4** (Figure 3) at N/P = 5, which would allow more pDNA to survive the cellular uptake and intracellular trafficking events from nuclease degradation at this low N/P ratio. At N/P = 10, **T4** still exhibited slightly higher gene expression. When the N/P ratios were increased further (15 to 30), **G4** clearly displayed the highest transfection efficiency with H9c2(2-1) cells. These results imply

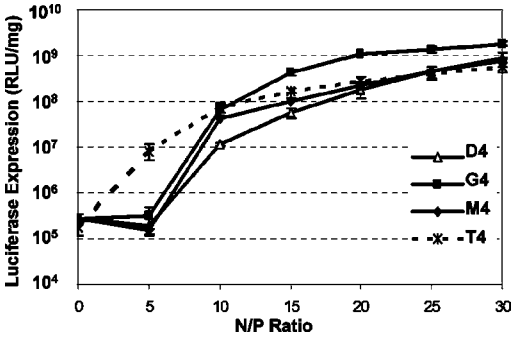

Figure 5. Luciferase gene expression (RLU/mg) in H9c2(2-1) cells with polyplexes formed with **D4**, **G4**, **M4**, and **T4** at N/P ratios between 0 (pDNA only) and 30. Transfections were performed in serum-free media (Opti-MEM) for the first four hours.

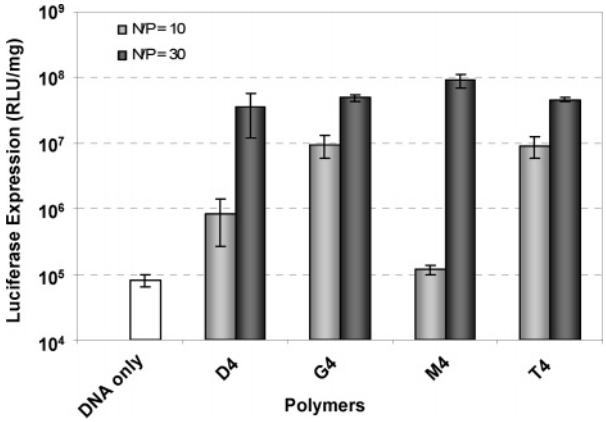

Figure 6. Luciferase gene expression (RLU/mg) in H9c2(2-1) cells with polyplexes formed with **D4**, **G4**, **M4**, and **T4** at N/P ratios 10 and 30 with DMEM containing 10% serum.

that both the number and the stereochemistry of the hydroxyl groups and the N/P ratio affect the gene delivery efficiency of polyplexes formed with the poly(glycoamidoamine)s with H9c2(2-1) cells. The carbohydrate type appears to play a role in the efficacy of gene transfection, and this effect is not clearly understood.

The luciferase expression with polyplexes formed with **D4**, **G4**, **M4**, and **T4** in the presence of serum was lower than that obtained in serum-free media. This is commonly observed with most nonviral vectors due to interaction of these systems with serum proteins (*30*−*32*). The maximum luciferase expression of polyplexes formed with all four polymers occurred at N/P = 30 under serum conditions. As shown in Figure 6, at N/P = 10, **G4** and **T4** polyplexes yielded gene expression values significantly higher than that of **D4** and **M4** polyplexes. This effect may again be attributed to the better DNase protection ability of **G4** and **T4** (Figure 3), which would allow more pDNA to survive the harsh extra- and intracellular degradative environment. However, at N/P = 30, gene expression values were higher, and similar values were obtained with all of the polymers. To our surprise, **M4** displayed slightly higher gene expression (at N/P = 30), which is not clearly understood.

Toxicity. All of the polyplexes revealed low toxicity profiles in H9c2(2-1) cells even at the high N/P ratio required for maximum gene expression (as shown in Figure 7, N/P = 30). The viability values with H9c2(2-1) cells, characterized by the cellular protein concentration (fraction of cell survival was normalized to untransfected cells), were all greater than 85% with **D4**, **G4**, **M4**, and **T4** in both serum-free and serum-supplemented transfection conditions. These results were similar to the high cell viability profiles generally observed with chitosan and uncomplexed DNA (*9*, *22*). As shown, **T4** exhibited

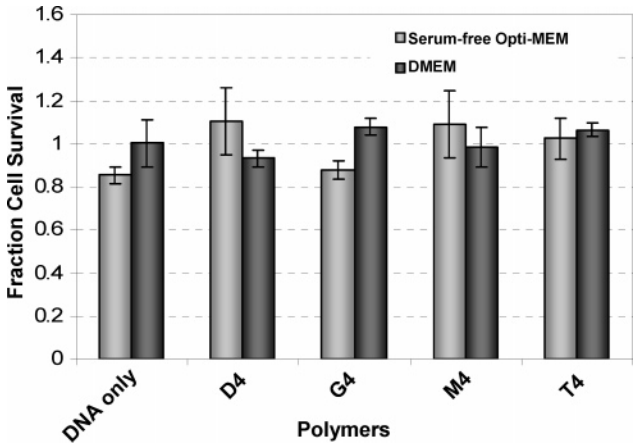

Figure 7. The fraction of cell survival of H9c2(2-1) cells transfected with naked DNA and polyplexes formed with **D4**, **G4**, **M4**, and **T4** and N/P=30. The toxicity values are normalized to untransfected cells (fraction of cell survival = 1.0).

the same toxicity profile as the other three poly(glycoamidoamine)s. These data indicate that the toxicity in H9c2(2-1) cells does not increase with the increase of amine density (by decreasing the hydroxyl number) along the polymer chain. This study demonstrates that by systematically incorporating monosaccharide units into a PEI-like backbone, the polymer biocompatibility can be greatly enhanced while retaining high delivery efficacy with H9c2(2-1) cells.

Cellular Uptake of the Polyplexes. Flow cytometry was performed to quantify the cellular uptake efficiency of fluorescein-labeled pDNA complexed with polymers **D4**, **G4**, **M4**, or **T4** at the N/P ratio of maximum luciferase gene expression (N/P = 30). This experiment yields the number of cells that uptake pDNA, as well as the average intensity of fluorescence (relative amount of pDNA) in the cells. The cells were incubated with each polyplex solution for 4 h in either Opti-MEM or FBS-supplemented DMEM to allow endocytosis. After removal of the cell surface bound polyplexes and further incubation with supplemented DMEM for 2 h, the cells were trypsinized and isolated for FACS analysis. The flow histograms of H9c2(2-1) cells transfected in serum-free media and supplemented DMEM are shown in Figure 8a,b. The mean fluorescence intensity and the percentage of positive cells are shown in Figure 8c. In this experiment, only 8% of H9c2(2-1) cells in serum-free media and less than 1% of cells in supplemented DMEM were transfected with the control, naked fluorescein-labeled pDNA. As shown, the poly(glycoamidoamine) delivery vehicles greatly improved the cellular uptake of the labeled pDNA. Greater than 90% of cells (with the exception of **T4** in supplemented DMEM, where about 88% cellular uptake was observed) were positive for fluorescence after 6 h of incubation with polyplexes formed with fluorescein-labeled pDNA and polymers **D4**, **G4**, **M4**, or **T4** (Figure 8c).

It is generally believed that the binding affinity between polymers and pDNA plays a significant role in the internalization of polyplexes via cell surface interaction (e.g., proteoglycans) (*21*, *33*, *34*). When the polyplex comes into contact with the cell surface, negatively charged proteoglycans may compete with polycation binding and disassemble the polyplex if the polymer−pDNA binding affinity is not strong enough. This would decrease the amount of polyplexes (and pDNA) that are internalized and/or decrease the protection of pDNA from nuclease degradation (both outside and inside the cells). As shown in Figure 8a,c, polyplexes formed with **D4** and **G4** revealed very similar cellular uptake efficacy in serum-free Opti-MEM, and both vectors transfected more cells than **M4**. These data are consistent with their binding affinity to pDNA (**G4** > **D4** > **M4**). However, to our surprise, the mean fluorescence intensities of these three polymers were higher than that of **T4**, which has an even stronger binding affinity for pDNA. This result is consistent with the luciferase expression results and suggests that polymer−pDNA binding affinity is not the only parameter that controls the cellular internalization of polyplexes formed with poly(glycoamidoamine)s in serum-free conditions. As shown in Figure 4a, polyplexes formed with **D4**, **G4**, **M4**,

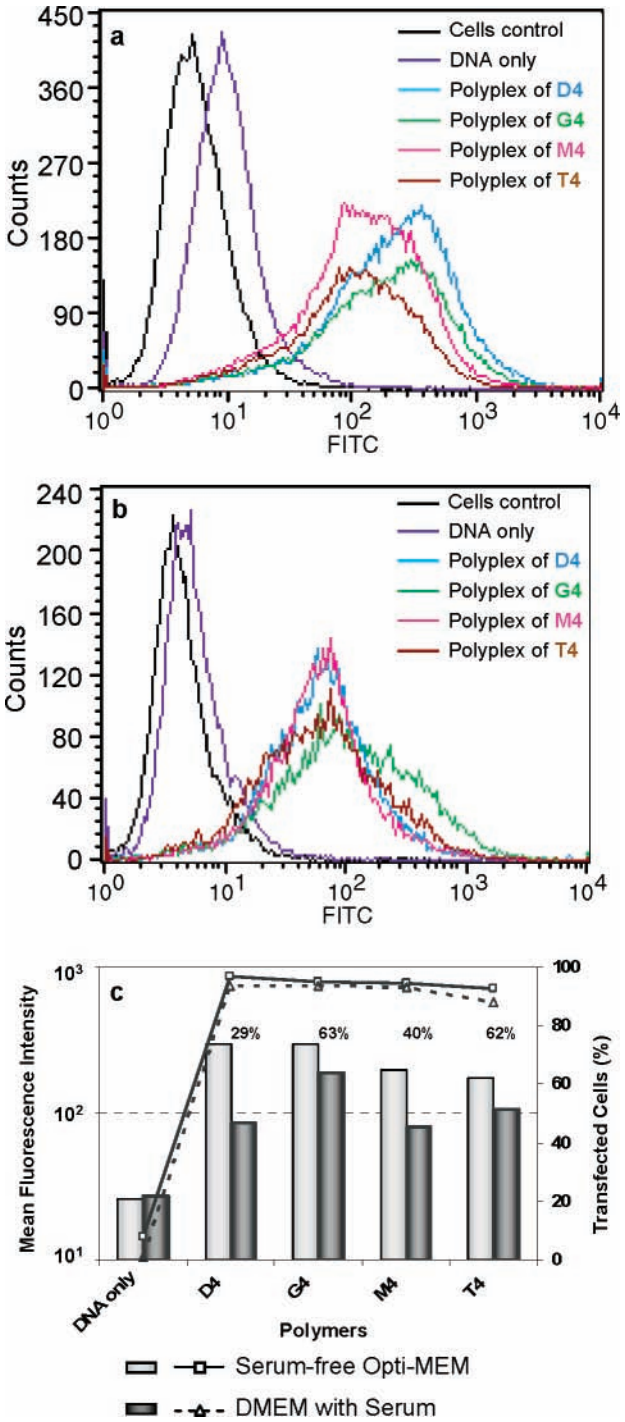

Figure 8. Cellular uptake of fluorescein-labeled pDNA complexed with **D4**, **G4**, **M4**, and **T4**. (a) Flow histogram of H9c2(2-1) cells after transfection in serum-free media. (b) Flow histogram of H9c2(2-1) cells after transfection in supplemented DMEM. (c) Mean fluorescence intensity (bars) and the percentage of cells positive for fluorescein (lines). The values shown above the bars are the percentages of the fluorescence intenisty retained for each vector in serum conditions as compared to the fluorescence intensity obtained in the serum-free conditions (= 100%).

and **T4** all aggregated similarly in serum-free media, and therefore the polyplex size should not contribute to this discrepancy. It is possible that the number and stereochemistry of the hydroxyl groups within the carbohydrate moieties may affect polyplex−cell surface binding and certain linear hydroxyl stereochemistries may increase signaling of cellular internalization via endocytosis with cardiomyocytes.

The percentage of cells that internalized the pDNA in the presence of serum (Figure 8b,c) did not significantly decrease as compared to the serum-free results. Also, the trend was similar to the Opti-MEM results where **D4**, **G4**, and **M4** polyplexes were all uptaken by the same number of cells and **T4** transfected the lowest number of cells. However, the mean fluorescence intensity (the amount of pDNA internalized) did decrease to a large degree as compared to the results in serum-free media, and an interesting trend was observed. As shown in Figure 8c, polyplexes formed with **G4** and **T4** retained greater than 60% of their respective fluorescence intensity values obtained in serum-free media. However, **D4** and **M4** polyplexes only retained 29 and 40%, respectively, of their fluorescence values obtained in serum-free media.

As highlighted in Figure 8c, **G4** polyplexes yielded the greatest fluorescence intensity in serum-containing media and therefore facilitated the greatest amount of pDNA to be internalized. Also, it was noticed that the cellular internalization in the presence of serum with polyplexes formed with the poly(glycoamidoamine)s followed an interesting trend (**G4** > **T4** > **D4** > **M4**), which is consistent with the luciferase gene expression results obtained with serum at N/P = 10. This trend could be due to a combined effect of the binding affinity, DNase protection ability, polyplex stability in serum, and the carbohydrate type within the polymer. Vectors **G4** and **T4** appear to yield the greatest efficacy in serum conditions with H9c2(2-1) cells. Polymers **G4** and **T4** both have high binding affinities (Figure 2) and DNase protection capabilities (Figure 3) with pDNA. Also, the polyplexes formulated with these two vectors do not form large aggregates with serum (Figure 4b), which suggests that they do not release pDNA from the polyplex in the presence of serum. **G4** delivers pDNA with the greatest efficacy, and this effect is not clearly understood. However, it is likely due to the hydroxyl number and/or stereochemistry along the polymer backbone where the hydroxyl stereochemistry in the linear galactose residues seems to facilitate greater cell surface interaction that triggers endocytosis with this cell line. **D4** and **M4** yield the lowest cellular internalization, and may be due to the fact that these vectors have a weaker binding affinity, do not protect pDNA from nuclease degradation, and also form large aggregates (possibly due to the release of some pDNA in the presence of serum). An interesting observation was that although **M4** facilitated the lowest cellular internalization in the presence of serum (Figure 8c), it demonstrated the highest luciferase gene expression at N/P = 30 (shown in Figure 6). Thus, it appears that on a per plasmid basis (luciferase expression/mean fluorescence intensity) **M4** is more efficient than the other systems. This indicates that **M4** could be more effective after cellular internalization, where this vector may facilitate higher endosomal and pDNA release than the other polymers. The low binding affinity of **M4** to pDNA may cause easier dissociation of the polyplexes within the endosome and cytoplasm, where the released pDNA can be expressed more readily. In addition, the dissociated **M4** polycations may chelate the proteoglycans on the interior of the endosomes causing endosomal membrane leakage and increased cytoplasmic pDNA release (thus enhancing gene expression). These phenomena are currently being investigated via confocal microscopy and flow cytometry experiments in our lab.

CONCLUSION

The poly(glycoamidoamine) nucleic acid delivery vectors **D4**, **G4**, **M4**, and **T4** have been investigated for their pDNA-binding affinity, DNase protection ability, and polyplex stability in the presence of salt and serum. Also, the luciferase gene delivery, cell viability, and the capacity of these vectors to promote cellular internalization of fluorescein-labeled pDNA have been studied with a rat cardiomyoblast cell line. We have found that both the number and the stereochemistry of the hydroxyl units significantly affect the biological properties. The results demonstrate that **T4** and **G4** have a stronger binding affinity and enhanced DNase protection ability. Also, the polyplexes formed with these vectors are more stable in the presence of serum, where they do not appear to release pDNA. Polyplexes formed with **D4** and **M4** reveal weaker pDNA binding, allow pDNA degradation in the presence of serum, and appear to release some pDNA in the presence of serum-containing media. Particularly, **G4** is found to promote the highest luciferase gene expression in serum-free media and higher cellular internalization of pDNA both in serum-free and serum-containing media than the other analogues. These results are likely an effect of more pDNA surviving the cellular uptake and intracellular trafficking events due to increased polyplex stability from pDNA release and degradation. Although **T4** reveals the highest pDNA binding affinity and DNase protection when compared to **D4**, **G4**, and **M4**, it does not show higher cell internalization and luciferase gene expression. It seems that both the distance of the amine functionalities and the carbohydrate type affect the gene delivery efficiency, where the carbohydrate residues, particularly with the linear galactarate stereochemistry, promote higher delivery efficacy with this cardiomyoblast cell line. This study presents our first step to facilitate the use of nucleic acid drugs for cardiovascular aliments by further examining the chemical properties of these new synthetic polymers and developing their potential as novel vectors for myocardial targets. PEGylation of these polymers to further stabilize the polyplexes from aggregation and examination of these vectors for in vivo myocardial gene delivery are currently being investigated.

Development of Nanoparticle Libraries for Biosensing

Eric Yi Sun, Lee Josephson, Kim A. Kelly, and Ralph Weissleder*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts 02129-2060. Received October 4, 2005; Revised Manuscript Received December 5, 2005

Magnetic and magnetofluorescent nanoparticles have become important materials for biological applications especially for sensing, separation, and imaging. To achieve target specificity, these nanomaterials are often covalently modified with binding proteins such as antibodies or proteins. Here we report on the creation of nanoparticle libraries that achieve specificity through multivalent modification with small molecules. We explore different synthetic routes to attach small molecules with anhydride, amine, hydroxyl carboxyl, thiol, and epoxy handles. We show that the derived nanomaterials have unique biological functions, possess different behaviors in cell screens, and can be used as substrates for biological screens.

INTRODUCTION

To use emerging nanomaterials more efficiently in biological applications, it is often essential to functionalize them with organic ligands to impart precise biological functions (*1*−*3*). Conversely, the creation of entire libraries of nanomaterials could greatly accelerate screening for use in biomedical applications. Magnetic and magnetofluorescent nanoparticles (MNPs and MFNPs) have become important materials in biomedicine for sensing (*4*), magnetic separation, and/or in vivo imaging (*5*). While prior research has focused on the design of specific nanoparticles (*6*, *7*, *20*) or polymers (*9*), detailed procedures for the synthesis and evaluation of surface-modified nanoparticle libraries using different conjugation strategies has not been described. The goal of this study was to develop, optimize, and characterize parallel conjugation chemistries for the creation of magnetofluorescent nanoparticle libraries.

We describe methods of attaching different types of small molecules with reactive handles (anhydride, amino, hydroxyl, carboxyl, thiol, and epoxy) to an aminated magnetofluorescent nanoparticle (amino-CLIO-FITC (*9*)). Although a variety of antibodies and proteins have been conjugated to this nanoparticle, small molecules of nonbiological origin were employed to avoid cost and regulatory issues if a member of the library is subsequently selected for scale-up and clinical use. Small molecules (<2 kDa) can also be separated from the nanoparticle (∼1000 kDa) easily. For each of the chemistries, a method of ensuring that modified particles have been produced is provided. This is particularly important when large numbers of surface-functionalized nanoparticles are made and screened for activity, since an unsuccessful nanoparticle modification cannot be readily distinguished from successful nanoparticle modification with inactivity due to a lack of recognition by a biomolecule. The presence of these types of errors in a database can thus lead to erroneous conclusions regarding structure activity relationships and the misdesign of subsequent libraries. We also show how modified nanoparticles can be used for library screens, analyte sensing, and microarray printing.

EXPERIMENTAL PROCEDURES

Materials. 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), sulfosuccinimidyl ester (sulfo-NHS), and Tris(2-carboxyethyl)phosphine hydrochloride (TCEP) were purchased from Pierce. *N*-Succinimidyl 3-(2-pyridyldithio) propionate (SPDP) and succinimidyl iodo acetate (SIA) were purchased from Molecular Biosciences. All other chemicals were purchased from Sigma Aldrich and used as received.

Magnetic Nanoparticle. The superparamagnetic nanoparticle used in this study consisted of an iron oxide core (5 nm diameter, 2064 Fe per average nanoparticle) with a thick shell of dextran (*10*). Amino-CLIO nanoparticles were synthesized by cross-linking the dextran coating with epichlorohydrin and reacting it with ammonia to provide primary amine groups (*11*). The number of amines per nanoparticle was determined using the SPDP method described previously (*12*). To attach FITC to amino-CLIO, a 2.0 mL DMSO fluorescein isothiocyanate (FITC, 5.0 mg, 12.8 mol) solution, 10 mL of amino-CLIO (10 mg/mL Fe) in 0.01 M sodium citrate buffer, pH 8.0 was added. Subsequently 100 μL of *N*,*N*-diisopropylethylamine (0.57 mmol) was added as catalyst. The mixture was incubated at room temperature overnight, and unreacted FITC was separated by gel filtration (Sephadex G-25), equilibrated, and eluted with PBS buffer, pH 7.4 (Cambrex, Rockland, ME). The number of FITC conjugated to CLIO was determined spectrophotometrically (extinction coefficient of 73 000 M^{-1} cm^{-1} at 494 nm). All batch syntheses were characterized by determining size by laser light scattering (38 nm), magnetic relaxivities (R1 of 21 mM s^{-1}, an R2 of 62 mM s^{-1}), magnetic susceptibility, and number of amines (n = 62 per 2000 Fe) and FITC (n = 2) conjugated.

Surface Modification of Nanoparticles. *Modification by Anhydrides.* To a 100 μL anhydride (50 mM, 5 μmol) DMSO solution, 200 μL of amino-CLIO (5.0 mgFe /mL, 0.4 μmol of amine) in 0.1 M bicarbonate buffer, pH 8.5 was added. The mixture was incubated at room temperature for 2 h with gentle shaking. Unreacted anhydride was separated with Sephadex G-25 column and eluted with PBS buffer, pH 7.4.

Modification by Amine Groups. We first converted amine groups on amino-CLIO to carboxyl groups by reaction with succinic anhydride at the conditions described above for the anhydride/CLIO surface modification. After purification of the sample, carboxylated CLIO was stored in MES buffer (50 mM MES, 0.1 M NaCl), pH 6.0 at a concentration of 5.0 mg/mL Fe. To react with amine molecules, a 200 μL COOH-CLIO solution was first reacted with EDC (0.96 mg, 5 μmol) and sulfo-NHS (1.1 mg, 5 μmol) at room temperature for 60 min. The mixture was then purified through Sephadex G-25 column eluted with PBS buffer, pH 7.4. Subsequently 100 μL of amine

Published on Web 12/30/2005

compound in DMSO (50 mM) was added to the above CLIO solution and reacted for 2 h at room temperature. Unreacted amines were separated by a Sephadex G-25 column eluted with PBS buffer, pH 7.4.

Modification by Hydroxyl Groups. Amino groups on the amino-CLIO nanoparticle were first converted to hydroxyl groups by reaction with SIA. Two milligrams of amino-CLIO was reacted with SIA (1.0 mg, 3.5 μmol) in PBS buffer, pH 7.4. The mixture was incubated at room temperature for overnight to allow displacement of iodine by hydroxyl groups. Hydroxylated CLIO was purified by a Sephadex 25 column eluted with PBS buffer, pH 7.4. Purified OH-CLIO was subsequently precipitated and washed with cold acetone for several times. One milligram of precipitated OH-CLIO was resuspended in 200 μL of anhydrous DMSO and activated by $SOCl_2$ (5 μL, 68.5 μmol). After 5 min reaction at room temperature, a drop of H_2O was added to decompose the excess $SOCl_2$. Subsequently, 200 μL of alcohol (50 mM) in DMSO was added with *N*,*N*-diisopropylethylamine (10 μL, 50 μmol) as catalyst. The mixture was incubated at room temperature for 3 h, and hydroxylated CLIO conjugates were purified by a Sephadex G-25 column eluted with PBS buffer, pH 7.4.

Modification by Carboxyl Groups. Amino-CLIO in PBS buffer, pH 7.4 was first exchanged with MES buffer (50 mM MES hydrate, 0.1 M NaCl), pH 6.0, and the solution was concentrated to 5.0 mg/mL. 100 μL (50 mM) of carboxylic compound in DMSO was added to 200 μL of amino-CLIO (5.0 mg/mL Fe) in MES solution, pH 6.0. This was followed by the addition of excess EDC (0.96 mg, 5 μmol) and sulfo-NHS (1.1 mg, 5 μmol) in 100 μL of DMSO. The reaction proceeded at room temperature for 2 h, and the product was purified by a Sephadex G-25 column and eluted with PBS buffer, pH 7.4.

Modification by Thiols. Amino-CLIO was first reacted with SPDP.[7] After purification of the sample, 200 μL of SPDP derived CLIO (5.0 mg/mL Fe) in PBS buffer, pH 7.4 was mixed with 100 μL of thiol compounds (50 mM) in DMSO. The reaction proceeded for 2 h at room temperature. The CLIO conjugate was separated by a Sephadex G-25 column and eluted with PBS buffer, pH 7.4. For the MRS assays, thiolated influenza hemagglutinin (HA) peptide with a cysteine terminus (YPYDVPDVAGGC) was synthesized by using Fmoc chemistry on Rink amide resin (Calbiochem, NovaBiochem) and was purified by reverse phase HPLC. The molecular weight of HA was confirmed by MALDI-TOF.

Modification by Epoxide Groups. Amino-CLIO in PBS buffer, pH 7.4 was first exchanged to a 0.15 M sodium bicarbonate buffer, pH 8.5, and the solution was concentrated to 5.0 mg/mL. To 200 μL above solution, 100 μL (50 mM) of epoxide compound in DMSO was added. The reaction proceeded at 80 °C for 4 h, and the product was purified by a Sephadex G-25 column and eluted with PBS buffer, pH 7.4.

Surface Characterization. *Surface Modification by Amine Loss.* The loss of amines on anhydrides or carboxyl reacted amino-CLIO was determined using with SPDP as reagent (*12*). SPDP is preferred as a reagent for amine group analysis over more conventional amine assay methods because after treatment with dithiothreitol the pyridine-2-thione (P2T) can be separated from iron based on size. Iron absorbs strongly in the ultraviolet region, a feature that interferes with many amine determining reagents. After reaction with SPDP, the nanoparticle is treated with a reducing agent (TCEP) and the released P2T separated from the nanoparticle by a spin column. P2T absorption can now be determined without the strong nanoparticle absorption at the wavelength of the P2T (343 nm). In a typical experiment, 150 μL of 50 mM SPDP solution in DMSO was added to 50 μL (2 mg Fe) of CLIO in PBS, pH 7.4. The mixture was allowed to react at room temperature for 1 h and purified by Sephadex 25 column. This solution was subsequently added with 50 μL of TCEP (Pierce) and UV-Vis absorption was read at 343 nm. The number of amines was calculated based on an extinction coefficient of 8080 M^{-1} cm^{-1} for P2T.

Magnetic Relaxation Switch Assay. The bioactivity of surface-modified CLIO nanoparticles was examined by their interaction with their corresponding binding molecules, a process that can be monitored by the change in the proton spin−spin relaxation time (T2) (*4*). When nanoparticles bind to their corresponding binding proteins, nanoscale aggregation occurs and the T2 decreases (Figure 2). Control samples were prepared with unmodified nanoparticles. Surface-modified nanoparticles at 10 μg/mL iron in PBS buffer, pH 7.4 were mixed with their binding protein at concentrations, which induced maximal T2 changes determined on a minispec MR spectrometer. Imaging was performed after a 30 min incubation of surface-modified nanoparticles with their corresponding binding proteins at 37 °C. T2 was measured by NMR imaging acquired in a 49 well plate using a 4.7 T superconducting magnet (Brucker, Karlsruhe, Germany). Imaging sequences included multi-echo T2-weighted spin−echo sequences with echo times (TE) ranging from 20−160 ms in increments of 20 ms and a repetition time (TR) of 2000 ms.

Array Printing and Imaging. Two strategies were used to print modified nanoparticles to glass slides. The first method utilized epoxy-modified glass slides. In this method, CLIO compounds were dissolved in 0.1 M carbonate buffer, pH 9.6 at a concentration of 0.1 mg/mL Fe. Each compound was spotted on epoxy glass slides in quadruplicate using a 0.5 μL pipet. Spotted slides were incubated at 80 °C in a humid chamber for 30 min. The alternative method used carboxylated glass slides, which were first activated with EDC and NHS in MES buffer (50 mM MES, pH 6.0) for 30 min followed by drying. Nanoparticles in 0.1 M bicarbonate buffer, pH 8.5 were spotted in quadruplicate using a 0.5 μL pipet. Spotted slides were allowed to dry under inert gas and stored at 4 °C for further use.

To reveal the binding of corresponding proteins to modified nanoparticles, slides were first washed for 2 h with DMF, and 1 h each with 2-propanol and PBS buffer (pH 7.4, containing 0.1% Tween-20). The slides were then blocked for 1 h by incubation with 0.1 M carbonate buffer containing 3% BSA, pH 8.5. After a brief rinse with PBS, fluorescently labeled target proteins (streptavidin-rhodamine, anti-IgG-Cy5.5) were then added at a concentration of 0.1 mg/mL in PBS supplemented with 1% BSA. The slides were incubated for 30 min and then washed 10 times with PBS. The slides were then dried at ambient temperature and imaged with a fluorescence imager. The following filter sets were employed: 680/700 nm excitation/emission filter set (2 s exposure); 560/590 nm excitation/emission filter set (1 s exposure).

Cell Uptake Experiments. U937 cells were obtained from the American Type Tissue Culture Collection (ATCC) and maintained according to ATTCC protocol. For differentiation into macrophages, the nonadherent monocyte-like undifferentiated U937 cells were induced to differentiate by a 48-h exposure to 40 nM PMA (Sigma). After addition of PMA, cells were plated onto gelatin-coated 96-well tissue culture plates. Cells were incubated with 0.1 mg/mL Fe of the indicated CLIO derivatives for 4 h at 37 °C in the presence of 5% CO_2. Following incubation, wells were washed 3× with PBS/0.1%BSA/0.05%Tween-20 wash buffer to remove any surface-bound materials. Cells were then analyzed via an immunoassay to quantitate FITC concentrations (*13*). All experiments were performed in triplicate. For each screening experiment, the uptake of FITC (pM) was log10 transformed, and the mean was determined for each cell line.

Table 1. Summary of Surface Modification

type	reagents	examples	binder	modification[a]	MRSW[b]
anhydride	direct	1,8-naphthalic anhydride	lysozyme	24	23 ms
amine	EDC, NHS	D-glucosamine	concavalin A	36	69 ms
alcohol	SIA, $SOCl_2$	digoxigenin	MAB to dig	30	65 ms
acid	EDC, NHS	folic acid	MAB to folate	32	63 ms
thiol	SPDP	HA peptide	MAB to HA	34	81 ms
epoxide	direct	glycidoxypropyltrimethoxy silane	glass slide	40	NA

[a] Refers to average number of small molecule bound per nanoparticle as determined analytically and assuming an average core of 2,064 Fe/nanoparticle. [b] T2 were measured in PBS buffer, pH 7.4, 37 °C, 0.47 T at an iron concentration of 10 μg/mL. Data are expressed as change in T2 relaxation times.

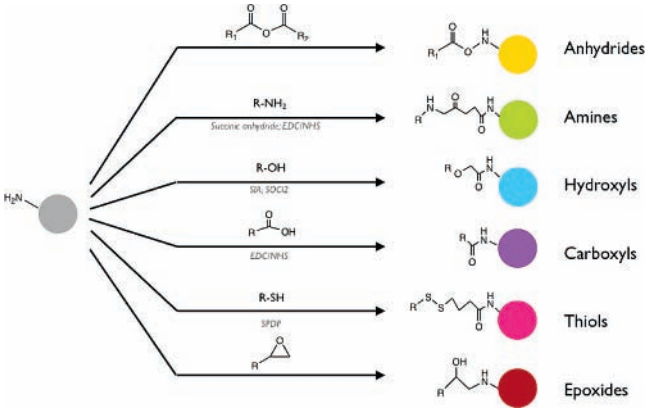

Figure 1. Conjugation strategies. Aminated magnetofluorescent nanoparticles (amino-CLIO-FITC) were reacted with small molecules with different reactivities. Reactions were analyzed by determining loss of amines[12] and the magnetic relaxation switch assay (see Figure 2).

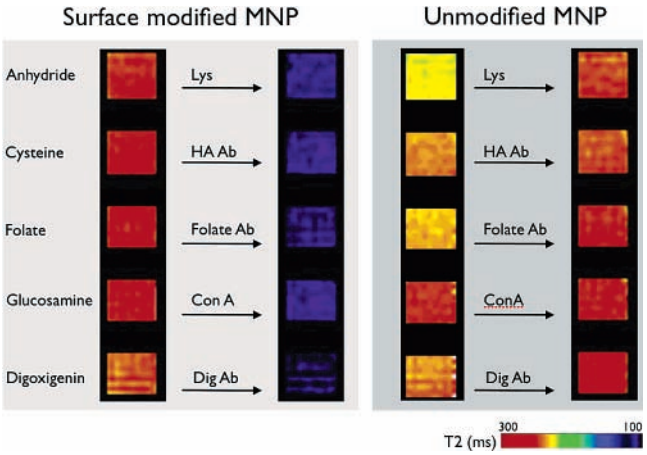

Figure 2. MRS assay confirms bioactivity of derivatized nanoparticles. Nanoparticle preparations modified according to Table 1 (left) or unmodified (right) were incubated with their corresponding binding protein that induces nanoparticle clustering and thus T2 decreases. It is clearly shown that T2 decreases dramatically when modified nanoparticles react with corresponding binding proteins (second column), while nonmodified nanoparticles did not show any visible binding interactions (third and fourth columns).

RESULTS AND DISCUSSION

The first step toward creation of libraries was to optimize the conjugation of six types of small molecules with "reactive handles" to a magnetofluorescent nanoparticle: anhydrides, amines, hydroxyls, carboxyls, thiols, and epoxides (Figure 1). The starting material consisted of a cross-linked dextran coated aminated magnetic nanoparticle of 38-nm diameter that had been reacted with two molecules of FITC (*9*). Each nanoparticle contained 62 amines and a magnetic core containing 2064 Fe per nanoparticle (*14*). For the specific task at hand, we chose representative examples of each class of small molecules to optimize conjugation protocols. The representative examples included diglycolic anhydride, glucosamine, digoxigenin, folic acid, cystein-containing HA peptide, and glycidoxypropyltrimethoxy silane. These specific molecules were chosen because each has a corresponding binding protein, which can be used to examine the bioactivity of the surface-functionalized nanoparticle.

The conjugation of anhydride molecules to amino CLIO was performed in bicarbonate buffer at pH 8.6. Higher pH facilitates the reaction of anhydride group and amino group on CLIO. There were an average of 24 modified amines per nanoparticle. To efficiently attach amine groups to amino-CLIO, we first converted primary amines on the nanoparticle to carboxylic groups. Subsequently, EDC and sulfo-NHS were used to conjugate carboxylate CLIO to amine compounds. To link hydroxyl groups to CLIO, we first treated amino CLIO with succimidyl iodoacetate (SIA). Hydrolysis of SIA-treated CLIO resulted in the conversion of amine groups on CLIO to hydroxyl groups. Hydroxylated CLIO was first precipitated by cold acetone and then resuspended in anhydrous DMSO. Subsequently, $SOCl_2$ was added to activate hydroxyl groups. Excess $SOCl_2$ was decomposed by a small amount of water. The alcohol molecules were added to chlorinated CLIO with the addition of a small quantity of NaOH as catalyst. With respect to carboxyl conjugation, we compared several conjugation methods and found that EDC conjugation was the most efficient. In this

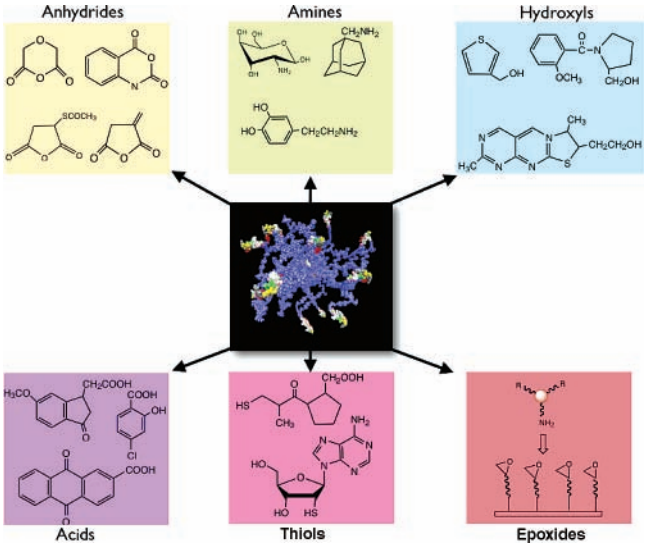

Figure 3. Nanoparticle library. Examples of small molecules attached to amino-CLIO to create a 96-member library (to fill one microtiter plate) that was subsequently used (see Figures 4 and 5).

reaction, the carboxylic molecule (in DMSO) was first activated by EDC in MES buffer, and the reaction to amino-CLIO was accomplished in room temperature in 3 h. Unreacted molecules were separated by a PD-10 column eluted with PBS buffer, pH 7.4. For the reaction of thiol molecules, CLIO was first activated with SPDP, and subsequently thiol molecules were conjugated. Attachment to epoxides was performed in 0.15 M sodium bicarbonate buffer, pH 8.5 by adding epoxides in DMSO. Reaction proceeded for 4 h, and the product was purified by Sephadex G-25 column chromatography.

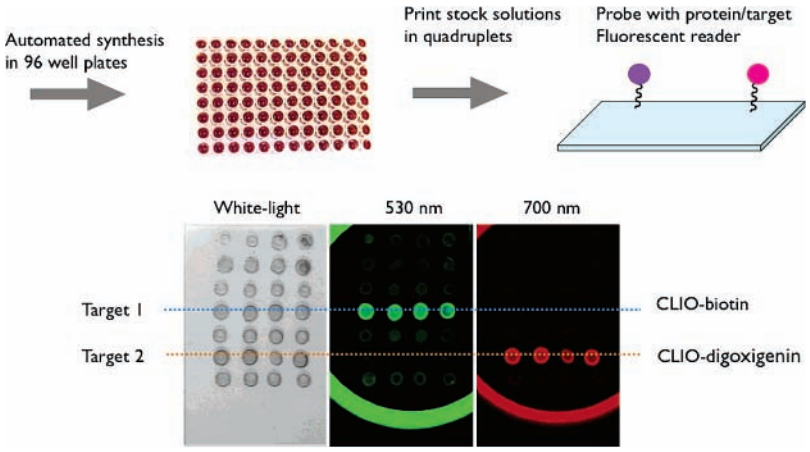

Figure 4. Microarray feasibility experiments. Surface-functionalized nanoparticles of different types were printed onto epoxy glass slides and then washed. Fourth row from top: CLIO-biotin; sixth row from top: CLIO-digoxigenin; remaining rows contained unmodified nanoparticles. Slides were incubated with a mixture of the binding proteins, streptavidin-rhodamine, and anti-digoxigenin, revealed by anti-IgG-Cy5.5, and scanned using a fluorescent reader. Note that the targets are clearly separated in the different channels. All experiments were performed in quadruplicate.

Surface modification of nanoparticles was monitored by two different assays, specifically developed for MFNP: (a) an assay for the modification of amines (amine loss) using SPDP as a reagent (*12*) and (b) a magnetic relaxation switch assay to demonstrate that both surface modification and the activity of the surface with a biological molecule (*4*). The strong absorption from iron oxide between 250 and 450 nm, nanoparticle superparamagnetism, and the presence of both the oxidizing ferrous ion and reducing ferric ions, mean that the nanoparticle interferes with many analytical methods that work well with other materials. The use of SPDP for amine determination permits separation of P2T, released from the nanoparticle with a reducing agent, from iron before quantitation. Second, biomolecules when attached to surfaces can interact with the surface and lose bioactivity (surface denaturation). On average, small molecule modification resulted in the attachment of 20−40 functional groups per nanoparticle. Table 1 summarizes the overall chemical conjugation and characterization conditions. The magnetic relaxation switch assay (MRS) was used to verify the bioactivity of a surface-functionalized CLIO made with each of the conjugation chemistries. This assay is based on the fact that water proton spin−spin relaxation time (T2) are altered upon self-assembly when surface-functionalized CLIO nanoparticles react with a biomolecule in solution (*4*, *15*−*17*). As can be seen from Figure 2, each representative example of a surface-modified nanoparticle showed a significant decrease in T2 relaxation time, whereas unmodified nanoparticles did not. Thus, each of the surface modification reactions employed was capable of producing a bioactive surface.

We next set out to develop a larger diverse library set based on the optimized conjugation strategies discussed above. Figure 3 lists some of the representative examples of each of the classes of small molecules bound to the nanoparticle. Overall, we created a nanoparticle library consisting of 96 compounds (Figure 4). This library was used to perform two different sets of biological experiments: (a) microarray screen after compounds were printed on glass slides and (b) fluid-phase experiments to determine nanoparticle uptake into macrophages (Figure 5). We first wished to determine if the nanoparticles could be printed onto glass slides to ultimately allow high-throughput screening against purified target proteins. We experimented with two different conjugation schemes: attachment of nanoparticles to epoxide-coated glass slides and to carboxylated glass slides. Either method resulted in visible attachment of nanoparticles to the glass surface, both by pipet spotting (Figure 4) as well as a by pin-printing. To determine whether functionalized nanoparticles would retain the ability

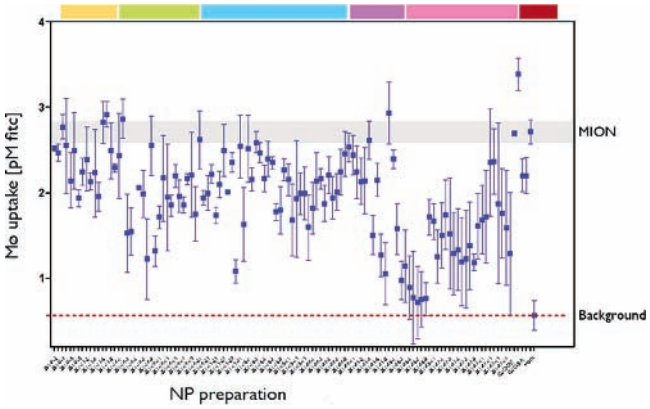

Figure 5. Screening of nanoparticle library in macrophages. Small molecule modified nanoparticle preparations were incubated with U937 macrophages, and cellular uptake was determined by a FITC-mediated immuno ELISA assay.[13] Note the variability in uptake upon small molecule modification compared to base material (MION).

to interact with binding proteins, we tested biotinylated and digoxigenated nanoparticles against fluorescent streptavidin-Cy3 and anti-digoxigenin-Cy5.5, respectively. As is shown in Figure 4, there was good distinction between the signals from the different fluorochromes.

We and others have previously shown that macrophages represent a prime target for systemically injected nanomaterials (*2*, *18*). To develop functionalized nanomaterials targeted to other cell types, it would therefore be desirable to minimize macrophage uptake of the parent compound. We therefore performed a cell-based screen of all synthesized nanoparticle preparations and compared binding/uptake to preparations currently in clinical use (MION-like dextran-coated compounds). As is apparent in Figure 5, several nanoparticle preparations had lower macrophage uptake than starting materials. More in-depth screens in primary human isolated macrophages are currently ongoing to identify novel nanomaterials with limited a priori macrophage affinity.

In conclusion, we have developed a series of highly general methods to modify the surface of magnetofluorescent nanoparticles with small molecules and demonstrated that these nanoparticles achieve specific interactions with protein targets. Analytical methods have been developed to ensure that the desired surface modification of nanoparticles has occurred, and magnetic relaxation switch assays have been used to demonstrate bioactivity, as the reaction of surface-modified nanoparticles with their corresponding binding protein. All materials used for

the modification of nanoparticles were low molecular weight and of nonbiological origin. The current approach has the potential to generate a larger and more diverse library of functional nanomaterials toward numerous biological targets. Moreover, these methods are readily adapted to automated synthesis and suitable for high-throughout screening of the interaction of surface-modified nanoparticles with specific types of cells or molecular targets.

ACKNOWLEDGMENT

The authors would like to acknowledge the help of Dr. Sergeyev for synthesizing CLIO. We also thank Rabi Upadhyay and Sarah Rhee for technical assistance with imaging. Part of this research was supported by P50 CA86355, P01 CA69246, R24 CA92782 and a grant from the Reynolds Foundation.

Enhanced Activity of Monomethylauristatin F through Monoclonal Antibody Delivery: Effects of Linker Technology on Efficacy and Toxicity

Svetlana O. Doronina,* Brian A. Mendelsohn, Tim D. Bovee, Charles G. Cerveny, Stephen C. Alley, Damon L. Meyer, Ezogelin Oflazoglu, Brian E. Toki, Russell J. Sanderson, Roger F. Zabinski, Alan F. Wahl, and Peter D. Senter

Seattle Genetics, Inc., 21823 30th Drive SE, Bothell, Washington 98021. Received October 4, 2005; Revised Manuscript Received October 19, 2005

We have previously shown that antibody−drug conjugates (ADCs) consisting of cAC10 (anti-CD30) linked to the antimitotic agent monomethylauristatin E (MMAE) lead to potent in vitro and in vivo activities against antigen positive tumor models. MMAF is a new antimitotic auristatin derivative with a charged C-terminal phenylalanine residue that attenuates its cytotoxic activity compared to its uncharged counterpart, MMAE, most likely due to impaired intracellular access. In vitro cytotoxicity studies indicated that mAb−maleimidocaproyl-valine-citrulline-*p*-aminobenzyloxycarbonyl−MMAF (mAb−L1−MMAF) conjugates were >2200-fold more potent than free MMAF on a large panel of CD30 positive hematologic cell lines. As with cAC10−L1−MMAE, the corresponding MMAF ADC induced cures and regressions of established xenograft tumors at well tolerated doses. To further optimize the ADC, several new linkers were generated in which various components within the L1 linker were either altered or deleted. One of the most promising linkers contained a noncleavable maleimidocaproyl (L4) spacer between the drug and the mAb. cAC10−L4−MMAF was approximately as potent in vitro as cAC10−L1−MMAF against a large panel of cell lines and was equally potent in vivo. Importantly, cAC10−L4−MMAF was tolerated at >3 times the MTD of cAC10−L1−MMAF. LCMS studies indicated that drug released from cAC10−L4−MMAF was the cysteine−L4−MMAF adduct, which likely arises from mAb degradation within the lysosomes of target cells. This new linker technology appears to be ideally suited for drugs that are both relatively cell-impermeable and tolerant of substitution with amino acids. Thus, alterations of the linker have pronounced impacts on toxicity and lead to new ADCs with greatly improved therapeutic indices.

INTRODUCTION

In recent years, the impact that monoclonal antibodies (mAbs)[1] have had in the clinical treatment of cancer has been pronounced. There are now several approved therapeutic antibodies, including trastuzumab (Herceptin), rituximab (Rituxan), cetuximab (Erbitux), and bevacizumab (Avastin), and many others are in late-stage development (reviewed in refs 1, 2). While these agents display significant activities through such mechanisms as antibody-dependent cellular cytotoxicity, complement-dependent cytotoxicity, and signal transduction, the activities are generally suboptimal, even when combined with conventional cancer chemotherapeutic agents. Consequently, significant attention has turned toward the use of mAb-based immunoconjugates, in which the mAb carries a toxic payload to tumor cells (reviewed in refs 3, 4). Three such agents are now clinically approved: ibritumomab tiuxetan (Zevalin), a ^{90}Y labeled anti-CD20 mAb; tositumomab (Bexxar), an ^{131}I labeled anti-CD20 mAb; and gemtuzumab ozogamicin (Mylotarg), an anti-CD33−calicheamicin conjugate. The activities of these conjugated mAbs provide validation for the concept, and a basis for developing other such agents for cancer therapy.

The goal of targeted therapy with mAb−drug conjugates is to achieve high degrees of therapeutic activity, while sparing normal tissues from chemotherapeutic damage. Toward this end, several critical parameters have been identified that must be addressed. These include the barriers to mAb extravasation, conjugate immunogenicity, widespread expression of the target antigen on normal tissue, metabolism at nontarget sites, low drug potency, and efficient release of the drug in forms that do not impair activity (*3*−*6*). Consequently, the focus in many laboratories has been to use chimeric or humanized mAbs against highly selective tumor-associated antigens, attached to potent drugs through linkers that allow for efficient drug release once the antibody−drug conjugate (ADC) has bound to the target and has undergone internalization. Examples of some advanced agents include C242-DM1 (cantuzumab mertansine), an anticarcinoma mAb linked to a derivative of maytansine (*7*), MLN2704, an anti-prostate cancer mAb attached to maytansine (*5*), and an anti-CD22−calicheamicin conjugate for the treatment of B-cell lymphomas (*8*).

In developing highly active agents that address the issues described for targeted therapy, we have focused considerable attention on the drug payload, the linker used for drug attachment, and the method by which the antibody is modified. This has led to the development of mAb−auristatin conjugates

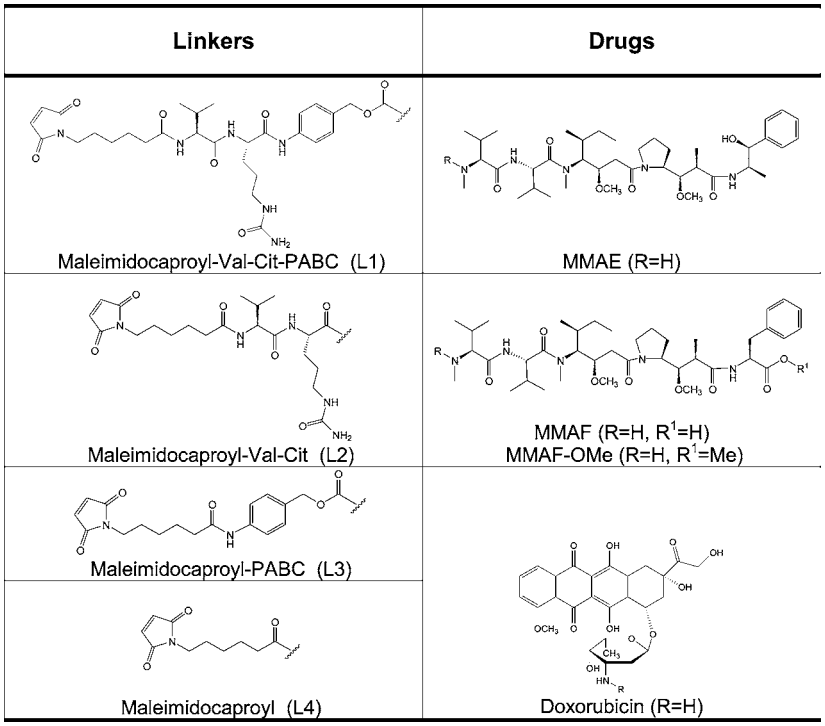

Figure 1. Structures of drugs and linkers.

that include a highly potent and totally synthetic drug attached to mAb cysteine residues through a proteolytically cleavable linker (*3, 6, 9*−*12*). The most advanced agent that we have described (*12*−*15*) is cAC10−maleimidocaproyl-valine-citrulline-*p*-aminobenzyloxycarbonyl-monomethylauristatin E (cAC10−maleimidocaproyl-Val-Cit-PABC−MMAE, or cAC10−L1−MMAE, shown in Figure 1). This is comprised of the highly potent antimitotic agent MMAE, attached to mAb−cysteines through the L1 linker that is cleaved by intracellular proteases such as cathepsin B. The optimal number of drugs/mAb was found to be four (*14*), where pronounced activities at well tolerated doses were obtained in CD30 positive hematologic malignancies.

Here, we describe the properties of a new auristatin, MMAF, that was designed to be much more active when actively delivered inside cells with a mAb, compared to treatment in the untargeted form. We viewed such an approach to targeted delivery as advantageous compared to that of drugs that have high potency in the untargeted form, since any drug that is systemically released would not be expected to contribute to toxic side-effects. Several linker technologies were evaluated to optimize the delivery of MMAF to target cells. In this report, we demonstrate that targeted MMAF is much more potent than the free drug, and that cAC10 conjugates of MMAF display pronounced activities, both in vitro and in vivo. In addition, conjugates of MMAF circumvent a common form of multidrug resistance (MDR). The development of this drug, together with the biological activities of ADCs derived from it, are described for the first time.

EXPERIMENTAL PROCEDURES

General. Unless otherwise noted, materials were obtained from commercial suppliers in the highest purity grade available and used without further purifications. Anhydrous DMF and CH_2Cl_2 were purchased from Aldrich. *N*-Fmoc-L-[ring-$^{13}C_6$]-Phenylalanine was obtained from Cambridge Isotope Laboratories, Inc. (Andover, MA). 2-Chlorotrityl chloride resin was purchased from Advanced ChemTech and loaded with *N*-Fmoc-L-[ring-$^{13}C_6$]-phenylalanine according to manufacturer's specifications. Phenylalanine-2-chlorotrityl resin was purchased from Novabiochem. Phenylalanine loading level of the resin was determined (0.55 mmol/gram) by extensive acylation with Fmoc-Cl followed by spectrophotometric Fmoc-quantitation assay. Solid-phase synthesis was performed in plastic syringes (National Scientific Company) fitted with a filter cut out of fritware PE medium grade porous sheet (Scienceware). Burrell wrist action shaker (Burrell Scientific, Pittsburgh, PA) was used for agitation. All solid-phase yields reported are based upon the initial phenylalanine substitution level of the resin and constitute a mass balance of isolated pure material from support, unless otherwise stated. Fmoc-Dap was custom synthesized by Albany Molecular Research, Inc. (Albany, NY).

HPLC assays were performed using C12 Phenomenex Synergy MAX-RP 4μ, 80 Å reversed-phase column, 150 × 2.0 mm. The eluent was a linear gradient of acetonitrile from 5% to 95% in 5 mM aqueous ammonium phosphate, pH 7.0, in 10 min, then 95% acetonitrile for 10 min, flow rate 1 mL/min, 215 nm detection. Preparative HPLC purifications were performed on Varian instrument equipped with C12 Phenomenex Synergy MAX-RP 4μ reversed phase column, 250 × 21.2 mm, eluting with 0.1% TFA in a water−acetonitrile gradient. Flash chromatography was carried out using Whatman 60 Å 230−400 mesh ASTM silica gel.

Low resolution mass spectra (LCMS) were recorded on a ZMD-Micromass Single Quadrupole Mass Spectrometer equipped with an electrospray ion source (45 eV) coupled with HP1100 HPLC system (reverse phase C12 Phenomenex column, 4 μ, 100 Å, 150 × 2.0 mm. The eluent was a linear gradient of acetonitrile from 5% to 95% in water in the presence of 0.1% formic acid in 10 min, then 95% acetonitrile for 5 min, flow rate 400 μL/min). High resolution (exact mass, HRMS) electrospray ionization (ESI) data were obtained at the University of Washington Medicinal Chemistry Mass Spectrometry Center on a Bruker APEXIII 47e [FT(ICR)]MS. NMR data were recorded on Varian Mercury 400 MHz Instrument. Chemical shifts (δ) are reported in ppm downfield from an internal solvent peak, and *J* values are in hertz.

The chimeric IgG_1 cAC10 (*16*) and cBR96 (*17*) mAbs recognize the CD30 and Lewis Y antigens, respectively. The human lymphoma cell lines Karpas 299, SUP-M2, SU-DHL-1, SR-786, DEL, HDLM-2, L428, KMH-2, and WSU-NHL were obtained from the DSMZ (Braunschweig, Germany). 786-O and Caki-1 renal cell carcinoma and HH lymphoma cell lines were purchased from the ATCC (Manassas, VA). H3396 breast carcinoma cells were obtained as described earlier (*16*). The parent/drug resistant cell line pair NCI-H69, NCI-H69/LX4 were obtained from the ECACC (Salisbury, England), and the Hodgkin's disease cell line L540cy has been previously described (*18*). All cell lines were grown according to the manufacturers' recommendations and routinely checked for mycoplasma contamination.

Maleimidocaproyl−MMAE (L4−MMAE). To a solution of MMAE (*12*) (72 mg, 0.1 mmol) in anhydrous CH_2Cl_2 (2 mL) 6-maleimidocaproic acid (30 mg, 0.15 mmol, 1.5 equiv) was added followed by DEPC (36 μL, 0.2 mmol, 2 equiv) and DIEA (55 μL, 0.3 mmol, 3 equiv). The reaction mixture was stirred at room temperature for 2 h. CH_2Cl_2 (30 mL) was added, and the mixture was washed with 10% aqueous citric acid (2 × 20 mL), water (20 mL), and brine (20 mL) and concentrated to near dryness. Product was isolated by flash chromatography on silica gel eluting with 5% MeOH in CH_2Cl_2 to give a white solid, 32 mg (35%). Reversed-phase HPLC analysis: 98% at 9.48 min. ^{1}H NMR (DMSO-d_6): δ 0.70−0.89 (18H, m), 0.95−1.05 (6H, m), 1.19−1.34 (m), 1.44−1.55 (m), 1.66−1.84 (m), 1.88−2.02 (m), 2.06−2.16 (m), 2.22−2.46 (m), 2.81 (s), 2.86 (s), 2.90 (s), 2.93 (s), 2.97 (d), 3.01−3.08 (m), 3.12 (d), 3.17 (d), 3.20 (d), 3.23 (dd), 3.35−3.40 (m), 3.42−3.50 (m), 3.52−3.59 (m), 3.77 (d), 3.93−4.04 (m), 4.37−4.54 (m), 4.59−4.64 (m), 4.70−4.78 (m), 5.36 (d), 5.43 (d), 7.01−7.02 (2H, m), 7.14−7.31 (5H, m), 7.65 (d), 7.74 (d), 7.78 (d), 7.89−7.92 (m), 8.56−8.61 (m). HRMS (ESI) calcd for $C_{49}H_{79}N_6O_{10}$ $(MH)^+$ 911.5858; found, *m*/*z* 911.5839.

Fmoc-MMAF-OMe. Fmoc-MeVal-Val-Dil (*12*) (0.50 g, 0.78 mmol) and Dap-Phe-OMe·HCl (*12*) (0.30 g, 0.78 mmol) were dissolved in CH_2Cl_2 (5 mL) followed by the addition of DIEA (0.30 mL, 1.71 mmol, 2.2 equiv). DEPC (0.20 mL, 1.17 mmol, 1.5 equiv) was added next while the contents stirred under Ar. Reaction was complete according to HPLC analysis after 1 h. The mixture was concentrated and purified on silica gel eluting with a step gradient of ethyl acetate (from 50% to 100%) in hexane to provide a white foam, 0.65 g (87%). Reversed-phase HPLC analysis: 95% at 16.2 min. ^{1}H NMR (DMSO-d_6): δ 0.71−0.95 (20H, m), 1.01−1.07 (3H, dd), 1.22−1.30 (m), 1.34−1.52 (m), 1.60−1.83 (m), 1.92−2.11 (m), 2.16−2.28 (2H, m), 2.31−2.42 (m), 2.79−2.89 (m), 2.96−3.07 (m), 3.15−3.16 (m), 3.19 (s), 3.24 (s), 3.29 (d), 3.42−3.55 (m), 3.63 (1.5H, s), 3.66 (1.5H, s), 3.75 (0.5H, d), 3.96 (1H, m), 4.09−4.11 (m), 4.21−4.51 (m), 4.61−4.74 (m), 7.15−7.23 (5H, m), 7.31 (2H, t), 7.41 (3H, t), 7.62 (2H, d), 7.89 (2H, d), 8.05 (0.5H, d), 8.11 (0.5H, d), 8.29 (0.5H, d), 8.51 (0.5H, d). LCMS (ESI): *m*/*z* 968.35 $(MH)^+$ (eluted at 14.84 min).

MMAF-OMe. Fmoc-MMAF-OMe (140 mg, 0.14 mmol) in CH_2Cl_2 (5 mL) was treated with diethylamine (2 mL). After 2 h, the reaction was concentrated and purified by preparative HPLC to give a TFA salt of MMAF-OMe as a white solid, 126 mg (98%). Reversed-phase HPLC analysis: 94% at 11.25 min.^{1}H NMR (DMSO-d_6): δ 0.77 (3H, m), 0.87−1.07 (19H, m), 1.22−1.32 (m), 1.37−1.52 (m), 1.60−1.88 (m), 1.96−2.12 (m), 2.18−2.29 (m), 2.32−2.54 (m), 2.83−2.90 (m), 2.99 (s), 3.07 (s), 3.16−3.20 (m), 3.26 (s), 3.42−3.58 (m), 3.64 (s), 3.66 (s), 3.75 (d), 3.98 (m), 4.43−4.52 (m), 4.55−4.76 (m), 7.17−7.58 (5H, m), 8.30 (0.5H, d), 8.56 (0.5H, d), 8.83−8.93 (3H, m). HRMS (ESI) calcd for $C_{40}H_{68}N_5O_8$ $(MH)^+$ 746.5068; found, *m*/*z* 746.5037.

Maleimidocaproyl-Val-Cit-PABC−MMAF-OMe (L1−MMAF-OMe). MMAF-OMe·TFA (110 mg, 0.13 mmol, 1.0 equiv), maleimidocaproyl-Val-Cit-PAB-OCO-pNP (*10*) (103 mg, 0.14 mmol, 1.1 equiv), and 1-hydroxybenzotriazole (HOBt, 3.4 mg, 26 μmol, 0.2 equiv) were dissolved in pyridine (0.5 mL) and DMF (2 mL) under Ar. To this mixture was added DIEA (22.5 μL, 0.13 mmol, 1.0 equiv). The resulting solution stirred for 3 h before more DIEA (22.5 μL) was added. After stirring for 40 h total, the mixture was concentrated, taken up in DMSO (2 mL). Preparative HPLC purification followed by precipitation from CH_2Cl_2 (2 mL) with ether resulted in 90 mg (52%) of white solid. Reversed-phase HPLC analysis: 95% at 9.48 min. ^{1}H NMR (DMSO-d_6): δ 0.72−0.94 (28H, m), 1.02−1.06 (3H, dd), 1.14−1.52 (m), 1.54−1.82 (m), 1.90−2.38 (m), 2.28−2.46 (m), 2.85 (br s), 2.97 (s), 3.04 (s), 3.16 (s), 3.18 (s), 3.20 (s), 3.25 (s), 3.28−3.30 (m), 3.42−3.58 (m), 3.63 (s), 3.66 (s), 3.75 (d), 3.96 (m), 4.17−4.21 (m), 4.23−4.28 (m), 4.32−4.42 (m), 4.44−4.55 (m), 4.60−4.74 (m), 4.94−5.12 (m), 6.01 (1H, br s), 7.01 (2H, s), 7.18−7.32 (9H, m), 7.58 (2H, m), 7.81 (1H, d), 8.07−8.12 (1.5H, m), 8.29 (1H, m), 8.51 (0.5H, d), 10.0 (1H, d). HRMS (ESI) calcd for $C_{69}H_{106}N_{11}O_{16}$ $(MH)^+$ 1344.7819; found, *m*/*z* 1344.7776.

Maleimidocaproyl-PAB-OCO-pNP. To a suspension of 6-maleimidocaproic acid (1.0 g, 4.52 mmol) in CH_2Cl_2 (13.0 mL) was added *p*-aminobenzyl alcohol (PABOH, 1.11 g, 9.04 mmol, 2.0 equiv) and 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ, 2.24 g, 9.04 mmol, 2.0 equiv). The reaction mixture was stirred at ambient temperature for 16 h, and then concentrated to near dryness. The residue was purified by flash chromatography on silica gel, eluting with a step gradient from 25 to100% ethyl acetate in hexane, to give 1.38 g (96%) of maleimidocaproyl-PABOH as a white solid. Maleimidocaproyl-PABOH (0.85 g, 2.69 mmol) was then activated by reaction with bis *p*-nitrophenyl carbonate (2.45 g, 8.07 mmol, 3 equiv) and DIEA (0.94 mL, 5.38 mmol, 2 equiv) in DMF (10 mL). After 1 h, HPLC analysis indicated complete consumption of starting material. Solvent was removed under reduced pressure, and the residue was triturated with diethyl ether (5 × 20 mL) resulting in 1.25 g (96%) of an off white solid. Reversed-phase HPLC analysis: 99% at 9.98 min. ^{1}H NMR ($CDCl_3$): δ 1.37 (2H, m), 1.64 (2H, m), 1.77 (2H, m), 2.37 (2H, t, J = 7.6), 3.54 (2H, t, J = 7.2), 6.68 (2H, s), 7.37 (2H, d, J = 9.2), 7.41 (2H, d, J = 8.8), 7.57 (2H, d, J = 8.8), 8.27 (2H, d, J = 9.2).

MeVal-Val-Dil-Dap-Phe-2-chlorotrityl Resin. Fmoc-Dap (450 mg, 1.1 mmol) and HATU (418 mg, 1.1 mmol, 2 equiv) were dissolved in anhydrous DMF (8 mL), and DIEA (384 μL, 2.2 mmol, 4 equiv). The resulting solution was added to the 20 mL syringe containing Phe-2-chlorotrityl resin (1 g, 0.55 mmol). Mixture was agitated for 3 h. Reaction completion was determined by LCMS analysis of material cleaved off a small amount of resin. The resin was filtered, washed with DMF (6 × 10 mL), CH_2Cl_2 (6 × 10 mL), ethyl ether (6 × 10 mL), and dried in vacuo for 2 h. A 20% piperidine in DMF solution (5 mL) was added to the syringe, and the mixture was agitated for 2 h. The resin was then filtered, rinsed with DMF (6 × 10 mL), CH_2Cl_2 (6 × 10 mL), and ethyl ether (6 × 10 mL), and dried in vacuo. In a separate flask Fmoc-MeVal-Val-Dil tripeptide (*12*) (702 mg, 1.1 mmol) and HATU (418 mg, 1.1 mmol, 2 equiv) were dissolved in anhydrous DMF (8 mL) followed by the addition of DIEA (384 μL, 2.2 mmol, 4 equiv). The solution was then transferred to the syringe containing the resin, and the mixture was agitated for 3 h. LCMC analysis of material cleaved from a small amount of resin was used to determine reaction completion. The resin was filtered, washed with DMF (6 × 10 mL), CH_2Cl_2 (6 × 10 mL), and ethyl ether (6 × 10 mL), and dried in vacuo for 2 h. A 20% piperidine solution in DMF (5 mL) was added to the resin, and the mixture

was agitated for 2 h. The resin was then filtered, washed with DMF (6 × 10 mL), CH_2Cl_2 (6 × 10 mL), and ethyl ether (6 × 10 mL), and dried in vacuo.

MMAF (MeVal-Val-Dil-Dap-Phe). MeVal-Val-Dil-Dap-Phe-2-chlorotrityl resin (100 mg, 0.044 mmol) in a 5 mL syringe was treated with 2% TFA in CH_2Cl_2 (4 mL) for 5 min at ambient temperature. Preparative HPLC purification provided 27 mg (73%) of white solid. Reversed-phase HPLC analysis: 95% at 5.74 min. ^{1}H NMR (DMF-d_7): δ 0.78 (3H, t), 0.90−1.15 (19H, m), 1.28−1.44 (m), 1.46−1.62 (m), 1.75−2.00 (m), 2.03−2.12 (m), 2.14−2.23 (m), 2.24−2.48 (m), 2.50−2.61 (m), 2.78−2.82 (m), 2.97−3.09 (m), 3.12 (s), 3.18−3.21 (m), 3.26 (d), 3.30 (s), 3.34 (s), 3.41−3.46 (m), 3.49 (d), 3.53−3.60 (m), 3.61−3.69 (m), 3.72−3.78 (m), 3.93 (d), 4.10 (2H, br d), 4.12−4.38 (1H, br), 4.64−4.92 (3H, m), 7.21−7.35 (5H, m), 8.12 (0.5H, d), 8.40 (0.5H, d), 8.78−8.83 (1H, m), 9.03 (1H, br s), 9.63 (1H, br s). HRMS (ESI) calcd for $C_{39}H_{66}N_5O_8$ $(MH)^+$ 732.4911; found, *m*/*z* 732.4890.

Maleimidocaproyl-Val-Cit-PABC−MMAF (L1−MMAF). MeVal-Val-Dil-Dap-Phe-2-chlorotrityl resin (120 mg, 0.053 mmol) in a 5 mL syringe was treated with a solution of maleimidocaproyl-Val-Cit-PAB-OCOpNP (313 mg, 0.42 mmol, 8 equiv), 1-hydroxy-7-azabenzotriazole (HOAt, 2 mg, 0.015 mmol, 0.3 equiv), and DIEA (148 μL, 0.84 mmol, 16 equiv) in DMF (4 mL) for 16 h. The resin was then filtered and washed with DMF (6 × 3 mL), CH_2Cl_2 (6 × 3 mL) and ethyl ether (6 × 3 mL). Cleavage from resin by treatment with 2% TFA in CH_2Cl_2 (4 mL) for 5 min and preparative HPLC purification of the released material generated 15 mg (21%) of white solid that was 98% pure by reversed-phase HPLC analysis (retention time 7.20 min).^{1}H NMR (DMSO-d_6): δ 0.75−0.95 (28H, m), 1.05 (3H, t), 1.14 (m), 1.22−1.53 (m), 1.53−1.80 (m), 1.80−2.40 (m), 2.80 (br s), 2.96 (d), 3.11 (s), 3.13 (s), 3.20 (s), 3.62−3.70 (d), 3.83−3.94 (m), 4.08−4.24 (m), 4.28−4.5 (m), 4.50−4.68 (m), 4.90−5.10 (m), 5.35 (s), 5.96 (1H, t), 7.02 (2H, s), 7.08−7.32 (9H, m), 7.54 (2H, d), 7.80 (d), 8.04−8.12 (m), 8.16−8.33 (m), 10.0 (1H, br s). HRMS (ESI) calcd for $C_{68}H_{104}N_{11}O_{16}$ $(MH)^+$ 1330.7663; found, *m*/*z* 1330.7665.

Maleimidocaproyl-Val-Cit−MMAF (L2−MMAF). Fmoc-Cit (140 mg, 0.352 mmol) and Fmoc-Val (60 mg, 0.176 mmol) were coupled sequentially to MeVal-Val-Dil-Dap-Phe-2-chlorotrityl resin (200 mg, 0.088 mmol) using HATU coupling chemistry as described above for MeVal-Val-Dil-Dap-Phe-2-chlorotrityl resin. Then, to the dry Val-Cit-MeVal-Val-Dil-Dap-Phe-2-chlorotrityl resin a solution of 6-maleimidocaproic acid *N*-hydroxysuccinimide ester (54 mg, 0.176 mmol) in DMF (3 mL) was added. The mixture was shaken at room temperature for 4 h. Cleavage from resin by treatment with 2% TFA in CH_2Cl_2 (4 mL) for 5 min provided 28 mg (27%) of white solid after preparative HPLC purification. Reversed-phase HPLC analysis: 98% at 6.16 min. ^{1}H NMR (DMF-d_7): δ 0.69−0.92 (28H, m), 1.01−1.06 (3H, m), 1.17 (m), 1.42−1.53 (m), 1.53−1.68 (m), 1.70−2.28 (m), 2.28−2.46 (m), 2.74−2.88 (m), 2.89−3.00 (m), 3.04−3.06 (m), 3.15 (s), 3.18 (s), 3.24 (s), 3.40−3.47 (m), 3.48−3.58 (m), 3.59−3.68 (m), 3.71−3.76 (d), 3.96 (m), 4.14 (t), 4.23 (m), 4.38−4.52 (m), 4.58−4.76 (m), 4.89 (m), 5.95 (m), 7.01 (2H, s), 7.17−7.28 (5H, m), 7.77 (m), 7.89 (m), 7.96 (m), 8.04 (m), 8.17 (m), 8.28 (m), 8.38 (d), 8.47 (m). HRMS (ESI) calcd for $C_{60}H_{97}N_{10}O_{14}$ $(MH)^+$ 1181.7186; found, *m*/*z* 1181.7164.

Maleimidocaproyl-PABC−MMAF (L3−MMAF). MeVal-Val-Dil-Dap-Phe-2-chlorotrityl resin (100 mg, 0.044 mmol) was treated with a solution of maleimidocaproyl-PAB-OCO-pNP (42 mg, 0.088 mmol, 2 equiv), 1-hydroxybenzotriazole (HOBt, 1 mg, 9 μmol, 0.1 equiv), and DIEA (30 μL, 0.176 mmol, 4 equiv) in DMF (3 mL) for 16 h. The resin was then filtered and washed with DMF (6 × 3 mL), CH_2Cl_2 (6 × 3 mL), and ethyl ether (6 × 3 mL). Cleavage from resin by treatment with 2% TFA in CH_2Cl_2 (4 mL) for 5 min followed by preparative HPLC purification provided 31 mg (66%) of white solid which was 99% pure by reversed-phase HPLC analysis (retention time 7.14 min).^{1}H NMR (DMF-d_7): δ 0.76−0.98 (18H, m), 1.04 (2H, d), 1.12 (3H, m), 1.25−1.40 (m), 1.51−1.61 (m), 1.63−1.69 (m), 1.76−1.90 (m), 1.94−2.40 (m), 1.35−2.38 (m), 2.50−2.60 (m), 2.96 (s), 3.10 (s), 3.23 (s), 3.27 (s), 3.30 (s), 3.34 (s), 3.41−3.50 (m), 3.50−3.80 (m), 3.90−4.20 (m), 4.33−4.48 (m), 4.54−4.62 (m), 4.63−4.77 (m), 4.82−4.93 (m), 5.06−5.20 (m), 7.02 (2H, s), 7.36−7.21 (9H, m), 7.70 (2H, d), 8.11 (0.5H, d), 8.36 (0.5H, d), 10.00 (1H, br s). HRMS (ESI) calcd for $C_{57}H_{84}N_7O_{13}$ $(MH)^+$ 1074.6127; found, *m*/*z* 1074.6095.

Maleimidocaproyl−MMAF (L4−MMAF). 6-Maleimidocaproic acid (37 mg, 0.176 mmol, 2 equiv) and HATU (67 mg, 0.176 mmol, 2 equiv) were dissolved in anhydrous DMF (3 mL), followed by the addition of DIEA (62 μL, 0.35 mmol, 4 equiv). The solution was then transferred to a 5 mL syringe containing MeVal-Val-Dil-Dap-Phe-2-chlorotrityl resin (200 mg, 0.088 mmol), and the mixture was agitated for 3 h. The resin was filtered, washed with DMF (6 × 3 mL), CH_2Cl_2 (6 × 3 mL), and ethyl ether (6 × 3 mL), and dried in vacuo. Drug−linker was cleaved off the resin by treatment with 2% TFA in CH_2Cl_2 (4 mL) for 5 min and then purified by preparative HPLC to give 57 mg (70%) of white solid. Reversed-phase HPLC analysis: 98% at 6.72 min. ^{1}H NMR (DMF-d_7): δ 0.78−0.96 (18H, m), 1.04 (2H, t), 1.12 (3H, m), 1.25−1.36 (m), 1.41 (2H, d), 1.46−1.65 (m), 1.73−1.87 (m), 1.88−2.07 (m), 2.08−2.26 (m), 2.32−2.48 (m), 2.48−2.67 (m), 2.79−2.84 (m), 2.96 (d), 3.02 (d), 3.10 (d), 3.23 (d), 3.27 (s), 3.30 (s), 3.34 (s), 3.45 (t), 3.52−3.61 (m), 3.62−3.80 (m), 3.93 (d), 4.09−4.28 (m), 4.54−4.78 (m), 4.82−4.91 (2H, m), 7.03 (2H, s), 7.21−7.35- (5H, m), 7.51 (0.5H, d), 8.11 (0.5H, d), 8.36 (0.5H, d), 8.48 (0.5H, d), 13.0 (br s). HRMS (ESI) calcd for $C_{49}H_{77}N_6O_{11}$ $(MH)^+$ 925.5650; found, *m*/*z* 925.5636.

Maleimidocaproyl−[^{13}C]MMAF (L4−[^{13}C]MMAF) was prepared as described above starting from *N*-Fmoc-L-[ring-$^{13}C_6$]-phenylalanine-2-chlorotrityl resin. LCMS (ESI): *m*/*z* 931.62 $(MH)^+$.

Preparation of Antibody−Drug Conjugates. The conjugates with eight drug molecules per antibody were prepared as described previously (*12*, *19*). Briefly, cBR96 or cAC10 (5−15 mg/mL) were mixed with DTT (10 mM, final) at 37 °C for 30 min, and the buffer was exchanged by elution through Sephadex G-25 resin with PBS containing 1 mmol/L diethylenetriaminepentaacetic acid. PBS containing 1 mmol/L diethylenetriaminepentaacetic acid was added to the reduced mAb bringing its final concentration to 2.5 mg/mL. The thiol concentration was ∼8.4 thiols/mAb as measured by Ellman's reagent, DTNB. A 9.5-fold molar excess of linker−drug (L1−MMAF, L1−Dox (*10*), L1−MMAE (*12*), or L4−MMAE) was added to the reduced antibody at 4 °C for 1 h, and the conjugation reaction was quenched by adding a 20-fold excess of cysteine. The reaction mixture was concentrated by centrifugal ultrafiltration and buffer-exchanged through Sephadex G-25 equilibrated with PBS at 4 °C. The conjugate was then sterile filtered through a 0.2-μm filter.

cAC10 antibody−drug conjugates with four drugs per antibody were prepared by partial reduction of the mAb (*14*, *20*) followed by reaction with desired linker−drug (L1−MMAF, L2−MMAF, L3−MMAF, or L4−MMAF). The antibody cAC10 (10 mg/mL) was partially reduced by addition of 3.0 molar equivalents of DTT at pH 8.0, followed by incubation at 37 °C for ∼2 h. The reduction reaction was then chilled to ∼10 °C and the excess DTT removed via diafiltration. The thiol concentration was determined by DTNB, and the SH/Ab ratio was found to be in the range of 3.8−4.5. The linker−drug was

then added to a linker−drug/thiol molar ratio of ∼1.15. The conjugation reaction was carried out in the presence of 15% v/v of DMSO. After conjugation, excess free cysteine (2 mol/L cysteine per mol/L linker−drug) was added to quench unreacted linker−drug to produce the cysteine−linker−drug adduct. The reaction mixture was purified and buffer-exchanged into PBS by diafiltration to obtain the partially loaded cAC10−linker−$drug_4$ conjugate. The molar ratio of drug substitution was determined according to previously published methods (*14, 20*).

Released Drug Identification. Lysosomal extracts of L540cy cells were prepared by swelling 2.4×10^8 cells in 9 mL of 0.25 M sucrose, 1 mM EDTA, and 10 mM HEPES (4-(2-hydroxyethyl)piperazine-1-ethansulfonic acid), pH 7.4. After 30 min on ice, cells were Dounce homogenized until >95% were broken as measured by Trypan Blue dye exclusion. Homogenates were centrifuged (3000*g*, 10 min, 4 °C) to pellet cellular debris, and the supernatant (4×10^7 cell equivalents per tube) was transferred to polyallomar ultracentrifuge tubes (13 × 51 mm) and centrifuged (17000*g*, 15 min, 4 °C) in a TLA100.3 rotor to isolate the lysosome-containing light mitochondrial pellet. Pellets were stored at −80 °C. The pellets were thawed and resuspended in 500 μL of 50 mM sodium acetate pH 5.0 and 2 mM DTT. cAC10−L4-[^{12}C]$MMAF_4$, cAC10−L4-[^{13}C]-$MMAF_4$, and cAC10−L4-[$^{12/13}$C]$MMAF_4$ (50 μg/mL) were independently added to one pellet. After three freeze/thaw cycles to break open lysosomes, samples were incubated for 24 h at 37 °C. Cold methanol (2 vol) was added to precipitate protein, the samples were centrifuged at 14000*g* to pellet debris, and 100 μL of supernatant was analyzed by low resolution mass spectrometry as described above. Authentic cysteine−L4−MMAF was prepared by treating 100 μM L4−MMAF with 1 mM cysteine in PBS at room temperature for 10 min.

In Vitro Growth Inhibition. Log phase cultures of cells were collected and cells plated at seeding densities ranging from 500 to 10000 cells/well according to predetermined conditions. After incubating 24 h to allow surface protein reconstitution, serial dilutions of test molecules were added and cultures incubated a further 4−6 days depending on cell line. Assessment of cellular growth and data reduction to generate IC_{50} values was done using Alamar Blue (Biosource International, Camarillo, CA) dye reduction assay as previously described, according to previously published methods (*12, 14, 15, 19*). Briefly, a 40% solution (wt/vol) of Alamar Blue was freshly prepared in complete media just before cultures were added. Ninety-two hours after drug exposure, Alamar Blue solution was added to cells to constitute 10% culture volume. Cells were incubated for 4 h, and dye reduction was measured on a Fusion HT fluorescent plate reader (Packard Instruments, Meriden, CT).

In Vivo Therapy Experiments. For the localized, subcutaneous disease model of anaplastic large cell lymphoma, 5×10^6 Karpas 299 cells were implanted into the right flanks of C.B.-17 SCID mice. Therapy was initiated when the tumor size in each group of six animals averaged approximately 100 mm^3. Treatments consisted of a single injection of solutions of the conjugates or controls in PBS intravenously (tail vein). Tumor volume was determined using the formula $(L \times W^2)/2$. For the disseminated ALCL model, 1×10^6 Karpas 299 were injected in the tail vein into C. B.-17 SCID mice**.** Single dose injection treatment was performed at 9 days after tumor injection. Mice that developed hind limb paralysis or other signs of significant disease were euthanized in accordance with Animal Care and Use Committee guidelines.

In Vivo Localization of Antibodies via Immunohistochemistry. When subcutaneous Karpas 299 tumor size reached 300 mm^3, three animals per group received one injection of 10 mg antibody component/kg body weight of either cAC10−L1−$MMAF_4$ or cBR96−L1−$MMAF_4$ intravenously. Tumors were then removed and placed in optimal cutting temperature (OCT) compound (Sakura Finetec, Torrence, CA), and 5 μm-thin frozen tissue sections were stained using immunohistochemistry evaluation. Briefly, frozen tissues on the slides were air-dried then fixed in 4% paraformaldehyde for 15 min at room temperature. Endogenous peroxidase activity was blocked using 0.6% H_2O_2 for 15 min. Additional blocking for endogenous biotin was done using the Avidin−Biotin Blocking kit (Vector Labs). Biotinylated-anti-human-Fc and biotinylated-anti-drug antibodies (both Seattle Genetics) were incubated on tissues at 2 μg/mL concentration for 1 h at room temperature. Following incubation of slides with avidin conjugated to HRP (Vectastatin Elite ABC kit, Vector Labs), 3,3′-diabenzidine (DAB) was used as a substrate for HRP. Tissues were counterstained using hematoxylin, slides were dehydrated, and slips were applied. Images were taken using the Zeiss Axiovert light microscope.

TUNEL Assay. Apoptosis was evaluated by TUNEL Staining (In Situ Cell Death Detection Kit, TR Red, Roche Applied Science, Germany) according to the manufacturer's instructions. TUNEL staining was carried out on sections of frozen specimens embedded in OCT. Labeling was visualized by Zeiss Axiovert fluorescence microscopy.

Table 1. In Vitro Cytotoxicity of Auristatins

		IC_{50} (nM)[a]		
cell line	type	MMAE	MMAF	MMAF-OMe
Karpas 299	anaplastic large cell lymphoma	0.5	119	<0.001
H3396	breast carcinoma	0.1	105	<0.001
786-O	renal cell carcinoma	2.0	257	0.01
Caki-1	renal cell carcinoma	0.7	200	<0.001

[a] Cells were exposed to the drugs, and the cytotoxic activities were determined 96 h later using Alamar Blue dye conversion as a measure of cell viability.

RESULTS

Development of MMAF-Based Conjugates. The structure of the antimitotic agent MMAE is shown in Figure 1. This drug has previously displayed IC_{50} values in the range of 1−5 nM on hematologic cell lines (*12, 15*) and was designed for mAb-based targeted delivery using peptide-based linkers appended to the N-terminal methylvaline residue (*12, 19*). The synthesis of MMAE proceeded through a solution-phase route involving the coupling of the amino-protected N-terminal trimer to the C-terminal dimer. Due to the convergent nature of the process, it was possible for us to produce a large number of auristatins with varied solubilities, potencies, and pharmacokinetic properties. One molecule that emerged was MMAF-OMe (Figure 1), a C-terminal phenylalanine containing auristatin that remains one of the most potent drugs we have ever made (Table 1). We regarded MMAF-OMe as a prodrug of MMAF (Figure 1), with the potential of having facilitated intracellular uptake due to the presence of a neutral C-terminus. In addition, intracellular ester hydrolysis of MMAF-OMe should rapidly generate MMAF, a C-terminally charged molecule expected to have impaired membrane translocation capabilities. Therefore, MMAF was synthesized using solid-phase synthetic methodology and as expected was much less potent than MMAE on all cell lines tested (Table 1). In addition, the maximum tolerated dose in mice of MMAF (>16 mg/kg) was much higher than MMAE (1 mg/kg). Thus, MMAF was of great interest for targeted delivery, since the free drug had attenuated potency, lower toxicity, and much higher aqueous solubility compared to MMAE. Facilitated intracellular transport was expected to greatly enhance its activity.

Conjugates of MMAF were produced using the maleimidocaproyl-Val-Cit-PABC linker (L1, Figure 1) as described

[a] Cytotoxicity was measured as indicated in Table 1. Concentrations of the ADCs are represented by the drug component. [b] Represents 1000 ng/mL mAb component. [c] Represents 1.36 ng/mL mAb component. [d] Represents 2.64 ng/mL mAb component.

earlier for MMAE (*12, 19*). The mAbs used were BR96 (*17*) and AC10 (*19*), chimeric IgG1 mAbs that bind to the LewisY antigen on human carcinomas, and the CD30 antigen on hematologic malignancies, respectively. Initial studies were undertaken with conjugates that had eight drugs/mAb, but more recent data demonstrating improved pharmacokinetic and toxicologic properties of conjugates having lower drug loadings (*14*) prompted us to investigate the activities of conjugates with fewer drugs/mAb. These were obtained through carefully controlled mAb disulfide reduction with limiting amounts of DTT sufficient to produce an average of four thiol groups/mAb. Alkylation with drugs bearing thiol-reactive maleimide functionalities led to the formation of conjugates having an average of four drugs/mAb. The resulting distributions of species were as previously described (*20*). It was found that the ability of the parent unmodified mAb to bind to cell-surface receptors was maintained in conjugates (*12*), and aggregate (<5%) and free drug levels (0.5%) were very low.

In Vitro Growth Inhibition. cAC10−L1−$MMAF_4$ was tested on a panel of both CD30 positive and negative cell lines as shown in Table 2. Cells were exposed to the ADCs continuously for 96 h, and the cytotoxic effects, as determined by Alamar Blue conversion, were compared to those of free MMAF. On a molar basis, the cAC10−L1−$MMAF_4$ was an average of >2200-fold more potent than free MMAF and was active on all the CD30-positive cell lines tested. The effects were immunologically specific, since WSU-NHL cells, which do not express detectable levels of the CD30 antigen, were unaffected by the conjugate. Limited studies were also undertaken with the cAC10−L1−MMAF-OMe_4-based conjugates, and it was found that they displayed IC_{50} values on Karpas 299 (0.04 nM) and L540cy (0.11 nM) cells that were comparable to those of cAC10−L1−$MMAF_4$ (Table 2). This is consistent with the assumption stated earlier that the active form of MMAF-OMe is the free acid MMAF.

Further studies were undertaken with MMAF and the cBR96−L1−$MMAF_8$ conjugate on a LewisY positive human small cell lung carcinoma cell line (H69) and its P-glycoprotein-overexpressing counterpart H69/LX4 (*18*). The results were compared to doxorubicin and cBR96−L1−$doxorubicin_8$, a previously described conjugate with eight doxorubicin molecules/mAb (*17, 21*). H69/LX-4 cells were approximately 100-times less sensitive to doxorubicin compared to the parental cell (Figure 2A), while there was only a 3-fold difference with MMAF (Figure 2B). This trend extended to the conjugates, in that the drug resistant cell line was refractory to BR96−L1−$doxorubicin_8$ (Figure 2C), but quite sensitive to the corresponding MMAF conjugate (Figure 2D). These results have been confirmed on several MDR positive cell lines (data not shown), in which it has been found that MMAF and MMAF-based immunoconjugates circumvent common forms of the MDR phenotype.

New Linker Technologies. The linker joining the drug to the mAb carrier plays a critical role in conjugate potency (*3, 21−24*). We applied our peptide linker technology to MMAF, based on its successful application with MMAE (*12, 14, 15, 19, 20*) and other drug classes (*6, 9−11*). To expand our understanding of the role that the linker plays in drug release and cytotoxicity, we made truncated linker−MMAF derivatives lacking the *p*-aminobenzyloxycarbonyl (PABC) self-immolative group (L2, Figure 1), the peptide (L3), and both the peptide and the PABC group (L4). The resulting modified drugs were attached to cAC10, forming ADCs with approximately four drugs/mAb. As expected from earlier work with related doxorubicin ADCs (*6, 9−11*), cAC10−L2−$MMAF_4$ was devoid of activity on Karpas 299 cells (Table 3). In contrast, both cAC10−L3−$MMAF_4$ and cAC10−L4−$MMAF_4$ were highly active, and were as active as the full-length construct (cAC10−L1−$MMAF_4$). Interestingly, ADCs with truncated linkers (L2, L3, and L4) were not substrates for human cathepsin B, which was a critical design element in forming the original proteolytically cleavable linker technology for doxorubicin (*6, 9−11*). The effects of the truncated linkers were drug-dependent, in that cAC10−L4−$MMAE_8$ had no cytotoxic activity above 50 nM (1000 ng/mL) on Karpas 299 cells.

The results prompted us to test cAC10−L4−$MMAF_4$ on the broad panel of hematologic cell lines shown in Table 2. The conjugate was active against all CD30 positive cell lines tested and had approximately half the activity of cAC10−L1−$MMAF_4$. In addition, the effects were immunologically specific, as CD30 negative SU-NHL cells were not affected by cAC10−L4−$MMAF_4$. Thus, MMAF can be attached to cAC10 through linkers not designed for proteolytic cleavage, without significant loss in potency.

The high potency and broad reactivity of cAC10−L4−$MMAF_4$ conjugates raised the question of precisely what drug related molecule might be released from the conjugate, since the L4 linker would appear to be noncleavable. To elucidate this, ^{13}C-phenylalanine substituted L4−MMAF was synthesized and conjugated to cAC10. ^{12}C, ^{13}C, and a 1:1 mixture of ^{12}C and ^{13}C cAC10−L4−$MMAF_4$ were then incubated in lysosomal extracts of L540cy cells. Low molecular weight products were separated from proteins and were analyzed by LCMS. The identification of released drugs was based on the 6 mass unit shifts between the ^{12}C and ^{13}C derivatives of the drug. After inspection of mass spectra for such shifts, the only detectable drug-related molecule that was found was the cysteine adduct of maleimidocaproyl−MMAF (Figure 3). To confirm this, an

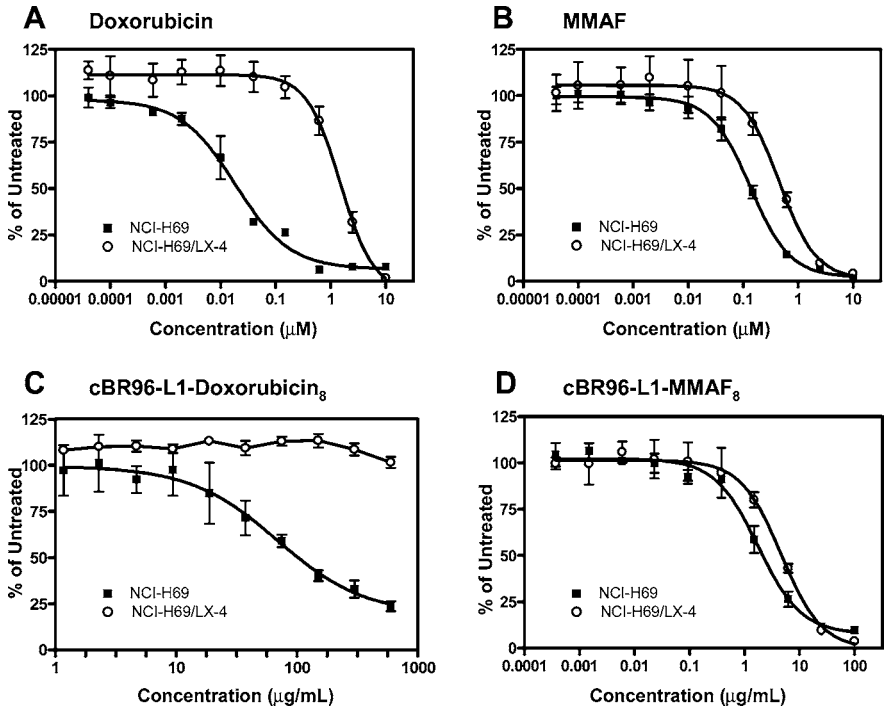

Figure 2. Cytotoxic effects of drugs (A, B) and cBR96-drug conjugates (C, D) on human small cell lung carcinoma cell line H69 (-■-) and its P-glycoprotein-overexpressing counterpart H69/LX-4 (-○-). Both cell lines are Lewis Y positive. The cells were incubated with either the drugs or the conjugates for 6 days, and the cytotoxic effects were determined by metabolism of Alamar Blue during the last 24 h of incubation.

Table 3. In Vitro Cytotoxicity of Drug−Linker Combinations

conjugate	target antigen	IC_{50} (nM) Karpas 299 cells[a]
cAC10−L1−$MMAF_4$	CD30	0.03
cAC10−L2−$MMAF_4$	CD30	>25
cAC10−L3−$MMAF_4$	CD30	0.055
cAC10−L4−$MMAF_4$	CD30	0.065
cAC10−L1−$MMAE_8$	CD30	0.18
cAC10−L4−$MMAE_8$	CD30	>50
cBR96−L1−$MMAF_4$	Lewis Y	>25
cBR96−L4−$MMAF_4$	Lewis Y	>25

[a] Karpas 299 cells are CD30 positive, Lewis Y negative. Cytotoxicity was measured as indicated in Table 1. Concentrations of the ADCs are represented by the drug component. The numbers reported are representative of at least two independent experiments.

authentic sample of cysteine−L4−MMAF was synthesized and was shown to have the same elution and LCMS profile as the drug released from the cAC10−L4−$MMAF_4$ ADC (data not shown). The mAb is the likely source for cysteine in cysteine−L4−MMAF, since this was the residue to which the drug was attached. Thus, drug release takes place through mAb degradation. Studies are currently ongoing to identify other products that might also be formed and to establish the rates and extent of drug release.

Maximum Tolerated Doses. The maximum tolerated doses (MTDs) of the cAC10−MMAF conjugates were determined in BALB/c mice and in Sprague−Dawley rats and are defined as the highest dose that did not induce >20% weight loss, distress, or overt toxicities in any of the animals. This dose was generally within 20% of doses where such events took place. cAC10−L1−$MMAF_4$ has an MTD of 50 mg/kg in mice and 15 mg/kg in rats. The corresponding cAC10−L4−$MMAF_4$ ADC was much less toxic, having MTDs in mice and rats of >150 mg/kg (the highest dose tested, which resulted in no apparent toxicity) and 90 mg/kg in rats, respectively. This clearly indicates that the method by which the drug is attached to the mAb can have a pronounced effect on ADC tolerability, and the ADC lacking the peptide spacer within the linker was much less toxic than the peptide-based ADC.

Immunohistochemical Analyses. Studies were undertaken to determine if cAC10−L1−$MMAF_4$ localized into subcutaneous Karpas 299 tumors in nude mice. Animals were injected intravenously with cAC10−L1−$MMAF_4$ or cBR96−L1−$MMAF_4$ at 10 mg antibody component/kg body weight. Tumors were removed 24 h later, and frozen sections were evaluated for the presence of the mAb and drug components using immunohistochemistry with biotinylated anti-human-Fc and anti−MMAF mAbs as secondary antibodies, respectively. Figures 4A and 4C show that cAC10−L1−$MMAF_4$ accumulated much more efficiently within Karpas 299 tumors compared to the cBR96 nonbinding control ADC (Figure 4B and 4D). Since both the mAb (Figure 4A) and drug (Figure 4C) moieties were detected throughout the tumor, we conclude that the ADC is delivered as an intact molecule.

Additional studies were undertaken to determine the effects of ADC localization on apoptosis. Figure 4E demonstrates that there were significant levels of fragmented DNA in tumors of animals that received cAC10−L1−$MMAF_4$. This was established by TUNEL analysis, which measures bromodeoxyuridine incorporation into fragmented DNA. A nonbinding control ADC (Figure 4F) did not induce nearly this level of fragmentation, which is consistent with the localization data.

In Vivo Therapy Studies. The therapeutic effects of the ADCs were determined in nude mice with subcutaneous or disseminated Karpas 299 tumors. In animals with subcutaneous tumors, significant antitumor effects were obtained with a single injection of either cAC10−L1−$MMAF_4$ or cAC10−L4−$MMAF_4$, which were indistinguishably potent and active (Figure 5A). Nearly all animals that received single ADC injections at 2 mg antibody component/kg body weight were cured. In lowering the dose to 1 mg/kg, efficacy for both ADCs, dropped off in an apparently equal manner. At this dose, there were still two of six and three of six animals cured with the cAC10−L1−$MMAF_4$ and cAC10−L4−$MMAF_4$ ADCs, respectively.

To establish disseminated tumors, Karpas 299 cells were injected intravenously and allowed to distribute and become established before therapy was initiated 9 days later. In the

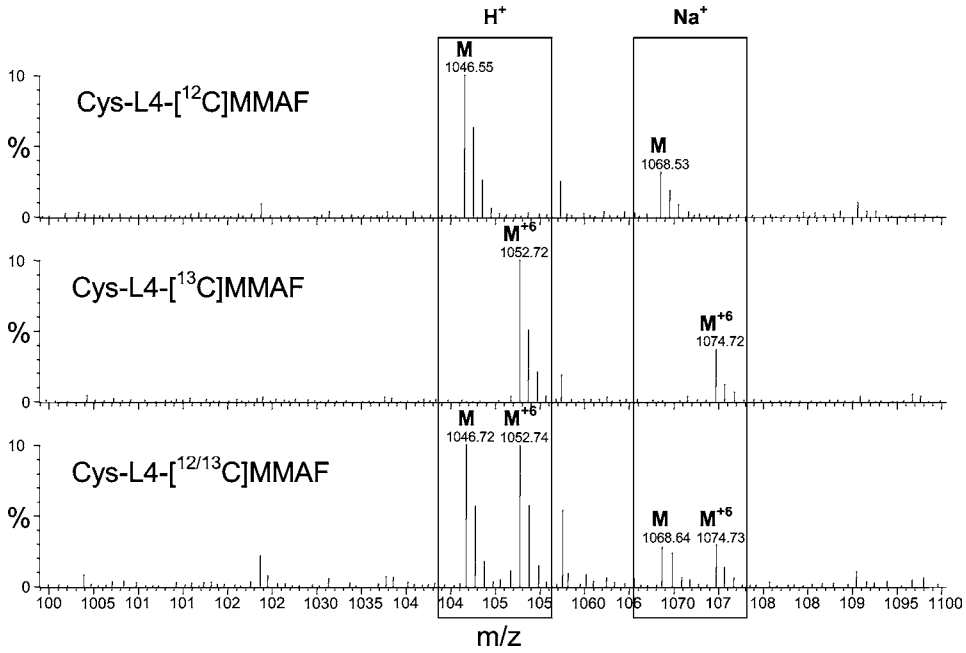

Figure 3. LCMS analysis of products released in lysosomal extracts of L540cy cells from cAC10−L4−MMAF$_4$ conjugate composed of [$^{12}C_6$-Phe]−MMAF (top), [$^{13}C_6$-Phe]−MMAF (middle), and a 1:1 mixture of these two conjugates (bottom). The fragments obtained from the co-mixture of the conjugates were analyzed for (M) and (M + 6) molecular ion clusters. Cysteine−L4−MMAF, *m*/*z* 1046/1052, was the only identifiable MMAF component.

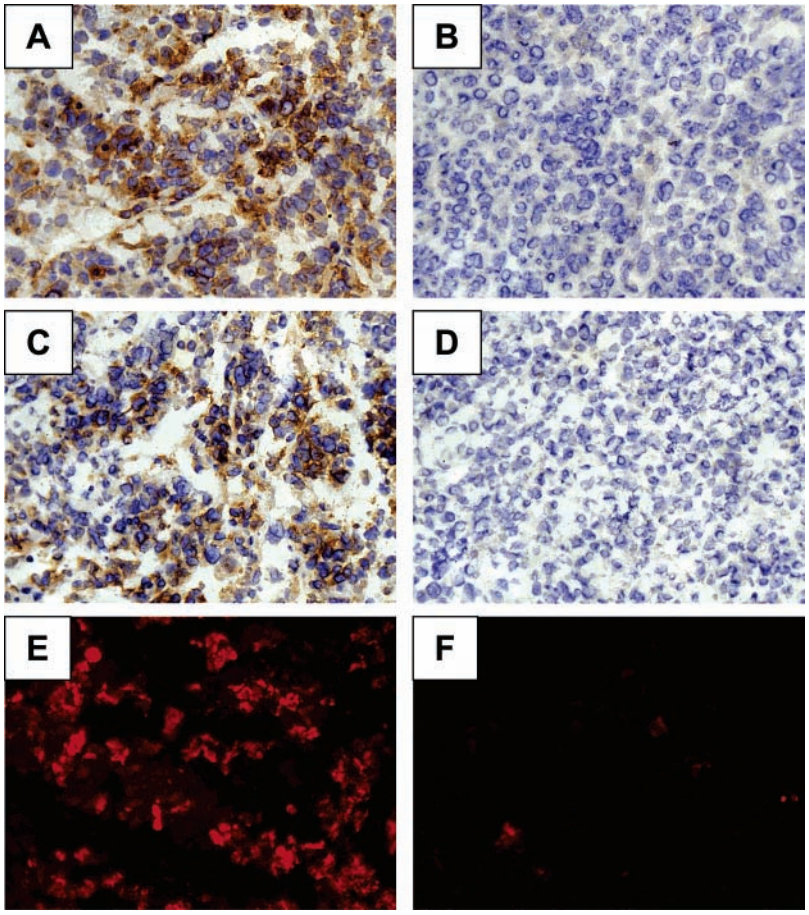

Figure 4. In vivo localization and activities of mAb−L1−MMAF$_4$ ADCs. Nude mice with subcutaneous Karpas 299 human tumors (cAC10 antigen positive, cBR96 antigen negative) were injected either with cAC10−L1−MMAF$_4$ (A, C, E) or with cBR96−L1−MMAF$_4$ (B, D, F) to investigate the localization and the induction of apoptosis on tumor xenografts. The presence of intratumoral mAb (A, B) and intratumoral MMAF (C, D) were determined by immunohistochemistry using either biotinylated anti-human-Fc or biotinylated anti-MMAF mAbs, respectively, as secondary antibodies. The tumors were excised and sectioned 24 h postconjugate administration. The apoptotic effect on Karpas 299 (E, F) were investigated using the TUNEL assay. The images were taken using 20× objectives on a Zeiss microscope.

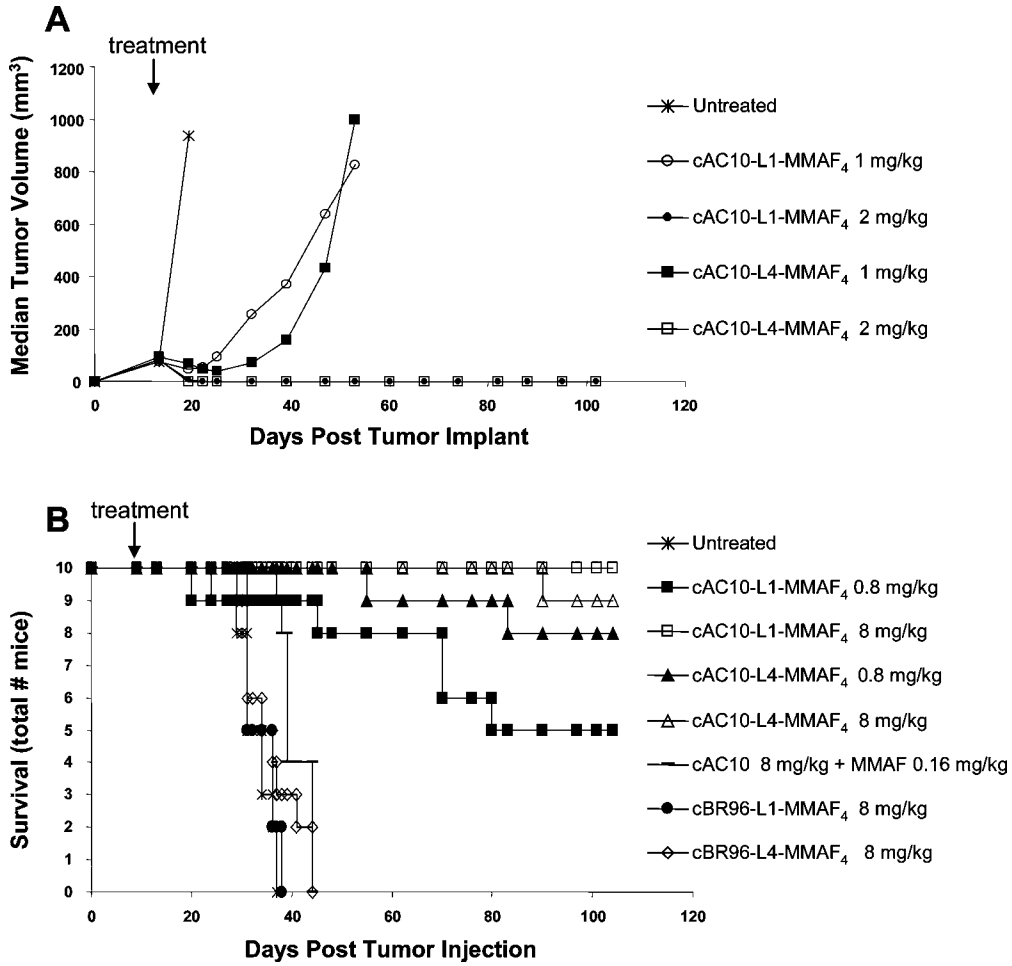

Figure 5. In vivo therapeutic efficacy of the conjugates in SCID mice. The data reported are representative of a number of independent studies. (A) Groups of mice (six/group) with subcutaneous Karpas 299 human ALCL tumors (cAC10 Ag^+) of approximately 100 mm^3 average in size were treated with cAC10−L1−$MMAF_4$ or cAC10−L4−$MMAF_4$ at 1 mg and 2 mg mAb component/kg. Cures: 1 mg/kg cAC10−L1−$MMAF_4$, two out of six; 1 mg/kg cAC10−L4−$MMAF_4$, three out of six; 2 mg/kg cAC10−L4−$MMAF_4$, five out of six; 2 mg/kg cAC10−L1−$MMAF_4$, six out of six. (B) Groups of mice (ten/group) with disseminated Karpas 299 ALCL tumor model (cAC10 Ag^+, cBR96 Ag^-) were treated on day 9 after tumor injection with cAC10−L1−$MMAF_4$, cAC10−L4−$MMAF_4$, cAC10 + unconjugated MMAF, cBR96−L1−$MMAF_4$, or cBR96−L4−$MMAF_4$ at the doses indicated.

absence of any treatment, all of the animals succumbed to disseminated disease by day 45. A single administration with either cAC10−L1−$MMAF_4$ or cAC10−L4−$MMAF_4$ was sufficient to cure most of the animals, with a slight dose response between 0.8 mg/kg and 8 mg/kg. The differences between the L1 and L4 linkers were not significant in this tumor model. One of the noteworthy findings in this experiment was the level of specificity. The nonbinding control ADCs, cBR96−L1−$MMAF_4$ and cBR96−L1−$MMAF_4$ were inactive, even at 8 mg/kg, which is 10-times the effective dose of the corresponding cAC10 ADCs. Thus, the MMAF conjugates exhibit pronounced activity at very well tolerated doses and are highly immunologically specific. Furthermore, the therapeutic window of cAC10−L4−$MMAF_4$ is measurably greater than that of cAC10−L1−$MMAF_4$, indicating that the linker technology plays a critical role in the design of effective ADCs that can be safely administered.

DISCUSSION

In this paper, we describe the synthesis and properties of MMAF, a new auristatin antimitotic agent designed for attachment to mAbs through the secondary amino terminus. MMAF has much lower cytotoxic activity than MMAE (*12, 14, 15, 19*), presumably owing to the charged C-terminal phenylalanine group that impairs intracellular access. This hypothesis is supported by the pronounced activity of MMAF-OMe, one of the most potent auristatins that we have developed. To further understand the precise cause of the attenuated activity of MMAF compared to the other drugs, studies are currently underway to measure intracellular concentrations in MDR positive and negative cell lines.

ADCs comprised of MMAF are distinct from those of other drugs, including MMAE. We show that the activities of MMAF are potentiated an average of 2200-fold when the drug is attached through the L1 linker to cAC10, a mAb that is efficiently taken up within the lysosomes of target cells (Table 2). With one exception that is likely cell line dependent (*25*), broad-scale drug potentiation through ADC formation is generally not seen, as evidenced by the in vitro results of MMAE (*12*) and other drug-containing ADCs (*23, 24, 26, 27*). The significance of this finding will become evident though detailed toxicological analyses, in which MMAE- and MMAF-based ADCs should be quite distinct if systemically released drug contributes to ADC toxicity.

One of the most striking results from this work surrounds the unexpected activity of cAC10−L4−$MMAF_4$, an ADC that has no built-in provision for drug release. Purified human enzymes that we have tested were unable to facilitate release of MMAF or any identifiable MMAF fragments, yet cAC10−L4−$MMAF_4$ is highly potent, both in vitro and in vivo. We

propose that the mechanism of drug release involves complete degradation of the mAb, based on the identification of the cysteine adduct of L4−MMAF. The finding that the released drug from the L4 linker is highly modified might explain why such truncated linker technology is not uniformly applicable, since many drugs lose activity as a result of derivatization. Indeed, MMAE was not tolerant of such modification (Table 3), and corresponding doxorubicin ADCs have also proven to be inactive (data not shown). The data in Table 3 also demonstrate that the various linkers within the MMAF ADC family provide a range of cytotoxic activities. The fact that cAC10−L2−$MMAF_4$ was inactive suggests that the released agent from the L2−MMAF ADC is highly attenuated in activity. We focused on cAC10−L4−$MMAF_4$ for further work rather than cAC10−L3−$MMAF_4$, since the PABC group in the L3 linker is hydrophobic and apparently unnecessary for activity.

The objective of the investigations with various linkers was to determine if the mode of drug release could affect ADC therapeutic index. We found that cAC10−L4−$MMAF_4$ differed from cAC10−L1−$MMAF_4$ by an average of only 2-fold on a large panel of hematologic cell lines (Table 2) although L1 linker cleavage is quite facile through enzymes such as cathepsin B, while drug release through the L4 linker requires antibody degradation. This provided the basis for in vivo experiments, since we anticipated that the different pathways required for drug elimination could strongly influence the therapeutic windows of the ADCs. Indeed, it was found that cAC10−L4−$MMAF_4$ was tolerated at significantly higher doses in rodents than cAC10−L1−$MMAF_4$ but was equally efficacious in vivo. Our results suggest that the therapeutic window is increased by at least 3-fold through the L4 linker system.

We are in the process of assessing several aspects of MMAF linker technology. Current studies include the application of mAb−L4−MMAF ADCs directed against antigens on an array of tumor types. Our preliminary data suggest that such ADCs are broadly active against hematologic malignancies but are only sporadically effective in the carcinomas we have evaluated. We are gaining insight into the factors that influence activity by assessing bound and unbound drug both inside and outside target cells. In addition, we are characterizing the mechanisms of drug release in target and nontarget cells in order to further understand the principles that influence activity and toxicity.

Linear Polyethyleneimine Grafted to a Hyperbranched Poly(ethylene glycol)-like Core: A Copolymer for Gene Delivery

Pallab Banerjee,* Ralph Weissleder, and Alexei Bogdanov, Jr.*

Center for Molecular Imaging Research, Massachusetts General Hospital, Building 149, 13th Street, Charlestown, Massachusetts 02129. Received March 18, 2005; Revised Manuscript Received November 21, 2005

A block copolymer of a hyperbranched poly(ethylene glycol)-like core and linear polyethylenimine (HBP) was synthesized by a facile synthetic route that included (1) a single-step cationic copolymerization of diepoxy and polyhydroxyl monomers, (2) derivatization of hydroxyl groups of the core HBPEG copolymer with either tosyl or chloromethylbenzoyl chlorides resulting in a corresponding macroinitiator, and (3) synthesis of HBPEG-*block*-poly(alkyl oxazolines). HBPEG-*block*-linear polyethyleneimine (HBP) was obtained by hydrolysis of HBPEG-*block*-poly(alkyl oxazolines). Linear PEI-bearing hyperbranched polycations (HBP) had lower inherent toxicity in cell culture than PEG-grafted linear polyethyleneimines (PEGLPEI). PEGLPEI formed a complex with DNA with an average diameter of 250 nm. The complexes were loosely condensed and formed aggregates and precipitates during storage. By contrast, hyperbranched polycations (HBP) formed ∼50 nm nanocomplexes with DNA that were stable for several weeks and showed resistance to DNAse I-mediated degradation. The 'inverted' block copolymers showed several orders of magnitude higher transfection efficiency than PEGLPEI in vitro. Because of the biocompatibility and higher transfection efficiency, the 'inverted' block copolymer merits further investigation as a gene carrier.

INTRODUCTION

Polyionic complexes between polycations (e.g. branched polyethyleneimine (BPEI) (*1*), "fractured" polyamidoamine (PAMAM) dendrimer fragments (*2, 3*)), and plasmid DNA were shown to transfect cells in vitro with high efficiency. Unfortunately, positively charged complexes with DNA induce acute inflammatory toxicity in vivo associated with the release of TNFα, complement activation, and erythrocyte aggregation (*4, 5*). Covalent modification of BPEI and PAMAM with poly(ethylene glycol) (*2, 6, 7*) for providing nonionic shells has been previously used to address the above problem and resulted in an overall lower systemic toxicity (*8*−*11*). Since poly(ethylene glycol) (PEG) partially shields a polycation's positive charge (*8*−*11*), large amounts of PEG-grafted polymers are usually required to obtain complexes with DNA for efficient cell transfection (*2*). Recently, Petersen et al. (*12*) reported synthesis and DNA-condensing properties of a block copolymer of low molecular weight branched polyethyleneimine grafted to a *star*-poly(ethylene glycol) core. The grafting of such low molecular mass PEI by block copolymerization enhanced the transfection efficacy of PEI which otherwise shows poor or low transfection (*12*). An alternative strategy of polycationic hydrophilic core-first polymer synthesis (*13*) has been also reported but the efficacy of resultant polymers for DNA delivery is yet to be explored. Our earlier work suggested that although PEG-grafted poly-L-lysine (protected graft copolymer, PGC) (*14*) showed a long blood circulation time in vivo, low cytotoxicity, and immunogenicity, its efficacy for in vivo gene transfer was limited (*15*). One potential explanation of this is in that grafted PEG chains provide shielding of the positive charge of the core polycation (*10*) and thus usually has limited use for in vivo gene delivery due to low binding to cells (*16*). However, the lack of efficacy in vitro does not preclude the potential use of PEG-grafted polycations for targeted delivery of expression vectors in vivo. To facilitate higher structural diversity of the "inverted", core-first polycationic gene delivery carriers, we extended the above studies by devising a hyperbranched PEG-like core polymer (HBPEG) and using the core as a macroinitiator for grafting it with linear polyethyleneimine obtained by using cationic polymerization of 2-alkyl-2-oxazolines.

Here we report a comparative study of two classes of polymers: (1) graft copolymers of PEI and PEG and (2) the above novel polycationic block copolymer-hyperbranched polycations (HBP). We compared their ability to form complexes with plasmid DNA, thus providing protection of DNA from nuclease degradation and cell transfection.

MATERIALS AND METHODS

Materials. Branched polyethyleneimine (BPEI) (M_n 10 kDa), linear polyethyleneimine (LPEI) (22 kDa) were obtained from Polyscience (Warrington, PA). Other chemicals were from Aldrich or Fisher Scientific. Detailed polymer syntheses are described in Supporting Information.

Characterization. Gel permeation chromatography (GPC) was performed by using PL aquagel-OH 40 8mm column (Polymer Laboratories Inc, Amherst, MA) coupled with two detectors, UV/vis, and differential refractive index (RI) at 30 °C. The column was eluted with 100 mM ammonium acetate (pH 7). Molecular mass was measured using poly(ethylene oxide) standards (5−920 kDa Polysciences, Inc, Warrington, PA). The weight average molecular mass was computed using refractive index data. Proton and ^{13}C NMR spectra were recorded in solutions (Spectral Data Service, Champaign, IL) at 400 MHz for ^{1}H and 100 MHz for ^{13}C spectra, respectively.

The quantitative ^{13}C spectra were acquired in DMSO-d_6 using inverse gated decoupling pulse sequences. The spectra were obtained by using 0.5 g/mL polymer solutions at 30 °C. The data were acquired with an 80° pulse and 10 s recycle delay.

Cell Culture. COS-1 cells were propagated in DMEM supplemented with 4 mM L-glutamine, 1% penicillin−streptomycin, and 10% fetal bovine serum at 37 °C in 5% CO_2.

Reporter Gene Plasmid. pCMV-Luc (3.2 MDa, 5.12 kb) plasmid vector encoding firefly luciferase was propagated in *E. coli* DH5α and using Megaprep kit (Qiagen, Valencia, CA). Plasmid integrity was confirmed by gel electrophoresis in agarose. DNA concentration and purity were determined by measuring absorbance at 260 nm and 280 nm.

Polymer−DNA Complexes. To prepare complexes of each individual polymer with plasmid DNA, polymer solutions were added to DNA solutions (20 μg DNA/mL in 25 mM HEPES/5% glucose buffer, pH 5.5), mixed by vortexing, and incubated for 20 min at room temperature before use, unless stated otherwise. Polymer stock solutions were diluted with the same buffer as above to desired concentration. Hydrodynamic diameters of complexes were measured daily for four weeks by using Zetasizer 1000HSA (Malvern Instruments Inc, Southborogh, MA), at a fixed angle of 90° at room temperature. All complexes were stored at 4 °C.

An ethidium bromide exclusion experiment was performed with a F-4500 fluorescence spectrophotometer (Hitachi, Danbury, CT) at $\lambda_{ex} = 366$ nm and $\lambda_{em} = 591$ nm, respectively. Briefly, 10 μg of DNA and 2 μL of ethidium bromide solution (0.4 mg/mL) were mixed in 2 mL of TE buffer (pH 7.1). Polymer solution was added in 4-5 μL aliquots (1.1 mg/mL).The mixture was incubated at room temperature for 6 min, and the fluorescence intensity was measured. Two consecutive measurements were performed, and intensity values were averaged and corrected for dilution.

Cytotoxicity Assay. Cells were plated at a density 10000 cells/well of 96-well plates in 150 mL of medium 24 h before the experiment. Medium was replaced by fresh 150 μL of serum-containing media before the addition of polymers. Polymer solutions in 50 μL were then added to each well and incubated at 48 h, 37 °C. Cytotoxicity assays ($n = 4$ experiments) were performed using CytoTox 96 assay (Promega, Madison, WI), as described by the manufacturer. Nontreated cells were used as controls.

Cell Transfection. Transfections with polymer−plasmid DNA complexes were performed, and the results were analyzed using standard assay for luciferase activity expression. Various amounts of polymer in 5% glucose, 25 mM HEPES, were added to the plasmid solution (0.5 μg pCMV-luc plasmid in 30 μL of 0.1 TE buffer), mixed, and incubated at room temperature for 30 min. Cells were plated at a density of 10000 cells/well in 96-well plates, 24 h prior to transfection. Before the addition of complexes, medium was replaced by fresh 100 μL of serum containing media. The complexes were then added to each well. The total volume did not exceed 150 μL/ well. The transfection was carried out for 24 h at 37 °C. The luciferase activity in cell lysates was determined using Microlumat LB96P (EG&G Berthold), by adding 50 μL of luciferin (Promega, Madison, WI) to 25 μL of cell lysate in each well using an automated injector ($n = 3$ independent experiments for each transfection reagent). Luciferase activity was integrated over 10 s with 2 s intervals. The protein concentration was measured in the rest of 25 μL cell lysate using standard protein assay reagent Pierce-Endogen, Rockford, IL). Results were expressed in relative light units per mg of cell protein. The significance of differences between data sets (here and below) was determined by using Student's unpaired, two-tailed test with Welch's correction.

DNAse I Protection Assay. DNA was prelabeled with Cy3 by using Label IT Cy3 kit (Mirus, Madison, WI) as described by the manufacturer. Labeled DNA was mixed with unlabeled pCMV−Luc at 1:6 w/w. The final concentration of DNA was 1 μg/μL. HBP and Cy3-labeled pCMV−Luc complexes were prepared at the best transfection efficiency ratio using 1.8 μg of DNA in 10 mM Tris buffer (pH 7.5). The DNA/polymer complex was first incubated for 20 min at room temperature. Various amounts of DNAse I were then added to either "naked" pCMV−Luc or to polymer complexes, and the samples were incubated at room temperature for 150 min. Samples were analyzed by 0.8% agarose gel electrophoresis. Gels were imaged using 530 nm excitation filter (Kodak 440CF) followed by staining with ethidium bromide.

RESULTS

Graft Copolymer Synthesis. To prepare a linear PEI backbone polymer (LPEI, Supporting Information, Figure S1A) commercially available poly(2-ethyl 2-oxazoline) was hydrolyzed as described (*17*). Proton NMR results suggested that hydrolysis was 90% complete. Two graft copolymers were prepared by grafting PEG chains onto linear polyethyleneimine (LPEI) as well as onto the branched polyethyleneimine (BPEI) (Supporting Information, Figure S1). The linear polyethyleneimine graft MPEG (PEGLPEI) was obtained by reacting the MPEG chloroformate with LPEI (Supporting Information, Figure S1A). The graft copolymer contained 5% PEG by weight (i.e. 2−3 PEG chains per molecule of LPEI), as calculated from ^1H NMR using the ratio of peak intensity of PEG ($-CH_2O-$, 3.57 ppm) to ethyleneimine peak intensity ($NHCH_2CH_2$, 3.0−3.3 ppm). Branched PEI (BPEI, M_n 10 kDa) was reacted with monomethoxy PEG carboxy-*N*-hydroxysuccinimide. The corresponding graft-copolymer obtained using BPEI as a backbone contained approximately 10 wt % of PEG calculated from ^1H NMR using the ratio of peak intensity of PEG ($-CH_2O$, 3.57 ppm) to ethyleneimine proton peak intensity ($NHCH_2CH_2$, 2.9−3.2 ppm).

Synthesis of Hyperbranched PEG-like Core Polymers (HBPEG). Cationic copolymerization of poly(ethylene glycol) diglycidyl ether (bearing two reactive epoxy groups) and pentaerithrytol ethoxylate (containing four hydroxyl groups) was accomplished by using boron trifluoride as a catalyst (Supporting Information, Figure S2). By varying the catalyst concentration, polymers with different molecular masses ranging from 25 to 35 kDa were obtained. Upon the omission of the polyol (pentaerithrytol ethoxylate), the formation of a gel instead of a soluble polymer was observed. The use of methylene chloride instead of THF as copolymerization solvent resulted in polymers with a lower molecular mass. Quantitative ^{13}C NMR showed incorporation of butylene ether moiety within the HBPEG composition (Figure 1B). The butylene ether moiety was absent from ^{13}C NMR spectra if the copolymerization was carried out in methylene chloride. The hyperbranched PEG-like polymers were isolated as semisolids that had excellent solubility in water and various organic solvents (e.g. methylene chloride, tetrahydrofuran). The obtained HBPEG polymers were analyzed by using a size-exclusion chromatography (Figure 1A, Table 1). Due to the fact that size exclusion chromatography (SEC) tends to underestimate the true molecular mass of branched polymers (*18*), the true molecular masses of branched polymers were likely to be higher than those suggested by SEC if linear polymers were used as standards. The polydispersity of obtained products was low due to the removal of low molecular weight polymer fraction during the dialysis. The presence of hydroxyl groups was determined by titration method as described (*19*). Titration of available hydroxyls in HBPEG gave a value of approximately 100 hydroxyl groups/HBPEG molecule. The

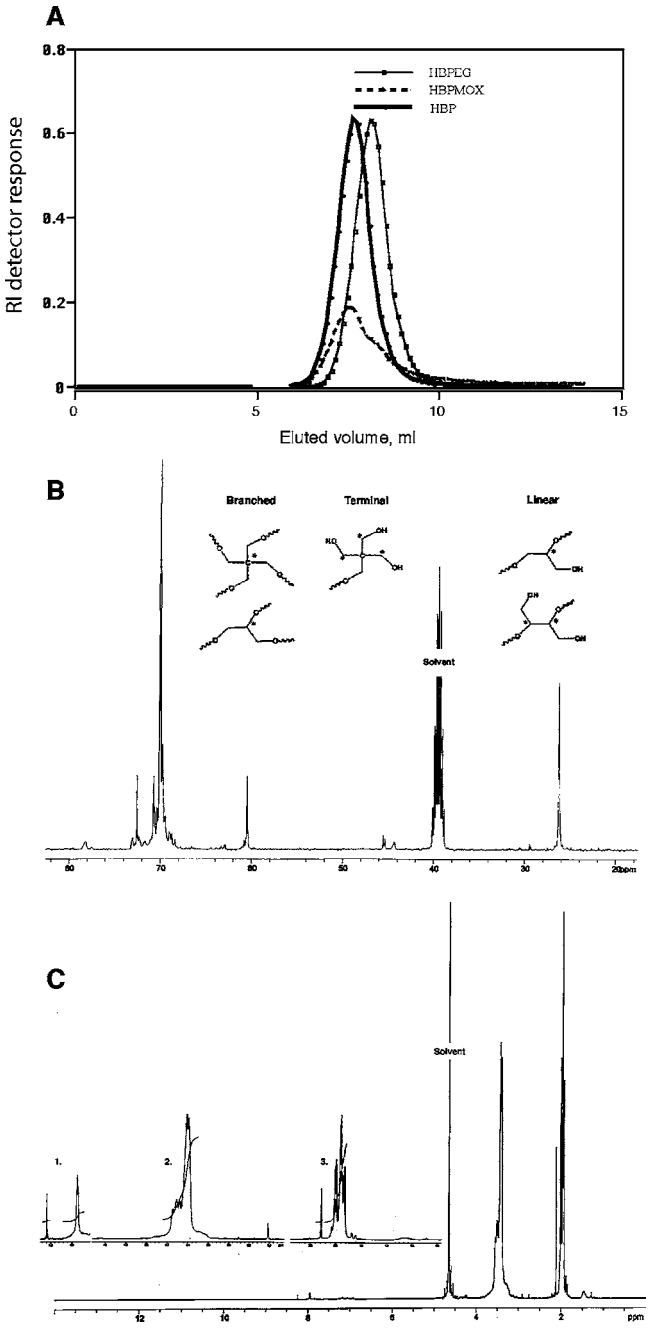

Figure 1. A. Gel permeation chromatography of HBPEG2 (M_n 24.7 kDa); "inverted" precursor, a block copolymer HBPMOX1 (M_n 56.2 kDa), and the hydrolyzed product (HBP1) (M_n 42.6kDa). B. Structural units of hyperbranched poly(ethylene glycol)-like core (HBPEG2, Table 1) predicted from quantitative ^{13}C NMR data in DMSO-d_6. Linear monomeric unit (l) 44.3 and 72.5−78.2 ppm; branch (t) peaks at 30.4, 44.5, 60.4−60.8, and 62.9 ppm; dendritic core (d) peaks at 29.4 and 72.4 ppm. C. ^1H NMR spectra of HBPMOX1 in D_2O. Inserts: enlarged view of spectras in the following ranges (1) 1.2−2.2 ppm; (2) 2.6−4.2 ppm; and (3) 7.9−8.2 ppm.

observed high content of terminal hydroxyl groups argues for the formation of extensive branching structure. To calculate the degree of branching, quantitative ^{13}C NMR data were used. We assigned the 44.3, 72.5−78.2 ppm peaks to the linear monomeric unit (l), whereas peaks corresponding to 30.4, 44.5, 60.4−60.8, and 62.9 ppm were assigned to the termini of branches (t). The peaks at 29.4 and 72.4 ppm correspond to the dendritic core (d). The degree of branching was calculated using the following formula as described in (*20*). The degree of branching, DB = $(N_d + N_t)/(N_d + N_t + N_l)$, where N is the integrated value of the peak; d, l, t are dendritic, linear, and terminal units, respectively (Figure 1B). The calculated DB values were 0.68 (HBPEG1) and 0.59 (HBPEG2). Both polymers were synthesized using identical conditions and various amounts of the catalyst (Table 1). According to published data, in hyperbranched polymers the degree of branching is approximately 0.5 (*21*).

HBP Block Copolymer Synthesis. We synthesized a cationic block copolymer (HBP) with grafted polyethyleneimine chains using hyperbranched PEG (HBPEG) as the inner core. First, we performed activation of surface hydroxyl groups of HBPEG using either 4-chloromethylbenzoyl chloride or *p*-toluenesulfonyl chloride. The above chlorides catalyze ring-opening polymerization of 2-oxazoline groups (*22*, *23*) (Supporting Information, Figure S3). The purified chloromethyl or tosyl derivative of HBPEG was characterized by ^{13}C NMR data that showed the presence of a sulfonyl derivative (δ 127.9 (aromatic ortho carbon $(CH)_2-C-SO_2^-$) and chloromethyl derivative (δ 128.4 (aromatic ortho carbon, $ClCH_2C(CH)_2$), respectively. The block copolymer prepared by reacting ethyl oxazoline with the tosyl derivative of HBPEG (HBPEOX) was precipitated in ethyl ether, dried in a vacuum, and characterized (Table 1). ^1H NMR peaks at 3.2−3.44 ppm ($(-CH_2CH_2NCOCH_2CH_2-$) and 1.49 ppm (CH_3CH_2CO-) confirmed the presence of poly(2-ethyl 2-oxazoline). The polymer was then hydrolyzed as described earlier (*23*), using sodium hydroxide in ethanol/ethylene glycol and purified by dialysis. The disappearance of peak at 3.2−3.4 ppm and the new peak at 2.59−3.09 ppm ($-NHCH_2CH_2-$) suggested that hydrolysis of the block copolymer proceeded efficiently and that the "inverted" block copolymer (HBP4) was formed (Table 1). The block copolymer of the chloromethyl derivative of HBPEG was prepared by the cationic polymerization method, using 2-methyl 2-oxazoline monomer in benzonitrile and potassium iodide as a coinitiator. Potassium iodide was used for exchanging chloride anion with iodide, that resulted in high efficacy of conversion into HBPEG−poly(methyl oxazoline) (Supporting Information, HBPMOX, Figure S3). Upon varying the reaction composition and time of polymerization we prepared different molecular weight HBPMOX (Table 1). We further analyzed the obtained polymers using GPC (Figure 1A) before and after the alkaline hydrolysis that demonstrated the progressive increase of the average mass of the polymer after the extension of poly(2-ethyl 2-oxazoline) chains and their hydrolysis (Table 1). Figure 1C depicts the ^1H NMR spectrum of HBPMOX1. The observed peak at 7.95 ppm (aromatic ortho hydrogen, $-NCH_2(CH)_2(CH)_2-$) pointed to the extension of the poly(2-methyl 2-oxazoline) block from the chloromethyl derivative HBPEG core as the reaction scheme (Supporting Information, Figure S3) suggested. The methyl protons of the acetyl group (1.9 ppm) were undetectable after the hydrolysis, whereas methylene protons adjacent to nitrogen shifted from 3.4 to 2.7 ppm.

Complex Formation with DNA. The formation of complexes between DNA and HBP polymers was monitored by fluorometry using the ethidium bromide displacement method. Control PEG-grafted polymers (PEGLPEI and PEGBPEI) showed a gradual decrease of fluorescence that reached 50% of the initial relative fluorescence intensity value in the presence of large polymer amounts (concentration exceeded 50 μg/mL, Figure 2). In the case of hyperbranched block copolymer (HBP), linear polyethyleneimine LPEI, and commercially available branched polyethyleneimine BPEI (Figure 2), a 50% decrease of fluorescence intensity was observed in the presence of much lower polymer amounts (approximately 10−13 μg/mL). DNA condensing properties of polymers were tested in parallel by measuring hydrodynamic radii of polymers and the complex with negatively charged DNA (Table 1). Initially, we measured

[l] Size exclusion chromatography was performed in 0.1 M ammonium acetate using poly(ethylene oxide)s as molecular weight standards. [m] Complex was prepared by mixing 25 μg of DNA and 50 μg of polymer in 1 mL of 5% glucose solution.

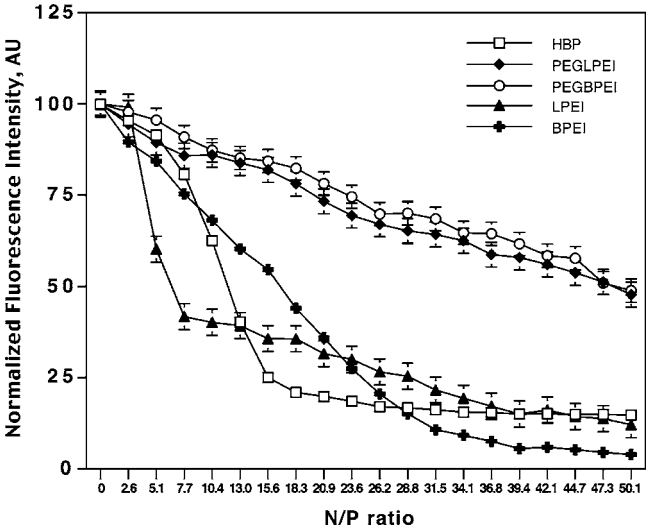

Figure 2. DNA-bound ethidium bromide displacement as a result of complex formation with polycations. The legend denotes complexes formed with BPEI (closed circles), LPEI (closed triangles), PEGBPEI (open circles), PEGLPEI (diamonds), and HBP1 (squares). The *y*-axis represents the normalized fluorescence intensity. Results of three independent experiments are shown as mean ± SD.

the hydrodynamic diameter of the HBPEG core (approximately 25 nm). After block copolymerization with the formation of the LPEI "corona", the diameter increased by ~10 nm. Further, we observed that complexes between the plasmid DNA and HBP formed in nonionic, isotonic solution (5% glucose in water) were small, ~50 nm in diameter, and that particle size did not change for at least 30 days. We further performed measurements of zeta potentials of complexes prepared using 25 μg of DNA and 50 μg of hyperbranched block copolymer (HBP2 or HBP3). Zeta potential of complexes was affected by changing the density of cationic residues in the polymer. We used two different molecular weight polymers for zeta potential measurement and established that higher molecular weight polymer (HBP2) yields more positive zeta potential of the complex than the low molar mass polymer HBP3 (Table 1).

The ability of the HBP to protect the nucleic acids from enzymatic cleavage was tested by using DNAse I treatment, and the data were compared to that obtained using LPEI and the conventional graft copolymer (PEGLPEI). The complex composition corresponded to that with the highest transfection efficiency in cell culture (see below). HBPs were able to protect DNA from degradation by DNAse I for at least 2 h (Figure 3), and only traces of DNA fragments were present at the highest concentrations of DNAse I used. The control "naked" DNA as well as PEGLPEI complex with DNA was completely degraded at concentrations of DNAse I exceeding 2.5 U/mL. In the case of the complex prepared using LPEI, ethidium bromide staining of the complex is much higher than the in the complexes prepared using HBPs.

Cell Transfection. Cell transfection efficacy was compared in COS-1 cell culture. Prepared in identical conditions, all complexes gave very different levels of luciferase expression. In case of both types of "conventional" graft copolymers transfection efficiency was low even when higher amounts of polymer were used for complex preparation (Figure 4A). The transfection efficacy observed in the case of HBP block copolymers was compared against linear polyethylneimine (LPEI). The resultant luciferase activity expressed in transfected cells was at least 5 orders of magnitude higher than any of PEGLPEI or PEGBPEI while the amount of hyperbranched block copolymer needed for transfection was less (at least 50 times). Used at similar weight ratio, hyperbranched block copolymers showed at least two orders higher transfection efficiency than that of positive control Superfect reagent (Figure 4A and Figure 4B). At slightly higher concentrations, hyperbranched block copolymer showed higher transfection efficiency than LPEI.

Cytotoxicity. Cytotoxicity of polymers was investigated in COS-1 cells at 48 h after the addition of polymers (Figure 4C). The highest molecular mass HBP had a very low cytoxicity even at a very high concentration (0.5 mg/mL). Although at lower concentration the toxicity of HBP was lower than that of LPEI, the observed differences were not significant.

DISCUSSION

It is well-known that upon mixing positively charged block copolymers with DNA, polycationic blocks induce DNA binding and condensation while PEG blocks provide steric protection for condensed DNA−polycation cargo (*7*, *24*). The major goal of our research was to compare "conventional" copolymers composed of polycationic PEI- and PEG-based blocks with HBPs, based on hyperbranched PEG-like polymer block surrounded with PEI blocks, i.e. "inverted" design. The "conventional" copolymers contained between 5 and 10% of PEG2000 by weight, respectively, which appears to prevent binding of the DNA−polymer complex to the cell (*16*, *25*), resulting in at least 4 orders of magnitude lower transfection efficiency than that of its 22 kDa PEG-free LPEI counterpart at all concentrations (*26*). Our experiments with similar copolymers also showed that even at very high concentrations of graft copolymers (1.5 mg/mL), the highest achieved transfection efficiency

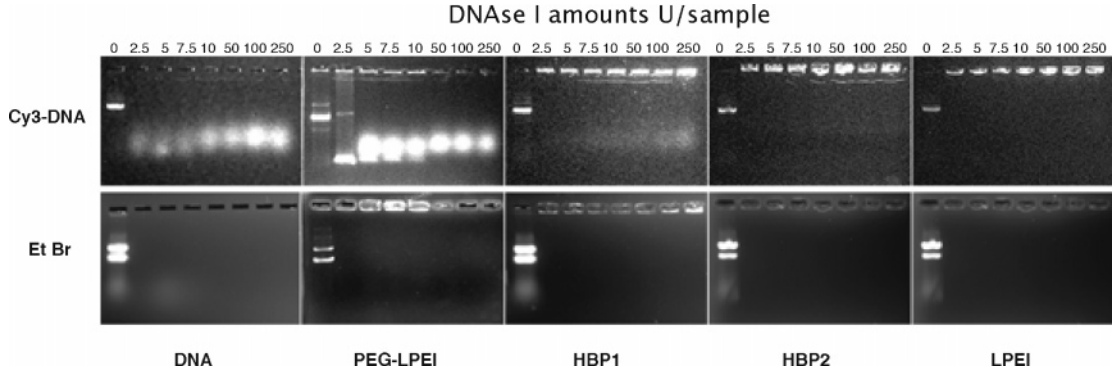

Figure 3. DNAse I protection assay. Lane 1 shows control pCMV−Luc/Cy3-pCMV−Luc mixture (6:1 by weight, 1.5 μg of DNA was loaded per lane). Lane 2−7 shows the same mixture at different amounts of DNAse I present: 2.5U, 5U, 7.5U, 10U, 50U, 100U, and 250U, respectively. DNAse I was incubated with DNA and polycation-containing samples for 2.5 h at room temperature followed by 0.8% agarose gel electrophoresis and imaging using Kodak 440CF equipped with Cy3 fluorescence filters (upper row), staining with ethidium bromide, and imaging (lower row). A typical result is shown.

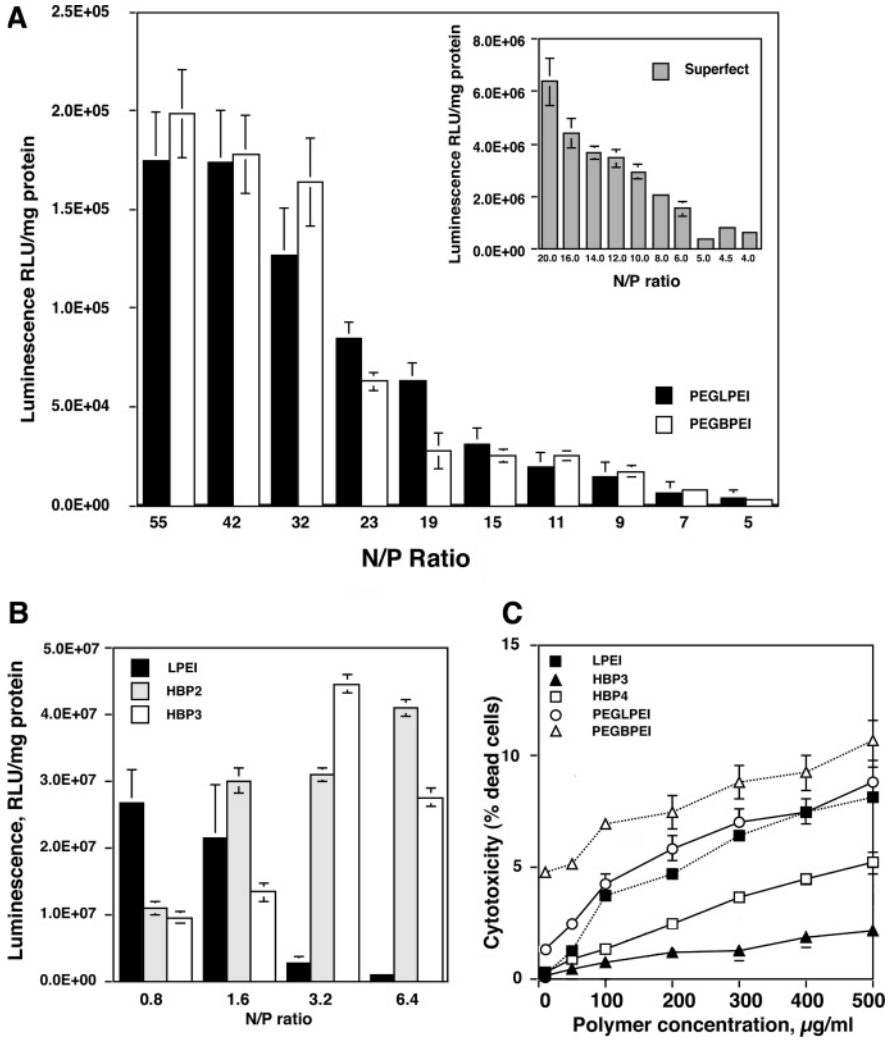

Figure 4. A. Luciferase expression in COS 1 cells after a 24 h transfection in serum-containing medium: transfection efficiency of PEGLPEI (solid bars), PEGBPEI (open bars) at various N/P ratios. Transfection results obtained using various concentrations of Superfect reagent are shown in the inset. Polymer complex with plasmid DNA was prepared by mixing 0.5 μg of pCMV-luc in 30 μL solvent with polymers at different concentrations. B. Luciferase expression in COS-1 cells after a 24 h transfection in serum-containing medium: transfection efficiency of LPEI (solid bars), HBP3 (shaded bars), and HBP2 (open bars). The complex was prepared by mixing 0.5 μg of pCMV-luc plasmid DNA with various polymer amounts (shown in *x*-axis). C. Cytotoxicity profiles of linear polyethyleneimine (closed squares) and hyperbranched block copolymers: HBP3 (closed triangles), HBP4 (open squares), PEGLPEI (open circles), and PEGBPEI (open triangles) in COS-1 cell culture after 48 h incubation. Results of four independent experiments are shown as mean ± SD.

was still at least 3 orders of magnitude lower than that of LPEI (Figure 4A,B). Ethidium bromide displacement results suggested that for the purposes of cell transfection, "conventional" PEG-grafted polymers are effectively shielded by PEG, resulting in only partial availability of positive charges of the polymer for complex formation with the DNA (Figure 2).

In choosing HBP architecture, we hypothesized that the PEG-based polymer core could still provide protection to bound DNA

while the polycationic "shell" could be fully functional in DNA binding. Thus, we expected that upon the formation of complexes with negatively charged DNA, the cationic residues would get neutralized and that the formation of nanosized complexes could be achieved.

We devised the synthesis of the above hyperbranched molecule using a mixture of poly(ethylene glycol) diglycidyl ether and pentaerythritol ethoxylate upon cationic polymerization. The method enabled us to obtain high molecular mass hydroxyl-terminated, hyperbranched PEG-like polymer (HBPEG) in a single step. The available hydroxyl groups in hyperbranched polymer could be easily modified using chloromethyl benzoyl chloride or *p*-toluene sulfonyl chloride, yielding a hyperbranched macroinitiator that enabled synthesis of a block copolymer with poly(2-alkyl 2-oxazoline). The molar mass of block copolymer (Mn) could be controlled by changing the reaction parameters (Table 1). By treating polyoxazoline blocks in mild alkaline conditions, we obtained final HBPEG−LPEI (HBP).

Unlike PEGylated PEI (e.g. PEGLPEI or PEGBPEI), HBP-mediated condensation of DNA appeared not to be affected by hyperbranched PEG-like core blocks, because the concentration of HBP required to achieve a half-maximal displacement of ethidium bromide initially bound to DNA in the complex was low (Figure 2). Consequently, the DNA condensing properties of the "inverted" block copolymer was superior to that of graft copolymers used in this study. At the same time, particle size and stability data suggested that HBP behaved differently from PEGBPEI, since the complex with plasmid DNA was very stable during the storage and was at least two times smaller than DNA complexes obtained using "conventional" PEG-grafted PEI (Table 1, see also ref 24). The observed lack of core interference with the complex formation was also apparent in experiments which investigated DNA-protective properties of HBP. We observed that ethidium bromide-negative, i.e., highly condensed complexes, were highly resistant to DNAse I degradation (Figure 3).

We further measured cytotoxicity as well as transfection efficacy of the resultant block copolymer and compared them with the PEG-grafted PEI and LPEI (22 kDa). Due to the presence of hyperbranched HBPEG core, a higher amount of block copolymer was required to achieve optimal cell transfection (Figure 4A) at the concentration that was less toxic than that of LPEI (Figure 4C). It is known that PEG-grafted BPEI always show less toxicity than BPEI alone (*10*). In our case, i.e., when PEG-like polymer comprised the inner core of the molecule, the effect of lesser toxicity was achieved in a manner similar to that of the "conventional" PEG coating (Figure 4C). This suggests that the presence of HBPEG inner core indeed reduced cytotoxicity, whereas complex condensation by "inverted" block copolymer HBPs was superior to that of PEG grafted PEI (*26*). The latter effect could be explained by the lack of interference with DNA binding to PEI.

In conclusion, we report here synthesis and properties of hyperbranched block copolymers based on PEG-like hyperbranched core-first design. We demonstrated that "inverted" block copolymers (HBPs) obtained using grafting of linear PEI showed low toxicity in vitro and formed stable nanosized complexes with plasmid vectors that were protected from degradation with DNAse I. Furthermore, these nanocomplexes showed high transfection efficacy in vitro. Since in vitro transfection efficacy is not ideal in predicting the ability of a polycation to deliver expression or silencing vectors in vivo, the latter properties of hyperbranched polycations with PEG-like cores are currently under investigation.

RNAi Silencing of Exogenous and Endogenous Reporter Genes Using a Macrocyclic Octaamine as a "Compact" siRNA Carrier. Studies on the Nonsilenced Residual Activity

Kazuki Matsui, Shohei Horiuchi, Shinsuke Sando, Takashi Sera, and Yasuhiro Aoyama*

Department of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Katsura, Nishikyo-ku, Kyoto 615-8510, Japan. Received April 14, 2005; Revised Manuscript Received August 26, 2005

A macrocyclic octaamine **1** having a covalently linked lipid-bundle structure was introduced as a new type of siRNA carrier. Gel electrophoresis, DLS, and SPR results indicate that it strongly binds to a luciferase-targeting 21-mer (42P) siRNA with a ratio of **1**/P ≅ 0.3 (**1**/N ≅ 2.4) to give remarkably compact **1**−siRNA complexes with an average size of ∼10 nm. The **1**-mediated siRNA silencing of the exogenous luciferase gene occurs with a 90−95% efficiency. The overall suppression−[siRNA] profile with a 5−10% residual activity in the saturation region is commonly observed irrespective of the cell type (HeLa, HepG2, or HEK293), the order, or timing (stepwise or simultaneous) of supply of the siRNA and that of the luciferase-encoding plasmid, the level of mRNA transcribed, or the type of carriers (**1** vs lipofectamine 2000). The silencing of the endogenous DsRed2 gene stably incorporated in the genome of HeLa cells also has a similar overall profile. These results suggest that (1) the cellular uptake of the plasmid and that of the siRNA are basically independent of each other and (2) the incomplete silencing is not due to insufficient siRNA delivery. Implication of item 2 is briefly discussed.

INTRODUCTION

RNA interference (RNAi) is the posttranscriptional gene silencing process mediated by a 21−23-mer duplex siRNA (si = small or short interfering) which is homologous in sequence with the silenced gene (*1*−*5*). The siRNA taken up in the cells forms the so-called RISC (RNA-induced silencing complex) containing the antisense strand; consequently the complex then attacks the sense mRNA to result in degradation and hence silencing of the latter (*6*, *7*). The activity of synthetic siRNA was demonstrated for the first time by Tuschl et al., in terms of siRNA-dependent suppression of an exogenous reporter gene provided in the form of plasmid (*8*). This simple analysis was based on the assumption that a substantial portion of the plasmid-transfected cells also contains siRNA. Actually, the suppression, in this pioneering work, of pGL3 luciferase was complete (∼100%) in Drosophila cells but less complete (90−95%) in mammalian cells (*8*). Efficient but incomplete silencing has been generally observed in many subsequently studies using mammalian cells (*9*−*15*).

We are concerned here about two matters. One is the nonsilenced "residual" ≥5% gene-expression activity. Does it simply reflect incomplete siRNA delivery or is it a consequence of essential incompleteness of RNAi? The other is size control of carrier−siRNA complexes, particularly in view of their in vivo performance. As is often a problem in artificial (nonviral) gene delivery, huge particles cannot simply diffuse into vascular periphery (*16*). Small particles, on the other hand, may be selectively taken up in malignant tissues by the so-called EPR (enhanced permeation and retention) effect (*17*). The size we aim at is ≤50 nm, which has not been precedented before for the siRNA complexes to the best of our knowledge.

We introduced a cone-shaped macrocyclic octaamine **1** of an amphiphilic character as siRNA carrier. We report here that it forms an unprecedented compact (∼10 nm) complex with siRNA and mediates effective gene silencing but not completely regardless of the cell type, transfection order (siRNA vs plasmid), extent of gene transcription, carrier type (**1** vs lipofectamine 2000), or gene type (exogenous vs endogenous). This led us to suggest that the incomplete silencing should be interpreted in terms of intrinsic incompleteness of RNAi.

EXPERIMENTAL PROCEDURES

Materials and General Analysis. Octaamine **1** in the form of octa(hydrochloride) was obtained from the corresponding free-base, prepared as described (*18*), upon treatment with HCl. Thus, 2 mL of concentrated hydrochloric acid was added to an ethanol solution (200 mL) of the free-base (200 mg). Most of the ethanol was removed and the white precipitates that separated were collected and dried in vacuo to give 225 mg (94%) of the octa(hydrochloride). Plasmids (pGL3, pGL2, and pGL3-Promoter), siRNAs, and lipofectamine were commercial products of Promega, TAKARA BIO, and Invitrogen, respectively. HeLa (Riken Cell Bank, RCB0007), HepG2 (Dainippon Pharmaceutical Co. Ltd., HB8-65), and HEK293 (Riken Cell Bank, RCB1637) cells were cultivated in DMEM (Dulbecco's modified Eagle's medium) containing 10% FCS (fetal calf serum) and antibiotics (penicillin−streptomycin, 50 μg/mL) with (HepG2) or without (HeLa, HEK293) 1% NEAA (nonessential amino acids) at 37 °C in a humidified atmosphere containing 5% CO_2. HeLa cells stably expressing DsRed2 were provided by Prof. Kazunari Taira and Dr. Yutaka Ikeda (Tokyo University) and were cultivated in a similar manner as above. Gel electrophoresis was performed with 0.7% agarose gel in Tris-acetate buffer and 20% polyacrylamide gel in Tris-borate-EDTA buffer for pGL3 and siRNA, respectively. Size distribution profiles (histograms) in reference to number of particles were obtained by NICOMP analysis of dynamic light scattering (DLS) data for solutions of pGL3 or siRNA (2 μM P) in water in the presence of varying amounts of octaamine **1** at 23 °C using a Particle Sizing Systems NICOMP 380 ZLS zeta potential/particle sizer at 100 mW green laser (532 nm). DLS measure-

ments were also carried out for solutions of **1** with or without siRNA in the transfection medium Opti-MEM. However, the formation of big (≥50 nm) particles as a result of siRNA-independent aggregation processes prohibited detailed analysis of the **1**−siRNA complexes. Surface plasmon resonance (SPR) response curves were recorded on a BIAcore X system docked with a hydrophobized (HPA) sensor chip by repeated injection of an aqueous solution of octaamine **1** (100 μM, 25 μL) or siRNA (100 μM P, 25 μL) under the flow of degassed water (10 μL/min). Microscopic images were taken with an Olympus IX70 microscope.

Transfection and Subsequent Analysis. Cells (Hela, HepG2, or HEK293) were seeded at a density of 1.0×10^4 cells/well in a 96-well plate and cultivated. After 24 h, the cells became ~60% confluent and were washed with 100 μL of PBS(−) (magnesium/calcium-free phosphate buffer). To the cells in each well was added under cotransfection conditions a transfection medium (100 μL of Opti-MEM (GIBCO)) containing 200 ng of pGL3 (625 μM P) and 0, 2, 10, 42, or 126 ng of siRNA (0, 6, 30, 125, or 372 μM P) in the absence or presence of a carrier, octaamine **1** (1088 ng; **1**/P = 1.0 (N/P = 8.0) with respect to pGL3) or lipofectamine (500 ng, according to the manufacturer's protocol). After incubation for 6 h at 37 °C, the medium was replaced by 100 μL of fresh DMEM containing 10% FCS, and the cells were further incubated for 48 h. Under pretransfection conditions, the cells were first treated with an Opti-MEM solution (100 μL) containing siRNA (0, 2, 10, 42, or 126 ng) and octaamine **1** (1088 ng) or lipofectamine 2000 (500 ng) for 6 h, washed with 100 μL of PBS(−), and then transfected with pGL3 (200 ng) and lipofectamine (500 ng) in 100 μL of Opti-MEM. After 6 h, the medium was replaced by DMEM and incubation was continued for 48 h as above.

Luciferase assay was performed by the conventional chemiluminescence method using a Lumat LB5907 luminometer (Berthold Detection System) and the luciferase assay kit (Promega). Luciferase relative light units (RLU) integrated over 10 s are normalized for the total protein content of the cell lysate, obtained by the Bradford assay (Bio-Rad Laboratories) using bovine serum albumin as a standard. For MTT assay of lively cells, 20 μL of a solution of the MTT reagent (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide) in PBS(−) (5 mg/mL) was added to each transfection mixture in a well. After incubation for 3 h, the medium was removed, a 10% SDS solution (200 μL) was added, and the absorbance at 570 nm of the resulting homogeneous solution was measured.

Gene silencing in HeLa cells stably expressing DsRed2 was carried out in essentially the same manner as above. After washing with PBS(−), the cells were dissolved in 25 μL of PLB (passive lysis buffer, Promega). The resulting solution was divided into two parts; one (2.5 μL) was analyzed for the total proteins and the other (20 μL) for the fluorescence intensity at 580 nm (excitation at 563 nm) after dilution with 380 μL of PBS(−).

RESULTS AND DISCUSSION

Complexation Behavior. The new carrier introduced here is a cone-shaped macrocyclic octaamine **1** (Figure 1), having four long alkyl (undecyl) chains and eight amino groups on the opposite sides of the calix[4]resorcarene macrocycle. It is obtained as octaammonium octachloride. Because of its amphiphilic structure, it is what may be called a covalently linked lipid bundle. The free-base compound served as precursor of glycocluster compounds (*18*, *19*) capable of stoichiometric gene coating to give transfectious "glycoviruses" (*16*, *20*). Cationic lipid aggregates (cationic liposomes) and polymers have so far been extensively used as nonviral gene carriers (*21*−*23*). While being a small molecule (mw, 1740), compound **1** unimolecularly

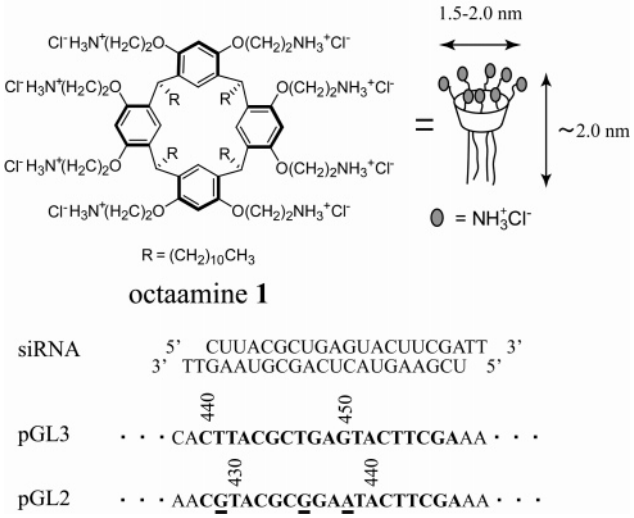

Figure 1. Structures of octaamine **1**, siRNA, and siRNA-relevant sequences (only sense strands are shown) of the luciferase genes in plasmids pGL3 and pGL2.

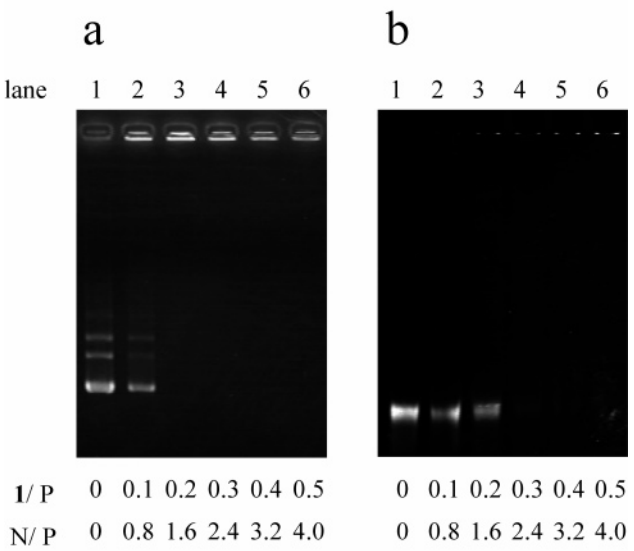

Figure 2. Electrophoretic gel shifts for pGL3 (a) and siRNA (b) in the absence (lane 1) and presence (lanes 2−6) of increasing amounts of octaamine **1** using 0.7% agarose gel in Tris-acetate buffer (a) or 20% polyacrylamide gel in Tris-borate-EDTA buffer (b); N and P stand for an ammonium group of octamine **1** and a phosphate moiety of the plasmid, respectively.

presents a characteristic amine/ammonium cluster motif with a well-defined geometry.

RNAi experiments were carried out using the same set of plasmid and siRNA (Figure 1) as used before (*8*). The plasmid is pGL3 (5256 base pairs) encoding a firefly protein luciferase under control of an SV40 promoter and an SV40 enhancer. The siRNA is a 21-mer duplex having two-nucleotide overhangs at the 3′-ends, the sense strand copying the 440−458 nucleotide sequence (shown in bold letters) of that of the luciferase gene in pGL3.

The complexation of octaamine **1** with pGL3 (a) and with siRNA (b) was monitored by gel (agarose and polyacrylamide, respectively) electrophoresis (Figure 2). The huge plasmid DNA duplex (pGL3) and the short linear RNA duplex (siRNA) are rendered completely immobile at a ratio of **1**/P in the range 0.1−0.2 (N/P 0.8−1.6) or 0.2−0.3 (N/P 1.6−2.4), respectively (N and P stand for an ammonium group of **1** and a phosphate moiety of DNA/RNA, respectively). Dynamic light scattering (DLS) also confirmed the complexation. When alone, octaamine

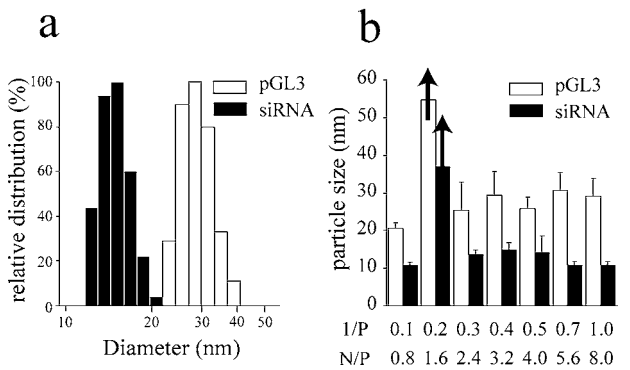

Figure 3. Typical size-distribution profiles (histograms) for the **1**−pGL3 and **1**−siRNA complexes at **1**/P = 0.4 (2 μM P) (a) and variation in the mean sizes thereof as a function of **1**/P or N/P (b) in reference to number of particles as evaluated by NICOMP analysis of the DLS data taken after 1 h from mixing of components. N and P stand for an ammonium group of octaamine **1** and a phosphate moiety of the plasmid, respectively.

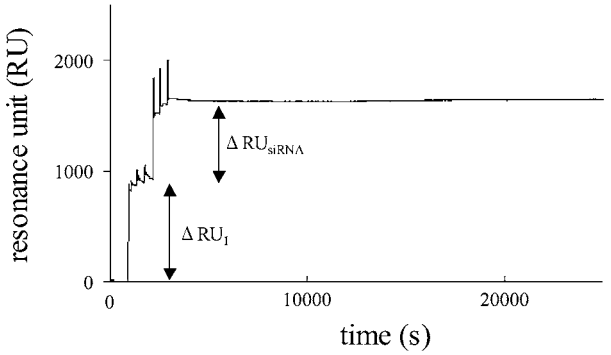

Figure 4. SPR response curve for the immobilization of octaamine **1** on a hydrophobized sensor chip and further adsorption of siRNA on the resulting monolayer of **1**. An aqueous solution of **1** (100 μM, 25 μL) or siRNA (100 μM P, 25 μL) was injected successively three times for immobilization of **1** or adsorption of siRNA, respectively, in the flow of water at a flow rate of 10 μL/min.

1 shows no tendency of forming aggregates of a size of ≥10 nm. However, in the presence of pGL3 or siRNA (2 μM P), the formation of particles (**1**-pGL3 or **1**−siRNA complexes) in that size range with a well-behaved size−distribution profile can be readily detected. In Figure 3a are shown typical histograms for the pGL3 and siRNA complexes at **1**/P = 0.4 (N/P = 3.2), both having a polydispersity index of 1.02. The mean sizes are plotted in Figure 3b as a function of **1**/P (N/P). The particle sizes are changeable and time-dependently grow at **1**/P = 0.2 (N/P = 1.6) probably as a result of cross-linking but are rendered time-stable and leveled off upon further increase in the amount of **1**. Saturation occurs at **1**/P ≅ 0.3 (N/P ≅ 2.4), and the saturation sizes for the **1**-pGL3 and **1**−siRNA complexes are d_{DLS} ≅ 30 and 10 nm, respectively, the latter being remarkably smaller than the size of cationic liposome−siRNA complexes (>100 nm) (*15*). The saturation ratio of **1**/P ≅ 0.3 or N/P ≅ 2.4 suggests that the complexation is primarily electrostatic in origin and that each siRNA molecule (42P) binds ∼12 molecules of **1**, having a width of 1.5−2.0 nm and a height of ∼2 nm (Figure 1). Amphiphile **1** in the cone shape may form small micelle-like nanoparticles but not huge vesicular/liposomal aggregates (*18*, *19*), and this may be at least partly why the present **1**−siRNA complex can be kept exceptionally compact (∼10 nm).

Surface plasmon resonance (SPR) shed more light on the **1**−siRNA interaction. Octaamine **1** (molecular weight, 1456) having four long alkyl chains can be readily immobilized on a hydrophobized (alkanethiol-coated) sensor chip (HPA) of SPR with an increase in resonance unit of ΔRU_1 = 960 (Figure 4). The latter, in light of the known relationship that ΔRU = 1000 corresponds to 1 ng/mm^2 of adsorbate, indicates that compound **1** is adsorbed with a packing density of 0.40 molecules/nm^2 or an occupation area of 2.5 nm^2/molecule, which is very close to the expected area of the octaammonium macrocycle with a diameter of 1.5−2.0 nm (Figure 1). Compound **1** must thus form a closely packed monolayer on the surface with its alkyl chains embedded in the hydrophobic forest of the sensor chip and the arrayed ammonium groups exposed to bulk water, as has been confirmed for the **1**-derived glycocluster compounds (*24*).

Treatment of the resulting **1**-coated sensor chip with siRNA gave a further increase in RU (Figure 4) as a result of adsorption of the siRNA (molecular weight per P or nucleotide, 320) via interaction with the ammonium groups on the surface. The interaction is strong or practically irreversible, since no notable dissociation of siRNA adsorbed was observed even after 24 h (ΔRU ≤ 20). The increase in RU of ΔRU_{siRNA} = 700 corresponds to a packing density of 1.3 P/nm^2 or an occupation area of 0.76 nm^2/P. These values, taken in conjunction with the corresponding values for octaamine**1** shown above, reveal the stoichiometry of **1**/P = 0.40/1.3 ≅ 0.3, which is in excellent agreement with that (**1**/P ≅ 0.3) evaluated from the DLS results. Neighboring phosphate groups in each strand of B-type duplex polynucleotides are separated by ∼0.7 nm from each other (*25*). The open conformation of the octaammonium motif of **1** has a diameter of ∼2 nm (Figure 1). Each molecule of **1** could thus cover three (2/0.7) P or nucleotide moieties with a stoichiometry of P/**1** ≅ 3. This is indeed what was observed (**1**/P ≅ 0.3). While the actual structure of complex **1**−siRNA is still not ready to be imaged, the present results and analysis suggest that (1) the anionic surface of siRNA is effectively coated with the cyclic array of the ammonium groups of rigid macrocycle **1** which is possibly micellized in small nanoparticles, (2) the coating stoichiometry is governed by steric factors, and (3) the resulting **1**−siRNA complex with insulated negative charges is free from further electrostatic aggregation.

Cotransfection. Cotransfection of cell culture was carried out by incubating HeLa (a human uterine cell line), HepG2 (a human hepatic cell line), or HEK293 (a human embryo kidney cell line) cells for 6 h in a transfection medium (Opti-MEM, 100 μL) containing a fixed amount (200 ng; 0.6 nM or 6.2 μM P) of pGL3 and a varying amount of siRNA in the presence of octaamine **1** as a carrier of both pGL3 and siRNA, followed by further incubation of the cells for 48 h in a fresh medium of DMEM (100 μL). The amount of carrier **1** (1088 ng per well) was set at **1**/P = 1.0 (N/P = 8) with respect to pGL3 to ensure complete complexation thereof. Each transfection mixture was analyzed for luciferase expression efficiency and for cytotoxicity. The cytotoxicity in reference to cell morphology and cell viability (Supporting Information) turned out to be slightly more pronounced than that of widely used lipofectamine 2000. In Figure 5 are shown the yields of luciferase, in terms of chemiluminescence relative light units (RLU) per mg total protein (top) or relative percentages (bottom), as a function of the amounts of siRNA (0, 2, 10, 42, and 126 ng; 0, 1.8, 7.0, 29, and 88 nM or 0, 0.08, 0.3, 1.2, or 3.7 μM P) for HeLa (a), HepG2 (b), or Hek293 (c) cells. The saturation-type yield-[siRNA] profile indicates that octaamine **1** acts as carrier for both pGL3 and siRNA. The **1**-mediated expression of luciferase becomes sharply suppressed with increasing amounts of siRNA but not perfectly. Thus, the suppression is evident at 2 ng of siRNA, reaches a plateau at ≥ 10 ng with 90−95% silencing, and remains in that level upon further increase in the amount of siRNA up to 126 ng. The suppression profiles with a 5−10% residual activity are remarkably similar or even superimposable for the three independent cell lines.

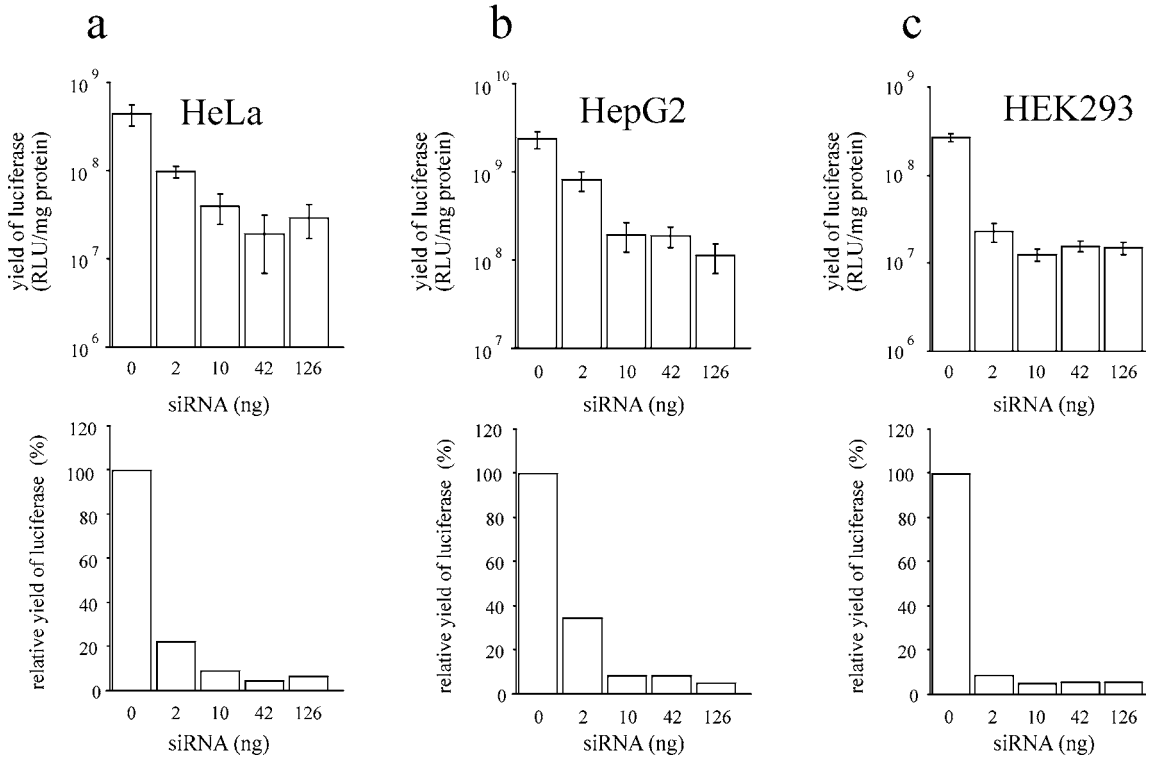

Figure 5. Transfection of HeLa (a), HepG2 (b), and HEK293 (c) cells under cotransfection conditions with siRNA and pGL3 (200 ng) as mediated by octaamine **1** (1088 ng). Yields of luciferase in terms of chemiluminescence relative light units (RLU) per mg total protein (top) or percentages relative to siRNA-free runs (bottom) are plotted as a function of the amounts of siRNA. Data are averages of about five experiments and error bars represent standard deviations.

Pretransfection. There are many conceivable explanations for the incomplete silencing. A simple one would assume that a small fraction (5−10%) of the cells cotreated with plasmid and siRNA actually incorporates only the plasmid and no siRNA for a statistical reason or as a result of competition between plasmid and siRNA. There is no way of efficient suppression in such plasmid(+)siRNA(− or Δ) cells. The question in a more general term is if or not the residual 5−10% activity arises anyhow from insufficient delivery of siRNA. If this is the case, the performance of the silencer siRNA might be improved when it is introduced in advance to enhance its population in the cells and to *wait* for its target, i.e., the mRNA coming from the plasmid taken afterward. If this pretransfection method is to work, the siRNA should be amply stable in the cells and should not seriously inhibit subsequent cellular uptake of the plasmid.

Thus, under the pretransfection conditions, the cells (HeLa, HepG2, or HEK293) were treated first with a mixture of siRNA (0−126 ng) and octaamine **1** (1088 ng) in Opti-MEM for 6 h, medium was removed, and the cells were washed for 1 h and then treated with a mixture of pGL3 (200 ng) and lipofectamine 2000 (500 ng) in Opti-MEM for 6 h, followed by further incubation for 48 h in a fresh medium of DMEM. It was in order to make the siRNA-delivery and plasmid-delivery steps distinguishable that we used different carriers for the plasmid and siRNA. We also used a reference gene contained in plasmid pGL2 (6047 base pairs) (Figure 1) (*8*). This also encodes luciferase but the key siRNA-relevant sequence (shown in bold letters) is different from that in pGL3 at three points underlined. Thus, the mRNA transcribed from pGL2 cannot be a target of the present siRNA. Each transfection mixture was analyzed for luciferase expression efficiency (Figure 6) and for cytotoxicity (Supporting Information), as above. An inspection of Figures 5 and 6 immediately shows that the overall feature remains unchanged as regards the general saturation profile and particularly the persisting 5−10% activity even at 126 ng of siRNA for the three different types of the cells. The siRNA introduced in the cells prior to the plasmid may competitively inhibit the uptake of the latter in a [siRNA]-dependent manner. This could explain the decreasing yields of luciferase with increasing [siRNA], but this cannot be the case. This is because the uptake of, and hence the expression of luciferase from, the RNAi-irrelevant pGL2 is not inhibited at all by the siRNA even at the highest 126 ng level (Figure 6, black bars). In this context, the [siRNA]-dependent suppression of pGL3 under the present pretransfection conditions should be ascribed to specific RNAi as in the case of cotransfection.

The similar suppression profiles under the cotransfection and pretransfection conditions can be interpreted as suggesting that cellular uptake of the plasmid and that of the siRNA are basically independent of (orthogonal with) each other. There is no evidence that the preintroduced siRNA notably inhibits subsequent uptake of the plasmid. There is no evidence either that the siRNA can be taken in the cells much more efficiently when alone under the pretransfection conditions than when in combination with the plasmid under the cotransfection conditions. Thus, the siRNA and the plasmid are not competitors with each other.

Control Runs. A couple of control runs were carried out. In one set of experiments, we used the pGL3-Promoter vector in place of pGL3; the former lacks the SV40 enhancer sequence which is present in the latter. With pGL3-Promoter, the nonsuppressed yields of luciferase at siRNA = 0 ng were one- or two-orders of magnitude lowered than those with the enhancer-containing pGL3 vector. Nevertheless, the general siRNA-suppression profile with a 5−10% residual activity under both cotransfection and pretransfection conditions (Supporting Information) remained remarkably the same as that shown in the bottom panels of Figures 5 and 6. In the other control, we carried out the same set of cotransfection and pretransfection experiments using lipofectamine 2000 in place of octaamine **1** under the otherwise identical conditions. All the results (shown in Supporting Information) not only reproduce the ∼90%

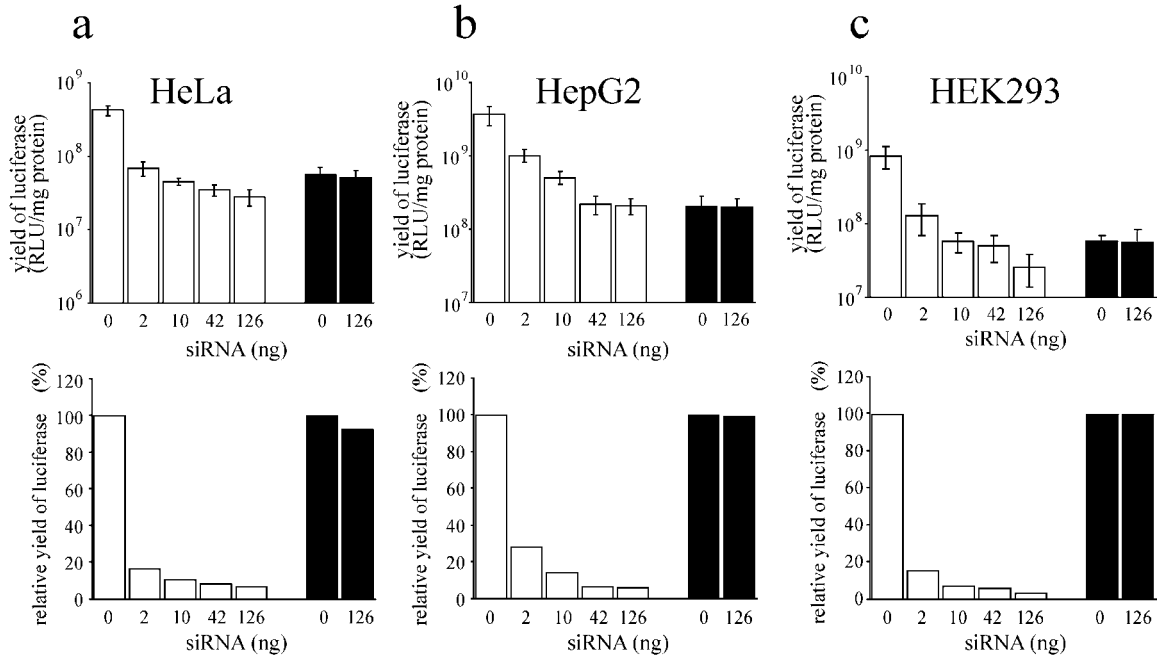

Figure 6. Transfection of Hela (a), HepG2 (b), and HEK293 (c) cells under pretransfection conditions with successive introduction of siRNA by the aid of octaamine **1** (1088 ng) followed by that of pGL3 (white bars) or pGL2 (black bars) (200 ng) by the aid of lipofectamine (500 ng). Yields of luciferase in terms of chemiluminescence relative light units (RLU) per mg total protein (top) or percentages relative to siRNA-free runs (bottom) are plotted as a function of the amounts of siRNA. Data are averages of about five experiments, and error bars represent standard deviations.

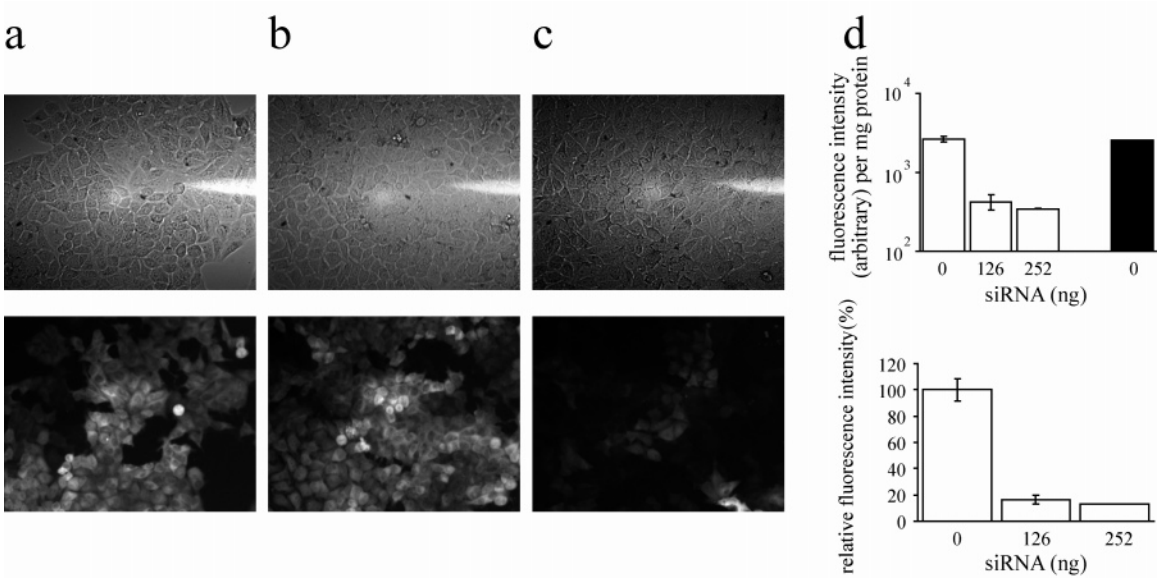

Figure 7. Optical micrographs (top) and their fluorescence images (bottom) of the DsRed2-expressing HeLa cells treated in Opti-MEM (100 μL) for 6 h. (a) In the presence of neither octaamine **1** nor siRNA, (b) in the presence of **1** (500 ng) without siRNA, and (c) in the presence of **1** (500 ng) and siRNA (126 ng). The fluorescence intensities (in arbitrary unit) normalized by the total protein content of the cell lysate (top) or as relative percentages (bottom) are plotted as a function of the amounts of siRNA in panel d. The black bar shows the reference intensity in the presence of neither **1** nor siRNA.

suppression previously reported (*8*) but also reveal that the overall feature with a saturation profile (*8, 12*) is essentially the same as that for octaamine **1** (Figures 5 and 6). Thus, the surviving 5−10% activity in the saturation range is neither cell-sensitive nor carrier-dependent, in accord with a previous report (*15*).

Silencing of Endogenous Gene. Silencing of endogenous gene is practically more significant and allows more direct evaluation of the performance of siRNA. The target gene here is that for fluorescent protein DsRed2 stably incorporated in the genome of HeLa cells. The latter constantly fluoresces at 580 nm when excited at 563 nm (Figure 7a). In the presence of the DsRed2-targeting siRNA (126 ng) conjugated with octaamine **1**, the otherwise fluorescent $HeLa_{DsRed2}$ cells were rendered remarkably nonfluorescent (Figure 7c) as a result of siRNA-silencing of the endogenous DsRed2 gene. The suppression is 84% or 87% in the saturation range of siRNA = 126 ng or 252 ng, as evaluated by referring to relative fluorescence intensities (Figure 7d). The residual activity of 13−16% of the present endogenous gene is slightly higher than that of 5−10% observed above in case of exogenous luciferase but the overall features (Figures 5 and 6 vs 7d) are quite similar to each other.

Residual Gene-Expression Activity. We have so far investigated the siRNA silencing of the exogenous luciferase gene using three cell lines, two expression vectors with or without

an enhancer, and two carriers under cotransfection and pretransfection conditions. Different cells have different transfectabilities, giving rise to different yields of luciferase at siRNA = 0 ng. The amounts of mRNA transcribed can be more directly changed by changing the expression vectors for a given cell type. The two carriers have different size properties. Octaamine **1** forms small particles which coat the plasmid or siRNA into a compact size (~30 or ~10 nm, respectively), while lipofectamine forms huge liposomes to which the plasmid or siRNA is attached (*26*). Nevertheless, the effects of increasing amounts of siRNA turned out to be essentially identical, leaving a 5−10% nonsuppressed gene-expression activity. Similar profiles are found in the literature (*9*−*15*). One report shows that the delivery efficacy of siRNA is not affected by the particle size (*15*). As far as residual activity is concerned, there is no essential difference between the exogenous luciferase and the endogenous DsRed2 genes to be silenced. The common profile should be interpreted as reflecting something essential rather than accidental.

It is beyond the scope of this work to go into the mechanistic aspect of RNAi. Obviously, however, the incomplete silencing should not be ascribed to insufficient (relative to mRNA in concern) siRNA delivery. Therefore, it is not a fault of the siRNA carrier. Formally, the mRNA transcribed would be captured either by the ribosome to get decoded into protein or by the RISC (RNA-induced silencing complex containing the antisense strand of siRNA) to give the mRNA−RISC adduct for cleavage. In terms of ribosome−RISC competition, the present results should be interpreted as suggesting that the competition is 90−95% in favor of the RISC pathway and 5−10% of the ribosome route irrespective of the cell type. Another possibility is that the mRNA is well saturated with the RISC, and it is the mRNA−RISC adduct itself that is responsible for the incomplete silencing. There has been considerable recent discussion on the formulation and functions of the RISCs (*26*). On the basis of the type of constituent proteins, these complexes can be divided into two general types, a cleaving RISC and a noncleaving RISC, which direct the complementary target mRNA either for cleavage or for translational repression, respectively. Even the cleaving RISC has such dual functions, depending on the base-pairing features between the small RNA and the target mRNA (*27*, *28*). It is tempting, although by no means convincing, to attribute the present 90−95/5−10 selectivity to the selectivity of the cleaving/noncleaving pathways.

CONCLUDING REMARKS

This work may be summarized as follows. (1) Cone-shaped quadruple-chain/octaammonium amphiphile **1** serves as a nonliposomal lipid capable of complexing plasmid DNA and siRNA in compact sizes of ~30 and ~10 nm, respectively. Its performance in vivo will be a subject of future work. (2) The carrier-mediated siRNA-silencing of reporter genes in the present type of cells is generally 90−95% at best. The residual ≥5% nonsilenced activity is most likely not a fault of the carrier but a fault of the RNAi process itself, where the choice of ~20-nucleotide target sequences of a given mRNA would be of a primary importance (*10*, *11*, *29*−*32*). The abilities of siRNA carriers should be judged in terms of such factors as minimal effective quantity (*8*), speed of action, maximal possible toxicity (*15*), versatility/selectivity (*33*), and particularly in vivo performance. (3) The plasmid and the siRNA are independent in their cellular uptake. The stepwise or pretransfection method works equally as the simultaneous or cotransfection procedure. Such a plasmid/siRNA orthogonality poses a new question. Is that because they are remarkably different in size, because one is DNA and the other RNA, or because the cellular uptake of nucleic acids is reversible to such an extent as to make the timing of supply less important? These remain to be better answered. From a practical point of view, controlled timing of introduction of siRNAs may find its unique application in the sequential knockdown of multiple genes, although possible interference between similarly sized plasmids and/or siRNAs should be kept in mind.

ACKNOWLEDGMENT

This work was supported by Grant-in-Aids for Scientific Research on Priority Areas (no. 16023230 and 16041222), Scientific Research (no. 16350087), and for 21st COE on Kyoto University Alliance for Chemistry from the Ministry of Education, Culture, Sports, Science, and Technology, Japan. We thank Prof. K. Taira and Dr. Y. Ikeda of Tokyo University for the generous gift of HeLa cells stably expressing DsRed2.

Received May 11, 2005; Revised Manuscript Received September 9, 2005

In this study, selective cancer cell targeting of biodegradable poly(lactic acid) (PLA) nanoparticles (NPs) has been investigated in vitro. SKOV-3 (HER2 positive) ovarian cancer and Daudi (CD20 positive) lymphoma cell targeting was mediated by anti-HER2 (trastuzumab, Herceptin) and anti-CD20 (rituximab, Mabthera) monoclonal antibodies (mAbs), respectively. The mAb against nonexpressed antigen serving on each cell as isotype matched irrelevant control. Two different targeting approaches have been studied, a direct method using antibody-labeled NPs (mAb-NPs) and a pretargeting method using the avidin−biotin technology. For the direct protocol, fluorescent PLA-NPs were prepared including 10% 1-pyrenebutanol (PB)-labeled PLA in the NP-preparation (PB-NP). Thiol groups were covalently bound to the PB-NP, and the resulting thiolated PB-NP were coupled with the two mAbs using a bifunctional cross-linker. The effective targeting of cells by mAb-PB-NP was shown by flow cytometry analysis. Clearly anti-HER2-PB-NP specifically bound to the SKOV-3 cells and not to the Daudi cells, while anti-CD20-PB-NPs bound to Daudi cells but not to SKOV-3 cells. Specific mAb-PB-NP binding to tumor cells produced a mean 10-fold or higher signal increase compared to irrelevant IgG-PB-NPs. For the pretargeting protocol, plain PLA-NPs were also thiolated and NeutrAvidin-Rhodamine Red-X (NAR) coupled to the functionalized PLA-NPs with sulfo-MBS. The two-step method was evaluated in vitro by incubating SKOV-3 cells first with biotinylated mAbs followed by NAR-NPs. The relative fluorescence associated to the specific binding of NPs produced a 6-fold increase in flow cytometry signal compared to nonspecific binding. In conclusion, these experiments have shown that NPs covalently coupled with antibodies or NAR can specifically and efficiently bind to cancer cells in both a pretargeting and a direct approach, suggesting that functionalized NPs may be a useful drug carrier for tumor targeting.

INTRODUCTION

One of the major problems facing cancer chemotherapy is the undesirable side effects. These are mainly of nonspecific nature due to distribution of the chemotherapeutic drugs to tissues other than tumor. To overcome the undesirable side effects and to increase local concentration of the drug at the target site, several drug-delivery systems have been investigated, such as drug−polymer conjugates (*1*), liposomes (*2*, *3*), micelles (*4*, *5*), and polymeric nanoparticles (NPs)[1] (*6*, *7*). Colloidal carrier systems, such as liposomes and NPs, present some relevant advantages over other drug carriers: (a) a high drug loading capacity; (b) the possibility to control size and permeability of the carrier; (c) the protection of the encapsulated drug from metabolism or early excretion. Among the different carriers, biodegradable NPs emerged as suitable means of carrying bioactive molecules to tissues of interest, especially due to their long shelf life, to the potential for control of release rate of the drug, and to the well established methods of preparation (*8*, *9*). Furthermore, long circulating "stealth" nanoparticles such as poly(ethylene glycol)-coated NP (PEG-NP) have proved to greatly enhance the therapeutic index of the drug (*10*−*12*). In fact, owing to their prolonged circulation time in blood, they more readily accumulate in areas with leaky vasculature, such as tumors, than plain NPs. However, a long-circulation time of NPs might be insufficient to obtain tumor control since a specific interaction with tumor cells does not occur. A promising strategy to achieve direct drug delivery is the development of active targeting of cancer cells via interactions mediated by ligands such as antibodies, lectins, and peptides, as presented with liposomes (*13*, *14*).

Active tumor targeting of NPs may be achieved with either direct targeting or the pretargeting-multistep method. In direct targeting, NPs should be covalently coupled with the ligand and the resulting drug carrier be administered at once. In the pretargeting approach, the therapeutic molecule is not coupled with the ligand and is administered after an appropriate delay time following the targeting ligand. This delay allows time for the antibody to localize and concentrate in the tumor. Commonly, pretargeting protocol involves an avidin−biotin system (*15*) or bispecific antibodies (*16*).

In this study, we explored the two approaches to target biodegradable poly(lactic acid) (PLA) NPs to tumor cells. Anti-HER2 mAbs (trastuzumab, Herceptin) and anti-CD20 mAbs (rituximab, Mabthera) were used as targeting ligands. Two cell lines were used, SKOV-3 human ovarian cancer cells expressing HER2 antigen, and Daudi lymphoma cells, expressing CD20 antigen. On each cell line, the antibody directed against the nonexpressed antigen served as isotype-matched irrelevant control immunoglobulin. In the direct approach, NPs exposing mAbs at their surface were incubated with the two tumor cell

lines. In the pretargeting protocol, tumor cells were pretargeted with biotinylated mAbs prior to the administration of avidin-labeled NPs. Cell interaction of fluorescence-labeled NPs was measured by flow cytometry.

EXPERIMENTAL PROCEDURES

Materials. Poly(DL-lactic acid) (PLA) (100DL 4A, Mw 57 kDa) was a gift from Alkermes (Cincinnati, OH). 4-Hydroxyazobenzene-2-carboxylic acid (HABA) and phosphate-buffered saline (PBS) were from Sigma (Buchs, Switzerland). *m*-Maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester (sulfo-MBS), sulfosuccinimidyl 6-(biotinamido)hexanoate (sulfo-NHS-LC-biotin), BCA protein assay kit, and D-Salt dextran plastic desalting columns were supplied by Pierce (Rockford, IL). NeutrAvidin Rhodamine Red-X (NAR) was from Molecular Probes (Leiden, The Netherlands).

Cell Lines. SKOV-3, human ovarian carcinoma cells expressing HER2, and Daudi, human B lymphoma cells expressing CD20 (American Type Culture Collection ATCC, Manassas, VA), were cultured in 75-cm^2 culture flasks in RPMI-1640 with Glutamax I (Gibco, Grand Island, NY) supplemented with 10% fetal calf serum (FCS) (Brunschwig, Basle Switzerland), 100 units/mL of penicillin, and 100 μg/mL of streptomycin (Gibco) in an atmosphere of 95% humidified air and 5% CO_2 at 37 °C. Cells were maintained in exponential growth using adequate splitting and renewal of medium. SKOV-3 cells were maintained as a monolayer, and for all the experiments, cells were harvested from subconfluent cultures using trypsin-EDTA (Gibco) and were resuspended in fresh complete medium. Unless stated otherwise, all in vitro studies were performed at 37 °C under gentle rotation in tubes containing phosphate-buffered saline (PBS) with 0.1% bovine serum albumin.

Biotinylated Antibodies. Antibodies for targeting assay included the anti-HER2 mAb (trastuzumab, Herceptin) and anti-CD20 mAb (rituximab, Mabthera) (Roche, Basle, Switzerland). Prior to the coupling reactions, the antibodies were purified by size exclusion chromatography using a D-Salt dextran plastic desalting column.

For the pretargeting approach, anti-HER2 and anti-CD20 mAbs were biotinylated as follows: 1 mL of purified mAbs (5 mg/mL) was mixed with sulfo-NHS-LC-biotin in bicarbonate buffer (pH 8.3) at a molar reaction ratio of 5 molecules of biotins per mAb molecule. After incubation for 1 h at room temperature, the unconjugated sulfo-NHS-LC-biotin molecules were removed from the mixture by size exclusion chromatography using a D-Salt dextran plastic desalting column. The fractions containing mAb were pooled, and the mAb concentration was determined by absorbance at 280 nm assuming an extinction coefficient of 1.4 M^{-1} cm^{-1} $(mg/mL)^{-1}$. The molar ratio of mAb-to-biotin was assessed by the colorimetric method using the dye 4-hydroxyazobenzene-2-carboxylic acid (HABA) (*17*). The biotinylated mAbs (mAb-biot) were stored at 4 °C until use.

The capacity of biotinylated mAbs to bind to cells was assessed in vitro on both SKOV-3 and Daudi cells using a two-step targeting protocol. SKOV-3 or Daudi cells in suspension (5×10^5 cells/mL) in PBS were incubated with 100 μg/mL of either biotinylated anti-HER2 or biotinylated anti-CD20 mAbs during 2 h. Unbound antibodies were removed by three successive centrifugations (400*g*, 5 min). Thereafter, 4 μL of NAR (1 mg/mL) were added to the cells and incubated for 1 h. The cells were rinsed with cold PBS three times before being analyzed by flow cytometry as described below.

Nanoparticles Coupled with NeutrAvidin Rhodamine Red-X. Plain NPs were prepared by a salting-out method according to a previously described method (*18*). Thiol functions were covalently bound to the surface of the plain nanoparticles to allow the subsequent covalent binding of ligands to the NPs. Optimization of the reaction conditions and characterization of the thiolated NPs has been presented elsewhere (*19*). Briefly, carboxylic acid groups of PLA NPs were activated with 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC) to allow the covalent binding of cystamine. Thereafter, disulfide bonds of cystamine were reduced using Tris(2-carboxyethyl)phosphine (TCEP). Thiolated NPs were subsequently used to covalently bind mAbs for the direct approach or NeutrAvidin Rhodamine Red-X (NAR) for the pretargeting protocol. The preparation and characterization of NAR-labeled NPs (NAR-NPs) has been described previously (*20*).

Antibody Coupling to Fluorescent Nanoparticles for Direct Targeting. Fluorescent NPs were prepared by the salting-out process with 10% (w/w) of 1-pyrenebutanol-labeled PLA and 90% of unlabeled PLA (*21*). The fluorescent polymer, 1-pyrenebutanol-labeled PLA, was used in this experiment as a fluorescent tracer for flow cytometry analysis. The fluorescence excitation and emission spectra of 1-pyrenebutanol contained in the NPs were determined in PBS (FluoroMax spectrofluorometer, Spec Indutries, NJ). The mean Z size of the labeled NPs was determined by dynamic light scattering (Malvern Instruments, Ltd, UK).

Thiol functions were covalently bound to fluorescent NPs as described above and the resulting thiolated PB-NP were coupled to purified Herceptin or Mabthera using the bifunctional cross-linker, sulfo-MBS. mAbs (2 mg/mL) were incubated over 45 min at room temperature with sulfo-MBS in PBS (pH 7.4) at four different molar ratios, 1:5; 1:10; 1:20; 1:40 (mAb:sulfo-MBS). The excess of sulfo-MBS was removed from the mixture by size exclusion chromatography using the desalting columns. The fractions containing the maleimide-activated mAbs were collected, and their concentration was determined. Thereafter, 500 μL of mAb (1 mg/mL) was incubated with 500 μL of thiolated PB-NP (20 mg/mL) and gently shaken for 60 min at room temperature. Subsequently, the uncoupled mAbs were removed by four cycles of centrifugation (20000*g*, 10 min). The supernatant of the centrifugation step was used for the determination of uncoupled mAb by a BCA assay (microplate procedure). Finally, mAb-conjugated NPs (mAb- PB-NP) were stored in PBS at 4 °C. Trials were carried out on plain PB-NP (without thiol functions) to determine the fraction of noncovalently attached mAb on the surface of the NPs.

Nanoparticle Binding. For the direct targeting, 100 μL of a 1 mg/mL suspension of specific or irrelevant mAb-PB-NP was incubated for 45 min with 5×10^5 SKOV-3 or Daudi cells. Cells were rinsed with three successive centrifugation steps (400*g*, 5 min) with cold PBS to remove unbound nanoparticles, and the mean relative fluorescence was measured by cytometry analysis.

For pretargeting experiments, SKOV-3 cells (5×10^5 cells/ml) were incubated for 2 h with 100 μg/mL of biotinylated anti-HER-2 or anti-CD20 mAbs (negative control). PBS containing unbound mAb was removed, and cells were washed with two cycles of successive centrifugations (400*g*, 5 min). Subsequently, 100 μL of a 1 mg/mL suspension of NAR-NPs was added, and cells wrer incubated for 1 h. Three successive centrifugation steps (400*g*, 5 min) with cold PBS were carried out to remove unbound NAR-NPs and resuspended in PBS for flow cytometry analysis.

For both targeting approaches, parallel incubations were performed with unlabeled NPs and with irrelevant mAbs to assess the nonspecific interaction of the nanoparticles with cells. Other controls included the incubation during 45 min of free mAb (100 μg) prior to the incubation of mAb-PB-NP or NAR-NPs.

Flow Cytometry Analysis. The capacity of mAb-NP−BPs and of biotinylated mAbs to bind cells was analyzed using flow

cytometry. The cells were suspended in 500 μL of cold PBS prior the measurements. For the pretargeting protocol, mean fluorescence intensity of 10000 cells was analyzed using a FACSfits cytometer (Becton Dickinson, San Jose, CA) equipped with an argon-ion laser adjusted to 488 nm. For the direct targeting method, the mean fluorescence intensity was measured using a FACSVAntage flow cytometer (Becton Dickinson, San Jose, CA). The excitation of 1-pyrenebutanol (PB-NP) was performed using an UV laser with two wavelengths at 351 and 364 nm (Coherent Laser, Inc. Santa Clara, CA) set at 20 mW. The emission signal was analyzed using the reading channel FL5-H corresponding to wavelengths ranging from 383 to 407 nm. Median fluorescence *F* was calculated using Cellquest software (Becton Dickinson) with the results presented as relative cell number versus log fluorescence intensity. Cells incubated with only PBS were used for background fluorescence calibration.

RESULTS

Fluorescent, Thiolated Nanoparticles. Plain NPs and fluorescent NPs were obtained by a salting-out procedure (18). For the fluorescent labeling of NP, the 1-pyrenebutanol-PLA conjugate was used at 10% of unconjugated PLA. Both plain NPs and fluorescent NPs (PB-NP) showed very similar characteristics in terms of particle size and redispersibility. The mean size of the plain NPs and PB-NP was 265 and 270 nm, respectively. After freeze-drying the NPs or PB-NPs, complete redispersion of all formulations could be achieved in water. Spectofluorimetric assay revealed that the PB-NP were efficiently loaded with 1-pyrenebutanol-PLA (results not shown). Further results suggested that notably no subsequent spontaneous release occurred. The maximum for the excitation and emission wavelengths of 1-pyrenebutanol NPs was found at 375 and 390 nm, respectively.

The thiolation reaction was very reproducible on both fluorescent and nonfluorescent NPs with an incorporation of 104 $\pm$ 2 mmol of thiol functions per mol of PLA, for nonfluorescent NPs and 89 $\pm$ 10 mmol for PB-NP. The average size of plain NPs and PB-NP after the thiolation reaction was 278 and 297 nm, respectively, corresponding to a size increase of 5 to 10% only compared to the original size.

Direct Coupling with Antibodies. The coupling reaction between the two different mAbs and the thiolated PB-NP was carried out in the presence of the bifunctional cross-linker sulfo-MBS. Four different molar ratios of sulfo-MBS to mAbs were evaluated. An equal concentration of maleimide-mAb was used for all the coupling reactions with thiolated PB-NP. Figure 1 summarizes the results of the coupling reaction between maleimide-mAbs and thiolated PB-NP. For both anti-CD20 and anti-HER2 mAbs the amount of mAbs bound to the surface of the PB-NP increased when an increased molar ratio between mAbs and sulfo-MBS was used. Amounts of 1.5, 2.5, and 5.6 mmol of mAbs per mol of PLA were bound to the PB-NP using a mAbs to sulfo-MBS molar ratio of 1:10, 1:20, and 1:40, respectively. These three formulations were retained for the in vitro studies. At the lowest molar ratio between sulfo-MBS and mAbs (1:5), no coupling of mAbs to the surface of the nanoparticles could be demonstrated. Between 2500 and 2700 mAbs (25 to 27% of total mAb) were coupled to the thiolated PB-NP surface at the highest molar ratio of sulfo-MBS. This corresponds to coupling of approximately 19% of the total measurable thiol functions on the surface of NPs. Control reactions on PB-NP lacking thiol functions showed that only a minor amount of mAbs (2.8%) bound nonspecifically to the particles. The average size of the mAb-PB-NP after the coupling reaction was ranging from 340 to 410 nm, depending on the amount of mAbs bound to the particles.

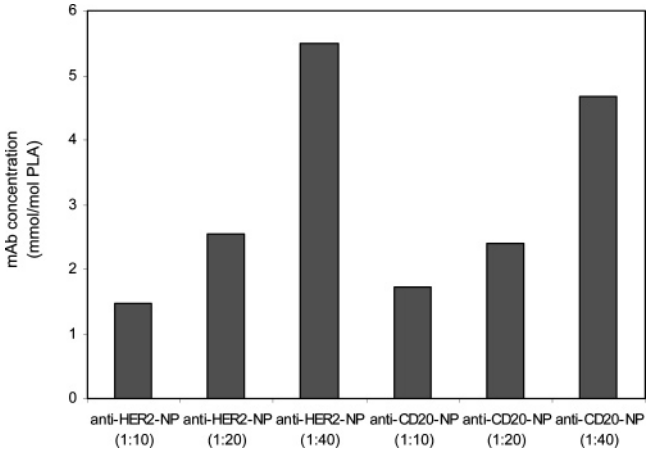

Figure 1. Summary of the coupling reaction between thiolated NPs and mAbs (anti-HER2 and anti-CD20 mAbs). Influence of the molar ratio (mAb:sulfo-MBS, values given in parentheses) on the coupling reaction on the ratio of mAbs obtained at the surface of the NPs.

NeutrAvidin-Rhodamine Red-X-Coupled NPs. After activation of NAR with sulfo-MBS, 500 μL of the activated NAR solution (360 μg/mL) was used for the coupling reaction with an equal volume of NPs (20 mg/mL). The quantification of the fluorescent Neutravidin on the NP surface revealed that 5.0 mmol of NAR per mol of PLA was covalently attached to the surface of the NAR-NP, corresponding to approximately 1300 molecules of NAR per NP. In control reactions the concentration of activated NAR nonspecifically bound to nonthiolated NPs was as low as 0.6 mmol of NAR per mol of PLA. The mean particle size increased from 278 nm before coupling to 320 nm after the coupling reaction.

Biotinylation of Antibodies. The water-soluble NHS-LC-biotin was chosen due to its extended spacer arm that limits steric hindrance and provides optimal reactivity with avidin and permits the biotin to reach the lysine groups (*22*). Starting with a NHS-LC-biotin-to-antibody molar ratio of 5:1, an average of three molecules of biotin was introduced per antibody molecule, as determined in the colorimetric assay with HABA reagent. The ability of biotinylated mAbs to bind to specific antigens was assessed in vitro with a two step-targeting protocol using free NAR. Anti-HER2 bound specifically to SKOV-3 cells but not to Daudi cells. On the contrary, anti-CD20 interacted with Daudi cells, but not with SKOV-3 cells (Figures 2A and 2B). Results of a competition assay with radiolabeled Rituximab indicated that the immunoreactivity of Rituximab coupled with 3 to 4 NHS-LC-biotin per antibody molecule as measured with the HABA assay was only slightly impaired with loss of about 25% compared with native Rituximab. Higher biotinylation degrees of the antibody resulted in stronger impairment of the immunoreactivity in this assay (data not shown).

Direct Targeting. The three retained PB-NP formulations were tested for each type of mAb. The targeting of SKOV-3 showed that all anti-HER2 formulations bound specifically to the cells. Whereas, when anti-CD20-PB-NP were incubated with SKOV-3 cells only little cell interaction was observed compared with plain NPs and no significant difference was observed among the three anti-CD20-PB-NP formulations (Figures 3A and 4A).

The binding efficiency of targeted NP to the cells was dependent on the mAb:sulfo-MBS ratio, since increased fluorescence was observed for the 1:20 molar ratio compared with 1:10. However, the highest ratio of sulfo-MBS (1:40) that resulted in the highest amount of antibody coupled per NP showed the lowest binding among the three NP formulations, suggesting that this formulation resulted in significant inactivation of antibody. Based on these results, the optimum molar

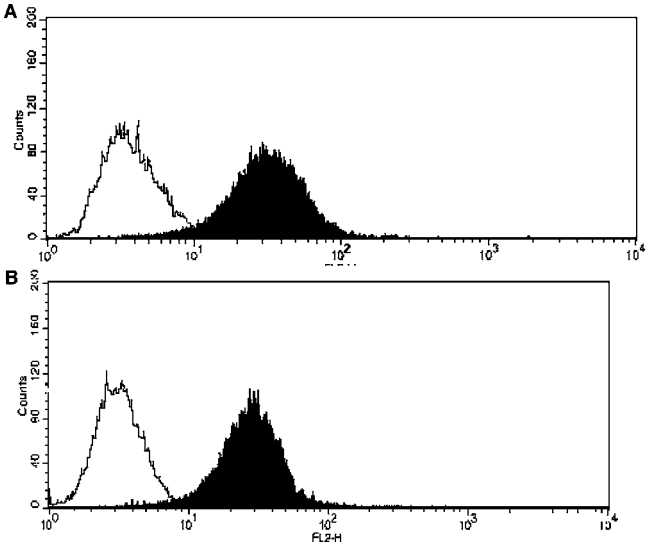

Figure 2. Flow cytometry analysis of biotinylated mAbs biding to SKOV-3 and Daudi cells. (A) SKOV-3 cells were preincubated with biotinylated anti-HER2 (black peak) or biotinylated anti-CD20 (white peak) followed by NAR. B) Daudi cells were preincubated with biotinylated anti-CD20 (black peak) or biotinylated anti-HER2 (white peak) followed by NAR.

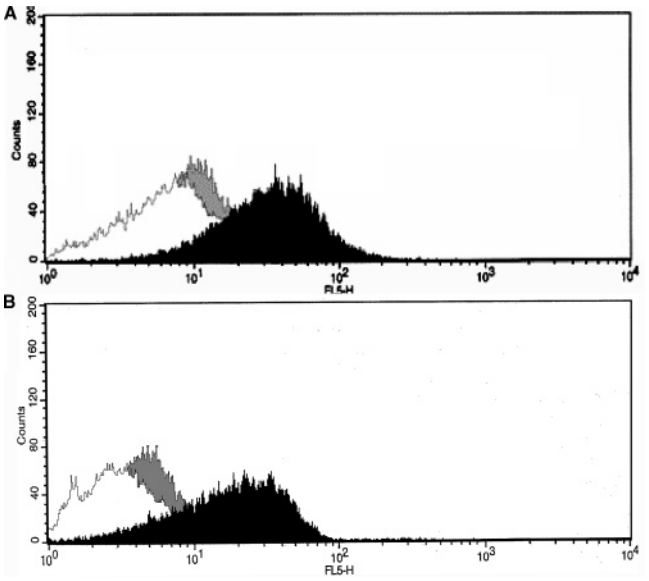

Figure 3. Direct targeting protocol. Flow cytometry analysis of targeted PB-NP binding to SKOV-3 and Daudi cells. (A) SKOV-3 cells were incubated with either anti-HER2−PB-NP (black peak) or anti-CD20-PB-NP (grey peak) during 45 min. (B) Daudi cells were incubated with either anti-CD20-PB-NP (black peak) or anti-HER2−PB-NP (grey peak) during 45 min. Cells incubated alone were used as background fluorescence (white peak).

ratio used was 1:20 (mAb:sulfo-MBS). This anti-HER2−PB-NP formulation showed significantly higher binding activity up to 13-fold than the equivalent anti-CD20-NPs formulation.

The targeting ability of the same mAb-PB-NP reagents was also assessed on Daudi cells. A very similar result as on SKOV-3 was again observed on Daudi cells with strong interaction of the specific mAb-coupled NPs and low background activity with irrelevant mAb. At the 1:20 molar ratio of activation with sulfo-MBS, binding impairment was also observed with rituximab (Figures 3B and 4B). The 1:20 anti-CD20-NP formulation showed up to 10-fold higher binding activity than anti-HER2-NPs in cells expressing CD20 antigens. No significant difference was observed among the three anti-HER2-NP formulations.

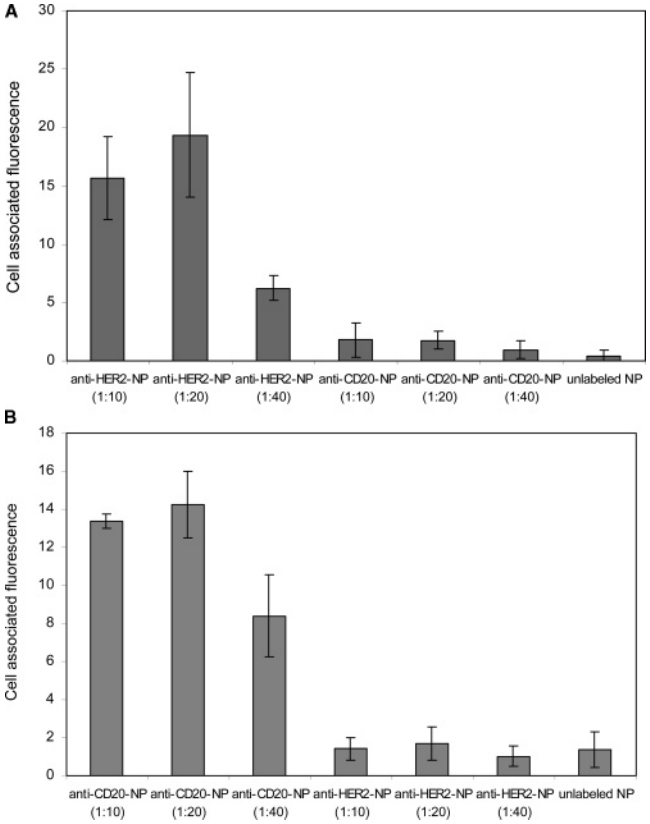

Figure 4. Direct targeting protocol. Effect of mAb:sulfo-MBS ratio on the binding capacity of mAbs-NPs to specific antigens expressed on the surface of the cells. (A) Anti-HER2-NPs incubated with SKOV-3 cells using anti-CD20-NPs and unlabeled NPs as negative controls. Data are mean of four independent experiments ± SD. (B) Anti-CD20-NPs incubated with Daudi cells using anti-HER2−PB-NP and unlabeled PB-NP as negative controls. Data are mean of three independent experiments ± SD. Values in parentheses indicate initial molar ratios mAb:sulfo-MBS.

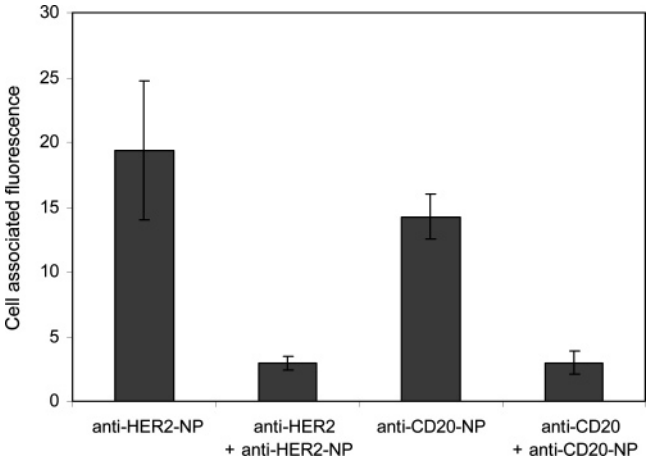

Figure 5. Direct targeting protocol. Study of the influence of free mAbs on the interaction between cells and targeted-NPs. Cells were incubated either with targeted-NPs for 45 min (1st and 3rd bar) or with free mAbs for 45 min followed by the incubation of targeted-NPs over 45 min (2nd and 4th bar). Data are mean of four independent experiments ± SD for anti-HER2-NPs on SKOV-3 cells and mean of three independent experiments ± SD for anti-CD20-NPs on Daudi cells.

As a further demonstration of the specificity of mAb-PB-NP interaction with cells, flow cytometry analyses were also carried out on both cells incubated with free mAbs followed by the treatment of mAb-NPs. As illustrated in Figure 5, the association of anti-HER-NPs with SKOV-3 could be competitively inhibited by the preincubation of free anti-HER2, indicating that the cell-

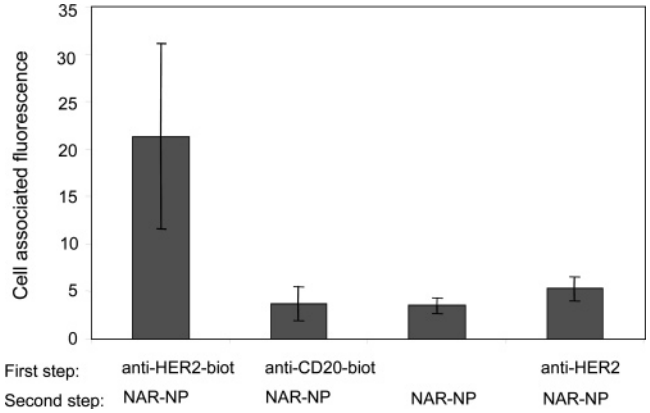

Figure 6. Pretargeting protocol. Study of the interaction between SKOV-3 cells prelabeled with biotinylated mAbs anti-HER2-biot and anti-CD20-biot followed by the incubation of NAR-NPs. First step: preincubation with mAbs during 2 h; second step: interaction with NAR-NPs during 60 min. Two control experiments were performed with free anti-HER2 (not biotin conjugated) or NAR-NPs without antibody. Data are mean of three independent experiments ± SD.

association with NPs was mediated through the HER2 antigens on SKOV-3 cells. Similar results were obtained with Daudi cells (Figure 5).

Two-Step Targeting. The cell association of NAR-NPs with the two-step approach was evaluated on SKOV-3 cells. Results shown in Figure 6 demonstrated that the cells preincubated with biotinylated anti-HER2 mAb showed significantly higher fluorescence intensity compared with those treated with biotinylated anti-CD20 mAbs.

The mean fluorescence of cell-associated NPs measured with biotinylated anti-HER2 was 6-fold higher that obtained with biotinylated anti-CD20 using equivalent concentrations of NAR-NPs. Cells incubated with NAR-NPs in the absence of mAbs confirmed that the specific binding of the NPs to the cells was mediated by the biotinylated-anti-HER2. When anti-HER2 mAbs without biotin were used to pretarget the cells, only a small amount of NAR-NPs interacted with the cells, demonstrating that the association between NPs and cells is due to the strong affinity between NAR and biotin.

DISCUSSION

Nanoparticle Fluorescence Labeling and Activation for Covalent Ligand Coupling. The use of biodegradable NPs for drug delivery of therapeutic agents is now well established (*23, 24*). Among different carrier systems, and particularly with respect to liposomes, NPs have proved to be suitable candidates for antitumor drug therapy. NPs present notably a high drug loading capacity and a variety of well-defined biodegradable polymers, allow the controlled release rate of the drug, and finally show a high storage and in vivo stability. To further improve the therapeutic index of anticancer agent, NPs must be designed to target cancer cells. The reliable way to achieve this goal is the tumor targeting mediated by ligands such as antibodies. To our knowledge, there are very few reports regarding tumor targeting using mAb-labeled biodegradable NPs (*25*−*27*) and no study at all on the multistep targeting approach. Hence, the main goal of the present study was the development of a novel concept of functionalized biodegradable NPs designed to specifically target antigen receptors on tumor cells. In the course of development of the NP-targeting, we made several unexpected observations. We previously described the evaluation and selection, among three different methods, of the NP thiolation used here based on EDAC and cystamine that provided low nonspecific reaction with the NPs (*19*). An unexpected difficulty was observed with the fluorescence labeling of the NPs. Initially, nile red loaded NPs had been selected for flow cytometry studies. Nile red is commercially available highly hydrophobic fluorescent marker. It has been used previously to label NPs for in vitro investigations (*28, 29*). However, in the setting presented here, nile red staining of NPs was unstable; the dye leaked out and labeled cells even in the absence of NP targeting. As an alternative, we coupled commercially available NeutrAvidin Rhodamine Red-X onto the NPs. In this reagent, biotin binding sites remain available (*20*), providing double function as fluorescent dye and two-step reagent for binding to biotinylated antibodies. As a drawback, however, the fluorescence labeling is not independent from the NP-targeting function in this approach. Even though we did not observe release of this reagent from the NPs, we cannot exclude that this happened at low level. 1-Pyrenebutanol coupled to PLA chains appeared finally as optimal fluorescence labeling. The use of 10% of 1-pyrenebutanol-PLA for the preparation PLA-NPs was efficient and gave a stable fluorescent labeling, well adapted for flow cytometry. The other functions of the NPs, such as solubility and particle size, were not altered in the presence of this fluorescent PLA.

The coupling reaction carried out on both fluorescent and nonfluorescent NPs were highly efficient leading to the formation of covalent thioether bonds. In this study, it was demonstrated that NPs can be easily labeled by two types of mAbs, anti-HER2 and anti-CD20 mAbs, and that by varying the molar ratio of the cross-linker, the mAb density on the particles be tailored.

Cancer Cell Association. The ability of NPs to specifically bind tumor cells was shown with the direct and two-step targeting approaches on two different cancer cell lines, SKOV-3 and Daudi. For direct targeting, mAbs were covalently bound to the surface of the PB-NP, and it was demonstrated that the antigen binding activity of the mAbs was dependent on the density of the mAb on the PB-NP surface. In fact, the amount of total cell-associated PB-NP decreased when a high molar ratio was used (1:40), suggesting that inactivation of the antigen binding domain had occurred. Increased sulfo-MBS substitution on mAbs resulted in a higher cell targeting capacity until a maximum was reached. Nevertheless, further studies must be carried out, particularly in vivo, to determine the most favorable mAb density, taking into account that excessive mAb densities on particles may induce rapid clearance from plasma, as shown with immunoliposomes (*30*). For the two types of cells, only minor NP−cell interaction was observed in the absence of mAbs, demonstrating that PB-NP bound specifically to the cells via the antigen−antibody interaction. This was also confirmed by the incubation of cells with NPs labeled with irrelevant mAbs.

The second approach investigated in this study was the pretargeting approach. Multistep targeting is promising since it has the potential of increasing tumor-to-normal-tissue ratios, and as a result, to enhance the therapeutic index of pretargeted drug compared with the use of direct targeting. Frequently, pretargeting protocols involve the use of the avidin−biotin system. Avidin−biotin presents the advantage of dose amplification, since avidin can bind four molecules of biotin. In this study, NeutrAvidin, a chemically deglycosylated avidin, has been preferred to avidin. NeutrAvidin is similar to avidin with respect to its biotin binding affinity but it present less nonspecific binding to cells and has an increased circulation time in the blood compartment. To allow FACS analysis, a fluorescent labeled NeutrAvidin has been chosen: NeutrAvidin Rhodamine Red-X (NAR). It has been shown in this study that NAR-NPs recognized and bound specifically to cells preincubated with biotinylated specific mAbs, demonstrating that the pretargeting approach is feasible with NPs. NAR-NP can be potentially used

for the conjugation of any biotinylated ligand. Furthermore, it may also be possible to simultaneously target different antigens with the same avidin-labeled formulation.

A surprising result, however, was observed in the use of the biotin−avidin reagents in single step targeting. The successful use of these reagents in the two-step NP-targeting had shown that they were perfectly operational, as indicated also by the quality controls. However, when trying to use the same reagents in a one-step targeting whereby the NAR-NPs were first precoated with the biotinylated antibodies, washed, and then incubated with cells, no targeting was observed. When trying to explain the apparent difference between the two- and one-step targeting result, we remained essentially with three hypotheses. First, the immunoreactivity of the antibodies coupled with a mean of three biotins per antibody molecule was conserved when used as soluble agent, but might be strongly reduced when reacted first with the NAR-NPs due to sterical hindrance on the NP surface. Second, when used as two-step reagent, antibodies with conserved immunoreactivity might be positively selected, while, when first reacted with the avidin-NPs, selection of antibodies might occur for the number of available biotin sites (from the Gaussian distribution) and therefore a higher probability of reduced immunoreactivity. Finally, in the two-step reaction, the number of reaction sites on the cell surface might become amplified by the three biotins per antibody molecule, while in the NAR-NP precoating, any loss of immunoreactivity due to sterical hindrance would result in a reduced number of potential binding sites for the cells. These different effects might possibly occur in combination and could explain the loss of binding capacity of the two-step reagents in a one-step targeting in combination with NPs.

Despite the numerous advantages of the pretargeting approach and the promising results in preclinical (*31*−*33*) and clinical studies (*34*, *35*), there are some points that must be considered. Avidin, like streptavidin, is a foreign protein for humans and, therefore, has shown considerable immunogenicity in vivo, thus limiting the number of times that it can be administered. As an alternative to both avidin and streptavidin, chemically modified avidins, such as NeutrAvidin, have been proposed, but their efficacy and their potential low immunogenicity remains to be demonstrated in vivo. Furthermore, it is not yet known to what extent the presence of endogenous biotin or biotinases can interfere in the pretargeting approach (*36*), even though clinical results have shown the feasibility of this multistep targeting. An important condition for good targeting results in pretargeting systems is the relatively slow internalization or even absence of internalization of the mAbs after binding the antigens. In fact, it has to be kept in mind that the antibodies should remain available for a sufficient period of time after binding to the target to allow the avidin−biotin interaction to take place. On the other hand, it has been proven that internalizing antibodies can be necessary for improved efficacy of certain therapeutic agents (*37*). In this study internalizing target HER2 and the noninternalizing target CD20 were used as models. Other internalizing mAbs can be coupled to the NPs for the therapy of lymphoma, such as anti-CD22, a humanized mAb (Epratuzumab) that is presently in clinical phase II study (*38*).

At the present stage of the work, it is not possible to define which targeting strategy is preferred to deliver NPs to tumor cells. More work has to be accomplished, especially in vivo studies have to be undertaken using different tumor models (solid and hematopoietic). Nevertheless, the proof-of-concept of cancer cell targeting with NPs has been demonstrated on two cell lines using two mAbs as models. Universal NPs have been designed to target specific antigens, and these targeted PLA NPs can be applied to other target antigens.

ACKNOWLEDGMENT

This work was supported by a grant from Cancer Research Switzerland (#938-09-1999) and from the Geneva Cancer League. The authors thank D. Wohlwend for technical assistance with regard to cytofluorometric experiments, Mrs. C. Grannavel and C. Paschoud for assistance in the preparation of particular reagents, and C. Nguyen for kindly supplying the 1-pyrenebutanol-labeled poly(lactic acid).

Human Serum Albumin Hybrid Incorporating Tailed Porphyrinatoiron(II) in the α,α,α,β-Conformer as an O_2-Binding Site

Akito Nakagawa, Teruyuki Komatsu,* Makoto Iizuka, and Eishun Tsuchida*

Advanced Research Institute for Science and Engineering, Waseda University, 3-4-1 Okubo, Shinjuku-ku, Tokyo 169-8555 Japan. Received June 1, 2005; Revised Manuscript Received October 30, 2005

We have found that recombinant human serum albumin (HSA) incorporating tailed porphyrinatoiron(II) in the α,α,α,β-conformer can reversibly bind and release O_2 under physiological conditions (pH 7.3, 37 °C) like hemoglobin and myoglobin. β-2-Methylimidazolyl-tailed porphyrinatoirons (**6a**, **6b**) are synthesized via four steps from the atropisomers of tetrakis(*o*-aminophenyl)porphyrin. The stereochemistry of the α,α,α,β-conformer has been determined by NMR spectroscopy. **6a** and **6b** form stable O_2-adduct complexes in toluene solution at room temperature. The association rate constants of O_2 are 3.1- and 1.9-fold lower than those of the corresponding α,α,α,α-conformers (**1a**, **1b**), indicating that the three substituents (cyclohexanamide or pivalamide groups) are close to each other on the porphyrin platform and construct a narrow encumbrance around the O_2-coordination site. Although **6a** and **6b** are incorporated into the hydrophobic domains of HSA to produce the albumin−heme hybrid, only HSA-**6a** can bind O_2 in aqueous medium. The cyclohexanamide fences are necessary for the tailed porphyrinatoiron to form a stable O_2-adduct complex under physiological conditions. The O_2-binding affinity ($P_{1/2}$) of HSA-**6a** is 45 Torr (37 °C), and the O_2 transporting efficiency between lungs and muscle tissues in the human body is estimated to be identical to that of human red blood cells. The HSA-**6a** solution will become one of the most promising materials for red blood cell substitutes, which can be manufactured on an industrial scale.

INTRODUCTION

To reproduce the O_2-binding ability of hemoglobin (Hb) and myoglobin (Mb), numerous numbers of model hemes have been synthesized over the past decades (*1*). These continuous approaches, aimed at understanding the precise mechanism of the O_2-binding reaction, have been mostly accomplished in organic solvents, and tetrakis(phenyl)porphyrin (TPP) was widely used as a molecular scaffold. We have also synthesized tetrakis{α,α,α,α-*o*-(1-methylcyclohexanamido)phenyl}porphinatoiron(II) bearing a covalently linked proximal imidazole (**1a**, Figure 1)[1] that forms a stable O_2-adduct complex in toluene solution at ambient temperature (*2*). The four cyclohexanamide fences on the distal-side (α-side) of the porphyrin plane are bulky enough to prevent μ-oxo dimer formation, and the 2-methylimidazolyl arm intramolecularly coordinated to the Fe^{2+} center from the proximal-side (β-side) modulates the O_2-binding affinity.

Some substantial efforts have been directed to prepare an artificial O_2 carrier involving a synthetic heme under physiological conditions (pH 7.3, 37 °C), which may become a red blood cell substitute (*1a, 3*). We have successfully incorporated **1a** into the hydrophobic domains of recombinant human serum albumin (HSA) and found that the albumin−heme hybrid (HSA−**1a**) could reversibly absorb O_2 in aqueous medium (*1a, 2, 4*). This red-colored albumin solution showed a long shelf life of over two years without precipitation. More recently, exchange transfusion experiments with HSA−**1a** into anesthetized rats demonstrated that it effectively rescitates the hemorrhagic shock state and transports O_2 to the muscle tissues (*5*). We are now developing this albumin−heme hybrid as an entirely synthetic red blood cell substitute that can be extensively used in a variety of medical situations (*6*).

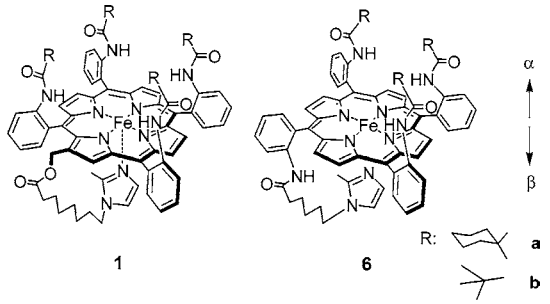

Figure 1. Structures of porphyrinatoiron derivatives in the α,α,α,α-conformer and α,α,α,β-conformer (tailed porphyrinatoiron).

The only disadvantage of this synthetic heme **1a** is that a great deal of labor is required to make the α,α,α,α (α^4)-conformer and to introduce the imidazolylalkyl arm at the porphyrin periphery via the Vilsmeier reaction (*2*). The starting material, tetrakis(α,α,α,α-*o*-aminophenyl)porphyrin (TAPP), is in a statistical mixture of the four possible atrop isomers (α,α,α,α, α,α,α,β, α,β,α,β, α,α,β,β; the ratio is 1:4:2:1), and the variable α^4-conformer used to be isolated by Lindsey's procedure with a silica gel column separation (*7*). The number of total steps for the synthesis of **1a** is, therefore, eight from TAPP.

In this study, we first incorporated a "tailed porphyrinatoiron" with the $\alpha^3\beta$-conformer as an O_2-binding site of the albumin−heme. A series of tailed porphyrins as the model compound of Hb and Mb were synthesized by Collman and co-worker (*8*). There are two advantages of the tailed porphyrin: (i) the statistical content of the $\alpha^3\beta$-conformer of TAPP is maximum

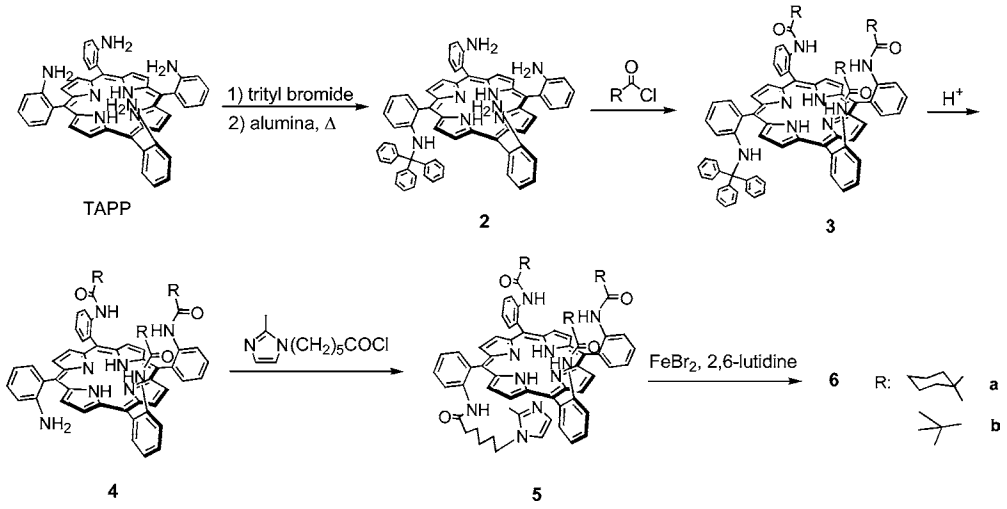
Scheme 1. Synthesis of Tailed Porphyrinatoirons



(50%), and (ii) there is no need to modify the porphyrin ring because the proximal base is attached to the fourth β-*o*-NH_2 group of the phenyl ring. This convenient synthetic procedure is a great advantage for the industrial scale-up of the manufacturing of the albumin−heme solution. However, we were not certain of the stability of the O_2-adduct complex of the tailed porphyrinatoiron(II) in an aqueous medium. It has been postulated that the four substituents were essential for preventing an unfavorable proton-driven oxidation of the central ferrous ion of the Fe^{2+}TPP derivatives in water (*1a*, *3*).

First, we describe the synthesis and stereochemistry of the 2-methylimidazole-tailed porphyrinatoirons (**6a**, **6b**) and compare their O_2-binding properties in toluene solution. The effects of the substituents on the O_2-binding parameters are discussed. Furthermore, the O_2-binding property of the albumin−heme hybrid including the tailed porphyrinatiron(II) **6a** has been characterized under physiological conditions. The 5 wt % albumin−heme solution involving the easily prepared **6a** could be the most promising artificial O_2 carrier suitable for mass production.

EXPERIMENTAL SECTION

Synthesis of Tailed Porphyrinatoirons. Experimental details of the synthesis and spectra (^{1}H NMR, IR, UV−Vis, HR-MS) are supplied as Supporting Information.

Reduction of Ferric Complex to Ferrous Complex in Toluene. Reduction to the porphyrinatoiron(II) was carried out using toluene-aq $Na_2S_2O_4$ in a heterogeneous two-phase system under an N_2 atmosphere as previously reported (*9*). After separation of the two phases, the organic layer containing the ferrous complex was transferred to a 1-cm quartz cuvette under an N_2 atmosphere. The UV−Vis absorption spectra were recorded by a JASCO V-570 spectrophotometer.

Preparation of Albumin−Heme Hybrid. The HSA (Albrec, 25 wt %) was obtained from the NIPRO Corp. (Osaka). Aqueous ascorbic acid (15 mM, 20 μL) was added to an ethanol solution of the porphyrinatoiron(III) derivative (37.5 μM, 4 mL) under CO. After complete reduction of the central ferric ion, the UV−Vis absorption spectrum showed the formation of the six-coordinated carbonyl complex. This ethanol solution was slowly injected into the phosphate buffered solution (pH 7.3, 8 mL) of HSA (9.38 μM) through a Teflon tube under a pressure of CO stream. The mixture was dialyzed using a cellulose membrane against phosphate buffer (pH 7.3) for 2 and 15 h at 4 °C. The ethanol concentration should be reduced to less than 100 ppm. Finally, the total volume was adjusted to 15 mL, thus producing the carbonyl albumin−heme solution (heme/HSA = 4 (mol/mol), [Fe]: 20 μM). The water was deionized using an ADVANTEC GS-200 system.

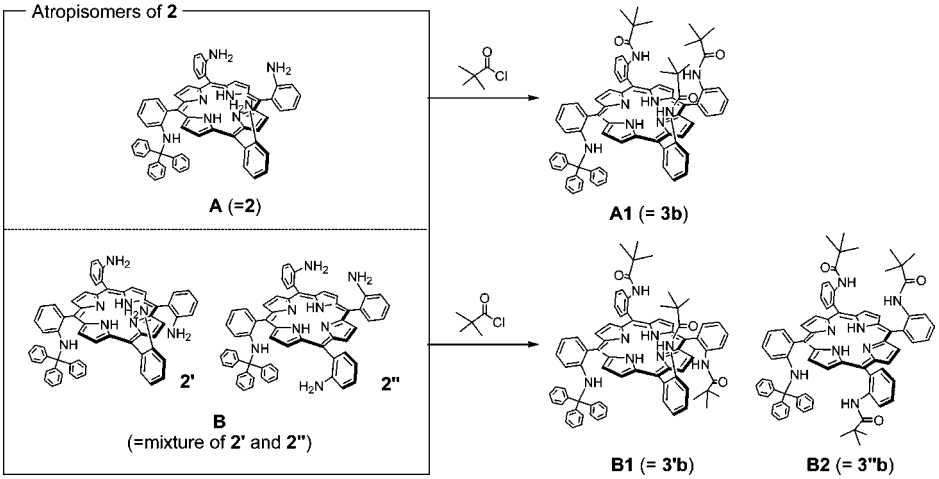
O_2-Coordination Equilibria and Kinetics. The O_2-binding affinity ($P_{1/2}$) of the porphyrinaoitron(II) in organic solvents or their albumin−hemes in aqueous solution were determined by the spectral changes at various partial pressures of O_2 in previous reports (*2*, *10*). The heme concentrations of 20 μM were normally used for the UV−Vis absorption spectroscopy. The spectra were recorded within the range of 350−700 nm. The O_2-association and -dissociation rate constants (k_{on}, k_{off}) were measured by a competitive rebinding technique (*11*, *12*) using a Unisoku TSP-1000WK-WIN time-resolved spectrophotometer with a Spectron Laser system SL803G-10 Q-switched Nd:YAG laser, which generated a 532 nm pulse of 6-ns duration (10 Hz).

Magnetic Circular Dichroism (MCD). The MCD for the phosphate buffered solutions (pH 7.3) of HSA−**6a** (20 μM) under N_2, O_2, and CO atmospheres were measured using a JASCO J-820 circular dichrometer fitted with a 1.5 T electromagnet at 25 °C. The accumulation times were normally five, and each spectra were subtracted by ones without the electromagnetic as a baseline.

RESULTS AND DISCUSSION

Synthesis of Tailed Porphyrinatoiron. The tailed porphyrinatoirons, **6a** and **6b**, can be synthesized via four reaction steps from TAPP with 6-{*N*-(2-methyl-1-imidazolyl}hexanoic acid (Scheme 1), and their structures were determined by IR, UV, mass and NMR (^{1}H NMR, H−H COSY, Nuclear Overhauser effect (NOE) experiment) spectroscopies. First, TAPP was monotritylated using tritylbromide at room temperature. Statistically, six atrop isomers of the monotritylated compound are formed. Collman and co-workers reported the superior synthesis of tris(α,α,α-aminopheny)-mono(β-tritylaminophenyl)porphyrin (**2**) using the alumina absorption technique in the dark (*13*). We isolated two major components from the reaction mixture according to the procedure with the R_f values (chloroform/ethyl acetate = 1:1 (v:v)) of 0.75 (compound **A**) and 0.90 (compound **B**). The coupling reaction of compound **A** with pivaloyl chloride gave a single product, tris(pivalamido)phenyl-monotritylphenyl-porphyrin (compound **A1**). On the other hand, the same coupling reaction of compound **B** provided two products (compounds **B1** and **B2**) with R_f values (chloroform/ethyl acetate = 2:1 (v/v)) of 0.68 and 0.62, respectively. The mass spectra of the above three compounds exactly demonstrated the same value (calcd. for $C_{78}H_{73}N_8O_3$: 1169.5806), indicating that **A1**, **B1**, and **B2** are atrop isomers. In ^{1}H NMR spectra of **A1** and **B1**, the peaks derived from the CH_3 protons in the pivalamide groups were

Scheme 2. Atropisomers of 2 and Their Pivalamide Derivatives



clearly separated into two peaks, and the patterns resembled those of the other $\alpha^3\beta$-structured TAPP derivatives (*14*, *15*) (see Figures ESI1−ESI3, Supporting Information). The differences in the chemical shift between the two peaks were 0.12 (**A1**) and 0.15 (**B1**) ppm, respectively. The CH_3 peaks of **B2** were also splited, but the peak separation was rather small, 0.01 ppm.

To clarify the stereochemistry of these atrop isomers and the geometry of the substituents, we employed the NOE differential spectra (*16*) (see Figures ESI1−ESI3, Supporting Information). In porphyrin **A1**, three pivalamide groups are directed toward the same side and a trityl group is directed only toward the other side, which means **A1** is the target compound **3b**. In **B1**, one of the pivalamide groups is in the same plane with the trityl group, but they do not interact with each other. This result suggests the formation of the $\alpha,\beta,\alpha,\beta$-conformer **3′b**. In **B2**, at least one pivalamide group is on the same side with the trityl group. In this case, there are four atrop isomers expected, but we concluded **B2** would be the $\alpha,\alpha,\beta,\beta$-structure (**3′′b**) because the parent compound **B** was less polar than compound **A** in the $\alpha^3\beta$-conformer. In summary (Scheme 2), (i) compound **A** is porphyrin **2** in the $\alpha^3\beta$-conformer, (ii) compound **B** is a mixture of **2′** ($\alpha,\beta,\alpha,\beta$-conformer) and **2′′** ($\alpha,\alpha,\beta,\beta$-conformer). Our attempts to perform the same NOE experiment on **3a** unfortunately failed because it was difficult to saturate only the peak of the 1-methyl group at the bottom of cyclohexane ring. The coupling reaction of **2** with 1-methylcyclohexanoyl chloride gave the desired **3a** (yield: 53%).

After detritylation under acidic conditions, 6-(2-methylimidazole-1-yl)hexanoic acid chloride was reacted with the β-*o*-NH_2 group of **4**. Iron insertions of these free base porphyrins were performed with an excess of $FeBr_2$ with 2,6-lutidine as the base. The total yields of **6a** and **6b** were 15 and 10% from the atrop-isomeric mixture of TAPP. All these compounds are now available in gram quantities.

During the synthesis of the tailed porphyrinatoiron, we are always careful to prevent the atrop isomerizations of the products. The bulky pivalamide or 1-methylcyclohexanamide substituted phenyl rings did not rotate with respect to the porphyrin plane by the ambient light and heating even at 100 °C in toluene for 2 h (*8*). However, the same heating of the detritylated porphyrin **4** afforded two components, the unchanged original **4** and the new one with a lower R_f value. They both showed identical molecular weights. The newly appearing compound is suspected to be the porphyrin **4′** in the α^4-conformer. Tritylation of **4′** again by the same procedure for TAPP with tritylbromide did not proceed at all due to the steric hindrance of the fence groups next to the NH_2 group.

Table 1. Absorption Maxima (λ_{max}) of Tailed Porphyrinatoiron(II) in Toluene

	λ_{max}

O_2-Binding Properties of Tailed Porphyrinatoiron(II) in Toluene Solution. UV−Vis absorption spectra of ferrous **6a** and **6b** in toluene solution under an N_2 atmosphere were very similar to those of the five-N-coordinate complexes of **1a** and **1b** (Table 1). This indicates that **6a** and **6b** are also five-N-coordinate high-spin Fe^{2+} complex with an intramolecularly coordinated imidazole tail. Upon bubbling of O_2 gas into these solutions, the absorption spectra immediately changed to that of the well-characterized O_2 adduct complex of the Fe^{2+}TPP derivative. After passing the CO gas, the spectral pattern was converted to the typical carbonyl complex. There is no significant difference in the λ_{max} values of **6a**, **6b**, **1a**, and **1b** within 6 nm.

The binding affinities ($P_{1/2}$), association and dissociation rate constants (k_{on}, k_{off}) of O_2 to the tailed porphyrinatoiron(II)s, **6a** and **6b**, were determined (Table 2). We thought that the reduction of the fence numbers on the porphyrin ring plane from four to three unfastens the steric hindrance around the O_2-coordination site and enhanced the association rate constant of O_2. It is generally recognized that the k_{on} value increases with the relaxing distal steric encumbrance (*1*, *11*, *12*, *15*). However, the reverse was the case. In contrast to our assumption, the k_{on} values of the tailed porphyrinatoirons, **6a** and **6b**, were 3.1- and 1.9-fold lower than the corresponding α^4-conformers (**1a** and **1b**), respectively, while their k_{off} values were nearly the same. This result suggests that the steric hindrances for the O_2 association to **6a** and **6b** are greater than those of **1a** and **1b**. Most probably, three fences on the amide bonds in the $\alpha^3\beta$-

conformer can easily move on the porphyrin platform compared to the crowded four fences of the α^4-conformer. These flexible geometries of the substituents, if anything, narrowed the encumbrance around the O_2-coordination site relative to the α^4 arrangement.

O_2-Binding Properties of HSA-Tailed Porphyrinatoiron in Aqueous Medium. The tailed porphyrinatoirons, **6a** and **6b**, in the $\alpha^3\beta$-conformer could be incorporated into hydrophobic domains of HSA, providing the corresponding albumin−heme hybrids. Their maximum binding numbers to HSA were determined to be approximately 8 (mol/mol), which is identical to those of **1a** and **1b** (*2, 10a*). It is known that HSA binds porphyrin derivatives and their binding sites largely depend on the chemical structures, hydrophobicity, and electrostaticity. Crystal structure analysis of HSA complexed with natural Fe^{3+} protoporphyrin IX, namely, hemin, revealed that hemin is accommodated into subdomain IB of HSA (*17*). On the other hand, hematoporphyrin is incorporated into subdomain IIIA (*18*), and tetrakis(*p*-sulfonatophenyl)porphyrin binds to subdomain IIA or IIIA (*19*). On the basis of the competitive binding inhibition, we supposed that the some of the binding sites of **1a** are subdomains IB, IIA, and IIIB (*10a*). Attempts to crystallize HSA−**6a** hybrid are now underway, but the porphyrin **6a** dissociated from albumin during the crystallization process due to the relatively low binding constants of **6a** to HSA (10^6−10^4 M^{-1}) and coexistence of poly(ethylene glycol) in the media. We suspect that the binding sites of **6a** and **6b** are the same places of **1a**. The isoelectric point ($pI = 4.8$) and circular dichroism spectral patterns of HSA−**6a** and HSA−**6b** were similar to those of HSA itself, indicating that the surface and conformation of albumin were unaltered after bindings of the tailed porphyrinatoirons.

UV−Vis absorption spectra of the freshly prepared ferrous HSA−**6a** showed λ_{max} values at 424 and 537 nm (Figure 2, Table 3). This spectrum was almost identical to that of the CO coordinated low-spin **6a** in toluene solution, implying that the incorporated tailed porphyrinatoiron(II) is still the CO adduct complex in HSA. Light irradiation to this aqueous HSA−**6a** using a 500-W halogen lamp under an O_2 atmosphere leads to

CO dissociation, giving a typical spectral pattern of the O_2 adduct complex. Upon exposure of the dioxygenated HSA−**6a** to N_2, the absorption spectrum changed to that of the five-N-coordinated ferrous complex with an intramolecularly coordinated axial imidazole. This O_2 binding and releasing were found to be reversible.

In contrast, the ferrous HSA−**6b** was irreversibly oxidized during the CO dissociation process under an O_2 atmosphere. We concluded that the bulky and hydrophobic substituent like the 1-methylcyclohexanamide fences are necessary for the tailed porphyrinatoiron(II) in the $\alpha^3\beta$-conformer to form a stable O_2 adduct complex under physiological conditions (pH 7.3, 37 °C).

The magnetic circular dichloisim (MCD) spectra of HSA−**6a** showed almost the same pattern as those of HSA−**1b** (Figure 3) (*20*). Under an N_2 atmosphere, the MCD spectrum of HSA−**6a** showed the formation of the five-coordinate ferrous high-spin complex of **6a** with the intramolecular coordinated proximal imidazole. This result showed no ligation of the amino acid residues of the protein, e.g., histidine, tyrosine, cysteine, to the sixth coordination site of the heme. The bulky fences on the porphyrin plane could prevent access of the neighboring peptide residues to the sixth coordination site of **6a**. Upon exposure of this solution to O_2, the spectrum immediately changed and showed an S-shaped A-term MCD in the Soret region, which indicates a transformation to the ferrous low-spin complex (*8, 21*). The CO adduct complex of HSA−**6a** also exhibited a similar A-term MCD band in the same region with a much stronger intensity. The wavelength where the value of $[\theta]_M$ is zero for the O_2 and CO adduct complex coincided well with the absorption maxima in their corresponding UV−Vis spectra.

The $P_{1/2}$ of the HSA−**6a** was determined by measuring the UV−Vis absorption spectral changes during the O_2 titration. The laser flash photolysis experiments provided the k_{on} and k_{off} values of the O_2 binding to HSA−**6a** (Table 4). The absorption decays accompanying the O_2 recombination were composed of two-phases of the first-order kinetics. The curve was fitted by

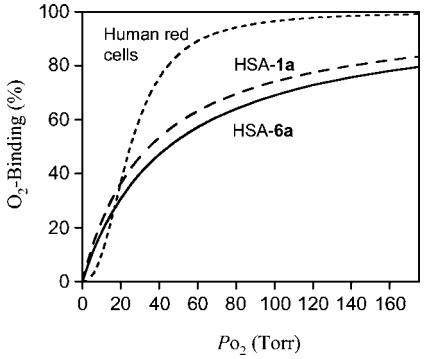

Figure 4. O_2-binding equilibrium curve of HSA−**6a** under physiological conditions (pH 7.3, 37 °C).

a double exponential equation, which was assigned to the fast and slow rebindings [k_{on}(fast) and k_{on}(slow)] of O_2. The k_{on}(fast) values were 7 times greater than k_{on}(slow), and the concentration ratio of the fast and slow reactions was 2:1. This is presumably because the O_2 association to **6a** in HSA is influenced by the molecular microenvironment in the hydrophobic domains (steric hindrance of the amino acid residue and difference in polarity). This behavior was similarly observed in HSA−**1a** and HSA−**1b** (*2*, *22*). The k_{on} values of HSA−**6a** are again 1.6−1.7-fold lower than those of HSA−**1a** in aqueous medium as observed in toluene solution. This is also caused by the narrow encumbrance on the porphyrin ring plane constructed by the three 1-methlcyclohexanamide fences of **6a**.

The HSA−**6a** did not show a cooperative O_2-binding profile like Hb; the Hill coefficient was 1.0 (Figure 4). Although the O_2-binding affinity of HSA−**6a** at 37 °C is relatively low ($P_{1/2}$ value (45 Torr) is high) compared to those of HSA−**1a** (35 Torr) and human red blood cells (28 Torr), the O_2-transporting efficiency of HSA−**6a** between the lungs (Po_2: 110 Torr) and muscle tissues (Po_2: 40 Torr) is estimated to be 22%, which is identical to human red blood cells and HSA−**1a**.

CONCLUSIONS

Tailed porphyrinatoirons have been first employed as an O_2-binding site of the synthetic hemoprotein, albumin−heme. **6a** and **6b** with a β-*o*-(2-methylimidazolyl)hexyramide tail have been easily synthesized via four steps from the TAPP scaffold compared to the eight steps of **1a**. The stereochemistry of the $\alpha^3\beta$-conformer was confirmed by NOE experiments. The association rates of O_2 were slower than for the corresponding α^4-conformers, which indicates that three substituents are close to the porphyrin platform and narrowed the encumbrance space around the O_2-coordination site. As an active site for the albumin−heme hybrid, **6a** was effective, but **6b** was rapidly oxidized. It can be concluded that bulky and hydrophobic substituents like the 1-methylcyclohexanamide fences are necessary for obtaining a stable O_2 adduct complex. The O_2 transporting ability of the HSA−**6a** was almost the same as human red blood cells. Currently, since HSA is manufactured on a large scale by yeast expression (*23*), the 5 wt % albumin−heme solution involving **6a** as O_2 binding site is the most promising material as a red blood cell substitute and O_2-carrying therapeutic reagent, which would be mass produced on an industrial scale.

PEI-g-chitosan, a Novel Gene Delivery System with Transfection Efficiency Comparable to Polyethylenimine in Vitro and after Liver Administration in Vivo

Kokhou Wong,[†] Guobin Sun,[†] Xueqing Zhang,[‡] Hui Dai,[‡] Ye Liu,*[,†] Chaobin He,[†] and Kam W. Leong[‡,§]

Institute of Materials Research and Engineering, 3 Research Link, Singapore 117602, Division of Johns Hopkins in Singapore, Singapore 138669, and Department of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205. Received June 5, 2005; Revised Manuscript Received November 21, 2005

Polyethylenimine-graft-chitosan (PEI-g-chitosan) was synthesized by performing cationic polymerization of aziridine in the presence of water-soluble oligo-chitosan ($M_n = 3400$). The absolute molecular weight and chemistry of the PEI-g-chitosan obtained were characterized using GPC, ^{13}C and ^{1}H NMR, respectively. The results indicated that all the amines of chitosan were grafted with oligo-PEI, and the average length of the oligo-PEI side chains was determined by the feed molar ratio of aziridne/amine in chitosan. PEI-g-chitosan of $M_n = 7400$ with a polydispersity index (PDI) of 1.50, and PEI side chains of $M_n = 206$ was prepared for gene delivery. Gel electrophoresis showed that DNA migration was retarded completely at a N/P ratio of 2.5/1, indicating good DNA condensation capability of PEI-g-chitosan. The sizes and the ζ-potentials of the complexes of PEI-g-chitosan/DNA were characterized. The cytotoxicity of PEI-g-chiotsan was evaluated, and the results reflected that PEI-g-chitosan had a lower cytotoxicity than PEI (25 K). Gene transfection efficiency of PEI-g-chitosan in HepG2, HeLa, and primary hepatocytes cells and after administration in the common bile duct of rat liver was determined. Remarkably, PEI-g-chitosan showed a higher transfection efficiency than that of PEI (25 K) both in vitro and in vivo. The systematic distribution and the distribution in liver of the gene expression of the complexes of PEI-chitosan/DNA were determined as well.

INTRODUCTION

Gene therapy is promising for curing various inherited or acquired diseases. However, lack of safe and efficient carriers for DNA currently is a main hurdle to the success of gene therapy. Great concerns about the safety of viral vectors make nonviral vectors more and more attractive. The good DNA delivery properties of polyethylenimines (PEI) initiated interests in applying polymers for preparing nonviral vectors due to improved safety, ease of synthesis, and adjustable structures of polymers (*1*−*3*). PEI of a certain high molecular weight is necessary for efficient delivery of DNA; however, a high molecular weight PEI is cytotoxic, and its long-term safety is problematic because of its nonbiodegradability (*3*). Other polymers have also been exploited for gene delivery, including natural products such as cyclodextrins (*4*) and chitosan (*5*, *6*), and synthetic polymers such as polyesters, polyphosphoesters, and polysaccharides with side amine groups (*7*−*12*), poly(amino ester)s (*13*−*18*). Recently, polymer-functionalized carbon nanotubes also have been explored for DNA delivery (*19*). Nevertheless, PEI is still one of the most efficient synthetic materials for gene delivery.

The cytotoxicity of PEI is dependent on its molecular weight. A lower molecular weight PEI has a lower cytotoxicity (*20*), e.g., PEI (5 K) was reported to have lower cytotoxicity and show DNA transfection efficiency comparable to PEI (25 K) in vitro, but no in vivo results were reported (*21*). One rational way was suggested to combine low molecular weight PEIs together using degradable links to form combined PEIs with suitable high molecular weights. It was expected that the toxicity should be reduced, and the long-term safety should be improved because those combined PEIs should be degraded to much less toxic low molecular weight PEIs after delivering DNA into cells; meanwhile, those combined PEIs should have good transfection efficiency for gene delivery for the high enough molecular weights (*22*−*25*). Some of those combined PEIs showed good transfection efficiency and low cytotoxicity (*22*, *25*), but gelation might occur easily in those reactions of the multifunctional low molecular weight PEIs with the degradable linkers (*26*). Even though soluble products could be obtained through carefully adjusting the reaction conditions, it was difficult to control the structures of the products such as the molecular weights and constitutions, and the reproducibility was inevitably very poor.

With the aim to prepare well-defined novel polymers with structures similar to the combined low molecular weight PEIs in a reproducible and controllable way, we prepared PEI-g-chitosan by performing cationic polymerization of aziridine in the presence of chitosan. As described in Scheme 1, oligo-PEI was combined together via grafting to biocompatible and biodegradable chitosan through the chain transfer reaction. The advantages of this approach is that no gelation occurred and the PEI length could be well controlled by adjusting the feed molar ratio of aziridine to amine of chitosan. PEI-g-chitosan showed good DNA condensation capability and lower cytotoxicity than PEI (25 K) but higher transfection efficiency for DNA delivery both in vitro and in vivo.

MATERIALS AND METHOD

General Characterization. ^{1}H NMR and ^{13}C NMR were performed on a Bruker DRX-400 spectrometer. Gel permeation chromatography (GPC) was implemented on a Waters 2690 apparatus with a Waters 410 refractive index detector and a miniDAWN light scattering detector and two columns in series (Waters Ultrahydrogel 250 and 200). 0.5 M acetic acid/0.5 M sodium acetate was used as eluent.

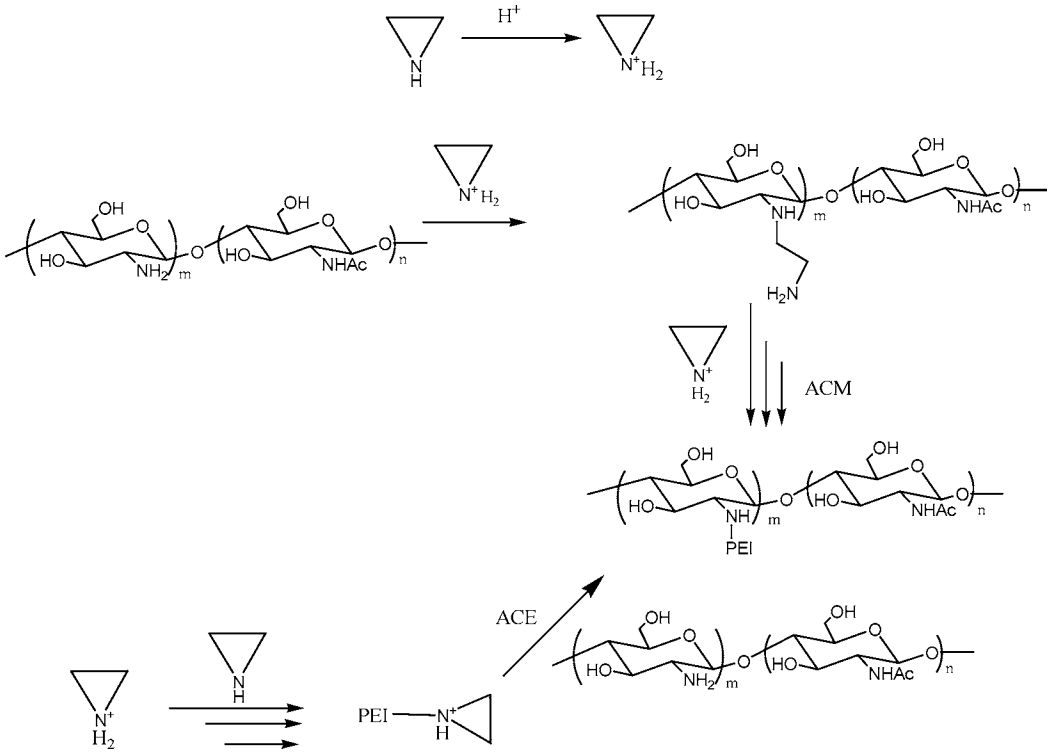
Scheme 1. Mechanism of Preparation of PEI-g-chitosan



Materials. Water-soluble chitosan was prepared by degradation of commercially available chitosan of a 80% deacetylation degree (Aldrich). Twenty-five grams of chitosan powder was dispersed in 500 mL of 0.5% H_2O_2 in an autoclave vessel. After the sample was purged with argon for 5 min, the vessel was sealed. Then the reaction was performed under 90 °C and 100 psi for 1 h. The filtered solution was precipitated in acetone. The precipitated oligo-chitosan was collected and purified by dissolving in water followed by lyophilization. Aziridine was synthesized from ethanolamine as reported (*27*).

(3-(4,5-Dimethyl-thiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) was from Aldrich (Milwaukee, WI). The other materials and solvents were used as received without further purification.

Synthesis and Characterization of PEI-g-chitosan. Typically, 0.4 g of water-soluble oligo-chitosan powder was dissolved in 5 mL of deionized water, and 3 M hydrochloric acid (HCl) was added with the molar ratio of HCl to the amine of chitosan to be 1:10. Then aziridine was added dropwise into the solution under stirring with the molar ratio of EI to amine of chitosan to be 5:1. The polymerization was performed at ambient temperature for 5 days. Finally, the temperature was increased to 60 °C for 1 day. After being purified by dialysis in water, the solution was lyophilized to give a light yellow powder.

Cytotoxicity Assay of PEI-g-chitosan. HepG2 cells (8000 cells/well), HeLa cells (8000 cells/well), and primary hepatocytes cells (4000 cells/well) were seeded in 96-well plates, respectively. The cells were incubated for 4 h with 200 μL of complete DMEM containing PEI-g-chitosan, or PEI at different concentrations. The medium in each well was replaced with 100 μL of fresh complete medium 4 h later. After 25 μL of MTT solution in PBS (5 mg/mL) was added, the cells were incubated for another 2 h. Then 100 μL of the extraction buffer (20% SDS in 50% DMF, PH 4.7) was added to the wells, and the cells were incubated overnight. The optical intensity was measured at 550 nm using a microplate reader (model 550, Bio-Rad Lab, Hercules, CA). The cell viability was expressed as a percentage of the intensity to that of the control experiment without polymers. The results were reported for triplicate samples.

Formation and Characterization of DNA/PEI-g-chitosan Complexes. A 1 mg/mL aqueous solution of plasmid DNA (pCMV-Luc) (Elim Biopharmaceuticals, California) was diluted to designed concentration (usually 0.5−2.0 μg/μL) using pure water under vortexing. Various amounts of aqueous solution of PEI-g-chiotosan of designed concentrations were added slowly to the DNA solutions. The amount of polymer added was calculated based on the chosen N/P ratios of PEI-g-chitosan/DNA. After the solution was incubated at ambient temperature for 30 min under gentle vortexing, the formed PEI-g-chiotosan/DNA complexes was mixed with a loading buffer and loaded onto a 1% agarose gel containing ethidium bromide. Gel electrophoresis was run at room temperature in TBE buffer at 80 V for 60 min. DNA bands were visualized by an UV (254 nm) illuminator. The particle sizes and ζ-potentials of the complexes of DNA/polymer were measured at 25 °C using a ZetaPALS dynamic light scattering detector (Brookhaven Instruments Corporation, Holtsville, NY, 15 mW laser, incident beam = 676 nm).

Transfection Efficiency in Vitro. The in vitro transfection efficiency of PEI-graft-chitosan was evaluated in HepG2, HeLa, and primary hepatocytes cells, using the complexes formed from PEI-g-chitosan and pVR 1255 DNA. Cells were seeded 24 h prior to transfection into 24-well plates (Becton-Dickinson, Lincoln Park, N.J) at densities of 8×10^4 per well for HepG2 cells and HeLa cells, and 4×10^4 per well for primary hepatocytes cells with 1 mL of indicated medium, respectively. At the time of transfection, the medium in each well was replaced with 300 μL of Opti-MEM. The complexes of polymer/DNA were incubated with the cells for 4 h at 37 °C. The medium was replaced with 1 mL of fresh complete medium, and the cells were further incubated for 44 h. After the incubation, cells were permeabilized with 200 μL of cell lysis buffer (Promega Co., Wis.). After two cycles of freezing and thawing, the lysate was transferred into microtubes and centri-

fuged for 5 min. Then the luciferase activity of the supernatants were measured using 100 μL of luciferase assay reagent (Promega Co., Madison, WI) on a single-well luminometer (Berthold Lumat LB 9507, Germany) for 10 s. The light units (LU) measured using a protein assay kit (Bio-Rad Labs, Hercules, California) were normalized against protein concentration in the cell extracts. Luciferase activity was expressed as relative light units (RLU ng/mg of protein). The data were reported for triplicate samples.

Transfection Efficiency in Vivo. Wistar rats (male, 200−250 g, 20−24 per group) were used for the in vivo transfection efficiency evaluation. Six- to eight-week-old male Wistar rats were obtained and housed in National University of Singapore Animal Holding Unit. Rats were maintained on ad libitum rodent feed and water at room temperature under 40% humidity. All animal procedures were approved by the Animal Care and Use Committee of Faculty of Medicine, National University of Singapore.

First the optimal N/P ratio for PEI-g-chitosan was screened. Four complexes of PEI-chitosan and VR1255 plasmid encoding firefly luciferase driven by CMV promoter were prepared with N/P ratios of 5:1; 10:1; 20:1, and 40:1 and evaluated in one rat, respectively. After identifying the optimal N/P ratio to be 10/1, the transfection efficiency of the complex of the optimal N/P ratio was compared with these of the complexes of chitosan and DNA (N/P = 3:1), PEI (25 K), and DNA (N/P ratio = 10:1), and naked DNA. The results were obtained from three rats.

Animals were laparotomized under general anesthesia, and the livers were then surgically isolated from the surrounding tissue. The complexes of polymers and DNA or naked DNA were administered at a dose equivalent to 200 μg of plasmid (~0.8 mg/kg of body weight) in 4 mL of medium into the common bile duct over 20 min (0.2 mL/min) using a syringe pump and 33-gauge needles. The needle was inserted into the common bile duct and a tie was used to secure the needle. A tie was then placed around the bile duct between the liver and the point of infusion to prevent back flow before the needle was withdrawn. After 30 min, all ties were removed. The needle hole in the bile duct might require a single 10-O nylon (Ethicon) stitch to prevent bile leakage. Rats were kept on normal diet if necessary. After 3 days, the rat from each group was sacrificed, and major organs (liver, heart, lung, spleen, and kidney) were harvested and stored at −80 °C. Each liver was divided into four sections composed of median, left, right, and caudate lobes. A total of 2 mL of lysis buffer (0.1% Triton X-100, 2 mmol/L ethylenediamine tetraacetic acid, and 0.1 mol/L Tris-HCl pH 7.8) per gram of organ was used on each sample, and the major organs were homogenized and then subjected to two cycles of freezing and thawing. The mixtures were centrifuged at 14 000 rpm for 10 min. The samples protein concentration in the supernatant was determined using a luciferase protein assay kit (Pierce, Rockford, IL). A total of 10 μL of supernatant was analyzed for luciferase activity. Luminescence was measured for 10 s of incubation, and the luciferase activity for each assay was presented as RLU per gram of tissue. The mean of luciferase activity of the liver was the sum of the values obtained by timing the RULs per gram of each lobe with the weight percentage of each lobe relative to the total liver weight.

RESULTS AND DISCUSSION

Synthesis and Characterization of PEI-g-chitosan. PEI-g-chitosan was prepared by performing the cationic polymerization of aziridine in the presence of chitosan. As described in Scheme 1, PEI was grafted onto chitosan through two mechanisms, i.e., by transferring of the iminium ion of a protonated aziridine monomer to amines of chitosan (activated monomer mechanism (AMM)) or by transferring of the iminium ion at the end of a propagation chain to the amines of chitosan (activated chain mechanism (ACM)) (*19*, *28*−*30*). To obtain PEI-g-chitosan with a homogeneous constitution, a water-soluble oligo-chitosan was adopted as a chain transfer reagent in the cationic polymerization of aziridine. The molar ratio of hydrochloride acid to the amine of chitosan was kept to be ca. 1:10. When the feed molar ratio of aziridine to amine of chitosan was 5:1, GPC results as shown in Figure 1a indicate that PEI-g-chitosan with a molecular weight of ca. 7400 (M_n) and a polydispersity index (PDI) of 1.50 was obtained. M_n of the water-soluble oligo-chiotsan adopted was ca. 3400 with a PDI of 1.36.

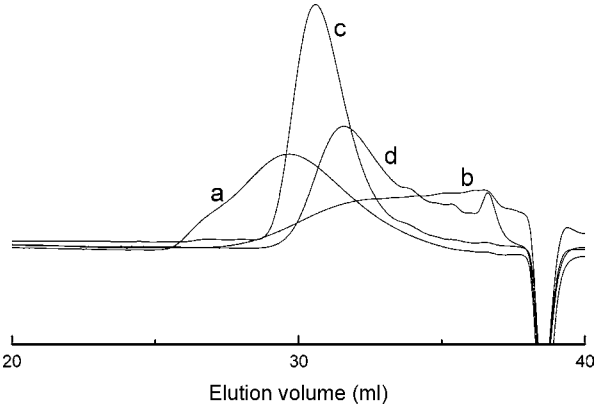


Figure 1. GPC profiles of (a) PEI-g-chitosan, (b) degraded PEI-g-chitosan obtained by treatment with 1% aqueous solution of H_2O_2 at 90 °C for 16 h, (c) PEI (2 K), and (d) degraded PEI (2 K) obtained by treatment with 1% aqueous solution of H_2O_2 at 90 °C for 16 h.

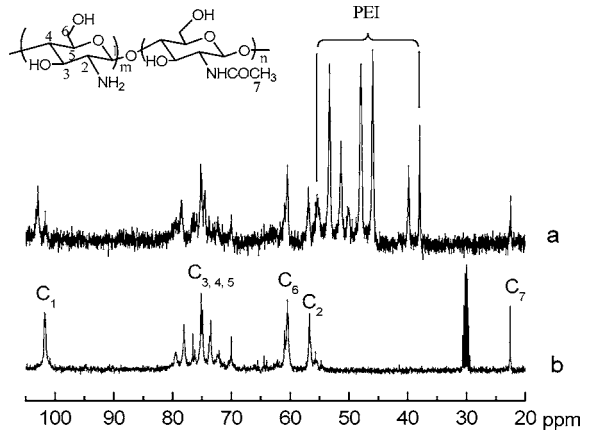

Figure 2. Comparison of ^{13}C NMR spectra of (a) PEI-g-chitosan and (b) water-soluble oligo-chitosan.

The chemistry of PEI-g-chiotsan was analyzed using ^{13}C NMR. On the basis of the ^{13}C NMR spectrum (INVGATE) as shown in Figure 2, the deacetylation degree was determined to be ca. 75% (deacetylation degree = $I_{22.5}/I_{60.5} \times 100\%$, where $I_{22.5}$ and $I_{60.46}$ stand for the integral intensity of the peaks at 22.5 and 60.5 ppm attributed to the carbon in acetyl units and C-6 in the β-(1-4)-2-amino-2-deoxy-D-glucopyranose repeating units of chitosan). Further, there was only one peak located at ca. 101.8 ppm ascribed to C-1 in the β-(1-4)-2-amino-2-deoxy-D-glucopyranose repeating units of chitosan, so acetylation/deacetylation might have little effect on the position of C-1 peak in ^{13}C NMR (*31*). However, after PEI was grafted onto chitosan, a new peak appeared at ca. 103.1 ppm as shown in Figure 2a, probably caused by the inductive effect of the grafted PEI. The integral intensity of the peak at ca. 103.1 and 101.8 ppm was ca. 71:28, therefore, almost all the amines of chitosan were grafted with PEI. The amine constitution could be determined

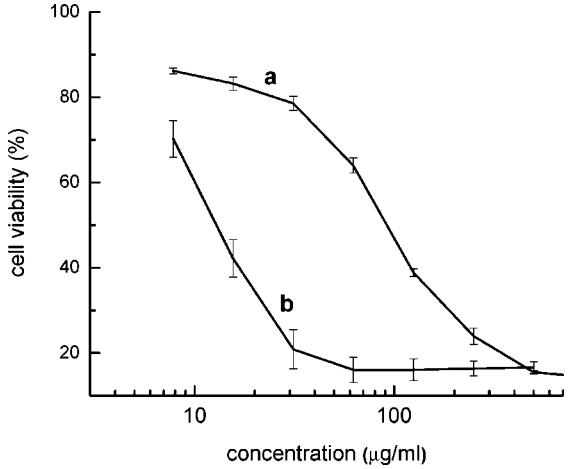

Figure 3. Comparison of the cytotoxicity of (a) PEI-g-chitosan with (b) PEI (25 K) in HeLa cells. Mean ± standard derivation ($n = 3$).

as well (*32*). The molar ratio of primary/secondary/tertiary amine was calculated to be around 1:1.97:1.23 based on the integral intensities of the corresponding peaks in Figure 2a. In addition, the ratio of PEI/chitosan unit was calculated to be around 4.8:1 based on the integral intensities of peaks located at 2.5−3.0 and 3.2−4.2 ppm in ^{1}H NMR ascribed to proton in PEI and attached to C2−6 in chitosan, which is close to the feed molar ratio. Therefore, one PEI side chain should contain around five ethylenimine units with a molecular weight of ca. 206 on average, which is in agreement with the GPC results.

To clarify whether PEI-g-chitosan was contaminated with high molecular weight PEIs, which were not expected due to the high toxicity and poor long-term safety, the degradation behavior of polymer obtained and PEI (2 K) in a 1% aqueous solution of H_2O_2 at 90 °C for 16 h was monitored using GPC. As shown in Figure 1, the degradation degree of PEI (2 K) was limited as shown by a still existing sharp elution peak with a shifting of the peak position from 2678 to 2074 and almost the same starting point of the elution peak. In comparison, the degradation of PEI-g-chitosan was significant as indicated by a very widening peak of the degraded product, the shifting of the whole peak to a much lower position, and the remarkable delay in the starting point of the elution peak. Hence, no high molecular weight PEI coexisted with PEI-g-chitosan.

Cytotoxicity of PEI-g-chitosan. MTT assay was carried out to determine the cytotoxicity of PEI-g-chitosan. Figure 3 shows that PEI-g-chitosan had a lower cytotoxicity as compared to PEI (25 K) in HeLa cells, as indicated by a IC_{50} of 97.3 μg/mL being around six times higher than 13.5 μg/mL for PEI (25 K). The cytotoxicity of cationic polymers was probably caused by polymer aggregation on cell surfaces impairing the important membrane functions (*33*). Also polymers may interfere with critical intracellular processes of cells; in particular, primary amine was reported to disrupt PKC function through disturbance of protein kinase activity (*34*). PEI-g-chitosan has an amine constitution similar to PEI (25 K); therefore, its low cytotoxicity should be caused by the lower molecular weight as reported for lower molecular weight PEI (*20*) and the lower amine content. In addition, PEI-g-chitosan may degrade in cells resulting in lower cytotoxicity as well. PEI-g-chitosan should degrade into chitosan units and nontoxic low molecular weight PEI (the average molecular weight of PEI side chain was 206); therefore, the biocompatibility and long-term safety of PEI-g-chitosan should be improved significantly as compared to PEI (25 K). In addition, here the cytotoxicity of the pure polymers was evaluated. When used for gene delivery, polymers would be complexed with DNA, and the complexes generally showed less toxicity than pure polymers.

Complexes of PEI-g-chitosan and DNA. The condensation capability of PEI-g-chitosan with DNA was evaluated using agarose gel electrophoresis. Figure 4 demonstrates that the migration of DNA was retarded completely when the N/P ratios of PEI-g-chitosan/DNA was around 2.5/1. Chitosan used for the preparation of PEI-g-chitosan with a M_n of ca. 3400 could not form stable complexes with DNA; even the N/P ratios were higher than 140, which was consistent with the reported result that only chitosan with a molecular weight higher than 4056 could form stable complexes with DNA (*35*). The condensation capability of PEI is also related to its molecular weight. For example, two times higher N/P ratio is needed to form stable complexes with DNA for PEI (5 K) as compared to PEI (25 k) (*21*). Herein M_n of PEI-g-chitosan was determined to be around 7400, but the stable complexes with DNA can be formed with the N/P ratio of 2.5/1 close to that of PEI (25 K). Probably the extended conformation of the hyperbranched PEI-g-linear chiotsan contributed to the good DNA condensation capability.

Figure 5 shows the sizes and ζ-potentials of the complexes with different N/P ratios. When the N/P was 10/1, the largest complex with a diameter of 2433.7 nm was formed. Under this condition, the complex was almost neutrally charged, so aggregation probably occurred. The complexes were negatively charged when the N/P ratio was below 10:1, and positively charged complexes were obtained when the N/P ratio was higher than 10:1. The charged complex surfaces hindered aggregation; therefore, the smaller complexes with diameters ranging from 182 to 403 nm were produced.

DNA Delivery in Vitro. DNA transfection efficiency of PEI-g-chitosan was evaluated in HepG2, HeLa, and primary hepatocytes cells. As shown in Figure 6, the complexes with N/P of 40:1 displayed the highest transfection efficiency in the three kinds of cells. Under this condition, PEI-g-chitosan showed DNA transfection efficiency being ca. 5.2-, 4.3-, and 1.5-fold higher than PEI (25 K) and much higher than naked DNA.

The higher transfection efficiency of PEI-g-chitosan should be attributed to a higher amine content of the complexes with a N/P ratio of 40:1. The higher amine content and an amine constitution similar to PEI make the complexes escape endosome easily due to a higher buffer capability. In addition, the low molecular weight PEI-g-chitosan may have a weaker

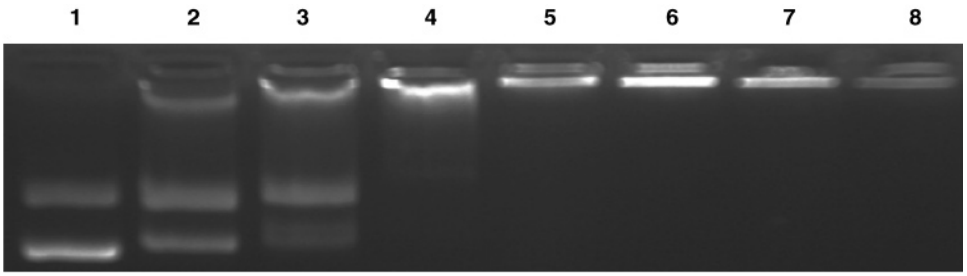

Figure 4. Agarose gel electrophoresis retardation of DNA (pCMV-Luc) by PEI-g-chitosan. Lane numbers correspond to different N/P ratios of PEI-g-chitosan/DNA as follows: (1) 0:1 (DNA only), (2) 0.6:1, (3) 0.8:1, (4) 1:1, (5) 1.5:1, (6) 2:1, (7) 3:1, (8) 4:1.

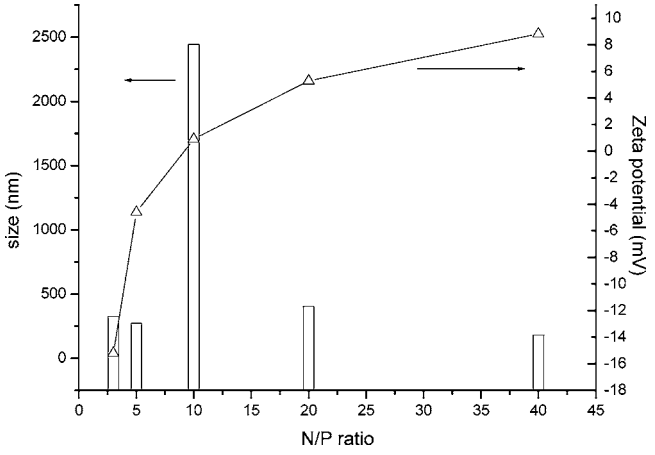

Figure 5. Effect of the N/P ratio on the diameter and ζ-potential of the complex formed from DNA (pCMV-Luc) and PEI-g-chitosan.

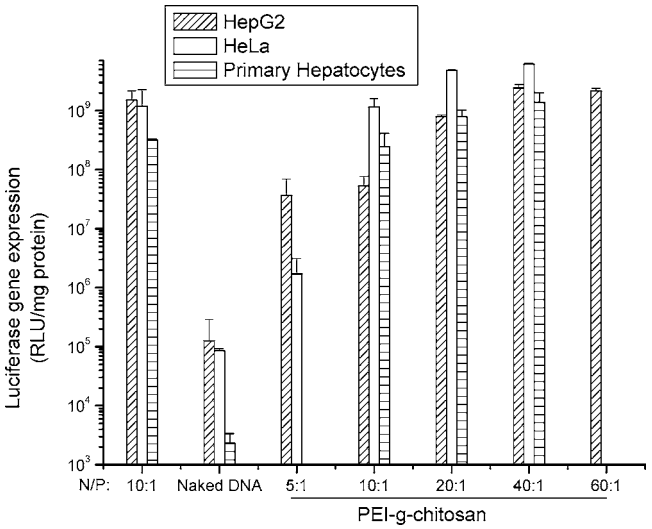

Figure 6. In vitro transfection efficiency of the complexes of PEI-g-chitosan/DNA in HepG2, HeLa, and primary hepatocytes cells in comparison with that of PEI (25 kDa). The transfection efficiency of PEI (25 K) was obtained with an optimal N/P ratio of 10:1. Mean ± standard derivation ($n = 3$).

condensation capability than PEI (25 K), which resulted in an easy release of DNA from the complexes after entering cells. This also would facilitate a higher transfection efficiency of DNA.

DNA Delivery in Vivo. The in vitro transfection efficiency of the complexes of PEI-g-chitosan/DNA was evaluated through administration in common bile duct in rat liver. A VR1255 plasmid encoding firefly luciferase driven by CMV promoter was used. The complexes of DNA and PEI-g-chitosan with N/P ratios of 5:1, 10:1, 20:1, and 40:1 were administered to screen the optimal N/P ratio for in vivo transfection. The results indicated that the complex of PEI-g-chitosan/DNA showed the highest transfection efficiency when the N/P ratio was 10:1. Then the transfection efficiency of the complexes of the optimal N/P ratio from PEI-g-chitosan was compared with these from the chitosan/DNA complexes of (N/P 3:1), PEI (25 K)/DNA (N/P 10:1), and naked DNA. Figure 7 reflects that under this condition the transfection efficiency in liver was ca. 141 times higher than that of naked DNA, 58 times higher than that of PEI (N/P 10:1), and 3 times higher than chitosan (N/P 3:1) after 3 days.

There is no relationship between the in vitro and in vivo transfection efficiency for PEI-g-chitosan in terms of the optimal N/P ratio. The complexes of the biggest size with an N/P ratio of 10:1 showed the highest transfection efficiency after admin-

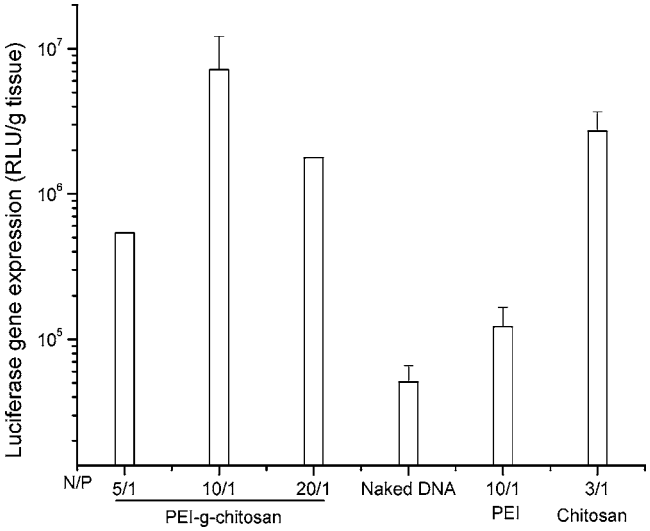

Figure 7. In vivo transfection efficiency of the complexes of PEI-g-chitosan/DNA in comparison with that of PEI (25 kDa) (N/P = 10:1) and chitosan (N/P = 3:1) after administration into common bile duct in rat liver. For the complexes of PEI-g-chitosan with N/P ratios of 5/1 and 10/1, the values were obtained from one rat. For the other samples, the values were mean ± standard derivation ($n = 3$).

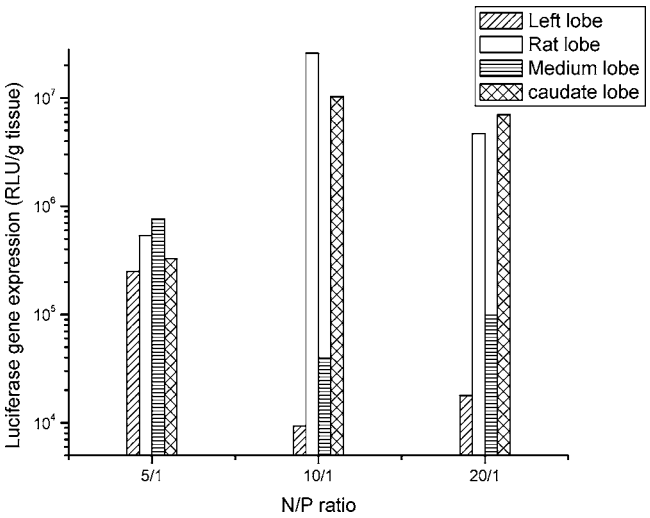

Figure 8. Gene expression in the different parts of rat liver after administration of the complexes of PEI-g-chitosan/DNA of different N/P ratios in the common bile duct in rat liver.

istration in liver. In contrast, the optimal N/P ratio for in vitro transfection was 40:1. The discrepancy may be because more stable complexes of PEI-g-chitosan/DNA are needed for efficient uptake by cells in vitro as compared to the in vivo transfection when a more concentrated suspension of the complexes was injected directly to the common bile duct.

PEI-g-chiotan still could protect pDNA from degradation efficiently with the N/P of 10:1; therefore, the complexes showed transfection efficiency still much higher than naked DNA. But factors other than the protection function should contribute to the transfection efficiency higher than PEI (25 K) and chitosan. Probably the weaker association of DNA and the low molecular weight PEI-g-chitosan would result in the ease of DNA release from the complexes, which would facilitate the transfection of DNA, together with the good buffer capability of PEI-g-chitosan. Similar results have been observed in transfection efficiency in vivo mediated by oligo-chitosan of suitable chain lengths (5).

Further, Figure 8 shows the distribution of the transgene product in different lobes of the transfected rat livers. Luciferase

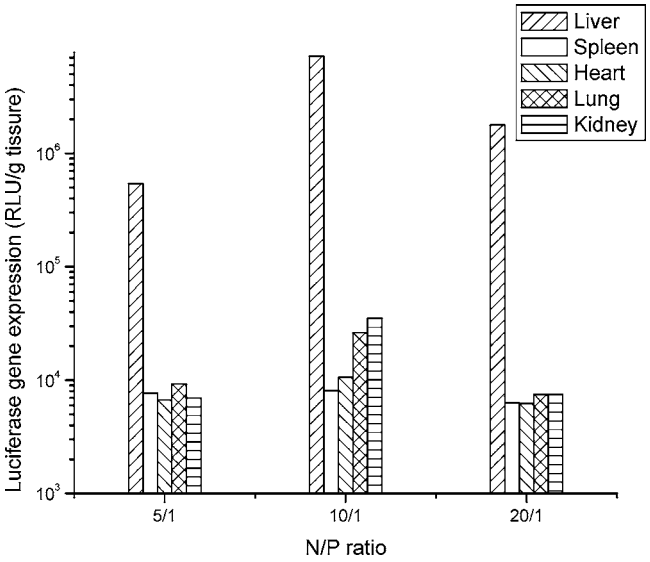

Figure 9. Gene expression in the different tissues after administration of the complexes of PEI-g-chitosan/DNA of different N/P ratios in common bile duct in rat liver.

expression in the left and medium lobes were about 5−1000-fold lower than that of the other lobes at the early time points for the complexes with N/P ratios of 10:1 or 20:1. In contrast, the expression levels were similar in different lobes for the complexes with an N/P ratio of 5: 1. Moreover, Figure 9 shows that the gene expression in kidney, lung, heart, and spleen were negligible in comparison with that in liver for the complexes of different N/P ratios.

In conclusion, PEI-g-chitosan, a kind of combined oligo-PEI, was synthesized by performing cationic polymerization of aziridine in the presence of chitosan. The length of the grafted PEI side chain could be controlled well through the feed molar ratio of aziridine/amine in chitosan. The obtained PEI-g-chiotsan has amine constitution similar to hyperbranched PEI. PEI-g-chitosan of a $M_n = 7400$ and PEI side chains of $M_n = 206$ showed good DNA condensation capability, much lower cytotoxicity, and transfection efficiency for DNA delivery higher than those of PEI (25 K) both in vitro and after administration in a rat liver. Improved biocompatibility and long-term safety could be expected for PEI-g-chitosan due to the degradable chitosan main chain and the short PEI ($M_n = 206$) side chains. So PEI-g-chitosan should be a promising nonviral gene carrier.

ACKNOWLEDGMENT

We are grateful to Mr. Wu Decheng for his help in measurement of the sizes and ζ-potentials of the complexes.

Division of Lipid Science and Technology, and Inorganic and Physical Chemistry Division, Indian Institute of Chemical Technology, Hyderabad-500 007, India. Received July 2, 2005; Revised Manuscript Received November 25, 2005

Recently, we demonstrated that covalent grafting of an endosome-disrupting single histidine functionality in the headgroup region imparts high gene transfer properties to cationic amphiphiles (Kumar, V. V., et al. *Gene Ther.* **2003**, *10,* 1206−1215). However, whether covalent attachment of multiple histidine functionalities in the headgroup region are capable of further enhancing the gene transfer efficacies of cationic amphiphiles remains to be explored. To this end, herein, we report on the design, syntheses, physicochemical characterizations, in vitro gene transfer properties, and serum compatibilites of three novel nontoxic cationic transfection amphiphiles containing mono-, di-, and tri-histidine functionalities in their headgroup regions (lipids **1**−**3**) in multiple cultured cells**.** Significantly, findings in both the reporter gene expression assay and the whole cell histochemical X-gal staining assay support the notion that there is no linear correlation between the in vitro transfection efficacies and the number of histidine functionalities in the polar headgroup regions for histidinylated cationic amphiphiles. The relative gene transfer efficiencies, as well as the serum compatibilities, of the present histidinylated cationic amphiphiles were found to be strikingly dependent on the medium of lipoplex formation. Most importantly, high serum compatibilities (up to 50% added serum) of the lipoplexes of lipids **1** and **3** make them promising nonviral transfection vectors for future systemic applications.

INTRODUCTION

Body cells are supplemented with normal functioning copies of the malfunctioning genes in gene therapy, the modality to combat myriads of inherited diseases, dreadful viral infections, and cancer. However, since both genes (DNA) and the biological cell surfaces are negatively charged, entry of genes into our body cells is not an efficient and spontaneous process. In other words, clinical success of gene therapy critically depends on the availability of safe, efficacious, and serum-compatible gene transfer reagents. Contemporary gene transfer reagents are broadly classified into two major categories: viral and nonviral. Despite their high gene transfer efficacies, serious biosafety concerns associated with the clinical uses of viral vectors have been raised (*1*−*5*). Viral vectors have a low insert-size limit (for the therapeutic genes they can pack inside) and are capable of generating: (a) inflammatory immunogenic responses against their structural components and (b) replication-competent virus through recombination events with the host genome (*6*−*10*). Such biosafety-related issues associated with the use of viral vectors have led to much effort in developing synthetic nonviral gene carriers. Contemporary major nonviral gene delivery reagents are mainly of two types: cationic polymers and cationic lipids. Cationic polymers, polylysines (*11, 12*), poly(ethylene imines) (PEI) (*13*), etc., are good in transfecting cells due to their abilities of condensing and thereby protecting DNA from the attack of DNase. However, such cationic polymers can be significantly cytotoxic (*11*) and may not be readily biodegradable (*14*). Because of their less immunogenic nature, ability to deliver large pieces of DNA, and ease of handling and preparation, cationic lipids are increasingly being demonstrated as the nonviral transfection vectors of choice for delivering genes into body cells (*15*−*22*). Detailed structure−activity investigations using libraries of cationic amphiphiles with varying headgroups, hydrophobic anchor chain lengths, linker functionalities, etc. are being actively pursued with a view to find more efficacious cationic transfection lipids for use in nonviral gene delivery (*23*−*34*).

Currently believed intracellular pathways involved in cationic lipid mediated gene transfer (lipofection) include (a) endocytotic cellular uptake of the lipid−DNA complex (lipoplex), (b) release of DNA from endosomes to cell cytoplasm, and (c) the nuclear transport of the endosomally released DNA followed by transcription and gene expression (*35*−*38*). Recently, toward enhancing gene transfer properties of cationic amphiphiles through use of endosome-disrupting headgroups (i.e., through improving the efficacies of step b mentioned above), we designed and synthesized two efficacious cationic amphiphiles containing a covalently grafted endosome-pH-sensitive single histidine functionality in their polar headgroup regions (*26, 32*). In the present structure−activity investigation, we address the issue of whether covalent grafting of increasing numbers of histidine functionalities in the polar headgroup region of cationic amphiphiles leads to further enhancement of their in vitro gene transfer efficacies. To this end, we have designed and synthesized three novel histidinylated cationic lipids containing mono-, di-, and tri-histidine functionalities in the polar headgroup regions (lipids **1**, **2**, and **3**, respectively, Schemes 1−3) and evaluated their efficacies in transfecting multiple cultured cells including COS-1 (African green monkey kidney cells), CHO (Chinese hamster ovarian cells), HepG2 (human hepatocarcinoma cells), and the highly transfectable HEK293T (SV-40 T-antigen transformed human embryonic kidney) cells both in the presence and in the absence of added serum. As described below, our present findings shows an absence of any linear correlation between the in vitro transfection efficacies and the

number of histidine functionalities in the polar headgroup regions for histidinylated cationic amphiphiles. Our findings also demonstrate that the relative in vitro gene transfer efficacies of the presently described histidinylated cationic amphiphiles are remarkably sensitive to the nature of the buffer used in preparing lipoplexes. In addition, in sharp contrast to serum incompatibilities of many cationic amphiphiles, the lipoplexes of both mono- and tri-histidinylated lipids **1** and **3** when prepared in HEPES[1] buffer remained remarkably transfection efficient in the presence of up to 50% (v/v) added serum at lipid/DNA charge ratios of 8:1 and 4:1.

[1] Abbreviations: BOC, *tert*-butyloxycarbonyl; Chol, cholesterol; DCC, dicyclohexylcarbodiimide; DCM, dichloromethane; DMAP, 4-(dimethylamino)pyridine; DMEM, Dulbecco's modified Eagle's medium; DMF, *N*,*N*-dimethylformamide; DOPE, 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine; DOTAP, *N*-[1-(2,3-dioleoyloxy)propyl]-*N*,*N*,*N*-trimethylammonium methyl sulfate FBS, fetal bovine serum; HOSu, *N*-hydroxysuccinimide; HEPES, [*N*-(2-hydroxyethyl)] piperazine-*N*′-[2-ethanesulfonic acid]; ONPG, *o*-nitrophenyl-β-D-galactopyranoside; PBS, phosphate-buffered saline; TFA, trifluoroacetic acid; Z, benzyloxycarbonyl: NP-40, nonylphenylpoly(ethylene glycol).

EXPERIMENTAL PROCEDURES

General Procedures and Materials. The FABMS data were acquired by the liquid secondary ion mass spectrometry (LSIMS) technique using *meta*-nitrobenzyl alcohol as the matrix. LSIMS analysis was performed in the scan range 100−1000 amu at the rate of 3 scans/s. ^{1}H NMR spectra were recorded on a Varian FT 200 MHz, AV 300 MHz, or Varian Unity 400 MHz. 1-Bromohexadecane, *n*-hexadecylamine, and 10% Pd/C were procured from Lancaster (Morecambe, England); L-lysine and N^{α}-*Z*-L-lysine used were a product of Aldrich (St. Louis, MO). The progress of the reactions was monitored by thin-layer chromatography on 0.25 mm silica gel plates. Column chromatography was performed with silica gel (Acme Synthetic Chemicals, India, 60−120 and 100−200 mesh). pCMV-SPORT-β-gal plasmid was a generous gift from Dr. Nalam Madhusudhana Rao (Centre for Cellular and Molecular Biology, Hyderabad, India). Lipofectamine was purchased from Invitrogen Life Technologies (Carlsbad, CA). Cell culture media, fetal bovine serum, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), poly(ethylene glycol) 8000, *o*-nitrophenyl-β-D-galactopyranoside, cholesterol, and bafilomycin A1 were pur-

Scheme 3. Synthesis of Lipids: Lipid 3[a]

chased from Sigma, St. Louis, MO. NP-40, antibiotics, and agarose were purchased from Hi-media, India. DOPE was purchased from Fluka (Switzerland). Unless otherwise stated, all the other reagents purchased from local commercial suppliers were of analytical grades and were used without further purification. COS-1 (SV-40 transformed African green monkey kidney), CHO (Chinese hamster ovary), and HepG2 (human hepatocarcinoma) cell lines were procured from the National Centre for Cell Sciences (NCCS), Pune, India. HEK293T cells (SV-40 T-antigen transformed human embryonic kidney) were a generous gift from Dr. V. Radha (Centre for Cellular and Molecular Biology, Hyderabad, India). Purity of all the final lipids (**1**−**3**) was determined by analytical HPLC (Shimadzu model LC10A) using a PARTISIL 5 ODS-3 WCS analytical column (4.6 mm × 250 mm, Whatman Inc., Clifton, NJ) in two different mobile phases. One solvent system (A) was methanol (100%) for 20 min with a flow rate of 1.2 mL/min. The other (B) was methanol/water/trifluoroacetic acid in the ratio 98:2:0.05 (v/v) for 20 min with a flow rate of 1.3 mL/min. Peaks were detected by UV absorption at 219 nm. All the target lipids (**1**−**3**) showed more than 95% purity. Retention times in mobile phase A and B were 2.25 and 2.22 min for lipid **1**; 2.14 and 2.24 min for lipid **2**, and 2.01 and 2.41 min for lipid **3**, respectively.

Synthesis. Lipids **1**−**3** were synthesized following strategies depicted in Schemes 1−3. ^{1}H NMR spectra for all the intermediates, as well as for the final lipids **1**−**3**, are provided in the Supporting Information. The final lipids **1**−**3** were further characterized by the molecular ion peaks in their FABMS, and their purities were confirmed by reverse phase analytical HPLC using two different mobile phases (Supporting Information).

Synthesis of lipid 1 (Scheme 1). *Step a.* Solid HOSu (0.125 g, 1.09 mmol) and DCC (0.23 g, 1.09 mmol) were added sequentially to an ice cold and stirred solution of N^{α},N^{im}-di-*tert*-butyloxycarbonyl-L-histidine (0.39 g, 1.09 mmol) in 10 mL of dry DCM/dry DMF (9:1, v/v). After half an hour, *N*-2-[*N*′-(N^{ϵ}-BOC-L-lysyl)]aminoethyl-*N*,*N*-di-*n*-hexadecylamine (**I**, 0.8 g, 1.09 mmol, prepared as described in ref *29*) and DMAP (catalytic) dissolved in dry DCM were added to the reaction mixture. The resulting solution was left stirring at room temperature for 24 h, solid DCU was filtered, and the solvent was evaporated from the filtrate. The residue was taken up in ethyl acetate (100 mL) and washed sequentially with ice-cold 1 N HCl (3 × 100 mL), saturated sodium bicarbonate (3 × 100 mL), and water (3 × 100 mL). The organic layer was dried over anhydrous sodium sulfate and filtered, and the solvent was removed from the filtrate by rotary evaporation. The residue upon column chromatographic purification with 60−120 mesh silica gel using 2.5−3% methanol−chloroform (v/v) as eluent afforded 0.28 g (24% yield) of the pure intermediate *N*-2-[*N*′-(N^{α},N^{im}-di-BOC-L-histidyl-N^{ϵ}-BOC-L-lysyl)]aminoethyl-*N*,*N*-di-*n*-hexadecylamine (R_f = 0.4, 5% methanol−chloroform, v/v).

Step b. The intermediate obtained in step a (0.28 g, 0.26 mmol) was dissolved in 1 mL of 2 N HCl in methanol at 0 °C. The resulting solution was left stirring at room temperature for 4 h to ensure complete deprotection. Excess HCl was removed by flushing with nitrogen to give the title compound as a chloride salt. Repeated crystallization from dry acetone/dichloromethane/methanol (8:1:1, v/v) afforded 0.175 g (overall yield of about 18%) of *N*,*N*-di-*n*-hexadecyl-*N*-2-[*N*′-(L-histidyl-L-lysyl)]aminoethylammonium chloride, lipid **1** (R_f = 0.1, 40% methanol in chloroform, v/v).

Synthesis of lipid 2 (Scheme 2). *Step a.* *N*-2-[*N*′-(*N*$^{\alpha}$,*N*$^{\epsilon}$-Di-BOC-L-lysyl)]aminoethyl-*N*,*N*-di-*n*-hexadecylamine (1.05 g, 1.26 mmol, prepared as described in ref *29*) was dissolved in 10 mL of dry DCM, and 5 mL of TFA was added at 0 °C. The resulting solution was left stirring at room temperature for 4 h to ensure complete deprotection. Excess TFA was removed by flushing with nitrogen followed by recrystallization of the resulting trifluoroacetate salt from methanol/diethyl ether (1:4 v/v) to afford 1.09 g (88% yield) of *N*,*N*-di-*n*-hexadecyl-*N*-2-[*N*′-(L-lysyl)]aminoethylammonium trifluoroacetate (R_f = 0.2, 20% methanol in chloroform, v/v).

Step b. *N*$^{\alpha}$,*N*^{im}-Di-*tert*-butyloxycarbonyl-L-histidine (0.73 g, 2.06 mmol) was coupled with the intermediate prepared in step a (1.0 g, 1.02 mmol) in the presence of solid HOSu (0.24 g, 2.06 mmol), DCC (0.47 g, 2.06 mmol), and triethylamine (0.85 mL, 6.14 mmol) following essentially the same protocol as described in step a of the lipid **1** synthesis. The resulting crude product upon column chromatographic purification with 60−120 mesh silica gel using 25% acetone in petroleum ether (v/v) as eluent afforded 0.32 g (50% yield) of *N*-2-[*N*′-{*N*$^{\alpha}$,*N*$^{\epsilon}$-di-(*N*$^{\alpha}$,*N*^{im}-di-*tert*-butyloxycarbonyl-L-histidyl)-L-lysyl}]aminoethyl-*N*,*N*-di-*n*-hexadecylamine intermediate as a white gummy solid (R_f = 0.41, 35% acetone in petroleum ether, v/v).

Step c. The intermediate obtained in step b (0.2 g, 0.15 mmol) was dissolved in 1 mL of 2 N HCl in methanol at 0 °C. The resulting solution was left stirring at room temperature for 4 h to ensure complete deprotection. Excess HCl was removed by flushing with nitrogen to give the title compound as a chloride salt. Repeated crystallization from dry acetone/dichloromethane/methanol (8:1:1) afforded 0.15 g (90% yield) of *N*,*N*-di-*n*-hexadecyl-*N*-2-[*N*′-{*N*$^{\alpha}$,*N*$^{\epsilon}$-di-(L-histidyl)-L-lysyl}]aminoethylammonium chloride, lipid **2** (R_f = 0.14, 40% methanol in chloroform, v/v).

Synthesis of lipid 3 (Scheme 3). *Step a.* *N*-2-[*N*′-(*N*$^{\alpha}$,*N*$^{\epsilon}$-Di-BOC-L-lysyl-*N*$^{\epsilon}$-BOC-L-lysyl)]aminoethyl-*N*,*N*-di-*n*-hexadecylamine {0.5 g, 0.47 mmol, prepared as described previously (*29*)}was dissolved in 4 mL of dry DCM, and TFA (2 mL) was added at 0 °C. The resulting solution was left stirring at room temperature for 4 h to ensure complete deprotection. Excess TFA was removed by flushing with nitrogen. Repeated crystallization of the resulting trifluoroacetate salt from methanol/diethyl ether (1:4, v/v) afforded 0.3 g (84% yield) of *N*,*N*-di-*n*-hexadecyl-*N*-2-[*N*′-(L-lysyl)$_2$]aminoethylammonium chloride as a white gummy solid (R_f = 0.15, 40% methanol in chloroform, v/v).

Step b. *N*$^{\alpha}$,*N*^{im}-Di-*tert*-butyloxycarbonyl-L-histidine (0.84 g, 2.35 mmol) was coupled with intermediated otained in step a (0.3 g, 0.39 mmol) in the presence of solid HOSu (0.27 g, 2.35 mmol), DCC (0.49 g, 2.35 mmol), and triethylamine (0.32 mL, 3.12 mmol) following essentially the same protocol as described in step a of the lipid **1** synthesis. The resulting crude product upon column chromatographic purification with 100−200 mesh silica gel using 4.5−5% methanol in chloroform (v/v) as eluent afforded 0.18 g (26% yield) of *N*-2-[*N*′-{*N*$^{\alpha}$,*N*$^{\epsilon}$-di-(*N*$^{\alpha}$,*N*^{im}-di-*tert*-butyloxycarbonyl-L-histidyl)-L-lysyl-*N*$^{\epsilon}$-(*N*$^{\alpha}$,*N*^{im}-di-*tert*-butyloxycarbonyl-L-histidyl)-L-lysyl}]aminoethyl-*N*,*N*-di-*n*-hexadecylamine as a gummy solid (R_f = 0.5, 10% methanol in chloroform, v/v).

Step c. The intermediate obtained in step b (0.17 g, 0.1 mmol) was dissolved in 1 mL of 2N HCl in methanol at 0 °C. The resulting solution was left stirring at room temperature for 4 h to ensure complete deprotection. Excess HCl was removed by flushing nitrogen to give the title compound as a chloride salt. Repeated crystallization from dry acetone/dichloromethane/methanol (8:1:1, v/v) afforded 0.062 g (45% yield) of *N*,*N*-di-*n*-hexadecyl-*N*-2-[*N*′-{*N*$^{\alpha}$,*N*$^{\epsilon}$-di-(L-histidyl)-L-lysyl-*N*$^{\epsilon}$-(L-histidyl)-L-lysyl}]aminoethylammonium chloride, lipid **3** (R_f = 0.1, 50% methanol in chloroform, v/v).

Cell Culture. COS-1 (SV-40 transformed African green monkey kidney), CHO (Chinese hamster ovary), HepG2 (Human hepatocarcinoma), and HEK293T (SV-40 T-antigen transformed human embryonic kidney) cell lines were cultured at 37 °C in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum, 50 μg/mL penicillin, 50 μg/mL streptomycin, and 20 μg/mL kanamycin in a humidified atmosphere containing 5% CO_2.

Preparation of Liposomes. The cationic lipids (**1**−**3**) and 1,2-di-oleoyl-*sn*-glycero-3-phosphatidyl ethanolamine (DOPE) in 1:1 mole ratio were dissolved in a mixture of chloroform and methanol (3:1, v/v) in a glass vial. The solvent was removed with a thin flow of moisture-free nitrogen gas, and the dried lipid film was then kept under high vacuum for 8 h. One milliliter of sterile deionized water was added to the vacuum-dried lipid film, and the mixture was allowed to swell overnight. The vial was then vortexed for 2−3 min at room temperature and occasionally sonicated in a bath sonicator to produce multilamellar vesicles (MLVs). MLVs were then sonicated in an ice bath until clarity using a Branson 450 sonifier at 100% duty cycle and 25 W output power to give a final lipid concentration of 1 mM. These resulting clear aqueous liposomes were used in forming lipoplexes.

Plasmid DNA. pCMV-SPORT-β-gal plasmid was amplified in the DH5α strain of *Escherichia coli*, isolated by the alkaline lysis procedure, and finally purified by PEG-8000 precipitation as described previously (*39*). The purity of the plasmid was checked by A_{260}/A_{280} ratio (around 1.9) and 1% agarose gel electrophoresis.

Transfection of Cells. Cells were seeded at a density of 15 000 (for COS-1) and 20 000 cells (for CHO, HepG2, and HEK293T) per well in a 96-well plate 18−24 h before the transfection. Plasmid DNA (0.3 μg) was complexed with varying amounts of lipids (to give ± charge ratios of 1:1, 2:1, 4:1, and 8:1) in plain DMEM or 10 mM HEPES buffer, pH 7.4 (total volume made up to 100 μL), for 30 min. When the complexation was carried out in HEPES buffer, the total volume of the lipoplexes was made up to 150 μL with 50 μL of DMEM, and the NaCl concentration was adjusted to 0.15 M with 5 M NaCl after the 30 min incubation period. Immediately prior to the addition of lipoplexes, cells plated in the 96-well plate were washed with PBS (2 × 100 μL). When the transfection efficacy was evaluated in the presence of serum, 100 μL of DMEM (or 150 μL of DMEM when the complexation was carried out in HEPES) containing 20%, 60%, or 100% FBS was added to cells to give an effective serum concentration of 10%, 30%, and 50%, respectively. After 4 h of incubation, the medium was changed to 10% complete medium. The medium was again replaced with 10% complete medium after 24 h, and the reporter gene activity was estimated after 48 h. The cells were washed with PBS (2 × 100 μL) and lysed in 50 μL of lysis buffer [0.25 M Tris-HCl (pH 8.0) and 0.5% NP-40]. Care was taken to ensure complete lysis. The β-galactosidase activity per well was estimated by adding 50 μL of 2×-substrate solution [1.33 mg/mL of ONPG, 0.2 M sodium phosphate (pH 7.3) and 2 mM magnesium chloride] to the lysate in a 96-well plate. Absorbance of the product ortho-nitrophenol at 405 nm was converted to β-galactosidase units by using calibration curve constructed using pure commercial β-galactosidase enzyme. Each transfection experiment was repeated two times on three different days. The transfection values reported here are average values from duplicate experiments performed on the same day. The values of β-galactosidase units in replicate plates assayed on the same day varied by less than 20%. The day to day variation in transfection efficiency values for identically treated transfection

plates was mostly within 2−3-fold and was dependent on the cell density and condition of the cells. When bafilomycin A1 was used, the cells were pretreated for 30 min at 37 °C with bafilomycin A1 (25 or 50 nM), and the transfection was carried out in the presence of the drug. After 4 h at 37 °C, the medium was replaced with fresh complete medium without bafilomycin A1, and the transfection activity was evaluated after 48 h as described above.

X-Gal Staining. Cells expressing β-galactosidase were histochemically stained with the substrate 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal) as described previously (*27*). Briefly, 48 h after transfection with lipoplexes in 96 well plates, the cells were washed (2 × 100 μL) with PBS (137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 2 mM KH_2PO_4, pH 7.4) and fixed with 0.5% glutaraldehyde in PBS (225 μL). After 15 min incubation at room temperature, the cells were washed again with PBS (3 × 250 μL) and, subsequently, were stained with 1.0 mg/mL X-gal in PBS containing 5.0 mM $K_3[Fe(CN)_6]$, 5.0 mM $K_4[Fe(CN)_6]$ and 1 mM $MgSO_4$ for 2−4 h at 37 °C. Blue colored cells were identified by light microscopy (Leica, Germany).

Toxicity Assay. Cytotoxicities of the lipids **1**−**3** were assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay as described earlier (*40*). The cytotoxicity assay was performed in 96-well plates by maintaining the ratio of number of cells to amount of cationic lipid the same as that used in the transfection experiments. MTT was added 3 h after addition of cationic lipid to the cells. Results were expressed as percent viability = [(A_{540}(treated cells) − background)/(A_{540}(untreated cells) − background)] × 100.

Size Measurements. The sizes of liposomes and lipoplexes were measured by photon correlation spectroscopy on a Zeta sizer 3000HS_A (Malvern, U.K.) in DMEM and HEPES buffer, pH 7.4, using a sample refractive index of 1.59 and a viscosity of 0.89. The system was calibrated by using the 200 ± 5 nm polystyrene polymer (Duke Scientific Corps., Palo Alto, CA). The diameters of liposomes and lipoplexes were calculated by using the automatic mode.

Gel Retardation Assay. The DNA binding ability of the cationic lipids **1**−**3** was assessed by gel retardation assay on a 1% agarose gel. pCMV-β-gal (0.30 μg) was complexed with varying amounts of cationic lipids (using the indicated lipid/DNA charge ratios in Figure 8A) in a total volume of 20 μL in HEPES buffer, pH 7.40, and incubated at room temperature for 20−25 min. Four microliters of 6× loading buffer (0.25% bromophenol blue, 40% sucrose) was added to it, and 20 μL of the resultant solution was loaded in each well. The samples were electrophoresed at 80 V for approximately 2 h, and the DNA bands were visualized by staining for 30 min with ethidium bromide solution.

DNase 1 Sensitivity Assay. Briefly, in a typical assay pCMV-β-gal (0.6 μg) was complexed with varying amounts of the cationic lipids (using the indicated lipid/DNA charge ratios in Figure 8B) in a total volume of 20 μL in HEPES buffer, pH 7.40, and incubated at room temperature for 30 min on a rotary shaker. Subsequently, the complexes were treated with 5 μL of DNase I (at a final concentration of 1 μg/mL) in the presence of 20 mM $MgCl_2$ in a final volume of 50 μL and incubated for 20 min at 37 °C. The reactions were then halted by adding EDTA (to a final concentration of 50 mM) and incubated at 60 °C for 10 min in a water bath. The aqueous layer was washed with 50 μL of phenol/chloroform/isoamyl alcohol (25:24:1mixture, v/v) and centrifuged at 10 000 rpm for 5 min. The aqueous supernatants (30 μL) were separated, 6 μL of 6× loading buffer (0.25% bromophenol blue, 40% sucrose) was added to it, and 20 μL of the resultant solution was loaded in each well on a 1% agarose gel and electrophoresed at 80 V for 2 h. The DNA bands were visualized by staining for 30 min with ethidium bromide solution.

Transmission Electron Microscopy. Transmission electron microscopy was performed on a FEI Tecnai 12 TEM apparatus operated at 100 kV. Lipoplex samples were transferred onto an ultrathin carbon-coated copper grid by placing the grid on top of a 10 μL drop of the sample for 1 min. After removing the excess fluid from one side, the grid was placed on a 20 μL water drop for a 30 s wash. The excess fluid was removed, and the grid was placed for 1 min on a 20 μL drop of freshly filtered uranyl acetate (1.33%). Once again, the excess fluid was wicked away, and the grid was air-dried.

RESULTS

Chemistry. The mono-histidinylated lipid **1** was synthesized by DCC coupling of N^{α},N^{im}-di-BOC-L-histidine with the N^{ϵ}-BOC-L-lysinyl tertiary amine precursor **I**, a commonly available precursor in our laboratory prepared as described previously (*29*), followed by acid deprotection of the resulting intermediate in 2 N HCl in methanol (Scheme 1). The di-histidinylated cationic lipid **2** was synthesized by DCC coupling of N^{α},N^{im}-di-BOC-L-histidine with the L-lysinyl tertiary amine precursor **II** {obtained by acid deprotection of *N*-2-[*N*′-(N^{α},N^{ϵ}-di-BOC-L-lysyl)]aminoethyl-*N*,*N*-di-*n*-hexadecylamine (*29*) with TFA}, followed by acid deprotection of the resulting intermediate (Scheme 2). Similarly, the tri-histidinylated cationic lipid **3** was prepared by DCC coupling of the dilysinylated precursor **III** {prepared by acid deprotection of *N*-2-[*N*′-(N^{α},N^{ϵ}-di-BOC-L-lysyl-N^{ϵ}-BOC-L-lysyl)]aminoethyl-*N*,*N*-di-*n*-hexadecylamine (*29*) with TFA}, followed by acid deprotection of the resulting intermediate in 2 N methanolic HCl (Scheme 3). Structures of all the synthetic intermediates and the final histidinylated cationic lipids **1**−**3** shown in Schemes 1−3 were confirmed by ^{1}H NMR and FABMS, and the purity of the final lipids was confirmed by quantitative reversed phase HPLC analysis using two different mobile phases (detailed spectral data for all the intermediates and the final lipids, as well as the HPLC chromatograms for all the final lipids are provided in the Supporting Information).

Transfection Biology. Figures 1 and 2 summarize the representative relative in vitro efficiency profiles of lipids **1**−**3** (in combination with equimolar amounts of DOPE as the colipid) in transfecting COS-1 and CHO cells, respectively. Similar transfection profiles for lipids **1**−**3** were also observed in HepG2 and HEK293T cells (Figures S1 and S2, Supporting Information). pCMV-SPORT-β-gal plasmid DNA was used as the reporter gene across the lipid/DNA charge ratios of 8:1 to 1:1. Interestingly, cholesterol, the other commonly used colipid in liposomal gene delivery, was found to be significantly less efficient in imparting gene transfer properties to lipids **1**−**3** (data not shown). The in vitro transfection profiles of lipids **1**−**3** in combination with equimolar amounts of DOPE were found to be remarkably influenced by the complexation medium used in preparing lipoplexes. Only the mono-histidinylated cationic lipid **1** was found to be transfection efficient, whereas the di- and tri-histidinylated lipids **2** and **3** were essentially incompetent in transfecting all the four cells when lipoplexes were prepared in the culture medium, DMEM. The relative transfection profiles in representative COS-1 and CHO cells are shown in part A of Figures 1 and 2. The corresponding transfection results for HepG2 and HEK293T cells are provided in the Supporting Information (part A, Figures S1 and S2, respectively). In contrast, when lipoplexes were prepared in HEPES buffer, the optimal gene transfer efficacies of the tri-histidinylated lipid **3** became comparable to (in COS-1, CHO, and HEK293T cells) or better than (in HepG2 cells) that of lipid **1**. Part B of Figures 1 and 2 summarizes the relative transfection profiles of the

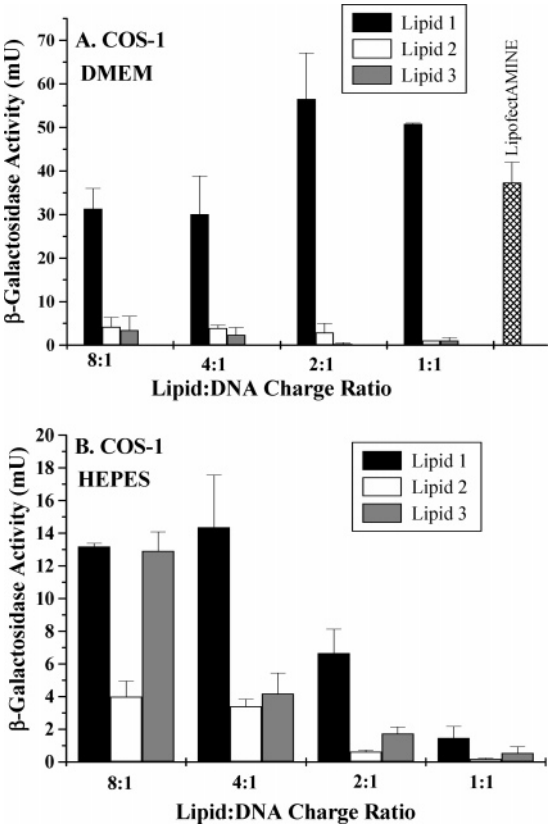

Figure 1. In vitro transfection efficiencies of lipids **1**, **2**, and **3** using reporter gene expression assays in COS-1 cells in combination with equimolar DOPE as colipid at lipid/DNA charge ratios of 8:1−1:1 with DMEM (A) and HEPES buffer (B) as complexing medium for preparing lipoplexes. Units of β-galactosidase activity were plotted against the varying lipid/DNA charge ratios. The transfection values shown are average of duplicate experiments performed on the same day. Details of the transfection assays are as described in the text.

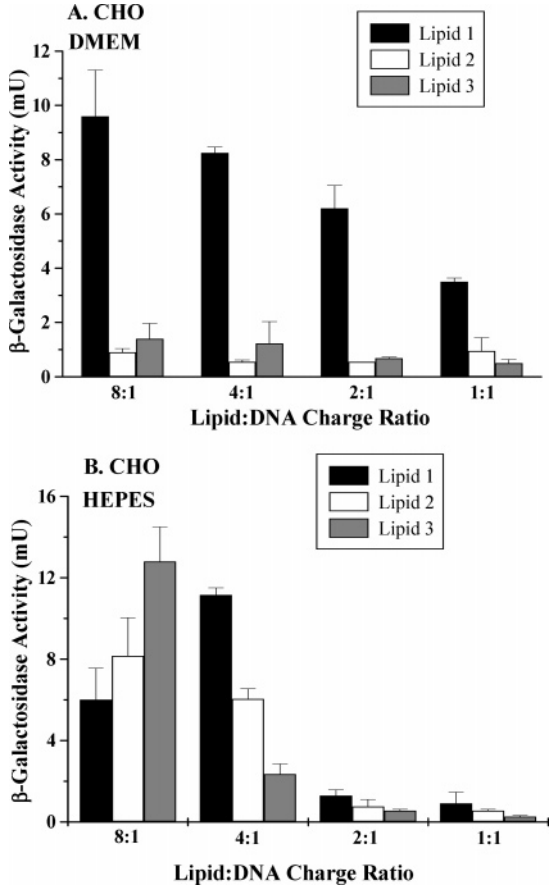

Figure 2. In vitro transfection efficiencies of lipids **1**, **2**, and **3** using reporter gene expression assays CHO cells in combination with equimolar DOPE as colipid at lipid/DNA charge ratios of 8:1−1:1 with DMEM (A) and HEPES buffer (B) as complexing medium for preparing lipoplexes. Units of β-galactosidase activity were plotted against the varying lipid/DNA charge ratios. The transfection values shown are average of duplicate experiments performed on the same day. Details of the transfection assays are as described in the text.

lipoplexes **1**−**3** prepared in HEPES buffer in representative COS-1 and CHO cells. The transfection profiles in HepG2 and HEK293T cells for the lipoplexes prepared in HEPES buffer are provided in the Supporting Information (part B, Figures S1 and S2, respectively).

The above-mentioned complexation-medium-dependent transfection profiles for lipids **1**−**3** observed in the reporter gene expression assays (Figures 1 and 2) were further confirmed by the whole cell histochemical X-gal staining assay in representative CHO cells. Consistent with the findings in the reporter gene expression assay (Figure 2, part A), the number of X-gal stained CHO cells transfected with the efficacious mono-histidinylated lipoplex prepared in DMEM at a representative lipid/DNA charge ratio of 4:1was found to be remarkably higher than those transfected by the lipoplexes of lipids **2** and **3** (Figure S3, part A, Supporting Information). Similarly, at the representative lipid/DNA charge ratio of 8:1, consistent with the higher transfection properties of lipid **3** measured by the reporter gene expression assay in CHO cells for lipoplexes prepared in HEPES buffer (Figure 2, part B), the number of X-gal stained CHO cells transfected with lipoplexes of lipid **3** prepared in HEPES buffer was found to be significantly higher than those transfected by lipid **1** lipoplexes prepared in HEPES buffer medium (Figure S3, part B, Supporting Information).

As to the possible component of the culture medium behind the compromised transfection efficacies of the lipoplexes **2** and **3** (parts A, Figures 1 and 2) (*41*), we suspected mainly two major components, namely, sodium chloride and sodium bicarbonate, used in preparing the culture medium (the molar concentrations of these two components in DMEM are about 150 mM and 44 mM, respectively). To find out which of these two major components (present in DMEM and absent in 10 mM HEPES buffer) might play some role in abolishing the transfection efficacies of lipids **2** and **3** in DMEM (parts A, Figures 1 and 2), we separately evaluated the relative gene transfer efficacies of the lipoplexes **1**−**3** prepared in 10 mM HEPES buffer containing 150 mM NaCl and those for the lipoplexes **1**−**3** prepared in 10 mM HEPES buffer containing 44 mM sodium bicarbonate (bringing the final pHs of the complexing medium to 7.4 in both the cases). The transfection efficacies of the lipoplexes **1**−**3** prepared in 10 mM HEPES buffer containing 150 mM NaCl were found to be either unaffected or enhanced compared with those for the lipoplexes **1**−**3** prepared in 10 mM HEPES buffer alone (data not shown). In contrast, the transfection efficacies of the lipoplexes **2** and **3** prepared in 10 mM HEPES buffer containing 44 mM sodium bicarbonate were found to be adversely affected compared with those of the lipoplexes prepared in 10 mM HEPES buffer alone (Figure 3, parts B and C).

Serum compatibilities for the presently described histidinylated cationic transfection lipids were evaluated across the lipid/DNA charge ratios 8:1−1:1 by measuring transfection efficacies of the lipids in the presence of increasing concentrations of added serum (10−50%, v/v). Several interesting features were revealed. At lipid/DNA charge ratios lower than 4:1, all three lipids failed to transfect (data not shown). However, at higher

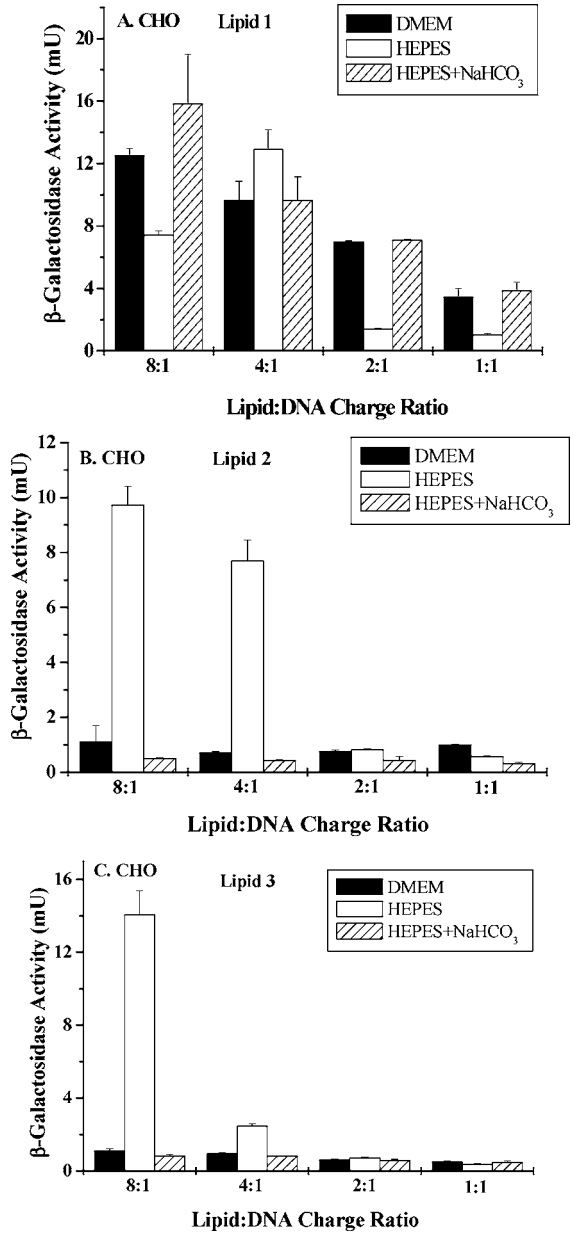

Figure 3. In vitro transfection efficiencies of lipids **1** (A), **2** (B), and **3** (C) using reporter gene expression assays in CHO cells in combination with equimolar DOPE as colipid at lipid/DNA charge ratios of 8:1−1:1 with DMEM, HEPES buffer, and HEPES buffer containing sodium bicarbonate (44 mM) as complexing medium for preparing lipoplexes. Units of β-galactosidase activity were plotted against the varying lipid/DNA charge ratios. The transfection values shown are average of duplicate experiments performed on the same day. Details of the transfection assays are as described in the text.

lipid/DNA charge ratios of 4:1 and 8:1, consistent with the in vitro transfection profiles of lipids **1**−**3** in the absence of added serum for lipoplexes prepared in culture medium (Figures 1 and 2, part A), only lipoplexes of lipid **1** prepared in DMEM were found to be efficient in transfecting all four cell lines in the presence of up to 50% added serum. Figures 4 and 5 (parts A−D) summarize the serum compatibility profiles of the lipoplexes **1**−**3** prepared both in DMEM and in 10 mM HEPES buffer in the representative COS-1 and CHO cells. The serum compatibility profiles of the lipoplexes **1**−**3** in HepG2 and HEK293T cells are provided in the Supporting Information (Figures S4 and S5, respectively). Interestingly, except in CHO cells where transfection efficacies of lipoplex **1** prepared in DMEM decreased with increasing serum content (Figure 5, parts A and C), the transfection efficacies of lipid **1** lipoplexes prepared in DMEM were comparable, improved (Figure 4, parts A and C; Figure S4, parts A and C), or significantly enhanced (Figure S5, parts A and C) with increasing concentrations of added serum (up to 50% v/v). Notably, at the highest lipid/DNA charge ratio of 8:1, the transfection efficiencies of the lipoplexes of both the di- and tri-histidinylated cationic lipids (**2** and **3**, respectively) prepared in HEPES buffer were either comparable to or better than those of the mono-histidine lipid **1** up to 50% added serum (parts B and D, Figures 4 and 5 and Figures S4 and S5).

Involvement of acid-mediated endosomal escape of DNA was assessed by measuring transfection properties of lipids **1**−**3** in representative CHO cells in the presence of bafilomycin A1, which is known to prevent endosomal acidification by inhibiting the vacuolar ATPase endosomal proton pump (*42*). The reporter gene expression efficacies of the lipoplexes prepared in HEPES buffer were inhibited by about 90% for lipid **1** and the lipoplexes prepared in HEPES buffer with lipids **2** and **3** became essentially transfection inefficient in the presence of 25 nM bafilomycin A1 (Figure 6). In presence of 50 nM bafilomycin A1, the transfection of all three lipoplexes prepared in HEPES buffers were completely abolished (data not shown). Such remarkable inhibition of gene transfer efficacies of lipids **1**−**3** in the presence of bafilomycin A1 (Figure 6) are consistent with the involvement of endosomal acidification as a crucial mechanistic event for the present class of histidinylated cationic amphiphiles.

Cell Viabilities. MTT-based cell viability assays were performed in representative CHO cells to gain insights into possible influence of the complexation medium on the percent cell viabilities for the lipoplexes of lipids **1**−**3**. The percent cell viabilities were found to be remarkably high (more than 80%) for lipoplexes prepared in DMEM and somewhat lower (more than 70%) for lipoplexes prepared in HEPES buffer across the entire lipid/DNA charge ratios used in the actual transfection experiments (Figure S6, Supporting Information). Thus, the contrasting complexation-medium-dependent transfection profiles of lipids **1**−**3** (Figures 1 and 2) cannot originate from varying cell cytotoxicity profiles of the present lipoplexes.

Physicochemical Characterizations of Liposomes and Lipoplexes. Sizes and ζ Potentials. With a view to gaining insights into whether the above-mentioned complexation-medium-dependent transfection profiles of lipids **1**−**3** could be related to varying lipoplex sizes, we measured the sizes of the lipoplexes prepared both in DMEM and in HEPES buffers using a dynamic laser light scattering technique. The sizes of the lipoplexes prepared in DMEM remained within the range 300−500 nm across the entire lipid/DNA charge ratios 1:1−8:1, and interestingly, the lipoplexes prepared in DMEM were significantly larger than those prepared in HEPES buffer throughout the lipid/DNA charge ratios 1:1−8:1 (Table 1). Transmission electron microscopic studies revealed similar spherical morphological features as well as similar sizes (around 500−1000 nm) for the lipoplexes prepared in DMEM and HEPES buffer containing 44 mM added sodium bicarbonate for the representative lipid **3** (Figure 7, parts A and B). Interestingly, lipoplexes of **3** prepared in HEPES buffer alone were found to be somewhat smaller in size (Figure 7, part C).

Lipid/DNA Binding Interactions and DNase I Sensitivities. The electrostatic binding interactions between the plasmid DNA and lipids **1**−**3** at varying lipid/DNA charge ratios were measured by both conventional electrophoretic gel retardation assay and DNase I sensitivity assays. The electrophoretic gel patterns in simple gel retardation assay (Figure 8, part A) revealed some interesting features. All three lipids were capable of completely inhibiting the electrophoretic mobility of plasmid DNA from lipoplexes prepared at a high lipid/DNA charge ratio

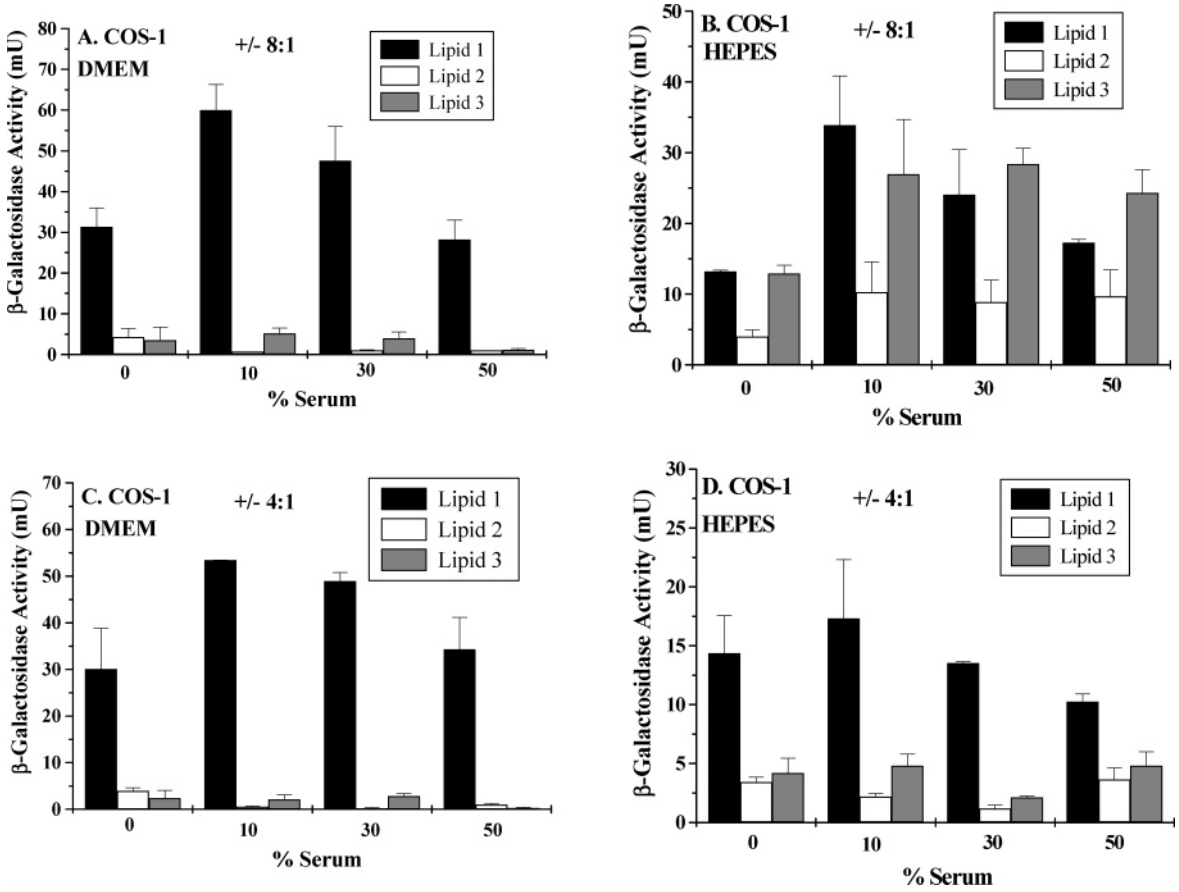

Figure 4. In vitro transfection efficiencies of lipids **1**, **2**, and **3** using reporter gene expression assays in the presence of 10%, 30%, and 50% added serum in COS-1 cells in combination with equimolar DOPE as colipid at lipid/DNA charge ratio of 8:1 (A and B) and 4:1 (C and D) with DMEM (A and C) and HEPES (B and D) as complexing medium for preparing lipoplexes. Units of β-galactosidase activity were plotted against the varying serum concentrations. The transfection values shown are average of duplicate experiments performed on the same day. Details of the transfection assays are as described in the text.

of 8:1 (Figure 8, part A). At lipid/DNA charge ratios of 4:1, all three lipids exhibited moderately strong DNA-binding properties, and at lipid/DNA charge ratios lower than 4:1, all the lipids showed poor DNA binding (Figure 8, part A). Such gel patterns are consistent with the notion that suboptimal lipid/DNA binding interactions could play some major role in abolishing the in vitro gene transfer efficacies of lipids **2** and **3** at lipid/DNA charge ratios lower than 4:1. However, this gel pattern (Figure 8, part A) is not consistent with the high gene transfer properties of lipid **1** at lower lipid/DNA charge ratios of 2:1 and 1:1 (Figures 1 and 2). The most surprising was the gel pattern found in the DNase I sensitivity assay. With a view to obtaining insights into the accessibilities of the lipoplex associated DNA to DNase I, DNase I sensitivity assays were carried out across the lipid/DNA charge ratios 1:1−8:1. After the free DNA digestion by DNase I, the total DNA (both digested and inaccessible DNA) was separated from the lipid and DNase I (by extracting with organic solvent) and loaded onto a 1% agarose gel. Across the entire range of lipid/DNA charge ratios 1:1−8:1, the band intensities of inaccessible and therefore undigested DNA were almost undetectable (Figure 8, part B).

DISCUSSION

One of the major mechanistic factors impeding the transfection efficacies of cationic liposomes is suboptimal release of plasmid DNA from endosome into cell cytoplasm. In the area of cationic polymer-mediated gene delivery, significantly improved transfection efficacies have been achieved through covalent grafting of endosome-disrupting multiple histidine functionalities in the molecular architecture of cationic polymers (*43*). Chen et al. succeeded in enhancing transfection efficacies of cationic liposomes by using them in combination with copolymers of histidine and lysine (*44*, *45*). In a recent collaborative research, we have demonstrated that covalent grafting of a single endosome-disrupting histidine functionality in the headgroup region imparts high gene transfer properties to cationic amphiphiles (*26*). In the present study, we have addressed the issue of how the presence of multiple histidine functionalities in the polar headgroup regions of cationic amphiphiles affects their in vitro transfection efficacies. To this end, we have designed and synthesized three novel cationic amphiphiles containing one, two, and three histidine functionalities in their polar headgroup region through use of lysine linkers (lipids **1**−**3**, Schemes 1−3) and have evaluated their in vitro gene transfer efficacies in multiple cultured cells.

Surprisingly, the relative in vitro gene transfection profiles of lipids **1**−**3** were found to be dependent on the medium of lipid/DNA complexation. In the absence of serum, the trihistidinylated lipid **3** showed higher or comparable transfection efficacies to lipid **1** only when lipoplexes were prepared in HEPES buffer at the highest lipid/DNA charge ratios of 8:1 (Figures 1 and 2). Size measurements by dynamic laser light scattering technique did not reveal any meaningful insights into the possible origin of the severely compromised transfection efficacies of lipids **2** and **3** (compared with that of lipid **1**) when lipoplexes were prepared in DMEM. Although the lipoplexes of lipids **1**−**3** prepared in DMEM were all relatively large (within the approximate range of 300−700 nm across the lipid/DNA charge ratios of 8:1−1:1, Table 1), only lipid **1** was transfection efficient (Figures 1 and 2, parts A). In other words,

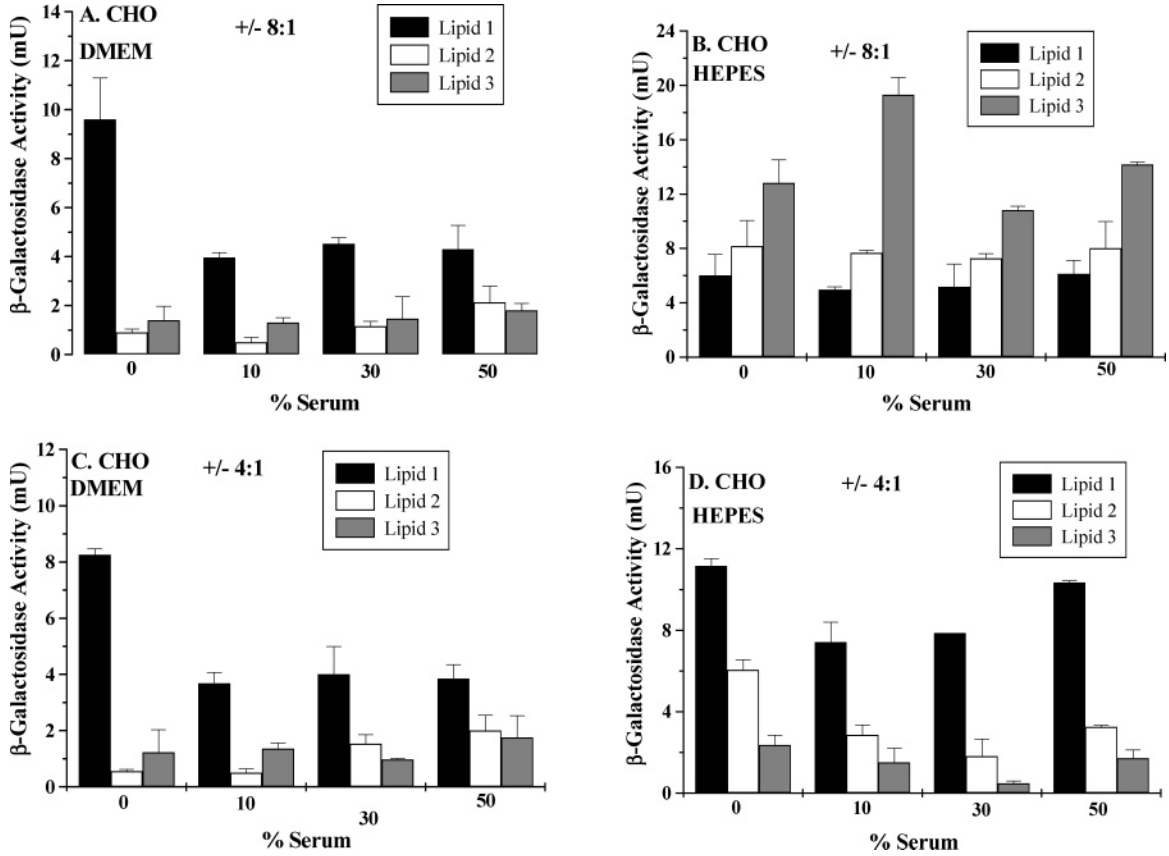

Figure 5. In vitro transfection efficiencies of lipids **1**, **2**, and **3** using reporter gene expression assays in the presence of 10%, 30%, and 50% added serum in CHO cells in combination with equimolar DOPE as colipid at lipid/DNA charge ratio of 8:1 (A and B) and 4:1 (C and D) with DMEM (A and C) and HEPES (B and D) as complexing medium for preparing lipoplexes. Units of β-galactosidase activity were plotted against the varying serum concentrations. The transfection values shown are average of duplicate experiments performed on the same day. Details of the transfection assays are as described in the text.

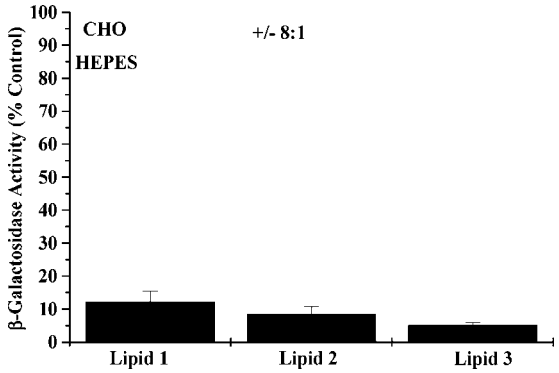

Figure 6. In vitro transfection efficiencies of lipids **1**, **2**, and **3** using reporter gene expression assays in representative CHO cells in the presence of bafilomycin A1 (25 nM) at lipid/DNA charge ratios of 8:1 with HEPES buffer as the complexing medium for preparing lipoplexes. Details of the treatment are as described in the text.

the similar size ranges for lipoplexes prepared in DMEM hint that the higher gene transfection efficacies of the lipoplexes prepared from lipid **1** compared with those of the lipoplexes prepared from lipids **2** and **3** in DMEM (Figures 1 and 2, parts A) are unlikely to originate from any grossly different endocytotic cellular uptake profiles. Interestingly, the sizes of all three lipoplexes prepared in HEPES buffer were smaller (170−350 nm, Table 1) than those prepared in DMEM across the entire range of lipid/DNA charge ratios 8:1−1:1. Such larger sizes for lipid/DNA complexes prepared in DMEM (compared with the corresponding lipoplexes prepared in HEPES) have also been reported previously for DOTAP−oligonucleotide complexes (46). Previously reported physicochemical and morphological characteristics of the cationic liposomes and oligonucleotide complexes (*47*) indicate that the larger sizes of the lipoplexes prepared in cell growth medium may originate from aggregation and fusion of liposomes after adding them to culture medium. Thus, the overall improved transfection efficacies of the lipoplexes of lipids **2** and **3** prepared in HEPES buffer in all four cell lines (Figures 1 and 2, part B; Figures S1 and S2, part B) may partly originate from their smaller lipoplex sizes.

The significantly reduced transfection efficacies of the lipoplexes **2** and **3** prepared in DMEM compared with the transfection efficiencies of the corresponding lipoplexes prepared in HEPES buffer might originate from some transfection inhibitory component of DMEM that is not present in HEPES buffer (*41*). Careful compositional analysis revealed that the two major DMEM components absent in 10 mM HEPES buffer are 150 mM sodium chloride and 44 mM sodium bicarbonate. Toward understanding which of these two components might play some role in the compromised transfection efficacies of the lipoplexes **2** and **3** prepared in DMEM (Figures 1 and 2, Figures S1 and S2), we measured the relative transfection profiles of the lipoplexes **1**−**3** prepared in four different media, namely, DMEM, HEPES buffer, HEPES buffer containing 44 mM sodium bicarbonate, and HEPES buffer containing 150 mM sodium chloride. Transfection efficacies of lipoplexes **2** and **3** in 10 mM HEPES buffer containing 150 mM NaCl either remained unaffected or were enhanced compared with their transfection efficacies in 10 mM HEPES buffer alone (data not shown). However, the transfection properties of the lipoplexes **2** and **3** prepared in 10 mM HEPES buffer were found to be severely compromised when the lipoplexes **2** and **3** were prepared in 10 mM HEPES buffer containing 44 mM sodium

Table 1. Hydrodynamic Diameters of Liposomes and Lipoplexes[a]

	size (nm)				
lipids	lipid/DNA (1:0)	lipid/DNA (1:1)	lipid/DNA (2:1)	lipid/DNA (4:1)	lipid/DNA (8:1)
lipid **1**/DOPE (1:1)	729.1 ± 39.7	332.0 ± 11.3	298.4 ± 11.7	338.5 ± 4.8	444.0 ± 8.4
	(141.2 ± 2.6)	(177.6 ± 3.3)	(171.7 ± 1.8)	(176.1 ± 4.7)	(284.2 ±24.5)
lipid **2**/DOPE (1:1)	630.1 ± 119.2	401.5 ± 78.5	396.9 ± 18.7	268.2 ± 53.8	445.6 ± 24.9
	(116.7 ± 1.6)	(170.3 ± 3.7)	(164.0 ± 2.0)	(189.0 ± 5.0)	(335.4 ± 42.9)

	(118.7 ± 2.3)	(186.4 ± 3.1)	(162.2 ± 3.4)	(194.0 ± 1.4)	(248.2 ± 7.9)

[a] Sizes of liposomes and lipoplexes in plain DMEM and HEPES buffer, pH 7.40 (values within parentheses), were measured by a laser light scattering technique using Zetasizer 3000A (Malvern Instruments, U.K.). Values shown are the averages obtained from three measurements.

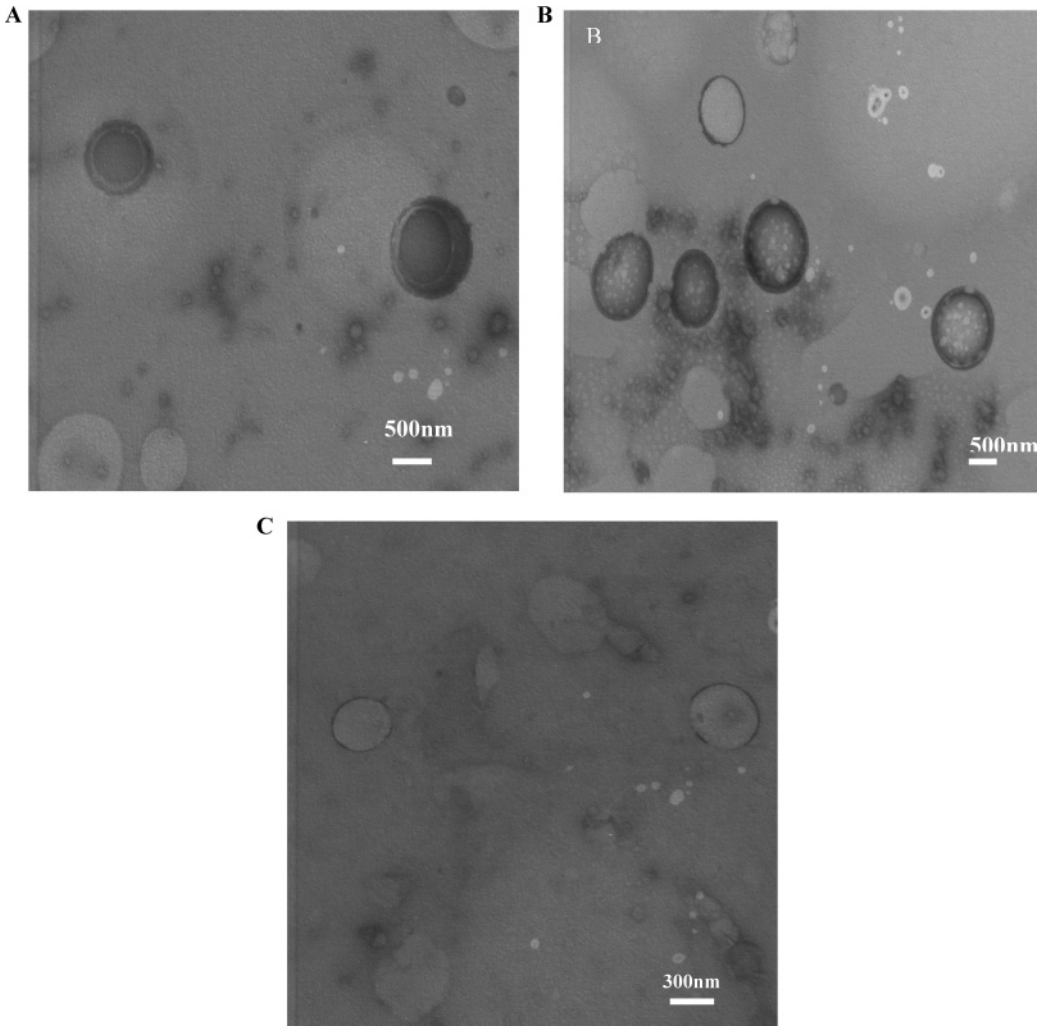

Figure 7. Transmission electron micrographs for lipoplexes **3** prepared in combination with equimolar DOPE as colipid at lipid/DNA charge ratios of 8:1 in DMEM (A), HEPES buffer containing 44 mM sodum bicarbonate (B), and HEPES buffer alone (C) as complexing medium for preparing lipoplexes. Bars correspond to 300 (A) and 500 nm (B and C).

bicarbonate (Figure 3). Thus, the transfection results summarized in Figure 3 are consistent with the notion that the sodium bicarbonate component of the culture medium might be responsible for the compromised transfection properties of lipoplexes **2** and **3** prepared in DMEM (part A, Figures 1and 2). Transmission electron microscopy studies revealed that the sizes of the lipoplexes prepared in the three different media (DMEM, 10 mM HEPES buffer alone, and 10 mM HEPES buffer containing 44 mM sodium bicarbonate) are within the range 300−1000 nm. Figure 7 shows the TEM pictures for the representative lipoplex **3**. Thus, sizes are unlikely to play any key role in modulating the in vitro gene transfer efficiencies of the present class of mono-, di-, and tri-histidinylated cationic amphiphiles.

In general, in cationic lipid mediated gene delivery, the gene transfer efficacies of libraries of novel cationic amphiphiles are evaluated either in the complete absence of added serum or in the presence of only 10% (v/v) serum as reported in many prior investigations (*15*−*22*), including our own (*23*−*31*). However, serum incompatibility still remains one of the major setbacks retarding clinical success of cationic transfection lipids. Quite often, the high in vitro gene transfer efficacies of cationic amphiphiles have been found to be adversely affected in the presence of serum (*48*−*58*). The usual serum incompatibility of cationic transfection lipids is believed to begin via adsorption of negatively charged serum proteins onto the positively charged cationic liposome surfaces preventing their efficient interaction with the cell surface or internalization (*54*, *59*−*62*). Clearly,

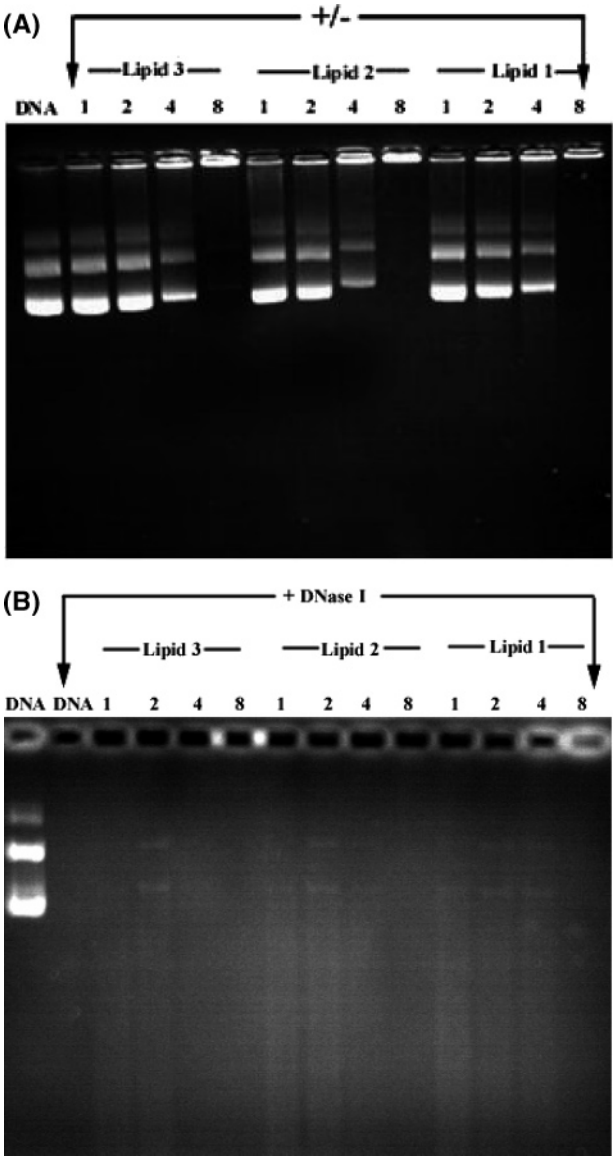

Figure 8. Electrophoretic gel patterns for DNA associated with lipoplexes of lipids **1**, **2**, and **3** (A) and DNase I sensitivity assay for DNA associated with lipoplexes of lipids **1**, **2**, and **3** (B) prepared with equimolar DOPE as colipid. The lipid/DNA charge ratios are indicated at the top of each lane. The details of treatment are as described in the text.

evaluation of gene transfer efficacies across a range of lipid/DNA charge ratios in multiple cultured cells in the presence of increasing concentrations of added serum is needed for obtaining meaningful systemic potential of any in vitro efficient cationic transfection lipid. To this end, we finally evaluated the serum compatibility of lipids **1**−**3** across the entire lipid/DNA charge ratios 8:1−1:1. Several interesting features on the relative serum compatibility issues for the present class of histidinylated cationic lipids were revealed. Below lipid/DNA charge ratios of 4:1, the gene transfer efficacies of all three lipids were found to be highly incompatible with the presence of added serum irrespective of whether the lipoplexes were prepared in the presence of DMEM or HEPES buffer (data not shown). Such serum incompatibility of the present lipids at lower lipid/DNA charge ratios are consistent with the previously reported findings of Yang and Huang in which it was shown that the inhibitory effect of serum in lipofection could be overcome by increasing the charge ratios of cationic liposome−DNA lipoplexes (*57*). However, given that serum contains nucleases, the striking DNase I sensitivities of the plasmid DNA associated with lipids **1**−**3** across the entire lipid/DNA charge ratios of 8:1−1:1 (Figure 8, part B) are clearly inconsistent with the high gene transfer properties of lipids **1**−**3** particularly for lipoplexes prepared in HEPES buffer at lipid/DNA charge ratios of 4:1 and 8:1 in the presence of up to 50% added serum (Figures 4 and 5, parts B and D). It has been previously demonstrated that incubation of lipoplexes prepared from either lipofectin or SAINT-2 (a dialkyl pyridinium cationic amphiphile)/DOPE with serum resulted in the binding of the same serum proteins to either complex (*63*). However, in the presence of serum, the transfection efficiencies of only lipofectin were found to be adversely affected and those of SAINT-2 were not. Such findings (*63*) indicated that parameters other than simple adsorption of negatively charged serum protein components onto the lipoplex surfaces are likely to be involved in modulating transfection efficacies of cationic amphiphiles in the presence of serum. Most significantly, when the lipoplexes were prepared in HEPES buffer using the high lipid/DNA charge ratio of 8:1, the gene delivery efficacies of all three lipids were highly serum compatible (up to 50% added serum). Perhaps adsorption of the negatively charged components of HEPES buffer on the lipoplexes prepared at high lipid/DNA charge ratios can prevent adsorption of negatively charged serum protein components to the lipoplex surfaces thereby enhancing their serum compatibilities.

The compromised transfection efficacies of the lipoplexes of lipids **2** and **3** prepared in HEPES buffer at lipid/DNA charge ratios lower than 4:1 (Figures 1 and 2, part B) could be partly related to the poor lipid/DNA binding interactions at lower lipid/DNA charge ratios as was revealed in the conventional gel retardation assay (Figure 8, part A). However, the findings in the gel retardation assay did not explain why lipid **1** despite having poor DNA binding at lipid/DNA charge ratios lower than 4:1 (Figure 8, part A) showed significant transfection efficacies at such lower lipid/DNA charge ratios (Figures 1 and 2, part A). Dramatic reduction of the transfection efficacies of all three lipids in the presence of bafilomycin A1 (Figure 6) are consistent with the involvement of endosomal protonation as an important mechanistic event in the intracellular transfection pathways for the presently described lipoplexes. In other words, the cytosolic release step of the endosomally trapped DNA complexed with the presently described cationic amphiphiles containing weakly basic histidine functionalities in their headgroup regions are likely to be mediated by protonation of the histidine headgroups in the acidic lumen (pH 5.5−6.5) of endosomes (*22*). The electrophoretic gel patterns observed in the DNase I sensitivity assays turned out to be the most puzzling result. In general, the gel pattern in such DNase I senstivity assays provides a useful hint of whether the compromised transfection efficacies of any cationic amphiphile could be related to the high DNase I accessibility of the lipoplex-associated DNA. However, for the present lipoplexes, the electrophoretic gel pattern in the DNase I protection experiment (Figure 8, part B) is consistent with the notion that the reporter genes associated with the present lipids are highly accessible to DNase I even at high lipid/DNA charge ratios of 8:1. Such extreme DNase I sensitivities is inconsistent particularly with the high gene transfer properties of lipid **1**, whose in vitro gene transfer efficacies are comparable to or better than those of LipofectAmine, a widely used commercially available liposomal transfection kit. One possibility is that the release kinetics from endosomes into cell cytoplasm for DNA associated with lipid **1** could be significantly faster than those for DNA associated lipids **2** and **3** thereby imparting overall higher gene delivery efficacies to lipid **1**.

To conclude, the findings of the present structure−activity investigation involving the use of three novel histidinylated

cationic amphiphiles (**1**−**3**, Schemes 1−3) demonstrate that the relative in vitro gene transfection profiles of mono-, di-, and tri-histidinylated cationic amphiphiles are remarkably dependent on the medium of lipoplex formation. Most importantly, the high serum compatibilities of the lipoplexes of lipids **1** and **3** make them promising nonviral transfection vectors for future systemic applications.

This paper investigates a series of dendrons based on the Newkome dendritic scaffold that displays a naturally occurring polyamine (spermine) on their surface. These dendrons have previously been shown to interact with DNA in a generation dependent manner with the more highly branched dendrons exhibiting a strong multivalency effect for the spermine surface groups. In this paper, we investigate the ability of these dendrons to transfect DNA into cells (human breast carcinoma cells, MDA-MB-231, and murine myoblast cells, C2C12) as determined by the luciferase assay. Although the dendrons are unable to transfect DNA in their own right, they are capable of delivering DNA in vitro when administered with chloroquine, which assists with escape from endocytic vesicles. The cytotoxicity of the dendrons was determined using the XTT assay, and it was shown that the dendrons were nontoxic either alone or in the presence of DNA. However, when administered with DNA and chloroquine, the most highly branched dendron did exhibit some cytotoxicity. This paper elucidates the relationship between in vitro transfection efficiency and toxicity. While transfection efficiencies are modest, the low toxicity of the dendrons, both in their own right, and in the presence of DNA, provides encouragement that this type of building block, which has a relatively high affinity for DNA, will provide a useful starting point for the further synthetic development of more effective gene transfection agents.

INTRODUCTION

The introduction of genetic material into cells (gene transfection) (*1*) has the potential to treat a wide variety of diseases such as those that are characterized by a single mutation at a well-defined position on the genome, for example muscular dystrophy (*2*) and cystic fibrosis (*3*). Gene therapy is also being investigated to treat a range of other diseases, including cancer (*4*) and AIDS (*5*), with the aim being to introduce genetic material into the affected cells and ultimately lead to their destruction. The key problem in gene therapy is the delivery of genetic material to the required cells within a patient. Ex vivo methods involve the removal, genetic modification, and re-administration of the patient's cells. The ex vivo approach enables well controlled localized delivery but has a number of limitations such as being labor intensive, requiring special production facilities, and only being applicable for accessible and robust cells. More interesting, however, is the development of in vivo gene therapies, and with this goal in mind, the development of novel vectors for gene delivery capable of navigating a series of extra- and intracellular barriers is of crucial importance.

Vectors fall into two main categories, viral and nonviral (synthetic) vectors. Viruses are naturally evolved vectors, in which part of the virus' genome is replaced with therapeutic genetic material (*6*). Although viral vectors are efficient gene delivery systems and have been utilized in the majority of clinical trials, there have been a number of problems with their application in human gene therapy, including poor targeting to cells, expensive production, and immunogenic and pathogenic responses. Nonviral vectors rely on the ability of synthetic systems to bind and condense the genetic material effectively (*7*). Cationic liposomes (*8*) (normally used in the presence of a helper lipid) are quite efficient, even in vivo, and there is good potential for synthetic modification of this class of delivery agent. However, they tend to be relatively unstable and toxic and often lack cell-specific targeting ability. Cationic polymers (*9*) are cheap and simple to modify in order to impart desirable properties such as degradation under certain conditions and cell-specific targeting.

In the last 10 years, there has been an explosion of interest in using dendrimers (*10*) (highly branched monodisperse polymers) as vectors. Their transfection ability is comparable to polymers, but many of them exhibit reduced toxicity. The commercially available spherical poly(amidoamine) (PAMAM) dendrimers have been extensively studied. It has been shown that fractured (i.e., partially degraded) PAMAMs can be more effective at gene transfection, potentially as a consequence of their greater flexibility and ability to compact DNA (*11*). PAMAM dendrimers have also been synthetically modified in order to improve solubility and cell membrane fusion and reduce toxicity (*12*). Other spherical dendritic polyamine scaffolds have also been investigated as gene delivery systems, such as those based on a poly(propyleneimine) (PPI) framework (*13*). Dendritic L-lysine derivatives have been widely exploited (*14*), and in a number of these cases, dendrons (individual dendritic branches) have been used as DNA binding and gene delivery agents, rather than fully formed spherical dendrimers. The inherent asymmetry of the dendron structure facilitates simple structural modification in a precisely controlled fashion, either at the surface, or at the focal point. This is not possible to the same extent with polymers or spherical dendrimers. The typical 'dendron strategy' is to use a branched molecule with a polycationic surface capable of interacting with the anionic phosphates on DNA and then subsequently functionalize the focal point with a unit capable of either hydrophobic groups

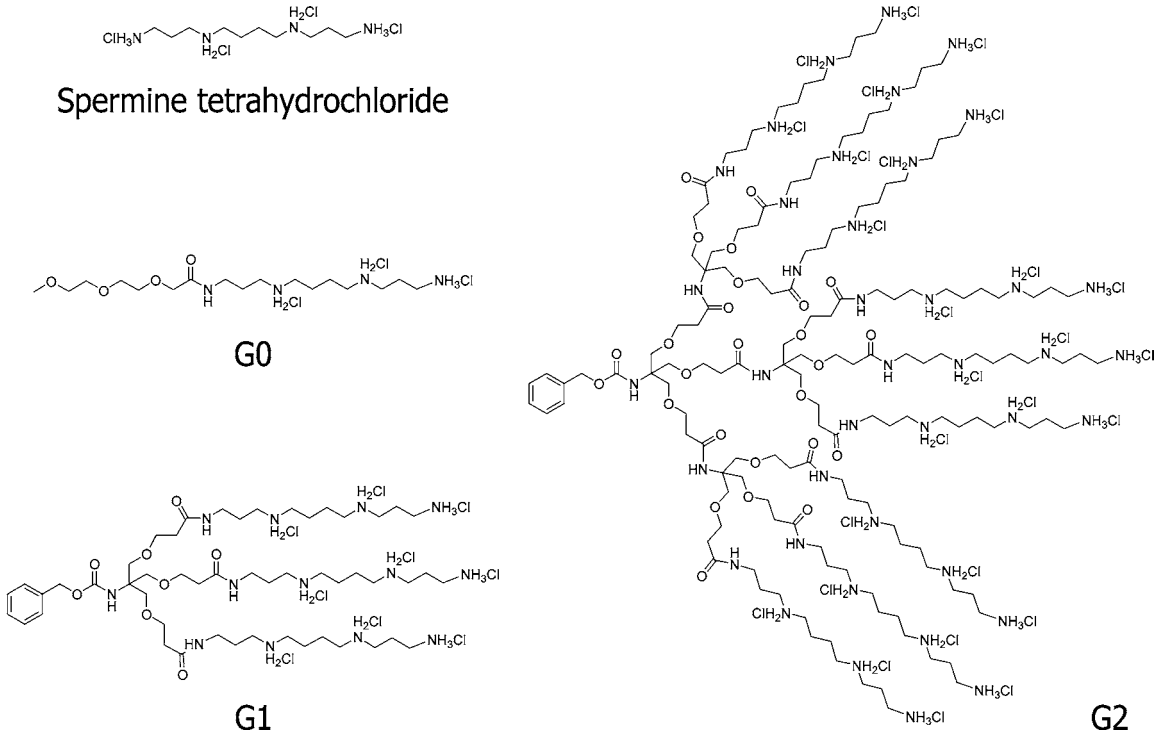

Figure 1. Polyamines based on spermine investigated in this paper for their transfection potential, including dendritic multivalent spermines, **G1** and **G2**.

which assist the process of membrane fusion (*15*) or polar groups assisting water solubility and biocompatibility (e.g., poly(ethylene glycol), PEG) (*12e*).

Spermine, a naturally occurring linear polyamine, is often utilized as the DNA binding portion of nondendritic vectors (*16*). Indeed, some commercially useful vectors (e.g. Transfectam (*17*), Genzyme Lipid #67 (*18*), and RPR-120535 (*19*)) incorporate spermine units. Biology itself makes use of simple tetraamines, such as spermine, to achieve DNA binding (*20*). Although spermine is significantly better than an isolated amine for binding DNA, however, the interaction is still relatively weak and generates a mobile complex. Consequently, spermine struggles to compete with DNA-bound inorganic cations (*21*).

We have recently reported (*22*) a series of dendrons utilizing the Newkome dendritic scaffold (*23*) which display multiple spermine groups on the dendritic surface (Figure 1). We demonstrated that these dendrons bind DNA in a generation dependent manner (i.e., **G0** < **G1** < **G2**), with higher generation dendrons exhibiting binding strengths which were independent of salt concentration. Dendron G2 showed very strong DNA binding, and we could ascribe this to a clear multivalency effect. Some multivalent arrays had been previously reported in which multiple spermine groups were grafted onto dextran polymers (*24*). However, we wanted to develop multivalent DNA binders with well-defined molecular structures, to enable the construction of structure−activity relationships, as well as developing monodisperse systems, with relatively low molecular weights, which have a greater chance of being licensed for therapeutic use in the longer term. In this new paper, we explore the in vitro transfection efficiency (as determined by luciferase assay) and the toxicity (as determined by XTT assay), using human breast carcinoma cells (MDA-MB-231) and murine myoblast cells (C2C12). Most importantly, using this approach, we identify the optimum unit (G1) which exhibits the greatest potential for future synthetic development as a nonviral vector.

MATERIALS AND METHODS

Polyamine Dendrons. The polyamine dendrons with spermine surface groups were synthesized using methods previously reported by us and fully characterized; all data were in agreement with those previously published (*22*).

Cells and Plasmid DNA. The MDA-MB-231 human breast carcinoma cell line was purchased from the American Type Culture Collection, and the C2C12 murine myoblast cell line was a gift from Prof. Stephen Kaufman (University of Illinois at Urbana Champaign, IL). All cell lines were maintained according to their respective ATCC protocols at 37 °C and 5% CO_2 but were adapted from fetal bovine serum to heat-inactivated horse serum. The 5.3 kilobase pair expression vector, pGL3 (Promega, Madison, WI), containing the luciferase gene driven by the SV40 promoter and enhancer, was grown in DH5α E. Coli (Gibco BRL, Rockville, MD) and purified using a commercial plasmid purification kit (Bio-Rad, Hercules, CA). Plasmids were further purified by ethanol precipitation; the ratio of absorbances at 260 and 280 nm was 1.8 or greater.

Gel Retardation Studies. Appropriate amounts of polyamine and DNA plasmid solutions in 150 mM NaCl (pH 7.3, 20 mM PIPES as buffer) were added to a further 10 μL of 150 mM NaCl (pH 7.3, 20 mM PIPES as buffer) to achieve the desired polyamine/DNA ratio. The resultant complexes were incubated at 4 °C for 15 min. Then, 3 μL Blue/Orange 6X loading dye (Promega, Madison, WI) was added, and the mixtures were incubated at 4 °C for a further 5 min. After this time, 15 μL was electrophoresed on a 0.75% agarose gel (70 V, 1 h). DNA was visualized with ethidium bromide staining (Bio-Rad, Hercules, CA). Samples were run in duplicate.

Dynamic Light Scattering Studies. DNA−polyamine complexes were prepared at room temperature, by the titration of polyamine solution into a solution of plasmid DNA (1 μg) in PBS-buffered Millipore water (500 μL) to achieve the desired mass ratios. The volume of polyamine solution added to the DNA solution did not exceed 5% of the total volume of the solution. Complex size determination was performed by dynamic light scattering on a DynaPro-MS800 particle sizer (Protein Solutions, Lakewood, NJ), and the data were analyzed with Dynamics v6.3 software (Protein Solutions).

(B and C) G1 and G2 respectively (polyamine:DNA, w:w): lane 1, 0:1; lane 2, 0.1:1; lane 3, 0.2:1; lane 4, 0.3:1; lane 5, 0.4:1; lane 6, 0.5:1; lane 7, 0.6:1; lane 8, 0.7:1; lane 9, 0.8:1; lane 10, 0.9:1; lane 11, 1:1; lane 12, 2:1; lane 13, 3:1; lane 14, 4:1; lane 15, 5:1.

Complex Formation and Transfection. DNA−polyamine complexes were prepared at room temperature in 150 mM NaCl (pH 7.3, 20 mM PIPES as buffer) by addition of 250 μL of polyamine solution to an equal volume of 10 μg of plasmid to achieve the desired polyamine/DNA ratio. The resultant complexes were incubated at 4 °C for 15 min. Cells were cultured in standard growth medium (DMEM supplemented according to ATCC protocols with 10% horse serum and 1% penicillin−streptomycin) and plated in 12-well plates at 1×10^5 cells per well 24 h before transfection. Immediately before transfection, the growth medium was replaced with serum-free medium, and 50 μL of complex (1 μg of plasmid per well) was added to each well (either with or without chloroquine at a final concentration of 100 μM). Transfection medium was replaced with growth medium 4 h after transfection. Luciferase expression was quantified 20 h later using a Promega luciferase assay system ($n \geq 6$) according to the manufacturer's protocol. Luciferase activity was measured in relative light units (RLU) using a Lumat LB9507 luminometer (Berthold, GMBH, Germany) and converted to luciferase concentration by comparison with recombinant luciferase standards (Promega). Results were normalized to total cell protein as determined using a Bio-Rad protein assay kit.

Cytotoxicity Determinations. Cytotoxicity was characterized as a decrease in metabolic activity using the XTT assay (*25*). Cells were placed in 96-well plates at an initial density of 5000 cells per well in 100 μL of growth medium for 24 h, after which time the growth medium was replaced with fresh serum-free medium. At this point a solution of: polyamine alone (5 μg of polyamine per well), polyamine/DNA complexes (1 μg of DNA and 5 μg of polyamine per well), or polyamine/DNA complexes with chloroquine (effective transfection conditions: 0.2 μg of DNA, 1.0 μg of polyamine per well, chloroquine at a final concentration of 100 μM), in 150 mM NaCl (pH 7.3, 20 mM PIPES as buffer) was added (volume equal to or less than 10 μL). Cells were incubated for 4 h, and the medium was replaced with complete growth medium for 16 h. Fresh XTT (1 mg/mL) and the coenzyme Q_0 (80 mg/mL) stock were prepared each day in PBS (0.5 μg/μL XTT and 0.04 μg/μL coenzyme Q_0), and 25 μL aliquots were added to each well. The samples were incubated for a further 4 h at 37 °C, and the absorbance was read at 450 nm relative to blank well prepared without cells ($n = 16$).

RESULTS

Gel Retardation Studies. As outlined in the Introduction, we have previously shown the dendrons to be capable of binding plasmid DNA and condensing it into well-defined nanoscale particles. The formation of these polyplexes can be observed as a reduction of mobility in gel electrophoresis (Figure 2). DNA was mixed with increasing amounts of polyamine in order to determine the ability of the polyamine to form complexes with the DNA. Both spermine and the **G0** model compound failed to retard the migration of DNA, even at mass ratios of 1:100 (DNA:polyamine). In contrast, however, dendritic spermine derivatives **G1** and **G2** both effectively retarded the migration of DNA at mass ratios of 1:1 (DNA:polyamine) and above. This highlights the cooperativity of the DNA binding afforded by using a dendritic scaffold for the placement of multiple spermine groups, as discussed in more detail in our previous publication (*22*).

Dynamic Light Scattering Studies. Polyplex size can be a crucial factor for efficient cell uptake, and we therefore investigated the effect of charge ratio on complex size. Complexes with polyamine/DNA ratios of 0:1 to 40:1 (w/w), typical of transfection experiments, were formed, and dynamic light scattering was used to measure complex size. Assuming that spherical aggregates were formed (as observed for **G1** and **G2** with plasmid DNA by transmission electron microscopy [TEM] methods), allowed us to calculate approximate diameters for the aggregates. These studies were performed with plasmid DNA alone, and in the presence of spermine, **G0**, **G1**, and **G2**. In each case, the experiments were performed at different polyamine:DNA mass ratios in order to see the effect of molar ratio on the aggregate formed. The data are presented in Figure 3.

In the absence of DNA, a diameter of 66 nm was determined for the DNA. Spermine and **G0** had little effect on the dimensions of the system − the diameter of the aggregate remained constant at around 40−50 nm, irrespective of the ratio of polyamine to DNA employed. This is in agreement with previous studies (*20a*). Dendron **G1** formed significantly larger aggregates in the presence of plasmid DNA. This was particularly true at higher polyamine:DNA mass ratios, where nanoscale complexes of around 100 nm were present in solution. Previous reports have indicated that complexes in this size range are efficiently endocytosed during transfection (*26*). The size of the aggregates formed between **G2** and plasmid DNA was significantly larger than that formed between **G1** and DNA, in agreement with the previous TEM studies (*22*). Once again, on increasing the polyamine:DNA mass ratio, the diameter of these complexes increased significantly (to over 200 nm).

Complex Formation and Transfection. Our groups are interested in the utilization of gene therapy for the treatment of cancer (*4*) and muscular dystrophy (*2*); hence, we investigated the efficacy of the polyamine dendrons in gene delivery to human breast carcinoma cells (MDA-MB-231) and murine myoblasts (C2C12). Both cell lines were transfected in vitro

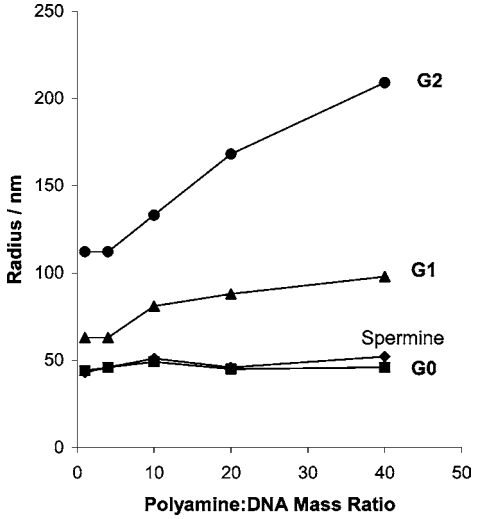

Figure 3. Dynamic light scattering results indicating the polyamine:DNA mass ratio and the approximate dimensions (nm) of the aggregate formed in each case. In the absence of polyamine, light scattering indicated a diameter of 66 nm.

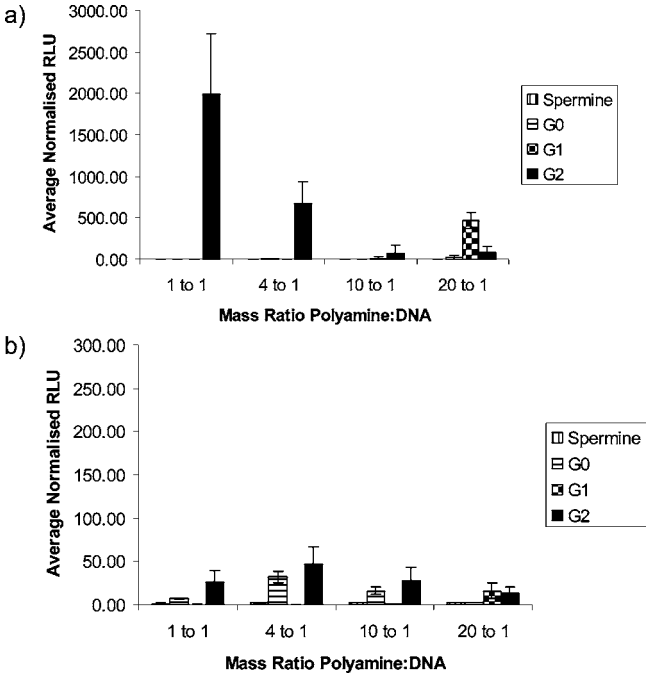

Figure 4. Transfection efficiency of spermine, the nondendritic model (**G0**), and the dendrons displaying spermine on the surface (**G1** and **G2**) in (a) C2C12 and (b) MDA-MB-231 cells. Luciferase expression was normalized by total cellular protein, i.e., data are given in RLU/mg of protein. ($N = 6$, error bars represent standard deviation). Transfection is performed in the presence of chloroquine (100 μM).

with 1 μg of plasmid DNA per 100 000 cells. In each case, the DNA was complexed with varying amounts of different polyamines. Gene transfection efficiency was measured as luciferase enzyme activity and normalized to total cell protein. Initially, the dendrons were investigated in their own right to determine their ability to transfect DNA into cells and allow expression of luciferase. However, no measurable transfection could be observed in any case.

However, in the presence of chloroquine (at a final concentration of 100 μM) measurable gene transfection was observed with some of the spermine derivatives (Figure 4). Chloroquine is widely used as a 'helper molecule' for gene transfection (*27*). Although the mechanism of action is not fully understood, it has been argued that chloroquine is a weak endosomotropic buffer, raising the endosomal pH, resulting in an increase in osmolarity and consequent endosome lysis. In this way chloroquine assists the escape of transfected DNA from the endosome. The nondendritic molecules (i.e., spermine and **G0**) induced no measurable gene expression over the range of polyamine:DNA mass ratios investigated (1:1 and 4:1). However, some transfection and subsequent luciferase expression was observed for the dendritic spermine derivatives in combination with chloroquine. At low polyamine:DNA mass ratios (1:1 and 4:1), the second generation dendron was significantly better at transfection than the first generation analogue. However, at higher polyamine:DNA mass ratios (10:1 and 20:1) the transfection efficiency of the second generation dendron was observed to decrease sharply. Under equivalent conditions, the transfection efficiency of the first generation analogue **G1** increased dramatically. Indeed, **G1** became more effective at transfection than **G2** at high polyamine:DNA mass ratios. A similar trend was observed for both cell lines, although the transfection into murine myoblasts C2C12 was higher than that for the human breast carcinoma cells (MDA-MB-231).

Cytotoxicity Determination. Polycationic molecules have been reported to damage cell membranes as a result of the electrostatic attraction of polycations to the plasma membrane, whereas neutral and anionic polymers cause minimal damage to cellular membranes. With this potential drawback of polycationic vectors firmly in mind, we assayed the cytotoxicity of our dendrons using an XTT assay (*25*). Human breast carcinoma cells (MDA-MB-231) and murine myoblasts (C2C12) were exposed to various conditions (i.e., polyamine, polyamine+DNA, polyamine+DNA+chloroquine) for 4 h, and metabolic activity was assayed 20 h later. The results of these studies are collected in Table 1.

No reduction in metabolic activity was observed when the polyamine alone was added at a concentration of 1 μg per 1000 cells. The one exception to this was when a polyamine control (25 kDa poly(ethyleneimine)) was employed, in which case the observed metabolic activity was reduced by 30% for the C2C12 cells. This is important as it indicates that our dendrons are significantly less cytotoxic than PEI. Similarly, when a combination of polyamine and DNA was added to the cells (0.2 μg DNA and 1 μg polyamine per 1000 cells), our dendrons (**G1** and **G2**) had no observable cytotoxicity. However, once again, the 25 kDa PEI control reduced metabolic activity, this time by 20% for the C2C12 cells.

Significant cytotoxicities, however, were observed in the presence of chloroquine, under experimental conditions identical to those in which transfection had been performed (i.e., 0.01 μg DNA and 0.1 μg polyamine per 1000 cells, and chloroquine at a final concentration of 100 μM). Under these conditions, chloroquine and DNA reduced metabolic activity by 50% (even in the absence of polyamines). In the presence of chloroquine, DNA, and either spermine, **G0**, or **G1**, the cells actually exhibited greater metabolic activities than they did in the absence of the polyamine. Indeed, in the presence of **G0** or **G1**, the metabolic activity of the cells was effectively normal. However, using chloroquine and DNA in the presence of **G2** gave rise to a marked reduction in metabolic activity (ca. 70% for C2C12 cells). In all cases, the MDA-MB-231 cells were found to be more robust, and the polyamines and chloroquine were found to have smaller effects on the metabolic activity than they do for C2C12 cells.

DISCUSSION

For effective transfection, plasmid DNA must be effectively bound and condensed under biological conditions (i.e., high salt concentrations, relevant pH values). We have previously shown that dendritic molecules **G1** and **G2** can do this very effectively.

Table 1. Cytotoxicity of Spermine, the Nondendritic Model (G0), and First (G1) and Second (G2) Generation Dendrons, as well as Poly(ethyleneimine) (PEI) in Murine Myoblast C2C12 and Human Breast Carcinoma MDA-MB-231 Cells[a]

		metabolic activity (relative to 1.000)					
cell line	conditions	spermine	G0	G1	G2	PEI	CQ[b]
C2C12	no polyamine						0.512
C2C12	polyamine alone	0.980	1.000	1.070	1.006	0.705	
C2C12	polyamine + DNA	1.659	1.032	1.032	1.015	0.808	
C2C12	polyamine + DNA + chloroquine	0.758	0.968	1.238	0.305		
MDA-MB-231	no polyamine						0.678

MDA-MB-231	polyamine + DNA	1.099	1.063	1.011	1.034	0.954	
MDA-MB-231	polyamine + DNA + chloroquine	0.886	0.979	0.988	0.398		

[a] Cytotoxicity is reported as the effective metabolic activity, using an XTT assay. In each case, the metabolic activity of a blank sample of cells (i.e. untreated by polyamine, DNA, or chloroquine) was taken as 1.000 [b] CQ = chloroquine; concentration = 100 μM.

We previously used ethidium bromide displacement assays to determine that the DNA binding strength was very low for the nondendritic systems (i.e., spermine and **G0**) and significantly higher for **G1** and **G2**. Indeed, for **G2** the binding of DNA was independent of salt concentration. The detailed gel retardation assays reported in this paper indicate that condensation of the DNA occurs from polyamine:DNA mass ratios of 1:1 and greater for **G1** and **G2**. Our previous TEM studies indicated that the G1:DNA complexes were approximately spherical and 100−150 nm in diameter. The G2:DNA complexes, however, were significantly larger (ca. 400 nm). In this paper, we have used light scattering methods to provide further evidence for the dimensions of the polyplexes formed between polyamines and DNA in solution. The results from these studies are in approximate agreement with the dimensions as visualized using TEM methods. Assuming the formation of spherical polyplexes, **G1** was calculated to form a polyplex with a diameter of up to 100 nm, while **G2** once again formed larger polyplexes up to approximately 210 nm.

The results from the in vitro tests reported in this paper indicate that the dendrons are ineffective transfection agents in their own right. This is clearly not due to an inability to condense the DNA effectively, and we postulate that transfection may fail due to an inability of the polyplex to escape from endocytic vesicles. This postulate is supported by the observation that in the presence of chloroquine the transfection efficiencies improved significantly. Spermine itself is almost completely protonated at physiological pH, and it is therefore possible that these constructs have limited capacity to act as proton sponges and buffer the endosome (a process associated with endosomal escape). Therefore chloroquine is required to enable the escape process. In this way, we propose that these dendritic spermine derivatives behave more like polylysine than proton sponge polymers such as PEI or PAMAM. One aspect of future work will focus on improving the ability of these dendritic constructs to cross cell membranes and escape from endosomes even in the absence of chloroquine. It should also be noted that an alternative postulate is that the polyplexes are so strongly bound that they are unable to release the DNA once within the cell.

In the presence of chloroquine, the nondendritic molecules (spermine and **G0**) are ineffective nonviral vectors for DNA. This is presumably because they fail to bind and condense DNA effectively (as shown by our previous ethidium bromide displacement assays and the gel electrophoresis reported in this paper). Dendron **G1** generally improved in its transfection efficiency on increasing the polyamine:DNA mass ratio. At low mass ratios, dendron **G2** was significantly more effective than **G1**. However, on increasing the mass ratio, the transfection efficiency achieved by **G2** was observed to drop significantly, and **G1** became the more effective transfection agent. We argue that this decrease in transfection efficiency observed with **G2** is a consequence of its toxicity when administered in the presence of chloroquine (Table 1). Dendron **G1** on the other hand has no significant toxicity in the presence of chloroquine and therefore became more effective than **G2** at high polyamine:DNA mass ratios. In this way, the results from our toxicity assay support the observed delivery results.

It must be noted here that even in the presence of chloroquine, the transfection efficiencies observed are too low for these structures to have clinically significant activity in vivo. In fact, transfection efficiencies would need to be improved by several orders of magnitude. The observed efficiencies are in line with low molecular weight poly(amidoamine) (PAMAM) dendrimers (*11*), which only form complexes with DNA at high N/P ratios. In general terms, an increase in molecular weight for PAMAMs yields a significant increase in transfection efficiency, and the same trend may be expected for higher molecular weight analogues of our dendrons. However, it is also possible to make other significant structural modifications to the structure of dendrons **G1** and **G2** which might be expected to enhance transfection efficiencies and would avoid the tedious and time-consuming syntheses required for higher generation dendritic molecules. Work to generate simple synthetically modified versions of our nontoxic dendrons is currently underway.

CONCLUSIONS

In summary, this paper has investigated the ability of our new simple dendron structures, functionalized on the surface with multiple spermine groups, to act as vectors in gene therapy. It has been shown that the dendrons can transfect DNA in the presence of chloroquine (which assists membrane permeation). The transfection efficiencies can be understood in terms of both the DNA affinities of the dendrons (**G2** > **G1** > **G0**) and the fact that **G2** shows some toxicity when administered in combination with DNA *and* chloroquine. The development of structure−activity relationships in the area of gene transfection is a goal of considerable importance in the field of gene therapy (*28*).

However, perhaps the most important observation from this study is that the dendrons exhibit negligible toxicities, either in their own right, or in the presence of DNA. This is an important first step in the development of potential vectors for application in gene therapy. It is also encouraging that the dendritic systems can be encouraged to transfect under certain conditions (i.e., addition of chloroquine to enable endosomal escape). We therefore believe that these systems have significant potential for application as the DNA binding subunit within more complex constructs designed for targeted gene therapy. However, this study has made clear that further synthetic modification of the basic dendron structure will be required, to enhance the transfection efficiencies of the nontoxic dendritic building blocks. Work targeting this goal is currently in progress within our laboratories, and we hope to report dendritic vectors for gene therapy applications, with significantly enhanced transfection efficiencies, in due course.

ACKNOWLEDGMENT

We gratefully acknowledge financial support from the EPSRC and Syngenta (J.G.H.) and a generous scholarship from the Worldwide Universities Network (WUN) which allowed J.G.H. to visit the laboratories in Illinois. Finally, we acknowledge financial support from the Erasmus-Socrates scheme (M.A.K.).

PEGylation of IFN-α has been used successfully to improve the pharmacokinetic properties and efficacy of the drug. To prepare a PEGylated form of human interferon-β-1a (IFN-β-1a) suitable for testing in vivo, we have synthesized 20 kDa mPEG-O-2-methylpropionaldehyde and used it to modify the N-terminal α-amino group of the cytokine. The PEGylated protein retained ∼50% of the activity of the unmodified protein and had significantly improved pharmacokinetic properties following intravenous administration in rats. The clearance and volume of distribution at steady state were reduced ∼30-fold and ∼4-fold, respectively, resulting in a significant increase in systemic exposure as determined by the area under the curve. The elimination half-life of the PEGylated protein was ∼13-fold greater than for the unmodified protein. The unmodified and PEGylated proteins were tested for their ability to inhibit the formation of radially oriented blood vessels entering the periphery of human SK-MEL-1 melanoma tumors in athymic nude homozygous (*nu*/*nu*) mice. In a single dose comparison study, administration of 1×10^6 units of unmodified IFN-β-1a resulted in a 29% reduction in vessel number, while 1×10^6 units of PEGylated IFN-β-1a resulted in a 58% reduction. Both treatments resulted in statistically significant reductions in mean vessel number as compared to the vehicle (control)-treated mice, with the PEGylated IFN-β-1a-treated mice showing a statistically significantly greater reduction in mean vessel number as compared to the unmodified IFN-β-1a-treated mice. In a multiple versus single dose comparison study, daily administration of 1×10^6 units of unmodified IFN-β-1a for 9 days resulted in a 51% reduction in vessel number, while a single dose of 1×10^6 units of the PEGylated protein resulted in a 66% reduction. Both treatments resulted in statistically significant reductions in mean vessel number as compared to the vehicle-treated mice, with the PEGylated IFN-β-1a-treated mice showing a statistically significantly greater reduction in mean vessel number as compared to the unmodified IFN-β-1a-treated mice. Therefore, the improved pharmacokinetic properties of the modified protein translated into improved efficacy. Since unmodified IFN-β is used for the treatment of multiple sclerosis and hepatitis C virus infection, a PEGylated form of the protein such as 20 kDa mPEG-O-2-methylpropionaldehyde-modified IFN-β-1a may serve as a useful adjunct for the treatment of these diseases. In addition, the antiangiogenic effects of PEGylated IFN-β-1a may be harnessed for the treatment of certain cancers, either as a sole agent or in combination with other antitumor drugs.

INTRODUCTION

Interferons (IFNs)[1] are a family of cytokines that mediate antiviral, antiproliferative, and immunomodulatory effects in response to biological and chemical stimuli (*1*−*3*). Two types of IFN are recognized on the basis of their physical and biological properties: Type I IFNs, members of which include the IFN-α subtypes, IFN-β, IFN-τ, and IFN-ω, and Type II, the only member of which is IFN-γ. The Type I IFN's signal through a common cell surface receptor composed of the IFNAR1 and IFNAR2 chains (*4*−*7*). The intracellular portions of IFNAR1 and IFNAR2 associate with the Janus tyrosine kinases Tyk2 and JAK1, respectively (*8*−*11*), and, following ligand binding, the kinases phosphorylate each other and the receptor chains, thereby creating binding sites for STAT proteins (*12*, *13*). The STAT proteins are subsequently phosphorylated, dimerize, migrate to the nucleus, and drive the expression of IFN-stimulated genes (*14*).

Type I IFNs have been approved for the treatment of a number of diseases for which their antiviral, antiproliferative, and immunomodulatory activities underlie their mechanism of action. Recombinant IFN-α-2b (Intron-A, Schering-Plough) has been approved for the treatment of chronic hepatitis B and hepatitis C virus (HCV) infection, genital warts, AIDS-related Kaposi's sarcoma, follicular non-Hodgkin's lymphoma, malignant melanoma, and hairy cell leukemia, while recombinant IFN-α-2a (Roferon-A, Hoffman La−Roche) is approved for the treatment of HCV, hairy cell leukemia, and chronic phase Philadelphia chromosome-positive chronic myelogenous leukemia. In addition, IFN-α-2b has been shown to be effective for the treatment of giant cell angioblastoma, a destructive pediatric tumor (*15*), and both IFN-α-2b and IFN-α-2a have been used for the treatment of life-threatening pediatric hemangiomas (*16*, *17*). Recombinant forms of IFN-β-1a (Avonex, BiogenIdec; Rebif, Serono) and IFN-β-1b (Betaferon, Schering

AG) are approved for the treatment of multiple sclerosis, while nonrecombinant forms of IFN-β (e.g. Feron, Toray) are approved in Japan for the treatment of HCV.

As with other small protein drugs, Type I IFNs have relatively short circulating half-lives that may necessitate frequent parenteral administration to achieve efficacy. To reduce the dosing frequency, and to improve the pharmacokinetics and efficacy, PEGylated forms of type I IFN's have been developed (*18*−*20*). PEGylation of IFN-α-2b with a linear 12 kDa PEG (PEG-Intron, Schering-Plough) increased the half-life following subcutaneous administration from 4−7 to 30−40 h (*21*) and improved the sustained virological response (SVR) against HCV from 12 to ∼24% (*22*). When given in combination with the antiviral drug ribavirin, the SVR with PEG-Intron increased to 54% (*23*). Similarly, PEGylation of IFN-α-2a with a branched 40 kDa PEG (Pegasys, Hoffman La−Roche) increased the half-life following intravenous administration from 3−8 to 65 h (*24*) and improved the SVR from 19 to 39% in HCV patients (*25*), and from 8 to 30% in HCV patients with concomitant cirrhosis of the liver (*26*). When administered in combination with ribavirin, the SVR of PEGylated IFN-α-2a improved to 56% (*27*). In addition to a significant improvement in the SVR, the frequency of dosing for the PEGylated proteins was reduced from thrice weekly to only once per week, a factor that increases patient compliance and therefore the effectiveness of the overall treatment regimen. A similar reduction in dosing frequency was observed upon modification of recombinant granulocyte colony-stimulating factor with a linear 20 kDa PEG (Neulasta, Amgen), administered for the treatment of neutropenia in cancer patients undergoing chemotherapy (*28*).

While the PEGylation of IFN-α-2b and IFN-α-2a serves as a clear example of the benefits that can be achieved by administering a longer half-life molecule, it is perhaps surprising that a PEGylated form of IFN-β has not been tested in clinical trials of either multiple sclerosis or HCV, especially when considering that the unmodified proteins used to treat these diseases often require frequent dosing to achieve efficacy. For multiple sclerosis, two of the three approved IFN-β products are administered multiple times per week: IFN-β-1a (Rebif) is injected subcutaneously thrice weekly (*29*), while IFN-β-1b (Betaferon) is injected subcutaneously every other day (*30*). For HCV, efficacy of recombinant IFN-β in European patients has been established following thrice weekly subcutaneous administration (*31*), and following daily dosing for 6 days a week for twelve weeks by intravenous administration (*32*). In Japan, where nonrecombinant forms of IFN-β have been used widely for the treatment of HCV, the unmodified protein is also administered frequently, typically every day for 2 weeks followed by thrice weekly for the remainder of the treatment regimen, although twice-daily regimens have also been tested (*33*−*35*). Therefore, development of a PEGylated form of IFN-β may be useful for the treatment of diseases such as multiple sclerosis or HCV where some of the current therapies require frequent dosing. Moreover, the use of a PEGylated form of IFN-β for the treatment of HCV may, in addition to reducing the dosing frequency, also offer the potential of a better safety profile compared to PEGylated IFN-α-2b and IFN-α-2a. While many patients must reduce the dose of PEGylated IFN-α or stop treatment due to adverse reactions, data from clinical trials of IFN-β in multiple sclerosis and HCV indicate that treatment with this cytokine is associated with a good safety and tolerability profile (*36*).

With the aim of developing a PEGylated form of IFN-β-1a suitable for testing in preclinical studies and potentially in human clinical trials, we have synthesized 20 kDa mPEG-O-2-methylpropionaldehyde for targeting the N-terminal α-amino group of the protein. Since the N-terminus of human IFN-β-1a is not critical for activity (alanine scanning mutagenesis of the N-terminal region (*37*), and deletion of the N-terminal methionine (*38*) have no effect on the antiviral activity), it was likely that modification of the protein with 20 kDa mPEG-O-2-methylpropionaldehyde would result in a protein that retained significant activity and that had improved pharmacokinetic properties. Indeed, Pepinsky et al. (*39*) have shown that modification of the N-terminal α-amino group of IFN-β-1a with 20 kDa mPEG-propionaldehyde resulted in a protein that retained full in vitro antiviral activity, had improved pharmacokinetic properties in mice, rats, and rhesus monkeys, and was pharmacologically active in the latter species as judged by the induction of the IFN-responsive markers neopterin and β2-microglobulin. However, while this report described the effects of PEGylation on the pharmacokinetic and pharmacodynamic properties of the protein, the unmodified and PEGylated proteins were not tested in an animal model of disease. Therefore, it remained an open question as to whether the improved pharmacokinetic properties would translate into improved efficacy.

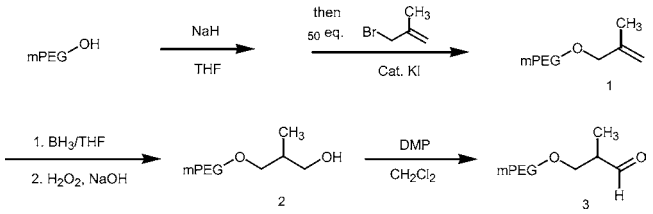

Figure 1. Schematic representation of the steps used in the synthesis of 20 kDa mPEG-O-2-methylpropionaldehyde.

Here we report on the synthesis and characterization of 20 kDa mPEG-O-2-methylpropionaldehyde, and the preparation and characterization of IFN-β-1a modified at the N-terminus with this PEG group. We further report on the pharmacokinetics of the unmodified and PEGylated proteins in rats, and the efficacy of the two proteins in a murine dermis model of angiogenesis inhibition. The improved efficacy of the PEGylated protein is shown to correlate with the improvement in its pharmacokinetic properties.

MATERIALS AND METHODS

Materials. SP-Sepharose, a Superose 6 HR 10/30 column, and ^{3}H-thymidine were obtained from GE Healthcare (Piscataway, NJ); 20 kDa mPEG-OH was from Sunbio (Anyang City, South Korea); recombinant human interferon-β-1a was from BiogenIdec (Cambridge, MA); sodium cyanoborohydride was from Sigma-Aldrich (St. Louis, MO); human serum albumin was from Instituto Grifols (Barcelona, Spain); endoproteinase Lys-C was from Wako Pure Chemical Industries (Osaka, Japan); sodium hydride (60% dispersion in mineral oil), 3-bromo-2-methylpropene, borane tetrahydrofuran complex (1 M in THF), and 30% hydrogen peroxide were from Aldrich (Milwaukee, WI); potassium iodide, sodium hydroxide, sodium bicarbonate, and sodium thiosulfate were from Fisher (Fair Lawn, NJ); and Dess−Martin periodinane was from Lancaster (Windham, NH).

Synthesis of 20 kDa mPEG-O-2-methylpropionaldehyde. The synthesis of 20 kDa mPEG-O-2-methylpropionaldehyde is given in Figure 1. Linear mPEG-OH with a molecular weight of 20000 Da (mPEG-OH 20 kDa; 2.0 g, 0.1 mmol) was treated with 60% NaH (32 mg, 0.8 mmol) in THF (35 mL). 3-Bromo-2-methylpropene (0.67 g, 5 mmol) and a catalytic amount of potassium iodide were added, and the mixture was heated to reflux for 17 h. The solvent was then removed under vacuum. CH_2Cl_2 (20 mL) was added to the residue, and the organic layer was separated and dried over anhydrous Na_2SO_4, and the volume was reduced to approximately 6 mL. The CH_2Cl_2 solution was added to ether (150 mL) dropwise. The resulting white precipitate was collected and dried under vacuum, yielding 1.8

g (~90% recovery) of compound **1**. ^{1}H NMR ($CDCl_3$, 400 MHz) and ^{1}H−^{13}C HSQC 2D NMR ($CDCl_3$, 400 MHz) showed ^{1}H δ 4.92 (s, 1H), 4.85 (s, 1H), 3.89 (s), 3.35 (s), 1.70 (s, 3H); ^{13}C δ 112, 76, 59, 20. To compound **1** (0.77 g, 0.04 mmol) in THF (7 mL) and CH_2Cl_2 (0.7 mL) at 0 °C was added BH_3·THF (1.0 M, 1.4 mL). The mixture was stirred in an ice bath for 1 h. NaOH (2 M, 1.0 mL) was added slowly, followed by 30% H_2O_2 (0.3 mL). The reaction was warmed to ambient temperature and stirred for 16 h. The above workup procedure was followed (CH_2Cl_2 extraction, followed by precipitation from ether and drying), to yield 0.60 g (~78% recovery) of compound **2** as a white solid. ^{1}H NMR ($CDCl_3$, 400 MHz), ^{1}H−^{1}H TOCSY 2D NMR ($CDCl_3$, 400 MHz), and ^{1}H−^{13}C HSQC 2D NMR ($CDCl_3$, 400 MHz) showed ^{1}H δ 3.35 (s), 2.01 (m, 1H), 0.84 (d, 3H); ^{13}C δ 59, 36, 13. Compound **2** (250 mg, 0.013 mmol) was dissolved in CH_2Cl_2 (2.5 mL) and Dess−Martin periodinane (DMP; 25 mg, 0.059 mmol) was added with stirring. The reaction was stirred for 30 min at ambient temperature. Saturated aqueous $NaHCO_3$ and $Na_2S_2O_3$ (2 mL each) were added, and the mixture was stirred at ambient temperature for 1 h. The above workup procedure was followed (CH_2Cl_2 extraction, followed by precipitation from ether and drying) to yield 194 mg (~77% recovery) of compound **3** (20 kDa mPEG-O-2-methylpropionaldehyde) as a white solid. ^{1}H NMR ($CDCl_3$, 400 MHz), ^{1}H−^{1}H TOCSY 2D NMR ($CDCl_3$, 400 MHz), and ^{1}H−^{13}C HSQC 2D NMR ($CDCl_3$, 400 MHz) showed ^{1}H δ 9.70 (s, 1H), 3.35, 2.63 (m), 1.09 (d, 3H); ^{13}C δ 59, 47, 11. The synthesis of 20 kDa mPEG-O-2-methylpropionaldehyde as described was repeated numerous times, up to a 20 g scale.

Preparation of 20 kDa mPEG-O-2-methylpropionaldehyde-modified IFN-β-1a. Recombinant human IFN-β-1a (5.6 mg at 1.1 mg/mL in 50 mM Na_2HPO_4 pH 6.0, 270 mM NaCl) was treated with 20 kDa mPEG-O-2-methylpropionaldehyde (5 mg/mL) in the presence of sodium cyanoborohydride (5 mM), in the dark for 19.25 h at ambient temperature. The reaction mixture was diluted with 4 volumes of 20 mM MES pH 5.0 and loaded under gravity onto a 4.5 mL (1 cm internal diameter × 5.7 cm) column of SP-Sepharose Fast Flow resin that had been equilibrated in 5 mM Na_2HPO_4 pH 5.5. The column was washed with 45 mL of 5 mM Na_2HPO_4 pH 5.5 and then bound protein eluted with 25 mM MES pH 6.4, 400 mM NaCl. Fractions containing protein were pooled and then concentrated with Centricon YM 3 concentrators (Millipore). The unmodified and PEGylated forms of IFN-β-1a were separated on a Superose 6 HR 10/30 column run at 0.4 mL/min in 5 mM Na_2HPO_4 pH 5.5, 150 mM NaCl as the mobile phase. Fractions were collected and analyzed by SDS−PAGE, and those containing only the singly modified protein were pooled. The PEGylated protein was filter-sterilized (0.2 μm), and the concentration of the protein determined as described below. The final yield of the PEGylated IFN-β-1a (excluding the mass of the attached PEG) was 27%. Sufficient protein was removed for analytical characterization, and the remainder was formulated at 100 μg/mL in 5 mM Na_2HPO_4 pH 5.5, 150 mM NaCl containing 45.6 mg/mL human serum albumin and stored at −70 °C.

Determination of Protein Concentration. The concentration of unmodified and PEGylated IFN-β-1a was determined by absorbance measurements at 280 nm using the predicted extinction coefficient of 29990 L mol^{-1} cm^{-1} based on the tryptophan, tyrosine, and cystine (disulfide) content (*40*). The same value for the extinction coefficient was used for the PEGylated protein as for the unmodified protein since the PEG group does not contribute to the absorbance at 280 nm (a 1 mg/mL solution of 20 kDa mPEG-O-2-methylpropionaldehyde was found to have an absorbance of 0.002 as compared to 1.50 for 1 mg/mL IFN-β-1a). Therefore, an identical absorbance at 280 nm equates to the same mass of IFN-β-1a irrespective of the presence of the attached PEG. When referring to the mass of the PEGylated protein, the contribution of the PEG moiety is not included.

Peptide Mapping. Peptides were generated by digestion of ~13 μg of unmodified or PEGylated IFN-β-1a with 20% (w/w) endoproteinase Lys-C in 100 μL of PBS pH 7.6, 1 mM EDTA, 5 mM DTT for 24 h at ambient temperature. 4 μL of 1 M DTT and 100 μL of 8 M urea were then added, and the digest was loaded onto a YMC (Milford, MA) C_{18} (1.0 mm internal diameter × 250 mm) reverse-phase HPLC column (AA12S052501WT). The column was developed with the following gradient at 0.07 mL/min where A = water, 0.03% TFA and B = acetonitrile, 0.024% TFA: 0−50% B in 50 min, 50−70% B in 10 min, 70% B in 10 min. Peptide peaks were detected on-line with a 2690/ZMD LC-MS system (Waters, Milford, MA). The digests were also loaded onto a Vydac (Hesperia, CA) C_4 (1.0 mm internal diameter × 250 mm) reverse-phase HPLC column (214TP51). The column was developed with the following gradient where A = water, 0.1% TFA and B = acetonitrile, 0.08% TFA: 0−63% B in 70 min, 63−80% B in 10 min. Peptide peaks were detected on-line with a Waters (Milford, MA) Model 996 photodiode array detector.

Determination of Antiviral Activity. The specific antiviral activity of IFN-β-1a was determined using a cytopathic effect (CPE) bioassay that measures the ability of the protein to protect human lung carcinoma A549 cells (grown at 37 °C/5% CO_2) challenged with encephalomyocarditis (EMC) virus. For the assay, 3 × 10^4 A549 cells in 100 μL of Dulbecco's modified eagles medium containing 10% fetal bovine serum, 2 mM L-glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin, were added to wells of 96-well microtiter plates and incubated for 5−6 h. Serial dilutions of duplicate IFN-β-1a standards and test samples were then added, and the cells were incubated for a further 24 h. The medium was removed, and EMC virus was added. The cells were incubated for 48 h, and 50 μL of 5 mg/mL 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) in PBS was then added. After a 1 h incubation, the medium was removed, the wells were washed with 100 μL of PBS, and the cells and dye were solubilized with 100 μL of 1.2 N HCl in 2-propanol. The plates were then read at 450 nm, and the data were analyzed using four-parameter curve fitting with Softmax Pro software (Molecular Devices, Sunnyvale, CA).

Determination of Antiproliferative Activity. The specific antiproliferative activity of IFN-β-1a was determined using a bioassay that measures the ability of the protein to inhibit the growth of Daudi human B cells (grown at 37 °C/5% CO_2). For the assay, 1 × 10^4 Daudi cells in 150 μL of RPMI-1640 medium containing 10% fetal bovine serum and 2 mM L-glutamine were added to wells of 96-well microtiter plates and incubated for 48 h with serial dilutions of quadruplet IFN-β-1a samples. ^{3}H-Thymidine (1 μCi in 50 μL medium/well) was added, the cells incubated for a further 16 h, and the cultures were harvested using a Tomtec (Hamden, CT) 96 Mach III harvester. Thymidine incorporation was measured using a Perkin-Elmer (Wellesley, MA) 1450 MicroBeta JET scintillation counter. The data were analyzed using four-parameter curve fitting with DeltaGraph software version 4.5 (SPSS Inc., Chicago, IL).

Determination of Pharmacokinetic Parameters. Pharmacokinetic parameters following intravenous administration of unmodified and PEGylated IFN-β-1a were determined using precannulated (jugular vein) female Lewis rats (weight 200−250 g) obtained from Charles River Laboratories (Research Triangle Park, Raleigh-Durham, NC). Three rats were used for the unmodified IFN-β-1a and three for the PEGylated protein. Animals were acclimated in the BiogenIdec animal facility prior to the experiment. Food was withheld overnight prior to beginning the study. Water was available ad libitum. Experimental procedures were carried out according to an approved

Institutional Animal Care and Use Committee (IACUC) protocol. Unmodified and PEGylated IFN-β-1a were formulated in 15 mg/mL human serum albumin in PBS, and a single dose of unmodified IFN-β-1a (80 μg/kg) or PEGylated IFN-β-1a (24 μg/kg) was administered. Blood samples (200 μL) were drawn at the following times: unmodified IFN-β-1a; 0, 0.083, 0.25, 0.5, 1.25, 3, and 5 h; PEGylated IFN-β-1a; 0, 0.083, 0.25, 0.5, 1.25, 3, 24, 48, and 72 h. To minimize blood volume depletion, each blood sample removed was replaced with an equivalent volume of sterile normal saline. Blood samples were allowed to clot for 60 min at ambient temperature and centrifuged, and serum was separated and stored at −70 °C. The amount of unmodified and PEGylated IFN-β-1a present in the serum samples was determined using the A549 cell/EMC virus CPE bioassay described above, using the unmodified or PEGylated protein as the standard, respectively. Pharmacokinetic parameters were calculated using WinNonLin software version 3 (Pharsight, Mountain View, CA) using noncompartmental analysis.

Determination of in Vivo Antiangiogenic Activity. Unmodified and PEGylated IFN-β-1a were tested for their ability to inhibit the formation of radially oriented blood vessels entering the periphery of human SK-MEL-1 melanoma tumors grown in athymic nude homozygous (*nu*/*nu*) mice. SK-MEL-1 cells (2×10^6) were inoculated on day 0 into the dermis in the flanks of the mid axillary line of 3-week-old *nu*/*nu* NCR mice. 24 h later (day 1), groups of four mice each received the following subcutaneous doses of human serum albumin solution (HSA, vehicle control), or HSA containing either unmodified or PEGylated IFN-β-1a: Group 1, 0.1 mL of 45.6 mg/mL HSA once on day 1 only; Group 2, 0.1 mL of 45.6 mg/mL HSA containing 1×10^6 units of unmodified IFN-β-1a once on day 1 only; and Group 3, 0.1 mL of 45.6 mg/mL HSA containing 1×10^6 units of PEGylated IFN-β-1a once on day 1 only. Mice were sacrificed on day 10 and the tumor inoculation site assessed for neovascularization, measured by an observer blinded as to the treatment (*41*). Every radially oriented vessel entering the periphery of the tumor was scored as a single vessel. In an independent study, groups of three mice each received the following subcutaneous doses of HSA, or HSA containing either unmodified or PEGylated IFN-β-1a: Group 1: 0.1 mL of 45.6 mg/mL HSA once on day 1 only; Group 2, 0.1 mL of 45.6 mg/mL HSA containing 1×10^6 units of PEGylated IFN-β-1a once on day 1 only; Group 3, 0.1 mL of 45.6 mg/mL HSA on days 1−9 inclusive; Group 4, 0.1 mL of 45.6 mg/mL HSA containing 1×10^6 units of unmodified IFN-β-1a on days 1−9 inclusive. Mice were sacrificed on day 10 and neovascularization of the tumors determined as described above. Experimental procedures were carried out according to an approved IACUC protocol. Statistical analysis of the data was carried out using GraphPad Prism software version 4 (GraphPad Software, San Diego, CA).

RESULTS

PEGylation of IFN-β-1a. IFN-β-1a was modified with 20 kDa mPEG-O-2-methylpropionaldehyde, and the pharmacokinetic and efficacy profiles of the unmodified and PEGylated proteins were compared. Reaction of IFN-β-1a with 20 kDa mPEG-O-2-methylpropionaldehyde resulted in the formation of predominantly singly modified protein, with lesser amounts of more highly modified forms present (data not shown). The unmodified and PEGylated forms were separated from one another by size exclusion chromatography. Figure 2, lane C shows that the singly modified protein was purified to homogeneity, with no unmodified or multiply modified forms detected. Incorporation of a single PEG resulted in an increase in the apparent M_r of the protein by reducing SDS−PAGE from ~25 kDa (Figure 2, lane B) to ~55 kDa (Figure 2, lane C). By size exclusion chromatography, the singly modified protein had an apparent M_r of 320000 Da. The ~10-fold increase in the apparent mass compared to the unmodified protein results from a large increase in the hydrodynamic volume of the PEGylated protein, a typical consequence of this type of modification.

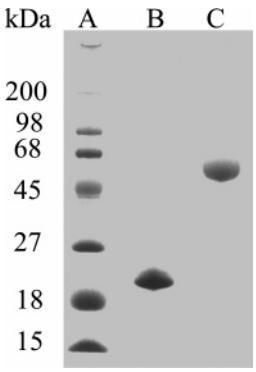

Figure 2. SDS−PAGE of unmodified and PEGylated human IFN-β-1a. Purified proteins (4 μg) were electrophoresed on a reducing 10−20% gradient gel and stained with Coomassie brilliant blue. Lane A, molecular weight markers; lane B, unmodified IFN-β-1a; lane C, PEGylated IFN-β-1a.

The specificity of the PEGylation reaction was determined by peptide mapping. Peptide maps of unmodified and PEGylated IFN-β-1a were generated with endoproteinase Lys-C (Figure 3). For the PEGylated protein, 93% of the PEG was attached to the N-terminal peptides consisting of residues 1−19 (MSYNLLGFLQRSSNFQCQK) and 2−19 (SYNLLGFLQRSSNFQCQK) as evident by their disappearance from the map (Figure 3, compare panels A and B). The presence of two N-terminal peptides stems from the fact that the preparation of IFN-β-1a used contained a small amount (11%) of a truncated species in which the N-terminal methionine was missing, and in which the α-amino group of the second residue, serine, was modified. The mapping data therefore show that the PEG is primarily attached to the N-terminal peptide(s). Furthermore, the observation that the peaks corresponding to the adjacent peptides (residues 20−30 and 20−33) do not decrease in size (Figure 3, compare panels A and B) suggests that the modification is at the N-terminal α-amino group rather than at the ϵ-amino group of Lys-19. Had Lys-19 been modified, endoproteinase Lys-C would not be expected to cleave the peptide bond between Lys-19 and Leu-20, and the amount of peptide 20−30 and 20−33 would have subsequently been reduced. However, while the PEGylated protein consists primarily of a species in which the N-terminal α-amino group is modified, the observation that some (~7%) of the N-terminal peptide corresponding to residues 1−19 remains (Figure 3, panel B) indicates that the preparation must also contain singly modified form(s) in which the PEG is attached at site(s) other than at the N-terminus. However, these are not readily assigned based on a comparison of the maps for unmodified and PEGylated protein, since they represent only a small fraction of the total population and the modification(s) may occur at more than one site.

To determine the effect of PEGylation on the specific antiviral activity of IFN-β-1a, the unmodified and PEGylated proteins were assayed in the A549 cell/EMC virus CPE bioassay. Figure 4A shows that incorporation of a single 20 kDa mPEG-O-2-methylpropionaldehyde moiety at the N-terminus of IFN-β-1a produces an approximately 2-fold loss of specific activity as compared to the unmodified protein. For the unmodified protein, the mean EC_{50} value was 5.7 ± 0.76 pg/mL ($n = 4$ replicates), while for the PEGylated protein, the mean EC_{50} value was 11.9 ± 0.85 pg/mL ($n = 4$ replicates). Therefore, the specific antiviral activity of the PEGylated IFN-β-1a is $\sim 1 \times 10^8$ units/mg. The unmodified and PEGylated proteins were also tested for their

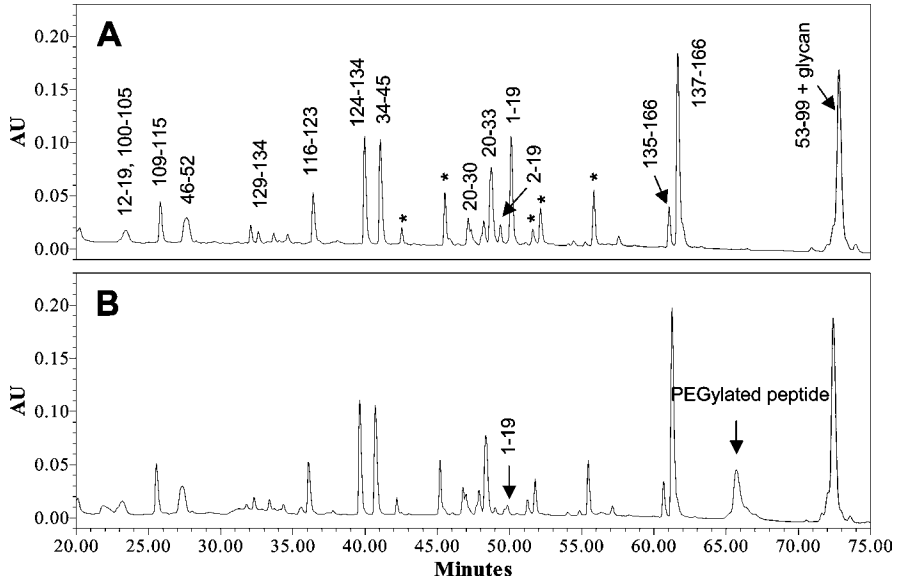

Figure 3. Endoproteinase Lys-C peptide maps of unmodified (A) and PEGylated (B) IFN-β-1a. Peptide peaks were detected on-line with a 2690/ZMD LC-MS system. Peptides are denoted by residue number and asterisks denote peptides from endoproteinase Lys-C generated by protease autodigestion.

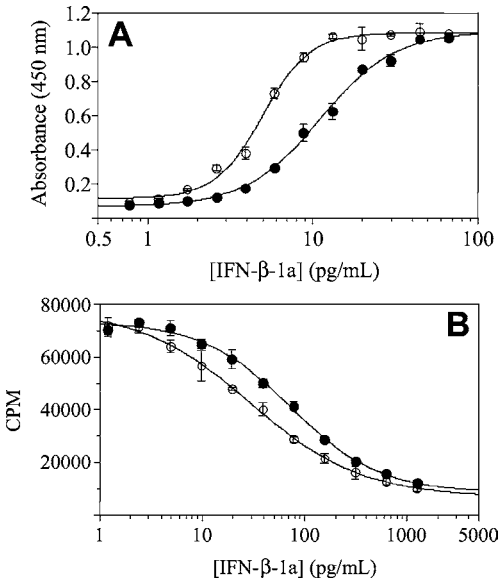

Figure 4. (A) Antiviral activity of unmodified and PEGylated IFN-β-1a assayed on human lung carcinoma A549 cells challenged with EMC virus. Assays were performed in duplicate and error bars show the spread between the determinations. The data were analyzed using four-parameter curve fitting. Unmodified IFN-β-1a (○), PEGylated IFN-β-1a (●). (B) Antiproliferative activity of unmodified and PEGylated IFN-β-1a assayed on Daudi human B cells. Assays were performed in quadruplet and error bars show the standard deviation about the mean. The data were analyzed using four-parameter curve fitting. Unmodified IFN-β-1a (○), PEGylated IFN-β-1a (●).

ability to inhibit the growth of Daudi human B cells. Figure 4B shows that the PEGylated protein was 2.4-fold less potent than the unmodified IFN-β-1a. For the unmodified protein, the IC_{50} value was 30 pg/mL, while for the PEGylated protein, the IC_{50} value was 73 pg/mL. Therefore, the PEGylated protein showed the same ∼2-fold loss of potency as compared to the unmodified protein in assays measuring antiviral and antiproliferative activities.

Pharmacokinetics of Unmodified and PEGylated IFN-β-1a. Pharmacokinetic parameters were determined for unmodified and PEGylated IFN-β-1a following intravenous administration in female Lewis rats. The mean blood serum curves for unmodified and PEGylated IFN-β-1a are shown in Figure 5 panels A and B, respectively. Systemic clearance, elimination half-life ($t_{1/2}$), and the volume of distribution at steady state (V_{ss}) were calculated and are shown in Table 1. Incorporation of 20 kDa mPEG-O-2-methylpropionaldehyde at the N-terminus of IFN-β-1a reduced the clearance by ∼30-fold and increased $t_{1/2}$ by ∼13-fold as compared to the unmodified protein (Table 1). In addition, the volume of distribution decreased ∼4-fold for the PEGylated protein, suggesting that the PEG moiety reduces the ability of the protein to distribute outside of the central vasculature. The maximal observed concentration (C_{max}) for the unmodified protein was ∼2-fold greater than for the PEGylated protein although this was not unexpected since the unmodified protein was dosed at 80 μg/kg as compared to 24 μg/kg for the PEGylated protein, i.e., ∼3-fold greater amount in terms of IFN-β-1a equivalents. The unmodified protein was dosed at a higher level to ensure that sufficient protein remained in circulation to be detected in the CPE bioassay and thus enable calculation of its pharmacokinetic parameters. The AUC for the PEGylated protein was ∼10-fold greater than for the unmodified protein, despite being dosed at a level ∼3-fold lower than the unmodified protein. Therefore, PEGylation of the N-terminus of IFN-β-1a with 20 kDa mPEG-O-2-methylpropionaldehyde results in a significant increase in the systemic exposure as compared to the unmodified protein.

In Vivo Efficacy of Unmodified and PEGylated IFN-β-1a. To determine whether the improved pharmacokinetic properties of the PEGylated IFN-β-1a translated into an improvement in efficacy, the unmodified and PEGylated proteins were tested for their ability to inhibit the formation of radially oriented blood vessels entering the periphery of human SK-MEL-1 melanoma tumors grown in athymic nude homozygous (*nu*/*nu*) mice. This murine dermis model, described by Bauer et al. (*42*), has been used previously to evaluate the antiangiogenic effects of unmodified and PEGylated IFN-α-2b and was therefore a useful system for comparing the efficacy of unmodified and PEGylated IFN-β-1a.

Two studies were performed to compare the efficacy of the unmodified and PEGylated proteins. In one study, groups of four mice carrying SK-MEL-1 melanoma tumors received either human serum albumin solution (HSA, vehicle control) once on day 1 only (Group 1), HSA containing 1×10^6 units of unmodified IFN-β-1a once on day 1 only (Group 2), or HSA containing 1×10^6 units of PEGylated IFN-β-1a once on day

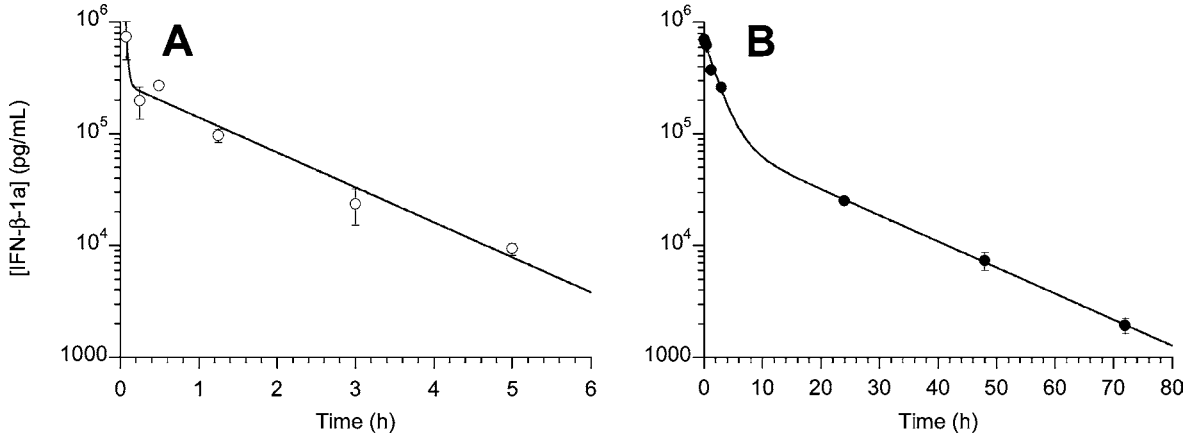

Figure 5. Pharmacokinetic profiles of unmodified and PEGylated IFN-β-1a in rats following intravenous administration. Female Lewis rats were injected with unmodified (A) or PEGylated (B) IFN-β-1a. Blood was collected at the time points indicated and assayed for serum levels of interferon by activity in the A549 cell/EMC virus CPE bioassay. Data points are means of values obtained from three rats. Pharmacokinetic parameters were calculated using noncompartmental analysis. For visual presentation, the data were fitted using a two-compartment model. Unmodified IFN-β-1a (○), PEGylated IFN-β-1a (●).

Table 1. Pharmacokinetic Parameters for Unmodified and PEGylated Human IFN-β-1a in Female Lewis Rats Following Intravenous Administration

protein	dose (μg/kg)	C_{max} (pg/mL)	AUC (pg/h/mL)	$t_{1/2}$ (h)	CL (mL/h/kg)	V_{ss} (mL/kg)
unmodified	80	1400000	510000	0.98	160	160
PEGylated	24	720000	4800000	13	5.0	39

1 only (Group 3) (Figure 6A). Since the PEGylated protein was shown to have a specific activity 2-fold lower than that of the unmodified protein (see above), the mice were administered with 5 μg of unmodified IFN-β-1a or 10 μg of PEGylated IFN-β-1a thus ensuring equal dosing on a unit (antiviral/antiproliferative activity) basis. As shown in Figure 6A, treatment of the mice on day 1 only with a single dose of 1×10^6 units of unmodified IFN-β-1a resulted in a mean vessel number of 36.0 ± 4.2 as compared to 50.8 ± 5.3 for the vehicle-treated mice (Figure 6A, compare Groups 2 and 1, respectively). By contrast, treatment with a single dose of 1×10^6 units of PEGylated IFN-β-1a resulted in a mean vessel number of 21.3 ± 3.9 (Figure 6A, compare Groups 3 and 1, respectively). Therefore, a single dose of the PEGylated protein resulted in a 58% reduction in vessel number as compared to a 29% reduction for the unmodified protein. Analysis of variance followed by a Newmann-Keuls multiple comparison test indicated that both treatments resulted in statistically significant reductions in mean vessel number as compared to the vehicle-treated mice ($p < 0.01$ for the unmodified IFN-β-1a-treated mice and $p < 0.001$ for the PEGylated IFN-β-1a-treated mice). Furthermore, the mean vessel number of the PEGylated IFN-β-1a-treated mice was statistically significantly different from that of the unmodified IFN-β-1a-treated mice ($p < 0.01$).

To determine whether the efficacy of the PEGylated IFN-β-1a could be matched by increasing the dose and frequency of the unmodified protein, an independent study was carried out in which groups of three mice carrying SK-MEL-1 melanoma tumors received either HSA once on day 1 only (Group 1), HSA containing 1×10^6 units of PEGylated IFN-β-1a once on day 1 only (Group 2), HSA daily on days 1−9 inclusive (Group 3), or HSA containing 1×10^6 units of unmodified IFN-β-1a daily on days 1−9 inclusive (Group 4) (Figure 6B). Results from Group 2 (single dose of PEGylated IFN-β-1a) were compared to Group 1 (single dose of vehicle control), while results from Group 4 (unmodified IFN-β-1a administered daily) were compared to Group 3 (vehicle control administered daily) to control for any effects resulting from the multiple dosing regimen. As shown in Figure 6B, treatment of the mice on day 1 only with a single dose of 1×10^6 units of PEGylated IFN-β-1a resulted in a mean vessel number of 17.3 ± 2.5 as compared to 51.0 ± 5.6 for the mice treated with vehicle control once on day 1 only (Figure 6B, compare Groups 2 and 1, respectively). For the multiply dosed mice, treatment with 1×10^6 units of unmodified IFN-β-1a daily resulted in a mean vessel number of 21.7 ± 4.0 as compared to 44.0 ± 4.6 for the mice treated daily with vehicle control (Figure 6B, compare Groups 4 and 3, respectively). Hence, a single dose of 1×10^6 units of the PEGylated protein resulted in a 66% reduction in vessel number compared to a 51% reduction following daily administration of 1×10^6 units of the unmodified protein. Analysis of the data using an unpaired Student's *t* test indicated that both treatments resulted in statistically significant reductions in mean vessel number as compared to the respective vehicle control ($p = 0.0032$ for the unmodified IFN-β-1a-treated mice, and $p = 0.0007$ for the PEGylated IFN-β-1a-treated mice). Further analysis was carried out to determine whether the difference in mean vessel number between the unmodified IFN-β-1a-treated mice and the PEGylated IFN-β-1a-treated mice was statistically significant. Mean vessel numbers for the test and the corresponding control group were ranked. Differences were calculated between each test and control value at the same rank level. The decrease in mean vessel number was 22.33 ± 0.33 for the unmodified IFN-β-1a-treated mice and 33.67 ± 1.86 for the PEGylated IFN-β-1a-treated mice. The mean decreases were then tested using an unpaired *t*-test that gave a *P* value of 0.0039, i.e., the resulting mean vessel number following a single dose of the PEGylated protein on day 1 only was significantly different from that when the unmodified protein was given on days 1−9 inclusive.

DISCUSSION

PEGylation of therapeutic proteins is an established method to improve pharmacokinetic properties, to reduce dosing frequency, and to potentially improve pharmacodynamic responses and clinical efficacy. The benefit of this technology is clearly seen in the case of IFN-α-2b and IFN-α-2a where dosing frequency was reduced and efficacy against HCV infection improved, following PEGylation (*22*, *23*, *25*−*27*). To prepare a PEGylated form of IFN-β-1a that could be tested and compared to the unmodified protein in preclinical studies and potentially in human clinical trials, we modified the protein at the N-terminal α-amino group with 20 kDa mPEG-O-2-methylpropionaldehyde.

N-Terminal PEGylation of IFN-β-1a with 20 kDa mPEG-O-2-methylpropionaldehyde significantly increased the systemic

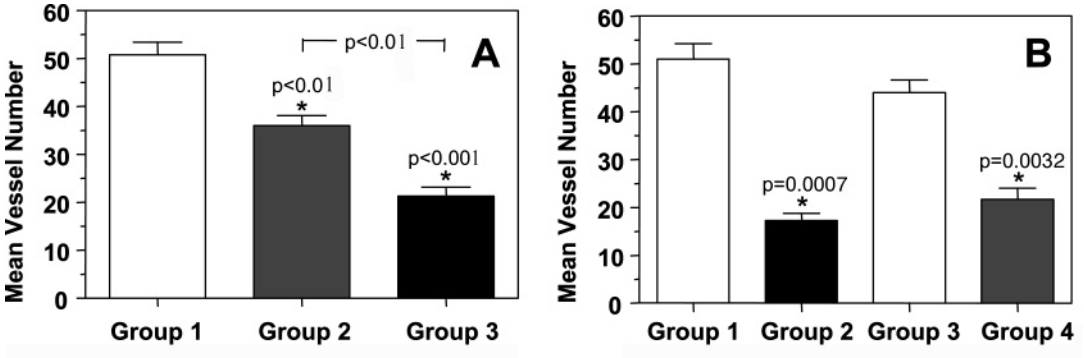

Figure 6. In vivo antiangiogenic activity of unmodified and PEGylated IFN-β-1a. The unmodified and PEGylated proteins were tested for their ability to inhibit the formation of radially oriented blood vessels entering the periphery of human SK-MEL-1 melanoma tumors grown in athymic nude homozygous (*nu*/*nu*) mice. Mice were injected with SK-MEL-1 cells (2×10^6) on day 0, followed by subcutaneous administration of either human serum albumin solution (HSA, vehicle control), HSA containing 1×10^6 units of unmodified IFN-β-1a, or HSA containing 1×10^6 units of PEGylated IFN-β-1a. For (A), groups of four mice received either HSA once on day 1 only (Group 1), HSA containing 1×10^6 units of unmodified IFN-β-1a once on day 1 only (Group 2), or HSA containing 1×10^6 units of PEGylated IFN-β-1a once on day 1 only (Group 3). For (B), groups of three mice received either HSA once on day 1 only (Group 1), HSA containing 1×10^6 units of PEGylated IFN-β-1a once on day 1 only (Group 2), HSA on days 1−9 inclusive (Group 3), or HSA containing 1×10^6 units of unmodified IFN-β-1a on days 1−9 inclusive (Group 4). Mice were sacrificed on day 10, and the tumor inoculation site was assessed for neovascularization, measured by an observer blinded as to the treatment. The mean vessel number ± the standard error of the mean is shown. Asterisks denote statistically significant differences between the unmodified or PEGylated IFN-β-1a-treated mice and the corresponding vehicle-treated mice.

exposure in rats following intravenous administration. The increase in $t_{1/2}$ and AUC for the PEGylated protein was ~13-fold and ~10-fold, respectively, compared to the unmodified protein, resulting from decreases in the clearance and volume of distribution at steady state (Table 1). While a direct side-by-side comparison of the pharmacokinetic parameters of 20 kDa mPEG-O-2-methylpropionaldehyde-modified IFN-β-1a and 20 kDa mPEG-propionaldehyde-modified IFN-β-1a was not carried out, a comparison of the $t_{1/2}$ values obtained for unmodified IFN-β-1a and the PEGylated forms in this and in the previously published study (*39*) indicates that they were comparable with respect to half-life. For the unmodified and 20 kDa mPEG-propionaldehyde-modified IFN-β-1a, the $t_{1/2}$ values were 1.47 and 10.13 h, respectively (*39*), while for the unmodified and 20 kDa mPEG-O-2-methylpropionaldehyde-modfied IFN-β-1a (this study), the $t_{1/2}$ values were 0.98 and 13 h, respectively (Table 1). While we did not determine the pharmacokinetic properties of 20 kDa mPEG-O-2-methylpropionaldehyde-modified IFN-β-1a following subcutaneous or intraperitoneal administration in rats, we anticipate that it will also show improved pharmacokinetic parameters compared to the unmodified protein since human IFN-β-1a and rat IFN-β modified at the N-terminus with 20 kDa mPEG-propionaldehyde both show improved pharmacokinetic parameters as compared to their respective unmodified forms following these routes of administration (*39*, *43*). Similar improvements in pharmacokinetic properties were observed for IFN-β-1a modified on Cys-17 with a 40 kDa branched PEG following subcutaneous administration to cynamologous monkeys (*44*).

The unmodified and 20 kDa mPEG-O-2-methylpropionaldehyde-modified IFN-β-1a were tested in a murine dermis model to determine whether the improved pharmacokinetics of the modified protein would translate into an improvement in efficacy. When a single dose of 1×10^6 units of unmodified IFN-β-1a was given once on day 1 only, the number of radially oriented blood vessels entering the periphery of the SK-MEL-1 tumors at day 10 was reduced 29% as compared to the vehicle control. By contrast, a single dose of 1×10^6 units of PEGylated IFN-β-1a given once on day 1 only resulted in a 58% reduction (Figure 6A). Both treatments resulted in statistically significant reductions in mean vessel number as compared to the vehicle-treated mice, with the PEGylated IFN-β-1a-treated mice showing a statistically significant reduction in mean vessel number as compared to the unmodified IFN-β-1a-treated mice. Therefore, the attached 20 kDa PEG moiety significantly improved the efficacy of the protein, indicating that the pharmacokinetic properties and efficacy are correlated. To address the question as to whether the efficacy of the unmodified protein could be improved to a level commensurate with that of the modified protein, a single dose of 1×10^6 units of PEGylated IFN-β-1a was administered once on day 1 only, and compared to administration of 1×10^6 units of unmodified IFN-β-1a given daily on days 1−9 inclusive. Treatment of the mice with a single dose of 1×10^6 units of PEGylated IFN-β-1a once on day 1 only resulted in a mean vessel number of 17.3 ± 2.5 as compared to 51.0 ± 5.6 for the mice treated with vehicle control once on day 1 only (66% reduction, Figure 6B). This result was very similar to that obtained for the same samples in the single dose comparison study, where a single dose of the PEGylated protein resulted in a mean vessel number of 21.3 ± 3.9 as compared to 50.8 ± 5.3 for the vehicle control (Figure 6A). For the multiply dosed mice, treatment with 1×10^6 units of unmodified IFN-β-1a daily on days 1−9 inclusive resulted in a mean vessel number of 21.7 ± 4.0 as compared to 44.0 ± 4.6 for the mice treated daily with vehicle control (51% reduction, Figure 6B). Both treatments resulted in statistically significant reductions in mean vessel number as compared to the respective vehicle-treated mice, with the PEGylated IFN-β-1a-treated mice showing a statistically significant reduction in mean vessel number as compared to the unmodified IFN-β-1a-treated mice. Therefore, even though the cumulative total dose of the unmodified protein was 9-fold greater than that of the PEGylated protein on a unit (activity) basis (4.5-fold greater on an IFN-β-1a mass basis), the PEGylated protein was still more efficacious than the unmodified protein. A similar study using the same murine dermis model was carried out to compare the efficacy of unmodified IFN-α-2b (Intron-A) and PEGylated IFN-α-2b (PEG-Intron) (*42*). In this study, mice received either 0, 1×10^3, 1×10^4, 1×10^5, 1×10^6, or 1×10^7 units of unmodified IFN-α-2b on days 1−10 inclusive, and the mean number of vessels compared to mice that received the same amount (units) of PEGylated IFN-α-2b (PEG-Intron) as a single dose. While at 1×10^3 units there was no effect with either protein, at 1×10^4 units and above there was a significant reduction in the vessel number as compared to the control-treated mice. However, there was no significant difference observed between mice receiving either a single dose of PEGylated IFN-α-2b or daily administration of the unmodified protein. Fol-

lowing a single dose of 1×10^6 units of PEGylated IFN-α-2b, the reduction in vessel number was ~70% (*42*), similar to the values obtained in this study for 1×10^6 units of PEGylated IFN-*β*-1a (58% and 66%, Figure 6).

PEGylation of IFN-*β*-1a at the N-terminus with 20 kDa mPEG-O-2-methylpropionaldehyde, in addition to improving pharmacokinetic properties and in vivo efficacy, also has the benefit of yielding a product with essentially a single site of modification; thereby simplifying product characterization. By contrast, PEGylated IFN-α-2b (PEG-Intron), which is modified with a linear 12 kDa PEG using a succinimidyl carbonate chemistry, is a mixture of 14 different monoPEGylated positional isomers in which the PEG chain is attached to either lysine, tyrosine, histidine, serine, or cysteine residues (*45*). Similarly, for PEGylated IFN-α-2a (Pegasys), modification with a branched 40 kDa PEG using an *N*-hydroxysuccinamide ester derivative results in a mixture of 6 different monoPEGylated positional isomers, all of which are attached to lysine residues (*46*). A consequence of using these nonspecific amine-coupling chemistries is that the product is a heterogeneous mixture that requires extensive analytical characterization following production to ensure batch-to-batch consistency. Furthermore, PEG chains can become attached at site(s) that interfere with the binding of the protein to the IFNAR1/IFNAR2 receptor. Indeed, many of the residues that are modified in these proteins have been shown by site-specific mutagenesis to be important for activity (*4*), and it is therefore not surprising that both PEGylated IFNs-α show a significant reduction in their in vitro antiviral activity as compared to their respective unmodified form. For PEG-Intron, the antiviral activity of the mixture is 28% of that of the unmodified protein and ranges from 6 to 37% for the individual species (*45*), while for Pegasys, the mixture has an antiviral activity of only 7% of the unmodified IFN-α-2a (*46*). The data for 20 kDa mPEG-O-2-methylpropionaldehyde-modified IFN-*β*-1a (50% retention of activity), and for 20 kDa mPEG-propionaldehyde-modified IFN-*β*-1a (*39*) and 20 kDa mPEG-propionaldehyde-modified rat IFN-*β* (*43*), both of which retain full in vitro antiviral activity, highlights the importance of modifying sites distal to receptor binding site(s) if retention of activity is a desired outcome. The N-terminus of IFN-*β*-1a therefore serves as an attractive site for modification since alanine scanning mutagenesis of the N-terminal region (*37*) and deletion of the N-terminal methionine (*38*) have no affect on activity, and analysis of the preliminary X-ray crystal structure of IFN-*β*-1a complexed with the extracellular portion of the human IFNAR2 chain shows that the N-terminus does not participate in the binding site (Ann Boriack-Sjodin, personal communication). In addition to IFN-*β*-1a, the N-terminus of IFN-α-2 also appears to be suitable for PEGylation. Using site-specific mutagenesis to replace glutamine at position 5 with a cysteine, Rosendahl et al. (*47*) have recently shown that the cysteine can be modified with linear 5 kDa, 10 kDa, or 20 kDa maleimide-PEGs, or with a branched 40 kDa maleimide PEG, resulting in the production of site-specific monoPEGylated proteins. The 5 kDa PEG-maleimide-modified protein retained ~50% of the antiproliferative activity of the unmodified wild type or Q5C mutant protein, while the activities of the 10 kDa, 20 kDa, and 40 kDa PEG-maleimide-modified proteins were within 3−4-fold of the unmodified wild type or Q5C mutant (*47*). As expected, the pharmacokinetic properties of the PEGylated proteins were superior to that of the unmodified protein. Following intravenous administration in rats, the $t_{1/2}$ value for the unmodified wild-type protein was 0.5 h, while for the 10 kDa, 20 kDa, and 40 kDa PEG-maleimide-modified proteins, the $t_{1/2}$ values were 22, 24, and 32 h, respectively (*47*). The superior retention of activity of the 40 kDa PEG-maleimide-modified IFN-α-2 (3−4-fold lower than that of the unmodified protein) as compared to Pegasys (14-fold lower) presumably reflects the fact that the N-terminal region of IFN-α-2, like that of IFN-*β*-1a, is not critical for receptor binding. Indeed, site-directed mutagenesis and modeling studies indicate that the N-terminus of the cytokine does not interact with the IFNAR2 chain, rather the binding interface between IFN-α-2 and IFNAR2 is formed by a primarily hydrophobic patch composed of several residues, the most N-terminal of which is leucine-26 (*48*−*50*).

PEGylation of the N-terminus of IFN-*β*-1a, with the retention of significant activity, is also desirable since a lower dose may be required to achieve efficacy as compared to the unmodified protein, or as compared to a protein that has lost substantial activity following modification. This not only affects factors such as the cost of making the drug, but may also play an important role in reducing immunogenicity and the formation of neutralizing antibodies. For IFN-*β*-1a, for example, administration of the two different products currently available for the treatment of multiple sclerosis results in the formation of different levels of neutralizing antibodies. In a side-by-side comparison of the efficacious dose of Rebif (Serono), given as a 44 *μ*g subcutaneous injection thrice weekly, and Avonex (BiogenIdec), given as a 30 *μ*g intramuscular injection once per week, 25% of the multiple sclerosis patients receiving Rebif were positive for neutralizing antibodies (defined as titers of ≥20 neutralizing units/mL), as compared to only 2% of patients receiving Avonex (*51*). Therefore, a higher dose given more frequently correlates with a higher incidence of neutralizing antibody formation. The ability to produce a PEGylated form of IFN-*β*-1a with high potency may enable a lower protein mass to be administered and possibly reduce the incidence and level of neutralizing antibodies. However, immunogenicity data from clinical trial(s) would be required to fully address this issue.

In summary, we have prepared a modified form of IFN-*β*-1a in which 20 kDa mPEG-O-2-methylpropionaldehyde is covalently attached to the N-terminal α-amino group of the protein. The modified protein retains ~50% of the in vitro antiviral and antiproliferative activity of the unmodified form, has improved pharmacokinetic properties in rats, and has improved efficacy with respect to its ability to inhibit the formation of tumor-induced blood vessels entering the periphery of human SK-MEL-1 melanoma tumors grown in athymic nude homozygous (*nu*/*nu*) mice. With the known efficacy of unmodified IFN-*β* in multiple sclerosis and HCV, this modified form of the protein may serve as a useful adjunct for the treatment of these diseases, not only in terms of potentially increasing efficacy but also by reducing dosing frequency, and thereby patient convenience and compliance. N-Terminally PEGylated IFN-*β*-1a may also be useful for the treatment of certain cancers, either as sole therapy or in combination with other drugs such as tamoxifen for example, that has been shown to have additive/synergistic antitumor effects when administered with IFN-*β* (*41*, *52*), or thalidomide, that has been shown to have synergistic antitumor effect when administered with IFN-α-2b (*42*).

Cellular Delivery of Polyheteroaromate−Peptide Nucleic Acid Conjugates Mediated by Cationic Lipids

Takehiko Shiraishi, Nadia Bendifallah, and Peter E. Nielsen*

Department of Medical Biochemistry and Genetics, The Panum Institute, University of Copenhagen, Blegdamsvej 3c, 2200 Copenhagen N, Denmark. Received August 11, 2005; Revised Manuscript Received November 8, 2005

In the search of facile and efficient methods for PNA cellular delivery, we have tested a series of PNA conjugates based on (hetero) aromatic, lipophilic compounds such as 9-aminoacridine, benzimidazoles, carbazole, anthraquinone, porphyrine, psoralen, pyrene, and phenyl-bis-benzimidazole ("Hoechst"). These chemically modified PNAs were delivered to cultured pLuc705HeLa cells mediated by cationic liposomes (LipofectAMINE or LiofectAMINE2000), and their nuclear delivery was inferred from induced luciferase activity as a consequence of pre-mRNA splicing correction by the antisense-PNA. PNAs modified with 9-aminoacridine, "Hoechst", or acetyl-"Hoechst" showed highest antisense activities (while unmodified PNA failed to show any significant antisense activity). In particular, bis-acridine-conjugated PNA showed nearly 60% splicing correction at 250 nM concentration in combination with LipofectAMINE2000. Interestingly, relative differences between the derivatives were observed when LipofectAMINE was used as compared to LipofectAMINE2000, but in general the latter yielded the higher antisense activity. The most active modifications of these PNA constructs were further tested for antisense down-regulation of luciferase in p53R cells in order to evaluate the cytoplasmic activity (uptake) of the PNAs. A dose-dependent down regulation of luciferase was demonstrated also in this system. The PNA conjugated to acetyl-Hoechst caused a reduction of luciferase activity to less than 40% of the control at a concentration of 1 μM. These results indicate that conjugation of (hetero) polyaromatic compounds to PNA can dramatically improve liposome-mediated cellular delivery both to cytoplasm as well as to the nucleus. However, no clear structure/activity relations are apparent from the present results, except that both 9-aminoacridine and "Hoechst" are also nucleic acid binding ligands.

INTRODUCTION

Peptide nucleic acids (PNA) (*1*) are potentially attractive candidates for discovery and development of gene therapeutic antisense and antigene drugs (*2*−*4*). However, rapid progress has been difficult because of a lack of facile and robust cellular delivery methods (*5*, *6*). Several methods have been devised, to improve the poor cellular uptake of the unmodified PNA. These methods involve conjugation of PNA to cell-penetrating peptides (*7*−*11*) (such as penetratin (*12*), transportan (*13*), oligo arginine (*14*), Tat-peptide (*15*), or a combination of these (*16*)) or the employment of cationic liposome carriers (*17*−*19*). In the former case, nontrivial synthesis of the conjugates is often encountered as well as relatively low efficacy of the conjugates due to endosomal entrapment (*11*). In the latter case, PNA modifications are required such as covalent (PNA-DNA chimera) (*20*) or noncovalent conjugation (PNA/DNA complexation by hybridization (*17*)) to DNA phosphodiester oligomers, or covalent conjugation to lipophilic compounds (*18*, *19*), all with the purpose of increasing the affinity of the PNAs for the cationic liposome carriers. Synthesis of PNA-DNA chimera requires tedious synthesis, and PNA/DNA hybrid transfection requires multistep transfection and careful optimization of the complementary DNA sequences for each PNA although this method is relatively efficient (*9*, *21*).

Conjugation of PNAs to fatty acids is straightforward and allows cationic liposome delivery of the conjugates (*18*, *19*), but unfortunately the conjugates have poor aqueous solubility and a high propensity for aggregation. However, we recently discovered that PNAs conjugated to the tricyclic, heteroaromatic DNA intercalator 9-aminoacridine can be effectively delivered to eucaryotic cells in culture by cationic lipids (*22*). We tentatively ascribed this effect of the acridine to its lipophilic character (of the nonprotonated form), combined with the reasonable aqueous solubility of the protonated form. These results would hold promise that other polycyclic heteroaromatic ligands could be identified that (more) effectively promote cationic lipid assisted PNA delivery.

To elucidate this possibility, we have synthesized eight new PNA conjugates with different lipophilic, polycyclic heteroaromatic ligands (including nucleic acid binding ligands) and tested these for lipid-mediated antisense activities both in HeLa pLuc 705 cells (splicing correction) and p53R cells (translational inhibition). These results show that simple modification of the PNAs with lipophilic compounds dramatically improved lipid-mediated delivery of the PNA both to cytoplasm as well as to the nucleus.

EXPERIMENTAL PROCEDURES

Synthesis of PNAs. The sequences and targets of the PNAs are listed in Table 1. PNA synthesis was carried out as reported previously (*23*). A variety of (hetero) polyaromatic ligands (Chart 1) obtained as carboxylic acid derivatives were covalently linked to PNA at the N-terminal on the solid support through a glycine, ethylene glycol linker (eg1, 8-amino-2,6-dioxaoctanoic acid) or 6-aminohexanoic acid (-aha-) via continuous synthesis (Table 1). All conjugates except those with benzimidazole and anthraquinone showed one major peak by reverse phase HPLC analysis of the raw product, and this was readily purified by HPLC and corresponded to the desired conjugates as characterized by MALDI-TOF mass spectrometry. The PNAs were lyophilized and stored at 4 °C until use, at which time they were dissolved in water and thereafter stored at −20 °C.

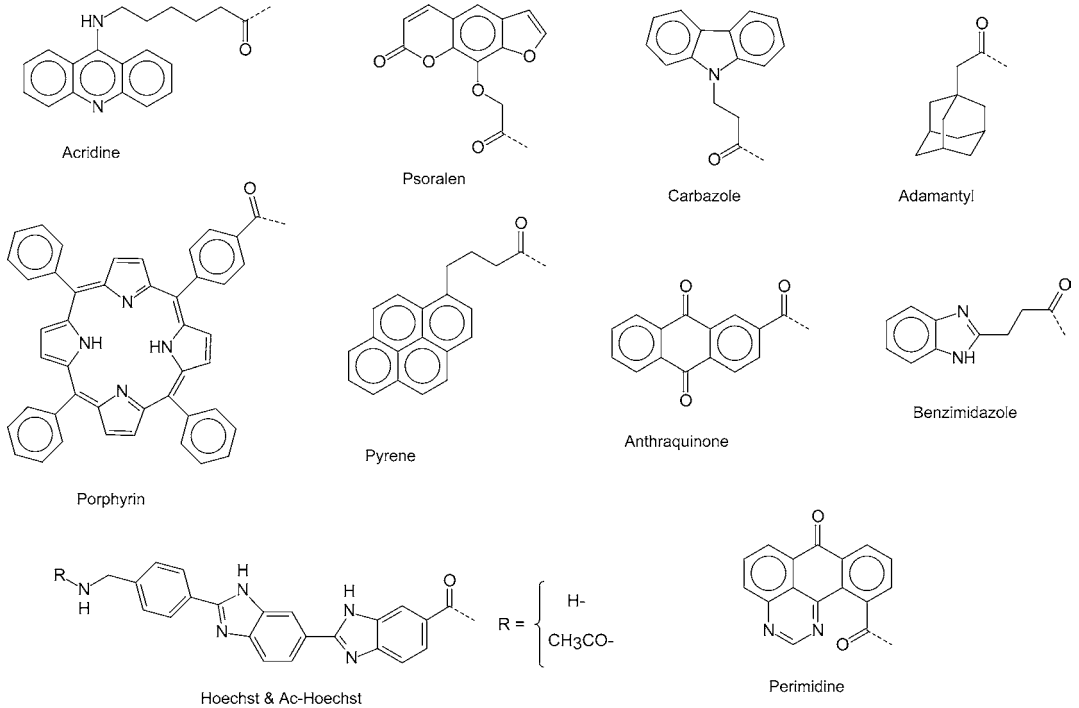
[a] 98+ corresponds to single HPLC peak; 95+ corresponds to single peak with slight foot. [b] Targeting aberrant splice site of luciferase pre-mRNA in HeLa pLuc705 cells. [c] Acr^{aeg} is a 9-aminoacridine monomer based on the aminoethylglycine PNA backbone (*27*). [d] Targeting translational initiation site of luciferase mRNA in p53R cells.

Chart 1. Chemical Structures of the Ligands Conjugated to PNA on the Solid Support[a]



[a] The carboxylic acid derivatives of the ligands were obtained from commercial sources (Sigma-Aldrich: adamantly, anthraquinone, benzimidazole, carbazole, perimidine, pyrene; Porhyrin Systems, Germany: porphyrin) or synthesized as described (acridine (*27*); Hoecshst (*28*); psoralen (*29*)).

Cell Culture. HeLa pLuc705 cells and p53R cells were purchased from Gene Tools and ATCC, respectively. The cells were cultured in RPMI-1640 medium (Sigma) supplemented with 10% fetal bovine serum (FBS), 1.5% glutamax (Gibco), penicillin (100 U/mL), and streptomycin (100 μg/mL) at 37 °C in humidified air with 5% CO_2. For the transfection studies in 96-well plate format, cells were trypsinized and seeded (1.2×10^4 cells/well) 16−24 h before transfection. For the 24-well plate, 7.2×10^4 cells/well were used.

Polyheteroaromate−PNA Conjugate Transfection. Cells, seeded in 96-well plates the day before transfections, were treated with 100 μL/well of OPTI-MEM (Gibco) containing the PNA/lipid complex at the desired concentration for 4 h. The PNA−lipid complex was formed by incubating 10 μL of PNA solution (in water) with LipofectAMINE (LFA, Invitrogen) or LipofectAMINE2000 (LFA2K, Invitrogen) in 10 μL OPTI-MEM for 5 min at room temperature. Following addition of 80 μL of OPTI-MEM, this mixture was added to the cells. (Concentrations of LFA or LFA2K were 12 μL/ml or 8 μL/ml (final concentration), respectively, unless otherwise stated). After 4 h incubation, 100 μL/well of growth medium (RPMI-1640 containing 20% FBS and 1.5% glutamax) was added to the transfection mixture and incubated further for 24 h. For the transfection in 24-well plate format, 0.25 mL/well of OPTI-MEM and growth medium were used.

PNA/DNA Heteroduplex Transfection. Cells, seeded in 24-well plates the day before transfections, were treated with 250 μL/well of OPTI-MEM (Gibco) containing the PNA/DNA/

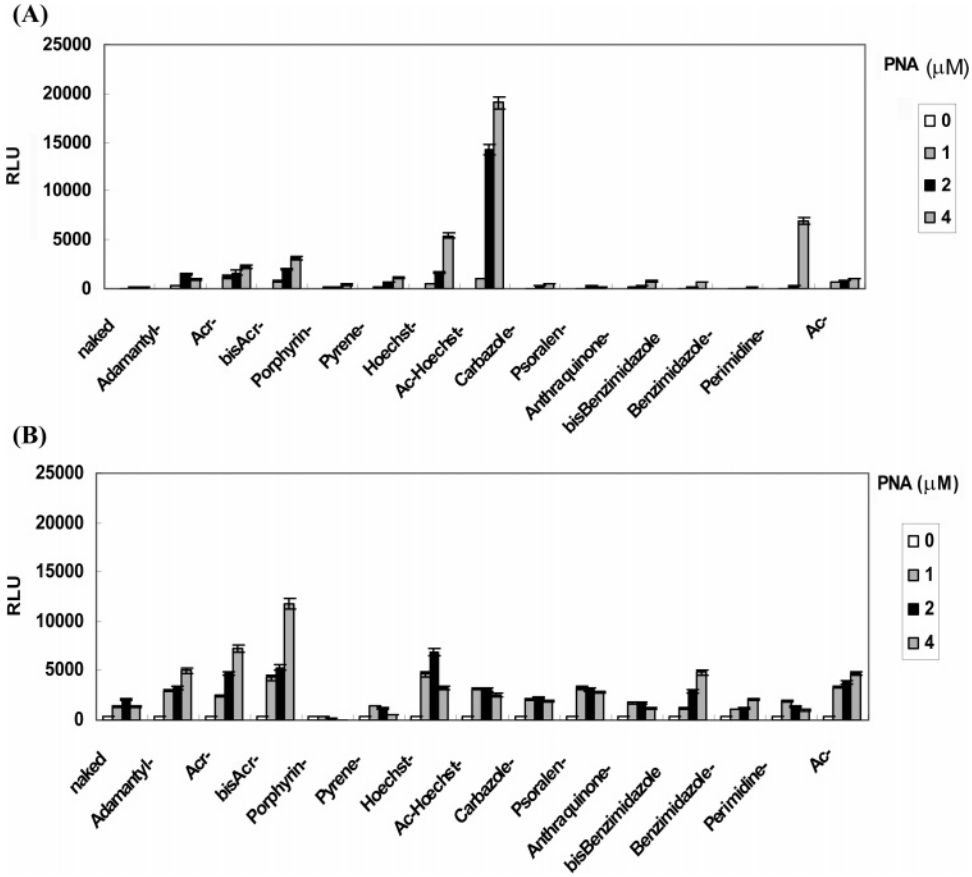


Figure 1. Screening of the PNAs conjugated with heteroaromatic compounds for the transfection in combination with cationic lipids. PNAs, targeting splicing correction, were listed in Table 1. PNAs were complexed with LipofectAMINE (LFA (A)) or LipofectAMINE2000 (LFA2K, (B)) and used for the transfection. HeLa pLuc705 cells were transfected with PNA/LFA or PNA LFA2K complex for 4 h in the absence of serum and incubated for an additional 24 h in the presence of serum. After PNA transfections, the cells were subjected to the luciferase assay with Bright-Glo assay (Promega). The values represent the mean ± SD of three experiments.

LFA2K complex at the desired concentration for 4 h. For the formation of PNA/DNA heteroduplex, PNA2389 was hybridized with DNA2389 (5′-AATATGTAACTGAGGTA-3′) as reported previously (*22*). The PNA/DNA heteroduplex was incubated with LFA2K in 50 μL of OPTI-MEM for 10 min and added to the cells after addition of 200 μL of OPTI-MEM. After 4 h transfection, 250 μL/well of growth medium (RPMI-1640 containing 20% FBS and 1.5% glutamax) was added to the transfection mixture and incubated further for 24 h.

Luciferase Assay. After PNA transfections, the cells were subjected to the luciferase analysis. Luciferase activity of the cells in 96-well plate format or 24-well plate format were measured by using Bright-Glo Luciferase assay system (Promega) or Luciferase Assay System (Promega), respectively, according to the manufacturer's instructions. Luminescent readings from 96-well plate formats (with background subtracted) are presented as relative light units (RLU). For the cells in 24-well plate formats, cell were lysed with Passive Lysis buffer (Promega) and subjected to the luciferase assay. Obtained RLU values were normalized by protein concentrations and are presented as RLU/mg protein. Protein concentrations were measured using BCA protein assay (Pierce) according to the manufacturer's instruction.

RT-PCR. Total RNA was extracted from the samples in Passive Lysis buffer using RNeasy Mini kit (Qiagen) according to the manufacturer's instruction. Three ng of total RNA was used for RT-PCR reaction (20 μL/reaction) by using OneStep RT-PCR kit (Qiagen). Primers for the RT-PCR were as follows: forward primer, 5′-TTGATATGTGGATTTCGAGTCGTC-3′; reverse primer, 5′-TGTCAAT-CAGAGTGCTTTTGGCG-3′. The RT-PCR program was as follows:{(55 °C, 35 min) × 1 cycle, (95 °C, 15 min) × 1 cycle, (94 °C, 0.5 min; 55 °C, 0.5 min; 72 °C, 0.5 min) × 26−28 cycles}. RT-PCR products were analyzed on 2% agarose gel with 1× TBE buffer and visualized by ethidium bromide staining. Gel images were captured by ImageMaster (Pharmacia Biotech) and analyzed by UN-SCAN-IT software (Silk Scientific Corporation).

RESULTS AND DISCUSSION

The PNA conjugates listed in Table 1 (splicing) were synthesized. These all contain the same PNA oligomer targeting the cryptic splice site within the luciferase gene in HeLa pLuc705 cells and previously shown to effectively correct missplicing of this modified luciferase gene and induce the production of normal luciferase protein (*22, 24*). Therefore, the antisense effect in this cellular system provides a very good measure of the cellular and nuclear uptake of the PNA conjugates. The PNAs were tested in combination with two types of cationic liposomes, LipofectAMINE (LFA) or LipofectAMINE 2000 (LFA2K) (Figure 1,parts A and B, respectively).

In this series of PNA conjugates, the PNA conjugated to the acetylated minor groove binder, "Ac-Hoechst" (Chart 1), showed the highest activity in combination with LFA (Figure 1A), being approximately 10 times more active than all other conjugates. As expected, unmodified PNA did not show any significant activities neither in the presence nor in the absence of cationic liposomes, but a few of the other new conjugates (apart from the already described adamantyl and acridine conjugates) were also active, in particular the Hoechst and the perimidine conjugates.

We also tested these PNAs in combination with a more recently introduced lipofection reagent, LFA2K (Figure 1B).

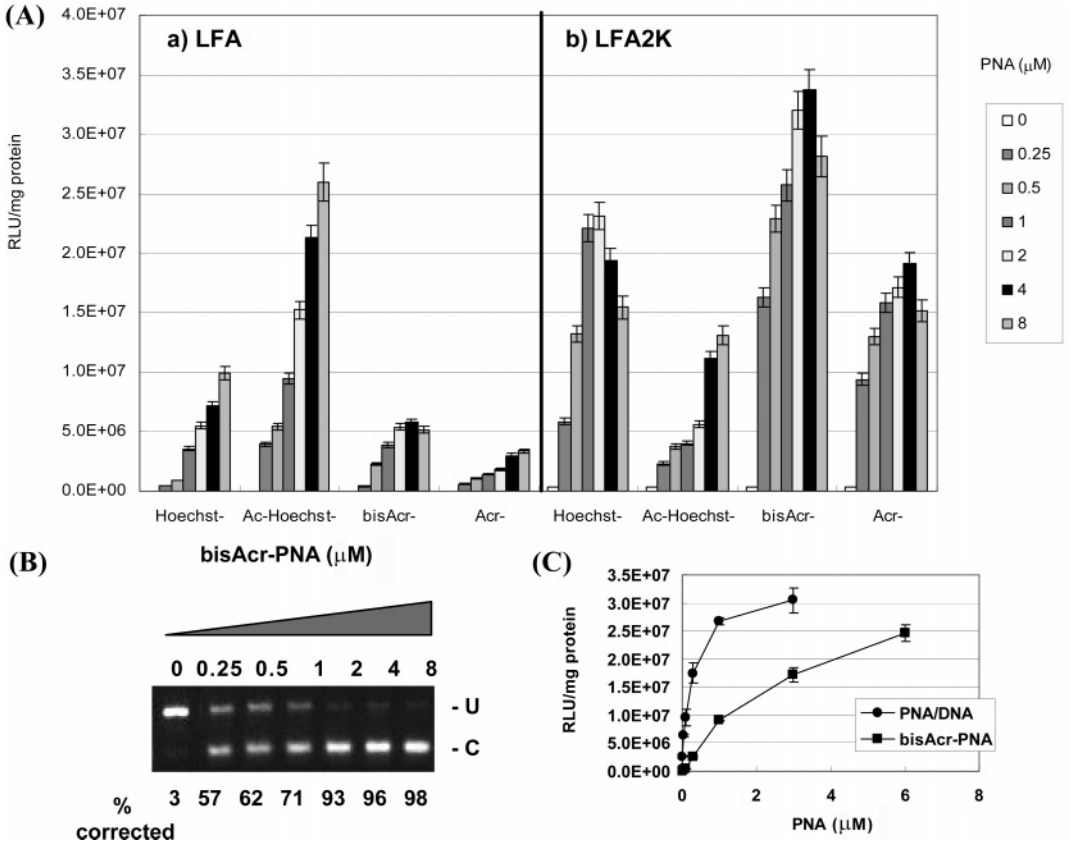

Figure 2. Transfection of the heteroaromate−PNAs (conjugated with Hoechst, acetyl-Hoechst (Ac-Hoechst), 9-aminoacridine (Acr), or bis-acridine (bisAcr)) or PNA/DNA heteroduplex in combination with LipofectAMINE (LFA) or LipofectAMINE2000 (LFA2K). (A) HeLa pLuc705 cells were transfected with Hoechst, Ac-Hoechst, Acr, and bisAcr−PNA in complex with LFA(a) or LFA2K (b) as mentioned in Figure 1. After 28 h transfection of the PNAs, cells were subjected to the luciferase analysis. Luciferase activities were measured using Luciferase Assay System (Promega) and normalized by protein concentration (shown as RLU/mg protein). The values represent the mean ± SD of three experiments. (B) RT-PCR analysis of the missplicing correction of luciferase pre-mRNAs by bisAcrPNA/LFA2k complex. Total RNA was extracted from the same samples in (A) and subjected to RT-PCR. U, fragments without mis-splicing correction (268 bp). C, fragments with mis-splicing correction (142 bp). The numbers under the figure indicate the relative amount (%) of the corrected form to the sum of corrected form and uncorrected form. (C) Comparison of cationic lipid mediated delivery between bisAcr−PNA and PNA/DNA heteroduplex. For the bisAcr−PNA transfection, PNA2490 was transfected to the cells in complex with LFA2K (8 μL/ml). For the PNA/DNA heteroduplex transfection, PNA2389 was hybridized with its complementary DNA (DNA2389) and transfected to the cells in complex with LFA2K (8 μL/mL). After 28 h transfection, cells were subjected to the luciferase analysis using Luciferase Assay System (Promega). Luciferase activity was normalized by protein concentration and shown as RLU/mg protein. The values represent the mean ± SD of three experiments.

Most of the PNA conjugates showed a higher effect than with LFA, and with this agent even unmodified and acetylated PNAs were somewhat active, but the best activity was observed with the acridine and in particular with a bis-acridine PNA conjugate. In contrast, Ac-Hoechst showed significantly lower activity than with LFA, while Hoechst PNA showed higher activity with LFA2K. These results clearly indicate the complexity of the lipid-mediated PNA delivery in terms of the combination of cationic liposome and auxiliary ligand. Thus, we decided to focus on the four seemingly most active PNA constructs (namely, Acr, bisAcr, Hoechst, and Ac-Hoechst) for further studies.

A more elaborate dose response experiment was performed with these four PNAs in combination with LFA and LFA2K (Figure 2A). These results confirm the results obtained from the initial screening (Figure 1) but provide a much more detailed picture of the activities. In particular, the superiority of the Ac-Hoechst conjugate in combination with LFA and the both relative and absolute superiority of the bis-acridine conjugate in combination with LFA2K is noteworthy. To further support that the increment of luciferase activity is indeed the result of splicing correction, we performed an RNA analysis by RT-PCR. Total RNA was extracted from the same samples as used for luciferase assay and subjected to RT-PCR analysis (Figure 2B). These results fully corroborate the enzyme activity data showing 57% splicing correction at 250 nM and essentially full correction at 2 μM.

However, it is important to realize that transfection experiments are not quantitatively reproducible from one set of experiments to the next due to differences in the exact state of the cell culture, subtle differences in the liposome preparation, etc. (Rasmussen, Nielsen, and Koppelhus et al., manuscript in preparation). Therefore, only results within the same experiment should be directly compared. In this context we performed a direct comparison of the antisense effect of the bis-acr−PNA conjugate delivered by LFA2K with that of the same unmodified PNA delivered by LFA2K as a sequence and length optimized DNA−PNA hybrid (Rasmussen, Nielsen, Koppelhus et al., manuscript in preparation). This experiment (Figure 2C) indicates that DNA mediated delivery is slightly (2−3-fold) more effective than "direct" delivery of the conjugate. Furthermore, the relative difference in efficacy most certainly will vary with cell type and gene target.

The antisense activity in the HeLa pLuc 705 cellular system only reflects the PNA concentrations in the nucleus although the size of the PNA molecules (<10 kDa) is considered sufficiently small not to hinder passage through the nuclear pores for efficient migration from the cytoplasm in to the nucleus. Indeed, it cannot be excluded that PNA oligomers and especially the conjugates with nucleic acid (DNA) binding ligands would

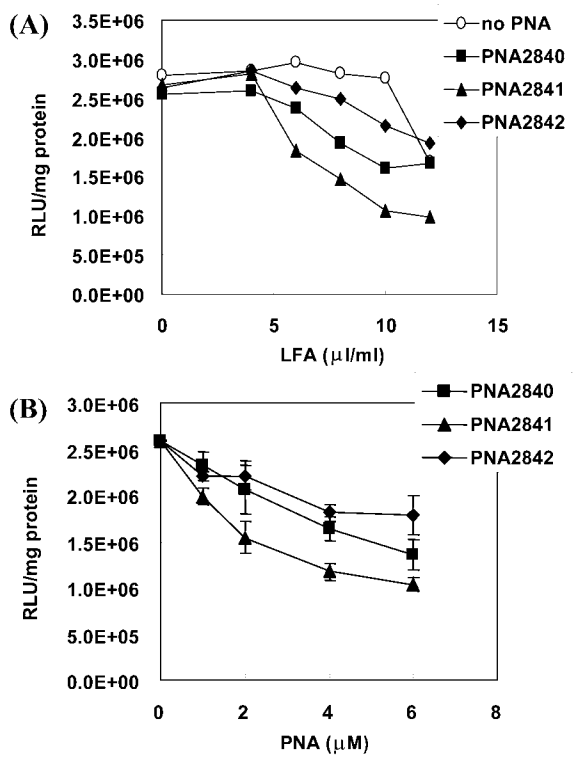

Figure 3. Screening of PNA sequences for the antisense down-regulation of luciferase in p53R cells. Three 9-aminoaridine-conjugated PNAs (15 mer), targeting three different position at the vicinity of start codon, were complexed with LipofectAMINE (LFA) and used for transfections. The p53R cells were transfected with PNA/LFA complex for 4 h and incubated for additional 24 h in the presence of serum. After 24 h, cells were subjected to the luciferase assay with luciferase assay (Promega). Luciferase activity was normalized by protein concentration and shown as RLU/mg protein. (A) Acr−PNA (2 μM) was complexed with the designated concentrations of LFA and used for transfections. Each data showed average of two independent experiments. (B) Different concentrations of Acr−PNAs were complexed with LFA (final concentration of 10 μL/ml) and used for transfections. The values represent the mean ± SD of three experiments

accumulate in the nucleus and thus possibly be depleted in the cytoplasm.

Therefore, to directly asses cytoplasmic delivery of the PNA conjugates by liposome-mediated transfection, we decided to test the transfection into p53R cells which are expressing normal luciferase. Initially, we tested three different PNA sequences (15 mer), targeting translation at three different locations at the vicinity of start codon, for the antisense down-regulation of luciferase in p53R cells. These PNAs (Table 1, 2840−2841) were modified by simple Acr derivatization because of the synthetic simplicity. For all PNAs (at 2 μM), an LFA-dose dependent decrease of luciferase activity was observed, while no such down-regulation was observed with LFA alone up to 10 μL/ml. However, a decrease in luciferase activity even for the control samples was seen at 12 μL/mL of LFA. This decrease is ascribed to a toxic effect of LFA itself. Based on this result, a dose−response experiment with the PNA complexed with LFA at 10 μL/mL was performed (Figure 3B). Among the three PNAs, PNA2841 showed the highest down-regulation at every concentration. With this PNA, the luciferase activity was decreased to 45% and 35% of the control at 4 μM and 6 μM PNA, respectively. Consequently, this PNA sequence (PNA2841) was selected for further studies, and we conjugated the PNA to Hoechst (PNA2882) or Ac-Hoechst (PNA2883). These three PNA conjugates (Acr−PNA, Hoechst−PNA, and Ac-Hoechst−PNA) were tested for their ability to down-regulate luciferase activity in p53R cells when delivered by LFA or LFA2K (Figure 4). In complex with LFA (Figure 4 A), Ac-Hoechst−PNA conjugate was the more active, whereas all three conjugates exhibited comparable activity when delivered with LFA2K (Figure 4B). It is noted that the absolute efficacy (corresponding to C_{50} values) of PNA-mediated gene silencing is considerable less in the p53R system as compared to the pluc705 system. We cannot at present provide the explanation for this difference as many factors may play a role: Two different molecular mechanisms that may exhibit different antisense sensitivities are involved, and these take place in two different cellular compartments (cytoplasm and nucleus). The sequence targets are unequally optimized, and the two cell types may respond differently to the (lipofection) delivery. However, the results unequivocally show that antisense targets in the cytoplasm as well as in the nucleus can be reached by the PNA conjugates via lipofection delivery.

CONCLUSION

The present results show that attachment of lipophilic poly (hetero) aromatic compounds to PNA can significantly improve cationic liposome-mediated cellular delivery of PNA oligomers uptake both to the cytoplasm as well as to the nucleus. It is also most likely that the activity of other uncharged antisense compounds such as the morpholino oligomers (*25*, *26*) should be improved through analogous conjugation. Although no clear structure/activity relationships are apparent from the present results, it is noteworthy that both 9-aminoacridine and "Hoechst"

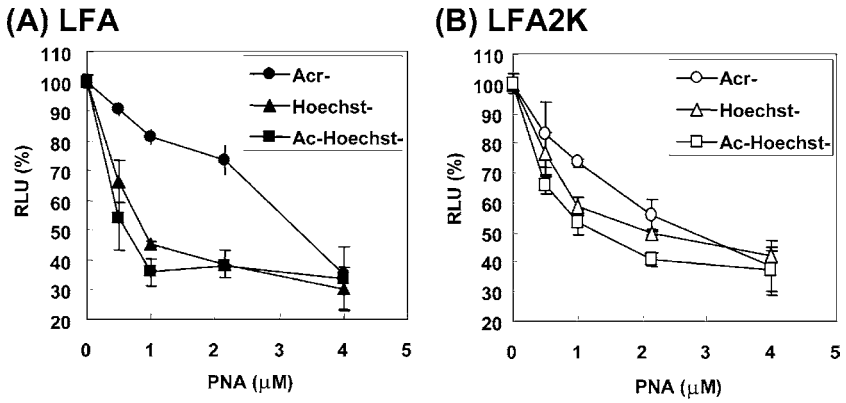

Figure 4. Comparison of antisense downregulation of PNAs conjugated with 9-aminoacridine (Acr−PNA), Hoechst (Hoechst−PNA), and acetyl Hoechst (Ac-Hoechst−PNA) in combination with LipofectAMINE (LFA) (A) or LipofecAMINE2000 (LFA2K) (B). PNA was complexed with LFA or LA2K and used for the transfections. p53R cells were transfected with PNA/LFA or PNA/LFA2K complex for 4 h and incubated for additional 24 h in the presence of serum. Luciferase activities were normalized by protein concentrations and showed as RLU/mg protein. The values represent the mean ± SD of three experiments.

which are the most active ligands in terms of uptake potentiation are also nucleic acid binding ligands. Furthermore, dsDNA targeted PNA oligomers conjugated to acridine or Hoechst have superior properties that can be exploited in the discovery of antigene agents (*30*, *31*). Therefore, these ligands may serve a dual role for PNA activity. In view of the number of alternative ligands that may be considered and possible combinations of these, it is likely that more potent conjugates may be discovered. The possibility of exploiting cleavable linkers could also be explored.

Synthesis and Evaluation of Glycosylated Octreotate Analogues Labeled with Radioiodine and ^{211}At via a Tin Precursor

G. Vaidyanathan,*,† D. J. Affleck,† M. Schottelius,‡ H. Wester,‡ H. S. Friedman,§ and M. R. Zalutsky†

Departments of Radiology and Neurooncology, Duke University Medical Center, Durham, North Carolina 27710 and Technical University of Munich, Munich, Germany. Received August 19, 2005; Revised Manuscript Received October 18, 2005

Carbohydration of N-terminus and substitution of a threonine for the threoninol residue at the C-terminus of Tyr^3-octreotide (TOC) has resulted in improved pharmacokinetics and tumor targeting of its radioiodinated derivatives. Yet, these peptides are very susceptible to in vivo deiodination due to the similarity of monoiodotyrosine (MIT) to thyroid hormone. The goal of this work was to develop octreotate analogues containing both a sugar moiety and a nontyrosine prosthetic group on which a radioiodine or ^{211}At can be introduced. Solid-phase synthesis and subsequent modifications delivered an iodo standard of the target peptide N^{α}-(1-deoxy-D-fructosyl)-N^{ϵ}-(3-iodobenzoyl)-Lys^0-octreotate (GIBLO) and the corresponding tin precursor N^{α}-(1-deoxy-D-fructosyl)-N^{ϵ}-[(3-tri-*n*-butylstannyl)benzoyl]-Lys^0-octreotate (GTBLO). GIBLO displaced [^{125}I]TOC from somatostatin receptor subtype 2 ($SSTR_2$)-positive AR42J rat pancreatic tumor cell membranes with an IC_{50} of 0.46 ± 0.05 nM suggesting that GIBLO retained affinity to $SSTR_2$. GTBLO was radiohalogenated to [^{131}I]GIBLO and N^{α}-(1-deoxy-D-fructosyl)-N^{ϵ}-(3-[^{211}At]astatobenzoyl)-Lys^0-octreotate ([^{211}At]GABLO) in 21.2 ± 4.9% and 46.8 ± 9.5% radiochemical yields, respectively. From a paired-label internalization assay using D341 Med medulloblastoma cells, the maximum specific internalized radioactivity from [^{131}I]GIBLO was 1.78 ± 0.8% of input dose compared to 9.67 ± 0.43% for N^{α}-(1-deoxy-D-fructosyl)-[^{125}I]iodo-Tyr^3-octreotate ([^{125}I]I-Gluc-TOCA). Over a 4 h period, the extent of internalization of [^{131}I]GIBLO and [^{211}At]GABLO was similar in this cell line. In D341 Med murine subcutaneous xenografts, the uptake of [^{125}I]I-Gluc-TOCA at 0.5, 1 and 4 h was 21.5 ± 4.0% ID/g, 18.8 ± 7.7% ID/g, and 0.9 ± 0.4% ID/g, respectively. In comparison, these values for [^{131}I]GIBLO were 6.9 ± 1.2% ID/g, 4.7 ± 1.4% ID/g, and 0.8 ± 0.5% ID/g. Both in vitro and in vivo catabolism studies did not suggest the severance of the lys^0 along with its appendages from the peptide. Taken together, although GIBLO maintained affinity to $SSTR_2$, its tumor uptake both in vitro and in vivo was substantially lower than that of I-Gluc-TOCA suggesting other factors such as net charge and overall geometry of the peptide may be important.

INTRODUCTION

The expression of high levels of somatostatin receptors (SSTR[1]) on a variety of tumors has provided the impetus for the development of radiolabeled octreotide derivatives, which target SSTR, and can be utilized for imaging and treating these cancers (*1*−*3*). Among the radionuclides investigated for these purposes are those of iodine, which have a range of physical characteristics suited for a variety of imaging (SPECT, PET) and therapy (*β*-particle, Auger electron) approaches. Direct radioiodination of peptides is achieved by substitution on constituent tyrosine residues; the absence of tyrosines in octreotide led to the development of Tyr^3-octreotide (TOC) (*4*). Although TOC can be readily labeled, it is not a useful radiopharmaceutical because it exhibits only marginal tumor targeting, due in part to the fact that it undergoes rapid deiodination.

A number of TOC structural modifications have been investigated with the goal of providing a labeled peptide with greater clinical potential. These include N-terminal sugar conjugation and Thr-for-Thr(ol) exchange (octreotide → octreotate), both of which have been shown to improve the intracellular retention of radioiodine in vitro as well as tumor-to-normal tissue ratios in mice bearing SSTR-expressing xenografts (*5*, *6*). Synergistic enhancements in tumor targeting were achieved when both tactics were combined, exemplified by the results obtained with N^{α}-(1-deoxy-D-fructosyl)-[^{131}I]I-Tyr^3-octreotate ([^{131}I]I-Gluc-TOCA). For example, 1 h after injection, tumor uptake of [^{131}I]I-Gluc-TOCA was about 5 times higher than that of coadministered [^{125}I]TOC (*7*).

An important consideration in peptide radiohalogenation is whether the procedure utilized for radioiodination can also be adapted for use with ^{211}At. Astatine-211 is a radiohalogen that emits α-particles, a type of radiation with many potential advantages for targeted radiotherapy, notably a higher cytotoxicity compared to *β*-particles (*8*). Furthermore, its half-life of 7.2 h is well matched to peptide pharmacokinetics. Even though peptides such as Gluc-TOCA offer many advantages compared with TOC, they still undergo radiohalogenation by direct substitution on Tyr^3. With radioiodine, this feature results in

extensive deiodination in vivo, presumably due to recognition by endogenous deiodinases; with ^{211}At, the known instability of astatotyrosine even under in vitro conditions excludes direct radioastatination as a viable labeling strategy (*9*, *10*).

To circumvent these problems, we have developed derivatives of octreotide and octreotate in which the radiohalogen resides in a prosthetic group attached to the N-terminus of the peptide (*11*, *12*). Radioiodinated and ^{211}At-labeled peptides could be synthesized in reasonable yield and were shown to be resistant to dehalogenation. Moreover, the second generation peptide, *N*-(4-guanidinomethyl-3-iodobenzoyl)-Phe^1-octreotate (GMIBO) had a significantly higher intracellular accumulation in vitro compared with [^{125}I]I-Gluc-TOCA (*12*). Unfortunately, normal organ levels, particularly in the liver and kidney, of [^{131}I]GMIBO were several-fold higher than those of [^{125}I]I-Gluc-TOCA, consistent with previous results demonstrating the ameliorative effects of N-terminal sugar conjugation on normal tissue uptake.

The goal of this study was to investigate the strategy of synthesizing an SSTR-avid peptide combining the three structural elements noted above: N-terminal sugar conjugation, Thr-for-Thr(ol) exchange, and a prosthetic group carrying the radiohalogen. Glucose was selected as the sugar, and as the prosthetic group, the halobenzoyl template was utilized (Chart 1). Because two functional groups are needed to attach these two subunits, an extra lysine was introduced at the N-terminus of octreotate. The synthesis, radiohalogenation, and evaluation of the radiohalogenated peptides are described herein.

EXPERIMENTAL PROCEDURES

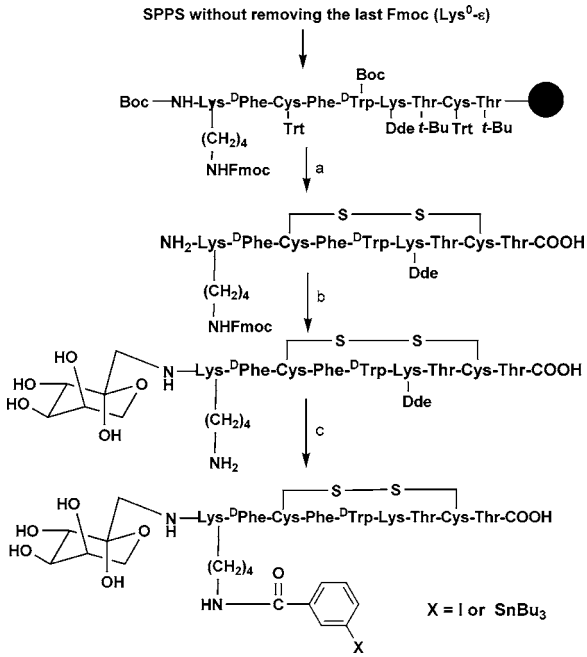
General. All chemicals were purchased from Sigma-Aldrich unless otherwise noted. Sodium [^{125}I]iodide and sodium [^{131}I]-iodide with specific activities of 2200 Ci/mmol and 1200 Ci/mmol, respectively, were obtained from Perkin-Elmer Life and Analytical Sciences (Boston, MA). The ^{211}At activity was produced on the Duke University Medical Center CS-30 cyclotron via the ^{209}Bi(α, 2n)^{211}At reaction by bombarding natural bismuth metal targets with 28 MeV α-particles (*13*), and the radioactivity was isolated from the target by dry distillation and extracted into chloroform. Unlabeled *N*-succinimidyl 3-iodobenzoate (SIB) as well as *N*-succinimidyl 3-(tri-*n*-butyl)stannylbenzoate (STB) were synthesized as reported (*14*). Octreotide (Sandostatin) was purchased as an aqueous solution (0.5 mg/mL) from the Duke University Medical Center Pharmacy (Durham, NC). TCP (trityl chloride polystyrene) resin was purchased from PepChem (Tubingen, Germany). Appropriately protected amino acids were obtained from Novabiochem (Bad Soden, Germany).

Solid-phase peptide syntheses were carried out manually using a flask shaker (St. Johns Associates, Inc., Beltsville, MD). Three HPLC systems were used. For radiochemistry, either of two Beckman systems (System Gold) was used. System 1 was equipped with a Model 126 programmable solvent module, a Model 168 diode array detector, and a Model 170 radioisotope detector, which was interfaced using a Model 406 analog interface module. System 2 was equipped with a Model 126 programmable solvent module, a Model 166 NM variable wavelength detector, a Model 170 radioisotope detector, and a Beckman System Gold remote interface module SS420X; data were acquired using 32 Karat software. For nonradioactive and preparative work, a Waters Model Delta 600 semi-prep system with a Model 600 controller and a Model 2487 dual wavelength absorbance detector were used; data were acquired using Millenium software. Waters XTerra C18 columns of dimensions 4.6 $\times$ 250 mm (5 μm) and 19 $\times$ 150 mm (7 μm) were used for analytical and semipreparative chromatography, respectively. Mass spectra were obtained on either a JEOL SX-102 high-resolution mass spectrometer (FAB), an Applied Biosystems Voyager DE Pro (MALDI), or an Agilent 1100 LC/MSD Trap SL (electrospray). Amino acid analysis was performed at the Protein Chemistry Lab, University of North Carolina (Chapel Hill, NC).

Peptide Syntheses. *Gluc-TOCA.* As reported previously (*7*), Tyr^3-octreotate, with its Lys^5, ϵ-amino function protected with a Dde group, was prepared by solid-phase synthesis. The peptide was cleaved from the resin and cyclized. The N-terminal amino group was glycosylated via a Maillard reaction and the Dde group was subsequently removed.

N$^\alpha$-(1-Deoxy-D-fructosyl)-N$^\epsilon$-(3-iodobenzoyl)-Lys^0-octreotate (GIBLO). The peptide sequence Boc-Lys(Fmoc)-DPhe-Cys-(Trt)-Phe-DTrp(Boc)-Lys(Dde)-Thr(tBu)-Cys(Trt) (Scheme 1) was assembled on resin-bound Thr(tBu) by manual solid-phase synthesis using the standard Fmoc protocol. The peptide was cleaved from the resin, cyclized, and glycosylated as reported previously for similar peptides (*2*, *5*, *6*). Then, the Fmoc protecting group on the Lys^0 side chain was removed using 20% piperidine in DMF and purified using preparative reversed-phase HPLC. To the above peptide (3.5−4 mg) in a 1 mL Reacti-vial was added a solution of SIB (5 mg) in 0.2 mL of 1% TEA in DMF. The homogeneous reaction mixture was left at room temperature under argon for 18 h. The progress of reaction was followed by analytical HPLC using the following gradient: 0.1% (w/v) TFA in water (solvent A) and 0.1% (w/v) TFA in acetonitrile (solvent B) at a flow rate of 1 mL/min, with %B increased from 30 to 60 over 30 min and then to 90 over another 10 min and then held at 90 for 5 min. The retention times of the starting peptide, SIB, and the SIB-modified peptide were 17.0, 26.8, and 24.9 min, respectively. The SIB modified peptide was precipitated by the addition of a large excess of ether, isolated by centrifugation, and washed several times with ether. MS (MALDI) *m*/*z*: Calcd for $C_{78}H_{101}IN_{12}O_{20}S_2$: 1717.7. Found: 1717.6 (M^+), 817.8, 556.5. The above peptide was taken

Scheme 1. Synthesis of GIBLO and Its Tin Precursor[a]



[a] Reagents and conditions: (a) i. 95:2.5:2.5 (v/v/v/) TFA:water: triisopropylsilane, ii. H_2O_2, THF, 0.05 M NH_4OAc; (b) i. D-glucose, HOAc/MeOH, ii. 20% piperidine in DMF; (c) i. *N*-succinimidyl 3-iodobenzoate or *N*-succinimidyl 3-(tri-n-butylstannyl)benzoate, DIEA/NMP, ii. 1:1 ethanolamine:EtOH.

up in 2.5 mL of ethanol, and 0.5 mL of ethanolamine was added. The reaction was determined to be complete in 1 h by HPLC (t_R = 16.9 min for the final product). The product was isolated by semipreparative HPLC using the same solvents and gradient described above but at a flow rate of 10 mL/min and using the semipreparative column. Solvents were evaporated from the HPLC fractions, and the peptide was redissolved in ethanol. The concentration of this solution was determined by amino acid analysis. MS (MALDI) *m*/*z*: Calcd for $C_{68}H_{89}IN_{12}O_{18}S_2$: 1553.5. Found: 1553.6 (M^+).

N^{α}-(1-Deoxy-D-fructosyl)-N^{ϵ}-(3-tri-n-butylstannyl-benzoyl)-Lys⁰-octreotate (GTBLO). This was prepared essentially as above but with STB as the acylation agent. The intermediate peptide with the Dde group had a retention time of 41.5 min (vs 49 min for STB) under the HPLC conditions used for GIBLO. MS (FAB^+) *m*/*z*: Calcd for $C_{90}H_{128}N_{12}O_{20}S_2{}^{120}Sn$: 1882.1. Found: cluster peaks around 1883.6 $(M + H)^+$. For the final step (removal Dde) a different gradient was used for both analytical and semipreparative chromatography. The solvents used were 0.2% HOAc in 30% methanol in water (A) and 0.2% HOAc in 90% MeOH in water (B). The %B was increased from 0 to 100 over 30 min and then run for another 10 min. The retention time of the product peptide under the analytical conditions was 29.5 min. MS (MALDI) *m*/z: Calcd for $C_{80}H_{116}N_{12}O_{18}S_2{}^{120}Sn$: 1717.9. Found: 1740 $(M + Na)^+$, 1717.5 (M^+).

N^{α}-(1-Deoxy-D-fructosyl)-Lys⁰(Dde)-TOCA (Gluc-Lys⁰-TOCA-Dde). This was synthesized as reported before (*15*, *16*).

N^{α}-(1-Deoxy-D-fructosyl)-N^{ϵ}-(3-iodobenzoyl)-lysine. This compound was synthesized for use as an HPLC standard. To a suspension of N^{α}-Boc-N^{ϵ}-(3-iodobenzoyl)lysine (*17*) (24 mg; 0.05 mmol) in 0.2 mL of methylene chloride in a Reacti-vial was added 0.2 mL of TFA, and the mixture was stirred at room temperature for 30 min. The solvents were evaporated using a stream of argon, and the residue was taken up in 0.5 mL of 5% acetic acid (v/v) in methanol. To the resultant solution was added 90 mg of α-D-glucose, and the capped vial was heated overnight at 60 °C. The reaction was followed by reversed-phase HPLC. For this, the analytical column was eluted at 1 mL/min with a gradient consisting of 0.1% TFA in each 90:10 water:acetonitrile (solvent A) and 10:90 water:acetonitrile (solvent B). The %B was held at 0 for 10 min, increased to 100 over the next 30 min, and held at 100 for another 5 min. Under these conditions, the starting material had a t_R of 25.1 min and the product, 24.3 min. Because HPLC analysis did not indicate much progress in the reaction, 107 mg of α-D-glucose in 1.3 mL of solvent was added and the heating continued for 2 days, after which only moderate progress was seen. Semipreparative HPLC using the same gradient as above at a flow rate of 10 mL/min yielded 0.6 mg of product: MS (ESI) *m*/*z*: 539.72 (MH^+); 561.52 $(M + Na)^+$ (100%); 583.02 $(M + 2Na - H)^+$.

Radiohalogenation. *[^{125}I]I-TOC and [^{125}I]I-Gluc-TOCA.* These were prepared as reported (*7*). Briefly, to a solution of sodium [^{125}I]iodide (1−2 mCi in 3 μL of 0.1 N NaOH) in a Reacti-vial was added 20 μL of 0.05 M phosphate buffer (pH 7.5) and a solution of 14 μg of Gluc-TOCA in 20 μL 0.05 M acetic acid. After vortexing this mixture, 0.16 μg of Chloramine-T in 20 μL of the above phosphate buffer was added. After a 1-min reaction at room temperature, the labeled peptide was isolated from the reaction mixture by reversed-phase HPLC.

[^{131}I]I-Gluc-Lys⁰-TOCA. Gluc-Lys⁰-Lys⁵(Dde)-TOCA was labeled with ^{131}I essentially as described above for [^{125}I]I-Gluc-TOCA. The reaction mixture was passed through an activated C-18 cartridge, which was further washed with 2 × 5 mL water, and the product was eluted with 0.25 mL portions of ethanol. The fractions containing the product were pooled and ethanol was evaporated. To the residual activity, 10 μL of a solution of hydrazine in DMF (2% v/v) was added. Ten minutes later, the reaction mixture was diluted with 25 μL of ethanol and injected onto a reversed-phase HPLC column. It was eluted with a linear gradient (10−40% B over a period of 30 min) consisting of solvents 0.1% TFA in water (A) and 0.1% TFA in acetonitrile (B) at a flow rate of 1 mL/min. The retention times of [^{131}I]I-Gluc-Lys⁰-TOCA and its Dde-protected precursor under these conditions were 26.1 and 36.2 min, respectively. The fractions containing the final labeled product were isolated and concentrated by solid-phase extraction as described above for the intermediate peptide.

[^{131}I]GIBLO and [^{211}At]GABLO. A solution of GTBLO (∼100 μg) in ethanol (50 μL) was transferred to a 1 mL Reacti-vial and the ethanol was evaporated with a gentle stream of argon. To this were added ^{131}I (0.5−2 mCi in 1−3 μl) and *N*-chlorosuccinimide (5 μg in 10 μL of HOAc), and the mixture was sonicated at room temperature for 2 min. The entire reaction mixture was injected into an analytical reversed-phase column. The column was eluted using the gradient described for the synthesis of unlabeled GIBLO (t_R = 17−18 min). The labeled peptide was isolated in 21.2 ± 4.9% radiochemical yields. For astatination, the ^{211}At activity in chloroform was first extracted into 1−2 μL of 0.1 N NaOH in a Reacti-vial, and the procedure described above for iodination was followed. [^{211}At]GABLO was obtained in about 46.8 ± 9.5% radiochemical yields. The HPLC fractions containing the labeled peptide were concentrated using a C18 solid-phase cartridge. A Waters tC18ENV Sep-pak cartridge was activated by elution with 5 mL each of water and ethanol. HPLC fractions were purged with an argon stream to remove most of the acetonitrile, diluted with water, and passed through the solid-phase cartridge. The cartridge was washed twice with 5 mL of water and then eluted with 0.25 mL portions of ethanol. The labeled peptide generally eluted in fractions 4−6. Ethanol was evaporated from the combined fractions, and the product was reconstituted in PBS containing 1% BSA.

Cells and Culture Conditions. The SSTR-expressing AR42J rat pancreatic tumor cell line (*18*) was obtained from American

Type Culture Collection (Manassas, VA) and grown in DMEM containing 2 mM glutamine, 10% FCS, and 5 g/L glucose. D341 Med is a human medulloblastoma cell line derived from a patient tumor biopsy (*19*) and grown in 10% FCS and zinc option medium. Cells were maintained in a humidified atmosphere (37 °C, 5% CO_2).

Receptor Binding Assay. The SSTR receptor binding affinity of GIBLO was determined by a competitive binding assay using AR42J membranes according to a literature protocol (*20*). About 50 μg of membranes was incubated in triplicate at 37 °C for 1 h with ~25 nCi of [^{125}I]TOC in the absence or presence of various concentrations of unlabeled GIBLO or octreotide. Radioactivity bound to the membranes in the presence of 50 nM unlabeled peptide was considered to be nonspecific binding. The IC_{50} values were calculated from the specific binding versus peptide concentration plots.

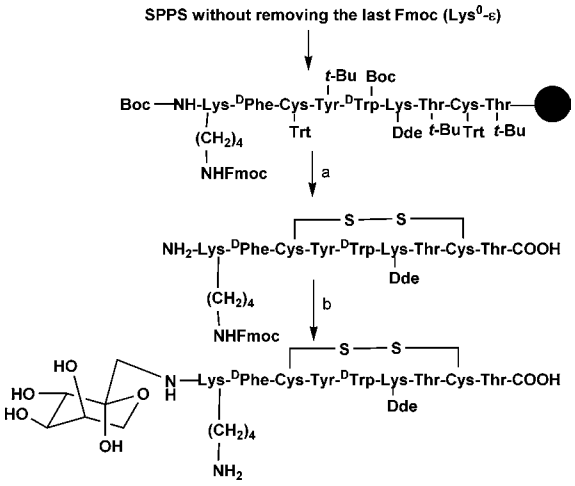
Internalization Assay. Three paired-label assays were performed following a previously reported protocol (*12*). D341 Med cells (5×10^5 per tube per mL) were incubated at 37 °C with (a) [^{125}I]I-Gluc-TOCA (5.1 fmol) and [^{131}I]GIBLO (31.0 fmol), (b) [^{131}I]GIBLO (19.4 fmol) and [^{211}At]GABLO (0.02 fmol), or (c) [^{125}I]I-Gluc-TOCA (13.8 fmol) and [^{131}I]I-GIu-Lys^0-TOCA (2.6 fmol) for 0.5, 1, 2, 3, and 4 h. At each time point, radioactivity in the cell culture supernatant, that bound to the cell surface, and that trapped inside the cells were determined. The percent of input dose that was internalized was plotted versus the time.

Tissue Distribution Experiments. Animal studies were performed under the guidelines established by the Duke University Institutional Animal Care and Use Committee. Athymic BALB/c-nu (SPF) mice weighing 20−25 g with subcutaneous D341 Med human medulloblastoma xenografts were utilized (*19*). The biodistribution studies were initiated when tumors were about 200−300 mm^3. Mice received 4 μCi of [^{125}I]I-Gluc-TOCA and 3 μCi of [^{131}I]GIBLO via the tail vein and groups of five animals were killed 0.5,1, 4, 16, and 24 h after injection. Mice were killed with an overdose of halothane, dissected and tissues of interest were isolated, weighed, and counted in a dual channel gamma counter. A paired Student's *t* test was used to determine the statistical significance of differences between the two peptides.

Paired-Label Catabolism [^{125}I]I-Gluc-TOCA and [^{131}I]-GIBLO. *In Vitro*. The internalization assay described above was repeated at 0.5 and 4 h with 10 μCi of each tracer. After washing off cell surface-bound radioactivity, the cells were lysed in 100 μL of 0.5% NP-40 in PBS. Reversed-phase HPLC of cell culture supernatant, cell lysate, and acid washes were performed along with intact peptide standards, 3-iodotyrosine, and N^{α}-(1-deoxy-D-fructosyl)-N^{ϵ}-(3-iodobenzoyl)-lysine. For this, a C-18 analytical column was eluted at 1 mL/min with a gradient consisting of solvents A, 0.1% TFA in water, and B, 0.1% TFA in acetonitrile. The percent B was held at 10 for 10 min and then increased to 90 over 30 min. Under these conditions, the retention times of I-Gluc-TOCA, GIBLO, 3-iodotyrosine, and N^{α}-(1-deoxy-D-fructosyl)-N^{ϵ}-(3-iodobenzoyl)-lysine were 25−26 min, 29−30 min, 18−19 min, and 25−26 min, respectively.

In Vivo. Two groups of three mice bearing the D-341 Med xenografts were injected with 10 μCi of each tracer. Necropsies were performed 0.5 and 1 h postinjection, and blood, urine, liver, kidney, and tumor were obtained. Serum was isolated from blood by centrifugation and urine was filtered through a Spin-X filter (Corning, New York, NY). Tissues were homogenized in 2 mL of 80:20 EtOH:HEPES (1.0 M, pH 7.0) with a hand-held homogenizer. The homogenates were centrifuged, and the pellets were extracted once more with one volume of the solvent.

Scheme 2. Synthesis of Gluc-Lys^0-Lys^5(Dde)-TOCA[a]



[a] Reagents and conditions: (a) i. 95:2.5:2.5 TFA:water:triisopropylsilane, ii. H_2O_2, THF, 0.05 M NH_4OAc; (b) i. D-glucose, HOAc/MeOH. ii. piperidine.

Aliquots of the combined supernatants were analyzed by HPLC as described above.

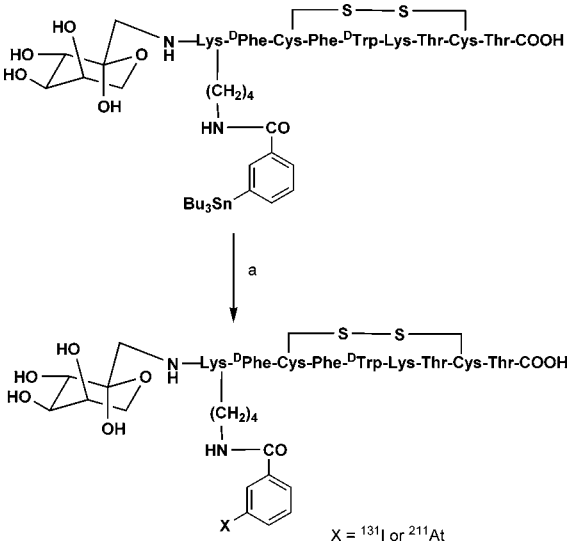
RESULTS AND DISCUSSION

The goal of this study was to synthesize an octreotate−glucose conjugate that also possessed a pendant group on which radioiodine or ^{211}At could be introduced in a stable fashion via a halodestannylation reaction in a single radiochemical step. To accomplish this, it was necessary to append an extra lysine at the N-terminus of octreotate. Because a tyrosine residue might compete with the tin precursor as a radioiodination site, octreotate was chosen as the peptide instead of TOCA. Unfortunately, a disadvantage of this approach is that the higher lipophilicity of octreotate compared with TOCA has been shown to yield less favorable pharmacokinetics (*21*, *22*).

Solid-phase peptide synthesis without the removal of the Fmoc group in the last step and subsequent cleavage from the resin delivered the N^{ϵ}-Fmoc-Lys^0-N^{ϵ}-Dde-Lys^5-octreotate (Scheme 1). A fructose unit was appended to the α amino group of Lys^0 of this peptide via a Maillard reaction with glucose and subsequent Amadori rearrangement (*23*). The Fmoc group on the ϵ-amino group of Lys^0 was removed, and the resultant peptide was treated with either *N*-succinimidyl 3-iodobenzoate (SIB) or *N*-succinimidyl 3-(tri-*n*-butylstannyl)benzoate (STB). Removal of the Dde group from the ϵ-amino group of Lys^5 of these peptides delivered the iodo standard of the target peptide (GIBLO; Chart 1) and its tin precursor, respectively. To investigate the effect of an extra lysine (Lys^0), Gluc-Lys^0-Lys^5(Dde)-TOCA was also synthesized (Scheme 2). The peptide was assembled on the resin as for the GIBLO synthesis except a Tyr^3 instead of a Phe^3 was used. The target peptide was obtained by glycosylation and subsequent removal of the Fmoc group (*15*, *16*).

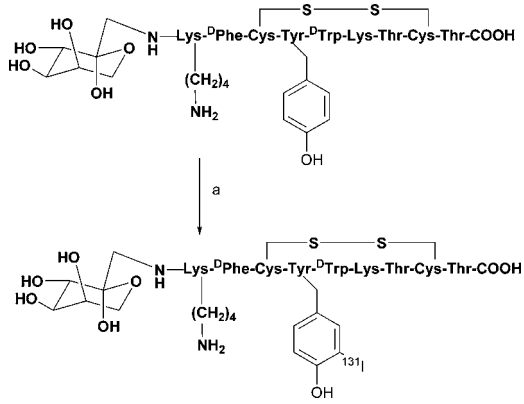
Radioiodination of the tin precursor with *N*-chlorosuccinimide as the oxidant and acetic acid as the solvent gave [^{131}I]GIBLO in about 21.2 ± 4.9% radiochemical yield (n = 10) (Scheme 3). The radiochemical yield of [^{211}At]GABLO was 46.8 ± 9.5% (n = 5); the difference between radioiodination and astatination yields is statistically significant. These results are enigmatic as astatination of the same tin precursor generally gives somewhat lower yields than radioiodination, presumably due to steric hindrance caused by the larger atomic size of astatine. It should be noted, however, that a radioactive peak of similar size as the product but with slightly higher retention time was seen in the HPLC trace of the radioiodination reaction mixture; the

Scheme 3. Synthesis of [*I]GIBLO and [^{211}At]GABLO



[a] Reagents and conditions: (a) ^{131}I or ^{211}At, NCS, HOAc.

Scheme 4. Radioiodination of Gluc-Lys^0-TOCA



[a] Reagents and conditions: (a) ^{131}I, Chloramine-T, phosphate buffer.

intensity of this peak was considerably lower in the case of astatination. The radiochemical purity of the labeled peptides was >90% with no detectable coeluting UV peaks present.

[^{131}I]I-Gluc-Lys^0-TOCA also was synthesized to investigate the effect of an extra lysine at the N-terminus on peptide behavior. Although it should be possible to remove the Dde protecting group from Gluc-Lys^0-Lys^5(Dde)-TOCA and generate [^{131}I]I-Gluc-Lys^0-TOCA from the resultant peptide in a single radiochemical step, we opted to first label Gluc-Lys^0-Lys^5(Dde)-TOCA and then remove the Dde group (Scheme 4) simply because of the limited availability of Gluc-Lys^0-Lys^5(Dde)-TOCA. Only a few reactions could be attempted, and [^{131}I]I-Gluc-Lys^0-TOCA was obtained after two steps in 25% radiochemical yield and >95% radiochemical purity.

The affinity of GIBLO was measured indirectly by a competitive binding assay using AR42J rat pancreatic tumor membranes. The "gold standard" approach in the literature used to determine the binding affinity of octreotide derivatives to SSTR involves the use of $SSTR_2$-expressing AR42J membranes. The ability of GIBLO to displace [^{125}I]TOC bound to AR42J membranes was determined. For comparison, the ability of octreotide to displace this tracer was also measured in a parallel assay. As shown in Figure 1, both GIBLO and octreotide displaced AR42J membrane-bound [^{125}I]TOC in a concentration-dependent manner. The calculated IC_{50} values for GIBLO and octreotide were 0.46 ± 0.05 nM and 0.99 ± 0.13 nM, respectively, indicating that the novel peptide bound with high affinity to SSTR. An IC_{50} of 2.8 ± 0.4 nM was reported for

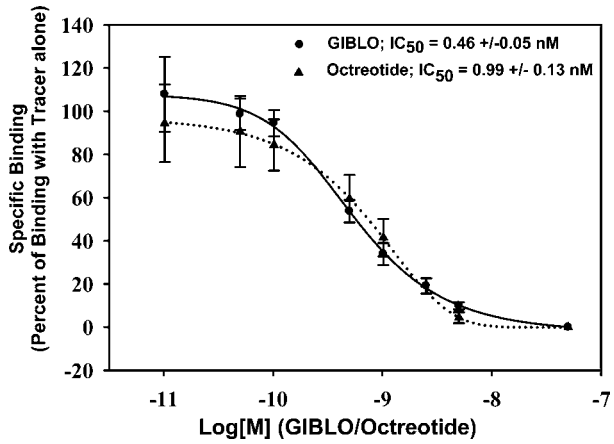


Figure 1. Competitive displacement of [^{125}I]TOC from sst_2-expressing AR42J rat pancreatic cell membranes by GIBLO (circles) and by octreotide (triangles). AR42J membranes were incubated with [^{125}I]-TOC and none or increasing concentrations of either octreotide or GIBLO. Specific binding, determined by subtracting the value at 50 nM concentration of the ligand from total binding, was plotted as a function of logarithm of ligand concentration.

Gluc-Lys^0-fluoropropionyl-TOCA, another peptide with a Lys^0 modification, to membranes from CHO cells transfected to express $SSTR_2$ (*15*, *16*). The IC_{50} values reported for other octreotide derivatives in displacing labeled analogues bound to AR42J rat pancreatic tumor membranes have been in the low nanomolar and sub-nanomolar range (see for example ref 21). Taken together, our results suggest that conjugation of an N-terminal sugar and a pendant prosthetic group for radiohalogenation to octreotate can be accomplished without compromising $SSTR_2$ binding affinity. Receptor binding affinity assay with D341 membranes was not performed, as we were not successful in the past in obtaining reproducible results using these membranes with other octreotate derivatives.

Because of our clinical interest in utilizing radiolabeled octreotide conjugates for the targeted radiotherapy of medulloblastoma, the internalization assays and the biodistribution study were performed with the D341 Med human medulloblastoma line. Previously we reported that, of the four radioiodinated octreotide analogues investigated, [^{125}I]I-Gluc-TOCA has the highest level of intracellularly trapped radioactivity, reaching 10−15% of added radioactivity after a 4 h incubation with D341 Med cells (*7*, *12*). Therefore, this peptide was selected as a positive control to evaluate the internalization of the carbohydrated peptides [^{131}I]GIBLO and [^{211}At]GABLO. As shown in Figure 2A, consistent with earlier results, about 10% of the input dose of [^{125}I]I-Gluc-TOCA was internalized at 4 h. Disappointingly however, the specific internalized radioactivity for [^{131}I]-GIBLO was considerably lower, <2% at 4 h. This degree of internalized counts is similar to that observed previously on this cell line for [^{125}I]TOC, the peptide lacking the N-terminal and C-terminal structural modifications previously shown to significantly increase internalization (*7*). The results presented in Figure 2B demonstrate that [^{211}At]GABLO behaved in fashion similar to [^{131}I]GIBLO, suggesting that substitution of ^{211}At for ^{131}I in this peptide had no significant effect on its uptake and internalization by D341 Med cells.

The subpar internalization of these novel labeled octreotate analogues could be due to multiple factors. The above results are not unprecedented; retention of SSTR affinity but with a substantial decrease in internalization has been observed for ^{99m}Tc-labeled TOCA derivatives with bulky lipophilic chelating groups on the Lys^0 side chain (Schottelius and Wester, unpublished results). Furthermore, while there are instances where the internalization is proportional to SSTR affinity (*24*), octreotide derivatives of similar affinities have demonstrated

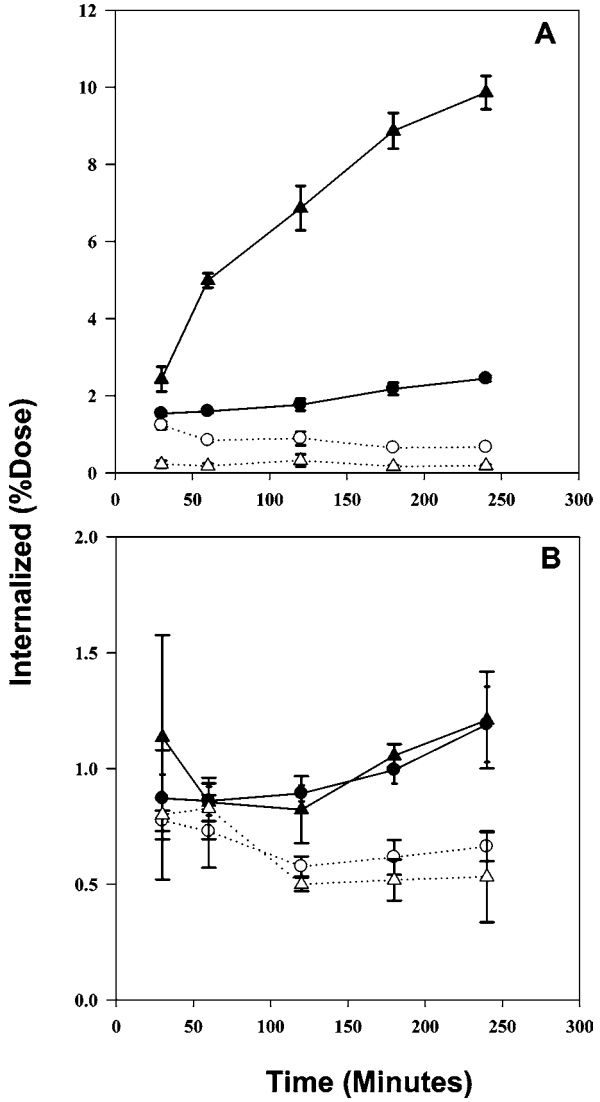

Figure 2. Time-dependent internalization of [^{125}I]I-Gluc-TOCA (triangle) and [^{131}I]GIBLO (circle) (A; upper panel) and of [^{131}I]GIBLO (circle) and [^{211}At]GABLO (triangle) (B; lower panel) by sst_2-expressing D341 human medulloblastoma cells in the presence (open symbols) and absence (closed symbols) of 1 μM octreotide. Percentage of radioactivity in the incubation medium that was trapped in the intracellular compartment as a function of time is shown.

different internalization efficiencies (*3*, *15*, *25*, *26*). The presence of bulky aromatic prosthetic groups may negatively influence the uptake and retention of these radiolabeled peptides in tumor cells (*15*). Net charge, geometry, and metabolism all also can play a role (*15*). In rats, ^{111}In-DTPA-octreotide is known to undergo metabolism with the cleavage of radiolabel-carrying N-terminus amino acids (*27*, *28*). If that were to happen with GIBLO and GABLO, the internalization results probably can be rationalized. A possible contributing factor is the higher lipophilicity of GIBLO compared to I-Gluc-TOCA not only because of the iodobenzoyl prosthetic group but also because of the presence of a Phe instead of Tyr at position 3 of the peptide backbone. The higher nonspecific binding of GIBLO seen in Figure 2A is consistent with this difference.

Another possibility is that the poor retention of radioiodine in the intracellular compartment was in some way related to the additional lysine residue added to the N-terminus of octreotate. To investigate this, we synthesized [^{131}I]I-GIu-Lys^0-TOCA and compared its internalization properties on D341 Med cells to that of [^{125}I]I-Gluc-TOCA, both labeled on their Tyr^3 residues. The absolute magnitude of internalization of [^{125}I]I-Gluc-TOCA was lower than that observed in the previous experiment (Figure 2A), perhaps due to some unknown difference in cell characteristics; however, this should not interfere with a direct comparison of two peptides in a paired-label format assay. As shown in Figure 3, receptor-mediated intracellular activity for [^{131}I]I-Gluc-Lys^0-TOCA was significantly lower than that of [^{125}I]I-Gluc-TOCA at all time points with the difference reaching about 3-fold at 4 h (Figure 3). In comparison, the receptor mediated intracellular activity for [^{131}I]GIBLO was about 4 times lower than that of coincubated [^{125}I]I-Gluc-TOCA at 4 h. It should be noted that a somewhat similar peptide, N^{α}-Gluc-N^{ϵ}-[^{18}F]fluoropropyl-lys^0-TOCA, has been synthesized but no internalization data were presented (*15*). However, specific targeting of an SSTR-expressing xenograft and delineation of tumor with high contrast in a carcinoid patient was possible with this ^{18}F-labeled peptide (*16*).

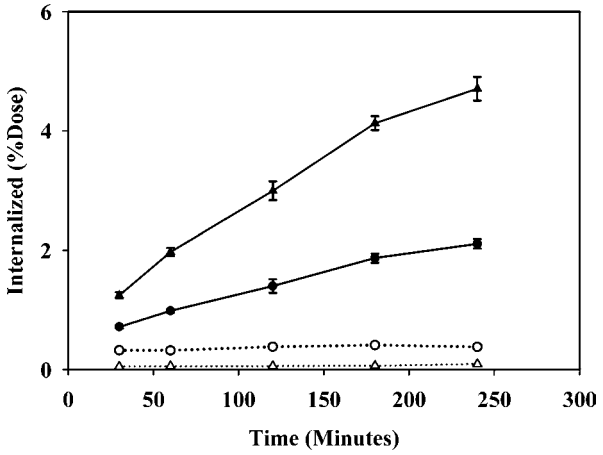

Figure 3. Time-dependent internalization of [^{125}I]I-Gluc-TOCA (triangle) and [^{131}I]I-GIu-Lys^0-TOCA (circle) by sst_2-expressing D341 human medulloblastoma cells in the presence (open symbols) and absence (closed symbols) of 1 μM octreotide. Percentage of radioactivity in the incubation medium that was trapped in the intracellular compartment as a function of time is shown.

We speculate that the amide bond between Lys^0 and D-Phe^1 may be susceptible to cleavage. In the case of [^{131}I]I-Gluc-Lys^0-TOCA, this would yield [^{131}I]I-TOCA, which, consistent with the current study, was shown to exhibit about 2.5 times lower internalized counts than [^{131}I]I-Gluc-TOCA (*7*). However, some additional feature must play a role in the case of GILBO, perhaps its lipophilicity or the size/geometry of the Lys^0-iodobenzoyl moiety. Appending a haloaryl moiety cannot be the sole cause because the internalization of *N*-(4-guanidinomethyl-3-iodobenzoyl)-Phe^1-octreotate (GMIBO) by D341 Med cells was 20−40% higher than that of [^{131}I]I-Gluc-TOCA (*12*). However, in this case, the prosthetic group was positively charged and was present on Phe^1 rather than Lys^0.

From the catabolism studies, for both peptides, the radioactivity HPLC profile of cell lysates, cell culture supernatants, and of surface-bound fractions at both time points was similar with the peak corresponding to intact peptide being the predominant species. For example, HPLC chromatograms of the cell lysate and cell culture supernatant obtained after the 4 h incubation period are shown in Figure 4A and 4B. No peak corresponding to [^{125}I]MIT (t_R = ~18 min) was seen. There was no evidence for the generation of N^{α}-(1-deoxy-D-fructosyl)-N^{ϵ}-(3-[^{131}I]iodobenzoyl)-lysine (t_R = 24−25 min), which would be the expected catabolite resulting from the cleavage of Lys^0 with its substituents from [^{131}I]GIBLO. This suggests that either cleavage of the peptide at Lys^0-Phe^1 did not occur, or was rapidly followed by further catabolism to unidentified labeled fragments. N^{ϵ}-(3-iodobenzoyl)-lysine (*17*), another potential catabolite, was also

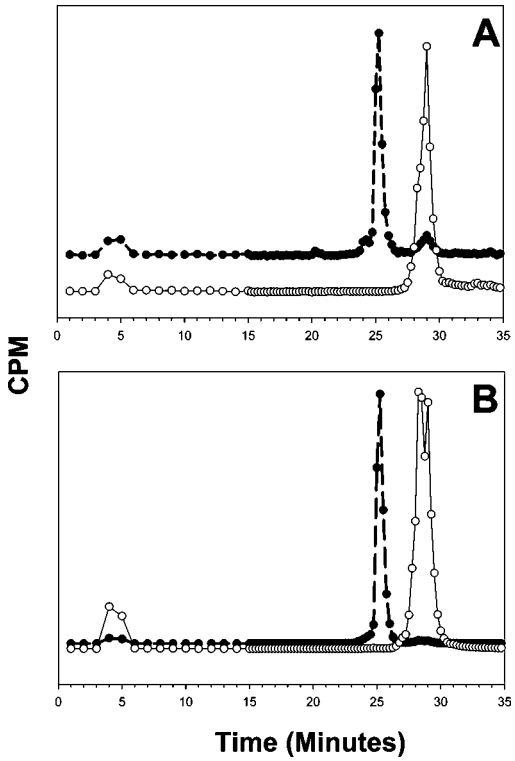

Figure 4. Paired-label in vitro catabolism: HPLC profiles of cell extracts (internalized) (A) and cell culture supernatants (B) at 4 h. A paired-label internalization assay was performed by incubating D341 Med cells with 10 μCi each of [^{125}I]Gluc-TOCA (filled circle) and [^{131}I]-GIBLO (open circle). Cell lysates (internalized), cell culture supernatants, and surface-bound fractions at 30 min and 4 h were analyzed by reversed-phase HPLC. Data shown are for cell lysates and cell culture supernatants at 4 h.

not present as this elutes at 21−22 min under the HPLC conditions used for the catabolism experiments.

We next evaluated the biodistribution of [^{131}I]GIBLO in comparison with [^{125}I]I-Gluc-TOCA in a paired-label format in athymic mice bearing subcutaneous D341 Med xenografts; data for selected time points are shown in Table 1. The tumor localization of [^{125}I]I-Gluc-TOCA was 2- to 3-fold higher than that of [^{131}I]GIBLO at early time points. For example, the tumor uptake of [^{125}I]I-Gluc-TOCA at 0.5 and 1 h was 21.5 ± 4.0% ID/g and 18.8 ± 7.7% ID/g compared to 6.9 ± 1.2% ID/g and 4.7 ± 1.4% ID/g, respectively for [^{131}I]GIBLO. The differences in uptake between the two tracers were statistically significant ($p < 0.05$). The tumor uptake of [^{125}I]I-Gluc-TOCA at these time points was consistent with that seen earlier in this xenograft model (*7*). Tumor levels of radioiodine for [^{131}I]GIBLO were higher than those for [^{125}I]I-Gluc-TOCA at 16 and 24 h; however, the difference was statistically significant only at 24 h (0.90 ± 0.20% ID/g versus 0.40 ± 0.07% ID/g).

Normal tissue radioiodine levels observed after administration of [^{131}I]GIBLO and [^{125}I]I-Gluc-TOCA are summarized in Table 1. As expected, the strategy of avoiding radioiodination of Tyr^3 resulted in significantly lower levels of radioiodine in the thyroid, consistent with a lower degree of deiodination. For example, 16 h after injection, the % injected dose in the thyroid for [^{131}I]GIBLO was more than 4 times lower than that for [^{125}I]I-Gluc-TOCA. The lower tumor uptake of [^{131}I]GIBLO at early time points might be due to its concomitantly higher uptake in liver, kidney and particularly, small intestine (Table 1). In contrast, uptake of [^{125}I]I-Gluc-TOCA was consistently higher in lungs and stomach, which are some of the tissues known to express somatostatin receptors (*7*). Alternatively, because of the proclivity of free iodide for the stomach, the higher accumulation of [^{125}I]I-Gluc-TOCA in this organ could reflect the greater degree of dehalogenation of this peptide.

HPLC analyses of tumor, kidney, liver, blood, and urine samples obtained 30 and 60 min after [^{125}I]I-Gluc-TOCA and [^{131}I]GIBLO injection were performed to determine the nature of the labeled species present in these tissues. In blood and urine, the majority of the radioactivity present at 30 and 60 min for both peptides eluted with a retention time corresponding to the intact peptide. In blood, 15 and 38% of the total ^{125}I activity eluted in the solvent front peak at 30 and 60 min, respectively; for ^{131}I, these values were 9 and 13%. In urine, about 3% of total ^{125}I activity was in the solvent front peak at both time points and for ^{131}I, 19% and 6% of total activity was in this peak at 30 and 60 min, respectively. In kidney and liver, very low levels of intact [^{125}I]I-Gluc-TOCA were seen at both time points; most of the radioactivity eluted at the solvent front. The HPLC profiles for [^{131}I]GIBLO catabolites indicated a distribution of ^{131}I in ratios of 3:1 and 2:1 for kidney and liver, respectively, between solvent front peak and intact peak. It is possible that the solvent front peak may reflect free iodide, and this is consistent with the fact that it accounts for a smaller fraction of the eluted activity for [^{131}I]GIBLO compared with [^{125}I]I-Gluc-TOCA. On the other hand, the radioactivity present in tumor for both peptides was predominantly in the solvent front peak (Figure 5) (~65−70% at both time points). Consistent with the results obtained in vitro with D341 Med medulloblastoma cells, peaks corresponding to [^{125}I]MIT and N^{α}-(1-deoxy-D-fructosyl)-N^{ϵ}-(3-[^{131}I]iodobenzoyl)-lysine were not seen in the HPLC profiles of any of the in vivo samples. Unfortunately, these catabolism results fail to offer a cogent explanation for the inferior tumor targeting properties of [^{131}I]GIBLO. Phe for Tyr substitution, addition of Lys^0, and the presence of bulky aromatic prosthetic group could have had a combined effect in

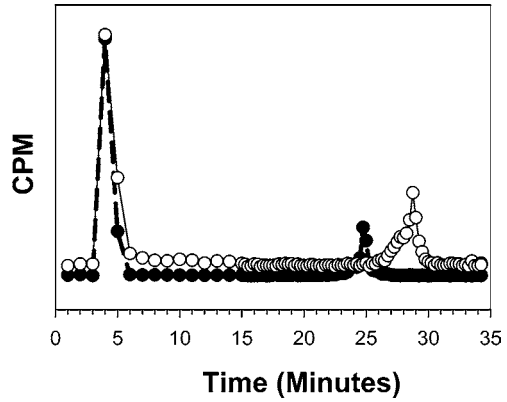

Figure 5. Paired-label in vivo catabolism: HPLC profile of tumor extracts in vivo at 60 min. Mice were injected with 10 μCi each of [^{125}I]Gluc-TOCA (filled circle) and [^{131}I]GIBLO (open circle). Necropsies were performed at 30 and 60 min postinjection. Tumor (and other tissues) was isolated and homogenized. The supernatant, after removal of cell debris, was analyzed by reversed-phase HPLC.

decreasing the extent of internalization and consequent decrease in tumor uptake.

In conclusion, we have developed methods for synthesizing octreotate derivatives with two prosthetic groups, one containing a carbohydrate unit and the other, a tin group-containing aryl moiety suitable for radiohalogenation. The new peptide conjugate, GIBLO, maintained high affinity for SSTR and exhibited lower levels of deiodination than I-Gluc-TOCA. Its internalization properties in vitro and tumor targeting in vivo, while inferior to that of I-Gluc-TOCA, were similar to those of I-TOC. Although the factors responsible for the less than ideal internalization and tumor targeting of GIBLO are not known at this time, it is clear that alternate approaches for maximizing the intracellular trapping of radiohalogen and concomitant improvement in pharmacokinetics are needed. Toward that goal, we are currently working on next-generation octreotate analogues that include hydrophilic, charged aryl tin precursors that can be labeled with either radioiodine nuclides or ^{211}At.

ACKNOWLEDGMENT

The authors want to thank Philip C. Welsh, Holly Legrand, and Kevin Alston for their excellent technical assistance. The work was supported by Grants CA91927, CA78417, CA42324, and CA93371 from the National Institutes of Health, as well as by a grant from the Pediatric Brain Tumor Foundation.

Use of the Sonogashira Coupling Reaction for the "Two-Step" Labeling of Phenylalanine Peptide Side Chains with Organometallic Compounds

Ulrich Hoffmanns and Nils Metzler-Nolte*

Institute of Pharmacy and Molecular Biotechnology, University of Heidelberg, Im Neuenheimer Feld 364, D-69120 Heidelberg, Germany. Received August 24, 2005; Revised Manuscript Received November 25, 2005

The Pd-catalyzed Sonogashira coupling of ferrocene alkyne derivatives as metal probes to iodophenylalanine containing peptides is described. 4-Iodophenylalanine was incorporated into dipeptides and the neuropeptide [Leu^5]-enkephalin (Enk) by solid phase peptide synthesis, thereby creating a functional group suitable for the Sonogashira coupling. The reaction with two different ferrocene alkynes resulted in the corresponding ferrocene-labeled derivatives, which were obtained in good yield and purity. All new compounds were comprehensively characterized, including elemental analysis, 1D and 2D NMR, EI-, FAB- or ESI-MS, IR and UV−vis spectroscopy, and electrochemistry of the ferrocene label. Unlike well-established conjugation methods for peptide side chains such as lysine and cystein, the phenyl group in Phe is not readily available for derivatization. This work presents a versatile procedure for the regioselective introduction of an organometallic label into biologically relevant peptides as exemplified for enkephalin.

INTRODUCTION

The search for mild and selective labeling of peptide side chains is an active field of research. In addition to the well-established methods using thiol (Cys), carboxylic acid (Asp and Glu), and amino (Lys) functional groups, the focus has shifted to other amino acids and their derivatives in recent years. One promising method for the formation of bioconjugates is the Sonogashira coupling (*1*, *2*). This Pd-catalyzed C−C cross coupling reaction uses alkynes and aromatic bromides, iodides, or triflates. It is compatible with many functional groups in biomolecules and can be performed under aerobic, aqueous conditions. It has been successfully applied to amino acids, peptides, and nucleic acid derivatives. In nucleic acid chemistry, iodouracil and bromoadenine are the preferred starting materials. Peptides were derivatized with compounds such as *p*-iodobenzoic acid or propargylamine to make them amendable to Sonogashira coupling reactions (*3*, *4*). The use of *p*-iodophenylalanine or *p*-ethynylphenylalanine as non-natural amino acids is an alternative starting point for this versatile derivatization method (*5*-*7*). In fact, *p*-ethynylphenylalanine, which is a potent inhibitor of tryptophan hydroxylase (*8*), is readily prepared from the *p*-iodoamino acid via Sonogashira coupling with silyl-protected ethyne (*9*).

Because it is a mild and chemically versatile derivatization method, the Sonogashira coupling seems particularly attractive for the introduction of organometallic compounds as labels. The area of bioorganometallic chemistry has recently attracted a lot of attention (*10*-*17*). Organometallic labels offer unique opportunities for detection of the conjugates, for instance by electrochemical methods (*18*−*20*), immunoassays (*21*−*23*), or infrared (*24*, *25*) or optical spectroscopy (*26*−*28*). The majority of compounds were prepared using ferrocene (dicyclopentadienyliron, Cp_2Fe) as the organometallic label. Ferrocene is chemically robust, and its chemistry is well explored, giving easy access to a variety of derivatives. In addition, its favorable electrochemical properties make it an ideal sensor in DNA detection devices (*15*, *18*, *19*, *29*) or electrochemical glucose sensor (*15*, *20*, *30*, *31*). Although a vast number of ferrocene derivatives of simple amino acids, proteins, sugars, and nucleic acids were prepared, there is a striking absence of ferrocene derivatives of small peptides (*15*). A few early attempts met with moderate success (*32*−*34*). The ferrocene peptides partly decomposed under the harsh conditions of the original Merrifield solid phase peptide synthesis (SPPS), in particular cleavage and side chain deprotection using concentrated HF. Some biological testing was performed, but the chemical characterization of those early ferrocene peptide conjugates is scarse (*33*, *35*, *36*). We have recently published the chemical synthesis of metallocene peptides and their cellular uptake and nuclear localization by fluorescence microscopy (*37*). Kraatz and co-workers published a series of papers on the use of ferrocenyl peptide derivatives in electrochemical sensors (*38*−*40*). Those compounds were invariably pepared by solution chemistry throughout. On the other hand, SPPS is the method of choice for the chemical synthesis of small to medium sized peptides. Obviously, much milder methods are required for a reliable labeling of peptides with ferrocene as an electrochemical marker.

In light of these early results, we set out to explore the use of Sonogashira coupling for the synthesis of ferrocene peptide derivatives. Phenylalanine was chosen as the site for derivatization, and we used Leu^5-enkephalin as the model peptide. Enkephalin (Enk, primary sequence H-Tyr-Gly-Gly-Phe-Xxx-OH) is a five amino acid neuropeptide which is a natural ligand for the opiate receptors (*41*−*43*). It is formed from proenkephalin and exists in two forms which differ in the C-terminal amino acid, namely [Met^5]-Enk (Xxx = Met) and [Leu^5]-Enk (Xxx = Leu) (*44*). The pentapeptides were detected in various human tissues but mainly in the brain and central nervous system. Upon binding to the opiate receptor, their function is primarily associated with pain sensation. [Leu^5]-Enk has been the most popular target peptide for the derivatization with organometallic markers. In those studies, the amino acid phenylalanine was replaced by the organometallic derivatives ferrocenylalanine (Fc-CH_2-$CH(NH_2)$-CO_2H) (*32*, *33*, *36*) or cymantrenylalanine ($((CO)_3MnC_5H_4$-CH_2-$CH(NH_2)$-CO_2H) (*45*). As noted above, the chemical synthesis of those peptides was not straightforward and partial decomposition was observed,

rendering the biological results questionable. We have recently reported two different organometallic Mo enkephalin derivatives (*46*, *47*). These compounds were obtained in high yield and purity using the Fmoc strategy and the HMBA linker, which can be cleaved with concentrated NH_3, thus replacing the harsh original Merrifield SPPS conditions.

In this paper, we describe the synthesis and full chemical characterization of several *p*-iodophenylalanine containing dipeptides and the preparation of *p*-iodophenylalanine enkephalin derivatives by SPPS. In addition, an enkephalin derivate with an *N*-terminal iodoarene is also described. All peptides were transformed into their ferrocene derivatives by Sonogashira coupling in solution under mild conditions using two different ferrocene alkynes.

EXPERIMENTAL PROCEDURES

All peptide synthesis reactions were carried out in ordinary glassware and solvents. Chemicals were obtained from Aldrich, Iris, or Novabiochem. DMF for peptide synthesis was obtained from Roth. Enantiomerically pure L-amino acids were used. The dipeptides Boc-Aa1-Aa2-OMe[1] were prepared according to standard peptide chemistry techniques from Boc-Aa1-OH and H-Aa2-OMe·HCl, employing isobutyl chloroformiate as the coupling reagent (*48*). The compounds *p*-iodophenylalanine (**1**) (*49*) and [Fe(Cp)(C_5H_4-CONH-CEt_2-CC-H)] (*4*) (**7**, H-DEPA-CO−Fc, Cp = η-C_5H_5) were synthesized according to the literature.

Elemental analyses were performed on a Foss Heraeus Vario EL Elementar Analysator in C,H,N mode. Infrared spectra were recorded on a Brucker Equinox55 FT-IR as KBr disks and/or in CH_2Cl_2 solution between NaCl windows. Frequencies ν are given in cm^{-1}. UV−vis spectra were measured on a Varian CARY 100 instrument in 1 cm quartz Suprasil cells thermostated at 20 °C. Absorption maxima (λ_{max}) and molar absorption coefficients (ϵ_{max}) are given in nm and M^{-1} cm^{-1}, respectively. Mass spectra were recorded on a Finnigan MAT 8200 instrument (EI, 70 eV) or on a Finnigan TSQ 700 mass spectrometer (ESI; solvent and detection mode are given in parentheses). Only characteristic fragments with possible composition are given in brackets. For fragments containing metals only the isotopomer with highest intensity was described. Cyclic voltammograms (CV) and square wave voltammograms (SWV) were recorded in CH_2Cl_2, with NBu_4PF_6 as supporting electrolyte, by using a Princeton Applied Research BES Potentiostat/Galvanostat. A three-electrode cell was employed with a glassy-carbon working electrode, a platinum wire auxiliary electrode, and a $Ag/AgNO_3$ reference electrode (0.01 M $AgNO_3$ in MeCN). For determination of the redox potentials, ferrocene was added as an internal standard. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM 360 spectrometer (^1H at 360.14 MHz, ^{13}C at 90.56 MHz) and a Bruker AM 300 (^1H at 300.16 MHz, ^{13}C at 75.47 MHz). ^1H and ^{13}C NMR spectra were referenced to TMS, using the ^{13}C or residual proton signals of the deuterated solvents as internal standards ($CDCl_3 \equiv 7.24$ (^1H) and 77.0 (^{13}C); DMSO $\equiv 2.49$ (^1H) and 39.5 (^{13}C)). High performance liquid chromatography (HPLC) was performed on a customized Varian ProStar system on reverse-phase Dynamax Microsorb 60-8 C_{18} columns (analytical: C18 microsorb 60 Å, diameter 4.5 mm, 250 mm; preparative: C18 microsorb 60 Å, diameter 21.4 mm, 250 mm) with water and acetonitrile, both containing 0.1% TFA, as eluents using the linear gradient 5 to 95% acetonitrile for 35 min.

Preparation of 4-Iodophenylalanine Methyl Ester Hydrochloride 2. Thionyl chloride (100 mmol, 11.90 g) was added dropwise to 100 mL of CH_3OH cooled with an ice-bath followed by the addition of 40 mmol of 4-iodophenylalanin (**1**) (11.64 g). After stirring for 12 h, the solvent was removed at 40 °C under reduced pressure to obtain the crude product. The slightly green solid was dissolved in as little CH_3OH as possible, and the solution was poured into 350 mL of diethyl ether to precipitate a white solid. After filtration and washing with an additional aliquot of 200 mL of diethyl ether, the pure product was dried in vacuo. Yield: 10.63 g (78.0%). Anal. Calc for $C_{10}H_{13}ClINO_2$ (340.96 g/mol): C, 35.16; H, 3.48; N, 4.10. Found: C, 34.52; H, 3.89; N, 4.00. IR (KBr): ν 2838 (vs, br, ν_{CH}), 1738 (vs, ν_{COO}), 1245 (s, ν_{C-O}), 835 (m, δ_{CH}). MS (FAB, pos): *m*/*z* 306 [$M^+ - Cl$], 289 [$M^+ - Cl - CH_3$]. ^1H NMR (D_2O, 360 MHz): δ 7.80 (d, 2H, $J = 8.0$, H_{Ar}), 7.08 (d, 2H, $J = 8.0$, H_{Ar}), 4.43 (t, 1H, $J = 6.7$, $C_\alpha H$), 3.38 (s, 3H, CH_3), 3.26 (m, 2H, $C_{\beta,Phe}H$). ^{13}C NMR (D_2O, 90 MHz): δ 170.8 (COO), 139.2, 132.3 (C_{Ar}), 134.5 ($C_{Ar,q}$), 94.0 (C_{Ar-I}), 54.8 (C_α), 54.5 (CH_3), 36.2 (C_β)

Preparation of 4-Iodophenylalanine Dipeptides 3−6. To a stirred solution of 10 mmol of the Boc-protected amino acid in THF was added *N*-methylmorpholine (1.12 mL, 1.02 g, 10 mmol) followed by the addition of isobutyl chloroformiate (1.32 mL, 1.36 g, 10 mmol), resulting in precipitation of a white solid. In a second flask, 4-iodo-L-phenylalanine-methylester hydrochloride (**2**) (3.41 g, 10 mmol) was suspended in 50 mL of THF containing triethylamine (1.38 mL, 1.02 g, 10 mmol). Both suspensions were mixed and stirred for 60 min at room temperature. After removal of the white precipitates by filtration, the solvent was removed under reduced pressure and the residual oil was dissolved in 100 mL of $CHCl_3$. The solution was washed with H_2O (50 mL), and the aqueous solution was extracted with three 50 mL aliquots of $CHCl_3$. The combined $CHCl_3$ solutions were dried over Na_2SO_4. Evaporation of the solvent under reduced pressure yielded the dipeptides **3**−**6** as a white solid. The products could be recrystallized from THF/heptane.

Analytical Data for **3**. Anal. Calc for $C_{18}H_{25}IN_2O_5$ (476.08 g/mol): C, 45.39; H, 5.29; N, 5.88. Found: C, 44.89; H, 5.26; N, 5.81. Preparation of Ferrocenoyldiethylpropargyl Amide (H-DEPA-CO-Fc) (7). To a suspension of 2.3 g of ferrocenecarboxylic acid (10 mmol) in 50 mL of dried and degassed DCM was added under argon 1.78 g of thionyl chloride (15 mmol). The mixture was heated at reflux for 1 h. The clear and orange solution was allowed to cool, and the solvent was removed under reduced pressure, leaving a dark orange solid. The latter was dissolved in 50 mL of dried DCM and treated with 1.1 g of 1,1-diethylpropargylamine (10 mmol) and 1.01 g of NEt_3 (10 mmol). After 6 h of stirring at ambient temperature and removal of triethylamine hydrochloride by filtration through Celite, the solvent was removed by rotary evaporation. The remaining orange solid was dissolved in 50 mL of chloroform and washed three times with water. After drying over Na_2SO_4 and filtration, the solution was rotary evaporated to dryness. The crude product could be recrystallized from methanol. Anal. Calc for $C_{18}H_{21}FeNO$ (323.10 g/mol): C, 66.89; H, 6.55; N, 4.33. Found: C, 66.65; H, 6.60; N, 4.30. UV−vis: 259 (3649), 304 (760), 444 (232). Yield: 2.89 g (89%).

Preparation of Ferrocenylated Dipeptides 8−11. 12 mL of dried THF and NEt_3 (1:1) was thoroughly degassed in a Schlenck tube. To this solution was added 1 mmol of the corresponding dipeptide **3**−**6** and 356 mg (1.1 mmol) of **7**. Then a mixture of 14 mg of $Pd(PPh_3)_2Cl_2$ (0.02 mmol, 2 mol %) and CuI (6 mg, 0.03 mmol, 3 mol %) was added as a catalyst. The mixture was stirred under argon until no more triethylamine hydroiodide precipitated (6h). After removal of the salts by filtration the solvents were removed under reduced pressure and the product was purified by column chromatography on silica using ethyl acetate/hexane (2:1).

Preparation of Ethynylferrocene-Substituted Dipeptides 12−15. 12 mL of dried THF and NEt_3 (1:1) was thoroughly degassed in a Schlenck tube. To this solution was added 1 mmol of the corresponding dipeptide **3**−**6** and 231 mg (1.1 mmol) of ethynylferrocene. Then a mixture of 14 mg of $Pd(PPh_3)_2Cl_2$ (0.02 mmol, 2 mol %) and CuI (6 mg, 0.03 mmol, 3 mol %) was added as a catalyst. The mixture was stirred under argon until no more triethylamine hydroiodide precipitated (6 h). After removal of the salts by filtration, the solvents were removed under reduced pressure and the product was purified by column chromatography on silica using ethyl acetate/hexane (4:5).

Preparation of Ac-Enk-[Phe^4(I)]-OH 16. The synthesis was performed manually in a syringe equipped with a porous filter (10 mL, MultiSynTech) using Fmoc-protected Leu−Wang resin (400 mg, loading 0.63 mmol/g, Novabiochem), Fmoc-protected amino acid monomers, 4-iodophenylalanine **1**, and amine free DMF as solvent. The tyrosine side chain protecting group was *tert*-butyl. Synthesis cycle: (A) *deprotection* using two times about 3 mL of a 20% piperidin solution in DMF, first at 5 min and then at 10 min, without washing in between; (B) *washing* 5 times with about 6 mL of DMF; (C) *coupling* using a solution of activated amino acid for 30 min; and (D) *washing* 5 times with 3 mL. The coupling mixture contained the protected amino acid monomer (5-fold excess), TBTU (396.4 mg, 4.9-fold excess), and HOBt (192.9 mg, 5-fold excess) dissolved in DMF (5 mL);); then DIPEA (325.8 mg, 10-fold excess, activation period 2 min) was added. Work up: After the resin was successively rinsed with DMF and DCM and dried under reduced pressure (1 h, 10 mbar), final deprotection and cleavage from the resin was performed with a TFA mixture (TFA/H_2O/TIS = 95:2.5:2.5, 3 mL, 3 h). The suspension was filtered and the resin washed with TFA (2 × 1.5 mL). The combined TFA solutions were poured into cold ether (10 mL, −30 °C), and the suspension was centrifuged (8000 rpm, 6 min). After decanting the supernatant, the crude product was washed with

cold ether (2 × 10 mL), dissolved in water, filtered, and lyophilized, yielding a white solid.

Analytical Data for $C_{30}H_{38}IN_5O_8$ (723.18 g/mol). MS (FAB, pos): *m/z* 746 [M^+ + Na], 724 [M^+ + H], 593 [M^+ − H-Leu-OH], 320 [M^+ − H-Phe(I)-Leu-OH], 263 [M^+ − H-Gly-Phe-(I)-Leu-OH]. ^{1}H NMR (DMSO-d_6, 360 MHz): δ 12.58 (s, br, 1H, COOH), 9.15 (s, br, 1H, OH_{Tyr}), 8.27 (d, 1H, J = 8.1, NH_{Leu}), 8.22 (t, 1H, J = 5.4, NH_{Gly}), 8.06 (d, 1H, J = 8.0, NH_{Tyr}), 7.99 (d, 1H, J = 8.5, N_{I-Phe}, 7.93 (t, 1H, J = 5.5, NH_{Gly}), 7.60 (d, 2H, J = 8.1, $H_{Ar,I-Phe}$), 7.07 (d, 2H, J = 8.2, $H_{Ar,I-Phe}$), 7.02 (d, 2H, J = 8.3, $H_{Ar,Tyr}$), 6.63 (d, 2H, J = 8.3, $H_{Ar,Tyr}$), 4.54 (dt, 1H, J = 3.7, 9.0, $C_{\alpha,I-Phe}H$), 4.39 (dt, 1H, J = 4.8, 9.1, $C_{\alpha,Tyr}H$), 4.21 (m, 1H, $C_{\alpha,Leu}H$), 3.66 (m, 4H, $C_{\alpha,Gly}H$), 2.81 (m, 4H, $C_{\beta,Phe,Tyr}H$), 1.61 (m, 1H, $CH(CH_3)_2$), 1.54 (m, 2H, $C_{\beta,Leu}H$), 0.87 (m, 6H, $CH(CH_3)_2$). ^{13}C NMR (DMSO-d_6, 90 MHz): δ 173.7 (COO), 171.8, 170.7, 169.3 (CON), 168.9 (CON_{Ac}), 168.3 (CON), 155.6 ($C_{Ar,Tyr}OH$), 137.5 ($C_{Ar,q,I-Phe}$), 136.7 ($C_{Ar,I-Phe}$), 131.7 ($C_{Ar,q,Tyr}$), 129.8, 128.0, 114.8 (C_{Ar}), 92.1 ($C_{Ar,q,I-Phe}$), 54.4 ($C_{\alpha,I-Phe}$), 53.2 ($C_{\alpha,Tyr}$), 50.2 ($C_{\alpha,Leu}$), 42.0, 41.7 ($C_{\alpha,Gly}$), 37.0 ($C_{\beta,Phe}$), 36.5 ($C_{\beta,Tyr}$), 24.2 ($C_{\beta,Leu}$), 22.7 ($CH_{3,Leu}$), 22.4 ($CH_{3,Ac}$), 21.2 ($CH(CH_3)_2$). Yield: 144 mg (79%).

Preparation of I-PBA-Enk-OH (17). The synthesis was carried out in analogy to that of Ac-Enk-[Phe^4(I)]-OH (**16**). Instead of 4-iodophenylalanine, L-phenylalanine was used. In one additional last coupling reaction, *p*-iodobenzoic acid (I-BA) was coupled to the N-terminal tyrosine group.

Analytical Data for $C_{35}H_{40}IN_5O_8$ (785.19 g/mol). MS (FAB, pos): *m/z* 808 [M^+ + Na], 786 [M^+ + H], 655 [M^+ − H-Leu-OH], 508 [M^+ − H-Phe-Leu-OH], 451 [M^+ − H-Gly-Phe-Leu-OH]. ^{1}H NMR (DMSO-d_6, 360 MHz): δ 12.54 (s, br, 1H, COOH), 9.12 (s, br, 1H, OH_{Tyr}), 8.61 (d, 1H, J = 8.2, NH_{Tyr}), 8.31 (t, 1H, J = 5.5, NH_{Gly}), 8.26 (d, 1H, J = 7.9, NH_{Leu}), 8.04 (d, 1H, J = 8.4, NH_{Phe}), 7.96 (t, 1H, J = 5.5, NH_{Gly}), 7.82 (d, 2H, J = 8.4, $H_{Ar,I-Ph}$), 7.57 (d, 2H, J = 8.4, $H_{Ar,I-Ph}$), 7.25 (m, 5H, $H_{Ar,Phe}$), 7.09 (d, 2H, J = 8.3, $H_{Ar,Tyr}$), 6.61 (d, 2H, J = 8.4, $H_{Ar,Tyr}$), 4.59 (m, 2H, $C_{\alpha,Phe,Tyr}H$), 4.22 (dd, 1H, J = 8.4, 14.0, $C_{\alpha,Leu}H$), 3.63 (m, 4H, $C_{\alpha,Gly}H$), 2.85 (m, 4H, $C_{\beta,Phe,Tyr}H$), 1.64 (m, 1H, $CH(CH_3)_2$), 1.54 (m, 2H, $C_{\beta,Leu}H$), 0.87 (m, 6H, $CH(CH_3)_2$). ^{13}C NMR (DMSO-d_6, 90 MHz): δ 173.7 (COO), 171.6, 170.9, 168.8, 168.1 (CON), 165.6 (CON_{I-Ph}), 155.6 ($C_{Ar,Tyr}OH$), 137.6 ($C_{Ar,q,Phe}$), 136.9 ($C_{Ar,I-Ph}$), 133.4 ($C_{Ar,q,I-Ph}$), 129.9, 129.3, 129.1 (C_{Ar}), 128.3 ($C_{Ar,q,Tyr}$), 127.9, 126.1, 114.8 (C_{Ar}), 98.7 ($C_{Ar,q,I-Ph}$), 55.2 ($C_{\alpha,Phe}$), 52.7 ($C_{\alpha,Phe}$), 53.4 ($C_{\alpha,Tyr}$), 50.2 ($C_{\alpha,Leu}$), 42.0, 41.6 ($C_{\alpha,Gly}$), 37.5 ($C_{\beta,Phe}$), 36.1 ($C_{\beta,Tyr}$), 24.2 ($C_{\beta,Leu}$), 22.7 ($CH_{3,Leu}$), 21.2 ($CH(CH_3)_2$). Yield: 184 mg (93%).

Preparation of Ac-Enk-[Phe^4(DEPA-CO-Fc)]-OH (18). Ac-Enk[Phe^4(I)]-OH (**16**) (100 mg, 0.134 mmol) was dissolved in 8 mL of a well degassed mixture of DMF/NEt_3 (1:1) in a Schlenck tube. After complete dissolution, 1.1 equiv (47.6 mg, 0.147 mmol) of H-DEPA-Fc (**7**) was dissolved in the reaction mixture, followed by another 15 min of degassing. Then CuI (14 mg) and $Pd(PPh_3)_2Cl_2$ (28 mg) were added and the mixture was stirred for 12 h. The solution was filtered through a syringe filter (22 μm pore size), the solvent was evaporated *in vacuo*, and the residual oil was redissolved in acetonitrile. The compound was purified by preparative HPLC.

Analytical Data for $C_{48}H_{58}IN_6O_9$ (918.36 g/mol). MS (ESI, neg): *m/z* 917.4 [M − H]$^-$. MS (ESI, pos): *m/z* 919.4 [M + H]$^+$, 941.4 [M^+ + Na], 957.5 [M^+ + K]. ^{1}H NMR (DMSO-d_6, 400 MHz): δ 12.59 (s, br, 1H, COOH), 9.17 (s, 1H, OH_{Tyr}), 8.30 (d, 1H, J = 7.9, NH_{Leu}), 8.25 (t, 1H, J = 5.6, NH_{Gly}), 8.07 (d, 1H, J = 8.1, NH_{Tyr}), 8.02 (d, 1H, J = 8.7, NH_{Phe}), 7.94 (t, 1H, J = 5.5, NH_{Gly}), 7.58 (m, 2H, $H_{Ar,Phe}$), 7.25 (d, 2H, J = 5.8, $H_{Ar,Phe}$), 7.01 (d, 2H, J = 8.4, $H_{Ar,Tyr}$), 6.63 (d, 2H, J = 8.4, $H_{Ar,Tyr}$), 4.92 (m, 2H, $CpH_{1,4}$), 4.56 (dt, 1H, J = 3.8, 9.5, $C_{\alpha,Phe}H$), 4.38 (dt, 1H, J = 4.6, 9.4, $C_{\alpha,Tyr}H$), 4.33 (m, 2H, $CpH_{2,3}$), 4.19 (s, 5H, CpH), 4.16 (m, 1H, $C_{\alpha,Leu}H$), 3.63 (m, 4H, $C_{\alpha,Gly}H$), 2.82 (m, 4H, $C_{\beta,Phe,Tyr}H$), 2.10 (m, 2H, $CH_{2,DEPA}$), 1.90 (m, 2H, $CH_{2,DEPA}$), 1.76 (s, 3H, $CH_{3,\ acetyl}$), 1.62 (m, 1H, $CH(CH_3)_2$), 1.54 (m, 2H, $C_{\beta,Leu}H$), 1.01 (pseudo-t, 6H, $CH_{3,DEPA}$), 0.87 (m, 6H, $CH(CH_3)_2$). ^{13}C NMR (DMSO-d_6, 100 MHz): δ 173.6 (COO), 171.7, 170.7 (CON), 169.1 (CON_{Ac}), 168.6, 168.0, 167.9 (CON), 155.4 ($C_{Ar,Tyr}OH$), 137.7 ($C_{Ar,q,Phe}$), 130.6 ($C_{Ar,q,Tyr}$), 129.7, 129.1, 127.8, 120.6, 114.5 (C_{Ar}), 91.6, 82.0 (C_{alkyne}), 76.5 ($C_{Cp,1}$), 69.6 ($C_{Cp,2,5}$), 68.9 ($C_{Cp'}$), 68.1 ($C_{Cp,3,4}$), 55.6 ($C_{DEPA,q}$), 54.2 ($C_{\alpha,\ Phe}$), 53.0 ($C_{\alpha,Tyr}$), 50.0 ($C_{\alpha,Leu}$), 41.7, 41.3 ($C_{\alpha,Gly}$), 37.2 ($C_{\beta,Phe}$), 36.3 ($C_{\beta,Tyr}$), 29.9 ($CH_{2,DEPA}$), 24.0 ($C_{\beta,Leu}$), 22.5 ($CH_{3,Leu}$), 22.1 ($CH_{3,Ac}$), 21.0 ($CH(CH_3)_2$), 8.4 ($CH_{3,DEPA}$). UV−vis: 246 (25165), 257 (22570), 444 (272). Yield: 58.6 mg (47.6%).

Preparation of Fc-CO-DEPA-BA-Enk-OH (19). The synthesis was carried out in analogy to that of **18**. I-Ph-Enk-OH (**17**) (100 mg, 0.127 mmol) was used. The product was purified by preparative HPLC.

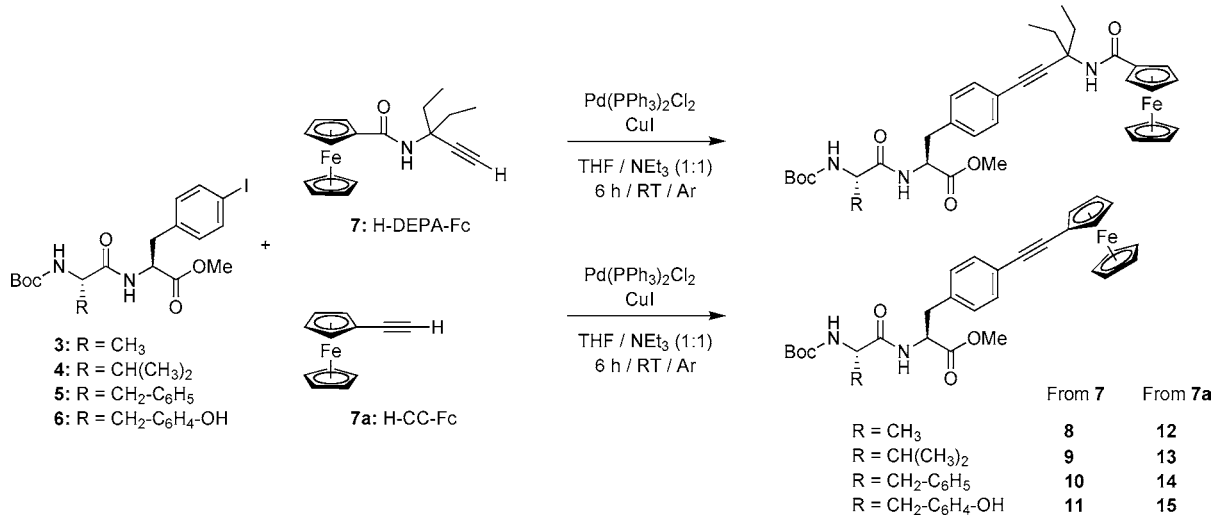
Analytical Data for $C_{53}H_{60}FeN_6O_9$ (980.38 g/mol). MS (ESI, neg): *m/z* 979.5 [M − H]$^-$. ^{1}H NMR (DMSO-d_6, 400 MHz): δ 12.58 (s, br, 1H, COOH), 9.16 (s, br, 1H, OH_{Tyr}), 8.64 (d, 1H, J = 8.1, NH_{Tyr}), 8.35 (t, 1H, J = 5.7, NH_{Gly}), 8.29 (d, 1H, J = 7.9, NH_{Leu}), 8.08 (d, 1H, J = 8.4, NH_{Phe}), 7.99 (t, 1H, J = 5.6, NH_{Gly}), 7.81 (d, 2H, J = 8.3, $H_{Ar,Ph}$), 7.48 (d, 2H, J = 8.3, $H_{Ar,Ph}$), 7.27 (m, 5H, $H_{Ar,Phe}$), 7.11 (d, 2H, J = 7.6, $H_{Ar,Tyr}$), 6.63 (d, 2H, J = 8.4, $H_{Ar,Tyr}$), 5.73 (s, 1H, NH_{Fc}), 4.95 (m, 2H, $CpH_{1,2}$), 4.62 (m, 2H, $C_{\alpha,Phe,Tyr}H$), 4.37 (m, 2H, $CpH_{3,4}$), 4.21 (s, 5H, CpH), 4.19 (m, 1H, $C_{\alpha,Leu}H$), 3.69 (m, 4H, $C_{\alpha,Gly}H$), 2.91 (m, 4H, $C_{\beta,Phe,Tyr}H$), 2.13 (m, 2H, $CH_{2,ethyl}$), 1.97 (m, 2H, $CH_{2,ethyl}$), 1.66 (m, 1H, $CH(CH_3)_2$), 1.55 (m, 2H, $C_{\beta,Leu}H$), 1.05 (t, 6H, $CH_{3,ethyl}$), 0.88 (m, 6H, $CH(CH_3)_2$). UV−vis: 269 (27210), 442 (329). Yield: 28.0 mg (22.5%).

RESULTS AND DISCUSSION

Synthesis of Dipeptides. The dipeptides **3**−**6** were synthesized from the N$^\alpha$-Boc-protected amino acids alanine, leucine, phenylalanine, and tyrosine with 4-iodophenylalanine methyl ester **(2)**. Activation of the Boc amino acids was achieved by isobutyl chloroformiate (Scheme 1). After filtration from salt precipitates, the dipeptide products were isolated in good yields (>75%) and could be comprehensively characterized. The spectroscopic data of the dipeptides **3**−**6** did not reveal any unexpected signals, and the reactions were straightforward. The elemental analyses confirm the correct chemical compositions. The FAB mass spectra show the calculated [M + 1]$^+$ peaks in all cases and also molecular fragments of the type ($M^+ - C_4H_9$) and (M^+ − Boc). The ^{1}H NMR spectrum shows the Boc amide proton between 6.76 and 6.87 ppm and the amide proton of 4-iodophenylalanine between 8.13 and 8.33 ppm. The aromatic protons of the 4-iodo-substituted phenyl ring resonate at 7.60 and 7.00 ppm, leaving a shift difference of 0.60 ppm between both signal groups. Since the *p*-iodophenylalanine is the location of attachment of the alkyne group, the chemical shift and shift difference of these signals are of interest for the monitoring of a successful reaction (Figure 1).

Sonogashira Coupling with Dipeptides. For the introduction of the ferrocene group into a iodophenyl-derivatized biomolecule via Sonogashira coupling, an alkyne group has to be present in the ferrocene molecule. This can be provided by derivatization of ferrocenecarboxylic acid. The synthesis of ferrocenoyl diethylpropargylamide (Fc-CO-DEPA-H) (**7**) using diethylpropargylamine has been described and was reproduced in this work. The X-ray single-crystal structure of **7** has also been reported (*4*). All dipeptides **3**−**6** were reacted with H-DEPA-CO-Fc (**7**) and also with commercially available ethynylferrocene **7a**, to explore the scope of the reaction. The reactions were carried out under argon and in degassed and thoroughly

Scheme 1. Sonogashira Coupling of *p*-Iodophenylalanine Dipeptides with Ferrocenyl Alkynes 7 and 7a



dried solvents. A mixture of $(Ph_3P)_2PdCl_2$ and CuI was used as the catalyst. After various attempts with different solvents and bases, a mixture of THF and NEt_3 in a ratio of 1:1 turned out to be most successful. Shortly after all reagents had been added, the clear solutions became cloudy and green ammonium salts precipitated, which indicated the proceeding reaction. After filtration from the precipitate, the solutions were purified by silica column chromatography, using mixtures of ethyl acetate and hexane. All products were isolated as orange powders, which readily dissolved in organic solvents such as CH_3CN, THF, DMF, DCM, EtOH, and CH_3OH but showed only moderate solubility in water. The purified DEPA-CO-Fc-labeled dipeptides **8**−**11** were submitted to elemental analysis, HPLC, NMR, and mass spectrometry, confirming the successful reaction. The FAB mass spectra show, in addition to the M^+ peaks, signals for $[M - Boc]^+$, $[M - Boc - Cp]^+$ and also fragments of $m/z = 213$ and 185, which can be assigned to $[Fc\text{-}CO]^+$ and $[Fc]^+$, respectively. Proton NMR signals for the Cp rings were observed at 4.64, 4.30, and 4.21 ppm in the usual 2−2−5 intensity pattern (*50*). The ^1H NMR spectrum also shows a singlet for the DEPA-CO-Fc amide proton at 5.74 ppm, which is the same for all four compounds. Protons of the para-substituted phenyl ring still show the typical two pseudodoublets of a AA′BB′ system. However, the signals have changed positions and show a much smaller shift difference compared to the case of the dipeptide starting material (Figure 1).

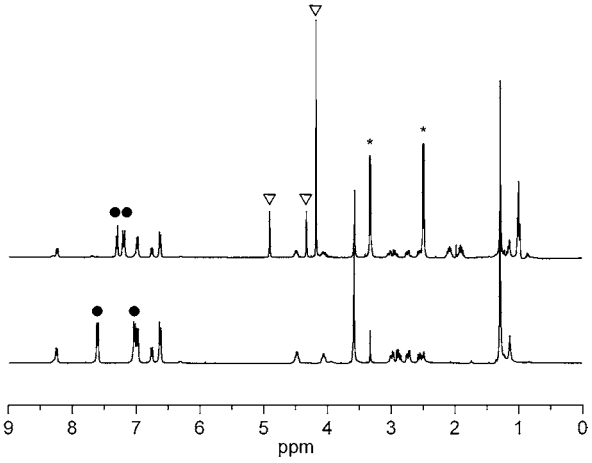


Figure 1. ^1H NMR overlay of Boc-Tyr-Phe(I)-OMe (**6**) and Sonogashira product Boc-Tyr-Phe(DEPA-CO−Fc)-OMe (**11**). Spectra were measured in DMSO-d_6 at 300.16 MHz; solvent and water signals are indicated by asterisk. Triangles indicate Cp signals; filled circles indicate *p*-substituted phenyl signals.

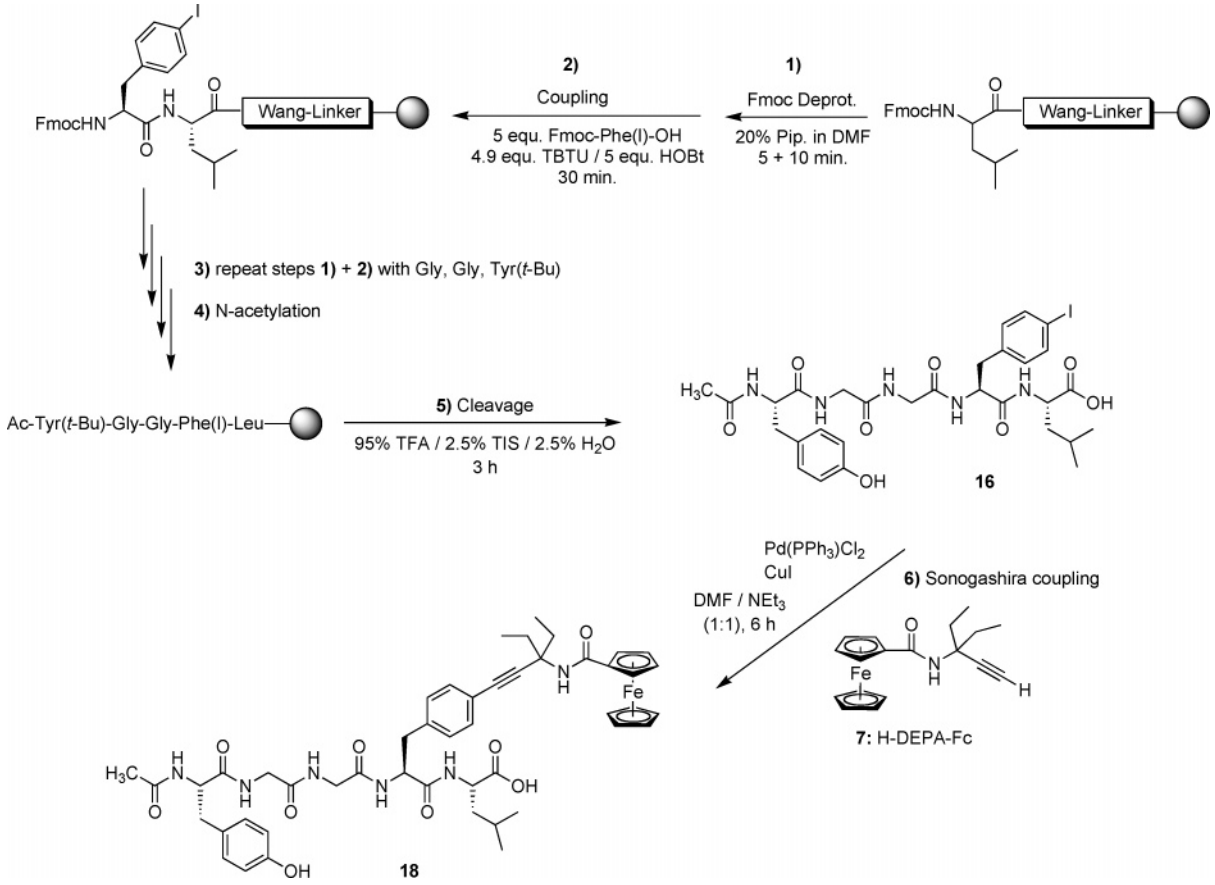
Enkephalin Derivatives. *Synthesis of Ac-Enk[Phe^4(I)]-OH (**16**).* Encouraged by the successful Sonogashira reaction using *p*-iodophenylalanine as a modified amino acid, the biologically relevant pentapeptide enkephalin (H-Tyr-Gly-Gly-Phe-Leu-OH) was modified accordingly. The compound Ac-Enk[Phe^4(I)]-OH (**16**) was synthesized by standard solid-phase peptide synthesis (Scheme 2). Fmoc-Phe-OH was replaced by the modified amino acid Fmoc-Phe(I)-OH, which had been synthesized from **1** using a standard Fmoc protection procedure. The synthesis was carried out on Wang resin, and the cleavage conditions comprised a mixture of 95% TFA, 2.5% H_2O, and 2.5% TIS and a duration of 3 h. The crude product (yield: 79%) was purified by preparative HPLC to give a white powder, which shows good solubility in both organic solvents and water. The FAB mass spectrum displays two product peaks for $m/z = 746$ $[M + Na]^+$ and 724 $[M + H]^+$ and a number of fragment signals which could be assigned to $[M\text{-(Leu-OH)}]^+$, $[M - \text{Phe(I)-Leu-OH}]^+$, and $[M - \text{Gly-Phe(I)-Leu-OH}]^+$, observable at $m/z = 593$, 320, and 263, respectively. All signals for [Leu]^5-enkephalin can be found in the proton NMR spectrum. In addition, two pseudo-doublets at 7.99 and 7.60 ppm are visible for the *p*-iodophenylalanine residue. The shift difference is 0.39 ppm smaller than the value of 0.57 ppm that was observed in the dipeptides. The assignment of all signals was supported by HH-COSY 2D NMR spectroscopy.

*Synthesis of I-BA-Enk-OH (**17**).* In some cases the target biomolecule may not offer a phenylalanine residue which can be replaced by the *p*-iodophenylalanine group. For such cases, the N-terminally modified enkephalin derivative I-BA-Enk-OH (**17**) was synthesized in order to explore an alternative route (I-BA: *p*-iodobenzoic acid). I-BA was introduced at the N-terminus of Enk as the last step in the SPPS. Cleavage of the product from the Wang resin was performed under standard conditions. After removal of the solvents and subsequent precipitation with diethyl ether, nearly pure **17** was obtained in 86% yield. The white powder was submitted to FAB mass spectrometry showing the correct peaks at $m/z = 808$ $[M + Na]^+$ and 786 $[M + H]^+$. Additional fragments were observed in analogy to **16**. The successful introduction of the *p*-iodophenyl residue at the N-terminal side of the peptide is confirmed by the corresponding ^1H NMR signals at 7.82 and 7.57 ppm. The ^{13}C NMR spectrum shows six carbonyl carbon resonances between 173.7 (*C*OOH) and 165.6 ppm (I-BA). In addition, all 12 aromatic carbon signals were detected between 155.6 ppm (Tyr) and the iodine bound carbon atom at 98.7 ppm. Similar to the case for compound **16**, the shielding effect of the iodine atom is responsible for the high-field shift and the cross-coupling

Scheme 2. Synthesis of Enkephalin Derivative 16 by SPPS and Sonogashira Coupling with H-DEPA-CO-Fc (7) To Yield the Organometallic Conjugate 18.



reaction is expected to make the signal move downfield by more than 30 ppm. Therefore, this signal is also indicative for a successful Sonogashira coupling.

Sonogashira Coupling with Enkephalins. *Synthesis of Ac-Enk-[Phe⁴(DEPA-CO-Fc)]-OH (**18**).* In contrast to the synthesis of the ferrocene dipeptides **3**−**6** and **8**−**11**, the side-chain-modified enkephalin derivative **16** was reacted in a mixture of DMF/NEt_3 (1:1) for solubility reasons (Scheme 2). The reaction was monitored by HPLC, and the synthesis was finished after 12 h, when no more peptide starting material could be detected. The solvents were removed on a vacuum pump, and the residual oil was redissolved in acetonitrile and purified by preparative HPLC. The light yellow powder was characterized by ESI (neg) mass spectrometry where the spectrum shows a peak for $[M-H]^-$ at $m/z = 917.4$. The ESI (pos) spectrum confirms this observation, showing three peaks at m/z 919.4 $[M + H]^+$, 941.4 $[M + Na]^+$, and 957.5 $[M + K]^+$. The successful coupling to the ferrocene label is also proven by the typical 2−2−5 Cp signal pattern in the ^1H NMR spectrum between 4 and 5 ppm. The cyclopentadienyl ^{13}C NMR signals were found between 76.5 and 68.2 ppm, also underlining the successful reaction. The carbon atom to which the iodine atom was connected has shifted from 92.1 ppm in **16** to 120.5 ppm in **18**, while the alkyne carbon atoms resonate at 91.7 and 82.0 ppm. The yellow color of the conjugate results from a characteristic absorbance at 444 nm for the ferrocenyl group in the UV−vis spectrum. The extinction coefficient $\epsilon = 272$ l mol^{-1} cm^{-1} corresponds well to all other DEPA-CO-Fc derivatives **3**−**6** and previous work. The ethynylferrocene dipeptides **8**−**11** have higher extinction coefficients between 535 and 585 l mol^{-1} cm^{-1}, albeit with the same absorbance maximum at 445 nm.

*Synthesis of Fc-CO-DEPA-BA-Enk-OH (**19**).* H-DEPA-CO-Fc (**7**) was coupled to the N-terminal I-BA-derivatized enkephalin **17** under the same reaction conditions as those for **18.** Again, the reaction progress was followed by analytical HPLC and the conversion was finished after 10 h. The solvents were removed, and the crude product was purified by preparative HPLC. However, the yield was significantly lower in comparison to that of **18**, and only a few milligrams of pure substance were obtained (Figure 2; Scheme 3). The peak at $m/z = 979.5$ (ESI, neg) can be assigned to the molecular $[M - H]^-$ anion. NMR signals similar to the ones observed for **18** confirm the constitution of **19** unambiguously. Also, the UV−vis experiment shows the ferrocene absorbance maximum at 442 nm, which is responsible for the yellow−orange color of all ferrocene containing bioconjugates.

Electrochemical Characterization. The characteristic electrochemical properties of the ferrocene moiety offer a very sensitive detection for such marked biomolecules using methods such as HPLC with electrochemical detection (HPLC-ECD), which range down to the picomolar scale. Therefore, cyclic voltammograms (CV) and square wave voltammograms (SWV) were recorded for all presented compounds (Table 1). Measurements were recorded in 5 mL of CH_3CN/H_2O (1:1), with $NaClO_4$ as the supporting electrolyte (0.1 M) and an analyte concentration of 1 mM. These electrochemical measurements revealed a one-electron, fully reversible behavior for the ferrocenyl group (Figure 3). For all DEPA-CO-Fc-modified peptides, half-wave potentials between 209.5 and 216 mV and peak separations between 80 and 87 mV were found. In comparison, the alkynylferrocene-labeled peptides show similar peak separations but a half-wave potential of around 160 mV.

DISCUSSION

The successful introduction of alkynylated Fc derivatives into dipeptides and different positions of a pentapeptide has been

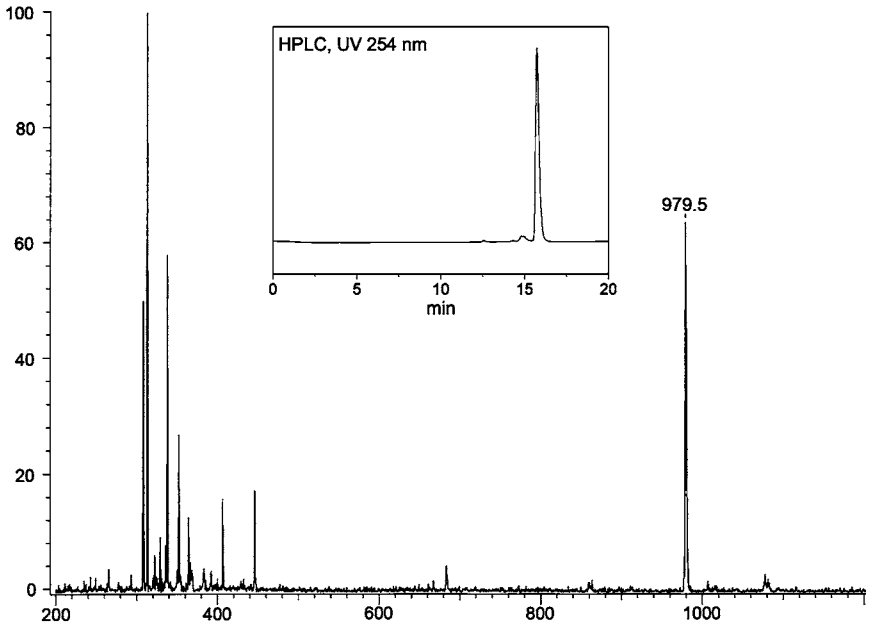


Figure 2. ESI (neg) mass spectrum and HPLC spectrum (RP-C18, 254 nm) of Fc-CO-DEPA-BA-Enk-OH (**19**).

Fc-CO-DEPA-BA-Enk-OH	**19**	216.0	80

presented. These results prove the Sonogashira coupling method to be of high value for the easy tethering of metal compounds to modified biomolecules. In this work, we have chosen phenylalanine as the site for modification, which is not easily achieved by other methods. Modification of the phenyl residue may of course alter the binding characteristics of the peptide enkephalin to the opiate receptor. Earlier work on organometallic enkephalin derivatives in which Phe is substituted by ferrocenylalanine ([Fer^4, Leu^5]-Enk) shows a reduced binding affinity (*32*, *33*). On the other hand, a bulky carboranylalanine derivative (Car), which was prepared as a structural probe for Enk ([Car^4, Leu^5]-Enk), shows a 3-fold increased affinity for the opiate receptor as shown in a naloxone displacement assay (*51*, *52*). These results show that there is at least some space in the opiate receptor to accommodate bulky substituents. An interesting Sonogashira method for the synthesis of ferrocene-labeled oligodeoxynucleotides had been presented by Grinstaff and co-workers (*53*). In their work, the Sonogashira coupling reaction was most successful when the oligodeoxynucleotide was still bound to the resin. However, no useful protocol for the regioselective labeling of small peptides was known. In our case, Sonogashira coupling on the resin usually gave a lesser yield of pure products. Therefore, binding of the marker molecule is performed under mild conditions in solution so that neither biomolecule nor labeling group decompose. This process should therefore be suitable for the labeling of more complicated and larger biomolecules. The "expansion of the genetic code" presented by Schultz and co-workers (*54*, *55*) may be an interface for that, since it provides the possibility to introduce unnatural amino acids such as 4-iodophenylalanine into a large number of proteins by recombinant methods (*56*). Such labeled

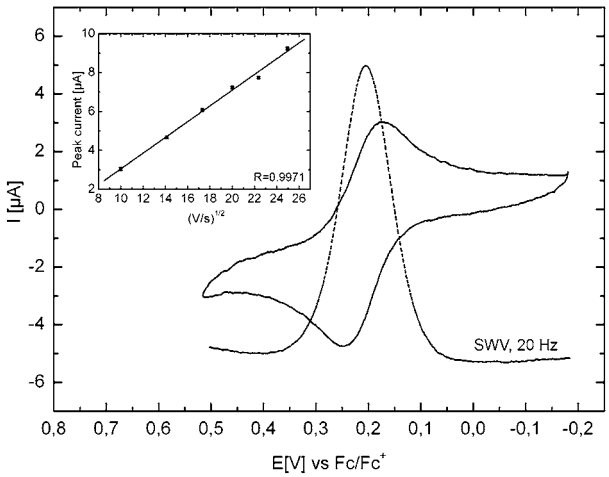

Figure 3. Cyclic and square wave voltammograms of Ac-Enk[Phe^4-(DEPA-CO-Fc)]-OH (**18**). The linearity of the inserted Randles−Sevcik plot indicates a reversible (Nernstian) behavior.

proteins could be purified by HPLC using the very favorable electrochemical properties of the ferrocene label for electrochemical detection, as shown herein.

ACKNOWLEDGMENT

This work was in part financially supported by the Deutsche Forschungsgemeinschaft (DFG) and the Fond der Chemischen Industrie. The authors are grateful to H. Rudy (MS), A. Seith (MS), T. Timmermann (NMR), and T. Coelho (NMR) for technical assistance. Experimental help and insightful discussions with Prof. T. J. J. Müller (Heidelberg) are gratefully appreciated.

Received October 7, 2005

Peptide nucleic acids (PNAs) are promising tools for gene regulation. One of the challenges of using PNAs as gene regulators is the need to optimize the efficiency of interaction with critical sequences of DNA. To improve the efficiency of binding between PNAs and the HER-2/neu promoter, mono- and bis-pyrimidine-rich PNAs were conjugated to a nitrogen mustard at either the amino or carboxy terminus. Gel shift analysis demonstrated that conjugation to an alkylating agent slowed PNA binding and favored PNA:DNA:DNA triplex helix formation while preserving a high binding affinity. Sites of DNA alkylation were visualized by piperidine cleavage and showed PNA binding first by Hoogsteen bond formation with the target duplex to form a stable PNA:DNA:DNA triplex structure which is later converted to a PNA:DNA:PNA triple helix by strand invasion and Watson−Crick base pairing by a second PNA molecule. In this way, PNA-directed DNA alkylation was used to deduce the mode of PNA binding. Transient transfection experiments demonstrated that the PNA−nitrogen mustard conjugates suppressed HER-2/neu expression by up to 80%. In comparison with an unmodified mono-PNA or a bis-PNA, these results indicate that the covalent adducts stabilized PNA binding in cells and suggest that the conjugation of PNAs to nitrogen mustards is a robust strategy for developing antigene PNA oligonucleotides to prevent transcription.

INTRODUCTION

Antigene and antisense strategies with peptide nucleic acids (PNAs)[1] have attracted a great deal of attention in medicinal and biological chemistry (*1*−*5*). The ability of oligonucleotides to recognize specific DNA or RNA sequences affords a versatile approach to control gene expression, but native DNA or RNA oligomers are susceptible to endogenous nucleases and lack the membrane permeability necessary for many in vivo applications. As a result, there has been considerable interest in the development of synthetic structures that specifically recognize and bind selectively to DNA, possess increased resistance to nuclease digestion, and optimize membrane permeability (*6*−*8*). Peptide nucleic acids are DNA mimics in which the sugar−phosphate backbone has been substituted by *N*-(2-aminoethyl)glycine units; therefore, PNAs possess a neutral backbone, which provides a unique advantage for hybridization relative to DNA or RNA oligomers (*9*−*11*). PNAs can bind to complementary sequences by Watson−Crick base pairing, and are able to discriminate single base mismatches. Binding is characterized by high affinity and high rates of association, together giving PNAs the ability to disrupt double stranded DNA by forming a DNA−PNA strand-invasion complex. PNAs are not substrates for endogenous nucleases or proteases, suggesting that they will be highly active in vivo (*12*−*14*).

The inhibition of gene transcription by PNAs presents a series of technical challenges. One of them is the need to optimize the efficiency of DNA binding to critical sequences within gene promoters, which might be accomplished by modifying the PNA via terminal conjugation of a small molecule. Different chelating and intercalating agents were successfully conjugated to PNAs in order to enhance the duplex invasion potency of the PNAs and increase the stability of the PNA−DNA complex (*15*−*20*). However, there are no reports on PNA terminal modification with small molecules resulting in more effective downregulation of gene expression. We postulated that PNA conjugation to a DNA alkylating agent would significantly improve gene regulation by stabilizing PNA binding to a target sequence. In this report we present the synthesis of a PNA−alkylator conjugate, using a short, symmetric PNA and a nitrogen mustard as an alkylating agent.

The HER-2/neu oncogene is overexpressed in a number of human cancers, and its overexpression correlates with poor clinical outcome (*21*−*23*). The results of clinical studies with HER-2/neu-directed therapies demonstrate that preventing the expression or function of the HER-2/neu gene product can induce the regression of metastatic tumors that overexpresses HER-2/neu (*24*, *25*). The HER-2/neu oncogene is a good target for antigene oligonucleotide strategies because of the presence of polypurine tracts capable of triplex formation with triplex-forming oligonucloetides (TFOs) that can prevent in vitro transcription (*26*, *27*) and transcription factor binding (*28*), and reduce HER-2/neu mRNA levels in a breast cancer cell line (*29*). The HER-2/neu promoter was successfully used for evaluating triplex formation with TFO−alkylator or TFO−minor groove binder conjugates (*30*−*32*) and strand invasion complex formation with PNAs (*33*). The polypurine tract is located from −218 to −245 upstream of the first codon (+1) in a region of the HER-2/neu promoter (Figure 1) that serves as an alternate transcription initiator that can function independently of the TATA box (*34*).

Nitrogen mustard derivatives are widely used in chemotherapy (*35*−*37*). The biological activity of these agents is usually

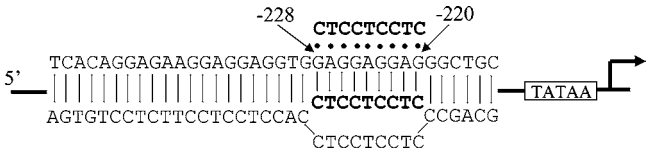

Figure 1. Schematic representation of the HER-2/neu promoter target sequence and two PNA molecules forming a strand invasion complex. The target sequence is a 9 bp purine/pyrimidine tract from −220 to −228 upstream of the first codon. Dots represent Hoogsteen hydrogen bonds and vertical lines represent Watson−Crick bonds.

mediated through alkylation at N-7 of guanine and subsequent DNA interstrand cross-linking (*38*−*40*). However, covalent binding can occur at multiple DNA sites, bringing nonspecific toxicity; moreover, the efficiency of the nitrogen mustards is limited because of deactivation by hydrolysis or due to reaction with nucleophilic molecules other than DNA. Nitrogen mustards have been conjugated to TFOs in order to direct highly specific DNA alkylation (*41*, *42*). Because PNAs are highly resistant to degradation by a variety of enzymes, we began investigating them as candidate antigene molecules for suppression of HER-2/neu expression. We initially postulated that PNA modification with an alkylating agent would not only stabilize the DNA/PNA complex but might also facilitate strand invasion by stabilizing Hoogsteen strand during the process of disrupting the duplex by a second PNA strand. Furthermore, PNA−alkylator conjugates can be used as tools to study the binding mechanism between DNA and PNA by positioning the alkylating moiety at different PNA ends and analyzing the sites of interaction with the target duplex.

In this report we describe the design and synthesis of novel bioconjugates of the nitrogen mustards (phenylacetic acid mustard (PAM) and chlorambucil (Chl)) to a PNA, demonstrate site-specific DNA alkylation with the target site in the HER-2/neu promoter, and show strong downregulation of HER-2/neu promoter activity in reporter gene assays.

EXPERIMENTAL PROCEDURES

Materials. Solvents and chemicals obtained from commercial sources were analytical grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μM) prior to use. PNA VII (see Table 1 for sequence information) was synthesized according to published procedures (*43*, *44*). PNAs I, III, V, and IX were purchased from BioSynthesis, Inc. (Lewisville, TX) on a 2 μM scale and obtained on solid support prior to final deprotection for further modification. A small portion of the PNAs (about 1/10 of the provided PNAs on resin) was cleaved from the solid support before modification for analysis. PNAs were cleaved from the solid support by mixing the resin with 300 μL of cleavage cocktail (95% TFA, 5% *m*-cresol). The mixture was agitated for 90 min, filtered off, and precipitated with cold diethyl ether, followed by HPLC purification. All PNAs were 95% pure or greater by C18 HPLC. Pentafluorophenyl esters of phenylacetate mustard (PFP−PAM) and chlorambucil (PFP−Chl) were synthesized in our group as previously described (*45*).

Spectral Analysis. Matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectra were acquired using a Micromass (Manchester, UK) MALDI-LR TOF mass spectrometer and Applied Biosystems Voyager DE-STR (Framingham, MA), operating a 337 nm nitrogen laser. Samples were mixed with an equal volume of a saturated α-cyano solution in 50% acetonitrile/50% water containing 0.1% trifluoroacetic acid (TFA), and 1 μL was spotted on the target plate and allowed to air-dry prior to mass analysis. Mass spectra acquired using the Micromass mass spectrometer were collected in Reflection mode with a 15000 V source voltage using a 0.5 ns sample period. The reflection voltage was set to 2000 V. The detector was held at 1800 V and 5 laser shots at 3 Hz were combined per mass spectrum recorded. Mass spectra acquired using the Applied Biosystems MALDI-TOF mass spectrometer were collected in positive reflection mode with an acceleratory voltage of 20000 V. The grid voltage was set at 66% with an extraction delay time of 275 ns. 400 laser shots at 20 Hz were combined per mass spectrum recorded. All modified and unmodified PNAs were analyzed by reverse phase HPLC using a VYDAC C18 250 × 10 mm column with a gradient of 0 to 80% solvent B over 40 min. Solvent B was 0.1% TFA in acetonitrile (flow rate 4 mL/min), solvent A was 0.1% TFA in water. Detection was carried out by UV absorbance at 260 nm. Preparative HPLC purification was performed on Varian proStar system equipped with a photodiode array (PDA) detector.

Synthesis of PNA−Mustard Conjugates. *Mono-PNA−5′PAM Conjugate (PNA II).* The mono-PNA (I) was obtained on solid support with the free 5′ (N-terminal) amino group but all other side chain protecting groups in place and was incubated in 300 μL of dry dichloromethane (DCM) for 2 h, then the resin was filtered and washed with DCM (2 × 2 mL). PFP−PAM (2.5 mg, 6 μmol) was dissolved in 150 μL of DCM and mixed with 150 μL of dry dimethylformamide (DMF) and 50 μL of triethylamine (Et_3N). The resulting mixture was added to the resin and bubbled through with argon for 3 h. The resin was filtered, washed with DMF (2 × 2 mL), DCM (2 × 2 mL), and dried under vacuum for 2 h and then overnight in a desiccator. The resulting PNA−5′PAM conjugate was then cleaved from the resin by using 500 μL of TFA/*m*-cresol cleavage cocktail as described for unmodified PNAs, HPLC purified (t_R = 19.4 min) and lyophilized. MALDI-TOF MS analysis for PNA II ($C_{123}H_{170}Cl_2N_{48}O_{37}$): calculated 2982.9; found 2983.5.

Mono-PNA−3′Chl Conjugate (PNA IV). The mono-PNA (III) was obtained on the solid support with standard protecting groups on the 5′ terminus and side chains except for a lysine at the 3′ end that was protected with methoxytrityl (Mmt) for selective deprotection. PNA IV had a cysteine (S) at the C-terminus to separate the target lysine from the solid support and provide a potential site for additional conjugation. The resin was incubated and washed with DCM as described for PNA I.

Table 1. PNA Analysis by MALDI-TOF and HPLC[a]

name	description	sequence	$M_{calcd.}$	$M_{obsd.}$	t_R, min
I	mono-PNA	CTCCTCCTC-O-KK	2724.5	2725.3	14.8
II	PNA−5′PAM	PAM-CTCCTCCTC-O-KK	2982.9	2983.5	19.4

VIII	bis-PNA(J)−5′Chl	Chl-KK-TCCTCCTCC-OOO-JJTJJTJJT-KSG	5881.7	5882.4	18.64
IX	bis-PNA	TCCTCCTCC-OOO-K-CCTCCTCCT	5193.2	5193.9	18.2

[a] C, T, J = cytosine, thymine, and pseudoisocytosine PNA residues; O = linker; K, S, G = lysine, cysteine, and glycine amino acid residues; PAM = phenylacetic acid mustard; Chl = chlorambucil.

To remove the Mmt protecting group, the resin was treated with 3% TFA in DCM (2 × 200 μL for 10 min each) and washed with DCM and DMF (2 × 2 mL) between and after each treatment. PFP−Chl (2.6 mg, 6 μmol) was dissolved in 150 μL of DCM and mixed with 150 μL of DMF and 50 μL of Et_3N. The resulting mixture was added to the resin and bubbled through with argon for 3 h. The resin was filtered and washed with DMF (2 × 2 mL) and DCM (2 × 2 mL). The PNA was then deprotected with 200 μL of piperidine/DMF (1/4 v/v) for 30 min. The resin was filtered, washed with DMF (2 × 2 mL) and DCM (2 × 2 mL), dried under vacuum for 2 h, and left overnight in a desiccator. The resulting PNA−3′Chl conjugate (IV) was cleaved from the resin with TFA/*m*-cresol, HPLC purified (t_R = 17.2 min) and lyophilized as described above. MALDI-TOF MS analysis for PNA IV ($C_{127}H_{177}Cl_2N_{49}O_{38}S$): calculated 3098.9; found 3100.6.

Bis-PNA−5′Chl Conjugates (PNAs VI and VIII). The unmodified bis-PNAs (V and VII) were obtained on solid support with the free 5′ (N-terminal) amino group but all other side chain protecting groups in place. They were conjugated to Chl at the 5′ end as described above for PNA II, except that PFP−Chl (2.6 mg, 6 μmol for each PNA) was used in place of PFP−PAM. After synthesis, the conjugates were HPLC purified (PNA VI t_R = 16.22 min; PNA VIII t_R = 18.64 min) and lyophilized. MALDI-TOF MS analysis for PNA VI ($C_{241}H_{339}Cl_2N_{97}O_{74}$): calculated 5847.9; found 5947.03. MALDI-TOF MS analysis for VIII ($C_{240}H_{360}Cl_2N_{97}O_{75}S$): calculated 5881.7; found 5882.4.

Electrophoretic Mobility Shift Assay (EMSA) Analysis of DNA/PNA Interaction. PNAs were incubated with a 36-base pair HER-2/neu duplex target sequence end-labeled on the pyrimidine strand. Reaction mixtures including increasing concentrations of the PNA with 0.01 μM target duplex in $NaPO_4$ buffer (10 mM, pH 6.5) were incubated for 24 h. The complexes were separated on a 10% nondenaturing gel at room temperature with 1× TAE (pH 6.5) in both the gel and running buffer and visualized by autoradiography. The rate of PNA binding was analyzed by adding 0.1 μM PNAs and 36-base pair HER-2/neu duplex target sequence (0.01 μM) end-labeled on the purine strand and stopping the reactions by freezing the samples at −80 °C at various time points from 1 to 18 h. The products were then separated on nondenaturing gels and visualized by autoradiography.

Piperidine Cleavage. A 250 base pairs (bp) Pst/XmaI fragment of the pGL3/HNP410 plasmid containing a 410 bp HER-2/neu promoter in the pGL3 basic luciferase plasmid (Promega) was used to create an end-labeled template by Klenow filling. DNA/PNA complex formation was performed by incubating 0.02 μM of labeled promoter fragment with 2 concentrations of PNA−5′PAM and PNA−3′Chl (0.1 and 1.0 μM) for 2, 4, 8, and 18 h in a final volume of 10 μL of 10 mM $NaPO_4$ (pH 6.5) at 37 °C. Reactions without PNAs were performed to show nonspecific cleavage sites of the radiolabled template by piperidine. Piperidine cleavage reactions were separated on a 10% denaturing gel and subjected to autoradiography. Maxam−Gilbert G-reactions were performed to identify alkylated guanine residues, and these reactions were run alongside the piperidine cleavage lanes as indicated in Figures 4 and 5; however, images from different autoradiographs were combined into composite figures in these illustrations in order to optimize the intensity of the exposure between the piperidine cleavage lanes and the G-reactions.

Transient Transfection Analysis. HeLa cells were obtained from the American Type Culture Collection and cultured as recommended by the supplier. The pGL3/HNP410 plasmid (2 μg) containing the HER-2/neu promoter was incubated in 10mM $NaPO_4$ (pH 6.5) at 37 °C with 1 and 10 μM of PNAs for 18 h. Transfection mixtures included the pGL3/HNP410 plasmid (with or without PNAs), 20 ng of an internal control plasmid (pRL/SV40, Promega), and 2 μL of Lipofectamine 2000 (Invitrogen). HeLa cells were incubated with the transfection mixture, cell lysates were obtained at 24, 48, and 72 h, and dual luciferase assays (Promega) were performed. All experiments were repeated three times, normalized for transfection efficiency, and are presented as a percentage of luciferase activity from plasmid without PNA treatment.

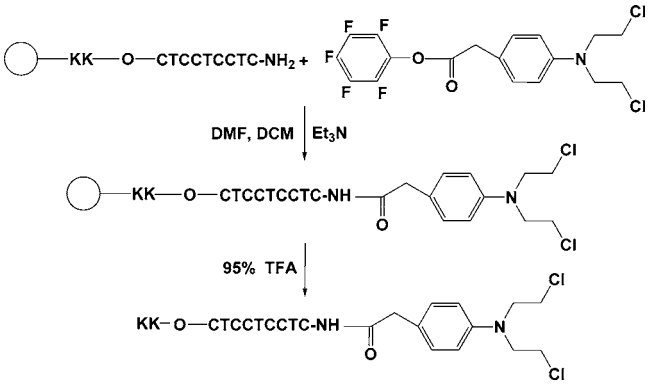
RESULTS

Design of the PNA−PAM Conjugates. Our previous results on targeting a polypurine tract in the HER-2/neu promoter with TFOs demonstrated that unmodified TFOs easily dissociated from the target sequence when transfected into tumor cells, while TFOs modified with an alkylating agent prevented helicase activity and suppressed HER-2/neu driven luciferase activity in cells for up to 72 h (*31*). We postulated that PNAs similarly modified with an alkylating agent would improve the stability of the PNA/DNA complex and improve the PNAs ability to prevent HER-2/neu expression. To simplify synthesis and product analysis, we decided to start with short mono-PNAs, and designed a mono-PNA (I) to target the HER-2/neu polypurine tract from −220 to −228 (Figure 1). This PNA, CTCCTCCTC, has perfect mirror symmetry and was designed to be able to simultaneously bind to the target sequence by Hoogsteen bonding (triplex formation) in parallel to the purine rich strand and by Watson−Crick bonding (strand invasion) in antiparallel orientation to the purine strand. To increase PNA solubility and strand invasion, two lysine residues were added to the C-terminus of the PNAs through a single 8-amino-2,6-dioxaoctanoic acid (O) linker (Table 1).

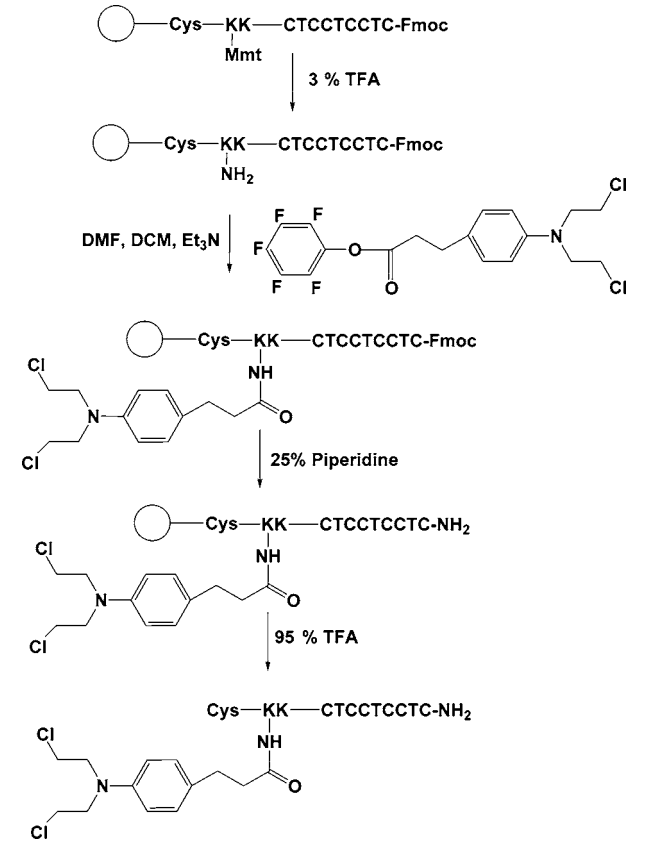
To conjugate the N-terminus of PNA I to the drug, we used the α-amino group of the peptide backbone of the last nucleic base in the PNA I sequence. To modify the C-terminus, we used the ϵ-amino group of one of the lysines of PNA III. That ϵ-amino group was protected with an acid-labile monomethoxytrityl (Mmt) protecting group. Deprotection of the Mmt group can be done with mild acidic conditions (3% TFA in DCM) while keeping nucleic bases, the other lysine side chain, and the N-terminus protected to create PNA−drug conjugation only at C-terminus (*46*). PNA III was also designed with a cysteine residue at the C-terminus that separated the target lysine from the solid support for the conjugation reaction and could eventually be used as a site of further conjugation, for example with a carrier peptide. For these studies we selected two commonly used nitrogen mustards, phenyl acetic acid mustard (PAM) and chlorambucil (Chl). To demonstrate the feasibility of the conjugation between PNA and alkylating agent, we started with commercially available chlorambucil, which was easily modified with PFP for conjugation in one step (*45*). PAM has a longer hydrolysis half-life but is slightly less reactive compared to chlorambucil. In this way we could evaluate the ability of two reactive nitrogen mustards conjugated to the PNA to direct site-specific DNA alkylation and regulate gene expression.

Conjugation of the Nitrogen Mustards to PNAs. The conjugation of the nitrogen mustard to the PNAs was done manually on solid support using an acylation reaction with the active ester of the nitrogen mustard and a free amino group of the PNA. Pentafluorophenyl esters are widely used in reactions with free amino groups to give amide bonds, and we synthesized the pentafluorophenyl (PFP) ester of phenylactate mustard and chlorambucil according to previously published methods (*45*). A mixture of anhydrous solvents was used for the coupling, with DMF as a traditional solvent for coupling in peptide synthesis on solid support, DCM as a more suitable solvent for the highly lipophilic PFP−PAM, and an excess of anhydrous triethylamine as an activating agent. The anhydrous conditions

Scheme 1. Synthesis of PNA−5′PAM (II)



Scheme 2. Synthesis of PNA−3′Chl (IV)



protect the nitrogen mustard from hydrolysis, and coupling requires only a small excess of PFP−PAM. PNA I on solid support had a free amino group at the N-terminus (Scheme 1) and was ready for conjugation unlike PNA III, which needed additional preparation for the coupling (Scheme 2). To put the drug molecule specifically on the C-terminus and avoid side reactions, we applied the strategy of selectively deprotecting a lysine bearing a labile protecting group, specifically an Mmt group on the ϵ-amine of the lysine at the C-terminus of PNA III. Mmt is a well-known acid-sensitive, trityl-type protecting group that can be removed with 3% TFA in DCM. The mild conditions allowed us to deprotect only the desired ϵ-amino group of the lysine at the C-terminus and proceed with coupling at this position. After the coupling reaction (3 h), the resin was dried and then cleaved using standard conditions. HPLC chromatograms (Figure 2) of the coupling reaction mixtures demonstrated the peak of unmodified PNA (t_R 14−15 min) and a smaller peak of conjugated product (t_R 17−19 min), the estimated yield was 20−40%, and prolonging the coupling reaction up to 18 h did not improve the yield. The conjugates

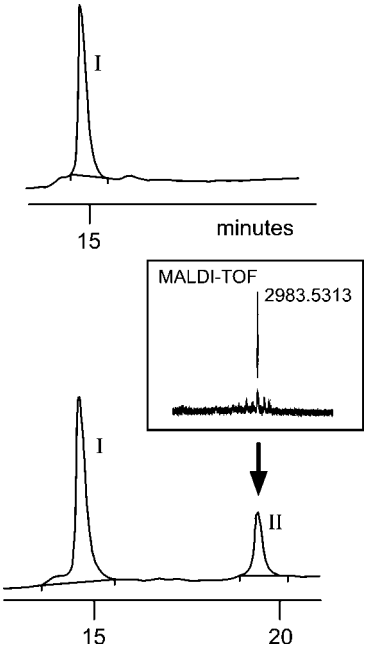


Figure 2. HPLC monitoring of the PNA−PAM conjugation reaction and MALDI-TOF spectra of conjugate II. The top chromatogram shows unconjugated mono-PNA (I), t_R= 14.8 min. The bottom chromatogram shows the reaction mixture with a new peak of the PNA−5′PAM conjugate (II), t_R= 19.4 min.

were characterized by mass spectral analysis, confirming the expected molecular weights (Table 1).

Analysis of PNA−Nitrogen Mustard Binding by EMSA. To evaluate the influence of the alkylating agent on the efficiency, mode, and rate of mono-PNA binding, PNA I (unmodified) was compared to PNA II (5′ PAM conjugate) by EMSA. The PNAs were incubated with a synthetic 36-mer duplex target sequence end-labeled on the pyrimidine strand in order to show displacement of the pyrimidine strand (Figure 3A). To monitor the rate of PNA binding, PNAs were incubated with the synthetic 36-mer duplex target end-labeled on the purine strand at a fixed concentration of the PNA, and reactions were stopped at various time points (Figure 3B). PNA I and PNA II showed similar affinities for the target duplex at pH 6.5, producing a transition of the target duplex to single stranded DNA and slow mobility complexes at 100 nM PNA concentrations, with complete disappearance of the duplex band at 1 μM (Figure 3A). PNAs and particularly covalently bound PNA−nitrogen mustard conjugates are not expected to dissociate from DNA in solution, so that equilibrium dissociation constants are not practical. C_{50} values (PNA concentration leading to 50% duplex DNA binding) can be used to estimate and compare the affinity of PNAs for duplex DNA under given experimental conditions, and C_{50} values for both PNA I and II would be $<$100 nM, slightly favoring PNA I, since this concentration leads to $>$50% DNA binding (shift in the duplex band to single stranded DNA and slow mobility PNA:DNA complexes at 100 nM PNA). Conjugation to a nitrogen mustard did not improve the pH dependent binding by the cytosine-rich PNA, and although binding was less efficient for both PNAs at pH 7.0, it was similar for PNA I and PNA II, again slightly favoring PNA I (not shown).

Interestingly, when the efficiency of PNA binding was evaluated over time, the presence of the nitrogen mustard on the PNA slowed binding to duplex DNA and appeared to favor binding by PNA$(DNA)_2$ triplex formation (Figure 3B). Both PNA I and II probably first bind by triplex formation with duplex DNA, forming PNA$(DNA)_2$ triplexes (seen as a shift in the duplex to a slower mobility complex at 100 nM PNA in

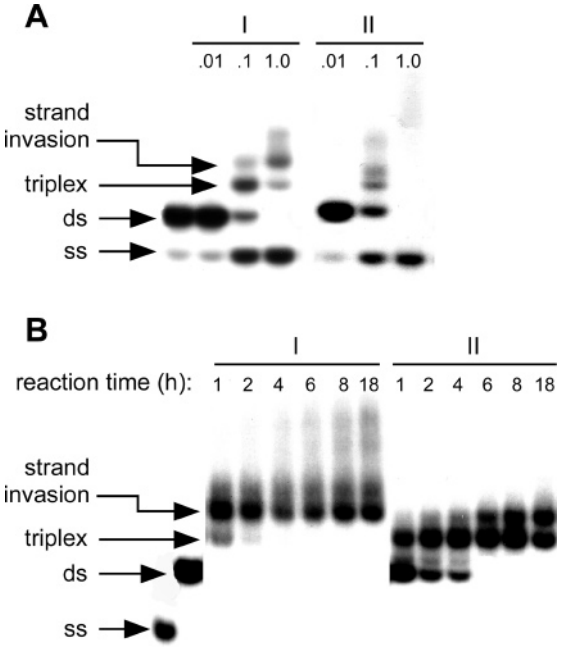

Figure 3. PNA binding to a synthetic duplex target sequence by EMSA. Representative native EMSAs comparing an unmodified mono-PNA (PNA I) to the same PNA conjugated to PAM at the 5′ terminus (PNA II). (A) Increasing concentrations of PNAs were mixed with duplex DNA radiolabeled on the pyrimidine strand for a fixed incubation time of 18 h at pH 6.5. (B) Fixed concentrations of the PNAs (100 nM) were mixed with duplex DNA radiolabeled on the purine strand for increasing incubation times at pH 6.5.

Figure 3A and 3B, accompanied by partial displacement of the pyrimidine strand in Figure 3A). Higher PNA concentrations (Figure 3A) or longer incubation times (Figure 3B) resulted in a further shift of the duplex to even slower mobility complexes (Figure 3A and 3B), accompanied by complete displacement of the pyrimidine DNA strand (Figure 3A), which is a characteristic of strand invasion and $(PNA)_2$DNA triplex formation with the binding of a second PNA molecule.

Piperidine Cleavage Analysis of Site-Directed DNA Alkylation by PNA−Nitrogen Mustard Conjugates. To determine the DNA alkylation sites and deduce the orientation of PNA−alkylator conjugate binding, piperidine cleavage was used. Sites of DNA alkylation can be visualized by converting these sites into single strand breaks with piperidine and heat as previously described (*30*). A 250 base pair promoter fragment was end-labeled on the purine-rich strand and incubated with 0.1 and 1 μM of 5′ and 3′ mono-PNA−alkylator conjugates (PNAs II and IV) over increasing amounts of time. The cleavage products were resolved on a sequencing gel and aligned with a G reaction to determine the alkylated bases.

PNA II (Figure 4A) demonstrated highly specific covalent adduct formation with G-229 with 0.1 μM of the conjugate, consistent with binding in a parallel orientation with Hoogsteen bonds to the duplex to direct the alkylation to the duplex/triplex junction. At higher concentrations and after prolonged incubation, alkylation of several additional guanines was observed, most prominently G-219, consistent with strand invasion and PNA binding in antiparallel orientation to the purine strand during the formation of a triplex invasion complex. Minor alkylation sites at G-241, G-238, and G-231 were also observed, probably due to binding of the PNA to less ideal binding sites in the highly repetitive HER-2/neu polypurine tract; for example, the PNA could bind to a single mismatch target sequence from −232 to −240, placing the alkylator at G-241 and G-231 at the junction of the duplex/triplex junction.

For PNA IV (Figure 4B), the major alkylation site is G-219, again consistent with the conjugate binding in parallel orientation to dsDNA through Hoogsteen bond formation. Minor alkylation at G-232 is most likely due to strand invasion and the influence of the spacing betweent the last PNA base and the alkylator moiety. In PNA IV the Chl is coupled to the ϵ-amino group of the second lysine residue and thus separated from the most 3′ PNA base by the 2,6-dioxaoctanoic acid linker, two amino acid residues, and the lysine side chain, resulting in a flexible, 18 atom linker between PNA and Chl. Alternately, the PNA could potentially bind (with less efficiency) to a single mismatch target sequence from −232 to −240, placing the chlorambucil in the proximity of G-232, but alkylation of a guanine in the PNA:DNA complex (G-232) would not be expected, since the N7 of this guanine would not be accessible to the Chl. Unconjugated PNAs did not demonstrate any cleavage sites (not shown). In both cases, the estimate of the alkylation efficiency at major sites was at least 80%. Figures 4C and 4D illustrate the deduced modes of binding and site-directed DNA alkylation by 5′ and 3′ PNA−alkylator conjugates, based on the major alkylation sites observed by piperidine cleavage.

We recently reported that a bis-PNA (PNA IX) composed of two linked 9-mers with $(TCC)_3$ sequences could target the HER-2/neu PPT at two adjacent $(GGA)_3$ or $(AGG)_3$ sequences (*33*). Because of the repetitive nature of the target sequence, this bis-PNA could bind in different orientations, depending on which of the PNA arms contributes to Hoogsteen binding versus Watson−Crick binding. If the N-terminal arm was the Hoogsteen strand, the bis-PNA would prefer to target 5′$(AGG)_3$ sequences with the linker oriented 3′ to the purine strand of the target sequence, whereas if the C-terminal arm was the Hoogsteen strand, the bis-PNA would prefer to target 5′$(GGA)_3$ sequences with the linker oriented 5′ to the purine strand (Figure 5A). We therefore synthesized bis-PNA−alkylator conjugates and probed for the orientation of bis-PNA binding by piperidine cleavage.

PNA V is a bis-PNA with linked $(TCC)_3$ arms, and PNA VII is an analogous bis-PNA with J-base substitutions in the C-terminal PNA arm [$(TCC)_3$-$(TJJ)_3$] to favor Hoogsteen binding by this arm of the bis-PNA at neutral pH. Compared to the PNA we previously studied (PNA IX), these PNAs were designed with additional lysine residues to enhance solubility and improve DNA binding. Both PNAs were conjugated to chlorambucil at their N-termini (PNAs VI and VIII). PNA V and VI could bind to adjacent $(AGG)_3$ sequences in the HER-2/neu PPT from −231 to −239 and from −219 to −227 if the N-terminal PNA arm serves as the Hoogsteen strand of the bis-PNA. Piperidine cleavage with PNA VI (Figure 5B) shows major alkylation products at G-228 and G-241, which is consistent with binding in this orientation, placing the alkylator at the guanines immediately adjacent (G-228) or near (G-241) the PNA/DNA junction (Figure 5D).

PNAs VII and VIII would prefer to bind to the $(GGA)_3$ sequence from −221 to −229, using the C-terminal PNA arm bearing J-base substitutions as the Hoogsteen strand of this bis-PNA. Piperidine cleavage with PNA VIII (Figure 5B) confirms this binding orientation with major alkylation products at G-218 and G-219, consistent with PNA binding to the HER-2/neu PPT from −221 to −229, placing the alkylator near the PNA/DNA junction (Figure 5C). An additional alkylation site at −231 is probably explained by PNA binding to an adjacent, single mismatch $(GGA)_3$ sequence from −233 to −241, placing the alkylator at G-231 near the PNA/DNA junction.

With TFO-nitrogen mustard conjugates, we and others have observed that guanine adducts form most efficiently with a guanine on the purine strand immediately adjacent to the triple helix (*30*, *31*, *47*). It is interesting to note that some of the PNA-

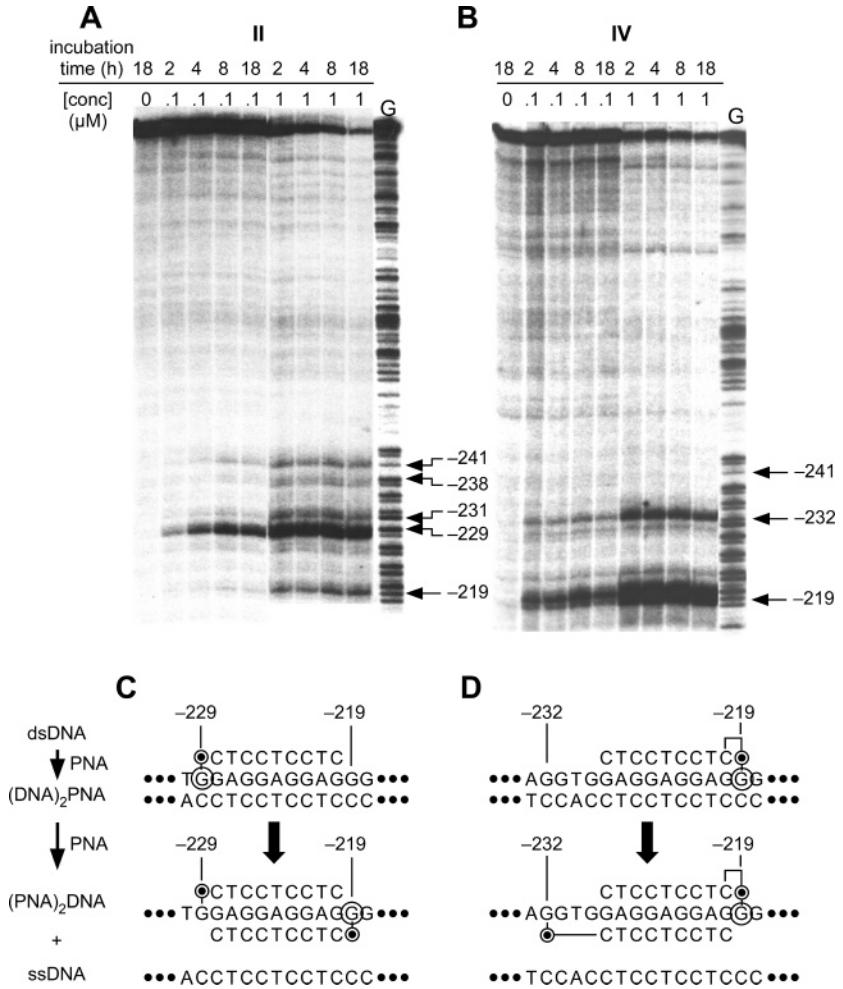

Figure 4. Representative piperidine cleavage gels demonstrating sites of alkylation for (A) the PNA−5′PAM conjugate (II) and (B) the PNA−3′Chl conjugate (IV). A ∼250 bp restriction fragment containing the HER-2/neu promoter was labeled on the 3′ end on the purine strand and incubated with 0.1−1 μM PNA for 2−18 h. Maxim-Gilbert G-reactions with the same template were used to identify the alkylation sites. Major alkylation sites are observed at G-229 for the 5′ alkylator conjugate (PNA II) and G-219 for the 3′ alkylator conjugate (PNA IV). Schematic representations of PNA−alkylator conjugate binding and covalent adduct formation deduced from piperidine cleavage analysis for PNA II (C) and PNA IV (D). The DNA:DNA:PNA triplex forms first and directs the nitrogen mustard to form a covalent adduct with the guanine adjacent to the triple helix, producing the major alkylation sites at G-229 for PNA II or G-219 for PNA IV. With either higher concentrations of the PNA−alkylators or prolonged incubation times, the PNA:DNA:PNA strand invasion complex is formed, producing the minor alkylation sites at G-219 for PNA II and G-232 for PNA IV. The linker in PNA IV allows the nitrogen mustard to reach G-232, 4 bp upstream of the strand invasion complex. Black circles represent the nitrogen mustards, and the guanines they bind are circled with open circles.

directed guanine adducts with PNAs IV, VI, and VIII are not immediately adjacent to the PNA/DNA junction. For example, it is surprising that PNA VIII does not form a guanine adduct with G-220, immediately adjacent to the PNA/DNA junction, but prefers G-218 and G-219. These findings are most likely explained by the spacing between the chlorambucil and the last PNA base, separated by two amino acid residues in PNA VI and VIII, and by the longer 18 atom linker in PNA IV. In contrast, the major and minor alkylation sites with PNA II, in which the PAM is conjugated to the α-amino group of the PNA base at the 5'terminus, occur immediately adjacent to the PNA binding site.

Inhibition of HER-2/neu Transcription. To determine whether conjugation with a nitrogen mustard can improve the antigene activity of a PNA, transient transfection analysis was performed using a HER-2/neu promoter-luciferase expression plasmid (pGL3/HNP410). In these experiments, PNAs were incubated with the plasmid prior to transfection, and the effect of PNA binding to the HER-2/neu promoter on HER-2/neu transcription was measured by luciferase activity (Figure 6). An indirect measurement of the stability of PNA binding in tumor cells is derived from the relative luciferase activity at various time points after transfection (Figure 6B). The specificity of PNA binding was also evaluated by treating a control luciferase expression plasmid containing the SV40 promoter (not shown). The mono- and bis-PNAs conjugated to nitrogen mustards were generally much more active than their unmodified counterparts in this assay, and two of the PNA−alkylator conjugates were capable of specifically suppressing HER-2/neu expression in HeLa cells by greater than 80%, depending on the concentration of PNA used to drive complete binding to the plasmid.

PNA II and PNA VIII demonstrated over 80% suppression of HER-2/neu transcription when the plasmid was incubated with 10 μM PNA and luciferase activity was analyzed at 24 h (Figure 6A). In comparison, the unmodified mono-PNA (I) had only a small effect on HER-2/neu transcription (13% suppression), and the unmodified bis-PNAs (PNAVII and IX) had a modest (40−55% suppression) impact on HER-2/neu transcription under these conditions. The high concentration of the PNAs (10 μM) was used to ensure rapid saturation of the PNA binding site(s) in the plasmid and thereby improve the efficiency of site-directed alkylation at the target sequence, since PNA binding must occur within the time frame of the hydrolysis half-life of the nitrogen mustards for alkylation to occur. Incubation of the SV40 control plasmid with this high concentration of the PNA−

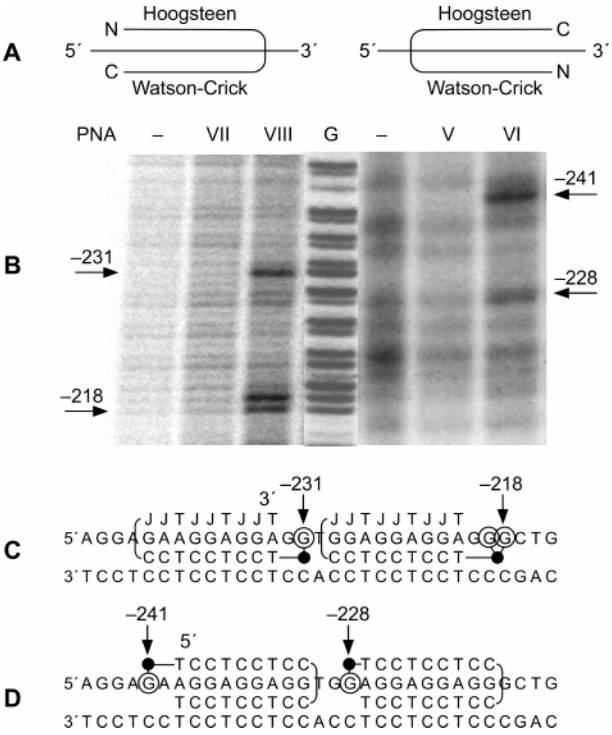

Figure 5. Representative piperidine cleavage gels demonstrating sites of alkylation for bis-PNA−5′Chl conjugate (VI) and bis-PNA(J)−5′Chl conjugate (VIII). (A) Possible orientations of bis-PNA binding to the purine strand of duplex DNA. (B) A ∼250 bp restriction fragment containing the HER-2/neu promoter was labeled on the 3′ end on the purine strand and incubated with 1 μM PNA for 18 h. Maxim−Gilbert G-reactions with the same template were used to identify the alkylation sites. Schematic representations of PNA−alkylator conjugate binding and covalent adduct formation deduced from piperidine cleavage analysis for PNA VIII (C) and PNA VI (D). Black circles represent the nitrogen mustards, and the guanines they bind are circled with open circles.

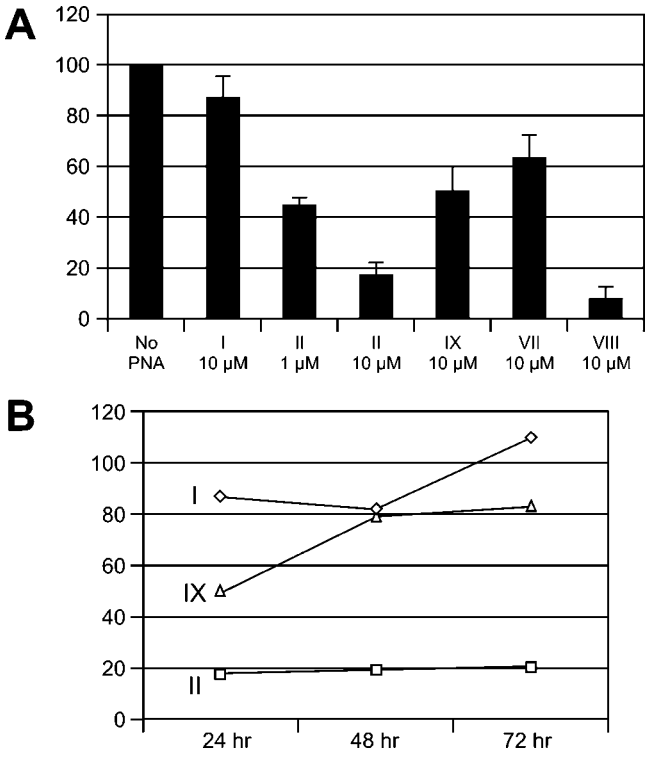

Figure 6. Transient transfection analysis of the HER-2/neu promoter-luciferase plasmid incubated with PNAs and transfected into HeLa cells. (A) Luciferase activity was analyzed with various PNAs at 24 h. (B) The stability of PNA binding and inhibition of HER-2/neu promoter activity was analyzed for up to 72 h with selected PNAs, when the plasmid was preincubated with the indicated PNA at 10 μM. The luciferase activity from cells transfected with untreated plasmid was defined as 100% promoter activity at each time point, and the effect of the PNAs on HER-2/neu transcription is presented as a percentage of full promoter activity.

alkylator conjugates also lead to a 15−20% decrease in SV40 driven luciferase activity, presumably due to some degree of nontarget binding by the PNA (not shown). Incubation of the HER-2/neu luciferase construct with a lower (1 μM) concentration of PNA II improved the specificity for the target sequence, but resulted in a lower level of suppression of HER-2/neu transcription, 55−60%, with minimal effect on the SV40 control plasmid. The effect of the mono-PNA−PAM conjugate (II) on HER-2/neu transcription at both concentrations remained stable for 72 h after transfection (Figure 6B). For comparison, we used the unmodified mono-PNA (I) as well as the unmodified bis-PNA (IX) from our recent studies (*33*), showing that the small effect observed with PNA I was not observed beyond 48 h and that the level of suppression by PNA IX decreased significantly at 72 h. Collectively, these data comparing unmodified PNAs with their nitrogen mustard conjugates demonstrate that the nitrogen mustard significantly improves the biological activity of the PNA and improves the stability of PNA binding within cells.

DISCUSSION

This is the first report of a PNA conjugated to a DNA alkylating agent. The PNA−alkylator conjugates directed the site-specific alkylation of the guanines adjacent to the bound PNA, stabilized the binding of the PNA in tumor cells, and markedly enhanced the ability of the PNA to suppress target gene transcription.

Intercalating agents have been shown to enhance helix invasion by homopyrimidine PNAs (*18*, *19*), but none have been shown to enhance the ability of a PNA to downregulate gene expression. In the present experiments, formation of helix invasion complexes with unmodified mono-PNA or bis-PNAs resulted in minimal to modest suppression of target gene transcription, while PNA binding stabilized by covalent adduct formation with a nitrogen mustard resulted in much higher inhibitory activity.

Nitrogen mustard conjugated to oligonucleotides have served as valuable probes for nucleic acid structure, for example in the Holliday junctions formed during DNA recombination events (*48*). The present PNA−alkylator conjugates also function as probes for studiyng the mechanism of PNA interaction with DNA. We took advantage of the ability of the nitrogen mustard to alkylate at a single site adjacent to the PNA binding site which could subsequently be converted to an easily detectable single strand scission by piperidine treatment. Visualizing the alkylation site allowed us to deduce not only the PNA binding site but also the orientation of PNA binding. The binding of a homopyrimidine PNA to dsDNA usually does not result in a conventional triplex with duplex DNA but rather in a triplex invasion complex as the thermodynamically most stable complex (*9*, *49*, *50*). However, as also demonstrated here, the formation of a traditional triple helix does indeed take place (at least for cytosine-rich PNAs) (*51*, *52*), and for the PNA−alkylator conjugates used in the present study, the conventional triplex is most probably responsible for their effect on gene transcription.

Oxidative cleavage or photocleavage by bis-PNAs conjugated to an anthraquinone DNA intercalator or to a metalloporphyrin metal chelator have previously been used to deduce the sites and modes of PNA binding (*17*, *19*). The present PNA−alkylator conjugates predominantly directed covalent adduct

formation to the duplex−triplex junction, similar to the sites of cleavage seen with the PNA−metalloporphyrin conjugate but in contrast to the PNA−anthraquinone conjugate, which caused the strongest cleavage sites within the displaced strand, perhaps because the single stranded loop is more prone to photooxidation. Our results are consistent with a mechanism in which the nitrogen mustard extends along the major groove and covalently binds to the exposed N7 of nearby guanines. It is well established that for PNA/DNA binding the antiparallel orientation is preferred for Watson−Crick duplex binding while the parallel orientation is preferred for Hoogsteen triplex binding (*52*). If triplex (invasion) PNA:DNA:PNA complexes are formed using only one type of PNA (mono-PNA), the overall parallel configuration is preferred (*52*). Concordingly, the mono-PNA−nitrogen mustard conjugate also prefers to bind in the parallel orientation. EMSAs with the PNA−PAM conjugate clearly demonstrate a discrete triplex band as well as additional bands of even lower mobility that are ascribed to helix invasion complexes, which are formed upon prolonged incubation or using higher PNA concentrations. We were able to differentiate triplex formation from strand invasion by monitoring the displacement of the pyrimidine strand.

The distance between the oligomer and the DNA interactive drug can significantly impact the reaction site and affinity of the conjugate. In the present work we did not systematically study linker length, but the piperidine cleavage experiments demonstrated that without a linker, PAM attached to the PNA N-terminus is able to effectively alkylate a guanine at the duplex/triplex junction. At the same time, the presence of a additional amino acid residues or a long 18 atom linker between the last PNA base and chlorambucil allows the nitrogen mustard to alkylate guanines a few base pairs away from the duplex/triplex junction, as demonstrated by a minor cleavage sites four base pairs away from the predicted PNA binding site for the PNA−3′chl conjugate.

In summary, we have demonstrated the facile synthesis of PNA−nitrogen mustard conjugates and their ability to suppress HER-2/neu transcription in a reporter plasmid model system. Such PNA−alkylator conjugates provide a new class of probes for sequence specific PNA−DNA interactions and warrant further study for gene targeting.

TECHNICAL NOTES

Novel and Efficient Preparation of Precursor $[^{188}Re(OH_2)_3(CO)_3]^+$ for the Labeling of Biomolecules

Sang Hyun Park,[†,*] Sepp Seifert,[‡] and Hans-Jurgen Pietzsch[‡]

Division of Radioisotope Production and Application, Korea Atomic Energy Research Institute, Daejeon, Republic of Korea, and Forschungszentrum Rossendorf, Institute for Bioinorganic and Radiopharmaceutical Chemistry, PF 510 119, D-01314 Dresden, Germany. Received June 30, 2005; Revised Manuscript Received September 8, 2005

A novel and efficient method for preparing ^{188}Re(I) tricarbonyl precursor $[^{188}Re(OH_2)_3(CO)_3]^+$ has been developed by reacting [^{188}Re]perrhenate with Schibli's kit in the presence of borohydride exchange resin (BER) as a reducing agent and an anion scavanger. The precursor was produced in more than 97% yield by reacting a solution of tetrahydroborate exchange resin (BER, 3 mg), borane−ammonia ($BH_3{\cdot}NH_3$, 3 mg), and potassium boranocarbonate ($K_2[H_3BCO_2]$, 3 mg) in 0.9% saline with a solution of sodium perrhenate ($Na^{188}ReO_4$) with up to 50 MBq and concentrated phosphoric acid (85%, 7 μL) at 60 °C for 15 min. HPLC and TLC revealed 0% unreacted [^{188}Re]-perrhenate ion and <3% of colloidal $^{188}ReO_2$. Since the precursor is produced with high radiochemical purity and labeling efficiency under the milder conditions than those required for the conventional reducing agents, the latter can be replaced.

INTRODUCTION

The ^{99m}Tc(I) and ^{188}Re(I) tricarbonyl precursors $[M(OH_2)_3(CO)_3]^+$ have been shown to be excellent starting materials for the synthesis of further ^{99m}Tc(I) and ^{188}Re(I) tricarbonyl complexes as well as radiolabeling of target specific biomolecules (*1*−*8*). Recently, a user-friendly kit formulation (IsoLink) was developed using potassium boranocarbonate, $K_2[BH_3CO_2]$, for preparation of the ^{99m}Tc precursor complex. This solid reagent serves both as a source of carbon monoxide and a reducing agent for technetium. It was also used by Schibli and co-workers for the preparation of the corresponding ^{188}Re precursor complex (*9*). [^{188}Re]Perrhenate eluate (1 mL) was reduced in neutral solution with 3 mg of $K_2[BH_3CO_2]$ and 5 mg of $BH_3{\cdot}NH_3$ by incubation at 60 °C for 15 min. The amount of reducing agents and acid (concentrated phosphoric acid) was carefully balanced not only to avoid fast hydrolysis of the boranes, but also to maintain a sufficient low pH to stabilize reduced rhenium intermediates. The preparations resulted in yields >85% of the desired precursor complex, remaining perrhenate (7±3%), colloidal $^{188}ReO_2$ (<5%), and a byproduct of unknown composition.

To overcome the moderate yields we used the recently described borohydride exchange resin (BER) as an additional reducing agent and an anion scavenger (*10*).

EXPERIMENTAL PROCEDURES

Unless otherwise stated, all chemicals were of reagent grade and used without further purification. Sodium perrhenate ($Na^{188}ReO_4$) was eluted from a $^{188}W/^{188}Re$ generator (Oak Ridge National Laboratories, Oak Ridge, TN) using 0.9% saline. For the separation of $[^{188}Re(OH_2)_3(CO)_3]^+$, HPLC analyses were performed on a Waters system equipped with a radiometric detector using a reversed phase XTerra RP_{18} 5 μm column (4.6 × 250 mm, Waters, Ireland). HPLC solvents consisted of methanol (solvent A) and 0.05 M TEAP (tetraethylammonium phosphate) buffer, pH 2.25, solvent B). HPLC gradient: 0−5 min: a linear gradient to 0% A/100% B from 100% A/0% B; 5−8 min: a linear gradient to 25% A/75% B from 0% A/100% B; 8−11 min: a linear gradient to 34% A/66% B from 25% A/75% B; 11−22 min: a linear gradient to 100% A/0% B from 34% A/66% B; 22−24 min: a linear gradient to 0% A/100% B from 100% A/0% B. The flow rate was 1 mL per min. For the separation of ^{188}Re(I) tricarbonyl histidine, HPLC analyses were performed on a Perkin Elmer system equipped with a radiometric detector (IsoScan LC gamma, Biostep, Germany) using a Hypersil ODS column (packing material 10 μm, 250 × 4 mm, Knauer, Berlin, Germany). HPLC solvents consisted of ethanol (solvent A) and 0.05 M TEAP (triethylammonium phosphate) buffer, pH 1.95 (solvent B). HPLC gradient: 0−10 min: a linear gradient to 100% A/0% B from 0% A/100% B; 10−20 min: 100% A; 20−25 min; a linear gradient to 0% A/100% B from 100% A/0% B. The flow rate was 1 mL per min. All solvents for the mobile phase were of HPLC grade and prefiltered with 0.2 μm pore size bottle filter. The instant thin-layer chromatography (ITLC) analyses were performed on a TLC analysis system equipped with a gamma-ray scanner (RITA TLC Analysis, Raytest, Germany). The thin-layer chromatography (TLC) system was performed using either silica gel plates ($60F_{254}$, Merck, Darmstadt, Germany) and 99% methanol/1% concentrated HCl as an evolving solvent or paper (Whatman No. 1) and 99.5% methanol/0.5% 6 M HCl as an evolving solvent.

1 **2**

mg) were capped with a rubber stopper. A solution of 1 mL of sodium perrhenate ($Na^{188}ReO_4$) with up to 50 MBq and 7 μL of concentrated phosphoric acid (85%) was added into the vial by a 20 mL syringe and then heated to 60 °C in a boiling water bath for 15 min. Pressure from the evolving gas (about 10 mL) was balanced with the syringe. After cooling to room temperature, the neutral ^{188}Re(I) tricarbonyl precursor was obtained (Scheme 1). Yield: >97% determined by means of HPLC and TLC.

^{188}Re(I) Tricarbonyl Histidine (2). A 10 mL vial containing histidine (500 μL) was capped with a rubber stopper. A solution of 800 μL of $[^{188}Re(OH_2)_3(CO)_3]^+$ with up to 50 MBq was added into the vial by a 1 mL syringe. The reaction vial was sealed and heated to 75 °C for 30 min. After 30 min, the reaction mixture was cooled to room temperature (Scheme 1). Yield: >97% determined by means of HPLC and TLC.

Tetrahydroborate Exchange Resin (BER). The tetrahydroborate exchange resin (BER) as a reducing agent was prepared by the reported method. Chloride-form resin (Amberlite ion-exchange resin, 12.5 g) was slurry-packed with water into a 30-mL fritted glass funnel mounted on a filter flask. Then, an aqueous sodium tetrahydroborate solution (200 mL, 0.25 M) was slowly passed through the resin over a period of 30 min. The resulting resins were washed thoroughly with distilled water until free of excess and finally with ethanol. The tetrahydroborate-form anion-exchange resin was then partially air-dried by removing ethanol on the surface of the BER. This resin was analyzed for its tetrahydroborate content by hydrogen evolution upon an acidification with 0.08 M HCl, and the average capacity of BER was found to be 2.5 mequiv of tetrahydroborate ion per gram.

RESULTS

The HPLC chromatogram of ^{188}Re(I) tricarbonyl precursor **1** and $^{188}ReO_4^-$ showed that retention times of those species are 4.7 and 9.8 min, respectively. The retention time of the ^{188}Re(I) tricarbonyl precursor was compared to that of ^{99m}Tc(I) tricarbonyl precursor and they were found to be identical. The radiolabeling yield of ^{188}Re(I) tricarbonyl precursor in the reaction mixture was determined by the HPLC analysis and found to be 100%. The HPLC chromatogram of ^{188}Re(I) tricarbonyl precursor in the reaction mixture is shown in Figure 1. The complex is stable (>95%) for approximately 3 h. After this time, decomposition of the complex was observed. Paper electrophoresis investigations in aqueous solution confirmed the cationic charge of ^{188}Re(I) tricarbonyl precursor in a neutral solution. The assay for the formation of the ^{188}Re(I) tricarbonyl precursor, reduced hydrolyzed ^{188}Re, and [^{188}Re]perrhenate ion

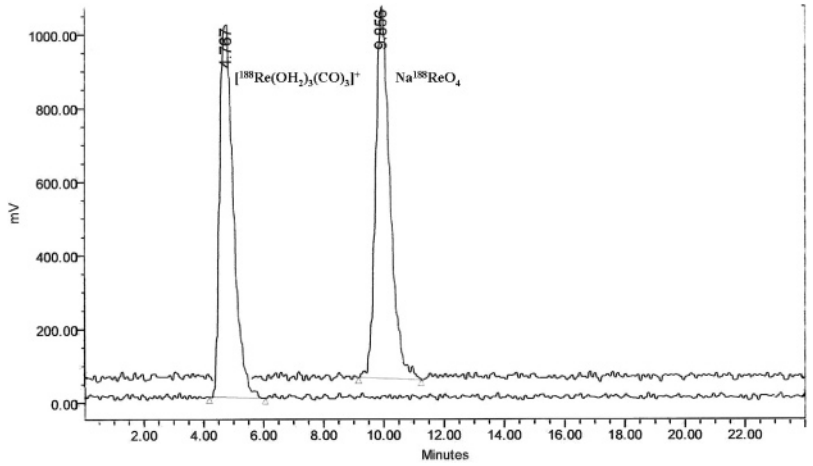

Figure 1. HPLC chromatograms of ^{188}Re(I) tricarbonyl precursor and $Na^{188}ReO_4$.

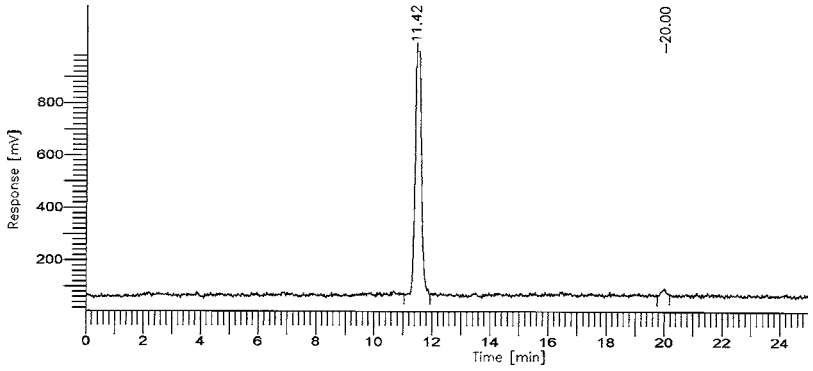

Figure 2. HPLC chromatogram of ^{188}Re(I) tricarbonyl histidine (**2**).

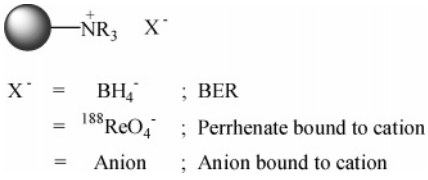

Figure 3. BER as a solid-phase reducing agent and an anion scavenger.

was achieved by investigating their positions using an instant thin-layer chromatography (ITLC). ^{188}Re(I) tricarbonyl precursor: >95% (R_f = 0.4); reduced hydrolyzed ^{188}Re: less than 3% (origin); [^{188}Re]perrhenate ion: 0% (R_f = 0.8). The HPLC chromatogram of ^{188}Re(I) tricarbonyl histidine showed that the retention time of the complex is 11.4 min. The radiolabeling yield of ^{188}Re(I) tricarbonyl histidine in the reaction mixture was determined by the HPLC analysis and found to be >97%. The HPLC chromatogram of ^{188}Re(I) tricarbonyl histidine (**2**) in the reaction mixture is shown in Figure 2. The retention time of the ^{188}Re(I) tricarbonyl histidine was compared to that of ^{99m}Tc(I) tricarbonyl histidine and they were found to be identical.

DISCUSSION

Tetrahydroborate exchange resin (BER) contains tetrahydroborate ion (BH_4^-) bound to the cation which is supported on polystyrene matrix, and the cation has a quaternary alkylammonium functionality used for adhering the tetrahydroborate ion or negatively charged species. BER is shown in Figure 3.

According to the present study, employing the borohydride exchange resin (BER) as a novel reducing agent and an anion scavenger, ^{188}Re(I) tricarbonyl precursor having high radiochemical purity and labeling efficiency can be prepared without nitrogen gas flushing and ice bath cooling compared to the conventional method (*9*). The BER is advantageous in terms of being stable over a wide range of pH (2−11) and applicable to biologically active molecules, as well as being easily removable through filtration when being administrated (*10*), thus providing the potential to economically and effectively produce ^{188}Re(I) tricarbonyl precursor without the formation of unreacted $^{188}ReO_4^-$, colloidal $^{188}ReO_2$, and negatively charged impurities by reinforcing the conventional reducing agent requiring very stringent condition for preparation.

ACKNOWLEDGMENT

This work was supported by the Nuclear R & D Program of the Korean Ministry of Science and Technology and the Technical Cooperation Program of the International Atomic Energy Agency. We would like to thank K. Landrock for her assistance in preparing HPLC, ITLC, and electrophoresis.

A Solid-Phase Labeling Strategy for the Preparation of Technetium and Rhenium Bifunctional Chelate Complexes and Associated Peptide Conjugates

R. William Riddoch, Paul Schaffer, and John F. Valliant*

Departments of Chemistry and Medical Physics and Applied Radiation Sciences, McMaster University, 1280 Main Street West, Hamilton, Ontario, Canada, L8S 4M1. Received July 21, 2005; Revised Manuscript Received October 21, 2005

A new solid-phase labeling strategy for the preparation of ^{99m}Tc and Re chelate complexes and associated peptide derivatives, was developed. Resin-bound monoamide monoamine (MAMA) chelates were prepared in such a manner that upon the addition of a suitable Re(V) and Tc(V) precursor the target metal complexes were selectively released from the resin. The desired products were isolated from unreacted ligand by a simple filtration/solid-phase extraction procedure. In addition to the preparation of a series of functionalized ligands, a peptide conjugate was constructed from one of the resin-bound chelates using a conventional automated peptide synthesizer. The yields of the Re chelate complexes were typically greater than 70%, while the maximum yield for reactions run at the tracer level using ^{99m}Tc was 50%. The reported approach has a number of attractive features, including the opportunity to prepare libraries of novel agents, the ability to isolate macroscopic amounts of Re complexes for use in in vitro screening studies and as well-characterized standards for tracer level work, and the ability to produce ^{99m}Tc complexes that are free of any unreacted starting material without having to employ preparative HPLC.

INTRODUCTION

Solid-phase labeling strategies (SPLS) are an attractive means of preparing radiotracers because they facilitate the process of separating the desired product from the excess starting materials used during standard labeling procedures (*1*). Removal of unlabeled ligands to give high effective specific activity formulations is particularly important in situations in which a precursor (i.e., unlabeled ligand) can compete with the tracer for the target receptor. It is also relevant to studies involving small animal positron emission tomography (PET) and single photon emission computed tomography (SPECT) scanners where minute amounts of unlabeled material can be toxic to the animal and/or have a significant impact on the distribution of a tracer (*2*). SPLS are easy to automate, which is important when high levels of activity are needed, and, although it has not been widely exploited, SPLS also engender the opportunity to incorporate modern drug discovery techniques, including combinatorial chemistry, into the radiopharmaceutical development process.

SPLS typically involve covalent attachment of a substrate to an insoluble support through a linker that is cleaved when the resin-bound material reacts with a particular radioisotope. For instance, Hunter and co-workers developed a convenient strategy for radio-iodinating aromatic rings by attaching benzoic acid and benzylamine derivatives to a solid support through a tin linker (*3*). In this way, iodinated compounds, including [^{131}I]-meta-iodobenzylguanidine (MIBG), were prepared in excellent yield, purity, and specific activity.

Similar strategies for labeling with ^{99m}Tc, the most widely used radionuclide in diagnostic medicine, have also been developed (*4*). Dunn-Dufault et al. showed that it was possible to label an N_3S chelate that was connected via the thiol residue (through a succinimidyl linker) to a variety of different supports (*5*). Although these systems afforded high (effective) specific activity formulations, radiochemical yields varied significantly (13−80%). Alternatively, the same chelate, derivatized with a peptide, was linked through a thiol group to a support consisting of gold particles (*6*). Upon labeling with ^{99m}Tc, the desired product was isolated in excellent radiochemical yield. More recently, Alberto et al. published a solid-phase labeling system for the technetium(I) tricarbonyl ($[Tc(CO)_3]^+$) core (*7*). In this approach, a derivative of diethylene triamine was attached to the solid support via the secondary amine. Upon the addition of $[^{99m}Tc(OH_2)_3(CO)_3]^+$, the technetium bound to the triamine ligand, and it was postulated that one of the displaced water molecules reacts with the carbon−nitrogen bond, thus freeing the coordination complex from the solid support.

Existing SPLS for technetium are often designed for incorporating ^{99m}Tc into compounds, but they have not been particularly effective at producing macroscopic quantities of Re or ^{99}Tc complexes which are needed for screening potential radiopharmaceuticals in vitro and as reference compounds for work done at the tracer level. Furthermore, there has been only limited investigation into the use of the supported synthons as platforms for preparing receptor targeted radiopharmaceuticals using automated solid-phase synthesis (*8*−*10*).

The objective of the work described herein was to develop a SPLS that could be used to prepare both Re and ^{99m}Tc complexes of functionalized chelates. The methodology was designed to enable the preparation of discrete compounds in useful quantities while also offering the opportunity to prepare libraries of peptide−chelate conjugates. Merrifield-type resins were selected as the support because an extensive collection of prefunctionalized derivatives are commercially available and the polystyrene-based resins are already widely used in automated peptide and organic synthesizers. The monoamide monoamine chelate (MAMA) (*11*, *12*) was chosen as one of many possible ligand systems because it forms neutral, stable, and well-defined complexes with both Tc(V) and Re(V), and it can be easily derivatized, regioselectively, with a wide range of different functional groups (*13*−*15*), which imparts a great deal of flexibility when designing libraries.

EXPERIMENTAL PROCEDURES

Instrumentation. All peptides were prepared on an Advanced ChemTech 348 Ω Peptide synthesizer using a 40-well reaction block. Electrospray ionization (ESI) mass spectrometry experiments were performed on a Micromass Quattro Ultima instrument where samples were dissolved in 1:1 CH_3OH/ H_2O or 1:1 CH_3CN/H_2O mixtures. High-resolution MS was obtained using a Micromass Global Q-TOF Ultima instrument. FTIR spectra were acquired on a Bio-Rad FTS-40 FTIR spectrometer. NMR experiments were performed using Bruker Avance DRX-500, Avance AV-600 or AC-200 spectrometers. For a pair of geminal protons, A refers to the proton associated with the higher frequency signal, while B refers to the proton giving rise to the lower frequency resonance. For the Re complexes, α refers to ring protons that are endo relative to the Re−oxygen bond, while β refers to protons that are oriented exo.

Analytical HPLC studies for nonradioactive samples were performed using a Varian Pro Star model 230 solvent delivery system, 330 PDA detector fitted with a C-18 Microsorb column (4.6 × 250 mm, 300 Å-5 μm). The elution protocol for nonpeptide based compounds was a gradient of 25 to 40% CH_3CN (containing 0.1% TFA) over 15 min at a flow rate of 1.0 mL/min. All analytical HPLC experiments were monitored at λ = 254 and 214 nm. For peptides, a gradient range of 5 to 20% CH_3CN over 15 min was used. For labeling reactions with ^{99m}Tc, approximately 100 μL of sample was removed from a reaction mixture and diluted to 1 mL with distilled water. A total of 10 μL of this solution was injected onto a Nucleosil C-18 column (250 × 4.6 mm, 5 μm). The runs employed the same gradients used for the Re analogues.

Materials, Methods, and Characterization Data. Unless otherwise stated, all reagents and solvents were ACS grade or higher and used without further purification from commercial suppliers. Polystyrene-based *N*-α-9-fluorenylmethoxycarbonyl (Fmoc)-glycine loaded SASRIN resin (0.69 mmol g^{-1}, 1% divinylbenzene, 200−400 mesh) was obtained from Bachem Inc. Fmoc-protected amino acids were purchased from Novabiochem, Bachem Inc, and Advanced ChemTech Inc. Cysteamine 4-methoxytrityl resin was purchased from Novabiochem and TentaGel S Trt-OH resin from Advanced ChemTech. ^{99m}Tc was obtained by elution of a generator obtained from Bristol-Myers Squibb.

***S*-(((4-Methoxyphenyl)diphenyl)methyl)-2-aminoethanethiol.** To a solution of cysteamine hydrochloride (7.7 g, 68.1 mmol) in TFA (100 mL) was added *p*-anisylchlorodiphenylmethane (20 g, 64.8 mmol). After 3 h of stirring of the sample under an atmosphere of N_2, the TFA was removed under reduced pressure, and the resulting colorless oil was suspended in CH_2Cl_2 (200 mL) and extracted with 3 N NaOH (3 × 100 mL) (Note: the oil does not go into CH_2Cl_2 until the addition of NaOH). The organic layer was dried over sodium sulfate and evaporated under reduced pressure to yield a white solid (16.6 g, 70%). TLC R_f = 0.11 (3% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 3058, 3001, 2955, 2927, 2855; ^{1}H NMR (200 MHz, $CDCl_3$): δ7.27 (bm, 12 H, H-aryl), 6.77 (d, J = 8.8, 2H, H-aryl), 3.69 (s, 3H, OCH_3), 2.54 (t, J = 6.3, 2H, C**H$_2$**NH_2), 2.29 (t, J = 6.3, 2H, TrS**CH$_2$**), 1.12 (b s, 2H, NH_2); ^{13}C NMR (50 MHz, $CDCl_3$): δ158, 145, 137, 130, 129, 128, 126, 113, 66, 55, 41, 36; MS (ESI): *m*/*z* 273 [$(MeOTr)^+$], 350 [$(M + H)^+$].

***S*-Linked Resin-Bound MAMA Chelate (4).** Cysteamine-4-methoxytrityl resin (1.0 g, 0.31 mmol/g) was suspended in 10 mL of dry DMF in a fritted vessel and argon was bubbled through the suspension for 15 min. The solution was filtered, and fresh DMF (10 mL) containing NMM (375 μL, 3.41 mmol) was added. In a separate flask, bromoacetic acid (431 mg, 3.1 mmol), HOBT (1.0 g, 3.1 mmol), and HBTU (1.17 g, 3.1 mmol) were dissolved in DMF (4 mL), and the sample was stirred for 5 min at room temperature. This solution was added to the suspension containing the polymer and the mixture agitated for 3 h. After filtration of the sample and thoroughly washing the resin with CH_2Cl_2, DMF, MeOH, DMF, and CH_2Cl_2, a solution of NMM (1.25 g, 12.4 mmol) in DMF (10 mL) was added, and the suspension was agitated with a flow of argon for 15 min. Methoxytrityl-protected cysteamine (4.7 g, 13.5 mmol) was subsequently added, and the reaction was agitated for an additional 48 h. Filtration followed by thorough washing with CH_2Cl_2, DMF, MeOH, DMF, and CH_2Cl_2 yielded a yellow solid (1.12 g, 89%). IR (KBr, cm^{-1}): 2926, 2865, 2363, 2337, 1685.

ReO-MAMA (1). Compound **4** (100 mg) was allowed to swell in a solution (v/v/v) of 5% MeOH, 1% pyridine in DMF (5 mL) for 5 min prior to the addition of $[NBu_4][ReOCl_4]$ (19 mg, 0.031 mmol). The resulting green suspension was stirred at 85 °C for 16 h. The solution was then filtered, and the DMF was removed under reduced pressure (55 °C at 1 Torr). The product (10 mg, 85%), a reddish-brown solid, was isolated by silica gel column chromatography (5% MeOH/CH_2Cl_2). TLC R_f = 0.15 (10% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 1654, 966; ^{1}H NMR (600 MHz, CD_3OD): δ5.00 (m, $J_{4\beta,4\alpha}$ = −18.6, H-4β), 4.07 (m, H-4α), 4.03 (m, $J_{2\beta,2\alpha}$ = −12.0, $J_{1\beta,2\beta}$ = 6.0, $J_{1\alpha,2\beta}$ = 6.0, H-2β), 3.83 (m, $J_{6\beta,6\alpha}$ = −10.2, $J_{5\alpha,6\beta}$ = 6.6, H-6β), 3.44 (m, $J_{1\beta,2\alpha}$ = 7.2, $J_{1\beta,2\alpha}$ = 7.2, H-2α), 3.21 (m, H-5 β), 2.96 (m, H-1β), 2.89 (m, $J_{1\beta,1\alpha}$ = −11.4, H-1α), 2.84 (m, $J_{5\beta,6\alpha}$ = 6.6, $J_{5\alpha,6\alpha}$ = 12.6, H-6α), 2.70 (m, $J_{5\beta,5\alpha}$ = −10.8, H-5α); ^{13}C NMR (151 MHz, $CDCl_3$): δ 191.1, 70.0, 66.1, 39.9, 39.8, 38.6; HRMS (TOF-EI) calcd. for $C_6H_{11}N_2S_2O_2Re$: 393.9820. Found 393.9807.

Methyl [2-(*S*-4′-methoxytrityl)-thioethyl)amino]acetate (6). Compound **5** (2.0 g, 5.73 mmol), *N*-methylmorpholine (700 μL) and methylbromoacetate (493 μL, 5.16 mmol) were dissolved in CH_2Cl_2 (50 mL). Following stirring for 24 h under N_2, the solution was extracted with water three times (50 mL each) and dried over Na_2SO_4. Removal of the solvent by rotary evaporation followed by silica gel column chromatography (50% ethyl acetate/hexanes) yielded the product as a colorless oil (1.96 g, 90%). TLC R_f = 0.50 (5% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 3336, 3059, 1742; ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.30 (m, 12H, H-aryl), 6.80 (d, J = 8.9 Hz, 2H, H-aryl), 3.79, (s, 3H, phenyl-OCH_3), 3.70 (S, 3H, (CO)-OCH_3), 3.30 (s, 2H, (CO)CH_2NH), 3.55 (t, J = 7.7 Hz, 2H, NHCH_2CH_2S), 3.36 (t, 2H, $NHCH_2CH_2$S), 1.97 (s, 1H, NH); ^{13}C NMR (50 MHz, $CDCl_3$): δ 171.5, 158.0, 145.0, 136.8, 130.7, 129.4, 127.8, 126.5, 113.1, 55.2, 51.8, 50.2, 47.9, 32.0; $ESMS^+$: *m*/*z* 273 [$(4\text{-MeOTr})^+$], 422 [$(M + H)^+$].

Methyl [2-(*S*-4′-methoxytrityl)-thioethyl)-*N*-benzyl-amino]-acetate (7). Compound **6** (410 mg, 0.973 mmol), NMM (1 mL), and benzyl bromide (1 mL, 8.36 mmol) were stirred in CH_2Cl_2 (75 mL) for 16 h. The solvent was removed under reduced pressure, and the product was purified by silica gel column chromatography (30% ethyl acetate/hexanes) yielding the product as a colorless oil (497 mg, 99%); TLC R_f = 0.90 (5% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 3059, 3030, 1742; ^{1}H NMR: (200 MHz, $CDCl_3$): δ7.30 (m, 17H, H-aryl), 6.80 (d, J = 8.9 Hz, 2H, H-aryl), 3.78, (s, 3H, phenyl-OCH_3), 3.65 (s, 2H, benzyl-CH_2), 3.63 (s, 3H, OCH_3), 3.18 (s, 2H, (CO)CH_2-NH), 2.66 (t, J = 7.7 Hz, 2H, NHCH_2CH_2S), 2.32 (t, 2H, $NHCH_2CH_2$S); ^{13}C NMR (50 MHz, $CDCl_3$): δ172.1, 158.2, 145.3, 130.8, 129.5, 128.9, 128.2, 127.8, 127.1, 126.5, 113.1, 111.7, 57.7, 55.2, 53.7, 53.0, 51.1, 30.4; MS (ESI): *m*/*z* 273 [$(4\text{-MeOTr})^+$], 512 [$(M + H)^+$].

Potassium [2-(*S*-4′-methoxytrityl)-thioethyl)-*N*-benzyl-amino]acetate (8). Compound **7** (497 mg, 0.973 mmol) was dissolved in diethyl ether (5 mL) and potassium trimethylsilanoate (156 mg, 1.22 mmol) was added and the suspension was stirred for 6 h. The resulting colorless precipitate was dissolved

in EtOAc and purified by silica gel column chromatography (3% MeOH/EtOAc then 10% MeOH/EtOAc) to give the product as a white foam (416 mg, 80%). TLC $R_f = 0.15$ (10% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 3351, 3059, 3031, 1654; ^1H NMR (200 MHz, $CDCl_3$): δ7.24 (m, 17H, H-aryl), 6.73 (d, $J = 8.9$ Hz, 2H, H-aryl), 3.77 (s, 3H, phenyl-OCH_3), 3.77 (s, 2H, benzyl-CH_2), 3.02 (s, 2H, $(CO)CH_2NH$), 2.45 (bs, 4H, SCH_2CH_2NH); ^{13}C NMR (50 MHz, $CDCl_3$): δ173.1, 158.0, 144.8, 136.6, 134.1, 130.6, 130.1, 129.4, 128.5, 127.8, 126.6, 113.1, 66.4, 57.4, 55.5, 55.1, 52.7; MS (ESI): *m*/*z* 497 $[(M)^-]$.

S-Linked Resin-Bound (*N*-Bn)-MAMA Chelate (9). Compound **8** (215 mg, 0.402 mmol), HOBt (540 mg, 4.02 mmol), and HBTU (1.52 g, 4.02 mmol) were dissolved in DMF (5 mL) and mixed using an orbital shaker for 5 min. At the same time, cysteamine-4-methoxytrityl resin (100 mg, 0.31 mmol/g) was swelled in a mixture of DMF (5 mL) and NMM (34 μL). The solution containing the carboxylic acid was then added to the resin, and the resulting mixture was shaken for 4 h. The resin was washed with DMF (2 × 20 mL, 10 min), MeOH (2 × 20 mL, 10 min), DMF (2 × 20 mL, 10 min), and CH_2Cl_2 (2 × 20 mL, 10 min).

ReO-MAMA-(*N*-Bn)(10). Compound **9** (200 mg) was allowed to swell in 5 mL of a solution of 5% MeOH and 1% pyridine in DMF (v/v/v). $[NBu_4][ReOCl_4]$ (37 mg, 0.063 mmol) was added, and the vial was heated at 85 °C for 16 h. The solvent was then removed, and the brownish red residue was dissolved in dichloromethane and purified by passing it through a short plug of silica (50:50 hexanes/EtOAc, then EtOAc) to give the product as a red solid (21 mg, 70%). TLC $R_f = 0.25$ (5% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 1654, 966; ^1H NMR (syn isomer, 600 MHz, $CDCl_3$): δ 7.72 (m, $J_{9,10} = 2.4$, $J_{10,11} = 2.4$, H-10), 7.49 (m, H-9, H-11), 5.11 (d, $J_{7A,7B} = -13.5$, H-7A), 5.00 (d, $J_{4\beta,4\alpha} = -16.2$, H-4$\beta$), 4.74 (m, $J_{5\alpha,7B} = 1.1$, H-7B), 4.44 (m, $J_{2\beta,2\alpha} = -12.4$, $J_{1\beta,2\beta} = 1.0$, $J_{1\alpha,2\beta} = 5.6$, H-2β), 4.12 (m, $J_{1\beta,1\alpha} = -11.3$, $J_{1\beta,2\beta} = 1.1$, $J_{1\beta,2\alpha} = 5.2$, H-1β), 3.82 (d, H-4α), 3.73 (m, $J_{6\beta,6\alpha} = -13.0$, $J_{5\beta,6\beta} = 3.8$, $J_{5\alpha,6\beta} = 13.0$, H-6$\beta$), 3.25 (m, H-1$\alpha$, H-2$\alpha$), 3.09 (m, $J_{5\beta,5\alpha} = -12.9$, $J_{5\beta,6\alpha} = 2.3$, H-5β), 2.91 (m, $J_{5\alpha,6\alpha} = 4.5$, H-6$\alpha$), 1.48 (m, H-5$\alpha$); ^{13}C NMR (syn isomer, 151 MHz, $CDCl_3$): δ 187.5, 132.3, 131.2, 129.4, 128.7, 65.4, 64.8, 62.7, 59.6, 46.9, 38.0. HRMS calcd. for $C_{13}H_{17}N_2S_2O_2Re$: 484.0289. Found 484.0274.

***S*-(Triphenylmethyl)-2-aminoethanethiol (11).** The method of O'Neil et al. was followed with minor modifications. To a solution of cysteamine hydrochloride (19.2 g, 170 mmol) in TFA (120 mL) was added triphenylmethanol (44.0 g, 169 mmol). After 3 h of stirring under an atmosphere of N_2, the TFA was removed under reduced pressure. The resulting white solid was suspended in CH_2Cl_2 (300 mL) and extracted with 3 N NaOH (4 × 150 mL) (Note: the solid does not go into CH_2Cl_2 until the addition of NaOH), H_2O (3 × 150 mL), $NaHCO_3$ (2 × 50 mL), and brine (2 × 50 mL). The organic layer was dried over sodium sulfate and evaporated under reduced pressure to yield the product (45 g, 85%) as a white solid. TLC $R_f = 0.12$ (3% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 3056, 3020; ^1H NMR (200 MHz, $CDCl_3$): δ7.27 (m, 15 H, H-aryl), 2.54 (t, $J = 6.3$, 2H, CH_2NH_2), 2.29 (t, $J = 6.3$, 2H, $TrSCH_2$), 1.12 (bs, 2H, NH_2); ^{13}C NMR (50 MHz, $CDCl_3$): δ158.1, 129.7, 127.8, 126.6, 125.6, 39.4, 34.4; MS (ESI): *m*/*z* 243 $[(Tr)^+]$, 320 $[(M+H)^+]$.

***S*-(Triphenylmethyl)-2-aminoethanethiol-*N*,*N*-diacetate-(13).** To a stirred solution of compound **11** (1.84 g, 5.77 mmol) in CH_2Cl_2 (20 mL) containing triethylamine (4.7 g, 46.16 mmol), bromo methyl acetate (7.1 g, 46.16 mmol) was added dropwise. The solution was stirred for 12 h under an atmosphere of nitrogen whereupon the solvent was concentrated in vacuo, and the resulting solution was loaded onto a column of silica (64 cm × 10 cm). The column was washed with hexanes (250 mL), 10% ethyl acetate/hexanes (250 mL), and 50% ethyl acetate/hexanes (250 mL). The solvent in the final fraction was evaporated, and the dimethyl ester (2.55 g) was dissolved in methanol (35 mL) and a solution of KOH (2.48 g, 44.2 mmol) in water (5 mL) was added. The resulting colorless solution was stirred for 12 h under argon. Upon removal of the solvent, the resulting semisolid was dissolved in water (75 mL), and the pH was adjusted to 2.0 by the dropwise addition of HCl which was accompanied by rapid stirring. The resulting precipitate (2.3 g, 92%) was isolated by filtration and washed with 10 mM HCl (3 × 10 mL). TLC $R_f = 0.05$ (10% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 3300, 3062, 3022, 1676; ^1H NMR (200 MHz, $CDCl_3$): δ7.21 (m, 15H, H-aryl), 3.70, (s, 4H, $CH_2(CO)$), 2.00 (m, 4H, S-CH_2CH_2NH); ^{13}C NMR (50 MHz, D_2O): δ171.5, 145.8, 130.74, 129.10, 128.06, 56.28, 55.58, 28.77, 28.72; MS (ESI): *m*/*z* 434 $[(M - H)^-]$.

***S*-Linked Resin-Bound (*N*-CH_2CO_2H)-MAMA Chelate (14).** Cysteamine-4-methoxytrityl-PS resin (100 mg, 0.31 mmol/g) was stirred with CH_2Cl_2 (2 × 10 mL, 10 min per wash) and DMF (2 × 10 mL, 10 min per wash), filtered, and then suspended for 5 min in DMF (5 mL) containing NMM (40 μL). Meanwhile, compound **13** (126 mg, 0.31 mmol), HBTU (117 mg, 0.31 mmol), and HOBT (42 mg, 0.31 mmol) were dissolved in DMF (1 mL) and mixed using an orbital shaker for 5 min. The solution containing the di-carboxylic acid was subsequently added to the amine and stirred by bubbling Ar through the mixture for 4 h at which time the resin was negative to the Kaiser test. The resin was washed with DMF (2 × 20 mL, 10 min per wash), CH_2Cl_2 (2 × 20 mL, 10 min per wash), and MeOH (2 × 20 mL, 10 min per wash) and then treated with a mixture of acetic anhydride in DMF (1:9 v/v) for 30 min. The solution was filtered, and the resin was washed with DMF (2 × 20 mL, 10 min per wash), CH_2Cl_2 (2 × 20 mL,10 min per wash), and MeOH (2 × 20 mL, 10 min per wash) and finally dried in vacuo. MS (ESI) (cleaved sample): *m*/*z* =251 $[(M - H)^-]$.

ReO-MAMA-(*N*-CH_2CO_2H) (15a). Compound **14** (100 mg) was washed with CH_2Cl_2 (2 × 10 mL, 10 min per wash) and DMF (2 × 10 mL, 10 min per wash) and then suspended in a 5 mL solution of 5% MeOH and 1% pyridine in DMF (v/v/v) containing $[NBu_4][ReOCl_4]$ (18.6 mg, 31.2 μmol). After the green suspension was heated to 85 °C in an oil bath for 16 h, the solution was filtered and concentrated in vacuo. The resulting red/brown solid was dissolved in 50/50 MeOH/CH_2Cl_2 and purified by passing it through a plug of silica (CH_2Cl_2, 50/50 MeOH/CH_2Cl_2). Concentration of the solvent by rotary evaporation gave the product as a red solid (10 mg, 70%). TLC $R_f = 0.25$ (5% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 1654, 966; ^1H NMR (600 MHz, CD_3OD): δ5.12 (d, $J_{4\beta,4\alpha} = -17.6$, H-4$\beta$), 4.65 (d, H-4$\alpha$), 4.47 (d, $J_{2\beta,2\alpha} = -12.8$, H-2$\beta$), 4.47 (d, $J_{7A,7B} = -16.6$, H-7β), 4.22 (m, $J_{5\alpha,7B} = 1.3$, H-7α), 4.12 (m, $J_{5\beta,5\alpha} = -12.3$, H-5$\beta$), 3.98 (m, $J_{1\beta,1\alpha} = -10.8$, $J_{1\beta,2\alpha} = 4.6$, H-1β), 3.42 (m, $J_{6\beta,6\alpha} = -13.3$, $J_{6\beta,5\beta} = 3.8$, $J_{6\beta,5\alpha} = 13.3$, H-6$\beta$), 3.11 (m, $J_{1\alpha,2\alpha} = 12.3$, H-2$\alpha$), 3.04 (m, $J_{1\alpha,2\beta} = 6.0$, H-1α), 2.88 (m, $J_{5\alpha,6\alpha} = 4.4$, H-6$\alpha$), 1.57 (m, H-5$\alpha$); ^{13}C NMR (151 MHz, CD_3OD): δ189.8, 170.1, 67.8, 64.4, 61.1, 58.6, 46.2, 38.2; HRMS (TOF-ESI) calcd. for $C_8H_{12}N_2S_2O_4Re$: 450.9793. Found 450.9797.

***S*-Linked Resin-Bound (*N*-$CH_2CONHCH_2CO_2Bn$)-MAMA Chelate (16).** Compound **14** (100 mg) was washed with CH_2Cl_2 (2 × 10 mL, 10 min per wash) and DMF (2 × 10 mL, 10 min per wash) and then suspended for 5 min in DMF (5 mL) containing HBTU (117 mg, 0.31 mmol) and HOBT (42 mg, 0.31 mmol). Meanwhile, O-Bn-glycine (62 mg, 0.31 mmol) and NMM (40 μL) were dissolved in DMF (1 mL), and the mixture was agitated for 5 min. The solution containing the amine was

added to the resin, and the mixture was stirred by bubbling Ar through the solution for 3 h at which time the resin was negative to the Kaiser test. The solution was filtered, and the resin was washed with DMF (2 × 20 mL, 10 min per wash), CH_2Cl_2 (2 × 20 mL, 10 min per wash), and MeOH (2 × 20 mL, 10 min per wash). MS(ESI) (cleaved sample): *m*/*z* 400 [$(M + H)^+$].

ReO-MAMA-(*N*-$CH_2CONHCH_2CO_2Bn$) (17). Compound **16** (100 mg) was washed with CH_2Cl_2 (2 × 10 mL, 10 min per wash) and DMF (2 × 10 mL, 10 min per wash) and then suspended in 5 mL of a solution of 5% MeOH and 1% pyridine in DMF (v/v/v) containing $[NBu_4][ReOCl_4]$ (19 mg, 31.2 μmol). After the green suspension was heated to 85 °C with an oil bath for 16 h, the resin was collected by filtration and the filtrate concentrated by rotary evaporation. The resulting red/brown solid was dissolved in CH_2Cl_2, washed with water, and then purified by passing it through a plug of silica (50/50 hexanes/EtOAc; 95/5 CH_2Cl_2/MeOH). Removal of the solvent by rotary evaporation gave the product as a red solid (12 mg, 68%). TLC $R_f = 0.25$ (5% MeOH/CH_2Cl_2); IR (NaCl disk, cm^{-1}): 1654, 966; ^1H NMR (600 MHz, $CDCl_3$): δ7.39 (m, H-aryl), 5.22 (d, $J = -10$, H-11A), 5.19 (d, H-11B), 4.92 (d, $J_{4\beta,4\alpha} = -17.4$, H-4$\beta$), 4.73 (d, H-4$\alpha$), 4.71 (d, $J_{7\beta,7\alpha} = -15.9$, H-7A), 4.65 (m, $J_{2\beta,2\alpha} = -10.4$, $J_{1\alpha,2\beta} = 4.1$, H-2β), 4.29 (d, H-7B), 4.16 (d, $J = -15$, H-9A), 4.12 (m, $J_{1\beta,1\alpha} = -10.6$, $J_{1\beta,2\alpha} = 4.6$, H-1β), 4.07 (d, H-9B), 3.86 (m, $J_{5\beta,5\alpha} = -12.3$, $J_{5\beta,6\beta} = 3.5$, H-5β), 3.39 (m, $J_{6\beta,6\alpha} = -13.7$, $J_{6\beta,5\alpha} = 13.6$, H-6$\beta$), 3.25 (m, $J_{1\alpha,2\alpha} = 12.3$, H-2$\alpha$), 3.18 (m, H-1$\alpha$), 2.86 (m, $J_{5\alpha,6\alpha} = 5.5$, H-6$\alpha$), 1.56 (m, H-5$\alpha$); MS(ESI): *m*/*z* 598 [$(M + H)^+$], 600 [$(M + H)^+$].

***S*-Linked Resin-Bound (*N*-$CH_2CONHCH_2CH_2NH_2$)-MAMA Chelate (18).** Compound **14** (100 mg) was washed CH_2Cl_2 (2 × 10 mL, 10 min per wash) and DMF (2 × 10 mL, 10 min per wash) and then suspended for 5 min in DMF (5 mL) containing HBTU (200 mg, 0.53 mmol) and HOBT (100 mg, 0.73 mmol). Ethylenediamine (2 mL) was then added to the resin, and the mixture was stirred by bubbling Ar through the solution for 3 h. The resin was collected by filtration and washed with DMF (2 × 20 mL, 10 min per wash), CH_2Cl_2 (2 × 20 mL, 10 min per wash), and MeOH (2 × 20 mL, 10 min per wash).

Resin-Bound MAMA−Peptide Conjugate (20). Compound **18** (150 mg) was added to two reaction wells, suspended in DMF (2 mL/well), and shaken at 900 rpm for 1 min. The wells were subsequently filtered, suspended in THF (2 mL/well), shaken at 900 rpm for 1 min, and drained for 90 s. The THF wash was repeated two more times. The DMF wash was then repeated a final two times to complete the general wash cycle. This procedure was used between every deprotection and coupling step. Fmoc deprotection was brought about through the addition of 20% v/v piperidine−DMF solution to the active vessels (2 mL/well) and shaking for 5 min at 900 rpm. Following filtration, the process was repeated, shaking for 10 min. The deprotected resin-bound amino acid was washed using the general wash procedure and subsequently coupled to the next Fmoc-protected amino acid using a standard HBTU coupling technique. Coupling reactions initially involved adding DMF (200 μL) to the active vessels followed by the addition of a 4-fold excess of the protected amino acid as a 0.5 M solution in DMF. Four equivalents of HBTU as a 0.5 M solution in DMF was then added followed by a 8-fold excess of DIPEA as 2.0 M solution in DMF. The reaction block was subsequently shaken for 80 min at 900 rpm. Following filtration, the resin was washed using the general washing procedure prior to the start of the next cycle.

Once the final amino acid had been added and the Fmoc group removed, a pause was introduced into the peptide program so that 10 equiv of the *n*-butyl isocyanate in DMF (0.5 M solution) could be added. The reaction block was then shaken at 900 rpm under nitrogen for 12 h. The reaction vessels were emptied, and the resins were washed using the general wash cycle. The cleavage cocktail, which consisted of 20% TFA and 2% TIS in DCM (v/v/v), was cooled to 0 °C and added to the resin. The mixture was allowed to warm to room temperature over 60 min and subsequently filtered into cold diethyl ether. The resulting heterogeneous solution was centrifuged at 3000 rpm and −5 °C for 10 min. MS (ESI): *m*/*z* 767 [$(M + H)^+$].

ReO-MAMA Peptide Conjugate (21a). Compound **20** (100 mg) was washed with CH_2Cl_2 (2 × 10 mL, 10 min per wash) and DMF (2 × 10 mL, 10 min per wash) and then suspended in 2 mL of a solution of 5% MeOH and 1% pyridine in DMF (v/v/v) containing $[NBu_4][ReOCl_4]$ (18.6 mg, 31.2 μmol). After the green suspension was heated to 85 °C in an oil bath for 16 h, the resin was collected by filtration and the filtrate was concentrated by rotary evaporation. The resulting red/brown solid was dissolved in a mixture of 10% MeOH in CH_2Cl_2 (v/v) and purified by passing the mixture through a plug of silica (CH_2Cl_2 then 50/50 MeOH/CH_2Cl_2). Concentration of the later fractions gave a red solid (14 mg, 47%). MS(ESI): *m*/*z* 966, 968 [$(M + H)^+$].

Tentagel-*S*-Tr-OH Resin MAMA−Peptide Conjugate. Tentagel-S-Trt-OH resin (1.0 g, 0.4 mmol/g) was suspended in a solution of 2-aminoethane thiol hydrochloride (1.0 g, 0.9 mmol) in TFA (10 mL). The solution was gently agitated with a stream of Ar, and after 2 h, the solution was filtered and the resin washed with CH_2Cl_2 (2 × 10 mL, 10 min per wash) and DMF (2 × 10 mL, 10 min per wash) and then suspended for 5 min in DMF (5 mL) containing DIP (40 μL). Meanwhile, compound **13** (1.26 g, 3.1 mmol), HBTU (1.17 g, 3.1 mmol), and HOBT (420 mg, 0.31 mmol) were dissolved in DMF (10 mL) and shaken for 5 min. The solution containing the di-carboxylic acid was then added to the resin-bound amine, and the mixture was stirred by bubbling Ar through the solution for 4 h at which time the resin was negative to the Kaiser test. The resin was collected by filtration, washed with DMF (2 × 20 mL, 10 min per wash), CH_2Cl_2 (2 × 20 mL, 10 min per wash), and MeOH (2 × 20 mL, 10 min per wash), and then treated with a solution of acetic anhydride−DMF (1:9 v/v). After 30 min, the resin was collected by filtration, washed with DMF (2 × 20 mL, 10 min per wash), CH_2Cl_2 (2 × 20 mL, 10 min per wash), and MeOH (2 × 20 mL, 10 min per wash), and finally dried in vacuo. MS(ESI) (cleaved sample): *m*/*z* 251 [$(M - H)^-$].

General Labeling Procedure. Na[$^{99m}TcO_4$] was eluted from a $^{99}Mo/^{99m}Tc$ generator using a solution of 0.9% saline. Transfer chelate-tin solutions were prepared by dissolving 12.5 g of the transfer chelate in 75 mL of nitrogen sparged water. Stannous chloride dihydrate (200 mg) was dissolved in 1 mL of 1 M HCl and added to the solution containing the transfer chelate. The pH of the resulting solution was adjusted to 7.2 using 1 N NaOH, and the volume was increased to 100 mL with nitrogen sparged water. Note that the solution must be used within 3 h of preparation to preserve the stannous chloride dihydrate.

The transfer chelate solution (0.1, 1 or 2 mL) was added to a serum vial containing the resin (25, 100, or 200 mg) and a stir-bar. The vial was crimp-sealed, and the headspace was replaced with nitrogen. Sodium pertechnetate was then added to each vial (2−15 mCi, 0.05−0.41 MBq), and the volume was adjusted to 2.5 mL with nitrogen sparged water. EtOH (250 μL) was then added, and the reaction mixture was allowed to proceed for 2.5−3 h. The reaction mixture was then heated to 80 °C in a Reacti-Therm heater-stirrer under a stream of N_2 to remove the residual ethanol, and the reaction mixture was subsequently cooled in an ice−water bath. The mixture was then loaded onto a C-18 Sep-Pak (Waters), which was washed

two times with 10 mL of water, and then the product was eluted using 100% ethanol.

RESULTS AND DISCUSSION

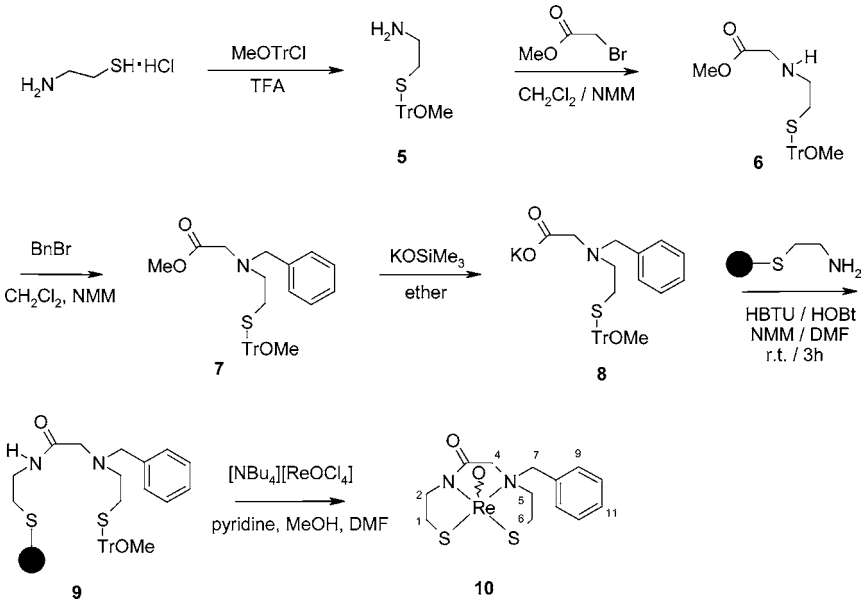
From some preliminary solution-phase studies, we found that *S*-*p*-methoxytrityl (PMT) groups on the MAMA chelate were readily cleaved in the presence of $[TcOCl_4]^-$ and $[ReOCl_4]^-$. Consequently, the MAMA chelate was prepared on a solid support, in which one of the pendant thiol groups was linked to a polystyrene resin through a PMT group. Commercially available 2-aminoethanethiol loaded-4-MeOTr-polystyrene resin was placed into a reaction chamber of a solid-phase synthesis vessel and swelled in DMF. Following the solution phase approach, bromoacetyl bromide was added at −30 °C in the presence of triethylamine under a constant bubbling of Ar. Despite a number of attempts using a variety of conditions, the yields of **3** were unacceptably low. In turn, success was achieved when bromoacetic acid was coupled to the resin-bound amine using HBTU−HOBt (*16*) (Scheme 1). After 2 h under these coupling conditions, the Kaiser test (*17*) indicated the reaction had gone to completion. The desired chelant **4** was prepared by adding a large excess of the thiol-protected cysteamine to drive the reaction to completion. The progress of the reaction was followed by cleaving small amounts of the resin using 5% TFA in CH_2Cl_2 and analyzing the products by HPLC-MS. After 48 h, the major peak in the chromatogram corresponded to that of the MAMA chelate.

The optimal conditions for preparing the Re-MAMA complexes were identified by varying the choice of solvent, base, and reaction temperature (Table 1). In a typical experiment, the resin was swelled in a solvent or solvent mixture and $[NBu_4][ReOCl_4]$ was added, and the contents of the vial were agitated using a platform mixer (300 rpm). For reactions run at room temperature in the absence of base, the color of the resin changed to deep green within 3 h. This, in our experience, indicated the presence of a partially chelated intermediate. The greenish resin was analyzed by IR, and a strong absorbance at 909 cm^{-1} was observed, which is indicative of a Re═O stretch (*18*). When the reaction mixture was left shaking overnight in CH_2Cl_2 in the absence of base, the solution took on a light orange color, and small amount of a red solid was seen in the bottom of the reaction vial. The precipitate was in fact the target compound, which was established by comparing the characterization data of the isolated product with that obtained from an authentic standard prepared by following literature procedures (*12*). The yield of the metal complex improved substantially when the temperature of the reaction was increased to 85 °C and when the solvent was changed to a mixture of DMF and MeOH. Methanol was added to trap the cation that is formed upon liberation of the protecting group and release of the chelate from the resin. In contrast, the use of triethylsilane as a scavenger in place of methanol did not improve the yield. An additional increase in yield to 85% was achieved when a small amount of pyridine was added to the reaction. Pyridine prevented disproportionation of the M(V) chlorides at the higher reaction temperatures and likely facilitated deprotonation of the amide group on the chelate. From this reaction, the product was isolated through a plug of silica gel or a silica gel Sep-Pak, which was necessary to separate the cleaved protecting group from the target compound.

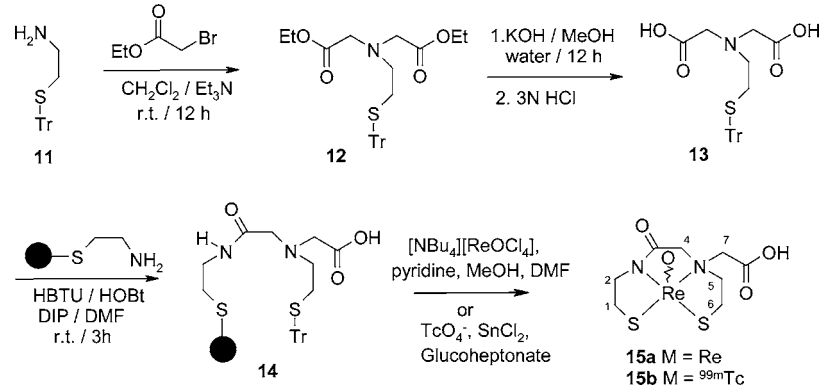
Direct functionalization of the amino group of **4** proved to be very difficult. The efficiency of the derivatization with a variety of reactive alkylating agents, including benzyl bromide and allyl bromide, was highly variable, and despite numerous attempts involving an array of reaction conditions, the yields of the desired products were not acceptable. To circumvent this issue, an alternate route was developed whereby a large portion of the chelate was synthesized in solution and then coupled to the resin in the final step using a robust amide bond forming reaction.

The initial target for the convergent approach was the *N*-benzyl MAMA derivative, which was previously prepared in solution by O'Neil et al. (*12*). The requisite precursor, compound **6**, was prepared in 90% yield by reacting methyl bromoacetate with *S*-(4-methoxytrityl)-2-aminoethane thiol (Scheme 2). Alkylation of **6** with benzyl bromide to give **7** occurred quantitatively in the presence of triethylamine. Conversion of the methyl ester to the acid was carried out by treating **7** with potassium trimethylsilanoate in ether (*19*). Over the course of 4 h, a thick white paste formed in the bottom of the reaction vessel, which was the potassium salt **8**. The product was collected by filtration and passed down a short column of silica to separate it from any excess potassium trimethylsilanoate. Compound **8** was subsequently coupled to the resin-bound amine using HBTU and HOBt. After 4 h, the resin gave a negative Kaiser test and was therefore filtered, washed rigorously, and dried under vacuum.

Scheme 2



Scheme 3



The complexation−cleavage reaction was run under the optimum conditions identified for the unsubstituted MAMA complex. The resin **9** (200 mg) was suspended in 5 mL of a solution containing MeOH (5%), pyridine (1%), and DMF. [TBA][$ReOCl_4$] was added and the vial was heated to 85 °C for 16 h. The Re complex **10** was isolated in 70% yield through a simple plug of silica. The spectroscopic data for the product were consistent with reported values. Interestingly, the ^{1}H NMR of the product showed that compound **10** was isolated as a mixture of syn and anti diastereomers in approximately a 12:1 ratio. In the case of compound **1** and all subsequent N-substituted ligands, only the syn isomers were observed in the ^{1}H NMR.

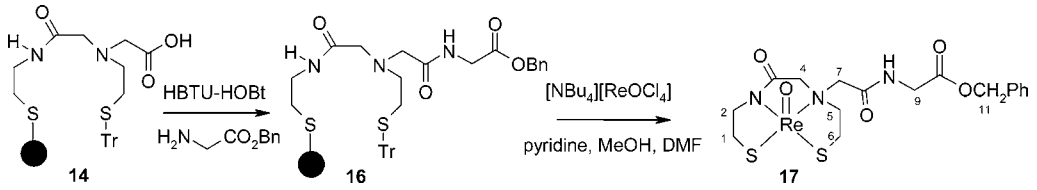
To introduce a functional group that can be used to link to amine groups, the resin-bound chelate **14** was prepared (Scheme 3). The synthesis involved first preparing the di-ester **12** by condensing 2 equiv of protected 2-aminoethanethiol with an excess of methylbromoacetate. Unfortunately, the reaction conditions required to prepare and isolate compound **12** necessitated the use of the trityl (Tr) protecting group in place of the PMT group. Compound **12** was converted to the diacid **13**, which was subsequently attached to the resin-bound amine via a HBTU−HOBt coupling procedure taking advantage of the inherently dilute nature of the resin to ensure monosubstitution. The resin-bound chelate was subsequently suspended in DMF containing 1% pyridine and 5% MeOH and treated with [NBu_4]-[$ReOCl_4$]. After 16 h, the dark orange solution was concentrated in vacuo yielding the desired product, as a red solid, in 70% yield.

The IR spectrum of **15a** showed a carbonyl stretch at 1654 cm^{-1} and the rhenium oxo stretch at 966 cm^{-1}. The splitting patterns present in the chelate portion of the ^{1}H NMR spectrum of **15a** are similar to those for compound **10**. The main difference was that the chemical shifts of the methylene protons in the chelate were for the most part shifted downfield relative to those in the benzyl derivative. The methylene protons for the pendent acid are diastereotopic and appear as a doublet (H-7A, 4.47 ppm) and a doublet of doublets (H-7B, 4.22 ppm), which in the latter case includes weak coupling to H-5α. The good yield of **15a** was achieved despite the fact that the trityl protecting group is much less reactive than the methoxy-trityl protecting group present in compound **9**.

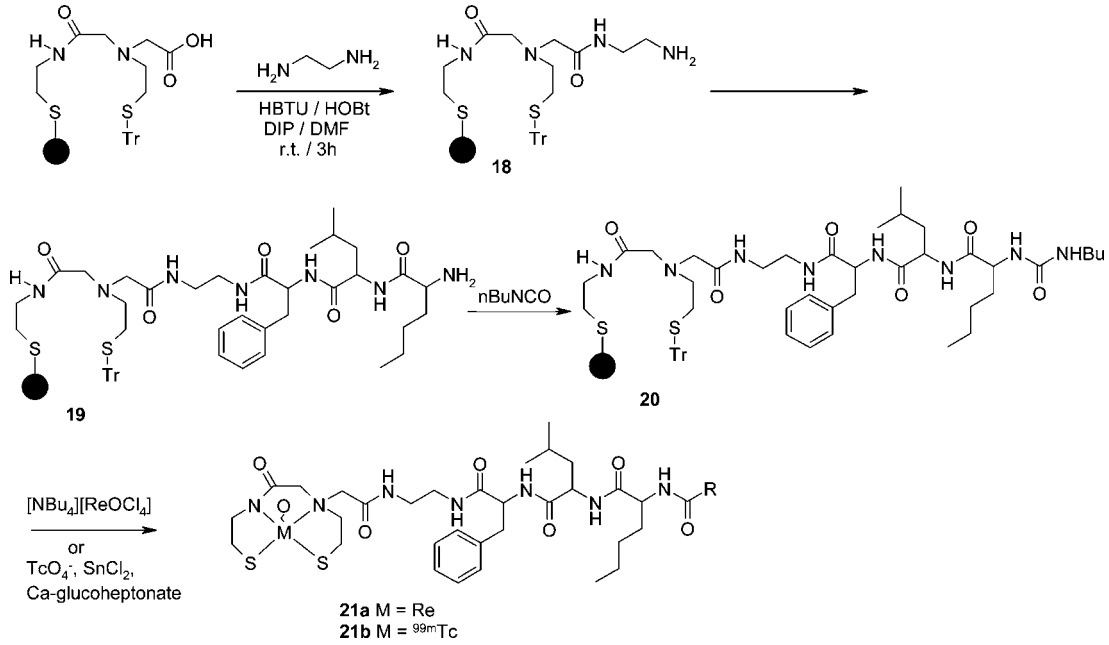
Prior to automated solid-phase synthesis work, the reactivity of the pendent group was investigated by attempting to couple O-benzyl glycine, as a model amine, to the resin-bound chelate **14** (Scheme 4). The amine and *N*-methyl morpholine (NMM) in DMF was added to the carboxylic acid, which had been premixed with HOBt/HBTU, and the mixture was agitated using a flow of Ar for 3 h. After the sample was filtered and washed, the Re-O-benzyl glycine-MAMA complex **17** was prepared by reacting the O-benzyl glycine functionalized resin **16** with [TBA][$ReOCl_4$]. The product, a red solid, was again isolated through a plug of silica in 68% yield. The ease with which the acid can be derivatized affords the opportunity to attach a wide array of targeting agents, beyond simply peptides, to the resin-bound chelate.

Peptide Conjugation. The next goal was to develop a system that would be suitable for the preparation of peptide−MAMA

Scheme 4



Scheme 5



conjugates. Although it is conceivable to build peptides off the carboxylic acid funtionalized MAMA derivative, automated peptide synthesis is more often performed starting from a primary amine using Fmoc-protected amino acids. A primary amine functionalized MAMA chelate was prepared by coupling a diamine to the carboxylic acid of **14** (Scheme 5). An excess of ethylenediamine was added to the carboxylic acid functionalized resin **14** in the presence of HBTU and HOBt and the reaction was allowed to proceed for 3 h at room temperature. A small sample of resin was cleaved and analyzed by ESMS, which showed a peak corresponding to the product and no signs of unreacted acid.

Compound **18** was subsequently added to the reaction well of an Advanced Chemtech automated synthesizer and a model peptide was built up using a standard Fmoc/HBTU protection/coupling method. The target peptide was a *n*-butyl urea derivative of Phe-Leu-Nle, which is an antagonist for the formyl peptide receptor (FPR) (*20*). This ligand was of interest because radiolabeled compounds that are capable of binding selectively to the FPR on white blood cells can be used to image sites of infection and inflammation (*21*). The synthesis of the model peptide began by reacting a 4-fold excess of Fmoc-protected phenyl alanine with **18** using HBTU as the coupling agent. After the resin was washed and the Fmoc group removed using 20% piperidine in DMF, the next two amino acids, Fmoc-leucine and Fmoc-norleucine were added in an analogous manner. After deprotection of the terminal amine, conversion to the urea was carried out by adding a 10 fold excess of *n*-butyl isocyanate and shaking the mixture for 12 h. To ensure the desired conjugate had formed, a sample was cleaved from the support using a cocktail consisting of 20% TFA and 2% triisopropylsilane in DCM and the solution analyzed by LC-MS, which showed only the desired product. The peptide-functionalized resin was subsequently treated with [TBA][$ReOCl_4$] and after the green suspension was heated in an oil bath for 16 h, the resin was removed by filtration and the filtrate concentrated by rotary evaporation. The resulting red/brown solid was dissolved in a mixture of methanol and dichloromethane and purified by passing it through a plug of silica to remove the residual protecting group. The product, which showed a single peak in the HPLC, was isolated in 47% yield.

Radiolabeling. Initial attempts at labeling with ^{99m}Tc were performed using the carboxylic acid functionalized chelate **14**. The resin (100 mg) was suspended in saline, and a solution of stannous chloride dihydrate and calcium glucoheptonate was added. The latter compound, which was selected by screening a number of transfer chelates, was added to prevent premature reduction of TcO_4^- to $TcO_2 \cdot 2H_2O$. To the suspension, freshly eluted pertechnetate was subsequently added, and the mixture was analyzed by HPLC as a function of time. The desired product appeared after 6 h at room temperature; however, it took 16 h to reach a maximum yield of 40% with the other major product being TcO_4^-. The addition of EtOH as a cosolvent and heating did not increase the overall yield of **15b** or change the kinetics of the reaction. The long reaction time and suboptimal yield is likely a result of the poor compatibility of the polystyrene-based resin with water. Despite the low concentration of technetium in the reaction, it also appeared as though there were insufficient numbers of accessible reaction sites on the support to afford high yields of the desired product. In the absence of the complexation reaction, oxidation becomes a competing reaction pathway, which explains the appearance of TcO_4^-.

In an attempt to improve the yield and/or reduce the reaction time, the polystyrene support was substituted with a Tentagel resin. Tentagel-type resins are copolymers consisting of a low cross-linked polystyrene matrix on which poly(ethylene glycol) (PEG) is grafted. The presence of PEG enables the support to

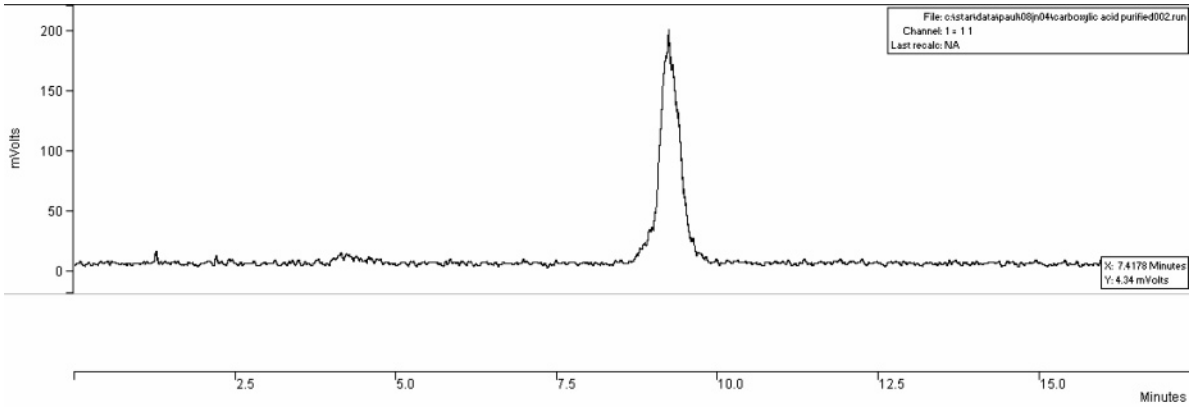


Figure 1. HPLC γ-radiochromatogram of **15b**.

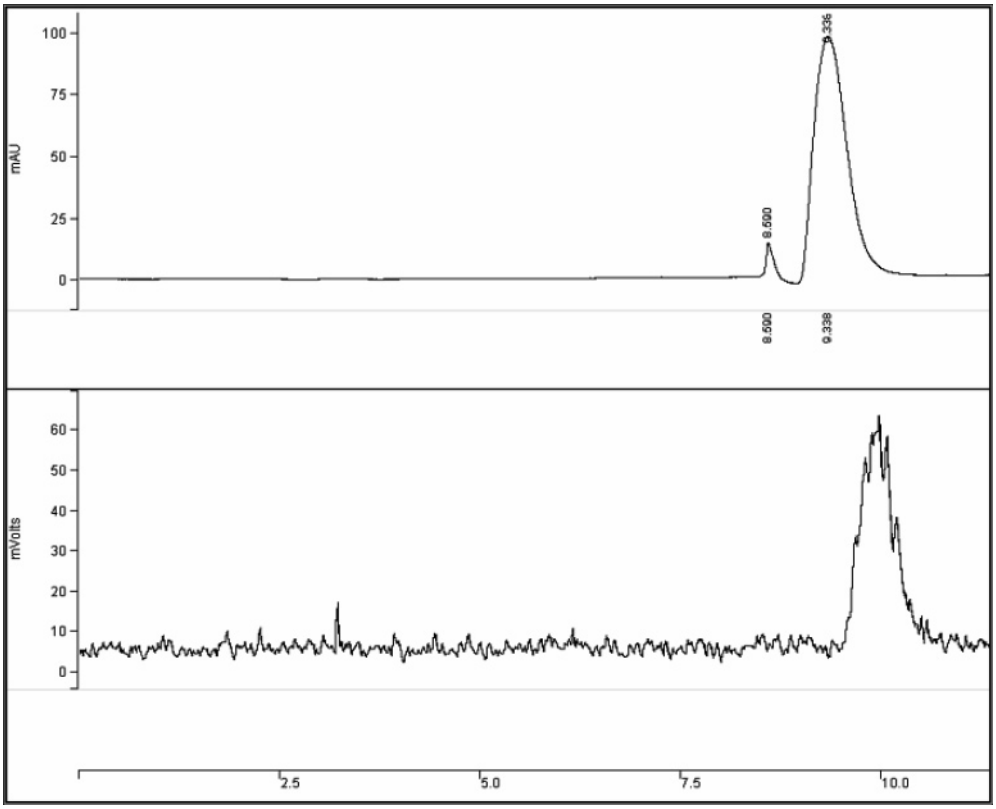

Figure 2. HPLC chromatograms of Re-peptide complex **21a** (UV, top) and ^{99m}Tc complex **21b** (γ). The difference in retention time corresponds to the separation of the detectors which are connected in series.

swell in polar solvents including water, a feature that was used successfully by Alberto et al. for the solid-phase synthesis of Tc(I) amine complexes (*7*). The one disadvantage of switching resins was that the commercially available form of the Tentagel resin has the trityl linker bound to the polymer via an electron with drawing carbonyl group. This could decrease the reactivity of the chelate derivative toward the complexation and cleavage reactions compared to the analogue bound to the methoxy-trityl substituted polystyrene resin.

After loading 2-aminoethane thiol was carried out, the carboxylic acid derivative was prepared on the Tentagel resin by coupling the resin-bound primary amine with the dicarboxylic acid **13** using HBTU, HOBt, and DIP following a similar methodology used to prepare the polystyrene analogue. After 3 h, a small amount of the resin was removed, filtered, washed, and tested for the presence of primary amines using the Kaiser test. No color (blue) developed even after extensively heating the resin, suggesting that the majority of the primary amine sites had reacted.

Radiolabeling of the TentaGel version of **14** was carried out using different amounts of resin in solutions containing varying amounts of calcium glucoheptonate and stannous chloride dihydrate. To prevent unwanted reoxidation, all reactions were performed in crimp-sealed vials in which the headspace gas was exchanged with nitrogen and all solvents were sparged with nitrogen. Reactions containing 2.5, 12.5, and 25 mg of the transfer chelator (and 100 mg of resin) were analyzed after 2 h by HPLC. There was three times the yield of the target when 12.5 mg of calcium glucoheptonate compared to the reaction with 2.5 mg of ligand, but no further increase in the amount of **15b** was observed when 25 mg was added to the reaction mixture. As a result, 12.5 mg of transfer chelate was used in all subsequent reactions.

Similar experiments were conducted to determine the optimal amount of resin. Reactions were carried out with 25, 100, or 200 mg of resin (10, 40, or 80 μmol of resin-bound substrate). Upon combining the resin with the calcium glucoheptonate−stannous chloride mixture and $^{99m}TcO_4^-$, the vials were heated

with stirring for 2 h. The radiochemical yield of the reaction with 200 mg of resin was 38%, while that for the 100 mg and 25 mg samples were 17 and 5%, respectively. The impact of changing the amount of resin on the radiochemical yield is somewhat surprising, given the large excess of reactive sites compared the amount of ^{99m}Tc even at the lowest amount of resin used. HPLC analysis of the reactions as a function of time revealed that after 2 h there was little change in radiochemical yield. At the time the yield reached a maximum there was still unreacted Tc-glucoheptonate present in solution, which suggests that even with the PEG modified resin, reactions were taking place only at a very small portion of the available reactive sites and that a kinetic barrier was limiting the overall yield.

To increase swelling as a means of improving accessibility to the chelate, a small amount of ethanol was added to the reaction immediately prior to heating. This resulted in a change in the appearance of the resin, which became an evenly distributed collection of beads as opposed to a congealed gellike mass. After 2 h of heating, HPLC indicated nearly 50% conversion versus 38% for the same reaction performed without EtOH present. Prior to purification, ethanol was removed by heating the reaction vial to 80 °C under a stream of nitrogen for 5 min. The reaction mixture was then loaded onto a C-18 Sep-Pak and washed two times with 10 mL of water. The activity that was eluted in these fractions corresponded to pertechnetate and Tc-glucoheptonate. Subsequent elution with 100% ethanol removed all of the remaining activity on the Sep-Pak where HPLC analysis (Figure 1) of the fraction showed a single peak whose retention time matched that for **15a**. The radiochemical purity of **15b** was 97%, which is greater than the radiochemical purity requirements for technetium kits and certainly acceptable for performing preclinical imaging studies.

The acid **14** attached to the Tentagel resin was subsequently derivatized with the model peptide in the same manner used to prepare **20**. Radiolabeling was conducted under the conditions developed for **14** using 555 MBq (15 mCi) of activity in saline containing 12.5 mg of glucoheptonate, 2 mg of $SnCl_2 \cdot 2H_2O$ and 250 μL of EtOH at pH 7.2. Purification was performed again using a simple solid-phase extraction on a C-18 cartridge where the product was isolated in 35% radiochemical yield with a radiochemical purity exceeding 99%. The peak in the γ-trace corresponded with the peak in the UV trace of the cold rhenium analogue (Figure 2). In the UV chromatogram of the HPLC trace, there was no evidence of unlabeled peptide.

The SPS labeling system described here is capable of producing Re-MAMA complexes in good yield and the corresponding ^{99m}Tc complexes in reasonable yield. The discrepancy between the two is likely associated with the fact that the Tc reactions are carried out at much lower concentrations and in a highly polar reaction medium using a hydrophilic starting material (Tc-gluconate complex). As part of the future work, the corresponding ^{186}Re and ^{188}Re complexes of the polymer bound ligands will be prepared, which will help validate our hypothesis in terms of the influences of the reaction medium and reagent concentrations. Despite the low yields of the ^{99m}Tc complexes, all products were isolated in high purity free from any unreacted starting material. The only impurities that had to be separated from the product were the cleaved protecting group and residual metal salts. This was accomplished by employing simple solid-phase extraction procedures, which can be easily automated. During the development of the solid-phase labeling system, a series of functionalized MAMA derivatives were prepared. Derivatives included both acid an amine functionalized resins. These compounds, which react efficiently with amines and carboxylic acids, respectively, can be used to prepare a wide range of other biomolecule conjugates and their corresponding Re and ^{99m}Tc complexes.

CONCLUSIONS

A convenient solid-phase synthesis methodology for the preparation of bifunctional Re and Tc chelate complexes was developed. The products, which can be prepared in parallel, can be isolated by a simple solid-phase extraction procedure that is easily automated. It was demonstrated that peptide conjugates of the functionalized resins can be prepared in high yield using traditional automated peptide synthesis protocols thereby creating the opportunity to prepare libraries of novel tracers. The yields of the products at tracer level were not quantitative, which is a barrier that will need to be overcome if this approach is to be used for the clinical production of radiotracers. This can be accomplished by screening different polymer supports and more reactive linkers. Notwithstanding, the ability to produce Re and high specific activity ^{99m}Tc complexes in parallel without the need to use HPLC along with the opportunity to prepare libraries of peptide−ligand conjugates using conventional automated peptide synthesis will render the reported method particularly useful for preclinical discovery work.

ACKNOWLEDGMENT

We would like to acknowledge the Ontario Research and Development Challenge Fund (ORDCF) and The National Sciences and Engineering Research Council (NSERC) of Canada for funding.

Encapsulation of Myoglobin with a Mesoporous Silicate Results in New Capabilities

Tetsuji Itoh,*,† Ryo Ishii,† Takeo Ebina,† Takaaki Hanaoka,† Yoshiaki Fukushima,‡ and Fujio Mizukami†

National Institute of Advanced Industrial Science and Technology (AIST), Nigatake 4-2-1, Miyagino-ku, Sendai, 983-8551, Japan, and Toyota Central R & D Labs. Inc., Yokomichi, Nagakute, Aichi 480-1192, Japan. Received August 5, 2005; Revised Manuscript Received October 4, 2005

A metmyoglobin (Fe^{3+}), an oxidized form of myoglobin (Fe^{2+}), was confined in nanospaces of about 4 nm in diameter in mesoporous silica (FSM; folded-sheet mesoporous material), forming a metmyoglobin (Fe^{3+})−FSM nanoconjugate. The spectral characteristics of metmyoglobin (Fe^{3+})− and myoglobin (Fe^{2+})−FSM show an absorption curve quite similar to that of native metmyoglobin, indicating that myoglobin retains its higher-order structure in the pores of FSM. The metmyoglobin (Fe^{3+})−FSM conjugate had not only a peroxidase-like activity in the presence of hydrogen peroxide (a hydrogen acceptor) and 2,2-azino-bis(3-ethylbenzothiazoline)-6-sulfomic acid (ABTS) or guaiacol (a hydrogen donor) but also an advanced molecular recognition ability enabling it to distinguish between ABTS and guaiacol. Furthermore, the metmyoglobin (Fe^{3+})−FSM showed the peroxidase-like activity even in an organic media using benzoyl peroxide as the hydrogen acceptor and leucocrystal violet as the hydrogen donor. The simple immobilization of metmyoglobin (Fe^{3+}) into FSM results in enhanced catalytic activity in organic media compared to that of native metmyoglobin (Fe^{3+}).

INTRODUCTION

For vital biological functions to occur, it is necessary that the components of which the organs consist are arranged on a nanoscale and assume highly ordered or, in other words, particular higher-order structures. In the biomimetic systems developed recently, different nanoparts, for instance, heme for the selective adsorption−desorption of O_2, CO, or NO (*1*, *2*), have been recognized and employed. However, we lack the means to organize nanoparts such as proteins, which, in the case of natural hemoglobin or myoglobin, is essential for their activation and enhancement. Myoglobin (Fe^{2+}), which is a constituent of muscle that binds oxygen reversibly, is a single polypeptide (153 amino acids) protein (globin protein) of 18000 Da with one protoheme prosthetic group (*3*, *4*). Its oxygenated form is called oxymyoglobin, MbO_2, while it is known as carboxymyoglobin, MbCO, when the oxygen is displaced by carbon monoxide. The myoglobin (Fe^{2+}) molecule has a compact spheroidal structure of 2.8 by 3.2 by 4.5 nm (*5*). Intercooperation between the heme and globin protein is likely to be important for it to achieve its functions. On the other hand, when the iron in myoglobin is oxidized from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}), the compound is called metmyoglobin (Fe^{3+}) and assumes a catalytic ability instead of losing its oxygen-binding capability, as well as a peroxidase-like activity in aqueous solution, as has been reported so far (*6*−*8*).

Much attention has been devoted to mesoporous materials such as MCM (mobile crystalline material) (*9*) and FSM (folded-sheet mesoporous material) (*10*) having honeycomb (hexagonal) structures with ordered cylindrical channels of 2−10 nm in diameter, larger than the microporous cavities of conventional zeolites (0.6−1.2 nm). Enzymes, horseradish peroxidase (*11*, *12*), cytochrome *c* (*13*, *14*), or lysozyme (*15*), have been introduced into mesoporous silica materials. We have also reported the incorporation of a large amount of chlorophyll *a* molecules into a FSM (*16*−*18*). The incorporation seems to increase the stability of the incorporated molecules, and such host−guest reactions should be useful for the arrangement and accumulation of the molecules and enzymes.

The present paper deals with the preparation and characterization of FSM conjugated with myoglobin and the catalytic activity and chemical stability of myoglobin encaged in the nanopores.

EXPERIMENTAL SECTION

General. Myoglobin from horse heart, 2,2-azino-bis(3-ethylbenzothiazoline)-6-sulfomic acid (ABTS), and *o*-methoxyphenol (guaiacol) were purchased from Wako Pure Chemical Industries, Ltd (Osaka, Japan). Docosyltrimethylammonium chloride [$C_{22}H_{45}N(CH_3)_3Cl$] was kindly donated by Lion Corporation (Tokyo, Japan). Kanemite (layered polysilicate) was kindly donated by Tokuyama Siltech Co., Ltd (Yamaguchi, Japan). Leucocrystal violet was obtained from Tokyo Kasei Co., Ltd. (Tokyo, Japan). Benzoyl peroxide was obtained from Nacalai Tesque, Inc. (Osaka, Japan). Mesoporous materials, FSM-16 and -22 materials, 2.7 and 4 nm in pore diameter, respectively, were prepared from kanemite (layered polysilicate) using alkyltrimethylammonium [$C_nH_{2n+1}N^+(CH_3)_3$] with different alkyl-chain lengths (n = 16 and 22), according to the method reported by Inagaki et al. (*10*). Other reagents were of analytical grade.

Characterization. Absorption spectra were measured with a Shimadzu (Kyoto, Japan) spectrophotometer, MPS-2400. Nitrogen adsorption isotherms were measured at 77 K on automatic gas adsorption apparatus, a Belsorp 28SA (BEL Japan, Inc. (Osaka, Japan). Specific surface areas were calculated by the BET method using adsorption data ranging from P/P_0 = 0.05 to 0.30, and the pore size distributions were determined by analyzing the adsorption branch by the BJH method (*19*).

Preparation of Metmyoglobin (Fe^{3+})−FSM. A metmyoglobin (Fe^{3+})−FSM conjugate was prepared as follows. To 5.0

mL of metmyoglobin (Fe^{3+}) obtained by the oxidation of myoglobin (Fe^{2+}) (0−30 mg) dissolved in phosphate buffer (pH 6.9) was added 100 mg of FSM-16 or FSM-22. The suspension was then shaken for 10 h at 25 °C to establish an adsorption equilibrium. The metmyoglobin (Fe^{3+})−FSM conjugate was collected by centrifugation. The amount of metmyoglobin (Fe^{3+}) adsorbed into the pores of the FSMs was spectrophotometrically determined by measuring the absorbance of the supernatant obtained after centrifugation at 420 nm, which is characteristic of the absorption band of metmyoglobin (Fe^{3+}).

Reaction of Carbon Monoxide and Myoglobin (Fe^{2+})−FSM. The metmyoglobin (Fe^{3+})−FSM conjugate (2.57 mg/mL: 0.57 mg as metmyoglobin) was reduced by the addition of sodium dithionite (10 mg) in water (10 mL), to yield a myoglobin (Fe^{2+})−FSM conjugate. Carbon monoxide was reacted with myoglobin (Fe^{2+})−FSM by bubbling CO gas in the aqueous solution containing the conjugate, after which the UV−visible spectra of 3 mL portions (3 mL: 0.077 mg/mL: 0.017 as metmyoglobin) of the solution were taken with a Shimadzu (Kyoto, Japan) spectrophotometer, MPS-2400.

Peroxidase-Like Activity of Metmyoglobin−FSM in Aqueous Solution. The experiments were conducted by measuring the peroxidase-like activity of the metmyoglobin−FSM using guaiacol and 2,2-azino-bis(3-methylbenzthiazoline)-6-sulfomic acid (ABTS), respectively, as the substrates. When the substrate was guaiacol (0.18 mmol), the metmyoglobin−FSM (0.95 mg: 0.21 mg as metmyoglobin) or metmyoglobin (0.2 mg) was suspended in 3 mL of phosphate buffer (pH 6.9) containing hydrogen peroxide (0.1%). In the case of ABTS acid (2.9 μmol), the metmyoglobin−FSM (0.0476 mg: 0.0093 mg as metmyoglobin) or metmyoglobin (0.009 mg) was suspended in 3 mL of phosphate buffer (pH 6.9) containing hydrogen peroxide (0.02%). The peroxidase activity of metmyoglobin (Fe^{3+})−FSM in the aqueous solution was spectrophotometrically determined by measuring the amount of oxidized guaiacol and ABTS using the respective molar extinction coefficients of $\epsilon_{at\ 435\ nm} = 2.55 \times 10^4\ M^{-1}\ cm^{-1}$ (*20*) and $\epsilon_{at\ 410\ nm} = 3.6 \times 10^4\ M^{-1}\ cm^{-1}$ (*21*).

Measurement of Peroxidase-Like Activity of Metmyoglobin−FSM in Toluene. The peroxidase activity of metmyoglobin (Fe^{3+})−FSM was tested by the modified method of Ajima et al. (*22*). The experiment was conducted in 3 mL of toluene, using metmyoglobin (Fe^{3+})−FSM (2 mg/mL: 0.4 mg as metmyoglobin) and metmyoglobin (Fe^{3+})(0.4 mg/mL). Benzoyl peroxide (0.28 mM) and leucocrystal violet (8 mM) were employed as a hydrogen acceptor and donor, respectively. The reaction was carried out for 200 s at 25 °C. The peroxidase activity of metmyoglobin(Fe^{3+})−FSM in the organic solvent was spectrophotometrically determined by measuring the amount of oxidized crystal violet using the molar extinction coefficient of $\epsilon_{at\ 604\ nm} = 1.2 \times 10^5\ M^{-1}\ cm^{-1}$ (*22*).

RESULTS AND DISCUSSION

Adsorption of Metmyoglobin (Fe^{3+}) into the Pores of FSMs. The adsorption amounts of metmyoglobin (Fe^{3+}) onto FSM-16 and -22 powder in phosphate buffer (pH 6.9) were spectrophotometically measured with respect to the equilibrium concentration of metmyoglobin (Fe^{3+}) (Figure 1). The adsorptions of metmyoglobin (Fe^{3+}) onto the FSM-16 and -22 of 2.7 and 4.0 nm in pore diameter, respectively, are shown by A and B, respectively. When the pores are large, the adsorption proceeds efficiently with an increase in the equilibrium concentration of metmyoglobin (Fe^{3+}) and reaches a constant level at 1.2 mg/mL (curve B). In this case, 24 mg of the 30 mg of metmyoglobin (Fe^{3+}) was adsorbed onto FSM (100 mg) in phosphate buffer (pH 6.9). On the other hand, the amount of metmyoglobin (Fe^{3+}) adsorbed onto FSM-16, the pore size of

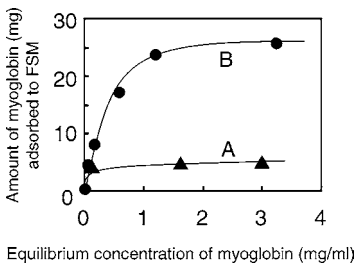

Figure 1. The adsorption of metmyoglobin (Fe^{3+}) onto FSM-16 (curve A) and FSM-22 (curve B) in phosphate buffer (pH 6.9), spectrophotometrically measured with respect to the equilibrium concentrations of metmyoglobin (Fe^{3+}) and metmyoglobin (Fe^{3+})−FSM.

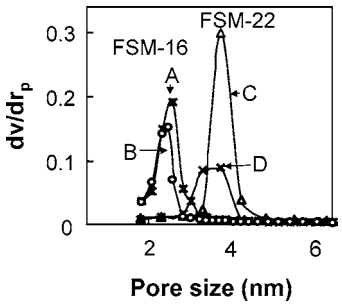

Figure 2. Pore size distributions obtained from the adsorption branch by the BJH method. Curves A, B, C, and D correspond to FSM-16, metmyoglobin-(Fe^{3+})−FSM-16, FSM-22, and metmyoglobin (Fe^{3+})−FSM-22, respectively.

which is smaller than that of FSM-22, was only slight (curve A). This difference in the adsorption behavior of metmyoglobin (Fe^{3+}) between FSM-16 and FSM-22 suggests that metmyoglobin (Fe^{3+}) is absorbed more easily into the pores than onto the outer surfaces. The corresponding pore size distributions of FSM-16 and -22 before and after metmyoglobin (Fe^{3+}) loading are shown in Figure 2. The pore volume of FSM-16 was little changed before (curve A) and after (curve B) metmyoglobin (Fe^{3+}) loading. The pore volume of FSM-22 dramatically decreased after the immobilization treatment (compare C and D). From the results, it can be seen that metmyoglobin (Fe^{3+}) molecules do not occupy the mesopore spaces of FSM-16 but exist on the outer surfaces of the particles, where as FSM-22, on the other hand, absorbs metmyoglobin (Fe^{3+}) molecules into the pores. This would further indicate that in the case of FSM, the pores of which are large enough to accommodate metmyoglobin (Fe^{3+}) or protein, such protein tends to be much more easily immobilized in the pores rather than on the outer surface, because the molecular size of metmyoglobin (Fe^{3+}) (2.8 by 3.2 by 4.5 nm) lies between the pore sizes of FSM-16 and -22, and the amount of metmyoglobin (Fe^{3+}) adsorbed onto FSM-16 was only slight.

The nitrogen adsorption isotherm of metmyoglobin (Fe^{3+}) was examined for FSM-22 (Figure 3a). With an increasing amount of metmyoglobin (Fe^{3+}) (0, 4.3, 9.2, 17, and 24 mg) confined into the pores of FSM-22 (100 mg), the amount of nitrogen adsorbed onto the metmyoglobin (Fe^{3+})−FSM decreased, as shown by curves A, B, C, D, and E, respectively. A steep increase in nitrogen uptake at the relative pressure of 0.4 for FSM is probably due to capillary condensation (curve A). On the other hand, the nitrogen uptakes by the metmyoglobin (Fe^{3+})−FSM (curves B−E) were lower than that of FSM. In the case of curve E, the pore volume of metmyoglobin (Fe^{3+})−FSM was only ca. 46% that of FSM-22. In line with the BET surface areas and pore volumes of FSM (Table 1), the pore peaks (Figure 3b) decreased with an increase in the amount of metmyoglobin (Fe^{3+}) adsorbed into the pores of FSM (Table 1). These results indicate that the pores of FSM were occupied

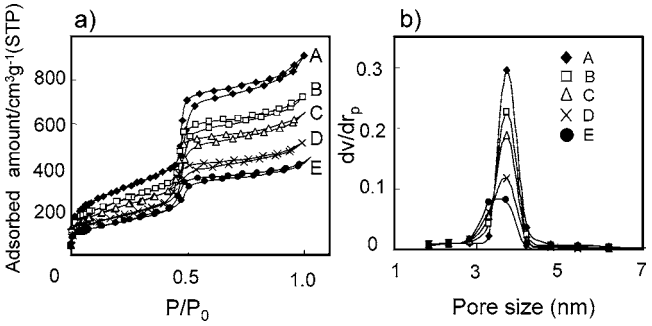

Figure 3. Changes in nitrogen adsorption isotherms of metmyoglobin (Fe^{3+})−FSM conjugates (a) and the corresponding pore size distributions obtained from the adsorption branch by the BJH method (b). Curves A, B, C, D, and E indicate the amounts of metmyoglobin (Fe^{3+}) adsorbed to the pores of FSM (100 mg), 0, 4.3, 9.2, 17.0, and 24.0 mg, respectively.

Table 1. Physicochemical Properties of the Myoglobin−FSM Conjugate

myoglobin adsorbed (mg/100 mg FSM)	pore volume ($cm^3\ g^{-1}$)	specific surface area ($m^2\ g^{-1}$)
0	1.39	1110
4.3	1.11	886
9.2	0.99	856
17.0	0.78	722
24.0	0.64	561

by metmyoglobin (Fe^{3+}) and support the opinion expressed in the preceding paragraph.

Reaction of Myoglobin (Fe^{2+})−FSM with Carbon Monoxide. The absorption spectrum of the myoglobin (Fe^{2+})−FSM conjugate in water, shown in Figure 4 (curve B), differs considerably from that of the metmyoglobin (Fe^{3+})−FSM conjugate (curve A). Upon reducing the conjugate with dithionate, the metmyoglobin (Fe^{3+})−FSM spectrum (curve A in Figure 4) changed remarkably, the Soret shifting from 420 to 431 nm and a sharp single peak appearing in the visible region at 557 nm (curve B in Figure 4). The single adsorption band (λ_{max} = 557 nm) in the α, β region compared favorably with the wavelengths of deoxymyoglobin (*23*). The addition of carbon monoxide to the myoglobin (Fe^{2+})−FSM conjugate caused the formation of a CO-myoglobin−FSM having absorption maxima at 567, 539, and 420 nm (Figure 4: curve C). The spectrum has two clearly split peaks (α- and β-bands) in the visible region and a Soret peak. It is well-known that deoxymyoglobin changes easily into carboxymyoglobin in the presence of carbon monoxide with a spectral change. Thus, the change of spectrum from B to C, that is, the band shift from 557 and 433 nm to 567, 539 and 420 nm, respectively, corresponds to the change of myoglobin (Fe^{2+})−FSM to CO-myoglobin (Fe^{2+})−FSM. In addition, CO-myoglobin (Fe^{2+})−FSM shows an absorption curve quite similar to that of CO-heme coupled with native myoglobin (*23*). From the results above, it is deduced that myoglobin retains its higher-order structure in the pores of FSM.

Peroxidase-Like Activity of Metmyoglobin (Fe^{3+})−FSM. Figures 5a and 5b show the peroxidase-like activity of the metmyoglobin (Fe^{3+})−FSM conjugate against incubation time in the reactions using hydrogen peroxide (a hydrogen acceptor) and guaiacol (*23*) or ABTS (*25*) (hydrogen donors) in aqueous solution (Scheme 1). When guaiacol was the hydrogen donor, the metmyoglobin (Fe^{3+})−FSM conjugate (Figure 5a, curve A) showed activity similar to that of the native form (Figure 5a, curve B). The reaction rate with the metmyoglobin (Fe^{3+})−FSM and the native form were 1.59×10^{-6} and 1.26×10^{-6} M/min, respectively. In the absence of myoglobin−FSM in the reaction systems, no oxidation of organic substrate occurs (date not shown). This clearly indicates that the metmyoglobin does not lose its activity by encapsulation into the pores of FSM and probably maintains its nominal higher-order structure. However, when ABTS was the hydrogen donor, the amount of oxidized hydrogen donor increased with time for both the metmyoglobin (Fe^{3+})−FSM and the native form (Figure 5b, curve B), but oxidation did proceed slightly with metmyoglobin (Fe^{3+})−FSM (Figure 5b, curve A). The reaction rate with the metmyoglobin (Fe^{3+})−FSM and the native form were 0.9×10^{-6} and 3.8×10^{-6} M/min, respectively. Generally, in a process catalyzed by an enzyme, the reaction proceeds with the enzyme first recognizing the substrate and/or reactant to form

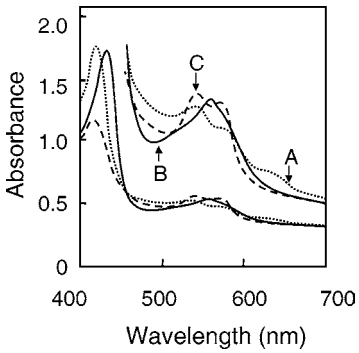

Figure 4. Absorption spectra of metmyoglobin (Fe^{3+})−FSM (curve A), deoxymyoglobin (Fe^{2+})−FSM (curve B), and CO−myoglobin (Fe^{2+})−FSM (curve C) in phosphate buffer (pH 6.9). Curve B in the spectrum of deoxymyoglobin (Fe^{2+})−FSM in phosphate buffer (pH 6.9) was obtained by adding dithionite to metmyoglobin (Fe^{3+})−FSM. The concentration of metmyoglobin (Fe^{3+})−FSM was 0.077 mg/mL (0.017 as metmyoglobin). The peak positions of the α, β, and Soret bands for metmyoglobin (Fe^{3+})−FSM change from 640, 538, and 420 nm to 557 and 432 nm, respectively. Curve C is the spectrum of CO−myoglobin (Fe^{2+})−FSM obtained by adding carbonmonoxide,CO, to deoxymyoglobin (Fe^{2+})−FSM. The peak positions of the α, β and Soret bands for deoxymyoglobin (Fe^{2+})−FSM change from 557 and 432 nm to 567, 539, and 420 nm, respectively.

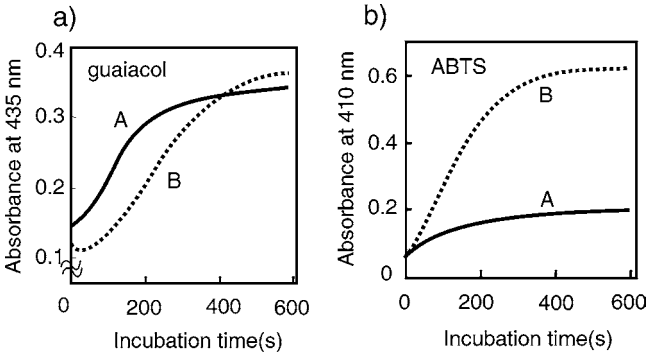

Figure 5. The peroxidase-like activity spectrophotometrically determined by measuring the absorbance at 435 and 410 nm for the respective oxidations of guaiacol (a) and 2,2-azino- bis(3-methylbenthzthiaoline)-6-sulfomic acid (ABTS) (b). (a) Oxidation of guaiacol (0.18 mmol) with hydrogen peroxide (0.1%) in 3 mL of phosphate buffer (pH 6.9) catalyzed by metmyoglobin−FSM (0.95 mg: 0.21 mg as metmyoglobin) (curve A) or metmyoglobin (0.2 mg) (curve B). (b) Oxidation of ABTS (2.9 μmol) with hydrogen peroxide (0.02%) in 3 mL of phosphate buffer (pH 6.9) catalyzed by myoglobin−FSM (0.0476 mg: 0.0093 mg as metmyoglobin) (curve A) or metmyoglobin (0.009 mg) (curve B).

a certain activation complex with them. Thus, the difference between the activities of metmyoglobin (Fe^{3+})−FSM conjugate for guaiacol and ABTS indicates that the metmyoglobin could not form such an activation complex with ABTS but could with guaiacol. In other words, it can be said that by the encapsulation, the metmyoglobin obtained an advanced molecular recognition ability that can distinguish between ABTS and guaiacol. Although it is not completely clear how the new ability comes about at present, it may be due to the limited flexibility in the higher-order structure of metmyoglobin and the selective adsorption properties (*16*−*18*) of metmyoglobin−FSM caused by the encapsulation.

Peroxidase-Like Activity of Metmyoglobin (Fe^{3+})−FSM in Toluene. The finding shown above suggested that we examine the action of metmyoglobin (Fe^{3+})−FSM conjugate in an organic solvent. Thus, the catalysis of metmyoglobin (Fe^{3+})−FSM was investigated for the oxidation of leucocrystal violet (*26*) (AH) with benzoyl peroxide in toluene as shown below (Scheme 2). The absorption spectrum of metmyoglobin (Fe^{3+})−FSM in toluene is shown as a solid line in Figure 6 and shows a sharp Soret band at 410 nm. The absorption spectrum of metmyoglobin (Fe^{3+}), the dashed line in Figure 6, shows a broad Soret band at approximate 420 nm, clearly indicating an agglutinated form of metmyoglobin (Fe^{3+}). From the results obtained above, it can be seen that metmyoglobin (Fe^{3+}) (native) is easily deactivated in the organic media, but the metmyoglobin (Fe^{3+}) encaged in the pore of FSM is not denatured. Figure 7 shows the oxidation of leucocrystal violet (AH) with benzoyl peroxide catalyzed by metmyoglobin−FSM in toluene. The peroxidase activities of metmyoglobin (Fe^{3+})−FSM and metmyoglobin (Fe^{3+}) against incubation time correspond to curves A and B, respectively. The activity of the metmyoglobin (Fe^{3+})−FSM increased with time, while the native form showed almost no activity. On the basis of the above results, we can point out the following. Although the aggregation of metmyoglobin is accelerated in toluene, it can be prevented by encapsulation with FSM. Another role of encapsulation is to retain metmyoglobin (Fe^{3+}) in its active form or, in other words, at the nominal higher-order structure, as can be seen from the high activity of metmyoglobin(Fe^{3+})−FSM for the reaction mentioned above. As for the reasons why the metmyoglobin (Fe^{3+}) encaged in FSM retains the nominal higher-order structure and acts as a catalyst even in toluene, various factors can be considered. First of all, if the pores of FSM are highly hydrophobic, they can expel toluene molecules. If so, toluene

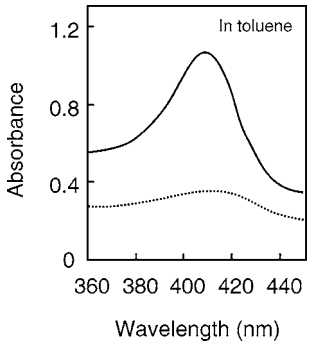

Figure 6. Absorption spectra of metmyoglobin (dashed line) and metmyoglobin−FSM (solid line) in toluene.

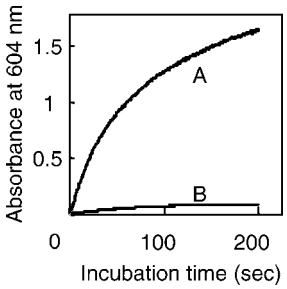

Figure 7. Oxidation of crystal violet with benzoyl peroxide catalyzed by metmyoglobin−FSM (curve A) and metmyoglobin (curve B) in toluene. Benzoyl peroxide (0.28 mM) and leucocrystal violet (8 mM) were used as a hydrogen acceptor and donor, respectively, in 3 mL of toluene. The reaction was carried out for 200 s at 25 °C. Curve A: metmyoglobin (Fe^{3+})−FSM (2 mg/mL: 0.4 mg as metmyoglobin). Curve B: metmyoglobin (Fe^{3+})(0.4 mg/mL). The reaction system is the same as that of curve A.

cannot do any damage to the metmyoglobin (Fe^{3+}). Thus, the adsorption isotherm of toluene into metmyoglobin (Fe^{3+})−FSM (20 mg of metmyoglobin /100 mg of FSM) was measured for the purpose of examining whether toluene molecules could enter into the pore cavity. The pore volume of metmyoglobin (Fe^{3+})−FSM calculated on the basis of the toluene adsorption isotherm was the same as that obtained from the corresponding nitrogen adsorption isotherm. Accordingly toluene molecules can enter the pore cavity of metmyoglobin (Fe^{3+})−FSM, yet they do not deactivate the metmyoglobin (Fe^{3+}). This may be due to the limited flexibility of metmyoglobin (Fe^{3+}) in the pores of FSM. Note that Wang et al. (*27*) have found that hemoglobin immobilized between titanate layers does not lose its activity in organic solvents; they postulate that water between the layers plays an important role in retaining the activity of the enzyme in its higher-order structure. Furthermore, the interlayer water is presumed to prevent organic solvents from taking water molecules which the enzyme originally possesses, resulting in retention of the activity and higher-order structure though the interaction between the interlayer water and the enzyme-bound water molecules. A similar mechanism may be considered relevant in this work.

In conclusion, the encapsulation of myoglobin into the silicate mesoporous increases not only the molecular recognition ability of myoglobin but also the resistance to organic solvents, or surroundings. Thus, the encapsulation of enzymes with mesoporous materials is quite useful for establishing new functions and will have wide application to different chemical processes.

Comparative Evaluation of Target-Specific GFP Gene Silencing Efficiencies for Antisense ODN, Synthetic siRNA, and siRNA Plasmid Complexed with PEI−PEG−FOL Conjugate

Sun Hwa Kim,[†] Hyejung Mok,[†] Ji Hoon Jeong,[‡] Sung Wan Kim,[‡] and Tae Gwan Park*,[†]

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon 305-701, South Korea, and Center for Controlled Chemical Delivery (CCCD)/Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112. Received October 4, 2005; Revised Manuscript Received November 1, 2005

Cell specific gene silencing effects of antisense oligodeoxynucleotide (AS-ODN), synthetic small interfering RNA (siRNA-S), and siRNA expressing plasmid (siRNA-P) were comparatively evaluated. Poly(ethylenimine) (PEI) and PEI−*graft*-poly(ethylene glycol)−folate (PEI−PEG−FOL) conjugate were used to form nanosized polyelectrolyte complexes with the above three nucleic acids coding for inhibition of green fluorescent protein (GFP) expression. The three nucleic acid complexes formulated with either PEI or PEI−PEG−FOL had comparable sizes and surface ζ potential values. Among the three inhibitory nucleic acids, siRNA-S, when complexed with PEI−PEG−FOL, exhibited the most dose-effective and fastest gene silencing effect for FOL receptor overexpressing KB cells, because the siRNA-S could be directly delivered, via FOL receptor-mediated endocytosis, into the cytoplasm compartment where the degradation processing of target GFP mRNA occurred in a sequence-specific manner.

INTRODUCTION

Posttranscriptional gene silencing approaches, using various nucleic acid based molecules such as antisense oligodeoxynucleotides (AS-ODNs), ribozymes, and small interfering RNAs (siRNAs), have drawn much attention because of their potential therapeutic impact on treating various genetic disorder and infectious diseases including cancer. For the last two decades, AS-ODNs and ribozymes have been popularly used to knock down expression of specific genes. Quite recently, siRNA, which inhibits specific genes by double-stranded RNA molecules having 21−23 nucleotides, has emerged as a more powerful therapeutic genetic agent (*1*−*3*). Both AS-ODN and siRNA similarly inhibit posttranscriptional process of a target mRNA in a sequence-specific manner, but their action mechanisms in a cellular and molecular basis are vastly different. Although both of them exhibit considerable gene inhibition effects in vitro, their transfection efficiencies still remain in a relatively low level mainly due to poor intracellular uptake and severe enzymatic degradations in serum conditions (*4*, *5*). To promote their gene inhibition effect, a wide range of cationic polymers and lipids have been employed to form nanoparticulate polyelectrolyte complexes with negatively charged AS-ODN and siRNA (*6*−*8*). The formation of nanosized complexes enhances the extent of intracellular uptake, increases stability against nucleases, and additionally confers cell specificity when conjugating a targeting moiety to the complexes.

Among the nonviral carriers, PEI has been popularly used for delivering plasmid DNA and AS-ODN for its superior transfection efficiency. A variety of chemically modified PEI derivatives such as PEGylated PEI and cross-linked PEI were also used to reduce its inherent cytotoxic problem and to enhance colloidal stability against aggregation under serum conditions (*9*−*11*). In our previous works, PEI was grafted with PEG chains having a folate (FOL) moiety at its distal end to produce PEI−PEG−FOL conjugate (*12*). When the conjugate was complexed with plasmid DNA to form nanosized polyelectrolyte particles, greatly increased specific cellular uptake to FOL receptor overexpressing cancer cells was observed with concomitantly improved colloidal stability, compared to unmodified PEI. As a result, gene transfection efficiency with PEI−PEG−FOL was enhanced to a greater extent than that with unmodified PEI for FOL receptor overexpressing cells. This was attributed to folate receptor mediated endocytosis.

It is of great interest to compare gene silencing efficiencies between AS-ODN and siRNA, using PEI−PEG−FOL conjugate as a cell-specific gene carrier, since their modes of action are fundamentally different. Herein we report comparative gene silencing effects of three types of nucleic acid based molecules coding for inhibiting green fluorescent protein (GFP) expression. AS-ODN, synthetic siRNA (siRNA-S), and siRNA plasmid (siRNA-P) were used to form polyelectrolyte complexes with PEI or PEI−PEG−FOL. The complexes were characterized in terms of diameter and surface charge value. Their gene inhibition extents of an exogenous GFP gene expressed in KB cells were quantitatively evaluated in terms of dose and incubation time.

EXPERIMENTAL PROCEDURES

1. Materials. Folate (FOL) was purchased from Sigma Chemical Co. (St. Louis, MO). Poly(ethylenimine) (branched PEI, MW 25 000) was obtained from Aldrich (Milwaukee, WI). Poly(ethylene glycol) ($COOH-PEG-NH_2$, MW 3400) was supplied by Nektar (Huntsville, AL). Dulbecco's phosphate buffered saline (PBS), fetal bovine serum (FBS), and Roswell Park Memorial Institute 1640 medium (RPMI 1640 w/o folate) were purchased from Gibco BRL (Grand Island, NY). A pEGFP-C1 vector was obtained from BD Bioscience Clontech (Palo Alto, CA). All other chemicals and reagents were of analytical grade.

2. Antisense ODN, Synthetic siRNA, and siRNA Plasmid. Antisense ODN, synthetic siRNA, and plasmid siRNA targeted

to the GFP gene were designed as shown in Table 1. HPLC-purified phosphorothioated antisense ODN was purchased from Bioneer (Daejeon, South Korea). Synthetic siRNA (antisense and sense strands) was obtained from Invitrogen (Carlsbad, CA). siRNA plasmid (pSUPER-siGFP), producing anti-GFP siRNA hairpin transcript in the cells, was constructed by using pSUPER-RNAi vector system (Oligoengine, Seattle, WA) and forward and reverse oligonucleotides (*1*). Forward and reverse oligonucleotides for cloning the pSUPER-siGFP were synthesized and purified by Bioneer (Daejeon, South Korea).

3. Preparation of PEI−PEG−FOL Conjugate. A cancer target ligand, folate, was introduced into the highly branched cationic polymer, PEI, to prepare a target-specific gene delivery vector. The PEI−PEG−FOL conjugate was synthesized according to the previous method (*10*, *12*). The stoichiometric conjugation molar ratio between PEI and PEG−FOL was 1:4.46 as determined by ^{1}H NMR spectra. The calculated molecular weight of the resulting conjugate was about MW 42824.

4. Preparation and Characterization of Polyelectrolyte Complexes between PEI−PEG−FOL Conjugate and Various Nucleic Acids. Anionic nucleic acids and cationic polymeric conjugates produced self-assembled polyelectrolyte complexes in an aqueous phase due to their electrical interactions. AS-ODN, siRNA-S, and siRNA-P were separately complexed with unmodified PEI and PEI−PEG−FOL conjugate under various conditions. Three types of the nucleic acids (4 μg) dissolved in 200 μL of phosphate buffered saline (PBS, pH 7.2) were respectively mixed with 10.6 μg of PEI−PEG−FOL (nitrogen/phosphate ratio = 16) in 300 μL of PBS solution. The mixtures were incubated for 20 min at room temperature and diluted 5-fold into PBS solution. To determine the hydrodynamic diameter and ζ potential of the PEI−PEG−FOL (or PEI)/nucleic acid complexes, the resulting complex solutions were analyzed by a dynamic light scattering instrument (Zeta-Plus, Brookhaven, NY).

5. Cell Culture and Transfection. KB cells (human epidermal carcinoma, Korean Cell Line Bank, Seoul, South Korea), were cultured in RPMI 1640 w/o folate medium supplemented with 10% FBS (the only source of folate) at 37 °C in a humidified atmosphere of 5% of CO_2. For gene silencing experiments, the nucleic acid complexes were cotransfected to KB cells along with the GFP plasmid according to the previously published method with minor modifications (*13*). Briefly, the cells were transfected with 2 μg of pEGFP-C1 vector using Lipofectamine 2000 reagent (2 mg/mL, Invitrogen, Carlsbad, CA) in 1 mL of RPMI1640 without folate containing 10% FBS for 3 h at 37 °C. The three nucleic acids were simultaneously cotransfected using 2 μg of AS-ODN, 0.5 μg of siRNA-S, or 2 μg of siRNA-P condensed with PEI or PEI−PEG−FOL conjugates at various nitrogen/phosphate (N/P) ratios from 0 to 24. To determine a dose dependence of the nucleic acids on the inhibition of the target gene expression, cells were transfected with the complexes prepared at an N/P ratio of 16. The concentrations of the nucleic acids were as follows. AS-ODN and siRNA-P: 0.0, 0.1, 0.5, 1.0, 2.0, and 4.0 μg. siRNA-S: 0.00, 0.05, 0.10, 0.25, 0.50, and 1.00 μg. After replacing the transfection medium with 1 mL of serum containing medium, the transfected cells were incubated for a further 24 h and harvested by treatment of a cell lysis buffer solution (CelLytic M cell lysis reagent, Sigma-Aldrich, St. Louis, MO). For a time dependent GFP expression trend, PEI−PEG−FOL complexes were prepared with AS-ODN (2 μg), siRNA-S (0.5 μg), and siRNA-P (2 μg) at an N/P ratio of 16 and incubated for different time intervals after transfection. The level of GFP fluorescence was determined using a spectrofluorophotometer (SLM-AMINCO 8100, SLM Instruments Inc., Rochester, NY) with an excitation and emission wavelength at 488 and 507 nm, respectively. All values were normalized by cellular protein content, as determined by Micro-BCA protein assay (Pierce, Rockford, IL). The relative GFP expression level was then calculated as a relative percentage of GFP gene expression for the pEGFP-C1 transfected KB cells (negative control) compared to those cotransfected with nucleic acid complexes (AS-ODN, siRNA-S, or siRNA-P) [% GFP expression = (GFP intensity in sample/GFP intensity in negative control) × 100].

RESULTS AND DISCUSSION

Table 1 shows nucleotide sequences of anti-GFP AS-ODN, siRNA-S, and siRNA-P. Both siRNA-S and siRNA-P have the same target site in an mRNA sequence of GFP, but AS-ODN has a different one. For siRNA-P construction, forward and reverse ODN oligomers were cloned with a pSUPER-RNAi vector system as reported in our previous study (*12*). The three anti-GFP nucleic acid molecules, AS-ODN, siRNA-S, and siRNA-P, were complexed with PEI or PEI−PEG−FOL at an N/P ratio of 16. As listed in Table 2, the complexes of PEI−PEG−FOL with AS-ODN, siRNA-S, and siRNA-P were 94.4 ± 20.0, 120 ± 34.5, and 108.5 ± 19.0 nm in diameter with positive surface charge values of 1.0 ± 0.5, 2.5 ± 0.9, and 1.3 ± 0.7 mV, respectively. The complexes with PEI had slightly larger particle sizes with greater surface charge values than those with PEI−PEG−FOL, which was likely due to a charge shielding effect by PEGylation (*14*). At a fixed N/P ratio, the PEI and PEI−PEG−FOL complexes respectively showed comparable sizes and surface charge values regardless of nucleic acid molecules.

Target-specific GFP silencing activities of the three complexes were comparatively determined with folate receptor overexpressing KB cells. Anti-GFP nucleic acids (AS-ODN, siRNA-S, and siRNA-P) were complexed with PEI or PEI−PEG−FOL at different N/P ratios, and the resultant complexes were cotransfected with Lipofectamine/GFP plasmid (pEGFP-C1 vector) complexes. GFP gene silencing efficiencies of the complexes are shown in Figure 1. With increasing the N/P ratio, PEI−PEG−FOL complexes exhibited greater suppression of GFP expression than PEI complexes for the three nucleic acids. At an N/P ratio of 16, PEI−PEG−FOL complexes with AS-ODN, siRNA-S, and siRNA-P showed 68.9 ± 8.0%, 75.0 ± 15.3%, and 59.2 ± 3.4% inhibition of GFP expression,

ζ potential (mV)	8.8 ± 1.3	10.3 ± 1.9	8.2 ± 2.0	1.0 ± 0.5	2.5 ± 0.9	1.3 ± 0.7

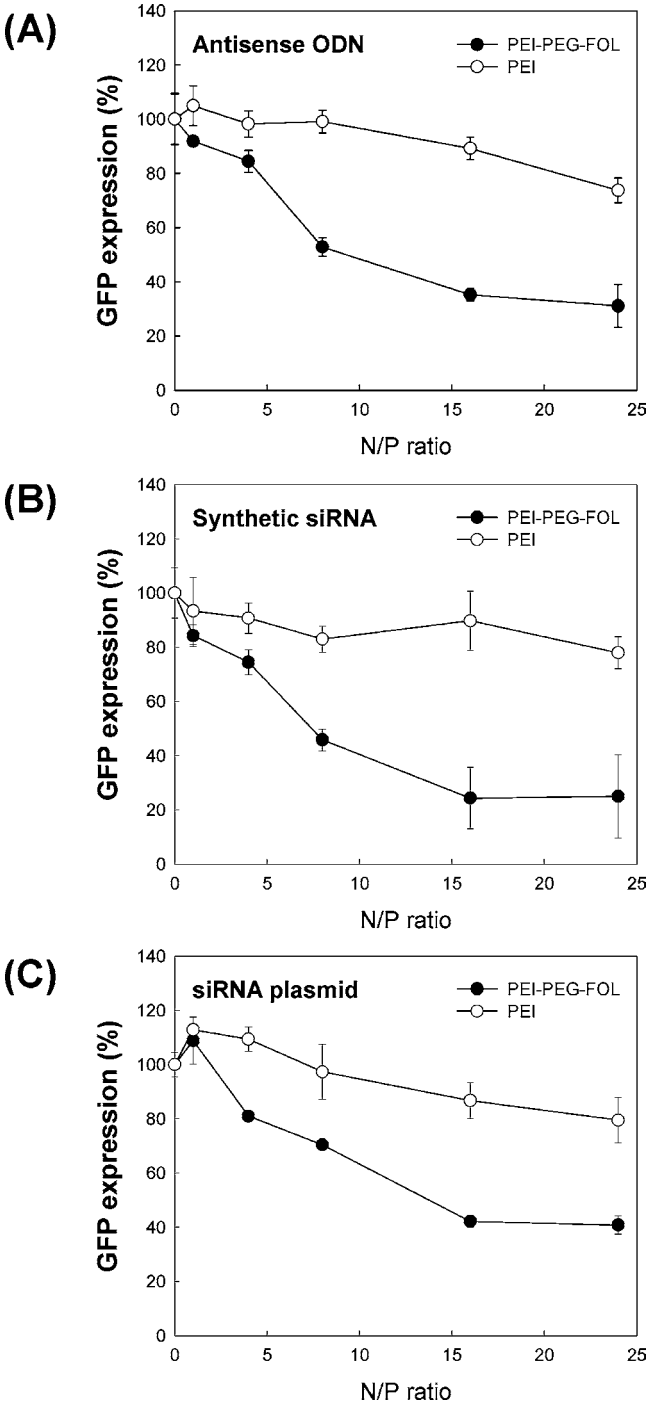

Figure 1. Cancer cell targeted GFP gene silencing effect of (A) antisense ODN, (B) synthetic siRNA, and (C) siRNA plasmid complexes with PEI (open circles) and PEI−PEG−FOL (filled circles) as a function of N/P ratio from 0 to 24 for KB cells.

respectively, while PEI complexes showed an inhibition degree of 26.3 ± 4.6%, 22.1 ± 5.9%, and 20.5 ± 8.4%, in the same order. These results evidently indicate that the PEI−PEG−FOL complexes were far more effective in GFP silencing than the PEI complexes due to their enhanced extents of cellular uptake (*12*). For the three PEI−PEG−FOL complexes, folate receptor mediated endocytosis certainly played a key role in facilitating them to transport within cells, resulting in effectively knocking down the expression of GFP gene. Since the gene transfection experiments were performed in the medium containing 10% serum, the gene silencing efficiencies of the PEI complexes were relatively lower compared to those of the PEI−PEG−FOL complexes. The enhanced gene silencing effects of the PEI−PEG−FOL complexes could be additionally attributed to the presence of a PEG protective layer on the surface, preventing nonspecific adsorption of serum proteins and minimizing interparticular aggregation (*15*). It should be noted that, in our previous study, anti-GFP siRNA-P complexed with PEI−PEG−FOL inhibited GFP expression up to 89.5% for the KB cells that were pretransfected with GFP plasmid (*12*). In that study, the KB cells were pretransfected with GFP plasmid, and only GFP-positive cells were sorted for the transfection experiment. The reduced inhibition extent (59.2%) of GFP expression observed in the current study was likely caused by the fact that the KB cells were cotransfected with GFP plasmid and anti-GFP siRNA. The mixed population of GFP-positive and GFP-negative KB cells might result in the reduced extent of gene inhibition by siRNA.

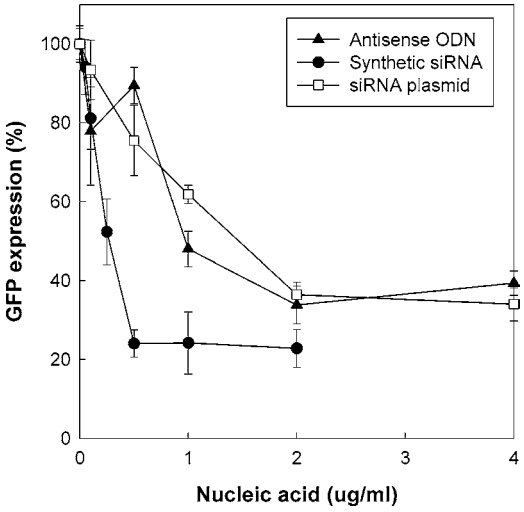

Figure 2. Comparative GFP gene suppression of antisense ODN (filled triangles), synthetic siRNA (filled circles), and siRNA plasmid (open squares) as a function of nucleic acid concentration. Antisense ODN and siRNA plasmid: 0.0−4.0 μg. Synthetic siRNA: 0.0−1.0 μg. Nucleic acids were complexed with PEI−PEG−FOL at an N/P ratio of 16.

Among the three nucleic acids, siRNA-S showed the most pronounced gene silencing effect. Although AS-ODN and siRNA-S have different GFP mRNA target sites, they must be delivered in the cytoplasm and inhibited translation of their respective target GFP mRNA sequences. siRNA-S exhibited a more effective gene inhibition effect than AS-ODN, which might be due to its greater specific gene suppression mechanism (*16*). It is also noted that siRNA-S showed greater gene silencing effects than siRNA-P with increasing N/P ratios. This was mostly likely caused by different intracellular gene trafficking and processing mechanisms between the two nucleic acids. siRNA-P must be located and transcribed in the nucleus prior to releasing several copies of siRNA transcripts to the cytoplasm. Thus it is reasonable to say that siRNA-S directly delivered in the cytoplasm exhibited more effective silencing of GFP expression compared to siRNA-P.

Dose-dependent anti-GFP activities of the three nucleic acids complexed with PEI−PEG−FOL (N/P ratio =16) are shown in Figure 2. With increasing the nucleic acid amount used in the transfection experiments, the three complexes inhibited GFP expression to a greater extent. However, siRNA-S complexes demonstrated the most powerful gene silencing effect. Nearly 76.0 ± 3.4% of GFP inhibition could be obtained at a dose of 0.5 μg/mL for siRNA-S, whereas 66.2 ± 4.8% and 63.5 ± 3.2% of GFP inhibition were attained at a dose of 2 μg/mL for AS-ODN and siRNA-P, respectively. These results reveal that target-specific gene silencing could be achieved by using much smaller amount of siRNA-S than AS-ODN and siRNA-P. This can be

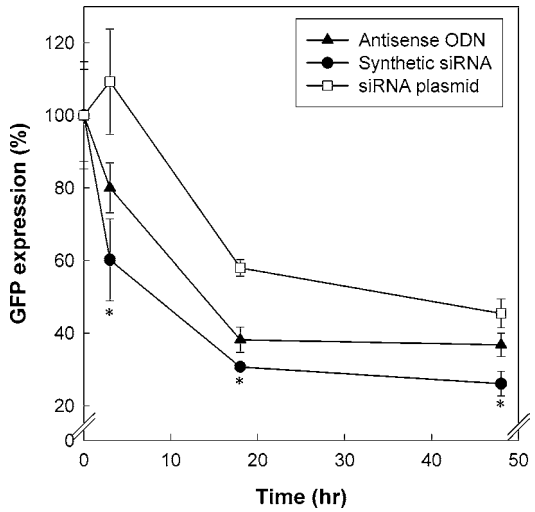

Figure 3. Time dependent inhibition of GFP gene expression by using antisense ODN (filled triangles), synthetic siRNA (filled circles), and siRNA plasmid (open squares). Nucleic acids were complexed with PEI−PEG−FOL at an N/P ratio of 16. Each dot represents the mean ± SD from three replicate experiments; (*) $P < 0.05$ versus AS-ODN (Student's *t*-test).

attributed to the inherently specific and unique gene inhibition mode of siRNA-S, as described in the literature (*16*). Figure 3 shows GFP gene suppression profiles of the three nucleic acid complexes (N/P ratio = 16; nucleic acid amount: 2.0 μg of AS-ODN, 0.5 μg of siRNA-S, and 2.0 μg of siRNA-P) as a function of time. siRNA-S and AS-ODN complexes inhibited GFP expression more rapidly than siRNA-P complexes. The siRNA-P complexes had a lag period before exerting its GFP gene silencing effect, presumably because they underwent a series of subcellular trafficking events, which hampers the production and localization of siRNA transcripts in the cytoplasm (*17*). Hence siRNA-P complexes exhibited more delayed gene silencing effect than siRNA-S and AS-ODN complexes.

In conclusion, three anti-GFP nucleic acids (AS-ODN, siRNA-S, and siRNA-P) were complexed with PEI−PEG−FOL conjugate and transfected to FOL receptor overexpressing cells to compare their FOL receptor-specific gene silencing efficiencies. All three complexes exhibited cancer cell specific gene inhibition behaviors, but siRNA-S was the most effective in gene silencing.

Conversion of a DNA chip to a nanocapsule array was performed by grafting on a liposome an oligonucleotide complementary to an oligonucleotide bound to the array. Each liposome may be loaded by a soluble molecule or may present a hydrophobic or amphiphilic molecule inserted in its wall. To detect liposomes on the chip, we used fluorescent dyes encapsulated in the liposome internal volume or fluorescent lipids. We observed that an oligonucleotide-grafted liposome containing a defined dye specifically accumulated on the area where its complementary oligonucleotide had been spotted on the array. The virtually unlimited amount of addresses allows the specific binding of large amounts of liposomes in one single batch.

INTRODUCTION

DNA microarrays or DNA chips allow us to analyze the expression of hundreds of genes in a single experiment (*1*). The technique consists of immobilizing a specific single stranded DNA sequence on a solid support using an automated spotting device. The obtained microstructured array is incubated with single stranded cDNA fragments obtained from RNA extracted from cells that are investigated. Complementary DNA fragments present in the solution will hybridize with the DNA linked to the array. Crossed correlation analysis of the hybridized DNA allows the discovery and the understanding of gene expression and metabolic pathway activation in organisms (*2*). This technology stimulated the development of other chips such as protein chips as diagnostic tools or as biosensors utilizing immobilized enzymes, antibodies, or membrane proteins (*3*, *4*). However, protein structures are fragile. Immobilization with a harsh chemical treatment often leads to an uncontrolled decrease in activity and limits the use of this technology.

The aim of this paper consists of using the nowadays well-established DNA microarray technology to allow immobilization of nanocontainers on the chip. Since proteins may be encapsulated in these containers in their native states, they remain in an ideal environment and resist protein denaturation due to dilution and to digestion by proteases (*5*, *6*). Hydrophobic or amphiphilic molecules such as membrane proteins may be inserted in the nanocapsule wall. Thus, conversion of a DNA chip to a nanocontainer chip may result in the conversion of a DNA chip to a protein chip (Figure 1).

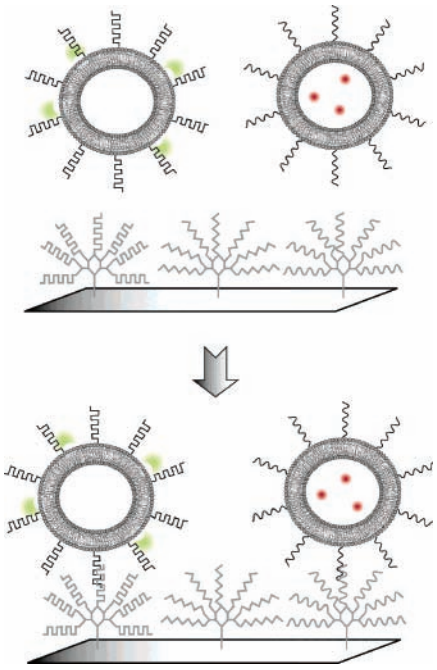

Figure 1. Specific liposome attachment on the array via oligonucleotide hybridization. The specificity of the binding is guaranteed by the sequence dependent hybridization between the liposome grafted one and the one bound on the array.

EXPERIMENTAL PROCEDURES

Liposomes were prepared by hydration of a lipid film followed by freeze−thaw cycles and extrusion. 100 μL of 100 mM eggPC lipids (Lipoid, Ludwigshafen, Germany) in $CHCl_3$ and 10 μL of 84 μM lipids DSPE-PEG(2000) Maleimide lipids (Avanti Polar Lipids, Alabaster, AL) in $CHCl_3$ were driedin a 15 mL glass tube under N_2 and then dried in a vacuum for 3 h.

To identify liposomes on the array, we used a fluorescent probe. A lipid grafted rhodamine was used as dye for labeling the liposome membrane. We used 3 μL of 0.8 mM Rhod-PE lipids (Avanti Polar Lipids, Alabaster, AL) in $CHCl_3$ in the formulation of the lipid film. As a soluble probe, we encapsulated the water-soluble fluorescent dye Cy5. The encapsulation was performed by freeze−thaw cycles in a buffer solution containing the probe to encapsulate (*6*, *7*). 100 μL of 4.4 mM Cy5 fluorescent dye (Molecular Probes, Eugene, OR) in 2xSSPE (20 mM sodium phosphate buffer pH 7.4, 300 mM NaCl, 2 mM EDTA) was added and firmly vortexed to peel off and

C : 5′-TAGACTAGTCGGATAGGCCCATGCTTT-NH2-3′.

Figure 2. Structures of dendrimer and oligonucleotides used.

dissolve the dried lipid film. The liposome suspension was frozen and thawed 30 times successively dipping the glass tube in liquid N_2 and a 37 °C water bath. Then the volume of the solution was increased to 10 mL with 2xSSPE, and the solution was extruded through a 200 μm membrane filter (Schleicher & Schuell, Dassel, Germany) to calibrate the liposomes. At last, nonencapsulated probe was removed by gel filtration using a desalting column previously equilibrated with 2xSSPE (PD10, Amersham Biosciences, Uppsala, Sweden).

To perform anchoring of oligonucleotides on the liposome surface, maleimide functionalized lipids were added in the lipid composition of the liposome membrane (1/100). The maleimide chemical function exhibited outside the liposome reacted with thiol chemical functions present at the 3′ end of the 27-base oligonucleotides A′ and B′ (Figure 2). The anchoring reaction occurred after 1 h at room temperature in 2xSSPE (1/1, thiol/maleimide group). The maleimide grafted lipids that had not reacted thus far with the oligonucleotides were inactivated with an excess of cystein. 10 μL of 2 mM *N*-acetylcystein (Sigma, St. Louis, MO) in H_2O was added to the liposome suspension, and the resulting mixture was incubated under agitation for 1 h.

As DNA chips, we used dendrislides, which showed better sensitivity than classical slides; they were prepared as described (*10, 11*). Briefly, microscope glass slides were cleaned with an alcoholic solution of NaOH (2.5 M in alcohol/water: 3/2, v/v), rinsed with water, and silanized with (3-aminopropyl)triethoxysilane. The silanized glass slides were activated by KOH, then rinsed by water, and incubated in a solution containing the generation 4 of a phosphorus dendrimer harboring aldehyde functions at its surface (Figure 2) (58 μM) in tetrahydrofuran. The slides were then washed with tetrahydrofuran and with ethanol. Then 27-base oligonucleotides modified with an amine function at their 3′ extremities were spotted onto this dendrimer surface and reacted with their aldehyde functions. Oligonucleotides A, B, and C (Figure 2) were spotted on the support as for standard DNA chips, A and B were complementary to oligonucleotides grafted to the lipid containers, and C was used as control. An automated spotting device (Chip Writer Pro from Bio-Rad) allowed attaching 200 fmol of oligonucleotides on the support in a 150 μm diameter spot. The imines function formed between probes and dendrimers, aminosilane and dendrimer, as well as the unreacted aldehyde were reduced by immersion of the slides into an aqueous solution containing $NaBH_4$ at 3.5 mg/mL, then washing with water during 5 min (3 times), and then drying under a stream of N_2 or by centrifugation (800 rpm, 8 min).

To bind liposomes on the slides, we took advantage of the complementarity between oligonucleotides grafted on liposomes and oligonucleotides spotted on the dendrislide. Liposome solutions were incubated overnight on the spotted coated glass slides. 1 mL of the liposome suspension (10 μM eggPC) was added to 9 mL of 2xSSPE and overnight incubated at 37 °C with the slide in a Petri dish. Following two washings with the same buffer, the reading of the fluorescence on the array was performed with a laser scanner (GenePix 4000A from Axon Inc.) at 532 and 635 nm, at appropriate sensitivity levels of the photomultiplier.

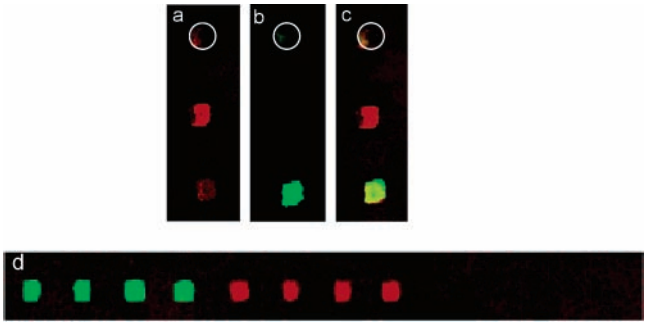

Figure 3. Fluorescence image of bound liposomes on a DNA chip. To demonstrate the selectivity of the process, two examples treated in a slightly different manner are shown. The first slide (parts 3a−c) was functionalized with three different oligonucleotide spots: the upper one contains a random sequence, the middle one the complement to the red labeled (Cy5 at 635 nm) liposomes, and the bottom one the complementary nucleotides for the green labeled (rhodamine labeled lipids at 532 nm) liposomes. Clearly outside the oligonucleotide spots, binding of labeled vesicles was negligible. (a) Visualization by excitation at 635 nm of the red liposomes alone revealed an intensive red spot in the middle but also two less intense but still clear spots. (b) The same slide but with exciting (at 532 nm) of only the green color. Here, in addition to the expected main spot at the bottom, a small background is visible for the random sequence. (c) Overlay of both colors. (d) Increasing washing time improved the selectivity. We spotted on the left side oligonucleotides for green liposomes and in the middle four corresponding to the red liposomes; in the four spots with random sequence no color is revealed.

RESULTS AND DISCUSSION

Liposomes containing Rhod-PE lipids were grafted with oligonucleotide A, and liposomes grafted with oligonucleotide B were loaded with fluorescent dye Cy5. Both liposome solutions were mixed and laid down a glass slide spotted with three oligonucleotides, A complementary to A′, B complementary to B′, and C a noncomplementary oligonucleotide. Following hybridization and extensive washing, reading of the fluorescence on the chip revealed colored spots corresponding to the two fluorescent dyes used; hybridization created a well-localized predefined liposome array (Figure 3). The red spots correspond to an accumulation of liposomes containing the soluble Cy5 dyes detected with an excitation at 635 nm. The green spots correspond to an accumulation of liposomes having the membrane cross-linked rhodamine dye, which were detected with an excitation at 532 nm. Each dye corresponds to a liposome preparation with a specific oligonucleotide grafted on the external surface of the lipid membrane. Each kind of liposome binds to the spots corresponding to the complementary oligonucleotide on the chip. Typically the signal detected over each spot was 4 times higher than the background for the red spots and 6 times higher than the background for the green spots. The digital combination of the images obtained by exciting at 635 and 532 nm gives a full vision of the localization of each kind of liposomes on the chip.

This experiment confirms that oligonucleotide hybridization may be used to tether a liposome on a surface (*8, 9*). We show here that, using a DNA chip and the specificity of hybridization, it is possible to immobilize liposomes at specific positions. Each liposome may contain a specific molecule and potentially protein; this allows a general conversion of a DNA chip into another chip such as a protein chip. On the basis of our previous work, the encapsulation procedure can be generalized for a wide range of water-soluble proteins. Encapsulation provides a controlled local environment for the protein and may avoid the

spreading of enzymatic products into the solution by trapping in the container when the product is charged (*5*). In addition, this method should be useful for membrane bound proteins (receptors, channels) which need to be in a lipid environment to keep their conformation and activity. The use of liposomes appears to be an alternative to the microspotting of lipidic membranes on γ-aminopropylsilane coated slides (*4*). An advantage of using nanocontainers is the possibility to substitute liposomes by polymersomes, which are usually more stable. Furthermore, this process allows their specific binding in a single step because of the high specificity of the oligonucleotide hybridization.

Oligonucleotide-grafted liposomes are very exciting building blocks to create networks and other superstructures. DNA provides a virtual addressing without limits. Earlier systems used competitive binding of oligonucleotide to DNA covered liposomes to probe for the presence of specific DNA fragments. However, the liposomes serve only as an amplifier due to their size (*12*). Others created a larger network, and cross-linking was observed via turbidity measurements. Here the presented system is different. The liposomes appear to be excellent carriers for molecules to design a new kind of chip. The use of oligonucleotides as a means of anchoring shows a very high specificity and simplifies the localization of molecules on the array. Then molecules can be directed to their assigned place on the array in a single incubation step. However, the possibility to detect chemical enzymatic reactions is still limited by the finding of a unique reaction substrate for all the spotted proteins, and a system to avoid the spreading of the detectable product on the surface of the array. Here again the use of containers could be an advantage to maintain proteins in a specific reaction environment and to trap the enzymatic reaction products.

Synthesis of Acid-Cleavable Light Isotope-Coded Affinity Tags (ICAT-*L*) for Potential Use in Proteomic Expression Profiling Analysis

Abdul H. Fauq,*,§ Rajashaker Kache,§ Murad A. Khan,§ and Irving E. Vega†

Chemistry Core Facility, Mayo Clinic Jacksonville, 4500 San Pablo Road, Jacksonville, Florida 32224, and Department of Neuroscience, Mayo Clinic Jacksonville, 4500 San Pablo Road, Jacksonville, Florida 32224. Received October 14, 2005; Revised Manuscript Received December 2, 2005

A convenient synthesis of some homologous light isotope-coded affinity tags (ICAT-*L*) containing an acid-labile moiety between the affinity component biotin and an electrophilic polar linker is described. These light ICAT reagents give smooth mass spectral signals in tandem mass spectrometry (MS/MS) analyses of some commercially available cysteine-containing peptides. However, these ICAT molecules are designed for use in identification and relative quantification of whole or partially purified cellular and tissue proteomes. Since the biotin moiety can be readily cleaved off the reagent after mass tagging, undesired residual fragmentation patterns caused by biotin of derived peptides, as normally observed using biotin-containing ICAT reagents, are effectively eliminated. This strategy should enhance peptide sequence coverage significantly which, in turn, should result in improving the quality of data obtained during data-dependent peptide mass and tandem mass spectral analysis of whole proteomes.

INTRODUCTION

The past decade has seen decoding of complete genomes of several lower and higher organisms. Many of these breakthrough discoveries have resulted in identification of novel proteins as drug targets. Recently, novel and high-throughput methodologies for protein identification and quantification have been uncovered using new and improved mass spectrometry techniques (*1*−*3*). Mass spectrometers are now routinely used in many labs to efficiently identify and quantify known proteins in complex proteomes of cell cultures and tissues (*4*, *5*). The absolute as well as relative quantification of proteins in complex biological mixtures is carried out by using several traditional separation techniques including 2D gel electrophoresis (*6*, *7*), high-performance liquid chromatography (HPLC) on reverse phase, and ion-exchange stationary phases (*8*). Recently, the use of computer-assisted mass spectrometry (MS) and tandem mass spectrometry (MS/MS) in electrospray (ES) modes has revolutionized the qualitative and quantitative analysis of whole proteomes (*9*). This technology has yielded high-value information about the nature and quantity, as well as function, of many proteins even in their complex association environments.

A number of methods for relative quantification of proteins have been described in the literature, including staining of proteins separated by two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) and their quantitation by fluorescence intensity measurement (*6*, *7*) and heavy-isotope-coded affinity tags (ICAT) (*10*−*14*). The latter technique has several advantages over the gel-based protein quantifications in terms of convenience, reduction in process time, accuracy, and throughput. Both solid-phase and solution-phase ICATs are known (*15*). Recently, a visible ICAT has also been reported (*16*). A prototypical solution-phase ICAT molecule has three parts in its molecular structural framework, namely, a peptide enrichment moiety that can greatly simplify analysis of complex mixtures of protein hydrolyzates, a heavy isotope carrier label, and an alkylator moiety that specifically labels reactive amino acids such as cysteine (Figure 1a). The peptide enrichment moiety is usually a biotin that can selectively serve to enrich exclusively ICAT-linked peptides based on its specific affinity for avidin employed as a coating on beads or other solid phases. The linker could be a C-13-labeled polyalanine peptide or a diamine with mono- or diethylene ether backbone. The alkylator moiety can be either a cysteine-reactive iodoacetamide or a maleimide that can react with the thiol group of cysteine by S_N2-displacement or 1,4-addition, respectively.

An ICAT can also be obtained with a reactive thiol group at one terminal that serves as a Michael donor for dephosphorylated proteins containing dehydroserine and dehydrothreonine residues, which, in turn, are obtained by base-catalyzed β-elimination of phosphoproteins (*17*, *18*). The latter is an important constituent of posttranslational modifications of proteins involved in important biological phenomena such as signal transduction and enzyme or receptor activation.

Reported herein is the synthesis of some novel light versions of homologous acid-cleavable ICAT reagents. Our preliminary results show that these versions furnish expected MS/MS spectral patterns when certain peptides are derivatized with any of the synthesized homologues of ICAT-*L*.

EXPERIMENTAL PROCEDURES

Materials and Instrumentation. The column chromatographic separations were performed with J. T. Baker Silica gel (230−400 mesh). THF and diethyl ether were distilled from sodium/benzophenone ketyl. Anhydrous DMF was purchased from Aldrich Chemicals.

Methylene chloride was distilled over CaH_2 or P_2O_5. Acetonitrile was reagent grade from E. M. SCIENCE and was used without further purification. Ethyl acetate and hexane were used as received. The purity of all reported compounds was shown to be >95% by TLC and high-field ^{1}H NMR (Brüker Avance-300 at 300 MHz frequency). The ^{1}H NMR chemical shifts are reported in δ ppm units downfield from the tetramethylsilane standard set at $\delta = 0$. IR spectra were measured with an Avatar 370 FT-IR instrument from ThermoNicolet. Mass spectral analyses were performed with Micromass Platform II with a

single quadrupole electrospray ionizer and MassLynx software, and the samples were infused in a 1:1 MeOH/$CHCl_3$ mixture containing 0.1 mM NH_4OAc.

Esterification of Bromoesters. 3-Bromopropanoic acid (30 g, 0.19 mol) was dissolved in dry MeOH (100 mL) and cooled to 0 °C. Through this, dry HCl gas was passed for 10−15 min, and the mixture was kept overnight at room temperature. Methanol was removed under reduced pressure, aq $NaHCO_3$ solution was added, and the compound was extracted with ether (×2). The combined ethereal layers were washed with water and brine, dried over anhydrous Na_2SO_4, and concentrated. The crude esters were used directly for the next reaction. Yield 14.0 g (43%). ^{1}H NMR ($CDCl_3$) 3.73 (s, 3H), 3.58 (t, 2H, J = 6.8 Hz), 2.93 (t, 2H, J = 6.8 Hz). The corresponding methyl esters from 4-bromobutanoic acid and 5-bromopentanoic acid were prepared and characterized in a similar fashion. Methyl 4-bromobutanoate: Yield 4.0 g (72%). ^{1}H NMR ($CDCl_3$) 3.69 (s, 3H), 3.47 (t, 2H, J = 6.8 Hz), 2.51 (t, 2H, J = 7.4 Hz), 2.18 (m, 2H). Methyl 5-bromopentanoate: Yield 85%. ^{1}H NMR ($CDCl_3$) 3.41 (t, 2H, J = 6.6 Hz), 2.35 (t, 2H, J = 7.5 Hz), 1.95−1.74 (m, 4H).

Reduction of Bromoesters to Tertiary Alcohols. The 3-bromopropanoic acid methyl ester (14 g, 0.083 mole) was taken up in dry ether (100 mL) under nitrogen and cooled to −20 °C. To this, CH_3MgBr (83 mL of 3.0 M solution in diethyl ether, 0.25 mol) was added in a dropwise fashion, and the resulting mixture stirred for 0.5 h. Reaction mixture was quenched by slow addition of cold aq NH_4Cl. The resulting suspension was extracted with diethyl ether (×2). The combined ethereal extracts were washed with water, dried over anhydrous Na_2SO_4, and concentrated and the product, 4-bromo-2-methyl-2-butanol, obtained as a colorless oil was used without purification for the next reaction. Yield 10.0 g (71%). ^{1}H NMR ($CDCl_3$) 3.43 (t, 2H, J = 8.3 Hz), 2.02 (t, 2H, J = 8.6 Hz), 1.19 (s, 6H). MS 149 (M − 17), 167 (M^+ + 1). IR: 3374, 2967, 1728, 1671, 1377, 1206, 1093, 922, 649 cm^{-1}. The corresponding tertiary alcohols from 4-bromobutanoic and 5-bromopentanoic acid methyl ester were prepared in a similar fashion. 5-Bromo-2-methyl-2-pentanol: Yield 82%. ^{1}H NMR ($CDCl_3$) 3.44 (t, 2H J = 6.8 Hz), 1.91−2.03 (m, 2H), 1.64−1.56 (m, 2H), 1.24 (s, 6H). 6-Bromo-2-methyl-2-hexanol: Yield 78%. ^{1}H NMR ($CDCl_3$) 3.43 (t, 2H, J = 6.8 Hz), 1.94−1.81 (m, 2H), 1.59−1.47 (m, 4H), 1.23 (s, 6H).

Azido Alcohols 10a−c. The 4-bromo-2-methyl-2-butanol (18.0 g, 0.107 mol) was dissolved in dry DMF (100 mL) under nitrogen. Sodium azide (42.0 g, 0.646 mol) was added, and the suspension was stirred at 90 °C for 16 h. The reaction mixture was diluted with excess ether, washed thoroughly with water and brine, and dried over anhydrous Na_2SO_4. Concentration under reduced pressure followed by purification by vacuum distillation produced the azide **10** as a colorless oil. Yield 5.44 g (39%). NMR ($CDCl_3$) 3.46 (t, 2H, J = 7.3 Hz), 1.77 (t, 2H, J = 7.4 Hz), 1.26 (s, 6 Hz). IR 3405, 2966, 2089, 1660, 1376, 1252, 1211, 1154 cm^{-1}. The homologous tertiary azido alcohols 5-azido-2-methyl-2-pentanol and 6-azido-2-methyl-2-hexanol were prepared as above. 5-Azido-2-methyl-2-pentanol **10b**: Yield 72%. ^{1}H NMR ($CDCl_3$) 3.30 (t, 2H, J = 6.3 Hz), 1.75−1.65 (m, 2H), 1.56−1.50 (m, 2H), 1.24 (s, 6H). MS 161.2 (M + NH^{4+}), 143.99 (M + 1). IR 3395, 2972, 2084, 1671, 1475, 1371, 1268, 1150, 917, 669 cm^{-1}. 6-Azido-2-methyl-2-hexanol **10c**: Yield 70%. ^{1}H NMR ($CDCl_3$) 3.29 (t, 2H, J = 6.8 Hz), 1.66−1.57 (m, 2H), 1.48−1.43 (m, 4H), 1.22 (s, 6H). IR 3385, 2966, 2939, 2089, 1465, 1374, 1266, 1137, 890 cm^{-1}.

Preparation of Chlorocarbonates 8a−c. The 4-azido-2-methyl-2-butanol (5.0 g, 38.7 mmol) and 1-chloroethyl chloroformate (6.10 g, 42.6 mmol) were dissolved in dry CH_2Cl_2 (12 mL) and cooled to 0 °C under nitrogen. Dry pyridine (3.68 g, 46.5 mmol) was added dropwise, and the reaction mixture was allowed to stir at room temperature for 15−16 h, at which point 0.5 M dil HCl was added and the reaction mixture was extracted with CH_2Cl_2 (×2). The CH_2Cl_2 washings were dried over anhydrous Na_2SO_4, filtered, and concentrated. The residue was purified by silica gel column chromatography (EtOAc/hexane as eluent) to furnish **8a** as a colorless oil. Yield 8.59 g (93%). ^{1}H NMR 6.35 ($CDCl_3$) (q, 1H, J = 5.8 Hz), 3.40 (t, 2H, J = 7.5 Hz), 2.19−2.01 (m, 2H), 1.81 (d, 3H, J = 5.8 Hz), 1.55 (s, 3H), 1.54 (s, 3H). MS 253/255 (M^+ + NH_4^+), 258/260 (M + Na^+). IR: 2092, 1754, 1258, 1094, 663 cm^{-1}. The homologous chloroformates **8b**,**c** were prepared in similar yields. Chlorocarbonate from the azidoalcohol **8b**. Yield 68%. ^{1}H NMR ($CDCl_3$) 6.38 (q, 1H), 3.30 (m, 2H), 1.91−183 (m, 2H), 1.81 (d, 3H, J = 5.9 Hz), 1.52 (s, 3H), 1.50 (s, 3H). Chlorocarbonate

from the azidoalochol **8c**. Yield 88%. ^{1}H NMR ($CDCl_3$) 6.38 (q, 1H), 3.29 (t, 2H, J = 7.1 Hz), 1.91−1.73 (m, 5H), 1.68−1.54 (m, 2H), 1.50 (s, 3H), 1.49 (s, 3H), 1.47−1.35 (m, 2H).

Coupling of Carbonates 8a−c with Diamine 4—Synthesis of Azidoamines 13a−c. Diamine **4** (2.80 g, 12.0 mmol) was dissolved in dry DMF (10 mL) under nitrogen at room temperature. The chlorocarbonate **8a** (3.0 g, 12.0 mmol) was dissolved separately in 20 mL of dry DMF under nitrogen and was added via a syringe pump to the reaction mixture over a period of 1 h. The clear reaction mixture was left stirring overnight. After completion of the reaction (TLC monitoring), the DMF was removed under reduced pressure. Water (50 mL) was added, and after the reaction mixture was stirred for 5 min (to decompose any unreacted carbonates), the reaction mixture was concentrated under rotary evaporation, and the residual moisture was removed by rigorous lyophilization. The residue was purified using column chromatography to give pure azidoamine **13a**. Yield 3.18 g (71%). ^{1}H NMR (D_2O) 3.70−3.66 (m, 10H), 3.58 (t, 2H, J = 6.5 Hz), 3.44 (t, 2H, 7.1 Hz), 3.18−3.09 (m, 4H), 2.09 (t, 2H, J = 7.2 Hz), 2.0−1.92 (m, 2H), 1.81−1.73 (m, 2H), 1.46 (s, 6H). MS 376 ($M^+ + 1$). The homologous compounds **13b**,**c** were prepared from appropriate starting materials in the same manner. Azidoamine **13b:** Yield 34%. ^{1}H NMR (D_2O) 3.70−3.65 (m, 10H), 3.58 (t, 2H, J = 6.3 Hz), 3.34 (t, 2H, J = 6.4 Hz), 3.17−3.09 (m, 4H), 1.96 (m, 2H), 1.86−1.62 (m, 6H), 1.43 (s, 6H). MS 390.3 (M + 1). IR 3348, 2939, 2869, 2090, 1703, 1525, 1364, 1262, 1111, 1127 cm^{-1}; Azidoamine **13c**: Yield 28%. ^{1}H NMR (D_2O) 3.73−3.62 (m, 8H), 3.58 (t, 2H J = 6.03 and 12.24 Hz), 3.38−3.31 (m, 4H), 1.96 (quintet, 2H, J = 6.03 and 6.96 Hz), 1.84−1.70 (m, 6H), 1.61 (quintet, 2H), 1.42 (s, 6H). MS 404.4 (M + 1), 426 (M + Na^+). IR 3364, 2924, 2859, 2090, 1697, 1504, 1251, 1106 cm^{-1}.

TEOC Protection of the Azidoamines 13a−c. Azidoamine **13a** (0.795 g, 2.1 mmol) was dissolved in dioxane/water (3:1 v/v) at room temperature. Solid $NaHCO_3$ (0.356 g, 4.2 mmols) was added. After the mixture was stirred for 2−3 min at room temperature, TEOC−succinimide (0.824 g, 3.2 mmol) was added portion-wise, and the stirring was continued for 12 h. The reaction mixture was diluted with ethyl acetate and filtered. The volatiles were removed by rotary evaporation, and the residue was chromatographed using EtOAc/hexane as eluent to give the TEOC-protected product **14a** as a colorless oil. Yield 0.67 g (60%). ^{1}H NMR ($CDCl_3$) 5.03−5.26 (m, 2H, 2NH), 4.09 (t, 2H, J = 8.0 Hz), 3.63−3.49 (m, 14H), 3.34−3.17 (m, 6H), 2.03 (t, 2H, 7.5 Hz), 1.81−1.71 (m, 4H), 1.43 (s, 6H), 0.93 (t, 2H, J = 8.3 Hz), 0.31 (s, 9H). MS 542 (M + Na^+). IR 3329, 2956, 2862, 2092, 1689, 1526, 1258 cm^{-1}. The homologous amines were protected to give **14b**,**c**. TEOC-protected **13b**: Yield 62.5%. ^{1}H NMR ($CDCl_3$) 5.24 (br s, NH), 5.09 (br s, NH), 4.09 (t, 2H, J = 8.3 Hz), 3.64−3.46 (m, 12H), 3.28−3.11 (m, 6H), 1.84−1.53 (m, 8H), 1.39 (s, 6H), 0.92 (t, 2H, J = 6.7 Hz), 0.30 (s, 9H). MS 556 (M+Na^+). IR 3351, 2952, 2867, 2093, 1694, 1514, 1245, 1125 cm^{-1}; TEOC−Protected **13c:** Yield 73%. ^{1}H NMR ($CDCl_3$) 5.11 (br s, NH, 1H), 4.94 (br s, 1H, NH), 4.10 (t, 2H, J = 7.4 Hz), 3.70−3.42 (m, 12H), 3.31−3.09 (m, 6H), 1.81−1.65 (m, 5H), 1.63−1.48 (m, 5H), 1.37 (s, 6H), 0.93 (t, 2H, J = 8.5 Hz), 0.29 (s, 9H). MS 548.5 (M+1), 570.7 (M+Na^+). IR 3337, 2948, 2852, 2084, 1691, 1528, 1249, 1134, 834 cm^{-1}.

Reduction of TEOC-azides 14a−c to TEOC-amines. The TEOC-protected azide **14a** (0.67 g, 1.3 mmols) was hydrogenated in ethyl acetate at a pressure of 1 atm of hydrogen gas in the presence of 10% Pd/C (0.150 g) for 12 h. The reaction mixture was filtered over Celite and concentrated. The residue was purified over silica gel using 10% MeOH in DCM to give monoprotected amines **15a** as an oil. Yield 0.122 g (19%). ^{1}H NMR ($CDCl_3$) 5.32 (br s, 1H, NH), 5.23 (br s, 1H, NH), 4.09 (t, 2H), 3.49−3.66 (m, 14H), 3.17−3.23 (m, 6H), 3.02 (br s, 2H), 2.95 (distorted t, 2H), 1.94−1.96 (distorted t, 2H), 1.73 (q, 4H), 1.42 (s, 6H), 0.93 (t, 2H, J = 8.2 Hz), 0.32 (s, 9H). TEOC protected **14b**: Yield 34%. ^{1}H NMR ($CDCl_3$) 5.24 (br s, 1H, NH), 5.00 (br s, 1H, NH), 4.09 (t, 2H, 17.1, 8.1 Hz), 3.65−3.44 (m, 12H), 3.30−3.07 (m, 4H), 2.65 (t, 2H, 14.1, 7.0 Hz), 1.80−1.64 (m, 6H), 1.58−1.42 (m, 2H), 1.38 (s, 6H), 0.93 (t, 2H, J = 8.1 Hz), 0.32 (s, 9H). MS 508 (M+1), 530 (M+Na^+). IR 3338, 2946, 2858, 1692, 1526, 1397, 1242, 1113, 1041, 855 cm^{-1}. TEOC protected **14c**: Yield 41%. ^{1}H NMR ($CDCl_3$) 5.17 (br s, 1H, NH), 4.96 (br s, 1H, NH), 4.10 (t, 2H, J = 14.3, 7.1 Hz), 3.64−3.45 (m, 12H), 3.31−3.04 (m, 4H), 2.66 (t, 2H, J = 7.0 Hz), 1.81−1.64 (m, 6H), 1.63−1.50 (m, 4H), 1.37 (s, 6H), 0.92 (t, 2H, J = 9.0 Hz), 0.29 (s, 9H)

Coupling of the TEOC-amines with Biotin To Give Compounds 15a−c. The amine obtained by reduction of the azide **14a** (1.0 g, 2.0 mmol) was dissolved in dry DMF (15 mL) under nitrogen at room temperature. Triethylamine (0.41 mL, 3.0 mmol) was added and the mixture was stirred for 5 min. Then, a solution of biotin succinimide (0.760 g, 2.23 mmol) in dry DMF (3 mL) was slowly added via cannula at room temperature and the resulting mixture was left stirred overnight. The DMF was removed by rotary evaporation at reduced pressure and the residue thus obtained was purified by column chromatography. Yield 0.63 g (43%). ^{1}H NMR ($CDCl_3$) 6.30 (br s, 1H, NH), 6.27 (br s, 1H, NH), 5.52 (br s, 1H, NH), 5.12−5.53 (m, 2H, 2NH), 4.47 (t, 2H, J = 7.0 Hz), 4.29 (t, 2H, J = 4.1 Hz), 4.09 (t, 2H, J = 7.9 Hz), 3.49−3.61 (m, 12H), 3.17−3.29 (m, 7H), 2.88 (dd, 1H, J = 12.5, 5 Hz), 2.71 (d, 1H, J = 12.5 Hz), 2.15 (t, 2H, 7.2 Hz), 1.97 (distorted t, 2H), 1.59−1.80 (m, 10H), 1.40 (s, 6H), 0.93 (t, 2H, 8.5 Hz), 0.30 (s, 9H). MS 720 ($M^+ + 1$), 742 (M + Na^+). The homologous biotinylated compounds **15b**,**c** were prepared in a similar manner. Compound **15b:** Yield 55%. ^{1}H NMR ($CDCl_3$) 6.05 (br s, NH), 5.66 (br s, NH), 5.20 (br s, 2H, 2NH), 5.03 (br s, NH), 4.53−4.46 (m, 1H), 4.34−4.26 (m, 1H), 4.14−4.03 (m, 2H), 3.65−3.45 (m, 12H), 3.29−3.06 (m, 7H), 2.89 (dd, 1H, J = 12.8, 5.0 Hz), 2.72 (s, 1H), 2.68 (2, 1H), 2.22−2.11 (m, 2H), 1.81 −1.55 (m, 14H), 1.36 (s, 6H), 0.93 (t, 2H, J = 17.1, 8.64 Hz), 0.29 (s, 9H). MS 735 (M + 1), 757 (M + Na^+). Compound **15c:** Yield 43%. ^{1}H NMR ($CDCl_3$) 6.50 (br s, NH, 1H), 6.32 (br s, NH, 1H), 5.79 (br s, NH, 2H), 5.21 (br, NH, 1H), 4.53−4.43 (m, 1H), 4.33−4.22 (m, 1H), 4.09 (t, 2H, J = 8.31, 17.16 Hz), 3.66−3.45 (m, 12H), 3.32−3.03 (m, 7H), 2.87 (dd, 1H, 5.69, 7.32 Hz), 2.70 (m, 1H), 2.16 (t, 2H, 7.92 Hz), 1.83−1.54 (m, 10H), 1.52−1.22 (m, 6H), 1.08−0.84 (m, 2H), 0.31 (s, 9H). Synthesis of ICAT Reagents 1b−d from the Amines 15a−c. The TEOC-protected biotinylated compound **15a** (112 mg, 0.16 mmol) was dissolved in dry DMSO (2 mL). After adding a solution of tetrabutylammonium fluoride (1 M in THF, 0.186 mmol, 186 μL) under nitrogen, the mixture was heated at 45 °C for 16 h. The volatiles were evaporated under high vacuum to leave a deprotected amine as a gummy residue. To a solution of the crude amine in DMF (2 mL) was added solid iodoacetic anhydride **5** (0.92 g, 2.61 mmol) and diisopropylethylamine (0.77 mL, 4.35 mmol). The resulting mixture was stirred 3 h. Solvent was removed under reduced pressure, and the product was purified to homogeneity by HPLC on a RP Vydac column (2.2 cm × 25 cm, 18 μm) using a gradient of 10% acetonitrile/water to 100% acetonitrile in 60 min, R_f 8 mL/min; R_t 23 min. The ICAT **1b** was obtained as a colorless oil. ^{1}H NMR (DMSO-

MS 744.8 (M + 1), 766.8 (M + Na^+). The acid-labile ICAT reagents **1c**,**d** were obtained in a similar fashion from appropriate amines **15b**,**c.** Spectral data for **1c:** ^{1}H NMR (DMSO-d_6) 8.21 (br t, 1H, NH), 7.76 (br t, NH), 6.75 (br s, NH), 6.41 (s, NH), 6.35 (br t, 1H, NH), 4.31 (m, 1H), 4.12 (m, 1H), 3.52−3.42 (m, 12H), 3.18−2.90 (m, 9H), 2.80 (dd, 1H, J = 12.5, 6.0 Hz), 2.55 (d, 1H, J = 12.5 Hz), 2.05 (t, 2H, J = 7.2 Hz), 1.68−1.5 (m, 12H), 1.31 (s, 6H). MS 758.8 (M + 1), 770.8 (M + Na^+). Spectral data for **1d:** ^{1}H NMR (DMSO-d_6) 8.22 (br t, 1H, NH), 7.79 (br t, NH), 6.75 (br s, NH), 6.42 (s, NH), 6.36 (br t, 1H, NH), 4.31 (m, 1H), 4.15 (m, 1H), 3.60−3.45 (m, 12H), 3.20−2.90 (m, 9H), 2.83 (dd, 1H, J = 12.5, 6.0 Hz), 2.58 (d, 1H, J = 12.5 Hz), 2.05 (t, 2H, J = 7.2 Hz), 1.63−1.46 (m, 14H), 1.33 (s, 6H). MS 772.8 (M + 1), 794.8 (M + Na^+).

RESULTS AND DISCUSSION

Unfortunately, the three-component ICAT system has some serious disadvantages. The biotin moiety, while crucial for tagged peptide enrichment and simplification, has been found to complicate the MS/MS analysis through undesired fragmentation paths. These superfluous fragmentations patterns yield significantly low sequence coverage of peptides resulting in unsatisfactory protein profiles of relatively complex biological milieu. It is therefore desirable that the biotin moiety is removed after the enrichment step and before the online chromatographic and MS/MS analysis routine. Recently, an acid-cleavable version has been made commercially available that has been used to analyze peptides without biotin (*15*, *18*−*23*). However, its detailed molecular structure has not been disclosed. We now report herein a series of novel four-component ICAT reagents that possess an acid-labile carbamate moiety inserted between the linker and biotin moieties (Figure 1, **1b**−**d**). This structural modification allows removal of biotin before MS and MS/MS analysis and is expected to significantly facilitate the sequence coverage of complex peptide mixtures. Higher sequence coverage of peptides is crucial to any extensive protein expression profiling protocol.

A general scheme for profiling protein concentration changes in two biological systems or cell states under study is given in Figure 2. Briefly, the proteins from the two cell or tissue states are separately extracted after homogenization. The extracts are reduced with a thiophilic reagent to convert disulfide bonds to thiols. One extract is labeled with the light form of the ICAT (ICAT-*L*), while the other is labeled with the heavy isotope form (ICAT-H) in otherwise identical conditions. The two extracts are then mixed together, and the mixture is proteolyzed with trypsin or some other proteolytic enzyme. The resulting peptide

hydrolyzate is enriched on an avidin column to concentrate only cysteine-modified ICAT-labeled peptides, which are then lyophilized, redissloved in buffers, and exposed to TFA-catalyzed acidolytic cleavage to remove the biotin moiety. The debiotinylated peptides are finally separated online by ion-exchange and RP-HPLC and analyzed on an ESI-based mass spectrometer.

The retrosynthetic analysis for the synthesis of the novel four-component, acid-labile ICAT reagents (Figure 1, **1b**−**d**) is presented in Figure 3. The diamine **4** required an orthogonal protection so that one end could be iodoacetylated while the other could be manipulated to introduce the acid cleavable and biotin moieties. The acid cleavable moiety, while requiring an electrophilic locus, also necessitated the presence of a terminally protected primary amino group for the attachment of the biotin. To this end, we envisaged synthesizing fragments **8a**−**c** (n = 1−3), which have an azido function as a protected form of an amino group, as well as a reactive electrophilic terminal for installation of an acid labile insert. This fragment is accessible through the commercially available acid chlorocarbonate **9** and azido alcohols **10** which, in turn, can be readily prepared from bromoesters **11**. The object of having two to four methylene groups between the amide nitrogen and a tertiary carbon atom was to assess limits of stability of the final ICAT molecules as well as flexibility of their solubility profiles in buffered solvents used during the ICAT-mediated analysis of protein mixtures.

In the synthetic direction (Schemes 1 and 2), the required carbonate fragments **8a**−**c** for coupling to the known diamine **4** were synthesized as outlined in Scheme 1. The bromoesters **11** containing two to four methylene group spacers were prepared by Fischer esterification of the corresponding carboxylic acids and were treated with methyl Grignard to yield tertiary alcohols. The azide displacement of the bromine in DMF yielded azido alcohols **10**. Several leaving groups of variants of chloroformate **9** were examined, such as, phenyl chloroformate (*24*), 2,2,2-trichloroethyl chloroformate (*25*), and 4-nitrophenyl chloroformate (*26*). These reagents have been reported for acylation of tertiary alcohols to give carbonates that could be carbamoylated with common amino acids. All of these reagents worked well for carbonate formation with the azides **10** to give analogues of **8a**−**c**. However, none of these carbonates gave acceptable yields of coupled products **13** (Scheme 2) when selective monocarbamoylation of the diamine **4** was attempted. Success was finally realized when the commercially available 1-chloroethyl chloroformate (*27*) was reacted with the tertiary azido alcohols **10** to give 1-chloroethyl carbonates **8a**−**c** (Scheme 2) that were then reacted with a slight excess of the diamine **4** to give the carbamates **13a**−**c**.

The synthesis of the diamine component **4** was completed following a literature procedure (Scheme 2) (*28*, *29*). Thus, two molar equivalents of diethylene glycol **7** were added in a 1,4-addtion reaction to acrylonitrile. The biscyanide thus obtained was reduced directly to the diamine **4**, which was then acylated with the carbonate reagents **8a**−**c** to give monocarbamoylated products **13a**−**c**. This fragment provides a locus for the acid-cleavable site in the middle of the molecule as well as a scaffold for holding the terminal biotin and iodoacetamide moieties. While the right-hand azido terminus of **13a**−**c** served as masked primary amino group, the left-hand was protected as a trimeth-

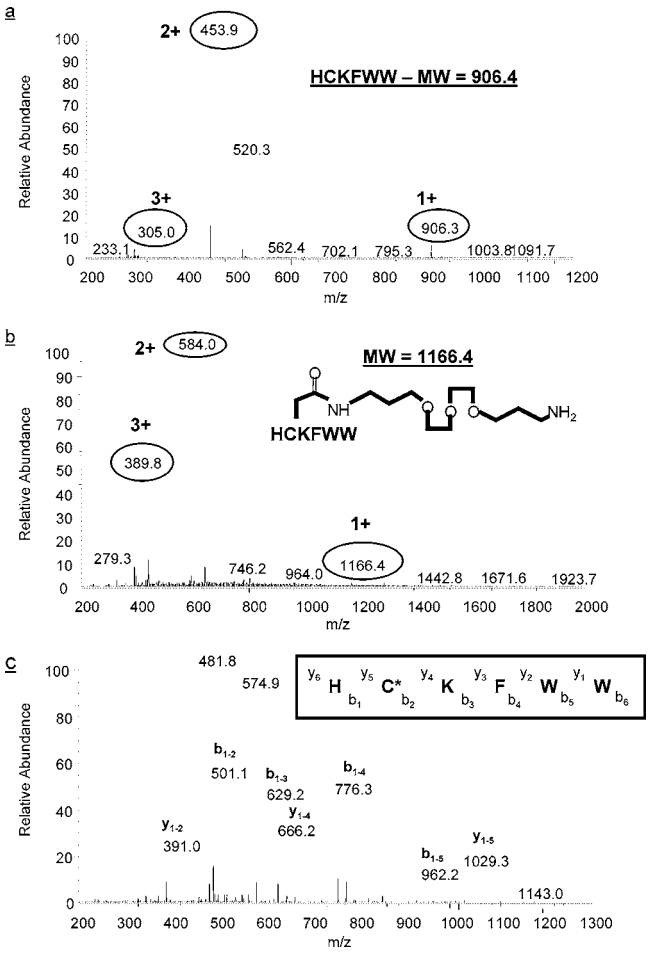

Figure 4. Peptide HCKFWW ICAT labeled after acidic cleavage.

ylsilylethoxycarbonyl (TEOC) group. This differential protection allowed reduction of the azide (10% Pd−C/H_2) function to a free amine that was readily linked to the biotin moiety under standard conditions for amide formation (biotin succinimide ester/DMF) to give compounds **15a**−**c**. The removal of the TEOC group required heating **15a**−**c** in dimethylsulfoxide at 40 °C. The crude **15a**−**c** obtained were immediately acylated with iodoacetic anhydride in DMF. The final ICAT reagents were purified by HPLC.

Since synthesis of a d_8- and C_6-labeled diamine **4** has been reported in the literature, the d_8- and C_6-labeled versions of the ICAT reagents **1b**−**d** (Figure 3) can be easily synthesized. However, before embarking on their preparation, it was deemed prudent to establish the utility of the "light" reagents in preliminary experiments.

To assess the utility of these unlabeled ICAT reagents, some commercially available cysteine-containing peptides were labeled with "light" ICAT molecules under standard buffer conditions and acidolyzed before infusion into the Finnigan Deca XP-Plus (ESI probe) for MS and tandem MS analysis. These tagged peptides gave satisfactory parent masses, as well as MS/MS peak patterns. A peptide HCKFWW was used as a model to measure the conjugation efficiency of the synthesized ICAT reagent. Figure 4a shows mass spectrometric analysis of the unmodified peptide used in one of these experiments. A distinct peak at 906.3 *m*/*z* was detected in the full mass spectrum. This peak corresponds to the monoisotopic mass of the unmodified peptide (906.4). The most abundant peak in the mass spectrum (453.9 *m*/*z*), however, corresponded to the doubly charged unmodified peptide. The double charge is due to the presence of a positively charged lysine in the peptide in addition to the peptide's amino terminus. A mass shift was detected after conjugation of the ICAT reagent to the peptide and acid treatment (Figure 4b). The mass spectrum of the modified peptide showed a peak at 1166.4. This peak corresponds to the monoisotopic mass of the peptide plus the acid-cleaved ICAT fragment (906.4 + 260 = 1166.4). As expected, the doubly charged ion was the most abundant in the mass spectrum (584.0 *m*/*z*). To confirm that the ICAT reagent was conjugated to a cysteine residue in the peptide sequence, the most abundant ion was subjected to collision-induced dissociation (CID). The b and y ions corresponding to the sequence of the modified peptides were detected in the MS/MS spectrum (Figure 4c). Importantly, the detection of the b1−2 and y1−5 product ions demonstrated that the acid-cleaved ICAT fragment was conjugated to the cysteine residue (Figure 4c). Therefore, these results demonstrated that the synthesized ICAT reagent can be conjugated to a thiol group of cysteine residues in the context of a peptide sequence as well as cleaved efficiently under acidic (TFA) conditions. Furthermore, the peak pattern of the MS/MS spectra did not indicate any significant undesired fragmentation that could possibly originate from the polyether linker.

The heavy isotope labeled analogues, such as d_8- or C_6, can be readily synthesized using commercially available acrylonitrile-d_3/diethylene glycol-d_2 for acid-cleavable ICAT-d_8, or acrylonitrile-$^{13}C_3$ for ICAT-$^{13}C_6$ synthesis employing protocols detailed in this report. These reagents will then be evaluated for their intended use in more complex proteomic analyses.

In summary, a practical synthesis of novel light isotope versions of acid-cleavable isotope-coded-affinity tags (ICAT-L) has been accomplished in overall reasonable yield. These ICAT reagents should avoid complications of MS/MS analysis of tagged peptide fragments introduced by the biotin moiety because the biotin, after isolation of tagged peptides, can be cleanly cleaved off by acid hydrolysis. Additionally, these light reagents can be readily converted to acid-cleavable PhIAT reagents in one step by reacting them with undeuterated and deuterated ethanedithiol. Some noncleavable PhIAT reagents for analysis of serine- and threonine-specific phosphoproteins have been reported (*30*). Studies are ongoing regarding the preparation of PhIAT and synthesis of heavy acid-cleavable ICAT versions (ICAT-H) leading to application of these reagents to more complex analyses of protein mixtures.

Fluorescence Probe with a pH-Sensitive Trigger

Amit K. Galande, Ralph Weissleder, and Ching-Hsuan Tung*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Charlestown, Massachusetts 02129. Received November 17, 2005; Revised Manuscript Received February 7, 2006

Acid-catalyzed hydrolysis was used as the mechanism to design a new type of environmentally sensitive fluorescence probe. A mild and selective periodate oxidation of the 2-amino alcohol of serine in the presence of a disulfide bond was developed to prepare dialdehyde peptides. Two identical fluorochrome hydrazide derivatives were then linked to the dialdehyde peptide forming an acid-labile hydrazone linkage. This self-quenched probe is weakly fluorescent at a physiological pH of 7.4 but shows more than 3-fold fluorescence enhancement at pH 4.5.

Molecular probes for imaging applications are often designed using fluorescence resonance energy transfer (FRET)-related mechanisms to reduce background (*1*). FRET-based probes typically incorporate a pair of two different dye molecules, a fluorescent donor, and a fluorescent acceptor or a fluorochrome and a nonfluorescent quencher. Recently, self-quenched fluorescent probes consisting of multiple copies of the same fluorescent dye molecule have also been developed for molecular imaging (*2*, *3*). Biological processes such as conformational changes of protein, receptor binding of ligands, and catalytic function of proteases have been exploited as molecular targets for various fluorescence emission probes (*4*−*8*). In addition, activity-based probes have also been developed for different enzyme classes (*9*, *10*). In this report, a new approach involving acid-catalyzed hydrolysis as the mechanism of fluorescence activation is demonstrated.

CY5G2, an aminopeptidase N (APN)-targeted fluorescence probe (Scheme 1), was constructed using an acid-sensitive hydrazone linkage. CY5G2 has been designed in such a way that it stays weakly fluorescent at the extracellular pH of 7.4 and becomes strongly fluorescent at the intracellular lysosomal pH of 4.5. CY5G2 incorporates a disulfide-constrained NGR (Asn-Gly-Arg) motif, which is a ligand for the APN receptor and is likely to facilitate entry of the probe into endosome and then into acidic lysosome (*8*, *11*, *12*). Here we report design and synthesis of CY5G2 along with its evaluation under physiologically relevant pH environments.

The probe was constructed on a flexible polyglycine backbone. The N-terminus of the peptide was extended to incorporate the disulfide-bridged NGR motif, while toward the C-terminus two molecules of Cy5 were conjugated via an acid-sensitive hydrazone linkage. Cy5 dyes were chosen because of their far-red fluorescence emission (670 nm). Fluorescence in the far-red to near-infrared region (650−900 nm) has been found to be most suitable for in vivo optical imaging (*13*). The two Cy5 dyes on CY5G2 are separated from the disulfide-constrained NGR motif by two glycine residues. Another short spacer (<10 Å) of two glycine residues separates the two Cy5 molecules from each other. Considering the close proximity of the dye molecules to each other and the narrow Stoke's shift of Cy5 (18 nm), the dyes are likely to be self-quenched due to a combination of static quenching and FRET mechanisms (*14*).

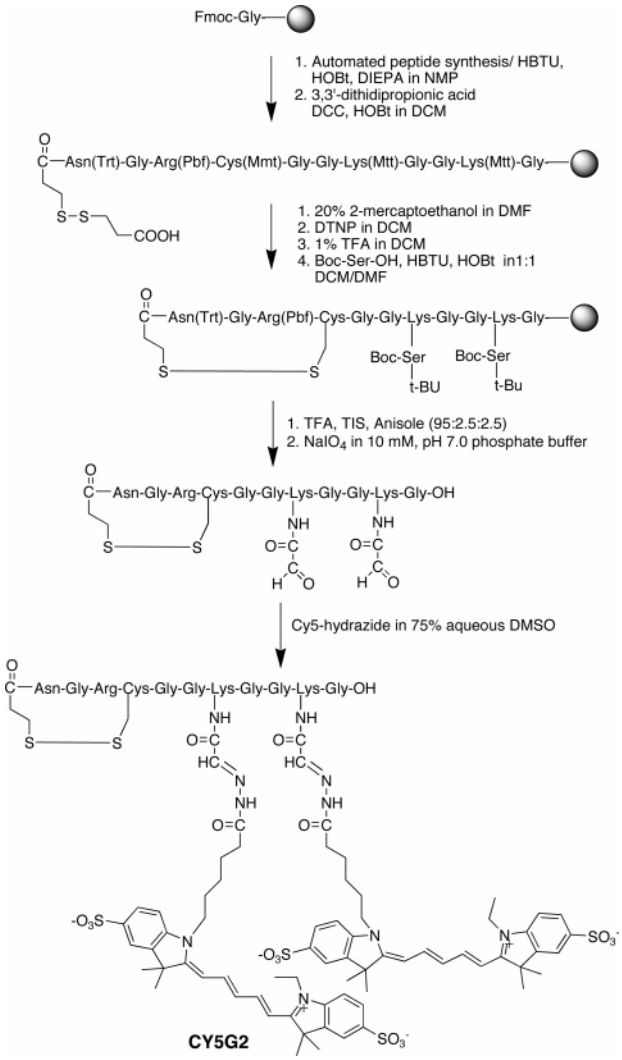
Scheme 1. Synthesis of CY5G2



The fluorescence quenching of CY5G2 is possible only when the hydrazone linkages are intact. In an acidic environment, however, hydrolysis of the hydrazone linkages would release the fluorochromes from the peptide backbone. This would eliminate distance-dependent quenching of the fluorochromes and show enhancement in the Cy5 fluorescence emission.

CY5G2 was synthesized by a combination of solid-phase and solution-phase reactions. The synthesis was started with Fmoc-Gly-Wang resin (0.66 mmol/g), on which the peptide chain was extended using an automated peptide synthesizer as shown in Scheme 1. To the N-terminus of the peptide, 3,3′-dithiodipropionic acid was manually incorporated using *N*,*N*′-dicyclohexycarbodiimide/1-hydroxybenzotriazole (DCC/HOBt) as coupling agents. This was followed by the construction of an intramolecular disulfide bridge on the solid support utilizing 2,2′-dithiobis(5-nitropyridine) (DTNP) as previously developed (*15*, *16*). Treatment of the resin with 1% trifluoroacetic acid (TFA) also selectively deprotected the methyltrityl (Mtt) groups of the lysine residues. Thereafter, side chain amines of these lysine residues were neutralized by washing the resin twice with 5% *N*,*N*′-diisopropylethylamine (DIPEA) in *N*,*N*′-dimethylformamide (DMF), and then Boc-Ser(t-But)-OH was coupled. The peptide was cleaved from the solid support under strong acidic conditions (Scheme 1). Then the crude peptide was purified using reversed phase-high-pressure liquid chromatography (RP-HPLC) and lyophilized to obtain the diserine peptide as white powder. The overall yield (by weight) of the purified diserine peptide based on the initial resin substitution was 50% (see Supporting Information for the product characterization).

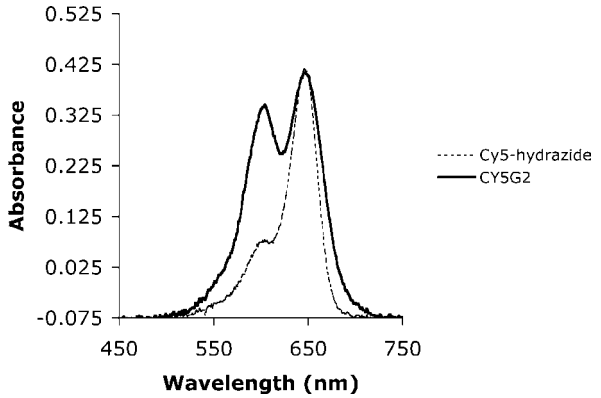


Figure 1. Absorption spectra of CY5G2 and Cy5-hydrazide.

Purified diserine peptide was converted into the dialdehyde peptide under mild oxidizing conditions of sodium periodate ($NaIO_4$) (Scheme 1). Transformation of an N-terminal seryl peptide into an N-terminal glyoxylyl peptide by periodate oxidation is a well-known reaction (*17*). Periodate oxidation of 2-amino alcohols, such as N-terminal serine, is reported to be about 1000-fold faster as compared to the oxidation of 1,2-diols under similar conditions (*17*). Hence instead of incorporating serine into the peptide chain, serine residues were conjugated to the side chain of the lysine residues, thus making the 2-amino alcohol moiety of serine available for the oxidation reaction. However, even under mild reaction conditions, $NaIO_4$ is known to oxidize residues such as the side chain thiol of cysteine and the thioether of the methionine side chain (*17*). A few disulfide proteins containing N-terminal serine have been treated with periodate (*18*), but no systematic efforts have been carried out to explore the selectivity of periodate treatment in the presence of a disulfide bond, in which the sulfur atoms are likely to get oxidized to sulfoxides. A variety of reaction conditions were attempted by changing reaction time and the amount of $NaIO_4$, and a protocol was established to selectively oxidize the 2-amino alcohol of serine in the presence of a disulfide bond. Longer reaction times or higher than 2.5 equiv of $NaIO_4$ showed oxidation of either one or both sulfur atoms of a disulfide as indicated by matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF-MS) analysis.

Hydrazide-functionalized dye (Cy5-hydrazide) was conjugated to the purified dialdehyde peptide to obtain CY5G2. Peptide aldehydes are susceptible to the nucleophilic attack from the primary amine of the peptide N-terminus yielding undesired intermolecular imine linkages. By substituting N-terminal cysteine with mercaptopropionic acid in the construction of the disulfide bridge, we eliminated such possible side reactions. Following the conjugation of Cy5-hydrazide, CY5G2 was purified on the RP-HPLC to remove excess Cy5-hydrazide. Following lyophilization, CY5G2 was obtained as a blue powder in 35% yield (see Supporting Information for the product characterization).

Absorption spectrum of CY5G2 was compared with that of free Cy5-hydrazide dye (Figure 1). Concentrations of Cy5-hydrazide and CY5G2 were adjusted to 0.4 optical density (OD) based on the absorption peak at 647 nm (Figure 1). CY5G2 showed an additional peak that is blue-shifted by about 40 nm. This peak indicates aggregation of the two Cy5 molecules attached to the peptide backbone to form an H-type dimeric complex. H-type aggregates tend to quench the fluorescence of cyanine dyes because of static quenching (*19*). Hence, CY5G2 is likely to have weak fluorescence emission from the dyes. Fluorescence measurements revealed about 75% quenching of

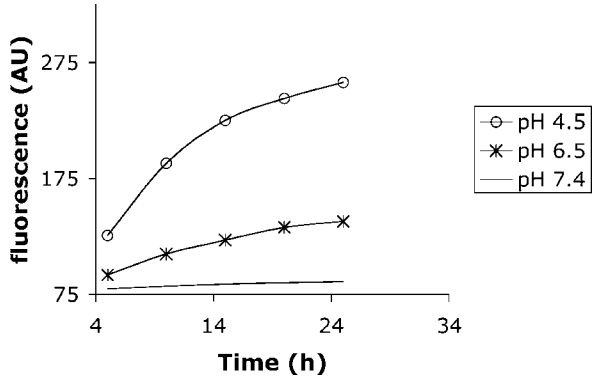

Figure 2. pH-Dependent fluorescence activation profile of CY5G2.

the fluorescence emission of CY5G2 as compared to that of Cy5-hydrazide of an equimolar (1.6 μM) concentration.

Next, fluorescence measurements were carried out to examine if the fluorescence emission of CY5G2 could be enhanced under acidic environment following hydrolytic cleavage of the hydrazone linkages. Accordingly, CY5G2 was incubated with buffer solutions of pH 4.5 (lysosomal compartment), pH 6.5 (tumor interstitial environment), and pH 7.4 (extracellular environment) at 37 °C. Figure 2 shows kinetic profiles of fluorescence activation of CY5G2 at different pH values. The fluorescence emission essentially remains unchanged at pH 7.4. Under mildly acidic conditions (pH 6.5), CY5G2 showed a slight increase in fluorescence emission, and under lysosomal acidic environment (pH 4.5) CY5G2 showed a three-fold increase in fluorescence after 24 h. Absorption spectra of CY5G2 recorded following 24 h incubation under pH 4.5 showed more than 80% elimination of the blue-shifted aggregation peak, indicating hydrolysis of hydrazone linkages and subsequent release of the fluorochromes from the peptide backbone.

Previously, we reported several examples of protease-sensitive NIR probes, which remain nonfluorescent or weakly fluorescent under normal physiological conditions and fluoresce brightly when cleaved by certain proteases overexpressed in the tumor environment (*20*). These enzyme-activatable fluorescent probes have been widely used for in vivo molecular imaging and involve cleavage of amide bonds of peptide substrates by the proteases to release fluorochromes. In this study, an environmentally sensitive probe was designed based on a completely different mechanism. CY5G2 demonstrates utility of the pH-sensitive hydrazone linkage for making activatable fluorescent probes. Because APN is overexpressed in tumor vasculature, CY5G2 has potential applications in monitoring tumor angiogenesis and probing the acidic environment of the tumor interstitium (*21*, *22*). It also provides a tool for in vivo imaging of pharmacokinetics of hydrazone-linked prodrugs (*23*−*25*).

Experimental Procedures

Automated peptide synthesis: Peptide synthesis was performed on an automated peptide synthesizer (ABI 433A, Applied Biosystems, Foster City, CA) employing the traditional Fmoc methodology using FastMoc 0.1 MonPrevPk protocol. Synthesis was started with Fmoc-Gly-wang resin (150 mg, ~0.1 mmol). All amino acids (10 equiv) were attached to the resin by stepwise elongation with HOBt (10 equiv), HBTU (10 equiv), and N,N-diisopropylethylethylamine (DIPEA, 20 equiv) as coupling reagents in the presence of N-methylpyrrolidone (NMP; 15 mL). The Fmoc protecting groups were removed by 20 % (v/v) of piperidine in NMP (15 mL).

Coupling of 3,3'-dithiodipropionic acid: 3,3'Dithiodipropionic acid (0.5 mmol) and HOBt (0.5 mmol) were dissolved in 4 mL 9:1 DCM/DMF. The solution was added to the resin (0.1 mmol, 0.66 mmol/g) and shaken for 10 min. To the resin suspension, solution of DCC in DCM (0.5 mmol in 0.1 mL) was added and the suspension was shaken for 3 h.

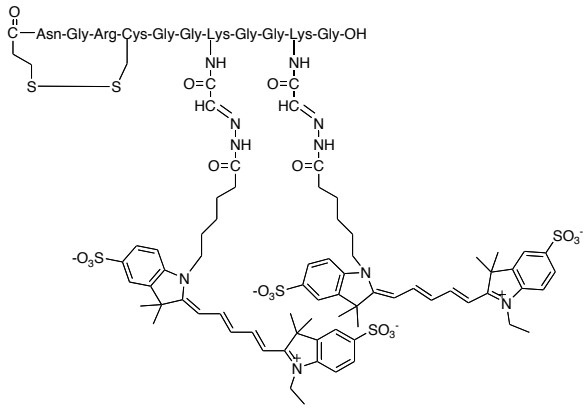
Coupling of Boc-Ser-OH: Boc-Ser-OH was purchased (EMD Biosciences, San Diego, CA) as its dicyclohexylamine (DCHA) salt. Free Boc-Ser-OH was generated by dissolving 1 mmol of Boc-Ser-OH.DCHA in 1.5 mL DCM and extracting this solution (3 × 3mL) with ice-cold aqueous solution (0.3 M) of $KHSO_4$. Following extraction and solvent evaporation, 1 mmol of Boc-Ser-OH, HBTU and HOBt were dissolved in 3 mL of 1:1 DMF/DCM followed by the addition of 2 mmol of DIPEA. The solution was then immediately added to the resin (0.1 mmol) without any preactivation to avoid possible racemization. Four hours later, the ninhydrin test confirmed quantitative coupling.

Periodate oxidation of the diserine peptide: Purified peptide (4.8 mg, 3.84 μmol) was dissolved in 75 μL of 10 mM phosphate buffer (pH 7.0). If required, pH of the solution was further adjusted using 0.1 N NaOH. To this, 120 μL of 140 mM $NaIO_4$ solution (2.2 equivalents) in 10 mM phosphate buffer (pH 7.0) was added. The solution was sonicated for 10 sec and further incubated for 17 min. The reaction mixture was then injected into the preparative RP-HPLC column and the fraction corresponding to the aldehyde peptide was collected.

Coupling of oxidized peptide: The aldehyde Peptide (0.4-0.5 mg, ~ 0.37 μmol) was dissolved in 50 μL of 10 mM phosphate buffer solution of pH 7.0; and 0.7 mg of the Cy5-hydrazide (0.89 μmol, 1.2 equivalents, purchased from Amersham Biosciences NJ, USA) was dissolved in 100 μL of DMSO. The dye solution was mixed with the peptide solution and incubated for 16 h. The reaction mixture was then passed through RP-HPLC (buffer A: 0.004% TFA in water, buffer B: 0.004% TFA in acetonitrile, C18 analytical column, Vydac, 218TP54, flow rate 1 ml/min. 100% buffer A to 100% buffer B in 50 min) and the fraction corresponding to CY5G2 (retention time 23.56 min) was collected.

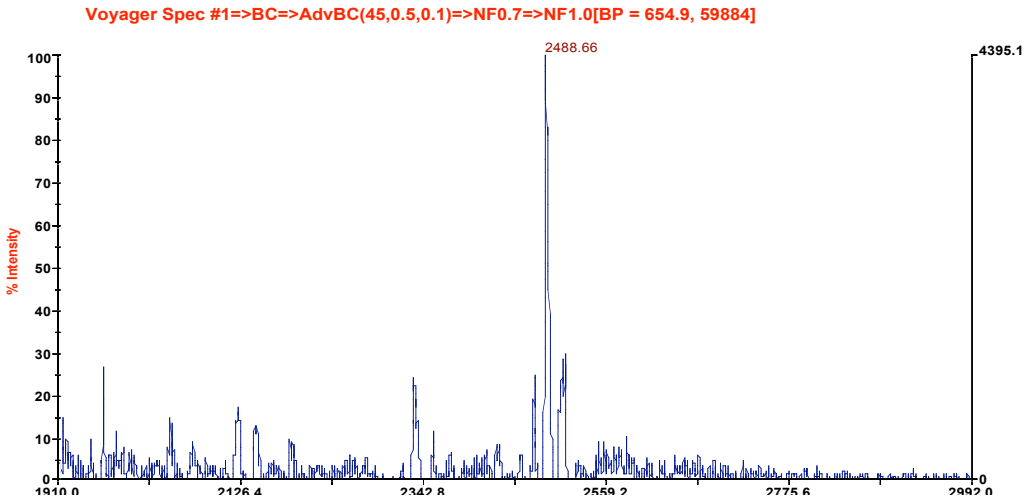
Fluorescence measurement: All the fluorescence measurements were performed in a 96-well assay plate 3603 (Corning Inc. NY USA). Fluorescence measurements were obtained in a fully modular monochromator-based microplate detection system (Safire^2, Tecan, San Jose, CA). Excitation and emission were set at 640 nm and 665 nm, respectively, with the bandwidth of 10 nm and the gain value of 40. Fluorescence emission was monitored at 37^0C.

Compound: CY5G2



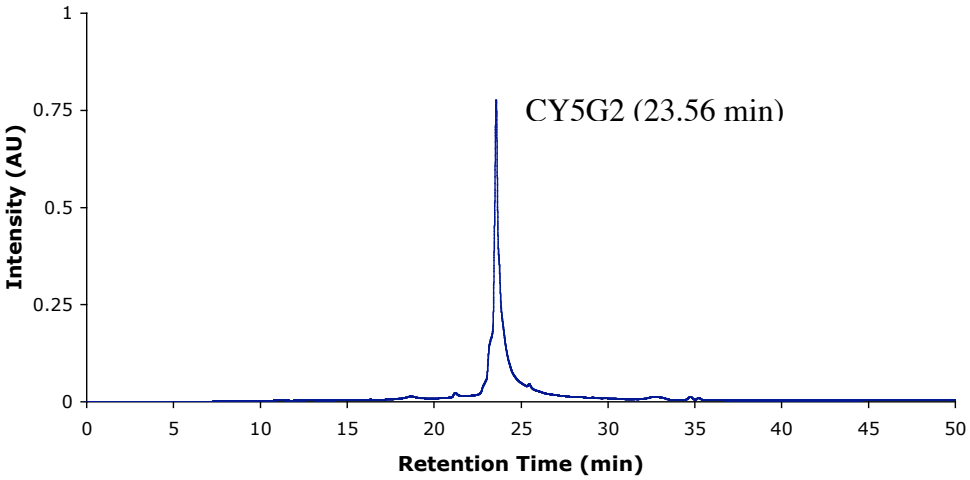
MALDI-TOF mass spectrogram:

MASS EXPECTED: 2488.91
MASS FOUND: 2488.66



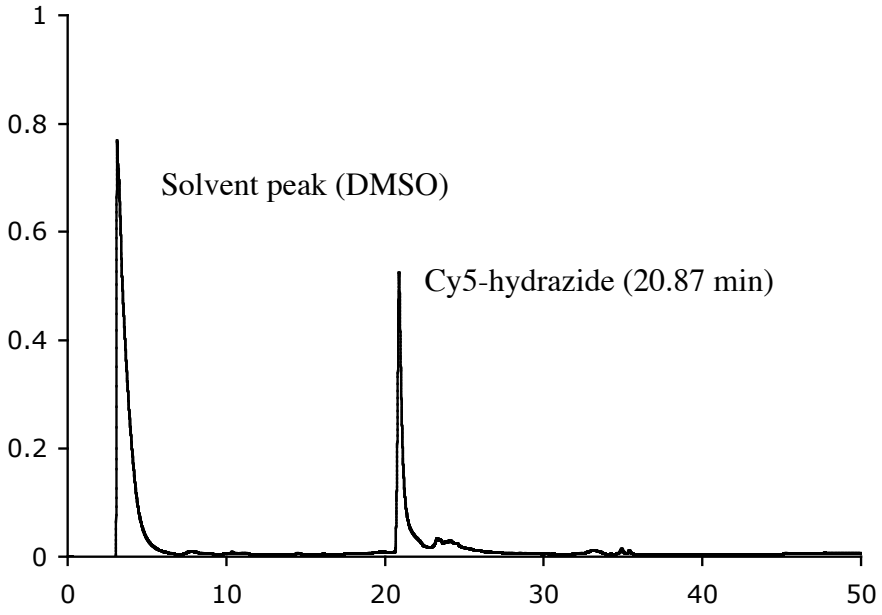
MALDI-TOF conditions: Instrument: Voyager-DE PRO (PerSeptive Biosystems), Instrument mode: Negative, VOLTAGES: Accelerating: 20000, Grid: 95, Guide Wire: 0.05, Delay Time: 100 nsec.
NOTE: Partial cleavage of the hydrazone linkage was observed under MALDI conditions (alpha-cyano-4-hydroxycinnamic acid as a matrix and 0.1% trifuoroacetic acid in 50% acetonitrile) homogeneity and purity of CY5G2 was confirmed using RP-HPLC (see below)

RP-HPLC Chromatogram

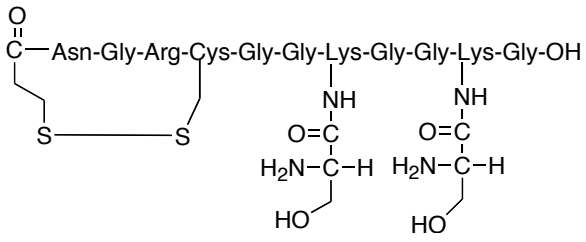


RP-HPLC conditions: Solvent A: 0.004% TFA in water, Solvent B: 0.004% TFA in acetonitrile, C18 analytical column,Vydac, 218TP54, flow rate 1 ml/min. 100% solvent A to 100% solvent B in 50 min.

Under the above-mentioned HPLC conditions, the hydrazide functionalized dye (Cy5-hydrazide) showed retention time of 20.87 min.

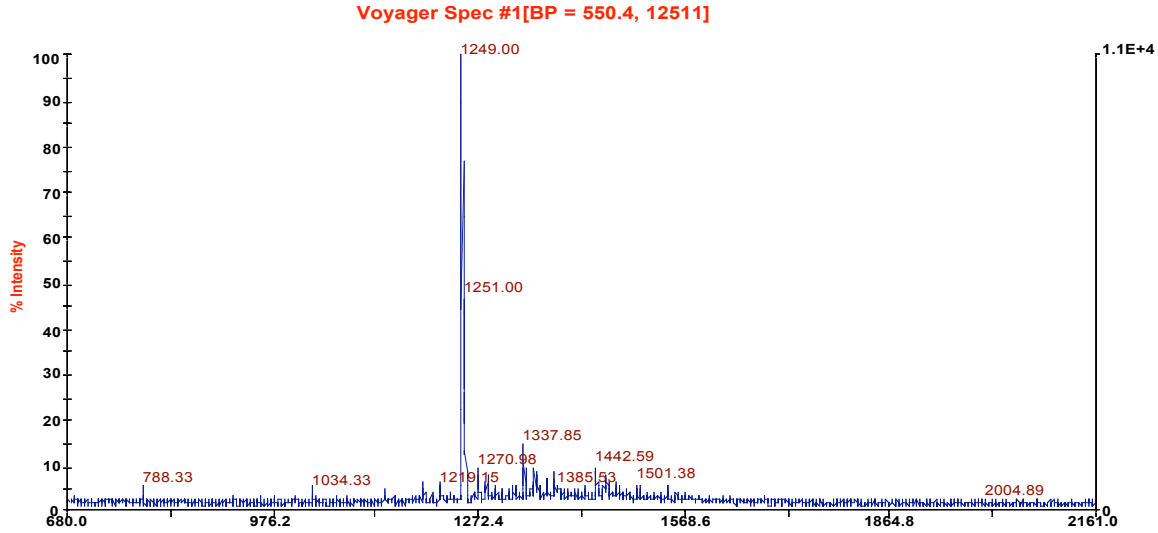


Compound: Diserine peptide

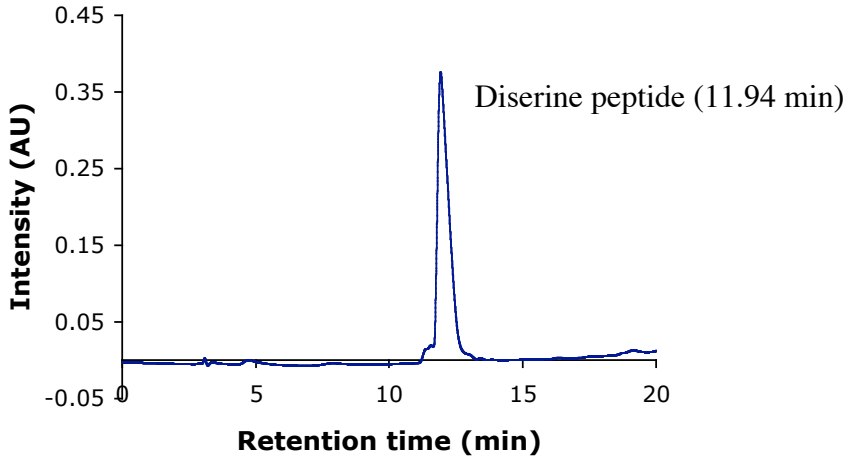


MALDI-TOF mass spectrogram

MASS EXPECTED: 1250.53
MASS FOUND: 1249.00



RP-HPLC Chromatogram



RP-HPLC conditions: Solvent A: 0.1% TFA in water, solvent B: 0.1% TFA in acetonitrile, C18 analytical column,Vydac, 218TP54, flow rate 1 ml/min. 100% solvent A to 100% solvent B in 50 min.

A General Approach for Antibody Purification Utilizing [Protein A-Catechol:Fe^{3+}] Macro-Complexes

Guy Patchornik[†,*] and Amnon Albeck[§]

Affisink Biotechnology Ltd, 11 Hamaccabee St. Kiryat-Ono 55572, Israel, and The Julius Spokojny Bioorganic Chemistry Laboratory, Department of Chemistry, Bar-Ilan University, Ramat-Gan 52900, Israel. Received December 23, 2005; Revised Manuscript Received January 27, 2006

A general platform for antibody purification utilizing free nonimmobilized Protein A modified with the strong metal chelator catechol (ProA-CAT) and Fe^{3+} ions is presented. The mechanism of purification requires formation and precipitation of macro-complexes composed of [ProA-CAT:IgG:Fe^{3+}]. Target IgGs are eluted directly from the precipitates (i.e. pellets) at pH 3 in high yields (71−80%) and high purity (>95%), without dissociating the [ProA-CAT:Fe^{3+}] insoluble macro-complex.

Highly purified antibody preparations represent a major scientific and industrial need. In a previous study (*1*) we presented a novel purification approach (affinity-sinking, AS[1]), utilizing free nonimmobilized desthiobiotinylated ligands (e.g., Protein A; Concanavalin A) and free avidin. The nonimmobilized state of the ligand circumvents the need for immobilizing ligands to polymeric supports; hence, polymers are excluded from the process and purification is accomplished without chromatographic columns. This study further demonstrates the implementation of AS on a novel, more challenging platform, the metal:chelator platform. Therefore, Protein A, a 42 kDa factor produced by several stains of *Staphylococcus aureus* which binds specifically to the Fc region of different classes of immunoglobulins (*2*), was covalently modified according to ref 3 with a synthesized active ester derivative of the strong metal chelator catechol, catechol-NHS (Figure 1; see synthesis in Supporting Information) (*4*). The modified Protein A (ProA-CAT) serves as the nonimmobilized ligand and is used for purification of rabbit and bovine IgGs from *E. coli* cell lysate.

The mechanism of purification according to AS requires three successive steps:

1. Incubation of the modified ligand (ProA-CAT) with the target IgG to initiate specific binding and formation of the [ProA-CAT:IgG] soluble complex (Figure 2A).

2. Precipitation of the [ProA-CAT:IgG] complex upon addition of Fe^{3+} ions which generate insoluble macro-complexes composed of [ProA-CAT:IgG:Fe^{3+}], whereas impurities are left in the supernatant and are discarded by centrifugation (Figure 2B).

3. Elution of the IgG from the [ProA-CAT:IgG:Fe^{3+}] insoluble macro-complex (i.e. pellet) under conditions which essentially do not dissociate the [ProA-CAT:Fe^{3+}] macro-complex, thus leading to a simple and fast recovery of the target IgG (Figure 2C).

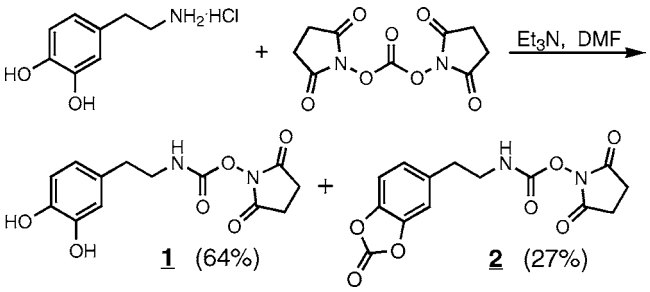


Figure 1. Synthesis of the catechol-NHS derivative **1** used to modify Protein A.

In a typical experiment, 0.46 mg/mL of ProA-CAT was added to *E. coli* cell lysate (first dialyzed to remove possible iron chelators) containing 0.5 mg/mL rabbit IgG, 10 mM NaPi, 400 mM NaCl at pH 7. After 3−5 min of incubation at 4 °C, 3 mM Fe^{3+} ions were added to initiate precipitation of the [ProA-CAT:IgG] soluble complex (Figure 2B). The short incubation time (3−5 min) reflects the advantage of binding in homogeneous solutions rather than heterogeneous solutions in affinity chromatography. To suppress nonspecific interactions between the generated macro-complexes and impurities possessing weak chelating amino acid residues (e.g., His, Cys), 200 mM imidazole was added as well. After a short spin at 14 000 rpm, the supernatant was analyzed and found to contain primarily impurities whereas ProA-CAT and the IgG were absent (Figure 3A, lane 7). The pellet (containing the complexed IgG) was then washed once with 100 μL of fresh buffer containing 20 mM NaPi pH 7, to remove traces of impurities.

Rabbit IgG was eluted from the washed pellet by resuspending it for 3−5 min at 4 °C in 0.4 M Gly and 0.3 M His at pH 3. After a short spin (20 s) at 14 000 rpm, the supernatant was removed, neutralized, and found to contain the target IgG. The average recovery yield was 80% with purity greater than 95% by densitometry (Figure 3A, lane 6). Similar results (yield: 71%; purity >95%) were obtained with bovine IgG, thus demonstrating the applicability of the approach to targets possessing lower affinity toward Protein A (data not shown).

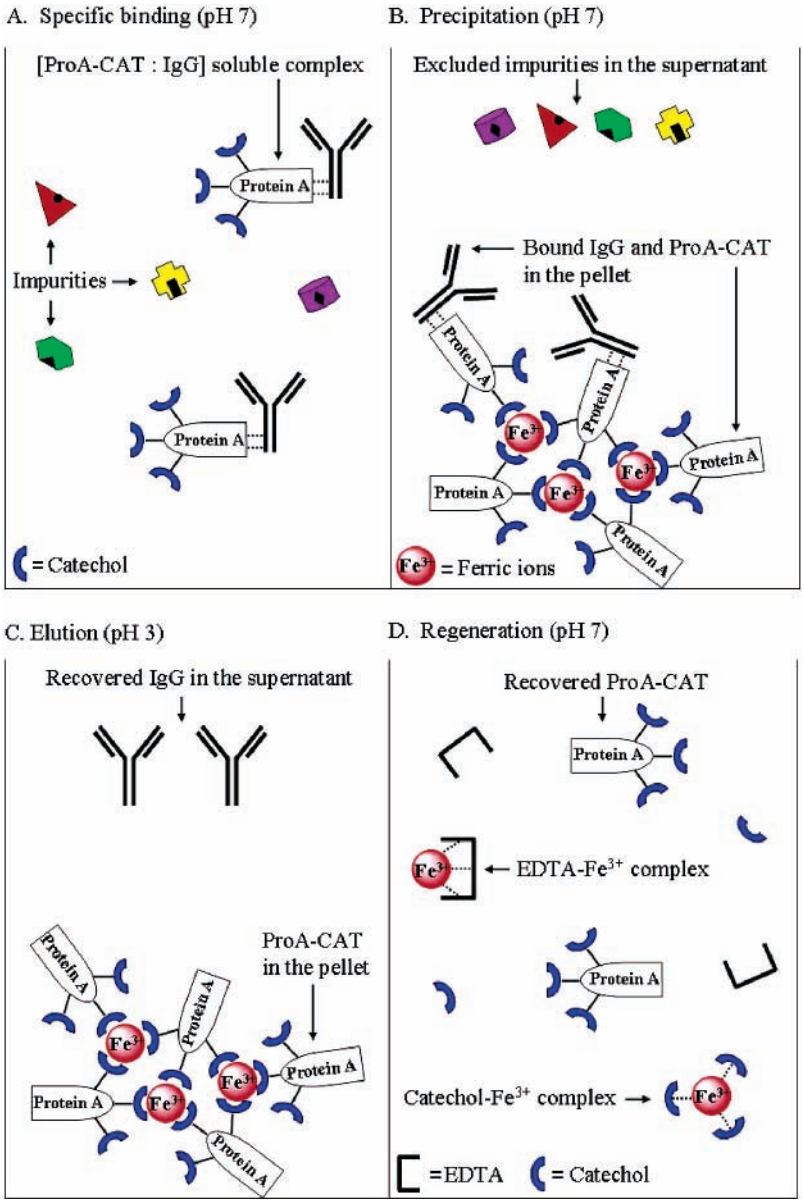

Figure 2. Illustration of antibody purification utilizing a modified Protein A (ProA-CAT) and Fe^{3+} ions. A. Specific binding of ProA-CAT to the target IgG leads to the formation of the [ProA-CAT:target IgG] soluble complex. B. Precipitation of the latter upon addition of Fe^{3+} ions, which generate insoluble macro-complexes containing the target IgG. Impurities, left in the supernatant are discarded by centrifugation. C. Target IgG is eluted under acidic conditions without dissociating the [ProA-CAT:Fe^{3+}] macro-complex, kept insoluble in the pellet. D. Regeneration of ProA-CAT in the presence of strong metal chelators which compete for the complexed Fe^{3+} ions thereby dissociating the macro-complex (i.e., pellet). The complexed Fe^{3+} ions and free chelators are excluded by dialysis while the free ProA-CAT can be reused.

Catechol was chosen as the preferred chelator since it (a) exhibits high affinity toward diverse transition metals (*5*, *6*), thus enabling utilization of a variety of transition metals, (b) requires three independent catechol moieties to chelate a single Fe^{3+} ion, thereby increasing the possibility of interconnecting adjacent [ProA-CAT:IgG] soluble complexes, and (c) was expected to retain its chelating ability even at acidic conditions (pH 3) due to the absence of basic atoms (e.g. nitrogen) required for complex formation. A nitrogen atom (if existed) would be protonated at low pH and presumably not be available for chelating Fe^{3+} ions.

ProA-CAT was regenerated without any chromatographic process at neutral pH in the presence of strong metal chelators such as EDTA and catechol. It was assumed that these chelators will compete with the ProA-CAT on the complexed Fe^{3+} ions, thereby leading to dissolution of the [ProA-CAT:Fe^{3+}] macro-complex (Figure 2D). Indeed, a short incubation (5 min) at 4 °C in the presence of 50 mM NaPi pH 7, 100 mM EDTA, 50 mM catechol, and 10% ethylene glycol led to quantitative dissolution of the pellet and regeneration of the ProA-CAT in 75−85% yield (data not shown). The recovery yield may increase in the presence of low concentration of a detergent such as SDS. Free and complexed chelators together with all other reagents could then be dialyzed, enabling the reuse of ProA-CAT.

Several independent results imply that Fe^{3+} ions function as the interconnecting entity: (a) Precipitation of the [ProA-CAT: IgG] complex was abolished in the presence of strong chelators (e.g., EDTA, catechol) as well as in the presence of a specific Fe^{3+} chelator: desferal (*7*, *8*). (b) Other transition metals (e.g., Cu^{2+}, Zn^{2+}, Mg^{2+}, Ni^{2+}) possessing lower affinity toward catechol (*5*, *6*) did not lead to substantial precipitation under identical precipitating conditions. (c) Regeneration of ProA-CAT at physiological pH was accomplished only in the presence of strong metal chelators.

Generally, greater volumes of buffer are required to remove

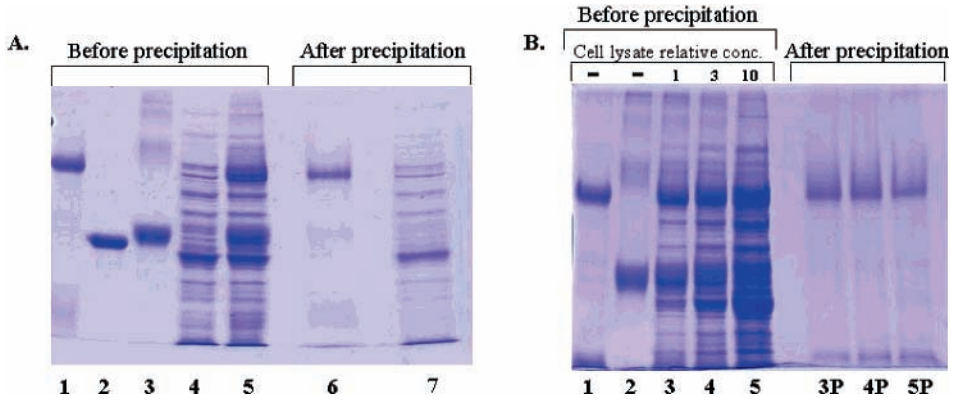

Figure 3. A. Purification of rabbit IgG from *E. coli* cell lysate utilizing ProA-CAT and Fe^{3+} ions. Lane 1 rabbit IgG; lane 2 native protein A; lane 3 ProA-CAT; lane 4 *E. coli* cell lysate; lane 5 rabbit IgG, ProA-CAT and *E. coli* cell lysate; lane 6 recovered rabbit IgG after elution at pH 3; lane 7 content of supernatant after addition of Fe^{3+} ions to the mixture shown in lane 5. B. The effect of increased background contamination on the purity of the recovered IgG. Lane 1 rabbit IgG; lane 2 ProA-CAT; lanes 3−5 constant concentration of rabbit IgG and ProA-CAT in the presence of increased *E. coli* cell lysate concentrations; lanes 3P−5P recovered IgG from pellets generated in lanes 3−5, respectively.

impurities that adsorb nonspecifically to polymeric matrixes in chromatographic columns as the contamination increases. Since no polymeric matrixes exist in AS, we postulated that an increase in the background contamination should not affect the purity of the recovered IgG. To demonstrate such a phenomenon, constant concentration of rabbit IgG and ProA-CAT were added into increasing concentrations of *E. coli* cell lysate (Figure 3B, lanes 3−5) and all generated pellets were washed only once with a minute volume (100 μL) of buffer regardless their contamination background. Though the recovery yield of the IgG decreased with increased contamination background (from ∼80% to ∼70−75%), the purity (>95%) was similar (Figure 3B, lanes 3P−5P), thus supporting our assumption and emphasizing the advantage of a purification approach lacking a polymeric component.

The following are points of emphasis: (a) Ligands other than Protein A may be utilized similarly (e.g. Protein G and L, lectins). (b) The simple (no HPLC) and fast purification process would be advantageous to targets that tend to aggregate or denature rapidly. (c) The purification process can be easily up scaled by the addition of higher concentrations of the modified ligand (being a reagent), whereas affinity columns are limited by the concentration of the immobilized ligand. Moreover, efficient capture of low abundance targets is expected due to the possibility of increasing the modified ligand concentration without significantly diluting the sample, thereby increasing the rate of complex formation (i.e. rate = k[free ligand][target]). (d) Targets are not diluted within the process (unlike column chromatography) and are eluted into small volumes of elution buffer, resulting in concentrated preparations which may be used for other applications such as crystallization. (e) The core macrocomplex [ProA-CAT:IgG:Fe^{3+}] can be further utilized for isolation of targets other than antibodies. For example, positive (or negative) cell selection can be performed by incubating a cell suspension with a mAb targeted at a specific epitope on the target cell, followed by the addition of ProA-CAT and Fe^{3+} ions. Immunoprecipitation and virus depletion can be performed accordingly.

In conclusion, the metal:chelator platform, together with the previously described desthiobiotin:avidin platform (*1*), represents two distinct practical alternatives with characteristic advantages to known purification methodologies utilizing immobilized ligands.

Synthesis of catechol-NHS

[2-(3,4-Dihydroxy-phenyl)-ethyl]-carbamic acid 2,5-dioxo-pyrrolidin-1-yl ester (catechol-NHS; **1**) was prepared according to the procedure of Wilchek and coworkers (*1*). A solution of dopamine hydrochloride (190 mg, 1 mmol) in DMF (2 mL) was added dropwise over 30 min to a solution of disuccinimidyl carbonate (512 mg, 2 mmol) in DMF (15 mL), followed by slow addition of triethylamine (277 μL, 2 mmol) while stirring. After 60 min, the solvent was partially evaporated (to 5 mL), 1N HCl (30 mL) was added, and the solution was extracted with EtOAc (30 mL). Evaporation of the organic phase to dryness and crystallization from EtOAc afforded a crystalline carbonated side product, [2-(2-Oxo-benzo[1,3]dioxol-5-yl)-ethyl]-carbamic acid 2,5-dioxo-pyrrolidin-1-yl ester (**2**) (27% yield) and the clean product **1** (64% yield) in the solution.

Received October 11, 2005; Revised Manuscript Received January 3, 2006

Small-molecule inhibitors of DNA methyltransferases such as RG108 represent promising candidates for cancer drug development. We report the synthesis and in vitro analysis of a biotinylated RG108 conjugate, 2-(1,3-dioxo-1,3-dihydro-isoindol-2-yl)-3-(5-{3-[5-(2-oxo-hexahydro-thieno[3,4-*d*]imidazol-4-yl)pentanoylamino]-propoxy}-1*H*-indol-3-yl)propionic acid (bio-RG108), for the evaluation of interactions with DNA methyltransferase enzymes. The structural design of the chemically modified inhibitor was aided by molecular modeling, which suggested the possibility for extensive chemical modifications at the 5-position of the tryptophan moiety in RG108. The inhibitory activity of the corresponding derivative was confirmed in a cell-free biochemical assay, where bio-RG108 showed an undiminished inhibition of DNA methyltransferase activity (IC_{50} = 40 nM). Bio-RG108 therefore represents a suitable bioconjugate for the elucidation of inhibitory mechanisms and for the affinity purification of RG108-associated proteins.

INTRODUCTION

The elucidation of protein interactions is a fundamental aspect in our understanding of biological processes. One approach to discover the identity of interacting proteins is the use of chemical cross-linking, a method capable of irreversibly capturing proteins by covalently fixing a biotin affinity handle to the compound interacting with the protein. The binding of biotin to (strept)-avidin has therefore found widespread application in life sciences, which is primarily due to its extraordinarily strong noncovalent interaction (*1*−*5*) with a binding constant of 1.3×10^{-15} M. Bioanalytical applications derived from biotin/(strept)avidin interaction have been used in enzymatic reactions, radiolabeling techniques, and fluorescence assays (*6*−*8*).

DNA methyltransferases catalyze the covalent addition of methyl groups to the carbon-5 position of cytosine residues in the context of genomic DNA (*9*). The resulting DNA methylation patterns play an important role in the regulation of gene expression and local hypermethylation has been frequently found to be associated with gene silencing (*10*). One of the most prominent examples for this phenomenon is the hypermethylation of tumor suppressor genes during tumorigenesis (*11*), which has established DNA methyltransferases as promising targets for oncology drug development (*12*).

The first DNA methyltransferase inhibitor 5-azacytidine has been synthesized 40 years ago (*13*), has shown clinical effectiveness in phase III trials (*14*), and has recently gained Food and Drug Administration approval as an anticancer drug. 5-Azacytidine and related compounds inhibit DNA methyltransferases by covalent enzyme trapping, which has been associated with their significant toxicity (*15*). This characteristic has complicated the clinical application of azanucleoside inhibitors and invigorated the search for novel compounds. More recent analyses have also suggested that noncovalent "active site blockers" of DNA methyltransferases might be characterized by higher specificity and less toxicity (*16*). This is exemplified by the molecular characteristics of RG108, the first rationally designed small-molecule inhibitor of DNA methyltransferases (*17*). More specifically, RG108 has been shown to be well-tolerated by human cancer cell lines and to inhibit DNA methyltransferases in a noncovalent manner (*17*). However, the molecular interactions between RG108 and the various DNA methyltransferases (and their associated factors) could not be demonstrated so far. A biotin-conjugated derivative of RG108 displaying the same binding characteristics as the original nonconjugated molecule could provide an opportunity to study the interactions between RG108 and its cellular targets in great detail. In addition, such a bioconjugate could also represent a valuable tool for the biochemical purification of DNA methyltransferase-associated protein factors.

EXPERIMENTAL SECTION

Chemicals and Reagents. Biotin, HBTU, and biotin nitrophenyl ester were purchased from Novabiochem (Merck). 5-Hydroxy-DL-tryptophan, 4-nitrobenzylbromide, triphenylphosphine, *tert*-butyl-3-hydroxypropyl carbamate, diethyl azodicarboxylate, 3-hydroxypropylcarbamic acid allyl ester, tetrakis(triphenylphosphine)palladium(0), 3-aminopropanol, 1,3-dimethoxybenzene, 5,5-dimethyl-1,3-cyclohexadione, and tetraeth-

ylammonium fluoride from Aldrich were used as received. Cesium carbonate was purchased from Alfa Aesar. *N*-Ethyldiisopropylamine, acetonitrile, DMF, methylene chloride, methanol, ethanol, ethyl acetate, cyclohexane, *n*-hexane, toluene, and chloroform were obtained from Merck and were used without further purification.

Instruments. ^{1}H NMR and ^{13}C NMR were recorded on a 400-MHz FT-NMR spectrometer (DRX 400, Bruker Analytik GmbH). FD-mass spectra and ESI mass spectra were obtained using a MAT90-spectrometer (Finnigan) and Navigator (ThermoQuest), respectively.

3-(5-Hydroxy-1*H*-indol-3-yl)-2-(1,3-dioxoisoindolin-2-yl)-propanoic Acid (2). 5-Hydroxy-DL-tryptophan (1) (440.4 mg, 2 mmol) and sodium carbonate (1.38 g, 10 mmol) were dissolved in water (15 mL). Phthalic acid mono succinimidyl ester (554 mg, 2 mmol) dissolved in acetonitrile (25 mL) was added, and the reaction mixture was stirred for 4 h until thin-layer chromatography showed the absence of starting material. The mixture was diluted with ethyl acetate (100 mL), and 1 N hydrochloric acid was added until pH reached 2. The organic phase was separated and washed twice with 1 N hydrochloric acid (50 mL) and water, respectively (50 mL). The organic phase was dried over sodium sulfate and evaporated to yield 660 mg (95%) of compound **2**. ^{1}H NMR: 13.10 (s_{br}, 1H); 10.42 (s, 1H); 8.56 (s, 1H); 7.82 (s, 4H); 7.15 (d, 1H, J = 8.85); 6.84 (d, 1H, J = 2.04 Hz); 6.79 (d, 1H, J = 2.04 Hz); 6.52 (dd, 1H, J = 2.04 Hz, J = 8.52 Hz); 5.1 (m, 1H); 3.5 (m, 2H). ^{13}C NMR: 171.25; 167.82; 150.52; 135.12; 131.56; 130.97; 128.17; 124.01; 123.85; 112.05; 111.75; 109.20; 102.04; 52.98; 24.53. FD mass spectroscopy: 350.2 ([M]$^+$, 100%). Elem. Anal. (%) calcd: C (65.14), H (4.03), N (8.06). Found: C (65.38), H (4.17), N (7.98).

4-Nitrobenzyl 3-(5-Hydroxy-1*H*-indol-3-yl)-2-(1,3-dioxoisoindolin-2-yl)propanoate (3). 2 (0.5 g, 1.4 mmol) was dissolved in ethanol (6.9 mL) and water (0.69 mL). Cesium carbonate solution (20%, 0.95 mL) was added, the mixture was stirred for 5 min at room temperature, and the solvents were removed in vacuo. For azeotropic drying, ethanol (3 mL) was added and the solvent again removed in vacuo. The dry residue was dissolved in dimethylformamide (6.9 mL), and 4-nitrobenzyl bromide (400 mg, 1.8 mmol) was added. The reaction mixture was stirred for 6 h. After filtration, the solvent was removed and the residue was purified via column chromatography (ethyl acetate/cyclohexane 50:50) to obtain 415 mg (60%) of **3**. ^{1}H NMR (DMSO-d_6): 10.5 (s, 1H); 8.5 (s, 1H); 8.2 (d, 2H, J = 8.86 Hz); 7.8 (s, 4H); 7.6 (d, 2H, J = 8.86 Hz); 7.1 (d, 1H, J = 8.52 Hz); 6.9 (d, 1H, J = 2.38 Hz); 6.8 (d, 1H, J = 2.38 Hz); 6.5 (dd, 1H, J = 2.04 Hz, J = 8.52 Hz); 5.4 (s, 2H); 5.3 (m, 1H); 3.5 (m, 2H). ^{13}C NMR (DMSO-d_6): 168.98;167.31; 150.63; 147.40; 143.72; 135.21; 131.02; 130.84; 128.74; 127.89; 124.25; 123.76; 112.02; 111.71; 108.76; 108.36; 102.19; 65.83; 52.67; 39.79; 39.58; 24.53; 24.41; 23.88. 3-[5-(3-Alloxycarbonylaminopropoxy)-1*H*-indol-3-yl]-2-(1,3-dioxoisoindolin-2-yl)propionic Acid 4-Nitrobenzyl Ester (6). 3 (300 mg, 0.62 mmol) was dissolved in methylene chloride (10.8 mL), and triphenylphosphine (0.243 g, 0.93 mmol) and 3-hydroxypropylcarbamic acid allyl ester (0.191 g, 1.2 mmol) were added. A solution of diethyl azodicarboxylate (0.145 mL) in methylene chloride (4 mL) was added dropwise over a period of 1 h. The reaction mixture was stirred for 2 h at room temperature. After evaporation of the solvent under reduced pressure and workup with column chromatography (ethyl acetate/*n*-hexane 3.5:4), 250 mg (65%) of **6** was obtained. ^{1}H NMR (DMSO-d_6): 10.60 (s, 1H); 8.98 (s, 1H); 8.20 (d, 2H, J = 8.85 Hz); 7.82 (s, 4H); 7.60 (d, 2H, J = 8.85 Hz); 7.13 (d, 2H, J = 8.85 Hz); 7.02 (d, 1H, J = 2.38 Hz); 6.97 (d, 1H, J = 2.38 Hz); 6.63 (dd, 1H, J = 2.04 Hz, J = 8.51 Hz); 5.85−5.96 (m, 1H); 5.38 (s, 2H); 5.35 (t, 1H, J = 5.45 Hz); 5.25−5.30 (m, 1H); 5.15−5.18 (m, 1H); 4.48 (d, 2H, J = 5.45 Hz); 3.76−3.90 (m, 2H); 3.49−3.6 (m, 2H); 3.13−3.18 (m, 2H); 1.80−1.86 (m, 2H). ^{13}C NMR (DMSO-d_6): 168.97; 167.26; 156.82; 156.24; 152.50; 147.39; 143.66; 135.21; 134.11; 131.48; 131.01; 128.66; 127.52; 123.70; 117.14; 112.26; 111.91; 109.11; 101.24; 65.77; 64.45; 60.71; 52.72; 37.79; 29.63; 24.51. FD mass spectroscopy: 626.2 ([M]$^+$, 100%). Elem. anal. (%) calcd: C (63.25), H (4.83), N (8.94). Found: C (63.28), H (4.85), N (8.92).

2-(1,3-Dioxoisoindolin-2-yl)-3-(5-{3-[5-(2-oxohexahydrothieno[3,4-*d*]imidazol-4-yl)pentanoylamino]propoxy}-1*H*-indol-3-yl)propionic Acid 4-Nitrobenzyl Ester (7) (via Boc-deprotection). 5 (1 g, 1.5 mmol) was dissolved in trifluoroacetic acid (40 mL) containing 1,3-dimethoxybenzene (0.55 mL). After stirring for 30 min, the trifluoroacetic acid was removed under reduced pressure. Last traces were coevaporated with 2 mL of toluene. The residue was dissolved in 10 mL of dimethylformamide, and 548 mg (1.5 mmol) biotin nitrophenyl ester was added. After stirring for 10 h, the solvent was removed under vacuum and the residue was purified via column chromatography (chloroform/methanol 9:1) to yield 179 mg (15%) of **7**.

2-(1,3-Dioxoisoindolin-2-yl)-3-(5-{3-[5-(2-oxohexahydrothieno[3,4-*d*]imidazol-4-yl)pentanoylamino]propoxy}-1*H*-indol-3-yl)propionic Acid 4-Nitrobenzyl Ester (7) (via Alloc-deprotection). 6 (430 mg, 0.68 mmol) was dissolved in tetrahydrofuran (5.3 mL) under argon atmosphere. Tetrakis-(triphenylphosphine)palladium(0) (77 mg, 0.066 mmol) and 5,5-dimethyl-1,3-cyclohexadione (0.71 g, 5 mmol) were added, and the reaction mixture was stirred for 30 min at room temperature. The solvent was removed under reduced pressure, and the residue was extracted with diethyl ether (40 mL). The slurry was filtrated and extracted four times with 20 mL of 0.5 N hydrochloric acid. The aqueous phase was adjusted to pH 10 with sodium carbonate and extracted with ethyl acetate (4 × 50 mL). After removal of the solvent, the residue was dissolved in dimethylformamide (5 mL) and biotin nitrophenyl ester (274 mg, 0.75 mmol) was added. After stirring for 10 h, the solvent was removed under vacuum and the residue was purified via column chromatography (chloroform/methanol 9:1) to yield 158 mg (30%) of compound **7**. ^{1}H NMR (DMSO-d_6): 10.60 (s, 1H); 8.21 (d, 2H, J = 8.85 Hz); 7.83 (s, 4H); 7.60 (d, 2H, J = 8.85

Hz); 7.13 (d, 1H; J = 8.85 Hz); 7.01 (d, 1H, J = 2.38 Hz); 6.95 (d, 1H, J = 2.38 Hz); 6.63 (dd, 1H, J = 2.38 Hz, J = 8.51 Hz); 6.61 (s, 1H); 6.34 (s, 1H); 5.38 (s, 2H); 5.35 (t, 1H, J = 5.10 Hz); 4.30−4.25 (m, 1H); 4.11−4.08 (m, 1H); 3.92−3.76 (m, 2H); 3.61−3.48 (m, 2H); 3.22−3.17 (m, 2H); 3.09−3.04 (m, 1H); 2.81−2.76 (m, 1H); 2.56 (d, 1H, J = 12.60 Hz); 2.10−2.06 (m, 2H); 1.84−1.78 (m, 2H); 1.58−1.41 (m, 4H); 1.36−1.23 (m, 2H). ^{13}C NMR (DMSO-d_6): 172.27; 168.97; 167.26; 162.94; 155.65; 152.49; 147.39; 145.25; 143.66; 135.23; 131.47; 131.01; 128.66; 127.54; 125.53; 123.78; 123.46; 112.26; 111.86; 109.08; 101.30; 65.96; 65.77; 61.28; 59.43; 55.67; 52.69; 35.93; 35.49; 33.45; 29.44; 28.48; 28.29; 25.58; 24.48. FD mass spectroscopy: 768.5 ([M]+, 100%). Elem. anal. (%) calcd: C (60.93), H (5.24), N (10.93). Found: C (61.10), H (5.11), N (11.61). The purity of compound **7** was additionally confirmed by HPLC: column: LiChrosorb RP select B 250 × 4 mm, solvent: 0 min: 70/30 water/acetonitrile; 30 min: 100% acetonitrile (flow: 0.7 mL/min, t_R (**7**): 18.1 min)

2-(1,3-Dioxoisoindolin-2-yl)-3-(5-{3-[5-(2-oxohexahydrothieno[3,4-*d*]imidazol-4-yl)pentanoylamino]propoxy}-1*H*-indol-3-yl)propionic Acid (8) (bio-RG108). **7** (65 mg, 0.084 mmol) was dissolved in dimethylformamide (2.3 mL). Tetraethylammonium fluoride (31.5 mg, 0.21 mmol) was added, and the reaction mixture was stirred for 30 min. The solvent was removed under vacuum, and the residue was taken up in ethyl acetate (3 mL) and washed with water (twice with 1.5 mL). The solvent was removed under reduced pressure, and 10 mL of a mixture of acetonitrile/diethyl ether (50:50) was added. The slurry was ultrasonicated for 5 min, and the resulting precipitate was filtered and washed with diethyl ether. The precipitate was dissolved in ethanol (2 mL), and 5 mL water was added. The resulting mixture was lyophilized overnight to yield compound 37 mg (70%) of compound **8**. ^{1}H NMR (DMSO-d_6): 10.56 (s, 1H); 7.86 (t, 1H, J = 6.80 Hz); 7.82 (s, 4H); 7.12 (d, 1H, J = 8.85 Hz); 6.98 (d, 1H, J = 2.38 Hz); 6.92 (d, 1H, J = 2.38 Hz); 6.65 (dd, 1H, J = 8.85 Hz, J = 2.04 Hz); 6.41 (s, 1H); 6.34 (s, 1H); 5.08 (t, 1H, J = 8.50 Hz); 4.26−4.33 (m, 1H); 3.74−3.92 (m, 2H); 3.5 (d, 2H, J = 6.8 Hz); 3.14−3.23 (m, 2H); 2.83−2.95 (m, 1H); 2.75−2.82 (m, 1H); 2.54 (d, 1H, J = 12.60 Hz); 2.04−2.13 (m, 2H); 1.17−1.27 (m, 2H); 1.26−1.66 (m, 6H). ^{13}C NMR: 172.27; 170.62; 167.45; 162.95; 161.46; 152.47; 135.10; 131.46; 131.16; 130.97; 127.53; 124.01; 123.58; 112.26; 109.75; 101.10; 70.20; 65.93; 61.28; 59.44; 56.05; 55.07; 52.89; 35,91; 35.49; 29.43; 28.30; 25.58; 24.38. ESI mass spectroscopy: 656.2 ([M + Na]$^+$, 100%). The purity of compound 8 was confirmed using two independent HPLC methods: First method: column: LiChrosorb RP select B 250 × 4 mm; solvent: 0 min: 100% water; 30 min: 100% acetonitrile; flow: 0.7 mL/min; t_R (8): 20.1 min, Second method: column: LiChrosorb RP select B 250 × 4 mm; solvent: 50:50 methanol/water; flow: 0.5 mL/min; t_R (8): 7.5 min

5-(Hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazol-4-yl)-*N*-(3-hydroxypropyl)pentamide (9). Biotin (1 g, 4.09 mmol) and HBTU (1.36 g, 3.6 mmol) were suspended in DMF (50 mL), and DIPEA (0.70 g, 5.4 mmol) was added with stirring. The clear solution was transferred into a dropping funnel and added dropwise to a solution of 3-aminopropanol (0.52 g, 7 mmol) in DMF (75 mL). The solvent was removed in vacuo, and the crude product was dissolved in a minimum amount of methanol (4−7 mL). Diethyl ether (20 mL) was added, and the solution was kept at −20 °C for 12 h. The white crystalline precipitate was filtered by suction and washed with cold diethyl ether to yield 1.1 g (89%) of the product. ^{1}H NMR (DMSO-d_6): 7.73 (t, 1H, J = 5.45 Hz); 6.43 (s, 1H); 6.36 (s, 1H); 4.40 (s_{br}, 1H); 4.31 (dd, 1H, J = 5.10 Hz, J = 7.49 Hz); 4.12 (dt, 1H, J = 1.70 Hz, J = 6.13 Hz); 3.38 (t, 2H, J = 6.13 Hz); 3.03−3.13 (m, 3H); 2.80 (dd, 1H, J = 5.10 Hz, J = 12.60 Hz); 2.57 (d, 1H, J = 12.60 Hz); 2.04 (t, 1H, J = 7.49 Hz); 1.40−1.57 (m, 6H); 1.20−1.36 (m, 2H). ^{13}C NMR (DMSO-d_6): 172.28; 162.99; 61.30; 59.46; 58.67; 55.66; 35.86; 35.45; 32.74; 28.46; 28.27; 25.57. FD mass spectroscopy: 302.2 ([M + H]$^+$, 100%). Elem. anal. (%) calcd: C (51.80); H (7.69); N (13.94). Found: C (52.11); H (7.56); N (14.61)

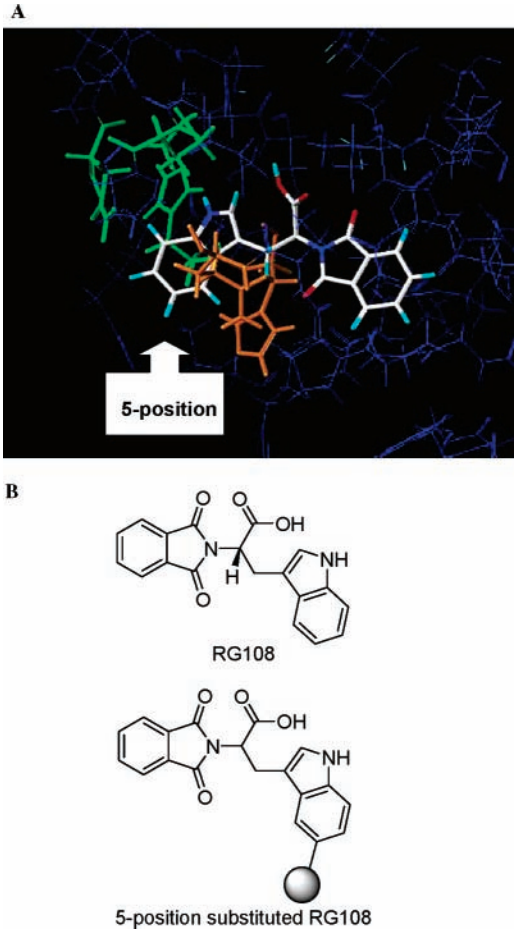

Figure 1. Molecular modeling and structure of 5-substituted RG108. A, RG108 docked into the active site of human DNMT1. Green and orange amino acids form the entry site to the catalytic pocket. The 5-position of the tryptophan moiety (arrow) appeared to protrude from the catalytic pocket and was therefore considered to be particularly amenable to functionally neutral chemical modification. B, chemical structure of original RG108 and 5-substituted RG108.

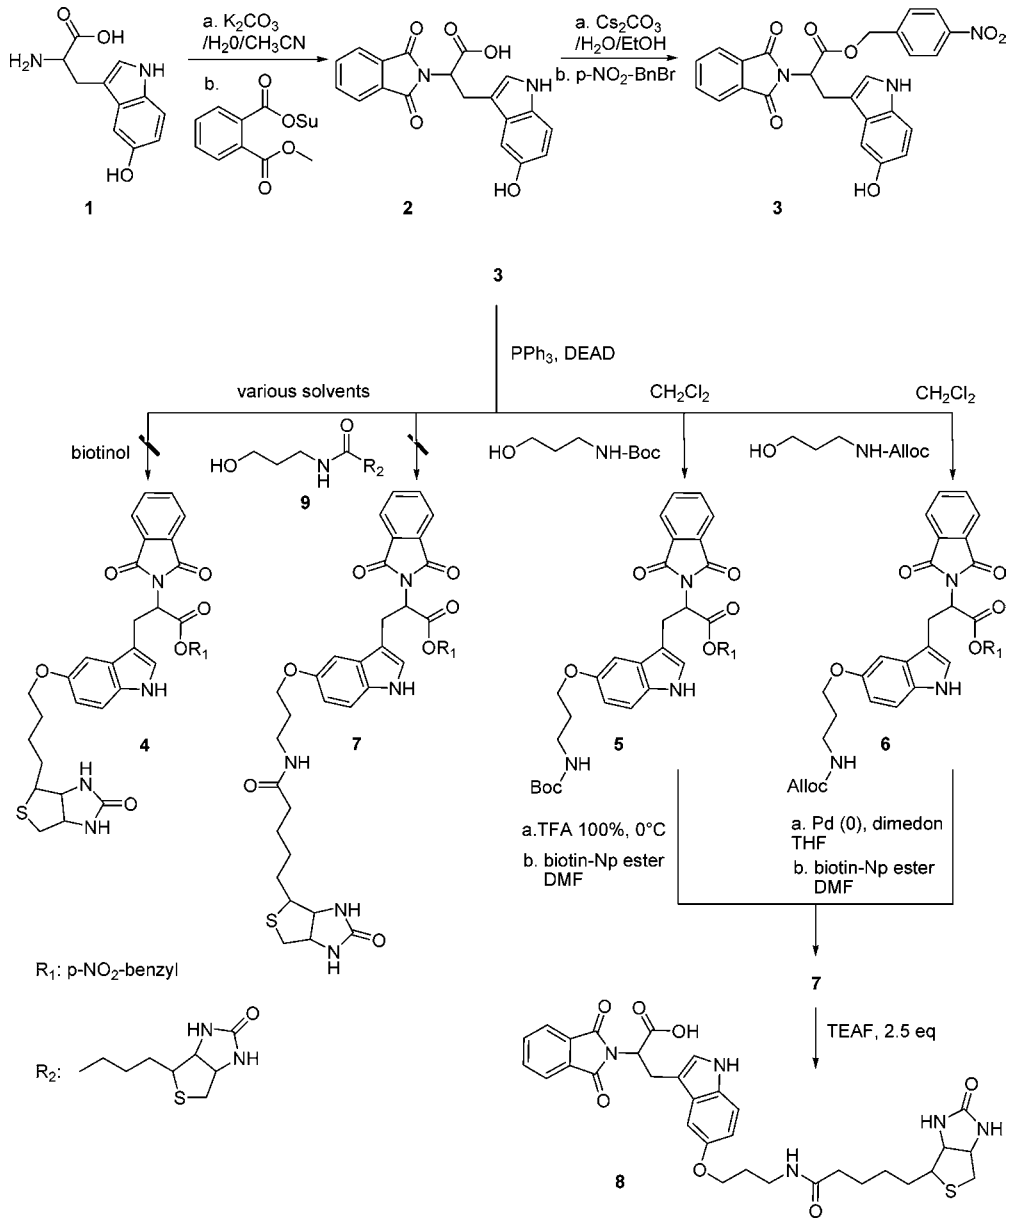
In Vitro Methylation Assay. A 798 bp promoter fragment (−423/+375 relative to the initiation codon) from the human p16^{Ink4a} gene was used as unmethylated substrate DNA. Four hundred nanograms of substrate DNA, 2 units of M.SssI methylase (New England Biolabs, Frankfurt, Germany), and the cofactor *S*-adenosyl-L-methionine (final concentration: 80 μM; New England Biolabs) were added to a final reaction volume of 50 μL. Test compounds were added to final concentrations of 10, 30, 100, 300, and 500 μM, and the reactions were incubated for 2 h at 37 °C. After incubation the reactions were purified using the QIAquick PCR Purification kit (Qiagen, Hilden, Germany). Three hundred nanograms of purified DNA was digested for 3 h at 60 °C with 30 units of *Bst*UI (New England Biolabs) and analyzed on 3% Tris-borate EDTA agarose gels.

RESULTS AND DISCUSSION

Previous results have strongly suggested that RG108 binds deep in the active site of DNA methyltransferases (*16*), which rendered the identification of chemically modifyable positions

Scheme 1



critically important. We therefore used molecular modeling and a previously established three-dimensional model of the human DNMT1 catalytic domain (*18*) for an analysis of the molecular interactions between RG108 and the DNA methyltransferase active site. Docking of RG108 revealed that the 5-position of the tryptophan moiety protruded from the active site pocket, suggesting that modifications at this position were unlikely to interfere with the various interactions between enzyme and inhibitor (Figure 1). This analysis also indicated that more extensive modifications could be accommodated by the addition of an aminoalkyl spacer (data not shown). Last, the synthesis of 5-substituted RG108 derivatives also appeared favorable in light of the fact that 5-hydroxytryptophan could be used as a convenient starting point for chemical syntheses which are amenable to various chemical alterations, such as Mitsunobu coupling of alcohols.

Biotinylated RG108 (bio-RG108) was synthesized starting from racemic 5-hydroxy-DL-tryptophan **1** (Scheme 1) which was phthaloylated using methyl 2-[(succinimido)oxycarbonyl]benzoate (*19*) to yield 5-hydroxy-RG108 (**2**) in almost quantitative yields. Racemic mixtures of RG108 have previously been shown to be effective in various assays (*16*), and therefore racemic compound **1** was used. The phthaloylation of **1** was slightly modified because the original procedure for the synthesis of RG108 (*17*) gave yields of 50−60% only. Potassium carbonate was used instead of sodium carbonate for the deprotonation of **1** and 1 N HCl instead of 2 N HCl for the final workup yielding **2** in high yields and high chemical purity, making further purification unnecessary. For further derivatization of **2** at the 5-position of tryptophan, it is essential to protect the carboxy moiety by esterification. Lescrinier et al. reported the successful synthesis of N-Treoc-protected 5-hydroxytryptophan *p*-nitrobenzyl ester for incorporation of 5-hydroxytryptophan in oligopeptides via conversion of the carboxylic acid into its cesium salt by titration to pH 7 with Cs_2CO_3 (*20*). This method was applied to the phthaloylated amino acid **2**, and the resulting Cs-salt was subsequently reacted with *p*-NO_2-benzyl bromide in DMF giving compound **3** in 65% yield after column chromatography.

Our first attempt to conjugate biotin to **3** was via Mitsunobu coupling of biotinol, which was obtained by reduction of biotin-SU ester with $NaBH_4$ (*21*). Unfortunately, the coupling reaction was unsuccessful due to the limited solubility of biotinol in solvents commonly applied in Mitsunobu reactions (CH_2Cl_2, $CHCl_3$, THF, benzene, ethyl acetate) and even in DMF or

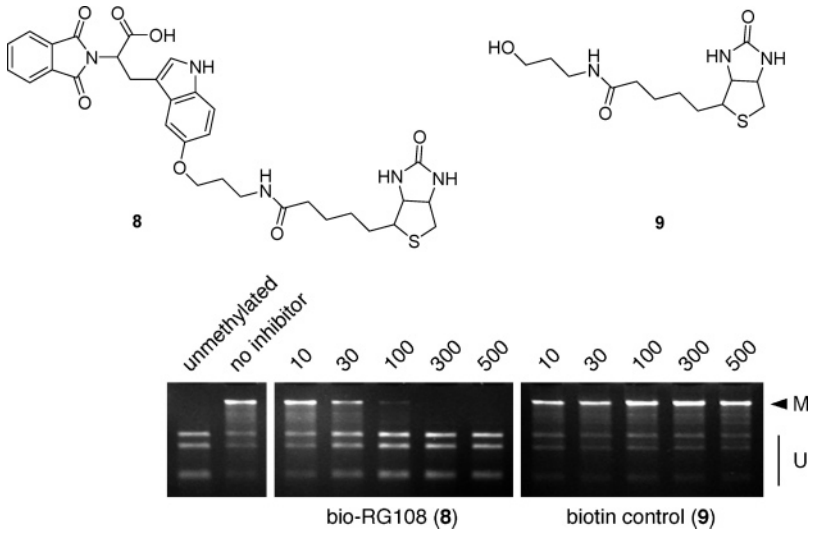


Figure 2. Inhibition of purified recombinant DNA methyltransferase activity by bio-RG108. Incubation of an unmethylated DNA fragment with purified SssI methylase results in the generation of a methylated fragment (M) that is protected against restriction cleavage by BstUI. Inhibition of DNMT activity generates unmethylated (U) fragments that are products of BstUI restriction. Numbers indicate inhibitor concentrations (in μM). An biotin derivative lacking the RG108 moiety (**9**) was analyzed in control experiments and did not show any detectable inhibitory activity.

HMPA. One further attempt with N-biotinylated 3-aminopropan-1-ol **9** was also found to be unsuitable, but N-Boc- and N-Alloc-protected 3-aminopropan-1-ol in CH_2Cl_2 could be coupled in moderate yields of 55−60% to yield compounds **5** and **6**. The deprotection of **5** with TFA at 0 °C and the subsequent workup to isolate the primary amine was unsuccessful due to decomposition on silica gel. We therefore decided to use the crude amine for direct reaction with commercially available biotin-Np ester in DMF and were able to isolate *p*-NO_2-benzyl ester protected **7** in 15% yield. Because of these unsatisfying results, we synthesized the Alloc-protected compound **6** which was deprotected with Pd(0) and dimedon in THF. The instability of the amine upon contact with silica gel was confirmed, and so the crude amine was further reacted with biotin-Np ester to yield *p*-NO_2-benzyl ester protected **7** in 30% yield. Despite the presence of acidic dimedon, the main product (65%) was an enamine built from excess dimedon and the primary amine. To obtain the final bio-RG108 **8**, the *p*-NO_2-benzyl ester was deprotected with 2.5 equiv of tetraethylammonium fluoride (TEAF) in DMF in 70% yield. The yields dramatically decreased when using more than 2.5 equiv which was proved by HPLC monitoring of the crude reaction mixture using 2−10 equiv of TEAF. Starting from commercially available 5-hydroxytryptophan and biotin nitrophenyl ester, final compound bio-RG108 could be synthesized in an overall chemical yield of 4% (via compound **5**) or 8% (via compound **6**). The purity of all compounds was determined by ^{1}H and ^{13}C NMR, mass spectroscopy, elemental analysis, and/or HPLC.

Due to the major structural alterations, we needed to analyze the inhibitory activity of bio-RG108 **8**. To this end, we used a cell-free in vitro assay with purified recombinant CpG methylase (*17*). The results showed that bio-RG108 was able to efficiently inhibit DNA methylation (Figure 2). After normalization to 1 nM enzyme concentration, the IC_{50} concentration of bio-RG108 was determined to be 40 nM. This is similar to the IC_{50} concentration of unmodified RG108 (115 nM, cf. ref 17) with the improved potency likely due to the better solubility of bio-RG108. Importantly, no inhibitory effect could be observed for a biotin derivative that lacks the RG108 moiety (Figure 2, biotin control), which further confirmed the specificity of bio-RG108.

In conclusion, we prepared a biotinylated derivative of the novel mechanism-independent DNA methyltransferase inhibitor RG108 for the evaluation of binding interactions using a biotin/(strept)avidin binding assay. Despite major derivatization, the novel compound bio-RG108 exhibited a high inhibitory activity with purified recombinant DNA methyltransferase, thus confirming the results from our molecular modeling approach. Bio-RG108 therefore represents a valuable probe for the selective immobilization of human DNA methyltransferases and further investigation of proteins interacting with RG108. Additionally, proving the 5-position of RG108 to be most suitable for chemical alterations provides an opportunity to synthesize various bioconjugates such as carbohydrate and peptide conjugates for specific tumor-targeting. A great variety of suitable linkers, e.g. hydroxyalkylcarboxylic acid esters, N-protected aminoalkyl alcohols, etc., can be conveniently attached to the 5-position of 5-hydroxy-RG108, applying mild Mitsunobu conditions and used for further derivatization.

ACKNOWLEDGMENT

The authors would like to thank B. Mathiasch, N. Haunold, and A. Vierengel for the recording of NMR and mass spectra. This work was supported by a grant from Cancer Research Technologies (to F.L).

Congestive heart failure (CHF) is a complex syndrome involving altered neurohormonal levels and impaired cardiac and renal function. In recent years, intravenous administration of exogenous human brain-type natriuretic peptide (hBNP) has become an important therapy in treating patients with acutely decompensated CHF. However, reports during the past year suggest that hBNP could play a prominent role in the chronic treatment of CHF patients as well. We are currently developing conjugates of hBNP suitable for oral delivery to provide a patient-friendly treatment option for chronic heart failure patients. In this report, we present in vitro activity results obtained from hBNP conjugates featuring a variety of rationally designed amphiphilic oligomers. Mapping studies revealed that the hydrophobic/hydrophilic balance of the oligomer impacted the regioselectivity of conjugation. Additionally, the regiochemistry and extent of conjugation had a significant impact on activity. Many monoconjugates retained activity comparable to native peptide and are currently under evaluation in subsequent in vivo screens.

INTRODUCTION

Cardiovascular diseases constitute the leading cause of death in the United States regardless of gender or ethnicity. Of these diseases, congestive heart failure (CHF) is the only one that is increasing in prevalence (*1*, *2*). Hospital expenses for the treatment of CHF are more than double those for all forms of cancer combined (*3*). Approximately 78% of CHF patients are being hospitalized at least twice per year, accounting for nearly 6 million hospital days in the United States alone (*4*). Despite the prevalence of this disease, there is still no curative therapeutic approach (*5*). Multiple hospitalizations and inadequate therapeutics define the current situation faced by those who suffer from CHF.

In August 2001, recombinant hBNP (human brain-type natriuretic peptide; Scios, Inc.) was approved by the FDA for the treatment of patients with acutely decompensated CHF with dyspnea at rest or with minimal activity. Although the current use of hBNP is limited to acute intravenous infusion, recent studies in patients with moderate to severe heart failure indicate that hBNP could play an important role as a chronically administered therapeutic (*6*−*8*). BNP is one of a family of peptides that are involved in cardiovascular, renal, and endocrine homeostasis (*9*). It has natriuretic, diuretic, vasorelaxant, lusitropic, anti-aldosterone, and anti-fibrotic properties (*10*). It was discovered in 1988 (*11*), almost a decade after the discovery of atrial natriuretic peptide (ANP). First isolated from porcine brain, it is known for its activity at receptors in cardiac, renal, vascular smooth muscle, and endothelial cells. BNP binds to the natriuretic peptide receptor A (NPR-A), a membrane-bound protein on the cell surface. The binding event triggers the synthesis of cGMP in the cytosol by guanylate cyclase. It is through this secondary messenger that BNP mediates its physiological effects.

Our objective has been to generate an amphiphilic conjugate of hBNP that would be suitable for oral administration and the chronic treatment of CHF as part of an outpatient or home-based therapy. The amphiphilic oligomers that were used are composed of both hydrophilic and hydrophobic moieties. The hydrophilic portion is composed of poly(ethylene glycol) (PEG), the attachment of which has been demonstrated to increase circulating half-life and reduce immunogenicity (*12*−*14*). The hydrophobic portion is composed of an alkyl group and is intended to provide amphiphilic balance, a feature that is an essential characteristic of oral drugs (*15*). While the conjugation of amphiphilic oligomers can be an important tool to improve the pharmacokinetics and pharmacodynamics of a drug, it is important that the agonist activity of the resultant conjugate is not severely compromised. In this report we describe the impact of various oligomers and the site of conjugation to hBNP on the in vitro production of cGMP by human aortic endothelial cells (HAEC). The lead conjugates from this activity screen are currently being tested in healthy dogs after oral administration. Preliminary results from these studies have recently been published (*16*).

EXPERIMENTAL PROCEDURES

General. Unless otherwise mentioned, all reagents were purchased from Aldrich (Milwaukee, WI). PEGs and MPEGs were purchased from TCI America (Portland, OR). Lysyl endopeptidase was purchased from Wako BioProducts (Richmond, VA). HPLC columns were purchased from Phenomenex

(Torrance, CA). ELISA kits were purchased from Molecular Devices (Sunnyvale, CA). Primary human aortic endothelial cells (HAEC) were purchased from Cambrex (Clonetics; East Rutherford, NJ). Chemical shifts are reported in reference to TMS internal standard.

General Procedure for Conjugation of Amphiphilic Oligomers to hBNP. *Method 1: Preparation of Monoconjugates.* hBNP (1 equiv) was dissolved in DMSO (1 mL/35 mg of hBNP). The activated oligomer (1.1 equiv) was dissolved in a minimal amount of THF and added to the solution. The progress of the reaction was monitored by HPLC: 50 μL aliquots were diluted in 500 μL of H_2O containing 0.1% TFA. Reactions were typically complete within 45 min.

Method 2: Preparation of Di-, Tri-, and Tetraconjugates. hBNP (1 equiv) was dissolved in DMSO (1 mL/35 mg of hBNP). Triethylamine (120 equiv) was added. After 5 min, the activated oligomer (2.2 equiv for diconjugate, 4 equiv for triconjugate, 5 equiv for tetraconjugate) was dissolved in a minimal amount of THF and added to the solution. The progress of the reaction was monitored by HPLC: 50 μL aliquots were diluted in 500 μL of H_2O containing 0.1% TFA. Reactions were typically complete within 45 min.

General Procedure for Purification of hBNP Conjugates. The conjugates prepared by Methods 1 and 2 were isolated using reversed-phase HPLC (C18, 1.0 cm. i.d. × 25 cm length). A single gradient system was sufficient for purification of most of the conjugates (A: H_2O with 0.1% TFA; B: acetonitrile with 0.1% TFA; %B: 25−75 over 120 min). Each conjugate was obtained as a white powder after rotary evaporation and lyophilization.

Activation of Oligomers. Method 1. The acid (1.0 equiv) and *N*-hydroxysuccinimide (1.1 equiv) were dissolved in dry CH_2Cl_2 (0.2 M with respect to acid). Ethyl dimethylaminopropyl carbodiimide hydrochloride (EDC, 1.0 equiv) was added. After being stirred at room-temperature overnight, the reaction mixture was diluted with CH_2Cl_2 and was washed with water (2×). The organic layer was dried ($MgSO_4$) and concentrated to a constant weight. The products were typically colorless oils.

Activation of Oligomers. Method 2. The alkyl-PEG (1.0 equiv) was dissolved in acetonitrile (0.1−0.2 M with respect to alkyl-PEG). After the addition of disuccinimidyl carbonate (DSC, 1.5 equiv), triethylamine (1.5 equiv) was added dropwise over the course of 10 min. After being stirred overnight at room temperature, the crude reaction mixture was concentrated, dissolved in sat. $NaHCO_3$, and extracted with ethyl acetate (2×). The organic layer was dried ($MgSO_4$) and concentrated. Purification by silica gel chromatography (EtOAc/MeOH, 10:1) afforded the activated products.

Activation of Oligomers. Method 3. The alkyl-PEG (1.0 equiv) dissolved in toluene was added dropwise to a stirring 20% phosgene solution in toluene at −10 °C (0.2 M with respect to alkyl-PEG). After 30 min, the reaction mixture was allowed to warm to room-temperature overnight. Phosgene and toluene were removed by vacuum distillation. The crude acid chloride was dissolved in CH_2Cl_2 (0.4 M with respect to acid chloride), and *N*-hydroxysuccinimide (1.1 equiv) was added. Triethylamine (1.1 equiv) was added dropwise over the course of 10 min. After being stirred overnight at room temperature, the crude reaction mixture was concentrated, dissolved in sat. $NaHCO_3$ (20 mL), and extracted with ethyl acetate (2×). The organic layer was dried ($MgSO_4$) and concentrated. Purification by silica gel chromatography (EtOAc) afforded the activated product.

$MPEG_7C_{16}$ Succinimidyl Ester (4). To a solution of the acid **21** (15.3 g, 45 mmol) in ethanol (300 mL) was added H_2SO_4 (1.5 mL, 31.25 mmol). After being stirred for 48 h, the crude reaction mixture was diluted with water and extracted with CH_2Cl_2 (2 × 300 mL). The organic layer was washed with H_2O (2 × 300 mL) and sat. $NaHCO_3$ (2 × 300 mL). The organic layer was then dried ($MgSO_4$) and evaporated to dryness to afford an off-white solid (16.03 g, 98%): MS (ESI+) 364 (M + 1).

To a solution of heptaethylene glycol monomethyl ether (8.51 g, 25 mmol) in THF (250 mL) was added potassium *tert*-butoxide (3.1 g, 27.5 mmol) in small portions over 30 min. The reaction mixture was then stirred for an additional 1 h. The ester (10 g, 27.5 mol in 90 mL THF) was added dropwise over 30 min, and the reaction mixture was stirred overnight. The crude reaction mixture was filtered through Celite and concentrated. The crude oil was purified by silica gel chromatography (2−5% MeOH in $CHCl_3$) to yield **24** as a clear yellow oil (2.48 g, 16%): MS (ESI+) 623 (M + 1), 645 (M + Na^+).

To a solution of the ester **24** (2.22 g, 3.56 mmol) in alcohol (1:1 MeOH:EtOH, 50 mL) was added 1 N NaOH (50.0 mL). After being stirred for 24 h, the reaction mixture was concentrated, acidified to pH 2 with 1 M HCl, saturated with NaCl, and extracted with CH_2Cl_2 (3 × 75 mL). The organic layers were combined, washed with sat. NaCl, dried ($MgSO_4$), and concentrated. Purification of the crude solid by silica gel chromatography (ethyl acetate) provided the amphiphilic acid as a white powder (858 mg, 40%): MS (ESI+) 617 (M + Na^+).

The acid (324 mg, 544 mmol) was activated according to Activation Method 1. The product **4** was obtained as a clear oil (290 mg, 77%): ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.27 (m, 18H), 1.40 (m, 2H), 1.58 (m, 2H), 1.73 (m, 4H), 2.60 (t, 2H), 2.84 (m, 4H), 3.38 (s, 3H), 3.45 (t, 2H), 3.56 (m, 6H), 3.62 (m, 22H); MS (ESI+) 714 (M + Na^+).

$MPEG_3C_3$ Succinimidyl Ester (1). Methyl triethylene glycol (3.84 g, 23.4 mmol) and *tert*-butyl acrylate (1.71 mL, 11.7 mmol) were dissolved in dry THF (10 mL). Sodium metal (27 mg, 0.117 mmol) was added to the solution. After being stirred for 4 h at room temperature, the reaction mixture was quenched by the addition of 1 M HCl (30 mL). The quenched reaction mixture was then extracted with CH_2Cl_2 (1 × 100 mL, 1 × 50 mL). The organic layer was dried ($MgSO_4$) and concentrated. After purification by silica gel chromatography (ethyl acetate), the product was obtained as an oil (2.94 g, 86%): MS (ESI+) 315 (M + Na^+).

The *tert*-butyl ester **25** (1.00 g, 3.42 mmol) was deprotected by stirring at room temperature in trifluoroacetic acid (5.0 mL). The contents were then concentrated to a constant weight (0.708 g, 88%): MS (ESI+) 236 (M^+), 239 (M + Na^+).

The acid (0.705 g, 2.99 mmol) was activated according to Activation Method 1. The product **1** was an oil (0.848 g, 85%): ^{1}H NMR (400 MHz, $CDCl_3$, δ): 2.81 (m, 4H), 2.87 (t, 2H), 3.35 (s, 3H), 3.52 (m, 2H), 3.61 (m, 10H), 3.82 (t, 2H); MS (ESI+) 356 (M + Na^+).

C_6PEG_7 Succinimidyl Carbonate (5). Triethylene glycol (30 g, 0.2 mol) was dissolved in 8 mL of 100% NaOH and stirred for 10 min. Benzyl chloride (7.8 g, 61.6 mmol) was added, and the reaction was stirred at reflux overnight. The reaction mixture was diluted with sat. NaCl (500 mL) and extracted with CH_2Cl_2 (2 × 400 mL). Organic layers were combined, washed sat. NaCl (800 mL), dried ($MgSO_4$), and evaporated to dryness. Silica gel chromatography (ethyl acetate) provided the protected PEG_3 as a yellowish oil (9.84 g, 66%): MS (FAB+) 241 (M + 1).

Triethylamine (7.1 mL, 0.054 mol) was added to a solution of benzyl PEG_3 (9.84 g, 0.041 mol) in CH_2Cl_2 (50 mL). The solution was cooled to 0 °C, and methanesulfonyl chloride (3.9 mL, 0.049 mol), dissolved in CH_2Cl_2 (10 mL), was added via addition funnel. The reaction was stirred for 0.5 h at 0 °C and then 4 h at room temperature. The reaction mixture was filtered through Celite and diluted with CH_2Cl_2 (150 mL). The filtrate was then washed with H_2O (200 mL), sat. $NaHCO_3$ (200 mL), and H_2O (200 mL). The organic layer was dried ($MgSO_4$) and

concentrated to a constant weight, affording the mesylate as a yellowish oil (10.85 g, 83%): MS (FAB+) 319 (M + 1).

NaH (0.45 g, 0.019 mol) was added portionwise over 0.5 h to a solution of tetraethylene glycol (7.32 g, 0.038 mol) in tetrahydrofuran (140 mL). The mixture was stirred for 1 h. Then the benzyl PEG_3 mesylate (6.0 g, 0.019 mol), dissolved in tetrahydrofuran (20 mL), was added dropwise via addition funnel. After being stirred overnight at room temperature, the reaction mixture was filtered through Celite and evaporated to dryness. The resultant oil was dissolved in CH_2Cl_2 (150 mL) and washed with H_2O (150 mL), sat. $NaHCO_3$ (150 mL), and H_2O (150 mL). The organic layer was dried ($MgSO_4$) and concentrated. Silica gel chromatography (ethyl acetate/methanol, 10:1) afforded benzyl PEG_7 (**26**) as a clear oil (3.83 g, 49%): MS (FAB+) 417 (M + 1).

To a solution of **26** (5.45 g, 0.013 mol) in tetrahydrofuran (160 mL) was added potassium *tert*-butoxide (1.6 g, 0.014 mol), and the reaction mixture was stirred for 1 h. Then hexylmethanesulfonate (2.59 g, 0.014 mol), dissolved in tetrahydrofuran (20 mL), was added via addition funnel, and the reaction was stirred overnight at room temperature. The reaction mixture was filtered through Celite and concentrated. The resultant oil was dissolved in ethyl acetate (150 mL), washed with H_2O (2 × 150 mL), dried ($MgSO_4$), and concentrated. Silica gel chromatography (ethyl acetate) afforded the protected alkyl PEG_7 (**27**) as a clear oil (2.40 g, 36%): MS (FAB+) 501 (M + 1).

To a solution of **27** (2.40 g, 4.8 mmol) in ethyl acetate (16 mL) was added palladium on activated carbon (1 g, 10wt % on carbon). The reaction vessel was stirred under H_2 atmosphere overnight at room temperature. The reaction mixture was then filtered through Celite and concentrated to afford the alkyl-PEG_7-OH as a clear oil (1.61 g, 82%): MS (FAB+) 411 (M + 1).

The alkyl-PEG_7OH (1.60 g, 3.9 mmol) was activated according to Activation Method 3. The product was a clear oil (1.06 g, 53%): ^{1}H NMR (400 MHz, $CDCl_3$, δ): 0.88 (m, 3H), 1.29 (m, 4H), 1.58 (m, 2H), 2.84 (m, 4H), 3.45 (t, 2H), 3.58 (m, 2H), 3.65 (m, 22H), 3.79 (m, 2H), 4.47 (m, 2H); MS (FAB+) 552 (M + 1).

(Branched $MPEG_4$) Urethanyl C_6 Succinimidyl Ester (11). Tetraethylene glycol monomethyl ether (14.0 g, 67 mmol) was dissolved in tetrahydrofuran (90 mL). NaH (1.77 g, 74 mmol) was added portionwise, and the reaction was stirred for 2 h. Then epichlorohydrin (26.3 mL, 0.34 mol) was added dropwise and the reaction was stirred at room temperature for 48 h. The crude reaction mixture was filtered through Celite and washed CH_2Cl_2 (250 mL). The filtrate was washed H_2O (2 × 250 mL), dried ($MgSO_4$), and evaporated to dryness. Column chromatography (silica, ethyl acetate) afforded **28** a clear oil (10.15 g, 57%): MS (ESI+) 287 (M + Na^+).

Tetraethylene glycol monomethyl ether (7.96 g, 0.038 mol) and **28** (10.1 g, 0.038 mol) were dissolved in CH_2Cl_2 (100 mL). $BF_3{\cdot}OEt_2$ (0.48 mL, 0.0038 mol) was added and the reaction mixture was stirred overnight at room temperature. The crude mix was diluted with CH_2Cl_2 (200 mL), washed with sat. $NaHCO_3$ (300 mL) and H_2O (300 mL), dried ($MgSO_4$), and evaporated to dryness. Column chromatography (silica, ethyl acetate/MeOH, 10:1) afforded **29** a clear oil (4.5 g, 25%): MS (ESI+) 495 (M + Na^+).

4-Nitrochloroformate (2.87 g, 14.3 mmol) and **29** (4.5 g, 9.5 mmol) were dissolved in CH_2Cl_2 (45 mL). After the reaction mixture was stirred for 10 min, TEA (2.1 mL, 15 mmol) was added and reaction stirred overnight at room temperature. The crude mix was diluted with CH_2Cl_2 (130 mL), washed with 1M HCl (175 mL) and H_2O (175 mL), dried ($MgSO_4$), and evaporated to dryness. Column chromatography (silica, ethyl acetate/MeOH, 15:1) afforded **30** a yellowish oil (2.38 g, 40%): MS (ESI+) 660 (M + Na^+).

6-Aminocaproic acid (0.126 g, 0.96 mmol) and K_2CO_3 (0.221 g, 1.6 mmol) were dissolved in H_2O (DI, 5 mL). Then **30** (0.5 g, 0.8 mmol) was dissolved in THF (0.7 mL) and added dropwise. After being stirred overnight at room temperature, the reaction mixture was diluted with H_2O (20 mL), acidified to pH ~ 1 with HCl, and extracted with CH_2Cl_2 (2 × 25 mL). The organic layers were combined, dried ($MgSO_4$), and evaporated to dryness. Column chromatograpy (silica, $CHCl_3$/MeOH, 15:1) afforded **31** a clear oil (0.428 g, 85%): MS (ESI+) 652 (M + Na^+).

The acid was activated using Method 1:**31** (0.40 g, 0.64 mmol), *N*-hydroxysuccinimide (0.088 g, 0.77 mmol), EDC (0.160 g, 0.83 mmol), and CH_2Cl_2 (5 mL). Column chromatography (silica, ethyl acetate/MeOH, 10:1) afforded **11** a clear oil (0.320 g, 69%): ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.45 (m, 2H), 1.53 (m, 2H), 1.77 (m, 2H), 1.87 (br s, 1H), 2.62 (t, 2H), 2.84 (m, 4H), 3.16 (m, 2H), 3.38 (s, 6H), 3.55 (m, 6H), 3.65 (m, 38H), 5.01 (m, 1H); MS (ESI+) 749 (M + Na^+).

Peptide Mapping. Either native hBNP or a conjugate (1.0 mg) and lysyl endopeptidase (2.0 ng) were incubated in 1.0 mL Tris buffer (0.1 M, pH 9) at 30 °C for 1 h. Reactions were quenched by the addition of 50% acetic acid (50 μL) to bring the solutions to pH ≈ 4. As a negative control, hBNP was also incubated at 30 °C without addition of the lysyl endopeptidase. All hBNP and conjugate solutions were analyzed by HPLC prior to incubation to determine purity and concentration. The incubated samples were analyzed by HPLC to reveal the fragment profile. Sites of conjugation were determined after subsequent isolation and mass spectral analyses of the peptide fragments.

cGMP Assay. Primary human aortic endothelial cells (HAEC) were thawed and placed in a T75 flask prior to use in an experiment. Cells were grown for 2 days until they reached 70−80% confluence and were then plated into 12-well plates at 2.5 × 10^4 cells/well. The next day the media was removed, and cells were preincubated for 10 min at 37 °C with 0.5 mM IBMX to inhibit phosphodiesterases. Conjugates to be screened were added to the cells for an additional 60 min at 37 °C. Incubation was stopped by lysing cells using Cell Lysis Solution (Molecular Devices; Sunnyvale, CA). The released intracellular cGMP was then acetylated using a 2:1 mixture of triethylamine to acetic anhydride. Acetylation of the cGMP lysate was found to increase the sensitivity of this assay 5-fold. Acetylated cGMP was then measured using an ELISA-based system (CatchPoint-cyclic GMP Fluorescent Assay Kit), which quantitates cGMP via a competitive immunoassay in 96-well format. Lysates were added to the coated microplate followed by the addition of an anti-cGMP antibody and a horseradish peroxidase (HRP)-cGMP conjugate. Plates were incubated for 2 h at room temperature, followed by four washes. A substrate solution was added and the fluorescent intensity of each well was quantitated. The fluorescent signal intensity decreased with increasing levels of cGMP. Native hBNP was tested in each experiment as a positive control. Statistical analyses were performed with SigmaStat using a one-way ANOVA and a post-hoc Dunnett's test with significance set at $p < 0.05$.

RESULTS AND DISCUSSION

Sites of Conjugation. The hormone hBNP is expressed as the inactive prepro-peptide (*17*−*19*), which is cleaved after translation by the enzyme Corin (*20*) to the mature peptide shown in Figure 1. It has four prominent sites for conjugation: Ser1, Lys3, Lys14, and Lys27. Because binding to the NPR-A is believed to occur mostly in the loop region, we expected that activity would likely be compromised upon conjugation to Lys14 and perhaps Lys27. Thus, we anticipated that mono- or

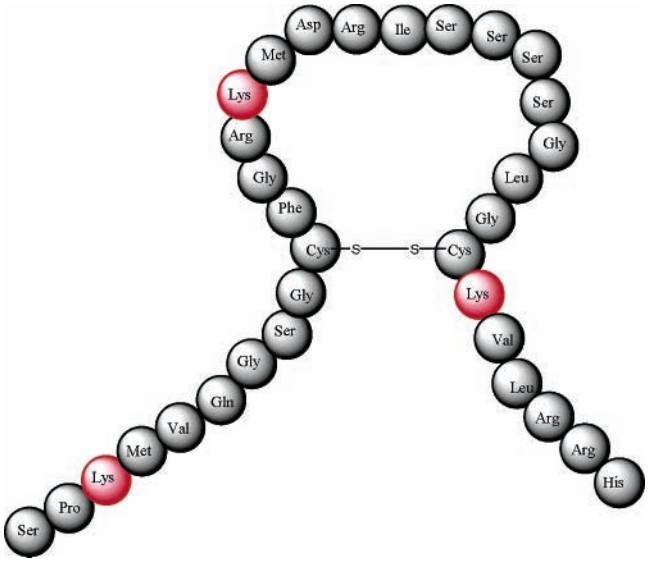

Figure 1. Primary structure of mature hBNP. It is a 32-amino acid peptide with a loop region composed of 17 residues, which is the characteristic loop size for the various natriuretic peptides. hBNP has four sites suitable for conjugation with these oligomers: the free N-terminus and three lysine residues (shown in red).

diconjugates composed only of Ser1 and Lys3 conjugates would have little adverse effect on activity, whereas mono-, di-, or triconjugates involving one or both of the Lys14 and Lys27 positions may reduce or eliminate activity. However, the verity of these assumptions and the extent of impact of conjugation at these sites had not yet been demonstrated.

Conjugation reactions performed in aqueous phosphate buffer (10 mM; pH 7.4 and 9.5) led to undesirable mixtures of products with little indication of selectivity. In contrast, reactions performed in polar organic solvents (DMSO and DMF) resulted in much cleaner product profiles. The sites of attachment of the oligomers were determined by peptide mapping studies using lysyl endopeptidase, followed by analyses of the fragments by HPLC and mass spectrometry. Characteristic results from these studies are presented in Table 1. The six potential fragments are listed in the table in addition to the intact hBNP or conjugate. The presence of specific fragments were verified by retention time (R_f) and molecular weight. Because the conjugated lysines are resistant to lysyl endopeptidase, the presence of particular fragments indicates the lysine residues that were not conjugated. Conversely, the absence of fragments indicates conjugation at a specific site. These indications are verified by the molecular weights of the fragments. Predictably, unconjugated hBNP was fragmented into the peptides expected from cleavage at each of the three lysine residues. Cleavage at Lys14 (for native hBNP or a conjugate) results in the peptide fragments that remain covalently attached through the disulfide linkage rather than through a peptide bond. The tri- and tetraconjugates were completely resistant to proteolysis with lysyl endopeptidase, resulting in no fragmentation.

The site preference for attachment of the oligomers in either DMSO or DMF followed the trend Lys3 > Lys14 > Lys27 ≫ Ser1 (Figure 2a). Conditions could be adjusted so that the Lys3 monoconjugate was the major product. Diconjugates tended to form only transiently. Rather than accumulating, the diconjugates were excellent substrates for conjugation and rapidly proceeded to the triconjugate, a phenomenon we have occasionally observed with other peptides. The N-terminus was so unreactive that the triconjugate could be obtained as the exclusive product. Nonetheless, the tetraconjugate could be formed by the addition of excess oligomer and extension of reaction times. The stated trend held true for the majority, but not all, of the oligomers that were tested. Oligomers that were very nonpolar overall or that consisted of a nonpolar moiety distal from the site of conjugation resulted in a different trend: Lys14 > Lys3 > Lys27 ≫ Ser1 (Figure 2b). Because other reaction conditions were unchanged, presumably the switch in selectivity is due to nonpolar interactions bringing the active ester of the hydrophobic oligomers proximal to the lysine of the loop region.

Oligomer Design. The objective through these conjugations is to maximize the benefits imparted to the peptide while minimizing perturbation and adverse effects on activity. The effects of the site and extent of conjugation on activity were first addressed using oligomer **2**, a linear oligomer of moderate length and balanced amphiphilicity that has been used effectively with insulin (*21*−*23*). Reactions with this oligomer led to the generation of the mono-, di-, tri-, and tetraconjugates. Oligomer **2** is representative of the Class I (nonhydrolyzable) oligomers, which are designed to remain intact from dosing to target. A series of linear and branched non-hydrolyzable oligomers are shown in Figure 3.

Because the tri- and tetraconjugates using **2** were virtually inactive, we did not know whether the higher conjugates were forbidden or if smaller oligomers would enable the higher conjugates to retain partial activity. To address this question, a series of micropegylated conjugates, which utilize Class II oligomers, were designed. These oligomers retain the amphiphilic properties of the Class I oligomers initially, but are intended to shed the hydrophobic portion before they reach the receptor (Figure 4). To mimic the activity of micropegylated conjugates after hydrolysis in vivo, a series of higher conjugates were prepared using oligomers of minimal size, ranging from one to three PEG units. Figure 5 illustrates the Class II oligomers that were used to make the various micropegylated conjugates. Also depicted are the corresponding oligomers that were intended to model the Class II oligomers after hydrolysis. We do note that the model oligomers end with a methoxy group rather than a hydroxy group. Nevertheless, both the Class II oligomers posthydrolysis and the model oligomers remove the charge of the lysines and contain the same number of ethylene

Table 1. Mapping Results from the Incubation of hBNP or hBNP Conjugates with Lysyl Endopeptidase[a]

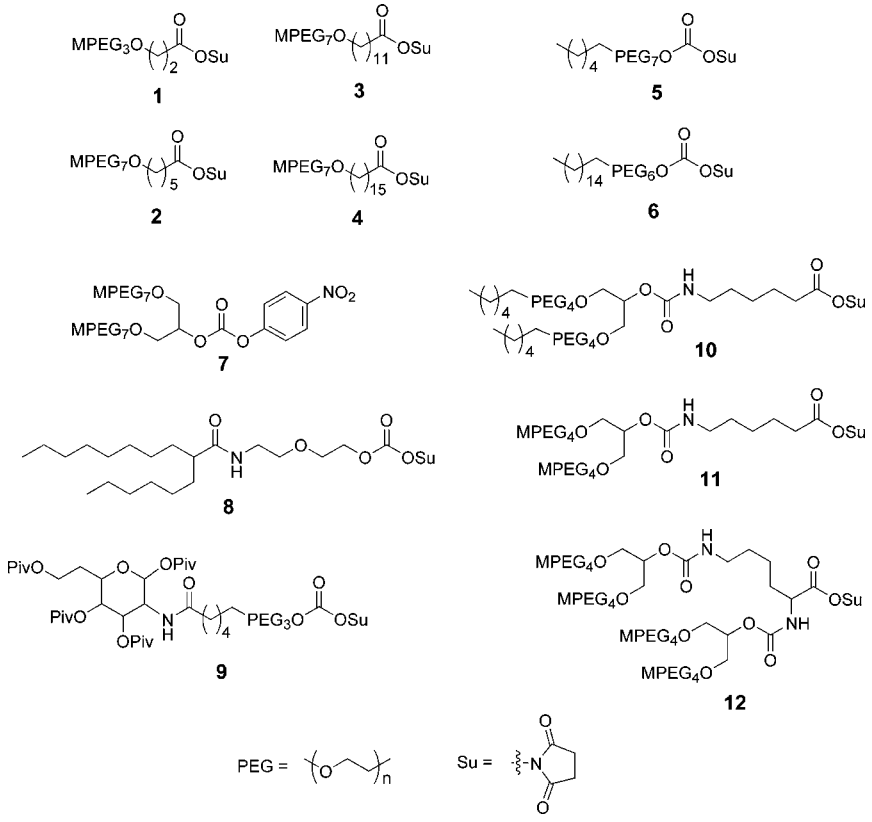

Figure 3. Linear and branched Class 1 oligomers.

glycol units. We therefore regarded them as acceptable models at this stage in screening.

Both the tri- and tetraconjugates were inactive even with the smallest of oligomers, prompting a focus on Lys3 monoconjugates. Even larger Class I oligomers attached at Lys3 resulted in active conjugates; therefore, Class II oligomers offered no advantage for this peptide.

Syntheses of Oligomers. The linear Class 1 oligomers were mostly prepared by similar methods, varying only according to the orientation of the polyetheylene glycol (PEG) and alkyl moieties (Scheme 1 A−C). For oligomers featuring the alkyl moiety inside, the substituted alkanoic acid was first esterified. The monomethoxy PEG (MPEG) was then attached. Depending on availability, either the terminal bromide or hydroxyl (activated as the mesylate) was used. Ester hydrolysis and activation as the succinimidyl ester led to the desired oligomers. The one exception to this group is the oligomer **1**. In this case, the MPEG moiety was coupled to *tert*-butyl acrylate in the presence of sodium catalyst. After deprotection of **25** in neat TFA, the oligomer was activated as previously described.

The oligomers featuring the PEG moiety inside were made by different means. Briefly, the PEG diol was singly protected

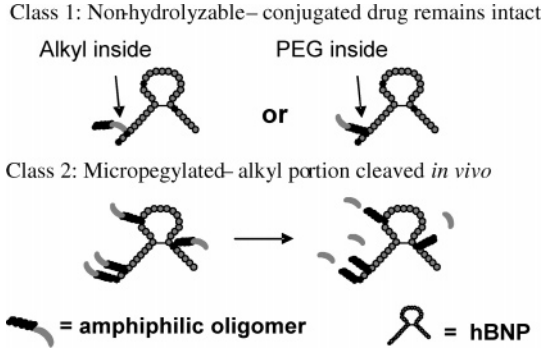

Figure 4. Different categories of oligomers used in the study. Class 1 oligomers had either the PEG or the alkyl moiety proximal to the peptide. Class 2 oligomers all featured the PEG portion proximal to the peptide.

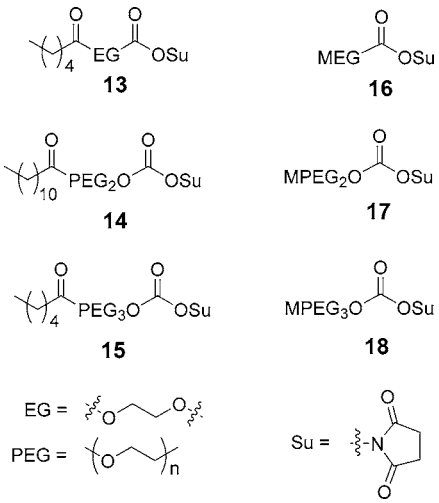

Figure 5. Class 2 oligomers and their corresponding model oligomers.

with a benzyl group. After coupling to an alkyl mesylate, the benzyl group was removed by hydrogenolysis. Subsequent activation afforded the desired succinimidyl carbonate.

The Class 2 oligomers were prepared in like manner. The benzyl PEG was first coupled with the appropriate alkanoic acid chloride. Hydrogenolysis followed by activation with disuccinimidyl carbonate completed the syntheses.

Many of the Class 1 oligomers featuring branched PEGs utilized glycerol as the source of branching. Rather than starting with a poor nucleophile like glycerol itself or a protected glycerol, we found it advantageous to use a good electrophile such as epichlorohydrin (Scheme 2). Our initial attempts to go directly from epichlorohydrin to the branched PEG required reflux conditions and led to undesirable product mixtures. In the stepwise approach, the first epoxide opening proceeded smoothly, but the second epoxide opening using catalytic NaH and refluxing conditions produced low yields and likewise resulted in a mixture of products. However, better yields and cleaner product distributions were attained at ambient temperatures when a Lewis acid catalyst was used for the second epoxide opening. This method worked well with short PEGs, but yields dropped with increasing PEG length.

Activation of the secondary alcohol was accomplished with *p*-nitrophenyl chloroformate, a reagent that proved more suitable than either phosgene or *N*,*N*′-disuccinimidyl carbonate. At this stage, the oligomer could either be conjugated to the peptide directly or be attached to a spacer, such as an ϵ-amino acid. Addition of the amino acid in an aqueous or aqueous/ethanol solution of potassium carbonate afforded the carbamate in good yield. Activation as the succinimidyl ester resulted in the branched amphiphilic oligomer, which could be conjugated to peptides.

In Vitro Activity. To evaluate the activity of each conjugate at the natriuretic peptide receptor A (NPR-A), conjugates were screened using a human aortic endothelial cell (HAEC) system. HAEC cultures contain normal primary aortic endothelial cells and when exposed to hBNP, produce cGMP in a dose-dependent manner. The activity of each of the conjugates was measured by assay of the extracellular levels of cGMP. The impact of the site and the extent of conjugation is well demonstrated by the various conjugates that were made with oligomer **2** (Figure 6). Conjugate **C1** (a Lys3 monoconjugate) retained good activity and potency in comparison to the unconjugated peptide. By contrast, **C7** (a Lys14 monoconjugate) exhibited a partial loss of both activity and potency. When both the Lys14 and Lys 27 positions were conjugated (**C2** and **C3**), the compounds did not induce cGMP production above background levels.

The results for conjugates utilizing Class 1 and Class 2 oligomers are listed in Table 2. In general, the Lys3 monoconjugates consistently performed well in the assay in terms of both potency and activity. The two exceptions were **C18** and **C21**. These conjugates share the trait of having a branched oligomer with hydrophobic portions distal from the site of attachment. It is possible that such oligomers induced a conformational change or aggregation that made them weaker agonists, but this question was not investigated. With those exceptions, oligomers of great variety of structure and size were conjugated to Lys3 while retaining activity comparable to the unconjugated peptide.

[a] The position of conjugation lists the residue numbers to which the particular oligomer was attached. Thus, diconjugates, triconjugates, and tetraconjugates have 2, 3, and 4 numbers, respectively. For C23, C24, and C27, the Lys3 and Lys14 conjugates coeluted during purification. These samples were evaluated as the mixtures of monoconjugates.

For the Class 2 oligomers, the conjugates were tested with and without the alkyl chain attached. It is clearly evident that tri- and tetraconjugates retain virtually none of the activity of the native peptide, even when the smallest oligomers are used. No accurate EC_{50} values could be calculated for these conjugates in the concentration range tested, but the EC_{50} values were greater than 10 000 nM. It was not expected that any of these conjugates would exhibit greater activity or potency than did the native peptide. Rather, we sought conjugates that would have minimal or no adverse effects on activity.

In Vivo Activity after Oral Dosing. Bioactivity studies in healthy dogs are ongoing. In these studies, the effects of acute oral dosing of the hBNP conjugates are being assessed by measuring mean arterial pressure (MAP) and systemic levels of cGMP. To provide indication whether the biochemical and hemodynamic effects are attributable to the exogenous hBNP conjugates or if they could be due to changing levels of natural canine hormones, systemic levels of hBNP conjugate, canine ANP, and canine BNP are being evaluated. Results from the oral dosing of conjugate **C14** have recently been reported (*16*). In this preliminary work, an acute oral dose of **C14** led to a statistically significant increase of cGMP and a statistically significant decrease of MAP. Neither of these parameters differed from baseline levels after an acute oral dose of either placebo or unconjugated hBNP was dosed to healthy dogs. Levels of endogenous canine natriuretic peptides were unchanged in each dosing group. Thus, after oral administration, only the conjugated hBNP led to the biochemical and hemodynamic effects expected from increased levels of a natriuretic peptide.

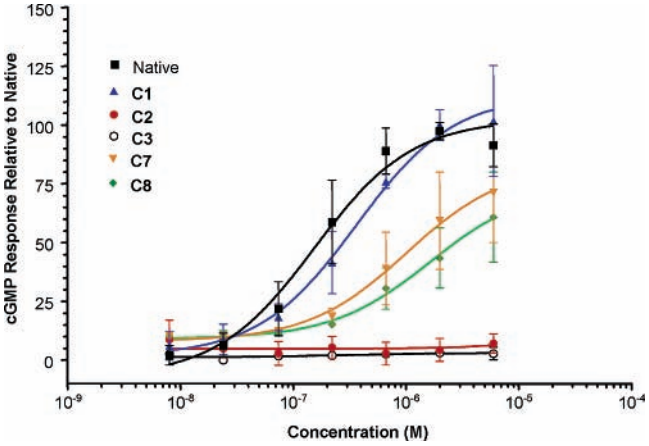

Figure 6. Activity curves depicting cGMP production from HAEC after exposure to conjugates utilizing oligomer **2**. The conjugates differ in site and/or extent of conjugation.

CONCLUSIONS

The cardiac hormone hBNP is a suitable substrate for conjugation technologies. By using the primary amines as sites for conjugation, various monoconjugates, one triconjugate, or one tetraconjugate could be readily obtained depending on the conditions for conjugation. Diconjugates were obtained only as minor products. The amphiphilic balance and the structure of the oligomer had some influence in the regioselectivity of conjugation. The cGMP assay in the HAEC line served as a good in vitro activity screen in our work toward a conjugated hBNP intended for oral administration. Of the oligomers used in this study, conjugation at one of the sites of the loop region (Lys14 or Lys27) resulted in partial agonists. Conjugation at both sites resulted in complete loss of agonist activity, even with the shortest of oligomers. However, conjugation at Lys3 generally resulted in conjugates displaying activity comparable to the native peptide. Some of the active hBNP conjugates are currently being evaluated in vivo and exhibit bioactivity after acute oral administration.

ACKNOWLEDGMENT

Activity of Dendrimer−Methotrexate Conjugates on Methotrexate-Sensitive and -Resistant Cell Lines

Dendritic nanostructures can play a key role in drug delivery, due to the high density and variety of surface functional groups that can facilitate and modulate the delivery process. We have investigated the effect of dendrimer end-functionality on the activity of polyamido amine (PAMAM) dendrimer−methotrexate (MTX) conjugates in MTX-sensitive and MTX-resistant human acute lymphoblastoid leukemia (CCRF-CEM) and Chinese hamster ovary (CHO) cell lines. Two amide-bonded PAMAM dendrimer−MTX conjugates were prepared using a dicyclohexylcarbodiimide (DCC) coupling reaction: one between a carboxylic acid-terminated G2.5 dendrimer and the amine groups of the MTX (conjugate A) and another between an amine-terminated G3 dendrimer and the carboxylic acid group of the MTX (conjugate B). Our studies suggest that conjugate A showed an increased drug activity compared to an equimolar amount of free MTX toward both sensitive and resistant cell lines, whereas conjugate B did not show significant activity on any of the cell lines. Despite substantially impaired MTX transport by MTX-resistant CEM/MTX and RII cells, conjugate A showed sensitivity increases of approximately 8- and 24-fold (based on IC_{50} values), respectively, compared to free MTX. Co-incubation of the cells with adenosine and thymidine along with either conjugate A or MTX resulted in almost complete protection, suggesting that the conjugate achieves its effect on dihyrofolate reductase (DHFR) enzyme through the same mechanism as that of MTX. The differences in cytotoxicity of these amide-bonded conjugates may be indicative of differences in the intracellular drug release from the cationic dendrimer (conjugate B) versus the anionic dendrimer (conjugate A), perhaps due to the differences in lysosomal residence times dictated by the surface functionality. These findings demonstrate the feasibility of using dendrimers as drug delivery vehicles for achieving higher therapeutic effects in chemotherapy, especially in drug-resistant cells.

INTRODUCTION

Polymers have been used as drug carriers due to their ability to release drugs in a controlled manner, prolong circulation times, and increase drug solubility. They have also demonstrated an affinity for preferential accumulation in tumor tissues as a result of enhanced permeability and retention (EPR) effect (*1*−*3*). For cancer therapy, it is desirable to achieve increased efficacy of drugs, enhanced cellular entry, and reduced side effects. To this end, several polymer-based drug delivery methods are being investigated in which the drug is encapsulated, complexed, or conjugated to polymers. Uptake of doxorubicin-PEG-coated liposomes with folate moieties by oral carcinoma KB cells was investigated and found to be 45 times higher than that of nontargeted liposomes (*4*). Several linear polymer−cancer drug conjugates have shown superior in vivo activities compared to those of the free drugs (*5*). The therapeutic effect of adriamycin coupled to *N*-(2-hydroxypropyl) methacrylamide copolymer in rat and mouse models was greater than that of free drug. It was observed that the half-life of the polymer−adriamcyin conjugate was 15 times higher compared to unconjugated drug (*6*). However, the in vitro activities of polymer−drug conjugates have mostly been lower than those of free drugs.

Recently, hyperbranched polymers and dendrimers have found a vast number of applications in delivering drugs and genetic materials into cells (*7*−*16*). Compared to conventional polymers, dendrimers have structural and functional advantages emanating from the multiplicity and additivity effects that can be achieved by manipulating the densely packed end groups. It is possible to encapsulate, complex, or conjugate several molecules onto one dendrimer molecule. At the same time, different entities can be easily attached to these end groups at once to target, treat, and signal. Cancer is one of the applications for these unique nanostructures. Typically, significant amounts of chemotherapeutic agents are lost in the circulation prior to cellular uptake of the drug by tumor cells. Moreover, cellular entry of chemotherapeutic drugs is often the limiting factor for their therapeutic effectiveness. To achieve improved therapeutic effects in the treatment of cancer, it is essential to increase tumor uptake of chemotherapeutic drugs by employing drug delivery vehicles. This study explores the use of dendritic polymers for this purpose.

Conjugation of methotrexate (MTX) and folic acid to hydrazide-terminated dendrimers revealed that MTX and folic acid can be coupled to the dendrimer with conjugation ratios of 4.7 and 12.6, respectively (*17*). In another study, a fifth generation PAMAM dendrimer was used for the synthesis of

nanodevices containing an anticancer drug (MTX), an imaging agent (fluorescein isothiocyanate, FITC), and folic acid (FA) as the targeting agent. The FA-containing conjugate possessing an ester bond between MTX and the dendrimer showed 5 times more cytotoxicity compared to free MTX against the KB cell line overexpressing the folate receptors. Furthermore, an untargeted analogue of this conjugate did not produce any cell growth inhibition in the same cell line (*16*). However, a MTX−dendrimer conjugate with an amide bond showed less activity than free MTX (*18*). In PEGylated PAMAM dendrimers, drug encapsulation efficiency depended on the dendrimer generation number, and the molecular weight of the grafted PEG units. Twenty-six molecules of MTX were encapsulated in the generation-4 PAMAM dendrimer with 63−65 PEG grafts of 2000 as the molecular weight. Since not only dendrimers but also cationic macromolecules can cause cell lysis as a result of destabilization of the cellular membrane, many researchers seek to manipulate the surface charge of these structures. In this respect, drug loading capacity, drug release, and the hemolytic effect of the PEGylated generation-4 PAMAM dendrimer were investigated by encapsulating 5-FU. PEGylation improved the drug loading while reducing the drug release and hemolytic effect (*19*).

The use of either conjugation or encapsulation approaches can change the cellular transport characteristics, pharmacodynamics, and pharmacokinetics of the parent drug, resulting in increased or decreased cytotoxicity, along with altered in vivo distribution. Polyester dendrimer−doxorubicin conjugates showed very slow drug release at neutral pH. On the other hand, a decrease in pH from 7.4 down to 4−6 facilitated drug release from the conjugate due to the pH-labile characteristics of the hydrazone bond. Although the conjugate hampered the cytotoxicity of the drug by 80−98%, it did not demonstrate significant accumulation in vital organs such as liver, heart, and lungs (*20*). PAMAM dendrimer−cisplatin conjugates formed using amide bonds showed 100 times less cytotoxicity against human lymphoblastoid leukemia cell line CCRF-CEM (*21*). In some cases, the drug may not need to be released from the conjugate to inhibit cell growth. Conjugation of MTX to PEG yielded conjugates, which were able to inhibit the activity of its target enzyme dihydrofolate reductase (DHFR) enzyme, even in the conjugated form, in cell-free activity assays. Yet, they were appreciably less active compared to free MTX (*22*).

MTX belongs to the class of antimetabolites. Understanding the mechanism of MTX action can help gain insights into the mode of action of dendrimer−MTX conjugates by employing correct tools. As an antifolate, MTX exerts profound effects on the distribution of intracellular reduced folates that act as cofactors for many of the enzymatic reactions leading to nucleotide biosynthesis. Thus, treatment of tumor cells with MTX inhibits purine and thymidylate biosynthesis, resulting in the inhibition of DNA replication (*23*, *24*). The transformation of MTX to its polyglutamate derivatives, driven by folylpolyglutamate synthase (FPGS), prolongs the retention time of the drug inside the cells (*23*).

Entry of MTX into mammalian cells is significantly restricted because of the charged character of the -COOH groups at physiological pH. Therefore, the contribution of diffusion to net MTX accumulation is nominal. The main uptake route for MTX into mammalian cells is carrier-mediated by the reduced folate carrier (RFC), where the driving force is provided by anion exchange gradients acting as exchange substrates (*25*). However, despite the high affinity of the carrier to MTX, cellular uptake of dianionic MTX by RFC is limited due to the capacity of the transport system and the negative charge of the cells. Moreover, loss of RFC function is a common mode of MTX resistance (*24*, *26*). MTX is highly cytotoxic against not only neoplastic cells but also rapidly replicating healthy cells such as bone-marrow cells. It causes bone-marrow depression, as well as disturbance and inflammation in the gastrointestinal tract, which is serious at high doses (*23*). Thus, to decrease the cytotoxicity of MTX to susceptible normal cells, it is crucial to modify the administered drug dose and schedule and the use of rescue or protection agents such as leucovorin ((6*R*,*S*) 5-formyltetrahydrofolate; 5-CHO-THF) or nucleosides. Additions such as adenosine, thymidine, and hypoxantine are exploited to rescue the cells in a noncompetitive manner (*24*, *27*, *28*). In contrast, leucovorin rescue shows a competitive relationship with MTX due to effects on membrane transport, polyglutamylation, and enzyme binding (*24*, *26*−*28*).

Recently, we have shown that complexes and conjugates of dendrimers with different drugs can be prepared with high drug payloads. The conjugates demonstrated rapid cellular entry and therapeutic activity in A549 human lung carcinoma cells (*10*−*13*). In this study, we report the carbodiimide-mediated conjugation of MTX to PAMAM-G2.5-COOH and PAMAM-G3-NH_2 dendrimers, employing either -NH_2 or -COOH groups of MTX. We investigated the importance of the functional groups involved in the conjugation and the surface charge of the overall conjugate on the cytotoxic activity of the conjugates toward both MTX-sensitive and MTX-resistant cell lines characterized by a nearly complete loss of RFC function. To understand the mechanism of action of conjugated MTX, cellular rescue was performed by co-incubating with adenosine and thymidine nucleosides.

EXPERIMENTAL PROCEDURES

Materials. MTX and leucovorin were obtained from National Cancer Institute (Drug Synthesis and Chemistry Branch, Developmental Therapeutics Program, Division of Cancer Treatment and Diagnosis). Polyamidoamine (PAMAM) dendrimers (generation 2.5 with -COOH end groups and generation 3 with -NH_2 end groups) were purchased from Aldrich Chemical Co. (some physical properties of these polymers as well as those of MTX can be found in Table 1). Other reagents were obtained from assorted vendors in the highest quality available and include *N*,*N*-dicyclohexyl carbodiimide (DCC, Fluka), RPMI 1640 culture medium (Invitrogen), penicillin and streptomycin (Invitrogen), dialyzed fetal bovine serum (Invitrogen), CellTiter Blue cell viability kit (Invitrogen), α-MEM culture medium (Mediatech), Hank's balanced salt solution (Sigma), Dulbecco's phosphate buffered saline (PBS) (Sigma), nucleosides (Sigma), iron supplemented defined bovine calf serum (HyClone), dihydrofolate reductase (DHFR) (Sigma), dihydrofolic acid (DHF) (Sigma), and β-nicotinamide adenosine dinucleotide phosphate, reduced form (β-NADPH) (Sigma). All the solvents used were purchased from Fisher Scientific except HPLC-grade dimethyl sulfoxide (OmniSolv methylsulfoxide) (VWR).

Synthesis of MTX−PAMAM Dendrimer Conjugates. *Scheme for Conjugate A. Conjugation of MTX to PAMAM-G2.5-COOH*. MTX and molar end group equivalent of PAMAM-G2.5-COOH were dissolved in 10 mL of anhydrous DMSO, followed by the addition of a molar equivalent amount of DCC. The reaction mixture was stirred continuously for 72 h at room temperature in the dark. After 72 h, it was filtered to remove dicyclohexyl urea (DCU), and the filtrate was dialyzed against an excess amount of DMSO using membrane (MW cutoff = 3500 Da) for 24 h to remove free MTX and unreacted DCC. The filtrate was vacuum-dried at room temperature to obtain MTX−dendrimer conjugate. The conjugate was formed as a result of the generation of an amide bond between -COOH groups of the dendrimer and -NH_2 group of MTX. This conjugate (conjugate A) was characterized using a Varian 400 MHz spectrometer to estimate the conjugation ratio between

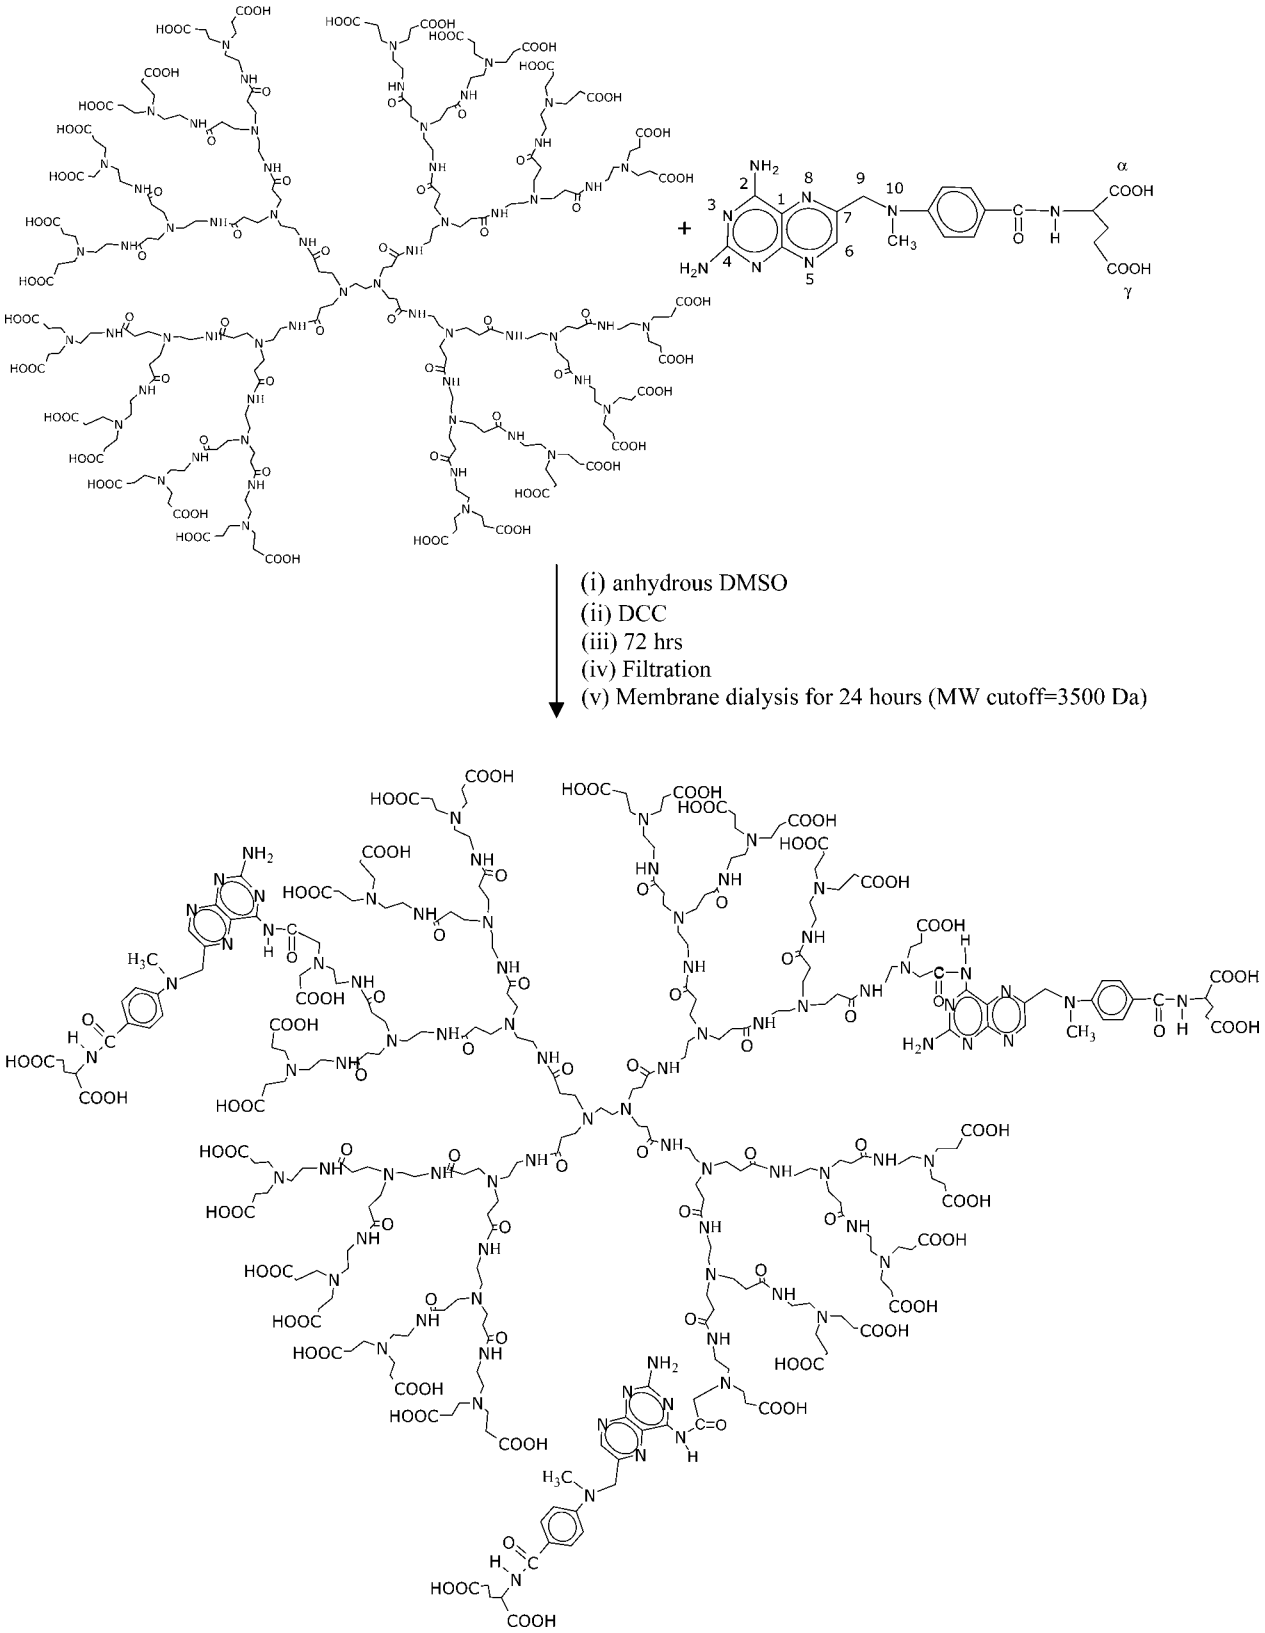

Figure 1. Synthesis scheme for PAMAM-G2.5-COOH-MTX conjugate (designated as conjugate A). (A similar procedure was used to synthesize conjugate B.)

MTX and the dendrimer. Figure 1 summarizes the synthesis scheme followed. ^{1}H NMR spectrum for the conjugate (Supplemental Figure A, Supporting Information) (400 MHz, DMSO-d_6): δ (ppm) 2.31−3.57 (m, 356 H, CH protons of PAMAM, overlapping with 9 H aliphatic singlets of MTX), 6.53 (s, 2 H, aromatic NH_2 of MTX), 6.82 (d, 2 H, aromatic CH of MTX), 7.67 (s, 2 H, aromatic NH_2 of MTX), 7.91 (d, 2 H, aromatic CH of MTX), 4.76 (s, 2 H, CH_2 of MTX), 8.5 (s, 1 H, aromatic CH of MTX).

Scheme for Conjugate B. Conjugation of MTX to PAMAM-G3-NH$_2$. MTX and molar end group equivalent of PAMAM-G3-NH_2 (60 mg, 8.68 μmol, based on 32 end functional groups) were dissolved in 10 mL of DMSO, followed by the addition of a molar equivalent of DCC (57.4 mg, 278 μmol). The reaction

	av mol wt (g/mol)	generation	end functionality	no. of end groups	conjugation ratio (MTX/polymer)	(%) payload
PAMAM-G2.5 dendrimer	6267[a]	2.5	COOH	32	0.40	2.8
PAMAM-G3 dendrimer	6909[a]	3	NH_2	32	4.4	22.4
MTX	454.45	N/A	COOH, NH_2	4	N/A	N/A

[a] Data supplied by Aldrich.

conditions and the purification steps were similar to those mentioned above. Conjugate B was formed as a result of amide bond formation between the -NH_2 groups of the dendrimer and the -COOH group of MTX. ^{1}H NMR spectrum for the conjugate (Supplemental Figure B, Supporting Information) (400 MHz, DMSO-d_6): δ (ppm) 2.18−3.46 (m, 484 H, CH protons of PAMAM, overlapping with 9 H aliphatic singlets of MTX), 6.77 (d, 2 H, aromatic CH of MTX), 7.54 (s, 2 H, aromatic NH_2 of MTX), 7.70 (d, 2H, aromatic CH of MTX), 7.95 (s, 2H, aromatic NH_2 of MTX), 4.76 (s, 2 H, CH_2 of MTX), 8.51 (s, 1 H, aromatic CH of MTX), 4.30 (s, 1 H, aliphatic CH of MTX).

The drug payload in the conjugate was estimated using the proton integration method, by taking the characteristic peaks of MTX and the PAMAM dendrimer into account, as explained elsewhere (*29*−*33*). We estimated the payload of MTX in Conjugates A and B to be 0.4 and 4.4, respectively (Table 1). It is possible that the product might contain unreacted dendrimer along with the successfully conjugated portion. Considering the fact that both of the conjugates have less than five MTX molecules per dendrimer, the separation of reacted and unreacted dendrimer is difficult, due to the restrictions related to mainly molecular weight and altered physicochemical characteristics of the dendrimer upon conjugation. However, extensive dialysis and lack of MTX release from the conjugate suggest that encapsulated MTX should be minimal (as discussed later).

Also, dendrimers and the conjugates were characterized by gel permeation chromatography coupled with Shimadzu LC-10ADVP liquid chromatography equipped with a CTO-10ASVP Shimadzu column oven and MesoPore 300 × 7.5 mm column (Polymer Laboratories) using HPLC-grade DMSO as the eluent at a flow rate of 0.5 mL/min at 35 °C.

MALDI-TOF mass spectrometry was also performed using a Bruker Daltonics Ultraflex matrix-assisted laser desorption/ionization mass spectrometer with time-of-flight mass analyzer (MALDI-TOF) (linear operation mode) for further characterization of the conjugates. For the amine-terminated cationic PAMAM dendrimer, MALDI-TOF proved to be a useful technique showing a strong peak corresponding to 6909 Da as the suggested theoretical molecular weight for this compound. MALDI-TOF analysis of a new batch of conjugate B (prepared using the same procedure, resulting in a slightly higher drug payload) agreed well with the results obtained from ^{1}H NMR (data not shown). This suggests that the ^{1}H NMR and GPC characterization provide a reasonable estimate of the drug payload in the present conjugates.

Cell Cultures. The human lymphoblastoid leukemia wild-type CCRF-CEM cell line and its MTX-resistant counterpart (CEM/MTX) were maintained in RPMI 1640, with iron supplemented fetal calf serum (Hyclone), glutamine (2 mM), penicillin (100 U/mL), and streptomycin (100 μg/mL) at 37 °C in 5% CO_2 atmosphere (*35*−*37*). CEM/MTX cells were supplemented with 500 nM MTX. In additional experiments, Chinese hamster ovary (CHO) cells were used including MTX-resistant MTXRIIOua^{R}2-4 (RII) and RII cells transfected with the human RFC (designated PC43/10) (*38*). CHO cells were grown in α-MEM including serum as previously described (*38*).

In Vitro Cytotoxicity Studies. In vitro cytotoxicity for the CCRF-CEM human leukemic cells (both MTX-sensitive and MTX-resistant), treated either with free MTX or with dendrimer-conjugated MTX, was assessed by direct counting using a hemacytometer. Cells were seeded in 24-well plates at 1.5 × 10^5/2 mL/well in complete RPMI media including 10% dialyzed fetal bovine serum and incubated over 96 h with serial dilutions of either free MTX or conjugated MTX. All experiments were done at least in duplicate.

For CHO cells, a fluorimetric assay was used for measuring drug sensitivities. Cells were plated in duplicate at 4000 cells/200μL/well in a 96-well culture plate in complete RPMI 1640 medium containing dialyzed serum and serial dilutions of MTX or conjugated MTX. Cells were grown for 4 days, and cell viabilities were determined with the CellTiter Blue assay kit. Incubations with the assay reagent were for 4 h, after which the number of viable cells in each well was determined by measuring the fluorescence at 560 nm (excitation) and 590 nm (emission) on a fluorescent multiplate reader. Experiments were performed three times. Cell viability is expressed as the percentage of that obtained for untreated control cells in parallel. For some experiments, cells were treated with free MTX or conjugated MTX along with nucleoside protection agents (60 μM adenosine and 10 μM thymidine), to confirm the antifolate activities of the drugs.

In all the experiments, amounts of conjugated MTX in the MTX−dendrimer conjugates were determined from the conjugation ratios estimated by ^{1}H NMR. The concentrations of conjugates in the incubations were adjusted to maintain equivalent molar amounts of MTX to that for the free MTX treatments.

DHFR Inhibition Assay. The effect of either free MTX or conjugated MTX on the target enzyme, DHFR, was measured in a microplate type of assay where oxidation of NADPH to $NAPD^+$ was followed at 340 nm. Assay mixture contained 0.05 M Tris buffer (pH of 7.5). 20 μL of test compound dissolved in 10 nM PBS to achieve final concentrations of 0−100 nM (or only the solvent for the control well), was added to a reaction mixture of 0.003 units of human recombinant DHFR enzyme expressed in E.Coli and 87 μM NADPH. Reaction mixture was allowed to stand for 5 min at room temperature, which was followed by the addition of 153 μM DHF completing the final volume to 300 μL. The change in the absorbance was measured using kinetic mode with a reading interval of 20 s for the duration of 20 min. Blank reaction rate was determined by processing the absorbance from 2 to 18 min. Comparison of the linear decrease in the same time period in the test wells with the blank well gave the DHFR inhibition activity of the test samples. Results were given as percent inhibition of the enzymatic activity in comparison to the control.

RESULTS

Synthesis and Characterization of Conjugates. MTX contains both α- and γ-COOH groups in the glutamate moiety, as well as -NH_2 groups at the second and fourth positions in the 2,4-diamino-6-pteridinyl group as shown in Figure 1. MTX was successfully conjugated to PAMAM-G2.5-COOH and PAMAM-G3-NH_2 dendrimers using DCC as a coupling agent using a one-pot reaction synthesis scheme. In the past, MTX has been conjugated with -NH_2 terminal dendrimers specifically using -COOH groups. Even though one might argue that in DCC coupling reactions two carboxylic acids can come together to

form acid anhydride as shown over long-chain fatty acids, this formation is highly unlikely in the presence of competitive reactants. Eventually, an amide-bonded conjugate of the dendrimer and the drug is likely (*39*). However, it has been reported that the presence of free -COOH groups, especially at the α-position, is critical for its cytotoxic activity in the conjugated form (*29*, *34*, *40*). Therefore, we decided that it was worthwhile to utilize the -NH_2 group in the pteridine of MTX for conjugation with -COOH terminal groups on the dendrimer, leaving the -COOH groups on MTX free.

The difference in the conjugation ratios of MTX to the dendrimers could be explained by the differences in the reactivities of the -COOH and -NH_2 groups of MTX toward the -NH_2 and -COOH functional groups of each dendrimer, respectively. Also, there are two -COOH groups on MTX readily available for the interaction with amines, which may improve the probability of reaction for conjugate B. As a result, the amine-terminated dendrimer when the -COOH group on MTX was used as the linkage site had higher drug loading. The COOH-terminated dendrimer had lower MTX loading due to lesser reactivity of sterically more stabilized -NH_2 in the 2,4-diamino-6-pteridinyl group of MTX with the dendrimer surface functional groups.

The MTX payload in conjugate B is comparable to that obtained in the literature (*17*, *18*). Even though we did not confirm which of the two -COOH groups in the glutamate moiety of MTX interacts with NH_2 groups of the dendrimer, it is most likely the carboxyl group at the γ-position, since Kono et al. showed that the conjugation of folic acid to hydrazide-terminated dendrimers could occur through its γ-COOH group, which is more reactive toward the amino groups in carbodiimide coupling reactions (*17*). Additionally, conjugation of MTX to human serum albumin occurred mainly through the involvement of the γ-COOH group of MTX (*41*). For conjugate A, it is not clear whether the -NH_2 at the second or the fourth position in the pteridinyl group is used for conjugation, even though the amine group at the fourth position is expected to be involved in the coupling reaction to a higher extent due to lesser sterical crowding. In addition, the feasibility of removing unreacted or encapsulated MTX from end product by dialysis, as well as the stability of the conjugate in DMSO was validated using conjugate B. A known amount of conjugate B dissolved in DMSO was placed in a dialysis membrane with a molecular cutoff size of 1000 Da where the outside phase contained only DMSO. Chromatographic analysis of the samples passing to the outside of the membrane collected over a period of 24 h indicated that a negligible fraction of drug from the conjugate was released from the dialysis bag. This suggests that conjugate is stable, and free MTX in the conjugate was minimal after purification.

Further characterization of the pure dendrimers and the conjugates has been done using gel permeation chromatography (GPC). The elution profiles of cationic PAMAM G3 dendrimer and the corresponding conjugate, measured using the light scattering detector, are displayed in Figure 2. Peak elution volume of the pure dendrimer was observed at 8.32 mL, while it was 8.1 mL for conjugate B. The monomodal nature, and a clear shift toward lower elution volume (and shorter elution times) for the conjugate, suggest the formation of a larger molecular weight object, which is monodisperse. The absence of a peak at 12 mL (peak elution volume for free MTX) for the conjugate is suggestive of the absence of unconjugated MTX in the conjugate (not shown). Conjugate A did not yield an appreciable shift in the elution profiles since it has only 0.4 MTX molecules attached to the dendrimer. Therefore, analysis method is insensitive to such small molecular weight change in the analyte. In these reactions, we expect dimers of MTX to

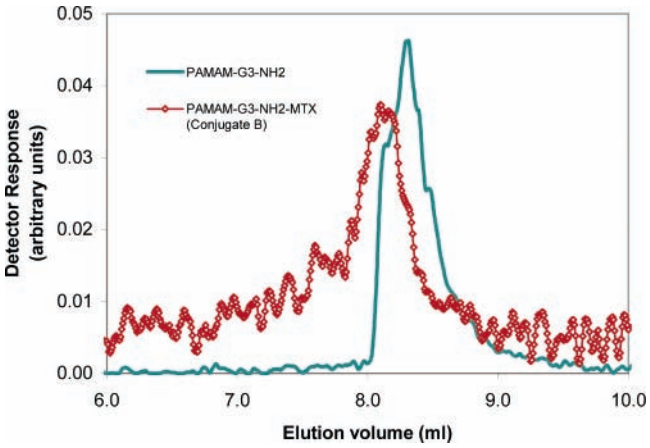

Figure 2. LC-GPC elution profiles of cationic third generation PAMAM dendrimer and the corresponding conjugate with MTX, conjugate B.

be dialyzed out during purification, as evidenced by the lack of additional peaks in GPC near the MTX peak. To improve the yield, we have started pursuing amine/carboxyl group protection approaches to enhance and optimize the conjugation scheme. For this, protection of either carboxyl or amine group of MTX is done by using ethyltrifluoroacetic acid (ETFA) or di-*tert*-butyl dicarbonate (N-boc), respectively.

In Vitro Evaluation of MTX, Dendrimers, and MTX−Dendrimer Conjugates. In vitro growth inhibition activities of free MTX, dendrimers, conjugate A, and conjugate B were investigated initially with the CCRF-CEM and CEM/MTX lymphoblastic leukemia cell lines. Following these initial studies, MTX-resistant and -sensitive CHO cells (designated RII and PC43/10) were studied using a fluorescence-based cell viability assay. Both CEM/MTX and RII cells are characterized by a nearly complete loss of RFC-mediated MTX uptake (*35*−*38*). Whereas a range of MTX and MTX-conjugate concentrations were used for these experiments, the molar equivalents of MTX added to cells were the same regardless of whether the conjugated or free drug forms were used.

In Vitro Cytotoxicity of MTX, PAMAM Dendrimers, and Dendrimer−MTX Conjugates. *In Vitro Cytotoxicities of PAMAM Dendrimers.* The CCRF-CEM and CEM/MTX human lymphoblastic leukemia cell lines (T-ALL) were treated with pure dendrimers (0−6667 nM for PAMAM-G2.5-COOH and 0−1112 nM for PAMAM-G3-NH_2), and growth was assayed as described earlier. These polymer concentrations correspond to the amounts of dendrimer that would be present in the MTX conjugates used for the cytotoxicity experiments.

Neither of the dendrimers showed significant cell toxicity over a wide range of concentrations (not shown). For the PAMAM-G2.5-COOH dendrimer, even at 6667 nM (0.042 mg/mL), more than 90% of the CEM/MTX cells were viable. Similarly, Malik et al. observed that the PAMAM-G2.5-COOH dendrimer did not exhibit any significant toxicity against B16F10 melanoma cells at 2 mg/mL, a much higher concentration than those used in our experiments. They also reported an IC_{50} for PAMAM-G3-NH_2 toward B16F10 cells of 0.05 mg/mL (*42*). The highest concentration used in our studies was only 1112 nM (0.0077 mg/mL). Cell viability of CEM/MTX cells treated with this concentration approached 100% (not shown).

In Vitro Cytotoxicities of Free MTX and Dendrimer−MTX Conjugates. The in vitro activities of MTX and both the conjugates were tested in terms of growth inhibition of human leukemia and hamster ovary cell lines. Figure 3a shows the responses of CCRF-CEM and CEM/MTX cell lines to both free MTX and conjugate A. The IC_{50} values for free MTX in the MTX-sensitive and -resistant (CEM/MTX) cell lines were

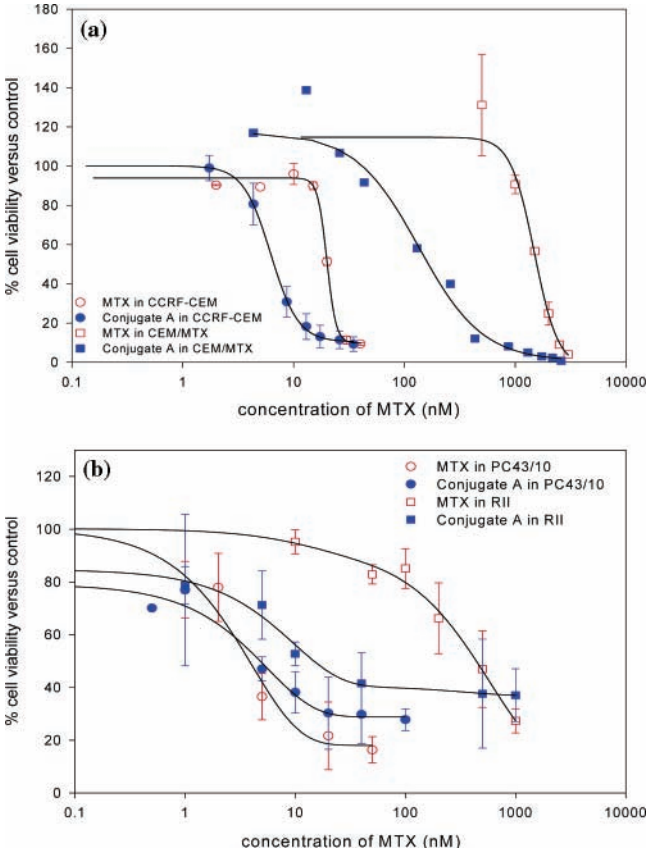

Figure 3. (a) Comparative growth inhibition profiles of free MTX and conjugate A in CCRF-CEM and CEM/MTX cell lines. (b) Comparative growth inhibition profiles of free MTX and conjugate A in RII and PC43/10 cell lines.

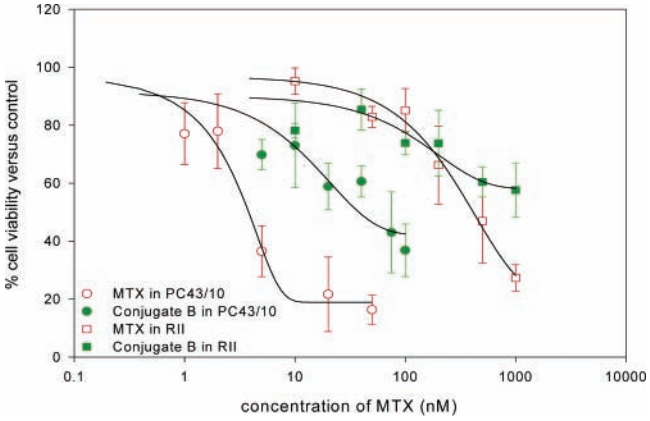

Figure 4. Comparative growth inhibition profiles of free MTX and conjugate B in RII and PC43/10 cell lines.

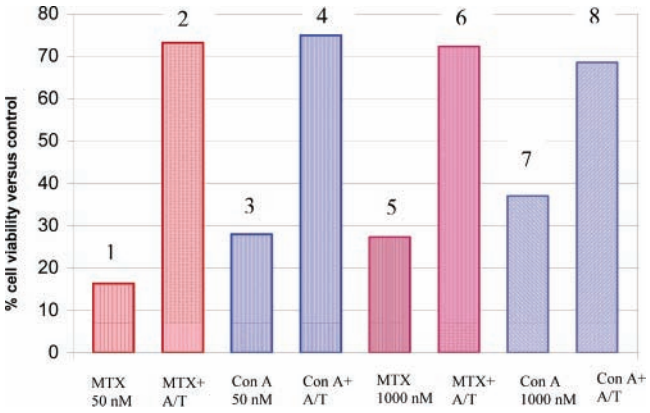

Figure 5. Comparative growth inhibition profiles of free MTX and conjugate A with and without rescue agents (60 μM adenosine + 10 μM thymidine) in RII and PC43/10 cell lines. Bars 1−4: PC43/10 cells; bars 5−8: RII cells.

approximately 20 and 1575 nM, respectively, comparable to the values reported in literature (*22*, *29*, *34*−*37*, *40*). By comparison,
the IC_{50} values for conjugate A (listed in MTX equivalents) in the CCRF-CEM and CEM/MTX cell lines were 6.8 and 206 nM, respectively. Thus, conjugate A is approximately 3-fold more potent than free MTX toward the MTX-sensitive CCRF-CEM cells and approximately 8-fold more potent toward the resistant CEM/MTX cell line.

With the CHO cells, similar in vitro growth inhibition profiles for free MTX and conjugate A were seen (Figure 3b). The MTX-sensitive CHO cells (PC43/10) expressing high levels of human RFC, showed an IC_{50} for free MTX of approximately 4 nM, similar to an earlier report (*38*). Likewise, the IC_{50} for the MTX transport impaired RII cells (420 nM) was only slightly different from the value previously reported by Wong et al. (*38*). Importantly, for conjugate A, an IC_{50} of 5 nM was measured in PC43/10 cells, whereas a value of 17 nM was recorded in the MTX-resistant CHO cell line, an increase of 24-fold over unconjugated MTX.

The conjugate of MTX with PAMAM-G3-NH_2 dendrimer (conjugate B) was also evaluated in terms of growth inhibition activity. For both the CCRF-CEM and CHO cell lines, sensitivity to conjugate B was significantly reduced compared to either MTX or conjugate A. Representative results are shown in Figure 4 for the CHO sublines. For PC43/10 cells, the IC_{50} was increased from that for MTX by about a factor of 10. In RII cells, 65% of maximal growth was seen in the presence of 1000 nM of conjugate B. Similar results were seen in the CCRF-CEM sublines (not shown).

Altogether, these data demonstrate that conjugation of MTX through an -NH_2 group on the pteridine ring in conjugate A results in a more potent growth inhibition than either free MTX or the conjugate formed between the -COOH group on MTX and the -NH_2 on the dendrimer (conjugate B). This was true in both the MTX-sensitive and MTX-resistant cells. Notably, conjugate A was able to significantly circumvent the loss of RFC function in both transport-impaired cell lines.

Long-term incubation of the cells (96 h) ensured the arrest of the cells mainly in S-phase as it is highly cell cycle-dependent. Capture of the cell in this phase prevents DNA synthesis, which will lead to the death of the cells when they are most susceptible to the drug. At the same time, MTX may also interfere with protein synthesis in G_1 phase especially at high concentrations as a result of prevention of amino acid interconversions. Thus, the cells that escaped from cytotoxic activity of the drug during S-phase will succumb due to deprived protein synthesis for a long period of time (*43*). In addition, a 4-day incubation period was found to be the best for the cell model in this experimental system in terms of the cellular viability difference between the control and the treatment wells.

To further investigate the possible mechanism responsible for the growth inhibitory effects of conjugate A, we cultured the CHO cells with the drug (either free drug or in conjugated form) in the presence of a combination of 60 μM adenosine and 10 μM thymidine. Previous studies have shown that individual nucleosides only partially circumvent the cytotoxic effects of DHFR inhibitors such as MTX, while a source of purines and thymidine can significantly rescue cells from antifolate activity of MTX (*27*, *28*). Figure 5 compares the cytotoxic effects of MTX and conjugate A toward PC43/10 and RII cells in the absence and in the presence of nucleosides. As expected, significant protection was seen at 50 nM free MTX

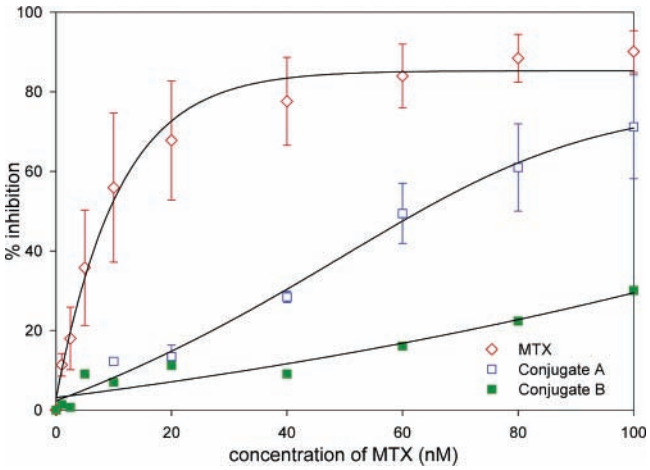

Figure 6. Comparative inhibition pattern of MTX and the conjugates against enzymatic activity of DHFR.

or conjugate A for the sensitive cells, and at 1000 nM MTX or conjugate A for the RII cells.

From these results, it can be concluded that mechanism of action (over 96 h) for the conjugated drug is most likely the same as that for free MTX, namely, via inhibition of DHFR. However, when the cells were supplied with nucleosides, this circumvents the effects on cell growth by bypassing the requirement for reduced folates for the synthesis of necessary nucleotides for de novo synthesis of DNA. In other experiments, 60 μM adenosine and 10 μM thymidine were ineffective in completely rescuing the MTX-sensitive PC43/10 cells from the growth inhibitory effects of conjugate B. The reasons for this response are currently under investigation.

DHFR Inhibition Activities of MTX and the Conjugates. The enzyme inhibition activities of free MTX and the conjugated MTX were evaluated in a cell-free assay (Figure 6). As can be seen from the figure, all three forms of the drug showed concentration-dependent inhibitory activity against the target enzyme. Free MTX showed an IC_{50} value of 7 nM, which agrees with the literature (*29*, *44*, *45*). Conjugate A showed an IC_{50} value of 65 nM, while even at the highest concentration of 100 nM conjugate B was able to circumvent only 30% of the enzyme activity. What is more interesting is that conjugate A inhibited more of the enzyme activity than conjugate B. If MTX were to show inhibitory activity in the conjugated form, one would expect conjugate B more active in a cell-free assay such as this since during the synthesis the enzyme-binding site, which is suggested as NH_2 at the fourth position in the pteridine ring, is left free for the interaction with the target in conjugate B (*46*, *47*). However, in conjugate A this site was occupied by the dendrimer. Therefore, in intact form it is highly unlikely for MTX in conjugate A to get into contact with the binding site in the enzyme and show even higher response than conjugate B. The reason for this difference is under investigation. Most importantly, the activity of the intact conjugates is significantly lower than those of free MTX. Therefore, the improved activity of Conjugate A is not likely because it is intact inside cells.

DISCUSSION

MTX has been coupled to many natural and synthetic carriers mainly in carbodiimide-mediated reactions, resulting in either amide or ester bond formation. Conjugation may inhibit its inherent cytotoxic activity, depending on the nature of the resultant bond as well as the inherent characteristics of the carrier. In our study, we compared two amide-bonded conjugates, where dendrimers with different surface groups were conjugated to distinct functional groups on the drug. Surprisingly, despite the relatively lower drug content of conjugate A (the amide-bonded conjugate between the anionic dendrimer [PAMAM-G2.5-COOH] and the -NH_2 group of MTX), it showed substantially higher cytotoxicity, up to 24 times higher than free drug, in MTX-resistant cells. On the other hand, for the amide-bonded conjugate between the cationic dendrimer (PAMAM-G3-NH_2) and the -COOH group of MTX (conjugate B) cytotoxicity was demonstrably reduced.

The improved cytotoxicity of amide-bonded conjugate A reported here is somewhat unique. Quintana et al. reported that a folic acid targeted MTX conjugate with fifth generation PAMAM dendrimers having an amide bond required approximately 2 times higher drug concentration, while the conjugate having an ester bond was able to reduce the IC_{50} value by 5-fold (*18*). Furthermore, a nontargeted analogue of this conjugate failed to demonstrate any cytotoxic activity on the same cell line. The amide-bonded conjugate of cisplatin with anionic 3.5 generation PAMAM dendrimer was significantly less active than free drug under in vitro conditions (*21*).

The higher growth inhibition activity of conjugate A can be envisaged to be related to three different aspects: (a) cellular uptake, (b) DHFR inhibition mechanisms, and (c) intracellular drug release from the conjugates. The higher antimetabolite activity of the conjugate A toward both of the MTX-resistant cell lines implies that conjugated MTX can be internalized in higher quantities than free MTX in this model. While only a small fraction, less than 5%, of the total amount of extracellular MTX is typically taken up under the normal conditions over several hours (*24*, *25*), a large fraction of dendrimer has been reported to enter A549 cells in as little as 1 h, most likely by fluid phase endocytosis, an internalization route for macromolecules (*10*−*12*). This is in accordance with the literature demonstrating the presence of an efficient uptake mechanism used by various generations of anionic and cationic PAMAM dendrimers in everted rat intestinal system (*15*). Also, recently Pillai et al. studied the different endocytotic pathways used by anionic and cationic PAMAM dendrimers, which are in question here (*48*). It has been shown that while anionic dendrimers appear to be primarily using caveolae-mediated endocytosis, cationic analogues are mostly internalized by clathrin-mediated fluid phase endocytosis. Still both of the dendrimers are taken up efficiently by the cells. Since CEM/MTX and RII cells are severely transport impaired due to loss of RFC (*36*−*38*), such a mechanism involving conjugated MTX could lead to a greater net uptake of MTX, resulting in a disproportionate level of cytotoxicity compared to MTX-sensitive cells. It does appear that dendrimers are effective in facilitating uptake of MTX inside the cells, as is evident from the significantly improved cytotoxicity of conjugate A in the resistant cell lines. In fact, the lack of toxicity of conjugate B is most likely not due to the lack of conjugate uptake but rather due to the surface charge of the dendrimer, which will be discussed later.

It is also likely for the drug to be active in the conjugated form. To evaluate the validity of this hypothesis, we determined DHFR enzyme inhibition activities in cell-free multiplate enzyme binding assays. Our preliminary results suggest that free MTX had an IC_{50} of approximately 7 nM, being the most active form of the drug. On the other hand, conjugates inhibited enzymatic activity to a much lesser extent. If the improved activity of conjugate A is because the conjugated drug is more active, we would expect a lower IC_{50} for the conjugate. Yet, it is a factor of 9 higher. Accordingly, we hypothesize that free MTX is most likely released from conjugate A within cells prior to the enzyme binding to achieve higher growth inhibition compared to the free drug as shown in Figure 3a,b.

In addition, in this current study, we addressed the mechanism of action of the conjugated MTX by employing salvage pathways where adenosine and thymidine nucleosides were used

as purine and prymidine base sources, respectively. For both free MTX and conjugated MTX, cell viabilities were close to 70% or higher in the presence of the nucleosides. This suggests that conjugated MTX in conjugate A still relies on the inhibition of DHFR as its primary target resulting in downstream effects on tetrahydrofolate-dependent reactions leading to synthesis of purines and thymidylate. However, the low level cytotoxicity seen with conjugate B in PC43/10 cells was incompletely reversed by adenosine and thymidine, suggesting a non-DHFR-mediated effect for this conjugate.

The third aspect of intracellular drug release could play a key role. Although we did not investigate the in vitro release of the drug from the conjugates in the absence of cells, we expect them to be stable in the culture media until internalization. Previous work suggested that linear polymer−drug conjugates with ester bonds typically release the drug very fast, up to 80% within in 1 h, showing an increasing amount of the released drug with a decrease in pH from 7.4 to 5.5 (*5*). However, amide-bonded conjugates either do not release the drug at all, or release very small quantities, less than 10%, over a period of 72 h (*5*). Our preliminary drug release studies in DMSO (using a dialysis membrane with 1000 MW cutoff size) showed no spontaneous drug release. This is also supported by the results of Malik et al. on the release profile of generation 3.5 PAMAM dendrimer conjugated cisplatin possessing a similar amide bond. In this study, less than 1% of the conjugated cisplatin was released in two different cell free media with pH of 7.4 and 5.5 (PBS and citrate buffer, respectively), even after incubation times as long as 74 h (*20*).

Since both conjugates are amide-bonded and are likely transported effectively into cells, differences in lysosomal residence times could be responsible for higher or lower activities of the conjugates, as lysosomal enzymes may play a crucial role in the release of free MTX from the conjugates. Preliminary studies involving FITC-labeled anionic and cationic PAMAM dendrimers gave evidence for the differences in the residence times of the dendrimers. The cells treated with 2.5 generation anionic dendrimer showed higher fluorescence intensity in the lysosomal compartments due to Lysotracker Red dye compared to those treated with cationic dendrimer. It can be explained by the displacement of small basic molecules by the macromolecules with highly cationic charge (*49*−*51*). An increase in the lysosomal pH and disruption of lysosomal membrane together called the lysosomotropic effect would be responsible for shorter lysosomal residence time as a result of a H^+ pump process leading to insufficient drug release from conjugate B. On the other hand, conjugate A involving anionic dendrimer may have a better chance to stay in the lysosomes to better interact with proteases, which would lead to higher amounts of released drug. Experiments are underway to address this question, using our dendrimers and confocal microscopy to assess colocalization of the conjugates and a lysosomal marker (Lysotracker Red DND-99) (*49*, *50*).

CONCLUSIONS

DCC conjugation of MTX to anionic and cationic dendrimers, through the formation of an amide bond, yielded conjugates of different characteristics in terms of both drug loading and cytotoxicity. Conjugate A showed significantly improved cytotoxicity in resistant cells (CEM/MTX and RII) compared to free MTX, whereas conjugate B showed relatively little cytotoxicity. The significantly improved activity (up to 24-fold improvement in the IC_{50} values) of the anionic dendrimer−MTX conjugate, even in the resistant cells, is unique. The differences in the activities of the anionic and cationic conjugates is hypothesized to result from the distinct intracellular release profiles of the drug from the conjugates, due the ionic nature of the dendrimer surface. While the present results suggest an augmentation of conjugate A independent of RFC status, for tumor cells that express the folate receptor (e.g., ovarian, cervical, and choriocarcinomas), use of targeting agents such as folic acid may further selectively enhance the level of internalized MTX due to specific accumulation of the nanodevice in tumor versus normal tissues.

Received July 14, 2005; Revised Manuscript Received December 22, 2005

In this paper we present surface modification strategies of boron carbide nanoparticles, which allow for bioconjugation of the transacting transcriptional activator (TAT) peptide and fluorescent dyes. Coated nanoparticles can be translocated into murine EL4 thymoma cells and B16 F10 maligant melanoma cells in amounts as high as 0.3 wt. % and 1 wt. %, respectively. Neutron irradiation of a test system consisting of untreated B16 cells mixed with B16 cells loaded with boron carbide nanoparticles were found to inhibit the proliferative capacity of untreated cells, showing that cells loaded with boron-containing nanoparticles can hinder the growth of neighboring cells upon neutron irradiation. This could provide the first step toward a T cell-guided boron neutron capture therapy.

INTRODUCTION

Boron neutron capture therapy (BNCT) relies critically on methods that can provide a significant ^{10}B contrast between malignant and normal tissue and an absolute ^{10}B concentration in malignant tissue above the therapeutic limit. Following delivery of a boron compound to the tumor, thermal neutrons are used to initiate a nuclear reaction in ^{10}B. In this reaction the main therapeutic effect is obtained by the emitted alpha particle which causes damage to the tissue within 10 μm from the site of the neutron capture. To reduce the damage to normal tissue, specific delivery of ^{10}B to the tumor site is needed. Traditionally, a molecular boron-containing compound, such as boronphenylalanine (BPA), is infused into the patient, resulting in a tumor-to-normal tissue ratio between 3:1 and 4:1 (*1*, *2*). The minimum boron concentration needed in tumor, to obtain a therapeutic effect, is 20−30 μg/g (*3*−*5*). The therapeutic effectiveness of this system is yet to be proven in clinical trials (*6*). The therapeutic efficiency could be improved by optimizing the delivery of boron compounds to the tumor tissue thereby increasing (1) the boron concentration in tumor tissue and (2) the boron contrast between tumor tissue and normal tissue (*7*).

As an alternative to intravenous infusion we suggest the use of boron carbide nanoparticles as a new carrier of ^{10}B (*8*) in conjunction with adoptive immunotherapy, where tumor specific T cells migrate to the tumor site (*9*−*11*). T cell-guided cancer therapy is based on using a patients own immune system to carry a cytotoxic compound to the tumor site (*12*). By loading T cells with boron-containing nanoparticles and re-injecting the loaded T cells into the patient, the boron would be selectively delivered to the tumor by T cells, thereby achieving a high local boron concentration.

A prerequisite in T cell-guided BNCT is thus to initially load a high amount of boron into the T cells. The experimental strategy of the present work has been to achieve this by loading T cells with solid boron-containing nanoparticles.

In traditional drug delivery systems where a molecule is to be internalized into cells, the drug is typically incapsulated into micelles/vesicles or polymeric structures (*13*). Several similar types of coatings have been used to encapsulate nanoparticles: Iron oxide nanoparticles have been coated with lipids (*14*, *15*) or dextran (*16*−*18*), CdSe−ZnS nanoparticles have been coated with peptide derivatives (*19*) and poly(D,L-lactic-*co*-glycolic acid) nanoparticles have been coated with di-*block*-copolymers (*20*).

Furthermore, the attachment of short cationic peptide sequences from the transacting transcriptional activator (TAT) protein derived from human immunodeficiency virus (HIV) have been shown to improve cellular uptake of nanoparticles and liposomes (*21*−*23*).

In this paper we describe various coating strategies based on both covalent binding to the particle surface and association by hydrophobic interaction, which enable labeling of boron carbide nanoparticles with fluorescent dyes and peptides. Details concerning the preparation and characterization of the boron carbide core is described in a recent publication (*24*). Cellular uptake of coated boron carbide nanoparticles were tested using two different cell lines, murine EL4 thymoma cells and B16 F10 melanoma cells. In addition, a test system consisting of particle-loaded and unloaded B16 F10 melanoma cells were used to evaluate the effects of neutron irradiation.

EXPERIMENTAL PROCEDURES

Reagents. Water was Millipore grade and 0.2 μm filtered. Octadecyltrichlorsilane (+90% 10,481-7), sodium hydride (60% in mineral oil, 45,291-2), 1,10-diaminodecane (97%, D1,420-4), polyoxyethylene lauryl ether (Brij30, P4391), sodium hydroxide (R06203), epichlorohydrin (24,069−9), 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylic acid *N*-hydroxysuccinimide (SMCC, M5525), RPMI-1640 × 10 (cat no R1145), HEPES buffer (HO887), L-glutamine (G7513), penicillin/streptomycin (P0781), and sodium bicarbonate (S5761) were purchased from Sigma-Aldrich. Boron carbide (043002) with natural abundance of ^{10}B was purchased from Alfa Aesar and ^{10}B (>96 at. %, B0008-046)-enriched boron carbide was purchased from Eagle Picher Technologies. Dichloromethane,

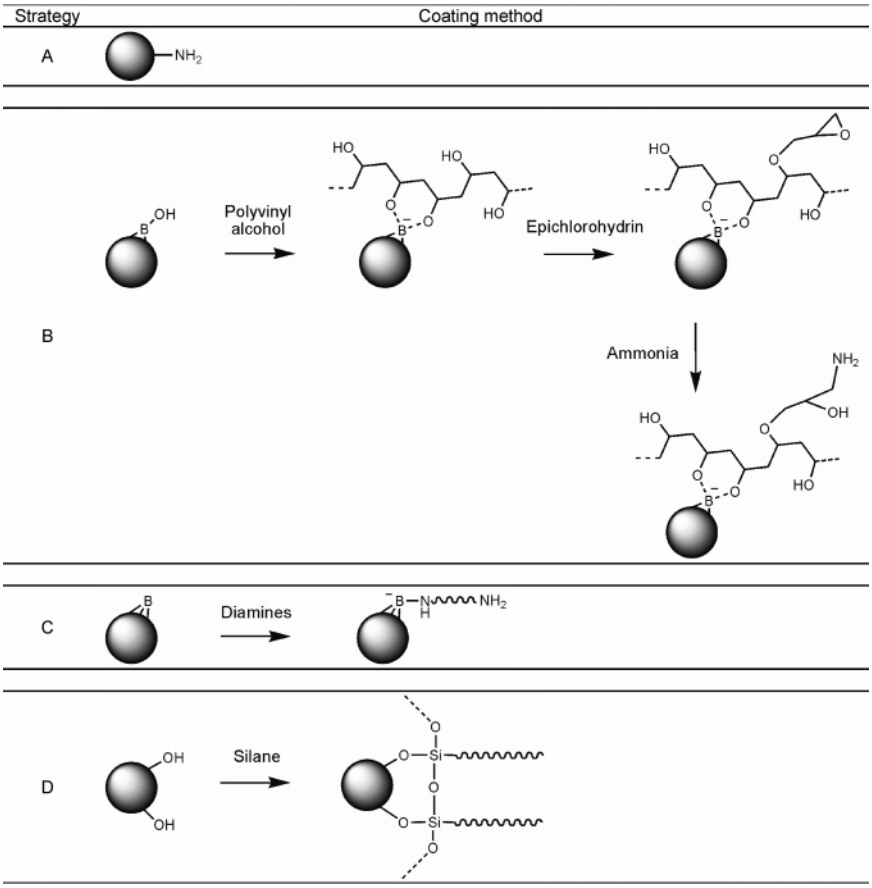
Table 1. Functionalization Strategy[a]



[a] Strategies A−C rely on the introduction of a chemically reactive amino group on the particle surface which could be used as a handle for covalent bioconjugation of dyes and peptides. Strategy A, utilize native surface amino groups. Strategy B, utilize a cross-linked and aminated poly(vinyl alcohol) coating. Strategy C, utilize a 1,10-diaminodecane coating. Strategy D, rely on the introduction of hydrocarbon chains on the particle surface using octadecyltrichlorosilane. Hydrophobic particles could be used as a template for association of amphiphilic molecules by hydrophobic interactions.

chloroform, methanol, toluene, acetonitrile, and dimethylformamide were HPLC grade purchased from LabScan-Analytical Sciences. Ammonia (25% aq) was purchased from Bie & Berntsen. Poly(vinyl alcohol) (PVA, MW 49000, 81383) and dodecyltrimethylammonium chloride (DDTMAC, 44242) were purchased from Fluka. Triethylamine (99%) was purchased from Acros Organics. Sodium Sulfate (1.06649.1000) was purchased from Merck. Two peptides, H-GRKKRRQRRRGY(K-FITC)C-NH_2 (HS-TAT-FITC) and C_{16}-GSGSGRKKRRQRRRGYK(C-FITC)-OH (C_{16}-TAT-FITC) where FITC is fluorescein isothiocyanate were synthesized by Shafer-Nielsen A/S. Rhodamin B sulfonyl chloride (Lissamine, L-20) was purchased from Molecular Probes. 2-Mercaptoethanol (31350−010) was purchased from Invitrogen and fetal calf serum (A15−043) was purchased from PAA Laboratories, GmbH. Cell separation media (CL5031) were purchased from Cedarlane. Sepharose CL4B was purchased from Amersham.

Preparation of Boron Carbide Nanoparticles. Commercially available boron carbide was processed by ball milling in an air, nitrogen, or argon atmosphere in order to reduce the particle size. Details on the preparation of boron carbide nanoparticles with respect to particle size and other physiochemical properties of ball milled boron carbide can be found in ref 24. All coating development studies were conducted on boron carbide with natural abundance of ^{10}B, whereas studies involving irradiation were conducted on enriched boron carbide.

Coating of Nanoparticles. The different strategies (A to D), described below, are summarized in Table 1.

Strategy A. Lissamine (1 mL, 6.45 mg/mL) and triethylamine (0.4 mL) were added to a suspension of boron carbide nanoparticles (40 mg, milled in nitrogen) in DMF (2 mL). The reaction mixture was stirred at RT overnight. The particles were pelleted by centrifugation (Eppendorf miniSpin+, 6 krpm, 5 min), and the supernatant was discarded. The pellet was resuspended in DMF and centrifuged again. The washing procedure was repeated a total of 5 times (×1 with DMF and ×4 with water). The particles were resuspended in water.

Strategy B. Poly(vinyl alcohol) (1.25 g) was dissolved in water (50 mL) by magnetic stirring for 1 h at 70−85 °C. Boron carbide nanoparticles (100 mg, argon milled) were suspended in an aqueous solution of NaOH (10 mL, 0.1 M) and added dropwise to the PVA solution. The suspension was stirred overnight at 70 °C. The suspension was allowed to cool to RT, the particles were pelleted by centrifugation (Eppendorf miniSpin+, 14.5 krpm, 90 s), and the supernatant was discarded. The pellet was resuspended in 0.1 M NaOH and centrifuged again. The washed product was resuspended in 0.1 M NaOH (5 mL). Epichlorohydrin (5 mL) and 2 M NaOH (0.25 mL) was added, and the suspension was stirred at least 4 h. The product was isolated by centrifugation (as described above) and resuspended in water (5 mL). Ammonia (25%) (10 mL) was added to the suspension, and the mixture was stirred at least overnight. The product was purified by successive centrifugation and washing (as described above) with water a total of three times and dried using nitrogen flow. The product (9.96 mg) was suspended in DMF (0.8 mL) whereupon triethylamine (10 μl), lissamine (0.1 mL, 23.9 mg/mL in DMF), and SMCC (0.1 mL, 12.6 mg/mL in DMF) were added. After 1 h the product was purified by successive centrifugation and washing (as described above) a total of four times (×3 DMF and ×1 HEPES

(10 mM)). The pellet was resuspended in HEPES (1 mL, 10 mM) and mixed with the peptide solution HS-TAT-FITC (1 mL, 40 μg/mL in HEPES). The suspension was allowed to incubate overnight, and the product was purified by successive centrifugation and washing with water (as described above) a total of four times. The particles were resuspended in water.

Strategy C. 1,10-Diaminodecane (2.1 g) was added to a suspension of boron carbide nanoparticles (400 mg, argon milled) in dry toluene (75 mL). Sodium hydride (0.6 g, 60% in mineral oil) was added in portions under nitrogen. The reaction mixture was stirred at RT for 30 min, whereupon the reaction mixture was heated to gentle reflux for 72 h. The heating was removed, and the reaction mixture was quenched with water. The hydrophobic product was pelleted by centrifugation, and the supernatant was discarded. The pellet was resuspended in water and centrifuged again. The washing procedure was repeated a total of four times ($\times$1 with water and $\times$3 with methanol). The washed product was dried with nitrogen flow. The product (107 mg) was suspended in acetonitrile (4 mL) by ultrasonication (Misonix Probe Sonicator, pulse time 9 $\times$ 1 s., 6 W) whereupon Lissamine (0.25 mg), SMCC (1.25 mg), and triethylamine (0.2 mL) were added. The suspension was stirred for 24 h at RT in a nitrogen atmosphere. The product was purified by successive centrifugation and washing (as described above) a total of eight times ($\times$3 with water and $\times$5 with acetonitrile) and resuspended in acetonitrile (3 mL). HS-TAT-FITC (0.5 mg) in acetonitrile (1 mL) was added to the suspension, and the reaction mixture was stirred for 24 h. The product was purified by successive centrifugation and washing (as described above) a total of four times ($\times$2 with water and $\times$2 with acetonitrile). The product was ultrasonicated (Misonix Probe Sonicator, 3 s, 6 W) in a suspension of Brij30 (4 mL, 1 mM) and stirred for 24 h. The product was purified by successive centrifugation and washing with water (as described above) a total of four times. The particles were resuspended in water.

Strategy D. Boron carbide nanoparticles (300 mg, air milled) were suspended in methylene chloride (18 mL) using ultrasonication (Misonix Probe Sonicator, pulse time 3 $\times$ 10 s, 0.5 W). Octadecyltrichlorsilane (2 mL) was added to the suspension and stirred at RT overnight. The particles were pelleted by centrifugation (Eppendorf miniSpin+, 14.5 krpm, 5 min), and the supernatant was discarded. The product was resuspended in methylene chloride and centrifuged again. The washing procedure was repeated a total of three times. The product was dried using nitrogen flow. Twenty milligrams of the hydrophobic powder was resuspended by ultrasonication (Misonix Probe Sonicator, pulse time 3 $\times$ 1 s, 0.5 W) in a 995:5 molar mixture of DDTMAC (2.6 mL, 12.42 mg/mL) and C_{16}-TAT-FITC (0.5 mL, 3.44 mg/mL) and stirred at RT overnight. The total detergent solution was $\sim$40 mM. The particle suspension (100 μL) was mixed with a solution of Na_2SO_4 (100 μL, 1 M) and applied on a gel filtration column equilibrated in water (Sepharose CL4B, width 1 cm, height 5 cm, 1 mL fractions were collected). The fractions (3 and 4) containing particles were pooled.

Fluorescence and Dark Field Microscopy of Nanoparticles. A Zeiss axiotech microscope was equipped with a dark field system in order to identify light scattering objects and a fluorescence system in order to identify the fluorophores (filter for FITC: Set 41017, exciter: HQ470/40, emitter: HQ525/50. Filters for rhodamine B: set 41004, exciter: HQ560/55, emitter: HQ645/75. Chroma Technology Corp.).

Loading of Cells with Boron Carbide Nanoparticles. Suspensions (1 mg/mL) of functionalized nanoparticles (prepared using strategy C) were mixed with a 10 x cell culture media master mix. After the addition of cell culture master mix, each milliliter of colloid contained 100 μL of RPMI-1640 x 10, 10 μL of 1 M HEPES buffer, 10 mL of 200 mM L-glutamine, 10 μL of penicillin/streptomycin, 50 μL of 40 mg/mL sodium bicarbonate, 1 μL of 50 mM 2-mercaptoethanol, and 100 μL of fetal calf serum.

This particle suspension was incubated for 1 h at RT to let large particles/aggregates sediment to the bottom of the tube (Since particles prepared according to strategy C were hydrophobic, some aggregates could not be solubilized by Brij30. The simplest way of removing these aggregates was by sedimentation for 1 h). The murine EL4 thymoma cell line (ATCC) was used in exponential growth. The particle colloid (leaving the sedimented aggregates) was finally mixed with the cells resulting in a cell concentration of 1 $\times$ 10^6 cells/mL. The cell/nanoparticle mix was incubated at 37 °C for 4 or 17 h. To remove non-cell-associated particles from the cell suspension lympholyte separation was performed. The samples were centrifuged (10 min at 1300 rpm), and the supernatant was discarded. Cells were washed $\times$2 in Hanks Balanced Salt Solution (HBSS). The cell concentration was adjusted to approximately 5 $\times$ 10^6 cells per mL in HBSS. Lympholyte cell separation media (3 mL) was carefully deposited in a 10 mL centrifugation tube, taking care not to leave droplets of lympholyte on the sides of the tube (in order not to mix the phases in the density gradient). Thereafter, 3 mL of the cell suspension was layered on top of the lympholyte solution using a pipet, taking care to cause as little mixing as possible between the two solutions. The tube was centrifuged for 20 min at 2100 rpm (approximately 1000 g) at RT, no brake. Following centrifugation, the interphase, containing the cells, was carefully collected and transferred to a 50 mL tube containing 25 mL of complete RPMI media. Cells were centrifuged for 10 min at 1200 rpm, the supernatant was discarded, and the wash step was repeated once. Negative control samples, where no particles were added but otherwise handled identically to particle-loaded cells, were referred to as mock-loaded cells.

Fluorescence Microscopy Analysis of Cells. Cells, prepared as described above, and cells without nanoparticles were resuspended in an appropriate volume of growth media and investigated using a Nikon eclipse 80*i* fluorescence microscope (filters: B-2E/C (FITC): ex 465−495, dm 505, ba 515−555, and G-2E/C (TRITC): ex 540/25, dm 565, ba 605/55).

Quantitative Determination of Cell-Associated Boron after Cellular Loading. The boron content of cells loaded with boron carbide nanoparticles (see above) and cell samples without nanoparticles (typically (0.5−2) $\times$ 10^6 cells/sample) was analyzed by Nuclear Research and Consultancy Group (NRG), Petten, The Netherlands, using inductively coupled plasma atomic emission spectroscopy (ICP-AES). The ICP-AES method was verified using boron carbide control samples with a known boron concentration 7.9 $\times$ 10^{-1} μg/g and 7.9 μg/g. The measured boron content in these samples was 8.1 $\times$ 10^{-1} μg/g and 7.9 μg/g, respectively.

Cellular Survival after Irradiation. B16 F10 melanoma cells (ATCC) were loaded with the functionalized nanoparticles followed by lympholyte separation in order to separate free nanoparticles from boron-loaded cells, as described above. The loaded cells were then irradiated at LFR Unit, Institute for Energy in Petten, The Netherlands. All irradiation experiments were done using a thermal neutron flux of 1.26 $\times$ 10^9 $cm^{-2}s^{-1}$, a γ dose rate of 0.02717 Gy min^{-1}, and a fast neutron dose rate of 0.00650 Gy min^{-1}. The cells were either left unirradiated or were irradiated for 5 or 10 min. Furthermore, the boron nanoparticle-loaded cells were either irradiated themselves or mixed with untreated B16 melanoma cells (1:2 ratio) before irradiation. After irradiation, the cells were pelleted by cen-

(B) As recorded images of functionalized boron carbide nanoparticles, rhodamine filter (left), fluorescein filter (center), and dark field (right).

trifugation, the medium was changed, and the cells were resuspended in fresh complete cell culture medium.

The survival of cells after irradiation was determined by following the proliferative capacity of the cells. In brief, 2 (or 2.5) $\times$ 10^4 cells/well were plated in the top wells of 96-well plates, and 2-fold dilutions were performed, leaving the final row without cells. Total volume in wells was 200 μL. The cells were incubated for 48 h at 37 °C, and during the last 6 h, the cells were pulsed with 1 μCi ^{3}H-thymidine/well. The cells were harvested using a semiautomated sample harvester, and the ^{3}H-thymidine incorporation was measured in a β-scintillation counter.

RESULTS AND DISCUSSION

Dark Field and Fluorescent Microscopy of Nanoparticles. An optical setup based on dark field microscopy was used to investigate the light scattering properties of boron carbide nanoparticles, (see Figure 1A). Boron carbide nanoparticles were found to be strong scattering objects when subjected to a standard 50 W halogen lamp. This method could therefore be used to monitor the position of a single boron carbide nanoparticle. To monitor the fluorescent labels, a fluorescence setup was installed with appropriate filters for monitoring fluorescein (FITC) and rhodamin B (Lissamine). By simply switching between the dark field light source and the fluorescence excitation source, fluorescence was seen to be correlated with scattering intensity (see Figure 1B). This method was used to evaluate if a fluorescent dye was associated with a nanoparticle.

Surface Functionalization. To achieve covalent bioconjugation to the particle surface, a chemically reactive group needs to be present on the particle surface. This functionality could either be a native chemical group on the surface of the particle or be introduced by first coating the particles with another species containing the desired functionality. The strategies suggested here (Table 1A−C) focus on the introduction of chemically reactive amino groups which could be used for covalent bioconjugation of dyes or peptides.

The amino reactive fluorophore, Rhodamine B sulfonyl chloride (lissamine), was used to covalently label the nanoparticles with a fluorescent dye and the bifunctional linker 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylic acid *N*-hydroxysuccinimide (SMCC) was used to couple a cysteine-containing peptide sequence (HS-TAT-FITC, the peptide sequence was labeled with a FITC fluorophore) to a surface-bound amino group.

Strategy A (Table 1 A) was based on covalent coupling to the uncoated boron carbide surface, since nanoparticles prepared by ball milling in an nitrogen-containing environment (*24*) were tested positive for ninhydrin, i.e., an indication of surface bound amino groups. (The formation of amino groups was most likely related to high chemical reactivity of newly exposed surface atoms in boron carbide during the milling process). Boron carbide nanoparticles could however not be labeled with lissamine, leading to the conclusion that the amino groups on the surface had too low reactivity for covalent bonding.

Strategy B (Table 1 B) was based on poly(vinyl alcohol) (PVA) as a coating material due to the fact that diol-containing species are known to form complexes with boric acid/borate ions in solution (*25*); hence, boric acid/borate surface groups could form similar complexes. The particles were first coated with PVA, and the adjunct polymer hydroxy groups were cross-linked using epichlorohydrin. Amino groups were finally introduced in the polymer by treating unreacted epoxy groups with ammonia according to Wunderbaldinger et al. (*26*). The polymer-coated nanoparticles were successfully labeled with Lissamine. Furthermore, the HS-TAT-FITC peptide was accordingly coupled to the aminated polymer surface using SMCC.

Strategy C (Table 1C) was based on 1,10-diaminodecane as a coating material. The mechanism of the covalent bond formation between deprotonated 1,10-diaminodecane and the boron surface was believed to be based on the reaction between a Lewis acid and a Lewis base. Boron, being electron deficient, will tend to acquire an electron pair from an electron donor such as 1,10-diaminodecane. The diamine-coated particles were successfully labeled with Lissamine and HS-TAT-FITC using the SMCC cross-linker. The water solubility of these particles was regulated using an amphiphilic polyoxyethylene lauryl ether (Brij30) solution.

Association of amphiphilic molecules using hydrophobic interactions were also investigated, as an alternative to covalent bioconjugation. This strategy was based on introducing hydrocarbon chains on the surface making the particles hydrophobic (Table 1D). By mixing hydrophobic particles with amphiphilic molecules in an aqueous solution, the amphiphilic molecules (such as the TAT peptide derivatized with a hydrocarbon tail C_{16}-TAT-FITC) could be expected to associate with the hydrophobic particle surface, due to hydrophobic interactions.

Strategy D (Table 1D) was based on octadecyltrichlorosilane as a coating material. The binding mechanism between octadecyltrichlorosilane (OTS) and the boron surface is believed to be silylation whereby a chlorosilane group Si−Cl reacts with a surface hydroxy group. In addition, hydration of Si−Cl to Si−OH and subsequent condensation reactions between silanol groups will result in the formation of a Si−O−Si network on the particle surface. By adding the hydrophobic particles to a solution of amphiphiles, the particles were solubilized in a mixture of dodecyltrimethylammonium chloride (DDTMAC) and C_{16}-TAT-FITC, thereby associating the TAT peptide sequence with the particles by hydrophobic interaction.

Covalent coupling of fluorescent dyes and peptides (strategies B and C) were preferred for cellular uptake experiments since the fluorescence intensity could then directly be interpreted as particle uptake, hence eliminating the risk of false positives due to desorption of fluorescent species which had not been covalently bonded to the particle surface. On the basis of initial uptake experiments the 1,10-diaminodecane-coated boron car-

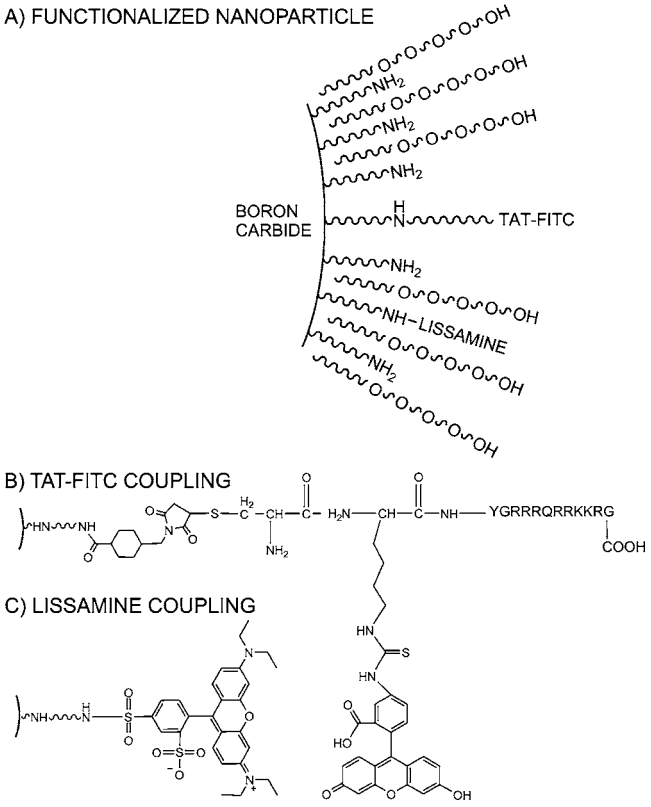


Figure 2. Sketch of functionalized boron carbide nanoparticle, according to strategy C, used for cellular uptake experiments. (A) The overall surface coating including Brij30 amphiphiles, (B) the specific HS-TAT-FITC coupling, and (C) the specific Lissamine coupling.

bide nanoparticle (Table 1 C) showed the best cellular uptake compared to the PVA-coated particles. A detailed sketch of the fully functionalized nanoparticle used for cellular uptake experiments is shown in Figure 2. Fully functionalized nanoparticles were inspected by fluorescence microscopy, just after completion of the synthesis and again just before cellular loading, to verify the stability of the conjugated species.

Cellular Loading with Boron-Containing Nanoparticles As Determined by Fluorescence Microscopy and Inductively Coupled Plasma Atomic Emission Spectroscopy. Analysis of cells by fluorescence microscopy following particle-loading revealed a significant fluorescent labeling of the cells. As seen in Figure 3B, cellular loading of EL4 T cells with the nanoparticles (particle-loading overnight), followed by lympholyte separation, resulted in a profound cell-associated lissamine signal, indicating particle-loading of the cells. Mock-loaded (handling of cells identical to particle-loaded cells, but without particles) cells did not result in any lissamine signal (Figure 3D). Figures 3A and 3C show the corresponding particle-loaded (A) and mock-loaded (C) cells using bright field instead of fluorescence microscopy.

Although fluorescence microscopy is an illustrative way of showing particle-loading of cells, it is a qualitative method of analysis and an indirect way of showing the presence of cell-associated boron. To formally prove the presence of cell-associated boron, the cell samples were further analyzed by ICP-AES to determine the boron content (Table 2). These analysis showed that the particle-loaded EL4 cell samples contained approximately 2.7−2.8 μg/g boron (correspond to approximately 0.8−1.8 pg/cell), whereas the concentration of boron in the mock-loaded cell samples was 0.024−0.085 μg/g (Table 2 column 4). Comparing to EL4 cells, the boron uptake in B16 melanoma cells was much higher (5−40 pg/cell). The boron uptake per cell (pg/cell) was calculated using the mass of the sample, the boron concentration of the sample determined by ICP-AES, and the number of cells in each sample. To make sure that the lympholyte separation did work properly, i.e., that free boron nanoparticles were not situated in the interphase where the cells are collected after the centrifugation, a control sample with particles only (no cells) was included in the experiment and went through the complete experimental procedure (Table 2, column 5). The boron concentration of these control samples was under the detection limit of 0.07 μg/g, strongly indicating that the measured boron after cellular loading is cell-associated. The highest boron content obtained in EL4 cells was thus ∼0.3 wt % and ∼1 wt % for B16 cells.

The Effect of Irradiation of Boron Nanoparticle-Loaded Cells. As a first step of evaluating our nanoparticles as an agent for BNCT, murine B16 melanoma cells were loaded with the nanoparticles and subsequently irradiated for either 5 or 10 min or left unirradiated. Two experimental setups were tested: (1) irradiation of particle-loaded B16 cells alone and (2) irradiation of a mixture of particle-loaded B16 cells and untreated B16 cells. Following irradiation, the proliferative capacity (viability) of the cells was analyzed by measuring ^{3}H-thymidine incorporation. The first approach, irradiating boron-loaded cells only, would simply tell us whether we induced cell death following irradiation of particle-containing cells. The latter approach would provide us with the information whether irradiation of nanoparticle-containing cells may induce cell death of unloaded cells that are situated in close vicinity to nanoparticle-containing cells.

Figure 4A shows the proliferative capacity after irradiation of particle-loaded B16 cells (∼5 pg/cell) compared to unloaded cells. As seen in the figure, the proliferation of particle-loaded cells is significantly inhibited after irradiation whereas particle-loading per se (no irradiation) does not seem to inhibit the proliferation significantly. Furthermore, no proliferative inhibition is observed following irradiation of mock-loaded or untreated B16 cells, strongly indicating that the proliferative inhibition of particle-loaded B16 cells is the effect of α-particles generated from ^{10}B during irradiation.

Moreover, irradiation of a mixture of particle-loaded (∼40 pg/cell) and untreated B16 cells (cell ratio 1:2) showed that also unloaded cells situated in close vicinity to particle-loaded cells where affected and a significant proliferative inhibition of these cells was observed (Figure 4B, right). As expected, irradiation of a mixture of mock-loaded and untreated B16 cells did not significantly affect the proliferative capacity (Figure 4B, left).

In conclusion, by introducing chemically reactive amino groups using coating strategies B and C, translocation peptides and fluorescent dyes were covalently coupled to the boron

Table 2. Cellular Uptake of Boron Carbide Nanoparticles Prepared Using Method C[a]

		boron concentration in sample measured by ICP-AES [μg/g]			boron content per cell [pg/cell]	boron concentration in cells [wt %]
cell type	incubation time	particle loaded	mock loaded	lympholyte interface	particle loaded	particle loaded
EL4	4 h	2.7	0.085	0.022	1.8	0.34
EL4	o.n.[b]	2.8	0.024	0.051	0.8	0.15
B16	o.n.	5	0.075	-	5	0.12
B16	o.n.	15	0.085	-	40	0.95

[a] Boron uptake in EL4 T cells and B16 melanoma cells using boron carbide nanoparticle-coated using Strategy C. The boron concentration, measured by ICP-AES, in each sample (particle-loaded, mock-loaded and Lympholyte interphase) is listed in columns 3, 4, and 5. The boron content in particle-loaded cells (column 6) were calculated using the boron concentration determined by ICP-AES of a sample with known mass and the number of cells in each sample. The boron concentration in a particle-loaded cell was estimated by calculating the mass of a cell using the size (diameter of EL4 $\sim$ 10 μm, diameter of B16 $\sim$ 20 μm) and density ($\sim$1 g/cm^3) of a cell (See column 7). [b] o.n.: overnight.

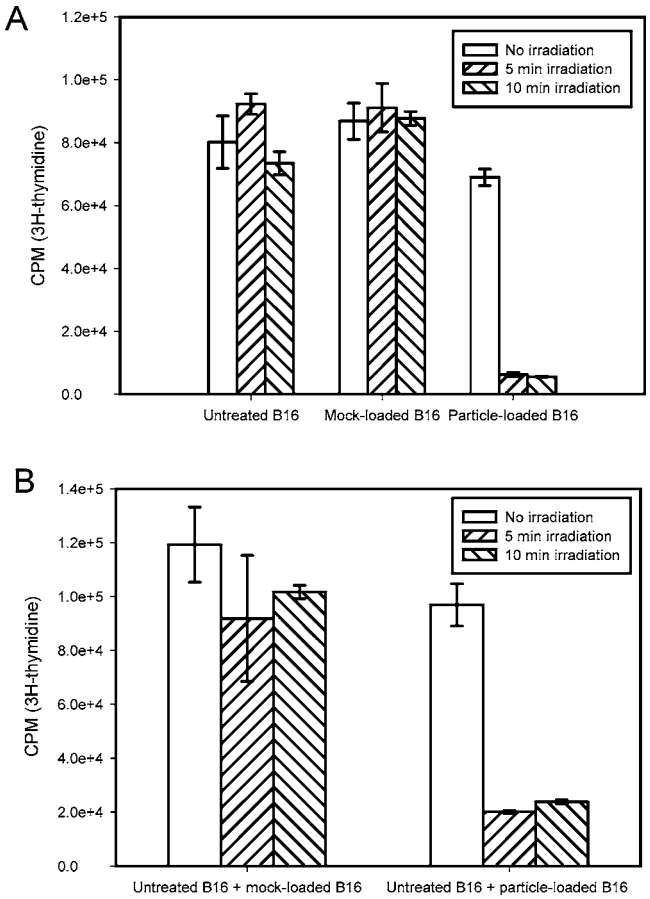

Figure 4. Irradiation of B16 melanoma cells. (A) The proliferative capacity of untreated B16, mock-loaded B16, and particle-loaded B16 cells evaluated by thymidine uptake. (B) The proliferative capacity of untreated cells mixed with mock-loaded B16 cells and untreated cells mixed with particle-loaded B16 cells evaluated by thymidine uptake. Error bars represent standard deviations (SD) on a triplicate analysis ($N = 3$).

carbide surface. As an alternative to covalent binding, association by hydrophobic interactions were also found to be a feasible method to associate amphiphilic molecules with hydrophobic particles (strategy D). Boron carbide particles modified according to strategy C resulted in a cellular boron loading of 0.3 wt % in EL4 cells and 1 wt % in B16 cells. The proliferative capacity of particle-loaded B16 cells was significantly inhibited upon neutron irradiation. More importantly the proliferative capacity of untreated cells in close proximity to particle-loaded cells was also significantly inhibited. The prerequisites for T cell-guided BNCT were initial high loading of T cells with ^{10}B (as demonstrated here using EL4 cells) and the effective killing of neighboring unloaded cells (as demonstrated here using B16 melanoma cells). Both of these goals were achieved using derivatized boron carbide nanoparticles and therefore conceptionally prove that these particles may be used for T cell-guided BNCT.

ACKNOWLEDGMENT

We would like to acknowledge A. B. Petersen for fruitful discussions concerning organic synthesis and R. Huiskamp (Nuclear Research and Consultancy Group (NRG), Petten, The Netherlands) for fruitful discussions concerning BNCT.

Paclitaxel-Loaded Poly(γ-glutamic acid)-poly(lactide) Nanoparticles as a Targeted Drug Delivery System against Cultured HepG2 Cells

Hsiang-Fa Liang,[†] Sung-Ching Chen,[†] Mei-Chin Chen,[†] Po-Wei Lee,[†] Chiung-Tong Chen,[‡] and Hsing-Wen Sung*[,†]

Department of Chemical Engineering, National Tsing Hua University, Hsinchu, Taiwan, R.O.C., and Division of Biotechnology and Pharmaceutical Research, National Health Research Institutes, Taipei, Taiwan, R.O.C.. Received July 19, 2005; Revised Manuscript Received December 20, 2005

The study was to develop paclitaxel-loaded formulations using a novel type of self-assembled nanoparticles that was composed of block copolymers synthesized from poly(γ-glutamic acid) and poly(lactide) via a simple coupling reaction. The nanoparticles (the NPs) were prepared with various feed weight ratios of paclitaxel to block copolymer (the P/BC ratio). The morphology of all prepared nanoparticles was spherical and the surfaces were smooth. Increasing the P/BC ratio significantly increased the drug loading content of the prepared nanoparticles, but remarkably reduced the drug loading efficiency. The release rate of paclitaxel from the NPs decreased significantly as the P/BC ratio increased. For the potential of targeting liver cancer cells, galactosamine was further conjugated on the prepared nanoparticles (the Gal-NPs) as a targeting moiety. It was found that the activity in inhibiting the growth of HepG2 cells (a liver cancer cell line) by the Gal-NPs was comparable to that of a clinically available paclitaxel formulation, while the NPs displayed a significantly less activity. This may be attributed to the fact that the Gal-NPs had a specific interaction with HepG2 cells via ligand−receptor recognition. Cells treated with distinct paclitaxel formulations resulted in arrest in the G2/M phase. The arrest of cells in the G2/M phase was highly suggestive of interference by paclitaxel with spindle formation and was consistent with the morphological findings presented herein. In conclusion, the active targeting nature of the Gal-NPs prepared in the study may be used as a potential drug delivery system for the targeted delivery to liver cancers.

INTRODUCTION

The toxicity of anticancer drugs to normal tissues limits the development of chemotherapeutic agents for the treatment of cancers. Various drug carriers have been investigated to reduce the toxicity and increase the therapeutic efficacy of anticancer drugs (*1*−*4*). The pharmaceutical applications of self-assembled nanoparticles have recently attracted considerable attention (*5*). The self-assembled nanoparticles, composed of amphiphilic block copolymers, have a hydrophobic inner core and a hydrophilic outer shell.

In our previous study, poly(γ-glutamic acid) (γ-PGA) and poly(lactide) (PLA) were used to synthesize amphiphilic block copolymers via a simple coupling reaction to prepare a novel type of self-assembled nanoparticles (*6*). γ-PGA, a natural compound, is produced as capsular substance or as slime by members of the genus *Bacillus* (*7*). It is uniquely composed of naturally occurring L-glutamic acids linked by amide bonds. It is known that γ-PGA is water-soluble, biodegradable, nontoxic (*7*), and relatively nonimmunogenic (*8*). In our previous stability study, no aggregation or precipitation of the nanoparticles was observed during storage for up to 1 month, since it was prevented by the electrostatic repulsion between the negatively charged nanoparticles (*6*).

The aim of this study was to develop paclitaxel-loaded formulations using the aforementioned nanoparticles that were composed of amphiphilic γ-PGA-PLA block copolymers. Galactosamine was further conjugated on the prepared nanoparticles as a targeting moiety to develop the potential of targeting liver cancer cells. The unique structure of paclitaxel enables it readily to enter mammalian cells and preferentially bind to tubulin in polymerized microtubules (*9*). This stabilizes microtubules and greatly interferes with microtubular reorganization necessary, among other processed, for spindle formation and cell division (*10*). Therefore, the exposure of susceptible cells to paclitaxel has been shown to arrest the G2/M phase initially and finally cause cell death through apoptosis (*11*).

However, the hydrophobicity of paclitaxel raises great difficulties in the preparation of formulations. Many research groups and pharmaceutical companies have endeavored to develop better and improved paclitaxel formulations that are suitable for different applications (*12*). Even though paclitaxel is mainly prescribed to treat breast and ovarian cancers, it is known that various cancer cells including hepatoma cells can be killed effectively by this drug (*13*, *14*).

In this study, the effects of the feeding ratio of drug to copolymer on the distribution of particle sizes, the zeta potential, the drug loading content, and the drug loading efficiency of the prepared nanoparticles and their in vitro release profiles were evaluated. The morphology of the prepared nanoparticles was examined by the transmission electron microscopy (TEM) and the atomic force microscopy (AFM). Additionally, the cytotoxicity of the prepared nanoparticles with or without galactosamine conjugated on HepG2 cells (a liver cancer cell line) was compared to that of a clinically available paclitaxel formulation in vitro. The effect of the prepared nanoparticles on the cellular microtubules and the restriction of HepG2 cells in specific cell cycle stages was investigated using a confocal laser scanning microscope (CLSM) and a flow cytometer.

obtained from Sinphar Pharmaceutical Co., Ltd. (Taipei, Taiwan). PLA [poly(L-lactide), M_n: 10 kDa, with a polydispersity of 1.1 determined by the GPC analysis] was kindly supplied by the Biomedical Engineering Center, Industrial Technology Research Institute (Hsinchu, Taiwan). Dimethyl sulfoxide (DMSO < 0.01% water), *N*,*N*′-carbonyldiimidazole (CDI, 98%), and dichloromethane were acquired from Fluka (Buchs, Switzerland). L-Glutamic acid (purity > 99%), *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide (EDC), *N*-hydroxysuccinimide (NHS), galactosamine, and sodium cholate were purchased from Sigma (St. Louis, MO). 4-(Dimethylamino)pyridine (DMAP) and 1,4-dioxane were obtained from ACROS (Janssen Pharmaceuticalaan, Belgium). All other used chemicals were reagent grade.

Production of γ-PGA. γ-PGA (Figure 1) was produced by *Bacillus licheniformis* (ATCC 9945, Bioresources Collection and Research Center, Hsinchu, Taiwan) and purified as per a method reported by Yoon et al. with slight modifications (*15*). Details of the methodology were reported in our previous publication (*6*).

Hydrolysis of γ-PGA. The average molecular weight (M_n) of the purified γ-PGA obtained via the previous fermentation procedure was about 320 kDa. The purified γ-PGA was then hydrolyzed in a tightly sealed steel container at 150 °C for specified durations (*16*). The average molecular weight along with the polydispersity of the hydrolyzed γ-PGA were determined using a gel permeation chromatography (GPC) system equipped with a series of PL aquagel-OH columns (one Guard 8 μm, 50 × 7.5 mm and two MIXED 8 μm, 300 × 7.5 mm, PL Laboratories, UK) and a refractive index (RI) detector (RI2000-F, SFD, Torrance, CA). Poly(ethylene glycol) (molecular weights of 106−22000 g/mol) and poly(ethylene oxide) (with molecular weights of 20000−1000000 g/mol) standards of narrow polydispersity (PL Laboratories, UK) were used to construct a calibration curve. The mobile phase contained 0.01 M NaH_2PO_4 and 0.2 M $NaNO_3$ and was brought to a pH of 7.0. The flow rate of the mobile phase was 1.0 mL/min, and the columns and the RI detector cell were maintained at 30 °C.

Synthesis of γ-PGA-PLA Block Copolymers. Block copolymers composed of γ-PGA and PLA were synthesized using CDI to activate the terminal hydroxyl group of PLA (*17*). CDI (82 mg) was dissolved in 1,4-dioxane (20 mL) in a nitrogen atmosphere and PLA (0.1 g) was subsequently added to the solution. The clear solution was stirred at 37 °C for 2 h. Afterward, the solution was dialyzed extensively against deionized water at 4 °C. Finally, the activated PLA was obtained via centrifugation.

The acidified form of the hydrolyzed γ-PGA (10 mg, M_n ~4 kDa, PDI = 1.3) was dissolved in DMSO (5 mL) in a dry, stoppered 20 mL round-bottomed flask in a nitrogen atmosphere. After DMAP (3 mg) was dissolved, a calculated amount of activated PLA (25 mg) was added. The solution was stirred at room temperature for 3 days, after which the reaction was stopped by adding 0.1 mL of concentrated HCl to neutralize DMAP and imidazole. The reaction mixture was transferred to a dialysis tube (MWCO: 6000−8000), followed by dialysis for 2 days against deionized water for several times at 4°C to remove the un-conjugated γ-PGA. Additionally, the un-conjugated PLA was separated due to its self-precipitation. Finally, the product was lyophilized and stored at −20 °C until used. The molecular weight distribution of the synthesized block copolymers was determined using a GPC system equipped with a Jordi Gel DVB Mixed Bed column (250 × 10 mm, Jordi Associates, Inc., MA) and an RI detector. Tetrahydrofuran (THF) was used as an elution solvent (1 mL/min) and polystyrene standards for column calibration.

Preparation of the Paclitaxel-loaded Nanoparticles. The paclitaxel-loaded nanoparticles were produced using an emulsion/solvent evaporation technique (*18*). Briefly, 10 mg of block copolymers were dissolved in 1 mL of methylene chloride, and paclitaxel was subsequently added with various feed weight ratios to block copolymer [paclitaxel/copolymer (P/BC) = 0.5/10, 1/10, 2/10, and 3/10]. The solution was then stirred for 2 h at room temperature and emulsified in 50 mL of a 0.1 wt % sodium cholate solution using a sonicator (VCX-750, Sonics & Materials Inc., Newtown, CT; cycles were of 1 s sonication followed by a 1 s pause, over a total period of 20 min). Afterward, the solvent was evaporated in a vacuum oven at 37 °C for 1 h. The resulting suspension was filtered through a 0.8 μm membrane filter (Whatman) and then centrifuged for 60 min at 18000 rpm at 4 °C. The supernatant was subsequently discarded and the pellet was resuspended in 10 mL of phosphate-buffered saline (PBS, pH 7.4, Sigma). The size distribution and

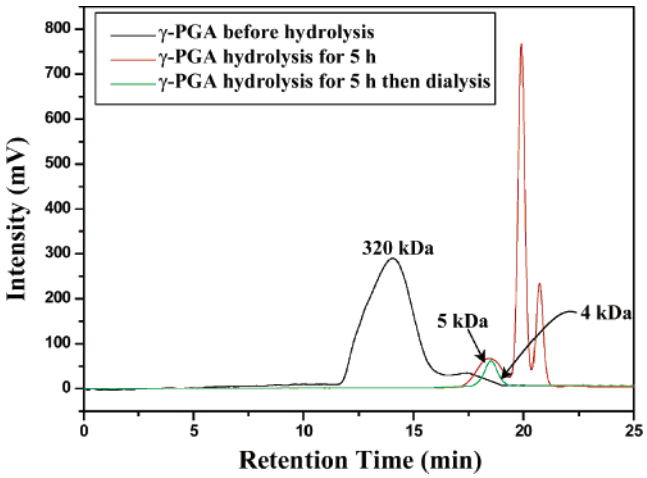

Figure 2. Chromatograms of purified γ-PGA obtained by fermentation (γ-PGA before hydrolysis), obtained γ-PGA after 5 h of hydrolysis at 150 °C (γ-PGA hydrolysis for 5h), and hydrolyzed γ-PGA after dialysis twice against deionized water (γ-PGA hydrolysis for 5 h then dialysis).

zeta potential of the prepared nanoparticles were measured using a Zetasizer (3000HS, Malvern Instruments Ltd., Worcestershire, UK).

TEM and AFM were used to observe the morphology of the paclitaxel-loaded nanoparticles. The TEM sample was prepared by placing a drop of the paclitaxel-loaded nanoparticle solution onto a 400 mesh copper grid coated with carbon. About 2 min after deposition, a filter paper was tapped to the grid to remove surface water and negatively stained using a 2% (by w/v) phosphortungsten acid (PTA) solution. The AFM sample was prepared by placing a drop of the paclitaxel-loaded nanoparticle solution on a glass slide and then drying it in a vacuum.

Table 1. Particle Size, Zeta Potential, and Drug Loading Content (LC) and Loading Efficiency (LE) of Nanoparticles Prepared with Various Feed Weight Ratios of Paclitaxel to Block Copolymer (the P/BC ratio)

P/BC ratio ($n = 4$)	particle size (nm)	zeta potential (mV)	LC (%)	LE (%)
0/10	115.4 ± 4.2	−21.4 ± 2.3	–	–
0.5/10	125.9 ± 5.5	−22.5 ± 3.2	3.7 ± 0.1	76.5 ± 2.4
1/10	128.8 ± 3.4	−19.6 ± 1.8	5.1 ± 0.2	53.7 ± 1.7
2/10	144.4 ± 2.6	−20.3 ± 2.7	5.8 ± 0.2	30.8 ± 2.3
3/10	263.2 ± 6.8	−19.2 ± 2.2	6.1 ± 0.2	21.7 ± 4.2

Loading Content and Loading Efficiency of the Paclitaxel-Loaded Nanoparticles. The drug loading content and the loading efficiency of the nanoparticles were determined using a high-performance liquid chromatography (HPLC) system equipped with a C_{18} analytic column (4.6 × 250 mm, particle size 5 μm, ThermoQuest, BDS, Runcorn, UK) (*19*). Two milligrams of the freeze-dried paclitaxel-loaded nanoparticles were dissolved in 1 mL dichloromethane with vigorous vortexing. This solution was dried by evaporating dichloromethane in a vacuum. It then was dissolved in a mixture of 50/50 (v/v) ethanol and deionized water to perform the HPLC analysis. The flow rate of the mobile phase (60% acetonitrile and 40% deionized water by v/v), delivered by an HPLC pump (TCP, P-100, Riviera Beach, FL), was 1 mL/min at 30 °C. The injection volume was 40 μL, and paclitaxel eluted from the column was monitored with an UV detector (Jasco 875-UV, Tokyo, Japan) at 227 nm. The drug loading content and the loading efficiency of the nanoparticles were calculated using the following equations (*20*).

$$\text{loading content (\%)} = \frac{\text{weight of paclitaxel in the nanoparticles}}{\text{weight of the nanoparticles}} \times 100\%$$

$$\text{loading efficiency (\%)} = \frac{\text{weight of paclitaxel in the nanoparticles}}{\text{weight of the feeding paclitaxel}} \times 100\%$$

Release of Paclitaxel from the Loaded Nanoparticles. The release profiles of paclitaxel from the prepared nanoparticles in PBS at 37 °C were investigated (*19*). The freeze-dried paclitaxel-loaded nanoparticles were weighed and resuspended in a centrifuge tube containing 20 mL of PBS. The tube was placed in a shaker water bath at 37 °C. At particular time intervals, the tube was removed and centrifuged. The supernatant was poured out, freeze-dried, and then dissolved in a mixture of 50/50 (v/v) ethanol and deionized water to conduct HPLC analysis. The pellet was resuspended in 20 mL of fresh PBS to make continuous release measurements. The paclitaxel released at each time point was calculated using a calibration curve (*19*).

Conjugation of Galactosamine to the Paclitaxel-Loaded Nanoparticles. Galactosamine was conjugated to the paclitaxel-loaded nanoparticles via an amide link by EDC in the presence of NHS (*21*, *22*). The conditions in our previous study, under which galactosamine was conjugated on nanoparticles that had the most nanoparticles internalized in HepG2 cells, were used herein (*6*). The obtained galactosylated nanoparticles were separated from unreacted molecules via ultrafiltration and then lyophilized. The content of galactosamine conjugated on the nanoparticles was determined by the Morgan Elson assay (*23*).

Viability of HepG2 Cells Treated with Distinct Paclitaxel Formulations. The cytotoxicity of the paclitaxel-loaded nanoparticles with or without galactosamine conjugated was evaluated in vitro by the MTT assay, using a clinically available paclitaxel formulation (Phyxol, Sinphar Pharmaceutical) as a control (*24*). The assay is based on mitochondrial dehydrogenase

cell activity as an indicator of cell viability. Briefly, MTT [3-(4,5-dimethyl-thiazol-yl)-2,5-diphenyltetrazolium bromide, Sigma] was dissolved in PBS to a concentration of 5 mg/mL as a stock MTT solution and filtered for sterilization. An amount of 5×10^4 HepG2 cells/well was seeded in 24-well plates and allowed to adhere overnight. The growth medium was replaced with a fresh medium that contained various concentrations (0.25−8 μg/mL) of the following paclitaxel formulations: Phyxol, nanoparticles without conjugated galactosamine (NPs), and nanoparticles with conjugated galactosamine (Gal-NPs).

The cells were then incubated for 3 days and washed twice in 1 mL of PBS. Subsequently, the cells were incubated in a growth medium that contained 1 mg/mL MTT agent for an additional 4 h at 37 °C; 500 μL of DMSO was added to each well to ensure that the formazan crystals dissolved. Finally, the optical density readings were taken using a multiwell scanning spectrophotometer (MRX Microplate Reader, Dynatech Laboratories Inc., Chantilly, VA) at a wavelength of 570 nm.

Immunofluorescence Analysis of HepG2 Cells Treated with Distinct Paclitaxel Formulations. HepG2 cells were grown on glass coverslips and then treated with distinct paclitaxel formulations with a final paclitaxel concentration of 8 μg/mL. After incubation for 3 days, the cells were fixed with 3.7% formaldehyde in PBS for 10 min at room temperature and then permeabilized in 0.1% Triton X-100 in PBS that contained 1% bovine serum albumin (PBS−BSA) and RNase 100 μg/mL. After they had been washed three times with PBS−BSA, the cells were treated with Oregon Green 514 palloidin (1:100 v/v, Molecular Probes) in PBS−BSA for 20 min. The cells were then incubated for 60 min with anti-bovine α-tubulin mouse mAb (1 μg/mL, Molecular Probes) in PBS−BSA. The Alexa Fluor 633-conjugated goat anti-mouse IgG antibody (2 μg/mL, Molecular Probes) was added, and the cells were incubated for another 60 min. They were then rinsed three times with PBS−BSA and treated with 100 nM propidium iodide (PI, Sigma) for 5 min.

Before the samples were mounted for CLSM examinations, they were again washed with PBS and deionized water. Oregon Green 514 palloidin, PI, or Alexa Fluor 633 stainings were visualized with excitations at 488, 543, and 633 nm, respectively, using an inverted CLSM (TCS SL, Leica, Germany). Images were imposed using LCS Lite software (version 2.0).

Altered Cycling States of HepG2 Cells Treated with Distinct Paclitaxel Formulations. To demonstrate whether paclitaxel released from the prepared NPs or the Gal-NPs could restrict HepG2 cells in specific cell cycle stages, flow cytrometric studies were performed. HepG2 cells treated with distinct paclitaxel formulations with a final paclitaxel concentration of 1 μg/mL for 3 days were pelleted at 1500 rpm for 5 min and then resuspended in PBS (*25*). Methanol (100%) precooled to −20 °C for 15 min was then added to the cell suspension, which was then centrifuged at 1500 rpm for 5 min. The supernatant was discarded, and the cell pellet was rehydrated with PBS. The pellet was stained with DNA staining solution (10 μg/mL PI and 1 mg/mL RNase A) for 45 min. The DNA content of each cell was measured using a Becton Dickinson FACSCalibur flow cytometer (San Jose, CA).

Statistical Analysis. Statistical analysis was performed to determine differences between the measured properties of groups. One-way analysis of variance was performed, and confidence intervals were determined using a statistical program (Statistical Analysis System, Version 6.08, SAS Institute Inc., Cary, NC). All data are presented as a mean value with its standard deviation indicated (mean ± SD).

RESULTS AND DISCUSSION

Production of γ-PGA. In the ^{1}H NMR spectrum of the purified γ-PGA produced by fermentation, the five main signals at 1.73, 1.94, 2.19, 4.14, and 8.15 ppm represented the protons of β-CH_2, γ-CH_2, α-CH, and amide, respectively. Additionally, the fermented product after purification showed no macromolecular impurity, according to the ^{1}H NMR analysis, suggesting that the obtained white γ-PGA powder was highly pure.

Hydrolysis of γ-PGA. Low-molecular-weight γ-PGA was produced by hydrolyzing purified γ-PGA obtained from fermentation at 150 °C for distinct durations. Solutions of purified γ-PGA obtained by fermentation and hydrolyzed γ-PGA were analyzed by a GPC system. Figure 2 shows that the purified γ-PGA obtained by fermentation had a high average molecular weight (M_n ~320 kDa) with a polydispersity of about 1.8. When γ-PGA was hydrolyzed at 150 °C for 5 h, its average molecular weight of γ-PGA was reduced to about 5 kDa. To reduce the polydispersity of the hydrolyzed γ-PGA, the hydrolyzed γ-PGA (~5 kDa) was further dialyzed twice (using a membrane with MWCO: 3500 and a membrane with MWCO: 6000−8000) against deionized water. Thus, the obtained γ-PGA had an average molecular weight of about 4 kDa with a polydispersity of 1.3 (Figure 2). This specific γ-PGA was used subsequently, together with PLA, to synthesize block copolymers to prepare the nanoparticles.

Synthesis of γ-PGA-PLA Block Copolymers. Figure 3a and 3b show the ^{1}H NMR spectrum and the GPC chromatogram of the synthesized γ-PGA-PLA block copolymers, respectively. In the ^{1}H NMR spectrum (Figure 3a), the chemical shifts at 1.42 and 5.20 ppm corresponded to the protons of the methyl group (CH_3) and methine (CH) on PLA, respectively, while the main chemical shifts exhibited by γ-PGA, described above, were also detected. The GPC chromatograms (Figure 3b) indicated that the molecular weight of γ-PGA-PLA slightly exceeded that of PLA. The aforementioned results indicated that γ-PGA was successfully conjugated to PLA by CDI.

Particle Size and Morphology of Paclitaxel-Loaded Nanoparticles. The distribution of sizes and the zeta potential of the prepared nanoparticles may importantly determine their fates after administration (*19*). As shown in Table 1, the particle sizes of the prepared nanoparticles increased significantly with the P/BC ratio. Dynamic light scattering measurements further demonstrated that all of the prepared nanoparticles had a narrow size distribution, with the exception of those prepared with a P/BC ratio of 3/10 (Figure 4). AFM and TEM showed that the morphologies of all of the prepared nanoparticles were spherical, and their surfaces were smooth (Figure 5).

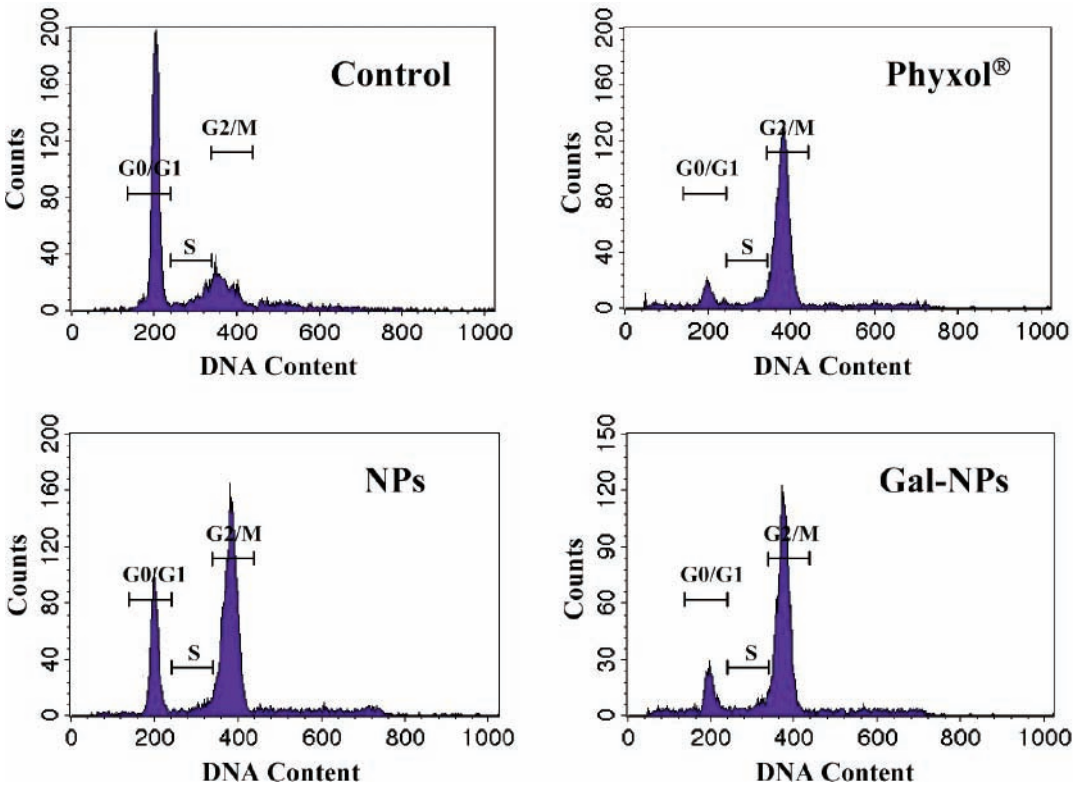

Figure 9. Analysis, using a flow cytometer, of DNA content in cell cycle of HepG2 cells treated with distinct paclitaxel formulations for 3 days. Control: untreated cells; Phyxol: cells treated with a clinically available paclitaxel formulation (Sinphar Pharmaceutical); NPs: cells treated with paclitaxel-loaded nanoparticles without conjugated galactosamine; and Gal-NPs: cells treated with paclitaxel-loaded nanoparticles with conjugated galactosamine.

Hashida et al. reported that the majority of the diameter of the fenestrate of the liver sinusoid is usually smaller than 200 nm (*26*). Thus, large particles hardly reach the parenchymal cells of the liver. Additionally, drug carriers with diameters of larger than 200 nm are readily scavenged nonspecifically by monocytes and the reticuloendothelial system (*27*). It was reported that smaller particles tended to accumulate at the tumor sites because of the EPR (enhanced permeability and retention) effect (*28*); greater internalization was also observed (*1*).

It was found that the prepared paclitaxel-loaded nanoparticles had a negative surface charge with a zeta potential of about −20 mV (Table 1), because of the carboxyl (COO) groups on the hydrophilic γ-PGA shell. This may affect the cellular uptake of the prepared nanoparticles due to electrostatic repulsion forces between the nanoparticles and the rather negatively charged surface of cells (*1*). However, Wakebayashi et al. suggested that the introduction of a specific ligand onto the nanoparticles may enhance their cellular uptake by receptor-mediated endocytosis (*29*). Additionally, positively charged carriers are reported to be able to induce a nonspecific interaction with unintended target tissues, particularly under in vivo conditions after administration (*29, 30*).

Loading Content and Loading Efficiency of Paclitaxel-Loaded Nanoparticles. Paclitaxel is highly hydrophobic and has a solubility of approximately 1 μg/mL in aqueous solution at pH 7.4 (*31*). Thus, in the drug loading process, the incorporation of paclitaxel in the nanoparticles competed with the precipitation of paclitaxel in aqueous solution (*31*). As the P/BC ratio increased, the incorporation of paclitaxel in the nanoparticles (the drug loading content) appeared to be increased, while the precipitation of paclitaxel in aqueous solution was more pronounced and thus significantly reduced the drug loading efficiency (Table 1, $p < 0.05$).

Release of Paclitaxel from Loaded Nanoparticles. As shown in Figure 6, paclitaxel was continuously released from nanoparticles prepared with distinct P/BC ratios. All samples released a burst of paclitaxel in the initial stage. An amount of 10−25% of the encapsulated drug was released in the first hour. This may be due to some of the drugs were deposited near the γ-PGA shell of the prepared nanoparticles.

As the P/BC ratio increased, the rate of release of paclitaxel from the prepared nanoparticles decreased significantly. It was reported that a hydrophobic drug encapsulated within nanoparticles partially crystallized at a higher drug loading content, while it formed a molecular dispersion at a lower drug loading content (*32*). The crystallized drug in the hydrophobic core of the nanoparticles is expected to dissolve more gradually and to diffuse to their outer aqueous phase more slowly than the drug in the form of a molecular dispersion (*2*). Additionally, the encapsulated drug took longer to diffuse through the polymer matrix to the aqueous medium when the nanoparticles were larger (i.e., as the P/BC ratio increased, as in Table 1) (*32*).

Conjugation of Galactosamine to Paclitaxel-Loaded Nanoparticles. As discussed above, the drug loading content of the prepared nanoparticles increased significantly with the P/BC ratio, while their drug loading efficiency decreased remarkably (Table 1). To obtain a comparatively high drug loading content with a high loading efficiency (Table 1), nanoparticles prepared with a P/BC ratio of 1/10 (the NPs) were used in the rest of this study. For the potential of targeting liver cancer cells, galactosamine was conjugated to the paclitaxel-loaded nanoparticles (the Gal-NPs). As determined by the Morgan Elson assay, the amount of galactosamine conjugated on the Gal-NPs was 66.2 ± 2.4 nmol/mg nanoparticles (or $4.0 \pm 0.1 \times 10^{16}$ galactosamine moieties per mg of the targeted nanoparticles, $n = 4$). The particle size of the Gal-NPs (127.5 ± 2.5 nm) was comparable to that of the NPs (128.8 ± 3.4 nm, $p > 0.05$). However, the zeta potential of the former (−10.6 ± 2.0 mV) was significantly lower than that of the latter (−19.6 ± 1.8 mV, $p < 0.05$), because galactosamine was conjugated to the

carboxyl (COO) groups on γ-PGA, reducing the negative surface charge of the Gal-NPs.

Viability of HepG2 Cells Treated with Distinct Paclitaxel Formulations. Figure 7 shows the viability of HepG2 cells treated with the paclitaxel formulations investigated herein. The inhibition of the growth of cells by the Gal-NPs was comparable to that of a clinically available paclitaxel formulation (Phyxol, $p > 0.05$); the NPs exhibited significantly less inhibitory activity ($p < 0.05$).

Hepatoma cells are known to recognize galactose- and *N*-acetylgalactosamine-terminated glycoproteins via the asialoglycoprotein (ASGP) receptors located on their surfaces (*33*). It was found in our previous study that during incubation with rhodamine-123-containing nanoparticles without conjugated galactosamine, little fluorescence was observed on the images of HepG2 cells taken by the CLSM (*6*). This indicated that without galactosamine only a small proportion of the nanoparticles could be internalized in the cells, because of the electrostatic repulsion forces between the nanoparticles and the cells as mentioned earlier. Hence, the NPs prepared herein released paclitaxel mainly outside the cells (in the culture medium). The released paclitaxel then diffused into the HepG2 cells, inhibiting the growth of the cells. Accordingly, under in vivo conditions after administration, the normal tissues may be nonselectively exposed to paclitaxel released from the NPs in the blood stream, potentially causing unwanted toxic side effects.

In contrast, with increasing the galactosamine content conjugated on the rhodamine-123-containing nanoparticles, the intensity of fluorescence observed in HepG2 cells increased significantly at 30 min after incubation (*6*). This indicated that the galactosylated nanoparticles interacted in a specified manner with HepG2 cells via ligand−receptor (ASGP) recognition. Therefore, the Gal-NPs prepared in this study were first internalized into HepG2 cells via the ASGP receptors, and then the encapsulated paclitaxel was released inside the cytoplasm, inhibiting the growth of the cells. Thus, the active targeting nature of the Gal-NPs may lead to high selectivity to the hepatic tumor and enhance their cellular uptake, with a consequent decrease in systemic toxicity.

Figure 8 shows CLSM images of HepG2 cells treated with Phyxol, the NPs, or the Gal-NPs. The untreated HepG2 cells (control) demonstrated normal nuclei, centrosomes, and microtubule networks. In contrast, HepG2 cells that had been exposed to Phyxol, NPs, or Gal-NPs exhibited significantly disrupted polar spindles of cells and the characteristic condensation of cytoplasmic microtubules. Additionally, improper mitotic spindle assembly caused micronuclear formation.

Figure 9 shows that HepG2 cells that had been treated with distinct paclitaxel formulations arrested the G2/M phase. The arrest of the growth of cells in the G2/M phase strongly suggested interference by paclitaxel with spindle formation and was consistent with the morphological findings presented in Figure 8. As compared to the untreated cells (control), the sharp peak observed in the G0/G1 phase was markedly attenuated and was instead mostly in the G2/M phase for the cells treated with Phyxol or the Gal-NPs. In contrast, for those cells treated with the NPs, this observation was less significant ($p < 0.05$). This finding again may be owing to that without galactosamine, only a small proportion of the nanoparticles (the NPs) could be internalized in the cells. Therefore, the NPs released paclitaxel mainly outside the HepG2 cells.

CONCLUSIONS

In conclusion, the aforementioned results indicated that the paclitaxel-loaded nanoparticles with conjugated galactosamine prepared herein may be internalized into HepG2 cells via receptor-mediated endocytosis, inhibiting the growth of cells. Therefore, the prepared nanoparticles may be used as a potential targeted drug delivery system to fight liver cancers.

ACKNOWLEDGMENT

The authors would like to thank the National Science Council of the Republic of China, Taiwan (Contract No. NSC 93-2213-B-007-051), and the National Health Research Institutes of the Republic of China, Taiwan (Contract No. NHRI-EX93-9221EI), for financially supporting this research.

NMR and Crystallographic Characterization of Adventitious Borate Binding by Trypsin

Thomas R. Transue, Scott A. Gabel, and Robert E. London*

National Institute of Environmental Health Sciences, Laboratory of Structural Biology, Box 12233, Research Triangle Park, North Carolina 27709. Received July 25, 2005; Revised Manuscript Received November 23, 2005

Recent ^{11}B NMR studies of the formation of ternary complexes of trypsin, borate, and S1-binding alcohols revealed evidence for an additional binding interaction external to the enzyme active site. We have explored this binding interaction as a prototypical interaction of borate and boronate ligands with residues on the protein surface. NMR studies of trypsin in which the active site is blocked with leupeptin or with the irreversible inhibitor 4-(2-aminoethyl) benzenesulfonyl fluoride hydrochloride (AEBSF) indicate the existence of a low-affinity borate binding site with an apparent dissociation constant of 97 mM, measured at pH 8.0. Observation of a field-dependent dynamic frequency shift of the ^{11}B resonance indicates that it corresponds to a complex for which $\omega\tau \gg 1$. The 0.12 ppm shift difference of the borate resonances measured at 11.75 and 7.05 T, corresponds to a quadrupole coupling constant of 260 kHz. A much larger 2.0 ppm shift is observed in the ^{11}B NMR spectra of trypsin complexed with benzene boronic acid (BBA), leading to a calculated quadrupole coupling constant of 1.1 MHz for this complex. Crystallographic studies identify the second borate binding site as a serine-rich region on the surface of the molecule. Specifically, a complex obtained at pH 10.6 shows a borate ion covalently bonded to the hydroxyl oxygen atoms of Ser164 and Ser167, with additional stabilization coming from two hydrogen-bonding interactions. A similar structure, although with low occupancy (30%), is observed for a trypsin−BBA complex. In this case, the BBA is also observed in the active site, covalently bound in two different conformations to both His57 Nϵ and Ser195 Oγ. An analysis of pairwise hydroxyl oxygen distances was able to predict the secondary borate binding site in porcine trypsin, and this approach is potentially useful for prediction of borate binding sites on the surfaces of other proteins. However, the distances between the Ser164/Ser167 Oγ atoms in all of the reported trypsin crystal structures is significantly greater than the Oγ distances of 2.2 and 1.9 Å observed in the trypsin complexes with borate and BBA, respectively. Thus, the ability of the hydroxyl oxygens to adopt a sufficiently close orientation to allow bidentate ligation is a critical limit on the borate binding affinity of surface-accessible serine/threonine/tyrosine residues.

INTRODUCTION

Analysis of the human genome is expected to expand the number of potential protein drug targets by an order of magnitude (*1*). In contrast with enzymatic targets for which activity-based assays are generally straightforward, it can be anticipated that in many cases drug development will target the interruption of protein−protein interactions involved in signal transduction processes. Target sites on protein surfaces are not typically characterized by the recessed cleft topology of most enzyme active sites and thus exhibit a reduced tendency to trap small molecules that can serve as lead compounds for ligand development. This analysis is supported by recent NMR screening studies, which indicate that the ability of small molecules to bind noncovalently to proteins is strongly dependent on local topology, being largely determined by the existence of pockets with optimal volume, compactness, and surface roughness (*2*).

Boric acid forms complexes with sugars and other small molecules containing hydroxyl, carboxyl, or ring nitrogen functionalities (*3*−*7*). The presence of these groups on proteins suggests that analogous protein complexes should exist. Consistent with this expectation, binding interactions between borate and cytochrome *c* have been detected by NMR spectroscopy (*8*, *9*). Noncovalently associated boric acid (*10*; pdb code 1B33) and borate (*11*; pdb code 1A95) occasionally have been observed in protein crystal structures; however, we are not aware of previous reports of covalent complexes involving borate and the residues on protein surfaces. Of course, the binding of boronate inhibitors to the active site of serine proteases has been studied extensively (*12*−*23* and references therein). Recent ^{11}B NMR studies of ternary complexes formed from trypsin, borate, and S1-binding alcohols revealed the existence of an additional borate binding site(s) of unknown location and composition (*24*, *25*). The ^{11}B NMR characteristics of this additional borate resonance are consistent with a polydentate, tetrahedral borate species that is in slow exchange with uncomplexed borate.

The present studies were undertaken to further clarify whether this resonance corresponds to a secondary binding site on the trypsin or to a contaminant, to characterize the binding affinity and structure of the adduct formed, to identify the boron ligands involved in the complex, and to evaluate whether structurally related boronate molecules might also interact with the putative secondary binding site. It was further postulated that if borate does bind to a secondary binding site on the surface of trypsin, then this type of binding interaction is unlikely to be unique. The specificity of such interactions might lead to a different type of ligand selectivity than that which can be achieved based on a combination of noncovalent hydrophobic and electrostatic interactions.

EXPERIMENTAL PROCEDURES

Crystallography. Type IX porcine pancreatic trypsin (Sigma, St. Louis, MO) was crystallized in the presence of 100 mM guanidino-3-propanol (G3P)[1] as described previously (*25*). For complexes containing borate bound at the second site, a crystal

was transferred in four 1 min steps to a final solution containing 90% saturated $MgSO_4$ (acting as a cryoprotectant), 200 mM borate, pH 10.6, 50 mM G3P, and 5 mM $CaCl_2$. The solutions for each step contained ratios of mother liquor to final solution of 50:50, 10:90, 0:100, and 0:100. The crystal was then flash frozen in liquid nitrogen and mounted for data collection. For benzene boronic acid (BBA), a crystal was transferred via several dilutions with mother liquor to a final solution containing 1 M CAPS buffer pH 10.5 (acting as a buffer and cryoprotectant) and 1 M BBA. The crystal was then frozen in liquid nitrogen and mounted for data collection.

Data were collected as described previously (*25*) using a Rigaku rotating anode generator and an R-AXIS IV detector (Molecular Structure Corporation). Data were reduced using DENZO and SCALEPACK (HKL Research) (*26*). All models were refined using a maximum likelihood target against all intensities using CNS (*27*). Force parameters were taken from the AMBER force field (*28*). The relative occupancy of alternate models (including alternate side chain conformations and alternately occupied borate or BBA binding sites) was iteratively estimated by minimizing difference electron density and by comparing the refined *B*-factors looking for a minimal difference. Water molecule occupancies were refined and then examined manually to avoid very low occupancies or very high *B* factors. For the borate crystal, a complete data set to 1.25 Å resolution was collected. The BBA complex crystal produced a data set complete to 1.5 Å. Data collection statistics as well as refinement statistics are provided in Table 1. Crystal structures showing the complex of trypsin with borate and with BBA have been deposited in the protein data bank with accession numbers 2A31 and 2A32, respectively.

[1] Abbreviations: 4AB, 4-amino-1-butanol; AEBSF, 4-(2-aminoethyl) benzenesulfonyl fluoride hydrochloride; AEBS−trypsin, AEBSF-modified trypsin; BBA, benzene boronic acid (sometimes referred to as phenylboronic acid); CAPS, *N*-cyclohexyl-3-aminopropanesulfonic acid; G3P, guanidino-3-propanol.

NMR Spectroscopy. ^{11}B NMR spectra were obtained on a Varian INOVA 500 NMR spectrometer operating at 160.6 MHz for boron or on a Varian Gemini 300 NMR spectrometer operating at 96.3 MHz. In both cases, the ^{11}B measurements were performed using quartz NMR tubes (Wilmad, Buena, NJ) and 5 mm variable-temperature broadband probes that had been modified to reduce the ^{11}B background signal. The probe used for the ^{11}B studies on the Gemini 300 was modified by JS Reasearch (Quincy, MA), and the probe used for the ^{11}B studies on the INOVA 500 was modified by Alex Funk. For the line width analysis and for determination of the apparent dissociation constant of the trypsin−borate complex involving the second binding site, the trypsin was pretreated with 5 mM 4-(2-aminoethyl) benzenesulfonyl fluoride hydrochloride (AEBSF) for 1 h at 4 °C to irreversibly block binding at the active site. We have referred to trypsin modified in this way as AEBS−trypsin. Additionally, 3 mM leupeptin (Bachem, King of Prussia, PA) was added to the sample to competitively bind to any unmodified active sites. Typical INOVA 500 spectral parameters were as follows: sweep width, 16 kHz; acquisition time, 1.0 s; transients, 2000. Gemini 300 spectral parameters were as follows: sweep width, 10 kHz; acquisition time, 0.6 s; transients, 44 400. ^{11}B shifts are referenced to external boric acid at pH 4.0. Since the boric acid/borate concentrations in most of the studies were relatively high, the spectra shown correspond to an expanded region around the bound borate species and do not include the resonance of the uncomplexed boric acid/borate. In most cases, the curved baseline resulting from the large boric acid/borate resonance was corrected using the polynomical fit of the Varian VNMR software.

Software. We developed a simple PERL script to check for neighboring hydroxyl oxygen atoms in any given PDB file. The script searches for serine, threonine, and tyrosine residues, records the coordinates of the hydroxyl oxygen atoms, and then computes pairwise distances. The residues, atoms, and distance

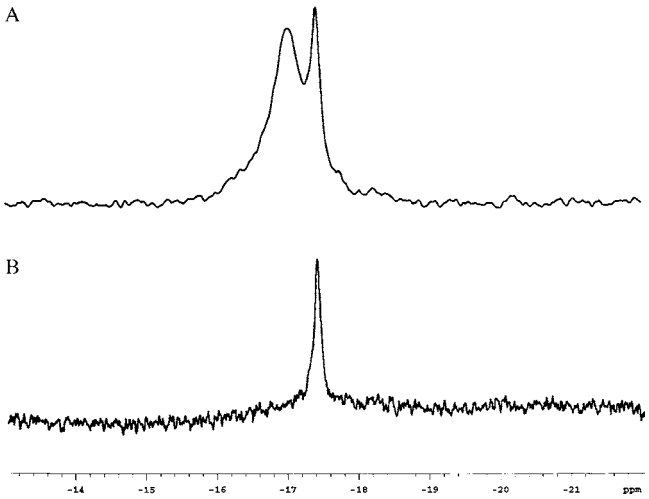

Figure 1. Effect of the leupeptin inhibitor on the binding of borate: (A) ^{11}B NMR spectrum of 2 mM trypsin, 50 mM borate, and 10 mM 4-aminobutanol in 50 mM HEPES, pH 8.0; (B) ^{11}B NMR spectrum of the sample shown in panel A with the addition of 3 mM leupeptin. ^{11}B spectra were obtained at 160.6 MHz on a Varian INOVA 500 at 25 °C.

for any pair closer than a defined distance (set to 6.0 Å in this case) are tabulated.

RESULTS

NMR Studies of the Trypsin−Borate Complex. Recent NMR studies of trypsin−borate complexes yielded evidence for additional borate binding interactions extending beyond the active site of the enzyme (*24*, *25*). For example, ^{11}B NMR studies reveal a resonance that can be assigned to a ternary trypsin−borate−4-aminobutanol (4AB) complex that forms at the active site in the presence of 5 mM borate. However, further increases in the borate concentration resulted in increased intensity of this resonance, which in some cases exhibited a structure indicating that it was composed of more than one component peak (Figure 1A). The presence of an additional binding site was confirmed by the addition of leupeptin, an inhibitor expected to compete with the active site borate−4AB complex (Figure 1B). Since borate binds to a large number of small molecule ligands that might be present in the enzyme preparation, for example, glycerol, citrate, tris buffer, etc., it was initially unclear whether this additional resonance resulted from an interaction with trypsin or with small molecule contaminants. However, ^{1}H NMR studies of the trypsin−borate complex failed to provide evidence of significant small molecule contaminants. Additional dialysis of the trypsin against buffer using a Slide-A-Lyzer also failed to eliminate the additional borate signal. Since protein surfaces contain the same functional groups present in many small borate ligands, it was hypothesized that low-affinity borate binding sites might be a general characteristic of protein surfaces. NMR evidence for the existence of such sites in cytochrome *c* has previously been reported (*8*, *9*). Exploration of the surface of the trypsin molecule immediately revealed a serine-rich region on the surface including residues Ser164, Ser166, Ser167, Ser170, and Ser171 as a potential borate binding site.

To obtain a more quantitative estimate of the binding affinity, the trypsin was treated with AEBSF, an irreversible, active-site-directed inhibitor of the enzyme, to eliminate this binding interaction. Boron-11 NMR studies were then performed on a sample containing 2 mM AEBS−trypsin, 2 mM lactate, and 50 mM HEPES buffer, pH 8.0. The sample also contained 3 mM leupeptin to further suppress any borate complex formation with unreacted trypsin. Lactate, which forms a binary lactate−borate complex (*3*), was used as an internal standard. As can be seen from Figure 2, the ^{11}B NMR spectrum shows the progressive formation of the borate−lactate and (AEBS−trypsin)−borate complexes, where the latter must arise from borate binding to a second site since the active site has been blocked. An additional resonance at $\delta = -19.5$ ppm apparent at higher borate concentrations, is assigned to the borate component of pentaborate, based on the shift data reported by Coddington and Taylor (*4*). Conceivably, the pentaborate or other polyborate species present at high borate concentrations could also bind to trypsin.

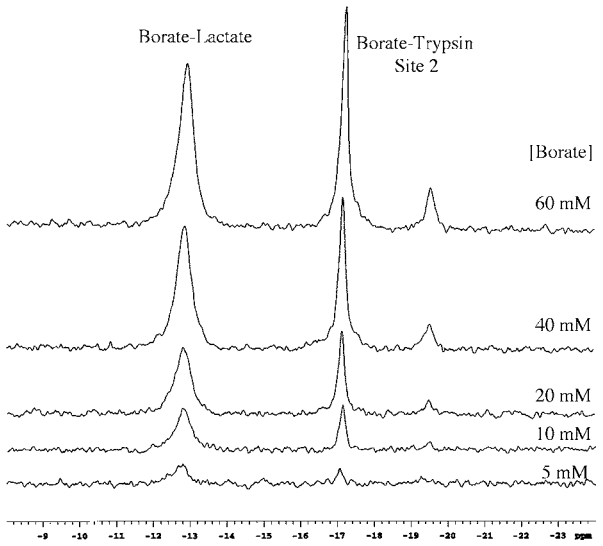

Figure 2. Borate titration of trypsin. ^{11}B NMR spectra of a sample containing 2.0 mM lactate, 2.0 mM AEBS−trypsin, 3 mM leupeptin, and 50 mM HEPES, pH 8.0, as a function of borate concentration. The identity of the upfield resonance at $\delta = -19.5$ ppm, which becomes apparent at high borate concentration, is tentatively assigned to pentaborate (*4*). ^{11}B spectra were obtained at 160.6 MHz on a Varian INOVA 500 at 22 °C.

Based on the data of Pizer and Selzer (*3*), the lactate−borate complex has an apparent K_D value of 128 mM at pH 8. To analyze the data of Figure 2, we also need to account for the fact that we are presumably only observing the central $^1/_2 \leftrightarrow -^1/_2$ transition for the borate−trypsin complex, corresponding to a fractional peak intensity given by (*29*)

$$I_{1/2,-1/2} = \frac{3}{2}\left(\frac{2s+1}{2s(2s+2)}\right) = 0.4 \quad \text{for} \quad ^{11}\text{B} \qquad (1)$$

where $I_{1/2,-1/2}$ is the fractional intensity of the central transition for a quadrupolar nucleus with half-integral spin value s with the latter equality corresponding to ^{11}B for which $s = {}^3/_2$. Analysis of the data shown in Figure 2 gave a value of $K_D =$ 97 mM for the (AEBS−trypsin)−borate complex. This interaction is similar to the inhibition constant of 80 mM measured previously for borate inhibition of trypsin (*24*). For reference, the apparent K_I for the inhibition of trypsin by borate is lowered to 18 mM in the presence of saturating 4-aminobutanol, which binds cooperatively (*24*).

Crystal Structure of the Borate Complex. Previous crystallographic studies have verified the formation of ternary and quaternary trypsin−borate−alcohol complexes that form in the active site (*25*, *30*), confirming the results of earlier NMR studies (*24*). As discussed previously, the nature of these complexes is also apparently influenced by crystal packing effects (*25*, *30*). No additional borate binding interactions were observed in crystallographic studies performed at pH 8.0 (e.g., Figure 3a). To obtain more specific insight into the second borate binding site on trypsin, a crystal containing a trypsin−G3P complex

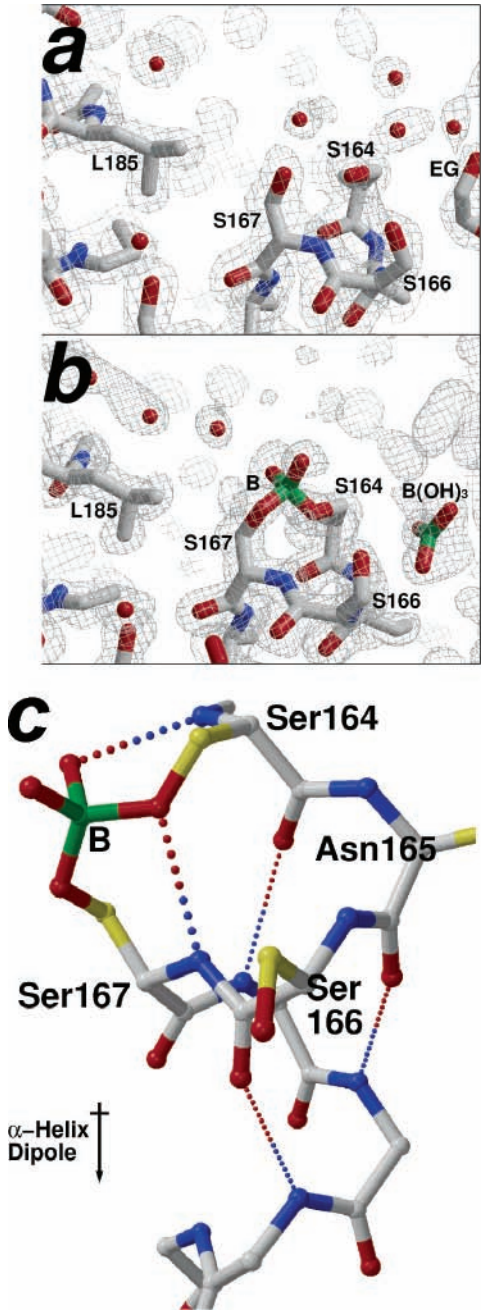

Figure 3. Crystallographic structure of the second borate binding site in trypsin: (a) X-ray structure of a serine-rich region of the trypsin surface obtained at pH 8.0 in the presence of 200 mM borate. PDB code: 1S6F; (b) structure of the same region of the protein crystallized at pH 10.6 in the presence of 200 mM borate, showing a borate ion covalently bound to the hydroxyl oxygens of Ser164 and Ser167; (c) covalent and hydrogen bonding interactions of borate bound at site 2. For clarity, the boron is indicated in green and the β-carbons in yellow. The two hydrogen bonding interactions involving the borate anion are indicated by large dotted lines. Small dotted lines indicate hydrogen bonds characteristic of α-helical secondary structure.

was soaked in a solution containing 200 mM borate at pH 10.6, and the resulting complex was analyzed by X-ray crystallography (Table 1). In this crystal form, a lattice contact inhibits ternary complex formation at the active site (*25*, *30*). However, the structure reveals a non-active-site bidentate borate complex with an occupancy of 50% formed from the Ser164 and Ser167 hydroxyl groups (Figure 3b). In addition to the covalent interactions with Ser164 and Ser167 hydroxyl oxygens, the complex is stabilized by a pair of hydrogen bonds (Figure 3c): the amide nitrogen of Ser164 is within hydrogen bonding range (2.8 Å) of one of the borate hydroxyl oxygens, and the amide nitrogen of Ser167 is within hydrogen bonding range (2.9 Å) of the covalently linked Ser164 Oγ. Electron density of the five electron boron atom is visible and continuous with that of the two serine oxygens, which are 2.2 Å apart. In the uncomplexed model representing the other 50% occupancy, the two serine hydroxyl oxygens are separated by 2.6 Å, and a water molecule is present at one of the sites occupied by a borate hydroxyl in the structure of the complex. At 1.25 Å resolution, the unbiased electron density ($F_o - F_c$ before modeling borate), as well as the final $2F_o - F_c$ density, unambiguously identifies this site as forming two covalent linkages to borate.

Crystal Structure of the Benzene Boronic Acid−Trypsin Complex. To further explore the borate binding site on the surface of trypsin that was identified by NMR and X-ray crystallography, we soaked the trypsin crystals in solutions containing a series of boronate ligands. In general, site 2 was found to be a relatively poor boronate binding site, presumably as a result of the lack of other useful interacting groups well positioned to stabilize the boronate complexes and, in the crystalline state, the potential limiting effects of crystal packing interactions. A complex of the enzyme with benzene boronic acid (BBA) bound to both the active and secondary sites was obtained at high pH using high BBA concentrations (Table 1). In this structure, BBA binds to the active site in either of two conformations, both of which involve bidentate covalent ligation to the His57 Nϵ and the Ser195 Oγ (Figure 4a). In one of the conformations, BBA(2), the phenyl ring extends into the S1 pocket and makes contact with the Cα and Cβ of Gln192, while in the second, BBA(1), it extends away from the pocket toward Phe41 and the Cys42−Cys58 disulfide bond. In this binding mode, the orientation of the BBA phenyl ring more closely approximates the P1′ residue (after the cleavage site) and the interactions are with trypsin residues in the S1′ subsite (e.g., see ref *31*). Binding to both the His Nϵ2 and the Ser Oγ has also been observed in some boronate complexes of γ-chymotrypsin (*19*).

The BBA is also bound to the second borate-binding site identified above in studies with borate, but with a 30% occupancy (Figure 4b). As with the borate complex (Figure 3b,c), the BBA molecule forms two covalent bonds with the serine hydroxyl groups, and two of the boron-bound oxygen atoms are within H-bonding distance of Ser164 NH (2.9 Å) and Ser167 NH (3.0 Å). The phenyl ring extends away from the surface of the protein so that the hydrogen bond from the Ser164 amide nitrogen to the only free hydroxyl is the same as that seen in the borate complex. Electron density does not support the alternate orientation of the phenyl ring, presumably because this would result in an amide nitrogen to aromatic carbon clash. There was apparently some borate present in the BBA sample used, because borate was alternately observed in site 2, also with 30% occupancy (i.e., the phenyl ring has lower occupancy than the other three heavy atoms). The remaining 40% appears to contain unbound serine 164 and 167, rotated slightly to place the Oγ atoms about 2.8 Å apart. The observation of equal populations of trypsin-complexed BBA and borate in this study was somewhat surprising, since the borate was present only as a contaminant. Based on a measurement of the resonance intensities in the ^{11}B NMR spectrum of the BBA, the borate contamination is ∼3%. BBA generally is expected to form tighter complexes due to the higher affinity for hydroxyl groups reflected in the lower p*K* value. An examination of lattice contacts suggests that unfavorable crystal packing effects may destabilize the trypsin−BBA complex. Specifically, the phenyl ring of the BBA comes in close proximity with the Ser61 and Arg62 residues of a symmetry-related molecule, which may exert a destabilizing effect. Alternatively, favorable interactions

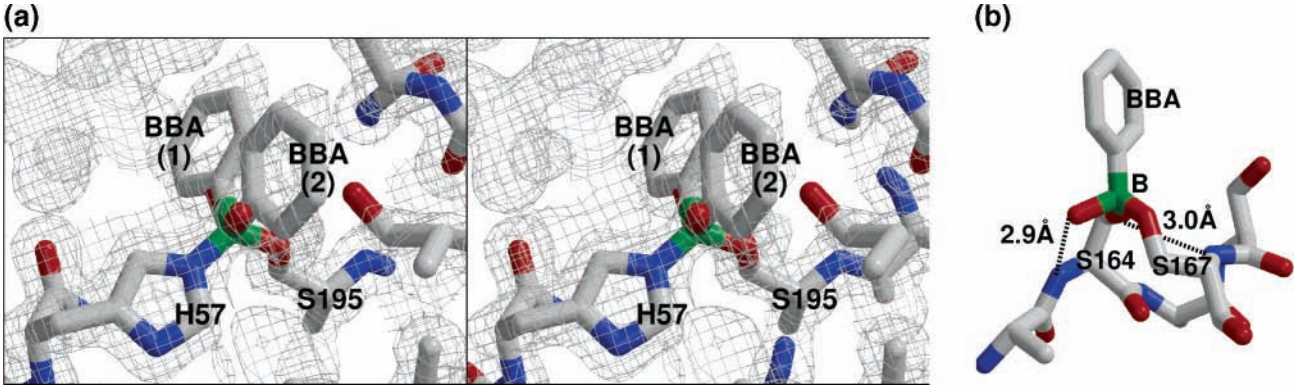

Figure 4. Crystal structure of the benzene boronic acid−trypsin complex: (a) Wall-eyed stereoview of the active site of the enzyme showing two similarly populated orientations of bound BBA; (b) interaction of BBA with the second borate bonding site formed from serine residues 164 and 167.

of borate with both of these residues might act to stabilize the borate complex. Of course, such interactions would not be present in solution. The Ser164/Ser167 Oγ−Oγ distances of 1.9 Å and 2.2 Å in the BBA and borate complexes, respectively, are significantly shorter than the distances observed for uncomplexed trypsin (see below). The need to force the Oγ nuclei together to achieve binding is thus probably an important constraint on the surface binding interactions observed here.

Analysis of Dynamic Frequency Shifts. To further characterize the borate/boronate binding interactions with trypsin, we performed field-dependent ^{11}B NMR studies on the complexes. In the slow tumbling limit, which characterizes the trypsin−borate complexes under study here, quadrupolar nuclei with half-integral spin, such as ^{11}B, exhibit unusual relaxation and shift characteristics, which can be useful for understanding the nature of the complex. In this limit, the $J(0)$ spectral density term, which typically makes the dominant contribution to transverse relaxation behavior in the slow tumbling limit, does not contribute to the relaxation of the central $^1/_2 \leftrightarrow -^1/_2$ transition, resulting in a relatively narrow signal, while the remaining transitions are very broad and generally unobserved (*29*, *32*−*34*).

The central transition for the ^{11}B in this slow tumbling limit is subject to a second-order dynamic frequency shift given by (*34*)

$$\delta = \frac{8s(s+1)-6}{s^2(2s-1)^2}\left(L^{Q}(\omega) - L^{Q}(2\omega)\right) \qquad (2)$$

where

$$L^{Q}(\omega) = \frac{3\chi^2}{160}\left(\frac{\omega\tau^2}{1+\omega^2\tau^2}\right) \qquad (3)$$

where χ, the quadrupolar coupling constant, is equal to $e^2Qq/(h/(2\pi))$, and τ is the isotropic rotational correlation time. In the limit $\omega\tau \gg 1$, we then obtain

$$\delta \approx \frac{4s(s+1)-3}{s^2(2s-1)^2}\left(\frac{3\chi^2}{160}\right)\left(\frac{1}{\omega}\right) \approx \frac{\chi^2}{40\omega} \quad \text{for} \quad s=\frac{3}{2} \qquad (4)$$

This can be expressed in ppm as (*35*)

$$\delta_{\text{ppm}} \approx \frac{-2.5\times10^4\chi^2}{\omega^2} = \frac{-2.5\times10^4}{\nu_0^2}\left(\frac{e^2Qq}{h}\right)^2 \qquad (5)$$

where we have introduced the negative sign indicating an upfield shift. The second equality above is useful if the quadrupole coupling constant is expressed in hertz rather than radians per second.

Boron-11 NMR spectra for solutions containing 2 mM trypsin, 6 mM lactate, 250 mM 4AB, and 50 mM borate in 50 mM HEPES, pH 8.0, were obtained at both 7 and 11.75 T to evaluate the relaxation behavior of the ^{11}B nucleus (Figure 5). The lactate standard was included to obtain a signal from a small molecule complex, which would not be subject to slow tumbling and should exhibit negligible dynamic frequency shifts. The ^{11}B NMR spectra show, in addition to the free boric acid resonance, a resonance corresponding to the lactate−borate complex at −13.0 ppm and two poorly resolved peaks at −17.1 ppm, which we assign to the ternary trypsin−4AB−borate complex at the active site and to the binary trypsin−borate complex that involves complex formation with Ser164 and Ser167 discussed above (Figure 3). We note that the resolution of the two component peaks in this study is somewhat poorer than that in Figure 1, apparently due to a small drop in pH of the sample, as well as to the higher 4AB concentration used. Although the field-dependent shift difference is small, using the borate−lactate complex as a reference, both of the components of the trypsin−borate complex shift downfield by 0.12 ppm at the higher magnetic field strength. Inserting the observed shift difference of 0.12 ppm into eq 5 and taking the ratio at the two fields gives

$$\frac{\delta_{500}}{\delta_{300}} = \frac{\delta_{500}}{\delta_{500}+0.12} = \left(\frac{300}{500}\right)^2 = 0.36 \qquad (6)$$

where we have assumed that χ is field-independent, giving for the dynamic frequency shift at 500 MHz, $\delta_{500} = 0.0675$ ppm. Based on this value, solution of eq 5 then gives $\chi = 264$ kHz. This small value is similar to typical values for deuterium and reflects the relative symmetry of the boron electronic structure in the bound borate.

To further probe these effects, similar field-dependent ^{11}B NMR studies were performed on a sample containing 2 mM trypsin, 6 mM lactate, 50 mM BBA, and 250 mM 4AB in 50 mM HEPES, pH 7.0. The lower pH was used in this case to provide better separation between the resonances of the free benzene boronic acid and the complexes, since this compound has a lower pK (8.72) than boric acid (8.98) (*36*). In contrast with the results for the borate complexes, the trypsin−BBA peaks, which cannot be individually resolved in this case,

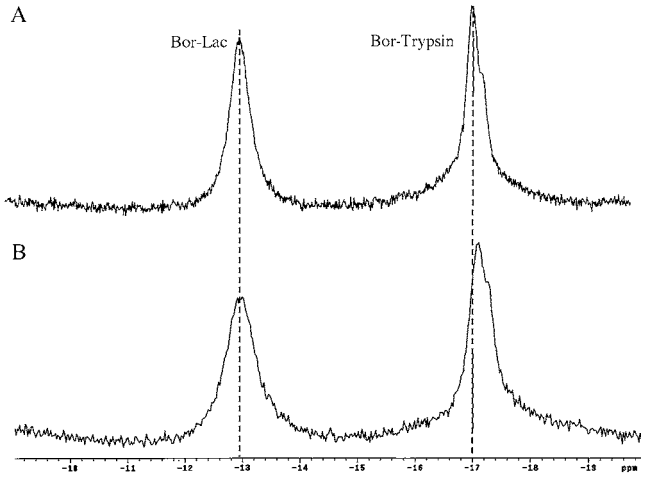

Figure 5. Frequency dependence of the ^{11}B NMR spectra of a trypsin−borate complex: (A) spectrum obtained at 7 T (^{11}B frequency = 96.326 MHz); (B) spectrum obtained at 11.75 T (^{11}B frequency 160.606 MHz). The sample contained 2.0 mM trypsin, 6.0 mM lactate, 50 mM borate, and 250 mM 4-aminobutanol in 50 mM HEPES, pH 8.0, buffer. Spectra were run at 25 °C.

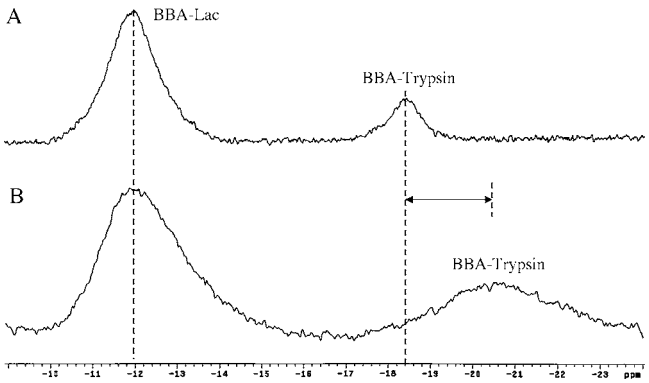

Figure 6. ^{11}B NMR spectra of a sample containing 6.0 mM lactate, 2.0 mM trypsin, 250 mM 4-aminobutanol, and 50 mM BBA in 50 mM HEPES, pH 7.0, buffer: (A) spectrum obtained at 7 T (^{11}B frequency = 96.326 MHz; (B) spectrum obtained at 11.75 T (^{11}B frequency 160.606 MHz). Spectra were run at 25 °C. There is an apparent dynamic frequency shift of 2.0 ppm.

experience a significantly greater upfield shift at the lower field (Figure 6). On the basis of the observed shift difference of 2.0 ppm and using eq 5, we have

$$\frac{\delta_{500}}{\delta_{300}} = \frac{\delta_{500}}{\delta_{500} + 2.0} = \left(\frac{300}{500}\right)^2 = 0.36 \qquad (7)$$

giving for the dynamic frequency shift at 500 MHz, $\delta_{500} = 1.125$ ppm. Insertion of this value into eq 5 gives $\chi = 1.08$ MHz for the quadrupole coupling constant of ^{11}B in the benzene boronate complex with trypsin. This value is similar to the 0.87 MHz determined from spin lattice relaxation measurements of BBA in the presence of chymotrypsin (*13*). Of course, as noted above, this value actually corresponds to a mixture of species. However, it is presumably dominated by the local environment of the boron and hence not strongly dependent on the detailed differences of the various component complexes. We note that if there were other small molecule complexes present in this system besides the borate−lactate complex that was specifically introduced, the field-dependent data should allow resolution of these species. The absence of additional resonances, particularly at the lower field, is consistent with our previous conclusion that the additional binding interaction observed in our previous studies (*24*, *25*) arose from binding to the second Ser164/Ser167

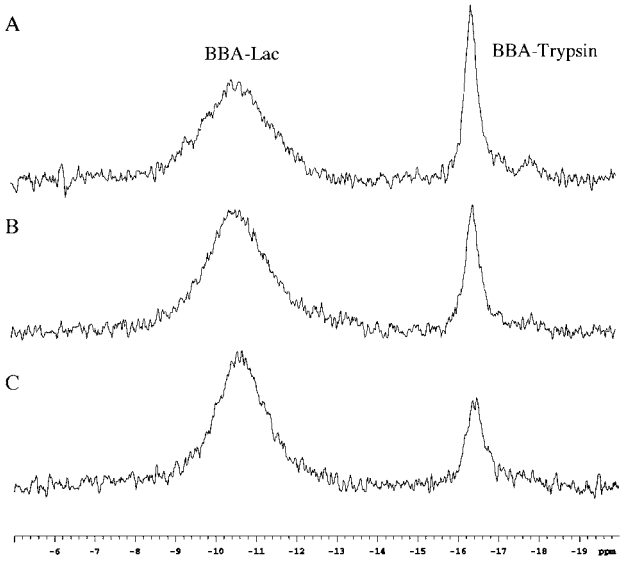

Figure 7. Temperature dependence of the ^{11}B NMR spectrum of the BBA−trypsin complex. To eliminate the contributions from BBA bound to the active site, the trypsin was treated with AEBSF, as described in the methods section. The sample contained 2 mM AEBS-trypsin, 2 mM lactate, and 50 mM benzene boronic acid in 50 mM HEPES, pH 8.0. ^{11}B NMR spectra were obtained at (A) 5, (B) 15, and (C) 25 °C.

binding site, rather than from binding to a small molecule contaminant.

To obtain further insight into this relaxation behavior, analogous studies were performed on benzene boronic acid in the presence of another serine protease, subtilisin Carlsberg. Benzene boronic acid (*13*) and its 4-fluoro analogue (*37*) have been shown to bind to this protease. Interestingly, the measured dynamic frequency shift was found to be 2.0 ppm, essentially identical to the result for trypsin with its multiple binding sites (data not shown). This result is consistent with eq 5, which indicates that the only significant parameter in predicting this shift under the slow tumbling approximation is the quadrupole coupling constant, which is presumably very similar for the benzene boronate, whether it is complexed with trypsin or subtilisin Carlsberg.

Line Width Effects in the BBA Complex. Temperature-dependent ^{11}B NMR spectra of the (AEBSF-treated trypsin)−BBA complex are shown in Figure 7. As in the above study, the sample also contained lactate (2 mM) to provide a reference borate complex. When the same set of approximations is used to analyze the relaxation behavior of the central component of the ^{11}B resonance, the line width of the central transition is given by (*29*, *34*)

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} = \frac{2s+3}{\pi s^2(2s-1)}\{2J_1^Q(\omega) + [(s+{}^3/_2)(s-{}^1/_2) - 1](J_2^Q(2\omega)\} \qquad (8)$$

where

$$J^Q(\omega) = \frac{3\chi^2}{160}\left(\frac{\tau}{1+\omega^2\tau^2}\right) \qquad (9)$$

where χ is the quadrupole coupling constant, $e^2Qq/(h/(2\pi))$, nucleus S has spin s and Larmor frequency ω, τ is the rotational correlation time, and isotropic motion is assumed. In

the limit $\omega\tau \gg 1$, we obtain

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} \approx \left(\frac{2(2s+3)}{\pi s^2(2s-1)}\right)\left(1 + \frac{1}{8}((s+{}^3/_2)(s-{}^1/_2)-1)\right)\frac{3\chi^2}{160}\frac{1}{\omega^2\tau} = \frac{\chi^2}{16\pi}\frac{1}{\omega^2\tau} = \frac{1}{16\pi}\left(\frac{e^2Qq}{h}\right)^2\frac{1}{\nu_0{}^2\tau} \quad \text{for} \quad s = \frac{3}{2} \quad (10)$$

where the second equality converts the quadrupole coupling constant to units of hertz.

This inverse dependence on τ contrasts with the line width predictions based on other relaxation mechanisms such as the dipolar interaction and chemical shift anisotropy, which predict $\Delta\nu_{1/2} \approx J(0) \approx \tau$. However, chemical exchange between uncomplexed and variously complexed forms of the borate ion also can make significant contributions to the line width. ^{11}B line widths measured for BBA complexed with AEBSF-treated trypsin to eliminate the contribution of BBA bound to the active site were measured at 5, 15, and 25 °C and yielded values of 51.5, 62.9, and 82.4 Hz, respectively.

We have compared this temperature dependence with the behavior predicted from an isotropic tumbling model:

$$\tau = \frac{4}{3}\pi r^3\frac{\eta}{kT} \quad (11)$$

where η is the viscosity of the solution. Using a table of water viscosity from the *Handbook of Chemistry and Physics* (*38*), the ratio of correlation times at the 5, 15, and 25 °C is calculated to be 1.0:0.74:0.55, so that based on eq 10 above, the ratios of the line widths at the three temperatures are predicted to be 1:1.35:1.82. The three experimental line widths given above have the ratio 1:1.22:1.60, in reasonable agreement with the prediction. Using eq 10, the rotational correlation times calculated from the line width of the central component of the ^{11}B signal at 5, 15, and 25 °C are 1.74×10^{-8}, 1.44×10^{-8}, and 1.10×10^{-8} s, respectively. These values are reasonable for a protein the size of trypsin (MW = 23 281).

Prediction of Adventitious Borate Binding Sites. Studies of model borate complexes indicate that borate readily interacts with hydroxyl, carboxyl, ring nitrogen, and occasionally amino groups. Typically, multidentate chelation is sufficient to give rise to slowly exchanging ^{11}B resonances, although at sufficiently high fields and low temperatures, even monodentate interactions can sometimes produce resolved resonances. Despite the ubiquitous occurrence of these potential ligands in proteins, the present NMR and crystallographic studies detected only one nonspecific binding site at borate concentrations under 100 mM involving a pair of serine hydroxyl groups. Since the multidentate complexes formed with hydroxyl ions are usually sufficiently stable to allow the observation of ^{11}B resonances that are in slow exchange (e.g., ref *4*), these are generally the easiest to observe. Based on the hypothesis that multidentate interactions with hydroxyl ligands provide the most prevalent basis for nonspecific borate binding, a calculation of the hydroxyl distances should provide a crude predictive tool for potential borate binding sites. Results of this analysis are summarized in Table 2. The closest pairing of hydroxyl groups occurs for the hydrogen-bonded S190 and Y228 residues that are buried in the interior of the protein and hence not accessible for binding. The S164−S167 site identified in the present study corresponded to the second shortest hydroxyl−hydroxyl distance, supporting the conclusion that this is a valid approach for predicting adventitious borate binding. Based on the results summarized in Table 2, we examined a sample containing bovine trypsin plus 50 mM borate under conditions similar to those of Figure 1 and observed a borate resonance with a shift similar to that of the bound borate in the procine trypsin−borate complex (spectrum not shown). Thus, it is likely that a similar complex forms with bovine trypsin.

Table 2. Hydroxyl Oxygen Distances in Crystal Structures

residue 1	residue 2	distances[a] min (mean)	distances[b] min (mean)
S190	Y228	2.74 (2.77)	2.70 (2.83)

[a] For porcine trypsin crystal structures 1S83, 1FNI, 1MCT, 1QQU, and 1AVW. [b] For bovine trypsin crystal structures 1HJ9, 1UTN, 1J8A, 1O3D, and 5PTP.

The Ser164−Ser167 Oγ−Oγ distance was determined to be 2.2 Å in the borate complex and 1.9 Å in the BBA complex. In contrast, the Ser164/Ser167 Oγ−Oγ distances in the crystal structures of uncomplexed trypsin are significantly longer so that a conformational change must occur upon borate/boronate complex formation. Depending on the protein, this geometric constraint may not be achievable. A survey of a series of proteins currently under study in our lab in the presence of 50 mM borate generally did not show a significant ^{11}B resonance corresponding to bound borate. The protein ubiquitin provides a good example of a protein containing a pair of hydroxyl groups, corresponding to Thr7 and Thr9, which appear to provide a potential borate binding site. Analysis of three high-resolution structures, 1UBQ, 1UBI, and 1D3Z, gave a mean Oγ−Oγ distance of 3.18 Å for Thr7/Thr9, shorter than the mean Oγ−Oγ distance for Ser64/Ser167 in trypsin, but at 50 mM borate, no bound resonance was observed. Analogous to the trypsin structure, the Oγ of Thr7 appears to be H-bonded to the Thr9 NH, orienting the side chain toward the Thr7 Oγ. In this case, variation of the χ1 angles for both threonine residues to achieve closest approach of the Oγ atoms reduces the Oγ−Oγ distance to ~2.6−2.7 Å, substantially greater than the distance of 2.2 Å for Ser164−Ser167 in the trypsin−borate complex, and achieving the 2.6 Å separation leads to significant steric conflict. Hence, the inability to reach sufficient proximity for bidentate ligation may be a limiting factor for borate complexation with Thr7/Thr9 in ubiquitin.

CONCLUSIONS

The complexes formed by boronate ligands with serine proteases and mechanistically related enzymes have been characterized extensively by X-ray crystallography, NMR spectroscopy, and other physical methods (*12*−*23*). These complexes generally contain a covalent bond between the active site serine Oγ and the boron to form a boronate structure believed to mimic the transition state, although binding to the active site histidine imidazole Nϵ2 has also been observed (*15*, *16*, *19*). Structurally analogous ternary and quaternary complexes involving serine proteases, borate, and alcohols also have been

observed recently (*24*, *25*, *30*). Recent ^{11}B NMR studies of trypsin complexes also provided evidence that at higher concentrations, an additional interaction between borate and trypsin was occurring (*24*, *25*). The studies described here were undertaken to more fully characterize this adventitious binding with a view toward exploitation of such interactions for the more general development of surface-directed protein ligands.

In the present studies, we have determined that the secondary trypsin−borate binding site involves covalent binding to the hydroxyl groups of Ser164 and Ser167, with additional stabilization resulting from a pair of hydrogen bonding interactions. An apparent borate dissociation constant of 97 mM at pH 8.0 was determined for this site, which can also be occupied by benzene boronic acid. Since the interaction does not involve residues of the serine protease active site, it is likely that this type of binding interaction is not unique. An upfield borate resonance with characteristics similar to the bound borate was also observed in a sample of bovine trypsin. Interesingly, the K_D value of 97 mM is similar to the K_I value for borate for the active site of trypsin (*24*) and other serine proteases (*39*). In contrast with the surface binding site, active site binding is typically monodentate (however, note Figure 4a) and is characterized by much higher k_{on} and k_{off} rates, so no separate ^{11}B resonance can be observed. In the presence of alcohols that form a ternary complex, a bidentate borate interaction with the enzyme and the alcohol creates a more stable complex so that a separate ^{11}B resonance does become observable (*24*, *25*).

It was initially anticipated that if borate binding to a second site located on the protein surface was occurring, then it would be possible to identify a boronate compound with greater affinity for this site due to the contribution of additional interactions with the substituent on the boron. However, none of the boronate compounds studied showed evidence of significantly enhanced affinity. One explanation for this observation is the significantly shorter Oγ−Oγ distance between the ligating Ser164/Ser167 hydroxyl oxygens observed in the BBA compared with the borate complex. Since these Oγ−Oγ distances are both substantially shorter than the values observed in the absence of borate/BBA (Table 2), it appears that in both cases the site must adjust for bidentate ligation, and the adjustment must be greater in the case of BBA. A second explanation suggested by the structure of the trypsin−BBA complex is that the phenyl ring of the BBA is approximately normal to the protein surface, precluding any additional interaction with the protein. Since serine residues contribute two of the oxygen ligands and a third hydroxyl group is hydrogen bonded to the Ser164 NH group, the carbon substituent of the boronate is forced to point away from the surface of the protein, so additional interactions of the boronate ligand with the protein in site 2 are essentially eliminated. In this orientation, unfavorable lattice contact may further destabilize the BBA complex, stabilize the borate complex, or both.

The results of the present study pose an interesting question: what properties of binding site 2 confer the borate binding affinity, and how unique is this type of interaction? Studies of small molecule complexes reveal that optimal positioning of boron ligands is essential for obtaining high binding affinity. For example, a study of the borate complexes formed by a series of pentoses demonstrated that borate complexes are formed exclusively with the *cis*-hydroxyl groups of the furanose and not the pyranose forms of the sugars (*40*). To form a borate binding site on the protein surface with reasonable affinity, it appears critical to have at least two boron ligands that are positioned to allow bidentate ligation. Hydroxyl groups that are not well positioned or that are highly dynamic and rapidly sample many different conformational states will not be optimal for borate binding. From this perspective, we note that the assigned hydrogen bonding interaction between Ser164 Oγ and the Ser167 NH group that characterizes the trypsin complexes with both borate and BBA appears to be present in a majority of the uncomplexed structures as well. This interaction probably contributes to borate binding by orienting the Ser164 side chain toward Ser167. Alternatively, in trypsin crystals with no borate bound to the second site, the side chain of Ser167 typically adopts multiple conformations, some oriented so that the OγH is within H-bonding range of the Ser167 carbonyl oxygen and some oriented with OγH within H-bonding distance of the Ser164 side chain. These results are consistent with a moderate affinity borate binding site and further suggest that a higher affinity borate binding site characterized by more optimally positioned and more conformationally constrained hydroxyl groups could, in principle, exist in other proteins. Most critically, the pair of Oγ ligands contributed by serine, threonine, or tyrosine must be able to move close enough to form a bidentate complex.

Additional stabilization of the trypsin complexes with both borate and BBA results from a hydrogen bond between one of the borate hydroxyl oxygens and the Ser164 NH (Figures 3 and 4b). Since this NH group is on the same residue involved in borate chelation, it is possible that this type of interaction could be a typical feature of other surface binding sites. A positively charged residue, functionally analogous to the oxyanion hole in the active site of a serine protease (*41*), could also provide additional stability. There appears to be no well-positioned cationic residue that could further stabilize the bound borate at site 2 of trypsin; however, proximity to the N-terminus of the α-helix with its associated dipole moment may make the Ser164/Ser167 binding site more favorable for anionic species.

Since the secondary borate binding site on the surface of trypsin identified in this study does not involve catalytic residues, it is unlikely that this type of binding interaction is unique to trypsin. Potentially, this type of borate binding interaction could form the basis for the development of boronate ligands that target the protein surface. A simple calculation of pairwise hydroxyl oxygen distances provides a rough predictive tool of potential borate binding sites, particularly if inaccessible sites are excluded. However, as illustrated by the lack of significant binding to ubiquitin, it must be possible to easily reorient the hydroxyl oxygens to within ∼2.5 Å, or perhaps slightly longer distances in some cases, without significantly perturbing the local protein structure to form a bidentate complex. The present results also illustrate the potential of dynamic frequency shifts of boronate ligands to distinguish ligands on the basis of rotational correlation times and hence molecular weight. This is a significant issue for borate and boronate compounds due to potential binding interactions with many small molecules. Additionally, this analysis provides a useful approach for the determination of quadrupole coupling constants and for obtaining dynamic information related to the protein−borate/boronate complex.

Lactosylated Chitosan for DNA Delivery into Hepatocytes: The Effect of Lactosylation on the Physicochemical Properties and Intracellular Trafficking of pDNA/Chitosan Complexes

Mayu Hashimoto,[†] Minoru Morimoto,[‡] Hiroyuki Saimoto,[‡] Yoshihiro Shigemasa,[‡] and Toshinori Sato[†,*]

Faculty of Science and Technology, Keio University, 3-14-1 Hiyoshi, Yokohama, 223-8522, Japan and Faculty of Engineering, Tottori University, 4-101 Koyama-Minami, Tottori 680-8552, Japan. Received July 28, 2005; Revised Manuscript Received December 15, 2005

Chitosan is a useful nonviral vector for gene delivery. To make a pDNA/chitosan complex specific to hepatocytes, lactose-modified chitosan (lac-chitosan) was synthesized. When the percentage of lactose residues substituted was 8%, lac-chitosan showed excellent DNA-binding ability, good protection of DNA from nuclease, and the suppression of self-aggregation and serum-induced aggregation. Although the cellular uptake efficiency of the pDNA/lac-chitosan complex was almost the same as that of the pDNA/chitosan complex, the cell transfection efficiency of the former was greater for HepG2 cells having asialoglycoprotein receptors. Inhibitor of endocytosis such as bafilomycin A_1 and nocodazole significantly reduced the transfection efficiency of the pDNA/lac-chitosan complex. Observations with a confocal laser scanning microscope indicated that the pDNA/lac-chitosan complexes traversed endocytic compartments more rapidly than the pDNA/chitosan complex. Furthermore, the pDNA/lac-chitosan complexes were delivered to the late endosome and have the advantage of delivering DNA to the perinuclear region.

INTRODUCTION

A number of nonviral vectors have been developed because of current interest in gene therapy. Cationic lipids and polymers have been widely employed as nonviral DNA carriers. Although the usage of cationic liposomes can bring about the strong expression of an exogeneous gene (plasmid DNA, pDNA), complexes of DNA/cationic liposome are unstable in vivo (*1*). Cationic polymers, such as poly(ethylene)imine (PEI), chitosan, and poly-L-lysine (PLL), have been also used frequently (*2*). Although PEI achieved the high-level expression of a transgene in vitro and in vivo, it was not biodegradable and showed cytotoxicity (*3*).

Chitosan is a naturally occurring polysaccharide consisting of D-glucosamine and *N*-acetyl-D-glucosamine linked by a β-(1→4) glycosidic bond and has the potential to condense anionic DNA into a compact structure through electrostatic interaction. DNA/chitosan complexes have shown high transfection efficiency in several cell lines (*4*−*10*). Chitosan plays an important role in the protection of DNA from nucleases, escape from the endosome, and nuclear transport of DNA as well as other cationic polymers (*11*, *12*). Moreover, chitosan is biodegradable and nontoxic compared to other synthetic polymers (*13*). However, an increase in transfection efficiency and target-specific delivery is required for the practical use of chitosan as a nonviral vector.

Receptor-mediated gene delivery is a promising way to achieve target-specificity. Various nonviral vectors conjugated with antibody, asialoglycoprotein, epidermal growth factor (EGF), glycosides, and transferrin as cell-recognition devices have been investigated (*14*). Notably, the transfer of genes to hepatocytes via the asialoglycoprotein receptor (ASGP-R) has been accomplished using a galactosylated polymer (*15*−*17*).

Gene carriers such as PEI and PLL have been modified with galactose or lactose to obtain specificity for hepatocytes or hepatoma, and the optimal degree of substitution of galactose residues was 40% (*17*) and 5% (*18*), respectively. Although galactosylated chitosan has been also examined (*19*−*21*), the influence of the extent of the substitution of galactose has not been investigated yet. The recognition of carbohydrates often depends on sugar density and is strengthened by the multivalent effect. However, the modification of amino groups in chitosan would decrease the charge density of chitosan and the DNA-binding strength (*18*). Thus, efficient cell transfection by receptor-mediated gene delivery would be accomplished by a balance between DNA condensation and carbohydrate recognition. Moreover, although the contribution of sugar residues to receptor-mediated cellular interaction has been well investigated, their effect on the intracellular trafficking of DNA complexes has not.

Here we employed lactosylated chitosan to obtain more information about the effect of the lactosylation of chitosan on the formation of DNA complexes and intracellular trafficking. First, the physicochemical characterization of pDNA/lac-chitosan complexes was carried out. Then, the cellular uptake and transfection efficiency were evaluated in vitro. Notably, the intracellular trafficking of DNA complexes was investigated by examining of subcellular distribution with a confocal laser scanning microscope and by evaluating the effect of endocytosis inhibitors on the cell transfection.

MATERIALS AND METHODS

Preparation of Lac-chitosan. Chitosan (the average molecular weight of 53 kDa, the degree of deacetylation was 93%) was obtained from Koyo Chemical Co. Ltd. Lactosylated chitosan (lac-chitosan) was synthesized according to the literature (Scheme 1) (*22*). Briefly, chitosan dissolved in 1% aqueous acetic acid was coupled with lactonolactone by reductive alkylation in the presence of sodium cyanoborohydride. The degree of substitution (DS) was calculated to be 8% and 33%

from elementary analysis. Calcd for 8% lac-chitosan ([$(C_8H_{13}NO_5)_{0.03}$ $(C_6H_{11}NO_4)_{0.89}$ $(C_{18}H_{32}NO_4)_{0.08}$] 1.1 H_2O): C, 40.62; H, 7.06; N, 6.67. Found: C, 40.49; H, 7.387; N, 6.585. Calcd for 33% lac-chitosan ([$(C_8H_{13}NO_5)_{0.03}$ $(C_6H_{11}NO_4)_{0.64}$ $(C_{18}H_{32}NO_4)_{0.33}$] 1.2 H_2O): C, 41.39; H, 6.35; N, 4.78. Found: C, 41.27; H, 7.379; N, 4.522.

Preparation of FITC-Labeled Chitosan. Chitosan and lac-chitosan were labeled with fluorescein isothiocyanate (FITC) as described previously (*23*). Briefly, chitosan or lac-chitosan (5 mg) was dissolved in water under acidic conditions caused by the addition of 1 N HCl, and thereafter the pH was adjusted to 6.5 with 1 N NaOH. FITC (0.1 mg, Dojindo) was added to the solution, and the mixture was stirred at room temperature for 24 h. The products were dialyzed in water using dialysis tubing and lyophilized. The amount of FITC in FITC-labeled chitosan was determined spectrophotometrically by visible absorption at 490 nm with reference to FITC. The average number of FITC residues was determined to be 1 per 100 monosaccharides.

Plasmid DNA. Plasmid DNA (pDNA), pGL3-Luc, encoding luciferase (Promega, Madison, WI) was amplified in *E. coli* DH5 α and isolated with a Qiagen Endotoxin-free Plasmid Giga Kit (Quiagen Inc., Chatsworth, CA) according to the instruction manual provided. pGL-3Luc was labeled with YOYO-1 (Molecular Probes Inc., Eugene, OR) (*24*). Briefly, 10 μL of pGL-3Luc (1 mg/mL) was mixed with 10 μL of 10 μM YOYO-1 and incubated at room temperature for 1 h in the dark.

Preparation of pDNA/Chitosan Complexes. pDNA/chitosan complexes were prepared as the method previously reported (*10*). The pDNA solution (0.1 mg/mL in water) was mixed with a given amount of chitosan solution (0.3 mg/mL) in PBS(−) adjusted to pH 6.5. The mixture of pDNA and chitosan was incubated at room temperature for 15 min. The YOYO-1-labeled pDNA described above was used for the evaluation of cellular uptake. The ratio of the plasmid's phosphate anion to chitosan's amino groups (N/P) was 5.

Atomic Force Microscopy (AFM). An aliquot of pDNA complexes (N/P = 5, [DNA] = 0.01 mg/mL) was dropped on freshly cleaved mica (1 cm × 1 cm). The excess liquid was removed by washing twice with 100 μL of deionized water, and the surface of the mica was dried with N_2 gas. AFM observation was carried out with a SPI-3700 system (SEIKO Instruments Inc., Japan).

Measurement of Zeta Potential and Particle Size. The concentration of pDNA was adjusted to 1.5 μg/mL by diluting with 20 mM HEPES buffer (pH 6.5). Zeta potentials of pDNA complexes were measured with a ZeeCom (Microtec Co. Ltd., Japan) at 25 °C. An average value for the zeta potential was calculated with the data from 40 particles tracked. Particle sizes were determined by dynamic light scattering (DLS) using a Laser Particle Size analyzer (HPPC, Malvern Instruments Co. Ltd.) at 25 °C.

DNase I Digestion Assay. The digestion of free pDNA (1 μg) and pDNA complexes by DNaseI (0.1 U, Takara, Japan) was assayed in 100 μL of 50 mM Tris-HCl buffer containing 10 mM $MgCl_2$, 100 mM NaCl, and 1 mM dithiotheretiol at 37 °C for 30 min. First, 4 μL of 0.5 M EDTA was added to all samples to inactivate DNase I. Subsequently, the pDNA complexes were mixed with 0.25 U/mL chitosanase (Seikagaku Kogyo Co., Ltd., Japan) at 42 °C and incubated for 4 h to release DNA from the chitosan completely. DNA was developed on 1% agarose gel and stained with ethidium bromide.

Lectin-Induced Aggregation. The pDNA complexes were incubated with 0.5 mg/mL *Ricinuns communis* agglutinin (RCA_{120}, Seikagaku Kogyo Co., Ltd.) in 100 μL of 10 mM HEPES buffer (pH6.5) at a final DNA concentration of 20 μg/mL. The turbidity at 350 nm was monitored with a UV−visible spectrophotometer (Ultrospec 300, Amersham Pharmacia).

BSA-Induced Aggregation. The pDNA complexes were incubated in the presence of bovine serum albumin (BSA, Sigma Co., Ltd.) for 1 h and 24 h at a final DNA concentration of 20 μg/mL. The concentration of BSA was 0.1, 0.2, 0.3, 0.4, 0.5, 1, and 2 mg/mL. The changes in turbidity at 350 nm upon the addition of BSA were monitored with a UV−visible spectrophotometer.

Cell Culture. COS7 cells and HepG2 cells were obtained from the Japanese Collection of Research Bioresources and RIKEN Cell Bank, respectively. COS7 cells were maintained in Dulbecco's Minimum Essential Medium (DMEM, Gibco BRL) containing 10% fetal bovine serum (FBS, JRH Biosciences Inc.), 100 U/mL penicillin, and 100 μg/mL streptomycin. HepG2 cells were maintained in Minimum Essential Medium (MEM, Nissui Pharm. Co., Ltd., Japan) containing 10% FBS and 10 mM nonessential amino acid (NEAA, Gibco BRL). Both cell lines were maintained at 37 °C in a 5% CO_2 humidified atmosphere.

Flow Cytofluorometry. COS7 and HepG2 cells were seeded at 2×10^5 cells/well in six-well plates 24 h prior to transfection. The pDNA complexes containing 5 μg of YOYO-1-labeled DNA were incubated with the cells in DMEM or MEM containing 10% FBS adjusted to pH 6.5 for 30 min. Then, the cells were washed twice with cold PBS (−) and harvested by trypsinization. To quench the extracellular fluorescence, the cell suspension was mixed with 50 μL of a 0.4% trypan blue (TB) solution in PBS (−). After 2 min, the cells were washed twice with cold PBS (−). The fluorescence intensity of the cells was measured with a flow cytofluorometer (Altra, Beckman Coulter) equipped with an argon ion laser. The experiments were carried out in triplicate.

Luciferase Assay. COS7 and HepG2 cells were seeded at 1×10^5 cells/well in 24-well plates 24 h prior to transfection. The pDNA complexes containing 2.5 μg of pDNA were incubated with cells in DMEM or MEM (pH 6.5) containing 10% FBS at 37 °C under a 5% CO_2 humidified atmosphere for 4 h. Then, the medium was replaced with fresh complete medium, and the cells were further incubated for 20 h before assays. Transfection with Lipofectin (Gibco BRL) was carried out according to the instruction manual. The transfected cells were washed three times with PBS (−) and lysed with the cell lysate buffer (Promega). Luciferase gene expression was measured using a Luciferase assay kit (Promega). The protein concentrations were determined with a DC protein assay kit

10	136	0.123	157	0.119	138	0.130

[a] Polydispersity index: [D(v, 90)-D(v, 10)]/D(v, 50), where D(v, 90), D(v, 50) and D(v, 10) are the equivalent volume diameters at 90, 50, and 10% cumulative volume, respectively.

(BIO-RAD, Hercules, CA). The relative light units (RLU) were measured with a luminometer and were corrected with the protein concentration.

For competition assay, HepG2 cells were preincubated with asialofetuin (4 mg/mL) for 15 min before the addition of pDNA complexes. Then, the cells were incubated with pDNA complexes for 4 h, and the luciferase activity was determined as described above.

The influence of endocytosis inhibitors on the transfection efficiency of pDNA/chitosan complexes was examined as follows. COS7 and HepG2 cells were preincubated for 30 min with 200 nM bafilomycin A_1 (Wako Pure Chem.) at 37 °C or 33 μM nocodazole (ICN Biomed. Inc.) at 4 °C. Then, the cells were incubated with pDNA complexes for 4 h and the luciferase activity was determined as described above.

Confocal Laser Scanning Microscopy. The subcellular distribution of pDNA/FITC-labeled chitosan complexes was observed with a confocal laser scanning microscope. Cells were seeded at 2×10^5 cells/well in glass-bottom dishes (ϕ35 mm, IWAKI) and incubated with pDNA/chitosan complexes for 15, 30, and 60 min. Renewal of the medium followed by washing with PBS (−). Cell fluorescence was analyzed with a confocal laser-scanning microscope (TCS−NT, Leica) equipped with a heating stage (Temp-Control 37−2, Leica) and a Kr/Ar laser.

RESULTS AND DISCUSSION

Formation of pDNA/Lac-chitosan Complexes. The DNA complexes were prepared by simple-mixing of the lac-chitosan and pDNA solutions in PBS (−) of pH 6.5. At N/P ≥ 3, the formation of pDNA/lac-chitosan complexes was confirmed by a gel retardation assay. The size of the complexes was determined by DLS as shown in Table 1. At N/P = 1, all complexes prepared in this study were more than 1 μm in size because the condensation of pDNA with chitosan or lac-chitosan was incomplete. At N/P ≥ 3, the pDNA/lac-chitosan complexes were particles with diameters of 140−170 nm with a relatively narrow distribution. At N/P = 3 and 5, the pDNA/lac-chitosan complexes were much smaller than the pDNA/chitosan complexes. The carbohydrate residues on the pDNA complexes are considered to contribute to the suppression of self-aggregation. Bettinger et al. reported the suppression of aggregation as an effect of glycosylation to pDNA/PEI complexes (*16*). Although PEI requires a tetrasaccharide with 5%DS to prevent self-aggregation, a disaccharide with 8%DS was enough to form stable pDNA/chitosan complexes.

Previously, we have shown that the optimum N/P ratio of pDNA/chitosan complex was 5 for cell transfection (*10*). When the N/P ratio was varied from 1 through 10, we found that both the pDNA/8% lac-chitosan complex and the pDNA/33% lac-chitosan complex had the highest transfection efficiency at N/P = 5. Therefore, the subsequent experiments were carried out at N/P = 5.

Table 2 shows the zeta potentials of the two pDNA/lac-chitosan complexes and the pDNA/chitosan complex at N/P = 5. The zeta potentials of the complexes were around 40−44 mV, with no significant difference among the three kinds of complexes.

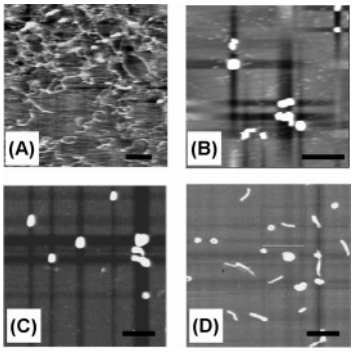

Figure 1. AFM images of pDNA complexes. (A) pDNA (pGL3-Luc), (B) pDNA/chitosan complex (N/P = 5), (C) pDNA/8% lac-chitosan complex (N/P = 5), (D) pDNA/33% lac-chitosan complex (N/P = 5). Scale bars represent 400 nm.

Table 2. ξ Potential of pDNA/Chitosan and pDNA/Lac-chitosan Complexes (N/P = 5)

complex	ξ potential (mV)
pDNA/chitosan	43.4 ± 7.0
pDNA/8% lac-chitosan	43.2 ± 5.8
pDNA/33% lac-chitosan	40.9 ± 8.1

AFM images revealed a difference in the morphology of the pDNA/8% lac-chitosan and the pDNA/33% lac-chitosan complexes (Figure 1), although the two complexes have almost the same particle size and zeta potential. The pDNA/8% lac-chitosan complex was spherical or short rodlike in structure similar to the pDNA/chitosan complex (Figure 1, parts B and C), while many of the pDNA/33% lac-chitosan complexes were long rod- and toroidlike (Figure 1D). The structure of several kinds of DNA complexes has been observed with AFM, TEM, or SEM. The spherical structure was observed in the pDNA/PEI complex (*12*). The short rod- and toroidlike structures were found in pDNA complexed with polycations such as poly(amidoamine)s (*25*), polylysine (*26*), and protamine (*27*). The short chain PLL of 4 kDa did not fully condense the pDNA and formed a long rodlike structure with the pDNA (*26*), similar in morphology to the pDNA/33% lac-chitosan complex. The conjugation of a large number of lactose residues to chitosan would result in steric hindrance and weaken the electrostatic interaction between the phosphate groups of DNA and amino groups of chitosan. Therefore, the degree of substitution of lactose residues in chitosan has to be controlled to retain the ability to bind with pDNA through electrostatic interaction.

Stability of pDNA/Lac-chitosan Complexes. The solubility in water and structural stability of pDNA/polycation complexes are often insufficient for practical use. Notably, cationic complexes bound with serum albumin and formed aggregates (*28*). The aggregation of pDNA complexes would induce a rapid clearance from plasma and be a disadvantage for nonviral gene delivery. Thus, the stability of the pDNA complexes in the

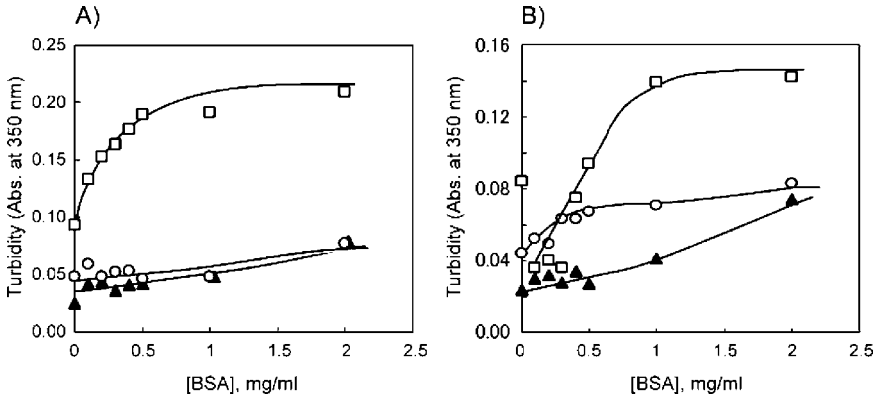

Figure 2. Turbidity of pDNA complexes at 1 h (A) and 24 h (B) after incubation with BSA. [pDNA] = 100 μg/mL. The pDNA complexes were formed at N/P = 5. □: pDNA/chitosan complex, ▲: pDNA/8%lac-chitosan complex, ○: pDNA/33%lac-chitosan complex.

Lactose (final concentration 10 mM) was added at the time marked by the arrow. □: pDNA/chitosan complex, ▲: pDNA/8%lac-chitosan complex, ○: pDNA/33%lac-chitosan complex.

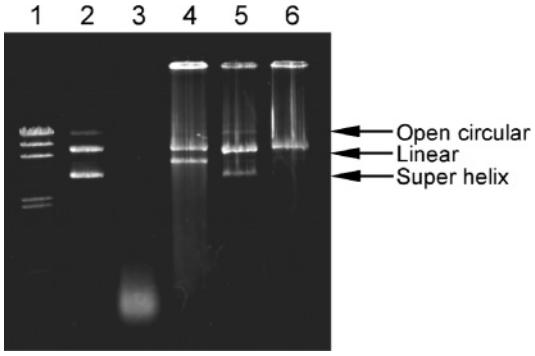

Figure 4. DNase I digestion assay of pDNA complexes. Naked pDNA and pDNA complexes were treated with 0.1 U of DNaseI and subsequently treated with chitosanase. Samples were subjected to 1% agarose gel electrophoresis. The samples were as follows, lane 1: λ-HindIII, lane 2: naked pDNA, lane 3: naked pDNA treated with DNase I, lane 4: pDNA/chitosan complex treated with DNase I and chitosanase, lane 5: pDNA/8% lac-chitosan complex treated with DNase I and chitosanase, lane 6: pDNA/33% lac-chitosan complex treated with DNase I and chitosanase.

presence of BSA was examined as a simple model. As shown in Figure 2, the pDNA/8% lac-chitosan complex and pDNA/33% lac-chitosan complex were very stable at 2 mg/mL of BSA, whereas the pDNA/chitosan complex showed a significant increase in turbidity. Even after incubation for 24 h with BSA, pDNA/lac-chitosan complexes were more stable than pDNA/chitosan complex (Figure 2B). AFM observation also supported the stability of pDNA/lac-chitosan complexes. The pDNA/lac-chitosan complex of 150 nm was observed after 1 h of incubation with BSA, although pDNA/chitosan complexes became large aggregates with a size of more than 1 μm (data not shown). Although the zeta-potential of the pDNA/lac-chitosan complexes was positive, BSA-induced aggregation was remarkably suppressed. This means that the modification of hydrophilic lactose residues to chitosan contributes to the stability of the pDNA complexes in the presence of serum.

Lectin-Induced Agglutination of pDNA/Lac-chitosan Complexes. The recognition of the pDNA/lac-chitosan complexes was determined by agglutination induced by galactose-binding RCA_{120}. With the addition of RCA_{120}, the turbidity of the pDNA/lac-chitosan complexes increased significantly, while the pDNA/chitosan complex showed no change of turbidity (Figure 3). Recognition of the pDNA/lac-chitosan complexes depended on the degree of substitution of lactose residues in chitosan. The change in turbidity of the pDNA/33% lac-chitosan complex was two times that of the pDNA/8% lac-chitosan complex. The agglutination of the pDNA/lac-chitosan complexes was reversed by adding of 10 mM lactose. These results indicated that the lactose moieties of pDNA complexes were specifically recognized by the sugar-binding protein. Murata et al. have reported that pDNA complexes with *N*,*N*,*N*-trimethylchitosan having 5 or 20% galactose residues were aggregated by APA lectin (*15*).

Resistance to DNase I Digestion. It is known that the condensation of pDNA by chitosan resulted in the protection of DNA from hydrolysis (*11*, *12*, *29*). Here, the resistance of pDNA/lac-chitosan complexes to DNA hydrolysis by DNase I was examined. Though naked pDNA was digested completely by the incubation with 0.1 U of DNase I for 30 min (Figure 4 lane 3), pDNA complexed with 8% lac-chitosan and 33% lac-chitosan showed resistance to DNase I (Figure 5 lane 5 and 6). After the treatment with DNase I, pDNA complexed with 8% lac-chitosan showed a supercoiled or linear structure, while pDNA complexed with 33% lac-chiotsan had only a linear structure. The pDNA complexed with conventional chitosan had a linear structure or unidentified structure between in linear and supercoiled (Figure 4, lane 4). Gebhart et al. detected a similar band between a linear and supercoiled structure for pDNA/pluronic-PEI complex digested with DNase I (*30*). They concluded that the unidentifiable structure is a stable secondary structure of pDNA.

The DNA digestion assay suggested that 33% lac-chitosan feebly formed a complex with DNA compared to chitosan and 8% lac-chitosan. As shown in Figure 1, AFM indicated that the pDNA was not sufficiently compacted by 33% lac-chitsoan because the morphology of pDNA/33% lac-chitosan complexes was not spherical. Thus, the results of the DNA digestion assay were well consistent with the AFM observation.

Through the physicochemical characterization, it was demonstrated that the lactosylation of chitosan suppressed the nonspecific interaction of the DNA/chitosan complex with BSA and increased the stability of the complex, in a manner

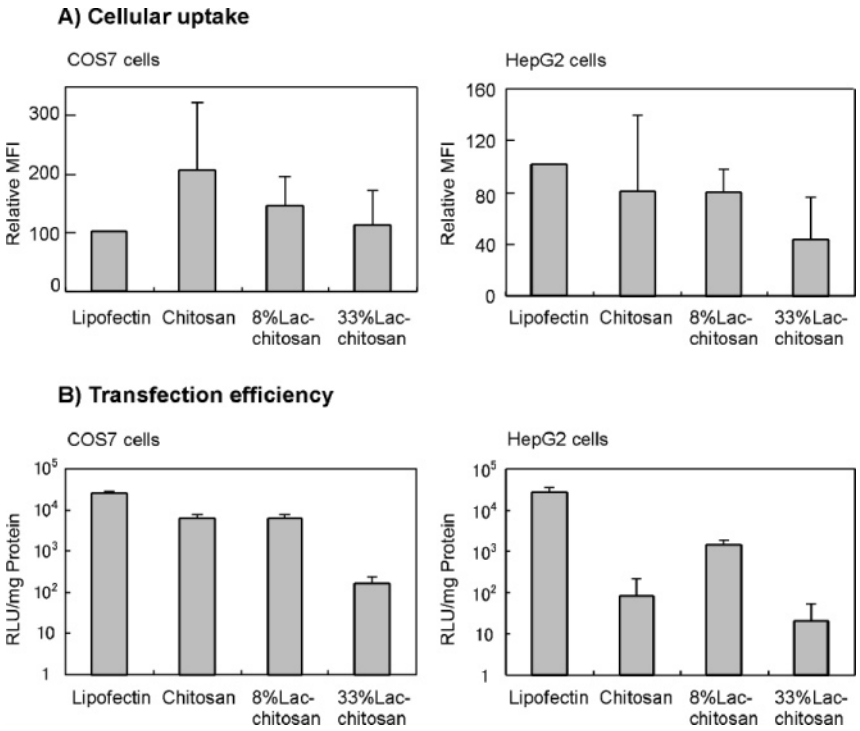

Figure 5. Cellular uptake and transfection efficiency of pDNA complexes for COS7 and HepG2 cells. (A) COS7 and HepG2 cells were incubated for 30 min with YOYO-1-labeled pDNA/chitosan complexes. After a subsequent washing and trypsinization, the mean fluorescence intensity (MFI) was analyzed with a flow cytofluorometer. MFI of pDNA/Lipofectin complex was normalized to 100. [pDNA] = 5 μg/mL, N/P = 5. (B) The cells were incubated for 4 h with the pDNA complexes. After the subsequent culture, the cells were lysed and the luciferae activities were measured. [pDNA] = 5 μg/mL. All pDNA complexes were prepared at N/P = 5.

independent of the substitution of lactose residues. The recognition of pDNA complexes depended on the degree of substitution of lactose residues, with 33% lac-chitosan being superior to 8% lac-chitosan. However, the condensation of pDNA governing enzymatic stability was sufficiently induced by 8% lac-chitosan but not by 33% lac-chitosan.

Cellular Uptake and Transfection with pDNA/Lac-chitosan Complexes. The cellular uptake and the cell transfection efficiency of pDNA complexes were investigated with HepG2 cells having asialoglycoprotein receptors, and COS7 cells as a control. To evaluate cellular uptake efficiency, pDNA was labeled with YOYO-1. The fluorescence of the complexes adsorbed on the cell surface was quenched by the addition of trypan blue to estimate the amount of pDNA internalized by cells (*31*). As shown in Figure 5A, there was no significant difference in mean fluorescence intensity (MFI) among pDNA/chitosan, pDNA/8% lac-chitosan, and pDNA/33% lac-chitosan complexes for both HepG2 cells and COS7 cells.

Figure 5B shows the transfection efficiency of pDNA/chitosan, pDNA/lac-chitosan complexes, and lipoplex for COS7 cells and HepG2 cells. For COS7 cells, the pDNA/8% lac-chitosan complex showed almost the same transfection efficiency as the pDNA/chitosan complex, whereas the transfection efficiency of the pDNA/33% lac-chitosan complex was 2 orders of magnitude lower. Since the pDNA/33% lac-chitosan complexes were easily hydrolyzed by DNase I as shown in Figure 4. They would be degraded by nuclease in the lysosome or cytosol after cellular uptake. Therefore, it was considered that the pDNA/33% lac-chitosan complex showed poor transfection despite being incorporated into cells as well as the pDNA/8% lac-chitosan complex.

Erbacher et al. examined the transfection of lac-chitosan, in which 3.3, 10, and 20% of lactose residues were substituted. However, the pDNA/lac-chitosan complex showed significantly less tranfection efficiency than the pDNA/chitosan complex for HeLa cells (*4*). The pDNA/chitosan complexes observed by TEM were donut-, rod-, or pretzellike in shape. These results suggest the interaction of pDNA with their lac-chitosan was relatively weak and the formation of the pDNA/chitosan complex was incomplete. Although they did not focus on the pH of the buffer used for the preparation of DNA complexes, we prepared the pDNA complex at pH 6.5 to protonate the amino groups of chitosan. Through the physicochemical characterization in our present study, it was demonstrated that 8% lac-chitosan had the potential to condense pDNA, although 33% lac-chitosan was too low in charge density to form complete complexes. The formation of incomplete complexes brought about a decrease in transgene expression even if they were well taken up into the cells.

For HepG2 cells, the transfection efficiency of pDNA/8% lac-chitosan complex was 16 times higher than that of pDNA/chitosan complex, although the cellular uptake efficiency showed no significant difference with the pDNA/chitosan complex. The low transfection efficiency of pDNA/33% lac-chitosan complexes seems to be caused by the instability in HepG2 cells as well as COS7 cells.

To confirm that cell transfection of pDNA/lac-chitosan complexes was mediated by asialoglycoprotein receptor, the competition assay was carried out using asialofetuin. The transfection efficiency of pDNA/chitosan complex was little affected by the addition of asialofatuin. On the other hand, those of the pDNA/8% lac-chitosan and the pDNA/33% lac-chitosan complexes were decreased by the addition of asialofetuin. These results suggested the pDNA/lac-chitosan complexes were internalized via asialoglycoprotein receptor.

The cationic pDNA/chitosan complexes would adsorb to the cell surface through electrostatic interaction and be internalized by endocytosis (*32*). On the other hand, the pDNA/8% lac-chitosan complex would bind to the asialoglycoprotein receptor. Therefore, it is suggested that both pDNA/chitosan and pDNA/lac-chitosan complexes brought about gene expression by different cellular uptake mechanisms and intracellular traffick-

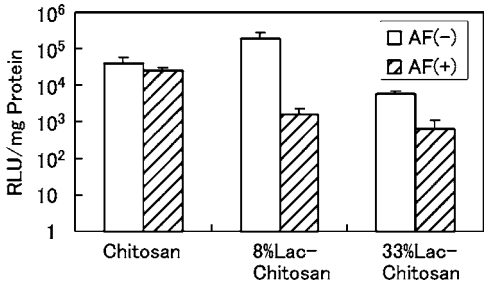

Figure 6. Competition assay of pDNA/lac-chitosan complexes by adding asialofetuin for HepG2 cells. 2 mg/well asialofetuin was added at 15 min before addition of pDNA complexes. The cells were incubated for 4 h with the pDNA complexes. After the subsequent culture, the cells were lysed and the luciferae activities were measured. [pDNA] = 5 μg/mL. All pDNA complexes were prepared at N/P = 5.

ing. It is reported that receptor-mediated and nonspecific endocytosis employs a different intracellular trafficking in hepatocytes (*33*). The rate of cellular uptake and degradation of asialo-orsomucoid, which was taken up via receptor-mediated endocytosis, and bovine serum albumin, which was taken up via pinocytosys, was affected by several endocytosis inhibitors independently. Thus, we assumed that the difference in intracellular trafficking between pDNA/chitosan and pDNA/lac-chitosan complexes resulted in the difference between the efficiency of cellular uptake and gene expression. Fajac et al. found a similar diferrence in gene transfer for airway epithelial cells, which have the mannose receptor, using sugar-modified PEI (*34*). Although the cellular uptake efficiencies of pDNA/Man-PEI, pDNA/Lac-PEI, and pDNA/PEI complexes complex were almost the same, pDNA/Lac-PEI complexes showed the highest transfection efficiency. However, the mechanism of gene transfer with pDNA/sugar-PEI complexes has not been clarified yet.

Subcellular Localization of the pDNA Complexes. The subcellular localization of pDNA complexes in HepG2 cells was observed with a confocal laser scanning microscope (Figure 7). The pDNA/chitosan complex was detected as large aggregates on the cell surface at 15 min, while the pDNA/8% lac-chitosan complex was distributed as small spot-like fluorescence on the cell surface and inside of cells at 5 min (Figure 7, parts A and D). Interestingly, the pDNA/8% lac-chitosan complexes were detected around the nucleus at 15 min (Figure 7, parts E and F). The localization of the pDNA/33% lac-chitosan complex was almost the same as that of the pDNA/8% lac-chitosan complex. Despite the large difference in cell transfection efficiency between the two pDNA/lac-chitosan complexes, their subcellular localization was almost the same. However, since pDNA/33% lac-chitosan complexes were easily hydrolyzed by DNase I, pDNA might be partly hydrolyzed by lysosome enzyme. In contrast, pDNA/chitosan complexes took over 4 h to concentrate around the nucleus (Figure 7, parts B and C). Godbey et al. have also observed that the pDNA/PEI complexes took over 4 h to be taken up into cells (*35*).

The pDNA/lac-chitosan complex also showed rapid intracellular trafficking in COS7 cells. Therefore, it is suggested that the lactose residue of pDNA/chitosan complexes contributed to the rapid intracellular delivery to the area around the nucleus for the two cell lines employed in this study. Next, we further investigated the cell transfection using endocytosis inhibitors, to know the correlation between their intracellular delivery and cell transfection.

Mechanism of Intracellular Trafficking of pDNA/Lac-chitosan. For a nonviral DNA delivery system, the escape of DNA complexes from the endosome is one of the most important processes for gene expression. The escape of pDNA/chitosan complexes from the endosome has been explained by

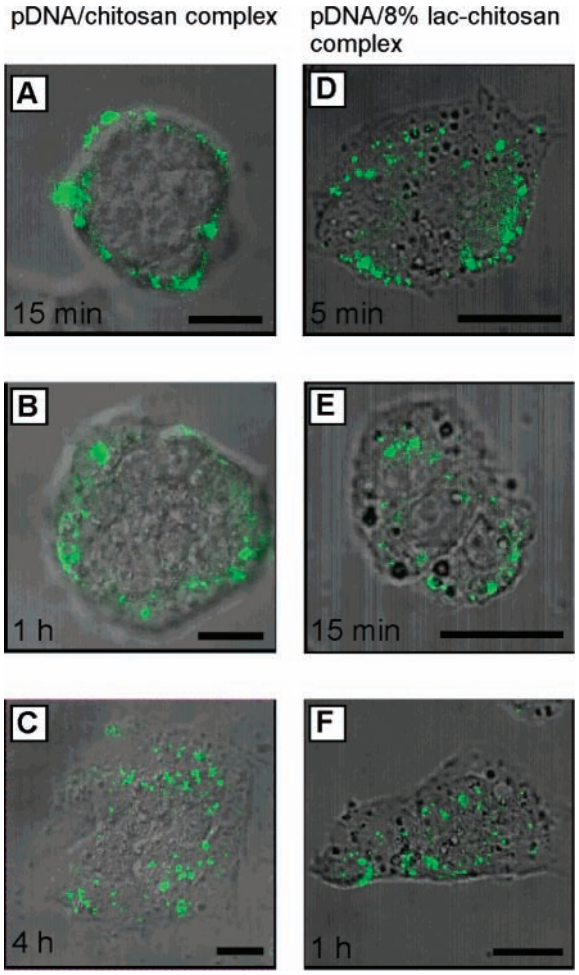

Figure 7. Time course of the subcellular localization of the pDNA/chitosan complex and pDNA/8% lac-chitosan complex in HepG2 cells. The cells were incubated with pDNA/FITC-labeled chitosan complex (A, B, C) and pDNA/FITC-labeled 8% lac-chitosan complex (D, E, F). Postaddition times were, (D) 5 min, (A, E) 15 min, (B, F) 1 h, and (C) 4 h. Scale bars represent 20 μm.

(1) a buffering effect (*11*), (2) membrane perturbation (*36*, *37*), and (3) water influx and swelling of the endosome caused by increasing osmolarity with chitosan degradation (*12*). In the present study, for a better understanding of the intracellular trafficking of the pDNA/lac-chitosan complexes, we examined the effect of the endocytosis inhibitors on the transfection efficiency in COS7 and HepG2 cells.

As shown in Figure 8A, Bafilomycin A_1, a proton pump inhibitor (*38*), greatly depressed the luciferase activity of both pDNA/chitosan and pDNA/lac-chitosan complexes. We also examined the effect of monensin, which is an inhibitor of endosomal acidification. Monensin also significantly decreased the gene expression of the pDNA/chitosan and pDNA/8% lac-chitosan complexes (data not shown). In a previous study, it has been implied that the influx of protons into the endosome is the mechanism by which pDNA/chitosan complexes escape from the endosome (*10*). In the present study, it is suggested that the pDNA/lac-chitosan complex also escapes from the endosome by the same mechanism as the pDNA/chitosan complex.

Nocodazole blocks transport from the early to late endosomes, resulting in an accumulation of cargo in the endosome compartment (*39*). Nocodazole increased the transfection efficiency of the pDNA/chitosan complex by 2−3-fold (Figure 8B). Since the pDNA/chitosan complexes were not transported to the late endosome and accumulated in the early endosome by nocodazole, they could escape the degradation in the late endosome.

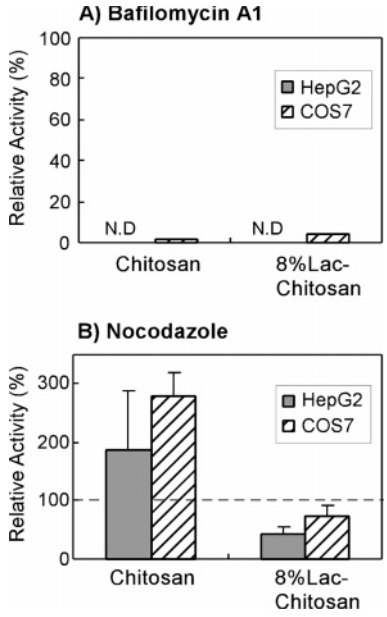

Figure 8. Effect of endocytosis inhibitors on transfection efficiency of the pDNA/chitosan and pDNA/8%lac-chitosan complexes for HepG2 cells. Prior to the incubation with pDNA complexes, HepG2 and COS7 cells were incubated for 30 min with 200 nM bafilomycin A_1 at 37 °C and 33 μM nocodazole at 4 °C. N.D. = not detected.

These results suggested that the pDNA/chitosan complex brought about high gene expression via release from the early endosome. Therefore, the localization of the pDNA/chitosan complexes in the late endosome around the nucleus might be disadvantageous for gene expression. In contrast, the transfection efficiency of pDNA/lac-chitosan complexes was not enhanced by nocodazole for COS 7 cells and was decreased to 60% of the control ($p < 0.05$) for HepG2 cells. These results infer that the entrapment of pDNA/8% lac-chitosan complexes in early endosome resulted in the obstruction of the release from the endosome and the transfer into the nucleus.

Chitosan is known to uniquely disturb the cell membrane (*36*, *37*), while lactosylation of chitosan would weaken the perturbation of the endosomal membrane. A further decrease of pH may be required for the pDNA/lac-chitosan complexes to escape from the endosome compartment. Although the transport of pDNA complexes to the late endosome/lysosome would raise the risk of the hydrolysis of DNA, the pDNA/8% lac-chitosan complex showed high transfection efficiency for HepG2 cells. This result suggested that the release of pDNA/8% lac-chitosan complexes from the late endosome is advantageous for the delivery of DNA to the perinuclear region. Some viruses, such as Semliki Forest virus and influenza virus, are known to escape specifically from the late endosome in the endocytosis pathway in order to gain access to the nucleus (*40*).

Ishii et al. has proposed the mechanism of cell transfection with pDNA/chitosan complexes (*11*). The pDNA/chitosan complexes were endocytosed and possibly released from the endosome due to swelling of the pDNA/chitosan complexes. Thereafter, the pDNA/chitosan complexes were accumulated in the nucleus. On the basis of the previous investigation, we considered the two possibilities to explain the high transfection efficiency of pDNA/lac-chitosan complex in HepG2 cells. One of the possibilities is that the endocytosis pathway of the pDNA/lac-chitosan complexes was distinct from that of the pDNA/chitosan complex and escaped from lysosome fusion. It has been reported that there is an endocytosis pathway in which the cargo such as the intracellular pathogen, mycobacteria, can escape delivery to and digestion in the lysosome (*41*). Thus, pDNA complexed with 8% lac-chitosan may escape from DNA digestion and efficiently transfer to the cytosol and nucleus. Another possibility is that the specific pathway from the late endosome to the nucleus may be ready for lactose-bearing nonviral delivery. Sugar-dependent nuclear import of a glycosylated protein has been reported (*42*). Although the size of pDNA complex is much larger than that of protein, the carbohydrate recognition may contribute to help nuclear import of the pDNA/lac-chitosan complexes.

Further experiments are needed to conclude the effect of lactosylation of pDNA/chitosan complexes on endocytosis pathway and nuclear transport. However, in this study, we investigated the intracellular trafficking of the pDNA/lac-chitosan complexes and found that the delivery of a sugar-modified DNA complex to late endosome was advantageous to gene expression.

SUMMARY

We investigated the effect of the lactosylation of chitosan on the formation of the DNA complex, cell transfection, and transfection mechanism. The lactosylation of chitosan increased the physicochemical stability of the pDNA complex and suppressed the BSA-induced aggregation. The pDNA/8% lac-chitosan complex showed high transfection efficiency for hepatocytes and the accumulation of DNA complexes in the late endosome/lysosome. The release from the late endosome may bring about the transfer into the perinuclear region. To our knowledge, this is the first finding on the effect of lactose on the intracellular delivery relating to gene expression. Finally, we concluded that the use of carbohydrates in gene delivery systems would widely contribute to the physicochemical properties, cellular interaction, intracellular delivery, and gene expression.

Received August 11, 2005; Revised Manuscript Received December 5, 2005

A new prototype of nanoconjugate, Polycefin, was synthesized for targeted delivery of antisense oligonucleotides and monoclonal antibodies to brain tumors. The macromolecular carrier contains: 1. biodegradable, nonimmunogenic, nontoxic β-poly(L-malic acid) of microbial origin; 2. Morpholino antisense oligonucleotides targeting laminin α4 and β1 chains of laminin-8, which is specifically overexpressed in glial brain tumors; 3. monoclonal anti-transferrin receptor antibody for specific tissue targeting; 4. oligonucleotide releasing disulfide units; 5. L-valine containing, pH-sensitive membrane disrupting unit(s), 6. protective poly(ethylene glycol); 7. a fluorescent dye (optional). Highly purified modules were conjugated directly with *N*-hydroxysuccinimidyl ester-activated β-poly(L-malic acid) at pendant carboxyl groups or at thiol containing spacers via thioether and disulfide bonds. Products were chemically validated by physical, chemical, and functional tests. In vitro experiments using two human glioma cell lines U87MG and T98G demonstrated that Polycefin was delivered into the tumor cells by a receptor-mediated endocytosis mechanism and was able to inhibit the synthesis of laminin-8 α4 and β1 chains at the same time. Inhibition of laminin-8 expression was in agreement with the designed endosomal membrane disruption and drug releasing activity. In vivo imaging showed the accumulation of intravenously injected Polycefin in brain tumor tissue via the antibody-targeted transferrin receptor-mediated endosomal pathway in addition to a less efficient mechanism known for high molecular mass biopolymers as enhanced permeability and retention effect. Polycefin was nontoxic to normal and tumor astrocytes in a wide range of concentrations, accumulated in brain tumor, and could be used for specific targeting of several biomarkers simultaneously.

INTRODUCTION

Targeted delivery of drugs reduces systemic toxicity and increases the drug concentration at the tumor site. It can be achieved by specific multicomponent nanoscale devices such as liposomes, particles, and nanoconjugates (*1*−*3*). High-molecular-mass nanoconjugates based on water-soluble macromolecules offer several advantages over direct delivery of drugs: 1. Delivery of both lipophilic and hydrophilic drugs, in particular, of antisense oligonucleotides, through biological barriers such as the blood−brain barrier (*4*, *5*); 2. Delivery of a multitude of different drugs by each single carrier molecule allowing synergism in recipient cells (*6*, *7*); 3. Targeting of a drug delivery device to tumors with minimal damage to healthy tissue; 4. Targeting to tumor cells due to an enhanced permeability and retention (EPR)[1] effect (*8*−*12*); 5. Targeting by receptor-mediated binding to surfaces of recipient cells and endosomal uptake into these cells (*13*−*16*); 6. Provision of an activity for disruption of endosomal membranes and for the release of the drug carrier system into the cytoplasm (*17*−*22*); 7. A cleavable linkage for the release of the drug from the carrier system (*23*−*26*); 8. A prolonged circulation through protection by PEG against degradation activities (*27*−*30*); and 9. Attachment of a fluorescent reporter for the localization of the carrier system. Available drug delivery systems either do not comply with a complete set of these demands or they have several of these properties but suffer from nonbiodegradability, immunogenicity and toxicity. We designed and synthesized a prototype nanoconjugate intended to fulfill the above criteria and to be used as a future anticancer drug delivery system to brain tumors.

Ideally, a nanoconjugate contains a central scaffold with numerous pendant chemical groups allowing for covalently attaching modules with the above functions. These can be designed to vary in the kind and number of prodrug(s), targeting specificity, and drug releasing activity (endosomal or cytoplasmic). Of the highly developed nanoconjugate delivery systems, scaffolds frequently represent copolymers of substituted acrylic acid, notably *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer (*31*−*35*). This kind of scaffold, however, suffers from resistance to biodegradation.

We report here on the chemical synthesis of a new nanoconjugate prototype of drug delivery system, by sequential conjugation of functional modules to a nontoxic, nonimmunogenic, biogenic scaffold, β-poly(L-malic acid) (PMLA) (*36*). This polymer has been highly purified from the myxomycete *Physarum polycephalum*. PMLA resembles HPMA in carrying abundant carboxyl groups, but as a polyester of L-malic acid, it is completely biodegraded to carbon dioxide and water. On the basis of established synthetic methods, we succeeded to chemically conjugate functional modules to the pendant carboxyl groups in a controlled, newly developed manner to form novel nanoscale structures. Specifically, these modules were: 1. The drugs: Morpholino antisense oligonucleotide (MORPH-AON) to laminin α4 and MORPH-AON to laminin β1 chains, 2. The targeting molecule: transferrin receptor monoclonal antibody (mAb OX-26 for rat and mAb R17217 for mouse), 3. The drug releasing module: disulfide bridges between the MORPH-AON and the scaffold (*26*), 4. The endosome escaping module: hydrophobic stretches of valine or leucine ethyl ester-conjugated scaffold (*17*−*22*), 5. The degradation protecting module: PEG (*27*−*30*), 6. The optional reporter module: Fluorescein or Alexa Fluor 680.

MORPH-AONs were designed to inhibit the synthesis of α4 and β1 chains of laminin-8, which is overexpressed in vessel walls of highly vascular glial tumors, breast cancer and their metastases (*37*, *38*). This inhibition has been shown to reduce invasion of human gliomas in vitro (*39*). MORPH-AONs, unlike other oligonucleotides, are resistant against nucleolytic degradation and are highly specific at low concentrations (*40*). Transferrin receptor antibody was chosen to target the delivery device beyond the blood−tumor barrier (BTB) in brain to the glioma target cells by promoting receptor binding and endosomal uptake (*41*−*45*). Targeting to tumor was reinforced by the EPR effect (*8*−*12*). The delivery system is based on a biologically produced scaffold and has a complex modular structure.

EXPERIMENTAL PROCEDURES

Reagents Used. Morpholino-3'-NH_2 antisense oligonucleotides AGC-TCA-AAG-CCA-TTT-CTC-CGC-TGA-C to laminin α4 (MORPH-AON-1) and CTA-GCA-ACT-GGA-GAA-GCC-CCA-TGC−C to laminin β1 (MORPH-AON-2) (*38*, *39*) chains were custom-made by Gene Tools (Philomath, OR). Mouse anti-rat mAb (clone OX-26, IgG_{2a},κ, 1 mg/mL in PBS; cross-reacting with human as shown in this work) and rat anti-mouse mAb (clone R17217, IgG_{2a},κ, 1 mg/mL in PBS) to transferrin receptor (CD71) were obtained from Chemicon International (Temecula, CA). β-Poly(L-malic acid) (PMLA) (**1**), a natural polymer of molecular mass $M_w = 50000$ (polydispersity $M_w/M_n = 1.3$) from the culture broth of *Physarum polycephalum*, was highly purified (*36*) and size-fractionated on Sephadex G25. The lyophilized polyacid was devoid of material absorbing at 260 and 280 nm wavelengths. If not mentioned otherwise, molar quantities refer to total malyl residues. Chromatographically pure $mPEG_{5000}$-amine and maleimide-PEG_{3400}-maleimide were obtained from Nektar Therapeutics (San Carlos, CA). 3-(2-Pyridyldithio)-propionate (PDP) was synthesized as described (*46*). Fluorescein-5-maleimide was obtained from Molecular Probes (Leiden, The Netherlands) and Alexa Fluor 680 C_2-maleimide from Molecular Probes-Invitrogen (Karlsruhe, Germany). Endosomal marker FM 4-64 was purchased from Molecular Probes. All other chemicals of highest purity were bought from Merck (Darmstadt, Germany), Sigma-Aldrich (Munich, Germany), and Pierce (Rockford, IL). Glioma cell lines U87MG and T98G were from American Type Culture Collection (Manassas, VA), and normal human embryonic astrocyte cell line HAST040 was obtained from Clonexpress (Gaithersburg, MD).

Cell Lines and Culture Conditions. Two types of human GBM cell lines (T98G and U87MG) were used. Cells were cultured in Eagle's MEM with 10% fetal calf serum, L-glutamine, sodium bicarbonate, nonessential amino acids, antibiotics, and sodium pyruvate. Normal embryonic brain astrocyte cell line HAST040 (Clonexpress) was also used in toxicity assays.

Cell Viability Assay. To measure cell viability, cells were quantified using the CellTiter 96 AQueous One Solution Cell Proliferation Assay kit (Promega Mannheim, Germany) designed for the determination of the number of viable cells with MTS reagent [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium, inner salt]. Protocols supplied by the company were exactly followed. A_{490} was recorded on a Spectra Max Plus 384 ELISA reader (IBB, Atlanta, GA). Concentration of Polycefin equal to 1.4 μM corresponds to the concentration of MORPH-AONs of 2.5 mg/kg. It is the working concentration recommended for antisense nucleotides to block mRNA synthesis in vitro and in vivo (*47*).

In Vivo Fluorescence Imaging. Xenogen IVIS 200 imaging system (Xenogen, Alameda, CA) was used on whole body and isolated organs of glioma-bearing mice 6−72 h following Polycefin injection and after PBS organ/body perfusion to remove the fluorescent drug from circulation. For imaging experiments on mice, Polycefin with attached L-leucine ethyl ester instead of L-valine, with rat mAb R17217 to mouse transferrin receptor and Alexa Fluor 680 dye. The excitation wavelength for the dye was 660 nm. Images were acquired and analyzed at 3.9 cm (organs) or 13 cm (whole mouse) field of view using Living Image Software 2.50. In preliminary experiments, a proprietary MISTI imaging system equipped with 20 nm bandwidth interference filter (ChromaTech) and emission wavelength 700 nm was used. Both imaging systems produced similar results.

Animals. All surgical and nonsurgical procedures were performed in full accordance with IACUC protocol 001462, obtained in May 2005 at Cedars-Sinai Medical Center and with the tenets of the Declaration of Helsinki.

Nude Mice [Tac:Cr:(MCr)-*Foxn*^{nu} mice], after intraperitoneal anesthesia by ketamine 75 mg/kg and medetomidine 1.0 mg/kg, were used. A 10 mm middle line skin incision was made on mouse's skull. A hole in the skull 2 mm laterally and 1 mm rostrally from the Bregma (sagittal and transverse lines crossing point) was made using a dental drill by aseptic technique. Mice underwent stereotactic intracranial injection of 5×10^4 U87MG human glioma cells to the right basal ganglia field using a 2 μL Hamilton syringe over a period of 1 min.

On day 21 after tumor implantation, the mice underwent the intravenous injection of Polycefin at the concentration of 5 mg/kg (*47*) dissolved in PBS via the tail vein using a 30-gauge needle 1 mL syringe, at a rate of 100 μL within 5 s.

Confocal Microscopy. A TCS SP spectral scanner (Leica Microsystems, Mannheim, Germany) was used for confocal microscopy. Image stacks of 160 by 160 μm in size and 7.5 μm in depth of live U87MG glioma cells were acquired with a Leica PlanApo 63/1.2 NA lens. Live cells were placed in an Attofluor incubation chamber (Molecular Probes). A temperature of 37 °C was maintained by a separate lens and chamber heating system. The fluorescein derivatives of Polycefin with (**8**) or without (**18**) conjugated transferrin receptor mAb OX-26 were added to cells in serum-free medium at a concentration of 1.4 μM MORPH-AON. Simultaneously with Polycefin, cells received 5 μg/mL (as per the manufacturer's instructions) of lipophilic styryl red fluorescent dye FM 4-64 (Molecular Probes) to visualize endosomes.

Hemolytic Assay. To assess membrane-disrupting activities, hemolytic properties of Polycefin and other conjugates were

measured by the red blood cell (RBC) hemolysis assay (*21*) for 2 nmol of conjugate per 10^8 RBCs after incubation at 37 °C (1 h) in 1.5 mL of 100 mM sodium phosphate buffer at several given pHs. Percent hemolysis $(A - A_o)/(A_{tot} - A_o)$ as averaged over three independent measurements and calculated from A_{541} (= A) of the clear supernatant after pelletting. A_o refers to spontaneous and A_{tot} to complete hemolysis in distilled water.

Western Blot Analysis. Reducing SDS−PAGE (with 20 mM DTT) on 10% polyacrylamide gels (samples boiled for 5 min in 5% SDS) and routine Western blotting were carried out as published (*39*).

Polycefin (**8**) at a concentration of 1.4 μM MORPH-AON (*38*) was added to the medium of human glioma U87MG and T98G cultures on day 1 and 4 in culture media. For the detection of laminins, serum-free conditioned medium was sampled at day 6 from culture supernatants above equal numbers of cells that has been cultured for the same period of time. Samples were concentrated 10-fold by filtering through Centriplus filtration devices (Millipore, Bedford, MA) and proteins were separated using Tris-acetate 3−8% gradient SDS−PAGE (Invitrogen) under reducing conditions. Lysates of human glioma T98G, known to express laminin-8 (*48*), were used as a positive control. The gels were blotted onto nitrocellulose membrane (Invitrogen). The membranes were probed with mAbs followed by chemiluminescent detection using the Immune-Star kit with alkaline phosphatase-conjugated secondary antibodies (Bio-Rad Hercules, CA). Antibodies were used to laminin α4 [mAb 8B12 (*48*)] and β1 chains (mAb LT3). Antibody to human fibronectin 8th type III repeat [mAb 568 (*39*)] was used to control for equal loading of gel lanes.

Densitometric Analysis. The intensities of the bands of interest after Western blot analysis were determined using the AlphaImager 2000 densitometer (Alpha Innotech, Inc., San Leandro, CA) and expressed relative to the fibronectin band intensities for the same specimens. Background was subtracted from each reading before determining the intensity ratios.

Test of the Morpholino Oligonucleotides Releasing Module of Polycefin. To demonstrate the activity of the oligonucleotide releasing module, Polycefin (0.25 mM bound MORPH-AONs) was incubated with 3 mM GSH (γ-L-glutamyl-L-cysteinylglycine) in 50 mM phosphate buffer pH 7.4 at 37 °C. Samples at various times were stopped with 20 mM *N*-ethylmaleimide, and the liberated reduced oligonucleotide was detected as the *N*-ethylmaleimidyl derivative by SEC−HPLC, A_{260}. 100% release was measured in the presence of 50 mM dithiothreitol (DTT) (60 min, 37 °C).

Analytical Chemical Methods. Thiol residues of conjugates were assayed by the method of Ellman after removal of free 2-MEA by diafiltration (5 kDa cutoff). Amounts of maleimido groups were quantified by their reaction with a given amount of 2-MEA. During the preparation of PMLA conjugates, the substitution of *N*-hydroxysuccinimidyl (NHS) residues was followed by RP-HPLC analysis of the reaction mixtures. Amino acids were quantified by RP-HPLC after hydrolysis of conjugates in 6 M HCl at 100 °C and colorimetry with trinitrofluorobenzene (TNBS) following standard protocols.

Instrumentation. ^{1}H NMR spectra were recorded on a Bruker Model DMX-500 Fourier transform spectrometer with MTS as internal standard. Chromatography was performed on a Merck-Hitachi (Ghent, Belgium) analytical LaChrom D-7000 HPLC-UV and fluorescence detector system with either Macherey & Nagel (Düren, Germany) C_{18}-Nucleosil reversed phase RP (250/4 mm) or size exclusion Bio-Sil SEC 250-5 (5 μm, 300/7.8 mm) columns. Molecular mass markers were polystyrene sulfonates from Machery-Nagel and proteins from Sigma-Aldrich. Merck precoated silica gel 60 F_{254} aluminum sheets were used in thin-layer chromatography with *n*-butanol, water, and acetic acid (4:2:1 by volume) as solvent.

Synthesis of Polycefin. Synthesis of Intermediates and Conjugates. Polycefin, fluorescent dye-Polycefin, and other conjugates have been synthesized from the following intermediates (Scheme 1):

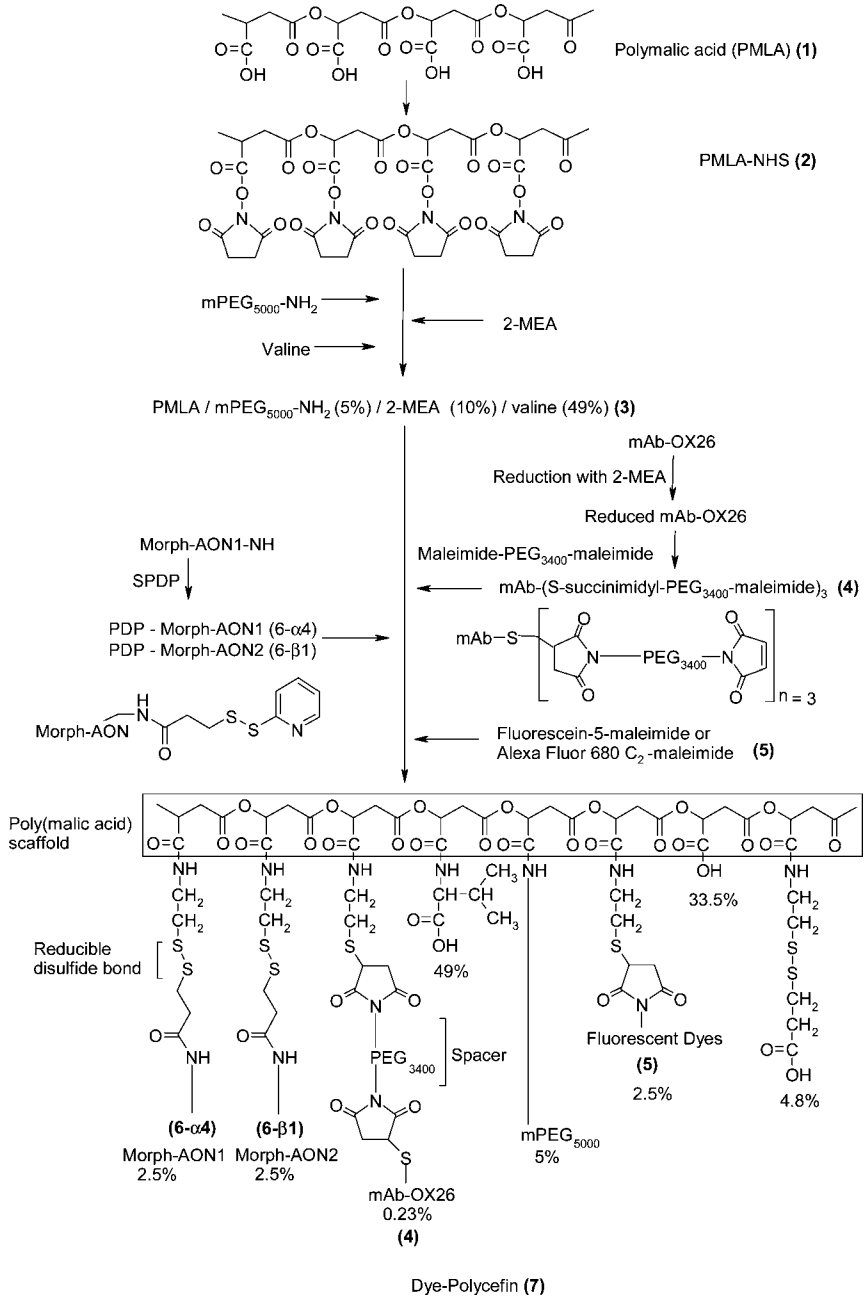
PMLA-N-hydroxysuccinimidyl Ester (PMLA-NHS) (2). A mixture of anhydrous 10 mmol PMLA (**1**), *N*-hydroxysuccinimide (NHS), and dicyclohexylcarbodiimide (DCC) (15 mmol) in DMF was incubated at room temperature. Dicyclohexylurea was exhaustively removed and product precipitated with ethyl acetate (P1), diethyl ether (P2), and *n*-hexane (P3) in this order. Products P1−P3 were dissolved in DMF, purified over Sephadex LH 20, and then stored as precipitates at −20 °C. PMLA-NHS ester was assayed by exhaustive reaction with *n*-butylamine and analysis of free NHS by RP-HPLC [aqueous 0.1% (v/v) TFA] recording A_{260} with reference to NHS standards. Contents were 35, 59, and 85% for P1, P2, and P3 (percentage refers to total PMLA-malyl residues). For the synthesis of Polycefin, P3 was used. Its overall yield was 50−60% with regard to input PMLA. ^{1}H NMR spectra of PMLA-NHS ester in $(CD_3)_2SO$ indicated chemical shifts at 2.8 ppm (singulet, 4H, N−CO−CH_2), 3.35 ppm (doublet, the methylene protons of the polyester backbone), and 5.85 ppm (triplet, the methine protons of the polyester backbone).

*(2-Pyridyldithio)propionyl Morpholino Antisense Oligonucleotides (PDP−MORPH-AONs) (conjugates **6**-α4 and **6**-β1 in Scheme 1).* Morpholino-3'-NH_2 oligonucleotide was coupled in 10% aqueous DMF with *N*-succinimidyl-3-(2-pyridyldithio)-propionate (SPDP) (2-fold excess, 20 °C). After passage over a Sephadex G-25 microspin column in 0.1 M sodium phosphate buffer (pH 6.5), 0.15 M NaCl, and 10 mM EDTA (Buffer A), the product was pure by TLC. The PDP-content was assayed by RP-HPLC after reaction with dithiothreitol (DTT). 2-Thiopyridone was detected at 341 nm wavelength and its concentration measured against reduced 2-aldrithiol as a standard. Yields were >80%.

*mAb OX-26-(S-succinimidyl-PEG_{3400}-maleimide)$_3$ (conjugate **4** in Scheme 1).* MAb OX-26 (20−30 nmol) or mAb R17217 was reduced in the presence of 53 μmol of solid 2-MEA hydrochloride in Buffer A (90 min at 37 °C). The product was washed over Sigma Ultrafree-CL microcentrifuge filters (30 kDa cutoff) to remove free 2-MEA (tests with Ellman's reagent). Free sulfhydryls were reacted with a 50-fold excess of maleimide-PEG_{3400}-maleimide over antibody, and excess reagent was removed by diafiltration (50 kDa cutoff). Purity was controlled by SEC−HPLC. Positions were 7.20−7.26 min for conjugate **4** and 13.4−13.7 min for maleimide-PEG_{3400}-maleimide. Of the thiol groups, 3.1−3.5 were detected in reduced antibody, and of the maleimido groups, 2.7−3.0 were detected in conjugate **4**, suggesting the formula mAb OX-26-(*S*-succinimidyl-PEG_{3400}-maleimide)$_3$ in Scheme 1.

*PMLA/$mPEG_{5000}$-NH_2 (5%)/2- MEA (10%)/valine (49%) (conjugate **3** in Scheme 1) and Other Conjugates.* The symbol "/" refers to conjugation of the indicated moiety with PMLA. PMLA-NHS esters dissolved in DMF were conjugated with $mPEG_{5000}$-NH_2, 2-MEA, and L-valine (or gylcine and L-alanine) by amide formation in this order. Specifically, PMLA-NHS P3 (1 mmol) was conjugated with 50 μmol $mPEG_{5000}$-NH_2 at 5% of the malyl residues (100% = all malyl groups in the preparation), followed by conjugation with 100 μmol of 2-MEA at 10% of the malyl residues. Completeness of each reaction was assayed by TLC and tested with ninhydrin. No precipitates were observed that could have affected stoichiometries. Finally, 1 mmol of L-valine (or glycine, L-alanine) was conjugated in DMF/PBS (a mixture of equal volumes) for 1 h at 20 °C. Again, no precipitate was observed. The product was transferred to

Scheme 1. Summary of the Synthesis of Dye-Polycefin (7)[a]



[a] Intermediates of the synthesis and of various modules are abbreviated by underlined numbers. Percent values refer to the number of malyl moieties of PMLA that are conjugated with a given module (100% = total malyl content). Polycefin (**8**) was synthesized with the omission of the fluorescent dye **5**. The distribution of conjugates along the scaffold is assumed to be random. Abbreviations are: PMLA, β-poly(L-malic acid); PMLA-NHS, *N*-hydroxysuccinimidyl ester at pending carboxyl groups of PMLA; $mPEG_{5000}$, methoxy poly(ethylene glycol) (5000 Da); 2-MEA, 2-mercaptoethylamine; mAb OX-26, mouse monoclonal antibody to rat transferrin receptor; maleimide-PEG_{3400}-maleimide, a bifunctional maleimide derivative of PEG (3400 Da); MORPH-AON-1, morpholino antisense oligonucleotide to laminin α4 chain; MORPH-AON-2, morpholino antisense oligonucleotide to laminin β1 chain.

Buffer A by solvent evaporation/complete resolubilization containing 0.5 mM DTT and purified over Sephadex G25 column. Lyophilized fractions were used in the synthesis of Polycefin. The composition of conjugate **3** was PMLA, $mPEG_{5000}$ (5%), 2-MEA (10%), and L-valine (49%). Each of the reactions was completed except for the amino acids, which were assayed after conjugation, validating the given composition. To measure effects of various conjugated groups (for instance on membrane stability by the hemolysis assay), additional conjugates were synthesized: **9** PMLA/$mPEG_{5000}$ (5%)/2-MEA (5%), **10** PMLA/$mPEG_{5000}$ (10%)/2-MEA (5%), **11** PMLA/$mPEG_{5000}$ (15%)/2-MEA (5%), **12** PMLA/$mPEG_{5000}$ (5%)/2-MEA (5%)/glycine (63%), **13** PMLA/$mPEG_{5000}$ (5%)/2-MEA (5%)/L-alanine (56%), **14** PMLA/$mPEG_{5000}$ (5%)/2-MEA (5%)/L-valine (55%), **15** PMLA/$mPEG_{5000}$-NH_2 (5%)/2-MEA (10%)/valine (15%), **16** PMLA/$mPEG_{5000}$-NH_2 (5%)/2-MEA (10%)/valine (34%), **17** PMLA/$mPEG_{5000}$-NH_2 (5%)/2-MEA (10%)/valine (55%), **18** PMLA/$mPEG_{5000}$-NH_2 (5%)/2-MEA (10%)/valine (50%)/(2-pyridyldithio)propionyl-morpholino AON to laminin α4 chain (2.5%)/(2-pyridyldithio)propionyl-morpholino AON to laminin β1 chain (2.5%)/3-(2-pyridyldithio)propionate, **19** PMLA/$mPEG_{5000}$-NH_2 (5%)/2-MEA (10%)/valine (50%)/mAB-(*S*-succinimidyl-PEG_{3400}-maleimide)$_3$ (0.23%)/3-(2-pyridyldithio)-propionate, **20** Polycefin variant with leucine ethyl ester instead of valine, with mAb R17217 to mouse, and with Alexa Fluor

680, **21** as for **20**, but without mAb. Free sulfhydryl groups were blocked with 3-(2-pyridyldithio)propionate (PDP).

*Synthesis of Dye-Polycefin (**7** in Scheme 1) and Polycefin (**8**).* Freshly prepared mAb OX-26-(*S*-succinyl-PEG_{3400}-maleimide)$_3$ (conjugate **4**) was added dropwise to conjugate **3** dissolved in Buffer A at 4 °C. Free thiol groups (conjugate **3**) were in 50-fold excess over maleimido groups (conjugate **4**). Next, 2.5 μmol of fluorescein-5-maleimide or Alexa Fluor 680 C_2-maleimide (compounds **5**), 5 μmol of PDP−Morph-AON1 (**6**-α4), and 5 μmol of PDP−Morph-AON2 (**6**-β1) were coupled overnight to the growing conjugate. To obtain Polycefin (**8**), the conjugation with **5** was omitted. Completeness of the reactions was indicated by a single peak after SEC−HPLC. Unreacted free sulfhydryl groups were blocked with 3-(2-pyridyldithio)propionate (PDP). The obtained conjugates **7** and **8** were purified by diafiltration (100 kDa cutoff) and lyophilized. The absolute yields were 75−80% with reference to conjugate **3** (100%), and the overall yield with reference to PMLA (**1**) input was 25%. For cell delivery and membrane disruption studies, conjugates resembling Polycefin, **18** either without mAb OX-26 or **19** without the oligonucleotides, and for imaging experiments, Polycefin variants **20** and **21**, were synthesized and purified by analogous methods.

RESULTS

Synthesis of Polycefin. The nanoscale synthesis of Polycefin outlined in Scheme 1 and described under Experimental Procedures afforded the highly controlled chemical coupling of macromolecular groups (modules) with the polymeric PMLA scaffold. In the beginning, the scaffold carboxyl groups were activated by forming *N*-hydroxysuccinimidyl esters of the polymer (PMLA-NHS) that were then substituted by PEG_{5000}-NH_2, 2-mercaptoethylamine (2-MEA), and L-valine in forming amide bonds with the carboxylates. The reactions were sequential without purification of intermediates. Products were validated by demonstrating complete consumption of the substituting amines and correlation with the released amount of NHS. Only the coupling of amino acids caused a small fraction of spontaneous hydrolysis of PMLA-NHS. The stoichiometry for valine and the other amino acids was derived from quantitative amino acid analysis. The multiple conjugate thus obtained (conjugate **3** in Scheme 1) contained 33−35% free carboxylates.

Probing PMLA and PMLA-NHS by SEC−HPLC indicated a dramatic change in conformation by the esterification from a probably extended to a compact structure in aqueous solution. The consequently decreased solubility in water was improved by conjugation of PEG_{5000}, which also should confer stability in body fluids (*27*−*30*). Only after conjugation of PEG, the pending thiol groups of conjugate **3** became accessible to the reactions with mAb OX-26 (or mAb R17217) and MORPH-AONs.

The reactions with mAb OX-26 or mAb R17217and MORPH-AONs required mild conditions in order to avoid irreversible denaturation. The conjugation of mAb involved at first a reduction of disulfide bridges resulting in the formation of 3 thiol residues per antibody and reaction with excessive maleimide-PEG_{3400}-maleimide forming the conjugate **4** (Scheme 1). The free unreacted maleimido groups were reserved to substitute at thiols of scaffold-bound 2-MEA (in conjugate **3**) forming thioether conjugates. SEC−HPLC and nonreducing SDS−PAGE prior to this conjugation indicated molecular masses of 150 kDa for both the reduced mAb and PEG-mAb, consistent with single mAb conjugates of maleimide-PEG_{3400}-maleimide (results not shown).

The cleavage site for the release of the MORPH-AONs from the carrier was constructed as an interspacing disulfide group between MORPH-AON and 2-MEA on the scaffold. This allowed the reductive cleavage by glutathione in the target cell cytoplasm. The disulfide was introduced by the disulfide exchange reaction of 2-MEA-thiol groups, bound to the scaffold, with PDP-MORPH-AONs (conjugates **6** in Scheme 1).

Polycefin and dye-Polycefin were assembled by the consecutive chemical coupling of the scaffold conjugate **3** with modules **4**, **5**, and **6** (Scheme 1). Their controlled synthesis together with their chromatographic and chemical characterization validated their structural composition, chemical functionality, and purity. At a 50-fold molar excess of thiol residues in conjugate **3** over conjugate **4**, the reaction with mAb was quantitative implicating an average of one molecule of antibody bound per molecule of scaffold. The covalent attachment of MORPH-AONs (conjugates **6**) was quantitative as verified by SEC−HPLC of educts and products.

Properties of Polycefin. The structure of dye-Polycefin is shown in Scheme 1 (in Polycefin, the dye module **5** is substituted by 3-thiopropionic acid). PMLA constitutes a scaffold that can bind a deliberate number of functional modules allowing versatile tissue-specific drug vehicles. The modules are statistically distributed over the scaffold at the abundances given in Scheme 1 in percentages of total malyl residues. The homogeneity of the scaffold-forming PMLA is characterized by its natural polydispersity. On the basis of a M_w of 50000 (corresponding to approximately 500 malyl residues), Polycefin molecules contain on average 1 molecule of mAb (targeting module), 11 molecules of conjugate **6**-α4, 11 molecules of conjugate **6**-β1, 22 molecules of $mPEG_{5000}$ (protecting module), 210−220 molecules of L-valine (membrane disrupting module), and 140−150 pending carboxylate residues. The composition accounted for a molecular mass of approximately 550000. The stoichiometry of 1:20−1:26 mAb relative to oligonucleotides was validated by disulfide reduction of Polycefin, separation of free protein and MORPH-AON by SEC−HPLC, and assessment of the amounts of MORPH-AON and protein on the basis of standardized A_{260} and the results of protein measurements. Freeze-dried Polycefin was colorless, nonhygroscopic, odorless, and stable at room temperature. The material was highly soluble in PBS and then stable for several days to weeks at 4 °C or at least 24 h at 37 °C. Polycefin had an UV-absorbance spectrum with a maximum at wavelengths <220 nm and a broad shoulder at 250−285 nm. The spectrum is indicative of carboxyl esters, carboxyamides, carboxylate, oligonucleotides, and protein. Dye-Polycefin showed also the absorbance and the fluorescence of the conjugated dye.

Analysis of Polycefin by Nonreducing SDS−PAGE. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE) of Fluorescein-Polycefin was performed to identify the number of mAb molecules (shown is the result with mAb OX-26) conjugated with the PMLA scaffold (Figure 1). A single band of conjugated mAb of approximately 150 kDa was revealed under nonreducing conditions. Bands of higher molecular masses were not observed excluding the possibility of multiplets of conjugated IgG's.

To visualize which of the IgGchains were conjugated to the scaffold, samples were examined by SDS−PAGE under reducing conditions, and results were compared with those for unsubstituted mAb OX-26. Western blots, Fluorescein-dependent fluorescence, and protein staining (Coomassie Brilliant Blue) revealed bands of variable intensities in the range of 50 kDa and 62 kDa that referred to the intact H-chain and a main proteolytic fragment of mAb OX-26 (lanes R1 and R5) and Fluorescein-Polycefin (lanes R2−R4). L-Chains (25 kDa) were only protein stained (R4 and R5). The results indicated that PMLA was exclusively conjugated with the H-chain. It should be mentioned that the molecular mass scale by the polypeptide markers is not valid for Fluorescein-Polycefin, because the

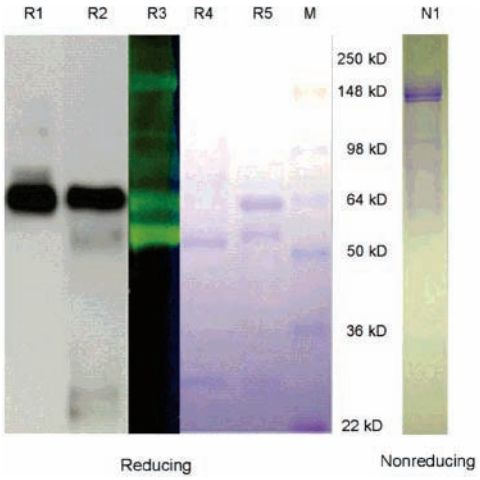


Figure 1. SDS−PAGE of mAb OX-26 and Fluorescein-Polycefin to demonstrate the conjugation of PMLA with the H-chain of the antibody, and the absence of multiple cross-linking of antibody. Lane N1, Fluorescein-Polycefin. Electrophoresis under nonreducing condition (DTT absent) showing the integral mAb after staining with Coomassie Brilliant Blue. Only the monomeric (150 kDa) but no multiple cross-linked mAbs (>150 kDa) are seen. Lanes R1−R5 and M, electrophoresis under reducing conditions (20 mM DTT) favoring dissociation into H- and L-chains. Detection of mAb OX-26 and its H-chains by Western blotting in lanes R1 and by Coomassie Brilliant Blue staining in lane R5. Detection by Western blotting in lane R2, by Fluorescein-specific fluorescence in lane R3, and by Coomassie Brilliant Blue in R4. Lane M, molecular mass markers. Bands in positions 150−165 kDa (R1−R5) refer to H-chain or a large fragment after a limited proteolytic nicking of the samples. Bands of approximately 25 kDa (R4 and R5) refer to L-chain. Fluorescence of the H-chain (fragment) in lane R3 indicates that this chain is conjugated with the scaffold.

PMLA scaffold, unlike polypeptides, has little or no affinity for SDS and does not measurably affect mobility retardation.

Morpholino Oligonucleotide Release from Polycefin. To test for the function of the MORPH-AON releasing module, Polycefin was incubated with glutathione at a concentration of 3 mM typical for cytoplasm. The time dependence of the observed disulfide exchange was biphasic, indicating the release of 50% MORPH-AONs after 30 min and 70% after 60 min. The release was completed after 4 h. Mixed disulfide between MORPH-AON and glutathione was an intermediate of the exchange reaction and amounted to 30% of total free and conjugated MORPH-AONs after 10 s, 50% after 30 min, 20% after 1 h, 12% after 3 h. The results are in agreement with Polycefin structure and suggest free MORPH-AONs shortly after entry into the cytoplasm.

Membrane Disruption. The membrane disrupting feature of Polycefin was tested by the hemolytic assay typically used elsewhere for measuring this kind of effects on biological membranes (*21*). Experiments were performed in the pH range 5−6 typically found in endosomes maturating to lysosomes. Figure 2a shows stimulation of cell rupture by Polycefin. The contribution by mAb OX-26 (comparison of conjugates **3** and **19**) was negligible, whereas the MORPH-AONs indicated a membrane stabilizing effect (comparison of conjugates **3** and **18**). Protection module $mPEG_{5000}$-NH_2 (5−15%) (comparison of conjugates **9**−**11**) also strongly stabilized red blood cells (Figure 2b), whereas 2-MEA residues alone had no effect (results not shown). Comparison of the amino acids glycine (63%), L-alanine (56%), and L-valine (55%) (conjugates **12**−**14**) in Figure 1c revealed amino acid side chain dependent rupture that increased according to hydrophobicity. The disrupting effect of L-valine increased as a function of scaffold loading (Figure 1d, conjugates **15**−**17**). The pH-dependence is in agreement with charge neutralization by protonation of carboxylates of PMLA and amino acid residues.

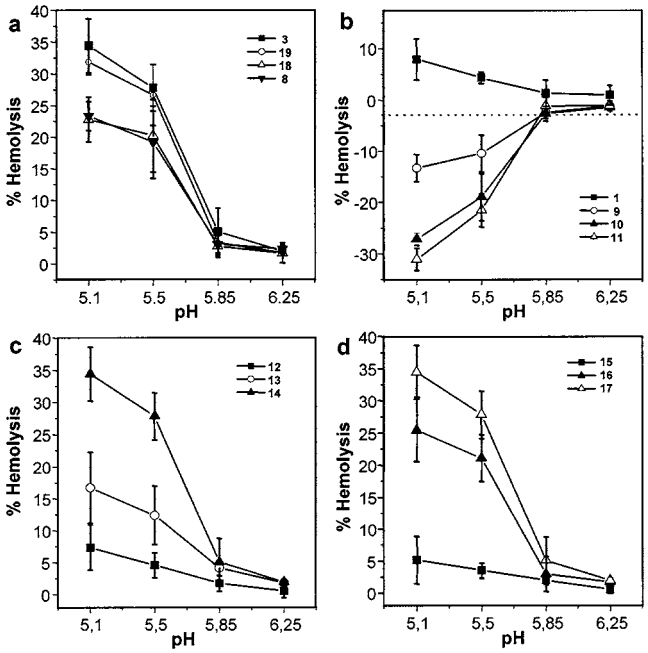

Figure 2. Comparison of the membrane disrupting activities of the Polycefin constituents measured by the hemolysis assay. Concentrations of tested conjugates were adjusted to 1.5×10^7 molecules per red blood cell. For referring numbers to conjugate compositions see Scheme 1 and text. Panel a, effects of the antibody and the oligonucleotides. **8**, Polycefin; **3**, Polycefin without antibody and oligonucleotides, **18**, Polycefin without antibody; **19**, Polycefin without oligonucleotides. Panel b, effect of $mPEG_{5000}$ at different loads. Unsubstituted PMLA **1** and 5% (**9**), 10% (**10**) or 15% (**11**) $mPEG_{5000}$. Panel c, effect of the hydrophobicity of the amino acid side chain. Glycine (**12**), L-alanine (**13**), or L-valine (**14**). Panel d, effect of different loads of valine. 13% (**15**), 34% (**16**), 55% (**17**) L-valine.

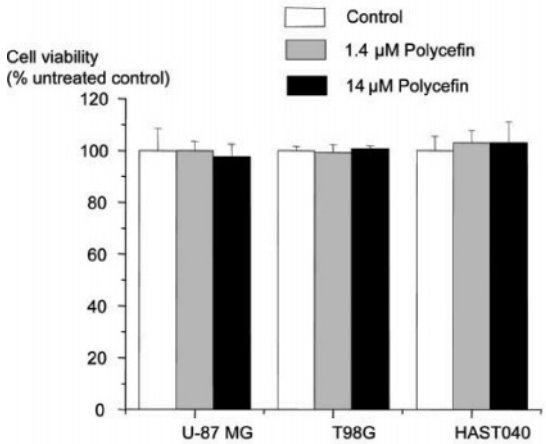

Figure 3. Cell viability of normal (HAST040) and malignant (U87MG and T98G) astrocyte cell culture after 48 h of Polycefin incubation. Different concentrations of Polycefin (1.4 μM and 14 μM) did not change the cell viability ($p > 0.05$) after 24 h (not shown) and 48 h treatment. 100% refers to conditions without treatment (control). Cell viability was measured twice in triplicates.

Polycefin Does Not Change Cell Viability. To evaluate the cytotoxicity, we have measured cell viability after treatment with Polycefin. The relative numbers of viable cells were measured in cultures of two human gliomas, U87MG and M059K, and normal human astrocytes, HAST 040. The numbers of treated cells were compared with those of replicate cultures without treatment (taken as 100%). Cell viability for each cell line in two separate experiments was higher than 90% (Figure 3). Untreated controls and treated cultures did not differ significantly from each other ($p > 0.05$). Based on these data we

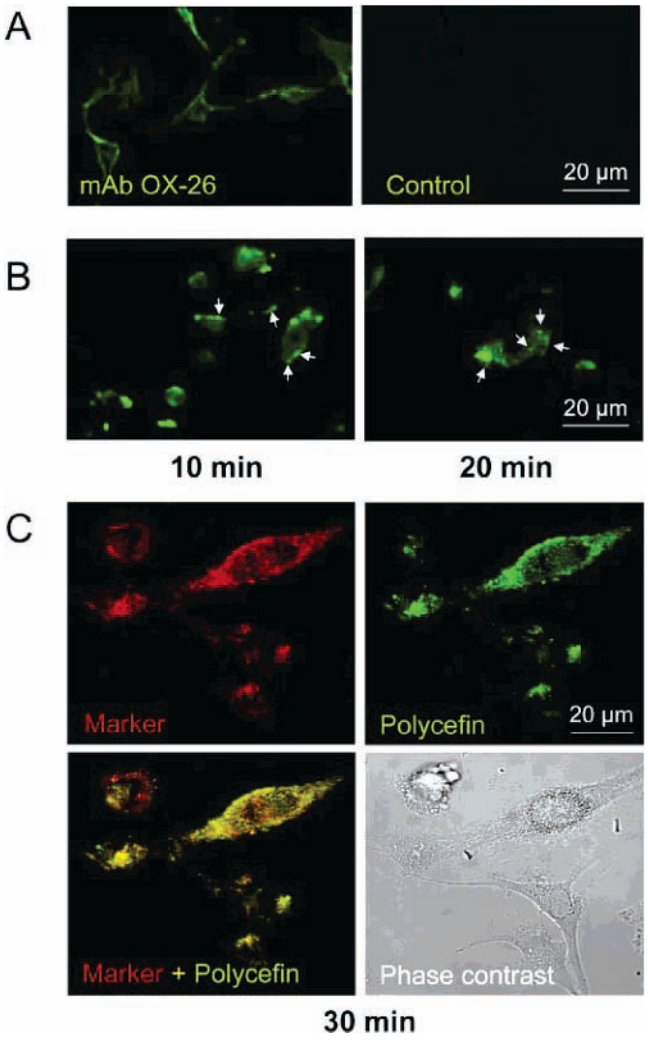

Figure 4. Drug delivery into cultured human glioma U87MG cells. A. U87MG glioma cells display surface staining with OX-26 antibody by indirect immunofluorescence demonstrating cross-reactivity with human antigen (left). Omission of primary antibody abolished staining (negative control, right). B. Left, 10 min of U87MG treatment with Fluorescein-labeled Polycefin. The location of Polycefin is indicated by green fluorescence near the cell membrane (arrows), and early endosomes are beginning to form. Right, endosomal formation after 20 min treatment with Polycefin. Maturing endosomes are visible inside the cells (arrows). C. Co-distribution of endosomal marker FM 4-64 (marker) with Fluorescein-Polycefin (30 min) in cultured U87MG cells 30 min after treatment. FM 4-64 stains endosomes (red color), and Polycefin is found in the same place (green color). Co-localization is revealed as yellow color (lower left). Confocal microscopy.

concluded that Polycefin at concentration 1.4 and 14 μM did not exert toxic effects on these cell lines.

In Vitro Studies of Polycefin Cell Delivery. In the in vitro studies with human U87MG and T98G glioblastoma cell lines, we have employed Polycefin (**8**) and its variant (**18**), Polycefin without mAb to transferrin receptor [Polycefin(-mAb)], both of them Fluorescein labeled.

We first established that anti-rat mAb OX-26 conjugated to Polycefin for subsequent intracranial glioma treatment in rats did cross-react with human transferrin receptor (Figure 4A). This Polycefin was further used to examine its internalization mechanism in U87MG glioma cultures. After treatment with Fluorescein-labeled Polycefin (**7**), fluorescence was localized near the cell membrane and in early endosomes after 10 min and inside the cells after 20 min after addition of the drug (Figure 4B). When U87MG were co-stained with fluorescent endosomal marker FM 4-64 (visualized with rhodamine filter),

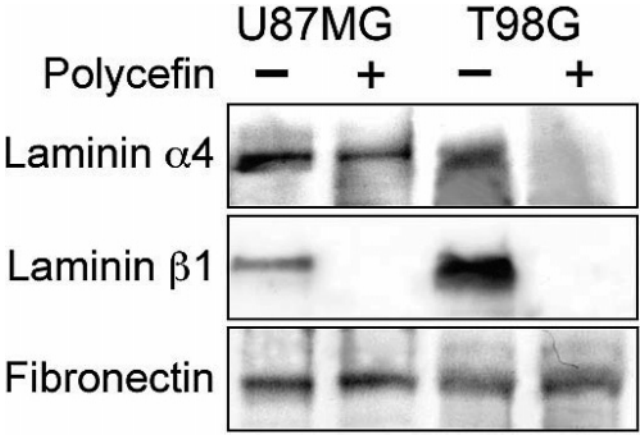

Figure 5. In vitro targeting and inhibition of laminin chain synthesis by Polycefin. Western blot analysis of laminin chain secretion into medium with or without Polycefin treatment. Conditioned media of both glioma cell lines, U87MG and T98G, contain α4 and β1 chains of laminin-8. Polycefin markedly inhibited secretion of both laminin chains, especially of β1 chain. Gel loading was normalized by the content of secreted fibronectin.

Table 1. Densitometric Evaluation of Western Blot Signal Intensities for Selected Proteins in Glioma-Conditioned Media with and without Polycefin Treatment[a]

	U87MG glioma cell line			T98G glioma cell line		
protein	control	treated	OD ratio	control	treated	OD ratio
laminin α4	924	301	0.33	675.5	0	0
laminin β1	187	0	0	2387.9	0	0
fibronectin	1014	1166	1.15	720.4	754.4	1.05

[a] Control, without Polycefin; Treated, with Polycefin; OD, optical density; OD ratio, treated/control

the staining for both Fluorescein-Polycefin (**7**) and FM 4-64 was co-localized after 30 min, indicated by the yellow color after superposition of red and green (Figure 4C). If cells were pretreated for 10 min with mAb OX-26 in order to block the cell surface transferrin receptor and then incubated with Polycefin, the drug was not internalized, and fluorescence was not seen inside the cells (result not shown). These experiments suggested that Polycefin delivery into the cells occurred by the mechanism of transferrin receptor-mediated endocytosis.

Fluorescein-labeled Polycefin(-mAb) (**18**) administered at the same concentration also passed through the cell membrane but was detected only 1 h after the first appearance inside the cells of Fluorescein-labeled Polycefin (**7**), about the time when free Fluorescein itself appeared, administered at the same concentration (data not shown). At this time, the fluorescence intensity of Fluorescein-Polycefin (**7**) inside the cells was markedly higher than in the controls. It was concluded that the mechanisms underlying cell penetration of Polycefin(-mAb) (**18**) and free Fluorescein were not receptor-mediated endocytosis.

To show that Polycefin was internalized into tumor cells via transferrin receptor mediated endocytosis followed by its escape through membrane disruption, the inhibition of laminin-8 chain synthesis in vitro was studied. Polycefin efficiently blocked secretion of laminin α4 and β1 chains in the culture medium of glioma cells as shown by semiquantitative Western blot analysis of conditioned culture media sampled after 6 days of culture (secreted human fibronectin served as gel loading control) as shown in Figure 5 and Table 1. In cultures treated with Polycefin (**8**) the expression of both chains was either significantly reduced (α4) or completely abolished (β1). The relative contents of both chains in U87MG and T98G glioma-conditioned medium before and after treatment were further analyzed semiquantitatively after densitometry with secreted human fibronectin as reference. Laminin α4 chain secretion was

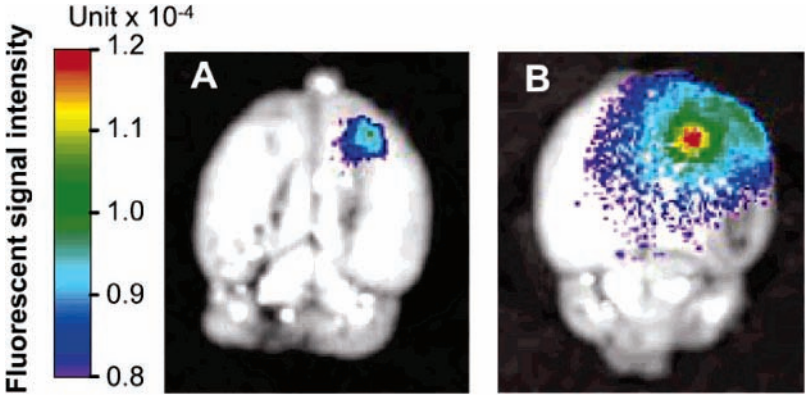

Figure 6. Xenogen IVIS 200 imaging of Polycefin in brain glioma. Polycefin variants **20** and Polycefin(-mAb) **21** are fluorescence labeled with Alexa Fluor 680, and the valine residue (Scheme 1) is replaced by L-leucine ethyl ester. Without targeting antibody, the drug still accumulates in tumor 72 h after intravenous injection (A). Complete Polycefin with mouse targeting antibody shows significantly higher tumor retention by both amount and area (B). Imaging was carried out after flushing perfused brains with sodium-buffered saline.

reduced in U87MG cells by 67% and was completely abolished in T98G cells after treatment, whereas β1 chain secretion was totally blocked in both cell lines (Table 1).

The results show that Polycefin was readily internalized by glioma cells via the transferrin receptor-mediated endocytosis mechanism, and that AON conjugated to the drug efficiently inhibited target protein expression in vitro.

Selective Accumulation of Polycefin in Tumor. To confirm that Polycefin was selectively accumulated in brain tumor, we have carried out intravenous injections into human brain tumor-bearing nude mice and monitored its distribution. In these experiments, we used Alexa-680-conjugated Polycefin variant **20** in comparison to Polycefin(-mAb) **21**. The replacement of Fluorescein by Alexa Fluor 680 was necessary, because Fluorescein-Polycefin had shown only a weak signal in preliminary imaging experiments at the border of detection and a high background in vivo. The new dye Alexa-680 has higher stability and gives stronger fluorescence intensity. Xenogen IVIS 200 imaging system was used to detect the drug distribution in whole body (not shown) and isolated mouse organs 5 min−72 h after injection. Repeated experiments have been conducted, giving qualitatively the same results as shown in typical images of whole brain in Figure 6. After 6 h, the drug signal was detected only in brain tumor and kidneys and was observed there during the whole examination time period up to 72 h. As shown in Figure 6A, 72 h after PBS perfusion Alexa-680-Polycefin-(-mAb) accumulated in tumor to some extent. However, a stronger signal was observed when Polycefin was conjugated with anti-transferrin receptor mAb (Figure 6B). Because this mAb may have also cross-reacted with human, it may have targeted the drug both to endothelial cells in the tumor and to tumor cells. Free dye administered in the same way was eliminated from the body in 1 h and did not accumulate in any organ (data not shown). In contrast, the accumulated drug could not be removed by flushing of the brain after perfusion. Polycefin(-mAb) may accumulate in tumors by EPR effect that has been reported for other high-molecular-mass drugs (*49*−*51*). The presence of the targeting anti-transferrin antibody resulted in a pronounced accumulation of the fluorescent label in the tumor to a far greater extent than seen for the antibody-free Polycefin variant. This demonstrated the importance of the receptor-mediated uptake mechanism. The results of the in vivo imaging experiment showed that Polycefin crossed BTB and accumulated in the brain tumor.

DISCUSSION

An ideal prototype of carrier system allows targeting of tumor tissue with the simultaneous delivery of more than a single kind of drugs at high site-directed concentrations. We have succeeded in synthesizing such a delivery system with a hitherto unprecedented variety of functionality. Our prototype complements commonly used HPMA copolymer in offering a biodegradable, nontoxic, and nonimmunogenic scaffold from a biological source, opening a new avenue for drug delivery without the danger of undegradable deposits and/or adverse reactions in the treated organism. This drug may be used for treating an individual patient's pathologic condition and for targeting multiple specific biomarkers in tissues and organs.

Our drug carrier composed of a multitude of low- and high-molecular-mass modules is a challenge for nanoscale synthesis. The strategy was based on the following rational: 1. Chemical activation of the PMLA scaffold at pendant carboxyl groups by virtue of the NHS-ester; 2. Exhaustive substitution of the highly reactive NHS-ester by formation of stable amide bonds with both the robust modules and with 2-mercaptoethylamine (2-MEA); 3. The coupling of the now scaffold-harbored thiols with the delicate, strictly water soluble modules such as proteins and nucleic acids; 4. High reaction yields and predictable stoichiometries; 5. Avoidance of side reactions/degradation of labile modules by employing mild reaction conditions; and 6. Simple and efficient purification of intermediates and end products.

Polymalic acid met the challenge as an optimal scaffold by several criteria: biological origin, highest optical and chemical purity, abundant pendant carboxyl groups for the attachment of a variety of residues, absence of rotational restriction around the polymer covalent bonds to achieve a minimum of molecular crowding, high solubility of the salt form in water, high solubility of the acid form in acetone, DMF, DMSO, and *N*-methylpyrrolidone. The biodegradability of PMLA and of its modules and the absence of toxicity of the nanoconjugate building blocks proved Polycefin to be nontoxic in the cell viability assay.

The composition and average structure of Polycefin in Scheme 1 as a conjugate with functional groups (modules) is in accord with chemical analysis and with the UV/vis/fluorescence spectra. Reducing SDS−PAGE revealed that the PMLA scaffold was conjugated with a single mAb at H-chains. Features in Scheme 1 are corroborated by the results of disulfide cleavage and membrane disruption assays. A release of the oligonucleotides by disulfide exchange in the presence of glutathione verified both the chemical presence of the prodrug in Polycefin and the function of the releasing module. The membrane disrupting module was demonstrated by the effect of Polycefin and especially by the amino acid substitutions on the lysis of red blood cells, showing the importance of the

hydrophobic valine side chains and of the carboxylate charge neutralization. Although the hemolysis assay did not represent an authentic test for endosomal membranes, the results qualitatively revealed the membrane stabilizing/destabilizing effects of PEG, MORPH-AONs, and amino acid conjugates.

The idea underlying the mechanisms that we have built into the structure of Polycefin was to cross BTB, enter glial tumor cells by the transferrin receptor-mediated endocytosis, and subsequently get released from endosomes by membrane destabilization. These features were successfully validated by the results of confocal microscopy and Western blotting, showing the cellular uptake of Polycefin via endosomes, the successful escape from endosomes, and the targeting of laminin chain coding antisense oligonucleotides to cytoplasm/nuclei, where they inhibited laminin protein synthesis. The mechanism of drug internalization was investigated in cultured U87MG glioma cells. It was shown that Polycefin-conjugated OX-26 anti-transferrin receptor mAb cross-reacted with human cells. This result was important for our xenogenic in vivo models to deliver the drug into both rat endothelial and human glioma cells. For mouse in vivo experiments we used Polycefin with anti-mouse/human transferrin receptor mAb. Thus, we prepared and tested Polycefin for future in vivo treatment and characterized its property for two independent species, rat and mouse, using anti-transferrin receptor mAb's recognizing these two species and cross-reacting with human for delivery into human tumors.

The function of antibody to transferrin receptor in targeting BTB and glioma cells was confirmed by the in vivo imaging experiments together with the confocal microscopic investigation of glioma cultures. These data demonstrate a substantial enhancement through antibody targeting in comparison to EPR effect-driven (*3*, *35*) macromolecule accumulation in the implanted brain tumor.

Previously described nanoconjugate drug delivery systems, such as poly(acrylic acid) based derivatives (*35*), contain in most cases a single lipophilic prodrug to be released by endosomal cleavage of a tetrapeptide unit, occasionally a tissue-targeting molecule, and in some cases an endosomal membrane disrupting module, but a complex multifunctional structure such as that of Polycefin and delivering simultaneously two kinds of antisense oligonucleotides has not been reported. The delivery by a single carrier molecule of multiple drugs has the effect to enhance the simultaneous (synergistic) action of drugs as compared to the delivery of mixtures of single drugs. This principle has been borne out for MORPH-AON-1 and MORPH-AON-2 in Polycefin. The synthesis of Polycefin as a prototype drug delivery device allows the development of carriers with variant conjugates of several drugs and functional modules per single carrier molecule. The drug as a high-molecular-mass chemical compound owns the basic EPR-mediated selective accumulation in tumors together with the enhanced accumulation by antibody targeting. In principle, using Polycefin as a prototype of multifunctional targeting system, it would be possible to achieve in the future an individual treatment of different human pathological conditions, based on molecular targets. These possibilities open interesting new therapeutic avenues.

ACKNOWLEDGMENT

The authors are indebted to Prof. Kiyotoshi Sekiguchi (Institute for Protein Research, Osaka University, Osaka, Japan) for kindly donating antibodies to laminin α4 chain. We thank Dr. John Young, Director of the Department of Comparative Medicine, Cedars-Sinai Medical Center, for invaluable help with IACUC protocols and animal work. The authors express their gratitude to Prof. Alexander V. Ljubimov for assisting in the preparation of the manuscript.

Note Added after ASAP Publication. In the version of the manuscript posted January 19, 2006, corrections were made to text in the first paragraph of Experimental Procedures and the last paragraph of Results. The corrected version of the manuscript was posted January 25, 2006.

Cell lines and primary cells exhibit varying degrees of resistance to DNA transfection strategies. In this study, we employed the synthetic peptide Tat−RGD (TR), composed of the HIV-1 derived translocation peptide Tat fused to the integrin binding RGD motif, as a tool for improving DNA transfer into pulmonary cells. Binding experiments between DNA and TR and cytotoxicity measurements of TR treated cells were undertaken to optimize DNA and TR concentrations for transfection. Addition of a complex of TR and DNA (TRD) to A549 cells yielded significant transgene expression. When TRD was combined with Lipofectamine (TRDL), the expression was increased by 5-fold over Lipofectamine (DL) and by ∼30-fold over TRD-mediated transfections. Also, in primary smooth muscle cells (SMC) and fibroblasts (FB) derived from pulmonary arteries, an increase in TRDL-mediated transfection efficiency was observed by a factor of ∼2 and ∼3 over that of DL. Laser scanning confocal microscopy for visualizing TR-dependent DNA uptake demonstrated that the internalization of TRDL complexes is linked to caveoli in the plasma membrane. Interfering with caveoli formation by methyl-*b*-cyclo-dextrin drastically decreased the transfection efficiency by TR. In conclusion, the Tat−RGD peptide mediates efficient gene delivery in human pulmonary cells, in particular when combined with a standard cationic lipid based transfection reagent. The enhancement of DNA uptake by Tat−RGD is suggested to be mediated by caveoli-dependent endocytosis.

INTRODUCTION

Nonviral strategies for gene transfer into eukaryotic cells include various chemical and physical approaches. The potencies of these diverse techniques differ in a cell-specific manner. Human primary cells are particularly resistant to established transfection techniques. Recently, methods have been developed for the delivery of exogenous proteins into living cells with the help of membrane-permeable carrier peptides. By genetically (*1*) or chemically (*2*) hybridizing these carrier peptides, efficient intracellular delivery of various oligopeptides and proteins was achieved (*3*). Among these proteins, the HIV-1 derived Tat protein (*4*), *Drosophila* Antennapedia protein (*5*), herpes simplex virus type-1 VP22 transcription factor (*6*), and various RNA and DNA binding proteins and polyarginines were described (*7*).

Tat is a transcriptional activator that binds to a short nascent stem−bulge−loop leader RNA for its transactivation. The best studied region of Tat resides in amino acids 49−72 (domain 4), which contains an arginine-rich basic motif. This motif confers Tat binding to RNA and is important for nuclear localization and uptake of Tat by cells (*8*). Part of this domain can be folded into an α-helix structure with amphipathic characteristics. Such helical structures have been considered as key determinants for the uptake of several enveloped viruses by fusion or endocytosis (*9*). Coupling of a Tat-derived peptide to several proteins allowed their functional internalization into several cell lines or tissues (*10*).

Integrins are a family of about 20 heterodimeric membrane proteins that bind to extracellular matrix proteins or membrane proteins of adjacent cells and play an important role in organ structuring and cell−cell communication. Integrin receptors are exploited by a diverse range of pathogens including bacteria and viruses for cell binding and entry. On this basis, it was proposed that integrin targeting may also be an optional pathway for the uptake of synthetic gene delivery vehicles (*11*). This is further buttressed by a study performed on adenovirus type 41 lacking an RGD alpha (v)-integrin binding motif on the penton base, undergoing a delayed uptake in A549 cells (*12*).

The objective of this study was to employ a peptide conjugate composed of a Tat motif and an RGD motif for improvement of DNA transfection in human pulmonary cells. To this end, we synthesized the fusion protein Tat−RGD (TR) consisting of a 21 amino acid sequence derived from Tat and a 10 amino acid sequence representing the RGD motif. We employed this peptide to enhance DNA transfection in the human lung A549 cell line and in human primary pulmonary artery cells. Significant improvement of transfection efficiency was noted, which was found to be linked to caveoli-dependent membrane internalization.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. The biotinylated Tat−RGD (TR) peptide consisting of the truncated Tat domain at the N-terminus and the domain with an RGD motif at the C-terminus had the following sequence: (biotin-GMLGISYGRKKRRQRRRPPQT GGCRGDMFGC). This peptide was synthesized (Peptide Synthesizer 432A, Applied Biosystems, Fmoc-chemistry) and labeled at the N-terminus with biotin. After deprotection, it was purified by HPLC. The two cysteine residues were oxidized by air oxygen and a second HPLC purification was performed.

TR−DNA Binding. Different amounts of the biotinylated TR were incubated with plasmid DNA in phosphate-buffered saline (PBS). Free TR and TR bound with DNA was separated by gel chromatography (Sephadex G-100 column). Positive column fractions were quantified by colorimetric detection employing peroxidase-labeled streptavidin.

Particle Size Measurement. For particle size measurement, 1 μg of DNA was mixed with different concentrations of TR in a final volume of 75 μL with Hank's balanced salt solution (HBSS) and incubated for 15 min to obtain the TRD mixtures. TRDL complexes were obtained by adding 2 μL of lipofectamine to these TRD mixtures and incubating for 15 min at room temperature. The mixtures were then measured for particle size using a zeta sizer.

Cell Culture. Culturing of human epithelial lung cell line A549 was performed according to the protocol given by the American Type Culture Collection. Human cell preparations were established from excess lung tissue originating from human donor lungs employed for transplantation. This protocol was approved by the Justus-Liebig University Ethics committee. Cells were isolated by careful dissection of parenchymal connective tissue as described. Primary adventitial fibroblasts (FB) and smooth muscle cells (SMC) from the pulmonary artery were isolated and cultured as described (*13*).

Cytotoxicity Assay. The cytotoxicity measurement was performed with the CytoTox-ONE homogeneous membrane integrity assay (Promega, Mannheim, Germany) based on the release of lactate dehydrogenase. Cells (5×10^4 per well) were plated in a 96-well plate. The cells were incubated with test compounds TRD or TRDL for 4 h at 37 °C. Then, Cyto-Tox reagent was added, and further experimental procedure was performed following the company's prescribed protocol.

Transfections. Transfection by Lipofectamin 2000 (Invitrogen, Carlsbad, CA) was performed as follows: 2.5×10^4 cells were plated per well in a 96-well plate. The cells were 80−85% confluent for transfection on the following day. In each well, 0.2 μg of DNA was diluted in 25 μL of Opti-MEM (Invitrogen, Carlsbad, CA). Lipofectamine 2000 (0.5 μL/well) was diluted in 25 μL of Opti-MEM and incubated for 5 min at room temperature. The diluted DNA was slowly added to the diluted Lipofectamine, and they were mixed and incubated for 15 min at room temperature to facilitate the formation of DNA−Lipofectamine (DL) complexes. The DL complexes were added to the cells and incubated at 37 °C. After 4 h, the medium was replaced with culture medium.

Transfection by TRD and TRDL was performed as follows: the cells were plated in a 96-well plate as described above. DNA (0.2 μg) was mixed with 2.5 μg/well or 0.8 μg/well of TR for cell line and primary cells, respectively, and the volume was made up to 25 μL with HBSS. The TRD mixture was vortexed and incubated at room temperature for 15 min. The resulting mixture was directly used for TRD-mediated transfection. For preparation of TRDL complexes, 0.5 μL/well of Lipofectamine was added to the TRD mixture and incubated at room temperature for 15 min. The TRD or TRDL mixtures were added to the cells and incubated at 37 °C. After 4 h, the medium was replaced, and cells were further cultured under standard conditions. Dependent on the experiment, TRD, TRDL, and DL transfections were performed in well plates of different diameters. The transfection mixtures were scaled in proportion to different well areas.

Reporter Assays. As reporter plamids, we used the pEGFP-N2 plasmid (BD Bioscience Clontech, Mountainview, CA) for expression of green fluorescent protein (GFP) or the pGL3 plasmid (Promega, Mannheim, Germany) for expression of firefly luciferase. After overnight incubation at 37 °C in 5% CO_2, the cells were either observed under a fluorescent microscope for GFP detection or subjected to luciferase assay (Luciferase detection assay, Promega). The cells were lysed with passive lysis buffer (Promega, Mannheim, Germany), and luciferase activity was measured by a luminometer (Spectrafluor Plus, TECAN, Crilsheim, Germany).

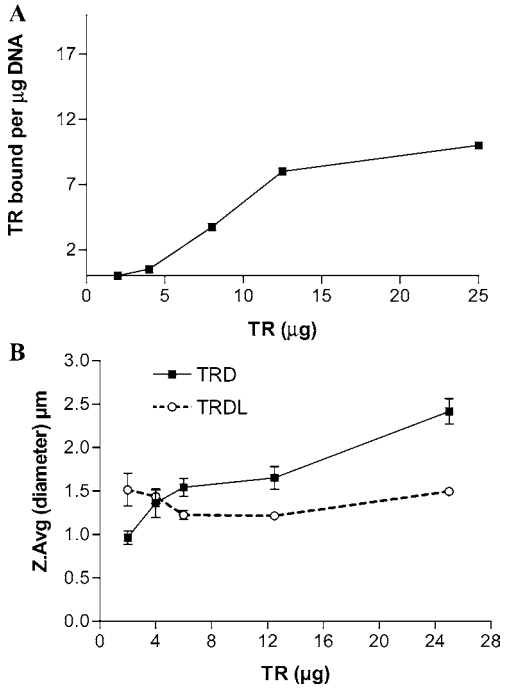

Figure 1. (A) Binding curve of TR and DNA. The *x*-coordinate shows the input amount of TR, the *y*-coordinate shows the amount of TR bound to 1 μg of DNA. (B) Measurement of particle sizes of different amounts of TR added to DNA (TRD) or different amounts of TR added to DNA complexed with Lipofectamine (TRDL). Z.Avg represents the average particle size (mean, SEM, $n = 3$).

Synthesis of DNA Fragment. DNA fragments of 400 bp were amplified from the pGL3 plasmid using the following primers (Metabion, Germany): forward 5′-ATG GAA AGT CCC TAT TGG CGT-3′ and reverse 5′-CTG TCC CCA GTG CAA GTG CA-3′. For generation of the fluorescent-labeled DNA fragment, the forward primer was labeled with fluorescein (FAM, Applied Biosystems, Weiterstadt, Germany). The PCR product was run in a regular agarose gel, and the 400 bp fragment was gel-eluted using the QIAEX II gel extraction kit (Qiagen, Hilden, Germany).

Cell-Adhesion Assay. A 48-well tissue culture plate was coated with fibronectin (20 μg/mL). After overnight incubation at 4 °C, the wells were washed twice with cold PBS. Bovine serum albumin (BSA, 1%) was added to the wells and incubated for 1 h to block the uncoated sites. The wells were washed twice with cold PBS. For the cell adhesion assay, confluent cultures of A549 cells were trypsinized, washed, and resuspended in medium containing specified concentrations of XJ735 (Sigma-Aldrich, Taufkirchen, Germany). Suspensions (200 μL) containing 0.5×10^5 cells/well were plated on the fibronectin-coated wells. Cell adhesion was allowed to occur for 2 h at 37 °C. Then, wells were washed once with PBS, trypsinized, and resuspended in culture medium. Ten microliters of this cell suspension was used for cell counting.

Confocal Imaging. *Tat−RGD and Caveolin-1 Colocalization.* A549 cells (0.5×10^5 cells/well) were plated in 8-well Permanox chamber slides (Lab-Tek, Naperville, IL) precoated with 300 μL of fibronectin (20 μg/mL). After overnight culturing, A549 cells were transfected with a 400 bp DNA fragment (CMV) employing the TRDL vector system. The cells were fixed at different time points for 2 h at room temperature with PFA (1 mL of 4% paraformaldehyde, 0.4 mL of 10× PBS,

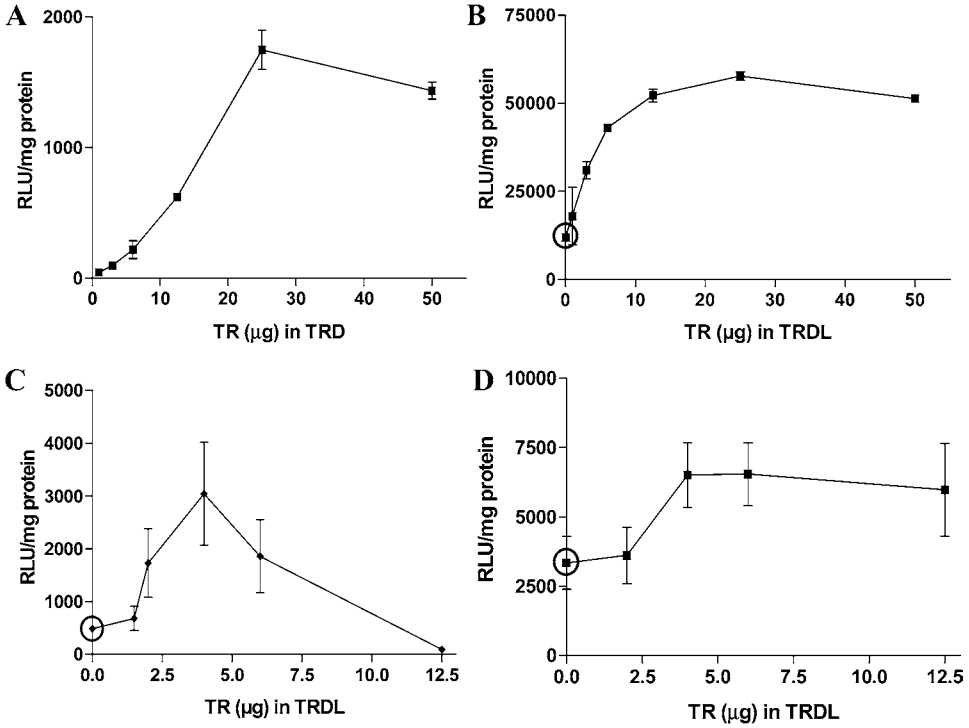

Figure 2. Analysis of luciferase reporter gene expression (RLU = relative light units) after transfection of cells with different amounts of TR: (A) A549 cells were transfected with different amounts TR added to 1 μg of DNA; (B) A549 cells were transfected with different amounts of TR added to 1 μg of DNA complexed with lipofectamine; (C) FB were transfected with different amounts of TR added to DNA complexed with lipofectamin; (D) SMC were transfected with different amounts of TR added to DNA complexed with lipofectamine (mean, SEM, $n > 2$). Note that transfections with DL alone correspond to 0 μg of TR (*x*-axis) and are circled.

and 2.6 mL of H_2O). The cells were washed three times with 1× PBS, and unspecific binding of the primary antibody was blocked for 1 h with 5% BSA and 5% normal goat serum in 1× PBS. Following this, the cells were washed and incubated overnight in a humid chamber with polyclonal rabbit anti-caveolin-1 primary antibody (1:400) (Santa Cruz, Santa Cruz, CA). The cells were washed and incubated for 1 h with Cy5-conjugated donkey anti-rabbit IgG secondary antibody (1:200) (Dianova, Hamburg, Germany). Then, the cells were washed and incubated for 1 h with Cy3-conjugated streptavidin (1:5000) (Dianova, Hamburg, Germany) for labeling biotin−Tat−RGD. The slides were mounted with a coverslip and analyzed by laser-scanning confocal fluorescence microscopy for TR and caveolin-1 colocalization.

Cellular Internalization of Tat−RGD. The cells were cultured, transfected, and fixed as mentioned above. Blocking and permeabilization was performed with 10% horse serum, 0.5% Tween 20, and 0.1% BSA in 1× PBS for 1 h. Permeabilization ensures that the secondary reagent (Cy3-conjugated streptavidin) enters the cells and labels the biotin−Tat−RGD, which can be analyzed by confocal microscopy for the cellular internalization of TR.

Intracellular Localization of DNA. Cells (A549 or SMC) were transfected with a FAM-labeled DNA fragment (FAM-CMV) employing that TRDL vector system and fixed at different time points with PFA. The cells were washed and blocked with 5% BSA and 5% normal goat serum in 1× PBS for 1 h. Following this, the cells were washed and incubated overnight in a humid chamber with polyclonal rabbit anti-caveolin-1 primary antibody (1:400) (Santa Cruz, Santa Cruz, CA). Then, the cells were washed and incubated for 1 h with Cy3-conjugated donkey anti-rabbit IgG secondary antibody (1:400) (Dianova, Hamburg, Germany). Afterward, the cells were incubated sequentially for 10 min with WGA-633 membrane dye (wheat germ agglutinin Alexa Fluor 663-conjugated, Molecular Probes, W-21404, 1:100) and TO-PRO-3 nuclear stain (Molecular Probes, 1:800). The cells were mounted with a coverslip and analyzed by laser-scanning confocal fluorescence microscopy for the intracellular localization of FAM-labeled DNA.

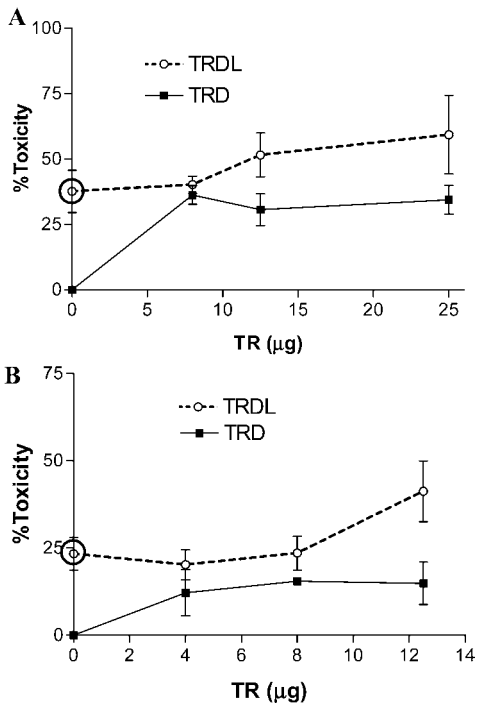

Figure 3. Measurement of cytotoxicity in (A) A549 cells and (B) FB treated with different concentrations of TR in the presence of a given amount (1 μg) of DNA (TRD) or of DNA and Lipofectamine (TRDL) (mean, SEM, $n = 3$). Note that cytotoxicities of cells transfected with DL alone correspond to 0 μg of TR (*x*-axis) and are circled.

The following laser lines were employed to detect the corresponding flurophores: FAM was detected using the 488

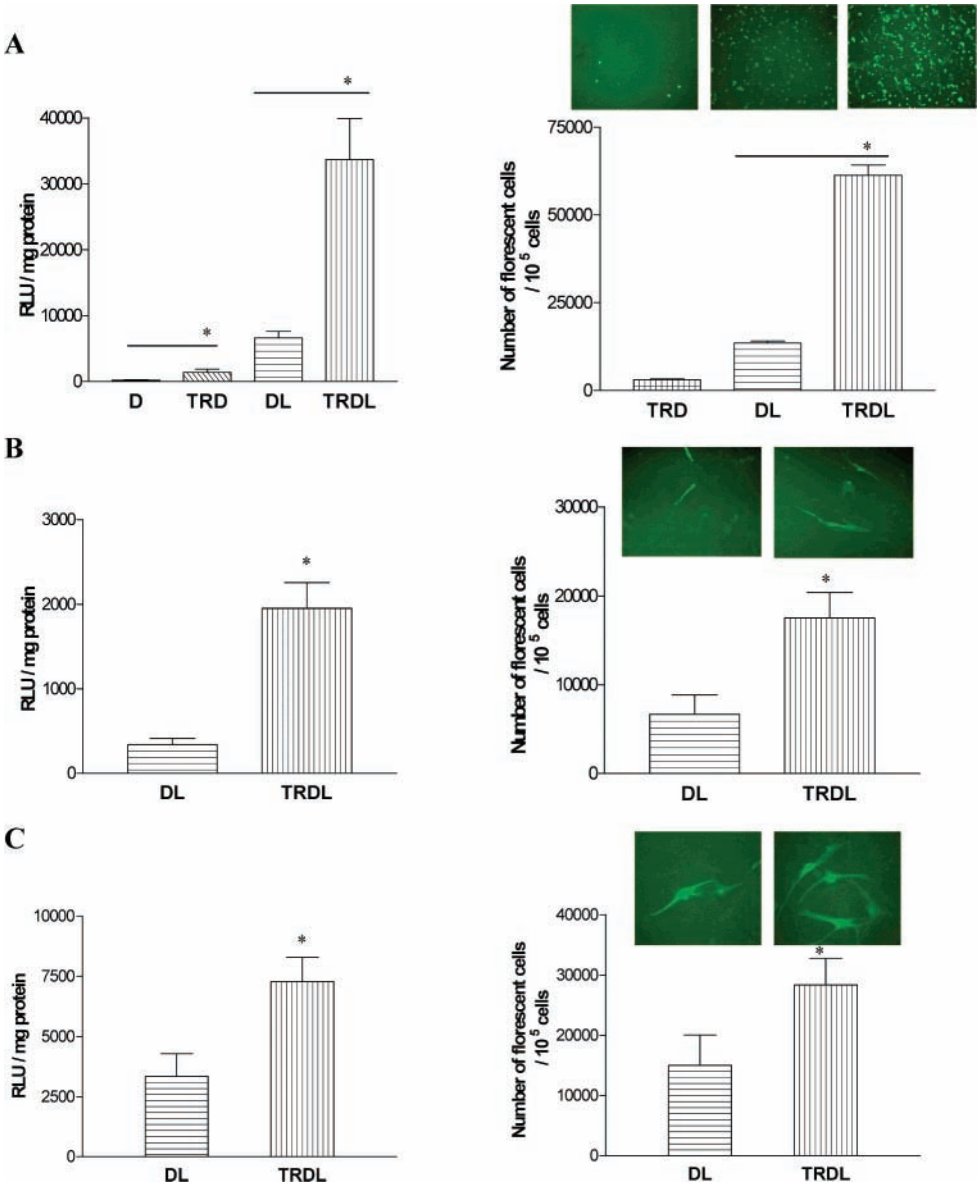

Figure 4. Summary of transgene expression levels employing different mixtures of TRD, DL, and TRDL as measured by luciferase reporter gene expression in the case of pGL3 transfection (RLU = relative light units; left, $n = 10$) or by counting the number of fluorescent cells in the case of pEGFP-N2 transfection (right, $n = 4$) in A549 (A), FB (B), and SMC (C) cells (mean, SEM, $*$ indicates $p < 0.05$, Man Whitney test).

nm laser line, Cy-3 was detected using the 543 nm laser line, and Cy-5, WGA-633, and TO-PRO-3 were detected using the 633 nm laser line, all with appropriate detection bandwidths for each fluorophore. Sequential scanning was performed to prevent bleed through into adjacent detection channels.

Gene Scan Analysis. Transfected FAM-labeled DNA fragments were recovered from cells by an extraction procedure with a PCR column purification kit (Qiagen, Hilden, Germany). The recovered samples were analyzed for their integrity (size) and quantity by capillary electrophoresis and a fluorescent detection unit (ABI Prism 310 genetic analyzer, Applied Biosystems, Weiterstadt, Germany).

RESULTS

The synthetic peptide Tat−RGD (TR) was employed for DNA transfection into different lung cells. Initially, we performed binding experiments between DNA and TR to determine an appropriate concentration ratio (Figure 1A). Binding saturated at approximately 10 μg of TR per microgram of DNA. Since the particle size is important for cellular internalization, also size measurements of TR complexed with DNA (TRD) or TR complexed with both DNA and Lipofectamine (TRDL) were performed (Figure 1B). The comparison of particle sizes of different ratios of TR and DNA is given in the presence and absence of Lipofectamine. Addition of Lipofectamine to TRD resulted in compaction of the particles, thus aiding internalization.

We next studied the effect of different TR amounts per microgram of DNA on transfection efficiency employing the luciferase reporter gene. In the case of A549 cells, we observed significant transfection efficiencies with TRD vectors (Figure 2A). Expression levels were observed to be substantially higher in the case of TRDL obtained by addition of Lipofectamine to TRD (Figure 2B).

In primary pulmonary artery cells, such as adventitial fibroblasts (FB) and smooth muscle cells (SMC), TR alone was not sufficient for DNA transfection. However, TRDL vectors significantly improved the luciferase expression levels over those of Lipofectamine standards (Figure 2C,D).

To derive an optimal TR concentration for transfection with minimally compromised cell viability, we assessed the cytotoxicitiy associated with different concentrations of TRD and

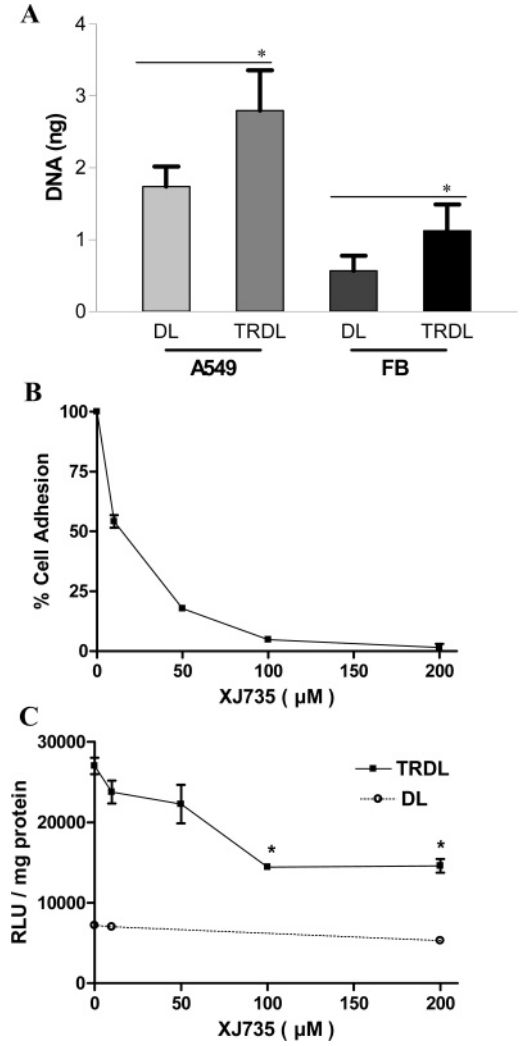

Figure 5. (A) Measurement by capillary gel electrophoresis of FAM-labeled DNA fragments recovered from transfected cells. A549 or FB cells were transfected by either DL or TRDL mixture. In cells containing TR in the transfection mixture, the cellular DNA recovery is increased over the non-TR-containing mixture, reflecting a higher DNA uptake in these cells (mean, SEM, $n = 3$, $*$ indicates $p < 0.05$, Man Whitney test). (B) Effect of XJ735 treatment on adhesion of A549 cells to fibronectin-coated plates. (C) Effect of XJ735 on transfection efficiency mediated by TRDL and DL. Cells were transfected with TRDL vectors in the presence of different concentrations of XJ735, and the luciferase reporter gene expression (RLU) was measured (mean, SEM, $n = 4$, $*$ indicates $p < 0.05$, Man Whitney test).

TRDL vectors on the A549 cell line and FB primary cells (Figure 3). Increasing amounts of TR enhanced the toxicity. Also, the toxicity was enhanced by the addition of Lipofectamine as observed when TRDL was delivered into the cells. Considering the curves of Figures 2 and 3, we estimated the optimal concentrations of TR (per microgram of DNA) to be employed in all further analysis using TRDL vectors as 12.5 μg for A549 and 4 μg for FB and SMC. The analysis of DNA transfection by TRD, DL, and TRDL is shown in comparison by measuring the reporter gene luciferase expression in cellular lysate or by counting the GFP positive cells by fluorescence microscopy (Figure 4). The improvement of transfection by addition of TR is demonstrated for A549 cells, as well as for primary FB and SMC cells. For characterization of the facilitated gene transfer, the cellular uptake of fluorescent FAM−DNA fragments was studied in A549 cells and FB transfected with either DL or TRDL (Figure 5A). These data showed that TRDL significantly enhanced cellular DNA uptake over that of the DL vector system and that the effect is more pronounced in A549 cells than in FB.

To analyze the significance of the RGD component of Tat−RGD for enhancing the affinity toward cells and thus relevance for improving the transfection efficiency, we treated A549 cells with different concentrations of XJ735, an antagonist of RGD (Figure 5B). At first, we confirmed that XJ735 could block the adhesion of A549 cells to fibronectin-coated culture dishes. Thus the expression of RGD binding integrins on the cell surface and their interaction with XJ735 were confirmed. Second, we performed transfection studies with TRDL and DL in the presence of different amounts of XJ375 and quantified it by luciferase reporter gene assay (Figure 5C). In the case of TRDL, we observed a decrease of ∼40% of luciferase expression, whereas in the case of DL no significant reduction was observed.

To explore whether the mode of internalization exploited by the TRDL vector system is linked with caveoli-mediated endocytosis, we performed laser scanning fluorescent confocal microscopic analysis by immunostaining the cells for caveolin-1 (blue) and TR (red). The cells were not permeabilized to detect only the TR localized at the membrane. In these experiments, we found a significant colocalization between caveolin and TR (pink color). The fluorescent signal of TR was visualized at different time points during transfection (Figure 6A, images a−c). The signal was initially localized on the cell membrane with subsequent time-dependent clearance of the signal from the cell membrane.

To show the time-dependent cellular internalization of TR, the cells were permeabilized and then stained with streptavidin−Cy3 (red) for intracellular tracking of TR. We observed a strong Cy3 signal at the cell periphery at 2 h, which gradually moved into the cell cytoplasm after longer incubation, resulting in a strong cytoplasmic signal after 15 h (Figure 6A, images d−f).

To examine whether DNA internalization corresponded with that of TR, the cells were transfected with a 400 bp FAM-labeled DNA fragment using the TRDL vector system, and the transfection process was examined by visualizing the uptake of FAM-labeled DNA into the cells at different time points (Figure 6B, images a−c). We employed Cy3-tagged secondary antibody for caveolin-1 in these experiments and labeled the cytoplasmic and nuclear compartments of the cell with WGA-633 and TO-PRO-3 for the membrane and nucleus, respectively. We observed a strong correlation in time between the cellular internalization of DNA and that of TR.

To demonstrate further that internalization of TRDL complexes exploits the caveolar endocytic system, we tested the effect of methyl-β-cyclodextrin (MBC), a drug that specifically disrupts the formation of caveoli without interfering with other modes of endocytosis (*14*). Cells were pretreated with 1% MBC for 30 min and transfected with TRDL complexes. MBC drastically decreased the transfection efficiency with the TRDL vector system, while that of DL remained unaffected (Figure 7), suggesting the role of caveoli in the cellular internalization of TRDL complexes.

For studying whether differences of TRDL transfection efficiencies depend on the expression of caveolin-1, we compared the expression of caveolin-1 in A549 cells and SMC cells (Figure 8). A549 cells revealed a significantly stronger caveolin-1 staining than SMC. In this experiment, we also detected that internalized FAM−DNA exhibited a much stronger signal in A549 cells than in SMC, suggesting that differences in caveolin-1 expression are a likely reason for the lower transfection efficiency observed in SMC as compared to that of A549 cells.

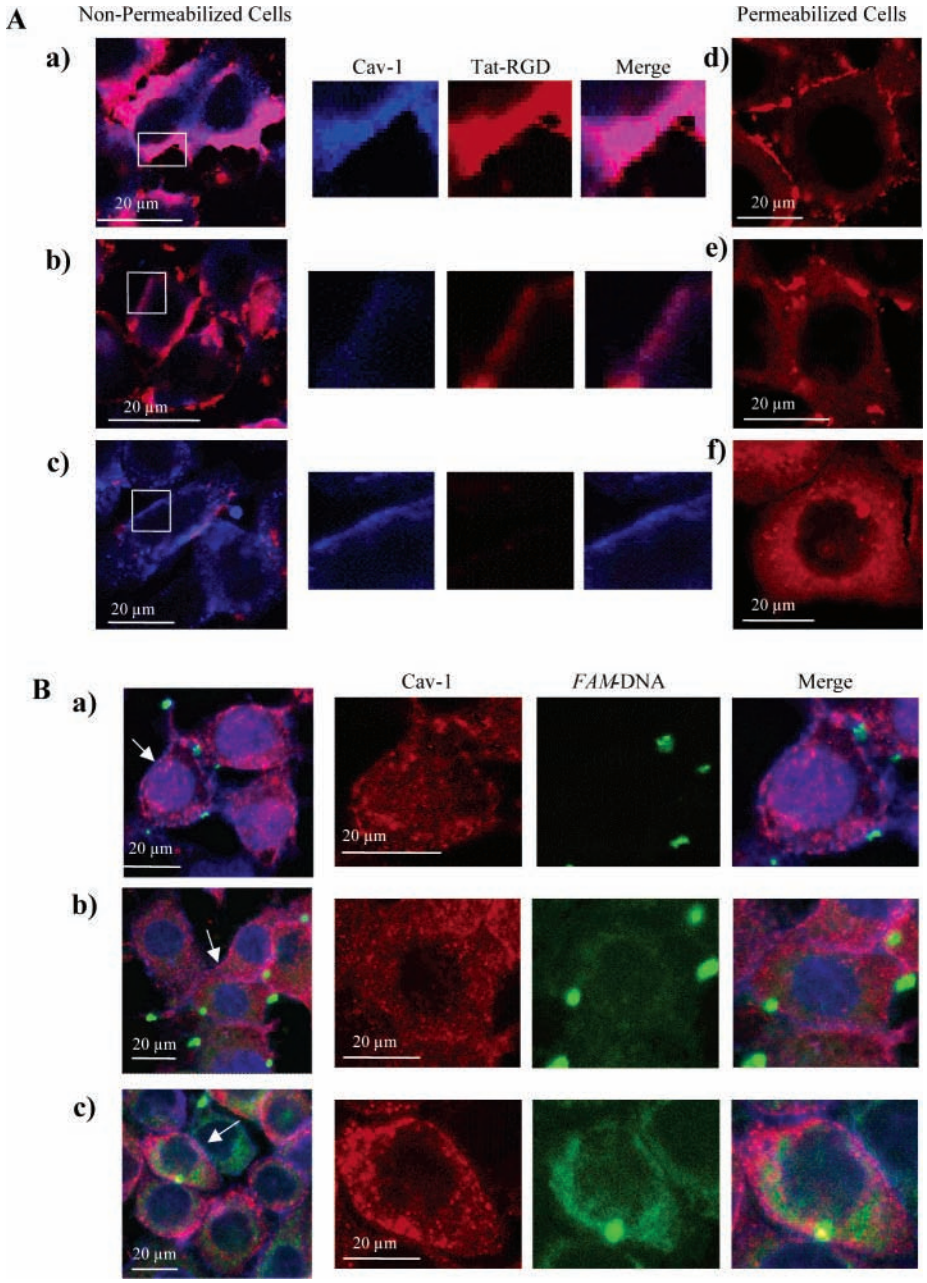

Figure 6. (A) Tat−RGD colocalization with caveolin-1 and its cellular internalization. A549 cells were transfected with a 400 bp DNA fragment using the TRDL vector system and fixed at 2 (a), 4 (b), and 15 h (c) time points, and without prior permeabilization immunostained for caveolin-1 (blue) and TR (red). We observed colocalization (merge) of TR with caveolin-1 (pink) and a time-dependent clearance of TR from the cell membrane. When cells were permeabilized and stained with streptavidin−Cy3 for biotin−TR, we observed a time-dependent internalization of TR (red) in the cytoplasmic compartment of the cells [2 (d), 4 (e), and 15 h (f)]. (B) TR-mediated DNA internalization in cellular compartments. A549 cells were transfected with a 400 bp FAM-labeled DNA fragment (400 bp, FAM) using the TRDL vector system, fixed at 2 (a), 4 (b), and 15 h (c) time points, and immunostained for caveolin-1 (red). To distinguish the cellular compartments, the cells were stained with WGA-633 and TO-PRO-3 for cell membrane and nucleus, respectively. We observed a time-dependent cellular internalization of FAM-labeled DNA, which corresponded with the internalization patterns of TR in permeabilized cells.

DISCUSSION

In this study, we have analyzed the potency and mode of transfection of pulmonary cells employing the peptide conjugate Tat−RGD (TR). HIV-1 derived Tat protein has been described to promote the delivery of proteins or nucleic acids (*1*, *2*, *4*, *8*). Here, we utilized a truncated 21-mer Tat peptide corresponding to the region between amino acid residues 43 and 60 consisting of a critical basic amino acid stretch (RKKRRQRRR) with six arginines. This domain is supposed to be involved in membrane translocation and in nuclear targeting. Particularly, it forms an amphipathic α-helical structure, which is involved in endocytosis (*9*). This Tat peptide was conjugated with a peptide sequence displaying an RGD motif containing one more arginine residue, which may further facilitate DNA binding and cellular uptake (*7*). Particularly, the RGD peptide motif has high affinity toward integrin receptors (α$V\beta3$, α$5\beta1$) expressed on cell surfaces and therefore may improve DNA binding to cells. Previous studies have proposed the role of integrin targeting as an efficient pathway for the uptake of synthetic gene delivery vehicles (*11*). Also, this motif has been described to mediate adenovirus uptake (*12*).

Since this peptide was labeled with biotin, we could perform binding studies between DNA and TR. Binding experiments demonstrated affinity between TR and DNA (TRD), which is most likely based on interaction between positively charged arginines of Tat and the DNA phosphate backbone. The data

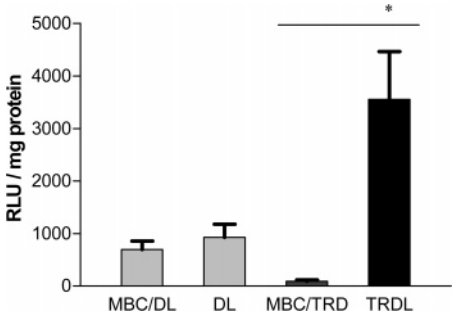

Figure 7. Effect of MBC pretreatment on TRDL uptake in A549 cells. A549 Cells were pretreated with 1% MBC for 30 min and transfected with TRDL and DL vector systems, and the luciferase reporter gene expression was measured. Cells untreated with MBC were taken as controls for both TRDL and DL transfection (mean, SEM, $n = 7$, $*$ indicates $p < 0.05$, Man Whitney test).

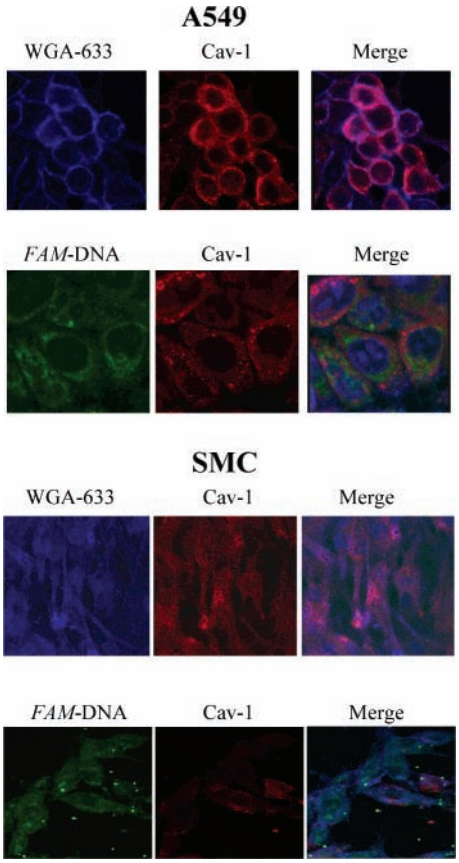

Figure 8. A549 cell line and SMC were transfected with FAM−DNA (green) employing the TRDL vector system and stained with WGA-633 (blue), TO-PRO-3 (blue), and anti-caveolin (red) for cell membrane, nucleus, and caveoli, respectively. We observed that the caveolin-1 staining at the cell membrane was strong in A549 cells and relatively weak in SMC cells (top rows). In accordance with our hypothesis that TRDL vector systems exploit caveoli-mediated internalization, we observed that FAM−DNA localization in the cellular and nuclear compartments was strong in A549 cells and relatively weak in SMC cells (bottom rows).

from these experiments suggested the most suitable concentration ratio of DNA and Tat−RGD.

Particle size measurements revealed lowering of the size of the TRD complexes upon Lipofectamine addition, which is an important feature for successful internalization of these complexes. Further, since the utility of such complexes is limited by their toxicity, we performed cytotoxicity assays to derive the optimal concentrations of TR for gene transfer in pulmonary cells.

TR was successfully applied for the improvement of DNA delivery into human pulmonary cell lines and primary cells. Addition of a complex of TR and DNA already yielded significant transgene expression levels in A549 cells. However, when TR was combined with Lipofectamine, the expression was increased 5-fold over Lipofectamine alone and ∼30-fold over TRD alone. This effect was also observed in primary SMC and FB from pulmonary artery, where transfection efficiencies were enhanced by a factor of ∼2 and ∼3, respectively, over Lipofectamine alone.

To check the role of RGD in Tat−RGD (TRDL)-mediated transfection, cells were treated with the cyclic RGD mimetic compound XJ735 (*14*). This compound is an antagonist of RGD binding to $\alpha V\beta 3$ integrins. XJ735 strongly affected the cell adhesion of A549 cells, thus revealing its interaction with A549 cells. Furthermore, treatment of cells with XJ735 caused a significant decrease in TRDL-mediated transfection efficiency. However, XJ735 had no effect on Lipofectamine-mediated transfection efficiency, which is suggested to be independent of cell surface integrins. These findings indicate the impact of the RGD motif for the cellular internalization process of Tat−RGD likely by enhancing its affinity toward the cell surface.

Biotinylation of TR allowed the monitoring of its cellular uptake. One possible mechanism to enter cells represents caveoli-dependent endocytosis. This pathway has been described for several nonenveloped viruses, some bacterial toxins, membrane constituents, and ligands (*15*). Caveoli are invaginated plasma membrane domains characterized by the presence of the integral membrane protein caveolin-1. They are also involved in many endogenous cellular processes such as cholesterol homeostasis, glycosphingolipid transport, and glycosyl-phosphatidyl-inositol anchored protein recycling (*16*). There is also evidence that HIV-1 Tat (*10*) and HIV-1 virus itself (*17*) can use caveoli for transcytosis across the endothelium. Interestingly, type 1 pneumocytes abundantly express caveolin-1 and have high numbers of caveoli. We investigated whether TRDL internalization follows a caveoli-mediated pathway. Our confocal microscopic analysis revealed colocalization of Tat−RGD and caveolin-1 in A549 cells transfected with TRDL vector systems. We also observed a time-dependent clearance of TR from the cell membrane. The cells were permeabilized to observe the cellular internalization of TR. At 2 h incubation, the TR signal was confined to the cell membrane, after 4 h, we observed moderate amounts of signal in the cytoplasm, and after 15 h incubation, we observed the maximum signal in the cytoplasm. Corresponding time-dependent internalization of FAM-labeled DNA was also observed. Thus, TR containing vectors are internalized through a slow internalization process similar to that observed with full length Tat (*10*). This slow movement is incompatible with the fast dynamics described for constitutive endocytic trafficking of clathrin-coated pits and vesicles (*18*). Slow dynamics associated with the endocytic pathway was recently demonstrated to involve a nonconstitutive and highly stable caveolin-1 positive endocytic pathway in transfected HeLa cells (*19*). Additional evidence for this mechanism and its dynamics can be found elsewhere (*20*).

To further demonstrate that TRDL complexes undergo caveoli-mediated internalization, disruption of the caveoli was performed employing the inhibitor methyl-β-cyclodextrin. This drug has been described to affect caveoli-mediated but not clathrin-mediated endocytosis (*21*, *22*). Treatment of cells with methyl-β-cyclodextrin drastically decreased the transfection efficiency of Tat−RGD. Interestingly, primary SMC, which showed less TR-dependent transfection efficiency, also revealed reduced levels of calveolin-1 expression when compared to A549 cells in immune cytochemical analysis. Therefore we

suggest a strong correlation between TR-mediated DNA internalization and the expression pattern of caveolins in these cell types.

In conclusion, the present work indicates that the Tat−RGD peptide mediates efficient gene delivery in human pulmonary cells. In particular, the combination of Tat−RGD with a standard cationic lipid based transfection reagent resulted in enhanced gene transfer. The improved DNA uptake by Tat−RGD appears to be mediated by caveoli-dependent endocytosis. Thus, Tat−RGD offers improved DNA uptake in lung cells and may also be considered for gene delivery in other transfection-resistant cell types.

ACKNOWLEDGMENT

We thank Dr. Michael Krause (Institute for Molecular Biology and Tumor Research, Microchemistry, Philipps-University, Marburg, Germany) for synthesis of the Tat−RGD fusion peptide. We thank C. Packhauser for helping with particle size measurements. We thank Prof. T. Kissel (Department of Pharmaceutics and Biopharmacy, Marburg, Germany) for useful discussions. We also thank Annette Tschuschner for technical support. This work was supported by the Deutsche Forschungsgemeinschaft: Sonderforschungsbereich SFB 547, project B9, and the Graduate Seminar (GK534) "Biological Fundamentals of Vascular Medicine" sponsoring A. Renigunta.

Synthesis and Screening of a Random Dimeric Peptide Library Using the One-Bead−One-Dimer Combinatorial Approach

Saurabh Aggarwal,[†] James L. Harden,[†] and Samuel R. Denmeade[†,§,*]

Department of Chemical and Biomolecular Engineering, The Johns Hopkins University Whiting School of Engineering, and The Sidney Kimmel Comprehensive Cancer Center, The Johns Hopkins University School of Medicine (SRD), Baltimore, Maryland 21231. Received September 1, 2005; Revised Manuscript Received October 24, 2005

Large combinatorial libraries of random peptides have been used for a variety of applications that include analysis of protein−protein interactions, epitope mapping, and drug targeting. The major obstacle in screening these libraries is the loss of specific but low affinity binding peptides during washing steps. Loss of these specific binders often results in isolation of peptides that bind nonspecifically to components used in the selection process. Previously, it has been demonstrated that dimerizing or multimerizing a peptide can remarkably improve its binding kinetics by 10- to 1000-fold due to an avidity effect. To take advantage of this observation, we constructed a random library of 12 amino acid dimeric peptides on polyethylene glycol acrylamide (PEGA) beads by modifying the 'one-bead−one-compound' approach. The chemical synthesis of 100 000 peptides as dimers can be problematic due to steric and aggregation effects and the presence of many peptide sequences that are difficult to synthesize. We have designed a method, described in detail here, to minimize the problems inherent in the synthesis of a dimeric library by modifying the existing 'split and pool' synthetic method. Using this approach the dimeric library was used to isolate a series of peptides that bound selectively to epithelial cancer cells. One peptide with the amino acid sequence QMARIPKRLARH bound as a dimer to prostate cancer cells spiked into the blood but did not bind to circulating hematopoeitic cells. The monomeric form of this peptide, however, did not bind well to the same LNCaP cell line. These data demonstrate that "hits" obtained from such a 'one-bead−one-dimer' library can be used directly for the final application or used as leads for construction of second generation libraries.

INTRODUCTION

Peptides are versatile small molecules that are increasingly being used alone or as part of bioconjugates in the therapy of a variety of human diseases, including cancer, diabetes, and osteoporosis. For example, peptide analogues of the luteinizing hormone-releasing hormone (LHRH) are the mainstay of treatment for metastatic prostate cancer. Peptides derived from fragments of human proteins such as the Arg-Gly-Asp (RGD)-based motifs from extracellular matrix (ECM)(*1*), endostatin from collagen, and angiostatin from plasminogen have been tested as anticancer therapies (*2*−*4*). Targeted peptides holds special promise for cancer, because many of the antibody-based targeted drugs have been shown to have difficulty permeating into tumors (*5*, *6*). Because of their size, small peptides can be more effective in delivering a therapeutic dose deep into tumors. On this basis, peptide-cytotoxin conjugates are under development that selectively target proteases and receptors within sites of cancer (*7*−*9*). Peptides are also under study as targeted imaging agents (*10*). As an additional application, our laboratory is interested in using peptides to develop indwelling probes or ex vivo blood filtration systems that can continuously extract circulating cancer cells from blood over an appropriate diagnostic period (*11*). As an alternative approach to antibody-based cell binding, we are instead identifying small peptides that bind selectively to epithelial cells. Small peptides of 12 amino acids are easily synthesized and are not highly immunogenic. Compared to antibodies, these peptides are relatively inexpensive, stable, and easily coupled to a probe surface.

Previously it has been demonstrated that dimerizing or multimerizing a peptide ligand can improve its binding kinetics 10−1000-fold due to an avidity effect (*12*−*15*). On this basis, using the one-bead one-peptide approach we synthesized a random dimeric peptide library using a C-terminal lysine residue as a branch point on poly(ethylene glycol) acrylamide (PEGA) beads (*11*). The production of a cell-binding surface coated with peptide ligand requires that the surface of the probe be relatively inert and not adsorb proteins and/or cells nonspecifically. Therefore, for this application, poly(ethylene glycol) (*16*) was selected as the screening surface because it has been demonstrated to be one of the most effective biomaterials for coating surfaces to prevent nonspecific adsorption (*17*−*19*). In this case, the synthesis of peptides on PEGA beads, which have a PEG outer surface, mimics potential catheter surface conditions from the outset in the selection of cell-binding peptides. In this previous study, no cell binding was observed on PEGA beads when peptides were synthesized as monomers (*11*). In contrast, screening of a dimeric peptide library containing approximately 100 000 peptides yielded a series of peptide ligands that bound selectively to human cancer cells in the blood, but did not bind to circulating leukocytes (*11*).

The synthesis and screening of a novel dimeric library, to our knowledge, has not been described previously. The use of such a dimeric library in screening strategies enhances the isolation of cell and/or protein specific ligands for applications such as drug targeting, imaging, and biosensors. The goal of this current study is to provide a detailed description of the methods used to synthesize, screen, and sequence a large combinatorial dimeric peptide library with the intent that this would allow for more widespread application in the future of the 'one-bead−one-compound' combinatorial approach in the selection of peptide binding ligands.

EXPERIMENTAL PROCEDURES

Materials. Poly(ethylene glycol) amide (PEGA) beads were from Polymer Labs (Amherst, MA). Fmoc-blocked amino acids, 1-hydroxybenzotriazole (HOBT), and 1,3-diisopropylcarbodiimide (DIC) were purchased from Advanced ChemTech, (Louisville, KY). *N*,*N*-Diisopropylethylamine (DIEPA), *N*-methyl-2-pyrrolidinone (NMP), dimethylformamide (DMF), and methylene chloride (DCM) were from Sigma. The human prostate cancer cell line LNCaP was obtained from ATCC (Manassas, VA). Cell Tracker Green and Orange were from Invitrogen (Rockville, MD). Unless otherwise specified, all other reagents were from Sigma (St. Louis, MO).

Synthesis of AG-73 Peptide on PEGA Beads. Heparin binding peptide sequence from laminin AG73 (RKRLQVQLSIRT)(*20*) was synthesized on Fmoc-Gly-loaded PEGA beads using an automated peptide synthesizer (PS-3, Rainin, Tucson, AZ). Dimeric peptides were synthesized by precoupling Fmoc-Lys(Fmoc)-OH to Gly-PEGA followed by solid-phase synthesis of the remaining peptide.

Preparation of PEGA Beads and Fmoc Amino Acids. PEGA beads with lower substitution level of 0.2 mmol/g were used to avoid any aggregation effect from higher loading. Five grams of PEGA beads [supplied beads are 10.7% w/w (i.e. 5 *g* = 46.7 g of suspension)] were washed with DMF. For the first overnight coupling, 1.5 mmol of Fmoc-Lys(Fmoc)-OH (0.88 g), 1.5 mmol of HOBT (0.208 g), and 1.69 mmoles of DIC (261 μL), and 6 mL of 10% DEIPA were added to 10 mL of DMF and activated for 30 min. Activated complex was added to the beads and allowed to react overnight at room temperature. Completion of coupling was verified by Kaiser test with a small subset of beads (*21*). Repeated couplings with 2-fold molar excess of the above-mentioned reagents were performed. The second coupling was done for 2 h at room temperature. Completion of coupling was again verified by Kaiser test. Beads were washed 5−6 times with DCM and DMF and stored at 4 °C in DMF until later use.

Fmoc was removed from preloaded Lys in the presence of 20% piperidine in NMP. Deprotection was repeated four times for 5 min each. After extensive washing, beads were split into 19 pools for coupling of all natural amino acids with the exception of cysteine. Pools were divided to have 50 μmol of total peptide in each reaction vessel. A combinatorial peptide synthesis platform from Advanced ChemTech was used for the split and pool couplings. This apparatus is designed specifically to generate split and mix peptide libraries. The library was always pooled in a polypropylene vessel.

Concentrated stock solutions of all 19 Fmoc amino acids with HOBT were prepared and stored at −20 °C. Fmoc amino acids (0.5 M) with HOBT (0.49 M) stocks were prepared in DMF (except for Fmoc-phenylalanine which was prepared in NMP).

Coupling of Fmoc Amino Acids To Generate 12-mer Library. Double coupling was done for all Fmoc amino acids. For the first coupling, 4× molar excess i.e., 200 μmol of Fmoc amino acid, and HOBT (400 μL of 0.5 M stock) and 50 μL of DIC were allowed to react for 45 min at room temp and then added to 19 reaction vessels. Beads were mixed for 1 min with the activated fmoc amino acids. DIEPA (0.5 mL of 10% solution) was added, and the reaction was allowed to continue for 2−4 h. After this coupling, the beads were washed extensively with NMP. Coupling was repeated for 30 min with 2× molar excess of the activated Fmoc amino acids. Beads were again washed with DMF. A final wash was done with methanol. A small number of beads from all 19 vessels were taken for the Kaiser test. Deprotection was done twice with 20% piperidine in NMP for 30 min each. Beads were washed extensively and later pooled into a beaker with methanol. Beads were stored at −20 °C till later use.

Before the removal of the final N-terminal Fmoc, the library was acetylated with a 1:3 dilution of acetic anhydride in 10% DIEPA in NMP. Acetylation was done for 30 min. Completion of reaction was confirmed by the Kaiser test. The final Fmoc was removed as mentioned above. After 8−9× volume wash with NMP and DCM the library was stored at −20 °C till later use.

The library was washed with methanol and partially dried under an aspiration setup. Beads were suspended in 20 mL of Reagent K (TFA:H_2O:thioanisole:ethanedithiol:phenol 85:5:5:2.5:2.5). This Reagent K solution was aspirated after 10 min, and the beads were suspended in another 20 mL. Deprotection was done for 3 h with gentle shaking. Beads were washed 10 times with NMP and DCM and finally stored in methanol at −20 °C.

Dimeric Library Screening for Cell Binding. An amount of 100 000 beads suspended in methanol were washed three times with water. Beads were washed and equilibrated in PBS and finally suspended in RPMI 1640 Media containing 10% fetal calf serum (Invitrogen, Rockville, MD). Beads were incubated with 10% serum containing media for 1 h at room temperature. LNCaP cells were removed from culture flasks with trypsin/EDTA, washed and re-suspended in RPMI 1640. Cells were incubated with Cell Tracker orange (10 μM for 30 min at 37 °C). To remove excess dye, cells were pelleted and resuspended in 10% serum containing media at a final density of 5 million cells/ml. The cell suspension was mixed with the beads and incubated at 37 °C with gentle shaking for 30−40 min. Beads were gently washed with Hanks Balanced Salt Solution (HBSS) and fixed for visualization with 80% Methanol in dH_2O. After fixation, the bead pool was evaluated under a fluorescent microscope equipped with the appropriate filter set for either FITC or rhodamine.

Isolation and Preparation of Beads for Sequencing. Single positive beads containing fluorescently tagged cells were identified using a fluorescent microscope under 2.5× objective magnification and removed manually with a 200 μL pipetter using pipet tips in which the last third of the tip had been removed with a razor blade. Selected beads were washed with water and stripped of cells with excess 8 M urea or 6 M guanidine HCl for 24−48 h with intense shaking. Urea or guanidine HCl was removed by 4−5 washes with water. A dissecting microscope was used to confirm that the beads were not lost during washing. Single beads suspended in water were sent for sequencing to University of Arizona Peptide Sequencing Core.

Sequencing of Single Beads with Edman Degradation. Peptide sequencing was completed by Wallace Clark at the University of Arizona using an Applied Biosystem 477A Protein/Peptide sequencer (Edman chemistry) interfaced with a 120A HPLC (C-18 PTH column, reverse-phase chromatography) analyzer to determine phenylthiohydantoin (PTH) amino acids. One sample bead was analyzed per sequence by placing onto a glass fiber filter, which was then assembled within a quartz cylinder and sequenced.

RESULTS

Dimerization Enhances Cell Binding. AG-73 (RKRLQVQLSIRT) is a heparin-binding peptide sequence derived from laminin that has previously been demonstrated to support cell attachment. The AG-73 peptide was synthesized on the PEGA beads as both a monomer and a dimer. Both types of beads were blocked with 10% serum containing media and then incubated with Cell Tracker Green labeled LNCaP cells and compared for the degree of cell binding. After 30 min incubation, excess cells were washed, and beads were fixed and visualized under a fluorescence microscope. No cells bound to

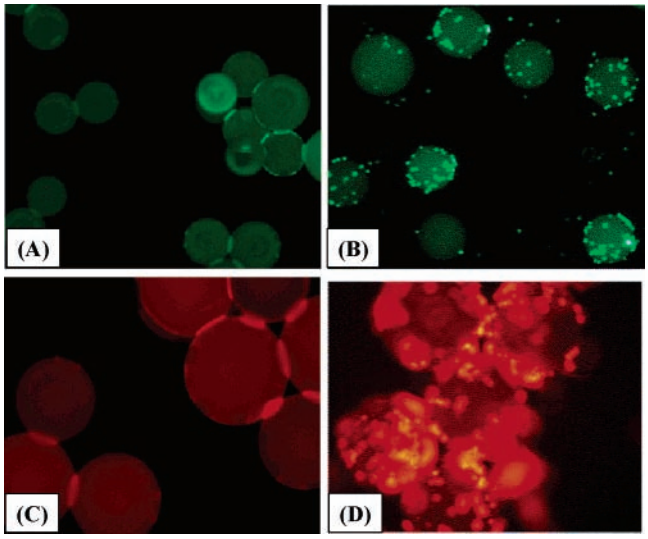

Figure 1. LNCaP cell binding to monomeric and dimeric peptides on PEGA beads. (a) Binding of Cell Tracker Green loaded cells to monomeric AG-73 (10× objective); (b) binding to dimeric AG-73 (10× objective); (c) binding of Cell Tracker Orange labeled cells to monomeric QMARIPKRLARH (20× objective); (d) dimeric QMARIP-KRLARH peptide (20× objective).

monomeric AG-73-containing beads, (Figure 1a). In contrast, LNCaP cells bound readily to the dimeric form of AG-73 (Figure 1b). These results support previous findings that dimeric peptides have enhanced cell binding capabilities due to an avidity effect.

Substitution Level of PEGA Beads with Fmoc-Lys (Fmoc)-OH Affects Synthesis. While these results with the AG-73 peptide demonstrated the superior binding characteristics of the dimeric compared to the monomeric peptide, the AG-73 peptide was initially selected solely for its ability to bind to a target antigen. Our goal in these studies was to identify peptides that can bind selectively to circulating epithelial cancer cells while not binding to highly abundant circulating leukocytes. Therefore, we opted to use the combinatorial-based peptide library approach to identify peptides meeting these two characteristics. As proof of concept, a strategy was developed to synthesize a library of dimeric peptides in which each "arm" of the peptide consisted of 12 positions of randomized to one of 19 amino acids (i.e. cysteine omitted) connected by a lysine linker. On this basis a library of $\sim 10^5$ peptides out of a total of 19^{12} (i.e. 2.2×10^{15}) possible members was generated and screened for selective epithelial cancer cell binding.

The steps used to synthesize this dimeric library are outlined in Figure 2. The synthesis of dimeric library of 12-mer peptides can be limiting for a fraction of a library because of steric hindrance of bulky side functional groups and bulky protection agents. Standard substitution levels of 0.4−0.5 mmol/g used in synthesis of a test dimeric peptides (e.g. Wang resin) markedly decreased peptide yield, Figure 3a. To minimize such a steric effect, PEGA beads with a lower substitution level of 0.2 mmol/ml were utilized. To produce a branched peptide, Fmoc-Lys-Fmoc-OH was coupled to the low substitution PEGA. Coupling was confirmed to be positive by a Kaiser test before proceeding with synthesis of the library using the two amino groups of deprotected lysine. The use of the lower substitution PEGA beads enhanced the yield of the test peptide and minimized incomplete coupling observed with the higher substitution PEGA, Figure 3b.

Quality Control of Library Synthesis with the Kaiser Test. The large scale manual nature of this procedure makes the syntheses liable to error, and hence it proved critical to check all 19 reaction vessels for completion of coupling (*21*). Although the Kaiser test is a qualitative test and will not be able to detect rare and partial incomplete couplings, it was, in general useful to rapidly confirm overall coupling efficiency. Subsequent coupling of amino acids were done twice and were checked for completion by the Kaiser test. In some cases, the couplings were repeated till a negative Kaiser test was confirmed.

Final Capping of Library before Removal of Terminal Fmoc. The sequencing of individual selected beads using Edman degradation depends on the completion of coupling after each round. In such a combinatorial synthesis of a large number of peptides there are some peptide sequences that contain difficult coupling steps that can lead to some percentage of partially synthesized peptide on an individual bead. These incomplete peptides can complicate interpretation of sequencing results and can make it difficult to determine the full sequence of the actual peptide, Figure 4a. Acetylating the amino terminal amine of any incomplete peptides using acetic anhydride can help to resolve this problem. For best results the capping should be done after each coupling. However, we determined that capping the terminal amine was sufficient and gave enough signal upon sequencing to identify the peptide sequence, Figure 4b. Capping was accomplished by acetylating the library with 1: 3 dilution of acetic anhydride in 10% DIEPA in NMP for 30 min prior to the removal of final N-terminal Fmoc of the full length peptide.

Screening the Library for Binding to Cells. The dimeric library on low substitution PEGA beads was blocked and incubated with LNCaP prostate cancer cells preloaded with Cell Tracker Orange. Cell Tracker Orange was used instead of the Cell Tracker Green used to screen the AG-73 peptide because the Orange dye provided better signal-to-noise and markedly less autofluorescence. This made the few positive beads in a field of thousands of negative beads easier to rapidly visualize and select. An amount of 100 000 beads was screened and, of these, approximately 100 cell-coated beads (i.e. "hits") were observed. The remaining 99.9% of the beads were totally negative for cell binding. The 100 positive beads were difficult to grade because each of them was highly coated with cells. Without a bead sorter these beads were picked manually based on the relative number of bound cells under a fluorescence microscope. On this basis, 10 beads were picked and subsequently sequenced by Edman degradation. The amount of peptide that can be obtained from a single PEGA bead with 0.2 mmol/mL substitution on average is ~40 pmol. This limits the number of analytical techniques which can be used for determining the sequence.

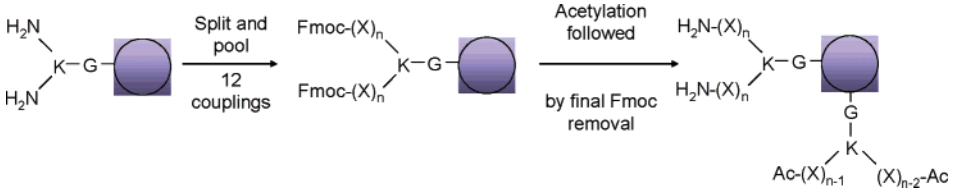

Figure 2. Schematic representation of random peptide library synthesized by 'split and mix' method where each bead contains multiple copies of a unique 12 amino acid peptide. One of 19 defined amino acids (i.e. cystein omitted) was added during each step of synthesis followed by mixing and then splitting into 19 separate flasks prior to addition of next set of defined amino acids. The scheme illustrates the utility of capping incompletely synthesized peptides with acetic anhydride prior to the removal of the final Fmoc protecting group on the N-terminal amine.

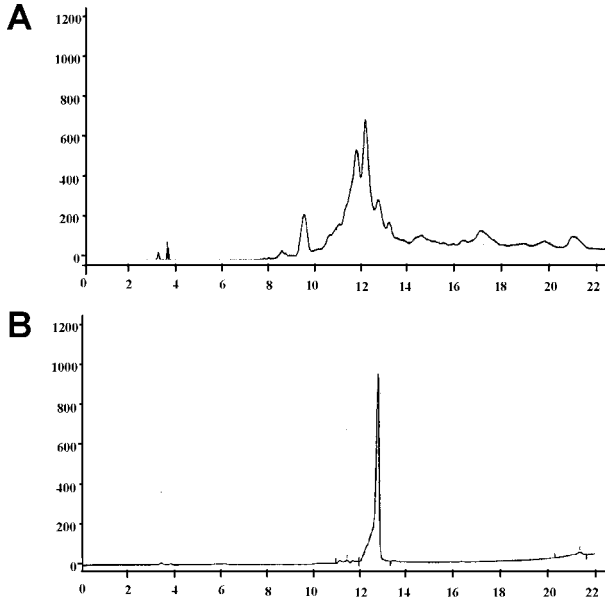

Figure 3. Reversed phase HPLC C_{18} chromatograms of dimeric peptide $(QMARIPKRLARH)_2KG$ synthesized on glycine Wang resin. (a) 0.4 mmol/g substitution level yields broad multiple peaks indicating mixture of peptides (b) 0.2 mmole/g substitution level yields narrow discrete peak consistent with high yield of single peptide.

Selected peptide sequences were synthesized again as either a monomer or a dimer on PEGA beads and rescreened for binding to different cell lines. LNCaP cells did not bind to resynthesized monomeric peptide beads to any significant degree, Figure 1c. In contrast, all of the dimeric versions of the peptides selected from the screen bound the LNCaP cells, Figure 1d. Additional analysis demonstrated that a subset of these selected peptide sequences bound only malignant epithelial cancer cells but not leukocytes.

DISCUSSION

Peptides that bind selectively to a specific cell type or protein have been identified from large combinatorial libraries of peptides. Such libraries can be either biologically synthesized as phage display libraries ($\sim 10^9$ different peptides) (*22*) or they can be chemically synthesized as the 'one-bead−one-peptide' libraries ($\sim 10^5-10^6$ different peptides) (*23*). Phage display libraries are widely used and have been employed to successfully isolate peptide ligands that bind to purified protein targets such as erythropoietin (EPO)(*12*), thrombopoetin (TPO) (*15*), and fibroblast growth factor (FGF) (*24*). However, the selection of cell-binding peptides from phage display libraries screened on whole cells has been problematic (*25*, *26*). A phage display library has the limitation of displaying only five copies of monomeric peptides on the pIII coat protein per individual phage. Initial screens of phage libraries typically yield peptides with low binding affinities and rapid off rates (on the order of few minutes). The fast dissociation of these low-affinity, but cell-type specific, binding peptides often results in isolation of more nonspecific than specific ones binding phage (*26*). To address the problem of low affinities, Zwick et al. (*27*) developed a method to make a phage display library of homodimeric peptides. However, as described by Zwick et al., the construction of this homodimeric phage library was complicated and would not be applicable for widespread use.

Synthetic peptide libraries have a number of unique attributes when compared to phage libraries. Such libraries allow for the incorporation of D-amino acids as well as unnatural amino acids which is not possible using phage display. In contrast to phage libraries, thousands to millions of copies of a unique peptide sequence can be displayed on the surface of a synthetic bead.

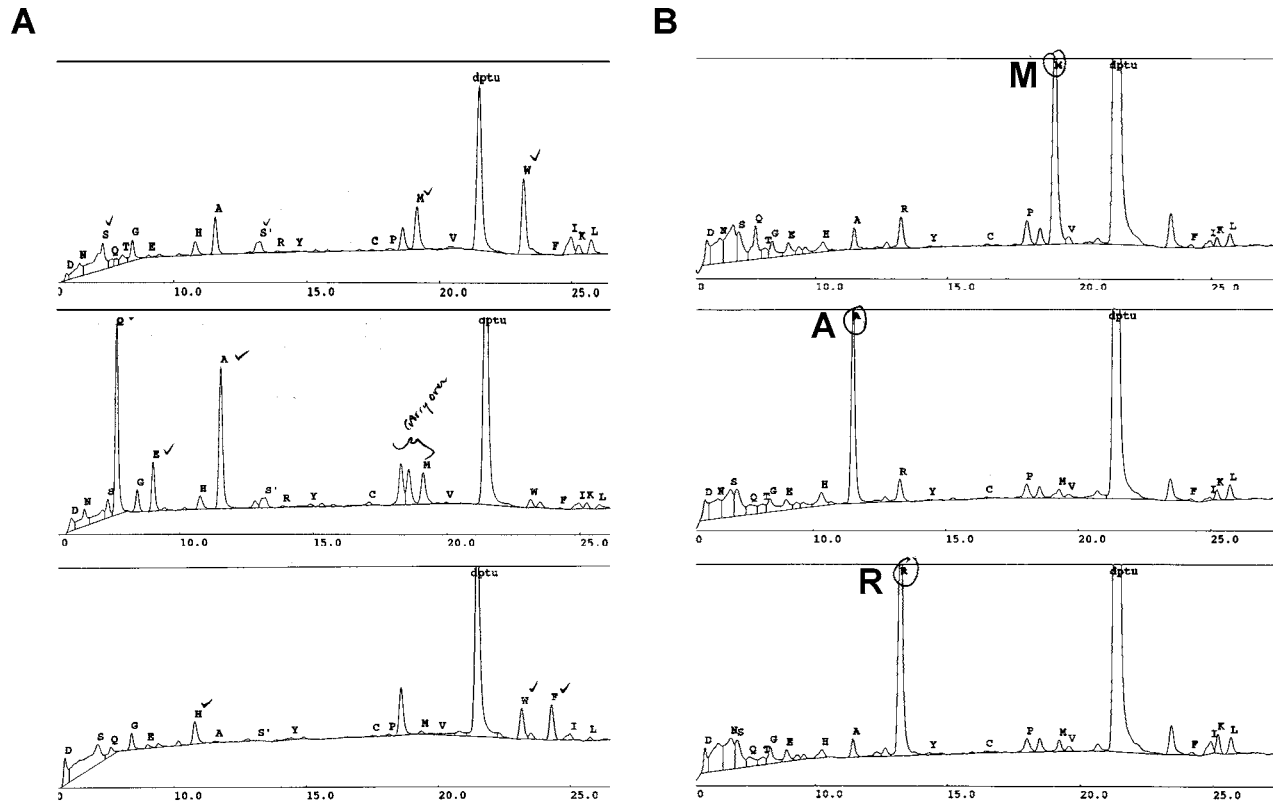

Figure 4. Sample chromatograms for three positions of Edman sequencing of a dimeric peptide on 0.2 mmol/g PEGA beads following (a) synthesis without final capping and (b) synthesis with a final capping. Without capping, sequencing reveals multiple amino acid peaks for each position, whereas with capping, distinct single peaks are observed.

Thus, bead-based libraries seem particularly suited for cell capture applications because the beads can provide multiple binding sites across the cell surface. However, since the first report describing this combinatorial method in 1991, there have been few reports on the use of such libraries for selection of cell binding ligands. The technical expertise and sophistication required in implementing the protocol for synthesis and screening such libraries, particularly those with cyclic peptides, appears to have limited the application of this screening method to only a few laboratories. In addition, like phage display, screening of bead-based libraries often yields low affinity peptides or nonspecific binders. Proteins for which peptides are not the natural ligands typically display low affinity interactions (*28*), and this leads to fast dissociation kinetics with k_{off} of the order of few minutes (*26*). Many of these specific but low affinity binders are lost during multiple washing steps involved in the screening process.

A number of studies have now demonstrated that dimerizing or multimerizing a peptide ligand can improve its binding kinetics due to an avidity effect. For example, Wrighton et al. had demonstrated that affinity for peptides binding to the erythropoietin receptor could be increased 100-fold when peptides were synthesized in a dimeric form (*12*). Previously a dimeric version of an RGD integrin-binding peptide was shown to have enhanced binding characteristics and nanomolar affinity. Dimeric RGD peptide has also been used by many groups for targeting drugs and for imaging applications (*29*). Previously, Terskikh et al. demonstrated that the affinity of a peptide isolated from phage display screening could be increased 200 000-fold by making a pentamer (i.e. "peptabody") using the pentamerization domain of a cartilage oligomeric protein (*13*). In our own studies we have demonstrated that incubation of biotinylated peptides with avidin forms a tetrameric species with enhanced binding characteristics compared to monomeric peptide (*11*).

To demonstrate the utility of screening a dimeric peptide library, a strategy was developed to synthesize a library of dimeric peptides in which each "arm" of the peptide consisted of 12 positions of randomized to one of 19 amino acids (i.e. cysteine omitted) connected by a lysine linker. On this basis a library of $\sim 10^5$ peptides out of a total of 19^{12} (i.e. 2.2×10^{15}) possible members was generated and screened for selective epithelial cancer cell binding. This library represents only a small fraction of potential peptide sequences. However, the use of the dimeric library can increase the chance of obtaining "hits" in the first round of screening. These "hits" can then later be optimized by synthesizing a second random library in which different positions in the original dimeric "hit" can be modified to evaluate the effect of modification on overall binding. This second round of synthesis and screening, based on the QMARIPKRLARH peptide, is currently underway in our laboratory

The solid-phase "split and mix" method used to synthesize this dimeric library was similar in many ways to previously published methods for synthesizing monomeric libraries. However, to optimize both the synthesis and identification of individual dimeric peptides in the library, a few modifications were made to the standard methodologies. First, synthesis of a test dimeric peptide $(QMARIPKRLARH)_2KG$ on standard substitution resins (0.4−0.5 mmol/g) yielded a mixture of peptides on an individual bead. This incomplete coupling of amino acids was due, most likely, to intermolecular steric hindrance of bulky side functional groups and bulky protection agents. Synthesis of the test peptide on resin with a lower substitution level of 0.2 mmol/g minimized such steric effects and resulted in higher yields of the dimeric test peptide. Additionally, with the use of lower substitution resin in the production of the dimeric library, the majority (i.e. >90%) of the selected beads from the screen yielded a complete 12 amino acid peptide sequence. However, even with this lower substitution resin, some of the selected dimeric peptides were difficult to resynthesize in large quantities in high yield again due to sequence-dependent intramolecular steric hindrance.

A second important modification to the standard screening methodology was the use of capping by acetylation of the amino terminus of incompletely synthesized peptides. This capping step is not always performed in the standard synthesis of monomeric libraries. In this case, however, the more complex nature of the dimeric peptide results in a higher percentage of incomplete couplings on an individual resin bead. Capping of incomplete peptides before removal of the final Fmoc group proved critical to the elucidation of the peptide sequence. Without capping, mixtures of amino acids were frequently observed after each round of Edman degradation.

In this study we provide further evidence demonstrating enhanced binding characteristics of dimeric peptides compared to monomers. However, unlike other reports in which the monomeric peptide sequence was first selected from a random pool and then dimerized, in this study we have directly screened a random dimeric peptide library. The use of this dimeric library improves chances of selecting binding peptides that might otherwise not been identified from a monomeric library screen. In fact, in each case, the monomeric version of the dimeric peptide selected in this screen did not bind to cells to any significant degree. Studies are underway in our laboratory to identify the cognate protein receptor for the $QMARIPKRLARH)_2KG$ peptide. The fact that the dimeric peptide binds better than the monomeric version suggests that the cognate receptor itself may be a dimeric protein. In this regard, Wrighton et al. synthesized a dimeric version of a 20 amino acid peptide using a single lysine as a branch point and demonstrated that this dimeric peptide had 100-fold increased affinity for the erythropoietin receptor compared to the monomeric peptide. The authors of this study concluded that the proposed mechanism of increased potency of the dimer over the monomer was that the dimeric peptide was able to span the cleft and interact with both molecules of the EPOR extracellular domain. This conclusion was based on the structure of a cocrystal of the EPOR binding peptide and the extracellular domain of the EPOR in which a noncovalent peptide dimer is seen spanning the cleft between two molecules of the EPOR extracellular domain (*30*).

On the basis of these results, therefore, we conclude that synthetic dimeric peptide libraries should be considered in the future for a variety of screening applications. We hope that the detailed methodologies described here can serve as a reference to aid other investigators interested in using this powerful combinatorial approach in peptide screening applications.

ACKNOWLEDGMENT

Linear and Branched Bicin Linkers for Releasable PEGylation of Macromolecules: Controlled Release in Vivo and in Vitro from Mono- and Multi-PEGylated Proteins

Hong Zhao, Karen Yang, Anthony Martinez, Amartya Basu, Ramesh Chintala, Hsien-Ching Liu, Ahsen Janjua, Maoliang Wang, and David Filpula*

Enzon Pharmaceuticals, Inc., 20 Kingsbridge Road, Piscataway, New Jersey 08854. Received September 6, 2005; Revised Manuscript Received January 12, 2006

The utility of PEGylation for improving therapeutic protein pharmacology would be substantially expanded if the authentic protein drugs could be regenerated in vivo. Diminution of kinetic constants of both enzymes and protein ligands are commonly encountered following permanent bioconjugation with poly(ethylene glycol) polymers. In further development of releasable linker technology, we investigated an amino PEG anchimeric prodrug system, based on either the linear or branched bicin3 (BCN3) linkage, one promising representative of several aliphatic ester structures synthesized from N-modifed bis-2-hydroxyethylglycinamide (bicin). Protein models included an enzyme, lysozyme, and a receptor ligand, interferon-beta-1b, for preparation of linear or branched mono- and multi-PEGylated conjugates as inactive PEG-BCN3 prodrugs. The kinetics of protein release, both in plasma (in vitro) and in mice (in vivo), correlated with the number of PEG attachments, and the plasma half-lives of PEG release spanned a duration of hours to days within the therapeutically relevant window. Capillary electrophoresis, SDS−PAGE, mass determination, and enzymatic and antiviral activity determinations demonstrated regeneration of equivalent native proteins from the inactive PEG-BCN3 conjugates. Pharmacokinetic analysis of the PEGylated interferon-beta-1b administered subcutaneously in mice demonstrated an over 20-fold expansion of the area under the curve exposure of bioactive protein when compared to native protein.

INTRODUCTION

Bioconjugation of proteins with poly(ethylene glycol) (PEG[1]) via permanent linkages, the locus classicus of PEGylation science, is a mature technology employed in at least six PEGylated protein therapeutics which are now on the market (*1*, *2*). A rapid clearance of proteins following parenteral administration may transpire from renal filtration, antibody or cellular recognition, or physical degradation. PEG attachments to proteins have significant benefits in prolonging the in vivo activity of proteins (*3*−*6*). A recent trend in PEGylation technology attempts to optimally design the composite bioconjugate using both protein engineering and improved chemical linkages (*7*−*10*). Site-specific attachments of PEG polymer strands may afford better retention of bioactivity, while abridging the heterogeneity of the conjugate compounds. However, even well designed bioconjugates may exhibit imperfect pharmacological properties, owing to an altered structure or function of the bioconjugate when compared to the native protein molecule, which itself may have intrinsic deficiencies when examined in therapeutic applications. Therefore, recent research has examined the potential development of releasable PEGylation, wherein covalent attachments of strands of PEG polymers are shed via a controlled release mechanism derived from a degradable linkage at the attachment site on the protein surface (*11*−*19*). Releasable PEGylation may offer the greatest benefits to small molecules which are inactivated by the bulky PEG partner. Examples are peptides, oligonucleotides, and analogues of protein domains. In addition, protein therapeutics, such as toxins and signal transduction domains, requiring intracellular entry and processing might also employ a releasable PEG format. Releasable PEGs provide the option of extensive surface modification of highly immunogenic or antigenic proteins with gradual release of the active compound. Finally, it will be instructional to examine the side-by-side in vivo efficacy performance of cytokine or growth factor therapeutics that already demonstrated superior performance as nonreleasable PEGylated derivatives. Two attractive features of rPEGylation that might justify this reinvestigation are (1) the potential for improved manufacturing yields by extensive rPEGylation of the therapeutic, which allows nearly complete product recovery, and (2) the capacity of rPEGylated therapeutics to release the authentic and fully active drug.

One prodrug strategy for releasable PEGylation employs the rapid hydrolysis of bis-*N*-2-hydroxyethylglycinamide (bicin) whereby an anchimeric assisted hydrolysis facilitates the release of amine-conjugated molecules (*20*). This is a promising linker design that is wholly aliphatic and compatible with amino group derivatization, a common linkage site for protein conjugation. By the use of α-substituents on the ester moiety between the bicin group and the PEG polymer, the half-life of the prodrugs can be adjusted for various applications. However, this PEG−protein conjugate (*20*, Scheme 1) is a double prodrug, and the stepwise release of PEG from the branched PEG leads initially to a monosubstituted linear PEGylated species. The branched PEG design, featuring more PEG mass per attachment, may be preferable for optimal protection of some therapeutics; however, the two-step releasing mechanism (Scheme 2) may result in excessively complex pharmacokinetic parameters for the released protein. Therefore it is desirable to design a bis-*N*-2-

hydroxyethylglycinamide-based system with a simpler, or one-step, releasing mechanism of the PEG. This report will focus, in part, on the design of such a system and the application of the releasable PEG linker, bicin3 (BCN3), to protein conjugation. BCN3 is so designated as the third of several BCN derivatives which we have synthesized. We also report further investigations on the in vivo performance of the branched BCN3 design.

As model proteins, we chose to investigate both an enzyme and a receptor-binding ligand. Lysozyme is one of the most thoroughly investigated enzymes and is also an important constituent of the innate immunity versus infection. Development of improved antimicrobial enzymes may ultimately be important as existing antibiotics are challenged by resistant organisms (*21*). Lysozyme lyses Gram-positive bacteria by hydrolyzing a 1−4 β-glycosidic linkage of the *N*-acetylmuramic: *N*-acetylglucosamine cell wall polymer. As an illustration of the sensitivity of the enzyme active site to steric disruption, this reaction may be inhibited by ester-linked *O*-acetyl C6 substitutions on *N*-acetylmuramic acid and by teichoic acid side chains; the enzyme action may also be inhibited by binding and neutralizing immunoglobulins (*22*). In this connection, we find a single attachment of 12 kDa PEG to one of the seven primary amines of lysozyme provides nearly complete inhibition of bacteriolytic activity. Complete release of enzymes from the experimental BCN3 mono- and multi-PEGylated conjugates may be measured by the regeneration of enzymatic activity.

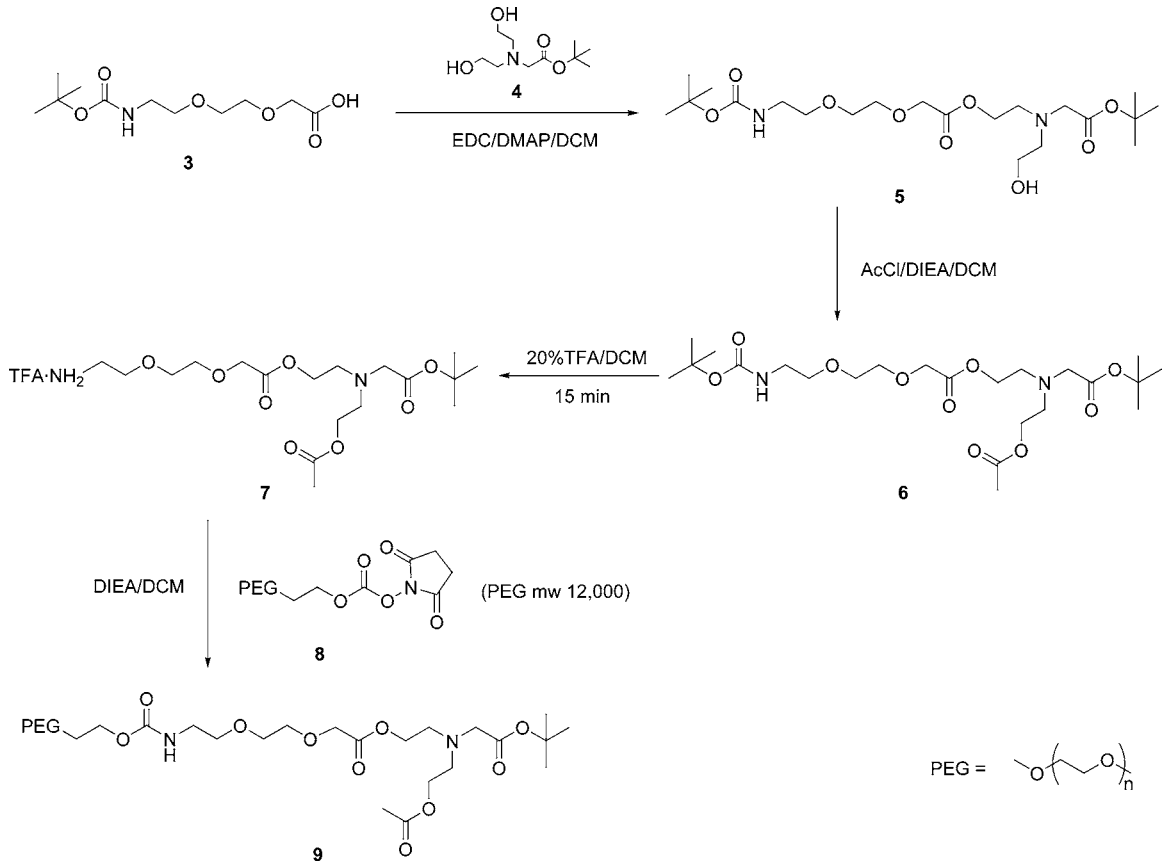
The second model investigates BCN3 PEGylated human interferon beta-1b (IFN-β-1b). The receptor signaling events mediated by IFN-β-1b are partially understood and the protection of cells from viral infection may be measured by bioassays based on reduction of the cytopathic effect (*23*, *24*). IFN-β-1b is a first-line therapy for relapsing-remitting multiple sclerosis. As demonstrated for many cytokines, interferons may be further engineered to improve their circulating half-life and drug exposure, while sometimes reducing immunogenicity (*4*, *5*, *25*). In particular, IFN-β-1b is a very hydrophobic protein presenting formulation challenges (*26*, *27*). IFN-β-1b clears rapidly following subcutaneous administration and has demonstrated substantial immunogenicity, including generation of neutralizing antibodies (*28*). Mono-PEGylation of interferons has proven to be productive, but PEGylation of interferons with multiple permanent attachments generally results in an inactivated protein (*4*, *9*, D. Filpula, unpublished results). We focused the current studies on releasable 24 kDa PEG-BCN3 and 40 kDa PEG-BCN3 conjugates with a defined multiple PEG number. Our investigations of the comparative pharmacokinetics of native IFN-β-1b and BCN3−PEGylated IFN-β-1b compounds demonstrate a new paradigm for interferon therapy through controlled release.

EXPERIMENTAL PROCEDURES

Materials. Chicken egg white lysozyme (EC 3.2.1.17), lysozyme substrate bacteria (*Micrococcus lysodeikticus*), and PBS (10 mM phosphate, pH 7.4, 138 mM NaCl, 2.7 mM KCl) were purchased from Sigma Inc. (St. Louis, MO). Hiload Superdex 200 was supplied by Amersham BioSciences (now GE Healthcare, Piscataway, NJ) and Poros HS was supplied by Applied Biosystems (Foster City, CA). Pre-cast 4−20% Tris-glycine SDS electrophoresis gels and the gel running buffer were obtained from Invitrogen (Carlsbad, CA). Recombinant human interferon-beta-1b (30 MIU/mg) was supplied by Enzon, Inc. Encephalomyocarditis virus (EMCV; VR-129B) and Vero cells (CCL-81) were from ATCC. SC-PEG-12 kDa and SPA-PEG-20 kDa were obtained from Enzon Pharmaceuticals and Nektar Therapeutics, respectively.

Chemistry. All reactions were run under an atmosphere of dry nitrogen or argon. Commercial reagents were used without further purification. All PEG compounds were dried under vacuum or by azeotropic distillation from toluene prior to use. NMR spectra were obtained using a Varian Mercury 300 NMR spectrometer and deuterated chloroform as the solvent unless otherwise specified. Chemical shifts (δ) are reported in parts per million (ppm) downfield from tetramethylsilane (TMS). Mass spectral analysis was performed by the W.M Keck Foundation Biotechnology Resource Laboratory, Yale University, New Haven, CT.

Scheme 3



Prior to synthesis of the linear PEG BCN linker, monofunctional bis-*N*-hydroxyethylglycine derivative **5** had to be prepared first (Scheme 3). To do so, protected acid **3** was reacted with equal moles of the *tert*-butyl ester of bicin **4**, and after the acid wash, pure **5** was obtained without any further purification. The free hydroxyl group of **5** was then capped by an acetyl group to give **6**. Subsequently, the BOC-glycine ester, compound **6**, was deblocked using mild conditions (20% TFA for 15 min) to give the amine salt **7** without altering the *tert*-butyl ester. Condensation of **7** with mPEG-succinimidyl carbonate (**8**, SC-PEG, mw 12000 used as an example; ref 29) produced the linear PEG-BCN3 derivative **9**, which was hydrolyzed using more concentrated TFA (33%) in DCM for a 15 h period, producing the linear PEG acid **10** (Scheme 4). Activation of **10** by EDC/NHS produced the NHS activated ester, **11**.

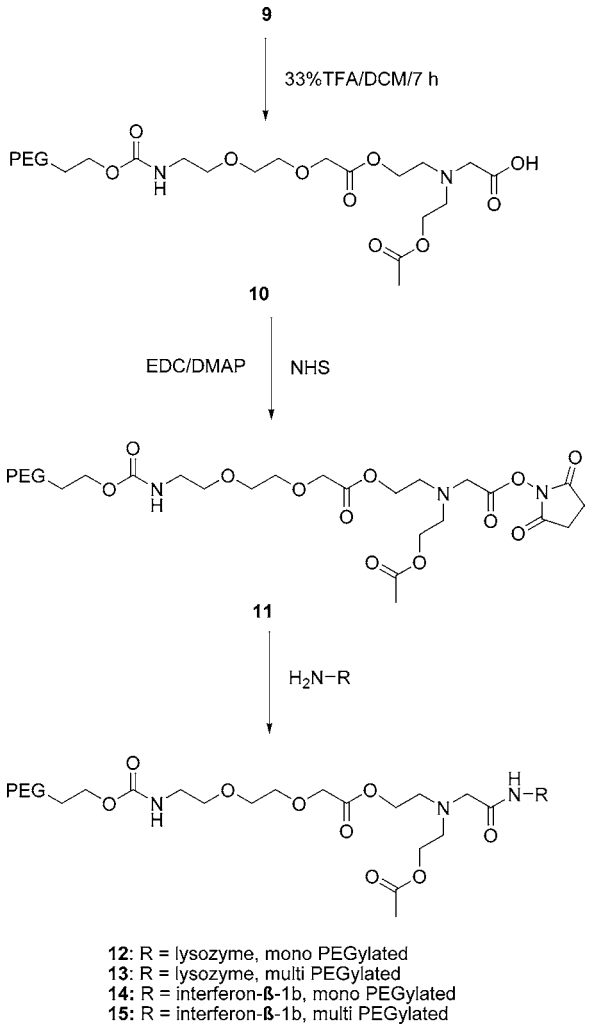
Compound 5. A solution of **3** (2.3 g, 8.7 mmol), **4** (1.9 g, 8.8 mmol), and DMAP (1.6 g, 12.9 mmol) in 30 mL of dry methylene chloride was cooled to 0 °C in an ice bath, followed by addition of EDC hydrochloride (2.3 g, 12.0 mmol). This mixture was allowed to warm to room-temperature overnight, followed by washing with 0.1 N HCl. The organic layer was dried over anhydrous sodium sulfate and filtered and the solvent removed from the filtrate by rotovaporation to yield **5** (3.6 g, 7.8 mmol, 90%). ^{13}C NMR (75.4 MHz, $CDCl_3$) δ 170.04, 169.86, 155.54, 80.87, 78.66, 70.49, 69.95, 68.14, 62.71, 55.85, 52.59, 40.02, 28.15, 27.91. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.44 (9H, s), 1.51 (9H, s), 3.24−3.36 (2H, m), 3.54 (2H, t), 3.57−3.69 (4H, m), 3.69−3.78 (2H, m), 3.79−3.90 (2H, br s), 4.00−4.10 (2H, br s) 4.13−4.23 (2H, br s), 4.27 (2H, s), 4.64−4.74 (2H, br s), 5.19 (1H, br s), 5.34 (1H, s). TOF MS (ES^+) calculated for $C_{21}H_{41}O_9N_2$ $(M + H)^+$ 465.56, found 465.42.

Compound 6. To a solution of **5** (1.8 g, 3.9 mmol) in 35 mL of dry methylene chloride was added acetyl chloride (0.49 g, 6.2 mmol), followed by diisopropylethylamine (1.82 g, 14 mmol). This mixture was stirred for 10 min at room temperature, at which time no starting material was detected by TLC. This mixture was washed with saturated sodium bicarbonate, dried over anhydrous sodium sulfate, and filtered, and the solvent was removed from the filtrate by rotovaporation to yield 1.6 g of crude product. This material was purified by column chromatography on silica gel and eluted with 2.5% acetonitrile in ethyl acetate to yield **6** (0.69 g, 1.4 mmol, 35%). ^{13}C NMR (75.4 MHz, $CDCl_3$) δ 170.60, 170.27, 170.02, 155.68, 80.99, 78.88, 70.68, 70.13, 70.10, 68.34, 62.93, 62.74, 56.11, 52.81, 52.76, 40.21, 28.29, 28.08, 20.88. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.42−1.52 (18H, m), 2.04−2.10 (3H, m), 2.94−3.06 (4H, m), 3.28−3.42 (4H, m), 3.52−3.62 (2H, m), 3.63−3.70 (2H, m), 3.70−3.77 (2H, m), 4.08−4.28 (6H, m), 5.11 (1H, s). HRMS calculated for $C_{23}H_{43}O_{10}N_2$ $(M + H)^+$ 507.2912, found 507.2895.

Compound 9. A 0.15 g (0.3 mmol) sample of **6** was stirred for 15 min in a solution of 20 mL of methylene chloride and 5 mL of TFA, followed by removal of the solvents by rotovaporation to generate **7**, which was combined with 5 mL of dry methylene chloride, followed by addition of DIEA until the pH was above 8.0. This solution of **7** was added to a solution of 3.0 g (0.15 mmol) of **8** in 45 mL of dry methylene chloride and stirred overnight at room temperature. At this time, the solvent was partially removed by rotovaporation, and the product was precipitated with ether, and collected and washed with ether. This crude product was recrystallized from 12% DMF/IPA to yield **9** (2.8 g, 93% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$) δ 170.31, 170.02, 169.74, 155.91, 80.72, 72.94−68.13(PEG), 63.51, 62.73, 62.52, 58.65, 55.92, 52.62, 40.44, 27.90, 20.69.

Compound 10. A solution of **9** (4.1 g, 0.13 mmol) in 50 mL of DCM and 25 mL of TFA was stirred for 15 h at room temperature, followed by partial removal of the solvent by rotovaporation, and precipitation of the product with ether. The solid was collected by filtration and washed several times with ether and dried to yield **10** (4.0 g, 98%) of product. ^{13}C NMR

Scheme 4



(75.4 MHz, $CDCl_3$) δ 171.19, 170.26, 169.73, 72.99−68.16 (PEG), 63.52, 62.35, 64.98, 58.67, 55.86, 53.13, 53.02, 40.46, 20.62.

Compound 11. A solution of **10** (3.9 g, 0.13 mmol), 0.059 g (0.51 mmol) of NHS, 0.2 mL (1.1 mmol) of DIEA, and 0.0015 g (0.012 mmol) of DMAP was combined with 30 mL of dry methylene chloride and cooled to 0 °C, followed by the addition of 0.2 g (1.03 mmol), of EDC hydrochloride. This mixture was allowed to warm to room temperature overnight. At this time, the solvent was partially removed by rotovaporation, and the product precipitated with ether, collected, and washed with ether. This crude product was recrystallized from 12% DMF/IPA to yield **11** (3.72 g, 95% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$) δ 170.34, 169.80, 168.52, 165.83, 155.96, 71.58−68.16 (PEG), 63.57, 62.64, 62.35, 58.70, 52.73, 52.53, 52.46, 40.49, 25.32, 20.66. Compound **11** was used in the preparation of mono-PEGylated or multi-PEGylated lysozyme and IFN-β-1b compounds (**12**, **13**, **14**, and **15**).

HPLC Methods. The reaction mixtures and the purity of intermediates and final products were monitored by a Beckman Coulter System Gold HPLC instrument employing a ZOBAX 300 SB C-8 reversed phase column (150 × 4.6 mm) or a Phenomenex Jupiter 300A C18 reversed phase column (150 × 4.6 mm) with a multiwavelength UV detector, using a gradient of 30−90% of acetonitrile in 0.5% trifluoroacetic acid (TFA) at a flow rate of 1 mL/min for 30 min.

Determination of Hydrolysis Rate and Reaction Rate. The hydrolysis of PEG compounds in 0.1 M sodium phosphate, pH 7.8, 23 °C was conducted on a Cary 50 Bio UV-Visible Spectrophotometer. The PEG compound concentration was 2×10^{-4} M based on polymer mass (1 mg/mL for 5 kDa, 2.4 mg/mL for 12 kDa, 4.8 mg/mL for 24 kDa, and 6 mg/mL for 30 kDa). The hydrolysis was monitored at 260 nm for the production of *N*-hydroxysuccinimide (NHS). The extinction coefficient of NHS in 0.1 M sodium phosphate, pH 7.8, 23 °C was 7.5×10^3 L·mol^{-1}·cm^{-1} ($R^2 = 0.999$). The hydrolysis rate was calculated with Cary WinUV software using a first-order kinetics model. The reaction of PEG linkers with glycine was conducted by adding glycine to a PEG linker solution at a 1:1 molar ratio. The reaction was monitored at 260 nm. The difference in kinetic constants between hydrolysis alone, and hydrolysis plus reaction with glycine, was determined for the corrected reaction rates.

Kinetic Studies in Rat Plasma. The PEG-BCN3 derivative, 15 mg, was dissolved in 1000 μL of a mixture of MeCN and MeOH (1:1, v/v). The solution (100 μL) was transferred to each vial (eight vials total, StepVial System II). Solvent was removed under reduced pressure, and 100 μL of rat plasma was added to each vial. The vial was sealed and vortexed for 1 min after which time the vial was incubated at 37 °C for 0, 0.5, 1, 2, 4, 6, and 20 h, respectively. To each vial was again added 400 μL of MeCN and MeOH (1:1, v/v) and the vial vortexed for 1 min. The mixture was filtered through a 0.45 micron filter membrane, and 50 μL of the filtrate was injected directly into the HPLC system.

Enzyme Activity Assay. In a typical lysozyme activity assay, 0.2 mL of 0.02% (w/v) *M. lysodeikticus* was added to 0.12−2.0 μg of lysozyme in 50 μL of 66 mM potassium phosphate, pH 6.2 containing 0.01% BSA, on a 96-well titer plate. The absorbance at 450 nm was followed for 5 min on a SpectraMax 190 instrument (Molecular Devices). The rate of decrease in absorbance was used as a measure of enzyme activity. One unit of enzyme activity produces a change of 0.001 absorbance units/min at 25 °C. Free PEG or rat plasma had no effect on this assay.
